This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Boston, Massachusetts

Laura E. Fischer, MD, MS
Department of Surgery
Oregon Health and Science University
Portland, Oregon

Robert J. Fitzgibbons, Jr., MD, FACS
Harry E. Stuckenhoff Professor and Chairman
Department of Surgery
Creighton University School of Medicine
Omaha, Nebraska

R. Jobe Fix, MD, FACS
Professor
Division of Plastic Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Spiros G. Frangos, MD, MPH
Professor, Department of Surgery
Professor, Department of Anesthesiology, Perioperative Care, and Pain Medicine
Chief of Surgery
Director of Trauma/Critical Care
Bellevue Hospital Center
Director, Division of Acute Care Surgery
NYU Langone Medical Center
New York, New York

Herbert R. Freund, MD
Hadassah University Medical Center
Jerusalem, Israel

Michael R. Freund, MD
Department of General Surgery, Shaare Zedek Medical Center
The Hebrew University School of Medicine
Jerusalem, Israel

Arlan F. Fuller, Jr., MD
Irene and Telemachus Demoulas Chair in Women's Health
Chief of Gynecologic Oncology
Associate Professor of OB/GYN
Tufts University School of Medicine
Winchester, Massachusetts

Wolfgang B. Gaertner, MD, MSc
Assistant Professor
Colon & Rectal Surgery
University of Minnesota
Staff Surgeon
Colon & Rectal Surgery
University of Minnesota Medical Center
Minneapolis, Minnesota

Susan Galandiuk, MD
Professor of Surgery
Program Director, Section of Colon & Rectal Surgery
Hiram C. Polk, Jr. MD Department of Surgery
Director, Price Institute of Surgical Research
University of Louisville
Louisville, Kentucky

Norman J. Galbraith, BSc, MBChB, MRCS
Price Institute of Surgical Research
Department of Surgery
University of Louisville School of Medicine
Medical Dental Research Building
Louisville, Kentucky

Ian Ganly, MD, PhD, MS, FRCS, FRCS-ORL
Associate Professor
Department of Otolaryngology—Head and Neck Surgery
Weill Cornell Medical College
Cornell University
Associate Attending Surgeon
Surgery, Head, and Neck Service
Memorial Sloan Kettering Cancer Center
New York, New York

Julio Garcia-Aguilar, MD, PhD
Surgeon
Chief, Colorectal Service
Benno C. Schmidt Chair in Surgical Oncology

Department of Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

Manuel Garcia-Toca, MD, FACS
Clinical Associate Professor of Surgery
Stanford University
Stanford, California

O. James Garden, CBE, MD, FRCSEd, FRCPEd, FRCScan(Hon), FRACS(Hon), FACS(Hon), FRSE
Regius Professor of Clinical Surgery
University of Edinburgh
Honorary Consultant Hepatobiliary Surgeon
Royal Infirmary of Edinburgh
Edinburgh, Scotland

Keith S. Gersin, MD, FACS, FASMBS
Clinical Professor of Surgery
UNC—Chapel Hill
Chapel Hill, North Carolina
Chief, Bariatric Surgery
Specialty Medical Director of Bariatrics & Metabolic Surgery
Carolinas HealthCare System Medical Group
Carolinas Medical Center
Charlotte, North Carolina

Karthik Ghosh, MD
Associate Professor of Medicine
Consultant, General Internal Medicine
Breast Diagnostic Clinic
Mayo Clinic
Rochester, Minnesota

Arthur I. Gilbert, MD, FACS
Voluntary Associate Professor
DeWitt Daughtry Family Department of Surgery
Leonard M. Miller School of Medicine
Miami, Florida

Ana Luiza Mandelli Gleisner, MD
Assistant Professor
Department of Surgery
University of Colorado Anschutz Medical Campus
Aurora, Colorado

Peter Gloviczki, MD, FACS
Roberts Professor of Surgery and Chair, Emeritus
Division of Vascular and Endovascular Surgery
Mayo Clinic
Rochester, Minnesota

Philip H. Gordon, MD, FRCS(C), FACS, FASCRS, FCSCRS, FRSM(Hon), FACPGBI(Hon)
Professor of Surgery and Oncology
Director, Colon & Rectal Surgery
McGill University
Montreal, Quebec

Jon C. Gould, MD
Chief of General Surgery
Walker Chair in General Surgery
Professor of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Clive S. Grant, MD
Professor, Emeritus
Department of Surgery
Mayo Clinic
Rochester, Minnesota

Arin K. Greene, MD, MMSc
Associate Professor
Department of Plastic and Oral Surgery
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

Gwen M. Grimsby, MD
Assistant Professor
Department of Urology
Mayo Clinic Hospital
Pediatric Urologist
Division of Urology
Department of Surgery
Phoenix Children's Hospital
Phoenix, Arizona

Lukasz Filip Grochola, MD, PhD
Department of Visceral and Transplantation Surgery

Swiss HPB and Transplant Center
University Hospital of Zurich
Zurich, Switzerland

Shawn S. Groth, MD
Assistant Professor of Surgery
Division of General Thoracic Surgery
Assistant Professor of Surgery
Division of Surgical Research
Director of Esophageal Surgical Services
Division of General Thoracic Surgery
Baylor College of Medicine
Attending Surgeon
Surgery
Baylor St. Luke's Medical Center
Houston, Texas

Jose G. Guillem, MD, MPH
Professor of Surgery
Weill Cornell Medical College
Attending
Department of Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

Juan P. Gurria, MD
Department of Surgery
University of Cincinnati
Division of Pediatric General and Thoracic Surgery
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Khurshid A. Guru, MD
Professor of Oncology
Director of Robotic Surgery
Department of Urology
Roswell Park Cancer Institute
Buffalo, New York

Ellen Hagopian, MD, FACS
Associate Professor
Department of Surgery
Seton Hall-Hackensack Meridian School of Medicine
South Orange, New Jersey
Hepato-Pancreato-Biliary Surgery

Department of Surgery
Hackensack University Medical Center
Hackensack, New Jersey

Michael E. Halkos, MD
Assistant Professor of Surgery
Division of Cardiothoracic Surgery
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Karem C. Harth, MD
Clinical Assistant Professor, Surgery
Department of Vascular Surgery
Case Western Reserve University School of Medicine
Cleveland, Ohio

Per-Olof Hasselgren, MD, PhD
George H.A. Clowes, Jr.,
Professor of Surgery
Harvard Medical School
Vice Chairman—Research
Director of Endocrine Surgery
Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Bruce H. Haughey, MD
Otolaryngology-Head and Neck Surgery
Washington University School of Medicine
St. Louis, Missouri

Robert J. Havlik, MD
Chairman and George Korkos Professor
Department of Plastic Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Jeffrey W. Hazey, MD, FACS
Memorial Health
Columbus, Ohio

R.J. Heald, CBE
Surgical Director
Pelican Cancer Foundation

United Kingdom

Peter Henke, MD
Leland Ira Doan Professor of Surgery
Section of Vascular Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Patrick C. Hettinger, MD
Assistant Professor
Plastic Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Frank Hinman, Jr., MD†
Clinical Professor
Department of Urology
University of California
San Francisco, California

Steven N. Hochwald, MD, MBA
Professor of Oncology
Vice Chair and Chief of GI Surgery
Roswell Park Cancer Institute
Professor of Surgery
University at Buffalo
Buffalo, New York

Mitchel S. Hoffman, MD
Senior Member
Moffitt Cancer Center
Professor
USF Morsani College of Medicine
Tampa, Florida

George W. Holcomb III, MD, MBA
Katharine Berry Richardson Professor of Pediatric Surgery
University of Missouri—Kansas City School of Medicine
Senior Vice-President
Director, Center for Minimally Invasive Surgery
Chief, Section of General Surgery
Children's Mercy Hospital
Kansas City, Missouri

James Jason Hoth, MD, PhD, FACS
Professor
Department of Surgery
Trauma Medical Director
Wake Forest Baptist Medical Center
Winston-Salem, North Carolina

Jeffrey D. Howard, Jr., MD
Department of Surgery
University of Louisville
Louisville, Kentucky

Thomas S. Huber, MD, PhD
Division of Vascular Surgery and Endovascular Therapy
Department of Surgery
University of Florida College of Medicine
Gainesville, Florida

Franziska Huettner, MD, PhD
Assistant Professor
Institute for Plastic Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Warner Huh, MD
Professor and Division Director of Gynecologic Oncology
University of Alabama at Birmingham
Birmingham, Alabama

Eric S. Hungness, MD, FACS
Associate Professor of Surgery
Northwestern University
Evanston, Illinois
Staff Surgeon
Northwestern Memorial Hospital
Chicago, Illinois

John G. Hunter, MD, FACS, FRCS(Edin)(hon)
Chief Clinical Officer
Mackenzie Professor
Department of Surgery
OHSU School of Medicine
Portland, Oregon

Ahmed A. Hussein, MD

Assistant Lecturer
Department of Urology
Cairo University
Cairo, Egypt

Elias S. Hyams, MD
Assistant Professor of Urology
Columbia University Medical Center
New York, New York

Neil H. Hyman, MD, FACS
Professor
Chief, Section of Colon and Rectal Surgery
Department of Surgery
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Corey W. Iqbal, MD, FAAP, FACS
Medical Director of Pediatric and Fetal Surgery
Overland Park Women and Children's Specialty Services
Overland Park Regional Medical Center
Overland Park, Kansas

Arjun Jayaraj, MBBS, MPH, RPVI
Vascular Surgeon
RANE Center for Venous and Lymphatic Disease
St. Dominic's Hospital
Jackson, Mississippi

Jeffrey Jim, MD, MS
Associate Professor
Vascular Surgery
Washington University School of Medicine
St. Louis, Missouri

Jay A. Johannigman, MD, FACS, FCCM
Professor of Surgery
Director, Division of Trauma, Critical Care, & Acute Care Surgery
University of Cincinnati
Cincinnati, Ohio
Attending Surgeon
University Hospital Inc
Cincinnati, Ohio
Col, US Army (R)

Daniel B. Jones, MD, MS, FACS
Professor of Surgery
Harvard Medical School
Vice-Chair of Surgery
Chief, Minimally Invasive Surgical Services
Director of the Bariatric Program
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Edward L. Jones, MD, FACS
Assistant Professor of Surgery
Section Chief, General Surgery
Denver Veterans Affairs Medical Center
Anschutz Medical Campus
University of Colorado
Denver, Colorado

Jeffrey R. Jorden, MD
Director of Robotic & Minimally Invasive Surgery
Hiram C. Polk, Jr., MD Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky

Thomas B. Julian, MD
Allegheny Health Network Cancer Institute
Allegheny General Hospital
National Surgical Adjuvant Breast and Bowel Project (NSABP)
Pittsburgh, Pennsylvania

Enjae Jung, MD
Assistant Professor
Vascular Surgery
OHSU Knight Cardiovascular Institute
Oregon Health & Science University
Portland, Oregon

Vikram S. Kashyap, MD
Professor, Surgery, Case Western Reserve University School of Medicine
Division Chief, Vascular Surgery, University Hospitals Cleveland Medical Center
Co-Director, Harrington Heart and Vascular Institute, University Hospitals Cleveland Medical Center
Cleveland, Ohio

Burkhard S. Kasper, MD

Privadozent, Neurologische Klinik
Stellvertretender Sektionsleiter Epilepsie
Universitaet Erlangen Germany

Ekkehard M. Kasper, MD, PhD
Associate Professor in Neurosurgery
Harvard Medical School
Director, Neurosurgical Oncology
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Louis R. Kavoussi, MD, MBA
Waldbaum Gardiner Professor and Chairman of Urology
Hofstra-Northwell School of Medicine
Hempstead, New York

Ahmed Kayssi, MD
Limb Preservation Fellow
Inova Health System, IFMC
Falls Church, Virginia

Michael R. B. Keighley, MBBS, FRCS (Edin), FRCS (Eng), MS
Emeritus Professor
University of Birmingham
President of the MASIC Foundation
Trustee, Bowel Disease Research Foundation
London, United Kingdom

Scott R. Kelley, MD, FACS, FASCRS
Assistant Professor of Surgery
Division of Colon and Rectal Surgery
Mayo Clinic
Rochester, Minnesota

Edward Kelly, MD
Assistant Professor
Department of Surgery
Harvard Medical School
Attending Surgeon
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Michael P. Kim, MD
Assistant Professor

Department of Surgical Oncology
MD Anderson Cancer Center
Houston, Texas

Dennis Y. Kim, MD
Associate Professor of Clinical Surgery
David Geffen School of Medicine at UCLA
Division of Trauma/Acute Care Surgery/Surgical Critical Care
Department of Surgery
Harbor-UCLA Medical Center
Torrance, California

Cindy Kin, MD
Colorectal Surgeon
Surgical Oncologist
Assistant Professor of Surgery (General Surgery)
Department of Surgery
Stanford University School of Medicine
Stanford, California

Allan D. Kirk, MD, PhD
David C. Sabiston, Jr., Professor and Chairman
Department of Surgery
Duke University Medical Center
Surgeon-in-Chief
Duke University Health System
Durham, North Carolina

V. Suzanne Klimberg, MD, PhD
Courtney M. Townsend, Jr., MD Distinguished Chair in Surgical Oncology
Vice Chair of the Department of Surgery
Chief of Surgical Oncology
Medical Director for the University of Texas Medical Branch Cancer Institute
Galveston, Texas

Badrinath R. Konety, MD, FACS, MBA
Professor and Chair
Department of Urology
Dougherty Family Chair in Uro-Oncology
Associate Director for Clinical Affairs
Masonic Cancer Center
University of Minnesota
Minneapolis, Minnesota

Matthew C. Koopmann, MD
Assistant Professor of Surgery
Division of Vascular Surgery
Oregon Health and Science University
Staff Vascular Surgeon
VA Portland Health Care System
Portland, Oregon

Kate H. Kraft, MD
Division of Pediatric Urology
Department of Urology
University of Michigan Health System
Ann Arbor, Michigan

Mukta Krane, MD
Associate Professor
Department of Surgery
University of Washington
Outpatient Medical Director—Surgical Specialties
University of Washington Medical Center
Seattle, Washington

Jake E. J. Krige, MBChB, MSc, FACS, FRCS, FCS (SA)
Professor
Department of Surgery
University of Cape Town Health Sciences Faculty
Cape Town, South Africa

Matthew Kroh, MD, FACS
Institute Chief, Associate Professor of Surgery
Digestive Disease Institute
Cleveland Clinic Abu Dhabi
Cleveland Clinic Lerner College of Medicine
Abu Dhabi, United Arab Emirates

Irving L. Kron, MD
Professor and Chair
Department of Surgery
University of Virginia
Charlottesville, Virginia

Helen Krontiras, MD
Professor of Surgery
UAB School of Medicine
Birmingham, Alabama

Robert D. Kugel, MD
Surgeon, Inventor
Hernia Treatment Center Northwest
Olympia, Washington

Moshim Kukar, MD
Assistant Professor
Department of Surgical Oncology
Roswell Park Cancer Institute
Buffalo, New York

Michael E. Kupferman, MD, MBA
Senior Vice-President, Clinical and Academic Network Development
Professor, Department of Head & Neck Surgery
The University of Texas MD Anderson Cancer Center
Houston, Texas

Moon O. Kwoun, MD, RVT, RPVI
Instructor in Surgery
Harvard Medical School
Cambridge Health Alliance
Cambridge, Massachusetts

Gregory J. Landry, MD
Professor
Vascular Surgery
Oregon Health & Science University
OHSU Knight Cardiovascular Institute
Portland, Oregon

Erin O. Lange, MD
Department of Surgery
University of Washington Medical Center
Seattle, Washington

Jacob C. Langer, MD
Professor
Department of Surgery
University of Toronto
Attending Pediatric Surgeon
Hospital for Sick Children
Toronto, Ontario

David W. Larson, MD, MBA, FACS, FASCRS
Chair of Colorectal Surgery

Director of Enterprise Cancer Quality
Mayo Clinic
Rochester, Minnesota

Michael Latzko, MD
Assistant Professor
Department of Surgery
University of Florida College of Medicine—Jacksonville
Jacksonville, Florida

Yosef Laviv, MD
Attending Neurosurgeon
Department of Neurosurgery
Rabin Medical Center
Tel Aviv, Israel

Simon Law, MBBChir, MS (HK), MA (Cantab), FRCSEd, FCSHK, FHKAM, FACS
Cheung Kung-Hai Professor in Gastrointestinal Surgery
Chief, Division of Esophageal and Upper Gastrointestinal Surgery
Department of Surgery
The University of Hong Kong
Queen Mary Hospital
Hong Kong

Anna M. Ledgerwood, MD
Professor
Department of Surgery
Wayne State University School of Medicine
Staff
Department of Surgery
Detroit Receiving Hospital & Harper University Hospital
Detroit, Michigan

Cheong J. Lee, MD, FACS
Division of Vascular Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Dr Peter J. Lee, MBBS, MSc (Med), MS, FRACS
Research Affiliate
The Institute of Academic Surgery at RPA & The Surgical Outcomes Research Centre
Colorectal Surgeon
Department of Colorectal Surgery

Royal Prince Alfred Hospital
Camperdown, Australia

Ken Lee, MD
Department of Surgery
George Washington University
Washington, DC

Toni Lerut, MD, PhD
Emeritus Professor
Department of Clinical and Experimental Medicine: Thoracic Surgery
KU Leuven University
Emeritus Chairman
Thoracic Surgery
University Hospital Gasthuisberg
Leuven, Belgium

Mark Levin, MD, MS
Fellow in Vascular Surgery
Section of Vascular & Endovascular Surgery
Department of Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Edward A. Levine, MD
Professor of Surgery
Chief, Surgical Oncology
Wake Forest University
Winston-Salem, North Carolina

Carol M. Lewis, MD, MPH, FACS
Associate Professor
Department of Head and Neck Surgery
University of Texas MD Anderson Cancer Center
Houston, Texas

Kui-Hin Liau, MBBS, MMed(Surgery), FRCS(Edin), FAMS (Surgery)
Medical Director & Senior Consultant Surgeon
Department of Surgery & Surgical Oncology
Nexus Surgical Associates Pte Ltd
Singapore

Keith D. Lillemoe, MD
W. Gerald Austen Professor
Harvard Medical School

Chief of Surgery
Surgeon in Chief
Massachusetts General Hospital
Boston, Massachusetts

Foong-Yen Lim, MD
Associate Professor
Department of Surgery
Cincinnati Children's Hospital and Medical Center
Surgical Director
Cincinnati Fetal Center
Cincinnati, Ohio

Ryan Little, MD
Department of Otolaryngology & Communication Sciences
Medical College of Wisconsin
Milwaukee, Wisconsin

Chung Mau Lo, MS, FRCS (Edin), FRACS, FACS
Department of Surgery
The University of Hong Kong
Queen Mary Hospital
Hong Kong, China

James N. Long, MD
Magnolia Regional Health Center
Corinth, Mississippi

Marios Loukas, MD, PhD
Chair and Professor
Department of Anatomical Sciences
School of Medicine at St George's University
Grenada, West Indies

Donald E. Low, MD, FACS, FRCS(C)
Head, Thoracic Oncology and Thoracic Surgery, Department of Surgery
Virginia Mason Medical Center
Clinical Assistant
Professor of Surgery
University of Washington School of Medicine
Seattle, Washington

Ann C. Lowry, MD
Clinical Professor
Division of Colon and Rectal Surgery

Department of Surgery
University of Minnesota
Minneapolis, Minnesota

Layla C. Lucas, MD
Arizona Vascular Specialists
Tucson, Arizona

Charles E. Lucas, MD
Professor
Department of Surgery
Wayne State University School of Medicine
Staff
Department of Surgery
Detroit Receiving Hospital & Harper University Hospital
Detroit, Michigan

Anthony Lucci, MD, FACS
Professor of Surgery
Departments of Breast Surgical Oncology and Surgical Oncology
The University of Texas MD Anderson Cancer Center
Houston, Texas

Natalie Lui, MD, MAS
Assistant Professor
Department of Cardiothoracic Surgery
Stanford University
Stanford, California

James D. Luketich, MD, FACS
Henry T. Bahnson Professor of Cardiothoracic Surgery
Chair, Department of Cardiothoracic Surgery
Chief, Division of Thoracic & Foregut Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Junji Machi, MD, PhD
Professor
Department of Surgery
Assistant Director, Office of Global Health and Medicine
John A. Burns School of Medicine
University of Hawaii
Honolulu, Hawaii

Robyn A. Macsata, MD

Chief, Vascular Surgery
Associate Professor of Surgery
The George Washington University
Washington, DC

Robert D. Madoff, MD
Professor and Stanley M. Goldberg Chair in Colon & Rectal Surgery
University of Minnesota
Staff Surgeon and Chief of the Division of Colon & Rectal Surgery
Colon & Rectal Surgery
University of Minnesota Medical Center
Minneapolis, Minnesota

James W. Maher, MD
Professor
Department of Surgery
Division of Bariatric and Gastrointestinal Surgery
Virginia Commonwealth University
Richmond Veterans Administration Medical Center
Richmond, Virginia

Brian A. Mailey, MD
Assistant Professor
Department of Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Mohan K. Mallipeddi, MD
Clinical Instructor
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

Eleftherios P. Mamounas, MD
National Surgical Adjuvant Breast and Bowel Project (NSABP)
Pittsburgh, Pennsylvania
UF Health Cancer Center at Orlando Health
Orlando, Florida

Paul Mansfield, MD, FACS
Professor
Department of Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Christopher R. Mantyh, MD, FACS, FASCRS
Professor
Department of Surgery
Duke University School of Medicine
Chief
Section of Colon and Rectal Surgery
Duke University Medical Center
Durham, North Carolina

Jeffrey M. Marks, MD, FACS, FASGE
Professor of Surgery
Director, Surgical Endoscopy
Program Director
Jeffrey L. Ponsky Professorship in Surgical Education
Case Western Reserve University School of Medicine/University Hospitals Cleveland Medical Center
Cleveland, Ohio

David J. Maron, MD, MBA
Vice Chair, Department of Colorectal Surgery
Director, Colorectal Surgery Residency Program
Cleveland Clinic Florida
Weston, Florida

Robert G. Martindale, MD, PhD
Professor of Surgery
Department of Surgery
Oregon Health & Science University
Chief and Director of Hospital Nutrition Services
Division of General and Gastrointestinal Surgery
Oregon Health & Science University
Portland, Oregon

Viraj Master, MD, PhD, FACS
Professor of Urology
Emory University School of Medicine
Atlanta, Georgia

Douglas J. Mathisen, MD
Hermes C. Grillo Professor of Surgery
Harvard Medical School Chief of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

James L. Mayo, MD

Aesthetic and Reconstructive Surgery Institute
Orlando Health
University of Florida Health Cancer Center
Orlando, Florida

Jack W. McAninch, MD, FACS (Eng)(Hon)
Professor of Urology
University of California, San Francisco
San Francisco, California

Jennifer M. McBride, PhD
Director of Virtual Anatomy Education
Director of Histology
Associate Professor of Surgery
Cleveland Clinic Lerner College of Medicine
Cleveland, Ohio

Daniel P. McCarthy, MD, MBA, MEM
Assistant Professor
Division of Cardiothoracic Surgery
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

John B. McCraw, MD
Crossgates River Oaks Hospital
University of Mississippi Medical Center
Jackson, Mississippi

Sarah A. McLaughlin, MD
Associate Professor
Department of Surgery
Medical Director, Robert and Monica Jacoby Center for Breast Health
Mayo Clinic
Jacksonville, Florida

James T. McPhee, MD
Assistant Professor
Department of Surgery
Boston University School of Medicine
Staff Surgeon
Vascular and Endovascular Surgery
VA Boston Healthcare System
Boston, Massachusetts

David S. Medich, MD, FACS, FASCRS
Division of Colon and Rectal Surgery
University of Pittsburg Medical Center
Pittsburgh, Pennsylvania

Manish Mehta, MD, MPH
Professor of Surgery
Albany Medical College
Albany Medical Center, Vascular Surgery
Albany, New York

W. Scott Melvin, MD
Department of Surgery
Montefiore Medical Center
Bronx, New York

Matthew T. Menard, MD
Assistant Professor of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Emanuele Lo Menzo, MD, PhD
Associate Professor of Surgery
Florida International University
Miami, Florida
Florida Atlantic University
Boca Raton, Florida
Director, Research Department
Staff Surgeon
The Bariatric and Metabolic Institute
Weston, Florida

Miguel A. Mercado, MD
Professor of Surgery
Post-Graduate School of Medicine
Universidad Nacional Autónoma de México
Professor and Chairman
Department of Surgery
Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán
Mexico City, Mexico

J. Wayne Meredith, MD
Professor
Department of Surgery
Wake Forest University Health Sciences

Winston-Salem, North Carolina

Fabrizio Michelassi, MD
Professor
Department of Surgery
Weill Cornell Medicine
Chairman and Surgeon-in-Chief
NewYork-Presbyterian Weill Cornell Medical Center
New York, New York

Dean J. Mikami, MD, FACS
Associate Professor of Surgery
Division Chief, General Surgery
John A. Burns School of Medicine
University of Hawaii
Honolulu, Hawaii

Miroslav N. Milicevic, MD, PhD
Professor of Surgery
The First Surgical Clinic, Clinical Center of Serbia
University of Belgrade
Belgrade, Serbia

Keith R. Miller, MD, FACS
Assistant Professor
Hiram C. Polk, Jr., MD Department of Surgery
University of Louisville
Director of Surgical Nutrition
Department of Surgery
University of Louisville Hospital
Louisville, Kentucky

Joseph L. Mills, Sr., MD
Reid Professor of Surgery
Chief Division of Vascular Surgery and Endovascular Therapy
Baylor College of Medicine
Chief, Vascular Surgery
CHI St. Luke's Medical Center
Houston, Texas

Petros Mirilas
Clinical Professor of Surgical Anatomy and Technique
Centers for Surgical Anatomy and Technique
Emory University School of Medicine
Atlanta, Georgia

Attending Pediatric Surgeon
Agia Sophia Children's Hospital
Athens, Greece

Gregory L. Moneta, MD
Professor of Surgery
Oregon Health & Science University
Chief, Vascular Surgery
OHSU Knight Cardiovascular Institute
Portland, Oregon

John R.T. Monson, MD, FRCS (Ire, Eng, Ed (Hon) Glas (Hon)), FASCRS, FACS
Professor of Surgery
University of Central Florida College of Medicine
Executive Director, Colorectal Surgery
Centre for Colon and Rectal Surgery
Florida Hospital
Orlando, Florida

Stephen G. Moon, MS
Instructor, Pathophysiology and Medical Illustration (former)
The School of Health and Rehabilitation Sciences
The Ohio State University College of Medicine
Columbus, Ohio

Harvey G. Moore, MD, FACS, FASCRS
Assistant Professor
Department of Surgery
Duke University School of Medicine
Durham, North Carolina
Attending Surgeon
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Thomas R. Moore, MD
Professor of Maternal Fetal Medicine
Dean for Clinical Affairs
CEO of Faculty Practice
UC San Diego Health
San Diego, California

Wesley S. Moore, MD
Professor and Chief

Emeritus
Division of Vascular and Endovascular Surgery
David Geffen School of Medicine at UCLA
Professor and Chief
Emeritus
Division of Vascular and Endovascular Surgery
Ronald Reagen UCLA Medical Center
Los Angeles, California

John T. Moore, MD, FACS
Program Director, Surgery Residency Program
Chair
Department of Surgery
Exempla Saint Joseph Hospital
Denver, Colorado

Christopher R. Morse, MD
Assistant Professor
Harvard Medical School
Associate Visiting Surgeon
Massachusetts General Hospital
Boston, Massachusetts

John T. Mullen, MD, FACS
Associate Professor of Surgery
Harvard Medical School
Program Director, General Surgery Residency
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

John B. Mulliken, MD
Professor of Surgery
Harvard Medical School
Director, Craniofacial Center
Co-Director, Vascular Anomalies Center
Department of Plastic and Oral Surgery
Boston Children's Hospital
Boston, Massachusetts

Noriko Murase, MD
Adjunct Associate Professor of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

Zuri Murrell, MD
Medical Director, Colon and Rectal Cancer Program
Samuel Oschin Comprehensive Cancer Institute
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California

Peter Muscarella, MD
Director of Pancreatic Surgery
Department of Surgery
Montefiore Medical Center
Bronx, New York

Philippe Nafteux, MD, PhD
Assistant Professor
Department of Clinical and Experimental Medicine: Thoracic Surgery
KU Leuven University
Clinical Head
Thoracic Surgery
University Hospital Gasthuisberg
Leuven, Belgium

Jaimie D. Nathan, MD
Associate Professor
Department of Surgery
University of Cincinnati
Surgical Director, Kidney and Intestinal Transplant Programs
Surgical Director, Pancreas Care Center, Division of Pediatric General and Thoracic Surgery
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

William H. Nealon, MD
Executive Director Perioperative Services
Clinical Chief
Yale New Haven Health System
Yale School of Medicine
New Haven, Connecticut

Mark R. Nehler, MD
Professor of Surgery
University of Colorado
Denver, Colorado

Uri Netz, MD

Department of Surgery
Price Institute of Surgical Research
Hiram C. Polk, Jr., MD Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky
Faculty of Health Sciences
Ben-Gurion University of the Negev
Department of Surgery
Soroka University Medical Center
Beersheba, Israel

Michael W. Neumeister, MD, FRCSC, FACS
Chair and Professor, Department of Surgery
Chairman of the Division of Plastic Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Richard F. Neville, MD
Associate Director
Inova Heart and Vascular Institute
Director, Vascular Services
Vice-Chairman, Department of Surgery
Inova Health System
Inova Fairfax Medical Center
Falls Church, Virginia

Kelvin K. Ng, MS, PhD, FRCS (Edin)
Department of Surgery
The University of Hong Kong
Queen Mary Hospital
Hong Kong, China

Heather R. Nolan, MD
Fetal Surgery Fellow
Division of Pediatric General and Thoracic Surgery
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Steven Nurkin, MD, MS, FACS
Assistant Professor
Department of Surgical Oncology
Roswell Park Cancer Institute
Buffalo, New York

Michael S. Nussbaum, MD, FACS

Professor and Chair
Department of Surgery
Virginia Tech Carilion School of Medicine
Senior Vice-President and Chair
Department of Surgery
Carilion Clinic
Roanoke, Virginia

Lloyd M. Nyhus, MD†
Department of Surgery
University of Illinois College of Medicine
Peoria, Illinois

Paul E. O'Brien, BBS(Hons), FRACS, MD
Emeritus Professor of Surgery
Emeritus Director
Centre for Obesity Research and Education
Monash University
Melbourne, Australia

Gustavo S. Oderich, MD
Associate Program Director and Director of Endovascular Therapy
Division of Vascular and Endovascular Surgery
Professor of Surgery
Mayo Clinic College of Medicine
Rochester, Minnesota

Kelly Olino, MD
Assistant Professor
Department of Surgery
Division of Surgical Oncology
University of Texas Medical Branch
Galveston, Texas

Marshall J. Orloff, MD
Distinguished Professor of Surgery, Emeritus
Founder of School of Medicine
Founder of Department of Surgery
University of California, San Diego
San Diego, California

Mark B. Orringer, MD
Cameron Haight Distinguished University Professor
Active Professor Emeritus of Surgery
University of Michigan

Ann Arbor, Michigan

Marc C. Osborne, MD
Clinical Associate Professor
Department of Surgery
University of Minnesota
Minneapolis, Minnesota
Staff Surgeon
Fairview Southdale Hospital
Edina, Minnesota

Harald C. Ott, MD
Associate Professor in Surgery
Harvard Medical School
Assistant Surgeon
Massachusetts General Hospital
Boston, Massachusetts

C. Keith Ozaki, MD
John A. Mannick Professor of Surgery
Department of Surgery
Harvard Medical School
Associate Surgeon
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

H. Leon Pachter, MD, FACS
The George David Stewart Professor
Chairman of the Department of Surgery
NYU Langone Medical Center
New York, New York

Theodore N. Pappas, MD
Professor
Department of Surgery
Duke University School of Medicine
Chief, Division of Advanced Oncologic & GI Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Catherine Caldwell Parker, MD
Assistant Professor
Division of Surgical Oncology

Department of Surgery
UAB School of Medicine
Birmingham, Alabama

Himanshu J. Patel, MD
Joe D. Morris Collegiate Professor
Section Head, Adult Cardiac Surgery
Department of Cardiac Surgery
University of Michigan Medical School
Ann Arbor, Michigan

Philip S. K. Paty, MD
Professor of Surgery
Albany Medical College
Albany Medical Center, Vascular Surgery
Albany, New York

Eric M. Pauli, MD, FACS, FASGE
Associate Professor of Surgery
Director of Endoscopic Surgery
Department of Surgery
Division of Minimally Invasive and Bariatric Surgery
Penn State Milton S. Hershey Medical Center
Hershey, Pennsylvania

Timothy M. Pawlik, MD, MPH, PhD
Professor and Chair, Department of Surgery
The Urban Meyer III and Shelley Meyer Chair for Cancer Research
The Ohio State University Wexner Medical Center
Columbus, Ohio

Jonathan P. Pearl, MD
Associate Professor
Department of General Surgery

Associate Professor
Department of Surgery
Baylor College of Medicine
Houston, Texas

Alan C. Wittgrove, MD, FACS, FASMBS
Department of Surgery
Scripps Memorial Hospital La Jolla
San Diego, California

Bo Yang, MD, PhD
Assistant Professor of Cardiac Surgery
Department of Cardiac Surgery
University of Michigan Medical School
Ann Arbor, Michigan

Jerrold Young, MD, FACS
Voluntary Associate Professor
DeWitt Daughtry Family Department of Surgery
Leonard M. Miller School of Medicine
Miami, Florida

Jonathan S. Zager, MD, FACS
Chair of Graduate Medical Education
Director of Regional Therapies
Senior Member, Moffitt Cancer Center
Departments of Cutaneous Oncology and Sarcoma
Professor of Surgery, University of South Florida School of Medicine
Moffitt Cancer Center
Tampa, Florida

Steven M. Zeitels, MD
Chief
Center for Laryngeal Surgery & Voice Rehabilitation

Massachusetts General Hospital
Boston, Massachusetts

Nicholas J. Zyromski, MD
Associate Professor
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

[†]Deceased.

PREFACE

I am writing from my favorite place in the world—Nantucket Island. I have only a few instruments with me—an ink pen, a pencil, and a pad of paper. An American flag is flying over the water, and a few boats are making their way through the harbor.

The scene is special to me. Our house, discovered by our son Erich after my wife Karen and I returned from Cincinnati to Boston after 23 years, is blessed by a 40-foot Osprey pole where the female is right now standing guard after feeding two rapidly growing chicks. And I am fortunate having some of my family here with me; Alexandra, who is resting a broken foot, and her husband Peter.

I recently turned 80 years old as did Karen. I have been blessed both professionally and personally. As one who slept on the couch when 8 to 10 years old living on the lower east side of New York City in the 1930s and 1940s in my grandparents' apartment, I have been privileged to have been able to work my way to a position where I hope that I have contributed at least somewhat to expanding the knowledge of surgical science and practice. It has indeed been a privilege to have taken a part in educating and mentoring some 105 Fellows from the United States and abroad and to know that today 22 of those Fellows have their own departments. It is also a privilege to have been part of great institutions during the course of my career—from the Massachusetts General Hospital to 23 years as Chairman of Surgery at the University of Cincinnati, then 8 years as Chairman of Surgery at Harvard at the Beth Israel Deaconess in Boston.

I also have been blessed personally. None of my professional accomplishments would have been possible without my wife Karen, a beautiful and very bright and articulate social worker whom I met on my first Saturday as an intern at the Massachusetts General Hospital in 1961. Karen and I have been together for 56 years and married for 52. She has been a source of advice, has played a central role in building my departments, and has raised two wonderful children—Erich and

Alexandra.

Erich, 50, is a successful business consultant who, with his wife Hallie, has given us two grandchildren—Asher and Aleksei. Asher, 4, is a very bright and articulate little boy who shows early signs of fascination with the medical profession (we can only hope!). When not swimming he is exploring the outside and playing with my vintage Lionel train set that has 32 engines, many cars and a huge number of accessories. He is also somewhat of a conman and very good at it. On the second day of camp this summer he ran down for breakfast exclaiming, "No camp today." At 7:30 AM of the same day Erich came down to the kitchen asking Asher if he was ready to leave for camp. Asher left without an apology. He is also a caring and vigilant older brother to Aleksei. At 2 months old, Aleksei is the newest member of the family, a relaxed baby (except when hungry!), he has started to smile—and we have all the best hopes for him. Our daughter-in-law Hallie recently "retired" from the financial world and is a graphic designer. She is very beautiful, very bright, and is an extremely attentive mother. She is currently progressing with her own graphic design business.

Alexandra, 47, did not fall far from the tree medically and chose to care for animals. She has been named one of the top veterinarians in Washington, DC and is married to Peter, an award-winning anesthesiologist who pilots his own plane and recently joined the Naval Reserves. They have no human children by choice but foster several dogs and cats—many of whom may outlive us all thanks to her.

The good Lord has been kind to us indeed. It has been a pleasure to contribute as editor to the third and fourth editions as well as produce the fifth, sixth and now seventh edition. I am pleased for how relevant the *Mastery of Surgery* remains despite radical changes in learning and media influence on our own society.

Principal mentors in my career, although there are many luminaries who have helped and supervised my development of my career, there are three who stand out:

Professor Claude Welch

As a surgeon and human being Claude Welch was my idol. He was a

quick, very accurate surgeon and very knowledgeable. He was especially quick in removing cancer. When I undertook cancer of the rectum I tried to allow patients to retain their rectum. He said I was wrong. But when I did not have recurrence he stopped criticizing but never adopted this approach himself.

Professor Julias Axelrod

He was a role model for me at the National Institutes of Health. He started as a technician and became the head of the Laboratory section. He never forgot his past. He was a great teacher and only had one technician who ground up the tissues and washed the glassware. Helen was African American, rare at that time.

Reuven Katz, Esquire

Mr. Katz was a wonderful attorney and head of a major Cincinnati law firm. He was a brilliant teacher and was a major influence on my success, for the 23 years I was chair of the Department of Surgery, and as how to relate to various people. He became a major influence in the 23 years I was chair of the Department of Surgery at the University of Cincinnati.

Josef E. Fischer

Nantucket, Massachusetts

CONTENTS

 *Chapters with icon are web-only*

VOLUME I

SECTION I

PERIOPERATIVE CARE OF THE SURGICAL PATIENT

CHAPTER 1: Metabolic and Inflammatory Responses to Trauma and Infection
Vance L. Albaugh • Igal Breitman Naji N. Abumrad

CHAPTER 2: Perioperative Management: Practical Principles, Molecular Basis of Risk, and Future Directions
Per-Olof Hasselgren • Jeremy W. Cannon Josef E. Fischer

CHAPTER 3: Enteral Nutrition Support
Keith R. Miller • Robert G. Martindale

CHAPTER 4: Cardiovascular Monitoring and Support
Eric J. Charles • Irving L. Kron

CHAPTER 5: Pulmonary Risk and Ventilatory Support
Jay A. Johannigman • Richard Branson

CHAPTER 6: Hemorrhagic Risk and Blood Components
Karen J. Brasel

CHAPTER 7: Perioperative Antimicrobial Prophylaxis and Treatment of Surgical Infection
Kui-Hin Liau • Giorgio Tarchini J.S. Solomkin

CHAPTER 8: Multiple Organ Dysfunction Syndrome: Prevention and Clinical Management
David J. Dries

CHAPTER 9: Immunosuppression in Organ Transplantation
Mani A. Daneshmand • Allan D. Kirk

 **CHAPTER 10: Surgeons and the Opioid Epidemic**

Jeffrey D. Howard, Jr. • *Hiram C. Polk, Jr.*

SECTION II
BASIC SURGICAL SKILLS: NEW AND EMERGING TECHNOLOGY

CHAPTER 11: Ventral Abdominal Hernia: Open and Minimally Invasive and Component Separation Release
Stephen R.T. Evans • *Parag Bhanot*

CHAPTER 12: Laparoscopic Suturing and Stapling
Jon C. Gould

CHAPTER 13: Ultrasonography by Surgeons
Ellen Hagopian • *Junji Machi*

CHAPTER 14: Tumor Ablation: Technologies and Clinical Applications
Michael S. Sabel

CHAPTER 15: Upper and Lower Gastrointestinal Endoscopy
Jeffrey L. Ponsky • *Jonathan P. Pearl*

CHAPTER 16: Soft Tissue Reconstruction With Flap Techniques
Luis O. Vásconez • *Salman Ashruf Franziska Huettner* • *Michael Ruebhausen*

CHAPTER 17: Hand Surgery: Traumatic and Infectious Emergencies
Brian A. Mailey • *Michael W. Neumeister*

CHAPTER 18: Robotic Surgery
Michael S. Nussbaum • *Michael Latzko*

CHAPTER 19: Surgical Energy
Edward L. Jones • *Dean J. Mikami*

SECTION III
THE HEAD AND NECK

CHAPTER 20: Anatomy of the Head and Neck
Aaron Ruhalter

CHAPTER 21: Surgery of the Major Salivary Glands
Carol M. Lewis • *Michael E. Kupferman*

CHAPTER 22: Anatomy of the Parotid Gland, Submandibular Triangle, and Floor of the Mouth
Aaron Ruhalter

CHAPTER 23: Lip Reconstruction
Patrick C. Hettinger • *Robert J. Havlik*

CHAPTER 24: Surgery for Cancer of the Oral Cavity
William R. Carroll

CHAPTER 25: Neck Dissection
Ian Ganly •Jatin P. Shah

CHAPTER 26: Congenital Lesions: Thyroglossal Duct Cysts, Branchial Cleft Anomalies, and Cystic Hygromas
Juan P. Gurria • Jaimie D. Nathan

CHAPTER 27: Vascular Anomalies of Infancy and Childhood
Arin K. Greene • John B. Mulliken

CHAPTER 28: Surgical Treatment of Laryngeal Cancer: A Legacy of Minimally Invasive Innovation and the Preservation of Airway, Swallowing, and Vocal Function
Steven M. Zeitels • John C. Wain

CHAPTER 29: Surgical Treatment of Pharyngeal Cancer
Bruce H. Haughey • Parul Sinha

CHAPTER 30: Malignant Melanoma and Skin Cancer
Hiram C. Polk, Jr. • Jane V. Carter • Uri Netz

CHAPTER 31: Melanoma
Douglas Tyler • Kelly Olino

CHAPTER 32: Inguinal Lymph Node Dissection: Indications and Surgical Technique
Steven Agle • Douglas Tyler

CHAPTER 33: Evaluation and Repair of Common Facial Injuries
Branko Bojovic

CHAPTER 34: Resection and Reconstruction of the Trachea
Natalie Lui • Harald C. Ott • Douglas J. Mathisen

CHAPTER 35: Penetrating Neck Injuries
Alain Corcos • Andrew B. Peitzman

CHAPTER 36: Neurosurgical and Neurologic Emergencies for Surgeons
Ekkehard M. Kasper • Yosef Laviv • Clark C. Chen • Burkhard S. Kasper

CHAPTER 37: Tracheotomy
Ryan Little • Jonathan M. Bock

SECTION IV
ENDOCRINE SURGERY

CHAPTER 38: Surgical Anatomy of the Thyroid, Parathyroid, and Adrenal Glands
Clive S. Grant

CHAPTER 39: Biopsy, Lobectomy, Total Thyroidectomy, and Lymph Node Dissection for Thyroid Cancer
Randall Scheri • Sanziana Roman • Julie Ann Sosa

CHAPTER 40: Comprehensive Parathyroidectomy for the Treatment of PHPT, Including Intraoperative Parathyroid Hormone Assay–Guided Parathyroidectomy
Azadeh A. Carr • Tracy S. Wang

CHAPTER 41: Minimally Invasive Parathyroidectomy
Robert Udelsman • Tobias Carling

CHAPTER 42: Secondary and Tertiary Hyperparathyroidism
Richard A. Prinz • Kaare J. Weber • Shalini Arora

CHAPTER 43: Transsternal, Transcervical, and Minimally Invasive Thymectomy for Benign and Malignant Disease
Daniel P. McCarthy • Malcolm M. DeCamp

CHAPTER 44: Adrenalectomy—Minimally Invasive and Open
L. Michael Brunt • Arghavan Salles

CHAPTER 45: Pancreatic Neuroendocrine Tumors
Michael P. Kim • Brian D. Badgwell

SECTION V
THE BREAST, CHEST, AND MEDIASTINUM

CHAPTER 46: Embryology and Anatomy of the Breast
Kirby I. Bland

CHAPTER 47: Benign Disease and Breast Pain
Amy C. Degnim • Karthik Ghosh

CHAPTER 48: Diagnostic Approach to Breast Abnormalities
Catherine Caldwell Parker • Heidi Umphrey Helen Krontiras • Kirby I. Bland

CHAPTER 49: Breast-Conserving Surgery
J. Michael Dixon

CHAPTER 50: Radiation Treatment, Whole and Partial Breast and Intraoperative Irradiation
Julia White

CHAPTER 51: Ablative Techniques for Benign and Malignant Breast

Tumors
Sheldon Feldman • Margaret Chen

CHAPTER 52: Sentinel Lymph Node Biopsy in Breast Cancer
Anthony Lucci • Sarah M. DeSnyder • Oluwadamilola (Lola) Fayanju

CHAPTER 53: Lymphedema—Pathophysiology, Prevention, and Treatment
Sarah A. McLaughlin

CHAPTER 54: Modified Radical Mastectomy and Radical Mastectomy
Kirby I. Bland

CHAPTER 55: Oncoplastic Techniques for Breast Conservation Surgery
Kristine E. Calhoun • Benjamin O. Anderson

CHAPTER 56: Breast Reconstruction Following Mastectomy
James N. Long • John B. McCraw • Jorge I. de la Torre • Luis O. Vásconez

CHAPTER 57: Chest Wall Resection and Reconstruction for Advanced/Recurrent Carcinoma of the Breast
Kirby I. Bland • Cristiano Boneti • R. Jobe Fix • Robert J. Cerfolio

CHAPTER 58: Clinical Trials and Follow-Up for Breast Cancer
Michael S. Cowher LaShondria Simpson-Camp Eleftherios P. Mamounas • Thomas B. Julian

CHAPTER 59: The Deep Inferior Epigastric Perforator Flap for Breast Reconstruction
Robert J. Allen • James L. Mayo

CHAPTER 60: Applied Anatomy of the Chest Wall and Mediastinum
Petros Mirilas • Michael E. Halkos • John D. Symbas • Panagiotis N. Symbas • Lee J. Skandalakis

CHAPTER 61: Thoracic Trauma
J. Wayne Meredith • James Jason Hoth

CHAPTER 62: Pulmonary Resection
Bryan M. Burt • Shawn S. Groth • David J. Sugarbaker

SECTION VI
THE DIAPHRAGM

CHAPTER 63: Surgical Anatomy of the Diaphragm
Petros Mirilas • Lee J. Skandalakis • Richard R. Ricketts • Marios Loukas

CHAPTER 64: Congenital Diaphragmatic Hernia
Corey W. Iqbal

CHAPTER 65: Eventration of the Diaphragm
Heather R. Nolan • Daniel von Allmen • Foong-Yen Lim

CHAPTER 66: Traumatic Injury to the Diaphragm
H. Leon Pachter • Chad T. Wilson • Spiros G. Frangos

CHAPTER 67: Paraesophageal Hernia—Open Repair
W. Scott Melvin • Kyle A. Perry

CHAPTER 68: Gastroesophageal Reflux Disease in Infants and Children
George W. Holcomb III • Brad W. Warner

SECTION VII
THE GASTROINTESTINAL TRACT
Part A: The Esophagus

CHAPTER 69: The Anatomy of the Esophagus

PERIOPERATIVE CARE OF THE SURGICAL PATIENT

1 Metabolic and Inflammatory Responses to Trauma and Infection

Vance L. Albaugh, Igal Breitman, and Naji N. Abumrad

INTRODUCTION

Surgery has its roots in providing care for those patients coping with injury or infection. The last several decades, especially with the advancements in molecular biology, have seen an enormous amount of progress describing the wide spectrum of illnesses that result following trauma or infection—from minor, local reactions to surgery, to systemic stress responses, to sepsis, to systemic inflammatory response syndrome (SIRS), and, finally, to multisystem organ failure (MSOF). The scientific tools and methods that have evolved over this time period have led to elaborate understandings of the cellular and molecular physiologic underpinnings of the response to trauma and infection. Regardless of the amount of progress, our knowledge continues to be refined as we are continually reminded of the intricacy of the body's response to trauma and infection. A thorough understanding of the mechanisms at work following trauma and infection is crucial for any practicing surgeon, as this understanding is the hallmark of transferring knowledge gained in research to innovative surgical care at the bedside.

OVERVIEW

Following extensive tissue damage or systemic insult (e.g., infection, hypoperfusion, hypothermia, acid–base disturbance, pain), a number of local and systemic physiologic and biochemical alternations can present and are referred to collectively as "the stress response." This systemic response is mediated by complex signaling systems, including afferent and efferent nervous signals, immunologic and hormonal adaptations, and systemic washout of locally produced substances (e.g., cytokines). Sir David Cuthbertson first referenced the stress response in the 1930s from his keen observations of a biphasic immune, inflammatory, and metabolic response to injury, which was further modified by Francis Moore in the

1970s. The early (<24 hours) hypometabolic phase (termed “ebb” by Cuthbertson) represents a coordinated response directed toward immediate survival of the overall organism. It starts with the activation of local coagulation and innate immune factors. At that time, while evidence of a systemic response may be minimal in subjects with mild injury, an insult of sufficient magnitude will trigger local activation of the stress response that is followed by systemic inflammatory and endocrine responses. These responses present as surges in plasma catecholamine, cortisol, and aldosterone concentrations that result in tachycardia, tachypnea, vasoconstriction, decreased cardiac output and oxygen consumption, lower basal metabolic rate, increased sodium and water retention, shunting of blood from the periphery to the vital organs, and acute-phase protein (APP) production. If the organs survive, there is transition from the initial “ebb” phase to the “flow” phase. The flow phase of the stress response is characterized by explosive metabolic and immune activity, enhanced enzymatic function, as well as tissue repair. Massive neuroendocrine flux involving the production and secretion of catecholamines, antidiuretic hormone (ADH), cortisol, insulin, glucagon, and growth hormone (GH) characterize the flow phase. Moreover, the increased adrenergic stimulation increases the glucagon to insulin ratio and, combined with the increased serum cortisol and cytokine concentrations, induces a state of enhanced proteolysis and lipolysis to mobilize carbon sources for hepatic gluconeogenesis.

This fuel mobilization typically comes from amino acid release from increased catabolism of skeletal muscle and visceral proteins. Some of these amino acids are then released into the plasma and are available to be taken up by the liver to be used as gluconeogenic substrates and hepatic protein synthesis, while others are used for enzyme synthesis and collagen deposition at the site of injury. During this time the energy needs of most other tissues are met by the increased availability of free fatty acids (FFAs) and ketone bodies that result from increased adipocyte lipolysis. This increased lipolytic flux is marked by adipocyte glycerol release that is used as a glucose precursor by the liver, while the FFAs are available for hepatic oxidation and energy production for these gluconeogenic processes.

Clearly this massive catabolic process requires augmented blood flow to the muscle, liver, and areas of tissue injury. As one might expect, individuals present with tachycardia and tachypnea, peripheral edema,

fever, hyperglycemia, leukocytosis, increased O_2 consumption, increased CO_2 production, increased minute ventilation, elevated resting energy expenditure (REE), and negative nitrogen balance. Consequently, the liver provides substrates through gluconeogenesis and synthesis of ketone bodies, detoxifies nitrogenous waste via the synthesis of urea, and elaborates a series of APPs that bind metabolic by-products or limit the activity of proteolytic enzymes secreted by activated leukocytes. Renal blood flow and glomerular filtration increase and aid excretion of nitrogenous by-products. Cytokines and adipokines released from macrophages and adipose tissue, respectively, result in disrupted capillary tight junctions, leading to vascular leak allowing fluid and substrates to flow toward the avascular area of injury, as well as to the interstitium in other body parts.

Manifestations of this hypermetabolic phase can be seen clinically in every postoperative patient. Patients retain fluid and sodium through urine concentration and redistribution of blood flow to vital organs, as well as compensate for the intravascular depletion secondary to capillary leak and possible external fluid losses (e.g., blood loss, insensible operative losses). If allowed to go unchecked, this catabolic response would deplete endogenous resources and become maladaptive. Systemic inflammatory response, severe metabolic depletion, and possible secondary infection can all cause damage to vital organs that were not initially compromised by the injury. Acute respiratory distress syndrome (ARDS), renal insufficiency, hepatic dysfunction, loss of gut epithelial barrier function, immunoparalysis, and sepsis may develop and the multiorgan dysfunction can be fatal. Fortunately, with appropriate support measures, the stress response nearly always resolves itself without complications.

The intensity and duration of the flow phase roughly correlate to the extent and type of injury, with the catabolic process usually peaking at approximately 48 to 72 hours postinjury. If the insult resolves, the body transitions to an anabolic state, marked by surges in insulin, GH, and insulin-like growth factor I (IGF-I) concentrations within 5 to 10 days of injury. These hormonal changes are associated with a flux of protein, fluid, and electrolytes returning to the depleted intracellular space, particularly the skeletal muscle. Interstitial edema fluid is reabsorbed and the excess fluid is eliminated with a brisk diuresis. As the cellular space re-expands, the need for electrochemical equilibrium mandates the movement of ions (K^+, Mg^{2+}, and PO_4^{3-}) from the blood into the cells, and subsequently

serum levels of these ions decrease which requires sufficient replacement. Anorexia and fatigue gradually resolve, and heart rate, respirations, and plasma glucose normalize. As the entire process nears resolution, nitrogen balance becomes positive and homeostasis is restored.

INFLAMMATORY RESPONSE

The inflammatory response to injury involves interplay between several hormones (catecholamines and cortisol) and a large number of mediators (cytokines and chemokines). The immune and inflammatory responses to injury are predictable and well-orchestrated, and adaptive series of events evolve leading to maximize healing potential. The inflammatory response is a normal and vital part of healing and recovery from either traumatic injury or elective surgery. A normal, balanced, and well-controlled inflammatory response in previously healthy patients almost always results in an uneventful recovery.

Innate Immune System

The immune response can be divided into early innate and later adaptive responses. The innate immune system is the first line of defense and its principal components are the epithelial barriers and the immune cells that reside within them. These cellular components of the innate immune system include phagocytes such as neutrophils, macrophages and dendritic cells, and natural killer (NK) cells. It is noteworthy that these antigen-presenting cells (e.g., macrophages, dendritic cells) also play important roles in the adaptive immune response as well as innate immunity. Tissue damage, or microorganisms invading one or more of the epithelial barriers, is immediately recognized by the multiple components of the innate response. This rapid response is due to an elaborate system of receptors expressed on innate immune cells that recognize nonself antigens and pathogen-associated molecular patterns (PAMPs) (also known as microorganism-associated molecular patterns [MAMPs]). The best known examples of PAMPs are lipopolysaccharides (LPS) in gram-negative bacteria, lipoteichoic acids in gram-positive bacteria, mannose-rich oligosaccharides in microbial glycoproteins, mannans, unmethylated CpG sequences in bacteria DNA, double-stranded RNA in replicating viruses, glucans, and N-formylmethionine (a bacterial eukaryotic protein).

The receptors that have evolved to recognize these PAMPs are called pattern-recognition receptors, and these can functionally be divided into

endocytic receptors, which internalize microorganisms for phagocytosis, and signaling receptors, which activate cellular signaling pathways that induce the expression of a variety of immune-response genes. The most important receptors that mediate endocytosis are the mannose receptors of the calcium-dependent lectin family, which recognize terminal mannose and fucose residues of glucoproteins and glycolipids that are characteristic of microorganisms, as well as the scavenger receptors that bind to bacterial cell walls. Among these signaling receptors, the two main groups of receptors are the Toll-like receptors (TLRs) and the G-protein–coupled receptors, of which the TLRs are the most prominent in the induction of immune and inflammatory responses.

Toll-like Receptors

The Toll signaling pathway was initially described in Drosophila in 1985, with the human homologue identified in 1997. TLRs are single, transmembrane spanning receptors that consist of an external ligand binding domain and an internal activation domain that transmits an intracellular signal. Binding of extracellular ligand (e.g., LPS, peptidoglycan) induces dimerization of receptors that appear to be necessary for a robust activation of the signaling pathway. At least 10 human TLRs have been described and are specific for different PAMP molecules. TLR1, 2, 4, 5, and 6 recognize bacterial products, of which TLR2 has been implicated in detection of gram-positive bacteria. The well-studied TLR4 binds LPS, while TLR3, TLR7, and TLR8 are specific for viral detection. TLR9 appears to be involved in both microbial and viral recognition.

TLRs are involved in crosstalk between the innate and the adaptive immune systems. They are expressed by dendritic cells and T-lymphocytes, as well as on a variety of parenchymal cells (e.g., adrenals, liver, and spleen). The adrenal-expressed TLRs influence the systemic inflammatory response by their effect on cortisol secretion. Upon “sensing” danger by binding their specific ligands, TLRs activate immune and endothelial cells resulting in the upregulation of nuclear factor (NF)-κB signaling. Prior to activation NF-κB is sequestered in the cytosol by inhibitor of κB (IκB). With activation of the TLR-coupled signaling cascade IκB is targeted for proteasomal degradation by ubiquitin, which allows NF-κB to translocate to the nucleus and transcriptionally activate a number of inflammatory mediators (e.g., chemokines, adhesion molecules, growth factors) and proinflammatory cytokines (e.g., tumor necrosis

factor-α [TNF-α] and interleukin-1 [IL-1]). With ligand binding the IL-1 and TNF-α receptors further activate the same signaling pathways amplifying the immune response (Fig. 1.1). TLRs are also involved in the recognition of endogenous ligands, which are released from damaged or dying cells, or come from a depredated extracellular matrix. These molecules include lipids, carbohydrates, proteins, and nucleic acids.

Extensive research has been conducted on whether genetic variations can be used to identify patients at high risk of developing sepsis and organ dysfunction during severe infection. There is evidence suggesting that genetic polymorphisms in TLRs may influence a patient's outcome in sepsis. For example, a single nucleotide polymorphism (SNP) of TLR1 (TLR1–7202A/G) is associated with higher organ dysfunction, increased gram-positive infections, and death by sepsis. Patients with a TLR4 gene mutation, especially those involving TLR4, $Asp^{299}Gly$ allele have a higher incidence of gram-negative infections; this polymorphism is also attributed to the severity of SIRS. Similar to other investigations of SNPs, however, further research is needed to validate and quantify the degree of clinical impact and whether or not any significant therapeutic potential might be leveraged.

G-Protein–Coupled Receptors

These receptors initiate intracellular responses transmitted by guanine nucleotide-binding G protein. These receptors are activated by chemokines, proteolytic products of complement proteins (e.g., C5a), and lipid mediators of inflammation (platelet-activating factor, prostaglandin E, and leukotriene B4).

Complement

The complement system consists of more than 30 proteins that initiate a cascade of events that ultimately results in destruction of foreign organisms. Complement is a nonspecific system that can be rapidly activated by one of three pathways: classic, alternative, and mannan-binding lectin. In the classical pathway an IgM or IgG antibody–antigen complex activates the complement cascade. The alternative pathway does not rely on an antibody–antigen complex, but is rather activated directly by bacterial cell wall components. The mannan-binding lectin pathway is homologous to the classical pathway, except that the cascade is initiated by a mannan-binding lectin protein produced by the liver. Each of these three pathways results in construction of the membrane attack complex, which

effectively creates pores within the membrane of the targeted cell (i.e., the invader/bacterium) that cause cell destruction. Aside from this microbial lysis, activation of the complement cascade results in platelet activation, histamine release, neutrophil recruitment through chemotactic factors, and stimulation of neutrophil degranulation.

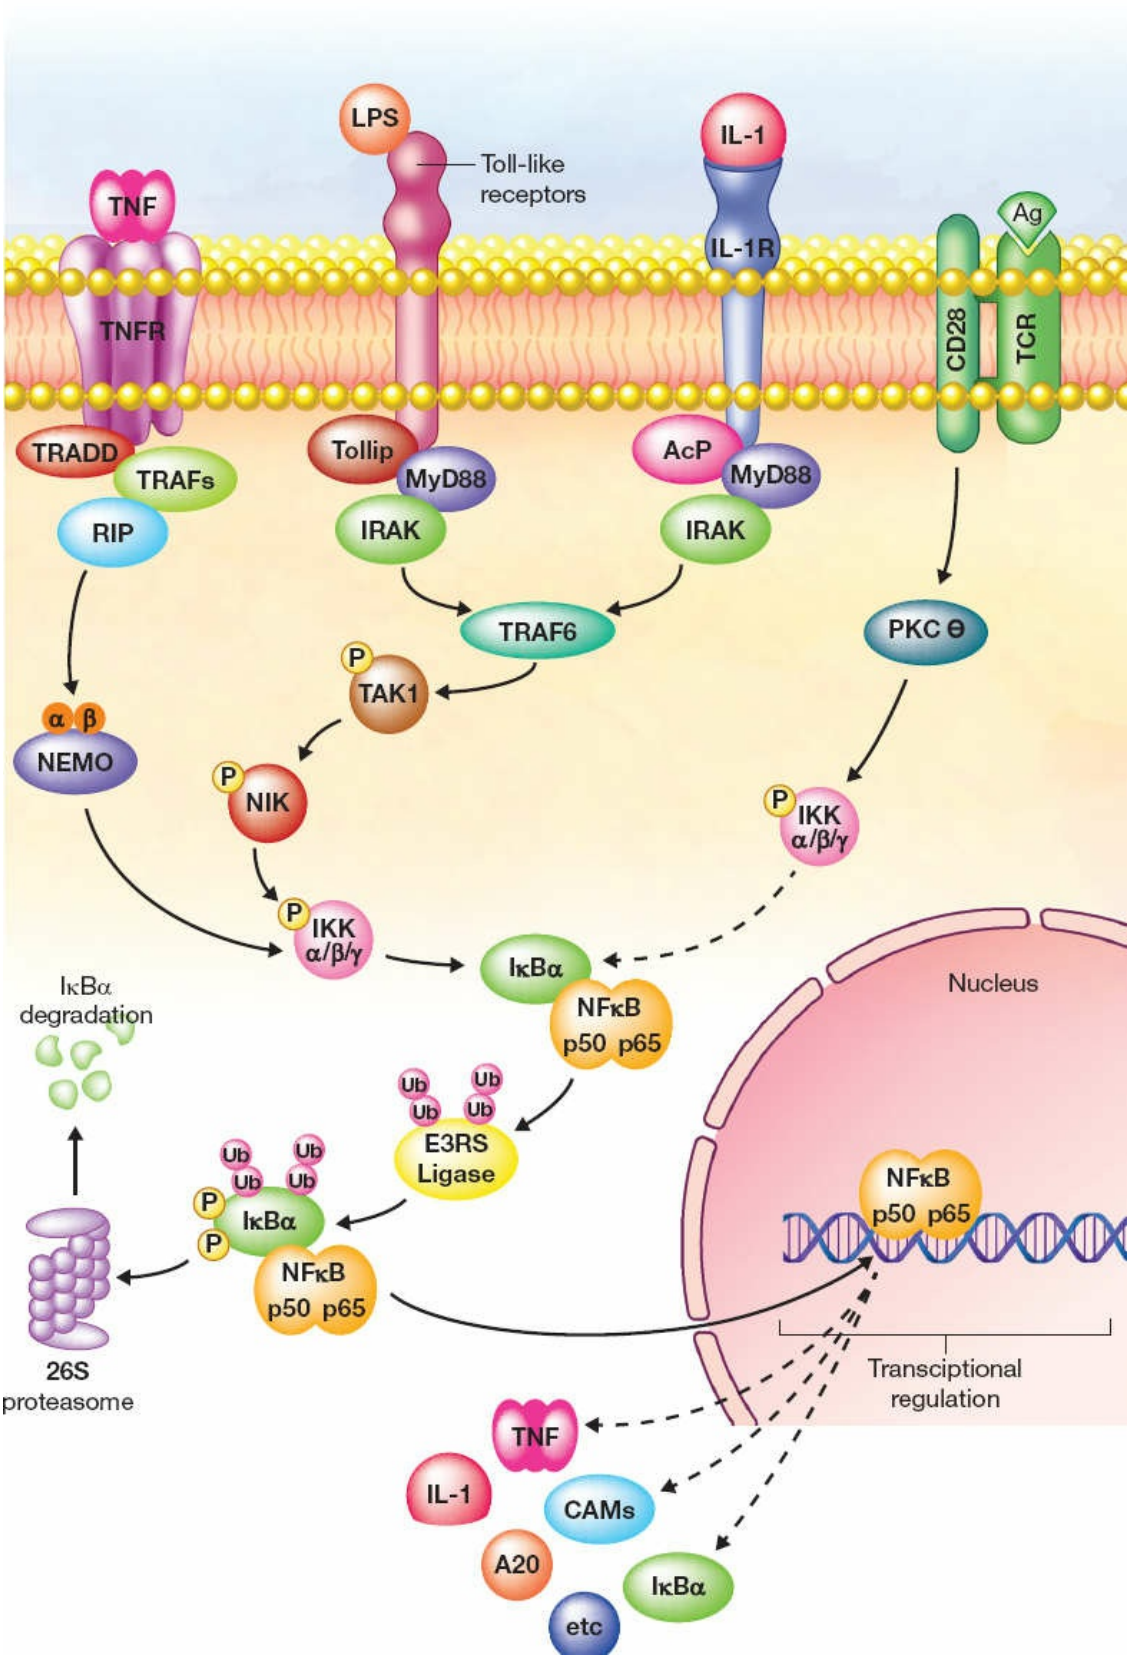

Figure 1.1. Brief overview of proinflammatory signal transduction pathways. ACP, accessory membrane-spanning protein; IKKα, inhibitory protein IκB kinase α; IKKβ, IκB kinase β IL-1, interleukin-1; IL-1R, IL-1 receptor; IRAK, IL-1R-activated kinase;

NIK, NF-κB-inducing kinase; NEMO, NF-κB essential modulator; RIP, receptor-interacting protein; TCR, T-cell receptor; TNFR, tumor necrosis factor receptor; TRADD, TNFR and associated death-domain protein; TRAF2, TNFR-associated factor 2. (Adapted from Baeuerle PA. Pro-inflammatory signaling last pieces in the NF-kappaB puzzle. *Curr Biol* 1998;8:R19, with permission.)

Complement activation pathways are regulated by a large number of regulatory complement-control proteins, preventing overactivation of the whole system; systemic overwhelming activation of the system can result in changes in hemodynamic parameters, leading to shock. Persistent elevation of the complement-derived chemotaxins C3a, C4a, and C5a have been correlated with increased remote organ damage and mortality following sepsis. Neutralization of C5a, using a monoclonal antibody, resulted in improved survival and decreased organ damage in animal models.

Alarmins

Activation of the immune system can also be triggered by injury or trauma without evidence of a bacterial focus, which is mediated by alarmins or damage-associated molecular patterns (DAMPs). Alarmins are released either after a nonprogrammed cell death (i.e., necrosis) or by cells of the immune system. Within this family of endogenous triggers are high mobility group box 1 (HMGB1), heat shock proteins (HSPs), beta-defensins, cathelicidin, eosinophil-derived neurotoxins (EDN), as well as others. These structurally diverse proteins serve as endogenous mediators of innate immunity as chemoattractants and activators of antigen-presenting cells.

HMGB1 was originally identified as a chromatin-binding protein that exists ubiquitously in the nucleus of all eukaryotic cells. HMGB1 plays a critical role in stabilizing nucleosome formation and in regulating transcription; it also plays an important role in signaling following tissue damage. When present in an extracellular location, HMGB1 can activate the innate immune system and promote inflammation. HMGB1 is passively released by necrotic cell death, but not during cells undergoing apoptosis cells as well as actively secreted by immune cells, macrophages, and NK cells upon activation with TNF. HMBG1 acts as a chemokine and is a chemoattractant for macrophages, neutrophils, and dendritic cells and

causes the secretion of several proinflammatory cytokines (e.g., TNF, IL-1a, IL-1b, IL-1RA, IL-6, IL-8, MIP-1a, and MIP2b) (Fig. 1.2).

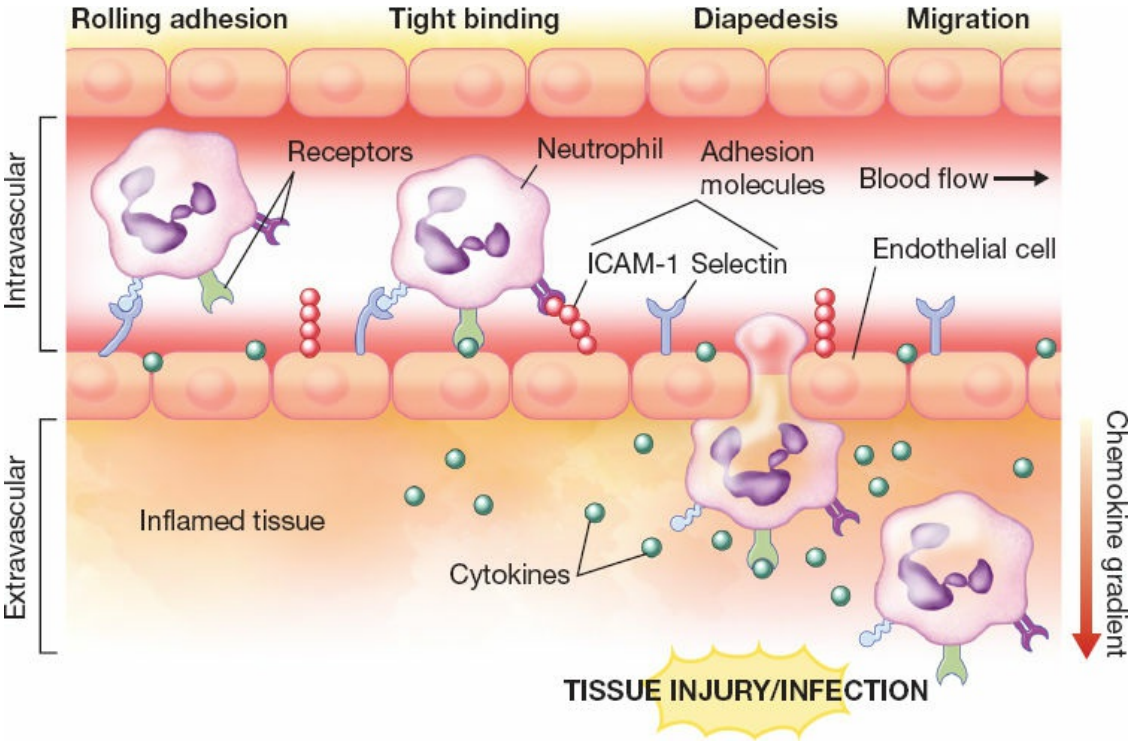

Figure 1.2. Schematic of the chemokine-mediated process of neutrophil recruitment and infiltration. Chemokines emanating from a source of injury and/or infection induce expression of cellular adhesion molecules on the endothelial surfaces. Adhesion molecules (e.g., selectins and integrins) allow for tumbling and adherence, respectively, of PMNs to the endothelial lumen wall. The adherent PMNs then move through the wall by diapedesis and migrate along the chemokine gradient, eventually infiltrating in and around the focus of injury. ROS, reactive oxygen species. (Adapted from Guyton and Hall Textbook of Medical Physiology, 13th edition, with permission.)

Adaptive Immune System

Adaptive immunity constitutes the second, but more specific response to pathogenic organisms and damaged tissues. It is subdivided into cellular and humoral immunity.

Cellular Immunity

Surgical insult leads to the activation of local host responses necessary for protection against invading microorganisms, as well as the initiation of tissue repair following injury. The sequence of events begins at the time of

injury, with activation of the coagulation cascade and the initiation of local inflammation. Local inflammatory mediators, such as cytokines, histamine, kinins, and arachidonic acid metabolites increase capillary permeability, which allows leukocyte infiltration (primarily neutrophils, followed by monocyte/macrophages). Immune cell migration is a complex process involving attachment to the endothelial cells and extravasation regulated by many substances, the most important of which are the chemokines and adhesion molecules. Most of these mediators act in a paracrine fashion and they are short-lived because of rapid metabolism. Therefore, serum measurements of these mediators may not reflect their activity in local tissues.

TLR activation increases cytokine (TNF-α and IL-1) and chemokine secretion, especially by local macrophages. Chemokines are produced and secreted into the extracellular matrix by activated leukocytes and various other cells (epithelial cells, fibroblasts, and endothelial cells) to mediate cell motility toward the site of injury/infection. The local microcirculatory inflammatory response is reflected by a pronounced leukocyte accumulation and adherence to the endothelial lining of postcapillary and collecting venules. This response is associated with an increase in microvascular permeability, indicating the disruption of endothelial integrity. In addition to the increased capillary permeability and leukocyte accumulation, cytokines act on endothelial cells, leukocytes, and cells within the extracellular matrix to induce expression of adhesion molecules (e.g., selectins, cadherins, integrins). These molecules allow low-affinity interactions between the endothelium, and leukocytes begin to roll along the endothelial surface in the direction of blood flow. Subsequently, the increased expression of adhesion molecules promotes the extravasation of leukocytes from the circulation toward the damaged or infected tissue along a chemotactic gradient.

Finally, at the time of injury, the production of proinflammatory cytokines and the expression of adhesion molecules and chemokines mediate the selective recruitment of cutaneous lymphocyte antigen (CLA)-positive T-cells into the wound. The local macrophages present antigens and express costimulatory molecules that are necessary for T-cell activation. After antigen binding and activation, T-cells differentiate preferentially into Th1 subsets, and secrete interferon-gamma (IFN-γ), the major macrophage-activating cytokine. Activated macrophages remove debris from dead cells to facilitate repair after the infection is controlled,

which promotes resolution of the inflammatory phase. The process of tissue repair ensues, with formation of granulation, re-epithelialization, and neovascularization.

In the normal host response, these processes are mostly limited to the site of trauma; however, every substantial traumatic injury also leads to a degree of systemic inflammation. Depending on the magnitude of tissue damage, the local inflammatory process will cause washout of proinflammatory mediators into the systemic circulation and inflicts a systemic inflammatory process. The systemic leak of cytokines leads to further activation of immune cells, mostly neutrophil priming, more cytokine secretion, activation of complement and the coagulation cascade, and secretion of APPs and neuroendocrine mediators. This systemic inflammation is followed by a compensatory anti-inflammatory response, creating a balance, which will have significant impact on the clinical outcome. Hence, the “right tuning” of systemic inflammation is crucial for restoration of homeostasis. Severe inflammation may lead to tissue destruction in organs not originally affected by the initial trauma by a process commonly referred to as the multiple-organ dysfunction syndrome (MODS). A lesser inflammatory response (or too much anti-inflammatory regulation) will induce a state of immunosuppression during the vulnerable time of recovery, which can result in deleterious sepsis for the host.

Cytokines

Cytokines are small protein hormones, secreted by systemic immune cells, macrophages, monocytes, or lymphocytes (T-cells and B-cells) and by diverse cell types at the site of injury. Cytokines are crucial mediators in cell immunity and inflammatory response. In healthy humans, they are produced at low constitutive levels, reaching just picograms per milliliter in plasma, and function in an endocrine, paracrine, or autocrine manner. Cytokine receptors are expressed on the surface of the majority of human cells, and some soluble cytokine receptors are detectable in plasma at low levels. Cytokines activate intracellular signaling pathways that regulate gene transcription. Examples include NF-κB, activating protein 1 (AP-1), signal transduction- and transcription-activating factor 3 (STAT-3), and members of the CCAAT/enhancer-binding protein (C/EBP) family of transcription factors, in particular C/EBP-β and δ.

The NF-κB family of transcription factors is well studied because of its central role in the inflammatory process, which targets expression of a number of cytokines that influence immune cell activity, differentiation,

proliferation, and survival. These mediators also regulate the production and activity of other cytokines in a watershed manner. There is a significant overlap in bioactivity among different cytokines.

Cytokines are not antigen-specific and their effect can be stimulatory or inhibitory. TNF, IL-1b, IL-6, IL-8, IL-12, and IFN-γ are the dominant stimulatory (or proinflammatory) cytokines and IL-4, IL-10, and IL-13 are considered inhibitory (or anti-inflammatory). Those compounds acting in between cells of the immune system are called ILs, and those inducing chemotaxis of leukocytes are referred to as chemokines. Including about 50 chemokines and 30 ILs, the number of characterized cytokines is now well in excess of 100.

During acute localized inflammation, connective tissue, endothelial cells, and local immune cells are first to secrete proinflammatory cytokines, mostly IL-1 and TNF. Excess cytokines may leak to the circulation and exceed the levels of soluble receptors, resulting in systemic inflammatory responses and possible development of SIRS and MODS. The monocyte/macrophage also produces the only natural and well-characterized competitive cytokine antagonist, IL-1 receptor antagonist (IL-1ra), as well as liberates soluble forms of TNF and IL-1 receptors (IL-1RI) that are able to bind and neutralize TNF and IL-1, respectively.

Interleukins

One of the best-described proinflammatory cytokines, TNF (originally known as cachectin) is produced by macrophages/monocytes and by T-cells, endothelial cells, fibroblasts, and adipose tissue. TNF is among the early cytokines secreted after trauma and acts through its receptors TNF-receptor 1 and TNF-receptor 2 (i.e., TNFR1 and TNFR2). TNF-R1 activates the caspase cascade and induces cellular apoptosis, as well as induction of transcription factors (e.g., NF-κB) and activation of the mitogen-activated protein kinase (MAPK) pathways, which are both involved in cell proliferation, transcription of inflammatory genes, and antiapoptosis. Binding of TNF to TNFR2 leads to activation and proliferation of immune cells. TNF induces secretion of a variety of pro- and anti-inflammatory cytokines (e.g., IL-6, IL-8, IFN-γ, and IL-10), increases synthesis of nitric oxide and arachidonic acid metabolites to induce activation of cyclooxygenase and lipoxygenase enzymes. This activation leads to the production of thromboxane A2 and prostaglandins E2, which have multiple physiologic effects, including increased permeability of endothelial cells. It also induces the production of

adhesion molecules (e.g., selectins), platelet-activating factors, and intracellular adhesion molecules (ICAM). In addition, TNF increases the procoagulated activity of endothelial cells. The local effects of TNF can be physiologic, but the systemic effects often lead to adverse outcomes. TNF has been identified as a principal mediator in septic shock. In the central nervous system (CNS), TNF stimulates the release of corticotropin-releasing hormone (CRH), induces fever, and reduces appetite. In the liver, it stimulates production and secretion of APPs, and also causes insulin resistance. Inhibition of TNF by either anti-TNF antibodies or soluble receptors for TNF has become a strategy in the treatment of patients with chronic inflammatory diseases, but this strategy does not work in septic patients.

IL-1 is another IL that was first described as endogenous pyrogen over a half century ago, because it caused fever when injected into rabbits. After being secreted by monocytes, macrophages, or endothelial cells, IL-1 has a half-life of only 6 minutes. IL-1 has two forms, IL-1α and IL-1β, which are regulated by different antigens, but bind to the same IL-1RI. IL-1 is a potent pyrogen, which influences the hypothalamus to reset the temperature of the body and induces fever. It is associated with local hyperalgesia. IL-1 has similar effects to TNF on the immune system following trauma. In fact, TNF and IL-1 are often described as synergistically acting mediators.

Similar to other cytokines, IL-6 is produced by a variety of cell types and is induced by TNF and IL-1. It is detectable within an hour of trauma, and peaks at 4 to 48 hours following surgery. IL-6 induces a proliferation and differentiation of B- and T-lymphocytes, activates NK cells and neutrophils, and inhibits its apoptosis. IL-6 also regulates hepatic synthesis of APP, such as C-reactive protein (CRP), fibrinogen, complement factors, α-2 macroglobulin, α1-antitrypsin, and others. IL-6 also induces the release of soluble TNF-R and IL-I receptor antagonist, and therefore plays a dual role in the inflammatory response by acting as both a proinflammatory and an anti-inflammatory mediator. IL-6 has a longer half-life than TNF or IL-1, which makes it easier to monitor, and seem to correlate with the magnitude of trauma. For example, despite similar procedure times, there is a greater degree of IL-6 elevation after abdominal aortic and colorectal surgery than after hip replacement; there are lower IL-6 levels after laparoscopy than after open procedures, including cholecystectomy and small-bowel and colon resection. Furthermore, IL-6

is regarded as a prognostic marker of trauma patients with SIRS, sepsis, or MODS and has been used in the intensive care unit (ICU) setting as an indicator for the severity of the inflammatory responses that is relatively independent of bacterial infections.

Chemokines

Overall, >18 chemokine receptors and >43 chemokines have been described, demonstrating a sharing of receptors. The name “chemokine” is a shortened version of “chemotactic cytokines,” which is the major function of these molecules—that is, they act as chemical attractants to almost all cell types of the innate and adaptive immune responses. In lower doses, chemokines act mostly as chemoattractants, while in increased concentrations they can lead to cell activation, including cytotoxicity and even respiratory burst. Their receptors have also been detected in endothelial cells, keratinocytes, and fibroblasts, suggesting that some chemokines also contribute to the regulation of epithelialization, angiogenesis, and tissue remodeling. The chemokine receptors belong to the family of G-protein–coupled receptors, and binding to these receptors leads to effects, including both chemotaxis and activation. IL-8 is a typical chemotactic cytokine and its secretion is induced by IL-1, TNF-α, C5a, microbes and their products, hypoxia, hyperoxia, and reperfusion. Interferons attenuate the expression of IL-8. It can be produced in an early state of inflammation following trauma and can persist over a long period of time, even weeks. It has the ability to act as potent angiogenic factor, as a potent chemoattractant, and as an activator of immune cells.

Cytokines Postelective Surgery

Elective surgery followed by an uneventful clinical course may induce only minor systemic inflammatory changes. As one could expect, the acute-phase response, post-elective surgery, is proportional to the surgery-related tissue trauma or to the severity of the procedures. Virtually, all inflammatory mediators (cellular, cytokines, and APPs) peak postinjury at about day 1 to 2 and then return to baseline levels by postinjury days 6 to 7. Persistent postoperative pain, stress, or a second insult will change that pattern.

THE NEURO-IMMUNE AXIS

The systemic and even local inflammatory responses posttrauma are

regulated by the nervous system. Evidence continues to identify that the autonomic nervous system is an important regulator of the inflammatory response, with both afferent sensory and efferent effector pathways having important roles. Considerable attention has been given to the effectiveness of parasympathetic nerve stimulation in suppressing the magnitude of the proinflammatory response, leading to coining of the term “inflammatory reflex”; however, like our understanding of the autonomic nervous system in classical physiologic responses, the inflammatory reflex comprises both afferent and efferent arms.

Afferent/Sensory Input to the Brain

During stress, afferent signals from the injury site can reach the CNS through two main routes: the neural route, mostly by afferent vagal or other autonomic nerve fibers throughout the body, and through blood-borne inflammatory mediators.

Neural Route

The neural afferents offer rapid means to activate the CNS in response to trauma, and the molecular mechanisms leading to their activation remains an important area of investigation. Various investigators have demonstrated the effects of complement (C5a) fragments, PGE_2, coagulation factors (Factor XII), kinins (bradykinin), and cytokines (TNF, IL-1, and IL-6) as afferent signals to the CNS. For example, intraperitoneal administration of LPS or IL-1 (typically resulting in fever, increased secretion of adrenocorticotrophic hormone [ACTH]) can be blocked or attenuated by subdiaphragmatic vagotomy. This vagal-dependent sensory arm can be also be activated by the presence of IL-1 in peripheral tissues.

Humoral Route

Cytokines are lipophobic molecules without direct access to the CNS, as the blood–brain barrier (BBB) excludes entry of such proteins. An exception is in regions where the BBB is less selective, such as around the circumventricular organs (CVOs), the meninges, and the choroid plexus or areas in which active transport of circulating cytokines by the vascular endothelium may exist. Alternatively, cytokines may damage and increase BBB permeability and enter the brain to stimulate central neural circuits through that route as well. Several factors have been implicated, most notably IL-1 and IL-6. Prostaglandins, mostly PGE_2, locally produced in

the hypothalamus in reaction to cytokines, play a crucial role in inducing pyrexic reaction, as known for many years from the ability of cyclooxygenase inhibitors to prevent fever.

Efferent Regulation

Following integration of afferent signals, the CNS has two major effector arms that regulate physiologic responses. The first is the activation of the hypothalamus–pituitary–adrenal (HPA) axis, and the second is the direct activation of the sympathetic and parasympathetic branches of the autonomic nervous system. Efferent CNS regulation of the inflammatory response suppresses the immune system through at least two main routes: (1) by increasing corticosteroid hormone levels (activation of the HPA axis) and (2) by activation of the cholinergic anti-inflammatory pathway. For example, TNF-α, IL-1, and IL-6 stimulate the HPA axis resulting in the release of ACTH and glucocorticoids (Fig. 1.3), which downregulates cytokine release from macrophages and other inflammatory cells. These negative feedback processes between glucocorticoids and cytokines is a major mechanism leading to prevention of overactivation of the inflammatory response.

Immunosuppression Following Trauma

Increasing evidence has demonstrated that the neurologic system plays a major role in the coordination of inflammatory and anti-inflammatory immune response. While minor surgery is suggested to stimulate components of the immune system, it is generally agreed that after the acute-phase response, major surgery, and to a higher extent, major trauma cause immunosuppression that may render the host anergic to opportunistic infections. The initial response to surgical trauma is characterized by activation of the specific and nonspecific immune system's release of proinflammatory cytokines (e.g., TNF, IL-1β, IL-6, IL-18, HMGB1), neutrophil activation, microvascular adherence, as well as PMN and macrophage oxidative burst, but this rapidly gives way to a state of depressed immune function.

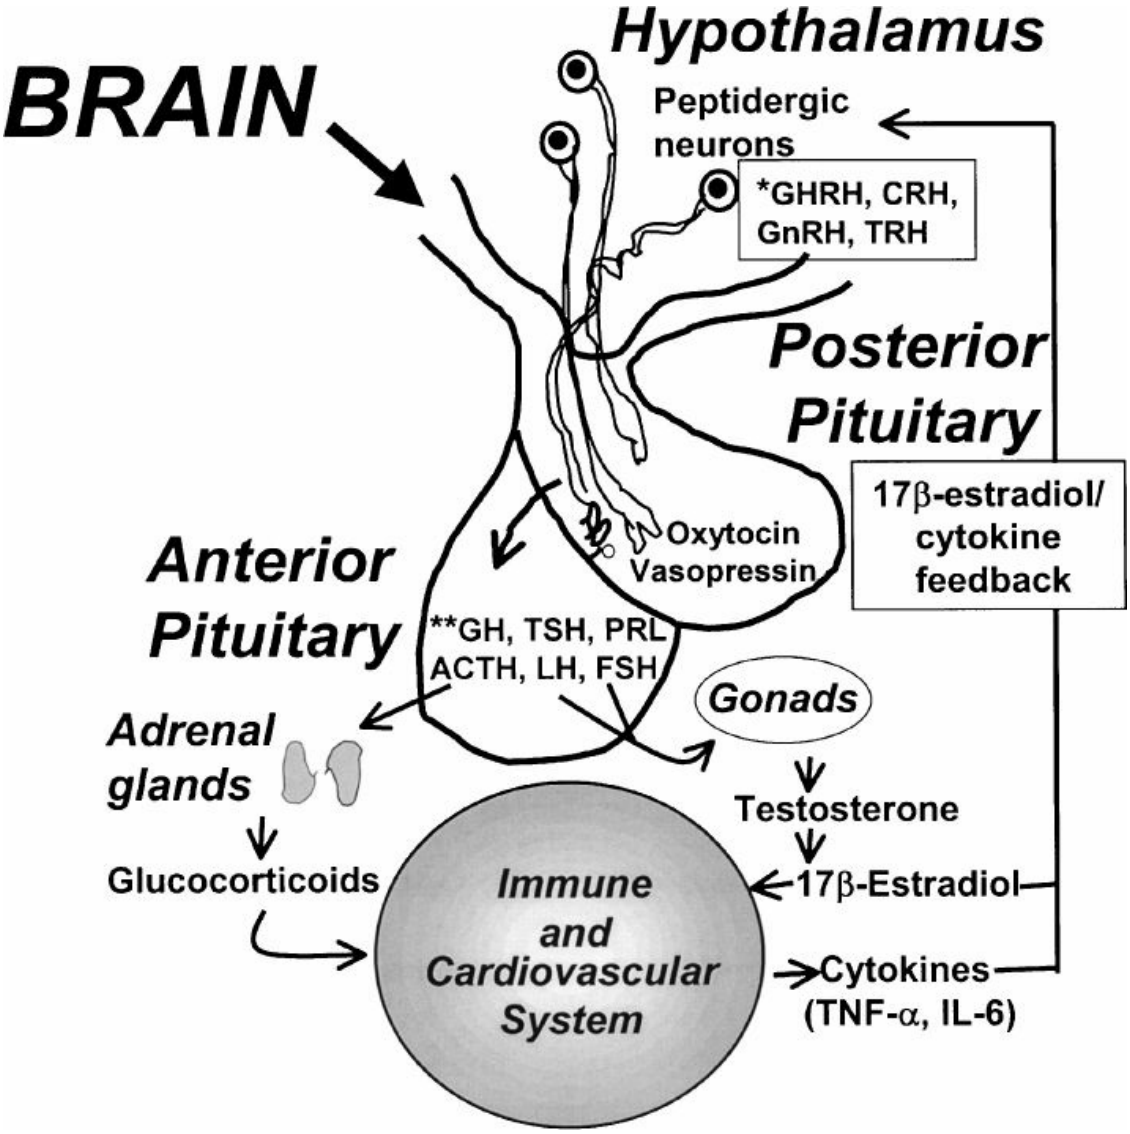

Figure 1.3. Relationship between the hypothalamus–pituitary–gonad-adrenal (HPA) axis and the immune system in physiologic responses to injury. The HPA is a neuroendocrine system that also has bidirectional communication with the immune system in homeostasis and in times of injury, giving the brain a major role in regulating endocrine and immune functions. The hormonal responses are apparent at three levels: the hypothalamus, the pituitary, and the adrenals. It can be seen that organs are coupled with one another (functioning as a biologic oscillators), with the coupling being mediated by neural, hormonal, and cytokine networks. Notably, cytokines and sex hormones are closely coupled in a counterregulatory fashion, which sheds light on the beneficial effects of sex hormones, especially β-estradiol, in responses to injury.

The production of immunoglobulins fall and many patients become

anergic as assessed by delayed hypersensitivity skin testing. Defects in neutrophil chemotaxis, phagocytosis, and lysosomal enzyme content and respiratory burst have all been reported. This condition is referred to as a compensatory anti-inflammatory response syndrome; it is induced by multiple mediators and affects all subtypes of immunity. The counter anti-inflammatory mechanism is as complex and multi-factorial as the proinflammatory one. It includes cytokines such as IL-10, TGF-β, TNF-binding protein, and hormones such as corticosteroids, adrenaline, and α-melanocyte stimulating hormone (α-MSH). These act in concert with local effectors, such as PGE_2, HSPs, and APPs. These factors interact to inhibit macrophage activation and downregulate the synthesis of proinflammatory cytokines.

The Cholinergic Anti-Inflammatory Pathway

In recent years the activation of the cholinergic pathway leading to acetylcholine release in the reticuloendothelial system (which includes the spleen, liver, lymphoid tissue, and GI tract) has been linked to anti-inflammatory pathways that quell the inflammatory response. Acetylcholine binds to acetylcholine receptors expressed on tissue macrophages, which inhibits the release of proinflammatory (e.g., TNF, IL-1β, IL-6, and IL-18), but not the anti-inflammatory cytokines (e.g., IL-10). In addition, direct electrical stimulation of the peripheral branches of the vagus in vivo during lethal endotoxemia in rats inhibits TNF synthesis in liver, attenuated peak serum TNF amounts, and prevents the development of shock. Several reports have confirmed that the activation of this pathway, is effective in ameliorating inflammation and improving survival in a number of experimental models, such as sepsis, hemorrhagic shock, pancreatitis, and postoperative ileus.

Cell-Mediated Immune Dysfunction

Cellular immuno-incompetence (also called “immune paralysis”) is induced by elevated PGE_2, IL-10, soluble cytokine receptors, and other anti-inflammatory mediators, mainly caused by the deactivation of monocytes. The central role of IL-10 and TGF-β in inducing monocyte “immune paralysis” is demonstrated by the upregulation of HLA-DR expression on monocytes following the application of an IL-10 neutralizing antibody and the restoration of macrophage antigen presentation by using TGF-β neutralizing antibodies.

Lymphocyte Dysfunction

Major surgical interventions are also associated with a significant decrease in total systemic lymphocyte counts, including $CD4^+$ and $CD8^+$ T-cells. This lymphocyte depression correlates with the duration of the surgical procedure and the volume of blood loss; however, this is not associated with the extent of the trauma, the age of the patient, or the type of intensive care intervention. These events are accompanied (within 24 hours) with elevated IL-10 and increased frequency of apoptosis of $CD4^+$ and $CD8^+$ cells accompanied by marked downregulation of antiapoptotic factors such as Bcl-2. Furthermore, the $CD4^+$ T cells can be subdivided into functionally distinct subsets, with Th1cells supporting proinflammatory responses by producing IL-2, IL-12, and IFN-γ and Th2 cells acting promoting anti-inflammatory responses by secreting IL-4, IL-5, IL-6, IL-10, and IL-13. Major trauma is associated with a shift of the Th1/Th2 balance toward a Th2 response.

The Second Hit Phenomenon

The so-called two-hit model of inflammatory insult has become a commonly accepted paradigm in the care of critically ill patients. It takes place in many common scenarios in which the patient has to undergo a surgical procedure following initial trauma or suffers further insults due to a complication. The second hit may be sterile- (operation after trauma) or a pathogen-induced infection postsurgery. Although influenced by many factors, the inflammatory and metabolic response is relatively predictable. The immune reaction to further insults is not as consistent or predictable. Variations in the competence of innate and adaptive immune defenses become evident; there is an innate immune tolerance and diminished adaptive immune capacity of response to a new antigen. On the other hand, recurrent immunologic activation causes a persistent systemic proinflammatory activity that may lead to SIRS and MOF. Depending on the patient the recurrent inflammation could trigger some aspects of immunity and not in others. An example of this is the continuation of coagulation system activation, even as other proinflammatory activity is waning. Not infrequently, a prolonged stress state manifests diminishing amplitude, frequency, and efficiency of autonomic and neuroendocrine signaling. Disturbances in circadian rhythmicity of neuroendocrine hormone secretion are also observed during prolonged inflammatory illness. The attenuated hormone rhythmicity and signal amplitude may

contribute to disordered metabolic and immune functions.

Systemic Inflammatory Response Syndrome and Multiple Organ Dysfunction Syndrome

Cytokine-mediated inflammation is usually short-lived and is resolved. In some cases, however, cytokine production can become excessive, and rather than resolving, inflammation persists or even spreads, causing damage in adjacent tissues. This hypermetabolic response, often called the SIRS, encompasses excessive whole body inflammation and is considered a major determinant in the development of MODs, often with a lethal result. The pathophysiology of SIRS and MODS is explored in subsequent chapters in this text.

Endocrine Response

Role of the Central Nervous System

The CNS response consists primarily of three parallel, coordinated effects: fever, HPA axis activation, and sickness behavior (such as anorexia or somnolence). Following integration of afferent signals, the hypothalamus has two major effector arms that are used to regulate physiologic responses —the activation of the HPA axis and the autonomic nervous system. At rest, the hypothalamus secretes, in a pulsing manner, CRH, thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), growth hormone-releasing hormone (GHRH), and dopamine. During stress, the afferent signals from the injury site reach the hypothalamus through the neural route mostly by afferent vagal fibers or through blood-borne inflammatory mediators. Humoral mediators reach the hypothalamic-hypophyseal portal capillaries in the median eminence through the anterior hypophyseal arteries. The cytokines can diffuse into the portal capillaries, areas that are free from the BBB.

Endogenous Opioids (Endorphins)

Many of the mediators released during inflammation of peripheral tissue are known to elicit pain by activation of specialized primary afferent neurons called “nociceptors” (defined as “neurons preferentially sensitive to a noxious stimulus or to a stimulus which would become noxious if prolonged”). Nociceptor stimuli propagate through the dorsal horn of the spinal cord to the supraspinal sites where a sensation of pain is eventually elicited. Various opioid peptides, such as β-endorphin, met-enkephalin, dynorphin, and endomorphins are produced and secreted by the

hypophysis, hypothalamus, and, as demonstrated most recently, locally by leukocytes. Opioid peptides can bind to opioid receptors. The most studied opioid receptor groups are μ, κ, and δ. These receptors are part of the G-protein–coupled receptors, which are synthesized in dorsal root ganglia and are transported intra-axonally. The opioid receptors are represented in the brain, spinal cord, sensory peripheral nerve endings, and in the intestinal tract. Agonist binding elicits potent analgesia, a quality often used to treat pain, with induction of external opioids.

Immune cells carry all three opioid receptors. Opioids have been shown to modulate a number of aspects of the immune response, including antibody responses in vitro and in vivo, phagocytic cell function, NK-cell activity, chemokine-induced chemotaxis, the development and function of T-cells in the thymus, and cytokine and cytokine receptor expression. Opiate-mediated immune effects have been postulated to result from either direct interaction with opioid receptors on cells of the immune system or indirectly through the activation of opioid receptors within the CNS, and the resulting modulation of HPA axis (cortisol) and the sympathetic nerve system activities. Although alternations in various aspects of immune function in patients exposed to opioid treatment were demonstrated in clinical practice (postelective abdominal surgery, orthopedic surgery, and in healthy volunteers), there are no actual prospective clinical studies exploring the possible interaction between exposure to opiates and rates of infection.

Hormonal Changes During Acute and Chronic Surgical Illness

There is a biphasic neuroendocrine response to critical illness. The acute phase is characterized by an actively secreting pituitary; whereas, in prolonged critical illness, there is a hypothalamic suppression of the neuroendocrine axes.

Glucocorticosteroids

In a stress-free healthy human, cortisol is secreted from the zona fasciculata of the adrenal cortex in a diurnal fashion. Cortisol release is controlled by ACTH produced by the pituitary, in turn under the influence of the hypothalamic CRH. Cortisol itself exerts negative-feedback control on CRH and ACTH. Approximately 10% cortisol is found free in the plasma. Of the remainder, 20% is bound to albumin, and 70% is bound to cortisol-binding globulin. Only the free hormone, however, is biologically active. Glucocorticoids exert their effects by binding to and activating an

intracellular receptor protein that acts as a transcriptional activator or repressor, and the cortisol–glucocorticoid receptor complex can modulating inflammatory transcriptional activity (e.g., NF-κB).

Cortisol Secretion During Stress

Cortisol levels usually rise in the early phase of critical illness. The excited neurons in the hypothalamus release CRH and arginine vasopressin (AVP) from their terminals into the capillaries of the hypothalamo-hypophyseal portal venous plexus. CRH and AVP act on CRH-1 and vasopressin-1β receptors on the anterior pituitary to stimulate ACTH secretion. Plasma ACTH levels rise directly due to increased secretion and due to resistance to or inhibition of the negative-feedback mechanism exerted by cortisol. Several of the elevated cytokines have been shown to modulate cortisol production, either by directly affecting the hypothalamus/pituitary (IL-1α, IL-1β, IL-6, and TNF-α) or by direct stimulation of the adrenal cortex (IL-1α, IL-1β, and IL-6). Cytokines can also influence glucocorticoid receptor numbers and affinity. During severe illness, corticosteroid-binding globulin levels are decreased, resulting in proportionate increases in the free hormone. The diurnal variation in cortisol secretion is lost in response to any type of acute illness or trauma. An appropriate activation of the HPA axis and cortisol in response to critical illness is essential for survival. The adrenal gland does not store cortisol; therefore, increased secretion arises due to increased synthesis of cortisol from its principal precursor, cholesterol.

Cortisol Influence on Posttrauma Physiology

The stress-induced hypercortisolism fosters the acute provision of energy. Glucocorticoids increase blood glucose concentrations by increasing the rate of hepatic gluconeogenesis and inhibiting adipose tissue glucose uptake. Hepatic gluconeogenesis is stimulated by increasing the expression of phosphoenolpyruvate carboxykinase and glucose-6-phosphatase as a result of binding of glucocorticoids to the glucocorticoid response elements of the genes for these enzymes. Glucocorticoids stimulate FFA release from adipose tissue and amino acid release from body proteins, which supplies energy sources and amino acid substrates for the response to stress and repair of injured tissues.

The rise in glucocorticoids also protects against excessive inflammation, acting as a negative feedback on the inflammatory response. The rise in glucocorticoids during acute illness plays a crucial role in

preventing hazardous overstimulation of the immune system, including lymphocytes, NK cells, monocytes, macrophages, eosinophils, neutrophils, mast cells, and basophils. Glucocorticoids decrease the accumulation and function of most of these cells at inflammatory sites. Most of the suppressive effects of glucocorticoids on immune and inflammatory reactions appear to be a consequence of the modulation of production or activity of cytokines, chemokines, eicosanoids, complement activation, and other inflammatory mediators.

A rise in glucocorticoid concentrations plays an important role in improving hemodynamic levels, by inducing fluid and sodium kidney retention. Glucocorticoids are also required for the needed increased sensitivity of the cardiovascular system to vasoconstrictors. The reactivity to angiotensin II, epinephrine (Epi), and norepinephrine (NE) contributes to the maintenance of cardiac contractility, vascular tone, and blood pressure. These effects are mediated partly by the increased transcription and expression of the receptors for these hormones. Glucocorticoids are required for the synthesis of Na^+, K^+-ATPase, and catecholamines. The effects of glucocorticoids on synthesis of catecholamines and catecholamine receptors are partially responsible for the positive inotropic effects of these hormones. Glucocorticoids also decrease the production of nitric oxide, a major vasorelaxant and modulator of vascular permeability.

During surgical procedures such as laparotomy, serum corticotropin and cortisol rise rapidly, peaking in the immediate postoperative period. The magnitude of the postoperative increase in serum cortisol concentration is correlated with the extent of the surgery. From a normal secretion rate of 10 mg/day, cortisol production rate increases to 75 to 150 mg/day following major surgery and can reach to 250 to 300 mg/day in severe stress. Unless there is a repeated insult, such as sepsis, the glucocorticoid concentrations decline to baseline levels over the next 72 hours. This decline can often be noticed clinically as increased diuresis, improved glucose control, and, occasionally, increased pain. In critical illness, the kinetics of the response differ from those mentioned above: pain, fever, hypovolemia, hypotension, and tissue damage all result in a sustained increase in corticotropin and cortisol secretion and a loss of the normal diurnal variation in these hormones. During severe illness, serum cortisol concentrations tend to be higher than even in patients undergoing major surgery (～30 μg/dL vs. 40 to 50 μg/dL).

Adrenal Insufficiency

Critical illness is associated with activation of the HPA axis; however, many factors can impair the integrity of the HPA axis, such as blunt normal response leading to either transient or, rarely, permanent adrenal insufficiency. This scenario can lead to a potentially lethal condition. Refractory hypotension is the most common aspect of acute adrenal insufficiency. Adrenal insufficiency should be suspected in any critically ill patient who has persistent hypotension and hemodynamic instability that persists despite adequate fluid resuscitation and/or requires vasopressor support. Other nonspecific signs can include MOD, otherwise unexplained hypoglycemia, hyponatremia, hyperkalemia metabolic acidosis, eosinophilia, hyperdynamic circulation, and other pituitary deficiencies (gonadotropin, thyroid, and diabetes insipidus). Much attention was previously focused on the so-called relative or functional adrenal insufficiency of critical illness, a condition defined as subnormal adrenal corticosteroid production in the absence of any structural defects of the HPA axis. The explanation for the development of this condition is hypothetical exhaustion of the secretory adrenocortical reserve as a result of ongoing near-maximal stimulation. Other contributing factors may include the suppression of cortisol and ACTH production by circulating cytokines and other inflammatory mediators, as well as the development of target tissue resistance to glucocorticoids and/or adrenal cortex resistance to ACTH action. A number of trials and other studies have attempted to identify a role for glucocorticoids in patients with critical illness, though none of them has been able to come to a consensus for diagnosis and treatment indications for adrenal insufficiency. These studies have examined the roles of provocative testing (i.e., ACTH stimulation tests) as well as other plasma markers such as the random cortisol concentration. These tests and laboratory values can be highly variable and skewed in critically ill patients and potentially misleading. As such, the Surviving Sepsis guidelines currently suggest that hydrocortisone therapy is warranted in resuscitated patients with pressor requirements who are suspected of having adrenocortical insufficiency. No provocative testing or other laboratory tests are warranted to confirm diagnosis.

Vasopressin

Vasopressin, also known as ADH, is synthesized as a large prohormone in the hypothalamus. The prohormone complex is transported to the posterior pituitary where it is stored in granules. Vasopressin is released mainly in response to hyperosmolality, hypotension, and hypovolemia, and has

vasopressor and antidiuretic effects. Vasopressin levels increase rapidly in the early phase of certain stressful situations, such as hemorrhagic and septic shock. With persistence of the septic shock state, however, vasopressin stores are depleted and plasma concentration falls to low levels.

Thyroid

TRH secreted by the hypothalamus stimulates the pituitary to produce thyrotropin (TSH), which, in turn, regulates the synthesis and secretion of thyroid hormones in the thyroid gland. The thyroid hormones, in turn, exert feedback control on both TRH and TSH secretions. The early response of the thyroid axis to a severe physical stress consists of a rapid decline in the circulating levels of T3 and a rise in rT3 levels, predominantly as a consequence of altered peripheral conversion of T4 to T3, a reaction that is catalyzed by 5′ monodeiodinase (or type 1 deiodinase) located in the kidney, the liver, and the muscle. TSH and T4 levels are elevated very briefly and subsequently return to "normal," although in more severe illness, T4 levels can be decreased. The low T3 levels persist beyond TSH normalization, a condition referred to as "the low T3 syndrome." The severity of illness is reflected in the degree of the fall in serum T3 during the first 24 hours after the insult. Furthermore, an inverse correlation between T3 levels and mortality has been demonstrated. Other factors involved in the low-T3 syndrome at the tissue level include low concentrations of thyroid hormone-binding proteins, and inhibition of hormone binding, transport, and metabolism by elevated levels of glucocorticoids, FFA, and some commonly used medications (amiodarone, iodine contrast). It remains controversial whether development of the aforementioned changes in thyroid metabolism reflects a protective mechanism (attempt to reduce the elevated energy expenditure) or a maladaptive process during illness.

In prolonged critical illness, a state of euthyroid sick syndrome is usually present, in which the pulsatile TSH secretion is dramatically reduced and serum levels of both T4 and T3 are low. Reduced *TRH* gene expression in the hypothalamus has been observed in chronically ill patients who died, which is in line with the predominantly central origin of the suppressed thyroid axis. Since the presence of euthyroid sick syndrome is associated with an increased mortality among critically ill patients, it could indicate an aberration that may delay recovery from acute illness and, therefore, would require intervention. To date, however, a routine

thyroid hormone therapy has not been demonstrated to improve clinical outcomes in critically ill patients with normal previous thyroid function. If hypothyroidism is suspected clinically (hypothermia, bradycardia, respiratory acidosis, pleural effusions, and failure to wean), thyroid function should be measured and corrected. In a critically ill patient with hypothyroidism, central hypothyroidism should be ruled out.

Growth Hormone

The regulation of the physiologic pulsatile release of GH by the somatotrope cells in the anterior pituitary is highly complex. Hypothalamic GHRH stimulates, while somatostatin inhibits the secretion of GH. But many other stimulating (ghrelin, androgens, estrogen, hypoglycemia, sleep, fasting, and exercise) and inhibiting (circulating GH and IGF-I, hyperglycemia, and glucocorticoids) factors have been identified. GH exerts both direct and indirect effects. It directly promotes muscle mass increase through sarcomere hyperplasia, lipolysis, protein synthesis, and liver gluconeogenesis. The indirect effects are mediated by increases in IGF-I, whose bioactivity is regulated by several IGF-binding proteins and it has growth stimulation effects on a wide variety of tissues. The pulsatile nature of GH secretion consists of peak serum GH levels alternating with virtually undetectable troughs. During the first hours to days after an acute insult, the GH profile changes dramatically. The amount of circulating GH rises, with increased pulsatile peak secretion and frequency. Concomitantly, a state of peripheral GH resistance develops, in part, triggered by cytokines such as TNFα and IL-6. These events are preceded by a drop in circulating GH-binding protein, which presumably reflects the functional GH receptor status. Theoretically, these effects could enhance the direct lipolytic and insulin antagonizing effects of GH, resulting in elevated fatty acid and glucose levels in the circulation, whereas the indirect, IGF-I-mediated somatotropic effects of GH are attenuated. As a result, costly anabolism, largely mediated by IGF-I and considered less vital at this time, could be postponed. Hence, from a teleologic point of view, this response to acute injury within the GH axis seems appropriate in the struggle for survival.

The role of GH in critical illness has been previously examined in a number of randomized studies and clinical scenarios. In contrast with the observations during the acute phase of critical illness, the pulsatile release of GH is suppressed in patients who are critically ill for a prolonged time. The loss of pulsatile GH release contributes to the low levels of IGF-I in

prolonged critical illness and a relative hyposomatotropism, which has been thought to contribute to the pathogenesis of the “wasting syndrome” commonly seen in critically ill patients. This “wasting syndrome” is believed to increase the rate of organ dysfunction, muscle weakness, prolonged mechanical ventilation, and length of stay in the ICU. Thus, recombinant GH supplementation in surgical trauma and burn injury patients was previously examined and adopted in critically ill patients; however, two large randomized trials demonstrated its increased morbidity and mortality. Thus, currently GH/IGF-1 replacement is not advocated in critical illness.

The Gonadal Axis

GnRH, secreted in a pulsatile pattern by the hypothalamus, stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the gonadotropes in the pituitary. In men, LH stimulates the production of androgens (testosterone and androstenedione) by the Leydig cells in the testes, whereas the combined action of FSH and testosterone on Sertoli cells supports spermatogenesis. In women, LH also mediates androgen production by the ovary, whereas FSH drives the aromatization of androgens to estrogens in the ovary. Sex steroids exert a negative feedback on GnRH and gonadotropin secretion.

Acute stress brings along an immediate fall in the serum levels of testosterone, even though LH levels are elevated. The enhanced release of CRH and β-endorphin suppresses GnRH release directly and indirectly through the release of glucocorticoids, which in turn also produce gonadotropin resistance at the gonads. Clinical data on the changes within the gonadal axis are scarce in critically ill women, as most patients are older and thus in the menopausal state. It seems that in the days directly following surgery, the FSH, LH, and estradiol levels decline, while the progesterone and prolactin levels do not change significantly. The state of relative hypogonadism is often expressed in premenopausal women by an unexpected menorrhagia shortly after trauma.

With prolongation of the disease, a more substantial hypogonadotropism in both men and women ensues. The circulating levels of testosterone become extremely low and are often even undetectable; yet the mean LH concentrations and pulsatile LH release are suppressed. Total estradiol levels in women are relatively low. Since exogenous GnRH is only partially and transiently effective in correcting these abnormalities, the profound hypoandrogenism must result from combined central and

peripheral defects.

Prolactin

Prolactin is synthesized and secreted by lactotrophs in the anterior pituitary. Prolactin levels are higher in females than in males, and the role of prolactin in male physiology is not completely understood. Like other pituitary hormones, secretion is pulsatile and diurnal; predominately under control of tonic inhibition from projecting hypothalamic dopaminergic neurons. Prolactin release is affected by a large variety of stimuli, the most important being suckling, increased levels of estrogen, and stress. Several neuropeptides have been identified as prolactin-releasing factors. These include TRH, oxytocin, vasoactive intestinal peptide (VIP), and neurotensin.

Prolactin is a well-known stress hormone and is presumed to have immune-enhancing properties. It increases the synthesis of IFN-γ and IL-2 by Th1 lymphocytes, and induces proinflammatory responses and antibody production. While the main physiologic functions of prolactin are related to the mammary glands and the ovaries, it has been shown to also have an important role in the innate and adaptive immune response. Prolactin receptors can be found throughout the immune system cells. Binding of prolactin to its receptor activates several signaling pathways, which include the Janus kinase-signal transducer and activator of transcription (Jak-Stat), the MAPK, and the phosphoinositide 3 kinase (PI3K). Activation of these cascades results in endpoints such as differentiation, proliferation, survival, and secretion.

Sympathetic Stress Response

Physiology of Sympathetic Activation

The sympathetic reaction is activated by a vast range of stressful stimuli, including both psychological and physical stressors. Afferent neurons of the sympathetic system are multiple in quantity and quality (chemoreceptors, baroreceptors, and visceral receptors). The activity of autonomic nerves is dependent on descending excitatory and inhibitory inputs from several brain regions, including the cortex and the hypothalamus. A major source of excitatory drive to sympathetic preganglionic neurons comes from the rostral ventrolateral medulla in the medulla oblongata. This region of the brain stem contains the cardiac, respiratory, and vasomotor autonomic centers, and connects the upper

brain area to the spinal cord. Medullary neurons project to the spinal cord to inhibit or excite sympathetic activity. In addition, many brain stem nuclei that feed directly into these pathways can modulate these activities. In contrast to the parasympathetic nervous system with its predominantly selective innervation of single effector organs, the sympathetic system often reacts with a "massive none organ specific discharge." Increased traffic down the spinal cord via the lateral funiculi causes an increased activity in the sympathetic preganglionic nerve fibers, which results in burst-pattern release of NE from the sympathetic postganglionic nerve terminals, as well as Epi (about 80% of the secretion), NE, and dopamine from the adrenal gland. The secretion of NE from nerve terminals is immediate following the trigger (some of it originating from a spinal reflex arc). After secretion into the synaptic gap, NE is cleared by reuptake into the nerve endings, degradation by the catechol-*o*-methyltransferase or diffusion into the extrasynaptic space and blood. During stress, the latter mechanism is the main source of circulating NE. In view of its richness in sympathetic nerve endings, the intestinal tract is the main producer of NE (40% of total body NE) and dopamine (>50% of total body dopamine). Circulating Epi and NE are degraded 5 to 10 times more slowly than when secreted into the synaptic gap (20 to 30 seconds). Mechanisms of degradation of circulating catecholamine are nonenzymatic (extraneural uptake in the lung, kidney, and intestines, and neural uptake into postsynaptic sympathetic nerve endings), and enzymatic (cytoplasmic monoamine-oxidase in sympathetic nerve endings, the liver, kidney, stomach, and jejunum).

Adrenal catecholamine secretion is rapid, taking place within seconds of stimulation because NE and Epi are stored in preformed granules within the adrenal medulla. Their exocytosis is initiated by preganglionic sympathetic fibers that innervate the adrenal medulla. The normal resting rate of secretion by the adrenal medulla is about 0.2 μg/kg/min of Epi and ~0.05 μg/kg/min NE. These quantities give rise to circulating levels of catecholamines that in basal conditions are enough to maintain the blood pressure near normal, even if all direct sympathetic pathways to the cardiovascular system are removed. During severe physical stress or sepsis, both plasma Epi and NE rise significantly.

Medullary Epi secretion is dependent not just on neural acetylcholine stimulation, but also on the hormonal HPA axis. The activity of phenylethanolamine *N*-methyltransferase (the rate-limiting enzyme in the

conversion of NE to Epi) is enhanced by high doses of glucocorticoids. The medulla is exposed to uniquely high doses of glucocorticosteroids directly through a cortical–medullary, intra-adrenal portal vascular system.

The sympathetic system plays a crucial role in the maintenance of homeostasis during the stress response, and the changes to this system affect almost every possible body system. The cardiac output increases by β-receptor enhancement of heart rate and myocardial contractility. Blood pressure increases by α-receptor-mediated vasoconstriction, and blood flow is redistributed in favor of the more vital functions. Bronchodilatation, through the β2 influence, eases the need for increased minute ventilation. Thermoregulation is reset. The kidneys retain water and sodium, and secrete renin. Bowel motility decreases. Based on these effects, Walter Cannon called the emergency-induced discharge of the noradrenergic system the “preparation for flight or fight.”

Adrenergic tone also plays a significant role in regulating intermediary metabolism in the body. Epi’s capacity to influence metabolism is 5 to 10 times greater than NE. Catecholamine-related hyperglycemia is induced by increased liver glucose secretion, on one side, and by decreased peripheral intake of glucose, due to insulin resistance and inhibition of insulin secretion, on the other. Catecholamines induce catabolism, leading to extensive lipolysis and protein breakdown, which are needed to supply energy for vital functions and substrates for synthesis of various enzymes, antibodies, and glucose.

Autonomic Dysfunction

The sophisticated sympathetic–parasympathetic balance of the autonomic nervous system is maintained by several reflex arcs: arterial baroreflex, peripheral arterial chemoreflex, central arterial chemoreflex, and pulmonary stretch reflex. These reflexes represent the major components of blood pressure control and breathing regulation. Aside from massive stimulation during critical illness, defects in the afferent and central pathways of the autonomic nervous system may develop, referred to as “autonomic dysfunction.” This is seen mostly in ICU patients suffering from MODS, sepsis, severe head and brain injuries, as well as Guillain–Barré syndrome or myocardial infarction. Clinically, the heart rate, which is strongly influenced by the impact of sympathetic and parasympathetic tones, is usually the most sensitive measure of autonomic dysfunction. Autonomic dysfunction is usually expressed as restricted heart rate variability. It is not clear whether this phenomenon is an integral part of

MODS or secondary to sedation, neuromuscular blocking agents, catecholamines, and mechanical ventilation, all frequently used in ICU setup. The reduction in physiologic heart rate variability is one of the strongest predictors of death in critically ill patients.

Adverse Effects of Adrenergic Stress

The adrenergic reaction is crucial to survive the insult of major trauma or injury; however, an overshooting influence of the sympathetic nervous system can become hazardous. This hazardous influence is exacerbated in commonly seen ICU requiring high-dose sympathetic support. Several organ systems may be affected. The heart seems to be most susceptible to sympathetic overstimulation: detrimental effects include impaired diastolic function, tachycardia and tachyarrhythmia, myocardial ischemia, apoptosis, and necrosis. Adverse catecholamine effects have also been observed in other organ functions, such as the lungs (pulmonary edema and elevated pulmonary arterial pressures), coagulation (hypercoagulability and thrombus formation), GI (hypoperfusion and inhibition of peristalsis), endocrinologic (decreased prolactin, thyroid, and GH secretion) immune systems (immunomodulation and stimulation of bacterial growth), metabolism (increase energy expenditure, hyperglycemia, catabolism, lipolysis, hyperlactatemia, and electrolyte changes), bone marrow (anemia), and skeletal muscles (enhanced protein degradation and apoptosis). Apart from their metabolic effects, catecholamines are known to have effects on the transcellular shift of electrolytes. Epi causes, at first, a transient increase in potassium (mediated by α1 and α2 receptor stimulation of hepatic calcium-dependent potassium channels), but shortly thereafter, β2 and β3 receptor stimulation of membrane-bound Na/K-ATPase in skeletal muscle and other tissues, as well as activation of the renin–angiotensin–aldosterone system, causes a decrease in serum potassium and magnesium concentrations. The electrolyte disturbances that increase the risk of cardiac arrhythmias can contribute to or induce neuromuscular weakness and result in difficulty weaning from mechanical ventilation. Other effects may include changes in renal (polyuria), gastrointestinal (intestinal paralysis), and metabolic (alkalosis) functions. Finally, it seems that prolonged sympathetic stimulation carries a myotoxic and apoptotic effect on skeletal and cardiac muscles, which contributes to myopathy, muscle wasting, and difficulty in ventilatory weaning.

METABOLIC ALTERATIONS

Injury and infection induce substantial changes in carbohydrate, lipid, and protein metabolism in most organs and tissues. The short initial ebb response is characterized by an enhanced gluconeogenesis, glycogenolysis, and lipolysis to mobilize potential energy sources. As the "stress response" continues, the energy needs, lack of dietary intake, and the body's limited available energy sources (i.e., glycogen) mandate the hypercatabolic state, which is the focus of this section. An integrative overview (Fig. 1.7) at the end of this chapter diagrams this complex fuel redistribution in trauma and/or infection injury.

Hypercatabolic Syndrome

Hypercatabolic syndrome is a biochemical state induced by increased circulating catabolic hormones (cortisol and catecholamines) and cytokines (TNF, IL-1β), as well as decreased anabolic insulin effects. The most important metabolic consequence of the hypercatabolic syndrome is the skeletal and cardiac muscle protein breakdown that releases amino acids, which, in turn, supports indispensable body energy requirements but also reduces skeletal and cardiac physiologic and metabolic functions (Fig. 1.4).

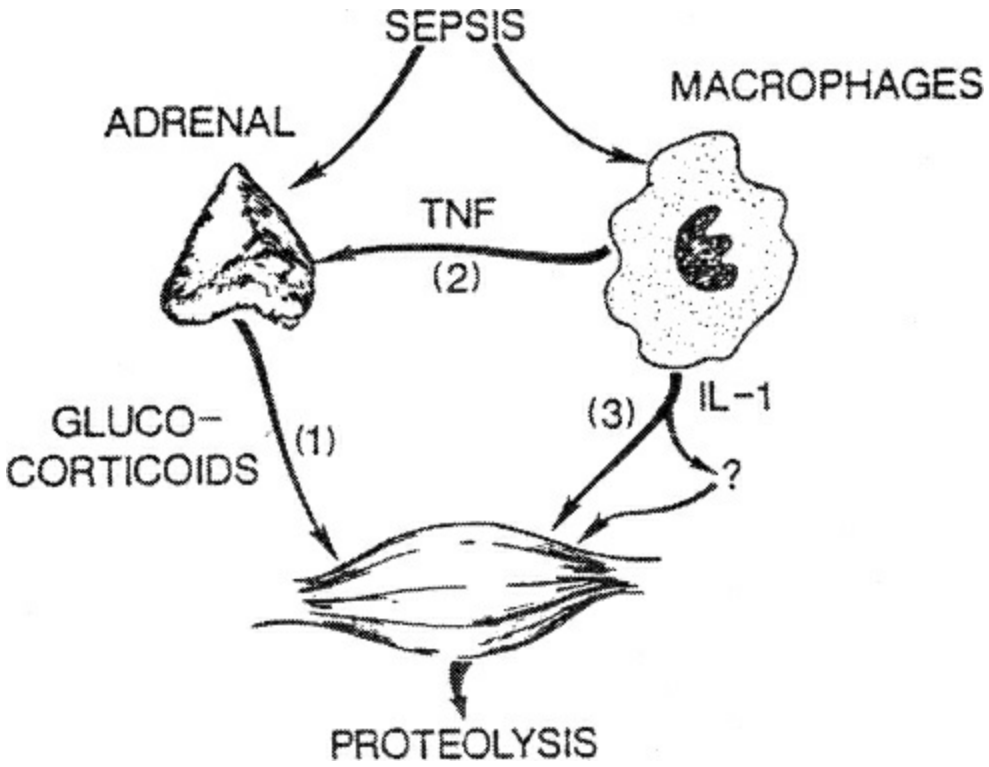

Figure 1.4. Interactions among (1) glucocorticoids, (2) tumor

necrosis factor (TNF), and (3) interleukin-1 (IL-1) in the regulation of sepsis-induced muscle proteolysis. The effect of TNF on muscle proteolysis is mediated primarily by glucocorticoids, whereas IL-1 regulates muscle proteolysis by glucocorticoid-independent pathway(s). (From Hasselgren PO. *Protein metabolism in sepsis*. Austin, TX: RG Landes; 1993, with permission from the author.)

An abundance of substrate is provided to ensure the function of essential visceral organs, supply building blocks for tissue repair, and support an upregulated and expanding immunologic system, postinjury or during infection. The total body energy requirements during the hypermetabolic period are not necessarily substantially higher than in a normal state. Although the REE is higher, the bed rest and diminished physical activity compensates for that change. Due to lack of dietary intake in the immediate posttrauma period, the metabolic energy requirements of the body must be provided by endogenous sources (i.e., glucose, FFAs). Glucose is the main source of energy in normal physiologic circumstances. The liver supplies the majority of endogenous glucose during this time mostly by using hepatic glycogen stores. The kidney has a role as well, but only becomes a significant contributor during prolonged fasting (>48 to 72 hours). The quantity of glucose stored as liver glycogen is about 65 g/kg of liver mass, which is about 100 g of glycogen for a normal 1,500 g adult liver. This amount of liver glycogen is limited to approximately 1 to 1.5 days of systemic glucose supply. Thus, at about 24 hours postinjury, hepatic glucose production changes from hepatic glycogenolysis to gluconeogenesis. An average human of 75 kg has roughly 15 kg of fat stored in 16 kg of adipose tissue (the rest is water) and 10 to 12 kg of protein suspended in 60 kg of lean body mass, mostly muscle. Nearly all of the body fat is expendable without serious adverse effects. Unfortunately, glucose synthesis by the liver to supply the glucose-dependent metabolism is primarily from protein, as the human body does not have the ability to convert lipid to glucose. Unlike lipids and glucose that can be stored as triglyceride (TG) and glycogen, respectively, there is no storage form of protein. The body protein component consists of muscle and visceral protein stores, which include structural protein, visceral organ proteins, as well as enzymes. Under normal circumstances, there is a continuous protein turnover, mostly of skeletal and cardiac muscles. In healthy humans under physiologic conditions, approximately

250 to 350 g of proteins are degraded each day. Most of the amino acids produced are reused to synthesize new proteins, but some are lost (energetic purposes, secreted in urine or feces). These protein losses are normally replaced by dietary protein.

In the postinjury period, the balance between muscle degradation and synthesis is altered because of the increase in catabolic hormones and cytokines produced as part of the inflammatory response, which is further exacerbated by the limitations imposed by bed rest and lack of dietary intake. The muscle is not merely an organ restricted to movement or contraction; it also plays an important role in maintaining the general metabolism of the human body. Muscle mass is ~45% of the dry weight of a healthy person, and most receptors for insulin, cortisol, and glucagon are located in the muscle.

With mild to moderate injury, this catabolic response causes minimal debility. In the more extensive injuries and/or infections, one can see a urinary loss of up to 30 g nitrogen/day, which represents degradation of about 180 g protein or 900 g muscle a day. Utilization of body protein may prolong convalescence and even contribute to mortality.

In contrast to fat, less than one half of the body's protein can be mobilized before death occurs, which means that only about 4 to 5 kg of protein (or 500 to 800 g of nitrogen) can be degraded. This suggests that only 1,500 to 2,400 g of glucose could be synthesized without an external source of glucose and/or proteins (1 g of nitrogen can be equated to hepatic synthesis of about 3 g of glucose). If the brain continued to oxidize 100 to 145 g of glucose each day during starvation, survival would be limited to 10 to 20 days. During "simple" fasting, the patient's body gradually adapts to use FFAs and ketone bodies as the main energy source, which decreases the daily glucose consumption to about 30 to 40 g. This enables the gradual decrease of the protein degradation rate to about 10 g/day of nitrogen after a week and about 5 g/day of nitrogen loss after 3 weeks of starvation, allowing a much longer survival period. (There are reports of up to 2 months of starvation with drinking.) Unlike in starvation, posttrauma patients are exposed to the persistent influence of catecholamines, glucocorticoids, and glucagon. These catabolic hormones preclude similar reduction in protein degradation and the hypercatabolism of muscle and organ protein continues as part of the systemic inflammatory process.

Mitochondria: The Center of Metabolism

Although metabolic dysfunction posttrauma or infection affects critical organs in a variety of ways, its genesis is generally linked to a single organelle, the mitochondrion (Fig. 1.5). The mitochondria are the sites of aerobic, oxidative metabolism that generates the overwhelming majority of ATP, the cellular energy currency. The energy is harnessed (~7 kcal per mole of ATP) in the terminal phosphate bond, whose hydrolysis can be coupled to energetically unfavorable reactions to drive them forward. ATP is a safe and stable fuel, which contains a large amount of energy that may be used to facilitate a wide variety of biologic processes. The oxidation of substrates (e.g., glucose, ketones, fatty acids, lactate) to generate ATP is accomplished via a highly efficient process that uses oxygen. Although it is extremely efficient, the process is not absolutely perfect as it has the capacity to "leak" electrons. As a consequence, these free electrons can generate oxygen-free radicals. Mitochondria can increase the output of ATP in response to a variety of triggering events. These include accumulation of ADP or the greater availability of "fuel" and oxygen. Cell-stimulatory signals, such as the presence of increased Ca^{2+} in the cytoplasm, also stimulate the mitochondria to generate more ATP. These stimuli are tied to an increased demand for work from the body, be it muscular (heart or skeletal muscle contraction), biosynthesis (production of proteins by the liver), cell division (immune responses or tissue repair), or the generation of heat (response to hypothermia). Clearly, all of these functions can be tied to the demands of dealing with infection and injury.

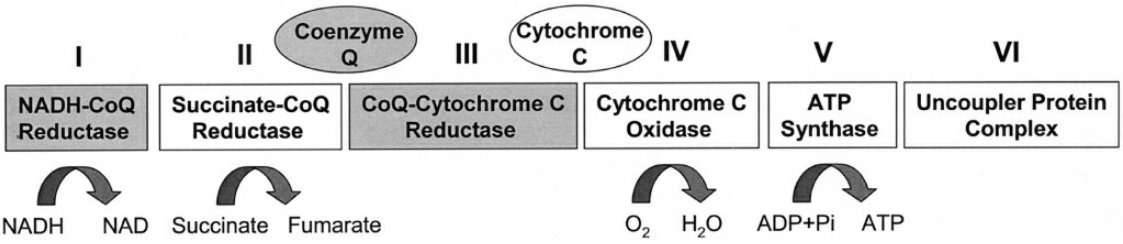

Figure 1.5. Oxidative phosphorylation in mitochondria. The diagram depicts the enzymes and cofactors involved in oxidative phosphorylation employed within the mitochondrion to produce ATP from a variety of substrates. Electrons are transferred via a sequence of redox acceptors, ultimately being accepted by oxygen. The molecules that shuttle electrons are coenzyme Q and cytochrome c. Gray shading denotes the points at which reactive oxygen species (ROS) may be liberated. ROS are prominent in injury, and have the potential to do damage to

biologic molecules, compromising cells and organs.

Mitochondrial Dysfunction

The failure of mitochondrial energy production lies not with the organelle itself, but with its various "supplies." Unlike sugars or fats, which are stored as glycogen or adipose tissue, respectively, there are no depot stores of ATP. Thus, with a failure to deliver any of the essential components (cardiac output and/or blood flow, lung oxygenation, glucose transport, etc.), there is a rapid onset of metabolic dysfunction of the mitochondrion. An immediate biochemical consequence of this dysfunction is the production of reactive oxygen species (ROS) that are toxic and can damage cells. These products take numerous forms, such as superoxide, peroxides, nitric oxide, and peroxynitrite. ROS are constitutively produced by mitochondria, and thus neutralizing compounds (antioxidants) such as glutathione normally buffer against the damage of ROS (Fig. 1.6). An additional consequence of mitochondrial dysfunction is leakage of the mitochondrial contents into the cytoplasm, which occurs at these times of stress by "permeability transition pores" open in response to stress, enabling molecules <1,500 Da to move between the inner mitochondrial membranes. Mitochondrial transition pore opening can subsequently lead to swelling and mitochondrial rupture. This rupture ultimately will allow larger molecules, such as cytochrome C, to enter the cytosol and trigger programmed cell death (apoptosis). Thus, besides failing to produce urgently needed ATP in times of crisis, the mitochondrion generates compounds that potentially cause considerable, often irreparable, damage and cell death. This is the stage in which insults of injury and infection can wreak havoc on metabolism.

Under conditions of severe injury and especially shock, there will very likely be severe morphologic damage to the mitochondria. This damage leads to decreasing mitochondrial ATP levels and increased ROS burden, exhausting the reserve of antioxidants that leads not only to the mitochondrion itself, but also other cellular organelles and molecules, including DNA. Serious impairment of vital (renal, hepatic, lung, and cardiac) and nonvital (skeletal muscle) organ functions can ensue. These failures are exacerbated by persistent hypotension, even in the face of more than adequate volume resuscitation. In most cases, these tissues exhibit a loss of mitochondrial function. Cellular tissue ATP levels will also fall, matched by a rise in ADP and adenosine monophosphate (AMP).

Although injuries vary greatly, serious injuries have common characteristics that can unfavorably affect mitochondrial metabolism. Hemorrhage effectively produces hypoxia, which initiates a cascade of responses that are directed toward adaptation to lowered oxygen, which, at the same time, can be damaging to an already injured body. Hypoxia and ischemia–reperfusion, with their lowered oxygen availability to the tissues, drive cells to depend on anaerobic glycolysis for ATP production. This can initiate a feedback situation, wherein lactic acid increases, effectively shutting down anaerobic glycolysis as an energy source. In this setting, FFA can also increase systemically, probably from peripheral adrenergic stimulation of lipolysis. However, limited oxygen availability also compromises β-oxidation, the principal means of converting fats to energy. This, in turn, causes a similar "stacking up" of FFA, acyl coenzyme A (acyl CoA), acylcarnitines, and so on, which compromises the heart. Under these conditions, the heart and other tissues are already at a disadvantage because, despite the high energy stored in fat, β-oxidation cannot match the efficiency of carbohydrate metabolism. Thus, reoxygenation, if it occurs, may take place in a setting in which aerobic metabolism is not possible, because of large-scale diversion of metabolism into the less efficient "backup" modes of β-oxidation and anaerobic glycolysis. There is one additional consequence of elevated lactic acid worth noting. As mentioned previously, an intracellular flux of calcium will cause a demand for increased ATP synthesis. The presence of increased lactic acid in the cell will cause calcium influx, providing a spurious signal for increased workload at a time when the metabolic machinery is incapable of reacting appropriately. This has the untoward effect of further depleting already low supplies of ATP.

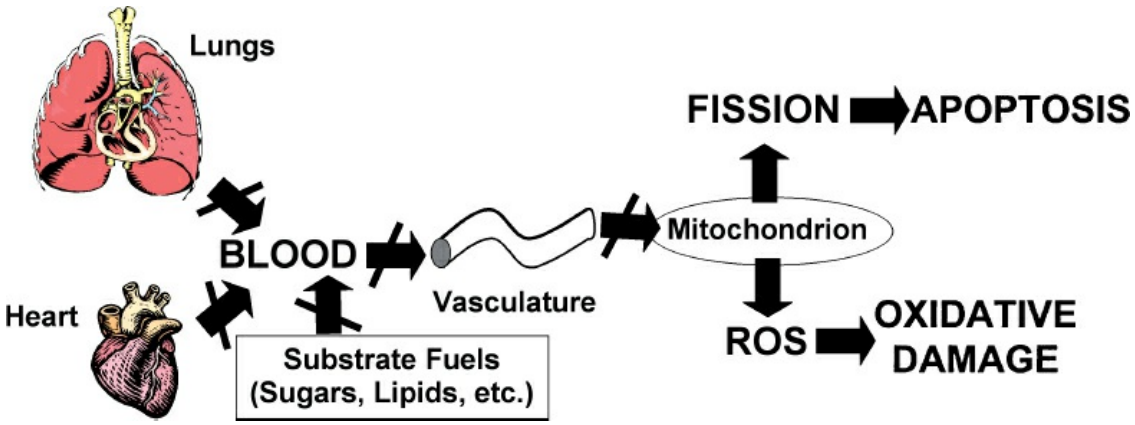

Figure 1.6. Consequences of mitochondrial dysfunction in injury. Mitochondrial dysfunction has several forms, the most important

of which are the generation of reactive oxygen species (ROS) and the opening of permeability transition pores. The transition pores release mitochondrial contents, which can cause severe damage to the cell, such as induction of apoptosis as mediated by mitochondrial cytochrome c. The combination of lung, heart, and vascular pathophysiology in injury can lead to mitochondrial dysfunction by virtue of inadequate respiration, poor blood flow, and vascular transport and delivery, which in turn adversely affects these same organs.

Carbohydrate Metabolism

Plasma glucose concentration in healthy subjects is strictly controlled. During the fed state, digested carbohydrates are delivered to the liver, with galactose and fructose rapidly converted into glucose. The glucose is either secreted to the circulation or used for storage in the form of glycogen or fat. An increased postprandial glucose level is followed by pancreatic β-cell insulin secretion, which enhances peripheral glucose utilization, as well as glycogen and fat synthesis. In the fasted state, the plasma glucose originates mostly from hepatic output. Liver glucose production arises from glycogen breakdown, synthesis from recycled carbons (lactate and glycerol), and (to a much lesser extent) de novo synthesis from amino acids such as alanine. Under normal conditions, the rates of liver glucose production and peripheral incorporation of glucose is matched exactly, keeping the plasma concentration of glucose set within a very strict limit.

After being actively taken up by peripheral tissues, the glucose is metabolized by glycolysis. The glycolytic pathway yields three products: ATP, pyruvate, and intermediates for amino acid production. Pyruvate can be further metabolized via the irreversible reaction of pyruvate dehydrogenase to yield acetyl-CoA, which can then enter the citric acid cycle to be completely metabolized to water and carbon dioxide to produce more ATP, or pyruvate be secreted into the blood stream as lactate.

Pathophysiology of Hyperglycemia in Critical Illness

Early in the course of the stress response, plasma glucose levels rise. Glucose availability is needed to supply the immediate energy demand during the posttrauma hypermetabolism, especially for the explosive immune activity. Glucose utilization is increased in multiple tissues, including liver, spleen, small intestine, skin, and some muscles. A common feature of some of these tissues is a high content of macrophages.

Studies have shown that in the liver, the high glucose uptake reflects increased utilization of glucose by Kupffer cells. However, because the overall rate of glucose secretion into the plasma exceeds the rate of glucose disposal, serum glucose levels are elevated.

Hyperglycemia as a sequela of critical illness commonly appears even in patients who do not have diabetes mellitus. There are many pre-existing conditions (diabetes mellitus, pancreatitis, cirrhosis, advancing age, and obesity) or possible iatrogenic causes (administration of corticosteroids, sympathomimetics, total parenteral nutrition, or excess dextrose) of hyperglycemia in the posttraumatic patient, but usually hyperglycemia is due to alterations in glucose metabolism secondary to the adaptive metabolic response. The synergistic activities of the HPA axis (catecholamines and glucocorticoids), pancreatic endocrine hormones (glucagon and insulin), and proinflammatory cytokines are central to those changes in glucose metabolism (Fig. 1.7).

Increased Sympathetic Tone and Hyperglycemia

Elevated catecholamine levels postinjury have well-established effects on glucose metabolism through a number of mechanisms. Epi directly promotes hepatic and skeletal muscle glycogenolysis, and hepatic gluconeogenesis independent of insulin or glucagon concentrations. Dufour et al. demonstrated that under constant insulin concentration, an increase of Epi plasma concentration from 100 to 2,000 pmol/L (which is equivalent to the levels observed during exercise at 60% to 80% of VO_{2max}) was followed by a 3-fold increase in glucose plasma concentration and a 2.5-fold increase in liver glucose production. During the first hour of Epi infusion, glycogenolysis was the source of 60% of glucose production and later gluconeogenesis accounted for about 80%.

Gluconeogenesis is further increased by catecholamines through the peripheral induction of lipolysis, which supplies the liver with glycerol. In addition, Epi stimulates pancreatic release of glucagon and inhibits release of insulin, further contributing to hyperglycemia. The catecholamines also affect glucose disposal through increased peripheral insulin resistance.

Hypercortisolism

Diabetes mellitus is very common (>50%) in patients with Cushing syndrome and hypercortisolism also occurs posttrauma. Elevated cortisol concentrations promotes hyperglycemia through a number of mechanisms. In the liver, cortisol stimulates phosphoenolpyruvate carboxykinase, the

enzyme that catalyzes the rate-controlling step of gluconeogenesis. Cortisol also stimulates the activity of the enzyme glucose-6-phosphatase, which catalyzes the completion of the final step in gluconeogenesis and glycogenolysis. Hepatic glucose production is further enhanced by the excessive flow of substrates to the liver, secondary to peripheral lipolysis and proteolysis. As with catecholamines, glucocorticosteroids not only increase the amount of glucose secreted to the blood stream, but also induce increased insulin resistance. In this manner, it contributes even more to hyperglycemia.

Insulin

Insulin levels vary depending on the phase of injury. During the ebb phase, insulin levels are reduced despite hyperglycemia. The combined effects of catecholamines, somatostatin, glucocorticoids, and reduced pancreatic blood flow may reduce pancreatic β-cell sensitivity to glucose. During the flow phase, β-cells regain their sensitivity, and insulin concentrations rise. Despite increased insulin concentrations, however, hyperglycemia may persist due to peripheral insulin resistance.

Insulin resistance is the inability of insulin to adequately stimulate glucose uptake, mainly into skeletal muscle, or to inhibit gluconeogenesis in the liver. Unlike in the case of chronic insulin resistance, such as in type 2 diabetes, which takes years and even decades to develop, insulin resistance postinjury develops within hours or minutes of insult. This form of insulin resistance is called “acute insulin resistance” and sometimes “stress diabetes” or “critical illness diabetes.” There are numerous studies on the development of chronic insulin resistance, but little is known regarding the pathophysiology of acute insulin resistance. Studies suggest that acute insulin resistance is complex and might differ in a tissue-specific manner, involving multiple causative factors and intracellular signaling pathways.

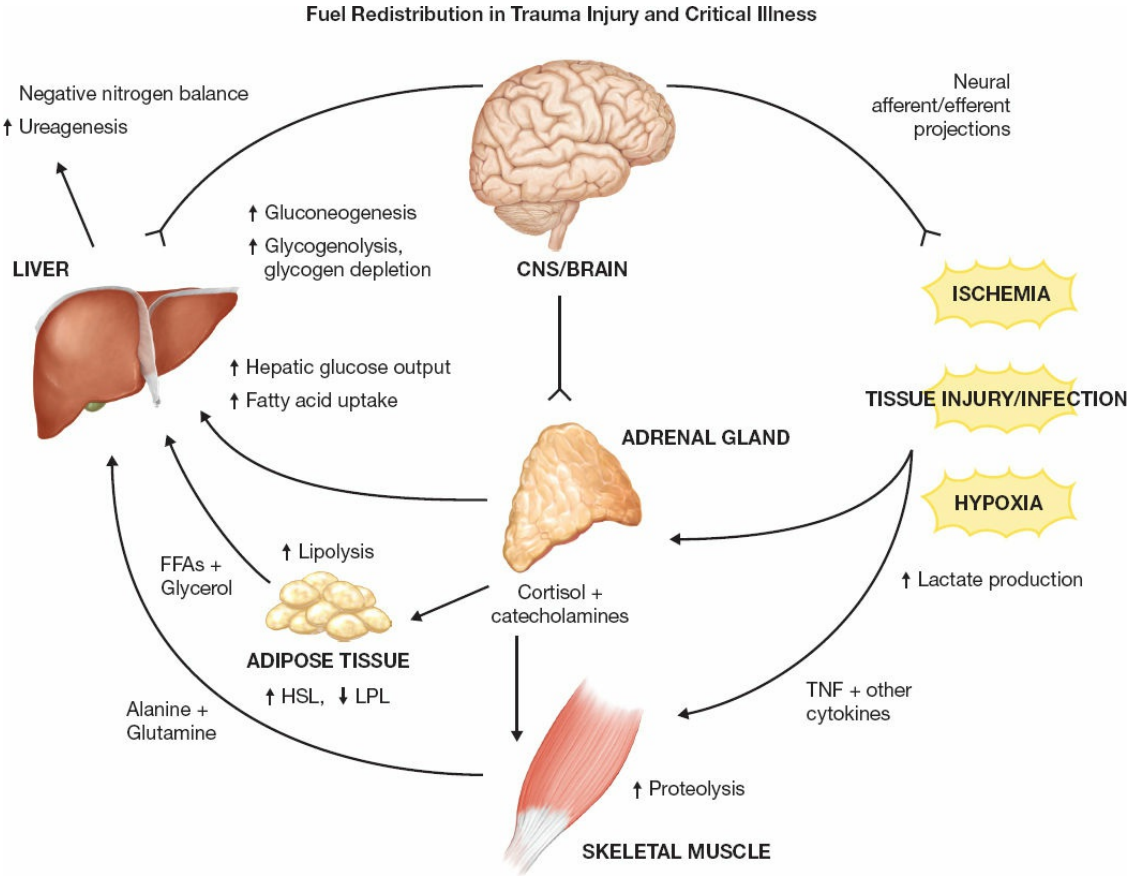

Figure 1.7. Metabolic fuels redistribute in response to severe trauma and/or infection. A number of pathways of fuel mobilization and usage are affected by critical illness and the accompanying inflammatory response. In general, the catabolic hormones (i.e., catecholamines and glucocorticoids) induce a state of increased proteolysis and lipolysis from muscle and adipose tissues, respectively. This increase in fuel release allows them to circulate in the blood and be used by the liver for gluconeogenesis as well as other energy-demanding processes like acute phase protein responses. The cytokines released as part of the inflammatory response at the site of injury, as well as afferent neural projections also add to the complex regulation and redistribution of metabolic fuel to aid in the body's response.

Insulin signaling is initiated by binding of insulin to its receptor, followed by activation of two main intracellular insulin-signaling pathways: the IRS/PI3K/Akt pathway and the MEK/ERK pathway. Several tissue-specific mechanisms are involved in the development of insulin resistance including alterations related to insulin receptors, such as impairment of receptor expression, or binding or inhibition of intermediaries involved in the insulin-signaling pathway for glucose

uptake. Studies investigating potential mechanisms of skeletal muscle insulin resistance in experimental animal models demonstrated decreased insulin signaling via the metabolic pathway following burn injury and reduced GLUT4 mRNA and protein levels in rat adipose tissue during sepsis. Epi has been reported to enhance insulin resistance through inhibition of insulin binding, GLUT-4 translocation, and IRS-1 (metabolic pathway). Moreover, different tissues have been shown to develop various degrees of insulin resistance and to be affected by different mechanisms. Some proinflammatory cytokines, including TNF, decrease insulin signaling via the metabolic pathway. Administration of a TNF-α neutralizing antibody following trauma and hemorrhage in rodents reverses the acute insulin-resistant state in the liver, but not in skeletal muscle. Overall, a number of tissue-specific mechanisms are involved in the development of insulin resistance.

Glucagon

Another counterregulatory hormone of interest during stress of the critically ill is glucagon. Glucagon, like Epi, is responsible for increased glucose production through both gluconeogenesis and glycogenolysis. The action of glucagon alone is not maintained over time; however, its action on gluconeogenesis is sustained in an additive manner with the presence of Epi, cortisol, and GH. Likewise, Epi and glucagon have an additive effect on glycogenolysis. The important role of hyperglucagonemia, present during sepsis, was demonstrated in experiments in which the hormone was blocked by infusion of somatostatin in septic rats, and the elevated rate of glucose production was reduced to control levels.

Cytokines

Proinflammatory cytokines promote hyperglycemia through stimulation of release of counterregulatory hormones, including cortisol, Epi, NE, and glucagon. The most extensively studied cytokine with regard to carbohydrate metabolism is TNF. Changes in glucose metabolism during endotoxemia and sepsis can be reproduced by administration of TNF, which increases hepatic glucose production, hyperglycemia, and stimulated glucose utilization by macrophage-rich tissues and the diaphragm. The hepatic increase in glucose production secondary to TNF can be blocked by an infusion of phentolamine and propranolol, suggesting that the TNF effect on the liver is secondary to adrenergic activation. In addition to the effect on the counterregulatory hormones,

TNF may have a direct effect on cellular glucose kinetics in muscle and adipose tissue.

Similar to TNF, IL-1 also can influence carbohydrate metabolism. According to animal models, it seems that the IL-1β main effect is in inducing hypoglycemia by binding the hypothalamic receptors. Other factors also play a role in the regulation of metabolism during infection and injury, including nitric oxide and prostaglandins.

Glucose Control in ICU

Persistent hyperglycemia is hazardous and has been shown to impair wound healing, increase susceptibility to infections, and even increase mortality. Not surprisingly, previous studies have asked the question of whether or not tighter control of blood glucose concentrations is associated with clinical benefits in critically ill patients. A single-center trial in Leuven, Belgium, published in the *N Engl J Med*, emphasized the importance of tight glucose and changed the approach to glucose control in the ICU. In this study that involved 1,548 patients, most of whom had undergone cardiac surgery, patient hyperglycemia was aggressively treated with insulin, and glucose levels were kept in between 80 and 110 mg/dL (4.4 and 6.1 mM) as compared with conventional insulin therapy, which had a target blood glucose level of 180 to 200 mg/dL (10.0 to 11.1 mM). This approach significantly reduced mortality from 8% in the controls to 4.6% in the experimental group. However, the study was criticized because of serious hypoglycemia that occurred in 5% of the patients. These improvements in mortality were unable to be reproduced in a subsequent study and were associated with an even greater increase in serious hypoglycemic episodes (18.7%). Moreover, several other studies including the Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE–SUGAR) have failed to demonstrate a benefit in mortality. These studies have culminated in current guidelines that emphasize less intensive insulin therapy to maintain blood glucose in the 140 to 180 mg/dL range, while minimizing the risk of hypoglycemia.

Lipid Metabolism

Lipids, as a class of biologic molecules, are the most efficient molecules for energy storage. The energy yield from 1 g of fatty acid is ~9 kcal, compared to ~4 kcal from 1 g of carbohydrates. Moreover, since lipids

are hydrophobic in nature, these molecules can be stored in a relatively water-free environment. Carbohydrates, on the other hand, are hydrophilic. This fact increases the total mass of glycogen storage; for example, 1 g of glycogen binds ~2 g of water, which translates to an actual 1.33 kcal/g stored. This means that fat can actually hold more than six times the amount of energy per weight unit than glycogen. As such, lipids, in the form of TGs, are the main source of stored energy. Lipids also play an important role in many other cellular functions, such as synthesis of cell membranes, and production of steroid hormones, intracellular signal mediators as prostaglandins, fat-soluble hormones, and others. Fatty acids are either derived from diet or synthesized in the liver from carbohydrates. Dietary lipids absorbed as fatty acids form into TG and are transported as chylomicrons. These newly synthesized FFAs as well as those derived from diet are converted to TG in the liver, a process called esterification. The insoluble esterified, hepatic TG are packaged into the soluble very low–density lipoproteins (VLDL) and secreted into the blood. TGs are mainly stored in adipocytes in distinct anatomic locations, such as fat tissue or within other tissue types, including muscle or liver. The endothelial enzyme lipoprotein lipase hydrolyzes circulating TGs to fatty acids, enabling their diffusion and transport into the cells of peripheral tissues.

Hydrolysis of TGs within adipocytes into FFA and glycerol is known as lipolysis, which is stimulated by various hormones. Some examples are glucagon during fasting/hypoglycemia; Epi, NE, and possibly cortisol during stress; and GH during anabolism. These hormones bind to cell-surface receptors that are coupled to the activation of adenylate cyclase upon ligand binding. The result is activation of cAMP-dependent protein kinase (also known as protein kinase A), which, in turn, activates hormone-sensitive lipase (HSL). The net result of the action of these enzymes is hydrolysis of TG to release FFA and glycerol. The FFAs diffuse from adipose cells, combine with albumin in the blood, and are transported to other tissues where they are transported into cells. Fatty acids are the most efficient source of energy for most cell types. For example, catabolism of 1 mole of a six-carbon fatty acid through the citric acid cycle to CO_2 and H_2O generates 44 moles of ATP, compared with the 38 moles generated by catabolism of 1 mole of the six-carbon carbohydrate glucose.

In the normal state, glucose is the dominant contributor of energy

production. Active glucose metabolism downregulates FFA oxidation, thereby shuttling those FFAs into TG stores in the muscle, liver, and adipose tissue. In the fasted state, however, FFA is the dominant contributor of energy production. The major site of fatty acid oxidation occurs within the mitochondria by β-oxidation, as this process occurs by recurrent oxidation of the fatty acid chain at the β-carbon position. The rate of FFA oxidation is determined by the rate of transfer into the mitochondria. Medium- and short-chain fatty acids can enter the mitochondria without difficulty, but long-chain fatty acids (the majority of FFAs) must be actively transferred through the mitochondrial outer membrane. This process transports fatty acids into the mitochondria by first conjugating them to carnitine. The fatty acyl-carnitine is then transferred to the mitochondria via the carnitine palmitoyltransferase enzyme system (CPT-I, CPT-II), which is the crucial point in the regulation of the FFA oxidation. Glucose availability and metabolism control the oxidation of fatty acyl-CoA by regulating CPT-I activity via changes in malonyl-CoA concentration. Malonyl-CoA inhibits fatty acyl-carnitine transport into the mitochondrion and favors lipid synthesis/storage.

Lipid Metabolism During Critical Illness

The increased influence of catabolic hormones (e.g., Epi, glucagon) and proinflammatory cytokines of critical illness promotes excessive peripheral lipolysis and mobilization of FFAs. Likewise, a concomitant increase in the de novo synthesis of FFAs takes place in the liver. The FFAs are used as an alternative, available energy source for the peripheral tissue in a time of need, which spares much needed glucose reserves for use by the nervous system and erythrocytes. TNF was found to play a major role in enhancing peripheral lipolysis and hepatic synthesis of FFAs. TNF has an inhibitory effect on peripheral lipoprotein lipase, which causes a peripheral resistance to TG resulting in increased lipemia. Other cytokines, including IL-1, IFN-α, β, and γ, may also influence lipid metabolism.

At the same time, while the organism recruits its energy sources, there is a paradoxical increase in liver esterification of FFAs to TG. A number of contributing factors play a part in this paradox:

1. FFA flux is elevated to a higher level than the oxidation rate of the body, which exposes the liver to an excess of FFAs.

2. Both glucose and FFA levels simultaneously increase in blood plasma. This hyperglycemia leads to increased hepatic glucose uptake and metabolism, which leads to inhibition of CPT-I and fatty acid oxidation, leading to more accumulation of hepatic pool FFAs.
3. The increased β-adrenergic stimulation causes increased peripheral glycolysis with concomitant production of pyruvate, which exceeds its capacity for metabolism and utilization by the mitochondria. The pyruvate–lactate equilibrium results in excessive secretion of lactate to the blood even without any hypoxia or hypoperfusion. This lactate is metabolized by the hepatocytes, increasing either gluconeogenesis or the citrate production through the Krebs cycle, and possibly the de novo fatty acid synthesis, thereby also contributing to the inhibition of FFA oxidation or TG synthesis in the liver.

The result of this process is an enhanced liver TG synthesis causing hypertriglyceridemia and often accumulation of hepatic TG that leads to a fatty liver. The reduced activity of the enzyme lipoprotein lipase in the muscle and the adipose tissue decreases the clearance of lipoproteins, leading to worsened hypertriglyceridemia. The clinical significance of this hyperlipidemia, hypertriglyceridemia, and the tendency for fatty liver during critical illness is not completely clear. However, these findings have important implications to the management of nutrition support in these patients. It has been observed with regularity that overfeeding, especially by parenteral access, causes enhanced steatohepatitis and a deteriorating prognosis for ICU patients.

Protein Metabolism

Proteins contribute to both structure (skeletal muscle) and the function (enzymes) of the body. The absolute amount of protein depends on the age, weight, disease state, and nutritional status of the patient. Skeletal muscle mass represents 30% to 50% of total body protein, is greater in men than women, and declines with age. Between the ages 20 and 80, total muscle cross-sectional area declines about 40%. Following injury, the increased urinary excretion of nitrogen from the body is roughly related to the extent of the injury. Nitrogen is primarily lost in the form of urea, which represents about 85% of the urinary nitrogen loss, although this proportion varies widely. Creatinine, ammonia, uric acid, and amino acids are also found in the urine in larger quantities than normal following injury. The nitrogen molecule is used as a surrogate marker of protein

because of the fixed relation between the two substances (6.25 g protein to 1 g of nitrogen). Thus, the net loss or gain of body protein is determined by nitrogen balance, and this is a general measure of the catabolic state.

Maintenance of protein within an individual tissue is a balance between rates of protein synthesis and breakdown. Synthesis and breakdown are often mismatched during catabolic states, resulting in organ protein loss or gain. The catabolic response occurs by a relative increase of breakdown over synthesis. Protein turnover responds to injury and infection in a manner that redistributes body protein to satisfy its needs. The synthesis rate is decreased in "nonessential" tissues (e.g., limb skeletal muscle or gut) and is maintained or enhanced in tissues where work is increased (respiratory and cardiac muscle, lung, liver, and spleen). These events result in translocation of protein from skeletal muscle to the visceral organs (primarily liver, spleen, and heart), which are vital for survival.

Two amino acids, alanine and glutamine, account for approximately 50% to 75% of the amino acid nitrogen released from skeletal muscle. Alanine is used as a building block for various proteins and it is an important glucose precursor. Glutamine plays a very important role during the stress response. Similar to alanine, glutamine is also a gluconeogenic substrate, but it mainly serves as a primary substrate for immune cells and enterocytes as both rely on glutamine for optimal function and energy production. Glutamine also participates in acid–base homeostasis, and serves as a precursor for glutathione, an important intracellular antioxidant. In critically ill patients, the intramuscular concentration of glutamine may fall by as much as 80% to 90%. Part of this drop is due to accelerated outward transport and partly due to a decrease in glutamine de novo synthesis. Glutamate serves as the precursor for both glutamine and alanine. Under a variety of circumstances, the formation of alanine from glutamate is the preferred pathway, leading to depletion of glutamate availability for glutamine synthesis. It has been hypothesized that the tissue requirements for glutamine may outstrip the body's ability to produce this amino acid. Hence, a relative deficiency state exists characterized by a fall in glutamine concentrations in both plasma and tissue compartments. Thus, glutamine is considered a conditional essential amino acid.

Muscle Catabolism

The story of muscle in the stress response is the story of protein degradation and wasting. Accelerated catabolism of muscle protein is a

universal problem in critically ill patients; loss of muscle mass and strength is secondary to protein breakdown due to the metabolic needs. The typical prolonged bed rest and inactivity play a large role in muscle wasting. Muscle wasting may impair recovery if severe enough and certainly limits the return of patients to normal function after recovery. Plank et al. demonstrated the changes in total body protein over a 21-day period, following onset of sepsis or major trauma. They noted that losses were greatest during the first 10 days, amounting to approximately 1.0% of total body protein per day during both sepsis and trauma. Total protein lost over the study period averaged 1.21 ± 0.13 kg in sepsis patients and 1.47 ± 0.20 kg in trauma patients. Approximately 70% of the total protein loss came from skeletal muscle. This loss occurred in sepsis patients during the first 10 days and in trauma patients in the first 5 days. After these intervals, more of the protein loss was derived from the nonmuscle tissues.

Liver

The liver plays a major role in a number of critical aspects of the stress response. It is the central metabolic organ coordinating the cardinal changes in glucose, protein, and lipid metabolism. The hepatic cell types that are involved in liver response to sepsis and SIRS include Kupffer cells, hepatocytes, and sinusoidal endothelial cells. These cell types communicate in a paracrine fashion and with bidirectional signaling via different mediators. These mediators modify the metabolic pathway of hepatocytes to support amino acid uptake, ureagenesis, increased synthesis of coagulant factors, complement factors, APPs, and antiproteolytic enzymes.

Immunologic Function

The liver contains the largest mass of macrophages (Kupffer cells) in the body and plays a crucial role in the inflammatory response, both as a source of inflammatory mediators and as a target organ for the effects of inflammatory mediators. The interaction between hepatocytes and Kupffer cells plays a key role in the regulation of the acute-phase response. Kupffer cells are pivotal in the hepatic response to sepsis. Once activated, Kupffer cells are a major source of soluble mediators of sepsis, including proinflammatory cytokines, chemokines, nitric oxide, reactive oxygen products, and eicosanoid mediators. Kupffer cells are also important in preventing the dissemination of bacteria and endotoxins from the portal

circulation to the systemic circulation. In animal models, within 5 minutes of intravenous injection, 50% of radiolabeled endotoxin is localized in the Kupffer cells. Hepatocytes play not only a crucial metabolic role, but also an immune role. Hepatocytes exhibit receptors for most of the soluble mediators of sepsis, including endotoxin, cytokines, inflammatory mediators, and vasoactive substances. Studies in rats showed that treatment with gadolinium chloride, which blocks Kupffer cell function, resulted in clearance of circulating endotoxin with endotoxin secreted in bile, where it was inactivated and secreted in the feces. The liver is also a major site for removal of bacteria from the systemic circulation. About 70% of radiolabeled *Escherichia coli* and 96% of *Pseudomonas aeruginosa* are localized within the liver only 10 minutes after intravenous injection.

Hepatic endothelial cells are in contact and interact with Kupffer cells and hepatocytes. The endothelial cells participate in the inflammatory reaction by secreting proinflammatory cytokines (IL-1 and IL-6). They also play an important role in the regulation of the hepatic, and to some extent, systemic circulation. The liver sinusoids, which are analogous to tissue capillaries, lack smooth muscle cells and, therefore, hepatic sinusoidal flow is instead regulated by NO and CO, which are released by the sinusoidal endothelium.

APP are plasma proteins primarily of hepatic origin; their plasma levels increased by at least 25% following sepsis, injury, or inflammation. The APPs consist of coagulation and anticoagulation (α2-macroglobulin), complement system components, and inflammatory (CRP, serum amyloid A), anti-inflammatory (α1-antitrypsin and α1-antichemotrypsin), and various other proteins (e.g., haptoglobin and ceruloplasmin). The concentration of other liver-derived proteins, particularly albumin, is reduced in sepsis (negative APP). In a rat model of chronic sepsis, studies showed that albumin synthesis was actually increased within 4 days of initiation of sepsis. It seems that the decreased circulating levels of albumin reflect increased leak of albumin to the extravascular compartment and possibly an increased rate of degradation, but not a reduced synthesis. The enhanced synthesis of all these APPs is regulated by the Kupffer cell–derived cytokines and is a part of the complex systemic and local changes needed to defend the host. Additional hepatic APP scavengers include ceruloplasmin and α2-macroglobulin, which inactivate reactive oxygen radicals. One of the key factors of APP is the

CRP, which functions as part of the innate immune system. Its main role is in binding to a phosphocholine present on the surface of dying cells and some bacteria, causing activation of the complement (classical pathway) and promotion of macrophage phagocytosis. The CRP level is elevated within hours of insult and peaks at about 48 hours postinjury. The measurement of CRP plasma level has become a common and reliable tool for the evaluation of the extent of a patient's inflammatory process.

Hypercoagulation

During the stress response, the liver promotes a hypercoagulable state by the enhanced synthesis of coagulation factors, such as fibrinogen, prothrombin, factor VIII, von Willebrand, and, at the same time, decreased synthesis of protein C and antithrombin III. The increased CRP plasma level also promotes the expression of tissue factor, the initial activator of the extrinsic clotting system, by mononuclear cells and neutrophils. Promotion of coagulation capacity by the liver is needed in case of tissue injury and possible excess consumption of coagulation factors, but it is also responsible for many fatal thrombotic and thromboembolic complications.

Liver Dysfunction During Critical Illness

The unusually high metabolic and inflammatory needs associated with severe illness must be met by a liver that may already be compromised due to stress (shock and sepsis), a situation that may lead to liver dysfunction. Liver dysfunction can be divided into primary and secondary dysfunction. In normal physiologic conditions, postprandial splanchnic blood flow accounts for up to 30% of total cardiac output. During the stress response period after a severe tissue trauma or sepsis, the portal flow, which arises from the splanchno-mesenteric vascular bed, is subject to disproportionate vasoconstriction (under the influences of α-adrenergic and renin–angiotensin stimulus). A physiologic compensatory process (referred to as hepatic arterial buffer response) of inverse changes in hepatic blood flow in response to changes in portal flow takes place, but this response of the hepatic artery is often altered during severe sepsis or shock, compromising hepatic blood flow. Primary hepatic dysfunction that occurs in the hours after the insult or onset of sepsis is most likely linked to hypoperfusion. The outcome of such acute liver dysfunction can be catastrophic with disseminated intravascular coagulation, reduced hepatic lactate and amino acid clearance with metabolic acidosis, decreased gluconeogenesis, and

glycogenolysis with subsequent hypoglycemia—all of which are potentially fatal.

Secondary hepatic dysfunction is thought to be a result of "spillover" of bacteria or endotoxin and the subsequent activation of inflammatory cytokines and mediators in the absence of circulatory changes. Mild cholestasis is a common sign of secondary liver dysfunction during critical illness. It is often an isolated finding secondary to intrahepatic cholestasis caused by rapid downregulation of transporter proteins, such as NTCP (a basolateral sodium-dependent bile salt transporter) and multidrug-resistant protein 2 (MRP2), which is a canalicular anionic conjugate transporter, and a bile salt pump.

Heat Shock Proteins

One of the hepatic mechanisms to deal with the stress and avoid a secondary liver dysfunction is dramatic upregulation of liver synthesis of HSPs. The HSPs are a group of proteins discovered during the 1960s in Drosophila cells that were exposed to sublethal temperature. Although named heat shock proteins after their discovery, HSPs actually serve as general survival proteins by increasing cellular resistance against a vast range of stressors and not just elevated temperatures. In normal physiologic conditions, HSPs act as regulatory intracellular proteins, stabilizing other proteins in proper formation by chaperoning proteins across cell membranes. HSPs have the capacity to repair denatured/injured proteins and serve as part of the cells' own repair system. HSPs serve as one of the most highly conserved mechanisms of cellular protection, are found in virtually all living organisms, and are a key part of cellular response to stress. Enhanced HSP expression, using transgenic mice or by a mild stress before the insult, has been shown to be cytoprotective in experimental models of sepsis and other types of stress. Increased expression of HSPs has been detected in a variety of clinical settings. In patients with severe trauma the ability to mount a higher HSP response is predictive of survival.

Glutathione

Cellular glutathione plays an important role in the cellular ability to detoxify free radicals and limit cellular damage in times of high oxidative stress that accompany severe illness. In an animal model of sepsis, a six-fold increase in de novo synthesis of glutathione by hepatocytes was demonstrated in the first 2 days of sepsis. In contrast to APPs, persistence

of stress response throughout the course of sepsis in rats (4 days after infection) led to depletion of liver glutathione. The mechanism of late glutathione depletion is not clear; one hypothesis is that it is secondary to selenium depletion. Selenium is an essential cofactor for glutathione peroxidase activity and it has been shown that depletion of that micronutrient in sepsis is associated with increased morbidity and mortality. The selenium requirement in sepsis increases in parallel with increased glutathione peroxidase activity and glutathione turnover. Randomized and placebo-controlled trials have indicated that high-dose selenium supplementation can improve outcomes in sepsis and septic shock.

Steatohepatitis

Another important factor related to liver dysfunction in critically ill patients is steatohepatitis. As mentioned previously, the liver in critically ill patients faces an increased flux of FFA, amino acids, and carbon-3 compounds, such as lactate and glycerol, together with conditions of hyperglycemia and hyperinsulinemia. The hepatic capacity of FFA oxidation and secretion seems to be inhibited, and TGs accumulate in hepatocytes leading to steatosis. Steatohepatitis in critically ill patients has been reported mostly in relation to artificial nutrition, especially total parenteral nutrition. Previous studies have confirmed that critical illness and liver dysfunction are associated with liver damage not only biochemically but pathologically as well.

Intestine and Gut Barrier

Our understanding of intestinal barrier function biology, its potential clinical importance, as well as the pathophysiology and consequences of gut barrier failure has changed considerably over the course of time. Now, it is clear that the intestinal mucosa functions physiologically as a local defense barrier to prevent bacteria and endotoxin, which normally are present within the intestinal lumen, from escaping and reaching extraintestinal tissues and organs. Moreover, it has become apparent that the gut can become proinflammatory and gut-derived factors, especially those liberated after periods of splanchnic hypoperfusion, can lead to acute distant organ dysfunction.

Initial interest in gut barrier failure and bacterial translocation was based on clinical observations that trauma, burn, and critically ill patients,

especially those developing MODs, frequently had life-threatening bacteremia with enteric organisms in the absence of an identifiable focus of infection. These clinical observations resulted in a large body of work investigating the relationships among gut barrier function, intestinal bacterial flora, systemic host defenses, and injury in an attempt to delineate the mechanisms by which bacteria contained within the GI tract can translocate to cause systemic infections. From these and subsequent studies, the current role of the gut and gut barrier function in the prevention and potentiation of systemic infections and MODS have evolved.

Gut Barrier and Bacterial Translocation

The tremendous importance of intestinal barrier function is obvious when one considers that the distal small bowel and colon contain enormous concentrations of bacteria and endotoxin ($\sim 10^{11}$ bacteria per gram of feces). Under certain clinical circumstances, intestinal barrier function becomes impaired, resulting in the uninhibited movement of bacteria and/or endotoxin to the systemic tissues. The underlying mechanisms of this bacterial translocation have been studied extensively. Although both an intact epithelial barrier and a normal functioning immune system are important for adequate gut barrier function, even an intact mucosa will prevent bacterial translocation in rats with selectively impaired cell-mediated immunity. Reduced splanchnic blood flow, leading to an ischemia–reperfusion-mediated gut injury has been shown to be a key factor in the loss of mucosal barrier function and bacterial translocation in models of thermal injury, hemorrhagic shock, and endotoxemia. In these models, mucosal injury appears secondary to a gut ischemia–reperfusion injury, which is mediated, in part, by xanthine oxidase–generated oxidants.

Nutrition and Gut Barrier

The area of nutrition continues to receive increasing clinical and experimental attention. The optimal functional and structural integrity of the GI tract depends on whether or not the gut is fed enterally. Enteral feeding supports intestinal structural integrity by maintaining mucosal mass, stimulating epithelial cell proliferation, maintaining villus height, and promoting the production of brush border enzymes. Functional integrity of the mucosa is also supported by enteral feeding through maintenance of epithelial tight junctions, stimulation of gut blood flow, and the production and release of a variety of endogenous agents that exert

trophic effect on the intestinal epithelium (e.g., bile acids, cholecystokinin, gastrin, and bombesin). Enteral feeding preserves intestinal barrier function better than parenteral feeding, with enterally fed animals better tolerating those fed an identical diet parenterally. These findings have been verified in several prospective randomized clinical studies involving burn and trauma patients and have influenced the current practices of nutritional support in critical illness. Although bacterial translocation has been demonstrated consistently in experimental animal models, results of clinical human trials failed to find bacteria or endotoxin in the portal blood of severely injured patients and its relevance to humans is uncertain. One possible explanation to resolve these discordant results, however, is that gut-derived factors contributing to systemic inflammation and organ injury reach the systemic circulation via the mesenteric lymphatics rather than the portal venous system. One important conceptual consequence of the gut–lymph hypothesis is that the lung rather than the liver would be the first major vascular bed to be exposed to gut-originated mesenteric lymphatic factors (mesenteric lymph bypasses the liver and follows the thoracic duct that empties into the subclavian vein and directly proximal to the pulmonary circulation). There is extensive clinical and experimental evidence showing that after hemorrhagic shock, trauma, or a major burn injury, the gut releases proinflammatory and tissue injurious factors that lead to acute lung injury.

EDITOR'S COMMENT

Nothing about surgery makes sense until one understands the metabolic and inflammatory responses to trauma and infection, and these are beautifully described in the current edition of Chapter 1. The commentator from the previous edition (J.E.F.) described this chapter as "encyclopedic," which in my opinion is not always a flattering descriptor, but in this case it is apt. The authors have diligently reviewed and outlined the cytokine, endocrine, and neurohormonal responses to surgical trauma and infection. To the uninitiated this material may be considered to be dry, but understanding these hormonal, cytokine, and neurologic responses of the body to surgical stress is paramount to understanding why our patients respond the way that they do after surgery and trauma. For any aspiring student of surgical physiology the importance of this chapter cannot be overemphasized.

From innumerable studies done in this field, we now have a scientific foundation for and have in some ways redefined the "ebb and flow" concept first described by Cuthbertson in the early 1930s. The concept has been broadened not only to include metabolism but also to explain another surgical

fascination—perioperative fluid avidity. This chapter clearly explains why our patients become sodium (and thereby water) avid in the immediate postoperative period, and likewise why fluid "mobilization" should be expected within 2 to 3 days after surgical/trauma encounters. The advent of laparoscopic surgery has allowed further insights, corroborating the importance of the magnitude of the insult relative to the subsequent inflammatory/hormonal response and resultant sodium avidity. It is worth noting that understanding this ebb and flow might tempt one to hasten postoperative recovery by use of diuretics. This implies a condition I term "lasixpenia," which I have yet to see in the index of any surgical text. A more patient practice is to wait for fluid mobilization to begin on its own. For those patients not mobilizing their fluids as expected, concern for ongoing stress (i.e., infection, ischemia, etc.) should be raised, thereby prompting early thoughtful investigations for possible complications.

Despite all of our progress, this chapter also shows that there is much more to be done. For example, we have just begun to scratch the surface of the neuroimmune axis. While it has been known for many years that the CNS influences hormonal responses to stress, the direct influence of the CNS on immune function has been a relatively new addition to the literature. There are compelling animal data now suggesting that vagotomy enhances inflammation during shock, and that vagal nerve stimulation might temper these immune responses. To my eye, the question of whether vagotomy enhances septic shock in people remains to be answered. I also find it a bit humbling to consider that for decades Western medicine has focused mostly on the bodily response to surgery, while the influence of the mind and spirit on surgical outcomes remains a relative mystery. Study in this area could contribute greatly to outcomes for our surgical patients.

Likewise, there is much more to learn about the impact that opiates have on immune function during surgical convalescence. It has been known for years that our immune cells express the three main opioid receptors, and there are growing data suggesting the immune suppressive influences that opiates have on their function. Nevertheless, poorly treated pain will also stimulate unwanted neural afferent and efferent activities enhancing the inflammatory response and perhaps neurologic attenuation of immune function. This latter concern and the assignment of pain as the "fifth vital sign" have led to a lean toward overuse of narcotics in postoperative patients. It is becoming increasingly evident that overprescribing is contributing to our national opiate dependence epidemic, but the earlier influences of such practice on patient immunity and infectious complications remain grossly understudied.

Another area that remains understudied is the differential response of individual patients to surgical stress. Despite the thoughtful catalog of physiologic responses to surgery presented here, the simple fact remains that not all patients respond the same way to comparable stress. We have been quick to assume that these differences must be due to genetics, and the authors rightly

point out that there are described polymorphisms of Toll-like receptors. Likewise, there are polymorphisms of other cytokines and receptors that might influence immune and inflammatory responses. Nevertheless, as studies of the influence of genetics on other diseases progress, it seems safer to conclude that genetics are likely only part of this puzzle, and not the entire puzzle.

To add to this puzzle, we must also consider the influence of pre-existing immunity on responses to surgery and trauma. We have learned from recent examples such as respiratory syncytial virus and H1N1 that viral infections can predispose hosts to dramatic and often fatal bacterial pneumonia. The potential detrimental influence of chronic viral infections, such as herpesviruses, on surgical outcomes is also receiving increasing attention. Likewise, it has become clear that critical illness has significant impact on epigenetic regulation, which might also influence surgical outcomes. Altogether these data suggest that immunologically, what has come before might indeed influence what happens next after surgery or trauma, and this area of research remains mostly unexplored.

Finally, once all of these holes in our knowledge have been filled (and yet others recognized), we will still be left with a somewhat bewildering pile of observations that need to be integrated and understood as a system. As intimated by the authors, there is significant overlap and interaction between the myriad cytokine and hormonal responses to surgical stress, and this complexity does not even consider genetics or immune memory. Lifelong practice and careful study certainly have allowed surgeons glimpses of the “big picture,” but as our dataset has continued to grow we have mostly surpassed this possibility as individuals. Future understanding will require rule engines and advanced statistical techniques, combining methods such as Ingenuity’s Pathway Analysis and Gene Wide Association Study (GWAS). By using such approaches, we will hopefully come to understand how individuals respond to surgical stress, allowing us to tailor our expectations and therapy for each of them.

In conclusion, after studying this chapter and perhaps this commentary, it is my sincere hope that some of you are inspired to continue the great work outlined here. Most of us spend our entire career at some level trying to understand why patients respond to our treatments the way that they do. Even if you choose not to pursue this subject academically, if you give this chapter the full attention that it deserves, your patients will be richly rewarded by your better understanding of their response to your ministrations.

Charles H. Cook

2 Perioperative Management: Practical Principles, Molecular Basis of Risk, and Future Directions

Per-Olof Hasselgren, Jeremy W. Cannon, and Josef E. Fischer

INTRODUCTION

Preparing patients for surgery has grown increasingly complex as the severity of chronic illness within our patients has worsened even as the options for managing these conditions in the perioperative period have expanded. In addition, over the past decade, the process of surgical care in the operating room (OR) and afterward has been refined in a number of respects aimed at improving patient safety and quality of care. Throughout this perioperative time, the patient's physiology is taxed to tolerate the surgical insult and then to heal the operative site. This chapter has three sections. First, practical and clinical aspects of the perioperative management of surgical patients are discussed, including preoperative evaluation, intraoperative considerations, and immediate postoperative management. The second part of the chapter provides a discussion of metabolic alterations and molecular mechanisms involved in muscle wasting, a prevalent and dreaded condition seen in many critically ill patients and that may have significant impact on the perioperative management and influence the outcome of surgical procedures. Finally, in the third section of the chapter, the perioperative assessment of the surgical patient from a nutritional standpoint, in particular the need for nutritional support in the malnourished patient and in patients with cancer or sepsis is highlighted. This section also provides a historical perspective dating back to the 1970s of the development of nutritional support in surgical patients.

Perioperative Evaluation and Management

The perioperative period is defined as the time from preoperative workup through the first 30 days of postoperative care. From the patient's perspective, a surgical procedure and the perioperative period are often a

momentous occasion, which involves significant loss of personal control. As such, the surgeon's responsibility is to engender trust that the decision to operate is sound and that every measure to ensure the patient's safety throughout the perioperative course is taken.

A careful preoperative history, review of systems, and physical examination will reveal pre-existing medical conditions and risk factors known to worsen surgical outcomes. This process can be facilitated by a screening questionnaire structured to trigger the patient's memory about significant medical illnesses or previous perioperative experiences (Table 2.1). Findings during this evaluation then guide the array of laboratory studies and additional tests needed to more specifically assess the patient's risk of an adverse perioperative event. Once all of this information is gathered, a perioperative management plan can be fashioned by the surgeon often with input from the patient's primary care physician and possibly other specialty consultants in fields such as cardiology, geriatrics, and anesthesiology. The following sections review many of the issues that arise during the perioperative period and provide a recommended approach based on current evidence.

TABLE 2.1 Preoperative Screening Questionnaire

1. Do you usually get chest pain or breathlessness when you climb up two flights of stairs at normal speed?
2. Do you have kidney disease?
3. Has anyone in your family (blood relatives) had a problem following an anesthetic?
4. Have you ever had a heart attack?
5. Have you ever been diagnosed with an irregular heartbeat?
6. Have you ever had a stroke?
7. If you have been put to sleep for an operation, were there any anesthetic problems?
8. Do you suffer from epilepsy or seizures?
9. Do you have any problems with pain, stiffness, or arthritis in your neck or jaw?
10. Do you have thyroid disease?
11. Do you suffer from angina?
12. Do you have liver disease?
13. Have you ever been diagnosed with heart failure?
14. Do you suffer from asthma?
15. Do you have diabetes that requires insulin?
16. Do you have diabetes that requires tablets only?
17. Do you suffer from bronchitis?

SCREENING TESTS IN GENERALLY HEALTHY PATIENTS

For patients with no or few comorbidities, a selective preoperative testing approach is advised (Table 2.2). Laboratory testing options include a complete blood count (CBC), electrolyte and renal function tests, serum glucose, liver function tests (LFTs), coagulation studies, urinalysis, and pregnancy test. With the exception of pregnancy test, these studies can be obtained within several months of the planned procedure. Patient's age has been identified as a minor predictor of morbidity and mortality although this seems to be related more to the associated comorbidities that develop with advancing age. Consequently, age alone should not be used in determining the types of preoperative tests to obtain with the exception of a baseline hemoglobin (Hb) for those over 65 years undergoing major surgery and any patient in whom significant blood loss is anticipated. The cost of an added white blood cell and platelet count is often minimal; so these are often obtained as part of the baseline Hb. Because renal insufficiency strongly correlates with poor perioperative outcomes, identifying patients with occult renal disease is essential. No consensus exists on the indications for such testing, but it has been suggested that a BUN and Cr should be obtained in patients over 50 years of age scheduled for intermediate- or high-risk surgery or when perioperative hypotension is considered likely or when nephrotoxic medications are planned. Routine electrolyte, serum glucose, and LFT are not recommended in healthy patients. Patients with a history of a bleeding disorder or an associated illness, which can result in abnormal coagulation function should have coagulation studies performed. Otherwise, routine testing of the partial thromboplastin time, prothrombin time, and international normalized ratio (INR) is not recommended. Routine urinalysis testing is a matter of ongoing debate. On the one hand, patients scheduled to have a surgical prosthesis implanted may be at an increased risk for wound or implant infections from a pre-existing urinary tract infection (UTI). However, even with treatment, patients with an asymptomatic preoperative UTI develop more postoperative infections, and the cost–benefit ratio of prosthetic infection prevention with routine urinalysis screening does not clearly favor testing the asymptomatic patient. Patients of childbearing age should have a urine or serum pregnancy test, which many institutions require as a matter of policy.

TABLE 2.2 Preoperative Laboratory Testing Indications

Laboratory Test	Indication
CBC	Age ≥65 + major surgery; anticipated significant blood loss
Renal function	Age ≥50 + major surgery; suspected renal disease; anticipated hypotension; planned nephrotoxic agents; poorly controlled hypertension
Serum electrolytes	Routine testing not recommended
Serum glucose	Routine testing not recommended
Liver function	Routine testing not recommended
Nutrition laboratory values	History of unintentional weight loss; chronic GI illness
Coagulation studies	Routine testing not recommended
Urinalysis	Routine testing not recommended
Pregnancy test	Women of childbearing age
Additional Basic Tests	**Indication**
EKG	Vascular surgery planned; history of cardiovascular disease; poorly controlled hypertension
CXR	Age ≥50 + AAA or upper abdominal/thoracic surgery; history of cardiopulmonary disease
PFT	Unexplained dyspnea

CBC, complete blood count; GI, gastrointestinal; EKG, electrocardiogram; CXR, chest x-ray; PFT, pulmonary function tests.

Additional basic testing options include a 12-lead electrocardiogram (EKG), PA and lateral chest x-ray (CXR), and pulmonary function test (PFT). We reserve these tests almost exclusively for patients with prior history of cardiovascular or cardiopulmonary disease. With regard to PFT, these are only obtained in patients with dyspnea in whom a thorough history and physical examination fails to reveal the source of this complaint. Our approach to obtaining these additional tests is also summarized in Table 2.2.

RISK ASSESSMENT AND MANAGEMENT IN PATIENTS WITH CHRONIC MEDICAL ILLNESS

The most common pre-existing medical condition requiring perioperative risk assessment and management is either known or suspected cardiovascular disease. Other common pre-existing conditions that are amenable to risk modification include pulmonary diseases, renal insufficiency, liver failure, diabetes mellitus, immunosuppression, and hematologic conditions. The surgeon's goal should be to minimize the impact of these conditions on the surgical outcome while using a surgical and anesthetic approach, which avoids any further deterioration of the

involved organ system and the patient. In each case, communication between the surgeon and the primary care physician or medical specialists involved in the patient's care is essential while preparing such patients for surgery.

Cardiovascular

Cardiovascular events are responsible for one third to one half of perioperative deaths, and of the patients who present for noncardiac surgery, nearly one third have a known diagnosis of cardiovascular disease. Consequently, cardiovascular risk stratification and modification are fundamental to the perioperative care of many patients.

Patients with a good functional status have a low risk of perioperative cardiovascular complications. This can be assessed by determining the types of daily routines the patient can perform, which translate into multiples of the amount of oxygen consumed while seated at rest (1 MET). Patients who are unable to walk up two flights of steps or four blocks (>4 METs) have an increased risk of postoperative cardiovascular events. In addition to functional status, cardiovascular risk scoring systems are useful in quantifying the risk of a major perioperative cardiovascular event. The Revised Cardiac Risk Index (RCRI) is the tool we prefer given its simplicity and validation in multiple clinical studies (Table 2.3).

In addition to basic laboratory studies, patients with cardiovascular disease should have a baseline EKG. Additional testing options include transthoracic echocardiography, exercise or chemical stress testing with or without supplemental echocardiography or radionuclide myocardial perfusion imaging, and coronary angiography. The 2014 American College of Cardiology/American Heart Association (ACC/AHA) guidelines reflect the most current recommended approach to the use of these additional studies (Fig. 2.1). Alternative algorithms have been proposed by the American College of Physicians (ACP) and by Fleisher and Eagle. In general, if the patient's cardiovascular disease warrants immediate intervention (i.e., the cardiovascular symptoms are more pressing than those that prompted surgical consultation), additional studies are warranted. Although these algorithms serve to identify and further evaluate patients deemed to be at either intermediate or high risk for adverse perioperative cardiovascular events, their use has, to date, not been shown to improve patient outcomes.

Based on the coronary artery revascularization prophylaxis (CARP)

trial and the DECREASE-V pilot study, prophylactic coronary revascularization by percutaneous coronary intervention (PCI) or coronary artery bypass grafting does not appear to alter postoperative outcomes. Accordingly, the current ACC/AHA guidelines recommend preoperative PCI only in patients with an acute coronary syndrome for whom PCI is independently indicated. Patients who undergo coronary revascularization with a bare metal stent should have surgery delayed for 4 to 6 weeks but no more than 12 weeks when the incidence of stent restenosis begins to rise. Conversely, patients who have a drug-eluting stent (DES) placed should have surgery delayed for a year if possible while the patient is on dual antiplatelet therapy. Aspirin should be continued in the perioperative period if at all possible, and thienopyridine therapy (e.g., clopidogrel) should be resumed as soon as possible after surgery to minimize the risk of stent thrombosis.

TABLE 2.3 Revised Cardiac Risk Index and Associated Rates of Significant Perioperative Cardiovascular Events

Risk Factor	Comment
High-risk surgery	Intraperitoneal, intrathoracic, or suprainguinal vascular procedures
Ischemic heart disease	History of myocardial infarction, history of a positive exercise test, current complaint of chest pain considered to be secondary to myocardial ischemia, use of nitrate therapy, or ECG with pathologic Q waves
History of heart failure	History of congestive heart failure, pulmonary edema, or paroxysmal nocturnal dyspnea; physical examination showing bilateral rales or S3 gallop; or chest radiograph showing pulmonary vascular redistribution
History of cerebrovascular disease	History of transient ischemic attack or stroke
Insulin therapy for diabetes	
Preoperative serum Cr >2 mg/dL	
Risk of perioperative cardiac complications including cardiac death, nonfatal MI, and nonfatal cardiac arrest based on the number of risk factors (% [95% CI])	
0	0.4 [0.1–0.8]
1	1.0 [0.5–1.4]
2	2.4 [1.3–3.5]
3	5.4 [2.8–7.9]

Adapted from Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 1999;100(10):1043–9 and Devereaux PJ, Goldman L, Cook DJ, et al. Perioperative cardiac events in patients undergoing noncardiac surgery: a review of the magnitude of the problem, the pathophysiology of the events and methods to estimate and communicate risk. *CMAJ* 2005;173(6):627–34.
MI, myocardial infarction; CI, confidence interval.

Patients with unstable angina or a recent MI bear special consideration. Historic studies suggested that a significant and persistent risk of reinfarction or death existed for up to 6 months after an acute MI. However, with improved perioperative monitoring and management, the rates of such complications after subsequent noncardiac surgery have dropped significantly. A stress test after MI or an episode of unstable angina reliably identifies patients who will benefit from revascularization. Those who have no evidence for at-risk myocardium have a low likelihood of reinfarction with noncardiac surgery and can likely be taken for surgery within 4 to 6 weeks.

Pre-existing essential hypertension is a common medical problem among patients facing surgery. Good blood pressure control (<140/90 mm Hg in most patients or <130/80 mm Hg in patients with DM or CKD) is ideal. However, national guidelines do not recommend delaying surgery unless the patient's blood pressure is over 180/110 mm Hg. Patients with

poorly controlled hypertension have an increased risk of perioperative blood pressure lability, arrhythmias, and myocardial ischemia. Such patients should have an EKG and renal function testing and should be evaluated for secondary hypertension prior to elective surgery if this workup has not been previously performed. Then, improved blood pressure control should be pursued for 6 to 8 weeks prior to surgery if the urgency of the indicated procedure permits.

Pulmonary

Patients with a known diagnosis of chronic obstructive pulmonary disease (COPD), asthma, upper respiratory tract infections, pneumonia, or other pulmonary conditions warrant special attention. In addition to an assessment of the patient's smoking status, pulmonary functional baseline, need for supplemental oxygen, and current pulmonary medications, use of a pulmonary risk index can aid in the quantification of the perioperative risk of respiratory failure (Table 2.4). Patients with pulmonary risk factors should have a preoperative CXR supplemented by PFTs in those with unexplained dyspnea. There is no role for routine preoperative arterial blood gas testing. The benefits of perioperative smoking cessation are discussed below. If the patient has had a recent deterioration in pulmonary function in the recent past due to a reversible cause, elective surgery should be deferred until the patient returns to their prior baseline. Patients with COPD should be managed with an inhaled anticholinergic (e.g., ipratropium) and as needed inhaled beta agonists. Patients with asthma should be maintained on their home medication regimen unless their current symptom control is poor. In these cases, a step-up in therapy in the perioperative period is warranted. Prophylactic administration of glucocorticoids to asthmatics is not required unless they are maintained on systemic or high-dose inhaled steroids. In patients at high risk for perioperative pulmonary complications, consideration should be given to use of spinal or epidural anesthesia over general anesthesia. Long-acting neuromuscular blockade (e.g., pancuronium) should be avoided. If a laparoscopic surgical option is available, this should be used over open surgery if possible. For postoperative risk mitigation, an epidural catheter for analgesia should be planned in these patients, and preoperative incentive spirometry teaching should be conducted so that the patient is prepared to participate in early and aggressive postoperative lung expansion.

Renal

Chronic renal insufficiency with a serum Cr of ≥2 mg/dL is an independent predictor of postoperative cardiac complications. In addition, the surgical team must take special care to avoid further kidney injury in these patients by maintaining euvolemia, taking appropriate precautions to avoid contrast-induced nephropathy, and by appropriately dosing all medications while minimizing the use of those with potential nephrotoxic effects. In addition, in the perioperative period, intravascular volume status can be more difficult to gauge in this patient population; so we are aggressive with employing all available monitors to assure adequate intravascular volume to include use of a pulmonary artery catheter in some cases.

Patients with end-stage renal disease (ESRD) require coordination of perioperative care between the surgical team, the anesthesia team, and nephrology. Preoperative electrolytes should be obtained in close proximity to the procedure to ensure that serum potassium is within normal limits and that there are no significant derangements in the other values. If the patient is on hemodialysis or peritoneal dialysis, the timing of pre- and postoperative dialysis should be decided upon in advance. Patients who are on the cusp of requiring renal replacement therapy (RRT) require similar surveillance and coordination in the event that transient RRT is required for postoperative electrolyte management, volume overload, or azotemia.

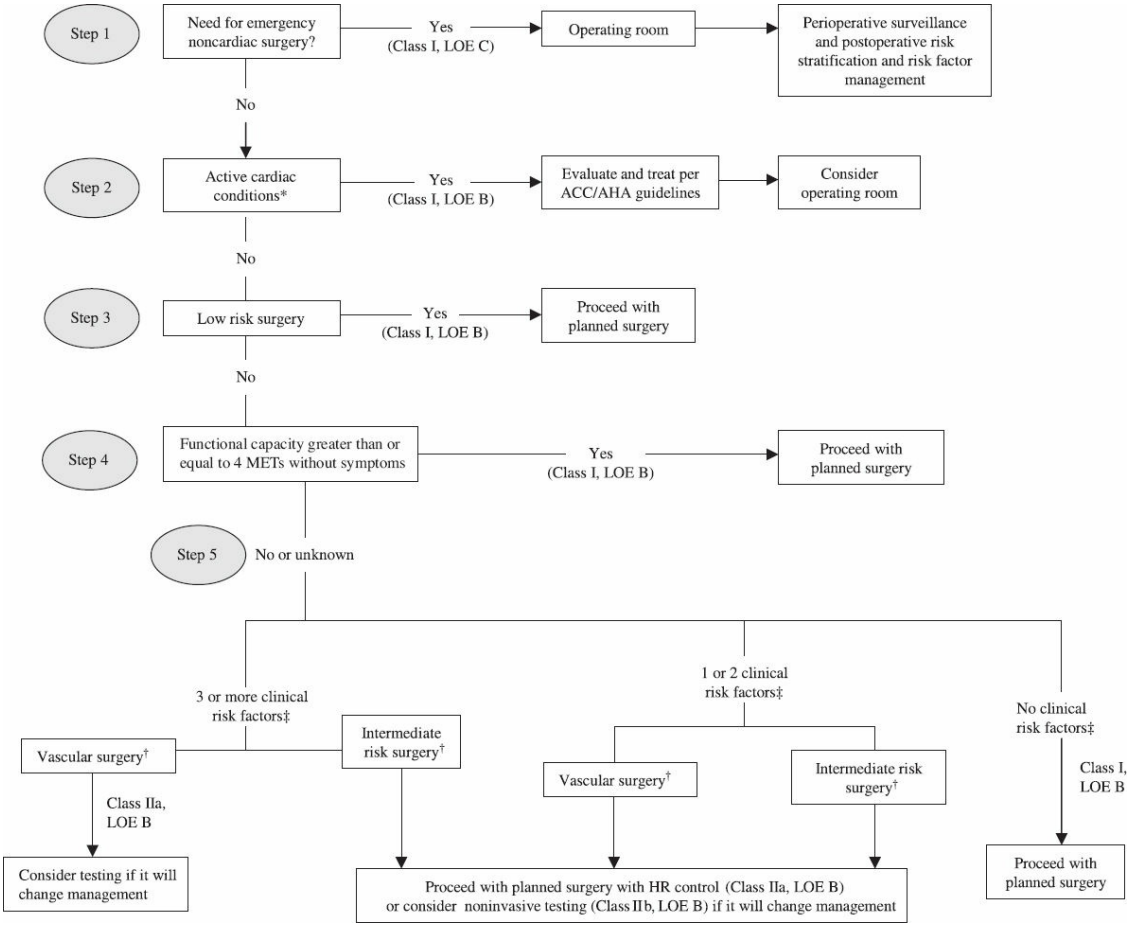

Figure 2.1. 2007 ACC/AHA algorithm for the perioperative cardiovascular management of patients aged 50 and above undergoing noncardiac surgery. (Adapted from Fleisher AJ, Bjork BJ, Bui TQ, et al. Mid-infrared time resolved frequency comb spectroscopy of transient free radicals. *J Phys Chem Lett* 2014;5(13):241–6). *Active cardiac conditions include unstable or severe angina, MI between 7 and 30 days prior, decompensated heart failure, significant arrhythmia, severe aortic stenosis, or symptomatic mitral stenosis. †Low risk surgery includes endoscopic procedures, superficial procedures, cataract surgery, breast surgery, and ambulatory surgery; intermediate risk surgery includes intraperitoneal/intrathoracic surgery, carotid endarterectomy, head and neck surgery, orthopedic surgery, and prostate surgery; vascular surgery includes aortic and other major vascular surgeries (except carotid endarterectomy) and peripheral vascular surgery. ‡Clinical risk factors are similar to the revised Cardiac Risk Index factors in Table 2.3 and include history of ischemic heart disease, cerebrovascular disease, compensated or prior heart failure, diabetes mellitus, and renal insufficiency.

Liver

Patients with pre-existing hepatic failure are at increased risk for complications and death after surgery. The Child–Turcotte and Child–Pugh classification schemes were originally developed to estimate the risk of death after portal-caval shunting and have since been validated as a good estimate for death following a range of other surgeries. More recently, the model for end-stage liver disease (MELD) score has also been used to assess perioperative risk in these patients (Table 2.5). An online calculator, which uses the patient's age, ASA class, and MELD score to calculate 7-day, 3-day, 90-day, 1-year, and 5-year predicted mortality is also available at http://www.mayoclinic.org/meld/mayomodel9.html.

In general, patients with mild cirrhosis (Child's A or MELD <10) tolerate surgery well while patients with fulminant hepatic failure, severe hepatitis, extrahepatic complications, and advanced cirrhosis (Child's C or MELD >15) are likely to have a poor postoperative outcome and should have surgery delayed until their liver function can be optimized or they undergo a liver transplantation if possible. Patients with moderate cirrhosis (Child's B or MELD 10 to 15) can be considered for surgery after careful preoperative evaluation. Reports of herniorrhaphy outcomes in these patients (both umbilical and inguinal) suggest that these operations can be performed safely. Similarly, cholecystectomy has been reported in patients with cirrhosis for a range of indications, and recent reports indicate that the laparoscopic approach is safe and appears to have improved outcomes when compared with open cholecystectomy. The preoperative preparation of these patients should focus on minimizing ascites, correcting vitamin deficiencies (especially vitamin K), and assessing for and correcting malnutrition.

TABLE 2.4 Arozullah Respiratory Failure Index and the Associated Risk of Respiratory Failure[a]

Preoperative Predictor	Points
Type of Surgery	
Abdominal aortic aneurysm	27
Thoracic	21
Neurosurgery, upper abdominal, peripheral vascular	14
Neck	11
Emergency surgery	11
Albumin <3 g/dL	9
BUN >30 mg/dL	8
Partially or fully dependent functional status	7
History of COPD	6
Age	
>70 years	6
60 to 69 years	4

Class	Points	Risk of Respiratory Failure (%)
1	≤10	0.5
2	11–19	1.8–2.1
3	20–27	4.2–5.3
4	28–40	10.1–11.9
5	>40	26.6–30.9

Adapted from Arozullah AM, Daley J, Henderson WG, et al. Multifactorial risk index for predicting postoperative respiratory failure in men after major noncardiac surgery. The national veterans administration surgical quality improvement program. *Ann Surg* 2001;232(2):242–53.
[a]Respiratory failure is defined as either mechanical ventilation for >48 hours after surgery or reintubation and mechanical ventilation after initial postoperative extubation.

TABLE 2.5 Use of the MELD Score for Preoperative Risk Assessment in Patients With Cirrhosis

MELD Score	Mortality (%)		
	7-day	30-day	90-day
0–7	1.9	5.7	9.7
8–11	3.3	10.3	17.7
12–15	7.7	25.4	32.3
16–20	14.6	44.0	55.8
21–25	23.0	53.8	66.7
≥26	30.0	90.0	90.0

MELD, model for end-stage liver disease.

Endocrinopathies and Obesity

Diabetes mellitus is a common medical condition present in up to 20% of surgical patients. As shown in Table 2.3, insulin-requiring diabetes is a marker for increased postoperative cardiac morbidity in the RCRI. Historic glycemic control is a known marker for postoperative infections (pneumonia, wound infection, UTI, and sepsis), and poor perioperative glycemic control has been shown to correlate with surgical complications and death. Thus, careful attention must be paid by the surgical team to cardiac risk modification in diabetic patients and to glucose management throughout the entire perioperative period to assure optimal outcomes.

A reliable measure of historic glycemic control over the previous 3 months is the hemoglobin A_{1C} (Hb A_{1C}). If the Hb A_{1C} is >7%, postoperative infections are increased while a preoperative glucose level of >200 mg/dL is associated with an increased rate of postoperative deep wound infections. Perioperative management of oral hypoglycemics and insulin is discussed below (see section on “Medication Management”).

Patients with hypothyroidism should continue on their baseline medication regimen throughout the postoperative period. Those who are nil per os (NPO) can have these medications safely held or converted to IV supplementation if a prolonged period of fasting is anticipated. Those with hyperthyroidism undergoing surgery should achieve a euthyroid state before surgical intervention and their antithyroid medications should be

continued up until the time of surgery. If urgent surgery is required in a thyrotoxic patient, consultation with an endocrinologist is warranted.

Obesity (BMI ≥30 kg/m^2) has been extensively evaluated as a risk factor for poor perioperative outcomes. Recent evidence suggests that, in fact, there may be a so-called “obesity paradox” in that such patients have fewer complications than controls. The exceptions to this paradox are wound and thromboembolic complications including deep venous thrombosis (DVT) and pulmonary embolism (PE). Furthermore, superobese patients (BMI >50 kg/m^2) are still considered to be at increased perioperative risk for a range of complications including death.

Important aspects in the preoperative evaluation of obese patients include calculating the BMI and eliciting a history of obstructive sleep apnea (OSA), hypertension, coronary artery disease, renal disease, diabetes mellitus, thromboembolic events, or any adverse outcome from prior to surgery. Obese patients who do not carry a diagnosis of OSA can be quickly screened with a questionnaire such as the STOP-BANG screening tool. Those at high risk for OSA should be referred to a sleep specialist for further testing prior to elective surgery. Many centers have special monitoring protocols for patients with OSA, and those who use CPAP at home should be continued on this therapy in the postoperative period.

In selecting the operative approach, a recent systematic review found that obese patients have significantly decreased wound infection rates following laparoscopic versus open surgery.

Malnutrition

Preoperative malnutrition has been recognized as an important risk factor for postoperative morbidity and mortality for over 70 years. Quantification of the degree of malnutrition and the correction of severe malnutrition preoperatively remain an important part of surgical management. Assessment of nutritional status begins with a thorough history and physical examination paying careful attention to dietary changes, evidence of malabsorption, and evidence for loss of lean body mass. The Subjective Global Assessment has been used to facilitate this evaluation. Laboratory testing should include albumin, transferrin, and prealbumin to assess the long-term, intermediate-term, and short-term nutritional state of the patient, respectively. If the patient is found to be severely malnourished, surgery should be delayed so that supplemental nutrition can be administered. Enteral supplementation is preferred if the patient can

tolerate this route; otherwise, parenteral nutrition (PN) should be initiated. In this population, improvements in nutritional status are assessed at regular intervals until surgery is deemed safe (after 7 to 15 days in some studies). Supplemental nutrition is then continued postoperatively until the patient can meet their caloric needs independently.

Coagulopathy

Patients with inherited coagulopathies and those who are maintained on therapeutic anticoagulation present special challenges with regard to achieving and maintaining postoperative hemostasis. Perioperative management of anticoagulant and antiplatelet medications is discussed below (see section on “Medication Management”). The most common intrinsic coagulopathies in surgical patients are von Willebrand disease and the hemophilias. Patients with chronic renal insufficiency also have some baseline degree of platelet dysfunction. The surgical review of systems should specifically focus on a predilection for prolonged epistaxis, easy bruising, and any bleeding complications during previous surgeries. If this evaluation is negative for a bleeding history and the physical examination does not reveal any petechiae or stigmata of chronic renal or liver disease, routine testing of coagulation studies is not indicated. If these studies are obtained and are abnormal, a mixing study is required to determine whether the abnormality is the result of a factor deficiency or an inhibitor (e.g., lupus anticoagulant). If the patient’s personal family history is strongly suggestive of an undiagnosed coagulopathy, consideration should be given to testing for von Willebrand disease using the triad of plasma von Willebrand factor (VWF) antigen, plasma VWF activity, and factor VIII activity. Patients who carry a diagnosis of von Willebrand disease should be pretreated in consultation with a hematologist with either desmopressin (DDAVP) for minor surgery if the patient has previously responded or with VWF concentrate for major surgery. Patients with mild hemophilia A or B can similarly be pretreated with DDAVP while those with severe hemophilia can be treated with specific factor concentrates (Factor VIII or IX) or activated Factor VII in the presence of inhibitors. Patients with thrombocytopenia (e.g., those with inherited thrombocytopenic purpura) should have a preoperative platelet transfusion targeting a minimum of 50,000/μL.

Malignancy and Immunocompromise

Patients with malignancy and those on immunosuppressive medications or with an inherited or acquired immunocompromised state frequently undergo surgery. The preoperative evaluation should proceed as described above guided by the patient's other medical conditions and nutritional status. For patients on chemotherapy, the timing of the last dose of chemotherapy, the projected cell count nadirs, and planned future therapy should be discussed with the patients and their oncologist. For patients with HIV, a history of an AIDS-defining illness and their current medication regimen should be elicited. Laboratory testing should include a CBC with differential, chemistries, renal function, and liver function studies. If malnutrition is suspected by history and physical examination, nutrition laboratory values should be obtained. Patients with HIV should have a CD4 and a viral load obtained as the former is a surrogate for immunocompetence while the latter has been specifically correlated with increased perioperative complications at a level of 30,000 copies/mL or greater. Patients with neutropenia should have surgery delayed if at all possible. For those with neutropenia in the postoperative state, development of fever should prompt treatment with broad-spectrum antibiotics and, in some cases, an antifungal agent as well. The role of colony stimulating factors in neutropenic patients is limited to those with additional indicators that prolonged neutropenia will be poorly tolerated such as poor functional status, poor nutrition, an open wound, or active infection. It has been shown that although these stimulating factors reverse the neutropenia, they do not reliably reduce hospital length of stay or culture-positive infections.

Rheumatologic

Patients with rheumatologic diseases have a high incidence of associated cardiovascular disease as well as unique pathology, which increases the risk of perioperative complications. Patients with rheumatologic conditions are often maintained on immune-modulating medications such as glucocorticoids, methotrexate, and so-called biologic agents that interfere with the action of TNF and IL-1. The perioperative management of these medications is discussed in section on "Medication Management." In patients with rheumatoid arthritis, lateral cervical spine films with flexion and extension should be obtained within a year of surgery to assess for atlanto-axial subluxation. Patients with ankylosing spondylitis with severe kyphotic deformities may be difficult to intubate, and thoracic cavity

restriction may require postoperative ventilator support. Thus, preoperative anesthesia and critical care consultations should be considered. Likewise, patients with scleroderma can present special anesthetic challenges, including a small oral aperture, difficult intravenous access, a propensity for vasospasm, prolonged response to local anesthetics, and a significant risk of aspiration due to esophageal dysmotility. In addition, preoperative detection of pulmonary or myocardial involvement is essential; so consideration should be given to obtaining PFTs, an arterial blood gas, and echocardiography in addition to a CXR and EKG. Patients with psoriatic arthritis should be advised of the risk for a psoriatic flare at both the surgical and the remote sites. In addition, these patients may be at increased risk for postoperative infection. Patients with systemic lupus erythematosus (SLE) are at increased risk for postoperative wound infection, renal insufficiency, and thrombotic complications, including PE. SLE patients with active disease and imminent vital organ failure can be treated with intravenous immunoglobulin in the perioperative period.

PREOPERATIVE BEHAVIORAL MODIFICATION

In addition to risk modification interventions discussed above, a number of preoperative behavioral modification strategies have been investigated in an attempt to improve surgical outcomes. The most widely published interventions include smoking cessation, preoperative weight loss, and various preoperative exercise regimens (so-called prehabilitation). Historic evidence suggested that smoking cessation within 8 weeks of surgery actually results in increased pulmonary complications, presumably from bronchorrhea. On the other hand, several smaller studies indicate that some complications such as wound infections and seromas are reduced if smoking cessation occurs as early as 4 weeks prior to surgery although these studies have been inadequately powered to detect differences in pulmonary complications.

Although obesity is associated with an overall increase in cardiovascular disease as well as perioperative wound and thromboembolic complications, the effect of preoperative weight loss on these risks has not been well studied. In patients preparing for bariatric surgery, preoperative weight loss has been correlated with more durable postoperative weight loss. However, improved perioperative surgical outcomes in terms of fewer surgical complications, cardiovascular events, or pulmonary complications have yet to be documented for either bariatric

surgery or other surgical procedures in the obese population.

Because functional status correlates strongly with cardiovascular and pulmonary complication rates, several groups have investigated the benefits of specifically targeting improved functionality in the preoperative period. Recent evidence suggests that a simple regimen of daily walking and deep breathing exercises improves exercise capacity in patients awaiting abdominal surgery, an effect that is preserved postoperatively. Similarly, preoperative inspiratory muscle training appears to result in fewer pulmonary complications and a shorter hospital stay.

MEDICATION MANAGEMENT

Adult patients facing surgery are often taking a number of medications for management of their chronic medical conditions. Prior to surgery, a complete list of all medications and herbal supplements must be obtained from the patient and reconciled with the most recent list of medications in their medical record. The most common outpatient medications and their recommended perioperative management are summarized in Table 2.6. In general, essential medications are continued through surgery with any doses due at the time of surgery taken with a sip of water. Essential medications and those with a significant risk of rebound effects (e.g., beta blockers and clonidine) are continued in an enteral, parenteral, transdermal, or inhaled form during the early postoperative period. As soon as feasible, the patient's outpatient medication regimen should be resumed or revised in consultation with their primary care physician or medical specialist.

Because of the risk of hemorrhage with surgical intervention, the management of outpatient therapeutic anticoagulation in the perioperative period bears special mention. Patients are maintained on anticoagulation for a range of indications from the management of thromboembolic events to anticoagulation for prosthetic heart valves. The indication for anticoagulation dictates the need for therapeutic "bridge" therapy with a short-acting agent while both the surgical procedure and the indication for anticoagulation are used to develop a postoperative anticoagulation plan. For patients with mechanical heart valves, the 2014 ACC/AHA guidelines are the most straightforward to apply. In a patient with a bi-leaflet mechanical aortic valve and no additional risk factors for hypercoagulability (e.g., atrial fibrillation or previous thromboembolism among others), warfarin can be held 48 to 72 hours prior to surgery with

an INR checked on the day of surgery targeting less than 1.5. All other patients (e.g., those with mechanical mitral valves and those with additional risk factors for thromboembolism or hypercoagulability) should be managed with bridge therapy. These guidelines recommend the use of therapeutic heparin during this time although therapeutic low-molecular-weight heparin is included in other guidelines. Postoperatively, in patients who do not require bridge therapy, warfarin is resumed 24 hours after surgery. Those on bridge therapy have their anticoagulation resumed as soon as the bleeding risk permits, usually at 24 hours after surgery.

In all other conditions for which patients are on therapeutic anticoagulation, the perioperative management of this regimen requires an estimate of the bleeding risk from surgery and the risk of a perioperative thromboembolic complication. There are no guidelines to inform practice, but some general practice recommendations can be made from the current literature on this topic. Patients with a recent episode of venous or arterial thromboembolism should have surgery delayed for at least 1 month if at all possible. Minor surgery (e.g., outpatient herniorrhaphy or cataract surgery) can be done safely in patients on warfarin so long as the INR is at the low end of the therapeutic range. Those undergoing major surgery should have warfarin therapy withheld approximately 5 days prior to surgery with an INR checked on the day of surgery. Those on the orally available direct thrombin inhibitor dabigatran (Pradaxa) should have this withheld 1 to 2 days before surgery if renal function is normal or 3 to 4 days with a Cr clearance <50 mL/min. Bridging anticoagulation with either intravenous heparin or therapeutic low-molecular-weight heparin should be used in patients at high or intermediate risk for a thromboembolic event. For many indications including atrial fibrillation, individual patient risk stratification should be conducted to determine the need for bridge therapy. Bridge therapy with heparin should be held 4 to 5 hours prior to surgery while low-molecular-weight heparin should be held 24 hours prior. As mentioned above, postoperative resumption of bridge therapy or oral anticoagulants depends on the risk of postoperative bleeding but generally can be considered after 24 hours.

Patients on antiplatelet therapy also commonly face noncardiac surgery. The availability of thienopyridines (e.g., clopidogrel) and the significant increase in DES implantation have also made the scenario of dual antiplatelet therapy in the surgical patient increasingly common. Patients on antiplatelet therapy should have a careful history taken to determine

their indication for treatment—primary prevention versus prophylaxis against stent thrombosis. As described above, in patients with coronary stents, the timing of surgery should take into consideration the type of stent and the age of the stent. Similarly, the risk of hemorrhage from the surgery should be considered. Cataract surgery is often performed in the patient on aspirin as is coronary artery bypass grafting. If aspirin is held, this should be 7 to 10 days prior to surgery and then resumed when surgical hemostasis is assured, typically within or at 24 hours of the operation. The use of clopidogrel or another thienopyridine either alone or in combination with aspirin should be elicited as well. Some limited data in the vascular surgery literature suggests that with careful attention to hemostasis, even major vascular operations can be done on dual antiplatelet therapy if necessary with no significant increase in perioperative bleeding complications. For patients on dual antiplatelet therapy, the Dual Anti-Platelet Therapy (DAPT) Score can be used to evaluate the specific risks associated with transitioning to monotherapy.

Patients with rheumatologic diseases as well as many other conditions ranging from reactive airway disease to inflammatory bowel disease are maintained on systemic glucocorticoids. Although historically, these patients were given additional steroid doses in the perioperative period, so-called stress dose steroids; recent evidence has called this routine practice into question. Patients who have been on prednisone doses of 20 mg/day (or the equivalent of another agent) for 3 weeks or more or who have a Cushingoid appearance should be presumed to have hypothalamic–pituitary–adrenal (HPA) suppression, which will require supplemental steroid dosing. For patients on lower doses, our usual approach is to resume their home dose or the equivalent in the postoperative period and observe for hemodynamic instability or significant malaise as a trigger for supplemental steroid dosing. An alternative strategy is to perform specific testing for HPA suppression using either high- or low-dose ACTH stimulation testing. Those who respond normally will likely not need supplemental steroid dosing postoperatively.

TABLE 2.6 Perioperative Management of Outpatient Medications and Herbal Supplements

Medication Class	Comment
Cardiovascular Medications	
Beta blockers and nondihydropyridine calcium channel blockers	Acute withdrawal of beta blockers can increase morbidity and mortality. Continue perioperatively. Consider substituting a beta blocker in patients taking nondihydropyridine calcium channel blockers.
Alpha-2 agonists	Acute withdrawal can precipitate rebound hypertension although this is usually at higher oral doses. Continue perioperatively.
ACE inhibitors, ARBs	Generally continue perioperatively when blood pressure is stabilized and renal function is at baseline. Consider holding one preoperative dose in patients with a low baseline blood pressure.
Dihydropyridine calcium channel blockers	Resume when blood pressure has stabilized.
Diuretics	Resume when blood pressure has stabilized and renal function is at baseline.
Statins	Withdrawal may increase perioperative cardiovascular events. Continue perioperatively.
Other lipid lowering agents	Increased risk of myopathy perioperatively with some (e.g., niacin); others interfere with GI absorption (e.g., colestipol). Hold perioperatively.
Agents Affecting Hemostasis	
Aspirin	Balance individual patient risk of cardiovascular event versus the consequences of a bleeding complication. Hold for 7 to 10 days preoperatively if bleeding would cause significant morbidity. Resume when hemostasis is adequate (e.g., within 12–24 hours of surgery).
Thienopyridines (e.g., clopidogrel and ticlopidine)	If given for a DES placed within the past year, consider delaying surgery. Hold for 5–10 days preoperatively if bleeding would cause significant morbidity. Resume when hemostasis is adequate (e.g., within 12 to 24 hours of surgery).
Dipyridamole	Hold for 2 days preoperatively if bleeding would cause significant morbidity.
NSAIDs/COX-2 Inhibitors	Hold NSAIDs for 24–72 hours preoperatively. COX-2 inhibitors have minimal effect on platelet function but have potential for renal toxicity and can lead to cardiovascular events.
Heparin/LMWH	Management depends on the indication and dose. Administer prophylactic doses preoperatively if indicated according to the patient's risk profile for a VTE complication; therapeutic doses are generally held for 6–12 hours preoperatively and are resumed when hemostasis is assured postoperatively (usually within 12–24 hours).
Warfarin	See discussion in the body of the chapter for recommendations on holding and resuming warfarin.
Dabigatran	See discussion in the body of the chapter for recommendations on holding and resuming dabigatran (Pradaxa).
Pulmonary Medications	
Inhaled bronchodilators	Continue perioperatively
Leukotriene inhibitors (e.g., montelukast [Singulair])	Resume when tolerating oral medication
Theophylline	May cause arrhythmias and neurotoxicity. Hold perioperatively.
Diabetic Medications	
Insulin	See discussion in the body of the chapter. Determine the sensitivity factor for patients using an insulin pump.
Oral hypoglycemics	Hold on the morning of surgery. Resume when tolerating a regular diet and risk of returning to NPO status is minimal. Ensure normal renal function prior to resuming metformin.
Other Endocrine/Hormonal Agents	
Thyroxine (T4)	Can be safely held for 5–7 days postoperatively; resume when tolerating oral medications. Parenteral dose is approximately 80% of the oral dose.
Oral contraceptives, HRT, and selective estrogen receptor modulators (e.g., tamoxifen)	In patients at increased risk for VTE, discontinue 6 weeks preoperatively. Resume when the risk of VTE has resolved.
Glucocorticoids	See discussion in the body of the chapter.
Rheumatologic Agents	
Antirheumatic agents	There is no definitive increased risk of wound complications with these agents. Methotrexate can be continued preoperatively in patients with normal renal function; sulfasalazine and azathioprine should be held for 7 days preoperatively; hydroxychloroquine can be continued perioperatively; biologic agents (e.g., etanercept [Humira] and rituximab [Rituxan]) should be held for 7 or more days preoperatively.
Gout agents	Hold on the morning of surgery. Resume when tolerating oral medications.

Neurologic Agents and Chronic Opioids	
Antiepileptic agents	Continue perioperatively. In patients at low risk of a generalized seizure, resume when tolerating oral medications. In patients at increased risk, administer a parenteral antiepileptic agent.
Anti-Parkinson agents	Anti-Parkinson agents increase the risk of perioperative hemodynamic lability and arrhythmias while abrupt withdrawal may result in neuroleptic malignant syndrome and worsening of Parkinsonian symptoms. Dopaminergic agents should be tapered to the lowest possible dose 2 weeks preoperatively and restarted at this dose postoperatively.
Chronic opioids	Patients on methadone should have their maintenance dose continued perioperatively. Methadone can be given subcutaneously or intramuscularly (at 1/2 to 2/3 of the usual dose divided into two to four equal doses) for patients who cannot tolerate oral medications.
Psychotropic Medications	
SSRI	May interfere with platelet aggregation; so balance the risk of bleeding against the risk of exacerbating the underlying disorder.
MAOI	Management of an MAOI perioperatively should involve consultation with an anesthesiologist and the patient's psychiatrist.
Lithium	Consider checking thyroid function tests preoperatively. Continue perioperatively; monitor for nephrogenic DI and serum lithium levels.
Antipsychotics	Continue with caution in patients at risk for exacerbation of psychosis; monitor QT interval; be aware of drug–drug interactions.
Anxiolytics	Continue perioperatively if used on a chronic, routine basis.
Psychostimulants (e.g., methylphenidate [Ritalin])	Hold on the day of surgery. Resume when the patient is stable.
Other	
Herbal medications	Some are associated with an increased risk of MI and stroke (ma huang), bleeding (ginko, ginseng, and garlic), hypoglycemia (ginseng), or altered drug effects. Hold for 7 days preoperatively.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; NSAID, nonsteroidal anti-inflammatory drug; LMWH, low-molecular-weight heparin; HRT, hormone replacement therapy; VTE, venous thromboembolism; SSRI, selective serotonin reuptake inhibitor; MAOI, monoamine oxidase inhibitor; DI, diabetes insipidus; MI, myocardial infarction.

There has been some recent interest in perioperative risk reduction through initiating new medications around the time of surgery. Examples include starting a beta blocker or statin in patients with cardiovascular risk factors in the immediate preoperative period. Enthusiasm for initiation of beta blockers around the time of surgery has been recently tempered by the results of the POISE trial and a subsequent meta-analysis, which indicated that although this practice reduces the incidence of perioperative MI, the incidence of perioperative stroke is increased and all-cause mortality is either increased or, at best, unchanged (although the dose of beta blockade in the POISE trial was moderately aggressive at 200 mg of extended release metoprolol daily). In light of these results, the ACC/AHA released a focused update to their perioperative guidelines in 2009, which recommend against the initiation of high-dose beta blockade without dose titration in beta blocker–naïve patients undergoing surgery. Similarly, the indications for perioperative statin initiation in those without classic indications for lipid lowering therapy have been clarified by recent studies. These indicate that vascular surgery patients likely benefit from this intervention with fewer episodes of myocardial ischemia and a lower perioperative cardiac death rate.

PREOPERATIVE SPECIALTY CONSULTATION

Patients with complex or refractory medical problems may benefit from preoperative consultation by a general medical internist, geriatrician, or other medical specialists. Studies evaluating patient outcomes and utilization of medical resources with this practice have generated mixed results. However, provided the consultant's role is clearly delineated in the initial request and the consultant makes evidence-based recommendations, surgeon satisfaction is high and the surgical patient's care is likely to improve. It should be evident from the discussion above that asking a medical consultant to "clear" a patient for surgery is a nonsequitur. Instead, the surgeon should ask specific questions relating to risk stratification and perioperative management of particular disease processes or medications. With this approach, the consultant's input is more likely to be useful to the surgeon and the surgical team in making decisions on surgical timing and perioperative management strategies. Postoperatively, continued involvement of these consultants or a medical hospitalist can, in some cases, improve the care of the patient and should be considered by the surgeon.

RISK REDUCTION IN THE IMMEDIATE PERIOPERATIVE PERIOD

Multiple interventions and quality improvement measures have been advanced in recent years to reduce the risk of adverse events in the OR ranging from wound infections to wrong-site surgery. This section reviews some of the processes that now routinely occur as a result of these initiatives and the management decisions that are most often made from the time the patient enters the preoperative area until the surgical intervention commences. In our view, surgeons should continue to take a leading role in directing the surgical team during this time in the patient's care as it sets the stage for the entire postoperative course.

SURGICAL CHECKLIST AND PREOPERATIVE TIMEOUT

Increased awareness of wrong-site surgery led to a summit to address this problem in 2003 and 2007. Attended by leaders from multiple surgical organizations and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the 2003 summit resulted in the introduction of the Universal Protocol for Preventing Wrong Site, Wrong Procedure,

Wrong Person Surgery in 2004. This protocol consists of three components: preoperative verification of patient information, surgical site marking to prevent ambiguity with unilateral procedures, and conducting a presurgical timeout to review the planned procedure and resolve any concerns. Many hospitals promote use of the final presurgical time out as an opportunity for the entire OR team to review the surgical plan and to confirm that all necessary medications have been given. Despite (or perhaps because of) this increased emphasis on patient safety, the number of reported wrong-site procedures has steadily increased since the introduction of the Universal Protocol. The anticipation by proponents of this culture of safety is that as the number of reports rise and the freedom to raise safety concerns in the OR disseminates, the frequency of major errors will decrease significantly.

The Safe Surgery Saves Lives Study Group has recently evaluated an intraoperative checklist developed from the World Health Organization (WHO) guidelines for improving perioperative surgical safety. The 19-item checklist used by this group (Fig. 2.2) emphasizes communication between the patient and all the various surgical team members in the immediate preoperative period and then focuses the team on critical decisions and communication points in the OR and at the conclusion of the procedure. Use of this checklist in eight different hospitals in eight countries resulted in fewer postoperative complications, including death. This report and others highlight the importance of communication between the surgeon, anesthesiologist, OR nurse, surgical technician, and the patient to ensure that the planned surgical procedure is conducted safely and unplanned intraoperative contingencies are readily identified and well managed.

PREVENTION OF DEEP VENOUS THROMBOSIS

Venous thromboembolic (VTE) complications are an all too common perioperative complication. Over half of surgical patients are at moderate risk or greater for VTE events in the postoperative period, and PE is still the most common preventable cause of hospital death. In a recent study of surgical inpatients in 358 hospitals in 32 different countries, although 64.4% of patients were found to be at-risk for VTE, only 58.5% of patients received appropriate VTE prophylaxis. The American College of Chest Physicians Evidence-based Clinical Practice Guidelines (8th edition) on the Prevention of Venous Thromboembolism have been used to establish local policies in many hospitals and serve as a benchmark for best practice in this area (Table 2.7). These guidelines stratify patients into low-, moderate-, and high-risk categories based principally on the nature of the surgical procedure—an approach that relies on overall group risk assessment as opposed to individual risk assessment. Although some investigators have attempted to develop individual patient risk assessment

models, to date, none of these models have been validated. In fact, it appears with few exceptions that the principal predictor of risk is the primary reason for the patient's hospitalization.

Mechanical thromboprophylaxis includes intermittent pneumatic compression devices, venous foot pumps, or graduated compression stockings. These modalities have been shown to reduce the risk of DVT in numerous patient populations. However, they have not been demonstrated to reduce the rate of PE or death, and compliance with their use is often poor in the postoperative period. Nonetheless, they are at low risk preventive measure that can be initiated prior to induction of anesthesia in most surgical patients. Those patients at moderate to high risk of VTE should be considered for pharmacologic prophylaxis starting preoperatively within 2 hours of surgery. If the patient is to receive an epidural catheter, local policies should be developed weighing the risk of VTE versus an epidural hematoma as detailed in the American Society of Regional Anesthesia and Pain Medicine (ASRA) evidence-based guideline on regional anesthesia in the patient receiving antithrombotic or thrombolytic therapy. In patients at moderate and greater risk of VTE perioperatively, pharmacologic prophylaxis should be started or resumed as soon as bleeding risk is acceptably low, often shortly postoperatively. This therapy should be continued through the inpatient course in most cases. High-risk general surgical patients, who have undergone major oncologic surgery should also be considered for extended pharmacologic prophylaxis for up to 28 days, even as an outpatient.

TABLE 2.7 Summary of the Level of Thromboembolism Risk and Recommended VTE Prophylaxis in Hospitalized Patients from the American College of Chest Physicians' Evidence-Based Clinical Practice Guideline on the Prevention of Venous Thromboembolism (8th Edition)

Risk Group	Group Characteristics	DVT Risk Without Prophylaxis	Suggested Prophylaxis
Low	Minor surgery in mobile patients	<10%	No specific prophylaxis; early, "aggressive" ambulation
Moderate	Most general surgery patients	10–40%	LMWH, LDUH BID or TID, fondaparinux
	Moderate VTE risk and high bleeding risk		Mechanical prophylaxis
High	Major trauma, SCI	40–80%	LMWH, fondaparinux, warfarin (INR 2–3)
High	High VTE risk and bleeding risk		Mechanical prophylaxis

Reprinted from Geerts WH, Bergqvist D, et al. Prevention of venous thromboembolism: American college of chest physicians evidence-based clinical practice guidelines (8th Ed.). *Chest* 2008; 133(6 Suppl):381S–453S; with permission from Elsevier.
LMWH, low-molecular-weight heparin; LDUH, low-dose unfractionated subcutaneous heparin; VTE, venous thromboembolism; SCI, spinal cord injury; INR, international normalized ratio.

POSTOPERATIVE ILEUS PREVENTION

Patients undergoing bowel resection are at risk for development of a postoperative ileus. The recent availability of peripherally acting mu-opioid receptor antagonists (PAM-OR) such as alvimopan (Entereg) allows surgeons to preemptively treat patients at risk for postoperative ileus. The first dose is given orally from 30 minutes to 5 hours prior to surgery and is then continued during the inpatient course. Use of this preventive strategy appears to result in earlier return of bowel function by multiple measures and shorter inpatient hospital length of stay. Use of chronic narcotics is a contraindication to use of this medication, and hospitals that wish to offer this medication must participate in the ENTEREG Access Support and Education (E.A.S.E.) Program.

WOUND INFECTION

The Surgical Care Improvement Project (SCIP) sought to reduce postoperative complications (primarily SSI and VTE) by 25% from 2006 to 2010. This broad-based initiative supported by numerous national organizations used a number of quality measures to achieve this goal by promoting evidence-based practice. SCIP quality measures specific to perioperative infectious complications include timely administration of prophylactic antibiotics (within 1 hour prior to the incision), use of appropriate antibiotics for SSI prophylaxis, timely discontinuation of

prophylactic antibiotics (within 24 hours of the end of the operation for noncardiac surgery or 48 hours for cardiac surgery), and appropriate hair removal (no hair removal or use of clippers). Additional SCIP measures relating to infectious complications include use of intraoperative temperature management, early removal of indwelling urinary catheters, and glycemic control on the morning after surgery in cardiac patients. Evidence of the impact of compliance with these measures is just now emerging—initial reports suggest that while global compliance may result in a small reduction in SSI, compliance on individual measures results in little or no improvement in SSI rates.

Recommended perioperative antimicrobial prophylaxis regimens are periodically updated in several publications including Treatment Guidelines from the Medical Letter (2016). In addition to timely antibiotic dosing described above, for long surgical procedures (>2 half-lives, e.g., 4 hours for cefazolin) and those with major blood loss (>1,500 mL), prophylactic antibiotics should be redosed intraoperatively. The role of several additional SSI reduction strategies have been clarified in the recent literature, including topical antisepsis, the role of mechanical bowel preparation for colorectal surgery, fascial closure techniques, and perioperative oxygen supplementation. A recent study comparing skin antisepsis with a chlorhexidine–alcohol preparation versus betadine in a range of clean contaminated surgical cases demonstrated significantly reduced SSI rates with the use of chlorhexidine–alcohol. However, there was no description of whether the betadine was allowed to dry, and a betadine–alcohol preparation was not included in the study. In addition, alcohol-containing solutions can increase the risk of OR fires if not allowed to dry completely and use of chlorhexidine-containing solutions is not recommended for preparation of exposed mucosal surfaces. Nonetheless, chlorhexidine–alcohol preparation appears to be a good choice for a range of surgical procedures.

Mechanical bowel preparation has been a mainstay of perioperative surgical practice aimed at reducing anastomotic and wound complications for decades. However, systematic study by multiple investigators and subsequent meta-analyses have not convincingly demonstrated any benefit to this practice with respect to either of these complications. In fact, there may be a slight reduction in anastomotic leakage when preoperative mechanical bowel preparation is not performed, although, as of 2003, mechanical bowel preparation was still widely practiced by colorectal

surgeons. Current guidelines leave the use of mechanical bowel preparation to the discretion of the surgeon for open low anterior resection and all laparoscopic colonic procedures where the site of the tumor may not be immediately obvious and where intraoperative colonoscopy may be required. In the 6th edition of mastery it was recommended that for all other colonic resections, preoperative mechanical bowel preparation can be safely eliminated. This has changed. Most authorities today use of oral antibiotics and mechanical bowel prep in elective colon and rectal surgery. The use of mechanical bowel prep **alone** before elective colorectal resection to prevent SSI is ineffective and should be abandoned. In contrast, oral antibiotics and mechanical bowel prep are associated with decreased risks of SSI and are not associated with increased risks of other adverse outcomes compared with no preparation. Prospective studies to determine the efficacy of oral antibiotics are warranted; in the interim, mechanical bowel prep and oral antibiotics should be used routinely before elective colorectal resection to prevent SSI. As a part of the first Perioperative Quality Initiative (POQI-1) workgroup meeting the American Society for Enhanced Recovery (ASER) and POQI recommends to reduce SSI there should be routine use of a combined isosmotic mechanical bowel preparation with oral antibiotics before elective colorectal surgery and that infection prevention strategies (also called bundles) be routinely implemented as part of colorectal early recovery programs. Fascial closure techniques for abdominal operations have also been evaluated over many years searching for the optimal method, which re-establishes abdominal domain while minimizing the risk of postoperative wound complications ranging from superficial wound infections to complete dehiscence with evisceration. Most studies evaluating fascial closure methods use incisional hernia as the primary endpoint, and until recently, SSI was thought to not be affected by the technique of fascial closure. However, a recent study suggests that when using a running absorbable suture technique, relatively small (5 to 8 mm), closely spaced fascial bites resulting in a suture to wound length ratio of ≥4:1 may reduce the incidence of SSI. Likewise, there is growing interest in using antibiotic-coated suture material that may also reduce the rate of wound infections.

Oxygen supplementation in the immediate postoperative period has also been evaluated by several randomized controlled trials, including the recently published Perioperative Oxygen Fraction (PROXI) study.

Although the original US-based study demonstrated increased infections in the oxygen-treated group and the PROXI study showed no benefit to 80% O_2 supplementation for 2 hours postoperatively, three other studies have shown a benefit to various types of O_2 supplementation. Consequently, pooled analysis of these results still falls in favor of perioperative hyperoxia although the likely benefit is relatively small.

INTRAOPERATIVE RESUSCITATION, VENTILATION, AND TEMPERATURE MANAGEMENT

Inappropriate management of intravenous fluid volumes during surgery can result in a number of postoperative complications ranging from pulmonary and renal dysfunction to anastomotic failure and sepsis. However, achieving the appropriate balance of adequate intravascular volume and oxygen delivery during the surgical procedure has proven difficult. This difficulty arises for many reasons, mostly because direct measures of intravascular volume and end-organ perfusion are not readily available while estimates of intraoperative bleeding and insensible losses are notoriously inaccurate. Furthermore, a standard nomenclature for the various fluid administration strategies is lacking, leading to imprecise and variable definitions from study to study. Recognizing these limitations, it has become clear that either too much or too little intravenous fluid administration of any type is harmful. In major abdominal operations where additional monitoring is justified, a “goal-directed” approach based on surrogates for intravascular volume measurement (e.g., esophageal Doppler measurement of changes in peak aortic stroke velocity or arterial waveform variability) while monitoring indicators of oxygen consumption such as $ScvO_2$ is appealing. Combining this approach with a relatively restrictive (but not too restrictive) background of intravenous fluid administration (e.g., 8 to 12 mL/kg/h) appears to balance the various risks of respiratory failure, renal insufficiency, wound infections, congestive heart failure, and postoperative arrhythmia.

Recent evidence suggests that intraoperative ventilator management significantly affects the postoperative course in patients undergoing major abdominal surgery. In one study, patients were randomized to lung-protective ventilation (defined as 6 to 8 mL/kg predicted body weight, PEEP of 6 to 10 cm H_2O, and intermittent recruitment maneuvers) or conventional ventilation (10 to 12 mL/kg predicted body weight, no PEEP,

and no recruitment maneuvers) intraoperatively. Those managed with lung protective ventilation had significantly fewer postoperative respiratory complications and a significantly shorter length of hospital stay. Surgeons should thus be in communication with the anesthesia team about ventilator management during major abdominal procedures. This approach likely has little downside in other long cases as well.

Finally, maintaining normothermia during anesthesia is critical to minimizing a number of intraoperative and postoperative complications. Coagulopathy and subsequent increased blood loss are the most widely reported complications related to mild intraoperative hypothermia (35° to 36°C). Other potential complications include increased surgical site infection, myocardial ischemia, prolonged anesthetic effect, and shivering. Using active surface warming measures (e.g., Bair Hugger, 3M Health Care, St. Paul, MN) effectively maintain normothermia and can significantly reduce these complications.

POSTOPERATIVE RISK MINIMIZATION

Relative to preoperative office visits and OR time, the postoperative course typically represents the time in which the patient has the most direct contact with the healthcare system. This poses both advantages and disadvantages—the patient is immediately at hand so that care can be directly monitored, although as the complexity of the system and the duration of contact increases, so too does the possibility of error. The overall goals of this phase of care should be to restore the patient to their preoperative functional level or to an even higher functional level as quickly as possible while minimizing iatrogenic events and nosocomial infections. Recent advances in postoperative care include the introduction of clinical care pathways, development of a systematic approach to care provider handoffs, recognition of the importance of early mobilization even in an intensive care unit (ICU) setting, refinement of our use of postoperative organ support devices and monitors, and clarifying the management goals for chronic illnesses (e.g., diabetes mellitus) in the postoperative time period.

CLINICAL PATHWAYS AND HANDOFFS

Clinical pathways are tools which incorporate evidence-based practice guidelines into a timeline, which is then tracked so that deviations can be monitored. Hospitals and clinical services may develop these pathways to

communicate expected postoperative events to patients and support staff while ensuring the consistent use of evidence-based practice for a given disease process. They are best applied to common surgical procedures within moderate- to high-volume centers. Examples include coronary artery bypass graft surgery, laparoscopic Roux-en-Y gastric bypass, and laparoscopic cholecystectomy. Use of these pathways has been shown to standardize patient care while reducing length of hospital stay and use of resources with improved patient satisfaction.

Multiple forces within healthcare from resident work hour restrictions to changing practice models have increased the frequency of patient handoffs between providers. This represents both a time when critical information can be reviewed and summarized and a time where lapses in communication can ultimately lead to poor patient care. Approaches to minimizing the latter include use of a standardized approach to handoffs such as the Situation–Background–Assessment–Recommendation model, specific training on how to perform a comprehensive patient handoff, and proctored simulation training on performing handoffs. There is emerging evidence that such efforts do indeed avoid lapses in patient care.

POSTOPERATIVE MONITORING AND MANAGEMENT OF CHRONIC MEDICAL ILLNESSES

Postoperatively, patients with chronic medical illnesses require monitoring of these illnesses and a plan for resuming their home medication regimen. Our general approach to postoperative medication management in patients with chronic medical conditions is included in Table 2.6. Regarding postoperative monitoring, selecting the appropriate level of monitoring usually depends on local hospital policies and unit expertise. In some cases, the type of surgery will dictate the level of care required such as craniotomy patients who need frequent neurologic examinations or vascular surgery patients who require frequent pulse checks in a specialized unit. Patients on a mechanical ventilator universally undergo postoperative care in an ICU for some period of time. For patients who do not require specialized checks or a ventilator, the patient's chronic illnesses and the extent of surgery will guide the need for postoperative monitoring. In recent years, enthusiasm for the use of pulmonary artery catheter for routine postoperative monitoring in certain patient populations has waned in the absence of any demonstrable benefit and significant risks of complications, including pulmonary artery embolism and rupture in

addition to incorrect management decisions made due to misinterpretation of available data. Other monitoring decisions are discussed below individually in the context of each specific organ system.

Patients with known cardiovascular disease should be considered for telemetry monitoring. Some recommend a postoperative 12-lead EKG and a single set of cardiac enzymes in these patients as well although this practice is not universal. These patients should have beta blockers and statins resumed as soon as feasible in the postoperative period. For patients with essential hypertension, target blood pressures are relaxed to avoid hypoperfusion with intervention warranted if systolic pressures trend around 180 mm Hg or diastolic pressures rise to 100 to 110 mm Hg. These patients should have pain and other causes of elevated blood pressure, such as urinary retention ruled out as well. Patients chronically on clonidine should have this resumed early in the postoperative course. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are generally resumed when intravascular volume shifts have subsided and renal function is shown to either remain at baseline or returns to baseline. Similarly, after major surgery, diuretics are resumed when the patient is ready to mobilize fluid or the patient is determined to have little risk for becoming excessively dehydrated.

Patients with chronic pulmonary conditions should be resumed on their home regimen of inhaled beta agonists and anticholinergics via metered dose inhaler or nebulizer either orally or in-line with the ventilator. Inhaled and systemic glucocorticoids for control of reactive airway disease should similarly be continued postoperatively. Leukotriene inhibitors (e.g., montelukast [Singulair]) can be resumed when the patient is taking oral medications. Theophylline should be discontinued perioperatively given its narrow therapeutic window.

Surgical intervention can result in poor glycemic control in diabetic patients or can unmask insulin resistance in patients not previously known to be diabetic. Much attention has been given to glycemic control in the perioperative period over the past decade. Initial enthusiasm for tight glycemic control has been tempered by the recognition of the significant deleterious effects of hypoglycemic events which, in some cases, negate the benefits of tight control. Current recommendations aim for “reasonable” control over normoglycemia in the postoperative period generally defined as most readings below 180 to 200 mg/dL. One benefit of this movement is that surgeons and surgical units are now much more

familiar with the management options for patients with hyperglycemia in both the fasted and the partially fasted state ranging from insulin infusions to resumption of subcutaneous insulin regimens. Patients on oral hypoglycemics can generally be managed with a short-acting insulin administered on a sliding scale until oral intake has reliably returned when most of these agents can be restarted. One exception is metformin, which should not be resumed until renal function is proven to be normal and there is little risk of significant intravascular volume shifts, which is generally proximate to the time of discharge.

Postoperative nutritional support is sometimes required if patients were severely malnourished preoperatively or if bowel function does not return within a week of surgery. Options include enteral and PN. If the patient is unable to take adequate calories due to critical illness but the gastrointestinal system is functional, enteral support is preferred. In cases where enteral support is not possible or only partial enteral support can be achieved, PN is used. When this strategy is chosen, care must be taken to meticulously care for the central venous catheter (CVC) to avoid bloodstream infections, glycemic control should be maintained in a "reasonable" range as described above often with insulin added to the PN mix, protein doses are initially estimated based on the patient's diagnosis and other chronic conditions and then adjusted to avoid azotemia, and fat is used sparingly in balancing the avoidance of fatty acid deficiency against the immunosuppressive effects of long-chain fatty acids and the concern that cholestasis and PN-associated hepatic injury may result from intravenous fat formulations currently available in the United States.

Patients with rheumatologic conditions should generally have their medications resumed with the initiation of a postoperative diet. Patients taking methotrexate should have normal renal function confirmed before this agent is restarted. Patients with a history of gouty arthropathy should have colchicine or any hypouricemic agents resumed when they can tolerate oral medications. If a gout flare occurs postoperatively in a patient who is an NPO, management options include intravenous ketorolac (Toradol), intra-articular steroid injections, or systemic steroids.

EARLY MOBILIZATION

Although bed rest was historically routinely prescribed after surgical interventions, the negative side effects of this practice ranging from pressure sores to osteopenia have been recognized for decades. As

discussed in the next section, loss of lean body mass is associated with a range of adverse outcomes in the postoperative period, and enforced bed rest has been shown to reduce lean body mass and total body strength in healthy adults. In fact, prolonged weakness is now recognized as one of the most durable and troublesome side effects of critical illness. Efforts to minimize this complication by increasing postoperative mobility have been advanced in a number of patient populations, including cardiac surgical patients, patients undergoing elective colon resection, and in those with respiratory failure on ventilator support. These interventions range from passive range of motion exercises performed by family members and bedside nurses to lengthy training sessions with physical therapists depending on the patient's clinical condition and tolerance. These interventions have been shown to reduce loss of lean body mass while accelerating postoperative recovery and reducing ventilator and ICU days.

Muscle Wasting in Surgical Disease

INTRODUCTION

Many surgical patients suffer from metabolic alterations related to both the disease state and the surgical trauma. Frequently, changes in lipid, carbohydrate, and protein metabolism occur in patients with surgical disease and all of these changes can significantly influence the perioperative care of the patients.

One of the most dramatic metabolic changes seen in surgical patients is altered protein metabolism in skeletal muscle, resulting in loss of muscle mass and strength. Proteins in skeletal muscle undergo constant synthesis and degradation (protein turnover). Under normal conditions, protein homeostasis is maintained by equal rates of synthesis and degradation. When this balance is perturbed, loss of muscle mass may occur. Muscle wasting can be caused by reduced protein synthesis, increased protein degradation, or a combination of these changes; the relative role of these changes probably differs between different catabolic conditions. Different proteins have different rates of turnover (short- and long-lived proteins) and may be regulated individually. In order for increased protein degradation to result in muscle wasting, the degradation needs to affect a large pool of cellular proteins. Contractile proteins (the myofibrillar proteins actin and myosin) make up a large portion of muscle proteins and in various muscle wasting conditions, the degradation of myofibrillar

proteins is increased, at least in part explaining why these conditions result in loss of muscle mass and strength.

MUSCLE WASTING IN SURGICAL PATIENTS

Muscle wasting occurs in a number of different disease states commonly cared for by surgeons, including cancer, severe injury (in particular head injury and severe burn injury), and sepsis. Other conditions in which loss of muscle mass occurs include uremia, diabetes, heart failure, and AIDS. Muscle atrophy in elderly patients (sarcopenia) may affect quality of life by reducing the capacity to perform daily physical activities and by increasing the risk of falls and fractures. Sarcopenia may also increase the risk of postoperative complications in elderly patients undergoing surgery.

Although some of the conditions associated with loss of muscle mass (such as sepsis) are involved in muscle wasting and weakness seen in patients in the ICU, critically ill patients cared for in the ICU have their own set of characteristics with regard to muscle atrophy. Thus, in addition to the primary disease, a number of ICU-associated conditions promote muscle wasting and weakness. Such conditions include reduced physical activity, prolonged bed rest, side effects of treatment with various drugs (in particular glucocorticoids and neuromuscular blocking agents), sedation, mechanical ventilation, and altered nutritional status. The term “intensive care unit-acquired weakness” (ICUAW) has been used to illustrate the fact that certain aspects of muscle weakness are unique for patients in the ICU. Recent aspects of muscle wasting in critical care have been published recently. Because sepsis is a common condition necessitating care in the ICU and is an important cause of muscle wasting, a substantial amount of recent information with regard to cellular and molecular mechanisms is related to sepsis-induced muscle wasting. Although different mechanisms may be involved in the loss of muscle mass in different disease states, there is evidence that muscle wasting shares many (albeit not all) mechanisms regardless of underlying cause.

CLINICAL CONSEQUENCES OF MUSCLE WASTING

At least three different aspects of muscle wasting are important in the surgical care. First, patients may present with evidence of muscle wasting having already occurred, including patients with advanced cancer (Fig. 2.3) or elderly patients with sarcopenia. Second, patients may present with a condition that typically results in loss of muscle mass, such as sepsis and

severe injury, in particular, head and burn injury. Third, patients may need care in the ICU, a situation that in itself commonly aggravates muscle wasting (Fig. 2.4).

Weight loss in cancer patients reflects not only loss of muscle mass, but also depletion of adipose tissue. The loss of body weight in these patients, however, closely reflects the loss of muscle tissue and strength. The pronounced loss of muscle in cancer patients is an important factor why these patients have reduced mobility and quality of life. In addition, impaired response to chemo- and radiotherapy has been reported in cancer patients with pronounced muscle cachexia. Studies suggest that in patients with nonresectable pancreatic cancer, death occurs with 25% to 30% loss of body weight. Pneumonia and other pulmonary complications, at least in part reflecting wasting of respiratory muscles, are common causes of death in patients with advanced cancer.

Figure 2.3. Patients with advanced cancer frequently develop severe muscle wasting and weakness. The patient shown in this figure was a 59-year-old man with metastasizing gastric cancer who had lost approximately 35% of his normal body weight during his illness. (Picture kindly provided by Dr. Maurizio Muscaritoli, Department of Clinical Medicine, Sapienza-University

of Rome, Rome, Italy.)

The most significant consequences of muscle wasting and weakness during critical illness cared for in the ICU include difficulty to wean the patient from ventilatory support, recurrence of respiratory failure after extubation, and inability to ambulate due to profound weakness (even quadriplegia). These manifestations reflect the fact that the wasting can affect both respiratory (diaphragm and intercostal muscles) and extremity muscles. Although loss of muscle mass is probably the most important cause of muscle weakness in the ICU, the weakness can also be caused by peripheral neuropathy, initially described in the setting of sepsis and multiorgan failure. Indeed, critical illness myopathy (CIM) and critical illness polyneuropathy (CIP) are commonly described as two separate entities although the muscle weakness can also be caused by a combination of CIM and CIP, so-called critical illness neuromyopathy.

Figure 2.4. Patients with critical illness cared for in an intensive care unit (ICU) are at risk of developing muscle wasting and weakness. Mechanical ventilatory support adds to the risk of muscle wasting. Because muscle wasting and weakness increase the need for ventilatory support, a vicious circle is created.

Importantly, mechanical ventilatory support in itself results in wasting and weakness of the diaphragm and other respiratory muscles. Studies suggest that muscle weakness occurs early during mechanical ventilation with >50% of ICU patients showing evidence of neuromuscular abnormalities after 5 to 7 days of mechanical ventilation. Septic shock was a predictor of respiratory muscle weakness in some reports. One consequence of respiratory muscle weakness is difficulty to wean the patient from ventilatory support resulting in prolonged need for mechanical ventilation thus creating a vicious circle. Another vicious circle is created by weakness of extremity muscles. Thus, weakness of peripheral muscles prevents ambulation resulting in prolonged bed rest. Bed rest in itself promotes loss of muscle mass and there is evidence that this effect of inactivity is potentiated by underlying disease. Bed rest is a potent mechanism of muscle wasting and a rapid and profound loss of muscle mass has been documented even in healthy volunteers during bed rest with the loss of 1% to 1.5% of quadriceps strength per day.

Muscle weakness in patients cared for in the ICU is commonly long-lasting with weakness significant enough to cause problems walking being present up to 5 years after the stay in the ICU. The persistent weakness clearly reduce the quality of life in these patients, sometimes manifesting itself as difficulty to walk and inability to perform other seemingly trivial tasks. In some studies, long-term weakness and important restrictions in daily functioning were reported in >50% of survivors of critical illness with restricted ability to walk being the most commonly impaired physical quality of life. It is obvious that loss of muscle mass and weakness acquired during critical illness have long-lasting effects in patients surviving ICU care with important personal and socioeconomic consequences.

ACUTE QUADRIPLEGIC MYOPATHY

A special condition sometimes seen in patients in the ICU is acute quadriplegic myopathy. This condition is caused by a specific decrease, or even an almost complete loss, of thick filament muscle proteins (myosin) and is characterized by a sometimes dramatic clinical picture of complete paralysis. The quadriplegia is typically symmetric and affects both proximal and distal muscle groups, whereas muscles innervated by the cranial nerves are not affected. The prognosis is usually good if the patients survive the underlying disease but recovery of muscle strength

may require several months. Although the mechanisms of acute quadriplegic myopathy are not fully understood at present, there is evidence that the synthesis of myosin is blocked at the transcriptional level concomitant with stimulated degradation of the protein. A number of risk factors for development of acute quadriplegic myopathy have been identified and include treatment with corticosteroids and neuromuscular blocking agents (perhaps the most important risk factors), mechanical ventilation, immobilization, and probably sepsis as well.

DIAGNOSIS OF MUSCLE WASTING

The diagnosis of muscle wasting and weakness is commonly obvious from bedside clinical observations. Patients will also experience and complain of weakness when trying to ambulate or use upper extremity muscles. Respiratory muscle weakness typically manifests itself as difficulty weaning the patient from the ventilator or respiratory failure after extubation. Objective measures of muscle atrophy can be obtained from various imaging tests such as CT, MRI, or ultrasound. More sophisticated methods are also available and can be used if more objective assessment is needed, such as in the research setting. Such methods include objective measurements of muscle strength, electrophysiologic tests, and muscle biopsy. Various methods to assess respiratory muscle strength and function have been described, including magnetic phrenic nerve stimulation.

When muscle biopsy is performed, the histopathologic picture is typically characterized by reduced fiber size (atrophy) and changes in fiber type. Electron microscopy may reveal sarcolemmal changes, disruption of the sarcomere, disintegration of Z-disks, and morphologic changes of mitochondria (including swelling and loss of membrane structures) and loss of mitochondria. Of note, reduced muscle-specific force generation may exist in the absence of atrophy although in most cases of muscle weakness, the loss of muscle strength is probably associated with morphologic abnormalities in skeletal muscle.

MECHANISMS OF MUSCLE WASTING

Loss of muscle mass during various catabolic conditions is regulated at multiple levels as illustrated in Figure 2.5. Circulating factors (including proinflammatory cytokines and glucocorticoids) as well as regulators that act in an autocrine or a paracrine fashion (e.g., myostatin) participate in the regulation of muscle mass in different conditions characterized by muscle

wasting. When the balance between anabolic factors, for example, insulin and insulin-like growth factor 1 (IGF-1), and catabolic factors, for example, TNFα, corticosteroids, and possibly myostatin, is perturbed, muscle mass may be lost. Although both reduced protein synthesis and increased protein degradation may contribute to muscle wasting, there is evidence that in sepsis, severe injury, and cancer, the loss of muscle mass mainly reflects stimulated protein breakdown.

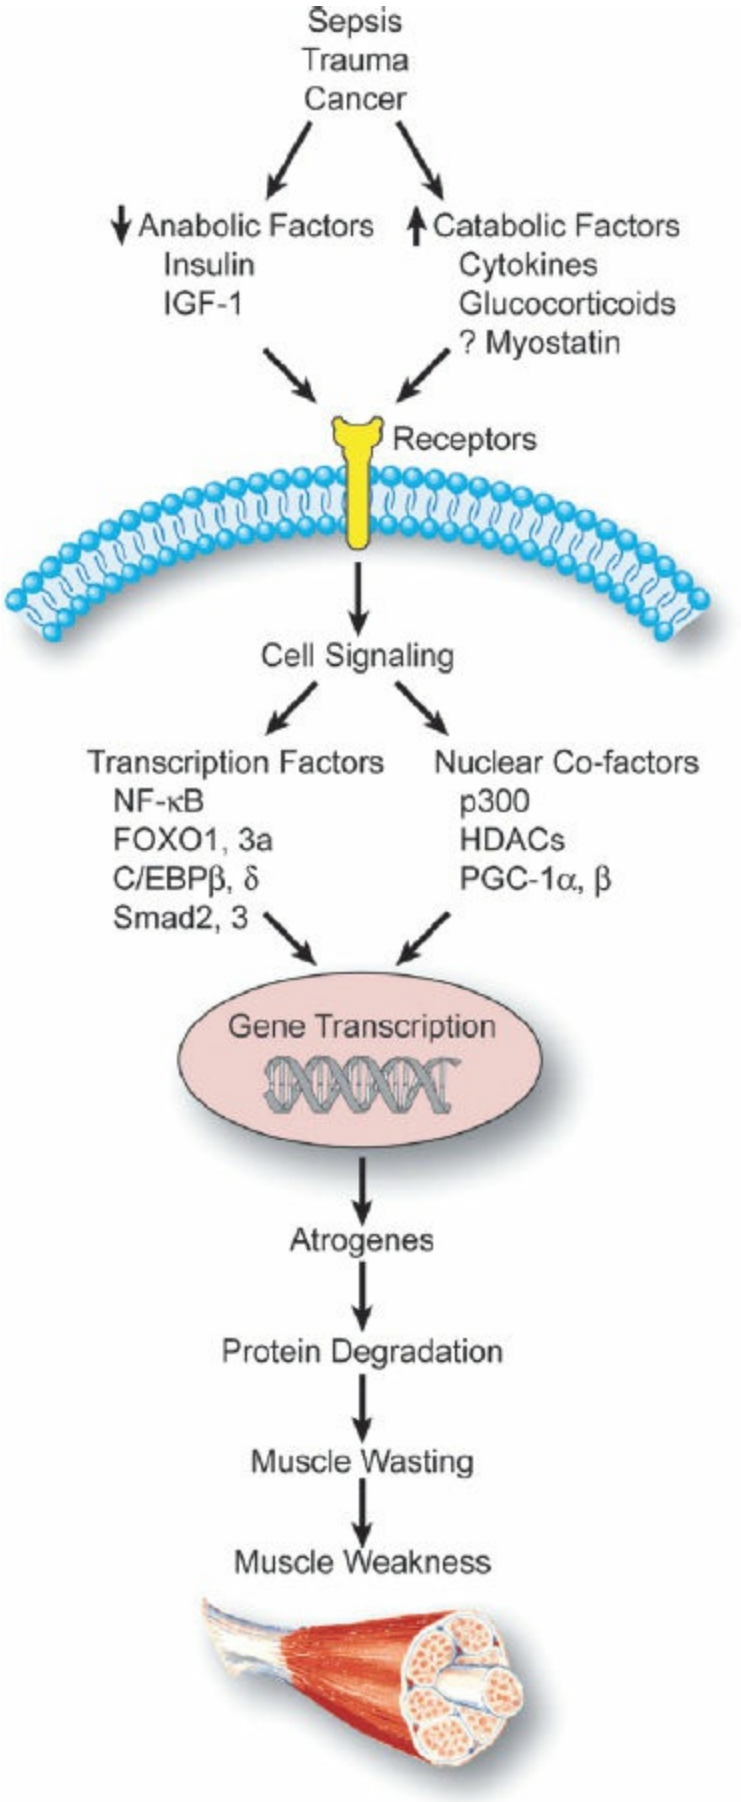

Figure 2.5. Muscle wasting in various catabolic conditions,

including cancer, sepsis, and severe injury, is regulated at multiple levels. Anabolic factors including insulin and IGF-I are reduced, and catabolic factors including cytokines and glucocorticoids are increased. These changes result in altered cell signaling and expression and activity of transcription factors and nuclear cofactors that regulated genes involved in muscle proteolysis. Loss of muscle mass, muscle weakness, and fatigue are the ultimate results of the molecular events set in motion by the catabolic conditions. (Reproduced by permission from Aversa et al., Critical Reviews in Laboratory and Clinical Investigations.)

Although initial reports of pronounced muscle hypertrophy in myostatin-deficient cattle are strong indicators that myostatin is a potent-negative regulator of muscle mass, the role of myostatin in muscle wasting during various catabolic conditions is somewhat controversial. Several reports in the literature, including a recent study in septic rats, suggest that myostatin expression and activity are not universally upregulated during muscle wasting conditions (but may actually even be downregulated). This is important to keep in mind when interpreting results from studies in which inhibition of myostatin was tested in the prevention and treatment of muscle wasting.

PROTEOLYTIC MECHANISMS INVOLVED IN MUSCLE BREAKDOWN

Intracellular proteins are degraded by multiple proteolytic mechanisms. It is beyond the scope of this chapter to give a detailed description of the different proteolytic pathways participating in the breakdown of intracellular proteins and they will be discussed only briefly here. More extensive reviews of muscle proteolysis during muscle wasting conditions have been provided elsewhere. Typically, three major proteolytic pathways account for the degradation of cellular proteins: lysosomal, calcium-dependent, and ubiquitin-proteasome-dependent pathways. Lysosomal degradation of proteins is regulated by intralysosomal enzymes (cathepsins) in an acidic environment. Early studies performed mainly in hepatocytes provided evidence that components of the cytoplasm can be taken up in so-called autophagosomes that are subsequently taken up and degraded by lysosomes. Importantly, recent reports suggest that autophagic/lysosomal degradation plays an essential role in the degradation of muscle proteins during various conditions characterized by

muscle wasting.

Among calcium-dependent mechanisms, calpain-regulated protein degradation plays an important role. Previous studies suggest that calpain-dependent mechanisms may be involved in the initial step of myofibrillar protein disassembly and cleavage, at least in muscle wasting caused by sepsis. In other studies, evidence was found that increased calpain activity in catabolic muscle is mainly caused by decreased activity of the endogenous calpain inhibitor calpastatin. It should be noted that the role of calpains in muscle wasting is somewhat controversial. Other studies suggest that caspase-3 participates in the early release of myofilaments from the sarcomere during muscle wasting caused by uremia. It is possible that the roles of calpains and caspases vary in different muscle wasting conditions.

Ubiquitin-proteasome-dependent degradation is probably the proteolytic mechanism that has attracted most interest in the field of muscle wasting during the last 15 to 20 years. In this mechanism, proteins are degraded inside the multicatalytic 26S proteasome after having been targeted for the proteasome by conjugation of multiple ubiquitin molecules. The ubiquitination of protein substrates is regulated by multiple enzymes, including the ubiquitin activating enzyme (E1), ubiquitin-conjugating enzymes (E2s), and ubiquitin ligases (E3s). The length of the ubiquitin chain conjugated to the protein destined for the proteasome can be edited by deconjugating enzymes that also play an important role for the proteasome-dependent proteolysis. Among the factors regulating the ubiquitination of proteins and subsequent degradation by the proteasome, ubiquitin ligases are particularly important because they account for substrate specificity, thereby deciding which protein(s) will be degraded. The muscle-specific ubiquitin ligases atrogin-1 (also called MAFbx) and MuRF1 play important roles in muscle wasting caused by a number of different catabolic conditions, including sepsis, severe injury, and cancer. Increased expression of atrogin-1 and MuRF1 is commonly used as a “molecular marker” of muscle wasting (although this is probably an oversimplification because there are multiple examples of conditions where there is not a close correlation between changes in the expression of atrogin-1 and MuRF1 and changes in protein breakdown rates).

Another recently described ubiquitin ligase, TRIM32, plays an important role in muscle wasting by targeting the Z-bands of the sarcomere and other proteins in the cytoskeletal network contributing to

the release and breakdown of myofibrillar proteins (Fig. 2.6).

Although most early information regarding the role of the ubiquitin–proteasome pathway in muscle wasting was generated in experimental animals with different models of sepsis, burn injury, cancer, and uremia, there is evidence that similar mechanisms are involved in patients. For example, it is almost 15 years ago that the gene expression of ubiquitin was reported to be upregulated in skeletal muscle from patients with sepsis and several subsequent reports have confirmed that the ubiquitin–proteasome pathway is activated in patients with sepsis and other catabolic conditions as well, including cancer and burn injury.

TRANSCRIPTION FACTORS AND MUSCLE WASTING

Because the expression of atrogin-1 and MuRF1 as well as other molecules involved in the regulation of muscle mass, such as molecules regulating the expression and activity of the autophagosome and the lysosomal enzyme cathepsin L, is upregulated at the transcriptional level in atrophying muscle, it is not surprising that a great deal of attention has been paid to the potential role of transcription factors and nuclear cofactors involved in the regulation of gene transcription. Genes that are upregulated in muscle wasting conditions are commonly referred to as “atrogenes.” Among transcription factors that are involved in the regulation of muscle mass, early studies provided evidence that NF-κB may play an important role, at least in muscle wasting associated with sepsis. In more recent studies, muscle-specific genetic manipulation of the expression and activity of NF-κB-regulated muscle mass at least in part by influencing the expression of MuRF1 (but not atrogin-1) and the rate of proteasome-dependent protein degradation. Other reports have also provided support for a role of NF-κB in muscle wasting.

Forkhead Box O 1 (FOXO1) and FOXO3a are additional transcription factors that participate in the expression of muscle wasting-related genes, including atrogin-1 and MuRF1, and were found in recent studies to play an important role in the development of muscle atrophy. In recent experiments, evidence was found that FOXO1 may be particularly important for muscle wasting in sepsis and other critical illness. Interestingly, recent studies suggest that FOXO transcription factors regulate the transcription of autophagy-related genes providing further support for the important role of FOXOs in muscle wasting.

An additional group of transcription factors that are involved in muscle

wasting are members of the family of C/EBP transcription factors, in particular C/EBPβ and δ. In recent experiments, the expression as well as DNA binding activity and transcriptional activity of these transcription factors were increased in skeletal muscle during sepsis and after treatment with glucocorticoids. In addition, genetic evidence suggests that C/EBPβ is involved in glucocorticoid-induced atrophy of skeletal muscle cells.

Of note, the activity of transcription factors can be regulated at different levels. First, the abundance of the transcription factors may be increased in catabolic muscle as found for FOXO transcription factors and C/EBPβ and δ. Second, the transcription factors may form complexes with other transcription factors or with nuclear cofactors. Finally, and perhaps most important, the activity of transcription factors can be regulated by posttranslational modifications, including phosphorylation, ubiquitination, and acetylation.

Additional transcription factors involved in the regulation of muscle mass include SMAD2 and SMAD3 mediating myostatin- and activinA-induced wasting.

Taken together, multiple studies suggest that several transcription factors may be involved in the regulation of muscle mass during various muscle wasting conditions. Most of these observations have been made in animal models of muscle atrophy and in cultured muscle cells and it will be important in future studies to determine whether these transcription factors are involved in muscle wasting in critically ill patients as well.

NUCLEAR COFACTORS AND MUSCLE WASTING

In addition to being regulated by transcription factors, gene transcription is also influenced by various nuclear cofactors (coactivator or repressor proteins) and proteins in the transcriptional machinery. Although transcription factors bind to DNA in a sequence-specific fashion, they typically lack enzymatic activities required for modification of chromatin, unwinding of DNA, and recruitment of RNA polymerase. In contrast, several nuclear cofactors exert enzymatic activities and influence gene transcription by modifying chromatin or by changing the structure and function of transcription factors or other nuclear cofactors. The function of some of the nuclear cofactors is also to serve as docking sites for other proteins that are recruited to transcription factors thereby influencing gene transcription.

In recent studies, the nuclear cofactor p300 was found to regulate

glucocorticoid-induced atrophy of cultured muscle cells and the role of p300 may at least in part reflect its interaction with muscle wasting-related transcription factors. Because an important function of p300 is to exert histone acetyl transferase (HAT) activity, the observations suggest that hyperacetylation may be involved in muscle wasting. This hypothesis was supported by the observation that the expression and activity of the histone deacetylases SIRT1, HDAC3, and HDAC6 are reduced in skeletal muscle during glucocorticoid- and sepsis-induced muscle wasting. In other experiments, treatment of cultured muscle cells or experimental animals with the HDAC inhibitor trichostatin A (TSA) resulted in increased expression of the ubiquitin ligase atrogin-1 and stimulated protein breakdown. Taken together, the observations discussed here suggest that hyperacetylation of transcription factors and probably other cellular proteins as well may be involved in muscle wasting. Indeed, acetylation is evolving as an important posttranslational modification that may even rival other posttranslational modifications, such as phosphorylation, in the regulation of many cellular metabolic events.

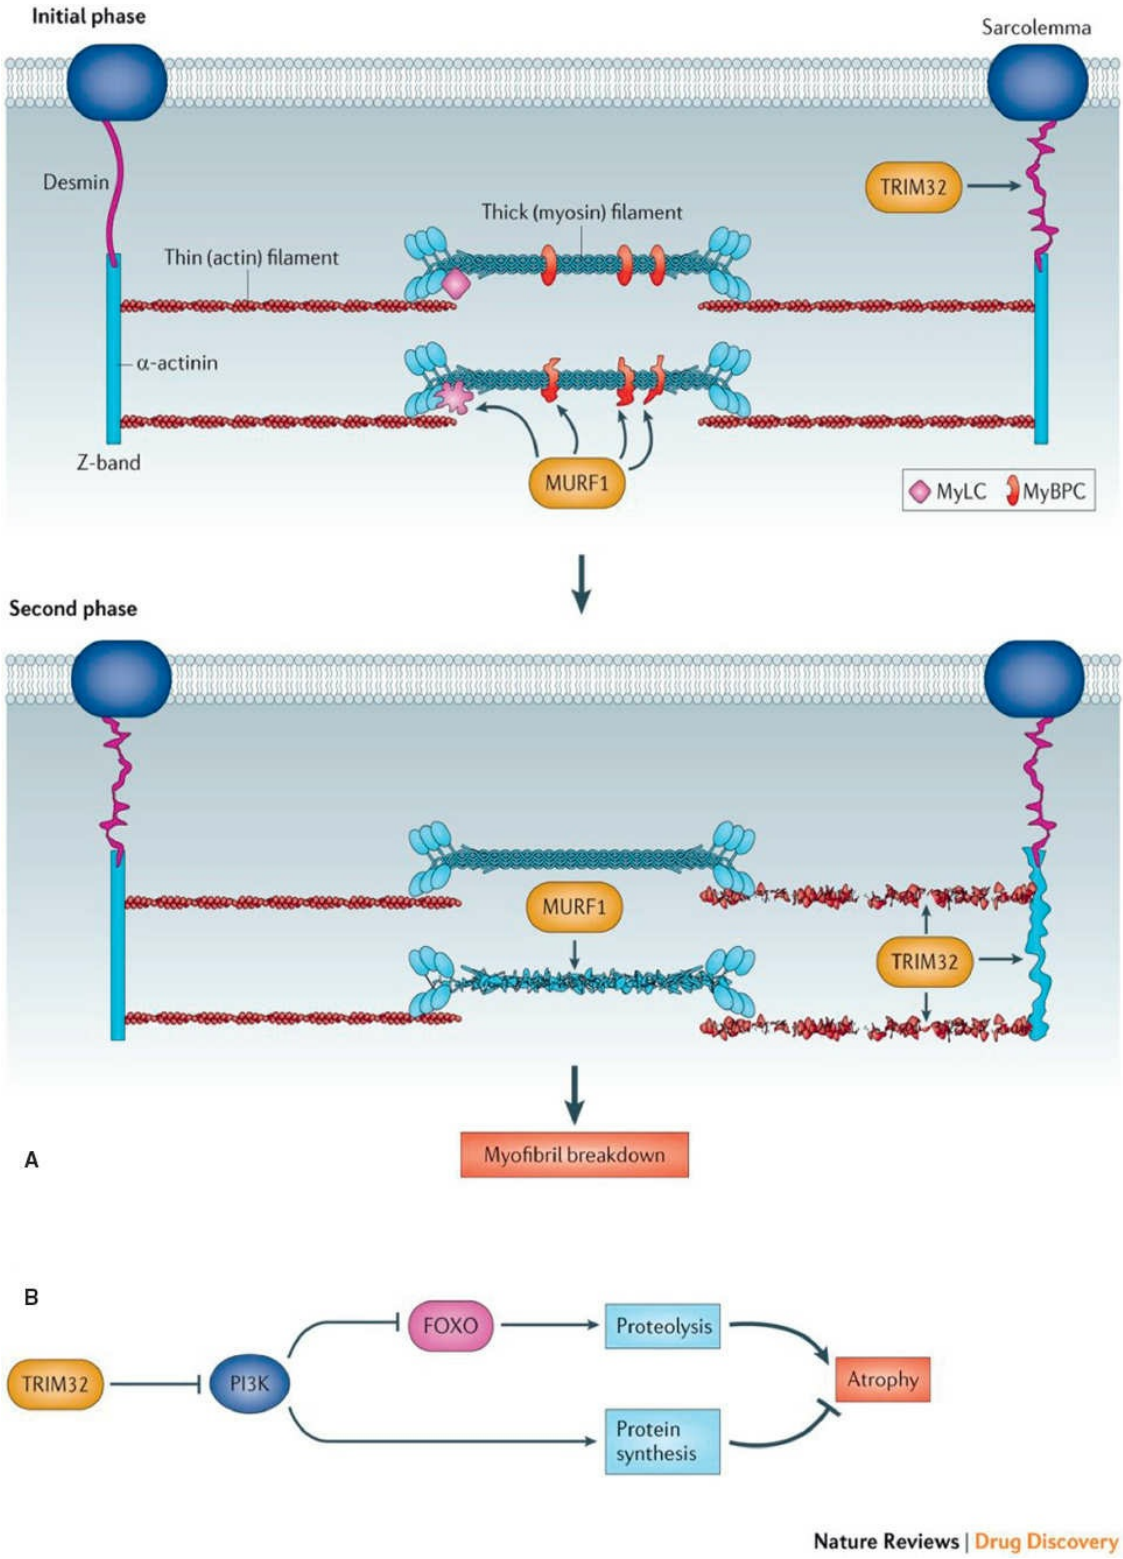

Figure 2.6. Mechanisms of myofibril breakdown and wasting. **A:** Loss of myofibrils during atrophy is primarily mediated by two ubiquitin ligases: MURF1 and TRIM32. MURF1 catalyzes the loss of thick filament stabilizing-proteins and then of myosin itself. Loss of the thin myofilament requires TRIM32, which also catalyzes the destruction of the Z-band and the desmin cytoskeleton. **B:** In addition to its role in degradation of myofibrils

and the cytoskeleton, TRIM32 also reduces PI3K-AKT signaling, which results in decreased protein synthesis and increased proteolysis. (Reprinted by permission from MacMillan Publishers Ltd: from Cohen S, Nathan JA, Goldberg AL, et al. Muscle wasting in disease: molecular mechanisms and promising therapies. *Nat Rev Drug Discov* 2015;14(1):58–74.)

Another group of nuclear cofactors that has been implicated in muscle wasting recently are members of the PPARγ co-activator-1 (PGC-1) family. There is evidence that PGC-1α and β are repressors of genes involved in muscle wasting, including some of the genes in the ubiquitin–proteasome pathway. Studies suggest that reduced expression and activity of both PGC-1α and β may induce muscle atrophy, at least in part secondary to increased expression of the ubiquitin-ligases atrogin-1 and MuRF1. In recent experiments, the expression of PGC-1α and β was substantially downregulated in skeletal muscle during sepsis in rats concomitant with increased expression of atrogin-1 and MuRF1. In the same study, overexpressing PGC-1β in cultured muscle cells reduced the expression of atrogin-1 and MuRF1, providing further support to the concept that PGC-1 cofactor may regulate muscle mass at least in part by regulating the expression of atrogin-1 and MuRF1.

Similar to transcription factors, most of the evidence suggesting a role of p300, HDACs, and PGC-1 cofactors has been generated in animal models of muscle wasting or in cultured muscle cells and it remains to be determined whether similar mechanisms are involved in patients with muscle wasting. The observations are important, however, because they suggest that it may be possible in the future to prevent or treat muscle wasting by targeting small molecules based on an increased understanding of the molecular regulation of processes involved in muscle wasting.

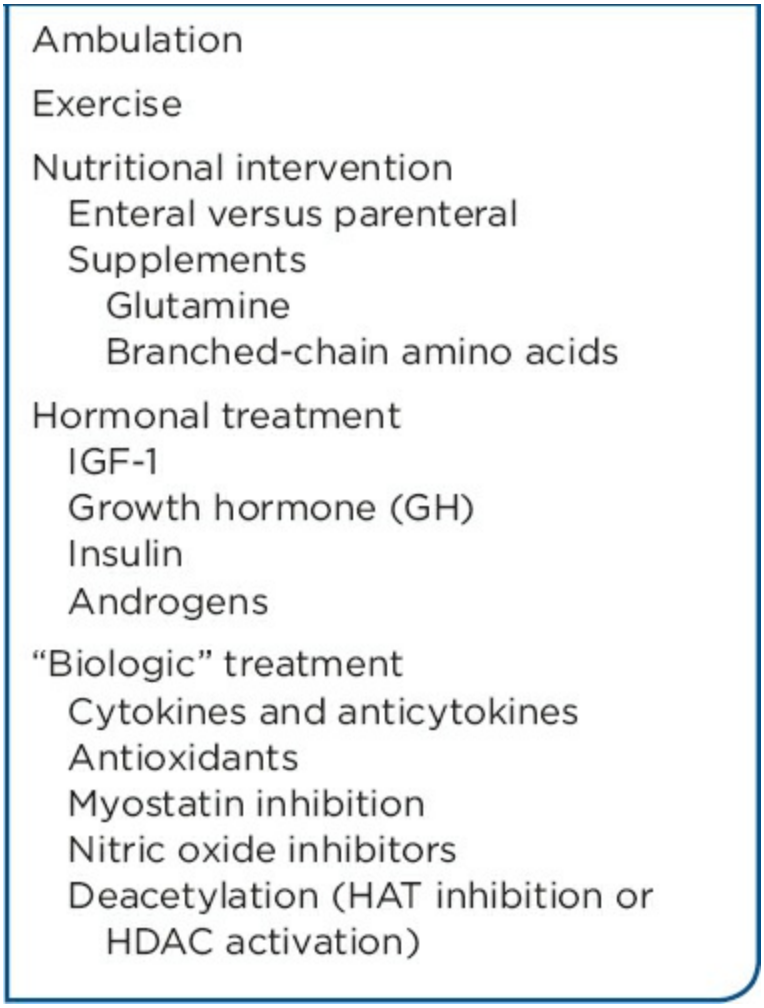
PREVENTION AND TREATMENT OF MUSCLE WASTING

In some patients with muscle wasting, correcting the underlying cause of the catabolic response will ameliorate the metabolic changes in skeletal muscle. There are situations, however, when the cause of muscle cachexia cannot always be corrected or is difficult to treat. For example, patients with advanced cancer cannot always be cured from their disease and in those patients, the accompanying muscle wasting may become a

significant factor reducing quality of life and may even contribute to death. Patients with severe and protracted sepsis who develop multiple organ failure and require long stay in the ICU, frequently on the ventilator, are another group that may benefit from more specific treatment of the catabolic response in skeletal muscle. Patients with burn injury develop severe muscle wasting even when the burn is managed by experts. AIDS is an additional example of a condition that cannot always be treated successfully and where effective treatment of muscle wasting would greatly benefit the patients. Finally, the growing population of elderly people makes the prevention and treatment of sarcopenia increasingly important.

Different strategies employed to prevent or treat muscle wasting are summarized in Table 2.8. Some of these strategies have been tested in patients, whereas other modalities are still experimental (or even speculative). Although mechanisms underlying loss of muscle mass may differ between various muscle wasting conditions, there are also multiple similarities that make strategies to prevent and treat muscle weakness applicable in several conditions.

TABLE 2.8 Strategies for Prevention and Treatment of Muscle Wasting and Weakness



AMBULATION AND EXERCISE

Because bed rest and inactivity are potent mechanisms of muscle atrophy, it is not surprising that attempts have been made to prevent muscle wasting by early ambulation and exercise. By nature, of course, patients in the ICU, frequently sedated and on a mechanical ventilator, cannot always ambulate or exercise. Even in patients without significant contraindications for ambulation, however, that aspect of the care is not always prioritized. One reason for this may be lack of resources (it requires the involvement of physical therapists and nursing personnel to ambulate the patients) but probably also concerns for safety to mobilize critically ill patients with complex surgical wounds, intravenous and intra-arterial lines, feeding tubes, and still on mechanical ventilator. Interestingly, several recent studies, including randomized controlled trials, have documented the safety and feasibility of early ambulation and mobility in the ICU, even in patients requiring mechanical ventilatory support, and have shown improved neuromuscular and physical function

by early mobilization of patients in the ICU. Studies suggest that early mobilization results in decreased ICU and total hospital length of stay and decreased duration of ventilatory support.

The involvement of physical therapists and active and passive exercises are additional important strategies that should be employed to prevent and treat muscle wasting and weakness. In general, resistance (strength) training is considered the most effective exercise for slowing the rate of loss of muscle mass and to improve muscle strength (as opposed to aerobic exercise training, which may be more beneficial from a cardiovascular standpoint). Even passive exercise of extremity muscles bedside in patients who are sedated may be beneficial and slow the process of muscle atrophy.

NUTRITIONAL INTERVENTION

The role of nutritional support in the prevention and treatment of muscle wasting is less clear. Although it is well documented that starvation and malnutrition will result in loss of muscle mass, the effects of nutritional intervention in critically ill patients with regard to muscle wasting have been disappointing, at least in patients with sepsis. Several previous reports suggested beneficial effects of early nutritional support, in particular enteral nutritional support, as they relate to overall clinical outcome, length of stay in the ICU, survival rates and infectious complications, but there is little evidence that nutritional intervention prevents of reverses muscle wasting.

Based on early studies in experimental animals, there has been a great deal of interest in the field of nutritional supplements to prevent the loss of muscle mass. In particular, supplementation with glutamine and branched-chain amino acids (especially leucine) has been used in this context. Recent studies suggest that the leucine metabolite β-hydroxy-β-methylbutyrate may be able to inhibit loss of muscle mass in various catabolic conditions, including cancer, but its role in the treatment of critically ill patients in the ICU remains to be defined. Other nutritional supplements that have been used in critical care include arginine, ω-3 polyunsaturated fatty acids, and RNA. Overall, however, the role of nutritional intervention, including supplementation with glutamine, branched-chain amino acids, and other substances, in the prevention and treatment of muscle wasting in critical illness, remains unclear.

HORMONAL TREATMENT

Hormones that have been used to reduce the catabolic response in skeletal muscle include growth hormone (GH) and IGF-1. These hormones exert an anabolic effect by stimulating protein synthesis and inhibiting protein breakdown in skeletal muscle. Although there was an early enthusiasm for treatment of critically ill patients with GH, some of that enthusiasm was stifled by reports of increased mortality in ICU patients treated with GH (possibly caused by suboptimal control of hyperglycemia). Subsequent studies in burn patients suggest, however, that treatment with GH is safe (provided blood glucose levels are monitored carefully) and may reduce the catabolic response in skeletal muscle.

In addition to GH, there is evidence that IGF-1 may exert muscle-sparing effects in critical illness. For example, there is evidence that treatment of burn victims with IGF-1 preserves muscle mass and improves clinical outcome. In animal experiments, protein synthesis in muscle from septic rats was stimulated by IGF-1, whereas protein breakdown was not influenced by the hormone, even at high concentrations, suggesting that muscle proteolysis becomes resistant to the effects of IGF-1 during sepsis. Because, at the same time, the regulation of protein synthesis by IGF-1 was unaffected by sepsis, it is likely that the sepsis-induced resistance of protein breakdown to IGF-1 reflects a postreceptor event. Interestingly, in other studies, treatment of burned rats with IGF-1 stimulated protein synthesis and inhibited protein breakdown without evidence of resistance to the hormone. Thus, muscle wasting in different catabolic conditions may respond differently to IGF-1, probably at least in part reflecting different mechanisms involved in muscle wasting in different disease states.

