Surgical treatment is effective and completed quickly with minimal impairment of form or function. The typical hospital stay is 1 or 2 nights, oral intake is resumed quickly, and patients typically resume full activity within 3 weeks. Even those individuals with occupations demanding precise oral function (attorneys, professors, salespersons) have typically enjoyed very favorable outcomes.

In planning resection, the surgeon must consider route of access, margin status, bone involvement, and whether or not lymphatics require treatment. Route of access is preferably transoral for smaller lesions. The margins must be clearly visible, however, and patients with full dentition or limited oral opening can present access challenges for even small lesions. A lip split and/or mandibulotomy may be required for adequate visualization of margins. Margins of 2 cm on all sides are ideal for these lesions.

As a word of caution, the first attempt at removing these lesions has the greatest chance of success. Each subsequent attempt at salvage has a decreasing yield. To withhold a full curative effort for a minimal cosmetic or functional benefit is a disservice to the patient.

Bone will not be grossly invaded in these early-stage I and II lesions, although dysplastic mucosa or the main malignancy may approach the teeth or mandibular periosteum. In general, the periosteum is an effective barrier if not previously radiated. If the tumor is freely mobile with relation to the bone, the periosteum is resected as a margin and the bone preserved. The alveolar surface of the mandible is vulnerable to microinvasion and allows access to the medullary cavity through the tooth sockets. The risk of microinvasion of the mandible is higher in an edentulous or previously radiated mandible. When tumor directly invades the periosteum, that segment of mandible should be resected with at least a rim mandibulectomy.

The risk of micrometastasis to cervical lymphatics is increased proportionally with the depth of tumor invasion. As a general rule, tumors that measure greater than 4 mm in thickness are at risk, and treatment of cervical lymphatics should be considered.

Sentinel Lymph Node Biopsy

Some centers, primarily in Europe, are using sentinel lymph node biopsy (SLNB) routinely in the management of early (T1 and T2) oral cavity cancers with clinically node-negative necks. (Clinically node-positive patients are treated with selective neck dissection.) Similar to SLNB in

melanoma or breast cancer, SLNB involves peritumoral injection with a radiocolloid, followed by lymphoscintigraphy and intraoperative gamma probe localization. The primary tumor is usually resected prior to lymph node localization so that radioactive “shine-through” from the primary site does not impede detection of radiotracer in adjacent lymph node levels. Most surgeons utilize SLNB in a staged fashion, allowing permanent analysis of sampled nodes before deciding if completion neck dissection is indicated.

In most studies, the negative predictive value of SLNB is 90% to 100% for oral cavity cancers. The serial sectioning and immunohistochemical analysis used in analyzing the sampled nodes improve predictive value and may upstage the nodal basin compared to traditional lymphadenectomy. SLNB may also identify unexpected patterns of lymphatic drainage, that is, nodes detected in levels that would not have been sampled in routine selective neck dissection. Authors have also demonstrated decreased wound complications and lower incidence of neuropraxia with SLNB compared to selective neck dissection.

SLNB has been primarily used in the setting of clinical trials in the United States. The National Comprehensive Cancer Network (NCCN) recognized the procedure in 2013 stating: “Sentinel lymph node biopsy is an alternative to elective neck dissection for the identification of occult cervical metastasis in patients with early (T1 or T2) oral cavity carcinoma in centers where experience for this procedure is available. Its advantages include decreased morbidity and improved cosmetic outcome.” Many surgeons remain concerned about the small numbers of false negatives (positive nodes become clinically evident at a later date). Others note that unlike melanoma or breast cancer, lymphadenectomy in oral cavity cancer has a distinct therapeutic role and is not primarily prognostic. These surgeons are concerned that SLNB may violate tissue planes adjacent to the great vessels and could allow recurrent disease to invade structures protected by undisturbed fascial barriers. SLNB is a procedure in evolution for oral cavity cancer. Elective node dissection or radiotherapy for at-risk patients with early-stage oral cancer in the United States remains standard for most US centers as of this writing.

T3 and T4 Carcinoma of the Oral Cavity

Large oral cavity cancers and those that deeply invade the tongue, bone, or adjacent spaces require multimodal therapy. Survival rates for T3 and T4

squamous cell carcinoma of the oral cavity are 50% to 65% in the absence of nodal metastases. Nodal metastases generally cut survival rates in half. Primary surgical resection remains the preferred initial treatment option. In contrast, advanced oropharyngeal malignancies are often treated initially with chemoradiation. When planning resection, the surgeon again must consider the lymphatics, access, bone involvement, and reconstruction as these defects can rarely be closed primarily.

Surgical treatment of the neck to control lymphatic disease and to provide access to the primary tumor is routine. Rarely can a T3 or T4 lesion be adequately resected by a transoral-only approach. Exposure of the neck allows preservation of important neurovascular structures and facilitates management of the deep margin of resection. Well-lateralized lesions that do not involve the deep tongue muscle may be adequately managed with a unilateral neck dissection. Clinically N0 necks are treated with a selective neck dissection, which carries very little morbidity (see Chapter 25). Edentulous patients with pliable perioral soft tissue may not require a lip split for access from the oral side. Again, if visualization of the margins is impaired, lip split or mandibulotomy is recommended as necessary to allow proper exposure. Complete tumor resection should be the primary concern.

Gross invasion of the mandible mandates a segmental resection. Whenever possible, the entire medullary cavity of the mandible should be resected. Tumor invading the mandible can spread widely through the loose cancellous bone. For example, if a lesion invades the midbody of the mandible, segmental resection of bone with a 2-cm margin is combined with rim removal of the remaining medullary cavity back to the sigmoid notch.

Reconstruction will often require more than primary closure. In some lateral composite resections, surprisingly large defects can be closed primarily when no bone reconstruction is planned. The disfigurement is pronounced, however, and most patients prefer immediate surgical reconstruction. Return of a more normal appearance and ability to chew are important aspects of quality of life. Large glossectomy and full-thickness buccal defects cannot be closed without supplemental tissue. Vascularized free tissue transfer has become the mainstay of surgical reconstruction for large oral cavity defects. Soft tissue defects are usually repaired with radial forearm, anterolateral thigh, or rectus abdominus flaps. Mandibular defects are managed with osteocutaneous flaps, the fibular flap

being the most common.

SITE-SPECIFIC SURGICAL MANAGEMENT

Floor of Mouth

The floor of mouth is the most common site for oral squamous cell carcinoma. The adjacent ventral tongue and lingual surface of the mandibular alveolus are involved early as the tumor enlarges. Anteriorly, floor-of-mouth lesions often involve the submandibular ducts and contralateral nodes are at risk. CT scans are useful in preoperative staging to assess tumor extent, nodal status, and early mandibular invasion.

T1 and T2 Carcinoma of the Floor of Mouth

T1 and T2 lesions of the floor of mouth are treated with wide local excision (Fig. 24.3). A margin of 2 cm is recommended and frozen section control of margins intraoperatively may avoid overlooking severe dysplasia in surprisingly normal-appearing mucosa. Lesions deeper than 4 mm have a higher incidence of nodal metastasis, and an elective selective neck dissection should be considered. Transoral access without lip split or mandibulotomy is often possible. Full dentition or poor oral opening can make access surprisingly difficult for small lesions. The patient should be prepared for mandibulotomy for access should this occur.

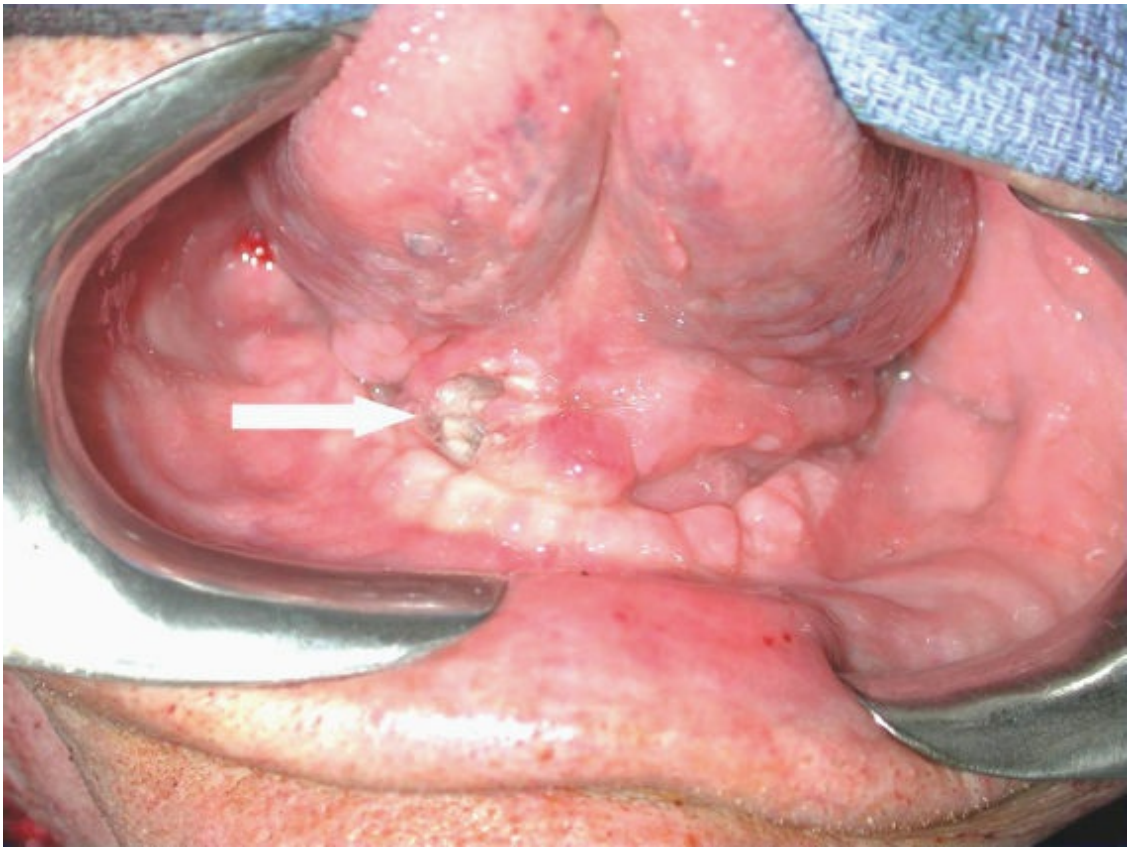

Figure 24.3. Early-stage carcinoma of the anterior floor of mouth.

When deep dissection in the lateral floor of mouth is combined with level 1 neck dissection, a through-and-through defect often results that can be surprisingly difficult to close. Pedicled flaps such as the platysma flap or submental island flap are useful to close these small defects. Radial forearm free flaps work very nicely as well. Pectoralis flaps are often too bulky for small defects in this site.

T3 and T4 Carcinoma of the Floor of Mouth

T3 and T4 floor-of-mouth lesions are usually resected in conjunction with cervical lymphadenectomy. A reasonable plan of surgical progression is outlined below. These steps will be adaptable for other subsites in the oral cavity as well.

1. Repeat examination under anesthesia. Assess size, depth, structures involved, and proximity to mandible. Finalize thoughts on access and bone invasion.
2. Tracheotomy in most circumstances.
3. Percutaneous gastrostomy. If a short period of tube feeding is anticipated, place a nasogastric tube at the conclusion instead.
4. Neck dissection. Extent determined by nodal status. See Chapter 25 for

details.

5. Approach primary. Split lip and perform stair-step mandibulotomy anterior to the mental foramen if necessary for access (Fig. 24.4). For large tumors with gross bone invasion, plan the mandibulotomy at the anterior margin of bone resection. Bend and apply reconstruction or fracture plates prior to cutting bone unless the tumor extends through the lateral cortex. This step optimizes dental occlusion postoperatively. If segmental composite resection is planned, tumor visualization will be easier if the posterior bone cuts are completed at this time as well.
6. For tumors that contact the mandible without gross bone destruction, perform a rim mandibulectomy to remove the occlusal surface and medullary cavity of the involved bone (Fig. 24.5). Take care in edentulous patients as the inferior mandibular remnant may be very thin and prone to pathologic fracture.

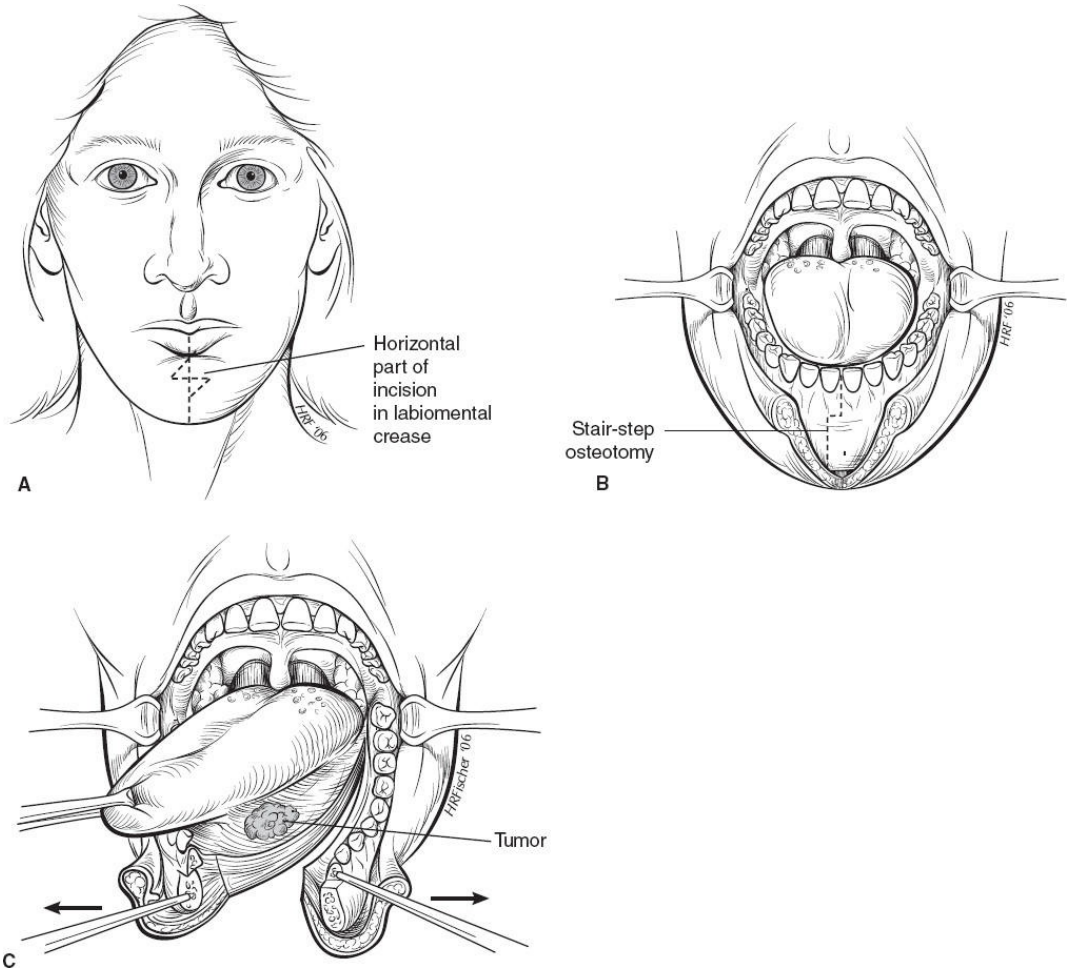

Figure 24.4. Transmandibular access to the floor of mouth. **A.** The lip split incision. The angles, based on the labiomental crease, prevent downward contracture from scarring. **B.** Stair-step osteotomy anterior to the mental foramen spares

sensation of the lip. **C.** Distraction of the segments allows exposure of the floor-of-mouth lesion.

7. Distract the mandible at the anterior osteotomy and visualize tumor margins. Make mucosal cuts 2 cm from obvious disease. As dissection progresses deeper, revisualize the hypoglossal nerve in the neck as it will often enter the tongue medial to the tumor and can be preserved. Control lingual artery branches with ligatures. Do not rely on cautery for the larger branches.
8. Remove the specimen and inspect. Orient the specimen for pathology. Check margins with frozen sections.
9. Inspect the defect and determine closure method. Avoid primary closure under tension or closures that will significantly tether the tongue. Often, the reconstructive team will have proceeded with flap elevation during the final phases of tumor extirpation.

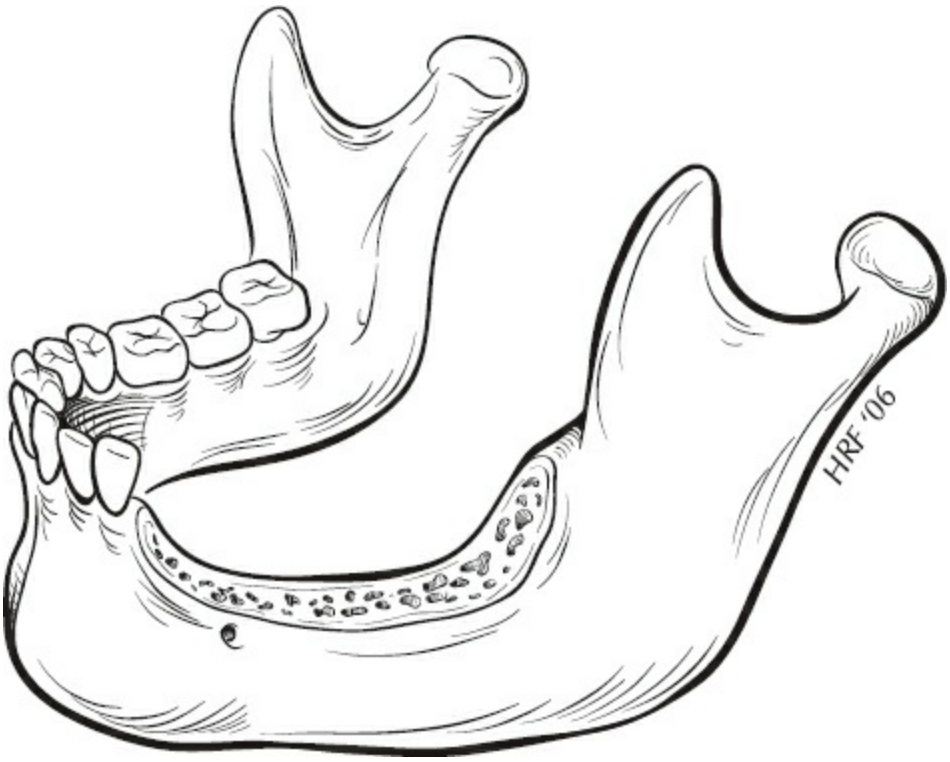

Figure 24.5. Rim mandibulectomy to resect disease involving periosteum or minimally invading the mandible. Resection includes the medullary cavity of the mandible.

Tongue

T1 and T2 Carcinoma of the Oral Tongue

Tongue cancers frequently have submucosal extension well beyond the

visible margin. Palpation and imaging studies are helpful in accurate staging. T2 and deep T1 (>4 mm) tongue cancers have occult metastatic rates approaching 30%. Treatment of the neck is usually recommended.

Small lateral tongue lesions can be widely excised with very little morbidity. These malignancies are generally more easily visualized than floor-of-mouth lesions and rarely require lip split or mandibulotomy. If possible, a deep wedge resection is designed in a vertical plane maintaining 2-cm margins at the peripheral and deep margins. The vertical resection allows closure of lateral tongue to corresponding lateral tongue and minimizes tethering (Fig. 24.6). Horizontal closure, in contrast, tethers the dorsal tongue to the floor of mouth and impairs mobility. Resection of superficial T2 tumors of the lateral tongue results in a defect involving most of the lateral surface (Fig. 24.7). These defects should be covered with a thin skin graft or allowed to granulate. The patient begins tongue mobility exercises early to prevent scar contracture and loss of function.

Dorsal tongue cancers are less common. These lesions are resected in a sagittal plane if possible and closed primarily. Function is usually excellent.

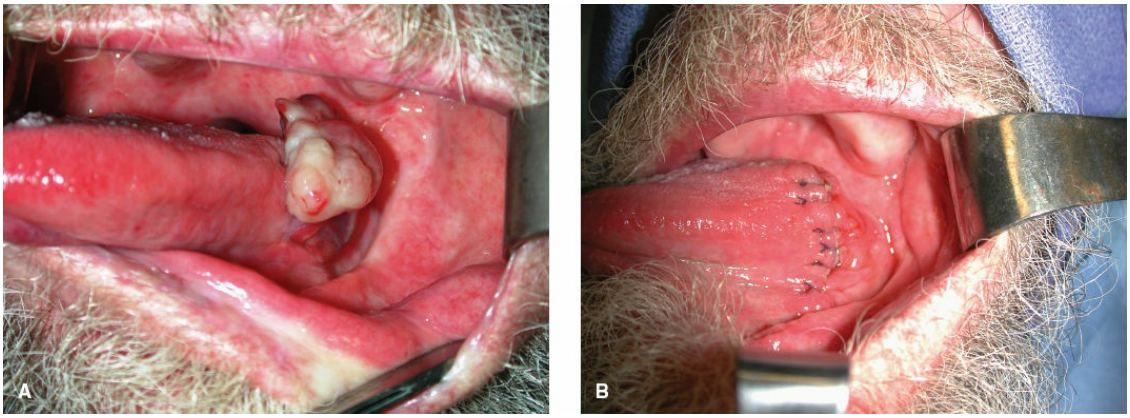

Figure 24.6. Resection of T1 carcinoma of the lateral tongue. **A.** Pedunculated lesion of the lateral tongue. **B.** Vertical excision and closure maintains optimal mobility.

Figure 24.7. Following resection of a T2 superficial lesion of the lateral tongue, primary closure is not feasible without severe restriction of motion. Options for closure include a split-thickness skin graft or healing by secondary intention.

T3 and T4 Carcinoma of the Oral Tongue

As noted, larger tongue cancers will require multimodal therapy. No treatment option has been found to be superior to surgery followed by radiotherapy for carcinoma of the oral tongue. These tumors may extend laterally into the adjacent mandible, or medially into the deep root of tongue musculature.

Large lateral tongue lesions are approached as described above under "Floor of Mouth." Osteotomies render the resection easier because the exposure is generous. These resections are the classic "commando" or "tongue–jaw–neck" procedures described for decades in the head and neck literature (Fig. 24.8). Primary closure of the buccal mucosa to the tongue remnant is often possible and speech and swallowing function are surprisingly good. The patient is unable to chew, however, and the appearance is dramatically altered. Immediate flap reconstruction is usually employed in modern resections.

For lesions that extend more centrally into the deep root of tongue musculature, an alternative pull-through approach to resection is required (Fig. 24.9). The steps are discussed below:

1. –3. Same as Floor of Mouth above.
4. Neck dissection should be bilateral for deep lesions extending toward the central tongue. A visor flap of the neck skin is raised to the inferior border of the mandible.
5. No lip split is usually required for access. The uninvolved floor-of-mouth mucosa is incised on the side of the tumor and continued onto the uninvolved contralateral tongue, maintaining 2-cm margins. Dissection will frequently extend across the midline. The mylohyoid muscle is transected from below. Working from above and below, the dissection progresses until the anterior and lateral cuts communicate from neck to oral cavity. The specimen is then delivered downward, under the intact mandible and into the neck. Following this maneuver, visualization of the posterior cuts is simplified and resection is completed (Fig. 24.10).
6. Assess margins grossly and by frozen section. Do not overlook deep tongue margins, which will extend down to the hyoid bone.
7. With an intact mandible, these lesions are nearly impossible to close without a pedicled or free flap.
8. If a large volume of tongue muscle is resected, the flap reconstruction should provide sufficient bulk to allow the neo-tongue to contact the palate. This will optimize speech and swallowing postoperatively. A radial forearm flap may not provide adequate volume in this setting.

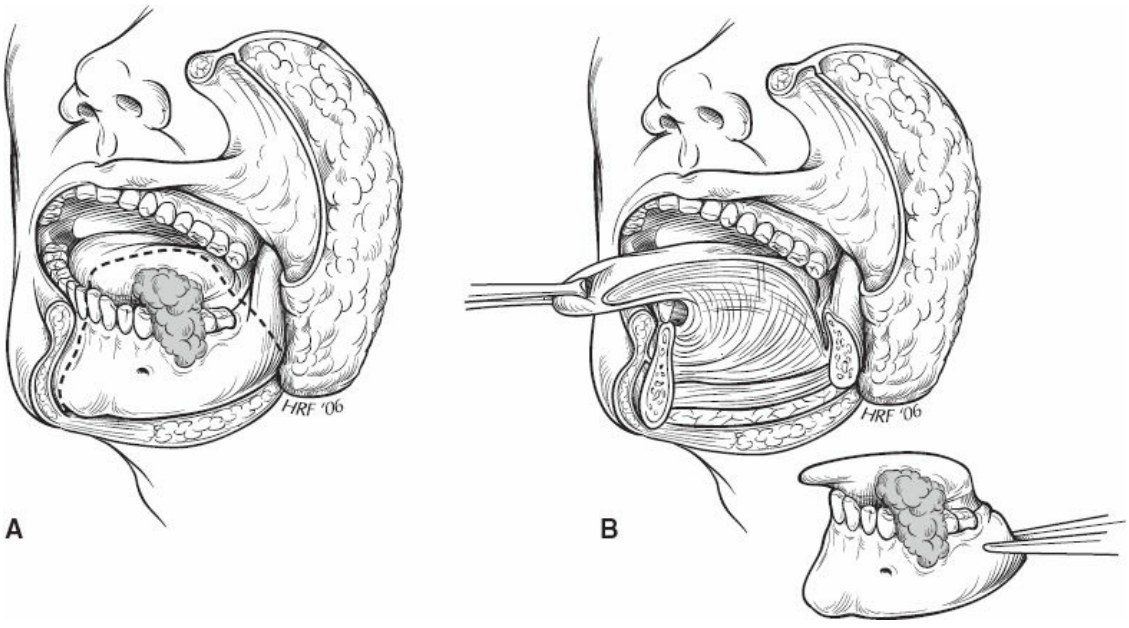

Figure 24.8. Composite resection for advanced oral tongue cancer involving the mandible. **A.** The cheek flap is reflected following a lip split. The bone cuts are positioned after

determining the location of tumor invasion. **B.** If the tumor does not extend lateral to the mandible, a reconstruction plate can be coapted prior to making the bone cuts.

Figure 24.9. Deeply invasive T3 carcinoma of the anterior tongue.

Large oral tongue lesions that arise more posteriorly warrant special mention. These lesions often involve the base of tongue extensively and/or may cross the midline anteriorly. Under these circumstances, surgical resection will require a near total glossectomy. The surgeon must carefully explain the functional implications of such a resection and ensure that the patient understands the alternative of concurrent chemotherapy and radiation with surgical salvage. In this particular circumstance, posttreatment function is probably superior with initial chemoradiation. The patient may wish to try nonsurgical treatment for organ preservation initially. Surgical salvage, if necessary, would still require a total glossectomy. Although no direct prospective comparisons exist for oral tongue primaries, case series data suggest that concurrent chemotherapy with surgical salvage should provide comparable cure rates to surgery and adjuvant radiation.

Buccal Mucosa and Retromolar Trigone

The buccal mucosa includes the pliable inner lining of the cheek, extending from the maxillary alveolus superiorly to the mandibular alveolus inferiorly. Posteriorly, the buccal mucosa is contiguous with the retromolar trigone. The mucosa of the retromolar trigone covers the ascending ramus of the mandible and extends posteriorly to the anterior tonsillar pillar at the start of the oropharynx. Carcinomas in this region usually are squamous cell and may be ulcerative, exophytic, or verrucous. Smokeless tobacco users are at higher risk of forming buccal cancer.

T1 and T2 Carcinomas of the Buccal Mucosa and Retromolar Trigone

Tumors of the buccal mucosa are relatively uncommon in the United States but are the most common site of oral cancer in countries of Southeast Asia (Fig. 24.11). In India, buccal cancer is the most common of all cancers occurring in men. Nodal metastases occur early (40% for T2 lesions in one meta-analysis). Early-stage carcinomas of this region are treated in a fashion similar to the floor of mouth. Wide local excision with 2-cm margins is recommended and primary closure for smaller defects is usually easily accomplished. Thin skin grafts also provide adequate coverage if the underlying buccinator muscle is intact. For all but the most superficial lesions, the buccinator should be taken as the deep margin of resection. Failure rates for early buccal carcinomas are high. Treatment of T1/T2 retromolar trigone (Fig. 24.12) lesions is similar.

T3 and T4 Carcinoma of the Buccal Mucosa and Retromolar Trigone

Large tumors of the buccal mucosa or retromolar trigine are difficult to manage (Fig. 24.13). The head and neck surgeon should keep the following facts in mind when planning treatment for advanced tumors in this region:

1. The layers of the buccal region are buccal mucosa, submucosa, buccinator muscle, subcutaneous fat, and cheek skin. Once a lesion is deep enough to invade the buccinator muscle, the overlying cheek skin is potentially involved. Resection frequently results in a through-and-through defect requiring at minimum local flap coverage.
2. Deep posterior invasion from both buccal and retromolar trigone tumors extends toward the masseteric space. Meticulous attention to this potential direction of spread is required to avoid local recurrence (Fig. 24.14).

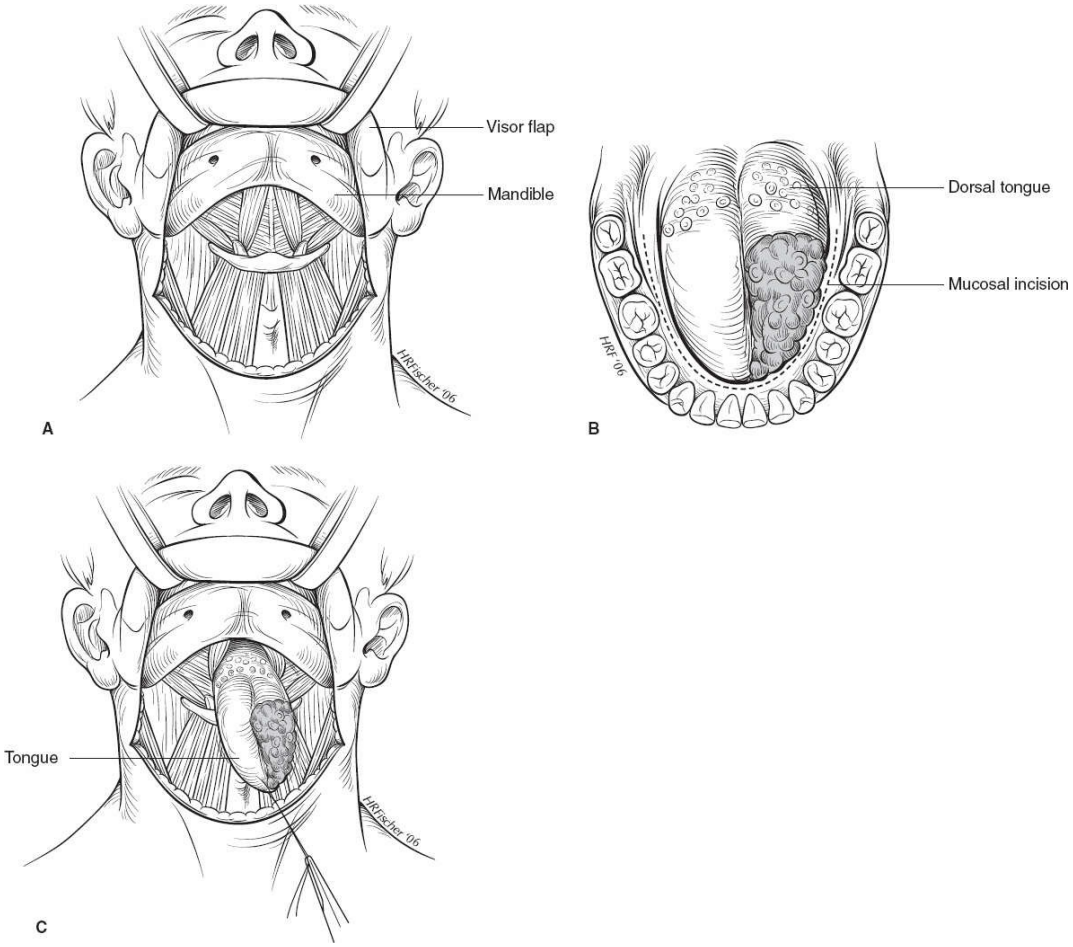

Figure 24.10. Pull-through approach for glossectomy. **A.** The skin flaps are elevated to the lower border of the mandible. **B.** Intraoral cuts along the uninvolved floor of mouth are connected with external cuts dividing the floor-of-mouth diaphragm. **C.** The specimen is pulled downward and into the neck, allowing visualization of more posterior cuts.

Figure 24.11. A patient demonstrates an early buccal mucosal carcinoma caused by smokeless tobacco use. Note the adjacent leukoplakia extending into the gingivobuccal sulcus.

3. The retromolar trigone mucosa provides reasonably thin cover over the ascending mandible. Larger tumors quickly invade the bone and continue into the masticator space as noted above.
4. Retromolar trigone tumors often extend posteriorly into the oropharynx. Many clinicians consider the biologic behavior to be more consistent with oropharyngeal carcinoma than oral cavity carcinoma. When there is bulky extension into the tonsil or soft palate, concurrent radiation and chemotherapy are given more consideration as first-line therapy to preserve speech and swallowing function. As is true for other oral cavity sites, however, no treatment has been proven superior to surgery and adjuvant radiation for buccal or retromolar trigone carcinomas.

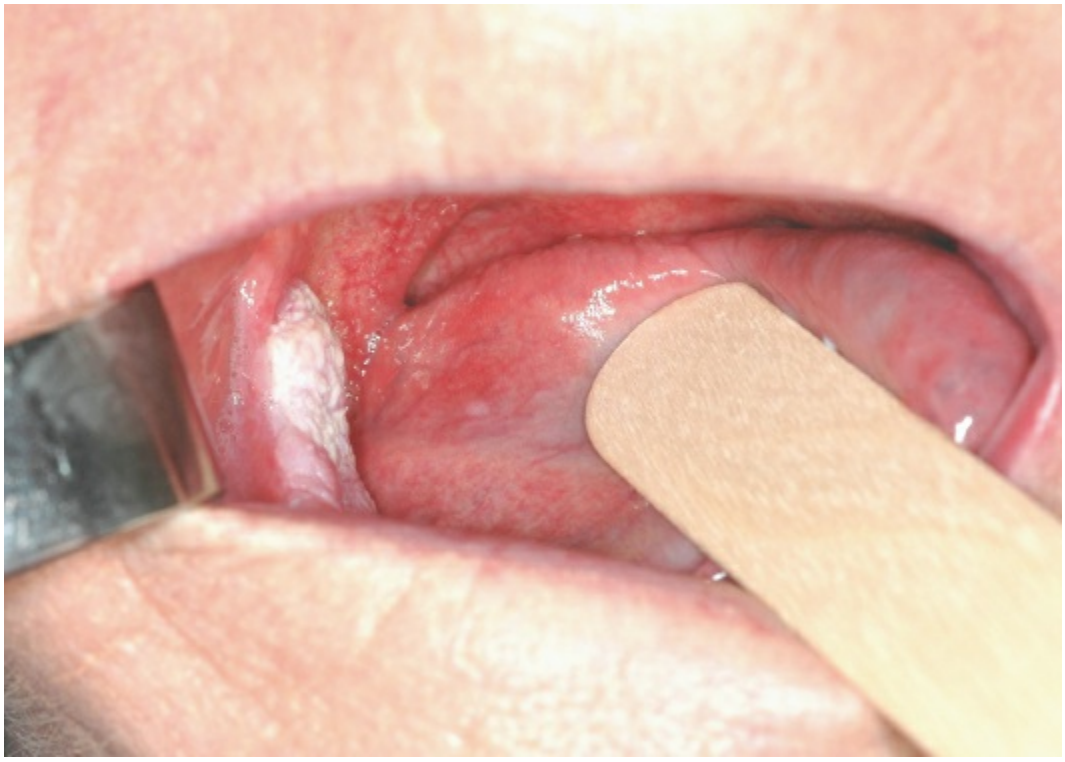

Figure 24.12. T1 carcinoma of the retromolar trigone. These lesions often invade the adjacent mandible or masseteric space early.

5. Perifacial nodes and parotid nodes are first-level nodal basins for these tumors.
6. Transoral exposure may be limited. Be prepared for a transfacial approach to improve access.

Hard Palate

T1 and T2 Carcinoma of the Hard Palate

Palatal carcinomas are uncommon. More nonsquamous cell cancers occur in the palate than any other oral cavity location. Minor salivary gland malignancies comprise the majority of other malignancies. All but the most superficial palatal lesions have the potential to invade underlying bone. The incisive and greater palatine foramina also provide pathways for perineural dissemination. Thin lesions of the hard palate may be managed with wide local excision. Peripheral margins are managed as discussed above. If uninvolved periosteum is interposed between the tumor and underlying bone, bone resection may be unnecessary. If any doubt exists, palatal bone can be drilled away down to nasal mucosa without creating an oronasal fistula. If a small fistula must be created, a rotational flap of

palatal mucosa or a buccinator myomucosal flap will usually close the defect effectively.

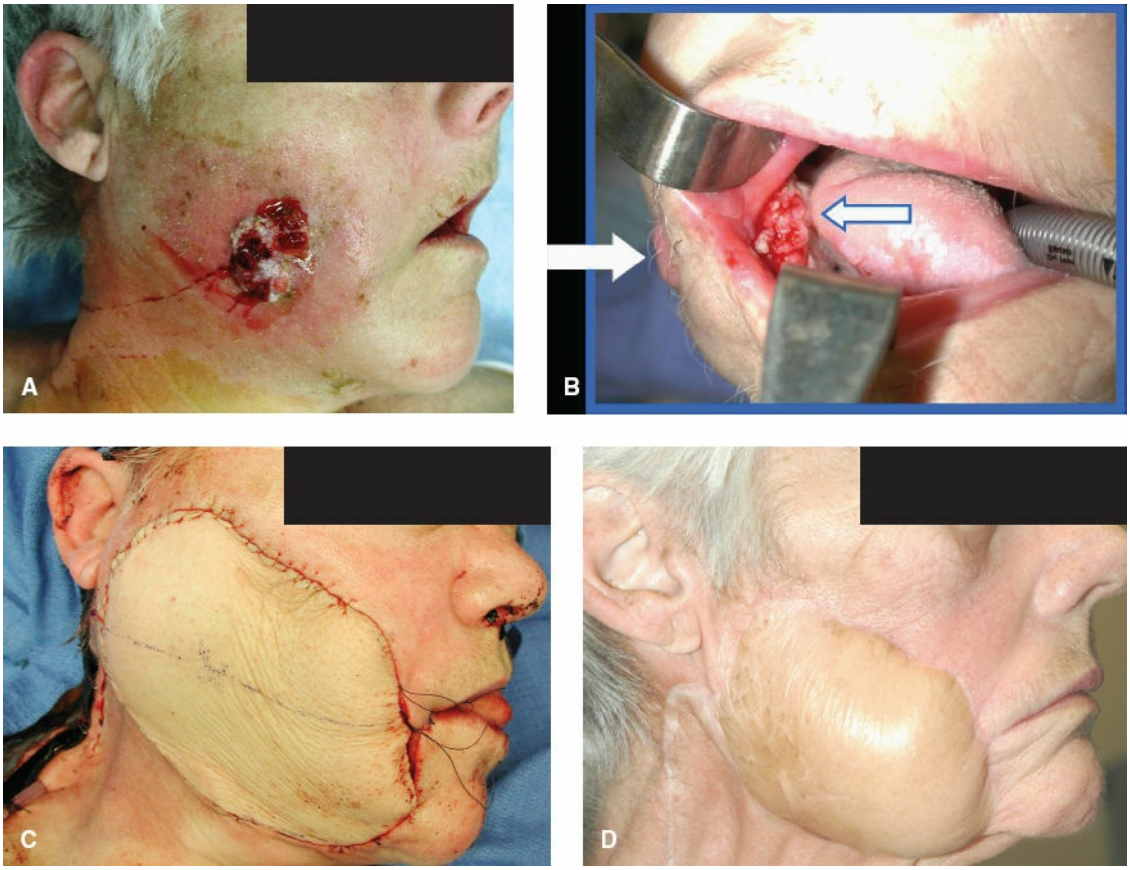

Figure 24.13. T4 carcinoma of the buccal mucosa with extension through overlying skin. **A.** Transbuccal extension. **B.** Extensive involvement of overlying skin. **C.** Wide resection to include most of the right cheek; rectus free flap reconstruction. **D.** Eighteen months postoperative. The patient was not interested in further flap debulking.

T3 and T4 Carcinoma of the Hard Palate

Larger palatal lesions characteristically involve bone. Preoperative CT scans are very helpful in assessing superior extension of disease into the nose or maxillary sinus (Fig. 24.15). An inferior maxillectomy is usually required for complete resection. These lesions may escape posteriorly into the pterygoid plates and pterygoid musculature and extend to the skull base. The pterygomaxillary space and foramen rotundum are sites of disease persistence in deeply invasive palatal carcinoma.

Reconstruction of palatal defects is essential for speech and swallowing. Reconstruction can be either prosthetic or surgical. A temporary dental obturator can be placed intraoperatively or after the first

postoperative visit around day 10. A final obturator can be fashioned a few months later when soft tissue contraction has stabilized (Fig. 24.16). The advantages are an open cavity for tumor surveillance and no additional surgical morbidity for the patient. The disadvantage is the requirement to maintain a well-fitting obturator in order to enjoy normal speech and swallowing. Many patients are frustrated by minor leaks or pain with an improper fit.

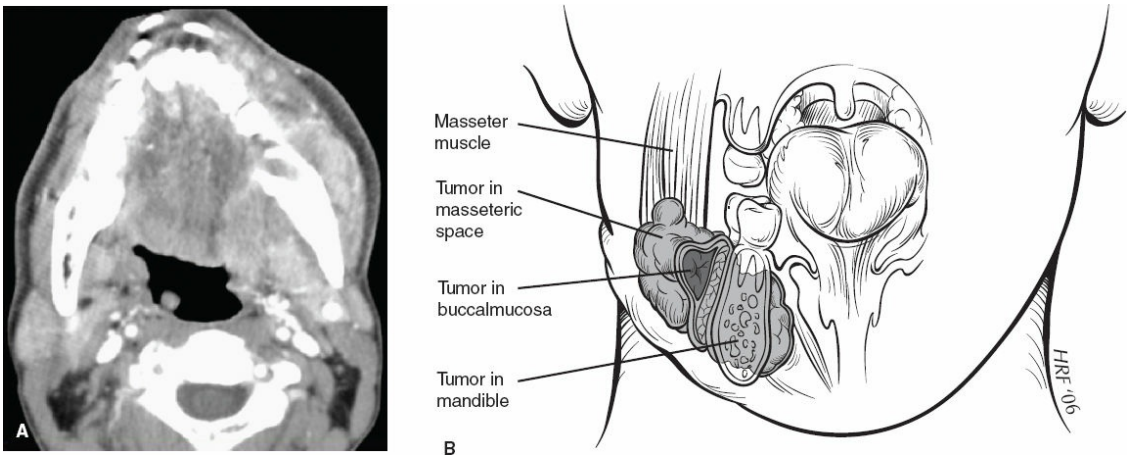

Figure 24.14. T4 carcinoma of buccal mucosa. **A.** Extensive involvement of masseteric space demonstrated by CT scan. **B.** The mandible and masseteric spaces illustrated here are the most common locations for failure of complete resection.

Surgical closure of larger defects typically requires free flap reconstruction. The option is worthwhile for younger patients who will not be forced to maintain a well-fitting prosthesis for the remainder of their lives. Flap reconstruction is usually offered at the time of primary excision. If doubt about margins remains, a temporary obturator can easily be fashioned and the defect reconstructed secondarily.

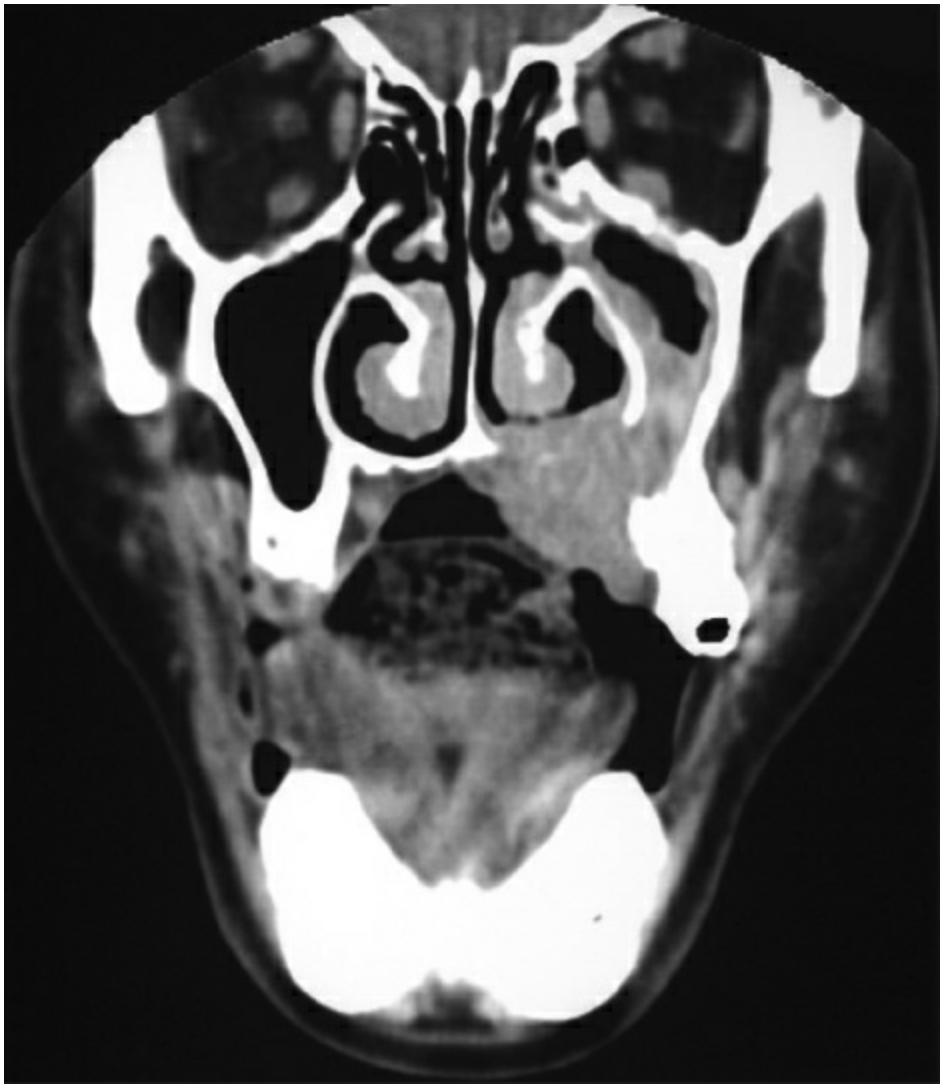

Figure 24.15. Carcinoma of the palate extending upward into the maxillary sinus and illustrating the importance of preoperative scanning in tumor staging.

POSTOPERATIVE CARE

Oral cavity cancer patients average 62 years of age at diagnosis and over 80% are long-term tobacco users. Cardiac disease, peripheral vascular disease, and COPD are common comorbidities that impact postoperative recovery and must be considered in the perioperative setting. While resections for advanced head and neck cancer may be tedious and time-consuming, recovery from surgery can also be surprisingly brisk. The fluid shifts and physiologic stress common to intra-abdominal and intrathoracic surgery are often less severe. Patients are typically encouraged to resume ambulation and enteral nutrition on the first post-operative day. Whenever the upper aerodigestive tract is surgically altered, however, the *airway*,

swallowing and *speech* require special consideration.

The oral *airway* is compromised by postoperative edema and added bulk from reconstructive flaps or gauze bolsters. Small lesions are typically removed with minimal alteration in airway patency. Larger resections, particularly when combined with neck dissection, have the potential to produce significant airway edema. Tracheotomy is preferred over prolonged intubation because the patient can be ambulatory immediately and the operative site more easily monitored. The surgical adage “If you think you might need a trach, do it…” remains relevant today.

There are two considerations related to *swallowing* that are important to consider. The first is when have the wounds healed adequately to resume oral intake. The second consideration is when can the patient swallow again without aspirating. If the resection has created an opening from the oral cavity into the neck, the patient is at risk for salivary fistula formation. If there is no evidence of a leak, oral intake may resume for most patients on post-op day 6 or 7. Even though an adequate seal is obtained, the swallow mechanism may still be impaired. Altered capacity to move food through the oral cavity and pharynx creates aspiration risk. Nasogastric or PEG tubes are commonly placed intraoperatively in anticipation of dysphagia. Speech pathology involvement early in the rehab process is recommended. Ultimate recovery of swallow function correlates inversely with the volume of normal tissue resected.

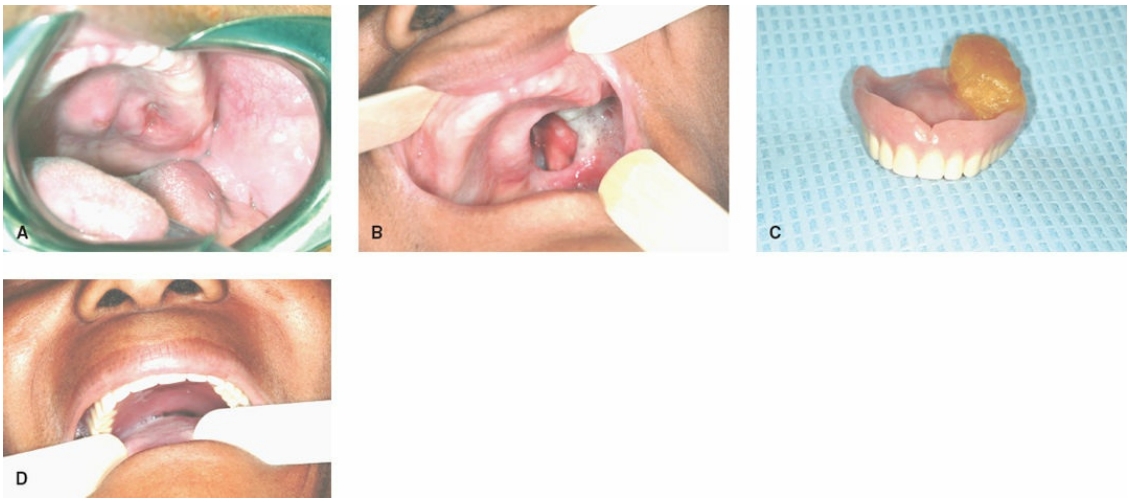

Figure 24.16. Minor salivary gland adenocarcinoma of the palate. **A.** Lesion involving left side of hard palate. **B.** Defect with clear margins. **C.** Initial obturator fashioned by prosthodontist to fill defect. **D.** Obturator in position allowing normal oral function.

Speech is also impacted by surgery for oral cancer. While speech is not a vital function, the patient should be prepared for the likelihood of speech difficulty and provided with a means of communicating post-op. Hospitalized patients who are trach tube dependent and cannot speak require special monitoring by nursing staff as they cannot use the “nurse-call” intercom system.

COMPLICATIONS

The best predictors of complications following surgery for oral cavity cancer are medical comorbidities, prior treatment with radiation/chemotherapy, and cancer-related cachexia. The common cardiovascular, pulmonary, renal, and wound-healing complications encountered in general surgical patients are seen in oral cancer patients as well.

Major complications in head and neck surgery occur in approximately 10% of patients. Major complications include those that require additional hospital stay, return to the operating room, or result in diminished recovery of function. The most common are wound infection, wound dehiscence with fistula formation, bleeding, and aspiration pneumonia.

With small oral cavity resections, delayed wound healing is a nuisance but not often lethal. With larger resections, particularly those in continuity with the neck, wound complications can be lethal. Salivary leak into the neck produces a poly-microbial infection manifesting as cellulitis, abscess, wound dehiscence, and potential hemorrhage from the great vessels. Steps to prevent wound complications include perioperative antibiotics, meticulous attention to obtaining a water-tight oral defect closure, and resumption of appropriate nutrition. The question of whether to delay surgery while improving nutrition remains controversial in head and neck surgery. Baseline nutritional parameters may improve with aggressive preoperative nutritional support. There are data from a chemoradiation trial, however, suggesting that those patients receiving pretreatment nutritional support had fewer complications of treatment but decreased overall survival; perhaps the nutritional support encouraged tumor growth. A reasonable is to establish nutritional support during the initial patient contact but not to delay treatment in the hopes of diminishing complications.

Previously radiated patients warrant special attention. Radiation dosages have escalated over the past decade and patients commonly

receive 70+ Gy—often with concurrent chemotherapy. Fistula rates as high as 70% are reported with salvage surgery for head and neck lesions following chemoradiation. Tension-free closure and liberal use of vascularized tissue from regional or free-flaps have been shown to diminish fistula rates in salvage situations. Fortunately, oral cavity cancers are less commonly treated with primary radiation and salvage surgery in a heavily radiated field is not required as often as laryngeal of pharyngeal primaries.

EDITOR'S COMMENT

Cancer of the oral cavity is one of the most common malignancies, especially in developing countries but also in the developed world. As pointed out squamous cell carcinoma (SCC) is the common histology and the main etiologic factors are tobacco and alcohol use. Although early diagnosis is usually easy, presentation with advanced disease is not uncommon. As this chapter points out the standard of care is primary surgical resection with or without postoperative adjuvant therapy. Early diagnosis is key to improved prognosis. Although reconstructive methods have improved quality-of-life issue of function for these patients, prognosis for advanced-stage disease has been relatively constant for many years.

This commentary will discuss the issues of preoperative evaluation including tumor thickness as a major predictor of the risk of nodal metastasis, human papillomavirus as a driver of oral cavity versus oropharyngeal cancer, and the use of new methods for detection of nodal disease in the neck.

Tumor Thickness

The chapter states "most surgeons feel that a T1 tumor with a depth of invasion greater than 4 mm has a greater chance of development nodal metastases than a T2 or T3 tumor that is very superficial." In general there is support for this clinical judgment in the literature. Kane et al. suggested that depth of invasion is the most significant histologic predictor of subclinical cervical lymph node metastases in early squamous carcinomas of the oral cavity (Kane SV, Gupta M, Kakade AC, et al. Depth of invasion is the most significant histological predictor of subclinical cervical lymph node metastasis in early squamous carcinomas of the oral cavity. *J Cancer surgery* 2006;32:795–803). Patients with T1/T2 N0M0 cancer of the oral cavity were included in this study. All the patients received wide excision of the tumor with an elective supraomohyoid node dissection as the primary treatment. The margins of the primary tumor and the base of excision were assessed by frozen section and were revised if found close. Comparison of the depth of invasion with lymphovascular invasion was compared. Statistical significance was not achieved for a depth of 5 mm but most of the patients with metastases had correlation with tumor depth.

A more recent study compared oral cancer of the tongue and floor of the mouth sites. Results of retrospective comparison of depth of lesion with pathologically proven nodal metastases showed a difference for tongue and floor of mouth lesions (FOM). In contrast to the usual depth of 4 mm as being critical, FOM lesions crossed the 20% threshold of probability for nodal metastases between 1 and 2 mm versus 4 mm for tongue lesions. Such differences suggest why a recent meta-analysis suggesting that elective neck dissection improves the outcomes in patients with clinically negative necks is a reasonable clinical guideline (Fasunla AJ, Greene BH, Timmesfeld N, et al. A

meta-analysis of the randomized controlled trials on elective neck dissection versus therapeutic neck dissection in oral cavity cancers with clinically nod-negative neck. *Oral Oncol* 2011;47(5):320–4).

Human Papillomavirus in Oral Cavity Cancer

HPV is a causal and prognostic factor for oropharyngeal cancer but its role in squamous cell carcinoma of the oral cavity (SCCOC) is less clear. (HPV 16.) The increase in oral cancer in younger patients without the usual risk factors led to the first work implicating HPV in cancer occurrence. A recent study analyzed a large cohort of SCCOC from a single tertiary cancer center. Multiple HPV detection methods were used and positive and negative tumors were compared to evaluate whether they differed in clinical presentation and outcomes (Zafereo ME, Xu L, Dahlstrom R, et al. Squamous cell carcinoma of the oral cavity often over expresses p16 but is rarely driven by human papillomavirus. *Oral Oncol* 2016;56:47–53). (A very low incidence of true HPV-driven SCCOC). A 6% prevalence was found but clinical correlation raised some doubt as to whether even this small minority of patients had truly HPV-driven oral cavity tumors. Better methods of HPV detection would improve the data.

The clinical usefulness of HPV testing is discussed in another interesting paper (Mirghani H, Amen F, Moreau F, et al. Do high-risk human papillomaviruses cause oral cavity squamous cell carcinoma? *Oral Oncol* 2015;51:229–36).

In particular, the presence of HPV DNA alone is insufficient evidence for a causal association and E6/E7 oncogenes in oral cavity squamous cell cancer have been detected. Given the lack of specificity of assays the question as to why do HPV-driven cancers develop preferentially in the oropahrynx is crucial, but as yet incompletely answered.

New Methods of Lymph Node Detection

The importance of detection of occult neck metastases in treatment planning for patients is critical. There is a high rate of unnoticed neck involvement reported. So elective neck dissection in the clinically node-negative neck is usually performed. Preoperative evaluation of the cN0 neck by ultrasonography (US), fine-needle aspiration, computed tomography, and magnetic resonance imaging are available. In a meta-analysis the sensitivity and specificity were higher with US than with CT and MRI although the range of results were wide. A recent study found US a promising modality although lack of patient randomization and small sample size were weaknesses. The results of the study suggest that one third of elective neck dissections could be omitted in these cases.

This chapter is a useful compilation of current evaluation, management, and care of the patient with oral cavity cancer. The three areas highlighted in the commentary offer future ways to improve patient care by better diagnosis and choice of surgical methods.