The anabolic effects of IGF-1 at least in part reflect stimulated PI3K/Akt signaling with downstream phosphorylation and activation of mTOR-regulated protein synthesis. It is possible that PI3K/Akt signaling is involved in the inhibition of muscle proteolysis as well. For example, PI3K/Akt-regulated phosphorylation of FOXO transcription factors results in inactivation of FOXOs and downregulated expression of atrogin-1 and MuRF1. The enzyme glycogen synthase-3β (GSK-3β) is an additional downstream target of the PI3K/Akt signaling pathway; increased phosphorylation of GSK-3β results in its inactivation, an important effect considering that activation of GSK-3β is probably involved in burn- and sepsis-induced muscle wasting.

The influence of insulin on muscle protein synthesis and degradation is

similar to that caused by IGF-1. In fact, some of the signaling of IGF-1 and insulin may be caused by a nonselective binding to and activation of the insulin and IGF-1 receptors, which in part explains why the metabolic effects of the hormones are similar. Interestingly, we reported previously that septic muscle becomes resistant to insulin with regard to regulation of protein degradation but retains its sensitivity to insulin's regulatory effects on protein synthesis (identical to the response to IGF-1 in septic muscle). Although the mechanisms of sepsis-induced resistance to IGF-1 and insulin in skeletal muscle are not fully understood, cytokine- and glucocorticoid-induced alterations of receptor-associated docking proteins may be involved. Interestingly, studies suggest that ghrelin may have muscle-sparing effects, possibly secondary to stimulation of the GH/IGF-1 axis.

Recent studies suggest that tight glucose control by the administration of insulin improves survival of patients in the ICU. In addition to improved survival, other effects, including reduced infectious complications and length of stay in the ICU have also been ascribed to tight glucose control protocols. It has also been suggested that tight glucose control may inhibit ICU-acquired muscle weakness. It should be noted that although the initial reports on the beneficial effects of tight glucose control were received with great enthusiasm and resulted in changes in the care of critically ill patients, recent studies have challenged the initial reports finding no evidence of beneficial effects of this protocol. Some studies have even reported increased mortality in ICU patients on a tight glucose control protocol, at least in some cases reflecting the development of significant hypoglycemia. The potential benefits of tight glucose control in the ICU with regard to prevention of muscle wasting and weakness need to be tested in randomized controlled trials.

There is solid evidence in the literature that androgens, such as testosterone, regulate muscle mass in humans. Although the use of testosterone by athletes has attracted a great deal of attention (and controversy), testosterone has also been used in certain patient groups to improve muscle mass and function, such as older men with normal or low testosterone levels and HIV-infected men with low serum testosterone. The best and most extensive support for a beneficial effect of testosterone, as well as the anabolic steroid oxandrolone, with regard to muscle wasting in critical illness has been generated in patients with severe burn injury. In several of those studies both short- and long-term beneficial effects were

reported with regard to muscle mass, strength, and function.

Selective androgen receptor modulators (SARMs) are a relatively new class of compounds that have been suggested to be beneficial for the treatment and prevention of muscle wasting without the potential cardiovascular and prostate cancer risks often associated with androgen therapy. Although experiments in rats suggest that some of the SARMs exhibit anabolic effects in skeletal muscle, the effects of these drugs on muscle wasting in ICU patients are not known.

BIOLOGIC TREATMENT

Most “biologic” treatments are experimental and await clinical trials. Some of the potential treatments discussed here can even be considered speculative. In general, though, the evolving understanding of the molecular mechanisms involved in muscle wasting over the last several decades has identified potential drug targets for specific interventions aimed at blocking or activating certain molecules depending on their roles in the loss of muscle mass.

The biologic treatment that has probably attracted most interest and that may be closest to definitive clinical trials is the one aimed at inhibiting myostatin, for example, with myostatin antibodies. The rationale for this treatment is previous observations that myostatin is a strong negative regulator of muscle growth and development. Myostatin is a member of the transforming growth factor β family that is produced in skeletal muscle and probably exerts most of its effects in muscle by autocrine and paracrine mechanisms. The potential role of myostatin in muscle wasting has been supported by studies in which the expression of myostatin was increased in skeletal muscle during various catabolic conditions. It should be noted, however, that the role of myostatin may vary in different catabolic conditions since its expression is not universally upregulated in all muscle wasting conditions. For example, in recent experiments, myostatin expression was not increased but was actually significantly decreased in skeletal muscle during sepsis in rats. Unchanged or even decreased expression of myostatin has been reported in other catabolic conditions as well. Thus, antimyostatin treatment may not be beneficial in all conditions characterized by loss of muscle mass.

Other biologic treatments that have been reported in animal experiments to have beneficial effects on muscle mass and function include treatment with interleukin-15, anti-TNFα antibodies, antioxidants,

and nitric oxide inhibitors. The effects of these treatments in patients with muscle wasting conditions are not known.

Recently, sepsis-induced muscle wasting in experimental animals was associated with increased expression and HAT activity of the nuclear cofactor p300 and reduced expression and activity of HDACs. Taken together, these changes set the stage for increased acetylation of cellular proteins. The potential role of hyperacetylation in muscle wasting was supported by upregulated expression of atrogin-1 and increased muscle proteolysis after treatment of rats with the HDAC inhibitor TSA. Based on these observations, it may be speculated that inhibition of acetylation may reduce loss of muscle mass in catabolic conditions, at least catabolic conditions in which there is evidence of hyperacetylation. Interestingly, the recent development of small molecules that can stimulate HDAC activity (resulting in reduced acetylation of cellular proteins) may provide an opportunity to test whether muscle wasting can be treated or prevented by reducing the level of acetylation. It may also be speculated that treatment with resveratrol, a compound that has both antioxidant and HDAC stimulatory effects, may be an additional avenue worth trying to prevent muscle wasting in critical illness. Importantly, the recent development of small molecules specifically targeting and inhibiting p300/HAT activity may offer an additional way to reduce hyperacetylation (and protein breakdown) in catabolic muscle.

Although many of the potential drug targets discussed in this section are still far from clinical application, a number of clinical trials are in progress to evaluate treatments of muscle wasting (Table 2.9). Presently, treatments aimed at blocking myostatin seems to be attracting the greater interest and perhaps promise.

Nutritional Assessment and the Need for Nutritional Support

Historical Perspective

It would have been fun to write this section in the early 1970s, as nutrition and nutritional support was wonderfully exciting. Dr. Stanley Dudrick had just wowed the world in the late 1960s by showing beagle puppies that had never eaten keeping up with puppies that were fed normal chow and were eating. A seminal observation was the baby who had not been fed and yet seemed to have fairly normal development. The senior editor of this book

was fortunate to be involved in the evolution of total parenteral nutrition (TPN) and to set, with Dudrick and others, some of the parameters by which nutritional support was carried out. Ron Abel, who was an intern on the pediatric surgical service when JEF was the chief pediatric resident, told about a young surgeon named Stanley Dudrick who was doing experiments with dogs and finally with babies to support them without eating at all. The residents were somewhat incredulous but Ron Abel suggested inviting him up to speak. He spoke to the residents and staff in the Bigelow Amphitheatre, who were astonished. In about 1968, they put together a nutritional support group to start supporting patients by hyperalimentation. The team included a pharmacist who was interested and who had heard about what was going on at the University of Pennsylvania at that time and agreed to make up the solutions in his spare time after hours. In the early years the team did not have the knowledge we have today and did just about everything wrong. The solutions had too many calories, a fat substitute was not available and the initial team gave too much volume and too much glucose. Despite this the hyperalimentation allowed some fistulas to close and supported patients who could not eat.

It was known that central venous access was needed and that the subclavian insertion site of the catheter needed a sterile dressing. (Dr. Robert Linton, who was consulted on this, said to leave it open with nothing on it—maybe that should have been done, although it seemed unlikely that with the bedclothes scraping on it that the catheter site would remain sterile.) The floor nurses were stretched much too thin and were terribly disinterested in doing this, hence a TPN nurse was added to the team. Regular dressing changes and insertion site care, kept the sepsis rate at a reasonably low level. The TPN service took off and grew to as many 70 patients. International fellows came from all parts of the world to learn about TPN. TPN has now evolved into a hospital service at many institutions and is a mainstay of nutritional support although it is only recommended is enteral feedings are not possible. We know so much more about the physiology of malnutrition today than we did in the early years of TPN based on the evolution of this technique.

There were many missed opportunities. Research money was very plentiful. Although the companies were competitive, they were pretty good about giving young, aggressive, mostly surgical investigators money for doing research in TPN. Unfortunately, the research was not of high quality

and most of it could never be funded by the NIH, although some of it was. Instead of competing, we should have gotten together and in fact we might have—there was an organization known as the Society of Parenteral Alimentation (SPIA), which was a 30-member organization by invitation only that had an annual meeting and a different format: only five papers, 2 hours each, material which had never been published, and if you used any of it, you were thrown out, never to be invited again. One person did and was never invited back. There were other opportunities lost. We failed to get CPT codes for initial assessment, nutritional support, daily visits and ordering of the bottles, and judging the electrolytes. We could have done a lot to maintain the field and to reproduce ourselves. But we were too busy competing with each other because we were all young and, to a certain extent, we were all male rhinoceroses competing for Lord knows what. It did not happen, and we did not reproduce ourselves. The problem now as this author sees it is that TPN has become something that you use until you can get rid of the catheter. The reason for this is because catheter infection has become a bugaboo on all services and, in addition to causing death and metastatic infection elsewhere, costs at least $63,000 per line infection. The TPN nurse, who metastasized to an IV nurse, no longer exists. The TPN nurse has been a casualty of hospital efficiency. It only takes the prevention of two line infections a year to actually pay for the salary and benefits of a TPN nurse, whose job it is to go endlessly around all the units and teach people aseptic technique and how to avoid line infection. As noted earlier, TPN is something that you put in when you are desperate and you try to prevent line infection if you can without adequate help, especially in the ICU, and then you get the line out as quickly as possible and go to enteral nutrition. Not that there is anything wrong with enteral nutrition, but this author would venture to say that with the inappropriate use of excessive osmolar nutritional aspects, there are probably more deaths with enteral nutrition and pneumatosis and bowel necrosis than there are in patients who get TPN. What has happened to TPN is that it is no longer a surgical discipline. If it is staffed at all, it is some reluctant gastroenterologist who takes this on. Surgeons are basically excluded or have excluded themselves from the management of the patient. The goal is to put people on TPN for as little time as possible and then to transition to enteral nutrition. This is not a bad idea but it is an idea that may never happen because patients may not be able to accept sufficient support by enteral nutrition.

TABLE 2.9 Summary of Clinical Trials Evaluating Treatments for Muscle Wasting

Drug/Target	Disease Process	Trial Details	Outcomes	Ref. or ClinicalTrials.gov Identifier
TNFα				
Etanercept (TNFα Ligand bound to Fc-IgG1)	Cancer	■ IV administration ■ RCT	No inhibition of muscle wasting	100
Infliximab (TNFα-specific mAb)	Non-small-cell lung cancer	■ IV administration ■ RCT	Trial stopped early because of decreased quality of life in infliximab-treated group	101
IL-6				
ALD518 (BMS-945429; IL-6-specific mAb)	Lung cancer	■ IV administration ■ Phase I/II	No inhibition of muscle wasting	108
Myostatin/activin				
BYM338 (bimagrumab; ActRIIB-specific mAb)	Sarcopenia	■ IV administration ■ RCT	In progress	NCT01669174
	COPD	■ IV administration ■ RCT	In progress	NCT01601600
	Cancer	■ IV administration ■ RCT	In progress	NCT01868685
	Mechanical ventilation	■ IV administration ■ RCT	In progress	NCT01433263
	Sporadic inclusion body myositis	■ IV administration ■ RCT	In progress	NCT01925209 (RESILIENT trial)
LY2495655 (myostatin-specific mAb)	Pancreatic cancer	■ IV administration ■ Phase II	In progress	NCT01505530
Ghrelin receptor				
Ghrelin	COPD	■ IV administration ■ RCT	Improvement in quality-of-life score but not physical activity	246
Anamorelin (growth hormone secretagogue receptor agonist)	Cancer	■ Oral administration ■ RCT	Improvement in symptoms score	247
	Non-small-cell lung cancer	■ Oral administration ■ RCT	In progress	NCT01387282
SUN11031 (ghrelin agonist)	COPD	■ SC administration ■ Phase II	Increased muscle mass but not function	NCT00698828
Androgen receptor				
Enobosarm	Ageing	■ Oral administration Phase II	Increased muscle mass and function	248
	Cancer	■ Oral administration ■ RCT	Increase muscle mass but not function	NCT01355484 and NCT01355497 (POWER trials); NCT00467844 (REF. 249)
MT-102 (SARM)	Non-small-cell lung cancer	■ Oral administration ■ RCT	In progress	ACT-ONE trial[250]
GSK2849466 (SARM)	Healthy volunteers	■ Oral administration ■ Phase 1	No serious adverse events	NCT01696604
LGD-4033 (SARM)	Healthy volunteers	■ Oral administration ■ Phase 1	No serious adverse events	251

ActRIIB, activin A receptor, type IIB; COPD, chronic obstructive pulmonary disease; IgG1, immunoglobulin G1; IV, intravenous; IL-6, interleukin-6; mAb, monoclonal antibody; RCT, randomized controlled trial; SARM, selective androgen receptor modulator; SC, subcutaneous; TNFα, tumor necrosis factor-α.

THE ROLE OF ALBUMIN MEASUREMENT IN NUTRITIONAL SUPPORT

For the past three editions, the approach to nutritional support and nutritional assessment has been in particular a European approach. In the third and fourth editions, Graham Hill, from the UK and working in Australia as Chair of a Department of Surgery, did wonderful things introducing enteral and PN in Australia. His approach is particularly

European. In the fifth edition, Peter Soeters, who spent several years with me in the laboratory and wrote the classic review of gastrointestinal cutaneous fistulas, wrote about the risk assessment and nutritional support, again with a strictly European cast. Unfortunately, it is not that way in this country, and the concepts, which are well regarded, that Graham Hill and Peter Soeters and his coworkers put forth in previous editions are all true and are all brought to bear. However, they are not the approach that we use in this country and so it is time to take a strictly American approach.

How do these approaches differ? The cardinal difference between the American point of view and the European approach is the role of albumin. Most of us can pick out a malnourished patient prior to operation. This was well proven in the study as carried out by the University of Pennsylvania team, and showing that patients who had lost between 10% and 15% of their body weight over 3 or 4 months were at risk of serious postoperative complications and failure to heal. Hence, the essence of operative risk as determined in the United States is a loss of lean body mass. It is lean body mass that we are trying to salvage with TPN and to stop from being broken down for energy. And yet it is more than that. Serum albumin and transferrin, which are used as indicators of nutritional adequacy, albumin being a rapid turnover protein with a half-life of approximately 20 days, allegedly tell us about the health of lean body mass. The European point of view is that albumin is not so much a characteristic of malnutrition but of inflammation. Although we do not think about this that way in the United States, albumin level in the serum is largely determined by the percentage of extravascular albumin since it is the rate of degradation rather than the rate of synthesis which is the biggest determinant of serum albumin. This was shown by Rothschild at his laboratory at the New York, VA in the late 1950s and early 1960s in which he showed that patients with cirrhotics who often presented with low serum albumins did so not because they were not making it but because the percentage of extravascular albumin to which the rate of catabolism related was more important in determining the level of serum albumin. The European point of view is that a low albumin, again brought about by increased catabolism rather than decreased synthesis, is usually the result of longstanding, chronic infection or, if not an infection, inflammation, and this is the signature of a low serum albumin, not so much starvation, not so much decreased synthesis, but increased degradation because of the percentage of extravascular albumin and its rate of degradation. The Europeans may be correct and it

may all be about inflammation. And it may be that inflammation poorly characterized, which is the sine qua non of patients who are in poor metabolic shape and even poorer metabolic shape to survive operation. These patients are most at risk because of the mechanism which a low serum albumin then brings forward.

Thus, we have come full circle. In 1936 at the University of Pennsylvania and independently in the University of Edinburgh, it was shown that a high level of serum albumin equaled survival following gastrectomy. It was thought that this represented increased synthesis, and perhaps it does. However, one must keep an eye over one's shoulder to think about albumin as being degraded and hence the depressed serum albumin level is a marker on ongoing inflammation.

Operative risk is best related to the status of lean body mass. Lean body mass is that operant amount of protein, which carries out the various functions that we characterize as being important in patients. To have a low serum albumin means that the lean body mass is deficient and hence lack certain enzyme systems and other systems of defense, which make the difference between survival and death. Let us now consider what we can do about a patient whom we believe to be at risk and has deficiencies not only in lean body mass, but also in those proteins, which we associate with the synthesis of lean body mass and thus perhaps survival. Included in these proteins that may be deficient with weight loss are the immunologic armamentarium of the body, various enzymatic and defense mechanisms and the inability to synthesize phagocytes and immunologic cells. Remember that there are 10 billion neutrophils released each day and programmed to die within a few hours by apoptosis. Some of the products of dying neutrophils may contribute to the resynthesis of valuable protein and defense mechanisms. Not to have these important recycling and immunologic functions puts the organism at risk.

RISK OF CATHETER-RELATED BLOOD STREAM INFECTION

The major risk of TPN is line sepsis. This is termed catheter-related blood stream infection (CLABSI) today. CLABSIs are associated with substantial morbidity and mortality. Although according to the CDC a 46% decrease in CLABSIs had occurred in hospitals across the United States from 2008 to 2013, an estimated 30,100 central line-associated bloodstream infections (CLABSI) still occur in ICUs and wards of US

acute care facilities each year. CLABSIs are preventable and are considered serious infections typically causing a prolongation of hospital stay and increased cost and risk of mortality. The infection rates vary in a wide range. Hospitals monitor such rates and compare to a risk adjusted incidence where a rate less than 1 is the goal…the lower the better. This data is readily available for providers and patients so the rates between hospitals. The national standardized infection ratio is 0.50. Employing CVC bundles and other strategies US hospitals reported a significant decrease in CLABSI. Among 2,442 hospitals in the United States with sufficient data to calculate the SIR 10% had an SIR significantly worse than 0.50 (2014 data published in 2016). CVC Bundles include: optimal site selection (avoid the femoral site), hand hygiene, alcohol-based chlorhexidine skin preparation, maximum barrier precautions, and catheter care guidelines.

The mean attributable cost and LOS between matched CLABSI cases (1,339) and non-CLABSI controls (2,678) was $55,646 (**2011 dollars**) and 19 days, respectively, in a study reported in March of 2014. The cost relates to blood cultures, perhaps time in the ICU, various diagnostic aspects, and nearly 3 weeks of hospitalization to get the line sepsis under control. CLABSI may be caused by bacteria or *Candida*. The mortality is greater with a yeast infection. Thus ideally TPN is something to be avoided, not surprisingly, because of the high infection rate. Line sepsis can be avoided by excellent nursing care but it needs to be continuous. In the past, TPN nurses needed to make their way from unit to unit, emphasizing the care of lines to which it is directly related. This was not rocket science. This has been known since a paper in the *New England Journal of Medicine* that our team published in 1973 (Abel RM, Beck Ch Jr, Abbott WM, et al. Improved survival from acute renal failure after treatment with intravenous essential L-amino acids and glucose. Results of a prospective, double-blind study. *N Engl J Med* 1973; 288(14):695–9). The introduction of TPN nurses in Cincinnati decreased the sepsis rate from 27% to 0.78%, which I think is about the lowest it can be. Today institutional practice guidelines exist and TPN and CVC care is highly regulated and monitored. Standard practice reduces errors and complications as well as infection. In general, either a port or a subclavian line has the lowest rate of sepsis. Internal jugular lines in the ICU, particularly in patients with a tracheostomy, will experience high rates of sepsis because it is almost impossible to keep a dressing on, especially

with trach ties and everything else. Line sepsis in the ICU, in addition to all the other disasters, is often a fatal coup de grace. In a well-run unit, it should be possible to have a line sepsis rate of less than 1%.

WHAT IS NEEDED FOR TOTAL ENERGY REQUIREMENT

It is highly unlikely that many patients will be in hospitals that have research functions to determine the total energy requirements. Thus, it is better to estimate this by calculating the resting metabolic expenditure. According to the Harris Benedict equation, basal metabolic rate and essentially what patients need can be computed using the following equations:

$$\begin{aligned}\text{Males} = {} & 66.5 + (13.8 \times \text{weight in kg}) \\ & + (5 \times \text{height in cm}) \\ & - (6.8 \times \text{age in years}) \\ \text{Females} = {} & 66.5 + (9.6 \times \text{weight in kg}) \\ & + (1.9 \times \text{height in cm}) \\ & - (4.7 \times \text{age in years})\end{aligned}$$

Thus, one can get a reasonably accurate estimate of not only the caloric requirements, but also how it might be administered and, utilizing 6.25× the number of calories, some idea of what the constituents of TPN might be.

What kind of energy requirements do we need? In general in the ill patient most of the calories should be supplied as glucose. Yes, one does need a modicum of fat, and this is thought by some to be in the range of 25 to 40 mL of a fat emulsion three times per week to provide essential fatty acids. Some authorities believe that large doses of fatty acids may be harmful, and it would be difficult for patients and their immunologic functions to tolerate it.

CALORIC REQUIREMENTS AND THE CALORIE TO NITROGEN RATIO

The main consideration when administering fat and carbohydrates in PN is not to overfeed the patient. The commonly used formula of 25 kcal/kg ideal body weight furnishes an approximate estimate of daily energy

expenditure and requirements. Under conditions of severe stress requirements may approach 30 kcal/kg ideal body weights.

Calorie to nitrogen ratio is normally 6.25 cal/g of nitrogen. The amount of protein that we need is 1.5 g protein/kg/day, which some have suggested to be the upper limit of normal. It may be, but certainly in certain protein-losing enteropathies, the loss is increased so what we would say in respect to nitrogen is that there is a range of 0.25 to 2.0 g nitrogen/kg/day. Some patients have protein needs much higher than those with normal metabolic processes. For example, patients with inflammatory bowel disease may lose 0.5 to 1.0 g protein/kg/day in the stool. I agree with the recommendations made by Professor Hill in the previous edition:

1. For maintenance, prescribe 1.0 to 1.5 g protein/kg/day.
2. For a hypercatabolic patient, prescribe 1.5 to 2.0 g protein/kg/day.
3. For those with excessive losses, prescribe up to 2.5 g protein/kg/day.

PATIENT SELECTION FOR TPN

Operative risk is the sum of various risk factors, which, in combination determine the type of complication that may occur in a surgical patient. One of these risk factors is malnutrition. Some of the key elements in determining operative risk and correcting it are:

1. Patients who have lost 10% to 15% of their body weight over the previous 4 months are at risk.
2. The period of time necessary to reconstitute the patient's nutritional status is probably between 5 to 7 days.
3. Serum albumin should be 3.0 g/dL (a value of 3.5 g/dL is better according to some).

Early experience on the Surgical Services at Mass General, demonstrated that with administration of TPN for 3 days before the patient was taken to the OR, there was a trend toward improvement, although that it was not statistically significant. From that study it was determined that we could (a) identify the patient at risk and (b) probably do something about the operative risk by supplementing TPN for probably 5 days prior to operation. Furthermore, 5 days was the point at which serum transferrin began to improve and most importantly, the patient began to feel better. Thus 5 days was determined as the time that the patient needed to restore lean body mass and the protein functions thereof. Since the early experience, the European Society for Enteral and Parenteral Nutrition

reviewed several studies that have “demonstrated that 7 to 10 days of preoperative PN improves postoperative outcome in patients with severe undernutrition who cannot be adequately orally or enterally fed.” Conversely, its use in well nourished or mildly undernourished patients is associated with either no benefit or with increased morbidity. Postoperative PN is recommended in patients who cannot meet their caloric requirements within 7 to 10 days orally or enterally. In patients who require postoperative artificial nutrition, enteral feeding or a combination of enteral and supplementary parenteral feeding is the first choice. The report of the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group “confirmed the lack of benefit of TPN in borderline malnourished patients, provided strong evidence against clinically important efficacy in mildly or moderately malnourished patients, and suggested but did not confirm efficacy in severely malnourished patients. In this report, the incidence of severely malnourished population was small, representing less than 5 percent of the surgical candidates.” They concluded that “in the absence of severe malnutrition or other specific indications for preoperative TPN, most patients are probably best served by prompt surgery.”

GENERAL INDICATIONS FOR TPN

1. TPN is useful either in patients who cannot or will not eat, or in patients who cannot eat adequate amounts. It is also used in patients who are ill or who are about to undergo elective surgery. This has been previously discussed and the author believes that the amount and duration of this TPN should be approximately 5 or 6 days, at which time we should see the patient feeling better and serum transferrin increasing.
2. When the alimentary tract is obstructed or with prolonged ileus postoperatively and nutrition is not possible in the postoperative period.
3. Caution is advised in the use of TPN in obstructive GI malignancy. The duration of the TPN should be short and that the patient should have the possibility of an operation without increasing the rate of the growth of the tumor. Malignancy with obstruction without any hope of removing the tumor is not an indication for TPN. In addition, TPN to foster chemotherapy is not appropriate unless the patient has a markedly responsive tumor, such as a lymphoma or a lymphosarcoma.

4. Short bowel syndrome. The limits of short bowel syndrome have been reasonably defined, and when patients have had a massive small bowel volvulus and only have less than 36 cm of small bowel with an ileocecal valve, there is an indication for TPN. One must try very hard to save the ileocecal valve, which one usually can do, with the ileocolic vessel branch so that 2 cm is sufficient. In addition, if the ileocecal valve's blood supply is problematic, it is worthwhile if there is any omentum left, to wrap the anastomosis in omentum and suture it around the ileocecal valve to heal. In general if the patient has 64 in or 2m of small bowel, even without the ileocecal valve, anastomosis of distal transverse colon or the sigmoid colon, it should be possible to ultimately wean from TPN.
5. Enterocutaneous fistula. Enterocutaneous fistula from the large bowel, can often be managed with enteral nutrition, but a high output small bowel fistula is an excellent indication for TPN. One can generally expect that between 33% and 38% of those patients whose anatomy is favorable (not obstructed, no stricture, reasonable small bowel) will ultimately heal without the need for operation.
6. Inflammatory bowel disease. Particularly in Crohn disease, TPN itself may prove to be healing and will quiet down the inflammation. When a fistula complicates Crohn disease, and is treated with infliximab, the fistula may close but it will reopen. The optimal approach is to allow the fistula to close, let the abdominal wall calm down, treat infection, and then operate and resect the area of the fistula.
7. Patients with major intra-abdominal sepsis or inflammatory processes such as pancreatitis, and in general when the gut is not usable, are excellent candidates.

PLACING A CENTRAL VENOUS CATHETER

A catheter may be placed by an internal jugular route, an external jugular route, or a subclavian route. Some prefer a peripherally inserted central catheter (PICC) line. The current literature supports that this is a safe alternative to a CVC provided that unnecessary catheters are discontinued promptly. For PICCs central line associated blood stream infection (CLABSI) rate has been reported at 2 to 2.3 for 1,000 catheter days. The longevity and complications of PICCs in burn patients differs little from CVCs. CVCs may have a higher rate of CR-BSI in burn patients than PICCs. Although PICCs are not adequate for the fluid volumes typically required during burn shock resuscitation, they can provide a safe and

effective alternative for central access in the ongoing care of the burn patient. There are many techniques for placement of a CVC. The following technique that is employed by the senior editor (JEF).

1. The patient should be supine in bed and three chucks or a small roll should be placed longitudinally between the patient's shoulder blades.
2. The patient's shoulders should be allowed to droop downward and back and relaxed. A small IV injection of valium for patients who are agitated or nervous is often helpful.
3. The arms are at the side and the neck is turned slightly to the opposite side.
4. After being prepped and draped, the patient should be placed at a 30-degree Trendelenburg. If the external jugular veins cannot be visualized, then a crystalloid or plasma (depending on the patient's need) should be utilized to make certain that the veins are of a proper diameter.
5. A careful prep of both sides, usually with povidone iodine followed by chlorhexidine after the povidone iodine is washed off with alcohol, is carried out. The operator should be totally gowned and draped, as should everyone else in the room, with a mask and a hat.
6. The subclavian vein is identified with a number 22 needle, which is placed just at one third of the clavicle. The periosteum of the clavicle is anesthetized the periosteum of the clavicle and aim for one finger breadth above the sternal notch. With practice, one injects the xylocaine and/or Marcaine and one feels the pop as the needle enters the subclavian vein. It is important that the needle not be any more than 10 degrees to the horizontal. If one keeps less than 10 degrees to the horizontal, one will not get a pneumothorax. After the needle enters the subclavian vein, one immediately takes a larger needle by the Seldinger technique, which is prepared, looks at how far in the number 22 needle is, and passes the Seldinger needle into the vein. A wire is then introduced through this needle and the catheter is then placed over the wire. The suture, which is absorbable but of sufficient dimensions such as a 3-0 pds, is then used to sew the catheter in place. The IV is then hooked up; I generally at that point ask the nurse to dress the catheter.
7. Infusion is done with 5% dextrose in saline and a CXR is obtained, making certain the catheter is in the right place. The operator should examine the x-ray themselves. The tip of the catheter should be at the junction of the superior vena cava and the right atrium. If the catheter

is in place and there is no pneumothorax and the bottle is lowered and the blood comes back into the catheter, the TPN can be hung and usually starts at 40 cc/hr. Care we have previously dealt with.

SUSPECTED CLABSI

The fever curve of CLABSI is usually a very low grade fever of several days before, followed by a fever spike and rigors. It may or may not be associated with a high white count and there is not another source of sepsis. One takes blood cultures from the catheter and also from a remote spot so to make certain that, if there is a positive blood culture, it is not a contaminant around the catheter. If this is correct, then after the starting of a peripheral IV, the catheter is withdrawn and the tip is cultured. If a fungus is suspected, an ophthalmologic examination for candida in the eye fundus is also necessary. If the sepsis occurs without prior prodrome when the new bottle is hung, the bottle is removed, the catheter is left in place, and the TPN is cultured; it is very rarely the source of sepsis.

If the catheter is a source of sepsis, 24 to 48 hours must elapse with adequate antibiotic coverage before another catheter is attempted. If a fungemia is present, then one must look for other sources of nutrition not including glucose and one must try especially hard to use enteral nutrition. One can only be certain that sepsis is no longer existent when one has 2 weeks of adequate therapy. If the therapy is not adequate, it may take 6 weeks for sepsis to subside.

TPN SOLUTIONS

Most hospitals have TPN solutions, which are made up and ordered by a system of prepared solutions. The average physician whose patient needs it only check the box and, based on electrolyte values, the additives to the patient's TPN. In this way, errors in TPN are omitted. The most likely errors occur in the lack of monitoring of solutions and the failure to make up, for example, for GI losses including the loss of chloride in nasogastric tube drainage and/or the loss of enteral contents in patients with gastrointestinal cutaneous fistulas. A particular area of loss that most do not pay much attention to is both the energy and the sodium loss of a hepatobiliary fistula. The sodium content as well as some other electrolytes of both a biliary and a pancreatic juice loss is particularly energy-dependent because it is hypertonic to the plasma. This means that patients who lose large amounts of bile and pancreatic juice may lose

fluids with a sodium content of up to 180 as compared to a plasma, which contains a sodium of 140. Potassium loss to excess is uncommon but may occur. Sending the drainage fluid to the laboratory for determination of electrolytes may be helpful in managing such patients. Calcium and phosphorus need to be carefully adjusted. Hypophosphatemia is manifest usually by a somewhat bizarre symptomatology beginning with numbness in the lower jaw and in the skin around the mouth and may, if untreated, end with hypophosphatemic coma. This usually occurs when the serum phosphorus reaches the level of 0.5 mEq/L. Other deficiencies may occur in multivitamins and bizarre amino acid patterns in the plasma. When, for example, multivitamin infusions were unavailable because of an FDA action, patients presented with a metabolic acidosis, which resembled the metabolic acidosis of dead bowel, and more than one patient was explored looking for dead bowel until amino acid patterns were obtained and were bizarre, with large amounts of hydroxyproline and proline and it became obvious that we were not dealing with dead bowel but with a shortage of various B vitamins.

Some of the trace metals need to be added and one must be aware of chromium, which has an additive effect to insulin. Absence of chromium may lead to uncontrolled blood sugars and chromium is part of the multivitamin and trace element solution, which is usually added to the TPN. Other rare occurrences include selenium, which has been rarely reported as it is so ubiquitous that deficiency almost never occurs. Zinc, however, particularly in patients with liver disease and in patients with diarrhea and inflammatory bowel disease, may be a real problem and one must be aware of the tendency of patients with large amounts of diarrhea to be zinc deficient. The symptomatology here is a pustular rash, which is usually perioral and a rash around the skin. Zinc levels are difficult to measure and take a long time, and if one sees a pustular rash around the mouth (this is usually where it first appears), it is better to add zinc to the solution particularly in patients who have profound diarrhea with inflammatory bowel disease.

MANAGEMENT OF TPN DURING OPERATION

For some reason, most surgeons who have patients on TPN stop the infusion before the operation and give patients 10% dextrose. This is not necessary. Patients can tolerate TPN during operation quite well, but because of the stress related to surgery and potential volume shifts the rate

needs to be decreased. The rate should be slowed on the day before operation and by midnight previous to the operation; the rate should be slowed again to 40 cc/hr, at which time there will be no hypoglycemia, which one chances when one decreases TPN at a time when the patient is physiologically secreting large amounts of insulin. After the operation is completed, one can then increase TPN to 60 cc/hr on the first night and carefully monitor glucose with patients who may require insulin prior to resuming the previous rate. Hyperglycemia in the postoperative period may very well mean infection in some place, anastomotic leak, or a latent wound infection and one must be completely vigilant to this particular aspect.

RELATIONSHIP BETWEEN TPN AND ENTERAL NUTRITION

The good Lord intended patients to take food orally, and indeed one of the characteristics important to the way food is administered is that calories and protein must be cleared by the gut and must pass through the liver. The liver will clear at least 75% of the glucose presented to it in the portal vein. It is controversial as to whether the liver should do this or in fact requires the passage of most of the calories and amino acids into it to maintain its function. The liver is dependent on first pass clearance of 75% of glucose and many other nutrients, and failure to do so will contribute to hepatic dysfunction. So a case can be made for enteral nutrition, not the least of which is hepatic health. On the other hand, the adage that enteral nutrition has far fewer complications than TPN is simply not true. In TPN, line sepsis and some incidences of electrolyte abnormalities are the principal complications. Patients certainly do die from line sepsis; they should not, but they do. However, the complications of enteral nutrition as currently given in various hospitals may have an equivocal or even a higher incidence of mortality than in TPN. The reason is the failure to understand the concept of the challenged bowel. To begin with, much of enteral nutrition is given into the stomach, especially in the elderly. The elderly patients' stomach may not take or tolerate hyperosmolar feeds as easily as younger patients. In addition, loss of motility, especially on the evening and night shift when patients are unattended, often leads to aspiration, pneumonia, and death. A well-run enteral nutrition unit will stop feedings at 9 PM (or earlier) and the patient should remain elevated at 45 degrees, which is difficult.

Another problem with enteral nutrition from my standpoint is the failure to understand hyperosmolality and its effect on the bowel. The manufacturers' guidelines for starting enteral nutrition take very little account of the hyperosmolality of many tube feedings and will start tube feedings on a hyperosmolality of 400 or 500. In patients in the ICU or in elderly patients, this requires an increase in cardiac output and increase in blood flow to the bowel to dilute the hyperosmolar material by secreting free water. The elderly bowel may not be able to do this and if one starts hyperosmolar tube feedings without being certain that the bowel can tolerate it, it leads to pneumatosis, bowel necrosis, and death. Starting hypo-osmolar tube feedings with a strength of 150 mOsm/L and gradually increasing it so that it never exceeds 280 mOsm/L will prevent any pneumatosis or hyperosmolar-related deaths from bowel necrosis. At times one cannot give as much bowel or enteral feeds as is necessary to maintain the patient totally, and in this case, one should opt for a combined enteral and parenteral nutritional support.

HEPATIC FAILURE

The administration of conventional amino acid mixtures to patients with hepatic encephalopathy and an impaired liver will almost certainly lead to worsening of hepatic encephalopathy. The reason is that hepatic encephalopathy is thought by many to lead to high levels of phenylalanine and other aromatic amino acids and tryptophan, while not total tryptophan but free tryptophan, across the blood/brain barrier, and results in derangement of the central nervous system neurotransmitters. Since the aromatic amino acids gain entry into the brain by competing with the branched-chain amino acids, a different solution has been proposed and has been in use since the 1970s. Randomized prospective trials have clearly shown an improvement in outcome, including close to improved survival in patients receiving a high branched-chain, low aromatic amino acid ratio in TPN. In addition, the studies have clearly shown that, when one gets to upper levels of amino acid infusion, between 80 and 120 g/24 hours, the results are better. Fat should not be used as an energy source in patients with liver disease because they do not metabolize it. Glucose is the preferred fuel and one needs to watch glucose intolerance. In other countries, the use of high branched-chain, low aromatic amino acids mixtures is very common and is part of the armamentarium, but in the United States, for the most part, this is not routine therapy. In patients with

impaired hepatic function, a high branched-chain, low aromatic amino acid ratio may result in improvement in liver function and survival in patients who otherwise might die. Such solutions have been tested both parenterally and orally, and except for the two studies that relied on fat as a major caloric source the results have all been positive. Use of oral branched-chain amino acids, notably in Europe, has shown improvement in long-term encephalopathy in patients with chronic liver disease as well.

RENAL FAILURE

Renal failure especially in surgical patients is an unfortunate concomitant of critically ill patients. To say that it complicates their management is an understatement. Approximately 40 years ago, there was a Giordano Giovanetti diet, which was intended for oral patients with chronic renal failure. The purpose was to avoid dialysis. In these studies, high biologic value protein such as egg yolk and other types of protein, which had little waste nitrogen, were part of a diet, which was very rigid, but in fact it was shown in chronic renal failure patients to decrease the frequency of dialysis. The essential amino acids are the amino acids, which could not be synthesized by the body. There were some additional essential amino acids from the standpoint of the inability to synthesize it such as arginine, and some have advocated using a more complete formula. The problem is that most situations in which one is using an essential amino acid regimen involved surgical patients in acute renal failure. The addition of any other amino acid other than the eight that have become the standard decreases the efficacy as far as the lowering of BUN, which is an essential part of the regimen. In surgical patients, the use of essential amino acids is so important. The glucose regimen is usually about 35%. The essential amino acid load is quite small, about 16 g/L, much lower than the 40 g/L that is usually given in TPN solutions. There is evidence that decreasing the protein load may aid more rapid recovery from acute renal failure, and in fact the addition of the eight essential amino acids only, which keep down the BUN, should help the recovery from renal failure. In fact, in a 1973 publication in the *New England Journal of Medicine*, the late Dr. Ron Abel and the rest of the team with the addition of the renal consulting unit at the Mass General Hospital carried out a randomized prospective trial of the essential amino acids and hypertonic dextrose versus isocaloric hypertonic dextrose alone. The use of essential amino acids and hypertonic dextrose versus caloric equivalent dextrose resulted in increased survival in the

group of patients receiving essential amino acids. In addition the outcomes with pneumonia and gastrointestinal hemorrhage were substantially better. Subsequently, Dr. Herbert Freund, later the Chair of the Hebrew University Department of Surgery at Mount Scopus, tried to conduct a study in which a diluted solution of standard amino acids was compared with the essential amino acids. Although there was some indication that the outcome might be better, the study was insufficiently powered to provide a definitive answer. Thus, our recommendation for patients in acute renal failure is that a solution consisting of 35% dextrose and 16 g essential amino acids/L does seem to confer some type of survival advantage in these critically ill patients.

RESPIRATORY FAILURE

There has been an attempt to have a respiratory solution in patients with acute respiratory failure who need nutritional support. Because of some data that John Kinney brought to our attention, the focus seemed to center on the amount of glucose that was given, which appeared to increase arterial CO_2 and thus perhaps delay the weaning of these patients from the ventilator.

In fact, this was a very good example of how a specific event with a few patients treated in a certain way was generalized to the entire group of patients with respiratory failure. The patients, who got a high dose of glucose early on acutely, without a gradual ramp up, did increase their CO_2 and actually by the numbers it made their respiratory failure worse. However, this was a very small group of patients who were put on TPN acutely. They were septic and their CO_2 went up markedly so that they got a larger dose of glucose than they should have. After reviewing the data, there is no reason to utilize a solution for respiratory failure unless the routine management of patients who are septic and in respiratory failure is to give them large doses of glucose. As currently use of high glucose solutions is avoided in respiratory failure, there is no need for a respiratory solution.

CARDIAC FAILURE

Earlier studies in nutrition carried out by Starling in 1912 suggested that the heart was spared the ravages of starvation. A careful look at these experiments revealed that Starling utilized two cats, one of which was

starved and the other was not. The unfortunate cat that was starved was sacrificed at a later date and it was found that its heart did not change remarkably during this period of starvation. Since then these experiments have been repeated and it does appear that after a prolonged period of time starvation does effect the heart in similar fashion to the way it effects other protein and other lean body mass, only much more slowly. In an initial attempt to devise a solution for cardiac failure, a concentrated solution of amino acids and glucose was administered to patients in congestive failure who could not eat. The results showed no change in cardiac parameters after 4 weeks, but we did see some changes in cardiac parameters after 6 weeks. Hence any beneficial effect in cardiac failure in giving nutritional support was bound to be delayed and probably was not going to be particularly useful. This does not mean that patients who are in cardiac failure and who require parenteral nutritional supplementation should get the standard solution. One should make an attempt to make certain that the solution is concentrated.

GLUTAMINE

For a while the research field went through a period in which glutamine was thought to be the best thing since sliced bread. There were large contracts written and there was an attempt to include glutamine in various amino acid solutions. Nussbaum utilizing 2% oral glutamine and 2% parenteral glutamine clearly indicated that in rats oral glutamine was quite efficacious in preserving GI fitness but no effect was seen with parenteral glutamine. Since that time, glutamine has been regularly utilized in enteral formulations.

IMMUNOLOGICALLY ACTIVE SOLUTIONS

Unfortunately, despite the fact that one of the holy grails in TPN is the desire to develop a solution, which is beneficial to patients who are infected or who have lower ability to respond to infection, there has been no success thus far. There have been solutions, mostly enteral, including various components such as glutamine, nucleic acids, and other such solutions which seem to have some efficacy, but there is no commercial solution which is currently available. The trial of glutamine-enriched solution by Bower and colleagues in patients who underwent large operations when they were malnourished and treated with enteral nutrition resulted in shorter length of stay, reduced incidence of infection, and an

enhanced recovery. There does seem to be a valid criticism of the study as the experimental and control solution were not given in an isonitrogenous fashion and there was a difference of about 20 g of amino acids/day.

COMPLICATIONS

I have mentioned many of the complications of nutritional support. Tables 2.10 and 2.11 show most of the complications that exist, most of which have been dealt with. However, there will always be complications that one has never seen before, such as the first observation of chromium deficiency in patients with diabetes and the inability to actually control blood glucose.

TABLE 2.10 Daily Vitamin Requirements for Enteral Feeding[a]

Vitamin	Daily Requirement
Thiamin	1.2 mg
Riboflavin	1.3 mg
Niacin	16 mg
Folic acid	400 µg
Pantothenic acid	5 mg
Vitamin B_6	1.7 mg
Vitamin B_{12}	2.4 µg
Biotin	30 µg
Choline	550 mg
Ascorbic acid	90 mg
Vitamin A	900 µg
Vitamin D	15 µg
Vitamin E	15 mg
Vitamin K	120 µg

[a]Prescriptions must be individualized per patient needs.

TABLE 2.11 Daily Trace Elements[a]

Trace Element	Daily Requirement
Chromium	30 µg
Copper	0.9 mg
Fluoride	4 mg
Iodine	150 µg
Iron	18 mg
Manganese	2.3 mg
Molybdenum	45 µg
Selenium	55 µg
Zinc	11 mg

[a]Prescriptions must be individualized per patient needs.

Our Inability to Support Patients Nutritionally With Sepsis and Cancer: A Hypothesis

In the last two chapters the influence of metabolism on the outcome in extremely ill surgical patients was discussed. One group of patients that still need effective metabolic and nutritional support are those with advanced cancer and cachexia and the patient with sepsis. Nonetheless, despite all efforts, these two classes of patients, stand as exceptions to an otherwise reasonably successful programs of nutritional and metabolic support. The two sources of calories in all patients are carbohydrate (glucose, generally) and fat. Carbohydrate as it is administered to patients is bimodal—it either increases ATP production by glycolysis or under certain hormonal circumstances ends up in glycogen for energy storage. Glycolysis is universal. The brain requires glucose as do red cells exclusively, but under certain circumstances the brain can switch over from glucose to ketone bodies to support it. The kidney can do this as well. Also, it is a sensitive negative feedback system, so that, when intracellular ATP is high, glycolysis is down, and, when it is low, glycolysis proceeds. The synthesis of ATP results from a base of phosphoenolpyruvate plus ADP to form pyruvate and ATP. Under normal circumstances, when we give sources of fuel, such as long-chain fatty acids, they are metabolized, and in the presence of acetyl coenzyme A, these are also important fuels for ATP production and can decrease glycolysis but not by themselves, and only when ATP levels are sufficiently high.

The hormonal environments which exist in distressed patients with either sepsis or cancer are well known (Fig. 2.7). The cytokines and mediators and hormones have also been elucidated and possibly also myostatin in sepsis, although Dr. Hasselgren has already stated that in experiments in his laboratory myostatin levels in sepsis are probably low. The counter regulatory hormones, mediated cytokines, and so forth, have been dealt with in great detail. They also break down in sepsis and probably in cancer, namely involving MuRF-1 and sometimes atrogin-1, have also been elucidated. There is one aspect, however, of nutritional support which has not been involved, and that is the cytoskeleton and the proximity of various enzymatic systems and sources of fuel for these enzymatic systems and not the three-dimensional space relationship and its effect on certain critical enzymatic and hormonal interactions. A hypothesis for why we cannot provide effective nutritional support and decrease the proteolysis in cancer and sepsis may involve the following observations and reasoning:

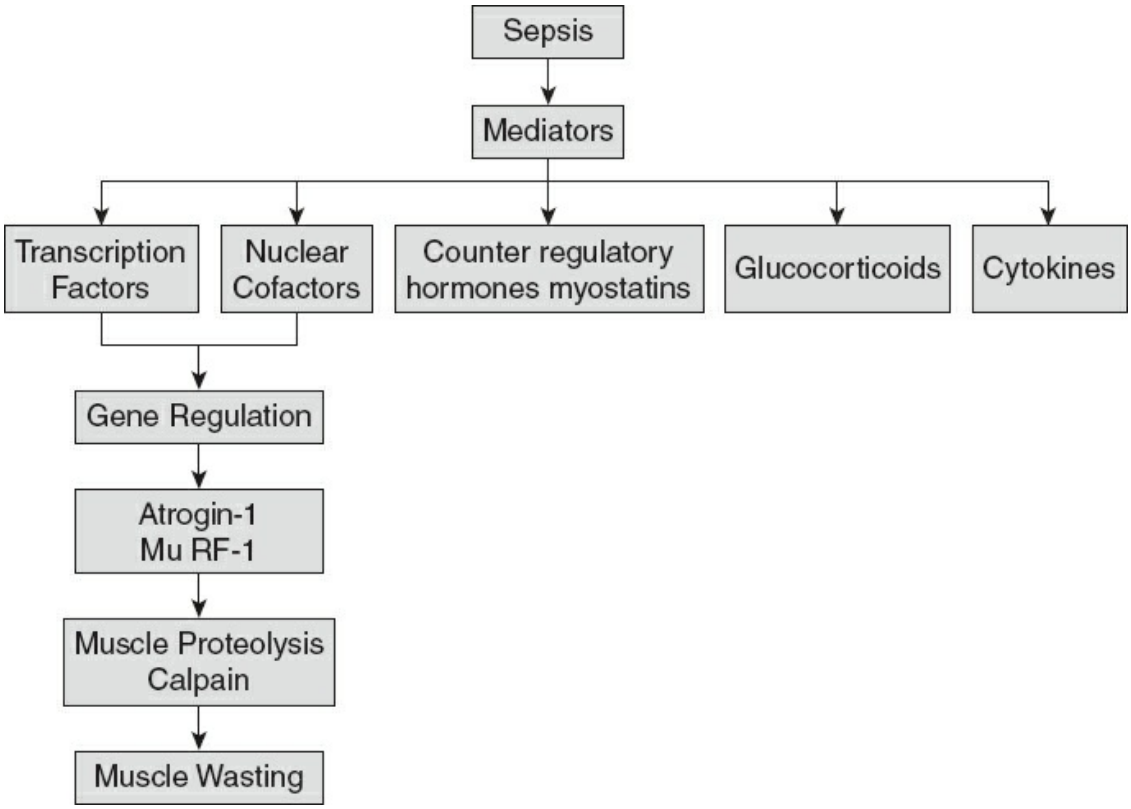

Figure 2.7. The factors involved in muscle breakdown and muscle wasting.

1. There is ineffective glycolysis, which results in an insufficient generation of ATP.

2. Under normal circumstances, fat administration for nutritional support decreases glycolysis in sepsis and cancer—but the “switch” that shuts off glycolysis in this case does not seem to work.
3. There appears to be a continued need for gluconeogenesis from protein —the inability to get glucose into certain cells may well be a membrane problem, in which there may be:
   a. Disordered submembrane space
   b. Insufficient transport mechanisms
   c. A pathologic increase in processes that depend on the cytoskeleton structure
4. The cell has an internal structure, and the internal structure is surrounded by a cell membrane. There are excrescences from the cell membrane, which break it into subcompartments arising from the membrane, which provide order into the interior of the cell, which we call a cytoskeletal structure. It may be, and this unfortunately is a teleologic argument, that there are various biochemical reactions that organize the cell, so that the reactions that are necessary may proceed better if there is a special relationship between two enzymatic or metabolic processes because they are adherent to the cell membrane. Thus, if there is a deviant pathophysiologic mechanism and two other mechanisms that are attached to the cells are adjacent to each other in the cytoskeletal structure, these pathologic processes may be increased by the proximity of these enzymatic processes and by the ready availability of fuel to run the enzymatic processes.
5. One may then ask the following question: in sepsis and cancer are there any cytoskeletally related processes that might explain some of the aberrant phenomena seen in these two diseases?
6. What is the role of aerobic glycolysis in these diseases? Aerobic glycolysis is a process involving sodium–potassium ATPase, which takes place in an area adjacent to the cell membrane and produces lactate. Lactate is usually an end product, and we are accustomed to viewing lactate as being an indicator of dead or dying cells or an incomplete end product of metabolism of glucose. The failure to process lactate further via the classic Kreb cycle means that the process of aerobic glycolysis results in only eight ATPase produced per molecule of glucose rather than the normal 32–36, if the process continued through a Cori cycle. Aerobic glycolysis is stimulated by epinephrine and produces lactate. Every intern and resident, at least on the surgical service, knows that, when blood lactate is higher, there is something dead, because lactate is usually the result of an anaerobic

end product. This is not necessarily the case, and the production of lactate by aerobic glycolysis is because of the proximity of stored glycogen, which fuels sodium potassium ATPase, which is spatially related to or close to the cell membrane. When aerobic glycolysis is stimulated by epinephrine (Fig. 2.8), which then releases glycogen, it is close to the enzymatic system of sodium potassium ATPase and yields a final end product of eight ATPs per molecule of glucose.

Not surprisingly, the absence of 32 ATP per molecule of glucose likely produces an energy shortage. Because of the shortage of ATP, increased gluconeogenesis results, and, when this happens, the glucose produced is transported to certain sites within the cell, avoiding the cell membrane block in glucose uptake, and when it is synthesized to glycogen, those sites probably are different from the sites normally circulating glucose, if it gets into cell and it gets into the liver. There is a membrane transport block for circulating glucose in the first place, which in sepsis is certainly well known. In the second place, it suggests that perhaps the mechanism by which glycogen is kept at a high level is somewhat deficient either because of spatial problems, which is unlikely, or more likely because of a transport block at the cell membrane. Thus, it may be that the only glucose that can get easily into the cell is when amino acids or other substrates get into the cell and are metabolized to glucose and then to glycogen. If this hypothesis is correct, the difference between the glucose, which is blocked at the cell membrane, and the relatively free availability of intracellular amino acids, which are broken down by proteolysis and then to glucose by intracellular gluconeogenesis, makes the source of the glycogen dependent on muscle-protein breakdown.

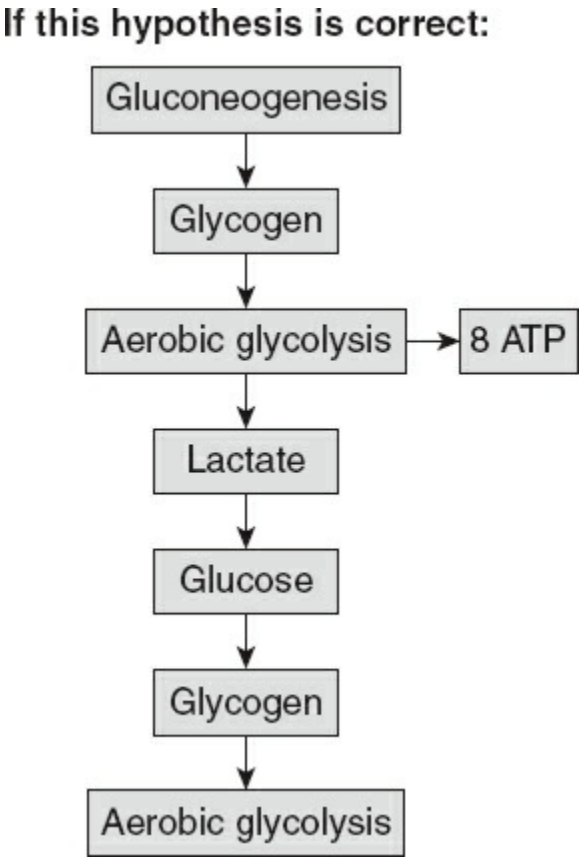

Figure 2.8. Brief outline of a futile cycle which may be involved in the metabolic derangements of sepsis and cancer.

Does lactate always mean dead bowel, hypoperfusion, or inadequate oxygenation? It is pretty clear that, whereas traditionally high blood lactate has been associated with hypotension, hypoperfusion and hypoxia, under certain circumstances blood lactate elevation does not mean these things. In the burn patient, 2 weeks after the burn, if one were to look at lactate as an indication that resuscitation is not completed, it would be dangerous because continued resuscitation with high volume of fluids may be injurious and in fact blood pressure, pulse, urine output, and PO_2 are normal at that time. The question has been raised, how does this happen? The answer is, if this theory is correct, resuscitation in the face of normal blood pressure, pulse, urine output, and PO_2 may be harmful, with which most people would agree but is due to still high circulating epinephrine. One way in which this might be explained is by some experiments done by Sir Miles Irving (1967 to 1969) that, after alpha and beta blockade in hemorrhaged dogs, as published in the Hunterian lectures, combination of phenoxybenzamine, an alpha blocker, and propranolol, a beta blocker, in hemorrhaged dogs, both plasma catecholamines and hyperlactatemia were

reduced. More recently, the senior editor's laboratory has shown that the production of lactate in vitro from extensor digitorum longus muscle in shocked, burned, or septic rats was decreased when ouabain was used to block the activity of sodium potassium ATPase. Although this was known somewhat previously, and indicated that the sodium potassium ATPase was essential for the production of lactate, these studies showed that the regulatory cascade controlling glycogen breakdown was often dependent on adenyl cyclase stimulated by epinephrine and mediated by the activation phosphorylase B Kinase to phosphorylase B to glycogen plus an organic phosphate and finally to glucose-6-phosphate. Furthermore, the stimulation of lactate production and extensor digitorum longus either by epinephrine or by amylin could be inhibited by ouabain. Thus James and colleagues proposed the following hypothesis:

1. Within cells, oxidative and glycolytic energy production can proceed in separate compartments intracellularly.
2. Most lactate production occurs in muscle and the source of the calories and fuel is glycogen.
3. Most lactate production is linked to aerobic glycolysis, which in turn is linked to sodium potassium ATPase.
4. Epinephrine and, to a lesser extent, insulin stimulate sodium potassium ATPase to maintain membrane polarity and muscle contraction. This then supposed that the sodium potassium pump function on glycolysis is likely associated with a degree of compartmentalization. This had been previously suggested by Paul and his coworkers, who suggested an association of glycolytic enzymes and calcium ATPase, or sodium–potassium ATPase at the plasma membrane, the segment of which is shown in the figure. This was supported by the effects of glycogen and the production of lactate—when ouabain is added, glycogen remains intact, and for the most part lactate production is diminished (Fig. 2.9). This indicates that sodium potassium ATPase stimulated by epinephrine is at least partially responsible for lactate production. In fact, as in the figure, when glycogen remaining versus lactate production is expressed as glucose equivalence after incubation in the presence or absence or either epinephrine or ouabain, an increase in lactate resulted in the decrease in glycogen, and, when epinephrine and ouabain were both added to the bath, the lactate production was largely blocked, whereas glycogen concentrations were maintained. It may be possible to explain these effects by some differential blockage of the actions of insulin—for example, if the glucose used by glycolysis is

not blocked in other areas such as glycogen storage. In that sense, the differential effects of insulin might conceivably participate in a disordered glucose metabolism, which we know exists in sepsis and cancer (Fig. 2.10).

5. Also, this hypothesis unifies the effects of epinephrine on these cells, which was traditionally viewed as stimulating two entirely different processes—increasing sodium potassium ATPase and separately increasing glycogen phosphorylase, which indirectly increased lactate production, thus increasing pumping-membrane hyperforce correlation. What our laboratory suggested was that these two processes are linked because of the cytoskeleton and because of proximity of both to the cell membrane, in the same area (Fig. 2.11).

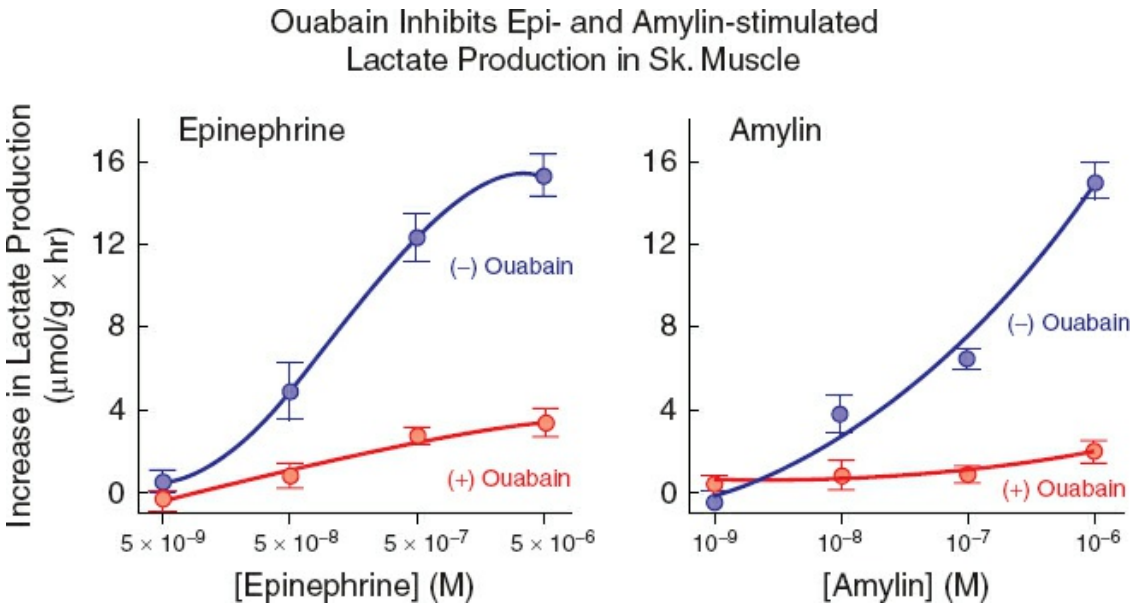

Figure 2.9. Epinephrine and amylin separately stimulate lactate production, but they are blocked by ouabain demonstrating that sodium/potassium ATPase must be active.

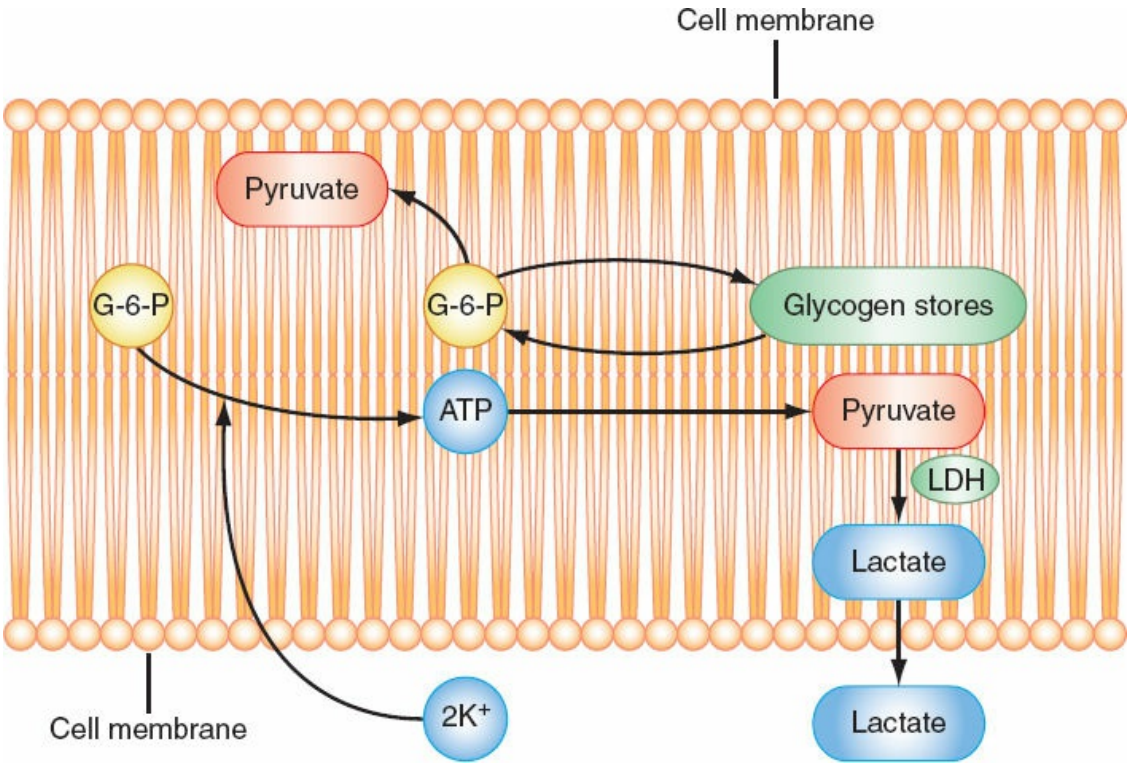

Figure 2.10. This figure attempts to show the two mechanisms, which are closely linked because of the cytoskeletal structure of the cell. It also attempts to show that the glucose derived from glycogen is preferentially from gluconeogenesis derived from amino acids.

Proteolysis and Sepsis in Cancer

In a normal organism, protein synthesis and degradation and in this case muscle synthesis and degradation are matched, and no net breakdown of protein takes place, and no synthesis takes place unless in the presence of exercise and increased caloric and protein intake. However, in cachexia brought on by a variety of stimuli, not the least of which are sepsis and cancer, muscle breakdown far exceeds muscle protein synthesis. The reasons for this have been previously detailed, in which it appears that the normal mechanisms of protein breakdown were seen as bad, but perhaps not always, in the initial phases of injury and sepsis, for example, increased production of acute-phase protein by amino acids derived from muscle breakdown might mean the difference between death and survival. It is only with the coming of the ICU, in which prolonged muscle breakdown takes place, under which terms in the past the patient would have been dead, that this becomes something which is not beneficial. Nutritional support our patients in the ICU in such a way that would derive

the benefits of both muscle breakdown and minimizing the breakdown, if by manipulating various fuels, so that it would not be necessary to have proteolysis to maintain these essential functions, muscle breakdown might be decreased.

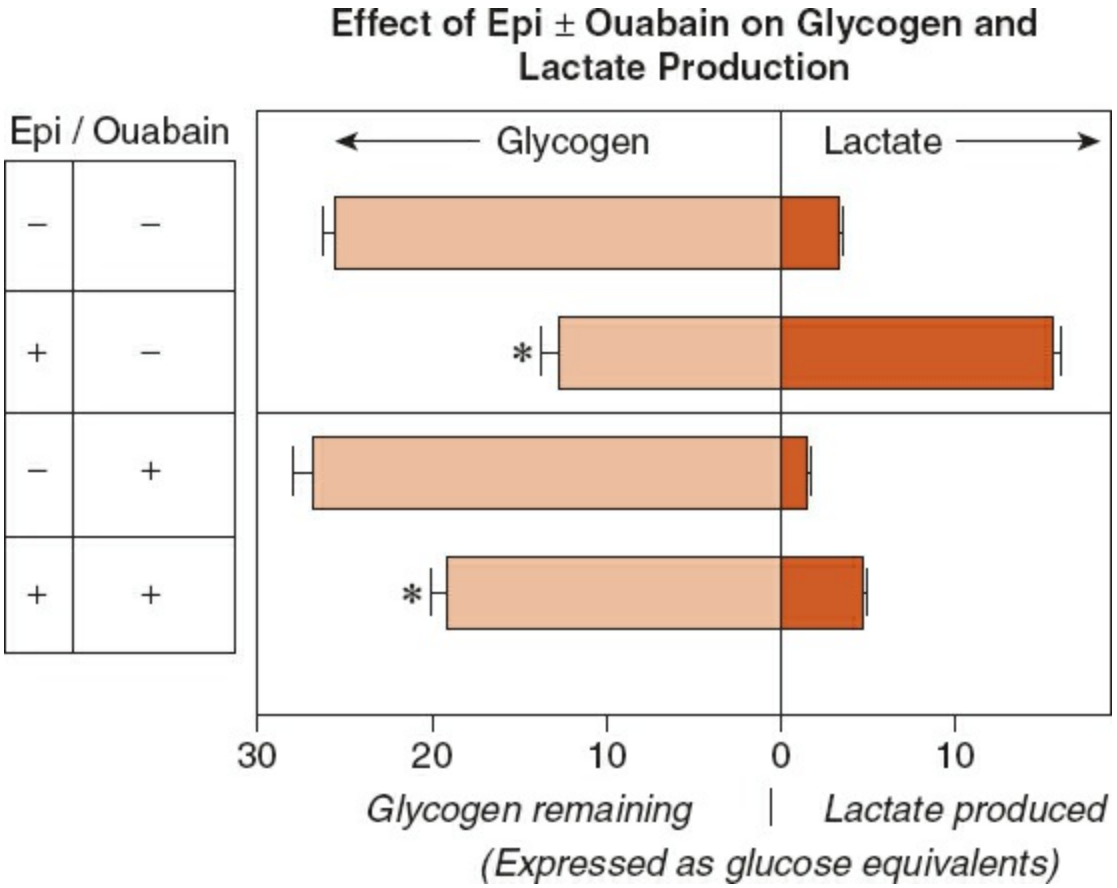

Figure 2.11. Note that when glycogen is broken down by epinephrine, the final product is lactate, despite the fact that hypoxia is not present. When sodium/potassium ATPase is blocked by ouabain, glycogen remains intact.

Myostatin

Myostatin has achieved some notoriety, and the most exciting thing about myostatin research is that, if one uses the myostatin antibody in certain catabolic situations, the catabolism and protein breakdown decreases. This has not gotten from the animal to the human type of experiment, and as stated earlier it would be nice if in sepsis and in cancer myostatin were increased. There has been more positive data from animal experiments in cancer, especially in the use of the antimyostatin antibody. It is too early to tell whether or not myostatin can be a summative aspect of support of patients in the ICU.

Possible Avenues of Support of Patients With Sepsis and Cancer

If the hypothesis concerning cytoskeletal proximity and different types of glucose and different destinations of glucose is true, then the appropriate way in which we might decrease muscle proteolysis is to provide substrate for gluconeogenesis, which openly goes to glycogen, and which is not derived from muscle-protein breakdown. Initially what seems most likely is, if you could overcome the metabolic block to glucose getting into a cell in the presence of sepsis and perhaps in cancer, in cancer it might be that it is not glucose not getting into the cell but the fact that the presence of the cancer "sops up," as it were, all of the glucose available, so there is nothing really to get into the cell in the form of glucose and nothing that goes to glycogen, allowing sodium potassium ATPase to have its first priority, which is keeping membrane integrity and the cell membrane functioning properly. In sepsis, the answer might be to provide a fuel, either protein or some other type of substrate which might get to glucose in the proper place to keep the glycogen stores fueled. Amino acids get past the cell membrane, and there is no such block as there is to glucose. Internal gluconeogenesis from protein might explain the accelerated decrease in proteolysis in an effort for the cell to keep its first priority, and that is cellular integrity. Alternatively, there might be other fuels, which get into the cell, and which do not have the block to their entry, and they can also keep glycogen full and sodium potassium ATPase functioning. Some have proposed that beta-hydroxybutyrate might be one such substrate, which might be utilized. In fact, this might be a key, because one of the problems that we have in sepsis is the fat/glucose switch.

The Fat/Glucose Switch

Traditionally, if fat is given, glucogenesis and proteolysis do not cease to occur in sepsis. A new type of hormone, if you will, was recently described by Cao and coworkers, which he identified as C16:1N7 palmito oleate that strongly stimulated insulin action in muscle and the liver as well. They called this molecule a cytokine and proposed a mechanism of action, which involves specific fatty acid-binding protein that then binds intracellular fatty acids and conveys them, as it were, to their ultimate cellular destination. Publication in *Cell* by Cao in 2008 excited enough that Olefsky, a well-known metabolic investigator, wrote a very favorable editorial as to the possibility that a lipokine might increase sensitivity in muscle and liver to insulin despite insulin resistance.

However, the sad part is that no one has been able to repeat what Cao published, and the status of lipokines is very much in doubt.

In summary, with respect to sepsis and cancer it will only be through our increased understanding of metabolism and what happens in these two diseases, to intracellular metabolism and to the interaction of different substrates and nutrients can we solve the problem of cancer cachexia and sepsis cachexia and maintain patients who are so afflicted.

CONCLUSION

There is little question that TPN and its introduction by Dudrick, followed by the unit at the Mass General Hospital, was a startling and remarkable advance in perisurgical care in patients who could not eat with some beneficial results. The enthusiasm of young surgeons, their involvement in TPN and the research they were doing, was really a wonderful thing to watch and be part of. Money was plentiful. TPN and nutrition and immunology were the hot topics. There is much work to be done in this field today particularly in cancer and sepsis and other proteolytic syndromes.

EDITOR'S COMMENT

The authors of this chapter are international authorities in perioperative care, metabolism, and nutrition. We all know that high-quality perioperative management is essential. My commentary will focus on some of the practical aspects of this chapter including Checklists, Enhanced Recovery After Surgery Protocols, and mechanical bowel prep.

The concept of using a checklist in surgical and anesthetic practice was energized by publication of the WHO Surgical Safety Checklist in 2008. The checklist movement began with the recognition that adverse events in health care are estimated to result in more deaths in the United States annually than car crashes. In Great Britain, adverse events accounted for an additional 3 million days in the hospital on an annual basis. The magnitude of improvement demonstrated by the WHO pilot studies has been surprising. Haynes et al. (A surgical safety checklist to reduce morbidity and mortality in a global population. *N Engl J Med* 2009:360:491–9) reported the effect of the WHO checklist in eight hospitals worldwide. The data prospectively collected was in-hospital complications which occurred within the first 30 days after noncardiac surgery. There were 3,733 before the checklist was implemented and 3,955 patients after the checklist was being used. There were four hospitals with high-income settings and four with low-income settings. The mortality rate was reduced from 1.5% to 0.8% ($p < 0.003$) and complications were reduced from 11.0% to 7% ($p < 0.001$). These findings have been verified in other studies and it is generally accepted that checklists enhance patient safety. Checklists are currently employed in more than 4,000 hospitals in 122 countries.

One of the valuable and perhaps unexpected outcomes of using checklists has the positive impact on institutional culture. When successfully used a checklist brings the focus of health care on the patient and engenders teamwork. Also we have learned that implementing checklists is not that easy. It requires a

cultural change. Successful implementation requires ownership of the checklist by the entire health care team. The next generation of checklists is focused on emergency care and treatment.

I think the natural evolution of checklists has been the development of practice guidelines and most recently Enhanced Recovery After Surgery (ERAS) protocols. A recent Medline search conducted on May 29, 2017 on this subject generated over 3,500 publication in the last 10 years. There are ERAS protocols for almost all surgical procedures. These are put together by multidisciplinary teams including surgeons, anesthesiologist, internal medicine physicians, nursing, physical therapy, respiratory therapy, and patients. This in essence is a proactive and evidence-based postoperative care plan rather than a reactive plan based on personal preference and anecdote. Essential elements include preoperative glucose loading, a pain management plan, IV fluid volume reduction methods, prophylaxis for thromboembolism and postoperative infection, early ambulation, early enteric nutrition post op, and planning for postacute care (Mosquera C, Koutlas NJ, Edwards KC, et al. Impact of malnutrition on gastrointestinal surgical patients. *J Surg Res* 2016;205:95–101). ERAS protocols have resulted in reduction of hospital stays by 30% to 50% and similar decreases on postoperative complications.

When preparing for a marathon athletes “carbohydrate load” to reduce “breakdown of muscle.” Pogatschnik and Steiger (Review of preoperative carbohydrate loading. *Nutr Clin Pract.* 2015;30:660–4) reviewed carbohydrate hydrate loading. The current recommendation from the ERAS Society is to include preoperative carbohydrate–containing liquids (generally 12% carbohydrate in a maltodextrin form) prior to surgery. The rationale for this is that carbohydrate metabolism is greatly impacted by the fed state achieved by giving preoperative carbohydrate fluids prior to surgery in contrast to the traditional midnight preoperative fast. Carbohydrate-rich fluids enhance patient comfort prior to surgery. In addition they may reduce insulin resistance, reducing catabolism, resulting in improved perioperative glucose control and reduced muscle breakdown. However, the benefits of preoperative carbohydrate fluid loading are difficult to prove. Outcome is often more related to the type of surgery and other factors. The use of carbohydrate-loading protocols is appealing as it is simple and engages in patients. There is evidence from animal studies that carbohydrate loading increases spontaneous postoperative food intake, maintains the intestinal barrier function and muscle catabolism. No doubt further study is required. Preoperative carbohydrate loading is just one of the myriad of interventions linked to the success of ERAS protocols.

Pain management is a critical aspect of postoperative management. Pain management does not mean more narcotics. With the raging opioid epidemic in the United States, more emphasis has been placed on techniques to reduce perioperative narcotics. This includes liberal use of epidural techniques, neuroaxial opiates (intrathecal morphine), alternative to opiates such as anti-inflammatory medication to reduce inflammation and use of gamma-

aminobutyric analogs to reduce treat nerve pain, and nerve blocks. Transversus abdominal pain (TAP) block has been shown to be an effective method of postoperative pain control. Brogi et al. reported a systemic review and meta-analysis of this technique. (Brogi E, Kazan R, Cyr S, et al. Transversus abdominal plane block for postoperative analgesia: a systematic review and meta-analysis of randomized-controlled trials. *Can J Anaesth* 2016;63(10):1184–96.) They identified 51 trials and reported that compared with placebo, TAP block reduced the pain scores and morphine consumption. TAP block proved beneficial in gynecologic surgery, appendectomy, inguinal surgery, bariatric surgery, and urologic surgery. However, in separate studies comparing intrathecal morphine with TAP block revealed that the former seemed to have a greater analgesic efficacy. Reducing opiates at discharge is considered an essential element in fighting the opioid epidemic. Current guidelines suggest that at discharge patients should receive less than 200 mg oral morphine equivalents. A study by Thiel and colleagues, from the Mayo Clinic, reported at the annual meeting of the American Surgical Association in April 2017 is instructive in this regard. This study, based on the National Surgical Quality Improvement Program data, showed that 75.2% of 5,756 opiate naïve received greater than 200 OME at discharge. This indicates that we have a long way to go to achieve this goal. ERAS pain management programs may lead to more prescribing practices aligned with current opiate guidelines.

There has been much debate about the use of mechanical bowel preparation in colon and rectal operations. Do they reduce skin and soft tissue infection and anastomotic leak or do they create more problems with dehydration and associated complications. Indeed in the 6th edition of this text there was a statement that such a preparation was no longer necessary. We have come full circle in the last 5 years. There are increasing reports about the efficacy of mechanical bowel preparation and oral antibiotics in reducing anastomotic leak and wound infection. Rencuzogullari et al. (Predictors of anastomotic leak in elderly patients after colectomy: nomogram-based assessment from the American College of Surgeons National Surgical Quality Program Procedure-Targeted Cohort. *Dis Colon Rectum* 2017;60:527–36) assessed data from the National Surgery Quality Program to determine predictors of anastomotic leak in patients greater than 65 years. A total of 10,392 patients were analyzed, and anastomotic leak occurred in 332 (3.2%). Factors associated with an increased risk of anastomotic leak were “ASA score III and IV ($p < 0.001$), chronic obstructive pulmonary disease ($p = 0.004$), diabetes mellitus ($p = 0.003$), smoking history ($p = 0.014$), weight loss ($p = 0.013$), previously infected wound ($p = 0.005$), omitting mechanical bowel preparation ($p = 0.005$) and/or preoperative oral antibiotic use ($p < 0.001$), and wounds classified as contaminated or dirty/infected ($p = 0.008$).” Increasing evidence is accumulating that ERAS for colon and rectal surgery should include bowel prep and oral antibiotics.

As for the future, I predict that when the 8th edition of Mastery is published

that many more ERAS protocols based on the metabolic response to surgery and disease and the molecular basis of risk will be developed with widespread implementation.

3 Enteral Nutrition Support

Keith R. Miller and Robert G. Martindale

INTRODUCTION

Clearly, pre-existing nutritional and metabolic deficiencies predispose patients to significant morbidity and mortality following major surgical insult and critical illness. Despite overwhelming acceptance of this principle, meticulous strategies regarding peri-operative nutrition support have not been widely adopted. The practicing surgeon must be able to consistently identify patients at increased nutrition risk and initiate appropriate nutrition support measures in order to optimize outcomes.

Enteral Nutrition

Dating to ancient Egypt and Greece, the importance of nutrition support during periods of illness has been appreciated. Early attempts to facilitate substrate provision in patients unable to tolerate volitional intake involved the colonic delivery of wine, eggs, and other foods via enemas. This practice continued into the late 19th century as nutrient enemas were given to President James Garfield following his assassination attempt from which he eventually succumbed 80 days after sustaining his injuries. These practices provided the foundation for the evolution of more proximal enteral access options to optimize absorption. Eel skin was utilized for the first reported “feeding tube” in 1598, followed by gastric feeding reports by John Hunter in 1790, and naso/orojejunal feeding tubes described by Ravdin and Stengal in 1939. Throughout this history, surgeons have been instrumental in the development of current enteral formulations as well as techniques utilized to obtain enteral access throughout the proximal gastrointestinal (GI) tract through increasingly less invasive means.

The enteral route remains optimal for the delivery of energy substrates. Oxygenation, perfusion, and substrate provision are fundamental requirements at the cellular, organ, and system levels. Macro and micronutrient absorption and incorporation are required for continual remodeling, tissue repair, and maintenance of structure and function.

Metabolic demand increases following surgery, burns, critical illness, and trauma to address increased requirements for tissue repair and to mount an appropriate inflammatory and reparative response to the insult. In addition to expertise in technical aspects of enteral access allowing for the delivery of nutrition support, surgeons have been instrumental contributors to our evolving understanding of the metabolic response to physiologic stress. Despite these contributions, nutrition support has remained an underemphasized and underutilized adjunctive measure in the care of the surgical patient. The last decade has seen resurgence in interest in critically examining the evidence supporting our nutrition support strategies. This increased scrutiny has culminated in significant recent contributions to the evidence available to assist with clinical decision making.

In the surgical, trauma, and critical care setting, increasing caloric deficits have consistently been demonstrated to be associated with poor outcomes, likely at least in part by serving as a marker for disease severity. Traditional objectives in nutrition support have involved emphasis on adequate provision of protein and calories in order to preserve lean body mass and to prevent metabolic complications associated with prolonged macro- and micronutrient depletion. There has been a recent paradigm shift as the focus has now become a multimodality approach composed of appropriate nutrition therapy, adjuncts to modulate the immune and metabolic response, and the prevention and treatment of oxidative cellular injury. The acknowledgment that nutrition support strategies can result in improved outcomes should also remind the clinician that inappropriate strategies can result in significant harm.

NUTRITION ASSESSMENT

The concept of nutrition risk has emerged over the last decade, replacing older categorizations of malnutrition. Malnutrition has proven to be exceedingly difficult to define in a meaningful way, and current definitions encompass distinctions for acute and chronic illness. The primary objective of nutrition assessment is to allow for identification and stratification of patients at risk for poor outcomes as a result of pre-existing nutritional status. Nutrition risk takes into account both pre-existing nutritional status in addition to disease severity. As will be discussed, there are significant limitations inherent in the available nutrition assessment tools and none are considered perfect. The ability to appropriately identify patients at nutrition risk is more important for the

practicing surgeon than the ability to assign an overall severity of malnutrition. The rate limiting step in the identification of nutrition risk is most commonly the surgeon's willingness to utilize any of the available tools in clinical practice.

Anthropometric and Body Composition Assessment

Although methods for the assessment of body composition have been developed, they are generally expensive, invasive, and inconvenient with limited applicability in the hospital setting. Anthropometrics involve the attempted quantification of body composition through multiple pre-determined measurements. Body weight and height are the most commonly obtained parameters and allow for determination of body mass index (BMI) expressed in kg/m^2. Increased morbidity and mortality are associated with both ends of the BMI spectrum, particularly <20 and >40. Dry weight, or usual weight, should be used in the setting of organ insufficiency to improve overall validity.

Skin fold thickness assessment (with the use of calipers) and mid-arm circumference (MAC) measurements have been used as surrogates for determining body fat composition. Bioelectric impedance (BIA) estimates fat-free mass by determining differences in electrical conductivity (as muscle has far greater conductivity than fat) as a current is transmitted through various tissues. The two predominant drawbacks in using either BIA or anthropometrics in the clinical setting include significant inter-observer variability and the fluid shifts and peripheral edema associated with resuscitation, capillary leak, and organ failure. Although useful in study populations, these tools are of little to no value in the hospital setting.

There has been recent enthusiasm surrounding the utilization of information derived from computed tomography (CT) and ultrasound as tools to assess body composition. With CT, quantification of lean body mass in a standardized fashion at the level of the third lumbar vertebrae (psoas) can now be relatively accurately determined through the utilization of varying tissue densities associated with adipose and muscle tissue. Diminished lean body mass, as calculated using these methods, has been demonstrated to be associated with poor outcomes in critically ill and cancer patients irrespective of BMI and other traditional measures. The lean body tissue using axial CT at L3 has been shown to be the best predictor of outcome for the majority of visceral malignancies. Ultrasound

has become readily accessible in the majority of intensive care units (ICUs), and attempts have been made to standardize techniques for evaluating muscle content in the thigh. Because of the relative commonality of CT imaging in surgical practice and availability of ultrasound, this will likely become increasingly more important as a component of nutrition assessment.

Functional Tests

Poor global functionality prior to insult will clearly yield poor outcomes. Much of the information relevant to functionality can be elicited during the history component with simple questions regarding ability to walk up a flight of stairs and involvement in activities of daily life. Muscle strength should be subjectively assessed at the bedside. Additional traditional adjuncts including hand dynamometry and immune competence testing have significant limitations and are not widely incorporated. Hand dynamometry correlates with functional recovery following critical illness but requires patient cooperation for assessment. Immune competence, as measured by delayed-hypersensitivity skin tests and lymphocyte counts, is subject to multiple confounding issues in the surgical and ICU populations and is of limited utility. Elements relevant to functional status should be noted acknowledging the patients baseline status (from history) in conjunction with bedside assessment of muscle strength and there is little gained from additional testing.

BIOCHEMICAL ASSESSMENT

Serum Creatinine and Nitrogen Balance Studies

Serum creatinine can provide some insight into the overall lean body mass as lower values can be attributed to lower muscle mass. Collection of urinary creatinine over 24-hour periods can be used to calculate creatinine-height index (CHI) based on the assumption that 20 kg of muscle is required to produce 1 g of creatinine. Given the multiple confounders associated with serum creatinine (dietary intake and renal insufficiency) and difficulties in accurate 24-hour collection, these variables provide limited information in the surgical population and values must be considered individually within the clinical context to have any value.

Amino acid metabolism and protein catabolism result in the production of nitrogen that is subsequently eliminated in the urine (urea). Urinary urea

nitrogen can then be collected over a 24-hour period and compared to intake in order to estimate nitrogen balance. A positive balance (2 to 4 g/day) would suggest whole body anabolism, and negative balances would be indicative of ongoing catabolism. Nitrogen balance g/day = (protein or amino acid intake/6.25) - (UUN + 4).

Additional estimates for insensible losses are included in the equation and are prone to inaccuracy in the setting of increased nitrogen losses (large wounds, high output fistulas/ostomies, and diuresis). Due primarily to these issues regarding accuracy of nitrogen intake and losses, nitrogen balance studies have significant limitations in clinical practice.

Serum Proteins

Because of the relative ease of obtaining visceral protein levels such as serum albumin, pre-albumin, transferrin, and retinol-binding protein, these parameters have unfortunately become synonymous with the biochemical assessment of nutritional status. In fact, they are merely surrogate markers for nutritional status and may better be surrogate markers indicative of ongoing inflammation. However, in the preoperative state, these values remain powerful prognostic indicators of surgical outcomes as demonstrated in the large VA Cooperative trial. Accurate biochemical markers for the sole assessment of nutrition risk have proven elusive. The evaluation of serum protein concentrations must consider synthesis, degradation, and distribution all of which can be impacted by the clinical context in which they are measured. Albumin serves several key physiologic functions including maintenance of colloid oncotic pressure, transportation of fatty acids, bile acids, cholesterol and metal ions, and has antioxidant potential. The half-life of albumin is 20 days, whereas pre-albumin has a half-life of 48 hours. This shorter half-life has led to pre-albumin becoming the more commonly assayed parameter in the settings of preoperative nutrition support and in the ICU.

The relevance of serum proteins to nutritional status must be viewed skeptically. Distribution is impacted by volume shifts from the intravascular to extravascular spaces, and hepatic reprioritization markedly alters synthesis. Hepatic reprioritization describes increased synthesis of acute phase proteins (such as C-reactive protein, fibrinogen, and alpha 1-antitripsyn), while the synthesis of constitutive proteins such as albumin (so called negative acute phase reactants) is decreased. Protein synthesis generally returns to baseline over several days following the insult unless

additional insults are incurred. In fact, serial monitoring of CRP: prealbumin ratios can often allow clinicians to anticipate the onset of secondary infectious complications in the hospital setting prior to overt symptomatology.

Nutrition Assessment Tools

Given the limitations discussed above, the history and physical examination remain the cornerstones of nutritional assessment. Multiple bedside tools have incorporated within their framework nutrition-specific variables in order to organize relevant parameters. Included in nearly every nutrition screening set are questions concerning unintentional weight loss and dietary tolerance. Unintentional weight loss, regardless of BMI, >5% (over the preceding month) or >10% (preceding 6 months) is the single most important factor in the assessment of nutrition risk.

In an attempt to organize these components, a multitude of nutritional assessment tools (SGA, MUST, NRS, etc.) have been developed and are composed of history and physical elements specific to nutrition risk. Unfortunately, many of these existing tools are complex, exhaustive, and unusable in clinical practice. However, the NRS-2002 is relatively easily applied and is composed of a nutritional impairment section (score 0–3) in addition to severity of disease section (score 0–3) resulting in a total score between 0 and 6 (Fig. 3.1). The NRS-2002 has been validated both in the perioperative setting and in critical illness as a predictor of morbidity and mortality. In the elective surgery setting, the magnitude of the surgical insult is considered a surrogate for disease severity as longer, more invasive procedures result in more dramatic metabolic alterations. By applying the NRS-2002 in both the hospital and outpatient settings, resources and time wasted on historical nutrition assessment maneuvers (body composition analysis, nitrogen balance studies, etc.) can better be dedicated to the development of individualized nutrition support strategies commiserate with nutrition risk.

Summary: Nutritional Assessment of the Surgical Patient

A thorough nutrition assessment in the surgical ICU includes one of the earlier described tools, composed primarily of physical examination and dietary history in conjunction with injury severity assessment. In the outpatient and elective surgery setting, a serum albumin should be obtained as well. Despite the problems associated with using albumin

following physiologic insult, albumin remains an excellent and inexpensive marker and has been demonstrated to share a nearly direct linear correlation with risk of major complication and death following surgery.

METABOLIC ALTERATIONS FOLLOWING INSULT

Severe illness is characterized by hypermetabolism, catabolism, and immune dysregulation, and metabolism during these periods differs markedly from times of health. Multiple factors contribute to this individualized response, including age, gender, genetic influences, body habitus, functional status, and pre-existing nutritional status. Seemingly similar insults can result in markedly different magnitudes of response in different individuals. In order to mount and sustain this response, readily available fuels are rapidly exhausted and there is reliance upon mobilization of endogenous fuel sources composed of protein, glycogen, and adipose. In addition, micronutrients are utilized quickly serving as co-factors in multiple biochemical processes and decreased serum levels are observed during critical illness. Readily available calories are minute (113 calories), as Cahill described 40 years ago. The largest caloric reservoir resides in visceral and peripheral adipose, but access to these stores varies markedly depending upon the presence (critical illness) or absence (starvation) of underlying inflammatory processes.

Fuel Utilization: Starvation Versus Hyperdynamic States

In the absence of exogenous fuel source, glycogenolysis (primarily from the liver) occurs in the first 2 to 4 hours in order to sustain obligate glucose dependent tissues. Additional energy is provided from mobilization of lean body mass that yields gluconeogenic substrates. Proteolysis, characterized by increasing urinary urea nitrogen, peaks during days 2 to 10 in the setting of starvation and replaces glycogen as the source of glucose, via gluconeogenesis. There are concomitant increases in lipolysis and ketogenesis that serve as the predominant energy sources due, in part, to alterations in insulin–glucagon ratios. Proteolysis subsequently decreases during the prolonged protein conservation stage of starvation. The central nervous system transitions to the use of fatty acids and ketones derived from adipose stores. The rate of weight loss is greatest during the first several days of starvation and stabilizes over the following days and weeks as resting energy expenditure (REE) decreases. The objective of these

underlying mechanisms is the avoidance of lean body mass mobilization and reliance upon endogenous fat stores for the provision of energy during prolonged starvation.

Following stress, there are significant changes in metabolism when compared to the state of unstressed starvation. This classically described response is characterized by increased circulation of mediators, including cortisol, ACTH, epinephrine, glucagon, growth hormone, and inflammatory cytokines. Liver synthetic activity increases as acute phase reactants are upregulated. REE increases substantially, peaks at 10 to 12 days following severe insult, and can remain persistently elevated for weeks following the insult before returning to baseline. The hypermetabolic response is characterized by fevers, increased oxygen and glucose consumption, accelerated proteolysis, insulin resistance, hyperglycemia, and increased oxidative stress.

Glycogen, during periods of stress, is rapidly mobilized and utilized within the first 4 to 6 hours. Gluconeogenesis continues at an accelerated pace, primarily from protein conversion to carbohydrate resulting in rapid and prolonged loss of lean body mass in the setting of persistent insult. Increased levels of glutamine and alanine are released from the muscle diverting glutamine to the GI tract and alanine to the liver for gluconeogenesis. Hyperglycemia results from accelerated gluconeogenesis and relative peripheral insulin resistance resulting in decreased peripheral glucose uptake. Increasing insulin resistance has been demonstrated relative to the severity or magnitude of surgical insult (laparoscopic vs. open interventions) as well. Additional protein is sacrificed in order to provide amino acids for the production of acute phase reactants (CRP, transferrin, cytokines, etc.), and visceral protein synthesis is downregulated resulting in rapid reductions in serum albumin. Due largely to advances allowing for rescue of patients in the setting of acute illness, prolonged critical illness has become increasingly common as patients continue to utilize protein at the expense of lean body mass. This prolonged state of catabolism has resulted in patients seemingly recovering from their initial injuries only to eventually succumb in long-term acute care facilities long after their initial injuries. Unfortunately, the triggers that induce the shift toward adipose utilization during periods of unstressed starvation have yet to be fully elucidated. This explains the inadequacy and futility of simple caloric provision in the setting of prolonged critical illness and suggests that a multimodality approach consisting of physical

therapy (resistance exercise), glycemic control, and substrate provision to be a more beneficial approach.

Nutrition Assessment - Nutrition Risk Screening (NRS 2002 System)*

Initial Screening

BMI <20.5?	Yes	No
Weight loss in last three months?	Yes	No
Reduced dietary intake in past week?	Yes	No
Severe illness?	Yes	No

Final Screening (Complete if "yes" to any of above questions)

Part I Impaired Nutritional Status

Absent	Score 0: Normal nutritional status
Mild	Score 1: Wt loss >5% in three months or food Intake <50–75% normal in last week
Moderate	Score 2: Wt loss >5% in last two months or BMI 18.5–20.5 Or food intake <25–50% normal in last week
Severe	Score 3: Wt loss >5% in last month (>15% in last 3 mos) Or BMI < 18.5 + impaired general condition Or food intake 0–25% normal in last week

Part II Severity of Disease

Absent	Score 0: Normal nutritional requirements
Mild	Score 1: Hip fracture, chronic patients (hemodialysis, diabetes, cancer, cirrhosis, COPD) with acute complication
Moderate	Score 2: Major abdominal surgery, stroke, severe pneumonia, hematologic malignancy
Severe	Score 3: Head injury, bone marrow transplantation, APACHE II score >10

Total Nutritional Risk Score

Part 1 Impaired NS score____ + Part II Severity of Disease Score____ + 1 (if age >70)____ = _____Total
[If total of 3 or more, nutritional support is indicated]

Consider Disease Severity and Comorbidities

Severity of Illness: Calculate score, as indicated by patient ICU admitting diagnosis
APACHE II, SOFA, Ranson, ISS,

Pre-existing conditions:

Diabetes mellitus?	Yes	No	If yes, carefully target glucose control
Liver Dysfunction?	Yes	No	If yes, carefully monitor protein tolerance
Renal Dysfunction?	Yes	No	If yes, carefully monitor protein tolerance
Alcohol abuse and related malnutrition?	Yes	No	If yes, carefully monitor for refeeding syndrome
Drug abuse and related malnutrition?	Yes	No	If yes, carefully monitor for refeeding syndrome

Determining Energy Requirements

Indirect Calorimetry if available:

Calories:

BMI <30:	**Use 25–30 kcal/kg ABW/day _____ kcal**	**ABW = Actual Body Weight**
BMI 30–50:	**Use 11–14 kcal/kg ABW/day _____ kcal**	**IBW = Ideal Body Weight**
BMI >50:	**Use 22–25 kcal/kg IBW/day _____ kcal**	

Protein:

BMI <30:	**Use 1.5–2.0 gm protein/kg ABW/day _____ gms protein**
BMI 30-40:	**Use 2.0 gm protein/kg IBW/day _____ gms protein**
BMI >40:	**Use 2.5 gm protein/kg IBW/day _____ gms protein**

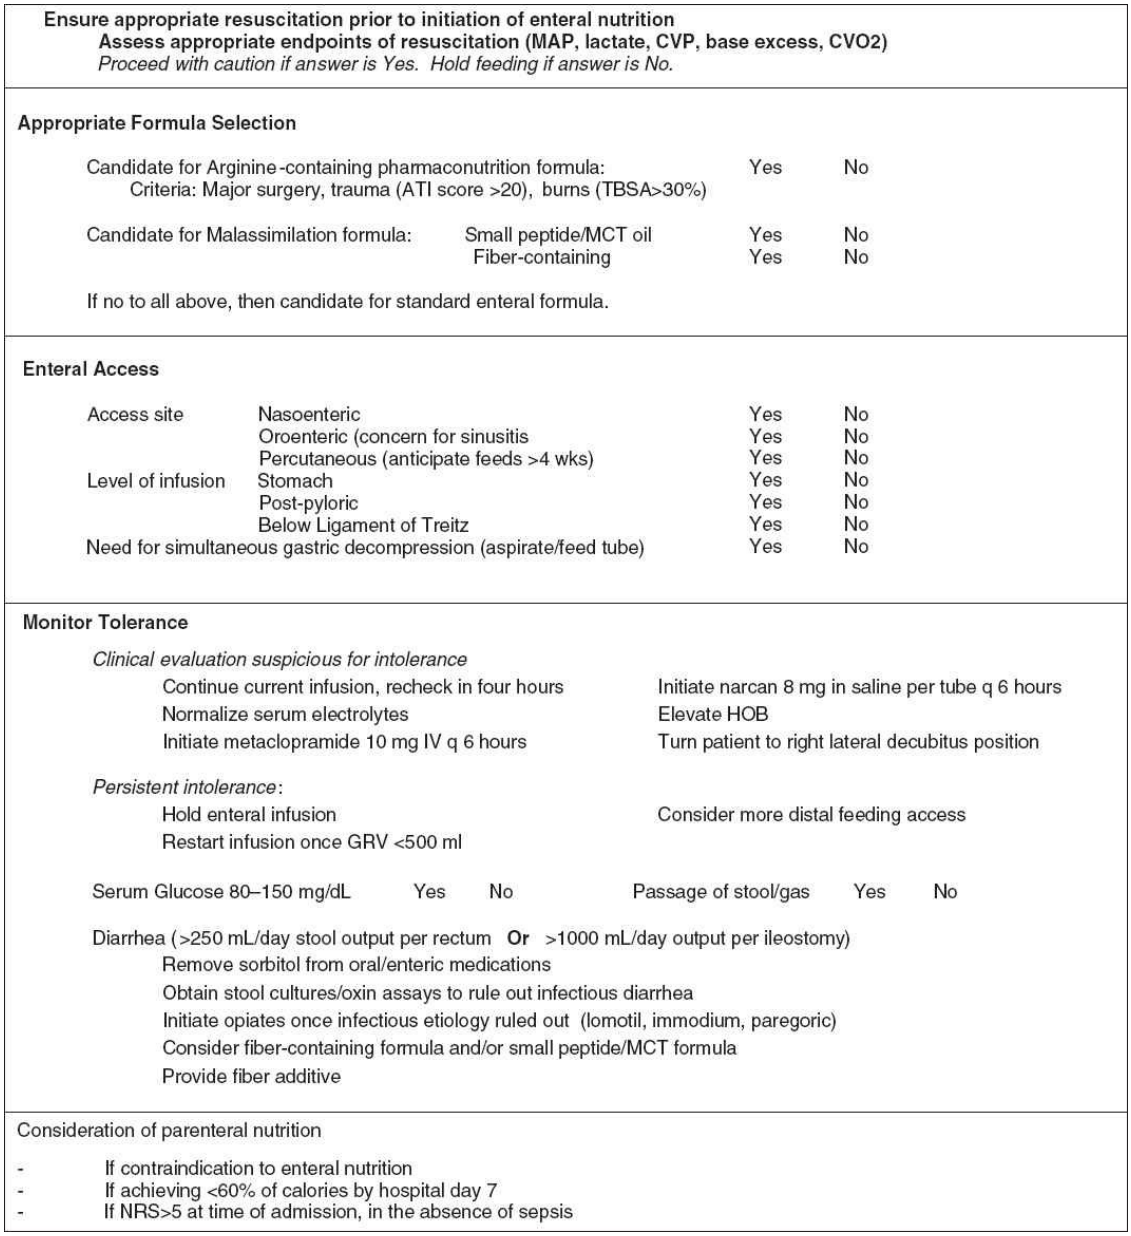

Figure 3.1. Synopsis of nutrition support algorithm. (Adapted from Miller KR et al. "Can we feed. "CAN WE FEED?" A Mnemonic to Merge Nutrition and Intensive Care Assessment of the Critically Ill Patient *JPEN J Parenter Enteral Nutr* 2011;35(5):643–59; copyright © 2011 by SAGE Publications, Inc; reprinted by Permission of SAGE Publications, Inc.)

ENERGY AND PROTEIN REQUIREMENTS

The determination of energy requirements has traditionally involved provision of substrate in quantities that meet resting energy requirements (REE) in addition to supplemental calories to address hypermetabolic alterations associated with illness. The traditional objective of substrate provision is to avoid the relentless assault upon lean body mass for energy

utilization. Unfortunately, the metabolic alterations discussed above limit the efficacy of simple exogenous substrate provision with regard to fuel utilization. Although appropriate caloric and protein dosing remain controversial, recent observational studies have suggested that 80% of goal calories is optimal with protein delivery up to 2.0 or 2.5 g/kg/day in the setting of major surgery and surgical critical illness.

Caloric Requirements

REE refers to the amount of energy (in kcal) required for ongoing function over a 24-hour period during the resting state. The gold standard for the determination of REE is indirect calorimetry (IC). IC involves the determination of REE through measurement of carbon dioxide production and oxygen consumption during steady-state conditions. Experienced personnel, cost, and patient confounders (high FiO_2 requirements, chest tubes, inability to achieve steady state) somewhat limit the applicability of IC. For these reasons, multiple predictive equations based predominately on body weight have been developed to assist in the determination of energy requirements. Predictive equations, although easily applied, have limitations including the tendency to overestimate caloric requirements. In the absence of these equations, estimates can generally be determined for short-term therapy simply by multiplying 25 to 30 kcal by ideal body weight in kilograms to determine caloric needs. Because of the inaccuracy of predictive equations when compared to IC in the setting of obesity, hypocaloric feeding strategies (60% to 70% of goal) are generally preferred. Current American Society of Parenteral and Enteral Nutrition (ASPEN) guidelines suggest, in the absence of IC, 11 to 14 kcal/kg/day of actual body weight (ABW) in patients with a BMI 30 to 50, and 22 to 25 kcal/kg/day of ideal body weight (IBW) in patients with BMI >50.

Protein Requirements

The recommendation for healthy unstressed adults is as least 0.8 g/kg per day but surgery or metabolic stress can result in substantial increases in protein requirements. The minimum amount of protein provided would ideally achieve nitrogen balance, although this is exceedingly difficult in critical illness and difficult to measure accurately. According to the recent ASPEN/SCCM guidelines, 1.5 to 2 g/kg of protein is recommended in the setting of critical illness and following major surgery. Recent data since the Guideline publications have shown fairly conclusive evidence to

support increasing the protein intake in severely stressed to up to 2.5 g/kg/day. In obese patients, targets should be 2 (BMI 30 to 40) to 2.5 mg/kg/day (BMI >40). Protein should rarely be withheld in the setting of organ failure or to prevent the need for dialysis in critically ill patients and, in fact, increased protein replacement (2.5 g/kg/day) is recommended in the setting of continuous renal replacement therapy due to substantial amino acid losses.

MACRONUTRIENTS: ABSORPTION AND UTILIZATION

The body is composed of 55% to 60% fluids with the majority of this being intracellular fluid. The solid component, consisting of roughly 30 kg in the 70-kg man with minimal body fat, is composed of 15-kg protein, 10-kg lipids, 3 kg of minerals, and 2 kg of carbohydrates. Each of these macronutrients is utilized in the maintenance of structure and ongoing function and has unique properties that determine the complexity by which they are absorbed and incorporated.

Carbohydrate

Carbohydrates yield 4 kcal/g of energy and are available for rapid utilization. Carbohydrate provision should be optimized to result in sparing of protein without resultant hyperglycemia. In addition to energy provision, carbohydrates are important in membranes as glycoproteins and glycolipids, as well as in the carbon backbone of lipid and nonessential amino acids. Carbohydrate is stored as glycogen that is housed in the liver, skeletal muscle, and cardiac muscle. Glycogen stored within the liver is most readily accessible and is the only systemically available free glucose source. Because of the absence of the enzyme glucose 6-phosphatase (the final step of glycogenolysis), muscle glycogen is used primarily by the muscle itself and is not readily available to other tissues.

Dietary carbohydrates consist of mono- and disaccharides, in addition to large molecular weight polysaccharides such as starch and glycogen. Fibers are large, indigestible sugars. Enteral formulas contain both simple sugars and starches, and these contribute to osmolality, sweetness, and digestibility. In general, the larger molecular weight carbohydrate molecules (e.g., starch) exert less osmotic pressure and require more digestion prior to absorption than simple sugars.

Enterocytes absorb carbohydrate exclusively as monosaccharides. The predominant three carbon sugars are glucose, galactose, and fructose, and

absorption occurs via multiple glucose transporters. Larger sugars require complete digestion in the intestinal lumen before absorption can occur. Starch and glycogen are substrates for the endosaccharidase α-amylase, which is secreted from the pancreas (and less so in the saliva) in response to a large intake of starch. The di- and oligosaccharides arising from α-amylase digestion are further broken down to monosaccharides by enterocyte surface saccharidases. Fiber in the diet is available as soluble and insoluble, but both are indigestible carbohydrate that occur naturally in food and cannot be broken down by the above enzymes in the small bowel. These soluble oligosaccharides remain unaltered through the proximal GI tract until fermented by colonic flora (e.g., bifidobacteria) producing lactate, acetate, butyrate, and other short chain fatty acids (SCFAs). SCFAs not only serve as the primary fuel source of the colonocyte but have recently been shown to have major regulatory influence on the maintenance of not only mucosal integrity but immune function. The additional byproducts of fermentation (lactate, acetate) assist in the maintenance of a suitable local environment within the GI lumen promoting proliferation of microbiome, which deters proliferation of pathogenic bacteria (*Clostridium difficile*) or the conversion to a "pathobiome."

Protein

Protein provides 3.5 kcal/g when utilized as an energy source, but no storage form of protein exists and all protein should be considered functional. Total body protein accounts for only 15% to 18% of body weight in a healthy man. Proteins and amino acids serve as enzymes, hormones, neurotransmitters, immunoglobulins, transporters, and are components of essential cell function including receptor binding, transport systems, and contractile elements. Obligate protein turnover rates of 2.5% of total body protein occur daily in adulthood, and these rates decrease with aging.

Protein intake is composed largely of intact protein, some free amino acids and peptides, and endogenous proteins. Protein digestion within the GI lumen is "incomplete" resulting in a mixture of free amino acids and oligopeptides with much of the subsequent conversion to free amino acids occurring within the luminal epithelial cell. Di/tripeptides, primarily in the proximal small bowel, are transported via the peptide transporter PEPT1 into the enterocyte accounting for the majority of protein uptake from a

meal, with individual amino acid transporters accounting for a lesser role. In addition to intake, significant protein recycling occurs arising from saliva, gastric, biliary, pancreatic, intestinal secretions as well as desquamated epithelial cells of the GI tract and can account for reabsorption of 50 to 60 g of protein per day.

Lipids

Complete oxidation of lipids results in 9 kcal/g, and adipose is the major metabolic energy reserve with an estimated 140,000 calories in a 70-kg male. In addition to serving as a storable energy source, lipids are integral in cell membrane structure due to their nonpolar and hydrophobic properties and are required for absorption of fat soluble vitamins (D, E, A, K). Lipids serve as lubricants for body surfaces, joints, and mucous membrane and are precursors for prostaglandin synthesis, thereby playing key roles in cell signaling, gene expression, and inflammation.

Following absorption, lipids are eventually stored (lipogenesis) or utilized for energy via ketogenesis or lipolysis. Beta-oxidation results in the production of fatty acyl-CoA in the outer mitochondrial membrane, which is then transported via a carnitine carrier to the inner membrane. Ketogenesis is generally triggered in the absence of available glucose to serve as an alternative fuel source and occurs primarily in the liver. Finally, lipogenesis is triggered by increasing mitochondrial concentrations of acyl-CoA derivatives (malonyl-CoA), thereby shunting acetyl-CoA to fatty acid and triglyceride synthesis and secretion from the liver as very low density lipoproteins (VLDLs) for storage.

In contrast to carbohydrates and proteins, lipids are poorly soluble in aqueous solutions and require several steps in order to transition from the GI tract to the blood for utilization. Because of these complexities, lipid absorption is particularly vulnerable during periods of altered physiology and illness. Dietary lipids are characterized by the relative length of the fatty acid chains linked to the glycerol backbone. Although long chain triacylglycerols (LCTs) have received recent scrutiny for poor utilization during periods of hypermetabolism and pro-inflammatory potential when given through the parenteral route, they are required for the provision of the essential fatty acids, linoleic and linolenic acid. Medium chain triglycerides (MCT), derived from tropical oils, have increased solubility relative to LCTs, are rapidly hydrolyzed, and require minimal pancreatic lipase or bile salts for absorption. MCTs can be transported via the

lymphatics or directly transported into the portal vein and do not require acyl-carnitine to cross mitochondrial membranes to be available for beta-oxidation.

Lipids encounter gastric lipase in the stomach and enter the proximal small intestine as small droplets. Pancreatic and biliary enzymes including lipase and co-lipase work at the oil–water interface in order to liberate free fatty acids and mono-acylglycerol. Phospholipase (phospholipids) and cholesterol esterase (cholesterol) activity forms mixed micelles that are then transitioned into the enterocyte via both passive uptake and carrier-mediated transport. Re-esterification occurs rapidly within the enterocyte forming triacylglycerol, phospholipids, and cholesterol esters in order to maintain low intracellular concentrations of free fatty acids to promote continued diffusion of fatty acids into the cell from the GI lumen. Re-esterified lipids are then transitioned into the endoplasmic reticulum and leave as VLDL or chylomicrons.

Vitamins and Minerals

Vitamins and minerals (trace elements) are essential substances that are not metabolized to carbon dioxide and water, unlike macronutrients, but instead facilitate and serve as cofactors in chemical reactions. Vitamins E, C, and β-carotene serve as nonenzymatic antioxidants and selenium, zinc, manganese, and iron facilitate enzymatic scavenger systems including superoxide dismutase, catalase, and glutathione peroxidase. The 13 essential vitamins include 8 B vitamins, ascorbic acid (C), and the fat soluble vitamins (ADEK). Vitamins and minerals are absorbed at various locations within the GI tract and predominately excreted in the kidneys. Deficiencies are often difficult to identify but can have catastrophic consequences when not recognized. Patients who have had major upper tract surgery, undergone bariatric surgery, or have significant loss of absorptive capacity (short gut) are the most common surgical patients in which vitamin deficiency is noted and must be monitored for.

ENTERAL NUTRITION

Benefits of Enteral Nutrition

Despite significant advances in parenteral support, enteral nutrition support remains the preferred nutrition support option in the hospitalized patient. Historically, when compared to parenteral nutrition, enteral

nutrition has resulted in improved patient outcomes with regard to morbidity, mortality, and cost and remains the route of choice in hospitalized patients. The objectives inherent in enteral support have transitioned from simple caloric and protein provision (nutrition support) to include the "nonnutritional" benefits (nutrition therapy) (Fig. 3.2). The GI tract serves as an internal integumentary system providing separation from the external environment (intraluminal toxins/bacteria) and this barrier function is essential to maintenance of homeostasis. In the absence of substrate within the GI lumen, villous atrophy and thinning of visceral mucous layers occur, which can be reversed with the provision of enteral nutrition. Physiologic stress can result in relative or absolute gut ischemia contributing to barrier function porosity, uncoupling of tight junctions, and increased permeability. Disruption in this barrier can result in translocation of bacterial cell wall fragments, free bacterial DNA, and cellular debris resulting in downstream activation of inflammatory cascades. The GI tract is a massive immunologic organ and contains approximately 60% of the body's immunoglobulin-producing cells with 80% of manufactured immunoglobulin secreted across the GI tract. The GI tract houses a significant proportion of our microbiome, and the GI ecosystem can be substantially disrupted during periods of illness resulting in increased virulence and pathogenicity of organisms. In addition to the underlying illness, many common medications including antibiotics, "GI prophylaxis" medications (H2 antagonists, PPIs), and opiates can contribute to bacterial overgrowth and alterations of the microbiome. Provision of enteral nutrition has been demonstrated to reduce permeability and membrane disruption, increase respiratory and GI IgA levels, attenuate the inflammatory cascade, and reduce bacterial virulence. Many of these nonnutritional benefits are likely achieved even in the absence of traditional "full caloric" support.

Contraindications

Contraindications to enteral nutrition support are few but must be recognized to prevent potentially catastrophic consequences. Bowel obstruction, loss of bowel wall integrity, persistent profound shock, acute peritonitis, GI ischemia, and inability to obtain enteral access are among accepted contraindications. Relative contraindications include high output fistula and paralytic ileus. GI intolerance, although often difficult to characterize, should not be considered an absolute contraindication to

enteral nutrition and can usually be addressed in a multimodal fashion to facilitate successful enteral support.

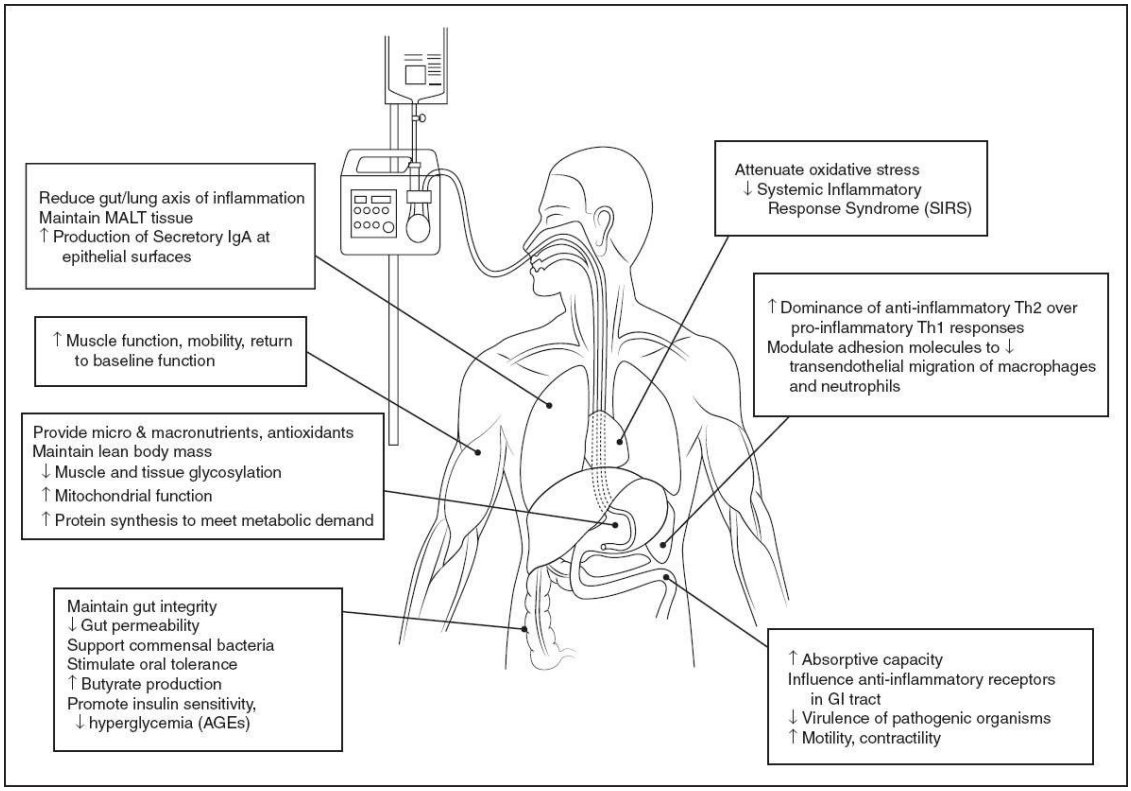

Figure 3.2. Benefits of enteral nutrition support. (From McClave SA, Martindale RG, Rice T, et al. Feeding the critically ill patient. *Crit Care Med* 2014;42(12):2600–10; with permission from Wolters Kluwer Health, Inc.)

Enteral Access

Enteral access is essential to successful nutrition support strategies and has become a multidisciplinary endeavor. A stepwise approach is appropriate in the hospital setting and is initiated with less invasive techniques such as naso/oroenteric access options. These large-bore tubes can also be utilized for decompression in the acute setting and later transitioned to feeding conduits. Various techniques are available for advancement of these tubes in a post-pyloric fashion and can be performed at the bedside with good success. In the event that longer access is required (typically >4 weeks), percutaneous access should be considered and is attainable in the stomach and jejunum via endoscopic and radiographic approaches. Surgical access remains exclusively within the domain of the surgeon and is now reserved only for the most complex patients where less invasive measures are prohibitive. When laparotomy is performed in the setting of critical illness,

the operating surgeon should always at least consider concomitant placement of enteral access via the appropriate route. As will be discussed later, careful risk–benefit analysis is imperative prior to surgical access procedures as they are not without complication (Table 3.1).

Administrative Methods of Enteral Nutrition

The administration of enteral nutrition support involves determining timing, level of infusion, dose and duration, and assessment of tolerance. Dosing has previously been discussed. The establishment of enteral nutrition support protocols has consistently demonstrated benefit with regard to caloric provision and should be adopted in order to address commonly encountered issues.

Timing of Initiation

It is generally accepted that the earlier enteral nutrition support is initiated, the better the outcomes with regard to the length of hospitalization and infectious complications. Much of this outcome has been attributed to the "nonnutritional" benefit of enteral nutrition discussed earlier including maintenance of barrier function and attenuation of the downstream inflammatory response. Early initiation has been recognized as within the first 24 to 48 hours following admission. This is most difficult in critically ill patients, and this may very well be the population where the impact is greatest. Initiation of enteral nutrition support should follow appropriate resuscitation and is generally avoided during periods of central hemodynamic instability or suspicion for splanchnic hypoperfusion. Permissive underfeeding strategies are easily implementable in the ICU and generally well-tolerated.

TABLE 3.1 Access Options in the Hospitalized Patient

Tube Type	Absolute Contraindications	Advantages	Disadvantages	Complications
Large bore Nasogastric/ Orogastric	Certain facial fractures/trauma	Avoid sedation Allows decompression	Blind placement Patient discomfort	Nasal septum necrosis, Tube malposition/ occlusion, Vocal cord paralysis Sinusitis, Tracheobronchial intubation, pneumothorax
Blind Nasojejunal Feeding Tubes	Certain facial fractures/trauma	Avoid sedation Cost Reduced aspiration	Blind placement Patient discomfort	Nasal septum necrosis, Malposition, Tube occlusion, Vocal cord paralysis Sinusitis, Tracheobronchial intubation, pneumothorax
Endoscopic Nasoenteric Tubes	Inability to pass the endoscope	Visual confirmation	Endoscopy Conscious sedation	Nasal septum necrosis, Tube occlusion Vocal paralysis, Sinusitis Scope trauma (perforation)
Percutaneous Endoscopic Gastronomy	Inability to pass the endoscope Relative: ascites, severe neutropenia	Long-term access	Endoscopy Conscious sedation	Bleeding, leakage, ulceration, inadvertent organ injury (colon, liver), peristomal wound infection, tube dislodgement, gastrocolic fistula, scope trauma (perforation)
Percutaneous Endoscopic Jejunostomy	Inability to pass the endoscope Relative: ascites, severe neutropenia	Long-term access Distal feeding	Endoscopy Conscious sedation	Bleeding, leakage, ulceration, inadvertent organ injury (colon, liver, small bowel), peristomal wound infection, tube dislodgement, scope trauma (perforation)
Radiologic Gastronomy	None	No endoscopic access required	Limited availability Conscious sedation	Bleeding, leakage, ulceration, inadvertent organ injury (colon, liver, small bowel), peristomal wound infection, tube dislodgement
Surgical Gastronomy/ Jejunostomy	None	Direct visualization	General anesthesia Laporatomy/ Laproscopy	Wound infection, inadvertent enterotomy/ organ injury, tube occlusion, wound dishiscence/hernia, complications of general anesthesia

Dosing and Permissive Underfeeding Strategies

Appropriate caloric revision in the critically ill patient remains in evolution. A teleologic argument can be made that a relative "anorexia of illness" develops after insult as a mechanism to avoid continued exposure of the host to substrate during a period where it simply cannot be utilized. Autophagy, or the degradation and recycling of nonfunctional intracellular debris, is essential to the maintenance of homeostasis and is suppressed in the setting of exogenous substrate. This has been a proposed mechanism as to how substrate provision during times of critical illness could be disadvantageous. Rather convincingly, recent evidence has suggested that permissive underfeeding can provide much of the benefit of "full" nutrition support in critically ill patients during initial phases of management (first 7 days) while at the same time minimizing the risk of overfeeding. Recent trials in heterogeneous ICU patient populations, perioperative patients in the ICU, and in acute lung injury have demonstrated "trophic" feeding rates to have equivalent outcomes when compared to traditional feeding strategies with regard to mortality, infectious complications, and hospital duration. Protein provision was similar between the groups, and the differences in caloric provision were predominately from carbohydrates. This has led to increased emphasis

upon the nonnutritional benefits of enteral support and protein provision in the ICU.

Level of Infusion

The level of infusion is characterized as gastric, duodenal (post-pyloric), or jejunal (distal to ligament of Treitz). In most surgical and critical care settings, it is common practice to attempt gastric feeding and only when unsuccessful more distal access is obtained. Tubes initially placed in the stomach can often migrate to more distal locations. Fortunately, gastric feeding is tolerated by the vast majority of patients. However, there are clinical scenarios where altering the level of infusion is desirable and can impact tolerance. In the setting of foregut reconstruction, jejunal access may be warranted in order to bypass tenuous anastomoses and prevent exacerbation of anastomotic complications. More distal tubes typically result in fewer aspiration events and are appropriate in patients with gastroparesis and those demonstrating intolerance to gastric feeding. Ongoing reassessment is necessary to achieve appropriate tolerance, and attempts should be made to advance tubes to more distal locations when intolerance is encountered.

Bolus, Intermittent, and Continuous Feeding Strategies

Bolus feedings, consisting of 200 to 500 mL (large amounts over a short time) of formula pushed via syringe several times per day, are the most physiologic and easiest method of administration. This method should only be utilized through the gastric route. They allow for limited access intervals, but patients should demonstrate adequate gastric emptying and the ability to protect their airway prior to initiation of this method.

Intermittent feeding refers to formula being infused over 20 to 30 minutes and is generally tolerated well. This method can be used with gastric and small bowel feeding tubes depending on the overall volume delivered.

Finally, continuous feeding is the most commonly applied strategy in the ICU. Infusion pumps administer smaller volumes over a 12- to 24-hour period and can be delivered through any available enteral access tube. GI intolerance is less common with this method than bolus or intermittent feeding strategies. Rates range from 10 to 50 mL/hr and are typically increased over several hours following initial administration. Feedings may be adjusted to nocturnal or cycled in order to increase appetite as the

patient transitions to oral intake. The obvious disadvantage to continuous feeding is the constant need for the tube to be accessed and connected to the infusion pump.

Monitoring Tolerance

GI intolerance has historically been defined by increased gastric residual volumes (GRVs) and clinical factors such as increasing distension, nausea, vomiting, and diarrhea. GRVs have come under increased scrutiny due to irreproducibility, highly variable methodology, and failure in recent randomized controlled trials to be of any utility. Clearly more important than GRVs, clinical examination remains the key component in assessment of tolerance. Abdominal distension, vomiting, and increasing pain suggest intolerance and demand attention. Diarrhea, defined as >250 g of liquid stool per day per rectum or >1,000 mL/day per ileostomy, is often attributed to tube feeds but is more commonly associated with sorbitol-based medications and other osmotic agents with enteral formulations being the causative agent in <20% of cases.

When intolerance is encountered, efforts should be continued to prevent aspiration. Measures to improve tolerance include the establishment of more distal feeding access and the use of prokinetic agents including metoclopramide and erythromycin. Institutional protocols designed to address intolerance clearly improve the overall efficacy of enteral nutrition support, particularly in the ICU setting, and should be incorporated (Fig. 3.1).

Enteral Formulations

Given the ubiquity of enteral nutrition support in the hospitalized patient, hundreds of enteral formulations have been developed and vary depending upon osmolality, renal solute load, caloric density, source of macro/micronutrients, soluble and insoluble fiber content, and various additives. Enteral products are classified as medical foods and do not require Food and Drug Administration (FDA) approval.

Osmolality, the preferred term in reference to enteral formulations, is essential to maintaining balances between extra- and intracellular fluids and ranges from 270 to 700 mOsm/kg in available formulas. Caloric density, ranging from 1 to 2 kcal/mL of formula, will impact osmolality as increasing densities are associated with increased osmolality and reduced amounts of free water composition. When calculating free water

supplementation, the concentration of water within the formula (generally approximately 80%) should be considered and additional free water is often appropriate with the use of high caloric density formulas. The renal solute load, composed predominately of protein, sodium, potassium, and chloride, can also impact free water requirements as renal excretion requires obligate water loss. The osmolality impacts GI tolerance and gastric emptying as gastric contents must generally reach iso-osmolarity prior to leaving the stomach. Concurrently administered medications (ranging from 450 to 11,000 mOsm/kg) can impact osmolality substantially and contribute to poor tolerance. In general, the more "broken down" the macronutrients (amino acids and simple sugars vs. proteins and starch) are within the formula, the higher the osmolality. Following attempts by NASA to develop chemically engineered diets to minimize fecal output during space travel, a multitude of disease-specific diets have become increasingly available in an attempt to simplify and individualize formula selection.

DISEASE-SPECIFIC FORMULATIONS AND ADDITIVES

Because of the ability to manipulate the various physical properties discussed above, attempts have been undertaken to develop disease-specific formulations in the setting of organ dysfunction. There is little evidence to support these formulations be used on a routine basis and standard high protein enteral formulations are appropriate in the vast majority of hospitalized surgical patients. The use of specific nutrients in surgical practice should be considered as part of an overall nutrition approach to the surgical patient, including treating undernutrition, optimizing lean body tissue when possible, and encouraging resistance exercise.

Pulmonary/Diabetic Formulas

Pulmonary formulas have been designed to provide higher fat to carbohydrate ratios in order minimize CO_2 production and manipulate the respiratory quotient (RQ). The RQ (CO_2 produced per O_2 utilized) is 1.0 for carbohydrate and 0.7 for fat. This lower RQ (CO_2 production) has been the basis for the development of relatively high fat (~45% to 55% of calories) and high caloric density enteral formulas. Ultimately, the goal is to minimize hypercapnia, reduce inflammation, and facilitate ventilator

weaning. Data regarding anti-inflammatory formulas and altered fat to carbohydrate ratios are lacking, and standard high protein formulas are recommended in these patients. The caloric density of enteral formulations is occasionally relevant in the setting of respiratory failure, and the use of higher density, fluid restrictive formulas can assist with minimizing overall volume repletion. High fat to carbohydrate ratio formulas utilizing fructose as a source of carbohydrates and additive fiber have been designed to assist with glycemic control in diabetic patients as well, but there are no supportive outcome data in the ICU or perioperative period.

Malabsorptive Formulas

Small peptide and MCT formulas, also referred to as semi-elemental formulas, have been developed for patients with reduced absorptive capacity or impaired digestion. Pancreatic insufficiency and malabsorptive disorders (inflammatory bowel disease) are common examples. MCTs, although lacking in essential fatty acids, can be absorbed directly into the portal vein across the small bowel interface dispensing with many of the complexities of lipid absorption. Soluble fibers are often utilized in this setting as well due to SCFA contributions and trophic effects on the GI mucosa. The high osmolarity and associated GI intolerance with these formulas is the major limitation for use in the clinical setting.

Renal Formulas

Historically, renal formulas consisted of reduced protein, potassium, magnesium, calcium, and phosphorus content, with the majority of available protein consisting of essential amino acids. Through the provision of essential amino acids, it was theorized that nitrogen recycling would allow for provision of nonessential amino acids, but unfortunately this does not appear to occur in the critically ill patients. Although renal formulas likely do have some benefit in patients with severe electrolyte abnormalities, protein requirements are substantially increased (due to increased protein loss) in the setting of renal replacement therapy and protein should not be withheld in the ICU.

Hepatic Formulations

The goal with formulas designed for use in patients with pre-existing liver disease is to manipulate the amino acid profile in order to minimize

increases in aromatic amino acids (AAA). Catabolism associated with liver disease results in increased utilization of branched-chain amino acids (BCAA) resulting in reduced BCAA:AAA ratios. This, in conjunction with hyperammonemia, is thought to contribute to encephalopathy as BCAAs move across the blood brain barrier and act as false neurotransmitters. Recent data would support the use of standard formulae in most settings of hepatic compromise and only resort to the high BCAA formulations in a very limited population Although some studies suggest reduced hospitalizations for encephalopathy in the outpatient setting, high protein standard formulas are preferred in the hospitalized and critical care setting.

Immune and Metabolic Modulation With Nutrition (Immunonutrition)

The concept that specific nutrients could modulate the metabolic response to surgery has been studied since the early 1980s. There are numerous nutrients that can alter or attenuate the immune and inflammatory components associated with surgery and trauma. Examples of metabolic modulating nutrients, or pharmaconutrition, include fish oils containing the omega-3 fatty acids (FA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA); amino acids such as glutamine, leucine, and arginine; antioxidants such as vitamin C and selenium; and probiotics and prebiotics. Current literature appears to support the benefit in the use of pharmaconutrition in the trauma and surgical ICUs, but data to support the routine use in medical ICU patients have not shown consistent benefit.

Recent animal and clinical research has led to the incorporation of omega-3 fatty acids into several enteral formulas. Omega-3 fatty acids found in fish EPA and DHA) have multiple beneficial effects in the perioperative period, including modulation of leukocyte function and regulation of cytokine release through nuclear signaling and gene expression. In addition, DHA and EPA are metabolized to a group of bioactive compounds called specialized pro-resolving molecules (SPMs), which play a role in accelerating the resolution of the inflammatory state. These SPMs stimulate the cardinal signs of resolution of inflammation, which include the cessation of leukocytic infiltration, a countering of the effects of pro-inflammatory mediators, stimulation of the uptake of apoptotic neutrophils, promotion of the clearance of necrotic cellular debris, and enhancement of the host’s ability to eliminate microbial

invasion. In contrast to EPA and DHA, omega-6 fatty acids are associated with higher inflammatory response and are precursors to leukotrienes, thromboxane, and prostaglandins, which are vasoconstrictive, and induce platelet aggregation. Data suggest that fish oil containing enteral formulations can lower total complications, anastomotic dehiscence, and potentially decrease mortality. Numerous reports using various in-vivo and in-vitro models suggest that the slight structural difference between omega-3 and omega-6 fatty acids supports the anti-inflammatory, antithrombotic, antiarrhythmic, hypolipidemic, and antiatherosclerotic effects of the omega-3 compounds.

Glutamine has been supplemented in the surgical and surgical critical care setting for the past three decades and until recently was a mainstay in surgical nutrition practice. Glutamine is a nonessential amino acid, which in times of trauma and severe catabolic illness is believed to become essential. Since the first descriptions of the benefits of glutamine in surgery and critical illness, multiple early studies reported benefit. Recently several multicenter trials have shown no clinical benefit of glutamine in the ICU and two large trials, REDOX and MetaPlus, suggested potential harm and increased mortality in the glutamine groups. Based on these trials, ASPEN/SCCM guidelines recommend against the use of supplemental parenteral glutamine to critically ill patients and should only be considered in specific situations.

In health, arginine is a nonessential amino acid. However, like glutamine, arginine is considered a conditionally essential amino acid due to endogenous supply falling short of demand during periods of physiologic stress. Over the past four decades, arginine has been used in the clinical setting for a wide variety of conditions from wound healing to pulmonary hypertension. Arginine is available to the host from the diet with the majority of arginine coming from endogenous production. Numerous studies, using differing doses of arginine from 5 to 30 g/day in the normal host, have shown generally beneficial results in the surgical population. It is estimated that, on average, a postop or SICU patient receiving an arginine-supplemented enteral feeding at goal delivery rates would receive between 15 and 30 g/day of arginine. The authors are unaware of any reports of toxicity when using immune modulation with arginine-containing formulations. Arginine acts via numerous mechanisms with immune function of key focus in the surgical population. Numerous reports have shown inadequate T-cell function with depleted arginine

availability and recent data show the importance of arginine in regulation and conversion of the M1 to M2 macrophage classes, which has been shown to enhance resolution of inflammation.

Lastly, since most studies in surgical patients have supplied arginine with other immune modifying agents (e.g., fish oils, arginine, glutamine and/or nucleic acids), the exact contribution of each agent has been difficult to discern. Potential metabolic interactions between arginine and other delivered nutrients must be considered. To date, the vast majority of clinical trials and meta-analysis using the arginine fish oil formulations have proven beneficial in surgical populations. These have been delivered and shown benefit as a pre-op formulation in order to modulate the metabolic response to the upcoming surgical insult or in both the pre-op and postop setting.

Antioxidant Additives/Supplementation

Numerous trials have reported a benefit from the provision of antioxidant cocktails to trauma and ICU patients. The most effective cocktails appear to contain selenium at higher doses, but the optimal combination and method of administration (bolus versus continuous infusion) are not clear. In the most recent large randomized control trial, combination therapy did not report any positive effects on outcome.

Probiotics and Prebiotics

Probiotics are defined as viable organisms that exert a beneficial health effect on the host when ingested in adequate amounts. Most probiotics are composed of anaerobic Lactobacillus and Bifidobacterium strains. Prebiotics are indigestible foods, such as oligosaccharides, that are ultimately fermented by colonic bacteria. Synbiotics are a combination of both prebiotics and probiotics. Given improved understanding regarding the importance of the microbiome in immunomodulation, colonization resistance, enhancement of the epithelial barrier, production of antimicroorganism substances, inhibition of pathogen adhesion, mucosal barrier support, and nutritional contributions, exogenous enteral administration of bacteria is now considered potential adjunctive therapy in the setting of acute and chronic illness.

The human microbiome has only recently been recognized as a key contributor to health and disease. The intestinal microbiome is diverse with over 1,000 species inhabiting the GI tract, and influences immune

function, host metabolism and physiology, nutritional status, and global well-being. Bacteria colonize the alimentary tract soon after birth, are altered throughout early growth and development, and later become relatively stable during healthy states in adulthood. However, periods of antibiotic exposure, surgery, illness, or even exposure to a new household pet can dramatically alter an individual's microbiome. The inhospitable environment created by gastric acid, bile, and constant peristalsis results in the proximal GI tract (stomach and small bowel) hosting reduced numbers and diversity of bacteria. The colonic microbiome is predominately composed of anaerobic bacteria (Bacteroides, Bifidobacterium, Clostridium, and Lactobacillus) with ratios of anaerobes to aerobes 100 to 1,000:1 and is essential to maintaining homeostasis within the colonic ecosystem. In addition to the inhibition of pathogen adhesion and enhancement of epithelial barrier function, colonic bacteria ferment insoluble fibers producing SCFAs that serve as fuel for the colonocyte, enhance macrophage function, and decrease microvascular thrombosis.

Following acute alterations in the microbiome as a result of physiologic insult, the concept of replenishing the "normal" microbiome has obvious theoretical advantages. Trials are highly variable with regard to dosing strategies, timing, and species administered. However, it is now well-established that prebiotics and probiotics can attenuate the inflammatory response, support the mucosal barrier, and improve immune function. Several meta-analyses have now shown benefits of probiotics in colorectal surgery, other visceral surgery, prevention of antibiotic associated diarrhea and *Clostridium difficile* diarrhea, and it has recently been shown to decrease sepsis in high-risk surgical cases.

ENTERAL FEEDING COMPLICATIONS

Enteral feeding, as with any other adjunctive therapeutic endeavor, is not without risk, and surgeons should be familiar with the recognition and management of these issues. The most common complications can be categorized as mechanical, metabolic, or GI.

GI complications include the clinical manifestations of GI intolerance. Nausea and vomiting occur in 10% to 20% of patients receiving enteral nutrition and is most commonly attributed to delayed gastric emptying. Abdominal distension and diarrhea are also commonly encountered issues and should warrant investigation. Aspiration is often cited as a reason for delaying the initiation of enteral nutrition and is a common occurrence

among critically ill patients. Interestingly, aspiration of GI contents does not appear to directly correlate with the development of pneumonia as this appears more closely linked to aspiration of oropharyngeal secretions. However, aspiration of significant amounts of tube feeding formulations or GI secretions can be catastrophic with resultant pneumonitis, adult respiratory distress syndrome (ARDS), and rapid respiratory decompensation. Avoidance of aspiration includes routine elevation of the head of bed to 45 degrees, utilization of continuous feeding strategies, reassessment of sedation and analgesia requirements, oropharyngeal decontamination, and distal feeding and use of prokinetic agents when appropriate. Patients deemed at high risk for aspiration or who have demonstrated prior intolerance to gastric feeds should undergo more distal access.

Not unlike parenteral nutrition support, much of the risk associated with enteral nutrition is related to the establishment and maintenance of access, and these are referred to as mechanical complications. Risk varies dependent on the access route undertaken as well as the skill and expertise of clinicians establishing access. Risk associated with the naso/oroenteric route includes sinusitis, tube dislodgement/occlusion (40% to 60%), and malpositioning (2%) with potential for pneumothorax and inadvertent administration of feeding into the tracheobronchial tree. Percutaneous gastrostomy and jejunostomy are infrequently associated with GI perforation, inadvertent organ injury (particularly the colon/stomach), and GI bleeding with a major complication rate of 1% to 3%. However, minor complications such as persistent leakage, erosion, and tube malfunction/dislodgment are likely underreported and as high as 30%. Open gastrostomy and jejunostomy are associated with complications inherent in laparoscopy and laparotomy that are discussed extensively throughout this text. Early recognition and correction of access issues is paramount to the provision of enteral support.

The metabolic complications of enteral nutrition include refeeding syndrome and nonocclusive mesenteric ischemia (NOMI) and, although rare, are associated with significant mortality. Refeeding syndrome can be seen with both enteral nutrition and parenteral nutrition support. Refeeding syndrome was first described following the surrender of thousands of French troops to Spanish forces following the Battle of Bailen of the Peninsula War where delayed shipments of food on Cabrera Island resulted in prolonged starvation. Following the arrival of food shipments,

hundreds of prisoners of war succumbed following their initial meals. Similar patterns were described following the liberation of Bergen-Belsen concentration camp in 1945. In addition to overt cachexia, alcoholism, anorexia nervosa, marasmus, rapid refeeding, and excessive dextrose infusion are identified as risk factors for the development of this syndrome. The hallmarks of refeeding syndrome are hypophosphatemia, hypokalemia, and hypomagnesemia following initiation of nutrition support in patients with severe pre-existing chronic malnutrition. Rapid fluid shifts and intracellular migration of potassium and phosphorus result in hemodynamic lability and death. Refeeding syndrome likely represents the severe end of a spectrum of clinical manifestations resulting from caloric and protein provision in the ICU. Recent data suggest that elements of refeeding occur in the majority of critically ill patients, and these alterations are only recognized when severe. The prevention of refeeding syndrome involves recognition of at-risk patients, hypocaloric support over the first several days (10 kcal/kg, advancing 5 kcal/kg day over days 2 to 4), interval electrolyte monitoring, and deliberate electrolyte replacement prior to advancement of nutrition support.

NOMI is associated with inadequate splanchnic perfusion to meet the increased metabolic demands in the setting of enteral nutrition support. enteral nutrition can increase splanchnic perfusion 40% to 60% (post-prandial hyperemia), and when demand is not met NOMI can ensue. Although extremely rare and difficult to predict, this is a devastating complication with mortality rates as high as 80%. Interestingly, NOMI has been more commonly associated with both surgical and nasoenteric jejunal feeding strategies. Current recommendations suggest withholding enteral nutrition until patients are fully resuscitated to avoid this catastrophic complication.

Appropriate patient assessment for needs and risks, proper feeding route, and formula selection, in addition to appropriate monitoring of the enteral nutrition feeding regimen, can increase the success of enteral feeding and reduce the incidence of enteral nutrition-associated complications.

SPECIAL CONSIDERATIONS IN THE ELECTIVE PERIOPERATIVE SETTING

In contrast to the post-injury or surgical emergency setting, elective surgery affords the luxury of knowing when the physiologic insult is to

occur and thereby allows for nutritional optimization prior to the insult. Just as weight loss, smoking, and cardiac optimization are routinely performed prior to elective surgery, so too should assessment and optimization of nutritional status. This requires nutrition assessment to be performed, risk to be recognized, and actions to be taken prior to the day of the operation. The NRS-2002 discussed earlier is a simple and easily applicable tool to identify nutrition risk and intervene. In addition to perioperative nutrition support, multiple components of the enhanced recovery pathways have incorporated carbohydrate loading and early initiation of enteral support into existing protocols with good success.

Perioperative Nutrition

In the setting of major elective surgery, perioperative administration of supplemental protein and calories in a regimented fashion for 5 days prior to and at least 5 days following the intervention has been demonstrated to improve outcomes and reduce postoperative infections. Two factors contribute to the overall efficacy of preoperative nutrition supplementation, including pre-existing nutritional status and the magnitude of the planned operation. For example, operations with a low complication rate would be expected to demonstrate minimal improvements. In contrast, patients with pre-existing nutrition risk (severe malnutrition) undergoing a lengthy operation with a high complication rate would benefit most from perioperative nutrition. Perioperative (both prior to and following) support strategies have been demonstrated to have more significant outcome benefits than either pre- or postoperative strategies alone. Immunonutrition formulas have demonstrated some efficacy over standard therapy with regard to infectious complications and length of stay. Perioperative nutrition support is a relatively inexpensive adjunctive therapy to improve outcomes but remains underutilized. The importance of compliance with nutrition support strategies should be highlighted as contributions patients can make to improve their own outcomes and should be emphasized by the surgeon.

Early Initiation of Enteral Support

As in critically ill populations, reduced infectious complications and length of stay have been demonstrated with early enteral nutrition support in the perioperative setting. Surgical dogma including delaying initiation of oral intake until the onset of bowel function has never been demonstrated to

improve outcomes, even in the setting of GI anastomosis, and yet is still widely practiced. Early discontinuation of decompressive nasogastric tubes following surgery is an integral component of most fast-track strategies. On-demand feeding strategies, whereby patients are provided oral intake when they feel ready, have demonstrated efficacy in the setting of acute pancreatitis and are likely applicable in the majority of postoperative patients.

In the event that operative intervention is deemed necessary, patients are determined to be at high nutrition risk, and sufficient enteral nutrition cannot be delivered, parenteral nutrition should be considered. Although the duration required to result in meaningful outcome improvements is controversial, most would suggest that 7 to 14 days of parenteral nutrition delivered preoperatively is appropriate.

Preoperative Carbohydrate Loading

Traditionally, the "NPO after midnight" order has been synonymous with surgical preparation. However, this notion has recently been challenged as preoperative carbohydrate loading has become more widely practiced as a component of "fast-track" surgical strategies. Emerging and relatively conclusive evidence suggests that the provision of clear liquids and carbohydrate up until 2 hours prior to the procedure results in no increased risk of aspiration as well as potential benefit. Complex carbohydrate (maltodextrin) drinks are given as 300 mL (12.6 g/100 mL) volumes the pre-op at least 3 hours before induction. This strategy is compliant with recent American Society of Anesthesiologist recommendations that suggest that solids are discontinued 6 hours prior and clear liquids 2 hours prior to induction. Perioperative fasting may not only be unnecessary, but also harmful as a contributor to postoperative insulin resistance, increased immunosuppression, and patient discomfort. Preoperative "carbohydrate loading" involves giving a carbohydrate-rich drink the night before and 3 hours prior to the scheduled procedure and has been demonstrated to reduce insulin resistance, attenuate resultant immunosuppression, and improve patient comfort.

SUMMARY

Surgeons have been instrumental in characterizing the metabolic response to stress and should have expertise in the establishment of enteral nutrition. Enteral nutrition therapy is an important and underemphasized adjunctive

therapy in the surgical patient. Strategies have shifted importance from caloric and protein provision to the additional “nonnutritional” benefits of enteral support including preservation of structure and function of the GI barrier and gut-associated lymphoid tissue and efficient nutrient utilization. There has been a recent shift in the goals of nutrition support from that of support (caloric and protein provision) to therapy (maintenance of GI structure and function, attenuation of the immune response). A multimodality approach consisting of nutrition support, appropriate supplementation, and resistance exercise should be initiated to combat the metabolic alterations associated with physiologic insult. Surgeons must be capable of recognizing patients with increased risk for morbidity and mortality as a result of pre-existing nutritional risk and in the implementation of an individualized nutrition support strategy. When appropriate, enteral nutrition should be the route of choice and efforts should be made to assess and troubleshoot GI intolerance. In the event that enteral nutrition is inappropriate, surgeons should understand the role of parenteral nutrition support and utilize it when necessary. Finally, as with any therapy, there are significant risks associated with the inappropriate administration and implementation of nutrition support strategies, and surgeons must be familiar with the recognition and management of these issues in order to optimize patient outcomes.

EDITOR'S COMMENT

As Dr. Mardindale and colleague so aptly put it, nutritional support has been an underemphasized and underutilized adjunctive to surgical care. I would even more strongly emphasize, nutritional repletion is integral to surgical success. One can do a technically successful and even perfectly carried out surgery only to have the wound fall apart days later because the patient cannot heal. The concept of nutritional risk takes into account pre-existing nutritional status as well as disease severity. Stratifying by risk and developing strategies and proactively implementing them prior to surgery are just as important as having a patient in good glucose control or to have them stop smoking prior to reconstruction.

There are many tools to assess nutritional status, but none are more valuable, as in all things, than a simple history and physical examination–what are their dietary habits, how much protein do they eat, what supplements do they take, if and how much weight have they lost, and how much exercise do they get? On physical examination, a quick look at hypothenar or malar muscle wasting can quickly identify the severely "at-risk" patient. Along with our authors, I would like to emphasize to not let the obese patient fool you. I would say that obesity by its very nature is considered malnutrition. The ever dieting or poorly dieting youth are likewise at risk. Again, a good history can help identify these patients before a complication occurs.

The authors have very nicely summarized biochemical assessment. I would emphasize that if the admitting albumin and phosphate are low on admission, then surgery should be delayed if possible and if not nutritional supplementation started immediately. If labs are normal on admission and nutrition is suspected or in a patient with advance cancer, repeat labs after the start of intravenous fluid as often the patients are dehydrated and labs are surreptitiously high. In addition, with the introduction of glucose and the occurrence of refeeding syndrome, phosphate will drop 1 or 2 days later or after surgery. In this day of

overzealous dieting, refeeding syndrome can be seen in seemingly fit and young patients. Poor dietary habits should always be suspected in the elderly patients especially if they live alone. One postop patient was diagnosed with Alzheimer's until her phosphate was found to be low and replenished. She made a complete recovery. In my practice, a postoperative ileus especially if accompanied by dysphoria is due to phosphate nearly every time. Hypophosphatemia itself is associated with risk or infectious complications. When severe enough patients can go into respiratory arrest, heart and/or liver failure.

The geriatric population is at special risk. In a study of 111 elderly patients (≥65 years of age) undergoing colorectal, heptopancreatobiliary or gastric/duodenal surgery undersent comprehensive baseline and geriatric assessment including functional status, nutritional status, comorbidity index, mental status, depression scale score, fatigue inventory scale, and polypharmacy scale. Variables associated with discharge to a nursing facility on multivariate analysis included weight loss ≥10% (OR 6.52, $p = 0.02$), ASA score ≥2 (OR 5.08, $p = 0.03$), and ECOG score ≥2 (OR 4.51, $p = 0.03$). Variables independently associated with prolonged hospital stay included ≥10% weight loss (OR 4.03, $p = 0.03$) and the presence of polypharmacy (OR 2.45, $p = 0.03$). Again a good history and physical examination are at the heart of a complete surgeon.

The release of alanine from the muscle during stress associated with catabolism after trauma, surgery, with advanced cancer, or during sepsis is well-known. Numerous strategies have been initiated to replenish muscle. What isn't clear is how early-stage cancer affects the protein metabolic response to major surgery. We looked a group of patients undergoing bilateral mastectomy and reconstruction, half for noncachectic breast cancer and half for genetic risk reduction. Whole body protein synthesis and breakdown rates were assessed after overnight fasting and after meal intake by stable isotope methodology in order to calculate net protein catabolism in the postabsorptive state and net protein anabolic response to a meal. As expected, the net anabolic response to a defined amino acid meal was reduced but was independent of early-stage breast cancer after major surgery. However, in the presence of severe malnutrition preoperative intravenous or enteral nutrition can significantly decrease infection and complications after surgery. How much and for how long to give nutritional repletion before surgery are not certain and are usually guided by albumin and acute phase reactants but vary with the underlying disease, the supplement and, to me, depend on good clinical judgment. Home infusion capability, nutrition at home with oral supplements when possible, and parenteral nutrition when not are easy and really required in today's cost saving environment. In the emergency setting or when a prolonged recovery period is expected, one should ask at the end of every case—do I need parenteral and/or enteral access? Enteral feeds are ideal, but early initiation of enteral nutrition in the setting of a tenuous blood supply is not always safe and parenteral nutrition can act as a bridge and

should not be frowned on.

4 Cardiovascular Monitoring and Support

Eric J. Charles and Irving L. Kron

Cardiovascular monitoring and support are essential to the care of surgical patients. The goals of cardiovascular monitoring are to ensure adequate tissue oxygenation and perfusion intraoperatively and postoperatively. Monitoring of the cardiovascular system involves an assessment of four major components:

1. Cardiac function
2. Peripheral and pulmonary vascular tone
3. Intravascular volume status
4. Oxygen metabolism

Accurate and thorough evaluation of all four components is a prerequisite to the proper management of cardiovascular support. It must be noted that measurement of these parameters is accompanied with an increase in the cost of care, complexity of management, and risks of harm to the patient. Therefore, the decision to utilize these technologies must take into account the usefulness and necessity of the data compared to the added risks and increased cost.

PHYSICAL FINDINGS

Cardiovascular monitoring involves a clinical assessment of organ-specific and systemic perfusion (Table 4.1). Physical signs are notoriously unreliable in estimating the adequacy of tissue perfusion, particularly in anesthetized or critically ill patients. Therefore, physical findings should be interpreted in the context of the patient and adjunct information obtained from more sophisticated monitoring techniques.

TABLE 4.1 Physical Signs of Organ-Specific and Systemic Perfusion

Physical Sign	Implication
Obtundation	Impaired cerebral perfusion
Oliguria	Impaired renal perfusion
Flat jugular veins	Intravascular volume depletion, impaired systemic perfusion
Weak or absent pulse(s)	Impaired regional or systemic perfusion
Cool, pale, or mottled skin	Impaired systemic perfusion

Electrocardiography

Continuous monitoring of the electrocardiogram (ECG) is the most sensitive, rapid, and cost-effective modality for detecting disturbances of cardiac rate, rhythm, and conduction and should therefore be routinely employed. Such disturbances are common during general anesthesia, in critical illness, and especially in patients with a history of arrhythmias or coronary artery disease.

One of the most useful features of continuous ECG monitoring is ST-segment monitoring, which is quite reliable for the early detection of myocardial ischemia and infarction. Leads II and V_5 are most commonly monitored, as these two leads together can detect >90% of intraoperative ischemic events in high-risk patients. Intraoperative ST-segment monitoring has become a standard practice in patients at high risk for cardiac events. Any electrical disturbances of the heart detected on continuous ECG monitoring (ST-segment changes, T-wave abnormalities, arrhythmias, etc.) should prompt a 12-lead ECG to confirm and further characterize the abnormality.

Blood Pressure Measurement

Blood pressure is the most commonly monitored cardiovascular parameter in current surgical practice. Blood pressure is prone to abrupt changes as a result of anesthesia, surgical procedures, changes in volume status and cardiac function, and underlying surgical illnesses. As arterial blood pressure is an indirect marker of systemic perfusion and a direct marker of

hemodynamic status, diligent monitoring of this parameter is essential to early detection and treatment of cardiovascular instability.

Noninvasive Methods

Together with continuous ECG, noninvasive blood pressure measurement is considered standard intraoperative cardiovascular monitor for the majority of patients undergoing routine surgery. Noninvasive blood pressure monitoring is considered indirect because no measurements are made with a device *within* the arterial lumen itself. Instead, such measurements are made with an inflatable cuff (sphygmomanometer) around the arm or leg and inflated to a pressure sufficient to compress the underlying artery. With the *auscultatory method*, gradual cuff deflation permits the artery to reopen and turbulent blood flow to produce Korotkoff sounds, which are heard with a stethoscope placed over the compressed artery. The pressures at which these sounds appear and then disappear during cuff deflation determine the systolic and diastolic blood pressures, respectively. Alternatively, the *oscillometric method* relies on the principle of plethysmography, in which the inflated cuff senses the pulsatile pressure changes in the underlying artery. On most devices available for clinical use, the systolic, diastolic, and mean arterial pressures and pulse are displayed on a digital screen for clinician review.

Although practical and noninvasive, these indirect techniques are limited by the time required to obtain each measurement and the likelihood of inaccurate results. For example, the use of an inappropriately small cuff in relation to the size of the limb will yield a spuriously elevated blood pressure reading. The American Heart Association (AHA) recommends the cuff bladder length should be 80% of the patient's limb circumference, and its width a minimum of 40%. Unfortunately both auscultatory and oscillatory methods are limited in the setting of hypotension. Therefore, in cases of sustained or expected hemodynamic instability, noninvasive blood pressure monitoring techniques should be abandoned in favor of more accurate and reliable invasive methods.

Invasive Methods

Invasive blood pressure monitoring provides a direct and accurate assessment of arterial pressure. The advantage of this approach is the rapid detection of fluctuations in blood pressure and immediate feedback on interventions that affect hemodynamics. Furthermore, these methods provide a convenient source for frequent arterial blood sampling, both in

the operating room and in mechanically ventilated patients in the intensive care unit (ICU). For these reasons, invasive blood pressure monitoring is recommended in patients that are or expected to become hemodynamically unstable, including those undergoing major abdominal, vascular, or cardiothoracic procedures. In addition, any major surgical operation in patients with a history of coronary artery disease, congestive heart failure, aortic stenosis, or poorly controlled hypertension should be accompanied by invasive blood pressure monitoring.

Direct blood pressure measurement is performed with an indwelling intra-arterial catheter connected to fluid-filled high-pressure tubing and a transducer. The zero reference point for the transducer is at the level of the right atrium, which corresponds to the midaxillary line at the fourth intercostal space. If the transducer is positioned below the level of the right atrium, the resultant pressure will be spuriously elevated. Conversely, if the transducer is situated above the right atrium, the displayed blood pressure will be falsely low. Specialized transducers exist, such as the FloTrac Sensor (Edwards Lifesciences, Irvine, California), that can be attached to the arterial catheter and provide additional data such as cardiac index (CI) and stroke volume variation.

The contour of the arterial pressure waveform in the aorta differs from that in the peripheral arteries (Fig. 4.1). As the propagating pressure wave migrates from the aortic root to the periphery, the systolic pressure gradually increases such that the peak systolic pressure in the radial artery can be 20 mm Hg higher than that in the proximal aorta. Thus, the mean arterial pressure, not the systolic pressure, determines the perfusion of blood into peripheral tissues. This increased systolic pressure in the distal arterial tree is due to less vascular elastic tissue and greater impedance, which is transmitted in a retrograde direction from vascular bifurcations and the artery–arteriolar junction. Such systolic amplification is especially prominent in more diseased, less compliant peripheral arteries, which is the physiologic basis for isolated systolic hypertension in the elderly. Amplification of peak systolic pressure in peripheral arteries is counterbalanced by a narrowing of the systolic waveform; the net result is that *mean* arterial pressure is unchanged. As a result, when peripherally placed intra-arterial catheters are employed, mean arterial pressure is the most accurate estimate of central arterial (aortic) pressure.

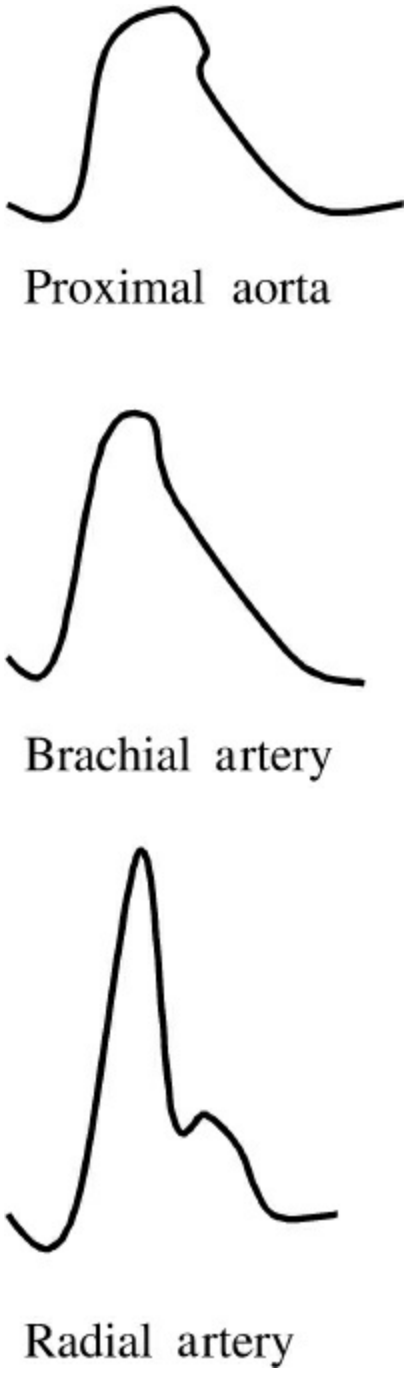

Figure 4.1. The appearance of the arterial pressure waveform at various sites in the circulation.

Radial Artery Cannulation

The radial artery at the wrist is the most common site for insertion of an intra-arterial catheter. The advantages of this site are that the vessel is fairly superficial and easily palpable, it is of adequate diameter to accept a standard-size catheter (18- or 20-gauge), and the area is easy to keep clean. To facilitate cannulation of the radial artery, the wrist should be gently hyperextended to bring the vessel to a more superficial location and allow

for cannulation without interference from the thenar eminence. The entry site is determined by digital palpation of the arterial pulse or with the use of ultrasound. Vessel entry is performed with a percutaneous Seldinger technique utilizing either an integrated catheter-over-needle device or a separate needle, guidewire, and catheter. Successful vessel entry is heralded by a flash of arterial blood in the catheter hub. At this point, it is important to advance the needle another 0.5 to 1 mm to ensure that its beveled tip is entirely within the vessel lumen and not partially within its wall. The catheter or guidewire may then be safely advanced into the vessel. Historically, the Allen test has been used prior to radial arterial cannulation to evaluate ulnar artery supply to the hand; however, it is now generally believed that this test does not always predict ischemic complications from radial artery cannulation. Other potential sites for arterial cannulation include the femoral and axillary arteries, both of which have the advantages of central arterial access and a low thrombotic rate. The pedal arteries are less often utilized as a result of their small diameter and lower successful cannulation rates. The brachial artery should be avoided since this vessel has no collateral blood supply and thrombosis of it could yield severe forearm and hand ischemia.

Complications of Arterial Cannulation. The most common complication associated with all sites of arterial cannulation is thrombosis. The risk of this complication increases with the duration of cannulation; the risk of radial artery thrombosis may be as high as 29% in vessels cannulated for >4 days. However, the risk of clinically significant distal ischemia is <1%, as most thrombosed vessels tend to recanalize. Arterial catheter insertion sites should be routinely inspected for signs of ischemia, the presence of which mandates immediate catheter removal. Signs of arterial insufficiency distal to the site of catheter removal may persist for several hours as a result of vasospasm. However, ischemia persisting beyond 6 hours after catheter removal is an indication for surgical exploration with an eye toward thrombectomy and vessel repair. In addition to the duration of cannulation, other risk factors for catheter-induced arterial thrombosis include use of a larger catheter, insertion during shock, multiple needle passes and/or careless insertion technique, infusion of vasoconstricting agents, and a small recipient vessel. Other clinically important complications of arterial catheterization are infection, bleeding, and cerebral embolism. The incidence of local wound infection is 10% to 15% for radial artery catheters, but systemic infectious

complications of such catheters are rare. Efforts to reduce the infection rate of radial artery catheterization include avoidance of a cutdown technique, replacement of the connector tubing every 48 hours, routine sterile dressing changes to the insertion site, and prompt removal of obviously infected catheters. However, in the absence of local or systemic infection, scheduled catheter changes are not necessary. Significant bleeding complications are most commonly associated with femoral and axillary artery lines, particularly in coagulopathic patients. For this reason, the radial artery is the preferred site of arterial catheterization in the presence of a bleeding diathesis. Although exceedingly rare, improper flushing of arterial lines has resulted in embolization of air and thrombi to the cerebral circulation. Employing small-volume, low-pressure flushes and evacuating all air from the tubing and transducer assembly can avoid this complication.

Pitfalls in Invasive Blood Pressure Monitoring

There are potential sources of error in the interpretation of data provided by invasive arterial pressure monitoring systems. In addition to improper positioning of the transducer, the monitoring system is vulnerable to artifacts that distort the contour of the arterial waveform and display false blood pressure readings. An *overdamped* system results in attenuation of the peak systolic pressure and an overestimation of diastolic pressure, yielding an incorrectly reduced pulse pressure. This is caused by a partial thrombus within the catheter, air bubbles within the tubing or transducer, or kinking of the catheter or tubing. Conversely, *underdamping* or *ringing* occurs with extraordinarily long lengths of tubing and is characterized by augmentation of the peak systolic pressure and a blunting of the diastolic pressure, producing a falsely elevated pulse pressure. It is important to note that with either an overdamped or underdamped system, the *mean arterial pressure is unaffected.* Hence, if there is ever any doubt as to the fidelity of an invasive arterial pressure monitoring system, only the mean pressure readings should be considered reliable. Finally, it should be mentioned that in intensely vasoconstricted patients, such as those undergoing treatment with α_1-agonists such as phenylephrine, invasive blood pressure readings via the radial artery may be significantly lower than central aortic pressure.

CENTRAL VENOUS CATHETERS

Cannulation of the central venous circulation facilitates both monitoring and support of the cardiovascular system, allowing for fluid resuscitation, drug administration, infusion of parenteral nutrition, passage of pacing electrodes into the right heart, hemodialysis, and monitoring of central venous pressure (CVP). CVP, or right atrial pressure, is an estimate of right ventricular preload. Although commonly monitored in the ICU setting, studies have shown that CVP is an inaccurate indication of a patient's responsiveness to fluid resuscitation. Other options for assessing changes in fluid status include measurement of inferior vena cava diameter and passive leg-raise maneuver. Nevertheless, a decreased CVP may indicate hypovolemia, while an elevated CVP may indicate hypervolemia, increased intrathoracic pressure, positive-pressure ventilation, pulmonary hypertension, or heart dysfunction. Normal CVP values range from 0 to 8 mm Hg and should be measured at end-expiration in both the mechanically ventilated and spontaneously breathing patient. The normal CVP tracing has three positive waves (*a*, *c*, and *v* waves) and two negative descents (*x* and *y*, Fig. 4.2). These waveforms reflect tricuspid valvular function as well as right atrial and ventricular size, compliance, and contraction. Characteristic abnormalities of the central venous waveforms may be seen in a variety of conditions, including tricuspid stenosis and regurgitation, dysrhythmias, and atrial septal defect. Similar to the setup for intra-arterial blood pressure monitoring, the central venous catheter is connected to a transducer that must be zeroed at the level of the right atrium. Considering that many decisions regarding implementation of cardiovascular support will be made based on both the blood pressure and CVP monitoring, proper zeroing of the transducers is absolutely essential and should not be overlooked.

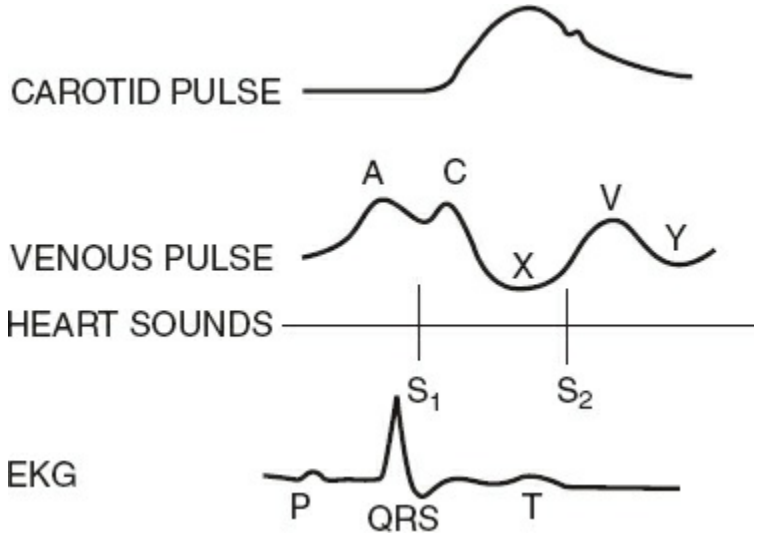

Figure 4.2. Central venous waves and descents. *a, c, v, x, y.*

Subclavian Vein Cannulation

All central venous cannulas should be placed under strict sterile technique, which includes sterile preparation of the skin and wide sterile draping of the entire patient and bed. Operators are required to wear sterile gown and gloves and all personnel in the patient room must wear hat and mask. The infraclavicular approach to the subclavian vein is fairly consistent with regard to anatomic landmarks, the exit site is more comfortable to the patient, and indwelling catheters at this site have a lower infection rate than the internal jugular (IJ) approach. The subclavian vein originates lateral to the first rib (Fig. 4.3). During its course, it passes anterior to the first rib and directly posterior to the clavicle. The external landmarks for the site where the vein passes between the first rib and the clavicle are: (a) the junction between the medial and middle thirds of the clavicle and (b) the lateral edge of the sternocleidomastoid muscle where it inserts into the clavicle. The skin, subcutaneous tissues, and periosteum of this area just below the clavicle should be infiltrated with 1% lidocaine. The classic method for accessing the subclavian vein is the Seldinger technique. With the patient in the Trendelenburg position, the needle should be advanced just beneath the clavicle and directed toward the suprasternal notch. To avoid causing a pneumothorax, it is very important to maintain a needle trajectory that is parallel to the floor. Return of free-flowing venous blood indicates entry into the lumen of the subclavian vein. At this point, the needle should be advanced a few millimeters to ensure that its beveled tip is completely within the vessel lumen. A J-tip guidewire is then carefully passed through the needle. If undue resistance is encountered upon passage

of the wire, both the needle and the wire should be removed and the process repeated. If vessel puncture is unsuccessful with the technique described above, a more cephalad direction of the needle may prove successful; occasionally, the subclavian vein is displaced superiorly by the apex of the lung, particularly in emphysematous patients. Ensuring puncture of the subclavian vein and not the artery is crucial and should be confirmed prior to dilating the tract leading into the blood vessel. A single-lumen 18-gauge angiocatheter can be inserted over the wire to facilitate this step. The options for accomplishing this step include (a) performing a blood gas analysis and comparing it to an arterial blood gas analysis from another location on the body, (b) transducing a pressure waveform, or (c) most commonly, by using extension tubing to set up a pressure column. After filling the extension tubing with blood and raising the distal end up in the air, a column of venous blood will fall while a column of arterial blood will continue to rise. Color of the blood or pulsatility after syringe removal are not acceptable methods for confirming venous puncture especially in critically ill patients who may be hypoxic or hypotensive. After confirmation of venous puncture, the wire is advanced back into the central venous circulation, the angiocatheter is removed, the skin exit site is enlarged with a scalpel blade, and a vascular dilator is passed slowly and progressively over the wire. It is critical to maintain control of the guidewire especially during maneuvers to advance the dilator and the catheter and ensure that it moves freely at all times. Once the subcutaneous tract and the hole into the vessel are dilated, the catheter is threaded over the guidewire; the latter can then be removed. For most types of indwelling central venous catheters, the catheter tip should be situated at the junction of the superior vena cava and right atrium. Table 4.2 is a useful guide for estimating the distance to this junction from the skin exit site for each of the subclavian and IJ venous approaches.

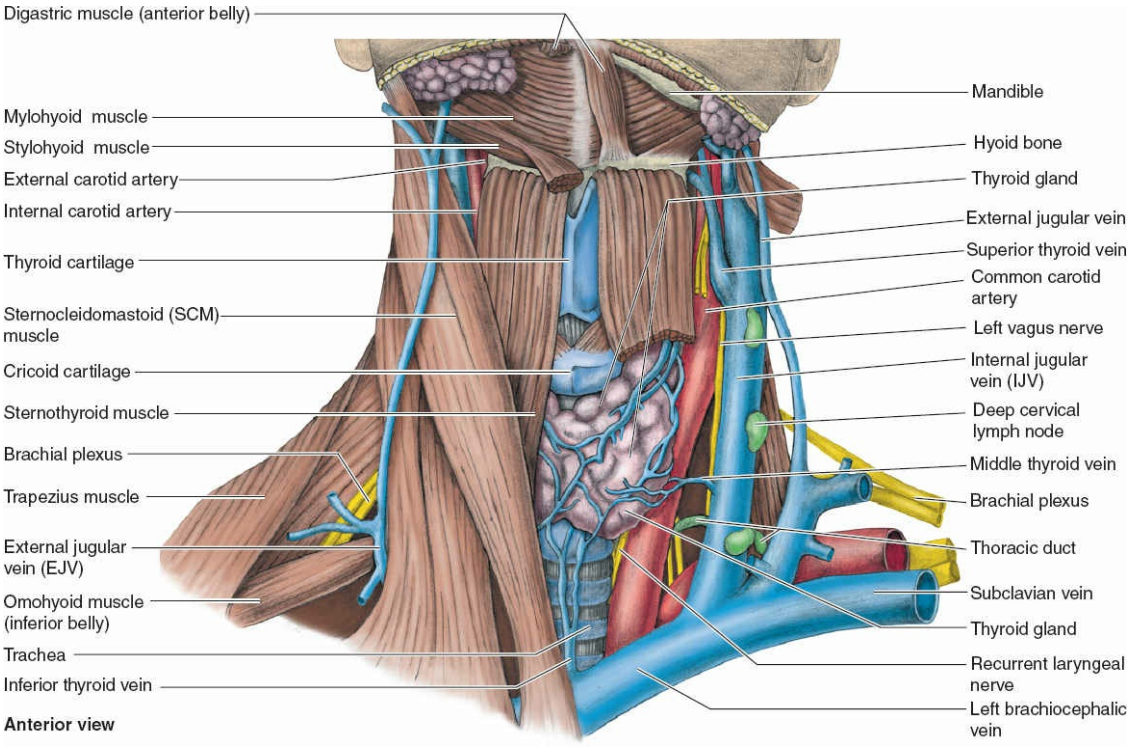

Figure 4.3. Anatomy of the neck. Note the relationship of the subclavian and internal jugular (IJ) veins. (From Moore KL, Dalley AF. Clinically Oriented Anatomy, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005, with permission.)

Internal Jugular Vein Cannulation

The IJ vein is an alternative to the subclavian vein for central venous cannulation. The advantages of this site over the subclavian approach are a lower risk of pneumothorax and a straighter course to the right atrium, especially on the right side. Shortcomings of the IJ approach are that it is occasionally more uncomfortable for the patient, carries a higher risk of arterial puncture, and has a higher reported infection rate. It is important to note that in approximately 70% of individuals, the IJ lies anterolateral to the carotid pulse at the base of the neck (see Fig. 4.3). However, one should be aware that not infrequently this vein may lie directly anterior or even deep to the carotid artery, thus increasing the risk of inadvertent arterial puncture. Use of ultrasound guidance for proper placement of the central venous catheter into the IJ vein is highly recommended as it reduces the risk of mechanical complications and increases the speed at which the procedure can be completed. The ubiquitous nature of ultrasound machines in today's healthcare environment make improper IJ catheter placement or pneumothorax after "blind" insertion indefensible unless performed in an emergent situation, during which the subclavian or

femoral veins should be accessed instead. With the patient in the Trendelenburg position and his/her head rotated to the contralateral side, the triangle formed by the two heads of the sternocleidomastoid muscle is identified. Using ultrasound to visualize the IJ vein, a needle is inserted at the apex of this triangle, keeping the carotid pulse medial to the course of the needle. The needle is slowly advanced toward the vein at a 45-degree angle to the skin. Once the operator is certain of needle entry into the lumen of the IJ and confirms venous puncture by one of the methods mentioned above, Seldinger technique is used to insert the catheter. After both IJ and subclavian central line placement, a chest radiograph must be ordered and visualized by the operator of the procedure to ensure proper placement and absence of pneumothorax.

TABLE 4.2 Approximate Distance From Skin Exit Site to Junction of Superior Vena Cava and Right Atrium (to Facilitate Correct Positioning of Central Venous Catheters)

Vessel	Distance (cm)
Right subclavian vein	(H/10) – 2
Right internal jugular vein	(H/10)
Left subclavian vein	(H/10) + 2
Left internal jugular vein	(H/10) + 4

H, patient height in cm.

Femoral Vein Cannulation

The femoral vein can be cannulated rather easily and expediently, and in select circumstances is the preferred route for central venous access. Examples include victims of burns to both sides of the neck and upper chest, trauma patients in extremis, and certain patients with acquired obstruction or congenital anatomic anomalies of the superior vena cava. The disadvantages of the femoral approach are a 10% risk of venous thrombosis, the need for the patient to remain supine and immobile, and a higher risk of catheter infection. The femoral vein is the most medial structure in the femoral sheath, lying just medial to the femoral artery. Puncture of the femoral vein is performed by first palpating the arterial pulse 2 cm below the inguinal ligament. At a point 1 to 2 cm medial to the

femoral pulse, the needle is advanced at a 45-degree angle through the skin until venous blood is encountered. If the femoral pulse is nonpalpable, the femoral vein can be located at a point 1 to 2 cm medial to the junction of the medial and middle thirds of the inguinal ligament. Ultrasound guidance can be used to facilitate proper catheter placement if preferred but is usually not necessary.

Complications of Central Venous Cannulation

Complications of central venous cannulation can be mechanical, infectious, or thrombotic. The most common mechanical complications are pneumothorax, hematoma formation, or inadvertent arterial puncture. Comparing IJ to subclavian, arterial puncture is more likely to occur with IJ cannulation, but the risk of pneumothorax is higher with subclavian cannulation. Considering that the risk of any mechanical complication is highest overall at the femoral location, IJ or subclavian central venous cannulation is recommended unless otherwise contraindicated. The following can help reduce the likelihood of mechanical complications: use ultrasound-guidance for IJ line placement, avoid routine central line changes, confirm venous puncture prior to introduction of the dilator, and involve an experienced operator whenever possible as performance of more than 50 central line placements has been shown to decrease the likelihood of mechanical complications by 50%. In addition, after three unsuccessful insertion attempts, the risk of mechanical complication increases six-fold. In the case of arterial puncture, unless the patient is coagulopathic, immediate withdrawal of the needle and 10 minutes of digital pressure is usually sufficient treatment. If it is apparent that the carotid, subclavian, or femoral artery has been cannulated with the dilator or catheter, these devices should not be removed blindly, particularly in an anticoagulated patient as this may produce serious life-threatening hemorrhage. It is safer to remove the dilator or catheter via direct surgical exposure, followed by suture repair of the artery. In addition, it is important to recognize that central venous cannulation of the subclavian vein increases the risk of subclavian vein stenosis which may be problematic in patients needing future dialysis catheter placement.

Risk factors for catheter infections include immunosuppression, insertion under emergent conditions or cutdown technique, and ineffective use of sterile barriers during insertion. Microorganisms at the skin insertion site are the most common cause of infections for nontunneled catheters left in place for less than 10 days. Organisms migrate from the

skin insertion site along the external surface of the catheter and form a biofilm, which prevents eradication with antibiotic treatment. Introduction of contamination via the catheter hub is another possible cause of infection. Subclavian vein cannulation has the lowest rate of infectious complications. Additional recommendations to avoid infection include (a) prompt removal of catheters when no longer clinically necessary, (b) avoidance of routine central line changes, (c) proper disinfection of catheter hubs prior to access, (d) use of antimicrobial-impregnated catheters (chlorhexidine, silver sulfadiazine, minocycline, or rifampin), (e) strict adherence to full sterile precautions at time of insertion, (f) use of central line care bundles (antimicrobial hubs and dressings), and (g) daily inspection of central line dressings, with sterile replacement if wet, soiled, or loose, or every 7 days otherwise.

Venous thrombosis is estimated to occur in approximately 15% of patients with indwelling central venous catheters but is often undiagnosed and not clinically significant. Nevertheless, thrombus formation carries the associated risk of embolization. Therefore, it is important to consider that subclavian central line placement has the lowest risk of thrombus formation.

Other less common complications include venous air embolism, central vein perforation, and embolization of catheter fragments or guidewire. During spontaneous inspiration, negative intrathoracic pressure may facilitate air entry into the central venous system through defects in the catheter, the uncapped hubs of the catheter, and the uncovered end of the needle during vessel puncture. This is a potentially fatal complication and may present initially as acute dyspnea and hypoxia. If suspected, place the patient in Trendelenburg position and rotate the patient into the left lateral decubitus position in an effort to minimize the likelihood of air migrating into the right ventricular outflow tract. An attempt can be made to withdraw air through the catheter. To avoid central vein perforation, ensure that the guidewire moves freely within the dilator and is not being bent against the wall of the vein. The dilator is quite stiff and can easily perforate a central vein if forcefully advanced. If embolization of catheter fragments or the guidewire occurs, it can usually be retrieved through a second catheter under fluoroscopic visualization.

Catheter-Related Bloodstream Infections

The topic of indwelling central venous catheter infections deserves special mention, as this is the number one cause of healthcare-associated

bloodstream infections. Such infections contribute significantly to morbidity, mortality, and increased healthcare costs. A catheter-related infection is diagnosed by semiquantitative culture when 15 or more colonies of the same pathogen grow from the catheter tip. There may or may not be accompanying signs of local infection (e.g., erythema, purulence, tenderness, or warmth at skin insertion site) or systemic inflammation (e.g., fever or leukocytosis). Catheter-related infection is a prelude to catheter-related bloodstream infection, which is defined as growth of the same organism from a peripheral blood culture and the catheter tip. Replacing central venous catheters at regularly scheduled intervals has not been shown to decrease the risk of catheter-related infections. However, the following guidelines are recommended: (a) If there are clear signs of infection at the skin exit site, the catheter should be promptly removed and, if clinically indicated, a new catheter should be inserted at a fresh site; (b) when a catheter-related infection is suspected (with or without signs of local exit site infection), the catheter should be exchanged over a guidewire; (c) if the tip of any catheter replaced via guidewire exchange grows >15 colonies of a pathogen in semiquantitative culture, the existing catheter should be removed and replaced at a new site; and (d) any catheter placed emergently and without strict sterile technique should undergo guidewire exchange. It is important to note that central line–associated bloodstream infections (CLABSIs) differ in that they are diagnosed with a laboratory-confirmed bloodstream infection in a patient who has, or had within the previous 48 hours, a central line and no other cause for the infection. CLABSI rates are an important hospital quality indicator. It is imperative to balance the patient's need for a central line with the potential for infection.

PULMONARY ARTERY CATHETERS

In 1970, Swan and colleagues introduced the concept of bedside right heart catheterization via manipulation of a flexible balloon-tipped catheter into the pulmonary artery (PA). Although many studies have shown no clinical benefit from use of PA catheters in both critically-ill medical or surgical patients, certain practitioners comfortable and familiar with their use continue to find the information they provide valuable. General indications for use of the PA catheter include characterization and management of shock states, assessment and management of pulmonary hypertension, and perioperative monitoring of patients at high risk for hemodynamic

instability. With specific regard to the latter, examples of such patients include those with significant cardiovascular disease, advanced age, and significant burns or trauma, as well as those undergoing a surgical procedure associated with increased risk of hemodynamic disturbances. Clearly, in such patients clinical evaluation alone is inaccurate. Furthermore, as cardiac function can be impaired for a variety of reasons in critically ill surgical patients, a central venous catheter is an unreliable surrogate for estimating left-sided filling pressures in such individuals.

Pulmonary Artery Catheter Features

The PA catheter is 100 to 110 cm in length and usually has three lumens: a distal lumen, which opens at the catheter tip into the PA for measurement of PA pressures, PA wedge pressure (PAWP), and cardiac output (CO); a proximal lumen 30 cm from the tip, which communicates with the right atrium and is used for measurement of CVP; and a third lumen approximately 15 cm from the tip, which can be used for infusion. In addition, the basic catheter is equipped with a temperature-sensing thermistor a few centimeters proximal to the catheter tip, as well as a 1.5-mL balloon surrounding the tip. Newer PA catheters are able to provide continuous monitoring of CO, measurement of right ventricular ejection fraction (RVEF), and continuous assessment of mixed venous oxygen saturation (SvO_2).

Pulmonary Artery Catheter Insertion

Prior to insertion, the balloon should be tested for defects by inflating it with 1.5 mL of air, all lumens should be flushed with sterile saline, and the distal port connected to a pressure transducer and an oscilloscope monitor. As described for invasive blood pressure monitoring, the pressure transducer must be zeroed at the level of the right atrium. The PA catheter is first placed through a sterile sheath to facilitate future manipulations, and is then inserted through a large-bore (7 or 8 French) introducer or multiaccess catheter in the subclavian or IJ vein. If necessary, a femoral vein approach may also be used. During insertion, pressure waveforms are monitored continuously via the *distal port* to identify the intravascular location of the catheter tip (Fig. 4.4). With the balloon fully deflated, the catheter should be inserted to a distance of 15 cm, where the CVP tracing of the superior vena cava or right atrium appears. At this point, the balloon is slowly inflated with 1.5 mL of air and the catheter is advanced into the

right ventricle. The characteristic right ventricular waveform is normally one of a pulsatile systolic pressure of 15 to 30 mm Hg and a diastolic pressure equal to CVP. With further advancement, the catheter should reach the PA, as identified by an abrupt increase in diastolic pressure while systolic pressure remains unchanged. As the catheter is manipulated farther into the pulmonary arterial system, the systolic waveform disappears and gives way to the characteristic pulmonary artery wedge (PAW) tracing. Under normal circumstances, the PAWP is similar to the PA diastolic pressure (6 to 12 mm Hg). With the appearance of the PAW tracing, the balloon is deflated, whereupon the pulsatile PA waveform should reappear. If not, the catheter may be advanced too far into a PA branch (colloquially termed "overwedged") and should be withdrawn slightly with the balloon deflated. When the tip of the catheter is in the proper position, the inflated balloon obstructs antegrade flow through the PA branch in which it is lodged. This creates a continuous stationary blood column from the catheter tip to the left atrium, such that the pressure measured through the distal port should be equivalent to left atrial pressure. Since under normal circumstances left atrial pressure is equivalent to left ventricular end-diastolic pressure (LVEDP), PAWP is used as an estimate of LVEDP or left ventricular (LV) preload. After PA catheter insertion, as with any cannulation of the central venous system, a chest radiograph must be obtained to confirm proper placement and lack of any complications.

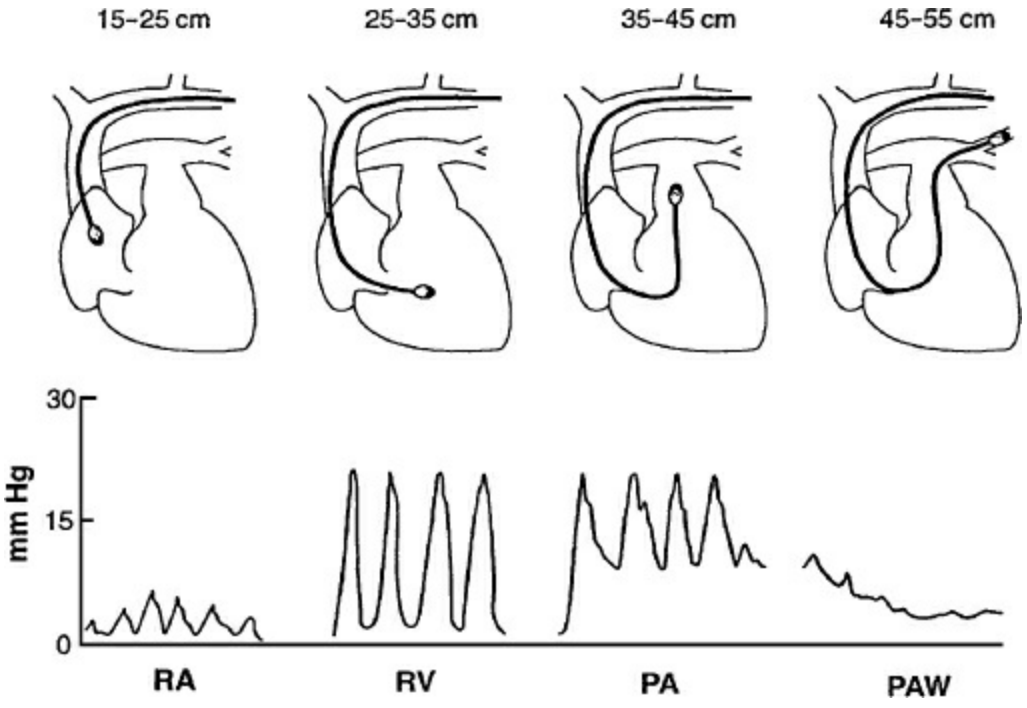

Figure 4.4. Pressure waveforms recorded during advancement of a pulmonary artery (PA) catheter through the right atrium (RA), right ventricle (RV), and PA, and ultimately into the pulmonary artery wedge (PAW) position. In this case, the catheter is inserted via the left subclavian vein. Approximate distances shown are from catheter tip to insertion site.

Pitfalls in Pulmonary Artery Catheter Insertion

A potential difficulty encountered during PA catheter insertion is failure of the catheter to advance into the PA. This is caused by coiling of the catheter in the right ventricle, and is most often a result of the catheter being advanced too rapidly and forcefully. A simple and often successful solution to this problem is to advance the catheter more slowly and continuously, avoiding thrusting. This technique takes full advantage of the balloon-flotation characteristics of the PA catheter, allowing it to float gently with the stream of blood across the pulmonary valve.

Another common problem of PA catheterization is failure to obtain a PAW tracing. Although, in most cases, the reason for this is uncertain, it may be due to a faulty balloon or eccentric inflation. After several unsuccessful attempts to obtain a PAW waveform, the catheter should be removed and the balloon retested. If the balloon is not the source of the problem, there are two options. First, if the patient does not have known pulmonary hypertension, the PA diastolic pressure can be monitored as an estimate of PAWP. However, in cases in which the presence of pulmonary hypertension confounds the use of PA diastolic pressure as a surrogate of PAWP and it is essential to patient management that PAWP be determined, the authors have had success utilizing portable fluoroscopic guidance to manipulate the catheter into the wedge position.

Pitfalls in Interpretation of Pulmonary Artery Wedge Pressure

There are several sources of potential error in interpreting PAWP (and CVP). As mentioned in the section on invasive arterial pressure monitoring, the transducer must remain at the level of the right atrium for pressure measurements to be valid. This is especially important in measuring right heart pressures, as the magnitude of the resultant error in the pressure reading due to transducer malposition is greatest in low-pressure systems.

A source of error in correlating PAWP with LV preload involves changes in intrathoracic pressure. Pressures measured by the PA catheter

are intravascular pressures, whereas the most accurate estimate of actual LV filling pressure is *transmural* pressure. Transmural pressure is equal to the difference between intravascular pressure and intrathoracic pressure. At end-expiration, intrathoracic pressure is normally equivalent to atmospheric pressure and thus considered negligible. For this reason, PAWP should only be determined at end expiration for both spontaneously breathing and mechanically ventilated patients (Fig. 4.5). However, in certain pathologic states (e.g., adult respiratory distress syndrome, high positive-pressure ventilatory settings, and tension pneumothorax), intrathoracic pressure may be significantly increased and produce a false elevation in intravascular pressure (i.e., PAWP). In this setting, the increased PAWP does not reflect a true increase in LV preload, since the physiologically more accurate transmural pressure remains unchanged.

Another situation in which PAWP does not accurately reflect LV preload occurs when the tip of the PA catheter is improperly positioned within the lung. Three physiologic lung zones have been described based on pulmonary arterial, alveolar, and venous pressures. Alveolar pressure exceeds both arterial and venous pressures in zone 1, and exceeds venous pressure in zone 2. As a result, in zones 1 and 2 PAWP is actually more a reflection of airway pressure than left atrial pressure. Only in zone 3 PAWP is accurately reflective of left atrial pressure and not subject to the confounding effects of alveolar pressure. In the supine patient, zone 3 represents the region of the lung posterior to the left atrium, which is the most dependent area of the lung. Since zone 3 has the greatest blood flow, the air-filled balloon tip of the PA catheter will most often float into this zone. However, clues that the PA catheter tip is not positioned within zone 3 are: (a) the presence of marked respiratory variation on the PAW tracing; (b) if the positive end-expiratory pressure (PEEP) is increased and the PAWP increases by 50% or more of the increased PEEP; and (c) if the PAWP is greater than the pulmonary artery diastolic pressure (PADP). The presence of any of these criteria should prompt repositioning of the catheter. It is important to note that any condition that decreases pulmonary vascular pressure (e.g., hypovolemia) or increases alveolar pressure (e.g., high PEEP) can reduce the total area of physiologic zone 3 in the lung, even if the catheter tip is positioned posterior to the plane of the left atrium.

Mitral stenosis creates another pitfall in correlating PAWP with LV preload. In this condition, there is a pressure gradient between the left

atrium and ventricle, such that left atrial pressure is higher than LV end-diastolic pressure. Therefore, although PAWP does reflect left atrial pressure in mitral stenosis, it cannot be used as an accurate predictor of LV preload in this condition.

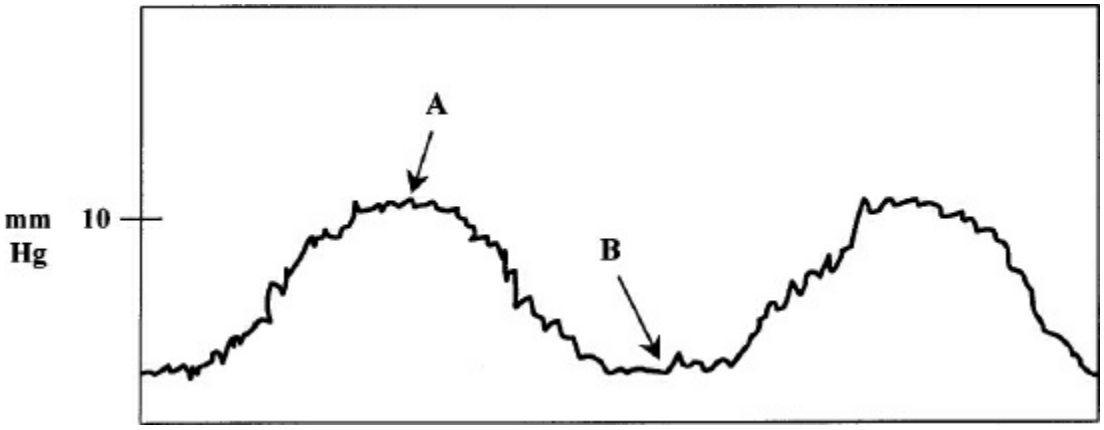

Figure 4.5. Pulmonary artery wedge (PAW) tracing with the usual cyclical respiratory variations. PAW pressure should be measured at end-expiration. This corresponds to the peak of the wedge tracing for spontaneously breathing patients (*point A*) and the valley of the tracing for patients undergoing positive-pressure ventilation (*point B*).

In the presence of normal LV compliance, PAWP provides an accurate estimation of LV end-diastolic volume and thus preload. However, in conditions associated with decreased LV compliance (e.g., ventricular hypertrophy and myocardial ischemia), PAWP may be high even in the face of a normal or even decreased preload. Hence, PAWP is not a reliable index of LV preload in the setting of a poorly compliant ventricle.

The physician who uses a PA catheter to assist in the management of critical illness should bear in mind the above-mentioned shortcomings of PAWP in estimating LV preload. In situations in which PAWP is an unreliable index of left heart filling pressures, there are other modalities currently available to estimate LV preload. These alternative modalities, such as transesophageal echocardiography (TEE) or RVEF obtained from the newer fast-response PA catheters, are discussed in detail below. Due to the increased risk of injury to the PA during wedging of the balloon and the uncertainty of how accurate the data may be, many intensivists follow the PADP in critically ill patients and avoid routine wedging.

Hemodynamic Variables

When used appropriately and knowledgeably, the PA catheter is capable of generating a great deal of information on cardiovascular status. The more commonly utilized hemodynamic variables obtained by the PA catheter are listed in Table 4.3. While many of these variables are measured directly, others must be derived by a calculation. A few parameters, such as CO and systemic vascular resistance (SVR), can be normalized for differences in body size by dividing by the patient's body surface area in square meters, thus yielding CI and systemic vascular resistance index (SVRI), respectively. It is important to mention that in assessing response to treatment interventions, trends in each of the hemodynamic indices listed in Table 4.3 are of more clinical importance than a single reading.

Right Ventricular Ejection Fraction

In 1986, a modified PA catheter was developed for bedside evaluation of right heart function. The device consists of a fast-response thermistor, which permits thermodilution measurement of RVEF and right ventricular end-diastolic volume (RVEDV). This technology provides a direct measurement of preload based on volume rather than estimating preload by pressure criteria (e.g., CVP and PAWP). This concept is particularly important in the setting of positive-pressure ventilation, in which pressure-derived estimates of preload can be inaccurate. The RVEF thermodilution catheter has been especially useful in resuscitation of multiply injured trauma victims. In such individuals, many of whom have significant fluid requirements in the face of high positive-pressure ventilatory requirements, evaluation of preload by conventional parameters (e.g., PAWP) is particularly unreliable.

TABLE 4.3 Hemodynamic Variables Obtained by the Pulmonary Artery Catheter

Variable	Derivation	Range of Normal Values
Central venous pressure (CVP)	N/A	0–8 mm Hg
Pulmonary artery systolic pressure (PASP)	N/A	15–30 mm Hg
Pulmonary artery diastolic pressure (PADP)	N/A	6–12 mm Hg
Mean pulmonary artery pressure (MPAP)	N/A	10–16 mm Hg
Pulmonary artery wedge pressure (PAWP)	N/A	6–12 mm Hg
Cardiac output (CO)	N/A	4.0–8.0 L/min
Cardiac index (CI)	N/A	2.5–4.5 L/min/m^2
Right ventricular ejection fraction (RVEF)	N/A	45–50%
Mixed venous oxygen saturation (SvO_2)	N/A	70–80%
Systemic vascular resistance (SVR)	$80 \times [(MAP - CVP)/CO]$	900–1,400 dynes·s·cm^{-5}
Systemic vascular resistance index (SVRI)	$80 \times [(MAP - CVP)/CI]$	1,600–2,400 dynes·s·cm^{-5}·m^2
Pulmonary vascular resistance (PVR)	$80 \times [(MPAP - PAWP)/CO]$	150–250 dynes·s·cm^{-5}
Pulmonary vascular resistance index (PVRI)	$80 \times [(MPAP - PAWP)/CI]$	200–400 dynes·s·cm^{-5}·m^2
Oxygen delivery (DO_2)	$CI \times 13.4 \times Hgb \times SaO_2$	520–570 mL/min·m^2
Oxygen consumption (VO_2)	$CI \times 13.4 \times Hgb \times (SaO_2 - SvO_2)$	110–150 mL/min·m^2

Hgb, hemoglobin; N/A, not applicable; SaO_2, arterial oxygen saturation.

Cardiac Output

CO, an index of cardiac performance, is defined as the product of heart rate and stroke volume. Stroke volume, in turn, is determined by preload (PAWP), afterload (SVR), and the contractile state of the heart. As a result, all of these factors must be considered when interpreting changes in CO and in making therapeutic decisions to optimize this parameter (see section “Cardiovascular Support”).

The thermodilution method for determining CO was introduced into clinical practice by Ganz and colleagues in 1971. This method is based on the indicator-dilution principle, in which an indicator is injected into the circulation and the CO is determined by the rate of change of the concentration of indicator in the bloodstream. The indicator may either be a dye (dye-dilution method) or a fluid at a temperature above or below that of the blood (thermodilution method). With regard to the latter, 10 mL of an iced or room temperature crystalloid solution (e.g., normal saline) is rapidly injected into the right atrium via the proximal port of the PA catheter. The cold solution then cools the blood with which it mixes in the right heart. As the cool blood flows into the PA, the thermistor near the tip of the catheter senses the change in blood temperature over time. From this data, a computer generates a thermodilution curve; the area under this curve is inversely proportional to the CO. Explained differently, with faster blood transit times through the right heart, the less the blood will be cooled by the cold solution. As a result, the thermistor will detect a lower magnitude of temperature change over time, and the computer will translate this information into a higher displayed CO.

There are a number of pitfalls in the thermodilution method of CO measurement. For example, the injection must be completed within 4 seconds to yield an accurate CO measurement. To reduce variability and

improve accuracy, it is recommended that the CO be determined from the average of three different injections, all of which should be initiated at the same point in the respiratory cycle. In tricuspid regurgitation, the cold solution is transported both antegrade and retrograde across the valve, producing a spuriously low CO. Tricuspid regurgitation can be a common source of error in CO determination in critically ill patients, as many such individuals will have high right-sided heart pressures from acute lung disease and high positive-pressure ventilatory settings. Accuracy of the thermodilution method for measuring CO is also limited in states of severely impaired cardiac performance. In such states, the system experiences difficulty in accurately measuring very low COs (below 2.0 mL/min), especially with the use of room temperature injectates. The use of iced injectates in patients with poor cardiac function can improve the likelihood of an accurate measurement. Finally, the presence of intracardiac shunts confounds interpretation of CO obtained by thermodilution. In both right-to-left and left-to-right shunts, the recorded CO is erroneously high.

Recent technologic advances have made possible the continuous measurement of CO, which obviates the labor-intensive task of manually injecting fluid. Some of the newer models of PA catheters are equipped with an accessory thermal filament approximately 20 cm from the catheter tip. This filament emits heat, which warms the surrounding blood. The thermistor located at the catheter tip detects changes in blood temperature over time in the same manner as described above for the cold fluid injectate method. A computer measures the average CO over a 3-minute interval and displays new values every 30 to 60 seconds. The ideal clinical scenario for use of continuous CO monitoring is the patient with extreme hemodynamic instability who requires frequent adjustments in cardiovascular support.

Indices of Oxygen Metabolism

Since the ultimate goal of cardiovascular monitoring is to ensure adequate tissue oxygenation, it is imperative that critically ill patients, particularly those suffering from shock, be monitored for disturbances in oxygen metabolism. Indeed, it has been demonstrated that in such patients this approach translates into improved survival. There are a variety of parameters reflecting the status of systemic oxygen metabolism, all of which can be measured with the PA catheter. SvO_2 represents the oxygen

saturation of “mixed” blood from three central veins: the superior vena cava, inferior vena cava, and coronary sinus. Normal SvO_2 values range from 60% to 80%. This parameter may be determined *in vitro* with use of a blood gas machine by measuring the oxygen saturation of a pulmonary arterial blood sample drawn through the distal port of the PA catheter. Alternatively, continuous *in vivo* SvO_2 monitoring via reflectance spectrophotometry is possible. This in-line oximetric technique, which is facilitated by a specialized PA catheter equipped with an accessory fiberoptic system, eliminates the cumbersome task of drawing serial PA blood samples and provides new data points at 5-second intervals. The indications for use of this device are similar to those described for continuous CO monitoring.

SvO_2 reflects the discrepancy between total body oxygen delivery (DO_2) and oxygen consumption (VO_2). Alternatively, this relationship is expressed as $SvO_2 = DO_2/VO_2$. Since DO_2 = CO × hemoglobin (Hgb) × arterial oxygen saturation (SaO_2), changes in SvO_2 must reflect a change in CO, Hgb, SaO_2, and/or VO_2. Hence, a low SvO_2 (<60%) indicates a systemic DO_2/VO_2 imbalance caused by one or more of the following: depressed cardiac function, anemia, arterial hypoxemia, or hypermetabolism. A critically ill patient with a decreasing SvO_2 should prompt investigation of the four parameters mentioned above, with an aim toward a specific therapeutic intervention. SvO_2 monitoring is an effective method for early detection and subsequent correction of derangements of these four parameters.

As Table 4.3 indicates, the normal range for DO_2 is 520 to 570 mL/min·m², while for VO_2 it is 110 to 150 mL/min·m². Thus, under normal physiologic conditions, DO_2 exceeds VO_2 by a 5:1 ratio and VO_2 is independent of DO_2 (i.e., supply independent). In a normal, healthy individual VO_2 remains independent over a wide range of DO_2 values. VO_2 can remain in the normal range even at lower DO_2 ranges, because as DO_2 falls the tissues respond by increasing the amount of oxygen they extract. However, increased oxygen extraction compensates only up to a point. If DO_2 continues to fall below a critically low level, as in cardiogenic shock, VO_2 will begin to decrease and become dependent on DO_2 (i.e., supply dependent). In this scenario, CO, Hgb, and SaO_2 should be examined and optimized to restore the supply-independent relationship

between DO_2 and VO_2. In septic shock, metabolic demands are dramatically increased and VO_2 must therefore rise concomitantly to meet these demands. However, if DO_2 does not rise proportionately, VO_2 will become limited by DO_2 and supply dependency will ensue. In general, a sudden decrease in SvO_2 heralds a developing supply-dependent situation. The goal of monitoring parameters of oxygen metabolism is to maintain an adequate DO_2, so that VO_2 remains supply independent and adequate tissue oxygenation is ensured. However, attempts to achieve supranormal DO_2, while once believed to improve outcomes in critically ill patients, have not proven beneficial.

Blood Lactate Levels

The use of blood lactate levels is a valuable adjunct to guide therapy and gauge illness severity in the management of both medical and surgical patients. As a practical matter, the ready availability of blood gas analyzers with immediate lactate turnaround increases the utility of lactate measurement to the clinician.

When tissue demands for oxygen exceed supply, anaerobic metabolism begins and metabolic acidosis results. Pyruvate is unable to enter the Krebs cycle and undergo oxidative phosphorylation secondary to inadequate oxygen supply. In states in which lactate production exceeds the capacity for clearance by the liver, kidneys, and skeletal muscle, elevated blood lactate levels result. Hyperlactatemia may occur in the setting of adequate tissue perfusion such as with catecholamine administration, alkalosis, or states of increased metabolic activity (i.e., sepsis and burns). In these cases, the body's buffering mechanisms may compensate for any fall in pH. In states of poor tissue perfusion, the body's buffering capacity is overwhelmed and metabolic acidosis results.

Substantial data exist for the use of serial lactate measurement as an endpoint for resuscitation in surgical patients. In addition, initial lactate levels and lactate clearance rates have been used to predict mortality rates in the ICU setting. Failure to normalize lactate levels within 96 hours uniformly predicted mortality. Although conflicting data on the utility of lactate monitoring exists, a recent multicenter randomized controlled trial found a reduction in hospital mortality with lactate-guided treatment and a meta-analysis found that lactate clearance in critically ill patients is predictive of lower mortality.

Complications of Pulmonary Artery Catheters

Although extremely useful, the PA catheter is an invasive monitoring device with a number of potential complications. Thus, the PA catheter should only be used when the benefit of the information provided by it outweighs the risks associated to the patient. Similarly, when the data obtained from a PA catheter are no longer clinically useful, it should be promptly removed.

In addition to adverse effects of central venous cannulation, the PA catheter insertion process can cause cardiac dysrhythmias. Premature ventricular contractions are quite common as the catheter tip traverses the right ventricle, and usually resolve spontaneously after the catheter is advanced into the PA. Rarely, ventricular tachycardia and fibrillation can occur, but usually resolve with electrical cardioversion. New right bundle branch block may occur in up to 3% of patients undergoing PA catheterization. This conduction disturbance is normally of a benign and transient nature, but in patients with preexisting left bundle branch block, complete heart block may result. Therefore, a transthoracic pacemaker should be immediately available when advancing a PA catheter in a patient with known left bundle branch block.

PA catheters can also cause thromboembolism of the central veins, right heart chambers and valves, and PA. Various degrees of venous thrombosis may occur in over half of individuals with a PA catheter in place, and when identified, mandates catheter removal and anticoagulation. Autopsy studies of patients who died with indwelling PA catheters have identified right-sided valvular injury as well as endocarditis.

Another infrequent complication is catheter knotting within the right ventricle. Risk factors for this include a dilated right ventricle and advancing long lengths of catheter too forcefully and quickly. A clue to the presence of a knotted intraventricular catheter is difficulty encountered during its removal. Most knotted catheters can be successfully removed with the assistance of fluoroscopy and angiographic techniques.

The most serious and potentially life-threatening complication of PA catheterization is PA rupture. The reported frequency of this unfortunate complication is approximately 1 in 800 catheterizations, with an attendant mortality of >50%. Risk factors for PA perforation include pulmonary hypertension, anticoagulation, and hypothermia. In addition, advancement of the catheter with the balloon fully deflated, as well as overinflation of the balloon, particularly in the “overwedged” position, predispose to this

complication. Massive hemoptysis usually heralds the onset of this devastating complication. Treatment consists of isolation of the contralateral lung with selective endobronchial intubation, initiation of PEEP, and maintenance of the catheter in its existing position. If these measures fail, emergent pulmonary resection is indicated. Should a pseudoaneurysm develop following clinical resolution of a ruptured PA, this can most often be managed with endovascular coil embolization.

TABLE 4.4 Hemodynamic Profile for Each Type of Shock

Type of Shock	PAWP	CI	SVRI	SvO_2
Hypovolemic	↓	↓	↑	↓
Cardiogenic	↑	↓	↑	↓
Early septic	↓	↑	↓	↑
Late septic	↑	↓	↓ or ↑	↓
Neurogenic	↓	↓ or ↔	↓	↓

CI, cardiac index; PAWP, pulmonary artery wedge pressure; SvO_2, mixed venous oxygen saturation; SVRI, systemic vascular resistance index.

Hemodynamic Profiles of Shock

Although the hallmark of all shock states is a deficit in tissue oxygenation, each type of shock has its characteristic hemodynamic profile (Table 4.4). The PA catheter is a useful instrument for generating these hemodynamic data to assist in differentiating between the various shock states. In hypovolemic shock, the primary problem is reduced intravascular volume, as reflected by a decreased PAWP. As a result of the decreased preload, CI is likewise decreased. The peripheral vascular tone increases in response to increased endogenous catecholamines, yielding an increased SVRI. In this case, DO_2 is markedly less than tissue oxygen extraction resulting in a fall in SvO_2. The hallmark of cardiogenic shock is a reduced CI, yielding a high PAWP and SVRI. The net result is a decrease in SvO_2. Conversely, early septic shock is characterized by a hyperdynamic state and extreme loss of vascular tone, producing a profound decrease in SVRI and an increase in CI. Early in sepsis, SvO_2 rises as a result of the hyperdynamic state, peripheral vascular shunting, and impaired tissue oxygen uptake. Late septic shock is complicated by cardiac failure, as indicated by a decreased CI. As the heart fails in the face of ongoing septic shock, the PAWP rises and the SVRI may increase or decrease, depending upon

which condition predominates. A falling SvO_2 in prolonged septic shock is an ominous sign that heralds an extreme deficit in tissue oxygenation. Finally, neurogenic shock is characterized by a primary deficit of vascular tone (i.e., low SVRI). As a result of peripheral blood pooling, PAWP decreases and consequently a decreased CI often results. SvO_2 is reduced by the same mechanism as in hypovolemic shock.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE plays a vital role in the hemodynamic evaluation of surgical patients as an integral diagnostic device for evaluation of the heart, aorta, and pericardial space. As a result of its portability, TEE is readily available for use in the ICU, emergency department, or operating room.

TEE is favored over transthoracic echocardiography (TTE) for the cardiovascular assessment of surgical patients for a variety of reasons: (a) Logistically, TEE is more practical for intraoperative use; (b) TEE offers better visualization of the left atrium and descending aorta; (c) critically ill trauma and postoperative surgical patients often have interfering dressings, central venous catheters, thoracostomy tubes, and chest wall abnormalities rendering TTE difficult or impossible; and (d) a mechanically ventilated patient who is difficult to properly position for optimal acoustic windows precludes an adequate TTE examination.

TEE provides excellent anatomic detail of the cardiac chambers and valves. It can be used to evaluate global and regional cardiac wall motion abnormalities, valvular structure and function, vegetations, cardioembolic sources, and intravascular volume status. In addition, TEE permits clear visualization of the pericardial space, and is therefore beneficial in evaluating pericardial effusions. Furthermore, since the esophagus lies directly adjacent to the descending aorta, the latter structure is particularly amenable to visualization with TEE.

TEE has proven itself as an essential tool in the critical care unit, especially in the setting of unexplained hypotension. Detection of cardiac contractile dysfunction and wall motion abnormalities suggestive of myocardial ischemia are important findings that prompt specific treatment. The diagnosis of new intraoperative segmental wall motion abnormalities was found to be a more sensitive indicator of myocardial ischemia than ECG monitoring. In addition, LV end-diastolic volume can be closely approximated with TEE, and is more reliable than PAWP in evaluating preload. The limitations of PAWP for assessing preload are discussed in

the section on PA catheters. A final application of TEE to critical illness is in patients with both unexplained hypotension and hypoxia, in whom a bedside TEE examination is an accurate and rapid technique for detecting pulmonary emboli.

The most common indication for TEE in trauma patients is the assessment of blunt cardiac injury. Disruption of the cardiac chambers, valvular injury, coronary artery thrombosis, and the echocardiographic stigmata of myocardial contusion may be visualized with TEE. Also, since severe myocardial contusion and cardiac tamponade from blunt cardiac trauma may present with identical clinical features, TEE is a valuable imaging modality for differentiating between these two. Finally, in experienced hands TEE has been shown to have high sensitivity and specificity to diagnose blunt aortic injury and can be performed rapidly in an unstable patient in the emergency room or operating room.

CARDIOVASCULAR SUPPORT

The goals of cardiovascular support of surgical patients are to maintain adequate tissue oxygenation and organ perfusion. The achievement of these goals requires effective clinical management and technical support. As mentioned in detail earlier in this chapter, a variety of cardiovascular monitors are available to facilitate interpretation of hemodynamic status. Once monitoring is properly established, cardiovascular support can be initiated in a safe and effective manner. Volume resuscitation warrants special consideration as traditional methods of liberal crystalloid infusion to improve fluid status have fallen out of favor. Current recommendations support early initiation of blood product administration in a 1:1:1 or 1:1:2 ratio of red blood cells to plasma to platelets when loss of blood volume is contributing to critical illness. Also important to the care of septic patients is the concept of goal-directed resuscitation which uses monitoring targets to help drive cardiovascular support. To date however, trials have not demonstrated a survival benefit with goal-directed resuscitation. Pharmacologic agents, the cornerstone of cardiovascular support, fall into three general categories, with some medications falling into more than one category: (a) inotropic agents, which strengthen the cardiac contraction and thereby increase CO and DO_2; (b) vasodilators, which decrease vascular resistance; and (c) vasopressors, which may be used to elevate blood pressure in acute situations of profound hypotension. All of these groups of drugs have the distinct advantages of a rapid onset and short

duration of action, while having anticipated and manageable adverse effects.

INOTROPIC AGENTS

Inotropic agents are usually administered in an attempt to improve cardiac performance and thus preserve vital organ perfusion. Inotropic support is frequently used in the surgical ICU to treat patients in the septic or posttraumatic state. Suboptimal CO in these settings leads to inadequate tissue perfusion, manifested by elevated lactate levels, decreased SvO_2, and multiorgan failure. In addition, short-term inotropic therapy is frequently needed during major surgical procedures (cardiac and noncardiac) for patients with chronic heart failure. Short-term cardiac support may also be needed for patients with acute heart failure, such as after acute myocardial infarction. Furthermore, inotropic support may be indicated as a "pharmacologic bridge" for patients who are awaiting more definitive treatment, such as coronary artery bypass surgery, valve repair/replacement, ventricular assist device placement, or cardiac transplantation. Finally, inotropic support is commonly used in the early period after cardiac surgery, in an attempt to optimize postoperative cardiac function until the heart fully recovers from cardiopulmonary bypass.

β-Adrenergic Receptor Agonists

To varying degrees, β-agonists enhance both myocardial contractility (inotropy) and diastolic relaxation (lusitropy) and increase heart rate (chronotropy). They function by binding cell surface β-receptors and activating guanine nucleotide-bound protein. This in turn activates adenylate cyclase, which catalyzes the synthesis of cyclic adenosine 3′, 5′ monophosphate (cAMP). cAMP-dependent protein kinases phosphorylate intracellular proteins, resulting in intracellular calcium influx and enhanced myocardial contraction.

Dobutamine

Dobutamine is a synthetic catecholamine existing as a racemic mixture of two stereoisomers and providing both α-adrenergic activity (levo-isomer) and β-adrenergic activity (dextro-isomer). Dobutamine is very effective in augmenting cardiac contractility, stroke volume, CO, and pulse pressure. In addition, it reduces right and LVEDPs, as well as systemic and

pulmonary vascular resistances, all with minimal change in heart rate. Dobutamine may also exert favorable metabolic effects on compromised or ischemic myocardium. Coronary perfusion pressure is augmented, coronary artery vasodilation occurs, and diastolic perfusion time is lengthened. The increased oxygen requirements of positive inotropy are countered by the favorable effects of ventricular unloading in both systole and diastole. As a result, coronary blood flow and myocardial perfusion are increased in proportion to or exceeding any increases in myocardial VO_2.

Traditionally, dobutamine has been primarily considered a myocardial β_1-agonist, while having minimal effects on peripheral vascular α_1- and β_2-receptors. However, this mechanism has been debated as more recent studies have demonstrated an increase in CO in the absence of enhanced ventricular contractility after racemic dobutamine infusions. Instead, peripheral β_2 stimulation augmented CO by reducing SVR. At the same time, stimulation of the α-receptors potentiated an increase in CO by reducing venous capacitance and thus increasing venous return. The combined properties of β_1-mediated inotropy and β_2-induced afterload reduction make dobutamine an ideal agent for treating the failing heart.

The typical dose of dobutamine ranges from 2 to 20 μg/kg/min. Infusion rates between 5 and 15 μg/kg/min predominantly cause an increase in cardiac contractility, peripheral vasodilation, and a dose-dependent increase in heart rate. This dose range is commonly used in patients with advanced heart failure, cardiac failure complicating septic or traumatic shock, cardiogenic shock after an acute myocardial infarction, or for hemodynamic support following cardiac surgery.

There are a few limitations of dobutamine. Higher doses may cause tachycardia, leading to an imbalance of myocardial oxygen supply and demand. At higher heart rates diastolic myocardial perfusion time shortens, while myocardial VO_2 increases. Although uncommon, atrial and ventricular arrhythmias may occur, particularly at higher doses.

Dopamine

As a biochemical precursor of epinephrine, dopamine activates α- and β-receptors in addition to dopamine 1 and 2 (DA_1 and DA_2) receptors. DA_1-receptor activation leads to renal, mesenteric, coronary, and cerebral arterial vasodilation, while DA_2-receptor activation inhibits endogenous norepinephrine release. Dopamine works in a dose-dependent fashion. At

low doses (1 to 3 μg/kg/min), it predominantly stimulates DA_1 receptors, producing renal artery vasodilation. This so-called renal dose of dopamine is touted to improve renal blood flow and urine output in patients at higher risk for acute renal failure, such as those in septic shock or those undergoing major surgical procedures who have preexisting renal artery stenosis or chronic renal insufficiency. Because of the splanchnic vasodilatory properties associated with DA_1 activation, low-dose dopamine infusion may improve intestinal perfusion during mesenteric ischemia.

At moderate doses (3 to 6 μg/kg/min), cardiac β_1-receptors are stimulated, leading to enhanced ventricular contractility with minimal effect on heart rate and blood pressure. However, at higher doses (>6 μg/kg/min), peripheral α_1-receptor stimulation occurs, causing vasoconstriction and elevation of blood pressure. With escalating doses, dopamine produces tachycardia and should be used cautiously in patients with coronary artery disease. Additionally, higher doses of dopamine cause increased ventricular wall stress, which can further disrupt the balance of myocardial oxygen supply and demand. This drug also has a dose-related arrhythmogenic effect. Since its effect is based on the release of endogenous catecholamines, dopamine is not as effective in patients who are catecholamine depleted. It is important to note that at least two randomized trials comparing dopamine to norepinephrine for treatment of sepsis do not demonstrate any greater renal protective effect with dopamine. In fact, there has been some suggestion of greater renal injury in those patients treated with dopamine.

Epinephrine

Epinephrine is an endogenous catecholamine secreted by the adrenal medulla. Pharmacologically, epinephrine stimulates β_1, β_2, and α-receptors in a dose-dependent manner. At lower doses of infusion (0.01 to 0.1 μg/kg/min), β-receptors are primarily stimulated, leading to increased cardiac contractility and heart rate (myocardial β_1), as well as peripheral vasodilation (peripheral β_2). At higher infusion rates (>1 μg/kg/min), peripheral α-adrenergic stimulation produces increased SVR (peripheral vasoconstriction) and a subsequent rise in arterial blood pressure (vasopressor activity). In addition, there is a dose-dependent rise in heart rate and an increased risk of arrhythmias and myocardial ischemia.

Norepinephrine

Norepinephrine is a potent catecholamine exerting both α- and β-adrenergic activity. It typically results in a significant increase in mean arterial pressure due to its vasoconstrictive effects, while causing minimal change in heart rate. It has some inotropic effects and will slightly increase CO. It is typically used in patients with profound hypotension in a setting of adequate volume resuscitation. Norepinephrine is traditionally used in patients with septic shock or following severe neurologic events with hypotension from decreased SVR (with preserved CO). There were historical concerns that further vasoconstriction may worsen the shock syndrome and perfusion, thus leading to end-organ ischemia (especially renal hypoperfusion resulting in oliguria and renal failure). However, several recent studies investigating norepinephrine in septic shock suggest that it can successfully increase blood pressure without causing the feared deterioration in organ function and in fact, may be the preferred agent for sepsis. It has been shown that when CO is maintained, treatment with norepinephrine alone has no negative effects on splanchnic tissue oxygenation. Norepinephrine effects on serum lactate levels in patients with septic shock have been studied. Tissue oxygenation, as assessed in several studies by serum lactate levels in patients with septic shock, does not worsen, and may even improve with norepinephrine. Clearly, there has been concern regarding the effects of norepinephrine on the kidney. In the setting of hypotension and hypovolemia during hemorrhagic shock, many vasoconstrictors, including norepinephrine, may have several harmful effects on renal function. However, in hyperdynamic septic shock, norepinephrine has been shown to cause a significant decrease in serum creatinine, blood urea nitrogen, free water clearance, and fractional excretion of sodium, while causing an increase in urine output, creatinine clearance, and osmolar clearance.

In summary, clinical experience with norepinephrine in patients with septic shock suggests that it can effectively increase blood pressure without causing deterioration in CI or end-organ function. Norepinephrine doses of 0.01 to 3 μg/kg/min have consistently been shown to improve hemodynamic variables in the large majority of patients with septic shock.

Isoproterenol

A synthetic catecholamine, isoproterenol, possesses potent β-agonist properties. Significant increases in CO, myocardial contractility, and

chronotropy all result from myocardial β_1-stimulation. Peripheral β_2-activation causes peripheral vasodilation, which decreases afterload and thereby facilitates an increase in CO and pulse pressure. Usual indications for isoproterenol infusions are limited to situations in which enhancement of both heart rate and contractility are desired, such as for early postoperative support of the denervated, bradycardic transplanted heart. A major advantage of isoproterenol is that it directly decreases pulmonary vascular resistance. Thus, this agent is also beneficial in right ventricular failure and chronic pulmonary hypertension. However, because of its potent β-adrenergic activity, myocardial oxygen demand is increased and tachycardia-induced diastolic coronary filling is decreased. Therefore, isoproterenol is contraindicated in patients with ongoing coronary ischemia.

Phosphodiesterase Inhibitors

Phosphodiesterase III inhibitors (PDIs) are a unique category of inotropic drugs. These agents inhibit myocardial cAMP phosphodiesterase activity, thus increasing cellular concentrations of cAMP and improving the myocardial contractile mechanism. In addition to enhancing ventricular performance, the increased cAMP in vascular smooth muscle causes peripheral vasodilation and reduced resistance.

Amrinone

Amrinone is the prototypical PDI. This agent concomitantly improves cardiac performance and decreases SVR. However, due to the absence of catecholamine effects, there are minimal associated increases in heart rate. As a result, amrinone does not affect myocardial oxygen demand. An additional advantage of amrinone is that it reduces pulmonary vascular resistance. As a result, this agent can be particularly effective in patients with left heart failure complicated by pulmonary hypertension as well as in right ventricular failure. Amrinone is frequently used in combination with other inotropic agents. Although these combined agents act through different mechanisms, they exert potentiative effects in enhancing myocardial contractility.

Amrinone is typically initiated as a 0.75 mg/kg loading dose over several minutes, followed by an infusion that is started at 5 μg/kg/min and can be titrated to 20 μg/kg/min. Although lower rates of infusion usually do not have much effect on blood pressure, higher infusion rates may lead

to profound vasodilation. Other drawbacks of this agent are its long half-life (3.5 hours), its potential for causing arrhythmias (particularly supraventricular), and the risk of thrombocytopenia with prolonged infusions.

Milrinone

Milrinone is the preferred PDI for clinical use. The drug's mechanisms of action and hemodynamic effects closely parallel those of amrinone. However, the potency of milrinone is 10 to 30 times higher than amrinone, which translates into smaller doses used and fewer side effects. Thrombocytopenia is unusual, arrhythmias are less frequent, and the half-life is much shorter (1.5 to 2 hours). The usual loading dose of milrinone is 50 μg/kg infused over 10 minutes, followed by a continuous infusion rate of 0.375 to 0.75 μg/kg/min. It is useful in patients who are unresponsive to β-agonists, and does not significantly increase myocardial O_2 demand.

Ionized Calcium

Calcium is a major regulatory cation that plays a central role in muscular contraction and relaxation by regulating the actomyosin contractile apparatus. In addition to being critical to optimal myocardial contraction, calcium is important for mediating contraction of vascular smooth muscle and maintenance of vascular tone. Ionized calcium is the physiologically active fraction that circulates in blood. Ionized calcium levels generally range from 4.0 to 5.0 mg/dL (1.0 to 1.25 mmol/L). As a result of altered protein binding, acid–base status, and other circulating factors, ionized calcium levels are frequently diminished during shock. Other causes of reduced ionized calcium include chronic renal failure, blood transfusions (containing calcium binding citrate), and cardiopulmonary bypass. While patients with mildly or moderately reduced ionized calcium levels may maintain a normal CO and blood pressure, those with severely reduced levels frequently have significant hypotension and cardiac contractile dysfunction. Therefore, patients with decreased ionized calcium levels usually manifest an immediate cardiovascular improvement from parenteral calcium administration.

Levosimendan

Levosimendan is a new inotrope currently being evaluated in a Phase III clinical trial (Levosimendan in Patients With Left Ventricular Systolic

Dysfunction Undergoing Cardiac Surgery on Cardiopulmonary Bypass [LEVO-CTS]) in the United States. It works as a calcium-sensitizing agent as it enhances the cardiac myocyte function by binding to cardiac troponin C, improving its response to calcium. The net effect on the heart is inotropy and lusitropy (cardiac relaxation). It also acts by opening ATP-dependent potassium channels on vascular smooth muscle cells and cardiac myocytes, leading to coronary and peripheral vasodilation and a resultant decrease in cardiac preload and afterload. A recently published meta-analysis of 25 trials that compared levosimendan to dobutamine or placebo in the treatment of decompensated heart failure found a reduction in total mortality with levosimendan but an increased risk of hypotension.

VASODILATORS

Parenteral vasodilators are useful in treatment of the failing ventricle. These agents reduce both preload and afterload, thus reducing metabolic demands of the myocardium. Arterial vasodilation decreases afterload, which decreases the systolic workload of the heart and allows it to eject more effectively. By causing venodilation, these drugs also reduce preload and thus myocardial wall tension. By the mechanisms just mentioned, a reduction in afterload or preload independently enhances the myocardial oxygen supply/demand ratio. Vasodilators are also useful in the setting of poorly controlled hypertension in the early postoperative period. In such cases, a reduction in blood pressure is desirable to reduce the risk of bleeding from operative sites.

Nitroprusside

Nitroprusside is an effective vasodilator acting on venous and arterial vascular smooth muscle in both the systemic and the pulmonary vascular beds. Systemic venodilation reduces blood pressure by decreasing venous return and thus CVP. Arterial vasodilation reduces afterload, thereby decreasing blood pressure and at the same time enhancing CO. Nitroprusside has the advantage of an extremely rapid onset of action, effectively lowering blood pressure within seconds to minutes. Similarly, its effects rapidly dissipate after decreasing or terminating the infusion, permitting precise titration of the desired blood pressure.

Infusion rates of nitroprusside typically begin at 0.5 μg/kg/min and can be titrated upward until the desired blood pressure is achieved. Hypotension may develop, particularly in patients with inadequate filling

pressures, thus stressing the need for continuous arterial blood pressure monitoring during nitroprusside therapy. Because nitroprusside is degraded by light exposure, the infusion bag must be wrapped in aluminum foil or other opaque materials.

A very rare but potentially serious side effect of nitroprusside is cyanide toxicity. This complication usually accompanies excessive dosages (>3 µg/kg/min) used over a prolonged period of time (>72 hours). Nitroprusside is metabolized by red blood cells and the liver to cyanide and thiocyanate, both of which inhibit aerobic metabolism. Toxicity is manifested by lactic acidosis from anaerobic tissue metabolism, as well as elevated SvO_2 as the result of a disturbance in oxidative phosphorylation. Clinically, toxicity is manifested as tremors, hypoxia, nausea, and disorientation. The diagnosis is confirmed with serum cyanide or thiocyanate levels. The treatment is immediate cessation of nitroprusside and administration of hydroxocobalamin, which converts cyanide to cyanocobalamin (a form of vitamin B_{12}).

Nitroglycerine

By acting directly on vascular smooth muscle, nitroglycerine predominately causes venodilation, while possessing some arterial vasodilatory properties as well. An important attribute of nitroglycerine is that it dilates coronary arteries; hence, this agent is preferable to nitroprusside in patients with coronary artery disease. Both large and small coronary arteries are dilated, which results in enhanced blood flow to vulnerable subendocardial myocardium. Postoperatively, nitroglycerine is also effective in preventing coronary artery vasospasm.

Nitroglycerine is available in intravenous, oral, sublingual, and topical forms, all of which are commonly used in the perioperative setting in patients at risk for myocardial ischemia. Intravenous infusion of nitroglycerine is typically started at a rate of 5 to 20 µg/min. The dose may be increased every few minutes in 10 µg increments until the desired blood pressure or improvement in angina is achieved. Nitroglycerine has a low risk of serious toxicity. Headache, nausea, dizziness, tachyphylaxis, and hypotension are adverse effects associated with this drug.

Inhaled Pulmonary Vasodilators

Inhaled Nitric Oxide

Pulmonary hypertension can be characterized by an increase in pulmonary vascular resistance, pulmonary arterial wall thickening, and right ventricular dysfunction, which results in impaired oxygen exchange. The goal of patients with clinically significant pulmonary hypertension is to improve right ventricular function without increasing myocardial oxygen demand or compromising the hemodynamic function of the systemic circulation. Experimental models have shown that inhaled nitric oxide (NO) reverses hypoxic pulmonary vasoconstriction without affecting systemic hemodynamic function.

NO is a naturally occurring local vasodilator synthesized by the vascular endothelium. Its synthesis is mediated by the activity of NO synthase on the amino acid L-arginine. NO activates guanylate cyclase, which generates cyclic guanosine 3, 5′-monophosphate (cGMP). The latter causes relaxation of adjacent vascular smooth muscle. Upon entering the bloodstream, NO binds hemoglobin with a high affinity and is quickly inactivated. Therefore, the molecule is essentially devoid of any systemic effects. Inhaled NO reaches pulmonary vascular smooth muscle by diffusion through ventilated alveoli, causing relaxation of adjacent PAs. This concept is important in patients with intrapulmonary shunts, because inhaled NO increases arterial oxygenation by redistributing blood flow to well-ventilated regions and thereby improving ventilation/perfusion mismatch. This is in contrast to intravenous vasodilators (e.g., nitroprusside), which may exacerbate the ventilation/perfusion mismatch by nonselectively dilating the entire pulmonary vasculature bed.

One of the most important clinical uses of inhaled NO is in the treatment of acute respiratory distress syndrome (ARDS). Patients with ARDS characteristically suffer from pulmonary arterial hypertension, intrapulmonary shunting, and reduced arterial oxygenation. Inhaled NO in patients with ARDS reduces pulmonary arterial pressure and increases arterial oxygenation by decreasing intrapulmonary shunting, all in the absence of systemic vasodilation.

Inhaled NO is also extremely effective in neonates with persistent pulmonary hypertension of the newborn. By reducing pulmonary arterial pressure and improving arterial oxygenation, inhaled NO often circumvents the need for extracorporeal membrane oxygenation. Another major clinical application of inhaled NO is in patients with severe pulmonary hypertension, right ventricular failure, and hypoxemia following certain cardiothoracic surgical procedures. Examples include

valvular surgery, coronary artery bypass, implantation of ventricular assist devices, heart transplantation, and lung transplantation.

The toxic effects of inhaled NO remain to be completely defined. Concentrations of >20 ppm in patients for several weeks have been used without any apparent untoward effects. However, there are concerns that methemoglobinemia and tachyphylaxis may complicate prolonged NO therapy.

Inhaled Epoprostenol

Inhaled epoprostenol (prostacyclin, PGI_2) has been used increasingly in patients with pulmonary hypertension. It acts by countering the effects of Thromboxane A_2, which stimulates platelet activation and aggregation. In addition to its function as a platelet inhibitor, epoprostenol is a potent vasodilator with a very short half-life (25 minutes), similar to NO. However, because it is less costly than NO, many centers utilized inhaled epoprostenol as a first-line agent for reversible pulmonary hypertension. While there is data to suggest that inhaled NO has greater beneficial effects in neonates and children, there is little data to support any superiority over inhaled epoprostenol in adults. It is increasingly being used after cardiothoracic surgery in select patients including those undergoing lung transplantation and postcardiopulmonary bypass. Specifically, patients with pulmonary hypertension undergoing cardiac surgery respond from inhaled epoprostenol with reduced pulmonary pressure and improved right ventricular function. With inhaled administration, there is no evidence of platelet dysfunction or increased risk of bleeding. The toxicity profile is quite low, although it does cause mild systemic vasodilation and resultant hypotension.

VASOPRESSORS

Vasopressor therapy is usually reserved for patients in septic or neurogenic shock whose blood pressure fails to respond to volume resuscitation. In these settings, peripheral vasoconstriction may increase SVR and blood pressure, thus improving coronary and cerebral blood flow. Another common setting in which these agents are used is in the perioperative maintenance of blood pressure that has been artificially lowered by general or regional anesthetics.

Vasopressin

Vasopressin, also termed antidiuretic hormone, is a peptide hormone produced in the hypothalamus and stored in the posterior lobe of the pituitary gland. Vasopressin affects numerous organ systems. In the brain, vasopressin acts as a neurotransmitter mediating thermoregulation, nociception, and release of adrenocorticotropic hormone. Moderate doses of vasopressin cause vasodilation in the pulmonary vasculature, whereas higher doses stimulate pulmonary vasoconstriction. Hematologically, vasopressin has several effects on thrombosis and hemostasis, including promotion of platelet aggregation and release of both factor VIIIa and von Willebrand factor from the vascular endothelium. In the distal tubule and collecting duct of the kidney, vasopressin stimulates water reabsorption, producing concentrated urine. High vasopressin levels stimulate smooth muscle contraction in both the uterus and the gastrointestinal tract and promote hepatic glycolysis. Finally, elevated concentrations of vasopressin produce vasoconstriction in vascular smooth muscle cells.

Vasopressin plays a critical role in the regulation of fluid balance. It is released in response to a decrease in blood volume and an increase in osmolarity. Two distinct receptor subtypes mediate the principal end-organ effects. The V_1 receptor is present on vascular smooth muscle cells throughout the body, particularly in the skin, skeletal muscle, and thyroid gland vasculature. The majority of end-organ effects are mediated by the V_1 receptor. The direct vasopressor effects are a result of V_1-mediated intracellular signal transduction. G protein-coupled activation of phospholipase C results in the release of calcium from the sarcoplasmic reticulum and a subsequent increase in peripheral resistance. The V_2 receptor is present in the distal and collecting tubules of the glomeruli and promotes water reabsorption. These effects are mediated by an increase in intracellular levels of cAMP and by activation of protein kinase A. A third receptor, V_3, is located in the posterior lobe of the pituitary gland.

Under normal physiologic conditions, endogenous vasopressin levels are below the vasoactive range. Septic shock-associated exhaustion of neurohypophyseal stores secondary to intense and prolonged stimulation, as well as impairment of baroreflex-mediated stimulation of vasopressin release, often lead to inappropriately low levels of endogenous vasopressin. Low doses of exogenous vasopressin stimulate the vascular V_1 receptors and have been shown to produce a significant rise in mean arterial pressure in septic shock, often leading to the discontinuation of traditional vasopressors. Clinical evidence suggests that vasopressin

therapy may be an available alternative or adjunct for patients in septic shock as well as refractory vasodilatory shock after cardiopulmonary bypass. As such, vasopressin is often a first-line agent for patients with sepsis or vasodilation after cardiopulmonary bypass. Vasopressin has been used clinically to treat a variety of disorders, both as an antidiuretic and as a vasoconstrictor. Other uses of vasopressin include diabetes insipidus and gastrointestinal bleeding. Desmopressin, a synthetic, longer-acting analog of vasopressin with minimal vasopressor activity, has been used to treat nocturnal enuresis, hemophilia A, and von Willebrand disease.

Vasopressin is distributed throughout the extracellular space. With a half-life of 10 to 35 minutes, the vasopressor effects after a single dose last about 30 to 60 minutes. When the goal is to maintain continuous hemodynamic support, vasopressin must be given by continuous intravenous infusion. The dosing range of 0.01 up to 0.1 U/min is most effective with vasodilatory shock without causing significant adverse effects. Vasopressin is inactivated and metabolized by the kidney and liver; 5% to 15% is excreted in the urine. Possible adverse effects of therapeutic vasopressin include decreased CO, angina, myocardial ischemia, ventricular dysrhythmia, bronchial constriction, and splanchnic ischemia.

Phenylephrine

Phenylephrine is a pure α_1-agonist. It is a potent pulmonary and systemic vasoconstrictor without significant direct cardiac effects. This drug has a rapid onset and short duration of action. Because of its pure α-adrenergic effects, phenylephrine can increase SVR and blood pressure without causing arrhythmias. Thus, this is a useful vasopressor if arrhythmias are complicating the therapy of inotropic agents such as dopamine or norepinephrine, and is the drug of choice when pure vasoconstriction is desired. Phenylephrine is often the drug of choice administered intraoperatively during general or regional anesthesia and can be extremely useful in maintaining blood pressure in patients with epidural anesthesia postoperatively, as these patients often develop profound vasodilation secondary to the local anesthetics used in the pump. The dose for infusion ranges from 20 to 200 μg/min.

Metaraminol

Metaraminol (Aramine) is an older indirect-acting sympathomimetic

amine with hemodynamic actions similar to norepinephrine. Systolic and diastolic blood pressures are increased predominately by vasoconstriction. Metaraminol will also cause venoconstriction and pulmonary vasoconstriction. Unlike norepinephrine and phenylephrine, it is a long-acting agent, with effects lasting from 20 to 60 minutes. Clinical indications for metaraminol parallel those of phenylephrine. However, the use of metaraminol has decreased because of the immediate and short-acting effects of phenylephrine. Metaraminol may cause cardiac arrhythmias, particularly in patients with myocardial infarctions and in patients receiving volatile anesthetics, such as halothane, which sensitize the heart to catecholamines.

INTRA-AORTIC BALLOON COUNTERPULSATION

Despite the recent availability of LV assist devices and other new devices to support the failing heart, the intra-aortic balloon pump (IABP) remains the mainstay of mechanical ventricular support. The basic physiologic principle behind the IABP, counterpulsation, was first described in 1958 by Harken. In 1962, Moulopoulos et al. proposed the use of a single-chambered IABP in the descending thoracic aorta to achieve counterpulsation. Counterpulsation is based on the premise that reducing LVEDP improves ventricular function. The mechanism of action of the IABP involves rapid balloon inflation with helium during diastole (concurrent with aortic valve closure). The balloon remains inflated until onset of systole, at which time the balloon rapidly deflates. Balloon inflation raises diastolic pressure within the proximal aorta, causing improved coronary and cerebral perfusion during diastole. With the rapid balloon deflation during systole, there is a sudden volume loss (equivalent to the volume of the balloon) in the aorta resulting in decreased afterload against which the heart must work (Fig. 4.6). Direct effects on the heart include improving coronary artery blood flow, and decreasing afterload resulting in improved CO and less myocardial oxygen demand. Early IABP insertion can decrease the size of the potential infarct area following coronary occlusion.

The clinical indications for the IABP have expanded over the past several years. There are many situations in the critical care setting in which temporary ventricular support of the failing heart is needed. It has been shown that early application of the IABP in patients who have experienced acute myocardial infarctions reduces the severity of

cardiogenic shock and improves patient survival. The IABP is often employed preoperatively in high-risk patients with acute cardiogenic shock and/or unstable angina prior to cardiac surgery. In this setting, IABP decreases perioperative morbidity and mortality. Although it is assumed that patients requiring IABP use in the cardiac surgical setting are a higher-risk group of patients, the overall survival rates for patients undergoing myocardial revascularization procedures who required the use of the IABP are similar to patients who did not require this device.

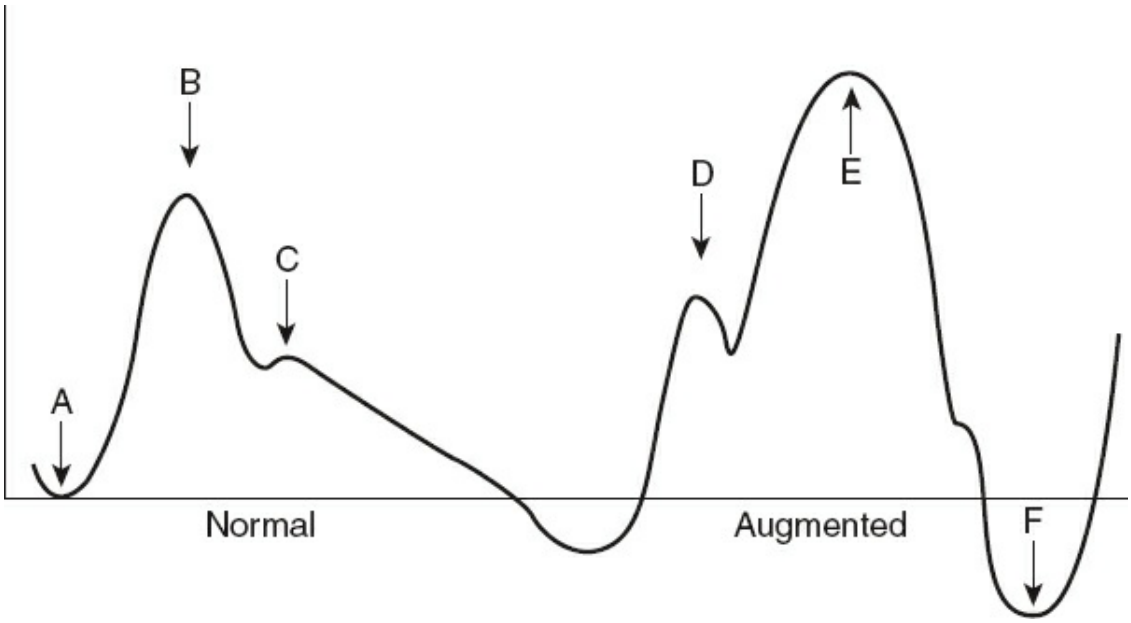

Figure 4.6. Intra-aortic balloon pump (IABP) counterpulsation results in diastolic augmentation and afterload reduction. (**A**) End-diastolic pressure. (**B**) Peak systolic pressure. (**C**) Dicrotic wave. (**D**) Reduced peak systolic pressure. (**E**) Diastolic augmentation. (**F**) Reduced end-diastolic pressure.

The IABP has also been used more recently in patients with septic shock. As a result of myocardial depressants that circulate in advanced septic states, CO can diminish significantly. Berger et al. examined the use of the IABP in septic patients with decreased ventricular function. Adequate CO was maintained in such patients and permitted application of more traditional treatment modalities for septic shock, such as fluid resuscitation. Another potential use of the IABP has been reported in experimental models of blunt chest trauma. Saunders and Doty produced blunt chest injury in dogs and demonstrated that early application of the IABP improves ventricular function following myocardial contusion. The clinical application of the IABP to blunt chest injuries, particularly in the

multitrauma patient, may also prove beneficial in select patients.

Absolute contraindications to use of the IABP include severe aortic insufficiency and acute aortic dissection. Aortic aneurysms, atherosclerotic aortas, aortoiliac occlusive disease, or mild aortic insufficiency are relative contraindications. Known complications of the IABP include bleeding, infection, and balloon leak or malfunction. Arterial injury can occur especially during guidewire and/or balloon advancement. Embolization to the visceral and renal vessels can occur from thrombus on the balloon or from atherosclerosis in the thoracic aorta and can lead to intestinal ischemia and/or renal failure. Careful and accurate placement of the IABP is necessary to prevent occlusion of the visceral vessels with each cardiac cycle. A rare and dreaded complication of the IABP is aortic dissection. As such, the IABP should be placed under fluoroscopic or echocardiographic (TEE) guidance. In addition, the balloon can produce lower limb ischemia as it is placed through the femoral vessels and can occlude iliac blood flow, which is usually relieved by balloon removal. Removal of the balloon must be carefully performed to eliminate the risk of distal embolization from a dislodged thrombus. Finally, thrombocytopenia and hemolysis can occur as a result of hematologic trauma produced by the IABP.

Percutaneous mechanical circulatory support systems, such as the TandemHeart (CardiacAssist, Inc, Pittsburgh, PA), are an additional option for support of the failing heart. The TandemHeart system is left atrial-to-femoral artery bypass system that can be rapidly implemented and provides up to 5.0 L/min of CO when used with a 17-French arterial return cannula. Via access through the femoral vein, a transseptal puncture is made allowing for placement of an inflow cannula directly into the left atrium. The integrated pump and motor then delivers the oxygenated blood back to the patient via the femoral artery return cannula. This device can be used to allow for cardiac recovery in patients with postcardiotomy cardiac failure, as a bridge to transplantation, or during high-risk coronary catheterization procedures. Compared to cardiogenic shock patients treated with IABP, a meta-analysis found that patients treated with percutaneous mechanical circulatory support systems such as the TandemHeart had improved hemodynamics (including CI and mean arterial pressure) but no improvement in 30-day mortality.

CARDIOVASCULAR RISK

An often difficult issue for surgeons is whether to pursue an aggressive cardiac evaluation for patients before considering noncardiac operations. With an aging population, more patients with unrecognized coronary artery disease are referred for these types of surgical procedures. It remains true that operative morbidity and mortality are most often direct results of cardiac complications, and the proper recognition of the “at-risk” patient is important in limiting these postoperative cardiac problems.

Quite often, elderly patients referred for surgical intervention have not had adequate health care evaluation and the challenge for the surgeon is to accurately assess the cardiac risk in a timely manner before performing an operative procedure. The surgeon should take a thoughtful approach to preoperative cardiac screening rather than simply referring the patient to a cardiologist. A thorough history and physical examination should be performed to uncover any signs or symptoms of underlying cardiac disease. Symptoms such as chest pain or shortness of breath should be thoroughly interrogated with specific attention to frequency, character, precipitating causes, and duration. Family and social histories are very important and should be noted, along with the findings of the physical examination. Chest radiographs and ECGs should be reviewed closely. Beyond the routine office evaluation, there are a myriad of noninvasive, invasive, functional, and anatomic imaging modalities to further quantify cardiac function. These tests may help identify patients with underlying silent cardiac disease who may be in need of further treatment. As with any decision in health care, the risk to benefit ratio of a diagnostic study or therapeutic intervention deserves thoughtful consideration before its implementation.

Clinical predictors of increased risk are stratified into major, intermediate, or minor. Major predictors include unstable coronary syndromes, decompensated heart failure, significant arrhythmias, or severe valve disease. Intermediate predictors include mild stable angina, previous myocardial infarction with stable compensated heart function on appropriate medical therapy, compensated heart failure, and diabetes mellitus. Minor predictors include advanced age, minor electrocardiographic changes, low functional capacity with no other intermediate or major risk factors, history of stroke, or uncontrolled hypertension. Procedural risk can also be classified as high, intermediate, or low. High-risk procedures include emergent operations in elderly patients, aortic or major vascular procedures, and prolonged operations

with large fluid shifts. Intermediate-risk procedures would include carotid endarterectomy; head and neck procedures; intraperitoneal, intrathoracic, and orthopedic procedures; and prostate surgery. Low-risk procedures include endoscopy, superficial procedures, cataract surgery, and breast and soft tissue operations. Based on this evaluation of clinical and procedural risk, many patients require no further testing if the overall risk is judged to be low or may need further noninvasive assessment if the overall risk is intermediate. There may also be some patients who are easily identified as being best served by coronary angiography. However, this group is the minority and consideration should be given with respect to the urgency of the intended operation. A diagnosis of significant coronary artery disease that may require percutaneous intervention or surgical coronary revascularization will delay the initial planned procedure.

Risk assessment strategies for preoperative evaluation of patients before noncardiac operations were reviewed comprehensively by the American College of Cardiology (ACC)/AHA Task Force on Practice Guidelines. The published guidelines were evidence-based and recommended the use of a combination of an initial clinical evaluation and functional testing in certain patient subsets. High-risk clinical variables include recent MI, history of diabetes mellitus, poor functional status, decompensated heart failure, significant arrhythmias, and severe valvular disease. Noninvasive testing is most useful in patients who have more than one clinical risk factor and are scheduled to undergo intermediate- or high-risk operations. Noninvasive testing includes resting ECG, echocardiography, treadmill exercise stress testing, stress perfusion imaging, and dobutamine stress echocardiography. These tests help further quantify cardiac function and help identify patients with underlying silent cardiac disease who may be in need of further work-up or treatment.

When assessing cardiovascular risk in the noncardiac surgical setting, the Goldman Cardiac Risk factors should be discussed. This multifactorial index was developed for preoperative identification of patients at risk for major perioperative cardiovascular complications. The data was obtained retrospectively from 1,001 patients over 40 years of age undergoing noncardiac surgery. By multivariate discriminant analysis, nine independent significant correlates of life-threatening and fatal cardiac complications were identified. These were preoperative third heart sound or jugular venous distention; myocardial infarction in the preceding 6 months; more than five premature ventricular contractions per minute

documented at any time before operation; rhythm other than sinus or presence of premature atrial contractions on preoperative ECG; age over 70 years; intraperitoneal, intrathoracic, or aortic operation; emergency operation; important valvular aortic stenosis; and poor medical condition. Patients in the highest-risk group (based on a point scale given to the risk factors) had a 56% incidence of death, with a 22% incidence of severe cardiovascular complications. Patients in the intermediate-risk group had a 4% incidence of death, with a 17% incidence of severe cardiovascular complications. Patients in the lowest-risk group had a 0.2% incidence of death and a 0.7% incidence of severe cardiovascular complications. With the advances made in anesthesia and medical care, this data is mentioned more for a historical perspective. However, these studies still provide a basis for presurgical evaluation today.

Several important factors should be considered when patients are screened. One obvious consideration is the urgency of the operation. Patients who undergo urgent/emergent surgery have a two- to fivefold increased rate of experiencing a cardiovascular complication than patients who undergo comparable surgery on an elective basis. There may also be times when the results of screening will not affect the decision to operate but may assist in alerting the anesthesia and surgical teams about the degree of risk. Currently, high-risk procedures carry a risk of nonfatal MI or cardiac death of 5% or more. Intermediate-risk procedures carry a combined risk of 1% to 4% and low-risk procedures carry a combined risk of <1%.

EDITOR'S COMMENT

Drs. Charles and Kron have written an exceptional and detailed chapter on cardiovascular monitoring. It is amazing how much progress has been made in this area in the past 20 years. Not only have new technologies been developed to more accurately assess cardiovascular function, but also our understanding of fluid resuscitation and other physiologic variables that matter in determining a patient's cardiovascular status has evolved as well.

Much has been learned about the pros and cons of different central venous access sites, proper line insertion techniques, and central line care as well as maintenance. I was a surgical resident in the late 1990s in the era before peripherally inserted central venous catheters caught on. Surgical residents, most often unsupervised interns, placed the majority of the central lines in our hospital. I learned how to place a central line by watching a second-year surgical resident place one. Sterile technique was fairly casual and nearly every line was placed in the subclavian vein. We got to be exceedingly good at placing these lines—even in the most challenging circumstances. Central line–associated blood stream infections were fairly commonplace. Occasional central line–associated complications including subclavian artery cannulation and pneumothorax were much more frequent than today when these have really become "never events." Much has changed in the past 20 years. We have simulator-based training, central line insertion bundles, and care protocols, and much more that have rendered the days of unsupervised and poorly trained residents throwing lines in patients all over the hospital a thing of the past.

The three most common insertion sites for central venous catheters are the internal jugular, the subclavian, and the femoral vein. A recently published Cochrane Review on central venous access sites for the prevention of venous thrombosis, stenosis, and infection included four studies with data from more than 1,500 subjects. Subclavian and internal jugular central venous access

routes were determined to have similar risks for catheter-related complications in long-term catheterization in cancer patients. Subclavian access was found to be preferable to femoral access in short-term catheterization because of lower risks of catheter colonization and thrombotic complications. In short-term hemodialysis catheterization, femoral and internal jugular routes have similar risks for catheter-related complications although internal jugular routes were associated with higher risks of mechanical complications. The 3SITES central venous catheter trial results were recently published in *the New England Journal of Medicine.* In this multicenter trial, adult patients in the ICU were randomly assigned to nontunneled central lines in the subclavian, jugular, or femoral vein. The primary outcome measure was a composite of catheter-related bloodstream infection and symptomatic deep-vein thrombosis. There were 3,471 catheters placed. In pairwise comparisons, the risk of the primary outcome was significantly higher in the femoral group than in the subclavian group (hazard ratio, 3.5; 95% confidence interval [CI], 1.5 to 7.8; $p = 0.003$) and in the jugular group than in the subclavian group (hazard ratio, 2.1; 95% CI, 1.0 to 4.3; $p = 0.04$). The risk in the femoral group was similar to that in the jugular group (hazard ratio, 1.3; 95% CI, 0.8 to 2.1; $p = 0.30$). Pneumothorax requiring chest tube insertion occurred in association with 1.5% of the subclavian vein insertions and 0.5% of the jugular vein insertions. The authors concluded that subclavian vein catheterization was associated with a lower risk of bloodstream infection and symptomatic thrombosis and a higher risk of pneumothorax than jugular vein or femoral vein catheterization.

Patients with acute kidney injury and chronic kidney disease frequently require nontunneled central venous catheterization for the treatment of acute illness. Temporary catheters are also widely used for emergent inpatient hemodialysis access. In addition to minimizing catheter-related complications, preserving veins for hemodialysis vascular access is an important goal for these patients. Central venous stenosis is a major barrier to arteriovenous access creation for hemodialysis. Central venous stenosis has been demonstrated to be associated with the number of catheter insertions, duration of catheter exposure, and use of the subclavian site. Catheter contact with the vessel wall is postulated to cause endothelial damage and turbulent flow, which may initiate release of prothrombotic cytokines leading to thrombosis, fibrosis, and stenosis. The catheter site with the least vessel wall contact is the right internal jugular vein. Clinical practice guidelines and position papers have recommended vein preservation for patients with estimated glomerular filtration rates of less than 30 mL/min per 1.73 m^2 (Kidney Disease Outcomes Quality Initiative). The complication rate of a central venous access site must be balanced against the potential need for dialysis access in the future in patients with chronic renal insufficiency.

Central line–associated blood stream infections (CLABSIs) result in thousands of deaths each year and billions of dollars to the US health care system. The Centers for Medicare and Medicaid Services (CMS) Hospital

Acquired Condition (HAC) Reduction Program is designed to encourage hospitals to improve patient safety and reduce the number of hospital-acquired conditions. Each year, Medicare withholds approximately $350 million in payments for care rendered for the hospitals that perform the worst on 6 HAC conditions—one of which is CLABSI. These data are reported publicly on the Hospital Compare website. CLABSIs are largely preventable. The Agency for Healthcare Research and Quality partnered with the American Hospital Association, the Johns Hopkins Medicine Armstrong Institute for Patient Safety and Quality, and the Michigan Health and Hospital Association's Keystone Center for Patient Safety and Quality on the project "Eliminating CLABSI: A National Patient Safety Imperative." Participating States reduced their CLABSI rate from a baseline of 1.915 infections per 1,000 line days to 1.133—a 41% relative reduction. The percentage of ICUs with zero CLABSIs for at least one quarter increased from 30% at baseline to 68% at quarter 6 of the study. The five steps included in the reducing CLABSI initiative were: (1) educate staff, (2) create a central line cart, (3) implement a central line checklist, (4) empower staff to stop the procedure, and (5) remove unnecessary lines. These policies and procedures have been adopted across the country saving many lives and significant expense. The Centers for Disease Control (CDC) estimates that the rate of mortality in CLABSI is 12% to 25% and the cost is approximately $16,550 per event.

Goal-directed resuscitation is discussed in this chapter—especially as it relates to sepsis and septic shock. There is a massive body of literature on this subject that is difficult to digest. The general consensus is that goal-directed therapy has not been definitively demonstrated to reduce mortality in sepsis. Two recent large multicenter randomized controlled trials, the Australasian Resuscitation in Sepsis Evaluation (ARISE) and Protocolized Care for Early Septic Shock (ProCESS) studies, examined goal-directed therapy in early septic shock. The ARISE study found no reduction in all-cause mortality at 90 days, and the ProCESS study showed no improvement in outcomes including 1-year mortality or the need for organ support. In studies evaluating goal-directed therapy, there is variability in the type of fluid administered, whether an inotrope is used, and the algorithms applied. The hemodynamic goal also varies with some studies using cardiac output or stroke volume while others utilize mixed venous oxygen saturation or another parameter. No single hemodynamic goal or monitoring method has been universally accepted in the literature. This makes it quite difficult to draw definitive conclusions about the value or lack thereof for goal-directed therapy.

As a surgeon at a large teaching institution, I have observed a lot of variability in fluid and vasopressor use, and the parameters that are used to guide these choices on a case-by-case basis by my anesthesia colleagues during the surgeries I perform. The concept of perioperative goal-directed therapy in some of my higher-risk gastrointestinal surgery patients is of interest to me. I stumbled upon an interesting study while doing research for this commentary.

The OPTIMISE trial (Optimization of Cardiovascular Management to Improve Surgical Outcome) was a multicenter randomized, observer-blinded trial of 734 high-risk patients (aged 50 and older) undergoing major gastrointestinal surgery. A systematic review and meta-analysis of similar randomized clinical trials were also included in the article. Patients were randomly assigned to a cardiac output–guided hemodynamic therapy algorithm for intravenous fluids and inotrope infusion during and 6 hours following surgery or to usual care. The primary outcome was a composite of predefined 30-day moderate or major complications and mortality. The primary outcome occurred in 36.6% of intervention and 43.4% of usual care participants (relative risk 0.84, absolute risk reduction, 6.8%). Findings of the meta-analysis of 38 trials, including data from this study, suggested that goal-directed perioperative therapy is associated with fewer complications versus control patients. Outside of a clinical trial, if nothing else goal-directed perioperative therapy gives the anesthesiologist a predefined target and forces him/her to pay close attention to exactly what is going on with my patient in a way that I find reassuring. I would rather resuscitate a patient in real time than spend the evening following an operation playing "catch up" and resuscitating a patient in the ICU.

This is a great chapter that includes information that is relevant to all surgeons. It is interesting to me how far we have come in the past few years, and how far we have to go still. This chapter on cardiovascular monitoring and support provides an excellent overview of past, present, and future.

Jon C. Gould

As the (very junior) faculty of the hyperalimentation unit at the Massachusetts General Hospital Professor Gould is absolutely correct that "central line–associated blood stream infections were fairly commonplace."

5 Pulmonary Risk and Ventilatory Support

Jay A. Johannigman and Richard Branson

INTRODUCTION

The pulmonary system includes a complex milieu consisting of the conducting airways, pulmonary parenchyma, the alveolar capillary interface, an intricate mechanism for control of breathing, a complex muscular interplay, and an elaborate defense mechanism. Yet despite the sophistication of the respiratory system, pulmonary complications are the single most common source of morbidity in the critically ill surgical patient. Postoperative pulmonary complications (PPCs) include atelectasis, bronchospasm, bronchitis, pneumonia, exacerbation of chronic lung disease, and pulmonary embolism (PE) (Table 5.1). Uniformly, these complications result in a predictable set of symptoms including tachypnea, hypoxemia and hypercapnia followed by respiratory failure each of which are associated with increased morbidity and mortality. Arozullah and colleagues found the need for reintubation and/or mechanical ventilation occurred in only 3% of patients in the VA database of almost 100,000 postoperative patients. Importantly, mortality in this group increased from 1% in those without respiratory failure to 27% in those with respiratory failure. Development of postoperative respiratory failure requiring mechanical ventilation results in an increased length of stay from 4.5 to 28 days. The definition of a PPC is often elusive. Radiographic atelectasis following cardiothoracic surgery is common, but rarely results in pulmonary symptoms or morbidity. This results in both overreporting and underreporting of pulmonary complications. The literature reveals an incidence of pulmonary complications from 2% to 19% after general surgical procedures and 8% to 39% following cardiothoracic surgery.

PPCs occur most commonly in those undergoing major abdominal and/or thoracic procedures. Other risk factors include advanced age, history of chronic obstructive pulmonary disease (COPD), and history of obstructive sleep apnea (OSA), use of nasogastric tubes, malnutrition,

renal failure, and duration of anesthesia. Diaphragmatic dysfunction, ventilation–perfusion (V/Q) mismatching, and a reduction in functional residual capacity (FRC) routinely occur after general anesthesia and surgery. Anesthetic-induced muscular paralysis during surgery results in a cephalic movement of the diaphragm into the domain of the dorsal lung compartment because of the displacement affected by the weight of the abdominal contents. Positive pressure ventilation results in preferential ventilation of nondependent (ventral) lung units while pulmonary blood flow is gravity dependent. This derangement created by mechanical positive pressure ventilation inherently accentuates the degree of ventilation to perfusion mismatching in the supine and sedated patient. General anesthesia has also been shown to inhibit intrinsic pulmonary defense mechanisms including altered alveolar macrophage function, disruption of the mucociliary escalator, and diminished surfactant release. Severe chronic lung disease is often thought to preclude the consideration of complex open thoracoabdominal procedures. The progressive evolution of minimally invasive surgery has facilitated postoperative pulmonary function and recovery in such patients. Advances in pain control (including epidural catheter analgesics) have also reduced morbidity in patients undergoing major surgery or with thoracic injuries. Comparisons of laparoscopic to open procedures demonstrate that in some cases (cholecystectomy, esophageal cancer) pulmonary complications are reduced, while in other procedures pulmonary complications are unchanged. This chapter will include sections on pulmonary anatomy and physiology, risk assessment, and management of acute lung injury (ALI) including mechanical ventilation, prevention and treatment of ventilator-associated pneumonia (VAP), and adjunctive surgical measures to treat complex intrathoracic infections.

TABLE 5.1 Common Perioperative Pulmonary Complications and Risk Factors

Common Complications Following General Surgery
Pulmonary embolus
Obstructive sleep apnea
ARDS
Ventilatory failure ($PaCO_2$ >60 mm Hg, pH <7.20)
Atelectasis
Infection—Pneumonia—Bronchitis
Bronchospasm
Aspiration of gastric contents
Exacerbation of chronic pulmonary disease

Intraoperative Risk Factors
Thoracic or upper abdominal incision

Common Complications Following Cardiothoracic Surgery
Bronchpleural fistula
General anesthesia
Duration of anesthesia/surgery
Pleural effusion
Emergent procedures
Phrenic nerve injury
Sternal wound infection and dehiscence
Empyema
Arrhythmias

Preoperative Risk Factors
COPD
Advanced age
Smoker
Pulmonary hypertension
Obstructive sleep apnea
Malnutrition
Obesity

ANATOMY AND PHYSIOLOGY

The lungs lie lateral to the mediastinum in the thoracic cavity. The lung surface is covered by a single cell layer of pleura, which also lines the parietal surface. A minute amount of pleural fluid is present to lubricate the lung/thorax interface reducing friction. The pleural space under normal circumstances is not a space at all, but can markedly increase in disease states. The right lung has three lobes and the left two, including the lingula, and each lobe contains two to five segments with tertiary order bronchi, which can be visualized on bronchoscopy. The basic functioning unit is the alveolus. The terminal alveolar unit is a grape-like cluster of individual air sacs often sharing a common wall surrounded by a web of capillaries, giving the lung its elastic nature. Ventilation–perfusion in the lungs based on an upright model divides the lung into three zones. In zone I (the upper lung fields), alveolar pressure is greater than both arterial and venous blood pressure resulting in an excess of ventilation to perfusion (high V/Q ratio). Regions of the lung in which ventilation exceeds perfusion are referred to as dead space. In zone II (mid-lung zones) arterial pressure is greater than alveolar pressure which is greater than venous pressure and V/Q is well matched. In zone III (lower lung fields), the

vascular pressures exceed alveolar pressure and V/Q is low. When perfusion exceeds ventilation, shunt results. The ICU patient is typically cared for in the supine position. This reorients the zones of the lung into a horizontally based consideration rather than a vertically based system (when a patient is standing). In the supine position the nondependent lung is shifted to the ventral aspect of the lung and the dependent lung is now in the dorsal position. Improvement in ventilation–perfusion matching during ALI helps explain the effects of positive end-expiratory pressure (PEEP) and changes in position (prone) on arterial oxygenation. Lymph drainage from the lungs occurs through the hilar and mediastinal lymph nodes to the thoracic duct via the mediastinal lymphatics.

The critical function of the lung is gas exchange, specifically oxygen extraction from the atmosphere and transfer to the intravascular space, and elimination of carbon dioxide. The latter is virtually dependent on minute ventilation (respiratory rate), while oxygen transport is dependent on the fractional inspired oxygen concentration (FIO_2), transport across the alveolar-capillary membrane, and V/Q matching. Blood oxygen content is determined primarily by hemoglobin concentration and percent oxygen saturation, while oxygen dissolved in plasma contributes minutely. Oxygen tension in the alveolus is described by the following alveolar air equation:

$$PAO_2 = [(P_B - P_{H_2O} \times FIO_2) - PACO_2/RER]$$

where P_B is the barometric pressure, P_{H2O} is the partial pressure of water vapor which is constant under alveolar conditions at 47 mm Hg, PCO_2 is the alveolar CO_2 concentration, and RER is the respiratory exchange ratio (normally = 0.8).

The arterial partial pressure of CO_2 ($PaCO_2$), readily available on routine blood gas measurement, can be substituted for $PACO_2$. Normal PAO_2 on room air is 95 to 100 mm Hg and PaO_2 is 85 to 95 mm Hg. The degree of V/Q mismatching will determine the shunt fraction of unsaturated blood. Shunt fraction is normally 2% to 5%, but can be significantly increased in the face of atelectasis, pneumonia, ALI, and acute respiratory distress syndrome (ARDS). The shunt fraction can be estimated by measurement of the alveolar–arterial (A-a) O_2 gradient. This is defined as:

$$\text{A-a}O_2 \text{ gradient} = (P_B - P_{H_2O}) \times FIO_2 - PaCO_2 - PaO_2$$

This is normally 10 mm Hg, but markedly increases in disease which limits gas exchange across the alveolar capillary membrane. The ratio of PaO_2/FIO_2 is commonly used to assess the severity of pulmonary dysfunction in disease states such as ALI, ARDS, and pneumonia in the mechanically ventilated patient. The normal value is over 500. A value <300 indicates ALI and <200 indicates ARDS, when observed concurrently with bilateral infiltrates on chest x-ray and a pulmonary capillary wedge pressure <18 mm Hg. The calculation of intrapulmonary shunt requires a pulmonary artery catheter, mixed venous blood from the pulmonary artery, and the measurement of cardiac output.

The $PaCO_2$ normally is responsible for central respiratory drive by CO_2 diffusion across the blood–brain barrier, producing a decrease in cerebrospinal fluid pH and an increase in minute ventilation. Normal $PaCO_2$ is 35 to 45 mm Hg, but can be elevated by disorders in the control of breathing and in ALI and ARDS by dead space. Physiologic dead space is defined as the dead space to tidal volume ratio (V_D/V_T) which is normally 0.3 owing to the anatomical dead space. V_D/V_T is calculated as

$$V_D/V_T = PaCO_2 - PECO_2/PaCO_2$$

where $PaCO_2$ is used as an approximate for alveolar CO_2 and $PECO_2$ is the mixed expired CO_2. In ARDS V_D/V_T predicts mortality, as values >0.7 are associated with >80% mortality.

PULMONARY MECHANICS AND LUNG VOLUMES

There are several lung volumes and capacities used to describe mechanical function of the lung, respiratory muscles, and chest wall (Fig. 5.1). Most of these are measured during pulmonary function testing. Tidal volume (V_T) is the amount of air exchanged per breath during normal breathing. Vital capacity (V_C) is the amount of air exchanged from peak inspiration to maximal expiration. FRC is the amount of residual air in the lung after maximal expiration. Compliance of the lung is a measure of elasticity and is defined as change in volume/change in pressure. During mechanical ventilation dynamic compliance is measured as the difference between peak inspiratory pressure (PIP) and $PEEP/V_T$. Static compliance is measured as the difference in plateau pressure and (Pplat) and $PEEP/V_T$.

Dynamic compliance includes the effects of airway resistance and lung compliance while static compliance estimates alveolar pressure and lung elasticity alone. Plateau pressure is important in both lung expansion and lung injury in ARDS. Data suggest that for every increase in plateau pressure of 6 cm H_2O, the development of ARDS (in patients initially without ARDS) increases by 50%. Pressure/volume curves can be produced which demonstrate the beginning of alveolar recruitment (lower inflection point) and the beginning of alveolar overdistention (upper inflection point) and can be used to guide the choice of V_T and PEEP. The pressure–volume curve is not a standard of care and should be used cautiously.

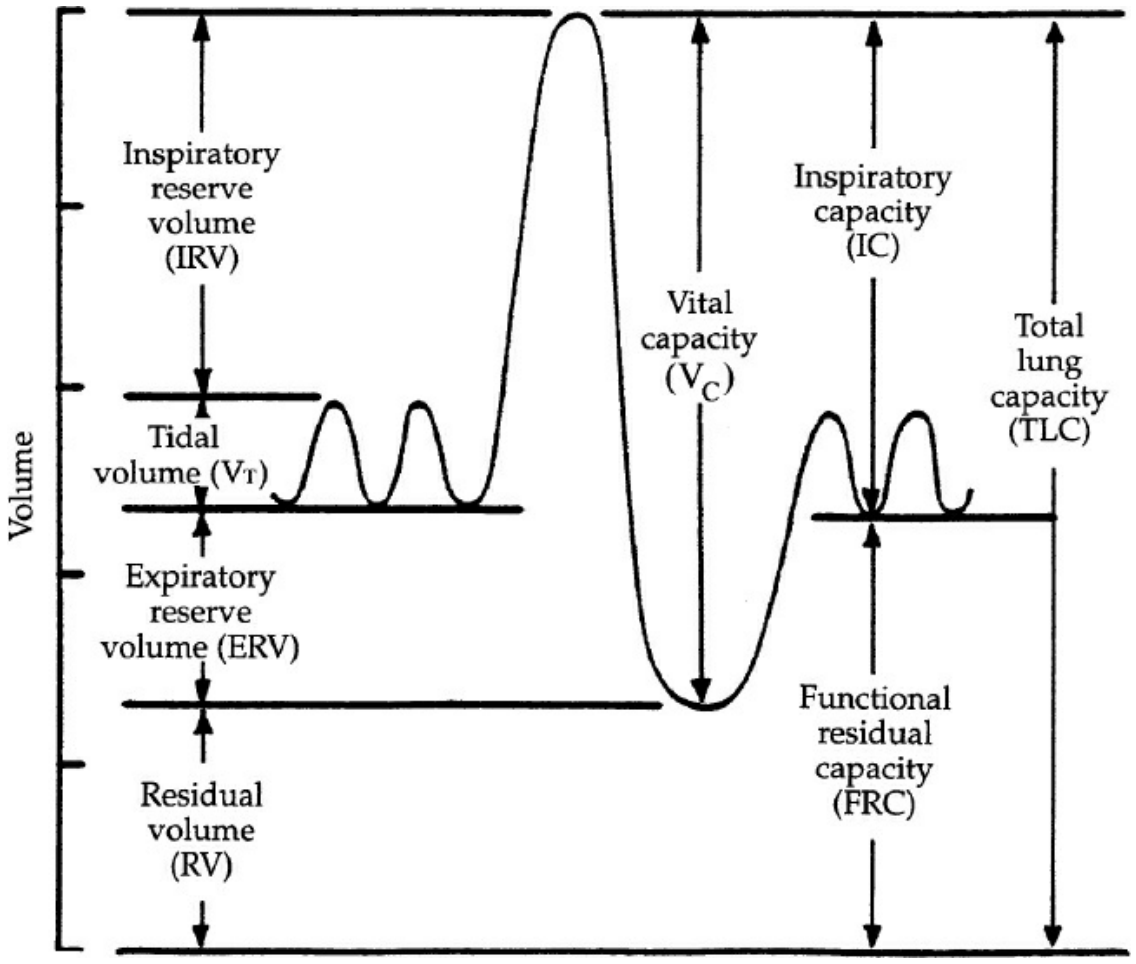

Figure 5.1. Standard measurements of lung volumes.

PREOPERATIVE ASSESSMENT

The ability of preoperative pulmonary function assessment to predict the incidence of pulmonary complications is relatively strong when individualized to a specific patient and clinical parameters. Despite this

observation, preoperative pulmonary function evaluations are not commonly performed. The reason for the relative paucity of standard preoperative pulmonary function testing remains unclear but may be related to an inadequate understanding of what testing can predict, the absence of guidelines detailing which test should be performed and in what populations and the utility of preventative postoperative care in all patients or just high-risk patients.

In emergency or urgent procedures the opportunity for preoperative assessment is not afforded and the surgical procedure must be undertaken regardless of the risk. Complete pulmonary function tests include lung volumes, spirometry, maximal respiratory pressures, diffusing capacities, and oximetry (Table 5.2). However, office-based observations such as ease of breathing, use of accessory muscles, ability to blow out a match with a wide-open mouth, and stair climbing are helpful indicators of pulmonary reserve (Table 5.3). Hypoxia or CO_2 retention on arterial blood gas measurements is also useful in patients with known chronic pulmonary disease. Development of office-based spirometry has afforded those physicians with an interest in treating such disorders with immediate access to results. Therapy and interventional treatment strategies may be initiated early based on such testing. The objectives of PFTs are to quantitate dysfunction and severity, and to assess long-term prognosis as endorsed by the American Thoracic Society. The National Lung Health Program has recommended routine use of spirometry by primary care physicians.

TABLE 5.2 Pulmonary Function Tests

Lung Volumes
- Total lung capacity (TLC)
- Vital capacity (VC)
- Reserve volume (RV)
- RV/TLC

Spirometry
- Forced vital capacity (FVC)
- Forced expiratory volume over the first second (FEV_1)
- FEV_1/FVC,
- Maximum voluntary ventilation (MVV)

Maximal Respiratory Pressures
- Maximal inspiratory pressure ($P_I$max)
- Maximal expiratory pressure ($P_E$max)

Diffusing Capacity
- Diffusing capacity of lung for carbon monoxide (D_{LCO})
- Alveolar volume (V_A)

Oximetry
- O_2 saturation

TABLE 5.3 Preoperative Assessment of Pulmonary Risk

History: Shortness of breath, dyspnea on exertion, fever, yellow or discolored sputum, smoking (current or past), COPD history

Physical Examination: Comfort of breathing, respiratory rate, thoracic excursion, temperature, use of accessory muscles to breathe, skin color, digital clubbing, wheezing, rales, rhonchi on auscultation

Chest X-ray: Hyperaeration, flattening of diaphragm, increase in width of lung fields, parenchymal changes

Arterial Blood Gas: Hypoxemia, hypercarbia

Pulmonary Function Testing: Elevated FRC, reduced FVC and FEV_1, reduced FEF 25–75%

The primary result of interest reported by preoperative spirometry is the forced vital capacity (FVC). FVC testing is accomplished by allowing the patient to inhale to total lung capacity and then exhale as fast and for as long as possible. FVC is the difference between total lung capacity and reserve volume. The forced expiratory volume over the first second is referred to as the FEV_1 and reflects the severity of obstruction to outflow (usually as a consequence of smoking). The ratio of FEV_1/FVC is also reported in addition to the maximal voluntary ventilation (MVV). The MVV is the maximal amount of ventilation over a 10- to 12-second period, and may vary widely based upon the fitness and effort expended by the patient. Predicted values for these parameters are calculated based on height, weight, and body mass index. Based on the observed values, a percent of predicted value is obtained, and is readily interpreted. These tests are performed before and after pharmacologic intervention such as bronchodilators, to determine the degree of reversibility of the airway disease. A significant response has been defined as a change of either a 12% or 0.2 L or more from baseline. Tests for lung volume and diffusing capacity are more complex and not routinely done for most patients. An

FEV_1 less than 50% of predictive value, resting hypoxemia, and hypercarbia have all been associated with increased postoperative pulmonary morbidity. The American Society of Anesthesiologists (ASA) has developed the ASA Class system which can be useful in predicting intraoperative and postoperative morbidity and mortality (Table 5.4). This system relies more on the overall physical condition of the patient, not the results in individual measurements.

TABLE 5.4 ASA Physical Status Classification and Rate of Postoperative Complications

ASA Class	Definition	Rate of Pulmonary Complications
I	A normally healthy patient	1.2%
II	A patient with mild systemic disease	5.4%
III	A patient with severe systemic disease but it is not incapacitating	11.4%
IV	A patient with incapacitating systemic disease that is a constant threat to life	10.9%
V	A patient not expected to survive 24 hours without surgery	NA
VI	A brain dead patient donating organs	NA

PREOPERATIVE ASSESSMENT OF PULMONARY RISK

The National Surgical Quality Improvement Program represents the most significant effort in identifying preoperative risk (Table 5.5). Factors associated with increased pulmonary morbidity, include age over 60, low serum albumin, renal failure, smoking, history of COPD, high ASA score, anesthetic time of 180 minutes or more, and type of operation. In the VA study, over 180,000 patients were studied. Postoperative respiratory failure was defined as the requirement for mechanical ventilation for more than 48 hours postoperatively, or reintubation and mechanical ventilation after postoperative extubation. This study more appropriately predicts postoperative respiratory failure, not PPCs. The study did not consider other findings such as atelectasis, pneumonia, or PE in the absence of mechanical ventilation. The study included noncardiac procedures done under general or regional anesthesia. The rate of postoperative respiratory failure was just less than 3%. Point values were assigned to these various factors and five classes of patients were then developed based on their scores. Class IV and V patients had predicted risks of 11% and 30%,

respectively, for development of postoperative respiratory failure, which closely matched the incidence from both phases of the study. Class I patients, which comprised almost half of the study population, had only a 0.5% risk of respiratory failure.

TABLE 5.5 Veterans Affairs Pulmonary Risk Index

Type of surgery (abdominal aortic aneurism > thoracic > neurosurgery, upper abdominal, or peripheral vascular > head and neck)
Emergency surgery
Serum albumin <3.0 g/L
Blood urea nitrogen >30 mg/dL
Partially or fully dependent functional status
History of chronic obstructive pulmonary disease
Age (>60)

Preoperative pulmonary risk has been studied thoroughly in patients who undergo thoracotomy and lung resection. Of major importance is the estimate of residual lung function to minimize the risk of permanent pulmonary dysfunction resulting in ventilator dependence. Lung cancer often occurs concurrently with COPD. Even when other risk factors are accounted for, the presence of COPD is the predominant risk factor for PPCs following thoracotomy. Lung volume is actually reduced by thoracotomy alone, and typically FEV_1 is reduced by 10% after lobectomy and by 30% after pneumonectomy. Methods for determining postoperative function after lung resection include PFTs, CT, and lung scanning. Split perfusion lung scanning has been found to be most accurate, as other methods consistently underestimate postoperative residual lung function. A predicted FEV_1 of at least 700 mL has been used as a cutoff for resectability. With regard to prediction of postoperative morbidity and mortality, the inability to climb two flights of stairs and a percentage of predicted DL_{CO} (derived from lung scan) less than 40% have consistently been shown to be associated with adverse clinical outcome.

Patients at Risk for Postoperative Pulmonary Complications

Several chronic disease states are associated with greater risk of pulmonary complications. These include chronic respiratory disease, cardiac comorbidities, and select surgical procedures. The most significant will be reviewed here.

The COPD Patient

COPD is an independent risk factor for the development of PPCs following both thoracic and nonthoracic surgery. COPD is characterized by airflow limitation and has been classified into five stages according to the Global Initiative for Chronic Obstructive Lung Disease (GOLD). The small airways from resected lung tissue of COPD patients demonstrate inflammatory leukocytes in both the lumen and walls. The severity of infiltration correlates with the GOLD stage, indicating the chronic inflammatory status of the lungs, which is often steroid resistant. Physiologically, COPD is characterized by decreased FEV_1, alveolar hypoventilation, reduction in alveolar capillary diffusing capacity, hypoxemia, and/or hypercarbia. The GOLD guidelines state that COPD is present when the FEV_1 is less than 80% of predicted and FEV_1/FVC is less than 0.7.

Pulmonary Hypertension

Pulmonary hypertension (defined as a right ventricular systolic pressure of >35 mm Hg) is a significant and often overlooked preoperative risk. In patients undergoing noncardiac surgery, a New York Heart Association functional class >2, a history of pulmonary embolus, or OSA postoperative pulmonary and cardiac complications are substantially increased. Postoperative congestive heart failure, cardiac ischemic events, arrhythmias, strokes, respiratory failure, hepatic dysfunction, renal dysfunction, and the need for postoperative inotropic or vasopressor support are known postoperative complications in this group. Postoperative respiratory failure is the most common complication.

Preoperative risk factors in patients with pulmonary hypertension include right-axis deviation on ECG, right ventricular hypertrophy, or a history of pulmonary embolus. In the absence of inhaled nitric oxide (iNO), the use of intraoperative epinephrine, or a right ventricular systolic pressure/systolic BP ratio of ≥0.66 is associated with increased perioperative morbidity and mortality.

Pulmonary hypertension patients unable to walk >332m during a 6-minute walk test have a higher mortality rate than those who can. The presence of a pericardial effusion, the presence of septal shift, or an enlarged right atrium on echocardiogram also predicts worse outcomes. If a patient has known pulmonary hypertension, determining their preoperative response to vasodilator therapy may be useful in managing postoperative complications.

Asthma

Although some evidence suggests that patients with asthma are at greater risk for PPCs, more recent studies have failed to corroborate this impression. Preoperatively patients should continue to use their inhaled medications to optimize peak expiratory flow. Intraoperatively, tracheal intubation and dry anesthetic gases may trigger bronchospasm in these patients. Short-acting β_2-agonists typically control this problem.

Smoking

A history of smoking increases the risk of pulmonary complications for patients undergoing any type of surgery. Patients who are smoking at the time of surgical intervention have an even greater risk.

Age

Patients >65 years of age undergoing nonthoracic surgery are at increased risk of PPCs.

Obstructive Sleep Apnea

Patients undergoing surgery should be screened for OSA. Preoperative evaluation for OSA can be a simple list of questions for the patient and their bed partner with regards to snoring, periods of apnea, and disrupted sleep pattern. Preoperative polysomnography has not been shown to assist in preventing postoperative complications. A study of 170 patients undergoing bariatric surgery found that only 15% of patients were diagnosed with OSA; however, the actual incidence was 77%, as documented by polysomnography. In the general surgical population the incidence of OSA has been estimated to be as low as 1% and as high as 9%. A plethora of studies have demonstrated that the presence of OSA correlates closely with increased postoperative morbidity and mortality. Sleep disturbances are exaggerated after surgery and general anesthesia. Appropriate preoperative treatment of OSA with continuous positive

airway pressure (CPAP) may reduce these risks.