Bruce Donoff

25 Neck Dissection

Ian Ganly and Jatin P. Shah

The single most important factor affecting prognosis for squamous cell carcinoma of the head and neck, the sixth most common cancer worldwide, is the status of the cervical lymph nodes. Metastasis to the regional lymph nodes reduces the 5-year survival rate by 50% compared with that of patients with early-stage disease (Fig. 25.1). The American Cancer Society has reported that 40% of patients with squamous carcinoma of the oral cavity and pharynx present with regional metastases (Fig. 25.2). Therefore, management of the cervical lymph nodes is an important component in the overall treatment plan for patients with squamous cell carcinoma of the head and neck.

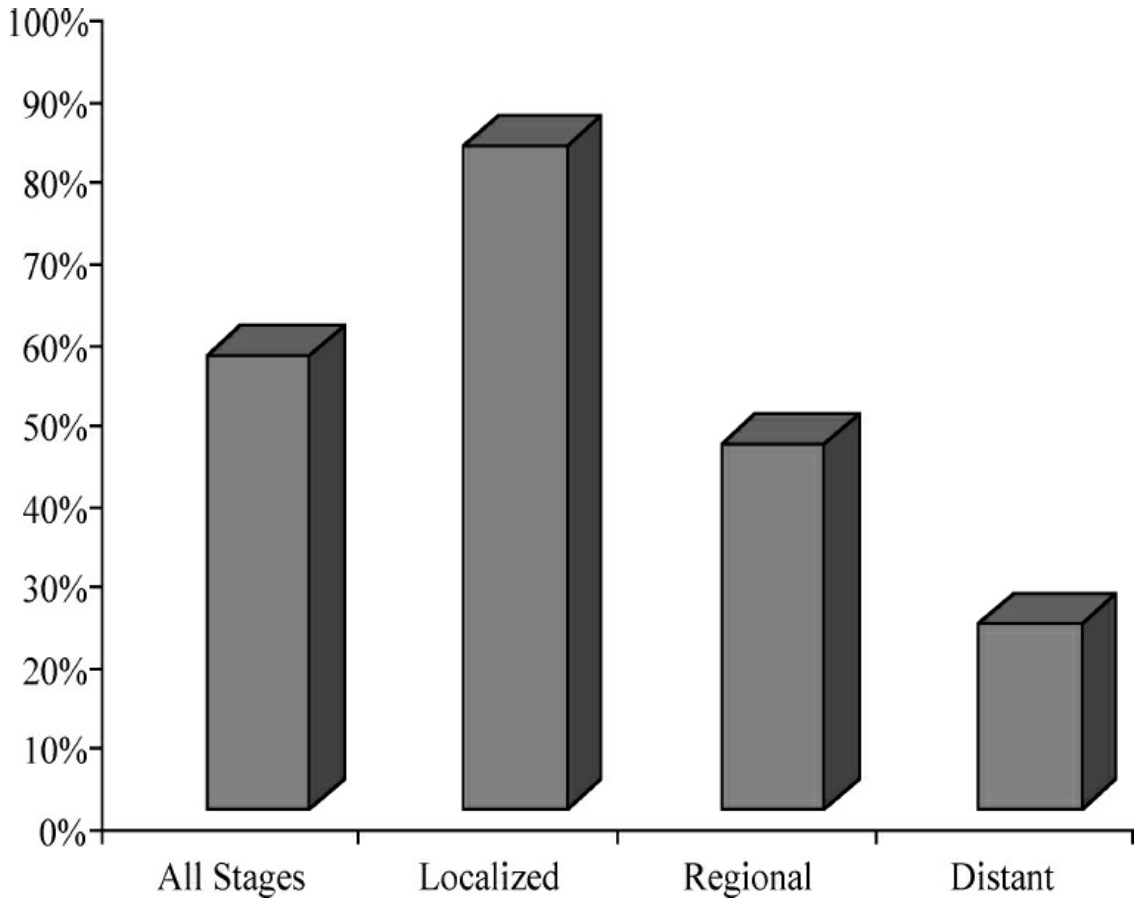

Figure 25.1. Five-year survival rates of squamous cell carcinoma of the head and neck in relation to extent of disease.

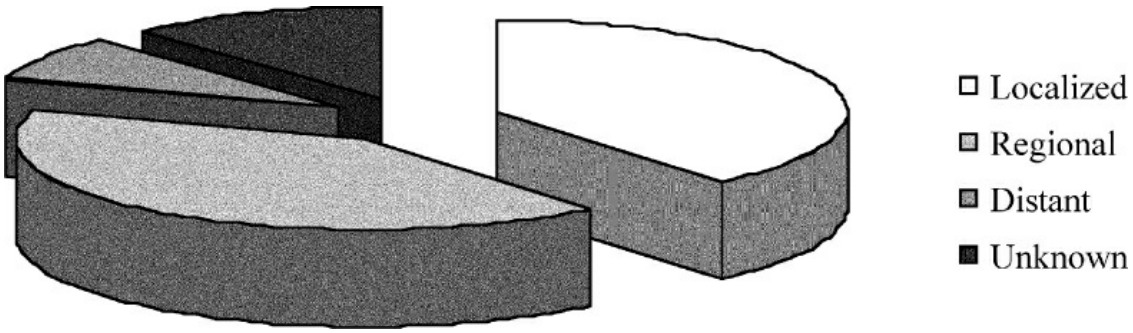

Figure 25.2. Distribution of patients with squamous cell carcinoma of the head and neck in relation to extent of disease at the time of initial diagnosis.

ANATOMY OF THE CERVICAL LYMPHATICS

Cervical lymph nodes are classified according to the system developed at Memorial Sloan-Kettering Cancer Center in the 1930s. This system divides the lymph nodes in the lateral aspect of the neck into five nodal levels, I through V, as shown in Figure 25.3. In addition, lymph nodes in the central compartment are categorized into level VI and those in the anterior superior mediastinum as level VII. Table 25.1 lists the clinical and surgical landmarks used to describe these levels. Recently, level I, II, and V nodes were subclassified into levels IA and IB, IIA and IIB, and VA and VB. Level IA includes the submental lymph nodes, whereas level IB includes the submandibular lymph nodes. Level IIA includes lymph nodes below the accessory nerve, whereas IIB includes nodes above the accessory nerve. The posterior triangle has been subdivided into levels VA and VB, with the dividing line being the accessory nerve in the posterior triangle. This subdivision is based on patterns of lymph node spread from various primaries. For example, level IA lymph node spread is rare except for tumors of the lower lip and anterior floor of mouth. Recent studies have shown that, in the patients with no level IIA nodes clinically, metastatic spread to level IIB nodes is rare. Similarly in thyroid cancer, studies have shown metastatic spread to level VA lymph nodes is exceedingly rare.

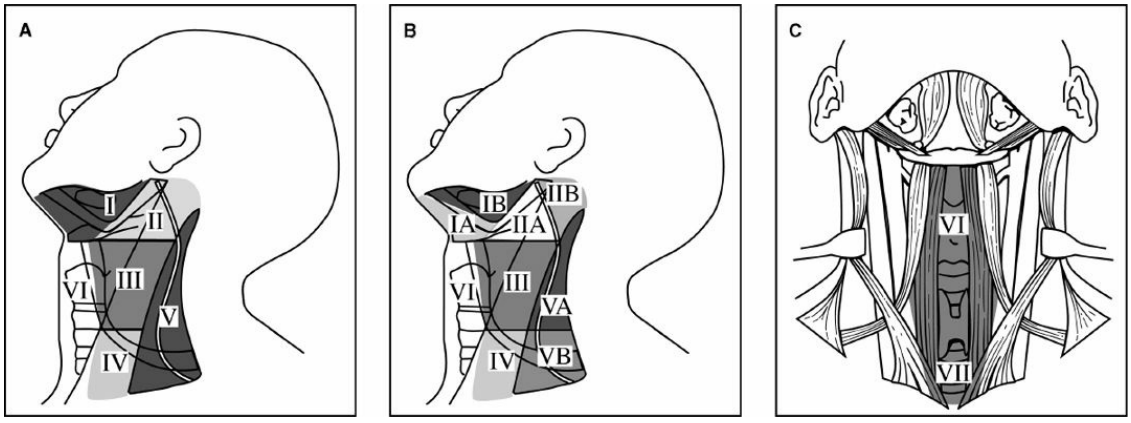

Figure 25.3. Memorial Sloan-Kettering Cancer Center leveling system of cervical lymph nodes (**A**); current modification of leveling system (**B**); and levels VI and VII (**C**).

TABLE 25.1 Clinical and Surgical Landmarks for Neck Node Levels

Node Level	Clinical Landmarks	Surgical Landmarks
Level I	Submental and submandibular triangles	Superior-lower border of the body of the mandible; posterior-posterior belly of digastric; inferior-hyoid bone
Level II	Upper jugular lymph nodes	Superior-base of skull; posterior-posterior border of sternocleidomastoid muscle; anterior-lateral limit of sternohyoid; inferior-hyoid bone
Level III	Middle jugular lymph nodes	Superior-hyoid bone; posterior-posterior border of sternocleidomastoid muscle; anterior-lateral limit of sternohyoid; inferior-cricothyroid membrane
Level IV	Lower jugular lymph nodes	Superior-cricothyroid membrane; posterior-posterior border of sternocleidomastoid muscle; anterior-lateral limit of sternohyoid; inferior-clavicle
Level V	Posterior triangle lymph nodes	Posterior-anterior border of trapezius muscle; anterior-posterior border of sternocleidomastoid muscle; inferior-clavicle
Level VI	Anterior compartment of the neck	Superior-hyoid bone; inferior-suprasternal notch; lateral-medial border of carotid sheath on either side
Level VII	Superior mediastinal lymph nodes	Superior-suprasternal notch; inferior-innominate artery

STAGING SYSTEM FOR METASTATIC SQUAMOUS CELL CARCINOMA OF THE NECK

A uniform staging system for regional metastases to cervical lymph nodes was established by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer. The staging system for squamous cell carcinoma has been recently updated by the AJCC. The 2016 staging system is now shown in Table 25.2 and Figure 25.4. The staging system for thyroid carcinoma is shown in Table 25.3. The staging system is based on both the size and the number of enlarged lymph nodes. Both of these factors have important prognostic significance. The prognosis worsens with increasing N stage. However, there are other nodal factors affecting prognosis that are not included in the staging system.

TABLE 25.2 Staging System of Regional Lymph Nodes (N Stage) for Squamous Cell Carcinoma of the Upper Aerodigestive Tract (AJCC-UICC 2016)

Nx	Regional lymph nodes cannot be assessed
N0	No clinical or pathologically positive node
N1	Single ipsilateral node <3 cm and extranodal extension ENE (–)
N2a	Single ipsilateral node >3 cm and ENE (–)
N2b	Multiple ipsilateral <6 cm and ENE (–)
N2c	Contralateral or bilateral ENE (–)
N3a	Single ipsilateral node >6 cm and ENE (–)
N3b	Single ipsilateral >3cm ENE (+) OR multiple ipsilateral, bilateral or contralateral nodes any with ENE (+)
Nodal staging for HPV+ve oropharynx cancer	
N0	No clinical or pathologically positive node
N1	1 or more ipsilateral nodes ≤6 cm
N2	contra or bilateral nodes, all ≤6 cm
N3	any node >6 cm
Nodal staging for nasopharynx cancer	
N0	No clinical or pathologically positive node
N1	Retropharyngeal (irrespective of laterality) Cervical: Unilateral, 6 cm, and above caudal border of cricoid cartilage
N2	Cervical: Bilateral, 6 cm, and [a]above caudal border of cricoid cartilage
N3	>6 cm and/or [b]below caudal border of cricoid cartilage (irrespective of laterality)

[a]Above caudal border of cricoid cartilage = Neck levels I, II, III, and/or Va
[b]Below caudal border of cricoid cartilage = Neck levels IVa-b, Vb-c

TABLE 25.3 Staging System of Regional Lymph Nodes (N stage) for Thyroid Carcinoma

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Regional lymph node metastases
N1a	Metastases in central compartment lymph nodes
N1b	Metastases in unilateral, bilateral, contralateral cervical or superior mediastinal lymph nodes

NODAL FACTORS AFFECTING PROGNOSIS

Characteristics of regional nodes that affect prognosis include the presence of pathologically positive nodes, size of the metastatic lymph node, the number of lymph nodes involved, and the location of the lymph nodes. Involvement of the lower cervical nodes (level IV) and the lower posterior triangle lymph nodes has a very poor prognosis. Another important prognostic factor is the presence of extranodal spread where the capsule of the lymph node is ruptured, resulting in invasion of the surrounding soft tissues. This increases both the incidence of regional recurrence and also distant metastases. In a clinically positive N1 neck, there is a 30% incidence of extranodal spread, whereas in the clinically positive N2a/N3 neck, extranodal spread is present in 50% to 70%. Perivascular and perineural infiltration by tumor also has a negative effect on prognosis. All of these factors must be considered when planning adjuvant treatment following neck dissection.

RISK FACTORS FOR NODAL METASTASIS

The risk for cervical node metastases is influenced by characteristics of the primary tumor such as location, size, and histology. As a general rule, the risk for lymph node metastases increases for more posteriorly located tumors, such as those of the oropharynx and hypopharynx compared to lips and oral cavity (Fig. 25.5). For example, oropharyngeal cancers are at higher risk than oral cavity tumors. Lesions of the tonsil and base of tongue have a very high incidence of nodal metastases. Tumors of the

hypopharynx universally have lymph node metastases. The risk of nodal metastases is higher for tumors of the supraglottic larynx compared with the glottic larynx because of the relative absence of lymphatic vessels in the glottic larynx. The greater the T size of the primary tumor, the greater the probability of having lymph node metastases. For example, T1, T2, and T3 tongue cancers have an incidence of metastatic disease to the neck of 30%, 50%, and 70%, respectively. Pathologic features such as endophytic versus exophytic tumors, poorer degree of differentiation, depth of invasion, vascular invasion, and perineural invasion also determine the risk of cervical metastases.

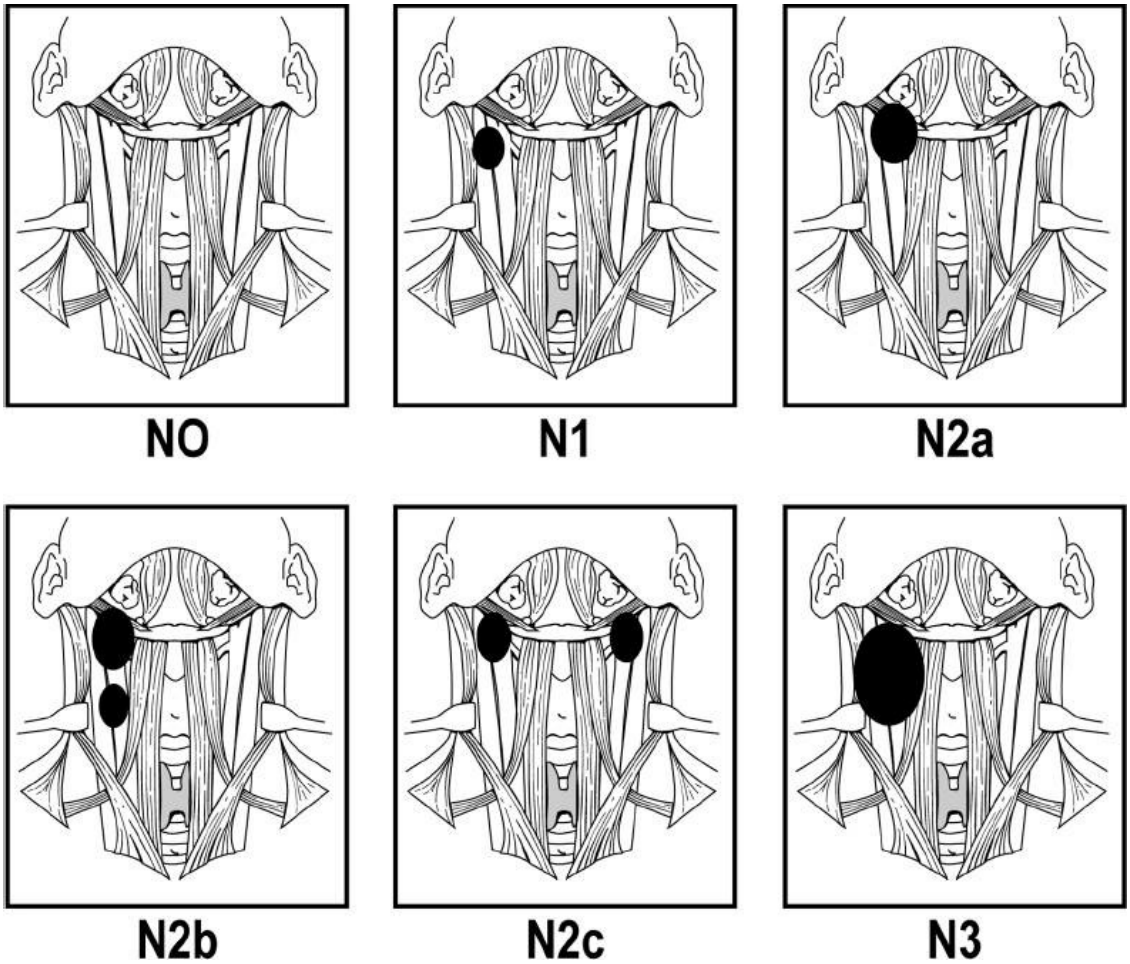

Figure 25.4. Staging system of regional lymph nodes (N stage) for squamous cell carcinoma of the upper aerodigestive tract, the nasopharynx.

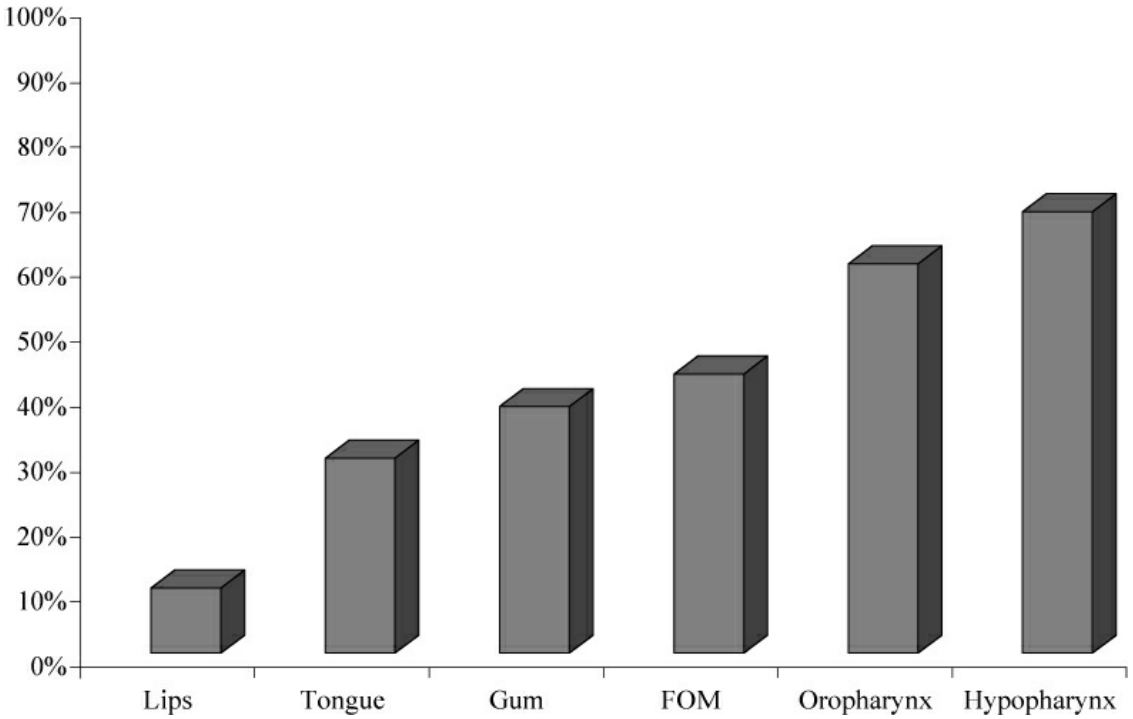

Figure 25.5. The risk of nodal metastasis increases in relation to location of the primary squamous cell carcinoma of the head and neck.

PATTERNS OF NODAL METASTASES

The location of metastases is mainly determined by the location of the primary site. Figure 25.6 illustrates the nodes typically affected by primary tumor location. Cancers of the oral cavity typically spread first to the nodes in levels I, II, and III, whereas cancers of the oropharynx, hypopharynx, and larynx spread first to the nodes in levels II, III, and IV. This observation is based on the philosophy that nodal spread of cancer proceeds in an orderly and predictable fashion as determined by the lymphatic drainage pattern in the neck. In 1972, Lindberg, from the M.D. Anderson Cancer Center, was the first to report that the lymph node groups most frequently involved in cancer of the oral cavity were level II/III, and in patients with cancer of the floor of mouth, oral tongue, and buccal mucosa, the nodes most frequently involved were located in the submandibular triangle (level IB). Lindberg also reported that cancers can metastasize to both sides of the neck and can skip the submandibular and jugulodigastric nodes metastasizing first to the midjugular nodes (level III).

The patterns of nodal metastasis were later well described by Shah, from Memorial Sloan-Kettering Cancer Center, in 1990. To determine

lymph node levels at risk from a particular primary site, Shah analyzed pathology specimens from 1,119 classic radical neck dissections (RNDs) for squamous cell carcinoma of the upper aerodigestive tract. This consisted of 343 RNDs for the clinically negative neck (N0) and 776 RNDs for the clinically positive neck. From these studies, the incidence of pathologically positive neck specimens was 82% for the clinically positive neck and 33% for the clinically negative neck. Tables 25.4 and 25.5 show the percentage of patients with pathologically positive nodes at each level for clinically positive and clinically negative disease.

In the clinically positive neck setting (Table 25.4), patients with primary oral cavity tumors had the majority of positive nodes in levels I to III; levels IV and V were involved in 20% and 4% of specimens, respectively. In patients with primary oropharyngeal tumors, the majority of positive nodes were in levels II to IV; levels I and V were involved in 17% and 11% of specimens, respectively. In patients with hypopharyngeal tumors, most positive nodes were in levels II to IV; levels I and V were involved in 10% and 11% of specimens, respectively. In patients with primary tumors of the larynx, most positive nodes were in levels II to IV; levels I and V were involved in 8% and 5%, respectively.

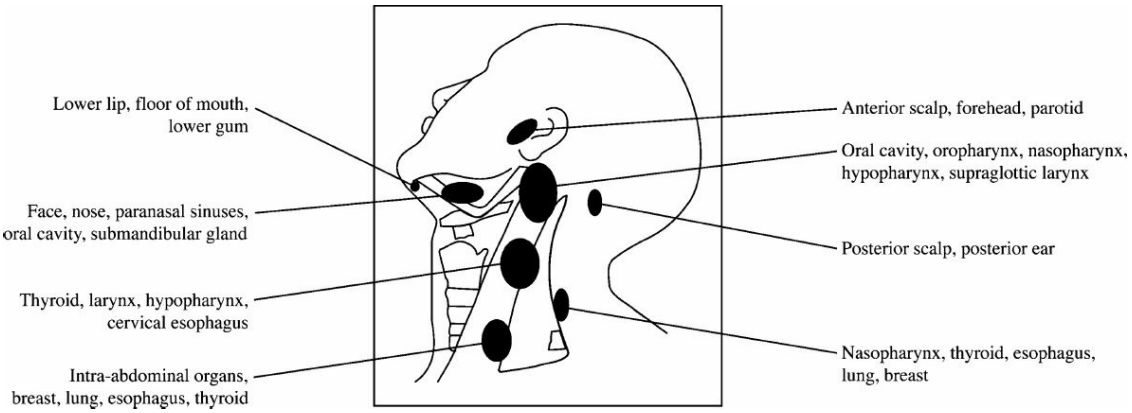

Figure 25.6. Regional lymph nodes draining at a specific primary site.

In the clinically negative neck setting (Table 25.5), patients with primary oral cavity tumors had the majority of positive nodes in levels I to III; levels IV and V were involved in 9% and 2% of specimens, respectively. In patients with primary oropharyngeal tumors, the majority of positive nodes were in levels II to IV; levels I and V were involved in 7%. In patients with hypopharyngeal tumors, most positive nodes were in levels II to IV; levels I and V were not involved. In patients with primary

tumors of the larynx, most positive nodes were in levels II to IV; levels I and V were involved in 14% and 7%, respectively.

The question of level V metastases was addressed in a separate study on 1,277 RNDs by Davidson et al. in 1993. Metastases were found in 40 (3%) patients. Level V metastases were highest in patients with hypopharyngeal and oropharyngeal primary sites (7% and 6%, respectively). Only 3 of 40 patients with a clinically negative neck had a positive level V lymph node. Therefore, the incidence of level V metastases is small and extremely unlikely in the clinically negative neck setting.

TABLE 25.4 Percentage of Positive Lymph Nodes in the cN+ Neck

Clinical N+ Neck					
% Positive Nodes at Each Lymph Node Level According to Primary Site					
Primary Site	I	II	III	IV	V
Oral cavity	61	57	44	20	4
Oropharynx	17	85	50	33	11
Hypopharynx	10	78	75	47	11
Larynx	8	68	70	35	5

CLASSIFICATION OF NECK DISSECTION AND INDICATIONS FOR NECK DISSECTION

History

The importance of the regional cervical lymphatics in oral cavity cancer was noted by Chelius in 1847 who commented, “the neighboring lymphatics become hard and painful” and “once the growth in the mouth has spread to the submaxillary gland, complete removal of the disease is impossible.” In 1847 Warren described the attempted removal of cancer in the neck through an incision from the masseter muscle to the clavicle, although this must have been an unplanned procedure, not based on any anatomical considerations. Kocher in 1880 described the removal of the tongue for cancer through the submaxillary triangle, first removing the lymphatics and submaxillary and sublingual salivary glands. He later proposed that the cervical lymphatics should be removed more widely and described the “Kocher” incision, a Y-shaped incision with the long arm running from the mastoid tip down the anterior border of sternocleidomastoid muscle to the omohyoid muscle, and the short limb

running at right angles to the submental region. Butlin in 1885 later described the removal of cervical lymph nodes for tongue cancer and even discussed the prophylactic removal of these “glands” for tongue cancer.

Solis-Cohen of Philadelphia, America’s first head and neck surgeon, later advocated the removal of cervical lymph nodes during total laryngectomy. However, most of the credit for neck dissection as a curative operation for cervical metastases belongs to George Washington Crile from the Cleveland Clinic. In 1900, he performed different types of neck dissections and subsequently described the classic operation of RND in his seminal article of 1905 published in the *Transactions of the Southern Surgical and Gynecological Association.* This operation is now considered to be the basic neck dissection, and all other procedures are considered to be modifications. George Crile later described his experience with 132 operations of RND in 1906. In this operation, all lymphatic tissues in the lateral neck from levels I to V are systematically removed in conjunction with the sternocleidomastoid muscle, internal jugular vein, the spinal accessory nerve, and the submandibular salivary gland. The operation was popularized by Hayes Martin from Memorial Sloan-Kettering Cancer Center, who described the stepwise procedure of RND in his classic article in 1951. However, this operation is not without morbidity, as it results in a cosmetic deformity and dysfunction of shoulder movement.

TABLE 25.5 Percentage of Positive Lymph Nodes in the cN0 Neck

Clinical N0 Neck					
% Positive Nodes at Each Lymph Node Level According to Primary Site					
Primary Site	I	II	III	IV	V
Oral cavity	58	51	26	9	2
Oropharynx	7	80	60	27	7
Hypopharynx	0	75	75	0	0
Larynx	14	52	55	24	7

This led to the development of modified/functional neck dissections. Oswaldo Suarez from Argentina was the first to describe functional neck dissection in 1963, now called modified radical neck dissection (MRND). He described the removal of all five lymph node levels in the neck while preserving the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein to limit any functional disability in the shoulder.

However, his publications were in Spanish and therefore the technique was not popularized until Ettore Bocca, who learned the technique from Suarez, and published it in the English literature in 1967. Selective removal of regional nodal groups based on predictable patterns of lymph node spread was later popularized by Ballantyne from M.D. Anderson Cancer Center. In 1985, Byers from M.D. Anderson Cancer Center used the terms “anterior” and “supraomohyoid” neck dissection to describe the selective neck dissection procedure for cancers of the oral cavity and pharynx. These neck dissections were described for use in patients with clinically negative neck and were based on the philosophy that nodal spread of cancer proceeded in an orderly and predictable fashion. Unfortunately, the terms “modified neck dissection,” “functional neck dissection,” and “selective neck dissection” led to considerable confusion. Therefore, in 1991 the American Academy of Otolaryngology-Head and Neck (AAOHN) Surgery published an article classifying neck dissections into comprehensive and selective. This was later updated in 2002. Structures removed and indications for these different types of neck dissection are shown in Table 25.6.

Comprehensive Neck Dissection

Comprehensive neck dissections involve the removal of all lymphatic tissue in the lateral neck (levels I to V) and are generally carried out for the clinically positive neck (N+). They can be classified into radical and modified RND (Fig. 25.7), depending on what other structures are excised. RND involves the removal of lymph nodes in levels I to V, and also the sternocleidomastoid muscle, internal jugular vein, spinal accessory nerve, and submandibular salivary gland (Fig. 25.7A). MRND is divided into type I, II, or III, depending on the structures that are preserved. Type I MRND involves preservation of one structure, the spinal accessory nerve (Fig. 25.7B). Type II involves preservation of two structures, the spinal accessory nerve and the sternocleidomastoid muscle (Fig. 25.7C). Type III involves preservation of the spinal accessory nerve, internal jugular vein, and the sternocleidomastoid muscle (Fig. 25.7D). Type I MRND is the most commonly employed neck dissection for squamous cell carcinoma of the upper aerodigestive tract with clinically positive neck disease. Type III MRND is most commonly employed for metastatic-differentiated carcinoma of the thyroid.

Selective Neck Dissection

Selective neck dissection spares all nonlymphatic tissue, including the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. However, it does not remove all the lymphatic tissue on the involved side of the neck as does a comprehensive neck dissection, but rather uses the selective removal of nodal regions at risk. This is determined by the predictive pattern of metastases based on the location of the primary tumor. It is based on the clinical observation that squamous cell carcinoma of the upper aerodigestive tract metastasizes in a predictable and sequential pattern. Selective neck dissections are therefore generally carried out for the clinically negative neck (N0), where there is at least a 15% to 20% risk of occult metastatic disease. Additional indications may be situations in which surgical access to the primary extends to lymph node groups at risk of metastases. More controversially, it may be used for nodal metastases confined to the first-echelon nodes (usually N1) when the primary is being treated by surgery. However, it is important to point out that the neck requires postoperative radiation therapy in this setting.

TABLE 25.6 Classification of Different Types of Neck Dissection With Clinical Indications

Comprehensive	Nodal Levels Removed	Structures Preserved	Indications
Radical neck dissection	Levels I–V	None	N+ neck for SCC where SAN involved and/or extensive soft tissue disease with invasion of SCM and IJV
Modified neck dissection type I	Levels I–V	SAN	N+ neck for SCC where SAN free of disease
Modified neck dissection type II	Levels I–V	SAN, SCM	N+ neck for SCC or thyroid cancer where IJV involved but SAN free of disease
Modified neck dissection type III	Levels I–V	SAN, SCM, IJV	Metastatic differentiated thyroid carcinoma
Selective			
Supraomohyoid neck dissection	Levels I–III	SAN, SCM, IJV	N0 neck for SCC of oral cavity and oropharynx (include level 4); N0 neck malignant melanoma where primary site is anterior to ear (include parotidectomy for face and scalp)

Extended suprao-mohyoid neck dissection	Levels I–IV	SAN, SCM, IJV	N0 neck for SCC of lateral tongue
Lateral neck dissection	Levels II–IV	SAN, SCM, IJV	N0 neck for SCC of larynx and hypopharynx
Posterolateral neck dissection	Levels II–V, subocciptial, retroauricu-lar nodes	SAN, SCM, IJV	N0 neck malignant melanoma where primary site is posterior to ear
Modified lateral neck dissection	Levels II – V	SCM, IJV, SAN, Sub-Max gland	Therapeutic neck dissection for thyroid cancer with lateral neck nodes
Central compart-ment neck dissection	Levels VI and VII	N/A	Therapeutic dissection for central compartment nodes for thyroid cancer

SAN, spinal accessory nerve; SCC, squamous cell carcinoma; SCM, sternocleidomastoid muscle; IJV, internal jugular vein.

Common selective neck dissections are shown in Figure 25.8. These include the supraomohyoid neck dissection (SOHND), in which lymph nodes in levels I to III and the submandibular salivary gland are removed (Fig. 25.8A); the extended SOHND, in which lymph nodes in levels I to IV and the submandibular gland are removed (Fig. 25.8B); the anterolateral neck dissection (LND), in which lymph nodes in levels II to IV are removed (Fig. 25.8C); posterolateral neck dissection (PLND), in which lymph nodes in levels II to V and also the suboccipital and retroauricular lymph nodes are removed (Fig. 25.8D); and central or anterior compartment neck dissection, in which lymph nodes at level VI in the prelaryngeal, pretracheal, and paratracheal regions are removed (Fig. 25.8E).

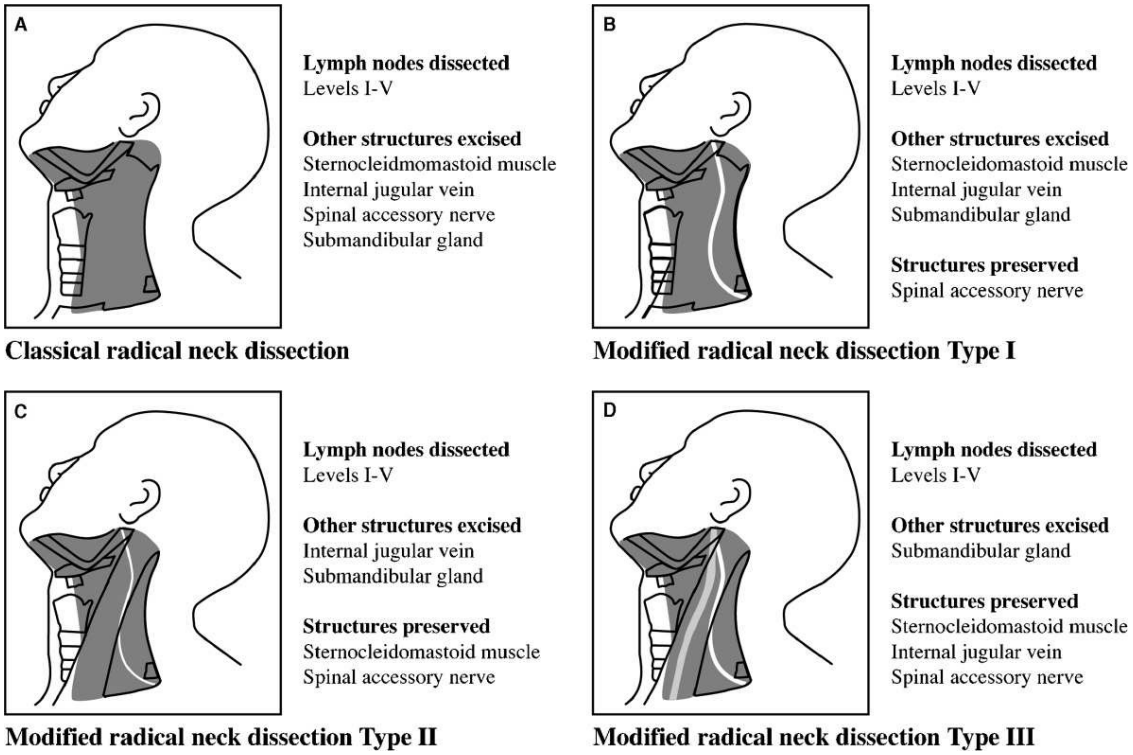

Figure 25.7. Classification of comprehensive neck dissections. **A.** Classical radical neck dissection. **B.** Modified neck dissection Type I. **C.** Modified neck dissection Type II. **D.** Modified neck dissection Type III.

SOHND is recommended for squamous cell carcinoma of the oral cavity with a high risk of micrometastases in a neck that is clinically negative for disease. Byers reported a recurrence rate of 5.8% in 154 N0 patients treated with SOHND. For node-positive disease, the results of selective SOHND are more variable. Byers reported a regional recurrence rate of 15%. In 1999, Byers reported that the regional recurrence rate was 36% in patients with pathologically positive N1 neck disease who had not received radiation therapy, but was 5.6% among those who had received postoperative radiation. For pathologically positive N2b disease, the failure rate was 8.8% with radiation and 14% without.

Extended supraomohyoid neck dissection is recommended for squamous cell carcinoma of the lateral tongue. This is based on the observation that patients with primary carcinoma of the lateral border of the oral tongue have a small but increased risk of skip metastases to level IV compared with other sites in the oral cavity. Therefore, selective treatment of the N0 neck in lateral tongue cancer should include level IV.

LND is recommended for squamous cell carcinoma of the larynx or pharynx with a high risk of micrometastases in a neck that is clinically

negative for disease. If the primary tumor crosses the midline, this procedure is carried out bilaterally. LND is indicated for cancer of the oropharynx when the primary tumor is treated with surgery in a neck that is clinically negative for disease. If postoperative radiation therapy is indicated, it is not necessary to perform bilateral LND because radiation alone is effective in treating the node-negative contralateral neck. Cancer of the hypopharynx frequently metastasizes to both sides of the neck. Therefore, bilateral LND is recommended in patients with a clinically negative neck setting. In supraglottic and advanced glottic cancer, bilateral neck dissection is generally recommended. LND is not indicated for early glottic lesions. In 1985, Byers reported efficacy data for recurrence rates following LND of 3.9% among 256 patients with pathologically negative neck (pN0) disease. He also reported a recurrence rate of 7.3% among 41 patients with pathologically positive neck disease (pN+) who underwent LND; 37 of the 41 patients received postoperative radiation. However, in patients with multiple positive lymph nodes, Byers reported a regional failure rate of 30% for those treated with postoperative radiation and 33% for those who were not. Selective neck dissection is therefore not indicated when there is evidence of multiple positive nodes.

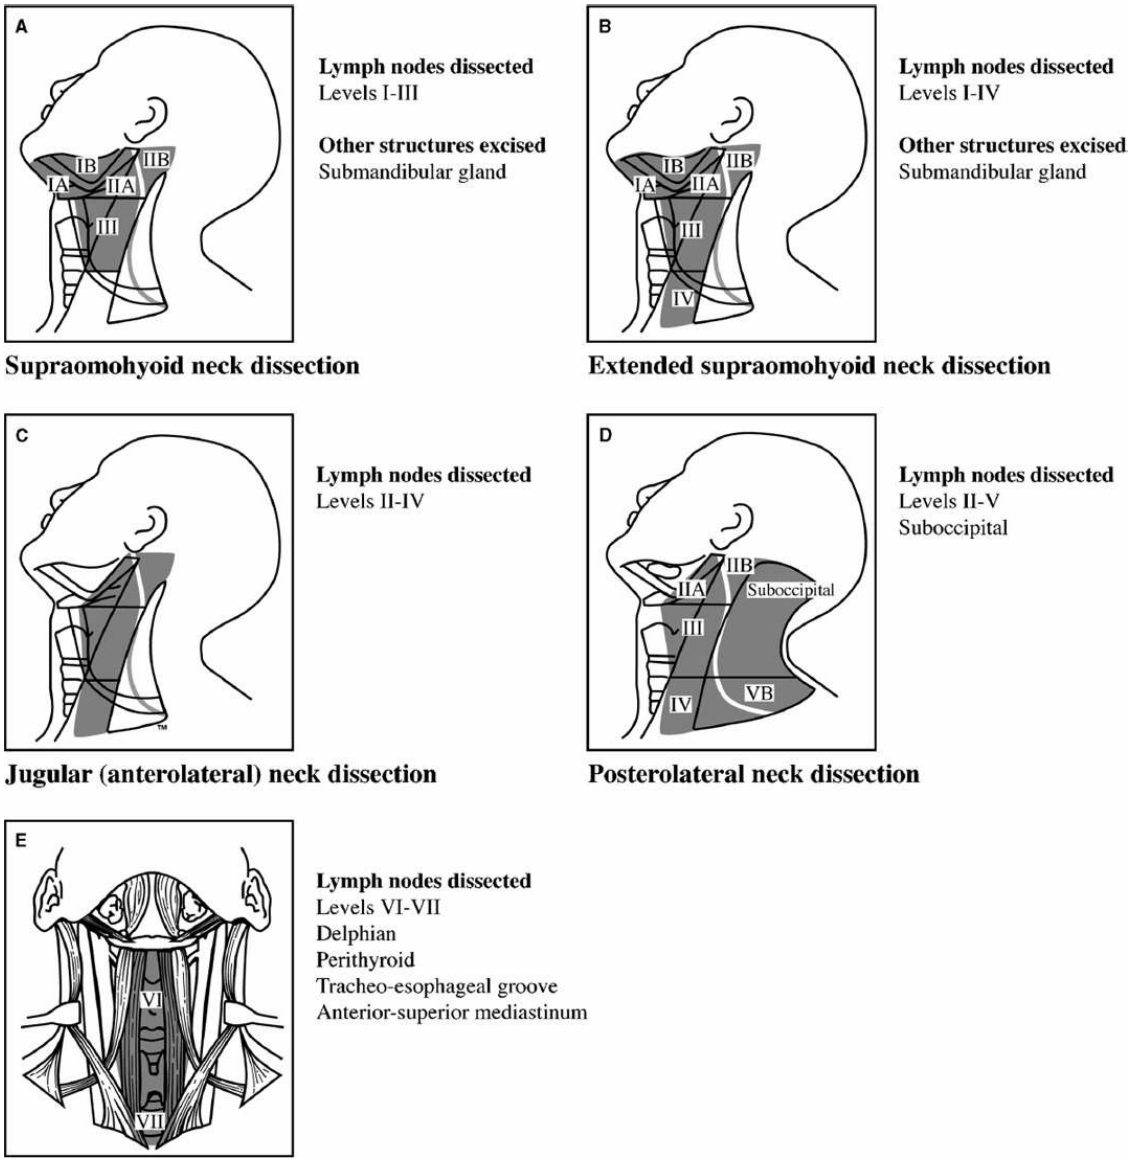

Figure 25.8. Classification of selective neck dissections. **A.** Supraomohyoid neck dissection. **B.** Extended supraomohyoid neck dissection. **C.** Jugular (anterolateral) neck dissection. **D.** Posterolateral neck dissection. **E.** Central compartment neck dissection.

PLND is recommended for primary cutaneous malignancies of the posterior scalp (e.g., melanoma and squamous cell carcinoma). *Central compartment neck dissection* is recommended for differentiated thyroid carcinoma in which the disease is limited to the pretracheal and paratracheal nodes.

Proposed New Neck Dissection Nomenclature

Recently a new neck dissection nomenclature has been suggested rather

than the American Association of Otolaryngology Head and Neck Surgery (AAO-HNS) current nomenclature. The nomenclature is as follows:

1. The symbol “ND” should be used to represent the term “neck dissection” and applied as the first component of the description. A prefix is included to denote the side of the neck using the abbreviation L for left, and R for right. If bilateral, both sides must be classified independently.
2. The second component of the description should be the neck levels and/or sublevels removed, each designated by the Roman numerals I through VII, in ascending order.
3. The third component of the description should be the nonlymphatic structures removed, each identified through the use of specified acronyms (symbols), all of which have been universally accepted.

Table 25.7 illustrates the new proposed nomenclature and how it relates to the current American Association Otolaryngology Head and Neck Surgery/American Head and Neck Society (AAO-HNS/AHNS) nomenclature.

Sentinel Node Biopsy

The sentinel lymph node is defined as the first echelon lymph node to which cancer spreads. The technique of sentinel lymph node biopsy (SLNB) allows focused examination of the lymph nodes at highest risk for metastases, so that neck dissection is performed only in patients with a positive node and the rest can be spared the morbidity of the operation. Identification of the sentinel node requires the use of preoperative lymphoscintigraphy using radioactive technetium and then blue dye injection (toluidine blue) at the time of surgery. The sentinel node is identified using a gamma probe and confirmed with the injection of blue dye at the time of biopsy. Pathology of the sentinel node requires both haematoxylin and eosin staining and also immunohistochemistry. The node requires serial sectioning at 150 micron sections for accurate analysis.

TABLE 25.7 Current and Proposed Nomenclature of Neck Dissections

AAO-HNS/AHNS Nomenclature	Proposed Nomenclature
Radical neck dissection	ND (I–V, SCM, IJV, CN XI)
Selective neck dissection (II–IV)	ND (II–IV)
Selective neck dissection (I–III)	ND (I–III)
Modified radical neck dissection with preservation of the SAN	ND (I–V, SCM, IJV)
Extended neck dissection with removal of the hypoglossal nerve	ND (I–V, SCM, IJV, CN XI and XII)
Selective neck dissection (II, III)	ND (II, III)
NA	ND (II–IV, SCM)
NA	ND (I–III, SCM, IJV, CN XI)
NA	ND (II–IV, VI)
Central compartment neck dissection or selective neck dissection (VI)	ND (VI)
Selective neck dissection (VI, VII)	ND (VI, VII)

Melanoma

Cutaneous melanoma is ideally suited to this technique because the primary tumor is easily visualized making injection into the tumor relatively straight forward. The usefulness and reliability of the technique have been well described in numerous publications since it was first reported in 1990 by Morton. In head and neck melanoma, SLNB is the most accurate way of staging the neck and is an important predictor of outcome. Patel et al. reported that the 2-year disease-specific survival for SLN-negative patients was 93% compared to 50% for SLN-positive patients (P = NS). If patients are SLN positive, they can be managed by either neck dissection or systemic therapy with immunomodulating agents such as interferon, interleukin, or vaccine-based therapy. A systematic review by Tanis et al. reported that there was no evidence to suggest that neck dissection in patients who are SLN positive improves overall survival compared to patients who did not have neck dissection. Whether or not to carry out a neck dissection in patients who are SLN positive is therefore an individual decision between surgeon and patient.

Mucosal Squamous Cell Cancer

The majority of oral cavity cancers are also easily visualized and are in general accessible to a direct injection. This has led to the suggestion that the sentinel node biopsy technique may be useful in neck management for oral cavity cancer. This technique for squamous cell carcinoma of the oral cavity was first reported in 2001 by Shoaib et al. where sentinel node biopsy was carried out prior to an elective neck dissection in patients with

a clinically negative neck. A report by Ross et al. examined SLNB in 57 clinically N0 necks in 48 patients and reported 15(35%) were upstaged by SLNB and 28 (65%) were staged SLN negative. With a mean follow-up of 18 months only one patient developed regional neck disease after being staged negative on SLNB. The overall sensitivity of the technique was 94%. However, this technique is still experimental and should only be carried out in centers with the necessary expertise and the appropriate volume of cases as it has been shown that centers who carry out this technique with less than 10 cases per year have a much lower sensitivity. Technical problems of "shine through," where the radioactivity level in the primary site potentially obscures the sentinel node, is one potential problem. The role of SLNB in advanced oral cavity cancers is limited due to false negatives resulting from obstruction of lymphatic flow caused by tumor and redirecting of flow to neighboring nodes.

Neck Dissection Post Chemoradiation

An increasing proportion of patients with advanced stage squamous cell carcinoma of the larynx and pharynx are treated with organ preservation protocols of Radiotherapy with Chemotherapy. Management of the cervical lymph nodes in these patients treated with a clinically positive neck remains an area of controversy. The neck may be managed in one of 3 ways; by observation, by planned neck dissection or by salvage neck dissection.

Observation

Observation of the neck can be done in patients who have a complete or near complete response to treatment. Evidence for this approach comes from studies by Corry et al. who have reported low regional recurrence rates. Corry et al. reported on 102 patients with N2/3 neck disease with a complete response clinically and radiologically at 12 weeks post chemoradiation where no planned neck dissection was done. With a median follow-up of 4.3 years, no patient had neck recurrence. Lau et al. reported that in patients who are observed following complete response post chemoradiation with N2/3 neck disease, the 2-year locoregional recurrence free survival was 95%. However, Rengen et al. reported on 65 patients who had a complete response to chemoradiation (CTRT) managed by neck observation. With a median follow-up of 9 years, there was a 10% to 15% incidence of neck recurrence. Patients who had a complete

response to induction chemotherapy were less likely to recur raising the suggestion that response to induction chemotherapy could be used as the indicator to who should have a planned neck dissection.

Planned Neck Dissection

Planned neck dissection is normally carried out in patients with N2 and N3 neck disease irrespective of the response to CTRT. The neck dissection is usually carried out 6 weeks after completion of chemoradiation; this has the advantage of carrying out the neck dissection before the onset of fibrosis, thereby making the neck dissection technically similar in complexity to a nonchemoradiation neck dissection. Evidence for a policy of planned neck dissection comes from studies that have shown the presence of tumor in neck dissection specimens in patients who have complete or near-complete radiologic and clinical response in the neck. Before the introduction of positron emission tomography (PET) scan, planned neck dissection was the conventional method for managing the neck following CTRT. Some groups still practice this policy due to limitations or nonavailability of PET. However, most groups now use a policy of salvage neck dissection.

Salvage Neck Dissection

Salvage neck dissection is normally carried out if there is clinical and/or radiologic evidence of neck disease after completion of chemoradiation. The use of fluorodeoxyglucose positron emission tomography (FDG-PET) has helped to identify patients at risk for residual cancer following CTRT allowing us to select patients who will benefit from a policy of salvage neck dissection. FDG-PET is usually carried out at 12 weeks following completion of CTRT to minimize any false-positive results from residual inflammation from CTRT. Salvage neck dissection in patients who have PET-positive nodes is therefore carried out after 12 weeks post CTRT. This has the disadvantage of making the operation technically more difficult due to the onset of fibrosis. This can result in increased morbidity in terms of shoulder dysfunction, wound complications, and quality of life compared to neck dissection carried out without chemoradiation. In addition, pathologic examination of specimen often fails to show evidence of disease outside of the positive nodes on the initial computed tomography (CT) scan. This has led many surgeons to question the need to carry out comprehensive neck dissection in this situation, and there are now several reports describing the use of selective or superselective

(removal of 2 or less contiguous neck levels) neck dissection to treat residual disease with no increase in regional recurrence.

Management of the Neck in Thyroid Cancer

In patients with a clinically negative neck, the incidence of occult micrometastases in the neck ranges from 30% to 70%. The incidence depends on the size of the primary (26% in tumors <1 cm and 66% in tumors >1 cm). Shaha reported on 1,038 patients at Memorial Sloan Kettering Cancer Center (MSKCC) and reported 56% of patients had a clinically positive neck at the initial evaluation. Given the fact that lymph node metastases are so common it may seem somewhat surprising that thyroid cancer has a 93% to 98% 10-year survival rate. There remains controversy about the impact of nodal metastasis on survival. Several studies suggest there is no decrease in survival in the presence of nodal disease, especially in the younger population of patients less than 45 years of age. Other studies report a reduced survival. Nodal size greater than 3 cm and extracapsular spread are poor prognostic signs. The management of the neck therefore is a controversial subject.

Management of the Clinically Negative Neck

Central Compartment Nodes

Because of the high incidence of occult metastases, many have recommended elective treatment of the central compartment lymph nodes. In a case control study of 195 patients having central compartment neck dissection, Tisell et al. reported that the 10-year survival was greater in the group having neck dissection compared with those who did not (98.4% vs. 89% to 92%). Other authors suggest that adjuvant radioactive iodine therapy may be an alternative treatment because central compartment dissection is associated with a high incidence of temporary and permanent hypoparathyroidism as well as increasing the risk of damage to the recurrent laryngeal nerves. As such, dissection of the central compartment should only be done if any nodes appear enlarged or suspicious.

Lateral Compartment Nodes

Even though occult metastases are seen in up to 40% of patients, studies have shown that in patients having a lateral neck dissection and those who do not, the regional recurrence rates were equivalent, suggesting that routine elective dissection of the lateral neck is not indicated. Radioactive

iodine therapy may be sufficient to treat occult metastatic disease. Elective treatment of the lateral neck is therefore not standard practice.

Treatment of the Clinically Positive Neck

If nodes are present in the central compartment, central compartment neck dissection is done. If nodes are present in the lateral compartment, then a lateral neck dissection should also be carried out. Patients who have positive lateral nodes but no nodes in the central compartment clinically (i.e., skip metastases) are treated with a combined lateral and central neck dissection as the incidence of positive nodes in the central neck is as high as 84%. The main debate is over what type of lateral neck dissection should be carried out. Several studies have shown that multiple neck levels are involved when the lateral neck is clinically positive. This is an argument against “berry picking” or superselective neck dissection as this may lead to a higher rate of missed disease and recurrent operations. It is recommended that a comprehensive MRND type III be carried out for the positive neck. In a 2006 study of 44 neck dissections in 39 patients, all patients had levels II to V dissected; the incidence of metastases was 52% in level II, 57% in level III, 41% in level IV, and 21% in level V. Another study by Roh reported 76% level IV and 70% level IIA and III nodes were involved, 17% of level IIb, 4% in level I, 16% in the infra-accessory compartment of level V but 0% in the supra-accessory nerve compartment of level V. These authors therefore recommended dissection of levels II to V including level IIb but sparing the supra-accessory compartment of level V.

Management of the Neck in Melanoma

Management of the Clinically Negative Neck

Regional nodal metastases are relatively rare in thin cutaneous melanomas (<1 mm in thickness) of the head and neck region and elective neck dissection is therefore not recommended. Thicker lesions (>4 mm) are associated with a high incidence of distant metastases, and therefore elective neck dissection is unlikely to impact on survival in this population. The role of elective neck dissection in patients with intermediate thickness (1.0 to 4 mm thick) melanomas continues to be debated, as only about 15% of patients will have histologically demonstrable metastatic nodes so that the remaining 85% may be considered to have undergone an unnecessary procedure. These patients

are selected for sentinel node biopsy to facilitate further management. Four randomized trials and a large, retrospective study in patients with intermediate thickness melanomas have failed to demonstrate any improvement in survival following elective neck dissection.

Management of the Clinically Positive Neck

Clinically apparent regional lymphatic spread to the parotid gland or to cervical lymph nodes should be managed with superficial parotidectomy and comprehensive neck dissection, with likely adjuvant radiation therapy. Originally believed to be a radioresistant tumor, cutaneous melanoma has a radiation response different from that of squamous cell carcinoma, demonstrating effective tumor cell death at a higher dose per fraction than that of squamous cell carcinoma. As a result, hypofractionation schemes utilizing large-dose fractions have been employed. Adjuvant hypofractionated radiotherapy has been shown to improve 5-year actuarial locoregional control rates for patients with stage II and III disease.

Management of the Neck in Salivary Gland Cancer

Management of the Clinically Negative Neck

Occult cervical metastases are uncommon in cancers of the major salivary glands. Armstrong et al. reported an incidence of occult metastases of 12% in 407 patients who were clinically node negative. Significant risk factors for occult nodal metastases from cancers of the major salivary glands include primary tumor size greater than 4 cm in size (20% vs. 4%), and high tumor grade (49% vs. 2%). Elective neck dissection should therefore be considered in patients with high-grade malignancies and T3/T4 tumors. Selective neck dissection for parotid cancer should encompass levels I, II, III, and IV. Alternatively, if it is anticipated that postoperative radiotherapy will be given to the primary site, then the ipsilateral neck can be treated by radiotherapy at the same time rather than by elective neck dissection.

Management of the Clinically Positive Neck

For clinically apparent nodal metastases, patients should be treated by parotidectomy, and comprehensive neck dissection followed by postoperative radiotherapy. Klussman et al. has reported that on multivariate analysis, lymph node involvement of level I was an independent predictor for poorer disease specific survival.

The benefit of adjuvant radiotherapy has been demonstrated in a matched-pair analysis of patients receiving combined surgery and postoperative radiotherapy compared to patients treated with surgery only. Five-year determinate survival for the combined therapy group was improved compared to the group undergoing surgery only (48.9% vs. 18.7%), and locoregional control was improved as well (69.1% vs. 40.2%). The benefit of postoperative radiation therapy was especially pronounced in patients with high-stage and high-grade primary tumors.

Management of the Neck in HPV-Positive Oropharyngeal Cancer

The incidence of oropharyngeal squamous cell carcinoma has increased dramatically over the past two decades. In a US study examining data from the Surveillance, Epidemiology, and End Results (SEER) program, the incidence of oropharyngeal cancers increased by 1.3% for tongue base cancers and by 0.6% for cancers of the tonsil for each year between 1973 and 2004. The reason for this increase is due to infection with human papilloma virus (HPV). The causal link between HPV and oropharyngeal cancer was first shown in a study by Gillison et al. It is now estimated that 70% of oropharyngeal cancers are associated with previous HPV infection. The high-risk HPV 16 subtype is found in 90% of these cancers with other high-risk subtypes 31, 33, and 18 identified in the other cases. Importantly, oropharyngeal cancers due to HPV have a different epidemiology, natural history, response to treatment, and outcome. Patients often present with smaller primary tumors but larger and cystic cervical nodal disease (Fig. 25.9). Therefore, patients often present with nodal disease, without typical head and neck cancer risk factors. The primary tumor is often a low T stage and can be small or not detectable by clinical examination or radiographic investigation.

There have been a large number of retrospective studies demonstrating patients with HPV-positive tumors of the oropharynx have a better prognosis than patients with HPV-negative tumors. The traditional TNM classification system has been reported to be less effective in predicting cancer-specific mortality in oropharynx cancers. Thus, the latest revision of the AJCC–UICC, TNM staging system has developed an entirely different staging system for HPV-positive oropharynx cancers (Ref: AJCC staging manual, 2016). Prognostic factors used in HPV-negative tumors such as margin status, lymphovascular invasion, pN status, and extra-

capsular spread were not predictive in HPV-positive tumors in a study reported by Iyer et al. In HPV-negative cancer, nodal stage has a very important predictor of outcome. However, the same is not true in HPV-positive disease. With the exception of N3 disease, nodal stage is not a predictor of outcome (Fig. 25.10). In patients with N2b disease, patients with >4 positive nodes had the same outcome as those with <4 positive nodes. Because these patients do so well, management of the positive neck in HPV-positive patients is more selective. Such patients may not require the traditional comprehensive neck dissection as advocated for HPV-negative disease. Rather, HPV-positive neck disease can be managed by a more selective approach with removal of levels 2, 3, 4 followed by adjuvant PORT.

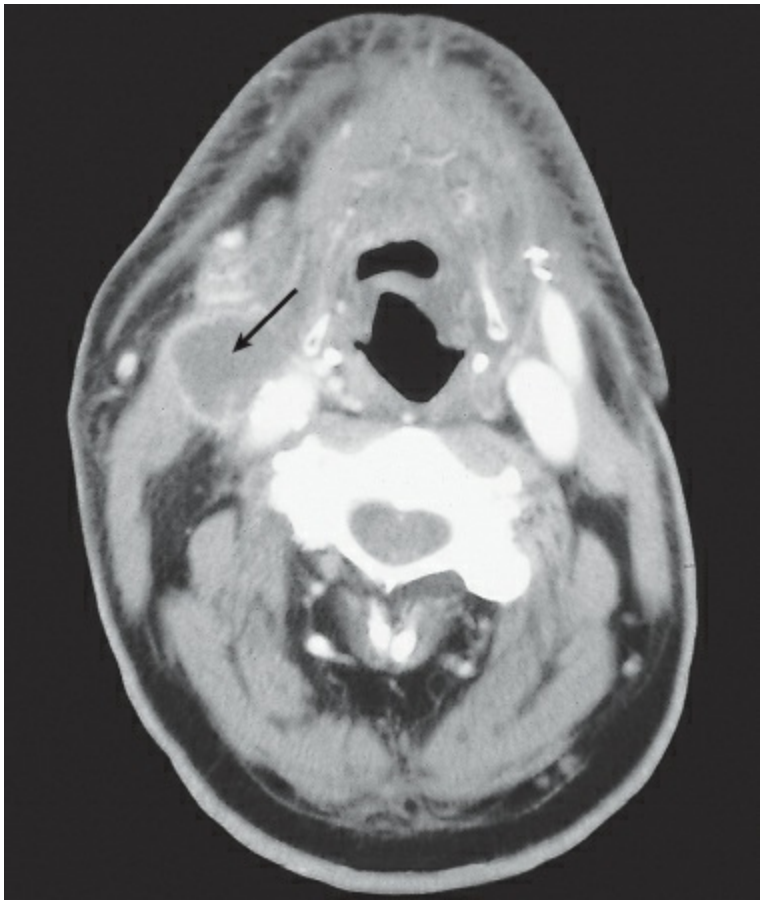

Figure 25.9. Typical cystic level II neck metastases as seen in patients with HPV-positive oropharynx cancer.

TECHNIQUE OF NECK DISSECTION

COMPREHENSIVE MODIFIED NECK DISSECTION: TYPE 1 (CMND TYPE 1)

This is currently the most frequently performed operation in patients with clinically positive neck disease (cN+) where the accessory nerve is not grossly involved by cancer.

Anesthesia

General endotracheal anesthesia with muscle relaxation is essential for performing a neck dissection. The patient is usually positioned in a supine position with the head elevated to 30 degrees. The neck is hyperextended and rotated to the opposite side.

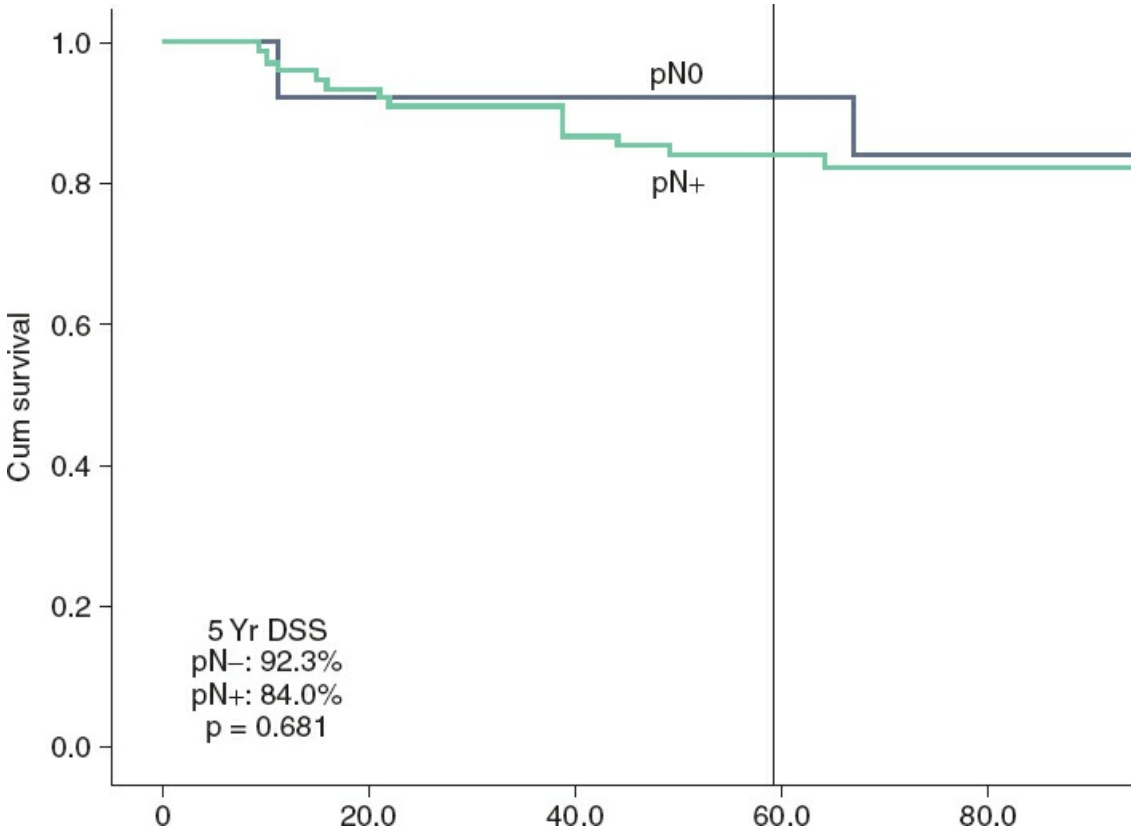

Figure 25.10. Impact of nodal disease on survival in patients with HPV-positive oropharynx cancer.

Incision

For CMND type I, a single trifurcate neck incision was the most frequently employed incision in the past. However, it is now possible that these operations can be carried out equally effectively with a single skin crease incision in the mid neck provided the incision is of sufficient length. Figure 25.11 illustrates different types of neck incisions that can be used in neck dissections.

Procedure

The dissection begins with elevation of the posterior skin flap. Skin is incised with the scalpel and then the remainder of the procedure is carried out using electrocautery. The skin incision is deepened through the subcutaneous tissue and then through the platysma muscle. The posterior flap is then raised in the subplatysmal plane by applying traction to the flap with skin hooks and countertraction of the deeper soft tissues. The flap is elevated up to the anterior border of the trapezius muscle (Fig. 25.12). During this elevation, care is taken not to enter the posterior triangle fat pad to prevent any injury to the spinal accessory nerve. The anterior border of trapezius muscle is skeletonized, and then care is taken to identify the spinal accessory nerve (Fig. 25.13). This can be done either by identifying it as it passes onto the undersurface of the trapezius muscle in the lower part of the neck, or by identifying it 1 cm superior to Erb point (which is a plexus of cervical cutaneous nerves on the posterior border of the sternocleidomastoid muscle ~6 cm from the inferior lobule of the ear). Once identified, the nerve is dissected out from its entry in the trapezius muscle up to the posterior border of sternocleidomastoid muscle. The nerve is then followed up through the sternocleidomastoid muscle, dividing the muscle with electrocautery while protecting the nerve with an Adson clamp under direct vision at all times.

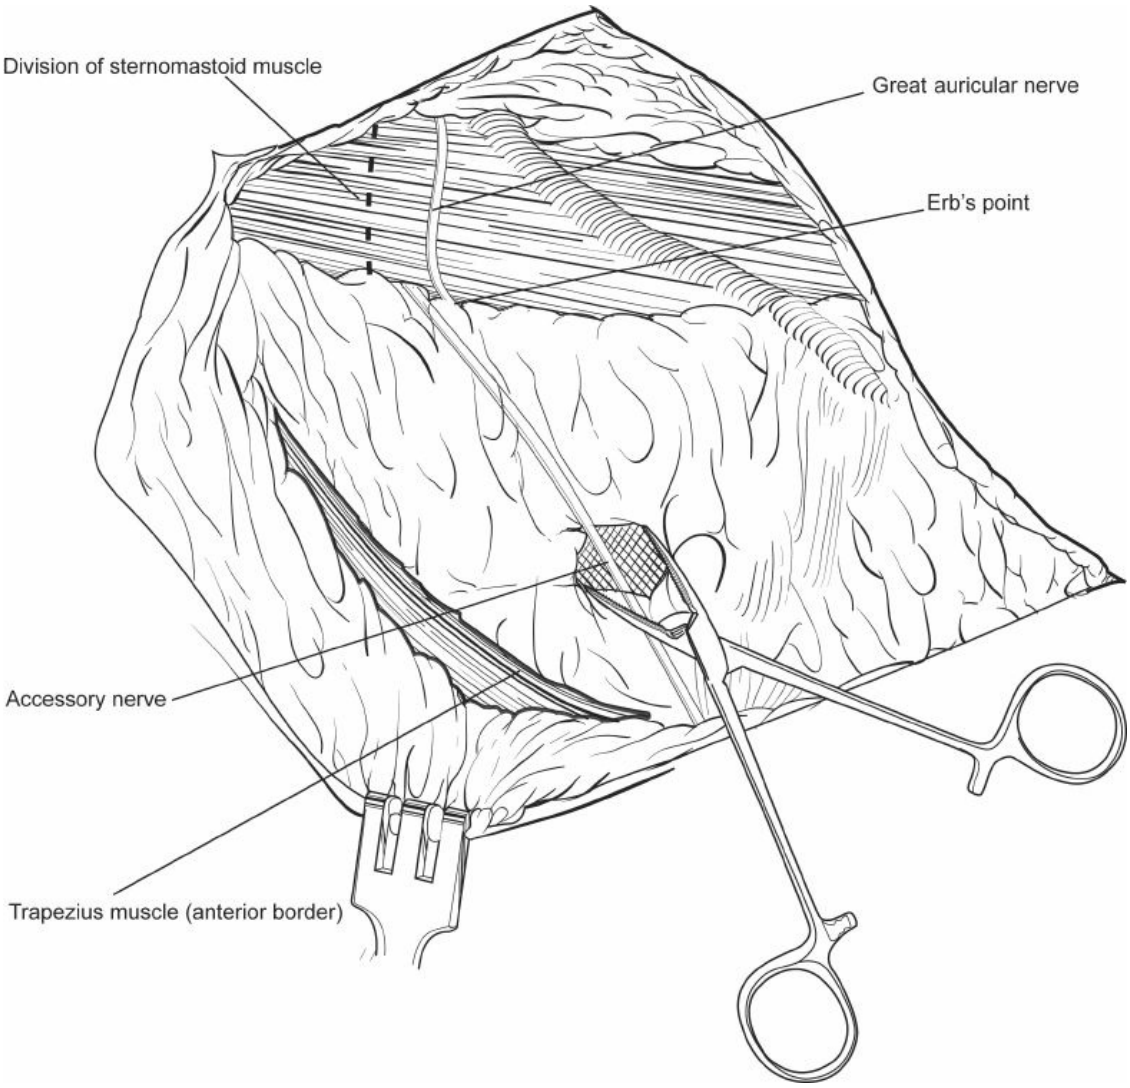

Figure 25.12. Elevation of the posterior skin flap.

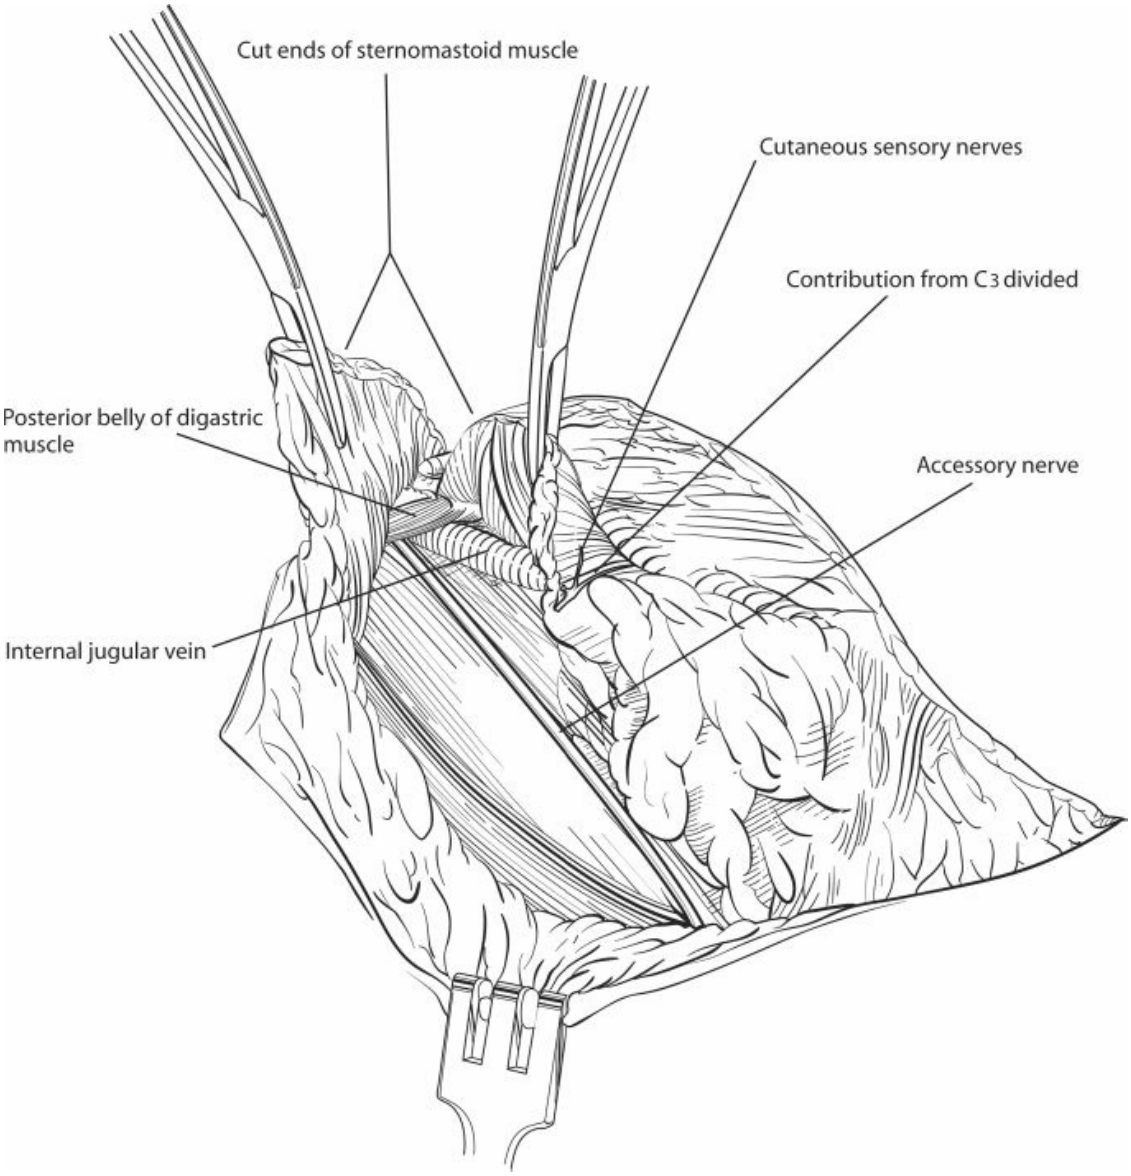

Figure 25.13. Identification of the spinal accessory nerve in the posterior triangle of the neck.

Retracting the anterior portion of the sternocleidomastoid muscle cephalad and the posterior portion caudad assists in the dissection of the nerve. The nerve is then carefully dissected out in a cephalad direction along the lateral border of the internal jugular vein up to its exit from the jugular foramen at the skull base under the posterior belly of the digastric muscle. Once this is done, the nerve is then carefully separated from underlying tissue using the Martin forceps and Reynolds scissors. The superior attachment of the sternocleidomastoid muscle is then detached from the mastoid process, and fibrofatty tissue lying in the supra-accessory triangle is dissected off the muscular floor, working from a lateral-to-medial direction. The tissue is sequentially dissected off the splenius

capitis muscle, followed by the levator scapulae muscle. At this point, the tissue is then able to be passed under the dissected accessory nerve and dissected off the rest of the muscular floor of the posterior triangle (Fig. 25.14). Working in a lateral-to-medial direction, the anterior border of each subsequent muscle is exposed. The posterior scalene muscle is exposed, and then the inferior belly of omohyoid muscle is divided at its attachment on the scapula. Transverse cervical vessels are encountered inferiorly and are divided between clamps and ligated with silk ties. This allows the specimen to be retracted medially, allowing further dissection of the muscular floor, first exposing the middle scalene muscle and then the anterior scalene muscle with the brachial plexus in between.

On the anterior surface of the anterior scalene muscle, the phrenic nerve is identified passing in a lateral-to-medial direction (Fig. 25.15). Care must be taken not to elevate this nerve with the overlying block of soft tissue. Once the phrenic nerve is identified and preserved, the dissection then continues in a cephalad direction, identifying the cutaneous cervical branches as they separate off the cervical rootlets. These branches are divided and the stumps of the nerve roots are ligated. This allows the specimen to be further retracted medially to expose the internal jugular vein, common carotid artery, and the vagus nerve.

At this point, the specimen is allowed to drop back into its natural position in the posterior triangle. Attention is then turned to the anterior skin flap. The transverse skin incision is completed from the trifurcation point up to its medial end. The skin, subcutaneous tissue, and platysma muscle are divided, and an anterior subplatysmal flap is elevated up to the midline superiorly and to the medial end of the sternocleidomastoid muscle at its attachment to the sternum inferiorly. A large loop retractor is used to increase exposure inferiorly. Using electrocautery with coagulating current, the sternal and clavicular heads of sternocleidomastoid muscle are divided. The muscle is then retracted in a cephalad direction, and loose areolar tissue is dissected to expose the carotid sheath. The lateral border of the strap muscles is retracted medially, allowing the carotid sheath to be fully exposed. The sheath is opened, and the common carotid artery, vagus nerve, and internal jugular vein identified and dissected. The internal jugular vein is then divided between clamps and doubly ligated with 2-0 silk ties (Fig. 25.16). A 3-0 chromic catgut transfixion suture is used to secure the distal end of the vein. Lymphatic tissue lying lateral to the internal jugular vein encompassing the thoracic duct on the left side and

unnamed lymphatics on the right hand side of the neck are carefully divided in clamps and ligated with silk ties to prevent chyle leakage. At this juncture, the proximal portion of the transverse cervical vessels is dissected, divided, and ligated with 3-0 silk.

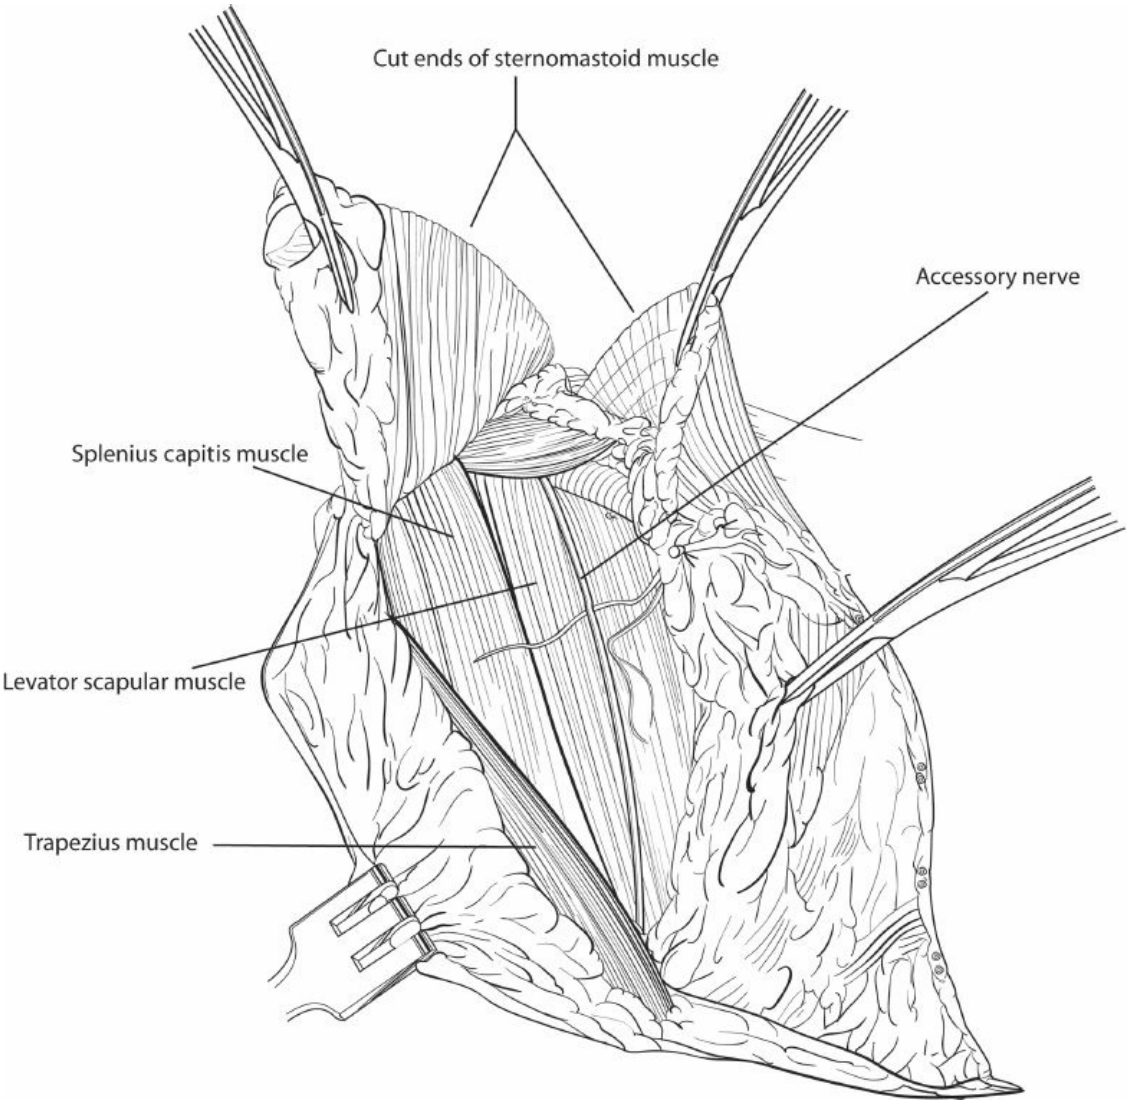

Figure 25.14. Dissection of fibrofatty tissue in the posterior triangle of the muscular floor proceeds in a lateral-to-medial direction.

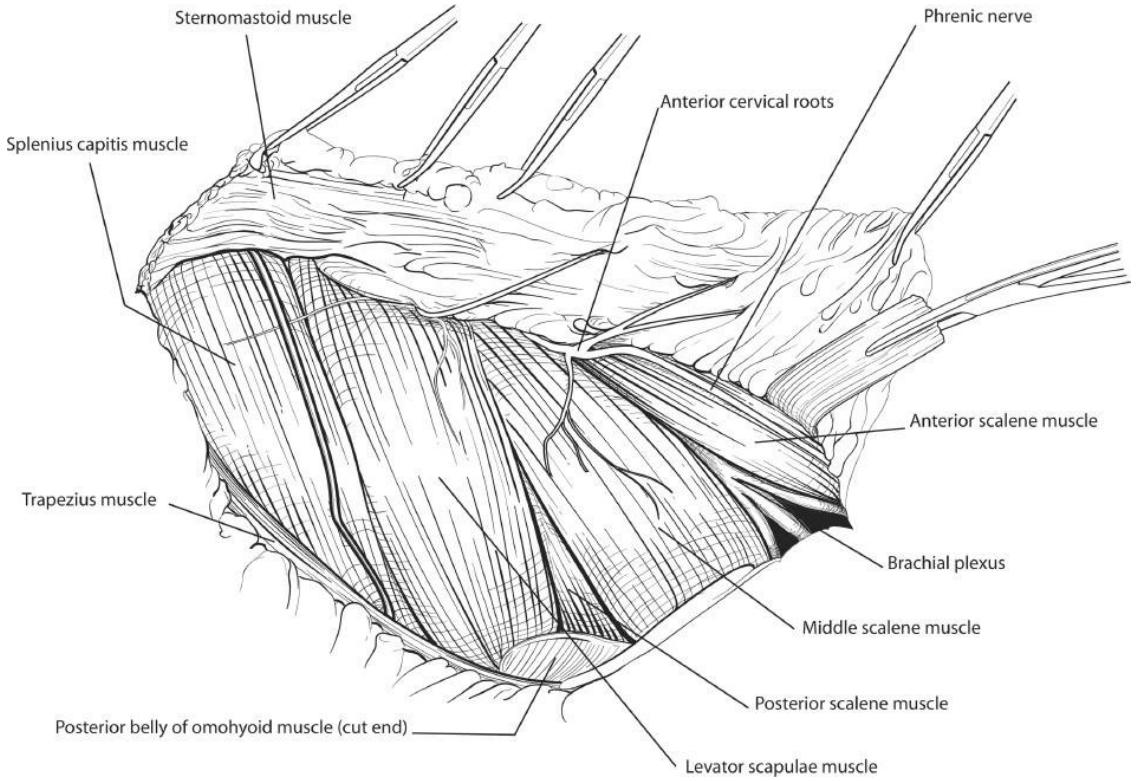

Figure 25.15. Identification of the phrenic nerve on the surface of the anterior scalene muscle.

The soft tissue, including sternocleidomastoid muscle and internal jugular vein, is now retracted in a cephalad direction and carefully dissected in the avascular plane off the vagus nerve and carotid artery (Fig. 25.17). The middle thyroid vein needs to be identified, divided, and ligated with 3-0 silk as it enters the medial aspect of the internal jugular vein. Working in a cephalad direction, the hypoglossal nerve is then identified beyond the bifurcation of the carotid artery. Additional medial mobilization of the specimen is obtained by dividing the superior cervical plexus. The anteromedial limit of the dissection is the anterior belly of the omohyoid muscle. This is incorporated into the specimen by dissecting it up to its attachment to the hyoid bone, where it is then detached. Careful dissection at this level allows identification of the superior thyroid vessels. The superior thyroid vein is divided and ligated, and the superior thyroid artery is preserved.

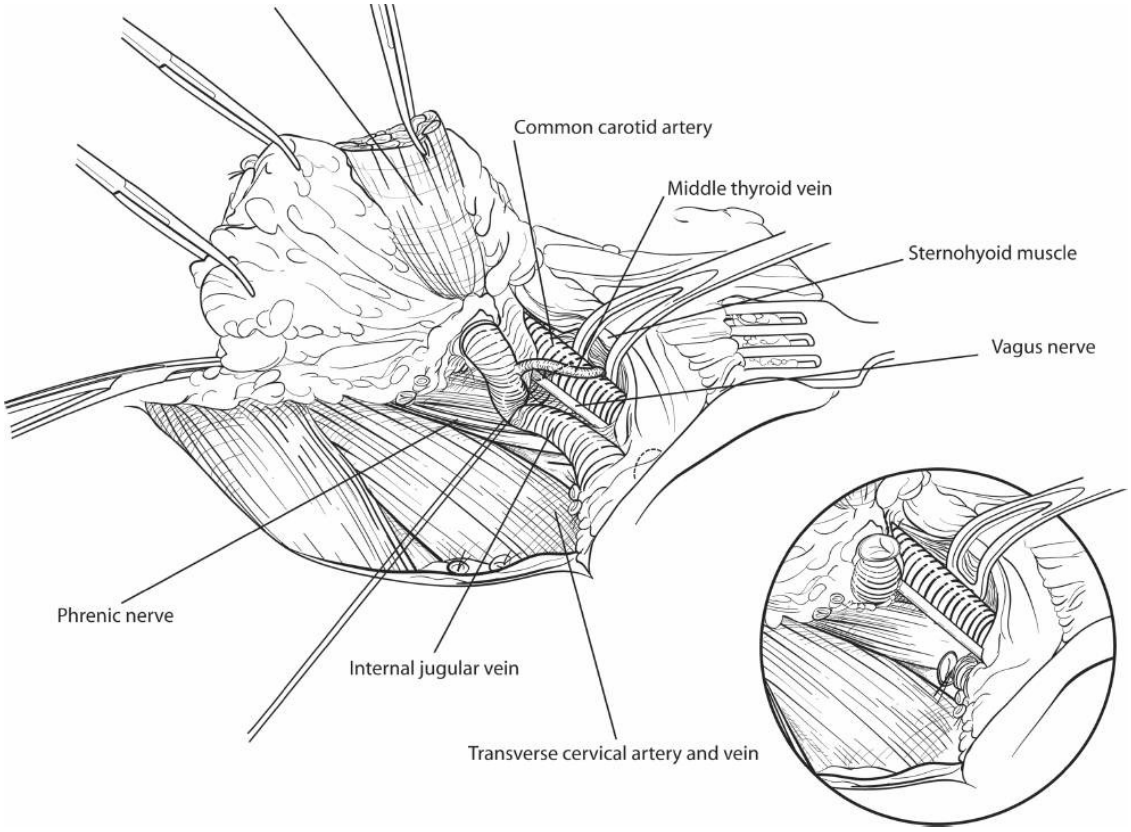

Figure 25.16. The lower end of the internal jugular vein is identified, dissected, and then divided between clamps.

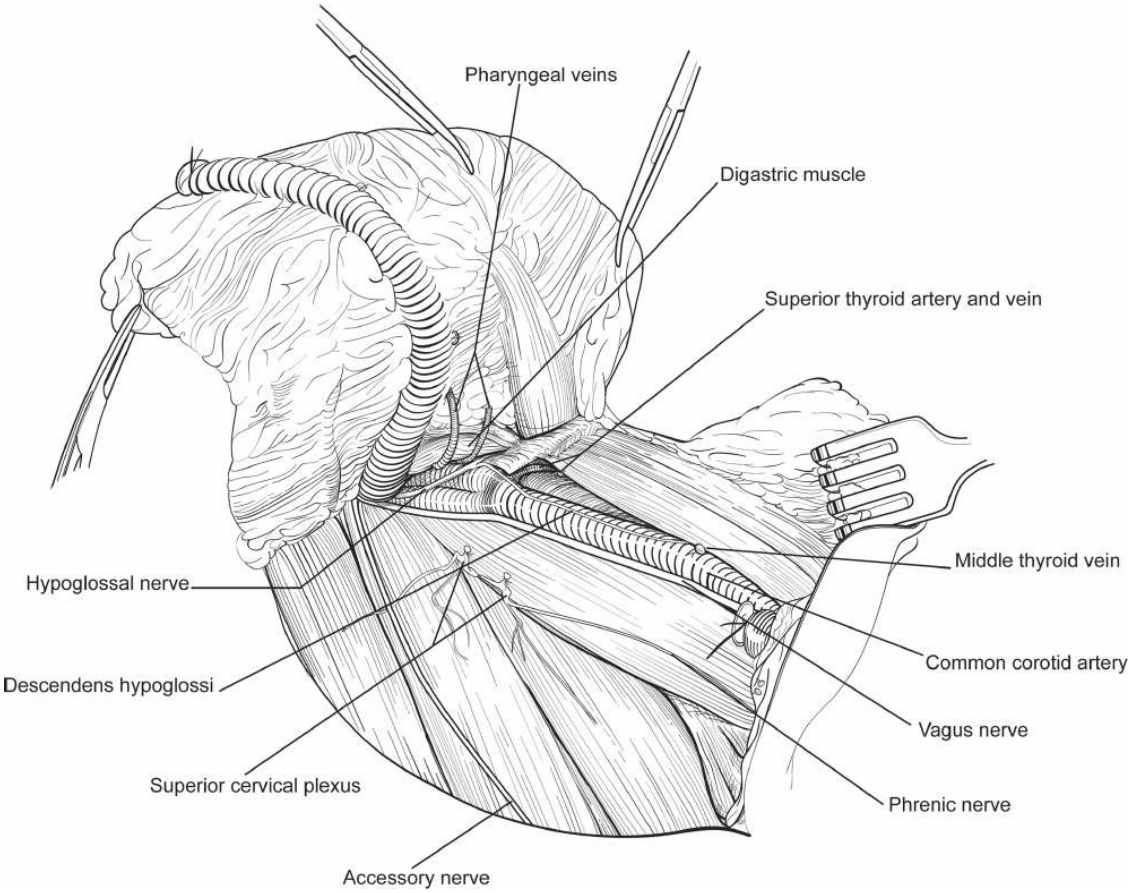

Figure 25.17. Dissection of the sternocleidomastoid muscle and internal jugular vein proceeds in a cephalad direction off the carotid artery and vagus nerve.

The superior skin flap is then elevated. Having divided the platysma muscle, the fascia on the inferior aspect of the submandibular gland is divided and dissected, allowing the superior skin flap to be raised in this plane. This allows the marginal mandibular branch of the facial nerve to be exposed, protected, and preserved. This nerve lies just anterior to the submandibular fascia and superficial to the posterior facial vein (Fig. 25.18). The vein is ligated and its upper stump retracted cephalad, protecting the marginal branch of the facial nerve (Fig. 25.19). Anteriorly, this dissection is carried out sharply, elevating the nerve with the skin flap. In performing this maneuver, the cervical branch of the facial nerve is identified and it may be divided distal to its separation from the marginal mandibular branch. Dissection now proceeds along the lower border of the mandible. The fascial attachment between the sternocleidomastoid muscle and angle of mandible is divided, and then dissection along the inferior border of the mandible allows the delivery of the prevascular facial lymph nodes. The facial vein and artery are divided at this point on the posterior superior aspect of the submandibular gland. Identification of the anterior belly of the ipsilateral and contralateral digastric muscles is then carried out. Nodal tissue in the submental triangle is dissected out, ligating vessels in the apex of the triangle with 3-0 silk ties.

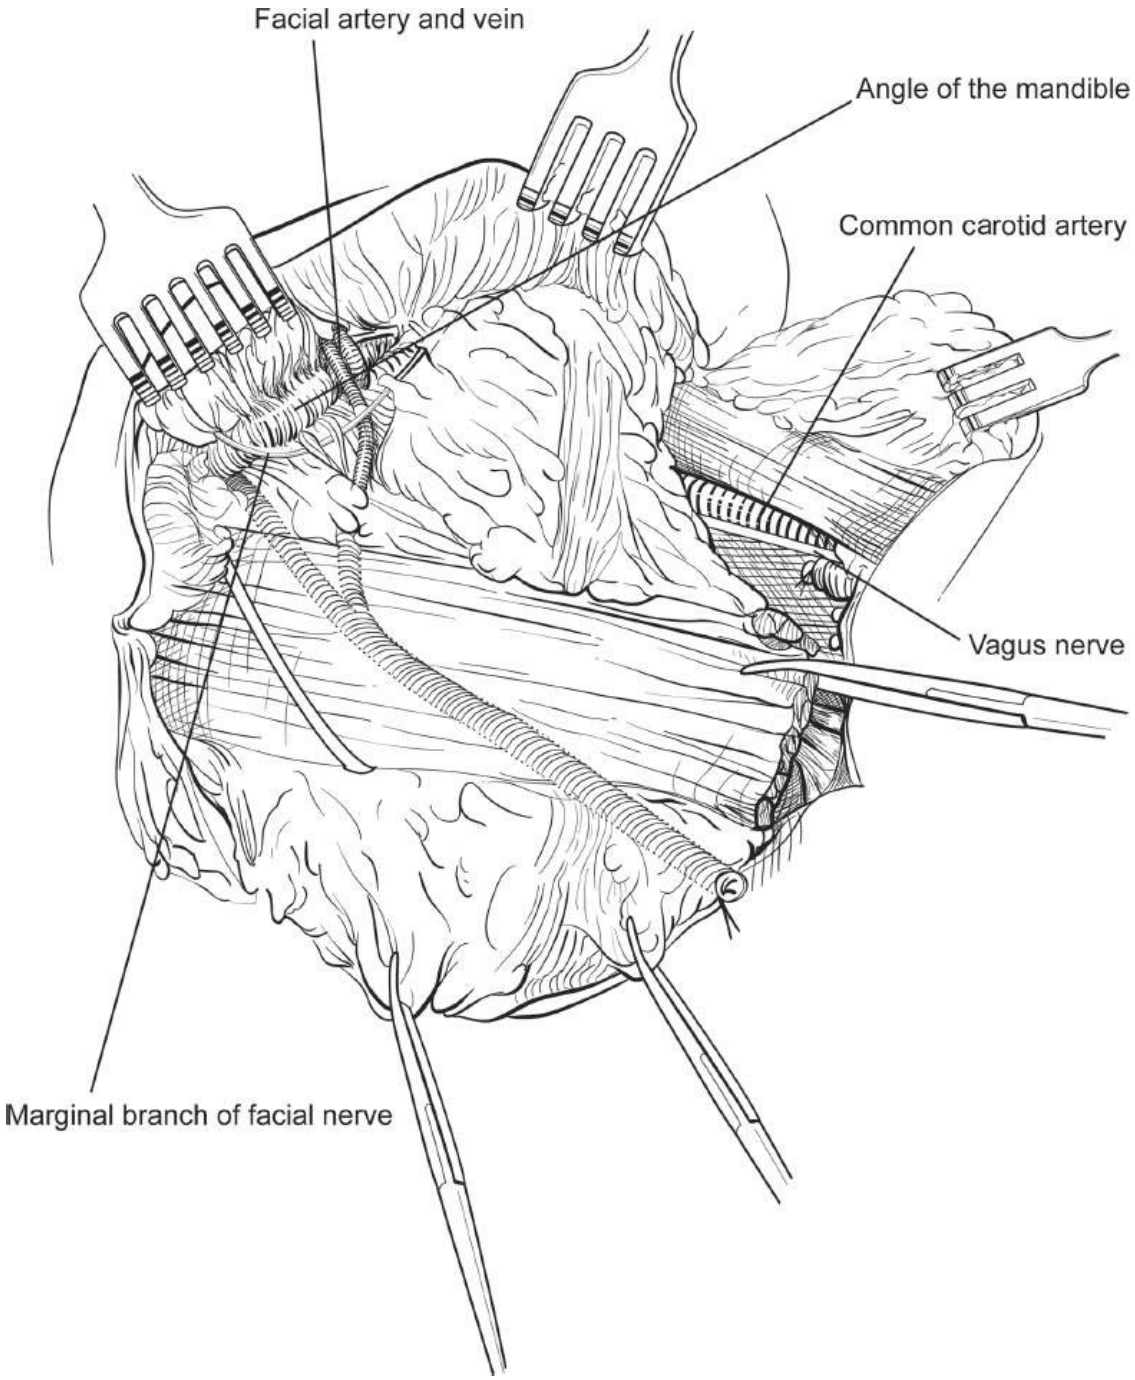

Figure 25.18. Identification of the marginal branch of the facial nerve anterior to the submandibular fascia and superficial to the posterior facial vein.

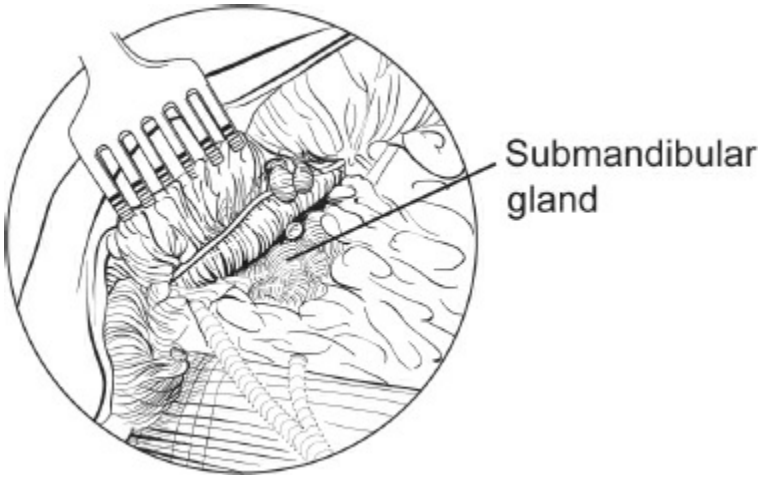

Figure 25.19. Ligation of the posterior facial vein with retraction of its upper stump cephalad to protect the marginal branch of the facial nerve.

The soft tissue from the submental triangle is then dissected off the ipsilateral anterior belly of the digastric muscle, followed by the mylohyoid muscle. The neurovascular bundle to the mylohyoid muscle is identified, divided, and ligated (Fig. 25.20). Several clamps are used to apply gentle traction on the submandibular gland, allowing it to be mobilized from its bed. A loop retractor is placed under the free edge of the mylohyoid muscle, retracting it superomedially. This maneuver allows exposure of the lingual nerve and the secretomotor fibers to the submandibular ganglion. These fibers are divided, taking care to protect and preserve the lingual nerve (Fig. 25.21). Following this, the submandibular duct is dissected, divided, and ligated. Care is taken not to enter the fascia of the hyoglossus muscle as it is in this plane that the hypoglossal nerve is located. The submandibular gland is now retracted laterally and separated from the posterior belly of the digastric muscle. The proximal portion of the facial artery is then identified on the posteromedial aspect of the posterior belly of the digastric muscle. It is divided in clamps and ligated with 3-0 silk (Fig. 25.22).

Following this, the tail of parotid is retracted cephalad, allowing access to the posterior belly of the digastric muscle. Several small pharyngeal veins need to be divided and ligated. After this, the posterior belly of the digastric muscle is retracted cephalad with a deep right-angled retractor. The occipital artery and vein lying superficial to the internal jugular vein are divided and ligated, allowing exposure of the upper end of the internal jugular vein at the base of the skull. The vein is then skeletonized

circumferentially and then doubly ligated with 2-0 silk (Fig. 25.23). The specimen is then able to be delivered.

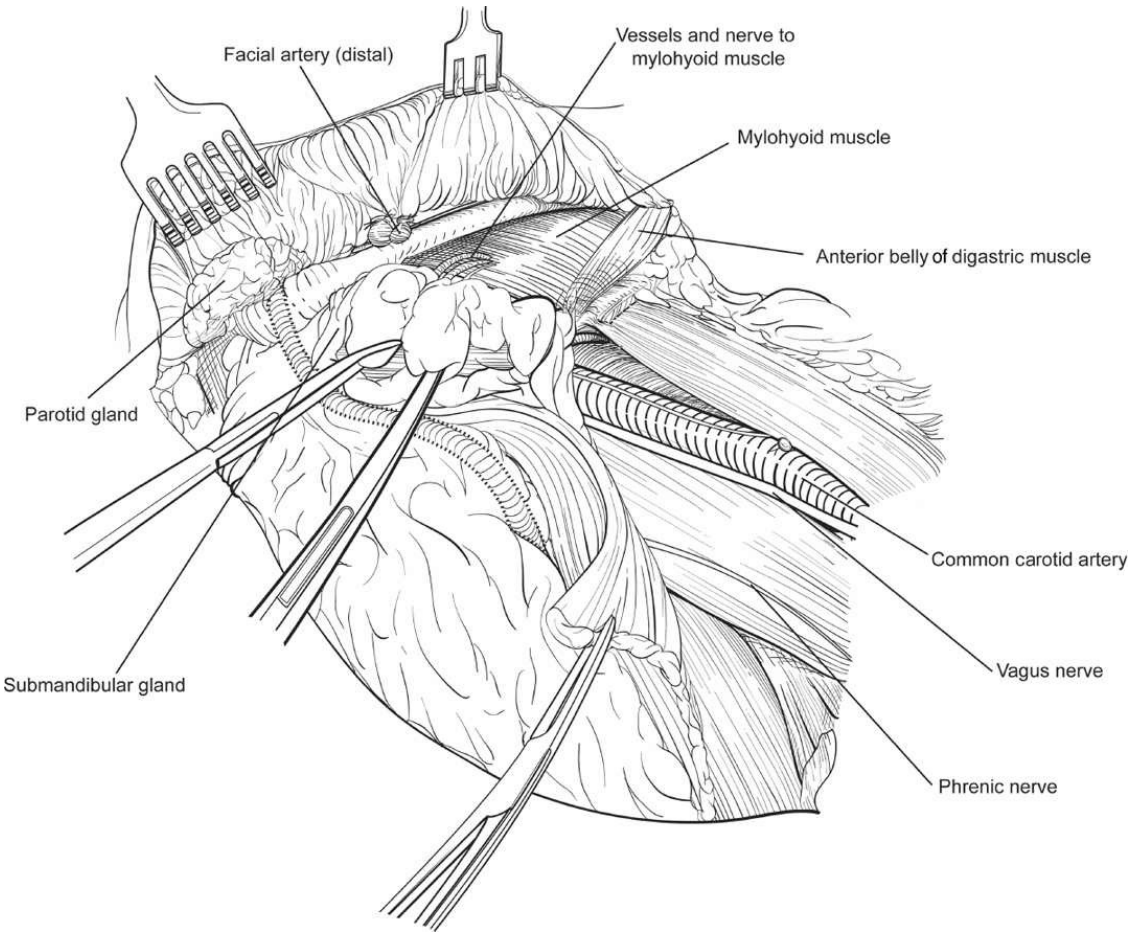

Figure 25.20. The neurovascular bundle to the mylohyoid muscle is identified, divided, and ligated.

Meticulous hemostasis is then secured with ligation or electrocautery and the wound irrigated with a plentiful amount of saline. Large suction drains are inserted through stab incisions in the lower skin flaps (Fig. 25.24). One drain is placed along the anterior border of the trapezius muscle and held in position with a loop of chromic catgut suture. An anterior drain is placed along the strap muscles, medial to the carotid artery, and again secured in place with a loop of chromic catgut suture. Both drains are secured to skin with a purse-string silk suture. The incision is then closed in two layers using 3-0 chromic catgut interrupted sutures for the platysma muscle and 5-0 nylon for skin.

Suction on the drains is maintained while the wound is being closed. An airtight closure is required to ensure adherence between the skin and deep structures of the neck. The drains remain in place for 4 to 7 days and

are removed only once minimal serous drainage is present.

SELECTIVE NECK DISSECTION

Supraomohyoid Neck Dissection (SOHND)

The skin incision used for the SOHND is a transverse incision in a skin crease approximately 2 fingerbreadths below the inferior border of the mandible (Fig. 25.11A). The skin incision is deepened through the platysma muscle with electrocautery. Care is taken to preserve the greater auricular nerve as it courses over the sternocleidomastoid muscle. The superior flap is raised first in the subplatysmal plane. Fascia overlying the submandibular gland containing the marginal branch of the facial nerve is incised, and this layer is raised along with the superior skin flap using blunt-end retractors. Dissection of the submental and submandibular triangles is then carried out in an identical fashion to that described for MRND type I. Dissection then proceeds to level II and III lymph nodes. An inferior skin flap is raised in the subplatysmal plane down to the posterior edge of the sternocleidomastoid muscle laterally and the sternal attachments of sternocleidomastoid muscle inferiorly. A loop retractor is used to retract the inferior flap. Fascia on the anterior border of the sternocleidomastoid muscle is incised, and the fascial attachments between the tail of parotid gland and sternocleidomastoid muscle are dissected, allowing exposure of the posterior belly of the digastric muscle. A large loop retractor is used to retract the sternocleidomastoid muscle laterally, dividing multiple small feeding vessels from the occipital and superior thyroid artery as they enter the sternocleidomastoid muscle.

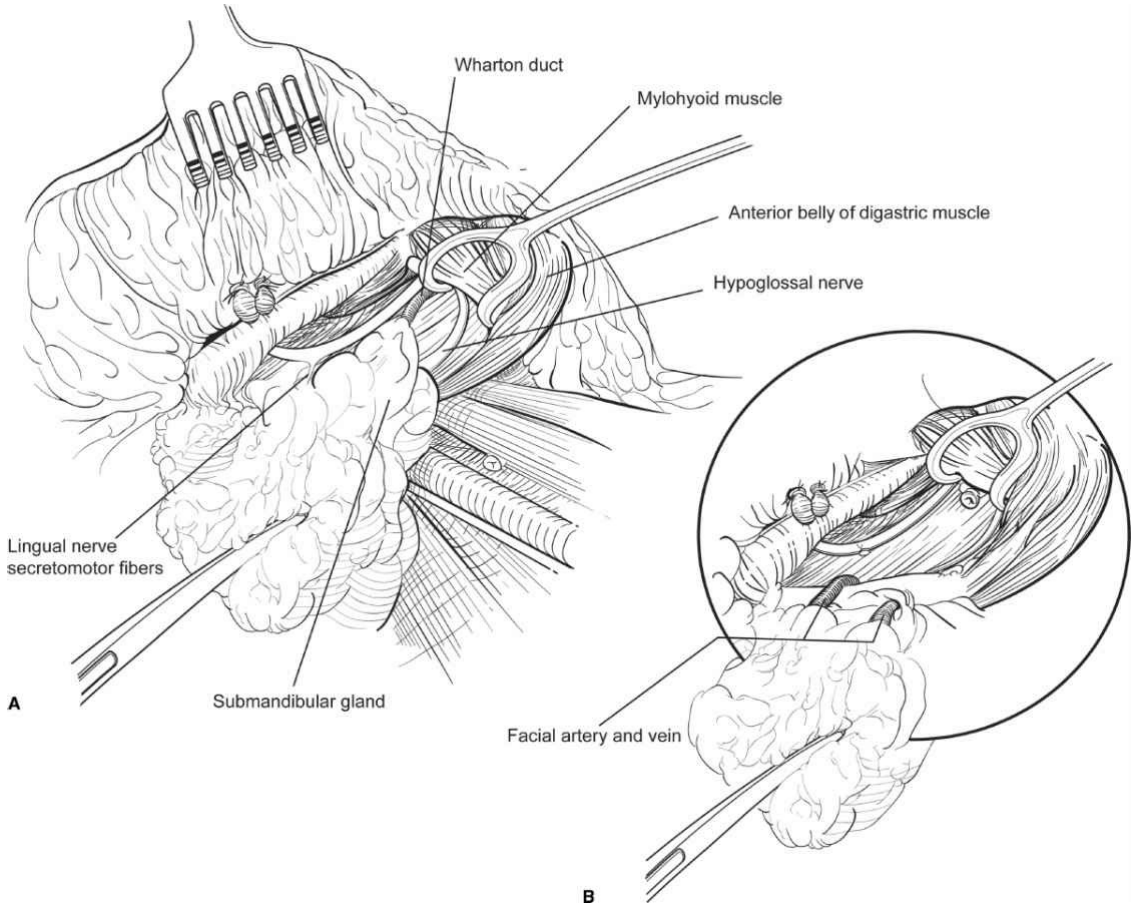

Figure 25.21. Exposure of the lingual nerve and the secretomotor fibers to the submandibular ganglion.

Next, the spinal accessory nerve is identified as it pierces the upper third of the sternocleidomastoid muscle. Using Reynolds scissors, the nerve is dissected out, up toward the proximal end of internal jugular vein and posterior belly of the digastric muscle. The fat pad and lymph nodes lying in level IIb are then carefully dissected out using electrocautery, taking great care not to damage the spinal accessory nerve. This tissue is then passed under the spinal accessory nerve and retracted in a medial direction using a clamp. With the sternocleidomastoid muscle retracted laterally using a Richardson retractor and countertraction on the soft tissue medially, the tissue overlying the cervical plexus of nerves is divided. Clamps are placed on the soft tissue and retracted medially, allowing the underlying nerves from the cervical plexus to be visualized.

Dissection then proceeds in a lateral-to-medial direction in a plane just superficial to these nerves. The lower limit of the dissection is the inferior belly of the omohyoid muscle lying in the inferior aspect of the posterior triangle. The phrenic nerve is then identified on the anterior scalene

muscle and carefully preserved. The carotid sheath fascia is divided, allowing exposure of the vagus nerve, carotid artery, and internal jugular vein. This is best done working from a cephalad-to-caudal direction using the Adson clamp to spread the fascial envelope for division with the electrocautery. Working from a lateral-to-medial direction, the soft tissue encompassing levels II and III lymph nodes is dissected off the internal jugular vein. The anteromedial limit of the dissection is the superior belly of the omohyoid muscle. The junction between this muscle, the sternocleidomastoid muscle, and the internal jugular vein is identified using a loop retractor. The soft tissue containing lymph nodes from the midjugular chain is then retracted in a cephalad direction and dissected off the internal jugular vein and superior belly of omohyoid muscle. Dissection is in a plane just superficial to the superior thyroid vessels. The superior thyroid artery is preserved but the vein needs to be divided and ligated on the medial aspect of the internal jugular vein. Superiorly, the common facial vein is then identified on the medial aspect of the internal jugular vein and divided in clamps and ligated with 3-0 silk. The hypoglossal nerve is identified and tissue lying lateral and inferior to it dissected. Several pharyngeal veins are encountered close to the hypoglossal nerve; these need to be individually ligated with 3-0 silk ties.

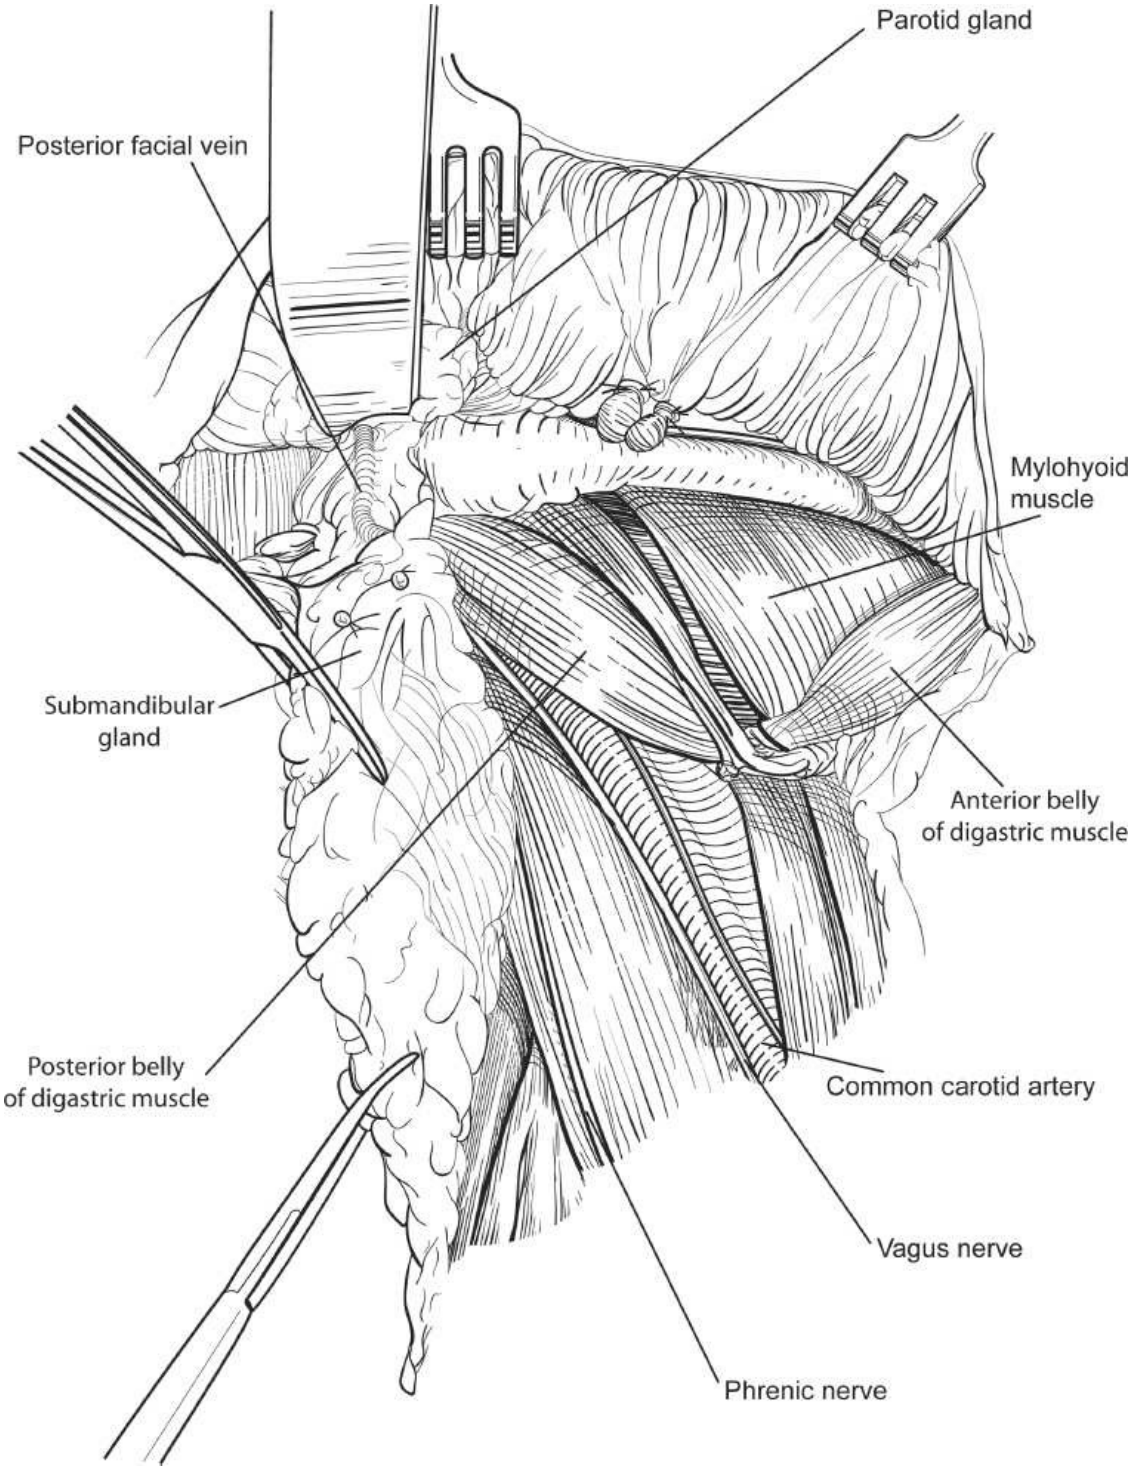

Figure 25.22. Separation of the submandibular gland from the posterior belly of the digastric muscle is achieved by ligating the proximal part of the facial artery.