TABLE 5.6 Preoperative Preparation of the High-Risk Patient

Identification that patient is at high risk
Reduce or stop smoking
Treat associated infection with antibiotics
Maximize lung function with medication and exercise
Regional anesthetic and appropriate sedation
Postoperative epidural analgesia

Perioperative Therapies to Prevent Postoperative Complications

Many interventions for reducing PPC have been explored (Table 5.6). These interventions should begin preoperatively, and continue through the intraoperative, perioperative, and postoperative periods. These interventions should be carried out regardless of the risk of the development of PPCs.

Smoking Cessation

Patients enrolling in a smoking cessation program 6 to 8 weeks prior to elective orthopedic surgery required less frequent postoperative mechanical ventilation. A number of other studies with varying durations of smoking cessation and operative interventions have demonstrated mixed results (http://chestjournal.chestpubs.org/content/132/5/1637). It long appears that to reduce PPCs, smoking cessation must begin a minimum of 6 weeks prior to the operation.

Preoperative Corticosteroids and Bronchodilators

Preoperative treatment with a β-agonist and methylprednisolone for 5 days, may reduce the incidence of bronchospasm during intubation in patients with asthma and bronchial hyperactivity. This is more effective in patient's naïve to routine β-agonists than those on long-term therapy.

Anesthesia and Analgesia

Anesthetic agents may contribute to the development of PPCs by

decreasing respiratory muscle tone and augmenting airway closure promoting atelectasis. Comprehensive reviews comparing the effect of general anesthesia, and spinal anesthesia on postoperative complications in patients undergoing nonthoracic surgical procedures have found no difference in the rate of postoperative pneumonia. A meta-analysis evaluating the incidence of postoperative pneumonia in patients undergoing hip surgery found no differences based on anesthetic technique. Despite conventional wisdom, regional anesthesia has not been clearly established as an approach for reducing PPCs. Patients receiving pancuronium and those with residual blockade have an increased incidence of postoperative pneumonia.

Surgical Techniques

Studies examining the incidence of PPCs using laparoscopic techniques compared to open techniques have generated variable outcomes and failed to favor one surgical approach over the other. However, common sense and clinical experience seems to favor laparoscopic techniques.

Lung-Expansion Maneuvers

Lung expansion maneuvers have been advocated to decrease the risk of complications by counteracting the adverse effects of surgery on pulmonary mechanics which predispose patients to atelectasis and retained secretions. Deep-breathing exercises, incentive spirometry, intermittent CPAP, and noninvasive ventilation have all been advanced as methods for lung expansion. Studies have failed to demonstrate the advantage of one technique over another and interestingly, several studies have shown that incentive spirometry has no advantage over deep breathing exercises alone. In summary, the techniques used for lung expansion appear to be equally effective in preventing PPCs. CPAP may be helpful in patient unable to perform deep-breathing exercises and in patients with OSA and/or obesity.

Use of Regional Anesthesia

Anesthesia is often classified into two main techniques: general anesthesia and regional anesthesia. General anesthesia refers to techniques that depress the central nervous system by a gaseous and/or intravenous delivery. Regional anesthesia refers to the delivery of pharmaceuticals directly to the spinal cord or nerves to locally anesthetize afferent and efferent neuronal pathways. Effective regional anesthesia for major

thoracic, abdominal, and limb surgery often requires the injection of these drugs into the subarachnoid space (spinal anesthesia) or into the epidural space (epidural anesthesia) to create a neuraxial blockade.

The use of neuraxial blockade for major general surgical procedures is well established though the additional benefit it may confer is controversial. These benefits are thought to originate through the attenuation of the neuroendocrine stress response that is reported during surgical interventions. When compared to patients undergoing systemic analgesia, the use of regional techniques is associated with a decrease in plasma levels of cortisol, catecholamines, and pro-inflammatory cytokines. The reduction of spinal sympathetic stimulation in the perioperative setting has presumed advantages for coagulation, pain relief, cardiovascular, pulmonary, gastrointestinal, and immunologic functions. Such techniques are appealing in that a blunted stress response during this period may translate into a reduction in morbidity and mortality especially in patients that have additional risk due to inherent co-morbidities.

When clinical outcomes are critically evaluated, the benefits of regional techniques become less clear. In a meta-analysis of 141 smaller randomized trials that included 9,559 patients, Rodgers et al. demonstrated a significant reduction in postoperative mortality for those patients that underwent neuraxial blockade. Furthermore, significant reductions in the odds of obtaining a deep vein thrombosis (DVT), PE, blood product transfusion, pneumonia, and respiratory depression were found in the blockade group. Rigg et al. examined the impact of epidural use during the operative and postoperative period in high-risk patients undergoing major abdominal or thoracic procedures when compared to a cohort receiving only systemic analgesia. This prospective, randomized trial of 915 patients demonstrated no difference in 30-day mortality. Of multiple morbid conditions that were examined postoperatively, only the rate of respiratory failure was significantly reduced in those with epidural use. In this group, there was a reduction in pain scores during the first 3 days of infusion though there was also a significant decrease in systolic blood pressure and maximal heart rate.

The implementation of such techniques in an elective surgical setting needs to be first discussed preoperatively with both the patient and in consultation with the anesthesiology team. Strong contraindications for placement include clotting defects and local sepsis at the insertion site. Clotting disorders, whether acquired or inherent, increase the risk of

epidural hematoma formation. Infection at the site of placement or in the locality of insertion could lead to spinal seeding and abscess formation. Patients with poor cardiac function should be evaluated closely in light of the heighted risk of cardiac dysfunction that may occur due to the spinal sympathetic block of neuraxial local anesthetics. Such patients may benefit from narcotic-only infusions or the removal of local anesthetics at the first signs of hypotension or bradycardia.

PROPHYLAXIS FOR VENOUS THROMBOEMBOLISM AND PULMONARY EMBOLISM

Venous thromboembolism (VTE), the formation of clot in the larger extremity or central veins, and PE, emboli from a large vein thrombus that occludes the pulmonary artery tree, continue to be the major health issues in the United States. These clots affect 350,000 to 600,000 Americans annually and are directly or indirectly related to 100,000 deaths over such a period. This crisis has grown to such a magnitude that a “Call to Action” was issued by the Surgeon General of the United States in 2008. The rationale for the prevention of VTE and PE is based on the premise that almost all hospitalized patients have at least one risk factor for formation and that approximately 40% have three or more (Table 5.7).

Without thromboprophylaxis, the rate of VTE is 10% to 40% in medical and surgical populations (moderate risk) with a rate as high as 40% to 60% following major orthopedic surgical interventions or major traumatic injury (high risk). Vast amounts of irrefutable evidence exist stating that VTE and PE are preventable entities. Based on these works, timely evidence-based clinical practice guidelines exist for the prevention of VTE and are the basis for this brief review.

The prevention of VTE begins with the institutional-wide identification of moderate to high-risk surgical patients. A formal, written policy for thromboprophylaxis and strategy for adherence has clear benefit. Low-risk surgical patients, those undergoing outpatient type procedures, have no additional thromboembolic risk and likely need nothing more than early and frequent ambulation. Most general surgical procedures incur a moderate risk of VTE though a high risk is often assigned to hip or knee operations, major trauma patients, and moderate risk patients with multiple individual risk factors. Risk factors for VTE in general surgical patients accrue based on the presence of obesity, cancer, increasing age, use of general anesthesia, duration of surgery, presence of postoperative

infection, and mobilization. The pathophysiologic basis of these risks is Virchow triad of vascular endothelial damage, venous stasis, and blood hypercoagulability. The use of mechanical methods for prophylaxis specifically graduated compression stockings, intermittent pneumatic compressions devices and venous foot pumps, have been appealing due to the lack of bleeding risk associated with such devices. Though the rate of DVT is lower with the use of these devices, no mechanical thromboprophylaxis option has been studied in such rigorous detail to impact PE or death rate and the quality of such trials is often debated.

TABLE 5.7 Risk Factors for Development of Venous Thromboembolism

Disease-Specific Risks	■ Surgery ■ Trauma (major trauma or injury to a lower extremity) ■ Cancer (active or occult) ■ Venous compression by tumor or hematoma ■ Inflammatory bowel disease ■ Nephrotic syndrome ■ Myeloproliferative disorders ■ Paroxysmal nocturnal hemoglobinuria ■ Inherited or acquired thrombophilia
Comorbid Risks	■ Immobility, lower-extremity paresis ■ Previous VTE ■ Increased age ■ Pregnancy and the postpartum period ■ Acute medical illness ■ Obesity
Drug and Treatment Risks	■ Cancer treatment (hormonal, chemotherapy, angiogenesis inhibitors, radiation) ■ Estrogen-containing oral contraceptives or hormone replacement therapy ■ Selective estrogen receptor modulators ■ Erythropoiesis-stimulating agents ■ Central venous catheterization

Current recommendations for those receiving major general surgical procedures focus on the early use of low-dose unfractionated heparin (LDUH), low-molecular-weight heparin (LMWH), or fondaparinux. Both LDUH and LMWH have been demonstrated to reduce the rate of symptomatic and asymptomatic VTE by 60%. In higher-risk patients undergoing oncologic surgical procedures, three times a day dosing of LDUH, LMWH or manufacture recommended dosing of fondaparinux is

recommended. The use of mechanical methods along with chemoprophylaxis is encouraged in any high-risk patient. The use of these agents, both mechanical and pharmaceutical, is to be used until discharge from the hospital. In patients with high risks or previous VTE, evidence exist that chemoprophylaxis with LMWH be considered after discharge for up to 28 days.

Recommendations for prophylaxis for surgical subspecialty patients do exist. The foundation of these recommendations is commonly based on the risk factors accumulated by the patient and not the type of surgical procedure to be performed. For high-risk patients undergoing vascular, laparoscopic, and thoracic surgery, the routine use of LMWH, LDUH, or fondaparinux is recommended. Those undergoing inpatient bariatric procedures often required higher doses of LMWH or LDUH than those given to nonobese patients. For surgical patients that require critical care who are at a moderate risk of VTE, the recommendation is for routine prophylaxis with LMWH or LDUH. Higher risk surgical critical care patients (often major trauma or orthopedic surgery) will require LMWH.

A great deal of evidence has accumulated for the prophylaxis of the traumatically injured patient. By the nature of a major trauma, these patients are considered high risk for the development of VTE. As such, routine thromboprophylaxis with LMWH is currently recommended. In those patients in whom the bleeding risk of chemoprophylaxis is too great, mechanical prophylaxis is to be started until LMWH can be initiated. For many, the risk of PE in this patient population is too high to rely solely on stocking and/or pneumatic compression devices. The insertion of inferior vena cava filters is growing in popularity to direct a method of mechanical prophylaxis above the common anatomical area of DVT formation. This attractiveness has spilled over to many patient subsets that have failed or cannot undergo the risk of chemoprophylaxis and/or full anticoagulation for known DVT or PE. However, these filters predispose patients to an increase risk of DVT in the lower extremities by reducing venous flow. Even more alarming is the incredibly low retrieval rate of these filters from patients with reversal factors for the formation of DVT. Many await large, prospective, multicenter studies to delineate the indication for filter use in those patient subsets that require chemoprophylaxis that is otherwise contraindicated.

DIAGNOSIS AND MANAGEMENT OF VENTILATOR-

ASSOCIATED PNEUMONIA

VAP is the most common infectious complication in critically ill surgical patients. Between 30% and 60% of mechanically ventilated patients will develop VAP varying between surgical population and diagnostic strategy. Critically ill trauma patients are at the highest risk of developing VAP followed by general surgical, cardiothoracic, burn, and neurosurgical patients. Although the attributable mortality in surgical patients is debated, VAP is independently associated with prolonged mechanical ventilation, and intensive care unit (ICU) and hospital lengths of stay. In addition, the excess cost of each episode of VAP exceeds $40,000. Risk factors for the development of VAP include patient comorbidities such as diabetes mellitus, malnutrition, alcoholism, immunosuppression, and COPD. Concomitant surgical risks include immunosuppressive effects of injury; breakdown of natural epithelial barriers by incision or instrumentation; manipulation of the alimentary tract; and prophylactic antibiotic therapy. Although lack of association between pneumonia and antacids or histamine-2 antagonists has been settled by meta-analysis, independent associations between proton pump inhibitor use and community- and hospital-acquired pneumonia have revived a debate surrounding gastric alkalinization for stress-related mucosal injury (SRMI) prophylaxis. Nevertheless, the Institute for Healthcare Improvement (IHI) recommends SRMI prophylaxis along with VTE prophylaxis, daily wake-up from sedation, head of bed elevation, and daily assessment for extubation as a bundle of interventions to diminish the risk and sequelae of VAP. Prevention of VAP using these and other evidence-based interventions (e.g., hand hygiene; oral care; infection control) should be routine in the management of critically ill patients.

The diagnosis and management of VAP in critically ill surgical patients include (1) a combination of clinical suspicion and quantitative, lower respiratory tract culture; (2) timely initiation of adequate (i.e., active against identified pathogen) empiric antibiotic therapy; (3) antibiotic de-escalation or discontinuation based on quantitative culture; and (4) appropriate duration of definitive antibiotic therapy. Interdisciplinary, evidence-based, institution-specific protocol implementation improves diagnostic accuracy, increases the frequency of adequate empiric antibiotic therapy, and decreases unnecessary antibiotic use.

In 2013, The Centers of Disease Control and Prevention (CDC) proposed a new method of monitoring VAP using a quality metric known

as ventilator-associated events (VAE). These definitions were developed to overcome shortcomings of traditional VAP definitions, including the subjectivity and low attributable mortality. However, these definitions include clinician response to changes in physiologic conditions, for instance an increase in PEEP to combat hypoxemia, which may be unrelated to any infectious process. A description of VAEs is provided in Figure 5.2.

The VAE definitions are fraught with difficulties, but the need to consistently diagnose pneumonia in an era of payers creating financial penalties for infections, inappropriately termed "never events" dictates compliance.

Despite the new CDC definitions, there remain two common strategies for the diagnosis of VAP: clinical and bacteriologic. Because traditional clinical criteria for VAP (e.g., new or changing infiltrate on chest radiograph [CXR]; macroscopically purulent sputum production; elevated white blood cell count; and elevated temperature) are overly sensitive and nonspecific, a bacteriologic diagnostic strategy using quantitative lower respiratory tract culture for definitive diagnosis can effectively differentiate VAP from noninfectious systemic inflammatory response syndrome (SIRS) or ARDS. Quantitative respiratory tract cultures, if possible, should be done before initiation of empiric antibiotic therapy and can be obtained using noninvasive endotracheal aspirate (EA), bronchoscopic protected specimen brush (PSB), or bronchoscopic/nonbronchoscopic bronchoalveolar lavage (BAL). Meta-analyses and large studies comparing EA and BAL are limited by clinical diagnostic defaults and relevant exclusion criteria, specifically patients at risk of more pathogenic organisms (e.g., *Pseudomonas aeruginosa*; methicillin-resistant *Staphylococcus aureus* [MRSA]). One of the more objective investigations was a large, randomized study in Spain that demonstrated an invasive strategy using bronchoscopic BAL (invasive) to obtain quantitative lower respiratory tract culture is associated with decreased unnecessary antibiotic use and decreased mortality compared to a strategy using quantitative EA (noninvasive). Consequently, concern exists surrounding potential upper respiratory tract contamination during noninvasive sampling and resultant false-positive culture.

The concept of quantitative culture for the diagnosis of VAP is not novel. In 1975, Polk performed serial quantitative cultures in EA in 97 surgical patients. He reported low false-positive and false-negative rates

when 100,000 colony forming units (cfu)/mL were used as the diagnostic threshold. Although debate persists around the appropriate diagnostic threshold for BAL, it has been repeatedly demonstrated that the threshold magnitude is inversely proportional to sensitivity and proportional to specificity, that is, a lower threshold has fewer false-negative, but higher false-positive results, whereas a higher threshold has fewer false-positive, but higher false-negative results. In a prospective study in critically ill trauma patients, Croce et al. noted that there is a poor predictability between clinical evidence of pneumonia and quantitative BAL culture. All enrolled patients received empiric antibiotic therapy based on clinical suspicion; however, patients with final quantitative BAL culture growth less than 100,000 cfu/mL were considered to have noninfectious SIRS and had their empiric antibiotic therapy discontinued. Based on subsequent investigation for VAP, the false-negative rate for quantitative BAL in this subset of patients was 7%. There was no difference in mortality between patients with false-negative and true-positive BAL. Overall, quantitative BAL and associated diagnostic threshold in this study had a sensitivity of 89% and specificity of 100%. Most data in critically ill surgical patients, primarily trauma, support a diagnostic threshold of 100,000 cfu/mL with consideration for using a threshold of 10,000 cfu/mL for *P. aeruginosa* in more severely injured or ill patients. As the progression of antibiotic resistance continues to challenge the fight against infectious complications, it may be reasonable to consider a more specific diagnostic strategy to avoid unnecessary antibiotic use. Nevertheless, contemporary guideline consensus and expert opinion stress the imperative of using a diagnostic threshold (e.g., 10,000 cfu/mL or 100,000 cfu/mL for BAL) rather than the specific threshold used.

Empiric antibiotic therapy for VAP should be guided by ICU-specific ecology, antibiogram data, and the presence of risk factors for multidrug-resistant (MDR) organisms. Commonly defined MDR risk factors include previous hospitalization or antibiotic use within 30 days; chronic hemodialysis; admission from long-term care facility; or immunosuppression. The most objective MDR risk factor influencing VAP pathogen prevalence is the duration of index hospitalization before developing VAP. Using a day cutoff, usually between 5 and 7 days, allows categorization of early- versus late-onset VAP.

Empiric antibiotic therapy should differ between early-onset VAP without other MDR risk factors compared to late-onset or early-onset VAP

with MDR risk factors (Table 5.8). Generally, patients without MDR risk factors who develop early-onset VAP are at risk for community-associated pathogens such as *Haemophilus influenzae;* methicillin-sensitive *S. aureus* (MSSA), α- or β-hemolytic *Streptococcus* spp., and limited-resistance enteric Gram-negative bacilli (e.g., *Escherichia coli; Klebsiella* spp.). Therefore, less broad-spectrum empiric antibiotic therapy is recommended. Institutions with high rates of community-acquired MRSA may need to consider anti-MRSA in these patients. In contrast, patients with late-onset VAP or those with MDR risk factors are at risk for *P. aeruginosa,* MRSA, *Enterobacter* spp., resistant *E. coli* or *Klebsiella* spp., and *Acinetobacter* spp. Because of the breadth of resistance mechanisms and bacterial classifications (i.e., Gram staining) encountered in these VAP episodes, a combination of anti-MRSA and anti-pseudomonal therapy is recommended. Reasonable options for MRSA include vancomycin (weight-based dosing) or linezolid, particularly for isolates wherein vancomycin minimum inhibitory concentration (MIC) exceeds 1 μg/L or if the patient experiences vancomycin intolerance. Empiric antibiotic therapy for Gram-negative bacilli should include an antipseudomonal β-lactam antibiotic and maximize the probability of initially covering *P. aeruginosa* based on local antibiogram. In institutions with low empiric resistance (e.g., less than 10%), it is reasonable to consider monotherapy antipseudomonal therapy, whereas institutions with unacceptable resistance rates should employ a combination of antipseudomonal β-lactam plus aminoglycoside or antipseudomonal fluoroquinolone. Subsequent to final culture result, empiric antibiotic therapy should be promptly de-escalated to the narrowest, organism-appropriate definitive regimen. This includes appropriate β-lactam (rather than vancomycin) for MSSA; monotherapy β-lactam for susceptible *P. aeruginosa;* monotherapy carbapenem for extended-spectrum β-lactamase (ESBL)-producing Gram-negative bacilli; and vancomycin for most MRSA strains. Unless obligated by MDR pathogens, monotherapy intravenous aminoglycoside therapy should be discouraged because of decreased clinical response and increased mortality. A key consideration to empiric and definitive antibiotic therapy regimens is the use of appropriate dosages to achieve acceptable pulmonary tissue concentrations. Strategies such as prolonged or continuous β-lactam infusions; aerosolized β-lactam or aminoglycoside therapy; and monitoring of real-time pulmonary antibiotic concentrations may be advantageous and are under broader investigation. Aerosolized

antibiotics may prove useful as adjunct to intravenous therapy. The use of aerosolized aminoglycosides allows maximum concentrations at the site of infection while limiting nephrotoxicity by minimizing blood concentrations. Current clinical trials are near completion to determine the utility of this therapy. The use of aerosolized antibiotics as monotherapy in uncomplicated, early pneumonia in trauma patients is attractive, but no evidence supports this regimen. Historical concerns related to aerosolized antibiotics, including development of resistance, appear to have been mitigated by improvements in aerosol delivery technology and management of the expired gas with filtration.

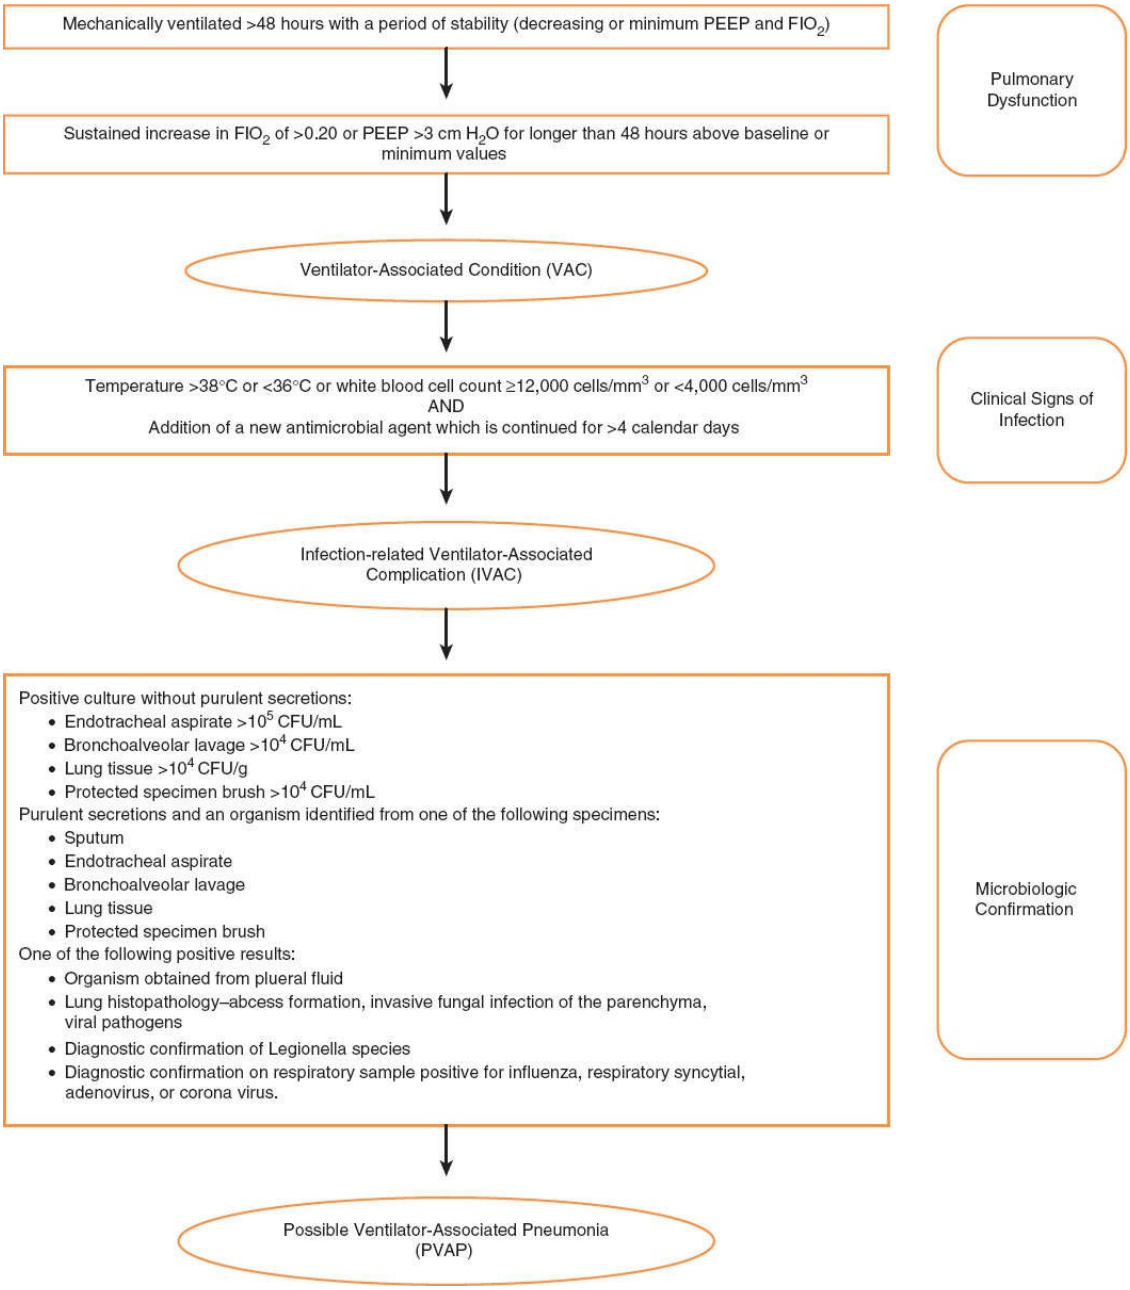

Figure 5.2. Ventilator-associated events surveillance algorithm.

TABLE 5.8 Empiric Antibiotic Regimens for Ventilator-Associated Pneumonia

VAP Classification	Antibiotic	Dosage, Intravenous[a]
Early-onset without MDR Risk Factors (choose one)	Ceftriaxone	2 g every 12–24 h
	Ampicillin/ Sulbactam	3 g every 6 h
	Moxifloxacin	400 mg every 24 h
	Levofloxacin	500–750 mg every 12–24 h
	Ertapenem	1 g every 24 h
Late-onset or early-onset with MDR risk factors (one primary agent, one combination agent, if necessary, and one anti-MRSA agent)	**Primary Agent**	
	Cefepime	2 g every 8–12 h (consider infusion over 4–6 h if suspect higher MIC *P. aeruginosa*)
	Piperacillin–Tazobactam[b]	3.375–4.5 g every 6 h (consider every 8 h infused over 4 h if suspect higher MIC *P. aeruginosa*)
	Imipenem	500 mg every 6 h
	Meropenem	1 g every 8 h
	Combination Agent	
	Tobramycin	7 mg/kg every 24 h
	Amikacin	25 mg/kg every 24 h
	Ciprofloxacin	400 mg every 8 h
	Anti-MRSA	
	Vancomycin	15–20 mg/kg every 8–12 h (consider goal serum trough concentration 15–20 μg/L)
	Linezolid	600 mg every 12 h

[a]Dosage for patients with creatinine clearance above 60 mL/min.
[b]Consider de-escalating to piperacillin (i.e., without tazobactam) 4 g every 4–6 h for piperacillin-sensitive *P. aeruginosa* based on final susceptibility results.
VAP, ventilator-associated pneumonia; MDR, multidrug resistance; MIC, minimum-inhibitory concentration; MRSA, methicillin-resistant *S. aureus*.

The optimal duration of antibiotic therapy for VAP is unknown, particularly in patients with nonlactose-fermenting Gram-negative bacilli (e.g., *P. aeruginosa*). Historically, antibiotic durations between 14 and 28 days were recommended for all patients with VAP. As with most typical bacterial infections, contemporary evidence demonstrates that shorter antibiotic durations result in similar patient outcomes, decrease antibiotic use, and may limit the progression of MDR. Moreover, low specificity of clinical response parameters (e.g., white blood cell count; temperature; sputum production) injects unacceptable subjectivity into the assessment of antibiotic duration. A landmark trial in France randomized 400 mostly critically ill medical patients with bronchoscopically diagnosed VAP (BAL greater than 10,000 cfu/mL) to 8 or 15 days of adequate antibiotic therapy regardless of clinical response. Overall, there was a significant

decrease in antibiotic-free days with no difference in VAP recurrence or 28-day mortality between the groups. On sub-group analysis, VAP relapse and mortality remained equivalent between groups for VAP caused by MRSA and lactose-fermenting Gram-negative bacilli. Conversely, patients with nonlactose-fermenting Gram-negative VAP, primarily *P. aeruginosa*, who received 8 days of therapy had significantly higher rates of VAP relapse (32.8% vs. 19.0%). However, of the patients who had a VAP relapse, those who received 15 days of therapy were 1.5 times more likely to have a MDR pathogen as the cause of the subsequent VAP.

In a concurrently conducted before-and-after, case-matched, single-center pilot study, antibiotic duration was compared in two groups of critically ill trauma patients with bronchoscopically diagnosed VAP (BAL greater than 100,000 cfu/mL): a control group whose antibiotic duration was at the discretion of the ICU service and a study group who underwent repeat BAL after 3 days of adequate antibiotic therapy. If pathogen growth on repeat BAL culture was less than 10,000 cfu/mL, then definitive antibiotic therapy was discontinued. Compared to control patients, study group patients received significantly shorter durations of definitive antibiotic therapy (9.8 days ± 3.8 days vs. 16.7 days ± 7.4 days; $p < 0.001$) with no difference in VAP recurrence or in-hospital mortality. Corroborating the results of the French trial, study patients with nonlactose-fermenting Gram-negative bacilli more often received longer durations of therapy because of persistence of significant growth on repeat BAL, whereas greater than 95% of all other pathogens had less than 10,000 cfu/mL on repeat BAL and were treated for 8.8 ± 3.3 days. Results of these studies support contemporary guideline recommendations for antibiotic duration in patients with VAP: most patients who receive adequate empiric antibiotic therapy and demonstrate reasonable clinical or microbiologic response should receive 7 to 8 days of antibiotic therapy, whereas patients with nonlactose-fermenting Gram-negative bacilli may require 14 days of antibiotic therapy.

PATHOPHYSIOLOGY AND TREATMENT OF ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is an acute inflammatory lung injury that was first described by Ashbaugh and colleagues in 1967. This syndrome is characterized by hypoxia, diffuse “ground-glass” pulmonary infiltrates on chest x-ray, and decreased lung compliance in the absence of ongoing heart failure (Fig.

5.3). The reported incidence of ARDS ranges between 1.5 and 13.5 per 100,000 population, with a mortality rate of 27% to 60%. Forty years after the initial description, the mortality as associated with ARDS remains high and is often part of the sequence of multiple organ failure (MOF). Recent investigations have suggested that the mortality associated solely to ARDS is declining to a range of 30%. Assuming that the finding of reduced mortality in ARDS is genuine, the cause is undoubtedly multifactorial. Over the past decades, improvements in understanding the pathogenesis of sepsis and multiorgan dysfunction, development of improved surveillance and treatments for infection, appreciation of the role of appropriate nutrition, and changing concepts in ventilatory support have likely all contributed. In addition, the development of consistent protocol-based approaches to the management of ARDS, as shown by the Acute Respiratory Distress Syndrome Network (ARDSNet) trial, appear to improve outcome. Finally, advances in ventilator technology, including airway graphics packages and improved dynamic monitoring capability have provided the practitioner with a more precise understanding of the dynamic interplay between patient and machine.

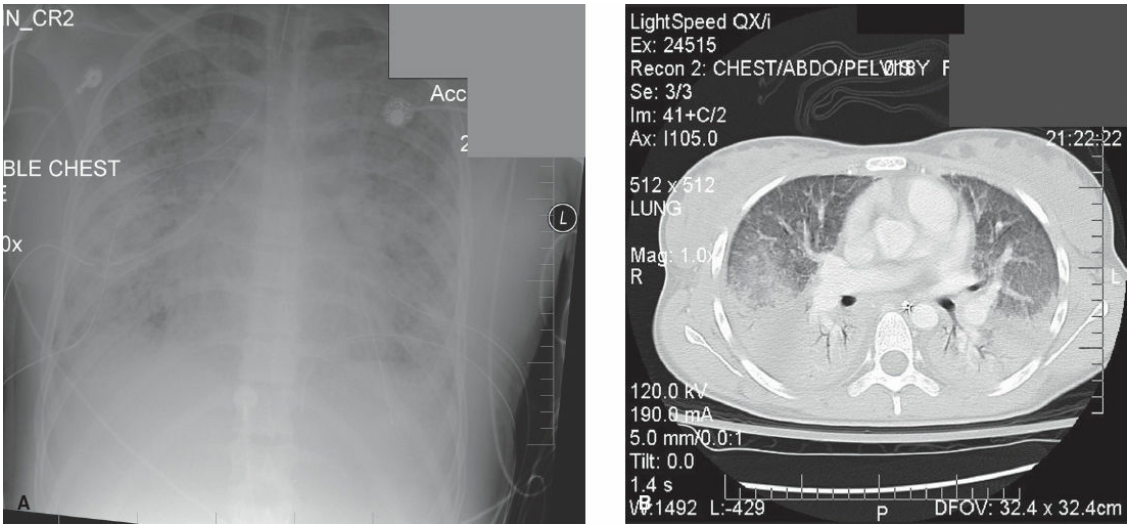

Figure 5.3. Characteristic chest radiograph (**A**) and CT scan (**B**) in a patient with severe ARDS following multiple trauma.

The hallmark clinical symptom of ARDS is hypoxemia refractory to oxygen therapy. The defining characteristics of ARDS have remained constant but a new one, the Berlin definition, was introduced in 2011. This system eliminates the definition of ALI and classifies ARDS into mild, moderate, and severe forms as detailed in Table 5.9.

The major difference in the new definition is the requirement for a minimum of 5 cm H_2O PEEP at the time of the oxygenation measurement. Categorizing ARDS based on oxygenation allows determination of the interval at which rescue therapies can be applied and aids in the determination of mortality. The observed clinical sequelae of ARDS results from ventilation–perfusion (V/Q) inequalities, specifically intrapulmonary shunt (perfusion in the absence of ventilation). Gravitational forces acting on the edematous lung induce consolidation in dependent lung regions altering distribution of ventilation and worsening V/Q matching. The preponderance of disease in dependent lung regions complicates mechanical ventilation, leads to maldistribution of tidal volume, and promotes ventilator-induced lung injury (VILI).

TABLE 5.9 Definition of Berlin Acute Respiratory Distress Syndrome

Timing	Acute onset within 1 wk of insult or new/worsening respiratory symptoms.		
Origin of lung edema	Known risk factors for lung edema not explained by cardiac failure or fluid overload. In the absence of known risk, objective assessment of cardiac failure or fluid overload must be undertaken.		
Radiographic findings	Bilateral opacities not explained by pleural effusion, lobar collapse or nodules.		
	Mild	**Moderate**	**Severe**
Oxygenation, Pao_2:Fio_2	201–300 PEEP/CPAP ≥5 cm H_2O	<200 PEEP ≥5 cm H_2O	<100 PEEP ≥5 cm H_2O

CPAP, continuous positive airway pressure; PEEP, positive end-expiratory pressure.

A more detailed and sophisticated approach to the various “types” of ARDS is obtained by understanding additional definitions that further refine the etiology and pathophysiology of ARDS. More importantly these discriminators highlight important differences in the very broad category that is ARDS. By understanding the evolution and key derangements present in the various “forms” of ARDS the clinician may more appropriately tailor the clinical response to the specific patient needs. An understanding of the various “forms” also allows one to understand that surgical patients with ARDS are often quite different from medical patients with ARDS. Understanding these distinctions both explains traditional differences in management strategies between the MICU and

the SICU as well as aids in the appropriate bedside management concepts. The key components to understanding the various "forms" of ARDS include the following:

Primary versus secondary ARDS
Early versus late ARDS
The role of extrapulmonary changes in compliance

The ensuing sections will attempt to distinguish these differences with specific attention to the surgical patient with ARDS.

Primary Versus Secondary ARDS

The distinguishing characteristic between primary and secondary ARDS is related to the locus of injury in the lung. In direct (primary) ARDS the injury occurs at the alveolar interface whereas with indirect (secondary) ARDS the injury occurs at the capillary side of the alveolus (as the result of substances/toxins transmitted via blood). The most common cause of direct lung injury is pulmonary infection and the presumed toxins/toxic effect exerted by bacteria in the alveoli (pneumonia). Other primary insults leading to ARDS include aspiration, barotrauma, atelectrauma, near-drowning, and inhalation injury. Most of these etiologies are managed within the MICU. Surgical sources of direct ARDS include pulmonary contusion, lung laceration, blast injury, and bronchial injury. In all cases, direct lung injury is characterized by an insult which impacts on the alveolar (as opposed to the capillary) side of the alveolar/capillary interface.

Indirect lung injury may be related to sepsis, shock, massive transfusion/resuscitation, fat/PE, pancreatitis, peritonitis, and the SIRS. In this instance the defining injury is on the capillary side of the alveolar/capillary interface and the majority of these patients reside within a SICU. The pathophysiology of ARDS is an area of significant continuing research as patients with these multiple risk factors demonstrate heterogeneity with respect to the expression of the disease state of ARDS. The "trigger" for the sequence of ALI to SIRS to ARDS to MOF is an unsolved scientific question and demonstrates variable expression among patients. Most investigators believe that increased lung capillary permeability with subsequent alveolar capillary leak occurs from a complex inflammatory response to a primary event and remains the cornerstone pathologic disturbance of this process. The diagnosis of ARDS

remains a clinical determination and the treatment primarily supportive.

Early Versus Late ARDS

A second key characteristic that aids in distinguishing the "forms" of ARDS is the distinction of early versus late ARDS. Early ARDS is a dynamic disease entity and the manifestation of lung edema may be quite variable. In early ARDS the lung remains malleable and is often recruitable with compliance approaching normal values. Late ARDS is a form of the disease which is more static in nature, less responsive to therapeutic recruitment maneuvers (PEEP, prone positioning, etc.), and more likely to be chronic and slowly changing. The transition point from early to late ARDS is variable but the may occur around the time of 5 to 7 days of clinically established ARDS. This subtle, and often overlooked distinction between early and late ARDS must be accounted for by the clinician as it may significantly impact on the success (or failure) of the therapeutic option(s) pursued in the management of the patient with ARDS.

Numerous clinical trials with various treatment protocols have been performed with the goal of supportive therapy to decrease VILI, improve oxygenation, and decrease the number of ventilator days. Similarly there have been additional trials of pharmacologic agents (including surfactants) which reduce the inflammatory response without increasing infectious complications and therefore potentially attenuate the severity of the clinical course. There have been a variety of ventilator protocols and surrogates to respiratory support studied as well. The outcome of most of these trials demonstrates a degree of improvement in oxygenation and limitation in VILI but with little impact on mortality of established ARDS or prevention of ALI. Pharmacologic studies have been even less promising with no approved agent currently for treatment of this disease. Otherwise, no major difference has been achieved with a series of failed or terminated clinical trials primarily focused on the inflammatory phase. Table 5.10 summarizes many of the supportive and pharmacologic modalities with their results.

The ARDSNet was established to facilitate the development of effective therapeutic protocols for the treatment of ARDS. The National Heart, Lung, and Blood Institute of the National Institutes of Health (NIH), initiated a clinical network in 1994 to carry out multicenter clinical trials of novel therapeutic agents for ARDS. More recently, NIH has established

the Prevention and Early Treatment of Acute Lung Injury (PETAL) network with the aim of preventing ARDS through early intervention. Current treatment of ARDS is primarily supportive, with the goal of minimizing further lung injury and allowing spontaneous resolution of the process. There remains some controversy as to what constitutes the best supportive measures and there is yet no current effective treatment for the pathophysiologic derangement of ARDS. The first ARDSNet trials that received widespread interest included ventilator management trials investigating lower tidal volume ventilation and higher PEEP. In the low tidal volume trial, an improved survival rate was observed when limiting ventilator tidal volumes to 6 mL/kg of idealized body weight. Success was attributed to decreasing volutrauma related to traditional higher tidal volumes. This trial was halted early with 861 subjects noting a decrease in mortality from 39.8% to 31% when comparing high to low tidal volume ventilation. It is important for the practitioner to remember that the tidal volume utilized in this trial is the *idealized* body weight (determined solely by gender and patient height). The second ventilator management trial examined the role of low and high PEEP with lower tidal volumes in patients with ARDS. No survival benefit was noted with the addition of higher PEEP than achieved by lower tidal volumes alone.

More recent data from the ARDSNet group suggests that fluid restriction based on pressure data from a central venous catheter is superior to more aggressive fluid strategies. This trial also noted no advantage to use of a pulmonary artery catheter in the management of fluids in ARDS. The role of steroids in late ARDS remains controversial. However, recent studies have demonstrated that steroids in late ARDS can be associated with an increased incidence of infection and mortality.

Early use of paralysis was associated with improved outcomes in a single center European trial. Cisatracurium for the first 3 days compared to analgesia and sedation demonstrated a decrease in mortality and duration of ventilation. This finding may relate to eliminating the need for patient–ventilator interaction and achieving absolute control of driving pressure and tidal volume. The PETAL network is currently re-exploring this treatment in a US multicenter trial.

In trauma patients, experience from the conflict in Iraq and Afghanistan has demonstrated that initial hypotensive resuscitation followed by a 1:1:1 ratio of blood to plasma and platelets results in a reduced incidence of ARDS. This observed benefit is clearly complex and multifactorial but

appears clearly supported by a growing body of published data. Robinson and the Prospective Observational Multicenter Massive Transfusion Trial (PROMMTT) study group evaluated the application of the Berlin definition in PROMMTT patients with respect to the impact of resuscitation on the incidence of hypoxemia. The PROMMTT study enrolled 1,245 patients undergoing massive transfusion following traumatic injuries. The authors concluded that severe chest injury, increasing age, and crystalloid-based resuscitation, but not blood transfusions, were associated with increased risk of developing moderate-to-severe hypoxemia following injury. At our own institution, we examined the impact of a change in our transfusion practice following the military clinical practice guidelines of damage control resuscitation (DCR) which emphasizes balanced blood component administration with limited crystalloid use. This study demonstrated that a military-derived DCR strategy can be implemented in the civilian setting. DCR led to significant increases in FFP transfusion, decreases in crystalloid use, and a statistically significant decrease in acute hypoxia.

TABLE 5.10 Supportive and Pharmacologic Interventions for ARDS

Respiratory Supportive Measures		Pharmacologic Interventions	
Intervention	Result	Intervention	Result
Prone ventilation	Improved oxygenation Improved outcomes in severe ARDS (PaO_2/FIO_2 <100)	Corticosteroids	No early benefit? Late benefit in fibroproliferative phase. May increase mortality in select groups.
Permissive hypercapnia	Decreased barotrauma? Survival benefit	Surfactant	No benefit
Pressure control ± inverse ratio ventilation and airway pressure release ventilation (APRV)	Commonly used for "rescue" when conventional ventilator modes fail Improved oxygenation using high mean airway pressures Requires additional fluid loading secondary to reduced cardiac output	Pentoxifylline/ Lisofylline	No benefit
High-frequency modes of ventilation	Recent trials demonstrate either no benefit or worse outcomes with high frequency owing to high mean airway pressure, excess sedation, and increased fluid requirements	Ketoconazole	No benefit
Extracorporeal cardiopulmonary bypass (ECMO)	Mixed results in adults, institution dependent	Antioxidants	No benefit
Inhaled nitric oxide	Improved oxygenation, no survival benefit	Paralysis (Cisatracurium)	Improved outcomes during paralysis for first 3 days of ventilator support
Recruitment maneuvers and increased PEEP	Recruitment maneuvers have been shown to increase PaO_2 and improve lung compliance but have not decreased mortality. Higher PEEP is associated with a shorter duration of ventilation, less frequent use of rescue therapy, and a mortality benefit in severe ARDS. Higher PEEP should be limited to severe ARDS	Prostaglandin	Improved oxygenation, no survival benefit

A Practical Approach to ARDS

Ventilatory management of the surgical patient with ARDS should follow the principles of lung protection. The approach to ventilation should begin with a determination of the mechanism of injury and the pattern of pulmonary involvement (direct versus indirect ARDS). The patient with direct ARDS resulting from postoperative pneumonia commonly has patchy infiltrates on CXR and moderate hypoxemia. The patient with indirect ARDS following multiple trauma, hypotension, and massive blood transfusion will demonstrate a pattern of diffuse alveolar infiltrates on CXR and profound hypoxemia. In each instance, the goals of ventilation should prioritize limiting plateau pressures, tidal volumes based on ideal body weight of 6 mL/kg, and PEEP sufficient to reduce FIO_2 <0.60.

Despite the success of the ARDSNet trial, the adjustment of ventilatory parameters based solely on rules for tidal volume and PEEP belies the complexity of ventilator management and the disease process. In patients with direct ARDS, PEEP should be adjusted to maintain oxygenation and tidal volume adjusted between 4 and 8 mL/kg of ideal body weight to maintain a plateau pressure <30 cm H_2O. Ideal body weight should be determined through the measurement of height (height is the major determinant of lung volume not weight) using the following equations.

$$\text{Men} - \text{IBW} = 50 + 2.3\ (\text{Height in inches} - 60)$$

$$\text{Women} - \text{IBW} = 45.5 + 2.3\ (\text{Height in inches} - 60)$$

Direct ARDS rarely requires PEEP >12 cm H_2O as higher pressures result in overdistension, increased shunt fraction, and a paradoxical decrement in oxygenation. This observation reflects the patchy/isolated nature of early direct ARDS. Indirect ARDS commonly requires PEEP up to 20 cm H_2O (diffuse widespread changes in pulmonary compliance) and similar adjustment of tidal volume based on IBW. This may also reflect global changes in thoracic and abdominal compliance due to third spacing and capillary leak which occurs at extrapulmonic locations; but is a result of the same inflammatory insult which generated the secondary ARDS. Measurement of the pressure–volume curve of the respiratory system can be useful in determining the lower and upper inflection points corresponding to the initiation and end of alveolar recruitment (Fig. 5.4). During the last decade a number of newer ventilators have incorporated

the ability to conduct an automated pressure/volume curve at the bedside. This relatively simple procedure requires the establishment of (temporary) muscular paralysis but in return may provide significant clinical information regarding the lower and upper inflection points of the lung. It is our practice to measure the P/V curve in most patients with moderate or severe ARDS and to repeat this maneuver as needed (daily) over the early phase of management.

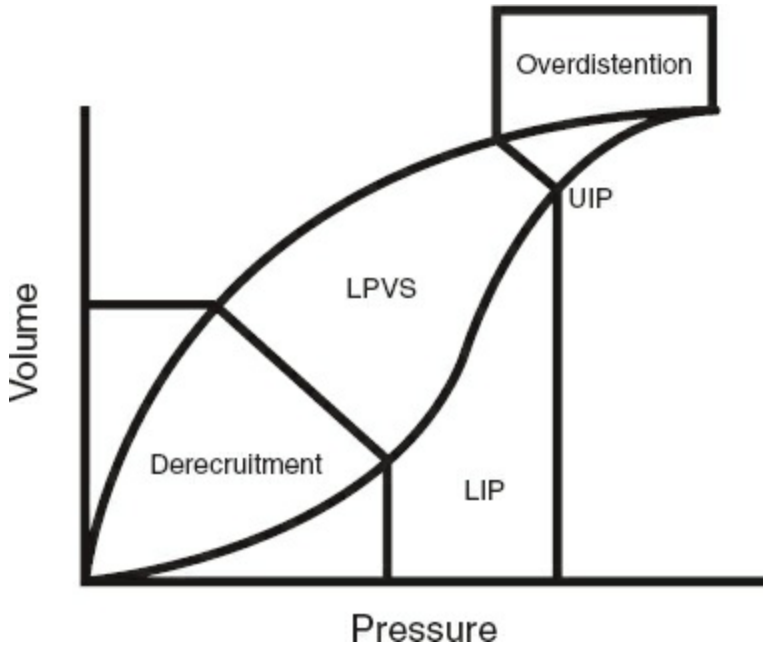

Figure 5.4. Pressure–volume curve of the respiratory system demonstrating the lower inflection point (LIP) representing the start of alveolar recruitment and the upper inflection point (UIP) representing the end of alveolar recruitment. Identification of these landmarks allows rapid adjustment of PEEP and tidal volume to maximize gas exchange and limit ventilator-induced lung injury.

Plateau pressure as measured during an inspiratory pause has been employed as a surrogate of alveolar pressure. This assumption is simplistic and may often be misleading in the surgical patient. More appropriately, the main determinant of lung inflation should be considered as related to the transalveolar distending pressure (alveolar pressure minus chest wall pressure). This observation remains one of the critical distinctions that must be understood by the surgical intensivist. The surgical patient often differs from their medical counterpart due to significant changes in chest and abdominal compliance prompted by surgical interventions and large

volume fluid resuscitation. These striking changes also often accompany the patient who has suffered an indirect (secondary) insult as the etiologic agent for ARDS. The surgical patient with reduced chest wall compliance as a consequence of fluid resuscitation, abdominal distension, or obesity frequently requires a plateau pressure higher than 35 cm H_2O in order to sustain an appropriate transalveolar distending pressure. Transalveolar distending pressure can be estimated by measurement of airway plateau pressure minus the esophageal or intra-abdominal pressure. Recent studies by Talmor and associates have demonstrated that this measurement algorithm may significantly impact on the management strategy of surgical patients with ARDS. Talmor's group examined surgical patients meeting the consensus criterion definition of ARDS the management of PEEP was randomly distributed between an algorithm utilizing the ARDSNet standard of care recommendations versus an algorithm that adjusted PEEP per measurements of esophageal pressure. This study was halted early after the enrollment of 61 patients secondary to the demonstration of a significant improvement in the ratio of partial pressure of arterial oxygen to the fraction of inspired oxygen (PaO_2/FiO_2 ratio) at 72 hours in the esophageal pressure–guided group. This effect was persistent over the entire follow-up time (24, 48, and 72 hours). This study lends support to the contention that surgical patients with elevated intra-abdominal pressures (fluid resuscitation, bowel distension, surgical changes, etc.) and/or noncompliant chest walls may respond in a fundamentally different fashion to increases in PEEP as compared to the patient with direct ARDS and pre-existing chronic lung disease. Further investigations of this modality must be conducted but it appears to be straightforward and to offer significant opportunity for improvement in ventilator management techniques.

Considerable controversy remains (and continues) regarding the ideal mode of ventilation and type of ventilator breaths delivered for the surgical patient. Volume control breaths provide constant flow and assure a constant minute ventilation (but varying peak pressure). Pressure control breaths may improve oxygenation by virtue of increased mean airway pressure, but this modality cannot guarantee tidal volume consistency. Either of these techniques can be used to provide lung protection but neither is lung protective per se. The volume and pressure delivered to the patient should follow the guidelines presented above. If these considerations are understood then there is no specific advantage of one

ventilator modality breath type over the other. Choices for modes of ventilation multiply with each passing year (and with increasing sophistication of mechanical ventilators), but the seminal issue remains the clinical decision to provide either full ventilatory support or allow spontaneous breathing. In the critically ill patient requiring heavy sedation and/or paralysis, full ventilatory support with continuous mandatory ventilation (often called assist control) is usually required. In the previously healthy patient with moderate hypoxemia, spontaneous breathing may be promoted by either synchronized intermittent mandatory ventilation (SIMV) or airway pressure release ventilation (APRV). Maintenance of spontaneous breathing improves V/Q matching, enhances venous return, and improves cardiac output. To date there is no compelling evidence which demonstrates an advantage of one technique over the other.

Following the establishment of initial ventilator settings an assessment of intravascular volume status should be accomplished, and fluid replacement and inotropic support implemented as required to promote effective ventilator management. Recruitment maneuvers to assess the degree of potential alveolar recruitment and improve gas exchange are warranted if gas exchange does not improve immediately. This can be accomplished by increasing PEEP to 30 cm H_2O for 40 seconds. Recruitment maneuvers are generally more effective in indirect than direct ARDS. An improvement in oxygenation and reduction in the minute ventilation to maintain the current CO_2 elimination are seen when the maneuver is successful. If the beneficial effects of recruitment maneuvers are short lived, increasing levels of PEEP following the maneuver are recommended to maintain recruitment. The normal ratio of inspiration to expiration (I:E) allows for a 2 to 3 times longer expiratory phase during gas exchange. Failure of increased PEEP to improve oxygenation can often be overcome by a reversal of the I:E ratio. Increasing the inspiratory phase allows a greater period of time for oxygen exchange at the alveolar level. Given that the normal diffusion process favors CO_2 elimination by a 20-fold difference, a shortened expiratory phase is usually not problematic. Reverse I:E ratios vary from 1:1 to 4:1 based on the severity of hypoxia. Caution should be exercised when increasing the I:E ratio. Often the increase in PaO_2 is offset by the decrease in cardiac output with a resulting fall in oxygen delivery.

Recent advances in ventilator mechanics and sophistication have

created the opportunity for the clinician to conduct bedside pressure/volume curve analysis to establish the optimum PEEP level. Establishing a pressure/volume curve requires a short period of chemical paralysis in order to eliminate the variability imposed by spontaneous respiratory effort. Once this is established the ventilator will complete a constant flow maneuver while simultaneously evaluating circuit pressure and volume delivered. This pressure/volume curve represents the global compliance of the respiratory system as well as allowing for the detection of the upper and lower inflection points. In an ideal situation PEEP is set at (or slightly above) the lower inflection point. This establishes an end-expiratory pressure which prevents repetitive alveolar collapse at the end of each ventilatory cycle. The upper inflection point establishes the upper plateau pressure limit which will aid in the elimination of alveolar overdistension. This technique allows the clinician to establish ventilator parameters which allow for "ventilating between the points." To date the utility of setting PEEP and plateau pressures via the utilization of modern ventilator pressure/volume curves has yet to be established despite the intuitive nature of this practice. If hypoxemia persists, a trial of prone positioning is warranted. Prone positioning improves the distribution of inspired volumes via alteration(s) in pleural pressure gradients. In addition, prone positioning changes the physical relationship of recruited versus collapsed lung segments as well as the physical location of displacing entities such as the heart. These combined effects result in more efficacious pressure gradients that favor recruitment. The duration of prone position should be based on patient tolerance as judged by edema formation and need to perform assessments or care procedures in the supine position. Ideally a period of 9 to 12 hours prone should be interspersed with 4 to 6 hours supine. In severe ARDS both aggressive PEEP and prone position provide a mortality benefit and shorter duration of ICU stay. Care must be exercised to avoid pressure points at the contact points between the patient's face and ventilator circuit. The authors also advocate for a trial of proning using simple pillows and pads to demonstrate potential efficacy before committing to the more expensive commercial bed devices. An objective demonstration of the benefit of proning would be the improvement of PaO_2/FiO_2 ratio of >20%.

When proning can be accomplished safely, the improvements are worth the risk in the patient with severe ARDS (PaO_2/FIO_2 <100). Prone positioning has shown to be effective in improving the PaO_2/FiO_2 ratio for

up to 10 days and can be discontinued when gas exchange benefits are no longer seen.

iNO may improve oxygenation by selective pulmonary vasodilation and subsequent improvement in V/Q. Several trials of iNO have demonstrated an improvement in the PaO_2/FiO_2 ratio but all have failed to demonstrate any survival benefit.

All of the above maneuvers (pressure–volume curves, prone positioning, recruitment maneuvers, and iNO) are correctly understood as adjuncts in the management of ARDS. Individually each of these maneuvers have been demonstrated to improve some aspect of the pulmonary dysfunction associated with ARDS (V/Q mismatch, hypoxemia, atelectasis, alveolar overdistension, etc.), but none have been associated with an improvement in mortality. It is up to the clinician to ascertain when, which, and for how long all of these maneuvers may be combined in the individual patient with ARDS. Managing ARDS is a dynamic process which requires vigilance and understanding of the pathophysiology of the disease. Protocol-driven treatment can be useful as a starting point, but modification of protocols to meet the needs of the critically ill surgical patient must be employed to maximize success.

INTRAOPERATIVE VENTILATORY SUPPORT

Previous editions of this chapter have focused on the preoperative, postoperative, and ICU aspects of pulmonary risk and ventilator support. Recent work by multiple investigators has focused on the potential impact of ventilator strategies and management techniques during surgery. This body of evidence suggests that this is an important additional consideration and is now included for consideration.

The observation (discussed above) by the ARDSNet study group and others that a limited tidal volume strategy improves outcomes in patients with ARDS stimulated investigations of a similar approach during operative intervention and anesthesia. Yang and colleagues completed a meta-analysis of intraoperative ventilation techniques and the impact on subsequent PPCs. Their work produced two separate analyses. The first was an examination of the impact of low tidal volume ventilation versus conventional tidal volume ventilation during surgery. The group demonstrated a decreased incidence of postoperative infection but no impact on the occurrence of ALI or atelectasis. The second analysis examined a protective lung strategy (limited tidal volume, PEEP 5 to 10

cm H_2O, and intermittent recruitment maneuvers during the procedure) versus conventional tidal volume use. This second analysis demonstrated a statistically significant reduction in ALI, pulmonary infection, and postoperative atelectasis.

In contrast, the PROtective VEntilation (PROVE) network evaluated the use of high level PEEP (12 cm) along with intermittent recruitment maneuvers and found no difference in the rate of PPC. In addition, the study group demonstrated an increased incidence of intraoperative hypotension and required more vasoactive drugs during surgery. This contrary finding may relate to this study's intentional enrollment criterion which selected patients at increased risk for the development of PPC as well as the relatively elevated (12 cm) level of PEEP utilized.

Finally, a recently published Cochrane analysis examined the intraoperative use of limited tidal volume ventilation and its impact on PPC. Their conclusions with a moderate quality of level of evidence included a lower incidence of pneumonia, a lower need for postoperative invasive as well as noninvasive ventilator support, and no difference in ICU or hospital length of stay. The finding of no difference in the primary endpoint of hospital mortality was judged to be low quality secondary to inadequate sample size.

POSTOPERATIVE VENTILATORY SUPPORT

Postoperatively the surgical patient may require mechanical ventilation for respiratory muscle weakness, pneumonia, prolonged effects of anesthesia, or chronic lung disease (COPD). The principles of ventilation for ARDS apply for the most part in these patients. In the patient without chronic lung disease, ventilation at a tidal volume of 6 to 8 mL/kg of IBW which maintains plateau pressure <30 cm H_2O should be used. Recent evidence suggests that patients requiring mechanical ventilation for reasons other than ALI are more likely to develop ALI if plateau pressures are excessive. The odds ratio of developing ALI is 1.5 for every 6 cm H_2O increase in plateau pressure. Spontaneous breathing should be encouraged and a PEEP of 5 cm H_2O should be considered the minimum value. PEEP should be adjusted to maintain adequate arterial oxygen saturation (>92%).

The patient with COPD represents a particular challenge. Noninvasive ventilation (ventilation via a face mask) can prevent the need for intubation, reduce hospital stay, and mortality in this patient population.

Much of this work is in the nonsurgical patient, but a trial of noninvasive ventilation may be warranted in the absence of abdominal distension in the cooperative surgical patient. Keys to the success of noninvasive ventilation include use of a full face mask, choice of a motivated, cooperative patient, use of pressure support or CMV, and a time period for respiratory therapist and nurse to acclimate the patient to the system. Success with noninvasive ventilation can be judged by monitoring pulse oximetry and evaluating patient comfort and rate of breathing. Failure to alleviate air hunger generally indicates failure and endotracheal intubation should be undertaken prior to respiratory collapse. PEEP at low levels (5 to 8 cm H_2O) should be used in the patient with COPD to overcome terminal airway collapse, promote more complete alveolar emptying, and improve the ability of the patient to trigger the ventilator. Set PEEP helps overcome intrinsic PEEP and reduces the effort required to initiate inspiration.

The use of nasogastric tubes in the postoperative period remains a surgical tradition; albeit one without evidence-based support. The incidence of PPCs appears to increase with the use of nasogastric decompression while the incidence of anastomotic leak, incisional hernia, gastric upset/vomiting is equivalent regardless of their placement.

LIBERATION FROM MECHANICAL VENTILATION

Discontinuing mechanical ventilation includes the processes commonly known as weaning and extubation. These terms are often confused, but are quite different events. One implies a progressive decrement in ventilatory support while the other describes the removal of the artificial airway (usually an endotracheal or tracheostomy tube). Consequently, a patient can be ready for discontinuing ventilatory support without being ready for extubation (i.e., a deeply comatose patient who is unable to clear secretions or maintain an adequate airway). Numerous reports now clearly demonstrate that the timing of discontinuation of mechanical ventilation is best determined through the use of a screening technique and daily spontaneous breathing trials (SBTs).

Evaluating Weaning Readiness

The most recent literature suggests that a protocol of daily screening for weaning readiness and an SBT are the best modalities for determining weaning readiness. The daily screen consists of evaluating the overall condition of the patient through the use of five criteria.

1. Patient coughs when suctioned suggesting intact gag reflex.
2. No continuous infusions of sedatives or vasopressors (hemodynamic stability).
3. PaO_2/FIO_2 >200 (FIO_2 <0.50)
4. PEEP ≤8 cm H_2O.
5. f/V_T ≤105 (measured while breathing spontaneously with respiratory rate off and pressure support off, for 1 minute).

If the patient passes the first 1-minute trial, then an SBT of 30 to 120 minutes is performed. The trial is successful if the patient tolerates 30 to 120 minutes of spontaneous breathing. The trial may be terminated if any of the following adverse events occur:

1. Respiratory rate is >35 for >5 minutes.
2. SpO_2 <90% for >30 seconds.
3. Heart rate increases >20% for >5 minutes.
4. Systolic blood pressure >180 mm Hg or <90 mm Hg for >1 minute.
5. Agitation, anxiety, or diaphoresis (compared to baseline) lasting >5 minutes.

Patients who tolerate an SBT without adverse events have a 90% chance of successfully remaining off the ventilator for 48 hours.

Determining the ability of the patient to protect the upper airway following extubation remains a subjective observation. Clearly patients who are awake and oriented are likely to remain extubated longer than those who are obtunded. The decision to extubate a patient who has successfully completed an SBT, but has an altered mental status remains an exercise in physician judgment. The use of tracheostomy in these selected cases may prove beneficial. Generally speaking, in the head-injured patient if the Glasgow Coma Score (GCS) is ≤8 (postinjury day >3) tracheostomy may facilitate discontinuation of ventilation and decrease the rate of ventilator-associated complications. If GCS is >8, patients can frequently be successfully extubated. Tracheostomy can also facilitate ventilator discontinuation in the elderly trauma patient or patient with COPD by reducing work of breathing, enhancing secretion removal, and improving patient comfort.

Weaning Failure

The most common cause of weaning failure is likely an underestimation of the ability of patients to adequately support their own oxygenation and

ventilation. Prior to weaning attempts, the underlying cause, which resulted in institution of mechanical ventilation, must be alleviated. Ely and others have developed a pneumonic to describe the difficulty to wean patient, "WHEANS NOT." This allows the clinician to evaluate the many potential causes of weaning failure:

Wheezes
Heart disease, **H**ypertension
Electrolyte imbalance
Anxiety, **A**irway abnormalities, (metabolic) **A**lkalosis
Neuromuscular disease, use of **N**euromuscular blockers
Sepsis, **S**edation
Nutrition (under and over feeding)
Opiates, **O**besity
Thyroid disease

Weaning failure typically results as a consequence of an imbalance between respiratory neuromuscular capacity and respiratory load. This imbalance leads to respiratory muscle failure. Common causes of respiratory muscle failure include dynamic hyperinflation, respiratory acidosis, decreased oxygen delivery, malnutrition, excessive CO_2 production, increased dead space ventilation, increased respiratory system impedance, and intrinsic PEEP.

Other causes of weaning failure include a decreased output of the respiratory control center caused by oversedation, neurologic dysfunction, or use of narcotic drugs. Cardiovascular dysfunction may also impede weaning and left heart failure has been demonstrated to be a cause of weaning failure in COPD. Myocardial ischemia may occur during weaning due to increased oxygen consumption of the respiratory muscles and stress.

Electrolyte abnormalities, acid–base disturbances, and unrecognized infection are also occasionally seen. Acidosis is commonly seen as a cause of weaning failure, but metabolic alkalosis can also depress respiratory drive. After fluid resuscitation with Lactated Ringer's, metabolic alkalosis is a common finding. Critical illness polyneuropathy is increasingly recognized as a potential cause of weaning failure. This syndrome has been reported in up to 20% of ventilator-dependent patients. Critical illness polyneuropathy is more common in patients with sepsis and the use of corticosteroids and neuromuscular blocking agents increase the incidence dramatically. This combination, which is common in the

asthmatic patient who requires mechanical ventilation, places that population at significant risk for polyneuropathy.

Improper ventilator settings may also interfere with weaning. Proper setting of sensitivity and matching of ventilator flow output to patient demand is necessary to eliminate patient/ventilator asynchrony. Asynchrony, leading to tachypnea in the patient with COPD can result in worsening hyperinflation, increased triggering effort, and impede weaning.

Nutritional state may also affect weaning readiness. Malnourished patients may have reduced respiratory muscle strength, blunted responses to hypoxemia and hypercarbia, and electrolyte abnormalities. Adequate nutrition should be provided early with an emphasis on isocaloric feeding. Overfeeding with carbohydrate calories has been implicated in weaning failure and generally includes not only excessive carbohydrate calories, but a total caloric intake in excess of patient requirements.

AIRWAY MANAGEMENT

Establishing a patent airway via intubation or surgical access is an essential skill of the surgical intensive care team. Airway management facilitates mechanical ventilation, allows for improved removal of secretions and can aid in the discontinuation of ventilation. Airway management should be undertaken under the supervision of the most skilled person available and the method of access dictated by patient condition. General indications for intubation including hypoxemia, hypercarbia, altered mental status, and respiratory muscle weakness are not always clinically practical. Generally speaking, the astute clinician can determine who needs to be intubated by clinical observation.

Endotracheal intubation with the largest internal diameter (ID) tube (7.0 to 7.5 mm for women and 8.0 to 8.5 for men) is the preferred method of airway control. Larger tubes allow bronchoscopy, facilitate secretion removal, and reduce the work of breathing. Nasotracheal intubation should be avoided unless there is a contraindication to endotracheal intubation. This is due to frequent traumatic insertion through the turbinates, increased incidence of sinusitis, need for a smaller ID tube, tortuous path that effectively reduces in vivo resistance, and patient discomfort. Nasotracheal intubation is often performed in the field, and conversion to an endotracheal tube is advocated in those patients thought to require prolonged mechanical ventilation. Elective endotracheal intubation should be accomplished in a controlled environment with adequate patient

sedation and paralysis if necessary, and rapid sequence intubation can be used if appropriately trained personnel are immediately available. Following tube placement appropriate position should be verified by the presence of carbon dioxide in expired gas. This can be accomplished by capnography or by CO_2 detector, a device that changes color in the presence of CO_2. Auscultation of bilateral breath sounds can be helpful, but misleading. Verification by CXR should eventually be performed.

Tracheostomy has been traditionally advocated for those patients who fail weaning over the first 2 weeks of illness. Rodriguez has shown that early tracheostomy reduced the risk of pneumonia, allowed earlier weaning, and was associated with fewer days in the ICU. Tracheostomy was initially performed at the bedside when first described, but because of occasional disastrous cases of lost airway and significant bleeding, was then advocated to be performed in the operating room. This is still the safest place in a patient who is stable enough for transport. However, bedside percutaneous tracheostomy has become a safe and standard procedure. This procedure allows for earlier tracheostomy and in some cases facilitates discontinuation of mechanical ventilation. After removal from the ventilator, the cuffed tracheostomy can be downsized over a few weeks followed by decannulation.

MANAGEMENT STRATEGIES FOR RETAINED HEMOTHORAX AND EMPYEMA

Hemothorax is frequent occurrence following blunt and penetrating trauma. The standard management of a hemothorax is drainage via a closed tube thoracostomy. Most patients are managed successfully with this strategy. In a small percentage (5% to 10%) of patients, the chest tube fails to completely evacuate the entire hemothorax. A retained collection can then lead to a fibrotic collection with entrapped lung and/or an empyema. Treatment options include placement of additional chest tubes, enzymatic debridement, video-assisted thoracoscopy (VATS), or thoracotomy with decortication. CXRs are of limited utility in the diagnosis of retained hemothorax. Pulmonary contusion, atelectasis with lobar collapse, or infiltrates can appear as persistent opacities on CXR making the diagnosis of retained hemothorax difficult with this study alone. Computed tomography (CT) of the chest is the preferred method for confirming the diagnosis. CT has been shown to be very accurate in the prediction of the amount of retained fluid and assisting with operative

decision making.

There remains some controversy in the choice of management following failure of initial chest tube drainage for hemothorax. Placement of a second CT is a reasonable option if positioning of the primary CT was not deemed adequate. Typically a second CT has the highest rate of success when placed early (<72 hours) following injury. A few small series have demonstrated a benefit to enzymatic treatment with urokinase or streptokinase. Both enzymes work by clot lysis and required serial treatments. This type of treatment strategy offers the advantage of continued nonoperative management in patients in whom operative intervention represents a high risk. The theoretic concern of increased bleeding has been suggested as a relative contraindication. The preferred method of treatment for retained hemothorax by the authors is VATS, as it has been found to be a safe and effective alternative to open thoracotomy for the management of retained hemothorax. The highest rate of success was obtained in patients who underwent VATS within 3 to 5 days post injury. VATS has also been useful in the treatment of persistent posttraumatic pneumothorax by mechanical pleurodesis. The rate of conversion to an open procedure increases daily for each day beyond 5 days postinjury. Once a fibrotic peel has been established or evidence of empyema is seen on CT, most patients will require open thoracotomy for decortication of the entrapped lung segment. Patients who have required mechanical ventilation in these scenarios will often wean quickly after re-expansion of the involved lung. Microorganisms cultured from empyemas are often *S. aureus* and differ from concomitant intrabronchial cultures, implying that these collections are seeded from skin through the chest tube itself. Chest tubes should therefore be placed with a sterile technique whenever possible.

EDITOR'S COMMENT

You may wonder why a colorectal surgeon is writing a commentary on a chapter on ventilatory risk assessment! Please realize; however, that I have for more than 25 years lived in a state that has the nation's highest rate of lung cancer and, depending on the year, ranks either first or second in the United States for having the highest number of adult cigarette smokers. For me, this is even more challenging since one of the main conditions that I see is Crohn disease, a disease whose severity is substantially worsened by cigarette smoking. A significant part of my time is spent in efforts aimed at behavioral modification, that is, trying to get patients to stop smoking one at a time. Due to the widespread extent of COPD, in my day-to-day clinical practice, much time is spent in preoperative risk assessment.

Several years ago, when we were trying to gauge the effect of cigarette smoking on the course of Crohn disease, we used the Behavioral Risk Factor Surveillance Survey (Remington PL, Smith MY, Williamson DF, et al. Design, characteristics, and usefulness of state-based behavioral risk factor surveillance: 1981–1987. *Public Health Rep* 1988;103:366–75) and modified it slightly to obtain data regarding pediatric smoke exposure. The data we obtained were astounding! Comparison of smoking data for Crohn patients with controls showed that greater number of Crohn patients were regular smokers by age 10 (OR, 3.65 [95% CI, 1.44–11.2]; $P = 0.005$) and by age 15 (OR, 3.06 [95% CI, 1.79–5.38]; $P < 0.001$) (Mahid SS, Minor KS, Stromberg A, et al. Active and passive smoking in childhood is related to the development of inflammatory bowel disease. *Inflamm Bowel Dis* 2007;13(4):431–8). It is therefore, not surprising that I have many patients who are two-to-three pack per day smokers and have been doing so for over 50 years!

Johannigman and Branson provide excellent information in this chapter, for example, the fact that postoperative respiratory failure increases mortality from 1% to 27% based on study of the VA database. In addition, postoperative respiratory failure results in a nearly sevenfold increase in the length of stay. This highlights the need for preventative action, based on an accurate preoperative assessment.

It may be that the increasing focus on enhanced recovery pathways may lead to a decrease in the frequency of pulmonary complications, not only because of the early patient mobilization but because of the decreased tendency for fluid

overload due to goal-directed intravenous fluid administration, and early postoperative discontinuation of intravenous fluids. Today, it seems that there is a constant lack of adequate nurse staffing, or that they are there, but busy entering data into the burdensome electronic health record. What that means practically is that there is no one to help the patient ambulate. Minimally invasive surgery does not always correlate with minimal pain. The significant torqueing of the abdominal wall that is associated in particular with robotic surgery can lead to significant abdominal wall pain. In these patients adequate pain control is as important as for patients with open procedures. Without adequate pain control following abdominal procedures, no matter the route of access; respiratory complications are likely to follow.

It seems that an increasing number of patients are diagnosed with sleep apnea; however, this may be due to the large amount of very significantly overweight (≥40 BMI) patients that we all encounter. Johannigman's description of preoperative smoke cessation and assessment of pulmonary hypertension is invaluable, accentuating the whole idea of pulmonary risk assessment. In the emergent setting, one has to play the cards one is given. However, in the elective setting, the entire idea of "pre-habilitation" is becoming more and more popular. The idea that if one has an operation that is not required immediately, one can precondition or improve, so to speak, the patient's physical condition, and specifically, in the context which we are discussing, improve their pulmonary condition. This was the case, for example, recently with a patient who was a 56-year-old, very thin white male who had two synchronous colon cancers who required a subtotal colectomy. He had a 60 pack-year history of smoking and at first assessment was unable to climb a flight of stairs. In fact, he was only able to step up three steps before he had to stop to catch his breath. Through the use of varenicline (Chantix®) preoperatively and through the intervention of a very loving wife who helped him with a preoperative exercise program, we were able to improve his condition preoperatively to such an extent that, with the aid of perioperative epidural analgesia, he was able to undergo an operation without any adverse pulmonary sequelae. While this is, of course, not the typical scenario, it illustrates that much can be gained from preoperative patient preparation with optimization of pulmonary function. In addition to pulmonary problems, smokers also have an increased incidence of all kinds of postoperative complications. The incidence of these will also hopefully be reduced following such intervention. Tønnesen et al. undertook an exploratory prospective trial to establish a preoperative smoking and alcohol cessation clinic for patient referral by general practitioners at the time of referral for surgery (Tønnesen H, Faurschou P, Ralov H, et al. Risk reduction before surgery. The role of the primary care provider in preoperative smoking and alcohol cessation. *BMC Health Serv Res* 2010;10:121). This showed that only 10% of patients were referred during the course of the study. Sadly, it is likely that such initiatives will have to be surgeon-led, as we have more at stake.

Recently there have been interesting efforts aimed at rehabilitation of frail patients, in other words those with decreased physiologic reserve using wearable fitness tracking devices (Rumer KK, Saraswathula A, Melcher ML. Prehabilitation in our most frail surgical patients: are wearable fitness devices the next frontier? *Curr Opin Organ Transplant* 2016;21(2):188–93). Such devices monitor and record the user's physical activity and can collect a variety of data points from steps taken to heart rate, sleep duration, and others. They include many different types of devices (Fitbit, Jawbone Up, Apple watch among others). These have been used on professional athletes, even on racehorses, why not on our patients to improve our postoperative outcomes with physician tracking? If you examine patient variables that affect postoperative outcome that can be changed in the preoperative period, these include nutritional status, optimal hemoglobin level, physical inactivity, excessive alcohol use, smoking, and anxiety (Levett DZ, Edwards M, Grocott M, et al. Preparing the patient for surgery to improve outcomes. *Best Pract Res Clin Anaesthesiol* 2016;30(2):145–57). Readers should see the excellent review "Preparing the patient for surgery to improve outcomes" (Levett DZ, Edwards M, Grocott M, et al. Preparing the patient for surgery to improve outcomes. *Best Pract Res Clin Anaesthesiol* 2016;30(2):145–57).

In elderly patients and in those with congestive heart failure, great care must be paid to avoiding fluid overload, as the same factors that prolong postoperative ileus, that is, increased fluids at the time of surgery, also adversely pulmonary function. In fact, these both work synergistically to worsen pulmonary function, for example, with the ileus; there is increased abdominal distension, increased upward pressure on the diaphragms, and decreased room for normal downward pulmonary excursion. As mentioned previously, it may be that with the increased use of early enhanced recovery after surgery pathways, which focus on goal-directed fluid administration intraoperatively, early resumption of diet, early discontinuation of postoperative intravenous fluids, avoidance of postoperative narcotics, early postoperative mobilization, and minimization of postoperative ileus, we may actually be doing much to improve postoperative ventilatory function.

The increased use of minimally invasive techniques should be associated with decreased ventilatory events. Even though there has been an increase in minimally invasive procedures, in our population we have seen a parallel increase in opioid medication for other uses. This means that, although we are inflicting less pain on our patients, that pain is more difficult to control, that is, requiring a greater amount of medication. This in itself is associated with respiratory depression. The large amount of narcotic further contributes to ileus, which promotes abdominal distention, difficulty breathing, and respiratory compromise. Hopefully, in the future, more effective prokinetic drugs, without many of the adverse cardiac effects of prior effective drugs, will allow rapid resumption of gastrointestinal function without any of the adverse cardiac effects and help diminish postoperative ileus and related subsequent undesirable

postoperative pulmonary complications.

6 Hemorrhagic Risk and Blood Components

Karen J. Brasel

INTRODUCTION

Surgeons are trained to control hemorrhage. However, the vast majority of that training relates to control of bleeding from visible vessels. There is less training on the management of so-called medical bleeding or bleeding due to inherited or acquired coagulopathy. The increasing use of oral anticoagulants and antiplatelet agents, along with the increasing medical complexity of surgical patients, demands that surgeons become knowledgeable about evaluation of bleeding risk prior to elective intervention along with evaluation and management of patients with massive hemorrhage. Familiarity with newer screening tools can help identify when additional help from consultants may be necessary. However, in the vast majority of these patients the management of identified abnormalities and the guidelines for blood product administration are relatively straightforward.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is the systemic activation of blood coagulation, leading to generation and deposition of fibrin and systemic microvascular thrombi. Depending on the degree and location of these clots, end-organ dysfunction may occur. If unchecked, it may proceed to consumption and subsequent exhaustion of coagulation proteins and platelets, resulting in accelerated fibrinolysis and severe bleeding. DIC is due to an underlying condition, such as trauma, sepsis, or amniotic fluid embolus, and can only be effectively treated by treating the underlying condition. Supportive care may involve blood product administration or anticoagulation to treat resultant thrombosis or coagulopathy.

Patients with DIC have variable laboratory parameters. Prothrombin time (PT) and partial thromboplastin time (PTT) may be normal or elevated, reflecting the depletion of clotting factors. Platelet count may be

normal, although the majority of patients with DIC have some degree of thrombocytopenia that can reach levels <50,000 μL. A steadily decreasing platelet count or a grossly reduced absolute platelet count is a sensitive but not specific indicator of DIC. Due to the microvascular thrombosis, platelet transfusion based on platelet count is not recommended. Fibrinogen levels are variable; although consumed through massive fibrin deposition, the increased production as an acute phase reactant results in this variability. Hypofibrinogenemia is seen in only 25% of cases, and only in those that are most severe.

The hallmark of DIC is fibrinolysis, so regardless of other laboratory parameters, there will be evidence of breakdown products of fibrinogen. Testing for D-dimer or fibrinogen degradation products (FDPs) may therefore be helpful for differentiating DIC from other conditions that are associated with a low platelet count and prolonged clotting times (CTs), such as chronic liver disease. The specificity of high levels of D-dimer and FDPs in isolation is limited; however, as many other conditions (thromboembolism, recent surgery, chronic inflammation) may be associated with elevated FDP levels.

ACUTE TRAUMATIC COAGULOPATHY

Acute traumatic coagulopathy (ATC) is present in approximately 25% of severely injured patients admitted to trauma centers, and is associated with a significantly higher mortality than similarly injured patients without ATC. It is an impairment of hemostasis with fibrinolytic activation that is independent of hypothermia, acidosis, and hemodilution. It is mediated by elevated levels of activated protein C, causing activation of the thrombomodulin-protein C system and irreversibly inactivating factor Va and VIIa. Generation of thrombin is inhibited, clot formation impaired, and fibrinolysis is enhanced. It is only seen in the setting of tissue damage and systemic hypoperfusion, and therefore early balanced resuscitation is the best treatment strategy, without waiting for results of coagulation parameters to use in a targeted resuscitation strategy.

DILUTIONAL COAGULOPATHY

Dilutional coagulopathy occurs in the setting of massive transfusion that is devoid of clotting factors, such as aggressive transfusion of crystalloid and/or packed red blood cells (pRBCs). This results in factor V and VIII deficiency, with both quantitative and qualitative platelet defects. It is

treated with administration of platelets and fresh frozen plasma (FFP), although a much better strategy is to use balanced resuscitation from the start in patients requiring massive transfusion, thus preventing dilutional coagulopathy.

INHERITED COAGULOPATHIES

Von Willebrand Disease

Von Willebrand disease (vWD) is a hereditary deficiency of von Willebrand factor (vWF). These patients have mild bleeding tendencies, which can become significant in the setting of major surgery or trauma. They may therefore be unknown by the patient, particularly if previous bleeding episodes have been negligible. Platelet count is normal, but the platelets do not function normally. PTT may be slightly elevated. The diagnosis is made by establishing low levels of vWF antigen and abnormal ristocetin cofactor activity. Treatment involves control of bleeding with replacement therapy (virally inactivated, intermediate-purity factor VIII concentrate) or desmopressin.

Hemophilia A and B

Hemophilias are hereditary bleeding disorders caused by deficiencies of either factor VIII (hemophilia A) or IX (hemophilia B). The severity of bleeding is determined by the amount of normal circulating factor. Most patients with hemophilia have levels <5%; some have extremely low levels (<1%). Similar to vWD, the diagnosis is suspected in a patient with an elevated PTT and normal PT and platelet count; it is confirmed by specific factor assays. Treatment includes replacement of the deficient factor. Normal hemostasis requires >30% of normal factor levels. Carriers usually have levels of about 50% and therefore do not require replacement prior to elective surgery.

COAGULOPATHY OF LIVER DISEASE

Patients with liver disease often have a prolonged PT. Previously thought to reflect a bleeding tendency, it is now clear that both a bleeding and a clotting tendency exist. The hypercoagulability is due to increases in factors produced in the endothelium of the blood vessels, such as factor VIII and vWF.

Bleeding events are more common than clotting events among

hospitalized patients with cirrhosis. The risk of postprocedure bleeding is about 20%. Assessment of bleeding risk in these patients is complex, as neither bleeding nor thrombosis risk is adequately assessed by standard laboratory evaluation. The PT test and international normalized ratio (INR) only measure the procoagulant pathway and do not detect the defects in the anticoagulant pathway, and targeting the INR or the PT alone leads to unnecessary volume expansion and overuse of plasma. Use of thromboelastography (TEG) can be valuable in determining whether the bleeding or clotting tendency predominates, and which factors may be necessary to correct it.

A platelet count >50,000 μL is associated with improved thrombin production. Adequate fibrinogen is also important in minimizing bleeding risk, as fibrinogen is the main target of thrombin and a final step in clot formation. If a patient is producing enough thrombin and has enough fibrinogen, then he or she should be able to form an adequate clot.

DRUG-INDUCED COAGULOPATHY AND REVERSAL

Current drugs in widespread use that commonly affect coagulation status and bleeding risk include warfarin, low–molecular-weight heparins, direct thrombin inhibitors, factor Xa inhibitors, aspirin, and clopidogrel. When intervention is required on patients taking anticoagulants or antiplatelet agents, interruption and/or reversal of their anticoagulation increases their thromboembolic risk. The decision on whether and how aggressively to correct their anticoagulants is an exercise in risk–benefit analysis.

Warfarin

Warfarin blocks vitamin-K–dependent protein synthesis (factors II, VII, IX, and X). Determination of resolution of warfarin effect is measured by the PT/INR. Timing of discontinuation of warfarin prior to elective surgery is dependent on the degree of INR elevation, patient age, and renal function. After warfarin is restarted postintervention, it takes approximately 5 to 10 days to achieve full anticoagulant effect (INR >2.0).

For those patients at excessive risk of thromboembolism, bridging therapy with heparin or low–molecular-weight heparin may be necessary. History of a prior thromboembolic event with discontinuation of warfarin therapy, systemic embolism or thromboembolic event within the previous 3 months, atrial fibrillation with a CHADS2 score of 5 or 6, mechanical mitral valve, or a mechanical aortic valve with an additional

thromboembolic risk factor are all situations in which periprocedural bridging is recommended.

Unfractionated and Low–Molecular-Weight Heparins

Management of bleeding in patients receiving heparin or low–molecular-weight heparin is based on the severity of bleeding, heparin level or aPTT (heparin) or anti-factor Xa activity, and the time since last dose. The half-life of intravenous heparin is 30 to 60 minutes, and so discontinuation results in normalization of coagulation status without intervention in a few hours. If reversal is needed more quickly, full neutralization can be achieved with the administration of protamine sulfate, 1 mg/100 units of heparin.

Protamine sulfate does not completely reverse low–molecular-weight heparins, but may help neutralize the higher–molecular-weight fractions that are thought to be more responsible for bleeding. For enoxaparin administered within the previous 8 hours, a dose of 1 mg protamine per 1 mg of enoxaparin is recommended. For enoxaparin administered >8 hours ago, 0.5 mg of protamine per 1 mg of enoxaparin is recommended. For dalteparin or tinzaparin, 1 mg of protamine per 100 anti-factor Xa units is recommended.

Direct Thrombin Inhibitor

The oral direct thrombin inhibitor dabigatran is now widely available as an alternative to warfarin for many patients. Although it must be taken twice daily, it does not require monitoring. Activated charcoal and hemodialysis have been used with some effect for dabigatran reversal, but it now has a specific reversal agent (idarucizumab) that is the recommended therapy. Idarucizumab consists of humanized dabigatran-specific antibody fragments and has no activity against oral factor Xa inhibitors or warfarin.

Factor Xa Inhibitors

Rivaroxaban, edoxaban, and apixaban are the currently available oral factor Xa inhibitors. Like dabigatran, they are approved for treating thromboembolic complications and the prevention of thromboembolism in patients with nonvalvular atrial fibrillation. Unlike dabigatran, there is no specific reversal agent for any of the oral factor Xa inhibitors, although trials of both specific and nonspecific agents are underway.

Antiplatelet Agents

Establishing that a patient has been taking an antiplatelet agent does not necessarily mean that these drugs are currently affecting platelet function. Resistance to both aspirin and clopidogrel has been described, although clopidogrel resistance is much more common. Resistance to an antiplatelet drug is a pharmacodynamic phenomenon where there is no clinically important change in platelet function after treatment as compared to the baseline. Aspirin resistance is defined as the inability of aspirin to inhibit platelet thromboxane A2 production or to inhibit tests of platelet function that are dependent on platelet thromboxane production. Using this method, aspirin resistance has been generally defined as ≥20% platelet aggregation when using 0.5 to 1.6 mg/mL arachidonic acid as the agonist.

Clopidogrel response variability was initially demonstrated by measuring adenosine diphosphate (ADP)-induced platelet aggregation, as well as p-selectin and activated GPIIb/IIIa expression. When the absolute difference between pre- and posttreatment platelet aggregation is ≤10%, patients are regarded as "resistant." The prevalence of resistant patients is time dependent; in one study it was 31% at day 5 and it fell to 15% at day 30.

The majority of guidelines suggest that patients should discontinue clopidogrel 5 to 10 days prior to elective operation and continue aspirin through the operation if at all possible. The outlier is the 2012 update to the Society of Thoracic Surgeons guideline on use of antiplatelet drugs in patients having noncardiac operations. These guidelines suggest that preoperative point-of-care testing to assess bleeding risk may be useful in identifying patients with high residual platelet reactivity after usual doses of antiplatelet drugs, and who can undergo operation without elevated bleeding risk.

EVALUATION OF BLEEDING RISK

In patients undergoing elective operations or other invasive procedures, evaluation of bleeding risk begins with a careful history and physical. Standard laboratory evaluation that includes platelet count, PTT, and INR is the appropriate next step if areas of concern are identified during the history and physical. The vast majority of inherited coagulopathies will be uncovered with this approach and can be addressed in collaboration with a hematologist. Thrombocytopenia can be associated with both bleeding and thrombotic risk, with thrombosis primarily seen in the setting of heparin-

induced thrombocytopenia (HIT) and DIC.

In patients undergoing massive transfusion, those taking medication affecting the coagulation system, and those with liver disease or other acquired coagulopathies, standard laboratory evaluation is often not adequate. In addition to measurement of fibrinogen, D-dimer, and FDPs, specific investigations may be appropriate.

Platelet Function

Several studies can be used to determine the degree to which both aspirin and clopidogrel affect platelet function. They should be used to determine whether administration of platelets or potentially DDAVP is warranted in the setting of normal platelet number. Most often, this is in the setting of patients known or suspected of taking antiplatelet agents, although it also may be indicated in patients with unexplained bleeding and otherwise normal coagulation parameters.

1. Aggregometry measures the degree to which ADP induces aggregation using platelet-rich plasma. It is not available as a point-of-care testing.
2. Flow cytometry is used to determine P2Y12 receptor reactivity.
3. VerifyNow is a point-of-care P2Y12 assay.
4. TEG with platelet mapping assay and the platelet function assay-100 are near point-of-care assays. Platelet mapping assays report percent inhibition and net platelet function; this is available as a point-of-care testing.

TEG and ROTEM

TEG was first described in 1948. Rotational thromboelastometry (ROTEM) is newer, but provides the same information. Unlike static tests, both provide dynamic information about in vivo clot development, stabilization, and dissolution. For both TEG and ROTEM, whole blood is used to measure global hemostasis reflecting both platelet function and coagulation. Initially, ROTEM was developed as a point-of-care testing with results available more quickly, although that advantage has disappeared with the advent of rapid TEG. ROTEM avoids some of the traditional limitations to TEG technology, including susceptibility to vibrations and mechanical shocks. They are available as a point-of-care testing, in the case of TEG both as standard and rapid TEG. It is common to use an activator for both standardization and to minimize the time required to obtain results.

TEG has been used to measure coagulation parameters and bleeding risk in liver transplantation, cardiac surgery, obstetrics, and trauma. Values obtained from TEG analysis include *r* time, *k* time, alpha angle, and mA. The *r* time is the time until first evidence of clot formation. *k* value is the speed of clot formation. The alpha angle also represents speed of clot formation. mA is maximum amplitude, a reflection of clot strength. Corresponding values from ROTEM include CT, EXTEM, INTEM, MCF (maximum clot firmness), and FIBTEM. The CT is the latency time from adding the start reagent to blood until the clot starts to form. INTEM tests the contact phase of hemostasis. EXTEM is a screening test for the extrinsic hemostasis system. FIBTEM eliminates the platelet contribution of clot formation by irreversibly inhibiting platelets. MCF reflects the absolute strength of the fibrin and platelet clot. ML, or maximum lysis, is the reduction in clot firmness after MCF. Increased ML is indicative of fibrinolysis, as is the finding of better clot formation with APTEM compared to EXTEM. APTEM is a method in which a fibrinolysis inhibitor is used together with an activator. In addition to numeric interpretation of the values, both TEG and ROTEM can be interpreted qualitatively by appearance (Fig. 6.1).

PACKED RED BLOOD CELLS

Most RBC products are derived by collection of 450 to 500 (±10%) mL of whole blood from volunteer donors and removal of the plasma by centrifugation. After removal of the plasma, the resulting product is red blood cells (pRBCs). The most commonly available RBC product in the United States has a 42-day blood bank shelf life and a hematocrit of 55% to 65%.

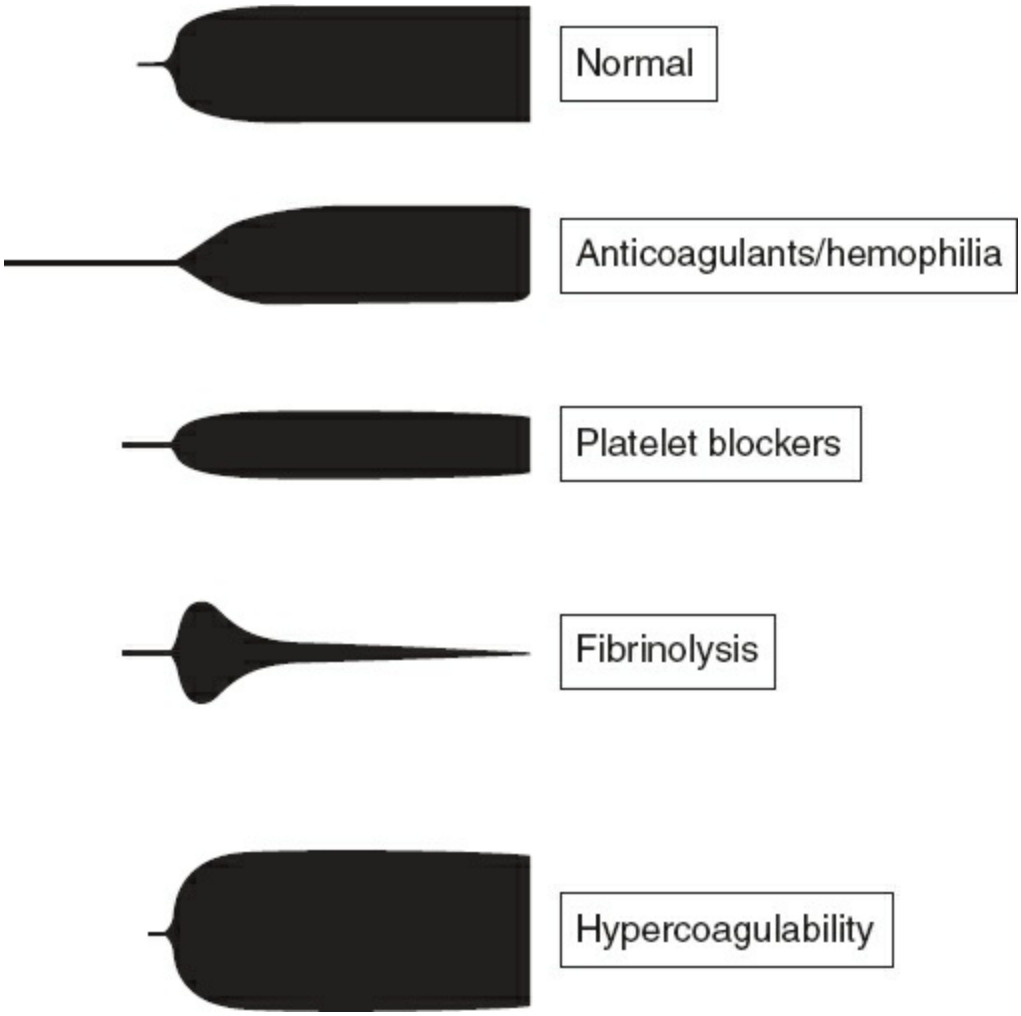

Figure 6.1. Representative thromboelastograms.

Leukoreduction, which is performed in approximately 85% of blood transfused in the United States, leaves residual leukocyte counts below 5×10^6, and generally below 1×10^6. This decreases the risk of recurrent febrile nonhemolytic transfusion reactions, decreases the risk of cytomegalovirus (CMV) transmission and decreases the risk of human leukocyte antigen (HLA) alloimmunization. Current risk of these complications is noted in Table 6.1. It also may decrease the risk of all late immunologically mediated complications.

Red cell transfusion is indicated in the treatment of symptomatic anemia, in patients with ongoing blood loss including massive hemorrhage, for exchange transfusion in patients with sickle cell disease and severe parasitic infection, patients with severe methemoglobinemia, and newborns with severe hyperbilirubinemia.

In general, guidelines recommend that transfusion is not indicated for a hemoglobin >10 g/dL, but the lower threshold varies from 6 to 8 g/dL. A

recent Cochrane review identified 19 randomized clinical trials comparing higher versus lower transfusion thresholds in a total of 6,264 medical and surgical patients (adults and children). Trials were included if transfusion was administered on the basis of a transfusion trigger, defined as a hemoglobin or hematocrit level below which a blood transfusion was to be given. Most trials compared outcomes in patients transfused at hemoglobin thresholds between 7 and 10 g/dL; specific thresholds differed for each trial. This review included the Transfusion Requirements in Critical Care (TRICC) trial of adult intensive care unit (ICU) patients. Compared with liberal transfusion strategies (higher thresholds), restrictive strategies (lower thresholds) resulted in fewer units of pRBCs transfused, no difference in the risk of myocardial infarction, and no difference in functional recovery, hospital or ICU stay.

A second meta-analysis that included eight trials, with 6,033 hospitalized patients, demonstrated a lower risk with restrictive versus liberal transfusion strategy (RR 0.84; 95% CI 0.73–0.96). Also, in a subset analysis of seven trials in which all RBC units were leukoreduced, infections were less frequent with a restrictive than with a liberal transfusion strategy (RR 0.83; 95% CI 0.69–0.99).

FRESH FROZEN PLASMA

FFP is the fluid portion of one unit of human blood that has been centrifuged, separated, and frozen solid at ≤–18.5°C within 6 to 8 hours of collection. It contains the labile and stable components of the coagulation, fibrinolytic, and complement systems, as well as other plasma proteins, fats, carbohydrates, and minerals. Once thawed, if not used it can be stored and used for up to 5 days. The factor with the greatest decrease in activity during extended thawed storage is factor VII, with 60% to 70% of activity remaining at day 5. There is a 20% to 30% decrease in levels of factor V, with <10% loss of remaining factors and little change in levels of fibrinogen, antithrombin, and protein C. Levels of protein S are much more variable.

Practice surrounding the transfusion of FFP is extremely variable. There is fairly good agreement on transfusion as apheretic treatment of thrombotic microangiopathies (thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, hemolytic anemia elevated liver enzymes, and low platelet count [HELLP] syndrome (grade of recommendation: 1A). The recommendation for use to reconstitute whole blood for

exchange transfusion is not as strong (grade of recommendation: 2C).

TABLE 6.1 TEG and ROTEM Values and Corresponding Suggested Treatment in the Bleeding Patient

	ROTEM			
TEG (standard and rapid)	CT EXTEM >100 s and/or CT INTEM >230 s	MCT FIBTEM <8 mm	MCF EXTEM <45 mm and MCF FIBTEM >10 mm	ML EXTEM >15%, better clot formation APTEM than EXTEM
r >9 min (standard) or Activated clotting time >128 s (rapid)	PLASMA			
k time >4 min (standard) or >2.5 min (rapid)		PLASMA and/or CRYO		
Alpha angle <60 degrees		CRYO		
mA <55 mm			PLATELETS	
LY30 >7.5% (standard) or LY30 >3% (rapid)				Antifibrinolytics

There is now fairly good agreement around the use of FFP in the setting of massive hemorrhage, where in the traumatic setting ratio-based resuscitation improves outcome. Currently accepted ratios are 1:1:1 to 1:1:2, or 1 to 2 units of FFP for every unit of pRBCs administered. As a component of massive transfusion protocols in busy clinical centers, thawed plasma is both useful and necessary for early resuscitation to achieve these ratios. The volume of massive transfusions required to allow storage of thawed plasma to be cost-effective is unknown.

Perhaps the most common reason for administration of FFP is vitamin K antagonist reversal. Although appropriate for those who have clinical bleeding in the setting of warfarin-induced coagulopathy, administration of an elevated INR in the absence of clinical bleeding is not recommended. This may be true even in the setting of proposed invasive procedures, as there is no correlation between bleeding risk and a mildly elevated INR (<2.0). In fact, many patients with a mildly elevated INR actually have a greater risk of thrombosis, such as those with liver disease. This suggests that additional measures to evaluate bleeding risk are necessary in these patients. FFP has optimal value when transfused at the appropriate dose. The recommended adult therapeutic dose of FFP is 12 to 15 mL/kg, and should always be at least 10 mL/kg.

Lyophilized plasma was developed by the US Army for the resuscitation of combat casualties during World War II. It is compatible with all blood types, can be stored at room temperature for up to 2 years, and reconstitution takes <5 minutes. It was first produced for use in France in 1949, although production stopped in 1987 due to the elevated risk of

HIV. Production began again after product received updated approval in 1994 and subsequently began undergoing even more rigorous safety processing in 2010 using a photochemical pathogen inactivation process. It contains approximately 75% of factor V and 80% of factor VIII, with unchanged activity in fibrinogen, antithrombin, proteins C and S, and factors XI and XIII. PT and activated PTTs were slightly increased compared to FFP, but in vitro hemostatic properties of plasma were not different after lyophilization using TEG. This product has been shown effective in a swine model of polytrauma and hemorrhage and has been used by the French Military in Afghanistan. It is not currently approved for human use in the United States.

Liquid plasma is plasma that has been separated from whole blood at any time from collection to 5 days after the whole blood unit expires. It is stored between 1°C and 6°C and has never been frozen. Depending on when it has been separated from the donor unit of whole blood, it has a shelf life of 1 to 26 days. Clotting factors, particularly factors V and VIII, decline during storage, but the majority of both clotting factors and inhibitors retain up to 90% of initial activities at day 26. When compared to thawed standard FFP, the hemostatic profile is at least similar, and early during storage significantly improved. It is indicated for the initial treatment of patients undergoing massive transfusion.

PROTHROMBIN COMPLEX CONCENTRATE

Prothrombin complex concentrates (PCCs) are inactivated concentrates of pooled plasma. They contain the vitamin K–dependent factors II, IX, and X with variable amounts of factor VII and are standardized according to factor IX content. It is the variability in the amount of factor VII that results in the classification of PCC as 3- or 4-factor.

PCCs have been available for some time, but their use has recently become more widespread with the availability of a 4-factor PCC that is FDA approved for warfarin reversal in patients with clinical bleeding. They are lyophilized and can therefore be reconstituted quickly in a small volume and rapidly administered. This, and their increased potency compared to FFP (approximately 25 times greater factor concentration), gives them a significant advantage over FFP for quick reversal of warfarin-induced coagulopathy. The use of PCC is currently recommended in the most recent clinical practice guideline by the American College of Chest Physicians for urgent vitamin K antagonist reversal in patients with

active bleeding or urgent procedures, although the recommendation is not strong (grade 2C). This recommendation is based on rapidity of INR correction to <1.5, which can occur in as little as 10 minutes, and the potential benefits of less volume administration. Despite these potential benefits, there are no randomized trial data demonstrating improved patient outcomes when compared to FFP. PCC dosing is based on INR and weight, with a range of 25 to 50 units of factor IX/kg body weight. Maximum dose in patients with an INR >6 should not exceed 5,000 units/kg of factor IX.

PCC has been suggested as a nonspecific reversal agent for bleeding associated with oral coagulants other than warfarin, including direct thrombin and factor Xa inhibitors. The majority of evidence supporting this practice comes from animal studies, and the clinical results are variable. Although it may be appropriate with massive anticoagulant-related bleeding, the increasing availability of specific reversal agents for these newer oral anticoagulants will hopefully make this strategy obsolete in the future.

Thromboembolic complications are the most concerning adverse event with PCC administration. To help prevent these complications, PCCs contain small amounts of heparin as well as the thromboinhibitor proteins C and S. Another disadvantage of PCC compared to FFP is cost.

PLATELETS

Platelets are prepared as single unit pooled from multiple donors, or apheresis platelets prepared from a single donor. Six units of pooled platelets or one apheresis unit both provide approximately 5×10^{11} platelets.

Apheresis platelets have the advantages of limiting the recipient exposure to a single donor, which potentially reduces the possibility of infection and alloimmunization; some centers use apheresis platelets exclusively. The platelet count increment and hemostatic effects of pooled and apheresis platelets are comparable.

Transfusion of platelets can be divided into two broad areas: prophylactic, to prevent spontaneous hemorrhage, and therapeutic, to treat active bleeding. There is a significantly increased risk of spontaneous hemorrhage when the platelet count is <5,000/μL, and the risk of bleeding does not seem to change between 10,000 and 100,000/μL. Approximately 7,500 μL are required for platelet–endothelial interaction; these

observations together form the basis for the recommendation of prophylactic transfusion to prevent bleeding at a threshold level of 10,000/μL.

Prophylactic transfusion is also recommended for patients with a platelet count <50,000/μL undergoing major surgery or invasive procedures. For patients undergoing surgical interventions in critical sites, such as ocular surgery and neurosurgery, a transfusion threshold of 100,000 platelets/μL is suggested. A standard dose of platelets for prophylactic therapy in adults is approximately one random donor unit per 10 kg of body weight, which translates to four to six units of pooled platelets or one apheresis unit, both providing approximately 3 to 4×10^{11} platelets.

Therapeutic platelet transfusion is suggested for patients with active bleeding and a platelet count of <50,000/μL. As a part of massive transfusion in patients with active hemorrhage, one unit of platelets should be given for every unit of pRBCs. As most platelets are now packaged as a pool of six individual units, this functionally ends up as one pooled unit for every six units of pRBCs.

Following a platelet transfusion, the platelet count should rise, with a peak at 10 minutes to 1 hour and a gradual decline over 72 hours. A general rule of thumb is that transfusion of six units of pooled platelets or one apheresis unit should increase the platelet count by approximately 30,000/μL in an adult of average size.

One of the more controversial areas of platelet administration is their use in patients taking the antiplatelet agents aspirin and clopidogrel. Current recommendations suggest that administration of platelets is warranted in patients with hemorrhage who are on antiplatelet agents; however, administration of platelets may not result in any improvement in platelet function as measured by platelet function assays and may in fact be harmful.

A recent randomized trial compared platelet transfusions with standard care in 190 individuals with intracerebral hemorrhage (ICH) in the setting of aspiring or other antiplatelet agents (the PATCH [Platelet Transfusion in Cerebral Hemorrhage] trial). Compared with those assigned to standard care, individuals who received platelet transfusions had a higher rate of a composite end point of death or lower score on the modified Rankin Scale for functional independence. When analyzed separately, the increase in mortality did not reach statistical significance. Serious adverse events were

more frequent in the platelet transfusion arm, and ICH enlargement was similar in both arms at approximately 15%.

CRYOPRECIPITATE

Cryoprecipitate is the insoluble material that comes out of solution after plasma is frozen and thawed at 4°C. The resulting precipitate is then frozen and can be used for up to 1 year. Cryoprecipitate contains virtually all of the fibrinogen (factor I), factor VIII, fibronectin, factor XIII, and vWF from one unit of FFP. Cryoprecipitate cannot be used to reverse the anticoagulant effect of warfarin or other vitamin K antagonists, because it does not contain the vitamin K–dependent factors. It is also ineffective in reversing other anticoagulants.

Cryoprecipitate can be provided as single units or as “pools” containing five or more units. In the average patient, each unit raises the plasma fibrinogen concentration by approximately 7 to 10 mg/dL; thus, 10 units will raise the fibrinogen by approximately 70 to 100 mg/dL in a 70-kg recipient.

Cryoprecipitate remains an effective therapy for bleeding in patients with fibrinogen disorders, liver disease, DIC, or uremia after desmopressin and transfusions are found to be ineffective.

TRANEXAMIC ACID

Tranexamic acid, or aminocaproic acid, is a synthetic derivative of the amino acid lysine that exerts its antifibrinolytic effect through the reversible blockade of lysine-binding sites on plasminogen molecules. It inhibits plasminogen activation and plasmin activity stabilizing clot formation. Similar to other approaches, tranexamic acid can be used empirically or when increased fibrinolytic activity is found on point-of-care testing. The dose of tranexamic acid is 1 g intravenously over 10 minutes followed by an infusion of 1 g over 8 hours.

Empiric use has been studied in the trauma population, with the CRASH-2 trial suggesting benefit in patients with massive hemorrhage when tranexamic acid was administered within 3 hours of injury. Due to its time-sensitive nature, it is now carried by many prehospital systems. It is currently undergoing investigation in prehospital trials of patients with severe traumatic brain injury. The primary adverse effect of tranexamic acid is an increase in the rate of thromboembolic events.

RECOMBINANT FACTOR VIIa

Recombinant factor VIIa was developed for the treatment of hemophilia and continues to be used for this purpose. Its use in the setting of warfarin-induced and traumatic coagulopathy is less clear, as it may reduce the number of red cell transfusions required but has no impact on overall mortality.

DESMOPRESSIN

Desmopressin is a synthetic vasopressin analog that has been used for the treatment of mild hemophilia A, vWD, and uremia. Use of desmopressin rather than blood component therapy eliminates the immunologic and infectious risk of factor transfusion and is therefore preferable in mild disease. It is effective in improving the bleeding time or in vitro tests of platelet dysfunction and appears to act by increasing the release of large factor VIII: vWF multimers from endothelial cells. Other factors may include increases in platelet membrane glycoprotein expression. It is most effective in patients with quantitative deficiencies, as the result in those with qualitative deficiency of vWF is to release large amounts of defective protein. An increase of two to six times the concentration of FVIII:C is seen in most patients that return to baseline within 8 hours. Whether desmopressin actually reduces active bleeding or the risk of clinically important bleeding associated with invasive procedures in patients with uremic platelet dysfunction has not been conclusively demonstrated.

COMPLICATIONS OF TRANSFUSION

The most clinically important adverse effects of transfusion in medical patients are infectious or immunologic phenomena. The most significant infectious risks are addressed during the donor screening process, and most blood centers employ bacteriologic surveillance measures on certain blood products (Table 6.2).

Other complications include those from excessive volume administration (transfusion-associated circulatory overload [TACO]) and immunologically mediated complications sometimes referred to as transfusion-related immunomodulation (TRIM). When any of these are suspected, the transfusion should be stopped immediately and reported to the blood bank. Blood should be drawn from the patient and sent for tests including complete blood count, bilirubin, haptoglobin, direct antiglobulin

test, and HLA typing (Table 6.2). Further blood bank investigation in the case of transfusion-related acute lung injury (TRALI) involves efforts to identify donors and test for HLA and human neutrophil antigen (HNA) antibodies.

Transfusion-Associated Circulatory Overload

TACO is volume overload in the setting of underlying congestive heart failure that occurs within 6 hours of administration of blood products. It is related to the volume transfused, and is therefore uncommon after infusion of cryoprecipitate and much more common when multiple units of pRBCs and FFP are transfused. Brain natriuretic peptide (BNP) and N-terminal pro-BNP are elevated in TACO, although this is not required for diagnosis.

Transfusion-Related Acute Lung Injury

TRALI is the rapid onset of hypoxemia within minutes to 6 hours of transfusion of blood products. In addition to hypoxemia, noncardiogenic pulmonary edema is a hallmark manifestation, along with fever and hypotension. Bilateral pulmonary infiltrates on chest x-ray are required for the diagnosis. The pathogenesis involves a two-hit phenomenon, first requiring neutrophils that have been sequestered and primed in the lung microvasculature which are then activated by a factor in the blood product.

TABLE 6.2 Transfusion-Related Complications, Presentation, and Treatment

	Incidence	Presentation	Action
HIV	1:1,467,000		
Hepatitis B	1:282,000		
Bacterial infection	1:2–3,000		
Acute hemolytic reaction	1:76,000		Stop transfusion, notify blood bank
ABO incompatibility	1:40,000 fatal 1:8,000,000	Fever, chills, hypotension, back pain, renal failure	Stop transfusion, administer fluids; pressors as needed, notify blood bank
Delayed hemolytic reaction		Fever, jaundice, anemia, newly positive antibody screen	
Febrile nonhemolytic reaction	1:100–1,000	≥1°C (2°F) rise in temperature within 2 h of start of transfusion with no other explanation for fever. Acetaminophen premedication if reactions are recurrent	
Allergic (urticarial reaction)	1:33–100	Pruritus, flushing, mild wheezing	Pause transfusion, administer antihistamines; may resume transfusion if reaction resolves, but still report reaction to blood bank
Anaphylaxis/anaphylactoid	1:20,000–50,000	Hypotension, urticaria, bronchospasm, angioedema, anxiety	Epinephrine 1:1,000 0.2–0.5 mL SC, antihistamines, corticosteroids, notify blood bank
TACO	1:100	Hypoxemia, hypertension, tachycardia, pulmonary edema, positive fluid balance	Stop transfusion, diuresis, oxygen, assist ventilation as needed
TRALI	1:10,000	Hypoxemia, hypotension, bilateral pulmonary edema, transient leucopenia, and fever within 6 hours of transfusion	Supportive care, notify blood bank, defer implicated donors

More remote complications are also likely immunologically mediated. These include an increased risk of postoperative infection, an increased incidence of tumor recurrence and metastasis, and an increase in renal allograft survival. The data on these complications, and their relationship to the use of leukoreduced blood, are inconsistent and somewhat conflicting.

SUMMARY

The increasing number and widespread use of anticoagulants, along with the general increase in complexity of surgical patients, have increased the depth and breadth of knowledge that surgeons should know relative to the assessment of coagulation status and hemorrhagic risk in both the elective and emergent setting. Traditional tests of coagulation do not adequately reflect patients' clinical bleeding or thromboembolic risk. For example, patients with liver disease and an elevated INR and thrombocytopenia may in fact be hypercoagulable; patients with normal platelet count may actually be at increased bleeding risk due to a qualitative platelet defect. Using point-of-care testing, either TEG or ROTEM, allows assessment of global hemostasis along with an indication of which aspect of the coagulation system should be treated. This is particularly important as the risks and adverse events, including increased mortality, associated with administration of platelets, pRBCs, and plasma become known.

In addition, the approach to resuscitation in patients with active

bleeding, along with better understanding of the risks of transfusion, mandates that surgeons guide ongoing resuscitation as well as administration of blood products administered in a less urgent manner. In the setting of massive hemorrhage, whether in the operating room, as a result of traumatic injury, or gastrointestinal (GI) bleeding, prevention of coagulopathy is paramount. This is accomplished with use of minimal crystalloid and a ratio of pRBCs to platelets and plasma of 1:1:1 to 1:1:2.

EDITOR'S COMMENT

The management of surgical hemostasis has changed significantly over the last decade. The reasons for this are multiple, but represent a shift from the constant and very real threat of hemorrhagic shock associated with even minor trauma of the liver, spleen, or vasculature to the management of patients who are on novel and strong anticoagulants and antithrombotic agents who must undergo emergent/urgent operations. A clear understanding of the reversible nature of many of these drugs is required even in the elective setting, especially when patients call to ask "when am I supposed to stop drug X before my surgery?"

In this chapter by Dr. Brasel focused on hemorrhage, but also importantly addressing clotting and thrombosis, we are once again reminded of the complexity of these systems and thus the tenuous nature of hemostasis. Having just taken my general and vascular surgery boards for the third time, I can assure you that all of this material is tested. The section of this chapter on "drug-induced coagulopathy" is especially important as an increasing number of patients are being placed on direct thrombin inhibitors (Pinho-Gomes AC, Hague A, Ghosh J. Management of novel oral anticoagulants in emergency and trauma surgery. *Surgeon* 2016;14(4):234–9). Originally, there was no antidote for these drugs and I suspect multiple patients suffered from this. Presently, there is a specific reversal agent idarucizumab, which is a humanized antibody, that has no activity against factor Xa inhibitors or warfarin. Factor Xa inhibitors are also discussed in detail in this chapter, of which there are at least three. These drugs are used for atrial fibrillation and to prevent thromboembolic complications. Unfortunately, there are no direct reversal agents for these drugs, and thus time is required to allow them to wear off.

The use of strong antiplatelet agents, such as Plavix, has become common especially in the setting of coronary and peripheral stenting. It has been shown specifically following drug eluting coronary stents that patients need to stay on these drugs for a year at best to prevent stent thrombosis. I so remember performing a carotid endarterectomy with a patch as a chief resident in 1997 in a patient on a strong antiplatelet agent in which I had to stand there with my hand on the neck holding pressure for about an hour while the patient received platelet transfusions. There is a fair amount of literature now suggesting that performing vascular surgery on patients on Plavix is safe (Saadeh C, Sfeir J. Discontinuation of preoperative clopidogrel is unnecessary in peripheral arterial surgery. *J Vasc Surg* 2013;58(6):1586–92) and may decrease stroke rates following carotid endarterectomy (Jones DW, Goodney PP, Conrad MF, et al. Dual antiplatelet therapy reduces stroke but increases bleeding at the time of carotid endarterectomy. *J Vasc Surg* 2016;63(5):1262–70). Other literature suggests there are more neck hematoma's on Plavix (Moon K, Nanaszko M, Levitt MR, et al. Carotid endarterectomy on antiplatelet agents in the era of point-of-care testing. *World Neurosurg* 2016;93:215–20). I will go on record as

saying I still will not perform an elective open abdominal aortic aneurysm (AAA) repair on a patient who needs to remain on Plavix.

Finally, the blood components and drugs to stop bleeding are described. I want to emphasize that similar to what Dr. Brasel suggests, I believe a 1:1:1 red cells to platelets to plasma seems to work. The use of whole blood transfusions also may be making a comeback! (Auten JD, Lunceford NL, Horton JL, et al. The safety of early fresh, whole blood transfusion among severely battle injured at US Marine Corps forward surgical care facilities in Afghanistan. *J Trauma Acute Care Surg* 2015;79(5):790–6) Most hospital systems have Blood Alerts or Massive Transfusion Protocols, which have helped to speed the resuscitation process along. I think that we have learned a lot about transfusion medicine from the war theater (Haider AH, Piper LC, Zogg CK, et al. Military-to-civilian translation of battlefield innovations in operative trauma care. *Surgery* 2015;158(6):1686–95). The use of thromboelastograms (see Fig. 6.1 in chapter) has allowed us to tailor our approach to intraoperative bleeding, rather than just transfusing based on a clinical hunch (Camazine MN, Hemmila MR, Leonard JC, et al. Massive transfusion policies at trauma centers participating in the American College of Surgeons Trauma Quality Improvement Program. *J Trauma Acute Care Surg* 2015;78(6 Suppl 1):S48–53). My guess is that we will continue to make significant and advanced scientific strides in this area over the next decade.

Gilbert R Upchurch Jr.

7 Perioperative Antimicrobial Prophylaxis and Treatment of Surgical Infection

Kui-Hin Liau, Giorgio Tarchini, and J.S. Solomkin

INTRODUCTION

The discovery of antimicrobial agents in the mid-20th century has revolutionized the practice of surgery. Antimicrobial agents are central to the practice of surgery in two different settings: the prophylaxis of surgical site infection (SSI) and the management of established infections. This effective solution creates other problems following prolonged use of the antimicrobial agents. A dramatic increase in antimicrobial resistance, by enzymatic mechanisms including extended spectrum β-lactamases (ESBLs) and carbapenem-resistant *Enterobacteriaceae* (CREs), and other nonenzymatic mechanisms, has created new sets of clinical problems. Antimicrobial stewardship programs have gained prominence in most medical centers as part of the immediate and longer-term solutions to the control of multidrug resistant microorganisms.

PRINCIPLES OF PREVENTION OF SURGICAL SITE INFECTION

SSIs remain an important problem for both patients and the health care system. Among an estimated 27 million surgical procedures performed each year in the United States, SSIs occur at a rate of 2 per 100 procedures, or approximately 500,000 per year. These infections may lead to increased duration of hospitalization, costs, morbidity, and risk of death.

The impact of an SSI on both the patient and health care system varies by infection type. Superficial incisional SSIs often do not require hospitalization and are inconsistently diagnosed by postdischarge surveillance. Collectively, deep incisional and organ/space infections are considered “complex” SSIs. In most series, complex SSIs represent about one third to one half of SSIs, although this varies according to procedure.

Complex SSIs typically require rehospitalization, drainage or debridement, and systemic antimicrobial therapy. These infections generate considerable morbidity, cost, and even mortality. Unfortunately, many surveys examining incidence, cost, morbidity, or mortality do not make a distinction between complex and superficial SSIs.

Definition and Classification

The definition and criteria for the diagnosis of SSI were standardized by the Centers for Disease Control and Prevention (CDC) and the National Nosocomial Infections Surveillance System (NNIS). The infection must fall within the timeline of 30 days after the primary operation or up to 1 year if an implant is present. Upon diagnosis, SSIs are classified into superficial incisional SSI, deep incisional SSI when deeper tissue layers are involved, and organ/space SSI as shown in Figure 7.1. The criteria for the classification are spelt out in Table 7.1.

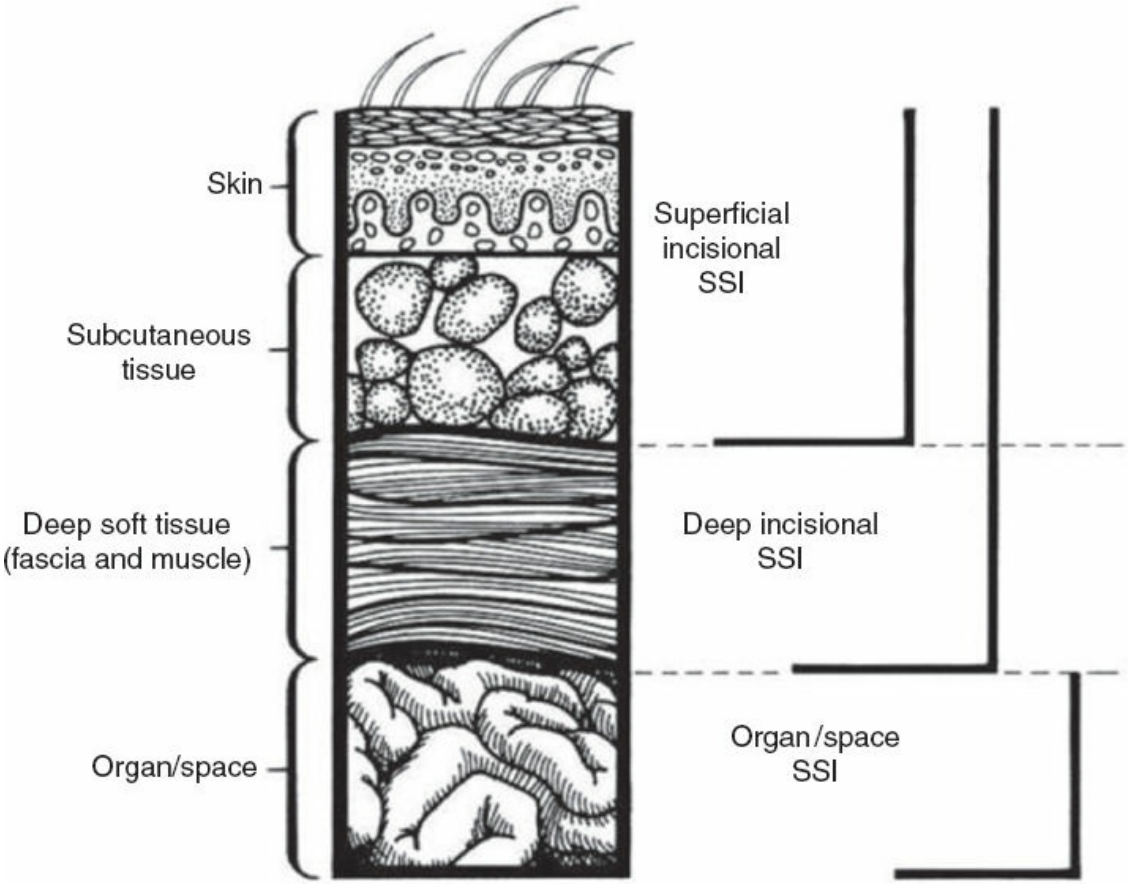

Figure 7.1. Infographic of the classification of surgical site infection.

TABLE 7.1 National Healthcare Safety Network Criteria for Defining a Surgical Site Infection

Superficial Incisional SSI

Occurs within 30 days postoperatively and involves skin or subcutaneous tissue of the incision and at least one of the following:

1. purulent drainage from the superficial incision,
2. organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision,
3. at least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat, and superficial incision is deliberately opened by surgeon and is culture-positive or not cultured (a culture-negative finding does not meet this criterion), and
4. diagnosis of superficial incisional SSI by the surgeon or attending physician.

Deep Incisional SSI

Occurs within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operative procedure, involves deep soft tissues (e.g., fascial and muscle layers) of the incision, and the patient has at least one of the following:

1. purulent drainage from the deep incision but not from the organ/space component of the surgical site,
2. a deep incision spontaneously dehisces or is deliberately opened by a surgeon and is culture-positive or not cultured and the patient has at least one of the following signs or symptoms: fever (>38°C) or localized pain or tenderness (a culture-negative finding does not meet this criterion),
3. an abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination, and
4. diagnosis of a deep incisional SSI by a surgeon or attending physician.

Organ/Space SSI

Involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure. Specific sites are assigned to organ/space SSI to further identify the location of the infection (e.g., endocarditis, endometritis, mediastinitis, vaginal cuff, and osteomyelitis).

Organ/space SSI must meet the following criteria:

1. infection occurs within 30 days after the operative procedure if no implant is in place or within 1 year if implant is in place and the infection appears to be related to the operative procedure,
2. infection involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure, and
3. the patient has at least one of the following:
   (a) purulent drainage from a drain that is placed through a stab wound into the organ/space,
   (b) organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space,
   (c) an abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination, and
   (d) diagnosis of an organ/space SSI by a surgeon or attending physician.

Data from Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection. *Infect Control Hosp Epidemiol* 1999;20:250–78; Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of health care-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–32.

TABLE 7.2 Established Risk Factors for Surgical Site Infections

Patient-Related Factors
Age
Obesity or malnutrition
Diabetes or hyperglycemia
Smoking
Colonization
Remote infection
Preoperative hospital stay

Procedure-Related Factors
Instrument cleaning, decontamination, and sterilization
Operating room ventilation
Preoperative shaving
Surgical skin preparation
Surgical scrub
Surgical technique
Surgical drains
Tourniquet time
Revision arthroplasty
Procedure duration

Risk Factors and Risk Scores

Risk factors for the development of SSI are typically divided into patient-related (preoperative), procedure-related (perioperative), and postoperative categories (Table 7.2). In general, patient-related risk factors for SSI can be categorized as either modifiable (e.g., poorly controlled diabetes mellitus, obesity, tobacco use, length of preoperative hospitalization, and colonization) or nonmodifiable (e.g., age). Procedure-related risk factors include, but are not limited to, wound class, organ site, and length of surgery. Postoperative risk factors can include wound care, postoperative blood transfusions, and hyperglycemia in both diabetic and nondiabetic patients.

TABLE 7.3 Wound Class by NNIS Class

Wound Class	All	NNIS 0	NNIS 1	NNIS 2	NNIS 3
Clean	2.1%	1.0%	2.3%	5.4%	N/A
Clean Contaminated	3.3%	2.1%	4.0%	9.5%	N/A
Contaminated	6.4%	N/A	3.4%	6.8%	13.2%
Dirty Infected	7.1%	N/A	3.1%	8.1%	12.8%
All	2.8%	1.5%	2.9%	6.8%	13.0%

National Nosocomial Infections Surveillance (NNIS) System report, data summary from January 1992–June 2001, issued August 2001. *Am J Infect Control* 2001;29:404–21.

In 1991, the CDC developed National Nosocomial Infections Surveillance System (NNIS) risk index. This is a composite index that predicts the risk of SSI after operation. It is defined by three independent and equally weighted variables, namely, American Society of Anesthesiology (ASA) score, information on risk factors for SSI such as wound class and duration of operation. NNIS SSI Risk Index is one of the common tools to predict SSI risk in a broad range of operations (Table 7.3). The clinical utilities of quantitative SSI risk scores are to predict the likelihood of SSI in a patient and guide decision on preventive strategies such as prophylactic antibiotics. In addition, it allows accurate and meaningful comparison of SSI rates between medical centers and health care providers.

Pathogenesis and Microbiology

The microorganisms causing SSIs are well known. Staphylococcal species are the predominant pathogens in all but gastrointestinal procedures (Table 7.4). In those procedures, particularly those involving the small and large intestines, *Escherichia coli, Pseudomonas aeruginosa, Klebsiella* spp., and other facultative and obligate aerobes predominate.

TABLE 7.4 Percentage of Surgical Site Infections With Select Pathogen, by Procedure Category, Deep Incision and Organ/Space Infections, Detected Upon Admission or Readmission, National Healthcare Safety Network, 2011[a,b]

	Procedure Category											
	All		Orthopedic		Abdominal		Cardiac		Ob/gyn		Neurologic	
Pathogen	N	%	N	%	N	%	N	%	N	%	N	%
Staphylococcus aureus												
MSSA[c]	1,656	14.2	1,112	24.9	131	3.1	272	20.3	35	4.1	61	19.6
MRSA[c]	1,199	10.3	779	17.4	141	3.3	193	14.4	34	4.0	21	6.7
Escherichia coli	1,184	10.2	203	4.5	773	18.1	55	4.1	123	14.4	8	2.6

[a]Preliminary analysis based on data available at 9/2012.
[b]The types of surgery included in each category are as follows: orthopedic: open reduction of fracture, hip prosthesis, knee prosthesis, limb amputation, spinal fusion, refusion of spine, and laminectomy; abdominal: appendectomy, bile duct, liver, or pancreatic surgery, gallbladder surgery, colon surgery, gastric surgery, herniorrhaphy, small-bowel surgery, spleen surgery, abdominal surgery, and rectal surgery; cardiac: cardiac surgery, coronary artery bypass graft with chest incision with or without donor incision, pacemaker surgery, and thoracic surgery; obstetric/gynecologic (Ob/gyn): cesarean section, abdominal hysterectomy, ovarian surgery, and vaginal hysterectomy; neurologic: craniotomy and ventricular shunt.
[c]MRSA denotes methicillin-resistant *S. aureus*, defined as resistant to methicillin, oxacillin, or cefoxitin; MSSA denotes not resistant to these antibiotics.

Staphylococcus aureus is an extraordinarily versatile pathogen that can survive in hostile environmental conditions; colonize mucous membranes and skin; and cause severe, nonpurulent, toxin-mediated disease or invasive pyogenic infection. There has been rapid appearance and spread of a particular genotype of *S. aureus*, which in the United States is predominately the USA300 strain. A variety of surface protein adhesins, excreted toxins, and complex translational and transcriptional regulatory systems allow this strain to be a highly virulent and common pathogen in skin and soft tissue infections (SSTIs), SSIs, pneumonia, bacteremia, and osteomyelitis. The incidence of soft tissue and pulmonary infections due to community-associated methicillin-resistant *Staphylococcus aureus* (MRSA) has increased dramatically, particularly in children and young, immunocompetent adults. Although initially described as community-associated or community-onset MRSA, this strain is now quite common in the health care settings, and has other strains of MRSA as a cause of health care–associated infections (HAIs). USA300 strain has also become a common pathogen for SSIs; it is the most common form of *S. aureus* found in SSIs in hospitalized patients. Methods to reduce the risk of infection due to this organism are an important focus for clinical research.

As part of ongoing efforts to reduce the incidence and burden of SSIs, the CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC) have updated recommendations for the prevention

of these infections made in 1999. Furthermore, the World Health Organization (WHO) has generated an even more recent guideline for prevention of SSIs.

While many elements of the 1999 guideline remain current, others warrant updating to incorporate new knowledge as well as changes in patient populations, operative techniques, emerging pathogens, and guideline development methodology. The background health of the US population has clearly changed, with increasing incidences of obesity, diabetes, and other metabolic diseases. The dramatic increase in the use of minimally invasive surgical techniques and implants may require a different approach to SSI prevention. The emergence of MRSA and other antimicrobial resistant pathogens may impact the rate and severity of SSI as well as potential prevention strategies.

Rationale and Concepts of Antibiotics Prophylaxis

SSIs are preventable HAIs, particularly in clean and clean/contaminated surgery. The primary goals of antibiotics prophylaxis in surgical patients are to prevent SSI and SSI-related morbidity and mortality. To meet these goals, the parenteral antibiotics used must be effective and active against the pathogens that are likely to contaminate the surgical site. To optimize the effectiveness of the antibiotics, appropriate dosage is administered at a time to ensure adequate tissue concentration during the period of potential contamination with redosing to maintain sufficient antibiotics concentration.

PREOPERATIVE ANTIMICROBIAL PROPHYLAXIS

There is a wide consensus on specific procedures that warrant antimicrobial prophylaxis. These are identified in clean surgery (with implants, cardiac, breast surgery, extensive soft tissue procedures, hernia) and clean-contaminated (gastrointestinal/colorectal and appendicitis) (Table 7.5). There is good evidence that extending surgical antimicrobial prophylaxis into the postoperative stage is of no value in reducing SSIs. Cardiothoracic surgery may be an exception to this rule. In such cases, there seem to be potential benefits in continuing antibiotic prophylaxis for up to 24 hours.

Another important aspect of surgical prophylaxis is antibiotic choice. In particular, there has been some degree of controversy about the optimal use of vancomycin in this setting. A recent review concluded that there is

not enough evidence to determine in what scenarios vancomycin is a critical component of perioperative prophylaxis. In addition, the authors pointed out that there are concerns about under dosing of vancomycin, particularly in obese patients, which would present a possible bias against the efficacy of this drug.

Preoperative antibiotics recommendation will follow the SHEA/IDSA reference. The recommendations for surgical antimicrobial prophylaxis are summarized in Table 7.6. Details on the strength of recommendations can be obtained from the reference.

ANTIMICROBIAL STEWARDSHIP

The release of the New Antimicrobial Stewardship Standard by the Joint Commission has sparked renewed interest in this topic in the United States by requiring more hospital leadership commitment and enterprise-wide accountability. Antibiotic stewardship programs are of particular importance to surgical specialties due to their prominent role in prophylactic antibiotic usage. The goal of such programs is not only to reduce the development of resistant organisms, but also to ensure that misguided overuse of prophylactic antibiotics does not result in direct deleterious effects to patients.

TABLE 7.5 National Healthcare Safety Network Criteria for Classifying Wounds

Clean

An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tracts are not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet the criteria.

Clean-Contaminated

Operative wounds in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.

Contaminated

Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered are included in this category.

Dirty or Infected

Includes old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation.

National Healthcare Safety Network. Patient safety component manual: key terms. www.cdc.gov/nhsn/PDFs/pscManual/16pscKeyTerms_current.pdf

TABLE 7.6 Summary of Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery

Type of Procedure	Recommended Agent	Alternative Agents in Patients With B-Lactam Allergy
Cardiac Surgery (e.g., coronary artery bypass)	Cefazolin, cefuroxime	Clindamycin, vancomycin
Thoracic Surgery (e.g., video-assisted thorascopic surgery)	Cefazolin, ampicillin-sulbactam	Clindamycin, vancomycin
Gastrointestinal Surgery (e.g., bariatric and Whipple's)	Cefazolin	Clindamycin or vancomycin+aminoglycoside or aztreonam or fluoroquinolone
Biliary Surgery (e.g., open procedure)	Cefazolin, cefoxitin, cefotetan, ceftriaxone, ampicillin-sulbactam	Clindamycin or vancomycin+aminoglycoside or aztreonam or fluoroquinolone; Metronidazole+aminoglycoside or fluoroquinolone
Small Bowel Surgery—Nonobstructed	Cefazolin	Clindamycin+aminoglycoside or aztreonam or fluoroquinolone
Small Bowel Surgery—Obstructed	Cefazolin+metronidazole, cefoxitin, cefotetan	Metronidazole+aminoglycoside or fluoroquinolone
Hernia Repair	Cefazolin	Clindamycin, vancomycin
Colorectal Surgery	Cefazolin+metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam, ceftriaxone+metronidazole, ertapenem	Clindamycin+aminoglycoside or aztreonam or fluoroquinolone, metronidazole+aminoglycoside or fluroquinolone
Cesarean Delivery	Cefazolin	Clindamycin+aminoglycoside
Vascular	Cefazolin	Clindamycin, vancomycin
Liver Transplantation	Piperacillin-tazobactam, cefotaxime+ampicillin	Clindamycin or vancomycin+aminoglycoside or aztreonam or fluoroquinolone
Orthopedics (e.g., hip fracture repair and total knee replacement)	Cefazolin	Clindamycin, vancomycin
Urologic Surgery—clean contaminated	Cefazolin+metronidazole, cefoxitin	Fluoroquinolone, aminoglycoside+metronidazole or clinidamycin
Head and Neck—clean contaminated cancer surgery	Cefazolin+metronidazole, cefuroxime+metronidazole, ampicillin-sulbactam,	Clindamycin

(Originally published in Bratzler DW, Dellinger EP, Olsen KM, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm* 2013;70(3):195–283. doi:10.2146/ajhp120568. ©2013, American Society of Health-System Pharmacists, Inc. All rights reserved. Adapted with permission.)

The intersection of stewardship and prophylaxis has become even more important because of the increase in methicillin-resistant *Staphylococci* and resistant gram-negatives encountered in bowel procedures. There is a growing consensus that patients scheduled for orthopedic implant, cardiac, and vascular surgery should undergo nasal swabs to detect *S. aureus* colonization. Aggressive treatment with intranasal mupirocin and chlorhexidine body washes greatly reduce the incidence of subsequent infection. These patients additionally are commonly treated with vancomycin.

In many areas of the world, intestinal colonization with gram-negatives possessing ESBLs is common. There have been no studies examining the benefits of anti-ESBL prophylaxis (carbapenems, particularly ertapenem) in these settings. Indirect evidence has accumulated from studies on patients undergoing transrectal prostate biopsy. As expected, individuals with fluoroquinolone-resistant *E. coli* rectal colonization were at a much higher risk of developing a post-biopsy infection, particularly if preoperative prophylaxis consisted only of a fluoroquinolone. As a proof of concept, it paves the way for further studies, such as one quality improvement study that compared targeted to empirical antibiotic prophylaxis in the same subset of patients. The authors concluded that the

targeted prophylaxis approach avoided the use of more than one empirical antibiotic without an increase in post-biopsy infections. Such models could be applied to other surgical specialties, where identifying carriage rates of multidrug resistant organisms with fecal cultures in target populations could also improve antibiotic selection. This approach is likely to provide more meaningful and actionable data than the current one that relies mainly on regional reported resistance rates.

A national action plan to prevent HAIs has been developed. The updated SSI guideline addresses concerns raised in the Health and Human Services plan. Beginning in 2012, hospitals participating in the Centers for Medicare & Medicaid Services (CMS) Inpatient Prospective Payment System were required to report SSI data related to two procedures, total abdominal hysterectomy and colon surgeries, through CDC's National Healthcare Safety Network (NHSN) surveillance system. These data are included in the Inpatient Quality Reporting data publicly reported by CMS through the Hospital Compare Web site.

The Elements of Antimicrobial Stewardship

The release of the New Antimicrobial Stewardship Standard by the Joint Commission has sparked renewed interest in this topic in the United States by requiring more hospital leadership commitment and enterprise-wide accountability. Antibiotic stewardship programs are of particular importance to surgical specialties due to their prominent role in prophylactic antibiotic usage and management of surgical infections. The goal of such programs is not only to reduce the development of resistant organisms, but also to ensure that misguided overuse or inappropriate use of prophylactic and therapeutic antibiotics does not result in direct deleterious effects to patients.

Currently, certain initiatives make implementation of specific care bundles mandatory or nearly so. Payers, such as CMS, are increasingly monitoring compliance with care bundles, such as process measures from the Surgical Care Improvement Project, both as a publicly reportable quality measure and as a tool to determine remuneration for certain medical services.

Care bundles include elements that cover across the preoperative phase, intraoperative and postoperative phase. Practices advocated in the preoperative phases are avoid routine hair removal and use electric clippers with a single-use head on the day of surgery if necessary.

Administer antibiotic prophylaxis to patients before clean surgery especially those involving the placement of a prosthesis or implant, clean-contaminated surgery, and contaminated surgery. Routine antibiotic prophylaxis for clean nonprosthetic uncomplicated surgery is not advocated. A single dose of antibiotic prophylaxis should be given intravenously within 60 minutes of incision.

GUIDELINES ON PREVENTION OF SURGICAL SITE INFECTION

Centers for Disease Control and Prevention Guidelines

HICPAC, a federal advisory committee to CDC, published the CDC/SSI guideline in 2016. The guideline covers six core topics applied to all surgical procedures, namely, parenteral antimicrobial prophylaxis, nonparenteral antimicrobial prophylaxis, glycemic control, normothermia, oxygenation, and antiseptic prophylaxis (Table 7.7). The other seven topics are related specifically to prosthetic joint arthroplasty procedures. The seven topics are blood transfusions, systemic immunosuppressive therapy, intra-articular corticosteroid injections, anticoagulation, orthopedic surgical space suit, postoperative antimicrobial prophylaxis, and biofilm.

World Health Organization Global Guidelines

In recognition of SSI as one of the major HAI affecting patient safety worldwide, the WHO published international guidelines for the prevention of surgical infection in 2016. These guidelines provide consistency in the interpretation of scientific evidence and strength of recommendations. The evidence-based recommendations for interventions cover pre-, intra-, and postoperative periods for prevention of SSI. Table 7.8 is the summary of the core topics and recommendations for the prevention of surgical sites infections.

WHO emphasizes the importance in the translation of these recommendations into practices in surgical services and operation rooms. The key step in developing these guidelines is to ensure its implementation, with the ultimate goal to achieve a reduction of harm due to SSI through the continuum of patient's surgical journey. A surgical champion can implement these guidelines successfully in an enabling environment supportive of patient safety culture. A well-chosen strategy

such as Surgical Unit-based Safety Program (SUSP), which has a package of more than 20 implementation tools, is crucial for the successful uptake and adoption of these recommendations.

TREATMENT OF SURGICAL INFECTION

Principles of Management of Surgical Infection

The principles in the management of surgical infection are based on two aspects, precise diagnosis and the three pillars of treatment. Prompt clinical assessment and microbiologic sampling are the key to a precise diagnosis of surgical infection. The three pillars, which should be treated as parallel priorities, consist of source control or focus elimination, appropriate use of antimicrobial agents, and organ supports through intensive care medicine. Source control refers to the therapeutic interventions that eliminate a focus of infection, control ongoing contamination, and restore premorbid anatomy and physiologic function. It involves managing the source of leakage of microbial pathogens from the gut, such as by resection or drainage. Conceptually, the principles embody the 3Ps: the **p**atient's complexity; the **p**athogen's virulence and its susceptibility; and the **p**hysician's knowledge, skills, and medicine.

TABLE 7.7 CDC and WHO Guideline Comparisons

Area of Recommendation	CDC Guideline	WHO Guideline
I. Parenteral Antimicrobial Prophylaxis	Administer preoperative antimicrobial agent(s) only when indicated, based on published clinical practice guidelines and timed such that a bactericidal concentration of the agent(s) is established in the serum and tissues when the incision is made. **(Category IB)** No further refinement of timing can be made for preoperative antimicrobial agent based on clinical outcomes. (**No recommendation/unresolved issue**) 1A.2 No further refinement of timing can be made for preoperative antimicrobial agent based No evidence for weight based or intra-op dosing. In clean and clean-contaminated procedures, do not administer additional prophylactic antimicrobial agent doses after the surgical incision is closed in the operating room, even in the presence of a drain. (**Category IA**)	The panel recommends that SAP should be administered prior to the surgical incision when indicated (depending on the type of operation). The panel recommends the administration of SAP within 120 minutes before incision, while considering the half-life of the antibiotic.
S. aureus nasal carriage		The panel recommends that patients undergoing cardiothoracic and orthopedic surgery with known nasal carriage of *S. aureus* should receive perioperative intranasal applications of mupirocin 2% ointment with or without a combination of CHG body wash.

II. Nonparenteral Antimicrobial Prophylaxis	2A.1. RCT evidence suggests uncertain trade-offs between benefits and harms regarding intraoperative antimicrobial irrigation (e.g., intra-abdominal, deep or subcutaneous tissues) for the prevention of SSI. Other organizations have made recommendations based on the existing evidence and a summary of these recommendations can be found in the Other guidelines section of the narrative summary for this question. (**No recommendation/unresolved issue**) 2B.1. Do not apply antimicrobial agents (i.e., ointments, solutions, powders) to the surgical incision for the prevention of SSI. (**Category IB**) 2B.2. Application of autologous platelet-rich plasma (APRP) is not necessary for the prevention of SSI. (**Category II**) 2C. Consider the use of triclosan-coated sutures for the prevention of SSI. (**Category II**) 2D. RCT evidence suggests uncertain trade-offs between benefits and harms regarding antimicrobial dressings applied to surgical incisions following primary closure in the operating room for the prevention of SSI. (**No recommendation/unresolved issue**)	
III. Glycemic Control	3A.1. Implement perioperative glycemic control and use blood glucose target levels <200 mg/dL in diabetic and nondiabetic patients. (**Category IA**)	
IV. Normothermia	4. Maintain perioperative normothermia. (**Category IA**)	
V. Oxygenation	6A. RCT evidence suggests uncertain trade-offs between benefits and harms regarding the administration of increased FiO_2 via endotracheal intubation during only the intraoperative period in patients with normal pulmonary function undergoing general anesthesia for the prevention of SSI. (**No recommendation/unresolved issue**) 6B. For patients with normal pulmonary function undergoing general anesthesia with endotracheal intubation administer increased fraction of inspired oxygen (FiO_2) both intraoperatively and post-extubation in the immediate postoperative period. To optimize tissue oxygen delivery, maintain perioperative normothermia and adequate volume replacement. (**Category IA**)	
VI. Antiseptic Prophylaxis	8A.1. Advise patients to shower or bathe (full body) with either soap (antimicrobial or nonantimicrobial) or an antiseptic agent on at least the night before the operative day. (**Category IB**) 8B. Perform intraoperative skin preparation with an alcohol-based antiseptic agent, unless contraindicated. (**Category IA**) 8C. Application of a microbial sealant immediately following intraoperative skin preparation is not necessary for the prevention of SSI. (**Category II**) 8D. Use of plastic adhesive drapes with or without antimicrobial properties is not necessary for the prevention of SSI. (**Category II**) 9A. Consider intraoperative irrigation of deep or subcutaneous tissues with aqueous iodophor solution for the prevention of SSI. Intraperitoneal lavage with aqueous iodophor solution in contaminated or dirty abdominal procedures is not necessary. (**Category II**) 9B. The search did not identify RCTs that evaluated soaking prosthetic devices in antiseptic solutions prior to implantation for the prevention of SSI. (**No recommendation/unresolved issue**) 10. RCT evidence is insufficient to evaluate the trade-offs between the benefits and harms of repeat application of antiseptic agents to the patient's skin immediately prior to closing the surgical incision for the prevention of SSI. (**No recommendation/unresolved issue**)	It is good clinical practice for patients to bathe or shower prior to surgery. The panel suggests that either plain soap or an antimicrobial soap may be used for this purpose.

TABLE 7.8 Summary of Core Topics and Recommendations for Prevention of Surgical Infection (WHO Global Guidelines for Prevention of Surgical Site Infection)

Topic	Research Questions	Recommendations	Strength	Quality of Evidence
Preoperative measures				
Preoperative bathing	1. Is preoperative bathing using an antimicrobial soap more effective in reducing the incidence of SSI in surgical patients compared to bathing with plain soap?	It is good clinical practice for patients to bathe or shower prior to surgery. The panel suggests that either plain soap or an antimicrobial soap may be used for this purpose.	Conditional	Moderate
	2. Is preoperative bathing with CHG-impregnated cloths more effective in reducing the incidence of SSI in surgical patients compared to bathing with antimicrobial soap?	The panel decided not to formulate a recommendation on the use of CHG-impregnated cloths for the purpose of reducing SSI due to the very low quality of evidence		
Decolonization with mupirocin ointment with or without CHG body wash for the prevention of *S. aureus* infection in nasal carriers	Is mupirocin nasal ointment in combination with or without CHG body wash effective in reducing the number of *S. aureus* infections in nasal carriers undergoing surgery?	The panel recommends that patients undergoing cardiothoracic and orthopedic surgery with known nasal carriage of *S. aureus* should receive perioperative intranasal applications of mupirocin 2% ointment with or without a combination of CHG body wash.	Strong	Moderate
		The panel suggests considering to treat also patients with known nasal carriage of *S. aureus* undergoing other types of surgery with perioperative intranasal applications of mupirocin 2% ointment with or without a combination of CHG body wash.	Conditional	Moderate
Screening of ESBL colonization and the impact on antibiotic prophylaxis	1. Should SAP be modified in high (>10%) ESBL prevalence areas? 2. Should SAP be modified in patients who are colonized with or a carrier of ESBL? 3. Should patients be screened for ESBL prior to surgery?	The panel decided not to formulate a recommendation due to the lack of evidence.	NA	NA
Optimal timing for preoperative SAP	How does the timing of SAP administration impact on the risk of SSI, and what is the precise optimal timing?	The panel recommends that SAP should be administered prior to the surgical incision when indicated (depending on the type of operation).	Strong	Low
		The panel recommends the administration of SAP within 120 minutes before incision, while considering the half-life of the antibiotic.	Strong	Moderate
Mechanical bowel preparation and the use of oral antibiotics	Is mechanical bowel preparation combined with or without oral antibiotics effective for the prevention of SSI in colorectal surgery?	The panel suggests that preoperative oral antibiotics combined with mechanical bowel preparation should be used to reduce the risk of SSI in adult patients undergoing elective colorectal surgery.	Conditional	Moderate
		The panel recommends that mechanical bowel preparation alone (without administration of oral antibiotics) should not be used for the purpose of reducing SSI in adult patients undergoing elective colorectal surgery.	Strong	Moderate

Hair removal	1. Does hair removal affect the incidence of SSI? 2. What method and timing of hair removal are associated with the reduction of SSI?	The panel recommends that in patients undergoing any surgical procedure, either hair should not be removed or, if absolutely necessary, it should be removed only with a clipper. Shaving is strongly discouraged at all times, whether preoperatively or in the OR.	Strong	Moderate
Surgical site preparation	Should alcohol-based antiseptic solutions or aqueous solutions be used for skin preparation in surgical patients and, more specifically, should CHG or PVP-I solutions be used?	The panel recommends alcohol-based antiseptic solutions based on CHG for surgical site skin preparation in patients undergoing surgical procedures.	Strong	Low to moderate
Antimicrobial skin sealants	Should antimicrobial sealants (in addition to standard surgical site skin preparation) be used in surgical patients for the prevention of SSI compared to standard surgical site skin preparation only?	The panel suggests that antimicrobial sealants should not be used after surgical site skin preparation for the purpose of reducing SSI.	Conditional	Very Low
Surgical hand preparation	1. What is the most effective type of product for surgical hand preparation to prevent SSI? 2. What is the most effective technique and ideal duration for surgical hand preparation?	The panel recommends that surgical hand preparation should be performed by scrubbing with either a suitable antimicrobial soap and water or usng a suitable alcohol-based handrub before donning sterile gloves.	Strong	Moderate
Preoperative and/or intraoperative measures				
Enhanced nutritional support	In surgical patients, should enhanced nutritional support be used for the prevention of SSI?	The panel suggests considering the administration of oral or enteral multiple nutrient-enhanced nutritional formulas for the purpose of preventing SSI in underweight patients who undergo major surgical operations.	Conditional	Very Low
Perioperative discontinuation of immunosuppressive agents	Should immunosuppressive agents be discontinued Perioperatively, and does this affect the incidence of SSI?	The panel suggests not to discontinue immunosuppressive medication prior to surgery for the purpose of preventing SSI.	Conditional	Very Low
Perioperative oxygenation	How safe and effective is the perioperative use of an increased fraction of inspired oxygen in reducing the risk of SSI?	The panel recommends that adult patients undergoing general anesthesia with endotracheal intubation for surgical procedures should receive an 80% fraction of inspired oxygen intraoperatively and, if feasible, in the immediate postoperative period for 2–6 hours to reduce the risk of SSI.	Strong	Moderate
Maintaining normal body temperature (normothermia)	Should systemic body warming vs. no warming be used for the prevention of SSI in surgical patients?	The panel suggests the use of warming devices in the OR and during the surgical procedure for patient body warming with the purpose of reducing SSI.	Conditional	Moderate

Use of protocols for intensive perioperative blood glucose control	1. Do protocols aiming to maintain optimal perioperative blood glucose levels reduce the risk of SSI?	The panel suggests the use of protocols for intensive perioperative blood glucose control for both diabetic and nondiabetic adult patients undergoing surgical procedures to reduce the risk of SSI.	Conditional	Low
	2. What are the optimal perioperative glucose target levels in diabetic and nondiabetic patients?	The panel decided not to formulate a recommendation on this topic due to the lack of evidence to answer question 2.		
Maintenance of adequate circulating volume control/ normovolemia	Does the use of specific fluid management strategies during surgery affect the incidence of SSI?	The panel suggests the use of goal-directed fluid therapy intraoperatively to reduce the risk of SSI.	Conditional	Low
Drapes and gowns	1. Is there a difference in SSI rates depending on the use of disposable nonwoven drapes and gowns or reusable woven drapes and gowns? 1.1. Is there a difference in SSI rates depending on the use of disposable nonwoven or reusable woven drapes? 1.2. Is there a difference in SSI rates depending on the use of disposable nonwoven or reusable woven gowns?	The panel suggests that either sterile, disposable nonwoven or sterile, reusable woven drapes and gowns can be used during surgical operations for the purpose of preventing SSI. No specific evidence was retrieved to answer to Questions 1.1 and 1.2.	Conditional	Moderate to very low
	2. Does the use of disposable, adhesive, incise drapes reduce the risk of SSI?	The panel suggests not to use plastic adhesive incise drapes with or without antimicrobial properties for the purpose of preventing SSI.	Conditional	Low to very low
Wound protector devices	Does the use of wound protector devices reduce the rate of SSI in open abdominal surgery?	The panel suggests considering the use of wound protector devices in clean-contaminated, contaminated and dirty abdominal surgical procedures for the purpose of reducing the rate of SSI.	Conditional	Very low
Incisional wound irrigation	Does intraoperative wound irrigation reduce the risk of SSI?	The panel considered that there is insufficient evidence to recommend for or against saline irrigation of incisional wounds before closure for the purpose of preventing SSI.	NA	NA
		The panel suggests considering the use of irrigation of the incisional wound with an aqueous PVP-I solution before closure for the purpose of preventing SSI, particularly in clean and clean-contaminated wounds. The panel suggests that antibiotic incisional wound irrigation should not be used for the purpose of preventing SSI.	Conditional	Low
Prophylactic negative pressure wound therapy	Does prophylactic negative pressure wound therapy reduce the rate of SSI compared to the use of conventional dressings?	The panel suggests the use of prophylactic negative pressure wound therapy in adult patients on primarily closed surgical incisions in high-risk wounds for the purpose of the prevention of SSI, while taking resources into account.	Conditional	Low

Use of surgical gloves	1. When is double-gloving recommended? 2. What are the criteria for changing gloves during an operation? 3. What type of gloves should be used?	The panel decided not to formulate a recommendation due to the lack of evidence to assess whether double-gloving or a change of gloves during the operation or the use of specific types of gloves is more effective in reducing the risk of SSI.	NA	NA
Changing of surgical instruments	At the time of wound closure, is there a difference in SSI when instruments are changed for fascial, subcutaneous, and skin closure using a new set of sterile instruments?	The panel decided not to formulate a recommendation on this topic due to the lack of evidence.	NA	NA
Antimicrobial-coated sutures	Are antimicrobial-coated sutures effective to prevent SSI? If yes, when and how should they be used?	The panel suggests the use of triclosan-coated sutures for the purpose of reducing the risk of SSI, independent of the type of surgery.	Conditional	Moderate
Laminar flow ventilation systems in the context of OR ventilation	1. Is the use of laminar air flow in the OR associated with the reduction of overall or deep SSI?	The panel suggests that laminar airflow ventilation systems should not be used to reduce the risk of SSI for patients undergoing total arthroplasty surgery.	Conditional	Low to very low
	2. Does the use of fans or cooling devices increase SSIs? 3. Is natural ventilation an acceptable alternative to mechanical ventilation?	The panel decided not to formulate a recommendation on these topics due to the lack of evidence to answer Questions 2 and 3.	NA	NA
Postoperative measures				
SAP prolongation	Does continued postoperative SAP reduce the risk of SSI compared with preoperative and (if necessary) intraoperative prophylaxis only?	The panel recommends against the prolongation of SAP after completion of the operation for the purpose of preventing SSI.	Strong	Moderate
Advanced dressings	In surgical patients, should advanced dressings vs. standard sterile wound dressings be used for the prevention of SSI?	The panel suggests not using any type of advanced dressing over a standard dressing on primarily closed surgical wounds for the purpose of preventing SSI.	Conditional	Low
Antimicrobial prophylaxis in the presence of a drain and optimal timing for wound drain removal	1. In the presence of drains, does prolonged antibiotic prophylaxis prevent SSI?	The panel suggests that preoperative antibiotic prophylaxis should not be continued in the presence of a wound drain for the purpose of preventing SSI.	Conditional	Low
	2. When using drains, how long should they be kept in place to minimize SSI as a complication?	The panel suggests removing the wound drain when clinically indicated. No evidence was found to allow making a recommendation on the optimal timing of wound drain removal for the purpose of preventing SSI.	Conditional	Very low

From Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis* 2010;50(2):133–64, by permission of Oxford University Press.

Complicated Intra-Abdominal Sepsis

More often than not, patients with intra-abdominal sepsis are managed under the leadership of a surgeon. The main reason is because the chances for surgical intervention in this group of patients are high. Intra-abdominal sepsis could be primary from infections arising from digestive system or secondary following an elective abdominal operation. In complicated intra-abdominal infections, the infectious process proceeds beyond the organ where infection originates. The infection may be complicated by localized peritonitis, abdominal abscess, or diffuse peritonitis, depending on the host immune response to contain the infection within the abdominal cavity. Intra-abdominal infections are often polymicrobial (aerobic, anaerobic, gram-negative and positive) in etiology. Mixed aerobic–

anaerobic bacteria act in synergy. Abscess forming obligate anaerobe such as *Bacteroides fragilis* increases the lethality of a nonlethal inoculum of the endotoxin generating facultative anaerobes such as *E. coli.*

Early clinical diagnosis, adequate source control, and prompt initiation of appropriate empirical therapy to arrest the infectious process and restore anatomical structures and physiologic function are the cornerstones in securing good clinical outcome in complicated intra-abdominal sepsis. Surgical interventions are required to achieve adequate source control in majority of these cases.

Diagnostic Workup

Initial diagnosis of complicated intra-abdominal infection can be made following clinical history, physical examination, and routine laboratory studies. Further evaluation is warranted to identify the source of infection, severity, and the nature of pathogen. In the presence of obvious diffuse peritonitis, no further radiologic studies are necessary so that emergent surgical intervention is not delayed. Noninvasive diagnostic imaging, including helical computed tomography (CT) scan and in some cases magnetic resonance imaging (MRI) scan, has greatly added to the accuracy of preoperative diagnosis and allowed patient-specific intervention plans to be developed. In patients whose physical signs are assessed to be unreliable such as an altered mental status from head injury, or spinal cord injury or immunocompromised patients, high index of suspicion for the diagnosis of intra-abdominal infection is needed especially when there is clinical evidence of infection from an undetermined source.

Timing and Nature of Empiric Antimicrobial Management

Most guidelines for antimicrobial management in complicated intra-abdominal infections are standardized accordingly to community-associated infections and HAIs, with recommendation of either monotherapy or combination therapy. Patients at high risk of having multidrugs resistant pathogens should be vigilantly identified. Consider antimicrobial coverage against enterococci in selected clinical situations, such as in patients with septic shock in previous prolonged cephalosporins treatment, immunosuppressed patients at risk for bacteraemia, patients with prosthetic heart valves and recurrent intra-abdominal infection complicated by severe sepsis. Administer antifungal therapy especially for patients at risk for invasive candidiasis, in particular, patients with

extended duration of antimicrobial therapy and immunosuppressed patients. Discipline in antimicrobial usage to balance between optimizing antibiotics therapy and avoiding unnecessary antimicrobial use should be exercised so as to combat and control the emergence of multidrug resistant pathogens.

Microbiology in Patients With Community-Associated Infections

In the era of organism-based rather than severity-based concept, what is the utility of microbiology to guide antimicrobial usage for community-associated infections? There are no data indicating that Gram stain, culture, and susceptibility results alter outcome in patients with a community-associated complicated intra-abdominal infection. This is in large part a consequence of the fact that most studies primarily include patients with acute appendicitis. However, there is increasing resistance of community-associated strains of gram-negative organisms to selected antibiotics in many locales.

If resistance for a given antibiotic is greater than 10% to 20% for a common intra-abdominal pathogen in the community, use of that agent should be avoided. Because of widespread resistance of *E. coli* to ampicillin/sulbactam, that antibiotic is no longer recommended for routine empiric therapy of complicated intra-abdominal infections. There is high penetration of fluoroquinolone-resistant *E. coli* in Latin America and East Asia, and locations with a high prevalence of ESBL-producing strains of *Klebsiella* sp. and *E. coli.* Quinolone-resistant *E. coli* are similarly becoming a problem in some areas, and this mandates review of hospital susceptibility data. In some populations and communities, a relatively high prevalence of more resistant nonenteric gram-negative organisms, such as *Pseudomonas aeruginosa,* will impact the selection of appropriate empiric antibiotic therapy.

Routine cultures of patients with community-associated intra-abdominal infections may facilitate recognition of local changes in resistance, and thereby optimal selection of antimicrobial agents for both definitive treatment and oral step-down therapy. There are marked differences in susceptibility patterns within and between different groups of patients.

Microbiology in Patients With Health Care-Associated Infections

For patients with HAIs, antimicrobial therapy that fails to cover eventual

pathogens has been associated with higher rates of treatment failure and mortality. Thus, Gram stains may be of value in detecting gram-positive cocci or yeast that would lead to additional empiric antimicrobial therapy before definitive culture results are available. Local susceptibility patterns for *S. aureus* and for enterococci might warrant addition of an MRSA-active agent until results of cultures and susceptibility testing are available. For enterococci, local susceptibilities should be monitored for penicillin and vancomycin resistance.

Risk factors for vancomycin resistant *Enterococcus faecium* (VRE) colonization include previous antibiotic therapy, the duration and multiplicity of antimicrobial therapy, extended hospital stay, intensive care unit (ICU) long stayer, and serious comorbidity. Therefore, in patients with postoperative or nosocomial infections, recent exposure to broad-spectrum antimicrobial agents especially cephalosporins, in immunocompromised patients and in patients with valvular heart disease or prosthetic intravascular materials, Enterococcal infection should be suspected.

The emergence of multidrug-resistant gram-negative bacteria in the recent years has presented a new dimension of challenges for both surgeons and physicians. This is partly contributed by the selective pressure from an intensive use of antimicrobial therapy and partly due to the increasing number of invasive procedures performed in more multimorbid patient populations. Other factors include higher patient volume in huge medical institutions with greater movement of patients and health care workers. *Pseudomonas aeruginosa, Acinetobacter baumannii, Stenotrophomonas maltophilia,* ESBL-producing *Enterobacteriaceae* and *Carbapenem-resistant Enterococci and Pseudomonas aeruginosa,* identified by the Antimicrobial Availability Task Force of the Infectious Diseases Society of America (IDSA), have become a universal clinical problem in the management of complicated intra-abdominal infection. Most recently, *Klebsiella pneumoniae* carbapenemase-producing bacteria and extended drug-resistant bacteria are major concerns.

TABLE 7.9 Initial Empirical Antimicrobials for Extra-Biliary Complicated Intra-Abdominal Infection

Regimen	Community-Acquired Infection in Pediatric Patients	Community-Acquired Infection in Adults: Mild-to-Moderate Severity: Perforated or Abscessed Appendicitis and Other Infections of Mild-to-Moderate Severity	Community-Acquired Infection in Adults: High Risk or Severity: Severe Physiologic Disturbance, Advanced Age, or Immunocompromised State
Single agent	Ertapenem, meropenem, imipenem-cilastatin, ticarcillin-clavulanate, and piperacillin-tazobactam	Cefoxitin, ertapenem, moxifloxacin, tigecycline, and ticarcillin-clavulanic acid	Imipenem-cilastatin, meropenem, doripenem, and piperacillin-tazobactam
Combination	Ceftriaxone, cefotaxime, cefepime, or ceftazidime, each in combination with metronidazole; gentamicin or tobramycin, each in combination with metronidazole or clindamycin, and with or without ampicillin	Cefazolin, cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levofloxacin, each in combination with metronidazole[a]	Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole[a]

[a]Because of increasing resistance of *E. coli* to fluoroquinolones, local population susceptibility profiles and, if available, isolate susceptibility should be reviewed.

From Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis* 2010;50(2):133–64, by permission of Oxford University Press.

If yeasts are identified on a Gram stain, additional therapy for *Candida* sp. may be considered. The failure to provide adequate antimicrobial therapy in such patients has been repeatedly associated with an increased incidence of therapeutic failure, and in some cases increased mortality. Numerous prospective, blinded, and randomized trials have compared regimens active against routine isolates of *Enterococcus* for community-associated infections. In at least six of these studies, the comparator regimen did not have similar coverage. None of these trials demonstrated an advantage to treatment for enterococci. There is no evidence that routine use of agents effective against enterococci improves outcome from community-associated infections, but the presence of this organism appears to increase failure rates in selected patient groups, primarily those with high severity infections. Isolation of staphylococci and yeast are quite uncommon in patients with community-associated intra-abdominal infections, and use of agents with effective methicillin resistant staphylococci and yeast is not indicated in the absence of evidence that such organisms are involved in the infection.

Broad-Spectrum Antimicrobial Therapy for Severe Community-Associated Infection

Recommended empiric regimens for patients with biliary and nonbiliary community-associated intra-abdominal infections are summarized in Tables 7.9 and 7.10. Several attempts have been made to identify clinical features in patients with complicated intra-abdominal infections that increase the risk of adverse outcomes. These analyses have identified parameters predictive of mortality rather than the risk of recurrent infection. These risk factors include higher APACHE II scores, poor

nutritional status, significant cardiovascular disease, and an inability to achieve adequate source control. Similarly, patients who are immunosuppressed by medical therapy for transplantation, cancer, or inflammatory disease are at higher risk of an adverse outcome. Prolonged prehospital length of stay (>5 days) and prolonged (>2 days) preoperative antimicrobial therapy are significant predictors of failure from recurrent infection. Patients with other acute and chronic diseases may also be immunosuppressed, although this is difficult to define. Intraoperative cultures, including cultures from percutaneous drainage procedures, are therefore central to the prescribing of definitive therapeutic regimens for these patients, and may allow de-escalation to less broad-spectrum therapy.

TABLE 7.10 Initial Empirical Antimicrobials for Biliary Complicated Intra-Abdominal Infection

Infection	Regimen
Community-acquired acute cholecystitis of mild-to-moderate severity	Cefazolin, cefuroxime, or ceftriaxone
Community-acquired acute cholecystitis of severe physiologic disturbance, advanced age, or immunocompromised state	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole[a]
Acute cholangitis following bilioenteric anastamosis of any severity	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole[a]
Health care–associated biliary infection of any severity	Imipenem-cilastatin, meropenem, doripenem, piperacillin-tazobactam, ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole, vancomycin added to each regimen[a]

[a]Because of increasing resistance of *E. coli* to fluoroquinolones, local population susceptibility profiles and, if available, isolate susceptibility should be reviewed.
From Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis* 2010;50(2):133–64, by permission of Oxford University Press.

In patients with such higher severity infections, the consequences of treatment failure may be more significant than in those patients with mild-to-moderate infections. The use of initial empiric antimicrobial regimens that are subsequently identified as lacking in in vitro activity against the

organisms actually isolated from the intra-abdominal infection has been associated with an increased need for additional source-control procedures and more aggressive antimicrobial therapy, increased hospital lengths of stay and costs, and increased mortality. As such, use of broader-spectrum agents providing activity and some gram-negative facultative and aerobic organisms occasionally isolated from such patients have the potential to improve outcome, although this hypothesis has not been rigorously examined in clinical trials.

In these cases, cultures and susceptibility tests are particularly important. The rationale for the widening of coverage to less common organisms is that the risk of treatment failure in such patients is higher and the consequences potentially greater. Increasing antimicrobial resistance with *B. fragilis* is similarly of concern, and there are data indicating higher failure rates if these organisms are treated with an inactive agent, particularly cefotetan and cefoxitin. No randomized clinical trials have been performed with this agent since resistance was first reported. Similarly, moxifloxacin use for the treatment of patients likely to have *B. fragilis* should be avoided if patients have recently received quinolone therapy, as organisms from such patients are likely to have quinolone-resistant isolates.

Local microbiology laboratories show great variation in reliably performing in vitro susceptibility tests. Sentinel studies of *B. fragilis*, the major pathogen, show uniform susceptibility to metronidazole, carbapenems, and β-lactam/β-lactamase inhibitors. Susceptibility testing of individual anaerobic isolates should be considered when there is persistent isolation of the organism, bacteremia, or when prolonged therapy is needed because of immunosuppression or prosthetic infection. Laboratories can purify and hold isolates for additional testing if requested by the clinician.

Antimicrobials in Patients With Health Care–Associated Intra-Abdominal Infections

Recommended empiric regimens for patients with health care–associated intra-abdominal infections include meropenem, imipenem/cilastatin, doripenem, piperacillin/tazobactam, ciprofloxacin plus metronidazole, ceftazidime or cefepime plus metronidazole, and aztreonam plus metronidazole plus vancomycin (Table 7.11). Empiric antibiotic therapy for hospital-acquired intra-abdominal infections should be guided by

knowledge of the flora seen at the particular hospital and their antimicrobial susceptibilities. In general, this will necessitate use of multidrug regimens with expanded spectra of activity against gram-negative aerobic and facultative bacilli, which may include aminoglycosides or colistin. Such broad-spectrum antimicrobial therapy should be tailored when culture and susceptibility reports become available to reduce the number and spectra of administered agents.

HAIs are commonly caused by a more resistant flora, which may include the nonfermenting gram-negatives *Psuedomonas aeruginosa* and *Acinetobacter* sp., extended spectrum β-lactamase-producing *Klebsiella* and *E. coli*, *Enterobacter* sp., *Proteus* sp., MRSA, *enterococci*, and *Candida* sp. For these infections, complex multidrug regimens are recommended because adequate empiric therapy appears important in determining postoperative complications and mortality. Failure to adequately treat resistant organisms has, in similar HAIs, been associated with increased death. Local resistance patterns of nosocomial isolates seen in the specific hospital should dictate empiric treatment, and treatment should be altered based upon a thorough microbiologic workup of infected fluid.

In infections occurring after elective or emergent operation, a more resistant flora is routinely encountered. The organisms seen are similar to those seen in other nosocomial infections, and anaerobes are not frequently important sources of resistant organisms. The selection of antibiotics would be tailored according to the known nosocomial flora present at the institution where the patient developed the infection.

TABLE 7.11 Recommendations for Empirical Antimicrobial Therapy for Health Care–Associated Complicated Intraabdominal Infection

Organisms Seen in Health Care–Associated Infection at the Local Institution	Regimen				
	Carbapenem[a]	Piperacillin-Tazobactam	Ceftazidime or Cefepime, Each With Metronidazole	Aminoglycoside	Vancomycin
<20% Resistant *Pseudomonas aeruginosa,* ESBL-producing Enterobacteriaceae, *Acinetobacter,* or other MDR GNB	Recommended	Recommended	Recommended	Not recommended	Not recommended
ESBL-producing Enterobacteriaceae	Recommended	Recommended	Not recommended	Recommended	Not recommended
P. aeruginosa >20% resistant to ceftazidime	Recommended	Recommended	Not recommended	Recommended	Not recommended
MRSA	Not recommended	Not recommended	Not recommended	Not recommended	Recommended

"Recommended" indicates that the listed agent or class is recommended for empiric use, before culture and susceptibility data are available, at institutions that encounter these isolates from other health care–associated infections. These may be unit- or hospital-specific.
[a]Imipenem-cilastatin, meropenem, or doripenem.
ESBL, extended-spectrum β-lactamase; GNB, gram-negative bacilli; MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus.*
From Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis* 2010;50(2):133–64, by permission of Oxford University Press.

Fungal infection has been the subject of recent guidelines from the Infectious Diseases Society of America. *Candida albicans* or other fungi are cultured from about 20% of patients with acute perforations of the gastrointestinal tract. Even when fungi are recovered, antifungal agents are unnecessary in adults unless the patient has recently received immunosuppressive therapy for neoplasm or has a perforation of a gastric ulcer on acid suppression or malignancy, transplantation, or inflammatory disease, or has postoperative or recurrent intra-abdominal infection. In neonates with necrotizing enterocolitis, Candida is not uncommon, and is more likely to represent a true pathogen than in previously healthy adults. Nonetheless, in the listed settings Candida is associated with increased mortality. Patients with health care–associated intra-abdominal infections are at higher risk for Candida peritonitis, particularly those with recurrent gastrointestinal perforations and surgically treated pancreatic infections.

Preemptive antifungal therapy with fluconazole may decrease the incidence of Candida peritonitis in such high-risk patients. There has been an evolution of the species of Candida seen in candidemia and candida peritonitis. Because of its high susceptibility to fluconazole, *C. albicans* has decreased in frequency and *C. glabrata* and other species have become somewhat more common. This observation, coupled with the common use of fluconazole prophylaxis in the ICU, suggests empiric use of echinocandins (caspofungin, anidulafungin, micafungin).

Certain patient groups are at particularly high risk for a poor outcome because of enterococcal infection, and include (i) immunocompromised patients, (ii) patients with health care–associated postoperative peritonitis,

(iii) patients with severe sepsis of abdominal origin who have previously received cephalosporins and other broad spectrum antibiotics selecting for *Enterococcus* spp., and (iv) patients with peritonitis and valvular heart disease or prosthetic intravascular material, which place them at high risk of endocarditis.

Isolation of *Enterococcus* is more common in patients with nosocomial intra-abdominal infections, particularly those with postoperative infections, and its isolation is a risk factor for treatment failure and death. Thus, in patients with health care associated intra-abdominal infections, including those with postoperative infections, a reasonable option would be to include coverage of Enterococcus in the empiric regimen, until definitive culture results are available. Ampicillin and vancomycin are agents that have activity against this organism, and could be added to a regimen lacking anti-enterococcal activity. Specific risk factors for vancomycin-resistant enterococci have been detailed, which center upon transmission from other colonized or infected patients in an epidemic manner.

MRSA isolates are recovered from patients with postoperative infections, pancreatic infections, and tertiary peritonitis. MRSA is not commonly isolated from patients with community-acquired intra-abdominal infections. There are no specific data with regard to antibiotic preferences in treatment of intra-abdominal infections because of MRSA. In general, vancomycin has been used to treat infections caused by this organism. Other antibiotics including quinupristin/dalfopristin, linezolid, daptomycin, and tigecycline have in vitro activity against methicillin-resistant staphylococci, but there are little published data regarding their efficacy in the treatment of patients with intra-abdominal infections. Thus, vancomycin should probably remain the first-line agent, with use of the others restricted to situations in which vancomycin cannot be used because of severe adverse reactions or when initial therapy with vancomycin is thought to have failed.

Pharmacokinetic and Pharmacodynamic Considerations in Intra-Abdominal Sepsis

Pharmacokinetic–pharmacodynamic properties of specific antibiotics should be considered in selecting an adequate dosing regimen. Antimicrobial dosing considerations are needed in critically ill patients. Physiologic changes can occur in both of these patient populations, which

may alter the apparent volume of distribution or clearance of commonly used antibiotics. In addition, if the estimate of a dosage regimen is dependent on renal function, an accurate estimate of creatinine clearance (CLCR) based on serum creatinine values and body weight may be difficult with commonly used equations and direct measurement of CLCR may be required. For β-lactams and aminoglycosides, the critically ill patient with the early stages of sepsis may have shifts in body fluid and be in hypermetabolic state, resulting in an increase in both, volume of distribution and clearance and lower serum antibiotic concentrations. These studies suggest that higher doses and more frequent administration of β-lactams may be needed in selected patients who are critically ill, with altered distribution and increased clearance of renally excreted antibiotics. Initial dosing regimens for aminoglycosides and vancomycin should be based on adjusted body weight and total body weight, respectively. Serum drug concentration monitoring is recommended for dosage individualization of aminoglycosides and vancomycin in these patient populations. There is considerable evidence that less frequent dosing of metronidazole, in particular, is effective. The metronidazoles are bactericidal through toxic metabolites, which cause DNA strand breakage. Resistance, both clinical and microbiologic, has been described only rarely. Liver disease leads to a decreased clearance of metronidazole and dosage reduction is recommended.

A duration of therapy no greater than 1 week was appropriate for most patients with intra-abdominal infections, with the exception of those who had inadequate source control. Within this window, resolution of clinical signs of infection provides the termination point for antimicrobial therapy. The risk of subsequent treatment failure appears to be quite low in patients who have no clinical evidence of infection at the time of cessation of antimicrobial therapy. This usually implies that the patients are afebrile, have normal white blood cell counts, and are tolerating an oral diet. These conditions are unlikely to occur in a critically ill patient in the ICU who is suffering from a postoperative infection with multisystem organ failure. These patients display persistent or recurrent signs of peritoneal irritation, failure of bowel function to return, or continued fever or leukocytosis, and are at high risk for an intra-abdominal or other infection that may require additional intervention to achieve source control. CT of the abdomen is usually the most accurate method by which to diagnose an ongoing or recurrent intra-abdominal infection. The possibility of an extra-abdominal

infection, such as nosocomial pneumonia or urinary tract infection, or a noninfectious cause of fever or leukocytosis, such as venous thrombosis or a pulmonary embolism, should also be considered. For complex patients in the ICU, with multiple organ failures, CT scans may be the only means to determine if conditions for cessation of therapy (no defined collections) are met.

Antimicrobial regimens should be adjusted according to the results of the diagnostic investigations. For patients with a confirmed intra-abdominal infection, this may require broadening the regimen to include agents with activity against health care–associated organisms typically isolated with these infections. Appropriate antimicrobial therapy, based upon cultures of the infected site, should be continued while the investigation proceeds, particularly if the patient manifests signs of sepsis, such as organ dysfunction. The current state of the art would be to terminate antimicrobial therapy and observe for worsening of the overall clinical condition of the patient. If the patient continues to be relatively stable, therapy should not be resumed unless a documented source is identified.

De-Escalation Approach for Polymicrobial Infections

It has been recommended that the two-stage approach of using initial broad spectrum therapy followed by de-escalation allows serious infection to be treated promptly, at the same time effectively avoiding antibiotic overuse and averting potential resistance. The concept in the likelihood of colonization with resistant microorganisms could be minimized by reducing antimicrobial exposure in patients is attractive. However, when clinicians treating critically ill patients with polymicrobial infection, decision to de-escalate is not so straightforward and often it is a tricky decision. Simply because the margin of error in ill patients is not wide, patients may deteriorate rapidly and fastidious organisms are often difficult to culture and identified. Anaerobic microorganism may not grow if sample collection, transport medium, and culture techniques are incorrect.

As it stands, surgeons managing intensive care patients are facing tremendous challenges in combating sepsis in critically ill patients. Moreover, current evidence on the safety and effectiveness of antimicrobial de-escalation in severe sepsis and septic shock patients is feeble and inadequate. Consensus on de-escalation in this group of patients

has yet to be reached. Existing data and literature have varied definition and elements on de-escalation strategy. More studies with consistency in definition and defined elements of de-escalation must be aligned to polymicrobial infection to answer the question. Elements such as when to switch from combination therapy to monotherapy, cessation of vancomycin, cessation of antimicrobial therapy, and using consistent and reliable end-points measures are equally helpful for studies comparison.

Data are available on bio-marker guiding antimicrobial therapy for pneumonia but not for polymicrobial infection in sick surgical patients. The search for bio-markers to guide de-escalation in surgical patients with polymicrobial infections should be one of our investigators agenda. Given the current situation, surgeons have to exercise their complex clinical judgment by weighing all the relevant information ranging from the possible pathogenic microorganisms with the likelihood of bacteria that are not reported in the culture as well, the antibiogram of the local institutions, dosage and frequency adjustment according to patients' physiology and pathology, the risks and benefits of combination therapy versus monotherapy and short versus extended duration therapy. Whether pathogen-based approach is more superior to severity-based approach and risk factors based approach in de-escalation is still every clinician conundrum. More randomized controlled trials are needed to address many of these unanswered questions before surgeons will know whether they are truly treating the patients rather than merely treating themselves.

Although the concept of de-escalation of antimicrobials in medical practice has gained strong support with current data and clinical evidence, the actual recipes as to when to de-escalate, how best to do it, mono or double therapy, duration of therapy remain elusive. This is even more so for polymicrobial infection in surgical patients. In the context of downsizing to fewer targeted and adequate antimicrobials, the pivotal elements in antimicrobial de-escalation are use of targeted antimicrobials in adequate dosage, reducing the duration of therapy, and stop as soon as bacterial eradication is evidenced. Even in the mid of its limitation and unresolved issues, surgeons are mindful that timely, appropriate, and adequate use of antimicrobials has significant impact on the morbidity and mortality of their surgical patients at hands, and de-escalation strategy assures excellent surgical outcomes in the future through the preservation of the antimicrobial effectiveness and retardation of bacterial resistance by limiting the antimicrobial exposure. The recommendation for de-escalation

of antimicrobial therapy remains compelling even though good-quality randomized control trials on this issue are lacking.

Newer Antimicrobial Agents

Ceftolozane/tazobactamis a novel second-generation cephalosporin β-lactam/β-lactamase combination antibiotic that retains activity against ESBL-producing *Enterobacteriaceae*. Ceftazidime/avibactam is another recently approved second-generation β-lactam/β-lactamase combination antibiotic with the added advantage of having activity against multidrug resistant *Pseudomonas aeruginosa*. Ceftazidime/avibactam plus metronidazole was also noninferior to meropenem in the treatment of complicated intra-abdominal infections. Efficacy was similar against infections caused by ceftazidime-susceptible and ceftazidime-resistant pathogens. The safety profile of ceftazidime-avibactam plus metronidazole was consistent with that previously observed with ceftazidime alone.

Both ceftolozane/tazobactam and ceftazidime/avibactam have suboptimal activity against *Bacteroides* species and, therefore, should be prescribed together with metronidazole for complicated intraabdominal infections. Baseline resistance to these novel antibiotics is present, and testing for sensitivity is therefore recommended. These antibiotics should be reserved for infections caused by known or strongly suspected gram-negative multidrug resistant organisms as widespread use will likely lead quickly to the development of further resistance.

Surgical Interventions and Nonoperative Procedures

Source control can be achieved either by radiologic-guided percutaneous drainage, endoscopic procedures, laparoscopic operations, or surgical intervention. With the availability of interventional radiology expertise, percutaneous drainage in selected patients is effective with cure rates of 62% to 91%. It also has acceptable morbidity and mortality rates. The technique in percutaneous drainage is dictated by the site and size of the abscess. In general, extraperitoneal approach is preferred to transperitoneal approach in accessing the abscess cavity for drainage because it minimizes the risk of peritoneum contamination and peritonitis. While localized intra-abdominal and liver abscess are indications for percutaneous drainage, the source of the infection must be identified. Acute cholangitis is no longer a surgical emergency as the biliary tract could be successfully decompressed and drained by endoscopic or radiology-guided percutaneous techniques.

Despite advances in nonoperative procedures, surgery remains an indispensable therapeutic armamentarium in the management of intra-abdominal source of infections.

With the availability of high-resolution imaging, the source of infection is rarely misdiagnosed. In situation, when the diagnosis on the source of infection is dubious, diagnostic laparoscopy may assist in determining the etiology of peritonitis, for instance, the uncertainty of right-lower-quadrant pathology in female patients. At the present day, exploratory laparotomy can rarely be justified in the management of complicated intra-abdominal infection.

Decision on the choice of procedure is influenced by a multitude of factors, ranging from anatomical source of infection, extent of peritoneal contamination and inflammation, metabolic response to sepsis to patient's comorbidity and general conditions. Surgical interventions to control the source of infection vary from debridement of necrotic tissue and simple repair of perforated viscus to resection of infected organ, bowel resection of ischemic gut or traumatic perforations. In general, the three fundamental principles are (1) drainage of abscesses; (2) debridement of nonviable or infected tissues; and (3) restoring physiologic function and anatomy, managing anatomic abnormality that causes the ongoing microbial contamination. Common conditions encountered in clinical practice that may require surgical interventions are colonic diverticular perforation, gastroduodenal perforation, acute appendicitis, acute emphysematous cholecystitis, acute perforated diverticulitis, peritonitis following blunt and penetrating abdominal injury.

Timing of Source of Control

To optimize clinical outcome, the source of infection must be addressed timely. Timing is issue. Delayed intervention is as unsatisfactory as inadequate drainage of the source of infection. The surgical maxim of "doing too little too early and doing too much too late" should be borne in mind. Timing and adequacy of source control are important prognostic factors in the management of intra-abdominal infections. Therefore, adequate and timely intervention has a positive impact on the outcome and conversely delayed in source control correlates with poor outcomes.

Adequacy of Source Control

The definition of adequacy of source control is based on the degree of

certainty of source control or the temporal relationship between the presumed acquisition of source control and the subsequent therapeutic intervention. For abdominal infections, adequate source control means drainage, lavage, repair of perforation, resection, restoring bowel continuity, exteriorization and closure of abdomen. Therapeutic antimicrobial therapy works best when the source of infection is adequately controlled by these interventions.

Adequacy of source control is an independent predictor of good clinical outcome. If clinical improvement is not witnessed within 24 to 72 hours following source control, inadequacy of drainage should be suspected. Search for extra-abdominal and intra-abdominal infection is warranted when patients have persistent signs of infection or fail to improve clinically. The principal reason for inadequate source control is misdiagnosis of the magnitude, extent, complexity, location of the abscess, or source of infection. Patients initially have percutaneous drainage and do not improve clinically should be reimaged to reevaluate the adequacy of source control. CT scan of the abdomen and tube sinogram to delineate the size of the residual source of infection may be indicated. Laparoscopy or laparotomy may be indicated to look for a surgically correctable intra-abdominal disorder.

In stable patients, second attempt with percutaneous drainage may be appropriate unless it is judged to be ineffective and where surgical intervention is mandated. For those patients who deteriorate after the initial percutaneous drainage, operative intervention should be considered and carried out promptly if indicated. Any delay in making the decision to intervene early will result increase the morbidity and mortality.

Prognosis and Clinical Outcome

Early prognostic evaluation of complicated intra-abdominal infections is important to assess the severity and the prognosis of the disease. Prognostic factors in patients with complicated intra-abdominal sepsis include advanced age, poor nutrition, comorbidities, immune-suppression, generalized peritonitis, septicemic shock, inadequate source control, multiorgan failures, prolonged ICU and hospital stays, and nosocomial infection.

Scoring systems have been used to predict the clinical outcome more precisely. These scoring systems generally do not guide clinical decision in managing the patients; however, they provide useful data for quality and

audit reviews as well as standardized score for inter-hospitals comparison.

Currently, there are broadly two groups of scoring systems—the disease-independent scores and peritonitis-specific scores for evaluation of critically ill patients requiring intensive medical care.

An example of disease-independent score is APACHE II. Mannheim peritonitis index (MPI) and Simplified Acute Physiology Score (SAPS II) are examples of peritonitis-specific score. The limitation of APACHE II in peritonitis evaluation is that it does not take into consideration the interventions that might significantly alter many of the physiologic variables and consequently the final score. The MPI, on the other hand, is specific for peritonitis evaluation. Moreover, its calculation is straightforward and the reliability in risk evaluation and classification for patients with peritonitis has been validated by Billing et al.

Skin and Soft Tissue Infection (SSTI)

SSTIs are among the most common bacterial infections in humans. They represent one of the most common indications for antibiotic treatment. SSTIs have a broad range of etiology, clinical manifestation, and severity. At one end of the spectrum, the outcome may be spontaneous resolution without antibiotics, but at the other end, it may present with sepsis with lethal outcome.

SSTI is one of the frequent focus for severe sepsis or septic shock, after pneumonia and abdominal infections. US Food and Drug Administration's (FDA) classification differentiates between uncomplicated and complicated SSTI according to the extent of infection. Classes 2, 3, and 4 are classified as complicated SSTI (Table 7.12). The complicated group is characterized by either deep soft tissue involvement with signs of systemic sepsis, severe immunosuppression in patients, or the necessity for major surgical intervention.

Useful classifications are those that differentiate SSTI according to urgency of surgical intervention. Three categories can be differentiated: infections treated conservatively (e.g., erysipelas), infections with the need for surgical intervention (e.g., infective diabetic foot), and severe SSTIs that require urgent surgery (e.g., necrotizing fasciitis).

TABLE 7.12 Classification of Skin and Soft-Tissue Infections

Class	Clinical Presentation of Patient With Skin Infection
Class 1	Localized infection, no signs or symptoms of systemic toxicity; afebrile and healthy, other than cellulitis
Class 2	Febrile and ill-appearing
Class 3	Toxic appearance or at least one unstable comorbidity
Class 4	Sepsis syndrome or life-threatening infection

Complicated Skin and Soft Tissue Infections (cSSTI)

The FDA defines the term "complicated skin and skin structure infections" according to the following three criteria. First, advanced infection that requires an extensive surgical intervention such as debridement on devitalized tissue, abscess drainage, removal of foreign bodies that facilitate infection, and operative fascia incision. Second, the infection process shows evidence of deeper soft tissue, fascia or muscle involvement. Third, severe concomitant systemic and/or localized disease is present that prevents an adequate response to therapy. These diseases are, among others, diabetes mellitus, bacteremia, cellulitis with more than 3% of the body surface area involvement, steroid therapy more than 7.5 mg per day prednisolone equivalent, neutropenia (granulocytes $<500/mm^3$), Child-Pugh classification B or C liver cirrhosis, burns more than 10% body surface area, local or systemic radiation therapy, history of alcoholism more than 6 months, orthotopic organ transplant recipients, malnutrition, and immunosuppressive therapy.

Common cSSTIs are listed in Table 7.13. Many of the deep-seated subcutaneous tissue infections are classified as complicated SSTIs, such as suppurative hidradenitis, deep or extensive subcutaneous abscesses, furuncle or carbuncle, acne inversa, anal abscess, iatrogenic injection abscesses, inguinal injection abscesses in intravenous drug abusers, SSIs, self-inflicted injury, diabetic foot syndrome, necrotizing fasciitis types I and II, clostridial myonecrosis, scalp phlegmon, pressure or decubitus ulcer, and radiation damage.

TABLE 7.13 Common Complicated Skin and Soft-Tissue Infections

Secondary infections of diseased skin
Acute wound infections (traumatic, bite-related, postoperative)
Chronic wound infections (diabetic foot infections, venous stasis ulcers, pressure sores)
Perianal cellulitis with or without abscess
Deeper soft tissue infections, or those that require surgical intervention
Infected ulcers, burns, major abscesses, and superficial infections or abscesses with a high risk of an anaerobic or gram-negative pathogen

Microbiology in cSSTIs

The two most pathogenic agents in SSTI are *S. aureus* and Group A *Streptococci.* Besides these gram-positive bacteria, SSTI can be caused by a multitude of other bacterial agents, including gram-negative enterococci and anaerobic bacteria with necrotizing, gangrenous infections, and those close to the trunk as well as bite injuries. More than half of all SSTIs were caused by staphylococcal or streptococcal species.

The bacteriology ranges from garden variety bacteria to resistant bacteria, which primarily are MRSA, VRE, ESBL-producing bacteria, and carbapenem-resistant strains. Similar to complicated intra-abdominal infection, in the recent decades, an increase trend in infections caused by multidrug resistant pathogens has been observed in both hospital- and community-acquired complicated skin and soft-tissue infections.

The causative pathogens associated with SSIs in US hospitals have changed over the past two decades. Importantly, community-acquired MRSA (CA-MRSA) is frequently isolated in cSSTI and necrotizing STI. Such epidemiologic shift toward drug-resistant pathogens in the context of limited number of currently available effective antimicrobial agents poses significant problems in managing seriously ill patients inflicted with complicated SSTI.

Antimicrobial Therapy

The therapeutic recommendations for cSSTIs are summarized in Table 7.14. We will now briefly discuss recently approved antibiotics useful in the treatment of such infections. Oritavancin is a long-acting antibiotic with activity against MRSA. It lends itself to the treatment of cSSTIs in the outpatient setting as only one single infusion is necessary for treatment. Telavancin is a semisynthetic, lipoglycopeptide antibiotic with similar efficacy to vancomycin. It also has a similar side effect profile with a comparable to possibly higher risk of nephrotoxicity. Its advantage lies in the once-daily dosing, which may simplify outpatient therapy in selected patients. Lastly, tedizolid is an oxazolidinone antibiotic similar to linezolid in its activity and efficacy. Advantages are provided by its once-daily dosing and by being a much weaker inhibitor of monoamine oxidase compared to linezolid. This probably confers a substantially lower risk of serotonin syndrome in patients using selective serotonin reuptake inhibitors (SSRIs).

TABLE 7.14 Recommendation for Antimicrobial Therapy for cSSTI

	Nonpurulent	Purulent
	Necrotizing Infection/ Cellulitis/Erisepelas	Furuncle/Carbuncle/Abscess
MILD	Oral Penicillin VK Oral Cephalosporin Oral Docloxacillin Oral Clindamycin	Surgical Drainage ■ Culture and sensitivity of CA-MRSA suspected
MODERATE	IV Penicillin IV Ceftriaxone IV Cefazolin IV Clindamycin	Surgical Drainage + Culture & Sensitivity *Empirical Therapy* ■ TMP/SMX ■ Doxycycline *Definitive Therapy* 1. MRSA ■ TMP/SMX ■ Tedizolid 2. MSSA ■ Doxycycline
SEVERE	Emergent Surgical Debridement Nonnecrotizing Infection *Empirical Therapy* ■ Vancomycin ■ Pip/Tazo *Definitive Therapy* **1. Monomicrobial** ■ *S. pyogenes* & *Clostridial*spp – Penicillin + Clindamycin ■ Vibrio vulnificus – Doxycycline + Ceftazidime ■ Aeromonas – Doxycycline + Ciprofloxacin **2. Polymicrobial** ■ Pip/Tao + Vancomycin	Surgical Drainage + Culture & Sensitivity *Empirical Therapy* ■ Vancomycin ■ Daptomycin ■ Linezolid ■ Tedizolid ■ Telavancin ■ Ceftaroline *Definitive Therapy* **1. MRSA** ■ Vancomycin ■ Daptomycin ■ Linezolid ■ Tedizolid ■ Telavancin ■ Oritavancin ■ Ceftaroline **2. MSSA** ■ Nafcillin ■ Clindamycin ■ Cefazolin

Principles of Surgical Intervention

Surgical debridement is the gold standard in managing cSSTI because it can reduce the risk of wound complications and facilitate the natural healing process. It is one of the central strategies in the management of cSSTIs. Aggressive surgical debridement is crucial to prevent progressive tissue destruction while repetitive surgical debridement may be indicated

to minimize the risk of mortality or limb amputation. The rationale for debridement is that by removing the dead tissue, which acts as a nidus of infection and also a rich culture medium for colonized bacteria to multiply, particularly anaerobic *Bacteroides* species, the source of infection is controlled, conditions for wound healing are optimized, and the risk of sepsis is minimized. Furthermore, most cSSTI wounds are difficult to assess unless all the devitalized tissue is removed to reveal the healthy underneath anatomy.

The surgical principle in debridement is that all gangrenous, necrotic, ischemic and devitalized tissues must be debrided. Care should be exercised to handle the tissue gently without causing unnecessary tissue devascularization and injury to the noninfected vital tissues or anatomical structures. Debride till healthy and well-vascularized tissue is witnessed. In situation of uncertainly of the extent of debridement, iterative surgical debridement to allow the tissue to demarcate itself is commonly practiced.

Necrotizing Soft Tissue Infection (STI)

Necrotizing STI is a life-threatening and rapidly progressive soft tissue infection caused by usually gas-forming bacteria. It carries a high mortality about 25%. The infection involves the superficial or deep fascia and extends rapidly along subcutaneous tissue planes. Necrosis of the subcutaneous tissues is common in necrotizing fasciitis, due to thrombosis of dermal vessels following inflammation of the deep fascia. The skin and underlying muscles are relatively spared. Those patients with myonecrosis, the prognosis is significantly worse.

Clinical presentation may be nonspecific. Pain may be out of proportion to the clinical findings. Clinical signs, if present, are diffuse erythema, marked edema, and livid geographical lesions with central necrosis. Cutaneous findings may be lacking. For this reason, misdiagnosis and delayed diagnosis resulting in spreading infection with subsequent septic complications are not uncommon. To the unwary, the extent of infection and severity may be initially unrecognized. High index of suspicion and clinical vigilance are needed to avoid misdiagnosing this challenging clinical entity late. Ecchymosis and blistering of the skin with and without tense and tender soft tissues may be the only early signs. Clear clinical anatomical boundaries or limit of infection in necrotizing fasciitis is often absence. Although radiology using CT or MRI may expedite making the diagnosis, frequently, the diagnosis is only confirmed following surgical

debridement. Whenever the diagnosis is dubious and clinical suspicion is high, surgical exploration or an incision over the suspected site in the operation theatre is indicated.

Early diagnosis followed by prompt surgical debridement, appropriate intravenous antibiotics, intensive care medical support, and analgesia are the cornerstones of effective therapy. Necrotizing fasciitis is a surgical emergency. Reiterative surgical debridement at 24 hourly or shorter interval is usually indicated to achieve the source control. Occasionally, amputation may be necessary to save life. In some cases, useful adjunctive therapies such as hyperbaric oxygen therapy, negative pressure dressing, and intravenous immunoglobulins may be considered.

Microbiologically, polymicrobial organisms involving *Staphylococcus* sp., *Streptococcus* sp., and anaerobes are the commonest. MRSA should be suspected in patients with HAI. a-hemolytic *Streptococcus pyogenes* is cultured in some patients with necrotizing STI. Other microorganisms responsible for necrotizing STI are clostridium, vibrio, and fungus.

Fournier Gangrene

Fournier gangrene is a form of necrotizing fasciitis. It was first described by the French Jean Alfred Fournier in 1883. It occurs in the fascial compartments of the pelvis, Colles', Dartos', and Buck's fascia, by polymicrobial organisms from the urogenital tract and perineal infections. It may spread to the penis and scrotum via Buck's and Dartos' fascii, or to the anterior abdominal wall via Scarpa fascia, or vice versa. The spread and progress of the infection are limited by the anatomy of Colles' fascia that is attached to the perineal body and urogenital diaphragm posteriorly and to the pubic rami laterally. Testicular involvement is rare because of the independent blood supply directly from the aorta. The common causative microorganisms are *Streptococcal* species, *Staphylococcal* species, *Enterobacteriaceae*, anaerobic organisms, and fungi.

cSSTI in Immunosuppressed Patients

Managing SSTIs in patients with immunosuppression called for special attention. Unusual and diverse pathogens, including fungi such as cryptococcosis or histoplasmosis, have to be considered. Infections often progress rapidly to become life-threatening. Establishing a diagnosis and performing susceptibility testing are crucial because empiric treatment regime may be ineffective due to drug resistance among gram-positive and

gram-negative bacteria in these patients.

Acute Bacterial Skin and Skin Structure Infection (ABSSSI)

An ABSSSI is defined as bacterial infection of the skin with a lesion size area of at least 75 $cm^{2.}$ It is measured by area of redness, edema, or induration. The minimum area of involvement is 75 cm^2. The quantitative size is chosen to select patients with acute bacterial skin infections for which a reliable control drug treatment effect can be estimated. ABSSSIs are common and encompass a variety of disease presentations and severity. It may be complicated or uncomplicated. With this definition, minor cutaneous abscess (<75 cm^2) can be distinguished from major cutaneous abscess (>75 cm^2), which is defined as an infection characterized by collection of pus within the dermis or deeper that is accompanied by redness, edema and /or induration.

The FDA classifies the uncomplicated category to include simple abscesses, impetiginous lesions, furuncles, and cellulitis. These are mainly caused by *S. aureus* and *S. pyogenes.* The complicated category includes infections either involving deeper soft tissue or requiring significant surgical intervention, such as infected ulcers, burns, and major abscesses or a significant underlying disease state that complicates the response to treatment. Superficial infections or abscesses in an anatomical site, such as the rectal area, where the risk of anaerobic or gram-negative pathogen involvement is higher, also should be considered complicated infections.

The mainstays of treatment continue to be appropriate antimicrobial therapy combined with prompt surgical intervention.

CONCLUSION

There have been important changes in the epidemiology of SSI in the United States and elsewhere in the world since the publication of the previous SSI prevention guideline in 1999. These include changes in risk factors for SSI, particularly the increased resistance and virulence of infecting organisms and the increasing use of surgical procedures in vulnerable patients at risk for infections due to underlying diseases such as obesity and diabetes. There have also been new insights into microbial mechanisms of infection as well as the mechanisms by which some disease processes lead to increased rates of infection. These developments warrant review and revision of previous recommendations for the prevention of SSI.

Antibiotics Stewardship Program has transformed the entire health care landscape, changing once opinion-based practice to evidence-based practice with the primary goal of delivery outcome-based health care end points. Improving the use of antibiotics and managing the microorganism ecology through antibiotics stewardship program are a common goal shared by both the surgical and medical disciplines. We all have the same mission.

In treating surgical infection, the fundamental principles revolve around timely and correct diagnosis, timely administration of appropriate and adequate antimicrobial therapy, and adequate and timely source control of the infection in conjunction with physiologic support. Sound knowledge, skills and experience in critical care medicine, diagnostic and interventional radiology, endoscopy, surgery, infectology medicine, antimicrobial pharmacology, and therapy are needed to deliver excellent outcomes to each patient with surgical infection.

EDITOR'S COMMENT

The authors present an excellent overview of contemporary antibiotic prophylaxis and treatment of surgical infection. I think the most important points are:

1. Methods of prevention of SSI
2. The importance of an effective antibiotic stewardship program.
3. Antibiotic selection
4. Intra-abdominal infection and source control
5. Complicated skin and soft tissue infection

Methods of SSI Prevention

Multiple recommendations exist for the prevention of SSI. These are of various evidential strength. Table 7.7 comparing CDC and WHO guidelines is very helpful. First there is conditional evidence of moderate quality that preoperative bathing can reduce SSI. Either a plain soap or an antimicrobial soap can be used for this purpose. Although some centers use CHG-impregnated cloths for the purpose of reducing SSI, it is supported by only low-quality evidence. In addition, there is strong evidence that supports patients undergoing cardiothoracic procedures and orthopedic surgery with known nasal carriage of *S. aureus* should receive perioperative intranasal applications of mupirocin 2% ointment with or without a combination of CHG body wash. In our institution we recommend preoperative nasal screening cultures for *S. aureus* (MRSA and MSSA) be collected on patients undergoing the following high-risk surgeries:

- All Cardiothoracic surgeries (CABG, valves, VADs, heart/lung transplants, etc.)
- Craniotomy, Laminectomy, Spinal Fusion, VP Shunt Placement (not for angiograms)
- Total Hip, Total Knee, and Total Shoulder Replacements, Geriatric Fractures

These cultures should be obtained not less than 3 days or more than 4 weeks prior to the operation. If MSSA or MRSA positive, we recommend starting mupirocin 2% nasal ointment to both nares BID × 5 days (total 10 doses). Treatment should be started at least 2 days before surgery or as soon as possible if surgery is imminent and continued in the postoperative period until treatment is complete. In addition, if MRSA is positive then contact isolation should be ordered. If MSSA is identified on nasal screening then Cefazolin 2 g is recommended preoperatively and if MRSA is identified then we recommend adding vancomycin to the prophylactic regimen.

An area of debate is whether there should be changes in your standard protocols if your hospital has a high prevalence (>10%) of extended spectrum beta lactamase producing bacteria. There is a lack of strong evidence to currently support any medication in prophylactic regimens and hence this is not recommended at this point in time.

The timing of administration of antibiotics prior to the surgical incision has strong supporting evidence. The antibiotic should be administered within 120 minutes of the incision. In our institution we recommend starting prophylactic antibiotics such as cefazolin within 60 minutes prior to incision and vancomycin, Cipro, and fluconazole 60 to 120 minutes prior to incision.

There is no strong evidence to support antibiotic irrigation, application of antimicrobial agents to incisions, application of autologous platelet-rich plasma, the use of antibiotic coated sutures or antimicrobial dressings.

There is evidence to support glycemic control, normothermia in prevention of infection. The data for increased oxygenation administration is less clear.

Antibiotic Stewardship

The loss of effective antibiotics profoundly impacts the practice of surgery. The days of being able to count on antibiotic prophylaxis to prevent postoperative infections are quickly disappearing due to the emergence of multidrug-resistant organisms. Antibiotic resistance limits the efficacy of antibiotic prophylaxis thereby leading to worse outcomes in surgical patients. A 30% reduction in the efficacy of antibiotic prophylaxis would result in 120,000 additional infections per year in the United States and 6,300 infection-related deaths. This in part has led to the development of antimicrobial stewardship programs.

Antimicrobial stewardship is a coordinated multidisciplinary program that promotes the appropriate use of antimicrobials (including antibiotics), improves patient outcomes, reduces microbial resistance, and decreases the spread of infections caused by multidrug-resistant organisms. The multidisciplinary team consisting of infectious diseases (ID) physicians, pharmacists, microbiologists, epidemiologists, and frequently a data manager.

Initially, antibiotic stewardship was more focused on cost savings. Physicians and surgeons responded negatively to that, because they often felt it was best to give patients the newest medication. While these programs do save hospitals' money, their most important benefit is that they improve patient outcomes and reduce the emergence of antibiotic resistance. More and more hospitals have developed these programs. The goal is to ensure the selection of the right antibiotic, at the right dose, for the right duration in order to cure infection while minimizing toxicity and emergence of resistance.

Antibiotic Selection

Appropriate antibiotic selection is critical to the treatment of infection. Hospital antibiograms are commonly used to help guide empiric antimicrobial treatment and are an important component of detecting and monitoring trends in antimicrobial resistance. Every surgeon should be familiar with the antibiogram for their unit and hospital. The hospital antibiogram is a periodic summary of antimicrobial susceptibilities of local bacterial isolates submitted to the hospital's clinical microbiology laboratory. Antibiograms are often used to assess local susceptibility rates, as an aid in selecting empiric antibiotic therapy, and in monitoring resistance trends over time within an institution. These can also be used to compare susceptibility rates across institutions and track resistance trends. Institutions may have developed antibiograms for specific units such as the intensive care unit or surgical services. To be effective antibiograms must be constructed using standardized methods that allow inter- and intrahospital comparisons. Antibiograms have several limitations, such as their inability to track emergence of resistance during therapy. The antibiogram can serve as a valuable tool in guiding antimicrobial therapy, but other patient factors, such as previous infection history and antibiotic use, also need to be considered.

In the initial selection of antibiotics it is helpful for the surgeon to use an antibiogram. Once cultures and sensitivities are determined the antibiotics can

be changed to a more specific and potentially more effective treatment.

Intra-Abdominal Infection and Source Control

The cornerstones of successful treatment of intra-abdominal infection are controlling the source of the infection and antibiotic therapy. In the treatment of complicated intra-abdominal infections, assessment of adequacy of the initial surgical approach to the management of the infection is of primary importance in determining outcome. Antibiotic therapy is not expected to adequately treat the infection if the surgical procedure was inadequate with respect to controlling the source of the infection. Both the timing and adequacy of source control are important. The most common source of infection in community-acquired intra-abdominal infections is the appendix, followed by the colon, and then the stomach. Anastomotic breakdown is a key cause in the postoperative patient.

Ultrasound and CT-guided percutaneous drainage of abdominal and extraperitoneal abscesses in selected patients are safe and effective. Numerous studies in the surgery and radiology literature have documented the effectiveness of percutaneous drainage in selected patients, with cure rates of 62% to 91% and with morbidity and mortality rates equivalent to those of surgical drainage. The principal cause for failure of percutaneous drainage however is misdiagnosis of the magnitude, extent, complexity, and location of the abscess. In these situations surgical exploration may be warranted. Surgical source control entails resection or suture of a diseased or perforated viscus (e.g., perorated duodenal ulcer), removal of the infected organ (e.g., appendix, gall bladder, sigmoid colon), debridement of necrotic tissue, resection of ischemic bowel and repair/resection of traumatic perforations. A laparotomy is best performed through a midline incision.

Complicated Skin and Soft Tissue Infections

The key to successful treatment is early diagnosis, debridement, and appropriate antibiotic therapy. Cellulitis can be deceptive and want appear as a superficial soft tissue infection may in fact be a deep infection and an early sign of necrotizing fasciitis. A high index of suspicion and early axial imaging with CT and in some cases MRI may be helpful. Source control is critical and may require multiple procedures for successful debridement. Antibiotic coverage should be broad spectrum and include aerobic and anaerobic coverage. As streptococcal species play a major role in necrotizing fasciitis penicillin or similar medications are important to consider. Clearly therapy should be guided by cultures.

Biomarkers to Monitor Antibiotic Therapy

It is important to continue antibiotic treatment for an appropriate duration. Making this decision is not easy. Clinical response with resolution of fever, tachycardia, and local signs of pain and redness are good indicators of

successful treatment as well as normalization of the white blood cell count. These indicators often lag behind other biomarkers or be less accurate than other biomarkers in determining treatment duration.

Over the last decade, the biomarkers and C-reactive protein (CRP) and procalcitonin (PCL) have gained interest in sepsis research to enhance diagnosis as well as monitoring and guiding antibiotic therapy. In particular both of these biomarkers may help determine when it is appropriate to discontinue antibiotic. Whether these markers are better predictors of successful treatment than the white blood cell count or clinical to monitor antibiotic therapy has not been determined with certainty. However, several randomized controlled trials (RCTs) have shown the safety and efficacy of measuring CRP and procalcitonin levels to guide discontinuation of antibiotic therapy in patients with severe sepsis or septic shock.

CRP is a general acute-phase reactant protein that rises in concentration up to 1,000-fold in the blood in response to inflammation and infection. Studies have shown CRP to be highly sensitive and also highly specific for infection. However, it is unclear if CRP can be used to distinguish gram-positive from gram-negative bacterial infections. CRP has also been studied as a diagnostic marker for other illnesses. A recent study on community-acquired pneumonia showed CRP as a prognostic marker in determining the severity of community-acquired pneumonia and the need for hospitalization when using a value of 110 mg/L. In some studies there is evidence that antibiotics may be monitored with CRP levels. However, the levels and decision points are highly variable in the literature. There is some evidence that a CRP level less than 60 mg/L when combined with other clinical indicators can be used as a point to determine when antibiotics can be discontinued or switched to an oral route.

Procalcitonin (PCT), a precursor to the hormone calcitonin, is another candidate biomarker for bacterial infection. It is reported to be present at very low concentrations of 0.033 ng/mL in the serum of healthy individuals and is known to increase by up to 1,000-fold under inflammatory conditions. It is reported to rise within 2 to 4 hours of infection and peak at 6 to 8 hours. Persistent elevated levels are indicative of persistent infection or sepsis. Procalcitonin has been shown to have high diagnostic accuracy for bacterial infection. Similar to the studies on CRP, there is variation in sensitivity and specificity. However, as a biomarker for bacterial infection, most studies find PCT to be a useful and accurate biomarker and more useful than other common inflammatory markers. Indeed it is an accurate biomarker for anastomotic leak in colon surgery. Several studies have reported significantly elevated levels of PCT in patients with sepsis compared with those without sepsis. Studies have also reported PCT being used as a prognostic marker indicating that levels of PCT are a good indicator of response to treatment severity of sepsis and mortality from sepsis. PCT has demonstrated utility in the risk stratification of patients with potential life-threatening bacterial infections. In addition, PCT has been documented as having a role in reducing the rate of unnecessary antibiotics

while positively impacting antibiotic resistance rates and cost savings. With greater emphasis on antimicrobial stewardship and cost it behooves surgeons to seek improved methods of monitoring response to antibiotic therapy that is likely to include biomarkers.

8 Multiple Organ Dysfunction Syndrome: Prevention and Clinical Management

David J. Dries

ETIOLOGY AND PATHOPHYSIOLOGY

Evolution of a Concept

Multiple organ failure (MOF) emerged in the 1970s as a result of advances in resuscitation and intensive care unit (ICU) technology resulting in survival of single organ failure. The epidemiology of multiple organ failure continues to change as management strategies evolve. In the late 1970s, reports by a variety of surgical investigators promoted the belief that multiple organ failure resulted from uncontrolled infection and research was focused on infection-driven multiple organ failure. Throughout the 1980s, infection became less common due to advances in surgery and intensive care management, including initial care for abdominal trauma, better use of perioperative antibiotics, and earlier diagnosis of postoperative intra-abdominal infection with drainage via computerized tomography.

At the same time, reports from Europe demonstrated that multiple organ failure could occur after blunt trauma without infection. Initially, this phenomenon was termed sepsis syndrome because patients appeared to be septic but had no obvious source of infection. Etiology of this sepsis syndrome remained unclear. As shock was a frequent early event in these patients, ischemia with reperfusion was an attractive mechanistic explanation. Other studies implicated the gut as the source of bacteria or bacterial products that produced the sepsis syndrome. Trials testing selective gut decontamination and early enteral nutrition found decreased rates of nosocomial infection with gut-directed therapy. This clinical work was supported by experimental data favoring bacterial translocation as a unifying mechanism characterizing noninfection-induced multiple organ failure.

By the mid-1990s, sepsis syndrome had evolved into the systemic inflammatory response syndrome (SIRS). SIRS was presumed to be inherently beneficial; however, if exaggerated, SIRS could progress to multiple organ failure independent of infection. More recent research suggests that SIRS in the absence of obvious microbial infection represents host response to a noninfectious insult and tissue injury with the release of endogenous mediators that serve as “danger signals.” Tissue damage, per se, releases molecules that can stimulate innate immunity through sensing systems including toll-like receptors. Noninfectious insults can elicit exaggerated inflammation through the same pathways used by microbial pathogens and produce similar SIRS.

Additional work in the 1990s revealed that multiple organ failure occurred early or late in the course of patients in the surgical intensive care unit (SICU). Two different patterns of SIRS induced early multiple organ failure. In one model, a massive initial insult culminated in fulminant SIRS and multiple organ failure, while in a “two-hit” setting, resuscitating severe injury with SIRS followed by an early second inflammatory insult (blood transfusion, infection, aspiration, orthopedic intervention) amplified SIRS to induce multiple organ failure. This was believed to be due to priming and activation of the innate immune response (neutrophil-medicated). In this two-hit model, SIRS was followed by delayed immunosuppression associated with late infection that appeared to precipitate later multiple organ failure (7 to 10 days).

Research after the turn of the millennium revealed that many interventions in the critical care unit (high tidal volume ventilation, large volume crystalloid resuscitation, liberal use of blood products, early parenteral nutrition, intermittent hemodialysis) were actually promoting nosocomial infection and late multiple organ failure. Over the last decade, with more consistent delivery of ICU care designed to minimize deleterious practices, abdominal compartment syndrome has become less frequent, death from traumatic shock-induced multiple organ failure has decreased substantially, and late multiple organ failure following trauma is much less common. Management strategies often require implementation of evidence-based operating procedures such as those demonstrated by the recent “Glue Grant” cohort, the Surviving Sepsis Campaign, and the ARDSNet. Despite the release of multicenter trials and generation of treatment strategies consistent with the weight of recent experimental work, low compliance with accepted treatment approaches is often noted

and outcomes are enhanced by strategies that improve compliance. Glue Grant participants found modest compliance with consensus protocols to be associated with a dramatic reduction in overall mortality from 22% before to 11% after protocol implementation.

A continuing problem is a large number of patients who linger in the critical care unit with manageable organ dysfunction but do not meet established criteria for late multiple organ failure. Clinical course of these patients is characterized by ongoing catabolism with poor nutrition status, inadequate wound healing, immunosuppression, and recurrent infection. These patients may be discharged to long-term care facilities but often develop secondary complications and are less likely to rehabilitate and return to functional life. Clinical management of patients with persistent inflammation and immunosuppression as they progress toward indolent death is one of the important contemporary challenges in surgical critical care.

With identification of proinflammatory cytokines and tumor necrosis factor in the 1980s, death, particularly from sepsis, was presumed to be caused by early, overabundant inflammatory response. Overproduction of proinflammatory mediators with neutrophil activation, endothelial injury, and tissue damage caused early multiple organ failure and led to death. There have been over 100 clinical trials of agents designed to block early proinflammatory response. The only Food and Drug Administration (FDA)-approved agent for severe sepsis and septic shock (activated Protein C) was voluntarily withdrawn from the market in late 2011 after failure of postmarketing clinical trials to confirm earlier outcome benefit. Anti-inflammatory approaches to sepsis may have failed because of treatments initiated hours after the onset of symptoms missed the early inflammatory mediator release and initiation of inflammatory cascades. This has been demonstrated in studies of early coagulopathy after trauma where a failing organ system is demonstrated in the field after injury and before standard interventions and diagnostic testing are feasible. In addition, redundancy of early inflammation made success of monotherapies unlikely.

The importance of immunosuppression was identified by Bone and other workers and initially termed compensatory anti-inflammatory response syndrome (CARS). CARS was described as an anti-inflammatory response characterized by increased appearance of anti-inflammatory cytokines and cytokine antagonists. Appearance of anti-inflammatory

cytokines was thought to be delayed when compared with early proinflammatory mediators. In patients with critical illness, concentrations of anti-inflammatory mediators were found to be increased for days and weeks, whereas proinflammatory cytokines seemed to disappear. In the 1990s, it was recognized that patients with sepsis and injury exhibited not only ongoing inflammation but also multiple defects in adaptive immunity. Many workers demonstrated that critical illness victims could not mount delayed type hypersensitivity response to common antigens and that T-cell proliferation was suppressed. CARS came to describe all shared defects in adaptive immunity that followed trauma and sepsis, including decreased antigen presentation, macrophage paralysis, depressed T-cell proliferation, increased lymphocyte and dendritic cell apoptosis, and shifts in T-cell phenotypes.

New data have led to the revision of the early proinflammatory to later anti-inflammatory SIRS to CARS sequence (Fig. 8.1). More recent reports suggest that production of anti- and proinflammatory cytokines actually occurs simultaneously. These findings and other work from the Glue Grant have generated a model to replace the classic SIRS–CARS construct. Persistent inflammation is characterized by persistent acute phase response, neutrophilia, increased immature granulocyte count, anemia, lymphopenia, and tachycardia. Although these patients are immunosuppressed, inflammation is also ongoing. The inflammation–immunosuppression process consumes energy derived from fat and protein catabolism, which has long been recognized as a consequence of critical illness. Despite aggressive nutritional intervention, ongoing catabolism frequently results in the loss of lean body mass and decrease in functional status.

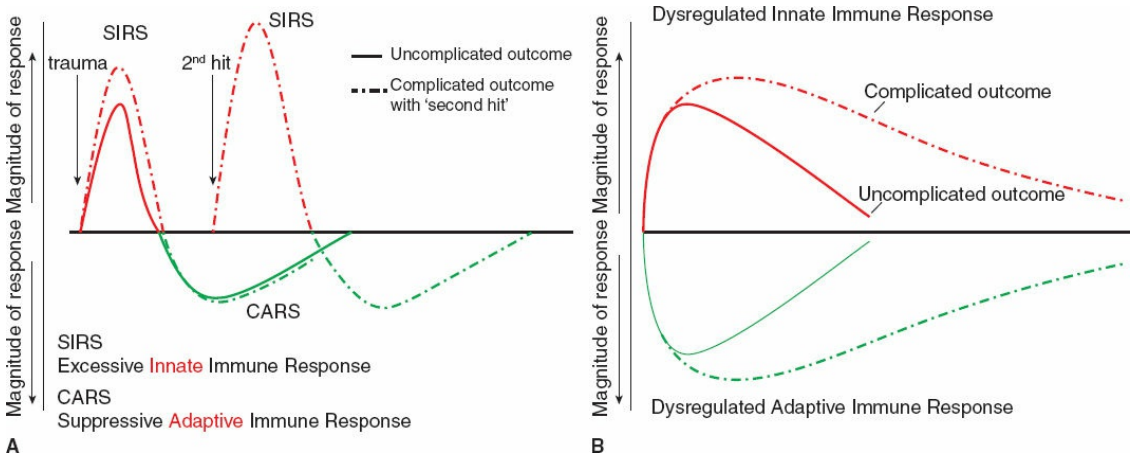

Figure 8.1. The genomic storm: refining the immune,

inflammatory paradigm in trauma. **A.** The current paradigm explains complications of severe injury as a result of excessive proinflammatory response (SIRS) followed temporally by CARS and suppression of adaptive immunity. A second hit phenomenon results from sequential insults, which lead to more severe recurrent SIRS and organ dysfunction. **B.** The proposed new paradigm involves simultaneous and rapid induction of innate (both proinflammatory and anti-inflammatory genes) and suppression of adaptive immunity genes. Complicated recoveries are delayed resulting in a prolonged dysregulated immune inflammatory state. (From Xiao W, Mindrinos MN, Seok J. et al. A genomic storm in critically injured humans. *J Exper Med* 2011;208(13):2581–90.)

The modern critical care unit effectively recognizes and manages the initial presentation of SIRS. Many patients survive their initial infection or emergency surgical insult only to encounter prolonged, complicated critical care stays. Contemporary emphasis has shifted beyond addressing exaggerated inflammation but identifying mechanisms of simultaneous immunosuppression, restoration of immune function, and, perhaps most important, prevention.

The Insult

Most clinicians know the innate immune response as inflammation. It is the first line of defence against pathogens that breech tissue barriers. Inflammation is nonspecific in that the response is the same for tissue injury and for the broad array of organisms that cause infection. Inflammation is distinct from adaptive immunity, but it is the first step in identification and processing of antigens that are critical for programming cellular and humoral responses.

The activation stimulus begins the inflammatory process (Fig. 8.2). Tissue injury, ischemia/reperfusion, and invasive infection result in disruption of both cells and the extracellular matrix. Micro- and macrocirculatory units are disrupted or thrombosed from injury or infection. Cellular contents are released, ischemic cells lose polarity and leak cytoplasmic proteins, collagen is exposed, and blood extravasates from the vascular compartment. The activation stimulus leads to important signals that initiate components of the inflammatory response. Tissue Factor, a protein residing on the surface of adventitial and perivascular

cells binds with coagulation system proteins to launch the intrinsic coagulation pathway. Exposed collagen and released adenosine diphosphate (ADP) serve to activate and aggregate platelets. Factor XII of the coagulation cascade is activated by contact with exposed tissue surfaces and by activated platelets to initiate the contact coagulation system.

The most important stimuli to activate inflammation are the Danger-Associated Molecular Patterns (DAMPs). DAMPs can be considered in two separate groups that are derived either intrinsically from host cells or extrinsically from pathogens. Alarmins are the DAMPs from the host, and they are typified by Human Mobility Box Group-1, which is an alarmin that is a normal nuclear protein released extracellularly with cell disruption or excreted by cells under stress. Other alarmins may be normal cellular constituents that are released with cellular necrosis or disruption or from cells in distress. A second group of exogenous DAMPs are the Pathogen-Associated Molecular Patterns (PAMPs). Representative PAMPs are structural or secreted products from pathogens found in injured or infected tissues. Alarmins and PAMPs bind to surface and intracellular receptors of myeloid cells and their derivatives to initiate the secretion of proinflammatory cytokine signals.

From the perspective of mediator production, the pathologic process of multiple organ dysfunction is composed of two phases. In the early phase, overproduction of numerous inflammatory mediators results in leukocyte and endothelial activation, increased endothelial permeability, and polymorphonuclear neutrophil adhesion and migration. Inflammatory cells in the spleen, liver, and bloodstream produce the first *"cytokine storm"* (Fig. 8.3).

In the second or later phase of multiple organ injury, intrinsic inflammatory cells in the interstitial compartment play an important role in the development of parenchymal injury. After adhesion to endothelium, activated leukocytes migrate to the interstitial space from postcapillary venules. Leukocytes, extravasated cytokines, and intrinsic inflammatory cells initiate and amplify inflammation in the interstitial space. As there are studies supporting organ dysfunction in the setting of leukopenia, high concentrations of selected cytokines in the interstitial space may prove directly toxic to vulnerable parenchyma (heart, skeletal muscle, etc.) and cytokines leaking into the bloodstream may induce remote organ injury by activating intrinsic inflammatory cells at those locations.

Within injured or infected tissue, a vasoactive response facilitates mobilization and infiltration of phagocytic cells. Vasodilation occurs as a consequence of bradykinin, histamine, and other local effects. Local vasodilatation increases blood flow to the area but slows flow velocity to accommodate margination of leukocytes. Increased permeability provides exit routes for marginated leukocytes to leave the intravascular compartment and enter injured or infected tissues. Edema is seen with this process. Chemokines contribute to leukocyte trafficking at this stage.

As the vasoactive phase progresses, the phagocytic phase begins. Neutrophils become adherent to the endothelial cells in the evolving site of inflammation. Upregulation of adhesion molecules on the surface of endothelial cells occurs in response to chemoattractants. Neutrophil-endothelial adherence results in margination of the phagocyte, and chemoattractant gradients provide direction for migration of neutrophils to the site of inflammation. Monocytes similarly migrate into the area, and proinflammatory cytokines are produced by monocytes and other cell populations. Among proinflammatory cytokines, Tumor Necrosis Factor, Interleukin-1, Interleukin-6, and others orchestrate the vigor of phagocytosis of pathogens or foreign bodies and the degradation or removal of dead host cells.

Unfortunately, containment of proinflammatory insults is not always achieved. The effects of necrotic cells, ischemia and reperfusion injury, and pathogenic bacteria causing infection may exceed the efficiency of the inflammatory response to achieve containment. Necrotic cellular elements, bacteria, bacterial products, bacterial toxins, alarmins, PAMPs, and other defined and undefined elements of local response gain systemic access in sufficient quantity to cause generalized inflammation. Failure of containment may reflect inadequate host response or quantity and virulence of the pathogen.

Lessons From Genetics

Data from the ongoing Glue Grant Trial demonstrate a consistent pattern of genome response after injury. Affected genes can be clustered into temporal patterns. First are genes that are shown to be upregulated as early as 12 hours after injury. This cluster of genes contains interleukin-1β and tumor necrosis factor-α. These genes recover to preinjury levels of expression within 24 hours of injury. Other genes recover to preinjury expression levels days to weeks after injury. IL-10 is an example of this

gene group. Some genes remain highly expressed even 28 days after injury. Compared to studies in normal volunteers, many genes that are highly expressed in healthy individuals are significantly downregulated after injury. In fact, more genes are downregulated relative to normal than are upregulated. The vast majority of gene expression changes occur within the first 24 hours after injury with the exception of a small proportion of genes with delayed maximum change in expression occurring days after injury.

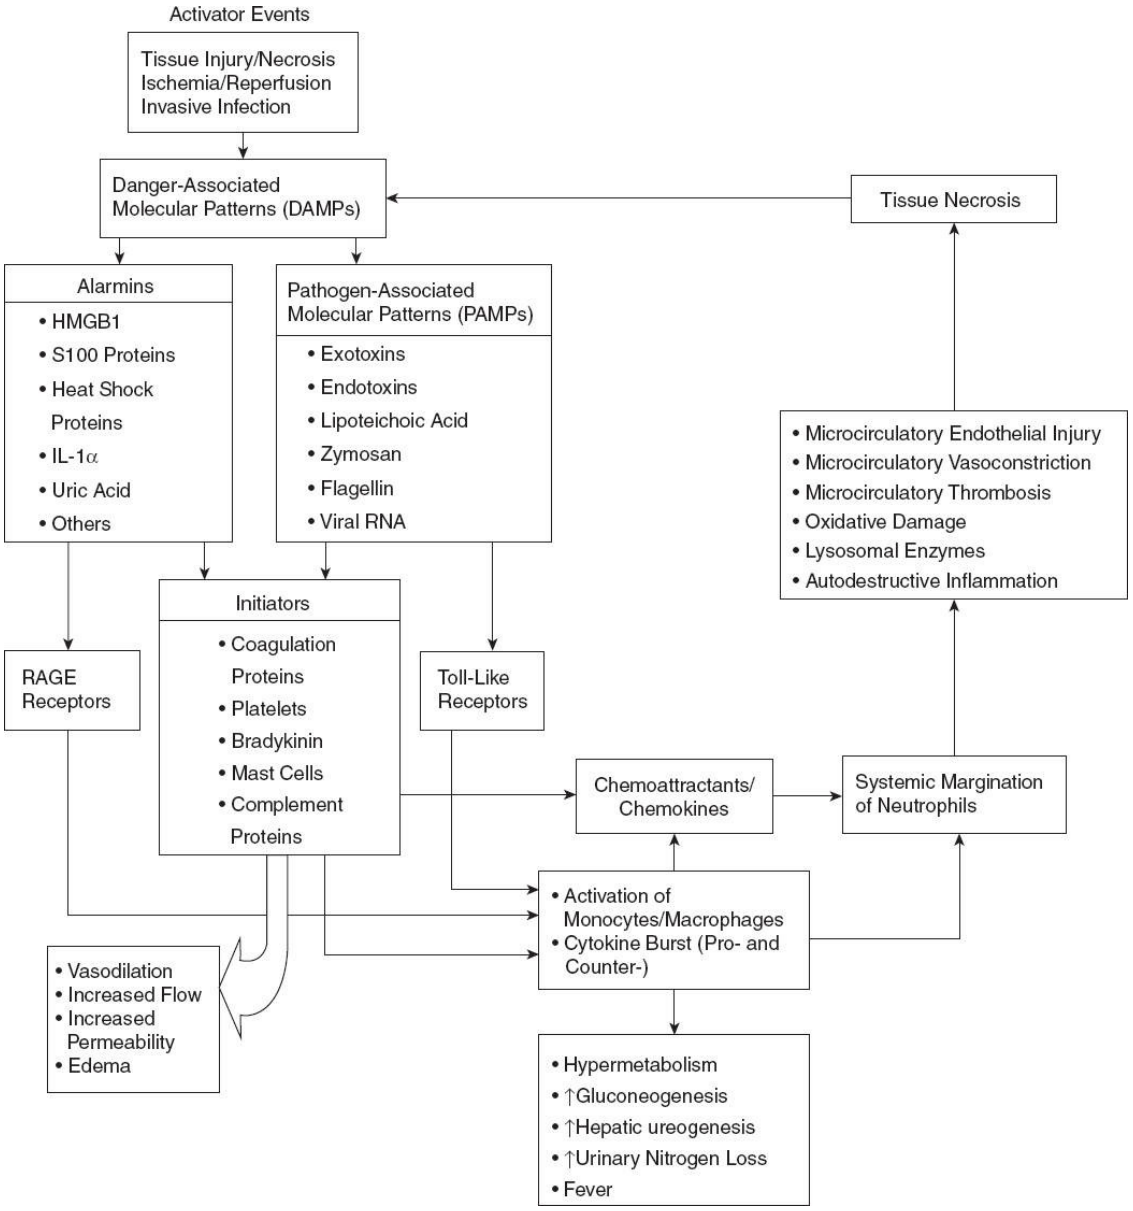

Figure 8.2. There are numerous components of the innate host response leading to SIRS and MODS. Release of danger-associated molecular patterns from damaged cells or bacteria results in binding to toll-like receptors, RAGE receptors, and activation of initiators of inflammation. Initiators lead to vasoactive changes in tissue and phase I of the inflammatory response. With systemic distribution of DAMPs, cytokines, and chemoattractants, the inflammatory cascade is activated on a systemic basis. Activation of leukocyte populations results in margination and activation at the site of injury and remote organs, which then leads to tissue damage from cellular products of leukocytes and consequences of damage to the microcirculation. Tissue ischemia and necrosis result in the release of additional DAMPs that perpetuate the process. A point may be reached where there has been resolution of the inciting event but the results of tissue

level inflammation provide the stimulus to repeat the entire cascade. (Republished with permission of Southeastern Surgical Congress from Fry DE. Sepsis, systemic inflammatory response, and multiple organ dysfunction: the mystery continues. *Am Surg* 2012;78:1–8; permission conveyed through Copyright Clearance Center, Inc.)

The Glue Grant examined two patient cohorts: uncomplicated patients simply responding to severe injury versus complicated patients responding not only to injury but also experiencing complications such as nosocomial infections and organ failure. Remarkably, the complicated and uncomplicated cohorts were not readily distinguishable by cytokine or white blood cell panels. Dozens of cytokine plasma concentrations were compared between complicated and uncomplicated patients. Only IL-6, IL-1 receptor antagonist, IL-8, and MCP-1 were different between the groups. No differences in white blood cell parameters were found between the complicated and uncomplicated cohorts. From over 1,000 genes that were significantly different by twofold for at least one time point, less than 100 genes were different between the complicated and uncomplicated cohorts at the twofold level at all time points studied. More than two thirds of these genes were directly related to protective immunity. Adaptive immunity studies showed suppression of genes involved in antigen presentation (e.g., HLA-DR), interferon and interferon-inducible genes. These HLA and interferon responsive genes downstream of the interferons were greatly suppressed in complicated patients relative to those genes in the uncomplicated patients. Thus, there are two distinct genomic patterns or signatures associated with different patient outcomes.

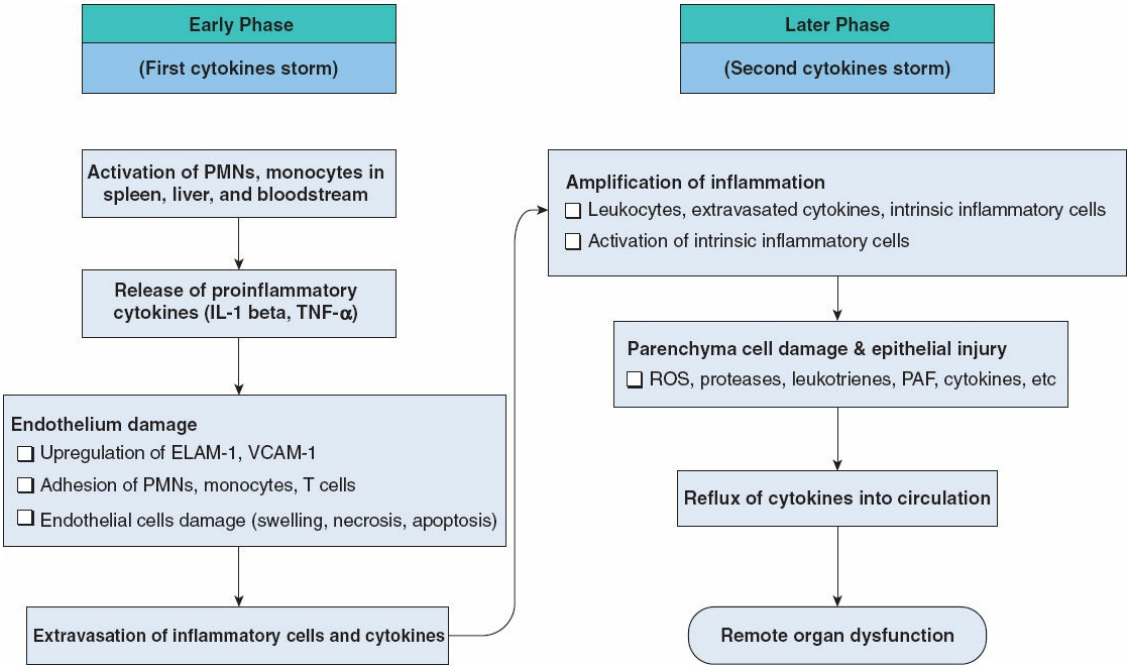

Figure 8.3. Main pathologic mechanisms in early and later phases of multiple organ dysfunction. ELAM-1, endothelial leukocyte adhesion molecule 1; PAF, platelet activating factor; TNF-α, tumor necrosis factor-α; VCAM-1, vascular cell adhesion molecule 1. (Reprinted from Wang H, Ma S. The cytokine storm and factors determining the sequence and severity of organ dysfunction in multiple organ dysfunction syndrome. *Am J Emerg Med* 2008;26(6):711–5. Copyright © 2008, with permission from Elsevier.)

When transcription is examined, there is an immediate genomic response causing upregulation of innate immune response and a downregulation of adaptive immune response. Transcription responses are triggered in the early hours after injury. These transcriptional changes are more dramatic and longer lasting in the complicated than in the uncomplicated patients. It is likely that these genomic changes translate into the phenotypic changes described as SIRS and CARS in critical care patients. The transcriptional responses leading to SIRS and CARS are simultaneous. The CARS response is not a compensatory response, and the transcriptional responses are continuous in nature and do not wax and wane. If an intervention to alter components of the innate immune or adaptive immune response is contemplated, it must be initiated very early after injury. At present, our management strategies cannot utilize the insight gleaned from molecular and genetic studies.

MANAGEMENT STRATEGIES

Fluids

The ideal resuscitation fluid should produce predictable sustained increase in intravascular volume and have chemical composition close to that of extracellular fluid. The ideal resuscitation fluid should also be metabolized and completely excreted without accumulation in tissue and not produce adverse metabolic or systemic effects. Finally, such a fluid should be cost-effective. Resuscitation fluids are broadly categorized into colloid and crystalloid solutions. Colloid solutions, of which the most popular is albumin, are suspensions of molecules that are relatively incapable of crossing healthy, semipermeable capillary membranes. Crystalloids are solutions of ions that are freely permeable but contain concentrations of sodium and chloride that determine the tonicity of the fluid.

A recent comparison of crystalloids and colloids is the Saline versus Albumin Fluid Evaluation (SAFE) study. No significant difference between albumin and saline was identified with respect to the rate of death or the development of new organ failure. Resuscitation with albumin was associated with a significant increase in the rate of death at 2 years among patients with traumatic brain injury. While a mechanism has not been demonstrated, this outcome has been referred to increased intracranial pressure, particularly during the first week after injury. Resuscitation with albumin was associated with a decrease in the adjusted risk of death at 28 days in patients with severe sepsis suggesting a potential, but unsubstantiated, benefit. No significant difference in hemodynamic resuscitation endpoints, such as mean arterial pressure or heart rate, was observed between albumin and saline groups, although the use of albumin was associated with a statistically significant but clinically small increase in central venous pressure (CVP). The ratio of volumes of albumin to saline administered to achieve comparable hemodynamic endpoints was 1:1.4. In acute illness, it appears that the hemodynamic reflects and effects on patient resuscitation outcomes for albumin are largely equivalent to those of saline.

The relative expense of human albumin has prompted development and increasing use of semisynthetic colloid solutions, particularly starches and gelatins. The use of high molecular weight starches may be associated with alterations in coagulation, specifically changes in viscoelastic measurements and fibrinolysis, although the clinical consequences of these effects in surgical patients are unclear. A recent Scandinavian study

reported that the use of 6% hydroxyethyl starch (HES) compared with Ringer's acetate was associated with a significant increase in the rate of death at 90 days and a significant relative increase in the rate of renal replacement therapy. Another large trial found that the use of 6% HES as compared to saline was not associated with a significant difference in the rate of death at 90 days but again, was associated with a significant relative increase in the need for renal replacement therapy. Whether these results are generalizable to the use of other semisynthetic colloids is unknown. In light of recent evidence of the lack of improved outcomes and potential nephrotoxicity, the use of semisynthetic colloids for fluid resuscitation in critically ill patients is not justified.

Among crystalloid solutions, sodium chloride is the most commonly used product on a global basis, particularly in the United States. Normal saline contains sodium and chloride in equal concentrations, which makes it isotonic as compared with extracellular fluid. Administration of large volumes of normal saline results in a hyperchloremic metabolic acidosis with adverse effects, including immune and renal dysfunction. Concern about sodium and water overload with saline resuscitation has resulted in the concept of small volume crystalloid administration with the use of hypertonic saline solutions. The early use of hypertonic saline for resuscitation has not improved short-term or longer-term outcomes. Given the concern regarding an excess of sodium chloride associated with normal saline administration, balanced salt solutions are increasingly recommended as first-line resuscitation fluids in patients undergoing surgery, victims of trauma, and patients with diabetic ketoacidosis. A recent comparison trial noted a significant decrease in the rate of major complications with the use of a calcium-free balanced salt solution (plasma-lyte) for replacement of fluid losses on the day of surgery in comparison to normal saline.

A number of observations can be made regarding fluids for resuscitation in critically ill patients. First, and most important, fluid should be considered with the same caution that is used with any intravenous drug. To avoid excessive administration of resuscitation fluid, catecholamine administration should be considered as concomitant treatment of shock. Fluid requirements change over time in the setting of critical illness. Excessive or prolonged fluid resuscitation is associated with pathologic edema and end organ dysfunction.

Blood Products

Hemorrhagic shock results in a significant rate of fatality in patients arriving at hospital with acute injury. Recognition of the morbidity associated with bleeding and coagulation changes can be traced to the 1960s. At that time, standard tests including prothrombin time and partial thromboplastin time correlated poorly with response of coagulation to acute resuscitation efforts. The American trauma community was drawn to coagulopathy after trauma with the description of the "*bloody vicious cycle*" by the Denver Health team over 20 years ago. These investigators noted the contribution of hypothermia, acidosis, and hemodilution associated with inadequate resuscitation and excessive use of crystalloids building on work of Lucas, Ledgerwood, and others. Subsequent work extended these observations describing early coagulopathy that could be independent of clotting factor deficiency.

Brohi and workers in the United Kingdom have reinvigorated this discussion after their observations regarding coagulopathy after injury by adding new laboratory techniques to earlier clinical observations (Fig. 8.4). These investigators emphasized the observation that acute coagulopathy could occur before significant fluid administration, which was attributable to injury itself and proportional to the volume of injured tissue. Development of coagulopathy was an independent predictor of poor outcome. Mediators associated with tissue trauma including humoral and cellular immune system activation with coagulation, fibrinolysis, complement and kallikrein cascades have since been associated with changes in hemostatic mechanisms similar to those identified in the setting of sepsis. A number of important cofactors must be present to stimulate coagulopathy in the setting of trauma. Shock is a dose-dependent cause of tissue hypoperfusion, and elevated base deficit has been associated with coagulopathy in as many as 25% of patients. Immediate postinjury coagulopathy is likely a combination of effects caused by large volume tissue trauma and hypoperfusion. Studies carefully examining the timing of blood component administration revealed that improved outcomes came with rapid administration of blood products in patients with clinical indications of significant bleeding featuring equivalent amounts of plasma, platelets, and red blood cells. Early administration of products is emphasized to minimize progression of coagulopathy and metabolic derangement associated with tissue hypoperfusion. One simple criterion for blood product administration is Class III shock as defined by the

American College of Surgeons and the *Advanced Trauma Life Support (ATLS) Program.*

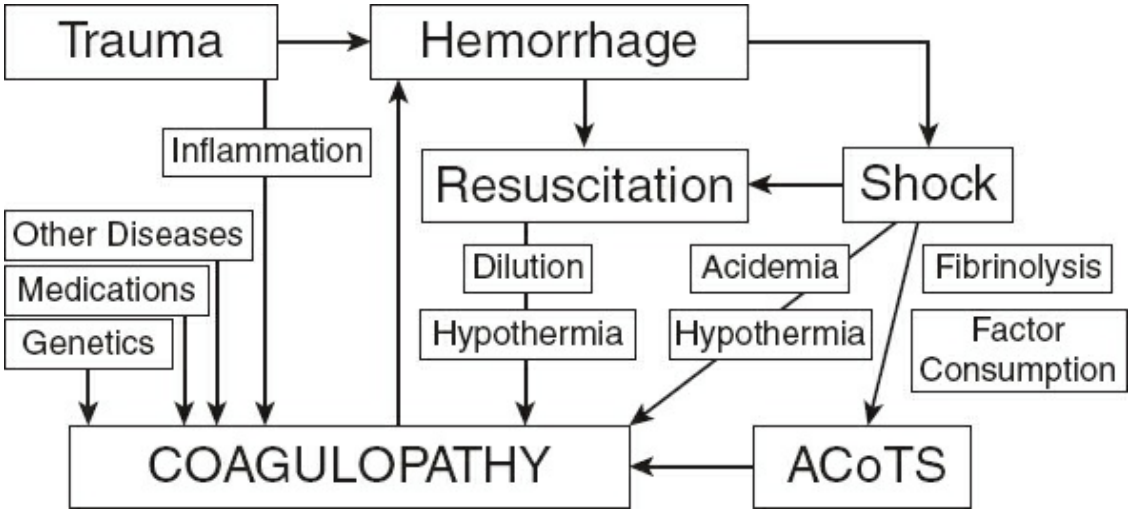

Figure 8.4. Mechanisms leading to coagulopathy in the injured. Trauma contributes to hemorrhage that requires resuscitation leading to dilution and hypothermia contributing to coagulopathy and further hemorrhage. Hemorrhage can also cause shock leading to acidosis and hypothermia with coagulopathy. Trauma and shock along with tissue injury contribute to the acute coagulopathy of trauma shock (ACoTS) with factor consumption and fibrinolysis. Coagulopathy is further associated with inflammation and modified by genetics, medications, and acquired disease. (From Hess JR, Brohi K, Dutton RP, et al. The coagulopathy of trauma: a review of mechanisms. *J Trauma* 2008;65:748–54.)

Endpoints of Resuscitation

Identification of normal hemodynamics is difficult in critically ill patients. Hemodynamic response is likely to be adequate when oxygen delivery to tissues is sufficient to maintain aerobic metabolism. This may occur in critical illness at values greater than or less than hemodynamic values considered normal in healthy subjects. In the setting of hypermetabolism, for example, cardiac output will be greater than normal to provide adequate oxygen delivery. On the contrary, when metabolic requirements are reduced such as with sleep or administration of neuromuscular blockade, aerobic metabolism may be realized with hemodynamic parameters lower than those considered normal in healthy subjects. Thus, hemodynamic response should be considered in the context of appropriate response of the patient.

Hemodynamic response becomes inadequate when signs of anaerobic metabolism appear despite activation of compensatory mechanisms normally maintaining homeostasis. Central venous oxygen saturation depends on oxygen delivery, appropriate match between oxygen consumption and metabolic requirements, and on cardiac output with the oxygen carrier (hemoglobin). Thus, all determinants of oxygen transport, as well as metabolic demand may influence central venous oxygen saturation making it a sensitive, though not specific, indicator of changes in respiratory, metabolic, cardiac, and hemoglobin status.

In normal conditions, the amount of oxygen extracted from the oxygen delivered is about 25%. Thus, central venous oxygen saturation is approximately 75%. The arbitrary recommended threshold of $ScvO_2$ used in multiple studies and in guidelines for sepsis management is 70%. $ScvO_2$ lower than the typical threshold is not necessarily associated with anaerobic metabolism. The most frequent reason for a low $ScvO_2$ in the critical care unit is cardiac failure. In the setting of cirrhosis or some phases of sepsis, $ScvO_2$ may be greater than 70% to 75%. Normal or higher than normal central venous oxygen saturation may be associated with abnormal hemodynamics caused by activation of compensatory mechanisms including the angiotensin–aldosterone system and vasopressin release. Failure of compensation is reflected by metabolic acidosis with increased plasma lactate concentration. Appearance of acidosis indicates the failure of tissues, which in the absence of correction may result in cellular and tissue death. The ultimate goal of hemodynamic support is maintenance of aerobic metabolism.

Clinical signs including thirst, skin turgor, blood pressure, and urine output are unreliable indices of intravascular volume status. Cardiac filling pressures including central venous pressure and pulmonary artery occlusion pressure are also poor predictors, although these tools and others, such as ultrasound, can be used to optimize pump performance. Heart–lung interaction during mechanical ventilation has more recently been used to evaluate variations in stroke volume, systolic pressure, and pulse pressure. Pulse pressure variation has been found to be predictive of a positive response to a fluid challenge. When hemodynamic changes are evaluated in the setting of cyclic increase or decrease of intrathoracic pressure during mechanical ventilation, change in left ventricular stroke volume of 12% to 13% has been reported predictive of volume responsiveness. These methods, however, are limited by the requirement

of specific tidal volume relationships to body weight and absence of vascular bed changes, spontaneous respiratory activity, and abnormality of cardiac rhythm.

SURGICAL TECHNIQUE

Damage Control Surgery

The major premise of damage control surgery is that the metabolic derangements associated with infection or ongoing bleeding supersede the need for definitive operation. Thus, the main thrust of damage control surgery is rapid surgical control of bleeding, the spillage of succus, and other sources of infection. Classic damage control begins with hemostasis and control of spillage of succus followed by transport to the critical care unit to address conditions of hypothermia, acidosis, and coagulopathy with subsequent return to the operating room for definitive repair of temporized injuries or body cavity closure.

In the case of laparotomy, a rapid midline incision is made with hemoperitoneum and clot removal, suture of bleeding points, packing as necessary, and other measures to control hemorrhage and contamination. Splenic and renal injuries are typically treated with rapid resection, nonbleeding pancreatic injuries are simply drained, and liver injuries typically are packed. Large vessel venous injuries including the inferior vena cava may be treated with ligation. Arterial injuries may be temporized with the placement of shunts with definitive repair to follow as the metabolic condition permits. Hollow viscus injury is managed with simple suture closure or rapid resection of the involved segment. No anastomoses are performed and ostomies are not matured. After control of surgical bleeding, fascia is left open. A variety of temporary dressings, including vacuum techniques, have been developed. These devices keep the skin dry, decrease the workload of the ICU nursing staff, and allow quantification of ongoing fluid or blood loss.

Techniques are also available for rapid control of bleeding or infection in other body regions. For example, damage control thoracotomy for pulmonary injury typically involves rapid tractotomy with suture ligation of bleeding vessels and rarely includes formal pulmonary resection. Injury to the hilum will usually require pneumonectomy for rapid control of hemorrhage. Extremity trauma in patients with multiple injuries usually involves ligation of venous injury and shunting of major arterial injury with external fixation for orthopedic stabilization. Improved outcomes

with damage control surgery have been accompanied by improved rates of recognition and earlier initiation of damage control measures, carefully targeted resuscitation, appropriate maintenance of body temperature, anticipation of blood loss, and avoidance of overresuscitation.

POSTOPERATIVE CARE

Key Interventions: Management of Analgesia and Sedation

One of the key recent developments in critical care management is consistent and coordinated management of pain, agitation/sedation, and delirium in an integrated and interdisciplinary fashion. Pain, agitation, and delirium (PAD) guidelines include tools for detection of over- and undersedation and delirium in the critically ill patients. PAD treatment strategies focus on approaches to management such as treatment of pain before administration of sedatives and maintaining a light level of sedation that allows patients to interact in a meaningful way with the critical care environment. Pain is assessed using standardized tools that, if possible, allow patients to self-report discomfort.

Agitation and anxiety also occur frequently in critically ill patients. Common causes of agitation and anxiety include untreated pain, delirium, hypoxemia, hypoglycemia, hypotension, or withdrawal from alcohol and other drugs. Sedation scoring systems have been developed to assess the degree of sedation and agitation. These scoring systems provide a basis for the use of sedatives in critically ill patients. Administration of sedatives without titration to specific scales generally results in oversedation. It is important to recognize that in the critically ill patients, even those who are mechanically ventilated, the need for sedative medications may be limited if pain is adequately managed. Patients managed with analgesia first have significant reductions in duration of mechanical ventilation and ICU length of stay. Opioids remain the primary analgesic of choice in critically ill patients with nonneuropathic pain. All intravenous opioids are equally effective at equipotent doses. Oral opioids may be variably absorbed with reduced bioavailability in the critically ill patients. Nonopioids, including nonsteroidal medications and ketamine, can provide adjunctive pain relief and reduce opioid requirements. First-line agents for neuropathic pain are gabapentin and carbamazepine.

Optimal sedation management includes use of sedatives only as needed while maintaining a light level of sedation. A level of consciousness allowing ICU patients to be responsive and aware is desirable. Sedative

choice in the critical care unit should be based upon recent data demonstrating reduced side effects and improved outcomes. For example, benzodiazepines, especially midazolam, are commonly employed in adult critical care patients followed by propofol and dexmedetomidine. Barbiturates, diazepam, and ketamine are rarely used for sedation in adults. Over the past decade, a growing body of evidence suggests that the use of intravenous benzodiazepines for sedation of critical care patients, particularly midazolam and lorazepam, is associated with a high risk of delirium relative to sedation with agents such as propofol and dexmedetomidine. Mechanical ventilation remains the major indication for administration of sedation. Ventilator weaning protocols including spontaneous breathing trials may significantly reduce the duration of mechanical ventilation and sedative use.

Delirium is characterized by acute onset of cerebral dysfunction with fluctuation in mental status, inattention, and either disorganized thinking or altered level of consciousness. Patients with delirium may be either agitated (hyperactive delirium), calm or lethargic (hypoactive delirium), or may fluctuate between the two subtypes. Hyperactive delirium is often associated with hallucinations and delusions, whereas hypoactive delirium is often characterized by confusion or somnolence and may be undetected. Delirium is common in critically ill patients. Up to 80% of critically ill patients exhibit delirium at some time during their ICU stay. The presence of delirium is associated with significant negative outcomes including prolonged mechanical ventilation and hospital length of stay. Delirium also increases postdischarge institutionalization, long-term cognitive dysfunction, and risk of death. Hypoactive delirium occurs more commonly than hyperactive delirium and is associated with longer duration of mechanical ventilation and ICU length of stay along with higher mortality risk than hyperactive delirium. Given the prevalence of this problem, all patients in the critical care unit should be screened for delirium.

The first step in managing delirium is to identify and eliminate contributing factors such as sepsis, shock states, glycemic dysregulation, electrolyte disorders, and hypoxia. Other factors contributing to delirium are inadequate pain management, drug withdrawal, discontinuation of psychiatric medications, exposure to deliriogenic medications, or adverse drug effects. Environmental factors including sleep deprivation, disorientation, and prolonged immobilization also contribute to delirium.

Delirium treatment should include nonpharmacologic and pharmacologic strategies with an emphasis on using nonpharmacologic interventions first. Proven nonpharamcologic delirium treatment strategies include frequent reorientation of patients, maintaining sleep–wake cycles, and advancing mobility during the day as tolerated. Pharmacologic management of delirium includes adequate analgesia, discontinuation of benzodiazepines except in patients with specific need for these medications, and resumption of any prior psychiatric medications. Drug withdrawal symptoms should be treated if suspected, and antipsychotics may be considered if needed. Haloperidol is the drug of choice to treat acute delirium. A management role for atypical antipsychotics is also being studied.

Prevention of PAD complications begins with awareness that any critical care procedure may be associated with a significant degree of pain. Procedural pain may trigger a significant stress response leading to hemodynamic instability, metabolic disorders, impaired wound healing, and increased risk of infection. Pain has significant short- and long-term psychological consequences, including sleep deprivation, persistent recollection (see posttraumatic stress disorder [PTSD]), and a higher likelihood of development of chronic pain.

Key Intervention: Mechanical Ventilation

With infrequent use of the pulmonary artery catheter (PAC), mechanical ventilation has become the defining modality of critical care practice. Low tidal volume ventilation and use of noninvasive ventilation after extubation and to manage chronic obstructive pulmonary disease (COPD) have strong evidence to support improved outcomes. Several precautions are needed to avoid iatrogenic complications related to mechanical ventilation. Among the first lessons of invasive mechanical ventilation was the deleterious effect of the endotracheal tube. This device not only increases airway resistance but also provides a pathway for infection and damages delicate tissues of the larynx and trachea. Accumulation of airway debris increases work of breathing, impairs gas exchange, and predisposes to bronchopulmonary infections. Better materials, lower cuff pressures, and improved nursing practices have addressed some of these problems. Noninvasive ventilation was born from the need to address complications related to invasive mechanical ventilation. With improving interfaces, noninvasive ventilation allows intubation avoidance, improved sleep quality, and safer treatment for patients with diverse cardiopulmonary

problems.

Few rules governing mechanical ventilation management apply across all phases and severities of illness. Choices must be conditioned by stage of illness and patient response. For example, high levels of PEEP are relatively helpful in the early stage of ARDS management when the lung is relatively wet and recruitable and benefit of PEEP application outweighs the hazard. Later in the course of ARDS, PEEP may simply increase peak and mean airway pressures increasing stress and tissue strain associated with a given tidal volume and creating dead space. Advisability of prone positioning may also be dependent on time and disease severity. Prone positioning appears to reduce mortality in those patients who are both severely affected by hypoxemic respiratory failure and in the early stage of illness.

It is also important to strike a balance between of benefits of spontaneous breathing and the dangers of oversedation and neuromuscular blockade. Ventilator-induced diaphragm dysfunction should be of concern when controlled ventilation is imposed for extended periods. Unlabored spontaneous patterns of breathing appear to be more mechanically efficient than are breaths administered to a passive patient. However, taking control of ventilation during the earliest phase of life-threatening sepsis and ARDS may enable reduction of potentially damaging mechanical forces arising from high cardiac output and minute ventilation. Brief use of muscle relaxants during the most vulnerable early period of illness is not associated with delayed neuromuscular recovery or with ventilator-associated diaphragmatic injury. On the other hand, sustained suppression of awareness by large doses of sedatives without periodic "*holidays*" increases the likelihood of prolonged mechanical ventilation, delirium, inability to wean, and adverse clinical outcomes.

Clinical trials offer guidance for mechanical ventilation prescriptions, which must be considered in context. For example, the simple rule of 6 mL/kg tidal volume based on predicted body weight, which is now seen frequently in daily practice, is not sufficient for all situations relating to body stature and ventilation demand. The guideline may need to be adjusted upward when patients are small and ventilation demands are high. This 6 mL/kg is also unsafe if tidal volume enters only a small aerated compartment. A tidal volume of 6 mL/kg, depending on aerated compartment capacity, may generate high local tidal volume and excessive transalveolar pressures with injury to the lung during passive inflation.

Physiologic need must also be considered in the prescription for mechanical ventilation. Employing a guideline-approved small tidal volume without addressing high minute ventilation (demand) may result in dyspnea and high breathing frequencies. Ventilation intensity should be reduced as possible along with patient demand for support. Controlling pain, agitation, body temperature, and metabolic acidosis are means to this end.

OUTCOMES

Disability After Critical Care

Critical illness is frequently a disabling process. In one popular model, diseases or injuries (*pathology*) result in dysfunction of body systems (*impairments*) leading to inability to perform basic physical and cognitive functions (*functional limitations*) altering the individual's capacity to meet demands of his or her environment (*disability*). Disability for activities of daily living is common after critical illness and has been noted in 33% to 58% of patients when follow-up occurred less than 3 months after index illness and 12% to 97% of patients for follow-up time points occurring more than 6 months after index illness. Multiple studies have reported newly developed dementia in 12% to 18% of patients assessed between 1 and 8 years after critical illness. Prevalent dementia was reported in 15% of patients at hospital discharge and in 10% of ICU survivors at 1-year follow-up. Mild to moderate cognitive impairment may be present in over 50% of patients.

Postcritical illness disability results from the interaction of baseline health status and vulnerability to the acute stress of critical illness with the effects of the acute illness itself and treatment practices during and after ICU admission. The focus on preventing disability lies with identification of critically ill patients who are at risk for developing or exacerbating disabilities and avoiding iatrogenic contributions to this postcritical illness insult.

Two of the most common and modifiable risk factors for subsequent functional and cognitive decline are immobility and delirium. Immobility is epidemic among hospitalized older adults with deleterious effects on subsequent physical and cognitive function. Delirium is among the strongest predictors of subsequent cognitive impairment. Both immobility and delirium magnify underlying age-related physiologic changes; thus, efforts to manage these insults may have substantial impact on postcritical

illness outcome.

ICU practitioners should assess functional and cognitive status of patients soon after admission with daily monitoring for potential changes. The ABCDE bundle has been recommended to reduce the harms associated with sedation, mechanical ventilation, delirium, and immobility in critically ill patients of all ages. Briefly, the ABCDE bundle includes daily spontaneous awakening and spontaneous breathing trial coordination (ABC), choosing to sedate patients only when necessary and to lighter levels (C), screening for delirium (D), and early mobilization with physical and occupational therapy (E). Implementation of the ABCDE bundle is independently associated with doubling the odds of a patient being mobilized and a 45% decrease in the odds of developing delirium. Individual components of ABCDE are associated with improved functional status at hospital discharge and decreased mortality following critical illness. It should be noted that older adults face additional risk factors for poor functional and cognitive outcomes, including social isolation, forced dependence with ADLs, restraints, poor nutrition, polypharmacy, and unnecessary medical tests and procedures. Thus, additional care models focused on the needs of the elderly patient are essential.

As mortality from critical illness decreases, there is a growing population of survivors who experience long-lasting physical, cognitive, and mental health impairments. PTSD is one important mental health outcome related to life-threatening ICU experiences. PTSD can be diagnosed if an individual is exposed to actual or threatened serious injury or death (typical in critical illness) and subsequently develops symptoms that cause significant distress or changes in functionality such as persistently reexperiencing an event and attempting to avoid trauma-related stimuli. Other manifestations are negative alterations in mood or cognition and new or increased arousal and reactivity. PTSD symptoms are reported in 5% to 63% of critical illness survivors and have a strong association with reduced health-related quality of life. Risk factors for PTSD include younger age, sedation with a benzodiazepine, and recall of frightening ICU experiences.

Pre-existing psychopathology is the only pre-ICU factor consistently associated with PTSD symptoms. PTSD symptoms are not associated with severity of illness, admission diagnosis, length of stay in the critical care unit, and mechanical ventilation. Two ICU-related variables have been

associated with PTSD: sedation and early memories of frightening ICU experiences. Two general management strategies advocated include changes in ICU practice associated with development of PTSD and cognitive therapy to reduce PTSD symptoms.

EDITOR'S COMMENT

Dr. Dries has written an exceptional chapter on multiple organ dysfunction syndrome (MODS). MODS is defined as a clinical syndrome with altered organ

function in an acutely ill patient requiring medical intervention to achieve homeostasis. It usually involves two or more organ systems. MODS is a hypometabolic, immunodepressed condition that develops following an acute injury or illness. MODS contributes to about 50% of intensive care unit (ICU) deaths. It remains unclear what triggers MODS and why it only seems to occur in certain patients. Almost any disease or event that results in significant tissue injury can result in MODS including sepsis, major trauma, burns, pancreatitis, poisoning, or ischemia–reperfusion injury. The mechanism likely involves a complex interplay of interdependent factors including genetics, comorbidities, medications and therapies, macro- and microcirculatory changes, inflammation, and mitochondrial dysfunction. As I performed my research for this commentary, I came across several interesting articles discussing the potential role of mitochondria in MODS. Sepsis damages the structure and function of the mitochondria, and conversely mitochondrial dysfunction aggravates sepsis. Reduced ATP production and mitochondrial dysfunction contribute to a compromise in normal metabolic function and organ dysfunction. Mitochondrial modification may be a potentially important therapeutic target in MODS.

There is an interesting discussion and good information on fluid resuscitation in this chapter. The colloid versus crystalloid discussion is relevant. This is a debate that has carried on for years, and it appears that a consensus has finally been reached that these are equivalent for resuscitation in critical illness. A Cochrane Systematic Review and meta-analysis evaluated randomized, controlled trials of colloids compared to crystalloids in critically ill patients. There were 78 eligible trials. The pooled relative risk (RR) of mortality of crystalloid compared to albumin or plasma protein fraction was 1.00 (0.92 to 1.09). The authors of this review conclude, "*There is no evidence from randomized controlled trials that resuscitation with colloids reduces the risk of death, compared to resuscitation with crystalloids, in patients with trauma, burns, or following surgery.*"

Damage control surgery is discussed in this chapter and is an important concept that represents a major advance in care of the critically injured patient. The concept is also applied to the critically septic patient undergoing surgery for a perforated viscus. Pringle described this technique in patients with substantial hepatic trauma in the early 20th century. Hepatic packing rather than definitive repair in the setting of massive hemorrhage evolved to a concept of "damage control" or temporization and prioritizing physiologic recovery over anatomic repair in patients who are coagulopathic, hypothermic, and acidotic. The damage control surgery concept has dramatically increased survival in the most seriously injured patients. Patients who are injured or sick enough to require a damage control approach may ultimately develop MODS. When initiated early and accompanied by damage control resuscitation, these critically ill patients who survive are probably less likely to develop MODS than if a more prolonged and definitive operation is performed when a temporizing procedure is more

appropriate.

Pain, agitation, and delirium are common issues that critically ill patients in the ICU may face. Assessing whether a patient in the ICU is in pain is difficult. Poorly controlled pain can contribute to agitation, which may lead to accidental removal of endotracheal tubes or lines and catheters. Restraints, sedatives, and analgesics have traditionally been employed to manage these patients. Studies confirm that the majority of patients who are treated in ICUs have pain. The short-term consequences of untreated pain include higher energy expenditure and immunomodulation. Longer-term, untreated pain increases the risk of posttraumatic stress disorder (PTSD). Only a minority of ICU patients has a clinical indication for continuous deep sedation (e.g., intracranial hypertension, status epilepticus, prevention of awareness in those who must be treated with neuromuscular blockade). Most ICU patients, including the majority of those on mechanical ventilation can be administered sedatives and analgesics with the goal of helping them to be calm, with minimal pain, lucid, interactive, and cooperative with their care. The American College of Critical Care Medicine published a revised and updated “Clinical Practice Guidelines for the Sustained Use of Sedatives and Analgesics in the Critically Ill Adult” in 2013. Pain management recommendations include things like routine pain assessments (self-reported in those who can communicate), preemptive analgesia prior to painful procedures like chest tube removal, opioids as first-line therapy, multimodal pain management to minimize opioids, and thoracic epidural in appropriate patients. Agitation recommendations include measures such as routine assessment of depth and quality of sedation, lightest possible sedation and/or daily sedation breaks, the use of analgesia-first sedation, and nonbenzodiazepines such as propofol or dexmedetomidine in mechanically ventilated ICU patients. Recommendations pertaining to delirium include routine assessment with validated tools, early mobilization, and promoting sleep (controlling light and noise, clustering patient care activities, and decreasing stimuli at night).

Care Bundles have been implemented successfully in many areas to address things like surgical site infections after colorectal resection. The ABCDEF bundle builds upon the Pain, Agitation, and Delirium Guidelines. The bundle represents an evidence-based guide for clinicians to approach the organizational changes needed for optimizing ICU patient recovery and outcomes. It stands for the Awakening and Breathing Coordination, Choice of drugs, Delirium monitoring and management, Early mobility, and Family engagement bundle. A recently published study examined the association between ABCDEF bundle compliance and outcomes including hospital survival and delirium-free and coma-free days in seven community hospitals. Of 6,064 patients, 9.7% died before hospital discharge. For every 10% increase in total bundle compliance, patients had 7% higher odds of hospital survival. Likewise, for every 10% increase in partial bundle compliance, patients had a 15% higher hospital survival. Patients experienced more days alive and free of delirium and coma

with both total bundle compliance and partial bundle compliance.

I am quite interested in the long-term effects of critical and prolonged illness, especially with regard to cognitive decline and PTSD. A systematic review and meta-analysis determined that substantial post-ICU PTSD symptoms occur in 25% to 44% of patients from 1 to 6 months post-ICIU and 17% to 34% at 7 to 12 months post-ICU. Significant risk factors for post-ICU PTSD included memories of in-ICU frightening or psychotic experiences, pre-ICU psychopathology, and the use of benzodiazepines. Health-related quality of life is substantially worse in patients with post-ICU PTSD. Treatment and prevention strategies have been investigated and are still being developed. Several studies have demonstrated that survivors of critical illness can suffer from a prolonged and disabling form of cognitive impairment. The Bringing to Light the Risk Factors and Incidence of Neuropsychological Dysfunction in ICU Survivors Study (BRAIN-ICU) was recently published in the New England Journal of Medicine and followed 821 patients with respiratory failure or shock in medical or surgical ICUs at multiple study centers. Of the 821 patients enrolled, 6% had cognitive impairment at baseline, and delirium developed in 74% during the hospital stay. At 3 months, 40% of the patients had global cognition scores that were 1.5 standard deviations below the population means and similar to scores for patients with moderate traumatic brain injury. Another 26% had scores 2 standard deviations below the population means (similar to scores for patients with mild Alzheimer disease). A longer duration of delirium was independently associated with worse global cognition and executive function at 3 and 12 months.

As mortality from single organ dysfunction has decreased, we have observed an increase in critically ill patients with multiple organ dysfunction. As mortality from critical illness decreases, the long-term sequelae for survivors are becoming more and more apparent. There is much work to be done to prevent and optimally treat these survivors. I find this to be a very interesting chapter that highlights these issues and challenges in a very logical and informative manner.

9 Immunosuppression in Organ Transplantation

Mani A. Daneshmand and Allan D. Kirk

Organ transplantation has been a longstanding human dream. Records of transplantation and grafting experiments date back to almost 3,000 years. Although these accounts typically represent myth, legend, and folklore, they demonstrate humanity's desire to heal the wounded with "spare parts" from other individuals. Modern day solid organ transplantation, however, was not technically possible before the advances in surgical anastomoses was developed and described by Alexis Carrel in the 19th century. Although Carrel's techniques won him the Nobel Prize in 1912, they represented only a small victory for transplantation. While the technical surgical hurdles were easily overcome by Carrel's techniques, the biologic barriers posed by the immune system have been more challenging.

Sir Peter Medawar, inspired in part by the clinical challenges of skin grafting for burn victims during World War II, first defined the role of the immune system in allograft rejection. More importantly, he first demonstrated the concept of "acquired immunologic tolerance," originally postulated by Sir F. Macfarlane Burnet, paving the conceptual path toward immune manipulation to facilitate allotransplantation, and establishing the underpinnings of the concepts of rejection, memory, and tolerance. These findings earned both Medawar and Burnet the Nobel Prize in 1960 and impelled the first successful isogenic transplant on December 23, 1954 by Joseph E Murray. At the same time, Gertrude Elion and George Hitchings introduced 6-mercaptopurine (6-MP), demonstrating that it impaired lymphocyte proliferation. The utility of this drug in countering the processes described by Medawar were recognized by a British surgical trainee, Roy Calne, who brought Elion and Hitching's agents to Murray's laboratory to perform the first allogenic transplants using preemptive immunosuppressive medications. These experiments launched initial clinical allograft studies in 1963, and established the fundamental concept of immunosuppressive medication as a means of facilitating organ engraftment. Subsequently, as more potent and specific

immunosuppressive agents have been discovered, organ transplantation has become a successful mainstream therapy for end-stage organ failure. In this chapter, we briefly examine the elements of the immune system that relate to organ transplantation and are targeted by immunosuppressive agents. We then describe established and emerging techniques of immunosuppression for the prevention and treatment of rejection of transplanted organs.

IMMUNE RECOGNITION AND REJECTION

The immune response is generally divided into two subsets: innate immunity and acquired, or adaptive, immunity. Generally, the innate immune system responds to generic molecular motifs associated with tissue injury or pathogenic microbes, and stimulates an initial, nonspecific protective response. The acquired immune system, in contrast, responses specifically to proteins or carbohydrate epitopes, and engenders a lasting, anamnestic, highly specific protective response. Acquired immunity is generally divided into humoral and cellular arms, as will be described below. The innate and acquired systems work in tandem, with the innate system typically activating the acquired system, and the acquired system typically quelling the innate response. Together they defend against infection, clear injured or transformed cells, and avoid autoimmunity.

Innate Immunity

The innate immune system is generally activated by conserved protein and carbohydrate motifs that are typically expressed during infection or tissue damage. The receptors that interact with these motifs exist on macrophages, neutrophils, natural killer cells, and free in the circulation (as in the complement system). These receptors bind common components of pathogenic organisms (like cell wall lipopolysaccharides) and injured tissue (such as mitochondrial DNA). The receptors of the innate immunity are identical within a species and do not contribute to rejection of a specific transplanted organ. However, numerous features associated with organ transplantation in general, such as ischemia, reperfusion injury, and procurement-associated trauma provide signals that foster innate immune system activation. As such, transplantation modulates the acquired system, particularly immediately after a transplant, recruiting cells of the acquired immune system to the region, and processing alloantigen for presentation to elements of the acquired system. For this reason, augmented, fairly

nonspecific immune suppression is required at the time of transplantation. This forms much of the biologic basis for induction immunosuppression, described below.

The main functions of the innate immune system are to facilitate containment of invading organisms and areas of cell death, chemotaxis of other immune elements to the site of injury, and antigen presentation to initiate an acquired response. Physiologically, the complement cascade is primarily activated through binding to mannose residues in microbial cell walls, and thereafter liberates molecules that covalently bind to neighboring cells, opsonizing them for phagocytosis. In the context of transplantation, complement is more typically activated by allospecific antibody (described below). Regardless, complement-mediated opsonization can initiate many initial steps in antigen presentation. Macrophages and dendritic cells engulf both pathogens/cells that are opsonized by complement and those that are recognized by foreign cell surface carbohydrate patterns. In addition, toll-like receptors (TLRs) play an important role in the activation of innate antigen-presenting cells (APCs). These TLRs bind pathogen-associated molecular patterns (PAMPs) such as LPS, flagellin, viral RNA, viral DNA, and heat shock proteins and subsequently promote downstream activation of the innate immune response. Cell injury caused by the transplant procedure itself is thought to liberate PAMPs, providing another means of innate immune system activation early after transplantation.

Antigen Recognition

A key component of the acquired immune system is antigen recognition. Specifically, the evolution of the acquired immune system has, (1) promoted increased specificity in the distinction of foreign, “invading,” tissue from normal tissue, and (2) permitted the development of immunologic “memory.” This recognition occurs through the binding of an antigen (any structural substance that can be bound by the receptors of the acquired immune system). The acquired immune response is mediated by T (cellular immunity) and B (humoral immunity) cells and their respective receptors: the T cell receptor (TCR) and the B cell receptor (or antibody). Each individual T and B cell expresses receptors that optimally bind one specific epitope, although it is now recognized that considerable cross-reactivity can occur. Cross-reactivity between environmental antigens and alloantigens is known as heterologous immunity and likely

plays an important role in the nature of transplant rejection responses and their control by certain types of immunosuppressants. In addition to effecting a highly specific immunologic response, the binding of TCRs or B cell receptors with antigenic epitopes results in a fundamental change in the immune system such that the future response to the same epitope (or heterologously related epitopes) is significantly faster and of higher potency. B cells, through their receptors and antibodies, can independently identify antigenic epitopes and elicit a response. On the other hand, the T cell requires antigens to be processed and presented to the TCR by transmembrane proteins called the major histocompatibility complex (MHC).

The MHC is a group of highly conserved transmembrane proteins. Their primary role within the immune system is the presentation of antigens to the TCR for recognition and response. There are essentially two classes of MHC. MHC class I bind primarily to T cells expressing CD8 (cytotoxic T cells) while MHC class II bind primarily T cells expressing CD4 (helper T cells). All nucleated cells express MHC class I, while only designated APC express MHC class II. APCs include innate immune cells including dendritic cells and mononuclear phagocytes, such that innate immune responses facilitate antigen presentation to CD4 T cells. Class II molecules can also be induced T cells, epithelial cells, and endothelial cells during states of inflammation, such that areas of inflammation develop APC-like capabilities until the inflammatory condition is quelled.

MHC molecules, whose gross structure is conserved across the species, vary in the fine details of their protein substructure, specifically in the area bound by the TCR. This variability, or polymorphism, allows cells expressing donor MHC to be recognized as foreign alloantigens by the recipient’s immune system. As such, rejection in solid organ transplantation is mediated by recognition of both MHC molecule polymorphisms and blood group antigens (A, B, and O). The genes encoding MHC molecules are found on the human leukocyte antigen (HLA) locus of chromosome 6. MHC class I is encoded primarily by HLA-A, B, and C genes, while class II molecules are encoded by HLA-DR, DP, and DQ genes. All adult transplant recipients have preformed antibodies to the blood group antigens; therefore, ABO incompatible transplantation is often complicated by an immediate antibody response, which, when antibodies are present in high concentration can lead to a

syndrome of immediate graft thrombosis known as hyperacute rejection. ABO-incompatible transplantation requires tailored depletion therapy in adults and children based on isohemagglutinin titers. In contrast, most recipients do not have antibodies against HLA antigens prior to transplantation unless they have been previously exposed to those antigens through prior transfusion, pregnancy, or transplantation. It is now generally accepted that T cell memory, established through heterologous immunity, can exist in patients even when there is no antibody response or prior exposure to the specific donor MHC antigens.

T Cell Maturation

Precursor T cells are formed in the fetal liver and bone marrow. These early cells lack TCRs and the associated structural proteins. After migration to the thymus, significant changes in DNA transcription and rearrangement within the precursor T cell lead to the production of the α, β, γ, and δ chains of the TCR as well as other T cell–specific cell surface proteins. TCRs are formed as either αβ or γδ paired chains. The T cell will initially code for a γδ TCR. If this fails to form properly, the more common αβ chain TCR is created. T cells with the more primitive γδ TCR typically recognize conserved moieties (such as heat shock proteins and MHC) and function similar to natural killer cells, while those with αβ TCR are limited to recognizing MHC bound to processed peptides. Each chain of the TCR has a constant domain and a variable domain. It is the combination of the αβ or γδ variable domains that result in the specific binding affinity of the TCR. Recombination yields over 10^9 unique TCR affinity possibilities, providing binding diversity that covers nearly all possible peptide–MHC combinations.

After undergoing DNA rearrangement, these naïve T cells express a TCR as well as both CD4 and CD8. CD4 and CD8 are accessory cell surface molecules that stabilize the interface of the TCR with MHC class II and class I, respectively. Thus early in development, the naïve T cell could potentially be activated by self-MHC expressing self-peptides. Therefore, developing T cells undergo a process of positive and negative thymic selection. Cortical thymic epithelial cells that express MHC and produce thymopoietin, thymosin, interleukin-7, and other cytokines perform “positive selection” of T cells that can recognize self-MHC. Those that do not properly recognize self-MHC, undergo apoptosis. The remaining cells travel to the thymic medulla and mature by losing either

CD4 or CD8. Within the thymic medulla, those cells that bind self-MHC with too high an affinity will also undergo programmed cell death. The remaining cells are either CD4 or CD8 positive cells that can recognize self-MHC without activation.

While the process of T cell maturation very efficiently generates cells that recognize self-MHC without activation, the process does not consider foreign antigens. By sheer chance, there will be TCRs that cross-react with non–self-MHCs. When exposed to these MHC–peptide complexes (as is the case with transplantation), the T cell will bind with sufficient affinity to lead to activation. Since they were not defined as self during the maturation of the T cell, the cell becomes activated and the process of cellular rejection may ensue. Although the frequency of naïve T cells available to react with any given MHC–peptide complex is as scarce as 1 in 500,000, because of the relative similarity between self- and non–self-MHC varieties, the prevalence of "alloreactive" T cells is 1% to 10% of T cells. Thus, T cells can be activated, (1) directly by allo-MHC as a result of a failure of thymic selection to anticipate foreign MHC; (2) indirectly, by allo-MHC being processed and presented by APCs; or (3) heterologously, by cross-reactivity between a self-MHC–foreign peptide complex and an allo-MHC molecule. Regardless, T cell activation is a seminal event in the recognition of allo-MHC and as such, most immunosuppression has been focused on thwarting physiologic T cell function.

T cells can be modified in the periphery leading to accentuated activation, or regulation. These mechanisms primarily exist to downregulate an immune response and activated T cell clones as a pathogen is controlled, and limit the potential for autoimmunity. The peripheral population of activated T cells is generally regulated by either programmed cell death or by being rendered inactive (or anergic). The primary mediator of apoptosis is CD95, or Fas. Fas, a tumor necrosis factor (TNF) receptor, is expressed on activated T cells. Activated T cells whose TCR is bound to MHC-peptide complex will undergo programmed cell death if their CD95 concomitantly binds CD178, also known as Fas ligand (FasL). Not unexpectedly, FasL is expressed in the periphery during inflammatory states to prevent T cells from damaging self tissue adjacent to sites of inflammation.

Alternatively, activated T cells can be controlled by inducing anergy. T cells require both TCR binding and an additional costimulatory signal (see

section on Costimulation) to activate. This costimulatory signal is typically provided by the APC. Without a costimulatory signal, TCR binding does not result in T cell activation. In some instances, TCR binding without costimulation will result in permanent anergy, even if the cell is later exposed to the appropriate signals.

The TCR only recognizes antigen bound to MHC—it will not recognize free antigen. This permits the T cell to destroy only cells expressing viral or mutated peptide sequences. To prevent inappropriate T cell activation by self-antigens that may be quite similar to foreign antigens, isolated TCR binding is insufficient to result in T cell activation. In fact, approximately 8,000 TCR interactions with the same antigen need to occur before T cell activation is achieved. Each TCR binding results in internalization of the TCR complex. This finding, combined with low cell surface TCR density, suggests that T cell activation requires several hours of antigen exposure. This threshold is modulated by costimulation signals.

Given its critical role in T cell activation, many immunosuppressive agents have been developed specifically to interfere with TCR binding and signaling. The TCR complex is comprised of the TCR heterodimer (αβ or γδ) plus several other transmembrane proteins. These include CD3 and the requisite accessory molecules (either CD8 or CD4). The accessory molecules allow for the TCR complex to only interact with either MHC class 1 or class 2, respectively. Binding of the TCR complex to MHC activates protein tyrosine kinases within the cytoplasm of the cell. Multiple binding signals combined with appropriate costimulation results in the ultimate release of inositol triphosphate (IP3) and diacyl glycerol (DAG). IP3 results in Ca^{2+} release, calmodulin binding, and activation of calcineurin. Calcineurin activates transcription factors NF-AT and NF-κB and thereby promotes subsequent production of cytokines, including IL-2 and its receptor (CD25). IL-2 functions in both an autocrine and paracrine manner to potentiate DAG activation of protein kinase C (PKC). Increased PKC activity ultimately results in cell division and proliferation of T cells. Only activated T cells express CD25; therefore, only those T cells activated in response to a presented antigen will proliferate as activated clone lineages. As antigen exposure decreases, the CD25 receptor is reabsorbed and the TCR returns to the cell surface resulting in quiescence.

T Cell Function and Immune Regulation

The accessory molecules (CD4 and CD8) stabilize the TCR interaction

with MHC. CD8 stabilizes interactions between the TCR and MHC class I, while CD4 stabilizes interactions between the TCR and MHC class II. Nearly all nucleated cells express MHC class I receptors that present intracellular peptide fragments for monitoring. $CD8^+$ T cells survey all nucleated cells and induce destruction of all altered cells. Accordingly, these lymphocytes are thus referred to as cytotoxic T cells. Alternatively, MHC class II is expressed primarily by APCs. MHC class II molecules express peptide samples from the phagocytosis of extracellular material and debris. Therefore, by virtue of their interaction with APCs, $CD4^+$ T cells have access to antigens as they invade the body and are engulfed by APCs. The $CD4^+$ cells then regulate the immune response, augmenting responses (helper T cells) or quelling specific responses (regulatory T cells).

Activated $CD8^+$ T cells eliminate infected or defective cells by way of either cytolytic agents or the induction of apoptosis. In the activated cytotoxic T cell, increasing intracellular Ca^{2+} releases granules containing a lytic protein (perforin) and serine proteases (granzymes). The perforin molecules then polymerize and create defects in the target cell's membrane, thus allowing the granzymes to lyse the cell. Alternatively, activated T cells upregulate CD178 (FasL) on their cell surface. This FasL binds CD95 (Fas) on the cell surface of the target cell, thereby initiating the apoptosis sequence.

Meanwhile, activated $CD4^+$ T cells promote APC release of cytokines and express costimulatory molecules that promote $CD8^+$ T cell activation. These $CD4^+$ helper T (T_H) cells in actuality belong to one of two cell types based upon their cytokine profile. T_{H1} cells express interferon-γ (IFN-γ) and TNF. These cytokines promote macrophage activity, cell-mediated immunity, and antibody production by the acquired immune system. T_{H2} cells produce IL-4 and IL-5. These cytokines inhibit macrophage activity while activating eosinophils and IgE production. T_H cells also impact and regulate each other's function. This results in a dynamic immune response whose character varies greatly with the milieu.

In addition to T_H cells, regulatory T cells (T_{REG}) have significant control over the immunologic response. This cell line modulates costimulatory signals, adhesion molecules, integrins, and cytokines, thereby controlling both effector cells and APCs. The subset of T_{REG} cells expressing CD25 has been extensively studied; this cell line has been the target of several attempts at immune response modification.

Costimulation

Costimulation refers to the pathways that modulate the outcome of antigen binding to the TCR. In general, recognition of the peptide/MHC complex via TCR binding is not sufficient in isolation to generate a response in a naïve T cell. Furthermore, TCR complex binding (signal 1) in the absence of costimulation (signal 2) may promote a state of anergy in which a T cell becomes unable to activate despite being provided appropriate stimulation. This anergic state permits tolerance of self-antigens as a means of preventing autoimmunity. It has been actively pursued as a therapeutic for its potential in achieving tolerance of an allograft.

Agents that influence the costimulatory pathway may facilitate or inhibit the efficacy of antigen presentation or recognition, or may alter the threshold for activation of naïve T lymphocytes. Targeting of the costimulatory pathway aims to permit a specific antigen-specific immune manipulation (as only cells undergoing antigen recognition are targets of costimulatory modulation), thereby limiting the extent of nonspecific side effects common to traditional immunosuppression.

CD28 is constitutively expressed on most naïve T cells. When bound by one of its two ligands, CD80 and CD86 (both expressed on APCs), the complex reduces the threshold required for TCR activation. This yields downstream cytokine (IL-4 and IL-8) and chemokine (RANTES) activation, in addition to the upregulation of antiapoptotic factors. In contrast, CD152 (cytotoxic T lymphocyte-associated antigen 4 [CTLA4]) is a molecule structurally similar to CD28 that competitively binds CD80 and CD86, yielding an inhibitory signal that terminates the immune response. CD152 is generally absent on naïve T cells, and is upregulated after antigen engagement. CD152 exhibits significantly (10 to 20 times) greater affinity for CD80/86 compared to CD28, and when upregulated, outcompetes CD28 for costimulatory dominance. In this elegant, reciprocal fashion CD28 and CD152 balance the immune response following stimulation by CD80 or CD86, as CD28 binding facilitates the immune response and CD152 binding quells the immune response.

The costimulatory pathway has been targeted with the development of monoclonal antibodies (MAb) and fusion proteins designed to inhibit T cell activation. The fundamental goal of costimulatory blockade remains induction of tolerance as a means to eliminate the need for maintenance of immunosuppression, though clinically to date these agents have been employed as a part of maintenance minimization strategies, in particular,

in calcineurin-sparing approaches.

B Cell Maturation and Function

Similar to T cells, B cells originate in the bone marrow. Unlike T cells, B cells also mature there. Derived from pluripotent bone marrow stem cells, the growth of pre-B cells is stimulated by IL-7 (produced by bone marrow stromal cells). Subsequently, these cells mature and proliferate as primed B cells following exposure to IL-4, 5, and 6. Similar to the T cell, the B cell has a cell surface bound receptor to recognize antigens. This immunoglobulin molecule is composed of two identical heavy chains and two identical light chains and can be secreted as an antibody to function in the extracellular environment. Similar to the T cell, each B cell is specific for a single antigen. The DNA sequences coding for the heavy chain are located on chromosome 14 in five different loci, and those for the light chains are located on chromosome 2 in two different loci. Each chain, like the TCR, has a variable region and a constant region. The antigen-binding site of the antibody is composed of the variable regions of both the heavy and light chains. DNA rearrangements and mutations in the variable regions of the heavy and light chains allow for an incredibly robust and diverse antigen-binding site. The constant regions of the heavy chains come together to form the fragment crystallizable (Fc) region of the antibody. This interacts with Fc receptors on phagocytes facilitating opsonization and antigen peptide processing. The Fc portion of some immunoglobulin isotypes (see below) also functions to activate the complement system.

There are nine different isotypes of immunoglobulins: IgM, IgD, IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, and IgE. The subtype of the antibody is defined by heavy chain usage. Each isotype has a unique immune function. IgM and IgG function as intravascular immune effectors, while IgA provides mucosal immunity in the gastrointestinal and respiratory tracts. Naïve B cells express IgD and IgM on their cell surface. After exposure to and binding of an antigen, naïve B cells produce an IgM response. This isotype is highly effective at binding of a complement, resulting in cell lysis and phagocytosis. Typically, B cell activation requires the binding of two cell surface antibodies by antigen. These antibodies are then physically approximated by way of a process referred to as cross-linking. This stimulates B cell activation, proliferation, and conversion to an antibody-producing plasma cell. The threshold for B cell activation is quite

high, but this can be modulated by the costimulation signals mediated by CD19 to CD21. B cells and T cells interact through both antigen presentation and costimulation signals thus controlling the immune response.

As the immune response expands, $CD4^+$ T cells induce isotype switching in the activated B cell, resulting in a decrease in IgM production and an increase in IgG production. Interestingly, during the immune response, the antibodies undergo further "somatic hypermutation" within the variable regions resulting in increased affinity of the immunoglobulin for its antigen. After activation, memory B cells remain to provide a more vigorous response to future exposure to the antigen. A portion of the secreted antibodies also remains circulating in the plasma in anticipation of exposure to antigen. In addition to these circulating high-affinity IgG, there are naturally occurring IgM antibodies with low affinity. These natural antibodies respond to a wide combination of carbohydrate epitopes found on bacterial pathogens. These natural antibodies are also responsible for ABO blood group and discordant xenotransplantation rejection.

REJECTION

Rejection is broadly classified into three definitions: (1) Hyperacute rejection, which occurs within minutes to days; (2) Acute rejection, which typically occurs in the first few months but can occur at any time; and (3) Chronic rejection, a fibrotic process that is the most common mode of allograft failure in the long term. More recently, classification has been restructured based on the mechanism of cell injury to include antibody-mediated rejection (ABMR) and T cell-mediated rejection (TCMR). Hyperacute rejection is generally an aggressive form of ABMR, whereas acute rejection can be pure ABMR, pure TCMR, or a hybrid of both. Chronic rejection can be induced by indolent or repetitive ABMR or TCMR, or can be the result of nonimmune insults such as is seen following hypoxia, viral injury, or drug toxicity. The mechanistic classification is much more important when considering immunosuppression, as it suggests the types of immunosuppressants required to mitigate the clinical injury.

Hyperacute Rejection

Primarily mediated by preformed antibodies, hyperacute rejection is a severe, untreatable thrombotic reaction. This reaction occurs within

minutes to hours of reperfusion. Antibodies bind the donor organ and subsequent complement-mediated cell lysis ensues. This proinflammatory milieu results in a procoagulable state and the graft immediately thromboses. The preformed antibodies that result in hyperacute rejection can be "natural antibodies," like those against blood group antigens, or as a result of prior exposure (as is the case with transfusion, prior transplant, or pregnancy). Regardless, hyperacute rejection is entirely preventable with proper tissue typing, antibody screening, and prospective cross-match.

A lymphocytotoxic cross-match is performed by mixing cells from the donor with complement and serum from the recipient. A positive cross-match occurs when preformed donor-specific antibodies (DSA) in the recipient serum result in donor cell lysis. A negative cross-match and correct ABO tissue type matching will prevent hyperacute rejection in nearly all transplants. Unfortunately, it is not possible to perform a prospective cross-match on all potential transplants. Therefore, a more common technique is to screen a patient's serum against a panel of random donor cells that represent the regional donor pool. This panel of reactive antibody assay (PRA) will provide an understanding of a patient's degree of sensitization. Typically expressed as a percentage of the panel showing a reaction, a nonsensitized patient will have a PRA of 0% while a highly sensitized patient may have a PRA of up to 100%. In the current era, the PRA test is performed using polystyrene beads coated with HLA antigens. The assay detects all anti-HLA antibodies and yields a PRA percentage based on the frequency of HLA types in the regional donor pool. Highly sensitized patients may be candidates for desensitization therapy using plasmapheresis, intravenous immunoglobulin (IVIg), or certain myelodepleting chemotherapeutic agents. The success with these therapies has been quite variable.

Acute Rejection

Most immunosuppressive therapies are designed to target cellular acute rejection, either pure TCMR or mixed TCMR and ABMR. Pure ABMR, like hyperacute rejection, is best avoided through preventive typing, as the agents available for its treatment are less well developed. Regardless, most treatments for acute rejection target the T cells driving the effector response (TCMR) or impelling the antibody response (ABMR). Fortunately, with improved T cell–specific immunosuppression, the rate of graft loss due to acute rejection has been significantly minimized. As

previously described, recipient T cells encounter their antigen, either through donor peptide presented by self MHC or by direct recognition of donor MHC. While the former is infrequent (occurring at a rate of less than 1 in 200,000 T cells), the latter occurs as frequently as 1 in 10 T cells. Once activated, these alloreactive T cells initiate the process of acute rejection. Quick and extensive influx of T cells and monocytes results in cytolysis and a general inflammatory milieu that leads to parenchymal dysfunction, small vessel thrombosis, and organ injury. To prevent and/or treat this, the bulk of immunosuppressive therapies are directed at T cells and the pathways that result in T cell activation. To prevent acute cellular rejection, most authors advocate for "induction therapy" early in the transplant phase. These agents (see below) globally deplete or inactivate T cells immediately posttransplant when the physiologic stress of surgery combined with the injuries associated with ischemia and reperfusion are most likely to promote immune recognition of the donor organ. Given the sensitive milieu immediately posttransplant, most immunosuppressive regiments focus on intensive immune suppression initially and then taper to lower levels over time.

In addition to TCMR, ABMR can occur in the early stages after a transplant. In the setting of ABMR, either preformed antibodies (at undetectable titers) or memory B cell clones capable of producing DSA attack the offending donor organ. In the setting of ABMR, there is rapid graft dysfunction after a "honeymoon" period of graft function. Rapid recognition and response are critical to ensure graft survival. ABMR can be treated with aggressive immunosuppression, antibody depletion with plasmapheresis, and IVIg. Unfortunately, graft damage is usually permanent and proportional to the magnitude of rejection.

Chronic Rejection

Chronic rejection is a poorly understood hybrid of both immune-mediated rejection and nonimmune-mediated graft fibrosis. Given that this clinical entity is not entirely due to repeated or indolent TCMR or ABMR, more appropriate organ-specific terms are used. Specifically, interstitial fibrosis and tubular atrophy (IF/TA) or chronic allograft nephropathy for kidneys, chronic allograft vasculopathy (CAV) for hearts, vanishing bile duct syndrome for livers, and bronchiolitis obliterans syndrome (BOS) for lungs are histologic findings used to characterize and stratify the degree of chronic rejection observed. Chronic rejection occurs over years and results

in fibrosis without significant lymphocyte infiltration. Chronic rejection is mediated by both long-term response to alloantigen as well as ischemia/reperfusion injury. Although chronic rejection is untreatable, several factors have been identified that contribute to its progression, most importantly, recurrent acute rejection. Therefore, better prevention of acute rejection is likely to decrease and postpone graft failure from chronic rejection.

IMMUNOSUPPRESSION

Contemporary immunosuppression consists primarily of multiagent strategies designed to prevent rejection of the allograft. Overall, these strategies yield excellent outcomes with respect to allograft survival. However, all agents presently in use target the global immune response, and do not target the recipient's specific response to the allograft. As such, the multidrug approach in common use today employs multiple agents to address the redundant nature of the immune system and thereby modulate the normal global immune response. While successful at the prevention of rejection, this strategy leaves the recipient at increased risk of bacterial and viral infections, and at a higher risk for virally driven malignancies. Immunosuppressive therapy is thus a dynamic process in which the risk of rejection must be weighed against risk of both immune and nonimmune side effects that pose a threat to the recipient.

The optimal degree of immunosuppression varies in the posttransplant period. Unfortunately, there is no method for measuring the individual's need for immunosuppression, either in type or magnitude. As such, general assumptions are made that are reasonable approximations of a person's needs based on the organ system involved. Immediately posttransplant, a high degree of immunosuppression is required given an increased risk of rejection. Graft injury due to the mandatory periods of ischemia and reperfusion at the time of transplant and initial antigen presentation contribute to an increased inflammatory state that drives innate immune activation, accentuates initiation of acquired immune responses, and thus mandates a higher degree of immunosuppression immediately posttransplant in order to establish a stable state of immunologic unresponsiveness. The amount of immunosuppression required in this period is typically unsustainable, and must be tapered fairly rapidly. Unfortunately, it is impossible to measure the degree of immunosuppression afforded by current medications, and the rate of taper

is based on broad generalizations, with drugs dosed to control side effects. Regardless, following an induction phase, patients are chronically treated with maintenance drugs. Maintenance immunosuppression is designed to be chronically tolerable. Current multidrug maintenance regimens are designed to suppress multiple pathways at subtoxic doses of medications. In some patients, this dosing may represent "over immunosuppression" while others may be "under immunosuppressed." Unfortunately, we cannot "measure" the degree of immunosuppression directly and therefore it is impossible to dose immunosuppression to "effect." Rescue therapies are designed to treat existing rejection, and like induction therapies, are chronically intolerable.

The agents below are reviewed both in mechanism as well as by their role in the multiagent drug therapy to achieve immunosuppression. Their relationships to the major pathways of T cell activation are shown in Figure 9.1. There are over 50 different combinations reported in the literature for kidney transplant immunosuppression alone, and many of the drugs used are approved only for very specific indications, but used for other indications (e.g., approved for adults and used in children, or approved for use with steroids, but used in steroid free regiments). It is fair to say that over half of the prescriptions written for transplant immunosuppressants are written for "off-label" indications. It is beyond the scope of this chapter to advocate any particular regimen, and the reader should recognize that immunosuppressive drug use requires considerable experience, and cannot be prescribed based on a "cookbook" format.

Corticosteroids

Steroids are commonly employed in induction, maintenance, and rescue immunosuppressive strategies. Prednisone is the most commonly employed oral glucocorticoid, while methylprednisolone is available as an intravenous equivalent, and is generally used when high-dose induction therapy is involved. While exhibiting potent immunosuppressive properties, steroids produce a particularly broad and nonspecific effect. Glucocorticoids bind an intracellular receptor that in complex enters the nucleus to act as a transcription factor. Inhibition of NF-κB is of particular importance, preventing activation of proinflammatory cytokines and decreasing T cell activation. Downstream, this results in diminished IL-1 and TNF-α production. In addition, the arachidonic acid cascade and vasodilation are inhibited. The broad effects of steroids make them

appropriate for use to control initial innate immune activation immediately after transplantation, to control immune activation as a maintenance drug, or for immunosuppressive augmentation to reverse acute rejection. These potent and diverse immunosuppressive properties must be weighed against their well-documented contributions to poor wound healing, the development of diabetes mellitus, hypertension, and osteoporosis.

Purine Analogs

Azathioprine (Imuran)

Azathioprine is a purine analog used to limit clonal expansion of T and B cells by means of inhibition of DNA synthesis. In this manner azathioprine nonselectively targets cells undergoing rapid division and nucleotide synthesis. Following hepatic conversion to 6-mercaptopurine (6-MP) and 6-thio-inosine monophosphage (6-tIMP), alkylation of DNA precursors results in the net drug effect. The drug is particularly active in rapidly dividing cells (like activated lymphocytes) and tissues with high cell turnover (like the skin, and gut). As such, azathioprine has toxicity seen as lymphopenia, GI distress, hepatic toxicity, and hypertrophic and malignant skin lesions.

Mycophenolate Mofetil (Cellcept)

Mycophenolate mofetil (or MMF, a derivative of the *Penicillium stoloniferum* fungus) acts in an antiproliferative manner similar to azathioprine. Hepatic metabolism yields the activated mycophenolic acid, which proceeds to inhibit inosine monophosphate dehydrogenase, the rate-limiting enzyme in the synthesis of guanine monophosphate (GMP) in the de novo purine synthesis pathway. While global inhibition of purine synthesis would potentially be catastrophic for the recipient, the majority of body tissues can generate adequate purine stores by way of a salvage pathway for GMP synthesis. Of great importance is the finding that lymphocytes lack the ability to utilize the GMP salvage pathway, yielding a relatively lymphocyte-specific mechanism of action for MMF. This results in a blockade of the proliferative response and expansion of both T and B cells in addition to the inhibition of antibody formation. MMF has succeeded AZA in many protocols as it has been shown to decrease the rate of biopsy-proven rejection in most organ systems. Its toxicity profile is better than that of azathioprine, given its more targeted intracellular mechanism. It still induces lymphopenia and gut irritation, but its impact

on skin and hepatic damage is substantially less than that seen with azathioprine. Economically, it is more expensive than azathioprine, and its therapeutic effect is largely equivalent as evidenced by modern comparative trials.

Calcineurin Inhibitors

Calcineurin inhibitors remain the mainstay of most multimodal immunosuppressive regimens regardless of the organ system transplanted. They are used in over 95% of patients, typically in combination with MMF or azathioprine with or without prednisone. They block signal transduction downstream of the TCR, and as such, inhibit T cell activation. Given the critical role of T cells in TCMR, and in providing B cell help for ABMR, calcineurin inhibitors target one of the most critical elements of the alloimmune response.

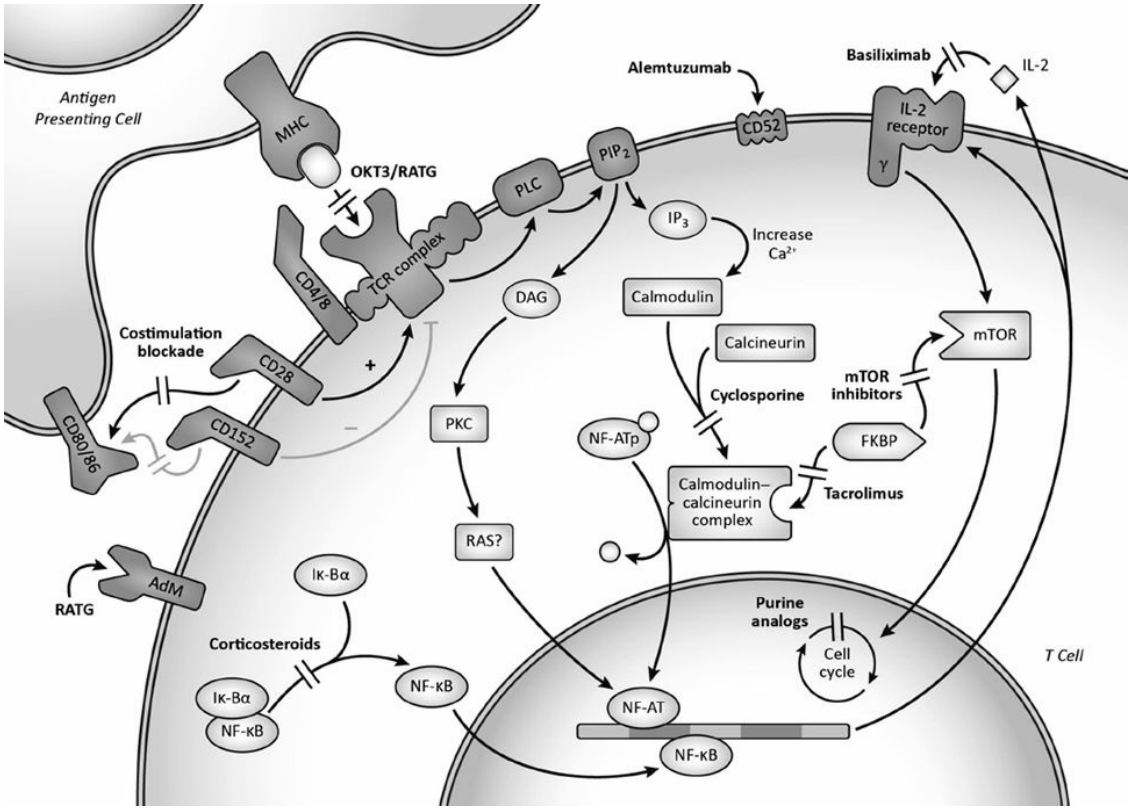

Figure 9.1. Sites of action of immunosuppressive drugs currently in use. Shown are stylized representations of the major pathways of T cell activation during association with an antigen presenting cell. Rabbit antithymocyte globulin (RATG) likely works at many sites, including blocking function of the T cell receptor (TCR) and numerous types of adhesion molecules (AdM). Note that costimulation blockade, such as that evoked with the fusion

protein belatacept, targets the activating interaction between CD28 and the CD80/86, but also has the potential to impede the mollifying effects of CD152, which also binds to CD80/86. Alemtuzumab facilitates T cell depletion after binding to CD52; the function of CD52 remains incompletely defined. Note also that the calcineurin pathway can be blocked by either CsA or tacrolimus such that there is no mechanistic rationale for using both of these agents concurrently. Although mTOR inhibitors bind to the same molecule as tacrolimus (FKBP), their effect is on a different pathway downstream of the common gamma chain of many cytokine receptors, including the IL-2 receptor.

Cyclosporine

Cyclosporine (CsA) was first approved in clinical medicine in 1983 and has played an important role in the advancement of the field of transplantation. Its approval dramatically improved the success of all transplanted organs and is generally considered as the drug that facilitated modern clinical transplantation. CsA is an 11-amino acid peptide from the fungus *Tolypocladium inflatum gams.* CsA blocks the calcineurin–calmodulin complex downstream of the TCR, and thus prevents all specific T cell functions (both activating and inhibitory). CsA is metabolized by the hepatic cytochrome P450 system, and as such serum levels are susceptible to agents that modulate the P450 pathway. Renal toxicity is an important side effect of CsA therapy due to vasoconstrictor effect on the proximal renal arterioles, resulting in significant decrease in renal blood flow. It also has substantial impact on systemic hypertension, worsens hyperlipidemia, and induces hirsutism and gingival hyperplasia. To control the numerous side effects and navigate its interaction with many P450-associated drugs, CsA is dosed based on 12-hour trough levels. CsA requires bile for enteral uptake, and as such its effect is limited in circumstances of hepatic dysfunction. Newer microemulsion preparations are less dependent on enterohepatic circulation and have become the dominant form of CsA prescribed for transplantation.

Tacrolimus

Tacrolimus (Prograf) is a macrolide derived from the fungus *Streptomyces tsukubaensis.* It arrests T cell activation through blockade of calcineurin pathway by binding to a component known as FK-binding protein. Though the side effect profile is similar to that of CsA with regard to renal toxicity and hypertension, its cosmetic side effects are markedly reduced. As such,

tacrolimus-based immunosuppression regimens are favored in many centers, particularly in North America. Tacrolimus has greater potential to induce neurotoxicity, particularly dose related tremors. Tacrolimus is not influenced by bile production and for this reason, tacrolimus is highly favored in liver transplant regimens. Comparator trials versus CsA seem to indicate better efficacy in liver transplantation, but its performance in other organ systems is comparable. Like CsA, tacrolimus is dosed based on 12-hour trough levels.

mTOR Inhibitors

Rapamycin, or sirolimus, is a macrolide derived from the bacterium *Streptomyces hygroscopicus.* Everolimus is an analogue with similarly potent immunosuppressive properties. Both bind to the FK-binding protein, but sterically hinder a site distinct from that bound by tacrolimus and thus block a pathway unrelated to the calcineurin pathway. As such, they do not inhibit TCR signaling. Rather, they block a protein called the mechanistic target of Rapamycin (mTOR). This molecule is downstream of the common gamma chain used by numerous cytokine receptors (those for IL-2, -4, -7, -15, and -21), and thus blocks the amplification signal of many T cells. Resultant inhibition of p70 S6 kinase activity arrests cell cycle progression, and has been shown to be effective in the prevention of rejection. In multidrug therapies, mTOR inhibition can be used as an alternative to calcineurin inhibition, though the efficacy in preventing rejection is typically lower than with calcineurin inhibitors. Side effects of hypercholesterolemia and thrombocytopenia may require discontinuation of therapy, limiting more widespread adoption of mTOR inhibition-based regimens. As T cell amplification is critically important to normal wound maturation, mTOR inhibitors are known to worsen early phases of wound healing and foster hernia formation. Their use in lung transplantation has been hampered by concerns over bronchial wound healing. They also impair mucosal healing and can promote nonhealing oral and gut ulceration. Regardless, the fact that they do not have the nephrotoxicity seen with calcineurin inhibitors has made them an attractive alternative for long-term maintenance therapy, particularly in patients with marginal renal function. mTOR inhibitors are dosed based on trough levels (24 hours for sirolimus and 12 hours for everolimus). Apart from a difference in half life, there are no demonstrated differences between everolimus and sirolimus.

Lymphocyte-Depleting Agents

Lymphocyte depletion is frequently employed as induction therapy in the peritransplant period, inducing profound immunosuppression and acceptance of the allograft, but this degree of immunosuppression is tolerated only for limited periods of time on account of increased risk of opportunistic infection. It can also be used for rescue therapy when faced with ongoing acute rejection.

Antilymphocyte Globulin

Antilymphocyte globulin is a polyclonal antibody preparation comprised of antibodies against multiple antigens on lymphocytes or thymocytes. This is prepared by the purification of gamma globulin fraction of sera of animals immunized with an inoculum of human lymphocytes. Most commonly employed preparations include rabbit antithymocyte globulin (RATG) and horse antithymocyte globulin (ATGAM). Each utilizes human thymocytes as the immunogen. Following administration, complement-mediated lysis and opsonization deplete recipient T cells, and sterically hinder numerous surface receptors for up to 3 months after administration. RATG is approved for the treatment of established acute rejection, but often used as an induction agent at the time of graft introduction as a means to achieve profound immunosuppression while minimizing the need for steroids and calcineurin inhibitors. While depletional therapy is well tolerated, side effects are related to polyclonal composition and can include thrombocytopenia, leukopenia, and anemia. Recipients are also at risk of viral reactivation and primary infection. Meta-analyses of induction depletion show that these agents clearly reduce the rate of acute rejection, but have failed to show convincing improvement in long-term graft or patient survival. Since RATG and ATGAM are made in other species, repeated use can be limited by neutralizing antibodies against rabbit or horse immunoglobulin, respectively. Both preparations can result in serum sickness with prolonged usage.

OKT3

Muromonab-CD3 (OKT3) is a monoclonal antibody against human CD3. This murine antibody was the first commercially used monoclonal antibody in any human indication. OKT3 binding of CD3 results in both internalization of the TCR complex (preventing antigen recognition) and

opsonization of the T cell for elimination by phagocytosis. OKT3 leads to elimination of peripheral $CD3^+$ T cells immediately after administration. Although $CD4^+$ and $CD8^+$ cells return to the periphery several days after administration, these cells lack a TCR and cannot bind antigen. OKT3 has been effective as both an induction agent and as a therapy for acute rejection, but its direct binding to the CD3 complex leads to pan-T cell activation and a resulting cytokine storm (fever, hypotension, and general malaise). For this reason, its use has been curtailed and it is now mentioned largely for historical context in interpreting older transplant literature. It results in depletion of both naïve and activated T cells. Unfortunately, most recipients will develop antimurine antibodies limiting the effect of OKT3, preventing subsequent dosing, and potentially resulting in a vigorous serum sickness.

Anti-IL-2 Receptor Antibodies

Daclizumab and basiliximab are (respectively) humanized and mouse–human chimeric antibodies directed against CD25. These agents are used in induction therapy to block the high-affinity conformation of the IL-2 receptor (specifically CD25). The disruption of the binding of IL-2 prevents T cell clonal expansion of naïve T cells encountering antigen for the first time. In induction therapy regimens, these anti-IL-2 receptor antibodies marginally reduce the rate of acute rejection, but have not shown substantial differences in graft or patient survival. Some authors suggest that they reduce the need for calcineurin inhibition or glucocorticoids early after transplantation. Daclizumab was the first humanized antibody approved for use in humans, and is currently off the market.

Costimulation Blockade

Costimulation blockade has been of great interest in transplantation as a potentially ideal target to permit immunosuppression. Belatacept is a second-generation fusion protein consisting of the extracellular component of CTLA-4 (CD152) and the heavy chain of the human IgG1. As described earlier, CD28 signaling (by way of CD80/CD86 interaction) provides permissive activation signals to allow for TCR signaling and T cell activation. CTLA-4 (CD152) outcompetes CD28 for binding positions at CD80 and CD86. During the immune response, activated T cells express CD152 to block CD28 binding and ensure that the immune response is

appropriately downregulated after the initial activation. Belatacept makes use of this pre-existing feedback by blocking the interaction of CD28 and CD80/CD86 and consequently impairing both costimulation and T cell activation. Of note, this pathway is only relevant when the TCR is activated, as such, use of costimulation with calcineurin inhibition limits the mechanistic rationale of this approach. Also, at high doses, belatacept can block both the stimulatory CD28 and the inhibitory CD152 signaling. As such, approved dosing regimens specifically limit the dose to avoid over dosing and producing a paradoxical activating effect similar to that seen in oncologic checkpoint inhibition. Belatacept is currently approved for use with MMF and prednisone in kidney transplant alone. Its optimal usage has not been defined. Importantly, it seems to be most efficacious for primary immune responses, and it appears to be less effective in sensitized patients, or patients with heterologous T cell alloimmunity.

Additional Monoclonal Antibody Therapies

Rituximab is a murine anti-human CD20 chimeric antibody used in the treatment of posttransplant lymphoproliferative disorder (PTLD). CD20 binding facilitates antibody-dependent cellular cytotoxicity of B cells. Indications for rituximab have broadened to treat disorders of autoimmunity. It is now being explored as a treatment for ABMR, and for use in alloantibody desensitization trials. As CD20 is not expressed on antibody producing plasma cells, the rational for its use in ABMR remains challengeable.

Alemtuzumab is a humanized antibody against CD52, a protein expressed on the surface of mature lymphocytes, and monocytes. Alemtuzumab has demonstrated efficacy in the depletion of T and B cells in both peripheral blood and in secondary lymphoid organs, providing a therapy for lymphoma in addition to use as an induction therapy in immunosuppressive regimens. Although it has not been approved for any transplant indication, it is now used off-label for approximately 10% of all kidney transplants in North America. It has recently been introduced as a therapy for multiple sclerosis and its availability for transplant usage is dependent on a specific compassionate use program from its maker.

CONCLUSIONS

Over 100 years after Alexis Carrel’s development of ground-breaking surgical techniques, clinical solid organ transplantation is a standard

therapy for end-stage organ failure. Given all of the advances of the last decade, transplantation is now stymied most by lack of donor organ availability. However, its practice is dominated by attempts to control immune rejection. As our understanding of the immune system has improved, so too has our ability to control rejection. Nevertheless, immune management remains a life-long imperative for transplant recipients, and as such, a long-term concern for all transplant surgeons.

EDITOR'S COMMENT

When I think of transplantation I think of complicated immunology and intricate pathways but transplantation really began with a surgeon, Alexis Carrel, developing techniques for something we think of as quite simple today, vascular anastomoses. After that it was all about immune manipulation to decrease rejection and invoke tolerance to facilitate allotransplantion. The innate immune system is taken care of by general immune suppression at the time of organ transplantation targeting activation caused by ischemia, reperfusion injury, and the trauma of procurement. However, the mainstay of transplantation modulates the acquired system, humoral (B-cell) and cellular (T-cell [helper and regulatory]) immunity. T cells require the presentation of antigens by the major histocompatibility complex (MHC). Rejection is mediated by recognition of both MHC molecule polymorphisms as well as blood group antigens (A, B, and O). Mismatch of blood group or prior exposure to antigens is the cause of hyperacute rejection (within minutes) and can be avoided by proper tissue typing, antibody screening, and prospective crossmatch. As such most immunosuppression is focused on preventing or quelling T-cell activation.

Acute rejection (first few months) can be mediated by B- or T-cell activation or a mix of both. Chronic rejection (over years) can be caused by repetitive acute rejection or by nonimmune insults such as hypoxia, viral or drug toxicity and is not treatable and best prevented by avoiding acute rejection. If activated, T cells can be controlled by programmed cell death or by inducing anergy and thus tolerance via preventing necessary coactivation with monoclonal antibodies. The latter has been employed as part of a maintenance minimization strategy.

T-cell manipulation, especially with induction therapy in the early posttransplant period to deplete or inactivate T cells, is responsible in large part for the significant diminution of acute rejection. If antibody-mediated rejection is at play as well then in addition to aggressive immunosuppression, antibody depletion with plasmapheresis and immunoglobulin are employed. Immune suppression strategies consist of a combination of corticosteroids, purine analogs (azathioprine, mycophenolate), calcineurin inhibitors (cyclosporine, tacrolimus), mTor inhibitors (everolimus, sirolimus), lymphocyte-depleting agents (antilymphocyte globulin, OKT3, anti–IL-2 receptor antibodies (daclizimab, basiliximab), costimulation blockade (belatacept), and other monoclonal antibody therapies (rituximab, alemtuzumab). There are over 50 different combinations of immunosuppressive regimens reported in the literature just for kidney transplant and that many more for other organs. Unfortunately, the degree of immunosuppression cannot be measured directly such that patients may be over or under immune suppressed and rescue therapies are designed to treat rejection. Complications of immunosuppression by the various treatments include poor wound healing; opportunistic infection; diabetes; hypertension; hyperlipidemia; osteoporosis; lymphopenia; gastroenteritis; hepatic, renal, and neurotoxicity, graft versus host disease; hypertrophic and malignant skin lesions.

More than 30,000 organ transplants were performed in 2015 in the United States, 20% of which were living donations. Half a million transplants have occurred since 1987 according to UNOS (United Network for Organ Sharing). The vast of number of organs transplanted are kidneys (58%), followed by liver (23%), heart (9%), lung or heart/lung (6%), pancreas or kidney/pancreas (3%), and intestine (0.5%). There have also been a handful of vascularized composite allotransplantations (VCA). These include transplantation of multiple tissues such as muscle, bone, nerve, and skin as a function unit (e.g., limbs and face). According to the Organ Procurement and Transplantation Network, failure of kidney transplantation is 4% at 1 year and 21% at 5 years. Failure for liver transplants is 30% at 1 year and 59% at 5 years (Jain A, Reyes J, Kashyap R, et al. Long-term survival after liver transplantation in 4,000 consecutive patients at a single center. *Ann Surg* 2000;232(4):490–500). The 1-year survival rate for heart transplants is 85% to 90% with an annual death rate of about 4% thereafter. The one-year survival rate for lung is 90% to 94% which drops to 55% at 5 years. For pancreas transplant, 65% of patients are insulin independent at 10 years. The rate of intestinal transplantation has dropped by 25% in the first

part of the decade but still is a viable option. Historically, the best 1-year intestinal graft survival of an isolated intestine transplant is 65%. For patients without complications, a survival of 86% to 93% (Sudan D. The current state of intestine transplantation: indications, techniques, outcomes and challenges. *Am J Transplant* 2014;14:1976–84.). Rates are better for females than males and young versus old and Caucasians versus minorities.

As lack of donors are a major deterrent to transplantation, a noteworthy law was fully enacted in 2015 called the HOPE act (HIV Organ Policy Equity Act). This act allows the recovery of transplantable organs from HIV-positive donors that will be used for HIV-positive recipients in an ongoing feasibility study.

In summary, tolerance as well as minimal multiple repressive agents from a variety of types thus decreasing long-term toxicity and improving survival with long-term suppression albeit with smaller doses of multiple agents give a hope of tolerance which is the Holy Grail of transplant biology.

10 Surgeons and the Opioid Epidemic

Jeffrey D. Howard, Jr. and Hiram C. Polk, Jr.

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

INTRODUCTION

In the short course of 30 years, the United States has dramatically lapsed into an opioid abuse epidemic. Since the late 1990s, overdose deaths have risen at unprecedented rates. During the same period, the number of dispensed opioid prescriptions has risen at an equally unprecedented rate. According to the Centers for Disease Control and Prevention (CDC), there were more than 50,000 overdose deaths in the United States in 2015. More than 30,000 of these deaths involved opioids.

Surgeons can play a vital role in combating this epidemic. More than 100 million surgical procedures are performed annually in the United States, and nearly all patients receive postoperative opioids to manage surgical pain. Some have even suggested that surgeons over-prescribe these drugs, which may contribute to this epidemic.

The etiology of this pervasive disease is bewilderingly complicated and involves, at least, the following: rise of pharmaceutical marketing, poorly performed and interpreted scientific studies, a paradigm change in physician and patient perspectives regarding the treatment of pain and usage of opiates, transition to consumer-based medicine, and a rapidly expanding cheap heroin market. Key historical events leading to the opioid epidemic are reviewed in this chapter (Table 10.1). Strategies for prevention and treatment as well as future aims are analyzed. The role of the surgeon is delineated throughout.

BRIEF HISTORY OF OPIOIDS

Opium is a liquid extracted from the seed pods of the opium poppy *Papaver somniferum.* In the early 1800s, German pharmacist's apprentice Friedrich Sertürner was the first to isolate morphine from opium. He

named this plant alkaloid “morphium” after the Greek god of dreams, Morpheus. More than 300 wars occurred during the 19th century, which was associated with explosive cultivation of opium as treatment for pain in soldiers. Opium itself was the primary basis for two wars between the British and Chinese during this period.

In 1853, Scottish physician Alexander Wood invented the hypodermic needle by modeling his design after a bee’s stinger. His primary intention for this instrument was the injection of opium preparations. By this time, the addictive power of opioids was appreciated by some.

In 1874, Charles Wright synthesized diacetylmorphine while attempting to create a nonaddictive opioid. Wright’s work was one of innumerable failed attempts to discover the “holy grail,” a nonaddictive opioid. Heinrich Dreser, a chemist who worked for Bayer Pharmaceutical, further developed diacetylmorphine, which was subsequently marketed as heroin. The term “heroin” was derived from the German for “heroische” meaning “heroic.”

At this time in history, heroin was generally believed to be nonaddictive. It was prescribed for a multitude of medicinal conditions, including respiratory ailments, diarrhea, and for the treatment of pain. Heroin was widely prescribed by physicians because of its effectiveness and the relative paucity of other therapeutic options. The increase in prescribing heroin occurred in direct proportion with the increase in the number of opioid addicts. This soaring increase in addicts prompted the Harrison Narcotics Act of 1914. Thereafter, the medicinal use of opiates decreased rapidly until the 1980s, when several events converged, thereby leading to the current opioid epidemic in America.

A REVOLUTION IN PHARMACEUTICAL ADVERTISING

In 1951, a psychiatrist working for an advertising entity landed the contract to market a new antibiotic for Pfizer. A grassroots advertising campaign was organized, which focused on outreach to individual physicians, a novel concept at the time. Terramycin (oxytetracycline) and its marketing campaign became a monumental success. A similar campaign was employed by the same ad company in 1963 for Hoffman La Roche’s drug Valium (diazepam). This campaign was also very successful. Valium became the pharmaceutical industry’s first $100 million drug and later the first $1 billion drug.

TABLE 10.1 Key Events Leading to the Opioid Epidemic

Early 1800s	Morphine is isolated from opium.
1898	Heroin marketed by Bayer for a variety of medical ailments.
1914	Because of rising addiction rates, the Harrison Narcotics Act is passed, which regulated the importation, production, and distribution of opium and coca products.
Early 1900s	Opiates are rarely used for medicinal purposes due to risk of addiction.
1951	Terramycin marketing campaign is a success leading to a revolution in pharmaceutical advertising.
1960	Valium becomes the first $100 million drug (later becomes first $1 billion drug).
1980	*NEJM* publishes a 101-word letter to the editor that suggests addiction is rare.
	Stjernsward named WHO cancer program chief and proclaims that it is a patient's "right" to be pain-free.
1986	Pain publishes a review of 38 cancer patients chronically using opioids, which opens the debate regarding expanded usage of opioids.
1990–1999	"Opioids are nonaddictive if used to treat pain" becomes accepted dogma.
	Cheap and accessible heroin spreads across the United States.
1996	Purdue Pharma release OxyContin.
	First "pill mill" established (South Shore, KY).
	"Pain as the Fifth Vital Sign" is introduced.
1998	JCAHO and VA adopt pain as the Fifth Vital Sign.
1999–2015	Overdose deaths increase fourfold.

These advertising campaigns are the basis of modern medical and pharmaceutical advertising. Direct-to-consumer and physician-directed advertising both originated in these campaigns. Thereafter, representatives and letters poured into hospitals and physician offices to promote a product. An infiltration of medicinal advertisements appeared in public entertainment venues. Pharmaceutical agencies even began to overtly target continuing medical education (CME) as an opportunity for advertising. By 2015, pharmaceutical advertising costs exceeded $5 billion. Arthur Sackler, the physician advertiser who engineered this revolution, along with his brothers, went on to purchase a small drug company, Purdue Pharma (formerly Purdue Frederick). This company eventually developed OxyContin—a drug that is essential to America's opioid epidemic.

MISCONSTRUED SCIENCE

In 1979, the *New England Journal of Medicine* (*NEJM*) published a Letter to the Editor framing the conversation regarding the addiction potential of opioids for years to come. This single paragraph, 101-word correspondence, retrospective review of hospitalized patients treated with an unknown quantity of narcotics, for an unknown time frame, while inpatient only, and in an era when physicians were notoriously stingy with opiates, became the cornerstone for the pro-opioid movement. In this published letter, the authors claimed that the "development of addiction was rare." Conversely, we know today that the development of addiction is anything but rare. Despite the total absence of data, this letter became widely and incorrectly cited. A 1990 *Scientific American* publication

referred to it erroneously as an “extensive study.” A 2001, *Time* article referred to it as “a landmark study” and went further to call the fear of addiction to be “exaggerated.” Moreover, the author’s “findings” were quoted in lecture after lecture as a staple of the pro-opioid movement, especially those supplied by opioid advertisers.

In 1986, the journal *Pain* published a review of 38 cancer patients with chronic pain who used opioid medications. Despite the limited cohort, this published article began to be fervently debated across the country. For pro-opioid individuals, the “Pain paper,” as it came to be known, in combination with the 101-word *NEJM* Letter to the Editor, served as clear evidence that opioids, even chronically prescribed, were safe.

Consideration must be given to the fact that these publications occurred during a time long before complete databases were archived online. As such, to review these articles, an interested party either had access to the original publication or had to travel to a medical school library, retrieve the journal, and then copy the article. As a result, much of science was spread by word of mouth. This promoted the propagation of incorrect analyses of these publications, which was not of themselves incorrect but rather grossly misinterpreted and systematically exaggerated. An analysis of the interpretation and dissemination of these publications demonstrates the great burden on journal editors to consider the impact that any paper may produce when published. The issue of overt and concealed conflicts of interests is currently being debated and certainly was present in the interpretation and dissemination of these publications.

PARADIGM CHANGE

During the same time frame that these publications were fallaciously guiding the scientific discussion regarding the use of opiates and their addiction potential, the culture of both patients and physicians alike began to shift dramatically. Prior to this time, physicians had been educated to avoid opiates at all costs. All too soon this changed!

In 1980, the year that the infamous *NEJM* letter to the editor was published, Stjernsward was named chief of the World Health Organization’s (WHO) cancer program. Prior to being appointed to this position, Stjernsward had worked at Kenyan hospitals, where he witnessed many patients suffering from debilitating pain related to cancer. With this background, he proclaimed it a patient’s “right” to be pain-free and developed the “WHO pain ladder,” which included the use of opioids.

Despite the lack of any supporting evidence, the idea that opiates would not, or at least were unlikely to, cause addiction if administered to a patient with pain began to gain a foothold. In fact, this idea became dogma for much of the 1990s and early 2000s. The American Pain Society even supported this claim on its website. Furthermore, it argued that if used to treat pain, opioids would not depress the respiratory system. Both claims are now known to be incorrect.

In 1996, the president of the American Pain Society altered the national conversation on pain, stating that physicians needed "to treat pain as a vital sign." Thereafter, the movement "Pain: The Fifth Vital Sign" was adopted and infiltrated much of medicine in very short order. Almost too quickly, the Joint Commission for Accreditation of Healthcare Organizations (JCAHO) and the Veterans Health Administration adopted this mantra. Hospitals were thereafter evaluated, at least in part, based on how they treated a patient's pain.

Pain is largely a subjective matter. Actual vital signs (temperature, heart rate, blood pressure, and respiratory rate) are objective measures. Pain depends upon a multitude of factors and varies tremendously from one patient to the next and thus does not lend itself to objectivity. The lack of precise objectivity makes interpretation of pain data and a pain response very difficult.

Nonetheless, a public disenchanted with physicians and what they perceived as inadequate pain management demanded medicinal—opioid—treatment for their pain. Hospital administrators, mostly business managers who were focused on consumer satisfaction, pressured physicians to treat pain more agressively. Over a period of no more than 10 years, the culture regarding the use of opioids changed dramatically.

A RAPID INCREASE IN PRESCRIPTION OPIOIDS

Yielding to public and administrative pressures, physicians began to prescribe opiates at staggering rates. Americans demonstrated an equally robust affinity for consuming these addictive drugs. In 2014, the United States consumed 69% of the world's opioid supply despite constituting only 4.6% of the world's population. This consumption included 99.7% of the hydrocodone, 73.1% of the oxycodone, and 51.2% of the morphine. By 2013, more than 250 million opiate prescriptions were dispensed annually in the United States, and pharmaceutical companies earned billions of dollars on these medications.

Physicians were not complete bystanders to this epidemic, however. By the mid-1990s, “pill mills” began to dot the map. Pill mills are cash-only clinics staffed by physicians willing to prescribe very large quantities of opioids and benzodiazepines. The typical cost per visit to one of these clinics was on the order of $200 cash if the patient was in-state. The first of these clinics is believed to have been established in South Shore, KY, which is just across the Ohio River from Portsmouth, Ohio, and is geographically located in the heart of this epidemic.

Often, the physicians staffing these clinics were not specifically trained in the practice of pain medicine. They would see 100 patients or more daily, often spending 3 minutes or less per patient. They would prescribe opioids with little or no medical reasoning and even less documentation. Throughout mid-America, long lines of patients and automobiles could be seen outside these offices. Rumors of these clinics spread rapidly among addict circles, and addicts would drive 10 or more hours to visit them. Prior to the tracking of narcotic prescriptions, addicts and drug dealers would visit multiple clinics, sometimes across state lines, to acquire huge quantities of these potentially lethal medications. Eventually, most of these clinics would be shut down, and in many cases, the physicians’ licenses restricted or revoked and they were prosecuted.

The number of opioid-related overdose deaths soared in direct correlation with the rising number of opioid prescriptions dispensed (Fig. 10.1). According to the CDC, from 1999 to 2015, the number of overdose deaths in the United States has increased fourfold. In 2015, drug overdose deaths (52,404) were greater than the HIV/AIDS epidemic at its peak in 1995 (43,115), motor vehicle accidents (38,022), and gun deaths (36,252) (Fig. 10.2).

In 1996, Purdue Pharma released OxyContin. This drug was marketed as a less addictive (and potentially nonaddictive) opioid. It contained oxycodone in a timed-release tablet. Theoretically, the time-release properties would prevent the euphoric highs and abrupt depressions, which make opioids addictive. The same year as its introduction, in a historic decision, the Food and Drug Administration (FDA) allowed Purdue to write on the warning label that the drug had a lower potential for abuse. The drug was available in tablet form containing up to 160 mg of oxycodone.

Ironically, the drug’s warning label explained to addicts how to subvert the time-released properties and thus immediately access the tablet’s large

concentration of oxycodone. The label read, "…swallowing broken, chewed, or crushed OxyContin tablets could lead to the rapid release and absorption of a potentially toxic dose of oxycodone." Addicts began crushing the tablet to immediately access its very large doses of oxycodone. In short order, it was discovered that the tablet could be dissolved and injected intravenously. OxyContin, because of its high concentration of oxycodone, became an addict's favorite. The drug's street value was $1 for every milligram. Thus, an 80-mg tablet was worth $80. Some patients were prescribed 90 pills per month.

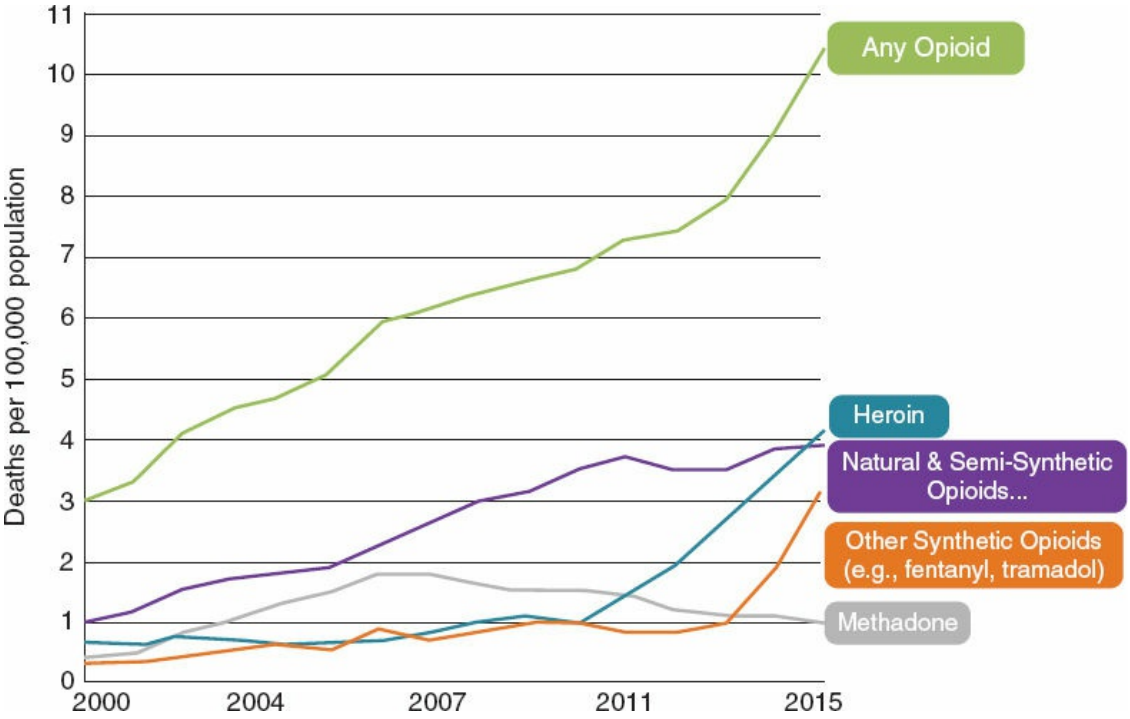

Figure 10.1. Overdose deaths involving opioids—United States, 2000–2015. According to the CDC, by 2015, greater than three fifths of overdose deaths involved opioids. (Modified from CDC/NHCS, National Vital Statistics System, Mortality. CDC WONDER, Atlanta, GA: US Department of Health and Human Services, CVC; 2016. https://wonder.cdc.gov/)

A MIDDLE-AMERICA PROBLEM

The opioid epidemic has witnessed the greatest growth in middle-American states such as Pennsylvania, Ohio, Indiana, Kentucky, Tennessee, and West Virginia. Also, it predominantly affects middle-class Whites. The reasons for these pattern are not completely understood.

Prior the dramatic change in opioid-prescribing habits of physicians, the primary means of obtaining these opioids was through unscrupulous drug

dealers and participants in organized crime. It has been postulated that the safe and relative easy access to opioids through physicians willing to prescribe these medications led to their increased use by middle-class Whites. Data from the CDC have shown that the greatest concentration of dispensed opioid prescriptions were in these mid-American states shown in Figure 10.3A. Correspondingly, the greatest number of overdose deaths was observed in the same geographic regions (Fig. 10.3B).

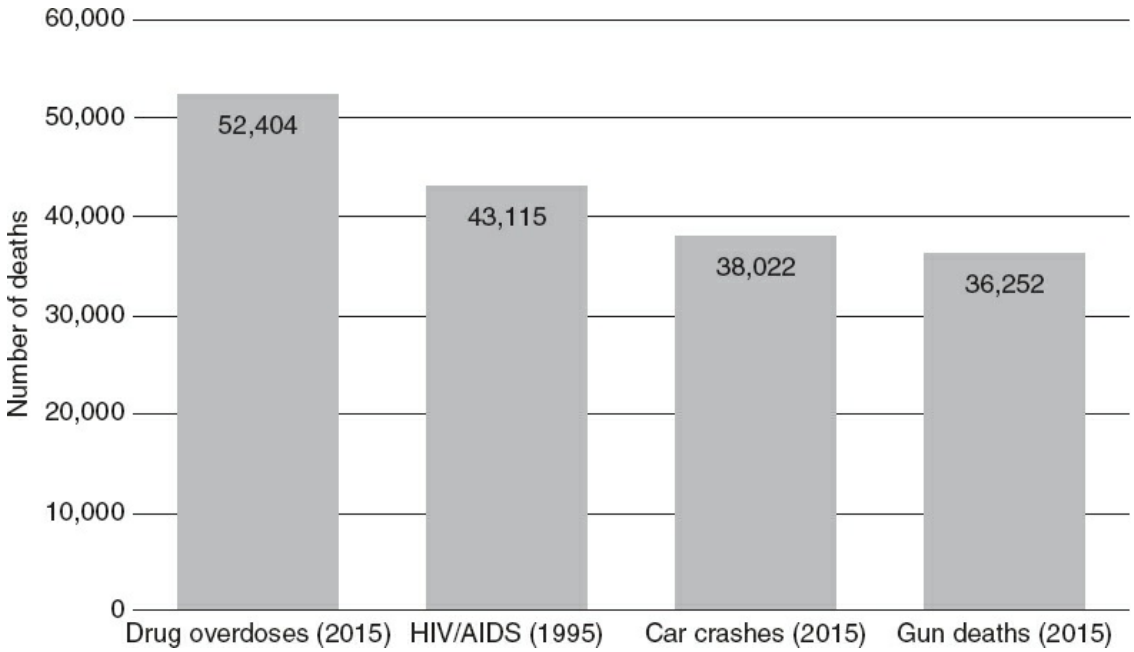

Figure 10.2. Number of annual deaths in the United States. In 2015, drug overdose deaths were greater than car crash and gun deaths. Also, drug overdose deaths were greater than deaths related to HIV/AIDS at the peak of its epidemic.

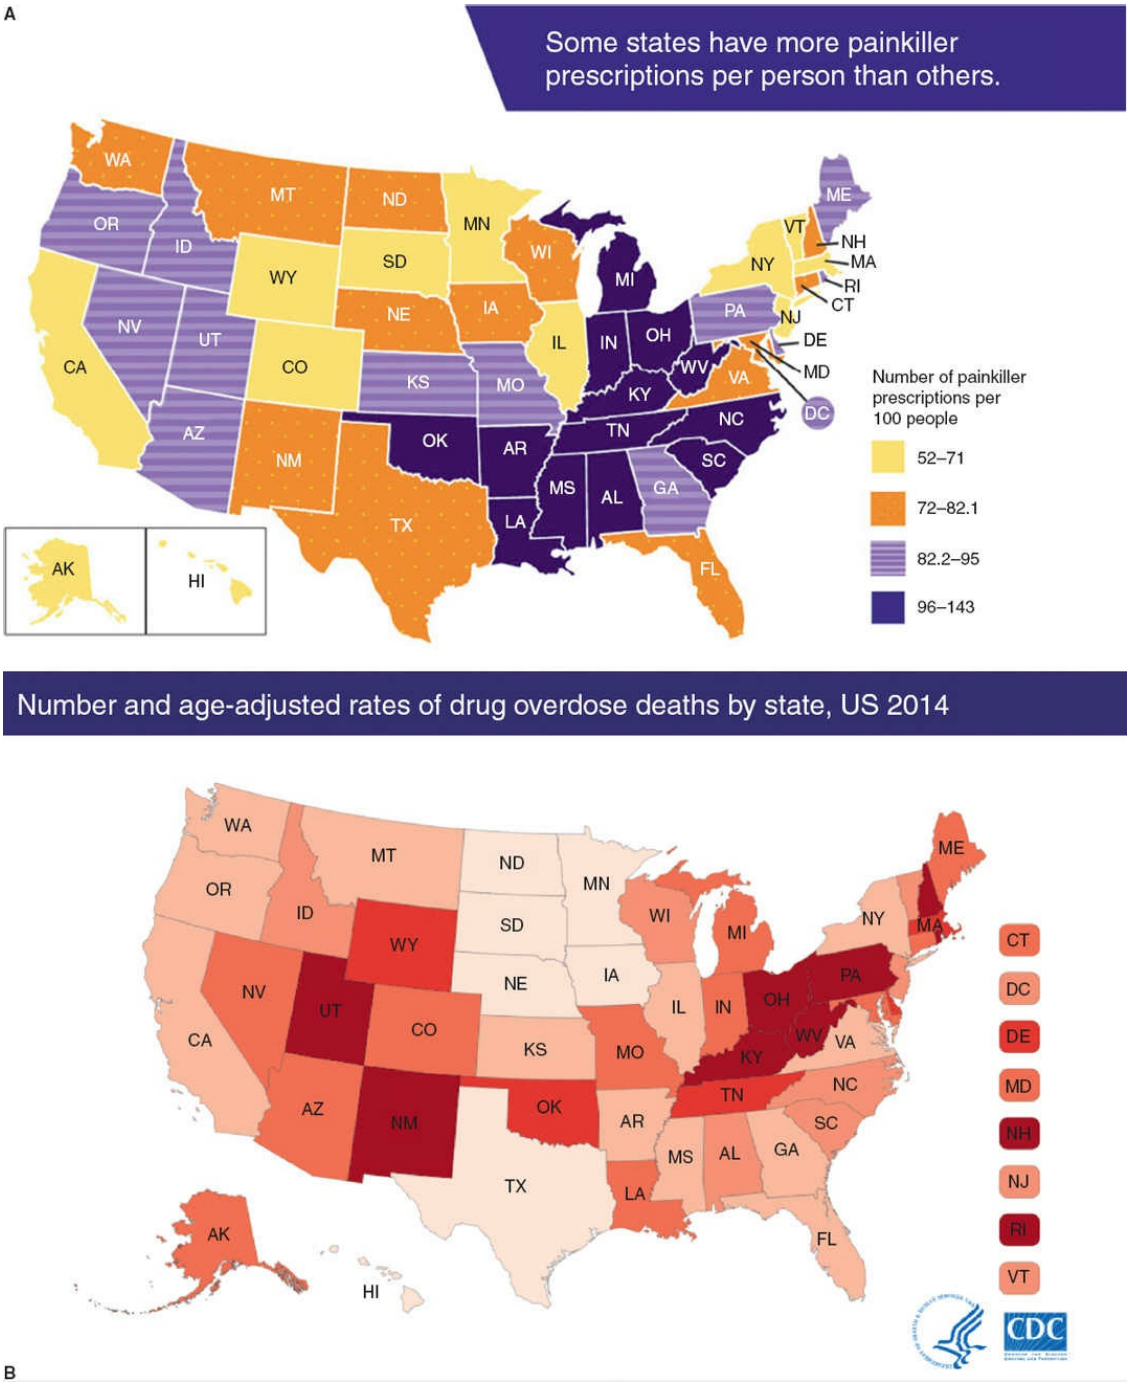

Figure 10.3. **A.** Map demonstrating the per capita number of opiate prescriptions. **B.** Map demonstrating geographic density of overdose deaths. Both overdose deaths and opioid prescriptions are concentrated in middle-America. (Modified from CDC/NHCS, Drug Overdose. CDC WONDER, Atlanta, GA: US Department of Health and Human Services, CVC; 2016. https://wonder.cdc.gov/)

Similar to a plague, the opioid epidemic spread across America from one small town to the next. Predictably, illegal opioid dealers migrated to

meet the needs of each new market of addicts. Opioid abusers became fixated on obtaining the next high no matter the costs. Most were unable to maintain a job, care for children, or perform other tasks expected of contributing members of society. Without a reliable workforce, businesses collapsed and moved from these areas. Addicts turned to thievery to fund their opioid needs. Families eventually lost faith in their addicted love ones after innumerable disappointments. Without the prospect of reasonable employment opportunities, promising young people moved away. In a period of a few short years, the social fabric of these towns collapsed. This story of socioeconomic demise occurred over and over throughout middle-America.

OPIOIDS AND THE SURGEON

During the course of providing surgical care, surgeons inflict pain and have a responsibility to treat this pain. As the early opioid history unveiled, a common scenario for prescribing opioid medications is to treat pain. For the surgeon, it is to treat perioperative pain. Unfortunately, there are no comprehensive guidelines to direct the surgeon in treating operation-related pain. The treatment of acute pain and the properties of common opioids are a minor inclusion in training curricula. The treatment of chronic pain as well as its associated sequelae is conspicuously absent from surgical training curricula, in-training examinations, and licensing examinations. Nonetheless, surgeons must now be knowledgeable regarding the negative potential of opioids, versed in the intricacies of chronic opioid use (COU), and vigilantly strive to prevent harm while adequately treating perioperative pain.

Preoperative Chronic Opioid Use

In the United States, 1 out of every 25 patients regularly uses prescription opioid medications. Some studies suggest that this underestimates the prevalence of COU in surgical populations. As such, surgeons are very likely to encounter patients chronically using opioids, both prescribed and not prescribed. Unfortunately, surgeons are incompletely prepared to treat chronic pain and manage the sequelae that are associated with COU.

COU has been associated with structural and central nervous system changes that mediate affect, impulse, reward, and motivation. These changes may result in a host of postoperative alterations, including increased sensitivity to pain, which may alter the typical postoperative

course. Chronic opioid users suffer increased morbidity and mortality of many kinds, owing to overdose, misuse, and conversion to heroin. COU is also associated with increased utilization of medical resources. A recent study demonstrated that preoperative COU is an independent risk factor for longer length of stay, higher 30-day readmission rates, lower probability of being discharged home, and greater overall expenditures. Moreover, the authors of this study noted a dose-dependent correlation with readmission rates, discharge destination, late health care expenditures, recovery of activities of daily living, and rehabilitation. Surgeons must evaluate previous history of opioid use in the preoperative setting and include appropriate considerations in operative risk assessment.

Surgeons Are Overprescribing Opioids for Postoperative Pain

Opioids remain the standard therapy utilized for the treatment of acute postoperative pain. Annually, more than 100 million surgical procedures are performed and 98.6% of patients receive an opioid to treat the acute pain caused by surgery. Some guidelines exist for the inpatient management of perioperative pain, which includes the use of regional anesthesia and patient-controlled analgesia techniques. However, we were unable to find any comprehensive evidenced-based guidelines for the management of postoperative pain in the outpatient setting.

The management of postoperative pain is complex and deserves serious consideration. Surgeons wish to treat pain adequately but must strive not to overprescribe nor cause addiction. Recent studies suggest that as much as 70% to 80% of opioid tablets prescribed postoperatively are not taken by the patient to whom they were prescribed. This suggests that surgeons are over- prescribing opioids for postoperative pain, and thus may be unintentionally contributing to the opioid epidemic by dispensing a larger than necessary number of opioids. This indirect act may thereby bolster the supply available for abuse. These circumstances beg the question, why are surgeons prescribing opioids in excessive amounts? One reason may be the altruistic desire to reduce the amount of pain experienced by patients. Another reason may be to prevent inconvenience for both the patient and physician. The conspicuous lack of data to guide prescribing practices certainly contributes. No matter the cause, the great burden of addiction requires the physician to become cognizant of the number of opioids that are dispensed. This is further discussed vide infra.

APPROACHES TO PREVENTION

Primary Prevention

Primary prevention is the most important means available to surgeons for gaining control of the opioid epidemic. As noted, recent studies have shown that surgeons are prescribing excess quantities of opioid medications. It has been shown that the majority of prescribed opioids used for abuse are obtained through diversion, mostly from family members with excess, but legally acquired, tablets. As such, reducing the quantity of circulating opioids is enormously important. To accomplish this, education of both patients and physicians is crucial.

Patient Education

Patients, being accustomed to current surgeon practices and conditioned by medical advertising, have come to expect opioid medications in very large quantities postoperatively. Many expect to be pain-free and return to normal activities immediately following an operation. These are unrealistic expectations. It is incumbent that surgeons, in the preoperative and immediate postoperative setting, have frank discussions with patients regarding expectations and risks associated with opioid use. The negative side-effects of opioids are shown in Tables 10.2 and 10.3. Rather than expecting complete absence of pain, patients should be conditioned to expect a manageable and functional level of pain. Furthermore, the patient should be assured that their surgeon will diligently work with them to establish an appropriate pain level. Patients seek surgical care to rid themselves of an existing problem, not to gain new problems. As such, when educated on the risks of opioid use, many patients will find themselves empowered to forego, or at least minimize, opioid usage.

Prescriber Education

Clinical education regarding appropriate opioid prescribing must be initiated at all clinical levels and must proceed with an urgency equal to the present situation. The effects of opioid use, both acute and chronic, must be instilled into the educational process and in medical examinations at all levels of surgical training. A socially conscious approach to opioid prescribing must be emphasized.

TABLE 10.2 Negative Side Effects of Opioids

Nausea
Constipation
Fatigue
Weight loss or gain
Dry mouth
Sweating
Somnolence
Respiratory depression
Pruritis
Hyperalgesia
Cognitive impairment
Addiction
Overdose
Conversion to heroin and other illegal drugs
Acquisition of diseases associated with drug use, including HIV and hepatitis

Abbreviations: HIV, human immunodeficiency virus.

Prescribers must avoid clinical inertia in prescribing of opioids. For example, consider the following patient scenario.

A patient visits the emergency department for a sprained ankle and is prescribed hydrocodone. Two weeks later, the patient visits his/her primary care physician, and the drug is added to their medication list. The patient is still experiencing pain, so the prescription is refilled. One month later, the patient develops constipation secondary to their opioids and revisits the emergency department complaining of abdominal pain. Imaging studies show cholelithiaisis. The patient is given a follow-up appointment with a surgeon one month later and their prescription is refilled again. By the time the patient visits the surgeon, he or she is physically and biochemically addicted to opioids. The surgeon performs cholecystectomy and provides the patient with a higher opioid dose because they have become sensitized to their current dosage. If this patient attempts to stop taking the opioid, they experience withdrawal.

TABLE 10.3 The Effect of Opioids on Surgical Outcomes

Increased morbidity and mortality Increased healthcare costs Increased readmission rates Increased probability of discharge destination other than home Slower return of ADLs Prolonged length of stay Delayed return of bowel function
Abbreviations: ADL, activities of daily living.

This is only one example of how a single prescription for acute pain can easily lead to addiction.

Research

Currently, there is a paucity of data demonstrating the appropriate medication, dosage, and quantity necessary to adequately manage postoperative pain. A recent study defined appropriate narcotic quantities for five outpatient procedures (partial mastectomy ± with sentinel lymph node biopsy, laparoscopic cholecystectomy, laparoscopic inguinal hernia repair, and open inguinal hernia repair). In this study, the authors found that only 28% of prescribed opioids were actively used. Further studies defining normative prescribing practices for common procedures and even trauma are needed to guide surgeons and diminish the number of circulating opioids available for abuse.

Secondary Prevention

Prescription Drug Monitoring

Nearly all states now implement prescription drug monitoring programs (PDMPs). These programs electronically store data regarding the prescribing and dispensing of opioid medications. Prescriber adherence to these programs is important to identify anomalies in prescription receipt, including “doctor shopping,” and thus preventing dispensation of opioids that may be used in diversion. Also, these programs may help identify at-risk populations for targeted intervention. Several states have demonstrated decreased overdose deaths after implementation of PDMPs, but direct causation has not been universally demonstrated. Many PDMPs are state-specific. As such, patients may receive prescriptions across state

lines to circumvent the effectiveness of PDMPs.

Opioid Disposal

Equally important is education regarding the appropriate disposal of dispensed opioids. Several recent studies have demonstrated that only a small percentage of patients understand how to appropriately dispose of excess opioids, and even fewer patients perform this task. This is currently an underutilized opportunity to reduce the number of circulating opioids. A host of disposal options are available to patients.

Many states have Drug Enforcement Agency (DEA)—authorized collectors that accept excess tablets for disposal.
Many pharmacies accept tablets for disposal and some even have mail back options for convenient disposal.
Specific information on prescription medication disposal can be found on the FDA website (https://www.fda.gov/drugs/resourcesforyou/consumers/buyingusingmedi

Deterrents

Several abuse deterrent (AD) mechanisms have been proposed and utilized in hopes of curbing the opioid epidemic and avoid adverse consequences secondary to opioids. Most of these deterrents serve to prevent or discourage crushing or dissolving tablets, which is done to enhance delivery in abuse behaviors. These ADs include physical barriers, combination of opioids with antagonist, formulations less amenable to injection, and combination with aversive agents such as niacin. The most commonly utilized AD is tablets containing an opioid and naloxone. If these pills are crushed, the naloxone is released, thereby rendering the opioid ineffective. Ten drugs have obtained the AD label credential from the FDA. Interestingly, OxyContin is one of the 10 drugs to obtain this label.

Overdose Prevention

Recently, naloxone distribution programs have become widely publicized. First responders, including police personnel, in many states now have been trained in the administration of intranasal naloxone. Further expansion of these programs is currently being pursued by some communities. Currently, anecdotal evidence suggests that widespread implementation of overdose awareness and naloxone education may reduce the number of fatal overdoses. The wide use of this dose in combination with the

expanding use of the powerful opioid, fentanyl, has led to a naloxone shortage.

APPROACHES TO ADDICTION TREATMENT

Addiction is a multifaceted problem that extends beyond physical and biochemical dependence on an opioid, with very complex social and psychiatric factors that involve the addicts, their family, and the community. Accordingly, the approach to treatment is multifaceted and involves physicians, psychologist, social workers, group therapy, medications, and the patient's friends, family, and community. All involved parties must understand that addiction is a chronic and relapsing disease. A full review of opioid abuse treatment is beyond the scope of this chapter; however, the key pharmacologic approaches that the surgeon may encounter are reviewed.

Methadone

Methadone is a long-acting synthetic opioid, which was developed in the late 1930s by German chemists. It is currently the major form of medical therapy utilized for treating opioid dependence. It prevents and reverses the symptoms of opioid withdrawal. It also decreases the euphoric effects of other opioids, thereby decreasing the use of illicit opioids. The resulting effects last for >24 hours, but requires a single daily dose. Thereby, methadone allows opioid addicts to return to normative activities. It can, however, be administered in fatal doses. This is problematic due to its long and variable half-life, which may result in toxic levels.

Methadone maintenance therapy (MMT) is the only opioid dependence therapy that has been clearly shown to decrease illicit opioid use and has been shown to decrease overall mortality in addicts. MMT involves the long-term usage of methadone typically via methadone clinics. Patients in MMT are still physically and biochemically addicted to opioids; however, their addiction is controlled. In a meta-analysis, MMT was shown to be superior to placebo and nonmedication treatment for opioid abuse disorder in terms of continued treatment and reduction of opioid use.

In the past two decades, methadone-related overdose deaths in the United States have increased in direct proportion to the increasing availability of the drug. Unfortunately, many methadone clinics have become for-profit organizations and many have abandoned their goal of eventually transitioning patients off all opioids including methadone. For-

profit methadone clinics are overt conflicts of interest, and these clinics are prime targets for dealers.

Buprenorphine

Buprenorphine is a partial mu-receptor agonist. It is combined with naloxone (Suboxone) for use as an addiction treatment drug. The purpose of combining buprenorphine with naloxone is to deter abuse via intravenous injection. Buprenorphine has less overdose potential than methadone because it has only partial mu-receptor activity. Unlike methadone, buprenorphine can be prescribed from a physician's office for addiction treatment. With a very high affinity for mu-receptors, this can cause withdrawal by displacing full mu-agonists. As such, the initiation of this drug must be undertaken with care. In a meta-analysis, buprenorphine decreased opioid use compared to placebo. It is now considered first-line treatment for opioid abuse by many authors. Unfortunately, this drug is abused by some addicts and has resale value as a street drug.

Naltrexone

Naltrexone is an opioid antagonist that may be used to prevent relapse of the opioid abuse disorder. It is available in a long-acting injectable formulation marketed as Vivitrol. In a meta-analysis comparing oral naltrexone to placebo, no difference was found in sustained abstinence and most other outcomes. The long-acting injectable formulation has been shown more effective than placebo in clinical trials but carries a retail price of approximately $1,700 per dose and duration of treatment of at least of 12 months.

HARM REDUCTIONS STRATEGIES

Needle Exchange Programs

A significant portion of new HIV, hepatitis B, and hepatitis C infections are associated with intravenous drug use (IVDU). Many states and localities have implemented needle exchange programs to allow intravenous drug users the opportunity to exchange old needles for new ones. The hypothesis supporting these programs is that, by eliminating old and contaminated needles, there will be an associated decrease in IVDU-associated disease prevalence and eventually diminished costs to the health care system. The CDC and U.S. Department of Health and Human

Services support needle exchange programs as effective means of decreasing IVDU-associated transmissible illnesses including HIV and hepatitis.

It is currently unclear if a causal relationship between decreasing rates of HIV and hepatitis infections related to needle exchange programs exists; however, anecdotal data indicate that a correlation does exist. The authors support needle exchange programs as a potential method of reductions of IVDU-related transmissible disease and thereby reduced overall health expenditures.

Supervised Injection Facilities

Currently, nine countries contain supervised injection facilities (SIFs). The facilities contain sterile equipment, medical staff, and often addiction treatment specialists. IVDUs can utilize these facilities, and the medical staff may intravenously inject opioids. Following the same logic as needle exchange programs, SIFs are hoped to diminish transmissible disease and injection complications. It is unclear if SIFs accomplish these goals in a cost-effective manner. Some international literature suggests that addicts utilizing SIFs are able to return to a somewhat normal life.

MULTIMODALITY ADDICTION STRATEGIES

Opioid addiction extends beyond physical and biochemical dependence on mu-receptor activation. Rather, there is a host of associated social and psychiatric derangements that accompany this illness. The patient's family, friends, and local community are all affected. As such, the treatment must not only involve correcting biochemical addiction, but also target the psychosocial aspects associated with addiction, including counseling, community involvement, family therapy, and transition to normative activities such as working and maintaining a household.

Recovering addict communities are vital to sustaining abstinence. Much like the Alcoholics Anonymous model, abstinence from opioids after suffering from opioid abuse disorder is a lifelong effort. The best results thus far are found in those who dedicate themselves to becoming recovery coaches and helping others achieve or maintain abstinence. Some communities have established addict hotlines, which allow current addicts, their families, and those in remission to call for assistance as needed. Expansion of such programs may help combat this epidemic.

MAINTAINING ABSTINENCE

The relapse rate for opioid abusers is very high. The overall “cure” rate is unclear secondary to lack of long-term follow-up and high attrition, but it is estimated to be 30% or less. Among patients who maintain abstinence for an extended period, they face the daunting task of piecing their lives back together. Often addicts are isolated from their family, friends, and community due to a history of lying, stealing, and other abuses. They are no longer trusted and, in many cases, no longer welcomed. The uphill psychosocial battle facing a recovering opioid addict is nearly unsurmountable and contributes to the relapse of many patients. Efforts to repair relationships and transition back to normative functions must be facilitated. For many, their life will never be as they hope. Family and friends may never invite them back into their lives, their community may never accept them, and they will forever remember the unfathomable acts they committed.

FINAL DISCUSSION

The rise of the opioid epidemic has occurred at an unprecedented rate. Over a mere 10 years, we transitioned from a medical culture known to be tight-fisted with opioid medications to the opposite. Changes in pharmaceutical advertising techniques and misinterpretation and fallacious dissemination of a few publications combined with shifting medical and public sentiments about the usage and addiction potential of opioids powered this transition. A pharmaceutical industry ready to capitalize stood waiting, and capitalize they did!

As a result, in the last 20 to 30 years, we have seen prescription dispensation, addiction, and overdose rise at shocking and unprecedented rates. Most physicians, secondary to an altruistic nature, prescribed opioids to treat patient pain. A very small number, the “pill-mill” doctors, did so to bolster their personal wealth. Nonetheless, the public and media that once lamented our grudging opioid prescribing habits now blame surgeons for their addiction.

As prescription opioid addiction spread preferentially across mid-America and infiltrated middle-class families, eager heroin dealers migrated to meet their needs. Cheap and powerful black-tar heroin became an addict favorite when OxyContin was not available. It is no surprise that the same mid-American towns became home to the nation’s highest overdose rates.

Surgeons hold an important role in this fight. The surgical patient population has a high rate of COU, which has been shown to result in negative surgical outcomes. Preoperative consideration of COU and inclusion in the risk assessment are necessary. Evidence shows that surgeons, similar to their colleagues, have been prescribing opioids in excessive quantities. Moreover, it has been shown that prescribed opioids are often used for abuse and may serve as a gateway to abuse of illicit opioids. Surgical education must expand to include COU and a more robust inclusion of optimized acute pain management.

Currently, treatment of opioid abuse includes several therapeutic modalities. The long-term cure rates are not very good, and the relapse rate is nearly 100%. Patients who can maintain abstinence face an uphill battle in re-establishing their lives. Vital to their success are transition programs that help the patient re-integrate into society as well as provide a scaffold of support.

Recently, the severity of the opioid epidemic has received national attention in the lay media and the medical community. In April of 2017, *Annals of Surgery* published a special supplement discussing the opioid epidemic. Publications about responsible opioid abuse and prescribing habits are frequent in surgical literature. However, there still exists a noticeable lack of comprehensive data and guidelines to aid surgeons in the management of postoperative pain. Future research aims should be to define normative medications, dosages, and quantities necessary to manage postoperative pain.

Despite the relative short period that was required for the emergence of this epidemic, the expectation of postoperatively prescribed opioids is engrained in our society. Patients often expect to be pain-free immediately after surgery. The arena for changing this perception is the preoperative setting. Surgeons, along with their patient, must develop a postoperative pain management plan. This discussion must condition the patient to expect manageable level of pain rather than be “pain-free.” If opioids are needed, the patient should understand the considerable risks that are associated with these medications.

The search for the “holy grail” continues. Utilization of abuse-deterrent technologies is promising, but currently is isolated to expensive name-brand drugs. Harm reduction programs have shown some promise but are highly politicized.

CONCLUSION

An end to America's opioid epidemic is obtainable. However, the difficult task of shifting both medical and societal norms and expectations is before us. This shift will not happen quickly. Medical and surgical literature alike has begun to reflect the rising awareness of these problems. As such, physicians appear to be upon the precipice of change. Our role as surgeons will be to decrease the number of prescribed opioids and help alter the societal norms surrounding opioids. This can be accomplished by careful and intentional patient education and community involvement. Surgeons are uniquely positioned to lead this fight.

BASIC SURGICAL SKILLS: NEW AND EMERGING TECHNOLOGY

11 Ventral Abdominal Hernia: Open and Minimally Invasive and Component Separation Release

Stephen R.T. Evans and Parag Bhanot

ABDOMINAL WALL INCISIONS

The success of any open abdominal operation requires adequate exposure via the appropriate selection of the incision as well as proper closure of the abdominal wall to limit unnecessary morbidity. In the current era of laparo-endoscopic surgery, the general surgeon must still be well versed with the anatomic principles of the abdominal wall. In the past several decades, there has been a broadening of the options available in selecting an incision for an abdominal operation. The primary factors that should be considered are the diagnosed intra-abdominal disease and the organ(s) that must be modified or removed to treat that disease process. Nevertheless, even among experienced surgeons, there are frequently differences of opinion about the best incision for treating a given disease in a particular patient.

There are three primary requirements for an incision to be used for any given operation. The incision must provide optimal exposure, be flexible, and allow for a reliable closure.

1. *Exposure must be optimal.* The incision must provide direct access to the peritoneal cavity without significant limitations if additional exposure is needed at a later point. There must be adequate visualization of the diseased organ or injured area, and provide sufficient working space so that the procedure can be performed directly and rapidly without limiting the intra-abdominal manipulation or excision; especially important in the trauma setting. Appropriate positioning of the patient (e.g., lithotomy for pelvic surgery) and application of abdominal wall retractors are ancillary measures. Inadequate lighting can make even a simple procedure very difficult; thus, headlights and lighted retractors should be readily available.
2. *Flexibility is a requirement of any operative incision.* The popularity of

the vertical midline incision is partly based on its ability to be extended if the scope of the operation dictates a larger incision. The limitations of the vertical incision are the xiphoid process and the pubis symphysis. To some extent, transverse incisions are also amenable to a curvilinear extension. Of concern is the innervation of the abdominal musculature should be minimally interfered with to preserve its functionality. This is a limitation with oblique and transverse incisions. Ideally, it is best to sacrifice less than one segmental nerve trunk ipsilaterally, regardless of the length of the incision. An incision should be so placed that it does not interfere with future stages of planned surgery.

3. *A reliable closure must be obtained, unless postoperative intra-abdominal hypertension is a concern.* The integrity of the abdominal wall must be maintained with adequate fascial closure. In cases involving contamination, such as a perforated viscus, we advocate delayed closure of the skin to minimize postoperative soft tissue infections.

The morbidity from abdominal incisions is poorly reported and probably underestimated. Any error such as a poorly placed incision and/or unsatisfactory method of closure can lead to complications, including hematoma, stitch abscess, infection, wound dehiscence or evisceration, incisional hernia, or an unsightly scar. Rarely, a misdiagnosis may necessitate making a different incision altogether.

TYPES OF INCISIONS

Figure 11.1 illustrates some common types of abdominal incisions.

1. *Vertical.* These incisions may be midline, paramedian, or even pararectus. They can be supraumbilical or infraumbilical and, if necessary (e.g., for extensive intra-abdominal trauma) can be extended in the midline upward to the xiphoid process and/or downward to the symphysis pubis.
2. *Transverse or oblique.* The best examples of these incisions are Kocher's subcostal incision for cholecystectomy, a supraumbilical or infraumbilical transverse incision for intestinal surgery, McBurney's or the Rockey-Davis incision for appendectomy, Pfannenstiel incision for gynecologic surgery, and a transverse or oblique central and lateral incision for exposure of the colon.
3. *Retroperitoneal and extraperitoneal approaches.* These incisions are

ideal for surgery of the kidney or adrenal gland, renal transplantation, and aortoiliac surgery.

4. *Thoracoabdominal.* This incision gives excellent exposure of the upper abdominal organs by connecting the mediastinum, pleural, and peritoneal cavities into a single operative field.
5. *Separate thoracic and abdominal incisions.* These incisions spare the costal margin and cause less postoperative pain and disability than does the thoracoabdominal incision, as in an Ivor-Lewis esophagectomy.

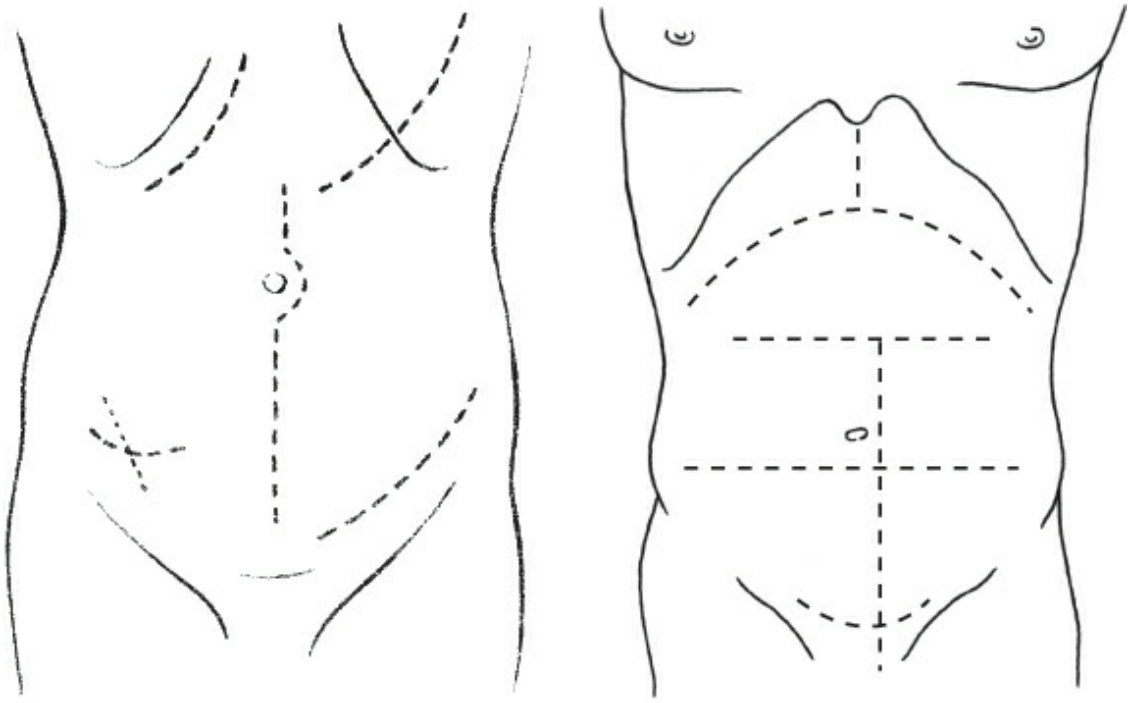

Figure 11.1. Common types of incisions. **A.** Clockwise from the upper right quadrant are subcostal (Kocher), thoracoabdominal, left lower quadrant (extraperitoneal), vertical midline, and Rockey-Davis (transverse)/McBurney (oblique). **B.** From superior to inferior are bilateral subcostal with vertical T extension, supraumbilical transverse, infraumbilical transverse, left paramedian, and Pfannenstiel incision.

SELECTION OF THE INCISION

The choice of incision varies with the surgeon's experience and preferences. Integral to the decision is the organ(s) or site that needs to be exposed, whether rapid access is needed as for severe hemorrhage or trauma, the certainty of the diagnosis, body habitus, the presence of

previous abdominal incisions, and cosmesis.

Many surgeons prefer oblique or transverse incisions when adequate exposure can be obtained because the direction of pull of the lateral abdominal muscles is parallel to the incision, and much less distracting tension occurs on the wound edges than with vertical incisions. The wounds are stronger and less liable to dehiscence or herniation; in general, they seldom dehisce unless infection is present. However, these are somewhat more time-consuming to make than a midline incision. Also noteworthy is that they cause somewhat less postoperative pain than does an upper midline incision.

In emergency operations for major intra-abdominal hemorrhage, the midline approach gives the most rapid access and, if necessary, can be quickly extended from the xiphoid to the symphysis pubis. In general, an upper midline incision may be preferable in a thin patient with a very narrow costal angle, but in a patient with a wide costal angle, a unilateral or bilateral subcostal or transverse incision gives excellent exposure of upper abdominal viscera, especially the pancreas, liver, biliary tract, or spleen.

The McBurney or Rockey-Davis muscle-splitting incision for appendectomy is ideal and can be easily extended medially or obliquely laterally (Weir extension) if greater exposure is required. If an ileostomy or colostomy is to be part of an operative procedure, the main incision should be kept as far from the stoma as possible, with use of either a midline incision or even a paramedian approach on the opposite side from the planned stoma. Transverse incisions above the umbilicus provide ample room for an infraumbilical stoma, or vice versa.

When reoperating on the abdomen, the surgeon should, if possible, enter through the previous incision, particularly if the surgery entails excision of a disfiguring scar or repair of an incisional hernia. When operating through a previous scar, one must be wary of adhesions from bowel or omentum. The surgeon should *never* make a new incision closely parallel to a previous one because it may cause ischemia of the tissue between the incisions and lead to necrosis of the intervening skin and fascia.

CLOSURE OF THE INCISION

Abdominal wall closure, irrespective of the incision, has changed significantly in the past two decades with regard to the type of suture

(absorbable or nonabsorbable) and technique (interrupted or continuous) utilized. For several reasons, most importantly the time consideration, continuous sutures have gradually become far more common closures than interrupted sutures in initial wound closure. In addition, slowly absorbable continuous suture (polydioxanone) has gradually begun to replace all permanent sutures, primarily because the polypropylene knots frequently the cause of draining suture sinuses. For most elective operations, therefore, slowly absorbable continuous sutures (PDS) are more commonly used than other types of suture. On the other hand, when repairing a dehisced incision, closure is done with interrupted permanent suture with consideration of retention sutures.

Regardless of the type of suture used, at least 1-cm bites must be taken from the wound edge, and must be placed at approximately 1-cm intervals, incorporating all layers of the abdominal wall, except for skin and subcutaneous fat. In the morbidly obese patient, it is preferable to clear the fascial edges for 2 cm to avoid loosening of the suture with incorporation of the fat. Some surgeons prefer to close a midline incision with two No. 1 continuous sutures, starting at either end (Fig. 11.2). Because of the bulky knot that occurs, an effort should be made to bury it. A reasonable alternative is to use simple interrupted sutures placed at least 1 cm from the cut fascial edges. The skin is then closed based on individual preferences with staples or sutures. The peritoneum need not be closed as numerous studies have shown that laparotomy wounds heal just as well whether or not the peritoneum is closed. Reperitonealization of the pelvis is worthwhile, however, when that peritoneum has been opened for dissection.

One should never bring drains or ostomies out through the main abdominal incision as they tend to weaken it, predispose to infection, and may precipitate wound sepsis and/or wound dehiscence.

Retention sutures through all the layers of the abdominal wall are seldom used for routine closure because they are painful and may leave unsightly scars. Furthermore, little evidence supports their use to prevent dehiscence or hernia. For difficult abdominal closures, one can use several widely spaced, buried, interrupted full-thickness sutures to reinforce the closure; the closure can be made with a continuous suture, but interrupted sutures may be better. In cases of abdominal dehiscence, some surgeons close the abdomen with deep bites of buried figure-of-eight sutures, but the Gambee suture (Fig. 11.3) is far better. The skin and subcutaneous tissues

are left open in all cases in which sepsis is encountered and a VAC dressing may be employed.

We prefer a two-layer closure of the abdominal wall muscles in a Kocher or transverse incision, closing the posterior rectus sheath and peritoneum with a continuous absorbable suture (Fig. 11.4) and the anterior rectus sheath with a separate, slowly absorbable or nonabsorbable suture. Rockey-Davis or McBurney's incisions are closed in layers, with the peritoneum and transversalis fascia included in one layer using long-acting absorbable sutures and subsequent fascial layers closed separately, as previously described.

INTRA-ABDOMINAL HYPERTENSION AND ABDOMINAL COMPARTMENT SYNDROME

In recent years, the importance of increased intra-abdominal pressure (IAP) leading to intra-abdominal hypertension (IAH) and the ensuing abdominal compartment syndrome (ACS) has been emphasized in patients with severe abdominal trauma and various surgical emergencies such as peritonitis, necrotizing pancreatitis, and intestinal obstruction. IAH is defined as sustained IAP ≥12 mm Hg and be caused by intestinal edema or congestion, accumulation of intraperitoneal or retroperitoneal blood and clot, and extensive retroperitoneal inflammation in acutely ill patients. ACS is a separate clinical entity and is defined as a sustained IAP >20 mm Hg with new organ dysfunction.

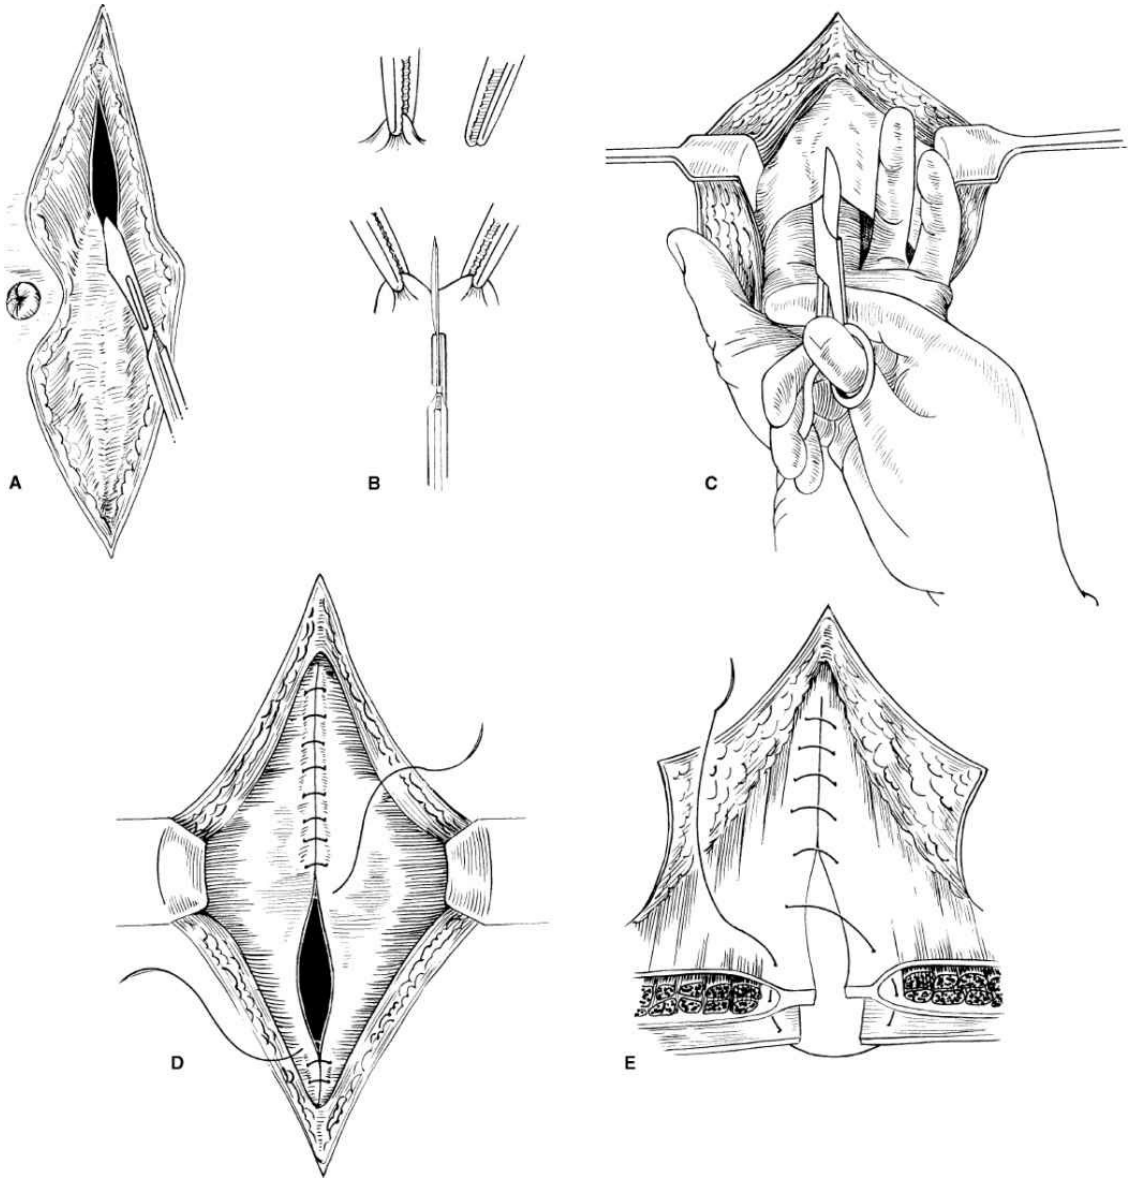

Figure 11.2. Vertical midline incision with gentle curve around the umbilicus, which is preferred over the keyhole. **A.** The peritoneum is opened with a knife, which requires that the surgeon's fingers or a malleable retractor protect the underlying intestine and omentum. **B.** The peritoneum and posterior fascia are grasped with two forceps so as not to crush the intestinal wall if it should happen to be trapped in the jaws of an instrument. The incision should not be made at the apex of the tented-up peritoneum, but 1 cm or so below the instruments, again to avoid cutting into a trapped loop of intestine. When air enters the small opening made with a scalpel, the intestine and omentum will fall away from the peritoneum, unless held there by adhesions. **C.** The peritoneum while the underlying structures are protected with two fingers of the other hand. **D.** The midline fascia and peritoneum can be closed with one layer of continuous suture, with either nonabsorbable or absorbable suture. **E.** Closure of

fascia in one layer with the peritoneum is the technique most surgeons use. For the average abdominal wall, the bites should be at least 1 cm from the cut edge.

Indirect IAP measurement has become an important study in patients following major abdominal trauma or in patients in the intensive care unit with progressive abdominal distention and allows for the definite diagnosis of ACS. IAP is most commonly measured indirectly using bladder pressures and can be done intermittently or continuously if the Foley catheter is connected to a pressure transducer with a recording device. The technique is simple, and the first step is to instill up to 70 mL of sterile saline into the bladder through the Foley catheter, which is then clamped. An 18-gauge needle is inserted into the aspiration port and attached to a pressure transducer. It is critical in order to obtain accurate measurements that the pressure is obtained at end-expiration and the transducer is zeroed at the midaxillary line. Bladder pressures may not provide an accurate measurement in patients with morbid obesity, massive ascites, pelvic hematomas, adhesions, or in a neurogenic bladder. In these situations, IAP can be measured using intragastric, intracolonic, or inferior vena cava catheters.

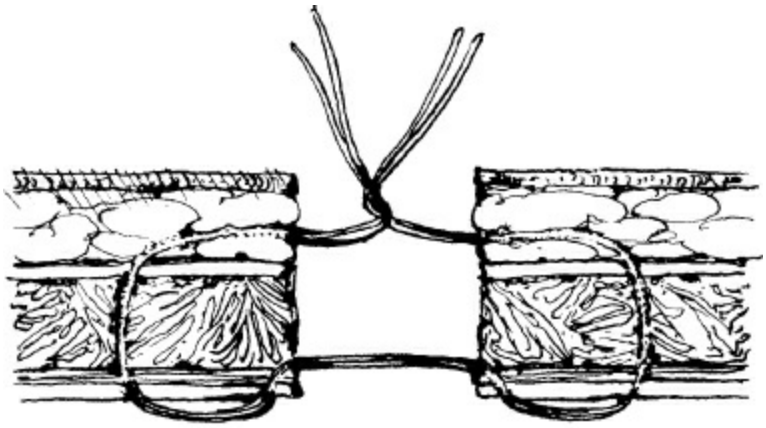

Figure 11.3. When a single full-thickness closure of the abdominal wall is desired, either including peritoneum and fascia or encompassing all layers, including skin as with retention suture closure, excellent closure can be obtained with a modified Gambee stitch. The suture is first introduced at an adequate distance from the wound edge, usually 2.5 to 3.0 cm with retention sutures and slightly less if the skin is not included, as shown. The needle is then passed through the peritoneum–posterior fascia from the inside up; the needle is reversed, and the other side is sewn in the same way. Finally, the needle is passed from peritoneal cavity to above fascia or through skin. The purpose of this suture technique is to prevent the "cheese cutter" effect of simple full-thickness sutures that may injure the underlying bowel. (From Baker RJ. Incisional hernia. In: Nyhus LM, Condon RE, eds. *Hernia*. 3rd ed. Philadelphia, PA: JB Lippincott, 1989, with permission.)

There are several factors involved in the development of ACS in patients regardless of the IAP such as abdominal wall compliance, systemic blood pressure, and body mass index. Thus, in a clinical setting, ACS can be defined as new organ dysfunction with IAH without strict IAP criteria. In general, patients with IAP <10 mm Hg do not have ACS, while a value >25 mm Hg predicts ACS. The incidence of ACS is highest in the most critically ill patients and includes trauma, severe burns, liver transplantation, and medical illnesses that require massive fluid resuscitation.

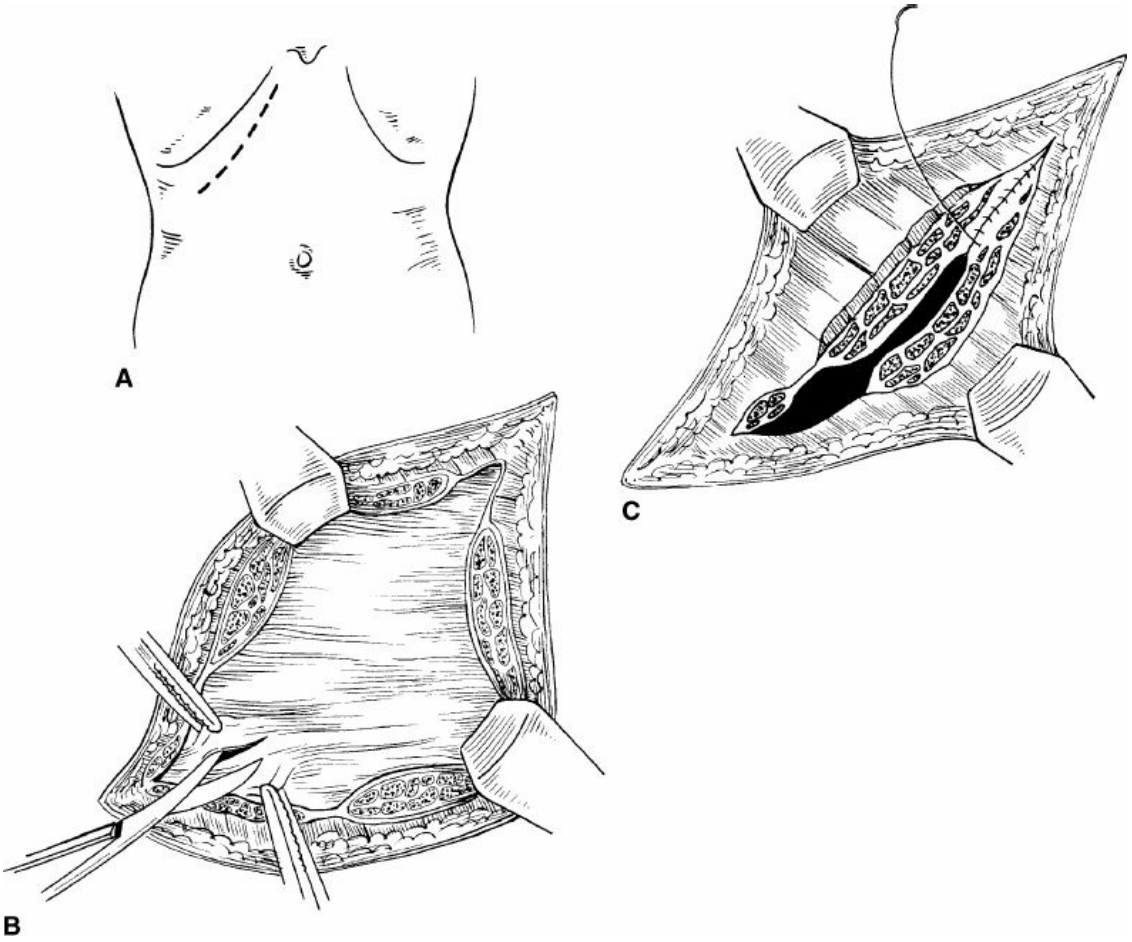

Figure 11.4. Kocher incision. **A.** The subcostal incision should be placed at least two fingerbreadths below the costal margin, which assures that ample fascia is available on the superior side below the costal margin to afford a secure closure. **B.** The rectus muscle is cut transversely or slightly obliquely, usually with monopolar cautery; other muscles can be split laterally as far as necessary to achieve the desired incision length. **C.** The incision is repaired in two layers; posterior fascia and peritoneum, as shown, are the deep layer, and the second layer is the anterior fascia and the aponeurosis of the external oblique. The subcutaneous tissue is irrigated copiously, and the skin is re-approximated with either staples or a continuous absorbable subdermal closure.

The clinical presentation of patients with ACS makes confirming the diagnosis difficult given that they are critically ill and may already have multi-organ dysfunction. Furthermore, imaging studies are not helpful. ACS can be exhibited in every organ system with a multitude of physiologic consequences (Table 11.1).

The management of ACS consists of ventilator and hemodynamic

support along with surgical decompression through the original incision in most cases. Burn patients may respond to escharotomy alone. High airway pressures may require a switch to a pressure limited mode, allowing for permissive hypercapnia. The administration of volume may temporarily improve hemodynamics, but if too much crystalloid is given, IAP will be adversely affected. It is critical that before the decision for surgery is finalized, perioperative morbidity and mortality are considered versus potential benefit for each patient.

TABLE 11.1 Physiologic and Clinical Consequences of IAH

CNS	Cardiac	Pulmonary	GI	Renal
↑ ICP	↑ CVP	↑ Peak pressures	↓ Blood flow	↑ Venous resistance
↓CCP	↑ PCWP	↓ Compliance	↓ Portal flow	Vasoconstriction
	↓ Cardiac output	↓ PaO2	↓ Lactate clearance	↓ GFR
	↓ Venous return	↑ PaCO2		
Cerebral ischemia	Impaired cardiac function	Barotrauma	Bowel edema	Oliguria
	DVT	Pulmonary edema	Bowel ischemia	Anuria
	Peripheral edema	Infection		

After decompression is performed, we advocate maintaining an open abdomen using temporary abdominal wall closure. One technique is to suture a 3-L intravenous fluid bag to the edges of the fascia loosely to allow for additional intra-abdominal expansion. The open wound is then covered with a towel, closed suction drains, and an adhesive drape (Fig. 11.5A). An alternative is the utilization of the vacuum-assisted wound closure (VAWC) dressing that has become increasingly recognized as an effective adjunctive technique in managing the open wound associated with acute abdominal wall defects (Fig. 11.5B). The application of a dressing that covers the open wound under subatmospheric pressure accelerates the healing process and time for complete wound closure. In the immediate postoperative period, it simplifies the wound management of these patients. The contra-indications to its use are a wound without complete debridement, without hemostasis, or the presence of a fistula.

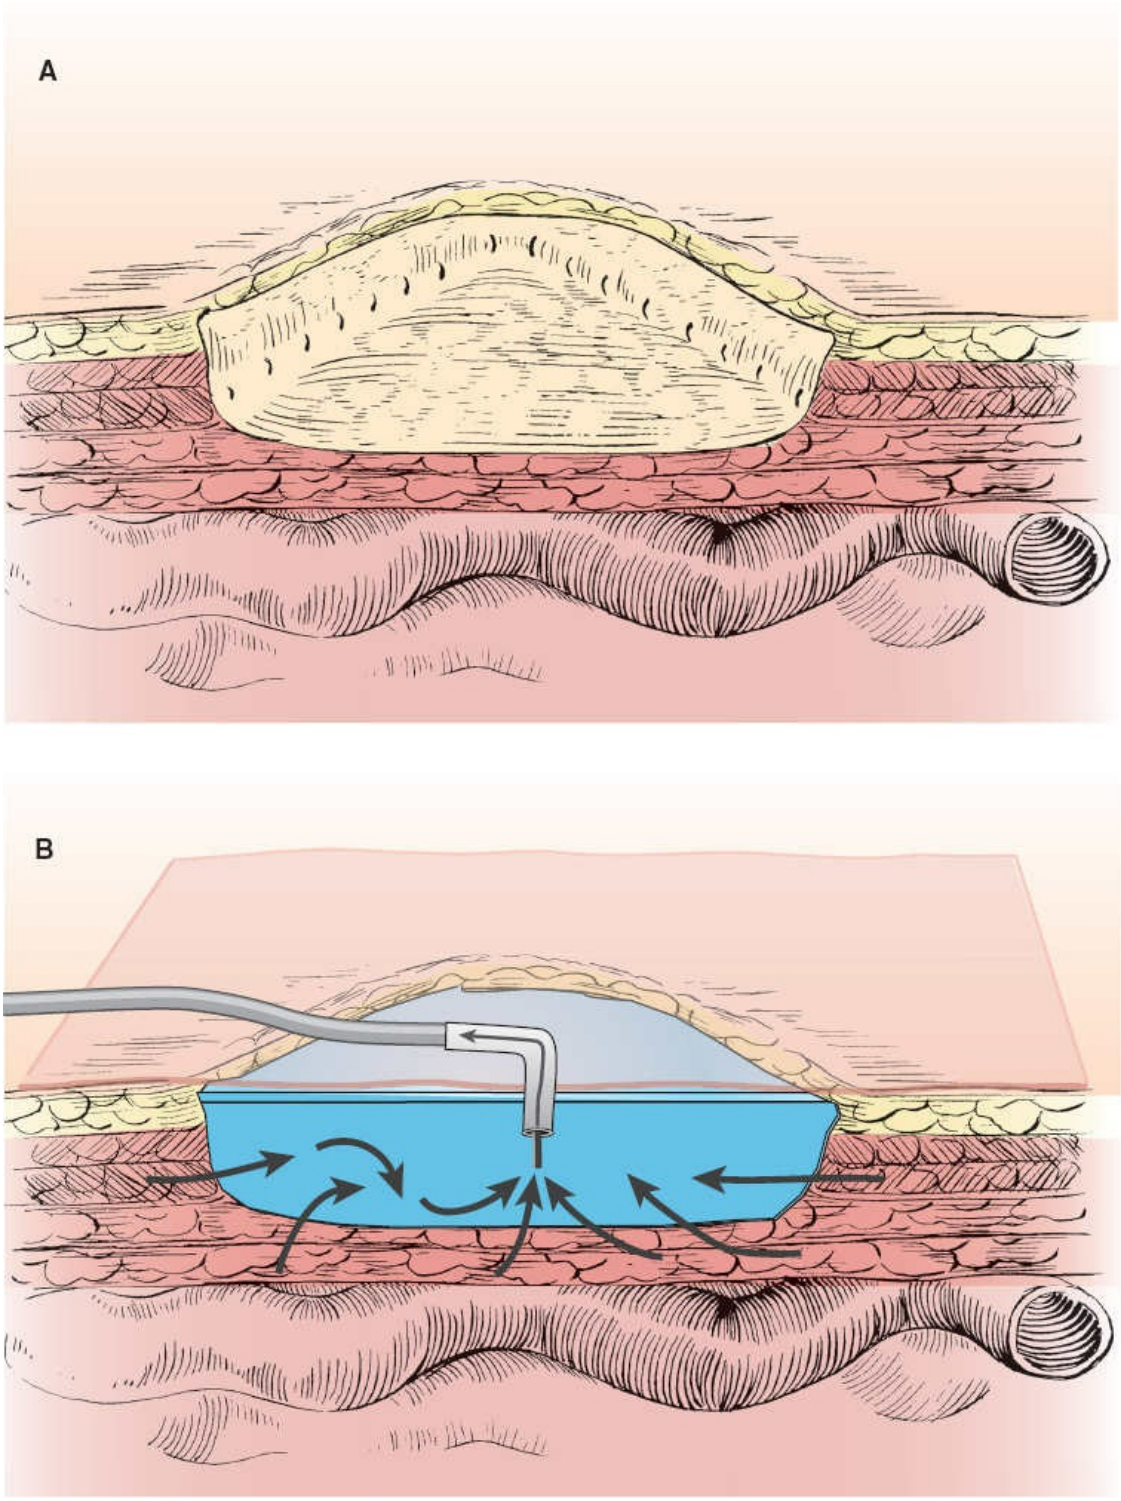

Figure 11.5. A. A temporary closure of the abdomen allows for expansion if necessary from ongoing resuscitation and bowel edema and is particularly useful in patients who require repeat explorations. Any sterile plastic sheet can be used and is sewn to the edges of the fascia with continuous sutures. This prevents excessive fluid loss from an open abdomen and also prevents retraction of the fascia. Suction drains are placed and covered with an adhesive sheet to keep the wound from being saturated

with peritoneal fluid. **B.** An alternative method is the application of a vacuum-assisted wound closure using subatmospheric pressure.

We do not advocate the use of absorbable or permanent mesh for several reasons. In some cases, re-exploration may be necessary wasting the previously placed mesh. The mesh also does not allow for expansion if needed. Absorbable mesh such as polygalactic acid (Vicryl) will require additional surgery at some point after the patient has recovered to repair the resultant hernia or for placement of a split-thickness skin graft. Synthetic mesh is prone to additional risks such as infection, fistulization, and adhesion formation. There are several biologic mesh products available that are ideally suited for this situation in which abdominal wall reconstruction (AWR) can be performed safely in high-risk patients avoiding all of the previously mentioned problems. If a temporary closure was performed, we advocate closure of the fascial defect when the intestinal edema and distension have subsided and as soon as the patient's general status permits. The surgeon should be prepared to schedule the patient for serial attempts at closure if necessary.

OPEN VENTRAL HERNIA REPAIR INCLUDING COMPONENT RELEASE

Introduction

Ventral hernias represent an incredibly varied clinical entity with a wide spectrum of disease. This contributes to the high recurrence rates that exist even with small to moderate defects. The Netherlands group published the long-term results of their randomized, prospective trial looking at suture repair versus mesh repair for incisional hernias with a maximal defect of 6 cm. The 11-year recurrence rate was 32% with mesh and 63% for suture repair.

It is important for the surgeon to be comfortable with several techniques as specific interventions may prove more or less favorable for a given hernia. Consequently, the reconstructive options for hernia repair are diverse and must be tailored to a given clinical situation. Patient comorbidities, hernia characteristics, and skin/soft tissue factors will each impact the technique chosen for the repair. In addition, intra-operative findings should guide the reconstructive approach to optimize outcomes. It is critical to perform the first hernia repair with the proper approach,

technique, and mesh selection to avoid even higher failure rates with subsequent repairs.

PATIENT SELECTION

Results following AWR are variable. Differences in surgical outcomes are partially attributed to differences in patient demographic. Age, gender, obesity, smoking, and medical comorbidities each independently impacts outcomes following ventral hernia repair (VHR). Postoperative morbidity following VHR is increased for each decade after 50 (OR 1.63), preoperative (partial or total) functional dependence (2.34), presence of ascites (9.71), pulmonary compromise (2.47), acute renal failure (11.45), and hyponatremia (3.34).

The risk of hernia recurrence increases proportionately with the number of prior failed repairs; patients presenting for an initial hernia repair are much less likely to develop a postoperative complication. The success of surgical repair is inversely related to the number of prior surgical attempts at VHR. Functional status is another critical element to consider as patients who are not functionally independent are significantly more likely to develop complications following hernia repair. Inactive and sedentary patients may not require surgical repair if there is no involvement of bowel within the hernia sac. It is critical to optimize the medical management of patient's comorbid conditions prior to surgery through a multidisciplinary approach for preoperative risk reduction, select patients for hernia repair with a baseline functional capacity warranting surgery, and determine the safest surgical procedure to ensure a successful repair.

APPROACH (OPEN OR LAPAROSCOPIC)

In addition to patient demographics, hernia morphology affects outcomes and should also dictate treatment. It is critical that the surgeon personally review the imaging study, if available, to determine the extent of the structural involvement to formulate the surgical plan. However, the authors do not advocate the routine use of imaging for small noncomplicated hernias. The factors that need to be considered include: (1) defect size, (2) number of defects, and (3) location of the defect(s).

In general, repairs can be classified as static or functional. Open repairs that do not re-approximate muscle and fascia and most laparoscopic repairs are considered static repairs because they do not restore the inherit anatomy of the abdominal wall. Small defects may be amenable to closure

with a laparoscopic approach as well and possibly offer additional advantage over traditional repair.

The following represents the authors' algorithm based on personal clinical experience and a review of the literature. A primary, single defect <3 cm in a nonobese patient may be repaired with suture repair alone (Fig. 11.6). This situation represents a compromise between a slightly higher recurrence rate and the avoidance of mesh-related complications. It is critical to assess the quality of the fascia if mesh is excluded from the repair. The approximation of poor quality tissue, regardless of the fascia defect size, will lead to an unacceptable recurrence rate. In addition, a rectus diasthesis should be addressed as well.

All other patients, in the optimal setting, should have a mesh reinforcement of the repair. The decision to proceed with a laparoscopic versus open approach is dependent not only on the size of the defect, but also on the quality of the skin and soft tissue coverage.

Adequate Skin/Soft Tissue Coverage

In these patients, the decision to proceed with a laparoscopic or open approach is dependent on the size of the defect. Recurrent hernias, single defects between 3 and 10 cm, several midline defects ("swiss cheese type"), or primary defects <3 cm in a morbidly obese individual are ideal for a laparoscopic approach with synthetic mesh. The presence of a significant rectus diastasis should prompt an open approach

Inadequate Skin/Soft Tissue Coverage

Regardless of the size of the defect, if there is a potential for exposure of the synthetic mesh or the repair is performed in the setting of contamination, we would favor the open approach with the use of a biologic mesh. There are currently no data to support the use of a biologic product via a laparoscopic approach.

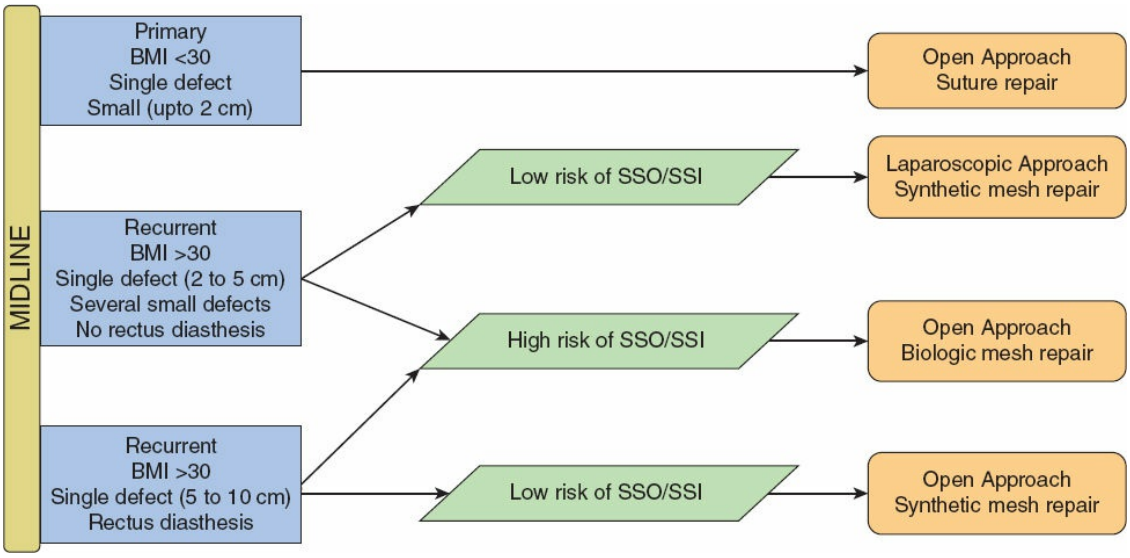

Figure 11.6. Algorithm for abdominal wall reconstruction involving midline defects. The type of repair is based upon both characteristics of the hernia and patient factors that may influence the development of a surgical site occurrence (SSO) or infection (SSI).

CHOICE OF MESH MATERIAL

Reinforcement of a hernia repair with implantable mesh has revolutionized AWR by significantly reducing rates of recurrence compared to suture only repair. However, there is little consensus on which type of reinforcement is best. Primary repair without mesh reinforcement is only appropriate in the setting of defects <2 cm, while all other defect repairs have been shown to reduce rates of recurrence with mesh reinforcement. There is growing evidence to support the use of synthetic mesh for the majority of repairs; however, biologic mesh may prove superior in the setting of high risk or contaminated surgical fields. Despite this, selecting the appropriate mesh for a given clinical scenario remains a matter of debate. Synthetic or biologic mesh may be chosen based upon a number of overlapping criteria including hernia and patient characteristics. It is important to consider the specific advantages and limitations of any mesh selected to reinforce the hernia repair.

The three main meshes available are polypropylene (PPM), polyester, and polytetrafluoroethylene (ePTFE) and various combinations of these materials with a myriad of anti-barrier coatings. It is beyond the scope of this chapter to discuss each product available to the surgeon. Nonetheless, it is the surgeon's responsibility to fully understand the prosthetic that is utilized as part of the repair. There should be comment however on the

recent support of light-weight PPM for reinforcement. Much of the support comes from the hypothesis that these meshes can be employed in the setting of contamination without having to resort to expensive biological mesh with little compromise in recurrence or mesh explantation. However, recent data do not support this rationale. Conze published his prospective randomized study in 2005, which showed a 17% recurrence rate in the light-weight group compared to 7% in the standard group. In the setting of contamination, Carbonell's study of 100 patients with <1 year follow-up showed 4 patients required explantation.

Biologic mesh is a potentially viable alternative to synthetic mesh in the properly selected clinically setting. They are essentially an acellular dermal matrix (ADM) from a variety of animal sources with different processing, which confers their different clinical properties. Much has been published since the last edition of *Mastery of Surgery* to allow surgeons a better insight into their appropriate use. Biologic meshes certainly have an advantage over synthetic mesh in contaminated wounds in allowing single-stage repairs, but their use is not cost-effective in all patient populations. It is also evident that their use in a bridged setting results in either a recurrence or eventration almost 100% with long-term follow-up. Those with and/or at high risk for wound complications should undergo repair with biologic mesh. Ultimately, more large-scale and long-term studies need to be performed to adequately assess the efficacy of biologic mesh products in AWR.

LOCATION OF MESH PLACEMENT

After selecting the ideal mesh product to reinforce a given VHR, the material may be placed in a number of different locations within the abdominal wall for reinforcement. Mesh may be sutured superficial to the primarily closed fascia (onlay), directly to the fascial edges as a bridged repair (interposition), posterior to the rectus abdominis muscle (retrorectus), or deep to the peritoneum (underlay). Each of these has distinct advantages given a particular clinical situation. In general, underlay or retrorectus mesh placement results in the lowest complication rates including less infection, seroma, and hernia recurrence as compared to onlay or interposition mesh placement. Within the context of biologic mesh, interposition mesh placement when primary fascial approximation is not feasible will result in the highest rate of hernia recurrence, approaching 100%.

SPECIFIC HERNIAS

Umbilical and Epigastric Hernias

Hernias involving the umbilicus can be congenital or occur spontaneously. Many congenital umbilical hernias will spontaneously close by 2 to 3 years of age. The repair of the pediatric hernia is not the focus of the following discussion. In adults, multiparity, obesity, ascites, and any pathology that elevates IAP increase the risk of a fascial defect. Although umbilical hernias are common, the differential diagnosis should include soft tissue tumors and urachal cysts. The contents of an umbilical hernia may include preperitoneal fat, mesenteric fat, and/or bowel. For this reason, the hernia should be repaired unless there is a strong contraindication.

Epigastric hernias are another common fascial defect encountered by general surgeons and may be present in up to 2% of the population. They mostly occur spontaneously as a function of the anatomy of the linea alba that becomes thinner and wider cephalad from the umbilicus. These hernias have a male prevalence and can have multiple defects in up to 20% of patients. Given the small defect size that often has a small piece of incarcerated preperitoneal fat, the level of discomfort can be more than expected. The diagnosis is usually made with the clinical examination confirming a palpable bulge. Imaging is not necessary, but can be obtained if the examination is equivocal.

As discussed, the size of the defect, comorbidities, and the skin factors all should be considered in the choice of surgical technique. With our established algorithm, most of the umbilical hernias repaired in our practice in the nonobese population are a primary suture repair without mesh reinforcement. This does represent a compromise between recurrence rates and mesh-related complications. A randomized study by Arroyo et al. showed that umbilical hernia repair with prosthetic mesh had a recurrence rate of 1% at 64 months compared to 11% with direct suture repair alone. Complications in both groups were similar.

Given the same small defect size in an obese individual, mesh reinforcement is necessary. The protocol for synthetic versus biologic mesh has been previously discussed. In the setting of appropriate skin coverage, a laparoscopic approach is recommended with synthetic mesh. Typically, these cases are short and can be performed as a same-day operation. With less than ideal skin coverage, absent or attenuated, a laparoscopic approach is not recommended. An open repair with synthetic

mesh is usually appropriate.

Technique for Open Repair With/Without Mesh Reinforcement

1. An incision is made over the fascial defect to provide proper exposure in either a vertical or a horizontal fashion. For umbilical hernias, the umbilical stalk is dissected free from the hernia sac. It is important not to button-hole the skin.
2. The hernia sac/contents are dissected away from the edges of the fascia. Without the involvement of omentum or bowel, violation of the peritoneal cavity should be avoided. Especially important is individuals with the presence of ascites.
3. (a) The fascial edges are clearly delineated. With a <2-cm defect, a primary repair is carried out using absorbable suture such as 0-PDS figure-of-eight sutures transversely. We typically place our corner sutures beyond the defect (Fig. 11.7). (b) With a defect >2 cm and/or accounting for patient risk factors, mesh can be utilized at this time. The authors recommend underlay mesh (intraperitoneal or sublay) rather than an onlay technique. The size of the mesh should allow for at least 3- to 4-cm support circumferential. The mesh is secured with at least 0-PDS sutures transfascial. The fascia is then re-approximated over the mesh (Fig. 11.8).
4. Closure of the incision. For umbilical hernias, the umbilicus is tacked back down to the linea alba with absorbable suture.

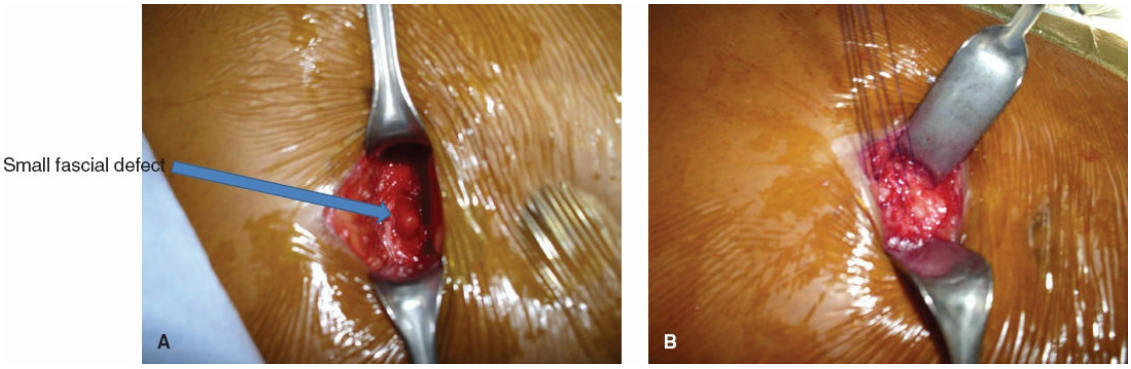

Figure 11.7. A. The small hernia defect size is delineated with healthy fascial edges. **B.** A primary suture repair is performed in a transverse fashion with figure-of-eight sutures extending beyond the corners of the defect.

Technique for Repair in Setting of Rectus Diastasis

1. The incision is a vertical midline incision to provide the proper

exposure from the xiphoid process infra-umbilical. The small fascial defect is repaired as described above with or without mesh reinforcement. The extent of the diastasis is delineated to allow for maximal plication.

2. Either a single or a double row of sutures can be utilized depending upon surgeon preference. The authors prefer either a single row of figure-of-eight No. 1-PDS sutures or a double row consisting of figure-of-eight 0-PDS sutures followed by running No. 1-PDS. Additional onlay mesh reinforcement is not necessary.

INCISIONAL HERNIAS

Incisional hernias develop in up to 20% of patients, which means that annually at least 150,000 patients will develop this issue from an abdominal surgery. As noted earlier, the best practice for abdominal wall closure has yet to be determined. The associated pathology is quite variable and thus so is the technique utilized for repair. A recent Cochrane database review of open surgical techniques for incisional hernias has shown that even in small defects, the use of suture repair was associated with less surgical site infection and seroma but an increased rate of recurrence. Therefore, mesh reinforcement is advocated for in all incisional hernias, regardless of defect size.

There are multiple randomized controlled trials evaluating laparoscopic versus open repair of abdominal wall hernias. The laparoscopic approach provides for lower overall complication rates, decreased wound complications, decreased length of stay, and decreased recurrence rates. However, there is a higher rate of bowel injury with inexperienced surgeons. Also, unless the fascial defect can be closed, the functionality of the abdominal wall remains compromised. This is especially an issue for moderate to large defects.

Preoperative preparation is critical in the patient with an incisional hernia as recurrence rates can be high leading to a much more difficult hernia repair with worsening results. Weight loss should always be considered in the obese patient. Although the authors do not have a strict cutoff, the literature has shown that a BMI >30 kg/m^2 is associated with higher recurrence rate. Not only does the weight loss make the operation technically more feasible, perhaps avoiding a bridge repair, but also it allows the patient an easier recovery. For those patients who are morbidly obese and are unsuccessful in their weight loss attempt, a consultation with

a bariatric program is advised. Smoking cessation is an absolute requirement as well given its negative impact on wound healing and higher incidence of surgical site infection. In the elective setting, the repair is not scheduled unless the patient can be verified to have at least 4 weeks successful with cessation. Lastly, in the diabetic patient, proper blood glucose control needs to be assessed with HgAlc level. A level >7.2 is associated with complications. Methicillin-resistant Staphylococcus aureus clearance and nutritional assessments are also important.

There are many different techniques that have been developed for the repair of the incisional hernia. The central theme of each repair has become midline re-approximation of the autologous tissue (usually rectus muscles) with physiologic tension and proper mesh reinforcement. Suture repair alone is associated with unacceptable recurrence rate and should not be the primary objective. The authors advocate for either intraperitoneal or retrorectus placement of the prosthetic mesh. Most of the literature is consistent with higher recurrence rates with an onlay positioning of the mesh.

TYPES OF REPAIRS

Rives–Stoppa Repair (Retro-Rectus)

Rives described this technique as early as 1973 in which the prosthetic material was placed above the posterior sheath in the retro-rectus location to isolate it from the viscera. This is quite different than the intraperitoneal placement of mesh. Flament reported a recurrence rate of 6.3% at 10-year follow-up on 693 patients. The advantage of the repair is that it allows uncoated inexpensive mesh to be utilized and may provide a more vascular space for the placement of biologic mesh if indicated.

The technique that follows reduction of the hernia contents and lysis of adhesions is the incision of the posterior sheath from the rectus muscle starting just lateral to the edge (Fig. 11.9). It is an avascular plane that can be carried out to the semilunaris line. The dissection can be further carried out if a transversus abdominis release (TAR) is performed. The same dissection is performed on the contralateral side. The posterior sheath is then approximated that isolates the prosthetic mesh from the viscera (Fig. 11.10). Any tearing of the posterior sheath can be primarily repaired or buttressed with omentum. The mesh is then sized accordingly and secured with several slowly absorbable sutures, such as No. 1 PDS, in a circumferential manner (Fig. 11.11). The rectus muscles are then re-

approximated restoring the functionality of the abdominal wall (Fig. 11.12).

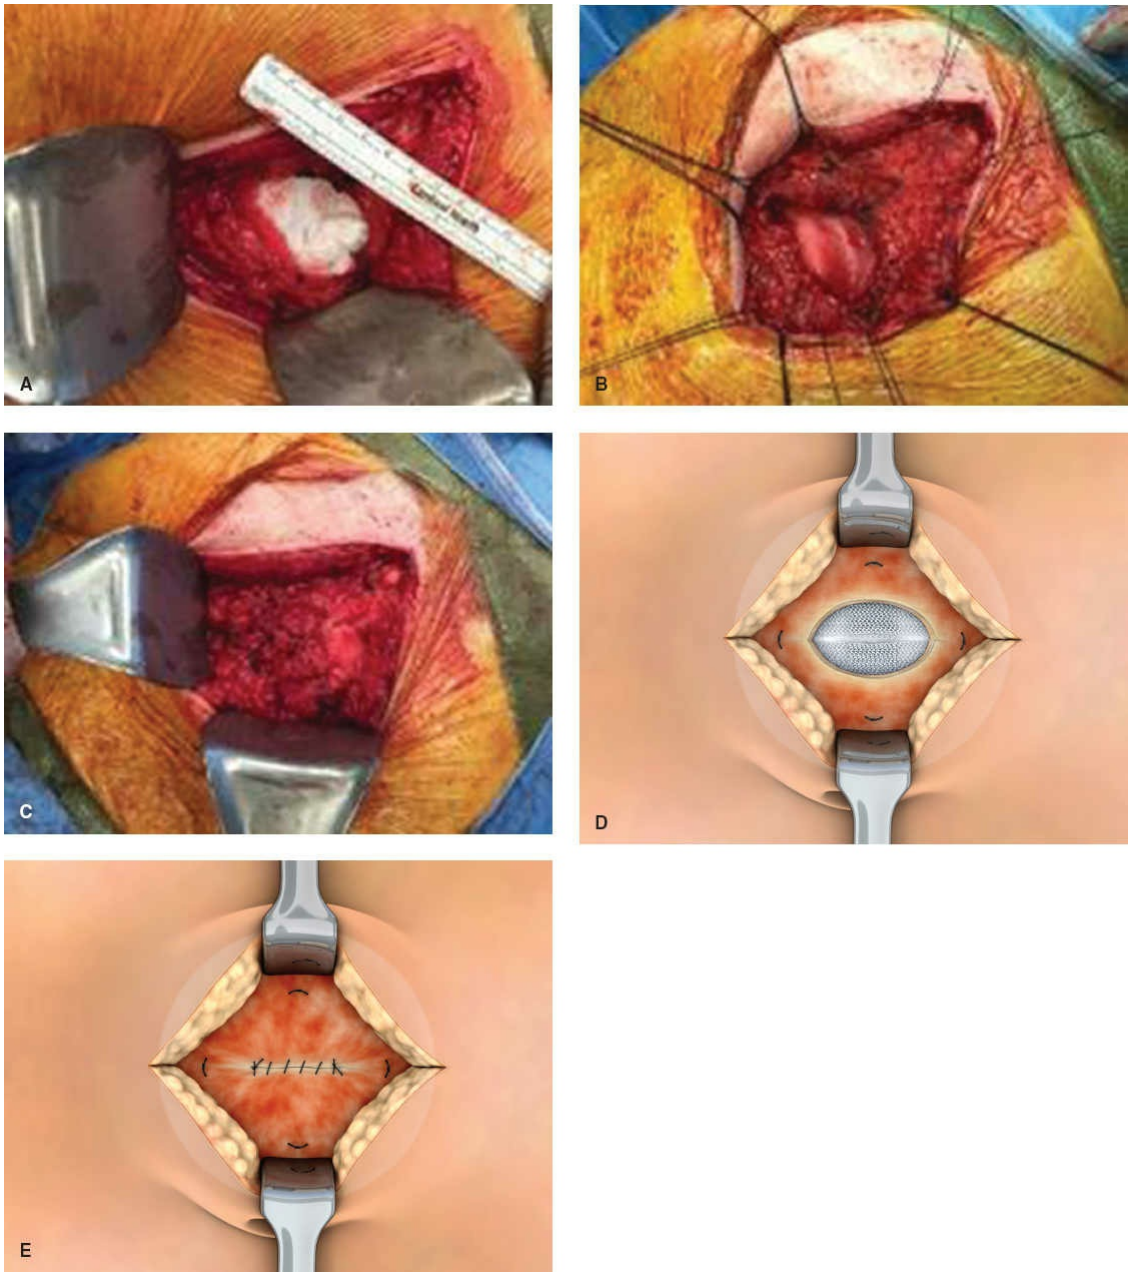

Figure 11.8. **A.** A moderate defect is exposed with fascial edges delineated. **B.** Mesh reinforcement in the intraperitoneal location is utilized given the defect size. The mesh is parachuted in after placement of transfascial sutures. **C.** After the mesh is secured, the fascia is then re-approximated with additional sutures, providing autologous tissue coverage. **D.** Illustration of mesh secured underneath the fascia. **E.** Illustration of the fascia closed over the mesh.

Intraperitoneal

This method remains the popular repair although rapidly losing ground to the retro-rectus repair. The laparoscopic approach to hernia repair is

largely responsible for its popularity as well as the advent of coated meshes. Unlike the retro-rectus repair, there is no limitation to the width of the mesh that can be placed intraperitoneal as the former is limited by the distance between semilunaris lines. Other advantages include it is quicker to do and requires less dissection. Also useful in the abdomen that has been repaired several times in which the posterior sheath is nonexistent or cannot be properly dissected. One disadvantage is the large number of sutures needed to secure the mesh to prevent migration of bowel above the mesh.

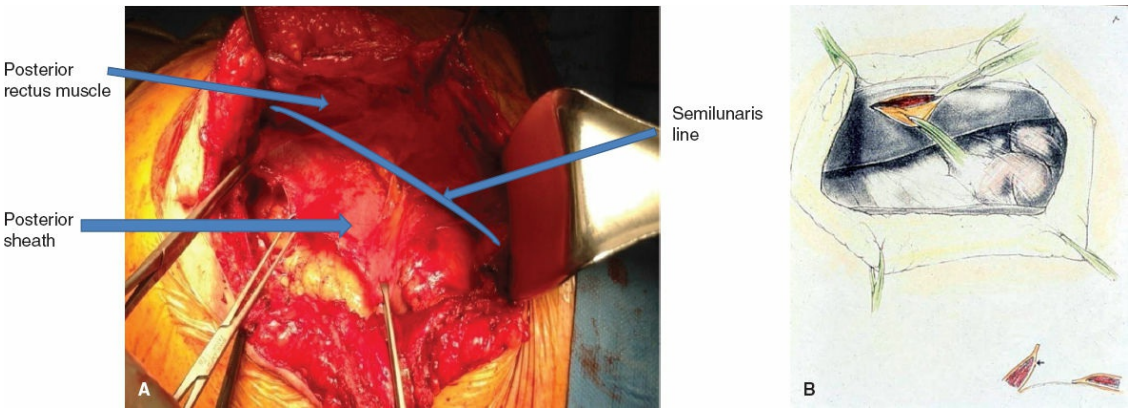

Figure 11.9. **A.** The unilateral dissection of the posterior sheath away from the posterior rectus muscle within an avascular plane to the semilunaris line. **B.** Illustration of the posterior sheath dissection.

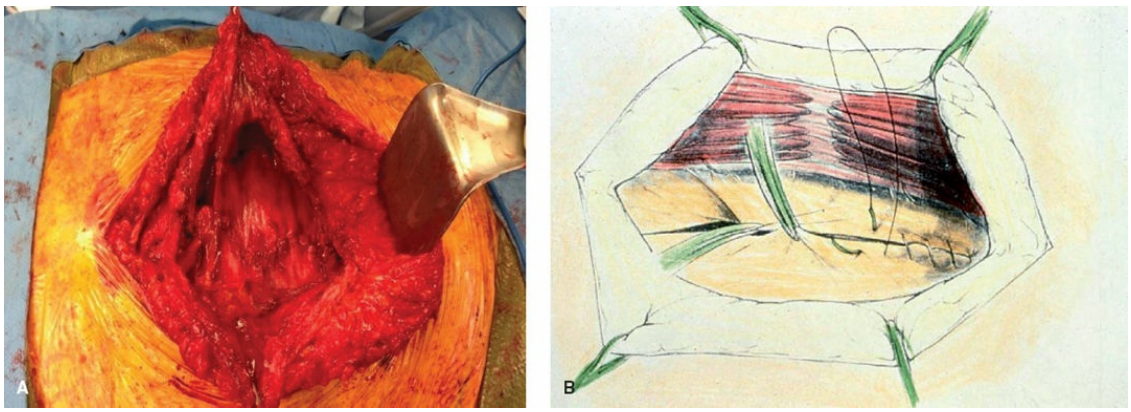

Figure 11.10. **A.** After bilateral dissection of the posterior sheaths from the rectus muscle, both sides are re-approximated with a running suture. **B.** Illustration of posterior sheath closure.

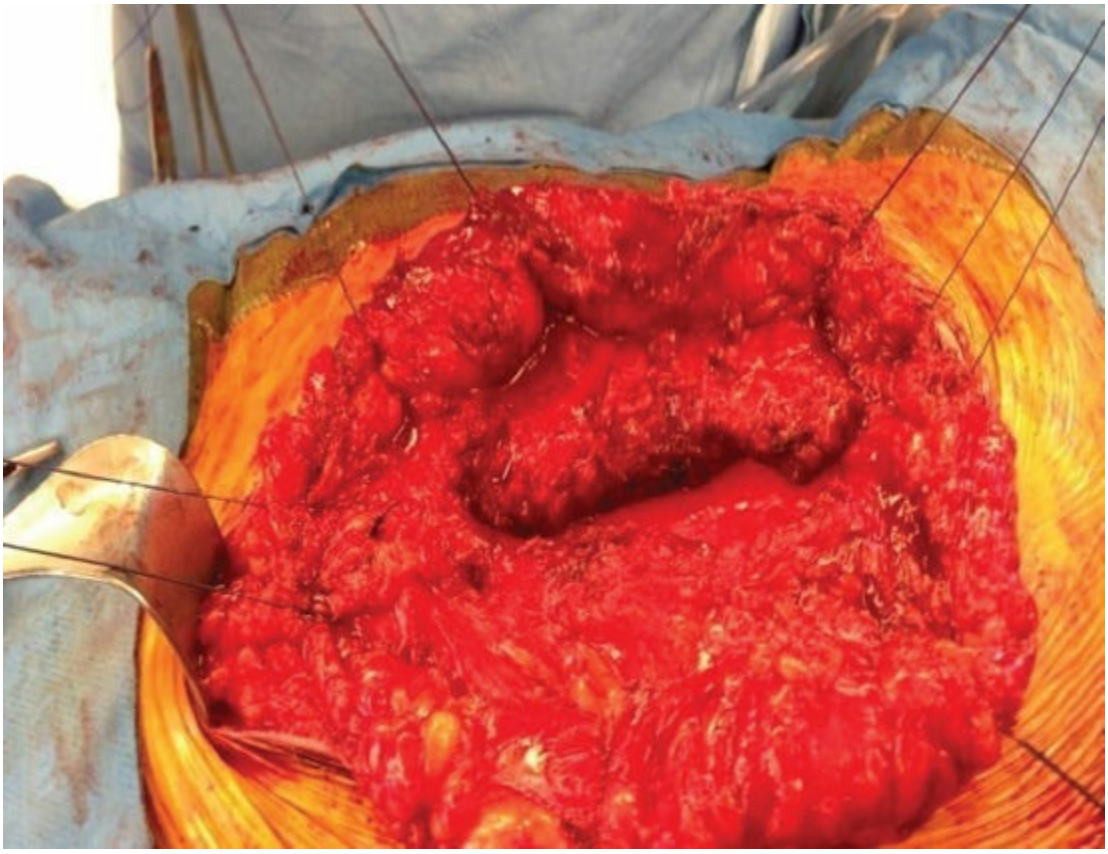

Figure 11.11. The mesh is then secured circumferentially underneath the fascia with tranfascial sutures.

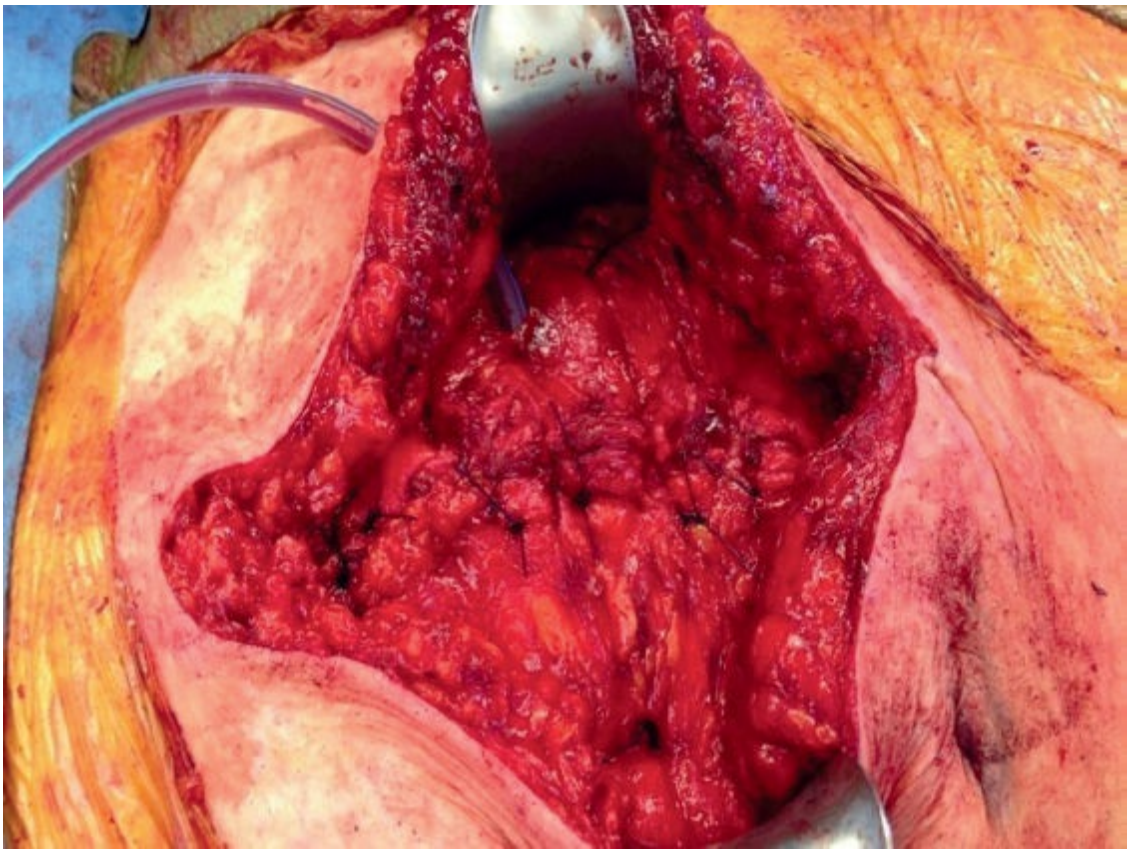

Figure 11.12. The rectus muscles are re-approximated with excessive tension.

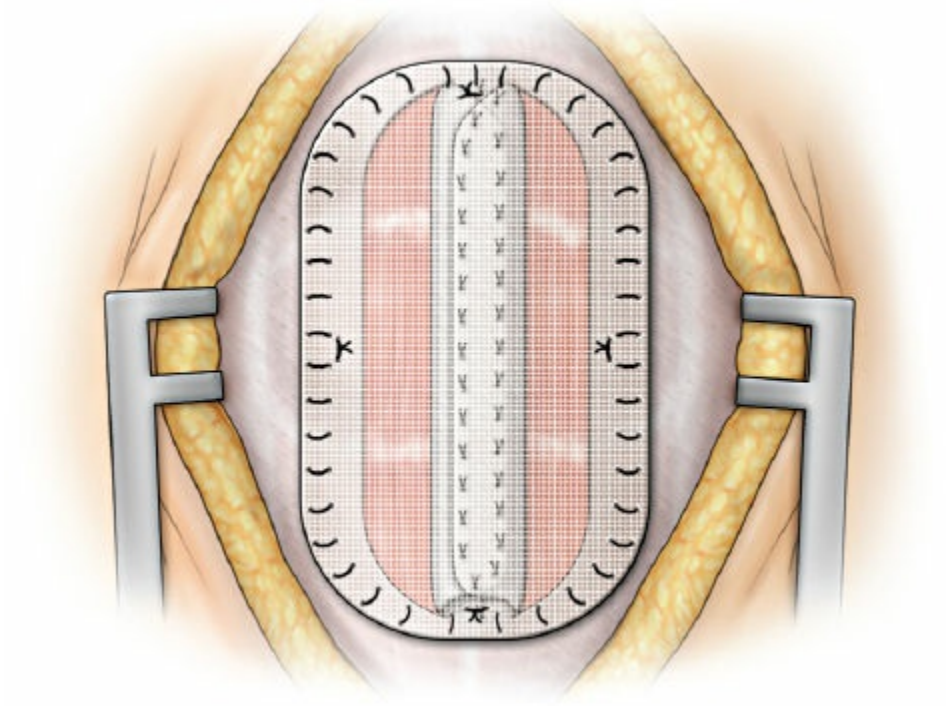

Figure 11.13. Chevrel onlay prosthesis.

The literature has shown essentially similar rates of recurrence with the Rives repair. Voeller reported a series of 115 patients in which there was <1% recurrence rate. This could be attributed to surgeon experience, advanced technical skills, and/or a repair performed well in good patient selection.

Onlay Technique (Chevrel)

This repair accounts for the minority of repairs performed, but should still be part of the surgeon's armenterium in certain cases such as a hostile abdomen with dense adhesions. The technique involves closure of the muscle followed by mesh placement. Relaxing incisions of anterior component separation procedure can be added if there is excessive tension on the closure. The onlay mesh was secured circumferentially as well as fixated centrally with either additional sutures or as described by Chevrel, fibrin glue (Fig. 11.13). Voeller has described and reported excellent results with complete glue fixation of the mesh.

The advantage to the repair is that the defect can be non-midline, unlike the Rives repair. As mentioned, aside from the reduction of the hernia, an

extensive lysis of adhesions is not necessary. The major drawback is the high potential for mesh infection and explantation with any surgical site infection as the mesh is positioned directly below the skin and soft tissue.

COMPONENT SEPARATION

In certain situations that involve large fascial defects in which the surgeon cannot achieve midline approximation of the rectus muscles, a components separation technique is extremely effective and should be in any general surgeon's armamentarium (Fig. 11.14). The neurovascular anatomy of the abdominal wall allows for a bilateral myofascial advancement of the rectus muscles while maintaining the dynamic functionality of the abdominal wall.

The most commonly employed technique involves an anterior or external oblique release described by Ramirez in 1990. The procedure is begun with the elevation of subcutaneous flaps from the underlying abdominal musculature to expose the linea semilunaris. It is critical to preserve the large peri-umbilical perforators to prevent ischemia of the skin flaps. The external oblique fascia is then incised 1 cm lateral to its insertion into the rectus sheath from above the costal margin to the inguinal ligament. This allows for the development of an avascular plane between the external oblique aponeurosis and internal oblique muscle as far as the posterior axillary line (Fig. 11.15). The developed myofascial complex allows for an 8- to 10-cm advancement at the waist; 3- to 5-cm advancement in the upper and lower abdomen. An additional 2-cm advancement can be achieved if the rectus muscle is elevated off of the posterior sheath.

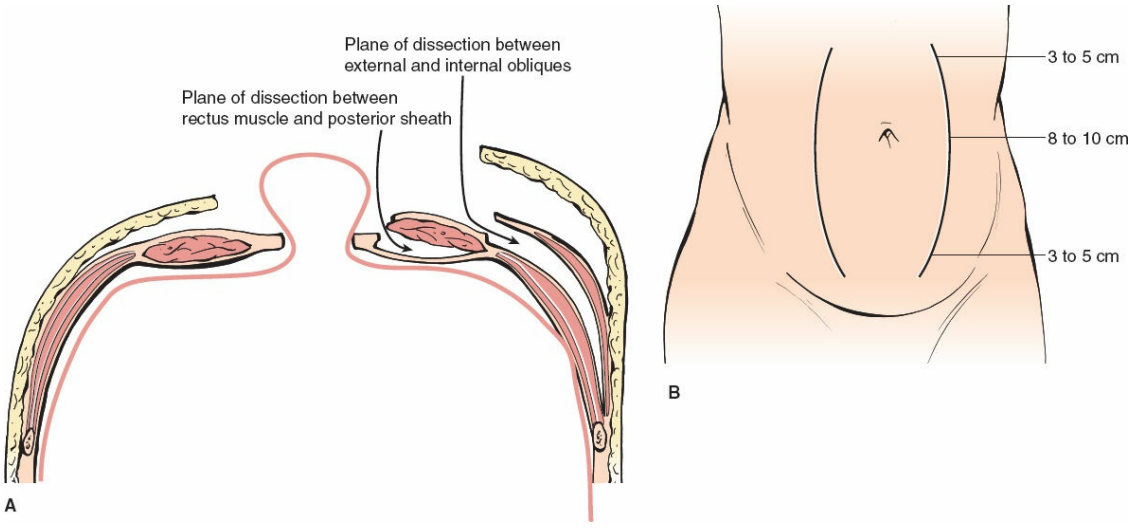

Figure 11.14. A. When a midline abdominal wall defect cannot be closed primarily, a components separation procedure can be utilized. The dissection begins with the elevation of subcutaneous flaps to the anterior axillary line to expose the underlying abdominal musculature. The linea semilunaris line is palpated and the external oblique fascia is then incised lateral to its insertion into the rectus sheath. An avascular plane is developed between the external oblique aponeurosis and internal oblique muscle to allow the rectus muscle to be advanced to the midline. The posterior sheath can also be incised and elevated off of the rectus muscle to achieve additional 2-cm advancement. **B.** There is a variable degree of advancement dependent upon location. The developed myofascial complex allows for an 8- to 10-cm advancement at the waist; 3- to 5-cm advancement in the upper and lower abdomen.

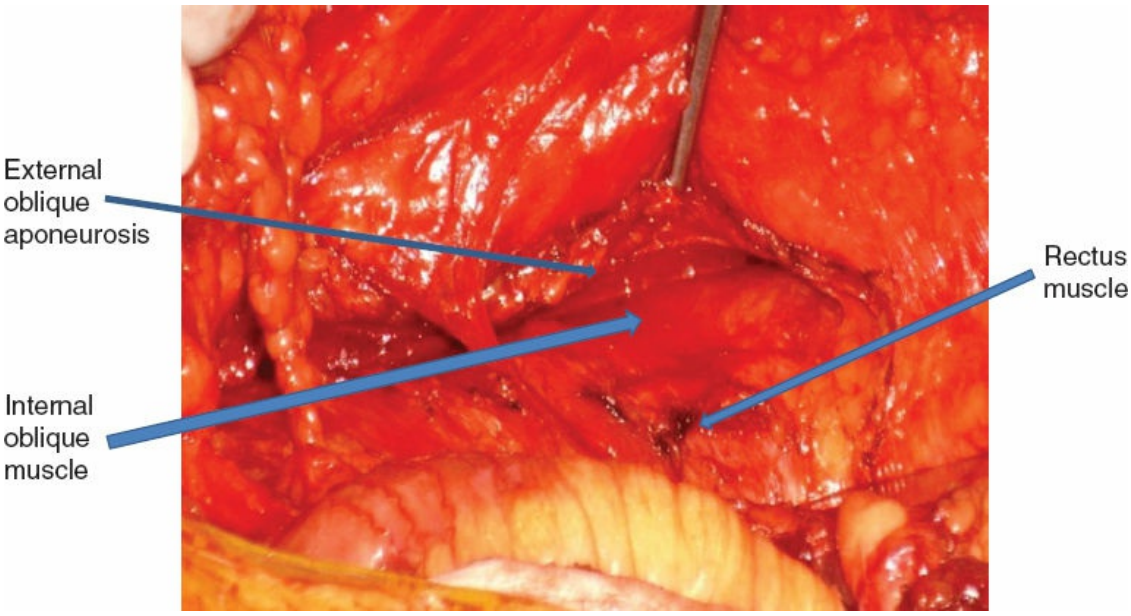

Figure 11.15. The external oblique aponeurosis has been separated from the underlying internal oblique musculature in an avascular plane. This results in a myofascial flap consisting of the internal oblique and transverses abdominis muscles.

Multiple variations have been described, but the one gaining immense popularity over the last few years is the TAR, described by Novistsky in 2012. It has a few advantages over the traditional anterior release. The most significant of which is the avoidance of large subcutaneous skin flaps potentially leading to a reduction in wound morbidity. The second advantage is the necessity of creating the retro-rectus space for mesh

placement, which isolates the prosthetic from the viscera. The dissection of the plane between the transverses abdominis and transversalsis fascia allows for a wide piece of mesh to be utilized. The disadvantage is the decreased advancement of the rectus muscles compared to the anterior release, which can be problematic in large defects. It is important to emphasize that the surgeon cannot perform an anterior release in this situation as the abdominal wall would be severely compromised.

The technique of the TAR as stated involves the separation of the posterior sheath from the rectus muscle to allow exposure of the transverses abdominis muscle. The next step is to incise the medial border of the muscle without injuring the underlying fascia or exposed nerves. Blunt dissection is used to retract the muscle laterally away from the posterior rectus sheath and up from the transversalis fascia (Fig. 11.16). The resultant plane is continuous with the retroperitoneum and can be developed further posterior to the costal margins to the space of Retzius, and laterally to the psoas muscles.

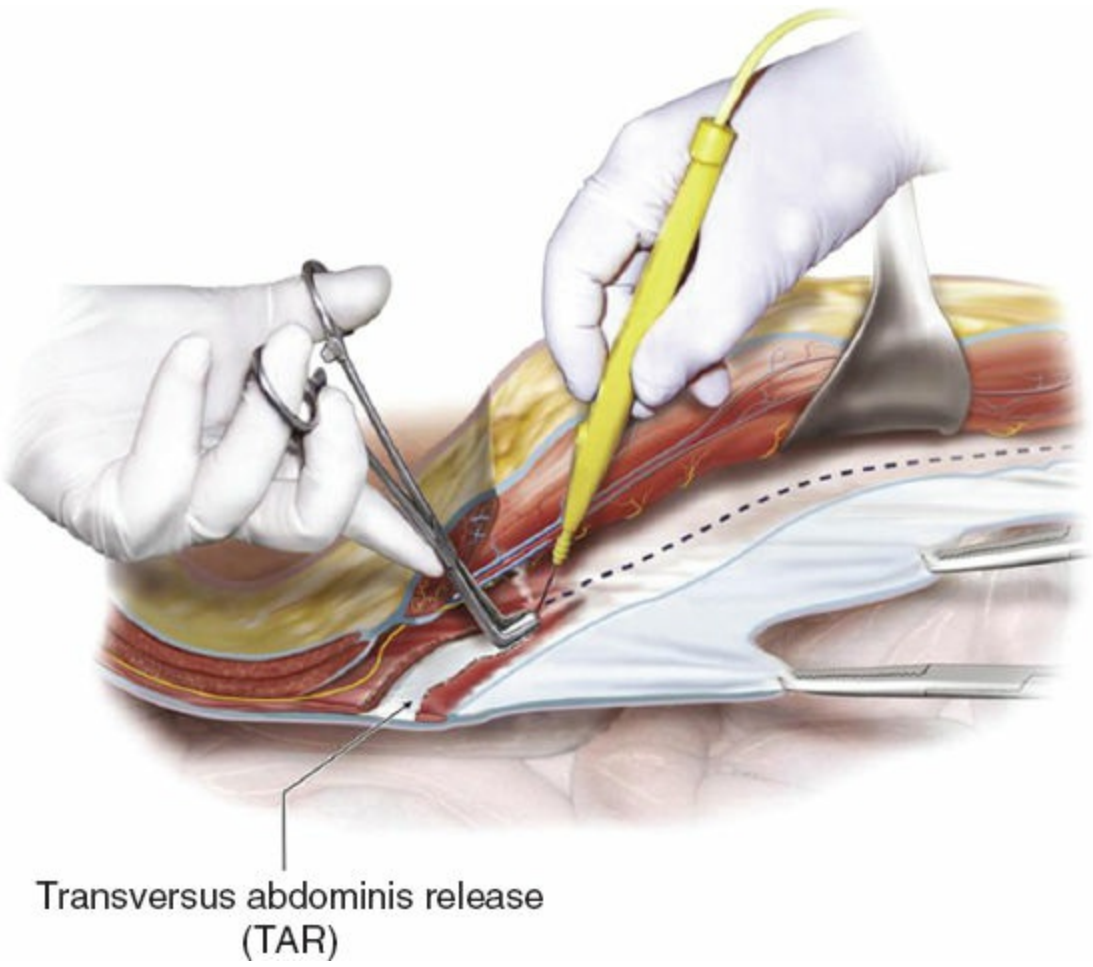

Figure 11.16. The transverses abdominis muscle is divided

above the peritoneum. The preperitoneal plane is then matured laterally between the transverses abdominis muscle and peritoneum/transversalis fascia to the psoas muscle. (From Petro CC, Como JJ, Yee S, et al. Posterior component separation and transversus abdominis muscle release for complex incisional hernia repair in patients with a history of an open abdomen. *J Trauma Acute Care Surg* 2015;78(2):422–9; with permission from Wolters Kluwer Health, Inc.)

LAPAROSCOPIC VENTRAL HERNIA REPAIR

Abdominal wall hernia repairs did not escape the laparoscopic proliferation of general surgery procedures in the 1990s. LeBlanc first described a laparoscopic ventral hernia repair (LVHR) in 1993. The popularity of the procedure coincided with the development of barrier-coated meshes that could be placed in the peritoneal cavity, which allowed tissue ingrowth against the posterior abdominal wall and ability to decrease adhesions with the viscera. As stated above, LVHR is tremendously successful dependent upon proper patient selection. Its distinct advantage is that the laparoscope allows for clear visualization of the abdominal wall to address all fascial defects, wide mesh coverage of the defect(s) without a large open incision, decreased surgical site occurrence/infection, and low recurrence rate.

Indications

The indications for an LVHR are similar to those for an open procedure. The presence of symptoms associated with the hernia such as pain and discomfort, bulging from the defect, and obstructive symptoms such as nausea and emesis. However, not all patients are candidates for the procedure. There are two major disadvantages to LVHR. The first is that it requires almost complete lysis of adhesions for trocar placement and wide mesh overlap. In patients with known history of dense adhesions or history of bowel injury from a hernia repair, there is a higher incidence of enterotomy compared to an open approach. The authors also prefer to avoid LVHR in patients with densely incarcerated viscera to prevent iatrogenic bowel injury. The second major disadvantage is the inability to close the defect in larger hernias. Although there is increasing number of surgeons who are attempting to do so with a myriad of techniques, the data do not reflect a lower recurrence rate. Closure of large defects is not

possible, which will leave the patient with a nonfunctional abdominal wall.

Equipment and Materials

The list of equipment for LVHR is not extensive. The authors prefer a 5-mm 30-degree angled scope that can then be placed through each trocar, which aids in the visualization of the repair. Our previously described technique involves placement of three 5-mm trocars and one 12-mm trocar. Most of the lysis of adhesions can be performed with laparoscopic shears, but ultrasonic shears can be employed for omentum and taking down the falciform ligament. Nontraumatic graspers to prevent serosal injury are important. A small gauze spinal needle is utilized for defect measurement. A suture passer device allows for transfascial suture fixation. The remainder of the mesh is secured with an absorbable tacker.

Perhaps, the most important is the selection of the proper mesh. With intraperitoneal placement, a barrier-coated mesh must be chosen and is based usually upon the facility the operation is performed in. The surgeon should be familiar with the mesh product including individual properties and sizes available. For example, a light-weight mesh would not be appropriate for large fascial defects without fascial closure.

Operative Technique

The following is our standard technique previously described and published (Fig. 11.17). Our method results in securing prolene-based barrier-coated mesh in intraperitoneal location with transabdominal suture fixation and absorbable tacks ensuring at least 3 cm of overlap. Conversion to open technique was performed if the laparoscopic repair was unable to be completed due to either technical issues or patient safety.

All patients receive prophylactic antibiotic prior to first incision based on individual drug allergy information. The patient is positioned supine on the operating table. Compression boots are employed for DVT prevention. A Foley catheter is frequently inserted depending on hernia location and size. Gastric decompression is accomplished with oral gastric tube in all patients.

A Veress needle is used to access the peritoneal cavity, with the location dependent upon the location of the hernia and prior surgical history. A Hasson technique is an alternative, but can be difficult in the morbidly obese patient. Pneumoperitoneum is established to 15 mm Hg. After placement of the first 5-mm trocar, two additional 5-mm and one 12-

mm nonbladed trocars are inserted under direct visualization. All trocars should be placed as lateral as possible to allow appropriate mesh overlap. A 5-mm 30-degree laparoscope is used to fully explore the abdomen and to perform the adhesiolysis. This is performed mainly using laparoscopic shears without energy source to prevent possible thermal injury to bowel. For an incisional hernia, a complete lysis of adhesions is performed to evaluate the entire length of the incision. The hernia sac contents are reduced, leaving the sac in situ. The defect is sized using a spinal needle, and the margins are marked on the abdominal wall.

Mesh is tailored to overlap the fascial defect by at least 3 cm. A minimum of four monofilament sutures are placed on the mesh. The mesh is then introduced through the 12-mm trocar. After proper positioning of the mesh, a suture passer is used to pull the transfascial sutures through separate incisions and tied down. Additional sutures are placed for larger mesh sizes. The circumference of the mesh is then tacked to the posterior fascia at 1- to 2-cm intervals. The absorbable tacker allows for placement of additional tacks in the center of mesh for better apposition to the posterior sheath.

At the completion of mesh placement, the bowel is examined for possible iatrogenic injury. The omentum is observed for hemostasis if involved in the hernia sac. Then the pneumoperitonuem is released. None of the trocar fascial defects are closed. The skin incisions are closed with absorbable sutures. No drains are placed.

Postoperative Care

Postoperative care is centered around return of bowel function and pain control. Thus, patients with smaller hernia repairs without extensive lysis of adhesions can be discharged the day of surgery. Otherwise, the average length of stay in our series is <2 days. An abdominal binder is recommended for comfort purposes.

SPECIAL CONSIDERATIONS

Enterotomy

As mentioned, the LVHR is associated with a higher enterotomy rate compared to open approach. If an injury occurs, it must be repaired either via laparoscopic approach dependent upon surgeon experience or conversion to open approach. A bowel resection may be necessary

dependent upon extent of injury. The lysis of adhesions is then completed. There are two options at this time. The first is to complete the hernia repair with biologic mesh as synthetic mesh is now contraindicated in a clean-contaminated case. The advantage of this option is a second operation does not have to be performed later in the admission. The second option would be to close the abdomen without mesh and admit the patient for antibiotics. The patient would then be brought back to the operating room if no signs of sepsis were evident for delayed placement of synthetic mesh.

Xiphoid Hernia

Subxiphoid hernias will require adjustment in trocar placement for proper triangulation of the defect. Usually, the falciform must be taken down using an energy source. This allows full visualization of the defect and proper mesh overlap. The authors do not advocate placement of sutures through the lower ribs or above the costal margin. There are risks of bleeding and chronic pain. We prefer to place the sutures just below the costal margin and then fixate the mesh superiorly with fibrin glue. Tacking is avoided to prevent injury to the pericardium or pleura.

Suprapubic Hernia

Again, trocar placement must be adjusted for suprapubic hernias. For proper fixation of the mesh, the space of Retzius must be dissected to expose the pubic symphysis and Cooper's ligaments (Fig. 11.18). This avoids injury to the bladder, iliac vessels, and nerves. The mesh is tacked to Cooper's ligament bilaterally similar to inguinal hernia repair. Transfascial sutures are then employed for the remainder of the mesh. We advocate for the placement of a three-way Foley to allow easy manipulation of the urinary bladder.

Flank Hernia

Defined as abdominal wall defects that occur between the costal margin and the iliac crest and between the anterior axillary line and the spine, these hernias can be challenging. The patient must be positioned in lateral decubitus position with the hernia side up (Fig. 11.19). Delineation of the fascial defect is not difficult, but the creation of space to allow mesh overlap can present a challenge. As the defect involves the retroperitoneum, the corresponding structures may have to be mobilized

such as the colon. Significantly more dissection is needed than an inexperienced surgeon may initially have planned such as mobilization inferiorly to expose Cooper's ligament and superiorly to the diaphragm. We prefer to fixate the mesh on three sides only, allowing the posterior mesh to be tucked into the retroperitoneum to prevent nerve injury.

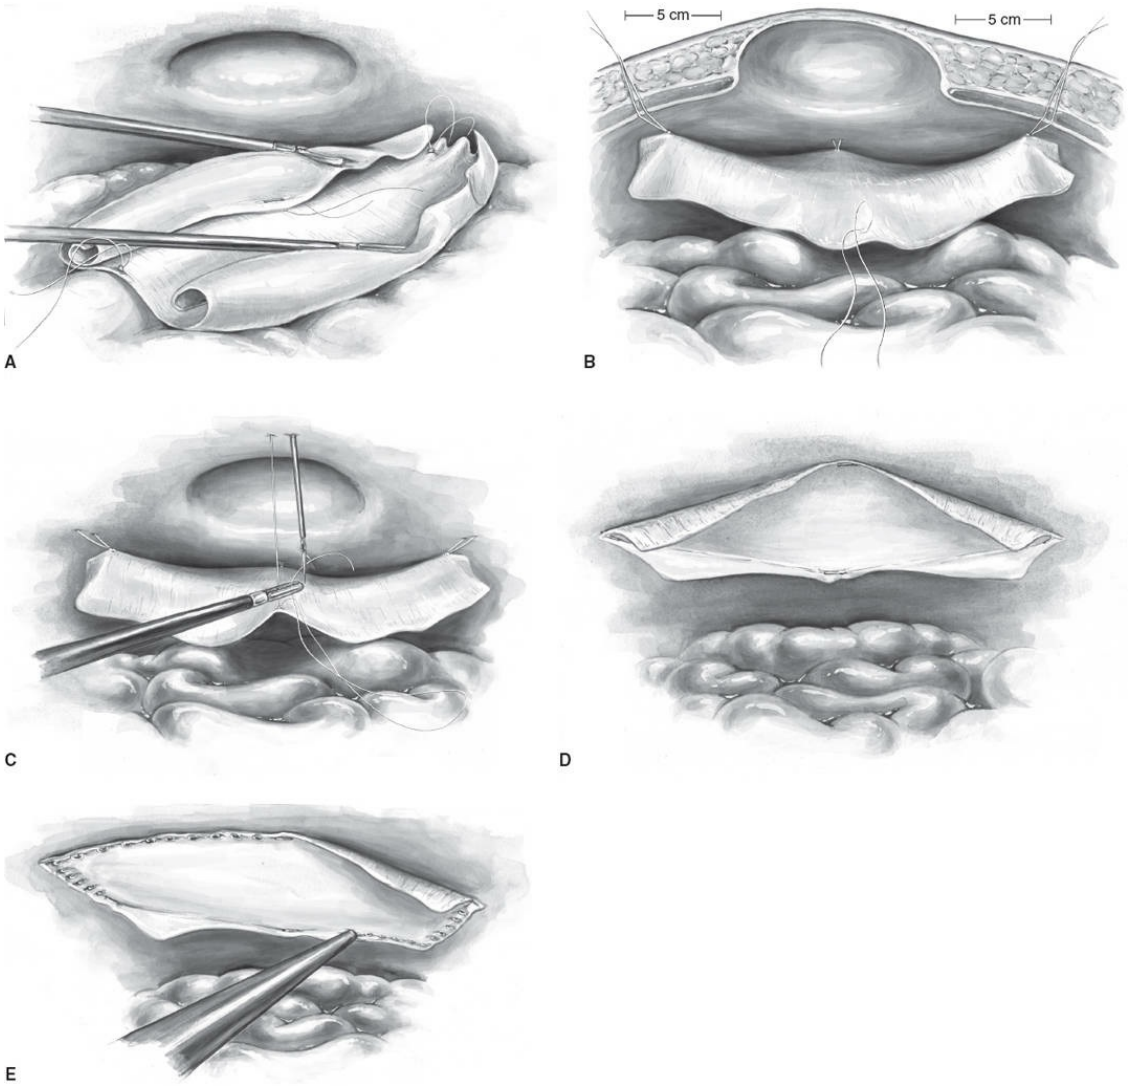

Figure 11.17. **A.** Mesh is oriented in the peritoneal cavity and then unrolled. Stabilizing the center of the mesh with one grasper and unfurling one side at a time works well. **B.** Sutures are preplaced 1 cm in from the mesh edge. The mesh is seen extending at least 5 cm beyond the edges of the hernia defect. The two legs of the suture are brought out of the same skin incision but enter at two different sites intra-abdominally, with at least 1 cm of fascia between the legs. **C.** Sutures are clamped but not tied until all four cardinal sutures have been externalized, allowing for adjustments in the placement of the transfascial sutures if necessary. Alternating between pulling the sutures tight and allowing slack help allow for precise suture placement. **D.** All four cardinal fixation sutures have been gently tied, and the mesh has the appropriate diamond shape, demonstrating tautness. **E.** The point-fixation device should be introduced from ports on the side of the abdomen opposite the area to be fixed. Ideally, the camera is on the same side as the device. Fixing one quadrant at a time and alternating between opposite quadrants help prevent

inadvertent shifting of the mesh across the abdomen. (From Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

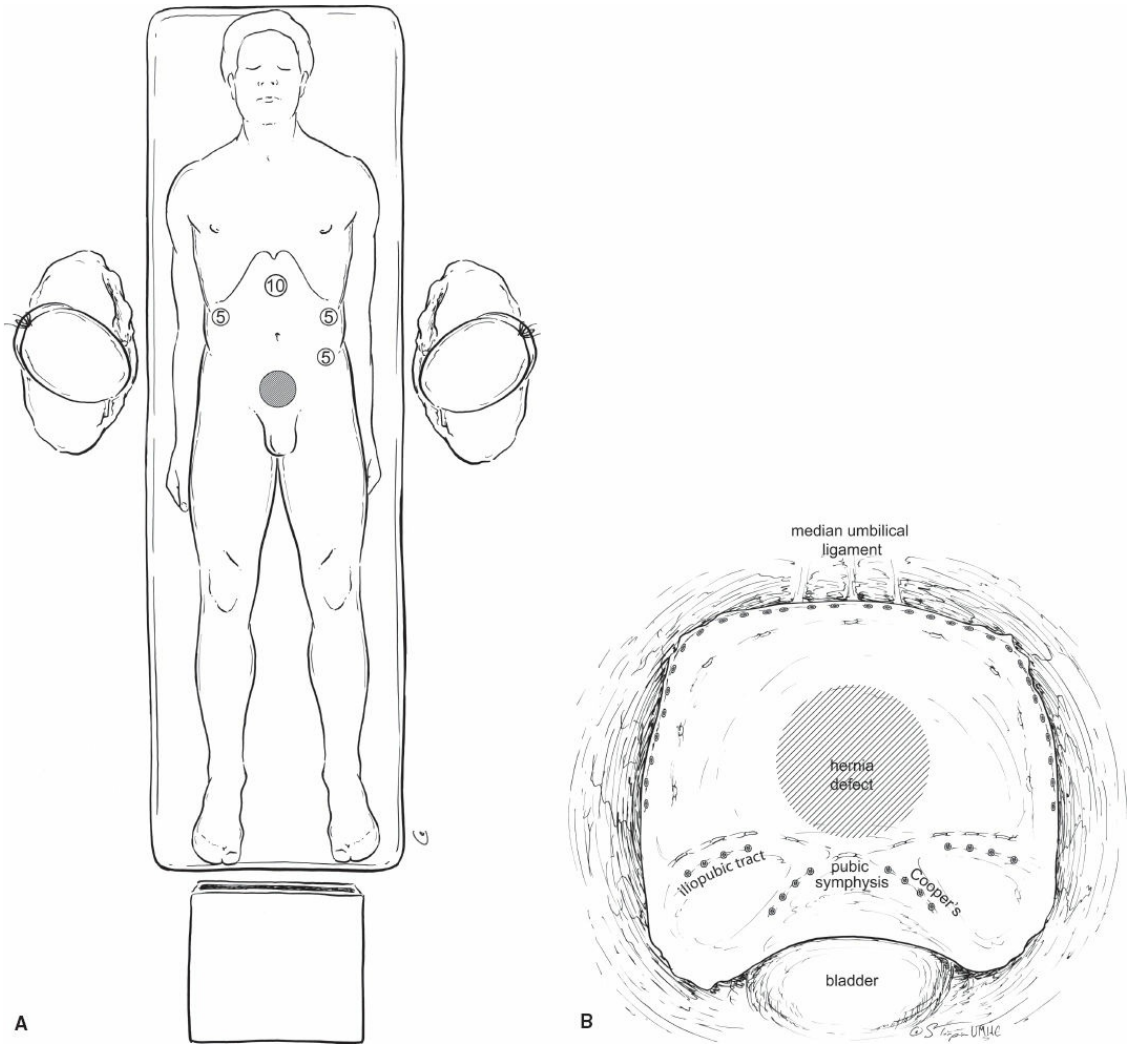

Figure 11.18. **A.** Trocar and operating room positioning for hernias below the umbilicus. **B.** Example of a completed suprapubic hernia repair. Note the extension of mesh below the pubic symphysis and Cooper ligament and the extra fixation along the iliopubic tract. (From Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

OUTCOMES

The laparoscopic approach for abdominal wall hernias is safe and effective. The largest meta-analysis of more than 5,300 patients found a lower rate of complications (22.7% vs. 41.7%), shorter length of stay (2.4 days vs. 4.3 days), and less recurrences (4.3% vs. 12.1%) compared to open approach. However, there was a higher rate of enterotomy. Heniford's series of 850 patients demonstrated a 1.7% incidence of intestinal or bladder injury. The success of LVHR is largely dependent

upon two factors: patient selection and surgeon experience.

SUMMARY

The success of an open abdominal operation requires adequate exposure and flexibility via the appropriate selection of the incision. This entails the surgeon having a fundamental knowledge of the anatomic principles of the abdominal wall. Equally as important is the proper closure of the abdominal wall to limit unnecessary morbidity. Immediate consequences result in surgical site occurrences (SSO), which may then develop into long-term morbidity of a hernia requiring another operation.

Reconstructive options for AWR are vast and should start with optimizing patient selection. The surgeon should have within his or her armamentarium a myriad of options to perform the optimal surgery. An algorithm should be incorporated into clinical practice based on high-level data that will allow the surgeon to define which approach, technique, and mesh reinforcement should be utilized for each individual patient. The ultimate goals of ventral hernia repair are to prevent complications from the hernia, restore functional abdominal wall, and minimize future complications including recurrence.

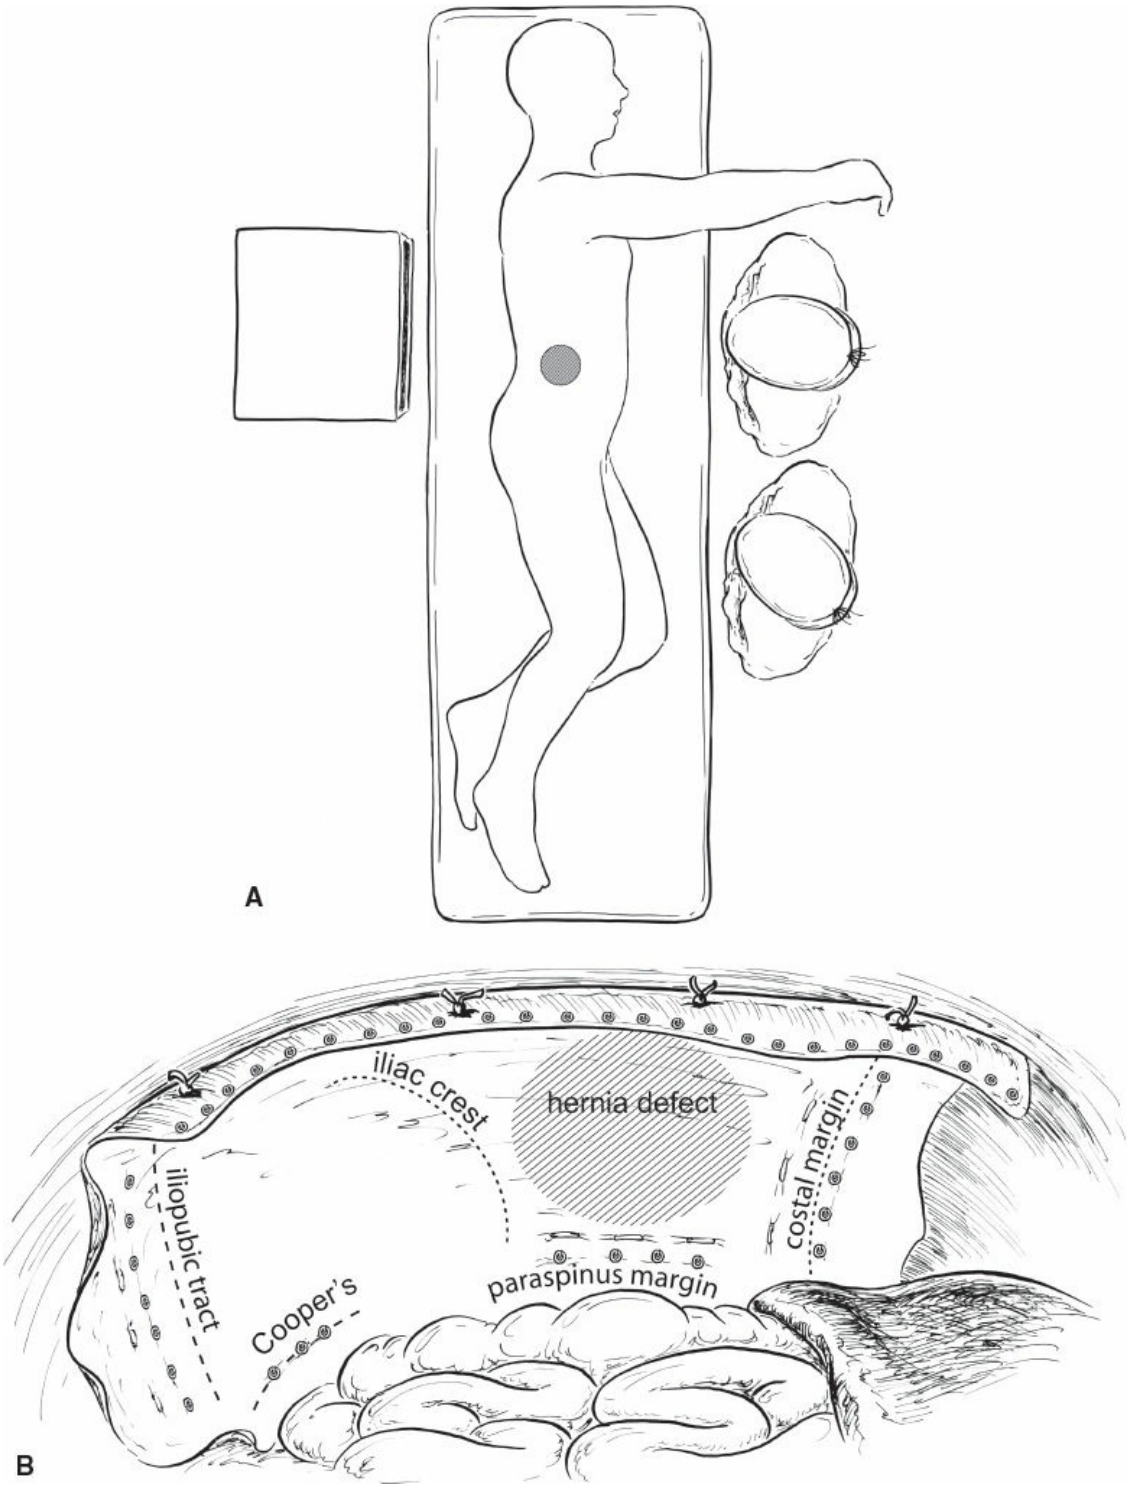

Figure 11.19. **A.** Patient positioning and operating room setup for repair of flank hernias. **B.** Retaining orientation to bony structures can be difficult during repair of flank hernias. This schematic demonstrates these relationships when the patient is in the lateral position, as well as the sites of point and suture fixation. EDITOR'S COMMENT

This is an important chapter. Clearly obtaining excellent exposure is an essential requirement of most abdominal incisions, and hence surgeons must be familiar with a variety of approaches. In addition, incisional hernia is a common problem after surgery. Surgeons should be aware of techniques that may reduce the incidence of postoperative ventral hernia as well as the variety of techniques for repair.

The choice of the incision is best left to the discretion of the surgeon. The basic rule in surgery is to make an incision big enough and adequately placed to

allow comfortable access to the area of operation. With today's focus on smaller incisions, it is important to emphasize that the incision should be such that the operating surgeon is comfortable with the exposure and access. One of my mentors advised me that incisions "heal from side to side and not end to end." In other words, do not hesitate to lengthen an incision if you are having difficulty exposing the area of pathology. The ideal incision allows:

- Easy access to the desired structures
- Easy extension
- Avoids cutting muscle heals quickly with minimal scarring
- Healing with minimal scarring

Plastic surgeons have long taught that in order to enhance the aesthetic appearance, incisions may be placed in the direction of lines of cleavage of the skin (Langer's lines). These lines correspond to the direction of collagen fibers in the dermis and epidermis. Another important point is that incisions should also be placed as far as possible from stoma sites in so as to avoid compromising the stoma site and causing complications such as stoma retraction and prolapse.

The midline incision is frequently employed in abdominal surgery as it provides adequate exposure of most if not all abdominal viscera, is associated with minimal bleeding of made through the linea alba, has minimal associated nerve and muscle injury, and can be made and closed quickly. A potential disadvantage is a midline scar and possibly a higher incidence of incisional hernia. Helm and colleagues reported on 150 female patients who were randomly allocated to cholecystectomy through midline or transverse incision. After a minimum of 12 months follow-up, they observed that 1.6% (1/60) of patients who had undergone the procedure through a transverse incision presented with an incisional hernia as opposed to 14% (9/63) of patients from the midline incision group (P = 0.017) (Halm JA, Lip H, Schmitz PI, et al. Incisional hernia after upper abdominal surgery: a randomised controlled trial of midline versus transverse incision. *Hernia* 2009;13(3):275–80).

The paramedian incision is probably of historic interest only. The incision is made about 2 to 5 cm to the left or right of the midline. It provides access to lateral organs. The surgeon incises the skin, fascia (camper's and scarpa's), and the anterior rectus sheath. The anterior rectus muscle is freed from the anterior sheath and retracted laterally. To gain access to the abdomen, the incision is carried through the posterior rectus sheath (if above the arcuate line) or transversalis fascia (if below the arcuate line) and peritoneum. The incision has few advantages over a midline or transverse incision. Disadvantages include the time it takes to open and close difficulty in extending proximally along the costal margin and that the incision tends to disrupt the lateral blood and nerve supply of the rectus muscle that can lead to atrophy of the muscle medial to the incision. If you are doing a laparotomy on a patient who has had a paramedian incision, I would advise against a midline incision as this may compromise the

blood supply to the tissue between the incisions. The best option is to use the preexisting paramedian incision.

I have already alluded to one advantage of a transverse incision. Interestingly some institutions make greater use of transverse incisions than midline incisions. A transverse incision has an advantage in children and in obesity as there is greater exposure. There is speculation that wound infections are more common; however, I have not observed this in my experience nor did Helm in his aforementioned prospective comparison.

The subcostal incision has excellent exposure to the upper abdomen and may be extended to a Chevron modification or a Mercedes providing excellent exposure to the stomach, liver, biliary tree, pancreas, and spleen. It takes more time to close; however, there is a dividend in the quality of the exposure, particularly in the obese patient and a trend to a lower rate of incisional hernia.

The authors review closure techniques. In choosing a suture material, one takes into consideration strength and qualities of the suture material. Absorbable and nonabsorbable sutures each have characteristics that make them appropriate in a variety of situations. Sutures are classified according to their degradation properties. Sutures that undergo rapid degradation in tissues, losing their tensile strength within 60 days, are considered absorbable sutures. Sutures that generally maintain their tensile strength for longer than 60 days are nonabsorbable sutures. Synthetic absorbable suture made from polyglycylic acid or other related polymers may degrade within 2 weeks. However, delayed absorbable sutures may retain strength for up to 2 months. (http://www.uphs.upenn.edu/surgery/Education/facilities/measey/Wound_Closure Accessed on February 25, 2016.)

The surgeon should be familiar with updates to the half-life and tensile strength of absorbable suture products from manufacturers. Absorbable sutures have many advantages, but they have some limitations. First in the patient with a fever or sepsis and in particular a wound infection, they may dissolve more rapidly. In addition, they may not be the best choice for patients with impaired healing. Nonabsorbable sutures may remain in the wound for up to 300 days and silk may remain permanently and have increased and prolonged tensile strength. As such it might then be predicted that nonabsorbable sutures should decrease the risk of wound dehiscence and hernia, as compared with absorbable sutures. However, the superiority of nonabsorbable sutures has not been consistently found in meta-analyses of randomized trials for midline closure. However, it has been observed that nonabsorbable sutures are associated with an increased risk of suture sinus and prolonged wound pain compared with synthetic absorbable suture (Hodgson NC, Malthaner RA, Ostbye T. The search for an ideal method of abdominal fascial closure: a meta-analysis. *Ann Surg* 2000;231:436).

The authors cite the 1-cm rule for width and depth of the sutures. The European Hernia Society guidelines based recommend a shorter width of 5 to 8 mm. This is based on two randomized trials showing fewer hernias in the

shorter width groups (18% vs. 5.6% in Milbourne D, Cengiz Y, Israelsson LA. Effect of stitch length on wound complications after closure of midline incisions: a randomized controlled trial. *Arch Surg* 2009;144:1056 and 21% vs. 13% in Deerenberg EB, Harlaar JJ, Steyerberg EW, et al. Small bites versus large bites for closure of abdominal midline incisions (STITCH): a double-blind, multicentre, randomised controlled trial. *Lancet* 2015;386:1254–60).

The incidence of incisional hernia following laparotomy is reported between 10% and 15%. The occurrence depends on many factors, including the type of suture, closure techniques, and patient-related factors such as nutritional status, obesity, and infection. As such there has been increased interest in using prophylactic mesh placement at the time of closure of the abdominal wound to reduce the incidence. A systematic review by Nachiappan (Nachiappan S, Markar S, Karthikesalingam A, et al. Prophylactic mesh placement in high-risk patients undergoing elective laparotomy: a systematic review. *World J Surg* 2013;37:1861–71) of five randomized controlled trials and four comparative studies suggested a benefit to prophylactic mesh placement during laparotomy closure in high-risk patients with a significantly reduced incidence of incisional hernia without any significant differences in seroma formation and wound infection rates. However, the studies did not examine the incidence of mesh-specific complications such as foreign body sensation and chronic pain, and the authors concluded that such analyses must be done prior to making definitive recommendations. In similar studies, the incidence of incisional hernia has been reduced from 18% to 4.7% (Timmermans L, Eker HH, Steyerberg EW, et al. Short-term results of a randomized controlled trial comparing primary suture with primary glued mesh augmentation to prevent incisional hernia. *Ann Surg* 2015;261:276) and 31% to 11.3% (Garcia-Urena MA, Lopez-Monclus J, Blazquez Hernando LA, et al. Randomized controlled trial of the use of a large-pore polypropylene mesh to prevent incisional hernia in colorectal surgery. *Ann Surg* 2015;261:876–81). Prior to a definitive recommendation, additional validation with nonindustry sponsored trials will be needed with follow-up to include the incidence of specific mesh-related complications.

The reported incidence of wound dehiscence in patients who have undergone major abdominal operations ranges from 1% to 3%. Theoretically retention sutures designed to reduce tension on the wound edges can reduce the incidence of this complication. Retention sutures were first described by Reid in 1933. He employed silver wire sutures placed with wide tissue bites through all layers of the abdominal wall and tied just tightly enough to allow approximation of tissue. Retention sutures available for use today are usually made of heavy, nonabsorbable synthetic material and often include an added buttress device for skin protection.

Despite the widespread utilization of retention sutures, their use is controversial. Khorgami Z et al. (Khorgami Z, Shoar S, Laghaie B, et al. Prophylactic retention sutures in midline laparotomy in high-risk patients for wound dehiscence: a randomized controlled trial. *J Surg Res* 2013

Apr;180(2):238–43) reported a study in which 300 high-risk patients undergoing a midline laparotomy with at least two risk factors between 2008 and 2010. They were randomly divided into two groups. In the control group, the fascia was continuously repaired using a running looped No. 1 nylon suture. For the intervention group, closure included the addition of retention sutures that included the skin, subcutaneous tissue, rectus muscle, and abdominal fascia. The end points were the rates of wound dehiscence, evisceration, wound infection, postoperative pain, post-dehiscence mortality, and late incisional hernia for these two groups. After excluding early mortalities, 147 patients were followed in the intervention group and 148 patients in the control group. Wound dehiscence occurred in 6 patients (4%) in the intervention group and 20 control patients (13.3%) (P = 0.007). Abdominal evisceration after surgery occurred in 1 patient (0.7%) with retention sutures and 4 control patients (2.7%) (P = 0.371). There was no significant difference in wound infection and incisional hernia between the two groups. From this study, prophylactic retention sutures reduce the occurrence of wound dehiscence following midline laparotomy in high-risk patients with multiple risk factors for impaired wound healing without imposing significant postoperative complications. That is not to say that they are appropriate in all situations. In the case of difficult abdominal closure under tension, retention sutures will not likely help. Rather they will erode through the tissues setting up a nidus for infection. In these cases, staged closure with a wound vac or temporary mesh closure is preferable. The problem that I have observed most frequently with retention sutures is that they are tied too tightly. As swelling occurs after surgery, the buttresses designed to protect the skin erode into the skin along with the sutures causing inflammation and pain. They should be tied loosely. The surgeon should be able to pick the loosely tied suture up and slide her or his finger under the suture.

The authors give an excellent overview of techniques for incisional hernia repair. Indeed repair of ventral hernias constitutes one of the most common surgical procedures. It is also one of the most common topics in the surgical literature with 1,134 publications on this topic in the last 5 years and 1,935 in the last 10 years (PubMed search Ventral Hernia Repair 2-26-17). Despite the publications, most deal with technique and which mesh to use. It is difficult to gather information on indications and contraindications for repair of ventral hernia. Evans KK et al. (Evans KK, Chim H, Patel KM, et al. Survey on ventral hernias: surgeon indications, contraindications, and management of large ventral hernias. *Am Surg* 2012;78(4):388–97) reported the results of two questionnaire sent to a population of general and plastic surgeons active in hernia surgery. The first explored indications and contraindications, and the second examined subjective outcomes. In total, 568 surgeons responded to the first survey and 336 responded to the second survey. They reported that the most common indications for elective repair of abdominal wall hernias were generalized pain (68.7%) and cosmesis (54.6%), whereas the most common contraindications were morbid obesity (43.3%), American Society of

Anesthesiologists Class III or IV (35.4%), and enterocutaneous fistula (33.1%). Interestingly, over two thirds of surgeons did not routinely repair large abdominal wall hernias in asymptomatic patients. Most surgeons reported that the majority of patients had resolution of pain and subjective impression of improved cosmesis after surgery.

The use of prosthetic material, synthetic or biologic, is extremely common in the repair of incisional hernias. These products can be very expensive. In order to reduce costs, it may be prudent for surgeons working in a single hospital to decide on which mesh to stock and employ routinely. This is an effective strategy in reducing the cost to the institution and hence the cost to the patient.

Component separation techniques are gaining popularity particularly if mesh avoidance is desirable. There is increasing evidence that the laparoscopic or endoscopic component separation may enhance outcomes and reduce infection rates. More studies are needed so stay tuned (Fox M, Cannon RM, Egger M, et al. Laparoscopic component separation reduces postoperative wound complications but does not alter recurrence rates in complex hernia repairs. *Am J Surg* 2013;206(6):869–74).

In summary, much progress has been made in repair of ventral hernias since the sixth edition. Evans and colleagues outline the various techniques of repair. It behooves the surgeon should know many different techniques and be able to apply them as indicated in individual patient situations.

12 Laparoscopic Suturing and Stapling

Jon C. Gould

BACKGROUND

Procedures popularized in the early days of laparoscopy included appendectomy and cholecystectomy. These were the first laparoscopic procedures, at least in part, because suturing was not required. Laparoscopic suturing is a complex task. The skill set required to perform this task is not derivative from open suturing skills. In the 25 or more years since the first laparoscopic cholecystectomy was performed, laparoscopic surgery has become pervasive. An entire generation of residents has completed their training since the American Board of Surgery first required surgeons to pass the Fundamentals of Laparoscopic Surgery (FLS) curriculum to become board certified. Two of the five tasks in the FLS curriculum at the current time are intracorporeal and extracorporeal knot tying. More advanced laparoscopic procedures requiring extensive and advanced suturing skills have become commonplace. Many new devices have been developed to facilitate suturing. In addition, surgical staplers have undergone a significant evolution and are now more reliable and enable a variety of complex procedures and maneuvers. As the field of minimally invasive surgery has evolved, so has the technology and teaching with regard to laparoscopic suturing and stapling.

LOOP LIGATURE

Ready-to-use and pre-tied loop ligatures are commercially available. These can be used for a variety of purposes including hemostasis and vessel ligation. These “endoloops” can also be used to secure a tissue pedicle in procedures such as appendectomy and cholecystectomy. Placement of a loop ligature is one of the five FLS tasks. A reusable ligating loop for practice on the FLS tasks is also commercially available, but is not intended for clinical use. Ligating loops consist of a prettied slipknot and a pushing rod through which a length of suture extends and is attached to a

breakaway tip of the rod.

Optimal Technique

The surgeon may choose to break the end of the rod and decrease the size of the loop before the device is passed into the abdominal cavity.

1. The loop is passed through a trocar with an appropriate angle and in proximity of the structure to be ligated (Fig. 12.1).
2. The loop is swept or manually placed over the target with a grasper.
3. The grasper is inserted through the loop and the tissue to be ligated is grasped and retracted anteriorly (Fig. 12.2).
4. Sliding the pushing rod down tightens the loop. Traction on the tissue to be ligated should be avoided to prevent avulsing the target tissue (Fig. 12.3).
5. The suture is cut

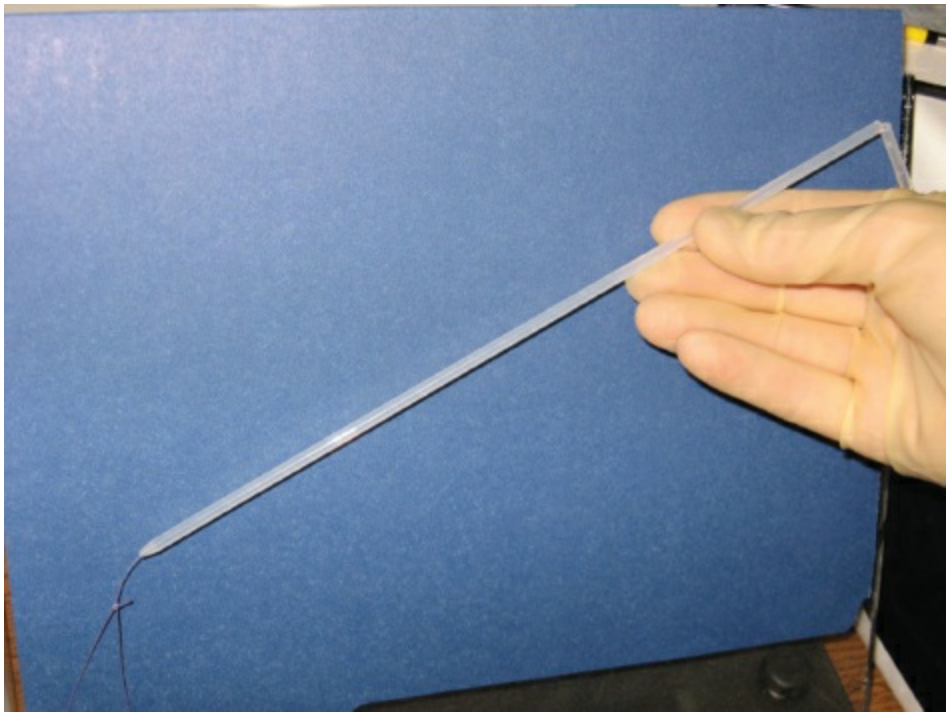

Figure 12.1. Endoloop.

In the FLS task, users are scored by accuracy in knot placement, security of the knot, and time to successfully place the knot.

SUTURING INSTRUMENTATION

Laparoscopic needle drivers come in a variety different handles, tip configurations, and lengths. The handles may be “pistol grip” or in-line.

In-line handles (Fig. 12.4) allow full rotation without compromising the position of the hand. Needle driver tips can be straight or curved. Curved tips can facilitate a line of site to the actual tip and can accentuate angles than can make intracorporeal knot tying easier. The problem with curved tip needle drivers is that in certain circumstances the tip may be pointed away from where the surgeon would like it to be requiring the surgeon to accommodate to this circumstance or to flip the needle driver over and hold it upside down. “Self-righting” tips are also available. These may facilitate needle control for suturing, although the lack of a fine tip can be an impediment to intracorporeal knot tying. Knot pushers are also necessary with some mechanical suturing devices. Knot pushers may be either closed or open ended. Closed ended knot pushers are easier to use and do not allow the knot to slip off the pusher. After the suture is threaded through the hole in the distal end of the pusher, it cannot be dislodged and sutures can be thrown quicker. To square a knot with a closed knot pusher, the suture tails would need to be switched with each throw. Practically speaking, many surgeons will overcome this potential issue by throwing three granny knots and then switching the knot pusher to the other suture tail for additional knots to prevent the original knot from slipping. With an open knot pusher, there is an open groove rather than a closed loop. The throws of the knot can be alternated and squared without rethreading the eye of the closed loop as for a closed knot pusher. The disadvantage to an open knot pusher is that the knot can easily slip off the pusher. If this happens while the knot is in the trocar, it can be difficult to recover. Should this happen, the knot should be pulled into the abdominal cavity until the knot can be visualized. The open knot pusher can then be placed on the knot under direct visualization, although this requires some practice and is especially difficult under less optimal ergonomic conditions sometimes encountered in the operating room.

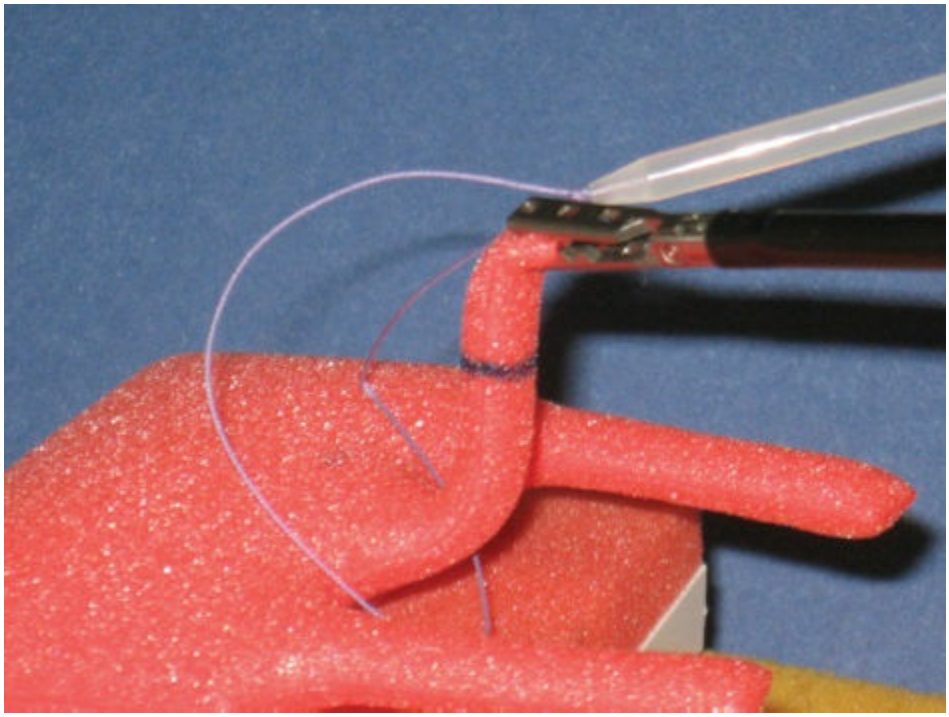

Figure 12.2. Retracting the target and using gravity for counter traction.

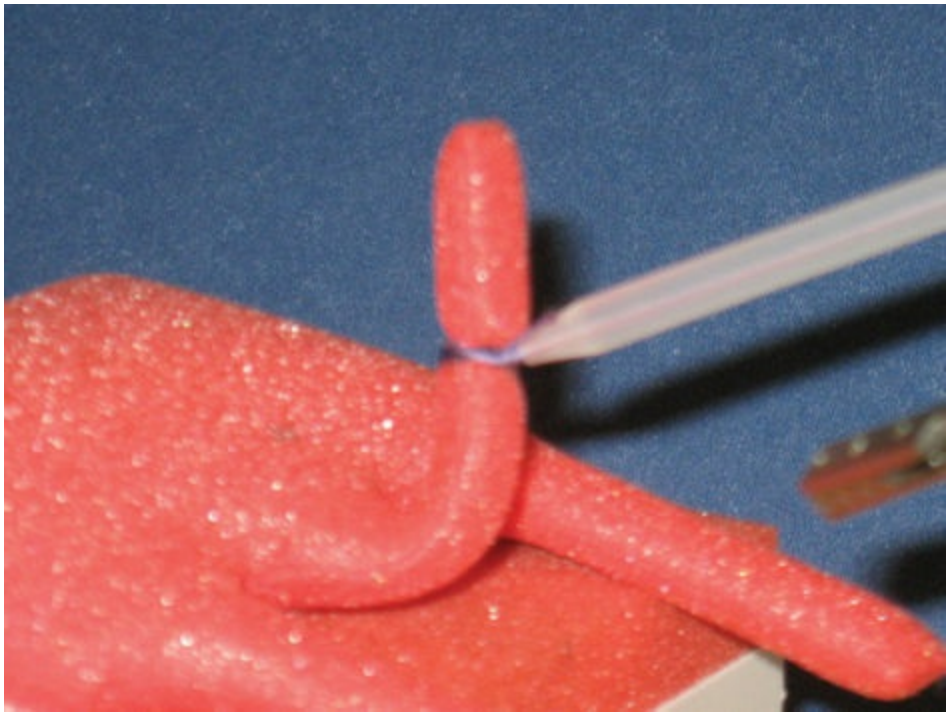

Figure 12.3. Tightening the slipknot completely.

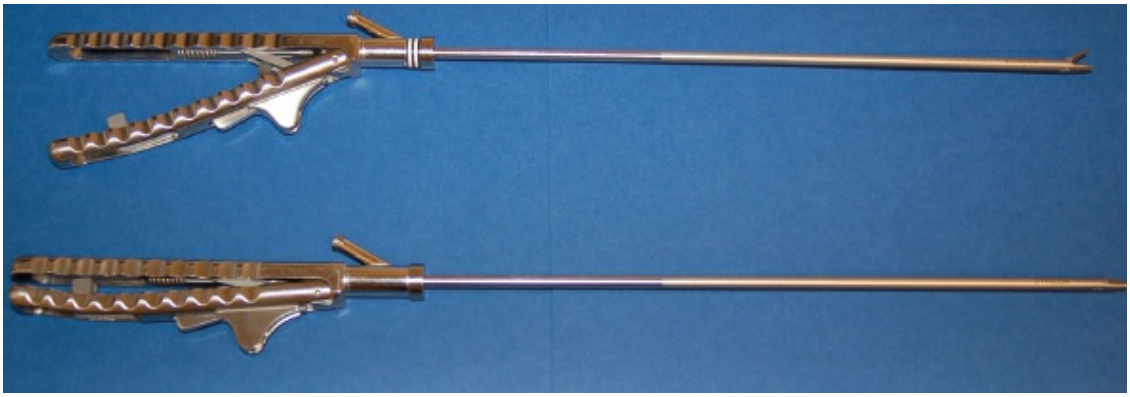

Figure 12.4. Needle driver handles.

EXTRACORPOREAL KNOT

The extracorporeal knot is useful for tying intra-abdominal knots when there is some tension on the target tissue—such as closing a large hiatal defect in a paraesophageal hernia repair. When tying an extracorporeal knot, some degree of tension must be maintained on each suture to prevent the knot from slipping/loosening. This makes an extracorporeal technique less desirable for suturing delicate tissue, such as a mucosal perforation that occurs during the course of a laparoscopic Heller myotomy. It is easier to learn how to successfully and safely tie an extracorporeal knot when compared to an intracorporeal knot. To tie an extracorporeal knot requires a full-length suture as both arms of the suture eventually need to reach from the tissue, out of the same cannula, and still be of sufficient length to hand tie a knot that can be pushed down onto the tissue.

Optimal Technique

1. Most curved needles do not fit through a 5-mm cannula. Since the extracorporeal technique requires surgeons to pass both suture arms and a needle though the same port, most surgeons who use this knot tying technique place their ports in a configuration that calls for a 10-mm port to be placed in a strategic location for suturing and knot pushing. Some “ski” or “canoe” needles will fit through a 5-mm port. Alternatively, a standard curved (SH) needle can be canoed manually by straightening the curve at the midpoint with a couple of handheld needle drivers. The suture should be at least 30-cm long for the ease of extracorporeal knot tying.
2. The needle and suture are passed into the abdominal cavity, most often with the nondominant hand. There are a variety of techniques that can be used to get the needle into the dominant hand in the optimal

position for suturing. One technique is to carefully drag the needle into the correct orientation on intra-abdominal tissue. As the needle is grasped with the dominant hand about two thirds from the tip, the suture still in the nondominant hand can be manipulated to help the needle rotate into the appropriate orientation as it is grasped.

3. The target tissue is sutured. One should make an effort to "follow the curve" of the needle as it passes through the tissue rather than lifting the shaft of the needle driver up or to the side when suturing.
4. Once the needle has been passed through the tissue, the suture near the needle is grasped with the same instrument that was used to pass the needle into the abdominal cavity. The opposite instrument is used as a pulley to protect the suture from sawing into the tissue. The needle and suture are removed through the same port through which the suture tail is hanging.
5. The needle is removed from the suture. It is often helpful to tag the tail of the suture with a clamp to prevent this from falling into the port as the needle is removed.
6. Knots are tied by hand extracorporeally. Either a closed or open-ended knot pusher may be used. Once the suture is secured, the tails are cut.

Extracorporeal knot tying is one of the five FLS tasks. Task performance is scored based on the accuracy of needle placement through the target, security of the knot, and efficiency (time) to successfully complete the task.

INTRACORPOREAL KNOT

To tie a secure surgical knot with laparoscopic instruments using intracorporeal knot tying techniques requires an advanced laparoscopic skill set. The fixed position of the trocars as well as the long instruments and fine maneuvers required under sometimes ergonomically challenging conditions combine to make this a difficult but critical task in advanced laparoscopic surgery. Many different techniques are described and can be effectively employed. Some surgeons choose to grasp the needle in the same hand and rotate clockwise and counterclockwise around the suture swage. The *swage* is the point where the suture material joins the needle. In the FLS intracorporeal knot-tying task, the technique has been standardized. This is the technique we will describe in the following section.

Optimal Technique

1. The suture length in the standardized FLS intracorporeal knot task is 15 cm. In very small spaces in the operating room, a suture of less than 15 cm may be ideal as this shorter length will allow the surgeon to tighten the throw without releasing and regrasping the suture or needle. Too long of a suture may also be an issue, as the surgeon may need to release and regrasp the suture multiple times to tighten each throw.
2. Grasp the suture about 1 to 2 cm behind the swage with the nondominant hand. Pass the needle through a trocar and into the abdominal cavity. The needle can be rested on an intra-abdominal structure and then grasped with the dominant hand needle driver approximately two third from the tip and at the appropriate angle. Avoid fully clamping the dominant hand needle driver or letting go over the suture with the nondominant hand until the angle of the needle is as desired.
3. Pass the needle through the target tissue. A common mistake of novice knot tiers is to lift or move the needle from side to side rather than rotating the needle through the tissue. In the FLS task, these maneuvers may dislodge the Penrose drain and result in a failed attempt. In the operating room, these maneuvers may avulse the tissue being sutured with undesirable consequences.
4. Pull the suture through until there is an approximately 1 to 2 cm tail. Pass the suture near the swage back to the hand that passed the needle (dominant hand).
5. For a surgeons knot, wrap the suture in the dominant hand around the tip of the empty nondominant hand needle driver twice. Grasp the tail of the suture with the nondominant hand. Pull the tail through the loop created around the tip of the nondominant hand needle driver without tightening the loop. Do not pull on or lengthen the tail of the suture, as this will compromise subsequent throws of the knot. Once the suture tail has been pulled out of the loop by the nondominant hand, tighten the loop almost entirely with the dominant hand. Be careful with the needle as it is pulled toward the periphery of your field of view.
6. Pass the suture to the other hand. Grasp the suture about 1 to 2 cm from the swage with the nondominant hand. Wrap the suture around the tip of the dominant hand needle driver once, grab the suture tail with the dominant hand and tighten the loop as in the previous step.
7. Pass the suture back to the dominant hand. Once again, grab the suture about 1 to 2 cm from the swage. Wrap the suture around the tip of the

nondominant hand needle driver once, grab the suture tail with the nondominant hand, and tighten the loop a final time.

8. Pass both tails of the suture to a single instrument. Through the opposite hand trocar, pass a scissors and cut both tails.

In the FLS task, three throws are all that is required. In the operating room, depending on the suture material, what is being sutured, and surgeon preference, additional throws may be placed by continuing the sequence as described. In the FLS task, performance is scored based on the accuracy of needle placement through the target, security of the knot, and efficiency (time) to successfully complete the task. More time (3 additional minutes) is allotted to complete an intracorporeal knot when compared to the extracorporeal knot before the task "times out."

MECHANICAL SUTURING DEIVCES

There are a number of mechanical devices designed to facilitate knot tying. These devices can help to enable the creation of secure knots laparoscopically—often with a shorter learning curve, less intraoperative time, and better ergonomics when compared to standard intracorporeal or extracorporeal techniques. These devices are useful for surgeons just learning to tie knots laparoscopically and for cases where extensive laparoscopic suturing may be necessary. The appropriateness of the various devices for different suturing applications is dependent on the tissue to be sutured, the tension on the tissue itself, and often the cost of the mechanical devices.

Examples of mechanical suturing assist devices include the Endo Stitch device (Covidien and Medtronic, Minneapolis, MN), the Suture Assist device (Ethicon, Somerville, NJ), and the TK-Knot device (LSI Solutions, Victor, NY). For some of these devices (Suture Assist and TK-Knot), standard laparoscopic needle drivers are used.

Endo Stitch Device Technique

The Endo Stitch is a reloadable, disposable laparoscopic mechanical suturing device. Currently, this device must be passed through a 10-mm or larger trocar. This device allows for the needle to be toggled between each arm of the device with a toggle switch located on the handle of the device. Both intracorporeal and extracorporeal knot tying techniques can be employed with this device. A traditional needle driver is not necessary.

Either running or interrupted sutures can be placed. A variety of suture materials are available. The surgeon places the Endo Stitch device in his/her dominant hand and controls the suture with a grasper (Maryland or other) in the other hand.

Optimal Technique—Intracorporeal Knot With Endo Stitch Device

1. Open jaws of Endo Stitch device.
2. Place jaws around tissue to be sutured and squeeze handles to close jaws on the tissue.
3. Toggle switch to move needle to other jaw and open jaws to gently pull needle through tissue and the suture follows through.
4. Lay the suture that extends directly from the needle over the top of the empty jaw.
5. Grasp the suture tail with another instrument, bring the suture tail in between the jaws of the instrument, close the jaws and pass the needle.
6. Pull the jaw through the needle back through the loop of the suture.
7. Clinch the knot with the jaws in the closed position.
8. Return the toggle lever back into the forward position. The needle should be in the same jaw as in step 6.
9. Lay the suture that extends directly from the needle over the top of the empty jaw.
10. Bring the suture in between the jaws of the instrument. Close the jaws and pass the needle.
11. Pull the jaw with the needle back through the loop of the suture.
12. Cinch the knot with the jaws closed. Repeat steps to place additional throws.

Optimal Technique—Extracorporeal Knot With Endo Stitch Device

1. Open jaws of Endo Stitch device.
2. Place jaws around tissue to be sutured and squeeze handles to close jaws on the tissue.
3. Toggle switch to move needle to other jaw and open jaws to gently pull needle through tissue and the suture follows through.
4. Pull device and suture out of port through originally passed. Be careful to avoid tearing through the tissue by shearing and creating friction at the suture. Another grasper can be placed inside the 2 sutures and the suture arm attached to the Endo Stitch device can be

angulated/displaced to minimize friction and tension on tissue as suture and device is removed.
5. Cut suture off device. Preserve maximum length of suture.
6. Hand tie the first throw of your knot. A surgeon's knot will not slide as easily.
7. Pass the knot from extracorporeally to the tissue to be sutured with a knot pusher device, closed or open depending on surgeon preference.

Other Mechanical Suturing Devices

The Suture Assist device (Ethicon) is a reloadable, disposable mechanical suturing device. The suture and pre-tied knot are loaded into the device prior to throwing each interrupted suture. Needles come in standard curved and "canoe" configuration. The canoe needle can be passed through a 5-mm trocar. The device is used in the nondominant hand, with a standard laparoscopic needle driver in the dominant hand. The back handle of the device can be opened and closed and controls the jaws of the device. The jaws can be used to grab the needle as it passes through tissue or to grab tissue itself. Once the needle and suture have been passed though the tissue to be sutured, the needle is dropped through a loop on the knot at the tip of the device. The suture arm with the needle is then pulled at a 90-degree angle to the tip of the suturing device. The trigger on the top of the device is then slowly deployed to tighten and secure the knot.

The TK Ti-Knot device is used to deploy a titanium "knot" to secure a suture. The device is reloadable and disposable. It can be deployed through a 5-mm cannula. After the suture is passed through the target tissue, each tail of the suture is pulled extracorporeally. The TK Ti-Knot device is used to pass and secure the titanium "knot" while concurrently cutting the sutures.

Unidirectional or barbed suture is available in a variety of materials and sizes. Circumferential barbs around the suture material anchor the tissue at numerous points, distributing tension. A major advantage of these sutures in laparoscopy is that the need for tying a knot is eliminated. In addition, when running a barbed suture, the need to maintain tension is eliminated. A third instrument to maintain tension on the suture in order to prevent the running closure from loosening is no longer necessary. This can save considerable time. Several studies have been published in hernia and gastrointestinal surgery demonstrating equivalent clinical outcomes and decreased cost and operative time for barbed compared to standard sutures.

Another technology that can eliminate the need to tie knots in laparoscopy is shape memory polymers such as nitinol clips. These biomaterials can change their shape, configuration, or dimension under appropriate stimuli such as heat, water, light, pH value, electricity, or magnetic field. The use of these materials in laparoscopic suturing is evolving.

LAPAROSCOPIC SUTURING SIMULATION AND TRAINING

As mentioned previously, laparoscopic suturing is a complex task requiring great dexterity. The skills needed to tie a knot laparoscopically are not derivative from those needed in open surgery. The FLS curriculum has been extensively validated and is now a core component of surgical residency programs and becoming FLS certified is required in order to become certified by the American Board of Surgery. Placement of a ligating loop, extracorporeal knot tying, and intracorporeal knot tying are three of the five tasks in the curriculum. Research has demonstrated that trainees can become proficient at laparoscopic suturing in the skills lab in a video trainer box. Unlike the early days of laparoscopic surgery, the learning curve to develop the skills necessary to efficiently perform these tasks has been moved out of the operating room and into the skills lab.

The FLS curriculum is based in a low fidelity video trainer box. Learners use real laparoscopic instruments and suture, but they suture Penrose drains and place loops around foam appendages. High fidelity, computer-based virtual reality simulators have been developed. Many of these commercially available virtual reality simulators have preprogrammed knot tying tasks. These computer-based simulators for the most part lack haptic feedback. They can also cost well over $100,000 in some cases.

STAPLING IN LAPAROSCOPY

The modern era of surgical stapling was launched in the 1800s when American surgeon Mark Ravitch observed a Russian surgeon in Kiev operating with a stapler on the lung. Surgical staplers are pervasive in the modern operating room. Without the use of stapling technology, many procedures that were commonly performed only via laparotomy 20 or more years ago would not have been amenable to a laparoscopic approach. Many kinds of staplers have been modified for laparoscopic use.

Commonly used laparoscopic staplers are of the linear and circular configuration.

Surgical staplers are expected to provide tissue approximation and hemostasis without causing ischemia or tearing of the tissue. Adequate performance of these devices relies on achieving optimal compression force that allows for hemostatic approximation while minimizing shearing and injury. When the stapler is fired, individual titanium staples travel through the target tissue until they hit a hard anvil on the opposite side that bends the staples into a “B” configuration.

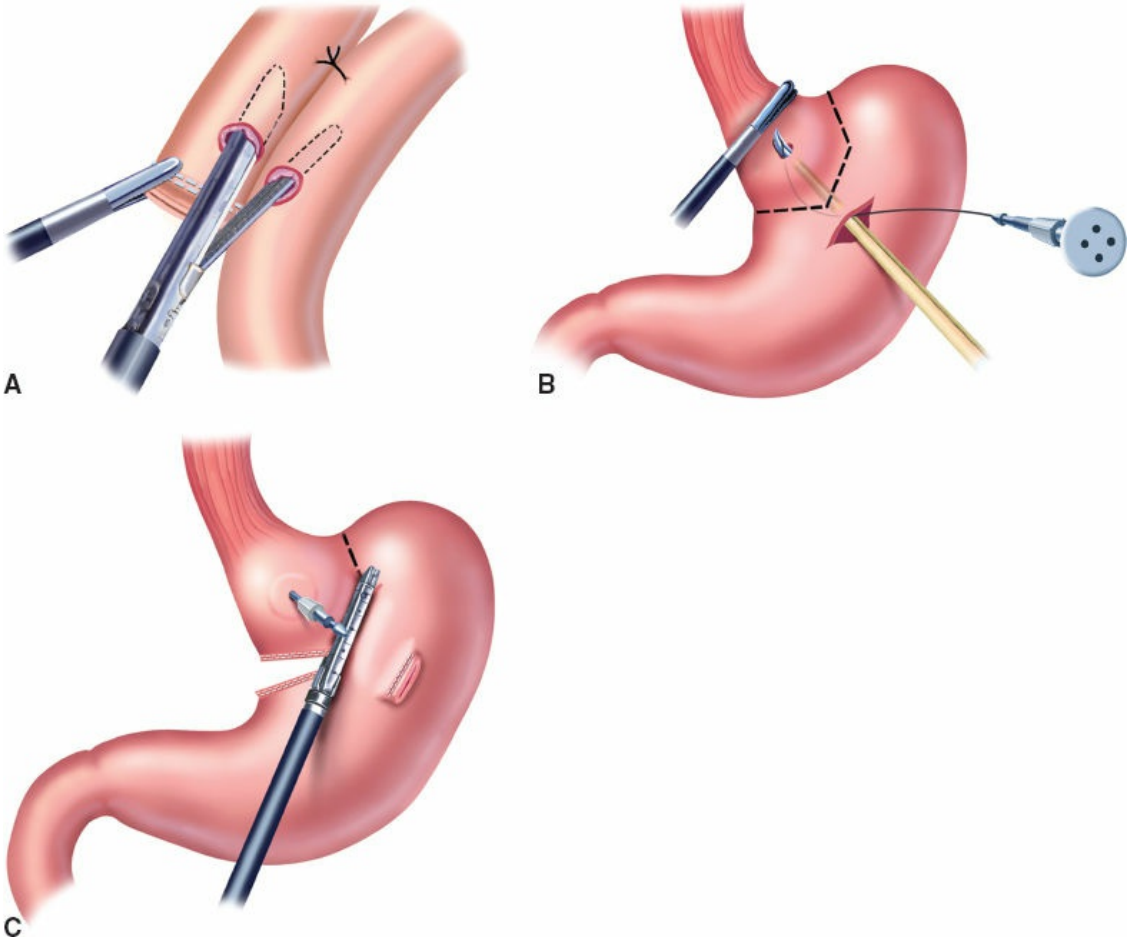
Optimal performance of staplers is dependent on picking the right stapler and staple type for the job. Linear staplers may articulate at the end to allow for stapling structures at an angle that would otherwise be difficult given the fixed position of the trocars. Linear staplers also come in various lengths (45-mm and 60-mm are the two most common stapler cartridge lengths). Modern staplers place six parallel rows of staples across the target tissue and a knife blade from within either the stapler cartridge or in the stapler deploys to divide the tissue in the middle.

It is important that surgeons familiarize themselves with the instructions for use (IFU) package insert on each device. The two largest endomechanical surgical stapling device manufacturers at the time of this writing are Ethicon and Covidien. Each of these company’s staplers are slightly different in terms of cartridges (color codes, final fired staple height may be of varied heights in subsequent rows) and methods for optimal use. When the knife blade is contained within the stapler itself and is reused from fire to fire, there is typically a maximum number of uses recommended before the stapler must be replaced. When the knife blade is in the cartridge, it is replaced with each new cartridge and more fires per stapler are usually safe and appropriate. Modern versions of each major manufacturer’s endomechanical linear staplers are internally powered. This allows for consistent firing on a steadier platform. It also facilitates the firing of these devices by surgeons with smaller hands.

Circular staplers differ from linear staplers in that they create round staple lines. They come in different sizes—usually a 21- and 25-mm anvil. A 25-mm anvil creates a stapled gastrointestinal anastomosis with a much smaller diameter—about 15 mm for one manufacturer. Two concentric stapled lines are placed and a circular knife blade on the inside of both is deployed to create a circular stapled anastomosis (Fig. 12.5). Like the linear stapler, staples come in different heights for different applications.

There is a version of this device in which the anvil of the circular device comes preattached to an orogastric tube to facilitate transoral passage for esophageal and high gastric anastomosis.

Choosing the appropriate staple height is important. A staple cartridge with staples that are 2.0 to 2.5 mm in height provides excellent hemostasis of larger arteries provided the vessels can comfortably compress to 0.75 to 1.0 mm. The final fired staple height is a function of the stapler, the selected stapler cartridge, and the tissue itself. Newer staplers employ a technique known as tissue gap control where the final fired staple height is consistent across the length of the staple line. Each individual manufacturer can provide surgeons with this information for the commercially available staple cartridges. In general:



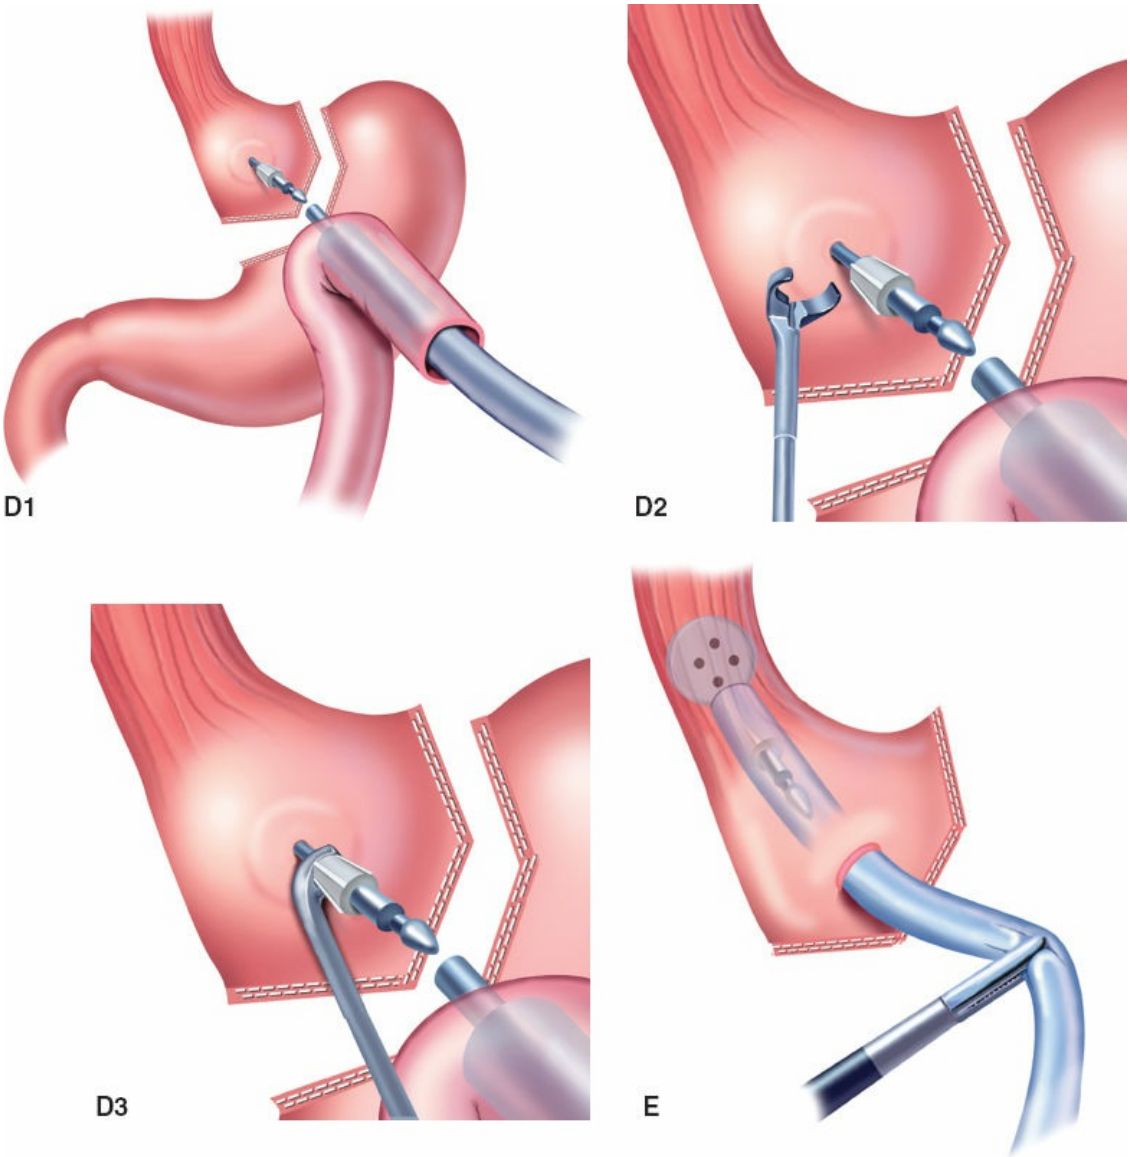


Figure 12.5. **A:** Stapler: linear. **B:** EEA anvil insertion. **C:** EEA pouch preparation. **D:** EEA anvil stapler mating. **E:** EEA anvil transoral placement.

For a 2.0 mm cartridge final tissue compression should be 0.75 to 1.0 mm. This “vascular” load is commonly used to divide arteries such as the splenic artery during laparoscopic splenectomy.
For a 2.5 mm cartridge final tissue compression should be 1.0 to 1.5 mm. This load is often used on small intestine.
For a 3.5 mm cartridge final tissue compression should be 1.5 to 2.0 mm. This load is commonly applied to medium thickness tissue such as the fundus of the stomach or nondiseased colon.
For a 4.8 mm cartridge final tissue compression should be 2.0 mm. This load is often used on thick tissue such as the antrum of the stomach or the lung.

Using too long or too a short staple will lead to bleeding after the stapler is fired. A short staple fired through thick tissue that cannot be compressed to the final staple height will not interlock properly, or will rip through the tissue. Conversely, too long a staple will not adequately compress the vessel or tissue and bleeding will occur through the staple line.

In an effort to increase the security of surgical staple lines and to improve hemostasis, buttressing material can be added to the jaws of laparoscopic stapling devices (Fig. 12.6). Buttressing material is derived from different sources such as bovine pericardium (Peri-Strips, Baxter Healthcare, Deerfield, IL) or synthetic polymer (glycolide copolymer as in Seamguard®, W L Gore, Flagstaff, AZ).

Linear staplers are more versatile and can be used for both resection (appendectomy, colectomy, small bowel resection) and anastomosis (colorectal anastomosis, small bowel anastomosis, gastrojejunostomy in gastric bypass). A linear stapled anastomosis requires an enterotomy in both structures to be anastomosed that must subsequently be closed. For example, in a gastric bypass a gastrotomy in the gastric pouch and an enterotomy in the jejunum must be created to allow the linear stapler to be placed in each lumen and fired. The common enterotomy that results must then be closed. This can be done either with sutures or with another load of the stapler (double stapled anastomosis). The caliber and size of the anastomosis are difficult to consistently control when linear stapled techniques are used when compared to a circular stapler. When a circular stapler is fired to create the anastomosis, the anastomosis itself is completely closed and of a consistent caliber.

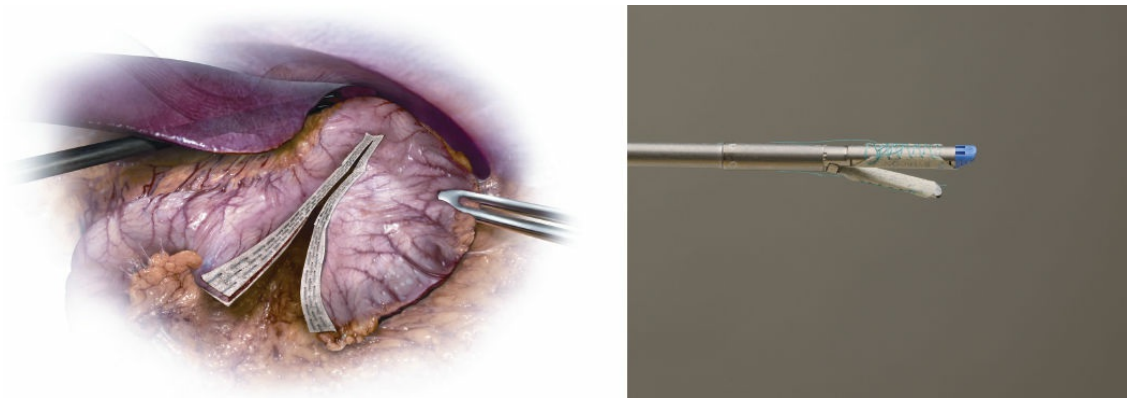

Figure 12.6. Buttress material seam guard.

A disadvantage to the circular stapler in gastrointestinal surgery is that

the stapler is large and often slightly curved at the end making this impossible to pass through a laparoscopic trocar. In gastric bypass surgery, the circular stapler is often passed through a dilated trocar site. Since the stapler is placed in the bowel lumen to create the circular stapled anastomosis, there has been a higher rate of wound infections observed in these cases when compared to linear stapled techniques.

Complications of Stapling

Bleeding from staple lines and gastrointestinal leaks from stapled anastomosis are the two most commonly observed complications related in part to surgical staplers. A brief search of the Food and Drug Administration (FDA) Manufacturer and User Facility Device Experience (MAUDE) database reveals 232 events of "surgical stapler" related adverse events in a recent 12-month period (9/1/15–8/31/15). There were no deaths reported in the database, 81 injuries, and 149 malfunctions included. Malfunctions generally include misfires and incomplete fires of the stapler, difficult opening of the stapler and releasing from tissue after fired, and tearing of the tissue. Many of the injuries involve torn tissue, extended operative time, and in some cases conversion from a laparoscopic to an open procedure.

While stapling technology has advanced dramatically since Ravitch brought that first device back from Russia, the MAUDE database is a testament to the fact that failures still occur. It is critical for surgeons performing laparoscopic stapling cases to understand the IFU on the different stapling platforms and how to select the right stapler and staple load for the application and tissue on which it is to be used. In depth knowledge when it comes to the proper preparation, reloading, and troubleshooting of the device in case of problems is also useful. Finally, the ability to suture laparoscopically as described in the preceding section of this chapter can help avoid the need to convert to an open procedure in the case of a stapler mishap.

CONCLUSIONS

Laparoscopic suturing is necessary in many common advanced laparoscopic surgical procedures. While a variety of devices exist to facilitate the creation of knots in laparoscopic surgery, surgeons should be encouraged to learn intra- and extracorporeal knot tying techniques as well. Given that these skills are now part of the FLS curriculum, a

mandatory requirement to become board certified, the modern laparoscopic surgeon is likely to be comfortable with these techniques. Surgical staplers continue to evolve. The technology readily available today greatly facilitates complex laparoscopic surgery. Surgeons need to be familiar with the proper techniques for using the different stapling devices to ensure the best chance of an optimal clinical outcome.

EDITOR'S COMMENT

The adage, "You can teach a monkey to operate," is not so readily repeated in the era of laparoscopy. With minimally invasive surgery, the surgeon views the operative field via a laparoscope on a 2D or 3D HD monitor. Thirty-centimeter long laparoscopic instruments lack haptic feedback. The range of motion is

restricted by using fixed ports through the abdominal wall. Laparoscopic suturing is just not that easy and requires deliberate practice to get good at it. In this chapter, Dr Gould reviews a few of the basic minimally invasive surgery (MIS) techniques to suture and staple.

In the early 1990s as laparoscopy became popular, surgeons realized that to do more than a laparoscopic cholecystectomy, surgeons either needed technology to obviate suturing or they needed to develop new skills. Technology advanced clips appliers, staplers, glues, and endosuturing devices. Courses were offered to teach laparoscopic suturing, and competitions such as Top Gun were developed to promote skill acquisition. Video trainers and simulators become commonplace in training programs to practice and eventually the American Board of Surgery required the fundamentals of laparoscopic surgery (FLS) to assure all residents had basic suturing and knot tying skills prior to sitting for their board exams in surgery.

Staplers made dividing and reconstructing tissues quick and easy. Staplers can be linear or circular and come in several sizes. Newer staplers even articulate. And as a general rule, stapled anastomoses do not need to be over sewn. One drawback is that staplers can be somewhat costly.

Over the last 20 years, surgeons have learned they can staple through just about any visceral tissue. The antrum, small bowel, and mesentery require thick, medium, and small staple height staplers respectfully. Failure to gauge the appropriate staple height results in staple line disruptions and leaks. Alternatively, too big of a staple may cause bleeding. Choosing the correct stapler is the most crucial decision to avoiding problems.

In 1995, I went to Gore and other companies with bioabsorbable materials and I proposed that we use buttress materials like the thoracic surgeons were doing for the lung to create a better seal with the staplers for the alimentary tract. Soon, many companies had buttress materials, often bioabsorbable, to reinforce the staple line. Surgeons were all too quick to pay whatever it cost for any product that might decrease the chance of a leak. It’s important to note, that if you choose to use buttress material, then you should consider a higher staple height. Be aware, the package insert on many stapler devices explicitly cautions that buttress material may adversely affect the stapler from closing properly.

It takes about 40 to 60 hours of deliberate practice to get good at laparoscopic suturing. A novice may take more than 5 minutes to lay down a suture in foam and place one surgeons knot and two half hitches. A master surgeon may take 20 seconds. The best way to progress from novice to expert is to practice regularly in a simulation center.

As you hone your skills, you also develop preferences. I rarely use the endoloop unless I am trying to close the peritoneum after a rent is made during a laparoscopic TEPP hernia repair. Through one 5 mm port I can pass the loop ligature and the other 5 mm port allows me to use a grasper to lift up the peritoneum. This prettied knot works fine but is a little more costly. In just about any other setting, I have more working space to intracorporeal suture

instead.

Extracorporeal suturing is best for closure of the paraesophageal hernia where I might be closing tissue against a little tension. I like to introduce no less than 10 cm of extra suture material into the abdominal cavity before I suture, so it's easier to pull back suture after throwing a bite of tissue. It takes less force to pull back suture material that has already been introduced than to pull it in and back through the tissue in one motion. I also like to place a grasper instrument as a pulley so that the tension is pulling back is on my instrument rather than the tissue itself. Once the suture is outside the abdomen, I have a few tricks to extracorporeal knot tying. First, I will place a clamp on the suture strand in my nondominant hand. This way I can keep track of the direction of my knots. Also, when creating my knot I ask my assistant to place a finger of the top of my port to exclude air leak and maintain suture tension. Lastly, I tend to throw a series of knots then advance them with my knot pusher instrument after my first two throws are laid. This is much quicker than doing one half hitch at a time.

In general, I prefer an intracorporeal technique to laparoscopic suturing. The suture length is about 12 to 15 cm long (approximately the length of an open scissors). Silk suture with less memory is easiest to use, especially if dampened with a little saline. The needle should be introduced through the port in your nondominant hand by grabbing the suture 1 cm behind the needle swage. The needle is then presented to your dominant hand. I avoid the self-righting needle holder as it limits the angle of needle presentation to 90 degrees and I usually prefer to have the needle oriented somewhat forward. I also use a curved needle rather than a ski needle. A gentle arch through tissue with a curved needle provides the best bite and precision. To tie a knot, I pull the suture through the tissue to have a short tail. I grab the tip to the needle and position the needle "smiley face up" between the grasper and needle holder instrument. The needle holder goes "in and out" above and below the needle to loop the suture around the needle. Then the tail is grasped by the needle holder and knot is laid. The direction of the loop alternates the half hitch to create a square knot.

I also like the Endo Stitch device. This is particularly nice when you have a lot of suturing to do and less than ideal port placement. (Ideal is laparoscope in the middle, port on left and right side, and target ahead.) The technique is well described and can be easily mastered with practice. With experience, the device can be toggled quicker using the third and pinky fingers. If too generous of a bite of tissue is attempted, the needle will fall off the device. Since it's a straight needle, the needle needs to go through the tissue linearly or it will get snagged. But with these few pearls in mind, the device is great.

All surgeons doing advanced laparoscopic surgery today should be skilled at laparoscopic suturing and not be relying on clips and staplers. This expertise is best learned using a box trainer and not on the job. Dr Gould describes basic steps to get you started. With deliberate practice your lap suturing will be less than 30 seconds and your Endo Stitch less than 15 seconds. And if this is not obtainable in your hands, you may decide that MIS surgery is not for you.

Daniel B. Jones

13 Ultrasonography by Surgeons

Ellen Hagopian and Junji Machi

Surgical ultrasound has become a vital tool of the surgeon. It is often referred to as the “stethoscope” of the surgeon as it allows the unseen to be seen and has naturally been used as an extension of the physical examination in multiple settings. In the operating room, ultrasound provides real-time imaging during a real-time operation. Once effectively performed by surgeons, ultrasound provides valuable intraoperative information to allow execution of the operation. Furthermore, ultrasound can be repeated throughout the operation to provide new information, confirm previous findings, and to potentially change the operative plan. In spite of advances in various preoperative imaging modalities, surgeons often make final decisions during surgery based on intraoperative findings. Meticulous exploration by inspection and palpation may not always be accurate or possible; this is particularly true in the evaluation of solid organs or deep structures. Intraoperative imaging methods can provide useful and, at times, critical information. The use of ultrasound during open or laparoscopic procedures is a valuable and widely applicable modality because it provides high-resolution images of the operative field in real-time, which cannot be obtained by other intraoperative studies.

The value of ultrasound has been demonstrated in a variety of surgical fields including general surgery, neurosurgery, cardiovascular surgery, urology, and gynecology and is recognized as an integral part of many operations. This chapter will provide an overview of the use of ultrasound in the operating room, with a particular focus on hepato-pancreato-biliary surgery. General principles including basic physics, instrumentation, and scanning techniques will be reviewed followed by the application of ultrasound in the operating room. We will end with a perspective on ultrasound training. We hope that the reader will gain an appreciation of the versatility and value of ultrasound in his/her practice of surgery.

INDICATIONS FOR INTRAOPERATIVE ULTRASOUND

Ultrasound procedures performed in the operating room are referred

collectively to as intraoperative ultrasound. Intraoperative ultrasound includes both open intraoperative ultrasound (IOUS) and laparoscopic ultrasound (LUS) procedures. The indications for the use of either IOUS or LUS are similar and can be divided into two general categories: *diagnosis* of disease and *guidance* of procedures. *Diagnostic* IOUS is the acquisition of information including the localization or exclusion of previously suspected lesion(s), the detection of occult lesion(s), and the definition of important anatomic information. IOUS is highly accurate compared to preoperative imaging studies or even to surgical exploration of deeper lesions or structures. Hepatic, endocrine, and other small tumors are often accurately detected and vascular invasion (e.g., portal vein invasion by pancreatic cancer) is precisely assessed. Because of its accuracy, IOUS can assess the extent of disease and detection occult tumor, not otherwise known from preoperative imaging. When used as a screening procedure, IOUS detects occult liver metastases from colorectal carcinoma in 5% to 10% of operations. Precise localization of nonpalpable lesions is possible, such as hepatic or pancreatic tumors or cysts. IOUS is an excellent means to localize pancreatic islet cell tumors. Furthermore, intrahepatic calculi and dilated pancreatic ducts are precisely localized and targeted. By providing important information early during the course of an operation, IOUS facilitates intraoperative decision making and procedure planning.

IOUS is an ideal modality to *guide* surgical procedures. Information obtained during the diagnostic ultrasound assists the surgeon in confirming the planned operation or altering to a different operation. For example, the discovery of extensive occult metastatic disease in the liver may lead to abandoning a planned hepatectomy. Without the use of ultrasound, resection might be undertaken, leaving the patient with residual disease. Detection of portal vein involvement, not seen on preoperative imaging, would prepare the surgeon for portal vein resection during pancreaticoduodenectomy. The real-time advantage of ultrasound allows real-time monitoring of the resection margin during hepatectomy and following specimen removal, and can be used to confirm clear resection margins. Furthermore, IOUS can be used to not only detect but then to confirm biliary stone clearance during laparoscopic cholecystectomy. We believe that intraoperative (laparoscopic) ultrasound can replace traditional operative cholangiography as a routine screening test. Table 13.1 lists some of the many uses of IOUS during liver, pancreatic, and biliary procedures.

TABLE 13.1 Indications for Open Intraoperative/Laparoscopic Ultrasound

LIVER
Evaluation of the extent of known liver lesions
Detection of unknown liver lesions
Staging of malignancies (i.e., colorectal, liver, and gastric)
Guidance of hepatic procedures (resection, targeting—biopsy, ablation)
- Needle/probe placement
- (biopsy/ablation)
- Procedure planning
- Guidance of liver resection
- Confirmation of completeness of resection

PANCREAS
Evaluation of known pancreatic tumor
Determination of vascular involvement of pancreas lesions
Staging of malignancy
Guidance of pancreatic procedures
- Localization and drainage of cysts
- Enucleation of islet tumors
- Cannulation of the pancreatic duct

BILIARY
Evaluation of extrahepatic bile duct (laparoscopic cholecystectomy)
Evaluation of intrahepatic bile ducts
Evaluation of the extent of bile duct/gallbladder tumors
Guidance of biliary procedures
- Confirmation of biliary stone extraction
- Guidance of biliary tumor resection

Ultrasound has been shown to be particularly advantageous during laparoscopic procedures. LUS can compensate for the lack of tactile feedback during minimally invasive procedures and allow examination of deeply located lesions or structures. With advances in laparoscopic instrumentation and technique, many operations are performed with a minimally invasive approach, thereby increasing the need for intraoperative imaging and imaging guidance. However, there are limitations of IOUS, whether performed during an open or laparoscopic procedure. Proper interpretation of ultrasound images and execution of the ultrasound exam requires skill in ultrasound. Overcoming the learning curve for the use and interpretation of ultrasound is resolved by training and practice. There is a learning curve for IOUS, and there is a steeper learning curve for LUS. Mastering the skill for IOUS prior to attempting LUS helps to flatten the LUS learning curve.

BASIC PHYSICS: THE PIEZOELECTRIC EFFECT

The ultrasound image that we are accustomed to viewing is a complex image created by sound waves. Ultrasound technology converts this sound energy into an electrical energy in order to display an image for interpretation. This process of energy conversion between electrical and acoustic energy is known as the piezoelectric effect.

Sound is an oscillation of mechanical waves of compression and decompression through a medium (i.e., tissue). Frequency is the number of times per second the sound wave is repeated, and is measured in cycles/second, or Hz. We can hear frequencies ranging from 20 to 20,000 Hz. Medical ultrasound imaging utilizes frequencies much higher than what the human ear can hear, between 2 and 20 million cycles per second (MHz).

As a sound wave moves through a medium, some of the energy is lost or transformed into other forms of energy. This is referred to as attenuation. As the wave moves through a medium, attenuation of energy occurs by either absorption, reflection, scatter, or refraction. Sound waves move through tissues at different velocities depending on the tissue's density and compressibility. Attenuation is dependent on tissue density, whereas fluid, such as water or saline, will have nearly no attenuation. What is important to understand is that reflection is the redirection of the sound wave back to its source caused by the incident wave striking an interface.

The ultrasound transducer (probe) converts between electrical and acoustic energies by the use of specialized "piezoelectric" crystals. The transducer converts electrical energy into acoustic energy for transmission through a medium, such as saline or gel. The transducer then "listens" for returning ("reflected") sound waves and captures the reflected echoes and converts them back into electrical energy.

Once the acoustic energy is captured and converted into electrical energy by the transducer, electrical voltages are then transmitted to the ultrasound monitor where images are formed (pulse-echo technique). Depending on the imaging mode utilized, the generated image can be depicted differently. The basic modes available include:

1. *A mode* (amplitude modulation): Depicts the amplitude of the acoustic waveform.
2. *B mode* (brightness modulation): Depicts varying shades of gray based on the amplitude of the reflected waves. This is the most common

image that we see in medical ultrasound.
3. *M mode* (time-motion mode): Depicts motion over time. This imaging modality is most often used in echocardiography.
4. *Doppler:* Enables quantification of flow velocity.
5. *Duplex:* Enables a combination of Doppler and B-mode imaging.

INSTRUMENTATION

Transducers (Probes)

The equipment of choice for IOUS and LUS is a so-called "small parts scanner," which is a high-frequency, high-resolution, real-time ultrasound system, which consists of three components: transducer, central processing unit, and display. The transducer (probe), as discussed above, utilizes frequencies ranging from 5 to 10 MHz for IOUS and LUS. Higher frequency probes offer better image resolution, but at the expense of less tissue penetration, due to greater attenuation of acoustic energy. Lower frequency probes provide better penetration of deeper structures, however, at the expense of image resolution. Higher frequency probes are preferable in IOUS and LUS where the greatest image resolution is obtained at the expense of less penetration. With a 7.5-MHz transducer, the sound penetration depth is about 8 to 10 cm, and small lesions such as 1 mm calculi and 3 to 5 mm tumors can be delineated. To meet special requirements of IOUS and LUS applications, several manufacturers have developed high-frequency probes specifically designed for use within the operative field.

IOUS Probes

Two basic shapes of IOUS probes are flat and cylindrical. Flat probes consist of linear-array or curvilinear-array (convex) transducers and are usually configured into "T" or "I" shape (Fig. 13.1). T-shaped probes are either side- or end- (front) viewing. Cylindrical probes consist of a curvilinear-array (convex) or phased-array transducers. They are pencil-like, often with flattened sides to achieve greater slimness. Flat probes are suitable for examination of relatively large, flat organs such as the liver, pancreas, and kidney. Flat side-viewing probes are particularly important for the scanning of the liver because the probe must be placed between the anterior surface of the liver and the diaphragm. However, cylindrical probes are useful for the examination of small target organs such as the extrahepatic biliary duct, especially when areas of interest are situated

deeply in the operative field where manipulation of the probe is limited. It is ideal to have both types of probes; however, a side-viewing flat T-shaped probe can be used for the examination of abdominal organs in almost all abdominal operations.

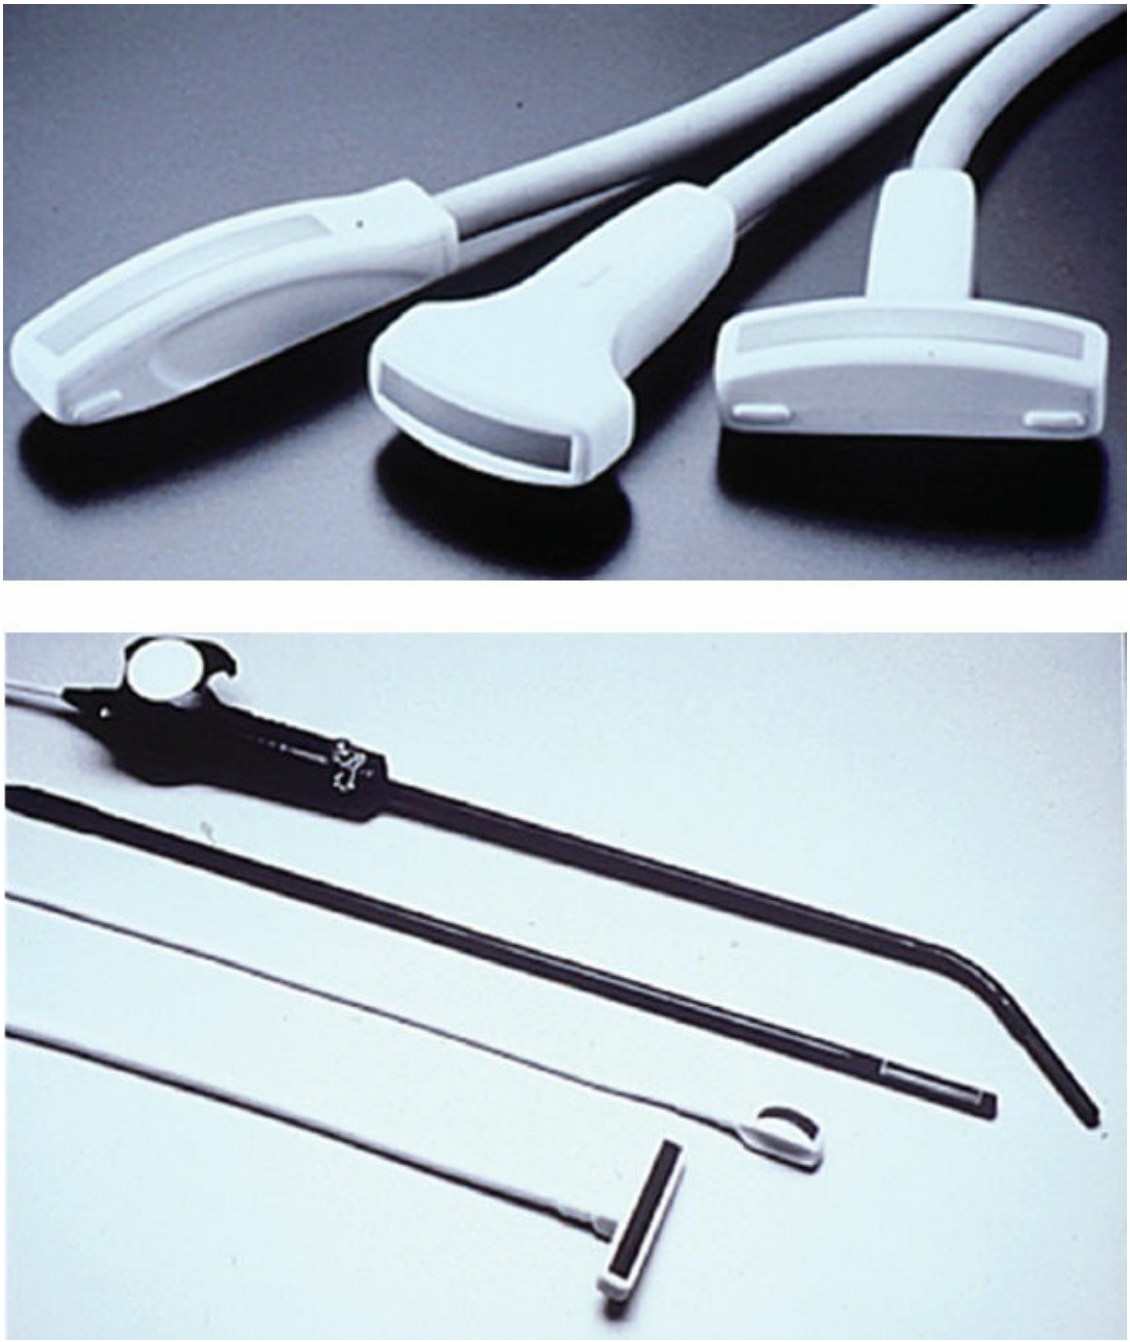

Figure 13.1. Upper picture: curvilinear array (convex) flat, T- or I-shaped, side-viewing or front-viewing IOUS probes. **Lower picture:** (top two probes) LUS side-viewing flexible and rigid probes, and (bottom two probes) IOUS side-viewing I- and T-shaped probes.

LUS Probes

LUS probes consist of transducers mounted on or near the tip of a slender shaft (Fig. 13.1). The shaft is usually 10 mm in diameter and 50 to 70 cm in length. Several types of LUS probes are presently available, providing linear-array, convex, or sector transducers. A probe can be either side-viewing (i.e., the scanning plane is at a right angle with the probe shaft) or front-viewing (i.e., the scanning plane parallel to the shaft). A side-viewing linear-array or convex probe can be used for LUS scanning of almost all organs of the abdomen and is essential for scanning of the liver. A front-viewing probe is suitable for scanning the extrahepatic bile duct. A rigid-shaft probe and a flexible-tip probe are available. A flexible tip is mobile in two or four directions (bi- or quad-directional). A flexible tip facilitates scanning of areas that are difficult to delineate with a rigid probe (e.g., behind the dome of the liver) and may reduce the number of trocar insertion sites.

Knobology

The ultrasound console can appear quite complex, given the multiple knobs and buttons that exist. As surgeons, we are typically interested in understanding in depth the complexity of each new venture. However, on the ultrasound console there are only a few key buttons to understand and be able to control with ease. These include frequency, gain, depth, focus, freeze, and measurements.

Frequency should be thought as the “resolution” of the image and sound penetration. As discussed above, higher frequency probes are unable to penetrate into deeper tissues, but provide better image resolution. Inversely, lower frequency probes penetrate into deeper tissues, however, with decreased image resolution.

Gain should be thought of as “volume” amplification of the reflected sound. Increasing the gain will amplify all the returning echoes from all depths and tissues. Think of it as increasing the volume in the radio, such that the ultrasound probe will increase its “listening” of the returning echos. Time gain compensation (TGC) selectively allows modifying the amplification of returning echos at different depths.

Depth is the “distance” the sound travels (and back). The depth of the target (area of interest from the transducer) changes the distance that the ultrasound wave travels. As the depth is increased (deeper target), the ultrasound wave travels to and is reflected back over a greater distance.

This can result in a decreased quality of image (lower resolution). The depth of images (use of magnification) should be adjusted to no more than what is required, together with appropriate focusing, for the best image resolution.

Focus is the “point of interest.” The probe can be focused at any depth to improve the image. The focus narrows the ultrasound beam to the point of interest to enhance resolution.

The ability to measure a lesion requires understanding where the *freeze* button and the *measurement* controls are located. As many ultrasound systems are different, it is necessary to familiarize yourself with these areas of the ultrasound console prior to starting an ultrasound exam.

Ultrasound Terminology

Before moving to a description of the various scanning techniques, it is necessary to understand some of the key terms in ultrasound jargon. Ultrasound characteristics of tissue are described in terms of “echogenicity.” Echogenicity refers to the brightness of the tumor, organ, or tissue that is being described. Aechoic describes tissue that is devoid of acoustic wave reflection and appears black on the ultrasound display. Whereas hyperechoic describes tissue that is brighter, hypoechoic is less bright, and isoechoic is the same brightness as compared to the reference tissue (e.g., liver or spleen). Echogenicity is determined by the character of the tissue (i.e., medium) where the velocity of the acoustic waves are determined (Fig. 13.2).

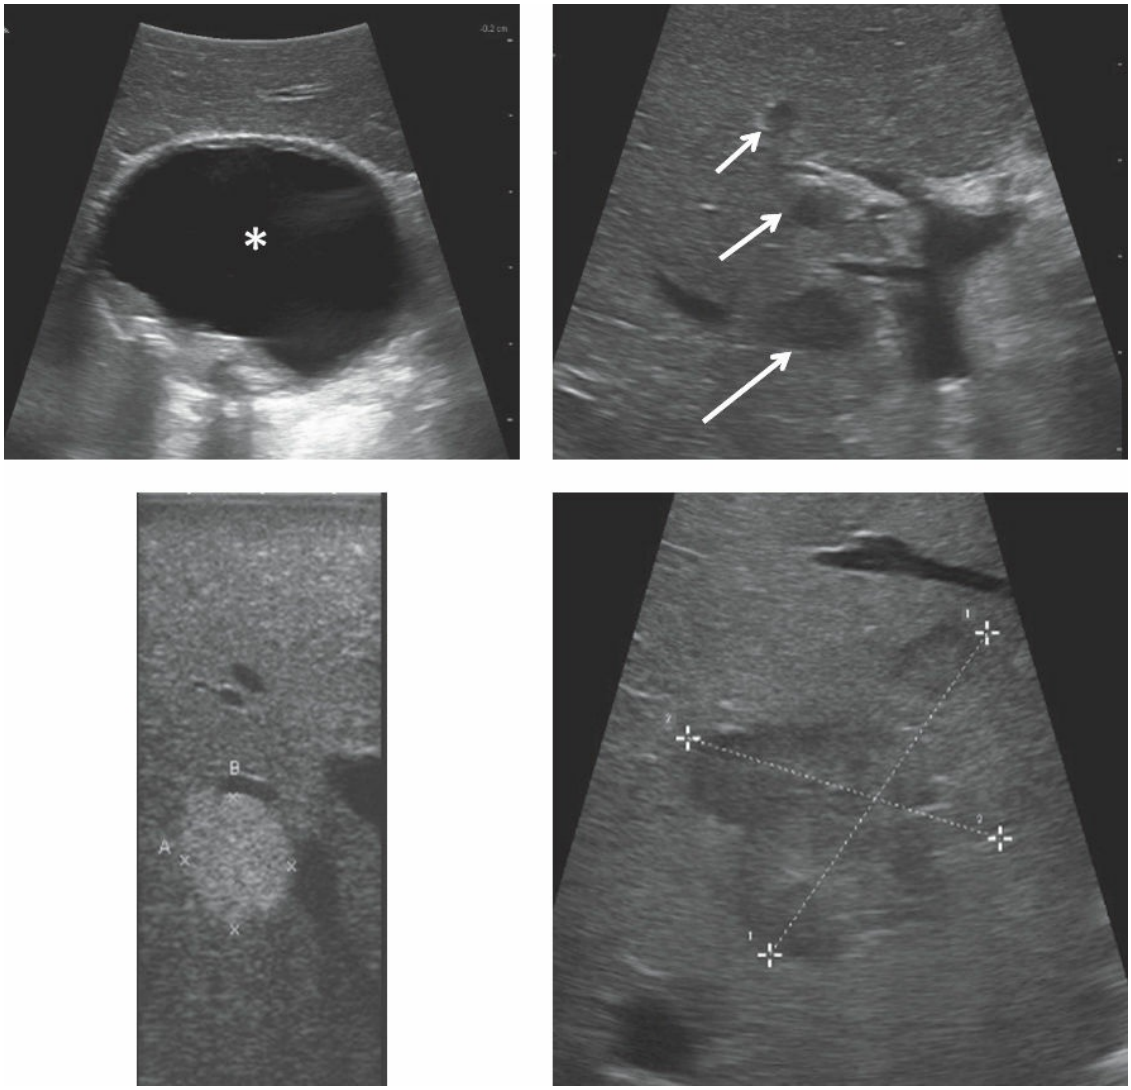

Figure 13.2. Upper left image: gallbladder filled with fluid appears "black" and is referred to as anechoic (*). **Upper right image:** hypoechoic liver masses (*arrows*). **Lower left image:** hyperechoic liver mass (marked by measurements). **Lower right image:** liver mass of mixed echocity—note the varying hypo-, iso-, and hyperechoic characteristics of this lesion (marked by measurements).

SCANNING TECHNIQUES

General Considerations

In the operating room, the person performing the scan should be in the surgeon's position. The monitor should be placed to permit easy viewing of the screen and the operative field with minimal change-of-gaze movement. Typically, the ultrasound system is placed on the opposite side of the table from the surgeon. Probe sterility for intraoperative use is achieved by cold gas sterilization or use of a sterile cover. A newer

sterilization method such as a low-temperature chemical sterilization, which can sterilize instruments in 30 to 60 minutes, is available, and some probes are amenable to this method. Because IOUS/LUS can be performed and repeated at any point during the operation, all ultrasound equipment should be kept available and the probe sterile for the duration of the operation.

There are two primary imaging planes in ultrasound, longitudinal and transverse. In terms of IOUS or LUS, the longitudinal view is parallel to the long axis of the structure or organ being examined, whereas a transverse view is at the right angle to the long axis. Oblique views are intermediate in position between longitudinal and transverse views (Fig. 13.3).

Coupling

A path for transmission of the sound waves between the probe and the target tissue must be established. Because air is an ineffective medium for sound wave transmission, it is necessary to displace air (called *coupling*) in the path (called the *acoustic interface*) between the probe and the target tissue. For transabdominal ultrasound, a gel is used most commonly. For IOUS and LUS, saline on the surface of the organ is all that is needed. The thickness of the acoustic interface can be manipulated and thereby altering the underlying image.

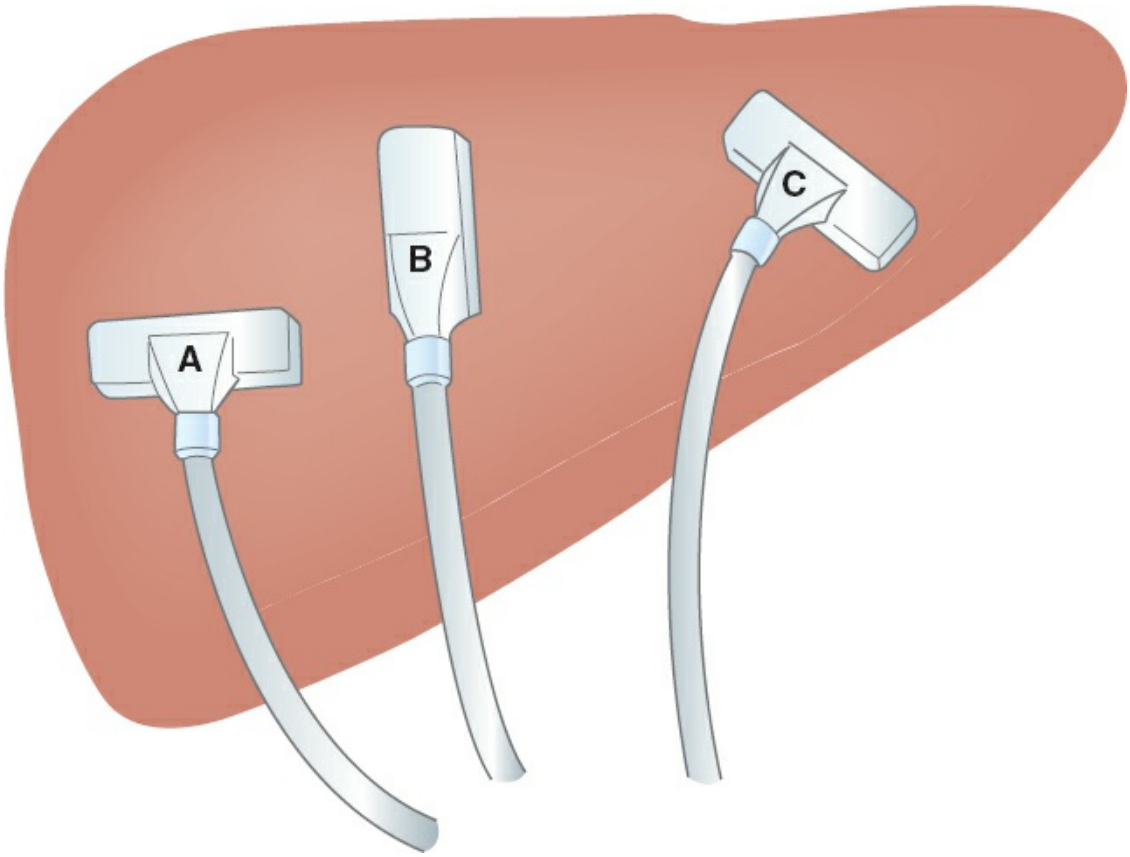

Figure 13.3. Transverse (**A**), longitudinal (**B**), and oblique (**C**) imaging of the liver. Note that the imaging plane is changed by "rotating" the probe.

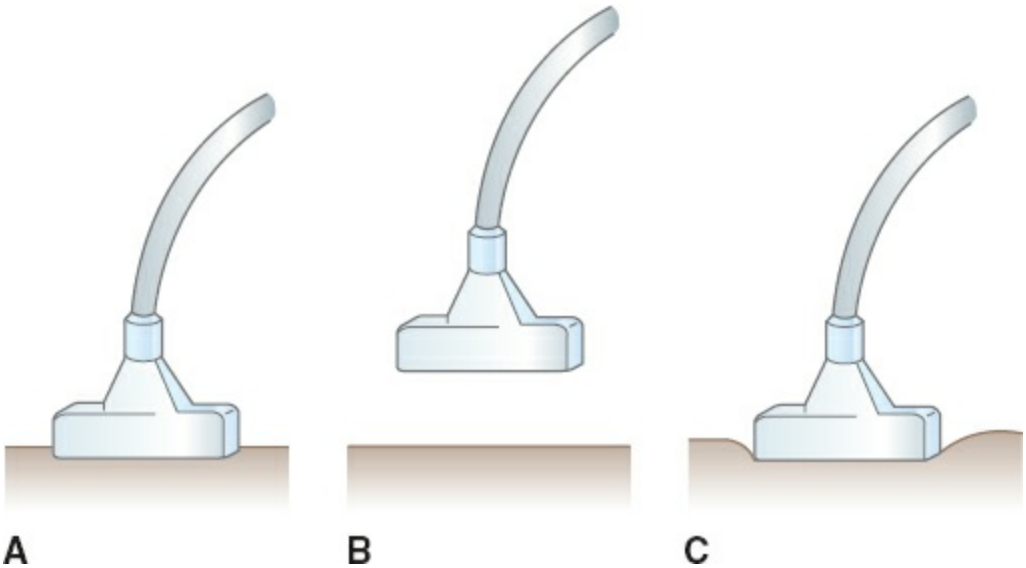

Figure 13.4. Open intraoperative ultrasound probe placement, including contact scanning (**A**), probe standoff scanning (**B**), and compression scanning (**C**).

Probe Placement

Ultrasound scanning is a two-step process: probe placement and probe movement. Various techniques can be performed to facilitate IOUS/LUS scanning and to obtain the best imaging information. Two basic transducer placement techniques of IOUS/LUS are contact scanning and probe standoff scanning. In contact scanning, the probe is placed in direct contact with the tissue or organ, whereas in probe standoff scanning the probe is positioned 1 to 2 cm away from the surface of structure (Fig. 13.4).

The size of the target organ and the distance from the probe to the area of interest in the organ determines which scanning technique should be used. Contact scanning is used for examination of the interior of the liver, kidney, or pancreas. However, when the surface of the superficial tissue needs to be examined, probe standoff scanning should be employed. Probe standoff is very important when the area of interest is within 0.5 to 1 cm from the surface of the tissue and is particularly helpful in the examination of relatively small superficial structures such as the extrahepatic bile ducts (Fig. 13.5). In probe standoff scanning, an acoustic interface is created between the target tissue and probe by filling the operative field with saline or by placing a saline-filled glove on the target tissue and scanning through the fluid-filled acoustic interface (Fig. 13.6). The probe standoff with saline immersion technique is a unique IOUS/LUS method that is not commonly used in transabdominal ultrasound. This permits placement of the target at the appropriate focal distance and also prevents inadvertent compression of structures by the probe. One additional useful technique is compression scanning, in which the tissue is compressed intentionally by the probe (Fig. 13.4). This technique helps to displace air between the transducer and the target tissue. Air in the gastrointestinal tract lumen that overlies a region of interest can be displaced by compression. This is especially effective when air in the duodenum obscures the distal common bile duct or air in the stomach obscures the underlying pancreas. Compression is also used to distinguish arteries from veins, which are more compressible.

Probe Movement/Manipulation

The second step in ultrasound scanning is probe movement. A target or suspected lesion should be scanned from various positions and directions and an organ should be scanned in a systematic fashion for a thorough IOUS/LUS examination. Although the scanning method varies depending on the organ examined, it is usually important to obtain longitudinal,

transverse, and at times oblique views of a lesion or organ (Fig. 13.3). Probe movements are the ways by which the probe is manipulated. There are four basic movements of the probe: sliding, rotating, rocking, and tilting. In “sliding,” the probe is moved across the target tissue without lifting the probe from the scanning surface. In “rotating,” the probe is rotated around its center axis, either clockwise or counter-clockwise, while switching between the longitudinal and transverse planes. With this technique, a lesion or structure is delineated continually through the longitudinal, oblique, and transverse views, providing a three-dimensional (3D) mental picture for the surgeon. During “rocking,” the probe is moved forward and backward along its long axis. This moves the ultrasound image *along* the same plane and therefore is referred to as “in-plane” motion. During “tilting,” the probe is moved side-to-side along its long axis. This moves the ultrasound image *across* different planes and therefore is referred to as “cross-plane” motion. In both rocking and tilting, the probe’s head (transducer surface side) remains in a relatively stationary place, while the shaft of the probe is moved or swung to different angles (Fig. 13.7). This technique is especially useful in a deep and restricted operative field where “sliding” of the probe is limited or impossible. These basic probe movements can be used individually or can be combined to obtain optimal ultrasound imaging.

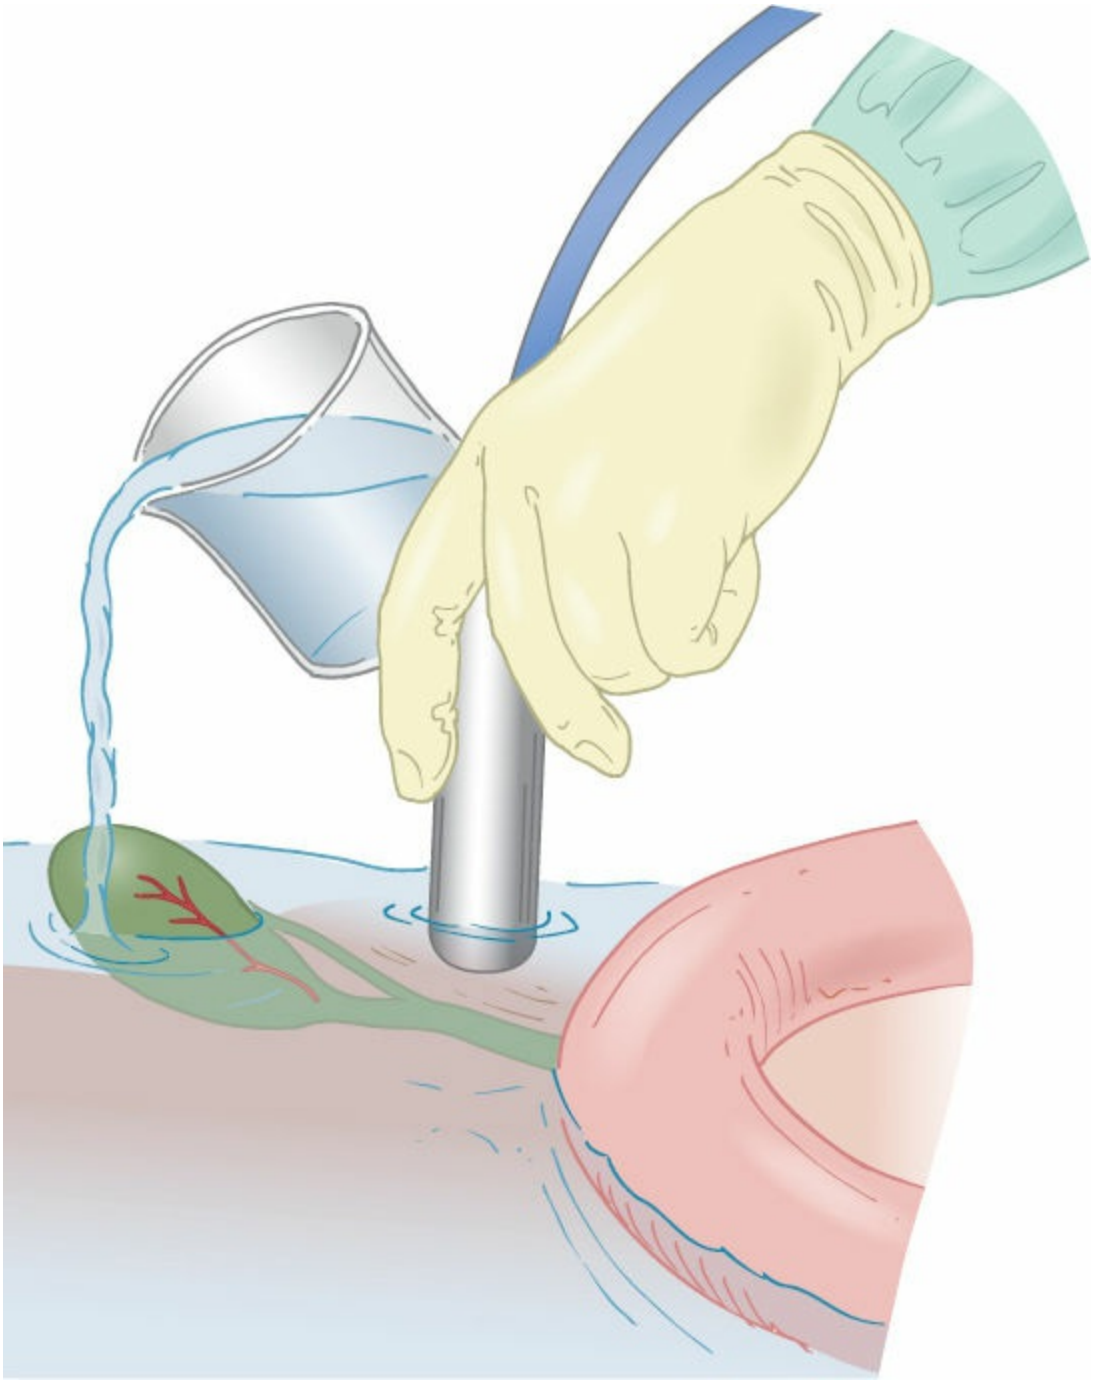

Figure 13.5. Open intraoperative ultrasound scanning of the extrahepatic bile duct using a probe standoff technique. The probe standoff is particularly important when the bile duct is exposed or located superficially in the hepatoduodenal ligament.