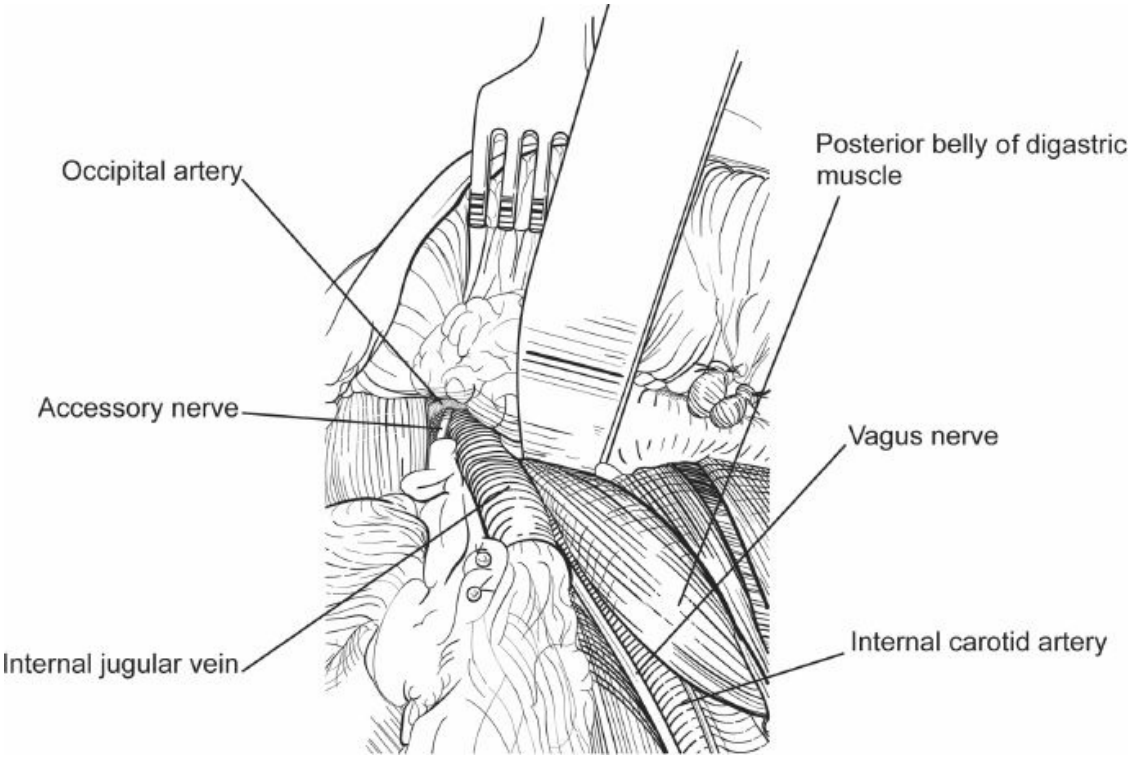

Figure 25.23. Exposure of the upper end of the internal jugular vein.

The specimen encompassing levels I, II, and III is then delivered. The wound is irrigated with saline, hemostasis obtained with electrocautery, and a single suction drain inserted via a separate stab incision and secured to skin with a purse-string suture. The incision is closed in two layers with interrupted 3-0 chromic catgut for the platysma muscle and 5-0 nylon for skin. The resultant functional and cosmetic deformity is insignificant.

Anterolateral Neck Dissection (Jugular Node Dissection)

This dissection is usually carried out as a staging procedure in conjunction with excision of primary carcinoma of the larynx or pharynx in a patient with a neck with clinically negative disease. The operation is now also acceptable for management of the positive neck in patients with metastatic neck disease from HPV-positive oropharynx cancer. This involves dissection of lymph nodes from levels II to IV. The incision is therefore planned according to resection of the primary tumor. This is usually a transverse incision at the level of the thyrohyoid membrane from the posterior border of one sternocleidomastoid muscle to the midline (Fig. 25.11D). Upper and lower skin flaps are raised in the subplatysmal plane. Fascia on the anterior border of the sternocleidomastoid muscle is incised

and elevated medially to expose the underlying jugular lymph nodes. The posterolateral extent of the dissection is the cervical nerve roots as they emerge from the vertebral column. The omohyoid muscle is divided inferiorly to allow dissection of level IV nodes. As in the SOHND, the accessory nerve is identified as it pierces the medial aspect of the sternocleidomastoid muscle and is traced superiorly. Lymph nodes in level IIb superior and lateral to the nerve are dissected as described for the SOHND.

Dissection again proceeds lateral to medial, identifying the anterior scalene muscle, phrenic nerve, and roots of the cervical plexus. The carotid sheath is opened to identify the vagus nerve, carotid artery, and internal jugular vein. Middle thyroid, superior thyroid, and common facial veins on the medial aspect of the internal jugular vein are divided and ligated with 3-0 silk to allow the specimen to be reflected medially. The specimen may be left attached to the primary tumor or may be removed separately. Insertion of drains and wound closure are as described previously.

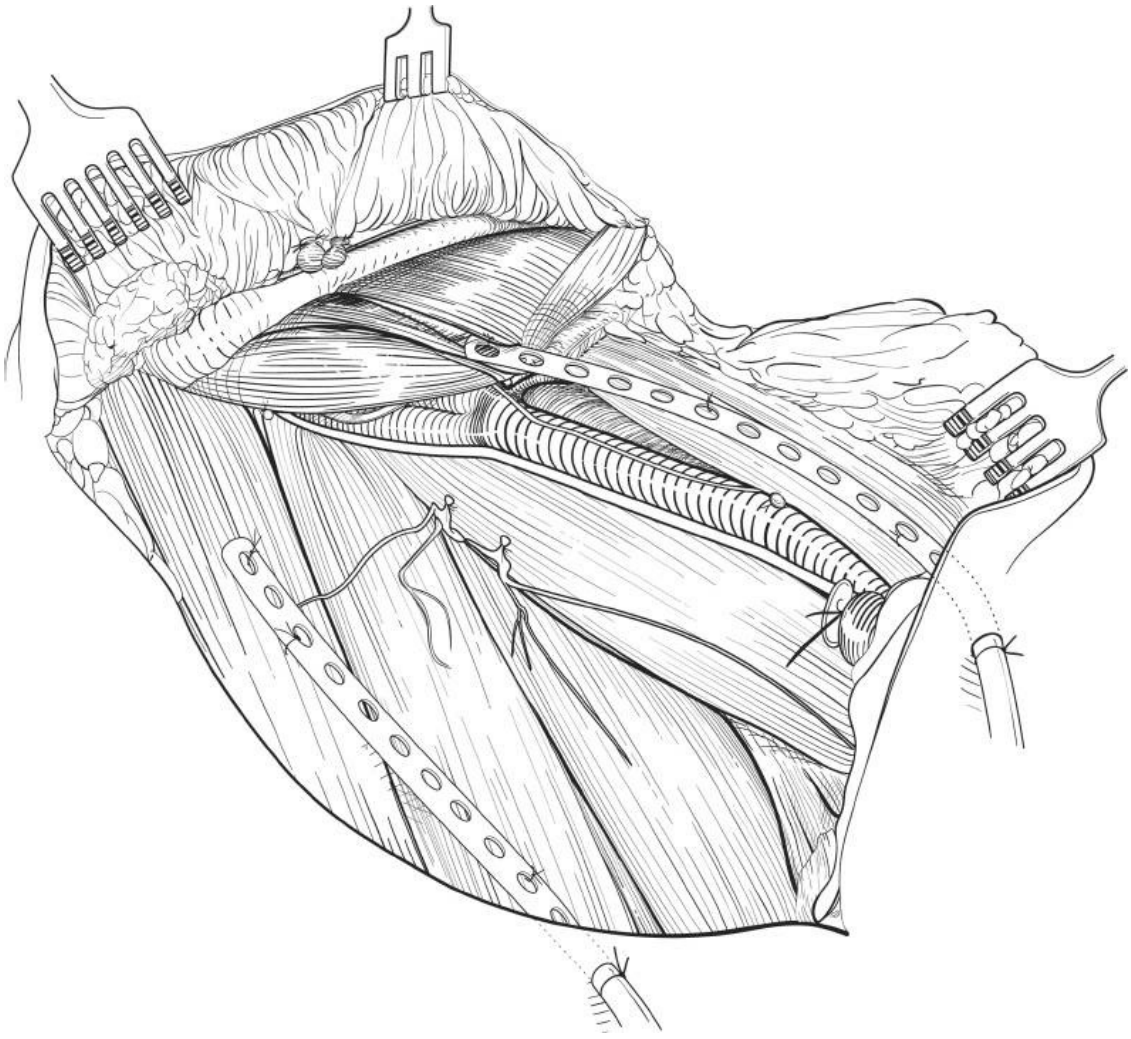

Figure 25.24. Suction drains are inserted through separate stab incisions in the lower skin flaps and positioned as shown.

Posterolateral Neck Dissection

This is carried out for clinically negative neck disease for either melanoma or squamous cell carcinoma of the posterior scalp. It involves the removal of lymph nodes in levels II to V, including the suboccipital and retroauricular lymph nodes. A hockey-stick incision is used, extending from the mastoid tip along the anterior border of the trapezius muscle and then curving anteriorly just superior to the clavicle. An anterior skin flap is elevated in the subplatysmal plane up to the anterior border of the sternocleidomastoid muscle. The spinal accessory nerve is identified in the posterior triangle as described previously and dissected out from the inferior aspect of the trapezius muscle up to the posterior border of the sternocleidomastoid muscle. Dissection of the posterior triangle lymph nodes proceeds as described previously. To dissect out the upper, middle, and lower jugular lymph nodes, the sternocleidomastoid muscle is retracted medially. The fascia of the carotid sheath is divided, identifying the carotid artery, vagus nerve, and internal jugular vein. Dissection of level II to IV lymph nodes proceeds in a caudal-to-cephalad fashion, and the specimen including the posterior triangle soft tissue is delivered. In order to include the postauricular and suboccipital lymph nodes, a lateral extension of the upper end of the skin incision from the mastoid process to the occipital tubercle is carried out. The trapezius muscle is then detached from its nuchal attachment, allowing exposure of lymph nodes in the suboccipital triangle, which are then removed as a separate specimen. Closed suction drains are inserted through a separate stab incision and the wound is closed in layers with 3-0 chromic catgut for the platysma muscle and 5-0 nylon for the skin.

EDITOR'S COMMENT

In this chapter, Drs. Shah and Ganly provide rich historical perspective in addition to a masterful description of the technique of neck dissection, ranging from the comprehensive modified neck dissection to the many varieties of selective neck dissection. In contrast to the measured pace of refinements to the technique of neck dissection, the role of neck dissection in the management of regional disease across the entire gamut of histologies, from squamous cell carcinoma, to cutaneous melanoma, to papillary thyroid carcinoma, is evolving rapidly. As chemoradiotherapy (CRT) has become the cornerstone of the primary treatment of squamous cell carcinoma of the head and neck, there has been great debate as to the appropriate treatment of advanced nodal disease (stage N2 or N3) in these patients. Since up to 40% of patients who undergo neck dissection after CRT have residual disease identified in their cervical nodes and may enjoy a survival advantage from it, some authors have argued for a planned neck dissection after the completion of CRT (Brizel DM, Prosnitz RG, Hunter S, et al. Necessity for adjuvant neck dissection in setting of concurrent chemoradiation for advanced head-and-neck cancer. *Int J Radiat Oncol Biol Phys* 2004;58:1418–23). Yet owing to dramatic improvements in cross-sectional imaging—in particular the combined anatomic and functional imaging offered by a PET-CT scan—other authors recommend an image-guided, response-based approach, reserving neck dissection for only those patients who show an incomplete or equivocal radiographic response (Porceddu SV, Pryor DI, Burmeister E, et al. Results of a prospective study of positron emission tomography-directed management of residual nodal abnormalities in node-positive head and neck cancer after definitive radiotherapy with or without systemic therapy. *Head Neck* 2011;33:1675–82). However, until recently with the publication of the PET-NECK Trial, level I evidence in support of either approach was lacking.

The PET-NECK Trial was a prospective, randomized, controlled trial which sought to compare the clinical usefulness and health economic outcomes of planned neck dissection versus PET-CT–guided surveillance in patients with squamous cell carcinoma of the head and neck and nodal stage N2 or N3 disease who received CRT as primary treatment (Mehanna H, Wong WL, McConkey CC, et al. PET-CT surveillance versus neck dissection in advanced head and neck cancer. *N Engl J Med* 2016;374:1444–54). Specifically, they assessed the noninferiority of PET-CT–guided surveillance, performed 12 weeks after the end of CRT (with neck dissection performed only if PET-CT showed an incomplete or equivocal response), to planned neck dissection, and the primary endpoint was overall survival. From 2007 to 2012, a total of 564 patients were recruited from 37 centers in the United Kingdom. A total of 84% of the patients had oropharyngeal cancer, and 75% had tumor specimens which stained positive for the p16 protein, indicating that the HPV had a role in the

causation of the cancer. At a median follow-up of 36 months, the 2-year overall survival rate was 84.9% in the PET-CT surveillance group and 81.5% in the planned surgery group, indicating that surveillance was not inferior to planned neck dissection. Further, PET-CT surveillance resulted in fewer neck dissections (54 vs. 221)—and thus fewer complications—than seen in the planned neck dissection group, as well as a savings of approximately $2190 per person over the duration of the trial.

The desire to limit unnecessary neck dissections brings me to the topic of SLNB for squamous cell carcinoma of the head and neck. Note that approximately 50% of patients with oral squamous cell carcinoma present with early-stage disease, and the main prognostic factor is occult lymph node metastasis in the neck, which is present in some 20% to 30% of patients. For many years, elective neck dissection has been the gold standard treatment for these patients, but such a strategy results in the overtreatment of at least 70% of patients, as well as considerable morbidity. In a meta-analysis of 66 studies evaluating the diagnostic efficacy of SLNB in early (T1–2) oral squamous cell carcinoma, Liu et al. reported an SLN identification rate of 96.3%, a pooled sensitivity of 0.87, and a pooled negative predictive value of 0.94 (Liu M, Wang SJ, Yang X, et al. Diagnostic efficacy of sentinel lymph node biopsy in early oral squamous cell carcinoma: a meta-analysis of 66 studies. *PLOS One* 2017;12:e0170322). The authors concluded that SLNB is an ideal alternative to elective neck dissection in patients with early-stage oral squamous cell carcinoma.

Similar to that seen with oral squamous cell carcinoma, SLNB is able to accurately identify early nodal metastatic disease in primary cutaneous melanoma of the head and neck, and lymph node status is the strongest prognostic factor for these patients. For patients with a positive SLNB, the standard of care is completion lymph node dissection (CLND), though only 14% of patients will have additional positive nodes found at CLND (de Rosa N, Lyman GH, Silbermins D, et al. Sentinel node biopsy for head and neck melanoma: a systematic review. *Otolaryngol Head Neck Surg* 2011;145:375–82). This then begs the question of whether to routinely pursue a CLND in all patients with a positive SLN, especially for those patients with a very low volume of metastatic disease in the SLN (i.e., size of tumor deposit <0.2 mm), in which case the likelihood of identifying additional metastatic disease in the nonsentinel lymph nodes is almost certainly less than 10%. Though the current standard of care is to offer all patients with a positive SLNB a CLND, given the low likelihood of finding additional disease in the nonsentinel nodes and the questionable survival benefit conferred by a CLND, many surgeons have increasingly moved away from offering a CLND to patients with cutaneous melanoma of all primary sites, including those of the head and neck (Kingham TP, Panageas KS, Ariyan CE, et al. Outcome of patients with a positive sentinel node who do not undergo completion lymphadenectomy. *Ann Surg Oncol* 2010;17:514–20). We eagerly await the results of the MSLT-2 trial to determine

the wisdom of this approach. Importantly, for those patients with head and neck melanoma who do undergo CLND, the majority of positive nonsentinel nodes are found either within or immediately adjacent to the nodal level containing the SLN (Gyorki DE, Boyle JO, Ganly I, et al. Incidence and location of positive nonsentinel lymph nodes in head and neck melanoma. *Eur J Surg Oncol* 2014;40:305–10).

As transoral robotic surgery (TORS) has gained increasing popularity in the surgical treatment of thyroid and head and neck cancers (particularly oropharyngeal cancer), some surgeons have naturally extended the use of the robot to perform neck dissections. Song et al. recently compared their outcomes with robotic selective neck dissection (SND, ≥3 levels of II–V) with total thyroidectomy by a gasless unilateral axillary (GUA) approach versus the conventional transcervical SND with total thyroidectomy in the treatment of papillary thyroid cancer (Song CM, Ji YB, Sung ES, et al. Comparison of robotic versus conventional selective neck dissection and total thyroidectomy for papillary thyroid carcinoma. *Otolaryngol Head Neck Surg* 2016;154:1005–13). Compared with the conventional group (n = 41), patients in the robotic group were younger and more likely to be female. Not surprisingly, mean total operative time was longer in the robotic group than in the conventional group (298 vs. 236 minutes), but postoperative cosmetic satisfaction was superior in the robotic group. There were no differences in the rate of complications or in the number of harvested lymph nodes between the groups. Importantly, however, there was a significantly higher incidence of anterior chest wall pain and paresthesia in the robotic group for as long as 1 month after the procedure, perhaps due to the large dissected flap and tension on the flap due to the retraction necessary to complete the robotic procedure. In the end, the authors concluded that for those patients concerned about cosmesis and thus the desire to avoid a surgical scar in the neck, that the robotic approach to thyroidectomy and neck dissection is a reasonable one. We will no doubt hear a lot more about robotic surgery in the treatment of head and neck cancer in the years to come.

John T. Mullen

26 Congenital Lesions: Thyroglossal Duct Cysts, Branchial Cleft Anomalies, and Cystic Hygromas

Juan P. Gurria and Jaimie D. Nathan

Congenital lesions of the neck are the anatomical result of abnormal development of or persistence of immature embryonic structures through gestation. Their clinical manifestation varies from a nodule to a mass and from a skin pit to a sinus. The varying presentations are well defined and include thyroglossal duct cysts, branchial cleft anomalies, and lymphatic malformations. Prompt diagnosis and early identification along with appropriate workup and detailed surgical treatment are the key in the treatment of these congenital lesions. It is important to fully understand the embryologic differentiation of the structures of the neck to adequately plan a surgical therapy that correctly includes the tissues from which the structure is originating in order to prevent recurrence. These tissues can include midline abnormalities, as well as cartilaginous and branchial arch and cleft remnants.

THYROGLOSSAL DUCT CYST

Etiology and Pathophysiology

Thyroglossal duct cyst is one of the most common lesions in the midline of the neck and is found in around 7% of the population. It results from a remnant structure of the median thyroid anlage as it descends to a caudad position during the 3rd gestational week to fuse with the lateral thyroid anlage. During its descent into the neck, it passes most commonly through the hyoid bone process as it develops from the second branchial arch, and this represents a key factor during surgical resection. The thyroid diverticulum develops at the foramen cecum and remains connected to it as it descends. During weeks 4 to 8 of gestation, the thyroid gland develops and finds its final position in the neck, and it is by this time that the thyroglossal duct and its connection to the tongue usually obliterate.

When there is lack of obliteration of these structures, an abnormal structure can be located anywhere along its migratory course (Fig. 26.1). The tissue that forms during this process is lined with secretory epithelium that matures into a cyst once the epithelium becomes activated.

Clinical Presentation

The majority of thyroglossal duct cysts are diagnosed during the first decade of life, and over two thirds of the anomalies are diagnosed within the first 30 years of life creating a common encounter for the pediatric surgeon. The classic finding of this lesion is a midline structure at or just below the level of the hyoid bone (Fig. 26.2). It typically presents as a painless mass that moves with swallowing due to its remnant connection to the base of the tongue. The cyst may be found anywhere from the base of the tongue to a position behind the sternum and can sometimes present as a painful swollen erythematous mass if it has become infected.

Physical examination can be the only tool needed for diagnosis and should include a thorough evaluation of the mouth, tongue, neck, and lymph node basins. Specific examination of the mass is critical, as protrusion of the tongue and swallowing typically elicit vertical displacement of the cyst. The cyst is soft and nontender with smooth edges, and it is easily delineated from other structures. Because of its connection to the base of the mouth, thyroglossal cysts can become infected with oral flora and almost one third of patients will present with an infected cyst.

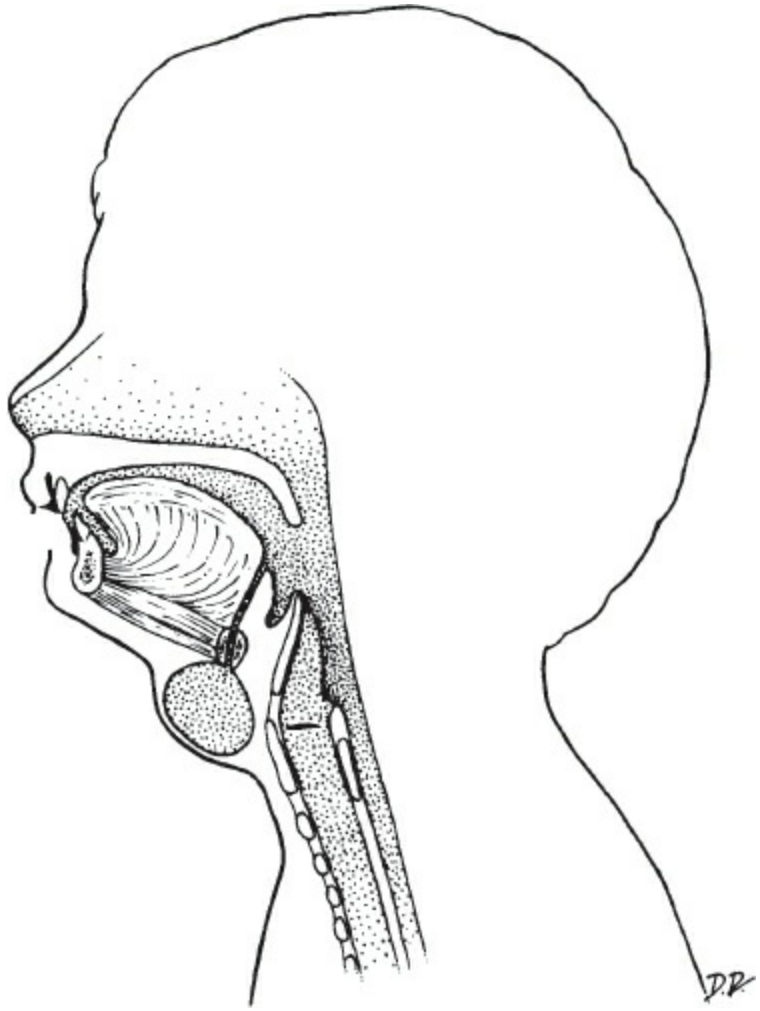

Figure 26.1. Thyroglossal duct cyst anterior to the hyoid bone with the thyroglossal duct tract passing through the hyoid bone and extending to the foramen cecum.

Indications and Contraindications

Surgical resection is indicated when a thyroglossal duct cyst is suspected and/or diagnosed after a thorough history and physical examination. Prior to operation, it is important to evaluate the thyroid function of the patient and perform additional imaging if results reflect hypothyroidism to exclude a median ectopic thyroid. Importantly, the presence of normal thyroid gland apart from the cystic structure must be confirmed, either by physical examination or by ultrasound study. There have been some documented cases of a thyroglossal duct cyst containing the only thyroidal tissue present in the patient, and in such circumstances, resection would cause permanent hypothyroidism. The incidence of ectopic thyroid tissue near the duct ranges from 10% to 40%. Surgical excision is recommended when a thyroglossal duct cyst is encountered to avoid both the potential

complication of infection and the less than 1% risk of developing malignancy within the cyst.

Preoperative Planning

History and physical examination will establish findings of uncomplicated versus infected thyroglossal duct cyst and will aid in ruling out thyroid gland abnormalities and malignancy. Ultrasonography is useful as the preoperative imaging modality of choice to evaluate the characteristics of the mass, to document the presence of normal thyroid gland, to rule out ectopic thyroid tissue, and to sample any abnormal tissue concerning for malignancy. Approximately 1% to 2% of patients with thyroglossal duct cysts will harbor their only thyroid tissue within this mass. The patient who presents with evidence of an infected thyroglossal duct cyst should be treated with needle aspiration of the cyst and antibiotic therapy directed against oral flora, prior to definitive surgical excision. Infected cysts managed with appropriately staged surgical excision 6 to 8 weeks following aspiration and antibiotic therapy can be resolved with an acceptably low recurrence rate, although recurrence risk is higher than in patients without prior history of infection.

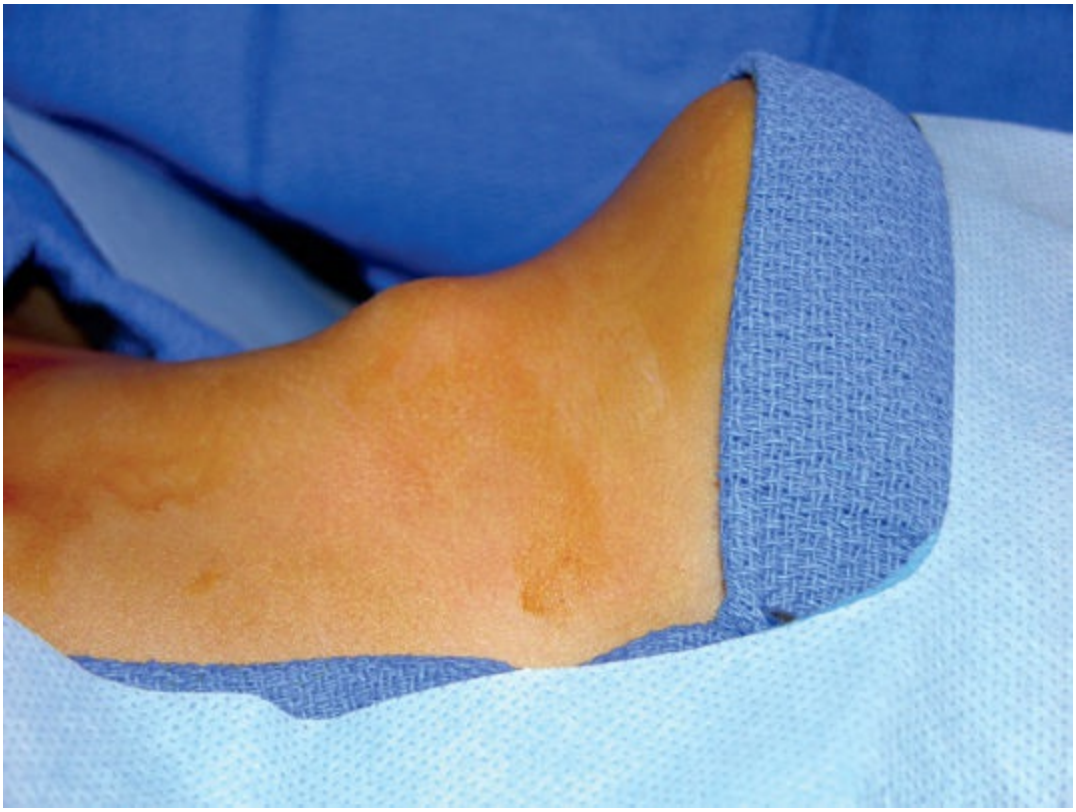

Figure 26.2. Photograph of a thyroglossal duct cyst.

Surgical Technique

Thyroglossal duct cysts are managed by elective surgical resection with the Sistrunk procedure with a recurrence rate of less than 5%. The procedure commences by placing the patient in the supine position with the neck slightly hyperextended. The addition of a back roll depends on the morphology of the patient and surgeon preference. Preoperative antibiotics should be administered covering both skin and oral flora. Methicillin-resistant *Staphylococcus aureus* (MRSA) should be covered if the patient has history of prior positive testing. A transverse incision is made in the skin overlying the cyst (Fig. 26.3), and the cyst is exposed by dissecting meticulously around the capsule with electrocautery. The duct is identified in a posterior and superior position to the cyst wall. Dissection is carried cephalad along the tissue surrounding the duct, including any accessory ducts thus minimizing the likelihood of recurrence, until the hyoid bone is reached. When a duct cannot be identified leading toward the hyoid bone, this suggests that the lesion is likely a dermoid cyst rather than a thyroglossal duct cyst. The muscle on both the superior and inferior edges of the hyoid bone is divided with electrocautery, and a bone cutter or angled scissors is used to transect the hyoid to remove a 1 to 1.5 cm segment of the central portion of the bone containing the duct (Fig. 26.4). The dissection continues cephalad to the base of the tract at the floor of the mouth. The duct and surrounding tissues are suture-ligated and divided at the foramen cecum (Fig. 26.5), and the specimen is removed. The dissection at this level may be made easier by inserting a gloved hand into the mouth to identify the most cephalad limit of the dissection. The wound is closed in layers with absorbable suture. The routine use of drains is unnecessary and not recommended.

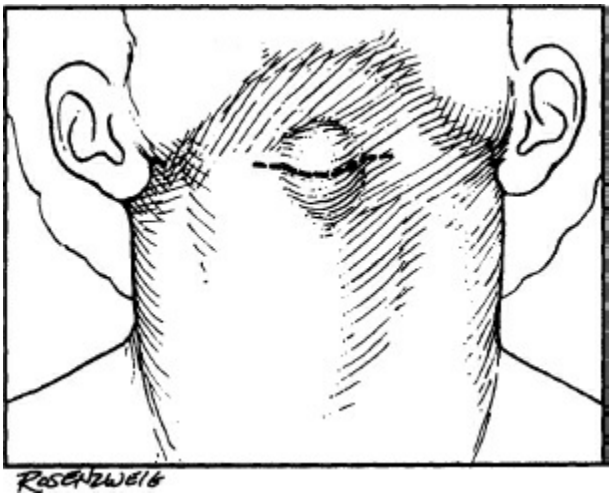

Figure 26.3. Thyroglossal duct cyst—technique of excision. Skin incision is made over the presenting cyst. No skin is excised.

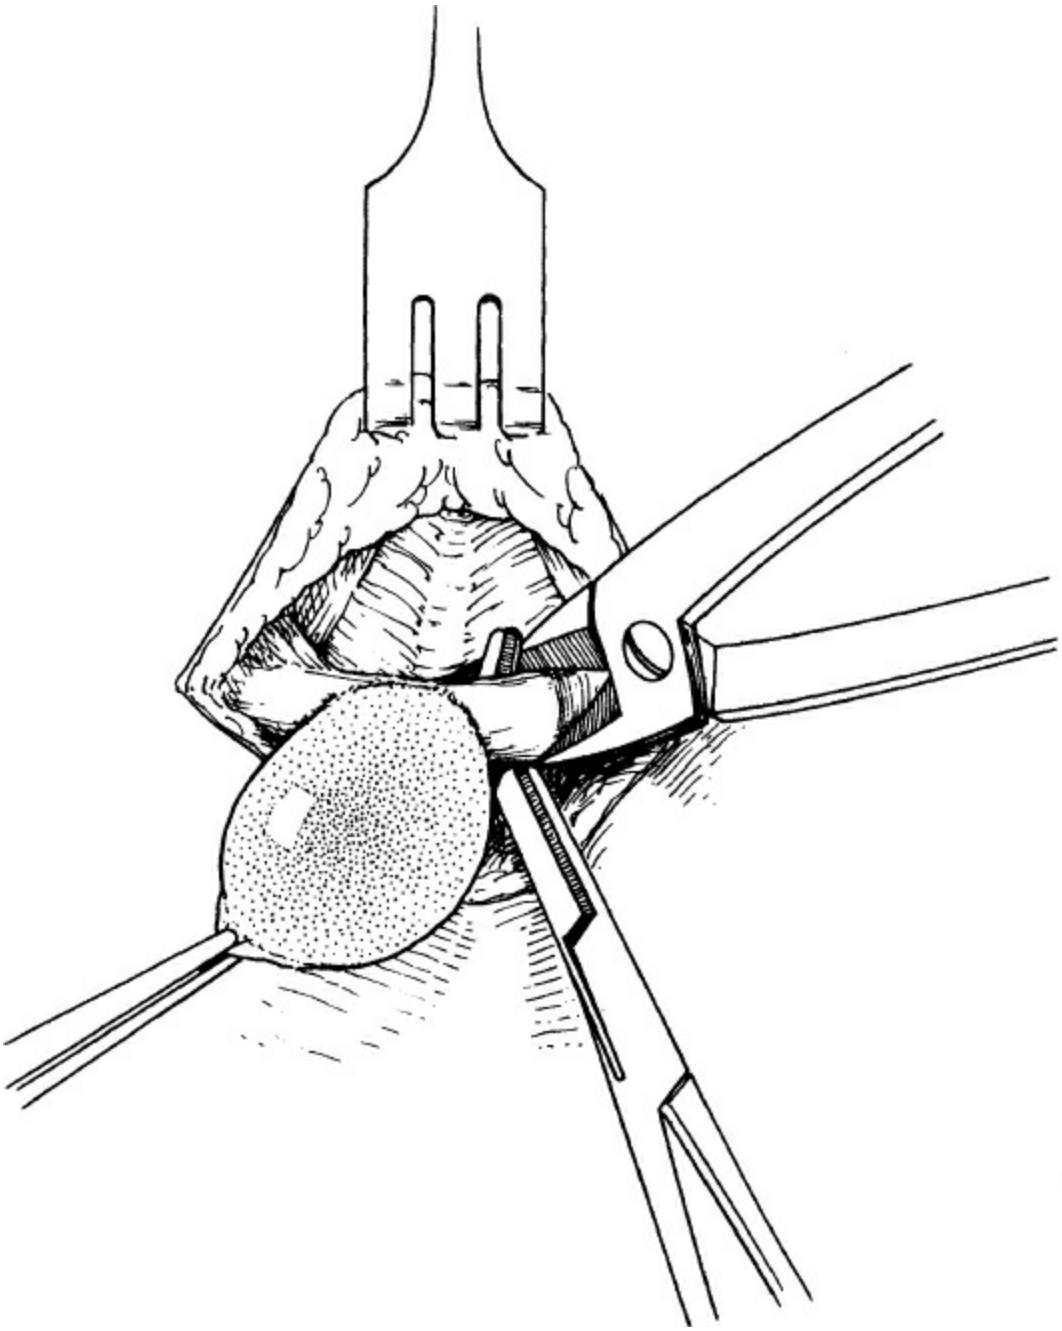

Figure 26.4. Thyroglossal duct cyst—technique of excision. The thyroglossal duct cyst has been dissected from surrounding tissues. The hyoid is exposed after division of the sternohyoid and thyrohyoid muscles at insertion. The bone is encircled with a short right-angle clamp 1 cm from its midpoint, where it is divided with a bone cutter or electrocautery.

Postoperative Care, Complications, and Their Management

The procedure can be performed as an elective operation on an outpatient basis. Diet can be started after the procedure and pain controlled by oral medications. Any procedure in the neck can have potential risk of airway compromise should a postoperative hemorrhage develop. While this complication is extremely rare, meticulous hemostatic dissection should be achieved during the procedure.

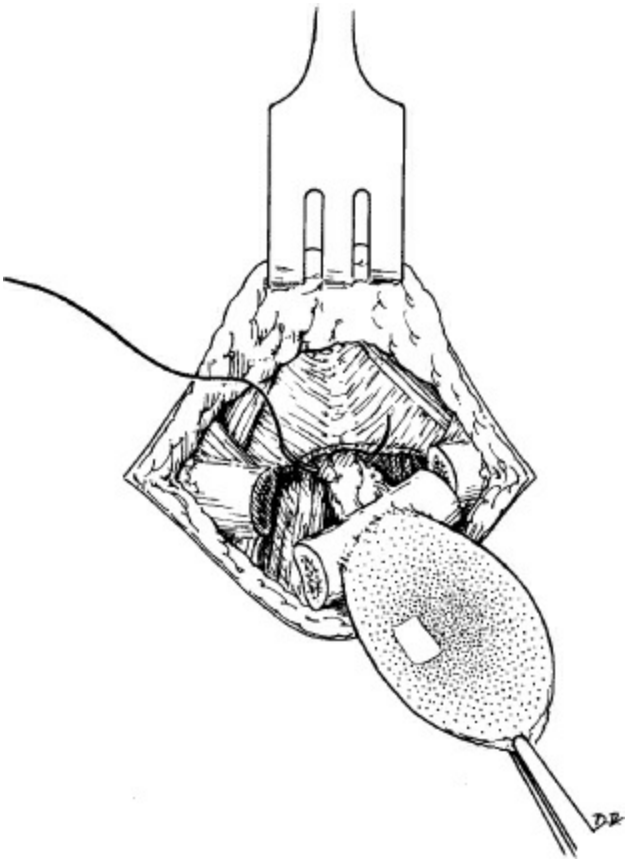

Figure 26.5. Thyroglossal duct cyst—technique of excision. Dissection proceeds cephalad to the foramen cecum where the tract and investing tissues are suture-ligated.

Dissection that violates the floor of the mouth or the tongue should be reapproximated with absorbable suture as part of a layered closure.

Outcomes

The risk of recurrence with complete excision including the central hyoid bone is low, approximating 2% to 5%, and usually manifests within the first year after operation with inflammation and sometimes drainage from the prior incision in the anterior neck. The recurrence risk is increased in patients who had an infection prior to initial resection or if the central

segment of the hyoid bone was left in place. The approach for this complication is to control the inflammatory process and infection with antibiotic therapy, followed by surgical re-excision. Reoperation should include wide excision of the previous incision and the inflamed tissue, a generous central hyoid bone resection, and excision of a core of tongue base musculature.

BRANCHIAL CLEFT ANOMALIES

Etiology and Pathophysiology

During the 4th and 5th gestational weeks, the head and neck structures develop from the branchial (or pharyngeal) arches, which consist of mesenchymal tissue bands separated by recesses known as pharyngeal clefts. Each arch is composed of muscle and cartilaginous components, as well as an artery and a cranial nerve. The pharyngeal clefts form on the outer ectodermal surface of the neck and line up with the pharyngeal pouches, which form on the inner endodermal surface. Any arrest in the embryologic process or failure of completion of the obliteration of these branchial clefts and pouches by mesenchyme will result in anatomical anomalies. Abnormalities of this complex structural process result in approximately 30% of congenital neck masses, and can present as cysts, cartilaginous remnants, sinuses, or fistulae.

It is critical to understand the anatomic patterns created by each of the arches and their relationships to neck structures. This will help predict the location of its associated abnormality. The different anomalies will be classified by the cleft or pouch of origin determined by the site of internal opening of the future sinus and its relationship to arteries, nerves, or muscles of the neck. These anomalies have contributions from clefts, arches, or pouches, and their presentation will differ depending on the site of failure. A sinus results from incomplete obliteration of a pharyngeal arch with communication with either the skin or mucosa. Failure of obliteration of both the cleft and the pouch will lead to a continuous communication between the mucosa and the skin, resulting in a branchial fistula. A cyst results from a pharyngeal cleft that forms an epidermis-lined cavity without the presence of a communication. Sinuses and fistulae will usually be lined by respiratory epithelium, whereas cysts will typically be lined by squamous epithelium.

The first branchial arch develops into structures of the middle ear and the facial nerve, leading to first branchial cleft anomalies that present as

either draining fistulae in the preauricular or postauricular areas, or as a fistulous tract or cysts near the facial nerve with involvement of the parotid gland in some circumstances. The second branchial arch forms the hyoid bone and the tonsillar and supratonsillar fossas, and anomalies arising from the second branchial cleft represent the most common branchial anomalies. Second cleft anomalies are located along the sternocleidomastoid muscle in the lateral aspect of the neck, and its associated fistulous tract usually enters the supratonsillar fossa. The third and fourth pouches form the inferior pharynx, and their anomalies will typically connect with the pyriform sinus. An externally seen cyst or a sinus will be located at the lower anterior border of the sternocleidomastoid muscle. These sinuses can course through the thyroid gland and can present as the cause of suppurative thyroiditis. Cysts and sinuses from the third branchial cleft are uncommon. Fourth branchial fistulae and cysts are also unusual and can present anywhere in the lower neck or upper mediastinum.

Clinical Presentation

In childhood, complete fistulae are more common than sinuses, and sinuses are more common than branchial cysts, unlike adults in which cysts are more commonly diagnosed due to absence of obvious drainage. All branchial remnants are congenital and are present at birth, and most are discovered within the first decade of life. Sinuses and fistulae are often found at birth due to obvious drainage. Cartilaginous remnants are usually palpated early in life, and cysts will commonly be found later in childhood. Up to one third of cases will present with signs and symptoms of infection with associated spontaneous mucous drainage along the edge of the sternocleidomastoid muscle. Overall, approximately 70% to 95% of cases are derived from the second pharyngeal arch structures with approximately 10% to 20% arising from first arch anomalies. The remaining lesions come from third and fourth pharyngeal arches.

A thorough clinical history and physical examination will help obtain an accurate diagnosis of branchial cleft anomalies and other abnormalities of the neck. Cysts and obstructed fistulae or external sinuses can present with infection. Skin tags or cartilage remnants commonly flag cutaneous openings harboring a sinus or a fistula. The tracts can be palpable with hyperextension of the neck as a cord-like structure, and usually mucoid drainage can be obtained with gentle compression of the tract.

Indications and Contraindications

A branchial cleft remnant should be surgically resected completely after a thorough investigation of its origin and contents. When the lesion presents with an acute infection, needle aspiration and antibiotics should be used before the excision, which should be delayed for 6 to 8 weeks. Debate exists for asymptomatic patients about the timing for surgery. Some surgeons prefer to excise the lesion upon diagnosis even in the neonatal period. Others advocate waiting until the child reaches 2 to 3 years of age. Both approaches are acceptable; however, waiting entails the risk of developing recurrent infections that will increase the risk of recurrence after surgical excision. Up to 20% of the lesions have been infected prior to excision. The surgeon should balance the risk of waiting, with the challenge of protecting vital structures during dissection on infants. General consensus suggests that dissection may be easier when the patient reaches 1 year of age.

Preoperative Planning

If a sinus or fistula tract is suspected but cannot be identified, upper endoscopy should be performed, and a third or fourth branchial cleft fistula can be identified entering the pyriform sinus. The tonsillar fossas should also be examined. A small feeding catheter can be used to cannulate the ostium and assist with the excision of the tract. Cysts can be more difficult to diagnose since they can be located near the edge of or under the sternocleidomastoid muscle. Although ultrasonography and magnetic resonance imaging (MRI) are useful in the evaluation of these lesions, computed tomography (CT) scanning is the imaging modality of choice for localization and for identification of the course of fistulous tracts in order to map the surgical resection. CT scanning can diagnose and delineate nearly 80% of sinus and fistula tracts.

Remnants of the second branchial cleft are the most common anomalies. Cysts represent about 65% of these lesions, and present as a lateral neck nodule adjacent to the sternocleidomastoid muscle (Fig. 26.6). It is important to rule out other neck masses, such as an enlarged lymph node, dermoid cyst, or lymphatic malformation. Sinuses represent about 30% of anomalies of the second branchial cleft. The tract of this sinus will pass between the internal and external carotid arteries just adjacent to the glossopharyngeal and hypoglossal nerves to finally reach the pharynx and tonsillar fossa (Fig. 26.7). For third and fourth cleft anomalies, endoscopy

and direct laryngoscopy should be performed prior to excision.

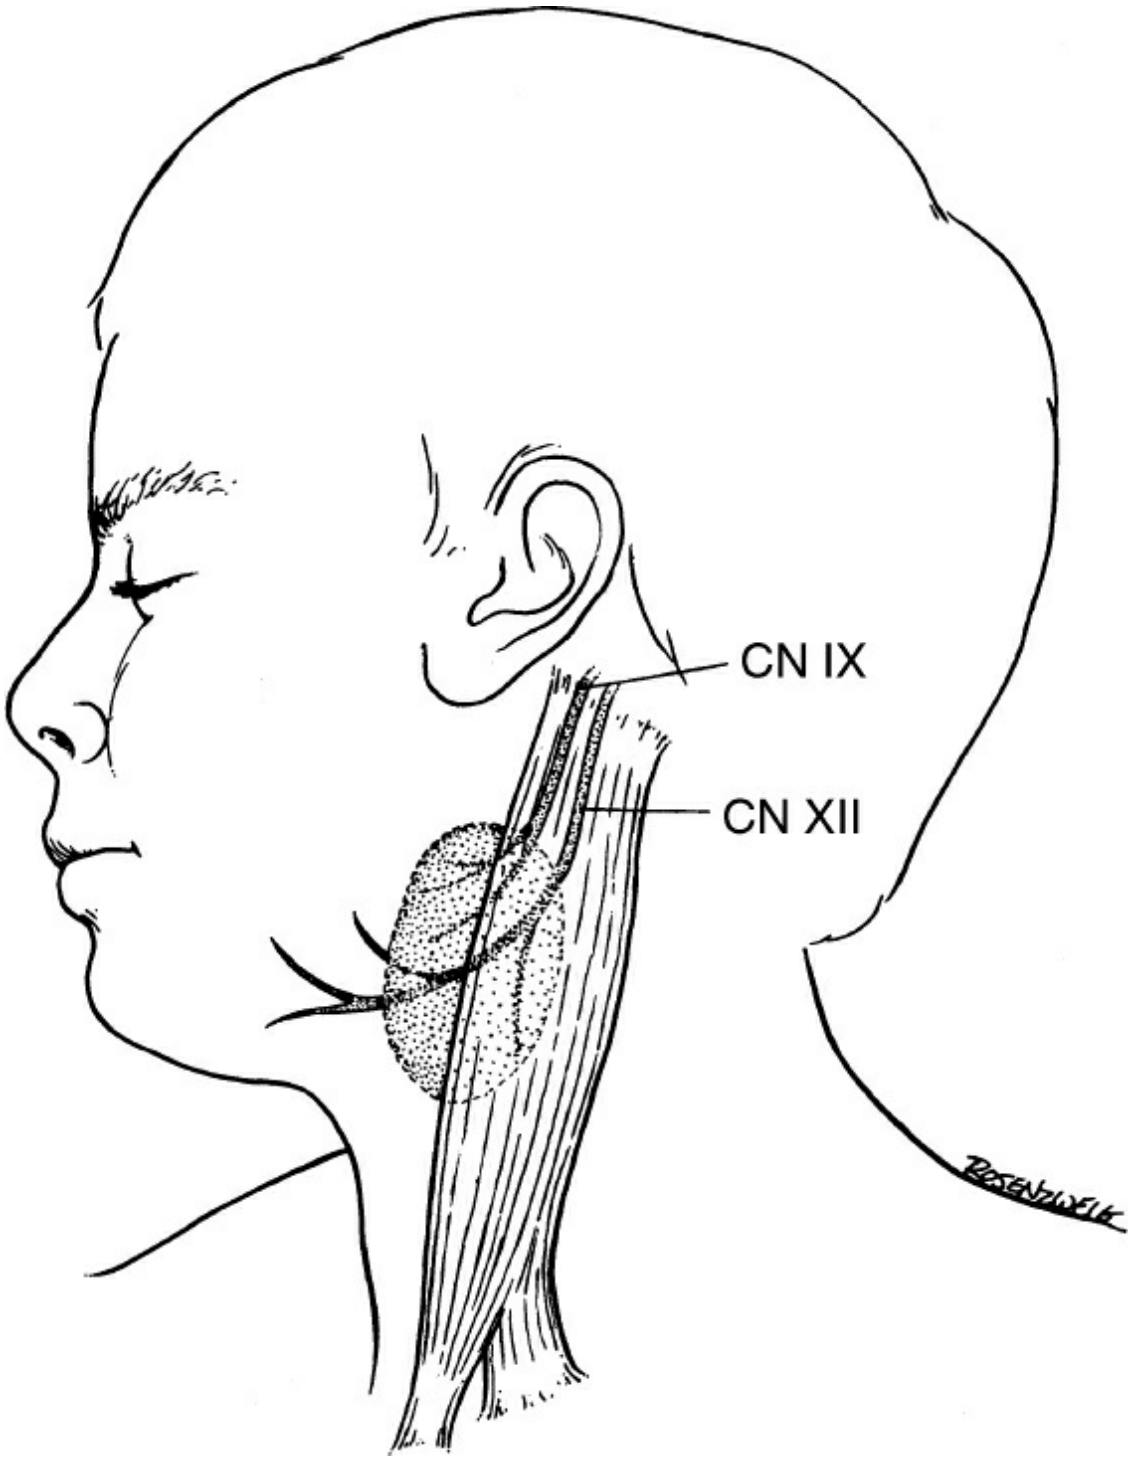

Figure 26.6. Typical location of a second branchial cleft cyst. The cyst is at the level of the carotid bifurcation. No external opening is present. Note the relationship to regional nerves. CN, cranial nerve.

Surgical Technique

Surgical resection is performed under general anesthesia, and perioperative antibiotics should be administered. The patient is positioned in the supine position with the head slightly tilted toward the opposite side of the lesion. An elliptical incision is made around the ostium previously identified with a lacrimal duct probe (Fig. 26.8). Dissection is carried deep to the cervical fascia from the inferior border of the incision so that the tract is identified from below to avoid transection. A small clamp or traction silk sutures are used as a handle to facilitate identification of the tract while precise sharp dissection with fine scissors or electrocautery is performed. Once dissection is carried cephalad enough that the tract can no longer be easily followed, a "ladder" counter incision higher in the neck is created and the tract is transposed cranially and exteriorized through it (Figs. 26.9 and 26.10). Dissection continues cephalad between the bifurcation of the carotid artery behind the posterior belly of the digastric and stylohyoid muscles, and in front of the hypoglossal nerve until the tonsillar fossa is reached in the pharynx. At this point, the fistulous tract should be resected and suture-ligated at its base with absorbable suture (Fig. 26.11). The incision is closed in layers with absorbable sutures. There is no need to use drains if resection is complete. Patients can usually be discharged home the same day.

First cleft anomalies are associated with facial deformities, including cleft lip and palate and internal and external ear abnormalities, and the lesions can present anterior or posterior to the earlobe or in a submandibular position. Resection often requires partial facial nerve dissection, superficial parotidectomy, and external auditory canal and middle ear dissection that often require staged procedures and require otolaryngology expertise and will not be described in this chapter.

Second branchial cleft cysts do not usually have a skin opening and should be excised via a transverse skin incision without entering the cavity to avoid recurrence. Of note, these lesions can be bilateral in up to 15% of patients.

Third and fourth cleft anomalies are removed in a similar fashion The associated fistulous tract can sometimes course through the thyrohyoid membrane to enter the pyriform sinus or through the thyroid gland and will require partial resection of the thyroid cartilage and thyroid lobectomy to achieve complete resection.

Postoperative Care, Complications, and Their Management

Patients can usually be discharged home the same day after surgery. The most common complications include infection that will require antibiotic treatment; bleeding that, despite being rare, in extreme cases requires operative intervention to protect the airway; injury to associated or nearby structures; and recurrence that will require re-intervention once diagnosed.

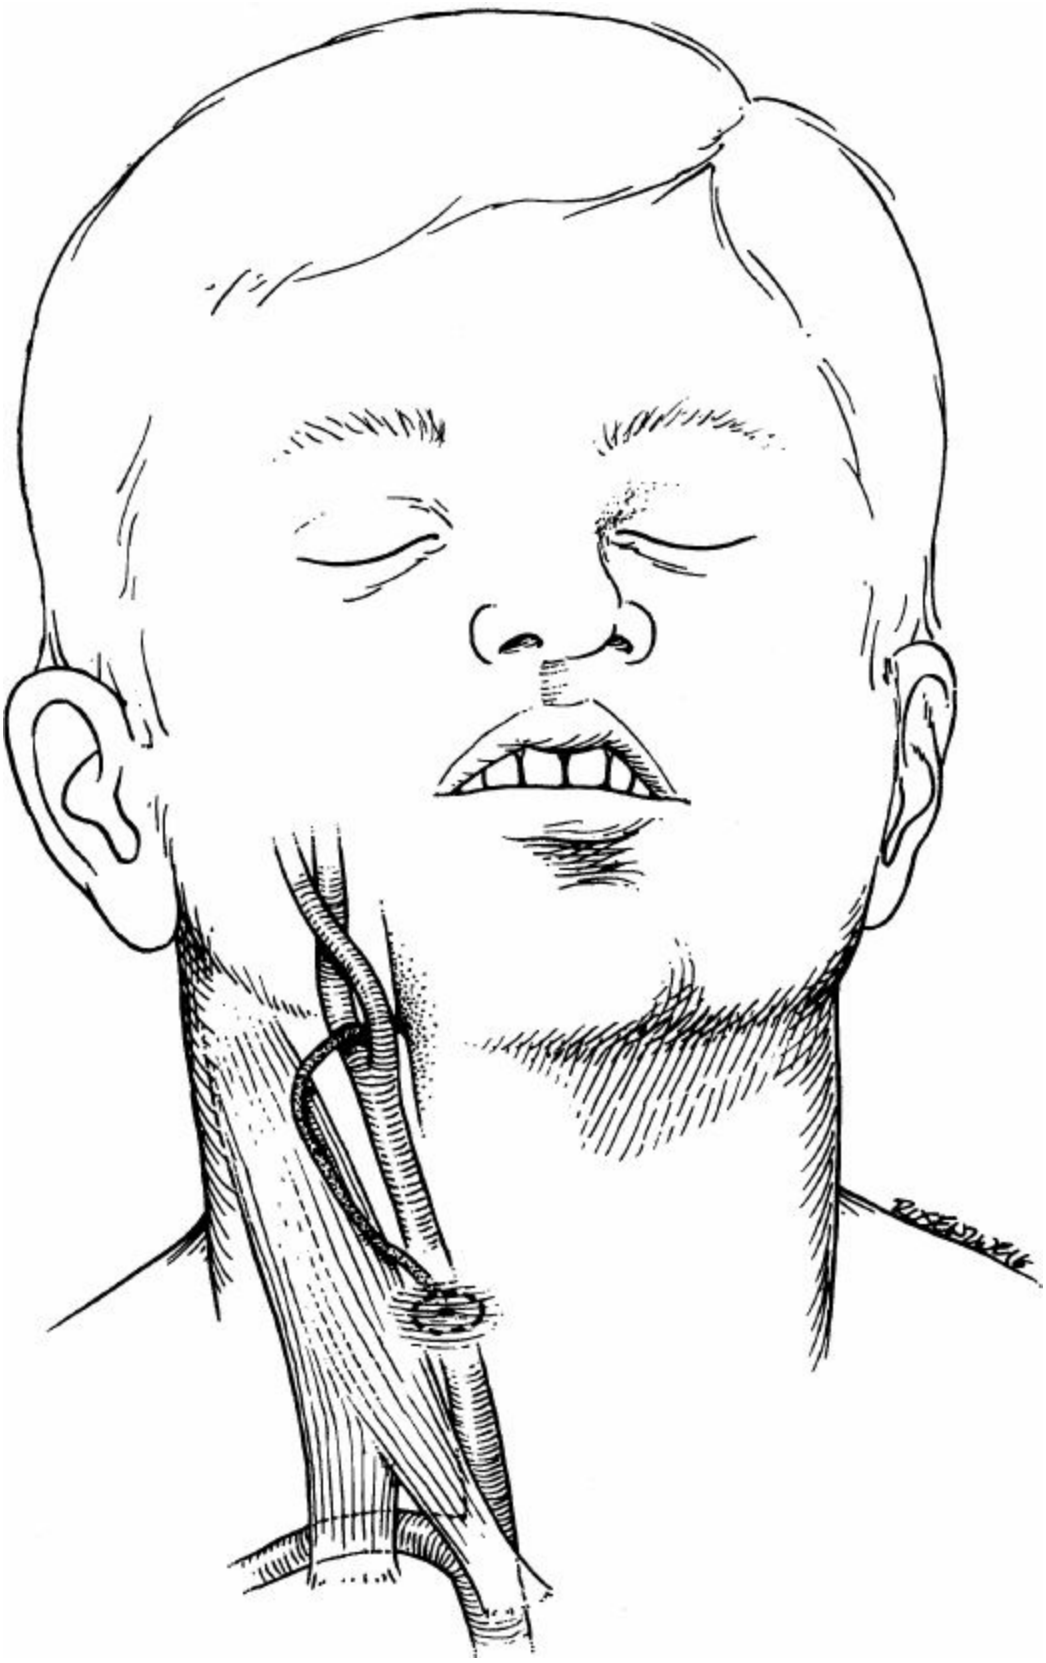

Figure 26.7. Course of a second branchial cleft fistula. The external ostium is at the anterior border of the sternocleidomastoid muscle. The fistula passes between the internal and external carotid arteries and enters the pharynx at

the tonsillar fossa.