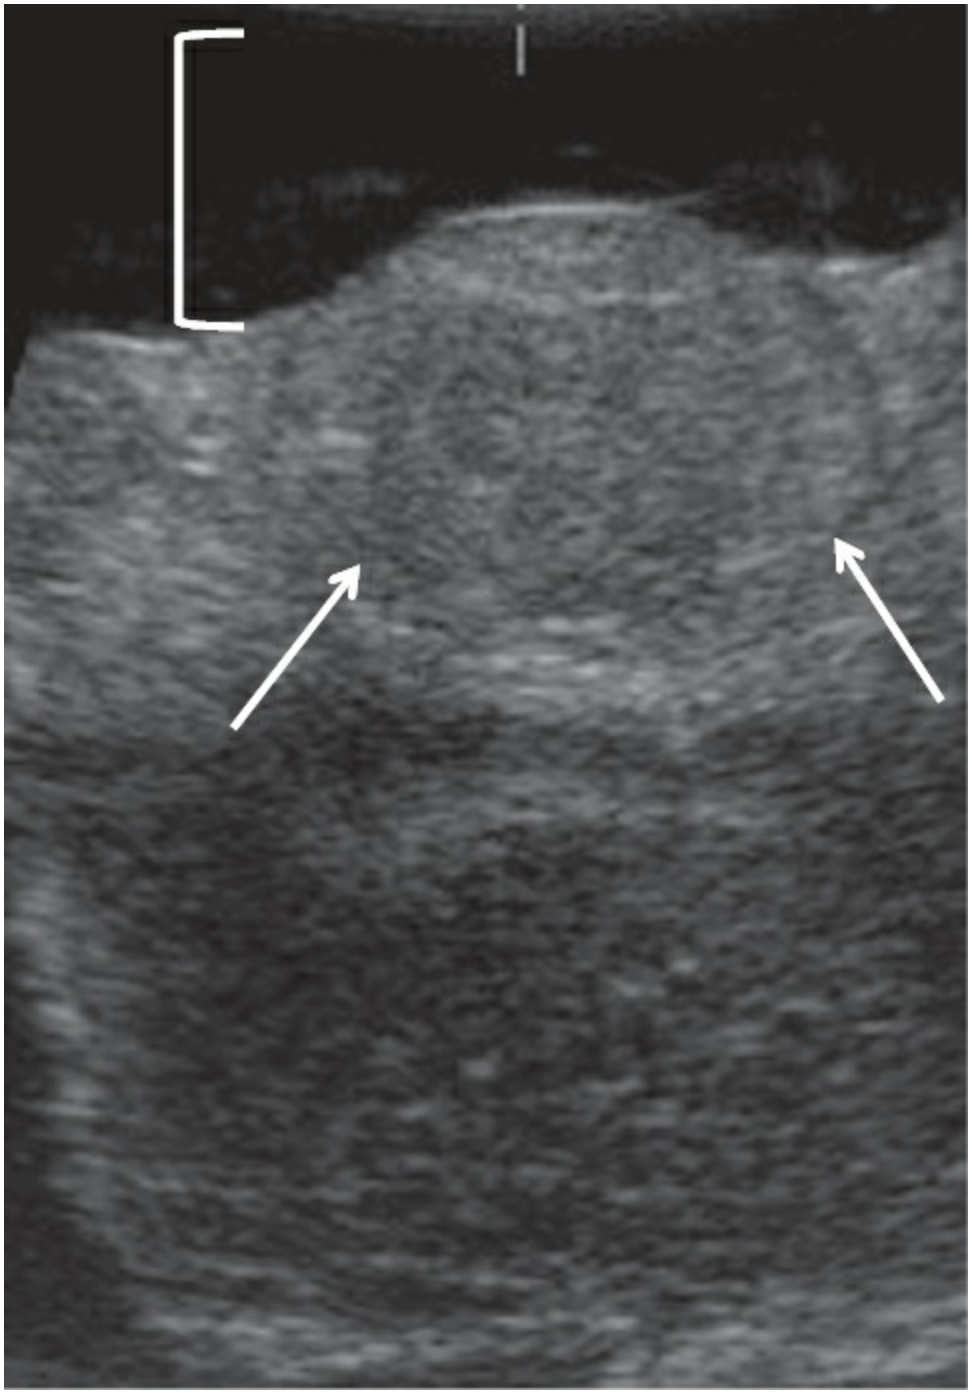

Figure 13.6. Probe standoff: saline is used as an acoustic window (*bracket*) in order to image the superficial surface of the liver. Notice the use of saline helps to define an isoechoic lesion (*arrows*) on the surface of the liver.

OPEN INTRAOPERATIVE ULTRASOUND

Open IOUS is a critical tool to evaluate and manage multiple abdominal diseases, in particular hepatic, biliary, and pancreatic diseases. It is a real-time view and can be used repeatedly throughout a procedure to re-

evaluate and guide the operation. It is important to develop a systematic scanning approach for each type of scan and for each organ.

Liver Scanning Method

The liver is best scanned with the side-viewing flat T-shaped probe. Many current probes are multifrequency, ranging from 5 to 10 MHz in frequency. Using a 7.5-MHz frequency is the most useful for liver ultrasound as this allows adequate penetration to view the entire organ while showing the detail of the intrahepatic structures. For a larger, steatotic or cirrhotic liver, a lower frequency, such as 5 MHz, is sometimes necessary to allow deeper penetration. The probe is passed over the liver surface under the abdominal wall or the diaphragm. Modern probes have a small profile which allows placement in narrow and limited working spaces.

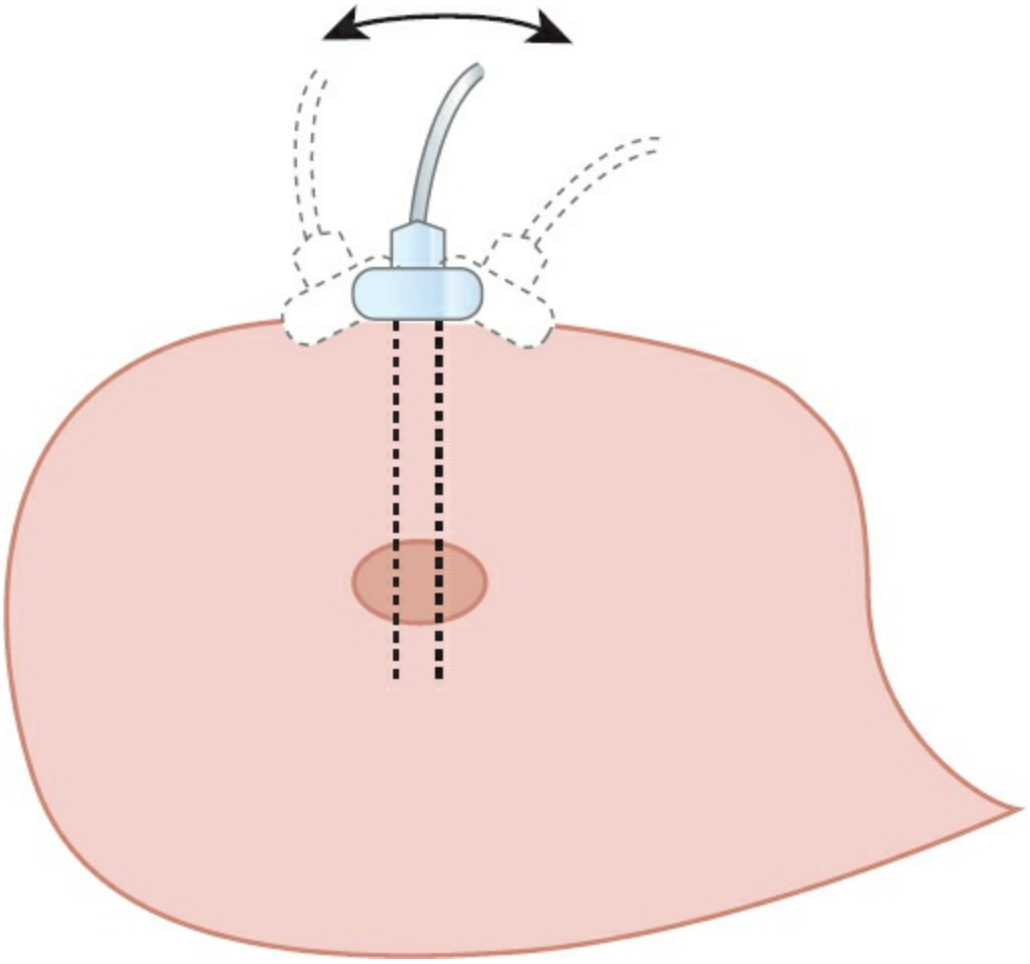

Figure 13.7. Tilting of the probe facilitates visualization of a target in the liver from one location, in different directions. Notice that the head of the transducer stays in one relative position as

the probe is “tilted” along its long axis, moving the image across different imaging planes.

Ultrasound examination of the liver begins with the placement of the probe in direct contact with the liver (contact scanning), typically on the anterior and diaphragmatic surfaces. Scanning from the inferior surface may also be needed. Contact scanning is very useful for most of the liver; however, it has limited visualization just beneath the probe (see above, *Probe Placement*). When a mass or structure is just beneath the probe or if an irregular surface exists (e.g., cirrhosis) whereby contact scanning is not possible, the probe standoff technique becomes very useful. Saline is an excellent interface to establish an acoustic window to enhance visualization of this limited area just beneath the probe (Fig. 13.6).

Table 13.2 outlines a systematic approach to liver ultrasound scanning for either an open or laparoscopic approach. For the open approach, the initial scan is done prior to any mobilization of the liver. Scanning before liver mobilization avoids creating artifact, such as the introduction of air into tissue planes that may have obscured the field of vision. If mobilization is then necessary, such as in a proposed resection, the scan is then repeated after such mobilization. Liver ultrasound scanning is performed with the goal of defining the segmental liver anatomy, its vasculature, and evaluating the liver parenchyma in a systematic fashion.

The liver is a large organ without many landmarks. Segmental anatomy of the liver is based on the hepatic veins and intrahepatic branches of the portal system, which is nicely defined by ultrasound. Several terminologies exist for hepatic anatomy, including Healy and Schroy, Couinaud, and Bismuth. Some refer to “lobes,” whereby others refer to “livers.” In order to standardize terminology, the International Hepato-Pancreato-Biliary Association has adopted the Brisbane 2000 Terminology as the accepted terminology for liver anatomy and resection so that all are “speaking the same language.” When discussing liver anatomy, we will use this accepted terminology in this chapter.

The liver ultrasound examination begins with transverse scanning followed by longitudinal and if needed, oblique views. Using probe movements including sliding, rotating, tilting, and rocking, the surgeon defines the intrahepatic vasculature, segmental anatomy, and any underlying tumor. Rotating the probe over an area of interest allows one to confirm the presence of a lesion and that it is indeed not an artifact.

Liver ultrasound scanning includes (1) identification of the hepatic veins, (2) identification of the portal veins and their branches, and (3) systematic scanning of the parenchyma (see Table 13.2). Begin in the transverse plane by placing a flat side-viewing ("T") probe in the center of liver, just to the right of the suspensory ligament (segment 4). By *tilting* the probe *upward*, the junction of the hepatic veins at the suprahepatic vena cava is demonstrated (Fig. 13.8). Once this image is obtained, each hepatic vein is followed peripherally to its terminus. Sliding the probe back to the junction of the hepatic veins, and rotating the probe in the longitudinal/oblique view, each hepatic vein is then re-examined to its terminus.

Next, the portal vein and its branches are identified. By sliding the probe back to the center of segment 4 and *tilting* the probe *downward* (or sliding the probe to the inferior aspect of segment 4), the bifurcation of the portal vein is seen just distal to the termination of the main portal vein (Fig. 13.9). Sliding the probe inferiorly along segment 4 allows visualization of the main portal vein in the transverse view. Sliding the probe back to the bifurcation and then toward the right, identifies the right portal vein (Fig. 13.10). The right portal vein is then followed peripherally into its division into the anterior (segments 5 and 8) and posterior (segments 6 and 7) branches, defining the segmental anatomy of the right liver (Fig. 13.11). Sliding the probe back to the portal bifurcation is continuing to slide to the left, identifies the horizontal portion of the left portal vein in its longitudinal view (Fig. 13.12). At the base of the umbilical fissure, the left portal vein turns and travels anteriorly and inferiorly in the umbilical fissure and is seen in a transverse view (Fig. 13.12). Continuing to follow the left portal vein identifies segmental branches to segments 2, 3, and 4 (Fig. 13.13). During examination of the left portal vein, segment 1 (caudate lobe) is clearly defined (Fig. 13.14).

TABLE 13.2 Systematic Approach to Liver Ultrasound Scanning

1. Identify hepatic veins (right, middle, and left)
   Identify junction with the vena cava ("trifurcation")
   Define relationship of the middle and left hepatic veins (common trunk)
   Follow each hepatic vein to its terminus
   Identify any anomalous tributaries
2. Identify portal branches
   Identify the main portal vein trunk and its bifurcation
   Identify the right portal vein, its anterior and posterior branches, and follow to their segmental branches
   Identify the left portal vein and follow to its segmental branches
   Identify any anomalous branches
3. Perform a systematic parenchymal scan
   Sweep scan of each individual section/sector
   Identify any lesion, its size, location, and echo characteristics
   Define any vascular or biliary involvement

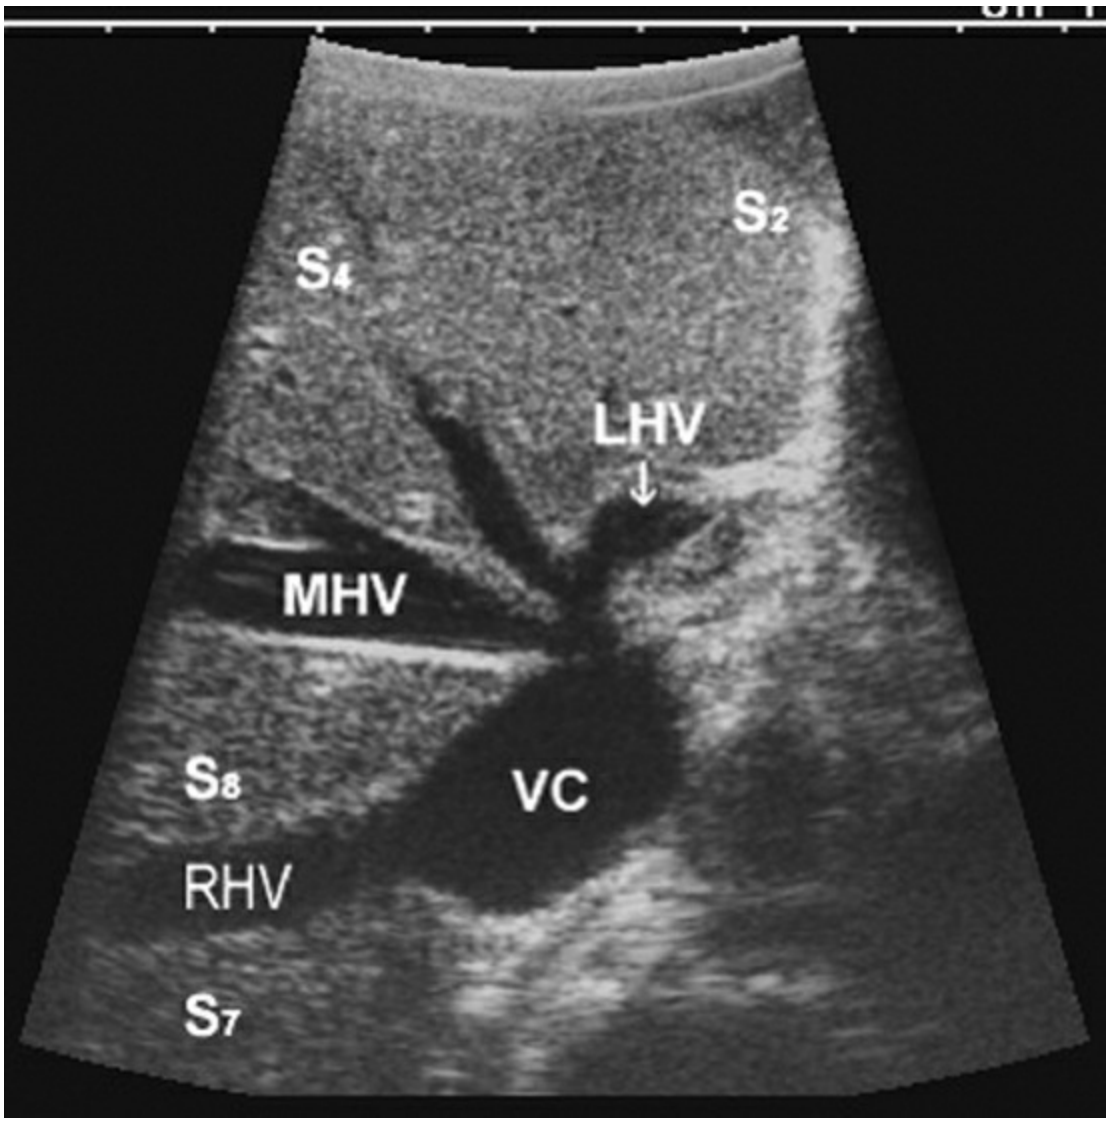

Figure 13.8. Intraoperative ultrasound of three hepatic veins. The right (RHV), middle (MHV), and left (LHV) veins are entering the vena cava (VC) separately, although it is common for the MHV

and the LHV to form a common channel. The relationship of the hepatic veins to the superior liver segments (S2, S4, S8, S7) is shown.

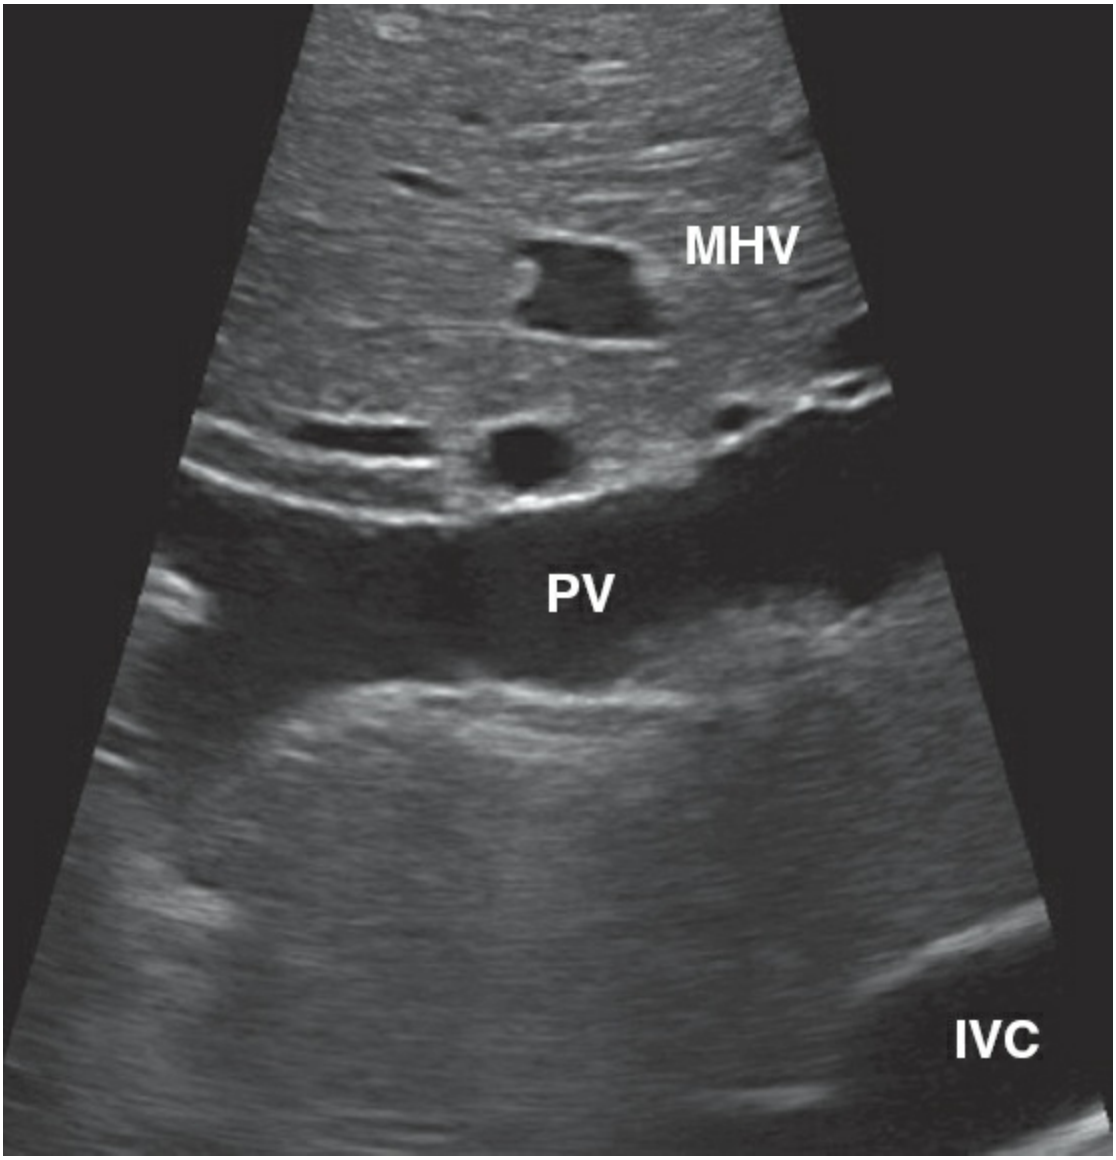

Figure 13.9. The portal bifurcation is seen by tilting the probe downward on segment 4 after visualizing the hepatic veins. Note that the middle hepatic vein (MHV) is located at the center of the bifurcation, indicating the division of the right and left livers.

The final component of the ultrasound examination of the liver includes a systematic survey of the liver parenchyma. Rotating the probe in the longitudinal/oblique view, or maintaining the probe in the transverse view, each section of the liver, as defined by the hepatic venous anatomy, is examined while sliding the probe across the liver parenchyma from right to left and left to right. This is done in a stepwise fashion while continuing

to move from the superior to the inferior aspect of each section. Alternatively, the probe is kept in the transverse view and each section is examined while sliding the probe from superior to inferior and inferior to superior (Fig. 13.15). This systematic survey is referred to as the *sweep-scan* or *lawnmower* method and ensures a complete examination of the liver parenchyma. During this portion of the examination, lesion location, size, and sonographic features are noted in addition to proximity to any vasculature or intrahepatic ducts. For any proposed resection, at this point, a decision can be made regarding resectability and extent of resection (Fig. 13.16).

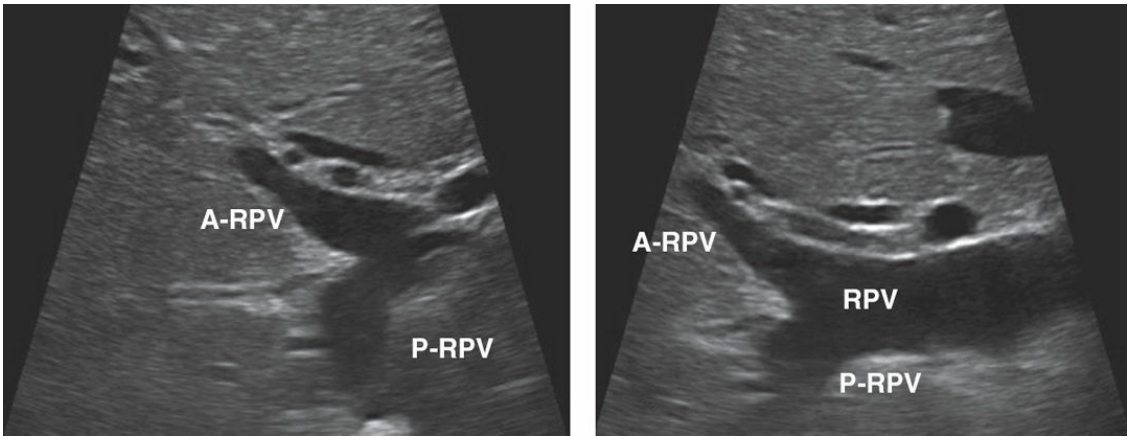

Figure 13.10. Left: Sliding the probe toward the right from the portal bifurcation identifies the right portal vein (RPV) and the beginning of its anterior (A-RPV) and posterior (P-RPV) branches. **Right:** Continuing to slide the probe to the right clearly defines the anterior (A-RPV) and posterior (P-RPV) branches of the right portal vein.

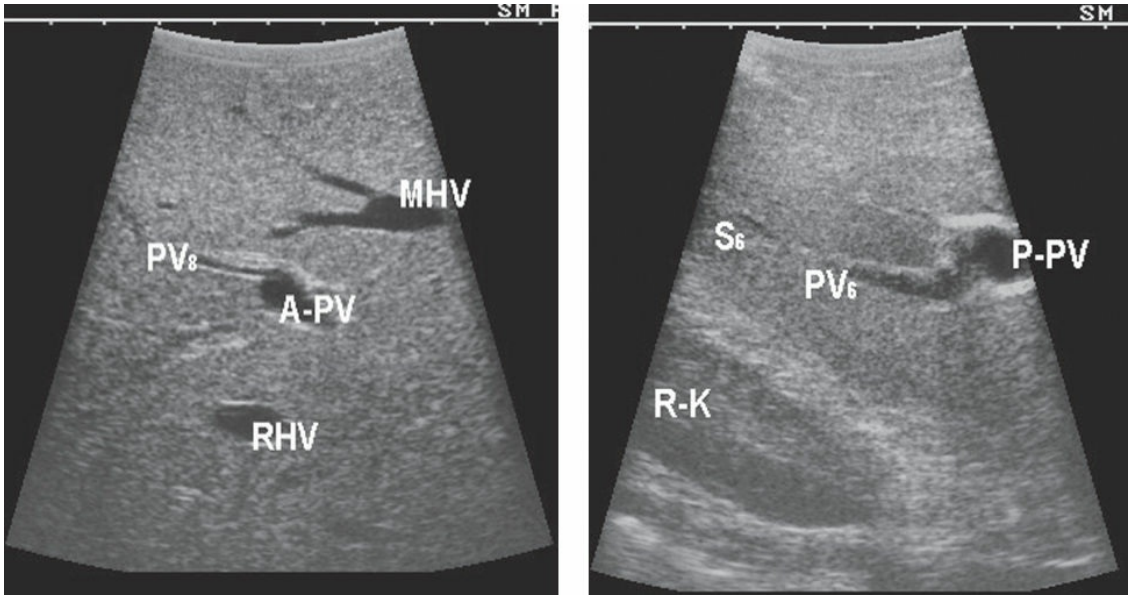

Figure 13.11. Segmental branches of the right anterior and posterior portal veins. The segment 8 branch (PV8) is from the anterior branch of right portal vein (A-PV), and the segment 6 branch is from the posterior branch of right portal vein (P-PV). Note that the A-PV is located between the middle hepatic vein (MHV) and right hepatic vein (RHV). The segment 6 (S6) is adjacent to the right kidney (R-K).

Biliary Scanning Method

Biliary scanning (gallbladder and extrahepatic bile ducts) is optimally performed using two different probes. A flat, side-viewing, linear transducer is very useful for contact scanning of the gallbladder, the intrahepatic bile ducts, or the extrahepatic bile ducts using the liver as an acoustic window. The gallbladder can also be scanned directly with the probe standoff technique using saline as an acoustic window. The extrahepatic bile ducts are best scanned with the end-viewing cylindrical probe, at a frequency higher than 7.5 MHz. Probe standoff scanning is critical for the exposed or superficially situated bile ducts (Fig. 13.5). Initial scanning should always occur prior to any dissection of the gallbladder or hepatoduodenal ligament. As was seen in liver mobilization, tissue dissection can introduce artifacts through entry of air in tissue planes and can limit visualization.

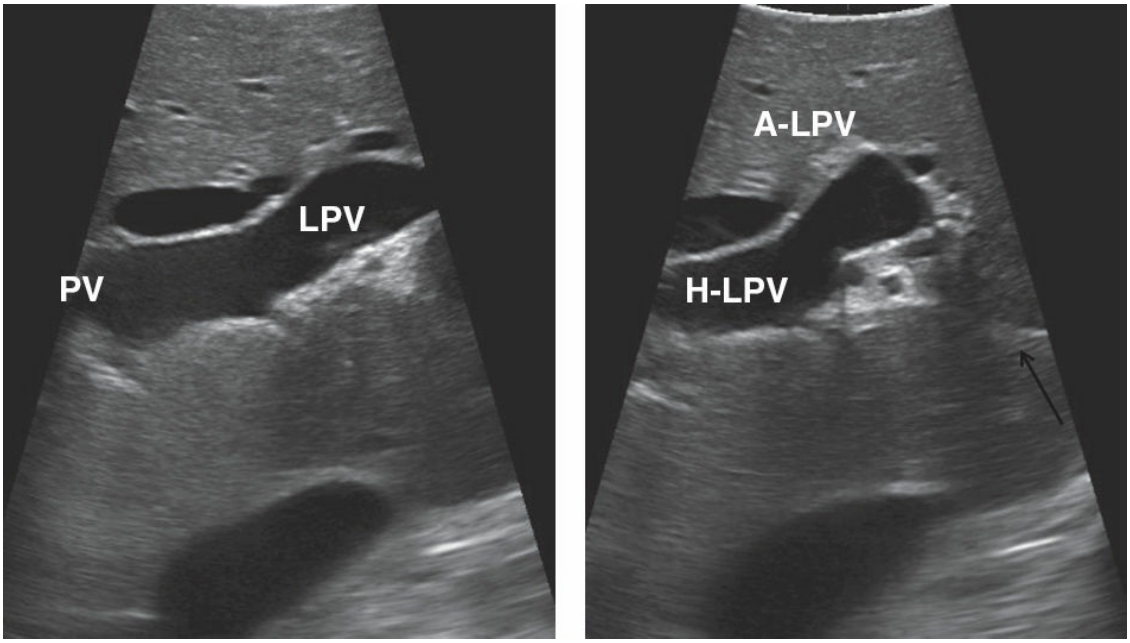

Figure 13.12. Left: Beginning at the portal bifurcation (PV) and sliding the probe to the left identifies the left portal vein (LPV). **Right:** Continuing to slide the probe to the left identifies the horizontal portion of the left portal vein (H-LPV) leading to the ascending portion of the left portal vein (A-LPV). These images were obtained with a T-probe and scanning in the transverse plane.

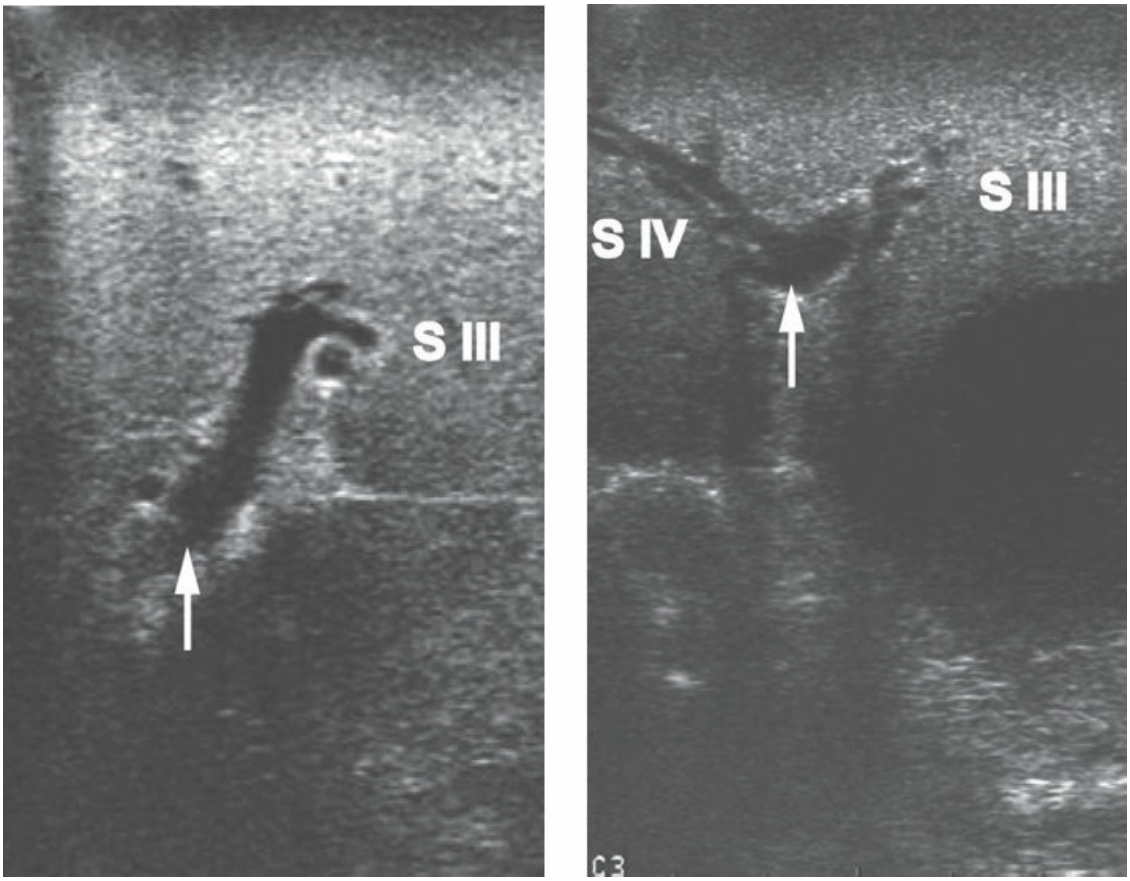

Figure 13.13. Continuing to slide the probe to the left identifies the left portal vein segmental branches. **Left:** Sliding the probe along the ascending portion of the left portal vein (*arrow*) leads to the segment 3 (S III) branch. Not depicted here is the segment 2 branch, the first branch of the ascending left portal vein. **Right:** Continuing to follow the left portal vein (*arrow*) leads to its termination at the segment 3 (S III) and segment 4 (S IV) branches.

A systematic approach to scanning the biliary tree and gallbladder is imperative to ensure a complete exam (Table 13.3). Begin the biliary ultrasound examination by contact scanning with use of the side-viewing transducer. Placing the probe at the anterior inferior aspect of the liver at the gallbladder, visualizes the gallbladder using the liver as an acoustic window (Fig. 13.17). Continuing to rotate the transducer and sliding it toward the lower aspect of segment 4, the main portal vein/portal bifurcation is visualized, as described above in liver scanning method. Anterior to the main portal vein is the confluence of the right and left hepatic ducts (Fig. 13.9). Next, contact scanning is used to image the gallbladder in transverse and then longitudinal planes and is followed down to the cystic duct/common hepatic duct junction (Fig. 13.18). Sliding

the transducer inferiorly visualizes the extrahepatic bile duct in its longitudinal plane. Once contact scanning is complete, probe standoff technique utilizing saline immersion is then performed. The gallbladder is initially scanned from the inferior aspect of the liver and this followed down to the cystic duct and extrahepatic bile duct.

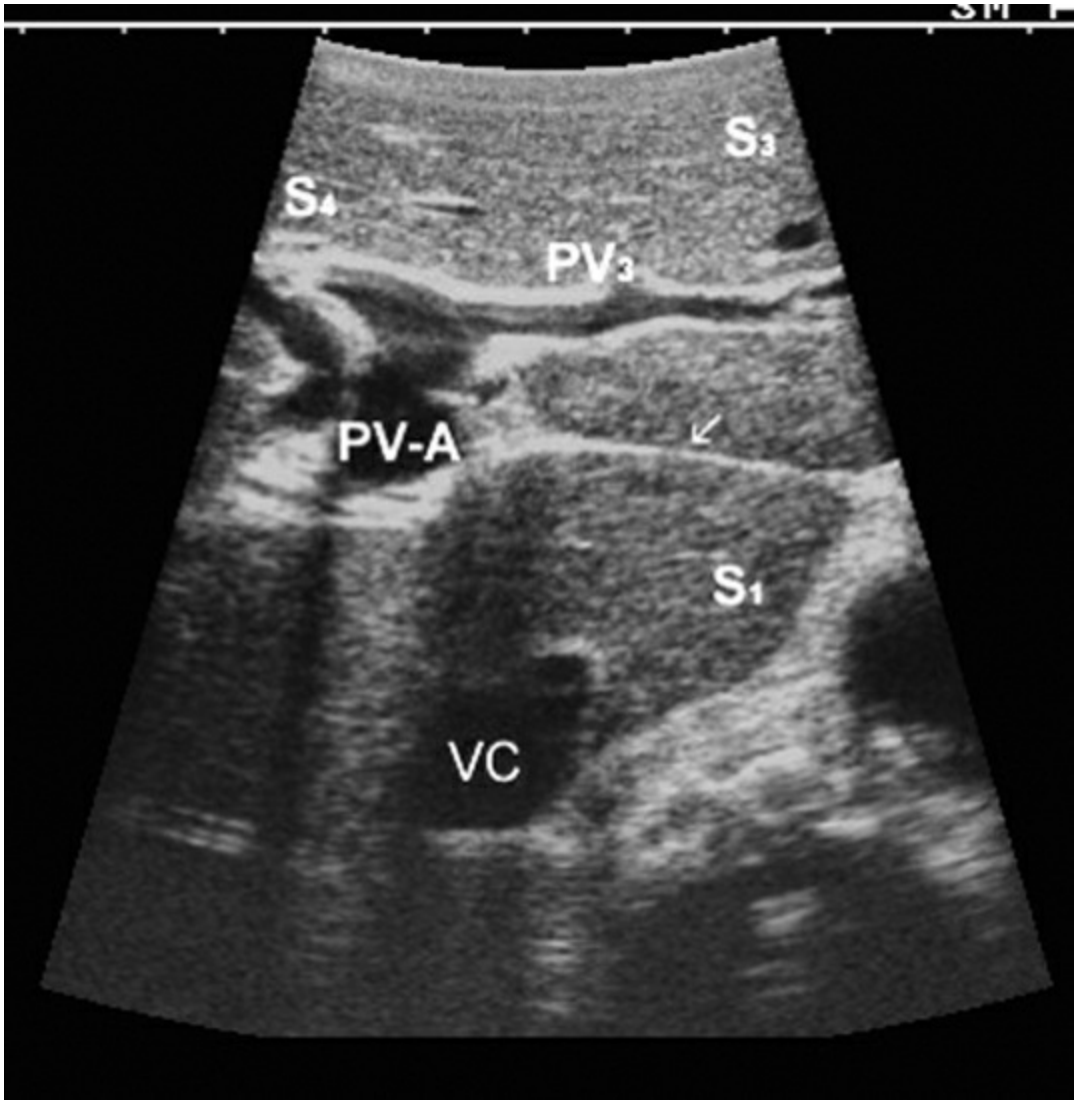

Figure 13.14. Caudate lobe (segment 1). Note the location of segment 1 (S1) to be posterior to the portal vein (in this image, posterior to the ascending left portal vein, PV-A) and the ligament venosum (*arrow*) and anterior and lateral to the vena cava (VC). PV3 = segment 3 portal vein branch, S3 = segment 3, S4 = segment 4.

Switching to the end-viewing transducer is optimal at this point to complete the exam (if available). The gallbladder, cystic duct, and extrahepatic bile duct are examined utilizing probe standoff technique

(Fig. 13.5). The supraduodenal portion of the bile duct is visualized longitudinally, as the probe is moved from the hepatic hilum to the duodenum. The retroduodenal and intrapancreatic bile ducts are then scanned through the duodenum, typically with gentle compression to expel any gas from the duodenum or by contact scanning on the pancreas (Fig. 13.19). The extrahepatic bile duct is also examined transversely, which also displays the portal vein and hepatic artery in transverse sections. Fig. 13.20 shows an extrahepatic cholangiocarcinoma, which was evaluated and determined to be resectable by IOUS.

Pancreas Scanning Method

Pancreatic ultrasound can be done with the use of either a side- (flat) or end-viewing probe. It is helpful to scan the pancreas using an indirect method prior to any dissection using the duodenum, stomach, gastrohepatic–gastrocolic ligaments, or the transverse mesocolon as an acoustic window. Once the anterior surface of the pancreas is exposed by entry into the lesser sac, a direct method is utilized, such as contact scanning. Because the pancreas is a thin organ, it is very helpful to also use probe standoff with saline immersion in order to visualize the surface and superficial areas of the pancreas. The entire pancreas is imaged using longitudinal and transverse planes, remembering that the axis of the plane is in relationship to the long axis of the pancreas. The pancreatic head and the uncinate process can be scanned together with the examination of the extrahepatic bile duct (intrapancreatic portion of the bile duct). The main pancreatic duct, even when normal-size, can be visualized by scanning from the head to the tail of the pancreas.

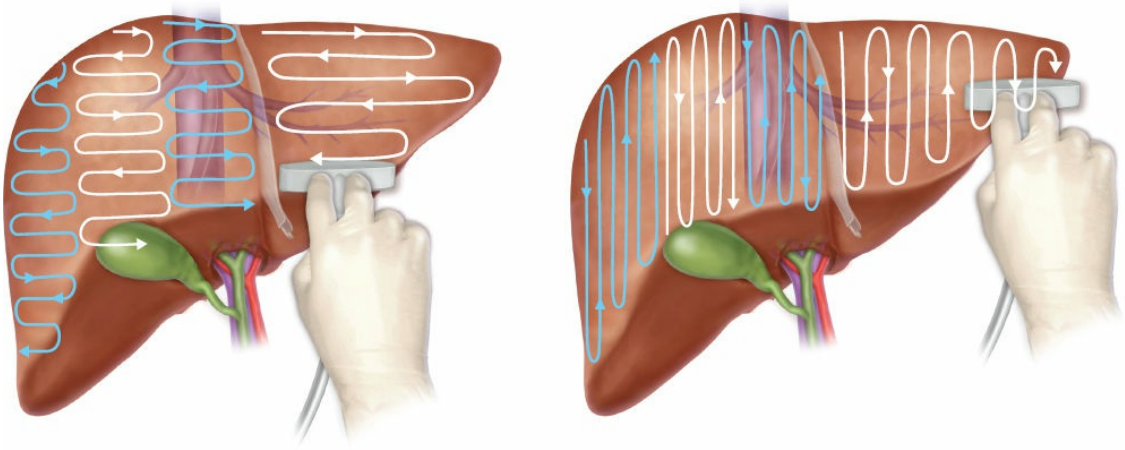

Figure 13.15. Sweep-scan of the liver parenchyma. The parenchymal scan is performed by sliding the probe across each

section of the liver from right to left across (**left image**) or up and down (**right image**) each section of the liver. Note that the probe is slid through each section, one section at a time without lifting the probe from the liver surface. To begin the next section, the probe is repositioned on the next section to be examined.

As noted in liver and biliary scanning, a systematic approach to pancreas scanning is imperative to ensure a complete and thorough scan of the organ (Table 13.4). The pancreas is imaged using indirect followed by direct (contact) scanning, and then by probe standoff in order to ensure a complete examination of the organ. It is helpful to identify the surrounding vessels in order to identify the pancreatic tissue (Fig. 13.21). Start the examination in the longitudinal plane by identifying the superior mesenteric vein or portal vein as it passes posteriorly to the pancreatic neck. Sliding the probe distally (toward the patient's left), the neck, body, and tail of the pancreas are scanned. The splenic vein, which is located just posterior to the pancreatic tissue, is seen in its long axis during this portion of the exam (Fig. 13.21). Also, locate the superior mesenteric artery, to the left of the portal vein/superior mesenteric vein. Identify the pancreatic duct location and size in addition to any lesion in the pancreas (Fig. 13.22). Note the proximity/involvement of any lesion to the vasculature. Once the neck, body, and tail are imaged, slide the probe back to the superior mesenteric vein/portal vein and then slide the probe proximally (toward the patient's right) in order to scan the head and uncinate process. Identify any lesion, its size, and characteristics in addition to vascular involvement/proximity. By turning the probe 90 degrees, repeat these steps in the transverse plane. Finally, when using the direct method (i.e., contact scanning), repeat the entire exam of the pancreas using a probe standoff technique in order to appreciate the superficial pancreas parenchyma.

TABLE 13.3 Systematic Approach to Biliary Ultrasound Scanning

1. Side-viewing probe
   a. Contact scanning (transhepatic)
      Gallbladder (transverse and longitudinal views)
      Intrahepatic bile ducts (transverse view)
      Extrahepatic bile ducts (transverse)
   b. Probe standoff technique (saline)
      Gallbladder, inferior aspect
      Extrahepatic/supraduodenal bile duct (transverse and longitudinal)
2. End-viewing probe
   a. Probe standoff technique (saline immersion)
      Gallbladder/cystic duct
      Extrahepatic/supraduodenal bile duct (transverse and longitudinal)
   b. Compression (transduodenal)/ Contact scanning (transpancreatic)
      Retroduodenal bile duct
      Intrapancreatic bile duct

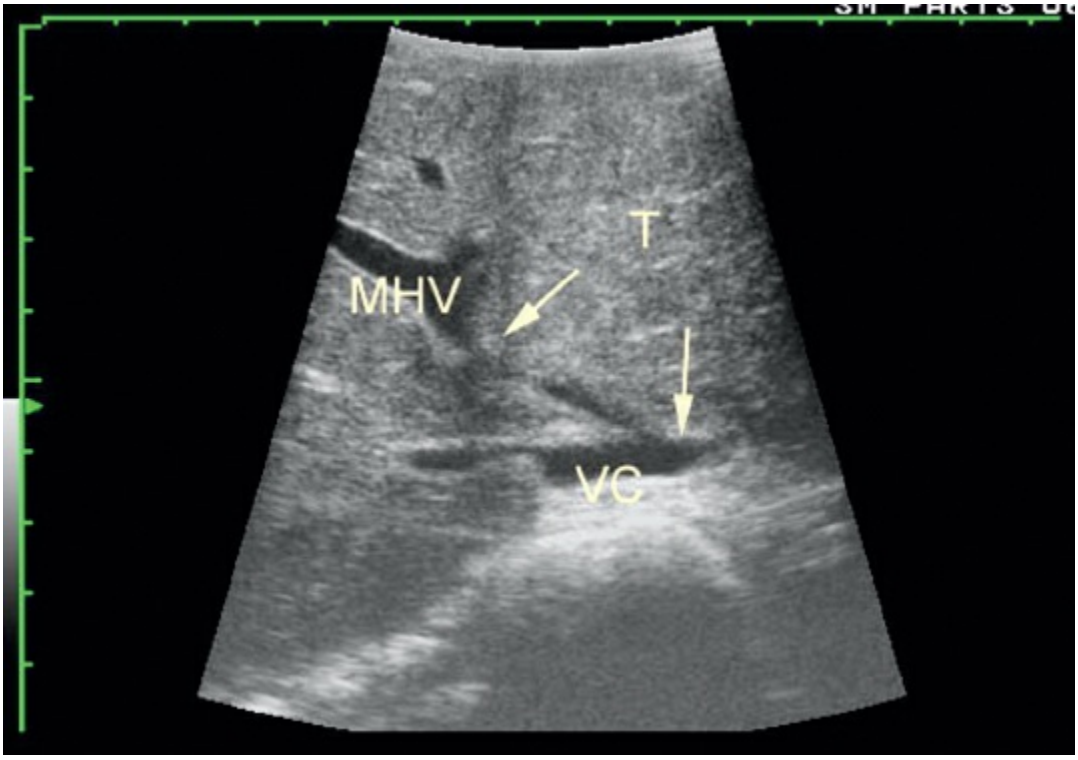

Figure 13.16. Intraoperative ultrasound is particularly important to determine the resectability of liver tumors. This was a metastatic liver tumor from a left colon cancer. The tumor (T) was located in segment 4 into segment 8, and it was invading the middle hepatic vein (MHV) and the vena cava (VC), as indicated by white arrows.

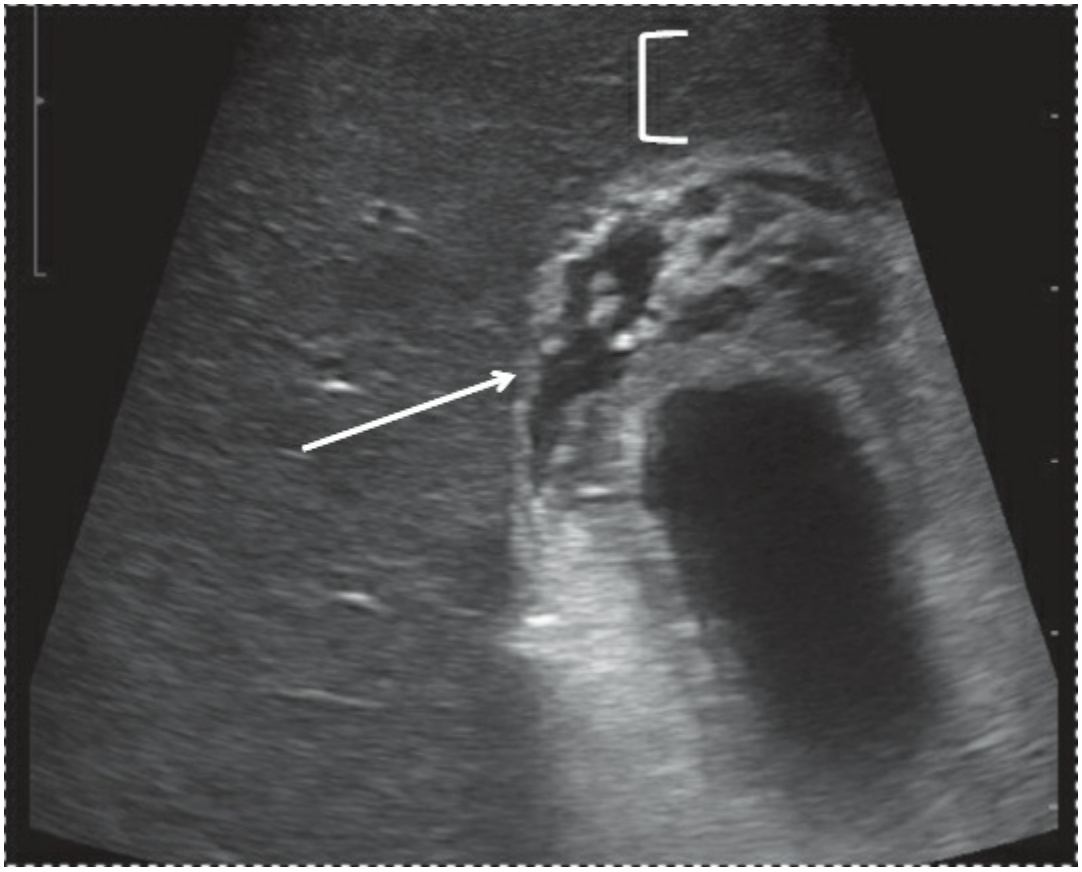

Figure 13.17. Using the liver as an acoustic window (*bracket*) is an excellent means to image the gallbladder and any underlying pathology. Demonstrated here is thickening and edema of the gallbladder wall (*arrow*) as seen in acute cholecystitis.

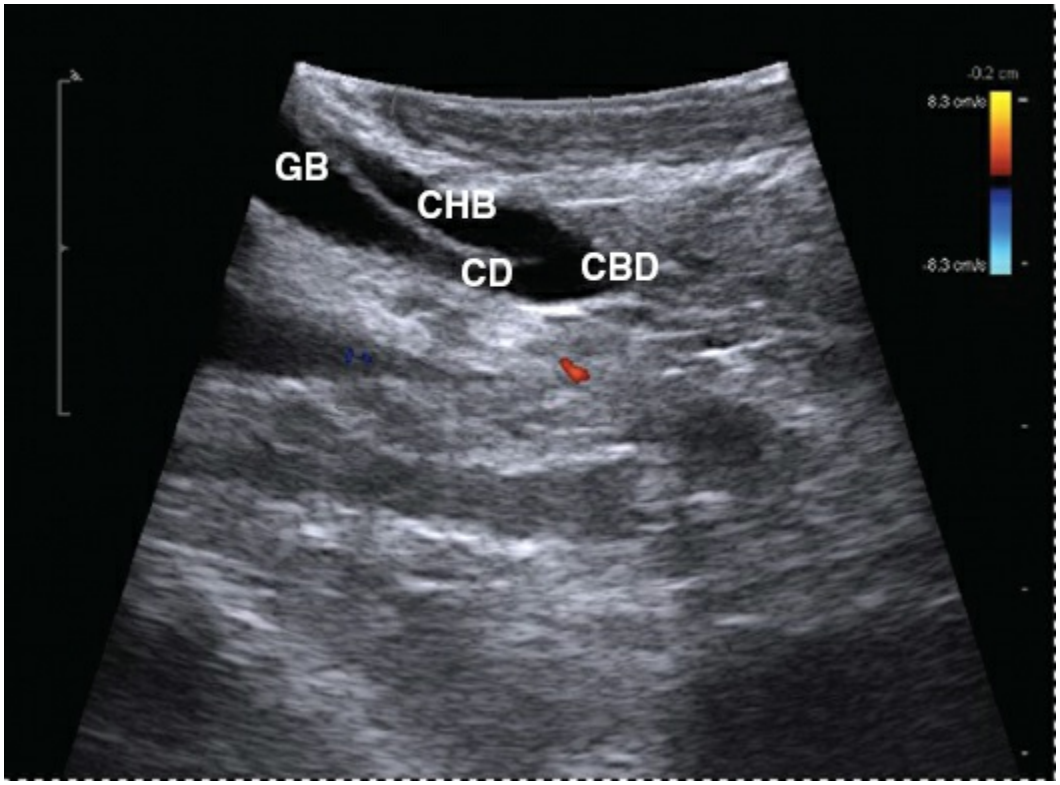

Figure 13.18. Scanning the gallbladder (GB) in the longitudinal plane toward the infundibulum leads to image the cystic duct (CD) and its junction with the common hepatic duct (CHB) to form the common bile duct (CBD).

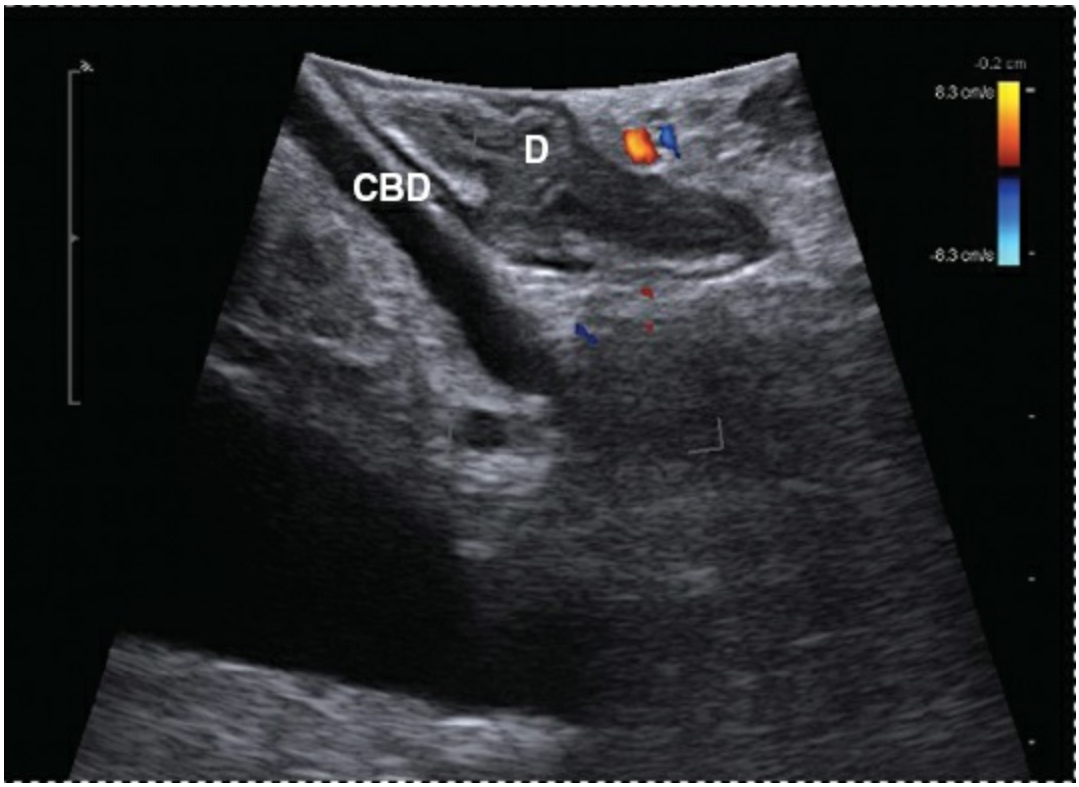

Figure 13.19. Laparoscopic scanning of the common bile duct is

an excellent means to screen for bile duct stones. Here the laparoscopic ultrasound is viewing the retroduodenal common bile duct (CBD) in its longitudinal axis, using the duodenum (D) as an acoustic window. The use of duplex is helpful to confirm the common bile duct.

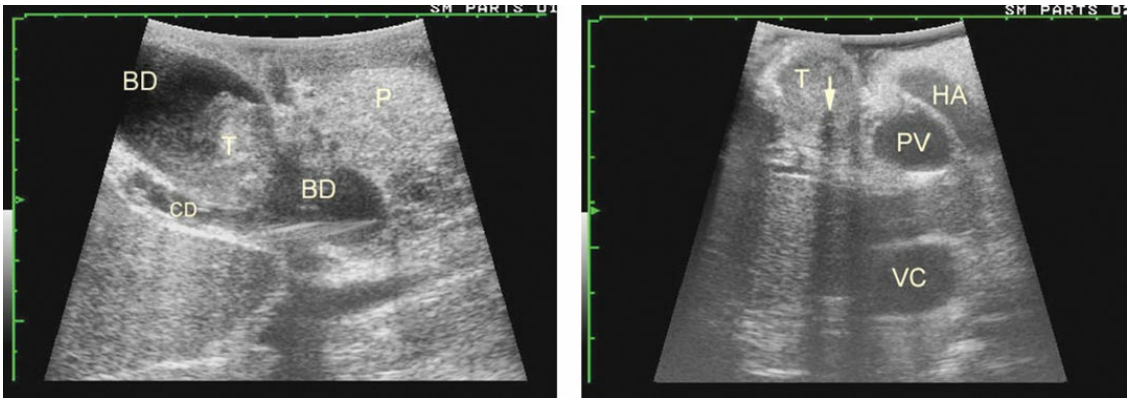

Figure 13.20. Intraoperative ultrasound showing a resectable bile duct cancer (cholangiocarcinoma). **Left:** a longitudinal view of the bile duct (BD) at the level of the junction with the cystic duct (CD). The proximal bile duct is dilated. The tumor (T) (bile duct cancer) was located at that area. It appeared to be a localized tumor. P, head of the pancreas. **Right:** in a transverse view of this cancer, there was no invasion of the tumor (T) to the portal vein (PV) and hepatic artery (HA). An arrow indicates a biliary catheter (associated with shadowing). VC, inferior vena cava.

TABLE 13.4 Systematic Approach to Pancreas Ultrasound Scanning

1. Scan the neck, body and tail (direct/contact, indirect, probe standoff)
   - Locate the portal vein/superior mesenteric vein/splenic vein
   - Scan to the right: neck, body and tail (longitudinal and transverse)
   - Identify the superior mesenteric artery
   - Scan pancreatic duct and note is size and appearance
   - Identify any lesion, its size, location, and echo characteristics
   - Define any vascular or duct involvement
2. Scan the head (direct/contact, indirect, probe standoff)
   - Locate the portal vein/superior mesenteric vein and extrahepatic bile duct
   - Scan to the left: head and uncinate process (longitudinal and transverse)
   - Identify the superior mesenteric artery
   - Identify any lesion, its size, location, and echo characteristics
   - Define any vascular involvement

LAPAROSCOPIC ULTRASOUND

LUS has become important as many of procedures are now performed by a minimally invasive approach. Because of the lack of tactile feedback, LUS is indispensable in staging laparoscopy, and in guiding laparoscopic liver resection or ablation procedures. LUS can identify critical structures during dissection and is extremely important to ensure a proper margin of resection. Screening for biliary stones and clarification of biliary tract anatomy during laparoscopic cholecystectomy has also grown in importance.

The methodology of LUS and IOUS is similar; however, there are important differences to consider in the setup and technique of LUS. The first consideration is the positioning of the ultrasound system. It is extremely important that the ultrasound machine with its display is placed on the same side as the laparoscopic monitor screen to facilitate ease of image visualization and interpretation and probe movement. If feasible, a picture-in-picture setup on the laparoscopic monitor is extremely helpful. The second difference is probe orientation. Because the laparoscopic probe is configured on a long shaft, it is difficult to replicate the transverse plane as seen during IOUS. Especially when imaging the liver, many of the images are seen in the longitudinal/oblique axis and therefore LUS may have a steeper learning curve. It is helpful to learn IOUS prior to LUS to facilitate ease of image interpretation. Probe movements during LUS are very similar as compared to IOUS, although sliding and tilting are the commonly used movements. Also similar to IOUS, contact (both indirect and direct methods) and probe standoff scanning techniques are used during LUS. Finally, the location of the trocar insertion sites depends strongly on the type of exam, the target organ of interest, and type of LUS probe (i.e., side-viewing versus front-viewing, rigid versus flexible probes) chosen. The most common trocar placement for LUS of upper abdominal organs includes periumbilical, right subcostal, and epigastric/subxiphoid positions.

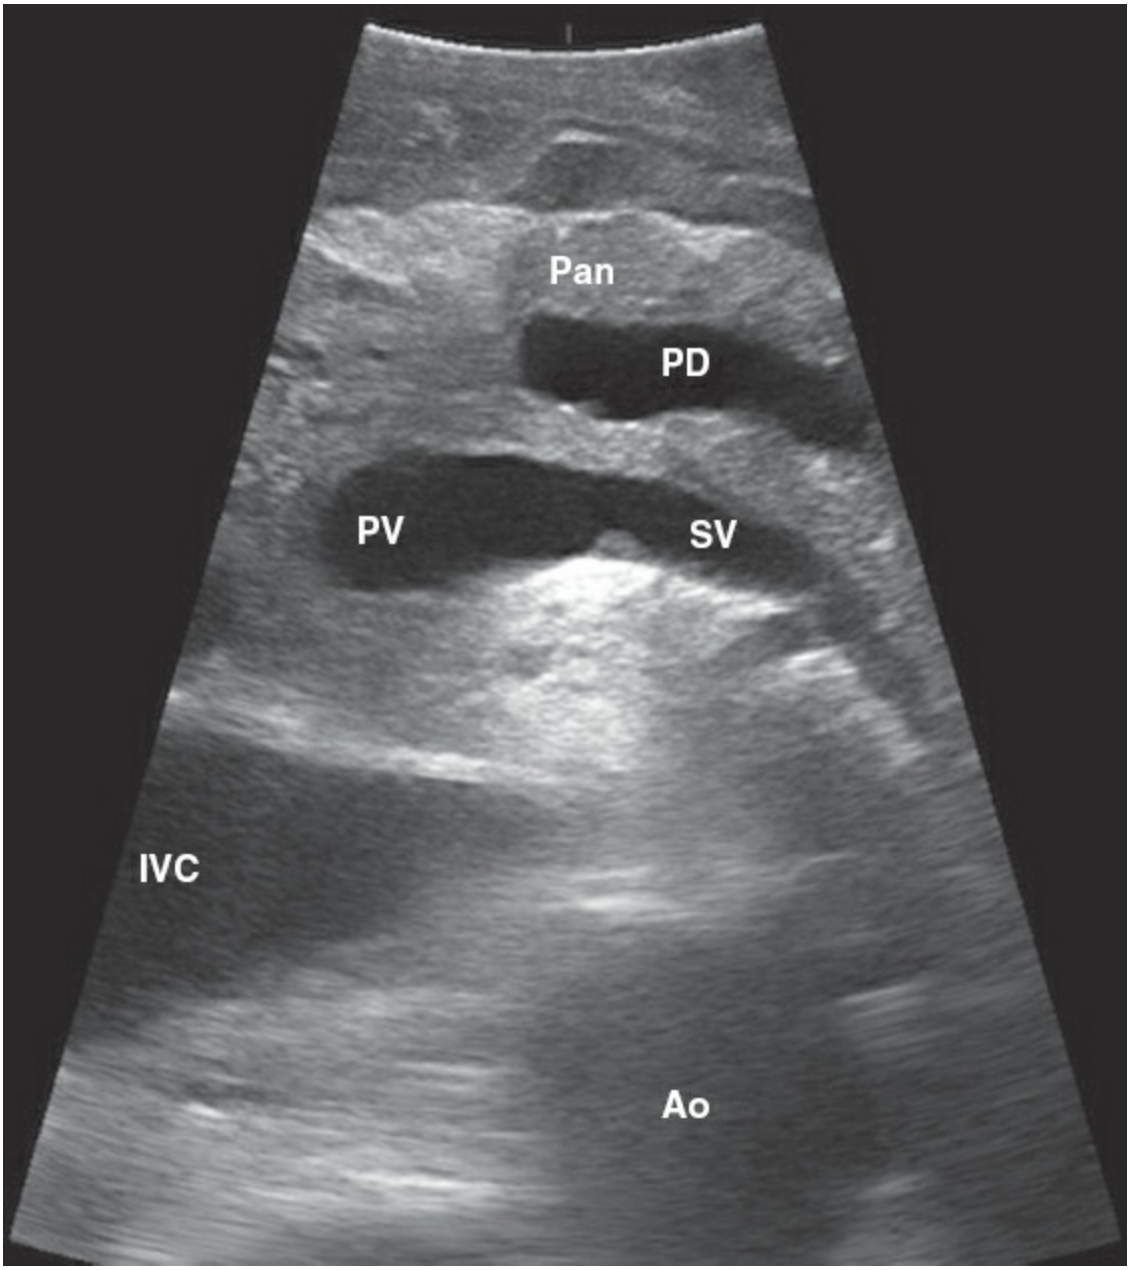

Figure 13.21. Intraoperative ultrasound of the pancreas. Using the stomach as an acoustic window (indirect scanning) is an excellent means to begin the examination of the longitudinal view of the pancreas (Pan). Identifying surrounding vasculature, such as the splenic vein (SV), portal vein (PV), and inferior vena cava (IVC), helps to clearly define the pancreatic parenchyma (Pan). Note the dilated pancreatic duct (PD) anterior to the SV and the aorta (Ao) posteriorly.

Liver Scanning Method

When performing LUS, it is very helpful to use a flexible laparoscopic probe through the right subcostal and epigastric ports. The systematic

approach for laparoscopic is similar to open intraoperative liver ultrasound as previously described (Table 13.2). It is best to begin by scanning from the right subcostal position as this offers the closest approximation to a transverse view. Scanning is begun at the superior aspect of the liver while identifying each hepatic vein and mapping its course. Next, the portal vein bifurcation is identified and each branch is followed to the segmental branches, as previously described. When scanning the portal bifurcation, it is best to move the LUS probe to the epigastric trocar to fully delineate the right portal vein and its branches. The left portal vein is easier to identify and delineate from the right subcostal port. A left subcostal trocar is rarely required for LUS. The vasculature is mapped out using a combination of sliding and tilting probe movements. Parenchymal scanning is then accomplished in the longitudinal/oblique plane beginning at the superior border of the liver and sliding the probe side to side within each section of the liver while sliding the probe toward the inferior edge of the liver. As previously described, these overlapping movements (the *sweep-scan*) allow complete scanning of the liver parenchyma. The *sweep-scan* is repeated within each section of the liver to allow a complete examination. Note the presence of any lesion, its characteristics, and proximity or involvement of vasculature. Lastly, a probe standoff technique (saline immersion) may be required, especially at the superior aspect of the liver and when evaluating superficial lesions. Alternatively, an end-viewing probe can be used for a more focused evaluation of liver lesions (rather than screening) and for subsequent ultrasound-guided liver aspiration, biopsy or ablation.

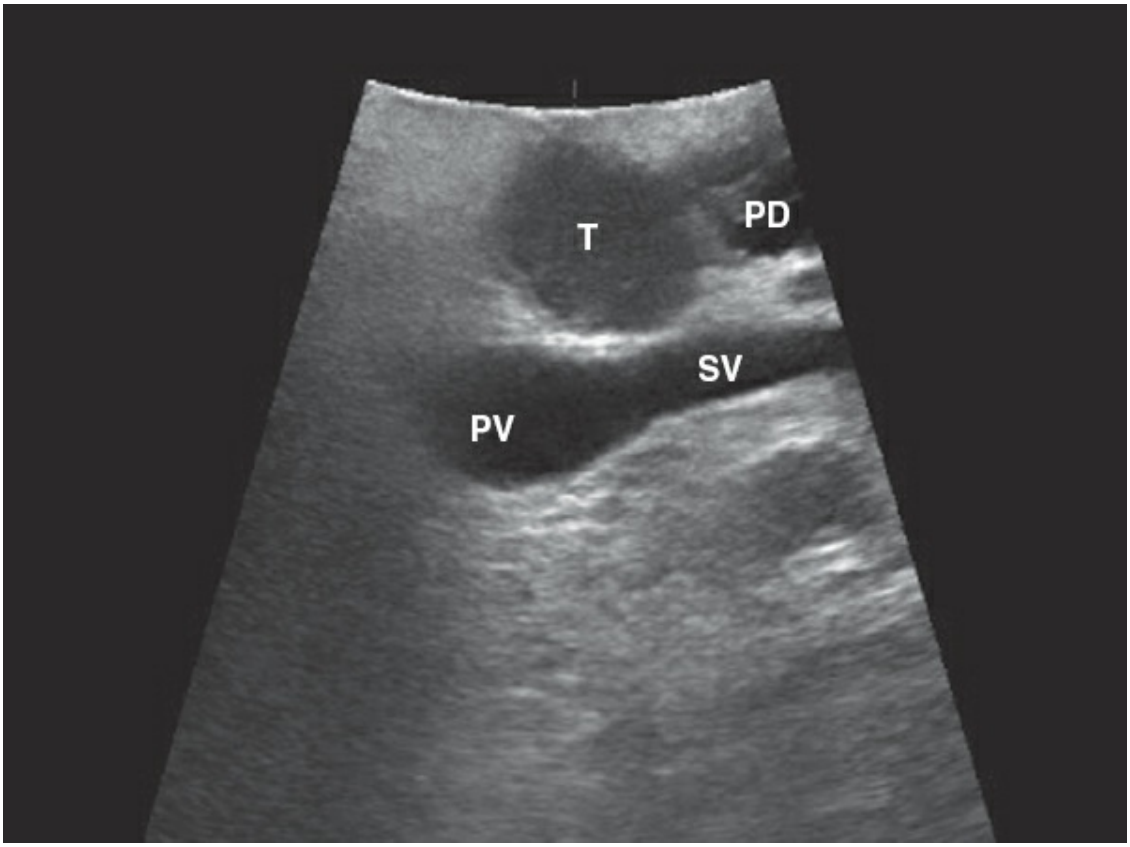

Figure 13.22. Neuroendocrine tumor of pancreas. Here seen is a hypoechoic tumor (T) of the pancreas causing compression and dilation of the pancreatic duct (PD) with the splenic vein (SV) and portal vein (PV) posteriorly. The well-defined, hypoechoic character of this lesion is a typical appearance of a neuroendocrine tumor in the pancreas.

Biliary Scanning Method

Laparoscopic biliary scanning can be achieved utilizing the flexible side-viewing probe or end-viewing probe. The choice of the probe depends on the target location of interest in addition to the surgeon's preference. As noted with IOUS, LUS of the biliary system should be undertaken prior to dissection in order to avoid introducing air into tissue planes and producing artifacts. Contact (direct and indirect) in addition to compression and probe standoff techniques is utilized. In order to ensure a complete exam, a systematic approach is imperative, as previously described (Table 13.3).

Using the flexible side-viewing probe, scanning is performed through the epigastric/subxiphoid and umbilical trocars. Begin the exam with the ultrasound probe through the epigastric/subxiphoid trocar. While retracting the fundus of the gallbladder cephalad, scan the gallbladder and slide the

probe along the gallbladder to the hepatoduodenal ligament to visualize the gallbladder and bile duct (Fig. 13.23). While the probe is positioned perpendicular and lateral to the hepatoduodenal ligament, slide (and tilt, if needed) the probe toward the liver hilum to visualize the common hepatic bile duct in the transverse plane. Sliding the ultrasound probe along the hepatoduodenal ligament produces the "Mickey Mouse" silhouette with the bile duct and hepatic artery anterior to the portal vein. The use of duplex or color Doppler ultrasound is very helpful to delineate these structures. Sliding the probe over the duodenum (compression scanning may be necessary) and the head of the pancreas visualizes the distal and intrapancreatic bile duct (Fig. 13.19). To examine the biliary system in the longitudinal plane, flex the probe tip upward (Fig. 13.23) or switch the ultrasound probe to the umbilical trocar. Place the probe on the hepatoduodenal ligament and slide it along the length of the ligament from superior to inferior. Moving the ultrasound probe down on the duodenum allows visualization of the distal bile duct (Fig. 13.24). During laparoscopic cholecystectomy, laparoscopic evaluation of the bile ducts can be accomplished for the screening of biliary stones and ensuring safety of the bile duct following cystic duct ligation (Fig. 13.25).

Pancreas Scanning Method

The basic steps of laparoscopic pancreas ultrasound are similar to those of IOUS. Scanning is best done from the right subcostal and periumbilical trocars. The pancreas is imaged in the longitudinal and transverse planes using the duodenum, stomach, or gastrohepatic/gastrocolic ligaments as an acoustic window. Because the pancreas is visualized through organs or tissues, exposure of the anterior surface of the pancreas is not required for a screening examination.

As seen in the liver and biliary scanning, a systematic approach to examination should be undertaken (Table 13.4). Scanning should begin from the right subcostal port to view the pancreas in the longitudinal view of the neck, body, and tail. Sliding the probe toward the patient's right allows examination of the pancreatic head and uncinate process. Switching the probe to the umbilical port allows examination of the pancreas in the transverse plane. Saline immersion may also be necessary. The head of pancreas is also examined from the subxiphoid port together with scanning of distal or intrapancreatic bile duct.

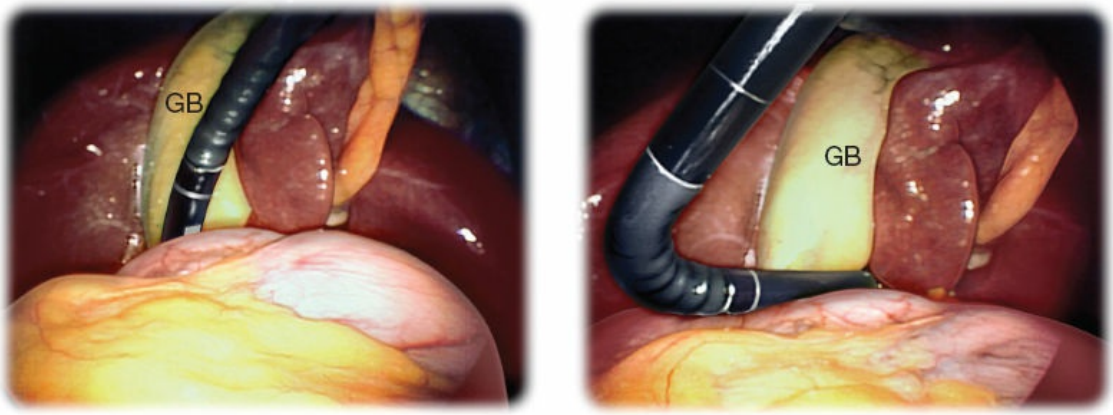

Figure 13.23. Laparoscopic ultrasound scanning of the gallbladder and bile duct using a flexible-tip probe via the subxiphoid port. The gallbladder (GB) is retracted superiorly over the liver. Sliding the probe along the gallbladder toward the bile duct demonstrates the bile duct in the transverse view (**left picture**). After upward flexion of the probe tip, the longitudinal view of the bile duct is then demonstrated (**right picture**).

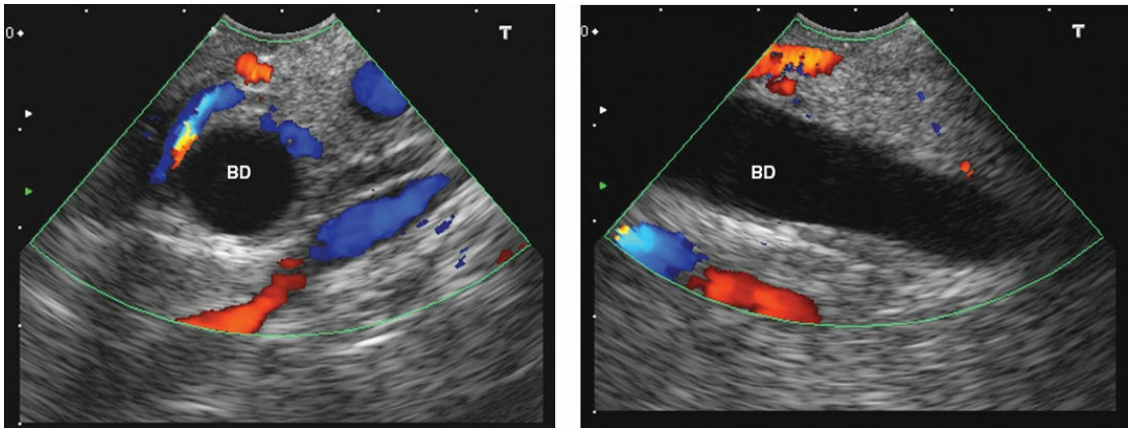

Figure 13.24. Laparoscopic scanning of the extrahepatic bile duct using an end-viewing LUS probe. The initial scan is performed in the transverse view (**left image**) and by rotating the probe demonstrates the longitudinal view (**right image**) of the extrahepatic hepatic bile duct. Note the use of duplex or color Doppler ultrasound helps to differentiate the extrahepatic bile duct from surrounding vasculature.

ULTRASOUND-GUIDED PROCEDURES

Ultrasound can be used to guide procedures in the operating room. These procedures can be divided into (1) ultrasound-guided targeting (biopsy, ablation, or duct cannulation), (2) ultrasound-guided procedure planning, and (3) ultrasound-guided tissue dissection.

Targeting

Technique

Targeting of a lesion for either biopsy or ablation can be performed under ultrasound guidance. It is necessary that the ultrasound probe be positioned *over* the lesion of interest and *flat* (not tilted) against the tissue to provide a clear image along the length of the probe. When targeting a lesion, it is preferable to perform "in-plane" targeting, which refers to passing the needle through the tissue parallel to and directly beneath the ultrasound probe. This allows visualization of the entire length of the needle during targeting. When performing IOUS-targeting, there is greater ease of motion with exposure of the organ of interest. However, during LUS-targeting, there is less flexibility of motion given the interference of the abdominal wall, and laparoscopic targeting becomes more challenging. Planning a proper needle trajectory ideally in line with the LUS probe is extremely important. If an "in-plane" approach is not feasible, then an "out-of-plane" approach becomes necessary. When a needle is inserted out of plane, it is passed perpendicular to the ultrasound probe and is visible only briefly as it passes the plane of the visualized tissue. This technique of targeting is technically difficult with limited experience. Some LUS devices have built-in biopsy channels or needle guidance systems. This is a useful adjunct when available.

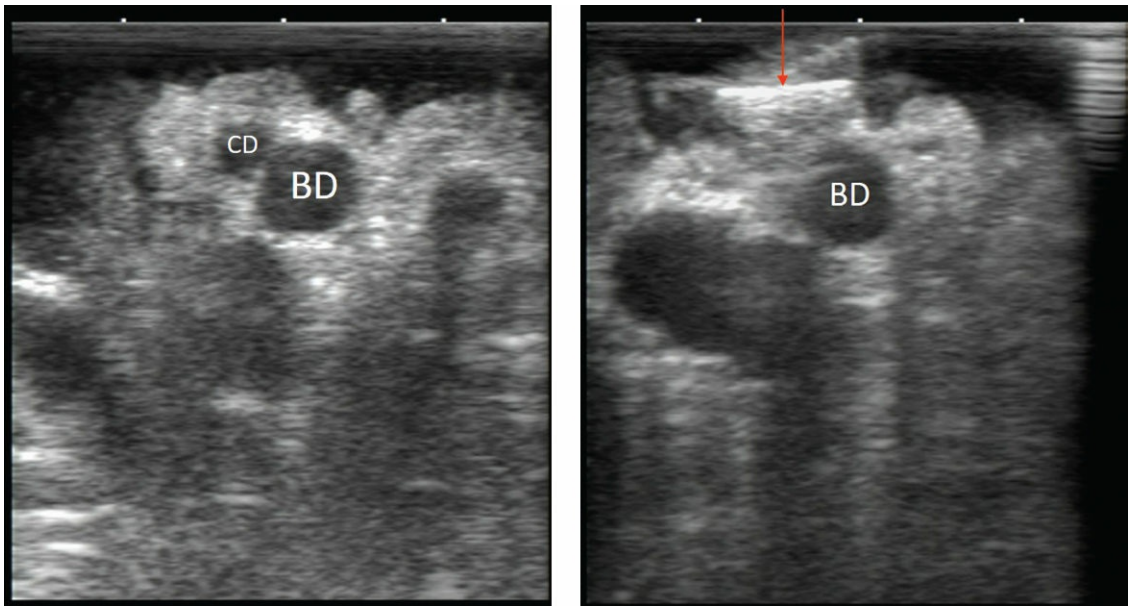

Figure 13.25. Biliary scanning during laparoscopic cholecystectomy. The bile duct (BD) and cystic duct (CD) are identified before tissue dissection and application of clips during cholecystectomy (**left image**). After clipping of the cystic duct, a

clip is visualized (*red arrow*) away from the bile duct (BD), which is intact (**right image**).

Procedures

Ultrasound-guided needle placement aids biopsy of tumors (especially nonpalpable tumors), aspiration of cystic lesions, injection of contrast or other agents, cannulation of bile or pancreatic duct, and ablation of tumors. Following needle placement under ultrasound guidance, biopsy of liver, pancreatic, or other abdominal tumors or suspicious lymph nodes can be performed. Ultrasound-guided needle biopsy is particularly indispensable for deeply located, invisible, nonpalpable tumors or lymph nodes. Ultrasound-guided fluid aspiration can be carried out for fluid-filled lesions, such as liver and pancreatic cysts, and intra-abdominal abscesses. Ultrasound-guided aspiration is also used to confirm the location of the bile duct or pancreatic duct. Agent injection, such as alcohol injection of small hepatocellular carcinomas or celiac ganglion block, can be guided by ultrasound. Ultrasound can also assist in bile duct cannulation and injection of contrast material for intraoperative radiographic examination (e.g., intraoperative cholangiography). Similar to ultrasound-guided needle placement for biopsy, an ablation cannula or probe can be passed into a tumor for thermal ablation, such as microwave or radiofrequency. Furthermore, the ablation process can be precisely planned and monitored with ultrasound (Fig. 13.26).

Ultrasound-Guided Procedure Planning

Ultrasound in the operating room can be used to stage malignancy, determine resectability, determine the extent of operation, and finally to plan the procedure. Certain malignancies are typically staged with diagnostic laparoscopy, and the use of ultrasound may determine, for example, occult metastatic disease in the liver and lead to a change in the plan of the procedure.

Use of ultrasound in the operating room for a planned oncologic resection can assist the surgeon to determine the extent of the operation and tumor resectability (Fig. 13.16). For example, use of ultrasound while operating for a pancreatic adenocarcinoma can assist in defining the limits of the tumor and potential vascular involvement. Similarly, ultrasound can determine involvement of the portal or arterial vasculature during resection of an extrahepatic biliary cancer (Fig. 13.20). Use of ultrasound during a

planned liver resection may find occult disease and the original planned extent of liver resection may be altered. A change in the operative plan with the use of ultrasound occurs between 10% and 15% of cases even with preoperative modern cross-sectional imaging.

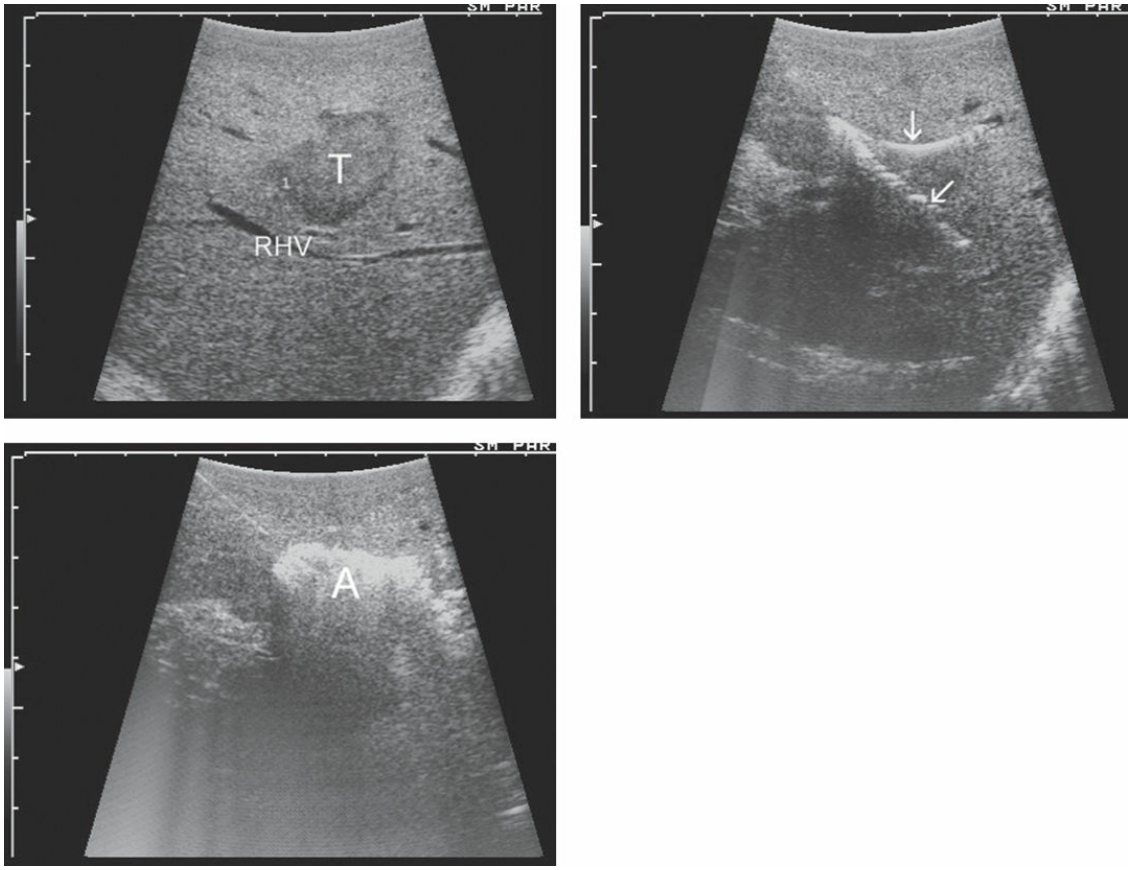

Figure 13.26. Ultrasound-guided radio frequency ablation process. A metastatic tumor (T) was found in segment 8 (**left upper image**). RFA needles (*arrows*) were deployed (**right upper image**), and ablation was undertaken. Ablated areas (A) became hyperechoic due to outgassing (**right lower image**). RHV, right hepatic vein.

The use of ultrasound during hepatic resection is imperative to define the vasculature. Recognizing the variations in portovenous and hepatic venous anatomy is critical in hepatic surgery. Ultrasound can identify the presence of clinically significant abnormalities, which can guide or alter the operation. For example, a significant percentage of patients have variations in both the number and organization of the hepatic veins. An inferior right hepatic vein is found 10% to 15% of patients which drains directly into the inferior vena cava caudal to the right hepatic vein. The presence of this accessory hepatic vein allows resection of segment 7 with

the right hepatic vein while allowing for the preservation of segment 6. Segmental anatomy, as defined by its portal supply, can be delineated easily with ultrasound, either IOUS or LUS, and a limited resection can be undertaken in a patient, for example, with cirrhosis. Knowledge of the particular patient's anatomy and the extent of disease are paramount in planning hepatobiliary and pancreatic resections and guiding surgery once it has begun.

Ultrasound-Guided Tissue Dissection

Ultrasound-guided tissue dissection can assist in guiding resection or incision of solid organs such as the liver or pancreas. During operations for chronic pancreatitis, dilated pancreatic ducts and small pancreatic pseudocysts are often not palpable. In such instances, incision of the pancreatic parenchyma (pancreatotomy) or incision of the cyst wall can be guided by ultrasound for internal drainage (e.g., Puestow operation or cystogastrostomy). For enucleation of islet cell tumors of the pancreas, especially those which are nonpalpable, ultrasound-guided pancreatotomy can be utilized in addition to initial accurate localization of the tumor.

Ultrasound-guided tissue dissection for resection is performed in various organs; however, it is used most frequently during hepatic resection, such as major hepatectomy, partial hepatectomy, segmentectomy, and other nonanatomical resections. During hepatic resection, the transecting plane of the liver is clearly delineated on ultrasound images, and therefore ultrasound can direct resection to ensure an adequate tumor margin and completeness of resection. Segmental liver resection is possible only by identifying the portal and hepatic veins under ultrasound to define the limits of resection. Tumors of the pancreas or biliary system can be also resected with the assistance of ultrasound guidance. When laparoscopic surgery is performed for these operations (e.g., hepatectomy, pancreatectomy, and cystogastrostomy), ultrasound guidance can be used laparoscopically in a manner similar to open surgery for incision or resection. As laparoscopic liver resection techniques continue to diffuse the surgical community, the use of ultrasound becomes imperative to identify tumors and to guide liver resection to ensure a proper margin in the absence of tactile feedback.

TRAINING IN SURGICAL ULTRASOUND

Realizing the value of surgical ultrasound is fundamental to motivating the

surgeon to train for proficiency in performing, interpreting, and utilizing ultrasound in practice. Interpretation of a 2D real-time ultrasound image requires familiarity with how the position of probe (transducer) relates to the image on the monitor screen. This probe-image orientation requires hand–eye coordination by the operator in order to understand where a particular anatomic region is represented on the screen. To acquire this type of orientation, the surgeon who is not familiar with the ultrasound probe and scan display on the monitor is well advised to practice with the probe in a small basin of water; for example, scanning a freshly excised surgical specimen such as a gallbladder. With such practice, image orientation of a target in relation to the position of the probe will be observed and interpretation of images will be facilitated. Although an ultrasound learning curve may appear steep, a surgeon's knowledge of 3D anatomy enables a faster understanding of ultrasound images.

The main obstacle to utilizing ultrasound in the operating room is the difficulty in obtaining sufficient training. Currently, ultrasound is incorporated into many, but not all, surgical residency and fellowship programs. For those surgical residencies without a formal curriculum, the American College of Surgeons offers *Ultrasound for Residents* exported course. A standardized ultrasound training platform for hepato-pancreato-biliary fellows is offered through Americas Hepato-Pancreato-Biliary Association annually. However, for surgeons in practice a formalized curriculum and consistent practice is extremely important. Formalized training in surgical ultrasound including hands-on sessions can be obtained through the American College of Surgeons (*Ultrasound for Surgeons* (basic course)*; Advanced HPB Ultrasound*) and through the Americas Hepato-Pancreato-Biliary Association (*HPB Ultrasound and Advanced Technology*). Taking such courses followed by practical application is helpful for surgeons, especially for the ultrasound neophyte, who is interested in getting started in ultrasound. For general surgeons, particularly hepatobiliary, pancreatic, surgical oncologists, and laparoscopic surgeons, it is critically important to master ultrasound skill.

CONCLUSIONS

Intraoperative ultrasound, both IOUS and LUS, can provide various diagnostic information which is otherwise not available and can guide or assist various surgical procedures in real-time. IOUS is commonly performed during hepatobiliary, pancreatic, endocrine, cardiovascular, and

neurologic surgery; however, its applications are expanding to other surgical fields. Advantages of IOUS, including safety, speed, high accuracy, comprehensive anatomical information and real-time guidance capability, outweigh its disadvantages such as specific equipment requirement and slow learning curve. The use of IOUS by surgeons is expected to increase along with more formal training and experience in ultrasound for surgeons. New ultrasound technologies such as ultrasound contrast enhancement, 3D and 4D ultrasound, elastography, and high-intensity focused ultrasound will be utilized more during future IOUS, and may potentially improve surgical outcome. Being safe, quick, accurate, and versatile intraoperatively, ultrasound is a valuable technique which is recommended to master for surgeons in various fields to improve intraoperative decision making and surgical procedures.

EDITOR'S COMMENT

The utility of IOUS has increased over the last three decades. An appreciation for the growth of this imaging modality must be firmly rooted in an understanding of the three remarkable periods in the history of IOUS. The first period was marked by the use of A-mode or non-real-time B-mode ultrasound in 1960s. The second period, which encompassed the late 1970s and the 1980s, included the expansion of IOUS with real-time B-mode ultrasound, while the current era includes the utility of laparoscopic ultrasound and color Doppler imaging.

Wild and Reid's diagnosis of a malignant cerebral tumor marked the first successful use of intraoperative A-mode ultrasound (White DN. Historical

survey. In: White DN, ed. *Ultrasound in Medical Diagnosis*. Kingston, Ontario: Ultramedison; 1976:1–36). Thereafter, several investigators utilized ultrasound for the intraoperative detection and localization of renal calculi, biliary calculi, and cerebral mass lesions (Takayasu H, Aso Y. Intraoperative diagnosis of retained renal calculi by ultrasound. *Jpn Soc Ultrason Med Proc* 1967;11:117–8; Yamakawa K, Naito S, Azuma K, et al. Laparoscopic diagnosis of intraabdominal organs: ultrasound diagnosis through laparoscopy. *Jpn J Gastroenterol* 1958;55:741; Hayashi S, Wagai T, Miyazawa R, et al. Ultrasonic diagnosis of breast tumor and cholelithiasis. *West J Surg Obstet Gynecol* 1962;70:34–40). The end of the first period was also significant for epicardial M-mode IOUS for the preoperative and postoperative evaluation of cardiac function in patients undergoing valve surgery (Johnson MC, Holmes JH, Spangler RD, et al. Usefulness of echocardiography in patients undergoing mitral valve surgery. *J Thorac Cardiovasc Surg* 1972;64:922–34; Spotnitz HM, Malm JR, King DL, et al. Outflow tract obstruction in tetralogy of Fallot. Intraoperative analysis by echocardiography. *NY State J Med* 1978;78:1100–3).

Real-time 2D B-mode imaging systems ushered in the second period of the IOUS era. Cook and Lytton in the United States and Makuuchi et al. in Japan were the first to describe the use of IOUS with B-mode real-time imaging (Cook JH III, Lytton B. Intraoperative localization of renal calculi during nephrolithotomy by ultrasound scanning. *J Urol* 1977;117:54; Makuuchi M, Kamiya K, Sugiura M, et al. Ultrasonic examination by electronic scanning during operation. Proceedings of the 32nd Meeting of the Japan Society of Ultrasonics in Medicine, 1977:129–130. 3–546). Cook and Lytton employed IOUS for precise localization of renal calculi to facilitate their removal while Makuuchi et al. applied IOUS for the examination of the liver and pancreas. The expansion of ultrasound technology quickly spread to endocrine (Sigel B, Kraft AR, Nyhus LM, et al. Identification of a parathyroid adenoma by operative ultrasonography. *Arch Surg* 1981;116:234–5; Lane RJ, Coupland GA. Operative ultrasonic features of insulinomas. *Am J Surg* 1982;144:585–7), neurologic (Dohrmann GJ, Rubin JM. Use of ultrasound in neurosurgical operations: a preliminary report. *Surg Neurol* 1981;16:362–6; Shkolink A, McLane DG. Intraoperative real-time ultrasonic guidance of ventricular shunt placement in infant. *Radiology* 1981;141:515–7) and cardiovascular indications (Wong CY, Spotnitz HM. Systolic and diastolic properties of the human left ventricle during valve replacement for chronic mitral regurgitation. *Am J Cardiol* 1981;47:40–9; Spotnitz HM, Malm JR. Two-dimensional ultrasound and cardiac operations. *J Thorac Cardiovasc Surg* 1982;83:43–51). IOUS use gradually increased through the 1980s, with refinement of real-time B-mode ultrasound. Four major benefits of IOUS refinement included the acquisition of new information useful for intraoperative decision making, its use as a complement to or replacement for intraoperative radiography, its utilization as guidance for various surgical procedures, and its role in the confirmation of completion of an operation.

The current era of ultrasound has been marked by the utility of laparoscopic ultrasound and color Doppler imaging. IOUS with color Doppler imaging was first performed during cardiovascular surgery to evaluate cardiac diseases and adequacy of valvular repair. This modality was also found to be useful for the detection of postreconstruction vascular defects and for supplemental hemodynamic information in renal, carotid, and peripheral arterial reconstructions (Bandyk DF, Govostis DM. Intraoperative color flow imaging of difficult arterial reconstructions. *Video J Color Flow Imaging* 1991;1:13–20; Machi J, Sigel B, Roberts AB, et al. Operative color Doppler imaging for vascular surgery. *J Ultrasound Med* 1992;11:65–71). As this chapter's authors have described, the addition of color Doppler to B mode ultrasound revolutionized hepatobiliary surgery by allowing for better delineation of small vessels and biliary ducts.

The use of laparoscopic ultrasound has grown in parallel with the widespread performance of laparoscopic cholecystectomy. Many applications of IOUS were developed to compensate for the loss of tactile feedback that occurs during laparoscopy, including the delineation of the biliary anatomy and evaluation of the common bile duct for calculi (Barteau JA, Castro D, Arregui ME, et al. A comparison of intraoperative ultrasound versus cholangiography in the evaluation of the common bile duct during laparoscopic cholecystectomy. *Surg Endosc* 1995;9:490–6; Goletti O, Buccianti P, Ferrari M, et al. Laparoscopic ultrasonography: a real alternative to cholangiography during laparoscopic cholecystectomy? *Hepato-Gastroenterol* 1995;42:612–8). The application of minimally invasive ultrasonography has also facilitated the accurate staging of esophageal, gastric, pancreatic, and thoracic malignancies (John TG, Greig JD, Garden OJ. Carcinoma of the pancreatic head and periampullary region: tumor staging with laparoscopy and laparoscopic ultrasonography. *Ann Surg* 1995;221:156–64; Murugiah M, Paterson-Brown S, Windsor JA, et al. Early experience of laparoscopic ultrasonography in the management of pancreatic carcinoma. *Surg Endosc* 1993;7:177–181; Pietrabissa A, Di Candio G, Giulianotti PG, et al. Laparoscopic exposure of the pancreas and staging of pancreatic cancer. *Semin Laparosc Surg* 1996;3:3–9). It is clear that the emergence of 3D technology, ultrasonographic contrast media, ultrasmall endoluminal probes, color Doppler, and power Doppler technologies will further support the growth of this field.

Given the history of ultrasonography, I believe it important to consider additional indications for this technology. Chief among these uses are trauma and breast surgery.

The use of ultrasound in the evaluation of abdominal trauma was first described in 1971 by Kristensen and colleagues (Kristensen JK, Buemann B, Kühl E. Ultrasonic scanning in the diagnosis of splenic haematomas. *Acta Chir Scand* 1971;137:653–7). Rozycki and colleagues coined the term FAST (focused assessment with sonography for trauma) in 1996 to describe an emergency room assessment of ultrasound evaluation of patients who suffered

truncal trauma (Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment. *J Trauma* 1995;39:492–8). The continued growth of this modality has transformed it from a method of detection of free intra-abdominal fluid to that of specific injury identification and from an adjunct for other screening/diagnostic modalities to an exclusive diagnostic modality in an effort to decrease cost and invasiveness. Many reports have demonstrated sensitivities between 67% and 80% due to multiple confounding variables. In contrast, specificity and accuracy have been reported to range from 98% to 100% and 98% to 99%, respectively (Rozycki GS, Ochsner MG, Schmidt JA, et al. A prospective study of surgeon-performed ultrasound as the primary adjuvant modality for injured patient assessment. *J Trauma* 1995;39:492–8; Miller MT, Pasquale MD, Bromberg WJ, et al. Not so FAST. *J Trauma* 2003;54:52–9; Rose JS, Levitt MA, Porter J, et al. Does the presence of ultrasound really affect computed tomographic scan use? A prospective randomized trial of ultrasound in trauma. *J Trauma* 2001;51:545–50; Ma OJ, Mateer JR, Ogata M, et al. Prospective analysis of a rapid trauma ultrasound examination performed by emergency physicians. *J Trauma* 1995;38:879–85; Luks FI, Lemire A, St-Vil D, et al. Blunt abdominal trauma in children: the practical value of ultrasonography. *J Trauma* 1993;34:607–10; McKenney M, Lentz K, Nunez D, et al. Can ultrasound replace diagnostic peritoneal lavage in the assessment of blunt trauma? *J Trauma* 1994;37:439–41; Tso P, Rodriguez A, Cooper C, et al. Sonography in blunt abdominal trauma: a preliminary progress report. *J Trauma* 1992;33:39–43; Jehle D, Guarino J, Karamanoukian H. Emergency department ultrasound in the evaluation of blunt abdominal trauma. *Am J Emerg Med* 1993;11:342–6).

The application of ultrasound technology to breast conservation therapy (BCT) for breast cancer has undergone significant expansion over the past decade. Although the primary goal of BCT is to obtain tumor-free resection margins, positive margins, and re-excisions after lumpectomy are still reported in up to 40% of patients (Sanchez C, Brem RF, McSwain AP, et al. Factors associated with re-excision in patients with early-stage breast cancer treated with breast conservation therapy. *Am Surg* 2010;76:331–4; Coopey S, Smith BL, Hanson S, et al. The safety of multiple re-excisions after lumpectomy for breast cancer. *Ann Surg Oncol* 2011;18:3797–801; Krekel N, Zonderhuis B, Muller S, et al. Excessive resections in breast-conserving surgery: a retrospective multicentre study. *Breast J* 2011;17:602–9; Singletary SE. Surgical margins in patients with early-stage breast cancer treated with breast conservation therapy. *Am J Surg* 2002;184:383–93; Krekel NM, Zonderhuis BM, Stockmann HB, et al. A comparison of three methods for nonpalpable breast cancer excision. *Eur J Surg Oncol* 2011;37:109–15). The secondary goal of BCT is the cosmetic outcome; however, up to 30% of patients report being unsatisfied with the cosmetic outcome (Vrieling C, Collette L, Fourquet A, et al. The influence of patient, tumor and treatment factors on the cosmetic results

after breast-conserving therapy in the EORTC “boost vs. no boost” trial. EORTC Radiotherapy and Breast Cancer Cooperative Groups. *Radiother Oncol* 2000;55:219–32; Wang HT, Barone CM, Steigelman MB, et al. Aesthetic outcomes in breast conservation therapy. *Aesthet Surg J* 2008;28:165–70; Parvez E, Cornacchi SD, Hodgson N, et al. A cosmesis outcome substudy in a prospective, randomized trial comparing radioguided seed localization with standard wire localization for nonpalpable, invasive, and in situ breast carcinomas. *Am J Surg* 2014;208:711–17). Taken together, these findings suggest that additional approaches to the acquisition of appropriate margins and cosmesis are much needed. Current data suggests that breast IOUS provides for a significantly improved acquisition of negative margins relative to other localization techniques for palpable and nonpalpable breast tumors. A 2013 meta-analysis of patients with nonpalpable breast cancer treated with IOUS versus wire-guided localization was performed on one randomized controlled trial (RCT) and nine cohort studies containing 739 patients. A statistically significant difference was found between IOUS and WGL in terms of tumor-free margins favoring IOUS (OR = 0.52; 95% CI: 0.38–0.71) (Ahmed M, Douek M. Intra-operative ultrasound versus wire-guided localization in the surgical management of non-palpable breast cancers: systematic review and meta-analysis. *Breast Cancer Res Treat* 2013;140:435–46). The COBALT trial was the first multicenter RCT for palpable cancer comparing IOUS with palpation alone to evaluate both oncologic and cosmetic outcomes. This trial demonstrated a 3% rate of tumor-involved margin rate for the invasive component in the IOUS group compared to 17% in the palpation-only group (Krekel NM, Haloua MH, Lopes Cardozo AM, et al. Intraoperative ultrasound guidance for palpable breast cancer excision (COBALT trial): a multicentre, randomised controlled trial. *Lancet Oncol* 2013;14:48–54). Current training in ultrasound techniques and emerging technology has extended the utility breast IOUS to achieve adequate margins with acceptable cosmesis.

The continued growth of IOUS has improved the management of patients with a variety of diseases; however, recent developments can extend the usefulness of IOUS. Ultrasonic elastography is a noninvasive method of estimating the elasticity of tissues and thereby identifying and characterizing breast and liver tumors (Itoh A, Ueno E, Tohno E, et al. Breast disease: clinical application of US elastography for diagnosis. *Radiology* 2006;239:341–50; Omichi K, Inoue Y, Hasegawa K, et al. Differential diagnosis of liver tumours using intraoperative real-time tissue elastography. *Br J Surg* 2015;102:246–53). In addition, IOUS elastography can provide real-time visualization of changes in tissue properties after local ablation techniques (Mariani A, Kwiecinski W, Pernot M, et al. Real time shear waves elastography monitoring of thermal ablation: in vivo evaluation in pig livers. *J Surg Res* 2014;188:37–43). Finally, the combination of preoperative planar imaging and IOUS guidance can provide updated information during surgery, thereby improving the precision of surgery.

John H. Stewart, IV

14 Tumor Ablation: Technologies and Clinical Applications

Michael S. Sabel

INTRODUCTION

The principal components of multimodality cancer therapy remain the systemic therapies (cytotoxic chemotherapies, biologic therapies, and targeted therapies), radiation therapy, and surgery. There have been tremendous advances in all three modalities. While surgery has become less invasive, with fewer complications, it still involves the extirpation of a tumor. An alternative to surgery is tumor ablation.

Tumor ablation is defined as the direct application of a chemical or energy-based (thermal and nonthermal) therapy to eradicate or substantially destroy focal tumors. This is in contrast to indirect ablation, which involves the use of oral, intravenous, intra-arterial, or intracavitary agents. Ablation techniques are used for both benign tumors (such as fibroadenomas or angiomyolipomas), metastatic lesions, and increasingly for primary tumors. In the case of cancer, the goal of ablation is 100% eradication of all viable malignant cells, and this often involves ablating the visible tumor along with an adequate margin of normal tissue surrounding it.

Ablative modalities can be divided into two categories. The first are the chemical ablations, or nonenergy based. The second are the energy-based ablations, which can be further divided into thermal and nonthermal. The terminology can often be confusing and misleading. Often these technologies are described as “minimally invasive”; however, this can refer to any approach that is less invasive than conventional surgery, and is more commonly used to describe endoscopic surgery. Another commonly used term is “percutaneous,” but this can also be misleading. While many of these modalities involve the percutaneous placement of an applicator or probe, several do not.

Ablative technologies are highly dependent upon *image guidance*, and optimal outcomes hinge on the ability to visualize the entire tumor mass

for appropriate pretreatment planning as well as through the treatment cycle. Several imaging modalities are used for tumor ablation, including ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET). In many cases, more than one imaging modality can be used for any available ablation technique, and one may be preferable over another depending on the site, size, and shape of the tumor mass to be ablated.

This chapter will review the present technologies available for tumor ablation, review the principles of ablation, and describe their present clinical uses and future potential.

POTENTIAL BENEFITS OF TUMOR ABLATION

One of the most significant potential advantages to tumor ablation is the ability to eliminate the malignant cells while minimizing damage and preserving as much normal tissue as possible. In some cases, this is critical such as the preservation of functional hepatic reserve in the cirrhotic patient, nephron-sparing approaches to the treatment of renal cell carcinoma (RCC), or maintaining lung function in the face of emphysema. Another significant advantage of tumor ablation is the decreased morbidity and cost as compared to surgical approaches. While the morbidity and mortality associated with surgery have improved significantly over the past several decades, surgery still carries risks. Complications of surgery can potentially delay the initiation of other modalities, such as systemic therapy or radiation. The cost of surgery is also substantial, and ablative technologies may be particularly cost-effective in comparison, potentially allowing greater access to treatment across the world.

Despite the tremendous potential for ablative technologies, their clinical use in cancer treatment is still limited. There are several reasons for this. While the theoretical potential is great, there are still several hurdles to overcome, particularly when compared to surgery—the gold-standard. Surgery permits pathologic confirmation of complete excision, allowing for evaluation of the margin status, which ablation does not. Tumor ablation is wholly dependent upon imaging studies to assure complete ablation, and therefore success is tied to the ability of the imaging modality to visualize the entire tumor. As tumor-imaging modalities improve, so too will the applicability of tumor ablation. While imaging is critical, it is important to keep in mind that the success or failure of ablative technologies is not solely related to the ability to visualize and

target the tumor tissue. Several of the ablative technologies take advantage of the unusual properties of the tumor microenvironment compared to the surrounding normal tissues. There are several characteristics of the primary organ as well as the tumor tissue (density, fibrosis, water content, vascularity) that can influence the extent of injury. These characteristics impact thermal conductivity, electrical conductivity or tissue elasticity, and for some modalities may be advantageous, while for others they may be prohibitive.

Combination Therapy

For many tumors, such as breast cancer or sarcoma, surgery and radiation are complementary as the former removes large tumor masses but can leave micrometastatic foci while radiation can eradicate small foci but is much less effective against larger deposits. This combination is what allows breast conservation for breast cancer or limb-salvage surgery for soft tissue sarcoma. There are likely similar synergistic effects between tumor ablation and other nonablative modalities.

Compared with surgery, tumor ablation is particularly well-suited toward combination therapy. Ablation is relatively quick, well-tolerated, and rarely associated with complications or wound healing issues that may delay the initiation of additional therapies. Combination therapy has several potential advantages: (1) treatment of residual microscopic disease that may be left behind outside of the ablation zone—similar to the combination of surgery with radiation or systemic therapy, (2) increasing the size of the ablation zone or the efficacy of ablation, and (3) increasing the downstream benefits of tumor ablation, such as the effects on the tumor vasculature or the immunologic response.

One example of synergy is the combination of ablation with radiation therapy. Radiation may help remove residual microscopic disease after ablation, but there may also be greater tumor necrosis with the combination of radiofrequency ablation (RFA) and radiation secondary to effects on the blood flow into the target lesion. Another example of synergy is the addition of regional therapies that may decrease blood flow near tumors. As with radiation, this may not only expand killing beyond the ablation zone, but be synergistic by overcoming the heat-sink effect. For example, regional chemotherapy to the liver using transarterial chemoembolization (TACE) has been combined with RFA. A recent meta-analysis reported that the combination of RFA and TACE improves the

overall survival rate for patients with intermediate and large-sized hepatocellular carcinomas (HCC) compared to RFA alone.

The heat-sink effect may also be overcome by combining ablation with pharmacologic agents that slow blood flow or are antiangiogenic. Agents such as arsenic trioxide or halothane, which decreases blood flow, appear to increase RFA-induced coagulative necrosis in animal models, but are limited clinically by their toxicities. RFA combined with the vascular endothelial growth factor (VEGF) inhibitor sorafenib appears to produce a therapeutic effect superior to RFA alone for small HCCs, although the STORM trial (NCT00692770) failed to show a clinical advantage of using sorafenib after either local ablation or surgical resection.

Other systemic therapies may also be used in combination with ablation. Combining chemotherapy with ablation may increase the overall volume of tumor necrosis by increasing the effects in the peripheral zone of hyperemia surrounding the central zone of ablation. The effects of ablation on blood flow may improve drug accumulation, and the ablation-induced reduction in cellular reparative mechanisms may allow for increased apoptosis or other cytotoxic mechanisms. As an example, in a phase II study of RFA for nonresectable colorectal liver metastases, the combination of RFA with systemic therapy improved progression-free survival over systemic therapy alone. The vascular effects of ablation may also make the combination of ablation with liposomal chemotherapy particularly attractive. Liposomes are artificial phospholipid vesicles that can be loaded with a variety of water-soluble drugs, including chemotherapeutic agents. Liposomal chemotherapy can result in increases in drug concentrations in solid tumors based on the increased permeability of the tumor microvasculature. At the periphery of an ablated tumor, failure may be secondary to the inability to heat tumor cells to lethal temperatures. However, the impact of hyperthermia on the microvasculature around the ablated tissue may increase the uptake of liposomal chemotherapy. This may be even further enhanced through the use of heat-sensitive liposomes, where the drug is released at higher temperatures.

Immunologic Benefit

One of the most interesting and unique aspects of ablation is its potential to stimulate an antitumor immune response. Leaving a tumor to die in situ may generate an antitumor immune response that may then lead to an

abscopal effect, where treatment of one tumor has an impact on distant, untreated tumors. The key to the antitumor immune response appears to be related to the mechanism of cell death induced by tumor ablation.

The two primary mechanisms of cell death are apoptosis and necrosis. Necrosis is characterized by the release of intracellular contents. Many of these intracellular contents can be immune-stimulatory, especially heat shock proteins (HSP), DNA, and RNA that are recognized by Toll-like receptors, or “danger signals” such as uric acid or the chromosomal protein HMGB1 (high mobility group box chromosomal protein 1), which can further activate the innate immune response. The immune system may also be alerted to massive cell death by disruption of tissue architecture and release of fibrinogen, oligosaccharides of hyaluronan, extra domain A (EDA)-containing fibronectin, and heparin sulfate proteoglycan. In this way, the necrosis caused by tumor ablation not only makes tumor-specific antigens available for uptake, but attracts and activates the necessary components of the immune system to generate a tumor-specific response. In contrast, apoptotic cells do not release their contents as do necrotic cells, but rather are taken up by macrophages and dendritic cells. This not only fails to stimulate an immune response, but may lead to immunosuppression. The continual transport of apoptotic cells and presentation of self-antigen may be one mechanism by which we induce tolerance of ‘self’ and prevent autoimmune diseases. While the immunologic response associated with in situ cell death is not completely clear and likely more complex than simply apoptosis versus necrosis, there is significant evidence that tumor ablation can lead to immune recognition and eradication of distant disease.

Development of an antitumor immune response has been associated with RFA and high-intensity focused ultrasound (HIFU), but the most significant correlation between ablation and immunity has been with cryoablation. The potential antitumor immune response triggered by cryoablation was initially reported clinically, when the regression of distant disease was observed after cryoablation of prostate, breast cancer. or lung metastases. These observations led to multiple preclinical and clinical studies examining the mechanisms behind the cryoimmunologic response.

While animal studies clearly demonstrate an antitumor immune response associated with tumor ablation, clinical observations suggest this occurs in a minority of patients, and in some cases, ablation has been

associated with immunosuppression. As stated above, one advantage of tumor ablation is the relative ease of combining ablation with systemic therapies, and this may be particularly valuable in augmenting the clinical benefit of ablation-associated immunity. While several agents have been used over the years, the strongest potential appears to be the combination of in-situ tumor ablation with check-point inhibitors, including anti-CTLA4 and anti-PD1 antibodies.

TECHNOLOGIES USED FOR TUMOR ABLATION

Chemical Ablation (Nonenergy)

Nonenergy-based ablation is typically chemical based; the injection of cytotoxic substances directly into the tumor. The most common use of chemical ablation has been in the liver, where unresectable hepatic tumors can be destroyed by injecting a variety of substances such as absolute ethanol, acetic acid, or heated hypertonic saline. One of the most common human solid malignancies in the world, only a minority of patients are suitable candidates for resection because of either the location of the tumor or the presence of chronic liver dysfunction, particularly cirrhosis. Resection of HCC in cirrhotic patients has an unacceptably high risk of liver failure.

Biologically, HCC are particularly well suited for chemical ablation. The lesions are often softer than the surrounding cirrhotic parenchyma and have a rich vascular network, so chemical agents easily diffuse throughout the lesion. There is often a capsule, so that the agent is trapped within the lesion. The liver is also one of the most common sites of metastases, and while a proportion of patients with hepatic metastases will benefit from surgical resection, many patients are poor candidates for resection due to the number and location of the tumors. However, metastatic lesions don’t have the same difference in tissue density between the malignant tissue and the primary hepatic parenchyma (which is less commonly cirrhotic) and they don’t have capsules. Thus, chemical ablation is less effective.

The most common modality used for chemical ablation is percutaneous ethanol injection (PEI). Using ultrasound or CT, a needle is inserted into the center of a tumor and 100% ethanol is injected into the tumor mass where it diffuses into the tumor cells (Fig. 14.1). Ethanol causes dehydration and protein denaturation, resulting in coagulative necrosis. As with several forms of ablation, this also leads to microvascular thrombosis and tumor ischemia.

Compared with other forms of tumor ablation, PEI is extremely simple and low-tech, as no special equipment is needed. It is very cost-efficient, which is important given the incidence of HCC in developing countries. There are disadvantages to PEI, however. It is limited to smaller lesions (typically <3 cm) and those with well-defined margins. Multiple sessions (5 or 6) are usually needed to completely destroy a tumor, secondary to the presence of intratumoral septations. These occur in approximately 50% of tumors between 1.5 and 2 cm, and in 70% of tumors between 2 and 3 cm in size. Ethanol has a reduced diffusion capacity across intratumoral septations, limiting its efficacy. Newer devices, using multipronged needles with multiple side holes, may help overcome this and allow for single-session PEI.

Another approach to overcoming the septations may be the use of 50% acetic acid instead of EtOH. Percutaneous acetic acid injection (PAI) uses about one third the volume as ethanol injection, but is otherwise similar. Acetic acid has stronger necrotizing power than ethanol because of its ability to dissolve lipids and extract collagen. Acetic acid injected in one nodule will penetrate through septa because of its low pH. This induces swelling of the fibers and promotes dissociation of intermolecular cross-links containing aldimine bonds of collagen within the septa. A meta-analysis found no differences between PEI and PAI regarding local recurrence or survival, but PAI may require fewer sessions.

Energy-Based Ablation

Energy-based ablation can be either thermal or nonthermal, although the majority of modalities are not only thermal, but hyperthermic, using elevated temperatures to kill cancer cells. Exceptions include cryoablation, which uses freezing temperatures, and both irreversible electroporation and histotripsy, which use nonthermal mechanical forces to ablate tumors.

Principles of Hyperthermic Ablation

There are several modalities that elevate tumor temperature, including RFA, microwave ablation (MWA), laser ablation, and HIFU. While they differ in the type of energy used to generate heat, they all depend on the interactions of heat with tissue to induce cell death. While cellular homeostasis is maintained with mild temperature elevations (40°C), when the temperature rises to 42°C to 45°C, the cells become more susceptible to damage from other sources. This includes chemotherapy and radiation,

and in fact this was the initial use of hyperthermia, as an adjuvant to improve the efficacy of these treatments. However, even if this temperature is prolonged, in the absence of other damage, mild hyperthermia will not kill all the cells within the targeted tissue.

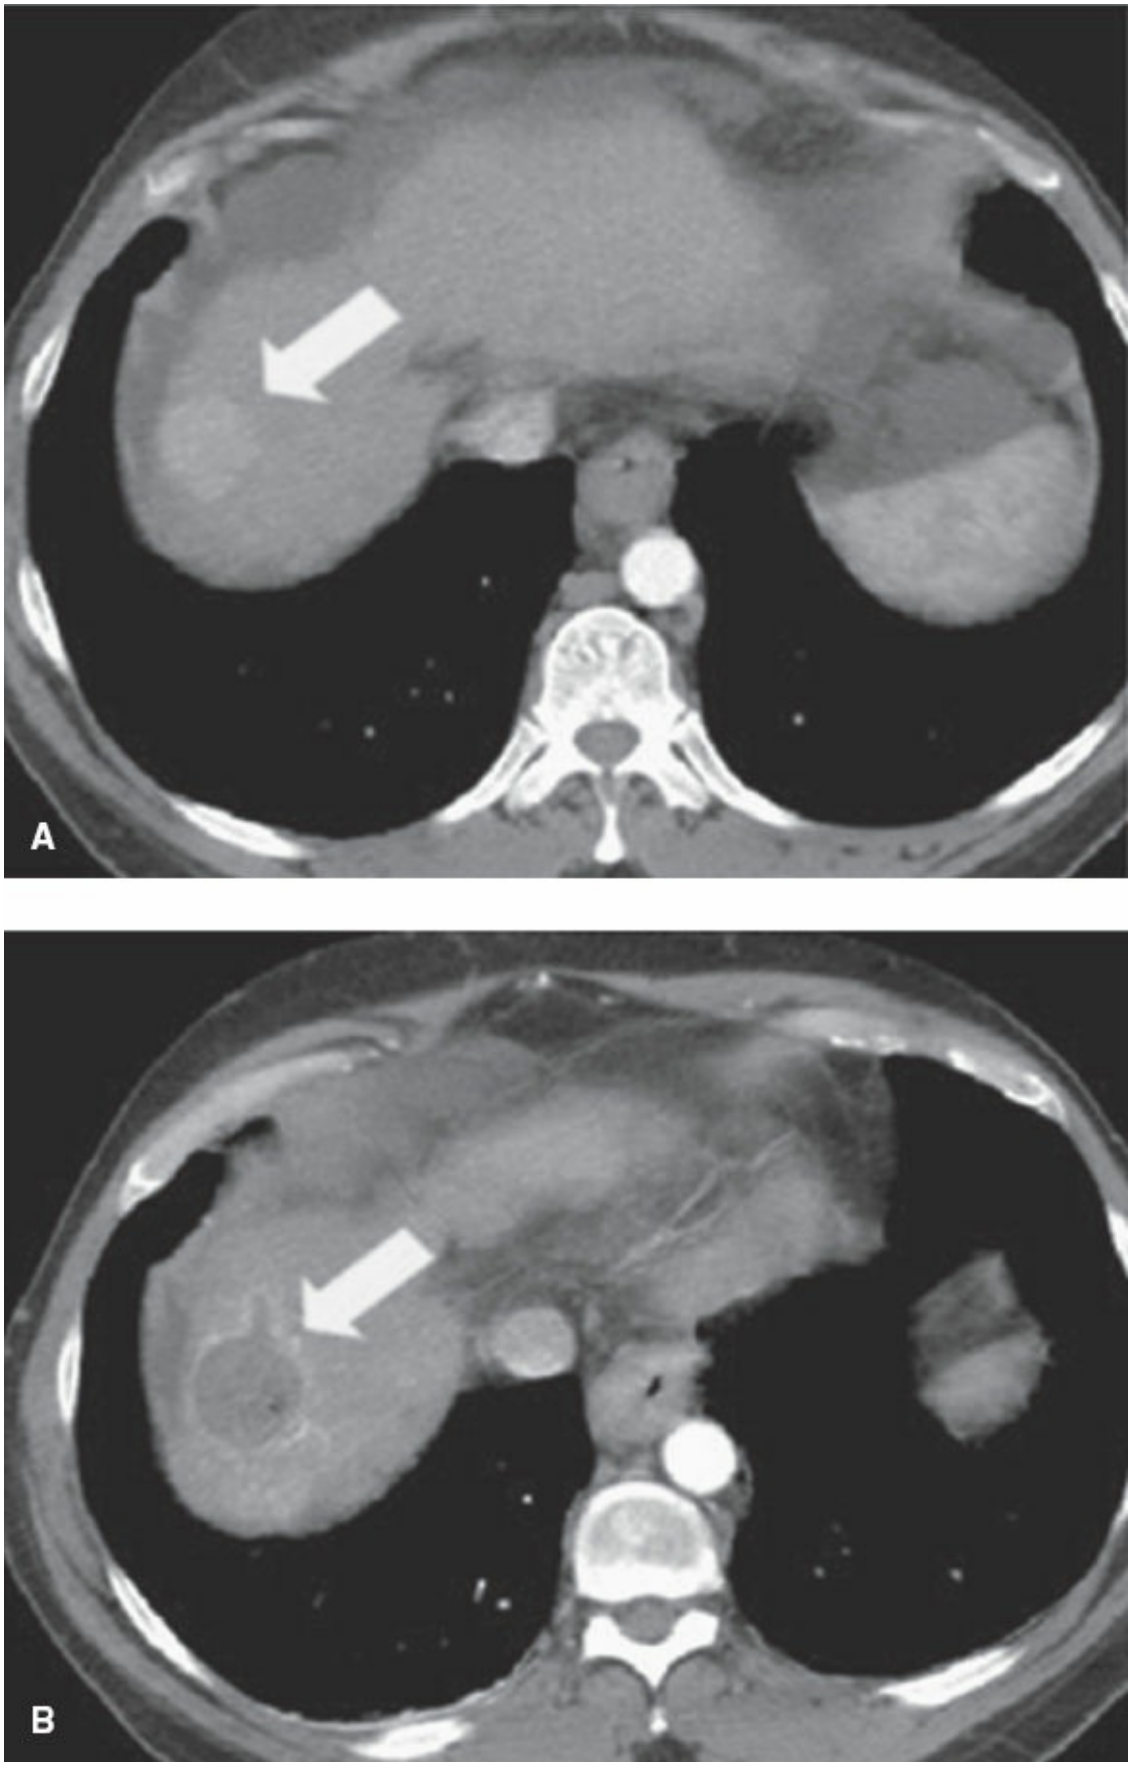

Figure 14.1. Pretreatment contrast-enhanced axial CT image demonstrates a focal hepatocellular carcinoma within the right

lobe of the liver (**A**). Follow-up imaging 3 months after ethanol instillation demonstrates focal tumor necrosis with minimal peripheral enhancement (**B**).

When the temperature is raised above 45°C, cell death is induced, but this is dependent on the time the tissue is maintained at that temperature. Tissue maintained at 46°C for 1 hour will result in irreversible cellular damage. This time is shortened to just minutes for temperatures of 50°C to 52°C. Almost instant coagulation of tissue is induced at temperatures between 60°C and 100°C, with irreversible damage to mitochondrial and cytosolic enzymes of the cells and to DNA. At more than 100°C to 110°C, tissue will vaporize and carbonize. However, this has a negative effect, as these changes decrease further energy transmission, limiting optimal ablation. Therefore, the goal of hyperthermic ablation is to maintain a temperature between 50°C and 100°C throughout the entire target volume.

While this sounds simple enough, the success and/or failure of hyperthermic ablation is dependent upon many factors that can interfere with the ability to heat an entire pre-determined volume to a uniform temperature. Some of these are technical, related to both the applicator and the imaging guidance, while some are related to tissue-specific properties.

Most (but not all) of the hyperthemic technologies are percutaneous, placing a probe into the center of a tumor with the heat propagating outward from the probe. Thus, the heat deposition is greatest surrounding the probe, with that heat falling off as the distance from the probe increases. Cytotoxic temperatures may be achieved at the center, but not at the periphery of the tumor. Increasing the energy deposition at the probe so that higher peripheral temperatures might be obtained won't always work, because if the temperature near the probe gets too high (>100°C), boiling and vaporization occur. The resultant gas formation serves as an insulator that prevents heat spread.

There are several strategies to overcome this. The most obvious would be to repeatedly remove and replace the probe in different positions, or use multiple probes simultaneously, but these approaches take more time and the precise positioning of multiple probes can be technically challenging. Alternatively, energy can be pulsed, alternating high-energy and low-energy deposition, so that time is allowed for the tissue nearest the probe to cool. This allows greater energy to be applied without vaporization and thus deeper heat penetration. The probe can also be internally cooled, for the same effect.

Differences in tissue can also either enhance or inhibit hyperthermic ablation. One example where ablation may be enhanced is the oven effect. In HCC within cirrhotic livers in particular, capsulation around the tumor can “trap” the heat within the lesion, leading to treatment volumes larger than expected. On the other hand, a factor that can inhibit achieving a uniform temperature across the tumor volume is the heat sink effect. Perfusion-mediated tissue cooling counters the thermal energy and leads to incomplete ablation by preventing high temperatures near large vessels or highly vascular regions of a tumor (such as the peripheral tumor–parenchyma interface). In some cases, obstructing blood flow temporarily during ablation may be beneficial, but may also be challenging clinically, requiring more invasive approaches (surgery, balloon occlusion, embolization) and again increasing the overall complexity of the procedure.

Radiofrequency Ablation

RFA is a percutaneous hyperthermic ablation modality. Image guidance for RFA can be via ultrasound, CT, or MRI. The term *radiofrequency* alludes to the alternating electric current oscillating in a high-frequency range between two electrodes (either an active and a reference electrode, or two active electrodes). RFA creates a closed loop circuit consisting of an RF generator, cabling, electrodes, grounding pads, and the patient (Fig. 14.2). As tissues are imperfect conductors of electricity, the current flow leads to agitation of ions within the tissue (known as the Joule effect). The ionic oscillatory agitation leads to frictional heat, which ultimately leads to coagulative necrosis if enough energy is deployed. This effect occurs in the immediate vicinity of the electrode (antenna), and is directly and proportionally dependent on the energy delivered. The heat then needs to disperse as a result of conductivity and convection effects, and the total thermal damage will be dependent on both the tissue temperature achieved and the duration of the heating, both of which can be impacted by several tissue- and technology-related factors. To assure tumor destruction, the tumor and an adequate margin surrounding it need to be treated to temperatures over 50°C for approximately 4 to 5 minutes.

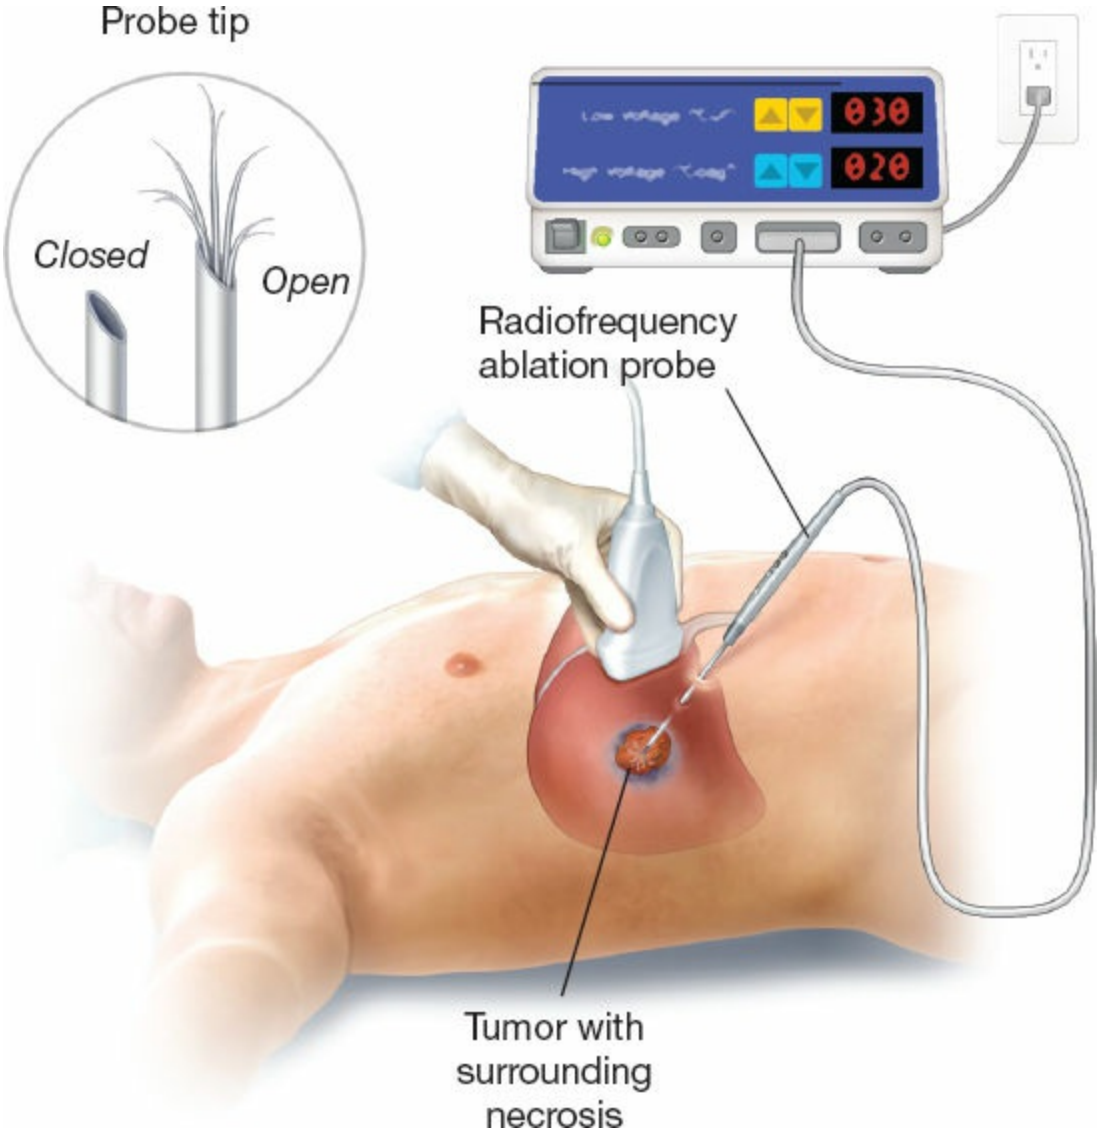

Figure 14.2. Radiofrequency ablation utilizes a closed loop circuit between the RF generator and the patient via electrodes and a grounding pad. Most commonly, an electrode with multiple tines emanating from a single sheath is placed at the site of the tumor and the tines deployed. This allows for greater energy deposition and a larger zone of ablation.

RFA has been the most commonly used thermal ablative technology, with considerable clinical and experimental data. It has been shown to be effective for tumor control, as discussed below. Disadvantages can include the technical complexity, the impact of the heat-sink effect, and the risk of skin burns at the site of the grounding pads. As RFA is increasingly explored as an alternative to resection even among surgical candidates, there is concern that RFA could promote tumorigenesis in nontarget tissues. In the liver, for example, RFA and other forms of ablation can lead

to a mechanism of liver regeneration in the presence of elevated cytokines and growth factors (such as IL-6 and hepatocyte growth factor). As these factors are active in tumorigenesis, the potential of RFA in promoting cancer has been raised in preclinical models.

Laser Ablation

Lasers have been used for some time to treat superficial processes, such as skin or ocular disorders. Newer technologies have made it possible to use lasers for deeper tissues as well. Interstitial laser therapy (ILT) involves the placement of a laser fiber with a diffusing tip through a trocar into a tumor. Laser light is then delivered directly to the target lesion. Absorption of the light leads to an interaction between the photons and the molecules of the tissue, resulting in a transformation of laser energy to heat, which like other modalities, increases the tissue temperature and creates a zone of thermal ablation.

Laser light is a very efficient and precise method of generating heat. Although ILT has several advantages, including the ability to use MR-guidance (the optical fibers are inherently MRI-compatible), early experience has presented challenges. As light is scattered and absorbed by tissue, penetration is less, limiting its use to smaller tumors (1 to 2 cm). In breast cancer, there is an ongoing, multicenter “ablate and resect” trial of ILT for patients with tumors <2 cm that is currently recruiting participants (ClinicalTrials.gov:NCT01478438).

Microwave Ablation

Another hyperthermic ablation uses microwaves (MWA), which has become much more feasible with the development of new antennae and new software tools. A “microwave” is electromagnetic energy in the range of 300 MHz to 300 GHz. When applied to tissue, this energy induces a rapid and continuous realignment of polar molecules (primarily water molecules) within the defined lesion. This molecular rotation results in kinetic energy and subsequently hyperthermia.

Initially, there was interest in focused microwave phased array thermotherapy. This system used transcutaneous opposing microwave waveguide applicators to produce a microwave field in a truly noninvasive manner. Results, however, were limited, and attention turned toward percutaneous MWA, where the microwave energy radiates into the tissue through an interstitial antenna that functions to couple energy from the generator power source to the tissue. The design of the antenna will impact

efficiency as well as the size and the pattern of the ablation zone. Thus, there are many forms of antennas, and multiple antennae can be used to create larger zones of coagulation necrosis. However, smaller-diameter antennas can have trouble handling higher power levels without unwanted thermal damage to tissues around the antenna shaft, requiring the use of cooling jackets and systems to reduce the incidence of skin burns and allow for increased power in smaller diameter antennas.

As the heat originates primarily from water agitation, tissues with a larger concentration of water are particularly susceptible to microwave heating. As cancer cells often have a larger concentration of water than surrounding noncancerous cells, MWA seems particularly well suited to tumor ablation. MWA has several potential advantages compared with other ablative technologies. Microwaves readily penetrate tissues where other forms of ablation are more limited. Whereas other modalities have inherent difficulties in tissue with low electrical conductivity (lung, bone, charred or dehydrated tissue), microwaves could potentially be used in these settings. MWA is presently being studied in the treatment of both lung cancer and lung metastases, and bone tumors. Microwaves also heat tissue more efficiently, and can be continually applied in order to obtain larger ablation zones and more uniform heating throughout the zone. Thus, larger zones of ablation can be created in less time. There may also be less impact by the “heat-sink effect” and thus MWA is being studied as an alternative to RFA in the liver.

Ultrasound Ablation

There are two methods for using ultrasound energy to ablate tumors: direct (or interstitial) and extracorporeal (or transcutaneous). The former involves either the percutaneous or intracavitary placement of a needle-like applicator into a tumor, which is referred to as interstitial ultrasound ablation. The latter is a truly noninvasive procedure, utilizing transcutaneous ultrasound to ablate the target tissue. This is most commonly referred to as high-intensity focused ultrasound, or HIFU.

Ultrasound is a form of vibrational energy. It propagates as a mechanical wave by the motion of particles in the medium. This wave propagation leads to compressions and rarefactions of the particles, so that a pressure wave is transmitted along with the mechanical movement of the particles. As the ultrasound beam propagates through the body, it loses energy due to attenuation in tissue, which is caused by both scattering and absorption. The absorption of this energy causes a local temperature rise in

the tissue if the rate of heating exceeds the rate of cooling.

While ultrasound beams transmit harmlessly through living tissue, they can be focused into a small volume with concentrated high-energy distribution within the body. This makes it possible to use an external source of focused ultrasound for therapeutic purposes. If ultrasound energy is sufficiently concentrated in the focal volume, it can directly kill cells by raising the temperature to destructive levels, similar to a magnifying glass focusing the sun's rays onto a point to set fire to a dry leaf (Fig. 14.3). It provides a noninvasive method of selective tissue ablation at depth without any damage to the surrounding or overlying tissues.

HIFU actually destroys tissues by two mechanisms. The first are the hyperthermic effects from the conversion of mechanical energy into heat. HIFU can raise the temperature to 80°C. Because there is a sharp temperature gradient between the focal volume and the nonfocal surrounding tissue, there is a sharp demarcation between treated and untreated tissue when examined histologically. But HIFU also kills cells through acoustic cavitation. This is defined as the interaction of a sound field with the microscopic gas bodies in a sonicated medium. In this case, the small gaseous nuclei within subcellular organelles and fluid in tissue provide the source of the cavitation. Under the influence of the acoustic pressure, these expand and contract. For some time, efforts were made to avoid cavitation, as the shape and position of the targeted tissue were less predictable than heating. However, recent studies have been investigating the idea of promoting cavitation for enhancing the level of ablation and reducing required exposure time.

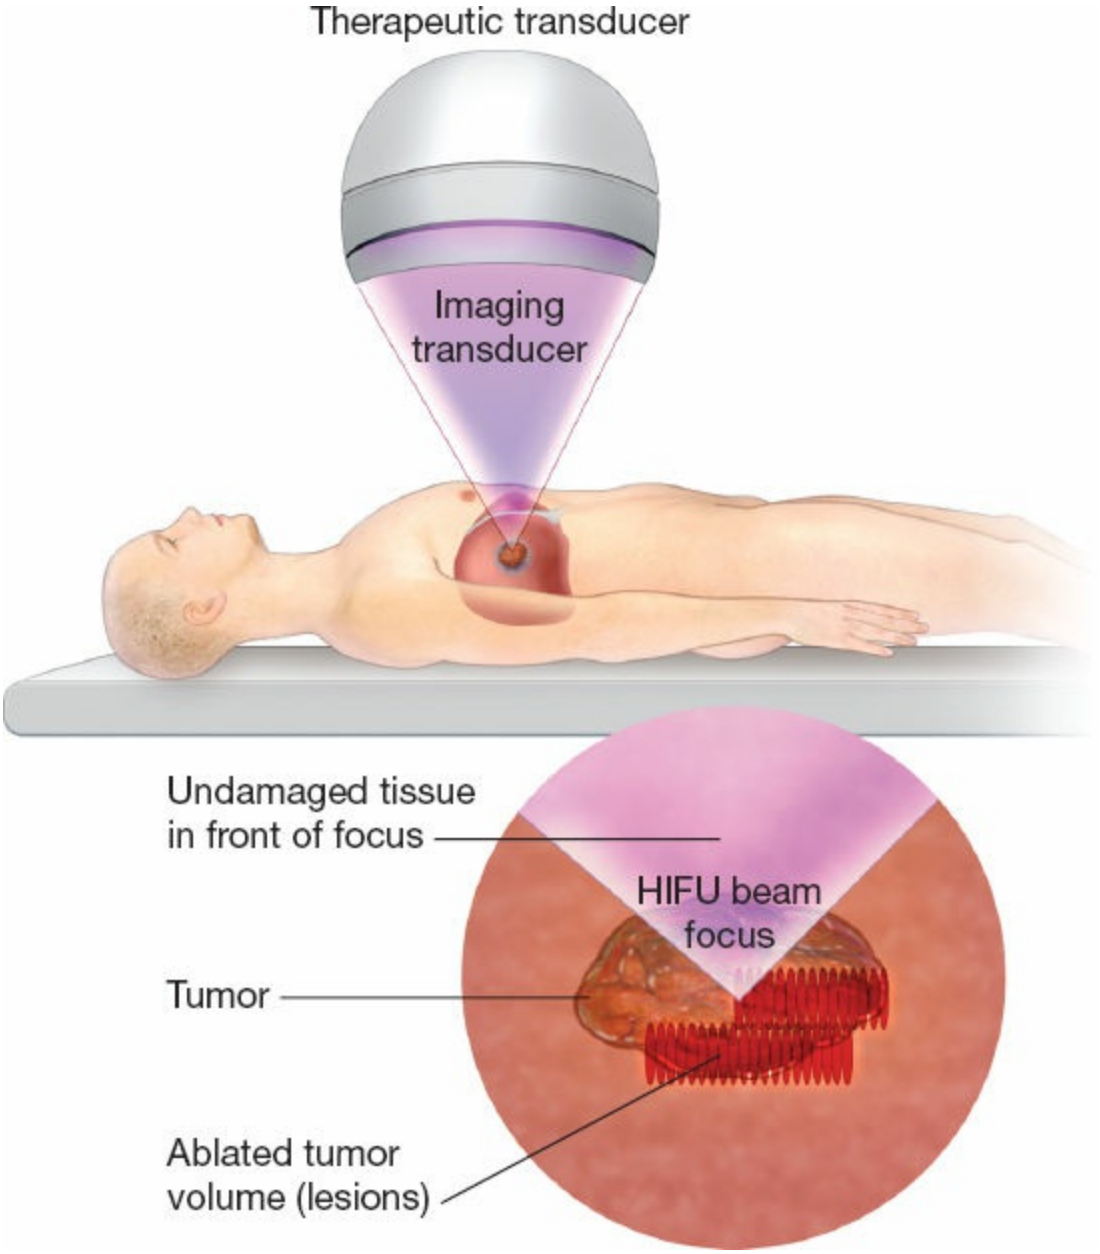

Figure 14.3. High-intensity focused ultrasound uses a therapeutic transducer to concentrate ultrasound energy in the focal volume. Tissue in front of the focus is undamaged.

Histotripsy

As stated above, HIFU is a hyperthermic ablation, primarily destroying cells through heat, although some cells may be destroyed through acoustic cavitation. While the development of HIFU centered on minimizing cavitation to improve the predictability of heating, an alternate approach uses only acoustic cavitation to destroy tumors in a nonhyperthermic form of ablation. In this manner, histotripsy is less like HIFU and more like shockwave lithotripsy.

Acoustic energy is delivered in the form of short (<50 microseconds) very high-intensity pulses to induce cavitation. Cavitation is a process that occurs when a sufficiently negative pressure is applied to a fluid to cause microbubble formation from fluid vaporization and release of dissolved gas. In the case of ablation, this negative pressure is applied to tissue, where the microbubbles exhibit highly dynamic patterns of oscillation and inertial collapse, producing cellular disruption and leading to mechanical homogenization of the target tissue. The tissue bioeffects can be delivered with relatively high accuracy within the targeted tissue, allowing for a very precise tissue ablation. The microbubble clouds reflect sound and appear as hyperechoic (bright) zones with ultrasound imaging, which is used to both guide and monitor the ablation.

The tissue effects of histotripsy are quite different from hyperthermia. With hyperthermic ablation, histologically the treated tissue ranges from coagulative necrosis to carbonization, depending on the highest temperature achieved and the time the tissue remains at that temperature. With histotripsy, the histologic results depend on whether the tissue is also heated or not. Histotripsy parameters can be set so that the cavitational mechanical effects are isolated, and the thermal elevation is minimized. Lesions were desiccated when histotripsy was performed with sonications where tissue temperature was elevated, while lesions were liquefied when sonications when the temperature was not significantly elevated. The in vivo response to the liquefied tissue is also different from other forms of ablation. The homogenized debris is resorbed within 45 to 60 days with little deposition of fibrotic tissue scar formation.

Irreversible Electrocorporation

Irreversible electrocorporation (IRE or IRE ablation) refers to those devices that cause cell death through the repeated application of short-duration high-voltage electrical pulses that create irreversible injuries to cellular membranes. This is considered a nonthermal form of ablation, although there may be some hyperthermic changes seen. Although there are still some questions regarding the exact molecular events that take place at the membrane level, the efficacy of electroporation is related to the creation of structural defects, or “pores” in the plasma membrane. These pores lead to a reversible permeability of the cell membrane, which was initially seen as a method of introducing foreign material into the cells (DNA, protein, chemotherapeutic agents). This is known as reversible

electroporation and has been used for decades for molecular and gene transfer in vivo. Eventually, electroporation shifted from being a delivery agent for other therapeutics to an ablative therapy. There were several potential advantages over other forms of ablation. As IRE is nonthermal, it avoids some of the collateral thermal effects and minimizes the impact of heat sinks (the impact of local perfusion on outcome).

There are four major types of IRE electrodes: plate, needle, clamp, and catheter, with the needle electrodes being the most popular for tissue destruction. The effects of electroporation are related to the behavior of the lipid plasma membrane under the stimulation of an external electric field. Pore formation is dependent upon both membrane properties and the applied external electric field. While there is general agreement about how the electrical field forms pores, there is less information about how the membrane recovers. Pore formation alone will not necessarily lead to cell death. The cellular injury comes from direct membrane destruction (an irreversible pore or cellular rupture) or from an osmolarity imbalance, loss of critical organelles, or influx of cytotoxic molecules.

Although electroporation has been used clinically for over 15 years, this has primarily been in combination with chemotherapy. IRE, as a stand-alone treatment, has only started to emerge over the last 5 years, with studies being performed in liver, kidney, and lung. There have also been some smaller studies of IRE in prostate and pancreatic cancer, with several studies presently accruing patients in the United States. However, IRE has not gained acceptance at the same rate as other ablative technologies do, in part due to the need for multiple electrodes or re-positioning the electrodes to destroy lesions >1 cm. While larger lesions can be destroyed with multiple electrodes or repeat treatments with repositioned electrodes, this greatly increases the complexity, and makes the treatment more invasive. Another drawback to IRE is the heterogeneity of cell death within the treatment zone. This may not be apparent on imaging studies and could lead to cancer recurrence. While hyperthermia and cryoablation may leave tumor cells at the periphery, which can be overcome with better imaging or combination therapy, incomplete ablation within the treatment zone is more unique to IRE and a key challenge for the use of this technology in cancer.

Cryoablation

Cryoablation is performed by placing a cryoprobe at the center of a tumor.

A cryoprobe is a high-pressure, closed loop gas expansion system, where the metal probe is insulated except for the tip. The cryoprobe is rapidly cooled by means of the Joule–Thopmson effect (rapid expansion of a gas results in a change in the temperature of the gas), removing heat from the tissue contacting the probe. For ablation of smaller tumors, a single probe is typically placed under ultrasound guidance through the center of a tumor. For larger tumors, multiple probes can be placed in order to generate cytotoxic isotherms.

Although cryoablation refers to the freezing of tissues, cell damage is induced by a variety of mechanisms during both the freezing and thawing process, as well as indirect damage to the microcirculation (Fig. 14.4). The method by which the cells die is related to the lowest temperature reached, the amount of time at subzero temperatures, and the number of freeze-thaw cycles (allowing the frozen tissue to thaw before freezing again). Close to the cryoprobe, the freezing rates are high enough to induce freezing of the intracellular fluid, or intracellular ice formation (IIF). This is a lethal event associated with irreversible membrane damage. Further from the probe, freezing rates are slower. Here, the extracellular fluid will freeze but the intracellular fluid has better protection by the lipid membrane. This leads to osmotic forces that shift pure water out of the cell, or cellular dehydration. When the tissue is thawed, the intracellular compartment is now hypertonic, and as the ice melts, fluid rushes into the damaged membranes and the cells burst. In addition to this, large ice crystals may form during re-crystallization in the warming period, and these create direct shearing forces that further disrupt the tissues. When the freezing is repeated, the damaged tissue conducts the cold much more efficiently, increasing the area of necrosis beyond the first cycle. Dells not killed by direct cryo-injury may also suffer apoptotic dell death secondary to cryo-induced destruction of the microvasculature and post-thaw platelet aggregation and vascular stasis.

Cryoablation has several advantages that have led to its emergence as a primary choice for ablation across several tumor types. As freezing is inherently anesthetic, it can often be performed without general anesthesia. The iceball that forms around the tumor can be visualized on US, CT, or MRI, allowing for real-time monitoring. That clear visualization also allows for greater safety when treating tumors near critical structures. Cryoablation also has less impact on collagen fibres, so it can be safer around critical structures. This also allows for improved re-modeling and

cosmesis for more superficial tumors. Smaller tumors can be ablated with a single probe placed centrally within the tumor, reducing the complexity of the procedure. Larger lesions can be treated with multiple probes, although this can be more complex and expensive. This can also be more time-consuming than other modalities.

TUMOR ABLATION IN CLINICAL PRACTICE

Liver

The liver is a common location of both primary and secondary malignancies. Worldwide, HCC is one of the most common cancers and the incidence may be rising. Surgical options include partial hepatectomy and liver transplantations, but only a minority (10% to 20%) of patients are candidates for these curative options. The liver is also one of the most common sites of secondary malignancies, particularly colorectal cancer. For patients with metastatic colorectal cancer limited to the liver, resection is the treatment of choice, but only an option in 20% to 30% of patients. This number may be rising with the increased efficacy of systemic agents and the use of novel approaches (radiochemotherapy, embolization), but as with HCC, this leaves a large number of patients with disease confined to the liver who are not candidates for surgery, because of either multifocal disease, inadequate residual size or function after surgery, or comorbid conditions. It is for this reason that interest in ablative therapies for the liver has grown.

Figure 14.4. **A.** During freezing, close to the probe, free water is trapped in the cells and intracellular ice forms, which shred the cells. Freezing is slower further from the probe, so ice forms in the extracellular fluid, increasing tonicity and drawing water from the cells. Blood vessels are also damaged by the ice. **B.** During the thaw, cells close to the probe undergo necrosis, while cells further from the probe burst due to the flow of water into the cells. Damage to the endothelial cell junctions leads to increased capillary permeability. **C.** Reperfusion brings platelets that cause thrombosis when they come in contact with the damaged endothelial cells, causing ischemia.

For the treatment of HCC, most of the ablative technologies described above have been used, including ethanol or acetic acid injection, RFA, MWA, cryoablation, and HIFU (Figs. 14.5 and 14.6). While there was initial excitement for cryoablation in HCC, the technique had limited application. The complication rate was significant, including the risk of "cryo-shock," secondary to the release of multiple inflammatory cytokines. HIFU (both ultrasound and MRI guided) and MWA are also being investigated for HCC ablation, but today the most common ablative techniques for the liver have been chemical ablation with ethanol and RFA. There have been five randomized trials comparing RFA to PEI for the treatment of early-stage HCC, three from Asia and two from Europe. While there is a consistent advantage to RFA regarding cancer ablation and local control, the impact on survival was less clear. The studies from Asia showed a statistically significant improvement in overall survival associated with RFA, while the European studies failed to achieve statistical significance. However, three meta-analyses including all RCTs have confirmed that RFA offers a survival benefit over PEI, establishing RFA as the standard percutaneous approach.

Beyond the applicability to nonresectable patients, RFA has several potential advantages to surgery, including shorter hospital stays and reduced costs, decreased morbidity, and increased preservation of hepatic parenchyma. Therefore, one might question why RFA shouldn't be considered as first-line therapy, even among resectable patients. Two systematic reviews compared RFA and resection and found no significant differences in survival among patients who meet the Milan criteria (one lesion <5 cm or up to three lesions <3 cm, no extrahepatic manifestations, no vascular invasion). However, RFA was associated with higher

recurrence rates. For patients outside the Milan criteria, resection provided better disease-free and overall survival rates. A meta-analysis of one randomized controlled trial and nine controlled studies also found that RFA was associated with a higher local recurrence and decreased disease-free and overall survival. Finally, a randomized controlled trial by Huang et al. of 230 patients fulfilling the Milan criteria also confirmed the superiority of surgical resection. Surgical resection is associated with not only improved outcomes, but also improved quality of life-adjusted survival in cirrhotic patients. Therefore, liver resection still remains the gold standard for the treatment of HCC, although ablation can be used as a first-line treatment for tumors ≤3 cm when the expected operative mortality rate is above 3%. Both RFA and PEI can be considered for patients with tumors <2 cm who are not surgical candidates, while RFA appears to be superior in patients with tumors >2 cm.

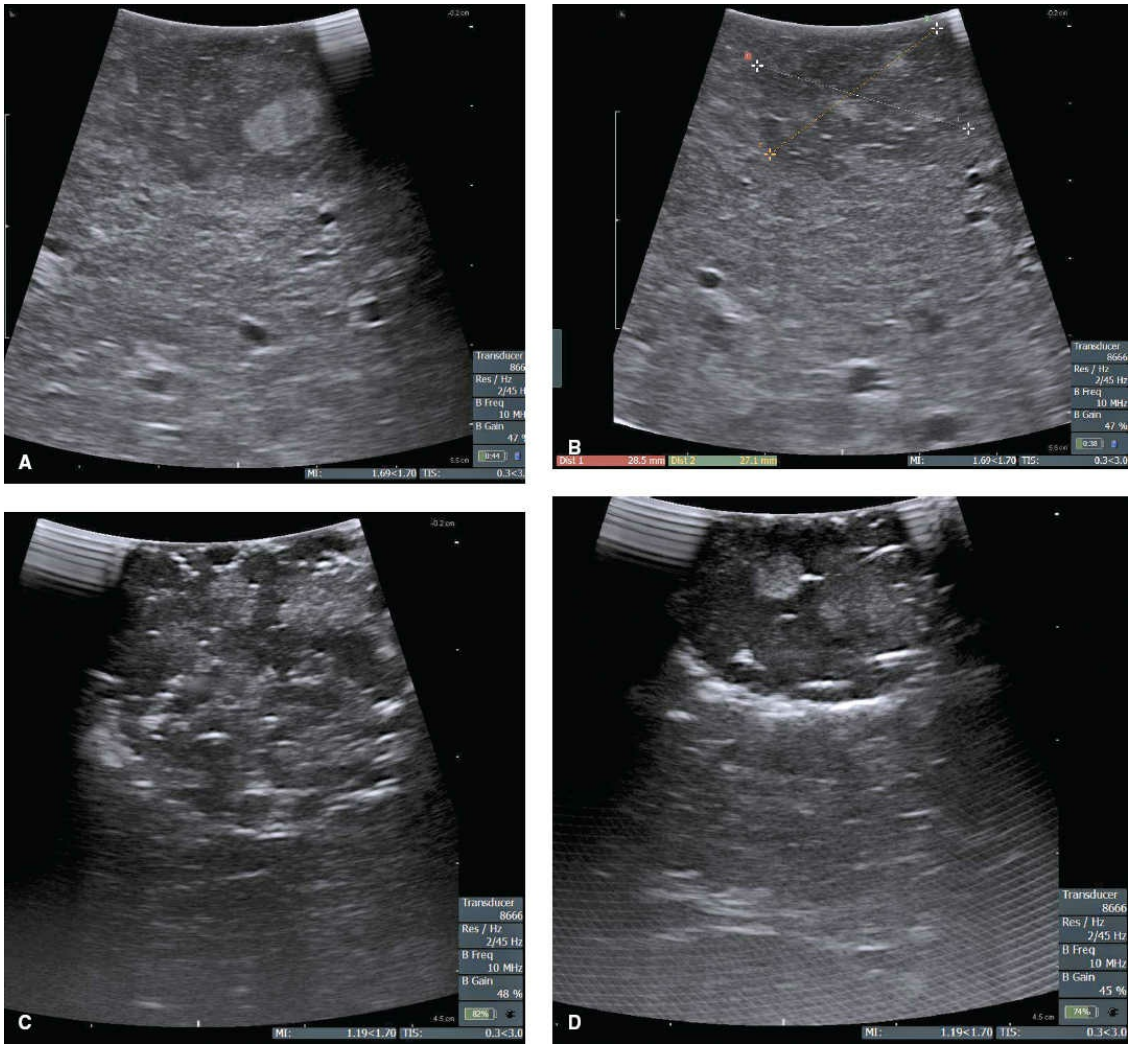

Figure 14.5. Laparoscopic ultrasound-guided RFA of a peripheral HCC. **A.** Before ablation. **B.** Lesion measurments. **C.** During ablation. **D.** Immediate postablation. (From Mulholland MW, Albo D, Dalman RL, et al. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

For metastases to the liver, PEI appears to be less effective than RFA in controlling disease, and RFA is the preferred method of ablation. Again, given the potential advantages of RFA over surgery, should ablation be considered as first-line therapy in patients with metastatic colorectal cancer? A meta-analysis by Wu et al. compared RFA and liver resection for solitary metastases, and found surgery to be superior to RFA for both local control and 5-year overall survival. There were no statistically significant differences in adverse events, and quality-adjusted life years also favored resection.

Prostate

Current treatment options for prostate cancer range from radical prostatectomy or radiation therapy to active surveillance. While prostate cancer is quite common, the majority of cases represent low-risk, organ-confined disease, which may be overtreated with conventional surgery or whole-gland external beam radiation. Focal ablative therapies have emerged as a potential middle ground—a treatment for patients with low-risk prostate cancer who either choose not to undergo active surveillance, have progressed and are now seeking treatment, or seek to avoid the undesired side effects associated with more radical therapies. Focal therapies seek to treat only localized tumors while focusing on tissue preservation, particularly near the urethral sphincter and the neurovascular bundles. Patient selection is the key, particularly with regard to tumor location and size; thus, consideration of ablative therapies is dependent upon highly accurate imaging and biopsies to assure focal versus multifocal disease. This can be accomplished through transperineal 3D-prostate mapping biopsies (3D-PMB) or more commonly, MRI-targeted biopsies.

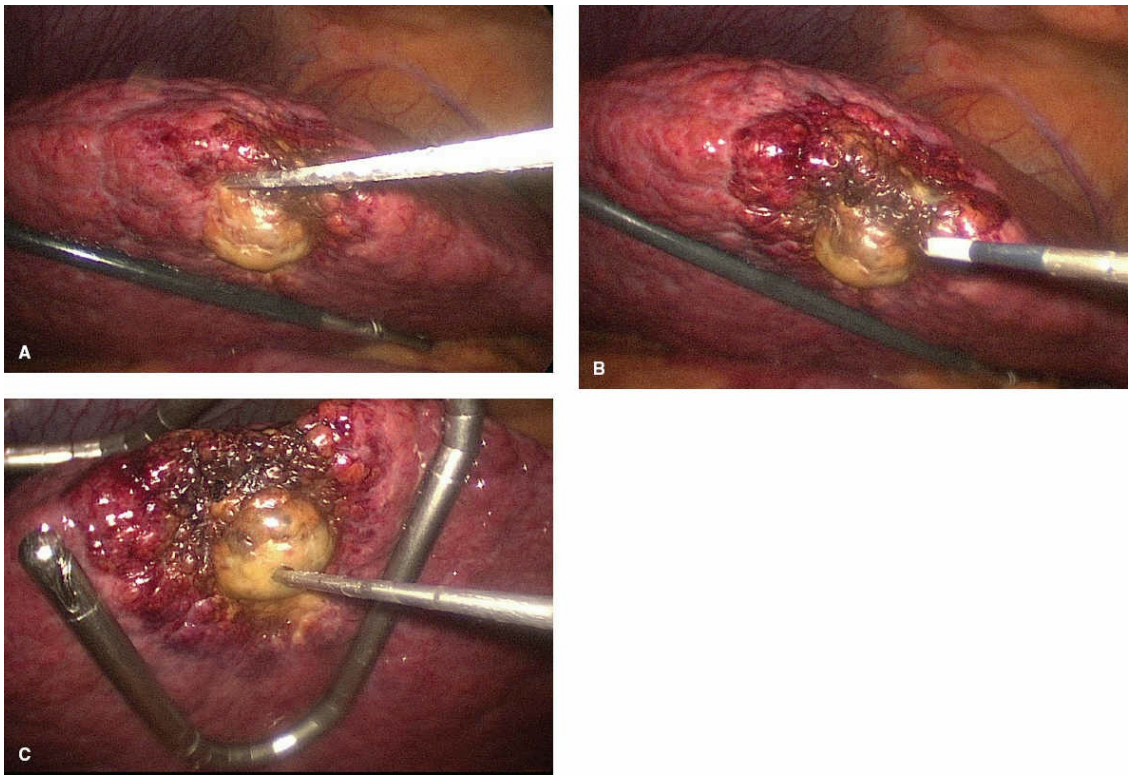

Figure 14.6. Laparoscopic ablation of an HCC using multiple deployments of a microwave probe. (From Mulholland MW, Albo D, Dalman RL, et al. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

Several modalities have been studied for ablation of prostate cancer. Both ILT and IRE have several potential benefits for prostate ablation, including precision, real-time monitoring, MRI compatibility, and low cost; however, there are limited studies of efficacy and these are still considered experimental. HIFU has been clinically utilized in the treatment of prostate cancer, with single institution series demonstrating promising results; however, this has not been compared to standard treatment approaches and thus is not considered a standard option for prostate cancer treatment.

There are more clinical data surrounding the use of cryotherapy for prostate cancer. Prostate cryotherapy is typically performed by placing multiple cryoprobes via a percutaneous transperineal approach, using high-precision transrectal ultrasound (TRUS) imaging. TRUS is also used to monitor in real time the prostate and surrounding structures and precisely control the tissue destruction. Cryotherapy can be considered as an alternative to standard therapies in three clinical settings: (1) primary therapy in patients with T1 or T2 tumors, (2) salvage therapy for men with locally recurrent disease, or (3) palliation for men with lower urinary tract symptoms in the face of metastatic disease. In two small randomized trials and in registry data, primary tumor cryoablation appears to be similar to radiation for disease-specific and overall survival; however, follow-up times are relatively short, and there is variability in tumor staging and grading, RT doses used, and the definition of a “biochemical treatment failure.”

Alternatively, there has been interest in focal cryotherapy, which attempts to ablate just the tumor and not the majority of the prostate tissue. The safety profile is greatly improved. Whole gland cryoablation takes longer and has higher rates of urinary morbidity and erectile dysfunction. These are reduced with more focal cryoablation, as the neurovascular bundles are preserved, but there are concerns regarding our ability to truly define the area of involvement and absence of disease in other parts of the gland. Therefore, careful patient selection based on estimated life expectancy and a thorough pretreatment imaging and biopsy evaluation is critical.

Kidney

With the increased use of modern cross-sectional imaging, the incidental diagnosis of renal masses and RCC is rising, resulting in not only an

increased incidence, but a substantially higher number of smaller tumors (<4 cm). Many of these have more indolent behavior, and are diagnosed in older individuals, with either overt or subtle decreases in renal function. Therefore, the preservation of renal function in patients with smaller RCC is increasingly important. While radical nephrectomy had been the standard of care for RCC, there has been a gradual shift toward partial nephrectomy, and ultimately to tumor ablation.

While there are no randomized trials comparing ablation to surgery, there are multiple series demonstrating excellent short-term disease control for both RFA and cryoablation. Most clinical experience has been with RFA, with several series showing excellent short-term outcomes and only a limited effect on renal function. In retrospective comparison of the oncologic outcomes of RFA with partial nephrectomy, there was nearly identical disease-free survival with a median follow-up of 6.5 years.

Cryoablation is also extremely well-tolerated with excellent tumor control. There is some suggestion that it may be more effective than RFA. A retrospective meta-analysis by Kunkle and Uzzo showed that RFA was more often associated with re-ablation than cryo (8.5% vs. 1.3%, $p < 0.0001$) as well as higher rates of local recurrence (12.9% vs. 5.2%, $p < .0001$) and distant metastases (2.5% vs. 1%, $p = 0.06$). However, the retrospective nature of this analysis opens it to criticism. Cryoablation may be more effective for tumors >4 cm when compared with RFA.

The American Urological Association (AUA) and the European Association of Urology are now recommending thermal ablation techniques as a potential treatment of localized renal tumors, particularly as an alternative to surgery for patients who may not be optimal surgical candidates. More long-term follow-up data are needed before RFA or cryoablation can be considered as an alternative to surgery in patients who are otherwise good candidates for definitive surgical resection.

Breast

Given the relative accessibility to tumors of the breast, the trend toward less invasive therapies in breast cancer, and the multiple breast-imaging modalities, the ablation of breast cancer seems the next logical step. As such, most of the modalities discussed in this chapter have been examined as a potential treatment for breast cancer, with the majority of studies involving ablation followed by surgical excision and pathologic confirmation of 100% ablation.

Some modalities did not pan out. Studies of ILT and MWA (using the transcutaneous microwave approach) had disappointing rates of women achieving complete ablation of the tumor, even among smaller size tumors. Percutaneous MWA of breast cancer had slightly better results, and further research is ongoing. Initial studies of HIFU were also disappointing; however, Wu et al., using a wide target that included 1.5 to 2 cm margin of normal tissue around the tumor, reported 100% ablation in 23 patients. This led to a trial of HIFU alone, followed by systemic therapy and radiation therapy. Among 22 patients treated in this manner, the 5-year recurrence-free survival rate was 89%, with the cosmetic result judged to be good to excellent by 94% of patients. Furisawa et al. also reported a local recurrence rate of 1 of 21 patients who underwent HIFU without surgical resection, with a mean follow-up of 14 months.

Several “ablate and resect” studies of RFA demonstrate rates of complete ablation from 76% to 100%. These led to several series of RFA as an alternative to lumpectomy, using MRI and biopsies to assure no residual disease. While results were promising, RFA has several drawbacks in the treatment of breast cancer. As with many hyperthermic approaches, it requires a general anesthesia, minimizing the benefits as compared with surgery. Complications can include burns of the skin, thermal damage to the chest muscle, and pneumothorax. And the procedure itself is relatively complex, requiring real-time sonographic monitoring to verify that the prongs are deployed in a symmetric fashion around the lesion.

Cryoablation has emerged as perhaps the most promising modality for ablation of breast cancer (Fig. 14.7). Compared with RFA, it is technically simpler (the probe is placed under ultrasound guidance within the center of the tumor) and, given the anesthetic effects of freezing, well-tolerated under local anesthesia. Several small “ablate and resect” studies demonstrated high success rates when the procedure was limited to tumors ≤1.5 cm, and certain tumor types were excluded (lobular carcinoma or patients with an extensive intraductal component [EIC]). There have been two studies looking at cryoablation alone. Using both ultrasound and CT guidance to place multiple cryoprobes, Littrup et al. treated 22 lesions in 11 patients who refused surgery. With a mean follow-up of 18 months, there have been no local recurrences. Fukuma et al. have presented results of two clinical trials of cryoablation alone for small breast cancer. More 50 patients with either luminal A invasive ductal carcinoma or DCIS <10 mm

in size were treated and with a median follow-up of 43 months, there have been no local recurrences. These results led to the American College of Surgeons Oncology Z1072 trial—a single arm, phase II trial of ablation followed by surgical resection with pre- and post-MRI to evaluate the ability of MRI to predict complete ablation. This demonstrated complete ablation of the targeted lesion in 80 of 87 patients (92%), although microscopic foci of invasive or in situ disease were found outside of the treatment zone in some patients. The success of this trial led to two ongoing studies of cryoablation as an alternative to lumpectomy for low-risk breast cancers (NCT02200705, NCT01992250).

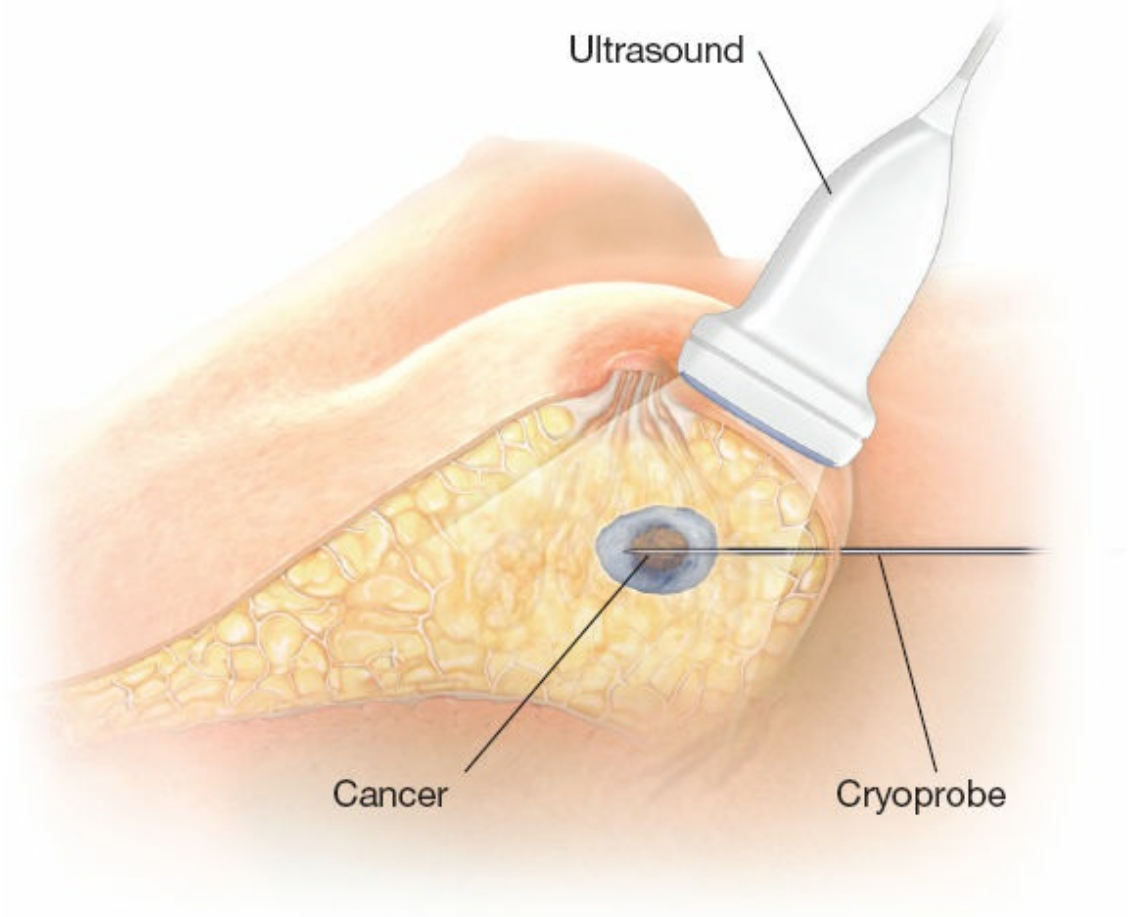

Figure 14.7. Cryoablation of breast tumors, both benign (fibroadenomas) and malignant, is accomplished using ultrasound guidance to place a cryoprobe directly into the center of the tumor. As the temperature at the tip of the probe drops, ultrasound is then used to monitor the development of the iceball around the tumor.

CONCLUSIONS

Tumor ablation is emerging as an alternative to surgery in the treatment of several malignancies, particularly for patients who are not ideal candidates for surgery, require maximum preservation of parenchyma, or with small localized primary tumors. Given the potential advantages of ablation as compared with surgery, particularly in terms of morbidity and cost, in the near future ablation may emerge as a primary modality in the treatment of several tumor types. However, this will require continued advancements in ablative technology (devices, probes) and imaging modalities, along with a better understanding of the mechanisms of tissue destruction induced by thermal or nonthermal energy. This will also be further enhanced through the combination of ablation with adjuvant therapies that can augment tissue destruction, eradicate remaining micrometastatic disease, and potentially increase some of the side benefits, such as the immunostimulatory properties of in situ cell death. Dedicated and rigorous translational research and clinical trials will be necessary to continue to ensure the continued advancement of tumor ablation.

EDITOR'S COMMENT

Dr. Sabel has presented a fairly comprehensive and well-written chapter on ablative technology and its applications. As described, the main problem with ablative techniques, in general, is the lack of sensitivity in presently available imaging techniques for not only imaging the full extent of the tumor but of the ablation zone and the margin for any one particular methodology. Further adding to this is the lack of precise image-guidance of the ablation probes. There is also the utter lack of information preoperatively that details the variability in the properties of any given tumor or for that matter of the surrounding normal native tissue. As has been used most widely in the past, ablation of intact tumors allowed only sampling of tumors and negates the known heterogeneity of tumors for tissue markers, chemosensitivity assays, and research. We know, for example, tumor and naïve tissue ablate at different speeds as do fatty versus dense breast tissue due to variabilities in impedance of those tissues. This potential leads to under- as well as over-ablation and the possibility of poor results or complications.

Dr. Sabel nicely details advances in combination therapies involving radiation and chemotherapy and ablation. What he neglects is the contrasting idea that is the studies of resection followed by ablation. This concept makes a lot of sense in light of the standard of resection followed by irradiation, for example, in treating residual occult breast cancer. Intraoperative trials of radiation of breast cancer followed by resection demonstrated much less efficacy than those of the standard of resection followed by radiation. Such trials have shown similar efficacy to those of whole breast postoperative irradiation. Resection followed by pericavitary radiofrequency ablation has been tried with liver as well as breast. After resection, the ablation can be applied uniformly to the margin of normal tissue of the tumor bed that could potentially harbor micrometastatic foci—mimicking the reasoning behind postoperative radiation therapy for breast, sarcomas, and other tumors.

Intraoperative pericavitary ablation, in a single institution prospective trial as well as an ongoing multi-institutional trial, demonstrated that lumpectomy followed by intraoperative pericavitary ablation is effective in sterilizing the margin and prevention of recurrence without radiation in favorable breast cancer tumors. This methodology lends itself to full tumor availability for

markers, sensitivity assays, and research. More importantly, such simple and relatively inexpensive technology can be easily accomplished by the general surgeon as well as in rural areas. This approach also lends itself to worldwide dissemination to countries where mastectomy is the standard because of the inavailability and cost of radiation. In a pilot study of percutaneous excision of breast tumors followed by ablation demonstrated complete 100% ablation of residual tumor. Residual tumor was detected in 50% of follow-up excisional removals of the ablated zone. This concept of excision followed by ablation primarily lends itself to radiofrequency ablation (RFA) as technologies like cryoablation and laser require direct contact with the tissue. In our studies, we found laser to be highly variable in producing a reproducible percutaneous ablation zone and the catheters too fragile for routine use.

Sensitive and accurate imaging of the tumor is the major downfall of all ablative techniques whether it is accomplished by surgery, chemical, thermal, and nonthermal extirpation. In the past, one of the reasons RFA has not become more widely utilized was the lack of accurate imaging of the ablation zone. However, using a resection followed by ablation approach, a simple Doppler US can demonstrate the off-gassing of nitrogen, i.e., bubbles that accompany complete ablation of tumor and tissue. In a laboratory model, the zone of Doppler imaging of this phenomenon correlated accurately with the zone of ablation. This technique is now used in intraoperatively breast cancer treatment to document the ablation zone as well as progression of the ablation and visualizing the proximity of skin and thus the avoidance of skin burns. In this way, variability in ablation progression due to the variability in tissue impedence can be determined.

Dr. Sabel also raises the issue of ablation causing increased risk of tumorigenesis in nontarget tissues due to the possibility of elevated cytokines and growth factors. In contrast, in a study of the zones around the radiofrequency ablation sites in a percutaneous excision-ablation-open excision human breast cancer protocol antitumor heat shock proteins were elevated. In an animal model of hepatic microwave ablation, low-energy ablation resulted in distant metastatic spread while high-energy ablation did not. Others have advanced the theory of killing tumor in situ would actually immunize the host. More work needs to be evaluated to exclude this concern.

Interest in the development of various ablation techniques holds promise in their ability to treat cancers without the need for costly interventions in an outpatient setting and for the most part without the need for radiation in favorable tumors. As health care costs soar, it makes little sense to develop expensive technologies that require MRI-guidance or other costly imaging modalities. In the United States, most surgeries are done by the general surgeon for all tumor types. To be utilitized on a wider scale, ablative procedures need to be safe, simple, and easy to use as well as effective. To this aim, McKay and colleagues have developed 13 recommendations for the implementation of tumor ablation services. Worldwide implementation requires the development

of low-cost uncomplicated procedures.

15 Upper and Lower Gastrointestinal Endoscopy

Jeffrey L. Ponsky and Jonathan P. Pearl

INTRODUCTION

Flexible endoscopy is the mainstay of diagnosis and treatment of many gastrointestinal (GI) disorders. Surgeons across the world practice flexible endoscopy and have been the innovators of many of today's advanced endoscopic techniques. As such, surgical training programs and practices have a newfound emphasis on flexible GI endoscopy.

Upper and lower endoscopy procedures are the most common operations performed by general surgeons in many parts of the United States. Surgical residency training now includes more endoscopy didactic and practical training than in years past. The modern GI and general surgeons are expected to offer comprehensive care for their patients, which includes the practice of flexible endoscopy.

INDICATIONS AND CONTRAINDICATIONS FOR DIGESTIVE ENDOSCOPY

Upper endoscopy may be prompted by complaints of dysphagia, odynophagia, or pyrosis. Suspected foreign body impaction, an abnormal barium radiograph, and GI bleeding will also indicate a need for endoscopic examination. Additional indications for esophagogastroduodenoscopy include the need for tube gastrostomy for feeding or drainage, persistent vomiting, unremitting epigastric pain, gastric polyposis, and surveillance for neoplasia in patients with conditions predisposing to malignancy such as Barrett's esophagus, gastric ulcer, pernicious anemia, and previous gastrectomy. In most cases, the endoscopist is prepared to deliver therapy at the time of diagnosis. Therapy may include removal of foreign bodies, dilation of strictures, ablation or stenting of tumors, sclerotherapy or ligation of varices, control of hemorrhage, placement of feeding tubes, and polypectomy.

Colonoscopy is most commonly performed as a screening tool for

colorectal cancer. Screening colonoscopy should begin at age 50 in average-risk patients. The recommended age for screening is lowered in patients with a family history of colorectal cancer, conditions that predispose to colorectal cancer, and high-risk ethnic groups. Patients with a family history of colon cancer require colonoscopy by age 40 or 10 years prior to the age at which their relative developed cancer. Other high-risk conditions, such as familial adenomatous polyposis, mandate colonoscopy in the teenage years.

Other common indications for colonoscopy include diagnosis of infectious or inflammatory colitis, surveillance for dysplasia or carcinoma in patients with ulcerative colitis, and lower GI bleeding. Colonoscopy may be used to decompress dilated bowel in colonic pseudo-obstruction and untwist the sigmoid colon in volvulus.

Endoscopy can be used to treat many conditions that previously required surgery. Barrett's esophagus with high-grade dysplasia can be managed with endoscopic ablation. Early stage, localized gastric cancers can be safely resected endoscopically. Endoscopic esophagomyotomy is effective for relieving the symptoms of achalasia.

There are few absolute contraindications for endoscopy. Severe comorbidities and inability to tolerate conscious sedation preclude safe endoscopy, although general anesthesia can be used in select cases. Endoscopic examinations should be performed with caution in patients with recent GI anastomoses or inflammation of the GI tract, such as diverticulitis. Endoscopy is not without complications and each case should be carefully considered prior to performance of the examination.

INSTRUMENTATION

A large variety of endoscopes are available for diagnostic and specialized therapeutic purposes in adults and children. These include small caliber (9 mm) gastroscopes and pediatric colonoscopes, large caliber (13 mm) and large working channel (6 mm) scopes for complex interventions, mother–daughter scope combinations for biliary and pancreatic ductoscopy, and long slender enteroscopes for small bowel examination. A balloon-assisted endoscope, which includes an overtube and a scope with a balloon at its tip, enables a large proportion of small bowel to be examined.

There has been a recent expansion of the tools available for therapeutic endoscopy. Biopsy forceps, cytology brushes, and snares are most commonly used for tissue sampling. Rotatable snares and snares of various

shapes facilitate difficult polypectomies. Nets may be passed through the working channel for retrieval of large specimens. Specialized electrosurgical devices, in the shape of a hook or triangle, may be used for dissection and tissue division. Powered endoscopic staplers and endoscopic suturing devices are used for resections and closure of enterotomies.

Injection of bleeding sources with epinephrine using a sclerotherapy needle is commonly used for hemostasis. Bipolar energy can be applied using a coapting probe. Nonthermal hemostasis can be achieved with hemostatic clips, loops, or bands. Large over-the-scope clips can be used on large vessels or in attempts to close fistulas or enterotomies.

ADVANCED IMAGING IN ENDOSCOPY

Visible light is the most common imaging modality for flexible endoscopy. High-definition imaging with visible light is becoming more common. While visually appealing, high-definition imaging has not been shown to increase colon polyp detection rate for experienced endoscopists. Wide-angle-view colonoscopies and mother–daughter retrospectoscopes are new imaging techniques that attempt to reduce the rate of missed polyps. Their clinical efficacy requires further investigation in clinical trials.

In another alternative technique, chromoendoscopy, a liquid dye such as methylene blue or Lugol's solution is applied to the GI mucosa using an endoscopic catheter. Barrett's esophagus and squamous cell carcinoma demonstrate differential staining from normal cells. Chromoendoscopy may be useful in patients with long-standing inflammatory bowel disease to detect occult malignancy.

Narrow band imaging (NBI) is available on most contemporary endoscopes. By changing the bandwidth of projected light from the endoscope, metaplasia and flat adenomas can be differentiated from normal mucosa. Large-scale studies have not shown a significant increase in polyp detection comparing NBI with white light imaging.

Optical coherence tomography (OCT) uses reflection of near-infrared light to produce real-time two-dimensional cross-sectional images of the GI tract. A small probe, similar to an endoscopic ultrasound probe, is passed through the scope. OCT produces a high-resolution image of the layers of the GI tract and might be used for early detection of dysplasia or metaplasia.

Technique of Esophagogastroduodenoscopy

Patients are prepared for upper endoscopy by assuring that their stomach is empty. This usually involves a 4- to 6-hour fast. The patient is positioned with the left side down and sedation is administered intravenously while vital signs and oxygen saturation are monitored. Topical posterior pharyngeal anesthesia may also be used. The endoscope handle is held in the left hand regardless of the surgeon's hand dominance. The up and down deflection knob is controlled by the left thumb, while the air, water, and suction buttons are manipulated by the left index and middle fingers. The smaller left–right deflection knob is usually managed by the right hand. The surgeon's right hand controls the shaft of the endoscope for advancing and rotating the instrument.

The safest method of introducing the endoscope into the esophagus is under direct vision (Fig. 15.1). The endoscope is slowly advanced over the tongue until the epiglottis and vocal cords are visualized. The tip is then angled posteriorly between the arytenoids, while the patient is asked to swallow. Gentle pressure is then applied to advance the scope into the esophageal introitus. If the tip of the scope slips into the piriform sinus, it is withdrawn and positioned in the midline above the esophageal introitus, and the patient is asked to swallow again.

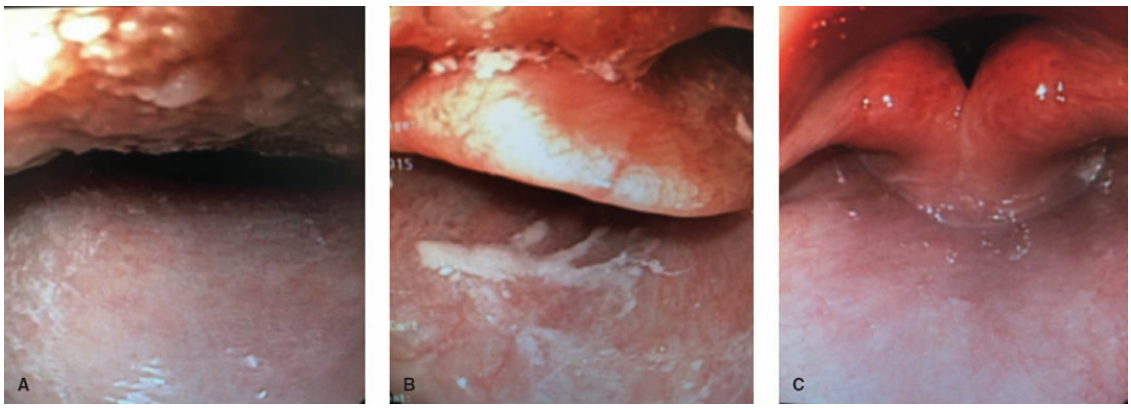

Figure 15.1. A. The scope is introduced under direct vision between the tongue (above) and the hard palate (below). The hard palate becomes continuous with the esophagus. **B.** As the scope is advanced, the epiglottis is visualized. The scope is directed posteriorly to the epiglottis. **C.** Just beyond the epiglottis, the vocal cords and arytenoid cartilages are seen. The scope is advanced in the midline and posteriorly into the esophagus.

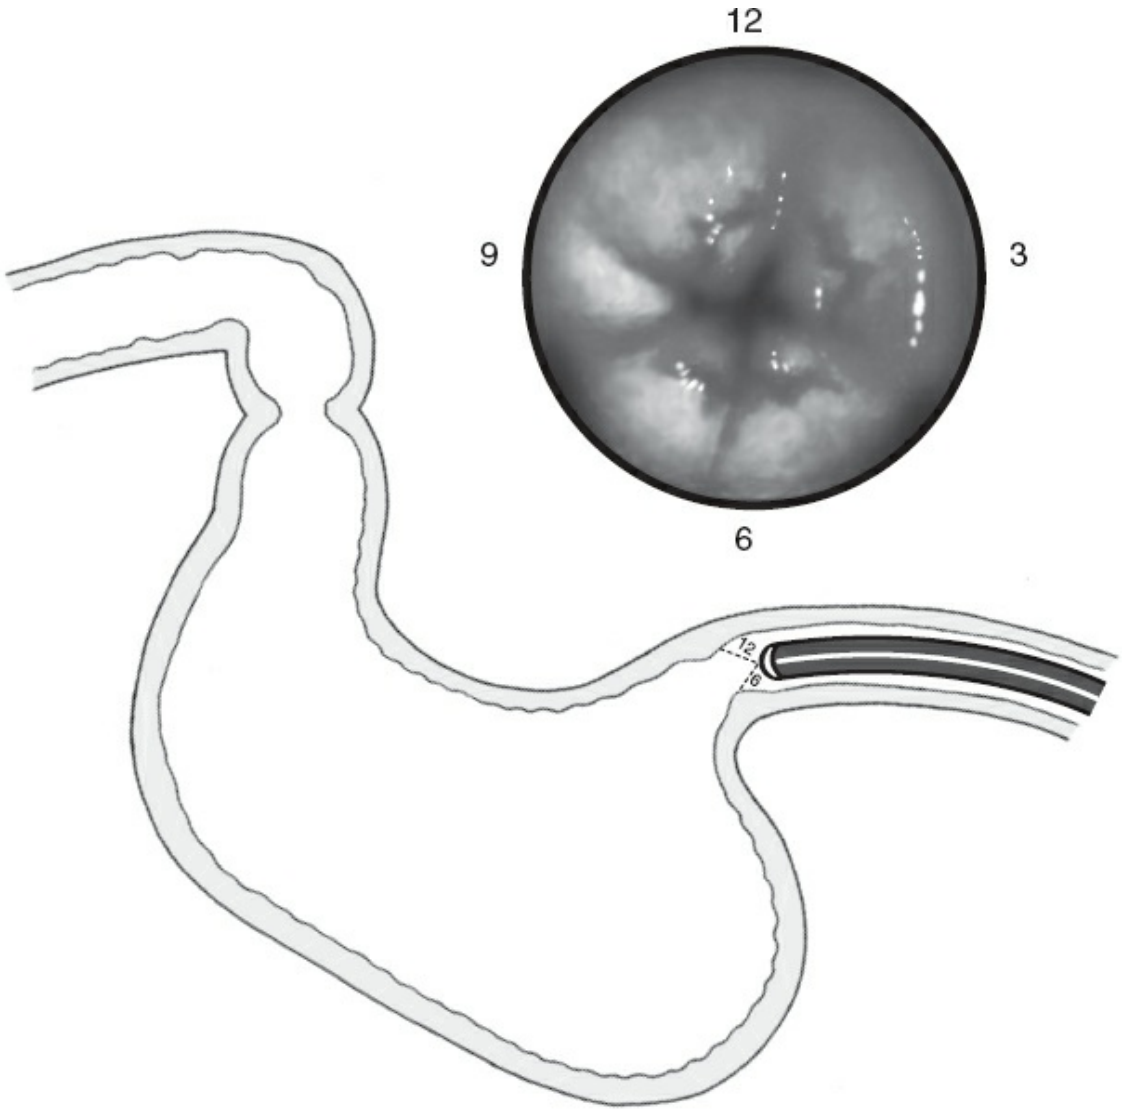

Figure 15.2. The “z” line appears at the esophagogastric junction. It represents the change from the squamous esophageal mucosa to the columnar epithelium of the stomach.

The esophageal lumen appears as a long, straight tube. Once it is entered, air is insufflated. A long view of the esophagus should be obtained and its mucosa inspected. Peristalsis should be noted, and evidence of inflammation or Barrett’s epithelium sought. The endoscope is advanced carefully and only while visualizing the lumen rather than sliding along the mucosa. Interruptions in the normal mucosa by inflammation or suspected neoplasm should be assessed by cytologic brushing and biopsy. A hiatal hernia will appear as a saccular portion of gastric mucosa above the pinching action of the diaphragm. Normally, the esophagus turns slightly to the left as it traverses the diaphragm and enters the abdomen. The esophagogastric junction is noted by the “z” line, an

irregular junction of the orange columnar gastric mucosa with the pale pink squamous mucosa of the esophagus (Fig. 15.2).

The stomach should be fully inflated with air. Any redundancy in the scope should be reduced and the mucosa carefully observed. The scope should be oriented in the gastric body so that the stomach's posterior wall is at the 3 o'clock position, the lesser curvature at the 12 o'clock position, the anterior wall at the 9 o'clock position, and the greater curvature at the 6 o'clock position (Fig. 15.3). Small movements of the control knobs will direct the tip of the scope in any desired direction. Abnormalities noted may include ulcerations, gastritis, vascular lesions, neoplasia, or extrinsic impressions upon the gastric wall. The location of such extrinsic impression may indicate the probable source. For example, a large impression on the posterior wall of the stomach, noted at the 3 o'clock position, may indicate a pancreatic mass such as a pseudocyst or tumor.

The endoscope is advanced toward the gastric antrum by following the lesser curvature, and the incisura angularis will be observed at the 12 o'clock position. It is a smooth curved arch dividing the gastric body from the antrum. Marked elevation of the instrument's tip and a small turn to the left while the scope is positioned at the gastric angle will usually permit a retroflexed view of the gastric cardia and fundus (Fig. 15.4). The shaft of the scope is then withdrawn to bring the tip of the scope toward the gastric cardia. The shaft of the retroflexed scope is rotated to allow careful assessment of the cardia, fundus, and the lesser curvature.

The large rugal folds noted on the greater curvature of the stomach's body disappear as the antrum is entered. The tip of the scope is elevated to permit its advancement toward the pylorus. Small circular motions of the scope's tip will permit visualization of the entire antrum. The pylorus is normally round and may be observed to open and close (Fig. 15.5). Irregularities of the pyloric shape may suggest past or present ulceration. While keeping the pyloric orifice directly in the center of view, the scope is advanced with gentle pressure and slight insufflation of air, into the duodenal bulb. The bulb has no folds and is a frequent site of inflammation and ulceration. Small motions of the instrument's tip will help reveal the more obscure corners of the bulb where ulcers may hide (Fig. 15.6). Once inspection of the anterior and posterior bulb is complete, the scope is advanced into the descending duodenum. This usually requires a maneuver, which is not under direct vision. The scope's tip is turned to the right as the shaft of the instrument is also rotated to the right. The tip is

first moved upward and then down. This turns the instrument posteriorly and then downward into the second portion of the duodenum. Once the lumen of the descending duodenum is in view, slight pressure may be applied to the shaft of the scope to introduce it farther. If resistance is encountered, the scope should be pulled back and straightened. This will usually result in the endoscope advancing further in the duodenum as the redundant gastric loop is straightened. The scope is then withdrawn while close attention is paid to the mucosal detail. The small bowel is noted by the semicircular folds, which are the hallmark of its architecture. The ampulla of Vater may be seen in profile at the 9 o'clock position in the descending duodenum (Fig. 15.7). Its orifice is usually difficult to observe with the end-viewing endoscope used for standard upper endoscopy. The accessory papilla, orifice of the duct of Santorini, may sometimes be observed slightly proximal to the ampulla of Vater in the 1 o'clock position. The instrument is pulled back, with the endoscopist slowly manipulating the controls to again survey the walls of the duodenum, stomach, and esophagus.

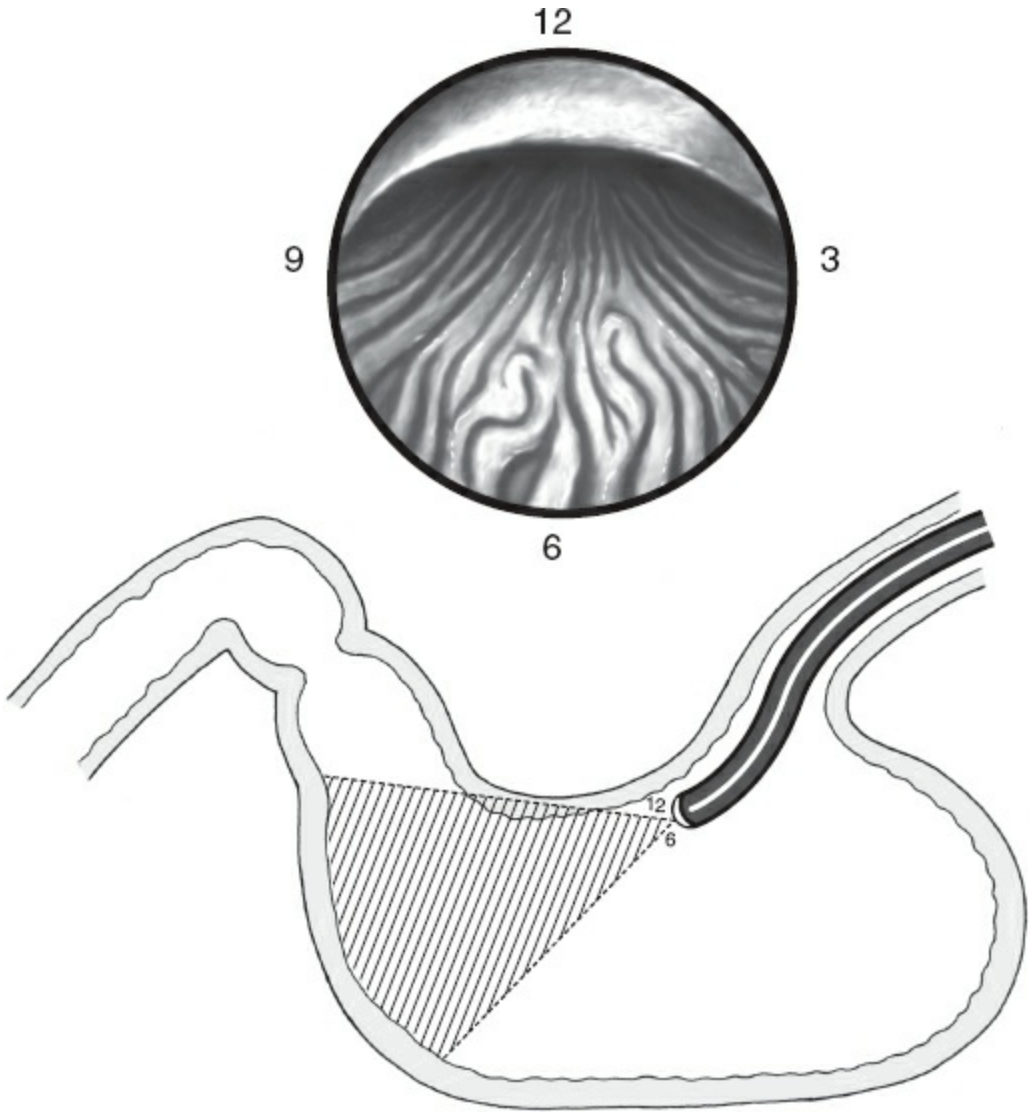

Figure 15.3. In the body of the stomach, with the patient in the left lateral decubitus position, the lesser curvature is at the 12 o'clock position, the posterior gastric wall at 3 o'clock, the anterior wall at 9 o'clock, and the greater curvature at the 6 o'clock position. The gastric angle, separating the gastric body from the antrum, is seen as a smooth arch along the lesser curvature.

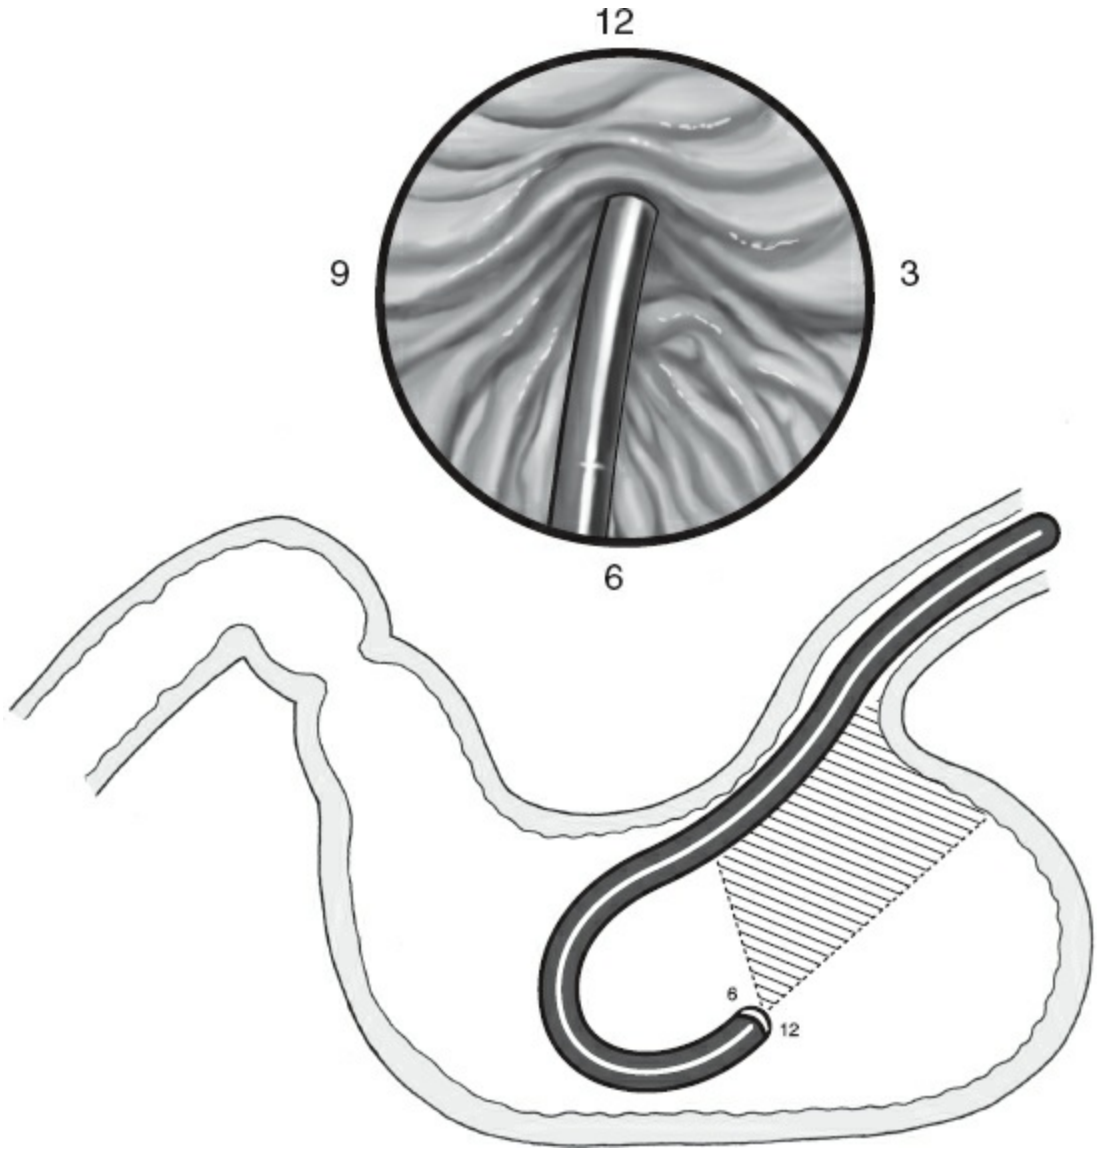

Figure 15.4. A retroflexed view can be easily accomplished and permits inspection of the cardia and fundus.

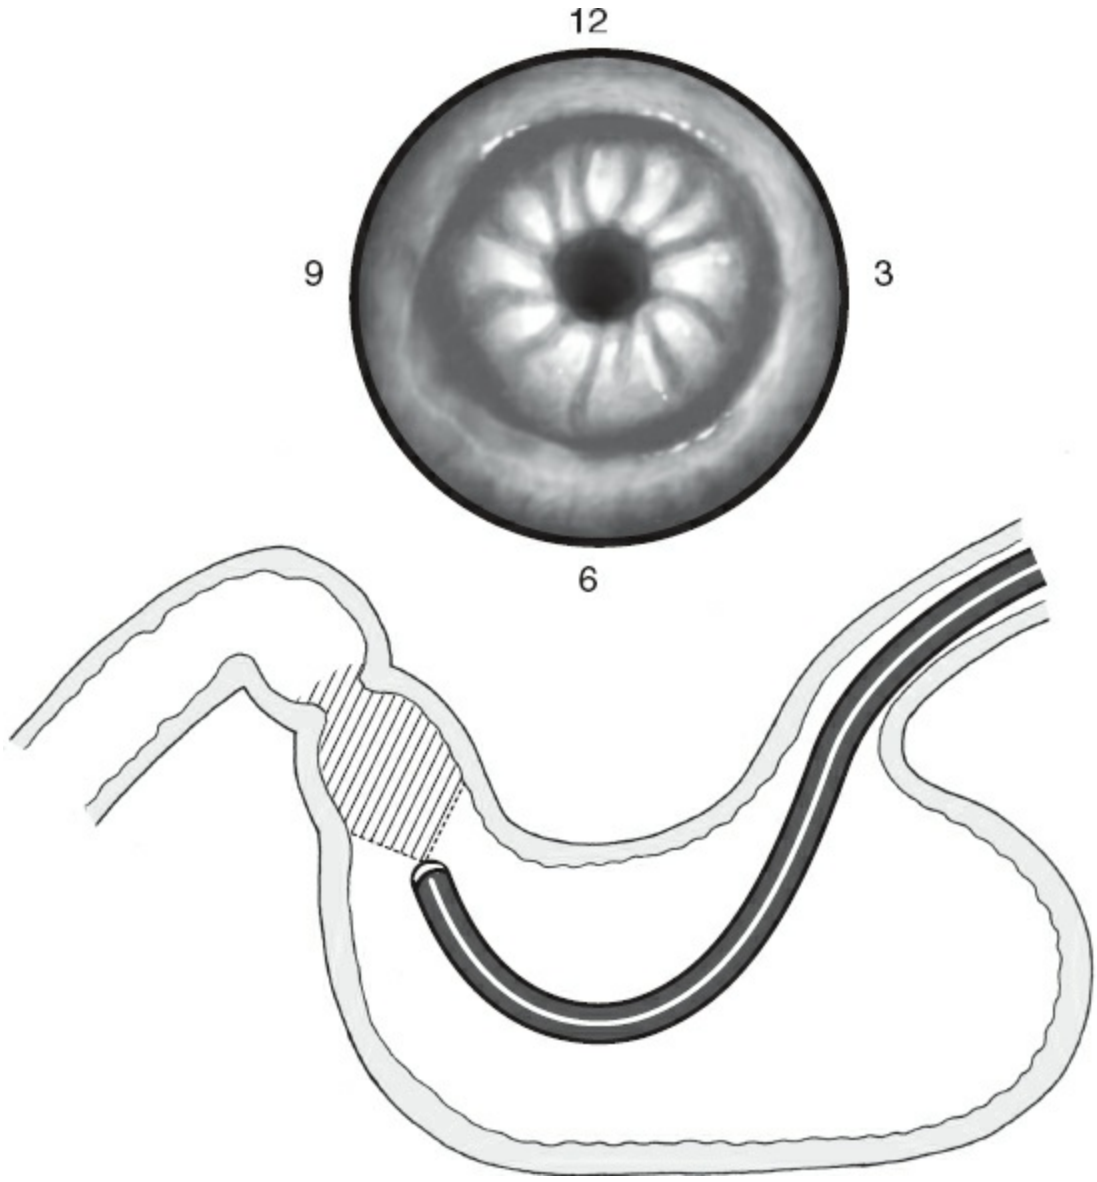

Figure 15.5. The antrum has few rugal folds. The pylorus is typically round and may be observed to open and close.

Therapeutic Interventions During Upper Endoscopy

The ability to deliver endoscopic therapy has increased greatly in recent years as technologies have been developed to permit treatment through the working channel of the endoscope. These applications have included the ability to coagulate bleeding lesions with monopolar or bipolar probes, or to inject them with long needle injection catheters. Esophageal varices can be treated with injection sclerotherapy or rubber band ligation, controlling hemorrhage and eventually obliterating the large venous trunks. Hydrostatic balloons can be introduced through the working channel to dilate esophageal, anastomotic, and pyloric strictures, and laser energy can

be directed through the scope to debulk obstructing esophageal tumors or to treat vascular lesions of the stomach.

Endoscopic mucosal resection (EMR) may be used to remove esophageal and gastric lesions including Barrett's esophagus, dysplasia, and early carcinoma. The most common resection technique uses saline injected beneath the lesion to elevate the mucosal lesion off the underlying submucosa. The area is then resected with a snare. Other EMR techniques include the suck-and-cut and suck-and-ligate techniques. Both of these use specially designed systems to resect lesions in the submucosal plane.

Endoscopic submucosal dissection (ESD) may be used to resect early esophageal neoplasms, localized gastric cancers, and, in rare cases, small duodenal cancers. There are a variety of techniques used to achieve an *en bloc* resection of localized lesions with clear margins. A liquid is first injected into the submucosal plane. The mucosa is then divided and the submucosal plane is entered. A combination of needle cautery and blunt endoscope cap dissection is used to complete the resection. The mucosal defect is typically closed with clips or by using a suturing device. In many parts of the world, ESD has become the standard method for resection of early upper GI malignancies.

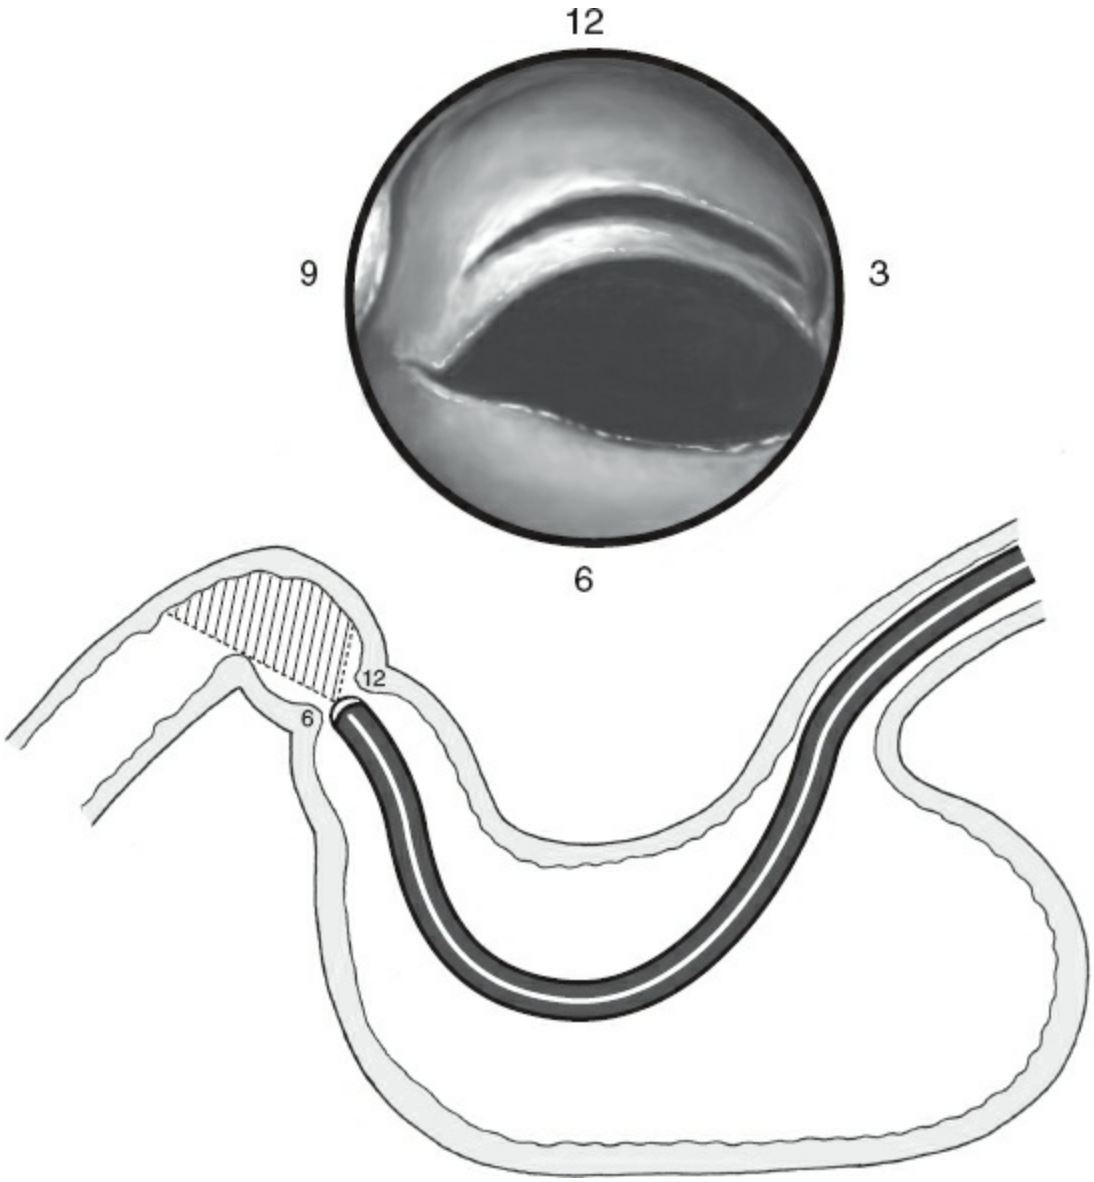

Figure 15.6. Inspection of the duodenal bulb is often best accomplished through the pylorus or with the scope's tip in the pyloric channel. The superior duodenal fold marks the downward turn of the second portion of the duodenum.

Barrett's esophagus with or without dysplasia may be treated with radio frequency ablation. Specially designed balloons deliver controlled doses of energy to the entire circumference of the distal esophagus in long-segment Barrett's. A cap can be affixed to the tip of the endoscope to deliver radio frequency energy to isolated areas of intestinal metaplasia. Radio frequency ablation with or without EMR or ESD has become the standard treatment for Barrett's esophagus with dysplasia. The same techniques are being studies in patients with Barrett's esophagus and intramucosal carcinoma and other early stage esophageal cancers.

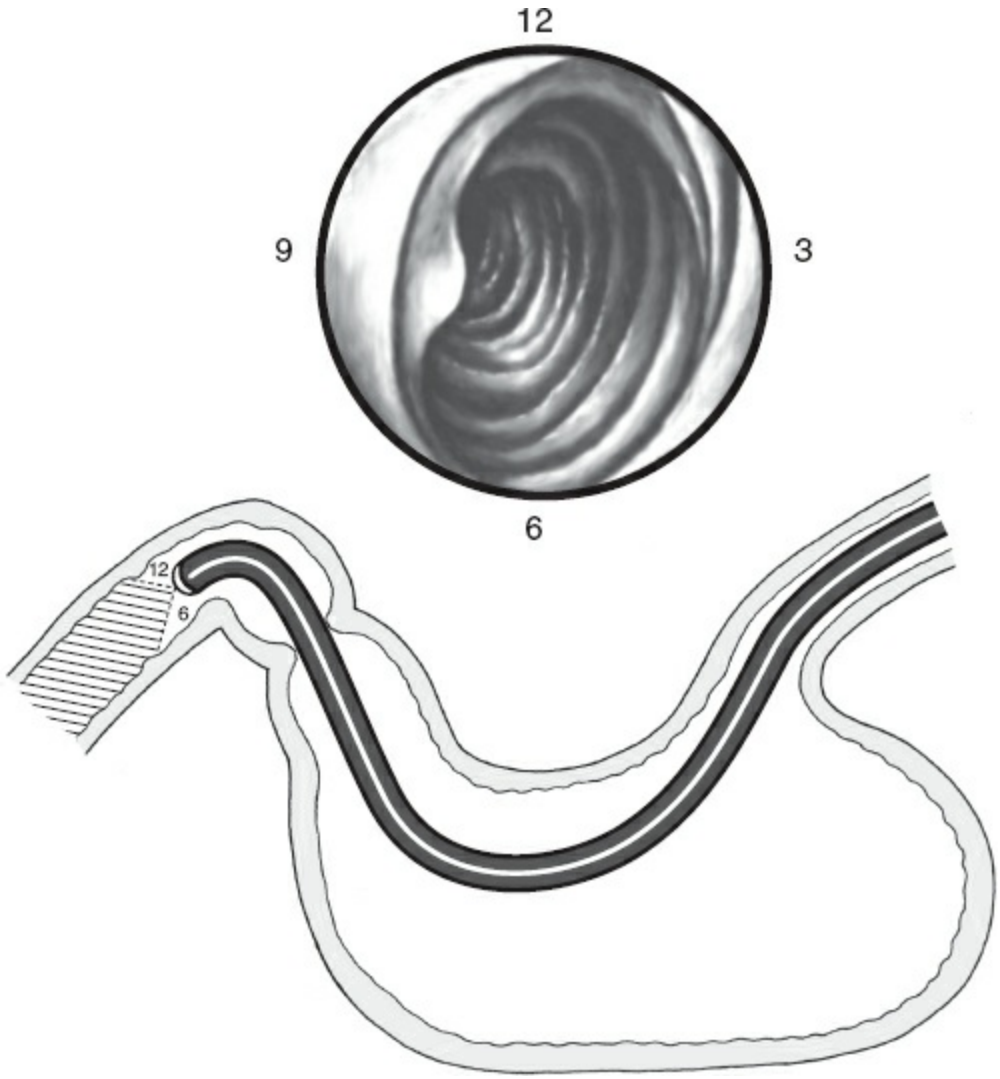

Figure 15.7. Once in the descending duodenum, the scope is pulled back and straightened. The ampulla of Vater may be seen in profile at the 9 o'clock position on the medical duodenal wall.

Upper GI stenting is useful in the management of postoperative stricture, anastomotic leak, or malignant stricture. Covered, self-expanding metal stents are frequently used in the management of staple line leaks after gastric bypass or sleeve gastrectomy. Many patients receive definitive management of the leak from the stents. In others, stenting may permit control of sepsis and nutritional repletion prior to definitive surgical management.

Transgastric natural orifice transluminal endoscopic surgery (NOTES) requires a gastrotomy to access the peritoneum. There are case series of NOTES cholecystectomy, appendectomy, oophorectomy, peritoneoscopy, and other procedures. Specialized instrument platforms have been developed to facilitate these operations. Concerns about reliable closure of

the gastrotomy, effective methods of retraction, and overall patient safety have led to limited adoption of pure NOTES procedures. Many of the techniques initially developed for NOTES have translated into other advanced endoscopic procedures such as ESD and endoscopic myotomy.

Per oral endoscopic myotomy (POEM) is an endoscopic therapy for patients with achalasia. Similar to ESD, the submucosal space of the midesophagus is entered by creating a submucosal bleb and incising the mucosa. A cap is affixed to the tip of the endoscope to facilitate submucosal dissection distally on the esophagus and onto the proximal stomach. The inner circular muscle fibers are then divided with an electrosurgical device, using care to carry the myotomy several centimeters onto the stomach. The mucosal defect is then closed using clips.

POEM is most commonly done under general anesthesia. Patients stay overnight in the hospital and commonly receive an upper GI fluoroscopic examination the following day. The short- and medium-term results of POEM have been favorable. There is good relief of symptoms without severe reflux symptoms. POEM may be used as a primary therapy for achalasia or in patients who have persistent symptoms after surgical esophagomyotomy. Severe complications, such as perforation and tension pneumothorax, have been low.

Technique of Colonoscopy

Mechanical bowel preparation is critical for proper colonoscopic examination. Large volume polyethylene glycol solutions effectively lavage the colon and are safe for most individuals. The dose may be given completely on the day prior to colonoscopy or split to include a portion on the day of the procedure. Sodium phosphate solutions require a lower volume to cleanse the colon but may induce hyperphosphatemia in patients with renal insufficiency.

The left lateral decubitus position is used to begin the procedure, although it is common to turn the patient occasionally during the course of the procedure to facilitate passage of the instrument through tortuous areas. A careful digital rectal examination should precede introduction of the scope, in order to dilate the rectum as well as to assure that no low-lying lesions are overlooked.

The colonoscope is positioned in the rectal vault and inserted proximally by a combination of maneuvers, which include manipulation of

the endoscope tip with the control knobs, advancement and torsion of the instrument shaft, repeated hooking of the scope's tip around colonic folds and withdrawal to remove redundant coils in the shaft, and repeated suctioning (Fig. 15.8).

The colonoscope should be advanced only when the lumen ahead is clearly visible. Blind insertion of the scope in hopes that it will "slide by" may cause perforation. While the latter method may occasionally be employed by experts in difficult circumstances, it remains risky and should be used sparingly. When the lumen is visible ahead, the scope may be inserted further. Should the lumen disappear, it is most effective to pull the shaft back slightly, inflate a bit, and reassess the position of the lumen. These repeated pullbacks and advancements can be accomplished quite rapidly and serve to telescope the colon on the endoscope (Fig. 15.9).

The optimal colonoscopy is performed without any looping of the scope. This can be gauged by the length of scope inserted. A straight scope usually reaches the splenic flexure in 50 to 55 cm, and the cecum can normally be reached in 100 cm or less. During negotiation of the sigmoid colon, a loop often forms. This should be reduced in the descending colon prior to traversing the sigmoid flexure. At times, in spite of the endoscopist's best efforts, insertion of the scope's shaft does not result in the advancement of the tip because of looping. Further introduction of the scope will usually exacerbate the looping, cause the patient discomfort, and risk of perforation. In such situations, it may be useful to have an assistant apply some pressure to, or lift, the left side of the abdomen. This will act to stiffen the sigmoid loop and allow advancement of the scope. Alternatively, the patient's position may be changed to alter the position of the colonic loops. Placing the patient in the supine position, while trying to proceed through a difficult sigmoid colonic segment, is often effective.

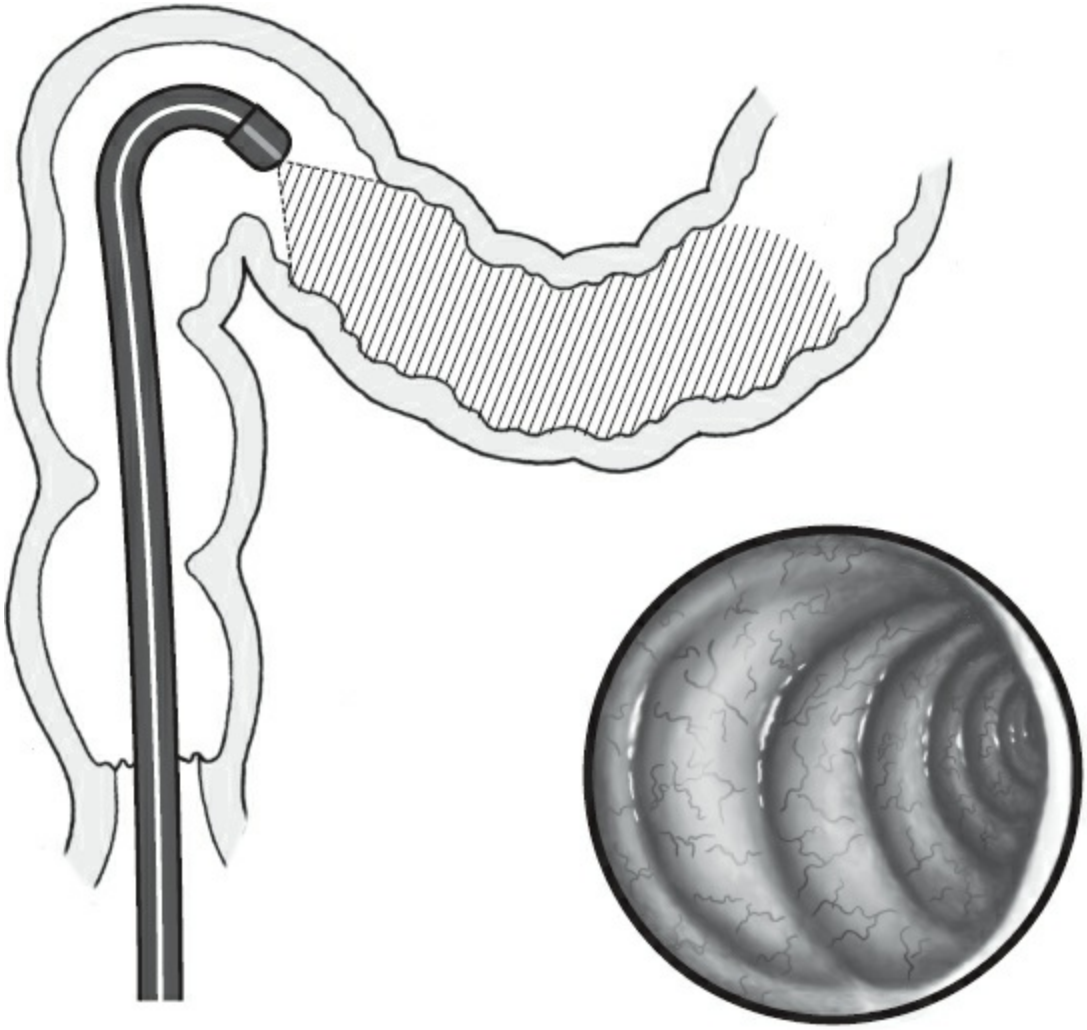

Figure 15.8. After insertion into the rectal vault, the colonoscope is inserted under direct vision.

Even when direct pressure continues to result in the advancement of the scope's tip, it is useful to remove redundant loops by stopping, hooking the tip, and pulling back, in an effort to telescope the colon onto the scope's shaft (Fig. 15.10). This is easily accomplished after entering the transverse colon, and after turning downward into the right colon. In fact, pulling back on the shaft may actually produce significant paradoxical advancement of the scope's tip. Finally, the application of suction, while the instrument is positioned in the center of the colonic lumen, will often draw colon up onto the scope and shorten the colon. The latter technique may be particularly useful in intubating the final several centimeters of the cecum.

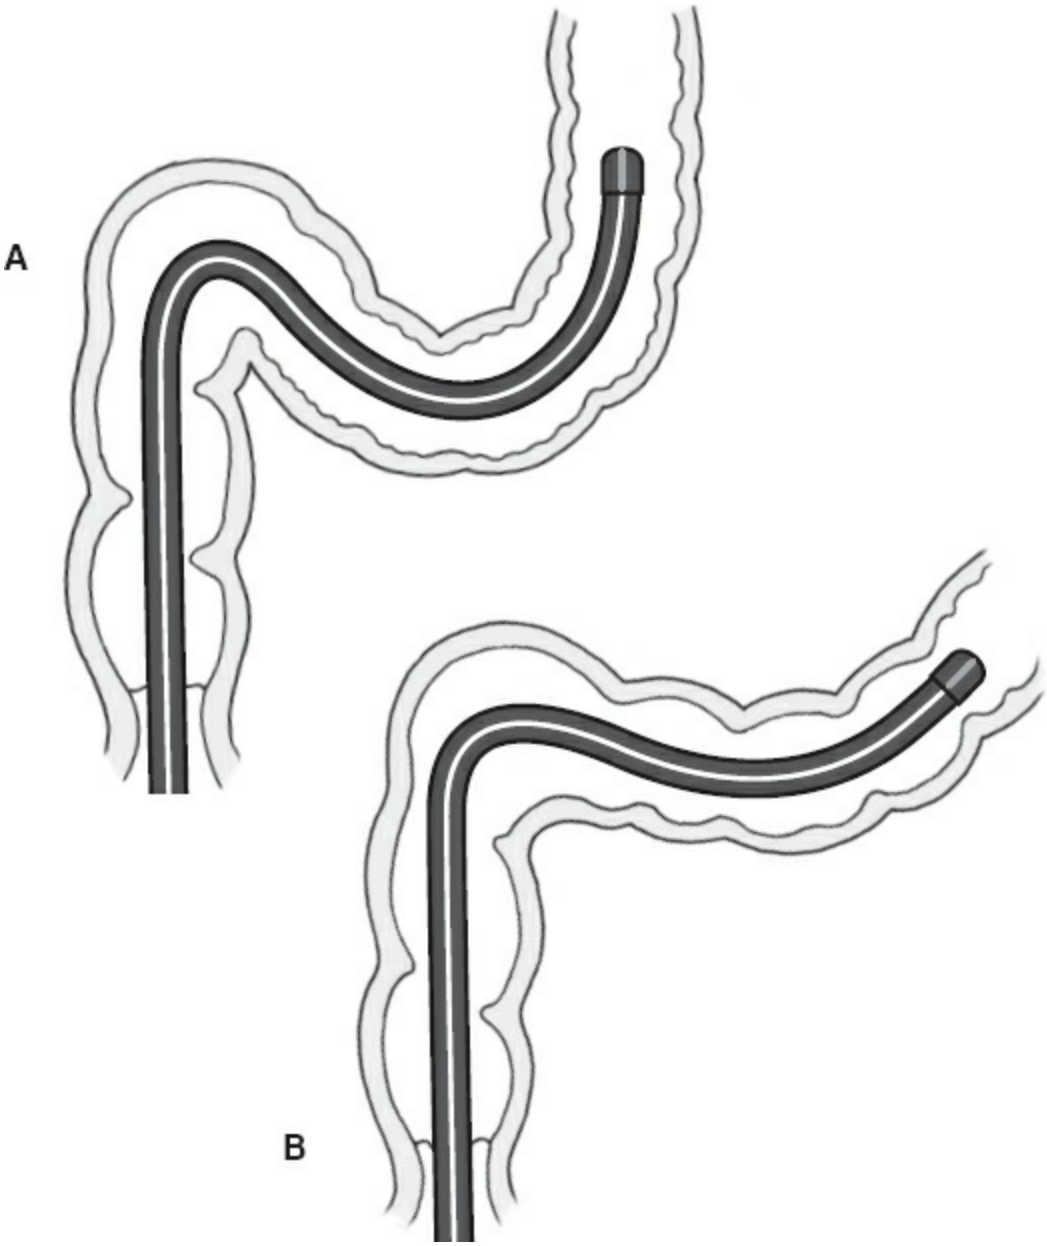

Figure 15.9. Hooking the tip of the scope around folds and pulling back often permits advancement through tortuous colonic turns.

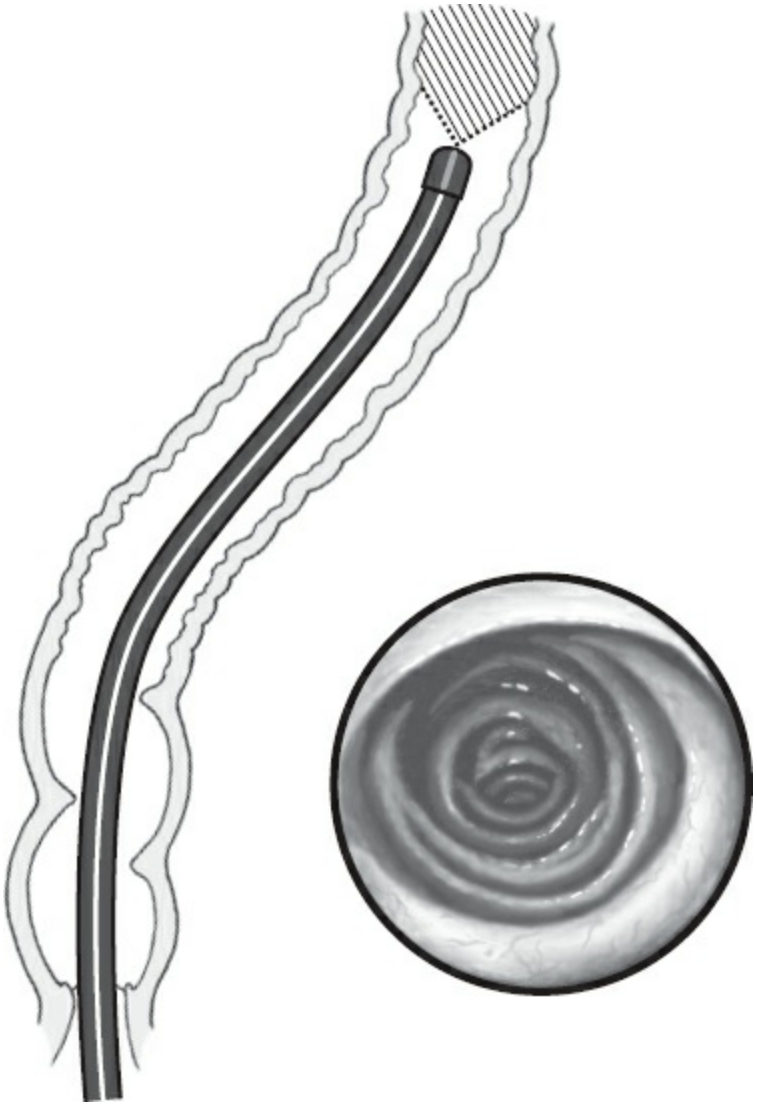

Figure 15.10. Multiple sequences of hooking and pulling back should result of straightening of the colonic loops and telescoping of the colonic segments onto the scope.

After insertion to the cecum, the instrument is slowly withdrawn while slight adjustments to the tip position are made to ensure complete visualization to the colonic mucosa. The varying appearance of the interior colon helps the endoscopist to define the location of the endoscope's tip and the location of any pathology encountered. The cecum demonstrates an arching convergence of the colonic tenia, often described as the "Mercedes sign," and the appendiceal orifice can usually be identified as a slit in the mucosa of the cecum. Just slightly above (distal) to this area is the ileocecal valve, appearing as a slightly thickened fold, occasionally yellow in hue due to some lipomatous infiltration (Fig. 15.11). The hepatic flexure transmits the bluish cast of the liver adjacent to it. Triangular folds

are the distinguishing anatomic feature of the transverse colon, and long segments of the lumen may be viewed at one time. Care should be taken to look behind large folds for lesions, such as small neoplasms, which may be hidden behind them.

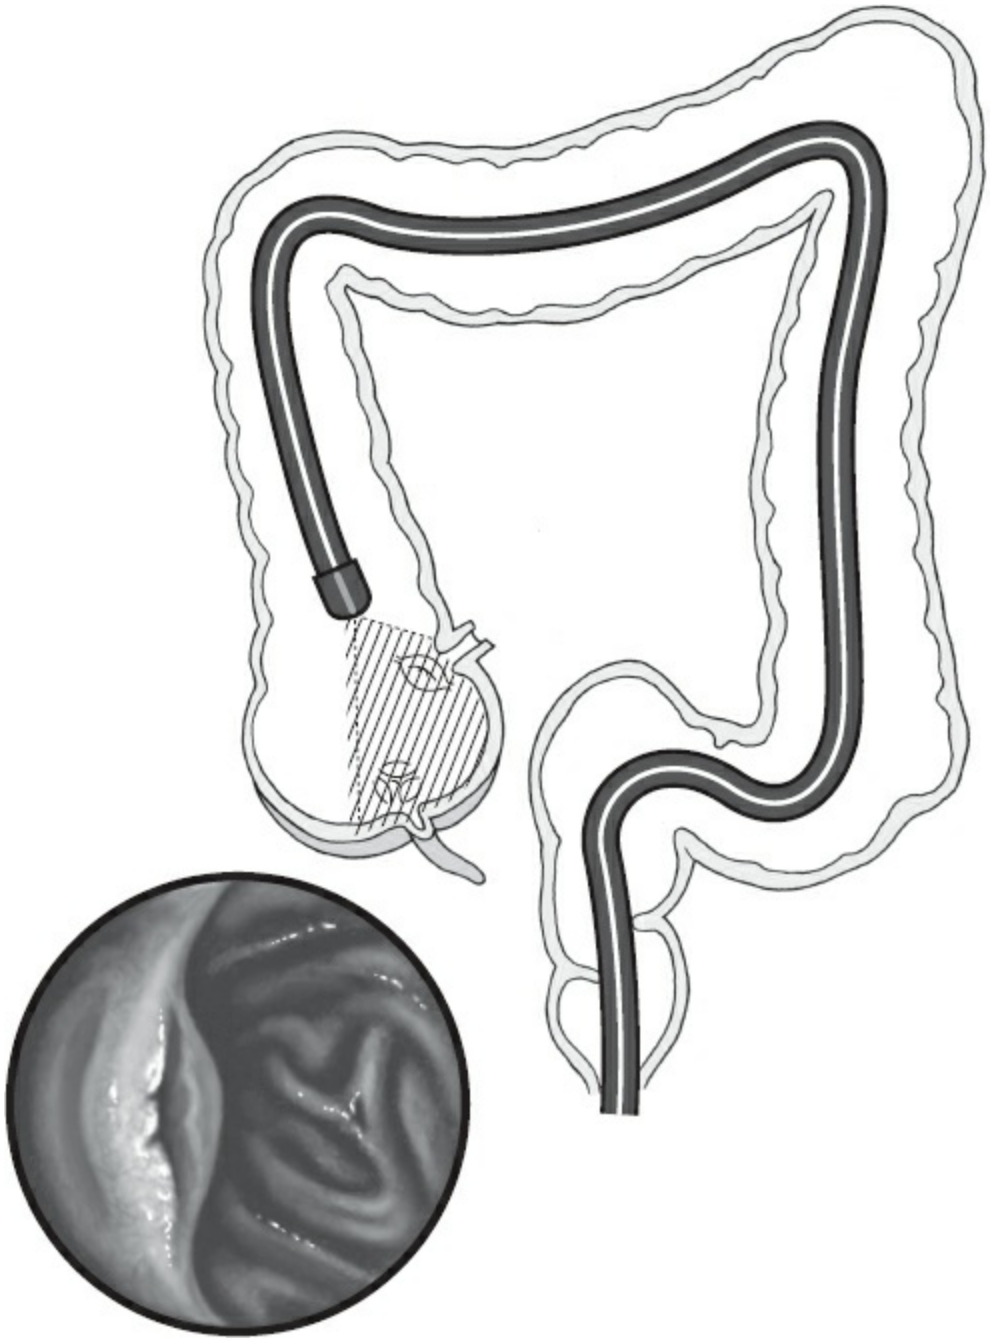

Figure 15.11. The cecum can be recognized by the confluence of the colonic tenia, the “Mercedes sign,” and the profile of the ileocecal valve.

As the scope is withdrawn from the transverse colon past the splenic

flexure, the sharp turns may hinder complete examination of the lumen, and reinsertion past this point several times may be necessary to accomplish satisfactory examination of the area. The descending colon usually appears as a long straight tube with little haustration, and the endoscopist will recognize entry into the sigmoid colon when the lumen turns frequently and folds become eccentric. Finally, the rectum will be noted to display prominent vasculature and a widened lumen. Once the colonoscope has been withdrawn to the level of the rectal columns, a retroflexed view of the rectal vault is usually performed to assure that lesions just adjacent to the anal opening are not overlooked. The retroflexion is accomplished by directing the tip of the instrument severely upward while rotating the shaft of the scope to the left and inserting it further. Should the patient experience pain with the maneuver, the scope should be withdrawn and the procedure started again. Satisfactory retroflexion will be recognized by visualization of the scope entering the rectum, and the dentate line will be clearly visible. In this position, the scope is brought closer to the dentate line by withdrawing the shaft. Rotation of the shaft permits full examination of the rectal vault. Finally, the scope is straightened, air suctioned from the colonic lumen, and removed.

There are several quality measures that all endoscopists should follow. Cecal intubation rate, adenoma detection rate, and rates of complications such as bleeding and perforation are routinely tracked. The cecum should be reached in over 90% of cases. The expected overall adenoma detection rate is over 25%. Perforations have been shown to occur in one of every 10,000 cases. High-quality colonoscopy is possible with a good bowel preparation, careful technique, and appropriate training in flexible endoscopy.

Therapy During Colonoscopy

The most frequent interventions performed at colonoscopy are biopsy and polypectomy. Biopsy forceps may be passed through the working channel of the colonoscope to sample tissue. Areas of suspected neoplasia, dysplasia, or inflammation are sampled. Insulated forceps with large jaws permit simultaneous biopsy and thermal destruction of small lesions (Fig. 15.12). Biopsy without electrocautery is commonly practiced today due to concerns about transmural injury to the colon wall.

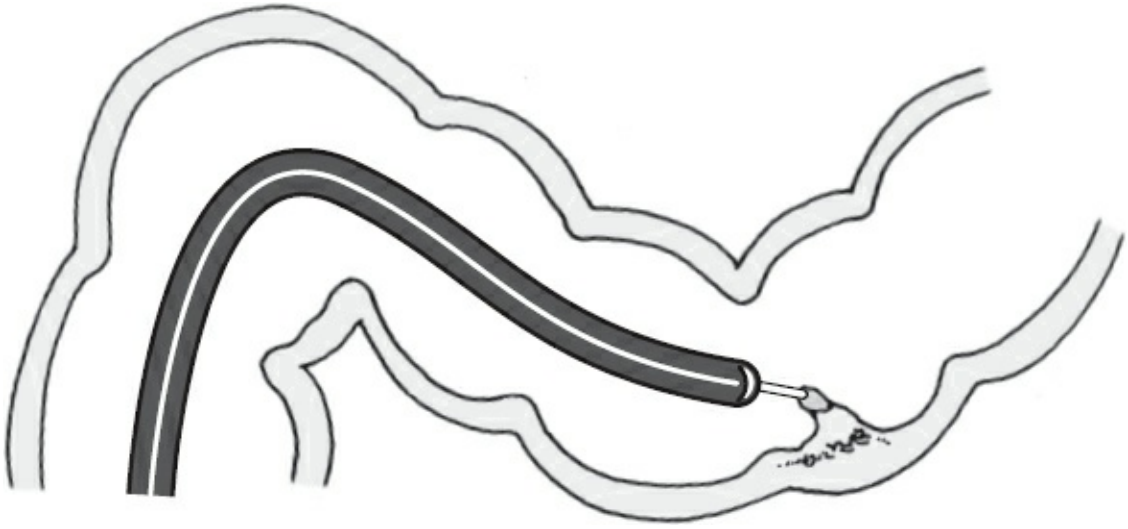

Figure 15.12. A hot biopsy forceps permits sampling of small lesions with their simultaneous destruction. Care must be taken to avoid excessive application of current with subsequent transmural injury.

Polypectomy is the most common therapeutic application of colonoscopy. These techniques have been well described, and involve the encirclement of polypoid tissue with a wire loop, subsequent tightening of the loop, and application of coagulation current to effect separation of the tissue (Fig. 15.13). Small or pedunculated polyps are removed with one application of the snare loop, while larger or sessile lesions usually require piecemeal excision. Cold snare polypectomy, without the application of energy, is being employed with regularity to limit the risk of thermal injury. Once again, with large or sessile lesions, EMR may be accomplished by first injecting saline to elevate the lesion, and then using the snare and cautery for resection. Samples are retrieved with suction, snare, or baskets and sent for pathologic examination (Fig. 15.14). ESD is occasionally used for the resection of large colon polyps. The colon wall is quite thin, especially in the cecum, and care must be taken to avoid full-thickness resections when using these advanced resection techniques.

Recent literature has shown that colonoscopy is less effective at polyp detection in the proximal colon compared to the distal colon. The rate of missed adenomas using a single forward view of the cecum and ascending colon is as high as 10%. To improve the detection rate, retroflexion in the cecum or a second forward-view of the right colon has been recommended. There is a small risk of perforation of the right colon with retroflexion, although large studies with expert endoscopists have shown no adverse events with retroflexion.

The traditional adenoma to carcinoma sequence of colorectal cancer is well known and provides the rationale for polypectomy. In recent years, an alternative serrated adenoma pathways was been elucidated. Serrated adenomas are the precursors for 10% to 40% of colorectal cancer, more commonly in the proximal colon. Serrated polyps arise in hyperplastic lesions and are more difficult to detect since they are flatter with less mucosal distortion than adenomas. While hyperplastic polyps were traditionally considered benign lesions, recent data have identified the risk of malignancy with hyperplasia and serrated polyps. The current recommendation is for resection of all hyperplastic lesions proximal to the sigmoid colon and any hyperplastic lesion greater than 5 mm located in the rectosigmoid region.

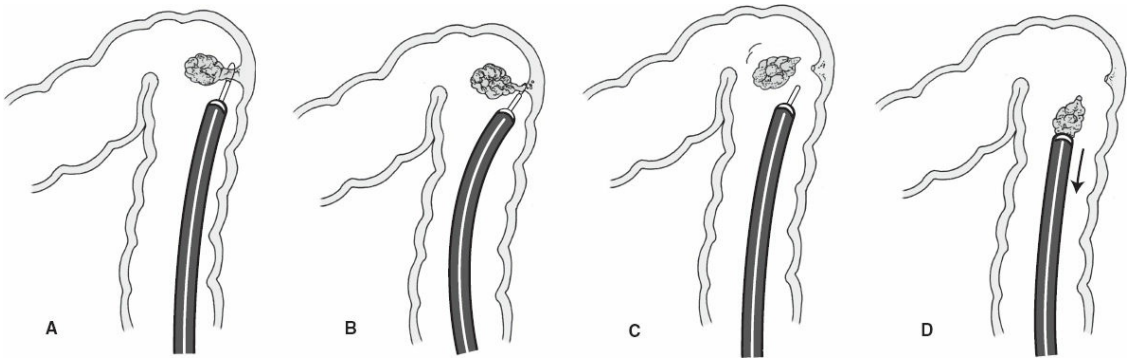

Figure 15.13. **A:** Pedunculated polyps are surrounded by a polypectomy snare. **B:** The snare is tightened at the junction of the stalk and the polyp head. **C:** Coagulation current is then used to transect the stalk. **D:** The head is then retrieved for pathologic examination.

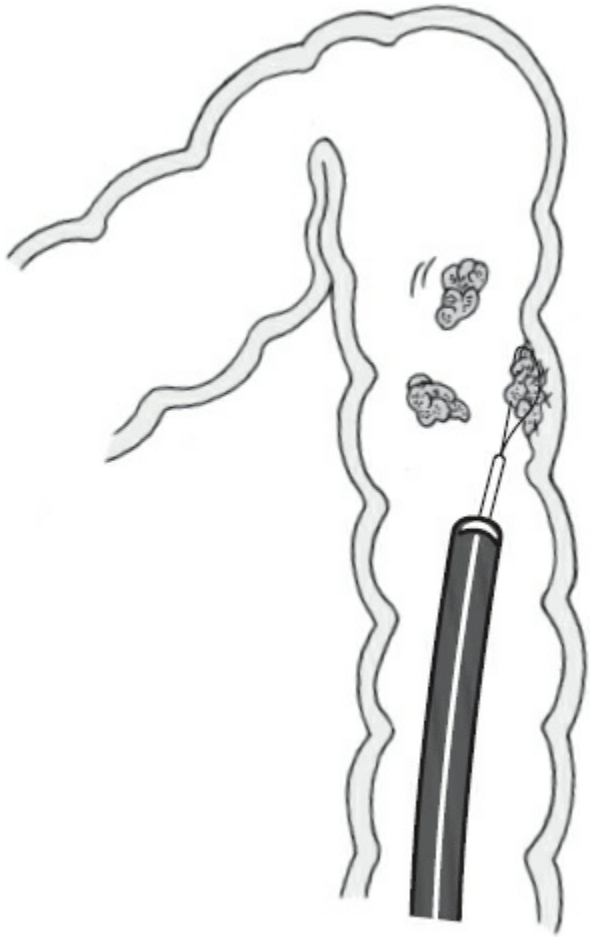

Figure 15.14. Sessile or large pedunculated polyps may require piecemeal excision. All fragments should then be retrieved for pathologic examination.

Stenting of near-obstructing colon neoplasms has been shown to be an effective bridge to definitive surgery and may avoid a colostomy in many cases. Descending and sigmoid colon lesions are most amenable to stenting. The endoscope is advanced to the near-obstructing lesion. A wire is advanced through the residual lumen and the stent is placed over the wire across the lesion. Its proper placement is confirmed endoscopically. Additional therapeutic interventions through the colonoscope include thermal ablation of tumors and vascular malformations, colonic decompression, and detorsion of volvulus.

New and Evolving Endoscopic Techniques

The goal of many evolving endoscopic techniques is to mimic a surgical procedure while limiting the discomfort and scarring which accompanies operation. Procedures which do not require organ resection are most suitable to endoscopic therapies.

POEM has been shown to produce similar outcomes compared to laparoscopic Heller myotomy. More than 90% of patients experience relief of their symptoms with POEM. The rates of clinically significant esophageal reflux are similar to standard myotomy and the complication rate is low.

Endoscopic restrictive and malabsorptive procedures have been developed to induce weight loss. An intragastric balloon may be inserted endoscopically and inflated. This space-occupying prosthesis limits the capacity of the stomach to accept food. A plastic gastroduodenal sleeve may be inserted using an endoscope. The food is transmitted from the stomach to midjejunum without contact with the duodenal and proximal jejunal mucosa. This limits absorption and promotes weight loss. Both techniques are investigational and have not yet been shown to yield significant and sustainable weight loss.

Transgastric endoscopy has been used to perform pancreatic necrosectomy in patients with complicated pancreatitis. This technique is evolved from transgastric drainage of pancreatic fluid collections. Endoscopic ultrasound is used to localize areas of pancreatic necrosis. The wall of the stomach abutting the necrosis is punctured. A self-expanding metal stent may be placed to maintain the tract. The endoscope is then passed through the tract and endoscopic baskets and forceps debride the necrotic tissue. Specialized centers have shown the technique to be safe and effective.

Endoscopic treatment of gastroesophageal reflux disease (GERD) has been attempted using injected polymers, suturing devices, and radio frequency energy. More recent endoscopic therapies for reflux try to mimic a surgical fundoplication. A device using a specialized retractor and T-fasteners can create a 270-degree posterior-to-anterior fundoplication. While appealing, the durability of symptom relief is not optimal.

Although pure NOTES procedures are not commonly performed today, the research and ingenuity devoted to NOTES have spawned many advances in endoscopy. Endoscopists have recognized the utility in accessing the submucosal space, which has led to the development of ESD and POEM. Advanced endoscopic tools meant for NOTES, such as suturing devices and clip appliers, have been used clinically to repair perforations, thus sparing conventional surgery.

CONCLUSION

Flexible endoscopy is a mainstay in surgery practices throughout the world. Emphasis on high-quality endoscopy has led to better endoscopic examinations and improved patient outcomes. Advanced techniques now permit endoscopic resection of localized neoplasms and performance of complex maneuvers, such as myotomy. It is incumbent upon surgeons to take the lead in these advanced techniques. Surgeons have the knowledge of the disease processes, the experience with surgical and endoscopic procedures, and the ability to manage any complications which might arise. The future of flexible endoscopy is certain to include continued advances with more complex techniques. Surgeons should not be left behind.

EDITOR'S COMMENT

At its inception, endoscopy was used strictly for diagnosis. In today's world, endoscopic procedures are performed in lieu of what had previously been completed via laparotomy and the discipline of GI endoscopic surgery is rapidly evolving. Novel endoscopic techniques and technologies are being developed to manage complications and treat disease in a manner not considered possible as recently as a decade ago.

Surgical endoscopy has a rich tradition, as many pioneers in interventional endoscopy were surgeons. In 1968, McCune reported the first cannulation of the ampulla of Vater in a precursor to what would become endoscopic retrograde cholangiopancreatography (ERCP). Shinya and Wolff introduced colonoscopic

polypectomy in 1975, essentially abolishing the then common practice of barium enema leading to laparotomy, colotomy, and polypectomy. Dr. Ponsky performed the first percutaneous endoscopic gastrostomy tube in 1979.

A brief discussion about training and credentialing in endoscopy is relevant and not covered in the current chapter in detail. Surgeons around the world provide essential endoscopy services. In the United States, gastroenterologists are rarely available in rural and underserved areas; in such areas surgeons may be the only providers of indispensable endoscopic services. Managing the continuity of disease, including complications of procedures, is important to good quality care. Given that many of the diseases identified at endoscopy are ultimately treated surgically, a surgeon's involvement in the early diagnosis and management is often optimal, to assure continuity of care. Surgical expertise is frequently required to evaluate and manage complications of endoscopy, especially those that are catastrophic or life threatening. There has been some controversy about competency as well as training and credentialing requirements in endoscopy. In recent years, GI and surgical societies have worked closely to define competency in endoscopy and to develop quality indicators and training guidelines (Rizk MK, Sawhney MS, Cohen J, et al. Quality indicators common to all GI endoscopic procedures. *Gastrointest Endosc* 2015;81(1):3–16). This effort is critical, because as the population ages and lives longer, the demand for high quality endoscopic services is increasing rapidly. In 2009, an estimated 6.9 million upper endoscopy procedures were performed in the United States (Peery AF, Dellon ES, Lund J, et al. Burden of gastrointestinal disease in the United States: 2012 update. *Gastroenterology* 2012;143:1179–87; e1–3). From 2000 to 2010, there was an estimated 50% increase in upper endoscopy for Medicare beneficiaries. Based on 2010 data, over 3.3 million outpatient colonoscopies are performed annually in the United States, with screening and polyp surveillance accounting for about half of the indications.

The American Board of Surgery will require all ABS-certified general surgeons to have completed a standard curriculum in the use of endoscopic techniques. This new requirement will apply to certification applicants who complete their residency training in the 2017 to 2018 academic year or thereafter. During their general surgery residency, applicants will be required to have completed the ABS Flexible Endoscopy Curriculum. In addition, one of the final steps in the curriculum is successful completion of the Fundamentals of Endoscopic Surgery (FES) program offered by SAGES. Evidence of FES certification will be required when applying for ABS certification. The FES program includes didactic materials, a multiple-choice examination, and a hands-on skills test (Hazey JW, Marks JM, Mellinger JD, et al. Why fundamentals of endoscopic surgery (FES)? *Surg Endosc* 2014;28(3):701–3).

In their chapter, Ponsky and Pearl discuss a variety of new endoscopic endoluminal and transluminal procedures. The ability to perform surgery through a natural orifice and without incisions has been an area of intense

interest since the early 2000s. More than 1,000 reports have been published describing various applications of NOTES in both animals and humans (Zhang F, Kalloo AN. NOTES: What is currently possible? In: Cameron JL, Cameron AM, eds. *Current Surgical Therapy*. 11th ed. Philadelphia, PA: Elsevier Saunders Publishing; 2014:1443–6). Many novels endoscopic interventions have been described over the past decade, but none has become commonly performed in humans or a standard of care. There are many preliminary data that suggest NOTES is feasible and safe, but true transluminal surgery remains in the preclinical and investigatory stage. There are a variety of reasons to explain the slow adoption of NOTES including a lack of instrumentation specifically designed for these procedures, technical difficulty and poor ergonomics related to the commonly used natural orifice access sites, the potential morbidity of access site incisions, poor insurance coverage, and a plethora of minimally invasive alternatives with already low morbidity rates (NOTES vs. laparoscopic cholecystectomy for example). The interest in NOTES has led to some progress in related areas such as single incision surgery (now even more feasible with the robotic single site platform), true endoluminal procedures (EMR, endoluminal GERD, and obesity procedures), and submucosal procedures (such as POEM). GERD and obesity are two particularly prevalent diseases for which surgery is underutilized (less than 1% of surgical candidates undergo surgery for each disease condition for a variety of reasons) (Funk LM, Kanji A, Scott Melvin W, et al. Elective antireflux surgery in the US: an analysis of national trends in utilization and inpatient outcomes from 2005 to 2010. *Surg Endosc* 2014;28(5):1712–9; Livingston EH. The incidence of bariatric surgery has plateaued in the U.S. *Am J Surg* 2010;200(3):378–85; Poulose BK, Holzman MD, Zhu Y, et al. National variations in morbid obesity and bariatric surgery use. *J Am Coll Surg* 2005;201(1):77–84). New devices offering incisionless approaches to treat these conditions appear on the market on a frequent basis. It will be important for GI and surgical societies to help organize surgeons and gastroenterologists applying these treatments to patients to understand the ideal patient for the different evolving treatment options and the long-term outcomes. It will be important as well for insurance companies to be willing to provide benefits for procedures determined to be both safe and effective, even when the return on investment and health care cost savings is realized in less than 1 year’s time.

As the line between what is in the professional and technical domain of GI surgeons (trained as surgeons) and GI endoscopists (gastroenterologists) has become increasingly blurred, it will be important for surgeons to remain at the forefront and lead these efforts.

16 Soft Tissue Reconstruction With Flap Techniques

Luis O. Vásconez, Salman Ashruf, Franziska Huettner, and Michael Ruebhausen

INTRODUCTION

Sound understanding of reconstructive surgery is imperative to all practicing general surgeons. The integumentary system is the largest organ system of the body. It is subject to systemic disease as well as the extremes of the environment. The ability to surgically manipulate and reconstruct acquired defects in an efficacious fashion is the learning objective of this chapter.

The most common approach to reconstruction begins with the so-called reconstructive ladder. The logical progression of the reconstructive ladder begins, as one does on a ladder, moving from the bottom to the top: primary closure, secondary closure, split- and full-thickness skin graft, local tissue rearrangement, local flaps, regional flaps, and free tissue transfer. There are varying degrees of each type of flap, with each involving more or less tissue, commensurate with the defect to be reconstructed. For reconstructive surgeons, the ladder is inherently more frequently explored from top to bottom; however, every surgeon will use some component of reconstruction with every case.

Skin grafts can include the entire epidermis and dermis, or the epidermis with a portion of the dermis. The former, known as a full-thickness graft, resists contraction, needs a well-vascularized recipient bed, maintains the adnexal structures, and has pigmentation similar to normal skin. Split-thickness skin grafts are more likely to contract or shrink, hyperpigment, and survive under less favorable conditions, and they leave less donor site morbidity. Factors that lead to skin grafts not “taking” include shear, hematoma, seroma, infection, and an avascular bed, such as that in an inadequately debrided wound. For a skin graft to take requires a vascularized bed. These recipient sites can be muscle, fascia, paratenon, or periosteum. When such a bed is absent, a well-vascularized flap is

necessary to provide reliable, durable coverage.

A flap is a unit of moveable tissue that remains attached to its original blood supply. Flaps can contain skin, muscle, bone, fascia, or any combination of these. When the flap contains a named septocutaneous or musculocutaneous blood vessel, it is known as an axial flap and can therefore be transferred reliably to different sites to reconstruct soft tissue defects. Vascular anatomy of any particular flap is well known at this time and makes it reliable as long as one includes the vascular pedicle within the flap. The so-called random flaps (except for the face), where the distinct vascular anatomy is unclear, should be avoided or at a minimum used with caution, because of the uncertainty of success. These flaps are perfused exclusively through the subdermal, or more accurately, the subcutaneous plexus and have no named blood vessel that supplies them. To improve viability of these flaps, length to width ratio traditionally should not exceed 3:1, though this has been challenged in recent years.

Exceptions to this include local tissue rearrangement and advancement flaps, such as rhomboid flaps and V-Y advancement flaps, which can be reliable used to close slightly larger wounds than can be closed by primary or secondary intention. Similarly, so-called delayed procedures, which have the objective to improve the vascularity of a flap, are rarely if ever indicated because there is no assurance that the safety of the flap will be increased. The “delay” procedure also has the disadvantage of an additional operation and the concomitant swelling and edema that ensue, making it more difficult to transfer such a flap. A microvascular free tissue transfer, or “free flap,” first reported in 1973, allows the transfer of tissues to distant sites with the reestablishment of blood flow to the flap by anastomosis of the artery and the vein to appropriate recipient vessels in the vicinity of the defect. The free flaps are most effective in providing coverage of areas with insufficient local or regional soft tissue options. Performed by experienced microsurgeons with an appropriate team, the free flap is one of the safest of all flaps, with a success rate exceeding 98%.

In today’s medical environment, however, the reconstructive ladder is no longer practical. Reconstructive surgeons must have a solid understanding of the surgical options available and those procedures that provide the best outcome, even though it may be the most complex solution.

In the management of large wounds created by extirpation of benign or

malignant tumors, postradiation ulcerations, or posttraumatic defects, the cooperative efforts between the general surgeon and the plastic surgeon will most likely result in satisfactory coverage of the wound and a shorter recovery and hospitalization for the patient. In the occasions when the wound cannot be closed primarily or in cases where a skin graft will not suffice, the use of flaps is the most appropriate option. Different approaches are required in different clinical settings, such as congenital defects, infected wounds, postradiation ulcers, and tumor excision. The coverage needed may be skin alone; skin and fat, such as for reconstruction of the breast; muscle or omentum for the coverage of postradiation wounds; composite tissue such as skin and muscle; and, often, muscle and bone of any combination. In this way, the native tissue and the resulting wound informs the type of reconstruction required.

During the initial evaluation, it is essential to recognize the type of soft tissue defect with which one is dealing. For example, if it is a loss of the skin such as a large excision of a melanoma of the face, the defect can be covered by an adjacent skin flap or skin graft. If one is dealing with a surgical loss of the breast, one needs to reconstruct by replacing the skin and the breast mound with either adipose tissue or, occasionally, the use of an implant. If, on the other hand, one is dealing with a postradiation persistent or recurrent tumor that requires a large extirpation, the defect needs to be covered with muscle, a musculocutaneous, or fasciocutaneous flap. In the case of postradiation wounds, although adjacent musculocutaneous flaps are given first priority, the use of free tissue transfer should be considered, as local or regional flap options or sufficient size and type may be limited.

The essential principle for reconstruction of soft tissue wounds is the application of the most effective flap that will succeed in covering the defect, regardless of the complexity of the procedure. Sufficient experience has determined what is more likely to succeed. One should forego the trial and error of using a simpler procedure that may not work and eventually end up with the appropriate albeit more complex flap reconstruction.

GENERAL PRINCIPLES FOR COVERAGE OF SOFT TISSUE WOUNDS

Difficult wounds usually fall into three categories: (a) superficially infected wounds, (b) wounds over exposed vital structures—such as bone

without periosteum, tendon without paratenon, or large blood vessels or nerves, and (c) postradiation wounds. We describe principles for their management individually.

Superficially Infected Wounds

Chronic wounds in which granulation tissue has been allowed to develop and to persist for a prolonged time are often difficult to treat. Pathophysiologically, one should note that granulation tissue is a combination of capillaries, fibroblasts, and bacteria. Of these three elements, only one is helpful to the surgeon: the capillaries. Consequently, if a wound is filled with granulation tissue, it is essential that one resect surgically in a tangential way until clean viable tissue is visible. Following that a simple meshed split-thickness skin graft may suffice. But in cases in which the wound cannot be completely cleansed or excised because that would entail the removal of essential structures, or in such patients with pressure sores, those infected wounds demand coverage with an adjacent muscle. Muscle has an antibacterial effect on the coverage of infected wounds, most likely because it brings in additional blood supply, which helps in the amelioration of the infection. The use of an adjacent fasciocutaneous flap is a second choice, although this is not as effective as muscle, owing to a diminished blood supply in comparison. Such flaps, however, have the added benefit of increased pliability, and thus better contour.

Wounds With Exposed Vital Structures

In these types of wounds, it is essential that one try to maintain the moisture of the exposed structures with frequent dressing changes. Perhaps the most common traumatic example of this is bone without periosteum. In a recently traumatized extremity with exposed tibia, one could use an adjacent fasciocutaneous flap. However, when dealing with cases in which there is active or chronic infection, such as in chronic osteomyelitis, the treatment is much different. Following an adequate debridement of the wound, it is essential that one cover that defect ideally immediately with an adjacent muscle to fill in the cavity and to cover the exposed bone. If the skull is exposed, as may occur following an electrical burn, it is not essential to remove the exposed skull but to cleanse it and to cover it with a free muscle flap, such as the latissimus dorsi. One has often rejoiced to see what appears to be dead bone revascularized or replenished once it is

covered with well-vascularized muscle (Fig. 16.1).

Figure 16.1. A, B. Knowledge of septocutaneous flaps allow us to move the fasciocutaneous flap in the leg for coverage of defects even in the lower third of the leg. The lowest septocutaneous perforator is located 5 to 6 cm above the medial malleolus.

Postradiation Wounds

The sophistication in the delivery of radiotherapy for the management of malignant tumors has resulted in the markedly decreased injury to the soft tissues, specifically the skin. We see much less ulceration or deformity following radiation. However, we often see postradiation-persistent and/or recurrent malignant tumors that must be salvaged with surgical excision. If one is dealing with a persistent or recurrent tumor, the amount of excision should be left to the oncology surgeon. On the other hand, if one is dealing with a postradiation ulceration, a previous biopsy is not essential because the treatment is going to be the same, and the pathologist is likely to report: “Chronic ulceration with postradiation effects but tumor cannot be ruled out.” In either case, the surgical treatment of these postradiation problems consists of the extirpation not only of the tumor or the ulceration, but also of the entire portal of radiation. One determines the entire portal of radiation by noticing the slight hyperpigmentation of the skin, the lack of the skin appendages, as well as the leathery appearance and feeling of the skin.

Following wide excision of the entire field that has been irradiated, one should immediately cover the defect with muscle, a musculocutaneous flap, or a fasciocutaneous flap, and if that is not available, with omentum.

A skin graft for postradiation wounds is not effective and is very likely to fail. Adjacent skin flaps similarly may not adhere to the underlying postradiation bed or to the skin edges. Muscle or omentum is successful because of the increase in blood supply they bring to the wound. Over the muscle or the omentum, one can immediately place a meshed split-thickness skin graft. A transverse rectus abdominis muscle (TRAM) flap, either pedicled or microvascular, is often successful if the skin edges to be approximated are beyond the field of radiation (Fig. 16.2).

SOFT TISSUE FLAP TECHNIQUES

We will describe specific soft tissue reconstruction with flap techniques throughout the body that are likely to be encountered in a busy general surgical practice.

Facial Defects

Facial defects often result from excision of malignant tumors such as basal cell carcinoma, squamous cell lesions, and melanoma, which is increasingly seen today. One must bear in mind, as with any oncologic resection, that immediate reconstruction will always carry the risk of re-excision should permanent pathology demonstrate persistent disease. The use of intraoperative margin assessment or a staged approach with permanent pathology is recommended (NCCN guidelines). We will describe reconstruction specifically of defects on the ear, nose, and cheek.

Defects of the Ear

Removal of large basal or squamous cell carcinomas of the ear requires immediate reconstruction. If a wedge resection of the upper one third of the ear is so large that it may result in deformity of the ear, a local technique described by Antia is the more desirable method of reconstruction (Fig. 16.3). Following the excision of the large defect along the helix of the ear, the lower portion of the ear is incised along the helix through the skin and underlying cartilage to the ear lobe. If necessary, the upper portion similarly below the helix is also incised through the skin and the cartilage. This leaves the two ends of the helix able to be moved toward each other and to be approximated, thus restoring the normal helical contour of the ear. The inferior cartilage and overlying skin are also approximated.

This method of reconstruction has the advantage of restoring the normal

shape of the ear and is relatively straightforward and effective. One does end up with a slightly smaller ear in comparison with the contralateral normal one, but this is not really a problem because we are seldom able to see both ears at the same time. A smaller, well-contoured ear is accepted by most casual observers.

Segmental helical rim defects can similarly be treated with local flap options. Specifically a posterior auricular interpolation flap (Fig. 16.4) is an example of a delayed flap that gives excellent contour and a well-hidden donor site wound which can almost always be closed with local tissue rearrangement, such as a rhomboid flap.

Defects of the Nose

Basal cell carcinomas that occur along the dorsum or the tip of the nose often require flap coverage for a satisfactory result. The flap coverage should be from adjacent nasal skin because it provides the same color and texture as well as thickness, and in elderly patients, the scar is almost imperceptible. On the other hand, skin grafts may leave a visible concavity and a patch appearance because of the different color of the surrounding skin. We do not favor the routine use of the nasolabial flap for defects of the nose because it is a different skin from the nose, and often leaves a “biscuit” type of appearance. For smaller defects, we advocate the use of the V-Y advancement flap, the banner flap, or the dorsal nasal flap. For total reconstruction of the nose, the midline or the paramedian forehead flap are safe and appropriate.

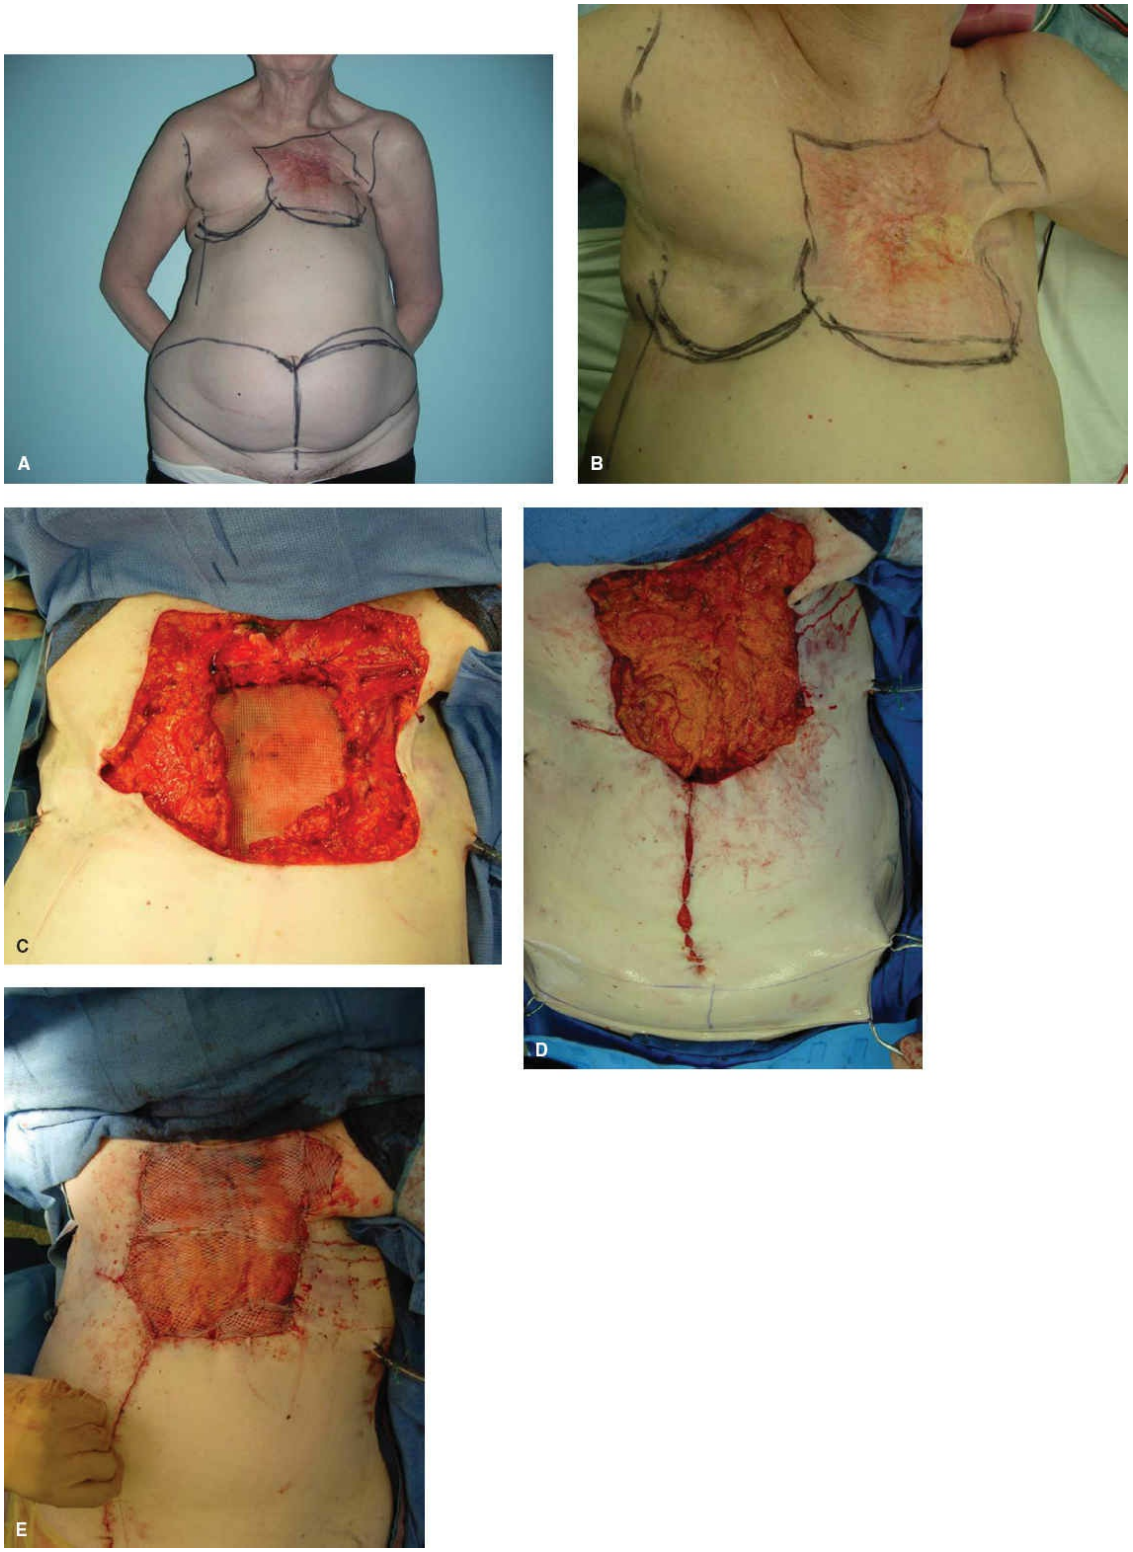

Figure 16.2. A–E. Patient who underwent bilateral mastectomies with radiation 24 years ago presented with large area of radiation necrosis over the sternum. TRAM flap reconstruction was not an option because radiation usually obliterates the arterial walls and in this particular patient, the resection entailed removal of both internal mammary arteries. The chest wall was stabilized with a polypropylene mesh. The omentum was transposed over the

mesh, with immediate application of a mesh split thickness skin graft. The omentum is passed through an opening in the upper abdominal incision at the subcutaneous tissue level. This is preferable to passage of the omentum through the diaphragm.

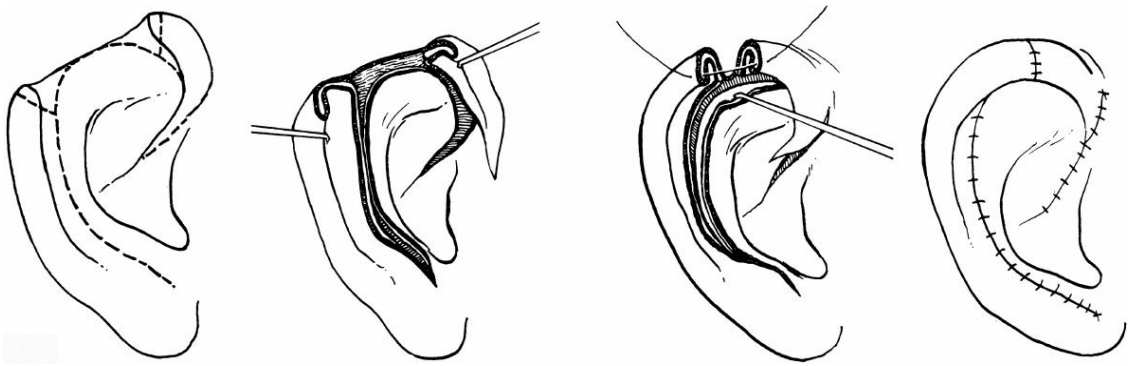

Figure 16.3. Diagrammatic representation of double chondrocutaneous advancement flaps for reconstruction of a large (3 to 4 cm) helical defect. (From Antia NH, Buch VI. Chondrocutaneous advancement flap for the marginal defect of the ear. *Plast Reconstr Surg* 1967;39:472, with permission.)

V-Y Advancement Flap

The V-Y advancement flap relies on the mobility of the subcutaneous layer (Fig. 16.5). For smaller defects on the dorsum or the lateral aspect of the nose one could design an adjacent V-Y flap that is incised and advanced to cover the defect. It is a simple and effective method for coverage of smaller defects. However, one should bear in mind that a true V-Y flap is based on a random blood supply, and extensive undermining of the skin disrupts the primary blood supply of the dermal and subdermal plexi.

Banner Flap

For smaller defects, usually along the tip of the nose, a banner flap is indicated (Fig. 16.6). Again, the created defect is noted, and one outlines a transposition flap, which is elevated and transposed to cover the primary defect while the secondary defect is covered in the form of an Z plasty from the adjacent tissue along the ala. There may be a slight elevation of the involved ala, but this is usually minimally noticeable.

Figure 16.4. **A.** The typical helical rim defect, which can be reconstructed by means of a posterior ear interpolation flap. **B.** The flap is elevated and inset at the time of initial cancer resection, after negative margins are assured. **C:** The flap is divided at 3 to 4 weeks, inset, and the donor site is closed with either a skin graft, or in this case, with local tissue rearrangement (a rhomboid flap).

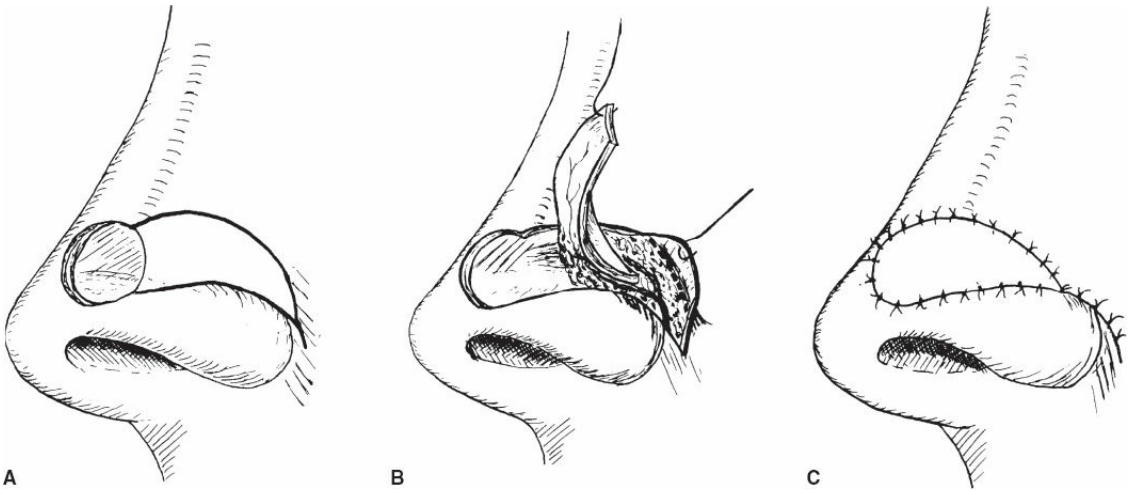

Figure 16.5. **A.** The typical defect is in a paramedian position on the nasal tip. The nasalis musculocutaneous flap is designed with its caudal line right at the alar groove and the cephalad line determined by the width of the defect. **B.** The flap is elevated down to the muscular attachments at the base of the piriform fossa. **C:** The flap is advanced. Any small dog ears resulting from the concave flap merging against a convex recipient area can by excised. (From Rybka FJ. Reconstruction of the nasal tip using nasalis myocutaneous sliding flaps. *Plast Reconstr Surg* 1983;71:40, with permission.)

For larger defects along the tip of the nose where the banner flap will not suffice, it is advisable to use the entire remaining skin on the dorsum of the nose by outlining a dorsal nasal flap that extends beyond the defect and along the lateral aspect of the nose to the glabella. By cutting it toward the opposite side, the angular vessel is maintained, and a skin flap is developed to cover the entire defect and the secondary defect along the glabella; this is closed in a VY type of fashion (Figs. 16.7 and 16.8). The dog-ear that occurs can be handled at the same time by resection, thus making it a single-stage procedure.

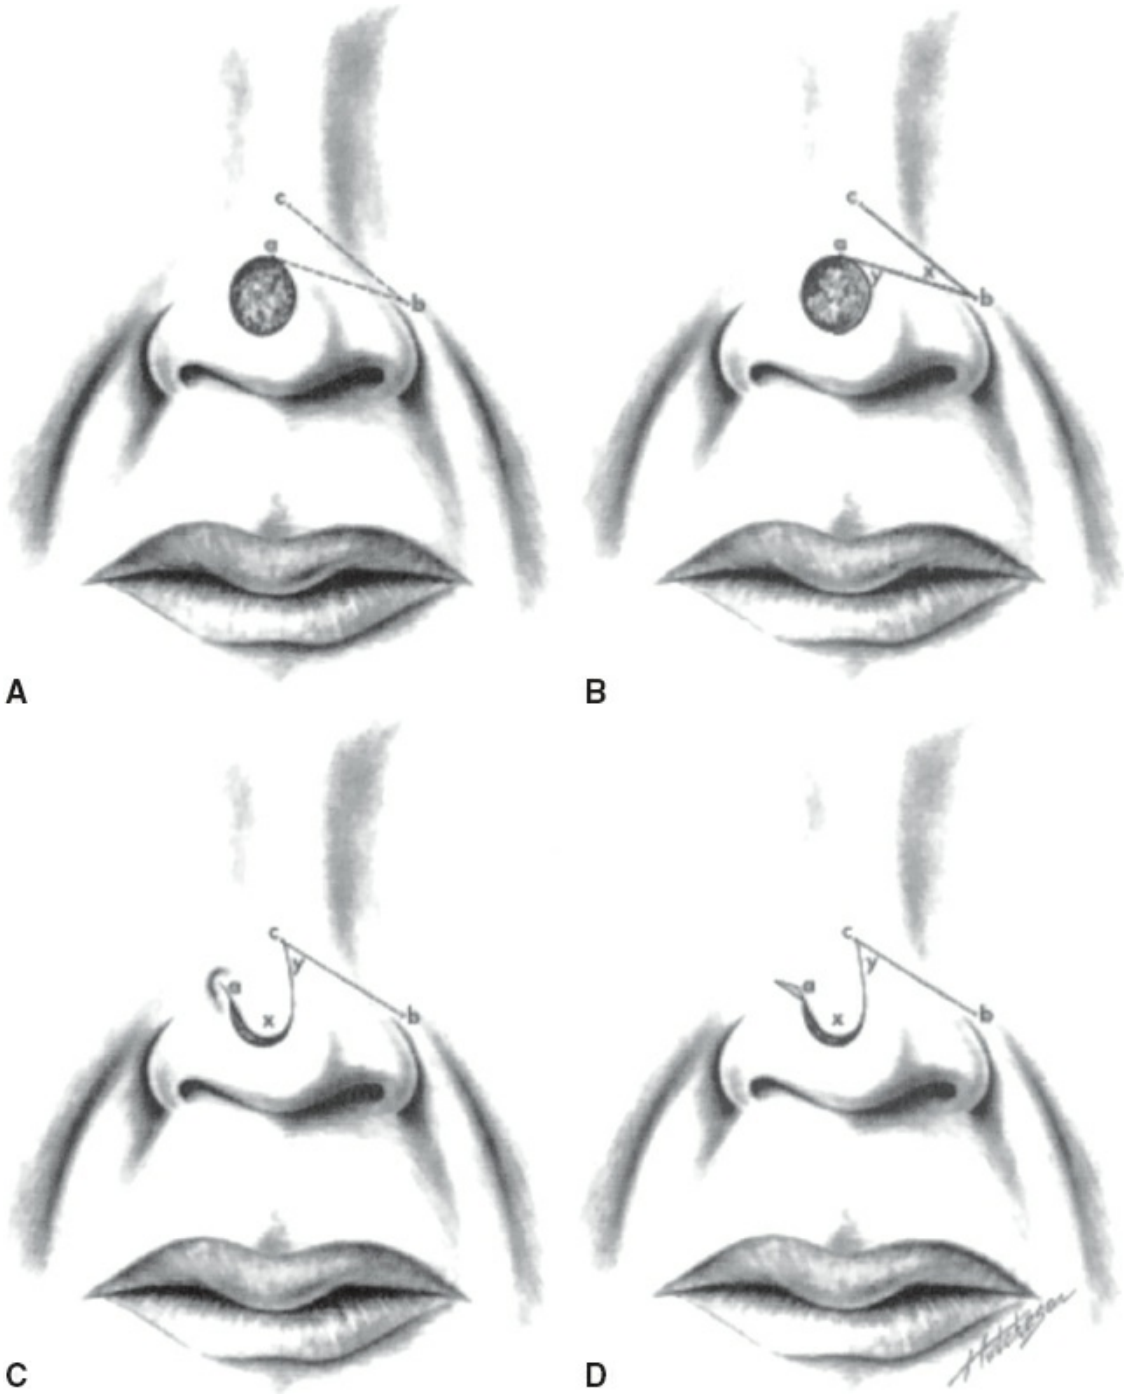

Figure 16.6. Principles of the banner flap procedure. **A.** Triangular flap is outlined by points *a, b,* and *c.* **B.** Larger flap *x* and smaller flap *y.* Each may be transposed as a modified Z-plasty. **C.** Flap *y* is inset, and the tip of flap *x* is trimmed to fit the residual defect. **D.** The resultant dog ear at point *a,* if excessive, may be reduced by a triangular excision (leaving the base untouched). (Reprinted from Masson JK, Mendelson BC. The banner flap. *Am J Surg* 1977;134(3):419–23. Copyright © 1977, with permission from Elsevier.)

Figure 16.7. The axial flap is based on vessels emerging at the level of the inner canthus. This allows increased mobility and precise adjustment. (From Marchac D, Toth B. The axial frontonasal flap revisited. *Plast Reconstr Surg* 1985;76:686, with permission.)

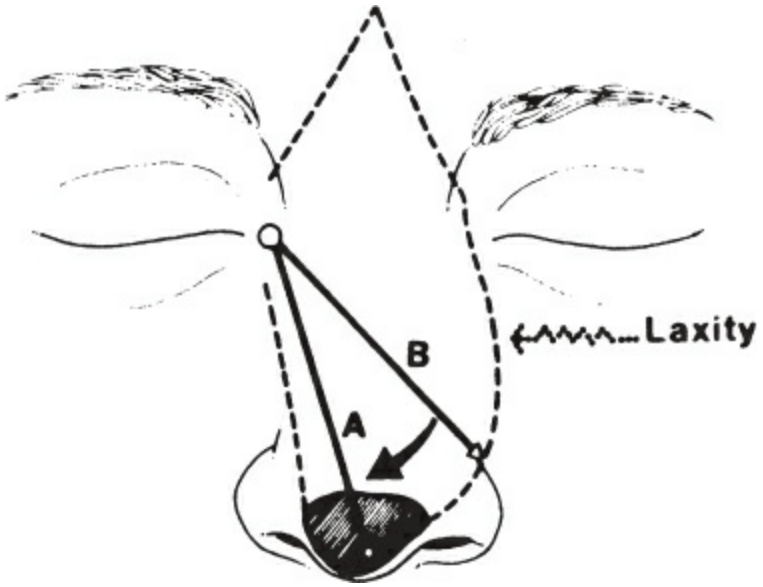

Figure 16.8. The axis of rotation should be considered and the incision taken rather low on the lateral side of the nose. (From Marchac D, Toth B. The axial frontonasal flap revisited. *Plast*

Reconstr Surg 1985;76:686, with permission.)

Total Reconstruction of the Nose With a Midline or Paramedian Forehead Flap

For patients with large basal or squamous cell carcinoma of the nose or postradiation persistent tumors, total excision of the overlying skin is indicated, and reconstruction, after appropriate margins have been obtained, is best done with a midline or paramedian forehead flap (Fig. 16.9).

The technique of the procedure is straightforward. A pattern is obtained of the acquired nasal defect and is transferred to the midline or paramedian area (centering on the supratrochlear vessel) of the forehead. One has to ensure adequate length of the flap to reach the distal part of the nose, which may require extending the flap into the hairline. The forehead flap is then incised and elevated at the subcutaneous tissue level to approximately 2 cm above the glabella. At this point, the flap is deepened to include the galea for the midline forehead flap, and the periosteum for the paramedian flap to ensure that the blood supply, which comes from the angular vessel and the supratrochlear vessel, respectively, is included. The flap is then turned on either the left or the right axis, whichever is easiest to reach the distal portion of the defect. Although it is advisable to save at least one of the supratrochlear and supraorbital vessels in the case of the midline forehead flap, it is not essential because the flap is supplied from the angular vessels of the nose that are located along the lower border of the nasal bones as it meets with the maxilla. In the case of the paramedian compared to the midline forehead flap the arc of rotation is decreased which can minimize the kinking of the pedicle, but the donor site leaves an inevitably asymmetric donor site scar, a disadvantage as compared with the midline forehead flap. Both flaps require a second stage, which is the division and insetting of the pedicle.

Figure 16.9. Forehead flap, based on supratrochlear vessels. It easily reaches the entire notes. The forehead defect is closed primarily as much as possible and the remaining is left open to heal. (Modified from Mathes S, Nahai F. *Reconstructive Surgery: Principles, Anatomy, and Technique*, Page 262, Copyright 1997 Elsevier.)

Additional refinements in nasal reconstruction include a three-stage approach that focuses on nasal subunits, pioneered by Menick in the 1980s. Additional investigation of cosmesis in these reconstructions has been undertaken. One recent study by Stahl et al. showed no difference in cosmetic outcome in two-stage versus three-stage reconstruction.

Breast Reconstruction

What was initially an imperfect product consisting only of the creation of a mound with an implant has now developed into a most satisfactory and acceptable method in which, following the extirpation of a breast, one is able to restore the removed structure and obtain symmetry with the opposite side.

This was made possible initially with of the introduction of the latissimus dorsi myocutaneous flap in 1977, as well as the more sophisticated TRAM flap in the early 1980s. Both methods have undergone considerable development and refinement to increase their safety and versatility. The addition of the muscle sparing TRAM, the DIEP, and other perforator flaps, like the PAP and TUG flaps, used as free tissue transfer, have added to the reconstructive breast surgeon's arsenal, providing additional options for patients with less donor site morbidity.

Most breast centers at the present time offer the patient different alternatives for treatment of breast cancer, and if the patient chooses mastectomy, some form of immediate reconstruction is often suggested.

Objectives and Principles of Breast Reconstruction

The objective of breast reconstruction is to perform a safe operative procedure that will obtain symmetry of both breasts. In the case of unilateral breast reconstruction, this often requires modifying the contralateral normal breast by either reduction mammaplasty or a mastopexy. Ideally this should be done at the same as the breast reconstruction. But in the event of a tissue expander placement, sometimes followed by radiation, it behooves the reconstructive surgeon to await subsequent expansion to perform a symmetry procedure, as expansion outcomes will vary greatly due to a number of factors. Conveniently, a second procedure is necessary in these individuals, as the expander will be replaced by an implant, and/or myocutaneous, or perforator flap, at a later time, which presents an ideal time for a symmetry procedure.

The principles of breast reconstruction, which apply to any method used, include: (a) the preservation or restoration of the inframammary fold, (b) obtaining satisfactory projection, (c) obtaining satisfactory and matching ptosis with the contralateral breast, and (d) closing the axillary defect in immediate reconstructions (Fig. 16.10).

The Inframammary Fold

The inframammary fold is nothing more than the end of the lower pole of the breast. Consequently, the oncology surgeon does not need to extend the dissection any further than the inframammary fold in completing the mastectomy. It is not unusual for some plastic surgeons to preoperatively place some percutaneous sutures or skin staples along the fold prior to the mastectomy to secure this landmark. In a reconstructed breast with a TRAM flap, the inframammary fold is the lower end of the flap. However,

if one has reconstructed the breast with the use of an implant or an expander, the inframammary fold represents the lower edge of the capsule around the implant. Because implants are likely to develop capsular contractures that raise the inframammary fold, most reconstructive surgeons place the expanders or the implants 2 to 3 cm below the inframammary fold so that the folds will be matched with the ensuing capsular contracture.

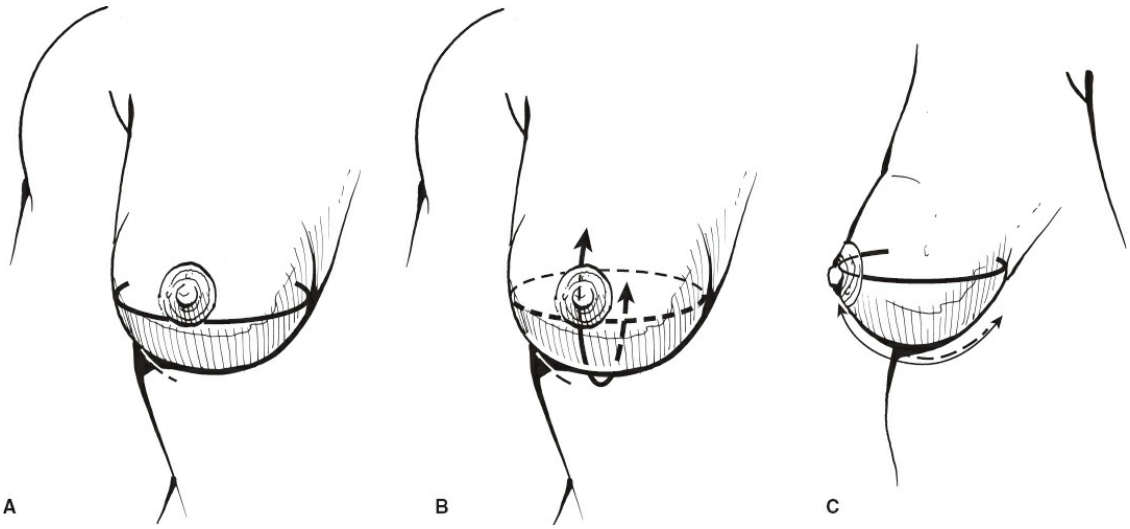

Figure 16.10. Diagrammatic demonstration of projection or ptosis of the breast. **A.** Projection is determined by the transverse diameter over the convex surface of the breast from the sternum to the anterior axillary line. **B.** Ptosis is determined by the vertical distance over the breast to the inframammary fold. **C.** Inframammary line is determined by the lower edge of the breast, or in the case of a reconstructed breast, by the lower edge of the TRAM flap. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:12, with permission.)

Projection

Projection is defined as the maximal dimension of distance from the chest wall along the transverse diameter from the sternum to the anterior axillary line. If one is to obtain more projection when a transverse incision has been used for the mastectomy, the upper end of the incision needs to be zigzagged so that the transverse diameter will be larger. This is avoided with the use of the skin-sparing mastectomy because the entire envelope of skin is present except for the nipple and areola, and one need to fill only the skin envelope with tissue, a pedicle or free flap, like the TRAM or

DIEP flap, to obtain satisfactory projection. Alternatively, coning of the flap and proper inset can reproduce an aesthetically pleasing breast mound with appropriate width and projection, regardless of the size, type, and location of mastectomy incision. While an intact breast envelope is ideal to work with, the oncologic burden, vis-à-vis location and size of tumor, informs the general surgeon's ability to leave such an envelope safely for reconstruction with minimal risk of recurrence.

Ptosis

Ptosis refers to a vertical dimension measured over a curved surface from the clavicle over the breast and down to the inframammary fold. It categorizes the relationship of the nipple areolar complex in relation to the breast tissue and the inframammary fold. If one has fixed the inframammary fold, either with sutures or preservation, one can place the flap in such a way that it will hang down below the inframammary fold to obtain ptosis. Usually this is done for a minimal amount of ptosis because it is preferable to modify the contralateral breast with a mastopexy or reduction mammoplasty. Ptosis is rarely possible with the use of an implant or an expander, except in the experienced hands of plastic surgeons who use anatomic type of implants. Ultimately, nipple–areolar complex position will determine ptosis. The ideal aesthetic breast will have a point of maximal projection that coincides with the NAC. If the tissue below the NAC falls below the inframammary fold, this is referred to as pseudoptosis, and is considered acceptable, especially in larger breasted patients. The descent of the NAC below the IMF, while possibly necessary for symmetry and natural appearance, should be minimized to maximize cosmesis, restoring a youthful appearance of the breast.

Closing the Axillary Defect

The fourth principle of breast reconstruction that should be addressed is closing the acquired axillary defect. The breast extends only to the anterior axillary line. The oncology surgeon, even with a skin-sparing mastectomy, dissects the skin flaps to the anterior border of the latissimus dorsi muscle, which is in the posterior axillary line; the surgeon also will perform a sentinel node biopsy of the axilla. Consequently, it is essential that the reconstructive surgeon closes and obliterates the axillary defect by approximating the lateral skin flap to the anterior axillary line with sutures and places a drain along the axilla, particularly in immediate breast reconstructions. In delayed breast reconstructions, the dissection of the

mastectomy flaps is done only to the anterior axillary line.

Bilateral Mastectomies

Presently, patients are electing to undergo bilateral mastectomies and immediate reconstruction. This usually entails doing the mastectomy and sentinel node biopsy on the side of the cancer, and a prophylactic skin-sparing mastectomy on the contralateral side.

Patients who request bilateral mastectomies include not only those done for prophylaxis due to BRCA 1–2 gene but also young patients who do not want to live with the burden of frequent checkups for recurrence of the cancer or the possibility of developing cancer in the opposite breast. Other groups who ask for bilateral mastectomies are those who have undergone previous lumpectomy, irradiation, and chemotherapy, and are fearful of suffering through possible radiation or chemotherapy in the future for cancer in the opposite breast (Fig. 16.11). A study by Boughey et al. indicates that contralateral prophylactic mastectomy (CPM) in high-risk women with a personal history of breast cancer is associated with a survival advantage, reflecting an improved overall and disease-free survival. In subsequent years, this has been challenged, as metachronous contralateral breast cancer is found to provide merely a coincidental improved survival rate, which may disappear if FGR levels are accounted for. Currently, the absolute number of CPMs has increased dramatically over the last decade, however the suggestion that a selection bias exists merits additional prospective, randomized, controlled trials before CPM should continue to be recommended.

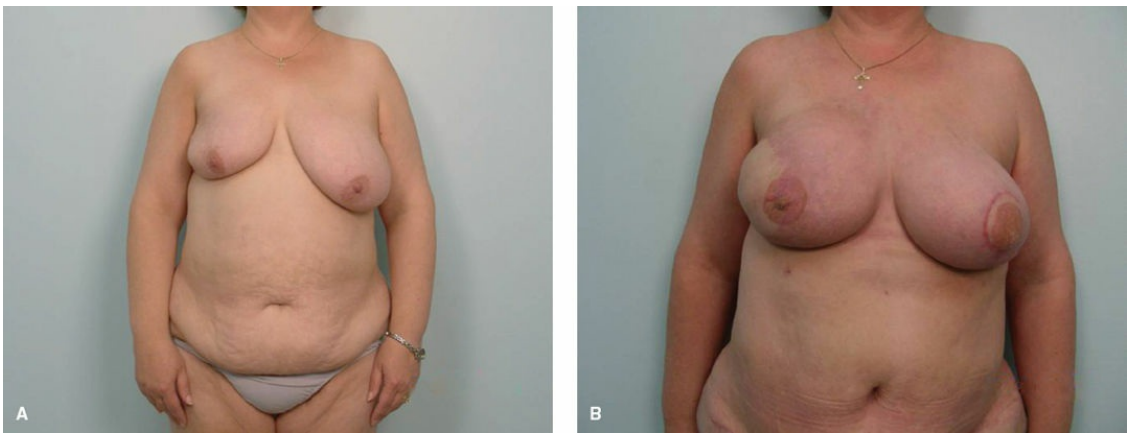

Figure 16.11. A, B. Patient status postlumpectomy and radiation. Above patient presented with postlumpectomy radiation with persistent and or recurrent carcinoma of the breast. Note the shrinking of the irradiated breast. Patient elected to have bilateral

mastectomies with immediate reconstruction. Skin sparing mastectomy was chosen on the left side, which left a larger skin envelope and thus the slight discrepancy in size.

Immediate Versus Delayed Breast Reconstruction

It is our experience that patients who are offered immediate reconstruction following skin-sparing mastectomy accept it and are pleased with the eventual results. A considerable amount of literature has been published indicating the positive and favorable psychologic effects of immediate breast reconstruction, particularly when it is done with relative simplicity, safety, and obtains symmetry with the opposite side. Questions that oncologists as well as patients ask and have been answered include: “Will reconstruction hide or delay the detection of recurrent cancer?” The answer is “No” because most of the recurrent cancers occur at the subcutaneous tissue level and alongside the mastectomy scar. This is easily detectable by palpation. Concerning the development of fat necrosis if a TRAM or perforator flap has been used, and which presents as a hardened mass, one can determine its exact nature by the rapidity of its appearance following the reconstruction (within weeks) and confirmation by fine-needle aspiration, which is read as fat necrosis. Will adjuvant therapy be delayed? No. Adjuvant chemotherapy is usually started 6 weeks following the mastectomy and reconstruction. In most cases, this is an appropriate schedule. In fact, studies have demonstrated that if there is no immediate breast reconstruction, the possibility of flap necrosis or seroma formation along the axilla often delays the initiation of chemotherapy beyond the 6-week interval.

Finally, patients ask whether they need blood transfusions. The answer is, most likely, no. Blood transfusions, although not proven deleterious for carcinoma of the breast as has been shown for carcinoma of the colon, are often not routinely necessary even when one performs unilateral or bilateral TRAM or perforator flaps. A study from 2013 cites the rate of transfusion at 9.1% in DIEP flap reconstruction, a rate much lower than previously described in the literature. Careful analysis of preoperative risk factors will help guide surgeons in proper flap selection to limit the risk of anemia and subsequent transfusion.

Patients in whom immediate reconstruction would not be indicated include those with systemic diseases, which may make reconstruction more hazardous, such as patients on steroids or with uncontrolled diabetes.

Similarly, if one knows preoperatively that the oncology surgeon plans to irradiate postoperatively, one would not perform an immediate definitive reconstruction because, even if one uses a TRAM or a perforator flap, it is likely to shrink and to become fibrotic.

If one were to use an implant, failure—as indicated by the exposure of the implant or infection—is a very likely possibility, and delayed definitive reconstruction is warranted. These risks also account for the use of expanders with planned radiation, but often preradiation expansion can maintain the skin envelope until delayed definitive reconstruction takes place. In patients with large tumors who receive preoperative chemotherapy to shrink the tumor, immediate reconstruction is appropriate, although it is done with caution and with the expectation of problems with delayed healing, not only of the flap used for reconstruction, but also for the secondary defect, most likely in the abdominal wall, if the TRAM flap was used. The reason for this is that the deleterious effect of chemotherapy on wound healing persists for 6 to 12 weeks following the cessation of chemotherapy. Despite this, more recent literature suggests that neoadjuvant chemotherapy does not portend a statistically different complication rate for all autologous breast reconstructions. A 2015 study in Gland Surgery indicated that pedicled TRAMs were more likely than free TRAMs or DIEP flaps to undergo fat necrosis, though no difference in donor site morbidity or wound complications were noted.

In patients with persistent or recurrent tumors, following lumpectomy and radiation requiring completion mastectomy, immediate reconstruction is essential, either with a latissimus dorsi muscle, TRAM, or perforator flap, because delayed wound healing or wound breakdown of the postradiation wound is likely to occur.

Nonetheless, a decreasing number of patients present months or even years later for delayed reconstruction. The aesthetic result is as satisfactory as with immediate reconstruction, although it has the disadvantage of requiring a second operative procedure and a second hospitalization.

Options for Breast Reconstruction

There are several methods for breast reconstruction, and each one must be discussed with the patient, addressing the advantages and disadvantages of each. The methods include the use of implants or expanders, the use of pedicled flaps such as the latissimus myocutaneous flap or the TRAM flap, and free flaps, such as the MS-TRAM, DIEP, TUG, and PAP flaps. These

techniques vary considerably in their complexity.

Implants and Expanders

Immediate breast reconstruction with implant placement represents only 29.4% of breast reconstructions. Patients need to have good skin tone, be nonsmokers, have small breasts, and will not be receiving radiotherapy postoperatively are good candidates.

Most patients undergo immediate placement of tissue expanders for two reasons: as a time and a placeholder. Often patients are unsure what type of reconstructions they definitively want and are often overwhelmed by the cancer diagnosis initially. Also, even if the patient is a candidate for immediate implant placement, one often does not want to add an additional insult, with underlying pressure, to the relatively thin overlying mastectomy skin flaps. In addition, with many mastectomies (except complete skin-sparing mastectomies), skin is removed and skin expansion is required over time.

The tissue expander or implant can be used for immediate or delayed reconstruction (Figs. 16.12 and 16.13). The expander is placed submuscularly beneath the pectoralis major muscle and the serratus fascia laterally, if possible, to provide an extra layer of tissue in the event of a skin breakdown.

If complete muscle coverage cannot be achieved, the use of acellular dermal matrix for inferior pole support can be added. The pectoralis muscle is release to the medial sternal border and the acellular dermal matrix is sewn to the IMF as well as the inferior aspect of the pectoralis muscle in order to achieve complete expander coverage. This does add additional cost and leads to higher seroma rate, but has been shown to be of benefit with lesser rate of expander loss in case of skin breakdown and better aesthetic result.

The majority of expanders used have a built-in port that is located anteriorly and can be identified with a magnet. The hospitalization is short—1 or 2 days—and the expansion is usually begun on the second week and proceeds at weekly or biweekly intervals for a period of 4 to 6 weeks, depending on the amount of expansion required and how much the patient can tolerate each time. After the expansion is complete, the expander is left in place for ~3 months in an effort to avoid the “recall phenomena,” thus allowing the expander capsule to mature so that contraction of the pocket does not occur once the expander is removed. In case of postoperative radiation the expander if left in place often a minimum of 6 months after

completion of radiation in order to allow for radiation changes of the skin to be completed. There is promising new data, that autologous fat grafting immediately after radiation could potentially stop the progression of radiation changes to the skin.

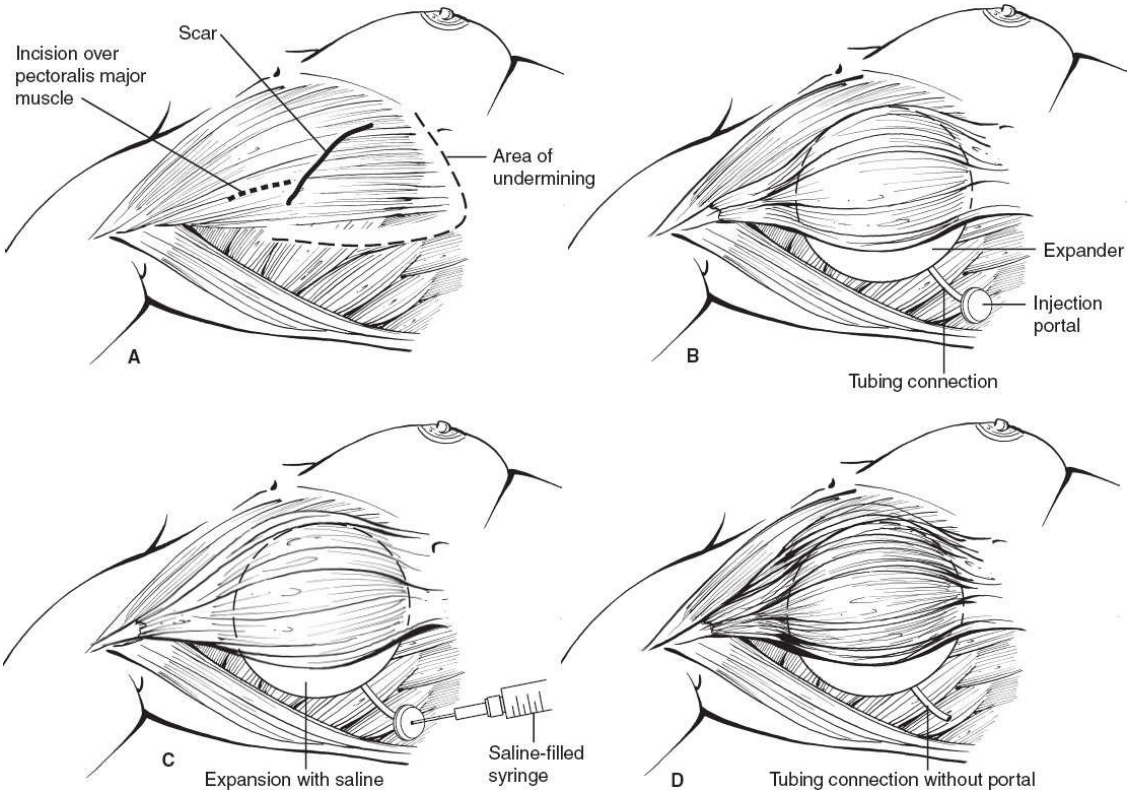

Figure 16.12. A–D. As seen in the diagrams, it is easy to place the expander too high because the pectoralis major does not extend to the inframammary fold. For proper and a lower positioning, the expander does not have muscle coverage in the distal third. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:22, with permission.)

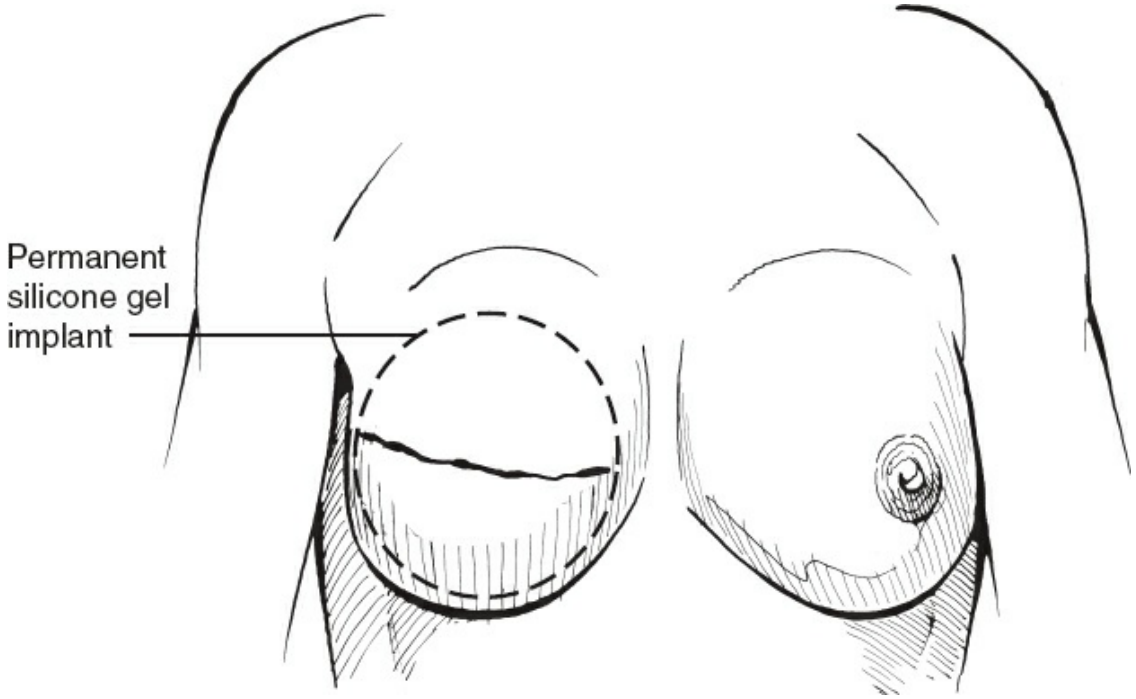

Figure 16.13. The permanent implant is placed 2 to 3 cm below the inframammary fold to allow for the capsular contracture which will invariably ensue. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:22, with permission.)

The expander is replaced with either a permanent prosthesis or autologous tissue.

Advantages Expander/Implant Reconstruction

1. Short operating time
2. Short recovery time
3. Lack of donor site scars
4. Lack of donor site morbidity

Disadvantages Expander/Implant Reconstruction

1. The breast is only partly reconstructed and requires an expansion.
2. The use of round implants in the reconstructed breast creates an unnatural upper pole fullness; to obtain symmetry, it is not unusual that one needs to perform a symmetry procedure on the contralateral side and put a smaller implant on the contralateral normal breast. The use of anatomic shaped implants can help create a more natural looking breast shape, with less step-off in the upper pole while providing a fuller lower pole.
3. The reconstructed breast has an unnatural feel, compared to the native

breast.

4. Potential complications are infection, capsular contracture, deflation, and extrusion. Capsular contracture may cause variable amounts of pain and an unnatural appearance of the breast. The incidence of capsular contracture has been reduced with submuscular placement of the implant. Capsulotomy or capsulectomy may be required for capsular contracture. Removal of the implant and autologous reconstruction with vascularized tissue may ultimately be required.

Additional Considerations

Although the use of expanders indicate a two-stage procedure, large multicenter studies have found that there is, in fact, an average of 3.07 operations per patient (vs. 2.32 in DIEP reconstruction) because of the problems with exposure of the implant, capsular contracture, elevation of the inframammary fold, as well as inadequate symmetry.

A second and most important consideration is the increasing use of skin-sparing mastectomy by oncology surgeons. This procedure develops thin skin flaps. Previous reports suggest flap necrosis rates as high as 15%, but more recent, large, multicenter studies suggest flap loss between 5.6% and 8%. Were one to put an implant or an expander under this relatively thin skin, exposure of the implant would be unavoidable. To avoid exposure, total muscle coverage of the implant is essential. Although the serratus muscle fascia does provide a certain amount of coverage to the lower pole of the implant, if one depends only on the serratus muscle fascia for such coverage, one is likely to place the implant higher than without, thus elevating the inframammary fold. Because of this consideration, in our practice when a skin-sparing mastectomy has been performed and an implant reconstruction is planned, we prefer to transpose the latissimus dorsi myocutaneous flap. This provides excellent muscle coverage for the lower portion of the implant and restores the skin island at the site of the nipple and areola. If this is done, as demonstrated in our practice, one does not need to put an expander; instead, a permanent implant is used, thus reducing the number of operative procedures. Even if the overlying skin flap were to necrose in a small portion, the implant is covered with muscle and is salvaged.

Use of Acellular Dermis and Biologic Mesh

If is not possible to cover the lower portion of an implant following a skin-sparing mastectomy, different options exist. We advocate lower coverage

of the implant with the latissimus dorsi muscle, although this entails a bigger operation and turning of the patient. To avoid that, one has the option of using acellular dermis. These materials come in two general classes: human collagen and pig collagen (AlloDerm, FlexHD, AlloMax vs. Strattice).

The materials, although helpful to provide coverage of the implant or reinforce the thin skin flaps, are fraught with deleterious effects. These effects may include the following: there is nearly always a low level of inflammation of the wound, which may be mistaken for an infection. This is due to the fact that collagen has a low level of antigenicity (perhaps more with the xenographic mesh—pig). In severe cases, this can result in a so-called "red-breast syndrome" requiring explantation of the ADM; there is invariable fluid collection or seroma, which requires the use of drains for a prolonged period of time; lastly, one has to be sure that the native skin flaps are well vascularized to avoid exposure of the mesh. Perhaps one of the greatest drawbacks is that the materials are quite costly. This has improved as the market has broadened, but variance in tissue thickness, type and quality makes the added cost difficult to justify at times. Much like any surgical technique, however, the use of ADMs in breast reconstruction varies greatly. Some surgeons will use it almost universally for implant coverage. Others, leery of the potential downfalls, choose autologous, vacularized tissue for coverage instead.

Latissimus Dorsi Myocutaneous Flap and Implant

This procedure is one of the safest methods of breast reconstruction; it is relatively straightforward and very well tolerated by the patient. This technique is particularly applicable to immediate reconstruction following skin-sparing mastectomy. The latissimus provides additional muscle coverage to the implant, particularly on the inferior pole.

The latissimus dorsi is a rhomboid-shaped muscle that originates along the paravertebral fascia in the back and inserts in the upper portion of the humerus. The upper border of the muscle is just above the tip of the scapula, extending obliquely posteriorly, and inferiorly it then reaches the iliac crest (Fig. 16.14). It is a "tree-climbing" muscle, but its function can be taken over by other adjacent muscles. The blood supply is from the thoracodorsal artery, which is a branch of the subscapular artery (third portion of the axillary artery). The pivot point should be as high as possible, limited only by the thoracodorsal pedicle. The insertion does not need to be transected, but the muscle should be freed up as high as

possible to make it transpose as a pendulum rather than rotating it to avoid the bulge along the axilla. The flap is usually harvested as a musculocutaneous flap with a skin island taken transversely across the back so that the scar will be covered with a brassiere. A skin island should usually be limited to no more than 6 to 8 cm to allow primary closure of the donor site.

Technique

The patient is marked in the standing position preoperatively. The anterior border of the latissimus dorsi muscle should be marked on the ipsilateral side, and the inframammary fold should also be marked. The skin paddle is oriented transversely to correspond with the brassiere line. If necessary, an extension along the anterior border of the latissimus dorsi muscle is done to gain access to the upper portion of the muscle.

Working in concert with the oncology surgeon, the flap can be elevated before the mastectomy or following it. If it is elevated before the mastectomy, the patient is placed on a bean bag in the lateral recumbent position. The flap, which is elevated and ready to be transposed, is placed on a sterile plastic bag, and the wound is closed with the insertion of drains. If the mastectomy is done first, the patient is then placed in the lateral decubitus position with the shoulder and arm resting at 90 degrees over a Mayo stand. The skin island is incised perpendicular to the skin through subcutaneous tissue and fascia down to the muscle. The skin flap is elevated superiorly above the tip of the scapula and inferiorly for at least 10 to 15 cm. The dissection of the muscle is begun superiorly, where the upper border of the latissimus dorsi is easily identified, and extends posteriorly along the paravertebral fascia down the inferior border of the dissection while dividing the muscular attachments with the cautery. The anterior border of the latissimus dorsi is identified, the muscle edge is grasped with an Allis clamp, and the elevation is continued by dividing the posterior intercostal attachments.

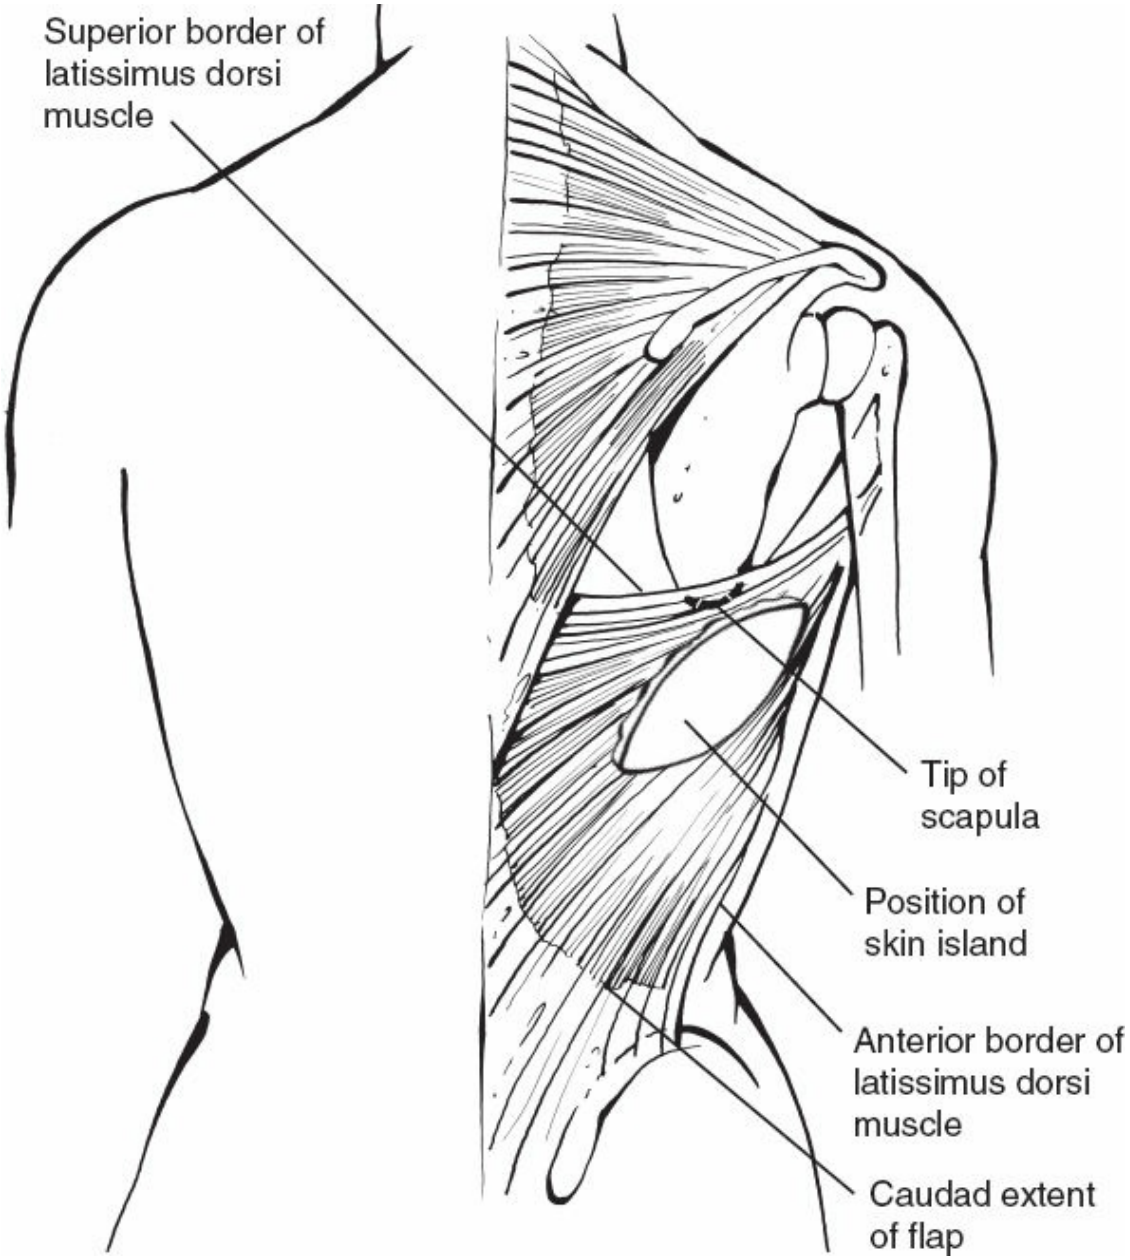

Figure 16.14. External landmarks of the latissimus dorsi muscle. The skin island is preferentially outlined transversely so that the scar will be covered by the brassiere. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:39, with permission.)

Care must be exercised to avoid elevating the serratus muscle. This is avoided by beginning the dissection superiorly where one finds the appropriate plane within the planned dissection. The muscle with the overlying skin island is freed up all the way around. The thoracodorsal vessel is easily identified in the axilla. Rarely, the serratus branch needs to be divided to improve the arc of rotation, but this is not routinely done.

The thoracodorsal vessel does not need to be skeletonized, but the muscle should be freed up posteriorly, almost all the way to the humerus. The latissimus myocutaneous flap is then tunneled to the anterior chest by making a very high tunnel through the skin-sparing mastectomy dissection or by using the axillary incision that may have been made for the sentinel node biopsy. Variations of the flap may be used instead (Fig. 16.15).

Once the myocutaneous unit is transposed anteriorly, one elevates the pectoralis major muscle, partially divides its origin along the sternum, and the latissimus dorsi muscle is sutured to the undersurface of the pectoralis major muscle and to the subcutaneous tissue of the skin in the inferior flap, in preference of suturing to the chest wall. An immediate implant is inserted and inflated to the proper volume, but it is advisable that the implant be placed at least 2 to 3 cm below the contralateral inframammary fold (Fig. 16.16). The reason for suturing the lower portion of the latissimus dorsi muscle to the subcutaneous tissue is to avoid restricting the implant pocket. A suction catheter is placed along the axilla.

The patient is then returned to the recumbent position, is sat up on the operating table, and appropriate adjustments are made if necessary by putting another smaller implant on the contralateral side or performing a mastopexy or potentially both.

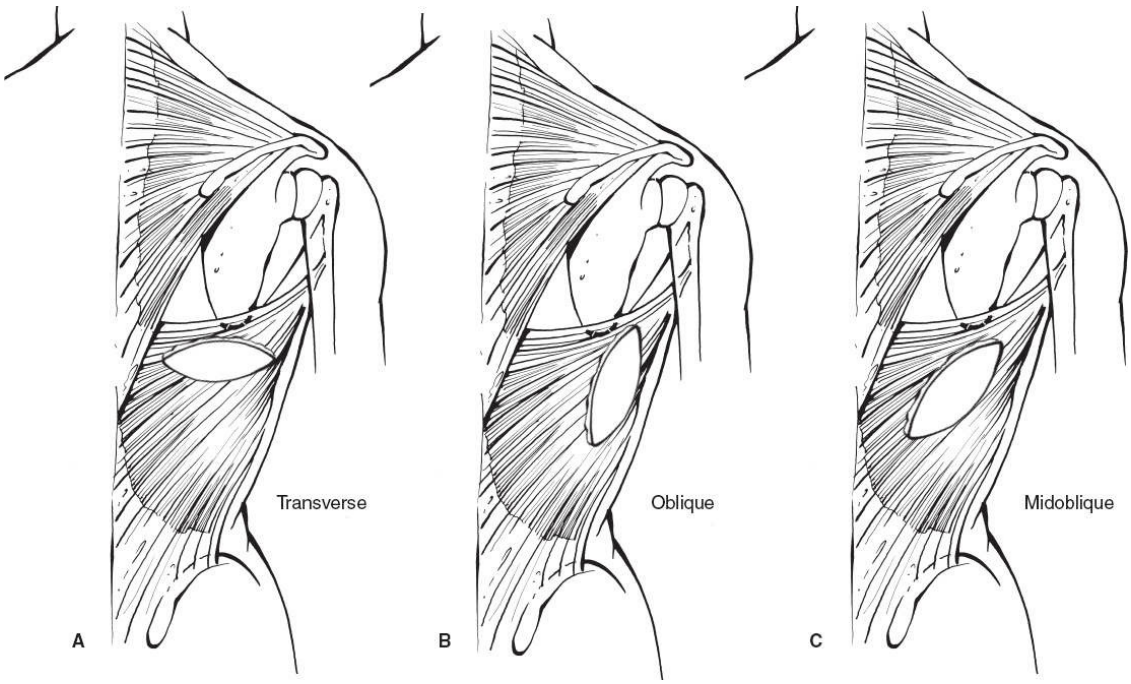

Figure 16.15. A–C. Outline the skin island to fit the different scars from the mastectomy. Transverse outline (**A**) is the most used. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB

Lippincott, 1991:3.9, with permission.)

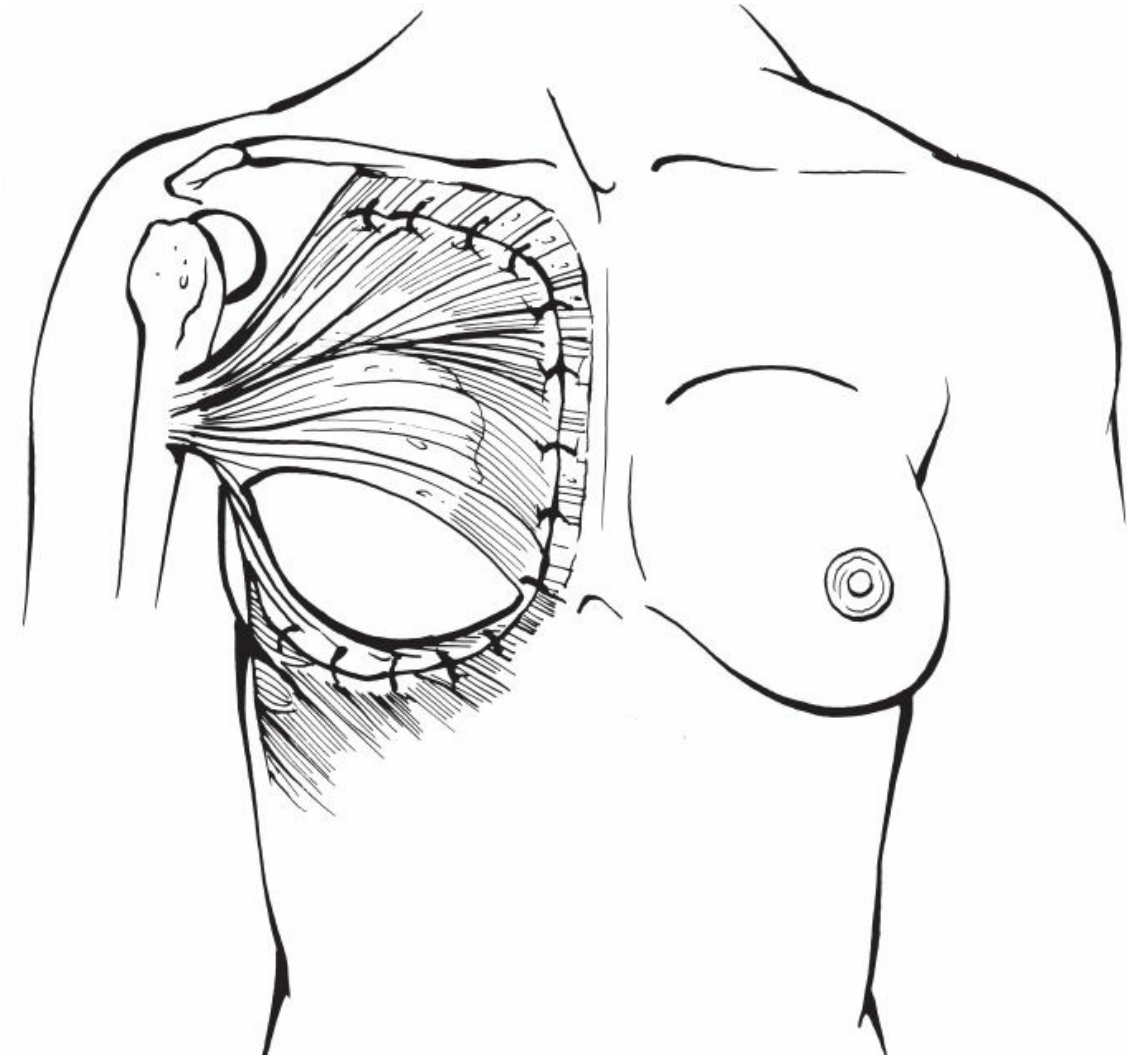

Figure 16.16. Most often the distal third of the implant is not covered by muscle, although occasionally the serratus muscle does help achieve lower coverage of the implant. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:3.9, with permission.)

Advantages

1. The implant is totally covered by muscle, and thus protected of the overlying soft tissue.
2. Although it requires repositioning of the patient, thus increasing the operating time, the recovery time and hospitalization are shorter, compared to TRAM or perforator flap reconstruction.

Disadvantages

1. Because an implant is used, capsular contracture remains a possibility even though there is total muscle coverage. Deflation of a saline implant, if used, is also possible, although extrusion is rare.
2. There is a donor site scar on the back, which usually is covered by the brassiere.
3. Seroma is very common at the donor site and is usually treated by a secondary stab wound percutaneous needle aspiration in the most dependent portion of the seroma.

Transverse Rectus Abdominis Myocutaneous Flap

The TRAM flap is the most commonly used method of autogenous reconstruction of the breast, though a paradigm shift toward free flap reconstruction, especially in the CPM group, has been noted in recent years. Nonetheless, it is one of the most natural methods of breast reconstruction, obtaining symmetry with the contralateral breast in the majority of cases. It supplies an abundant amount of soft tissue; however, the recovery time is longer and the hospitalization may be 4 to 6 days. The blood supply is the deep inferior epigastric artery, from the external iliac artery and the superior epigastric artery from the internal thoracic artery (Fig. 16.17). They communicate through a series of vascular interconnections just above the umbilicus, thus forming the epigastric arcade. In addition, the segmental and intercostal vessels join the arcade at the deep portion of the muscle.

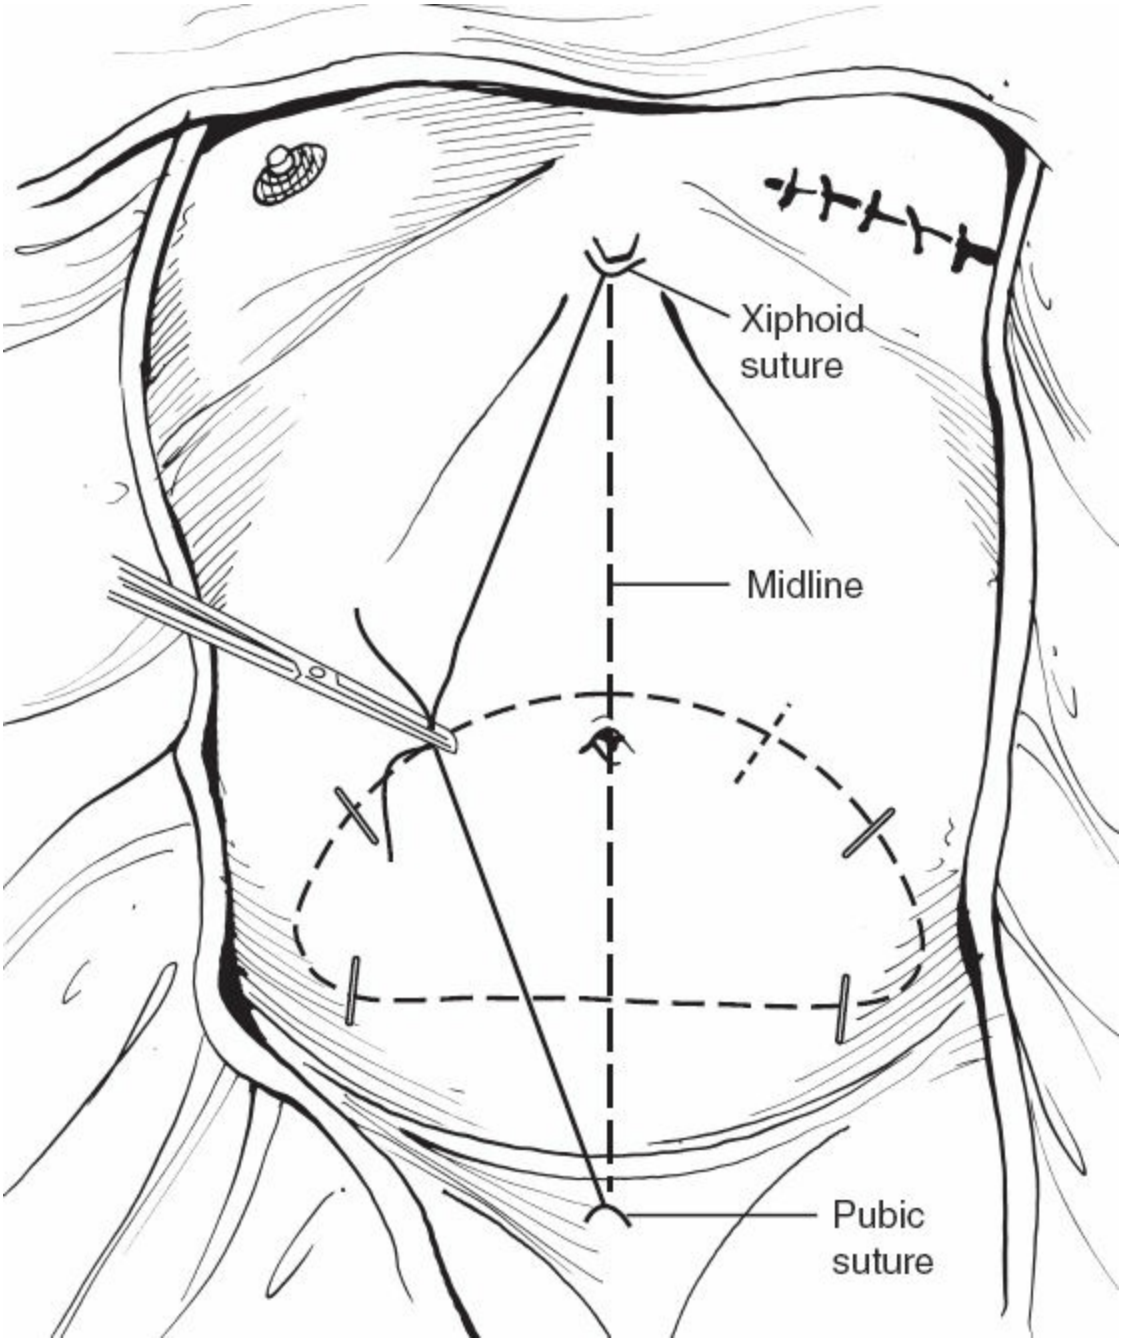

Figure 16.17. Two sutures: one placed on the xiphoid and the second on the mid-pubis allow us to obtain bilateral symmetry by triangulation. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.31, with permission.)

The inferior epigastric artery is the dominant blood supply and enters the muscle laterally at the semilunar line. The pedicle length is 8 to 10 cm. The blood supply to the overlying skin is through musculocutaneous perforators thought to be arranged in a medial row and a lateral row. The perforators are primarily periumbilical, with few, if any, perforators below

this semicircular line. As determined by the so-called perforator flap, the entire flap is probably nourished by a large periumbilical perforator. This is important to know because the flap should never be outlined with the upper incision below the umbilicus to ensure the inclusion of this perforator. Four zones are designed on a transverse elliptical skin island to describe the availability of the blood supply based on the superior epigastric vessels. The hemiflap is totally reliable, and lateral extension into the flank is also reliable. Interestingly, the only independent risk factor for complications in these patients is smoking history.

The standard design for breast reconstruction is an elliptical lower abdominal transverse skin island at the level of the umbilicus to above the pubis to allow for the direct closure with acceptable tension. Depending on the volume of tissue necessary for the reconstruction, the flap is harvested as a unipedicle, bipedicle, free TRAM flap, or perforator flap. The entire skin paddle can be transferred with a bipedicle flap, and 75% can be transferred as a free tissue transfer. We do not favor bipedicle TRAM flaps for unilateral breast reconstructions except in postradiation cases in which a large amount of skin has been resected from the chest wall.

Unipedicle Transverse Rectus Abdominis Flap

The unipedicle TRAM flap is based on the superior epigastric artery and vein (Figs. 16.18 and 16.19). We advise the use of the ipsilateral TRAM flap because of the shorter arc of rotation and the avoidance of the epigastric fullness. However, when the ipsilateral flap is used, the tunnel must be in the midline and, preferably, extends to the contralateral side so as to preserve at least the lateral half of the inframammary fold. The contralateral rectus may also be used, depending on previous abdominal incisions.

Delayed Unipedicle TRAM

The addition of a delay procedure can improve the viability and performance of the superior epigastric arterial system, especially in zone III. This is performed by dividing the inferior epigastric vessels in a first phase 2 weeks prior to the proposed mastectomy and reconstructive TRAM flap.

Technique

The procedure is begun by circumscribing the umbilicus and leaving it in place. The upper abdominal incision is then made to the anterior rectus

sheath, and the superior abdominal flap is undermined to the costal margin bilaterally and then to the xiphoid in the midline. At this point, working from the chest by either the mastectomy defect or reopening the mastectomy scar in a delayed reconstruction, a midline tunnel is created of sufficient size to allow the passage of the flap. Again, the tunnel must be midline and extend to the contralateral side to preserve the inframammary fold. Having elevated the upper abdominal flap, the anterior rectus sheath is exposed and one can see the location of the perforating vessels, which have either been controlled with hemoclips or electrocautery. A 5-cm wide anterior rectus sheath is preserved with the perforating vessels in the midline, and this anterior rectus sheath is incised on each side, preserving the midline fascia as well as the lateral fascia and freeing up the entire muscle from the posterior rectus sheath.

The lower incision is then made as far down toward the pubis to allow for direct closure. The contralateral side is first elevated rapidly, just past the midline to correspond to the medial incision of the anterior rectus sheath superiorly, and then the fascia along the midline is also divided toward the pubis, preserving the linea alba. The lateral flap is then elevated rapidly, again to the lateral edge of the muscle, and using the incision along the anterior rectus sheath superiorly as a guide, the dissection extends to that level where the fascia is divided again toward the pubis, communicating through a transverse incision with the midline dissection.

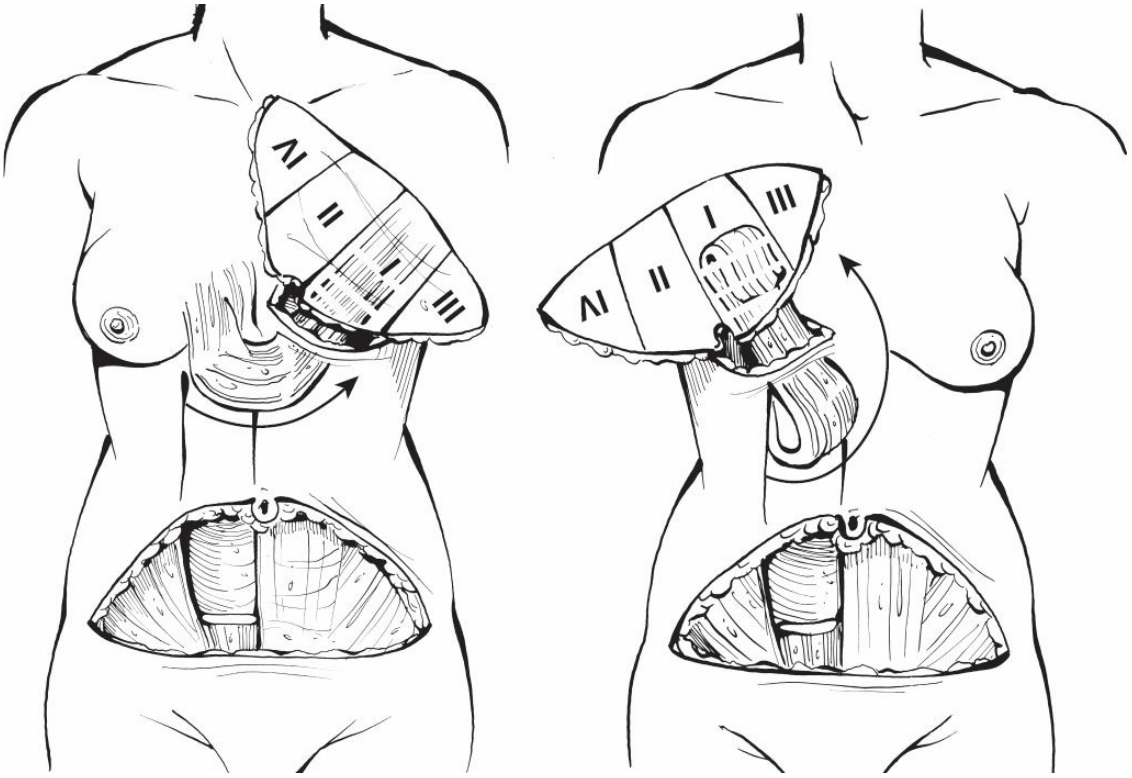

Figure 16.18. Presently, the ipsilateral flap is the first choice. In either case, the tunnel is on the midline of the abdomen and chest. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.10, with permission.)

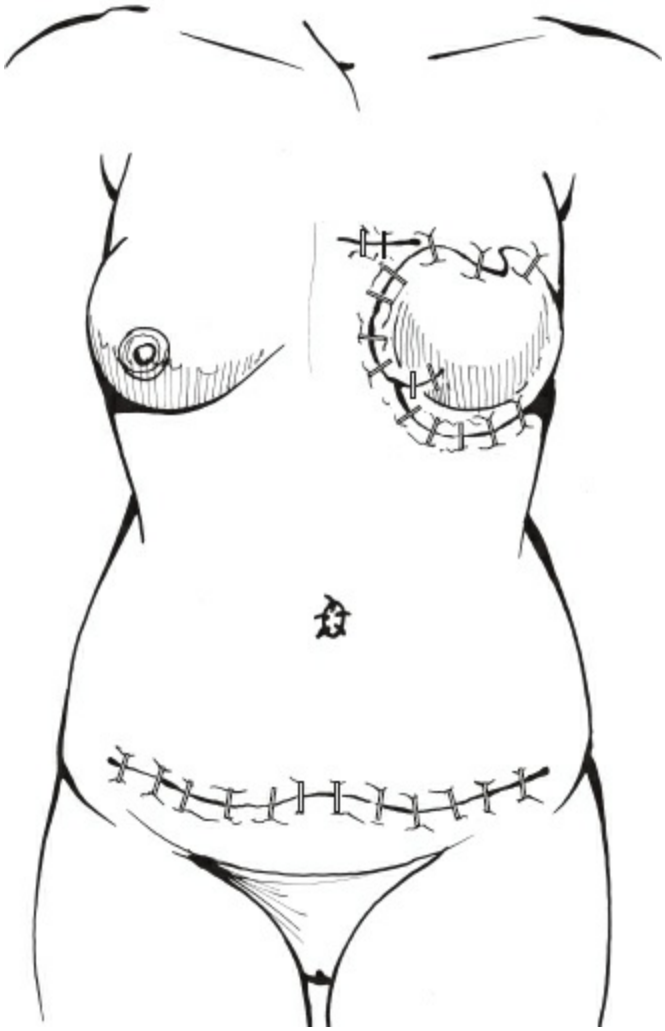

Figure 16.19. In molding the breast, attention is paid to projection, ptosis, and the equal placement of the inframammary fold bilaterally. It is essential to be able to sit the patient intraoperatively, to determine symmetry. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.10, with permission.)

The rectus muscle is then freed up from the lateral aspect as well as from the medial aspect; the deep inferior epigastric vessels, which are located below the semicircular line, and surrounded by fat, are identified and then divided between hemoclips. The rectus abdominis muscle is then also divided just below this semicircular line, preserving the divided inferior epigastric pedicle. The flap unit is elevated by dividing the segmental intercostal vessels and freed up from the posterior rectus sheath. Once appropriate hemostasis has been obtained, the flap is passed through the midline tunnel toward the chest. The flap is turned with the skin side

out and the distal portion of the contralateral side (zone 4) is discarded, as are additional portions of so-called zone 2. The best way to evaluate the viability of the flap is by observing bright red bleeding from the skin edges. This is observed even if one has used lidocaine with epinephrine for the vasoconstricting effect. The presence of dark blood is indicative of inadequate blood supply and further resection should be performed.

An additional way of checking perfusion is the use of Indocyanine green using the Spy Elite machine. Following injection of ICG into the flap, perforators can be checked individually for flap perfusion. In doing so, perforasomes may be more clearly defined, increasing flap viability when using fasciocutaneous or free-style perforator flaps.

The orientation of the flap is relatively simple as the tip of the flap is placed to simulate the axillary tail of the breast. The remaining flap is allowed to hang down obliquely or vertically, or very simply to fill the envelope of skin-sparing mastectomy (Fig. 16.20). In a case of a delayed reconstruction in which the mastectomy has been done with a transverse incision, the upper edge of the skin flap may be zigzagged to obtain more projection and the lower skin may actually be resected close to the inframammary fold to allow for satisfactory projection and ptosis of the flap. The closure of the abdominal defect is essential, and the most important admonition is to close either separately or together the external and the internal oblique fascias below the umbilicus (Figs. 16.21 and 16.22). One should remember that the anterior rectus sheath splits into the external and internal oblique fascia approximately halfway between the umbilicus and the pubis. The internal oblique fascia has a tendency to retract, and if one does not identify this internal layer and approximate it to the midline, either together or separately with the external oblique, a lower abdominal bulge or pseudohernia will appear.

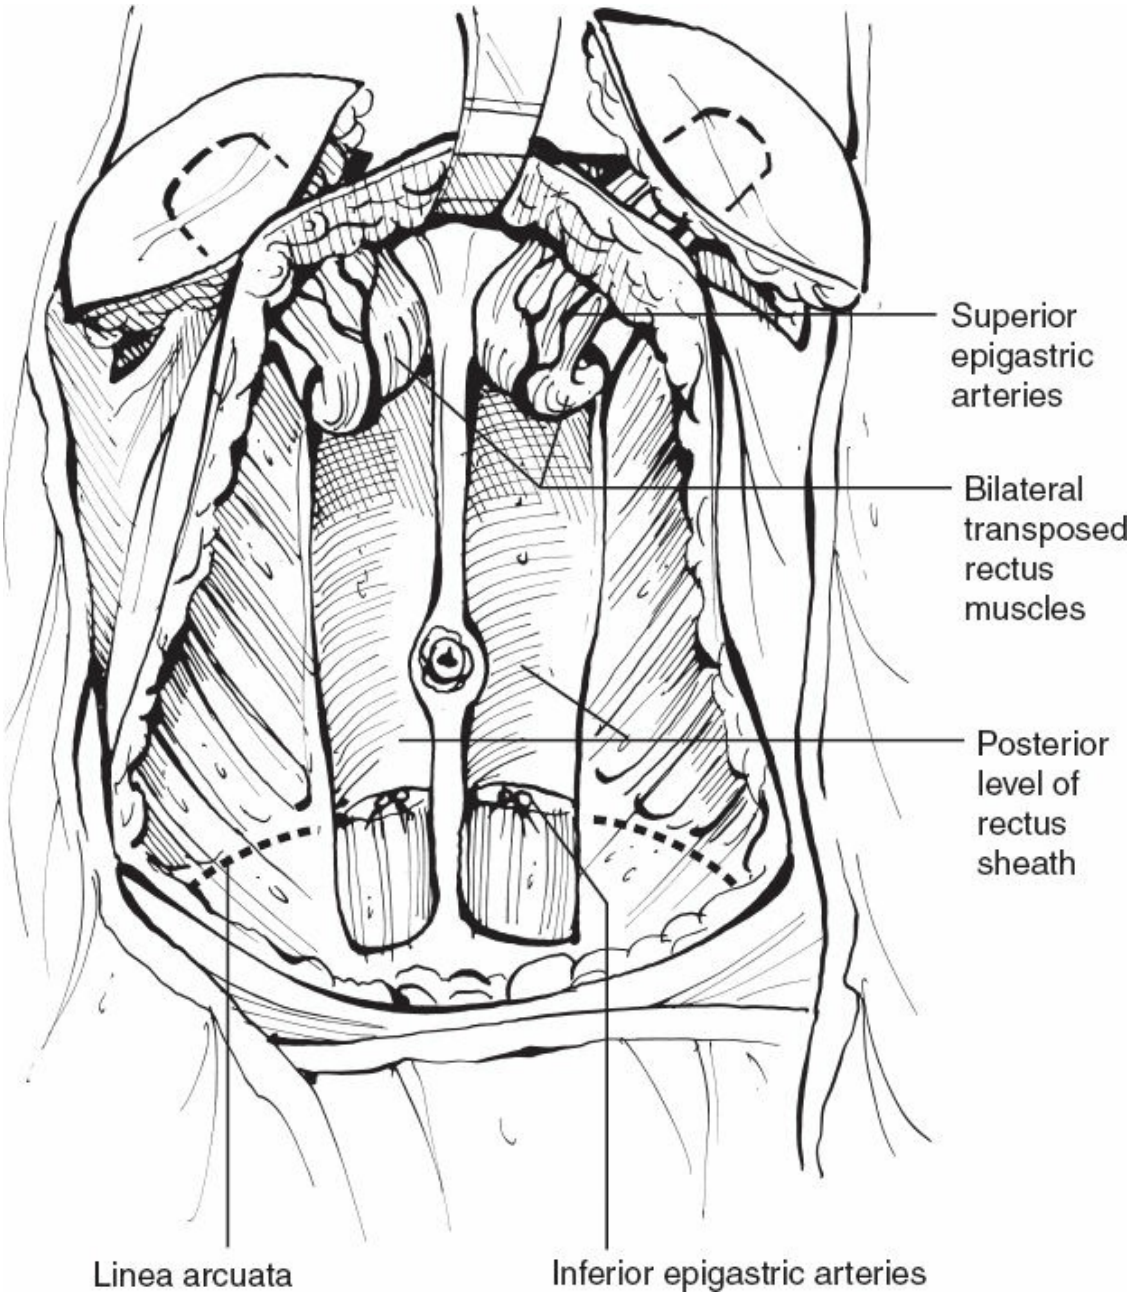

Figure 16.20. For bilateral reconstruction, it is important to design ipsilateral flaps. Rotation of the flap either in clockwise or in anticlockwise direction is safe. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.10, with permission.)

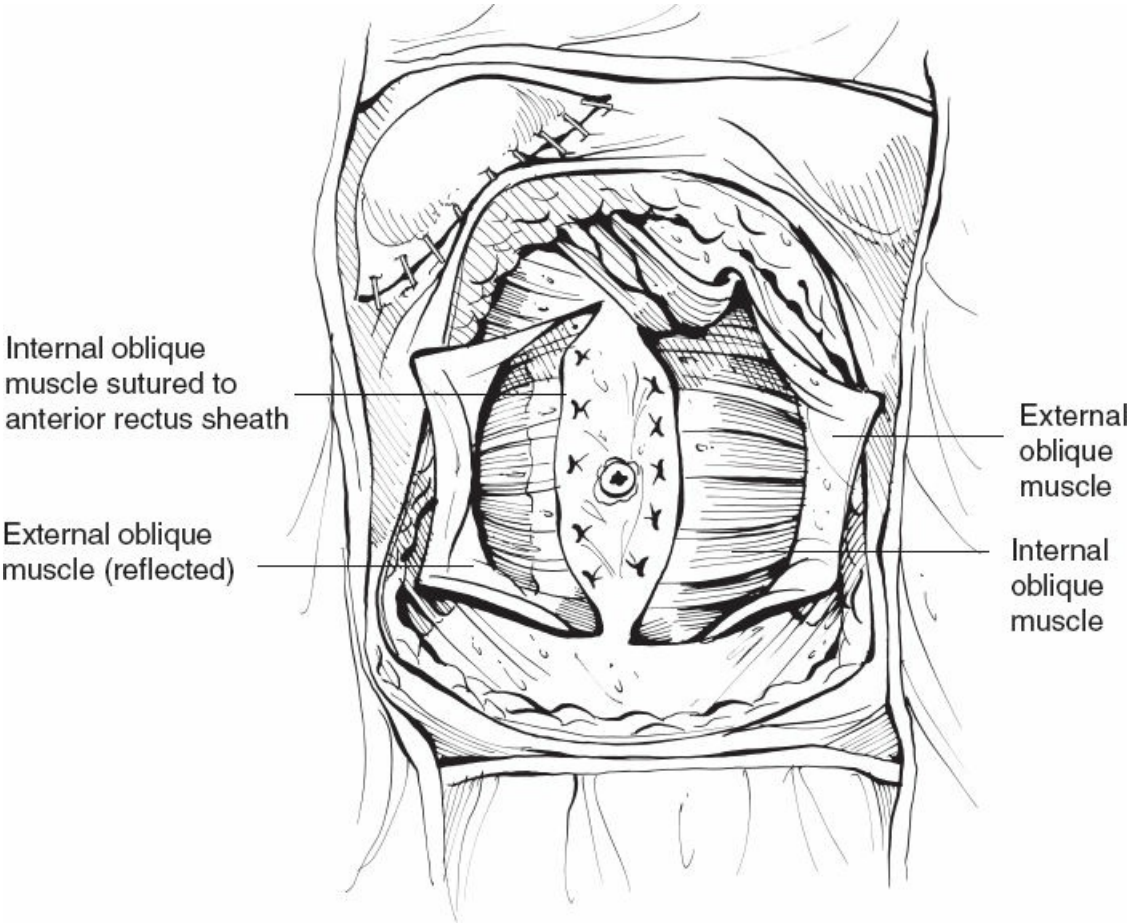

Figure 16.21. The external oblique muscles are freed up to the flanks. The internal oblique muscles are approximated as close to the midline as possible. It is not possible to make them reach the midline. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.22, with permission.)

In unilateral breast reconstructions, direct closure is almost always possible. To accomplish this, we place three retention sutures of 0 Prolene, one at the level of the umbilicus and one above and one below the umbilicus. Once these sutures are approximated to the midline, we run a loop suture from just below the turn of the muscle in the epigastrium down to the pubis. To centralize the umbilicus, which has been moved to the side of the flap, the contralateral intact anterior rectus sheath is also plicated with interrupted or continuous sutures of Prolene for ~4 cm. If the umbilicus is on a large stalk, additional centralization can be obtained by suturing the umbilicus with interrupted nylon sutures to the anterior rectus sheath as it is pulled toward the center.

The abdominal wound is then closed, and the umbilicus is re-exteriorized at the appropriate level and sutured with fine nylon. Suction

catheters are placed. It should be noted that seromas in a TRAM flap procedure are relatively rare. This is in contrast to the almost universal seromas that are seen in abdominoplasties. The reason for this is not clear, but a possible explanation may be that fluid is suctioned intra-abdominally through small openings in the abdominal sheaths, particularly below the semicircular line.

Advantages

1. Large volume of tissue sufficient to provide excellent shape and symmetry with the contralateral breast.
2. Abdominoplasty results with donor site closure.

Disadvantages

1. Fat necrosis and partial flap loss in 5% to 15% of patients.
2. Pseudohernia is 4%.
3. Possibility of total loss of the flap, particularly in smokers and very obese patients, though not as high as in free tissue transfer.

Bipedicle Transverse Rectus Abdominis Myocutaneous Flap

In cases in which a bilateral mastectomy is performed, bilateral TRAM flaps are performed, again on the ipsilateral side but always with the midline tunnel preserving the inframammary fold in each side. Rarely, a bipedicle TRAM flap is needed for postradiation defects in which large amounts of skin are resected. In such cases, the skin paddle is reliably from the ipsilateral anterior axillary line fold to the contralateral anterior axillary line fold. The flap is harvested in the same manner as the pedicle flap except that both rectus abdominis muscles are harvested along with the transverse skin paddle, preserving both superior epigastric vessels. Although one preserves the linea alba or midline fascia for at least 2 cm as well as the lateral portion of the anterior rectus sheath bilaterally, and primary closure can be done in a good number of patients, mesh is sometimes necessary as an inlay to approximate the remaining fascias. Again, we emphasize that attention must be paid to approximate the internal oblique fascia. If mesh is used, we prefer the use of folded polypropylene mesh, usually four thicknesses, and approximate it with Prolene suture on each side. The use of an onlay mesh is less satisfactory.

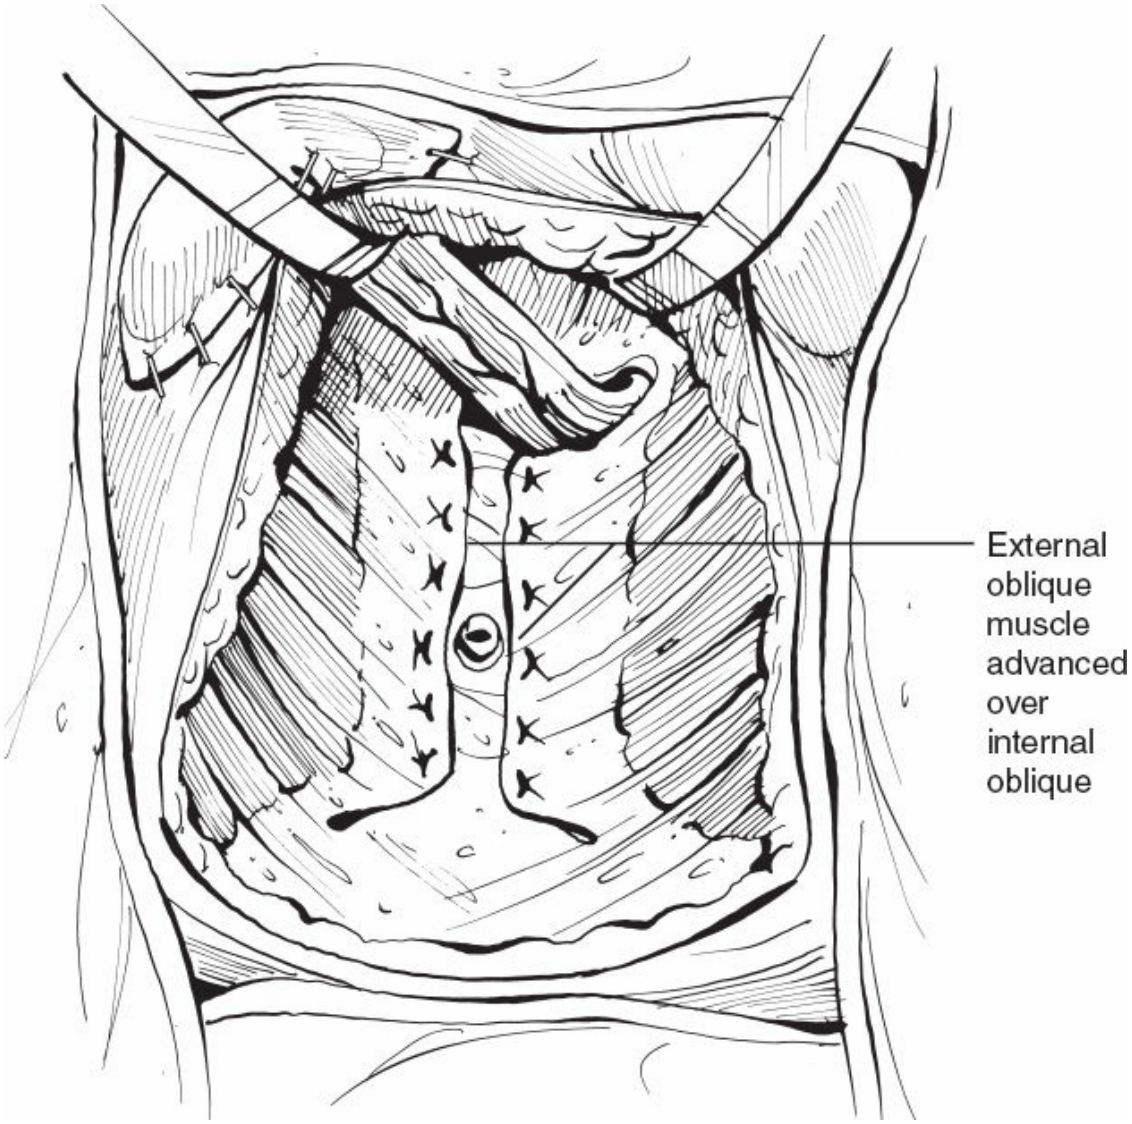

Figure 16.22. Once the internal oblique muscles are plicated, the leaves of the external obliques easily reach the midline. It is imperative that the closure be performed simultaneously on both sides. Otherwise, closure of the second side is nearly impossible due to fascial tears. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:4.22, with permission.)

Advantages

1. Larger volume of tissue.
2. Makes for bilateral symmetric reconstructions of the breasts. Preferred also in patients who are markedly obese and have had previous chest wall radiation (patients who have had previous mediastinal irradiation such as for Hodgkin disease, in which internal mammary damage is possible) are best treated with a free TRAM flap anastomosed to the thoracodorsal or other appropriate vessel.

Disadvantages

1. Often requires the placement of mesh.
2. Longer operating time.
3. Greater risk of abdominal wall complications.

Free Transverse Rectus Abdominis Myocutaneous Flap

The dominant blood supply of the free TRAM flap is the deep inferior epigastric vessels. The flap is harvested in the same way as the previously described flaps except that the deep inferior epigastric vessel is preserved along with a small segment of rectus abdominis muscle (Fig. 16.23). It is not necessary to take the entire width of the muscle. The vessel is identified entering the rectus muscle near the semicircular line, traced down to its origin at the external iliac vessels, and ligated at this point. The recipient vessel often used for the anastomosis is the internal mammary artery and its accompanying vein. The thoracodorsal vessel is a second choice at present. The reason for this change is the popularity of the sentinel node dissection. By using the sentinel node, the thoracodorsal vessel is not skeletonized as it was with an axillary dissection, and there is the rare possibility that an initial negative sentinel node may turn out to be positive in the permanent sections, requiring the return to the axilla, where the anastomosis may be compromised. In addition, the internal mammary artery provides a very satisfactory way of molding the breast to match the opposite side.

Advantages

1. Preferred in smokers, obese patients, and patients with mediastinal irradiation for lymphomas
2. Larger volume of tissue
3. Greater freedom of rotation
4. Less incidence of fat necrosis

Disadvantages

1. Longer operating time
2. Requires microsurgical expertise and well-trained team for small artery anastomosis

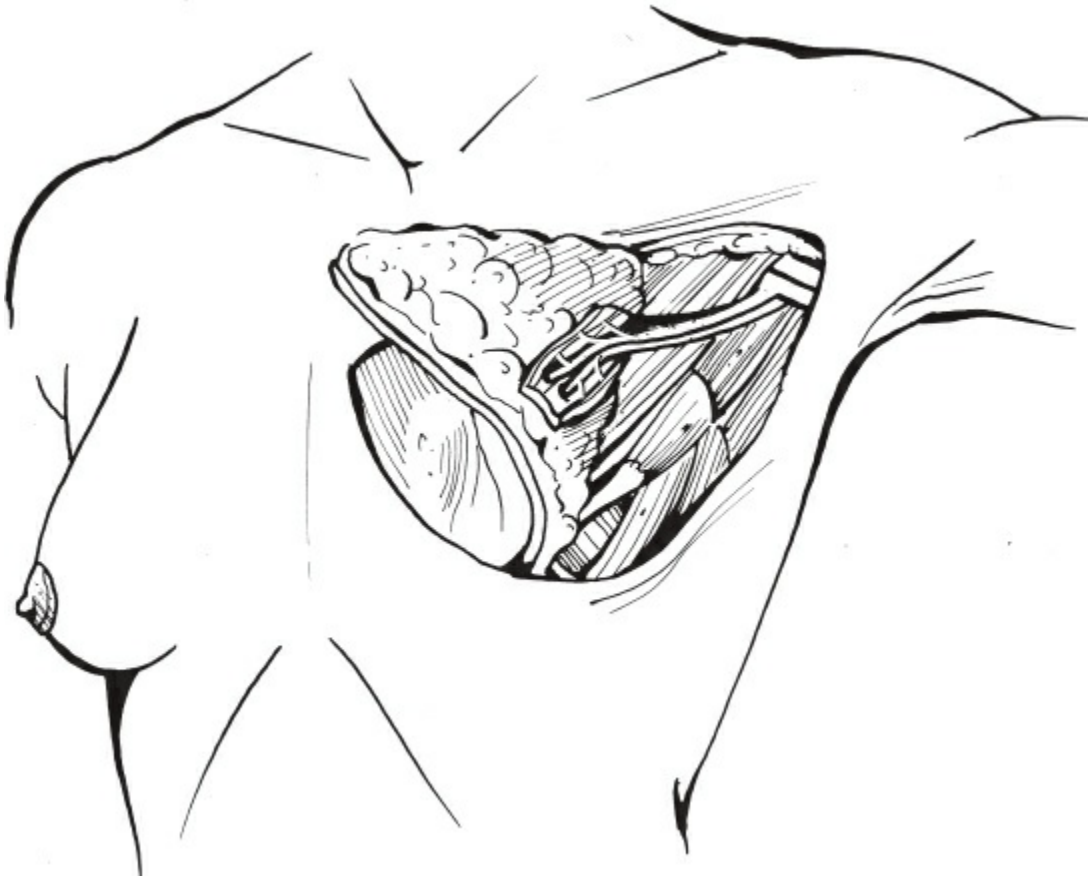

Figure 16.23. For a free TRAM flap, the anastomosis is made to the thoracodorsal vessels as shown above. Presently, most microsurgeons prefer to do the anastomosis to the internal thoracic artery and vein or veins. (Modified from Vasconez LO, Lejeur M, Gamboa-Bobadilla M. *Atlas of Breast Reconstruction.* Philadelphia, PA: JB Lippincott, 1991:13.6, with permission.)

Perforator Flap ("DIEP" Flap)

A modification of the free TRAM flap is the free perforator flap. This entails the preservation of the periumbilical perforator with its accompanying veins dissected along with the deep inferior epigastric vessel, but preserving almost the entire integrity of the rectus abdominis muscle (Figs. 16.24 and 16.25). The proponents of this flap indicate the advantages, such as increasing integrity of the abdominal wall, but it does take a more meticulous and lengthier dissection, at least in less-experienced hands.

One can usually predetermine if a perforator flap type of reconstruction is possible, by performing a CT angiogram. It accurately indicates if the perforators are appropriate for the anastomosis, avoiding the need to visually dissect those vessels. The perforator flap is gaining popularity

because it preserves the integrity of the rectus muscle and of the abdominal wall.

Superficial Inferior Epigastric Breast Reconstruction

This option is a possibility in a minority of the patients who elect microvascular breast reconstruction.

The CT angiogram visualizes the superficial inferior epigastric vessels and one can determine if those vessels are large and long enough to perform the breast reconstruction. It does require additional expertise and does not offer the safety of the deep inferior epigastric vessels. Reconstruction with the superficial inferior epigastric vessels is a superior option taken by well-qualified teams. The vessels can nourish the same amount of abdominal tissue.

A Note on Perforator-Based Flaps

An increasing preference has been noted for perforator flaps due to the decreased rate of morbidity associated with these flaps. Unfortunately, in the less-experienced surgeon—or at least in the case of the surgeon less familiar with these procedures—the so-called perforasome is a somewhat nebulous idea as compared with the angiosome of the more well-characterized musculocutaneous flaps. Fortunately, technology has afforded newer techniques in designing flaps that will be successful. Prior to division, perfusion of an individual perforator can be assessed using intraoperative laser angiography in combination with indocyanine green. This “SPY” system allows the surgeon to confidently assess the viability of the flap on a single (or multiple) perforators prior to committing to flap division. As explained by Gurtner et al. (2013), consensus recommendation regarding intraoperative assessment of flaps suggests this is a safe and potentially beneficial practice.

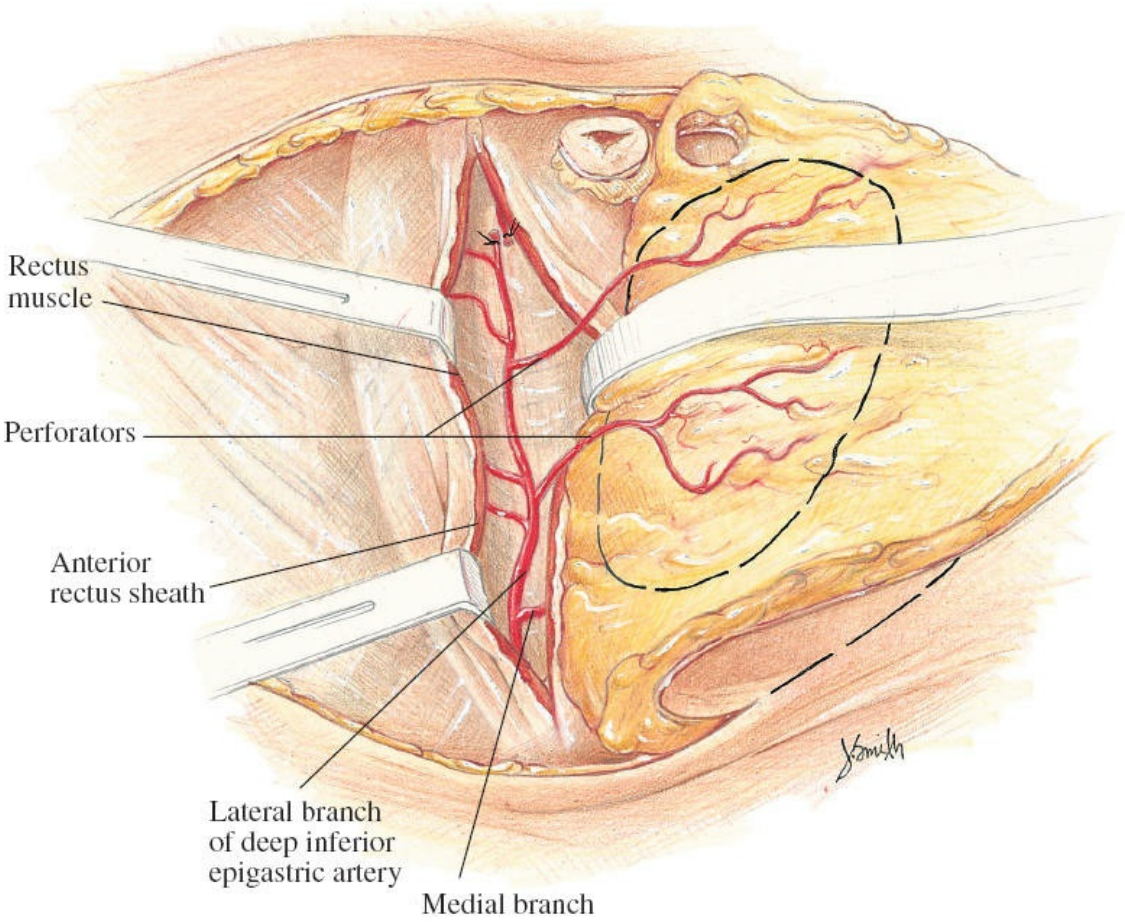

Figure 16.24. Diagrammatic demonstration of the perforators from the deep inferior epigastric vessels. The main perforator is near the umbilicus. (From Spear SL, Little JW, Wood WC, eds. *Surgery of the Breast: Principles and Art,* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006:814.)

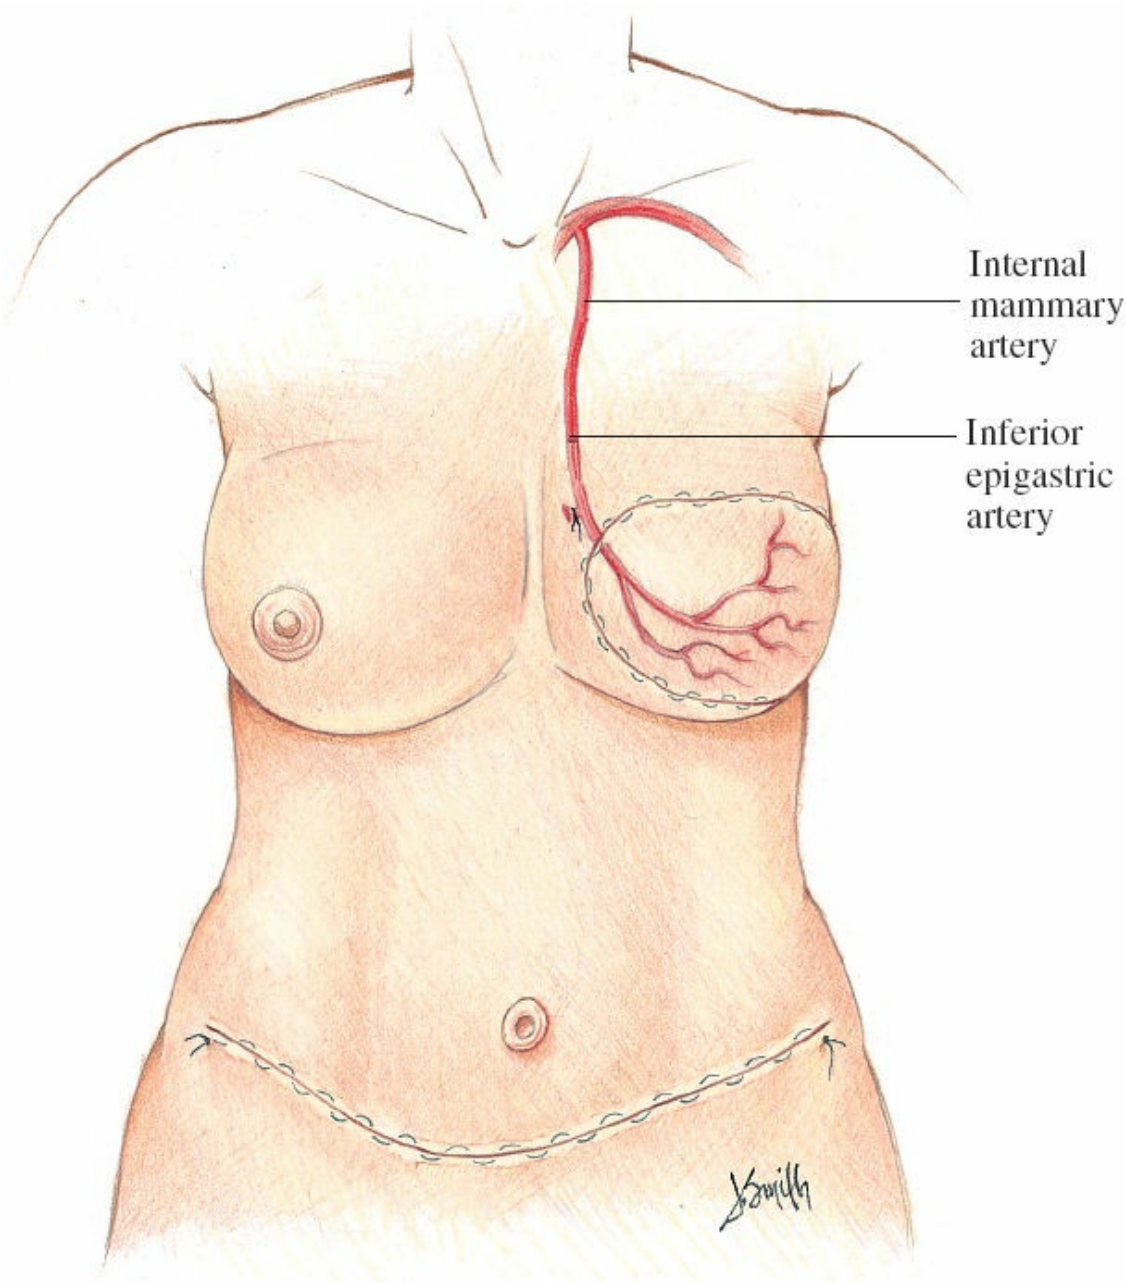

Figure 16.25. The preferred method of anastomosis. It has the advantage of leaving the axillary region free for a possible additional axillary dissection. (From Spear SL, Little JW, Wood WC, eds. *Surgery of the Breast: Principles and Art,* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006:815.)

Other Autologous Options

The TRAM flap may not be indicated in patients who have had previous abdominal operations that have transected the rectus muscle, patients who have had previous abdominoplasty, or in patients in whom there is inadequate abdominal fat to make a breast mound. These following additional free flaps can be offered. (a) The gluteal free flap, based on

either the inferior or more recently the superior gluteal artery, which provides an abundant amount of tissue to be transferred. The pedicle is of good length, 8 to 10 cm, but the patient must be prone during the harvest of the flap and needs to be turned over for the reconstruction. (b) The "Rubens flap," which uses the fat in the flank over the iliac crest region. It is based on the deep circumflex iliac artery and offers adequate volume for breast reconstruction. The vessels offer good caliber and length, 6 to 7 cm, and the donor site scar is hidden underneath pants. During surgery, the patient is supine with the hip lifted by a bean bag during the harvest. (c) The trochanteric free flap, which is applicable to patients who have trochanteric lipodystrophy with a relatively narrow torso. In such patients, the fat from the trochanter can be harvested based on the vessel of the tensor fascia lata, leaving an acceptable defect with a linear incision on the lateral aspect of the leg. If a unilateral reconstruction is performed, a subsequent procedure, such as liposuction, will be needed to match the opposite side. Presently, it is rarely used, although its proper application is clear.

The gracilis free flap is a potential option for thin patients who have small breasts. It is harvested with a transverse orientation, leaving a most acceptable scar, the aptly names TUG flap (Transverse Upper Gracilis). The limiting factor is the relatively small volume of tissue.

Nipple and Areola Reconstruction

With the sophistication and increasing excellence of breast reconstruction, most patients want completion of the reconstruction by having the nipple and areola reconstructed. This is usually performed 3 to 6 months after breast reconstruction, or later if the patient has undergone chemotherapy or radiotherapy. One should wait for the breast to be stable and symmetry has been achieved. In reconstructions using the TRAM flap in which the contralateral flap is modified at the same time, usually by a reduction mammoplasty, the nipple reconstruction is performed on the second operative procedure along with whatever modifications are needed on the reconstructed or the contralateral breast to obtain symmetry, as well as liposuction of the bulging of the epigastrium and the persistent dog ears along the flanks.

The position of the nipple is determined preoperatively with the patient sitting up. No measurements are performed because the nipple sits in relation to the breast itself. The most accurate and effective way to determine the location of the nipple is by visual marking and confirming it

with a digital photograph. Slight asymmetries are easily seen in the picture.

The nipple itself is reconstructed in a TRAM flap by using the adjacent tissue in the form of a flap, the so-called skate flap, which entails elevating a portion of the underlying fat on a superiorly based flap and using the wings from the lateral aspects to wrap the base of the flap (Figs. 16.26 and 16.27). For the areola, tattooing is the method of choice. Occasionally, we tattoo the contralateral areola to obtain satisfactory skin color match. The reconstructed nipple must be planned and made larger than the desired final size because it contracts in the first few months postoperatively. Rarely, if the patient has a very large contralateral nipple, part of the nipple can be used as a free graft to provide adequate size and projection. The use of skin grafts from the medial thigh or any other area of the body to reconstruct the areola has been supplanted with tattooing. The advance in tattooing technology is immense and 3D tattooing has become increasingly common, giving the perception of projection in a 2D image.

Management of Postlumpectomy; Postradiation-Persistent or Recurrent Breast Cancer

Presently, the Multi Center Fischer Study has surpassed 25 years of follow-up. Patients who elected to be treated by lumpectomy and irradiation are now seeking help because of an increasing number of breast cancer recurrences. Though more aggressive local treatment has been found to be associated with lower risk of recurrence, the implementation of conservative breast surgery has inevitably led to an increase in locoregional recurrence as refinements in technique have been undertaken. The treatment for those patients is completion mastectomy. Often those patients elect bilateral mastectomies and immediate reconstruction with autologous tissue. Less often, the reconstruction is done with the latissimus dorsi musculocutaneous flap and an implant. The use of expanders or implants, even with the added attribute of acellular dermis is fraught with complications and is not recommended.

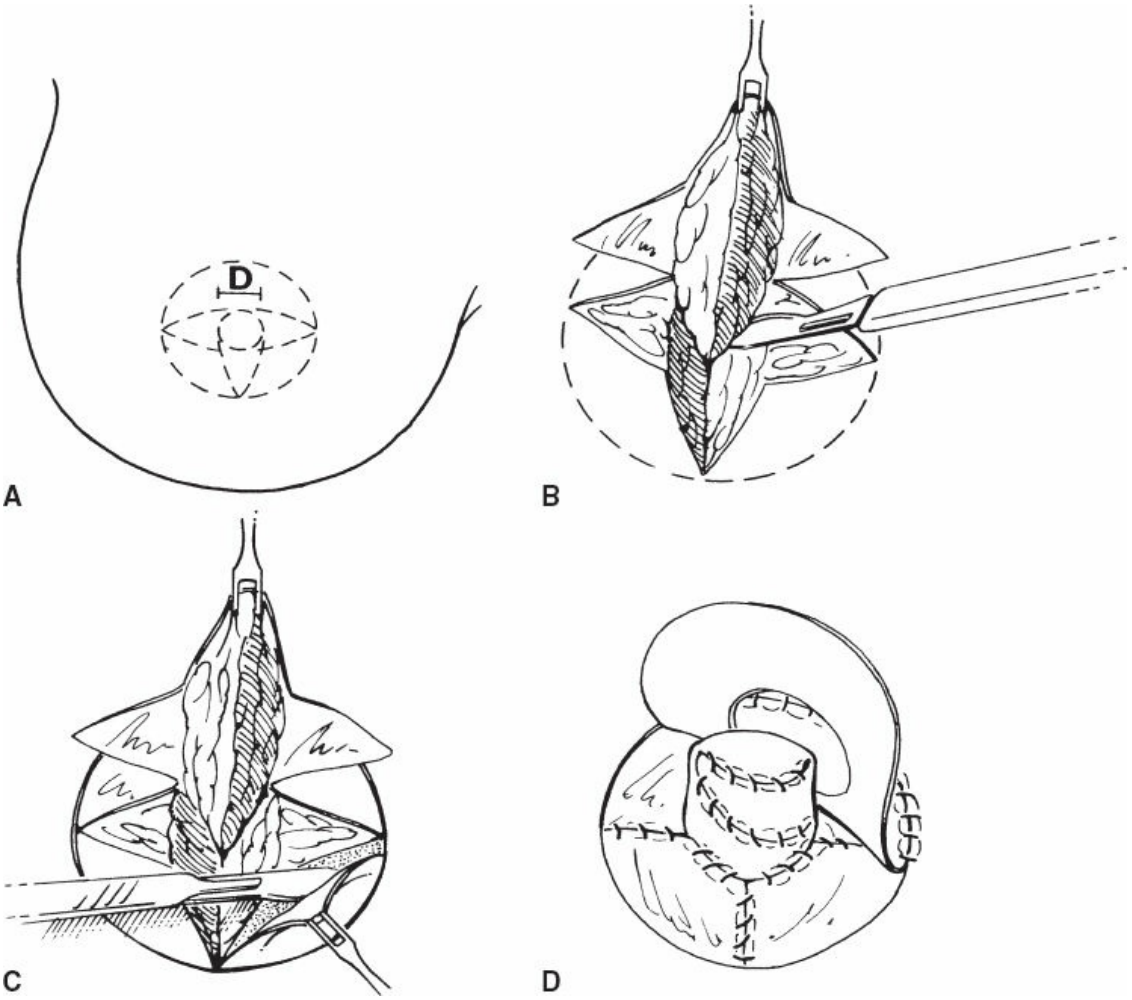

Figure 16.26. **A.** Diagram of modified skate flap on the breast. Flaps extend to the neoareola margin. **B.** Flap elevation is complete, with care taken near the flap base to avoid vascular compromise. **C.** Neoareola is de-epithelialized and grafted. Donor sites may be closed primarily. **D.** Tip of the dermal-fat flap may be de-epithelialized and buried if needed. Closure is complete. Optional areolar grafting is shown. (From Strauch B, Vasconez LO, Hall-Findlay E. *Grabb's Encyclopedia of Flaps.* Philadelphia, PA: JB Lippincott, 1998:1365.)

(From Strauch B, Vasconez LO, Hall-Findlay E. *Grabb's Encyclopedia of Flaps.* Philadelphia, PA: JB Lippincott, 1998:1365.)

Oncoplastic Surgery

The popularity of lumpectomy and irradiation even in the case of larger tumors (over 4 cm) often leaves a significant and unattractive defect in the breast. The so-called oncoplastic techniques have been developed to correct the depression and the asymmetry left by the large removal of breast tissue with the tumor. These maneuvers entail rearrangement of the remaining breast tissue, similar to a breast reduction procedure. It requires considerable knowledge of the anatomy and particularly the blood supply to the breast, to avoid creating worse defects. It is usually accompanied by

a reduction of the opposite breast.

Although such surgical manipulations are possible, and symmetry may be obtained, it does not replace the skin sparing mastectomy and immediate reconstruction in the quality of the appearance of the new breasts, and particularly in diminishing the fear of the patient for a possible cancer recurrence. It should be noted that the recurrence rate following skin sparing mastectomy is between 1.4% and 4%. One drawback of the oncoplastic procedure is the potential need for completion mastectomy in case of positive permanent margins.

While this is of concern, a study published by Losken et al. in 2014 showed that oncoplastic reduction actually decreased the rate of completion mastectomy. The argument with this approach is that more tissue is resected at the time of initial breast cancer treatment, resulting in a more complete margin excision, more frequently, as compares with tumor excision alone. Not only were completion mastectomy rates lower, but re-excision rates were lower as well, suggesting that oncoplastic approaches may convey therapeutic benefits outside of the already superior cosmetic benefits.

Chest Wall Reconstruction

The reconstructive surgeon is presented with thoracic wounds that result from trauma, tumor resection, infection, radiation, and congenital defects. The following principles must be considered: (a) Complete surgical resection and/or debridement. The tumor is completely excised with tumor-free frozen section margins. If dealing with a radiation ulcer, the ulceration as well as the entire surrounding portal of irradiation should be excised, including the underlying ribs if they are affected, leaving only essential or nonirradiated tissue. Infected tissue, whether from empyema, mediastinitis, or necrotic tissue, requires debridement above all, drainage, and appropriate intravenous antibiotics. (b) Obliteration of the intrathoracic dead space. The reconstruction should be performed from the inside to outside. The pleural cavity should first be filled and the intrathoracic organs must be protected. (c) Skeletal stabilization. Paradoxical respiratory motion of the inflated chest must be prevented. Skeletal stabilization is usually required for rib resections of more than four ribs or a defect larger than 5 cm. (d) Soft tissue coverage that is well vascularized, tension-free, and leak-free must be provided.

Bronchopleural Fistulas

Bronchopleural fistulas usually occur following empyema and occasionally following treatment for malignant tumors with irradiation. In most patients with these fistulas, a thoracotomy has been performed; consequently, the use of available muscle flaps such as the latissimus is limited.

Proper treatment requires removal of the fistulous tract, approaching the leaking bronchus in as safe a fashion as possible. The bronchus should be plugged with the use of adjacent muscle. The latissimus dorsi muscle was often divided during the thoracotomy, but there may be portions of the serratus or even the upper portion of the latissimus muscle that can be used to plug the fistula. This still leaves a large cavity or tract. This cavity can be obliterated with the use of the omentum transposed by passing it through the subcostal region based on the right gastroepiploic vessels. The omentum is used to fill in the cavity, the skin edges can be approximated directly (Figs. 16.28 and 16.29). The use of the omentum alone is usually unsatisfactory because it can be blown away with the persistent fistula. It is better to plug it with muscle first, and then additional omentum will provide a second line of defense. Methods for omental transposition will be described later.

Postradiation Ulcerations in the Anterior Chest

Commonly seen in the past with the methods of external irradiation, postradiation ulcerations are much rarer now. Nonetheless, when they occur, the approach follows the principles previously outlined for postradiation ulcers. One should resect not only the ulceration but also all the surrounding tissues that have been irradiated; that is, the entire portal of irradiation. Most often, this also requires the resection of the underlying ribs, which will appear chalky, friable, and devascularized. A formidable defect is thus produced.

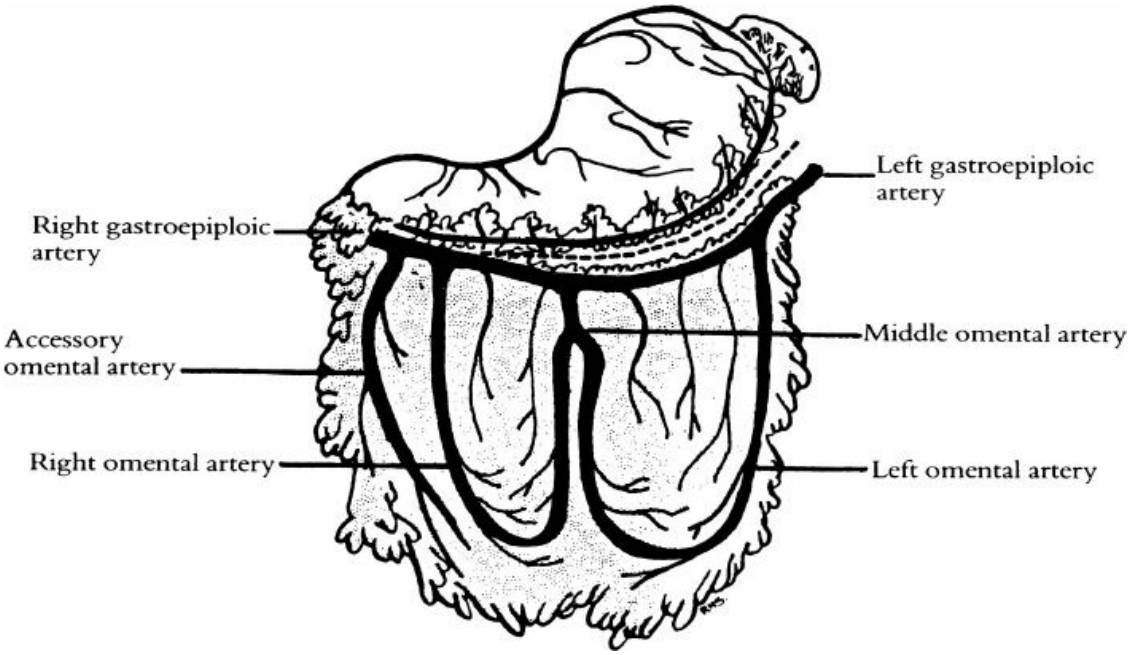

Figure 16.28. Division of the left gastroepiploic artery and detachment of the gastroepiploic arch from the curvature of the stomach. The right gastroepiploic artery is preserved. (From Strauch B, Vasconez LO, Hall-Findlay E. *Grabb's Encyclopedia of Flaps.* Philadelphia, PA: JB Lippincott, 1998:1427.)

For the reconstruction, one must first stabilize the chest wall. To do this, we prefer the use of polypropylene mesh sutured to the ribs, or whatever firm and healthy tissue is found all the way around. We have not found any significant advantage of the newer composite meshes to advocate its use. This mesh is sufficient to provide stabilization of the chest wall and allow for extubation at an early time. Following the placement of the mesh, the omentum is transposed through a midline upper epigastric incision, through the subcutaneous tissue, and over the chest wall. It is preferable not to tunnel the omentum, and to make an incision on the remaining bridge of skin to avoid any undue pressure. The omentum is then spread over the entire wound defect, particularly over the mesh, and stabilized with sutures all the way around; immediately, the meshed split-thickness skin graft is placed over the omentum. By bringing out the omentum in the epigastrium, one would think that a possible hernia site is produced, but this has not occurred because the omentum fills in the defect nicely. We prefer this method to bring the omentum through an opening across the diaphragm and the chest wall.

The advantages of the use of the omentum include the following: (a) A large amount of well-vascularized tissue is available, (b) dissection is

straightforward and reliable, (c) early extubation is possible with the mesh stabilization of the chest wall, and (d) often minimal invasive laparoscopic harvest possible with avoidance of laparotomy. The disadvantages are: (a) the need for laparotomy, if laparoscopy is not an option, (b) improper handling may result in hematomas of the omentum, and (c) herniation of intra-abdominal organs is possible, although unlikely.

Skeletal Stabilization

Skeletal stabilization is required in chest wall resections of more than four ribs and on an area of resection larger than 5 cm to prevent paradoxical motion and inflated chest (flail chest). Location of the skeletal defect also determines whether skeletal stabilization is necessary. Posterior and superior defects near the scapula do not require skeletal stabilization because of the shielding effect of the scapula. Prosthetic and autogenous materials can be used to replace the rigid chest wall.

Prosthetic Options

Prosthetic materials can be used in uninfected and clearly cleansed wounds. (a) Prolene mesh: polypropylene is a fine-grade mesh that is rigid in two directions and allows fibrovascular ingrowth. This mesh is easily handled, cheap, and readily available. (b) Marlex mesh is presently also being made of polypropylene, and is similar to Prolene. (c) GoreTex is a polytetrafluoroethylene mesh, which does not adhere to the underlying lung. It is moldable and flexible, and adapts well to the chest wall movements. It has superior durability and strength, but unfortunately it is easily infected, in which case it has to be removed. We do not favor the use of GoreTex for most chest wall reconstructions.

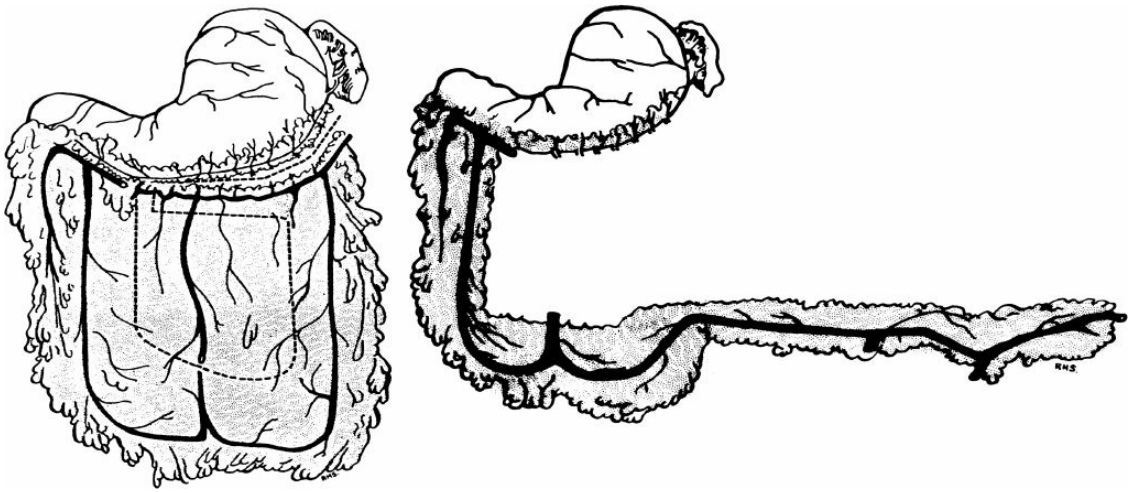

Figure 16.29. Division of the omental arcade along the *dotted*

line converts the omentum into a long vascularized pedicle. (From Strauch B, Vasconez LO, Hall-Findlay E. *Grabb's Encyclopedia of Flaps.* Philadelphia, PA: JB Lippincott, 1998:1427.)

Increasingly, titanium mesh fixation systems are being implemented in place of prosthetic mesh with methyl methacrylate. A recent review by Ng states, "Titanium STRATOS bars and MatrixRIB plates, which have different systems for securing to the chest wall. In general, these new approaches are user friendly, are more ergonomic, and may avoid certain complications associated with the more conventional methods of reconstruction."

Autogenous Options

Split-rib grafts can be used to bridge skeletal defects, but it is not necessary to perform this involved and difficult procedure when simpler procedures are available that are just as effective. If they are used, ribs may resorb with time. They leave a fibrous capsule and are subject to fractures.

It should also be noted that if a latissimus dorsi flap is used occasionally for chest wall coverage and the chest wall defect is relatively small, the muscle itself will be satisfactory to provide skeletal stabilization in a relatively short time, requiring no additional chest wall stabilization.

Fascia Lata Graft

The tensor fascia lata muscle has a long fascial extension that can be harvested in the supine position. An axial incision is made in the lateral thigh beginning approximately 12 to 14 cm below the anterior superior iliac spine. The length of the incision varies, depending on the size of the graft needed. The dissection is carried down to the fascia lata, and skin flaps are elevated medially and laterally. The fascia lata graft can be taken up to 25 to 28 cm in length and 14 to 16 cm in width. The posterior part of the fascia lata is preserved to prevent lateral instability. The graft can be used to cover chest wall defects for skeletal stability. The donor site is then closed with drains.

Advantages

1. Large portion of the fascia lata can be used.
2. Ease of dissection.

3. Minimal functional morbidity.

Disadvantages

1. Graft stretches and becomes flaccid with time.
2. Prosthetic materials are just as effective.

Sternal Wound Reconstruction

Sternal wounds complicating cardiac procedures most often occur in patients who have diabetes, pulmonary disease, and who use steroids. Mediastinitis occurs in 1% to 2.5% of patients who undergo median sternotomy. This represents pooled data, however and is likely representative of overall sternal wound dehiscence, whether sterile or infectious. Fu et al. points out that the rate of sternal wound infection is actually closer to 0.5%, with sterile sternal dehiscence occurring at a rate of 0.9%, for a combined rate of 1.4%, similar to that previously reported in the literature. Regardless, dehiscence is a surgical problem necessitating consultation with a reconstructive surgeon. Risk factors during cardiac surgery include the duration of surgery; excessive bleeding, necessitating reentry; the use of internal mammary arteries, particularly bilaterally; and, most importantly, the length of postoperative intubation. A sudden, otherwise unexplained rise in the blood glucose levels of the patient can be the only sign of a developing septic picture due to sternal wound infection and impending mediastinitis. Sternal wound infections must be treated with adequate debridement of the necrotic tissue, foreign material, blood clots, granulation tissue, and devascularized bone, and exposed cartilage must be removed. Judicious use of antibiotics for infected organisms is necessary. Sometimes, if one is not certain of the debridement or there is a considerable amount of purulence, the wound must be left open, with dressing changes and topical antibacterials prior to a second debridement and definitive coverage.

Temporary coverage utilizing a negative pressure vacuum device system (“wound vac”) between debridements and until final coverage can be considered. Once the wound is clean, coverage is usually possible with the use of the pectoralis advancement musculocutaneous flaps, omental flap, or both. The rectus abdominis muscle is used less often, particularly if the internal mammary artery has been used for revascularization of the heart.

It should be noted that we used to believe that obliteration of the dead

space with larger swaths of tissue was essential for the management of mediastinal wounds, but this is no longer true; the potential dead space is rapidly obliterated with pectoralis myocutaneous flaps and the use of suction.

Flap Options

Pectoralis Major Muscle Flap

When using a pectoralis major muscle flap the mediastinal wound is debrided, resecting the remnants of the sternum on both sides. If the costal cartilages are exposed, they must be removed, particularly if they are devoid of perichondrium; otherwise, they are likely to result in draining fistulous tracts. Following debridement, a myocutaneous flap of pectoralis major muscle is elevated (Fig. 16.30). One divides the origin of the pectoralis major muscle from the lateral aspect of the sternum on both sides and bluntly undermines toward the anterior axillary line and the clavicle. It is not necessary to divide the insertion of the pectoralis major muscle from the clavicle or acromion. Once this mobilization has been obtained, the muscles are sutured with permanent sutures in the midline and over drains, and the overlying subcutaneous tissue and skin are also closed. If the mediastinal wound extends inferiorly, where the pectoralis major muscle cannot cover it, it is possible to free up the origin of the rectus abdominis muscle from the costal cartilages bilaterally and advance it superiorly and suture it to each other. This is preferable to making the formal transposition of the rectus abdominis muscle based superiorly. We do not favor the use of turnover pectoralis major flaps based on the perforating vessels of the internal mammary artery.

The blood supply to the pectoralis myocutaneous flap is from the thoracoacromial blood vessels. The pectoral or the thoracoacromial branch follows a path marked from the tip of the acromion to the xiphoid and is left undisturbed as one frees it from the chest wall. The pectoralis minor muscle is left in place and undisturbed.

The advantage is the ease of dissection and effectiveness, particularly for the upper two thirds of the mediastinal wounds. The disadvantages are that it will not cover the lower-third of the mediastinum, and hematoma is possible, particularly in patients who have been anticoagulated.

Omentum

In patients who have large mediastinal defects in which both internal mammary arteries have been used and the sternum is chalky and necrotic,

and particularly in patients with heart transplants, the omentum is an ideal and most satisfactory method for reconstruction.

The omentum is a large flap, providing 25 × 35 cm of vascularized tissue. It can be used as a pedicle or even as a free flap to fill pleural defects, chest wall wounds, and sternal wounds. It is usually folded as an apron based on the right gastroepiploic vessels, but occasionally, if additional length is needed, it can be based on either one of the gastroepiploic vessels. Selective omental division can be performed to lengthen the omentum. The right gastroepiploic vessel is usually the dominant blood supply. Omentum can be harvested as a pedicle flap by tunneling through the upper end of the midline incision, which is used to dissect the omentum.

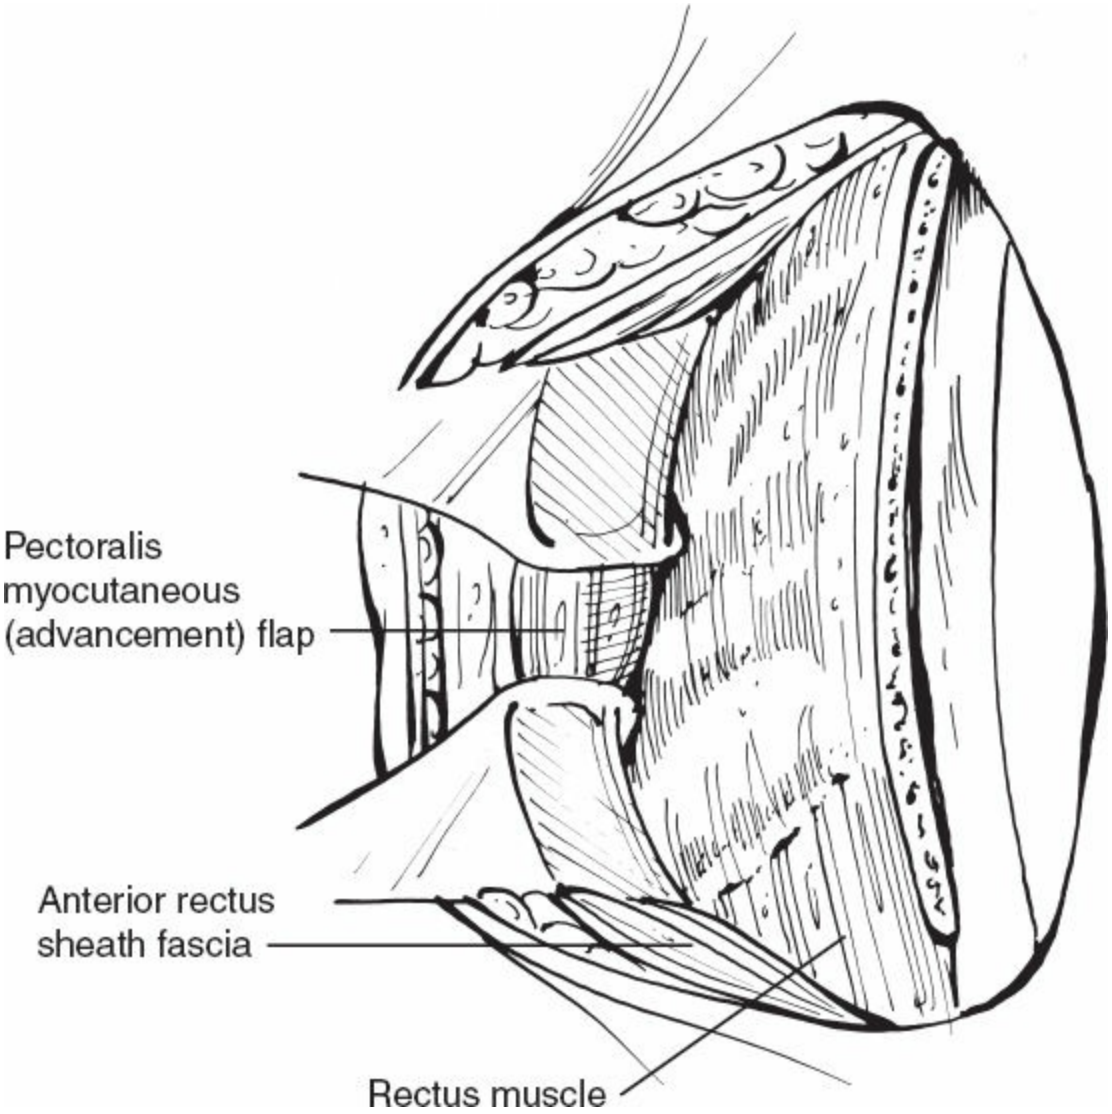

Figure 16.30. The pectoralis muscle and the overlying skin are elevated as a unit. Often, the insertion of the pectoralis muscle

over the humerus is left intact. (Modified from Ascherman JA, Patel SM, Malhotra SM, et al. Management of sternal wounds with bilateral pectoralis major myocutaneous advancement flaps in 114 consecutively treated patients: refinements in technique and outcomes analysis. *Plast Reconstr Surg* 2004;114:678, with permission.)

Technique

The omentum is exposed through a midline laparotomy incision or visualized via minimal invasive laparoscopic approach. It is placed on traction, and separated from its vascular attachments to the transverse colon. The short vessels between the gastroepiploic system and the stomach may be individually clamped and ligated as far as the antrum and duodenum. The right and left gastroepiploic vessels are alternately uprooted to determine the competency of the blood supply. The right gastroepiploic vessel is usually the more pulsatile and larger of the two, and thus the left gastroepiploic vessels may be sacrificed. Depending on the location of the defect, the omental flap can be lengthened by selective omental division. A tunnel is created in the subcutaneous space for passage of the omental flap through the upper midline laparotomy incision. In case of a minimal invasive laparoscopic approach a small opening in the epigastric area is created for the pull through. Care should be taken not to twist the pedicle. Tacking sutures can be placed from the omentum to the exit wound to help secure the flap, although this is usually unnecessary. We prefer exiting the omentum through the upper laparotomy midline incision in case of an open approach, rather than through the diaphragm or a separate incision, which may create more problems. The advantage is that a large flap is created. The disadvantage is that it requires an intra-abdominal operation with subsequent abdominal pain, which may compromise respiratory function.

Postradiation Posterior Neck and Upper Dorsal Wound Reconstruction

Neurosurgical wounds in the lower cervical or upper dorsal spinal cord may have been treated by surgery followed by irradiation. The wounds do not heal because of the radiation, and present a challenging problem to the reconstructive surgeon. For wounds in the occiput, down to the level of the midscapula, the trapezius myocutaneous flap is useful and effective.

Flap Options—Trapezius

The trapezius myocutaneous flap is nourished from the transverse cervical artery, and its minor blood supply comes from branches of the occipital vessels, dorsal scapular vessels, and posterior intercostal vessels (Fig. 16.31). The muscle measures 34 × 18 cm in most patients. A myocutaneous paddle-like flap is outlined at the border of the defect and extends beyond it. It is elevated with the underlying muscle and extends it superiorly by dividing the muscle at the posterior neck, but preserving the transverse cervical artery. The flap is then transposed to cover the defect or rotated to cover the occiput and the upper cervical spine. Care must be used to elevate the skin and/or muscle flap, preserving the underlying latissimus dorsi and rhomboid muscles but dividing the fibers of insertion to the scapula as needed.

Abdomen Reconstruction

The abdominal wall plays multiple functional roles. Its various muscles are arranged in a complex fashion. The muscle fibers are arranged vertically, obliquely, and transversely. These muscles are important in maintaining posture, standing, ambulation, bending, and lifting objects. The abdominal wall also protects the internal organs and regulates the intra-abdominal pressure to assist in defecation, urination, coughing, and vomiting.

There are multiple layers of the abdominal wall; these include skin, Camper and Scarpa fascia, oblique and transverses muscles and their aponeuroses, two recti muscles, preperitoneal fat, and peritoneum. The muscles of the anterior abdomen are the external oblique, internal oblique, transversus abdominis, rectus abdominis, and pyramidalis.

Abdominal wall defects may involve a deficiency of skin, fascia, or both. The most frequent causes of defects include trauma, tumor resection, infection, incisional hernia, congenital anomalies, and radiation therapy. Acute traumatic wounds require multiple stages for abdominal wound closure. These injuries require extensive debridement as abdominal organs are frequently injured. It is best to avoid closure of acute injuries by elevation of local soft tissue flaps. This will open new tissue planes that may spread infection; it also increases operative times. Therefore, in the acute setting of loss of abdominal wall the best operative choice is to apply a trauma dressing a split-thickness skin graft.

Infectious processes involving the abdomen are of special note. Necrotizing fasciitis requires wide surgical debridement of all involved

fascia and overlying skin and subcutaneous tissue. Clostridial myonecrosis involves all layers of the abdominal wall, and therefore requires full-thickness resection. This is a mixed anaerobic and aerobic infection involving at least one *Clostridium* species. These organisms produce a number of exotoxins including lecithinase, collagenase, and hyaluronidase, which allow the infective process to penetrate all layers of the abdominal wall. These infections require prompt diagnosis, intravenous antibiotics, and wide surgical debridement.

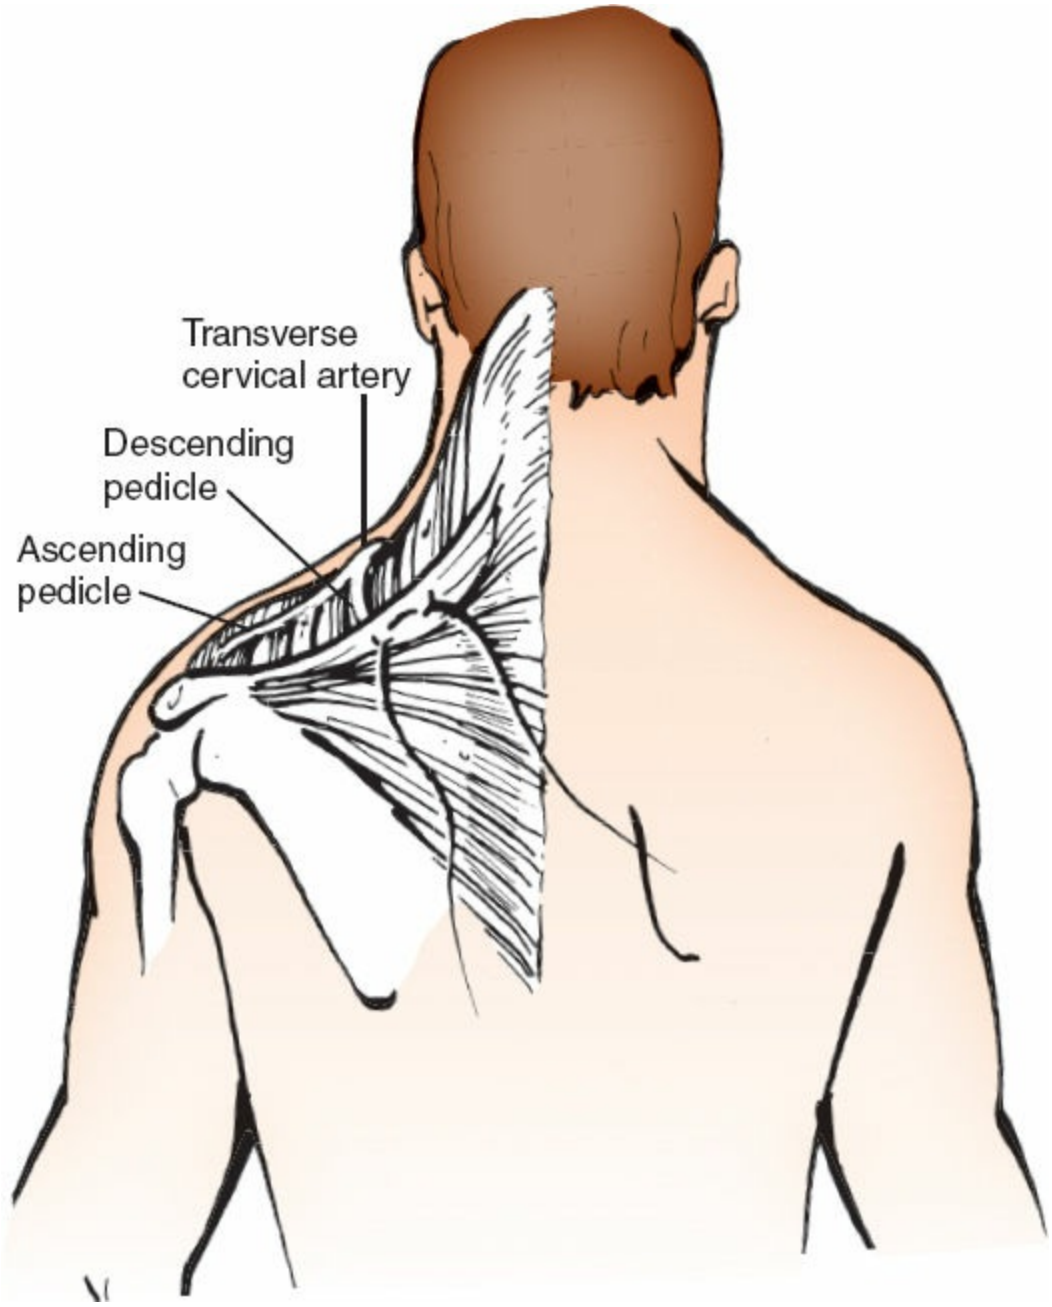

Figure 16.31. Diagrammatic demonstration of the trapezius muscle and its vascular supply from the transverse cervical

artery.

The reconstructive options for abdominal wall reconstruction are varied. Prosthetic materials are used for abdominal wall support. When massive abdominal trauma is present, skin grafts may be required. These are then removed when the wound is stable and the hernia is to be reconstructed. Local flaps such as the external oblique and rectus abdominis muscle may be used with care to avoid creating a larger defect. Regional flaps such as the tensor fascia lata and rectus femoris are also options. Distant flaps include the omentum, latissimus dorsi, and free flaps.

Direct approximation of fascial defects is possible in a good number of cases. In 1990, Ramirez described the components separation technique to allow for closure of large defects (Fig. 16.32). This technique separates the rectus abdominis from the posterior sheath and the external oblique muscle from the internal oblique muscle. Therefore, a composite flap of rectus muscle, anterior sheath, and attached internal oblique and transversus abdominis muscle is advanced toward the midline. Closure of epigastric defects of 6 cm, midabdominal defects of 12 cm and lower abdominal wall defects of 10 cm can be achieved, especially if implemented with a posterior rectus approach, which allows for additional onlay mesh graft. This posterior rectus component separation with rectus abdominis release affords recurrence rates around 5% at 2 year follow-up and allows for durable reconstruction of complex ventral hernias. A simpler technique would be to perform an external oblique flap. To accomplish this, the external oblique fascia is incised along its lateral aspect. The linea alba is then approximated.

Flap Options—Rectus Femoris Fasciocutaneous and Musculocutaneous Flap

Although the tensor fascia lata flap was advocated for autologous reconstruction of abdominal wall defects because of its versatility and distal fascial extension, it now has been supplanted by the rectus femoris fasciocutaneous or musculocutaneous flap (Figs. 16.33 and 16.34). This is because of the latter flap's shorter arc of rotation, higher reach, and the increasing versatility in that one can move the fasciocutaneous unit separately from the rectus femoris muscle. The tensor fascia lata, on the other hand, has to pivot on a wider arc of rotation to reach the abdomen. In addition, the distal third of the tensor lata flap is somewhat unreliable,

making it impossible to reach defects past the midline (Fig. 16.35).

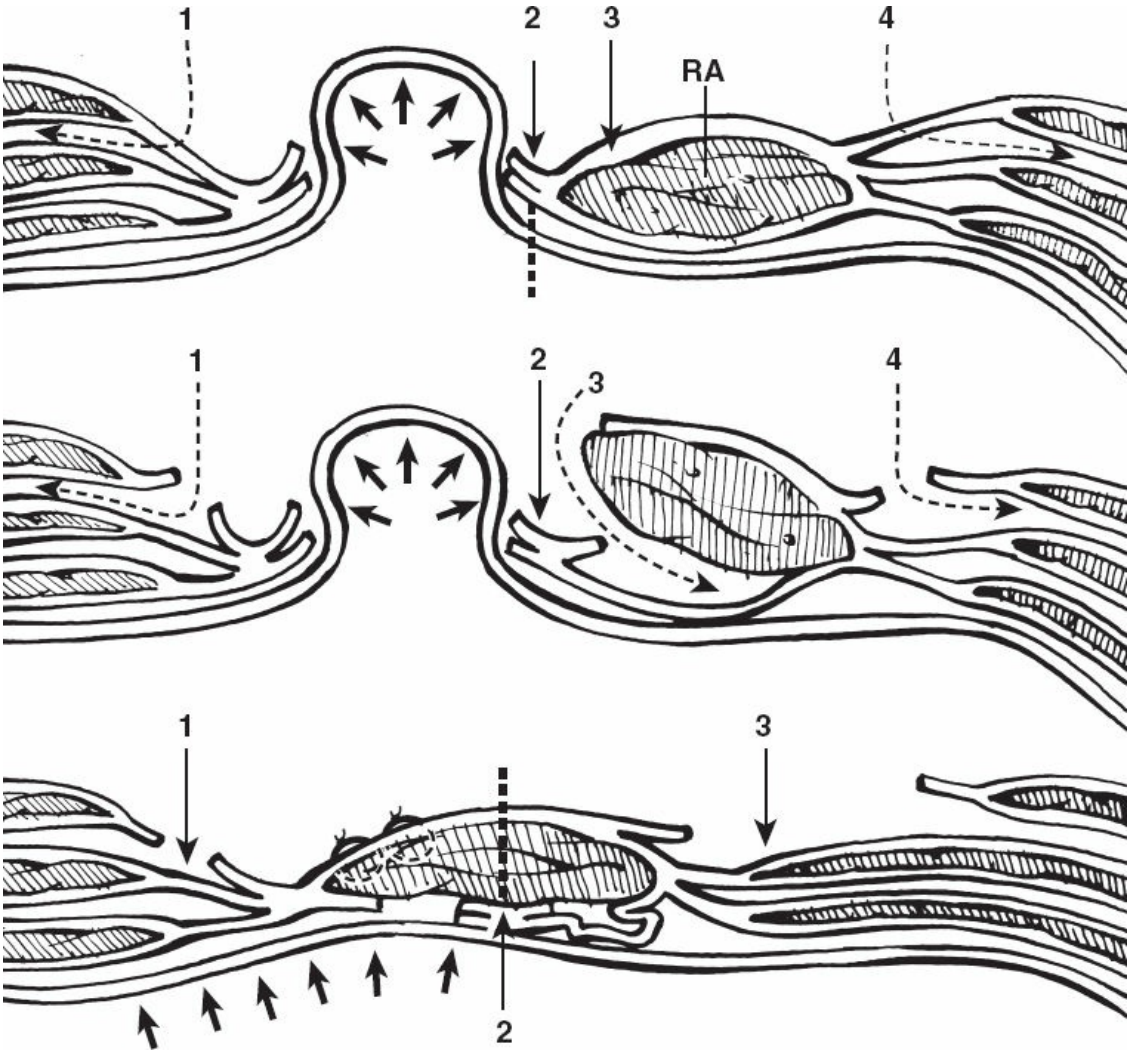

Figure 16.32. Components separation for closure of abdominal wall defects. RA, rectus abdominus (Modified from Ramirez OM, Ruas E, Dellon AL. "Components separation" method for closure of abdominal wall defects: an anatomic and clinical study. *Plast Reconstr Surg* 1990;86:519, with permission.)

The rectus femoris muscle originates from the anterior iliac spine and inserts into the complex of the quadriceps extensor tendon. Dividing its insertion does not interfere with full extension of the knee if the remaining quadriceps tendon is reapproximated with sutures. Its blood supply is from the lateral circumflex femoral artery that enters at its proximal third and has a perforator branch that emerges through the muscle at approximately the same level to supply the overlying skin and fascial unit. As long as one preserves this vascular supply, it is possible to use the two components separately for reconstructive purposes. The rectus femoris muscle can be

harvested alone for lower abdominal defects or for coverage for defects along the groin. If additional skin and fascial coverage is needed, the overlying fasciocutaneous unit can also be elevated, sometimes with a wider extension at the fascial level. The fasciocutaneous unit can also be used to cover defects in the groin, whether because of trauma or following large excisions of carcinomas of the vulva or for postradiation ulcerations in the groin following groin dissections. The use of both rectus femoris musculocutaneous flaps as four separate units allows reconstruction of the entire abdominal wall, and although results are arguably satisfactory, these units have been used to reconstruct the prune belly type of defect of the abdomen. There is an increasing popularity in the use of acellular or biologic meshes for reconstruction of the abdominal wall or in the repair of large incisional herniae. The mesh is used either as an inlay or an overlay type of coverage. No clear advantages have been demonstrated, and the disadvantages include fluid collection, low antigenicity, stretching of the mesh, as well as the possibility for the biologic mesh to serve as culture medium. This fact, however, remains controversial. A recent study of the retrorectus approach to incisional hernia repair compared demonstrated no statistical significance in complication or recurrence rates between synthetic and biologic mesh reconstructions.

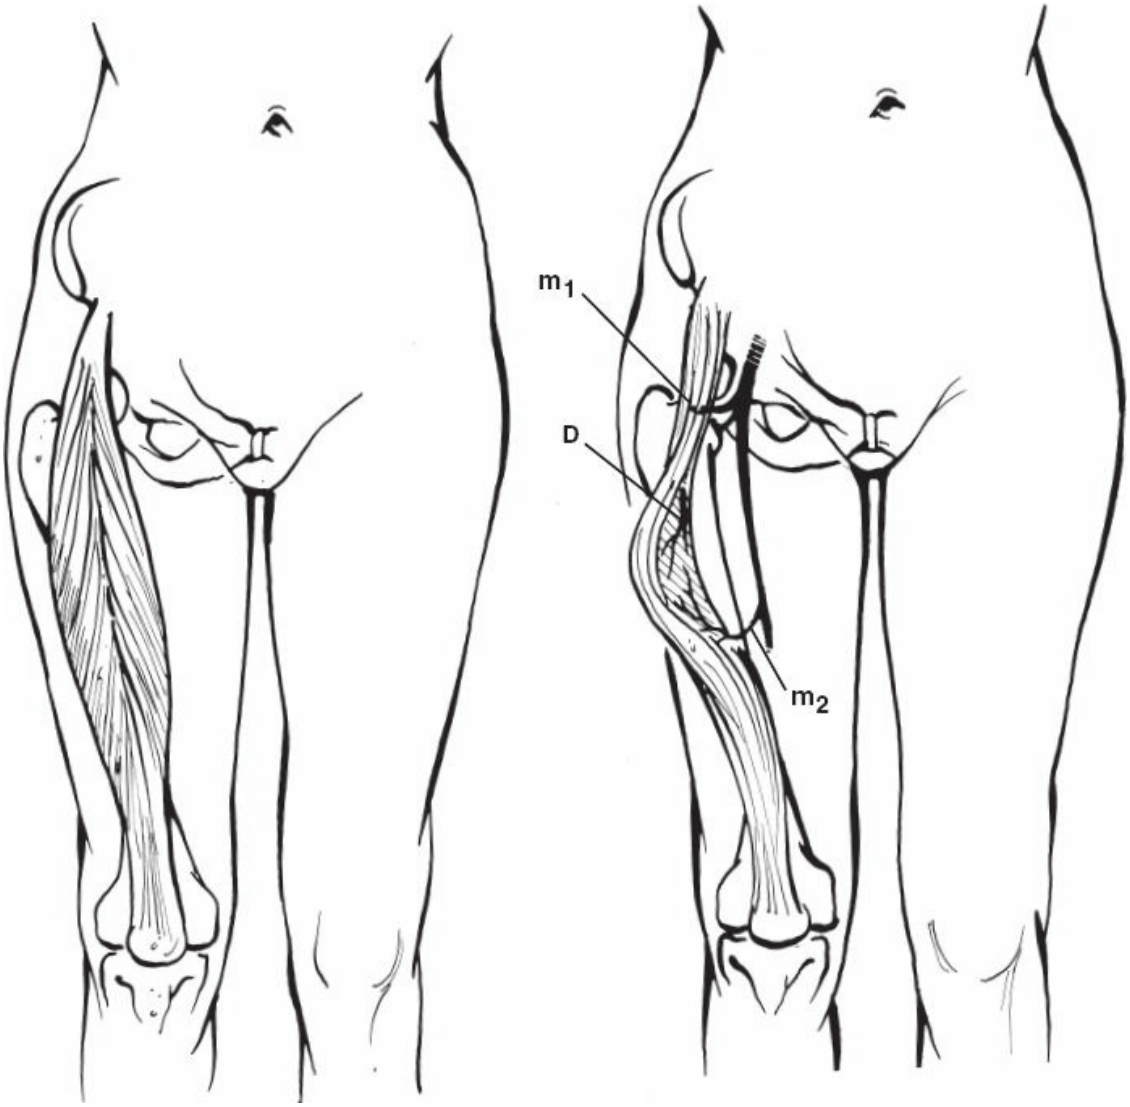

Figure 16.33. The rectus femoris fasciocutaneous and musculocutaneous flaps for abdominal reconstruction. M1 is a secondary pedicle from the trunk of the transverse and ascending lateral circumflex femoral artery. M2 is a distal secondary pedicle from the superficial femoral artery. D is the main pedicle for the rectus femoris muscle, the descending branch of the lateral circumflex femoral artery. (Modified from Mathes S, Nahai F. *Reconstructive Surgery: Principles, Anatomy, and Technique.* New York: Churchill Livingstone, 1997:1234. Copyright © 1997 Elsevier.)

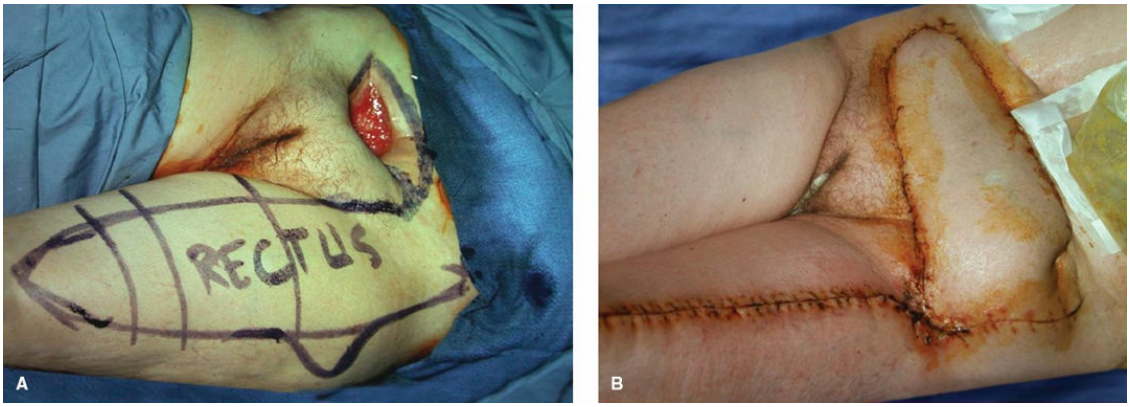

Figure 16.34. A, B. Postradiation defect in the suprapubic region. It is best covered with the rectus femoris myocutaneous flap.

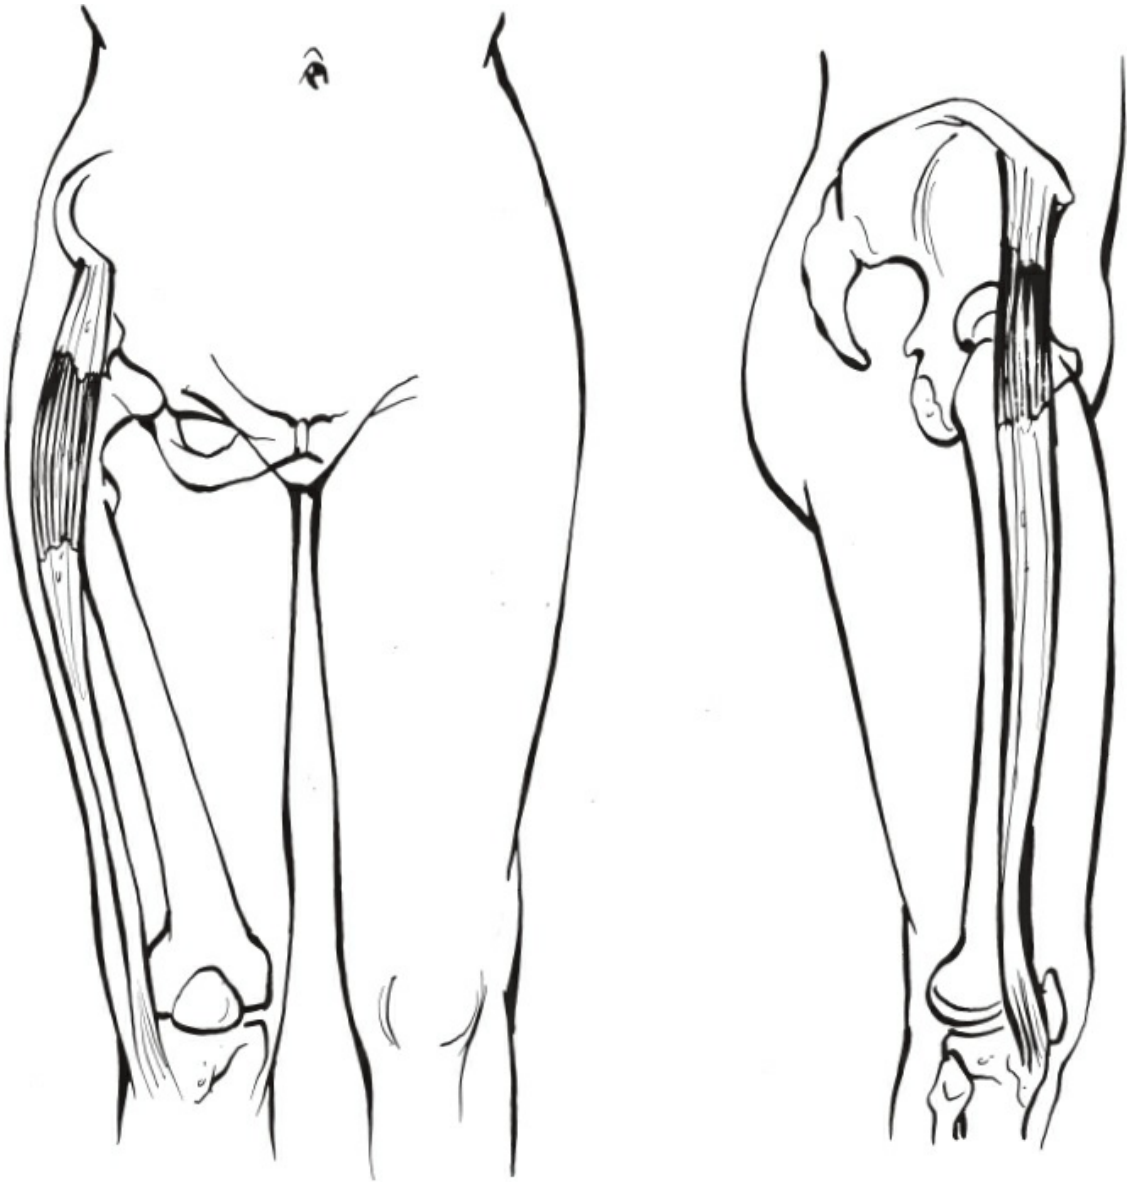

Figure 16.35. The tensor fascia lata flap. (Modified from Mathes S, Nahai F. *Reconstructive Surgery: Principles, Anatomy, and*

Technique. New York: Churchill Livingstone, 1997:1272. Copyright © 1997 Elsevier.)

Advantages

1. Predictable vascular pedicle.
2. A large cutaneous component can be elevated separately from the underlying muscle.
3. Wide arc of rotation, shorter to cover the groin and the abdominal wall.
4. May be used for full-thickness abdominal wall defects in the lower abdomen.

Disadvantages

1. Potential for functional weakness during knee extension and hip flexion
2. Visible and unsightly donor site when a large cutaneous component is required
3. Generally limited to lower abdominal wall reconstruction

Perineal Wound Reconstruction

Abdominal perineal resections for rectal carcinoma or inflammatory bowel disease were initially treated openly, producing large defects requiring open packing and long-term dressing changes. Fortunately, they have been supplanted by the reintroduction of primary closure with closed suction drainage, resulting in an improved quality of life, shorter hospital stay, and decreased perineal pain.

Nonetheless, the present treatment of persistent and/or recurrent carcinoma of the anus, which requires chemotherapy and radiation, does present challenging problems for reconstruction following excision of these perineal cancers.

The treatment of choice for these large perineal wounds is the use of the bilateral gluteus maximus myocutaneous flaps. Previous experience with the use of gracilis flaps was only partly successful. The use of the rectus abdominis muscle is effective in reaching the perineum and closing those wounds, but requires that the muscle be introduced intra-abdominally through an opening in the intra-abdominal cavity.

Flap Options

Bilateral Gluteus Maximus Musculocutaneous Flap

The lithotomy position is often used for the resection of postradiation persistent and/or recurrent carcinoma of the anus and the rectum. The large defect that is thus created necessitates the advancement of the musculocutaneous units from the gluteus maximus region to obliterate the dead space approximating the muscles and the skin in the midline (Figs. 16.36 to 16.38).

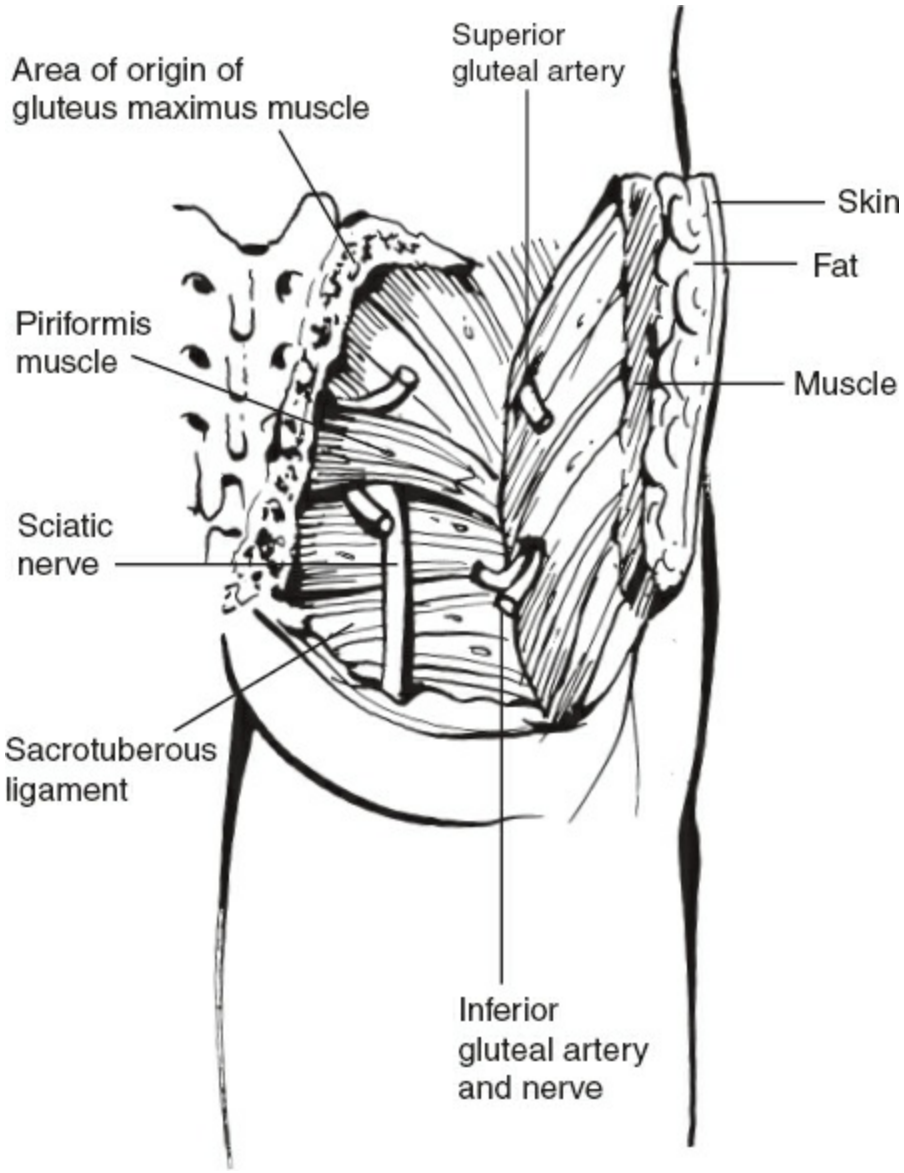

Figure 16.36. The dissection is difficult and bloody, as one needs to disinsert (divide) the origin of the muscle from the sacrum. Once it is disinserted on both sides, it can be approximated to each other to cover defects over the perineum. (Modified from Ramirez OM, Orlando JC, Hurwitz DJ. The sliding gluteus maximus myocutaneous flap: its relevance in ambulatory patients. *Plast Reconstr Surg* 1984;74:68, with permission.)

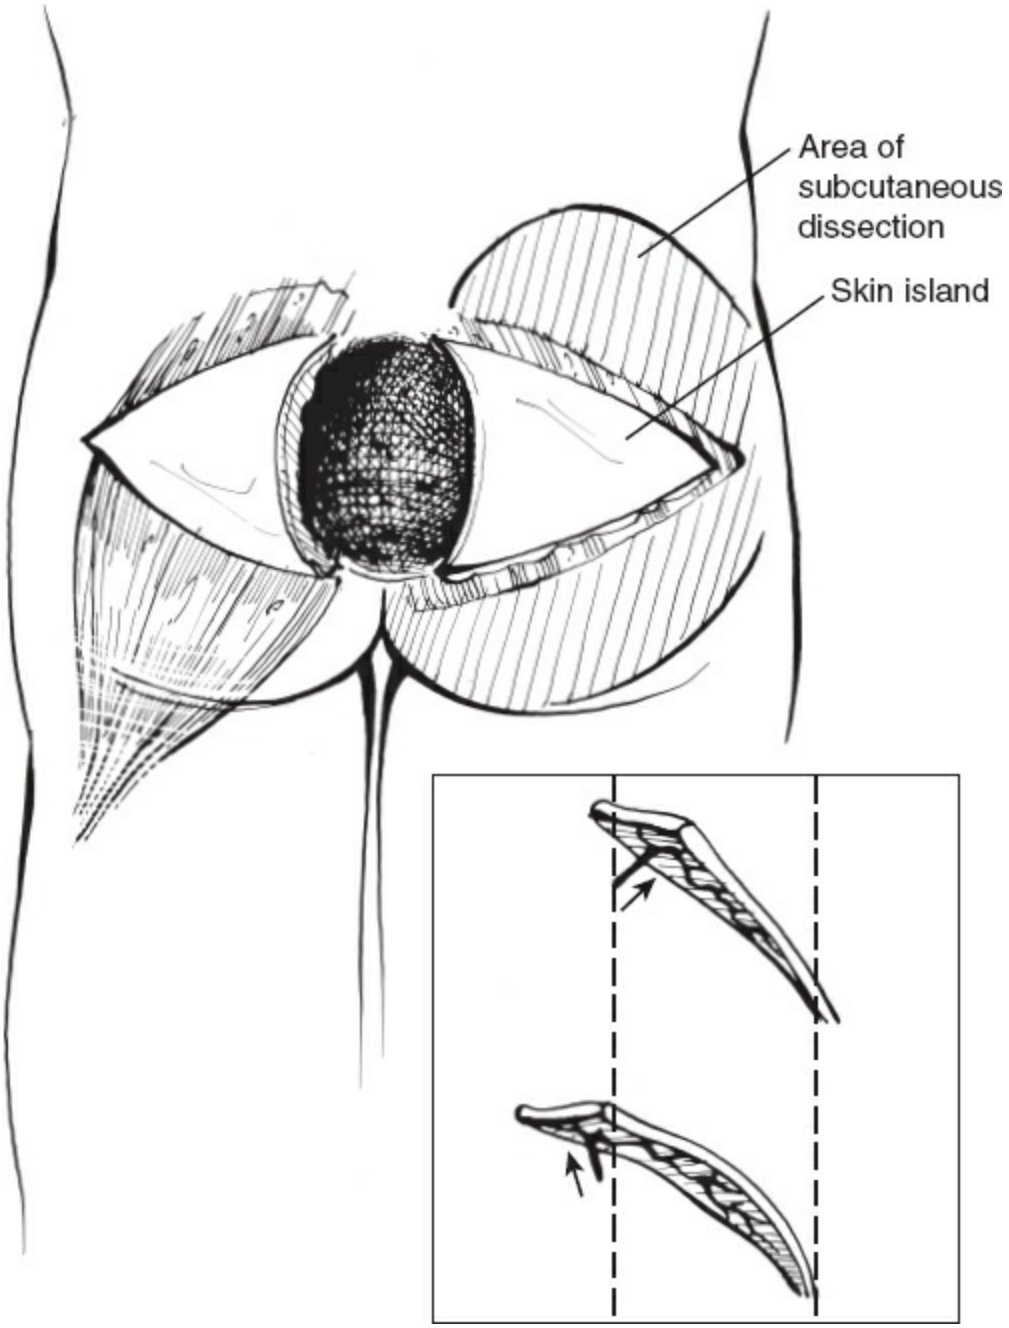

Figure 16.37. Ambulatory patients are also good candidates for the procedure. They will need help, temporarily, in ambulation and particularly climbing stairs. (Modified from Ramirez OM, Orlando JC, Hurwitz DJ. The sliding gluteus maximus myocutaneous flap: its relevance in ambulatory patients. *Plast Reconstr Surg* 1984;74:68, with permission.)

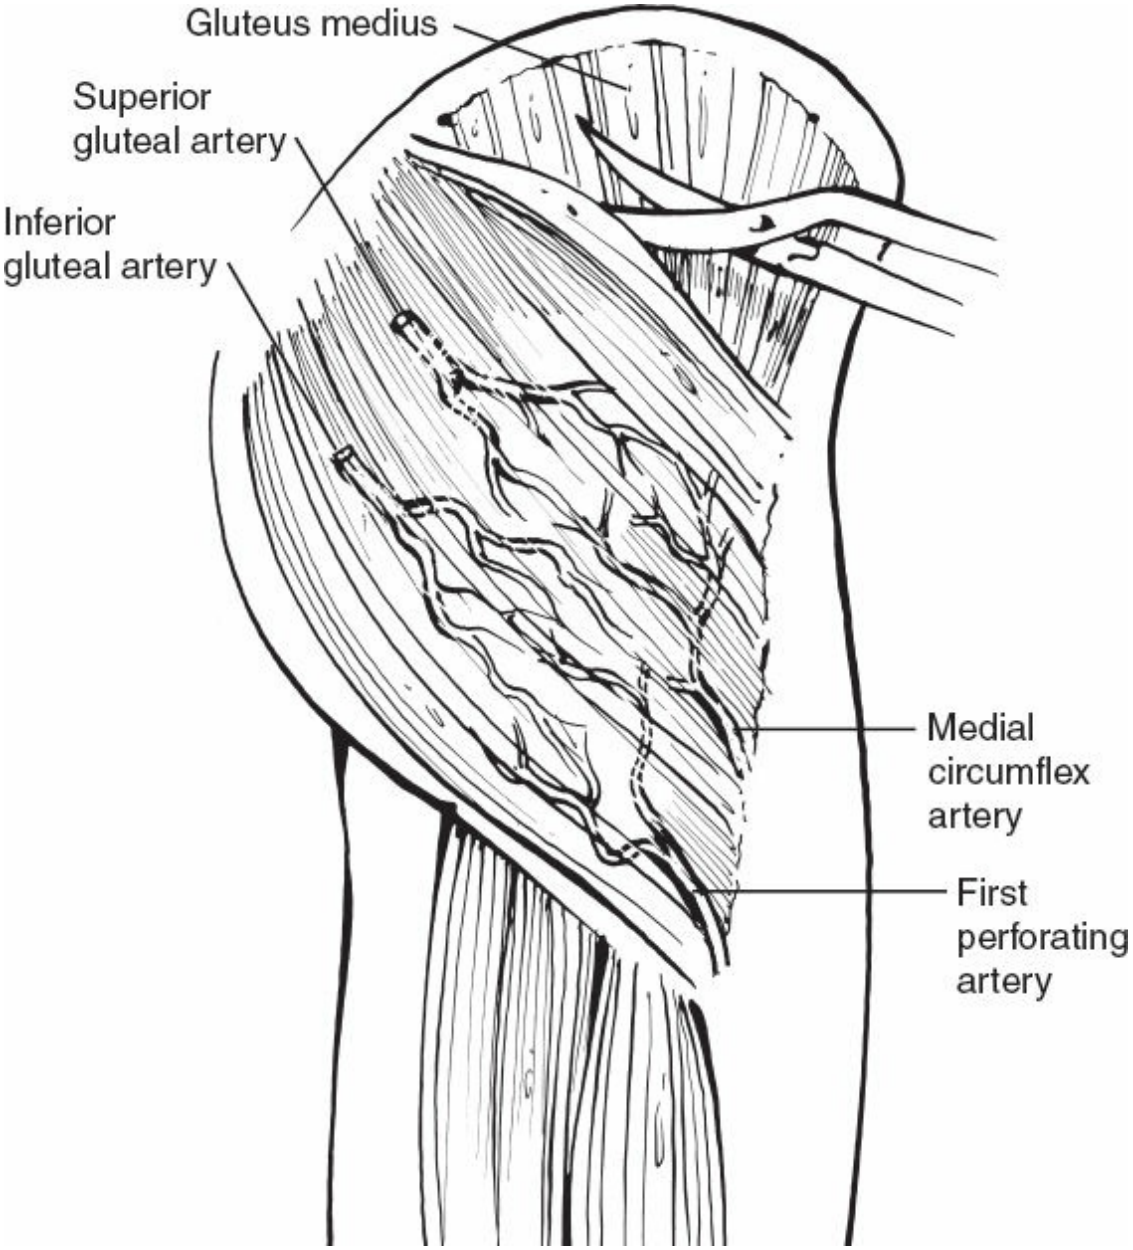

Figure 16.38. Diagrammatic demonstration of the vascular supply to the gluteus maximus. (Modified from Ramirez OM, Orlando JC, Hurwitz DJ. The sliding gluteus maximus myocutaneous flap: its relevance in ambulatory patients. *Plast Reconstr Surg* 1984;4:68, with permission.)

The patient must be changed to the prone position with the legs abducted. The posterior iliac spine as well as the greater trochanters is noted. Bilateral skin islands in the form of triangles are outlined below the iliac crest and with the apex toward the trochanter and the base, along the medial defect on each side of the perineum. The skin island is incised and skin flaps are elevated superiorly and inferiorly to expose the upper and lower portion of the gluteus maximus on each side. The gluteus maximus

is then freed up by careful dissection from the sacrum. This is a bloody dissection because one has to divide a number of the sacral vessels, but once this is accomplished, a blunt dissection is continued with the finger to identify the superior and the inferior gluteal arteries. The inferior gluteal artery is a key, in that the sciatic nerve is inferior and lateral to it and should be protected. With the gluteus maximus freed up medially, one can then incise the upper portion of the gluteus maximus down to the medius superiorly and inferiorly, as much as is necessary to advance it to the midline. This is done bilaterally. Once the mobilization has been accomplished, the muscles are sutured in the midline to each other over drains (Fig. 16.39). The overlying skin is also approximated by a VY maneuver, which is straightforward and easy.

Advantages

1. Healthy muscle and overlying skin is sufficient to obliterate the perineal defect.
2. Different from what was previously believed, the procedure can be done in ambulatory patients without any dysfunction.

Disadvantages

1. The patient needs to be repositioned on the operating table.
2. The dissection is bloody and somewhat difficult, particularly as the gluteus maximus is freed up from the sacrum.
3. There is a possibility of injury to the bladder as well as to the sciatic nerve, although both are rare.

Gluteus Maximus to Reconstruct Anal Sphincter

Particularly in children with Hirschsprung disease, who have weak or absent anal sphincters, a local procedure using portions of the gluteus maximus are effective and synergistic (Fig. 16.40). The anus is circumscribed and a linear incision is extended over the gluteus maximus on each side. A segment of the gluteus maximus, ~2 cm wide and 10 cm long, is removed and freed from the gluteus medius. Each segment of muscle is then turned around and extends circles ~270 degrees, with the anus on each side forming a figure-of-eight type of arrangement. Each end is sutured with sufficient tension so that when the muscle contracts, the anus is obliterated. The secondary defects are closed directly. This is the most effective and synergistic muscle for anal sphincter control.

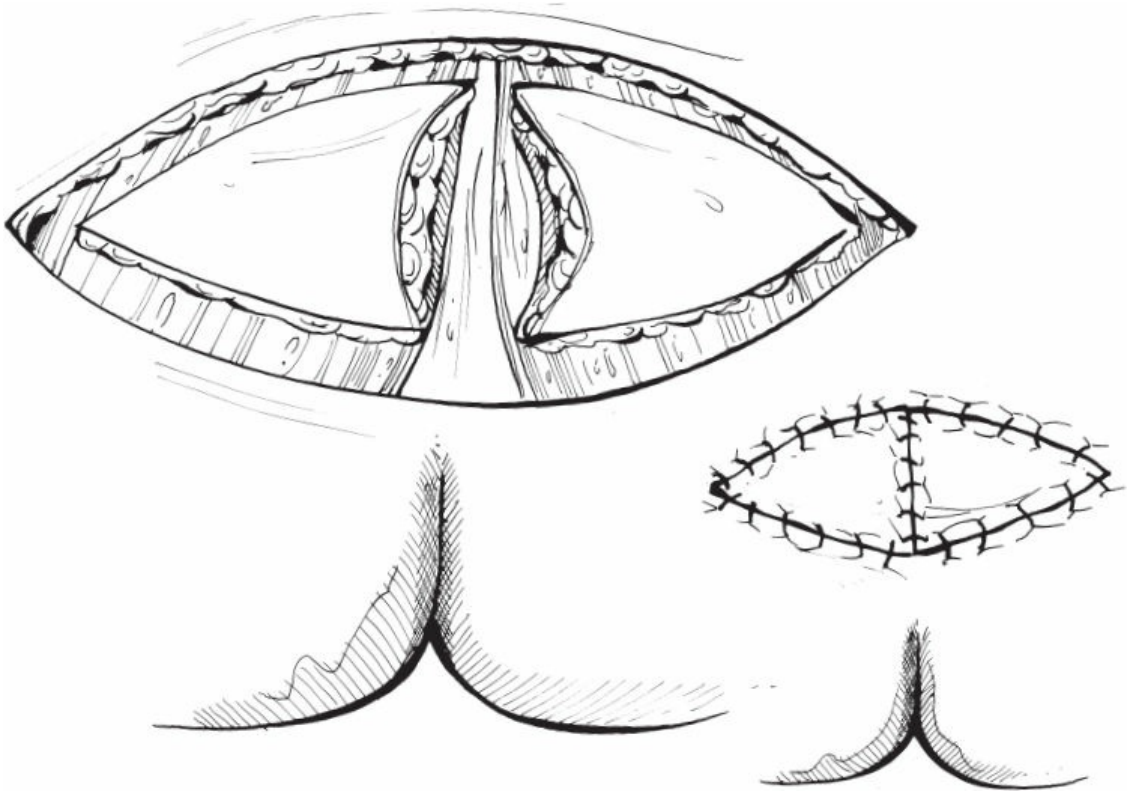

Figure 16.39. Freed up bilaterally, the muscle units can be approximated in the midline, and the skin islands can be moved in a V-Y manner. (Modified from Ramirez OM, Orlando JC, Hurwitz DJ. The sliding gluteus maximus myocutaneous flap: its relevance in ambulatory patients. *Plast Reconstr Surg* 1984;4:68, with permission.)

Advantages

1. The gluteus maximus is synergistic, and the patient can learn a voluntary control of the anal sphincter.
2. The muscle is located in the same operative field.

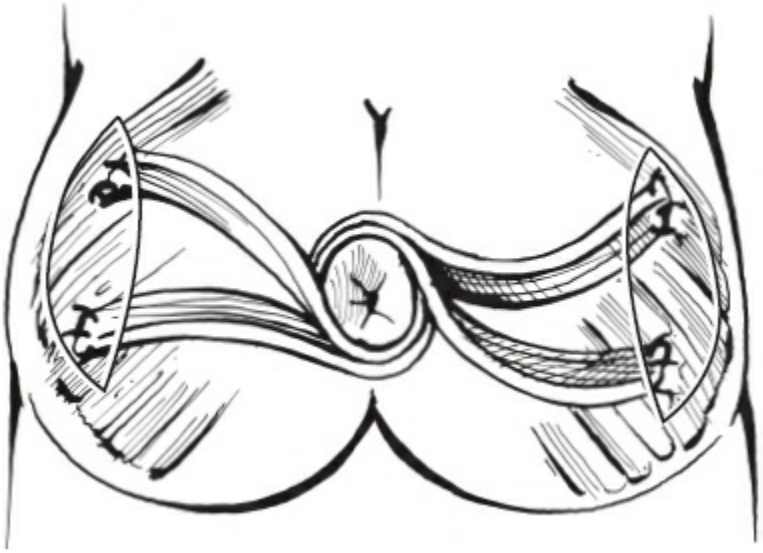

Figure 16.40. Portions of the gluteus maximus are taken from both sides. They are crossed in a figure-eight fashion to allow them to simulate a sphincter as they contract.

Disadvantages

1. Proper tension must be obtained for an effective sphincter control.
2. The dissection is bloody at times.

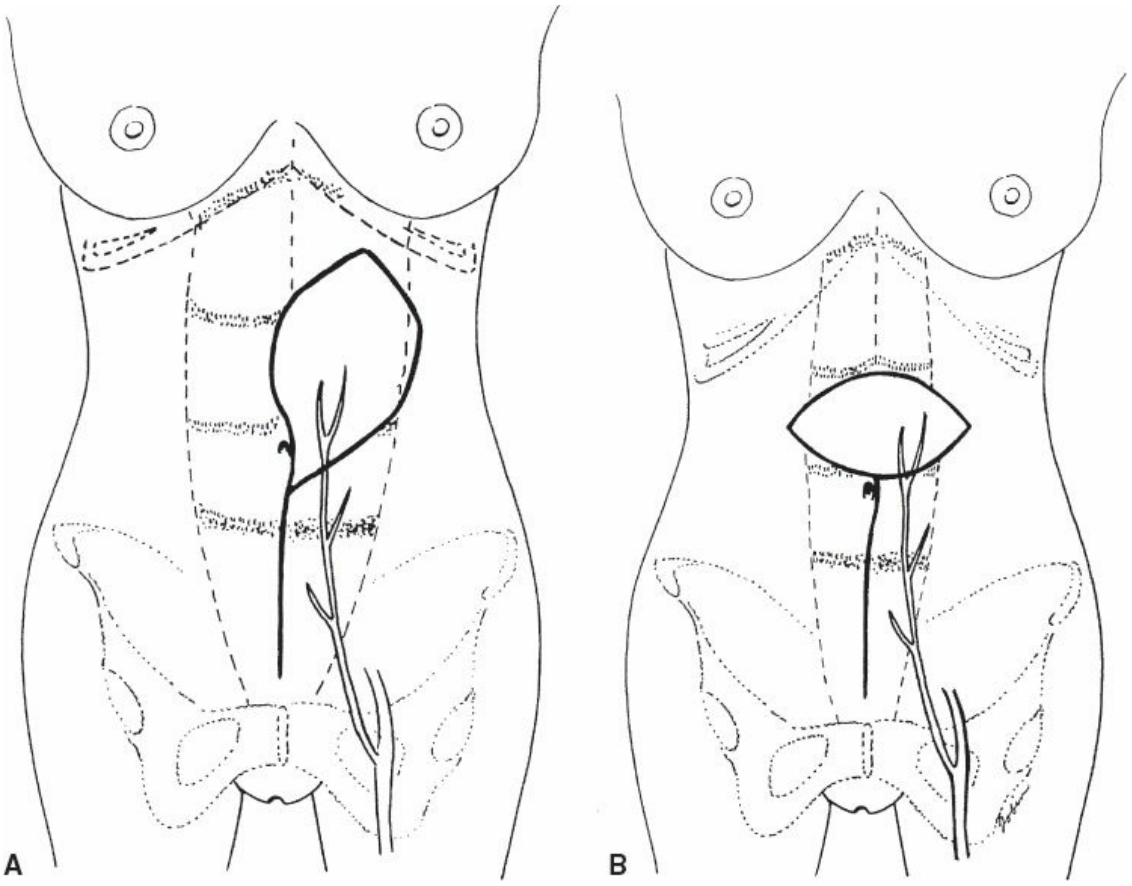

Figure 16.41. Cutaneous paddle design of rectus abdominis flaps for reconstruction showing the relationship of the paddle to the muscle, vascular pedicle, laparotomy incision, and surface landmarks. **A.** Diagram of the most frequently used design, with a vertical paddle axis aligned with the muscle. **B.** Diagram of the transverse paddle, which can be used to lessen tissue bulk in the deep pelvis. (Published in Tobin GR, Persell SH, Day TG. Refinements in vaginal reconstruction using rectus abdominis flaps. *Clin Plast Surg* 1990;17(4):705–12. Copyright © 1990 Elsevier.)

Rectus Abdominis Musculocutaneous Flap

If skin and soft tissue are required for perineal coverage to supplement the filling of dead space by the rectus muscle, the rectus muscle with the overlying skin and soft tissues can be mobilized as a unit. A large skin paddle can be used when designed to include multiple musculocutaneous perforators (Fig. 16.41). The greatest density of perforators exists in the periumbilical region and, therefore, it is often included during the flap design. The skin paddle can be oriented on the vertical, oblique, or transverse fashion, depending on the reconstructive necessity. The skin paddle, whether vertically (known as the VRAM flap) or transversely oriented (known as the TRAM flap), is incised right down to the anterior rectus sheath. The musculocutaneous perforators should be maintained intact to supply the overlying skin. A portion of anterior rectus sheath is included with the flap for ~4 cm, which will facilitate the removal of the entire rectus muscle with its superior and inferior extensions. The medial and lateral borders of the rectus muscles are freed up, and then the muscle is also freed up from the posterior rectus sheath. The superior end of the muscle toward the insertion in the costal margin is divided, and the whole unit is introduced intra-abdominally, usually just above the semicircular line. The unit is then grasped through the perineum, and the skin or muscle is used to obliterate the perineal cavity. The secondary defect is closed by approximating the remaining anterior rectus sheath, making sure that one does not leave too large a defect at the point of entrance of the muscle intra-abdominally (Figs. 16.42 and 16.43).

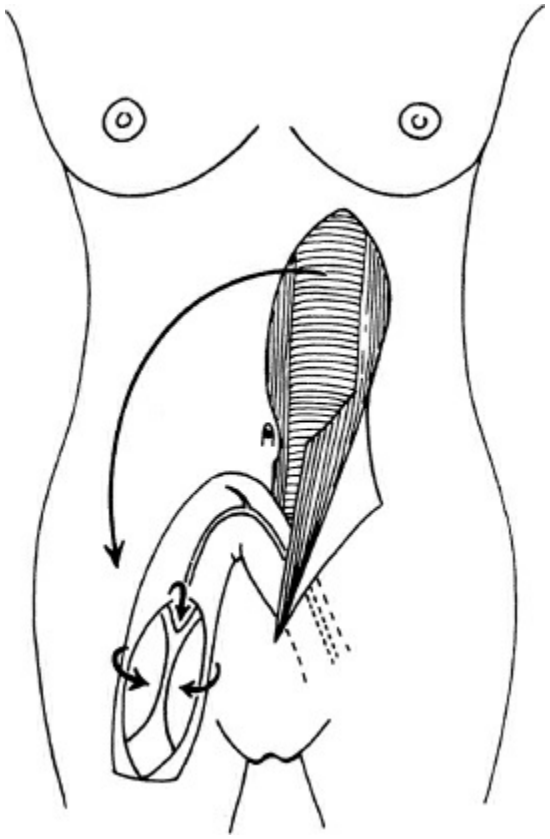

Figure 16.42. Demonstrating steps of the operative procedure. Schema of a vertical flap transposition from the abdominal field to the groin region for formation of the vaginal pouch, which allows simultaneous construction of the urinary conduit and colostomy. (Published in Tobin GR, Persell SH, Day TG. Refinements in vaginal reconstruction using rectus abdominis flaps. *Clin Plast Surg* 1990;17(4):705–12. Copyright © 1990 Elsevier.)

Advantages

1. No change in position of the patient is needed if the abdominal perineal resection was done in the lithotomy position.
2. Large amounts of muscle and skin are easily obtained.

Disadvantages

1. A site of intra-abdominal entrance is necessary for the musculocutaneous unit.
2. A bulge remains in the suprapubic region.

Gracilis Muscle and Musculocutaneous Flaps

The gracilis muscle and musculocutaneous flaps are presently used for reconstruction of the vagina following the rare pelvic exenterations and also for coverage of defects along the ischium. Its use is disappointing in

obliterating defects following abdominal perineal resections or following large excisions for Crohn disease.

The gracilis is the most superficial muscle of the adductor group of the medial side of the thigh. It is a long strap-like muscle with motor innervation arising from the anterior branch of the obturator nerve. It serves to adduct the thigh and to flex and medially rotate the leg. It has an aponeurotic origin from the body and inferior ramus of the pubis, and inserts into the medial surface of the tibia between the sartorius and the semitendinosus muscles. It lies posterior to the adductor longus and anterior to the semimembranosus muscles and superficial to the adductor magnus muscle. Its superficial surface is covered by the deep fascia of the thigh.

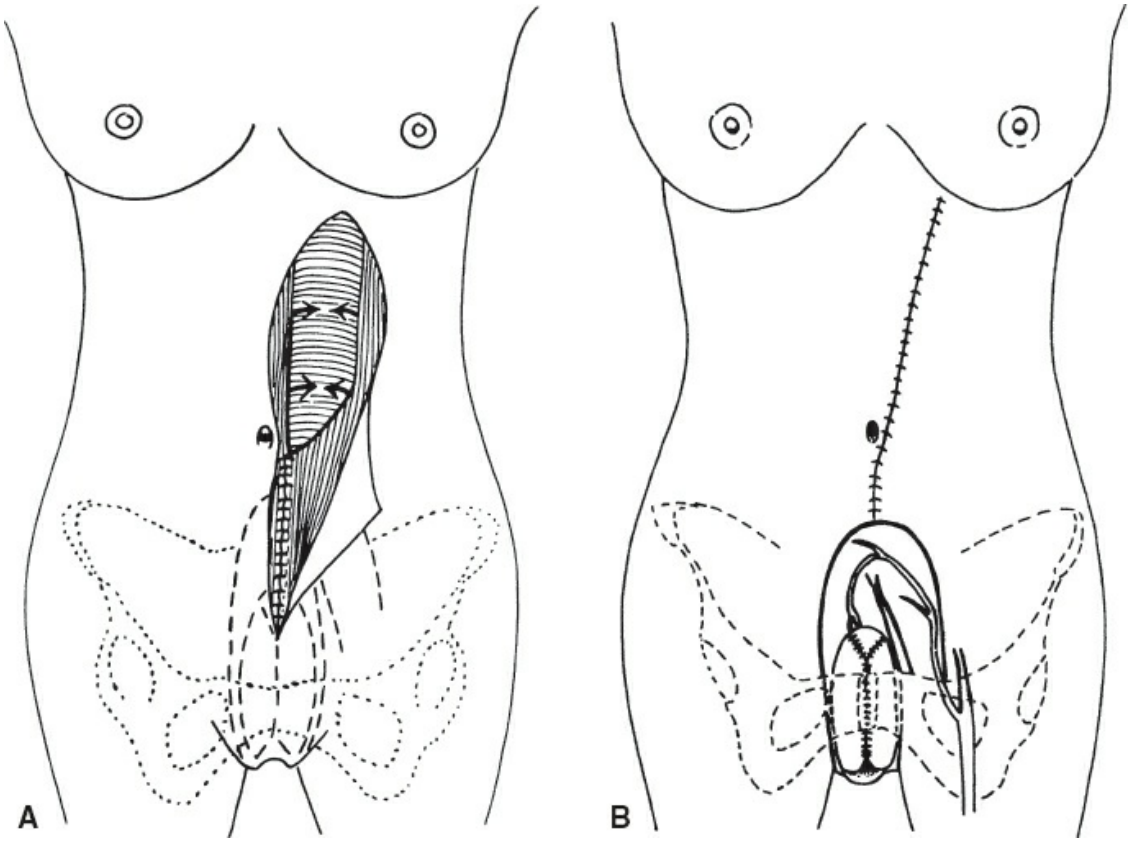

Figure 16.43. Closure of the donor defect after inset of neovagina and stomas. **A.** Diagram illustrating direct closure of the anterior rectus fascia donor site above the umbilicus (*arrows*) and abdominal wall closure below the umbilicus by suture of the anterior rectus fascia to the linea alba. **B.** Direct closure of the cutaneous donor site in continuity with the laparotomy. (Published in Tobin GR, Persell SH, Day TG. Refinements in vaginal reconstruction using rectus abdominis flaps. *Clin Plast Surg* 1990;17(4):705–12. Copyright © 1990 Elsevier.)

Advantages

1. Relative proximity to the perineum
2. An expendable muscle providing a minimal donor deformity with minimal functional loss
3. Relative inconspicuous incision on the inner thigh

Disadvantages

1. Unreliable distal cutaneous territory
2. Most limited arc of rotation of the pedicle, which does not reach the depth of a perineal wound
3. Relatively narrow muscle belly

Puborectalis Fasciocutaneous Flap for Vaginal Reconstruction (Wei Flap)

For vaginal reconstruction in patients who have not undergone radiation, a simple and effective method has been described by Wei. Two fasciocutaneous flaps inferiorly based on the pudendal arteries are elevated on each side of the labia majora. The flaps are made into an island, if necessary, as long as one maintains its proximal blood supply. They are sutured to each other to form a tube and introduced into the vagina in a relatively straightforward fashion. The secondary defect is closed primarily (Fig. 16.44).

Advantages

1. Adjacent, well-vascularized flaps that allow an easy dissection
2. Allows for a one-stage procedure

Disadvantages

Not applicable to patients who have undergone radiation to the vulva or perineum.

Shortly after the repair, the patient is free of pain except for the incisional surgical pain. The rehabilitation is done during a period of 3 months, and most patients are able to return to their athletic endeavors.

Singapore Flap

If defects are small or minimal donor site morbidity is desired, a perforator-based flap can be used. The so-called Singapore flap is based on one of the many perforators arising from the pudendal artery in the line just posterior to the medial groin crease. Additionally, this captures

innervation to this area, making this an excellent sensate reconstructive option. The flap can measure approximately 15 × 6 cm and can be paired with the contralateral side. The flap is raised in an anterior to posterior fashion, incising down through the skin and subcutaneous tissue, but remaining suprafascial. This is elevated until an island is developed about the perforator. One should take care in this posterior elevation, as large veins are sometimes encountered and should be preserved whenever possible. This island can then be elevated, rotated 90 degrees, and tunneled for posterior defects or transposed anteriorly, as in the Wei flap, for anterior introitus defects. The defect is closed primarily behind the flap.

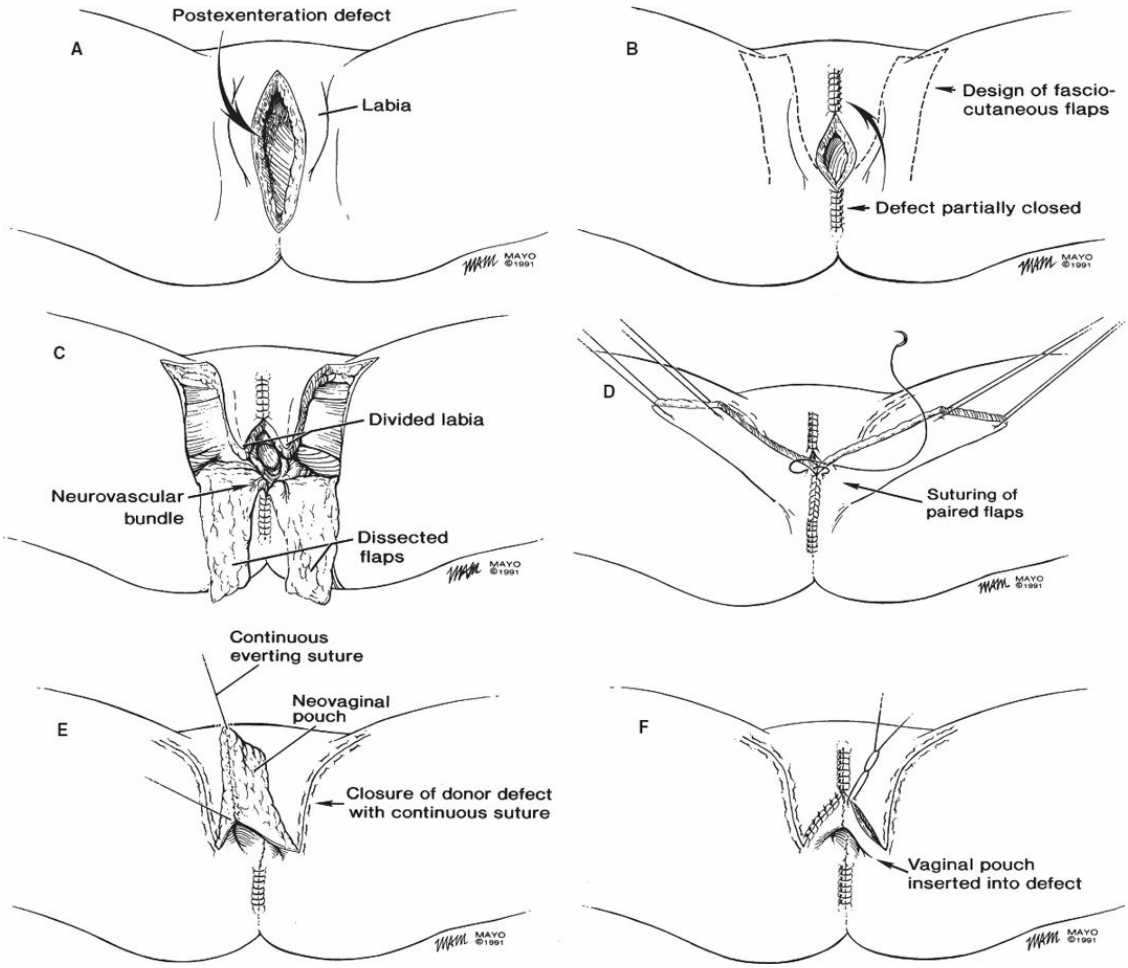

Figure 16.44. Diagrammatic representation of vaginal reconstruction using the modified Singapore flap. **A.** Exenteration defect prior to reconstruction. **B.** Partial suturing of defect with 6 × 15 cm flaps straddling the inguinal crease. **C.** Flaps elevated at the subfascial level, with division of the labia posteriorly, to allow easy insetting of the neovagina without incision of the skin at the base of the flaps. **D.** Initial suturing of the flaps is carried out to even the flap edges into the neovagina, avoiding burial of the

dermis. **E.** The completed pouch prior to insetting. Note preliminary closure of the donor defects. **F.** Nearly completed suturing of neovagina after insetting. (From Woods JE, Alter G, Meland B, et al. Experience with vaginal reconstruction utilizing the modified Singapore flap. *Plast Reconstr Surg* 1992;90:280, with permission. Modified from Strauch B, Vasconez LO, Hall-Findlay E. *Grabb's Encyclopedia of Flaps.* Philadelphia, PA: JB Lippincott, 1998:1477.)

Advantages

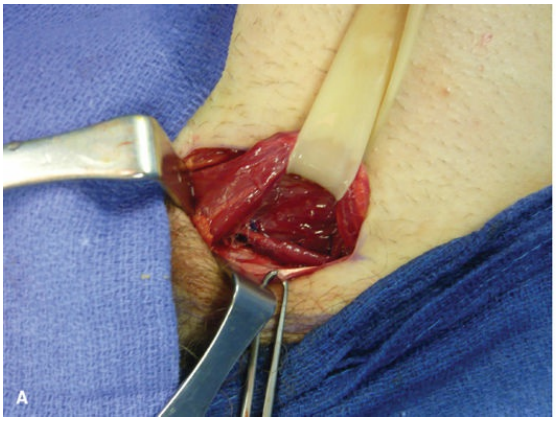
1. Minimal donor site morbidity
2. Reliable vasculature that is "perforator-rich."
3. Sensate flap

Disadvantages

1. No muscle coverage, which some may prefer for coverage of irradiated fields
2. Comparatively small
3. Nonaxial blood supply which may become kinked or pinched when tunneled

Internal Oblique Muscle Flap for Athletic Pubalgia

A clinical entity that is probably more common than previously diagnosed is the so-called athletic pubalgia, more commonly known as "sports hernia." Although the pathophysiology is not clear, it appears that this represents a partial rupture of portions of the rectus abdominis muscle as they insert into the pubic tubercle. The patient presents with pain over the pubis and this is exacerbated by forced abduction of the involved thigh. More often than not, radiographs and magnetic resonance images are interpreted as normal, and are not diagnostic.



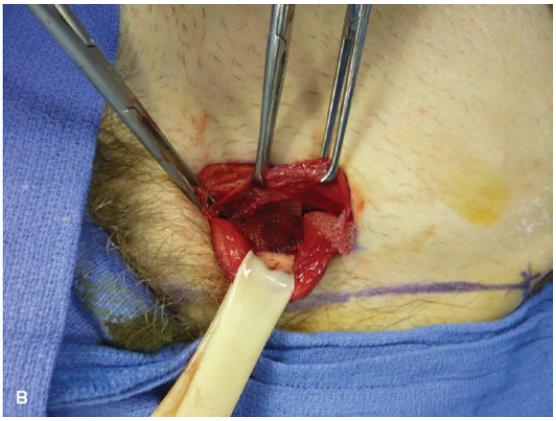


Figure 16.45. **A.** The internal oblique muscle is exposed and then retracted to visualize the origin of the rectus abdominis muscle from the pubis. The Penrose drain is retracting the cord structures. **B.** The mesh is placed in the properitoneal space and deep to the origin of the rectus muscle, prior to advancing the internal oblique to cover the mesh.

Its treatment is straightforward once the proper diagnosis has been made. General surgeons often see patients with this entity because they are referred for the possibility of an inguinal hernia, but when none is found, they are rejected for surgery, even though the patient continues with incapacitating pain, particularly if the patient is an athlete.

The approach for its correction is simple and effective. Access is gained through an incision similar to that used in an inguinal hernia repair. In a male patient, the spermatic cord is isolated and efforts are made to check for an indirect inguinal hernia even if it was not present clinically. As one dissects the floor of the inguinal region, one notices a weakness in that area but no direct hernia. The repair consists in placing a piece of mesh to strengthen the pelvic floor and, over the polypropylene mesh, the conjoined tendon, which is a junction of the internal and transverse abdominis muscle, is approximated to the inguinal ligament. The wound is then closed similar to a hernia repair (Fig. 16.45).

EDITOR'S COMMENT

Plastic surgery and its ability to restore individuals not only to function, but also to psychologically function is one of the marvels of surgery over the past 30 or 40 years. We are indeed privileged to have Dr. Luis Vasconez as the senior author of this important chapter. This chapter demonstrates how far reconstruction has continued to come with the essence of being the restoration

of function, both psychologically and physically and functionally. The main advance over the last decade has been the increasing indications for flap reconstruction and the wider applicability to our patient population.

Professor Vasconez points out the types of difficult wounds that need coverage because of the destruction of tissues around the wounds. These difficult wounds include the following:

- Superficially infected wounds regarding the obvious coverage and the inability to cut out the infection.
- Wounds over bone that do not have periosteum, thereby inhibiting the ability of bone to heal.
- Postradiation wounds, in which all the tissues around the wounds are dead and need transplantation as these were swinging over a flap in order to provide blood supply, muscle, and skin which will survive.

In reconstruction of the face, especially the nose and lips there are four main techniques: skin grafting, tissue rearrangement, nasolabial and forehead flaps and one not really discussed is allowing the defect to heal by secondary intention followed by secondary flap reconstruction. Most such excisions are done for skin cancer and therefore have a clean base and reconstruction can be done immediately. However, in trauma, the main watchword is irrigating and cleaning the wound copiously and if necessary coming back at another time with anything except simple closure at the initial setting. However, one can get away with quite a lot because of the infinite vascularity of the face.

A second difficult area where flaps are needed and perhaps most difficult to perform is when periosteum is denuded from bone in association with crush injuries, most commonly in vehicular collisions. The main goals of treatment after establishing or reestablishing blood are debridement of devitalized tissue and swinging in vascularized tissue. Hyperbaric oxygen can be useful to counteract tissue hypoxia and stimulate wound healing (Chiang IH, Tzeng YS, Chang SC. Is hyperbaric oxygen therapy indispensable for saving mutilated hand injuries? *Int Wound J* 2017. doi: 10.1111/iwj.12730. [Epub ahead of print]) Soft tissue coverage can be obtained with an iliac flap, the adipofascial lateral arm flap, and the gracilis flap as well as corticoperiosteal flaps for the bone defects (Del Piñal F, Urrutia E, Klich M. Severe crush injury to the forearm and hand: The role of microsurgery. *Clin Plast Surg* 2017;44(2):233–55). Restoring functionality to the hand, in particular, may also require digit transfer from foot to hand. Such flaps are also necessary when treating decubitus ulcers where the same principles apply. In addition, diversion of the fecal stream is often necessary to get the wound clean and ready for coverage with a flap.

The third area where flaps can be critical is in prior irradiated fields. This is largely seen in patients who have had a mastectomy and subsequent radiation to the chest wall. Reconstructive options rely on flap reconstruction from a variety of sources most commonly today from deep inferior epigastric perforator

(DIEP) flaps. Healthy vascularized tissue under an irradiated skin can actually revitalize tough leathery skin. Reconstruction with tissue expanders and implants post irradiation never do well or appear normal. Often they can be painful as well. The same cannot be said for tissue expander placed on the chest wall and expanded prior to radiation. This saves the space and skin and then improved reconstruction can be completed with tissue or implant with good cosmetic results (Tanos G, Prousskaia E, Chow W, et al. Locally advanced breast cancer: autologuous versus implant-based reconstruction. *Plast Reconstr Surg Glob Open* 2016;4(2):e622.).

Finally, where flaps are perhaps used the most is in breast reconstruction. Much of the advances with flaps have been made for this purpose. Indications for offering breast reconstruction are broadening. Not offering or delaying reconstruction produces the greatest scar emotionally. Once reconstruction was only be limited to those with stage 0 to IIa but recent studies have shown skin-sparing mastectomy to be safe even with locally advanced breast cancer (Burdge EC, Yuen J, Hardee M, et al. Nipple skin-sparing mastectomy is feasible for advanced disease. *Ann Surg Oncol* 2013;20(10):3294–30; Boneti C, Yuen J, Santiago C, et al. Oncologic safety of nipple skin-sparing or total skin-sparing mastectomies with immediate reconstruction. *J Am Coll Surg* 2011;212(4):686–93; discussion 693–5). Systemic presurgical chemotherapy can be offered to the patients with more aggressive disease who will need radiation, or to those patients who need time to stop smoking. Patients with a recurrence after conservative breast surgery and radiation can also have good results using newer flap dissection techniques. Complication rates are higher in the obese, but some are more than willing to accept this for a chance to look and feel normal. Tissue reconstruction in these patients and the use of their own dermis can lower such complications. In addition, there is no doubt that contralateral prophylactic mastectomy (CPM) is on the rise, increasing from 0.4% in 1998 to 4.7% in 2007 to approximately one third in 2016. Why and whether CPM carries a survival benefit is controversial. Patients often elect CPM out of fear of recurrence or to lessen surveillance. The majority of average-risk women will obtain no oncologic benefit from a CPM with the risk of finding occult disease in a CPM of about 1.8%. Bilateral flap reconstruction can be accomplished with DIEP flaps sparing the abdominal wall musculature or in the slim patient with a combination of flaps and/or implants. An individualized approach is necessary with thorough discussion of the risks and benefits but ultimately is decided by the patient.

There has been amazing progress in reconstructive techniques improving the lives of so many that would be otherwise disfigured or crippled.

V. Suzanne Klimberg

17 Hand Surgery: Traumatic and Infectious Emergencies

Brian A. Mailey and Michael W. Neumeister

INTRODUCTION

Hand injuries and infections represent 20% of all exhibiting visits to emergency departments. The fingers, hand, wrist, and forearm contain a dense amount of anatomic structures that can be challenging to recall for practitioners who infrequently treat this area of the body. This chapter will present a description of high-yield anatomy and the initial management of the most common hand surgery emergencies.

Traumatic injuries often occur from lacerations, avulsions, axial loading, or crush injuries affecting multiple structures. Understanding the anatomy and biomechanics assists in rendering a treatment plan based on a sequential and structured physical examination. The anatomical cutoff for what is covered by the hand surgeon varies by institution; we consider everything distal to the elbow and any nerve injury along the course of the brachial plexus to be included.

HIGH-YIELD HAND, WRIST AND FOREARM ANATOMY

Hand and forearm function is under the control of three peripheral nerves. The radial nerve is primarily responsible for extensor function, while the median and ulnar nerves power wrist and finger flexion and innervate the intrinsic muscles. The median and radial nerves give off an anterior and posterior interosseous nerve branch in the proximal forearm, respectively. These interosseous nerves supply extrinsic motor function proximally and sensation and proprioception to the wrist joint distally. The median nerve and its branches innervate the radial aspect of the volar hand and forearm, which is the part of the hand primarily responsible for fine pincer movements and key pinch. The ulnar nerve innervates the ulnar one and a half digits of the hand and is the part of the hand primarily functioning in heavy lift and carry. This distinction becomes important when evaluating a patient with a mutilating hand injury. Defining the occupation of the

patient can guide the hand surgeon on priorities of salvage. The dorsal aspect of the hand receives its sensory innervation from the superficial branch of the radial nerve and dorsal cutaneous branch of the ulnar nerve on the radial and ulnar aspects, respectively (Fig. 17.1). These nerves supply sensation reliably up to and over the dorsal aspect of the proximal phalanx, but little sensation distal to that, which is received from vertical perforating branches of the respective volar digital nerves. The median and ulnar nerves each have a motor branch distal to the wrist that innervates the intrinsic musculature. The remainder of nerve fascicles supplies the digital sensory nerves for tactile feedback. Each digit has a proper digital nerve located along the midlateral line of the digit approximately the junction between the glabrous and nonglabrous skin.

The muscles of the hand/forearm unit can be classified as extrinsic muscles, which control wrist flexion and power grip and intrinsic muscles, which allow fine motor movement and a chuck grip of large objects (*e.g.*, throwing a baseball and opening a door knob). These unique complex motor tasks are accomplished by the interossei and lumbrical muscles, which permit metacarpophalangeal (MP) flexion with concomitant proximal interphalangeal (PIP) joint extension. Along with the thenar and hypothenar muscle groups (Fig. 17.2), these muscles distinguish many human behaviors from other animals and primates.

The bony skeleton consists of two forearm bones. The ulna is anchored to the humerus and can be thought of as the flagpole with which the radius, carpus, and hand representing the flag are able to rotate around this ulnar axis (Fig. 17.3). Pronation and supination are accomplished by the proximal and distal radioulnar joints (PRUJ and DRUJ, respectively). Flexion and extension of the wrist occur through motion at both the radiocarpal and midcarpal joints; however, their contribution is not equal (sun js, 2000).[1–3] Compensatory motion can occur in one of these joints during conditions limiting motion at the other (*e.g.*, increased midcarpal motion can occur in conditions limiting radiocarpal motion). Radioulnar deviation is thought to occur mostly at the midcarpal joint; however, depending on the lunate articulations (type I: capitate only *vs.* type II: capitate and hamate), the relative motion at each joint can vary.[2] The functional motion of the wrist at which most activities are performed is termed to be the dart-throwers motion (dorsoradial to volar–ulnar deviation).[3] During this motion, there ARE limited radiocarpal or scapholunate movement and it is an important early hand rehabilitation

activity to prevent stiffness.

The wrist comprises eight carpal bones (Fig. 17.4) separated into two rows, termed the proximal and distal carpal rows. The proximal row (scaphoid, lunate, triquetrum, and pisiform) is known as the intercalated segment due its lack of tendinous or muscle insertions. The scaphoid bone, *aka* the navicular bone, has the largest amount of overall motion of all carpal bones. Therefore, it is not surprising that fractures occur in this bone more commonly than all of the others combined (70% of carpal bone fractures). The scaphoid is 80% articular with vascular pedicles entering at the distal tubercle (supplying distal 20%) and along the dorsal ridge (supplying 80% of the scaphoid).[4,5] The proximal pole relies on a retrograde vascular supply and predisposes this bone to nonunion and delayed union.[5] Scaphoid fractures and scapholunate ligament injuries comprise the great majority of carpal bone attention from acute trauma.

In hand injuries, the thumb takes priority in salvage and reconstruction. This digit is considered to possess 40% of overall hand function and resources should be allocated to saving thumb function. Similar to the other digits, thumb movements consist of flexion and extension. However, unlike the other fingers, the thumb can pronate and supinate outside the plane of the hand and abduct in both a radial and palmar direction. During this movement of palmar abduction, the thumb also supinates to meet the other fingers in a pad-to-pad fashion; this motion is known as opposition.

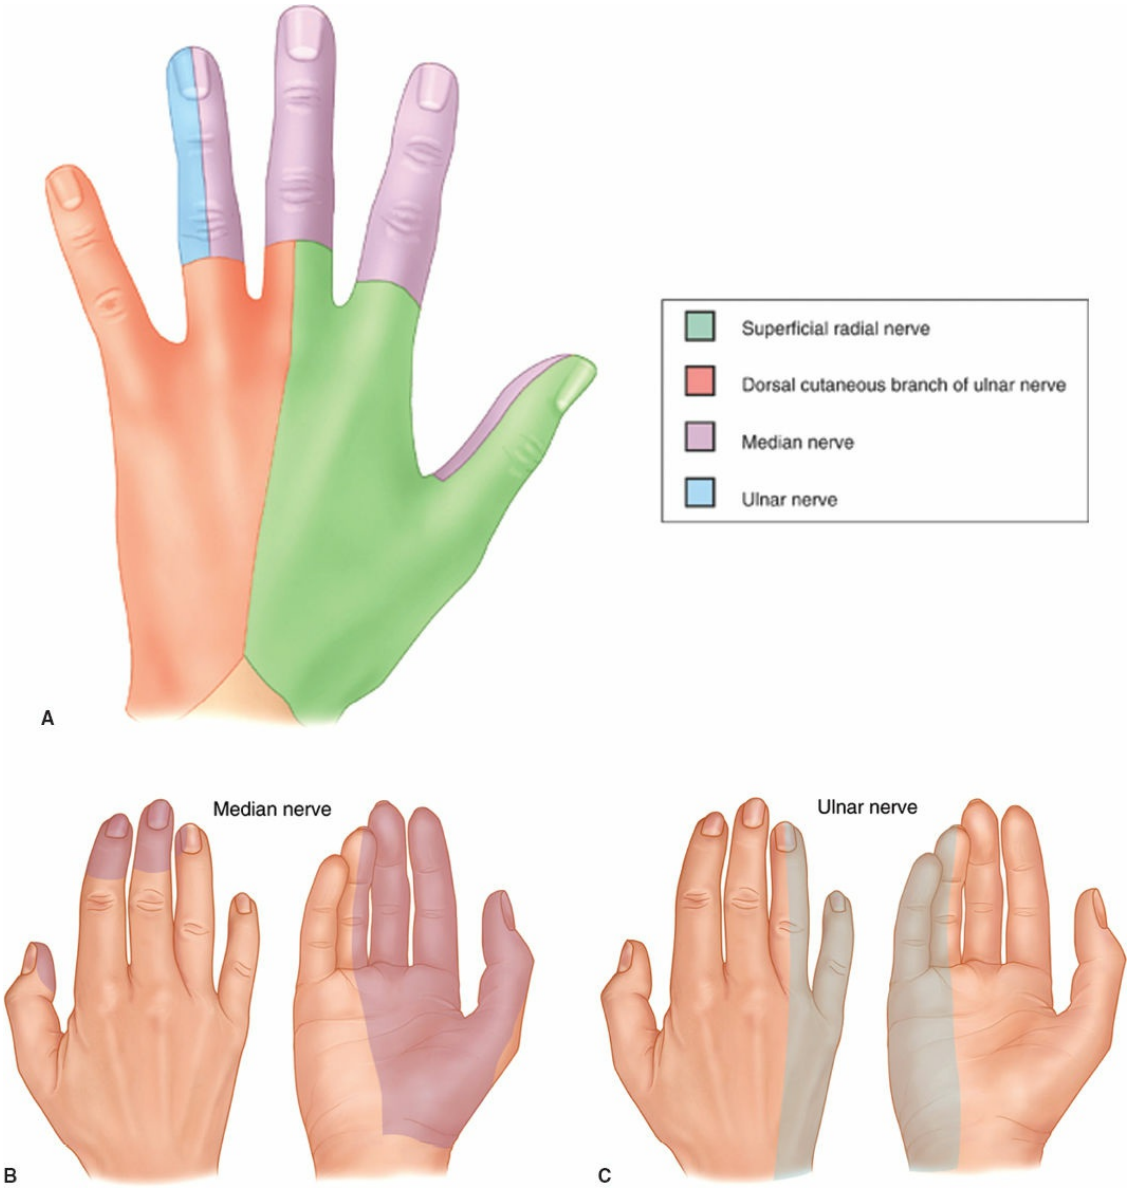

Figure 17.1. Anatomical nerve territory of the hand. (**A**) The dorsal aspect of the hand receives its sensory innervation from the superficial branch of the radial nerve and dorsal cutaneous branch of the ulnar nerve on the radial and ulnar aspects, respectively, up to and over the dorsal aspect of the proximal phalanx, but little sensation distal to that point. Vertical perforating branches of the respective volar digital nerves supply the dorsal aspect of the remainder of the fingers. (**B** and **C**) Volar common and proper digital nerves supply sensation to the volar aspect of the hand and fingers, respectively.

The metacarpal bones link the fingers to the wrist (Fig. 17.5) and create the skeletal structure separating the interossei muscles. When fractured, the metacarpal bones can tolerate a fair amount of dorsovolar angulation

and shortening, with the small finger metacarpal being able to tolerate the most displacement (>40 degrees). Radioulnar angulation, however, can lead to a rotational scissoring deformity and should be reduced or repaired. Each finger, except the thumb, contains three phalanges progressively decreasing in size. The proximal phalanx does not have any direct tendinous insertions from extrinsic musculature, but is primarily under the control of intrinsics and a lasso effect of the extensor tendon. Therefore, the proximal phalanx can both flex and extend, even if the remainder of the finger distal to the PIP joint is lost. The middle phalanx contains the insertions from the flexor digitorum superficialis (FDS) and the central slip from the extensor tendon. The FDS tendon is responsible for independent finger flexion. The flexor digitorum profundus (FDP) tendon and terminal tendon insert on the distal phalanx. Tuft fractures of the distal phalanx with a subungual hematoma were classically thought of as “open fractures” which required removal of the nail plate and repair of the nail bed. It is now acceptable to trephinate the hematoma for pain and manage these injuries closed.

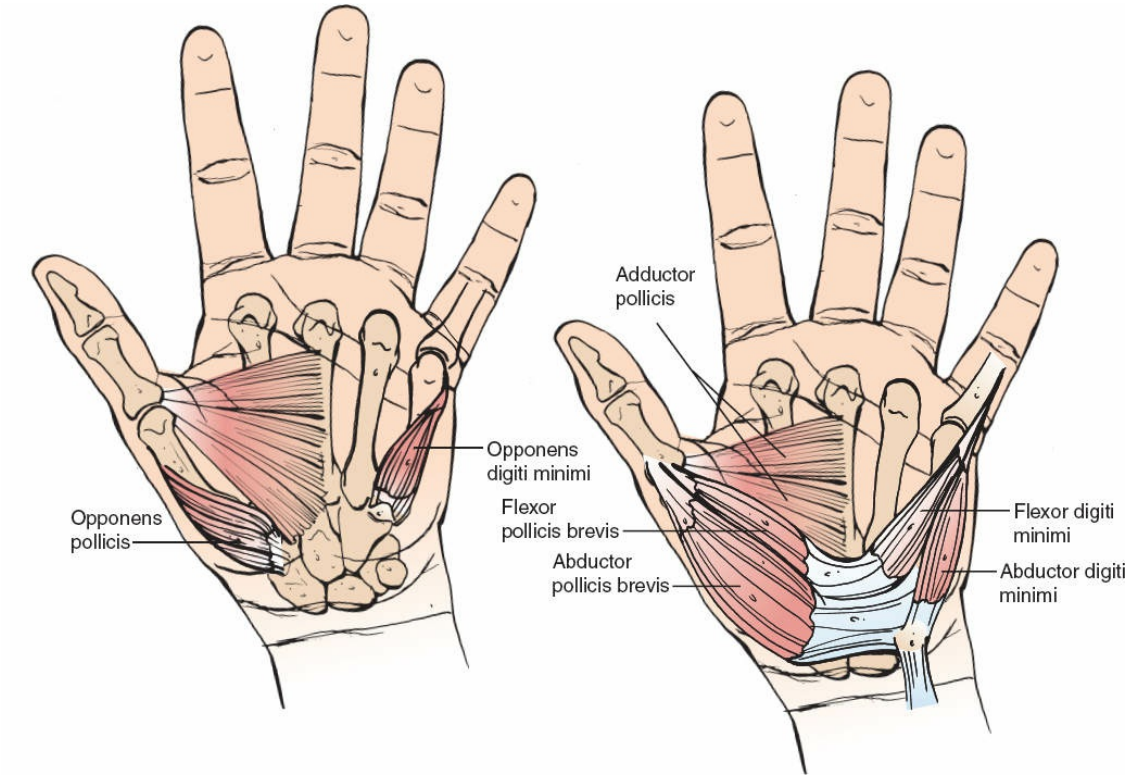

Figure 17.2. Thenar and hypothenar intrinsic muscles of the hand. Complex and fine motor movements of the hand are accomplished by the intrinsic musculature. They allow metacarpal phalangeal flexion with concomitant proximal interphalangeal joint extension. These muscles distinguish many

human behaviors from other animals and primates.

Figure 17.3. The bony skeleton consists of two forearm bones. The ulna is anchored to the humerus and can be thought of as a flagpole or doorframe with which the radius, carpus, and hand representing the flag (or door) are able to rotate around this ulnar axis. Pronation and supination are accomplished by the proximal and distal radioulnar joints, which can be thought of as the hinges of the door or attachments of the flap to the pole.

CLINICAL PRESENTATION AND HAND EXAMINATION

A complete hand examination does not need to be tedious, lengthy, or esoteric. The contralateral hand can be used for comparison in evaluating strength, sensation, and range of motion. The examination commences with inspection. The normal hand is held with natural “C” curvatures, with a “C” curvature made between the thumb and fingers, another one on the

palmar aspect between the thenar and hypothenar areas and a dorsal curvature over the metacarpal heads. Loss or flattening of one of these is indicative of a nerve injury (Fig. 17.6). After inspection, a sensory test can be accomplished by instructing the patient to rate their sensation on a scale of 0 to 10, with 10 being normal sensation. Start by assessing an uninjured area and then move to the injured areas. Generally, even in areas with a complete nerve transection, patients will relay some element of sensation; however, quantifying their sensation less than 5 is indicative of a nerve injury. Finally motor function is assessed. The patient's ability to flex, extend, pronate, and supinate the wrist is evaluated. Various muscle tendon units perform redundant functions; therefore, an injury is suspected when a particular motion is either weaker or produces pain—not necessarily completely incapable of performing.

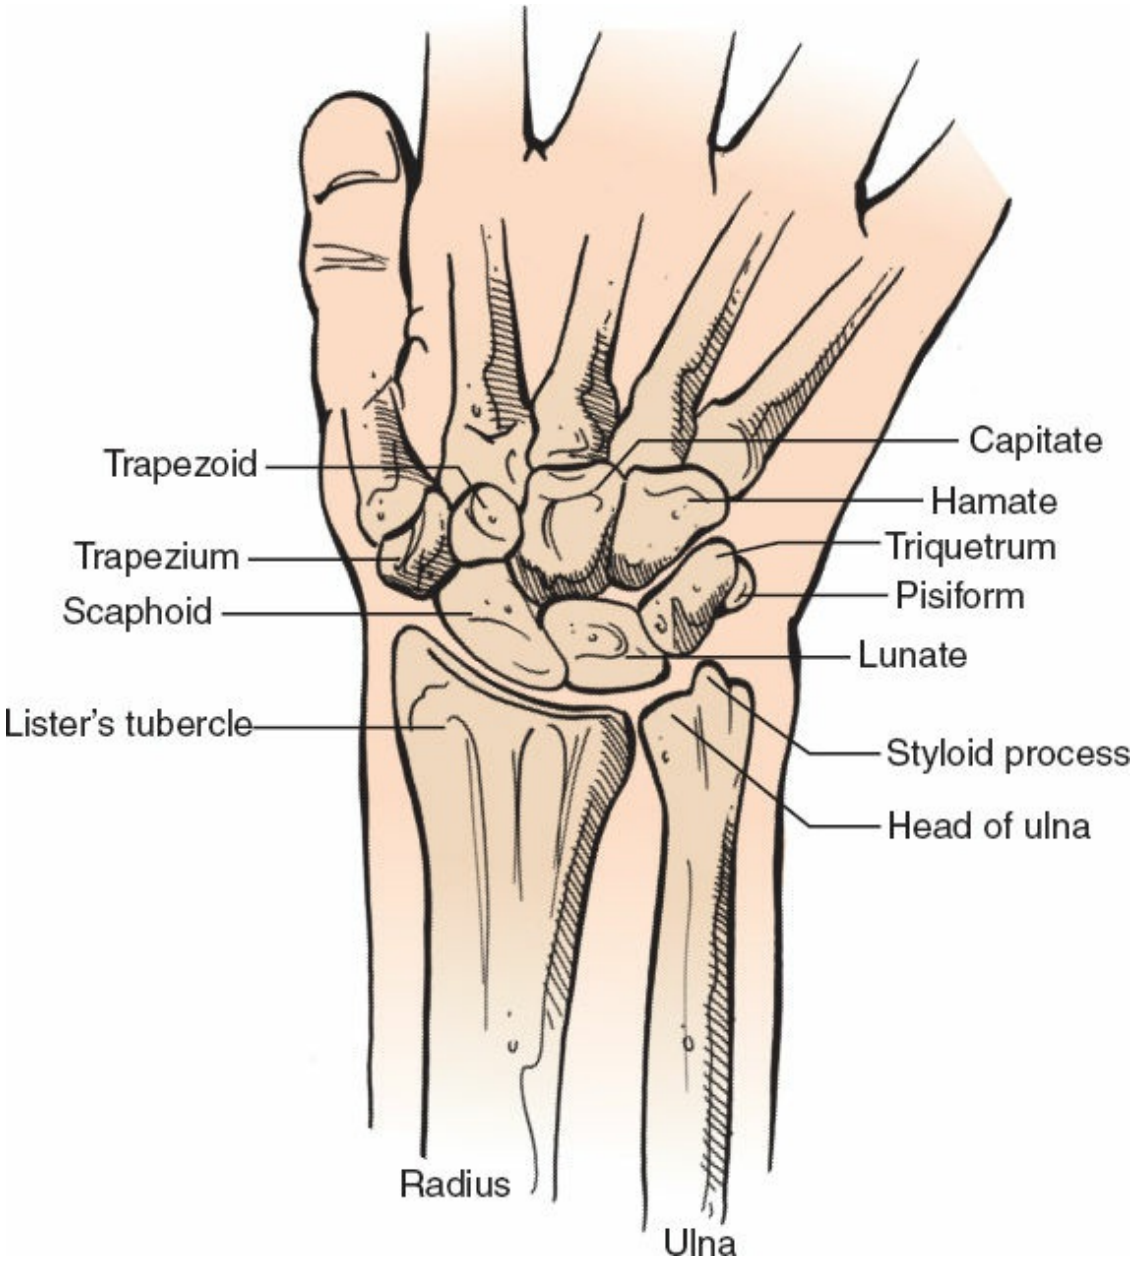

Figure 17.4. The wrist consists of eight carpal bones separated into a proximal and a distal carpal row. The proximal row—scaphoid, lunate, triquetrum, and pisiform—is known as the intercalated segment due its lack of tendinous or muscle insertions.

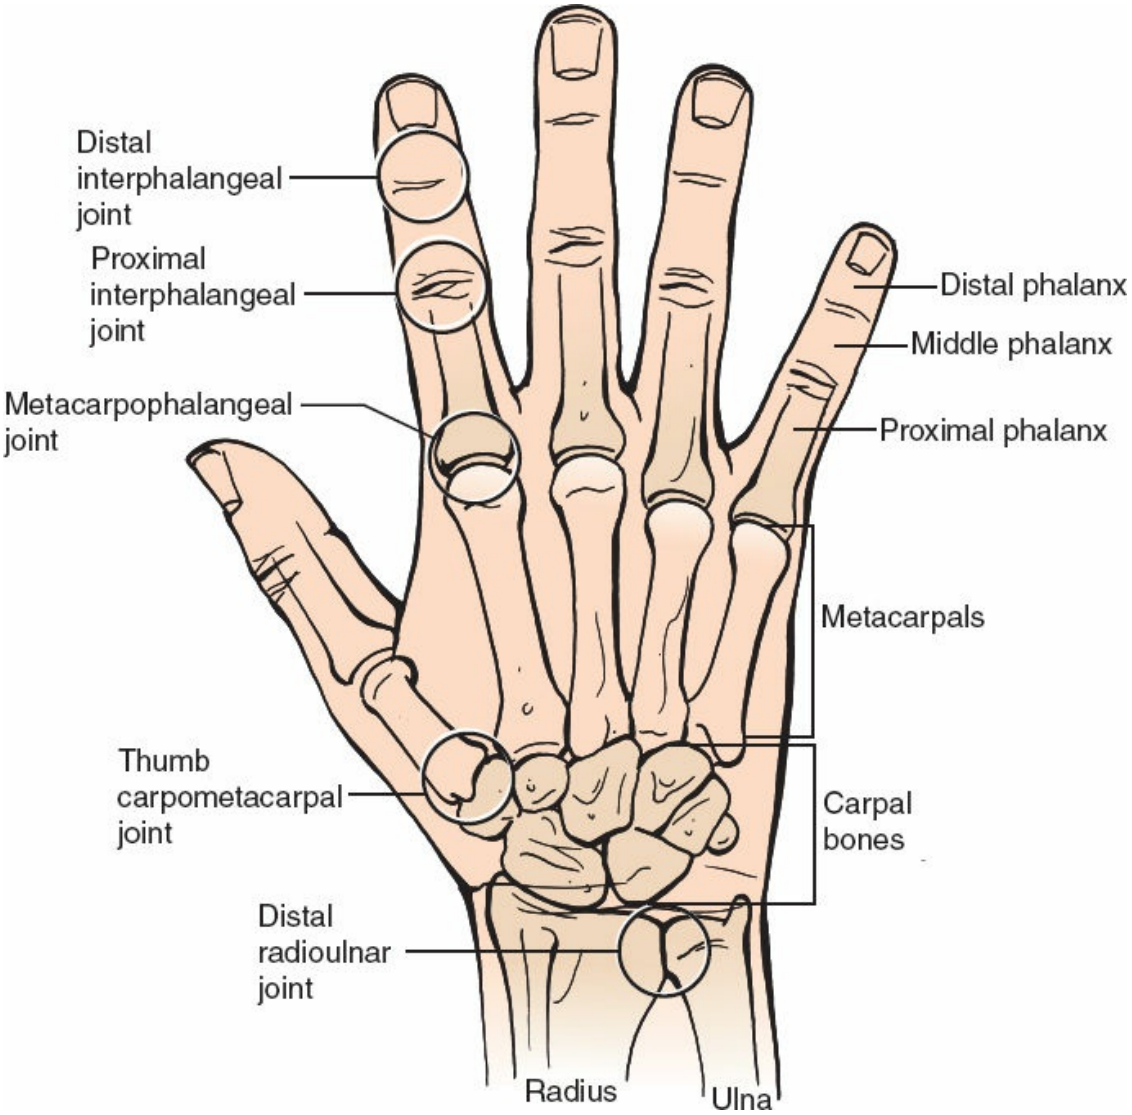

Figure 17.5. The metacarpal bones link the fingers to the wrist and create the skeletal structure separating the interossei muscles. When fractured, the metacarpal bones can tolerate a fair amount of dorsovolar angulation and shortening, with the small finger metacarpal being able to tolerate the most displacement. Indications for repair of metacarpal fractures include extensor lag or rotational deformity.

Assessing finger extension can be misleading, as the juncturae tendineae collate the extensor digitorum communis tendons (Fig. 17.7) over the hand causing the examiner to miss an injury proximal to these structures. An extensor tendon injury is suspected when an extensor lag is present or independent finger extension is weaker or elicits pain. If the patient is too uncomfortable to be examined, a local anesthesia digital block can be performed to elicit pain-free finger motion. Finger flexion is assessed for the FDP and FDS tendons independently. Each FDP tendon

can be examined by having the patient flex at the distal interphalangeal (DIP) joint. The FDS tendons are examined by having the patient independently flex the digit at the PIP joint level while extending the other digits; this prevents FDP finger flexion. Intrinsic function is evaluated by having the patient cross the index finger under the long finger (Fig. 17.8). Alternatively, the patient can radially abduct the index finger to resistance. This assesses the ulnar innervated first dorsal interosseous muscle. Confirming thumb opposition provides information regarding the integrity of the motor branch of the median nerve distal to the wrist (Fig. 17.9). Confirming hypothenar muscle function can be assessed by having the patient hold all fingers together in extension. Loss of hypothenar muscle balance will allow the radial nerve innervated extensor tendons to pull the small finger in an abducted position from the other fingers; this is known as Wartenberg's sign.

The perfusion of the hand and digits is evaluated by assessing the radial and ulnar arteries at the wrist (Fig. 17.10), the presence of a Doppler signal in the superficial palmar arch, and at the lateral aspect of each digit. A dorsal blood supply does exist; however, it is primarily reliably for the thumb but becomes decreasingly present in a radial to ulnar direction. Color, temperature, and turgor remain the most reliable indicators of digital tissue perfusion. Subungual capillary refill is not a reliable indicator of distal tissue perfusion, as this can remain positive even in the immediate postmortem state.

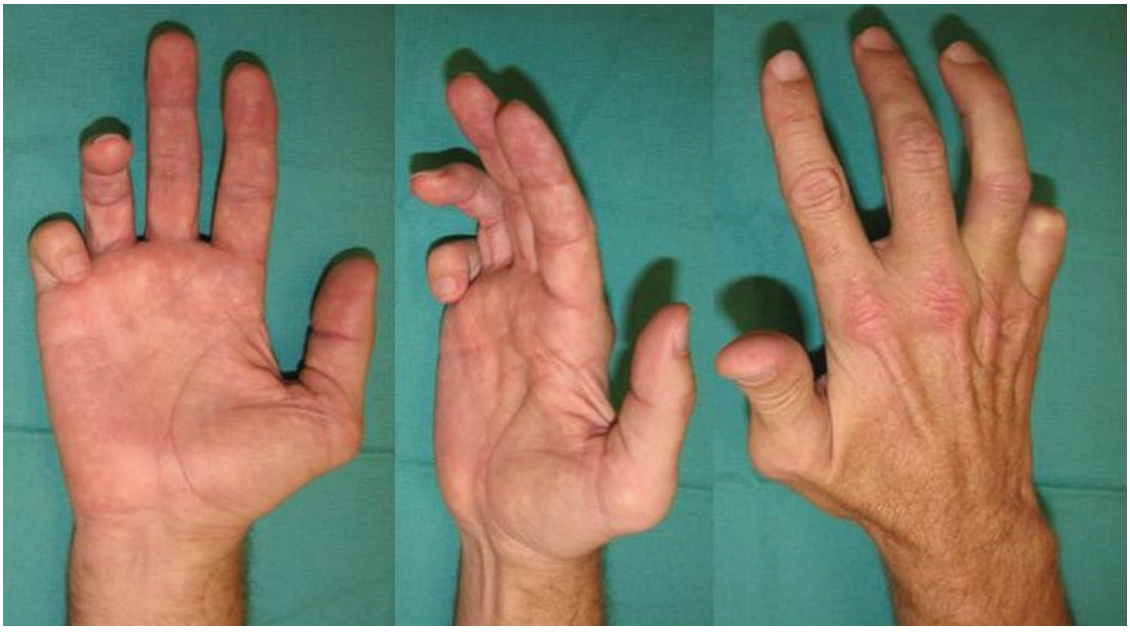

Figure 17.6. The normal hand is held with natural "C" curvatures,

with a “C” curvature made between the thumb and fingers, another one on the palmar aspect between the thenar and hypothenar areas and a dorsal curvature over the metacarpal heads. Loss or flattening of one of these is indicative of a nerve injury. This patient has a claw hand from an ulnar nerve injury. The position of the index and long fingers is still somewhat maintained; this is accomplished by the median nerve innervated lumbricals.

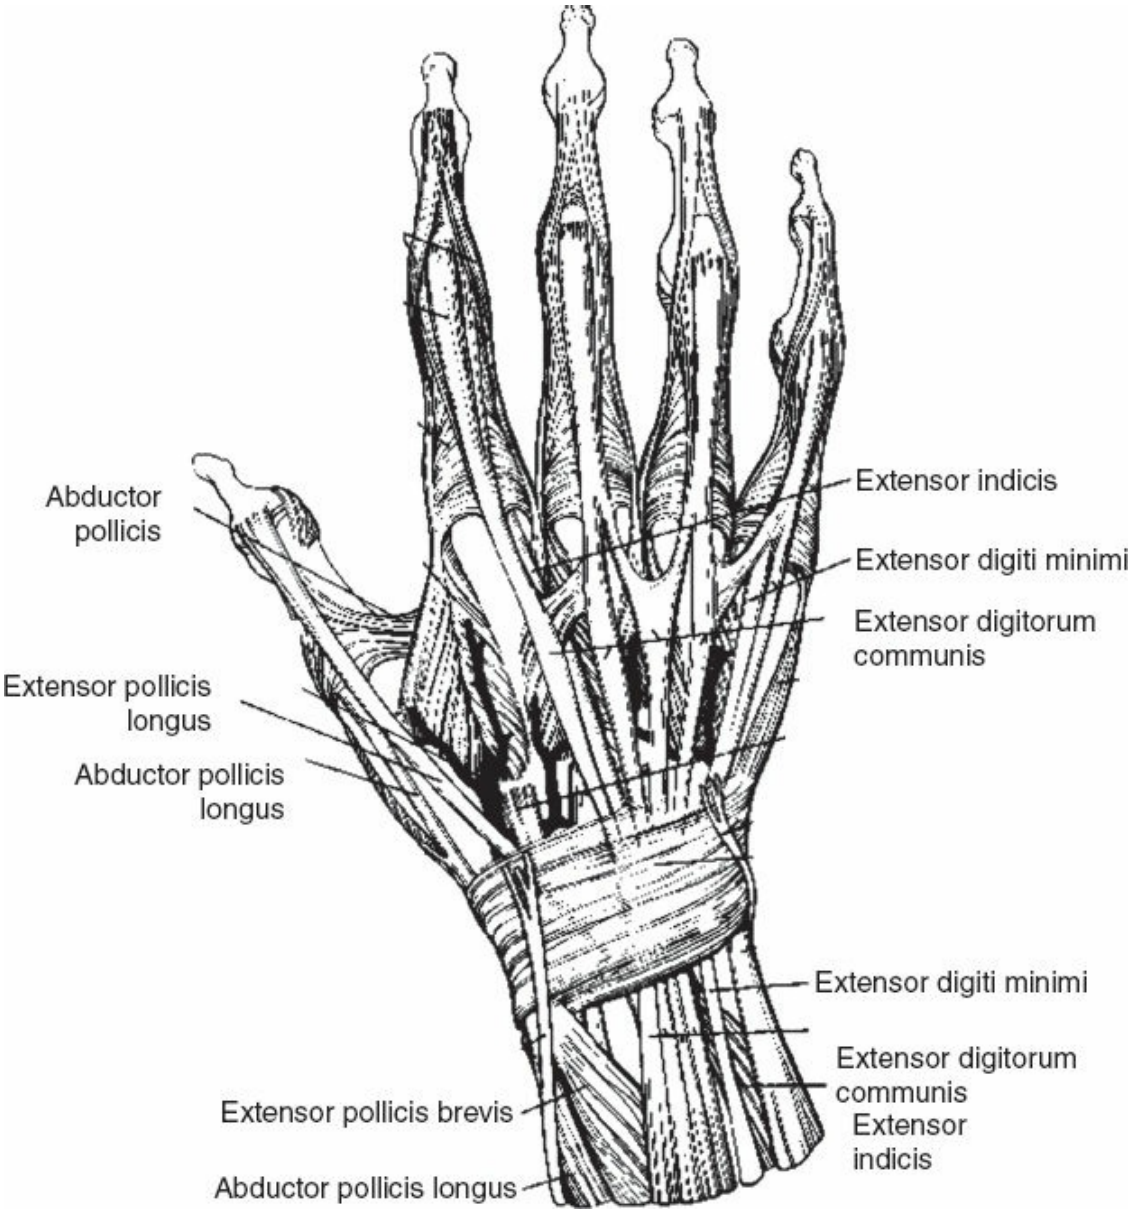

Figure 17.7. Assessing finger extension after a dorsal land laceration can be misleading. The juncturae tendineae collate the extensor digitorum communis tendons over the hand causing the examiner to miss an injury proximal to these structures. An extensor tendon injury is suspected when an extensor lag is present or independent finger extension is weaker or elicits pain.

PREOPERATIVE PLANNING AND MANAGEMENT OF HAND TRAUMA PATIENTS

Hand and wrist radiographs are essential in all hand trauma patients. X-rays are important even in patients with sharp lacerations or injuries, as foreign bodies can frequently be seen and lead to infections if not addressed.

The constellation of hand injuries can be separated into three categories of urgency. A professor of mine, Dr. James Chao, termed these categories as “run, walk, roll-over” divided by the urgency needed to take these patients to the operating room. The most emergent cases include high-pressure injections, compartment syndromes, amputations, and deep space infections, including flexor tenosynovitis and septic arthritis.

Less emergent injuries that require attention of some element on the day of injury but may not require care in the operating room include open fractures, joint and carpal bone dislocations, open wounds, lacerations, nail bed injuries, and lesser infections like paronychias, felons, dorsal subcutaneous abscesses.

Injuries that require elective attention and can usually be treated initially with a referral to clinic include closed fractures (most common is the 5th metacarpal or boxer’s fracture) and tendon, muscle, and nerve injuries.

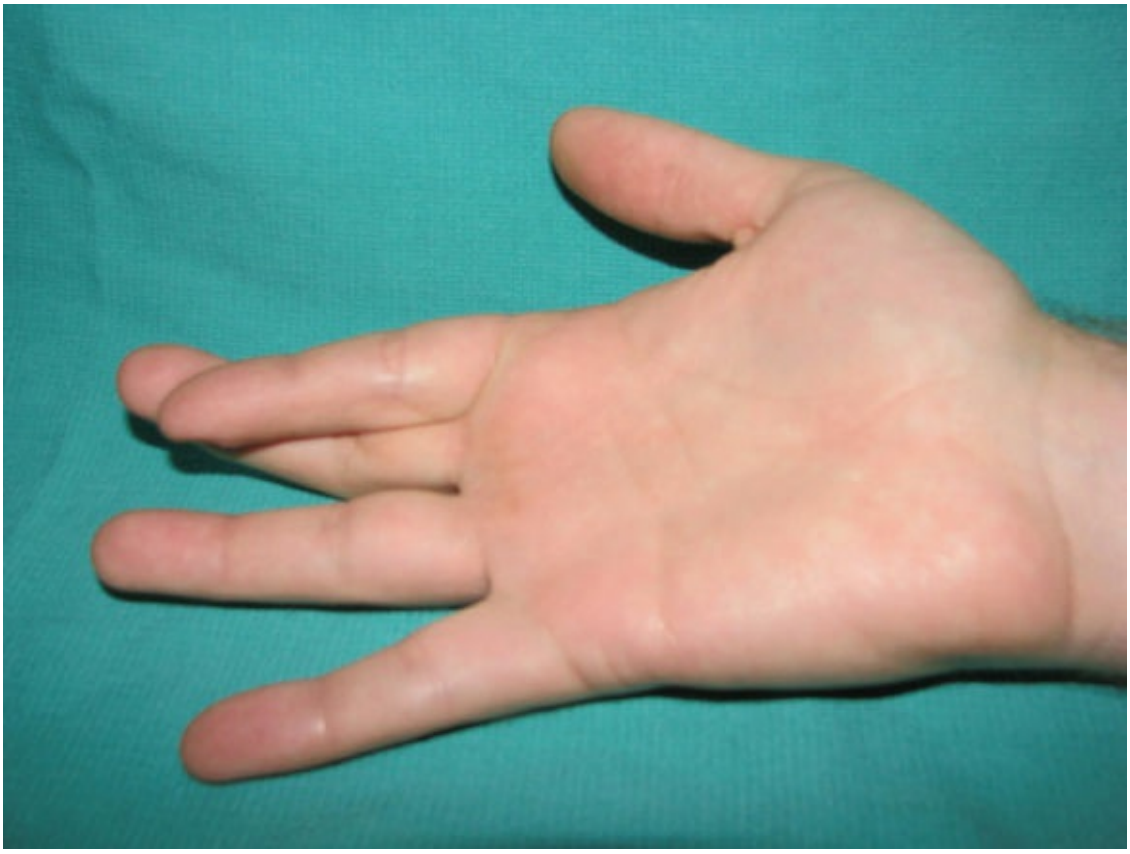

Figure 17.8. Assessing intrinsic function is evaluated by having the patient cross the index finger under the long finger. Alternatively, the patient can radially abduct the index finger to resistance. This maneuver assesses the ulnar innervated first dorsal interosseous muscle.

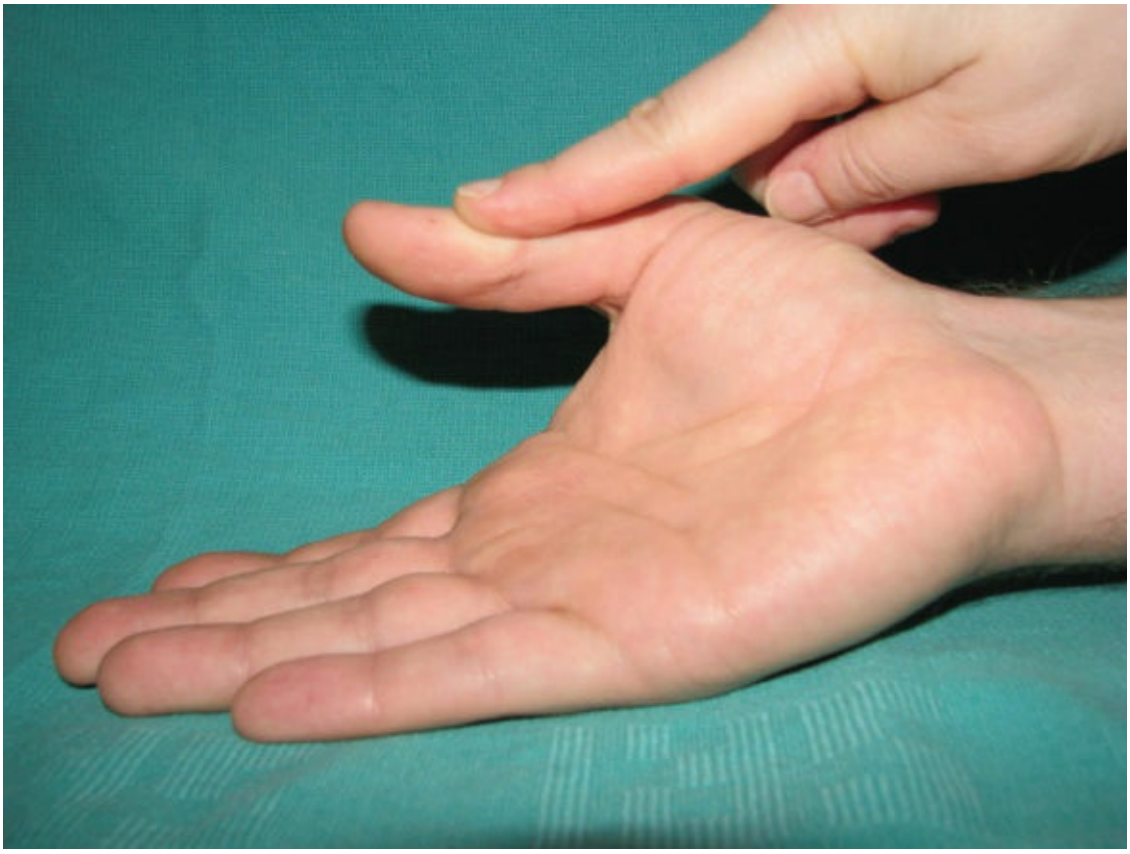

Figure 17.9. Confirming thumb opposition provides information regarding the integrity of the motor branch of the median nerve distal to the wrist. Confirming hypothenar muscle function can be assessed by having the patient hold all fingers together in extension. Abduction of the small finger occurs from the unopposed pull of the extensor tendons.

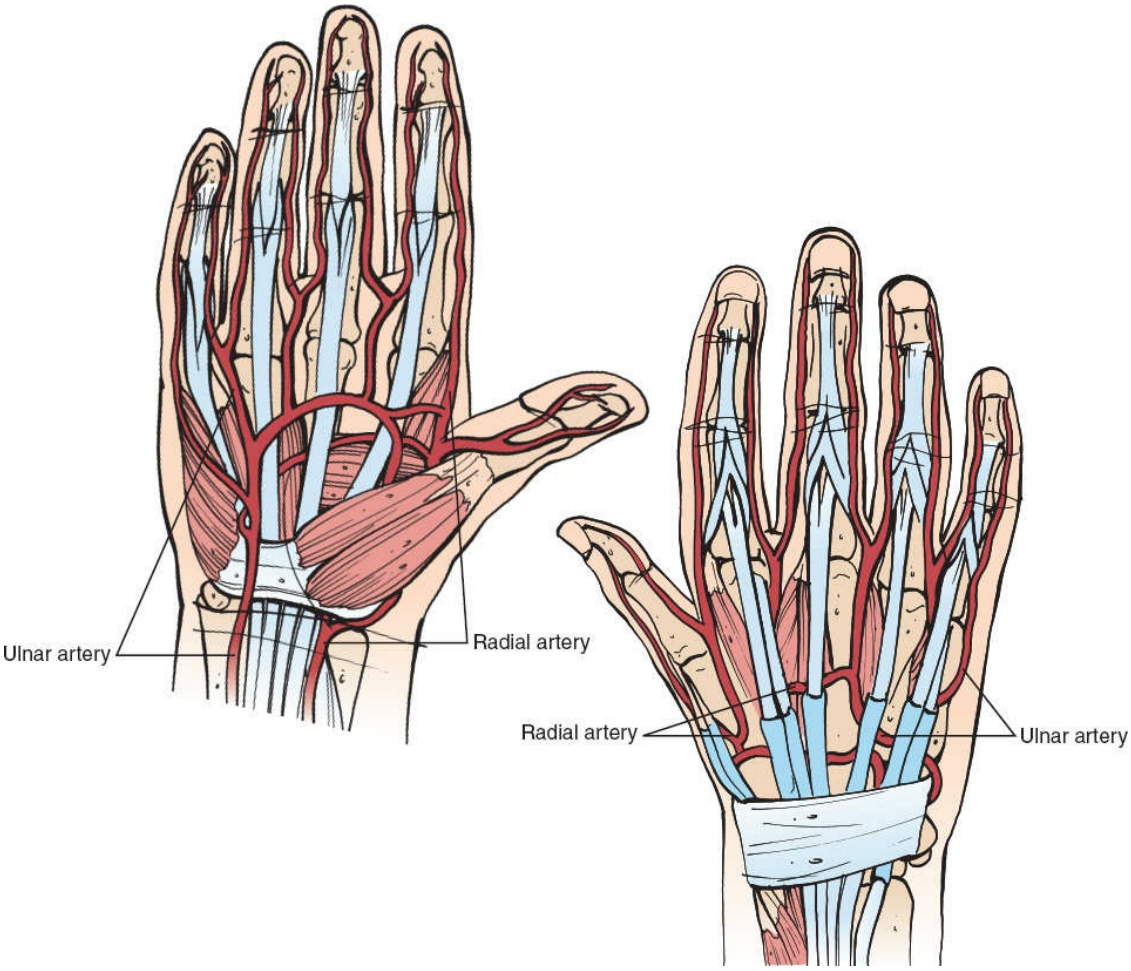

Figure 17.10. Perfusion of the hand and digits is evaluated by assessing the radial and ulnar arteries at the wrist. The presence of a Doppler signal in the superficial palmar arch and at the lateral aspect of each digit. A dorsal blood supply does exist; however, it is only reliable for the thumb and becomes decreasingly present in a radial to ulnar direction.

Describing the management for all injuries would require devotion of an entire separate text. The primary resource referenced by hand surgery fellows and trainees is *Green's Operative Hand Surgery* (Elsevier, Philadelphia, PA). The remainder of this text will describe the initial management of hand emergencies.

VASCULAR COMPROMISE: AMPUTATION, REPLANTATION, AND REVASCULARIZATION

The critical time period for an amputated digit, hand, or extremity to be replanted can be extended by wrapping the specimen in clean, damp gauze, and then placing it into a plastic bag on top of ice with an open lid.

Submerging the piece in ice can cause frostbite rendering it unusable. The maximum amount of time elapsed from injury until reattachment varies in the literature. Reports of extended time period for multiple days have been documented.[6] The usual acceptable time periods are approximately 12 hours of warm ischemia time and 24 hours of cold ischemia time for digits; times are halved for segments with greater amounts of muscle mass. In the United States with modern communication technology and air flight capabilities, it is uncommon for a patient with an amputated digit to be 24 hours away from a replant center; however, occasionally this may occur in a rock or mountain climber or if transportation is hindered by inclement weather. A more common scenario would occur in a patient with multisystem injuries who may not be amenable to replantation on initial presentation. In this scenario, the amputated segment can be placed on ice for 24 hours and reattached when the patient is stabilized. Reports in the Asian literature have successful replantation 94 hours after injury.[6] Certain replant centers even advocate scheduling this procedure for the morning if it comes in during the late hours of night.

The order for repairing structures varies slightly, but the mnemonic BEFANV ("Beef and V") can be remembered. The skeletal fixation is performed first (*i.e.*, bone) (Fig. 17.11), followed by the extensor and flexor tendons. This is followed by repairing the volar digital artery and nerve and finally a dorsal vein. Vein grafts are frequently necessary. When this is necessary, we advocate the use of vein couplers to speed anastamoses. If the replant is successful, the plastic coupler may be palpable or exposed; after 2 weeks, it can be removed without consequence.

Sharp amputations portend a better prognosis than avulsion or crush injuries.[7] The zone of injury is much greater when the amputated segment is avulsed by a blunt or avulsive force. These situations almost universally necessitate a vein graft.

The informed consent process should always include the likelihood of revision amputation, the need for blood transfusions, and a prolonged hospital stay. Patients have a longer time period to return of work if replantation is undertaken and will universally deal with issues of joint stiffness and numbness that will last many months or be permanent.[8,9] The success rate in the best of conditions can be upward of 80%; however, most patients are not "ideal" candidates or have an "ideal" mechanism for replantation.[8]

In the United States, the most common etiology for digit amputations are table and skill saws (Fig. 17.12).[9] This type of machinery causes a ripping and tearing of the tissues extending the zone of injury on the vessels by a number of centimeters. Avulsion injuries occur from water sports, roping injuries, ring avulsions, folding chairs, animal leashes, etc.

Intraoperatively, a thorough debridement is performed first removing all nonviable tissue, foreign material, and blood clot obscuring visualization. We generally perform this step prior to insufflating the tourniquet. Once the tourniquet is up, the surgical team has to work quickly to perform skeletal fixation, tendon repair, and selection of vessels and nerves to anastamose within 2 hours. By the time the patient requires a tourniquet break, it is important to be at a place that diffuses bleeding will not interrupt the flow of work or obscure dissected structures. Tagging structures that still require repair with hemaclips or sutures attached to a labeled hemostat help prevent redundant work. Skin edges are also frequently tacked open; it is important to remember to release these at the tourniquet break to prevent additional tissue ischemia and open wounds. Intraoperatively, concentrated plain lidocaine or papaverine is used to prevent vasospasm. We have also begun instituting the use of botulinum toxin as a long-acting agent for preventing sympathetic restriction of blood flow.[10–12]

Postoperative care varies greatly by surgeon. The decision on admission bed status relies on the surgeon's willingness for a postoperative take back. Many will give a valiant attempt at salvage, but will not attempt a secondary salvage for vascular compromise. After surgery, if the venous anastomoses were tenuous or small or inadequate, we will begin leech therapy immediately. This will constitute one leech every 4 hours. The patient will need to be on *Aeromonas* bacterial coverage with ciprofloxacin, bactrim, or another agent.[13] We will also start systemic amlodipine to promote systemic vasodilation, keep an indwelling brachial plexus catheter in place for 72 hours and immediate hyperbaric oxygen therapy for 5 to 10 days. Full-strength aspirin and prophylactic low-molecular weight prophylactic heparin dosing are also given. Admittedly, the evidence behind many of the adjunctive measures is lacking or inconclusive; however, we have had success with these measures, and given the amount of time and resource investment put forth, we believe it is worth the added adjunctive measures.

Vascular compromise can also result from prolonged ischemia due to a

ring that is too tight in the face of massive edema or a tourniquet from any cause. Figure 17.13 demonstrates an infant with a piece of his mother's hair wrapped around a toe causing a so-called *hair tourniquet.*

EMERGENT INFECTIONS: FLEXOR TENOSYNOVITIS, SEPTIC ARTHRITIS, DEEP SPACE INFECTIONS

Purulent infections within a tendon sheath can destroy and scar synovial lining preventing tendon gliding. These infections can also spread quickly into adjacent areas permanently damaging hand function (Fig. 17.14).

Bacterial infections within a joint can destroy articular surfaces and corrode joint surfaces. The most common infectious organisms are staphylococcus and streptococcus.[14] Mycobacterial or fungi can present as atypical or chronic infections. Cultures should be obtained as soon as possible so that antibiotics can be begun; however, institution of antibiotics should not be delayed out of fear of altering the microbiology specimen. The primary treatment of purulent infections is surgical irrigation and drainage. The most common community-acquired organism in many parts of the United States is methicillin-resistant *Staphylococcus aureus* (MRSA) (60%).[14] The patient should presumptively be treated for MRSA until cultures are identified. Many strains of MRSA are susceptible to trimethoprim/sulfamethoxazole, clindamycin, doxycycline, rifampin, tetracycline, and/or erythromycin.[14]

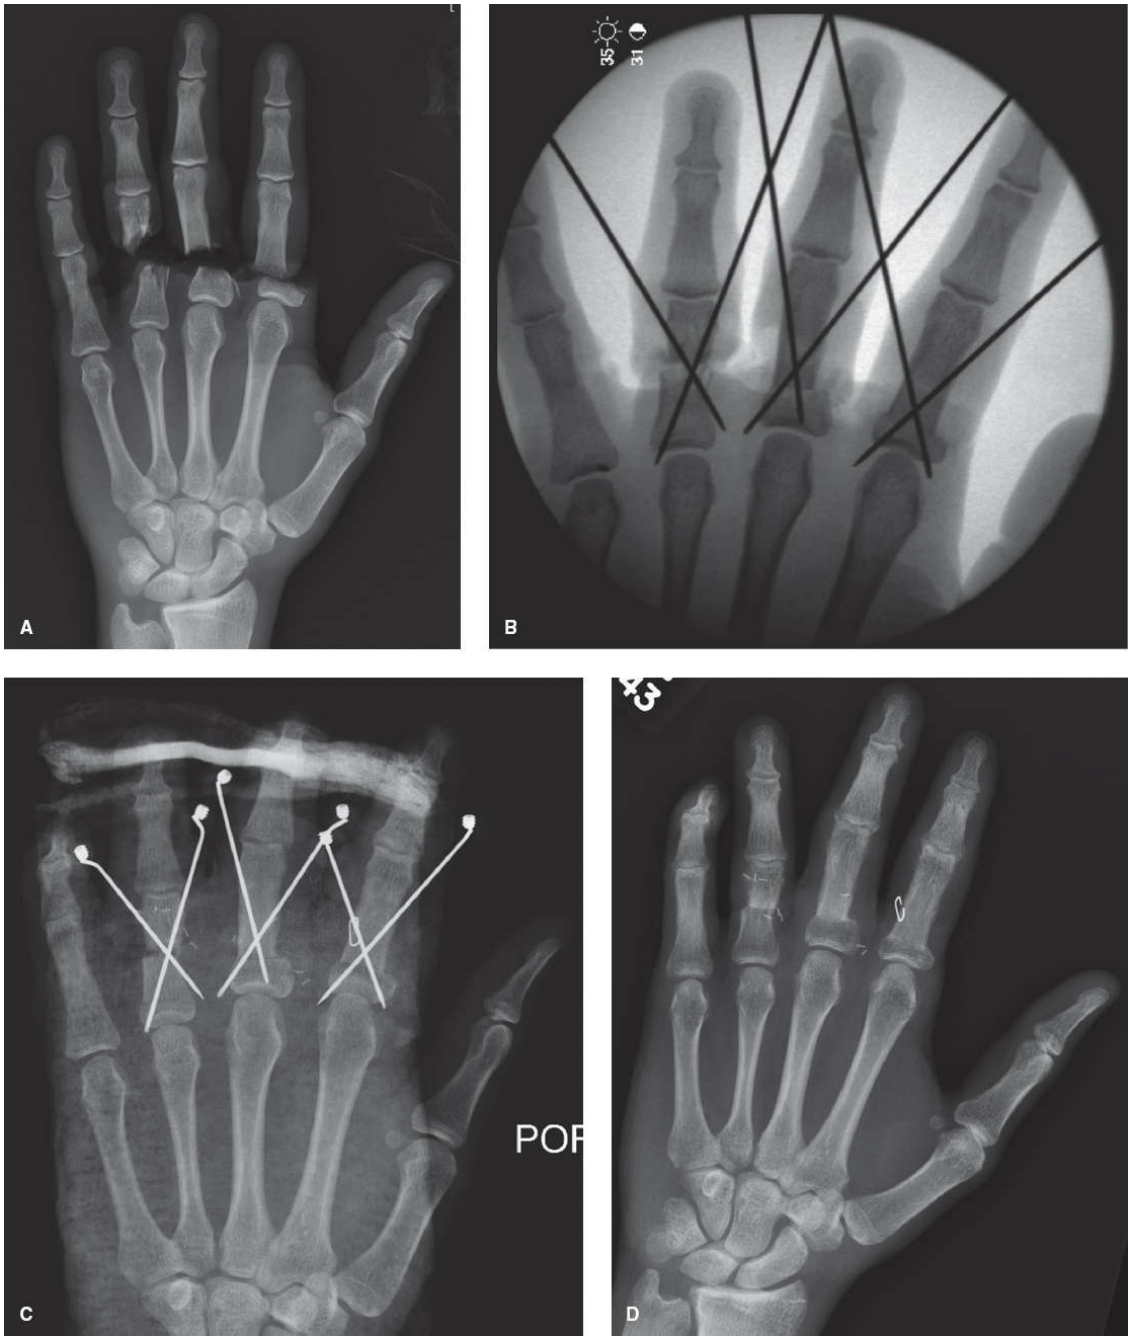

Figure 17.11. **A.** A 23-year-old man suffered a multidigit injury from a table saw accident. **B.** In performing a replantation, the skeletal fixation is performed first (i.e., bone). In this case, it is achieved with crossing k-wires. **C.** The patient is seen at 2 weeks postoperative. **D.** X-ray of the replanted digits at 4 weeks postoperative when the k-wires were removed.

Figure 17.12. A. Clinical picture of the same patient in Figure 17.11. The long and ring fingers were completely detached. The index finger had a small dorsal skin bridge. The volar structures were transected in the small finger, but the bone and dorsal structures were intact. **B.** Early postoperative image of the hand

with k-wires in place. (**C**) At 2-month postoperative, the patient was already regaining a significant amount of function including opposition, (**D**) finger extension, and (**E**) metacarpal phalangeal flexion.

Figure 17.13. Vascular compromise of a digit due to a hair tourniquet. This infant had a piece of his mother's hair wrapped around a toe causing vascular compromise in an infant.

The patients history almost usually includes at least a minor trauma, such as a splinter, spider bite, small penetrating injury, or animal bite, although new onset diabetes mellitus has been reported as the only presenting condition associated with an extremity infection.[15] The tetanus history should be obtained. Patients particularly susceptible to infection include immunosuppressed patients, including diabetics, AIDS, transplant patient, autoimmune disorders, malnutrition, renal failure, or those with

occupation or behavioral factors that increase risk: dental workers—herpetic whitlow; dishwashers—chronic paronychia; nail biting—paronychia.

Flexor Tenosynovitis

The classic signs of flexor sheath infection are known as the four Kanavel signs: fusiform swelling, redness along the finger, tenderness with palpation over the flexor tendons, and pain with passive extension of the finger (Fig. 17.14). These signs point to an infection of the flexor tendon sheath that may propagate along the tendon sheath into the wrist.[16] The most common infectious organisms are gram-positive bacteria being streptococcus and staphylococcus. Flexor tenosynovitis (FTS) should be distinguished from other etiologies like herpes simplex virus (HSV), which is classically seen in the hands of dental workers.

Management of FTS is surgical. There are a number of techniques available and can all be used depending on the clinical scenario. The least invasive method of treating this pathology is using closed catheter irrigation. A small opening is made at the A1 pulley through a V incision and sheathotomy. A separate midlateral incision over the noncontact ulnar surface of the DIP joint in the flexor tendon sheath distal on the finger to provide egress of fluid that is irrigated into the flexor tendon sheath proximally. An 18-gauge catheter is carefully threaded into the sheath and gently irrigated the tendon sheath to evacuate all purulence. The incisions are left open to contract and heal secondarily. If there is concern for residual infection, a 5-french feeding tube can also be placed into the tendon sheath by suturing it to the skin and allowing continuous irrigation after the procedure every 8 hours for 48 hours to evacuate any additional infectious material. The patient is initially placed on broad-spectrum antibiotics until the culture sensitivities return and then the coverage is narrowed. The patient is managed in-house initially in a resting splint and elevated in a sling connected to an intravenous pole.

The more aggressive open approach in which the entire flexor tendon sheath is exposed is used for severe aggressive infections that cannot be adequately treated with the closed catheter system. This is performed by elevating a skin flap over the flexor tendon sheath (Fig. 17.14). The tendon sheath is entered but making sure to preserve the A2 and A4 pulleys. The infection is irrigated and the skin flap loosely tacked back into position.

Deep Space Infections

There are five other potential deep spaces in the hand and wrist susceptible to abscesses.[17] Infections in these areas are suspected by erythema, tenderness, and loss of the normal concavities on the hand (Fig. 17.14). As the infection progresses, these areas become very tender, warm, erythematous, and convex in appearance. The thenar space is bounded by the midpalmar septum on the ulnar side and the dorsal and radial sides by the adductor pollicis fascia and adductor insertion, respectively.[17] This can be approached by an incision in the web space or over the adductor muscle. The choice of incision is generally made over the area of greatest fluctuance.

A midpalmar space abscess occurs deep to the flexor tendons between the thenar and hypothenar areas. It is characterized by loss of volar concavity in the midpalm. This space is bounded by the second and third interossei fascia dorsally and the tendon sheaths of the long, ring and small fingers volarly. Great care must be taken to avoid injury to the superficial palmar arch and the common digital nerves. The common digital nerve to the third web space is the most superficial and most commonly injured.[18]

Infections in the hypothenar space are the least frequently encountered. This infection occurs in the area between the hypothenar septum and hypothenar muscles. The dorsal boundary is the periosteum of the fifth metacarpal and fascia of deep hypothenar muscles.

Parona's space is located in the distal forearm between the pronator quadratus and the FDP tendon sheaths. Infections in this area should be suspected when there is an infection in the thumb flexor tendon sheath or small finger flexor tendon sheath, as they may propagate proximally to the radial and ulnar bursas, respectively. These bursas communicate via parona's space and can lead to a horseshoe abscess.

A collar button abscess occurs in the interdigital web space that is restricted by the deep intermetacarpal ligament. Treatment requires both dorsal and volar incisions.

Fight-Bite and Animal Bite Infections

These infections occur from inoculation by oral flora contamination. The causative organisms are frequently *Staphylococcus, Streptococcus, Bacteroides Eikenella corrodens,* and *Pasturella.* The external skin wound may be unimpressive. Probing this wound with the fingers extended may not reveal injured deeper structures; however, the examiner can be fooled

if the hand is not also examined with the fingers in the position it was in when the injury occurred. This frequently reveals extensor tendon injuries and rents in the joint capsule with inoculation into the metacarpal phalangeal joint. An adequate surgical exploration requires the skin laceration to be opened significantly.

Figure 17.14. **A.** Flexor tenosynovitis of the right ring finger. These infections can spread quickly into adjacent areas permanently damaging hand function. The four signs of flexor sheath infection are known as the four Kanavel signs and include fusiform swelling, redness along the finger, tenderness with palpation over the flexor tendons, and pain with passive extension of the finger. **B.** This finger was not amenable to a minimally invasive approach and required filleting open the finger and the flexor tendon sheath. The A2 and A4 pulleys were preserved. **C.** Thenar space infection in a middle-aged woman.

Septic Wrist Arthritis

Septic arthritis presents as an infection within a joint space and can degrade the articular surface quickly leading to irreversible arthritic changes and progress to osteomyelitis.[19] The diagnosis is made by aspirating the joint and sending the synovial fluid for analysis (Fig. 17.15). A white blood cell count greater than 50,000 per mm^3 is consistent with

joint sepsis.[19] The fluid should also be analyzed for Gram stain, aerobic, anaerobic, afb, and fungal cultures. Crystalline arthropathies (Fig. 17.16) in the wrist can present similar to an infection and therefore the fluid should also be sent for cell count and crystals.[20] Chondrocalcinosis of the triangular fibrocartilage complex is pathognomonic for pseudogout of the wrist.[20]

A septic joint is typically secondary to a penetrating trauma with *Staphylococcus aureus* being the most common pathogen. The infection may also occur from hematogenous seeding. In children, an infectious source somewhere else in the body should be suspected and worked up. For otherwise healthy adults with a single joint arthritis, the clinician should suspect *Gonoccoccus.* On physical examination, the joint is warm, erythematous, tender, and has pain with passive range of motion.

Figure 17.15. A. Right wrist of a middle-aged man with septic arthritis. This infection is within the joint space and can degrade the articular surface quickly leading to irreversible arthritic changes and progress to osteomyelitis. **B.** The diagnosis is made by aspirating the joint and sending the synovial fluid for analysis. A white blood cell count greater than 50,000 per mm^3 is consistent with joint sepsis. The fluid should also be analyzed for Gram stain, aerobic, anaerobic, afb, and fungal cultures. **C.** This septic joint was explored via an arthroscopic approach. The joint space was copiously irrigated, debrided, and the status of the articular surfaces documented.

All septic joints must be explored via an arthroscopic or open procedure

(Fig. 17.15). The joint space is copiously irrigated, debrided, and the status of the articular surfaces documented. The wounds are generally packed open with daily dressing changes until closure by secondary intention or delayed primary closure. A closed irrigation catheter system can also be placed intraoperatively to irrigate the joint for 48 to 72 hours after surgery. It is important to empirically cover for MRSA and until cultures are returned. *Gonococcus* should also be covered in the suspected patient with ceftriaxone or its equivalent. Silver sulfadiazine cream is an excellent local antibiotic and may help prevent tendon dessication for exposed wounds.

HIGH-PRESSURE INJECTIONS

High-pressure injections can lead to extensive internal soft tissue damage (Fig. 17.17).[21] The entry wound and skin may be benign in appearance, but will not be a good representative of the internal tissue. The material is injected through the skin at pressures up to 7,000 psi. The nondominant index finger is the most common site for these injuries. It is important to inquire the specific agent injected; oil-based solvents cause more damage than water-based ones.[21] Amputation rates are reported as high as 50% with oil-based paints.[22] Emergent surgical decompression and debridement are required. The removal of all foreign material may not be possible and the patient may require an additional washout.

COMPARTMENT SYNDROMES

Acute compartment syndrome (ACS) is a limb-threatening condition caused by increased pressure within the confined spaces of a fascial compartment (Fig. 17.18).[23] The condition occurs when tissue pressure (TP) exceeds perfusion pressure. TP is determined by subtracting the interstitial fluid pressure from the capillary perfusion pressure (CPP). Normal cellular metabolism easily maintains an oxygen tension in the tissues of 5 to 7 mm Hg when the CPP is at a physiologic vale of 25 mm Hg with an interstitial pressure of 4 to 6 mm Hg. In ACS, rising interstitial pressure overwhelms perfusion pressure and when venous pressure is higher than CPP, capillaries collapse. The pressure at which this collapse occurs is debated; however, an intracompartmental (*i.e.*, interstitial) pressure greater than 30 requires intervention. At this value, blood flow through the capillaries stops. If the pressure is left unrelieved, tissue necrosis and permanent functional impairment occur as nerve, muscle, and other tissues are deprived of adequate blood flow exchange.[23] ACS can

occur in the hand, forearm, upper arm, buttock, abdomen, and lower extremity.

The conditions leading to ACS can be divided into increased compartment volume (*e.g.*, vascular injury leading to ischemia–reperfusion, crush injury, hemorrhage, envenomation, and fractures) and reduced compartment volumes (*e.g.*, burns, tight dressings or casts or prolonged limb positioning—like Saturday night palsy or prolonged surgery). The most common affected compartment in the body is the anterior one of the leg followed by the deep posterior compartment in the leg.

In the forearm, ACS most commonly affects the deepest compartment muscles first, consisting of the flexor pollicis longus and FDP. Clinically, these can be examined by having the patient flex their thumb at the interphalangeal joint or the other digits at the DIP joints. The classic 6 P's describe the physical exam findings of ACS, consisting of pain, pallor, poikilothermia, pressure, paresthesias/paralysis, and pulselessness. Paraesthesias and paralysis relay to nervous function; sensory nerves are affected before motor nerves, which are observed as the numbness of paresthesias occurs prior to muscle paralysis. The diagnosis of compartment syndrome is further verified with measuring the intercompartmental pressure (ICP). The normal ICP is less than 10 mm Hg and decompression is recommended for pressure greater than 30 mm Hg. When measuring compartment pressure, it is recommended to obtain a pressure within 5 cm of the fracture site.

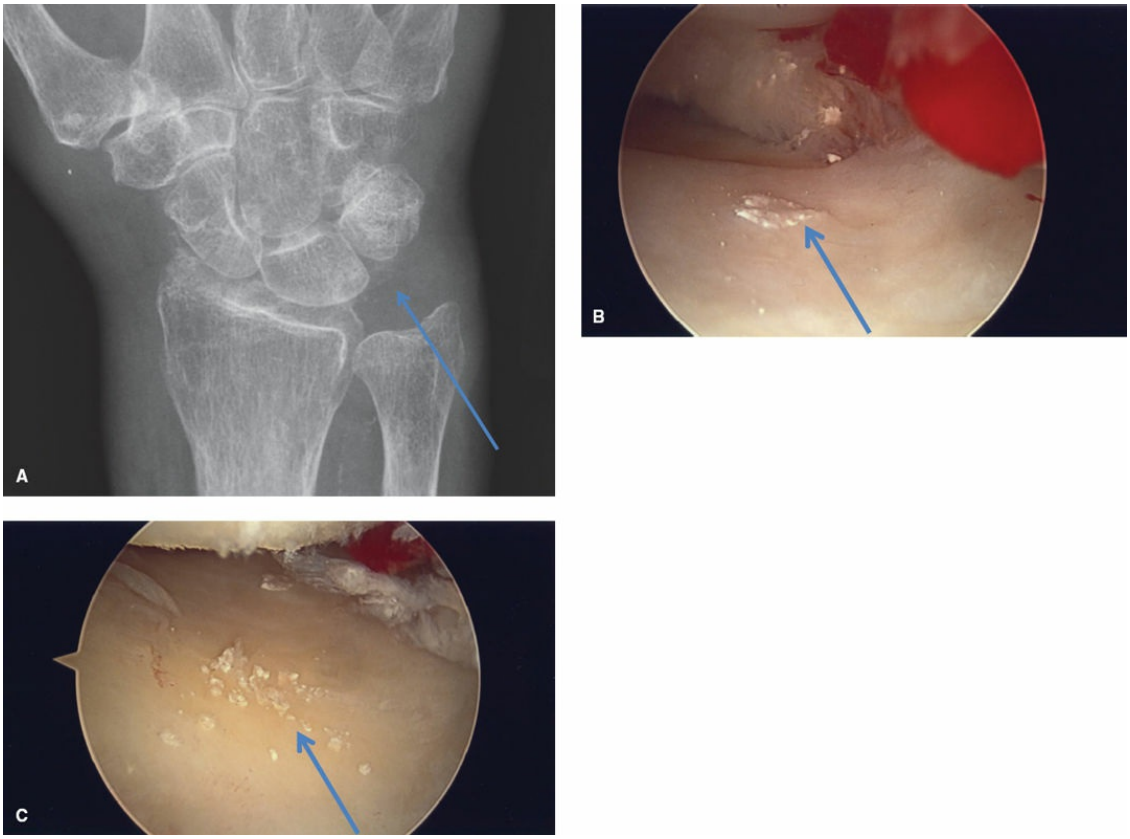

Figure 17.16. **A.** Wrist radiograph from an elderly woman with the crystalline arthropathy pseudogout. This presents similar to an infection and therefore aspirated fluid should be sent for cell count and crystals. The arrow points to chondrocalcinosis of the triangular fibrocartilage complex. This finding is pathognomonic for pseudogout of the wrist. **B** and **C.** Arthroscopic images demonstrating the crystalline deposits on the triangular fibrocartilage complex.

Figure 17.17. High-pressure paint injection into the hand. These injuries can lead to extensive internal soft tissue damage. The entry wound and skin may be benign in appearance, but will not be a good representative of the internal tissue. The material is injected through the skin at pressures up to 7,000 psi. The nondominant index finger is the most common site for these injuries.

Early intervention is critical in the treatment of ACS. Surgical decompression consists of fasciotomy of all involved compartments. In the arm, an incision can be made directly over the biceps muscle. In the forearm, a volar curvilinear incision is made extending from the biceps to the carpal tunnel. The incision is carried down to relieve the pressure on the deep muscles consisting of the flexor pollicis longus, FDP, and pronator quadratus. Dorsally, a straight incision is made over the mobile wad and extensor muscles. In the hand, the interossei muscles are relieved from a dorsal incision and the thenar and hypothenar muscles are relieved volarly.

Figure 17.18. **A.** Intracompartmental needle pressure demonstrating 53 mm Hg. **B** and **C.** Images of a patient with acute compartment syndrome (ACS) after an elbow fracture with dashed lines demonstrating incisions that could be used to decompress the arm. **D.** The kit with the intracompartmental pressure needle is usually stored in the operating room or emergency department at most hospitals. ACS is a limb-threatening condition caused by increased pressure within the confined spaces of a fascial compartment. The condition occurs when tissue pressure (TP) exceeds perfusion pressure. Most agree a value greater than 30 mm Hg can lead to tissue loss.

EDITOR'S COMMENT

Traumatic injuries of the hand are common in the emergency department. If you are on call, you are likely to encounter such injuries. As a result of the complexity of hand anatomy, treating hand injuries can be challenging and treatment by the inexperienced physician may lead to unsatisfactory outcomes. In many instances, a specialist in hand surgery is consulted. However, in many regions of the United States and in other countries, a specialist may not be available. In these circumstances, the initial evaluation by the general surgeon is in actuality a triage function in which less consequential injuries may be taken care of by the general surgeon and the more consequential and complicated injuries are referred to a local or regional hand surgeon after initial triage and perhaps emergency management. It behooves the general surgeon to be familiar with the basics of hand anatomy and the principles of a hand examination. Drs. Mailey and Neumeister present a systematic approach to the evaluation of the injured hand founded on the anatomy of the structures, the knowledge of how to do a relevant and focused examination, and an understanding of the principles of treatment.

Traumatic injuries of the hand may occur from laceration or crush accidents. A full understanding of the anatomy of the hand is essential to developing a treatment plan based on a sequential and structured physical examination, rather than haphazard probing of the injured limb. The hand has six distinct structure including the bone, tendon, nerve, blood vessel, joint, and skin. Complex injuries of the hand involving any combination of these structures can be challenging largely owing to the uncertainty of what structures should be treated first.

The first principle is that "Life over Limb" the second above all else do no harm! Chang in the 6th edition described the Do's and Don'ts of the initial

evaluation and management of the patient with an injured hand. I think they are well worth repeating (Table 17.1).

The purpose of the hand examination is to understand the extent of injury. As noted by the authors, the complete examination of the hand does not need to be time intensive, but rather a rapid, sequential examination of the hand and upper limb. The examination in the conscious and alert patient can yield important information about nerve and vascular damage. The injury should not be probed. Clearly, the physician must have a basic understanding of hand anatomy. The authors conceptual "high yield anatomy" is helpful. The key points to me are: compare to the opposite hand if it is uninjured, the three nerves, extrinsic and intrinsic muscles, the ulna as the flagpole and the radius, carpus and hand are the flag, eight carpal bones if the wrist, the thumb takes priority as it possesses 40% of overall hand function!

As the authors point out, after an initial hand examination "hand and wrist radiographs are essential in all hand trauma patients. X-rays are important even in patients with sharp lacerations or injuries, as foreign bodies can frequently be seen and lead to infections if not addressed."

When should a hand surgeon be involved in the emergency care of a hand injury patient? There are two situations in which such consultations are absolutely essential: (1) vascular problems that compromise the viability of the digits or the hand and (2) infection. If blood flow is compromised to the hand or fingers regardless of the mechanism of injury (crush or laceration), then immediate revascularization by an experienced microsurgeon is in order. Infections of the finger or hand that need to be drained, such as bacterial tenosynovitis, should be considered surgical emergencies. It is important that abscesses be properly drained, particularly for patients who are immunocompromised. The majority of other hand injuries can be referred to a hand surgeon for elective treatment including digital nerve injuries that can be repaired within 2 to 3 weeks, tendon injuries that can be repaired within 10 days, and displaced fractures that may be reduced in the emergency setting with definitive fixation within 1 or 2 weeks.

Traumatic hand or digit amputations can be catastrophic injuries and often occur in young productive patients. Figures from the US national database have shown that amputation injuries represent 1% of all trauma occurrences. Finger and thumb amputations were most common (69%). Patients with amputations involving the fingers or thumb are assessed according to the Advanced Trauma Life Support (ATLS) protocol and resuscitated. A detailed history should include the time of injury to establish the duration of ischemia, the mechanism of injury, any coexisting injuries, age, handedness, occupation and hobbies, general medical status (especially in relation to diabetes, vascular diseases, and smoking), and patient's expectations. These are considered important when deciding whether replantation is technically possible and result in a functional outcome. If the amputation results from a severe crush injury, then replantation is less likely to be successful.

TABLE 17.1 Do's and Don'ts of Assessing a Patient with Hand Injury

Do's	Don'ts
1. Put the patient in a quiet room for hand examination. 2. Examine the patient expediently. 3. Give pain medicine and local anesthesia after full sensory examination. 4. Irrigate the wound copiously with saline and suture close the wound, for nonurgent injuries. 5. Get x-rays to evaluate potential bone injuries. 6. Consult a hand surgeon expediently if an operation is required immediately, such as a devascularized limb or severe infection that requires urgent drainage.	1. Probe the wound. 2. Give pain medicine until after a full examination. 3. Give local anesthesia until after the sensory examination is done. 4. Close a contaminated traumatic wound.

Key to successful replantation is the management of the amputated part. This is particularly true if the patient will require transport. There should be minimal handling of the part. The amputated part should be placed on a sterile towel, photographed and radiographed. An effort should be made to preserve any and all amputated fragments as these may be used for skin, bone, or nerve grafting. In order to detect any unexpected bony injuries that may preclude replantation, radiologic imaging of the stump and the amputated part in two planes is essential before a decision to attempt replantation.

Preservation of the amputated part is critical. It should be wrapped in sterile saline soaked gauze, placed in a sealed plastic bag, and either refrigerated at 4°C or placed in iced water solution without placing it directly on ice because this can cause frostbite. Muscle has the highest metabolic demand of any tissue, and deteriorates rapidly during warm ischemia. At 20°C to 25°C, irreversible muscle damage may occur after 6 hours. Replantation is not recommended when warm ischemia time has exceeded 10 to 12 hours for a digit. The technique of preservation described above can extend the ischemia time. Amazingly, successful digital replantation of a preserved finger has been reported after a delay of up to 94 hours.

Fingertip injuries can occur in accidents at home, work, or play. An injury can involve a sharp cut, a crushing injury, a tearing injury, or a combination. If the fingertip is completely amputated, it should be managed as outlined above. After gently cleaning with sterile saline solution, it should be covered in a moistened gauze wrap and placed it in a watertight bag and placed in ice in a sealed container or another watertight bag. Again the amputated part should not be in direct contact with ice as it could be damaged further.

If there is a small fingertip wound which is not deep enough to expose bone, it may heal on its own. A protective dressing is placed over the wound and you may recommend a splint to protect the area while it heals. After about 24 to 48

hours, it is recommended to soak the finger daily in a solution of warm, soapy water or saline solution with peroxide or Betadine. After 48 hours, range-of-motion finger exercises may be started to avoid stiffness. Complete healing usually takes from 2 to 4 weeks, although stiffness and hypersensitivity may remain longer, depending on the severity of the injury.

If the fingertip wound is large and open, there may be insufficient remaining skin to heal and cover the open area. In some cases, the wound may be left open to heal by secondary intention. If it is deemed that simple closure or healing by secondary intention is not appropriate, then referral to hand surgeon should be considered for skin grafting or reconstructive surgery.

Michael S. Nussbaum and Michael Latzko

INTRODUCTION

The human nature of the surgeon has been to gain the maximal access to the surgical area of interest while inflicting as minimal trauma to the patient as possible. As operative techniques and technologies have evolved, the ability to achieve that goal has advanced tremendously. Surgeons have gained the ability and technical expertise first to make smaller, more strategically located incisions for open surgical access, then to perform the same operation utilizing surgical telescopes and minimal access tools. Finally, through the use of computer-aided technologies and robotics, surgeons are now able to further gain full access to what otherwise would have been difficult-to-approach surgical areas of interest while achieving nearly negligible secondary surgical trauma to the patient.

The minimally invasive surgical revolution began three decades ago with the advent of videochip technology. Since that time, the laparoscopic approach to a wide variety of surgical procedures has become the preferred choice. This allows surgeons to perform a wide variety of operations using small incisions, videoscopes, and long instruments. The benefits of minimally invasive procedures are many including decreased length of hospital stay, less pain and scarring with smaller less obvious incision(s), less risk of infection, less blood loss and fewer transfusions, an accelerated return to normal activities, decreased need for postoperative narcotics, and an overall faster recovery. However, laparoscopic surgery requires a unique set of skills, which may be difficult for some surgeons to acquire. There are also a number of technical limitations to a laparoscopic approach, including a lack of three-dimensional (3D) visualization, limited range of motion due to rigid instrumentation, poor ergonomics, counterintuitive motion, amplification of physiologic tremor, decreased sense of touch, and the fulcrum effect. Robotic integration allows a surgeon to perform more complex minimally invasive procedures utilizing enhanced 3D visualization, improved dexterity, increased range of motion, improved ergonomics, and superior access to difficult to reach areas of the

body. This translates to more minimally invasive procedures with increased technical precision. The next generation of robots are being built smaller, smarter, and at a decreased cost. As these technologies continue to demonstrate their utility and value in improving the surgeon's ability to safely and superiorly treat disease, their use will ultimately become ubiquitous in the operating room much as the surgical telescopic devices have infiltrated surgical practice in recent years.

For the patient, a robotic-assisted procedure offers all of the potential benefits of a minimally invasive operation and clinical studies suggest that robotics may help surgeons provide better clinical outcomes than conventional technologies allow in certain specific clinical settings. Robotics also provides a unique possibility of separating the surgeon from the patient. This separation can be measured in feet or in thousands of miles. Telesurgery along with telementoring has now been tested in several environments and shown to be feasible and beneficial. The removal of a gallbladder across the Atlantic Ocean and the mentoring of surgeons in Canada are examples of how technology is rapidly approaching the day when any surgeon can be connected to a number of colleagues who may be able to consult and in some cases assist during complex surgical procedures. Other robotic technology allows the surgeon to make rounds while sitting in a remote location allowing "telepresence." This enables the physician to be remotely present by controlling robot movements via the Internet. Patients surveyed felt that such encounters are positive and were able to completely believe that they were communicating with their physician in person even if the physician was far removed from the bedside.

Hurdles to overcome include developing and improving the technology and its limitations, improving physician training and expertise to maximize their abilities to safely and effectively use these tools, incorporating the latest available technology into the surgical education of various disciplines, and of course managing the increased cost in a manner that will ultimately allow patients' increased access to the best care available.