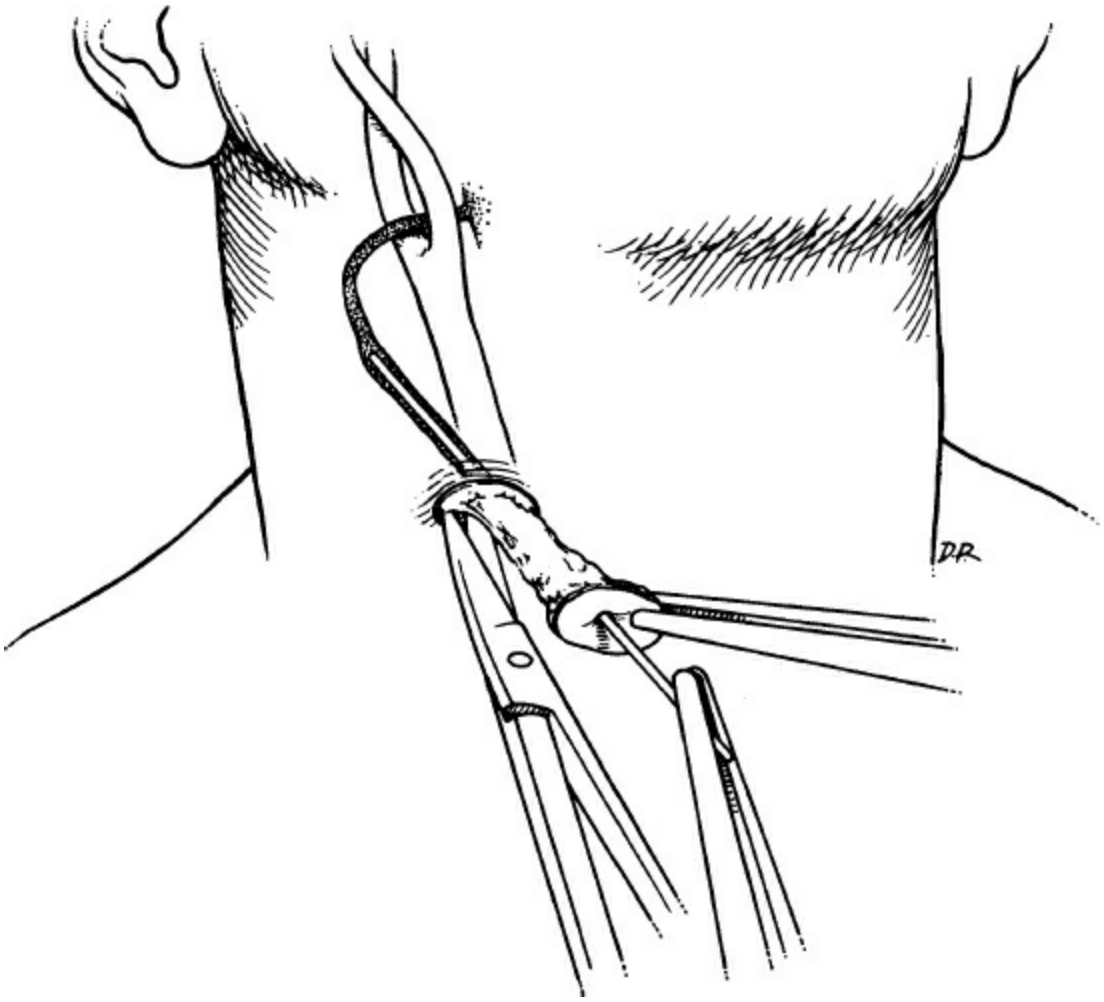

Figure 26.8. Technique of excision of second branchial cleft fistula. The skin ostium is incorporated in the elliptical incision. Note the lacrimal duct probe in the tract to facilitate its dissection.

Outcomes

Incidence of recurrence is overall low. Rate is increased in lesions that presented initially infected and were treated with incision and drainage, antibiotics, and staged excision. Recurrence is more frequent following resection of lesions arising from the first branchial cleft, probably due to incomplete removal due to its association with the facial nerve and parotid gland.

LYMPHATIC MALFORMATIONS

Etiology and Pathophysiology

The lymphatic system forms from lymph sacs present throughout the body, rich in endothelial cells, that merge into ducts to form a complex system that brings extravascular fluid back to the circulation in the form of lymph. During development, the lymphatic channels separate from blood vessels after a common embryonic derivation. A lymphatic malformation will occur when there is failure of the lymphatic vessels to fuse into complete channels. They originate from sequestration of lymphatic tissue from lymphatic sacs that fail to communicate with other channels.

Clinical Presentation

Most congenital lymphatic malformations present as painless soft compressible neck masses, and almost all are evident before 2 years of age. The malformation may also present with symptoms, such as respiratory distress, feeding difficulty, and fever, and sudden increase in size or infection in the lesion can exacerbate symptoms. They are classically located in the posterior or anterior triangles of the neck (Fig. 26.12), and sudden growth of the lesion can be precipitated by an upper respiratory infection. They are classified according to the size of the endothelial cysts that lie within them, from smaller to larger as: capillary lymphangioma, cavernous lymphangioma, and cystic lymphangioma (or cystic hygroma). Over two thirds of neonatal lesions can be associated with other anomalies, including Down syndrome, Turner syndrome, Trisomy 13, Trisomy 18, and Noonan syndrome.

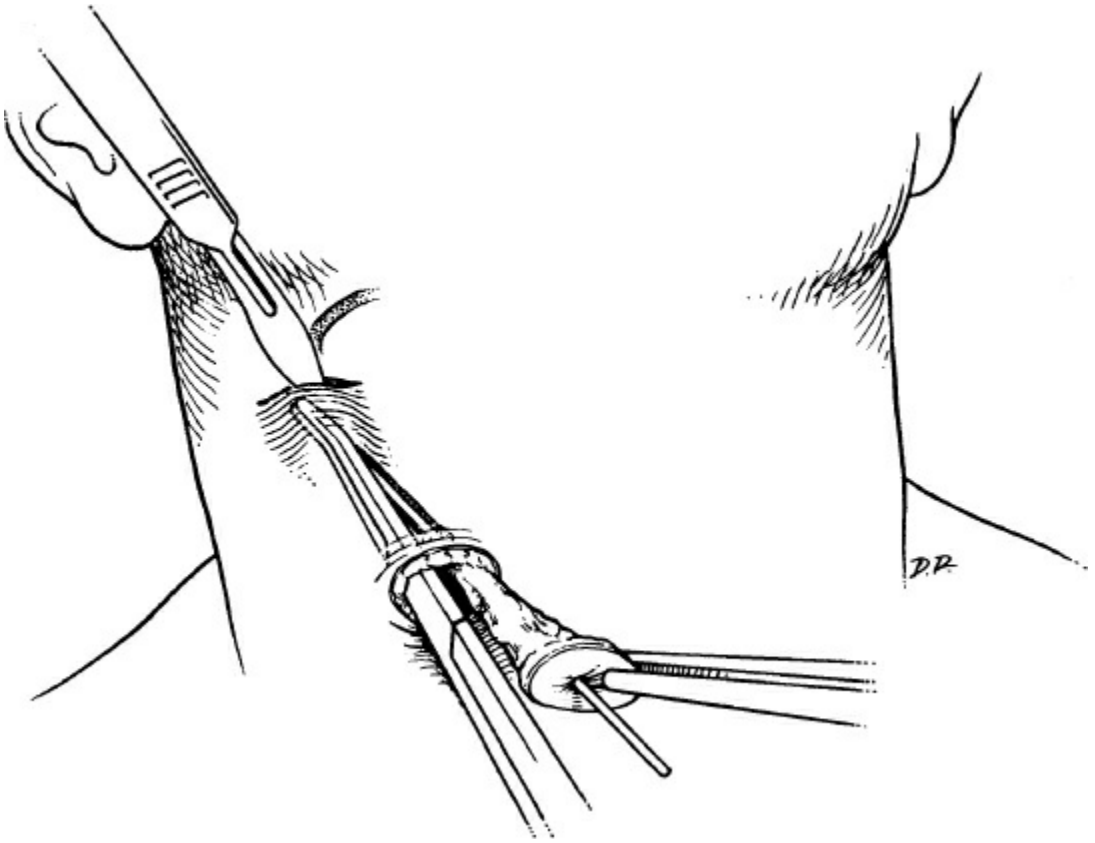

Figure 26.9. The extent of the tract of a second branchial cleft fistula eventually limits the dissection. A clamp is passed along the dissected tract to guide the creation of a counterincision or “stepladder” incision.

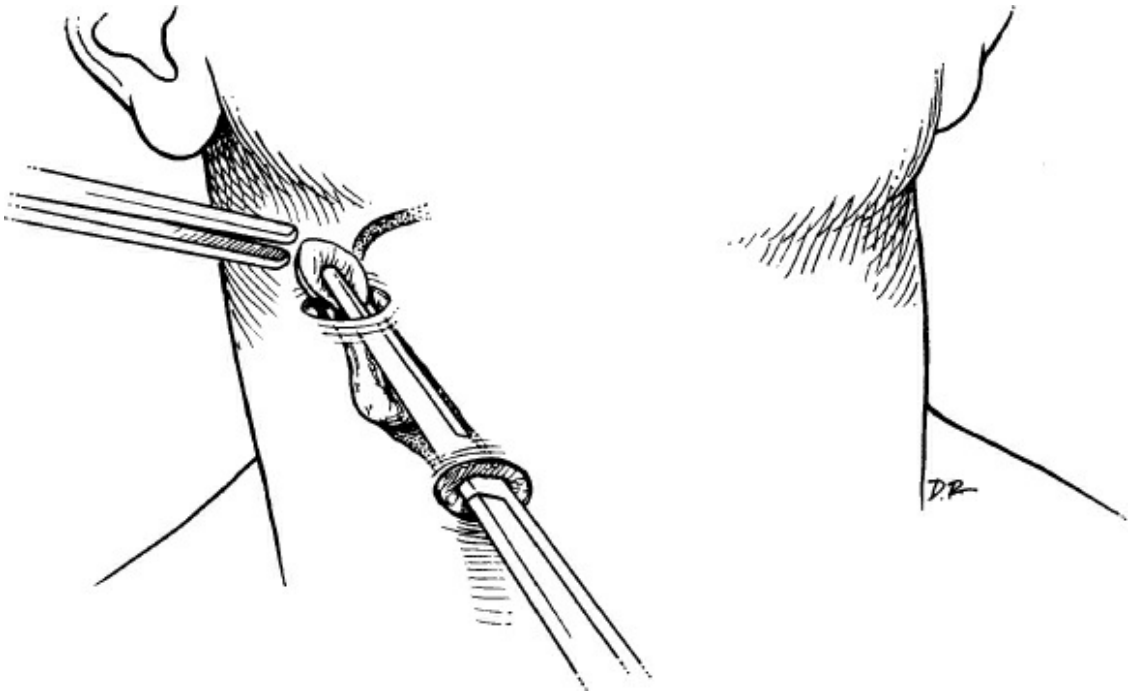

Figure 26.10. The previously mobilized second branchial cleft fistula tract is passed from the original incision to the

counterincision.

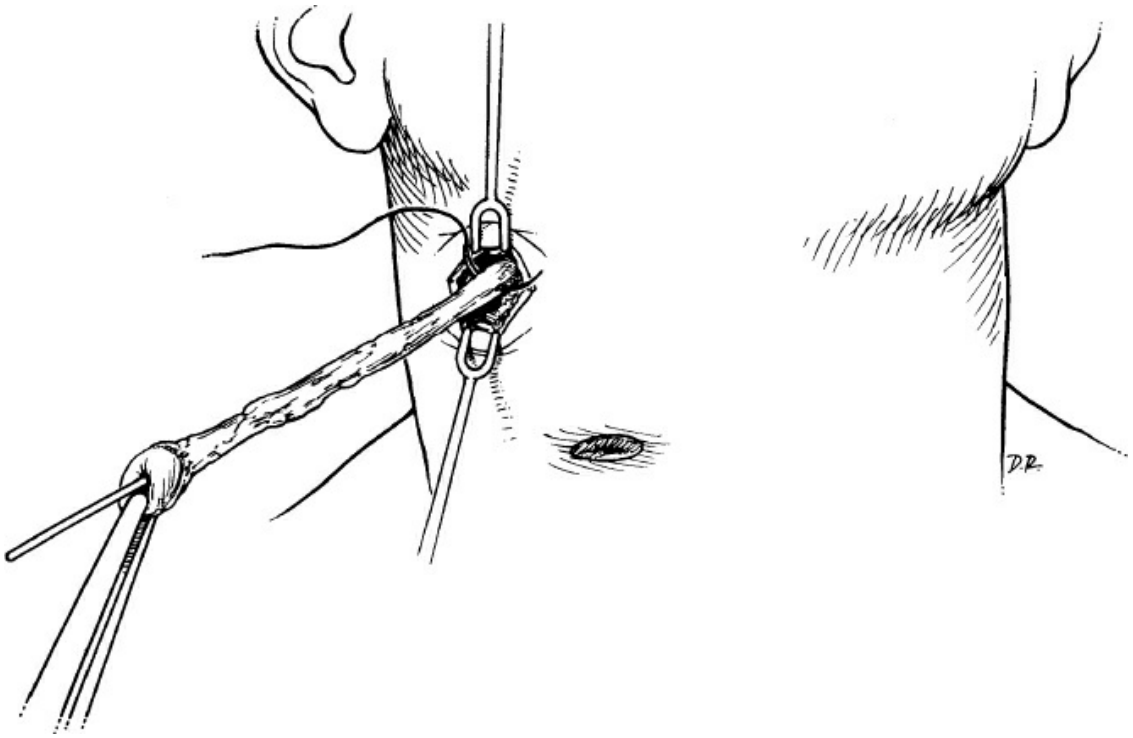

Figure 26.11. Passage of the previously mobilized tract to the counterincision facilitates further dissection of the tract in a superomedial direction to its termination at the tonsillar fossa, where it is suture-ligated and divided.

Indications and Contraindications

These lesions are benign; however, complete surgical resection is recommended upon diagnosis. Normal anatomic structures can lie adjacent to these lesions and should not be sacrificed to achieve complete resection. When a vital structure is identified within the lesion, it should be spared and protected during dissection or complete resection should not be attempted. Treatment options can include surgery, sclerotherapy, or a combination of both modalities. Newer modalities, such as laser therapy or radiofrequency ablation, are gaining attention and have been employed with variable results.

Preoperative Planning

MRI is the modality of choice to determine the extent of the lesion, delineate surrounding structures, and evaluate vital involvement by the malformation.

Surgical Technique

The procedure is performed under general anesthesia, with the administration of perioperative antibiotics. A transverse skin incision is made over the lesion following a skin crease line. Dissection is carried down through the platysma to reach the lesion. Careful dissection is performed around the lesion with sharp scissors, electrocautery or bipolar device, assuring avoidance of injury to adjacent vessels or nerves. Dissection of the lesion is facilitated by avoidance of entrance into the lesion, thereby preserving its distension. The mass is submitted for pathology evaluation, and hemostasis is assured in the dissection bed. Most surgeons prefer to leave a closed-suction drain at the completion of operation that remains until no output is observed.

Postoperative Care, Complications, and Their Management

Patients are usually admitted overnight when dissection has been extensive and to monitor drain output. The most common complications of surgical management of lymphatic malformations include bleeding, recurrence, infection, and injury to adjacent structures. Recurrent lesions are treated with sclerotherapy.

Outcomes

When complete resection is achieved, less than 10% of lesions will recur. This rate increases to 50% to 100% for lesions that have been incompletely resected. For this reason, in the case of complex lymphatic lesions with large cystic sacs insinuating around vital structures, emerging consensus is that initial management should be sclerotherapy, rather than surgery. Sclerotherapy can be successfully achieved with ethanol, bleomycin, doxycycline, or Picibanil (OK-432). It is usually performed under ultrasound guidance by aspirating the cyst and instilling the cavity with the sclerosant agent of choice for 10 to 15 minutes. This maneuver can be repeated as needed, especially for large and complex macrocystic cystic hygromas, in which excellent results can be achieved by sclerotherapy in over 80% of cases.

EDITOR'S COMMENT

Thyroglossal duct cysts and branchial cleft remnants are common congenital lesions of the head and neck that are dealt with frequently by pediatric, general, and ENT surgeons. In contrast, cystic hygromas are less common and require multidisciplinary management as treatment strategies have evolved significantly. The authors present a concise overview of these three conditions. As the authors note, all three conditions are caused by developmental abnormalities of structures in the neck. Thyroglossal duct cysts are the residual of abnormal descent and formation of the thyroid gland, branchial cleft remnants are the residuals/arrest of branchial cleft/arch/neck formation and a cystic hygroma is an abnormality in the development of the lymphatic system.

Thyroglossal duct cysts are common and diagnosed most frequently in the pediatric population. Once diagnosed, the cyst should be excised as the risk of infection is high and if infection occurs, converts a straightforward procedure into a more technically challenging one with some morbidity. The authors nicely review the treatment options and the surgical approach. When performing surgical excision—the Sistrunk procedure—the most critical step is the removal of the central portion of the hyoid bone as if this is not resected recurrence rates are high (Rohoff D, Honings J, Theunisse HJ, et al. Recurrences after thyroglossal duct cyst surgery: Results in 207 consecutive cases and review of the literature. *Head Neck* 2015;37(12):1699–704). Although removal is required, the hyoid bone in patients with thyroglossal duct cysts can be abnormal in shape and excision must be done with some care as the trachea lies beneath the hyoid and overaggressive manipulation can cause inadvertent tracheal injury—a catastrophic complication. When the patient has an active infection, the best choice may be to stage the procedure where the cyst is either aspirated or incised and drained and the patient treated with a course of

antibiotics. If incision and drainage is performed, this can make the subsequent resection more difficult as anatomic planes will be less clear. We prefer aspiration with excision scheduled near the end of the course of antibiotics. This maintains the integrity of the cyst wall and will allow for a cleaner dissection of the duct up to the hyoid bone. When incision and drainage have been performed, typically prior to referral, we may observe the patient for a period of time as often, the cyst will reform allowing for a more straightforward resection. Postoperative recovery is usually uncomplicated. In the past, all patients were hospitalized overnight but now, we will only admit for 23-hour observation, children under 3 as given their smaller airways, the combination of intubation and anterior tracheal dissection may cause some stridor that can be alleviated with respiratory treatments.

Complications are rare with recurrence the most problematic. Recurrence has been linked to both pre- and postoperative infections. Recurrence, especially if a central hyoid resection was performed during the initial resection, can be challenged and may require an anterior neck dissection (O'Neill LM, Gunaratne DA, Cheng AT, et al. Wide anterior neck dissection for management of recurrent thyroglossal duct cysts in adults. *J Laryngol Otol* 2016;130 Suppl 4:S41–4).

As the authors note, on occasion the thyroglossal duct cyst will contain the patient's only thyroid tissue. Although ultrasound can be performed to help document cyst type and presence of thyroid tissue, physical exam can still delineate the presence of thyroid tissue even in infants. Resection should still be performed as the risk of malignancy precludes leaving the thyroid containing cyst in situ. Although disconcerting, especially as it can be a pediatric patient, maintenance on long-term thyroid replacement hormones without developmental impact can be readily achieved. Careful counseling of family of the risks of the procedure and treatment necessary should ectopic thyroid tissue be found is helpful to reduce postoperative anxiety.

Malignancy arising in a thyroglossal duct cyst although rare is usually found incidentally on pathologic analysis and has been reported in both pediatric and adult patients. Papillary and squamous malignancies have been reported. Treatment, should a malignancy be detected may not require anything more than surveillance. A retrospective pooled analysis by Patel et al. of 62 cases in the literature found that the Sistrunk procedure, if a clinically and radiologically normal thyroid gland was present, was adequate as in cases where the addition of total thyroidectomy was performed, no abnormalities were identified (Patel SG, Escrig M, Shaha AR, et al. Management of well-differentiated thyroid carcinoma presenting within a thyroglossal duct cyst. *J Surg Onc* 2002;79:134–9).

Branchial cleft anomalies are interesting anatomic abnormalities resulting from remnants of the closure of the branchial cleft arches. The authors provide an excellent review of the developmental and anatomic basis by which these remnants arise. The most common abnormalities arise from the first and second

branchial cleft with third and fourth remnants uncommon. The clinical manifestations of the remnants range from a small cyst to a cartilaginous containing nodule to a sinus to an actual fistula. The treatment is always surgical with careful preoperative mapping to ensure an understanding of the anatomy such that damage to critical structures of the neck can be minimized. Great care must be taken when excising first branchial cleft remnants as the facial nerve will be involved. Excision of the second branchial cleft remnants is technically straightforward. For fistulas, the placement of a fine lacrimal duct probe in the tract can facilitate dissection. Complications following branchial cleft remnant excision are uncommon.

Although branchial cleft remnants are common, surgeons should be aware of the Branchio-otorenal (BOR) syndrome, which is characterized by branchial arch anomalies, preauricular pits, hearing impairment, and renal malformations. As noted by the authors, most branchial cleft remnants are self-limited, however, in patients with a branchial fistula associated with external ear anomalies an additional workup should be performed to eliminate the possibility of BOR syndrome especially if there is a family history of either branchial cleft remnants, hearing loss, or kidney disease (Senel E, Kocak H, Akbiyik F, et al. From a branchial fistula to a branchiootorenal syndrome: a case report and review of the literature. *J Pediatr Surg* 2009;44(3):623–5).

Lymphatic malformations arising in the neck, termed cystic hygromas, are in addition to the author's concise review, discussed at length in the accompanying vascular malformations chapter. Treatment options have expanded beyond surgery as effective medical strategies have been developed. Multidisciplinary teams comprised of oncologists, interventional radiologists, pediatric ENT, plastics and general surgeons have developed and matured at multiple major children's hospitals focused on this cohort of patients. These teams have integrated medical management, interventional procedures, and surgery to address lymphatic and vascular malformations. Preoperative imaging is critical as treatment strategies are tailored to the size of the cystic lesions. mTOR inhibitors (sirolimus and everlimus) have been shown to be effective treatment options for microcystic lymphatic malformations (Ivars M, Redondo P. Efficacy of Topical Sirolimus (Rapamycin) for the Treatment of Microcystic Lymphatic Malformations. *JAMA Dermatol* 2017;153(1):103–5). Should medical management fail, sclerotherapy is an alternative and if neither successful, surgical excision can be considered but should not be performed at the expense of compromise of important structures especially nerves.

Gregory M. Tiao

27 Vascular Anomalies of Infancy and Childhood

Arin K. Greene and John B. Mulliken

INTRODUCTION

Vascular anomalies is a field involving several medical and surgical specialties. Lesions all look quite similar, in varying shades of red, pink, and blue. The field has been handicapped by its own confusing clinical and histopathologic terminology. The traditional diagnostic terms failed to guide management. The word “hemangioma” is the most egregious example; it has been used in a generic sense for any type of vascular lesion (Table 27.1).

A biologic classification of vascular anomalies, first proposed in 1982, was based on clinical findings, natural history, and cellular characteristics. This binary scheme was accepted by the International Society for the Study of Vascular Anomalies (ISSVA) in 1996. Vascular anomalies are broadly divided into two groups: *tumors* and *malformations* (Table 27.2). Vascular tumors are characterized by endothelial cell proliferation. Vascular malformations arise by dysmorphogenesis and have minimal endothelial cell turnover. Based on this classification, vascular anomalies can be diagnosed by history and physical examination in 90% of patients. Ten percent of patients require radiographical studies for diagnostic confirmation; histopathology is rarely necessary.

The most common vascular tumors are infantile hemangioma (IH), congenital hemangioma (rapidly involuting congenital hemangioma [RICH], noninvoluting congenital hemangioma [NICH]), kaposiform hemangioendothelioma (KHE), and pyogenic granuloma (PG) (Fig. 27.1). Malformations are divided into slow-flow lesions (capillary malformation [CM], venous malformation [VM], lymphatic malformation [LM]) and fast-flow anomalies (arterial malformations [aneurysm, ectasia, stenosis, fistulas] or arteriovenous malformation [AVM]) (Fig. 27.2). There are also combined vascular anomalies, often eponymous because of the physician credited for the initial description.

TABLE 27.1 Incorrect Terminology Commonly Used to Describe Vascular Anomalies

Tumors		Malformations	
Biologic Name	Incorrect Term	Biologic Name	Incorrect Term
Infantile hemangioma	"Strawberry hemangioma" "Capillary hemangioma" "Cavernous hemangioma"	Capillary malformation	"Port-wine stain" "Capillary hemangioma"
Congenital hemangioma	"Infantile hemangioma"	Lymphatic malformation	"Cystic hygroma" "Lymphangioma"
Kaposiform hemangioendothelioma	"Capillary hemangioma"	Venous malformation	"Cavernous hemangioma"
Pyogenic granuloma	"Hemangioma"	Arteriovenous malformation	"Arteriovenous hemangioma"

Patients with a vascular anomaly often wander from one specialist to another. Their problem seems to fall outside the purview of the general surgeon and vascular surgeon. Since most vascular anomalies present in the skin, these "medical nomads" are usually seen by a dermatologist or plastic surgeon, and sometimes an oncologist because their lesion is considered to be some kind of tumor.

The biologic separation of the two major categories, tumors and malformations, has stimulated the formation of vascular anomalies centers in the major referring hospitals. It is clear that no one specialist can have sufficient knowledge to care for these patients. The field of vascular anomalies insinuates among all the surgical specialties, many of the medical disciplines, as well as interventional radiology and pathology. Molecular geneticists are also involved. Causative genes for inheritable and somatic lesions have been discovered recently (Table 27.3).

This chapter was written as a primer, to encourage general surgeons to adopt the modern terminology of vascular lesions. Surgeons, who are curious and fascinated by these common and often insoluble disorders, are encouraged to join a vascular anomalies team.

VASCULAR TUMORS

Infantile Hemangioma

Clinical Presentation

IH is a benign endothelial tumor that occurs in approximately 4% to 5% of Caucasian infants. The old terms “capillary,” “cavernous,” and “strawberry” hemangioma are imprecise and no longer used. IH is more frequent in premature children and in females (4:1). IH is typically single (80%) and involves the head and neck (60%), trunk (25%), or extremity (15%). The median age of appearance is 2 weeks; 50% of lesions are noted at birth as a telangiectatic stain or ecchymotic area. IH grows faster than the child during the first 9 months of age (proliferating phase); 80% of its size is achieved by 3.2 (±1.7) months. IH is red when it involves the superficial dermis. A lesion beneath the skin may not be appreciated until 3 to 4 months of age when it has grown large enough to cause a visible mass; the overlying skin may appear bluish. After 12 months, the tumor begins to regress (involuting phase); the color fades and the lesion flattens. Involution ceases in most children by the age of 4 years (involuted phase). After involution, one half of patients will have residual telangiectasias, scarring, fibrofatty residuum, redundant skin, or destroyed anatomical structures.

Head and Neck Hemangiomas

The majority of IH are small, harmless lesions that can be monitored under the watchful eye of a pediatrician. However, 10% of proliferating IH cause significant deformity or complications, usually when located on the head or neck. Ulcerated lesions may destroy the eyelid, ear, nose, or lip. IH of the scalp or eyebrow can result in alopecia. Periorbital hemangioma can block the visual axis or distort the cornea causing amblyopia. Subglottic hemangioma may obstruct the airway.

Multiple Hemangiomas

Approximately 20% of infants have more than one IH. Infants with five or more small (<5 mm) IHs have a 16% risk of having hepatic hemangioma which are typically asymptomatic. An ultrasonogram should be considered to rule out hepatic IH.

Hepatic Hemangiomas

The liver is the most common extracutaneous site for IH. Ninety percent of fast-flow hepatic lesions are IH. The differential diagnosis includes AVM, hepatoblastoma, and metastatic neuroblastoma which do not demonstrate significant shunting on imaging. There are three subtypes of hepatic

hemangioma: focal, multifocal, or diffuse. Although most hepatic IH are nonproblematic and discovered incidentally, large tumors can cause heart failure, hepatomegaly, anemia, or hypothyroidism. Focal hepatic hemangioma are usually asymptomatic and not associated with cutaneous lesions; they are often identified prenatally. Solitary hepatic hemangioma is a "rapidly involuting congenital hemangioma (RICH)." Occasionally this tumor can cause cardiac overload and thrombocytopenia; however, these symptoms resolve as the tumor regresses. Multifocal hepatic IH are often accompanied by cutaneous lesions. Although usually asymptomatic, multifocal lesions can cause high output cardiac failure which is managed by corticosteroid or embolization. Diffuse hepatic IH can cause massive hepatomegaly, respiratory compromise, or abdominal compartment syndrome. In addition, very large IH may cause hypothyroidism because the endothelium of hemangiomas produce type 3 iodothyronine deiodinase which inactivates circulating thyroid hormone; infants are at risk for hypothyroidism and irreversible brain injury. Consequently, patients with diffuse hepatic hemangiomas require thyroid stimulating hormone monitoring and, if abnormal, intravenous thyroid hormone replacement until the hemangioma begins to regress.

Figure 27.1. Vascular tumors of infancy and childhood. **A.** A 5-month-old male with superficial infantile hemangioma of cheek. **B.** A newborn infant with rapidly involuting congenital hemangioma (RICH) of lower extremity. **C.** An 11-month-old male with kaposiform hemangioendothelioma of trunk. **D.** A 23-month-old female with pyogenic granuloma of right lower eyelid.

Hemangiomas and Structural Anomalies

PHACE association affects 2.3% of patients with IH, and consists of a plaque-like IH in a regional distribution of the face with at least one of the following anomalies: *P*osterior fossa brain malformation; *H*emangioma; *A*rterial cerebrovascular anomalies; *C*oarctation of the aorta and cardiac defects; *E*ye/*E*ndocrine abnormalities. When ventral developmental defects (*S*ternal clefting or *S*upraumbilical raphe) are present, an "S" is

added (PHACES). Ninety percent of infants are female and cerebrovascular anomalies are the most common associated finding (72%). Because 8% of children with PHACE have a stroke in infancy, patients should have an MRI to evaluate the brain and cerebrovasculature. Infants are referred for ophthalmologic, endocrine, and cardiac evaluation to rule out these associated anomalies.

Figure 27.2. Vascular malformations. **A.** A newborn infant with capillary malformation of the trunk. **B.** A 9-year-old female with left facial lymphatic malformation. **C.** A 2-year-old female with upper labial venous malformation. **D.** A 14-year-old male with left facial arteriovenous malformation. **E.** An 18-month-old female with a combined capillary-lymphatic-venous malformation of right lower extremity and overgrowth (Klippel–Trenaunay syndrome).

LUMBAR association (*L*ower body IH, *U*rogenital anomalies, *M*yelopathy, *B*ony deformities, *A*norectal malformations, *R*enal anomalies) typically affects the sacral area or lumbar region. Ultrasonography (US) is obtained to rule out associated anomalies in infants less than 4 months of age. MRI is indicated in older infants or when ultrasound is equivocal.

Diagnosis

Most cutaneous IH are easily diagnosed by history and physical examination; these tumors are usually red, appear during the first 2 weeks of life, and grow rapidly during early infancy. Fast-flow is confirmed using a hand-held Doppler device. By formal US, IH appears as a soft tissue mass with fast-flow, decreased arterial resistance, and increased venous drainage. Involuting IH has increased lobularity and adipose tissue; the number of vessels and flow is reduced. Rarely, biopsy is indicated if malignancy is suspected or if the diagnosis remains unclear following imaging studies. Positive erythrocyte-type glucose transporter (GLUT 1) immunostaining differentiates IH from other vascular tumors and malformations.

Nonoperative Treatment

Most IHs are simply observed because 90% are small, localized, and do not involve anatomically important areas. During the proliferative phase 16% of lesions will ulcerate, most commonly on the lips, neck, and anogenital region. Other complications include bleeding and infection. IH is kept moist during the proliferative phase with hydrated petroleum to minimize desiccation as well as to protect against incidental trauma. IH may be further protected by using a petroleum gauze barrier. If an ulceration develops it is managed with local wound care; often healing takes 2 to 4 weeks.

Topical Pharmacotherapy

Topical corticosteroid is relatively ineffective; especially if IH involves the deep dermis and subcutis. Although lightening may occur, if there is deep component it will not be affected. Adverse effects include hypopigmentation and cutaneous atrophy. Topical timolol may be effective for superficial lesions, but will not affect IHs with a subcutaneous component.

TABLE 27.3 Mutations Associated With Vascular Anomalies

Condition	Mutated Gene	Inheritance
Capillary Malformation	*GNAQ*	Somatic
Venous Malformations

Hereditary hemorrhagic telangiectasia type 2 (HHT2)	*ACVRLK1*	Dominant
PTEN-associated vascular anomaly	*PTEN*	Dominant

Intralesional Corticosteroid

Problematic IHs that are well localized and <3 cm are best managed by an intralesional corticosteroid. Triamcinolone (not to exceed 3 mg/kg) will stop the growth of the lesion; two thirds will decrease in size. The corticosteroid lasts 2 to 3 weeks, and thus infants may require 2 to 3 injections during the proliferative phase. Intralesional corticosteroid may cause subcutaneous fat atrophy (2%). Blindness has been reported following injection of deep periorbital hemangioma due to embolic occlusion of the retinal artery.

Systemic Pharmacotherapy

Problematic IHs >3 cm are managed by oral prednisolone or propranolol. Prednisolone has been used to treat IH for over 45 years and has proven to be very safe and effective. Patients are given 3 mg/kg/day for 1 month; the drug is then tapered by 0.5 cc every 2 to 4 weeks until it is discontinued between 10 and 12 months of age when the tumor is no longer proliferating. The drug is given once a day in the morning, and infants have monthly outpatient follow-up. Using this protocol, all tumors will stabilize in growth and 88% will become smaller (accelerated regression). Twenty percent of infants will develop a cushingoid appearance that resolves during tapering of therapy. Approximately 12% exhibit decreased gain in height, but return to their pretreatment growth curve by 24 months of age.

Propranolol dosing typically is 2 mg/kg/day. Approximately 90% of tumors will stop growing or regress. Risks (<3%) include bronchospasm, bradycardia, hypotension, hypoglycemia, seizures, and hyperkalemia. Preterm infants and those <3 months of age are more likely to have adverse events. Patients usually have cardiology consultation, electrocardiogram, echocardiogram, glucose/electrolyte measurements, and frequent blood pressure, heart rate, and respiratory examinations. Inpatient initiation of treatment is used for premature or infants less than 3 months of age. Potential contraindications include asthma, glucose abnormalities, heart disease, hypotension, bradycardia, PHACES association. The drug should be discontinued if the infant is ill because reduced oral intake can increase the risk of hypoglycemia and seizures. Patients treated with propranolol experience later rebound growth compared to prednisolone, and thus may necessitate longer treatment. Recently, concern has been raised about potentially negative long-term neurocognitive effects of propranolol when given to infants.

Laser Therapy

There is little, if any, role for pulsed-dye laser treatment for proliferating IH. The laser penetrates only 0.75 to 1.2 mm into the dermis, and thus only affects the superficial portion of the tumor. Although lightening may occur, the mass of IH is not affected. Instead, patients have an increased risk of skin atrophy and hypopigmentation. The thermal injury delivered by the laser to the ischemic dermis increases the risk of ulceration, pain, bleeding, and scarring. Pulsed-dye laser is indicated during the involuted phase to fade residual telangiectasias.

Operative Treatment

Resection generally is not recommended during the proliferating phase. The tumor is highly vascular and there is a risk for blood loss, iatrogenic injury, and an inferior outcome, compared to excising residual tissue after the tumor has regressed. Approximately 50% of IH leave behind fibrofatty tissue or damaged skin after the tumor regresses causing a deformity. It is preferable to intervene surgically between 3 and 4 years of age (Fig. 27.3). During this period the IH will no longer improve significantly, and the procedure is performed before the child's long-term memory and self-esteem begin to form at about 4 years of age. Also, waiting until the IH is at its smallest will result in the shortest possible scar and the most favorable outcome. Circular lesions located in visible areas, particularly the face, are best removed by circular excision and purse-string closure (Fig. 27.4). This technique minimizes the length of the scar as well as distortion of surrounding structures. Lenticular excision of a circular IH results in a scar as long as three times the diameter of the lesion. In comparison, a two-stage circular resection followed by lenticular excision/linear closure will leave a scar approximately the same length as the diameter of the original lesion.

Congenital Hemangiomas

Clinical Presentation

There are rare hemangiomas that arise in the fetus, are fully grown at birth, and do not have postnatal growth. These congenital hemangiomas are red-violaceous with coarse telangiectasias, central pallor, and a peripheral pale halo. These lesions are more common in the extremities, have an equal sex distribution, and are solitary with an average diameter of 5 cm. There are two forms: RICH and NICH. RICH regresses rapidly after birth; 50% have

completed regression by 7 months of age. RICH affects the head or neck (42%), limbs (52%), or trunk (6%). RICH does not leave behind a significant adipose component, unlike IH. NICH, in contrast, does not undergo involution; there is persistent fast-flow. It involves the head or neck (43%), limbs (38%), or trunk (19%).

Treatment

RICH usually does not require resection in infancy because it undergoes accelerated regression. Occasionally, RICH is complicated by congestive heart failure which is controlled by corticosteroid or embolization as the lesion involutes. After regression RICH may leave behind atrophic skin and subcutaneous tissue. Reconstruction with autologous grafts (fat, dermis) or acellular dermis may be indicated. NICH is rarely problematic in infancy; it is observed until the diagnosis is clear. Resection of NICH may be indicated to improve the appearance of the affected area, as long as the surgical scar will be less noticeable than the lesion.

Figure 27.3. A 2-year-old female with involuting phase infantile hemangioma of the scalp resulting in fibrofatty residuum and alopecia: lenticular excision (**A**) and linear closure (**B**).

Kaposiform Hemangioendothelioma

Clinical Presentation

KHE is a rare vascular neoplasm that is locally aggressive, but does not metastasize. Although one half of lesions are present at birth, KHE may develop during infancy (58%), between age 1 and 10 years (32%), or after 11 years of age (10%). KHE has an equal sex distribution, is solitary, and affects the head/neck (40%), trunk (30%), or extremity (30%). The tumor is often greater than 5 cm in diameter, and thus larger than the typical IH.

KHE causes a visible deformity as well as pain. In addition, 50% of patients have Kasabach–Merritt phenomenon (KMP) (thrombocytopenia <25,000/mm^3, petechiae, bleeding). KHE partially regresses after 2 years of age, although it usually persists long-term causing chronic pain and stiffness.

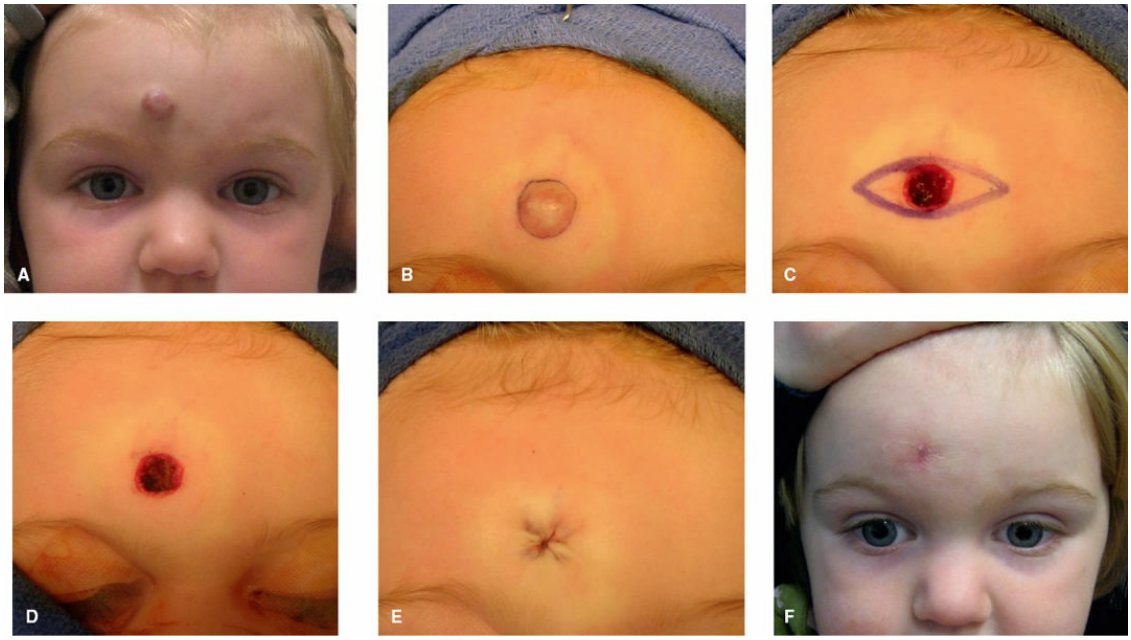

Figure 27.4. **A, B.** A 2.5-year-old female with frontal infantile hemangioma and fibrofatty residuum. **C.** Lenticular excision would result in a scar approximately three times the diameter of the tumor. **D, E.** Circular excision/purse-string closure. **F.** A small scar 3 months postoperatively.

Diagnosis

The diagnosis is established by history, physical examination, and imaging. Unlike IH, KHE is usually present at birth as a flat, reddish-purple, edematous lesion. It does not exhibit rapid postnatal growth; however, the tumor can expand with the onset of KMP. MRI is indicated for diagnostic confirmation and to asses the extent of the tumor. MRI shows poorly defined margins, small vessels, and invasion of adjacent tissues. There is T2 hyperintensity, postgadolinium enhancement, and signal voids also may be present. Histologically, KHE has infiltrating sheets or nodules of endothelial cells lining capillaries. Hemosiderin-filled slit-like vascular spaces with red blood cell fragments, as well as dilated lymphatics, are present.

Treatment

Most lesions are extensive, involving multiple tissues, and are beyond the limits of resection. Patients with KMP require systemic treatment to prevent life-threatening complications. Large, asymptomatic tumors without KMP are also managed with pharmacotherapy to minimize fibrosis and subsequent long-term pain and stiffness. Vincristine is first-line therapy, the response rate is 90%. Recently, patients have been treated with sirolimus with good efficacy. KHE does not respond as well to second-line drugs, interferons (50%), or corticosteroids (10%). Thrombocytopenia will not be significantly improved with platelet transfusion because the platelets are trapped in the tumor. Transfusion also worsens swelling and should be avoided unless there is active bleeding or a surgical procedure is planned. By 2 years of age, the tumor often undergoes partial involution and the platelet count normalizes.

Pyogenic Granuloma

PG is neither "pyogenic" nor "granulomatous." Some pathologists call it *lobular capillary hemangioma.* PG is a solitary, red papule that grows rapidly on a stalk. It is small, with an average diameter of 6.5 mm; the mean age of onset is 6.7 years. The male:female ratio is 2:1. PG is complicated by bleeding (64%) and ulceration (36%). PG primarily involves the skin (88%), but can involve mucous membranes as well (11%). PG is distributed on the head or neck (62%), trunk (19%), upper extremity (13%), or lower extremity (5%). In the head and neck region, affected sites include cheek (29%), oral cavity (14%), scalp (11%), forehead (10%), eyelid (9%), or lips (9%).

PGs require intervention to prevent ulceration and bleeding. Numerous methods have been described: curettage, shave excision, laser therapy, or excision. Because the lesion involves the reticular dermis, it is out of the reach of the pulsed-dye laser, cautery, or shave excision. Consequently, these modalities have a recurrence rate of 50%. Full-thickness skin excision is more definitive.

VASCULAR MALFORMATIONS

Capillary Malformations

Clinical Presentation

CM is now the accepted term for the familiar "port-wine" stain. Histopathologic examination shows dilated capillaries and venular vessels

in the superficial dermis. CM is most often solitary; it can be localized or extensive. The lesion is caused by a somatic mutation in *GNAQ*. Over time the stain darkens and exhibits fibrovascular overgrowth. It can be associated with soft tissue and skeletal hypertrophy. Sturge–Weber syndrome is characterized by CM in the ophthalmic (V1) trigeminal dermatome associated with ipsilateral ocular and leptomeningeal vascular anomalies. Leptomeningeal anomalies can cause seizures, contralateral hemiplegia, and delayed development. Patients are at risk for retinal detachment and glaucoma; they should be followed closely by an ophthalmologist.

Treatment

Pulse-dye laser (585 nm) therapy can improve the appearance of CM; the head and neck region responds better than the extremities. Outcome also is superior for smaller lesions and those treated at a younger age. Fifteen percent of patients achieve at least 90% lightening, 65% improve 50% to 90%, and 20% respond poorly. Multiple treatments, spaced 6 weeks apart, are often required until the CM no longer improves with additional treatments. After laser treatment, CM often redarkens over time.

CM can also be associated with soft tissue and skeletal overgrowth. Labial hypertrophy is improved by contour resection. Enlargement of the maxilla or mandible can result in an occlusal cant and malocclusion. Malocclusion may be corrected in adolescence by orthodontic manipulation and/or an orthognathic procedure. CM of the trunk or extremity may be associated with fatty overgrowth causing asymmetry and leg-length discrepancy. In severe cases, cutaneous thickening and cobblestoning can be resected and reconstructed either by linear closure, skin grafts, or local flaps. Facial asymmetry caused by overgrowth of the zygoma, maxilla, or mandible can be improved by contour burring.

Lymphatic Malformation

Clinical Presentation

LM is caused by an error in the embryonic development of the lymphatic system. LM is characterized by the size of the malformed channels: microcystic, macrocystic, or combined. Macrocystic lesions are defined as cysts large enough to be punctured by a needle and treated with sclerotherapy. LM is usually noted at birth or within the first 2 years of life. LM is most commonly located on the head and neck; other frequent

sites include the axilla, chest, and perineum. Lesions are soft and compressible. The overlying skin may be normal, have a bluish hue, or be studded with pink-red vesicles.

LM typically causes deformity and psychosocial issues, especially when it involves the head and neck. The two most common complications associated with LM are bleeding and infection. Intralesional bleeding occurs in up to 35% of lesions causing ecchymotic discoloration, pain, or swelling. Infection complicates as many as 70% of lesions and can progress rapidly to sepsis. Cutaneous vesicles can bleed and cause malodorous drainage. Oral lesions may lead to macroglossia, poor oral hygiene, and caries. Swelling due to bleeding, localized infection, or systemic illness may obstruct vital structures. Two thirds of infants with cervicofacial LM require tracheostomy. Bony overgrowth is another complication; the mandible is most commonly involved resulting in an open bite and prognathism. Thoracic or abdominal LM may lead to pleural, pericardial, or peritoneal chylous effusions. Periorbital LM causes a permanent reduction in vision (40%), and 7% of patients become blind in the affected eye. Generalized LM presents with multifocal or osteolytic bony lesions in association with pleural and/or pericardial effusions; so-called “lymphangiectasia” of the bowel with protein-losing enteropathy also may be present.

Diagnosis

Ninety percent of LM are diagnosed by history and physical examination. Small, superficial lesions do not require further diagnostic evaluation. Large or deep lesions are assessed by MRI to: (1) confirm the diagnosis; (2) define the extent of the malformation; and (3) plan treatment. LM appears as either a macrocystic, microcystic, or combined lesion with septations of variable thickness. It is hyperintense on T2-weighted sequences and does not show diffuse enhancement. Although US is not as accurate as MRI, it may provide diagnostic confirmation or document intralesional bleeding. US findings for macrocystic LM include anechoic cysts with internal septations, often with debris or fluid–fluid levels. Microcystic LM appears as ill-defined echogenic masses with diffuse involvement of adjacent tissues. Histologic confirmation of LM is rarely necessary. LM shows abnormally walled vascular spaces with eosinophilic, protein-rich fluid, and collections of lymphocytes. Immunostaining with the lymphatic markers D2–40 and LYVE-1 are positive.

Treatment

LM is a benign lesion; intervention is not mandatory. Small or asymptomatic lesions may be observed. An infected LM often cannot be controlled with oral antibiotics and intravenous antimicrobial therapy usually is required. Intervention for LM is reserved for symptomatic lesions that cause pain, significant deformity, or threaten vital structures.

Sclerotherapy

Sclerotherapy is first-line management for large or problematic macrocystic/combined LM. Cysts are aspirated followed by the injection of an inflammatory substance which causes scarring of the cyst walls to each other. Sclerotherapy has superior efficacy and a lower complication rate than excision. Several scleroscents are used to shrink LM: doxycycline, sodium tetradecyl sulfate (STS), ethanol, bleomycin, and OK-432 (penicillin/heat inactivated *Streptococcus pyogenes*). We prefer doxycycline because it is effective (83% reduction in size) and safe (less than 5% risk of skin ulceration). STS is our second-line agent. Ethanol is an effective sclerosant but has the highest complication rate. It can be used for small lesions, but large volumes should be avoided to reduce the risk of local and systemic toxicity. Ethanol can injure nerves and thus should not be used in proximity to important structures. The use of OK-432 is limited because it is not widely available.

The most common complication of sclerotherapy for LM is cutaneous ulceration (<5%). Ethanol is associated with additional systemic toxicity: CNS depression, pulmonary hypertension, hemolysis, thromboembolism, and arrhythmias. Extravasation of the sclerosant into muscle can cause atrophy and contracture. LM often re-expands over time; 9% recur within 3 years following OK-432 treatment and most will re-expand with longer follow-up. Consequently, patients often need repeated sclerotherapy over the course of their lifetime. If a problematic LM recurs and macrocysts are no longer present in the lesion, then resection is the next alternative. Recently, bleomycin sclerotherapy has shown efficacy for microcystic LMs. This modality can be considered for problematic lesions where resection would be unfavorable; approximately 10% reduction in the size of the lesion can be expected.

Resection

Attempts at extirpation of LM can cause significant morbidity: major blood loss, iatrogenic injury, and deformity. For example, resection of

cervicofacial LM can injure the facial or hypoglossal nerve. Excision is usually subtotal because LM involves multiple tissue planes and important structures; recurrence thus is common (35% to 64%). Resection is reserved for: (1) symptomatic microcystic LM causing bleeding, infection, distortion of vital structures, or significant deformity; (2) symptomatic macrocystic/combined LM that no longer can be managed with sclerotherapy because all macrocysts have been treated; (3) small, well-localized LM (microcystic or macrocystic) that may be completely excised. When considering resection, the postoperative scar/deformity following removal of the LM should be weighed against the preoperative appearance of the lesion.

For diffuse malformations, staged resection of defined anatomic areas is recommended. Subtotal excision of problematic areas, such as bleeding vesicles or a hypertrophied lip, should be carried out rather than attempting "complete" resection of a benign lesion which would result in a worse deformity than the malformation itself. Macroglossia may require reduction to return the tongue to the oral cavity or to correct an open-bite deformity. Bony overgrowth is improved by osseous contouring and malocclusion may require orthognathic correction, usually after skeletal maturity.

Bleeding or leaking cutaneous vesicles may be managed by resection if they are localized and the wound can be closed by direct approximation of tissues. Vesicles often recur through the scar. Large areas of vesicular bleeding or drainage are best managed by sclerotherapy or carbon dioxide laser; alternatively, wide resection and skin graft coverage is required. Microcystic vesicles involving the oral cavity respond well to radiofrequency ablation. Recently, sirolimus has shown efficacy for severe microcystic disease. Patients and families are counseled that LM can expand following any intervention, and thus additional treatments are often required in the future.

Venous Malformation

Clinical Presentation

VM results from an error in vascular morphogenesis; the anomalous channels are dilated with thin walls and abnormal smooth muscle. Consequently, flow stagnates, lesions expand, and clotting occurs. Lesions are blue, soft, and compressible; calcified phleboliths may be palpated. VM range from small, localized cutaneous lesions to diffuse

malformations involving multiple tissue planes and vital structures. VM is typically sporadic and solitary in 90% of patients; however, 50% have a somatic mutation in the endothelial receptor TIE2. Sporadic VM is usually greater than 5 cm (56%), single (99%), and located on the head/neck (47%), extremities (40%), or trunk (13%). Almost all lesions involve the skin, mucosa, or subcutaneous tissue; 50% also affect deeper structures (i.e., muscle, bone, joints, viscera).

Approximately 10% of patients with VM have multifocal, familial lesions. *Glomuvenous malformation* (GVM) is the most common type, *cutaneomucosal-venous malformation* (CMVM) is rare. GVM is an autosomal dominant condition with abnormal smooth muscle-like glomus cells along the ectatic veins. It is caused by a loss-of-function mutation in the *glomulin* gene. Lesions are typically multiple (70%), small (two thirds <5 cm), and located in the skin and subcutaneous tissue; deeper structures are not affected. GVM involves the extremities (76%), trunk (14%), or head/neck (10%). Lesions are more painful than typical VM.

CMVM are small, multifocal mucocutaneous lesions caused by a gain-of-function mutation in the *TIE2* receptor. The condition is autosomal dominant and less common than GVM. Lesions are small (76% <5 cm), multiple (73%), and located on the head/neck (typically tongue or buccal mucosa) (50%), extremity (37%), or trunk (13%).

Cerebral cavernous malformation (CCM) is a rare familial disorder with VM involving the brain and spinal cord; patients also may have hyperkeratotic skin lesions. The disorder results from mutations in CCM1/(*KRIT1*), CCM2, and CCM3 genes and patients are at risk for development of new intracranial lesions and hemorrhage.

Blue rubber bleb nevus syndrome (BRBNS) is a rare condition with multiple, small (<2 cm) VM involving the skin, soft tissue, and gastrointestinal tract. Morbidity is associated with gastrointestinal bleeding requiring chronic blood transfusions.

Verrucous venous malformation (VVM) (previously called “verrucous hemangioma”) is a low-flow vascular malformation that is similar to a hyperkeratotic VM. Lesions range from 2 to 8 cm and are located on an extremity (91%) or trunk (9%). VH involves the skin and subcutis, becomes more hyperkeratotic over time, and frequently causes bleeding. Recently, *MAP3K3* mutations have been found in VVMs. Treatment is carbon dioxide laser or resection.

Fibroadipose vascular anomaly (FAVA) shares features with

intramuscular VM and is caused by a *PIK3CA* mutation. It affects the calf most frequently followed by the thigh, forearm, gluteal area, and ankle/foot. It is differentiated from intramuscular VM by significant pain, contractures, and a nonspongiform venous cutaneous component (phlebectasia, CM, or lymphatic vesicles). On MRI FAVA exhibits fat and fibrosis, minimal signal on T2 images, and heterogeneous small channels. Sclerotherapy is not effective because FAVA is solid. Treatment is either corticosteroid injection, cryotherapy, or resection.

Complications of VM include pain, swelling, and psychosocial issues. Head and neck VM may present with mucosal bleeding or progressive distortion leading to airway or orbital compromise. Extremity VM can cause leg-length discrepancy, hypoplasia due to disuse atrophy, pathologic fracture, hemarthrosis, and degenerative arthritis. VM of muscle may result in fibrosis and subsequent pain and disability. A large VM involving the deep venous system is at risk for thrombosis and pulmonary embolism. Gastrointestinal VM can cause bleeding and chronic anemia. Stagnation within a large VM results in a localized intravascular coagulopathy (LIC) and painful phlebothromboses.

Diagnosis

At least 90% of VMs are diagnosed by history and physical examination. Dependent positioning of the affected region usually confirms the diagnosis. Small, superficial VM do not require further diagnostic workup. Large or deeper lesions are evaluated by MRI to: (1) confirm the diagnosis; (2) define the extent of the malformation; and (3) plan treatment. VM is hyperintense on T2-weighted sequences. In contrast to LM, VM enhances with contrast, often shows phleboliths as signal voids, and is more likely to involve muscle. US may be used for some localized lesions; findings include compressible, anechoic–hypoechoic channels separated by more solid regions of variable echogenicity. Phleboliths are hyperechoic with acoustic shadowing. CT is occasionally indicated to assess osseous VM. Histologic diagnosis of VM is rarely necessary.

Treatment

Patients with an extensive extremity VM are prescribed custom-fitted compression garments to reduce blood stagnation and thus minimize expansion, LIC, phlebolith formation, and pain. Patients with recurrent pain secondary to phlebothrombosis are given prophylactic daily aspirin (81 mg) to prevent thrombosis. Large lesions are at risk for coagulation of

stagnant blood, stimulation of thrombin, and conversion of fibrinogen to fibrin. LIC can become disseminated intravascular coagulopathy (DIC) following trauma or therapeutic intervention. The chronic consumptive coagulopathy can cause either thrombosis (phleboliths) or bleeding (hemarthrosis, hematoma, intraoperative blood loss). Low-molecular-weight heparin (LMWH) is considered for patients with significant LIC who are at risk for DIC. Patients who develop a serious thrombotic event require long-term anticoagulation or a vena caval filter.

Sclerotherapy

Intervention for VM is reserved for symptomatic lesions that cause pain, deformity, obstruction (i.e., vision, airway), or gastrointestinal bleeding. First-line treatment is sclerotherapy, which is safer and more effective than resection. Diffuse malformations are managed by targeting specific symptomatic areas; often the entire lesion is too extensive to treat at one time. Sclerotherapy is repeated until symptoms are alleviated or when injectable vascular spaces are no longer present. Although sclerotherapy effectively reduces the size of the lesion and improves symptoms, the malformation remains. Consequently, patients who have a mass or visible deformity after treatment, may be improved by resection. In addition, VM usually re-expands after sclerotherapy, and thus patients often require additional treatments.

The preferred scleroscents for VM are STS and ethanol; STS is most commonly used. Although ethanol is more effective than STS, it has a higher complication rate. Most patients, especially children, are managed under general anesthesia using US or fluoroscopic imaging. The most common local complication of sclerotherapy for VM is cutaneous ulceration (<5%). Extravasation of the sclerosant into muscle can cause atrophy and contracture. Posttreatment swelling may necessitate close monitoring. Compartment syndrome is a serious consequence of sclerotherapy for extremity VM. Systemic adverse events from sclerotherapy, including hemolysis, hemoglobinuria, and DIC, are more common if large lesions are treated. Consequently, patients with a large, diffuse VM have fibrinogen levels measured before sclerotherapy or resection. If fibrinogen levels are low, patients are given LMWH 14 days before and after the procedure. Anticoagulation is held for 24 hours perioperatively (12 hours before and after the intervention) to prevent bleeding complications.

Resection

Extirpation of VM can cause major morbidity; that is, blood loss, iatrogenic injury, and deformity. In contrast to sclerotherapy, resection is rarely primary treatment because: (1) the entire lesion is difficult to remove; (2) the risk of recurrence is high because channels adjacent to the visible lesion are not treated; and (3) the risk of blood loss and iatrogenic injury is greater. Resection should be considered for: (1) small, well-localized lesions that can be completely removed or (2) persistent mass or deformity after completion of sclerotherapy (patent channels are no longer accessible for further injection). When considering resection, the postoperative scar/deformity following removal of the VM should be weighed against the preoperative appearance of the lesion. Subtotal resection of a problematic area, such as labial hypertrophy, is indicated rather than attempting "complete" excision of a benign lesion that might result in a worse deformity than the malformation itself. Patients and families are counseled that VM can expand following excision, and additional operative intervention may be required in the future.