ROBOTIC PLATFORMS AND EVOLUTION

The early 2000s brought the convergent digital technology revolution, leading to significant enhancements in information, simulation, telecommunication, and robotic technologies. Historically, current commercial robotic systems for medical use originated from two major

research efforts. The National Aeronautics and Space Administration (NASA) developed robotics initially for space operations, but under a NASA Small Business Innovation Research Contract from the Jet Propulsion Laboratory, Computer Motion Inc., Santa Barbara, CA, developed the Automated Endoscopic System for Optimal Positioning (AESOP)—a robotic arm system whose applications entered the operating room allowing the surgeon to control the surgical camera first with a foot–pedal interface, then later by voice commands. Computer Motion Inc. subsequently developed the Zeus Robotic Surgical System, which was a master-slave robotic system that allowed the surgeon to control up to three surgical arms in addition to the camera system from a separate control console. In parallel, the Defense Advanced Research Projects Agency (DARPA) was developing robotics for battlefield needs including providing remote surgical care in the field.

The Stanford Research Institute (SRI) developed a robotic surgical system with research funded from the National Institutes of Health and with interest from DARPA. Ultimately, becoming the da Vinci Robotic Surgical System by Intuitive Surgical of Mountain View, CA, the *da Vinci*® robot is a master-slave robotic system with some very distinct advantages over its progenitors and conventional laparoscopic surgery. The system has 3D stereoscopic visualization of the operating field, a 7-degree range of motion, tremor elimination, and comfortable seated operating posture. The target anatomy appears at high magnification, in brilliant color and with natural depth of field. The *EndoWrist*® instruments exceed the natural range of motion of the human hand, thus allowing wristed and finger movements that standard laparoscopic instruments do not have; sophisticated motion scaling and tremor reduction further interpret and refine the surgeon’s hand movements. These advantages provide surgeons with hand-like dexterity and enhanced precision through minimally invasive techniques that more closely mimics open surgery. Other robotic systems being developed today include *RoboDoc*® (Curexo Technology Corp., Fremont, CA), *Acrobot*® (London, England), and *SPORT*® (Single Port Orifice Robotic Technology) (Titan Medical Inc., Toronto, Canada).

The *da Vinci* surgical robotic platform has gone through four major system overhauls since its development and release in 1999. Although the core design of the system has remained unchanged, several significant modifications and additions have been introduced since its inception. The

system has a surgeon console where the operator receives a binocular image from the surgical field and operates the robotic arms through a computerized system using master controls. The image is acquired and delivered simultaneously to the console's two monitors and is observed in a parallel binocular fashion by the surgeon's eyes, allowing a magnified 3D stereoscopic view with depth perception. The position of the camera is controlled by the operator at the console. The instrument tips have seven degrees of freedom and wrist action controlled by the surgeon hand controls at the console allowing more complex and delicate tasks than the standard laparoscopic instrumentation at the tissue level. A clutching system allows readjustment of the surgeon hand positions at the console to maintain ergonomic control of the instruments within the surgical field of interest.

The *da Vinci* robot was first introduced to the market in 1999 and upgraded in 2003. The upgrade added a fourth arm to the initial three arm configuration allowing the console surgeon to have greater control of retraction and dissection without reliance on a skilled assistant. The *da Vinci* Surgical System, released in 2006, added high-definition (HD) vision and multi-image display, and is still in use at many institutions across the world today. The *da Vinci* Si was released in 2009 and added several notable adjuncts. Integrated fluorescence imagining capability was incorporated which provides real-time image-guided identification of key anatomical structures using near-infrared technology. It increased the capabilities of the robot immensely by allowing surgeons to perform real-time intraoperative angiography, cholangiography, and other tasks without any additional equipment needs or setup. Dual console capability was also later added to this model, which revolutionized the robotic training regimen, and enabled the fourth arm to be used at the same time as the other three. The second console allows two surgeons to visualize the 3D field simultaneously, as well as swap control of one or more arms between surgeons. Stapling and vessel sealing devices were later also added to the *da Vinci* Si armamentarium of instruments.

Figure 18.1. *da Vinci* Xi robotic surgical arm cart featuring extendable rotating boom. (© 2018 Intuitive Surgical, Inc., Sunnyvale, CA, USA. Used with permission.)

The most current generation of the da Vinci robot at the publication of this chapter is the Xi that was released in 2014 and stands to make this generation of robots the most accessible and user-friendly yet. The upgrades to this platform corrected many of the limitations of the earlier systems that restricted many surgeons' enthusiasm to incorporate robotic technology into their skill set. Two of the most significant limitations of the first three generations of robots were the time involved in docking the robot as well as a very narrow surgical field. The previous generations of robots had a mobile patient cart on which fixed robotic arms were mounted, which is driven to the side of the patient's bed to allow docking of the robot arms and severely limited the working space of the robotic arms in the surgical field based on the location of the cart. For example,

surgery in more than one quadrant of the abdomen was nearly impossible without undocking and maneuvering the patient cart; a time- and labor-intensive process. The Xi, however, utilizes a completely redesigned surgical cart that combines extendable, articulating, boom-mounted robotic arms with the flexibility of a mobile cart (Fig. 18.1). This new cart works with newly tooled software and targeting algorithms to standardize and automate a large percentage of the docking process after the user simply chooses the operation to be performed and the desired location of the patient cart. New port, robotic arm, and camera designs allow the camera to be placed in any working port. These and several other small changes enable robotic surgery in a much wider surgical field, more similar to conventional laparoscopy and thoracoscopy.

The U.S. Food and Drug Administration (FDA) has cleared the da Vinci Surgical System for use in urologic surgical procedures, general surgical procedures, gynecologic surgical procedures, transoral otolaryngology surgical procedures restricted to benign and malignant tumors classified as T1 and T2, general thoracic surgical procedures, and thoracoscopically assisted cardiotomy procedures. The system can also be employed with adjunctive mediastinotomy to perform coronary anastomosis during cardiac revascularization. The system is indicated for adult and pediatric use and was recently approved for transoral otolaryngology surgical procedures. It is intended for use by trained physicians in an operating room environment in accordance with representative, specific procedures set forth in the Professional Instructions for Use.

Representative Uses: According to Intuitive Surgical, Inc., the da Vinci Surgical System has been successfully used in the following procedures, among others:

1. Urology
   - Radical prostatectomy, pyeloplasty, cystectomy, nephrectomy, ureteral reimplantation.
2. Gynecology
   - Hysterectomy, myomectomy, and sacrocolpopexy.
3. General Surgery
   - Cholecystectomy, hernia repair, Nissen fundoplication, Heller myotomy, gastric bypass, gastrectomy, donor nephrectomy, adrenalectomy, splenectomy, and bowel resection.
4. Cardiac Surgery

- Internal mammary artery mobilization, cardiac tissue ablation, mitral valve repair, endoscopic atrial septal defect closure, and mammary to left anterior descending (LAD) coronary artery anastomosis for cardiac revascularization with adjunctive mediastinotomy.

5. Otolaryngology
   - Oropharyngeal, laryngeal, and hypopharyngeal resections; floor of mouth and oral cavity resections.
6. Endocrine Surgery
   - Thyroidectomy, parathyroidectomy, adrenalectomy, partial and total pancreatectomy.

EQUIPMENT AND SETUP FUNDAMENTALS

Principles of triangulation are generally employed with robotic system setup, although with the release of the *da Vanci® Xi*, the stringency of the setup requirements have decreased significantly. Most commonly, the patient cart, camera arm, and camera port are aligned in a straight line with the field of interest. The two working ports are placed on either side of the camera, allowing triangulation to the target field, with the fourth port being ideally placed on the side to be controlled by the surgeon's dominant hand. In situations where abdominal access is gained from a small area at the skin level, as in single incision surgery, curved cannulas are used and the working ports are reversed to allow a wide degree of freedom within the cavity, maintaining triangulation and minimizing equipment conflict.

Cannulas are marked with a fulcrum point such that when the ports are inserted into the cavity of interest to the depth noted on the cannula, the full range of motion is optimized by the premeasured fulcrum point into this remote center of focus as designed in the translational software of the robotic system to minimize torque applied to the patient at the port entry site. Standard robotic cannulas are 8 mm currently and can accommodate most 5 to 8mm robotic instruments, with the exception of the robotic stapling device which requires a 12 mm cannula. Finally the camera and instrument arms are docked while utilizing arm clutches to maximize the space between the instrument arms (Fig. 18.2).

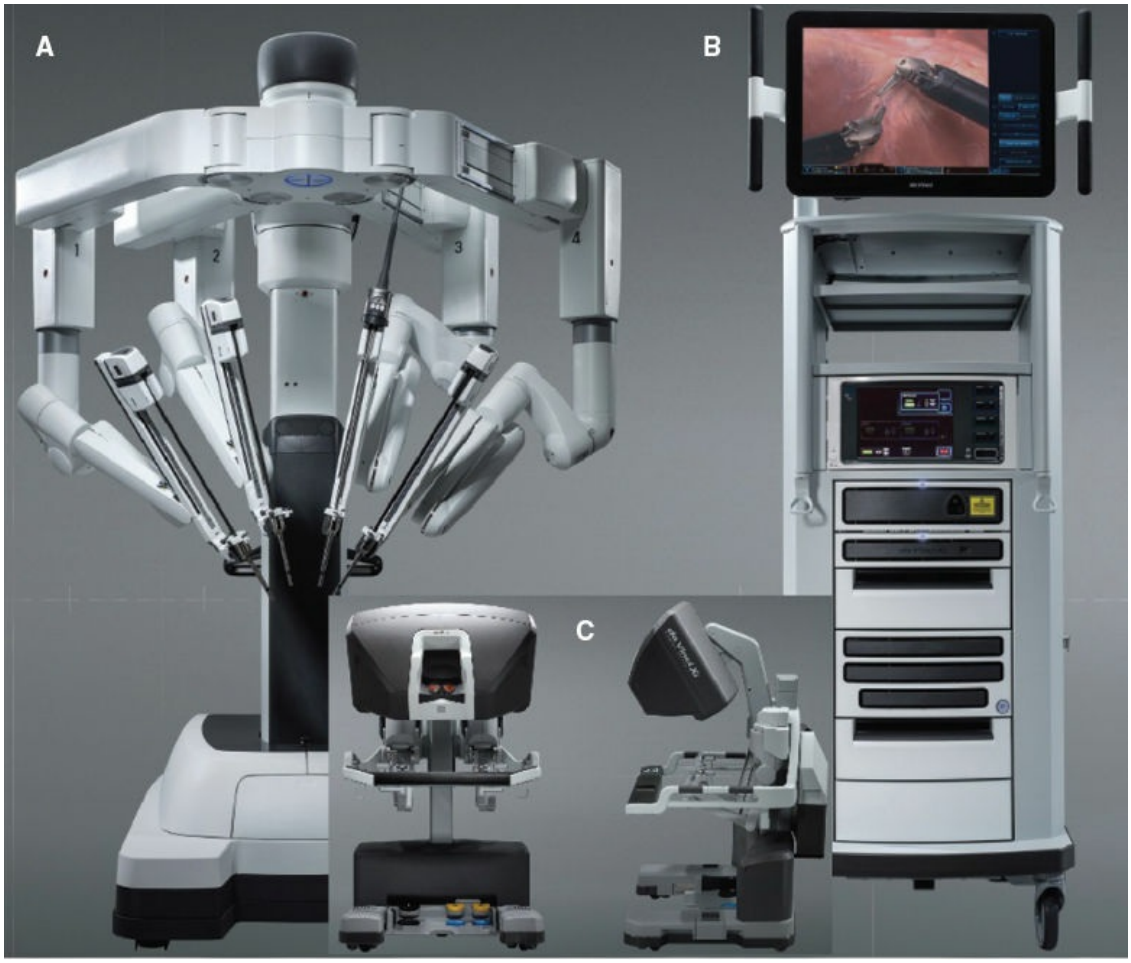

Figure 18.2. (**A**) Surgical arm cart in stowed position, (**B**) control tower, and (**C**) dual surgeon console. (© 2018 Intuitive Surgical, Inc., Sunnyvale, CA, USA. Used with permission.)

ROBOTIC SYSTEM SUMMARY

1. Surgeon console: The surgeon operates while seated at a console using four pedals, a set of console switches, and two hand controls. The movements of the surgeon's fingers are transmitted by the hand controls to the instrument located inside the patient. A 3D image of the surgical field is obtained using a telescope, which contains two cameras that integrate images.
2. Control tower: This component contains a monitor, light sources, and cord attachments for the cameras.
3. Surgical arm cart: This component provides four robotic arms, three instrument arms, and one endoscope arm, which execute the surgeon's commands.
4. Detachable instruments

GENERAL SURGERY

Robotic Foregut Surgery

Gastric Fundoplication and Paraesophageal Hernia Repair

One of the earliest applications of the robot in general surgery was performed in the area of antireflux surgery. The first two cases of robot-assisted Nissen fundoplication were performed by Cadiere et al. in Brussels utilizing the first-generation three-arm Mona *da Vinci*® robot. Comparisons of laparoscopic versus robotic Nissen fundoplication in multiple subsequent trials have demonstrated relatively equivalent results with low morbidity and similar outcomes but with longer operative times at a much greater cost. Increased cost for the robot-assisted cases was attributed to many causes, ranging from the initial investment and maintenance of the technology, to costs for the specialized robotic instrumentation with a limited number of uses, to the increased staff and hospital costs for longer cases. In a retrospective review by Ceccarelli in 2009 comparing robotic fundoplication to conventional laparoscopic fundoplication he noted that subjectively, surgeons felt as though the robot's maneuverability and image magnification facilitated hiatal dissection and made the procedure easier. However, these subjective improvements did not correlate with a measurable improvement in patient outcomes.

Discordance between the surgeon's impressions and the objective results of the procedure is a common finding in studies dealing with robot-assisted surgery. It is conceivable that the exclusive use of robotics in the more difficult procedures could impart a real advantage with regard to improved precision, ergonomics, and tissue handling. Such advantages might be beneficial in the more complex cases involving large paraesophageal hiatal hernias requiring more intricate dissection and manipulation or in the setting of reoperation as improved visualization of the anatomy with the magnified 3D, HD stereoscopic camera facilitates fine dissection with stable, articulating tools, thus allowing the surgeon to successfully and safely identify vital anatomy such as the vagus nerves, aorta, vena cava, pleura, and pericardium in the often difficult reoperative field. Although it is true that no randomized controlled data exists to demonstrate the superiority of robotic antireflux procedures or hiatal hernia repair when compared with conventional laparoscopy, it is fair to note that all relevant existing data on this subject was gathered utilizing already outdated generations of robots by surgeons who were still

experimenting with the optimum setup and application of robotics for this procedure. As operative times and costs decrease, and available instrumentation and mechanical assistance continue to improve, surgeons will be hard-pressed not to choose the approach that provides better visualization and dissection capability.

Heller Myotomy

Achalasia is a rare condition of the esophagus, with an estimated annual incidence in the United States of about 1 in 100,000 individuals. Laparoscopic lower esophageal sphincter myotomy, or Heller myotomy, has become the gold-standard surgical treatment option of achalasia. The minimally invasive approach has proved effective at relieving symptoms in >90% of patients. Mucosal perforation is the most significant complication specific to this procedure with a reported incidence of 1 to 15%. Although a recognized mucosal perforation which is adequately repaired at the time of myotomy has not been demonstrated to adversely affect clinical outcomes, it does take time and skill to repair such a perforation and an undetected or inadequately repaired perforation can be catastrophic. Melvin et al., in a series of 104 patients who underwent robotic Heller myotomy, reported no esophageal mucosa perforations and suggested that the robotic approach may provide superior outcomes. Horgan and colleagues later performed a prospective multi-institutional study comparing 121 patients (62 laparoscopic patients vs. 59 robotically assisted) and demonstrated a 0% perforation rate in the robotic-assisted myotomy group compared to 16% in the laparoscopic group. The authors believe that the magnified 3D visualization of individual muscular fibers and transition to mucosa afforded by the robotic-assisted approach along with superior freedom of movement and instrument control were paramount to ensuring an adequate and safe myotomy. Furthermore, although operative times were initially substantially longer in the robotic-assisted group, in the last 30 cases there was no difference in operative times between the two groups. These observations have been duplicated in subsequent studies by our group and others.

The operative technique for the robotic-assisted procedure is essentially the same as the laparoscopic approach described later in our chapter on the minimally invasive treatment of achalasia with a few small caveats. Because of the increased working length of the robotic endoscope and instruments, the ports should be placed at least 2 cm further caudad and about 4 finger-breadths apart to maximize the strengths of the robot while

allowing full range of motion of the robotic arms without external arm clashing. Additionally, the ports should be placed in a straight line across the abdomen because the working distance of the ports from the operative field is less of a concern in robotic surgery than conventional laparoscopic surgery. However, optimal port placement sites and spacing will likely change with subsequent generations of robots, and general principles of robotic port placement should be followed as opposed to a procedure-specific selection. The right lateral subcostal port is still used for the static placement of a 5 mm liver retractor; the other three ports are for robotic instruments and can be either 8 mm or 5 mm in size depending on the size of the robotic hand instruments available. An additional port can be placed on the far left for the fourth arm to assist in retraction.

Bariatric Surgery

Roux-en-Y Gastric Bypass

Robotic technology has become increasingly prevalent in bariatric surgery. The first robotic Roux-en-Y gastric bypass (RYGB) was reported by Horgan and colleagues in 2001. Since that initial report, several major large studies have compared robotic RYGB to the conventional laparoscopic approach. The largest study published to date, from the University of Texas at Houston compared 320 robotic RYGB to 365 laparoscopic RYGB. They noted the robotic group to have a substantially lower gastrointestinal leak rate (0% vs. 1.7%) and a major complication rate of only 2.8%. The robotic approach has been noted to facilitate a hand-sewn anastomosis and in a major systematic literature review comparing the laparoscopic approach with the robotic one, anastomotic strictures occurred at a lower rate in robotic patients with hand-sewn anastomoses. Interestingly enough, although cost has always been one of the greatest deterrents to robotic adoption, a study published by Hagen et al. in 2012 compared a laparoscopic RYGB using stapled anastomosis with robotic cases performed using a hand-sewn technique and found the robotic cases to be lower in cost. Furthermore, with regard to costs, extra overheads of the robot are absorbed by the hospital by increasing market share, and probably result in increased revenue when properly marketed as patients often seek out new technology. This fact is especially evident in bariatric surgery. Robotic-assisted RYGB has been demonstrated to be safe with similar if not better outcomes than laparoscopic surgery. The robot may shorten the learning curve and is not necessarily more

expensive than the laparoscopic approach.

Sleeve Gastrectomy

Robotic-assisted vertical sleeve gastrectomy has become more widely utilized as results of laparoscopic sleeve gastrectomy are confirming the long-term success of this surgical option in bariatric patients. The advantages of robotic technology have been described in super morbidly obese (BMI >60 kg/m^2) patients. It can liberate the surgeon from torque, which is often substantial in the laparoscopic approach because of the thickness of the abdominal wall. It can also decrease port site trauma because of the remote center technology; however, more studies are needed to adequately define the degree of this benefit. Particularly useful is the facilitation of hand-sewn staple line reinforcement which was reported to be an acceptable practice by the International Sleeve Gastrectomy Expert panel in 2011, although no consensus has ever been reached as to whether this practice does in fact decrease the incidence of bleeding or gastric leak.

Robotic sleeve gastrectomy was recently reported to be an excellent procedure to incorporate into resident education, since less than 10% of surgical residents today have any experience operating the robotic console despite the recent boom in robotic surgery. In a study by Ecker and colleagues in 2015, the learning curve of surgical residents was examined when they were the exclusive operator of the robot console, after completing online training. They were observed to have a very short learning period before initial plateau of only five cases despite it being their first exposure to the robotic interface. The total cost difference between a laparoscopic versus robotic sleeve gastrectomy was noted to be $349.00 in this study with comparable operative times after the initial five cases. The increased cost of utilizing the robot for this procedure should be weighed against potential for resident education and enhanced ergonomics.

Adjustable Gastric Banding

Cadiere and colleagues reported the first robotic gastric band placement in 1999. Utility of robotic assistance in adjustable gastric banding has been demonstrated in the super morbidly obese for some of the same reasons noted regarding robotic sleeve gastrectomy. However, the success of adjustable gastric banding in these patients compared to other operations such as sleeve gastrectomy or gastric bypass should be considered.

Colorectal Surgery

Minimally invasive colorectal surgery has evolved dramatically since the first reports of laparoscopic colorectal operations in 1991. Laparoscopic colectomy for both benign and malignant disease has been shown in numerous randomized studies to provide decreased patient morbidity, reduced hospital stays, lower surgical site infection rates, less postoperative pain, and faster recovery with improved cosmesis and patient satisfaction when compared to open operation. Despite these notable benefits, laparoscopic adoption across the country has been variable and relatively slow and a study by Stamos et al. in 2015 demonstrated an overall national implementation rate of 55%. This under-utilization of laparoscopic colectomy in spite of overwhelming evidence of its superiority is likely not due to lack of appropriate equipment as laparoscopy has become ubiquitous in all US hospitals, but rather due to inherent shortcomings of laparoscopy. These limitations include amplification of physiologic tremor, dependence on a skilled assistant, comparatively low-quality 2D imaging, reduced dexterity in dissection and suturing, and a relatively slow learning curve even with formal laparoscopic skills training.

In recent years, there has been a growing interest in robotic colorectal surgery, evidenced by the steady increase in the number of publications on this subject every year. The first robotic colectomy was reported in 2002 by Weber, and several studies soon followed touting reduced blood loss, decreased conversion rates, and shorter hospital stays with the robotic approach when compared to the conventional laparoscopy albeit at an increased cost. In a recent study by Pryor et al. comparing laparoscopic versus robotic-assisted outcomes of five major common general surgical procedures, colectomy was the only procedure noted to have a significantly higher rate of overall complications and length of stay in the laparoscopic group. There are several theoretical advantages to the robotic approach. First, stable camera positioning combined with 3D imaging, digital zoom, and articulating instruments provides excellent visualization without the crowding and clashing of instruments and camera that often makes dissection in the narrow confines of the pelvis quite challenging. Second, the fourth arm can act as a fixed retractor and is not subject to fatigue and tremor like a skilled assistant. Third, fine motion scaling and tremor filters enable the robot to simplify complex surgical maneuvers such as suturing or creation of an intracorporeal anastomosis.

Intracorporeal anastomosis has been reported to contribute to faster bowel recovery due to decreased visceral trauma and stretching, which may explain why this phenomenon has been observed in several robotic colectomy studies. Moreover, the robot also allows for a somewhat smaller extraction site, which could decrease surgical site infections and hernia rates with slightly improved cosmesis. For these reasons, while robotic-assisted colectomy adoption rates are still low nationwide, robotic colon resection has become the preferred minimally invasive operative approach at numerous academic institutions and community hospitals alike.

Robotic surgery in multiple abdominal quadrants was initially problematic and several early strategies for robotic left-sided colectomies supported a hybrid approach, taking down the splenic flexure laparoscopically first and then docking the robot. However, as robotic technology has improved with the release of *da Vinci Xi*, fully robotic left colon, total colon, and rectal cancer resections have been described without the need to move the robotic patient cart (Fig. 18.3).

Abdominal Wall Hernia Repair

Although repair of an abdominal wall hernia is one of the most commonly performed operations by general surgeons worldwide, utilization of robotic-assisted technology for these procedures has been largely overlooked until recently. Interest in robotic ventral and inguinal hernia repair has grown rapidly in the last decade. This growth in the utilization of robotics for hernia repair has been prompted primarily by several trends in the literature. First, with regard to ventral hernias, evidence is growing steadily that primary suture closure of the hernia defect prior to mesh underlay can reduce hernia recurrence rates. Laparoscopic transfascial suture placement to close these defects is often challenging, associated with increased pain, and at times impossible altogether in patients with large hernia defects. Robotic-assisted ventral hernia repair allows for precise and easy intracorporeal suturing in an ergonomically friendly environment. This allows the surgeon to close abdominal wall defects primarily using a running continuous suture to distribute tension evenly along the suture line as well as secure the mesh to the abdominal wall with suture obviating the need for a helical tacking device. Although more randomized-controlled data is needed, this should provide for lower recurrence rates with less pain along with improved visualization and ergonomics for the surgeon. Second, little has drawn more attention to

improvement of hernia repair in the last two decades than the popularization of the component separation technique. First introduced by Oscar Ramirez, MD, in 1990, anterior component separation utilized a release of the external oblique allowing for midline advancement to facilitate primary fascial closure. In 2006, Novitsky and Rosen developed a novel technique for posterior component separation using transversus abdominis release for repair of large complex ventral hernias. Although the technique was originally developed for open repair, surgeons quickly realized that the procedure could be performed in a minimally invasive fashion by using the robot. The robot enables the surgeon to dissect and suture at difficult angles, in confined spaces, and perform a component release without creation of large subcutaneous flaps or subcutaneous tunnels.

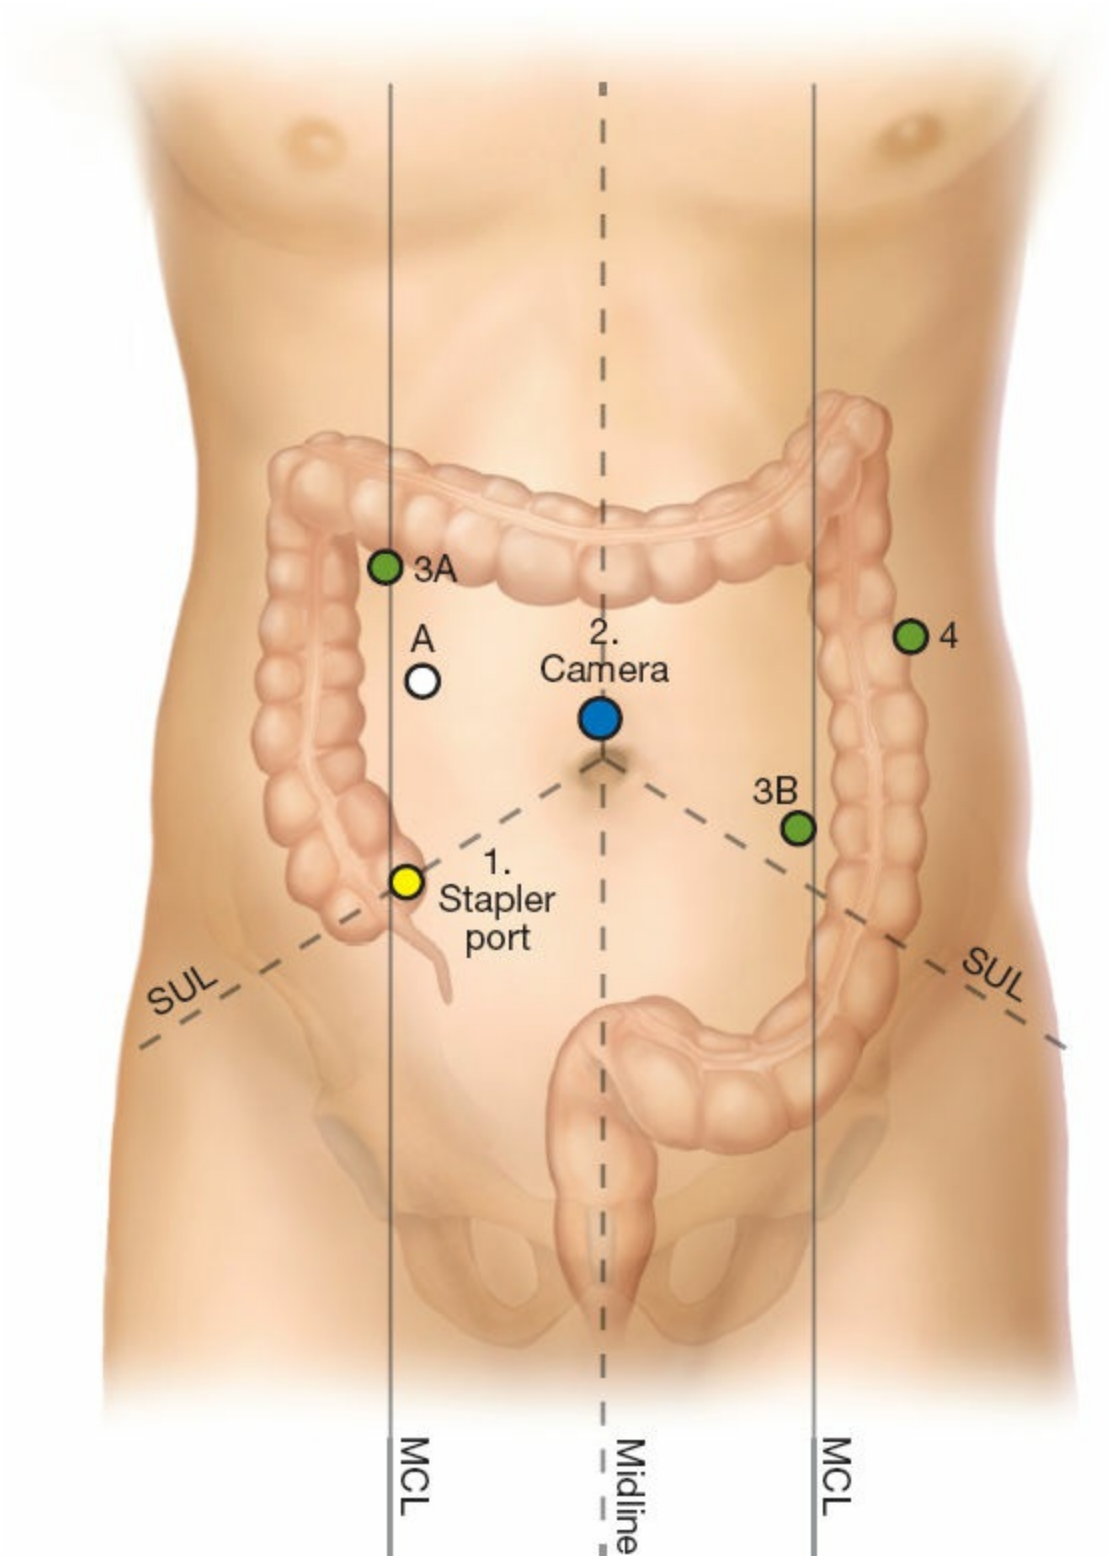

Figure 18.3. Potential port placement for robotic-assisted left colectomy. Numbers correspond to docking position of da Vinci arms. (Arm 1) 12 mm port to accommodate stapler. (Arm 2). Camera port. (A) assistant port. (3A) Position of arm 3 during mobilization of traverse colon, descending colon, and splenic flexure. Can also be used as assistant port once arm moved to 3B position. (3B) Position of arm 3 during pelvic dissection or

ascending colon mobilization. (4) Arm 4 is docked after descending colon and splenic flexure mobilization to aid in remaining dissection.

In regard to inguinal hernia repair, the benefits provided by the robotic platform are less pronounced. Robotic transabdominal preperitoneal inguinal hernia with suture fixation of the implanted mesh has been shown to be feasible in several reports, but no superiority to standard laparoscopic repair has ever been demonstrated. However, since a balloon dissector and tacking device are not used in the robotic approach when compared to the laparoscopic totally extraperitoneal approach, costs are very similar between the two with the robotic technique being much more ergonomically comfortable for the surgeon. Robotic inguinal hernia repair also presents a unique opportunity for resident education in that the procedure is not particularly challenging, costly, or time-consuming and residents can quickly become facile with robotic techniques and instrumentation without additional burden on the institution.

Thoracic Surgery

Noncardiac Thoracic Surgery

Minimally invasive thoracic surgery has come a long way since its inception. Several additional developments may change how we use robotics in the near future. These new technologies are still in an experimental stage but offer a glimpse of what the next generation of robots will offer.

Esophageal Surgery

Esophagectomy for benign or malignant disease can be associated with a high morbidity and mortality rate. Minimally invasive esophagectomy was first reported and popularized by Luketich et al. in 1998. Its role has been well established following multiple institutional series and systematic reviews which have shown its superior outcomes to open esophagectomy. It has always been a technically challenging operation and as surgical techniques have evolved, surgeons have begun to employ robotic assistance.

Horgan and colleagues reported their initial experience with a case of robotically assisted transhiatal total esophagectomy in 2003. The total operative time was 246 min and the patient lost <50 mL of blood. There

were no major perioperative complications. In their report, the authors comment that the 3D image and the articulating wrists allowed them to perform a nearly bloodless dissection of the esophagus. In addition, they found that they could mobilize the esophagus beyond the level of the carina through a transabdominal robotic approach. These surgeons felt that this was due to the fact that the robotic instruments are 7.5 cm longer than standard laparoscopic instruments. A thoracoscopic approach to complete esophageal dissection and mobilization was avoided in this case. The robotic-assisted transhiatal approach has also been validated by Gutt et al. for patients who are too ill to undergo an Ivor-Lewis approach with single-lung ventilation.

Kernstine and colleagues reported their experience using the robotic platform for the thoracic and abdominal portion of a three-field esophagectomy in 2007. However, they noted long average operative times of around 11 hours and were only able to complete the operation robotically in 8 of 14 patients.

Cerfolio et al. reported the first series of robotic cases with an intrathoracic anastomosis. The authors noted a significantly high morbidity and leak rate in the initial six patients undergoing a posterior stapled and anterior hand-sewn anastomosis. The remaining 16 patients in the study underwent a robotically hand-sewn anastomosis with substantially decreased morbidity and no leaks leading the authors to advocate this approach for robotic esophagectomy. Median operative time was initially 556 minutes, which dropped to 414 minutes for the last five cases.

The largest series of robotic-assisted Ivor-Lewis esophagectomy was published by de la Fuente et al. reporting their initial experience with this approach at the H. Lee Moffit Cancer Center and Research institute (Tampa, Florida). Fifty patients with esophageal cancer were included in the study. A median hospital stay of 9 days was observed, with two patients experiencing gastrointestinal leak. The authors noted a lower postoperative morbidity, higher lymph node yield, and higher R0 resection rates when compared with their historical reported outcomes. Median operative times were reduced from 479 to 414 minutes during the second 25 cases. The authors attributed the steep learning curve to a relative lack of standardization of robotic techniques.

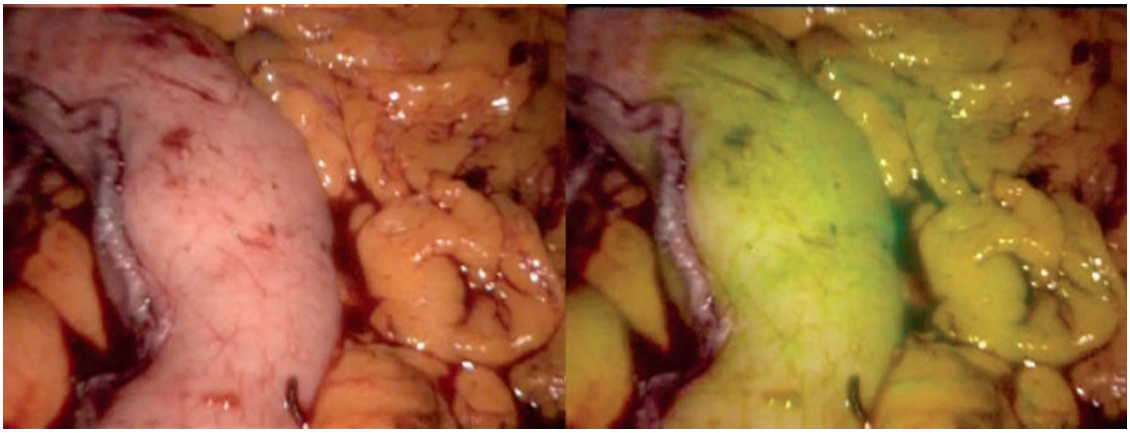

Figure 18.4. Florescent angiography demonstrating areas of perfused (shown in green) and un-perfused stomach during creation of gastric conduit.

A potential advantage of robotic assistance is the ability to assess gastric conduit and esophageal remnant perfusion in real time using fluorescence angiography. Intraoperative fluorescence angiography using near-infrared fluorescence imaging allows for the visualization of vascular structures and therefore organ perfusion after administration of indocyanine green (ICG) (Fig. 18.4). Near-infrared fluorescence imaging platforms are commercially available for open, laparoscopic, and robotic systems. However, in the robotic platform the technology is fully integrated and does not require purchase of additional equipment or require additional setup. A dramatic decrease in anastomotic leak rates from 20% to 0% was reported by Campbell et al. when ICG fluorescence angiography was performed to assess conduit perfusion using the SPY Elite System (LifeCell, Bridgewater, NJ) for open surgery. These results have yet to be duplicated in totally robotic groups. Feasibility studies out of Henry Ford and Memorial Sloan Kettering describe intraoperative fluorescence angiography as a useful adjunct to gastric mobilization and conduit formation that may help prevent unintentional injuries, especially early in a surgeon's learning curve.

Robotic-assisted esophageal surgery is still in its infancy and experience is limited, but its applications continue to expand. No prospective randomized data comparing robotic esophagectomy with open or laparoscopic procedures currently exists. However, current trials including a study by Sarkaria and Rizk at Memorial Sloan-Kettering Cancer Center (ClinicalTrials.gov: NCT01558648), and a Dutch trial known as the ROBOT trial (ClinicalTrials.gov: NCT01544790) are

accruing patients to assess outcomes comparing robotic-assisted esophagectomy with open esophagectomy. Robot-assisted esophagectomy appears to be at least as safe and feasible as a traditional laparoscopic or thoracoscopic approach. Robotic instruments that are long and multiarticulated may facilitate the completion of minimally invasive esophagectomy to a greater degree than conventional rigid laparoscopic instruments in some cases. Further research and clinical experience in this area will be necessary to answer these questions.

Anterior Mediastinum

The narrow confines of the anterior mediastinum represent an anatomic area ideally suited for robotic surgery, and there have been numerous reports on the value of robotic surgery for mediastinal diseases. The treacherous anatomy in this region accentuates the maximal advantage gained by the use of 3D, magnified stereoscopic cameras to allow safe identification of vital structures during delicate dissection with increased dexterity and articulating instruments.

Robotic-assisted resection of a mediastinal mass was first described by Yoshino et al. in 2001. Robotic thymectomy is the most published operation in the mediastinum with over 3,500 cases of robotic thymectomy registered with Intuitive Surgical since that time. Early studies demonstrated the feasibility of robotic-assisted thymectomy with decreased risk of postoperative wound complications. Caker et al. published the first study comparing minimally invasive robotic thymectomy with the open approach via median sternotomy touting decreased complications and length of stay in the robotic group. Weksler and his colleagues published similar results the following year additionally demonstrating decreased intraoperative blood loss with acceptable complete remission rates in myasthenia gravis patients. Thymectomy can be performed through either a left- or right-sided approach depending on the preference of the surgeon and his interpretation of the advantages and disadvantages of each approach. The largest series of robotic thymectomies was reported by Ismail and colleagues including 317 patients utilizing a left-sided approach with three ports in all patients except those with a thymoma on the right side. Robotic-assisted thymectomy was compared to videothoracoscopic thymectomy by Rucker et al. who observed no differences in operative time, conversion rates, or intraoperative blood loss. Several surgeons who have performed over 100 thymectomies with the assistance of robotic technology report that the

improved dexterity and articulated instrumentation simplifies and expedites radical dissection of all thymic tissue.

Tumors occurring less frequently within the anterior mediastinum and posterior mediastinum have also been removed robotically. Robotic excision of neurogenic tumors, germ cell tumors, ectopic thyroid and parathyroid, esophageal and bronchogenic cysts has all been reported.

Pulmonary Resection

Video-assisted thoracoscopic surgery (VATS) has been practiced since 1991 and has been shown unequivocally to be safe and effective. Despite the mountain of data that VATS offers reduced postoperative pain, shorter length of stays, reduced chest tube duration, and improved aesthetics, it has not been widely adopted by the thoracic surgical community. The benefits of minimally invasive surgery for this patient population should not be ignored. Recent reviews have shown that only 30% of stage I lung cancer operations are currently being performed by VATS in the United States and that number is closer to 10% in Europe. Successful thoracoscopic surgery is surgeon-dependent and there are several reasons why the outcomes being claimed by large-scale expert VATS groups are not being reproduced uniformly across the thoracic surgical community.

Minimally invasive surgery in the thoracic cavity can be very challenging due to the variable space between the ribs to place trocars and instruments with the ribs often acting as fulcrum points that increase torque on the surgeon's instruments which are rigid and nonarticulating. This lack of maneuverability coupled with suboptimal 2D vision, lack of depth perception, uncomfortable surgeon position, and lack of scaling down movements can make dealing with the delicate pulmonary anatomy quite demanding.

With the technological improvements afforded by the robotic platform, surgeons now have the ability to perform more complex procedures where conventional VATS might fail. Robotic thoracic surgery still has a steep learning curve, and a study by Veronesi et al. estimated that a surgeon needs to complete at least 20 cases to obtain competency. However, this is largely affected by the lack of standardization of robotic surgical techniques as well as underdevelopment of robotic instrumentation, and the authors felt that the length of the learning curve was still far superior to that of conventional thoracoscopic surgery. The recent development of wristed robotic staplers and energy devices as well as improved docking capability of the *da Vinci Xi* will undoubtedly decrease operative times and

the surgeons' dependence on a skilled assistant.

A recent meta-analysis by Velez-Cubian examined 23 robotic VATS series in combination with 600 cases performed by their own group. They concluded that robotic VATS was largely equivalent to conventional VATS with the caveat that the meticulous and detailed lymph node dissection provided by the robot improved the early detection of metastatic disease and resulted in a nodal upstaging rate of 19%. A comparative study by Kent et al. analyzing the State Inpatient Databases (SID) recently reported the superiority of robotic-assisted lobectomy and segmentectomy when compared with both open and conventional VATS. The overall complication rate, mortality, and average length of stay were all lower in the robotic group. Robotic VATS appears to be a safe and appropriate alternative to conventional VATS with similar improvements in outcomes when compared to open thoracotomy. Its increasing popularity will likely result in a broader acceptance and application of minimally invasive techniques by thoracic surgeons.

Cardiac Surgery

Cardiac Revascularization

Coronary artery disease remains the leading cause of death in the United States. Myocardial revascularization, traditionally performed via median sternotomy, is an effective strategy to prolong survival; however, the morbidities associated with sternotomy and cardiovascular bypass are not inconsequential. The heart was the first area that the robot was felt to be useful; but robotic endoscopic coronary artery bypass graft (CABG) is still only rarely performed at a small number of specialized centers due to its high cost, need for highly specialized equipment, lack of full reimbursement, and technical complexity.

Totally robotic cardiac bypass can be performed with or without cardiopulmonary bypass utilizing a left chest approach. The left internal mammary artery (LIMA) can be harvested and a LIMA to LAD anastomosis performed utilizing automatic anastomosis devices or polypropylene sutures. Robotic surgery off pump was only recently made possible by the development of robotic endostabilizers which transform a moving target into a static one. Due to the relative novelty of this procedure, data is still scarce and relatively limited in scope. Seco et al. recently published a systematic review of arrested heart and beating heart cardiac bypass procedures. Conversion to sternotomy was required in

approximately 10% of patients. Comparison to sternotomy, robotic CABG was limited by strict selection of elective low-risk patients for the robotic procedures. However, in selected analyses robotic CABG appears to be associated with lower mortality, shorter hospital stays, lower pain levels, and lower rates of new-onset atrial fibrillation at much greater initial costs.

With patency rates comparable to traditional techniques, robotic coronary artery bypass has the potential to further decrease the morbidity of cardiac surgery through utilization of the latest technology and techniques.

Valve Repair

Robotic-assisted mitral and tricuspid valve repair has been shown to be feasible and safe with low stroke risk and acceptable outcomes. In a study published by Yanagawa and colleagues in 2015, shorter length of stays was noted in robotic valve replacement patients which may offset the higher initial cost of robotic cardiac surgery. The role of robotic instrumentation in cardiac valvular surgery is still evolving, but initial results are promising.

Other Cardiac Surgery

As the techniques and durability of the robotic platform continue to be developed and accepted, the success of utilizing minimally invasive robotic techniques in cardiac surgery is growing. This includes, but is not limited to cardiac resynchronization, cardiac tissue ablation, atrial septal defect repair, aortic valve reconstruction or replacement, and pulmonary vein isolation or ablation.

Endocrine Surgery

Thyroidectomy and Parathyroidectomy

Many alternative approaches to the traditional open methods for thyroid and parathyroid surgery originally developed by Kocher in the 1800s have been pioneered over the years in attempts to avoid a neck incision. Robotic thyroidectomy was pioneered and developed in Korea and is now the preferred approach for the management of both benign and malignant thyroid and parathyroid disease in that country. Several large studies out of Korea have since confirmed its safety and feasibility in their patient population. The advancement of this approach is thought to be largely driven by the cultural aversion to a scar on the neck in many Asian

countries. Minimally invasive thyroidectomy and parathyroidectomy can be performed via a breast, axillary, posterior auricular, or transoral incision.

In the United States less than 1% of thyroidectomies are performed robotically and this is largely due to the controversy surrounding its safety and oncologic equivalence to the traditional approach. Several early studies out of the United States demonstrated higher complication rates, including hemorrhage, chest paresthesias, and nerve and trachea injuries in robotic-assisted thyroidectomy when compared to conventional thyroidectomy. These results are discordant with the Korean studies which report low incidence of recurrent laryngeal nerve and vascular injuries. This may be due to relative differences in body habitus in that American patients are typically larger and more obese resulting in greater technical difficulty. Additionally, most studies support a high-volume learning curve with a 40 to 50 case requirement to become comfortable and few centers in North America are performing that case volume. As a result, the adoption of minimally invasive robotic techniques for thyroid and parathyroid surgery has remained low in the United States and its role remains to be defined.

Adrenalectomy

Laparoscopic adrenalectomy has become the standard of care for the management of adrenal disease and both retroperitoneal and transperitoneal approaches have been well described. Robotic-assisted adrenalectomy was first reported in 1998 by Piazza utilizing the AESOP robotic platform. Since that time, several studies have compared robotic and laparoscopic adrenalectomy. A recent meta-analysis that examined nine such trials found that operative times and conversion rates were equal between the two groups. A slightly shorter length of stay and lower estimated blood loss were reported in the robotic group; however, although these results were statistically significant, they were not pronounced enough to be clinically significant. The author's did note that the robotic platform made surgery in obese patients much easier and the operation was able to be conducted without difficulty in patients with a BMI as high as 44 kg/m^2.

Pancreatectomy

Pancreatic cancer is associated with an abysmal prognosis, with yearly incidence and mortality rates that are nearly equivalent. Pancreatic

procedures, specifically pancreaticoduodenectomy, have always been linked with significantly high morbidity and mortality rates. Even with recent efforts by high-volume centers to improve and standardize surgical techniques and perioperative care, morbidity remains quite high and can approach 40%. Although laparoscopic surgical techniques have been very effective in reducing surgical morbidity for a variety of abdominal operations, the limitations of laparoscopy are only amplified when applied to highly complex pancreatic resections and thus adoption rates are extremely low. Even Pomp & Gagner, the progenitors of the laparoscopic pancreaticoduodenectomy, felt that the procedure was just too complex and time consuming to ever gain widespread acceptance or improve postoperative outcomes when they first described it in 1994. Some 20 years later, we see their predictions ring true.

With the emergence of robotics as both an adjunct and alternative to laparoscopic surgery, we are beginning to see some hope for minimally invasive techniques to improve outcomes in complex pancreatic surgery. Robotic distal pancreatectomy in capable hands has already been shown to be superior to laparoscopic distal pancreatectomy in several studies. The benefits of the robotic approach include reduced potential for blood loss, decreased conversion rates which result in shorter length of stay and ICU costs, as well as improved oncologic outcomes as evidenced by lower positive margin rates with improved lymph node yields.

Giulianotti et al. published the first report of robotic pancreaticoduodenectomy in 2003 and reported a mean operative time of 270 minutes which was far more promising than the initial laparoscopic reports. While robotic pancreaticoduodectomy is far from prevalent in the United States today it does represent an astute solution to the problem of how to improve on current outcomes, and reports of robotic pancreatic surgery are steadily increasing. The largest series to date on robotic pancreas resections was reported from the University of Pittsburgh in 2013 and analyzed 250 procedures including 132 robotic Whipple procedures. They reported a 30-day mortality rate of 1.5% and a clinically significant leak rate of 7.4% in their pancreaticoduodenectomy patient cohort. Conversion rates were also lower than laparoscopic historical controls and continually decreased with increasing experience. Surgeons have been much more welcoming of the robotic approach to minimally invasive pancreatectomy procedures, and this is likely because dissection and reconstruction techniques much more closely resemble those used in open

surgery due to the improved dexterity and visualization afforded by the robotic platform. This allows the procedure to be more easily reproduced and adopted by surgeons that already perform a high volume of open resections, which was certainly not the case with the laparoscopic approach. Robotic-assisted pancreaticoduodenectomy is associated with a reduction in length of stay and intraoperative blood loss and will likely be demonstrated to reduce overall complications in the near future. A truly meaningful comparison of two surgical approaches mandates that they both have reached a plateau phase which is not yet the case, but as robotic utilization for pancreas resection continues to increase, results are growing more and more promising.

Urologic Surgery

Prostatectomy

Urologists were unquestionably the first group of surgeons to generate interest in and popularize robotic surgery. Robotic prostatectomy for prostate cancer was truly the first robotic operation to gain widespread acceptance and penetrance in the surgical community. It is one of the few procedures today for which the robotic approach has become the standard of care.

Robotic prostatectomy for prostate cancer has indisputably been shown in numerous clinical studies and meta-analyses to provide lower positive surgical margin rates, reduced blood loss, reduced length of stay, decreased incidence of incontinence and sexual dysfunction, and greater overall patient satisfaction when compared to both open and laparoscopic prostatectomy. Additionally, robot acquisition has been associated in several studies with increased volume of prostatectomy at surgical centers around the word despite the ongoing debate over cost-effectiveness.

The reasons for the widespread adoption of robotic prostatectomy are as follows. Even the earliest versions of the *da Vinci* system were well suited to prostate surgery, and none of its early limitations which are rapidly disappearing prevented the early adoption of robotic prostatectomy. The instruments in fact are well designed for working in the tight space of the male pelvis and the magnified 3D, HD imaging allows for maximum visualization leading to minimal disruption of key neurovascular bundles. Additionally, while urologists in general have a reasonable minimally invasive surgery skill set in that they use endoscopy and basic laparoscopy routinely, only a minority of urologist are skilled enough to perform a

prostatectomy with standard laparoscopy which can be quite difficult so the complexity is high enough to justify the need for robotic precision. The balance of all of these factors led to an early adoption of robotic surgery among the urologic surgery community and has generated great confidence in the ability of robotic platform to improve the penetrance of minimally invasive surgery in other fields.

Nephrectomy and Partial Nephrectomy

Nephrectomy, partial nephrectomy, and nephroureterectomy have all been demonstrated to be feasible and safe. The morbidity associated with wide subcostal or midline incisions in an open approach is clearly mitigated by laparoscopic techniques. However, laparoscopic suturing of the bladder cuff such as in nephroureterectomy or in closure of renal parenchyma during partial nephrectomy can be a daunting task for any skilled laparoscopic surgeon. Recent evidence suggests that robotic partial nephrectomy holds the promise of better intraoperative outcomes and long-term nephron preservation. This appears to be due to the shorter warm ischemic time and reduced blood loss the robotic platform affords by making complex tasks like suturing quick and easy.

The relatively short learning curve of robotic surgery has provided a comparative advantage over laparoscopic techniques and is rapidly making robotics the minimally invasive modality of choice for urologists. Articles are already being published reporting quicker operative times with reduced redocking needs utilizing the latest fourth-generation robotic platform; the *da Vinci Xi.* With improvements in equipment and techniques, the measurable benefits of robotics for these procedures will only continue to grow.

Other Urologic Surgery

Feasibility of computer-enhanced robotic surgery has been demonstrated in cystectomy, pyeloplasty, and ureteropelvic obstruction. Long-term studies are still needed to demonstrate broad applicability of these operations relative to the current standards.

Gynecologic Surgery

Gynecology is another specialty like urology with high robotic usage when compared to general surgery for many of the same reasons. The robotic platform has always been well suited to pelvic surgery, and this fact along

with low surgeon endoscopic comfort with complex procedures has helped to drive its adoption among gynecologists. The benefits of a minimally invasive approach are clear, whether in regard to hysterectomy, sacrocolpopexy, salpingo-oophorectomy, retroperitoneal lymph node dissection, or other pelvic procedures. However, prior to the inception of robotic technology most patients received a laparotomy for the treatment of benign and malignant gynecologic conditions for a variety of reasons similar to those mentioned in the discussion on urologic surgery. Today, most cases of endometrial cancer are treated utilizing a robotic approach representing a swift transformation in surgical practice. Patients with endometrial cancer have seen the largest benefit from this transformation, because these patients are commonly obese with a high complication rate from laparotomy and their habitus often makes a traditional laparoscopic approach near impossible. Robotic-assisted surgery allows these high-risk patients to be afforded the benefits of minimally invasive surgery without the steep learning curve of laparoscopy.

Pediatric Surgery

The tremendous benefit of computer-enhanced robotic surgery is truly magnified in the pediatric patient. These patients' smaller size, confined operative fields, and demand for precision dissection are logarithmically enhanced with the robotic tools and enhanced visualization.

Fundoplication and pyeloplasty are the standout applications at present, accounting for around 50% of all pediatric robotic cases performed to date. Examples of other robotic pediatric procedures performed include small bowel resection, mediastinal mass resection, Ladd's procedure, proctocolectomy with pull-through, cholecystectomy, Kasai procedure, duodenal atresia repair, and many others. Limitations due to patient size are reported to become significant in patients below 3 kg. Although the platform has not yet gained significant penetrance among pediatric surgeons, those who are using it report that it is particularly well suited to hepatobiliary surgery and thoracic surgery especially with regard to solid chest tumors. Robotics is slowly enabling pediatric surgeons to perform complex procedures in a minimally invasive fashion where previously only an open procedure would have been possible.

Figure 18.5. The *da Vinci* Sp (single port) robotic system with fully articulating instruments and camera which fit through a single 25 mm cannula that is slated for release in the near future. (© 2018 Intuitive Surgical, Inc., Sunnyvale, CA, USA. Used with permission.)

Otolaryngology

Prior to the development of robotic technologies for the surgical management of oropharyngeal squamous cell carcinoma, these procedures were performed using comparatively morbid open techniques. Transoral robotic surgery was first pioneered in 2005 and since that time a few select studies have demonstrated its feasibility in the surgical management of obstructive sleep apnea, chronic tonsillitis, supraglottic laryngeal tumors, as well as pharyngeal and hypopharyngeal tumors. The recent development of unique retractors and lasers adapted for use with the *da Vinci* surgical system has facilitated transoral supraglottic laryngectomy, total laryngectomy, and hypopharyngectomy. The advancement of robotic transoral surgery has been somewhat limited by line-of-sight limitations associated with rigid endoscopy; however, new emerging technologies are being developed to overcome these barriers. Several systems which show tremendous promise are the Robotic Endolaryngeal Flexible Scope (Robo-ELF), as well as Titan Medical Incorporated's Single Port Orifice Robotic Technology (SPORT) system, and Intuitive's new flexible instrument single incision platform, the *da Vinci* Sp (Fig. 18.5). Although long-term data and outcome analysis are needed, minimally invasive surgical

techniques are likely to become much more commonplace in head and neck surgery in the near future.

CONCLUSION

Some of the current limitations of the robotic platform include lack of haptic feedback; however, the technology for incorporating haptic feedback does exist in other robotic systems and will likely be a part of future *da Vinci* robotic platforms. Another criticism of robotic surgery is its increased cost when compared to standard laparoscopy. These arguments are not unfamiliar and many are the same that were made against the adoption of laparoscopic cholecystectomy when minimally invasive surgery was still in its infancy. The fact is that comparing robotic-assisted surgery to laparoscopy is always likely to show an increased cost of robotics in this current era, but this assessment fails to capture the entire clinical situation. Innovation requires vision and procedure conversion to a minimally invasive surgical (MIS) approach increases procedure value, which can attract higher patient volume. It is widely understood and accepted that patients seek out the newest and most innovative treatments and techniques, but there is no good way to incorporate this fact into cost analysis. The alternative is to not take advantage of this rapidly evolving technology and all of its potential benefits, which is a truly self-defeating premise because increased utilization and improved patient outcomes will result in overall institutional savings.

The *da Vinci* Surgical System remains the only commercially available therapeutic robotic system currently available. It has allowed surgeons to perform procedures that previously were thought to be either too complicated or too risky to be performed in a laparoscopic fashion. New technology has since improved, allowing one to reach areas that could not be reached before and to perform operations without scars, such as natural orifice surgery. With the development of new types of devices that are smaller, cheaper, and based on more modular components, each device will be tailored to a given operation. New technologies are sure to follow along, and this field will not look the same in 10 to 15 years. It can be expected that we will continue to move toward more automation, more computer interface, and more mechanical assist and further away from the open surgical techniques that were pioneered in the years before. As technological advances occur, we will be challenged to assure appropriate training and credentialing on these new devices and technology.

EDITOR'S COMMENT

In this chapter on robotic surgery, Nussbam and Latzko do an excellent job of summarizing the many different surgical applications for the da Vinci surgical platform. Since the da Vinci Surgical System received approval from the FDA for use in General Surgery in the year 2000, the clinical application of robotic-assisted surgery has increased dramatically. In 2010, there were a total of almost 1,800 systems installed worldwide. In 2015, Intuitive Surgical reports 3,477 installed systems worldwide, with 2,344 in the United States alone. According to a 2015 ERCI Institute Report, one in four US hospitals has a da Vinci robot,

and 79% of all robotic procedures worldwide are performed in the United States. In 2014, there were 570,000 robotic procedures performed worldwide, a 178% increase since 2009. The number and variety of procedures performed per installed system continue to rise. The market share of robotic prostatectomy compared to laparoscopic and open prostatectomy is estimated to exceed 80% in the United States according to the manufacturer. Robotic surgical procedure growth in Urology and Gynecology seems to have levels off in the recent past, and much of the recent growth has been in General Surgery, especially hernia.

Specialty societies have attempted to examine the role of robotics in General Surgery at the current level of technology. The European Association of Endoscopic Surgeons (EAES) consensus statement of the use of robotics in General Surgery published in 2015 concludes that "…To date, in the vast majority of clinical settings, there is little or no advantage in using robotic systems in General Surgery in terms of clinical outcome." The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) Technology and Value Assessment Committee recently published a safety and efficacy analysis of the da Vinci Surgical System. SAGES concludes "gastrointestinal surgery with the da Vinci Surgical System is safe and comparable, but not superior to standard laparoscopic approaches. Although clinically acceptable, its use may be costly for select gastrointestinal procedures."

When the outcomes are at best equivalent, it is hard to justify a robotic approach when an established and readily available laparoscopic alternative exists. Emotional and subjective arguments about better precision and ergonomics with robotics need to translate into actual patient benefit. What is not often discussed is the impact that a lack of tactile haptic feedback has on the ability to perform fine dissection and delicate surgery when using the robotic platform. The robotic platform is an enabling technology for surgeons early in their learning curve or for those who lack an advanced laparoscopic skill set for very complex procedures (e.g., reoperative cases). This statement is in no way intended to imply that surgeons who use the robot preferentially for minimally invasive General Surgery are unskilled, but I personally become concerned when a surgeon feels empowered to take on a particularly difficult robotic case (e.g., a large recurrent paraesophageal hernia) when such a case is not something that he/she has experienced with otherwise and would not have attempted but for the availability of a robot. The complex surgery attempted robotically should be well within a particular surgeon's domain of expertise and experience.

According to the Intuitive Surgical website, "our business model is essentially a 'razor/razor blade' operation. Initially, we sell and install the da Vinci Surgical System into new customer accounts. Once systems are sold into accounts, we generate recurring revenue as our customer's use the system to perform surgery, and in the process buy and consume our EndoWrist instruments and accessory products. We also generate recurring revenue from system service." A survey of average quoted process for the da Vinci Surgical

System (Q2 2014–Q1 1015) reveals that the da Vinci Xi single console costs approximately $1.85 million and the Xi dual console sells for $2.31 million. Service contracts generally run at about 10% of the purchase price. Instruments cost approximately $2,000 and are programmed to only allow use for 10 cases. While there are various cost analysis and comparisons that have been published with regard to robotic surgery, in general it appears that robotic surgery is more costly than the laparoscopic counterpart in General Surgery. A systematic review of economic evaluations of robotic versus either open or laparoscopic surgery revealed that robotic surgery costs were consistently higher than open or laparoscopic surgery. The 2015 ERCI publication referenced above suggests that the incremental cost per robotic procedure is $3,000 to $6,000.

The argument that a hospital will recover any lost revenue from converting laparoscopic procedures to robotic ones by attracting patients who seek out this robotic approach becomes less valid as most competing hospitals in a market acquire a robot (currently the case in multiple markets across the country). The contention that patients will seek out surgeons who perform specific procedures robotically rather than laparoscopically could be addressed if hospitals were honest in their marketing efforts about the benefits of robotic surgery. A peer-reviewed article published in 2011 revealed that in a systematic analysis of 400 randomly selected hospital websites, that 41% described robotic surgery. Statements of clinical superiority were made on 86% of websites, with 32% describing improved cancer control, and 2% described a reference group. No hospital website mentioned risks. Materials provided by hospitals regarding the surgical robot were found to overestimate benefits, largely ignore risks, and were strongly influenced by the manufacturer.

In 2002, the Institute of Medicine published Crossing the Quality Chasm, an influential book that has framed recent discussions of quality health care. Among the six specific aims of quality health care defined was efficiency: care and service should be cost-effective. The proposed measure for this aim was to assess the cost of care by patient, provider, organization, and community. The Center for Medicare and Medicaid Services Value Based Purchasing Program bases their payments to hospitals for care provided to Medicare beneficiaries using various domains to assess quality. In fiscal year 2016, 25% of the quality assessment was based on efficiency or cost per Medicare beneficiary. Private insurers are driving patients to health care systems with the highest quality AND the lowest cost. Cost is becoming increasingly relevant to surgeons, and we need to ensure that the procedures we perform are of the highest possible quality and safety and as cost-effective and efficient as possible. For robotic surgery, we will need to demonstrate clear clinical benefit or create other cogent arguments to make any potential increased cost justifiable.

Despite how the above may appear, I believe that there is a prominent future for robotics in surgery and even in General Surgery. For certain complex procedures rarely if ever done laparoscopically (pancreaticoduodenectomy for example), we have seen that the introduction of robotics has enabled a

minimally invasive approach when the alternative was a laparotomy or even a thoracotomy. Patients are likely to benefit in these cases much like they do when a case can be performed laparoscopically rather than open. As the technology progresses, robotic surgical systems will become capable performing tasks not possible at the current time. Truly robotic surgical systems that can perform portions of a procedure autonomously (e.g., tying a knot or creating an anastomosis) are likely on the horizon. Tiny in vivo or endoluminal robots may make natural orifice surgery a real viable possibility in the future. New technologies may become integrated into robotic surgical systems that allow surgeons to do things like visualize tumor margins in real time, see tumors that cannot be visualized with current imaging technology (tumors deep in the parenchyma of the liver or an insulinoma not yet localized by current conventional methodology for example). As competing robotic surgical systems arrive on the market, the focus of robotic surgical companies will shift from utilization to enhanced capabilities and more cost-effective platforms. As outlined in the EAES consensus statement, "There is a severe lack of high-quality data on robotic surgery, and there is a great need for rigorously controlled, unbiased clinical trials. These trials should be urged to address the cost-effectiveness issues as well." From this same document, "Robotic surgery is still at its infancy, and there is a great potential in sophisticated electromechanical systems to perform complex surgical tasks when these systems evolve." I could not agree more.

19 Surgical Energy

Edward L. Jones and Dean J. Mikami

INTRODUCTION

Surgical energy is an essential part of every operation; yet, the basic principles and application remain poorly understood among surgeons of all ages and experiences. Electrosurgical injuries account for over 5% of *all* laparoscopic complications and can result in severe disability or death as well as a source litigation. Public awareness of surgical energy complications significantly increased following the 2010 death of Pennsylvania Congressman John Murtha likely secondary to an electrosurgical injury. This event, combined with recent articles in the lay press and medical literature, has prompted a renewed interest in both research and education about energy use in surgery.

To combat the widespread lack of in-depth knowledge, the Society of American Gastrointestinal and Endoscopic Surgeons developed the Fundamental Use of Surgical Energy (FUSE) curricula and certification. The FUSE curriculum has proven robust especially when accompanied by an interactive component and is being rapidly accepted and applied internationally. The didactic content is freely available online and universal certification will eventually be required of all surgical trainees if not all surgical energy users.

This chapter seeks to provide the reader a strong basic understanding of energy use in the operating room but is not a substitute for FUSE certification which should be sought by anyone who uses energy in surgery. We will review the most common types of energy used, the eight patterns of injury as a result of energy use and lastly, provide a guide to selecting the best device for the desired tissue effect.

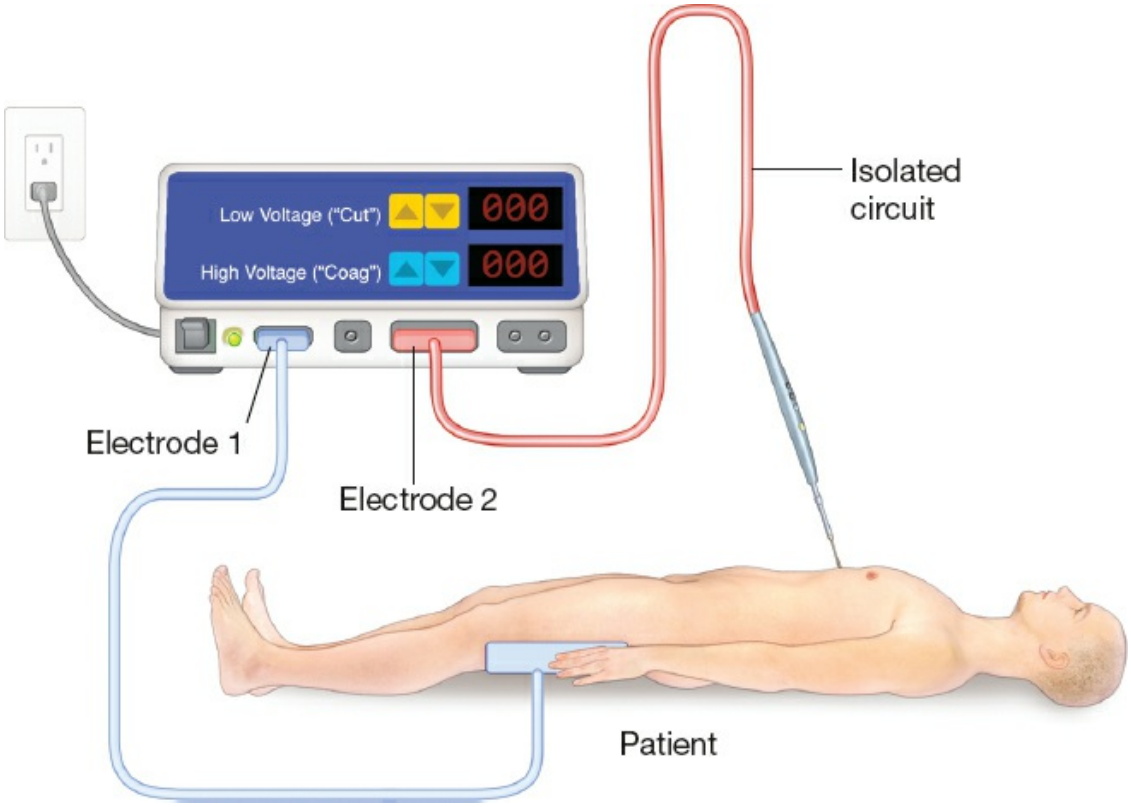

Figure 19.1. Monopolar radiofrequency energy circuit. Radiofrequency alternating current travels from the generator to the instrument tip and through the targeted tissue. It then passes through the patient and returns to the generator via the dispersive electrode.

TYPES OF ENERGY IN THE OPERATING ROOM

Monopolar Radiofrequency Energy

The most common device in today's operating room is based upon the monopolar device originally popularized by Dr. William Bovie and Dr. Harvey Cushing in the 1920s. The "Bovie," as it is commonly called in North American surgical suites, is a highly versatile device that is used in open surgery, laparoscopy, and endoscopy and permeates through all surgical specialties. When activated, the electrosurgical unit (ESU) converts 60 Hz alternating current from an electrical outlet to approximately 500,000 Hz of radiofrequency energy. This travels from the tip of the instrument, through the tissue, and into the patient and returns to the ESU via a dispersive electrode or "grounding pad" (Fig. 19.1). The most common modes of activation and surgical application techniques are discussed below.

Varying the duration of energy discharged (i.e., selecting "cut," "coag,"

or “blend” mode) from the generator as well as the proximity of the tip to the tissue (e.g., current density) creates three different clinic effects: vaporization, desiccation, or fulguration. To cut or vaporize tissue, a low voltage/high current mode is selected (i.e., cut mode). This is combined with a surgical technique that creates high current density (treating a small amount of tissue near the thin tip of the instrument) during activation. This focuses energy on a small area of tissue resulting in rapid heating of the cells to the boiling point. Linear movement of the instrument cuts tissue with less than 200 μm of lateral thermal injury (Fig. 19.2A).

To achieve more coagulative effect yet still move through tissue, a high voltage/low current mode is typically selected (coag mode) and the current density reduced by increasing the area of tissue contact with the instrument. This raises cell temperatures more slowly to 60° to 95°C which results in protein coagulation or “desiccation,” as opposed to vaporization (Fig. 19.2B). A “blended” mode is a combination of the cut and coag waveforms which seeks to maximize energy effectiveness by creating a safer, low voltage mode that can both cut and coagulate tissue.

Desiccation of tissue with the coag mode is an effective way to increase coagulation during dissection but should not be used for vessel sealing. This is better accomplished in cut mode while grasping and occluding the vessel with forceps. The apparent paradox (“cut” mode is more effective than “coag” mode for vessel sealing) is due to the fact that the continuous cut waveform more evenly heats tissues for a homogenous vessel seal as it cannot vaporize the cells due to the low current density created by the relatively large amount of tissue held between the tips of the tissue forceps.

Superficial coagulation or “fulguration” is achieved most commonly in a high voltage/low current flow mode (coag mode) while holding the instrument close but not contacting the tissue. Energy can then arc to the superficial tissues creating temperatures in excess of 200°C. The low current density rapidly heats and cools cells creating black eschar as a result of the breakdown of elements, especially carbon, into their atomic components. Thermal penetration is typically 5 mm or less (Fig. 19.2C).

The versatility and effectiveness of monopolar radiofrequency energy in surgery continues to increase as alternative modes and techniques of operation emerge. Energy devices and generators that continuously monitor tissue effect during activation are already available. When combined, these new devices and techniques all bring the surgeon closer to

the ultimate goal of energy application: the ability to utilize the smallest amount of energy possible to create the desired tissue effect.

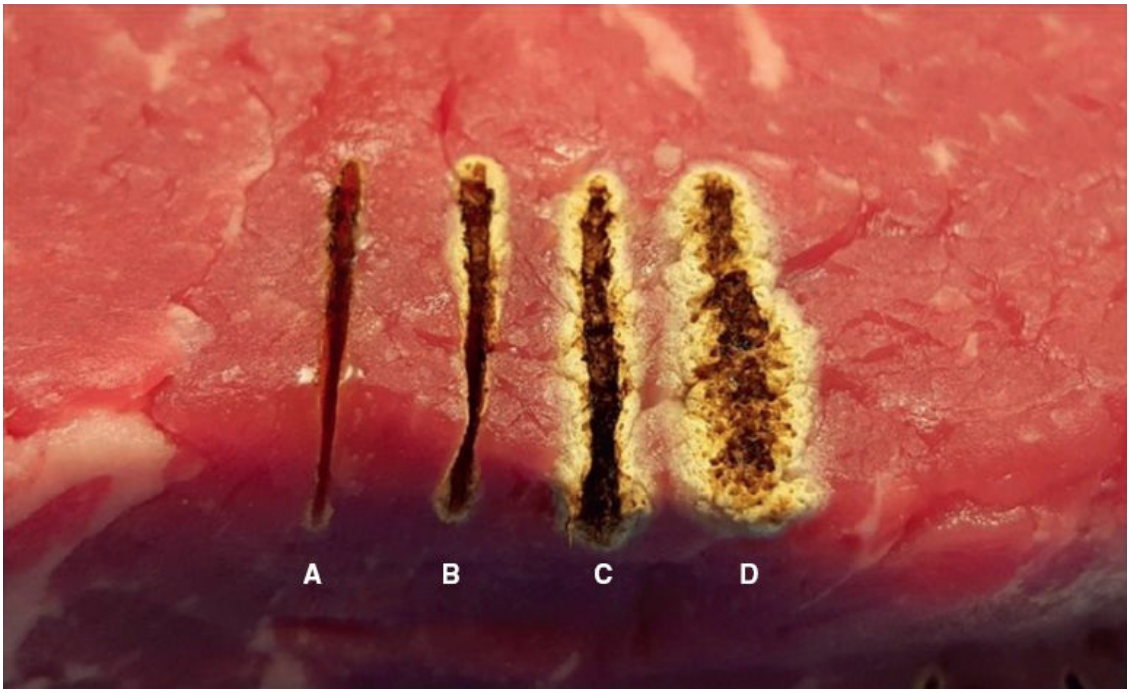

Figure 19.2. Monopolar energy tissue effect. Different tissue effects of monopolar radiofrequency energy: rapid tissue heating with high current density resulting in vaporization and minimal lateral thermal spread (“cut” mode) (**A**); rapid tissue heating with moderate current density and a blend of vaporization and dessication (a “blended” mode) (**B**); rapid tissue heating to 60° to 95°C with resultant desiccation and coagulation (“coag” mode set to “fulguration”) (**C**); spray energy arcing to tissue with rapid heating to >200°C with resultant fulguration and carbonization, depth of penetration typically <5 mm (coag mode set to “spray”) (**D**).

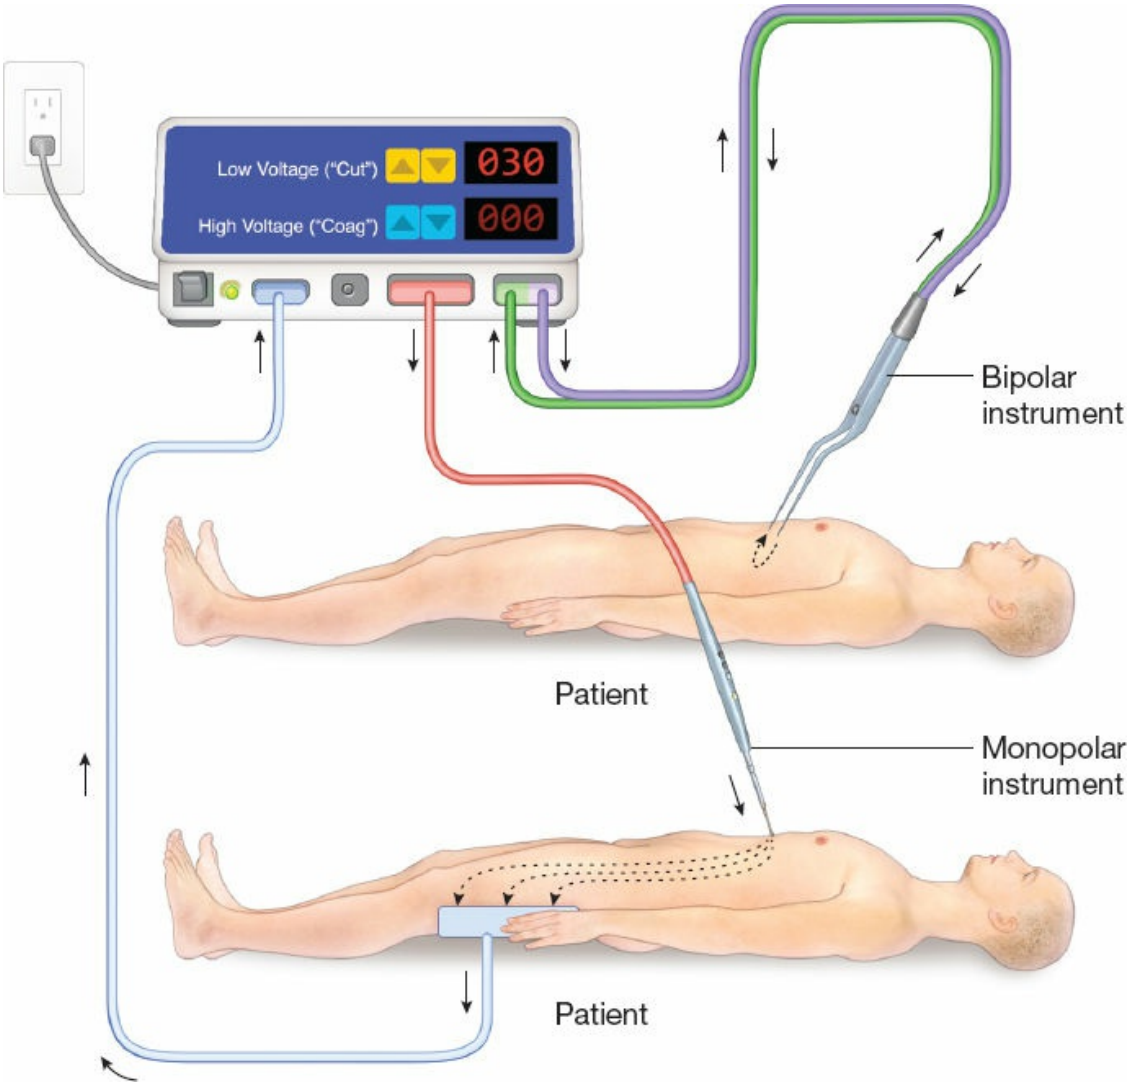

Figure 19.3. Bipolar energy circuit. Radiofrequency energy travels from the generator to the instrument and through the tissue between the instrument tips and back to the generator. This is in contrast to the monopolar instrument where energy must pass through the entire patient and return to the ESU via the dispersive electrode or "grounding pad."

Bipolar Radiofrequency Energy

Bipolar devices contain both limbs of the electrical circuit in a single device so as to focus radiofrequency energy solely on the tissue between the instrument's tips (Fig. 19.3). This reduces the required voltage from 1,400 to 9,000 V during monopolar energy use to approximately 100 to 200 V. Basic bipolar devices are designed for coagulation of tissue alone; however, newer devices are available that have added a cutting blade to transect tissue. These "advanced" bipolar devices often include tissue feedback mechanisms and audible tones to notify the surgeon when the

tissue is ready for transection. This slightly increase operative time and smoke production when compared to other devices but has the benefit of consistently sealing vessels up to 7 mm in diameter.

Ultrasonic Energy

Ultrasonic devices convert low-voltage radiofrequency energy into high-frequency (approximately 44,000 Hz) mechanical vibrations via piezoelectric crystals in the device handle. These rapid vibrations generate friction that heats tissue, denatures proteins (coagulates), and creates tissue separation (cuts) at temperatures below boiling. A transient mist is formed due to the cavitation effect of the vibration but minimal charring (tissue temperatures do not exceed 100°C) and lateral thermal spread is seen on low settings. This facilitates dissection and decreases operative time in contrast to monopolar and bipolar instruments. Ultrasonic devices can effectively seal vascular structures up to 3 mm in size although newer devices can reportedly seal larger vessels by increasing dwell time.

Plasma Energy

Radiofrequency energy can be applied in short, 40 μs bursts to create plasma energy along the edge of a device. Plasma energy can also be carried onto the tissue itself by an inert gas, most commonly, argon (Fig. 19.4). When combined with short bursts of high-voltage radiofrequency energy, plasma energy can provide tissue cutting and coagulation functions with minimal thermal spread. Argon plasma coagulators are thus designed for the superficial coagulation of diffusely bleeding tissue (e.g., cut liver or spleen). They are highly effective in a bleeding or debris-filled field and produce less smoke than monopolar or bipolar devices with a constant thermal spread of 2 to 3 mm. However, intravascular embolism of insoluble argon gas has resulted in cardiac arrest and death; thus, avoidance of direct tissue contact and minimal gas flow volume is recommended.

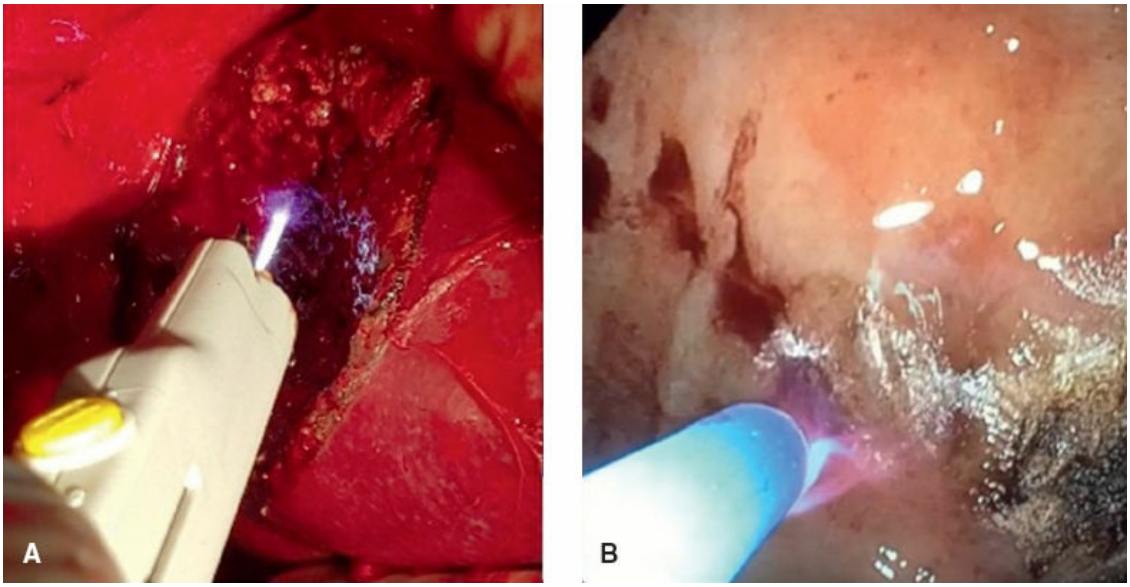

Figure 19.4. Plasma energy. Monopolar radiofrequency energy is conducted via inert argon gas to create plasma energy on the surface of tissue resulting in superficial coagulation. Argon gas is continuously insufflated during activation and so procedures within a closed space (e.g., laparoscopy, endoscopy) must be closely monitored and vented. **A.** Argon plasma coagulation during laparoscopy. **B.** Argon plasma coagulation during endoscopy.

Lasers

Lasers generate heat by focusing a concentrated beam of light on tissue. They can be used for both cutting and coagulating tissue and were quite common in the 1980s and early 1990s. Due to their high cost, need for specialized training and general increase in operating times lasers have been relegated to use in limited, specific scenarios. Precise control of the depth of penetration promotes their continued use in dental, eye, cosmetic, and gynecologic fertility procedures.

Microwave and Radiofrequency Energy Ablation

Microwave or radiofrequency energy can be applied directly to tissue to induce necrosis in either an open or percutaneous fashion. The goal of this directed use is typically tumor necrosis or arrhythmia ablation. Radiofrequency ablation devices take many different forms (bipolar, monopolar, internally cooled, etc.) and function via the principles of monopolar and bipolar energy discussed above. Significantly larger amounts of radiofrequency energy are used and extra care should be taken

to decrease the risk of electrosurgical complication.

Microwave ablation devices function within a different part of the electromagnetic spectrum (frequencies between 915 MHz and 9.2 GHz) and create tissue effect via dielectric heating. The microwave energy causes rapid alternation of the positive and negative poles within cells. The charged ions (especially water) rotate every time the positive and negative poles switch polarity (approximately 10^9 times per second) and this creates rapid and uniform heating of cells within the microwave field. No dispersive electrode is needed as no circuit is created—heating is a direct result of the microwave energy on the cells.

Both radiofrequency energy and microwave ablation are susceptible to nearby perfusion which can reduce complete ablation rates. Radiofrequency energy will follow the path of least resistance as it travels to the dispersive electrode so nearby vasculature, bile ducts, lymphatics, and so forth can serve as an “electric sink.” Microwave ablation can also be affected by nearby perfusion acting as a “thermal sink.” As no circuit is created, no electrons are stolen but the constant flow of liquid removes heat just as an automobile radiator cools an engine. A distinct benefit of microwave ablation is the ability to achieve high tissue temperatures (150°C) in contrast to the 60° to 100°C limit that guides energy flow during radiofrequency energy ablation. This can result in shorter ablation times (typically 4 to 10 minutes).

Both modalities can be successfully used to achieve complete tumor ablation and use is often guided by availability and experience. All surgeons should be aware of the different mechanisms of action in order to minimize the risk of electrosurgical complication. Due to each device’s complexity and relative rarity of use, utilization with imaging guidance and manufacturer assistance is recommended.

THE EIGHT REPRODUCIBLE PATTERNS OF ELECTROSURGICAL INJURY

Energy-based device have become ubiquitous in the contemporary operative room. Increasing use has resulted in more complications that adhere to eight common patterns of injury: fires, antenna coupling, insulation failure, residual heat, direct application interaction with electronic devices, direct coupling, and capacitive coupling. The authors have also included techniques to mitigate the risk of injury with each mechanism beginning with the most common and clinically relevant.

Fires

Operating room fires and explosions are fortunately rare events (550 to 650 per year) but can result in significant injury or death. To combat OR fires, the Joint Commission issued a sentinel event alert on fire prevention in 2003 and the most recent update (January 2015) to the hospital accreditation manual defines this as “fire, flame or unanticipated smoke, heat or flashes during an episode of patient care.” This results in mandatory hospital review of all such events even without patient injury.

Several professional organizations have published educational material to assist in the avoidance of OR fires including the SAGES FUSE training, the Association of peri-Operative Registered Nurses (AORN), the Emergency Care Research Institute (ECRI), the US Council of Surgical and Perioperative Safety (CSPS), and the Anesthesia Patient Safety Foundation (APSF). In order for a fire to occur, three elements must be present: (1) heat or an ignition source (i.e., surgical energy, patient or fluid warmer), (2) fuel (alcohol-based prep, surgical drapes, etc.), and (3) oxygen. The majority of surgical fires occur in the airway (21%) or around the upper chest, head, and neck (44%) likely due to increased oxygen content. Utilization of closed breathing circuits (i.e., endotracheal tube) as opposed to nasal cannula or mask oxygenation as well as maintaining oxygen content at ≤30% will minimize risk.

Should a fire or explosion happen the following steps should be immediately undertaken: (1) stop the flow of all airway gases and disconnect the patient from the breathing circuit including removing the endotracheal tube during an airway fire; (2) remove any burning or burned materials; (3) extinguish the fire from the burning materials by dousing it with saline, smothering it or utilizing a carbon dioxide fire extinguisher. If the fire is not contained by these steps then practitioners should follow the acronym RACE: Rescue; attempt to rescue the patient or staff. Alert; activate the fire alarm and alert nearby staff. Confine; isolate the fire by closing doors, shutting of medical gas and electrical power. Evacuate; evacuate the incident room and entire surgical suite if necessary.

Clinical Examples: (1) Surgical drapes are placed immediately after applying an alcohol-based prep resulting in a difficult-to-see blue flame fire as the alcohol ignites the drapes. (2) During a tracheostomy, the surgeon enters the airway with surgical energy resulting in an explosion both externally and within the patient’s airway. (3) While changing from the 10 mm laparoscopic telescope to the 5 mm, the fiber optic light cord is

left at 100% power and burns through the drape and onto the patient's skin.

Preventative Strategies: (1) Education of the surgeon and operating room staff on the three elements needed for fire creation taking special note of oxygen-rich environments such as the airway or under surgical drapes. (2) Do not place surgical drapes until alcohol-based preps are completely dry without pooling. (3) Enter the airway with cold surgical instruments with the patient on the minimal amount of oxygen enrichment necessary to maintain appropriate saturations (goal oxygen content <30%). (4) Maintain the fiber optic light in stand-by or "off" mode any time that it is not connected to the laparoscopic telescope. (5) Include a fire risk assessment in the preoperative timeout.

Antenna Coupling

Electrosurgical injury due to antenna coupling has only recently been elucidated but is thought to be a major source of thermal injury. Radiofrequency energy, most commonly from the wire/cable of monopolar devices, can be transmitted into the air (through intact insulation) and into nearby conductors (cables, instruments, or monitoring electrodes) similar to a radio station broadcasting music that is picked up by your car's antenna. Antenna coupling is one of the most ubiquitous sources of electrosurgical complications during monopolar energy use as any wire/cable that lay within close proximity of the "Bovie" cord (or return electrode cord) will pick up stray energy and can burn the patient.

Increasing amounts of stray energy are transferred with increased power settings (e.g., increasing power from 15 to 30 W nearly doubles energy transferred). Close proximity and parallel alignment of instruments/wires/cables has also been shown to increase tissue temperatures nearly 60°C. The forced parallel alignment and close proximity of Single Incision Laparoscopic Surgery (SILS) also increases antenna coupling and the resultant thermal injuries may be an explanation for the increased postoperative hernias and incisional pain. The simple maneuver of separating the cords has been consistently shown in benchtop and in vivo trials to reduce the incidence of antenna coupling.

Clinical Examples: (1) The monopolar "bovie" wire lays in parallel with a neuromonitoring lead during a spinal surgery and burns are noted at the insertion site due to energy transferred to the neuromonitoring lead via antenna coupling. (2) During a laparoscopic cholecystectomy the surgeon

bundles the camera, light, and bovie cords together and, when activating the “bovie,” energy transfers into the laparoscopic camera cord and then arcs from the tip of the telescope directly to the bowel. This happens outside of the surgeon’s view thus resulting in a missed bowel injury.

Preventative Strategies: (1) Separate the active electrode and dispersive electrode cords from other nearby wires/cords. (2) Minimize voltage by decreasing power, using lower power modes (cut or blend), or switching to lower power bipolar/ultrasonic devices. (3) Avoid use of monopolar energy during single incision laparoscopic surgery.

Insulation Failure

Electrosurgical injury via insulation failure is thought to be one of the most common causes of inadvertent thermal injury during laparoscopy. It may also be the most easily managed. Insulation defects can be found in up to 39% of monopolar instruments, typically near the instrument tip as the insulation begins to thin and taper. Interestingly, these defects (and resultant injuries) are more common during robotic surgery. Unfortunately, just 10% of insulation defects are visible to the naked eye; thus, some authors suggest routine use of porosity detectors during sterile processing of laparoscopic instruments.

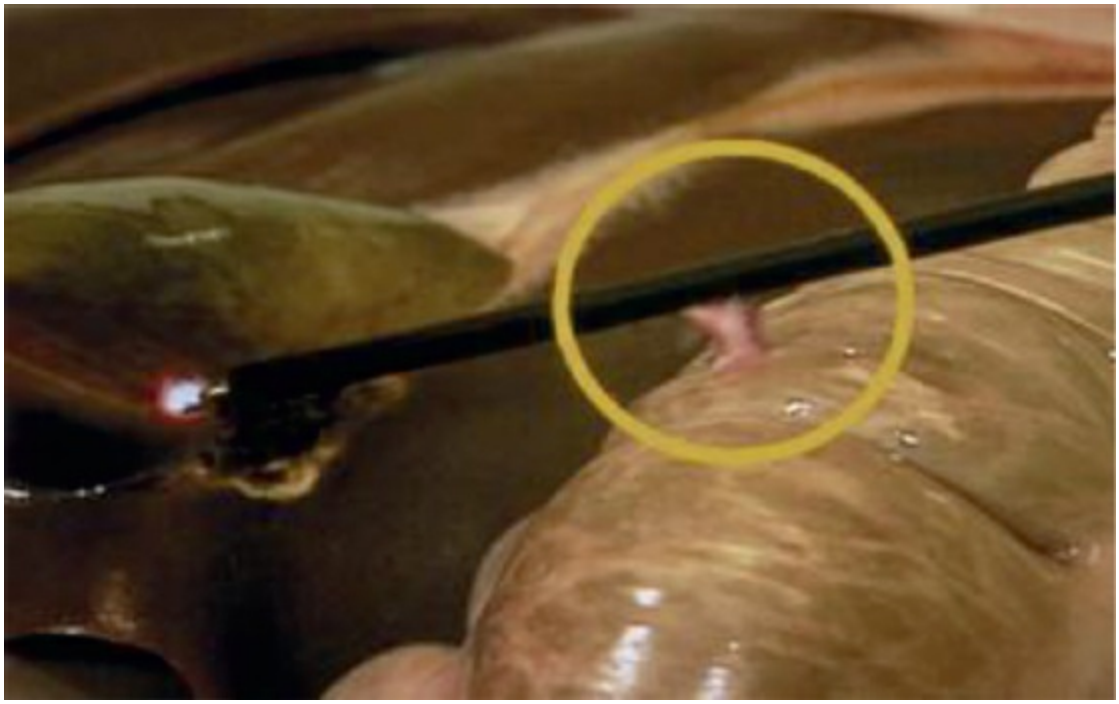

Figure 19.5. Insulation failure during laparoscopy. All electrosurgical devices should be carefully inspected for cracks or breaks in the insulation. However, only 10% of these can be

seen with the naked eye and so regular testing should be done as well as careful visualization of the entire instrument during activation. (Reprinted from Odell RC. Surgical complications specific to monopolar electrosurgical energy: Engineering changes that have made electrosurgery safer. *J Minim Invasive Gynecol* 2013;20(3):288–98. Copyright © 2013, with permission from Elsevier.)

Clinical Example: While using the monopolar "bovie" to remove the gallbladder from the fossa energy arcs from a break in the instrument shaft to nearby liver or bowel (Fig. 19.5).

Preventative Strategies: (1) Careful inspection of the instrument prior to use for obvious breaks in insulation. (2) Maximize visualization of entire instrument during activation to identify aberrant energy arcs. For laparoscopy and endoscopy this often requires pulling the telescope back into the port or out of the patient to see the "big picture." (3) Routine porosity detection of reusable laparoscopic instruments including any devices that may be connected to energy (e.g., L-hook, spatula, graspers, and/or scissors).

Residual Heat

Residual heat is defined as the increased instrument temperature after energy activation is completed. The rate of increase and maximal instrument temperature is unique to each device and causes injury when the tip touches tissue prior to complete heat dissipation. This is most commonly seen with ultrasonic devices which reach higher maximum temperature (>200°C) and remain hot longer than bipolar or monopolar devices (Fig. 19.6).

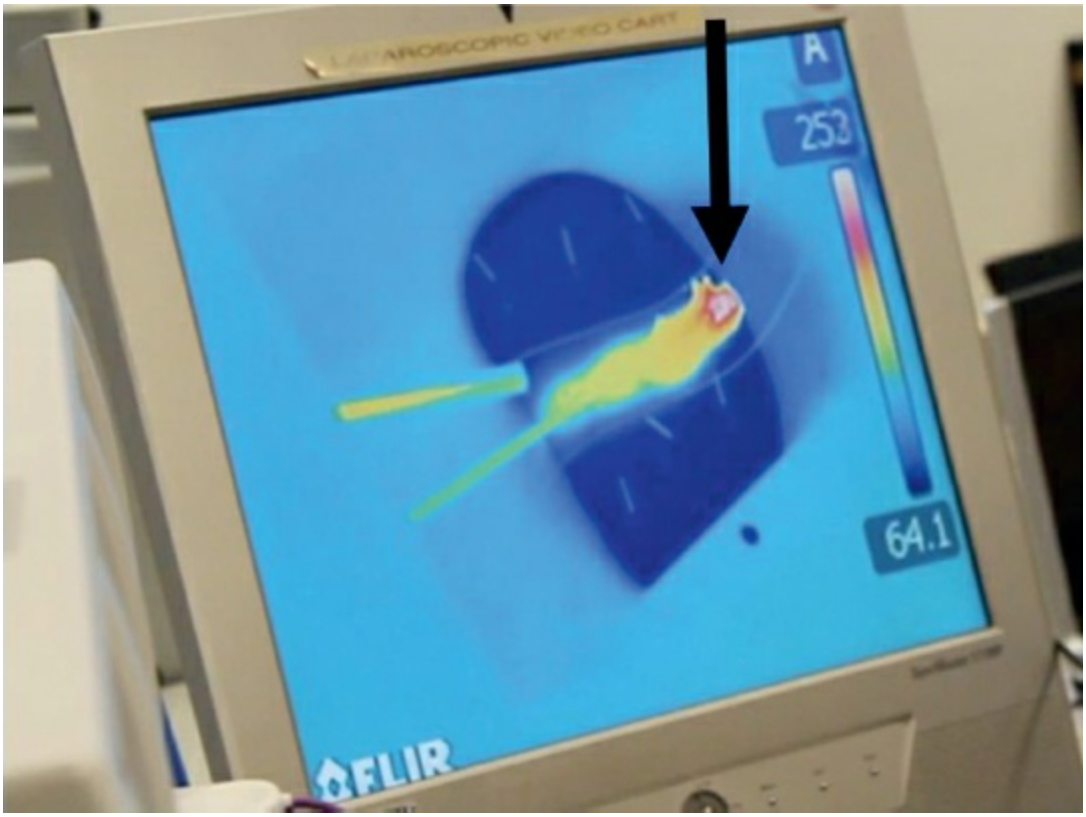

Figure 19.6. Residual heat. All energy devices are elevated to at least 60°C in order to effectively denature proteins and cool rapidly after activation is stopped. Ultrasonic devices commonly hit maximum temperatures ≥200°C and remain hot enough to cause full thickness injuries to bowel if the surgeon does not wait for the tip to cool before manipulating tissue. Instrument tip at approximately 253°C (*black arrow*).

Clinical Examples: During laparoscopic hemi-colectomy, the ultrasonic device is used to transect the transverse mesocolon and then immediately used to grasp/retract small bowel resulting in a full thickness injury and delayed perforation.

Preventative Strategies: Delay use of ultrasonic devices for grasping or dissecting until at least 5 seconds have passed after activation (2 seconds for advanced bipolar and monopolar devices).

Direct Application

Electrosurgical injury via direct application is a result of unintentional activation of any type of instrument while contacting tissue. A recent study of FDA's Manufacturer and User Facility Device Experience (MAUDE) database demonstrated that, of voluntarily reported injuries, the most common mechanism for thermal injury was direct application (84%). The

authors did not report the specific surgical techniques that resulted in injury; however, unintentional activation during device use or incomplete activation with inadvertent transection are likely mechanisms.

Clinical Examples: (1) While leaning against the patient, the surgeon unintentionally activates the monopolar device resulting in a burn to the patient at a site remote from the surgery. (2) The monopolar "bovie" is activated directly on the staple line of an intestinal anastomosis and focuses on a single staple resulting in enormous current density and melting of the staple with staple-line breakdown (Fig. 19.7).

Preventative Strategies: (1) Routine use of protective "holsters" or "sleeves" when devices are not in use. (2) Activate devices with the tips fully visualized and containing only the tissue intended to coagulate and/or cut. (3) Understand the activation cycle of each device.

Interaction With Electronic Devices

Radiofrequency energy transmitted through the air interferes with nearby monitoring devices such as ECG leads, neuromonitoring devices, and even implanted cardiac devices. The transfer of energy into monitoring cables hampers waveform interpretation and can cause direct thermal injury via antenna coupling. In addition, the transferred energy can interfere with implanted cardiac device sensing and cause malfunction. Just as separating the cords reduces antenna coupling, so does avoiding the energy vector of the pacemaker/defibrillator leads (Fig. 19.8). In addition, preferential use of low energy devices will also decrease the risk of stray energy transfer to implanted cardiac devices (Table 19.1).

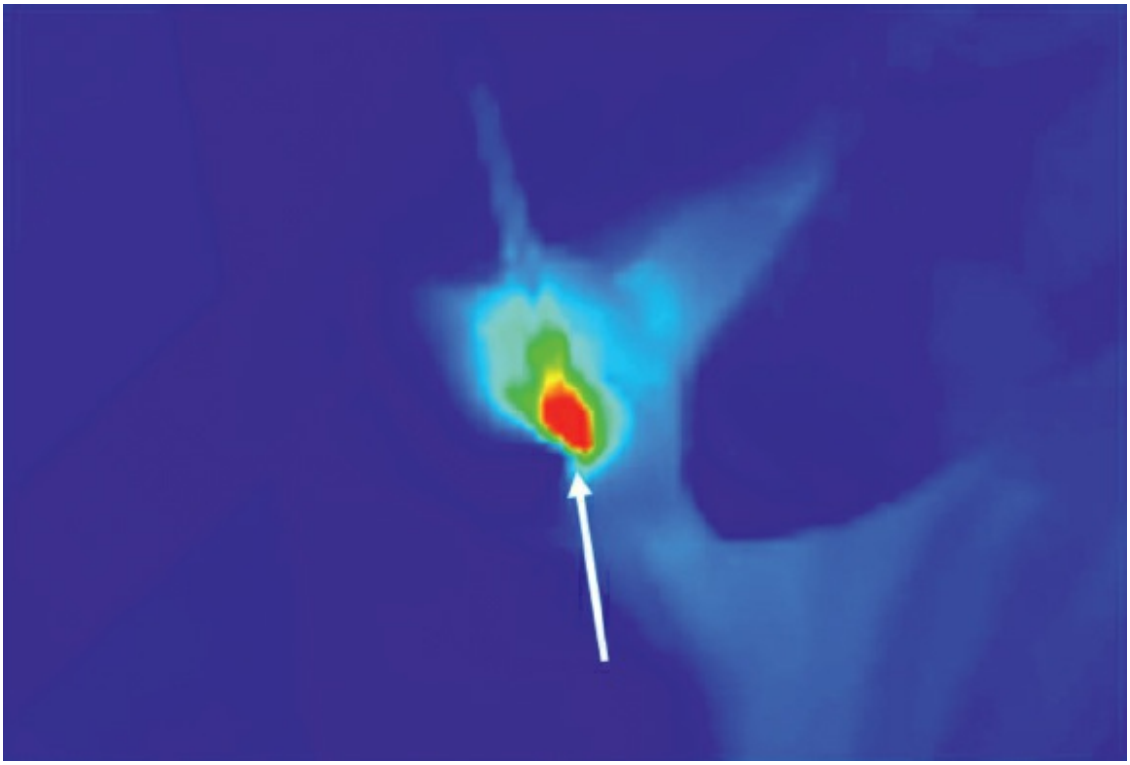

Figure 19.7. Direct coupling to a staple line. Direct coupling can result in astronomic temperatures if the current density is high as it is when activating monopolar energy on a staple line. The *white arrow* identifies the corner of a bowel staple-line where tissue temperatures exceeded the measurement capability of the thermal camera (≥200°C) and have been documented to hit temperatures nearing 1,000°C resulting in liquidation of the staples.

Clinical Examples: During activation of the monopolar "bovie" a cardiac defibrillator inappropriately senses cardiac dysrhythmia and administers a shock.

Preventative Strategies: (1) Utilize low power settings or low energy devices (bipolar, ultrasonic) when operating on patients with implanted cardiac devices. (2) Avoid use of energy devices near or parallel to the implantable device current vector.

Direct Coupling

Direct coupling is intentionally created when the surgeon touches the monopolar device to a forceps or other conductor while grasping tissue to coagulate. Complications arise when energy is unintentionally transferred to a nonelectrically active conductor.

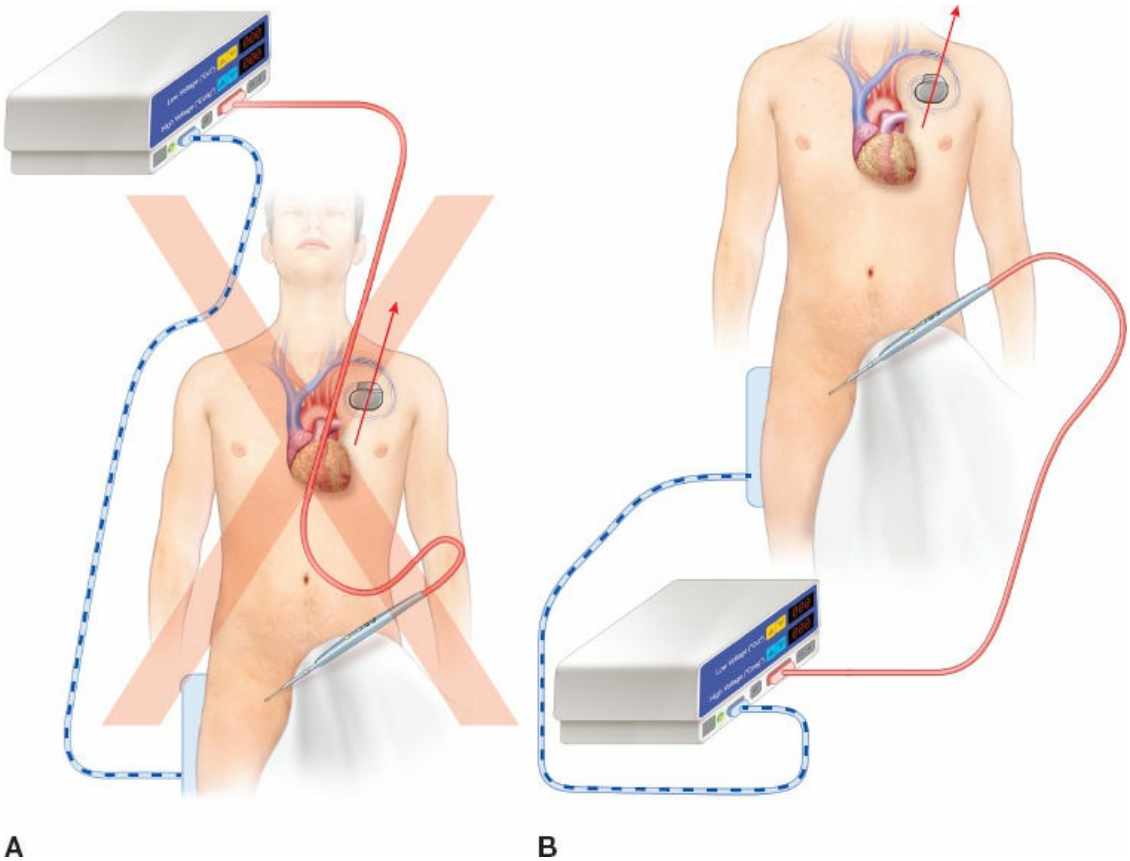

Figure 19.8. Energy vector of implanted cardiac devices. Pacemaker/defibrillator current vector (*red arrow*) is in parallel alignment with monopolar active electrode, "Bovie," cord (*blue*) (**A**) and dispersive electrode (*dotted blue*) cord which nearly doubles electromagnetic interference when compared to complete separation of the pacemaker/defibrillator current vector from the energy device cables (**B**).

TABLE 19.1 Surgical Energy-Based Devices and Electromagnetic Interference Occurring on Implanted Cardiac Devices

Low Risk EMI <0.2 mV	Intermediate Risk EMI 0.2–1 mV	High Risk EMI >1 mV
Traditional bipolar 0.01 ± 0.004 mV	Monopolar "bovie" 0.21 ± 0.07 – 0.92 ± 0.63 mV	Argon plasma energy 2.58 ± 0.34 mV
Advanced bipolar 0.00 ± 0.003 mV		Plasma energy 3.48 ± 0.78 mV
Ultrasonic shears 0.01 ± 0.004 mV		

All devices were activated for 5 seconds at a uniform location 2.5 cm inferior to the generator's lower edge. Traditional bipolar forceps were activated on a Force FX generator (Covidien, Boulder, CO) at 30 W bipolar mode. Advanced bipolar device (Ligasure; Covidien) activated on 3 "Bar" setting. Ultrasonic shears (Harmonic, Ethicon, Cincinnati, OH) activated on "Max" setting. Monopolar handheld "Bovie" was activated without tissue contact (least energy transferred), on 30 W coag mode and on 30 W blend mode (most energy transferred) creating the range of electromagnetic interference above. Argon plasma energy (Argon Beam Coagulator, ConMed, Utica, NY) was activated on 30 W coag mode. Plasma energy (Peak Plasma Blade, Medtronics, Minneapolis, MN) was activated on a "6" setting.

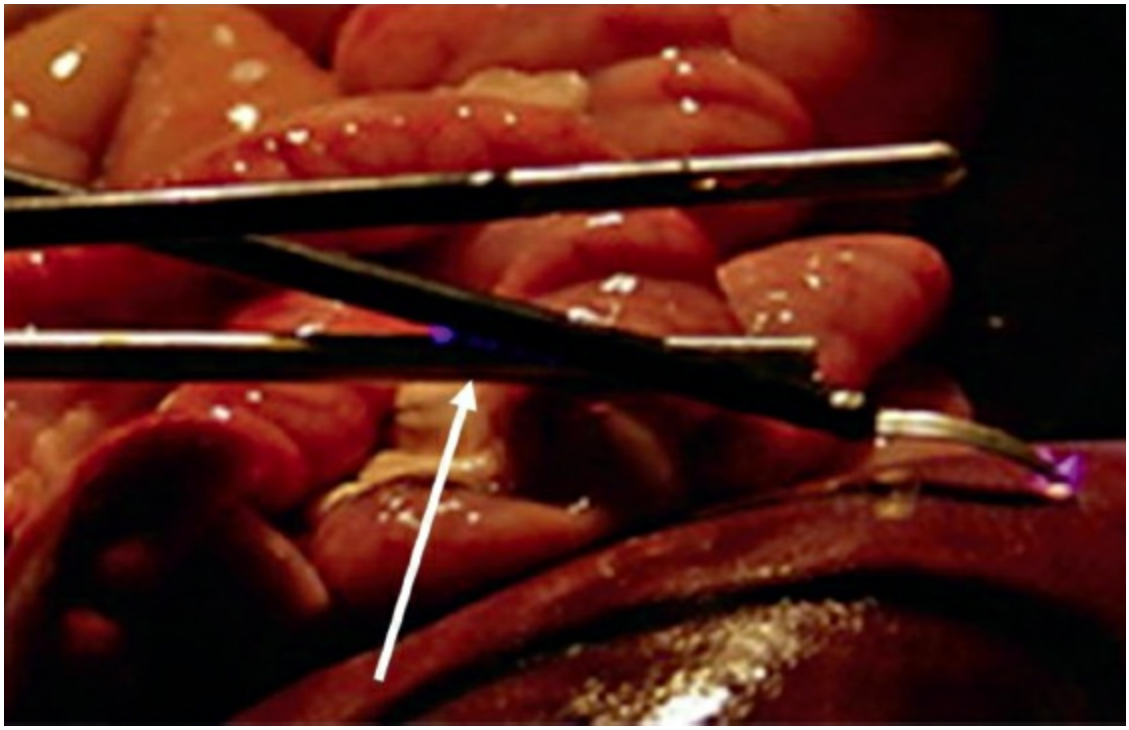

Figure 19.9. Direct coupling. Direct contact between the active electrode and nearby metal objects results in transfer of energy whether intentionally or unintentionally. The *white arrow* depicts unintentional transfer of stray energy to the laparoscopic suction device via direct coupling. (Reprinted from Odell RC. Surgical complications specific to monopolar electrosurgical energy: Engineering changes that have made electrosurgery safer. *J*

Minim Invasive Gynecol 2013;20(3):288–98. Copyright © 2013, with permission from Elsevier.)

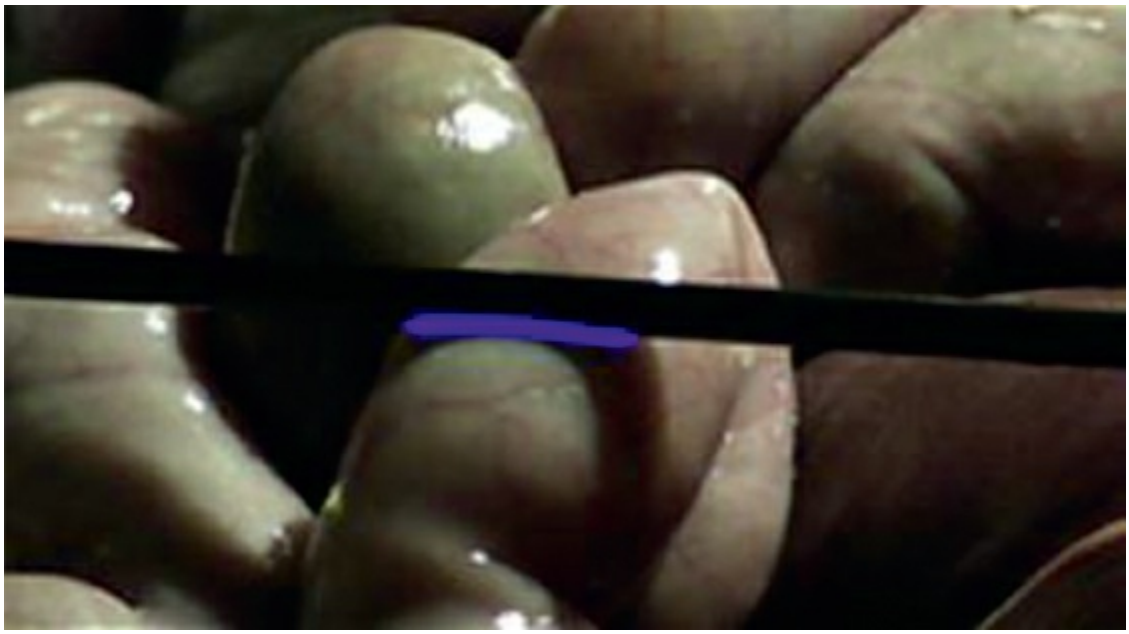

Figure 19.10. Capacitive coupling. Activation of monopolar L-hook with resultant transfer of stray energy directly to bowel via capacitive coupling. (Reprinted from Odell RC. Surgical complications specific to monopolar electrosurgical energy: Engineering changes that have made electrosurgery safer. *J Minim Invasive Gynecol* 2013;20(3):288–98. Copyright © 2013, with permission from Elsevier.)

Clinical Examples: (1) A monopolar instrument with an extension is activated in the pelvis while unintentionally touching a forceps that is retracting the ureter during a low anterior resection resulting in delayed ureteral injury. (2) A monopolar, laparoscopic L-hook is activated near the tip of the metal suction–irrigation resulting in energy transfer to the suction tip and into unintended tissue (Fig. 19.9).

Preventative Strategies: (1) Avoid contact with other conductive instruments prior to activation. (2) Maintain complete visualization of the monopolar electrode in contact with the tissue.

Capacitive Coupling

Capacitance is stored electric charge when two conductors are separated by an insulator. This stored energy can be transferred, through intact insulation, into nearby conductors (such as the bowel) resulting in thermal injury (Fig. 19.10). Capacitive coupling occurs almost exclusively with

monopolar energy use due to its high voltage. Open air activation (activation without touching tissue/completing the circuit) maximizes the risk of stray energy transfer to the patient via all mechanisms of unintentional energy transfer. The close proximity and parallel alignment of SILS also increases the risk of unintentional thermal injuries secondary to capacitive coupling.

Clinical Examples: (1) The laparoscopic monopolar L-hook is activated and capacitive energy is discharged directly into bowel contacting the insulated shaft of the instrument resulting in a delayed bowel injury (Fig. 19.10). (2) Prior to the development of video cameras for laparoscopy, surgeons looking directly through the eyepiece of the laparoendoscope would suffer burns to their eyes due to capacitive coupling.

Preventative Strategies: (1) Utilize lowest power setting to achieve effect or low energy devices (bipolar, ultrasonic). (2) Avoid the use of combined metal/plastic laparoscopic trocars. (3) Maintain complete visualization of instruments during energy activation.

SPECIAL CONSIDERATIONS

Endoscopy

Endoscopy is the standard tool for the evaluation and treatment of gastrointestinal disorders. The risk of major complications such as bleeding or perforation is less than 1:500. This risk increases to as much as 1:5 during complex procedures such as endoscopic mucosal or submucosal resections and large polypectomies, most of which cannot be completed without energy. Multiple studies have now defined the use of energy in any form during endoscopy as a risk for of postpolypectomy syndrome, bleeding, and perforation.

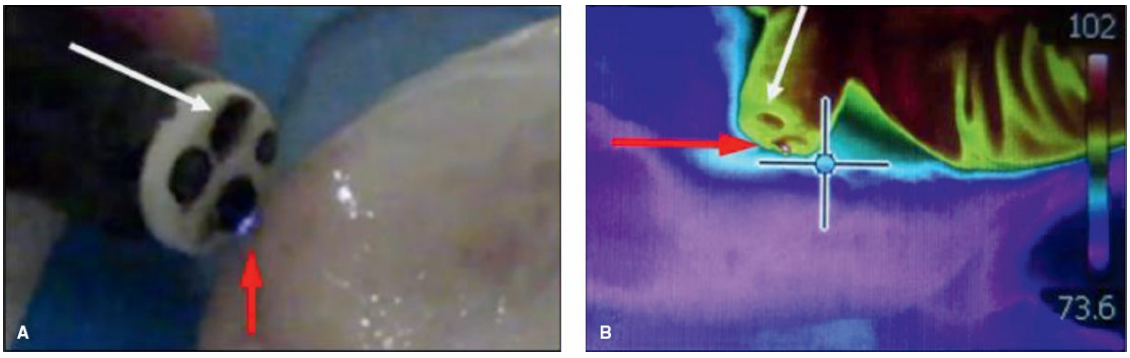

Figure 19.11. Stray energy transfer during endoscopy. **A.** Energy

is transferred directly to bowel from the endoscope camera lens (*red arrow*) when the monopolar snare is activated (retracted into the working channel) (*white arrow*). **B.** Thermal imaging by a separate camera demonstrating tissue temperatures in excess of 100°C (*red arrow*).

Monopolar energy remains the most common modality used during endoscopy and is vulnerable to the same mechanisms of stray energy transfer as open or laparoscopic surgery. Preliminary studies by the authors have demonstrated significant energy transfer within the endoscope itself secondary to antenna and capacitive coupling (Fig. 19.11). This likely results in energy transfer directly to the bowel wall from the endoscopic camera cord/lens that is not within the endoscopist's field of view and may be the source of increased complications with energy use during endoscopy (Fig. 19.12).

Another source of unintended bowel injury during endoscopy takes place via direct coupling. While activating the monopolar energy during polypectomy, energy can transfer through the polyp and into the opposing bowel wall if it is contacting, or near the tip of the polyp (Fig. 19.13). This can be avoided by fully insufflating the bowel during polypectomy to avoid any contact of the polyp to nearby structures. Alternatively, if complete insufflation is not possible, rapid movements or "wiggling" the polyp to avoid prolonged contact with the opposing bowel wall will decrease the risk of thermal injury.

One final situation bears special mention: the use of argon plasma devices during endoscopy. Plasma devices heat superficially, so perforation is rare; however, they utilize high voltage which places patients at increased risk for injury via stray energy transfer to the endoscopic camera cord and lens. In addition, continuous insufflation of argon gas can lead to significant organ distention, perforation, and gas explosion. Avoidance of prolonged argon plasma coagulator activation and use of the minimal power settings necessary for tissue effect are recommended.

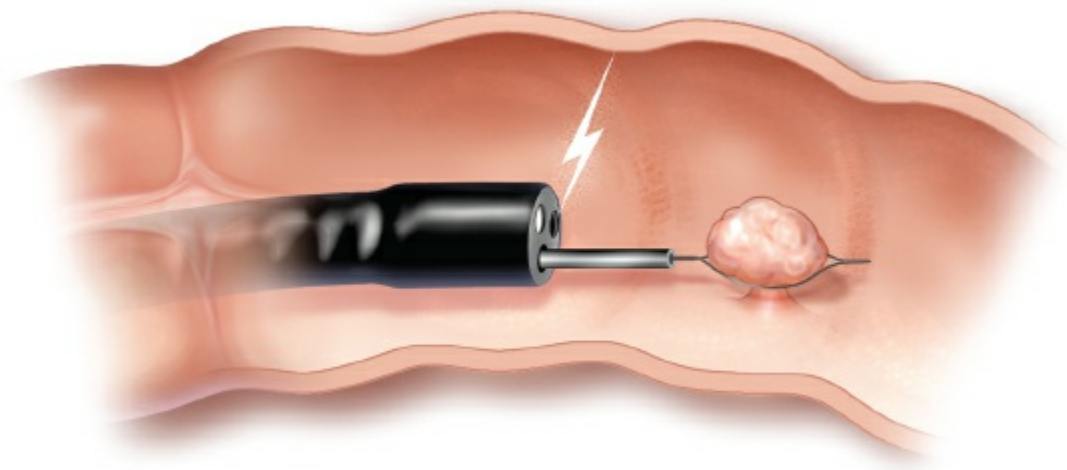

Figure 19.12. Stray energy transfer directly to bowel wall during endoscopy. Stray energy transferred within the endoscope may concentrate on the camera wire and discharge directly from the lens and into the bowel outside of the endoscopist's field of view. This may result in delayed bleeding and/or perforation as it is.

Pregnancy and Pediatric Surgery

Surgical energy can be used safely in patients of all ages and states. It bears special mention that children and infants have limited surface area to accommodate monitors, dispersive electrodes, and the surgical site. This can make adherence of the dispersive electrode difficult and smaller pads should be used for all children less than 13.6 kg (30 lb). Adult size dispersive electrodes should *never* be "cut to size" for small children and infants.

The high body surface area to volume ratio as well as elevated total body water content makes current flow less predictable in children than in adults. Similar redistribution of water in pregnant women warrants reduction in energy settings to only that necessary to generate tissue effect. Many clinicians use power settings at 50% of those in adults when operating on pregnant women or children. While specific studies have not been done, there appears to be no additional risk to the fetus at any point in gestation when using electrosurgical devices.

CONCLUSION

The best energy device for a particular patient and surgery is dependent on a multitude of factors. The characteristics of each energy device should be considered in addition to other factors such as device availability and user

experience which are not universally quantifiable (Table 19.2). Monopolar energy remains the most common and versatile instrument in the surgeon's energy armamentarium. However, that versatility brings the highest risks for electrosurgical complications and is inappropriate for certain applications such as sealing of large vessels. An industry-sponsored proliferation of advanced devices that seek to fill that gap complicates the surgeon's decision and limits the validity of blanket recommendations for a single device for every situation. Instead, the universal goal of decreasing the complications of stray energy can be had by following the summative strategies listed in Table 19.3.

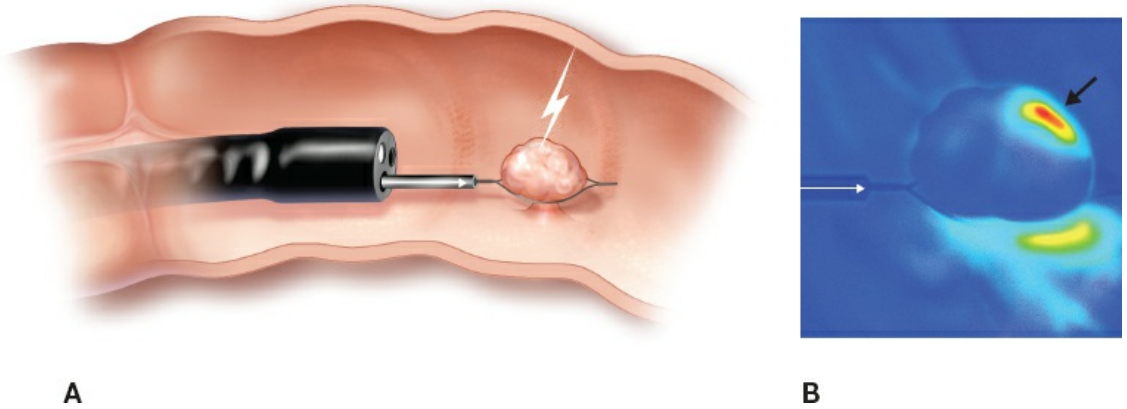

Figure 19.13. Direct coupling during endoscopy. **A.** During endoscopic polypectomy stray energy transfers directly through the polyp and into the opposing bowel wall. **B.** Thermal imaging demonstrating temperatures ≥98°C (red color at tip of *black arrow*) due to direct coupling to the bowel wall opposite the polyp (*white arrows* indicate the snare protruding from the endoscope).

TABLE 19.2 Common Electrosurgical Device Comparisons

	Monopolar	Bipolar	Ultrasonic
Energy ouptut	1,400–9,000 V	100–150 V	N/A
Cost	$10	$10—500	$500
Ability to incise skin	Excellent	Poor	Poor
Vascular sealing	≤2 mm	≤7 mm	≤3 mm
Smoke production	Low	High	Moderate
Electrosurgical Risk			
Insulation failure	**High**	Low	Low
Antenna coupling	**High**	Minimal	Minimal
Residual heat	Low	Moderate	**High**
Direct coupling	Moderate	Low	Low
Device interaction	**High**	Low	Low
Direct application	Moderate	Low	Moderate
Capacitive coupling	Moderate	Low	Low

Costs are based upon average operating room charge at a large academic center.

TABLE 19.3 Practical Steps to Minimize Risk of Electrosurgical Complications

Techniques to Minimize Risk of Electrosurgical Injury

- Reduce power setting to the lowest necessary
- Separate the active electrode ("Bovie") and dispersive electrode cord from all other cords
- Utilize low voltage cut or blended modes or low voltage devices (bipolar, ultrasonic)
- Avoid instrument activation when it is not completely within view
- Avoid instrument activation when not contacting tissue
- Maintain a low oxygen environment, especially when operating around the face or airway
- Always place the device in a sleeve or holster when not in use

Practice techniques to decrease risk of unintentional thermal injury when using electrosurgical devices.

It is everyone's responsibility in the operating room to understand how electrosurgery works and to take steps to ensure the patient's safety. As our understanding of surgical energy device function increases so should the safety of our operating rooms. Choosing the right tool for the job requires an evidence-based approach as well as lifelong learning. This chapter provides a basic understanding of the common devices and their applications but this should be supplemented with more in-depth training via FUSE certification and/or other energy-based curriculum.

EDITOR’S COMMENT

Drs. Mikami and Jones have scripted a brilliant chapter on energy devices and safety. Critical is the basic understanding of the physics of an energy source for its best utilization in the operating room theater. It is even more important to ensure the safety of the patient and the staff alike. The fact that energy devices account for 5% of injuries in the operating room is incredible. The authors review the most common types of energy used, the most common patterns of injury (fires, antenna coupling, insulation failure, residual heat, direct application interaction with electronic devices, direct coupling and capacitive coupling) and provide a guide to selecting the best device for the desired tissue effect and avoiding a device-related injury. They admonish the reader that it is right and proper for everyone to obtain FUSE certification.

The FUSE didactics are available to everyone, free-of-charge at http://www.fusedidactic.org/ (accessed April 19, 2017). The curriculum is also available to take at the Society of Gastrointestinal and Endoscopic Surgeons (SAGES), American College of Surgeons (ACS), or at regional testing centers. One can obtain 6, Part I, self-assessment continuing medical education (CME) credits by taking the course. The curriculum covers the fundamentals of electrosurgery in more detail than Mikami and Jones in this chapter including physics of the electrosurgical generators and the biochemical effects on cells. The FUSE course further describes the circumstances, mechanisms, and prevention of injuries by a variety of instruments and in a mélange of situations. The FUSE curriculum also focuses on prevention strategies and how to report and handle adverse device events as well as meet regulatory requirements.

One area not mentioned in this chapter is the type of energy used to develop flaps for any procedure. In my practice, an important area is how one uses cautery or plasma energy devices in the development of skin flaps during a nipple skin–sparing mastectomy. It is critical to use the right energy or mode in developing such flaps. In my view, coag should be used sparingly as the heat generated in this mode can injure the vascularity of the flap and frequently cause flap necrosis and subsequent infection. When cauterizing a blood vessel

care should be used to aim the cautery parallel to the skin so the current does not arc and burn a hole right through the skin flap. As described in this chapter, it is better and more effective to pick up the blood vessel with forceps and use the cut or high current mode. The plasma blade is the coolest of these but should also be used parallel to the skin. As so aply put by the authors “the ultimate goal of energy application is the ability to utilize the smallest amount of energy possible to create the desired tissue effect.”

Radiofrequency ablation (RFA) is increasingly used in a number of surgeries today. Key to the more effective use of many of the electrosurgery instruments commonly used in the operating room is maximizing the use of current density to achieve the desired tissue effect as well as understanding the difference between using radiofrequency for electrosurgical use versus that of volumetric ablation. By manufacturing specifications it is safe to use RFA devices in the presence of a pacemaker or defibrillator but I perfer to turn them off and have an external device in the OR if necessary. However, as Mikami and Jones show any internal or external wires should not be in parallel with those of the RFA device. Grounding pads should be distant to any cardiac-related devices and any metal hardware. Compared with the other more common entities used for ablation (cryoablation, laser and microwave), RFA is by far and away the most reliable and consistent. We have also published a reliable Doppler method of following and determining the extent of ablation by RFA as well as help avoid the injuries described within this chapter. Microwave is the most inconsistent method of ablation and its use poses the greatest risk of injury. I use the analogy of putting a frozen hot dog in a home microwave. At the end of the allotted cooking time, half of the hot dog will still be frozen and the other half would have exploded because it got too hot. Research will help solve this issue in the future as focused ultrasound holds great promise for incisionless ablation.

This chapter is also very thorough in detailing the various mistakes one can make while performing endoscopy especially polypectomies. A risk of one in five is incredible but believable. How many of us have not been consulted for a perforation after an endoscopic polypectomy? The authors provide scenarios and illustrations on how these injuries happen and how to avoid them. In the case of laparoscopic injuries even some clues of where to look when injures occur.

The fact is that high energy devices are the most common cause of injury in operating room. There are also a major reason behind surgical fires and burns and the subsequent litigation. In a 33-year review of medical litigation from Mayo and Marshfield Clinic, Choudhry and colleagues review 139 cases. Most of these (82%) were operative burns and the rest surgical fires. One fourth of these were burns to the face. The most common source of the injury (43%) was a high energy device with death reported in two cases. Young age and the mention of a nonsurgical physician as a defendant both were shown to be independently associated with award payout which occurred in 60% of the cases. Median award pay-out was $215,000. The authors concluded that

understanding and addressing pitfalls in operating room may mitigate errors and hypothetically lessen impending liability. Surgery is a team approach and all members of the team should be knowledgable and empowered to make the operating room safe and avoid errors. Recent work by Molina and colleagues from the Brigham and Women's Hospital and Harvard demonstrated that even the perception of safety of surgical practice and respect among operating room personnel is associated with hospital-level 30-day postoperative death. A culture of safety is a priority for the whole team. It is incumbent upon the surgeon to lead this effort and do it in such a way that operating room personnel feel respected and invited to speak up on behalf of patient safety.

SECTION III

THE HEAD AND NECK

20 Anatomy of the Head and Neck

Aaron Ruhalter

SURFACE ANATOMY

Surface anatomy is the relationship between structures that are visible and/or palpable with structures that are not visible and/or palpable. Visible and/or palpable structures in the neck include the following:

1. Sternocleidomastoid (sternomastoid) muscle that attaches to the superior aspect of the manubrium sternum by a tendinous head and from the medial third of the clavicle by a muscular head. It passes superiorly in a lateral, and then posterior, direction. Its superior attachment is to the mastoid process, and the lateral end of the superior nuchal line. Unilateral contraction of the muscle approximates the ear to the ipsilateral shoulder, while rotating the chin to the contralateral side. Bilateral contraction of the muscle can result in either flexion or extension of the head. If the head is slightly flexed, bilateral contraction will result in increased flexion. If the head is slightly extended, bilateral contraction will result in increased extension. The pulsation of the carotid artery is palpable, anterior to the edge of the muscle.
2. Trapezius muscle that has a very broad origin from the medial portion of the superior nuchal line, external occipital protuberance, ligamentum nuchae, spinous processes, and the supraspinous ligaments of the thoracic vertebrae. The muscle fibers converge and insert on the lateral third of the clavicle and the acromion process of the scapula. Because of the extensive origin of the muscle, differential contraction will create different movements. Contraction of the upper fibers will cause elevation of the scapula. Depression of the scapula is created by contraction of the inferior fibers. The middle fibers will cause the medial edge of the scapula to approach the midline. The external branch of the accessory nerve provides innervation to the trapezius and sternocleidomastoid muscles. Branches from the second and third cervical nerves provide added innervation.
3. Mastoid process.

4. Ramus of mandible.
5. Hyoid bone, palpable in the midline of the neck when the mandible is slightly depressed. It is located at the level of the third cervical vertebra. The greater horn of the hyoid bone can be traced to its lateral termination. This is the approximate level of origin of the lingual branch of the external carotid artery. The superior thyroid branch arises just inferior to this point, and the facial branch begins just superior to the same palpable landmark.
6. Fused laminae of the thyroid cartilage. The upper edge of this palpable structure is situated at the level of the fourth cervical vertebra. It represents the site of bifurcation of the common carotid artery.
7. Arch of the cricoid cartilage, palpable below the inferior end of the thyroid laminae. A small defect separates them. The cricoid cartilage represents an "anatomical bonanza" because it is a landmark for many anatomical occurrences. It may be referred to as the "cricoid plane."

   - The larynx ends, and the trachea begins.
   - The pharynx ends, and the esophagus begins.
   - The cricoid cartilage is at the level of the sixth cervical vertebra.
   - The intermediate tendon of the omohyoid muscle is found anterior to the carotid sheath.
   - The inferior thyroid artery passes posterior to the carotid sheath on its way to the lateral lobe of the thyroid gland.
   - The middle cervical sympathetic ganglion lies on the transverse mass of the sixth cervical vertebra.
   - The recurrent laryngeal nerve enters the larynx.
   - The ansa cervicalis is found anterior to the carotid sheath.
   - The vertebral artery enters a foramen in the transverse mass of the sixth cervical vertebra. This occurs at the apex of a muscular triangle formed by the anterior scalene and longus coli muscles. The base of the triangle is the first portion of the subclavian artery.
   - The superior pair of parathyroid glands is often found at this level.

8. Upper tracheal rings that are palpable between the cricoid cartilage and the superior edge of the manubrium sternum.
9. Superior edge of the manubrium of the sternum. It is at the level of the second thoracic vertebra.

STRUCTURE OF THE NECK

Skeletal Background

The cervical portion of the vertebral column creates the skeletal background. It is composed of seven cervical vertebrae, with a characteristic anterior convex curvature. Vertebrae C3 through C6 are considered to be typical cervical vertebrae. Vertebrae C1, C2, and C7 are atypical cervical vertebrae. C1 (atlas) has no body. C2 (axis) has incorporated the body of C1 in its structure. The combination of the two bodies results in a tooth-like projection called the odontoid process, or dens epistrophe.

This provides an axis of rotation for the skull on the atlas. C7 has a large transverse mass with a primitive foramen and a prominent spinous process (vertebra prominens). The typical cervical vertebrae have a bifid spinous process and a distinct foramen in the transverse mass. There are anterior and posterior tubercles related to the transverse mass. The first rib must be included in the skeletal background. Many of the neck structures are attached to, or pass over, the first rib. The superior surface of the first rib is flattened. This will avoid trauma to the neurovascular structures that travel over it. Midway between the vertebral and the sternal ends of this rib is the scalene tubercle, point of insertion of the anterior scalene muscle. A vascular sulcus is found on both sides of the scalene tubercle. The anterior sulcus provides passage for the subclavian vein. The subclavian artery passes over the posterior sulcus. The anterior scalene muscle attaches to the first rib between the subclavian vessels. The middle scalene muscle attaches to the first rib posterior to the groove for the subclavian artery. Therefore, the subclavian artery passes through the scalene triangle that is created by the anterior and middle scalene muscles. This area is referred to as the root of the neck. It will be described in more detail later in this chapter.

Ligamentous Background

The ligamentous background includes supporting structures for the atlanto-occipital and atlantoaxial joints. The anterior longitudinal ligament is found on the anterior aspect of the vertebral bodies. It extends from the atlas down to the upper sacral segment. It is attached to the intervertebral disc and that portion of the vertebral body lying just superior and inferior to the disc. The nuchal ligament covers the spinous processes of all the cervical vertebrae.

Muscular Background

The muscular background includes muscles that are attached to the anterior aspect of the vertebra (anterior vertebral) and muscles that are attached to the lateral mass of the vertebra (lateral vertebral). Both of these groups are combined and are referred to as prevertebral muscles. The longus coli and longus capitis muscles are anterior to the vertebral column. The longus coli is a complex muscle that is attached inferiorly to the upper thoracic portion of the anterior longitudinal ligament. These lower fibers pass superolaterally and attach to the transverse masses of the typical cervical vertebrae. Fibers of this same muscle then pass superomedially and attach to the anterior portion of the arch of the atlas. There are vertical fibers of this same muscle that lie between the two oblique portions laterally and the anterior longitudinal ligament medially.

The longus capitis muscle lies anterior to the superomedial fibers of the longus coli muscle. It passes from the base of the skull to the tubercles of the typical cervical vertebrae. The muscles that are lateral vertebral in position are the levator scapula, middle, and anterior scalene muscles. The levator scapula muscle is the most posterior of this lateral group. It arises from the posterior tubercles of the transverse masses of the first four cervical vertebrae, descends, and attaches to the superior portion of the vertebral border of the scapula. The middle scalene muscle is on a more anterior plane (Fig. 20.1).

The middle scalene muscle may be attached to the posterior tubercles of all cervical vertebrae. It descends and affixes to the superior flattened surface of the first rib, posterior to the groove for the subclavian artery. A few muscle fibers extend down to the second rib and create the posterior scalene muscle. The most anterior of the lateral vertebral muscles is the anterior scalene (Fig. 20.1). It arises from the anterior tubercles of the transverse masses of the typical cervical vertebrae and attaches below to the scalene tubercle of the first rib. It is in the same frontal plane as the longus capitis muscle. The anterior vertebral muscles will flex the cervical spine. The lateral vertebral muscles will cause lateral bending of the same area. Motor innervation is provided by ventral rami of cervical nerves.

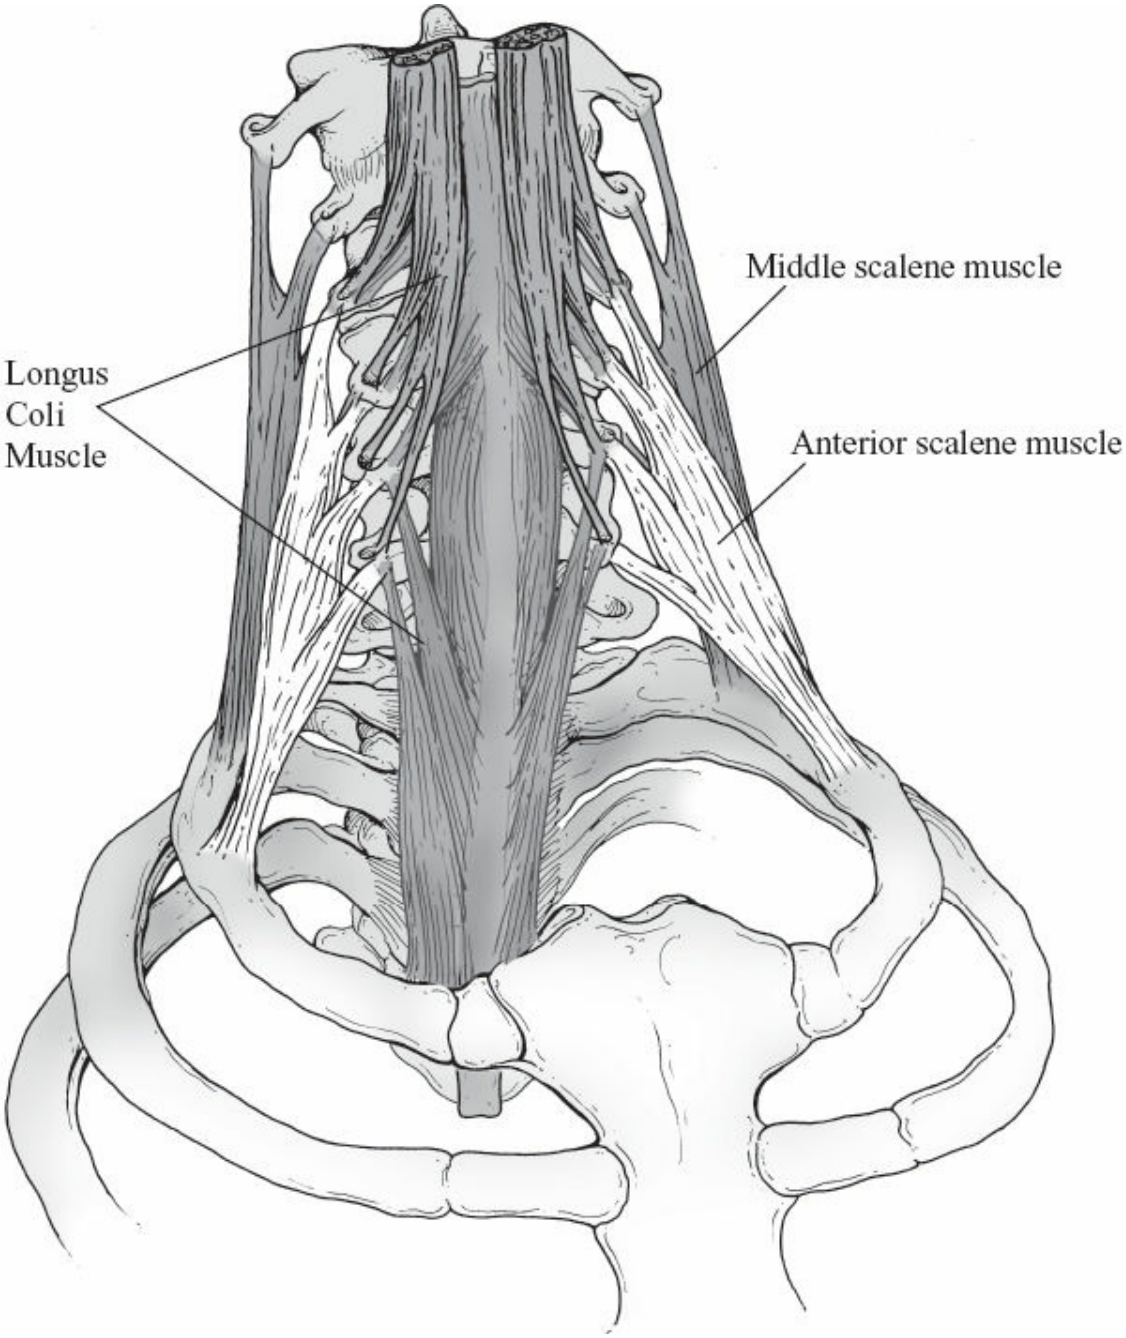

Figure 20.1. Structures of the Neck-1. Scalene muscles of the neck.

Nerve Background

The nerve layer should now be inserted. The nerves and the muscles are intimately related, so that the term “neuromuscular layer” is appropriate. The cervical and brachial plexuses and the cervical sympathetic chains are now encountered as we continue the reconstruction of the neck.

The cervical sympathetic chain consists of three ganglia with connecting branches. The superior ganglion is the largest, and it is found

on the transverse mass of the second and third cervical vertebrae. It is >1 in long and lies on the longus capitis muscle, posterior to the carotid sheath. The middle cervical ganglion is the smallest and lies on the transverse mass of the sixth cervical vertebra. The inferior cervical ganglion is related to the vertebral end of the first rib and the transverse mass of the seventh cervical vertebra. It frequently joins with the first thoracic ganglion to form a dumbbell-shaped structure called the cervicothoracic, or stellate, ganglion. Stellate refers to the star-like appearance created by the multiple branches that are emitted. It is posterior to the vertebral artery. At times, branches from the middle cervical ganglion will form a loop around the subclavian artery before entering the inferior ganglion. This is referred to as the ansa subclavia.

The cervical plexus is formed by the ventral rami of the first four cervical nerves. These nerves connect to each other by forming loops that lie in the interval between the levator scapula, or the middle scalene, muscle posteriorly, and the longus capitis or its inferior continuation, the anterior scalene muscle, anteriorly (Fig. 20.2).

Each of the first four cervical ventral rami receives a branch from the superior cervical ganglion. The cervical nerves lie within the prevertebral fascia. The cervical plexus provides muscular and cutaneous innervation. There are cutaneous branches from a superficial cervical plexus and muscular branches from a deep cervical plexus. The cutaneous branches will be described with the posterior triangle. Muscular branches innervate the prevertebral muscles. In addition, a branch from C1 travels with the hypoglossal nerve and gives rise to the superior limb (descending hypoglossal nerve) of the ansa cervicalis. Branches from C2 and C3 will form the inferior limb (descending cervical nerve). The two limbs unite and form the ansa cervicalis. This nerve loop is on the anterior aspect of the carotid sheath, in the cricoid plane. Branches arise from the ansa cervicalis that provide motor innervation to the strap muscles in the muscular triangle. Other branches of C1, traveling with the hypoglossal nerve, provide motor innervation to the thyrohyoid and geniohyoid muscles. A branch from C4 descends on the anterior surface of the anterior scalene muscle, within the prevertebral fascia. It is the phrenic nerve and it may receive branches from C3 and C5. It is, at first, seen on the lateral aspect of the anterior scalene muscle, but as it descends it passes obliquely across the anterior surface of the muscle and reaches its medial edge in the root of the neck. It then passes anterior to the subclavian artery and courses

medial to the internal mammary artery before entering the thorax. It provides sensory and motor innervation to the respiratory diaphragm (Fig. 20.2). There are some proprioceptive branches arising from the cervical plexus that pass to the sternocleidomastoid and trapezius muscles.

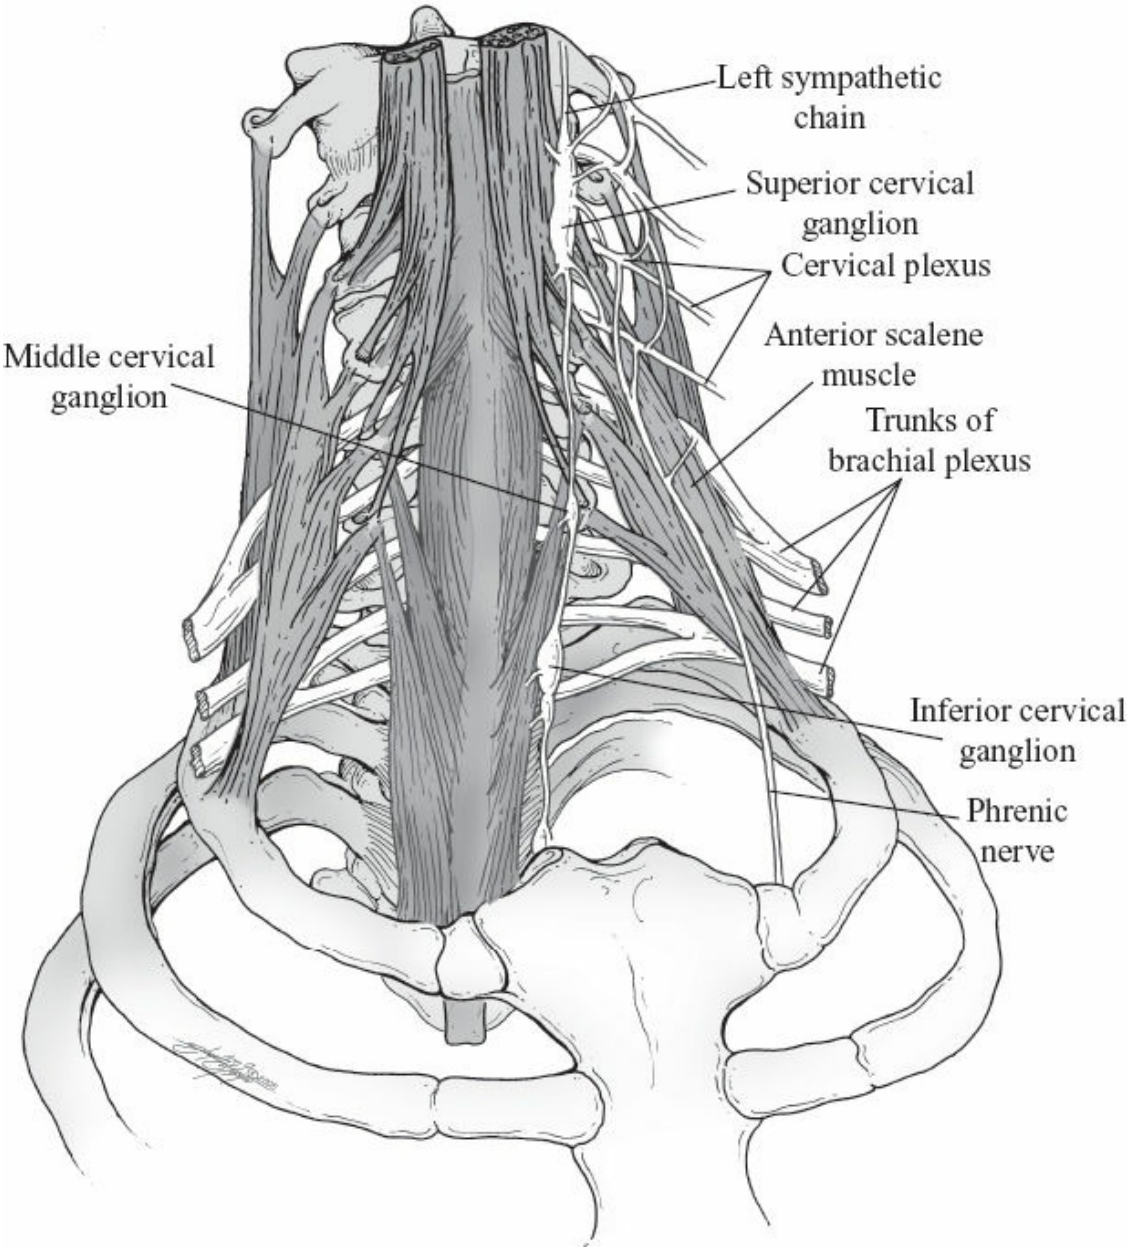

Figure 20.2. Structures of the Neck-2. Ganglia and cervical plexus structures.

As we pass inferiorly in the cervical region, the nerves now encountered will consist of the roots and trunks of the brachial plexus. The brachial plexus is created by the ventral rami of C5 through T1. These roots will form three trunks. C5 and C6 join to form the upper trunk. The

C7 root will become the middle trunk, and roots C8 and T1 will merge and form the lower trunk. These roots and trunks pass between the middle and the anterior scalene muscles. The lower trunk is draped over the first rib immediately posterior to the subclavian artery (Fig. 20.2).

The subclavian vein, unlike the accompanying artery, does not pass between the scalene muscles. It passes anterior to the anterior scalene muscle. Enclosing the skeletal background and the neuromuscular layer is the prevertebral portion of the deep cervical fascia. The neurovascular structures will pierce the deep cervical fascia and drag a portion of it along with them, creating the axillary, or cervicoaxillary, sheath.

Fascia of the Neck

The cervical fascia is composed of superficial and deep layers. The superficial fascia is not well developed and not easy to find. It consists of fat and some connective tissue. The platysma muscle is in the superficial fascia. It arises inferiorly from the fascia of the pectoralis major muscle and its fibers converge as they ascend to their insertion in the inferior part of the mandibular region. Some of the muscle fibers ascend and mix with the intrinsic depressor muscles of the lips. The cutaneous nerves and the superficial veins course below this muscle of facial expression. The cervical branch of the facial nerve innervates this muscle.

The deep cervical fascia consists of several layers. The superficial, or investing, layer of the deep cervical fascia splits to invest the trapezius and sternocleidomastoid muscles and the submandibular and parotid glands. It creates a complete tube that surrounds the neck. The deep layer of the deep cervical fascia, or prevertebral fascia, encloses the vertebral column and the attached erector spinae and prevertebral muscles and proximal portions of the cervical and brachial plexuses. It creates a complete tube.

The pretracheal fascia creates a tube that encircles the pharynx and esophagus, larynx and trachea, and the thyroid and parathyroid glands. The buccopharyngeal fascia is the posterior extension of the pretracheal fascia that covers the constrictor muscles of the pharynx. It is in contact with the anterior, or prevertebral, portion of the prevertebral fascia. This potential space between the prevertebral and the buccopharyngeal fascia layers extends from the neck down to the mediastinum. This retropharyngeal space can serve as a pathway for the spread of an infection from the neck to the thorax. The middle cervical fascia extends from the hyoid bone to the sternum. It encompasses all the strap muscles. This fascia layer extends

laterally to the omohyoid muscle and therefore is only related to the muscular and subclavian triangles.

The carotid sheath is a protective, tubular fascial sheath found between the base of the skull and the root of the neck. It receives tissue contributions from all layers of the deep cervical fascia and encloses the common carotid and internal jugular vascular conduits and vagus nerve. After the bifurcation of the common carotid artery, the internal carotid branch will assume its position in the sheath. The vein is anterolateral to the artery, except at the base of the skull, where the vein lies posterior to the artery. The vagus nerve is between, and slightly posterior to, the blood vessels. The ansa cervicalis is on the anterior surface of the sheath in the cricoid plane. The sympathetic chain is in contact with the posterior surface of the sheath.

ROOT OF THE NECK

The root of the neck is the anatomical intersection between the thorax, neck, and axilla. The superior thoracic aperture, or thoracic inlet, and axillary (or cervicoaxillary) sheath create a pathway for the neurovascular structures found in this area. Neck structures also contribute to the complexity of the anatomy in this important region. Passing between the clavicle and the first rib are nerves, arteries, and veins of the upper extremity. Narrowing of this costoclavicular canal can cause compression of these neurovascular structures. The thoracic inlet is created by the upper end of the manubrium anteriorly, the first rib and its costal cartilage laterally, and the first thoracic vertebra posteriorly. Structures passing through this area are medial or lateral in position. The esophagus and the trachea are medial as they enter the mediastinum. The thoracic duct lies just to the left of, and posterior to, the esophagus. In the root of the neck, at the level of C7, the duct passes laterally. It courses anterior to the left vertebral and left inferior thyroid arteries and posterior to the carotid sheath. It then travels anterior to the anterior scalene muscle. It is superficial to the prevertebral layer of the deep cervical fascia. The duct then descends anterior to the left subclavian artery and terminates at the lateral edge of the junction between the left internal jugular and the left subclavian veins (see Fig. 20.5).

The equivalent of the thoracic duct on the right side of the root of the neck is called the right lymphatic duct. It is much smaller and may be represented by several small ducts. It receives lymph from the right

hemithorax, right upper extremity, and right side of the head and the neck. Lymph from all other parts of the body is transported by the thoracic duct. The sympathetic chains are in contact with the head of the rib at this level. The recurrent laryngeal nerves, branches of the vagus (X) nerve, are also medial. The right recurrent laryngeal nerve arises in the root of the neck, loops around the right subclavian artery, and passes superomedially as it courses toward the tracheoesophageal groove. Its counterpart on the left arises in the mediastinum, loops around the aortic arch, and then ascends into the neck by way of the left tracheoesophageal groove. The right recurrent nerve, in the root of the neck, travels toward the right tracheoesophageal groove, but it may not yet have reached this protected position and is therefore more exposed to injury.

The apex of the cervical parietal pleura ascends to the neck of the first rib. The anterior end of the rib is lower than the posterior end; therefore, the apex of the lung can ascend out of the thorax into the root of the neck (Fig. 20.3). This ascension is most marked during deep inspiration and occupies the lateral portion of the superior thoracic inlet. This portion of the cervical pleura may extend above the superior edge of the clavicle. A tent-like thickening of the prevertebral fascia extends from the transverse mass of C7 to the first rib. It is called Sibson, or vertebropleural, fascia and provides some protection to the pleura when incisions are made in this area.

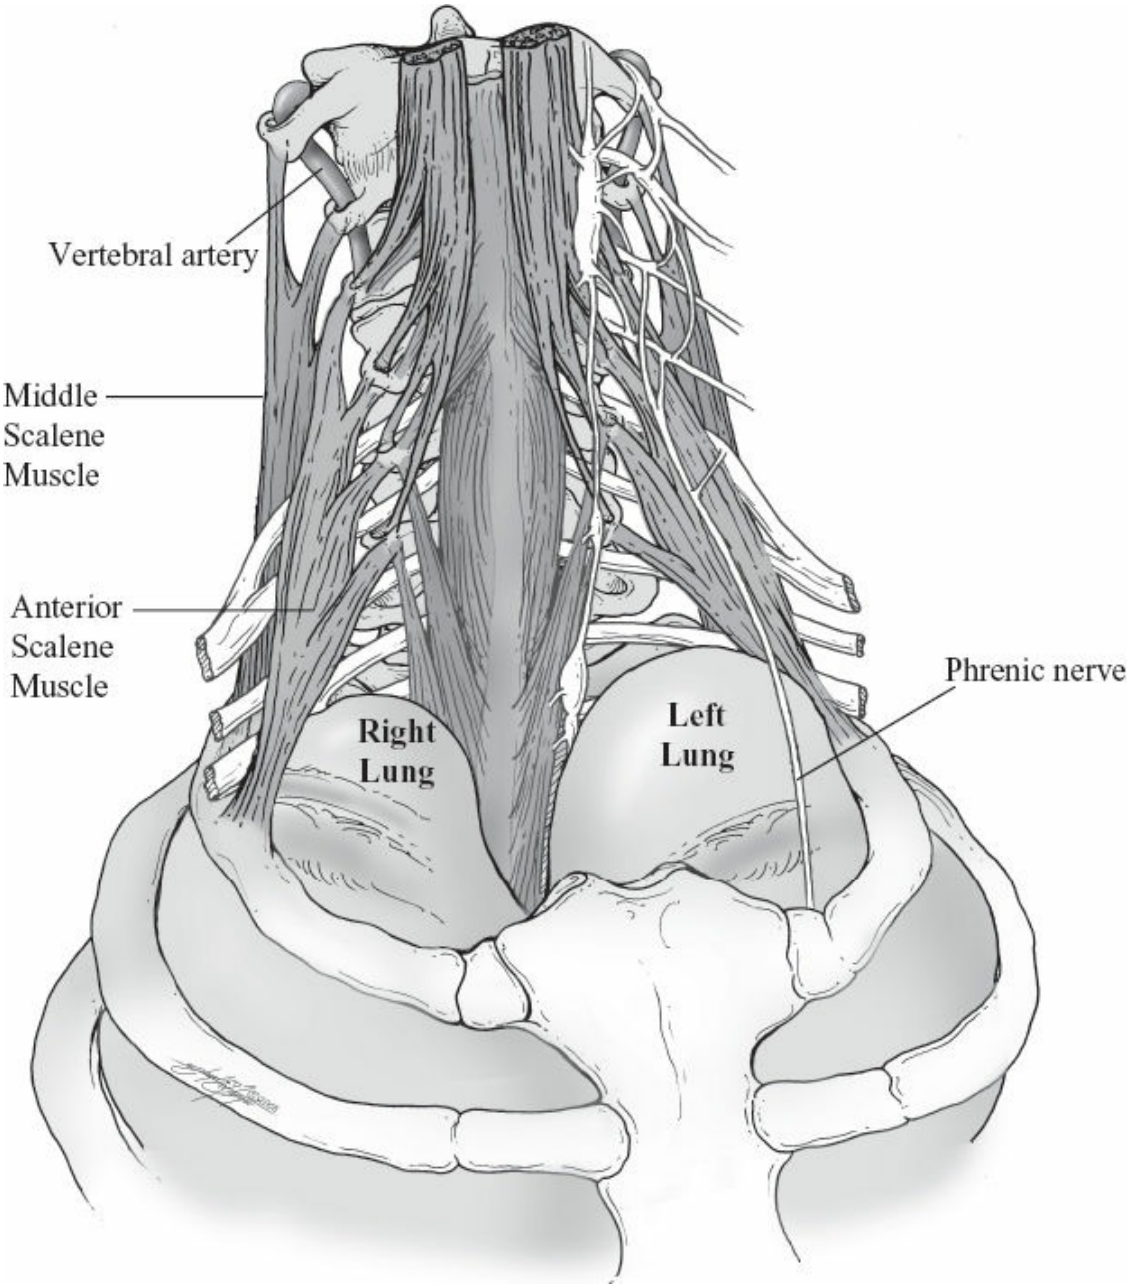

Figure 20.3. The apex of the lung ascends out of the thorax into the root of the neck.

Lateral structures include the subclavian artery and subclavian vein and their branches, and nerve branches from the cervical and brachial plexuses. The cervical or apical area of the lung is also found in the lateral portion of the root of the neck. The first rib and the scalene muscles have important spatial relationships with the anatomy in this area.

The brachiocephalic trunk is the first branch of the arch of the aorta (Fig. 20.4). It passes superolaterally and bifurcates at the level of the right sternoclavicular joint into the right common carotid and right subclavian arteries. The common carotid artery will pass superiorly on the right side

of the neck in the carotid sheath. It will be discussed in more detail later in this chapter. The next branch of the arch of the aorta is the left common carotid artery. The last branch of the aortic arch is the left subclavian artery (Fig. 20.4). The anterior scalene muscle divides the subclavian artery into three segments. The first portion extends from the origin of the vessel to the medial edge of the anterior scalene muscle. The second part lies behind the muscle, and the third segment extends from the lateral edge of the muscle to the lower edge of the first rib. Most of the branches of the subclavian artery arise from the first portion. The first and largest branch is the vertebral artery. It arises from the superior edge of the parent vessel, ascends vertically, and enters a foramen in the transverse mass of the sixth cervical vertebra. The accompanying vein covers it.

The foramen is situated at the apex of a muscular triangle created by the longus coli muscle medially and the anterior scalene muscle laterally. This is referred to as the triangle of the vertebral artery. The second branch is the thyrocervical trunk, which also arises from the superior surface and has a short course before it divides into the following branches. The inferior thyroid artery passes superiorly, anterior to the anterior scalene muscle. The phrenic nerve is within the prevertebral fascia as it passes inferiorly on the anterior surface of this muscle. The inferior thyroid artery is superficial to the prevertebral fascia. At about the level of the apex of the triangle of the vertebral artery the inferior thyroid artery passes medially, coursing posterior to the carotid sheath but anterior to the vertebral artery, and enters the substance of the lateral lobe of the thyroid gland. The transverse cervical and the suprascapular arteries are branches of the thyrocervical trunk that run transversely as they head for the lateral aspect of the neck. They cross the anterior scalene muscle and the phrenic nerve, but are superficial to the prevertebral fascia. The transverse cervical artery will divide into an ascending and descending branch when it reaches the margin of the trapezius muscle. The suprascapular artery will dip down below the clavicle after entering the posterior triangle, pass inferiorly, and contribute to the periscapular vasculature.

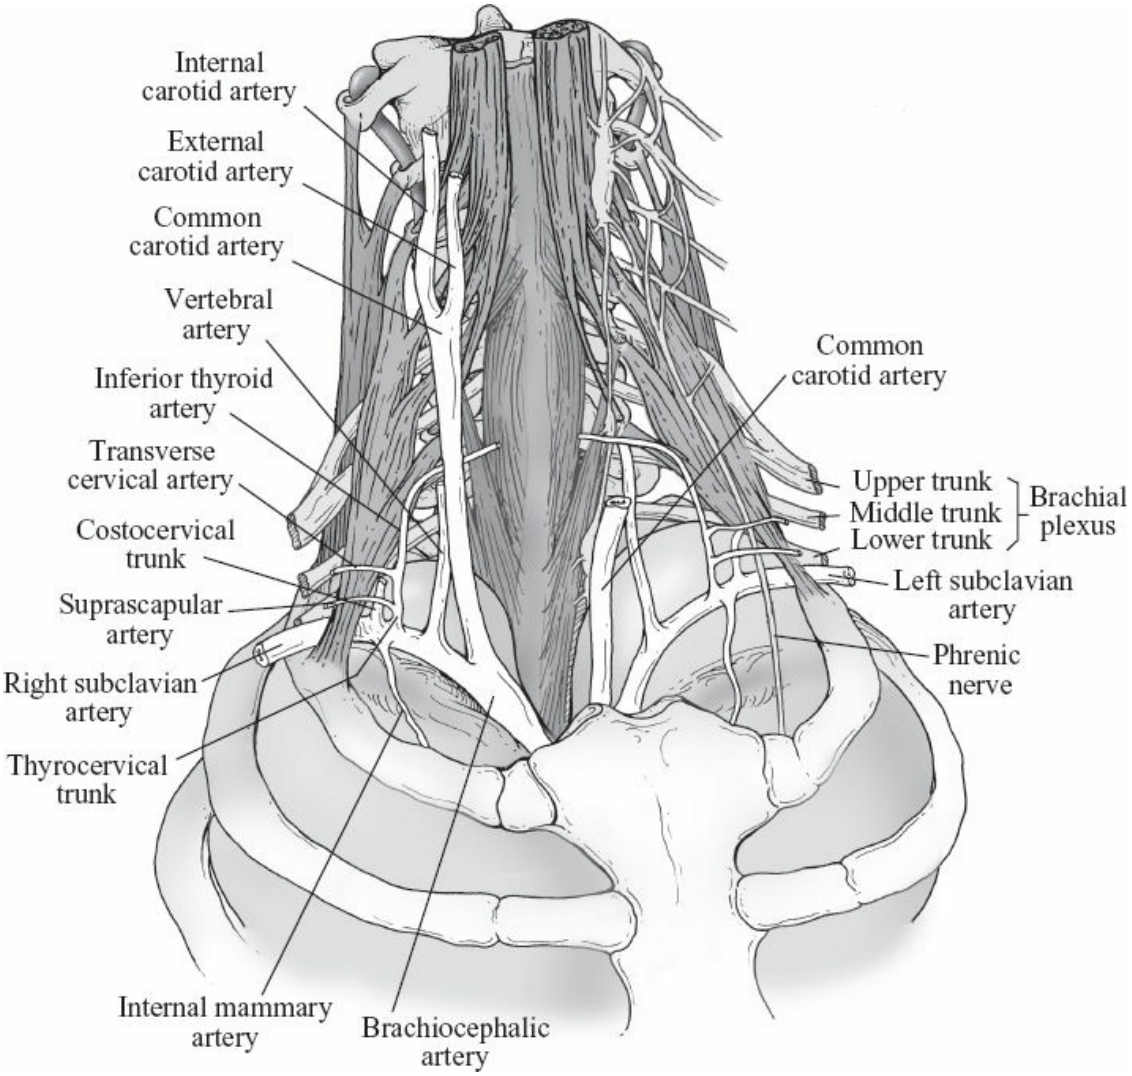

Figure 20.4. Structures of the Neck-3. Branch of the aortic arch.

The next branch originating from the superior aspect of the subclavian artery is the costocervical trunk (Fig. 20.4). It may arise from the second portion of the subclavian, and is therefore less at risk during surgical procedures. It arches over the cervical pleura and, when it reaches the neck of the first rib, divides into the deep cervical artery that passes up and supplies the muscles in the back of the neck and the supreme intercostal artery that creates the first and second posterior intercostal arteries. The first posterior intercostal vein that will enter the ipsilateral brachiocephalic vein, accompanies it.

The last branch of the subclavian artery is the internal thoracic or internal mammary artery. It arises from the inferior aspect of the subclavian artery across from the thyrocervical trunk. It passes inferomedially, courses posterior to the subclavian vein, and initially is in contact with the cervical pleura as it heads for the first costal cartilage. It

then assumes its characteristic location parallel to the lateral edge of the sternum. The subclavian vein begins at the outer end of the first rib and then passes anterior to the anterior scalene muscle (Fig. 20.5). It receives the external jugular vein before reaching the medial edge of this muscle.

When the vein is medial to this muscle, it is joined by the internal jugular vein, forming the brachiocephalic vein. The left brachiocephalic vein will pass to the right, just inferior to the superior edge of the manubrium sternum, and join with its right counterpart behind the right first costal cartilage to create the superior vena cava. Each brachiocephalic vein will receive the corresponding vertebral vein. Each vagus nerve passes anterior to the related subclavian artery. The left nerve then passes posterior to the left brachiocephalic vein. The right nerve is posterolateral to the related brachiocephalic vein.

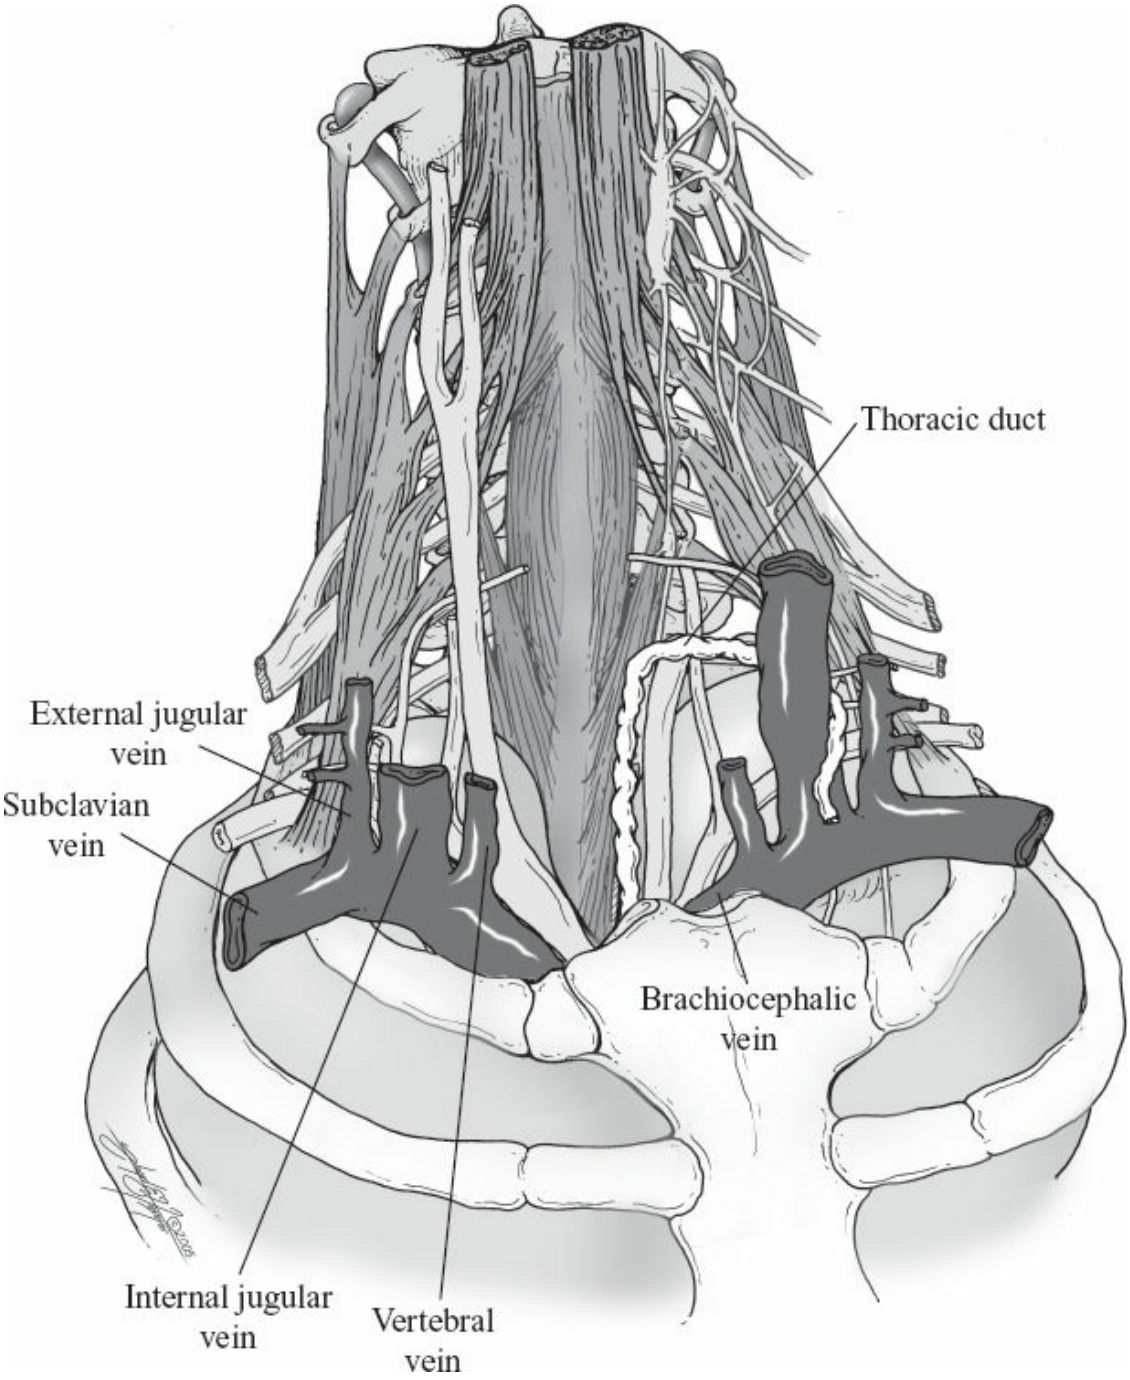

Figure 20.5. Structures of the Neck-4. Subclavian vein origin.

Anterior to this anatomical jungle is the thymus gland. It is largest during the childhood years, and then starts to regress with the onset of sexual maturation. The gland may extend from the thyroid cartilage above, to the pericardial sac below. Therefore, its superior portion is part of the medial, or anterior, aspect of the root of the neck. The gland is composed of two separate, asymmetrical lobes. The gland is contiguous with the large veins previously described. This explains why venous invasion is frequently seen with malignant disease of the gland.

The roots of the brachial plexus, C5 through T1, will create three trunks: an upper trunk (C5, C6), middle trunk (C7), and lower trunk (C8, T1) (Fig. 20.4). They will pass between the anterior and the middle scalene muscles on their way to the axilla. It is the lower trunk that is in direct contact with the upper surface of the first rib. It lies immediately posterior to the subclavian artery. The trunks pass through the posterior triangle. Each trunk will divide into an anterior and posterior division. These divisions, along with the accompanying subclavian vessels, will then pass through the costoclavicular space. The subclavian vein is the most medial of the structures passing through this space (Fig. 20.5). This vein is anteroinferior to the accompanying subclavian artery and can, therefore, be approached after the pulsations of the accompanying artery are palpated. The roots and trunks of the brachial plexus are within the prevertebral layer of the deep cervical fascia. As they head for the axilla, accompanied by the subclavian vessels, they drag some of this deep fascia along with them and create a protective tubular sheath for these neurovascular items called the cervicoaxillary, or axillary, sheath. These nerves and blood vessels, on their way to the axilla, pass under the insertion of the pectoralis minor muscle to the coracoid process of the scapula.

The Anatomy of the Root of the Neck Compression Syndromes

The root of the neck compression syndromes include the following:

Costoclavicular compression syndrome
Cervical rib syndrome
Anterior scalene compression syndrome
Pectoralis minor syndrome

If the space between the first rib and the clavicle should be decreased, there could be compression of the neurovascular structures traversing this area (Fig. 20.5). The subclavian vein is the most medial of the neurovascular structures passing through the costoclavicular space. The vein is in the narrowest portion of this space, and if additional narrowing occurs, venous outflow from the upper extremity may be impaired.

A cervical rib may present itself in several ways. It is frequently bilateral. It is an extension of the transverse mass of the seventh cervical vertebra and it may be a complete rib that articulates with the sternum. At times, it may fuse with the first rib or present as a fibrous band that attaches to the first rib. In some patients, it may have an anterior end that is

free. The subclavian vessels and the brachial plexus, especially the lower trunk, will be affected adversely when they try to pass over this additional obstacle.

The anterior scalene compression syndrome results from spasm, or hypertrophy, of the anterior scalene muscle, with resultant constriction of the neurovascular elements as they pass through the scalene triangle. If the clinician treats this condition by transecting the anterior scalene muscle near its insertion, the position of the phrenic nerve and the subclavian vein, passing anterior to the muscle, must be remembered.

The term “thoracic outlet compression syndrome” is frequently used when defining some clinical conditions encountered in the root of the neck. Thoracic outlet is a misnomer when used to identify the clinical problems in this area. The true anatomical thoracic outlet is the area related to the respiratory diaphragm. Correct terms for these conditions would include superior thoracic aperture compression syndrome or cervicoaxillary compression syndrome.

All of these compression syndromes can result in neurologic deficits and/or arterial and venous circulatory problems in the upper extremity.

Clinical Anatomical Applications

1. Cervical incisions should be made parallel to the skin lines (lines of Langer) for good cosmesis. The neurovascular structures lie deep to the platysma muscle. The muscle must be carefully repaired for the best cosmetic result.
2. The middle cervical ganglion block: this sympathetic ganglion is found anterior to the transverse mass of the sixth cervical vertebra. At the level of the cricoid cartilage, retract the carotid sheath laterally and inject the medication after the needle strikes the lateral mass of the vertebra.
3. Control of bleeding may be possible if the common carotid artery is compressed against the transverse mass of the sixth cervical vertebra. This is the cricoid plane.
4. Carotid angiography: the common carotid artery is palpable in the carotid triangle. It is partially covered by the sternocleidomastoid muscle. Lateral retraction of the muscle will facilitate insertion of a catheter into the palpable artery.
5. Internal jugular vein catheterization: the internal jugular vein accompanies the common and internal carotid vessels. They all lie within the carotid sheath. The vein is anterolateral to the palpable

artery.

6. The right internal jugular and right brachiocephalic veins, along with the superior vena cava, create a straight conduit to the right atrium and the inferior vena cava.
7. The subclavian vessels can be approached while passing through the costoclavicular space. The artery is palpable and the vein is situated anterior and medial to the artery. The vein is the most medial structure passing through the costoclavicular interval. A supraclavicular, or infraclavicular, technique can be used for catheterization.
8. The brachial plexus block approaches the nerves as they pass through the costoclavicular space. The subclavian artery is anterior to the branches of the plexus.
9. In cricothyroidotomy, the interior of the larynx is entered through the cricothyroid interval. The cricothyroid artery, a branch of the superior thyroid, pierces the cricothyroid ligament near the middle of the interval between the cricoid and the thyroid cartilages. A transverse incision, made close to the upper border of the cricoid arch, will avoid injury to this artery. The vocal ligaments are spared because they are superior to the point of entry.
10. For drainage of the retropharyngeal space, an incision is made at the level of the cricoid cartilage. The sternocleidomastoid muscle and carotid sheath are retracted posteriorly, and the lateral lobe of the thyroid gland is retracted anteriorly.
11. Using the external jugular vein as a conduit for central venous access, the external jugular vein is readily accessible because of its superficial position. It empties into the subclavian vein in the posterior triangle, but it may be difficult to negotiate the angle at the termination when attempting to introduce a device into the central portion of the circulatory system. Direct approach to the larger veins, right internal jugular or right subclavian, would eliminate this technical problem.

TRIANGLES OF THE NECK

The layer-by-layer recreation of the neck anatomy now requires the addition of the carotid sheath with the vascular contents and their branches, the last four cranial nerves, and the viscera of the neck, which includes the thyroid and parathyroid glands, pharynx, and larynx. The superficial cervical plexus will also be outlined. The cervical lymphatic pathways will then be described, and finally the superficial venous circulation will be examined. This information is presented with a

discussion of the triangles of the neck.

Anterior and Posterior Triangles

The sternocleidomastoid and trapezius muscles divide the neck into anterior and posterior triangles (Fig. 20.6; also see Fig. 20.13). The boundaries of the posterior triangle are the trapezius muscle posteriorly and the sternocleidomastoid muscle anteriorly. The middle third of the clavicle creates the inferior limit, and the apex of the triangle extends to the superior nuchal line. The triangle is spiral in shape. The inferior portion is anterior in the neck, but the apex is posterior. The anterior triangle includes the area between the anterior edges of the sternocleidomastoid muscles. The superior limit is the mandible and a line drawn from the angle of the mandible to the tip of the mastoid process. Two double-bellied muscles, omohyoid and digastric, subdivide the triangles. The inferior belly of the omohyoid muscle attaches to the superior transverse scapular ligament and a portion of the adjacent superior edge of the scapula. It passes superior to the clavicle and enters the lower portion of the posterior triangle. The intermediate tendon is in the cricoid plane, anterior to the carotid sheath, and is angulated by a fascial sling attached to the clavicle and the manubrium. The superior belly ascends to the hyoid bone.

The posterior triangle now consists of the large occipital and the smaller subclavian triangles. The digastric is the other double-bellied muscle that creates subdivisions of the anterior triangle. The posterior belly attaches just medial to the mastoid process. The intermediate tendon is tethered to the hyoid bone by a fold of deep cervical fascia. The stylohyoid muscle arises from the styloid process of the temporal bone and is in intimate contact with the anterior surface of the posterior belly of the digastric muscle. The tendon of insertion of the stylohyoid muscle to the hyoid bone is split and allows for passage of the intermediate tendon of the digastric muscle. The anterior triangle includes the submandibular and carotid triangles. They are separated from each other by median submental and muscular triangles.

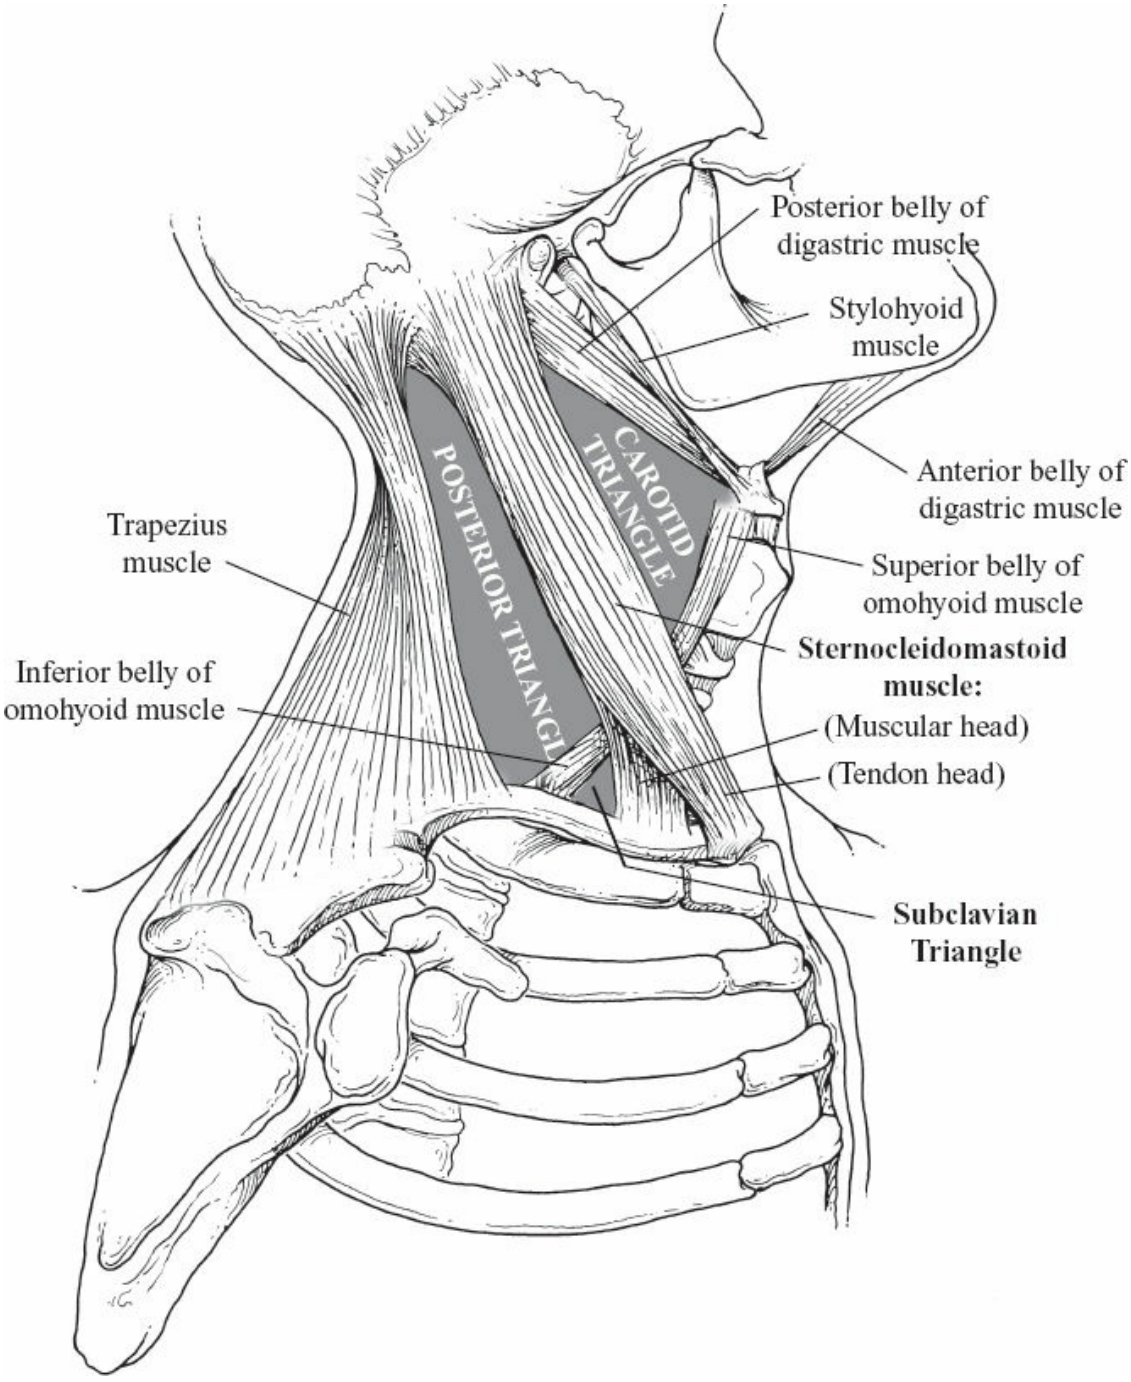

Figure 20.6. Boundaries of the triangles of the neck (see also Fig. 20.14).

The hyoid bone is a central structure in the neck. It is directly or indirectly attached to most of the muscular and membranous entities in the anterior triangle and in the floor of the mouth. If one considers the hyoid bone and the attached posterior belly of the digastric muscle, it is possible to divide the anterior triangle into suprahyoid and infrahyoid portions. The submandibular, or digastric triangles, and the submental triangle, are suprahyoid entities and are related to the floor of the mouth. They have

been discussed in another chapter. The carotid and the muscular triangles are found in the infrahyoid portion of the anterior triangle.

Carotid Triangle

The muscular boundaries of the carotid triangle are the sternocleidomastoid muscle posteriorly, the posterior belly of the digastric muscle anterosuperiorly, and the superior belly of the omohyoid muscle anteroinferiorly (Fig. 20.7). The greater horn of the hyoid bone is part of the anterior and superior segment of the floor of this triangle. The hyoglossus and thyrohyoid muscles are attached to this portion of the hyoid bone, and are part of the anterior portion of the muscular floor. A small portion of the thyrohyoid membrane is found just behind the thyrohyoid muscle and makes up a small area of the floor. The middle and inferior pharyngeal constrictor muscles create the posterior section of the muscular floor of the carotid triangle. The longus capitis, a prevertebral muscle, also contributes to the posterior portion of the muscular floor of this triangle. The pretracheal layer of the deep cervical fascia creates the fascial carpet. The investing layer of the deep fascia creates a fascial roof.

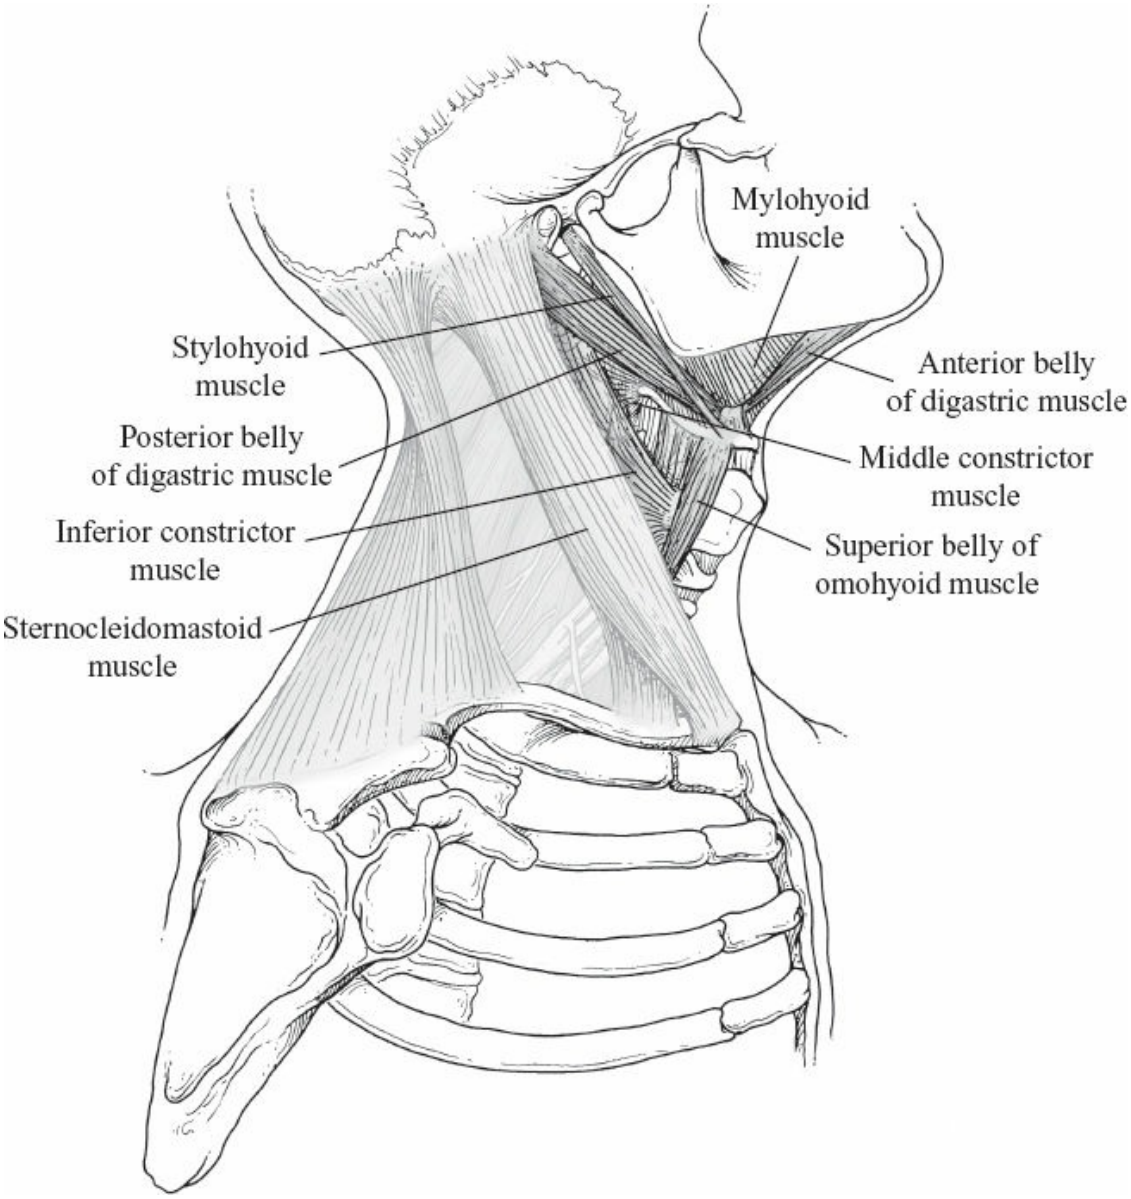

Figure 20.7. Muscular boundaries and muscular floor of the carotid triangle.

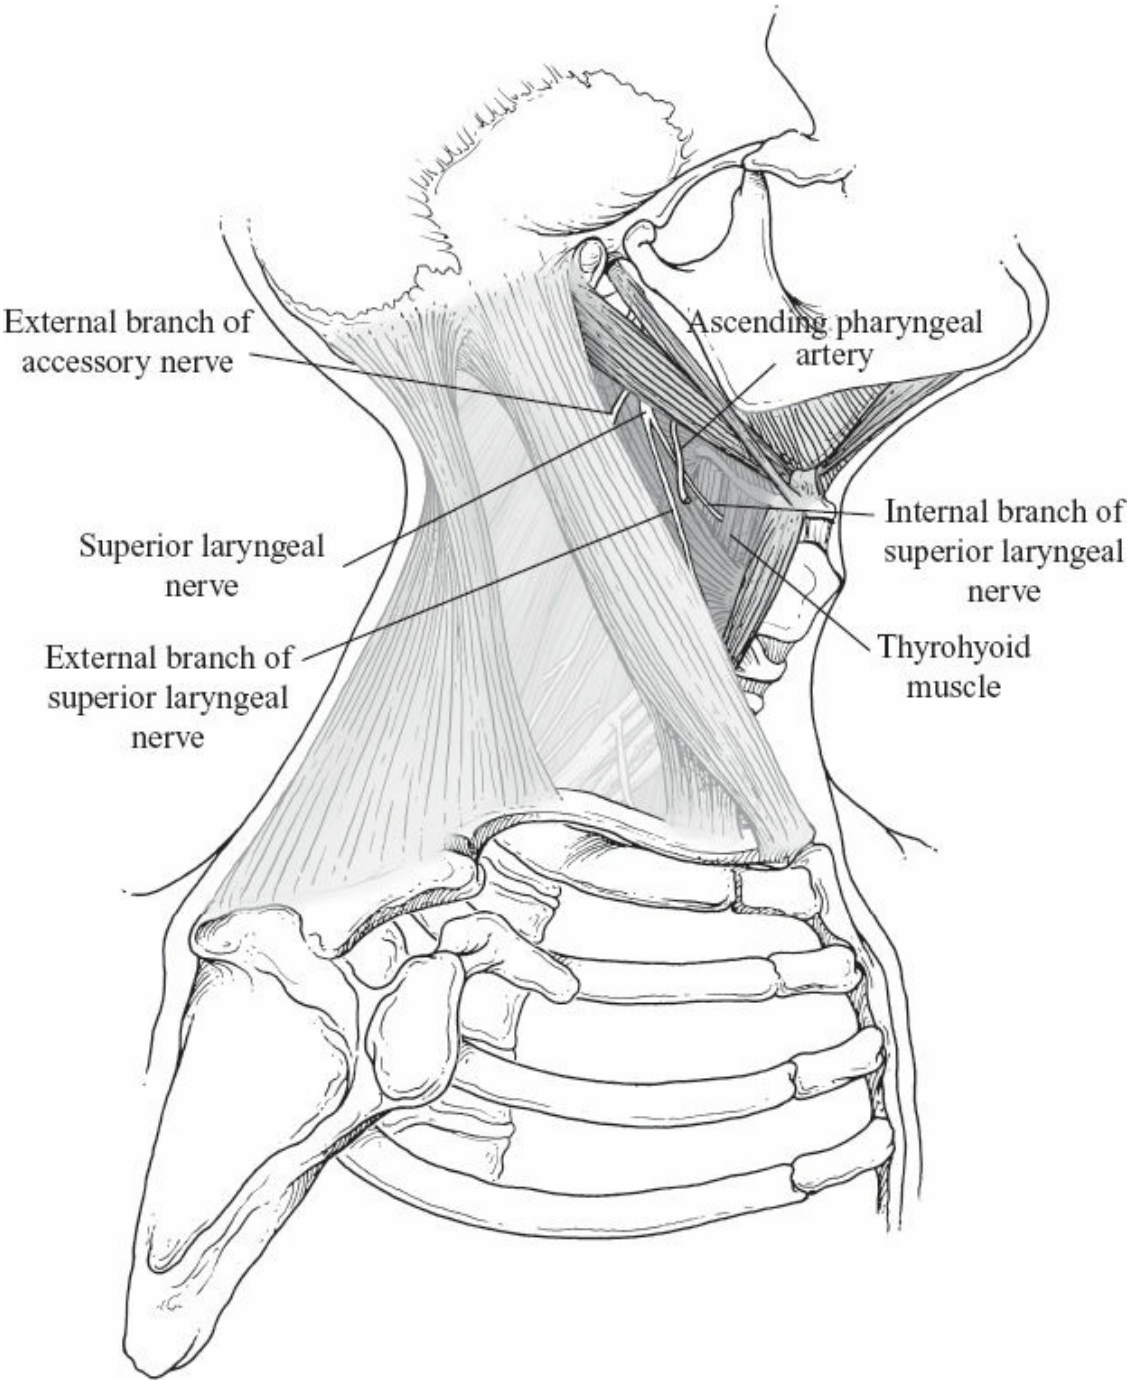

Figure 20.8. The deepest structures of the carotid triangle.

The contents of the triangle will be described beginning with the deepest structures (Fig. 20.8). The superior laryngeal nerve is a branch of the vagus nerve that is given off at the base of the skull. It travels inferiorly, in contact with the superior constrictor, courses deep to the internal and external carotid arteries, passes under the posterior belly of the digastric muscle, and is now in the carotid triangle. When it reaches the middle constrictor muscle, it creates an internal and external branch. The

internal branch enters the larynx after piercing the thyrohyoid membrane. It provides sensory innervation to the interior of the larynx above the vocal ligaments. The external branch passes inferiorly, in contact with the inferior constrictor, and gives some branches to this muscle. It also provides motor innervation to the cricothyroid, one of the intrinsic muscles of the larynx. This nerve, for a portion of its course just superior to the thyroid gland, is very close to the medial side of the superior thyroid vascular bundle. It should be located and swept medially in order to avoid its injury when ligating and dividing these blood vessels. In the superior part of this triangle, the spinal accessory nerve is seen as it passes inferolaterally, deep to the sternocleidomastoid muscle, and enters the posterior triangle.

The ascending pharyngeal artery, a branch of the proximal portion of the external carotid artery, ascends on the constrictor muscles as it heads for the base of the skull. The remaining contents of this triangle include the common carotid artery and its branches, the internal jugular vein and its branches, the cranial nerves X, XI, XII, and the ansa cervicalis of the deep cervical plexus.

The common carotid artery begins in the root of the neck and passes cephalad in the carotid sheath (Fig. 20.9). It is medial to the accompanying internal jugular vein. The vagus nerve (X) is between, but slightly posterior to, the blood vessels. At about the level of the superior aspect of the thyroid cartilage, the common carotid artery bifurcates and gives rise to the internal and external carotid vessels. The internal carotid artery, at its origin, has a small area of dilatation, the carotid sinus. It contains specialized nerve cells, which regulate blood pressure. This area receives autonomic, glossopharyngeal, and vagus nerve branches (Fig. 20.10). There is also an area of thickening in the arterial wall at the site of bifurcation of the common carotid artery. This is the carotid body, which contains chemoreceptor cells receiving branches from the glossopharyngeal nerve. The common and internal carotid arteries do not provide any branches in the neck.

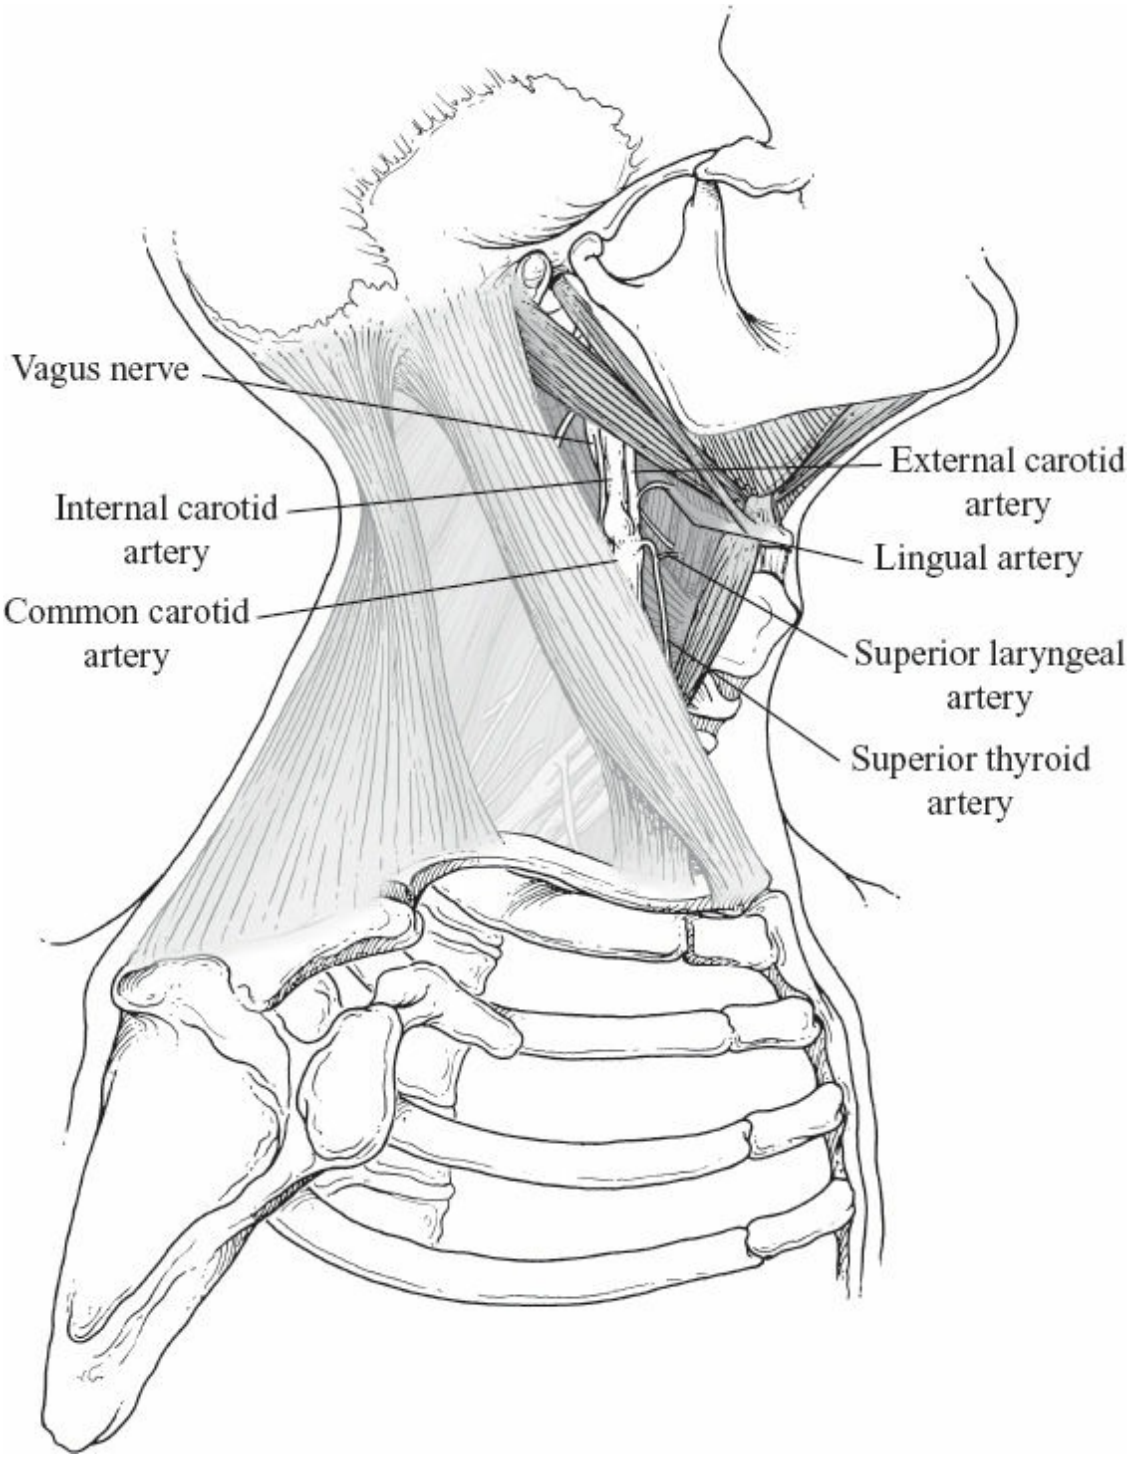

Figure 20.9. Common carotid artery and branches.

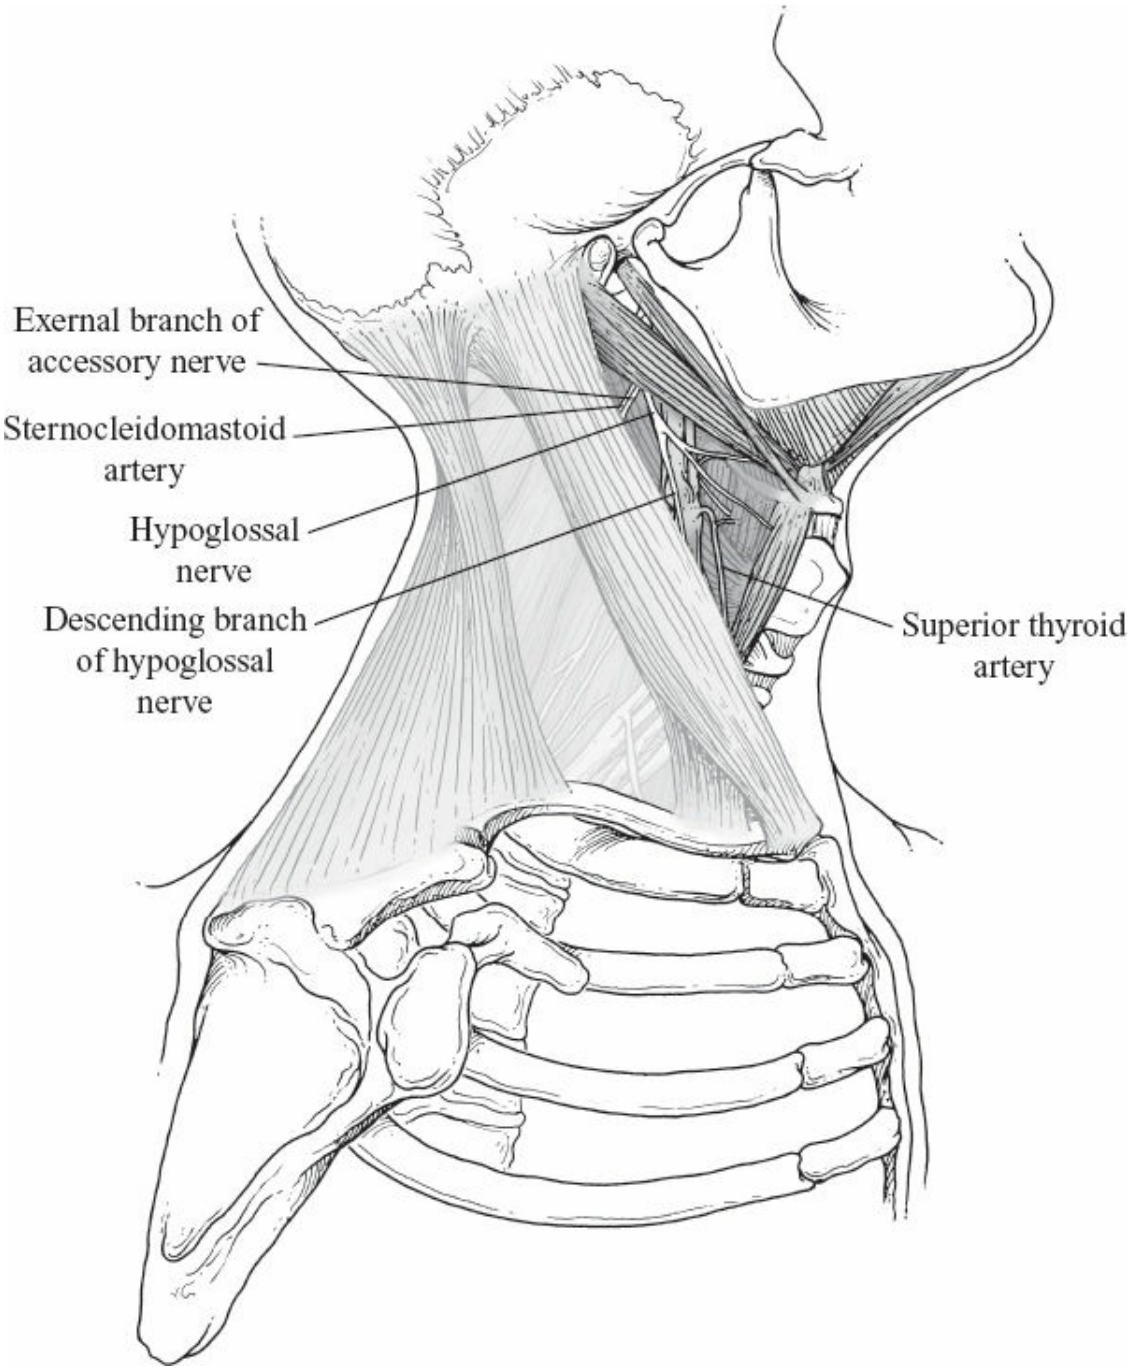

Figure 20.10. External carotid artery.

The external carotid artery leaves the carotid sheath and, at first, is anteromedial to the internal carotid artery. It will become anterolateral in position at a higher level, after passing superficial to the carotid sheath. It is the external carotid artery that provides vascular flow to the cervical structures. The branches are medial and posterior. The medial branches are the superior thyroid, lingual, and facial (external maxillary) arteries. The posterior branches include the ascending pharyngeal, occipital, and posterior auricular arteries. The occipital branch runs along the inferior

edge of the posterior belly of the digastric muscle. The posterior auricular branch follows a similar course on the superior aspect of this important muscle. The external carotid artery continues superiorly to the parotid region. At the neck of the condylar process of the mandible, the end branches arise. They are the superficial temporal and internal maxillary arteries.

The internal jugular vein begins at the base of the skull (Fig. 20.11). At this point, it is posterior to the internal carotid artery. The last four cranial nerves pass between these vessels and then head for their specific destinations. The vein passes inferiorly, quickly assuming a more anterolateral position to the internal and common carotid arteries, while in the carotid sheath. It receives the following branches: common facial vein, lingual vein, superior thyroid vein, branches from the pharyngeal venous plexus, and the middle thyroid vein. At its termination, it will receive the thoracic duct (left) and the right lymphatic duct (right). The vagus nerve (X) is found with the vascular structures in the carotid sheath. It lies between, and slightly posterior to, the artery and the vein. In the root of the neck, it will pass posterior to the large veins and enter the thorax. The spinal accessory nerve (XI) will pass obliquely across the superior part of the carotid triangle, continue under the sternocleidomastoid muscle, travel across the posterior triangle, and disappear under the trapezius muscle (Fig. 20.12). It provides motor innervation to both of those muscles. The hypoglossal nerve (XII) passes between the internal jugular vein and the internal carotid artery, and then descends below the posterior belly of the digastric muscle to enter the carotid triangle. It frequently hooks around a branch of the occipital artery, passes superficial to internal and external carotid arteries, and then leaves the carotid triangle by passing back under the posterior belly to reenter the submandibular triangle. The glossopharyngeal nerve (IX) is also found between the internal jugular vein and the internal carotid artery near the base of the skull. It passes inferiorly, travels between the internal and the external carotid arteries, and then enters the interval between superior and middle pharyngeal constrictors. The stylopharyngeus muscle accompanies this nerve. After penetrating the wall of the pharynx, the muscle attaches to the posterior free end of the thyroid cartilage lamina and is now part of the muscular wall of the pharynx. The cervical sympathetic chain lies on the prevertebral fascia. It is posterior to the carotid sheath.

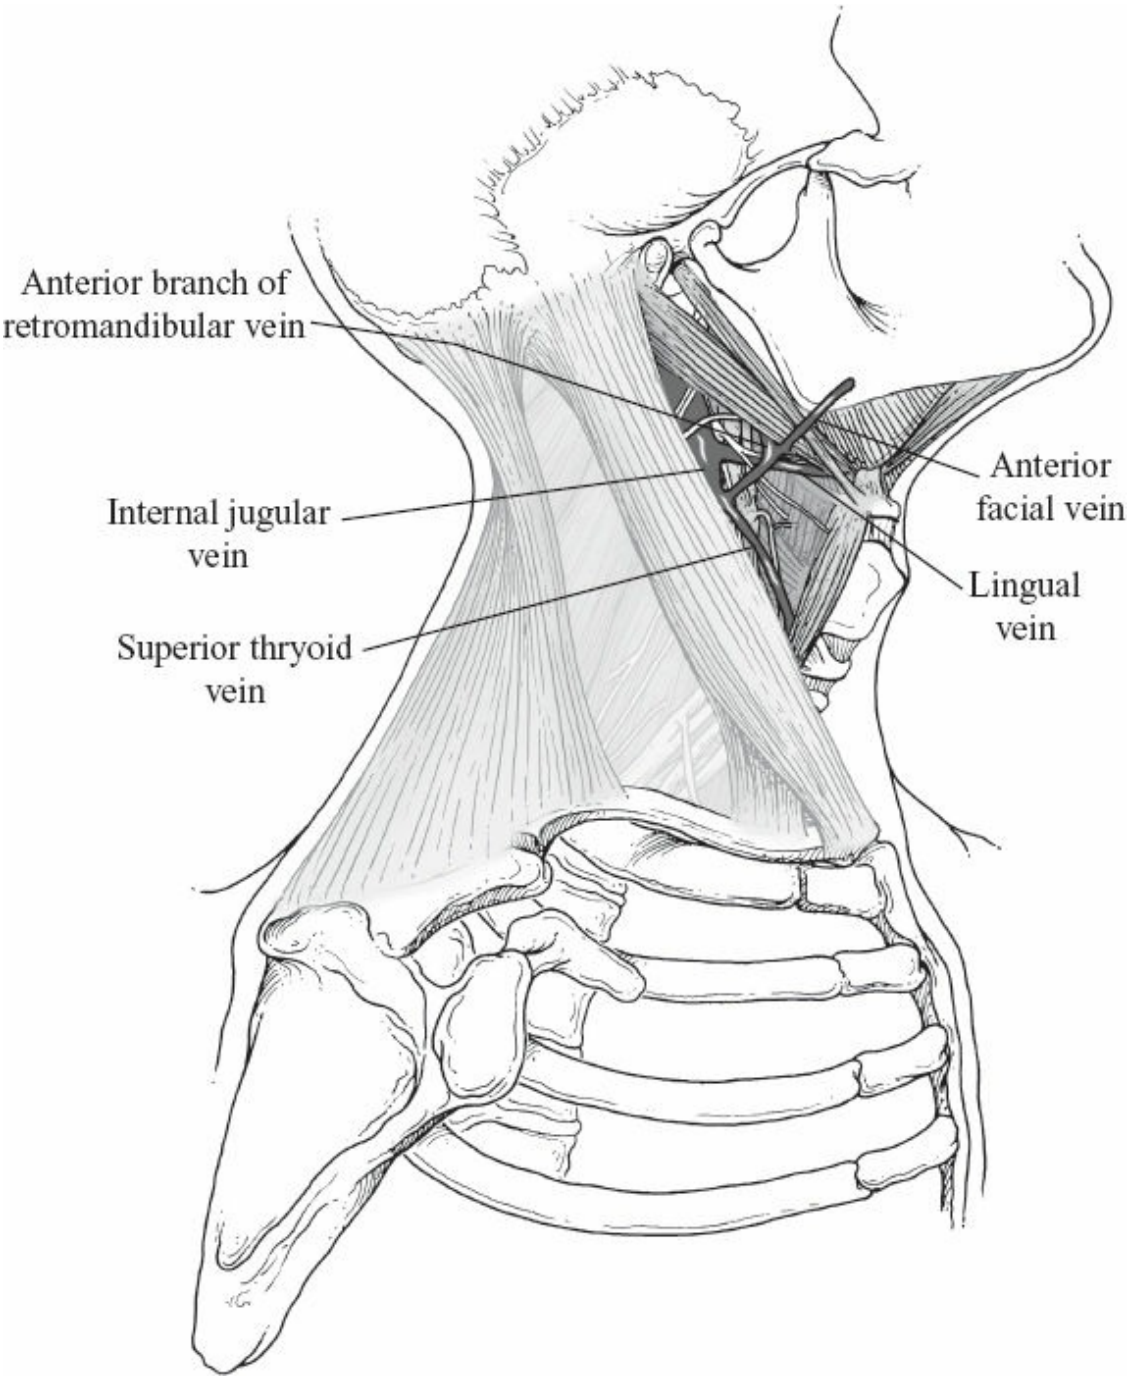

Figure 20.11. Internal jugular vein.

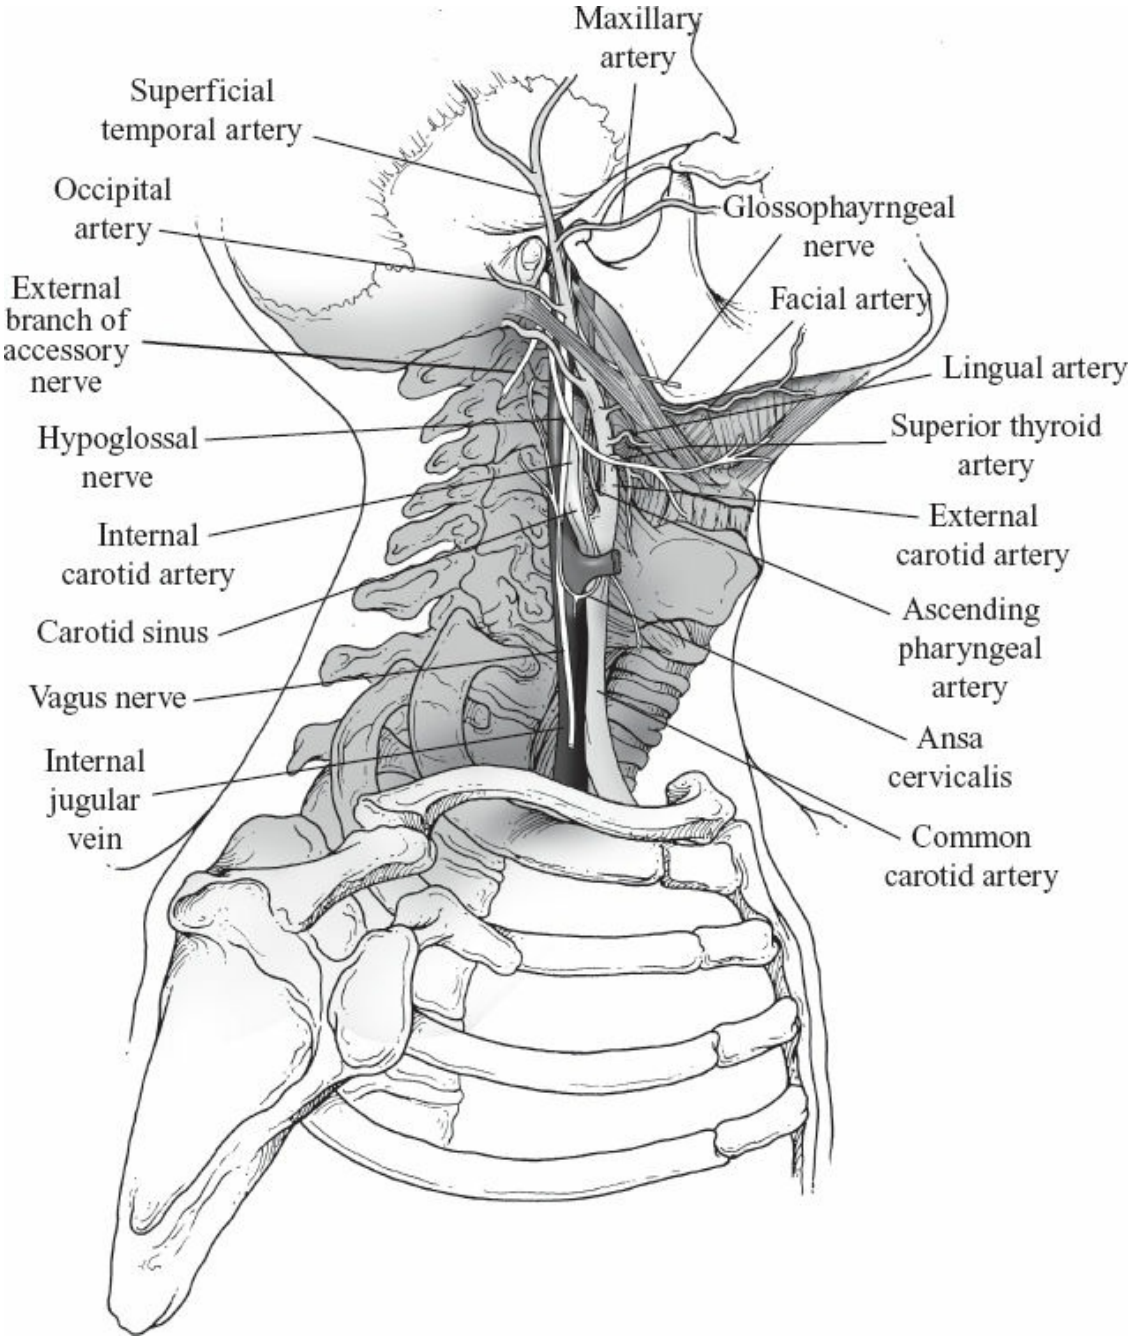

Figure 20.12. Carotid triangle with the sternocleidomastoid muscle removed.

The posterior belly of the digastric muscle plays an important role in this area. It is superficial to all of these neurovascular structures. It presses them against the pharyngeal wall. Incisions can be made on the posterior belly without risk of injury to nerves or arteries in this area. There may be some superficial veins and, occasionally, a low-lying cervical branch of the facial nerve found in the area superficial to this relatively safe landmark.

Muscular Triangle

The boundaries of the muscular triangle are the superior bellies of the omohyoid muscles superolaterally and the inferior part of the sternocleidomastoid muscles inferolaterally (Fig. 20.13). The hyoid bone is superior, and the upper edge of the manubrium sternum creates the inferior limit. The triangle contains the thyroid and parathyroid glands, larynx and trachea, and pharynx and esophagus. These cervical viscera are found below the muscular floor. The muscles are paired and referred to as the strap muscles. They are all infrahyoid in location and present in two layers. The superficial layer is composed of two long muscles. The omohyoid muscle is lateral and is composed of two muscle bundles that are separated by an intermediate tendon. The intermediate tendon is in the cricoid plane. The inferior belly is attached to the superior surface of the scapula. It subdivides the posterior triangle and then passes anterior to the carotid sheath. The intermediate tendon is tethered to the clavicle. The superior belly passes up to the hyoid bone. Medial to this is the sternohyoid muscle, which passes from the sternum to the hyoid bone. The deeper layer is composed of shorter structures. The sternohyoid muscle is attached inferiorly to the manubrium of the sternum, and extends up to the oblique line of the thyroid cartilage. This upper attachment is just superior to the lateral lobe of the thyroid gland, and prevents enlargement of the lobe from extending in a superior direction. The thyrohyoid muscle seems to be its superior continuation that passes from the oblique line to the hyoid bone. The inferior pharyngeal constrictor is also attached to the oblique line of the thyroid cartilage. The middle layer of the deep cervical fascia surrounds the strap muscles. It is not only found in the muscular triangle, but also extends laterally to the inferior belly of the omohyoid muscle. This belly creates the lateral boundary of the subclavian subdivision of the posterior triangle.

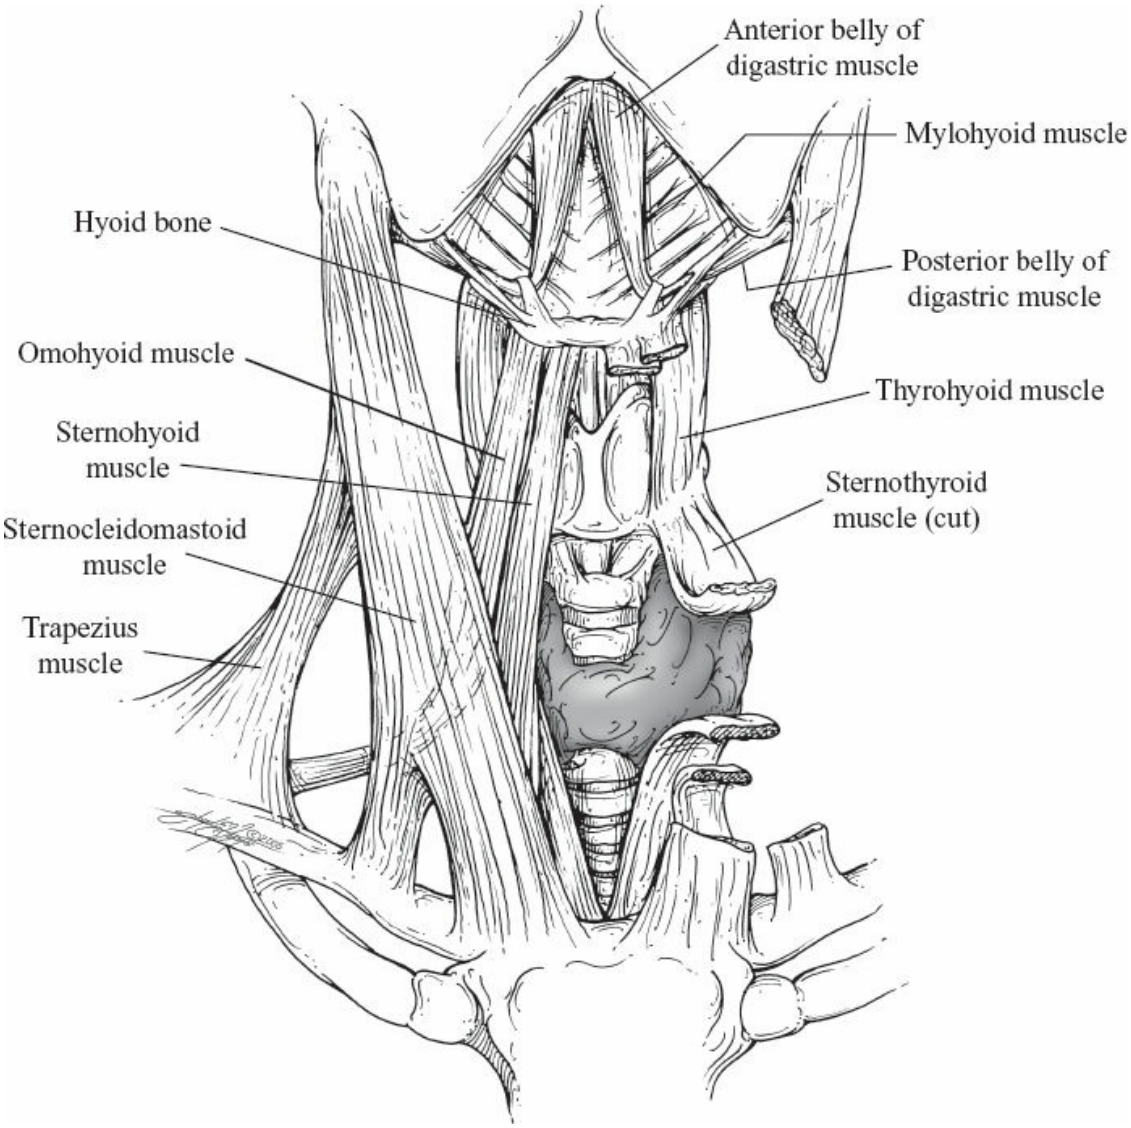

Figure 20.13. The boundaries of the muscular triangle of the neck.

All the strap muscles are depressors of the larynx. The nerve supply comes from the deep cervical plexus (C1, C2, and C3) by way of the ansa cervicalis. The nerves enter the inferior portion of the muscle. A branch of C1, which travels with the hypoglossal nerve, innervates the thyrohyoid muscle.

Clinical Anatomical Aids

1. Transection of strap muscles should be done closer to the superior end to preserve nervous innervation, which enters the muscle near its inferior end.
2. Proper entrance into the cleavage plane between the sternothyroid muscle and the thyroid gland provides excellent exposure of, and

facilitates surgical approach to, the gland.

Posterior Triangle

The boundaries of the posterior triangle are the anterior border of the trapezius muscle and the posterior edge of the sternocleidomastoid muscle, and the middle third of the clavicle is the base. The apex of this triangle is the superior nuchal line. This triangle, therefore, presents as a spiral as the base is anterior and the apex is posterior. The triangle is subdivided by the inferior belly of the omohyoid muscle into smaller entities that are named for the blood vessels found in them. There now is a larger, superior, occipital triangle, and the smaller, inferior, subclavian triangle. The muscular floor of the entire posterior triangle is composed mainly of three muscles whose fibers run inferolaterally. They are, from above down, the splenius capitis, the levator scapula, and the middle scalene muscles (Fig. 20.14). The anterior scalene muscle is not seen in the posterior triangle because the sternocleidomastoid muscle covers it. In the apex are seen a few vertically oriented fibers of the semispinalis capitis muscle. It is, along with the splenius capitis, classified as a back muscle.

The muscles of the floor are covered by prevertebral fascia, which creates a fascial carpet. There is also a fascial roof, generated by the investing layer of the deep cervical fascia. The contents of the triangle will be described layer by layer, beginning with the deeper contents found below the fascial carpet in contact with the muscular floor (Fig. 20.15). They include: (a) the occipital artery, which frequently exits the posterior triangle at its apex; (b) branches of the deep cervical plexus passing inferolaterally on the surface of the levator scapula muscle, destined to provide innervation to the inferior portion of the trapezius muscle; and (c) portions of the brachial plexus. The roots of the plexus combine deep to the sternocleidomastoid. The C5 and C6 roots combine to create the upper trunk, C7 becomes the middle trunk, and C8 and T1 create the lower trunk. The trunks are seen in the posterior triangle. There are branches arising from these roots and trunks that are seen in the posterior triangle. The dorsoscapular nerve (C5) pierces the middle scalene muscle and passes laterally toward the rhomboid and levator scapula muscles, which it innervates. The long thoracic nerve (C5, C6, and C7) courses inferiorly, passes deep to the other portions of the brachial plexus, and then passes over the first rib to reach the superficial surface of the serratus ventralis, where it innervates. Arising from the upper trunk of the plexus is the

suprascapular nerve, which is seen just above the upper trunk, passes across the posterior triangle to the scapula, and innervates the supraspinatus and infraspinatus muscles. The subclavius nerve is also seen in the posterior triangle. It arises from the upper trunk, passes inferiorly, and crosses the main portion of the brachial plexus superficially. It innervates the subclavius muscle.

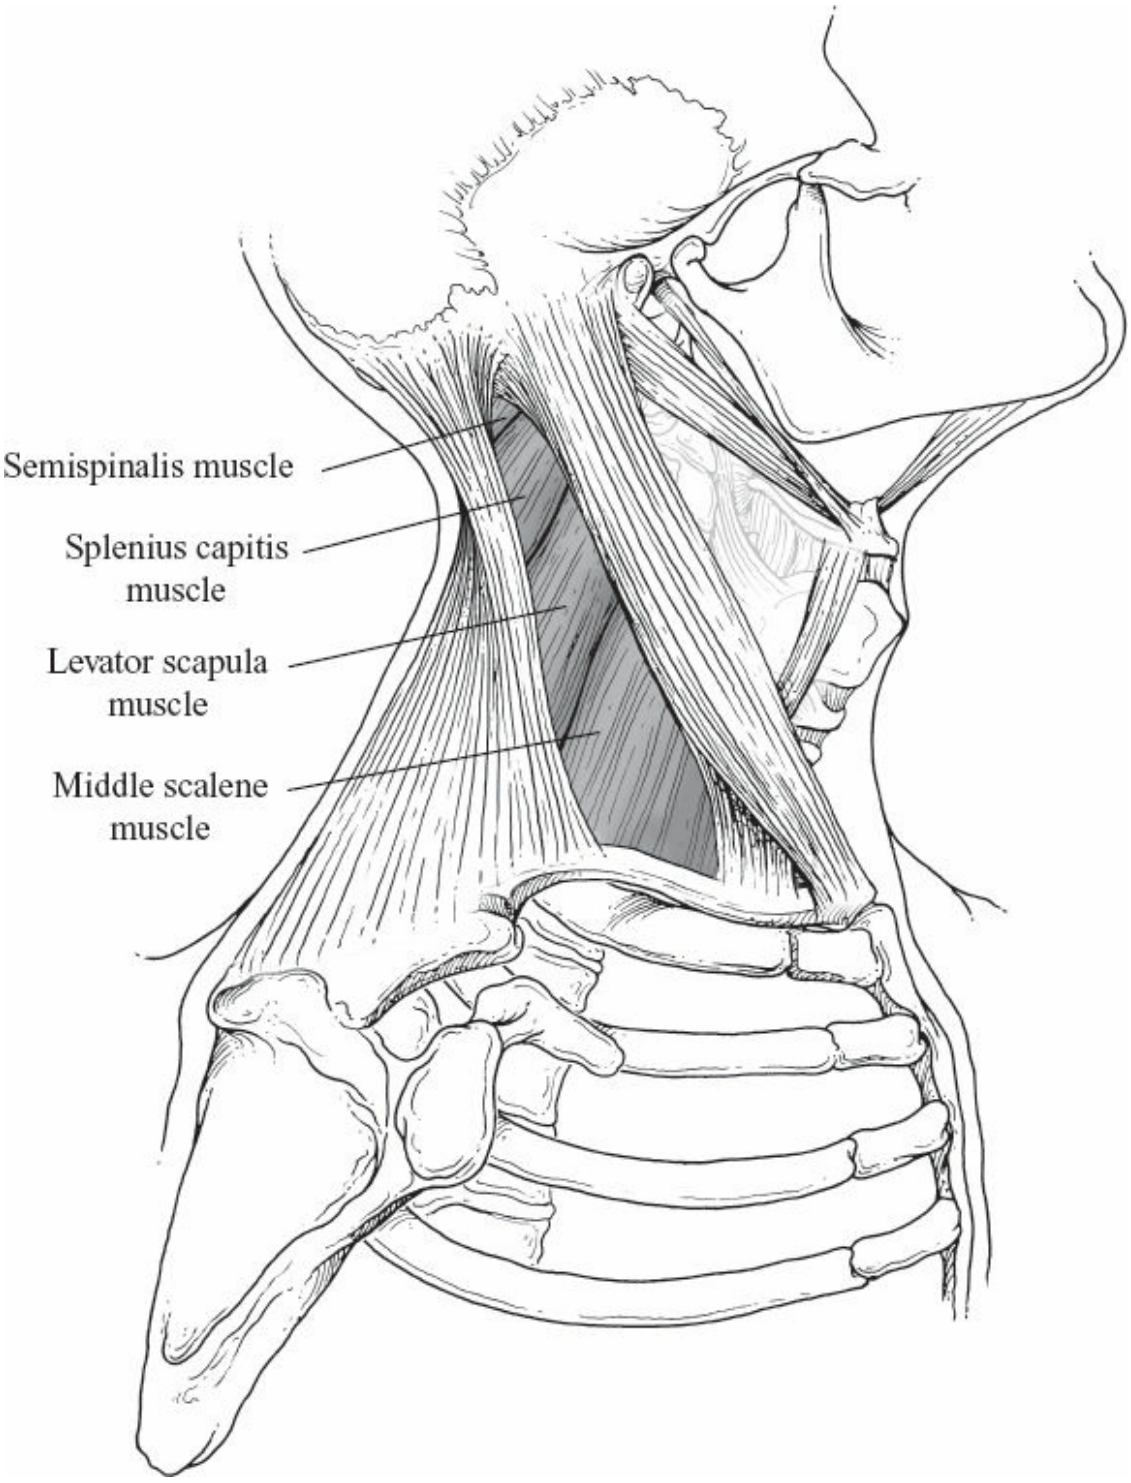

Figure 20.14. Muscular floor of the posterior triangle.

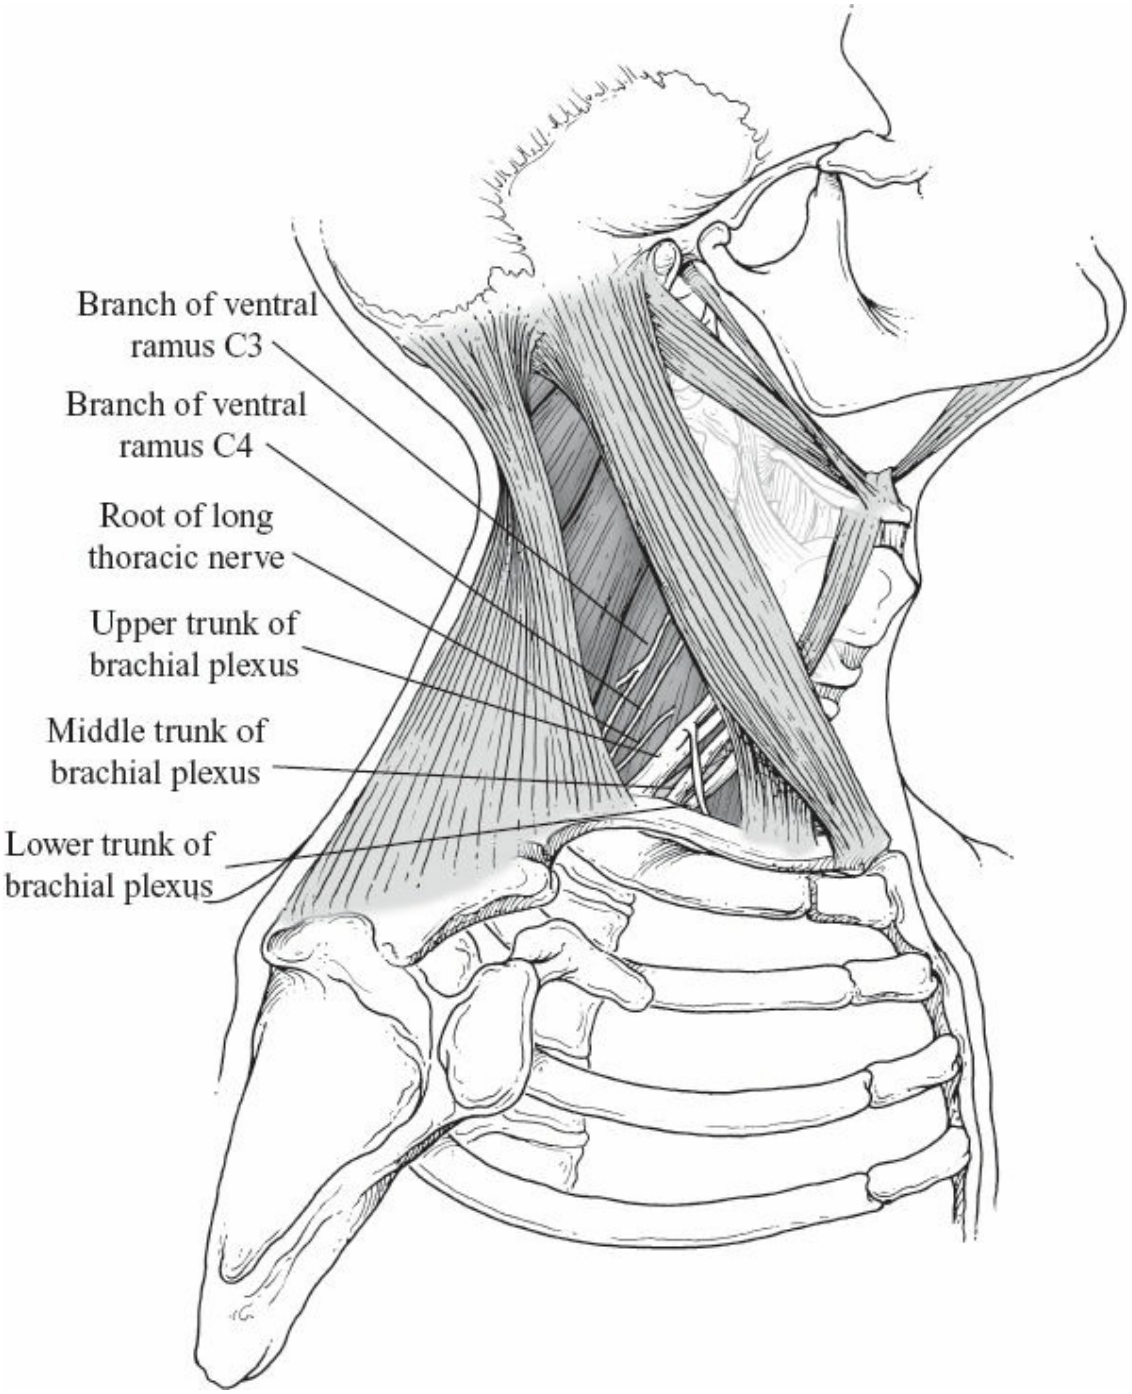

Figure 20.15. Structures below fascia floor of the posterior triangle.

The trunks create anterior and posterior divisions that will pass under the clavicle, and when reaching the axilla, create other combinations called cords. The cords will give rise to the named nerves of the upper extremity and the third portion of the subclavian artery is also related to the fascial floor of the posterior triangle. It can be palpated as it passes under the

midportion of the clavicle and over the first rib. The subclavian artery and the brachial plexus branches, after passing between the scalene muscles, will drag a portion of the prevertebral fascia along with them and create the cervicoaxillary sheath (Figs. 20.16 and 20.17).

Structures that pass between the fascial floor and the fascial roof include the transverse cervical and suprascapular (transverse scapular) branches of the thyrocervical trunk, originating from the first portion of the subclavian artery. They pass transversely across the anterior aspect of the anterior scalene muscle and are separated from the phrenic nerve by the prevertebral fascia. After entering the posterior triangle, the suprascapular artery will pass below the clavicle and participate in important collateral vascular channels that exist in the scapular region. The spinal accessory nerve (XI) as it traverses the posterior triangle. It is found on the anterior surface of, and runs with, the levator scapula muscle. It will disappear under the trapezius muscle about 2 in superior to the clavicle. There are some motor branches from the deep cervical plexus that travel with this cranial nerve. These nerves, and the spinal accessory nerve, are the only motor branches that are superficial to the prevertebral layer of the deep cervical fascia in the posterior triangle.

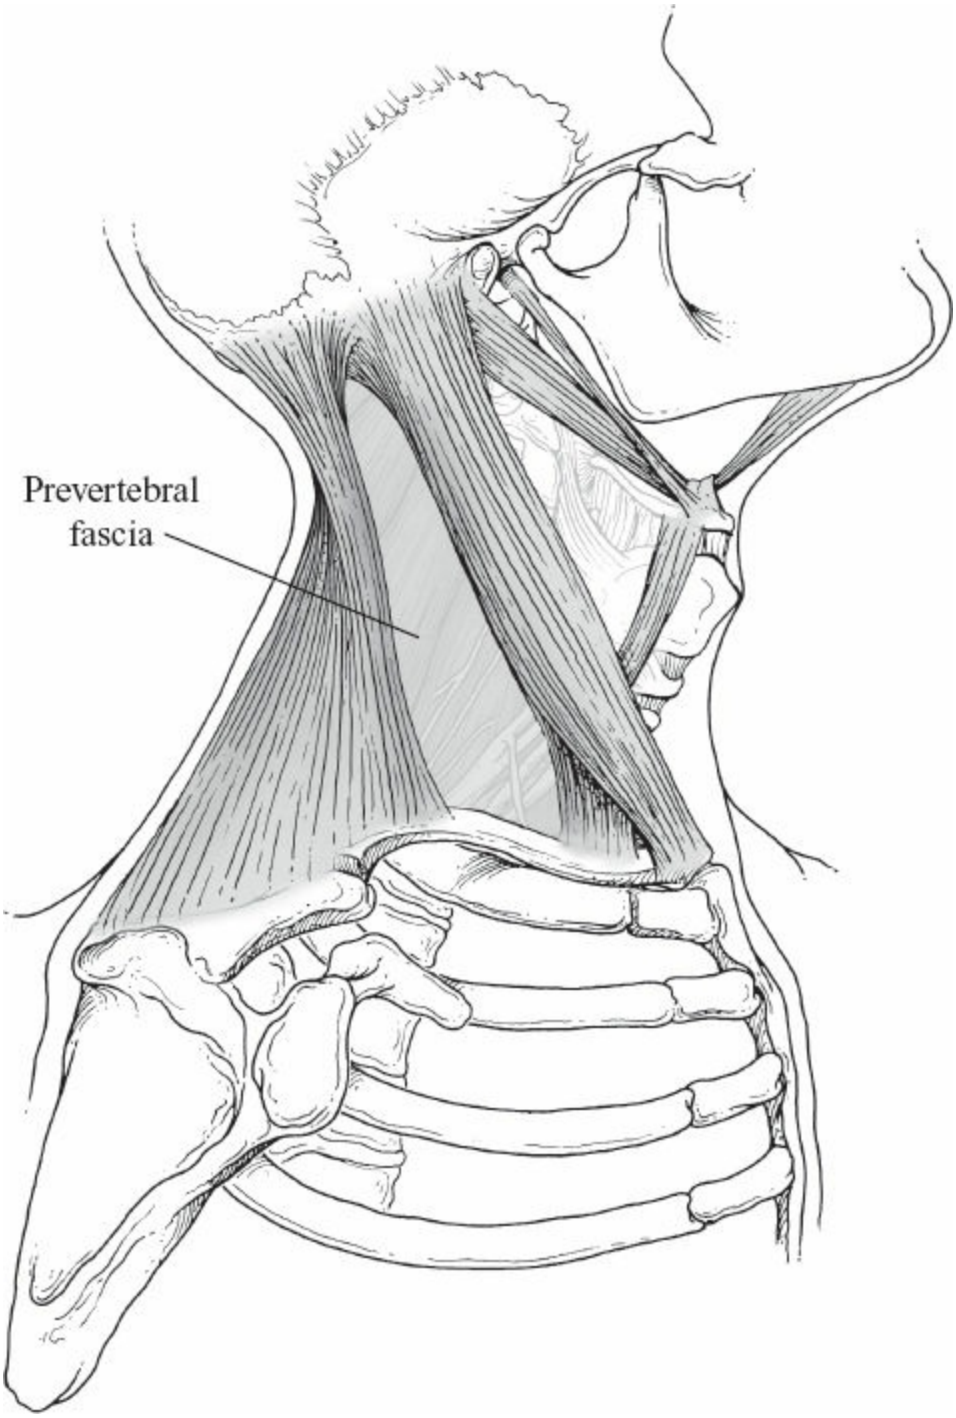

Figure 20.16. Fascial floor of the posterior triangle.

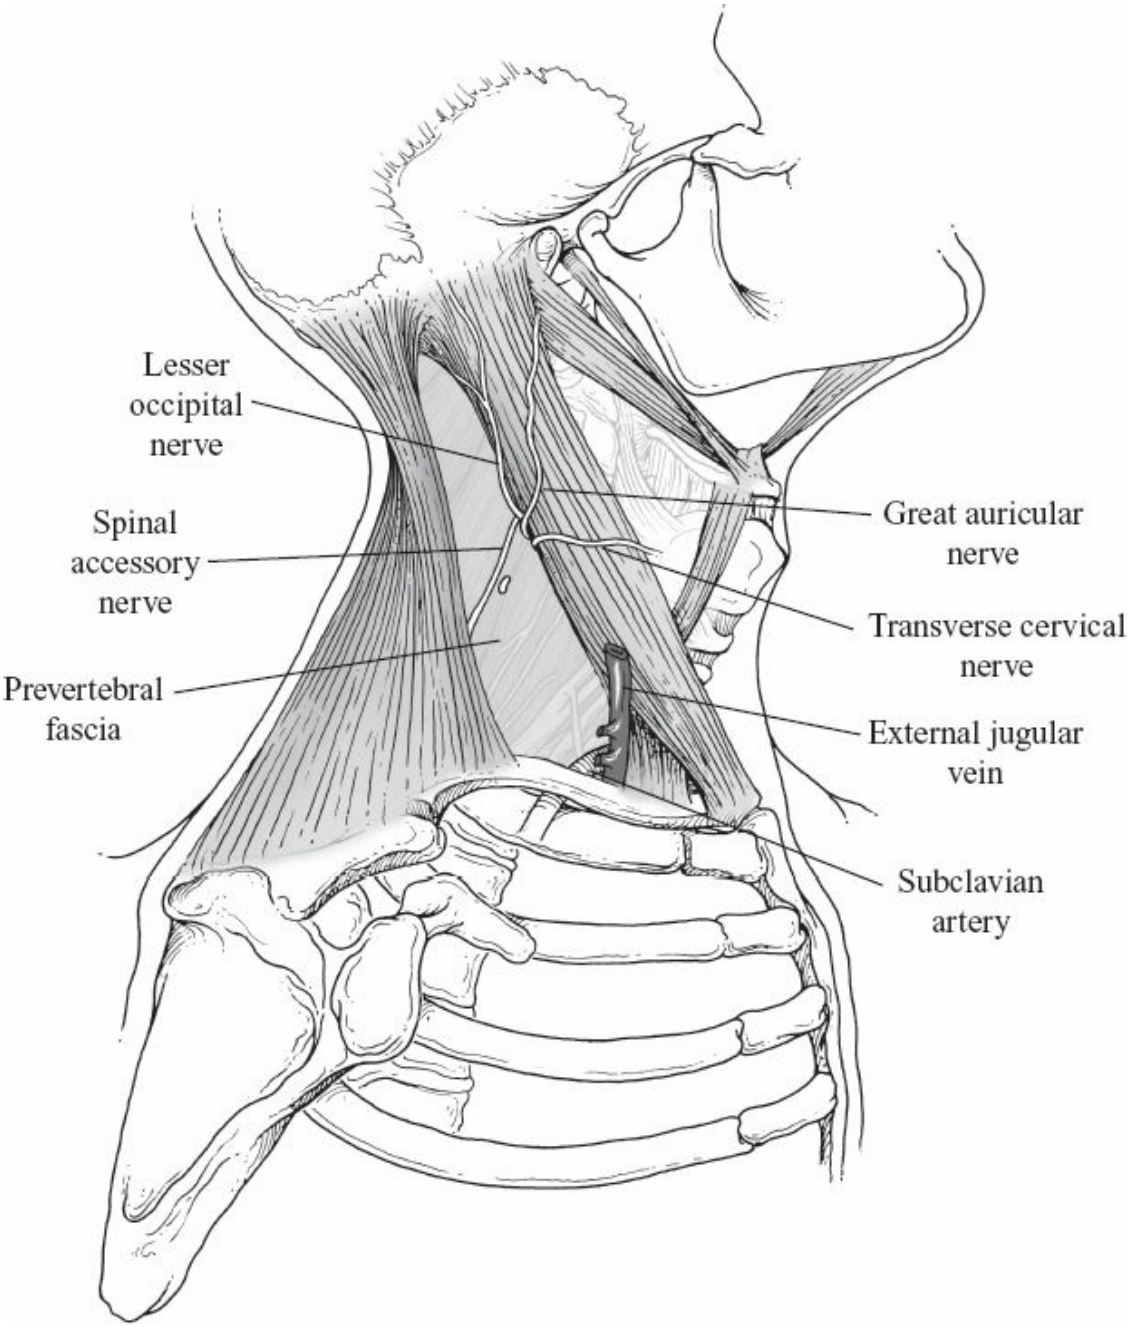

Figure 20.17. Structures superficial to fascial floor of the posterior triangle.

The external jugular vein, which passes obliquely across the sternocleidomastoid muscle, pierces the deep cervical fascial layers of the subclavian triangle, and ends in the subclavian vein. The transverse cervical, suprascapular, and anterior jugular veins are tributaries of the external jugular vein. The inferior belly of the omohyoid muscle creates the lateral boundary of the subclavian triangle. It is attached inferiorly to the superior surface of the scapula, courses anterosuperiorly, and passes deep to the sternocleidomastoid muscle, where its intermediate tendon is

angulated by attachments of deep cervical fascia to the clavicle. The superior belly continues to the hyoid bone. The superficial cervical plexus is created by the ventral rami of C2, C3, and C4. It includes the lesser occipital nerve (C2), which appears at the posterior edge of the sternocleidomastoid muscle just inferior to the spinal accessory nerve. It ascends near the posterior edge of the muscle and will provide sensory innervation to the external ear and the adjacent skin. The superficial cervical plexus also includes the great auricular nerve (C2, C3), which emerges from the cover of the sternocleidomastoid muscle just inferior to the lesser occipital nerve, hooks around the posterior edge of the muscle, and now lies on its superficial surface (Figs. 20.17 and 20.18). It then passes superiorly toward the parotid region and provides sensory innervation to the overlying skin and a portion of the ear. This nerve can frequently be found just posterior to the external jugular vein as it passes obliquely across the muscle. The transverse cervical nerve (C2, C3) also appears at the posterior edge of the sternocleidomastoid muscle in the vicinity of the other nerves of this plexus. It wraps itself around the posterior edge of the muscle and passes transversely across its external surface to reach the anterior triangle. It will then divide into ascending and descending branches that will provide cutaneous sensory innervation to the anterior triangle.

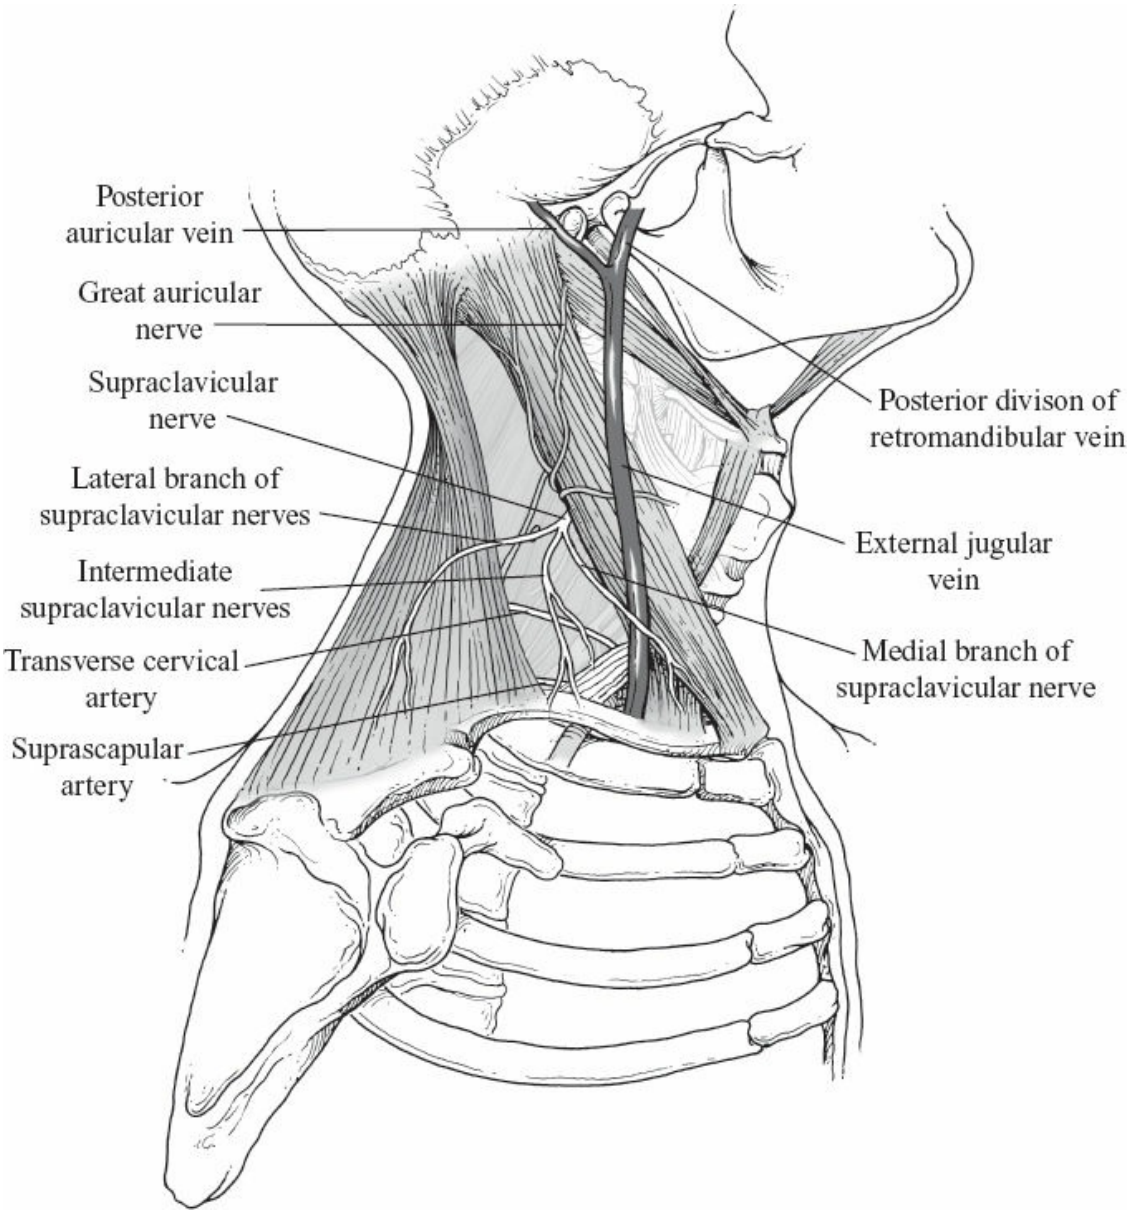

Figure 20.18. Superficial structures of the posterior triangle.

The supraclavicular nerves (C3, C4) first appear in the same area, just below the site of emergence of the other nerves, and then divide into medial, intermediate, and lateral branches. They provide cutaneous sensory innervation to the anterior aspect of the thorax down to the level of the second rib. All branches of the superficial cervical plexus, and the spinal accessory nerve, are quite close to each other as they first appear in the posterior triangle at the edge of the sternocleidomastoid muscle. If one divides the posterior edge of this muscle into thirds, at the junction of the middle and superior third is the site where all these nerves can be found gathered in a small localized area. This is referred to as the nerve point. They will then diverge as they head toward their specific destinations. As

the nerves pass through the posterior triangle, it will be seen that the spinal accessory nerve is the most superior of all the nerves that are in the triangle. Therefore, incisions that are made superior to the spinal accessory nerve are not likely to encounter any important nerves. This area has been referred to as the carefree area; whereas, an incision made below this nerve can injure major structures and is called the careful area.

Clinical Anatomical Aids

1. Superficial cervical plexus nerve block. The nerve point is located and the local anesthetic is injected in that region of the posterior edge of the sternocleidomastoid muscle. It can provide adequate anesthesia to the anterior triangle if bilateral nerve point injection is performed.
2. Catheterization of the subclavian artery or vein. The third portion of the artery is palpable as it passes between the midportion of the clavicle and the first rib. The accompanying vein is anteroinferior to the artery and is the most medial of the neurovascular structures that pass through the costoclavicular space.
3. Dissection can be performed safely in the posterior triangle in the area superior to the spinal accessory nerve (XI).
4. There are one or two motor branches for the trapezius muscle that originate from the deep cervical plexus. They run with, but are slightly inferior to, the spinal accessory nerve in the posterior triangle. In this area, these cervical nerves and the spinal accessory nerve are the only motor nerves that lie external to the prevertebral layer of the deep cervical fascia.
5. When veins pass through layers of fascia, the wall of the vein is adherent to the margins of the opening in the tissue being breached. If a vein is transected at the level of fascia penetration, bleeding may be prolonged because the attachments to the vessel wall may prevent it from going into spasm. Spasm of the cut end of a blood vessel assists in achieving hemostasis.

VISCERA OF THE NECK

Thyroid Gland

The development of the thyroid gland begins with the appearance of the foramen caecum (Fig. 20.19). This is a pit or depression that appears at the junction of the anterior two-thirds with the posterior third of the tongue. It continues inferiorly and creates the thyroglossal duct, which continues

caudad and becomes the thyroid gland. The duct is a midline structure down to the thyroid cartilage and then usually deviates to the left. The pyramidal lobe of the gland represents the distal portion of this embryologic structure. The duct has a tortuous U-shaped course around the body of the hyoid bone. Portions of this duct may remain patent and create thyroglossal duct cysts. These will be median in position, but closer to the gland they can deviate from the midline. Cysts found below the hyoid bone require excision of the central portion of this bone in order to include the tortuous portion of this persistently patent remnant of the thyroglossal duct. Accessory thyroid tissue may be found anywhere along the pathway of this developmental entity. The most frequent site is the posterior portion of the tongue near the foramen caecum.

The thyroid gland is composed of two pyramidal-shaped lateral lobes, connected by a transverse bridge of glandular tissue, that crosses anterior to the second, third, and fourth tracheal rings. This connection across the midline is the isthmus. There may be a superior extension of glandular tissue originating from the left portion of the isthmus. This is the pyramidal lobe, and it may be connected to the hyoid bone by a fibrous band. If there are muscle fibers in this band, it is called the levator glandulae thyroidea. The lateral lobe extends from the oblique line of the thyroid cartilage down to the sixth tracheal ring. The gland possesses a true capsule, created by condensation of the normal stroma, and is enveloped by the pretracheal layer of the deep cervical fascia, creating the false or surgical capsule. The pretracheal fascia surrounding the isthmus is adherent to the trachea. This deep cervical fascia also attaches the posteromedial aspect of the lateral lobe to the first and second tracheal rings. This is the ligament of Berry, which usually contains some small blood vessels. These attachments are responsible for superior and inferior movement of the thyroid gland during the act of swallowing. Medial relations of the lateral lobe include thyroid and cricoid cartilages, trachea, esophagus, cricothyroid and inferior constrictor muscles, external branch of the superior laryngeal, and the recurrent laryngeal nerves. The carotid sheath and inferior thyroid artery are posterior. The superior thyroid vessels and the external laryngeal branch of the superior laryngeal nerve approach the lobe from above. The sternohyoid, omohyoid, and sternothyroid muscles are anterior relations. The left lateral lobe is related to the thoracic duct as it travels superiorly, just to the left of the esophagus. It maintains this position until C7, where it arches laterally.

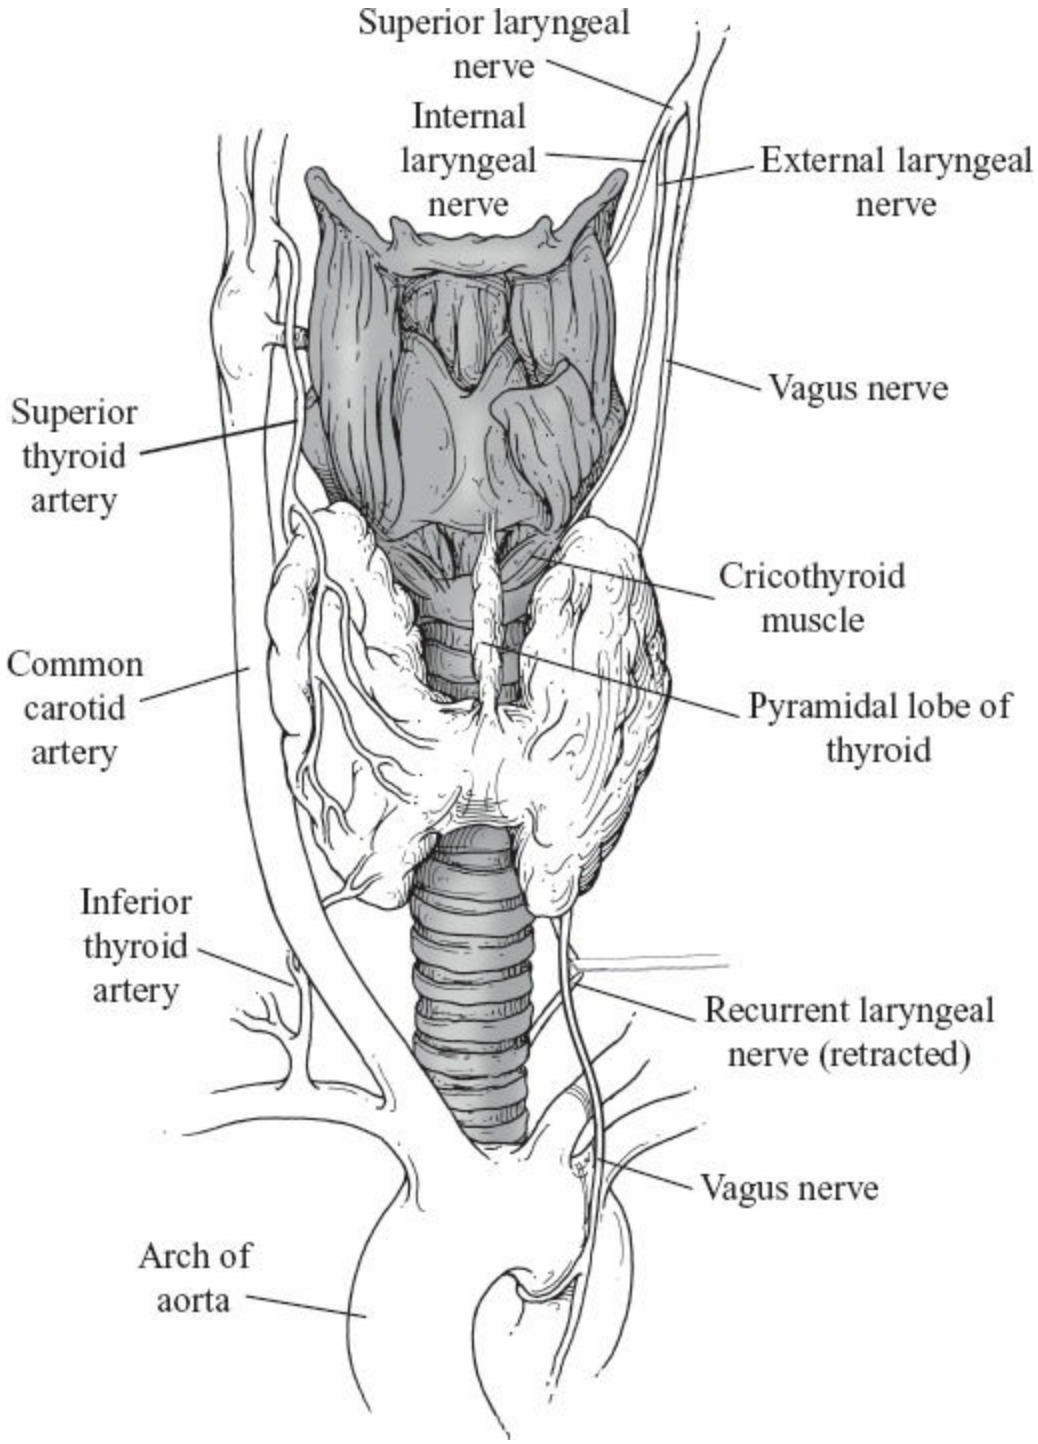

Figure 20.19. Thyroid gland anatomy.

The superior and inferior thyroid arteries provide the vascular supply (Fig. 20.20). In 8% to 10% of the individuals, a thyroid ima artery is present. It may be a direct branch of the arch of the aorta, appearing between the brachiocephalic and the left common carotid vessels. Occasionally, it may arise from the brachiocephalic trunk or the right common carotid artery. The superior thyroid artery is the first of the

anteromedial branches of the external carotid artery. It creates a superior laryngeal vessel that enters the larynx, after piercing the thyrohyoid membrane, along with the superior laryngeal vein and the internal branch of the superior laryngeal nerve. This nerve provides sensory innervation to the interior of the larynx above the vocal ligaments. The superior thyroid artery then passes vertically downward, accompanied by the superior thyroid vein, as it heads for the superior pole of the lateral lobe. Accompanying these blood vessels is the external branch of the superior laryngeal nerve. It is medial, and very close to the vessels. The nerve will turn medially, just superior to the upper pole of the lateral lobe, and head for the larynx. It provides motor innervation to the inferior part of the inferior constrictor of the pharynx and the cricothyroid muscle of the larynx.

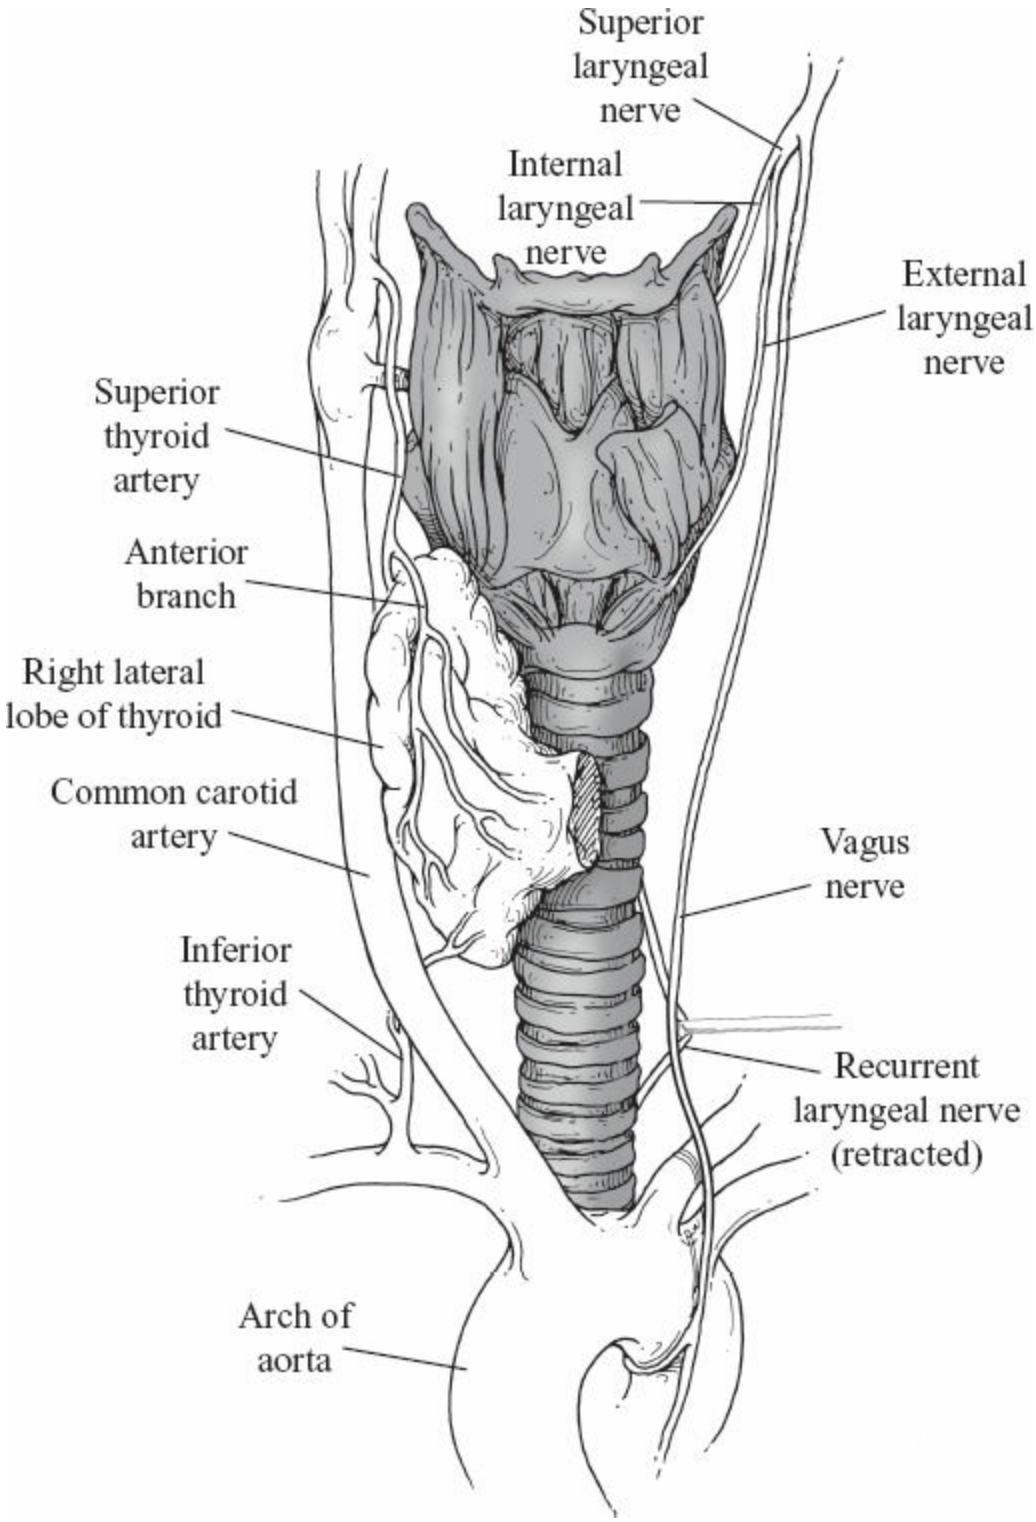

Figure 20.20. Vascular supply to thyroid gland.

The inferior thyroid artery arises from the thyrocervical trunk, a branch of the first portion of the subclavian artery (Fig. 20.21). It will ascend to the cricoid plane, passes posterior to the carotid sheath, and then passes inferomedially to reach the posterior surface of the lateral lobe. In this area, the artery is intimately related to the recurrent laryngeal nerve, a

branch of the vagus (X), providing motor innervation to all the intrinsic muscles of the larynx except the cricothyroid.

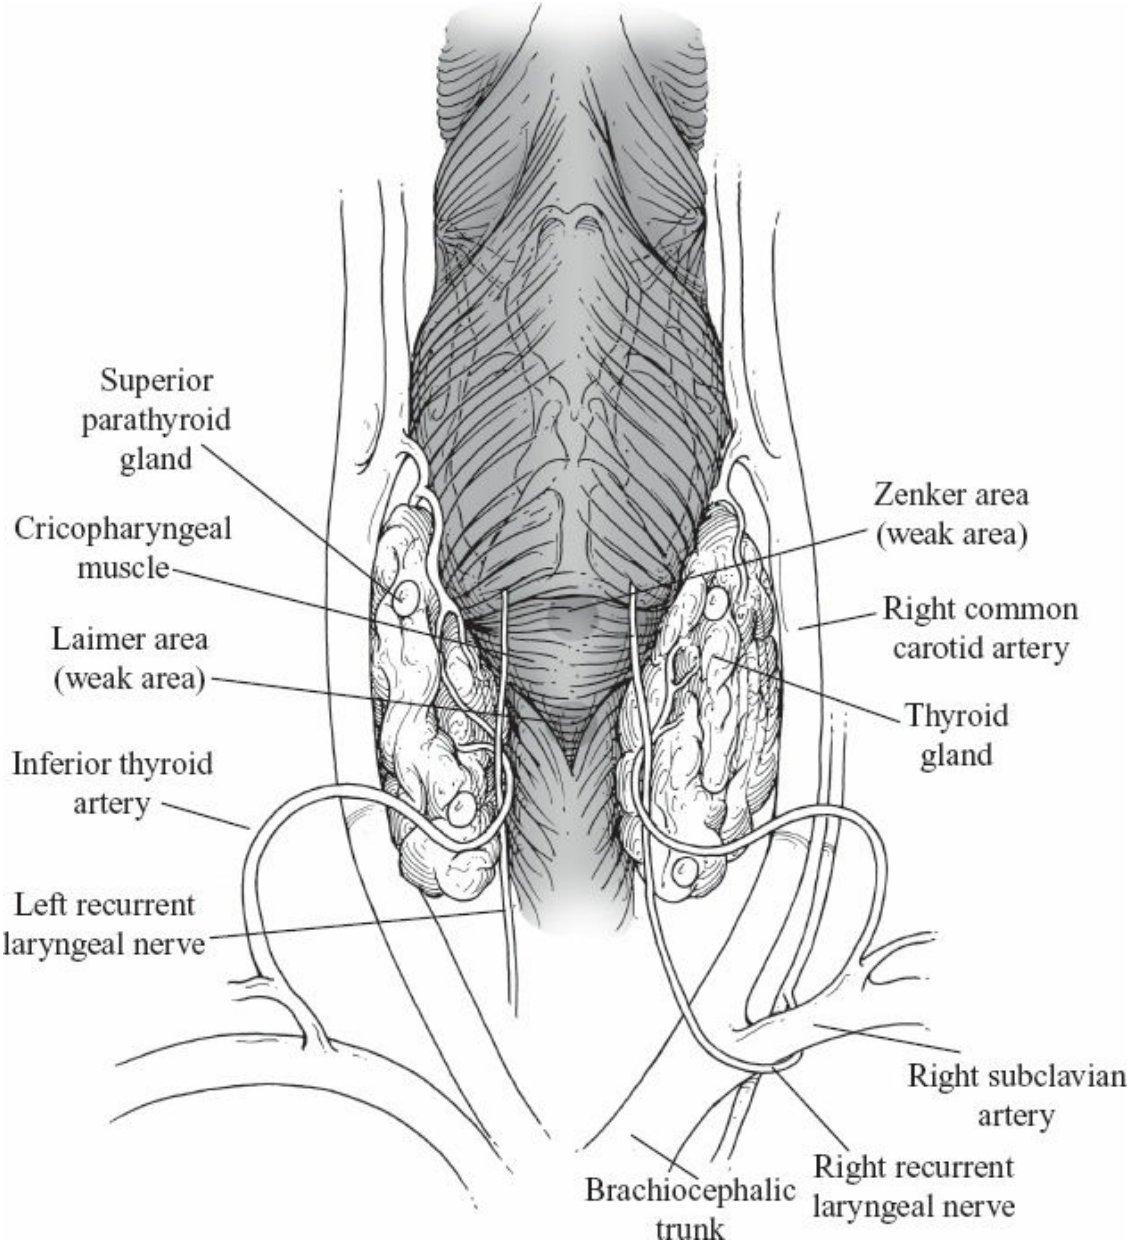

Figure 20.21. Posterior view of thyroid gland.

The superior thyroid artery will provide an anterior and posterior branch (Fig. 20.22). The anterior branch will communicate with its contralateral counterpart through branches that cross the midline by way of the isthmus. The posterior branch of the superior thyroid artery communicates with branches of the inferior thyroid artery. The venous drainage is *via* the superior thyroid vein into the internal jugular or common facial vein, the short middle thyroid vein into the internal jugular

vein, and the inferior thyroid veins into the brachiocephalic vein.

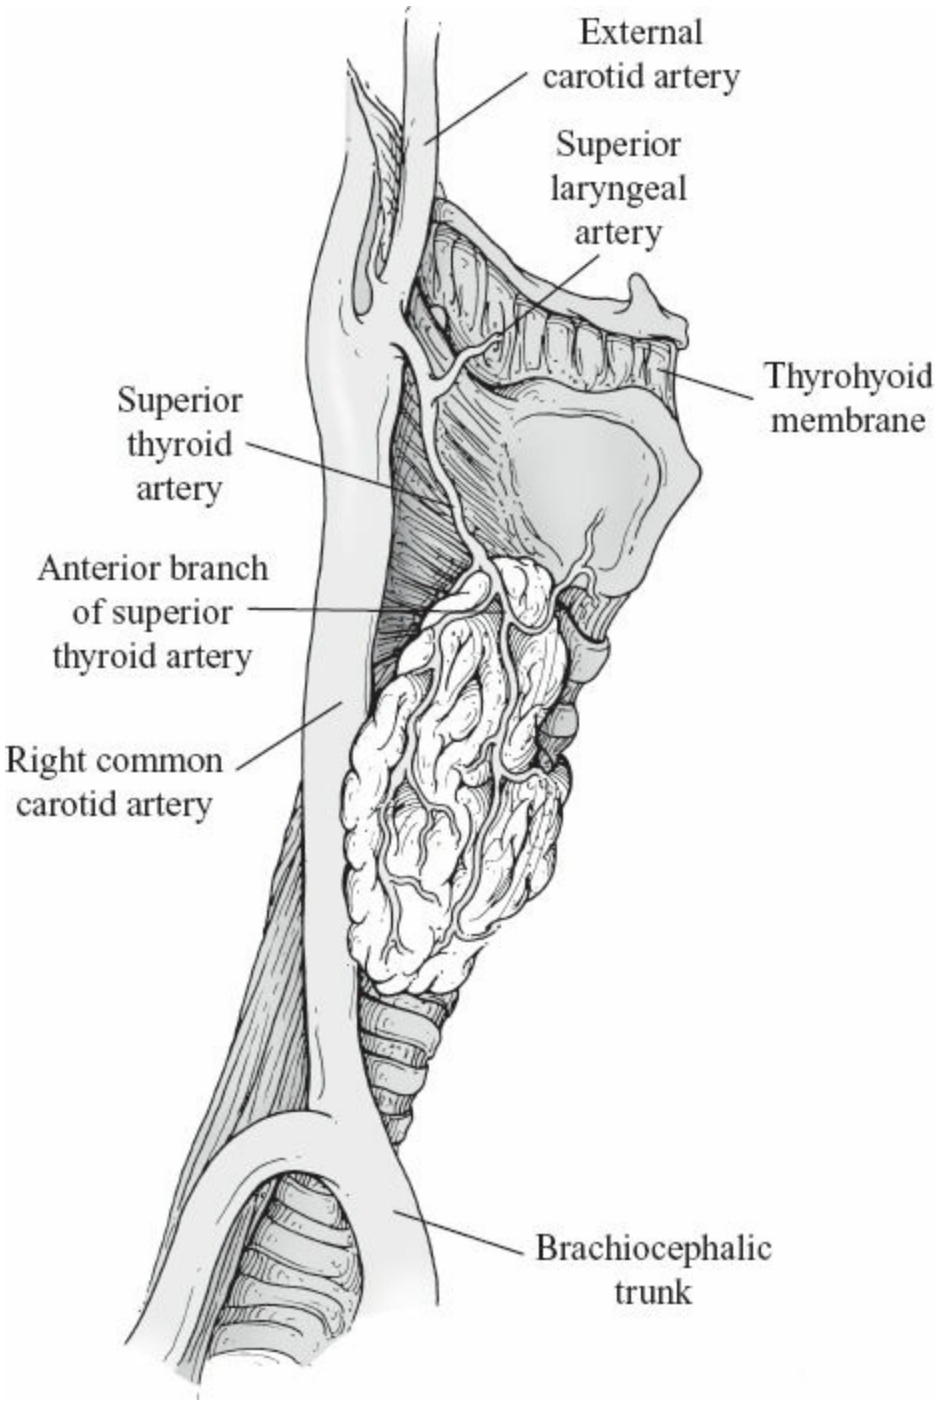

Figure 20.22. Right lateral view of thyroid gland.