Almost all VMs should have sclerotherapy prior to operative intervention. After adequate sclerotherapy, the VM is replaced by scar and thus the risk of blood loss, iatrogenic injury, and recurrence is reduced. In addition, fibrosis facilitates resection and reconstruction. Because GVM are usually small and less amenable to sclerotherapy, first-line therapy for painful lesions may be resection. Nd:YAG photocoagulation can be an adjuvant to sclerotherapy for the management of difficult airway lesions. Gastrointestinal VM with chronic bleeding, anemia, and transfusion requirements are typically managed by resection. Solitary lesions can be treated by endoscopic banding or sclerotherapy. Multifocal lesions of BRBNS require removal of as many lesions as possible through multiple enterotomies, instead of bowel resection, to preserve the length of intestine. Diffuse, problematic colorectal VM may require colectomy, anorectal mucosectomy, and endorectal pull-through.

Arteriovenous Malformation

Clinical Presentation

AVM results from an error in vasculogenesis during embryonic development. An absent capillary bed causes shunting of blood directly from the arterial to venous circulation, through a fistula (direct connection of an artery to a vein) or nidus (abnormal channels bridging the feeding

artery to the draining veins). Genetic abnormalities cause certain types of familial AVM. *Hereditary hemorrhagic telangiectasia* (HHT) is caused by mutations in endoglin and activin receptor-like kinase 1 (ALK-1), which affect transforming growth factor-beta (TGF-β) signaling. *Capillary malformation-arteriovenous malformation* (CM-AVM) results from a mutation in *RASA1*.

The head and neck is the most common site of extracranial AVM, followed by the limbs, trunk, and viscera. Although present at birth, AVM may not become evident until childhood. Arteriovenous shunting reduces capillary oxygen delivery causing ischemia; patients are at risk for pain, ulceration, bleeding, and congestive heart failure. AVM also may cause disfigurement, destruction of tissues, and obstruction of vital structures. As AVM worsens over time, the lesion can be classified according to the Schobinger staging system (Table 27.4).

Diagnosis

Most AVMs are diagnosed by history and physical examination. If AVM is suspected, the diagnosis should be confirmed by US with color Doppler examination showing fast-flow and shunting. MRI also is obtained to: (1) confirm the diagnosis; (2) determine the extent of the lesion; and (3) plan treatment. MRI shows dilated feeding arteries and draining veins, enhancement, and flow-voids on T2-weighted imaging. In rare instances, diagnostic angiography is needed. Angiography also is indicated if embolization or resection is planned to determine the flow dynamics of the lesion. AVM exhibits tortuous, dilated arteries with venous shunting and dilated draining veins on angiogram. Often, a blush illustrates the nidus of the lesion. Histopathologic diagnosis of AVM is rarely necessary.

TABLE 27.4 Schobinger Staging of Arteriovenous Malformation (AVM)

Stage	Clinical Findings
I (Quiescence)	Warm, pink-blue, shunting on Doppler
II (Expansion)	Enlargement, pulsation, thrill, bruit, tortuous veins
III (Destruction)	Dystrophic skin changes, ulceration, bleeding, pain
IV (Decompensation)	Cardiac failure

Treatment

Because AVM is often diffuse, involving multiple tissue planes and important structures, cure is rare. The goal of treatment usually is to *control* the malformation. Intervention is focused on alleviating symptoms (i.e., bleeding, pain, ulceration), preserving vital functions (i.e., vision, mastication), and improving a visible deformity. Management options include embolization, resection, or a combination. Resection offers the best chance for long-term control, but the re-expansion rate is high and extirpation may cause a worse deformity. Almost all AVM will re-expand after embolization. Consequently, embolization is most commonly used preoperatively to reduce blood loss during resection, or sometimes for palliation of unresectable lesions.

Asymptomatic AVM should be observed unless it can be completely removed with minimal morbidity; embolization or incomplete excision of an asymptomatic lesion may stimulate it to enlarge and become problematic. Intervention is determined by: (1) the size and location of the AVM; (2) the age of the patient; and (3) Schobinger stage. Although resection of an asymptomatic Stage I AVM offers the best chance for long-term control or "cure," intervention must be individualized based on the deformity that would be caused by resection and reconstruction. For example, a large Stage I AVM in a nonanatomically important location (i.e., trunk, proximal extremity) may be resected without consequence, before it progresses to a higher stage where resection is more difficult, and

the recurrence rate is greater. Similarly, a small, well-localized AVM in a more difficult location (i.e., face, hand) may be excised for possible “cure” before it expands and complete extirpation is no longer possible.

In contrast, a large, asymptomatic AVM located in an anatomically sensitive area is best observed; especially in a young child who is not psychologically ready for major resection and reconstruction. Resection and reconstruction may result in a more noticeable deformity or functional problem than the malformation. Although the recurrence rate is lower when Stage I AVM is resected, it is still high, and thus even after major resection and reconstruction the malformation can recur. Some patients (17.4%) do not have significant morbidity from their lesion long-term.

Intervention for Stage II AVMs is similar to Stage I lesions. The threshold for treatment is lower if an enlarging lesion is causing a worsening deformity or if functional problems are occurring. Stage III and IV AVMs require intervention to control pain, bleeding, ulceration, or congestive heart failure.

Embolization

Embolization is the delivery of an inert substance, through a catheter proximal to the AVM, to occlude blood flow and/or fill a vascular space. Ischemia and scarring reduce arteriovenous shunting, shrink the lesion, and diminish symptoms. Embolization is used either as a preoperative adjunct to resection or as monotherapy for lesions not amenable to extirpation. Because the AVM is not removed, almost all lesions eventually re-expand after treatment. Stage I AVM has a lower recurrence rate than higher-staged lesions. Most recurrences occur within the first year after embolization, and 98% re-expand within 5 years. Despite the high likelihood of re-expansion, embolization can effectively palliate an AVM by reducing its size, slowing expansion, and alleviating pain and bleeding. Preoperative embolization also reduces blood loss during extirpation, but not the extent of resection.

Substances used for embolization are either liquid (n-butyl cyanoacrylate [n-BCA], Onyx) or solid (polyvinyl alcohol [PVA] particles, coils). The goal of embolization is occlusion of the nidus and proximal venous outflow. The embolic material is delivered to the nidus, *not* to the proximal arterial feeding vessels. Occlusion of inflow will cause collateralization and expansion of the AVM; access to the nidus also will be blocked preventing future embolization. For preoperative embolization, temporary occlusive substances (gelfoam powder, PVA, embospheres) that

undergo phagocytosis are used. Permanent liquid agents capable of permeating the nidus (n-BCA, Onyx) are used when embolization is the primary treatment. The most frequent complication of embolization is ulceration.

Resection

Resection of AVM has a lower recurrence rate than embolization alone and is considered for well-localized lesions or to correct focal deformities (i.e., bleeding or ulcerated areas, labial hypertrophy). Wide extirpation and reconstruction of large, diffuse AVM should be exercised with caution because: (1) cure is rare and the recurrence rate is high; (2) the resulting deformity is often worse than the appearance of the malformation; (3) resection is associated with significant blood loss, iatrogenic injury, and morbidity. When excision is planned, preoperative embolization will facilitate the procedure by reducing the size of the AVM, minimizing blood loss, and creating scar tissue to aid the dissection. Multiple embolizations, spaced 6 weeks apart, may be required prior to resection. Excision should be done 24 to 72 hours after embolization, before recanalization restores blood flow to the lesion.

Resection margins are best determined clinically, by assessing the amount of bleeding from the wound edges. Most defects can be reconstructed by advancing local skin flaps. Skin grafting ulcerated areas has a high failure rate because the underlying tissue is ischemic; excision with regional flap transfer may be required. Free-flap reconstruction permits wide resection and primary closure of complicated defects, but does not appear to improve long-term AVM control. Despite sub-total and presumed “complete” extirpation, most AVMs treated by resection recur. The majority of recurrences occur within the first year after intervention and 86% re-expand within 5 years of resection. Nevertheless, many of these patients remain asymptomatic. Patients and families are counseled that AVM is likely to re-expand following resection, and thus additional treatment may be required in the future.

Capillary Malformation-Arteriovenous Malformation

CM-AVM is a familial disorder; the prevalence is 1 in 100,000. CM-AVM is an autosomal dominant condition caused by a loss-of-function mutation in the *RASA1* gene. Patients have atypical CMs that are small, multifocal, round, pinkish-red, and often surrounded by a pale halo (50%). Thirty percent of individuals also have an AVM: Parkes Weber syndrome (PWS)

(12%), extracerebral AVM (11%), or intracerebral AVM (7%). PWS refers to a diffuse AVM in an overgrown extremity with an overlying CM. PWS involves the lower extremity approximately twice as often as the upper extremity; patients have microshunting in muscle. A patient presenting with multiple CMs, especially with a family history of similar lesions, should be evaluated for possible AVMs on physical examination. Because 7% of patients with CM-AVM will have an intracranial fast-flow lesion, brain MRI should be considered. Exploratory imaging of other anatomical areas is not necessary because extracranial AVM have not been found to involve the viscera. Although the CM is rarely problematic, associated AVMs can cause major morbidity.

Vascular Malformation Overgrowth Syndromes

CLOVES Syndrome

*C*ongenital *L*ipomatosis *O*vergrowth, *V*ascular malformations, *E*pidermal nevi, and *S*coliosis (CLOVES) represents a newly described overgrowth syndrome caused by a *PIK3CA* mutation. Many of these children previously were thought to have "Proteus syndrome." All patients have a truncal lipomatous mass, a slow-flow vascular malformation (most commonly a CM overlying the lipomatous mass), and hand/foot anomalies (increased width, macrodactyly, first web-space sandal gap). Patients also may have AVM (28%), neurologic impairment (50%), or scoliosis (33%). Treatment for the lipomatous lesions is resection, but the recurrence rate is high.

Klippel–Trénaunay Syndrome

Klippel–Trénaunay syndrome (KTS) denotes a slow-flow, capillary-lymphatic-venous malformation (CLVM) of an extremity in association with soft tissue and/or skeletal overgrowth. There is tremendous variability in the presentation of this disorder, from a slightly enlarged extremity with a capillary stain to a grotesquely enlarged limb with malformed digits. KTS affects the lower extremity in 95% of patients, the upper extremity in 5% of patients, and least commonly the trunk. Sometimes the contralateral foot or hand is enlarged, often with a macrodactylous component and frequently in the absence of a capillary stain. In 10% of patients with KTS, the involved limb is hypoplastic. Pelvic involvement is common with CLVM of the lower extremity. It is usually asymptomatic, although hematuria, bladder outlet obstruction, cystitis, and hematochezia can

occur. The CM is distributed in a geographic pattern over the lateral side of the extremity, buttock, or thorax. Whereas the CM is typically macular in a neonate, later it becomes studded with hemolymphatic vesicles. The venous component of CLVM manifests as abnormal drainage of the affected area. The lymphatic abnormalities are typically macrocystic in the pelvis and thighs and microcystic in the abdominal wall, buttock, and distal limb.

MRI is obtained to confirm the diagnosis and determine the extent of the anomalies. A large, embryonal vein in the subcutaneous tissue (the marginal vein of Servelle) is often located in the lateral calf and thigh and communicates with the deep venous system. Complications include thrombophlebitis (20% to 45%) and pulmonary embolism (4% to 24). Unlike some other hemihypertrophy syndromes, patients with KTS are not at increased risk for Wilms tumor and screening US is unnecessary. By 2 years of age, radiologic surveillance of leg length by plain radiography is indicated. If the discrepancy is >1.5 cm, a shoe-lift for the shorter limb can prevent limping and scoliosis. Epiphysiodesis of the distal femoral growth plate is typically done around 11 years of age. Enlargement of the foot may require a ray, midfoot, or Syme amputation to allow the use of footwear. Management of the VM component is conservative with compressive stockings for insufficiency and aspirin to minimize phlebothrombosis. Symptomatic varicose veins may be removed or sclerosed. Sclerotherapy may be necessary for focal macrocystic LM or to treat cutaneous vesicles. Excision and grafting is occasionally necessary for diffuse bleeding and/or oozing cutaneous vesicles. Circumferential overgrowth may be managed by staged contour resection. Venous insufficiency does not occur following staged subcutaneous excision or removal of the marginal vein of Servelle. A functioning deep venous system is present, although it is often difficult to visualize because of predominant flow in the superficial veins.

Parkes Weber Syndrome

PWS is a diffuse AVM in an overgrown extremity with an overlying CM. The disease can be caused by a mutation in *RASA1*. PWS involves the lower extremity approximately twice as often as the upper extremity; patients have microshunting in muscle. The malformation is evident at birth with symmetric enlargement and pink staining of the involved limb. The cutaneous stain tends to be confluent rather than patchy and is typically warmer than a banal CM. The diagnosis is confirmed by the

detection of a bruit or thrill. MRI is obtained to evaluate the extent of the malformation. Overgrowth in an affected extremity is subcutaneous, muscular, and bony with diffuse microfistulas. The enlarged limb muscles and bones exhibit an abnormal signal and enhancement. Angiography demonstrates discrete arteriovenous shunts.

Treatment is predicated on symptoms. In rare instances, an infant presents with high-output congestive heart failure secondary to shunting through arteriovenous fistulas. This situation mandates emergent embolization with permanent occlusive agents, often followed by repeated procedures. Children are observed annually with careful monitoring for axial overgrowth and development of cutaneous problems. Embolization may be useful for pain or cutaneous ischemic changes. Occasionally, amputation is necessary.

PTEN Hamartoma-tumor Syndrome

Patients with *PTEN* mutations, a tumor suppressor gene, have PTEN hamartoma-tumor syndrome (PHTS). This autosomal dominant condition is also referred to as Cowden syndrome or Bannayan–Riley–Ruvalcaba syndrome. Males and females are equally affected, and approximately one half (54%) of patients have a unique fast-flow vascular anomaly with arteriovenous shunting, referred to as a PTEN-associated vascular anomaly. Patients may have multiple lesions (57%), and 85% are intramuscular.

Suspicion of a PTEN-associated vascular anomaly usually is initiated after reviewing the MRI or angiographic study of a patient suspected of having an AVM. Unlike typical AVM, these lesions may be multifocal, are associated with ectopic adipose tissue, and have disproportionate, segmental dilation of the draining veins. If a patient is suspected of having a PTEN-associated vascular anomaly on imaging, a physical examination is performed. Patients with PHTS have macrocephaly (>97th percentile), and all males have penile freckling. In addition, PHTS is associated with mental retardation/autism (19%), thyroid lesions (31%), or gastrointestinal polyps (30%). Biopsy may aid the diagnosis of a PTEN fast-flow lesion. Histopathology shows skeletal muscle infiltration with adipose tissue, fibrous bands, and lymphoid aggregates. In addition, tortuous arteries with transmural muscular hyperplasia and clusters of abnormal veins with variable smooth muscle are present. Genetic testing is confirmative, although a germline mutation is not found in 9% of families clinically diagnosed with PHTS.

If physical examination is consistent with PHTS, molecular testing is necessary because this mutation is associated with multiple benign and malignant tumors which require surveillance. Patients are followed closely for the presence of tumors, particularly endocrine and gastrointestinal malignancies. In addition, the patient and family are counseled about the risk of transmitting the gene to their offspring. Symptomatic lesions are managed similarly to nonsyndromic AVM, with embolization or resection. It is our experience that the recurrence rate after these interventions is even higher than for nonsyndromic AVM, possibly because the loss of the tumor suppressor protein favors a more proliferative environment.

Vascular anomalies are complex disorders encountered by virtually all disciplines of pediatric medicine and surgery. As these anomalies are optimally cared for by multiple specialties, collaboration between pediatricians, pediatric dermatologists, interventional radiologists, ENT, plastics and general surgeons are required. The authors present an excellent overview of a topic.

The nomenclature used to describe these disorders has been difficult to interpret and communicate across specialties. Hemangiomas or AVMs were used to incorrectly label virtually every vascular anomaly. A classification system proposed in 1982 by the senior author of the chapter formed the basis of biologic classification (Mulliken JB, Glowacki J. Hemangiomas and vascular malformations in infants and children: a classification based on endothelial characteristics. *Plast Reconstr Surg* 1982;69(3):412–22). This classification was adopted by the International Society for the Study of Vascular Anomalies (ISSVA). The classification system separated lesions into vascular tumors or vascular malformations. Vascular tumors are differentiated from malformations by the presence of growth. Vascular malformations are thought to be secondary to embryologic errors in the development of blood vessels: capillaries, veins, arteries, lymphatics, or combinations thereof. ISSVA adopted an expanded version of the classification. This revised system again classifies vascular anomalies into tumors and malformations but provides greater detail including newly named anomalies, clinical associations, and genes linked to lesions—further details can be found at the ISSVA website http://issva.org.

As the authors note, infantile hemangiomas (IHs) are the most common tumor of infancy and childhood, occurring in ~4% of children. Ulceration, the most common complication, occurs most frequently in perioral and perineal sites, and often comes to the attention of the pediatric surgeon for management. Patients with an IH should be screened for associated abnormalities. Two primary associations in patients with hemangiomas are noteworthy—the PHACES and LUMBAR syndromes (Metry D, Heyer G, Hess C, et al. Consensus statement on diagnostic criteria for PHACE Syndrome. *Pediatrics* 2009;124(5):1447–56; Iacobas I, Burrows PE, Frieden IJ, et al. LUMBAR: association between cutaneous infantile hemangiomas of the lower body and regional congenital anomalies. *J Pediatr* 2010;157(5):795–801). There is an increased incidence of airway hemangiomas in patients with the PHACES association therefore these patients may require an airway evaluation. For patients with a LUMBAR association, the presence of anorectal malformations and arterial anomalies will require the involvement of a pediatric surgeon. Hepatic hemangiomas are screened for when a patient has greater than 5 cutaneous lesions; however, can occur as solitary or diffuse lesions without cutaneous involvement. Some of these patients present in high output cardiac failure and if medical management fails, may require resection or in the worst case, liver transplantation. The first-line treatment of hemangiomas is no longer oral or intralesional corticosteroids as oral propranolol has been shown to be more effective (Drolet BA, Frommelt PC, Chamlin SL, et al. Initiation and use

of propranolol for infantile hemangioma: report of a consensus conference. *Pediatrics* 2013;131(1):128–40). Patients are treated with dosages of 1 to 3 mg/kg/day. At the initiation of therapy, glucose and vital sign monitoring are warranted. The duration of treatment is for the proliferative phase which is the first year of life. Surgical excision is reserved for lesions that are acutely affecting function or lesions that have involuted and contain fibrofatty residual tissue. Laser treatment can be used for ulcerations and residual telangiectatic vessels.

As the authors observe, lymphatic malformations encompass a wide spectrum of abnormalities and are categorized into three primary types: microcystic, macrocystic, and combined. Lymphatic malformations can be seen in any anatomical region but are more commonly seen the head and neck, axilla, mediastinum, groin, and retroperitoneum. With the significant advances in fetal imaging, the prenatal diagnosis of cervical lymphatic malformations has become common. Large anterior cervical and lingual lesions may be associated with airway obstruction and these patients may require the presence of a fetal surgical team capable of performing an ex utero intrapartum treatment (EXIT) where an airway is secured while the infant is still under maternal placental support (Laje P, Peranteau WH, Hedrick HL, et al. Ex utero intrapartum treatment (EXIT) in the management of cervical lymphatic malformation. *J Pediatr Surg* 2015;50(2):311–4). Treatment of a patient with lymphatic malformations depends on the clinical presentation, the size of the lesion, the anatomical location, and the presenting complications and is best managed by a multidisciplinary team. First-line medical management for complex lymphatic anomalies has become rapamycin (Sirolimus), an m-Tor inhibitor that has been shown to improve quality of life and decrease burden of disease (Adams DM, Trenor CC 3rd, Hammill AM, et al. Efficacy and safety of sirolimus in the treatment of complicated vascular anomalies. *Pediatrics* 2016;137(2):e20153257). Monitoring of rapamycin levels is warranted with a target therapeutic range of 8 to 10 ng/mL.

As the authors recommend, sclerotherapy using doxycycline, ethanol, or OK-432 if available, is the first-line interventional treatment for symptomatic macrocystic lymphatic malformations. Surgical intervention continues to play an important role in the management of lymphatic malformations especially in the resection of microcystic disease. Extensive lesions which involve deep structures of the neck, tongue, and mediastinum engender the risk of multiple complications, including fistula formation, infection, damage to vascular structures and nerves along with a cosmetic deformity therefore should be managed by experienced vascular malformation teams. Surgical debulking in patients with overgrowth secondary to lymphatic malformations can increase function and improve mobility. From a technical perspective, the judicious use of fibrin glue and long-term closed suction drains are critical to minimize the challenge of lymphatic leakage. The adjunctive use of rapamycin may assist in the timely removal of drains and decrease postoperative complications.

Lymphatic blebs that are present in the skin overlying lymphatic malformations represent dermal involvement and may occur within resection scars. They can be treated with CO_2 or KTP laser ablation reducing cellulitis. Recently, topical rapamycin cream has shown efficacy.

Vascular malformations are anomalies that are usually present at birth but may not become symptomatic until the child is older. Venous malformations (VMs) are common consisting of abnormal veins that can be localized or diffuse. VMs are comprised of mitotically inactive endothelium with scant mural smooth muscle and lack valves. As noted in the chapter, most VMs occur sporadically but genetic abnormalities such as the germline mutation in the endothelial cell tyrosine kinase receptor TIE2 must be tested for when multiple isolated VMs are noted, or in patients with a family history of VM (Boscolo E, Limaye N, Huang L, et al. Rapamycin improves TIE2-mutated venous malformation in murine model and human subjects. *J Clin Invest* 2015;125(9):3491–504). Coagulation abnormalities are common with VM. Patients develop pain secondary to the development of a localized LIC caused by stasis and abnormal venous endothelium. Patients with extensive VMs are prone to both bleeding and clotting. This may present as superficial clotting within the malformation or systemic clotting such as pulmonary emboli. When localized within superficial malformations, symptomatic treatment such as warm compresses and anti-inflammatories may be employed. For clots within larger deeper vessels, prolonged systemic anticoagulation is required. Patients should be carefully educated on the symptoms of pulmonary embolus as multiple deaths from PE in these patients have been reported (Huiras EE, Barnes CJ, Eichenfield LF, et al, Pulmonary thromboembolism associated with Klippel-Trenaunay syndrome. *Pediatrics* 2005;116(4):e596–600). Management strategies of VMs include custom compression garments, anticoagulants, sclerotherapy, glue embolization combined with surgical resection. Endovenous laser or radiofrequency ablation is used for ectatic anomalous veins to help prevent the risk of pulmonary embolism from these large capacity veins.

There are multiple subtypes of VM—one of particular interest to the surgeon is the Blue rubber bleb nevus syndrome, which is characterized by discrete VMs of varying size usually between 1 and 2 cm in size present within the skin and GI tract (Jin XL, Wang ZH, Xiao XB, et al. Blue rubber bleb nevus syndrome: a case report and literature review. *World J Gastroenterol* 2014;20(45):17254–9). Lesions within the GI tract may be associated with significant bleeding. These GI venous lesions are often numerous (hundreds of lesions) and are addressed by resection assisted by push enteroscopy.

The author’s present an excellent overview of the established vascular malformation overgrowth syndromes. For CLOVES and hemihypertrophy patients, it is important for the patients to undergo screening for malignancies (liver and kidney) until age 7 as they are at high risk of hepatoblastoma and Wilms tumor.

Great strides have been made within the field of vascular malformations as

an understanding of genetic basis has provided treatment options that were previously unrecognized. Multidisciplinary collaboration in highly specialized vascular centers are the ideal means of treating these complex patients as they do not fall in the purview of a single specialty.

28 Surgical Treatment of Laryngeal Cancer: A Legacy of Minimally Invasive Innovation and the Preservation of Airway, Swallowing, and Vocal Function

Steven M. Zeitels and John C. Wain

INTRODUCTION

Successful surgical management of laryngeal cancer requires that the clinician integrate a complex algorithm of interdependent host and tumor issues. The patient and surgeon must mutually consider the optimal treatment modality. This is based on the efficacy of cure along with the potential detrimental effects of those interventions on airway patency, voice, and swallowing. The functional outcomes must be assimilated into patients' age, vocal needs, and pulmonary reserve, as well as the skill sets of the surgeon, availability of technology, and prior oncologic history of the patient. These concepts were initiated in the 19th century and progressively established through the 20th century due to the increasing frequency of laryngeal cancer subsequent to the introduction of mass-produced cigarettes.

Remarkably, in the past decade we have observed a substantial change in the epidemiology in laryngeal cancer. New evidence suggests that glottic cancer is clinically and demographically metamorphosing. It is now commonplace for glottic cancer patients to present with morphologically papillary cancer as a result of human papilloma virus (HPV). Furthermore, frequently these individuals have never smoked and develop the disease at a younger age, which is distinctly different from conventional wisdom. It is likely evolving comparably to the experience encountered in HPV oropharynx cancer over the past decade, and similarly the lesions tend to be well-suited to endoscopic treatment. Unlike oropharynx cancer, there is a frequently encountered morphologically similar benign disease recurrent respiratory papillomatosis (RRP), which has been an omnitemporal

problem in laryngeal surgery over the past 150 years. This is of great concern because benign and malignant papillary glottal neoplasms frequently require vastly different treatment so that highly vigilant pathologic assessment is imperative.

The surgical treatment of laryngeal cancer during the last two centuries comprises a rich history chronicling the development of minimally invasive endoscopic laryngeal surgery, upper airway management, swallowing rehabilitation, and voice preservation. Independent and interdependent advances have led to current philosophies in which curative treatment is routine with serviceable airway and swallowing function while optimal vocal outcome remains a pursuit.

HISTORY AND DEVELOPMENT OF GLOTTIC CANCER TREATMENT: THE 19TH CENTURY

Horace Green: The First Direct Laryngoscopic Resection of a Laryngeal Neoplasm

The first endolaryngeal resection of a laryngeal neoplasm can be traced to the monumental achievements of Horace Greene (Fig. 28.1A,B) in the 1840s.

Having been first to routinely treat the trachea transorally, Green's skill and confidence mounted so that his next achievement became one of the most important in human airway management. He was faced with a child who had developed obstructive apnea with accompanying stridor. Using a bent-tongue spatula, along with sunlight for illumination, he performed the first direct laryngoscopy.

Having successfully viewed the laryngeal introitus directly, he observed a ball-valving fibroepithelial polyp that was obstructing the glottal aperture. He proceeded to use a curved forceps to remove the mass. This became the first visually controlled endoscopic resection of a laryngeal lesion, which predated the routine use of mirror laryngoscopy and mirror-guided endolaryngeal surgery.

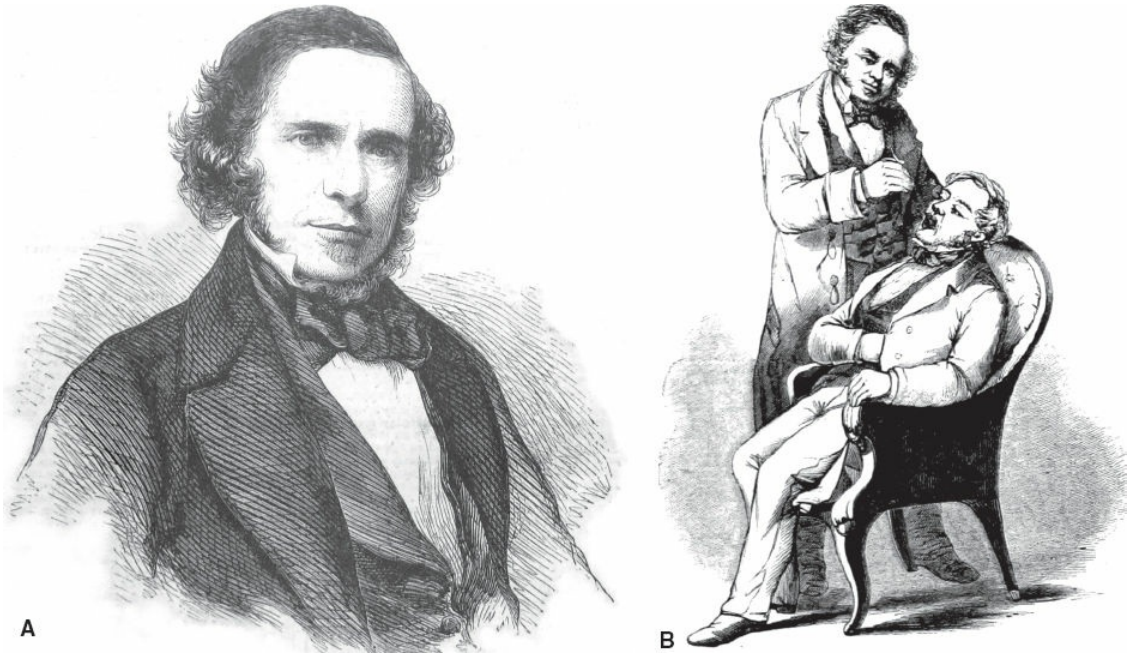

Figure 28.1. A. Horace Green (1802–1866) was the "Father of American Laryngology." **B.** Green demonstrating blind intubation of the tracheobronchial tree. (From *Harper's Weekly: Dr. Horace Green and His Method.* 1859, February 5:88–90.)

THE EARLY CURES FOR LARYNGEAL CANCER

Remarkably, several years after Green's triumph, Garcia presented mirror laryngoscopy, which catalyzed the formal development of laryngology by Czermak and Turck. Laryngology became highly developed as a result of office-based indirect endolaryngeal diagnoses and procedures.

During this period, Solis Cohen (Fig. 28.2) likely achieved the first cure of laryngeal cancer by performing a laryngofissure and cordectomy for early glottic cancer (1869). To the best that the author can determine, he is the first surgeon to specialize in laryngology having been trained by Samuel Gross and serving the Union as a general surgeon for 4 years of the Civil War. Although there was intermittent use of laryngofissure and cordectomy with varied success in the late 19th century, the procedure was established by Semon, Butlin, and Jackson. Billroth (Fig. 28.3) performed the first total laryngectomy for laryngeal cancer (1874). Although Billroth successfully achieved the resection, Solis Cohen and Gluck perfected the procedure by suturing the trachea to the skin and separating the airway from the pharyngo-esophagus.

Figure 28.2. Jacob Solis Cohen (1838–1927). (Photograph circa 1868, courtesy of Thomas Jefferson University, Archives & Special Collections, Scott Memorial Library, Philadelphia.)

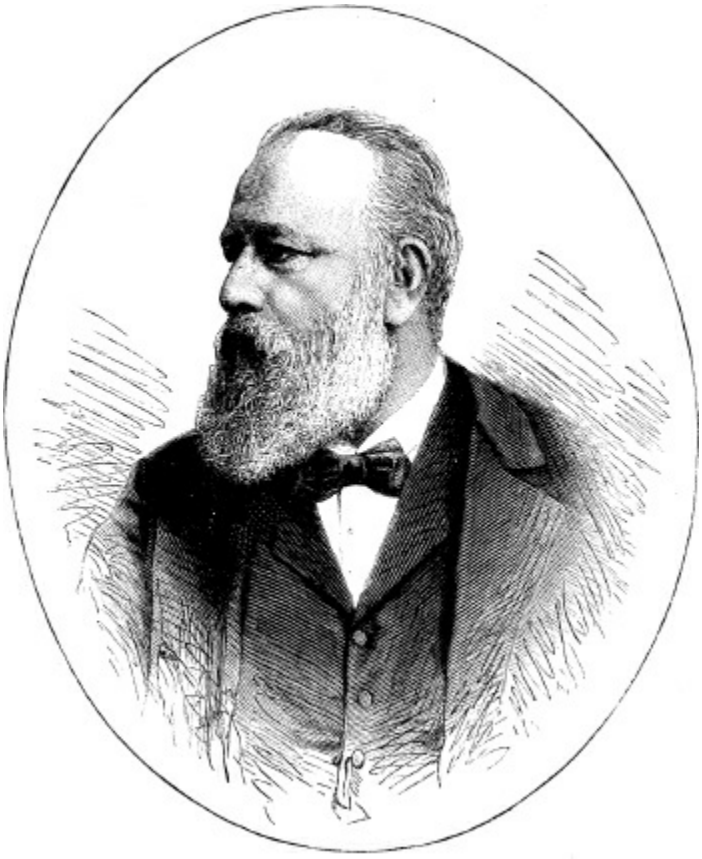

Figure 28.3. Theodor Billroth (1829–1894).

Figure 28.4. Bernhard Fraenkel (1836–1911).

In 1884, Koller and Jelinek introduced topical cocaine for mucosal anesthesia, which became a key chemical platform technology that greatly advanced office-based laryngeal surgery. Soon thereafter, Fraenkel (Fig. 28.4) performed the first successful transoral endoscopic resection of glottic cancer using mirror guidance. It is possible that this represents the first minimally invasive endoscopic cancer cure as well. There were further similar isolated reports over the next 30 years. This early endoscopic cancer treatment achievement did not significantly alter management strategies for glottic cancer, which were primarily composed of transcervical open laryngectomy procedures.

HISTORY AND DEVELOPMENT OF GLOTTIC CANCER TREATMENT: THE 20TH CENTURY

Formal Direct Laryngoscopic Treatment of Glottic Cancer

In 1895, Kirstein (Fig. 28.5) reintroduced direct laryngoscopy, described tracheoscopy, and established this technique as a routine surgical

methodology. It can be argued that this advancement was the most influential in the history of laryngology given the ensuing development of general endotracheal anesthesia, cardiopulmonary resuscitation, and critical care management. Pursuant to our specialty, direct laryngoscopy became the foundation for a majority endoscopic cancer treatment of the upper aerodigestive tract. Kirstein also predicted that Oertel's laryngeal stroboscope would be combined with direct laryngoscopy to enhance patient management of vocal-fold lesions. It was the promise of increased precision associated with direct laryngoscopy and commensurate advancements in anesthesia that subsequently promulgated the migration of direct endolaryngeal cancer surgery to the operating room, where most complex endolaryngeal surgery was done in the 20th century.

Figure 28.5. Alfred Kirstein (1863–1922).

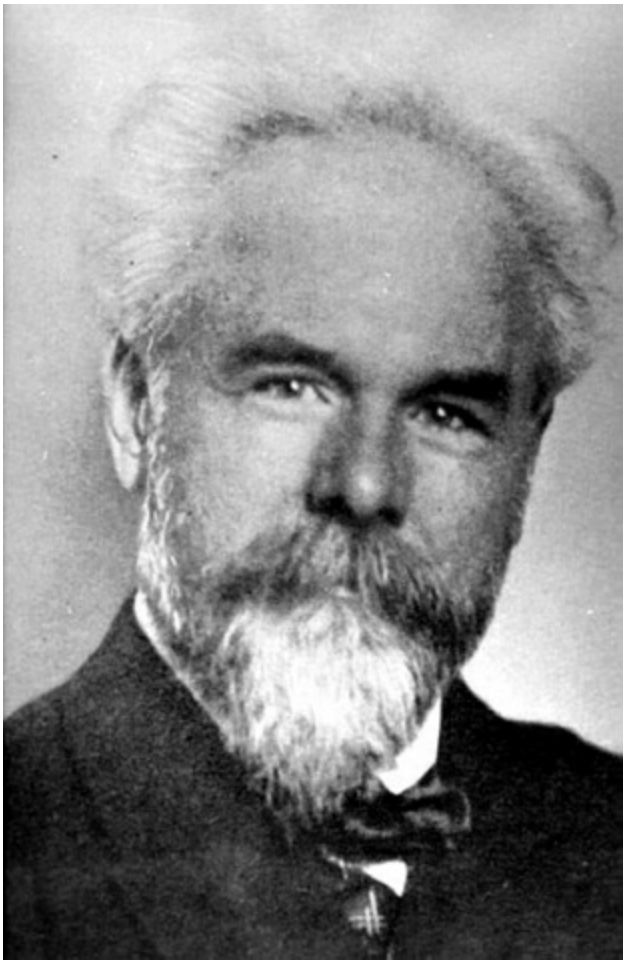

Figure 28.6. Gustav Killian (1860–1921).

Killian (Fig. 28.6) acknowledged Kirstein's achievements and based on this work introduced rigid bronchoscopy and suspension laryngoscopy. After modifying the Killian suspension laryngoscope, Lynch (Fig. 28.7) published a series of 39 patients whose early glottic cancers were excised en bloc by suspension laryngoscopy. This became the first substantial series of endoscopic glottic cancer resections. He carefully selected lesions that were exposed adequately, of small volume, limited to a single vocal cord, and did not extend to the anterior commissure or vocal process. Because of the technical difficulties of suspension laryngoscopy without general endotracheal anesthesia, this approach remained obscure.

Figure 28.7. Robert Clyde Lynch (1880–1931).

Jako commenced experiments with laser technology to remove human tissue in the mid-1960s. By the early 1970s, Jako, Strong, and Vaughan were likely the first surgeons to remove human tissue with a laser and shortly thereafter employed this groundbreaking technology to resect glottic cancer. Thirty years later, Zeitels et al. introduced angiolytic laser treatment of glottic cancer based on Folkman's principles of neoplastic angiogenesis.

GLOTTIC CANCER

Disease Presentation and Philosophy of Management

In the United States, glottic cancer comprises ~6,500 of the new ~10,000 laryngeal cancer cases per annum. Hoarseness is the primary presenting symptom; however, with larger neoplasms, patients may also report airway

restriction, discomfort, hemoptysis, dysphagia, odynophagia, and referred ear pain (otalgia). Glottic cancer is unique as compared with other sites of the upper aerodigestive tract due to the low incidence of regional metastasis and the ease in which the disease is cured locally if the correct surgical procedure is selected.

The success of local control of the primary tumor arises from the fact that the anatomy of the larynx is a relatively isolated "box." It is bounded by a thick cartilaginous frame and dense connective tissue that are resistant to local and regional cancer spread while creating a series of self-contained compartments. This structural composition facilitates a variety of transoral (endoscopic) and transcervical (open neck) partial laryngectomy procedures that strive to preserve the three most critical functions of the larynx: (a) patent adequate airway caliber, (b) competent valve to preclude aspiration during deglutition, and (c) phonation and voice.

Glottic carcinoma is unique as the site of an organ cancer since very small lesions (2 mm) or even precancerous dysplasia can cause a discernable functional deficit, hoarseness. Furthermore, in the overwhelming majority of patients, voice loss is the sole or dominant symptom, which is easily recognizable to friends and family. Since local control is routine and aspiration can typically be avoided, the primary metrics for success in management are airway patency and voice restoration/preservation.

Because of the relative paucity of lymphatics in the true vocal folds, it is uncommon for patients to present with regional metastasis with T1 and T2 diseases. Therefore, small- to mid-sized glottic cancers are ideal for single-modality endoscopic minimally invasive treatment. Remarkably, even those with T3 and T4 lesions often do not have associated adenopathy. However, the surgical treatment majority of T3 and T4 glottic cancers require an open (transcervical) resection with removal of some or all of the cartilage framework (total laryngectomy).

Laryngeal cancer is staged using the standard TNM classification system (Table 28.1) based on the subsite affected (supraglottis, glottis, or subglottis). As with other cancers, the TNM staging has prognostic value for survival. As treatment decisions are often made based on the staging of the cancer, it is valuable to become familiar with this system.

Surgery Versus Radiation

The two definitive treatment modalities for glottic carcinoma are radiation

therapy (XRT) and surgery. Surgical therapy for glottic cancer can be divided into open or endoscopic techniques. Unlike radiotherapy, surgery treats only the areas of disease without ablating and distorting the remaining normal anatomy. Glottic cancer surgery can be done with millimeter margins, thereby decreasing surgical morbidity by sparing normal tissue several millimeters away from the tumor margin. Therefore, surgical resection of selected glottic cancer can be performed with phonosurgical techniques, which allow for precise control of disease with preservation of the vocal ligament, thyroarytenoid muscle, and the superficial lamina propria (SLP). Accordingly, postoperative voice results are excellent, especially when phonosurgical reconstruction is done. Other advantages of surgery include lower cost, diminished time of intercurrent disease, and a very low complication rate. Unlike XRT, endoscopic treatment preserves all treatment modalities, including further endoscopic management. Furthermore, vocal function resulting from angiolytic laser treatment of glottic cancer has resulted in the best voice results to date with continuing cure rates that are >90%.

Radiotherapy treatment of early glottic cancer successfully controls local disease in a majority of cases; however, this advantage is mitigated by the fact that XRT is a single-use treatment and patients with laryngeal cancer frequently have metachronous neoplasms. However, despite a century of success with higher cure rates employing transoral and transcervical function-sparing surgical procedures, glottic carcinoma is typically treated with external beam radiotherapy (XRT) in a majority of Western countries. T1 and T2 diseases are treated with radiotherapy alone, while T3 and T4 lesions are typically treated with XRT and chemotherapy. The primary advantage of this approach is uniformity of management not necessitating highly individualized skills, a key requisite of optimal surgical interventions.

For early disease, the disadvantages of XRT include damage to noncancerous glottal tissue including (e.g., contralateral vocal fold), which is the primary voice source as well as ablation of the saccular glands, which are vital for lubrication of the glottis to facilitate vocal-fold vibration. For advanced disease, it is commonplace for radiation and chemotherapy to cause airway swelling and/or stenosis requiring a tracheotomy as well as severe dysphagia and/or pharyngo-esophageal stenosis, both of which are usually not present pretreatment and extremely difficult to resolve.

Radiation also commonly causes chronic mucositis often masking recurrence while resulting in discomfort, dryness, and taste changes. Less common, patients develop frank osteoradionecrosis of the laryngeal cartilages resulting in any of the aforementioned functional symptoms as well as wound infections. Finally, it is well recognized that a majority of the undesirable effects of radiation therapy are long-lasting and usually irreversible.

In the later 20th century, radiotherapy became the mainstay of treatment for most stages of laryngeal cancer with chemotherapy used adjunctively. This was in part due to the fact that surgeons lack confidence that they could achieve optimal functional results. However, it has now been recognized that there is substantially diminished survival in a variety of stages if surgery is not employed as a primary initial treatment modality. Furthermore, complications and poor functional outcomes (voice, swallowing, and airway) from the nonsurgical regimens are being increasingly recognized. For both initial and salvage treatments, this has catalyzed new opportunities for surgeons skilled in endoscopic approaches for small- to mid-sized tumors as well as open partial techniques for larger tumors. The endoscopic methods for supraglottic primaries will likely be further advanced by robotic innovation due to frequent restrictions in optimal laryngoscopic exposure.

TABLE 28.1 TNM Staging of Laryngeal Cancer

Primary tumor (T)

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ

Supraglottis

- T1: Tumor limited to one subsite of supraglottis with normal vocal cord mobility
- T2: Tumor invades mucosa of more than one adjacent subsite* of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, or medial wall of pyriform sinus) without fixation of the larynx
- T3: Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
- T4a: Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
- T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Subsites include the following:

- Ventricular bands (false cords)
- Arytenoids
- Suprahyoid epiglottis
- Infrahyoid epiglottis
- Aryepiglottic folds (laryngeal aspect)

Glottis

- T1: Tumor limited to the vocal cord(s), which may involve anterior or posterior commissure, with normal mobility
  - T1a: Tumor limited to one vocal cord
  - T1b: Tumor involves both vocal cords

- T2: Tumor extends to supraglottis, subglottis, and/or with impaired vocal cord mobility
  - T2a: Tumor limited to one vocal cord
  - T2b: Tumor involves both vocal cords
- T3: Tumor limited to the larynx with vocal cord fixation, invades paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
  - T3a: Tumor limited to one vocal cord
  - T3b: Tumor involves both vocal cords
- T4a: Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck, including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
- T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

(The authors employ the (a, b) unilateral versus bilateral designation used for T1 lesions with T2 and T3 lesions as well)

Subglottis

- T1: Tumor limited to the subglottis
  - T1a: Tumor limited to one vocal cord
  - T1b: Tumor involves both vocal cords
- T2: Tumor extends to vocal cord(s) with normal or impaired mobility
  - T2a: Tumor limited to one vocal cord
  - T2b: Tumor involves both vocal cords
- T3: Tumor limited to larynx with vocal cord fixation
  - T3a: Tumor limited to one vocal cord
  - T3b: Tumor involves both vocal cords
- T4a: Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck, including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
- T4b: Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

(The authors employ the (a, b) unilateral versus bilateral designation used for T1 glottic lesions with T1, T2, and T3 subglottic lesions as well)

Classical Endoscopic Glottic Surgery for Early Cancer

The overarching key to successful endoscopic treatment of laryngeal cancer is obtaining the best possible laryngoscopic exposure, which comprises optimal anatomic positioning along with the largest well-designed speculum and laryngoscope holder. Toward that end, we methodically described the key principles for success as well as designing a universal modular glottiscope and a new suspension gallows.

The goal of endoscopic treatment of early glottic cancer is eradication of the disease with maximal preservation of the normal layered microstructure. This approach results in the optimal postoperative voice without compromising oncologic cure. There are four basic procedures that are based on the depth of treatment (Fig. 28.8): (a) dissection just deep to the epithelial basement membrane and superficial to the SLP for

epithelial atypia and microinvasive cancer, (b) dissection within the SLP microinvasive cancer that is not attached to the vocal ligament, (c) dissection between the deep lamina propria (vocal ligament) and the vocalis muscle for lesions that are attached to the ligament but not through it, and (d) dissection within the thyroarytenoid muscle for lesions penetrating the vocal ligament and invading the vocalis. This approach can be fine-tuned further by performing partial resections of any of the layered microstructure.

In the classical surgical paradigm, if dissection is performed in the SLP, cold instruments facilitate precise tangential dissection around the curving vocal fold. This allows for maximal preservation of the SLP and for pliability of the regenerating epithelium. Dissection between the vocal ligament and the vocalis muscle can be performed equally well with cold instruments alone or with assistance by a laser. Dissection within the muscle is performed most precisely with a cutting laser, which allows for improved visualization because of hemostatic cutting properties.

Subepithelial saline–epinephrine infusion into Reinke space improves pre-excisional assessment of lesion depth. If the tumor has invaded the vocal ligament, the SLP at the perimeter of the lesion will distend creating a contour depression in the region of the cancer. The subepithelial infusion assists with the surgeon’s technical execution of the surgery in a number of other ways: (a) The infusion facilitates mucosal incisions by improving visualization of the lateral border of the lesion and by distending the SLP so that the overlying epithelium is under tension. (b) The infusion also increases the depth of the SLP, which facilitates less traumatic dissection in this layer and leads to regenerated epithelium that is more pliable. (c) The epinephrine and hydrostatic pressure of the infusion vasoconstricts the microvasculature in the SLP, and this improves visualization and precise dissection. (d) If a laser is used, the saline acts as a heat sink, which decreases thermal trauma to the normal vocal-fold tissue.

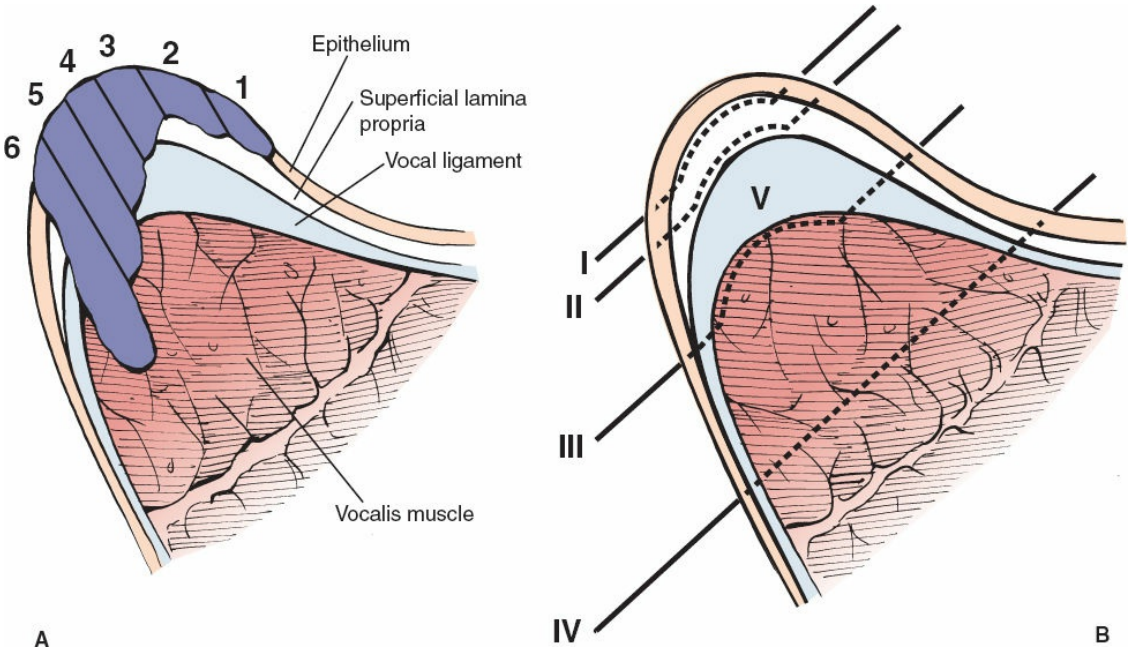

Figure 28.8. Coronal section of the mid-vocal fold displaying. **A.** Different potential depths of tumor invasion. **B.** Classification of different resection depths.

When substantial soft tissue of the glottis was resected, it was commonplace to have some vocal dysfunction due to aerodynamic glottal insufficiency. During the 1990s, we developed a variety of procedures to reconstruct the glottal valve, which were adopted domestically and abroad. The lost paraglottic soft tissue was augmented with fat and/or Gore-tex, and the anterior commissure tendon was reconstructed by means of an anterior laryngofissure and thyroid-lamina subluxation. However, restoring phonatory mucosal pliability remains a challenge.

After a decade of research, we have designed a promising vocal biogel and hope to commence human trials in 2012. This vocal biogel retains the possibility of restoring millions of voices, including hundreds of thousands hoarse laryngeal cancer patients. It will likely even facilitate voice enhancement in patients who have undergone partial or total laryngectomy. In the latter, the mucosal vibration associated with esophageal speech and phonation with tracheo-esophageal valve speech will be made more effective.

Endoscopic Angiolytic Laser Treatment of Early Glottic Cancer

Recently, the surgical resection model was developed further so that fiber-based angiolytic lasers were employed. We had introduced angiolytic lasers (585-nm pulsed-dye laser, 532-nm pulsed-KTP laser) to facilitate

microflap resection of glottal dysplasia in the late 1990s. Photoangiolysis of the subepithelial microcirculation allowed for extremely precise microflap epithelial resection, preservation of histopathologic architecture, and minimal collateral thermal damage to the perivascular SLP.

The promise of the angiolytic laser treatment of early glottic cancer was further supported by concepts of aberrant neovascularity described by Jako and Kleinsasser (Fig. 28.9) in 1966 and intralesional tumor angiogenesis (Figs. 28.10 and 28.11) established by Folkman shortly thereafter in 1971.

Over the past 12 years, >250 neoplasms have been treated by angiolysis with ~95% cure rate. It is likely that this is the first demonstration of employing nonionizing radiation without chemical enhancement (e.g., photosensitizing agents) to involute and treat cancer without resection or gross ablation. This approach combines elements of surgery and radiation to create a unique hybrid approach. The voice results that we have achieved in the cohort of patients herein are typically superior to what we have been able to achieve in the past. This is especially so for those patients who have bilateral disease. There are a number of reasons for the improved voices, all of which can be explained by improvements in posttreatment aerodynamic competency of the glottis and/or enhanced phonatory mucosal pliability through increased preservation of glottal soft tissue including noncancerous SLP, the layer necessary for glottal vibration.

Unlike prior microlaryngeal laser techniques that are used exclusively as a scalpel or indiscriminate ablating device (e.g., CO_2, continuous-wave KTP, and thulium), angiolytic lasers concentrate the energy within the dense aberrant angiogenic microcirculation of the tumors while not penetrating deeply into the normal soft tissue of the vocal fold. Thick tumors are vaporized in a continuous wave mode with simultaneous cooling until the interface with normal underlying soft tissue. The interface is treated in a pulsed mode, and frozen section margins are obtained from the patient to establish that the tumor has been removed. By confining the pulse width to ≤15 ms, the angiolytic laser induces selective heating of the lesions' intralesional/subepithelial microcirculation. This minimizes thermal trauma and fibrosis of the extralesional underlying normal glottal soft tissue, thereby optimally preserving vocal-fold soft tissue necessary for phonatory vibration. Photoangiolytic pulsed-laser treatment of early glottic cancer has the capability of preserving paraglottic-space soft tissue in deeper neoplasms as well as mucosal SLP in more superficial tumors

(Fig. 28.12).

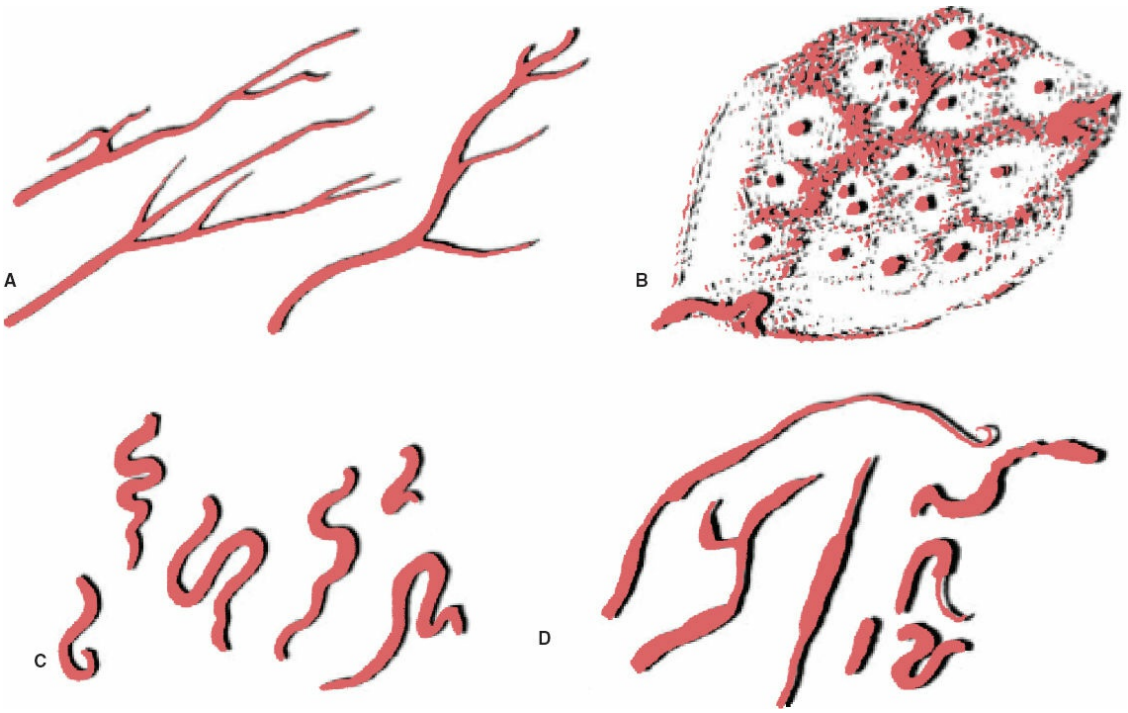

Figure 28.9. **A.** Vascular pattern of normal arborizing microcirculation seen through the transparent epithelium and within the superficial lamina propria of the phonatory mucosa. **B.** Precancerous dysplasia of the epithelium obscures visualization of the subepithelial microcirculation. **C** and **D.** Invasive carcinoma is composed of aberrant disordered and dense microvasculature. Figure 28.10. Early vocal-fold cancer demonstrating complex looping angiogenic microcirculation.

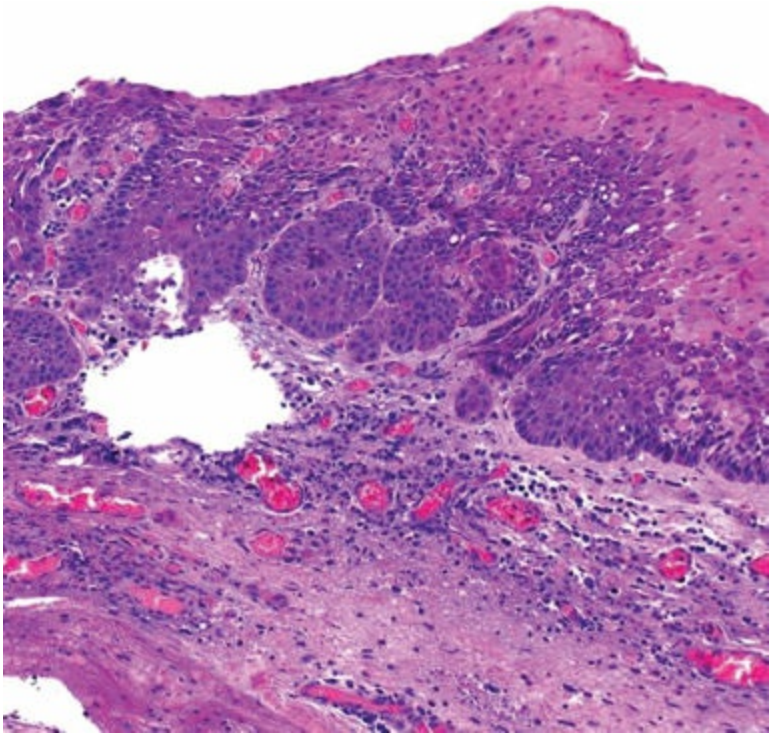

Figure 28.11. Histology of a T1 vocal-fold cancer. Note the vascular channels at the base of the nests of malignant epithelial

cells and the ingrowth of vessels within the neoplasm.

Cancer involvement of the anterior-commissure tendon and/or the arytenoid cartilage is not a contraindication to this technique if adequate laryngoscopic exposure can be obtained. Thyroid cartilage invasion is a contraindication to this approach and requires a transcervical removal of the thyroid lamina. To preserve the architecture of the anterior commissure, it is common to remove tumors with bilateral disease in two stages.