The lymphatic drainage of the thyroid gland can be divided into superior or ascending, and inferior or descending pathways. They can be further subdivided into lateral and medial components. The superomedial pathway leads to the prelaryngeal or Delphian node found anterior to the cricothyroid membrane. The superolateral channels pass, with the superior

thyroid artery, to nodes situated at the bifurcation of the common carotid artery, or to the omohyoid nodes of the internal jugular chain. The inferomedial lymph vessels are related to nodes found anterior, and adjacent, to the trachea. The inferolateral lymph flow is to the supraclavicular nodes.

Parathyroid Gland

The parathyroid glands are found on the posterior surface of the thyroid gland between the surgical and the true capsule (see Fig. 20.21). They may also be situated outside the surgical capsule, or within the true capsule (intraglandular). There are usually four glands, and each one measures only 5 to 6 mm in diameter. The upper pair is found at the level of the cricoid cartilage and is frequently adjacent to a descending branch of the superior thyroid artery that anastomoses with an ascending branch of the inferior thyroid artery. They are yellowish brown and, therefore, distinguishable from normal thyroid tissue, which is reddish pink. The inferior pair of glands is found superior or inferior to the inferior thyroid artery, as this vessel passes transversely across the posterior aspect of the lower pole of the lateral thyroid lobe. They receive their blood supply from the superior and inferior thyroid arteries. Aberrant glandular tissue is not uncommon.

Clinical Anatomical Aids

1. A parathyroid gland may resemble a small lymph node, but the glandular tissue is softer when palpated, compared with the firmer feel of the node.
2. Superior enlargement of the thyroid lobe is prevented by the insertion of the sternothyroid muscle into the oblique line of the thyroid cartilage. Lateral expansion can occur.
3. Occasionally, there may be extralaryngeal branching of the recurrent nerve, resulting in loss of a single main trunk. This will usually occur superior to the inferior thyroid artery. Therefore, it is better to look for the main trunk of the nerve inferior to the artery.
4. The inferior thyroid artery will usually divide into two or three branches before entering the parenchyma of the thyroid gland. The recurrent nerve usually passes between these branches.
5. If the inferior thyroid artery is divided laterally, just after passing posterior to the carotid sheath, nerve injury is unlikely.
6. Anteromedial retraction of the lateral lobe of the thyroid gland will

displace the recurrent laryngeal nerve from its expected position in the tracheoesophageal groove, toward the posterolateral aspect of the trachea.

7. There may not be a recurrent laryngeal nerve found in the tracheoesophageal groove if there is a high origin of the nerve. This is referred to as a nonrecurring nerve.
8. A cricothyroidotomy provides access to the infraglottic space. This area of the larynx is below the vocal ligaments.

Pharynx

The pharynx is a muscular tube, approximately 5 in long, that extends from the base of the skull to the cricoid cartilage, where it is continuous with the esophagus (Fig. 20.23). An anterior wall is lacking where it faces the nasal and oral cavities and the larynx. This creates nasopharynx, oropharynx, and laryngopharynx subdivisions. The nasopharynx is between the soft palate and the base of the skull. The soft palate is attached to the posterior end of the hard palate. It is a soft tissue shelf, approximately 2 in long. A small grape-like swelling, the uvula, is attached to its free end. It contains the small, paired, uvular muscles. There are four additional paired muscles in the soft palate area: palatoglossus, palatopharyngeus, levator, and tensor palati. They narrow the oropharyngeal junction, tense the soft palate, and elevate the uvula in order for the oropharynx to be separated from the nasopharynx and oral cavity during deglutition. The posterior and lateral walls are immobile; therefore, the nasopharynx is always patent. In the lateral wall, at the level of the inferior nasal concha, is the opening of the auditory tube (eustachian). There is a bulge at the posterior end of the tube created by the cartilage in its wall. Passing inferiorly from this elevation is the salpingopharyngeal fold, created by the salpingopharyngeus muscle. Posterior to the bulge and the fold is the pharyngeal recess. On the posterior wall, there may be collections of lymphatic tissue referred to as pharyngeal tonsils, or adenoids. An anterior wall is created by the nasal cavity.

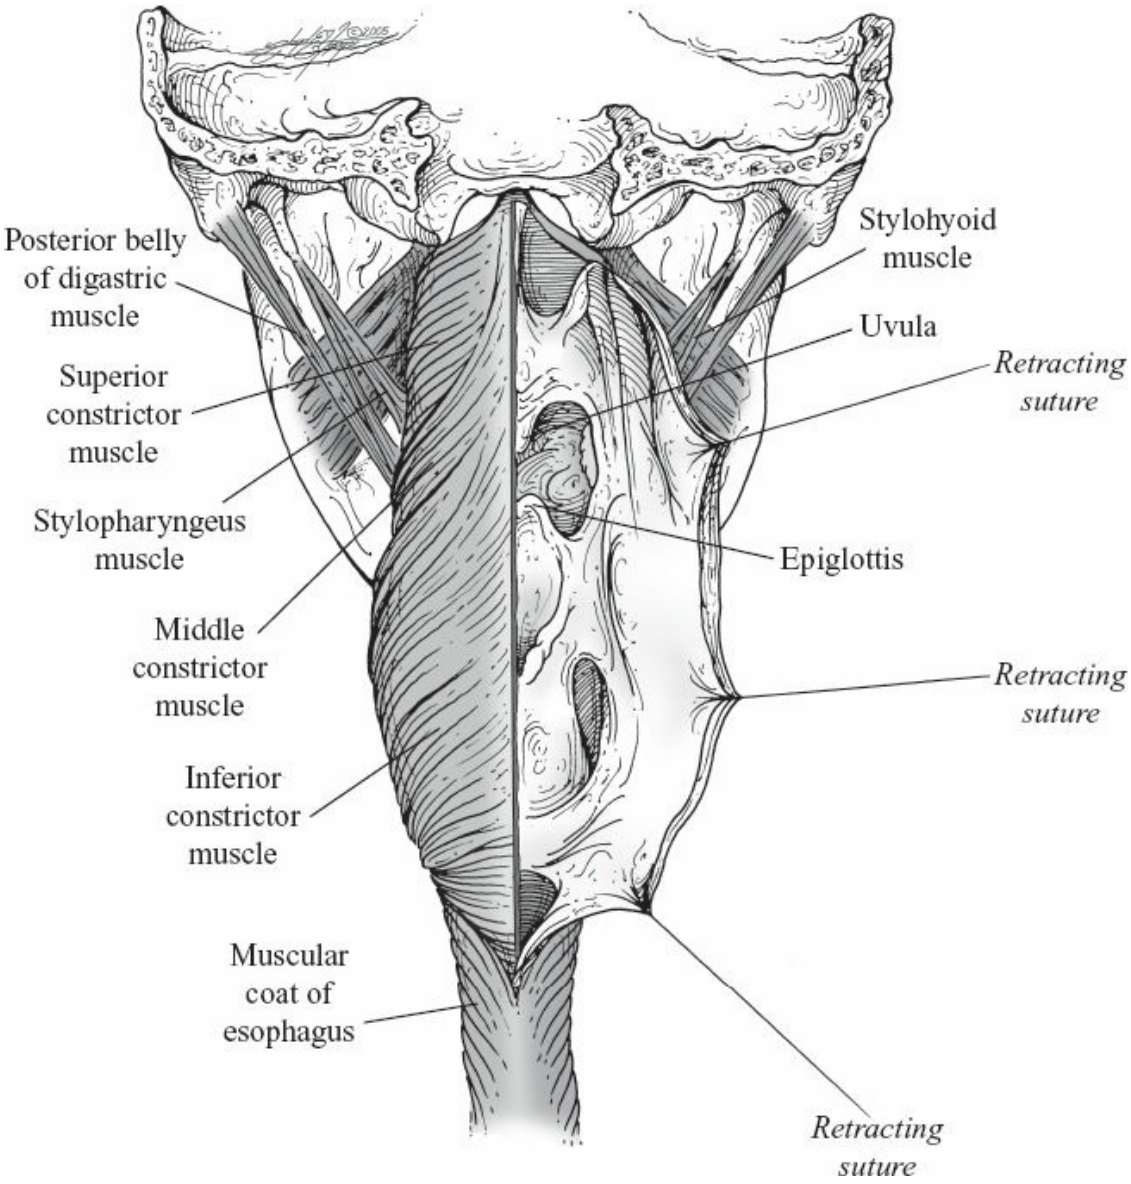

Figure 20.23. Posterior view of pharynx with right portion of constrictor muscle retracted laterally.

The oropharynx faces the oral cavity and the posterior surface of the tongue (Fig. 20.24). The palatoglossal arch is located at the junction between the mouth and the oropharynx. Posterior, and slightly lateral to this arch, is the palatopharyngeal arch. The arches are named for the muscles they enclose. Between the arches is the palatine or tonsillar fossa, a space for the palatine tonsil. The fauces is considered as the area between the oral cavity and the pharynx. The posterior third of the tongue contains lymphatic tissue called lingual tonsil. Behind the tongue is the upper free edge of the epiglottis. Its anterior surface and lateral edges are attached to the tongue by mucosal folds named glossoepiglottic folds. Shallow depressions between the folds are the valleculae. The buccopharyngeal

fascia covering the posterior aspect of the pharyngeal wall is in contact with the prevertebral fascia lying anterior to the upper cervical vertebrae.

The laryngopharynx receives, in its upper portion, products of the digestive and respiratory systems. Its lower segment is related only to the digestive system. The anterior wall is created by the entrance into the vestibule of the larynx, bounded laterally by the aryepiglottic fold, the arytenoid cartilages, and the lamina of the cricoid cartilage. The posterior wall is in contact with the prevertebral fascia situated anterior to the lower cervical vertebrae. The anterior and posterior walls of the distal segment of pharynx are in contact but are separated by the passage of food. The lateral wall is supported by the posterior free edge of the thyroid lamina. A small piriform recess is found between the thyroid lamina laterally and the aryepiglottic fold medially. This space receives sensory innervation from the internal laryngeal nerve, and if a foreign body, or a morsel of food, is trapped in this area, it will cause severe and persistent coughing.

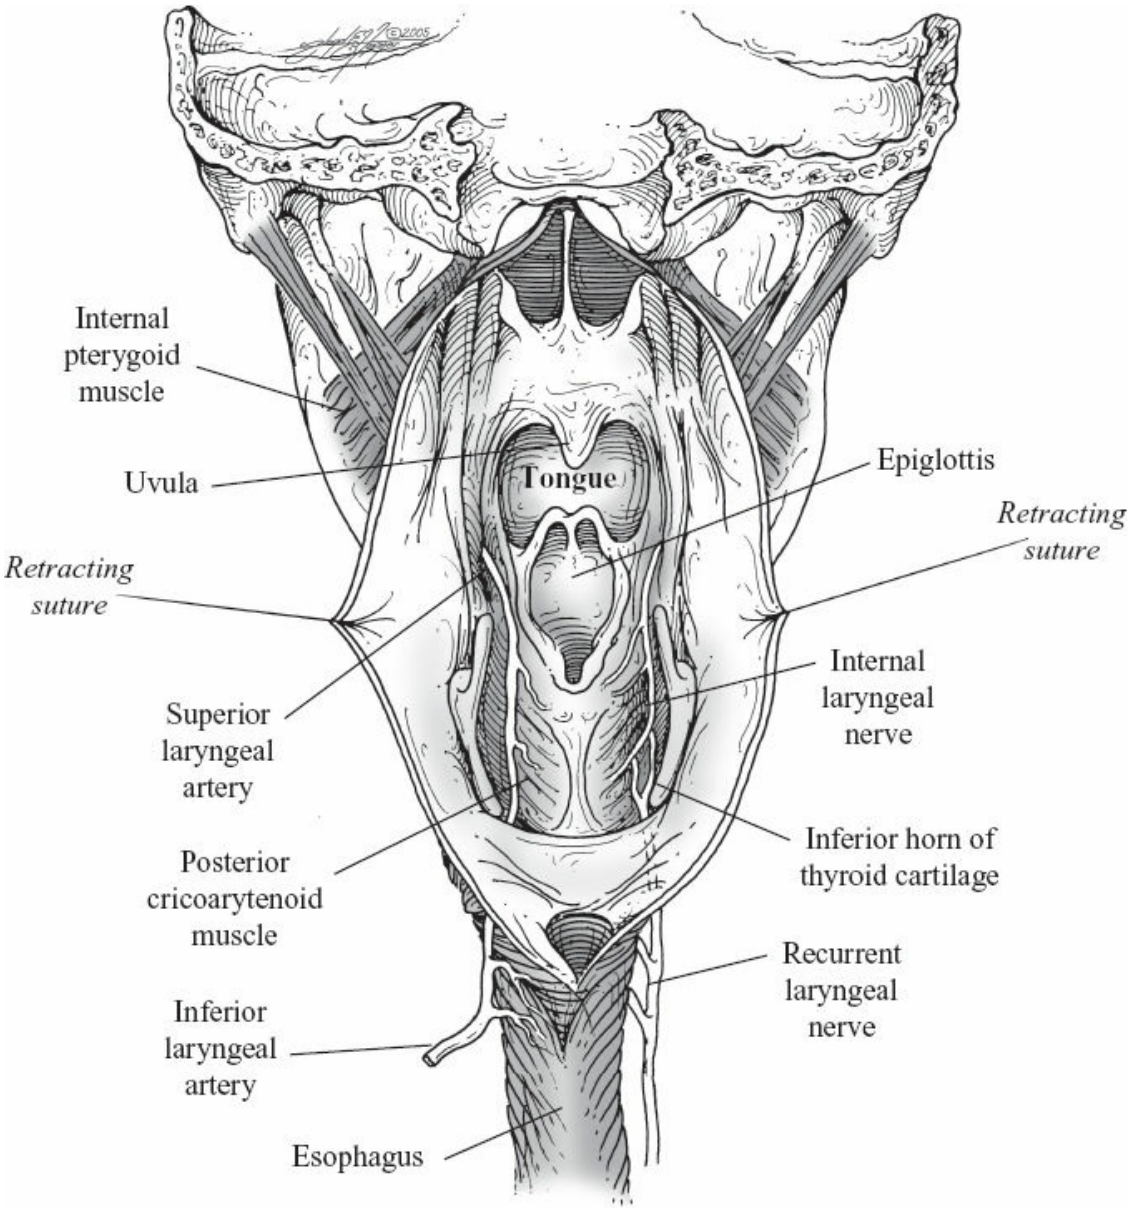

Figure 20.24. Interior view of pharynx.

Ligamentous Background

1. Stylohyoid ligament is found between the tip of the styloid process of the skull and the lesser horn of the hyoid bone (Fig. 20.25). It supports the hyoid, and through the thyrohyoid membrane is also responsible for suspension of the larynx.
2. Pharyngeal raphe is a fibrous seam, which represents the posterior site of attachment for the left and right constrictor muscles. It is attached superiorly to the pharyngeal tubercle found on the basal portion of the occipital bone, 1/2 in anterior to the foramen magnum. Inferiorly, it merges with the esophageal wall.
3. Pterygomandibular raphe is a fibrous structure between the pterygoid

hamulus and the mandible. It provides attachment for the superior constrictor and the buccinator muscles.

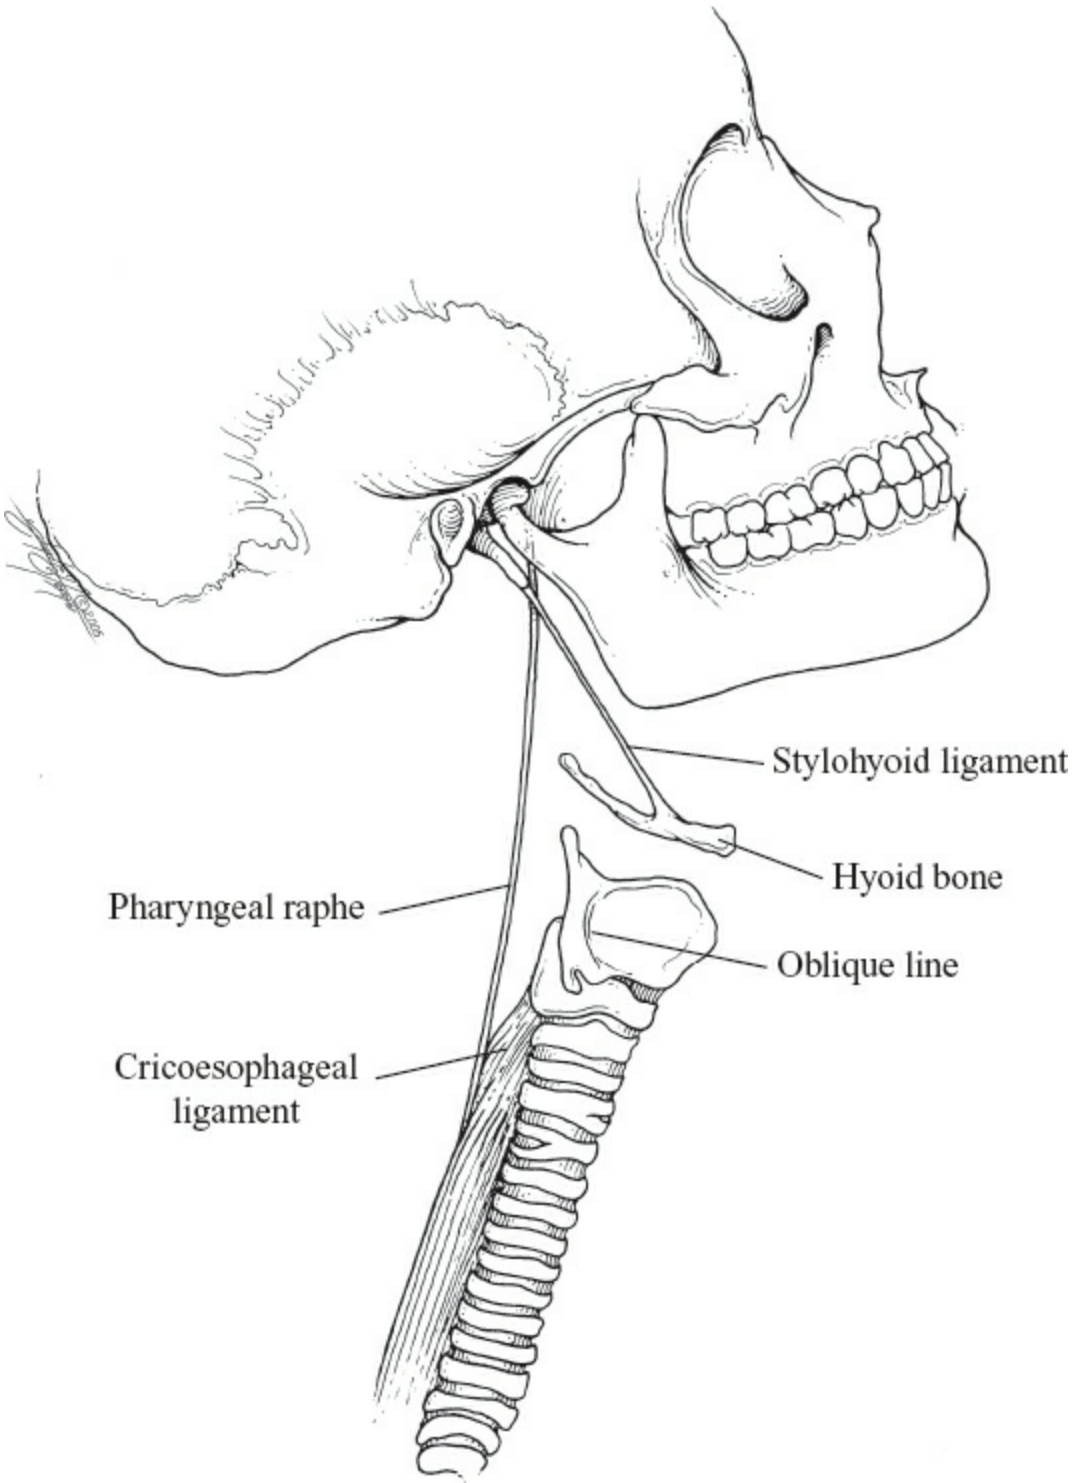

Figure 20.25. Skeletal framework of pharynx.

Muscular Background

There are five paired voluntary muscles contributing to the pharyngeal

wall. The superior, middle, and inferior constrictors create an external circular muscle layer (Fig. 20.26). The stylopharyngeus and the palatopharyngeus create an inner longitudinal muscle layer. Each constrictor muscle partially overlaps, externally, the inferior edge of the muscle above. The superior constrictor arises from the posterior edge of the lower part of the medial pterygoid plate, pterygoid hamulus, pterygomandibular raphe, side of the tongue, and the mylohyoid line of the mandible. The middle constrictor arises from the inferior end of the stylohyoid ligament and the lesser and greater horns of the hyoid bone. The inferior constrictor arises from the oblique line of the thyroid cartilage, the lateral aspect of the arch of the cricoid, and from the fascia overlying the cricothyroid muscle of the larynx. These muscles widen as they pass laterally and then posteriorly, where they insert into the posterior midline pharyngeal raphe. The lowest fibers of the inferior constrictor that arise from the cricoid cartilage create the cricopharyngeus muscle (Fig. 20.27). This is the superior esophageal sphincter, which can regulate flow into the esophagus. The upper fibers of the muscle pass superomedially and attach to the pharyngeal raphe, but the lower fibers pass transversely. There is a slight muscular defect between the transverse and the oblique portions of the cricopharyngeus muscle. This is Zenker area, a weak point, where pulsion diverticula may develop, and is a potential site for endoscopic perforation.

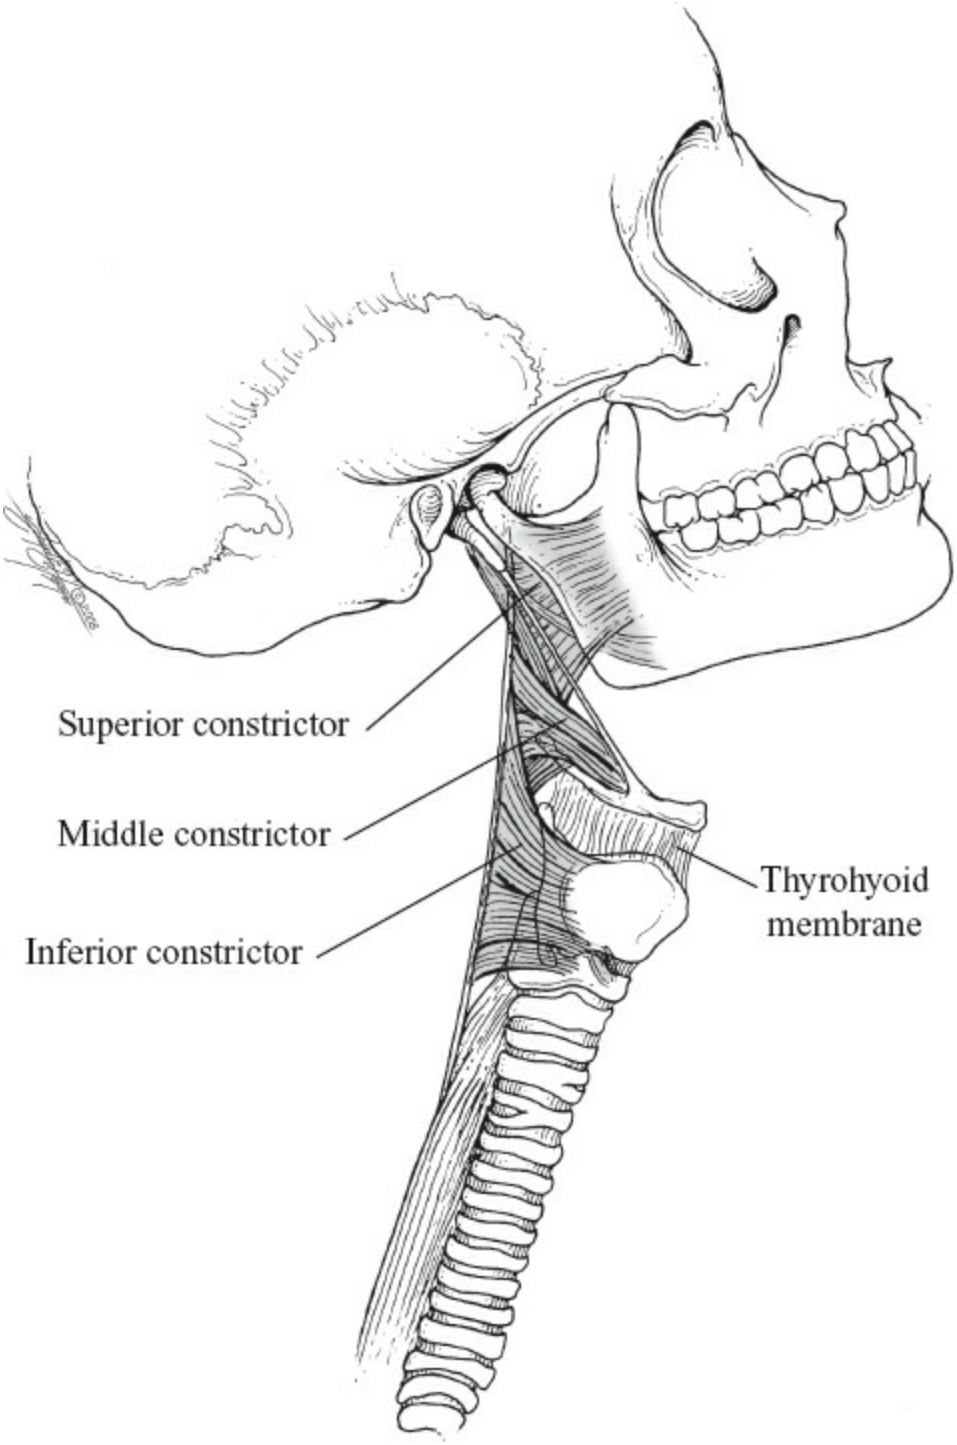

Figure 20.26. Constrictor muscles of pharynx.

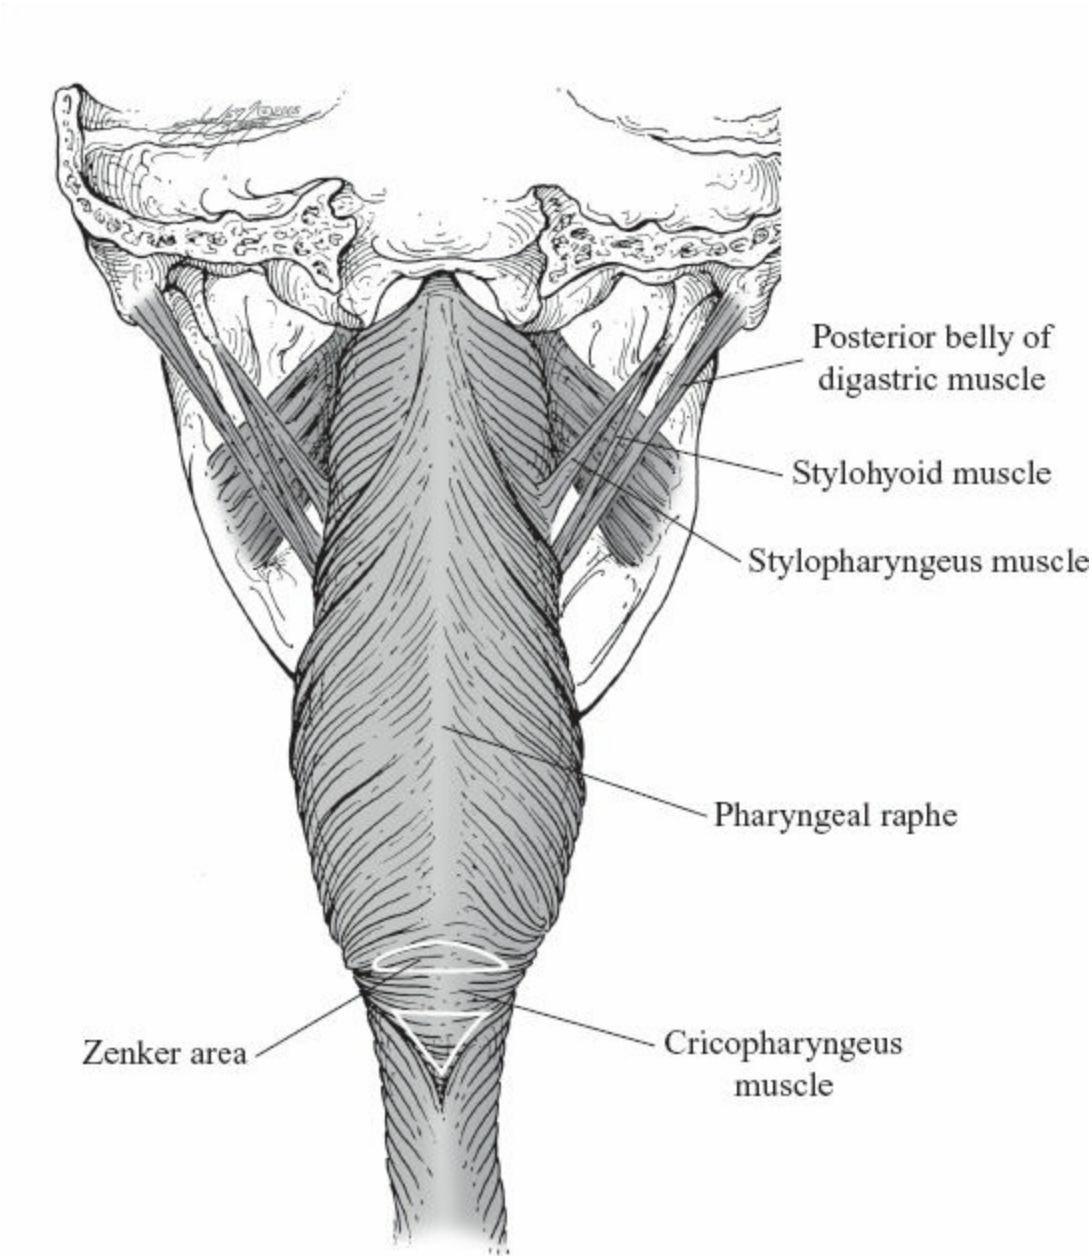

Figure 20.27. Posterior view of pharynx.

The stylopharyngeus and palatopharyngeus muscles create the internal longitudinal muscle layer. The stylopharyngeus muscle receives motor innervation from the glossopharyngeal nerve. The remainder of the muscular wall is supplied by the vagus and glossopharyngeal nerves *via* the pharyngeal plexus. The superior laryngeal nerve arises from the vagus at the base of the skull. It creates the external laryngeal nerve, which innervates the lower portion of the inferior constrictor, and the cricothyroid muscle of the larynx.

Completion of the Wall of the Pharynx

There are defects in the pharyngeal wall superior and inferior to the narrow origins of the constrictor muscles. There are structures that pass through these areas of muscular deficiency. Two layers of fascia close these openings: (a) buccopharyngeal fascia, which also creates an external covering of the constrictors, and (b) pharyngobasilar fascia, which is submucosal in position, and internal to the muscular wall.

The pharyngeal nervous plexus and the pharyngeal venous plexus are found between the constrictor muscles and the buccopharyngeal fascia. In addition, there are submucosal venous plexuses. The uppermost opening, between the base of the skull and the superior constrictor, provides passage for the cartilaginous portion of the auditory tube, levator palatine muscle, and small palatine vessels. The stylopharyngeus muscle and the glossopharyngeal nerve pass between the superior and the middle constrictor muscles (Fig. 20.28). The third gap, between the middle and the inferior constrictors, includes the area between the greater horn of the hyoid and the thyroid cartilage. The thyrohyoid membrane is found here and is penetrated by the superior laryngeal artery arising from the superior thyroid, the internal branch of the superior laryngeal nerve providing sensory innervation to the laryngeal mucosa above the vocal folds, and the superior laryngeal vein. Passing between the inferior constrictor and the esophagus are the continuation of the recurrent laryngeal nerve and the inferior laryngeal artery and vein (Fig. 20.24).

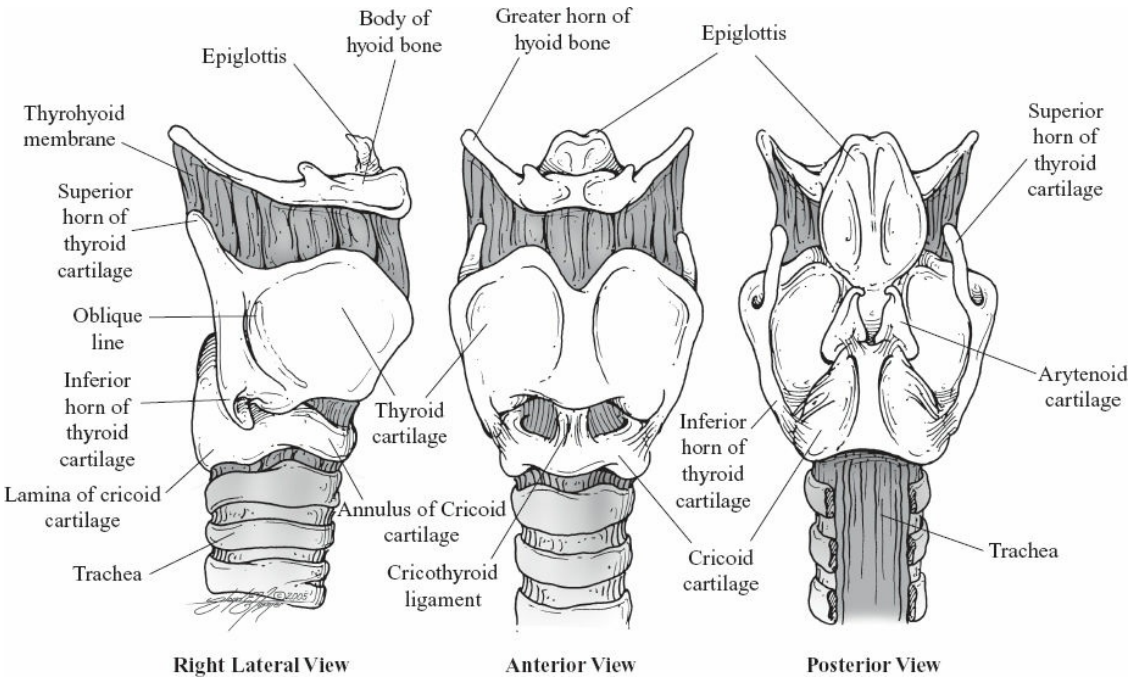

Figure 20.28. Cartilages of the larynx.

Innervation of the Pharynx

The pharyngeal plexus, created by the vagus (X) and glossopharyngeal (IX) nerves, supplies motor innervation to the pharyngeal muscles. The stylopharyngeus muscle receives motor innervation from the glossopharyngeal nerve. The superior laryngeal nerve arises from the vagus at the base of the skull. It creates the external laryngeal nerve that innervates the lower portion of the inferior constrictor and the cricothyroid muscle of the larynx. The remainder of the muscular wall receives motor innervation from the pharyngeal plexus. Sensory innervation is provided by the glossopharyngeal nerve *via* the pharyngeal plexus.

Larynx

The larynx is responsible for vocalization. The superior opening faces the laryngopharynx. The inferior end is at the cricoid cartilage, where it becomes continuous with the trachea. It is anterior to vertebral bodies C3 through C6. The anterior wall of the larynx is related to cervical fascia and skin. The strap muscles are anterolateral. The thyroid gland and the carotid sheath are lateral. The laryngopharynx separates the larynx from the vertebral column. It has some degree of rigidity and is composed of bone and cartilage that are held together by membranes, ligaments, and synovial joints. The hyoid bone is part of the anatomy of the floor of the mouth, but as it provides important support for the larynx, it will be discussed in this section.

Skeleton of Larynx

The hyoid bone is a U-shaped structure with a central body, measuring 1 in wide and 1/2 in high. It is continuous, on each side, with the greater horn that passes posterolaterally for approximately 1½ in. The free end of the greater horn is directly inferior to the angle of the mandible. The lesser horns are small, superior protrusions found at the junction of the body and greater horns. The stylohyoid ligament, which suspends the hyoid bone from the base of the skull, is attached here.

Laryngeal Cartilages

There are three unpaired and three paired cartilages (Fig. 20.28). The larger unpaired cartilages are the thyroid, cricoid, and epiglottis. The paired cartilages are the arytenoid, corniculate, and cuneiform.

The hyoid bone and the thyroid and cricoid cartilages provide the

principal support of the larynx. The thyroid cartilage is palpable 1/2 in below the body of the hyoid bone. It is composed of hyaline cartilage and formed by two laminae that fuse anteriorly. The anterosuperior point of fusion is incomplete, leaving a palpable V-shaped notch called the laryngeal, or thyroid, prominence. It is also referred to as Adam's apple, and is a more prominent structure in males. The posterior border of each lamina is free and creates projections called the superior and inferior horns. The superior horn extends up approximately 1/2 in toward, and is vertically inferior to, the tip of the greater horn of the hyoid. The inferior horn is only 1/4 in long, and extends down from the free edge of the thyroid lamina toward the posterior end of the arch of the cricoid cartilage. There is a ridge beginning at the root of the superior horn that extends inferomedially toward the lower edge of the fused thyroid laminae. This is the oblique line, and it represents the point of attachment of three muscles: sternothyroid, thyrohyoid, and the inferior constrictor of the pharynx.

The cricoid cartilage creates a complete ring. It is the only complete cartilaginous ring in the respiratory system. The anterior and lateral portion of the ring is narrow and creates the arch. The posterior part widens and creates the lamina. It does resemble a signet ring. The arch has been identified as the cricoid plane. This is the level that was referred to as an anatomical bonanza earlier in this chapter. The cricoid participates in two synovial joints: cricoarytenoid and cricothyroid. The epiglottis is the third of the unpaired cartilages. It is composed of elastic cartilage, which allows this racket-shaped structure to help seal off the entrance into the larynx during deglutition. Its lower pointed end is attached to the thyroid cartilage just inferior to the laryngeal prominence by the thyroepiglottic ligament. The superior edge extends above the body of the hyoid bone. The hyoepiglottic ligament attaches to the posterior aspect of the body of the hyoid. The anterior aspect is connected to the dorsum of the tongue by left, right, and median glossoepiglottic folds. Between the folds are depressions referred to as vallecula epiglottica. The superior edge of the epiglottis may be visible during oral examination if the dorsum of the tongue is depressed. The posterior surface of this cartilage is part of the anterior wall of the laryngeal vestibule.

The arytenoids are the largest of the paired cartilages. They lie on the superior border of the lamina of the cricoid cartilage and participate in the cricoarytenoid joint. They are pyramidal in shape and measure 1/2 to 3/4 in in height. The base is on the superior surface of the lamina of the

cricoid. The medial end of the base is prolonged anteriorly to create the vocal process. The posterolateral angle of the base is enlarged and forms the muscular process. The medial surface faces its partner. The anterolateral surface provides attachment for muscles inferiorly and the quadrangular membrane superiorly. The arytenoid is composed of hyaline cartilage, but the apex is created by elastic cartilage. The corniculate and cuneiform are small bars of elastic cartilage that lie within the aryepiglottic fold, just above the apex of the arytenoid.

Membranes and Ligaments

The thyroid cartilage is suspended from the body and greater horn of the hyoid bone by the thyrohyoid membrane. This membrane is thickened in the midline and at each edge, creating the median and lateral thyrohyoid ligaments. The median cricothyroid ligament is a midline thickening between the anterior aspect of the cricoid arch below, and the inferior end of the thyroid cartilage above (Fig. 20.28). Other strong fibers arise from the remainder of the arch of the cricoid and pass superomedially. The anterior fibers pass to the internal aspect of the thyroid cartilage below the thyroid notch (Fig. 20.29). The posterior fibers attach to the vocal process and the base of the arytenoids. The fibers between these anterior and posterior attachments are free and are called the vocal ligaments. The vocal ligaments are the superior free edge of the cone-shaped structure that attaches below to the arch of the cricoid cartilage. It is called the conus elasticus and encloses the infraglottic space of the larynx (Fig. 20.30). The cricotracheal ligament attaches the cricoid to the first tracheal cartilage. Above the level of the vocal ligaments is a thinner membrane, which passes from the anterolateral surface of the arytenoid cartilage to the lateral edge of the epiglottis, below its superior edge, and to the thyroepiglottic ligament. This is the quadrangular membrane. The lower edge, between the arytenoids and the thyroepiglottic ligament, is free, and forms the vestibular ligaments, or false vocal cords. The distance between the vocal ligaments and the more superiorly located vestibular ligaments separates the conus elasticus and the quadrangular membrane from each other inferiorly. The two structures create the fibroelastic membrane of the larynx. Both are cone-shaped and are aligned so that they resemble an hourglass.

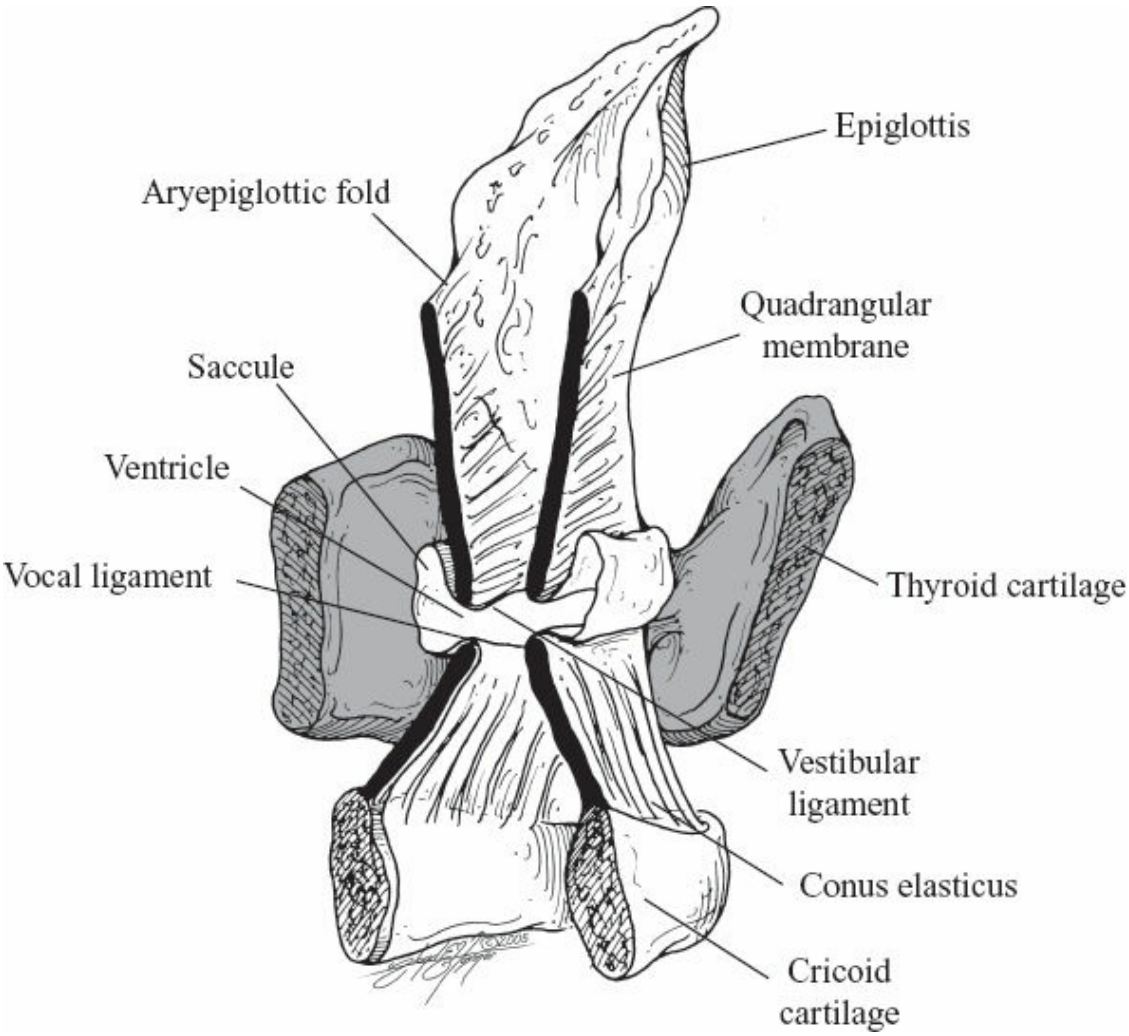

Figure 20.29. Membranes of the interior of the larynx.

Interior of the Larynx

The membranes and ligaments previously described are lined by mucosa. The larynx is divided into three portions (Fig. 20.29). The vestibule is superior and the infraglottic space is inferior. Separating these two areas is the ventricle. The vestibule is bounded anteriorly by the epiglottis. The quadrangular membrane is the lateral limit, and posteroinferiorly are the arytenoids and the interarytenoid fold. The mucosa covering the superior edge of the quadrangular membrane forms the aryepiglottic fold. The space between the aryepiglottic folds is the entrance into the vestibule. It is the laryngeal aditus. The mucosa covering the vestibular ligament creates the vestibular fold, which is the inferior end of the vestibule. The space between the vestibular folds is the rima vestibuli. Below the vestibular folds are the vocal folds. The mucosa covering the vocal ligaments creates the vocal folds. It is very adherent and has a white coloration. The mucosa of this fold is stratified squamous. The remainder of the laryngeal mucosa

is pseudostratified ciliated columnar. The space between the vocal folds is the rima glottidis. It is found 1/4 in below the rima vestibuli and is easily visualized by endoscopic examination through the wider rima vestibuli.

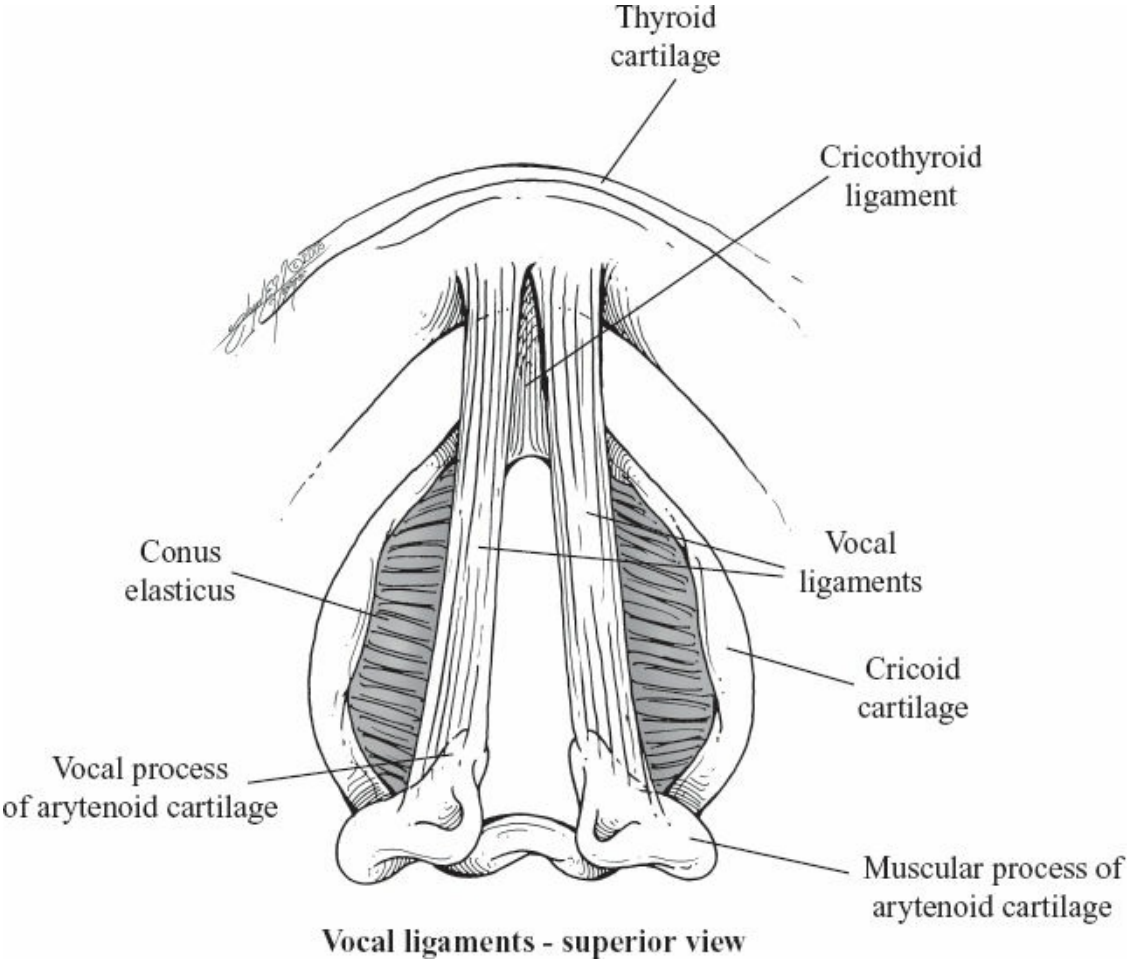

Figure 20.30. Superior view of the vocal ligaments.

The middle portion of the larynx is the ventricle. It separates the vestibule superiorly from the infraglottic space inferiorly. It is found between the rima vestibuli and the rima glottidis. The mucosa extends laterally between the vestibular and the vocal folds and creates the sinus. A small outpouching from this area ascends for a short distance, lateral to the vestibular fold, and creates the saccule. Numerous mucous-secreting glands are found here. The infraglottic space is internal to the conus elasticus and the cricoid cartilage. The rima glottidis is the upper limit, and inferiorly it is continuous with the lumen of the trachea.

Joints and Intrinsic Muscles of the Larynx

The cricothyroid and cricoarytenoid joints are synovial and created by

hyaline cartilaginous structures. The cricothyroid joint allows a pivoting movement, which elevates the arch of the cricoid cartilage while depressing the lamina and the arytenoid cartilages found on its superior surface (Fig. 20.30). This results in tensing of the vocal ligaments, which creates high-pitched sounds. The axis of rotation is transverse, through both cricothyroid joints. The cricoarytenoid joint permits two types of movements of the arytenoid cartilage. Rotation around a vertical axis passing through the arytenoids will result in adduction or abduction of the vocal ligaments. In addition, a gliding movement can occur, which allows the arytenoids to move toward, or away from, each other. The rima glottidis is triangular, and the base is the interval between the vocal processes. The transverse gliding movement, or the rotation of the arytenoids around a vertical axis, can result in either widening or narrowing of the rima glottidis. There are nine intrinsic muscles of the larynx, eight are paired and one is unpaired. Six of the paired and the unpaired act directly on the arytenoids, with resultant effect on the vestibular and vocal ligaments. The muscles can be divided into three functional groups. The first provides protection by sphincter-like activities. They are in the aryepiglottic fold. The aryepiglottic muscle passes from the posterior surface of the arytenoids to the lateral aspect of the epiglottis (Fig. 20.31). The thyroepiglottic muscle extends from the internal aspect of the thyroid lamina to the lateral aspect of the epiglottis. These muscles help close the laryngeal aditus. The second group of muscles tenses, relaxes, or adducts the vocal ligaments. The cricothyroid muscle, found between the arch of the cricoid and the internal aspect of the fused thyroid lamina, causes elevation of the arch of the cricoid and depression of the lamina. This results in tensing of the vocal ligaments. The thyroarytenoid muscle, which is found between the thyroid cartilage anteriorly, and the arytenoids oppose this action posteriorly. It pulls the vocal processes anteriorly and relaxes the vocal ligaments. Fibers from the medial aspect of this muscle attach directly to the vocal ligaments and can cause differential contraction and relaxation of portions of the vocal ligament. These specialized fibers are named the vocalis muscle. The lateral cricoarytenoid muscle, between the posterior portion of the arch of the cricoid and the muscular process of the arytenoids, is the main adductor of the vocal ligaments. The transverse arytenoid is the only unpaired muscle of the larynx; it passes between the arytenoids and causes narrowing of the rima glottidis and the rima vestibuli. The third group of muscles is

responsible for widening of the rima glottidis. The posterior cricoarytenoid muscle passes obliquely between the posterior surface of the cricoid lamina and the muscular process of the arytenoid. It widens the rima glottidis by abducting the vocal process of the arytenoid cartilage.

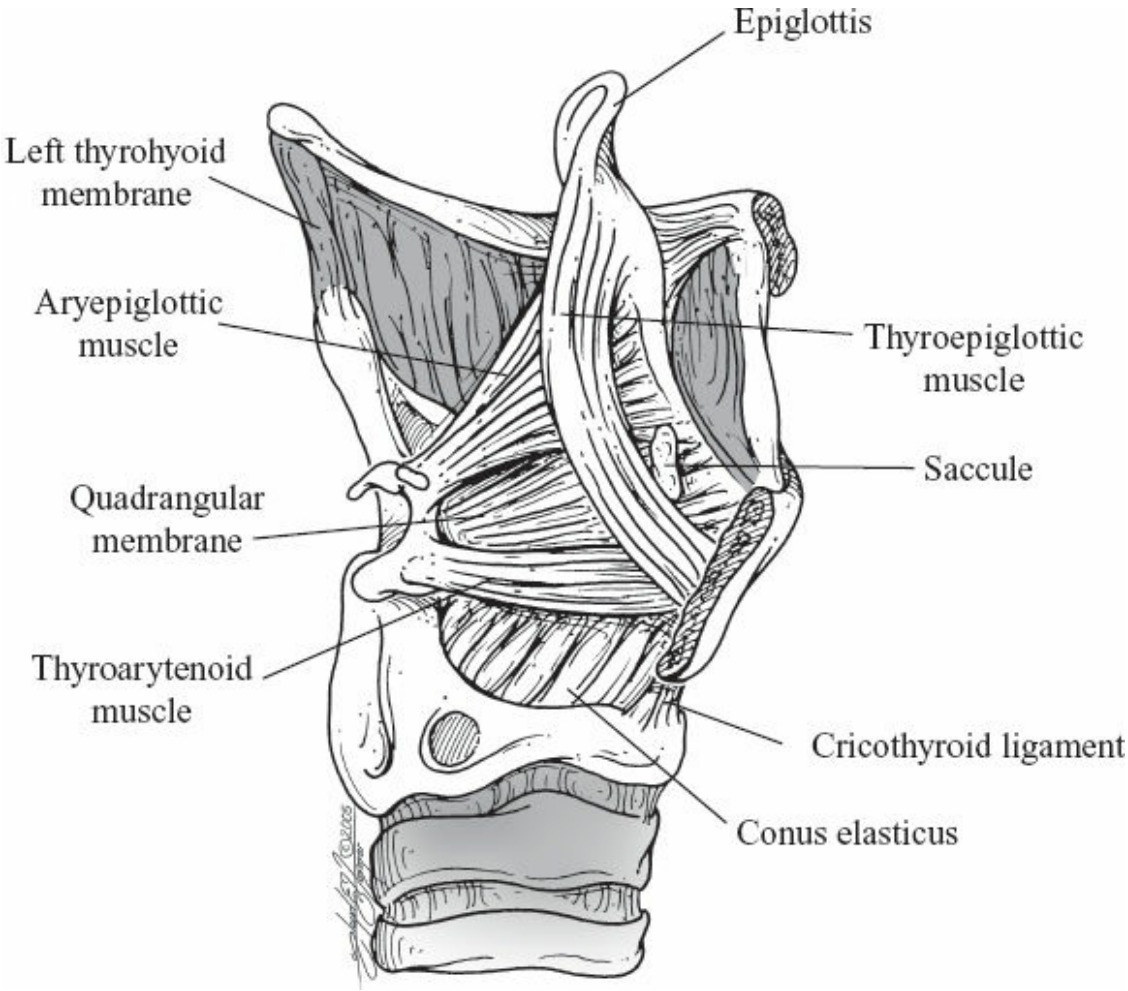

Figure 20.31. Interior of the larynx after the removal of the right portion of hyoid and thyroid cartilages.

Blood Supply and Nervous Innervation of the Larynx

The superior laryngeal branch of the superior thyroid artery provides vascular flow. It enters the larynx through the thyrohyoid membrane, along with the internal laryngeal nerve and superior laryngeal veins. Vascular inflow also occurs *via* the inferior laryngeal artery, a branch of the inferior thyroid that enters the larynx below the lower edge of the inferior constrictor muscle, along with the inferior laryngeal nerve. This nerve is the intralaryngeal continuation of the recurrent laryngeal nerve.

Vagus nerve branches provide all sensory and motor innervation. Sensory innervation, above the vocal folds, comes from the internal branch

of the superior laryngeal nerve. The inferior laryngeal nerve supplies sensory innervation to the infraglottic space and trachea. The external branch of the superior laryngeal nerve innervates the cricothyroid muscle. The inferior laryngeal nerve supplies all the other intrinsic laryngeal muscles.

Laryngeal nerve injury may occasionally occur during thyroid surgery. Knowledge of anatomy will allow the surgeon to perform any procedure, anywhere in the body, expeditiously and safely.

Division of the superior laryngeal nerve will cause loss of sensory innervation of the larynx above the vocal folds (internal laryngeal branch). The cough reflex will be lost. In addition, there will be loss of motor innervation of the cricothyroid muscle. The voice will become husky and unable to reach high tones.

Unilateral division of the recurrent laryngeal nerve will result in the vocal ligament being midway between adduction and abduction. This is the cadaveric position. The uninjured cord can cross the midline and approach its partner so that the voice changes may be minimal. If both recurrent nerves are cut, the vocal ligaments become lax, resulting in voice changes but no respiratory problems. Within several months, the voice will begin to reappear as a result of fibrotic changes and tightening of the vocal ligaments. This will also result in narrowing of the rima glottidis and the appearance of respiratory problems. If there is bilateral injury, created by crushing, stretching, or incorporation in a ligature, without transection, then a different set of symptoms may occur. Respiratory problems appear early. This may be explained by Semon's law, which states that in progressive disease of motor laryngeal nerves, the abductors are occasionally the only muscles affected. In addition, the unopposed action of the cricothyroid muscles, and narrowing of the rima glottidis and respiratory difficulties are to be expected.

SUPERFICIAL VENOUS SYSTEM

These veins and the other superficial neurovascular structures are deep to the platysma muscle.

1. Common facial vein is formed by the union of the anterior facial vein with the anterior division of the retromandibular (posterior facial) vein. It passes over the submandibular triangle and the posterior belly of the digastric muscle, and empties into the internal jugular vein in the superior portion of the carotid triangle.

2. External jugular vein is created by the union of the posterior auricular vein with the posterior division of the retromandibular vein. The vein passes inferolaterally, runs obliquely across the superficial aspect of the sternocleidomastoid muscle, pierces the deep cervical fascia in the subclavian division of the posterior triangle, and empties into the subclavian vein. The great auricular nerve (C2, C3) is posterior to this superficial vein in the upper part of the neck.
3. Anterior jugular vein begins in the suprahyoid portion of the neck and descends vertically, close to the midline, down to the clavicle. It then pierces the investing layer of the deep cervical fascia, passes deep to the sternocleidomastoid, and ends in the ipsilateral external jugular vein. It frequently gives a branch in the suprasternal area that crosses the midline and joins with the contralateral anterior jugular vein. This transverse communicating branch is referred to as the jugular venous arch.
4. Vein of Kocher arises in the submandibular area as a branch of the anterior facial vein, descends on the anterior edge of the sternocleidomastoid muscle, and terminates in the jugular venous arch, or the internal jugular vein.

LYMPHATIC PATHWAYS OF THE NECK

The lymphatic pathways of the neck (Fig. 20.32) can be divided into a superior horizontal group found at the junction of the head and the neck. It includes the submental, submandibular, parotid (preauricular), mastoid (postauricular), and occipital nodes. It creates a ring of lymph nodes in this area.

1. A vertical group that receives the lymphatic drainage from the superior horizontal components (Fig. 20.33). There are three pathways possible in this grouping. (a) The posterior cervical group consists of superficial nodes traveling with the external jugular vein and a deep group of nodes that journey with the spinal accessory nerve (XI). They are in the posterior triangle. (b) The jugular group is intermediate in position and is frequently referred to as the deep cervical group. This pathway is the most important. It consists of nodes at several levels, as this vertical channel descends with the internal jugular vein. There is a juguloparotid node located near the angle of the mandible, a jugulodigastric node where the posterior belly of the digastric muscle crosses the internal jugular vein, a jugulocarotid node near the bifurcation of the common carotid artery, and a jugulo-omohyoid node

where the omohyoid muscle crosses the internal jugular vein. The jugulodigastric node receives drainage from the tonsil. The jugulo-omohyoid node receives drainage from the tongue. (c) The visceral chain is the most anterior of the vertical pathways and drains all the cervical viscera. The individual components of this nodal chain are parapharyngeal, paralaryngeal, prelaryngeal or Delphian, paratracheal, and pretracheal. The Delphian node is a constant finding and receives lymphatic drainage from the larynx and the thyroid gland.

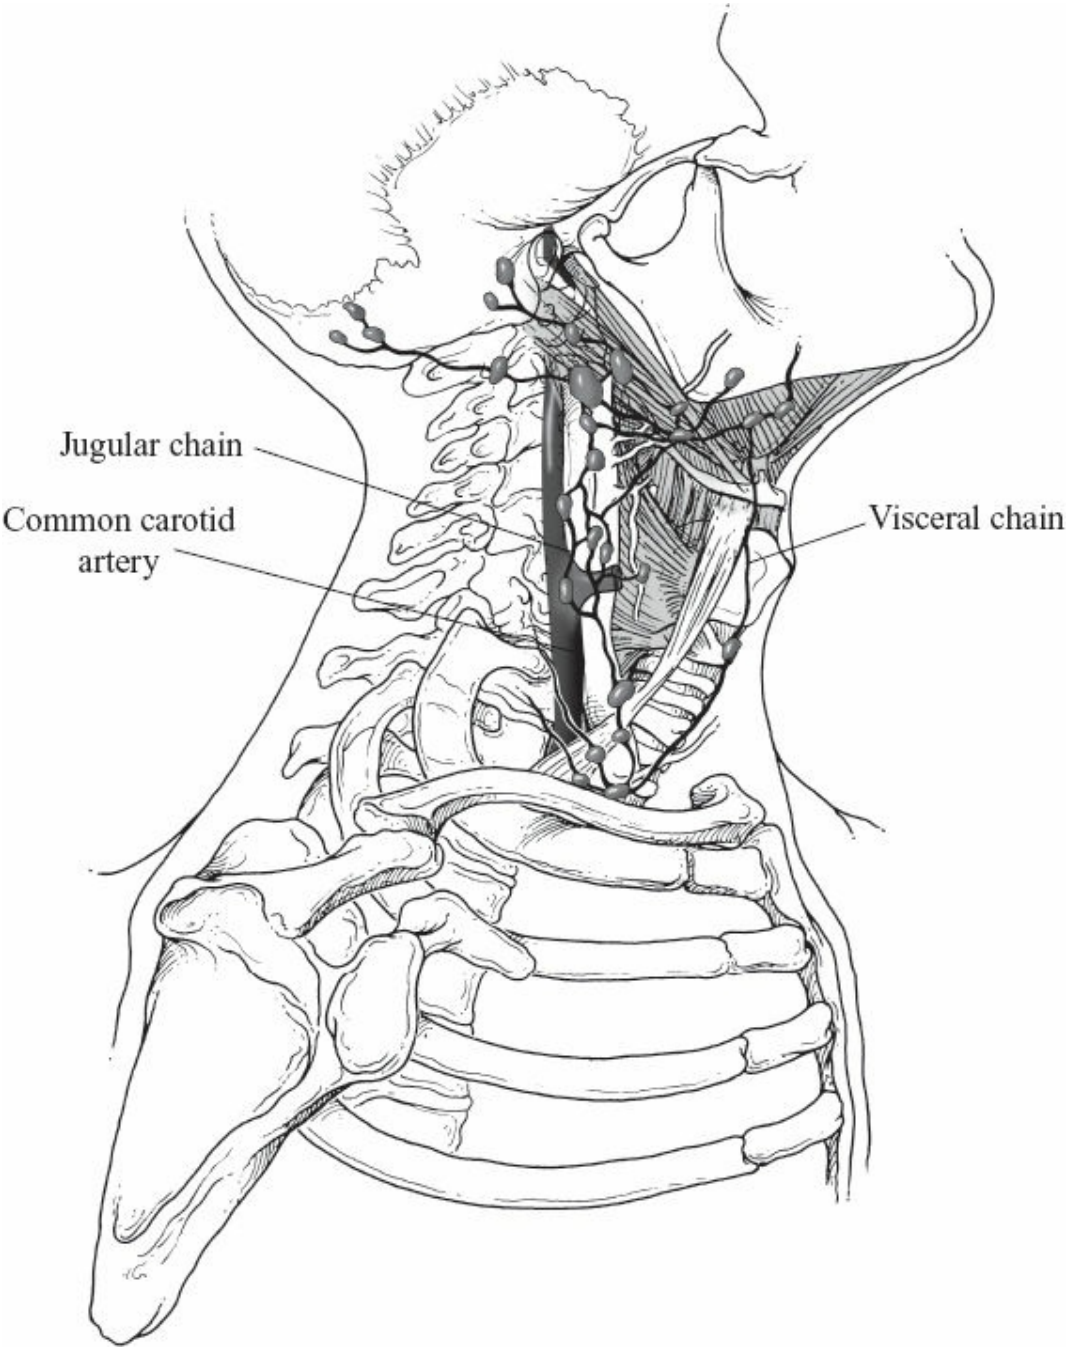

Figure 20.32. Deep lymphatic drainage.

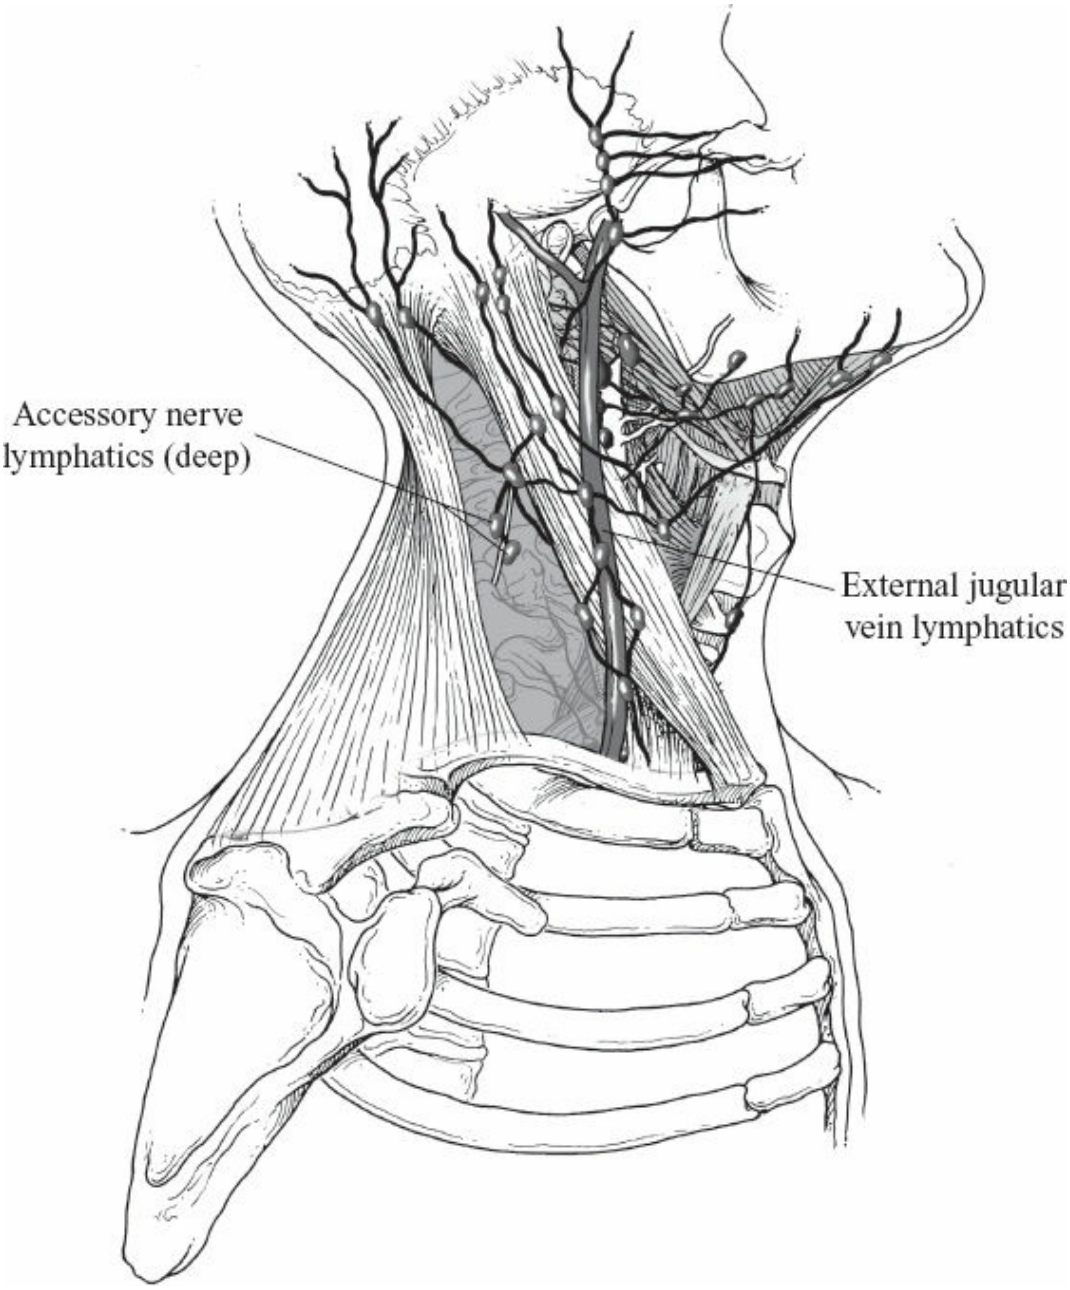

Figure 20.33. Lymphatic drainage.

2. An inferior horizontal group, called supraclavicular nodes, is found in the subclavian triangle. They receive lymphatic flow from the vertical cervical channels and the upper extremity, axilla, and the thoracic wall. They communicate, by way of efferent channels, with internal jugular and subclavian conduits. Some of these supraclavicular nodes lying anterior to the anterior scalene muscle are referred to as scalene nodes. They receive bronchomediastinal channels from the thorax and may be enlarged as a result of spread from an intrathoracic disease process.
3. The thoracic duct receives inflow from all lymphatics below the respiratory diaphragm, the left hemithorax by way of the left

bronchomediastinal trunk, the left side of head and neck *via* the left vertical cervical trunks, and from the left upper extremity through the left subclavian trunk. It empties into the venous system on the lateral aspect of the junction between the left internal jugular and the left subclavian veins. The trunks may enter separately into the venous circulation. On the right side, it is unusual for the bronchomediastinal, subclavian, and vertical cervical trunks to combine before entering the venous circulation. They frequently empty, as separate entities, into the vascular compartment.

EDITOR'S COMMENT

There is little attention paid nowadays to the neck. It is almost as if general surgeons are abrogating their responsibility and interest in the neck except in cases of diseases of the thyroid and parathyroid, and even in those circumstances, interest may be waning, or at least the interest of others such as otorhinolaryngologists seems to have increased. The reason for this is difficult to know.

1. Otorhinolaryngologists were liberated from the destructive surgery, for example, in mastoids and with otitis media, with the advent of effective antibiotics. In addition, pharyngeal neck abscesses from various colds and infections also vanished from the scene with effective antibiotics. Thus, they tried to reinvent themselves in the same area in which they were trained, but in which much of the destructive surgery based on infectious disease was not cared for with antibiotics. In those cases, they turned, as well as others, from destructive surgery to constructive surgery.
2. The rise of oral surgery. Oral surgery emerged as differentiated from dentistry some time in the early 1940s and gradually developed in the 1950s and 1960s. Carcinoma of the tongue, carcinoma of the tonsil, and pharyngeal maxillary cancer to a certain extent. This was also when submandibular cancer became part of the repertoire of the oral surgeon in some geographical areas.

3. General surgeons were held in sway by some leaders who didn't believe in the resection of nodes for thyroid cancer. A papillary carcinoma, of course, has a low mortality, and so it is difficult for some surgeons to believe that general surgeons, especially those taking care of thyroid cancer, should pursue the adenopathy, since mortality is so low. Others believed that carcinoma of the thyroid could be treated with psychiatry. In any event, this tide has turned, and at this point in time, most surgeons dealing with thyroid cancer have gotten much more aggressive at attacking the adenopathy with node dissections.
4. Other specialties began to concentrate on parathyroid surgery, which previously was the field of general surgery and endocrine services. In other chapters of this book, it does appear that the rates of success between ENT surgeons and general surgeons differ. In some of the well-recognized centers for parathyroid surgery, a success rate of 99% is expected. For those in the ENT field, it does appear as if perhaps a 95% or 96% rate of success in "curing" hypoparathyroidism is the norm.

In addition, medical schools stopped teaching anatomy. As medical schools became more research oriented, bragging rights was not about how well the students were taught but was about the NIH grants and the total number of NIH dollars appropriated to that school. In addition, in schools that have not given up anatomy, there were inappropriate instructors who were utilized to [make] up the funds that were [not] appropriated in their NIH grants. A classic example of this is to have acute abdomen taught by internists who were not called to the emergency room to see patients with acute abdomen. In many schools, surgeons are no longer asked to teach the acute abdomen. It is also now thought that medical students can learn in a truncated general surgery rotation, which is now increasingly shared with other surgical specialties, such as ophthalmology, in the time frame which in the past was solely utilized by general surgery. I am not criticizing ophthalmology in this statement, but I am just pointing out that those surgical specialties have now lost their own space to surgery time.

One appreciable thing about this chapter is that Professor Ruhalter is very well aware of clinical correlation and anatomic correlation. I just list these because I think they are of interest and have some clinical relevancy.

Anatomic goodies:

1. The cricoid bone is an anatomic bonanza, as is detailed in this chapter.
2. The superior surfaces of the first rib are flattened, so that neurovascular structures can travel over it without compression. This, of course, is true of thoracic outlet syndrome, in which the vasculature and sometimes the nerves are compressed.
3. The subclavian artery passes over the posterior sulcus of the scalene tubercle. The anterior scalene muscle attaches to the first rib between the subclavian vessels and, therefore, is in a position to compress the subclavian artery, giving rise to the thoracic outlet syndrome.

4. The cervical sympathetic chain has as its apex a “dumbbell-shaped structure, called the cervicothoracic, or stellate, ganglion.” The reason for it being called stellate ganglion is that it is star-like and gives out the multiple branches. The stellate ganglion, when invaded by a tumor at the apex of the lung on one side or the other, gives rise to the Horner’s syndrome and is often the first symptom or sign of the presence of that tumor.
5. The brachial plexus is formed by the ventral rami of C5 through T1. These nerve roots will form three trunks—C5 and C6 form the upper trunk, C7 root forms the middle trunk, and C8 and T1 form the lower trunk. These pass between the middle and anterior scalene muscles.
6. The lower trunk of the brachial plexus is draped over the first rib immediately posterior to the subclavian artery.
7. The fascia of the neck: The superficial fascia, which is often is not well developed, forms the platysma, which may or may not be very robust; the cervical branch of the facial nerve enervates the platysma, which contributes to facial expression.
8. The cutaneous branches and the superficial veins are below the muscles of facial expression, which are the platysma.
9. Deep cervical fascia: The superficial or investing layer of the deep cervical fascia splits to surround the trapezius and the sternocleidomastoid muscle and the submandibular and parotid glands.
10. The carotid sheath, which is part of the deep cervical fascia, surrounds the common carotid, the internal jugular, and the vagus nerve. The vagus nerve is between the common carotid and the internal jugular, which is somewhat posterior to the common carotid.
11. When the common carotid artery divides the internal carotid, it immediately goes anterior to the carotid, except at the base of the skull; the vein is anterolateral to the artery.
12. The sympathetic chain is in contact with the posterior sheath.
13. The thoracic duct is to the left of, and posterior to, the esophagus. It enters at the junction of the internal jugular vein and the subclavian vein.
14. The right lymphatic duct, which is the counterpart of the left thoracic duct, is not large as the thoracic duct and consists of several smaller lymphatics. It drains the right upper extremity and the upper right hemithorax.
15. The right recurrent laryngeal nerve loops around the right subclavian. The left recurrent nerve loops the aortic arch on the left. The right recurrent nerve is less well protected, as it comes up lateral to the tracheoesophageal groove, but, to get to the tracheoesophageal groove on the right, it is more superficial and more widely exposed.
16. Sibson’s fascia is at the apex of the lung and runs between C7 and the first rib. It is somewhat protective of the apex of the lung.
17. The inferior thyroid artery is superficial to the prevertebral fascia. It courses posterior to the carotid sheath and anterior to the vertebral artery.
18. The last branch given off by the subclavian artery, as it goes from medial to

lateral, is the internal mammary, which then travels behind the sternum and attaches to the sternum medial to the ribs.

19. The anatomy of the root-of-the-neck compression syndromes includes the following:
    a. Costoclavicular compression syndrome.
    b. Cervical-rib compression syndrome.
    c. Anterior scalene compression syndrome (thoracic-outlet syndrome).
    d. Pectoralis minor syndrome.
20. The following are the clinical anatomic applications, which are practical in the surgery of this area.
21. Cervical incisions should be made parallel to the skin lines for good cosmesis.
22. Control of bleeding may be possible, if the common carotid artery is compressed against the transverse mass of the sixth cervical vertebra, which is the cricoid plane.
23. The hyoid bone is the central structure of the neck. Most of the structures of the neck—muscular and membranous—attach to the hyoid bone. If one considers the hyoid bone and the attached posterior belly of the digastic muscle, it is possible to divide the anterior triangle into suprahyoid and infrahyoid portions.
24. The vagus nerve is behind and slightly posterior to the carotid and internal jugular vessels.
25. The posterior belly of the digastic muscle is superficial to the neurovascular structures and presses them against the pharyngeal wall. Therefore, owing to this structure, incisions can be made without the risk of injuring the nerves or arteries.
26. The intermediate tendon of the omohyoid between the two bellies is in the cricoid plane with a number of other venous and tendinous structures.
27. The transection of the strap muscles closer to the superior end will preserve the nervous innervation, since the nerve enters the muscle near the inferior end. Most individuals who divide the strap muscles to get at the thyroid do so at the interior end. Personally, I have never been taught that one divides the strap muscles at the superior end because the nerve enters inferiorly, but it is something good to remember, because one of the cosmetic difficulties following thyroid surgery is the denervation of the strap muscles, at times with a bulge in the lower neck.
28. When one enters the cleavage between the sternothyroid muscle and the thyroid gland, this provides excellent exposure of and facilitates surgical approach to the gland, which is avascular.
29. The long thoracic nerve originates from C5, C6, and C7 and courses inferiorly, passing to the other portions of the brachial plexus, and then passing over the first rib to reach the superficial surface of the serratus ventralis, which it innervates.
30. Dissection on the posterior triangle is safe in the area superior to the spinal

accessory nerve.

31. A good landmark for the upper thyroid glands is that they are usually at the level of the thyroid cartilage.
32. If there is a high origin of the recurrent laryngeal nerve, it may not be in the tracheoesophageal groove and it is called a nonrecurring nerve. Obviously, if there is a high origin, it is more exposed and not protected by not being in the tracheoesophageal groove.

The neck is a very hostile place from the standpoint of anatomy. We are very privileged to have an anatomist of Professor Ruhalter's skill and knowledge to keep us out of trouble.

J.E.F.

21 Surgery of the Major Salivary Glands

Carol M. Lewis and Michael E. Kupferman

INTRODUCTION

Surgery of the major salivary glands (parotid, submandibular, and sublingual) requires an understanding of the anatomy of a small region of the human body. Surgical knowledge of this area for either preservation or safe extirpation of critical structures enables the surgeon to determine appropriate indications for surgical intervention and to competently perform such procedures. This holds true for trauma, infection, obstruction, or neoplasm. This chapter focuses on the indications for surgery, as well as surgical approaches to the sublingual, submandibular, and parotid glands.

ANATOMY

The parotid gland extends from the zygoma superiorly, the external auditory canal posteriorly, the masseter muscle anteriorly, and lateral pharyngeal space medially. Inferiorly, the gland extends over the sternocleidomastoid muscle (SCM) and mastoid tip; this portion is called the tail of the parotid. The facial nerve runs through the gland, and surgically serves to separate the superficial from deep lobes, although these distinctions are not anatomic. The parotid gland empties into Stenson duct, which is located at the anterior superficial lobe roughly mid-way between the zygomatic arch and the corner of the mouth, and travels over the masseter, not uncommonly with accessory parotid tissue. It pierces the buccinator muscle and empties through a papilla opposite the maxillary second molar (Figs. 21.1 and 21.2).

The facial nerve exits the skull base through the stylomastoid foramen. Its main trunk can be found roughly 1 centimeter (cm) medial and inferior to the cartilaginous tragal pointer and 0.5 to 1 cm deep to the tympanomastoid suture line, at roughly the level of attachment of the posterior belly of the digastric muscle. The facial nerve can also be

identified intratemporally in the mastoid tip or peripherally with retrograde dissection. Within the parotid gland, the main trunk of the facial nerve splits into temporofacial and cervicofacial divisions at the pes anserinus, the temporofacial segment supplies the temporal, zygomatic, and buccal branches, while the cervicofacial segment supplies the marginal mandibular and cervical branches.

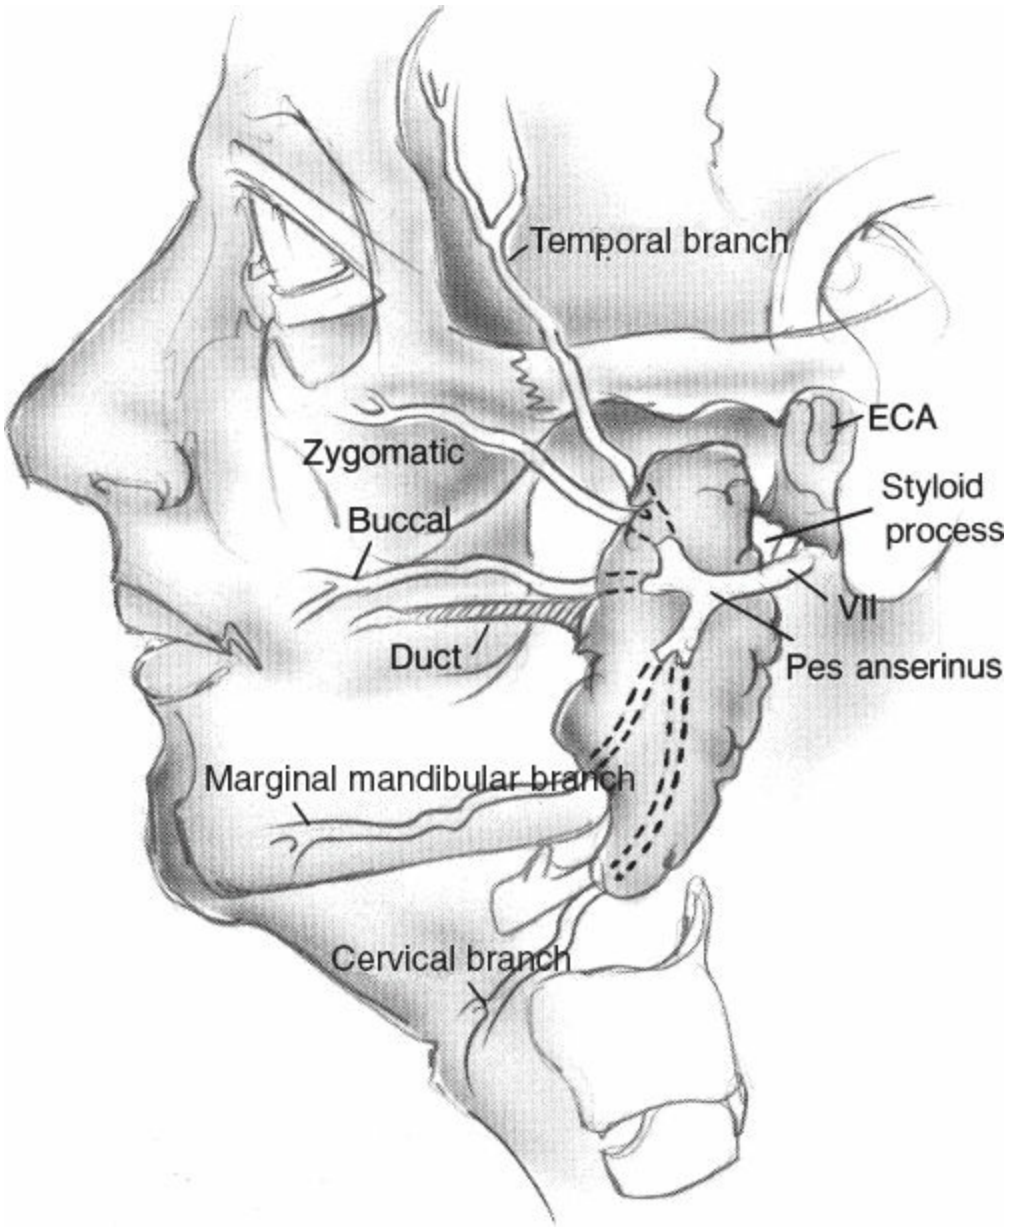

Figure 21.1. The parotid gland and the facial nerve. Note that the nerve exits the stylomastoid foramen lateral to the styloid process. Also, note the relationship of the nerve branches to the surrounding structures.

The mylohyoid muscle separates the sublingual space from the

submandibular triangle. The sublingual space is bounded anteriorly and laterally by the mandible, superiorly by the mucosa of the floor of mouth, and inferiorly by the mylohyoid muscle. This space contains the sublingual gland and associated connective tissue, the hypoglossal nerve, and the deep portion of the submandibular gland (Fig. 21.3).

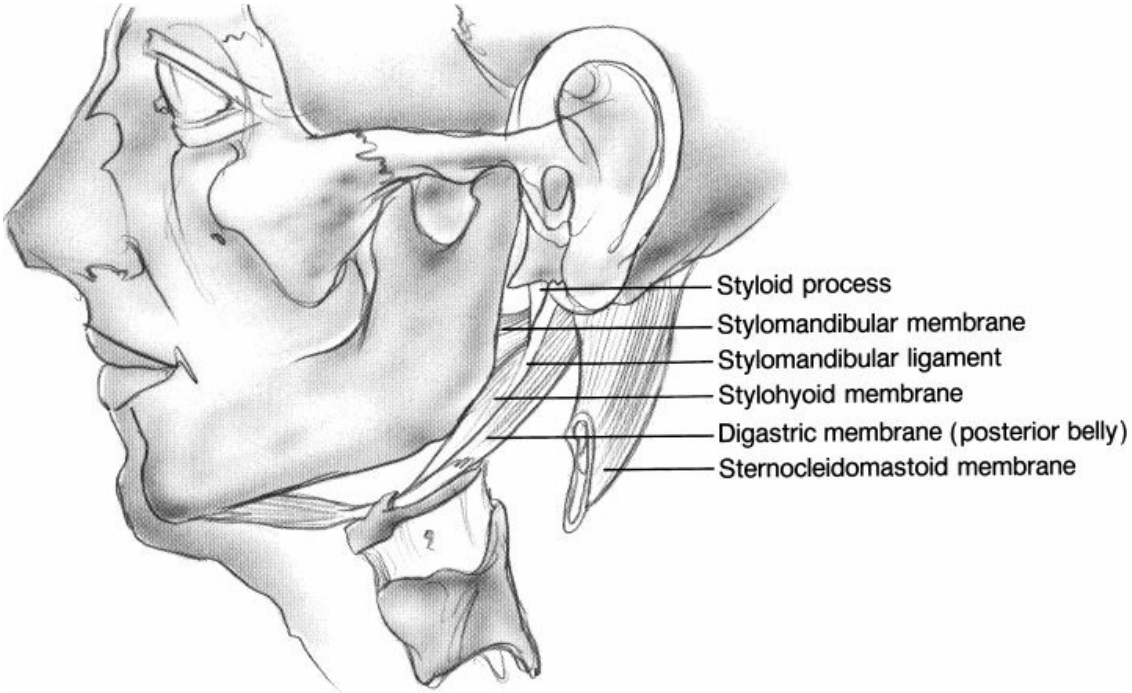

Figure 21.2. Stylomandibular membrane (deep layer of parotid fascia). Herniations of parotid tissue through this membrane can result in a parapharyngeal mass.

The submandibular triangle is bounded anteriorly by the anterior belly of the digastric muscle, superiorly by the inferior border of the body of the mandible and the mylohyoid muscle, inferiorly by the trochlea and posterior belly of the digastric muscle, and posteriorly by the posterior border of the submandibular gland (Figs. 21.3 and 21.4). This triangle contains the submandibular gland and associated Wharton duct, lingual nerve and submandibular ganglion, hypoglossal nerve, and neurovascular bundle to the mylohyoid muscle. It is imperative to be familiar with these structures and their anatomic relationships both in neutral and surgical positions.

CLINICAL, RADIOLOGIC, AND PATHOLOGIC EVALUATION

The evaluation of every patient begins with a thorough history and physical examination. Significant tenderness usually indicates acute infection, but can occasionally be attributed to neoplasms predisposed to perineural involvement, such as adenoid cystic carcinoma. Fluctuation of the size of the mass, most notably when eating, is a characteristic of an obstructed parotid or submandibular gland. Given the potential for disease metastatic to the lymph nodes of the parotid or submandibular triangle, any history of previous cancer is relevant; in addition to cancers of the upper aerodigestive tract or skin of the head and neck, breast, lung, gastrointestinal tract, or genitourinary tract can metastasize to this region. Occasionally, squamous cell carcinomas of the oral cavity can involve the sublingual or submandibular glands by direct extension.

Prior to the specific examination of the parotid or submandibular triangle, a thorough head and neck examination, including inspection of the upper aerodigestive tract and the skin of the head and neck, is mandatory. Cervical palpation should be performed to identify any associated lymphadenopathy or masses in other levels of the neck. Bimanual palpation is a useful diagnostic maneuver to evaluate the floor of mouth or submandibular triangle, performed with one finger palpating intraorally and the other hand assessing the mass from the neck. The mass should be evaluated for qualities such as tenderness, mobility, consistency (solid vs. cystic), and whether it is single, multiple, or lobulated. In addition, intraoral palpation allows for evaluation of calculi along Wharton duct or Stenson duct in cases of sialadenitis. Examination of the lateral oropharyngeal wall may reveal a tumor of the parapharyngeal space, which may be a deep lobe parotid mass. A cranial nerve examination with specific attention to the facial, trigeminal, and hypoglossal nerves is critical; cranial neuropathies are suggestive of malignancy.

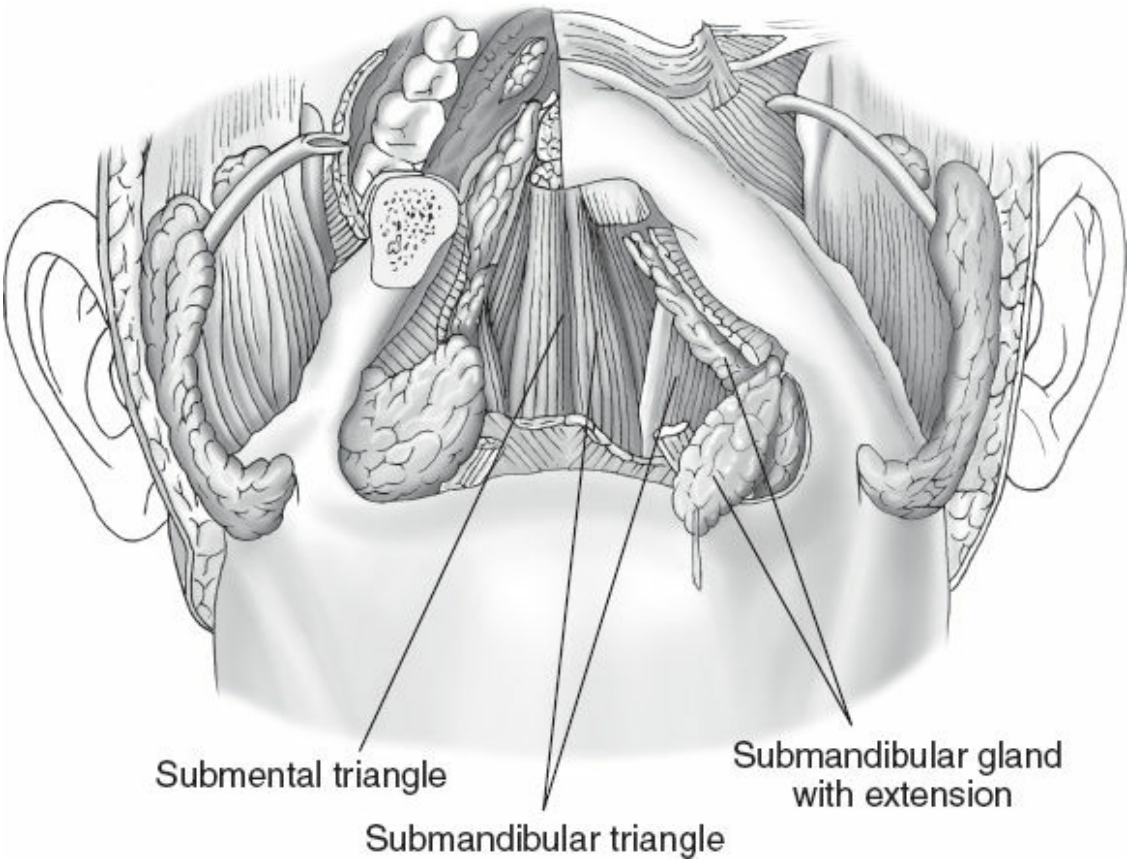

Figure 21.3. The submental triangle is bounded by the mandible, mylohyoid muscle (cut edge shown here), and superiorly by the oral mucosa.

The utility of fine-needle aspirate biopsy (FNAB), often performed in conjunction with an ultrasound, is controversial. While an FNAB may provide a preliminary diagnosis, some may argue that surgical removal will be necessary regardless. However, if the FNAB reveals a salivary gland malignancy, the surgical approach may require a comprehensive neck dissection. Further, the patient may need to be counseled on the role of cranial nerve resection, should a malignancy involve these structures. In addition, if the FNAB demonstrates carcinoma that is not of salivary gland origin, the work-up should involve identification of the primary tumor. Of note, FNAB is 80% to 90% sensitive for the diagnosis of salivary gland malignancies. Thus, FNAB findings may impact both work-up evaluation and surgical planning.

Axial imaging, most commonly computed tomography, can be helpful in determining if a mass is in, adjacent to, or invading the gland, as well as its cystic or solid qualities. It can also demonstrate other associated lymphadenopathy or, if the lesion is metastatic, the primary tumor.

Alternatively, ultrasound or magnetic resonance imaging scan may be performed. A sialogram is useful if obstructive sialadenitis is suspected. Metabolic imaging is indicated for suspected metastatic disease to other sites or metastatic disease to the salivary glands.

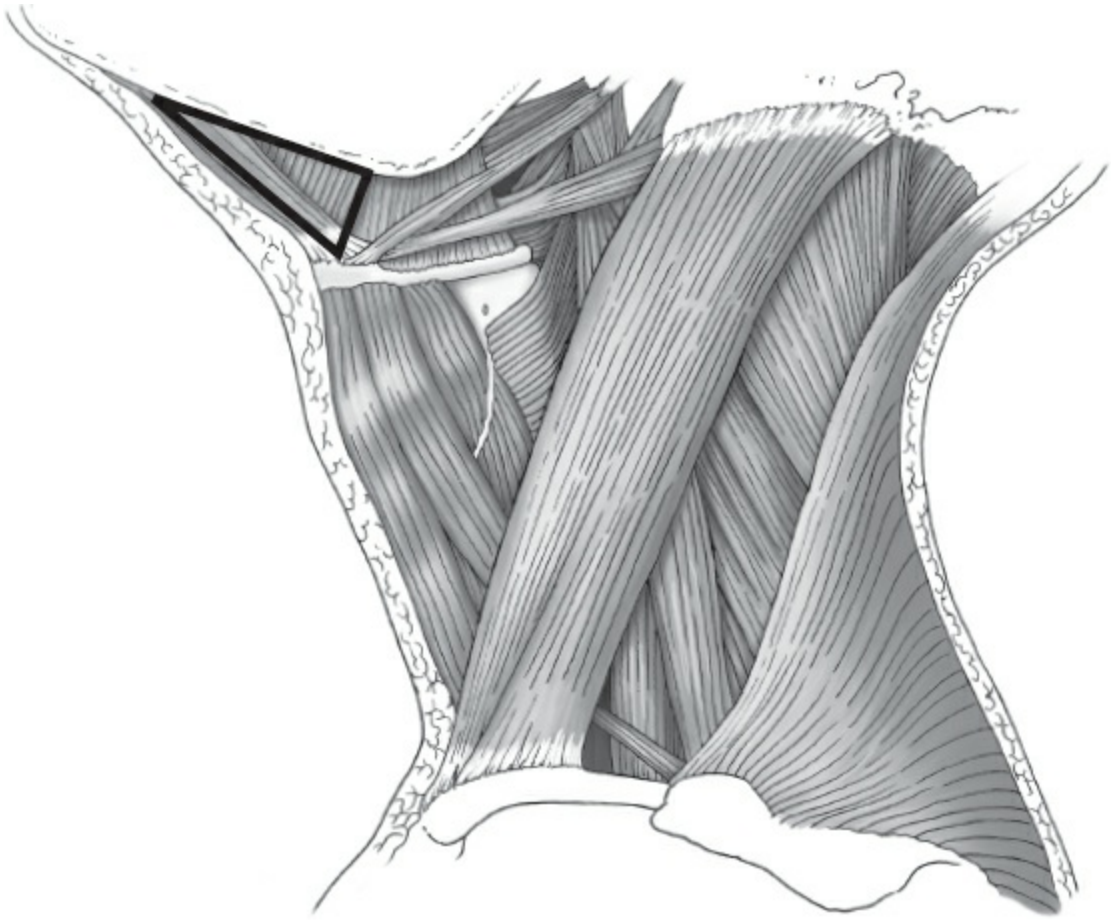

Figure 21.4. The muscular boundaries of the submandibular triangle.

INDICATIONS FOR SURGERY

The most common indications for removal of the parotid or submandibular glands are suspicion of neoplasm and chronic obstruction of Stenson duct or Wharton duct by calculi with resultant sialadenitis. Neoplasms of the sublingual gland are rare, with most sublingual gland excisions being performed for ranulas.

Neoplasm

The incidence of salivary gland tumors in the general population is 2.5 per 100,000, representing 0.3% of all cancers and 1% to 3% of all head and

neck tumors. There are various neoplasms that may involve the parotid, submandibular, and sublingual glands; submandibular and sublingual salivary gland neoplasms represent 70%, 7% to 15%, and <1% of all salivary gland tumors, respectively. Of these neoplasms, 25% of parotid, 40% to 50% of submandibular gland, and >70% of sublingual gland neoplasms are malignant. The more common neoplasms and their defining characteristics are detailed here.

Pleomorphic adenoma (benign mixed tumor) is the most common benign salivary neoplasm, accounting for roughly 80% of benign salivary gland tumors. Histologically, it contains mesenchymal, epithelial, and myxoid stromal components. This tumor is slow growing, nonpainful, and nontender, and can recur if not completely excised. It also has the potential for malignant degeneration (carcinoma ex pleomorphic adenoma), often heralded by rapid growth and/or neurologic symptoms.

Warthin tumor (papillary cystadenoma lymphomatosum) is the second most common benign salivary gland tumor, comprising roughly 10%. Warthin tumors are found predominantly in the parotid, and can be bilateral in 10%. These tumors have an association with smoking. These tumors may recur if not completely excised or if multifocal disease is not completely removed.

Adenoid cystic carcinoma is the most common submandibular gland malignancy, comprising 15% to 43% of malignancies at this site; 47% extend through the capsule on presentation. Ten to fifteen percent of adenoid cystic carcinomas occur in the parotid. A hallmark of this tumor is perineural invasion, such that postoperative radiotherapy is indicated with this diagnosis. Patients must have at least a 10-year follow-up due to the frequent occurrence of delayed recurrence or distant metastasis; a 39% 10-year survival is expected. There are three histologic varieties: cribriform, tubular, and solid; the solid variety carries a worse prognosis. This disease is associated with a high rate of local recurrence, and distant metastasis—most commonly, pulmonary occurs in approximately 50% of patients. These patients have a median survival of 3.5 years after the identification of distant disease.

Mucoepidermoid carcinoma is the most common salivary gland malignancy of the parotid, comprising about 70% of parotid malignancies. It is the second most common malignant tumor of the submandibular gland, comprising 17% of all submandibular malignancies. Histologically, it is composed of mucoid and epithelial elements; the higher the amount of

the epithelial component, the higher the grade of the tumor. Low-grade tumors have a good prognosis (71% 5-year survival); high-grade tumors are more aggressive and are associated with worse prognoses. The latter usually requires postoperative radiation and accompanying neck dissection at the time of primary tumor removal. Controversy exists regarding the outcomes of patients with intermediate-grade tumors, but emerging data suggests that these patients have favorable outcomes that approximate those with low-grade tumors.

Adenocarcinoma accounts for 16% to 20% of salivary gland malignancies. Histologic patterns include papillary, acinus, and solid; the amount of glandular elements determines the grade. These tumors are aggressive and tend to recur; intermediate- and high-grade histology usually indicates the need for postoperative radiotherapy.

Squamous cell carcinoma comprises 5% of salivary gland malignancies. The differential diagnosis should include high-grade mucoepidermoid carcinoma, metastases, and contiguous spread. There is a very poor prognosis (24% 5-year survival) associated with this disease and postoperative radiotherapy is generally indicated.

Malignant mixed tumor generally presents as a slowly growing mass that has a sudden increase in size, and accounts for 5% to 12% of salivary gland malignancies. The malignant component of the tumor may be undifferentiated carcinoma, adenocarcinoma, or squamous cell carcinoma. A 56% 5-year survival and 31% 10-year survival are to be expected.

Sialadenitis

A submandibular or sublingual mass is most commonly sialadenitis caused by sialolithiasis. Eighty percent, 5%, and 1% of salivary calculi occur in the submandibular, parotid, and sublingual gland, respectively. A single stone is the cause in 75% of cases. If the calculus can be palpated along the course of Wharton duct or Stenson duct intraorally, an incision may be made just above the stone to release it. Medical management includes frequent massage of the gland, sialogogues, and hydration; antibiotics may be indicated if purulence is expressed from the duct with gland massage. Multiply recurrent sialadenitis with calculi can be treated with lithotripsy, sialoendoscopy with basket retrieval of stones, or excision of the submandibular gland.

Other causes of sialadenitis include neoplastic obstruction and ductal stenosis. The latter can be addressed using sialendoscopy with sialoplasty

or with removal of the gland.

Ranula

The term *ranula* derives from the Latin word for *frog*, so named because of the appearance of patients with plunging ranulas. A simple ranula can be either a mucus retention cyst or pseudocyst from mucus extravasation that is confined to the floor of the mouth. A plunging ranula is a mucus extravasation pseudocyst arising from the sublingual gland that extends into the neck, either through the muscular dehiscence for the neurovascular bundle of the mylohyoid muscle or around the posterior border of the mylohyoid muscle. This usually presents as a soft, cystic neck swelling. If any portion of the suspected ranula is solid to palpation, the possibility of a neoplasm should remain in the differential diagnosis. Also, although rare, lymphatic malformations should remain in the differential diagnosis, particularly in children.

Drainage of the cyst, either spontaneously or by aspiration, usually results in recurrence. Observation is appropriate if the ranula is small and does not interfere with tongue function. Marsupialization of the cyst results in a 50% recurrence rate. The most definitive treatment of a ranula is excision of the sublingual gland with the pseudocyst; this reduces the recurrence rate to <2%. Most small ranulas can be excised with the sublingual gland transorally, taking care to identify and preserve the lingual nerve. The approach for a sublingual gland neoplasm that is suspicious for cancer should be done transcervically by retracting the mylohyoid muscle anteriorly for a more definitive procedure.

SURGICAL TECHNIQUE

Parotidectomy

Patients are positioned with their head turned to the side opposite the tumor and draped to expose the entire ipsilateral face for monitoring of facial nerve function during surgery. A shoulder roll should be placed if the need for a neck dissection is anticipated. A discussion with the anesthesia team beforehand should emphasize the need to avoid paralysis for facial nerve monitoring. Such monitoring may take the form of having an assistant observe the patient’s face for movement intraoperatively or more formal electromyographic (EMG) monitoring; the latter is most commonly used for revision surgeries or cases in which dissection is

anticipated to be difficult, such as a setting of chronic inflammation.

A modified Blair incision is most commonly used, extending vertically in a pre-tragal crease, curving posteroinferiorly around the earlobe and tail of parotid, and ending horizontally in a natural skin crease 2 or more cm below the angle of the mandible. Alternatively, the incision could continue posteriorly in the postauricular hairline (as a facelift incision), but this approach is generally reserved for known benign disease involving the tail or mid-parotid. A hatch mark should be made before incision to assist with proper alignment of the earlobe at closure. Skin flaps are elevated in a subcutaneous fascial plane to the anterior aspect of the parotid gland; care must be taken not to extent this dissection too far anteriorly over the masseter where distal facial nerve branches become superficial.

The tail of parotid is then elevated off of the underlying SCM. The greater auricular nerve is generally sacrificed, although postauricular branches should be preserved when possible. The posterior belly of the digastric muscle is identified at the anterior border of the SCM near the angle of the mandible and followed posteriorly to the mastoid. Overlying parotid parenchyma should be dissected off of these muscles. Superiorly, the parotid is the then dissected off the tragal cartilage in a supraperichondrial plane down to the palpable tragal pointer. The tympanomastoid suture line should be palpable at this point. Meticulous dissection using bipolar cautery for hemostasis should be used to identify the main trunk of the facial nerve as it exits the stylomastoid foramen; it is usually identified 1 cm inferomedial to the tragal pointer and 0.5 to 1 cm deep to the tympanomastoid suture line, at the level of the attachments of the posterior belly of the digastric muscle.

Once identified, the nerve is followed carefully into the gland with dissection proceeding over and parallel to the direction of the nerve, with division of overlying parotid parenchyma. Once the pes anserinus is encountered, dissection then proceeds in a stepwise fashion along the branches of the facial nerve in such a way that the superficial lobe and tumor are removed en bloc. The patient’s face should be closely monitored for movement to avoid injury to the facial nerve. Once adequate margins of parenchyma are obtained around the mass, the parotid and tumor are removed. Branches of the facial nerve should never be sacrificed unless there was a loss of function preoperatively or the nerve is encased in malignant tumor; every effort should be made to preserve nerves that are adherent to tumors, even in the case of malignancy. Nerve grafting should

be considered in cases where facial nerve sacrifice is expected.

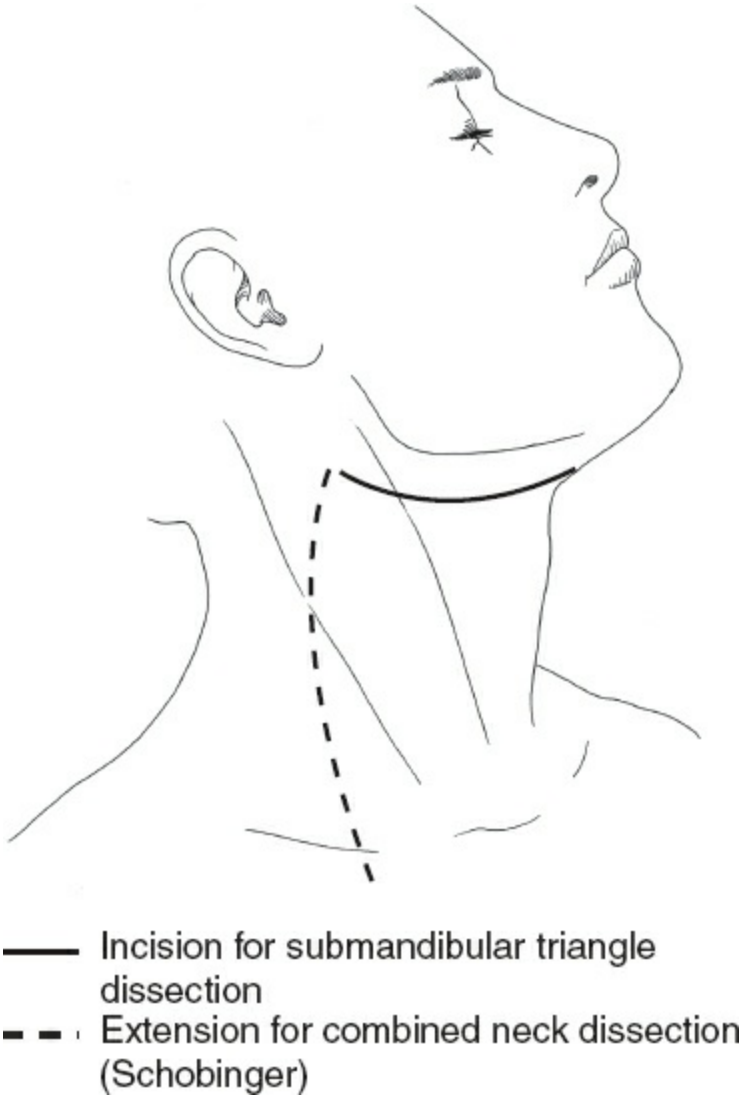

Figure 21.5. Incision site for a submandibular triangle dissection and extension for combined neck dissection.

The wound bed is then irrigated and hemostasis obtained with bipolar cautery. The incision is then closed in layers, after placement of a bulb suction drain.

The most common complication is hematoma. Infection is a rare complication, occurring in less than 5% of cases. Unintentional facial nerve injury has been reported in 3% to 5%; if the nerve has been left intact, however, full recovery should be expected. Sialoceles are rare when bulb suction drain is used; these are managed most often with repeat aspiration and compression dressings, and rarely with oral anticholinergics and Botox injection. Gustatory sweating (Frey syndrome) results from

aberrant regrowth of parasympathetic fibers into skin, possibly facilitated by excessively thin skin flaps; despite a high actual incidence, only a small percent of patients are symptomatic and can be managed with antiperspirants or topical anticholinergic agents, with Botox injection reserved for more severe cases.

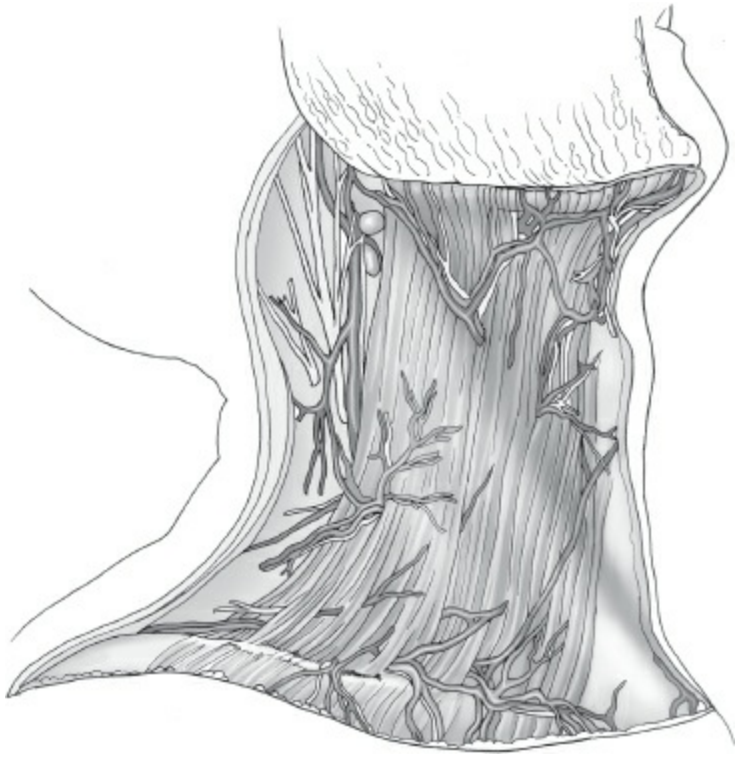

Figure 21.6. Skin flap raised superiorly with platysma muscle left in place.

SUBMANDIBULAR TRIANGLE DISSECTION

Lateral Transcervical Approach

This is performed through a curvilinear incision from the lateral hyoid to the anterior border of the SCM, approximately 3 fingerbreadths below the lower border of the horizontal ramus of the mandible (Fig. 21.5). The surgeon must make a determination as to whether the depth of the incision should be deep to the platysma muscle or superficial to it (Fig. 21.6); this is important if the procedure is being performed for a mass that is close to the skin such that including platysma in the resection provides an oncologic margin. In most cases, the flap is elevated in a subplatysmal plane (Fig. 21.7).

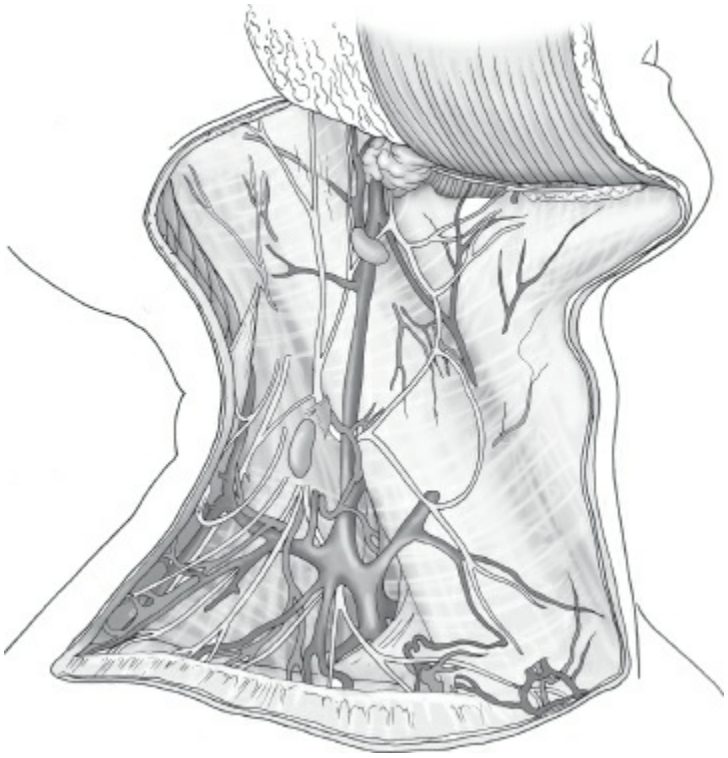

Figure 21.7. Skin flap raised superiorly in a subplatysmal plane.

As the flap elevation approaches the mandible, the surgeon must be aware of the course of the marginal branch of the facial nerve. It is important to identify this nerve and mobilize it for retraction superiorly; this allows the adjacent facial artery lymph nodes, which lie superior to the nerve as it courses lateral to the ramus of the mandible, to be removed with the mass while preserving the nerve (Fig. 21.8). The procedure of ligating the facial artery and vein at the lower border of the mandible and reflecting them superiorly (Hayes Martin maneuver) preserves this nerve, and also preserves the facial artery lymph nodes. Removing these lymph nodes is oncologically important if the mass is a metastasis or a primary tumor of the submandibular gland. The manipulation of this nerve, even if it is minimal, will undoubtedly result in some weakness of the ipsilateral corner of the mouth. Therefore, all patients should be informed of this preoperatively. In most patients, this weakness is temporary.

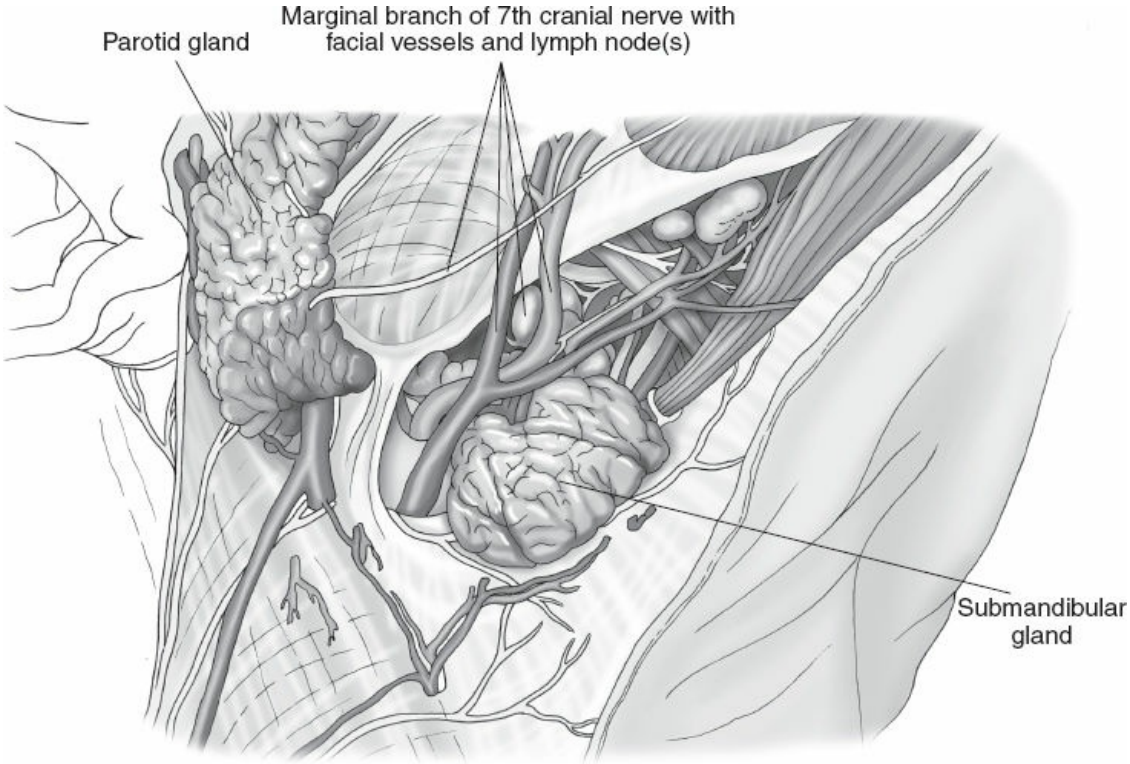

Figure 21.8. Marginal branch of the facial nerve and its relationship with the facial vessels. Note also the lymph nodes in the area of the marginal branch of the facial nerve and underneath the mandible on top of the mylohyoid muscle.

Once the nerve is retracted out of harm's way and the facial artery lymph nodes are retracted inferiorly, the facial vessels can be ligated. If the mass is fixed to the periosteum on the lower border of the mandible, this should be included with the specimen as an oncologic margin (Fig. 21.8). If the mass is not adherent to the periosteum, a plane of dissection should be developed along the free inferior edge of the ramus of the mandible from the midline to just posterior to the angle of the mandible. Dissection then continues, sweeping the fibrofatty lymph node packet inferiorly. This exposes the anterior belly of the digastric muscle and the nerve supplying the mylohyoid muscle. The latter must be divided in order to release the gland posteriorly. If the mass is malignant, pathologic examination of this nerve may be necessary, particularly if the mass is an adenoid cystic carcinoma; it is important to know if this nerve has been invaded because it defines the behavior and the extent of the disease, and may determine whether the patient requires postoperative radiation.

The surgeon can now proceed by dissecting the fibrofatty lymph node packet inferoposteriorly, exposing the anterior belly of the digastric muscle. Once this is accomplished, the anterior belly of the digastric

muscle can be retracted medially. All nodal and adipose tissues are removed from deep to this muscle down to the lateral surface of the mylohyoid muscle; this is particularly important if disease in the submandibular triangle represents extension of or metastases from a floor of mouth malignancy. Dissection should then continue along the lateral aspect of the mylohyoid muscle and will reveal the distal portion of the mylohyoid nerve and associated vascular bundle, which needs to be transected. Blunt dissection should then define the plane along the deep surface of the mylohyoid muscle, allowing it to be retracted medially. This exposes the hypoglossal nerve and associated veins inferiorly, the duct to the submandibular gland, and, superiorly, the genu of the lingual nerve with its attachment to the submandibular ganglion (Figs. 21.9 and 21.10). As with the nerve to the mylohyoid muscle, if malignancy is suspected, this nerve attachment should undergo pathologic examination. This nerve should be divided superior to the submandibular ganglion such that the ganglion is included with the specimen. If the mass extends under the mylohyoid muscle to the submucosa of the floor of the mouth, Wharton duct must be removed in its entirety with a portion of the surrounding floor of mouth mucosa (Fig. 21.10) as an oncologic margin.

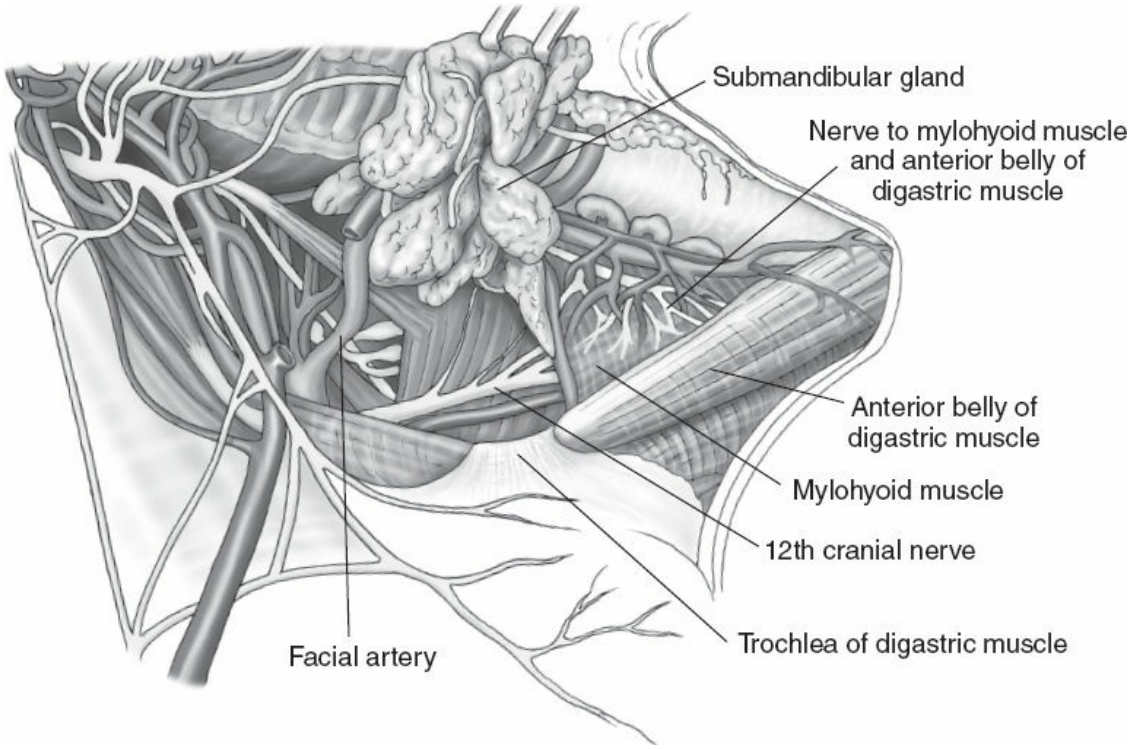

Figure 21.9. Detail of the submandibular triangle with the submaxillary gland resected superiorly, showing its duct going underneath the mylohyoid muscle. Note also the nerve to the

mylohyoid muscle, the anterior belly of the digastric muscle, the 12th cranial nerve, the facial artery, and the trochlea of the digastric muscle between the anterior and posterior belly of the digastric muscles.

Once the attachments to the submandibular gland have been released anteriorly and superiorly, the gland can be retracted posteriorly and inferiorly. If the mass is not adherent to the fascia overlying the hypoglossal nerve and associated venous plexus, the plane of dissection is very easily established superficial to these structures such that the entire gland with its preglandular and postglandular nodes can be elevated. With this elevation, the inferior aspect of the triangle should be dissected along the posterior belly of the digastric muscle, continuing posteriorly until the facial vein is encountered crossing over this muscle, where it should be ligated. As the remainder of the fibrofatty lymph node packet is dissected free along the deep plane, the last remaining attachment should be the facial artery, as it crosses deep to the posterior belly of the digastric muscle (Fig. 21.9). This should be ligated with at least a 1-cm cuff to prevent retraction under the muscle, thus releasing the contents of the submandibular triangle.

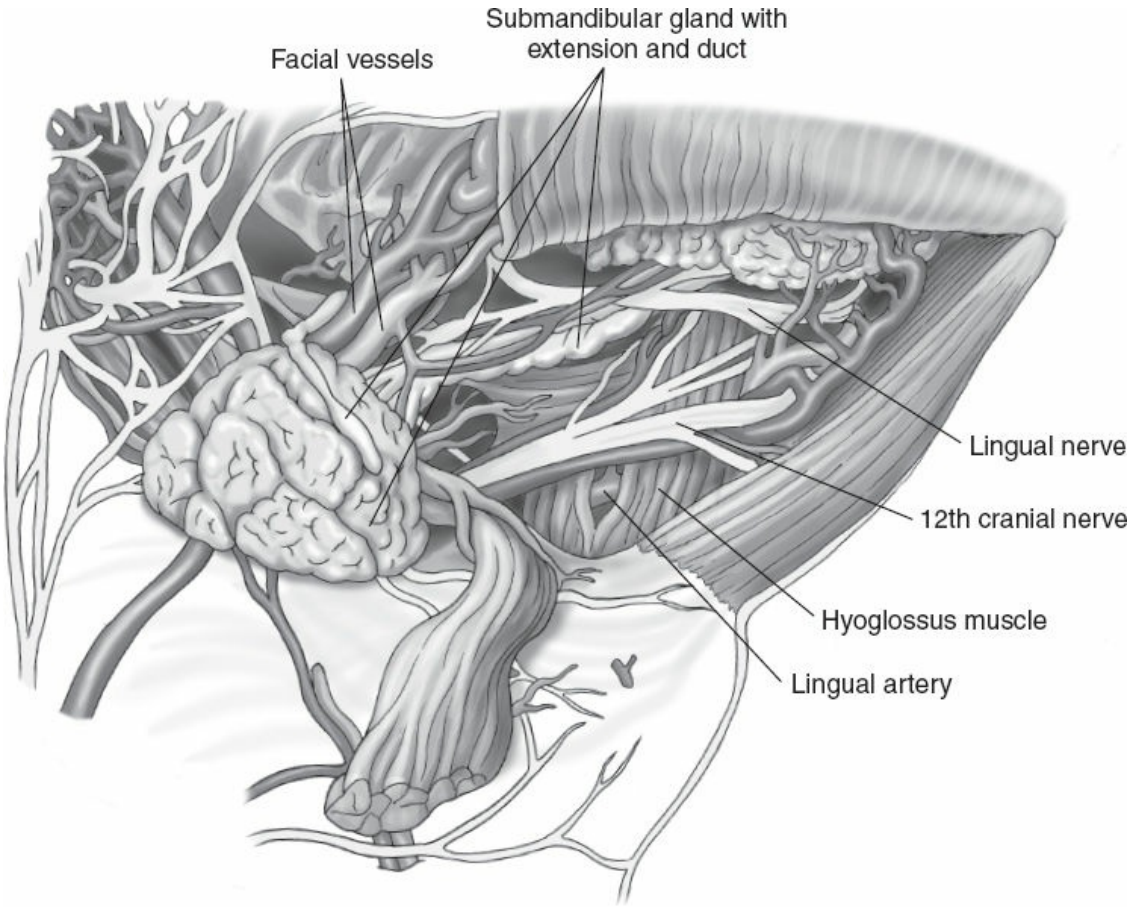

Figure 21.10. Facial vessels with the submandibular gland resected back. Note also the lingual nerve and the 12th cranial nerve.

The full indications for an associated neck dissection and adjuvant treatment are beyond the scope of this chapter. Briefly, if the mass is malignant and there is concurrent nodal disease in the neck, a selective neck dissection should be performed. If there is perineural or lymphovascular invasion, or if there are multiple positive lymph nodes in the resection specimen, postoperative radiation is indicated. Likewise, if the mass is a high- or intermediate-grade salivary gland malignancy, postoperative radiation is indicated for the dissected site and, in some cases, should include the entire ipsilateral neck to the clavicle.

Complications of a submandibular triangle dissection through a lateral transcervical incision include hematoma (2% to 10%), fistula formation (1% to 3%), wound infection (2% to 9%), injury to the marginal mandibular (7.7% to 36%), lingual (0% to 22.5%), and hypoglossal (0% to 7%) nerves.

Other Transcervical Approaches

Two other transcervical approaches have been described: submental and retroauricular. Neither of these is suited for complete submandibular triangle dissection and should be reserved for cases in which the pathology is confirmed preoperatively to be benign, requiring only removal of the submandibular gland. The reader should note that these are nonstandard approaches.

The submental approach occurs through a midline horizontal incision determined by the submental-cervical crease, usually at the level of the hyoid. Dissection proceeds posterolaterally in a subplatysmal plane until the gland is encountered. It is bluntly dissected free of fascial attachments, and the facial vessels are ligated. Lastly, the attachments of the submandibular ganglion and duct are divided, releasing the gland.

The retroauricular approach occurs through an incision placed in the lower portion of the postauricular sulcus, continuing posteriorly along the hairline, as in a facelift incision. Dissection, which can be extensive, continues in the plane superficial to the fascia of the SCM, taking care to preserve the external jugular vein and greater auricular nerve, continuing anteriorly in a subplatysmal plane. Extirpation of the gland then proceeds in a posterior to anterior direction.

Transoral Approach

As with the submental and retroauricular approaches, this nonstandard approach is only indicated in confirmed benign disease, as it only allows for extirpation of the submandibular gland and not the entire contents of the submandibular triangle. Complications associated with this procedure include abnormal tongue sensation in 43% to 74% and restriction of tongue movement due to scar contracture in up to 10%.

Briefly, an incision is made in the floor of the mouth mucosa from the papilla of Wharton duct to the retromolar trigone, leaving a cuff of mucosa between the incision and the gingival to limit postoperative contracture. The lingual nerve is identified and the submandibular ganglion and duct attachments are divided. The gland is dissected free of facial attachments, allowing for delivery into the wound using gentle transcervical pressure. The hypoglossal nerve is identified and preserved. The facial vessels are then divided, allowing removal of the gland.

Endoscopic Approaches

As with the previously described nonstandard approaches, endoscopic

approaches should not be undertaken when oncologic resection is indicated. Endoscopic-assisted approaches have been described for transoral and submental approaches, enabling successful extirpation of the submandibular gland through smaller incisions. Completely endoscopic approaches have only been described in animal models.

REVISION SURGERY

Often, there is a dilemma as to how best to proceed when a cancer has been previously "shelled out" of the parotid gland or submandibular triangle and the patient is referred for further treatment. If the previous resection margins are positive for tumor, but there is no residual disease by palpation or imaging, then there is nothing to be gained by further surgery and postoperative radiation is indicated. If gross residual disease is present, however, either clinically or radiologically, revision surgery is necessary, but is fraught with potential problems and the patient should be appropriately counseled. Not only are the critical structures at greater risk for injury, but many times, the extent of the procedure must be more radical and may involve resection of these structures to ensure an adequate oncologic margin. The type of incision used to accomplish this is dictated by the previous surgery; the existing scar should be excised and consideration should be given to extension along a modified Schobinger incision (Fig. 21.5).

EDITOR'S COMMENT

Salivary gland tumors constitute an uncommon, heterogeneous group of neoplasms that vary considerably in their anatomical location, biologic behavior, and histology. Parotid gland remains the most common site of salivary gland tumors.

Approximately, 25% of parotid, 40% to 45% of submandibular, and 70% to 90% of sublingual gland tumors are malignant in nature (Guzzo M, Locati LD, Prott FJ, et al. Major and minor salivary gland tumors. *Crit Rev Onco Hematol* 2010;74:134–48). These malignant cancers compromise a broad range of histology, including mucoepidermoid, acinic, adenocarcinoma, adenoid cystic, malignant tumors, and squamous carcinoma. The most common malignant salivary gland tumors are mucoepidermoid and adenoid cystic comprising approximately one half of all the malignant salivary gland tumors. The primary squamous cell carcinoma of the parotid gland is rare; however, parotid gland is a common site of metastasis from skin cancers.

Recently, there has been rapid evolution of our understanding of salivary

gland lesions including description of new entities such as mammary analogue secretory carcinoma (MASC), hyalinizing clear cell carcinoma, and IgG4-related chronic sclerosing sialadenitis (Gupta R, Balasubramanian D, Clark JR. Salivary gland lesions: recent advances and evolving concepts. *Oral Surg Oral Med Oral Pathol Oral Radiol* 2015;119(6):661–74).

MASC is a low-grade neoplasm of the parotid gland described by Skalova et al. in 2010 (Skálová A, Vanecek T, Sima R, et al. Mammary analogue secretory carcinoma of salivary glands, containing the ETV6-NTRK3 fusion gene: a hitherto undescribed salivary gland tumor entity. *Am Journ of Surg Path* 2010;34(5)599–608). It is characterized by morphologic and molecular features similar to the secretory carcinoma of the breast and is known to occur in both men and women in both major and minor salivary tissues. Previously these tumors were categorized as zymogen granule-poor acinic cell carcinoma.

The major point of distinction between MASC and acinic cell carcinoma is the presence of intracytoplasmic zymogenic granules in acinic cell carcinoma and their absence in MASC. Although the prognostic information regarding these tumors is still evolving, these are usually considered as a low-grade malignant neoplasm.

Hyalinizing clear cell carcinoma have been described as “clear cell carcinoma, not otherwise classified” under World Health organization 2005 classification system. However, the presence of a specific translocation (EWSR1-ATF1 fusion t(12;22) (q13;q12)) indicates these tumors to be a rare distinct entity. These tumors are considered as low grade and most show an indolent course (Antonescu CR, Katabi N, Zhang L, et al. *Genes Chromosomes Cancer* 2011;50(7):559–70).

IgG4-related disease is a multiorgan inflammatory disease affecting many organs but most commonly involving salivary glands, pancreaticobiliary tree, lacrimal glands, and periorbital tissue (Deshpande V, Zen Y, Chan JK, et al. Consensus statement on the pathology of IgG4-related disease. *Mod Pathol* 2012;25(9):1181–92). Most patients with head and neck lesions present with bilateral, firm, nontender swelling of the salivary glands, especially submandibular glands. FNA is not useful and yields either lymphoplasmacytic or acellular aspirate based upon extent of sclerosis. Histology is considered as gold standard for the diagnosis. Most important differential includes carcinoma or lymphoma. IgG4-related chronic sialadenitis is usually managed by glucocorticoids. Prognosis depends upon extent of sclerosis and loss of the functional units.

Various factors like radiation exposure, smoking, viral infection (EBV, HIV, and HPV) and environmental exposure have been implicated in causation of salivary gland tumors. Radiation exposure has been linked with both benign and malignant tumors of salivary glands (Boukheris H, Ron E, Dores GM, et al. Risk of radiation-related salivary gland carcinomas among survivors of Hodgkin lymphoma: a population-based analysis. *Cancer* 2008;113(11):3153–9). Warthin tumors are known to have a strong association with smoking

(Pinkston JA, Cole P. Cigarette smoking and Warthin's tumor. *Am J Epidemiol* 1996;144(2):183–7). Rare lymphoepithelial carcinoma of salivary glands has been strongly associated with Epstein–Barr virus (EBV) in areas where this virus is endemic (Tumours of the salivary glands. In: Barnes L, Eveson JW, Reichart P, et al., eds. *Pathology and Genetics of Head and Neck Tumours.* Lyon: IARC/World Health Organization; 2005:209). Individuals with AIDS are reported to have high risks for lymphoepithelial carcinoma and squamous cell carcinoma of salivary glands (Shebl FM, Bhatia K, Engels EA. Salivary gland and nasopharyngeal cancers in individuals with acquired immunodeficiency syndrome in United States. *Int J Cancer* 2010;126:2503). Few studies have reported presence of high-risk serotypes of human papilloma virus in mucoepidermoid carcinoma (Isayeva T, Said-Al-Naief N, Ren Z, et al. Salivary mucoepidermoid carcinoma: demonstration of transcriptionally active human papillomavirus 16/18. *Head Neck Pathol* 2013:7:135–48). Occupation exposure such as rubber manufacturing and nickel compounds has been described to be associated with salivary glands tumors (Swanson GM, Burns PB. Cancers of the salivary gland: workplace risks among women and men. *Ann Epidemiol* 1997:7:369).

Most patients with salivary gland tumors usually present with a painless mass or swelling. Presence of neurologic signs and symptoms like facial nerve paralysis are almost always suggestive of a malignant tumor.

The preoperative definitive diagnosis of salivary gland lesions is critical for avoiding unnecessary surgery for nonmalignant lesions, and for therapeutic planning for malignant tumors. Fine-needle aspiration (FNA) is most widely used preoperative diagnostic technique for salivary gland lesions. However, FNA usually has relatively low sensitivity in comparison with its high specificity for diagnosing salivary gland tumors. According to a meta-analysis by Schmidt et al., the average sensitivity and specificity determined in 6,169 cases were 80% and 97%, respectively (Schmidt RL, Hall BJ, Wilson AR, et al. A systematic review and meta-analysis of the diagnostic accuracy of fine-needle aspiration cytology for parotid gland lesions. *Am J Clin Pathol* 2011;136:45–59). The low sensitivity of FNA can be ascribed to several factors including diversity and rarity of salivary gland carcinomas, and difficulty of diagnosing low-grade carcinomas by cellular morphology alone. In addition, pathologists' experience and expertise can affect the accuracy of FNA.

Core-needle biopsy (CNB) is a relatively new technique for diagnosing salivary gland lesions. It has many advantages over FNA, including the ability to attain a bigger specimen with preserved tissue architecture for possible immunohistochemical staining. A recent meta-analysis by Witt et al. included 12 studies to estimate the sensitivity and specificity of core-needle biopsy of salivary gland lesions. They reported 96% sensitivity and 100% specificity of core-needle biopsy for diagnosis of malignancy of salivary gland. There was no significant heterogeneity in accuracy between studies (Witt BL, Schmidt RL. Ultrasound-guided core needle biopsy of salivary gland lesions: a systematic

review and meta-analysis. *Laryngoscope* 2014;124:695–700).

Imaging studies like computed tomography (CT) and magnetic resonance imaging (MRI) may provide the clinicians with critical information to plan the type and extent of surgical intervention. With recent advances in imaging techniques, it may be possible to differentiate between malignant and benign salivary gland tumors using MR spectroscopy (Lee YY, Wong KT, King AD, et al. Imaging of salivary gland tumours. *Eur J Radiol* 2008;66:419–36).

The major therapeutic option for salivary gland malignant cancer is surgical resection. Surgical resection requires careful planning and execution. This is especially true in cases of parotid gland tumors because of the presence of the facial nerve in the gland. As a general principle, if the facial nerve function is normal preoperatively then every effort to preserve facial nerve function should be made during parotidectomy and if the facial nerve is scarified or incised intraoperatively then immediate microsurgical repair should be considered. Neck dissection should be considered for all malignant tumors of the parotid except for low-grade neoplasms. Adjuvant radiation is recommended for high grade or large tumors and/or those with preoperative facial nerve weakness, positive surgical margins, extracapsular spread, and perineural invasion (Sood S, McGurk M, Vaz F. Management of Salivary Gland Tumours: United Kingdom National Multidisciplinary Guidelines. *J Laryngol Otol* 2016;130(S2):S142–9).

22 Anatomy of the Parotid Gland, Submandibular Triangle, and Floor of the Mouth

Aaron Ruhalter

ANATOMY OF THE PAROTID GLAND

The parotid gland is the largest of the paired salivary glands. The gland is wedged into the parotid space.

Parotid Space

The parotid space has a skeletal background created by the ramus of the mandible anteriorly, the styloid process medially, the mastoid process posteriorly, and the external acoustic meatus and the posterior part of the temporomandibular joint posterosuperiorly (Fig. 22.1). A soft tissue background is created by the muscles that are attached to these bony landmarks—the masseter, medial pterygoid, and temporalis muscles on the mandible; the stylohyoid, styloglossus, and stylopharyngeus muscles arising from the styloid process of the temporal bone; and the sternocleidomastoid and digastric muscles related to the mastoid process and the lateral portion of the posterior occipital line.

Parotid Gland

The superficial surface of the parotid gland is triangular in shape, with the apex pointing inferiorly (Fig. 22.2). The deep surface of the gland is wedged into this parotid space and presents anteromedial and posteromedial surfaces. The gland frequently extends beyond the limits of the parotid space. Glandular tissue may extend from the anterosuperior edge of the superficial surface, creating what is called the *facial process*, and is superior to the parotid duct. The extension of glandular tissue may be separate from the main portion of the gland. This isolated segment of gland (accessory parotid) has a duct that empties into the main duct. Frequently, extensions are found from the deep surface of the gland toward

the pharynx or the medial pterygoid muscle.

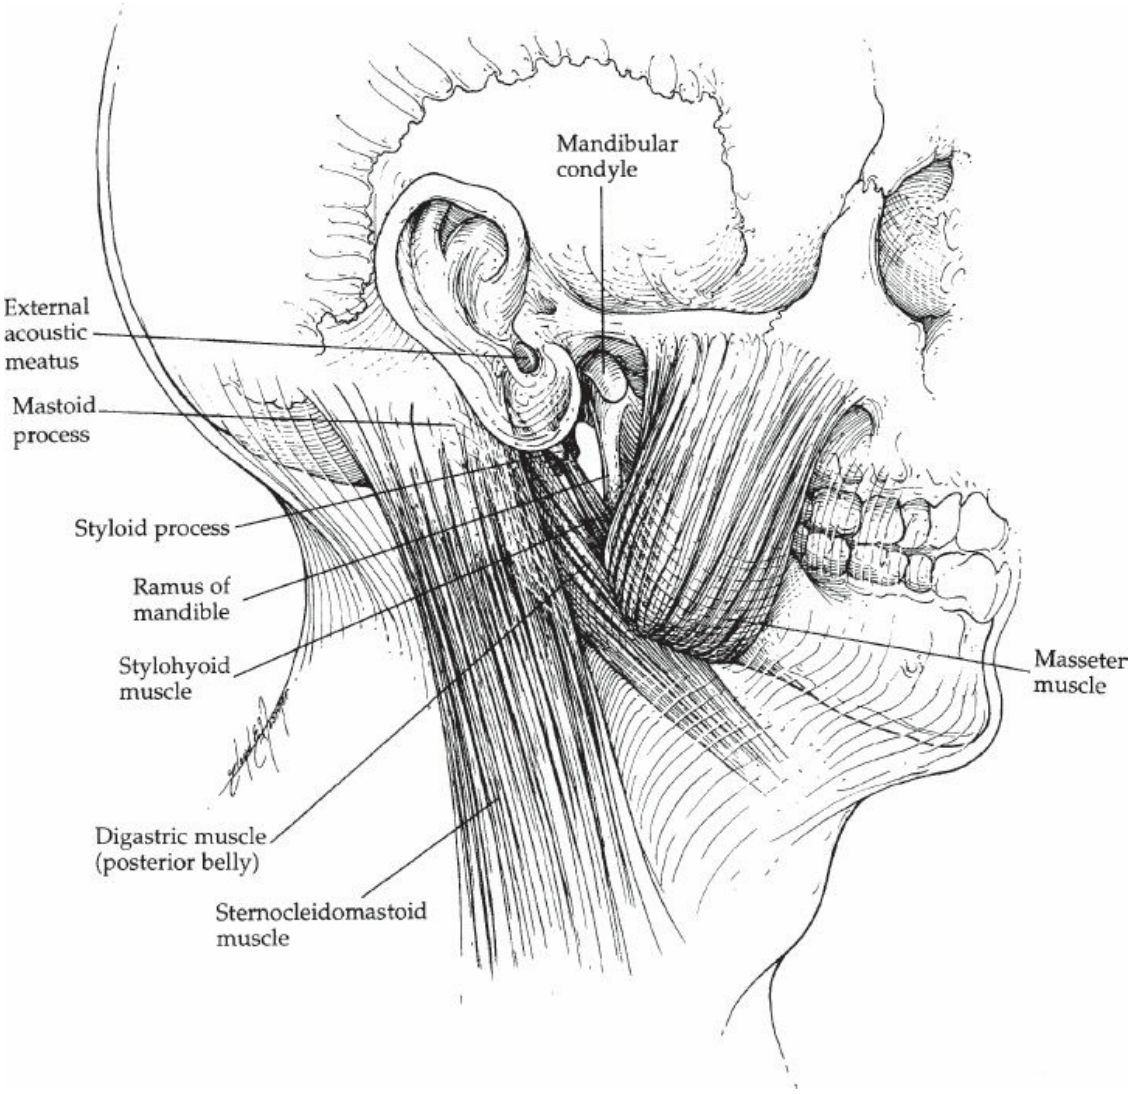

Figure 22.1. Parotid bed.

The parotid gland is somewhat artificially divided into two lobes by the facial nerve as it passes through. Endofacial (deep) and exofacial (superficial) portions are created. Multiple communications exist between the lobes, however, created by bridges of glandular tissue. A large area of communication, referred to as the *isthmus*, is related to the proximal part of the intraparotid portion of the facial nerve.

The parotid duct is approximately 5 cm long and lies on the superficial surface of the masseter muscle, approximately 1 cm below the zygomatic arch. The transverse facial artery is interposed between the duct and the arch, whereas the buccal branches of the facial nerve can be found inferior and superior to the duct. When this conduit reaches the anterior margin of

the masseter muscle, it turns sharply, penetrates the buccinator muscle, and ends in the vestibule of the oral cavity opposite the upper second molar tooth.

Fascial Relations

The gland is encased by a split in the investing layer of the deep cervical fascia. The deep layer passes superiorly and attaches to the base of the skull. A portion of this fascia between the tip of the styloid process and the angle of the mandible is thickened, creating the stylomandibular ligament. This ligament supports the temporomandibular joint and separates the parotid gland from the submandibular gland. The superficial layer of this fascial split is much thicker, invests the masseter muscle, and attaches to the zygomatic arch. Its thickness and unyielding nature are responsible for the severe pain that results from enlargement of the gland.

Neurovascular Relations

Neurovascular structures pass through the parenchyma of the gland and can conveniently be described in layers or planes. From deep to superficial are found the arterial, venous, and nerve layers.

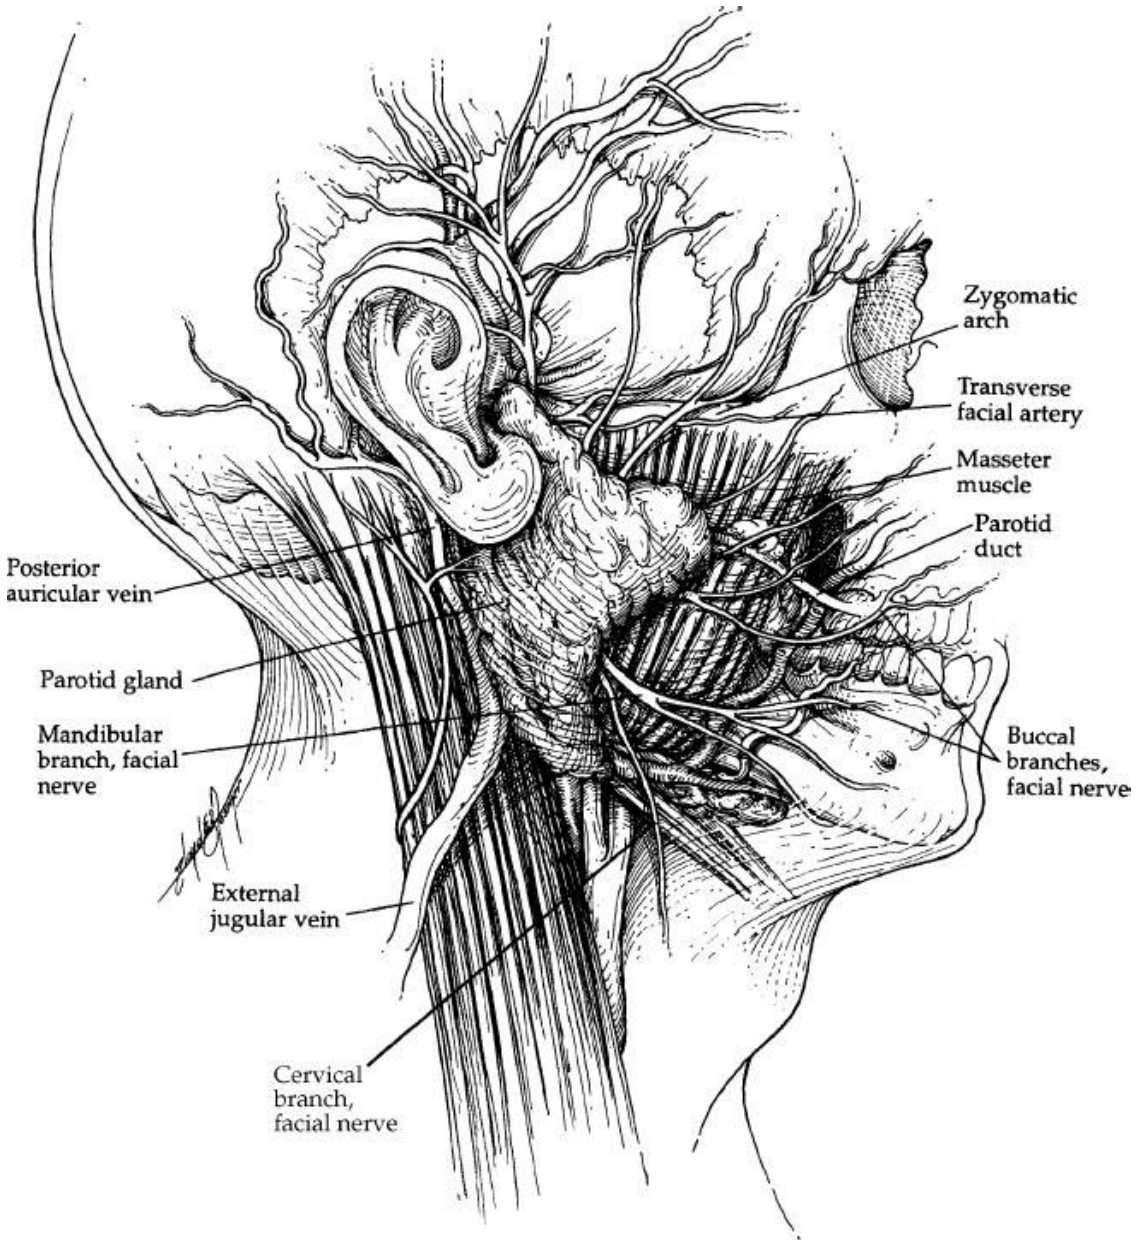

Figure 22.2. Superficial view of the parotid region.

Arterial Plane

The arterial layer includes the *external carotid artery*, which enters the parotid space after passing deep to the posterior belly of the digastric muscle (Fig. 22.3). At this point the external carotid artery gives rise to the *posterior auricular artery*, which gives off a *stylohyoid branch* that enters the stylomastoid foramen. This blood vessel is usually superficial to the facial nerve trunk as it exits from the skull by way of this same foramen. The posterior auricular artery then continues posteriorly, running under cover of, and parallel to, the superior edge of the posterior belly of the digastric muscle. One should note that this muscle passes superficial to and

protects almost all of the structures passing between the submandibular triangle superiorly and the carotid triangle inferiorly. This includes the *internal jugular vein* and the *internal carotid artery* in the carotid sheath, the last four cranial nerves, and the external carotid artery. The *retromandibular vein* or its branches, the *cervical branch of the facial nerve,* and the *greater auricular nerve,* however, pass superficial to the posterior belly of the digastric muscle.

The external carotid artery then pierces the medial surface of the parotid gland, and when it reaches the neck of the condylar process of the mandible it ends by giving rise to the *maxillary artery* and the superficial temporal artery. The maxillary artery passes medial to the condylar process of the mandible and enters the infratemporal fossa. The superficial temporal artery continues superiorly, accompanied by *superficial temporal veins.* The *transverse facial artery,* which arises from the proximal part of the superficial temporal artery, courses just superior to the parotid duct. The superficial temporal artery then enters the temporal region after passing between the external acoustic meatus and the temporomandibular joint. Accompanying these vascular structures at this level is the auriculotemporal nerve, which arises from the mandibular branch of the trigeminal nerve in the roof of the infratemporal fossa. It provides sensory innervation to the external acoustic meatus, external surface of the tympanic membrane, and temporomandibular joint, and cutaneous sensory innervation to the auricle and temporal scalp region.

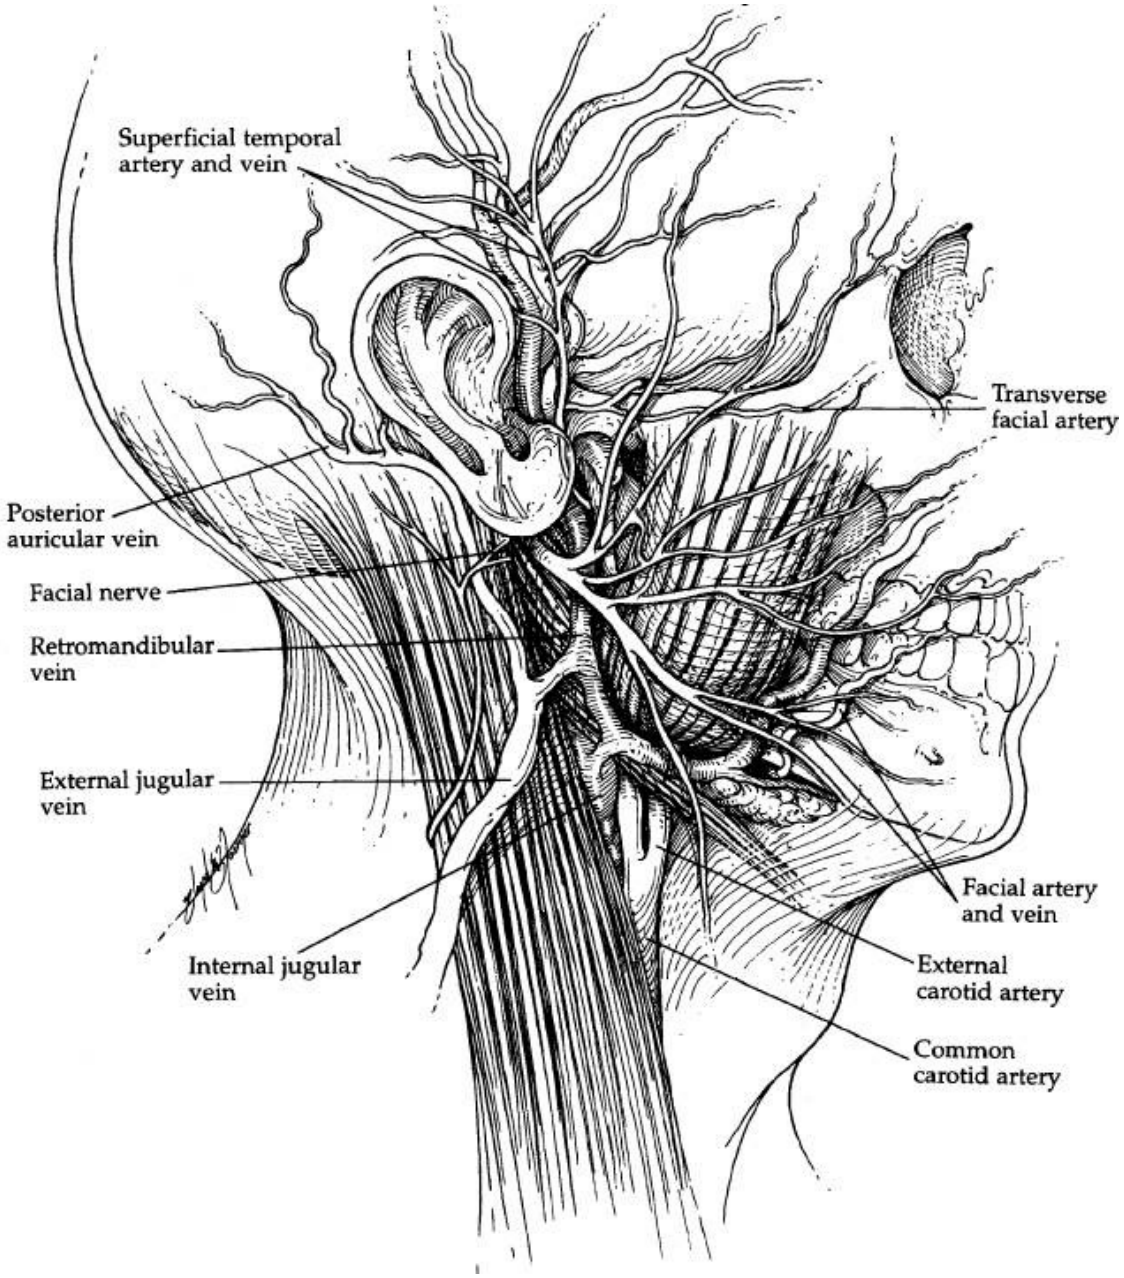

Figure 22.3. Vascular background.

Venous Plane

The venous plane is superficial to the arterial plane (Fig. 22.3). It includes the *retromandibular vein* and its branches. The retromandibular vein is created by the union of the superficial temporal and maxillary veins. The maxillary vein is formed by the union of veins that are part of a large plexus of veins surrounding the lateral pterygoid muscle. This venous plexus communicates with veins of the face as well as with the cavernous sinus within the skull. The parotid veins also communicate with the pterygoid venous plexus. This pterygoid venous plexus in turn represents a potential pathway for the spread of superficial cutaneous infections to the

cavernous sinus. This is a potentially lethal condition.

The retromandibular vein passes inferiorly through the substance of the parotid gland and is found between the branches of the facial nerve and the arterial layer. The retromandibular vein terminates at the lower edge of the gland by giving off anterior and posterior branches. The posterior branch joins with the *posterior auricular vein* to form the *external jugular vein,* which continues inferiorly, superficial to the posterior belly of the digastric muscle, then passes obliquely across the sternocleidomastoid muscle. It is frequently found just anterior to the great auricular nerve, which is on its way to the skin overlying the parotid gland. The anterior branch of the retromandibular vein unites with the anterior facial vein, forming the common facial vein. This passes inferiorly, superficial to the digastric muscle, to empty into the internal jugular vein.

Nerve Plane

The nerve plane is created by the facial nerve and its branches (Fig. 22.4). The *facial nerve* (seventh cranial nerve) exits from the skull through the stylomastoid foramen. At this point it is found with the stylomastoid branch of the posterior auricular artery, which enters the foramen and supplies the mucosa of the tympanic cavity, the mastoid cells, and the semicircular canals. The artery is usually superficial to the facial nerve. After emerging from the foramen, two branches arise from the facial nerve before it enters the parotid gland. The first branch, the *posterior auricular nerve,* provides innervation to the posterior auricular muscles and the intrinsic muscles of the auricle. The second branch, arising from the extraparotid portion of the facial nerve, provides motor innervation to the posterior belly of the digastric and stylohyoid muscles. This portion of the nerve, approximately 1 cm in length, then penetrates the posteromedial surface of the parotid gland. This nerve trunk passes forward in the glandular parenchyma for a distance of approximately 1 cm or less, then divides into two branches—a larger *temporofacial branch,* which creates *temporal* and *zygomatic* nerves, and a smaller *cervicofacial branch,* which gives rise to *buccal*, *marginal mandibular*, and *cervical nerves.* An isthmus of glandular tissue separates the temporofacial branch from the cervicofacial branch.

The facial nerve provides motor innervation to the muscles of facial expression. The platysma is included in this category of muscle. The nerve branches, as they pass through the parotid gland, divide it into two portions. The part of the gland that is superficial to the nerves is referred to

as the *superficial (exofacial) lobe*, and the portion of the gland that is internal to the nerve layer is referred to as the *deep (endofacial) lobe.* Multiple communications are found between the nerve branches as they pass through the gland. The zygomatic and temporal nerves are frequently multiple, whereas the mandibular and cervical branches are often single. The cervical and mandibular branches can extend below the mandible, whereas the cervical branch passes superficial to the posterior belly of the digastric muscle. The nerves become more superficial as they pass distally.

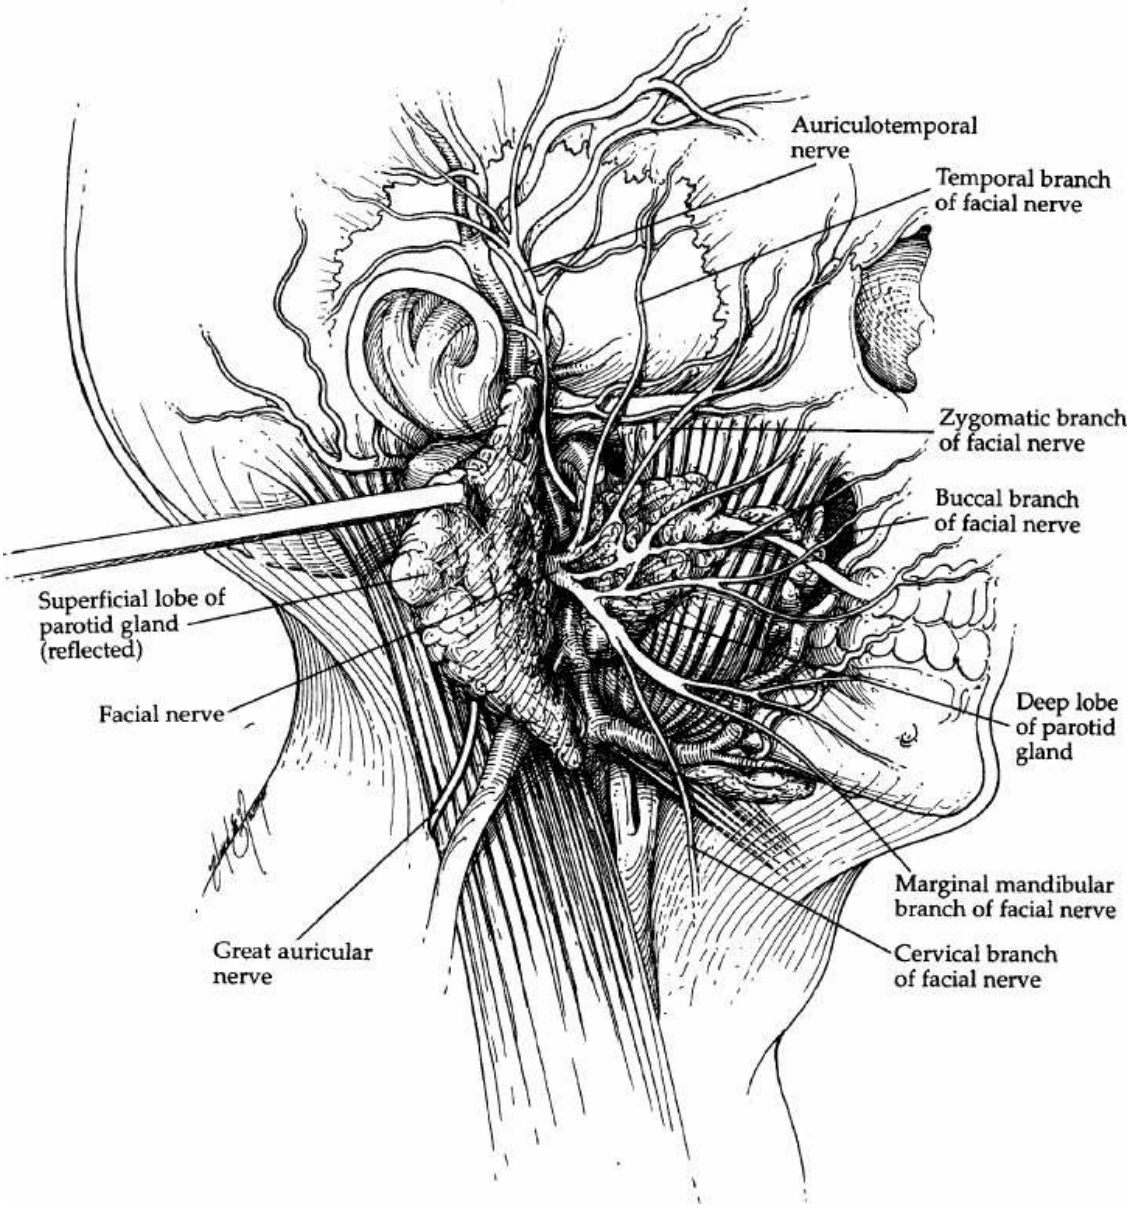

Figure 22.4. Nerve plane.

Innervation

The parotid gland receives postganglionic sympathetic fibers from a

plexus of nerves that travel with the external carotid artery. Secretomotor postganglionic parasympathetic fibers reach the infratemporal fossa by way of the lesser petrosal nerve, synapse in the otic ganglion, and then travel to the parotid gland by way of the auriculotemporal nerve.

Lymphatic Drainage

The lymphatic drainage of the parotid gland is related to two systems. Superficial nodes in the superficial fascia (preauricular) drain into the superficial system of cervical nodes. These are related to the external jugular vein and pass to the supraclavicular nodes in the posterior triangle. The second set of nodes is found within the fascial covering of the parotid gland. These nodes drain into the deep cervical nodes and the jugular chain.

Anatomic Aids

The main trunk of the facial nerve can be found by tracing one of its branches proximally. The mandibular and cervical branches are more frequently used because they are often single and more convenient to find.

The parotid duct is approximately 1 cm inferior to the lower edge of the zygomatic arch. The pathway of the duct can be recreated by a line between the lower end of the tragus of the ear and the commissure of the mouth.

Two nerves may be found with the superficial temporal vessels. The auriculotemporal nerve is posterior, whereas the temporal branches of the facial nerve lie anterior to these vessels.

The *great auricular nerve* is frequently found posterior to the external jugular vein. This nerve and vein travel together until the inferior edge of the parotid gland is reached. The nerve passes to the subcutaneous tissues superficial to the gland, providing sensory innervation to the skin overlying the parotid gland. The remainder of the face receives its sensory innervation only from the trigeminal nerve. The vein is seen to emerge from the substance of the gland.

The *external carotid artery* is related to the medial boundary of the parotid space. The *internal carotid artery* is slightly deeper. The two vessels should not be confused. One must remember that the internal carotid artery does not have any branches in the neck. Separating the external carotid artery from the internal carotid artery are the styloid process or stylohyoid ligament, the stylopharyngeus muscle, and the

glossopharyngeal nerve.

The stylohyoid muscle and the posterior belly of the digastric muscle diverge at their points of attachment to the skull. The main trunk of the facial nerve passes through this interval.

At the junction of the cartilaginous portion and the osseous portion of the auditory canal, a downward projection of cartilage frequently exists that points to the main trunk of the facial nerve.

When the external jugular vein is traced superiorly to its parent structure, the retromandibular vein, it leads to the interval between the superficial and deep lobes of the parotid gland. It is also a means of locating the cervical or mandibular branches of the facial nerve, because they pass superficial to the vein.

The stylomastoid branch of the posterior auricular artery enters the stylomastoid foramen and is superficial to the facial nerve trunk.

The internal jugular vein may be in contact with the deep surface of the gland.

ANATOMY OF THE SUPRAHYOID PORTION OF THE ANTERIOR TRIANGLE

The posterior belly of the digastric muscle and the hyoid bone divide the anterior triangle of the neck into suprahyoid and infrahyoid areas. The submandibular and submental triangles are suprahyoid in position, and are described in this chapter.

ANATOMY OF THE SUBMANDIBULAR TRIANGLE

The submandibular triangle is part of the anterior triangle of the neck and is suprahyoid in position. It is sometimes referred to as the *digastric* or *submaxillary triangle*.

Muscular Boundaries

The muscular boundaries of the submandibular triangle are the *posterior belly of the digastric* and *stylohyoid muscles* posteriorly, and the *anterior belly of the digastric muscle* anteriorly (Fig. 22.5). The inferior margin of the body of the mandible creates a superior boundary to this triangular area. The digastric muscle attaches posterosuperiorly to the *mastoid process* of the temporal bone, posterior to the stylohyoid muscle, which arises from the posterolateral surface of the styloid process. The two

muscles quickly approach each other and remain in intimate contact down to the region of the hyoid bone, where an intermediate tendon of this double-bellied muscle is found. This tendon passes through a split in the tendon of insertion of the stylohyoid muscle. The intermediate tendon is bound to the hyoid bone by a fascial thickening. The anterior belly then passes superomedially and ends by attaching to the internal aspect of the mandible near the midline. The digastric muscle elevates the hyoid bone and assists in depression of the mandible. The posterior belly of the digastric and the stylohyoid muscles is innervated by the facial nerve, and the anterior belly of the digastric muscle is innervated by the mylohyoid nerve branch of the inferior alveolar nerve. This latter nerve is a branch of the posterior division of the mandibular nerve.

Muscular Floor

The muscular floor of the submandibular triangle consists of four muscles (Fig. 22.5). The direction of the muscular fibers of each of the muscles is characteristic and allows for recognition of the boundaries between neighboring muscles. These muscles do not lie in the same plane. The anterior muscles are more superficial than those posterior, which creates a step-like pattern to this muscular floor of the submandibular triangle. Passing from anterior to posterior, one encounters the *mylohyoid* and then the *hyoglossus muscle.* The inferior portion of the *superior constrictor muscle* and the superior portion of the *middle constrictor muscle* complete the floor of the submandibular triangle.

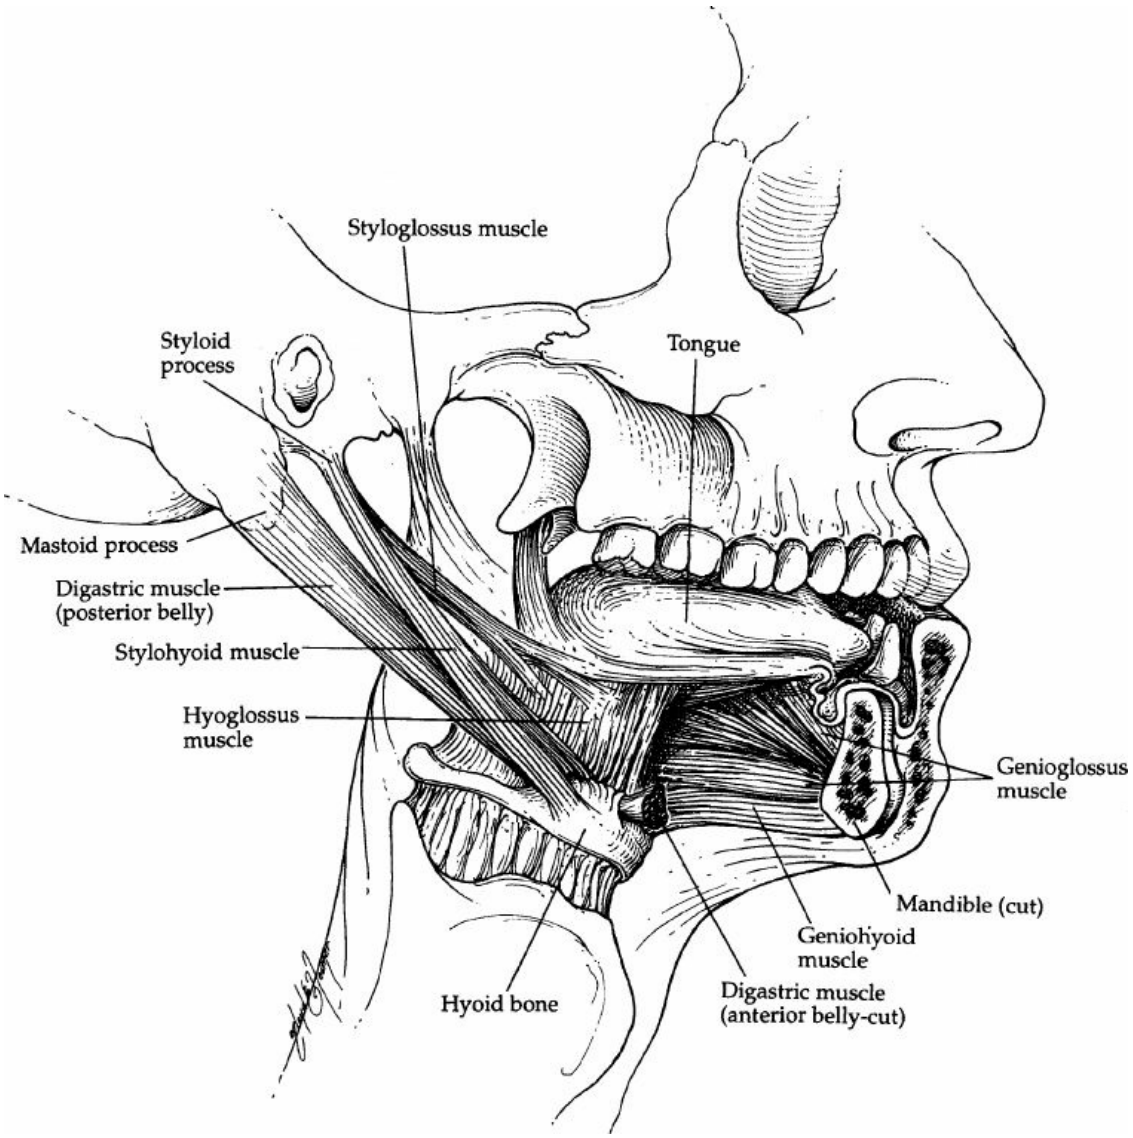

Figure 22.5. Musculoskeletal background and floor of the mouth.

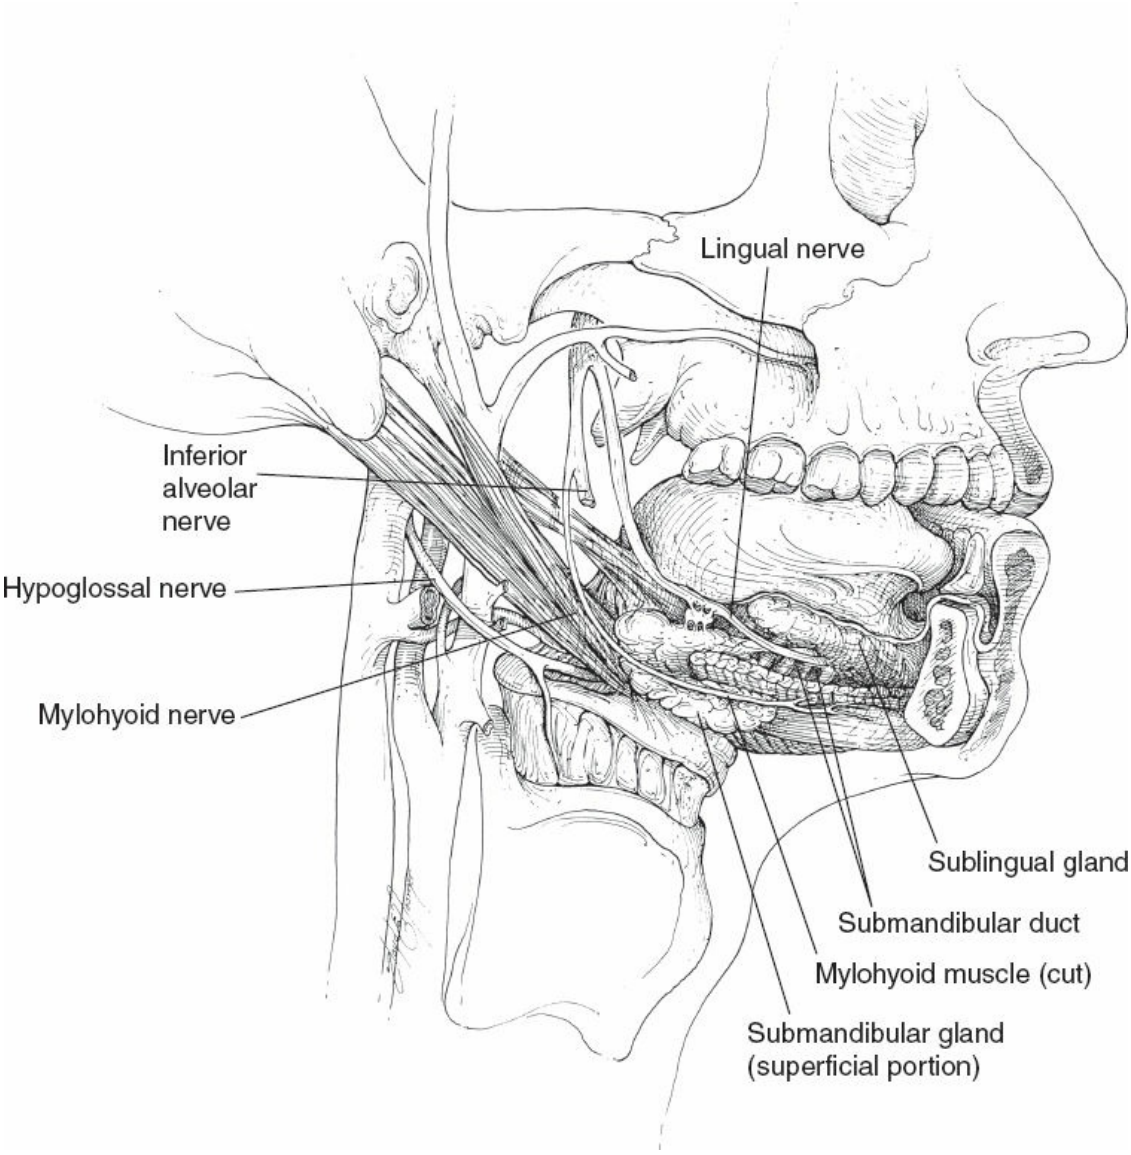

Figure 22.6. Submandibular triangle and floor of the mouth. This figure illustrates nerve contents and superficial and deep portions of the submandibular gland.

The mylohyoid muscle (Fig. 22.6) is the most anterior and superficial of the muscles creating the floor of the mouth. It arises from the inner aspect of the mandible, and the two halves pass inferomedially where the majority of the fibers insert into a midline fibrous raphe extending from the midportion of the mandible to the center of the body of the hyoid bone. The more posterior fibers insert into the body of the hyoid bone. The two halves of the muscle create a floor for the oral cavity. The mylohyoid muscle presents a posterior free edge. When this muscle contracts, it raises the floor of the mouth, causing elevation and posterior displacement of the tongue. This is an integral part of the swallowing mechanism.

The hyoglossus is a quadrangular muscle that arises from the entire length of the greater horn of the hyoid bone. It passes superiorly and attaches to the lateral surface of the tongue. Its deep relations include the *stylohyoid ligament*, the *glossopharyngeal nerve*, and the *lingual artery*. Passing superficial to the hyoglossus muscle are the *lingual nerve*, the *hypoglossal nerve* and its *two venae comitantes*, and the *submandibular duct*. Those structures that are superficial to the hyoglossus muscle become deep relations of the mylohyoid muscle when they reach the free posterior edge of the mylohyoid muscle and then travel in the interval between these muscles. The hypoglossal nerve innervates the hyoglossus muscle and the other extrinsic tongue muscles, as well as all of the intrinsic muscles of the tongue. The mylohyoid muscle and the anterior belly of the digastric muscle are innervated by the mylohyoid nerve, which arises from the inferior alveolar branch of the mandibular nerve.

Fascial Coverings

A fascial roof and carpet are created by the investing layer of the deep cervical fascia when it splits to invest the submandibular gland. The superficial layer attaches to the inferior edge of the mandible, whereas the deep layer attaches to the inner aspect of the mandible, just below the attachment of the mylohyoid muscle.

Contents of the Submandibular Triangle

Submandibular Gland

The submandibular gland is the main content of the submandibular triangle (Fig. 22.6). It actually overflows and extends beyond its boundaries. The gland wraps itself around the posterior free edge of the mylohyoid muscle. This creates a superficial lobe that lies on the external surface of the mylohyoid and a smaller deep lobe that lies internal to the mylohyoid muscle. The duct of the gland passes medial to the deep lobe and ends in the floor of the mouth at a small elevation just lateral to the frenulum. The lingual nerve at first is superior to the duct as they both pass superficial to the hyoglossus muscle. The hypoglossal nerve is at a more inferior level.

Neurovascular Structures

The structures that are superficial to the submandibular gland include the cervical branch of the facial nerve and the distal ends of the anterior facial vein and anterior branch of the retromandibular (posterior facial) vein (Fig.

22.7). These veins unite in the tissues overlying the submandibular triangle, creating the common facial vein, which passes inferiorly to empty into the internal jugular vein. Occasionally, the mandibular branch of the facial nerve descends below the inferior edge of the mandible and can be injured when incisions are made in this area.

Structures in the submandibular triangle found between the submandibular gland and the mylohyoid muscle include the facial artery and the mylohyoid nerve and vessels. The facial artery is the most superior of the vessels that arise from the anteromedial surface of the external carotid artery. It begins in the carotid triangle, just superior to the tip of the greater cornu of the hyoid bone, passes deep to the posterior belly of the digastric muscle, and enters the submandibular triangle. It passes superiorly and reaches a point well above and medial to the lower edge of the body of the mandible. It then passes over the superior and lateral surfaces of the gland and is adherent to these surfaces. It now arches superiorly in contact with the external surface of the mandible, creating a groove just anterior to the insertion of the masseter muscle. It gives a submental branch that runs along the inferior surface of the mandible in contact with the upper surface of the gland.

Appearing at the anterior edge of the gland are the mylohyoid nerve and vessels. The nerve arises from the inferior alveolar branch of the mandibular nerve. Neurovascular structures are found deep to the submandibular gland, but on the other side of (deep to) the mylohyoid muscle. They are located in the interval between the hyoglossus and mylohyoid muscles, and are responsible for tongue function and nutrition.

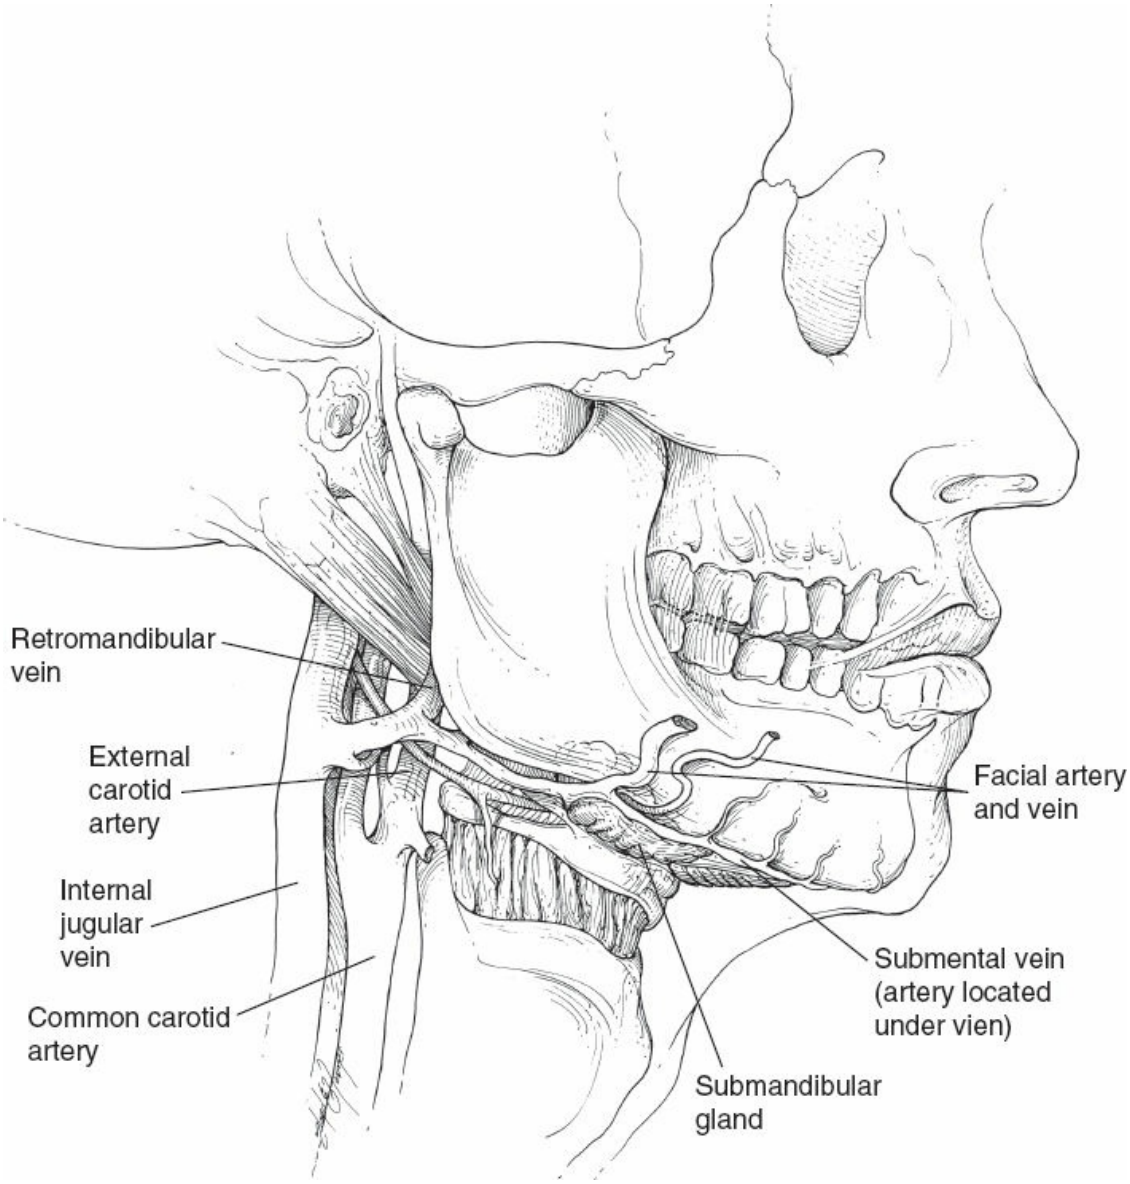

Figure 22.7. Submandibular triangle.

The lingual nerve, a branch of the mandibular nerve, passes through the interval until it reaches the anterior margin of the hyoglossus muscle. It then turns medially, after looping around the submandibular duct, and penetrates the tongue. It provides general sensation for the anterior two thirds of the tongue.

The chorda tympani (arising from the facial nerve) joins the lingual nerve in the upper part of the infratemporal fossa. It carries taste fibers from the tongue and brings preganglionic parasympathetic fibers to the submandibular ganglion. This ganglion is attached to the lingual nerve and is the site of synapse for these preganglionic fibers. Postganglionic secretomotor fibers then pass to the sublingual and submandibular glands. The hypoglossal nerve and lingual veins are also seen in this region.

Accompanying these neurovascular structures is the submandibular duct (Wharton duct). The deep lobe of the submandibular gland is also found internal to the mylohyoid muscle.

Lymphatic Drainage

The lymphatics of the submandibular gland are found within its parenchyma, whereas other lymph nodes are outside the fascial covering of the gland. The lymphatics of the mandibular region can be divided into horizontal and vertical systems. The horizontal chain runs along the mandible from the parotid gland to the midline, receiving afferent channels from the ipsilateral face and oral cavity. The lymphatics of the submental triangle also drain into this horizontal system. From this submandibular collecting area, vertical channels pass to the system of nodes related to the internal jugular vein (deep cervical nodes). Other vertical channels pass into the posterior triangle to the superficial posterior cervical system (found with the external jugular vein) and the deep posterior cervical system (found with the spinal accessory nerve). Named lymph nodes are located in the internal jugular channels, which are found where double-bellied muscles pass superficial to the internal jugular vein (i.e., jugulodigastric and jugulomylohyoid).

Anatomic Aids

The mandibular and cervical branches of the facial nerve may extend below the lower edge of the mandible. All other structures of concern lie deep to the posterior belly of the digastric muscle. Incisions can be made down to this muscle with little fear of injuring any vital neurovascular structures.

The fascial coverings of the submandibular gland are less adherent to the gland surface than are the coverings of the parotid gland. This allows for easier enucleation of the submandibular gland.

The facial artery is very adherent to the internal and superior surfaces of the gland and must frequently be removed with the gland after proximal and distal control is obtained.

The hyoglossus muscle is an anatomic landmark. It is superficial to the glossopharyngeal nerve and the lingual artery but is found internal to the lingual and hypoglossal nerves, the submandibular duct, and a deep process of the submandibular gland. The lingual veins are also superficial to this muscle and are closely related to the hypoglossal nerve.

The lingual nerve is superior to the deep process of the submandibular gland and its duct before forming a loop around the duct by passing lateral and then inferior to it before penetrating the framework of the tongue. The hypoglossal nerve and its venae comitantes are inferior to the duct.

The hypoglossal nerve crosses the internal and external carotid arteries superficially. The glossopharyngeal nerve, the pharyngeal nerves arising from the vagus, and the stylopharyngeus muscle pass between these same arteries, whereas the superior laryngeal nerve (arising from the vagus nerve near the base of the skull) passes deep to those arteries.

Small nerve branches arise from the lingual nerve and submandibular ganglion, which enter the submandibular gland. These must be transected during excision of the gland to prevent avulsion injuries to the lingual nerve.

ANATOMY OF THE SUBMENTAL TRIANGLE

This space is found in the suprahyoid portion of the neck (Fig. 22.8). It separates the submandibular triangles and contributes to the structure of the floor of the mouth. The anterior bellies of the digastric muscles create lateral boundaries of this triangle. The body of the hyoid bone is the base, and the apex is the symphysis menti. The mylohyoid creates a muscular floor. Its fibers arise from the mylohyoid line, on the medial aspect of the mandible; pass inferomedially; and attach to the body of the hyoid bone and a midline raphe found between the hyoid and the mandible. Contraction of the muscle will result in elevation of the floor of the mouth. The mylohyoid branch of the inferior alveolar nerve provides motor innervation. The investing layer of the deep cervical fascia creates a fascial roof. The only contents of the triangle are the submental lymph nodes, which drain the tip of the tongue, floor of the mouth, lower lip, and chin. Efferent channels pass to the submandibular nodes, or to jugular nodes of the vertical cervical chain. Anterior jugular veins are found in the tissues superficial to the submental triangle. Incisions made in this area will not injure major neurovascular structures.

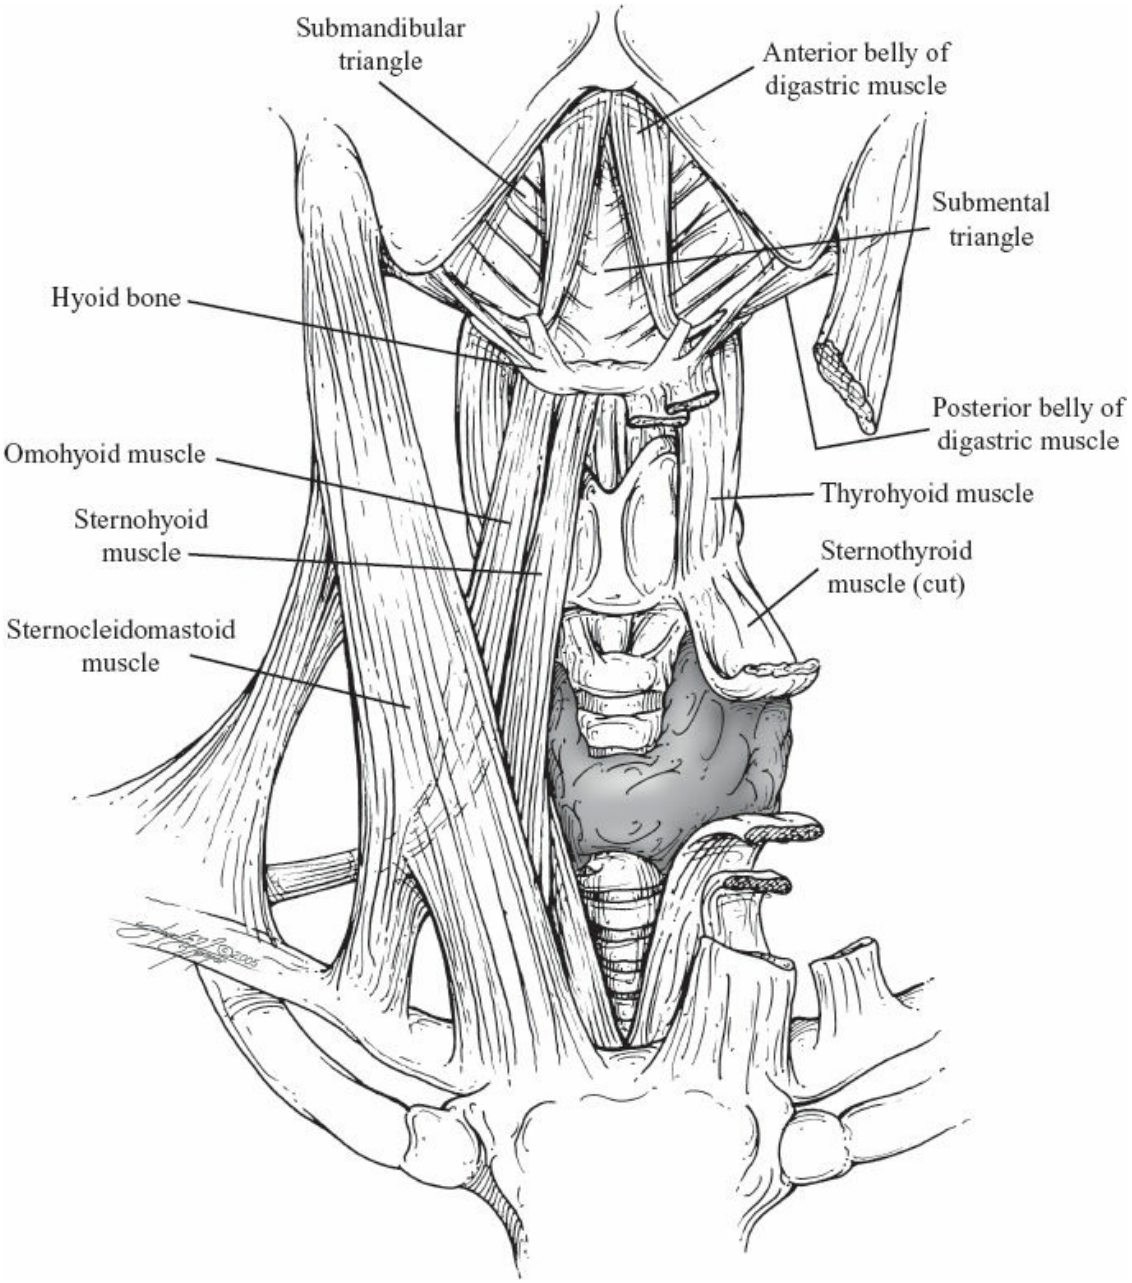

Figure 22.8. Submental triangle.

ANATOMY OF THE FLOOR OF THE MOUTH

The mylohyoid muscle is the anatomic structure that separates the oral cavity from the neck, and thereby creates the floor of the mouth. The attachments of this muscle have been mentioned previously. The hyoglossus muscle contributes a posterolateral boundary to this separation between the floor of the mouth and the submandibular triangle (part of the anterior neck). The floor of the mouth can also be defined as the area between the tongue and its lateral mucosal reflections, and the mylohyoid muscle.

Tongue

The tongue is a massive muscular structure that faces the oral cavity and the pharynx (Figs. 22.5 and 22.6). It is attached to the floor of the mouth, the mandible, and the hyoid bone.

Extrinsic Muscles

The extrinsic muscles of the tongue include the genioglossus, hyoglossus, styloglossus, and palatoglossus. The genioglossus muscle arises from the genial tubercles found on the internal aspect of the midportion of the mandible and passes to most of the dorsum of the tongue. The hyoglossus arises from the hyoid bone, passes superiorly, and attaches to the lateral aspect of the tongue. The styloglossus muscle arises from the tip of the styloid process and the proximal part of the stylohyoid ligament. Its fibers pass anteroinferiorly and attach to the lateral surface of the tongue, where they interdigitate with the fibers of the hyoglossus muscle.

Intrinsic Muscles

The intrinsic muscles of the tongue consist of longitudinal, horizontal, and vertical fibers that create an interlocking network.

Movements

Because of the extensive interdigitation of the muscles of the tongue, a wide variety of movements are possible. In addition, the mylohyoid muscle is displaced by movements of the hyoid bone. These movements are created by contraction of the suprahyoid and infrahyoid muscle groups. The mandible can be depressed by contraction of the mylohyoid, stylohyoid, digastric, and geniohyoid muscles if the hyoid bone is fixed in position by contraction of the infrahyoid musculature.

Innervation

All of the intrinsic and extrinsic muscles of the tongue receive their innervation from the hypoglossal nerve. The one exception is the palatoglossus muscle, which is innervated by the pharyngeal plexus of nerves. Sensory innervation of the anterior portion of the floor of the mouth is provided by the lingual nerve. Traveling with this nerve are fibers of the chorda tympani (seventh) nerve, which provides taste sensation for the anterior portion of the tongue, and preganglionic secretomotor fibers on their way to synapse in the submandibular ganglion before proceeding to the submandibular and sublingual glands. Sensation and taste for the

posterior one-third of the tongue are provided by the glossopharyngeal nerve.

Vascular Supply

The vascular supply to the tongue is provided by the lingual artery, which arises from the external carotid artery in the carotid triangle, passes into the submandibular triangle, and enters the region of the floor of the mouth after passing deep to the hyoglossus muscle. It gives a sublingual branch and then, as the deep lingual artery, passes to the apex of the tongue just lateral to the midline. Little communication exists across the midline between the left and right deep lingual vessels.

Contents of the Floor of the Mouth

Geniohyoid Muscle

The geniohyoid muscle originates just below the origin of the genioglossus and passes anteroinferiorly to attach to the body of the hyoid bone. The left and right parts of this muscle lie side by side. When they contract, the hyoid bone is displaced anteriorly and superiorly.

Salivary Glands and Their Ducts

The sublingual gland is found in the floor of the mouth, between the geniohyoid muscle and the mandible (Fig. 22.9). It is the smallest of the three paired salivary glands and frequently has two systems of ducts. One is composed of multiple ductules, which empty directly into the floor of the mouth. The second system consists of a duct (or ducts) of varying size emptying into the larger submandibular duct. In this same area is found the deep process of the submandibular gland and its duct. This deep process may be of significant size and may appear to blend in with the sublingual gland. The submandibular duct, lingual nerve and veins, and the hypoglossal nerve are medial to the sublingual gland. Anatomic flow exists between the submandibular triangle and the floor of the mouth (sublingual space), which allows for passage of the contents of one area into the domain of the other.

Lymphatic Drainage

The lymphatic drainage of the floor of the mouth is complex. Lesions from the central part of the floor of the mouth and the tip of the tongue can drain into submandibular glands on either side, or drain directly into submental nodes, and then into submandibular nodes (horizontal system). The

drainage is then directed primarily toward the deep cervical system, which is associated with the vertical system of lymphatics found with the internal jugular vein. Some spread may occur to the superficial posterior cervical system in the posterior triangle, which is found with the external jugular vein. The lymph drainage from the posterior part of the tongue is directly into the deep cervical nodes of either or both sides.

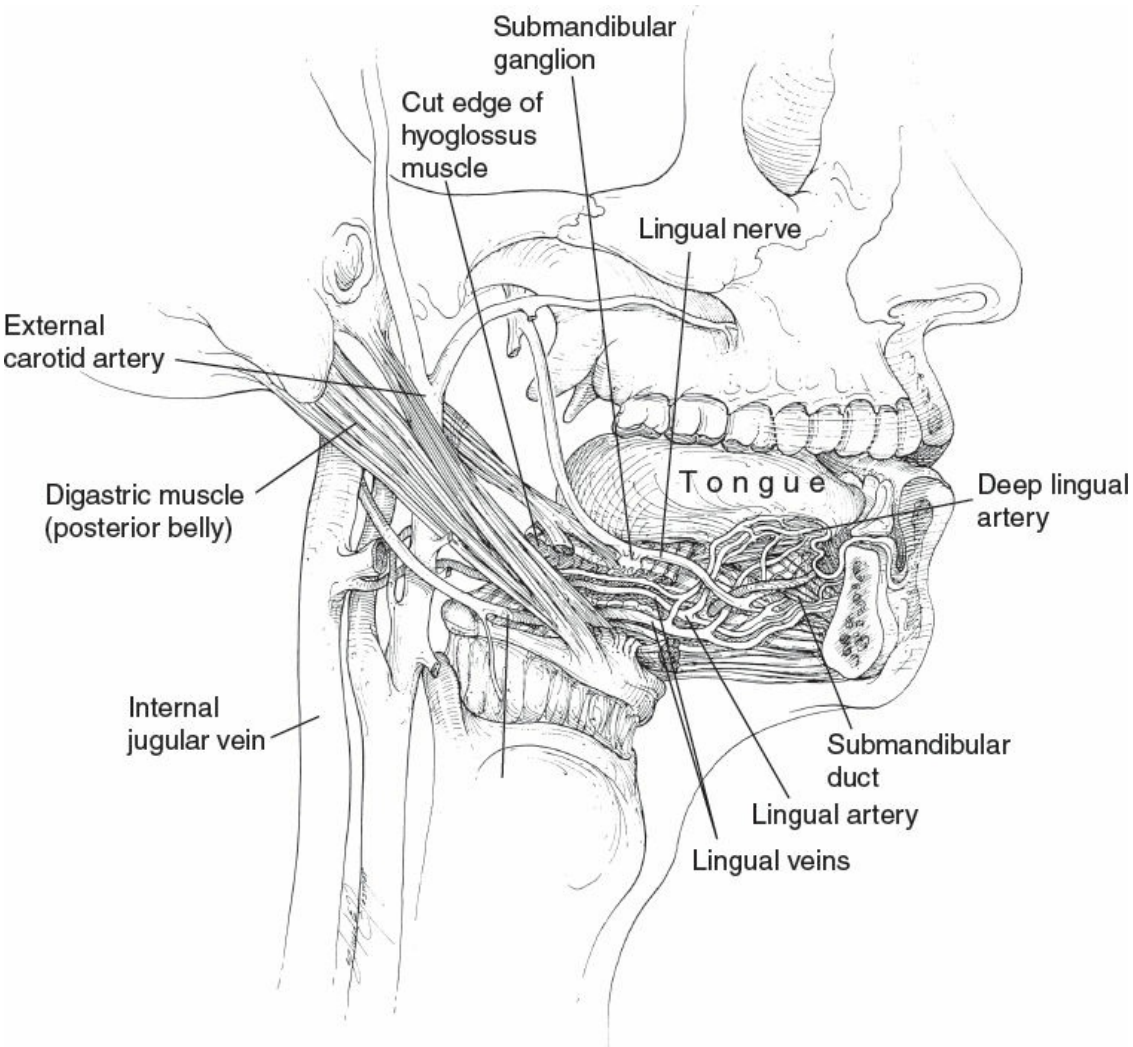

Figure 22.9. Submandibular triangle and floor of the mouth (deep structures).

Anatomic Aids

Little communication is found across the midline of the tongue between the deep lingual arteries. This limits blood loss at the time of hemiglossectomy.

EDITOR'S COMMENT

This is not an area in which general surgeons have a great deal of experience. Even the parotid gland which does appear every now and then in a busy surgical practice yields little familiarity to the average general surgeon. This may be different in the case of the rural general surgeon in which setting there is probably no ear, nose and throat surgeon and the area of tenderness may be beyond the expertise of the general practitioner or the family physician. While the general surgeon may have some familiarity with parotid disease in this case the most important aspect is to know the difference between a parotitis and some type of tumor, many of which are benign, in the case of the submandibular gland and the submaxillary gland there is even less familiarity with inflammation.

The most common malady that the general surgeon is called upon to treat is a chronic sialadenitis. It's commonly associated with an acute chronic inflammation and an obstruction of the excretory duct. But the differentiation between chronic sialadenitis and obstruction of the excretory duct is difficult even the best of circumstances. Stones are responsible for about 60–70% and may occasionally be palpated, stenosis in 15–25%, and inflammation of the duct alone in about 5–10%. Anatomic variations or foreign bodies (the latter difficult to comprehend) are only about 1–3%. In the past as Koch M, et al. (*Otolaryngology Clinics of North America* 2009;42:1173–1792) point out the operative removal of the gland was recommended as the therapeutic method of choice after unsuccessful non-operative treatment. As with many other things, minimally invasive techniques have led to tremendous differences in approach. Interventional sialography and other radiologically controlled methods such as ultrasound-guided techniques and sialendoscopy all have been developed lately and make the therapy of inflammation of the gland a much more direct and informed concept than just taking the gland out. If there is direct visualization of the findings without the use on contrast material and with lack of exposure to radiation, there is a high success rate. There are other gland preserving techniques such as transoral duct slitting or transcutaneous stone retrieval which likely will not be utilized by the average general surgeon. In this nicely authored article there is an algorithm for the treatment of various diseases of the salivary glands starting with the necessity of oral therapeutic diagnostic examination which include, as mentioned earlier, ultrasound and sialendoscopy. Ultrasound enables the presumptive diagnosis to make quickly, safely and cost effectively and in the hands of experienced people with great precision. Endoscopy serves

as a direct determination of the obstruction. Endoscopy controlled treatment such as interventional sialendoscopy also is a boon to non-destructive operations on the salivary glands.

Less than 5 mm stones and mobile stones located in the main excretory ducts and possibly even as far as the first and second branching ducts may be successful in the hands of the skilled endoscopist of which most general surgeon will not be. The stones may be fragmented during intervention and the fragments then retrieved by endoscopically controlled means. Micro-instruments also exist but probably will require a specialist. Radiologically controlled or fluoroscopic methods can be preformed with a success rate of up to 80%. Shock-wave lithotripsy represents a therapeutic alternative of the first choice in the parotid gland and the fragments may be extracted in an endoscopically controlled manner.

Stones are difficult to feel manually. I recently had a patient who had a neck procedure elsewhere and developed pain in her neck and it appeared as she pointed to the right side of the neck that she probably did have a sialadenitis of the submandibular gland with a sympathetic adenopathy going down the entire right neck. I had started her on antibiotics prior to seeing her because that what it sounded like and indeed she told me that an ENT person she had seen years ago that she had stones in her duct. I could not feel it nor could I milk anything out through the bottom of the mouth but I am certain that’s what she had. It subsided.

In the parotid gland which is not the subject of this particular exposition the 25% of all stones have an intraparenchymal location and therefore are more difficult to deal with.

Stenoses are another major cause of symptomatic sialadenitis and may be seen by endoscopy. However some stenoses may be multiple, they may be in difficult locations, they may be long and the tissue of the stenosis may be fibrotic. Sialendoscopy has the advantage of a direct assessment and does allow an inflammatory stenosis to be differentiated from a fibrous stenosis. The major of the inflammatory stenoses may be treated non-operatively with irrigation and intraductal steroid placement. In regard to the submandibular gland, symptom free stenosis, especially if one can recognize atrophy of the gland require no or exclusively conservative form of treatment. The basic treatment rule applies for symptomatic stenosis, as inflammatory stenoses are treated primarily non-operative whereas fibrous stenoses are operated on. This is an extensive paper and the detail that is contained in it is beyond the scope of what I wish to impart but it is readable and informative and the practitioner who deals with these may want to avail themselves of the wisdom in this particular paper.

Beahm, David D, et al. (*International Journal of Surgery* 2009;7:503–509) reviewed the surgical approaches to the submandibular gland. Surgical incision of the submandibular gland is commonly indicated in patients with neoplasm or occasional with chronic sialadenitis and ranula and drooling. In the past, traditional SMG surgery has involved a direct transcervical approach while

more recently alternative approaches through the submandibular gland excision have been described to avoid scarring and to offer minimally invasive options with better cosmetic results. In this paper the authors utilize dissection of cadavers which were dissection via both the transcervical and transoral approaches together with the use of endoscopic assistance when indicated. The authors conclude that while tradition submandibular gland excision (nobody seems to bother much with the submaxillary gland) a direct transcervical approach is what is preferred. The modes of excision include open, endoscopic and robotic-assisted dissections.

Ranulas, so named for frogs, may be the result of inspissated mucus and may not be an indication of malignancy or a situation which requires excision of the duct or the gland. Should such excision be required however Kauffman RM, et al., *Laryngoscopoe* 2009;119:502–507 propose a transoral surgical approach to excising the submandibular gland. They describe relevant anatomy and what to avoid. They describe nine patients in which this approach was attempted over the past ten years. Of the nine patients who underwent attempted transoral submandibular gland excision, eight operations were completed transorally and only one operation was aborted and converted to a standard external approach because of severe scarring. Six of the nine patients had chronic sialadenitis and three had obstructing sialoliths. Three other patients presented with other benign cystic lesions consistent with a ranula, an infected mucocele, and a cystic teratoma. The only complication with a patient with incisional breakdown and delayed healing because of a prior irradiated field. The lingual nerve, or hypoglossal nerves, were spared and there were no hemostatic complications. The authors conclude that this option actually is safe and there are no external scars. Obviously some skill and association with a thorough knowledge of anatomy is useful.

Finally Yu C, et al. *Journal of Oral and Maxillofacial Surgery* 2010;68:1770–1775) writing from the Shanghai 9th People's Hospital at Shanghai University report on endoscopy observation and management of obstructing submandibular sialadenitis. 128 cases, a very substantial number, were identified endoscopically and radiographically. They had three types of sialoliths in 114 or 89%, mucus plugs in 8 (6%) and stenosis in 5% (6). 47 were removed successfully for a success rate of 92% of 51 obstructions treated surgically. Of 63 patients treated using interventional sialendoscopy, 52 were removed with a success rate of 83%. The remaining unsuccessful cases were treated endoscopically or surgically. Obstructive symptoms were relieved in 12 of 14 patients without stones using dilation and irrigation under sialendoscopy. Of the 114 patients with a stone, the sialoliths of 67 (59%) in the distal region behind the first molar. It stands to reason that their conclusion that the more posterior the stone the more difficult it was to remove and that was correct. Three patients with treatment failure underwent resection of the gland. A basin-like structure in the hilus region was found in 67%. In 5 patients a fishbone was found surrounded by a sialolith. The authors conclude that this is a relatively

new technique and is sparing of the submandibular gland and holds great promise. I agree.

23 Lip Reconstruction

Patrick C. Hettinger and Robert J. Havlik

Reconstruction of the lip may be required for a defect created from resection of malignancy, following traumatic injury, or as the result of a congenital anomaly. The incidence of oral/pharyngeal cancers in the United States is approximately 45,000 per year, with approximately 13,000 affecting the mouth directly. Approximately 25% to 30% of these malignancies involve the lips, thereby yielding a total annual incidence of approximately 4,000 cases. The number of traumatic injuries to the lips is difficult to determine accurately, but these injuries are not uncommon, and frequently occur following dog bites and motor vehicle accidents. The incidence of cleft lip, with or without cleft palate, in the United States is approximately 4,400 cases per year. While all of these patients will benefit from lip reconstruction, the majority of the latter group of congenital anomalies are cared for by specialized teams in children's hospitals, frequently follow more complex paradigms involving treatment of other facial structures in addition to the lip, and their treatment will not be discussed further here. Therefore, this chapter will focus on lip reconstruction following resection of lip cancer or traumatic injury—the principles involved in these reconstructions are similar.

Lip cancer is strongly associated with smoking, alcohol use, and sun exposure. Smoking and alcohol have significant "synergy" in the pathogenesis of all oral cancers and the effects together are multiplicative, noted to be as high as 20-fold the occurrence with either smoking or alcohol use. Unlike other oral and mucosal cancers, sun exposure is also a prime consideration in the pathogenesis of cancer of the lips. The upper lip has a more prominent position, projecting in front of the lower lip and shrouding the lower lip, but the vermillion surface is largely facing downward, away from the sunlight. It is the cutaneous surface of the upper lip that sustains the most significant exposure. The majority of lesions on the skin of the upper lip are basal cell carcinomas. In distinct contrast, the majority of lesions on the lower lip involve the vermillion and are the more aggressive squamous cell carcinomas. The lower lip vermillion is

facing upward and outward, and is prone to damage by direct sunlight. Actinic exposure is believed to play an important role in squamous cell cancer of the lower lip, as judged by association with occupation and geographic location.

Cancer of the lip differs from other cancers of the oral cavity in that the prominence of the lips in everyday activities often leads to early recognition of the presence of the lesion. Once the lesion has been recognized, diagnosis is made by surgical biopsy. A recent Cochrane review found that other alternatives for diagnosis (fine needle aspiration, etc.) were not as accurate as surgical biopsy. Clinical examination of the neck for involved nodes is crucial in staging this disease. Regional spread and nodal involvement at the time of diagnosis of lip cancer, unlike other oropharyngeal cancers, are relatively uncommon. The central portion of the lip drains to submental lymph nodes, whereas the lateral portion of each lip drains to the ipsilateral submandibular lymph nodes. Computed tomography (CT)/magnetic resonance imaging (MRI) may be warranted for evaluation for potential nodal involvement. However, a large number of patients with lip cancer will have nodal enlargement on the basis of inflammatory changes, which can be difficult to differentiate on digital scans. In follow-up of a large series of patients who had treatment of the primary lesion alone, only 8% to 10% will develop nodal disease. In addition, lymph node involvement seems to correlate with tumor stage: 4% in T1 lesions (<2 cm), 35% in T2 lesions (2 to 4 cm), and 63% in T3 lesions (>4 cm). If nodal disease does occur, it can be difficult to manage, with a 5-year survival of only 50% in these patients.

ANATOMY

Topographically, the lips dominate the lower third of the face. The lips have a number of surface landmarks that are important for successfully approaching reconstruction (Fig. 23.1). Accurate alignment of these landmarks is essential for an acceptable result—tolerances in discrepancies are a millimeter or less. As you pass from superiorly to inferiorly, the skin of the upper lip develops a slight prominence, the “white roll,” before transitioning across the linear mucocutaneous junction, or vermillion border, to the pink vermillion of the upper lip. The vermillion’s matte pink appearance is created by a dense network of blood vessels extending beneath a thin layer of nonkeratinizing epithelium. The dry appearing vermillion transitions to the wet appearing mucosa at the “wet line” where

the upper and lower lips meet. A similar transition of mucosa, vermillion, and skin occurs in the lower lip. In the upper lip, two ridges extend from the base of the columella of the nose to the peaks of the upper lip on either side of the midline, the philtral columns. These two philtral columns demarcate the central upper lip, and also serve as the lateral boundaries for Cupid's bow, the curved area of the transition between the skin and the vermillion border of the central upper lip. The philtral columns are created by the insertion of the largely transverse fibers of the orbicularis oris muscle fibers into the skin along the height of the columns. The central upper lip is aesthetically discrete from the adjacent lateral upper lip segments. The central upper lip is also anchored to the boney pyriform aperture. The labiomental crease is a depression in the cutaneous portion of the lower lip that is located roughly half-way between the vermillion border of the lower lip and the chin point.

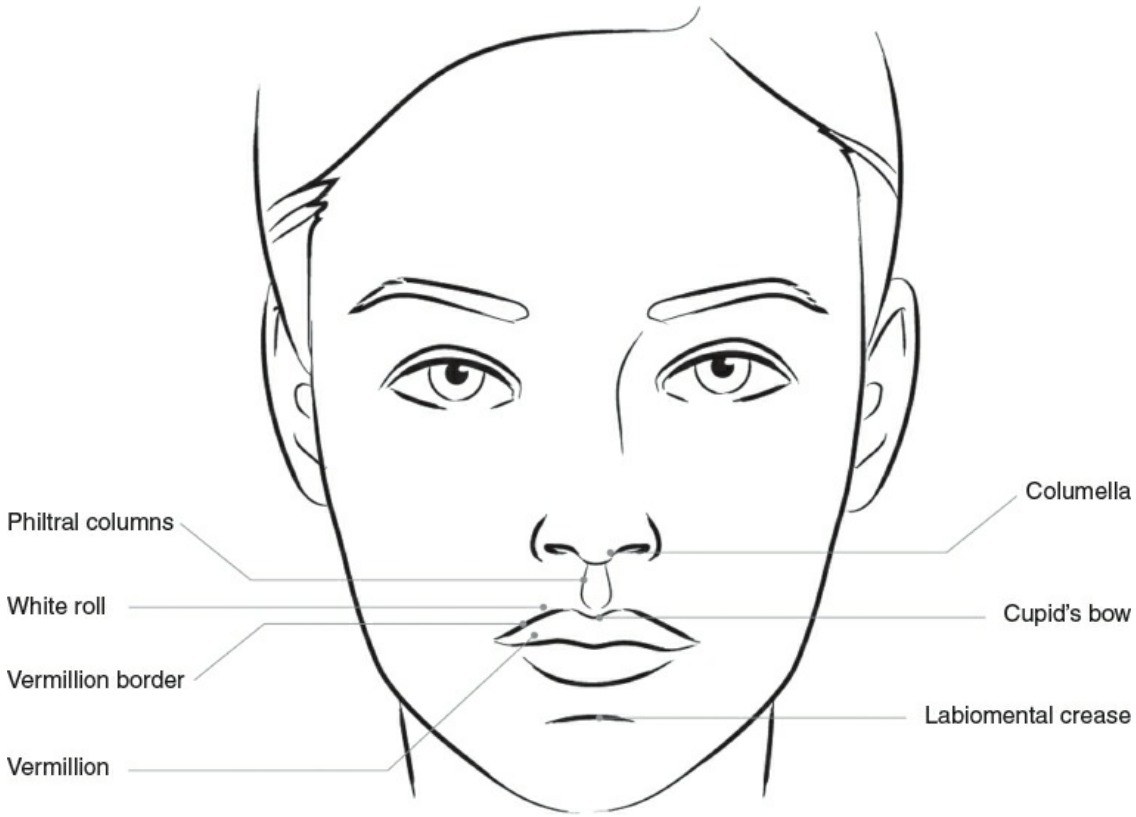

Figure 23.1. Surface landmarks of the lips.

Deep to the surface, the muscular architecture supports the lens-shaped oral opening (Fig. 23.2). Each side of the oral opening is known as the oral commissure. Just lateral to each oral commissure is the modiolus, a fibromuscular area of confluence of several muscles. This area is

noteworthy because it is a critical insertion point for many muscles that affect lip motion, and accordingly is also extremely difficult to reconstruct. Extending in an almost horizontal orientation across both the upper and lower lips is the orbicularis oris. The orbicularis oris muscle is responsible for the majority of the bulk of the lip. As noted above, in the upper lip some fibers of the orbicularis oris insert into the skin to create the ridge of the philtral columns, whereas in the lower lip all of the fibers pass transversely and horizontally and join with orbicularis oris fibers extending from the contralateral modiolus. In the upper lip, the levator labii superiorus, the zygomaticus major, and the levator anguli oris are the major lip elevators (Fig. 23.2). The levator labii superiorus arises from the inferior and medial orbital margin and wraps around the nasal ala and passes over the fibers of the orbicularis oris muscle to insert into the orbicularis oris fibers and the lower portion of the ipsilateral philtral column. The levator angulii oris arises just below the levator labii superiorus and inserts into the modiolus. The zygomaticus major muscle extends from the body of the zygoma to insert into the modiolus. There are several other muscles that arise from the pyriform aperture and the nose and can effect upper lip function, but are less significant in their overall impact, and will not be discussed here.

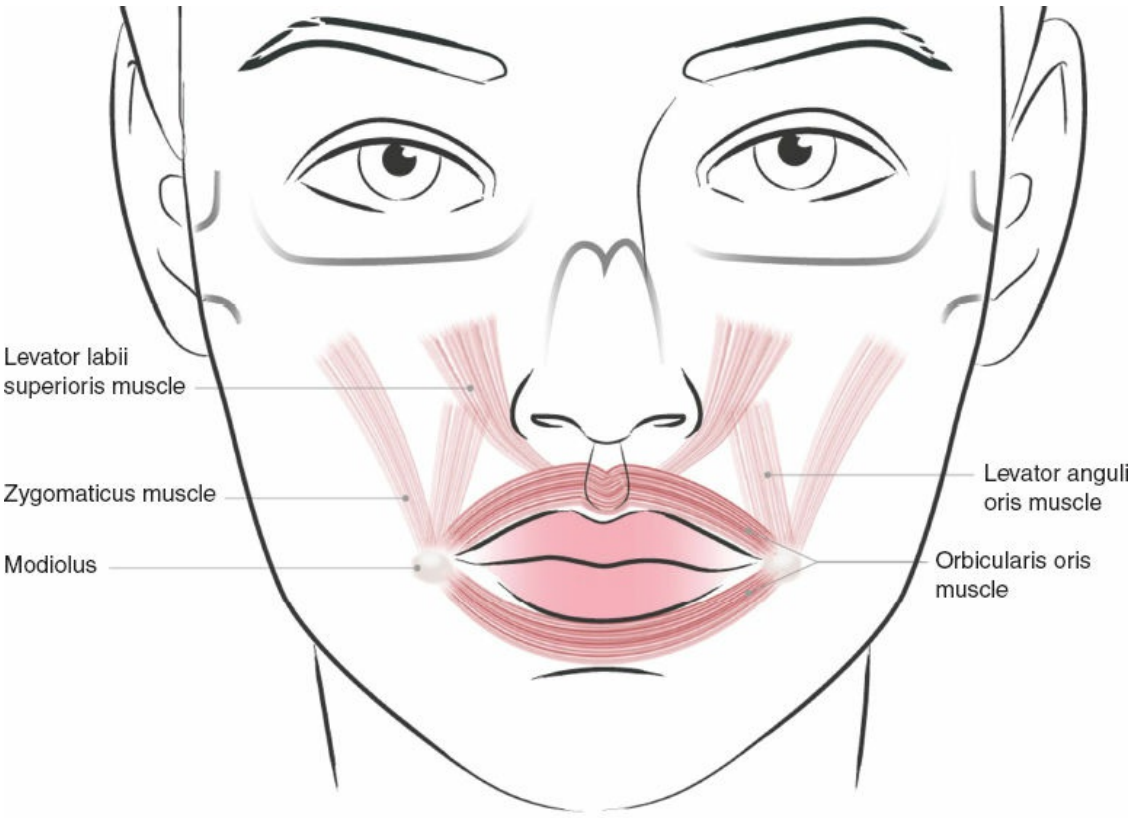

Figure 23.2. Muscles of the upper lip.

The buccinator muscle is the main muscle of the soft tissue wall of the cheek. It originates from the pterygomandibular raphe and maxillary and mandibular alveolar ridges of the posterior mouth and passes anteriorly, inserting on the modiolus and muscles of the upper and lower lips.

In the lower lip (Fig. 23.3), the depressor labii inferioris arises from the inferior border of the mandible from the area of the mental foramen to the symphysis and its fibers pass medially and superiorly and intermingle with the fibers of the orbicularis along the length of the ipsilateral lower lip. This muscle pulls the lower lip down. The depressor angulii oris arises inferior to the origin of the depressor labii inferiorus and its fibers pass laterally, superiorly, and superficial to the fibers of the depressor labii inferiorus to insert on the modiolus. The origin of the depressor angulii orus muscle interdigitates with the fibers of the platysma muscle, and these two muscles act to pull the modiolus (and the corner of the mouth) downward. The mentalis muscles originate from the parasagittal areas of the mandible below the vestibular sulcus, and pass inferiorly and toward the surface to insert into the skin. When they contract, they pull chin and the lower lip upward in the central area to facilitate lip closure and establish competence.

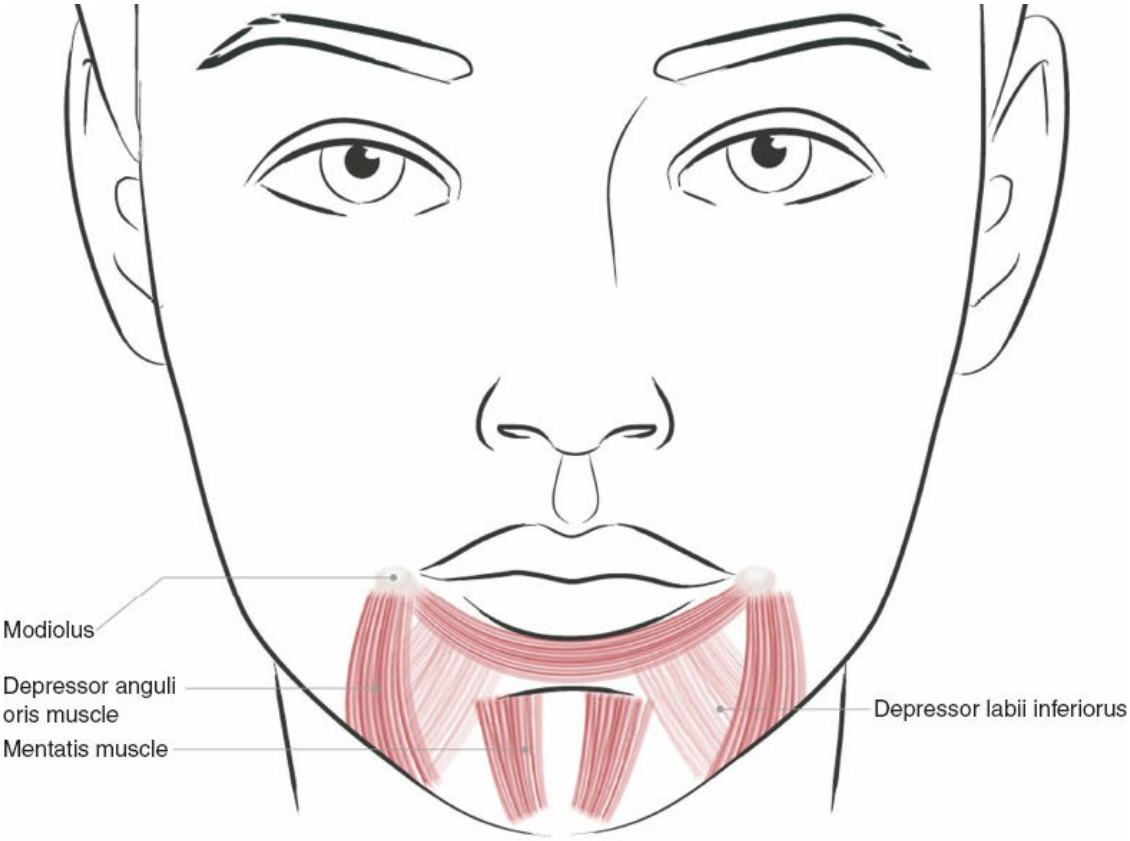

Figure 23.3. Muscles of the lower lip.

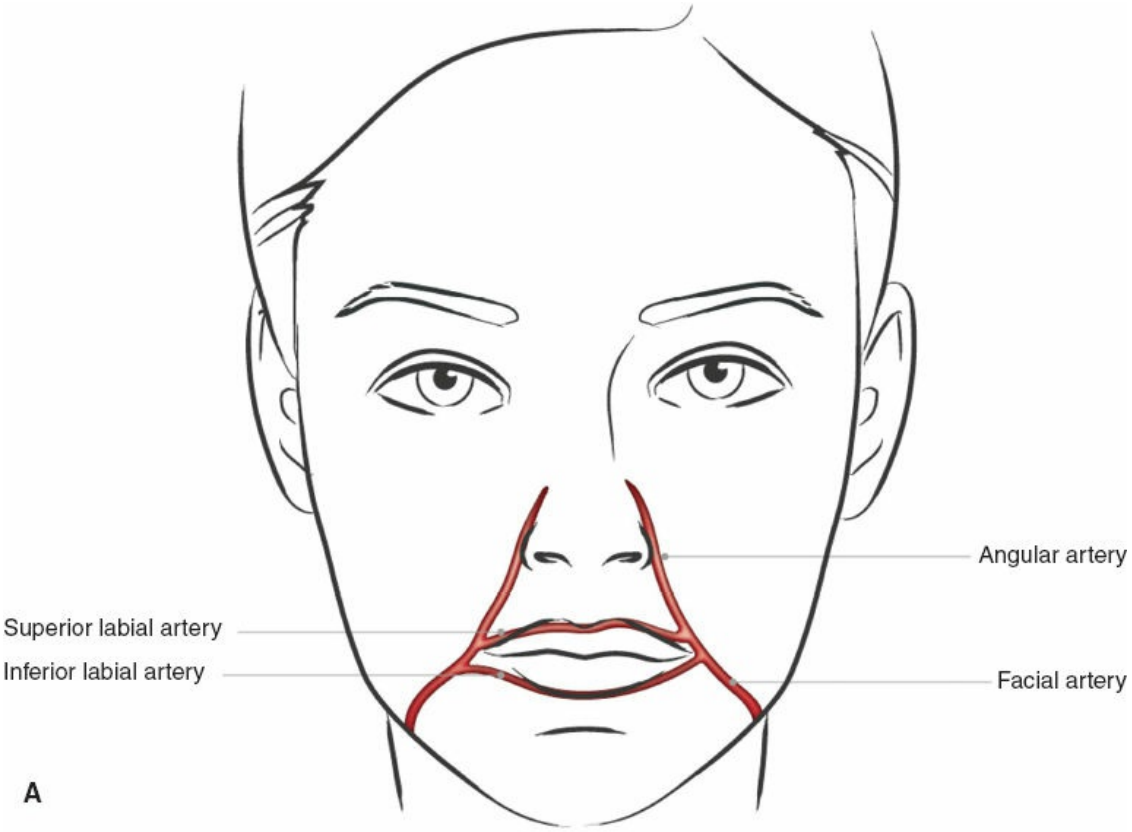
The motor innervation of the muscles of the upper lip is by the buccal branches of the facial nerve, whereas the lower lip muscles are innervated by the marginal mandibular branches of the facial nerve. Sensory innervation of the upper lip is provided by branches of the infraorbital nerve (V2), whereas sensory innervation of the lower lip is by branches of the inferior alveolar nerve (V3) via the mental foramen. The mental foramen is located at the level of the second mandibular premolar.

Of critical importance in reconstruction, the blood supply of the lips is provided by branches of the facial artery—the superior and inferior labial arteries (Fig. 23.4A). These arteries travel roughly parallel to the lip surface and connect with the superior and inferior labial arteries from the contralateral side, forming a ring around the mouth. The labial arteries are found at the level of the mucocutaneous junction horizontally, but closer to the mucosal surface than the skin (Fig. 23.4B). They are approximately 1 mm in diameter. These vessels not only assure a rich blood supply to the lips and anterior mouth, they also have adequate flow to serve as the basis for the regional flaps used in reconstruction of the lips.



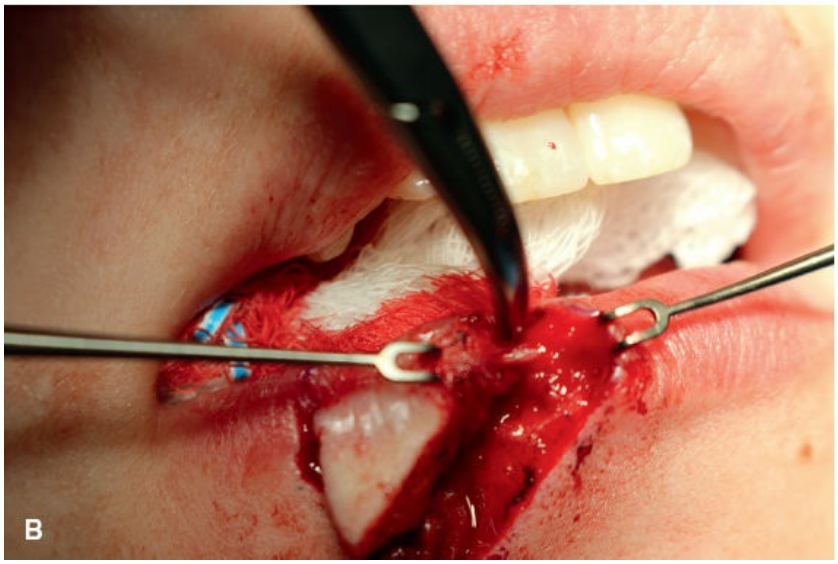


Figure 23.4. **A.** Arterial supply of the lips. **B.** Intra-op photo illustrating the position of the labial artery within the lip.

RECONSTRUCTION OF LIP DEFECTS

Reconstruction of the lip must address both aesthetic and functional concerns. The lips are a center point of the face, and serve a crucial role in facial aesthetics and beauty. They are a focal point of human interaction. Therefore, attention to principles in reconstruction is essential for an

optimal aesthetic outcome. Burget and Menick, in a major contribution, developed the principles of aesthetic subunits, and an understanding of these principles is essential for optimizing aesthetic results. The upper lip protrudes further in front of the lower lip, and partially drapes over the lower lip. Consequently, the upper lip has a more important role in facial aesthetics than the lower lip does. This is a critical feature for repair of upper and lower lips.

It is equally crucial to recognize that the lip serves as a barrier, or dam, to prevent the escape of oral contents. The lower lip is more important in this function than the upper lip. An essential goal in lip reconstruction is to restore this barrier function, and to prevent drooling. No matter how perfect the lip reconstruction, drooling is an unacceptable functional outcome and will need to be either avoided or corrected. The lips form a well-coordinated sphincteric mechanism to allow for oral intake, and control the passage of solids, liquids, and air. The latter is very important for the role the lips play in speech production.

Whether the defect in the lip is due to trauma or cancer extirpation, there are certain fundamental principles that need to be followed in lip reconstruction. The first principle is that healing by secondary intention is not an acceptable approach. The lips are soft and supple, which is important in their appearance and their sphincteric function, and healing by secondary intention leads to significant cicatricial change and fibrosis. Furthermore, an additional important consideration is that when the ring of muscle surrounding the mouth has been interrupted, the ends will pull apart, and healing by secondary intention will often lead to a larger defect. Therefore, all defects of the orbicularis oris muscle need to be repaired at the muscle level. The second basic principle is that the use of “like” adjacent tissue is preferable in lip reconstruction for two primary reasons. The color match of the adjacent tissue is superior to other options in reconstructing this aesthetically sensitive area. Furthermore, the use of adjacent tissue allows en bloc reconstruction of the trilaminar defect (skin, muscle, and mucosa) created in full thickness lip loss. Also, although the tissue at time of transfer/reconstruction may be denervated, there is a demonstrated ability for this tissue to become reinnervated and regain adequate sensation and reasonable function. Primarily for these reasons, local and regional flap reconstruction of the lip is preferred where possible. It is important to be aware that any reconstruction of the lower lip must have adequate depth of the lower lip sulcus, otherwise drooling may result.

This is very important.

PRINCIPLES OF LIP RECONSTRUCTION

- Complete skin covering and oral lining
- Semblance of a vermillion
- Adequate stomal diameter to allow mouth opening
- Sensation
- Competent oral sphincter
- Adequate depth of the lower lip sulcus
- Favorable color match is desirable

VERMILLION DEFECTS AND PREMALIGNANT LESIONS

Resection limited to the vermillion is used for superficial lesions and premalignant change. Occasionally, it can be used in actinic cheilitis, a dysplastic condition of primarily the lower lip. Following resection of the vermillion, a procedure known as a “lip shave,” the lower lip is reconstructed by either release of the mucosa in the labial sulcus and direct advancement and repair of the defect through the use of this bipedicle technique, or by undermining the mucosa of the lower lip into the sulcus and advancing this flap and closing the defect. The latter approach has significantly more swelling, but both are effective. Additionally (and importantly), the vermillion can be resurfaced through the use of V-to-Y advancement flaps, buccal mucosal flaps, or a two-stage operation using a mucosal flap from the ventral surface of the tongue, with subsequent division and inset.

UPPER LIP DEFECT LESS THAN 30% OF LIP LENGTH

The upper and lower lips are approximately 7.5 cm to 8 cm in width, so excision of a 1.5-cm lesion with 5- to 7-mm margin will fall into the upper limits of this category of a 30% defect. In the lateral upper lip (lateral to the philtral columns), excision of lesions that are this size or smaller can be accomplished with a V-shaped excision or laterally extended V-shaped excision. In smaller lesions, since the majority are basal cell cancers, it may not be necessary to perform full-thickness excision. In larger lesions, it is frequently necessary to perform full-thickness excision. Great care must be exercised to appropriately align the white roll, the vermillion

border, and the free border of the lip. In full thickness excision, prior to injection of anesthetic with epinephrine, it is necessary to “tattoo” the lip at the vermillion border/white roll with a full thickness through and through passage of a 30-gauge needle coated with methylene blue. When injected with topical anesthetic with epinephrine, the lip will blanch due to the vasoconstrictive effects of the epinephrine. This makes recognition of the landmarks and vermillion border difficult to detect and accurate repair exceedingly difficult. The methylene blue tattoo points facilitate accurate repair. In addition, care should be taken to design the incisions such that they cross the vermillion border at a 90-degree angle, perpendicular to the lip. This helps with accurate alignment in repair and favorable healing.

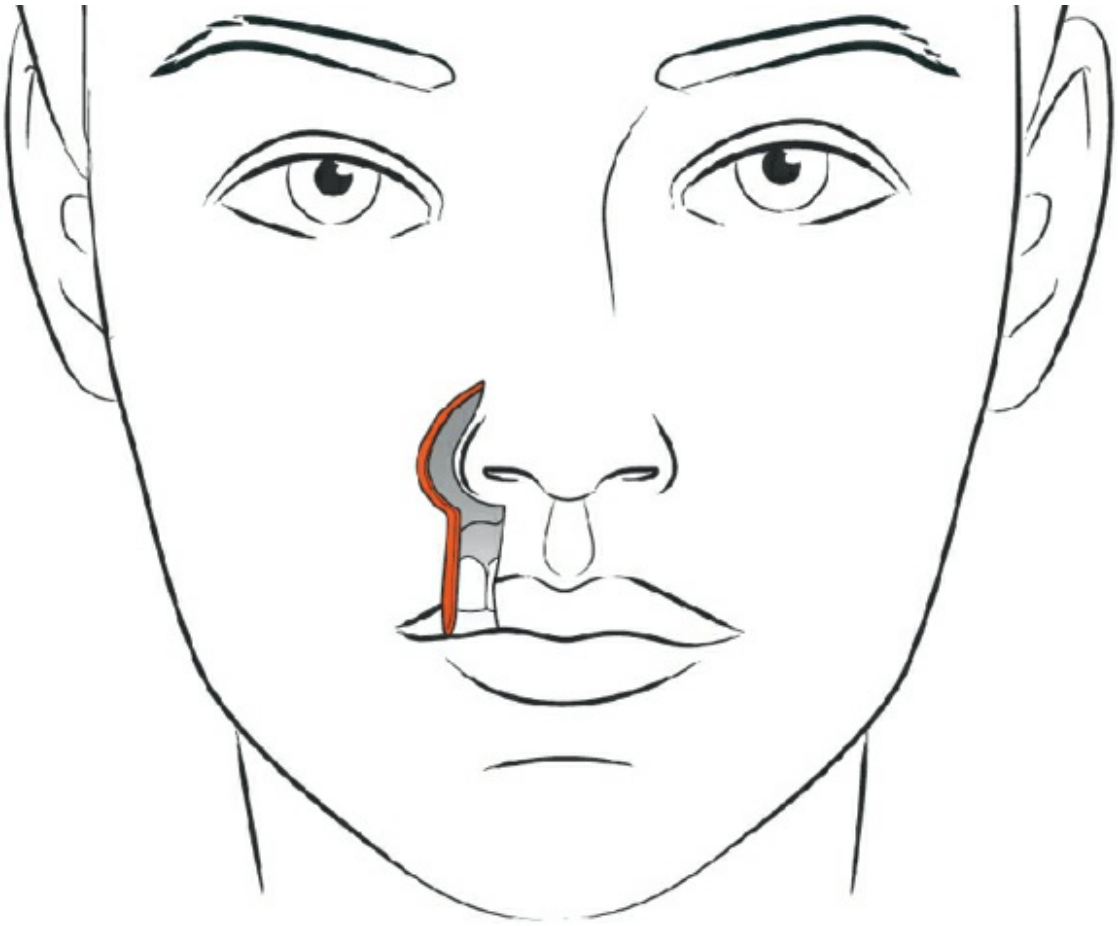

Figure 23.5. Peri-alar crescentic excision to facilitate lip closure.

It is important to understand that the upper lip will tolerate less of an excision than the lower lip before it appears and feels tight. Release of the tissue from the pyriform aperture by means of a full thickness incision through the upper labial sulcus can help, but displacement of the philtral columns and central upper lip must be avoided to prevent an unnatural

appearance. Webster described crescentic excision of peri-alar tissue in 1955 as an adjunct to lip excision, and this can also be performed to aid mobility of the upper lip flaps and improve the aesthetic result of the reconstruction by minimizing tension and deformity (Fig. 23.5).

If the site of the upper lip defect involves the majority of the central upper lip, repair can either utilize bilateral peri-alar excisions, or tissue can be transferred in from the lower lip through the use of an Abbe flap. The Abbe cross-lip flap is a workhorse in upper lip reconstruction that can minimize tightness of the upper lip, and can also lead to an improved aesthetic result. The disadvantage of the Abbe flap is that it requires a second stage for division and inset.

For reconstruction of the upper lip, the Abbe flap is based upon the inferior labial artery (Fig. 23.6A). The labial artery traverses the lower lip beneath the inner mucosal surface of the lip. It typically runs at the same horizontal level as the vermillion border, but in regard to depth lies more between the inner mucosal aspect of the lip and the center of the lower lip (Fig. 23.4B). The Abbe flap is designed such that the pedicle or hinge point is centered toward the edge of the excision on the contralateral lip. The flap should be designed to be approximately one-half the width of the upper lip defect, with the hinge point designed approximately one-half the way across the upper lip defect (again, very important). The flap is cut as a full thickness flap through skin, mucosa, and muscle. The dissection toward the labial artery from below the labial artery must be done meticulously. The hinge point/pedicle should be maintained at the full width of the vermillion to allow venous drainage and to provide strength to the pedicle to protect from the tension if the patient tries to open his mouth (Fig. 23.6B). The patient remains on a liquid diet.

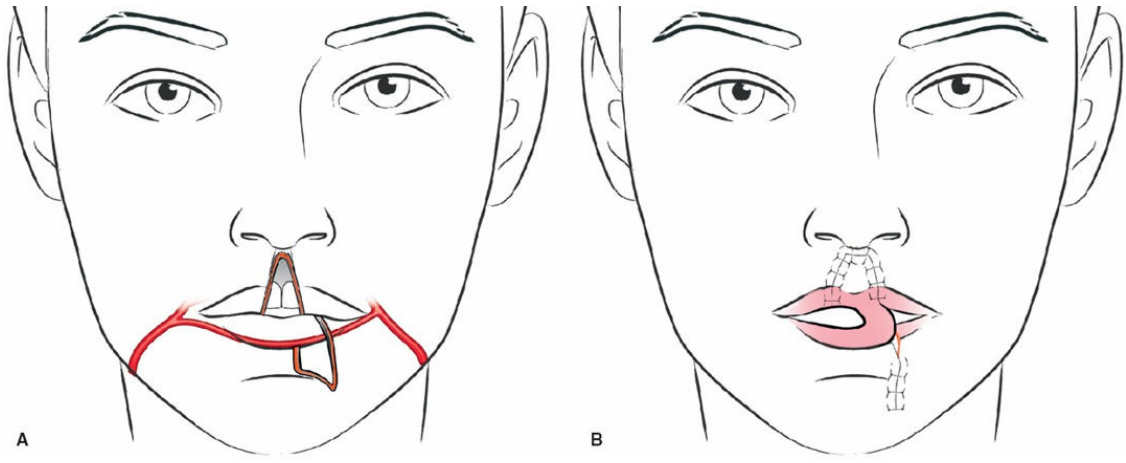

Figure 23.6. A. Abbe flap for reconstruction of central defect of

upper lip. **B.** Abbe flap following transfer and inset.

During the second stage, which occurs 2 to 3 weeks later, the labial artery is ligated and the pedicle completely divided. Care must be taken during the closure of the donor lip to align the vermillion border and the free border of the lip. This donor lip usually heals favorably. The inset of the flap in the upper lip is then undertaken, taking care to align the vermillion border. However, unlike the “donor” lip (lower lip in this case), it is frequently necessary to revise the inset. This can usually be accomplished under local anesthesia.

LOWER LIP DEFECT LESS THAN 30% OF LIP LENGTH

Unlike the upper lip, the lower lip does not have the discrete central area of Cupid’s bow and the philtral columns. If the defect in the lower lip is less than 30% of the lip width, V-shaped excision and direct closure is the preferable choice. The lower lip, however, does have the labiomental crease that is best avoided. An incision that violates the labiomental crease is prone to hypertrophic scarring and banding across the sulcus, a problem that is difficult to rectify in this area. The excision can be designed to create a V-shaped defect or a laterally extended V-shaped defect if the excision would cross the labiomental crease, since crossing this frequently leads to unfavorable hypertrophic scarring (Fig. 23.7). W-shaped excisions may also be used (Fig. 23.8). Again, like the upper lip, accurate alignment of the vermillion border is crucial, and the same techniques with methylene blue tattoo may be employed.

UPPER LIP DEFECT FROM 30% TO 60% OF LIP LENGTH

Moderate size defects of the upper lip can be reconstructed in three ways. Webster described the technique of peri-alar crescentic excision (Fig. 23.5). This is a powerful technique that allows cheek tissue to be swept in to reconstruct the upper lip defect. It enjoys favorable color match and favorable tissue characteristics, and yields very favorable aesthetic results. As the upper lip defect increases in size, it is frequently necessary to combine different options for optimal results. This frequently involves a pedicled local flap transfer. If the defect in the lateral upper lip segment involves more than 50% to 60% of the width of that lateral segment, the

reconstruction of the lateral segment can be accomplished with an Abbe flap (Fig. 23.6A,B). The Abbe flap, described above, can be used as an adjunct to peri-alar crescentic excision if the defect includes the central portion of the upper lip, or if the defect involves a greater extent of the upper lip and additional tissue is required to avoid tightness. Burget and Menick recommend completion of resection of the subunit of the lateral upper lip and transfer of a “block” of tissue as an Abbe flap to reconstruct the lateral upper lip.

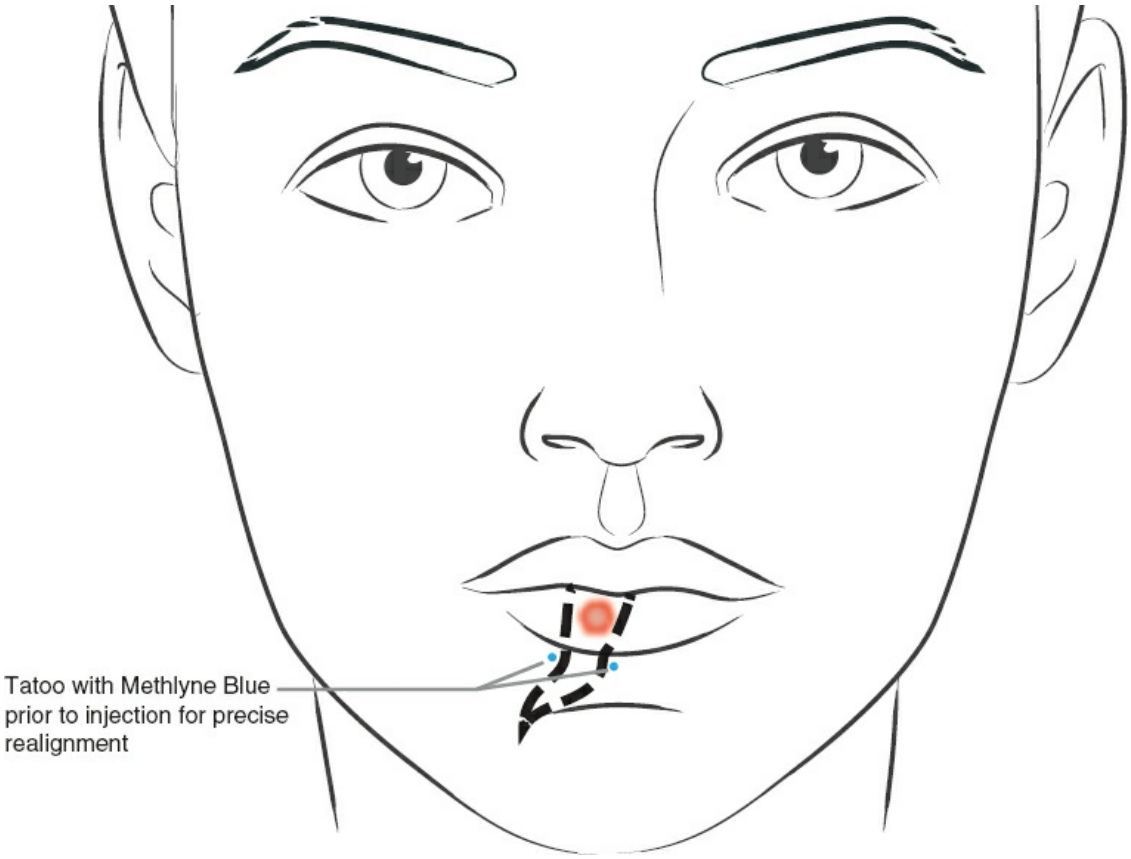

Figure 23.7. Laterally extended V-excision to avoid labiomental crease.

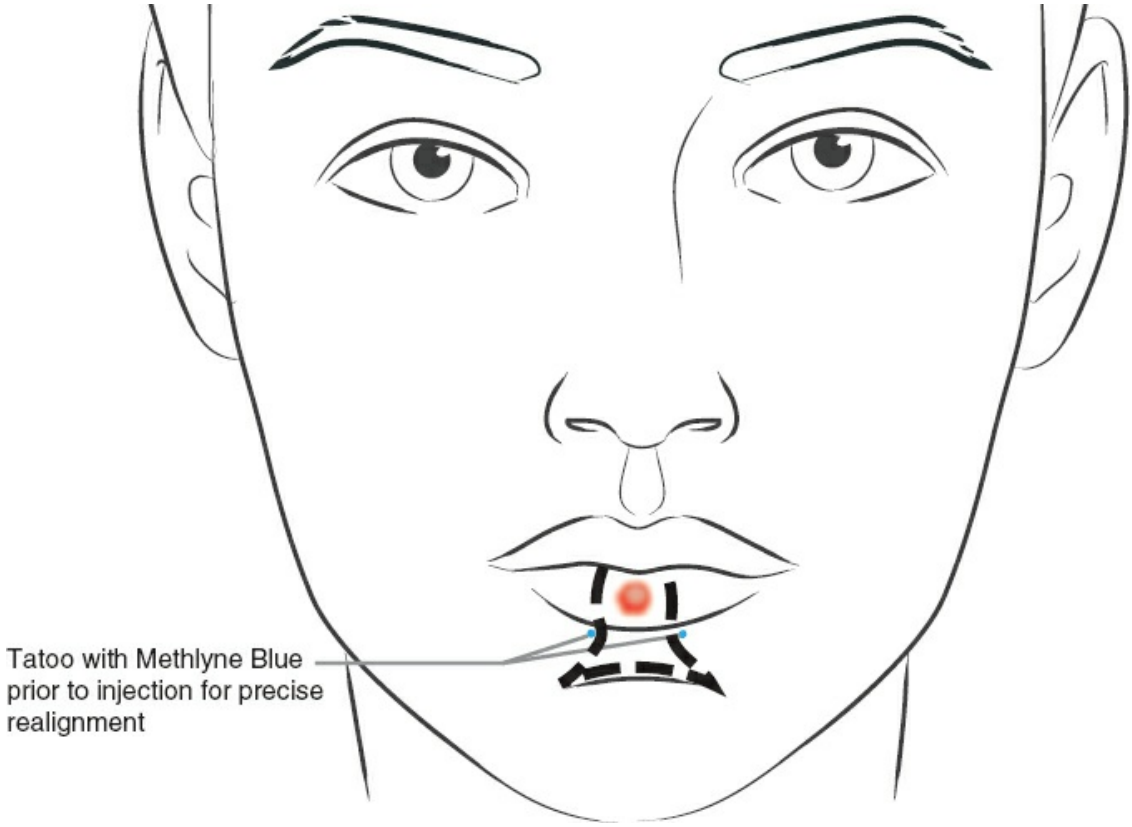

Figure 23.8. W-shaped excision of central lower lip.

LOWER LIP DEFECT FROM 30% TO 60% OF LIP LENGTH

As the lower lip defect approaches or exceeds 40% of the lower lip, simple excision and closure results in too large of a defect to allow closure without lower lip tightness. Fortunately, a number of options are available to help maintain oral competence and closure. In planning these operations, one must always be cognizant of incisions and denervation of tissue, since denervation can contribute to drooling and a loss of competence of the oral sphincter.

For central defects of the lower lip, the Schuchardt operation is analogous conceptually to the crescentic excisions around the alar bases, except that the crescents are taken around the chin. The crescentic excision provides for additional central movement of lateral lip elements to reconstruct a central lower lip defect (Fig. 23.9). The Bernard operation is an extension of the principle of the Schuchardt operation, but adds additional movement. The Bernard operation added full thickness excision of triangles of the upper lip along the nasolabial lines, enhancing movement and allowing larger defects to be corrected (Fig. 23.10).

Webster suggested a modification of this operation that included making only partial thickness nasolabial excisions (not full thickness), more extensive mobilization of the lower lip flaps, and using mucosal flaps to recreate a semblance of vermillion (Fig. 23.10).

Other options in lower lip reconstruction include the Estlander pedicle flap, which essentially is a modification of the Abbe flap that pivots around the intact oral commissure (Fig. 23.11). This flap allows a large block of composite tissue to be transferred to the lower lip, thereby restoring competence, and minimizing tightness of the lower lip. Like the Abbe flap, this flap should be designed to be approximately one-half the size of the lower lip defect. The Gillies fan flap is a modification of the Estlander flap that moves the commissure and causes some distortion because of this movement of the commissure (Fig. 23.12). McGregor described an alternative flap to the Gillies flap that pivots around the commissure, which causes less distortion (Fig. 23.13). However, the McGregor flap does change the axis of muscle fibers in the lip reconstruction, and this does interfere with sphincteric function, lessening the oral competence of this type of reconstruction.

UPPER OR LOWER LIP DEFECTS GREATER THAN 66%

If greater than two thirds of the upper lip or the lower lip has been lost, the ability to transfer local adjacent tissue and avoid microstomia is limited. There are two techniques for local tissue rearrangement that merit consideration. Karpandzic described a circumoral incision and release of the skin and muscle, preserving the neurovascular bundles to preserve blood flow and both motor and sensory innervation (Fig. 23.14). This is a challenging operation to perform because of the requisite identification of the nerve fibers, and can be assisted through the use of a nerve stimulator. The operation can be used in defects of up to 80% of the upper lip or the lower lip. The scars in the Karapandzic operation can be problematic, and microstomia is also a common complication.

Fujimori described the use of “gate flaps” for reconstruction of the lower lip, which essentially are inferiorly based pedicle flaps that harvest angular artery and the block of tissue between the nasolabial fold and the oral commissure and nasal ala, turning them medially for lower lip reconstruction (Fig. 23.15). The flaps are harvested with a contiguous flap of buccal mucosa, which are turned over and used to create a semblance of the vermillion. The flaps are insensate and lack effective motor function, but can provide an effective “dam” function. It should be noted that this technique also effectively denervates the upper lip to a large degree also.

When lip defects exceed 80%, local/regional flap transfer becomes limiting for many reasons—compromise of adjacent structures, microstomia, loss of sensation, and vascularity. It is at this point that reconstruction of the upper or lower lip often has to shift to free tissue transfer. Despite the fact that the transferred free tissue often has poor color match, lack of functionality, and compromised sensation, when lower defects become this large it is necessary to bring in tissue from elsewhere. An ideal tissue transfer that meets all the needs imposed by lip reconstruction (sensation, color match, functionality, tri-laminar construct) has yet to be identified. Reconstruction of the upper lip is perhaps easier to accomplish because the demands on the upper lip in providing lip competence are not as great as in the lower lip. If a static upper lip exists, then the lower lip can elevate and be brought into opposition. The

compromised sensation and significant demands imposed by the need to prevent drooling and maintain competence are not easily accomplished. The preferred choice by many surgeons for reconstruction of the upper or lower lip is the radial forearm flap, harvesting the palmaris longus tendon with the flap to serve as a sling for the free border of the upper or lower lip reconstruction. The ends of the palmaris longus tendon are anchored into either the modiolus, or an additional length of this tendon is harvested and the ends can be attached to the zygomas. If the tendon is inset too tightly, entropion of the lower lip can occur. A microneural anastomosis between the mental nerve and the lateral antebrachial cutaneous nerve can be performed to provide sensation, provided adequate length of the mental nerve exists following tumor resection.

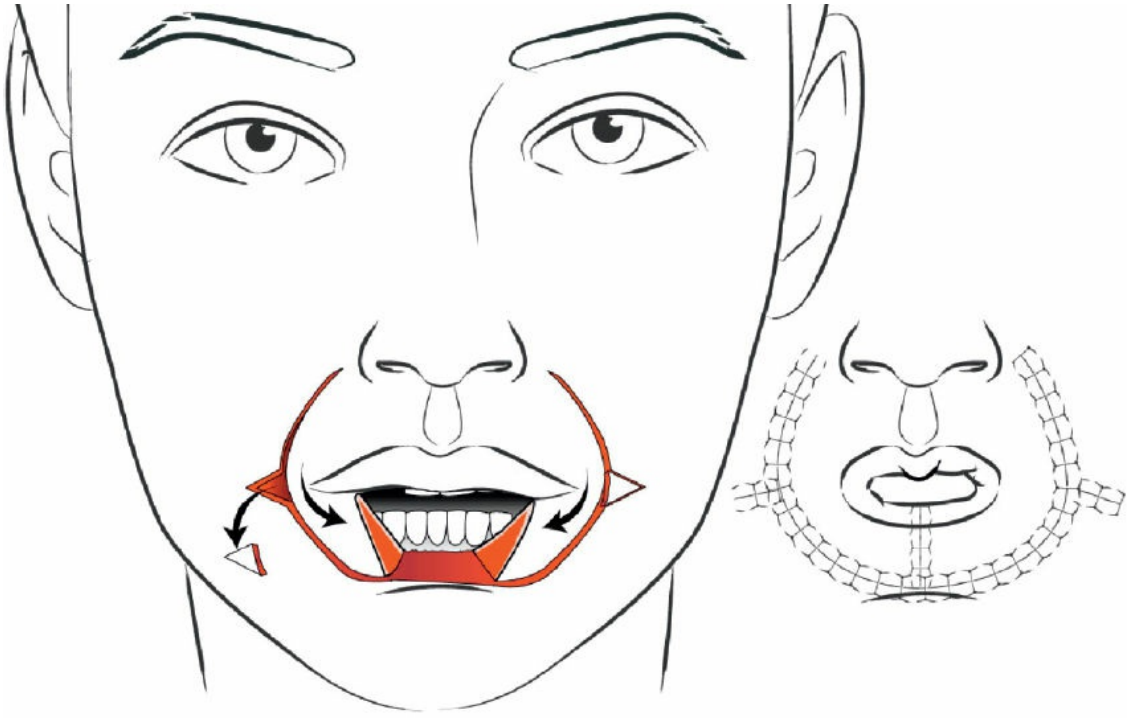

Figure 23.14. Karapandzic operation for reconstruction of larger upper and lower lip defects.

SUMMARY

Lip reconstruction must ideally attain two goals: reconstruction of an aesthetically acceptable lower face and reconstruction of the competence of the sphincteric function of the lips to prevent drooling. The upper lip is more important for aesthetic appearance, and the lower lip plays a larger role in lip function and competence to prevent drooling. Lip reconstruction for defects less than one third of the upper or lower lip is relatively straight

forward and can be readily accomplished with acceptable aesthetic and functional results. If the defect lies between one third and two thirds of the upper or lower lip, effective reconstruction relies upon labial artery vascular pedicle flap techniques, which may also be combined with adjunctive techniques (e.g., peri-alar crescentic excision and advancement). These techniques have the advantage of excellent color match and favorable aesthetic and acceptable functional results. As the defect begins to exceed two thirds of the upper or lower lip, the options for reconstruction begin to switch in favor of free tissue transfer for reconstruction. Common choices include the radial forearm flap or the parascapular flap. These tissues provide pliable reconstruction of the lip contours. In all cases, the tongue can be used to transfer mucosa for the pink vermillion and mucosa.

EDITOR'S COMMENT

Lip reconstruction is one of the most aesthetically and functionally important techniques in surgery. The lips are the focal point of the lower face and differences in anatomic alignment as little as 1 mm will be noticeable to others. Loss of lip function/oral competence results in drooling, difficulty eating, and social isolation greatly diminishing the quality of life for affected individuals. Successful reconstruction addresses both the aesthetic and functional deficits by following fundamental principles and first and foremost among them is that healing by secondary intent is not acceptable. The underlying muscles will pull the defect apart making it larger and the scar will not match and will distort the unique and delicate anatomy of the lips. Thus, there needs to be a plan for immediate lip reconstruction prior to taking the patient to the operating theater.

Detailed knowledge of the anatomy of the lips is essential to the planning and execution of a successful reconstruction. The lips have an outer layer of either skin and/or vermillion (dry mucosa) with the junction of the skin and vermillion highlighted by the white roll; a central layer consisting of the muscles, nerves, labial vessels, and salivary glands; and an inner layer or lining consisting of oral mucosa. All three layers must be repaired or replaced when

performing lip reconstruction. Since this anatomy is so unique, adjacent tissues provide the best match to replace like with like and are generally used for reconstruction. The goals of lip reconstruction are clearly stated in the chapter: (1) replacement of skin and oral lining, (2) vermillion reconstruction, (3) adequate size oral aperture to prevent microstomia, (4) sensation, (5) oral competence, (6) well-defined lower lip sulcus of adequate depth, and (7) color match of soft tissues. The unique anatomy, the contribution of lip appearance to self-image, and multiple operative goals to restore function and appearance make lip reconstruction a demanding surgical procedure.

The approach to lip reconstruction depends on the size and location of the defect. Defects less than 30% of the length of the lip can generally be closed primarily. However, defects of the central upper lip are frequently reconstructed using an Abbe flap, which entails transferring tissue from the lower lip to the upper lip, to preserve or reconstruct the philtral columns. This provides a better aesthetic result than direct primary closure. The most challenging lip reconstruction cases are defects that involve all three layers of the lips and exceed 66% of lip length. There are multiple flaps that have been described to reconstruct these full-thickness defects including the Karapandzic, Nakajima, Webster-Bernard and Gillies fan flaps; and free tissue transfer using radial forearm flaps with palmaris longus tendon for full length defects of the lower lip. All of these flaps have limitations regarding their ability to achieve *all* the goals of lip reconstruction. The search for an optimal surgical technique to reconstruct these defects continues.

A group from China published the largest reported case series of 87 patients who had total (n = 73) or near-total (n = 14) lip reconstruction in a single stage using a variety of flaps. The total lip defects were all full thickness. Patients were assessed with regard to drooling severity and aesthetic appearance. The paper includes an algorithm for flap selection (Bai S, Li R-W, Xu Z-F, et al. Total and near-total lower lip reconstruction: 20 year experience. *J Craniomaxillofac Surg* 2015;43:367–72). Gupta et al. described the repair of a full-thickness total lower lip defect use of bilateral apposing nasolabial flaps to create the lining and skin and then a bipedicle (bucket-handle) flap containing a portion of the orbicularis oris muscle and lip mucosa to reconstruct the vermillion and provide functional muscle for oral competence. The patient had oral competence and sphincteric function, adequate mouth opening, and a good aesthetic result (Gupta S, Chattopadhyay D, Murmur MB, et al. A new technique for one-stage total lower lip reconstruction: Achieving the perfect balance. *Can J Plas Surg* 2013 Spring;21(1):57–61). A British group reported a new technique for single-stage reconstruction of full-thickness lower lip defects in two patients with near-total (70% to 90%) lip defects. They used bilateral commissurotomy to create skin and mucosal flaps and mobilized the risorius, depressor angularis oris, and depressor labii inferioris to reconstruct the three layers of lips. The muscles were mobilized and approximated in the midline and then covered with the skin and mucosal flaps. The distance between the

commissures was maintained by suturing the lateral ends of the skin flaps to the buccal mucosa in the desired position. Both patients had full muscle and sensory function with oral competence, adequate oral opening, and an excellent cosmetic result (Sayan A, Paraneetharan S, Hsu DWK, et al. Reconstruction of the lower lip using bilateral commissurotomy and advancement of skin, muscle and mucosal flaps. *Br J of Oral and Maxillofac Surg* 2016;54:1012–5). Lip reconstruction continues to challenge surgeons, but each innovation in surgical technique moves us closer to achieving the optimal results desired for our patients.

Gayle Gordillo

24 Surgery for Cancer of the Oral Cavity

William R. Carroll

In 1893, the 24th President of the United States set sail on a clandestine cruise from New York to his summer home in Massachusetts. On board, physicians had transformed the deck to a makeshift operating room. Grover Cleveland was anesthetized and a malignant oral cavity tumor was resected. The President recovered and lived another 16 years. The operation was later described as a remarkable procedure for the time. Ulysses Grant, Sigmund Freud, George Harrison, and Sammy Davis Jr. all suffered from oral cancer.

INCIDENCE, MORTALITY, AND ETIOLOGY

Worldwide, oral cavity cancer is the sixth most common cancer type. The American Cancer Society estimated that 39,500 new cases of cancer of the oral cavity and pharynx would occur in the United States in the year 2015. Approximately 7,500 will die of the disease. The mean age at diagnosis is 62 years and over 70% of patients are male. The death rate has been decreasing over the last 30 years. These cancers are more than twice as common in men. Surveillance Epidemiology and End Results (SEER) data from the National Cancer Institute reveal that the overall 5-year survival rate is 61.2. Racial/ethnic disparity for oral cancer is among the most striking for all cancer types and is most evident among men. Five-year survival rates are 63.7% for white men, and 38.3% for black men. Causes of the disparate survival rates likely include comorbidities, later-stage disease at presentation, differences in treatment received, and possible biologic differences in the tumor and host.

Eighty to 90% of oral cancers are squamous cell carcinoma. Roughly 90% of patients use tobacco in some form and 75% use alcohol. The effect is synergistic and the relative risk of developing oral cancer is increased 16-fold for individuals who use both. The risk of developing a second primary tumor is also dramatically increased in those who continue to

smoke following initial treatment (37% vs. 6% risk).

Disturbing cases of oral cancer are also seen in patients without obvious risk factors. Other possible causes include prolonged minor trauma from poor dentition, a diet low in fruits and vegetables, immunosuppression, and exposure to the human papillomavirus (HPV). HPV types 16 and 18 are closely linked with cervical cancer and are responsible for approximately 75% to 80% of oropharyngeal cancers in the western world. A much smaller percentage of oral cavity cancers may also be caused by oncogenic HPV subtypes but the the majority are related to other risk factors. Cancer of the lip is classified with oral cancer and is strongly correlated with sun exposure in fair-skinned individuals. AIDS patients, transplant recipients, and others who are immunocompromised by disease or medical therapy are at increased risk for oral cancer. The cancers that occur in these individuals are unfortunately biologically very aggressive.

Genetic changes within the oral mucosa are measurable well before the development of invasive carcinoma. Chronic exposure to carcinogens damages DNA over the mucosal field. The “field effect” of altered mucosa may be evident as far as 7 cm from an established malignancy. These alterations may activate or amplify oncogenes that promote tumor cell proliferation and inhibit or inactivate tumor suppressor genes. Tumor cells are able to escape programmed cell death and proliferate self-sufficiently. It was found that 70% to 80% of oral premalignant lesions contain changes in chromosome 9p21, which encodes the tumor suppressor genes p16 and $p14^{ARF}$. The epigenetic process of methylation of these genes is the apparent mechanism of inactivation. Mutation of the p53 tumor suppressor gene has received much attention in the literature but is probably a later event in malignant transformation. p53 mutations at the margin of resection have also been correlated with increased rate of recurrence despite histologically clear margins.

ANATOMY AND CLINICAL PRESENTATION

The oral cavity extends from the vermillion border of the lips to the anterior tonsillar pillar (Fig. 24.1). For staging purposes, the following subsites are considered part of the oral cavity: lip, oral tongue (anterior two thirds), floor of mouth, buccal mucosa, upper and lower alveolus, hard palate, and retromolar trigone. The oral cavity has rich lymphatic supply, and regional nodal metastases are typically the first site of spread. The primary lymphatic drainage basins are the perifacial, upper jugular,

submandibular, and submental nodes. Sites close to the midline often drain bilaterally.

The most common symptom of oral cancer is a nonhealing ulcer in the mouth followed by persistent pain. Other common symptoms include a mass, persistent halitosis, or bleeding. Trismus, loose teeth, neck mass, and difficulty with speech or swallowing usually indicate more advanced disease. When symptoms persist longer than 3 weeks, a focused examination for oral cancer is imperative.

Oral cancer arises most commonly in the floor of mouth, followed by the lateral tongue. The distribution by site is summarized in Figure 24.1. Diagnosis is usually made in the office by simple physical examination and biopsy using local anesthesia. Oral cancer is often very curable when detected at an early stage. The same is not true of later-stage disease. The ease of examination and access for biopsy make late recognition of disease particularly regrettable.

STAGING AND DIAGNOSTIC WORK-UP

Oral cavity cancers are staged according to 7th edition (2010) American Joint Committee on Cancer (AJCC) guidelines. T1 to T3 tumors are staged only on the basis of size (Table 24.1). T4 tumors are subdivided into T4a and T4b according to the degree of invasion of surrounding structures and ultimate resectability. The TNM staging system does not yet include depth of invasion as a staging variable for oral cavity tumors. Many investigators have shown, however, that depth of invasion correlates directly with frequency of nodal metastasis. Most surgeons feel that a T1 tumor with a depth of invasion greater than 4 mm has a greater chance of developing nodal metastases than a T2 or T3 tumor that is very superficial.

The staging workup for oral cavity tumors includes a complete physical examination with focused mucosal examination of the upper aerodigestive tract and careful nodal examination. Careful palpation of the oral cavity is crucial in the staging workup as many of these tumors have unsuspected submucosal extension (particularly tongue cancers). Computed tomography (CT) scans of the primary site and neck may assist accurate locoregional staging. A search for distant metastases includes a chest radiograph and liver function tests at a minimum. CT scans of the chest and abdomen are indicated in patients considered to be at higher risk of distant disease. Positron emission tomography (PET) scans are not considered a routine part of the staging workup for head and neck cancer

at this time. Because second primary tumors are detected in about 10% of patients, an examination under anesthesia (direct laryngoscopy, esophagoscopy) is performed prior to treatment initiation. Bronchoscopy is recommended only for patients with evidence of subglottic disease, persistent cough, or suspicious chest radiography findings.

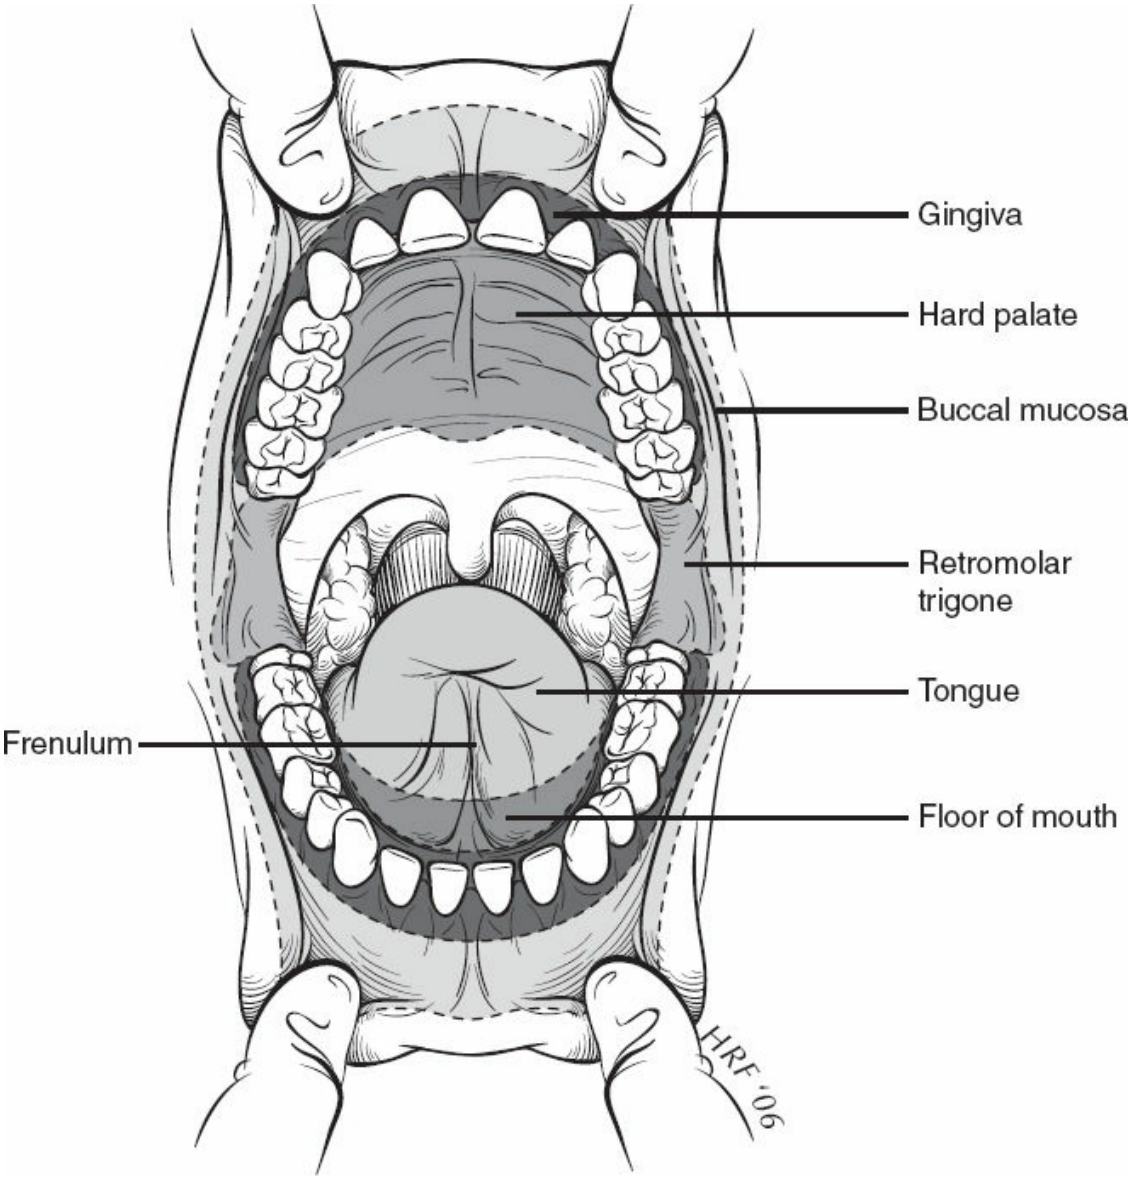

Figure 24.1. Subsites of the oral cavity.

TABLE 24.1 AJCC TNM Staging of Oral Cavity Cancer

T1: Tumor less than or equal to 2-cm diameter
T2: Tumor 2–4-cm diameter
T3: Tumor is greater than 4-cm diameter.
T4a: (Moderately advanced local disease)
Tumor invading adjacent structures (mandible, maxilla, extrinsic muscle of tongue, facial skin)
T4b: (very advanced local disease)
Tumor invading adjacent structures and in many cases considered unresectable (pterygoid plates, skull base, masticator space, carotid artery)

Imaging techniques designed to detect dysplastic changes in oral mucosa may ultimately improve early detection and margin control for oral cavity cancer. Confocal microscopy, radiolabelled antibodies to tumor markers, narrow band imaging, and multiwavelength fluorescence and reflectance technology are technologies designed to detect subclinical disease in at risk patients or to identify dysplasia at the margins of known cancers.

TREATMENT

Current treatment guidelines for head and neck squamous cell carcinoma are published by the National Comprehensive Cancer Network (www.nccn.org). The guidelines include staging information, recommendations for pretreatment assessment, and a balanced approach to treatment options for oral cavity cancers. Optimal treatment of head and neck cancer requires a multidisciplinary effort. Team members include a head and neck surgeon, reconstructive surgeon, radiation oncologist, and medical oncologist. Speech and swallowing pathologists rehabilitate function lost during multimodal therapy. Other important team members include dentists, prosthodontists, nutritionists, and social workers. For patients with advanced or recurrent disease, treatment recommendations are optimally considered in a multispecialty tumor-board format. A

coordinated team approach is essential.

In this chapter, treatment of oral cancer will be divided into two main sections: a general discussion of early-stage and locally advanced disease followed by specific recommendations for each subsite. The primary focus is surgical management. Alternative options will be included, but detailed descriptions are beyond the scope of this chapter. Treatment of metastatic neck disease is covered elsewhere in this text and is integral to proper management of the primary site.

Carcinoma in Situ or Microinvasive Carcinoma

Early, very superficial disease within the oral cavity is best treated by wide local excision. When disease is limited to carcinoma in situ on final pathology, an excisional biopsy with clear margins is adequate therapy. The site should be followed closely clinically with a low threshold for rebiopsy or reexcision. Microinvasive carcinoma should be excised with a 1- to 2-cm margin on the peripheral and deep aspects. Frozen sections are studied intraoperatively as severe dysplasia at the margin can be difficult to discern grossly (Fig. 24.2). Early-stage cancers of the floor of the mouth may involve the salivary ducts, and gain early access to the neck. The nodal status requires careful assessment.

Primary closure of the site is optimal if it can be accomplished without tethering the tongue or obliterating normal sulci. The surgeon should have little hesitation to allow these superficial defects to granulate. Healing by secondary intention is preferable to a closure that impairs mobility. Occasionally, a larger but very superficial lesion will be excised at the submucosal layer. A thin split-thickness skin graft will cover a larger area effectively and speed the recovery process. Commercially available dermal allografts have been uniformly unsuccessful in the oral cavity in our hands.

Figure 24.2. Leukoplakia of the lateral tongue. One nodular area contained microinvasive carcinoma.

T1 and T2 Carcinoma of the Oral Cavity

Five-year survival rates are 85% to 90% for stage I and 70% to 80% for stage II squamous cell carcinomas of the oral cavity. Single modality therapy is usually adequate. Surgery and radiotherapy are generally considered equally effective, but in most cases surgery is preferred for early-stage disease. Radiation therapy for early-stage oral cavity cancer is effective when delivered either by external beam or by brachytherapy. Xerostomia and dental disease are more commonly seen following radiotherapy, and there is risk of osteoradionecrosis of the mandible. Fewer studies have critically compared functional outcomes of radiation therapy with surgery. Whichever modality is chosen, treatment of the primary site and neck should be consistent. In other words, if the primary site is treated surgically and there is concern over micrometastases, the neck should be treated surgically as well. Likewise, if the oral cavity is treated with radiation, the lymphatics are treated similarly.

Surgical treatment for stage I and II oral cavity cancer is consistently recommended initially by our institution’s multispecialty tumor board.