Two-staged pulsed photoangiolytic laser treatment by surgeons using nonionizing radiation retains elements of current phonomicrosurgery and radiotherapy models synthesizing key assets of both and comprises a significant revision of the typical surgical paradigm, which implies effective management as a solitary intervention. This is in contradistinction to radiotherapy and chemotherapy, which are incremental. For the promise of enhanced function, these nonsurgical cancer treatments have achieved acceptability despite the fact that patients have intercurrent disease during months of treatment. Moreover, it has been commonplace for decades for patients with *advanced* primary disease and regional metastasis to undergo incremental chemotherapy and XRT while intercurrent disease is left for 3 to 6 months. Considering this, and the fact that from microlaryngoscopic biopsy to completion of XRT is typically at least 2 months for early glottic cancer, there is no reason to believe that incremental staged endoscopic surgical treatment over the same time period will result in added risk to patients.

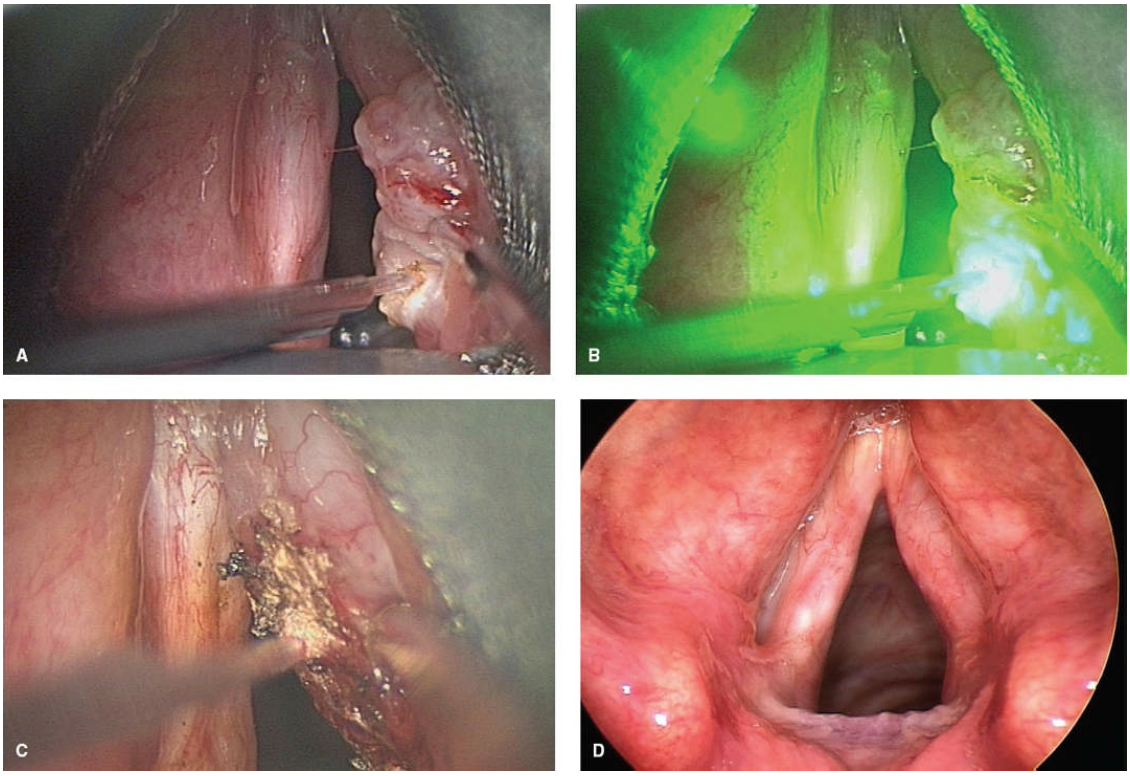

Figure 28.12. **A.** Microlaryngoscopic examination of a right vocal-fold cancer with a 0.4-mm KTP laser fiber directed at the tumor. **B.** A 15-ms pulse of green light is absorbed at the intralesional microcirculation. **C.** Toward the end of the cancer treatment. **D.** Office laryngoscopic examination after healing—the patient is over 4 years without recurrence.

Considering that the three conventional cancer treatments (surgery, radiotherapy, and cytotoxic chemotherapy) evolved from the primary basic sciences (biology, physics, and chemistry), anti-angiogenesis agents became the fourth cancer treatment. However, these agents are used as an adjuvant with other conventional treatment modalities. Based on discussions with Dr. J. Folkman (personal communication), pulsed-photoangiolytic laser treatment of the glottis is likely the first single-modality organ cancer treatment, which capitalizes on his philosophy and represents the fifth cancer treatment.

Endoscopic Angiolytic Laser Treatment of Cancer: Future Considerations

Vocal folds are a unique site to study localized minimally invasive cancer of the upper aerodigestive tract. As stated earlier, metastasis associated with early glottic cancer is extraordinarily rare so that intercurrent disease

is of minimal risk. This provides a unique window of opportunity to design novel strategies that accommodate the distinctive biomechanical and functional requirements of vocal-fold soft tissue. The impediment to future translation will likely be the cost of the instrumentation, which is ~ $850,000. Considering that ~60% of organ cancer is mucosal in origin, concepts developed for the vocal fold might be extrapolated to other sites such as the bladder, gut, tracheo-bronchial tree, and cervix. Furthermore, pulsed-laser photoangiolysis can be done during open procedures or endoscopic ones, and the small laser fibers can be introduced through rigid or flexible endoscopes. Angiolytic lasers could also be considered as a useful adjunct treatment at the perimeter of conventional resections if there are questionable close margins or in fields of condemned mucosa at resection margins.

The findings from the initial investigation support the fact that further research into developing laser technology that is capable of selectively ablating intralesional/sublesional tumor vascularity is a laudable goal. It is not difficult to envision that laser photoangiolytic treatment can be used as a single modality as in this report or it might serve as a cytoreduction and adjuvant treatment. Induction light treatment could be applied at the time of staging endoscopy. Given our office experience with the pulsed photoangiolytic laser treatment of glottal dysplasia with topical anesthesia, it is conceivable that further induction treatment could be continued in the clinic prior to full-course radiotherapy for larger primaries. Given the migration of many surgical interventions to be minimally invasive and/or office procedures, these prospects are not inconceivable.

Endoscopic Vertical Partial Laryngectomy

Endoscopic laser vertical partial laryngectomy can technically be done for a majority of T2 glottic lesions; however, it does require substantial experience. Steiner championed these techniques after visiting with the Boston University group (Jako, Strong, and Vaughan) in the late 1970s. These tumors often encroach or invade intrinsic glottic muscles in the paraglottic compartment. Three-dimensional geographic determination of tumors is done by means of careful staging endoscopy and imaging studies (CT scan or MRI). These resections may be done with a CO_2 laser, with or without a fiber, as well as the thulium and KTP lasers, which are both delivered with a fiber. The primary difference between endoscopic and open transcervical partial laryngectomy procedures is that the cartilage

framework is resected in open procedures. Although laryngoscopic procedures can usually be done without a tracheotomy, transoral procedures preclude immediate vocal reconstruction. After healing has taken place, various reconstructive procedures (previously mentioned) can be utilized (injection laryngoplasty with or without medialization thyroplasty) to restore a laryngeal phonation source. Because of the delayed reconstruction, some surgeons still opt to employ classic open partial laryngectomy techniques.

Open (Transcervical) Cancer Surgery: General Considerations

As reviewed earlier, there has been a rich history in surgical innovation for transcervical removal of laryngeal cancer. Many of the early designs for cancer resection procedures were based on surgeons' experiences in the management of penetrating trauma from hand-to-hand combat as well as homicides and suicides. Furthermore, the techniques for tumor removal and reconstruction have not substantially changed in decades. Furthermore, nuances in variation of the details of these methods are expansive with textbooks devoted to this subject and therefore well beyond the scope of this chapter. Finally, open partial laryngectomy is being done with decreasing frequency except for selected centers of excellence. Therefore, highlights of transcervical resection techniques (Fig. 28.13) will be provided with the reader being encouraged to review comprehensive specialized sources for details.

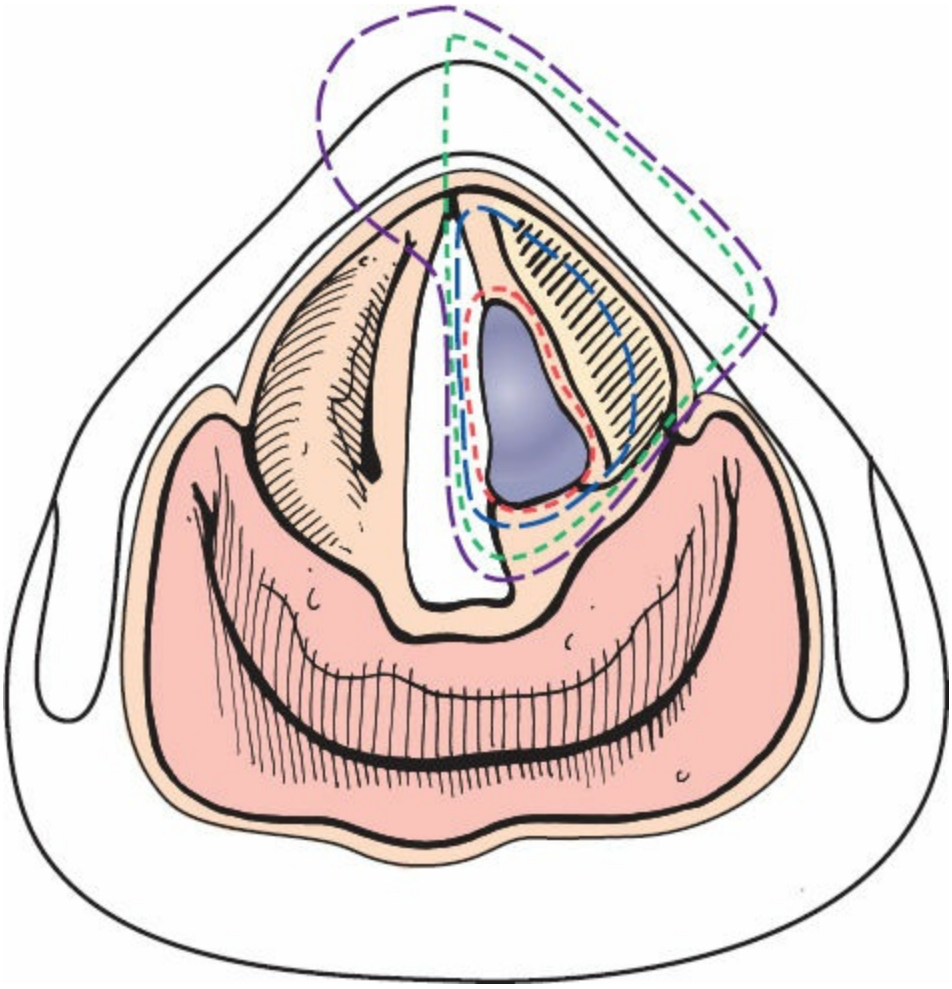

Figure 28.13. Different types of vertical partial laryngectomy procedures based on the size of the lesion to treat glottic carcinoma.

Transcervical Laryngofissure and Cordectomy

Open cordectomy can be used for patients with T1 and selected T2 lesions of the true vocal fold and subglottis who are not candidates for endoscopic laser resection because of limited laryngoscopic exposure. In this procedure, the thyroid cartilage is preserved. After exposing the laryngeal cartilage framework, a tracheotomy is performed prior to entering the larynx. Then thyroid cartilage is separated anteriorly without entering the airway. Next, the cricothyroid membrane is entered to view the glottic tumor from below to adequately resect it. Care is taken to preserve each side of the anterior-commissure tendon insertions. As the laryngofissure is opened, adequate visualization of the neoplasm is achieved; magnifying loupes can be helpful. Once the tumor has been resected, the false cord can be unfolded to reconstruct the resected glottic soft tissue. The thyroid lamina is reapproximated with two 2-0 prolene sutures above and below

the glottis. The strap muscles are reapproximated, and a subplatysmal penrose drain is placed, which helps prevent subcutaneous emphysema.

Transcervical Partial Vertical Laryngectomy

Vertical partial laryngectomy is typically used for T2 transglottic neoplasms extending through the ventricle to the lower false cords but not to the epilaryngeal regions. This initial procedure is similar to laryngofissure and cordectomy including a tracheotomy. However, the anterior thyroid lamina as well as the false cord, true cord, and subglottis are resected en bloc. The classical vertical partial laryngectomy can be extended to include the arytenoid, upper cricoid cartilage, and portions of the contralateral thyroid ala. The reconstruction is achieved by rotating local tissues such as the hypopharynx mucosa, epiglottis, posterior thyroid lamina, and extrinsic strap musculature. There are extensive variations in the use of these local tissues, which are beyond the scope of this chapter and detailed in dedicated texts for laryngeal cancer surgery. The primary goals are to preserve deglutition and when possible, to create an airway caliber that allows for removal of the tracheotomy tube. Until recently, tracheotomy decannulation was unlikely when substantial full-thickness segments of the cricoid cartilage require resection and/or one cricoarytenoid joint. Although a lung-powered laryngeal sound source is routinely achieved, the voice typically has limited pitch range and is often strained and breathy.

Supracricoid Laryngectomy With Cricohyoidopexy

Selected patients with T2 lesions of the glottis or T2 and T3 infrahyoid lesions of the supraglottis who have adequate pulmonary function (similar to horizontal partial laryngectomy patients) are candidates for supracricoid laryngectomy. Typically, the glottic tissue from the arytenoid forward along with the false cords and underlying thyroid laminae is removed. Initial postoperative aspiration is common as in horizontal partial laryngectomy patients. Preservation of both cricoarytenoid joints facilitates eventual tracheotomy decannulation and recover of swallowing function. The phonatory sound source is low-pitched and monotone; however, it is frequently quite strong and arises from oscillation of the peri-corniculate arytenoid mucosa and aryepiglottic folds.

Extended Open Partial Laryngectomy With Aortic Homograft

Reconstruction

Classical extended partial laryngectomy methods are often constrained by the balance of achieving an adequate oncologic resection with retaining enough structural cartilaginous scaffolding and internal soft tissues to achieve tracheotomy decannulation. Local soft tissues and/or regional flaps typically close the defect adequately, but also collapse and narrow the intralaryngeal airway lumen, frequently limiting the ability to decannulate the patient.

In 2009, we initiated wide-field reconstruction of extended partial laryngectomy defects with cryopreserved homograft aorta (Fig. 28.14). Preliminary results thus far are extremely promising, suggesting that this approach will provide new opportunities for organ and function preservation for patients with large laryngeal cancers. In the initial pilot group of seven patients, all of the patients had >40% of the cricoid cartilage removed along with >50% of the laryngeal thyroid cartilage. Four of seven patients had previously failed radiotherapy and five of seven were over 65 years of age. With aortic homograft reconstruction, there were no fistulas or significant complications, all patients resumed a full per-oral diet, and all cases have been decannulated. It is remarkable that there had been prior bench work using aortic homograft for tracheal reconstruction over 50 years ago and renewed interest in recent years.

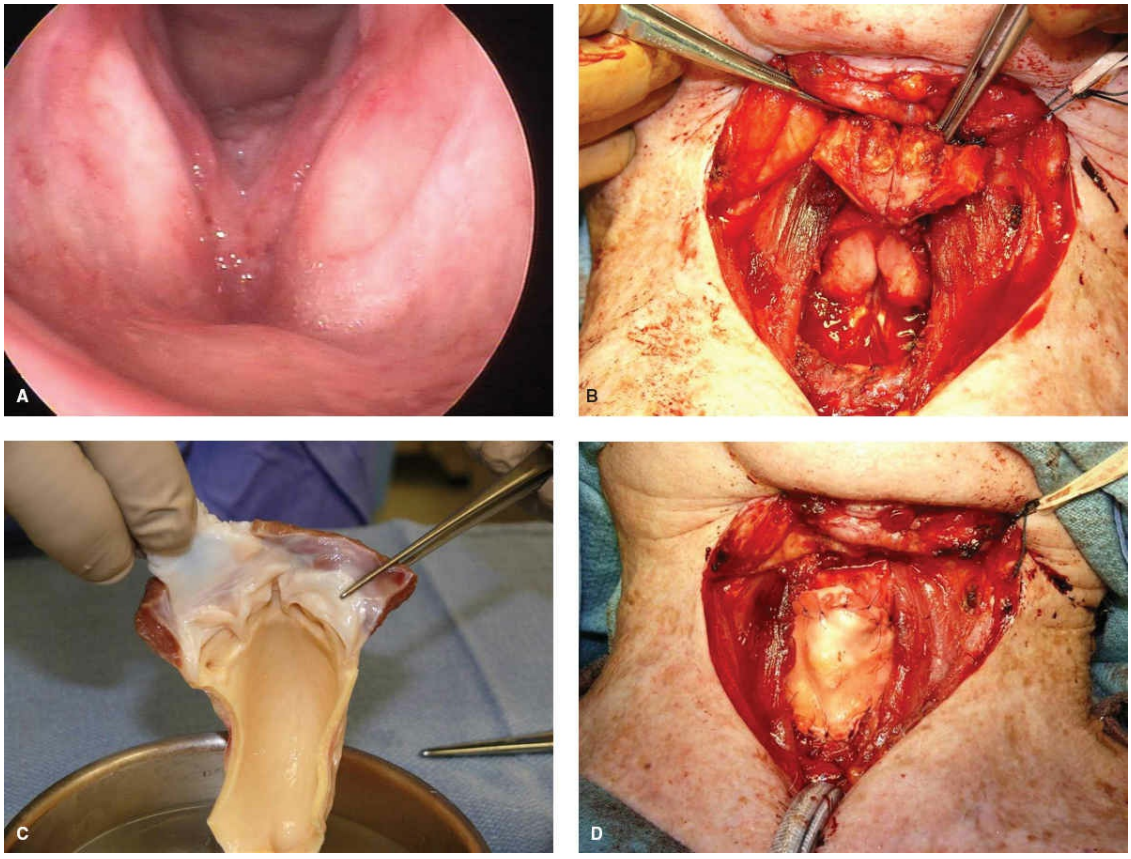

Figure 28.14. **A.** Clinic examination of a medium–large recurrence of a left glottic carcinoma with substantial extension to the subglottis and contralateral right vocal fold. **B.** The specimen is shown including the glottis and subglottis. The undersurface of the false cords is seen remaining in the patient. **C.** The arch of the aortic homograft will be used for the reconstruction. **D.** The aortic homograft is sutured in position to replace the resected areas of the cartilage framework.

Reliably replacing the aforementioned volume of laryngeal cartilage framework with consistent restoration of airway and swallowing function has not been achieved previously. The cryopreserved aortic homograft is unique in several aspects. It is essentially an acellular scaffold so that chemical immunotherapy is unnecessary. The aortic homograft is pliant and retains its rheology in a tubular form, which maintains the airway lumen. The graft is texturally robust so that it is easy to suture into place as a patch and its use requires routine surgical oncologic skills.

The aortic homograft appears to be extremely tolerant of exposure to upper aerodigestive tract reflux, barotrauma from coughing, and microbial flora. It maintains its structural integrity following implantation for prolonged periods of time. Based on our observations, there is ingrowth of

microcirculation from the soft tissues of the neck, which maintains the viability of the graft. However, there is a prolonged period of intraluminal granulation in the airway (2 to 4 months) prior to epithelialization that is similar to wide-field endoscopic resections. This is more substantial in previously irradiated patients but does not preclude decannulation during this period. In the future, it is likely that these grafts will be seeded with patients' mucosal epithelium retrieved in a clinic biopsy, prior to the cancer resection, to hasten epithelialization of the reconstruction, which we have observed to eventually occur.

Total Laryngectomy

Complete extirpation of the larynx has not changed dramatically over the past 125 years apart from diminishing the perimeter margins to preserve uninvolved pharyngo-esophageal soft tissue and developing innovative methods of pharyngo-esophageal reconstruction. Fortunately, this procedure with its attendant morbidity of a permanent tracheostomy and the loss of a lung-powered laryngeal phonation has become relatively infrequent in recent decades. The reason for this decline is multifactorial and includes extensive experience with endoscopic and transcervical partial laryngectomy techniques along with enhanced results with radiotherapy and chemotherapy. Despite these advancements, total laryngectomy remains a valuable treatment option that is often life-preserving in patients who have extremely large neoplasms or have failed prior treatments. A major concern of surgeons who must perform total laryngectomy in those who have failed prior radiotherapy and chemotherapy is the high incidence of severe pharyngo-cutaneous fistula formation. Vascularized nonirradiated flaps have only provided limited mitigation of this morbid routine outcome.

SUPRAGLOTTIC CARCINOMA

Disease Presentation and Philosophy of Management

Supraglottic cancer comprises approximately one third of new laryngeal cancer cases per annum in the United States. Discomfort and a neck mass are of the most common presenting symptoms; however, with larger neoplasms, patients may also report voice changes, airway restriction, dysphagia, odynophagia, hemoptysis, and referred ear pain (otalgia). Unlike glottic cancer, supraglottic cancer frequents presents with regional

metastasis, which is the primary determinant of survival. Similar to glottic cancer, controlling the disease at the primary site is typical with careful treatment selection and vigilant surveillance. However, achieving local control with preservation of optimal airway, swallowing, and vocal function remains as a challenge.

The general success of controlling supraglottic cancer locally is similar to glottic cancer. It is due to the fact that the anatomy of the larynx is composed of a thick cartilaginous frame and dense connective tissue that are resistant to local invasion outside the larynx, thereby creating a series of self-contained compartments. Like glottic cancer, this structural composition facilitates a variety of transoral (endoscopic) and transcervical (open neck) partial laryngectomy procedures.

Unlike the glottis, supraglottic carcinoma typically presents with advanced disease. Initial presentation of precancerous mucosa and early cancer are relatively rare since these lesions are unaccompanied by symptoms. They are typically identified because a patient is under surveillance for previous aerodigestive tract cancer. Pathologic assessment of tumors initially staged as T1 and T2 reveals that the largest majority are T3 and T4. Because of the rich lymphatics of the supraglottis, it is commonplace for patients with supraglottic cancer to present with clinical evidence of regional lymph-node metastasis or occult adenopathy discovered on elective neck dissection.

Preservation of laryngeal function can be a substantial challenge with advanced supraglottic primaries regardless of treatment modality. Smaller volume neoplsms are typically controlled locally with endoscopic removal, open supraglottic laryngectomy, or radiotherapy. Larger supraglottic tumors often require surgery and radiotherapy often including chemotherapy as well. Preservation of normal laryngeal function can be extremely difficult with large supraglottic cancers. Regardless of treatment selection of the primary site, neck lymphatics should always be considered carefully when designing a treatment regimen.

Endoscopic Resection of Supraglottic Cancer

Jackson described piecemeal endoscopic removal of supraglottic cancer over 70 years ago, and this philosophy is conformed to and deemed acceptable to the present. Vaughan championed this approach and performed the first endoscopic supraglottic laryngectomies in the 1970s when the Boston University Otolaryngology group introduced laser

technology to facilitate soft-tissue dissection and surgical oncology. Cutting the tumor into segments was done because the field of resection was substantially larger than the laryngoscope speculae. Steiner, who has been the primary proponent of this philosophy over the past two decades, visited Boston in the late 1970s and subsequently advanced this approach technically. Through steadfast perseverance as well as relentless lecturing and teaching, he has secured worldwide recognition of the effectiveness of endoscopic treatment of laryngeal cancer.

Endoscopic resection of supraglottic cancer provides several advantages over open supraglottic laryngectomy (Fig. 28.15). In most circumstances, a perioperative tracheotomy is not necessary. In addition, the superior laryngeal nerves are not cut so that critically important sensory function of the neosupraglottic valve is retained. This is a key determinant of posttreatment swallowing function in preventing aspiration. With endolaryngeal treatment, wound breakdown leading to fistula formation does not occur. Finally, supraglottic cancer, even in the deep compartments, is typically encased by a capsule, which enhances endoscopic feasibility and efficacy.

There have been two general approaches to endoscopic treatment of supraglottic cancer. This is composed of single-modality transoral resection and the use of endoscopic resection combined with postoperative radiotherapy. The logic of the latter approach is that treating most supraglottic cancers with radiation (alone or with chemotherapy) results in local failure in 25% to 40% of cases and subsequent total laryngectomy becomes necessary. If the primary cancer has been removed endoscopically prior to radiotherapy (induction surgery), local failure is <10%. This endoscopic approach mitigates functional deficits while maximizing larynx preservation. In accordance with this philosophy, our group now performs total or near-total endoscopic tumor removal with the angiolytic KTP laser.

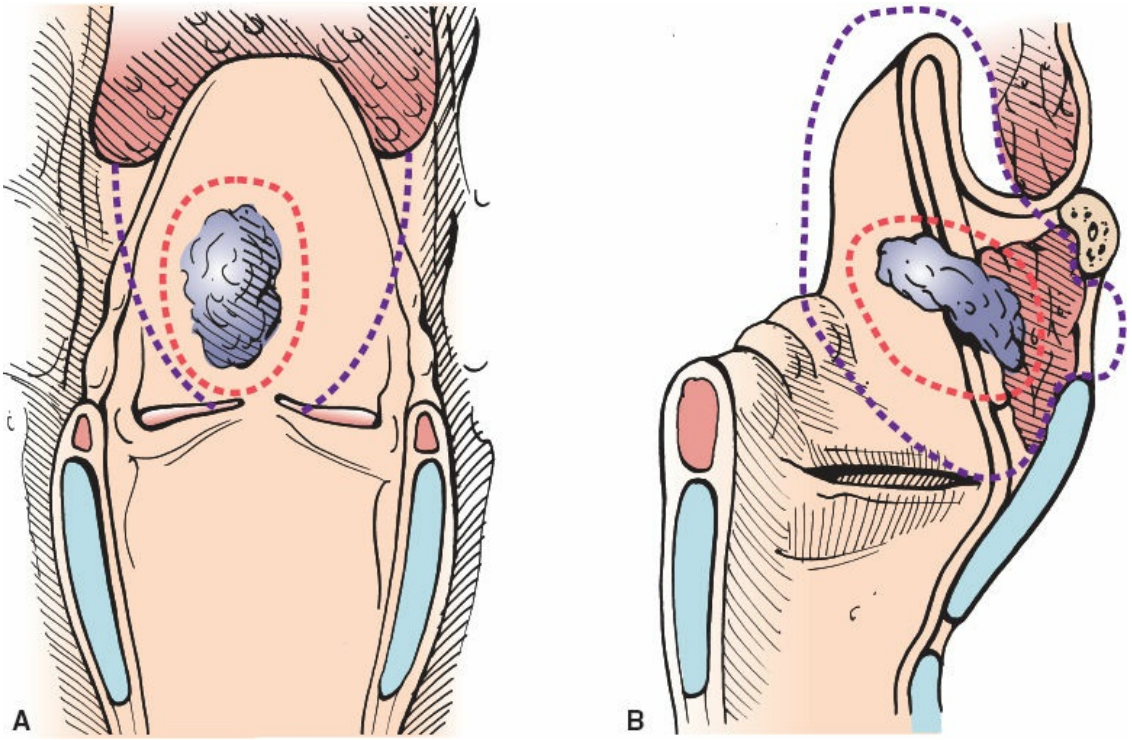

Figure 28.15. **A.** Infrahyoid epiglottic cancer demonstrating the resection boundaries for a wide-field supraglottic laryngectomy and a narrow-field tumor removal. **B.** The same tumor is seen on a sagittal. The piecemeal resection philosophy has always remained problematic for a majority of surgeons trained in classical techniques requiring en bloc removal of the tumor. To address this, over 20 years ago, Zeitels designed a wide bivalve adjustable supraglottiscope that would allow for en bloc supraglottic cancer resection. Despite the success in simulating en bloc open surgery through an endoscopic approach, the technique remained time-consuming and difficult. Remarkably, en bloc resection is being resurrected today with the technical advantages of transoral robotic surgery.

Open Horizontal Supraglottic Laryngectomy (Supraglottic Laryngectomy)

The horizontal supraglottic laryngectomy procedure was perfected in the mid-20th century for T1 to T3 carcinomas confined to the supraglottic soft tissues. This procedure can be extended in all directions to include portions of the tongue base, pyriform sinus, and glottis. Understandably, with wider swaths of pharyngeal and laryngeal soft tissue, there is increased difficulty preserving airway, swallowing, and vocal function. Since aspiration and pneumonia are common complications, patients must have adequate pulmonary reserve and will need to work with a speech language

pathologist postoperatively for swallowing rehabilitation.

A tracheotomy is necessary to perform a supraglottic laryngectomy. Once this is done, a pharyngotomy entry to view the tumor is performed in the oropharyngeal vallecula, glossoepiglottica, or in the pyriform sinus as a lateral pharyngotomy. In 1991, Zeitels described a reliable precise suprahyoid pharyngotomy technique that is valuable for a majority of cancers in the tongue base, larynx, and/or hypopharynx. It is useful to preserve some soft tissue of the supraglottis and its neurovascular pedicle if oncologically feasible since it can be valuable for reconstructing the neo-supraglottic valve for swallowing rehabilitation.

In a classic supraglottic laryngectomy, the upper thyroid laminae are resected with the tumor; however, often this is not necessary if the neoplasm is not adjacent to the cartilage. It is valuable to use magnifying loupes when it is necessary to preserve critical soft tissue such as the anterior-commissure infrapetiole region. To mitigate postoperative aspiration, it is important to resuspend the residual larynx by affixing the thyroid laminae to the hyoid bone with 0 prolene sutures. Complete mucosal closure is not typically feasible so that epithelialization occurs by regional approximation of soft tissues. The tracheotomy tube is removed when the perioperative edema diminishes to sustain an adequate airway lumen and when aspiration is mostly resolved so that tracheobronchial access is not necessary.

SUMMARY

The larynx retains the most complex neuromuscular function of any human organ, which supports human communication as well as balancing respiration and deglutition. Surgical treatment of larynx cancer has been recognized for over a century as an extremely effective treatment. Regardless of size, the overwhelming majority of larynx cancers are controlled locally with surgical removal if the tumor is removed with the correct procedure. Preservation of an adequate airway, as well as swallowing and voice function, becomes the key goal while performing larynx cancer surgery. Remarkably, transoral surgery of laryngeal lesions chronicles a 150-year development of minimally invasive surgery. Solis Cohen established that managing laryngeal disease required high-level skills in endoscopic and open surgery, and this continues to be a requirement of laryngeal surgeons today. These disparate skill sets are especially valuable for larynx cancer surgery. It is not surprising that Solis

Cohen was probably the first surgeon to become a laryngologist and he was also likely the first individual to cure larynx cancer.

EDITOR'S COMMENT

Treatment of laryngeal cancer is multidisciplinary. Surgeons and therapists who deal with cancer of this condition have a particularly heavy burden. The challenge is that the patient may have significant comorbidities and present at an advanced stage of disease. Treatment is focused on organ preservation. The surgeon's role is attempt to cure the cancer while preserving the critical functions of the larynx and surrounding structures including voice, the ability to swallow, and maintain nutrition and respiration. The authors present the rich history of treatment of laryngeal cancer and most recent advances in larynx preservation including transoral endoscopic treatment employing the angiolytic laser with excellent voice preservation and up to 90% cure rates, partial laryngectomy, and phonosurgical reconstruction that preserve critical structures to retain voice function.

The incidence of laryngeal cancer decreased from over four cases per 100,000 persons to about three cases for 100,000. The epidemiology has changed dramatically as will be discussed below. The overall 5-year survival rate is 60.7% (http://seer.cancer.gov/statfacts/html/laryn.html, accessed September 26, 2016). However, the 5-year expected survival rates vary based on the site and stage. For supraglottic tumors, the 5-year survival is: stage 1, 59%; stage 2, 59%; stage 3, 53%; stage 4, 34%. For glottic tumors, including the vocal cords, the 5-year survival is: stage 1, 90%; stage 2, 74%; stage 3, 56%; stage 4, 44%. For subglottic tumors, the numbers are smaller, but the following represent expected 5-year survival: stage 1, 65%; stage 2, 56%; stage 3, 47%; stage 4, 32%.

NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines) are very helpful and should be reviewed (http://www.medsci.cn/webeditor/uploadfile/201505/20150518152341736.pdf, accessed September 26, 2016). Early-stage laryngeal carcinomas (stage I–II) are ideally treated with either radiation or surgical techniques (either endoscopic or open) that preserve laryngeal function. For carcinoma in situ or early-stage invasive glottic or supraglottic cancer, endoscopic surgical excision and radiation therapy are both equally effective with similar functional outcomes. Certain early-stage lesions may require more extensive resection, in which case open partial laryngectomy options exist that provide good oncologic control, although usually with worse voice outcomes than endoscopic surgery or radiation. Indeed, a recent review of the recent literature demonstrated a paucity of new reports of conventional conservation surgery as initial treatment for early-stage glottic and supraglottic cancer. (Silver CE, Beitler JJ, Shaha AR, et al. *Eur Arch Otorhinolaryngol* 2009;266(9):1333–52.) These authors reported that "transoral endoscopic laser microsurgery (TLS) and radiation therapy (RT)

with or without laser surgery or concomittent chemotherapy have become the standard initial treatments for T1, T2, and selected T3 laryngeal cancer." In addition they indicate "results of TLS are equivalent to those obtained by conventional conservation surgery, with considerably less morbidity, less hospital time, and better postoperative function and oncologic results of TLS and RT are equivalent for glottic cancer, but with better voice results for RT in patients who require more extensive cordectomy."

Whereas T1 and T2 lesions are amendable to a variety of endoscopic techniques, treatment of advanced laryngeal carcinoma may require multimodality treatment and in some cases total laryngectomy. However, it is evident that the role of open surgery for management of laryngeal cancer has been greatly diminished during the past decade. The development of transoral endoscopic laser microsurgery, improvements in delivery of radiation therapy and the advent of multimodality protocols, particularly concomitant chemoradiotherapy have supplanted the previously standard techniques of open partial laryngectomy for early cancer and total laryngectomy followed by adjuvant RT for advanced cancer. In these advanced lesions, induction chemotherapy may play a role as does radiation therapy. The optimal treatment of patients with T3 laryngeal carcinoma seems most controversial. The available options include open partial laryngectomy, transoral laser microsurgery, and radiation therapy alone or combined with chemotherapy. Treatment guidelines, experts' opinions, and clinical studies are highly contradictory. (Riga M, Chelis L, Danielides V. *Eur J Surg Oncol.* 2016 June 10.)

For T3 lesions, an alternative to conventional surgery is concomitant chemotherapy and radiation therapy. Current recommendations of the NCCN Guidelines for achieving laryngeal preservation in cases of locally advanced laryngeal cancer are concurrent radiation therapy and cisplatin 100 mg/m^2 on days 1, 22, and 43. Radiation therapy alone can be considered for patients who are medically unfit to undergo chemotherapy. Accelerated and hyperfractionated treatment schemes may improve the efficacy of radiation therapy. If the patient is not a candidate for the above, then for T3N0 laryngectomy and ipsilateral thyroidectomy are recommended. For T3N1 laryngectomy with ipsilateral thyroidectomy, ipsilateral neck dissection or bilateral neck dissection is indicated.

For T4a lesions, surgery or consideration of concurrent chemoradiation treatment followed by function preserving surgery is an option as is total laryngectomy with thyroidectomy and unilateral or bilateral lymph node dissection. More advanced lesions are usually not amendable to phonation preserving surgery.

The most significant change in our understanding of laryngeal cancer since the sixth edition of *Mastery of Surgery* is the changing epidemiology. Whereas in the past the patient with laryngeal and hypopharyngeal cancer was frequently a heavy smoker and user of alcohol and likely addicted to both, today there is an

increasing number of patients who are younger and never used tobacco products or alcohol but who have HPV infections. The association and clinical significance of HPV infections with a subset of head and neck cancers, particularly for oropharyngeal carcinoma, have been well established. Epidemiologic studies on HPV-associated cervical cancer have clearly demonstrated that HPVs are transmitted by sexual contact, and today there are several studies suggesting that HPV-positive head and neck tumors are also sexually transmitted. However, the involvement of HPV in laryngeal cancer has only recently been clarified. Investigators using several methods of detection have shown HPV DNA in benign (papillomatosis), indolent (verrucous carcinoma), and malignant (squamous cell carcinoma [SCC]) lesions of the larynx. Consistent with the known oncogenic risk of HPV infections, the prevalent HPV types associated with laryngeal neoplasms include those known to have an oncogenic relationship with other oropharyngeal neoplasms. Laryngeal papillomatosis is associated with low-risk HPV types 6 and 11, and neoplastic lesions (verrucous carcinoma and SCC) are more commonly associated with high-risk HPV types 16 and 18.

The larynx is among the most significant anatomic sites in terms of HPV involvement. This is because HPV infection is the etiologic agent of a clinically significant disease known as laryngeal papilloma (papillomatosis). Traditionally, four distinct entities of laryngeal papilloma were considered on the basis of the onset, clinical appearance, and natural history: (1) juvenile solitary, (2) juvenile multiple, (3) adult solitary, and (4) adult multiple. More recently, however, this nomenclature has been replaced by the term RRP, which more accurately describes the widespread extent of the disease and its tendency for repeated recurrence. The observed prevalence of HPV is 80% RPP and is almost as high as in genital condylomas and cervical cancer, which are well-established HPV-associated diseases. The vast majority of RRP are benign squamous cell proliferations induced by HPV types 6 and 11. Despite the basically benign character of these lesions, however, malignant transformation into laryngeal (tracheal, bronchial) SCCs occurs in a certain proportion of cases.

Laryngeal carcinoma may arise as a late complication of pre-existing RRP, but according to the literature the vast majority of these malignant lesions develop without any antedating papilloma, through cancer precursor lesions (dysplasia, intraepithelial neoplasia, carcinoma in situ). Meta-analyses have demonstrated that >25% of laryngeal SCCs harbor HPV infections, with common involvement of high-risk HPV types 16 (highest frequency) and 18. One such study reviewed published studies on HPV infection and laryngeal cancer and quantitatively summarized the prevalence of HPV infection and its association with the risk of laryngeal cancer by means of meta-analysis. (Li X, Li H, Gao J, et al. *J Inf Disease* 2012;10;1093). They included 55 eligible studies. The overall HPV prevalence in laryngeal cancer tissues was 28.0% (95% confidence interval [CI], 23.5%–32.9%). They observed that 26.6% of laryngeal cancer patients were infected with high-risk types of HPV. HPV-16

was most frequently observed with a prevalence of 19.8%. The meta-analysis based on 12 eligible case-control studies suggests a strong association between HPV infection and laryngeal SCC with a summarized odds ratio (OR) of 5.39 (95% CI, 3.25–8.94). Different magnitude of the association was observed for HPV-16 (OR = 6.07, 95% CI: 3.44–10.70) and HPV-18 (OR = 4.16, 95% CI: 0.87–20.04) ($p < 0.01$). Stratified analyses were performed with respect to HPV genotypes and characteristics of the study population.

The clinical implications of HPV-positive laryngeal carcinoma are not fully characterized. However, it may be similar to the prognosis for HPV-positive oropharyngeal cancer patients which is better than that for patients with HPV-negative tumors independent of treatment strategy, nodal status, age, stage, tumor differentiation, or gender. While it is still unclear whether tobacco is a risk factor for HPV-induced oropharyngeal tumors, smoking negatively impacts relapse rates and survival for the HPV-positive tumors. It is estimated that the risk of death and cancer relapse increased by 1% for each additional pack year of tobacco smoking.

Treatment of larynx cancer and epidemiology have changed dramatically over the past several years. HPV plays a role in the etiology. Novel modalities of treatment have been introduced as organ preservation has been developed. In addition, new targeted therapies have appeared; concomitant chemotherapy and improvements in radiotherapeutics and surgical techniques have been introduced. Treatment is multidisciplinary. The variety of treatment options is increasing local control rates and overall survival; however, selecting the most appropriate treatment remains a challenging decision. Organ preservation is a primary goal along with cancer control.

29 Surgical Treatment of Pharyngeal Cancer

Bruce H. Haughey and Parul Sinha

The complexity of anatomical and physiologic structure makes pharyngeal cancer surgery one of the most challenging tasks for head and neck surgeons. Cancer originating in each of the pharyngeal subsites—nasopharynx, oropharynx, and hypopharynx—is unique in its biology, epidemiology, and response to treatment and merits a site-specific discussion of the appropriate surgical approach.

NASOPHARYNX

Etiology and Pathophysiology

Nasopharyngeal carcinomas (NPC) are rare head and neck neoplasms characterized by marked geographical, environmental, and ethnic variations. The most recent 2012 report of the International Agency of Research on Cancer estimated the worldwide age-standardized rate (ASR) for NPC to be 1.2 per 100,000. Higher rates have been observed in South East Asia, particularly Southern China, and in certain other ethnic populations like Alaskans and Greenland Eskimos. A genetic susceptibility conferred by alterations in human leukocyte antigen typing or chromosomal patterns and environmental risk factors including consumption of nitrosamine-rich salted fish have been postulated to play an important role in the etiology of NPC. Epstein–Barr virus (EBV) infection has also been documented as a strong oncogenic precursor.

Anatomy

The nasopharynx (Fig. 29.1) is approximately a 4 × 4 × 2 cm space behind the posterior apertures of the nasal cavities (opposite C1 to C2) bound superiorly by the body of sphenoid, petrous apices, and basiocciput and inferiorly by the upper surface of the soft palate. The mucoperiosteum of the roof merges with the posterior soft tissue wall. The posterior wall consists of four layers that run across the entire length of the pharynx—

from inside out, the mucosa, pharyngobasilar fascia, pharyngeal muscles, and bucco-pharyngeal fascia. The lateral walls of the nasopharynx contain the opening of the eustachian tubes (ET). Posterior and medial to the mucosal elevation formed by the ET opening (*torus tubarius*) is a deep recess, “fossa of Rosenmüller,” considered to be the commonest site for harboring NPC. The tumor may spread anteriorly from the fossa to block the ET opening. The proximity of this fossa to skull base structures and parapharyngeal space accounts for direct spread of disease across and through the skull base via invasion of the pharyngobasilar fascia. The nasopharyngeal mucosa is rich in lymphatics, with the lateral retropharyngeal group being the first echelon of nodes (uppermost known as *node of Rouvière*). The lymphatic disease spreads to the upper deep jugular nodes (level II) or the spinal accessory chain of nodes (level V). Lymphatics can also cross the midline to drain in the contralateral neck nodes.

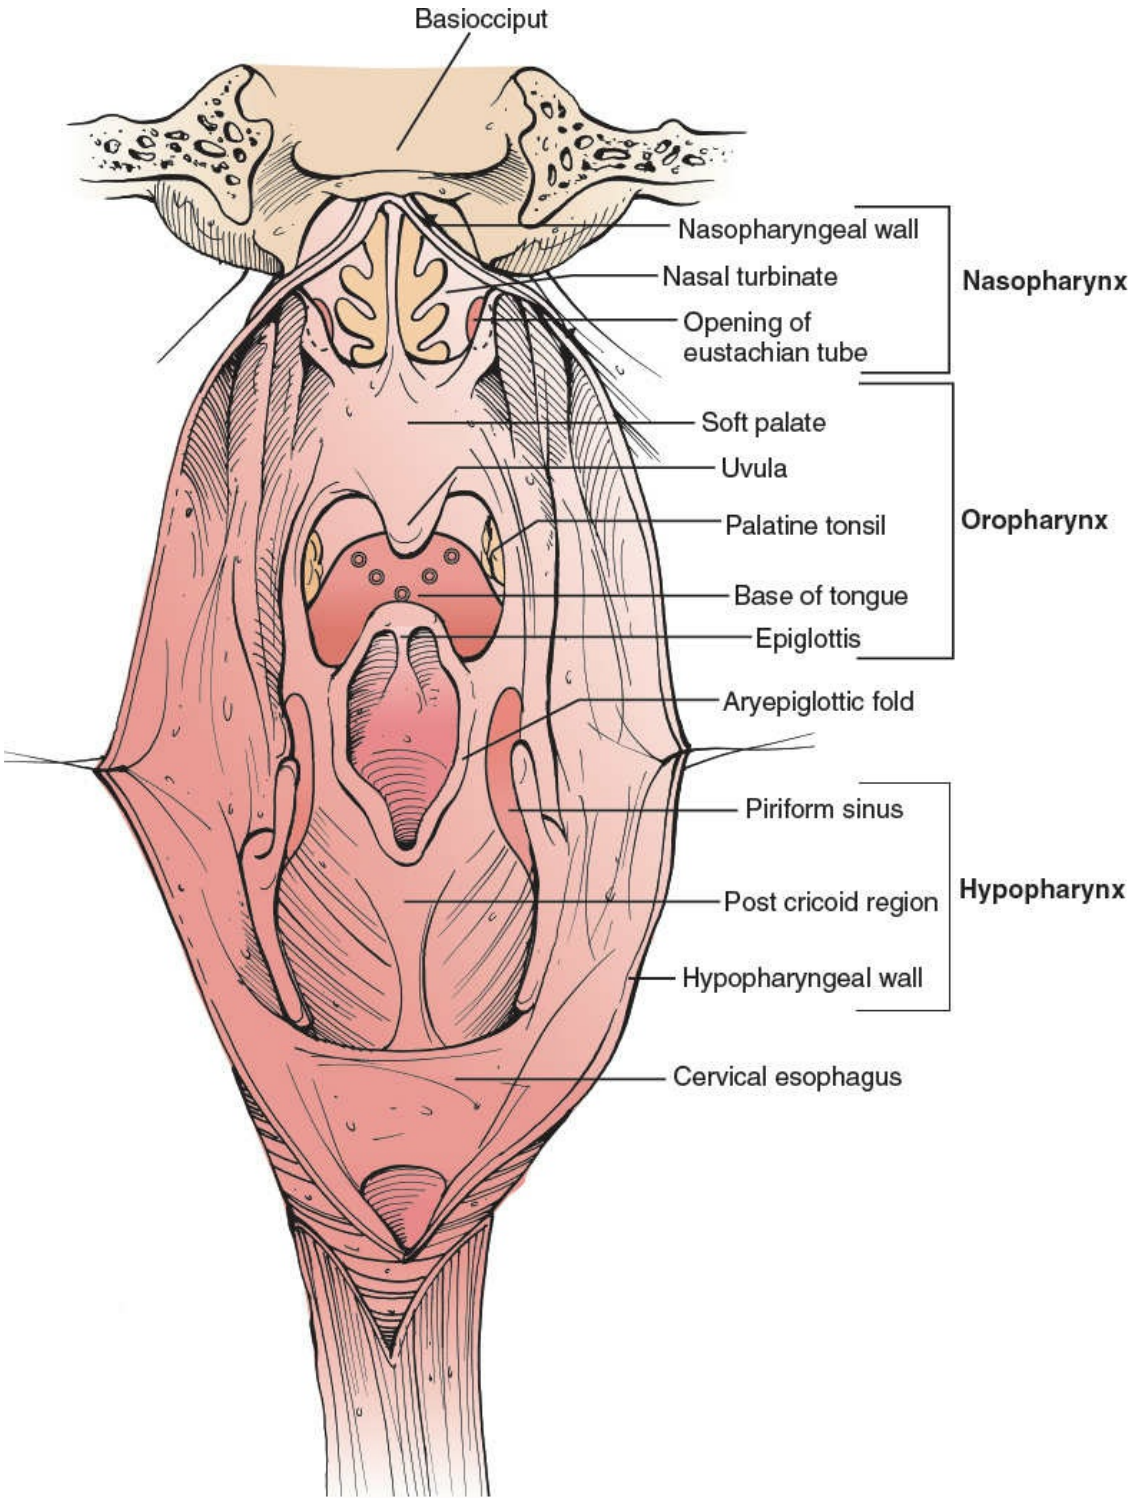

Figure 29.1. Posterior view depicting subdivisions of pharynx.

Clinical Presentation

Patients with NPC commonly present with painless metastatic neck mass(es); otologic symptoms, such as conductive deafness, aural fullness, otalgia or tinnitus; and nasal symptoms, including epistaxis or obstruction. Cranial nerve involvement can result in diplopia (VI, III, IV), facial pain

or dysesthesias (V), palatal and vocal cord paralysis (IX, X), or Horner's syndrome (sympathetic trunk). The characteristic symptoms of local tumor spread in NPC—conductive deafness, facial pain, and palatal paralysis—are collectively referred to as *Trotter's triad.*

Preoperative Planning

A complete head and neck evaluation including rigid or flexible endoscopy with careful assessment of the posterior nasal space along with the examination of the cranial nerves should be performed. Radiologic investigations including computed tomography (CT) and magnetic resonance imaging (MRI) are important to determine the extent and stage (Table 29.1) of tumor and also the appropriate surgical approach.

Treatment

The radiosensitivity of NPC and restricted surgical access owing to the proximity of vital structures have made nonsurgical therapy the primary modality of treatment. The role of surgery is limited to salvage of recurrent or persistent cancer at the primary site without any intracranial spread or neck dissection. The size, location, and extent of tumor as well as involvement of the adjacent soft tissue determine the appropriate surgical approach.

Surgical Technique

Endoscopic

Small lesions without any lateral extension may be amenable to transnasal endoscopic excision but often, the exposure is not sufficient for oncologic resection.

Transpalatal

Retraction or division of the soft palate can provide access to the nasopharynx. Wider exposure is achieved by detaching the soft palate from the hard palate or by incising the palate in midline, which allows retraction after elevating the mucoperiosteum over the hard palate. These approaches need minimal reconstruction but provide limited exposure. For lateral wall tumors, *surgical robot* has been combined with transpalatal approach to enhance visualization and maneuverability of the instruments.

Transcervical

An incision is made parallel to the lower border of mandible. Skin flaps are elevated and the mandible is retracted to expose parapharyngeal and nasopharyngeal space. A wider exposure is acquired through division of lip and mandibular symphysis.

TABLE 29.1 American Joint Committee on Cancer TNM Staging of Pharyngeal Cancer (2010)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Nasopharynx	
T1	Tumor confined to the nasopharynx, or extends to oropharynx and/or nasal cavity without parapharyngeal extension[a]
T2	Tumor with parapharyngeal extension[a]
T3	Tumor involves bony structures of skull base and/or paranasal sinuses
T4	Tumor with intracranial extension and/or involvement of involvement of cranial nerves, hypopharynx, orbit, or with extension to the infratemporal fossa/masticator space
Oropharynx	
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension or extension to lingual surface of epiglottis
T4a	Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible[b]
T4b	Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery
Hypopharynx	
T1	Tumor limited to one subsite of hypopharynx and/or 2 cm or less in greatest dimension
T2	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation ofhemilarynx
T3	Tumor more than 4 cm in greatest dimension or with fixation of hemilarynx or extension to esophagus
T4a	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or

	central compartment soft tissue[c]
T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
Nasopharynx	
N1	Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa, and/or unilateral or bilateral, retropharyngeal lymph nodes, 6 cm or less, in greatest dimension[d]
N2	Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa[d]
N3	Metastasis in a lymph node(s)[d] >6 cm and/or extension to supraclavicular fossa
N3a	Greater than 6 cm in dimension
N3b	Extension to the supraclavicular fossa
Oropharynx and Hypopharynx	
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatestdimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

[a]Parapharyngeal extension denotes posterolateral infiltration of tumor.
[b]Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of larynx.
[c]Central compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat.
[d]Midline nodes are considered ipsilateral nodes.

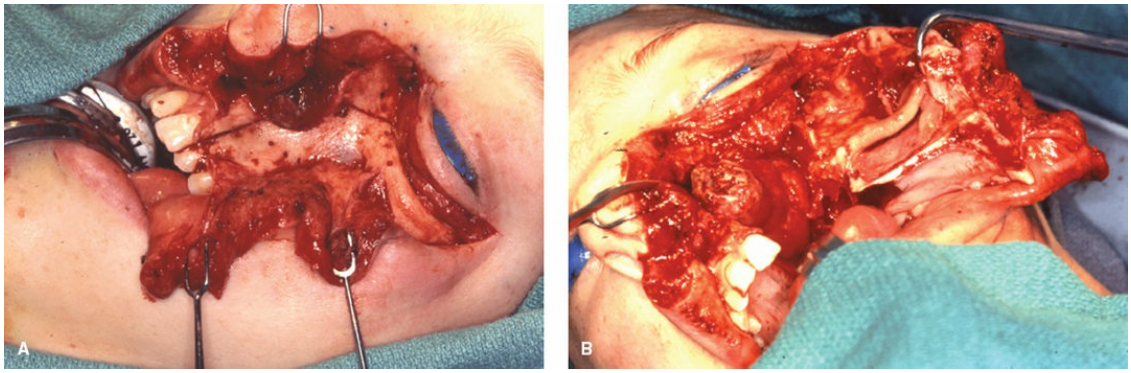

Figure 29.2. Maxillary swing approach: (**A**) elevation of left cheek flap, (**B**) lateral swing of left maxilla with attached skin flap to expose nasopharynx.

Maxillary Swing

First described by Hernandez Altemir (1986), this approach provides a wide exposure for resection of nasopharyngeal tumor. A cheek flap is elevated to expose the anterior wall of maxilla. The osteotomy cuts are made below the roof of orbit, across the zygomatic arch, medial wall of maxilla below the middle turbinate, and hard palate in the midline. The pterygoid plates are removed from the maxillary tuberosity, and after detaching all bony connections the whole maxilla is dropped inferiorly with the attached cheek flap for preserving vascular supply. The entire osteocutaneous complex is swung laterally to expose the nasopharynx for complete extirpation of tumor (Fig. 29.2).

Lateral

Fisch's lateral infratemporal fossa approach can be used to remove tumors in the lateral nasopharyngeal region. The procedure includes a radical mastoidectomy, delineation and mobilization of the facial nerve and internal carotid artery, and division and displacement of zygomatic arch and the mandibular condyle with the muscular attachments to expose the infratemporal fossa. The mandibular branch of trigeminal nerve is divided, and the bone at the middle cranial skull base is removed to access the nasopharyngeal space.

Complications

Palatal fistula may occur in transpalatal approaches, especially in irradiated patients. Maxillary swing approach can lead to ectropion, trismus, and/or malocclusion. The lateral approach is associated with significant functional morbidity, including hearing loss and damage to cranial nerves V and VII.

OROPHARYNX

Etiology and Pathophysiology

Cancer of the oropharynx constitutes about 10% to 12% of all head and neck cancers and annually accounts for about 10,000 cases in the United States. The growing recognition of a disparate shift in its epidemiology, particularly in the Western world, has made oropharyngeal malignancy an intriguing clinical entity among all head and neck sites. The numbers of newly diagnosed oropharyngeal squamous cell carcinomas (OPSCC),

mainly tonsillar and tongue base, are increasing in certain populations at an approximate rate of 4% and 2% each year, respectively. The rise is attributed to a strong etiologic association with oncogenic human papillomavirus (HPV) exposures. HPV-related OPSCC classically presents at younger ages and in persons with none or minimal tobacco exposure. The mode of HPV transmission is yet to be fully elucidated but high-risk sexual behaviors like orogenital contact and multiple lifetime partners are likely contributors.

Anatomy and Surgical Pathology

The oropharynx is anatomically subdivided into (a) base of tongue, (b) tonsils and faucial pillars, (c) soft palate, and (d) pharyngeal wall (Fig. 29.1). Anteriorly, the oropharynx is demarcated by circumvallate papillae, junction of hard and soft palate, and the anterior faucial pillars. The bucco-pharyngeal fascia in the posterior pharyngeal wall (PPW) acts as a natural barrier to prevent the posterior extension of carcinoma. Lateral pharyngeal wall, palatine tonsils, and the faucial pillars delineate the lateral limits of the oropharynx. Inferiorly the oropharynx extends to the vallecula and includes the glossopharyngeal and pharyngoepiglottic folds. Absence of anatomic barriers between the subsites allows oropharyngeal tumors to spread locally in contiguity without restriction. Tumor extending through the lateral wall can involve the parapharyngeal space, including the pterygoid muscles and the carotid sheath structures. Waldeyer's ring, a circumferential, mucosa-associated lymphoid tissue ring in oropharynx comprising the lingual tonsils, palatine tonsils, and inferior part of adenoids, may give rise to primary tumors that metastasize at an early stage and often present as *unknown primaries.* A rich lymphatic network is responsible for the high probability of cervical metastasis from the oropharyngeal tumors. The primary echelon of drainage is the jugulodigastric nodes in the upper jugular chain (level II) and the retropharyngeal and parapharyngeal nodes. Lymphatic spread may advance from level II to middle jugular (level III) and lower jugular nodes (level IV). The medial base of tongue and other midline structures often drain bilaterally.

Clinical Presentation

Oropharyngeal cancer tends to present at an advanced stage. Patients often present with a mass in the neck detected by direct observation or with

symptoms of fullness in the primary site such as sore throat, otalgia, dysphagia, or trismus by which time the tumor has usually progressed to a significant size (Fig. 29.3). A frequent presentation of OPSCC, particularly submucosal tongue base tumors, is in the form of an *unknown primary*, in which patients present with enlarged metastatic neck nodes but no clinically detectable or symptomatic primary tumor. OPSCC is also associated with a high incidence of distant metastases and synchronous primaries at the time of presentation.

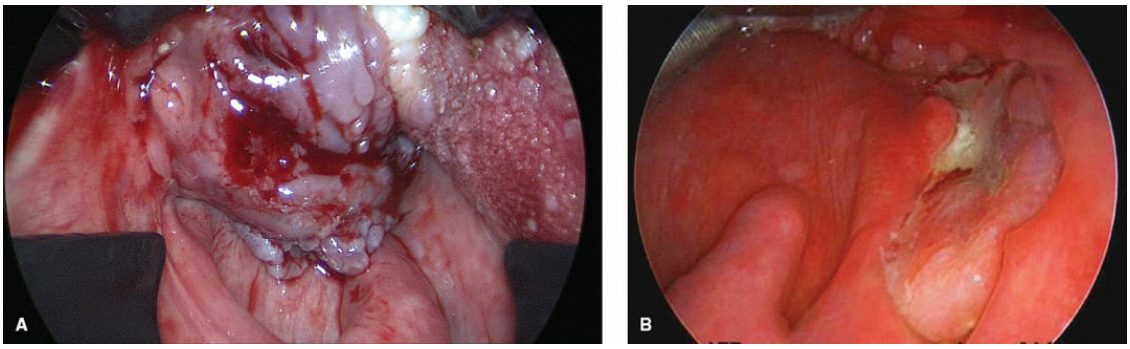

Figure 29.3. (**A**) Exophytic tumor of left tongue base, (**B**) endophytic tumor of right tonsil.

Preoperative Planning

A complete workup to assess the site and stage of primary tumor and presence of cervical lymphadenopathy is indicated. This includes history, physical examination, and a thorough head and neck evaluation including mirror examination, palpation, and office flexible fiberoptic laryngoscopy for direct visualization. Radiologic evaluation with a CT/MRI is performed to determine the extent of primary with greater accuracy as well as to assess the retropharyngeal metastasis. The cervical lymphadenopathy can be reliably assessed by Gray scale ultrasonography, supplemented by ultrasound-guided fine needle aspiration, if indicated. The latter is particularly useful in decision making for or against treating the contralateral neck. Chest radiography, CT, or positron emission tomography (PET) is used to evaluate distant metastasis or second primary tumors.

A systematic rigid pharyngolaryngoscopy examination under anesthesia (EUA) of the upper aerodigestive tract (UADT) along with photo documentation should be performed to assess the primary tumor, detect synchronous primaries, obtain biopsies, and decide the ideal surgical approach—transoral or open. This procedure forms a significant

component of tumor staging, treatment, and reconstruction planning. For patients with *unknown primaries*, a common mode of presentation for OPSCC, we employ transoral laser microsurgery (TLM) with traditional EUA, wherein the potential sites of occult primaries or other suspicious mucosal lesions are biopsied, followed by frozen section and finally by palatine and lingual tonsillectomies if no primary site is identified. The tumor is staged according to the American Joint Commission Cancer staging system based on all information gleaned from clinical, radiologic, and endoscopic evaluations (Table 29.1). An evaluation of the patient's dentition and necessary restorative dental procedures are also recommended prior to initiation of treatment.

Treatment

Definitive surgery with adjuvant radiotherapy has been the cornerstone of curative treatment for OPSCC. Issues of organ preservation and functional morbidity subsequent to conventional open *en bloc* surgery have instigated advocation of nonsurgical management of OPSCC with chemoradiotherapy (CRT), a modality associated with modest survival outcomes and a higher acute and long-term toxicity profile. Rapid advances in technology have shifted the paradigm of surgical management of OPSCC toward minimally invasive endoscopic transoral approaches (Fig. 29.4). These approaches allow primary tumor-targeted treatment, minimal blood loss, rapid wound healing, avoidance of tracheostomy except for extensive oropharyngeal resections with flap reconstruction, better functional preservation, shorter hospital stay, faster rehabilitation, and also facilitation of a less morbid, pathologically stratified, risk-based adjuvant therapy. Biofactors like presence of HPV or its surrogate marker, p16, are reported to confer a favorable prognosis in surgically managed OPSCC. Other independently prognostic variables in such reports of advanced OPSCC were T-classification, margins, and use of adjuvant radiotherapy. The decision for the optimal therapeutic modality is often made by a multidisciplinary team based on tumor site and stage, patient preference, comorbidity, performance status, and available technical expertise.

Transoral Procedures

Transoral Laser Microsurgery

Transoral carbon dioxide (CO_2) laser microsurgery can be used for

resection of both early and advanced stage tumor at all oropharyngeal subsites depending on the individual's surgical skills and training. The basic requirements for TLM include a competent surgical training, knowledge of pharyngeal and neck anatomy "from the inside out," good anatomic access, and strict enforcement of laser-specific precautions in the operating room. The core principles of TLM for oropharynx cancer, as first enunciated by Steiner, are summarized below:

Figure 29.4. Minimally invasive transoral laser microsurgery approach for oropharynx.

1. Utilization of microscope for adequate illumination and magnification of the operative field, and clear distinction between tumor and normal tissue.
2. Expeditious coring of large bulky tumors (with cautery or laser) to leave a thin rind of tumor.
3. Multiple transtumoral cuts to assess the deepest extent.
4. Multibloc resection with meticulous inking and labeling for orientation.
5. Securing clear margins with frozen section analyses; a 1- to 1.5-cm margin of normal tissue beyond the invading front of the tumor is recommended.

An optimum visualization of the operative site is paramount for TLM and is achieved with a combination of modified mouth gags, such as Dingman or Feyh–Kastenbauer, and laryngoscopes, such as Steiner or

Kleinsasser. The instruments may need repositioning during the procedure to obtain a satisfactory exposure; as exposure diminishes, the surgeon progresses from the expanding scopes to the smaller fixed-bore laryngoscopes. Transoral resection of OPSCC is performed with CO_2 laser via either microendoscopy or a handheld device, following the above-mentioned principles. Surgical techniques specific to an oropharynx subsite are described below. The contraindications to TLM include inadequate endoscopic access and tumor extent that may result in incomplete resection, for example, lateral extension through the infratemporal fossa with invasion of the great vessels. In the presence of inadequate access, the transoral approach can be combined with transhyoid or lateral pharyngotomy, using the same incision as neck dissection. The requirement of free flap reconstruction is not a contraindication to the TLM approach, and we have utilized techniques to accomplish suturing in free flaps through the mouth, with the vascular pedicle exiting to the neck through a small pharyngotomy.

Tonsil

Small (<10 mm), well-circumscribed, and truly superficial tonsillar lesions can be resected *en bloc* by performing a tonsillectomy. Larger tonsillar tumors require partial lateral pharyngectomy (Fig. 29.5). They are transected at multiple levels, and a dissection plane is developed deep to the pharyngeal constrictors into the parapharyngeal space and out to the medial pterygoid and/or styloglossus muscle more inferiorly. The tonsillar bed is excised thoroughly by continuing the dissection in the parapharyngeal space from superior to inferior. The superior loop of the facial artery is frequently transected here and requires clipping, also often exposing the lingual nerve and the posterior submandibular gland. The resection is extended to the base of the tongue as required and connected with a cut down the posterolateral pharyngeal wall, thus excising the posterior tonsillar pillar and completing the partial pharyngectomy. The lingual branch of the glossopharyngeal nerve may need to be sacrificed while working just deep to the inferior pole of the tonsil. In very deep tumors of the tonsillar fossa or lateral oropharyngeal wall, it is helpful to perform neck dissection prior to transoral resection since the internal carotid artery can be delineated and cottonoids inserted in the space between the artery and the pharyngeal wall for protection.

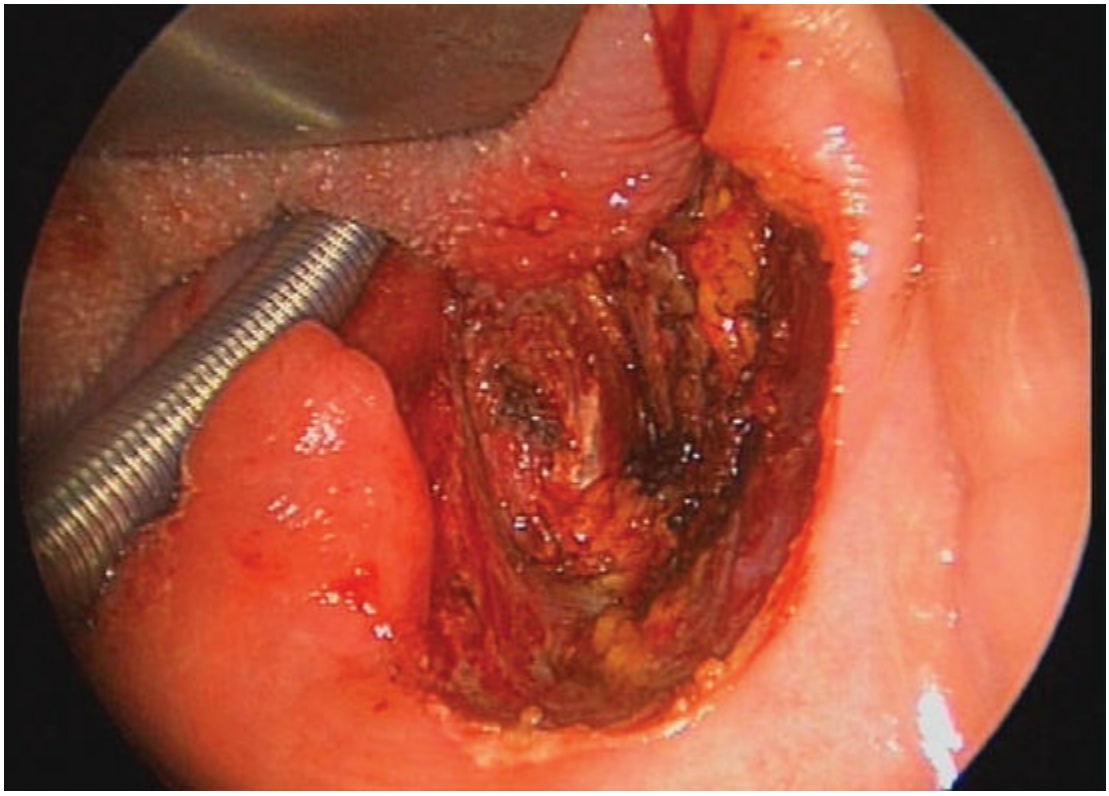

Figure 29.5. Limited partial pharyngectomy for tonsil primary—transoral laser microsurgery approach.

Base of Tongue

The significant intramuscular, submucosal extension of tongue base tumors requires a careful histologic analysis for margin negativity in all dimensions of the resected tumor segment. Achieving negative margins may require complete internal skeletonization of hyoid bone and exposure/excision of pre-epiglottic fat. The lingual artery or its branches need to be clipped if they are exposed, heat-injured, or transected during the dissection. Just lateral to this, from the inside out, is the hypoglossal nerve, which may be exposed or occasionally removed. When the tumor extends in an anterior direction, the lateral posterior floor of mouth needs to be accessed, which is usually accomplished with fixed-bore laryngoscopes. Here the lingual nerve and submandibular gland may be exposed.

Posterior Oropharyngeal Wall

Tumors of the PPW can be completely resected with the TLM approach. The superior and inferior extent of the tumor should be adequately exposed to secure clear margins. The tumors in this subsite and in the tonsil or soft palate may extend superiorly into the nasopharynx and their

resection may result in varying degrees of velopharyngeal incompetence or nasopharyngeal stenosis, which can be prevented by adequate reconstruction.

Hemostasis

It is important to achieve meticulous hemostasis at the completion of all procedures for oropharyngeal tumors, particularly tonsillar and tongue base lesions, because of proximity or transection of large named branches of the external carotid artery. If the lingual, facial arteries or their major branches are involved in the resection, the named vessel of origin is clipped in the neck during the neck dissection, obviating secondary hemorrhage, which can be catastrophic.

Transoral Robotic Surgery

Transoral surgery with robotic assistance (da Vinci Surgical system) is an emerging approach that has been found to be feasible for small oropharyngeal tumor resection with minimal disruption of function and structure (Fig. 29.6). Unlike TLM, the tumor is usually removed *en bloc* in transoral robotic surgery (TORS) with a cuff of normal tissue. The setup time, expense, access difficulty for rigid robotic arms, and compatibility issues of TORS with the routine operating requirements such as neck dissection currently confine it to select treatment centers and smaller, less deeply invasive primaries. The technique requires an assistant who has to perform suction and hemostasis around the three arms of the robot. The desired outcome of TORS is the same as for TLM, that is, a margin negative primary tumor resection accomplished entirely through the mouth. Technology improvements such as flexible delivery of the working tips, better robotic haemostatic capability, and miniaturization may promote more widespread use of the robot in future.

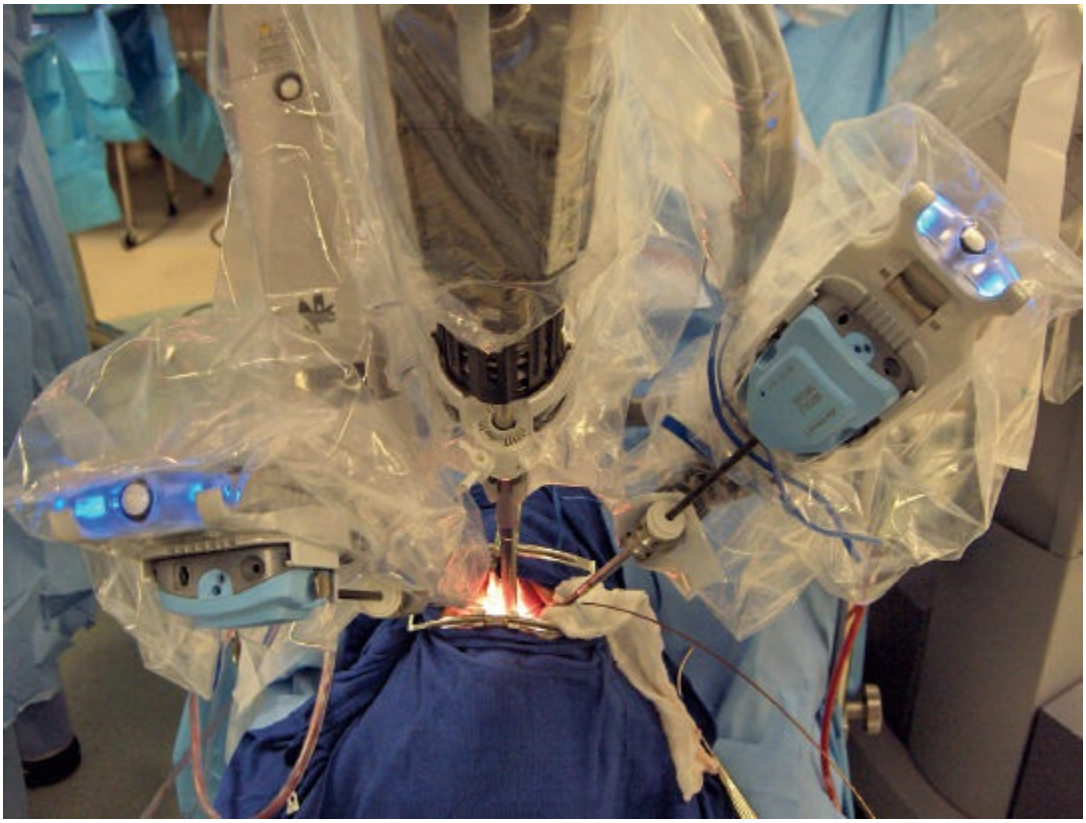

Figure 29.6. Transoral robotic surgery approach for oropharynx.

Transoral Approach to Unknown Primary

The oropharynx is a common site for detection of an occult, clinically undetectable primary tumor in patients presenting with metastatic neck nodes, which are HPV and/or p16-positive. Panendoscopy, tonsillectomy, and directed biopsies have been the traditional diagnostic procedures for an unknown primary. At Washington University in St. Louis, a TLM approach was developed for detection of unknown primary, which resulted in higher detection rates and an opportunity to simultaneously remove the primary to a negative margin. The TLM approach includes examination under anaesthesia followed by biopsy of pharyngeal sites with mucosal abnormalities as observed under the highly magnified view of an operating microscope, or the endoscopic camera of a da Vinci robot. In the absence of pathologic detection of a distinct primary site on frozen section of the biopsy, removal of the ipsilateral lingual and palatine tonsils is performed using the TLM technique. Similar approach to detection of unknown primaries has also been reported using TORS, although targeted primary resection is less common using robotic technology.

Open Procedures

Transhyoid Pharyngotomy

Small base of tongue tumors can be accessed through a transverse incision made at the level of hyoid. The suprahyoid muscles are divided from the hyoid bone, and the oropharynx can be entered through incision of the vallecular mucosa. Care should be taken to avoid injury to the superior laryngeal nerve, the hypoglossal nerve, and the lingual artery.

Lateral Pharyngotomy

A temporary tracheostomy is usually recommended in patients undergoing lateral pharyngotomy to prevent the potential airway obstruction secondary to postoperative pharyngeal edema. The skin incision is made at the level of the superior border of the thyroid cartilage extending from the midline to the posterior border of sternocleidomastoid. The suprahyoid muscles are detached from the hyoid above its lateral end, the mucosa is divided, and the pharynx is entered through the vallecula. A pharyngocutaneous fistula may develop as a complication in cases with significant mucosal resection, warranting a careful pharyngeal closure with inverting mucosal sutures.

Mandibular Swing

Advanced oropharyngeal tumors in patients with factors limiting transoral surgery may require an *en bloc* resection through the transmandibular approach (Fig. 29.7). A tracheostomy is performed prior to these procedures. A stepped skin incision is usually performed through the midline of the lip (full thickness) down to the mentum, and is continued into the neck dissection incision below the mandible. Inside the oral cavity, it is extended laterally in the gingivobuccal sulcus, leaving a cuff of approximately 5-mm mucosa for closure at the completion of procedure. As an alternative to the lip-splitting incision, a visor flap can be raised with a horizontal incision in the submandibular skin crease carried across to the angle of the mandible on either side. The soft tissues and periosteum are incised and elevated from the bone in the region of the mandibular split. At the site of intended osteotomy, fixation plates are placed and screw holes are drilled and sized to facilitate accurate alignment of bone during reconstruction. A stepped midline or paramedian mandibulotomy is performed using an electric saw, anterior to the mental foramen and through the middle of a tooth socket or between teeth. The floor of mouth mucosa, mylohyoid muscle, and other soft tissues are divided, preserving the lingual nerve medially, and the mandible is retracted laterally to expose the oropharyngeal tumor. Proper stabilization of the mandibular segments

and a close approximation of mucosa and soft tissue at the end of procedure are imperative to minimize complications with healing.

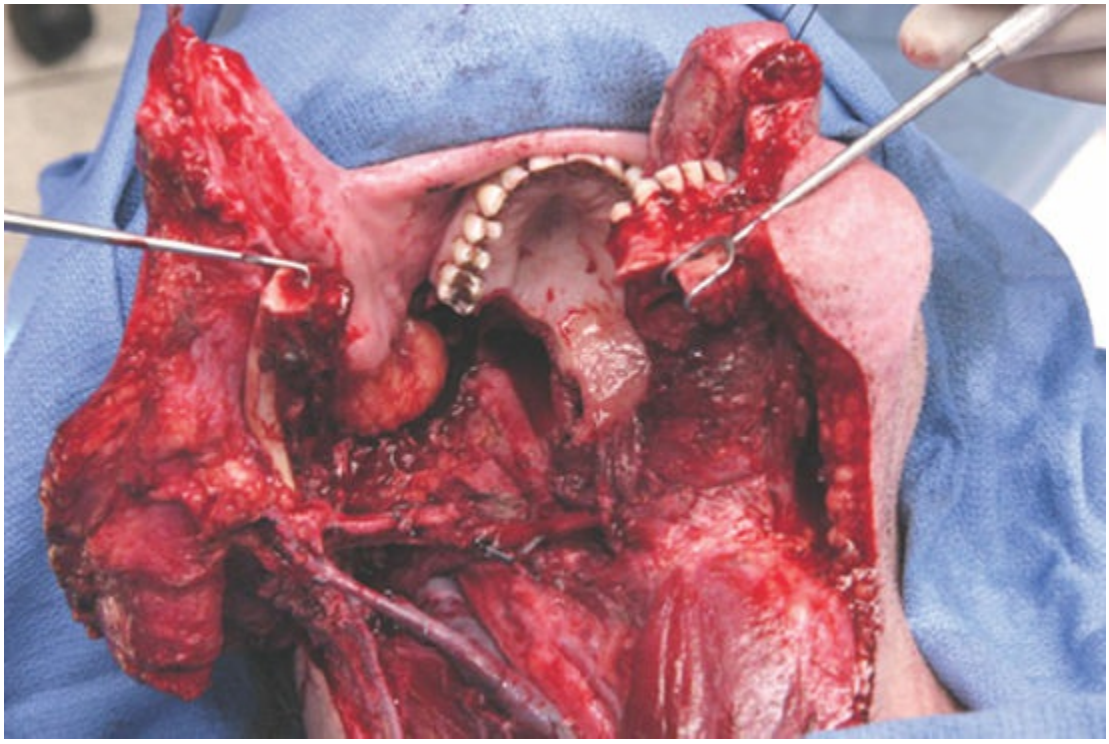

Figure 29.7. Mandibular swing access following *en bloc* resection of advanced oropharynx cancer.

Oropharyngeal Reconstruction

The oropharynx subserves the fundamental functions of swallowing, speech, and respiration; hence, oropharyngeal defect reconstruction should be in utmost consonance with the physiologic mechanisms underlying these functions. The size and site of defect as well as various patient- and surgeon-related factors determine the type of reconstruction.

Base of Tongue

Tongue base reconstruction is critical to deglutition and prevention of aspiration. Free fasciocutaneous flaps have become the standard technique of reconstruction for tongue base defects, with radial free forearm flap (RFFF) being the most commonly used followed by anterolateral thigh (ALT) flap. For RFFF, adequacy of radioulnar collaterals should be ascertained preoperatively with Allen's test. Free musculocutaneous flaps like innervated latissimus dorsi can provide adequate reconstruction for total glossectomy defect. Regional myocutaneous flaps are used for patients who are poor candidates for free tissue transfer.

Soft Palate

Large, full-thickness soft palate defects (50% or more) result in velopharyngeal incompetence, in turn resulting in nasal regurgitation and unintelligible speech. The aim of palatal reconstruction is to fabricate a functional velum and minimize unwanted communication between the nasopharynx and the oropharynx. Local flaps like uvulopalatal rotation flap, superior or inferior pharyngeal flap, and palatal island flap can provide adequate reconstruction for limited lateral palatal defects, but for through-and-through defects, RFFF is the technique of choice.

Tonsil and Pharyngeal Wall

Tonsillar and pharyngeal wall defects of less than 4 cm can be left to heal by secondary intention. Split skin grafting may be used for superficial pharyngeal defects. For larger defects with significant palatal involvement, we prefer use of a folded RFFF.

Management of the Neck

A selective or modified radical neck dissection is performed in patients with clinically positive necks. The ipsilateral clinically N0 neck should be addressed electively due to a high incidence of occult nodal metastases in oropharynx. Tumors of tongue base and tonsil approaching or extending across the midline present a rationale for contralateral elective neck dissection or radiation due to a greater risk of occult contralateral metastases.

Postoperative Care

A vigilant monitoring of vital signs, flap viability, nutritional status, and wound care is performed. A nasogastric tube is inserted for feeding in the immediate postoperative period. Swallowing recovers faster in patients undergoing TLM; however, a gastrostomy tube may be required in patients with extensive resection, slower recovery of swallowing, or in those planned for adjuvant therapy. Prophylactic antibiotics and mouthwashes are administered to maintain oral hygiene and prevent infections subsequent to salivary pooling or food retention in tongue base or vallecular wound defects.

Complications

Injury to blood vessels and cranial nerves V, VII, IX to XII; trismus; wound breakdown; dysphagia; and dysarthria may occur with the open

approach. Mandibular nonunion can result due to incomplete stabilization of the mandibulotomy site in open approaches. The complications rates are significantly reduced with TLM and skilled reconstruction techniques. Pain, bleeding, aspiration, dysphagia, or velopharyngeal insufficiency may occur following TLM resection, with a varying incidence for different oropharyngeal subsites.

HYPOPHARYNX

Etiology and Pathophysiology

Hypopharyngeal squamous cell carcinoma accounts for about 4% of all tumors in head and neck, with about 3,400 diagnosed cases in the United States, according to the most recent 2015 estimates of the American Cancer Society. It has been considered to portend a poor prognosis mostly due to the advanced stage of disease at presentation. Heavy alcohol and tobacco consumption are the two well-established risk factors. In Scandinavian regions, iron deficiency has been implicated in causation of postcricoid carcinoma in females with Plummer–Vinson syndrome.

Anatomy and Surgical Pathology

The hypopharynx extends from the level of hyoid to the lower border of the cricoid cartilage (opposite C3 to C6 vertebrae) and is subdivided into three regions—the pyriform sinus (PFS), the postcricoid area, and the PPW (Fig. 29.1). The PFS lies on either side of the larynx and extends from the pharyngoepiglottic fold superiorly down to the upper end of esophagus. It is bound by the thyroid cartilage laterally and the aryepiglottic fold and arytenoids medially. The postcricoid area extends from the level of arytenoids to the inferior border of cricoid. The PPW extends from the plane of floor of vallecula to the inferior border of cricoid. The lateral and medial wall of the PFS is continuous with the PPW and postcricoid area, respectively. The PFS is richly supplied by lymphatics that drain into the lower deep jugular chain (level IV); the inferior part along with the postcricoid area can also drain into paratracheal chain (level VI) nodes. The lymphatics from the PPW drain into the deep cervical lymph nodes bilaterally through the lateral pharyngeal or retropharyngeal nodes.

Extension of hypopharyngeal tumors beyond their subsite of origin is critical for surgical planning. PFS tumors tend to spread medially around

on to the postcricoid area and invade the posterior cricoarytenoid muscle. Laterally they extend around or invade the posterior border of the thyroid cartilage, to reach the neck and carotid sheath area. Postcricoid tumors tend to spread inferiorly and submucosally toward the esophagus, and likewise posterior wall tumors. The latter may also invade posteriorly outside the bucco-pharyngeal fascia into the prevertebral space.

Clinical Presentation

The chief presenting symptoms of patients with hypopharyngeal cancer include dysphagia, referred otalgia, neck mass, and sensation of lump in throat. Approximately two thirds of patients have nodal metastases at presentation, and most patients complain of weight loss consequent to impairment of swallowing. Other symptoms of hoarseness, aspiration, and hemoptysis may occur depending on the extension of the tumor.

Preoperative Planning

A complete head and neck examination with office fiberoptic laryngoscopy should be performed to evaluate the primary tumor and mobility of vocal cords and arytenoids. CT/MRI is required for assessment of tumor stage (Table 29.1) and extent in hypopharyngeal cancers, particularly inferior, extralaryngeal, and cartilage involvement. Ultrasound examination of neck is the preferred method for evaluating nodal metastases. Hypopharyngeal tumors are associated with high rates of distant metastasis ranging from 10% to 27% and need adequate investigation with chest x-ray, PET, and relevant laboratory tests. A direct endoscopic examination of the pharynx, larynx, and upper esophagus under general anesthesia is important for accurate evaluation of the tumor spread, for detection of synchronous primaries, and for obtaining both diagnostic and mapping biopsies. A careful endoscopic evaluation also serves to determine access for transoral approaches, criteria for partial operations versus total laryngopharyngectomies, and type of reconstruction of the pharyngeal defect following tumor resection. In patients possibly requiring a flap reconstruction, the adequacy of potential donor sites should be ascertained. Routine blood tests along with a preoperative baseline level for calcium and thyroid function are performed. The pulmonary function status should be assessed during preoperative planning of a conservation surgery since patients with inadequate pulmonary reserve are at a greater risk of aspiration.

Treatment

A combined therapy comprising surgical resection followed by adjuvant radiotherapy is the standard treatment for all stages of hypopharyngeal cancers as recommended by the United States National Cancer Institute. Conventionally, open neck procedures have been used to resect hypopharyngeal cancers, but in recent years, as an organ preserving minimally invasive strategy, the application of transoral approaches is increasing for early and selected advanced tumors of specific subsites such as PFS and PPW.

Transoral Procedures

Transoral Laser Microsurgery

Early stage hypopharyngeal tumors with minimal or no extension to the apex of the PFS or cricoid cartilage invasion can be adequately resected through transoral approach using CO_2 laser microsurgery as first described by Steiner (Fig. 29.8). The indications have expanded to include advanced PFS tumors in the hands of experienced surgeons depending on the extension of tumor, with some resections being possible down to the esophageal inlet. In comparison with open surgery, the TLM approach leads to avoidance of extensive reconstruction due to minimal resection of healthy tissues and also a diminished need of tracheotomy or dependency on feeding tubes.

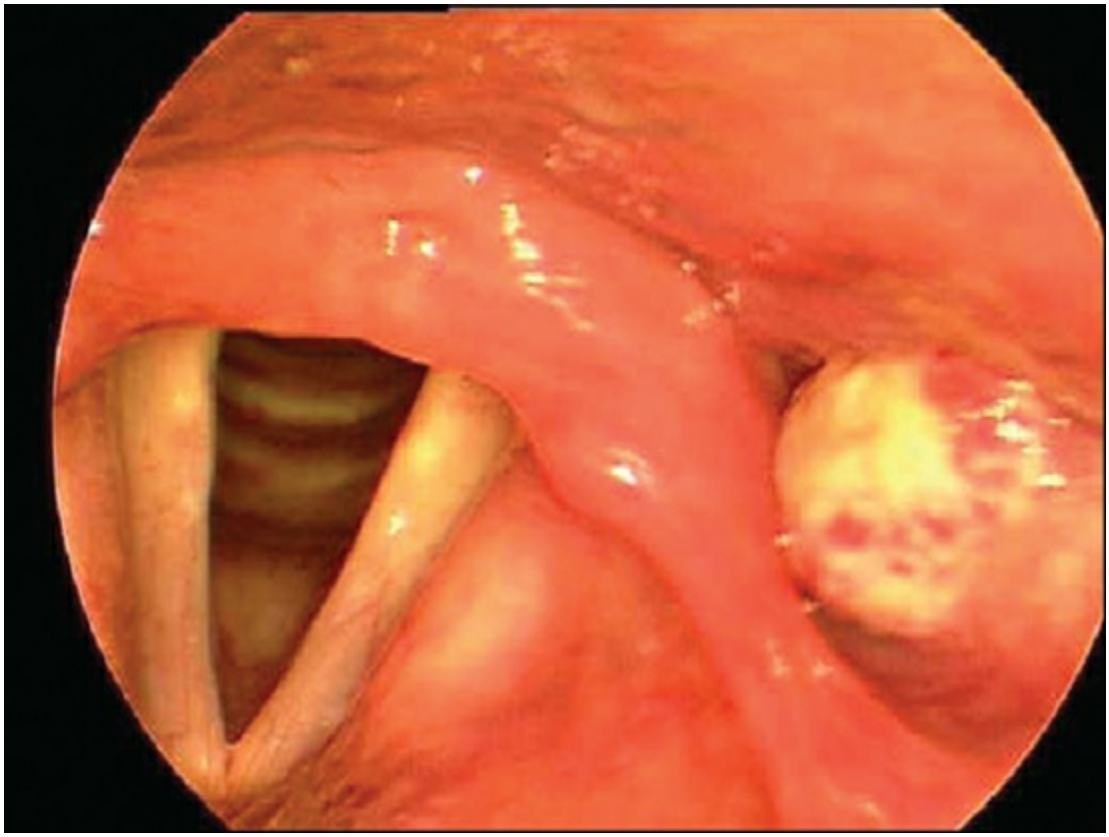

Figure 29.8. Tumor in left pyriform sinus.

The surgical principles for TLM of hypopharyngeal tumors are similar to those for resection of oropharyngeal cancer. The PFS tumors are transected to estimate the depth of tumor and resections are “multibloc,” until healthy tissue is identified and a negative margin achieved. For PFS tumors, resection is commenced laterally, from proximal to distal, and followed around the anterior extent toward the medial side. A margin of at least 5 mm for superficial small tumors and 5 to 10 mm for larger infiltrating tumors is recommended. If there is no frank invasion of the aryepiglottic fold, a relatively narrower margin can be kept for medial wall PFS tumors to avoid resection of arytenoids by carefully removing the mucosa alone in order to prevent impairment of swallowing. This precautionary technique also preserves the lateral cricoarytenoid muscle and the terminal recurrent laryngeal nerve.

Tumors confined to the postcricoid area and the posterior hypopharyngeal wall can also be excised by TLM, the former lesions being most suitable if they are superficial. Posterior wall lesions usually afford excellent access and are often ideal candidates for transoral approaches. Extension beyond the prevertebral fascia into the muscles and anterior spinal ligament are not limitations for TLM but may lead to

complications like vertebral osteomyelitis or abscess formation.

Open Procedures

Partial Pharyngectomy

Tumors of PPW that do not extend below the arytenoids inferiorly or into the PFS laterally can be excised through a lateral pharyngotomy. Smaller tumors in the lower part of PPW without any extension to postcricoid area can be adequately resected through a transhyoid partial pharyngectomy. The pharyngeal defects can be left to heal by secondary intention, or a split-thickness skin graft can be used.

Partial Laryngopharyngectomy

Partial laryngopharyngectomy is appropriate for PFS or PPW tumors, which can be excised adequately without compromising laryngeal or pharyngeal function. The tumor should not have any involvement of apex of PFS, base of tongue, postcricoid mucosa, or thyroid cartilage. The ipsilateral vocal cord and arytenoid should be fully mobile, and there should not be any transglottic laryngeal involvement. Inadequate pulmonary function is a contraindication to this procedure.

A transverse incision is made at the level of the thyrohyoid membrane. Skin flaps are elevated and strap muscles are divided for exposure of hyoid and thyroid cartilage. The suprahyoid muscles are separated from hyoid, and the pharynx is entered through the contralateral vallecula. The upper part of the thyroid cartilage is cut inferiorly and laterally with an oblique cut from the midline. Under direct view, tumor in the hypopharynx is resected, ensuring an adequate mucosal margin along with resection of the ipsilateral half of the supraglottic larynx by incising through the ventricle. A cricopharyngeal myotomy is performed, and the larynx is resurfaced by suturing the cut edges of hypopharyngeal mucosa to the edges of false cords. The base of tongue is impacted into the larynx by placing sutures between the muscles and the thyroid perichondrium to close the pharyngeal directly without tension. The cut ends of strap muscles are sutured to provide an additional layer of closure. For larger defects, a small free fasciocutaneous flap provides faster healing and better functional recovery.

Total Laryngectomy With Partial Pharyngectomy

This procedure is indicated for PFS tumors that extend to involve the apex

of PFS inferiorly, larynx medially, thyroid or cricoid cartilage laterally, or postcricoid mucosa posteriorly. A preliminary tracheostomy under local anesthesia is preferred at the onset. A long curvilinear incision is made from mastoid to mastoid, and skin flaps are elevated superiorly and inferiorly in the subplatysmal plane, exposing the sternocleidomastoid and strap muscles. The investing layer of deep fascia is incised longitudinally along the medial border of sternocleidomastoid on either sides, and the muscle is retracted laterally to identify the carotid sheath. The omohyoid tendon is divided, and the carotid artery is retracted laterally along with the internal jugular vein. The middle and inferior thyroid veins are divided, and the paracarotid tunnel is dissected down to the clavicle to allow adequate laryngeal mobilization on both sides. The strap muscles are divided inferiorly above the sternum, and are elevated to skeletonize the larynx and expose the thyroid gland. The superior and inferior thyroid pedicles are divided on the side on which ipsilateral thyroid lobectomy is to be performed. The contralateral thyroid lobe is dissected away from the larynx, and caution is exercised to preserve the inferior thyroid artery on the side. The superior laryngeal pedicle is divided on each side carefully, preserving the hypoglossal nerve and the lingual artery. The suprahyoid muscles are separated from the hyoid, and the inferior constrictors are divided from the posterolateral aspect of the thyroid lamina. The PFS mucosa is separated from the undersurface of the thyroid lamina. The tracheal wall is skeletonized and neck dissection is completed, ensuring removal of paratracheal, level IV, and VI nodes. The trachea is divided with an upward bevel about two rings inferior to the previously placed tracheostoma, following which the larynx is separated from below upward with a sharp dissection of the tracheoesophageal party wall. Intubation is continued through the newly created stoma.

The pharynx is entered through the contralateral vallecula by placing a Deaver retractor in the vallecula and making an incision at the site of its protrusion in the neck. The epiglottis is grasped through the pharyngotomy and pulled anteriorly. Lateral to the epiglottis, the pharyngeal mucosa is first resected on the less involved side, preserving maximal normal mucosa and progressing inferiorly toward the posterior part of the arytenoid. The pharyngeal wall on the side of the tumor is resected, ensuring adequate margins. The pharyngeal cuts are joined posteriorly inferior to the cricoarytenoid joint and the specimen is removed, followed by frozen section analysis of the pharyngeal margins.

For primary voice restoration, a tracheoesophageal puncture (TEP) is made between the upper esophagus and the tracheostome and a soft Silastic feeding tube is advanced through the tracheoesophageal party wall into the esophageal lumen. A primary closure in a T-shaped configuration is performed for a pharyngeal defect of less than one third of the circumference (sufficient mucosa to wrap around a 36 French dilator). Interrupted sutures between the tongue base and the pharyngeal wall form the horizontal segment of T and the vertical segment comprises interrupted/running extra mucosal inverting sutures between the edges of pharyngeal mucosae. Approximation of the strap muscles reinforces the pharyngeal repair. A tight pharyngeal closure may result in dysphagia and fistula formation and should always be avoided. For resections with greater pharyngeal defect, “patch” flap augmentation should be considered with a pedicled myocutaneous or a microvascular-free fasciocutaneous flap, for example, the ALT.

Total Laryngopharyngectomy/Total Laryngopharyngoesophagectomy

A total laryngopharyngectomy is indicated for circumferential postcricoid tumors, PFS tumors with posterior extension across midline, and advanced PPW cancer extending inferiorly below the arytenoids. The cervical esophagus may require resection in continuity. The initial steps are similar to total laryngectomy with partial pharyngectomy except that the PFS mucosa is not separated free from the thyroid lamina and the larynx and pharynx are mobilized together. Caution should be exercised to check for posterior extension into the prevertebral fascia. These patients may require microvascular reconstruction; thus, suitable arteries and veins should be preserved during the neck dissection. The pharynx is entered through the contralateral vallecula or a lateral pharyngotomy if the tumor has significant superior extension into oropharynx. Ensuring adequate margins, the pharyngeal cuts are made horizontally around the posterior wall to release the laryngopharyngeal unit followed by division of the trachea (Fig. 29.9).

Resection of cervical esophagus is indicated if hypopharyngeal tumors extend into the esophagus and complete oncologic clearance cannot be achieved with resection of hypopharynx alone (Fig. 29.10). This requires careful blunt dissection of esophagus to prevent injury of the posterior tracheal wall and absolute hemostasis of esophageal blood supply. Extensive esophagectomy will necessitate a gastric pull-up repair unless the upper esophageal stump is accessible for anastomosis to a tubed free

flap.

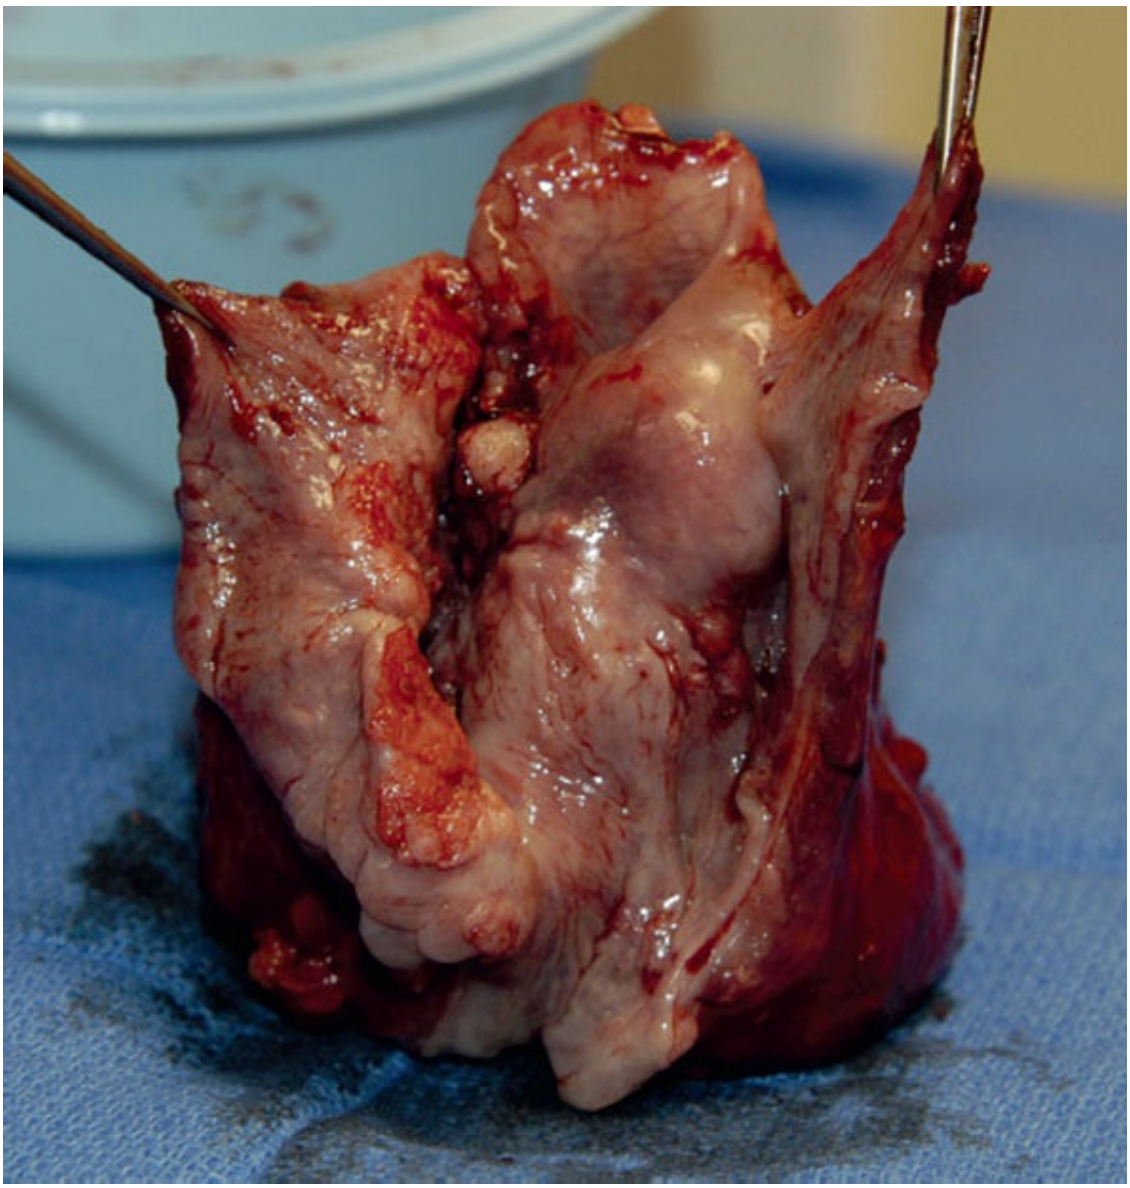

Figure 29.9. Specimen depicting total laryngopharyngectomy.

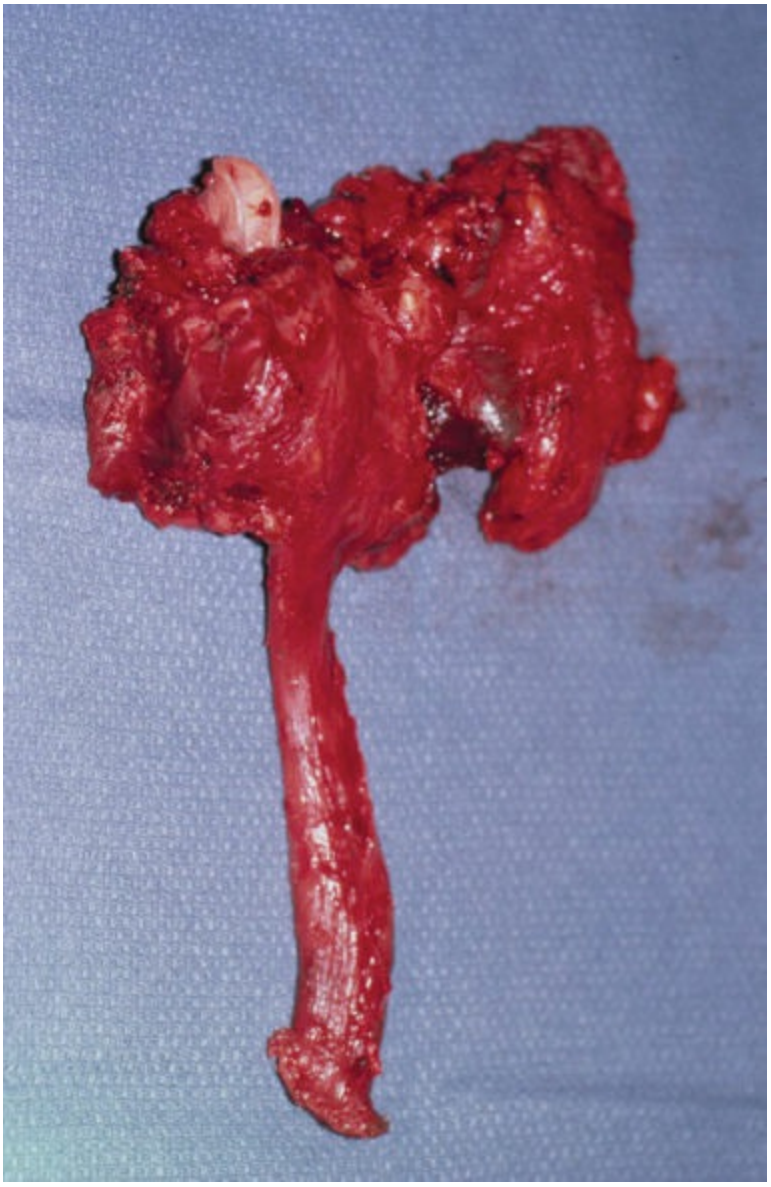

Figure 29.10. Specimen depicting total laryngopharyngoesophagectomy.

Hypopharyngeal Reconstruction

The hypopharynx represents a major functional conduit related to respiration and swallowing. Any treatment-related anatomical and physiologic disruption leads to varying severity of swallowing dysfunction and aspiration, emphasizing the importance of a competent reconstruction within any surgical procedure for pharyngeal cancers. A variety of techniques have been described for reconstruction of circumferential pharyngeal defects resulting from total laryngectomy with pharyngectomy. Free jejunal graft had been a popular option historically, but the association with donor site morbidity and poorer functional outcomes in

terms of dysphagia due to persistent muscular contractility and an unsatisfactory tracheojejunal voice shifted the focus over use of microvascular fasciocutaneous flaps (Fig. 29.11). The preferred option in our practice is a tubed radial forearm free flap. As compared with a pedicled pectoralis major myocutaneous flap, which is difficult to tube due to the muscle bulk, and enteric grafts with greater morbidity, use of a thinner, pliable tubed RFFF provides better functional reconstruction with minimal donor site problems. In patients unfit for RFFF, an ALT flap may be used if permitted by the patient's body habitus (Fig. 29.12). Free jejunal autografts are an option if none of the above techniques are feasible. Patients with total esophagectomy require a gastric pull-up procedure, which entails mobilization and thoracic transposition of stomach into the neck to restore continuity of the alimentary tract. The key surgical issues, herein, are a tensionless anastomosis at the junction between the oropharynx and stomach and an adequate pyloromyotomy for efficient gastric drainage in order to prevent postoperative regurgitation of food.

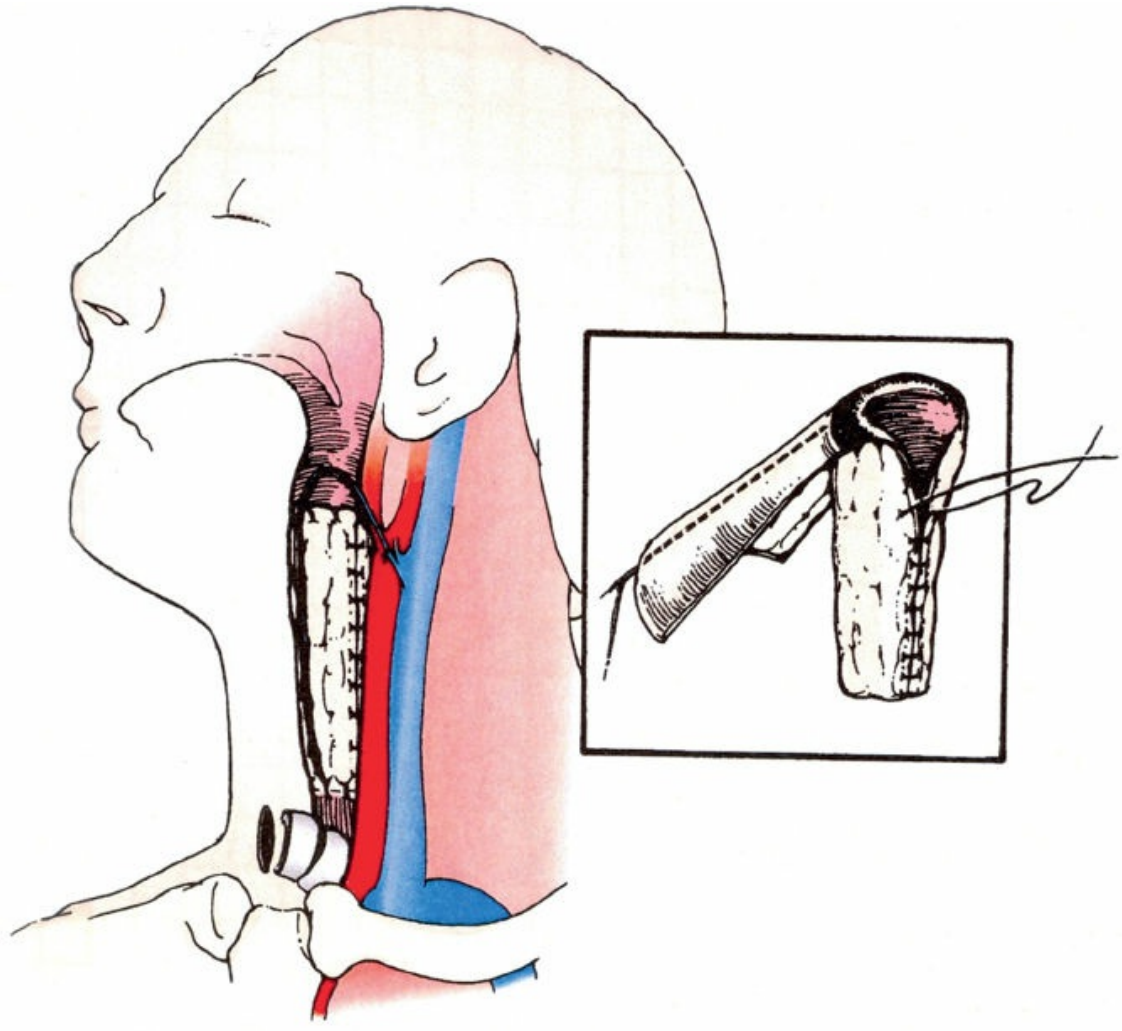

Figure 29.11. Hypopharyngeal reconstruction with a fasciocutaneous flap. Inset shows a tubed flap with an attached skin paddle that may be used for resurfacing any deficient neck skin along with pharyngeal reconstruction.

Management of Neck

A high incidence of occult metastases (30% to 40%) in hypopharyngeal cancer warrants addressing the N0 necks with selective neck dissection (level II, III, and IV). In clinically positive necks, a functional neck dissection clearing levels II, III, IV, and VI should be part of the neck management for PFS and postcricoid tumors, with inclusion of retropharyngeal nodes in the PPW. A contralateral selective neck dissection is recommended for circumferential tumors and tumors extending to or across the midline.

Postoperative Care

Patients are kept on negative pressure drains with perioperative antibiotics. Nasogastric alimentation is continued for 7 to 10 days in primary and 12 to 14 days in irradiated patients. Adequate fluid and nutritional balance, and wound and tracheostomy tube care are administered. Patients with flap reconstruction should undergo a vigilant monitoring of the flap viability along with care of the donor site. Calcium, parathyroid, and thyroid hormone levels should be assessed as indicated.

Complications

The early complications include hemorrhage, postoperative wound infection/dehiscence, pharyngocutaneous fistula, and complications related to neck dissection and flap necrosis if performed. Gastric pull-up procedures are associated with significant pulmonary complications. Late complications include stomal stenosis and dysphagia, which may be structural due to stricture formation at the inferior end of pharyngeal reconstruction or functional due to reconstruction-related dysmotility.

Rehabilitation

Swallowing and voice rehabilitation are major components of management in patients undergoing surgery for hypopharyngeal cancer. A primary TEP is the most commonly used technique for voice restoration. In patients undergoing total laryngopharyngectomy, we create the TEP in the inlet of the esophageal stump through to the infrastomal trachea, prior to

anastomosing the lower end of the flap to the esophagus. This eliminates any leakage around the prosthesis and leads to better voice outcomes. Other methods of voice rehabilitation include electromechanical devices and esophageal speech.

EDITOR'S COMMENT

Dr. Haughey and Sinha have written an incredibly comprehensive and detailed chapter on pharyngeal cancer. As a general surgeon, I know relatively little about what is described in this chapter. I find pharyngeal cancer to be an interesting disease for a multitude of reasons. First off, the epidemiology of these tumors is of interest. Nasopharyngeal cancer (NPC) is relatively rare in the United States. According to the American Cancer Society, fewer than 1 in 100,000 people in North America develop this type of cancer. Epstein–Barr virus (EBV) is heavily implicated in the development of NPC. In fact, EBV was the first virus determined to cause cancer in humans—a fact I recall learning very early in medical school. EBV is one of the most common viruses worldwide. It is estimated that 95% of all people in the United States are exposed to this virus by the time they are 30 to 40 years old. In most people, EBV causes no harm. EBV infections trigger 200,000 new cases of cancer and more than 140,000 deaths worldwide each year. Interestingly, NPC is much more common in other parts of the world. In the southern regions of China, these types of cancer are quite common and account for as much as 18% of all cancers diagnosed. This high incidence of NPC may relate to the South East

Asian diet predominant in this part of the world that includes a diet heavy in salted vegetables, fish, and meat. Environmental influences (diet and exposure to certain carcinogens), EBV infection, and genetic predisposition or mutations all play a role in the development of NPC. EBV DNA levels have in fact been demonstrated to relate to overall prognosis and survival in NPC. A meta-analysis pooled 23 eligible studies including 10,732 patients with NPC. High expression levels of EBV DNA were found to predict poor prognosis in NPC.

In keeping with the theme of viruses causing cancer (seems to be most prevalent or best described in head and neck cancers), human papillomavirus (HPV) has been implicated in head and neck squamous cell carcinoma. HPV+ head and neck squamous cell carcinoma is increasing in incidence. More than 400,000 cases of oropharyngeal squamous cell carcinoma (OPSCC) are diagnosed each year worldwide. HPV-associated OPSCC affects younger patients and often presents at a higher stage; however, it is associated with a better prognosis. A recent systematic review included 56 articles and determined that HPV+ tumors had an improved prognosis and lower rates of adverse events when compared to HPV− head and neck squamous cell cancers. HPV− cancers had significantly worse outcomes when treated with primary radiation and compared to primary surgery.

Given the evolving understanding of the etiology of head and neck cancer and the emergence of new minimally invasive treatment options, the field seems to be undergoing a bit of a paradigm shift. The surgical treatment of pharyngeal cancer has historically been associated with major resections and reconstruction procedures that lead to significant potential morbidity and functional impairment. The emergence of chemoradiotherapy as an effective treatment option has made nonsurgical therapy the primary modality of treatment. The evolving understanding of the role that HPV status plays in outcome has led some surgeons to pursue minimally invasive surgical procedures as an alternative to chemoradiotherapy in select patients. Interventions have now evolved with computerized planning and intensity-modulated radiotherapy. Endoscopic head and neck surgery options are available and can provide the potential for decreased treatment-associated morbidity. Minimally invasive techniques are increasingly being used for resection of T1–T2 lesions with no evidence of distant metastatic spread instead of primary radiotherapy. A recent Cochrane review evaluated randomized controlled trials conducted in these kinds of patients to determine the evidence to support this approach. There were no completed studies that met inclusion criteria for the review, although two ongoing trials at the time fulfilled selection criteria but were not yet complete. The ORATOR trial (early-stage squamous cell carcinoma of the oropharynx: radiotherapy vs. transoral robotic surgery) is a phase II randomized controlled trial in small volume (T1–2, N0–2) OPSCC. It is estimated that this trial will be completed in June 2021. Another trial (European Organization for Research and Treatment of Cancer 1420) is a randomized study assessing radiotherapy compared to transoral robotic surgery/transoral laser microsurgery in patients

with T1–2, N0 OPSCC and squamous cell carcinoma of the base of the tongue. This trial was to begin accruing subjects in 2016. The authors of the Cochrane review concluded: "*The role of endoscopic head and neck surgery in the management of OPSCC is clearly expanding as evidenced by its more overt incorporation into the current National Comprehensive Cancer Network guidelines. Data are mounting regarding its outcomes both in terms of survival and lower morbidity. As confidence increases, it is being used in the management of more advanced OPSCC.*" It will be interesting to see if technological advances that have led to the proliferation of minimally invasive approaches to resection of OPSCC will result in surgery once again becoming the first line of therapy for many of these tumors.

As a general surgeon who performs abdominal robotic surgery, I am very interested in the transoral robotic approach to these oropharyngeal tumors. Otolaryngologists and head and neck surgeons had relatively little experience in robotic surgery prior to the introduction of transoral surgery. The concept of a learning curve when the techniques and technology are so novel to a surgical discipline is of interest. A recently published retrospective review of a single institutional series of 382 transoral robotic surgical resections performed by one of three surgeons examined the learning curve for this procedure. Positive margin rate and time of surgery were the two metrics used to define the learning curve. While the learning curve for transoral robotic resection of OPSCC was somewhat surgeon-specific, the inflection point (learning curve) was between 20 and 30 cases. When discussing robotic surgery, the issue of cost and cost-effectiveness is bound to come up. A microsimulation state transition model was developed to compare transoral robotic surgery to radiation therapy in OPSCC. Transoral robotic resection was associated with modest gains in quality-adjusted life years (QALYs). Radiation therapy yielded 10.43 QALYs at a cost of $123,410 per patient, whereas transoral robotic surgery yielded 11.10 QALYs at a cost of $178,480. This resulted in an incremental cost-effectiveness ratio of $82,190/QALY gained. The authors determined that transoral robotic resection may be a cost-effective alternative to radiation therapy in early OPSCC, but this was very sensitive to assumptions made in the model around quality of life after the two treatments.

Minimally invasive, transoral surgery has many limitations including difficult access to critical anatomic structures in a very confined space. The daVinci robotic surgical system provides several features that facilitate the transoral resection of early oropharyngeal cancers. These include three-dimensional and high-definition visualization, long robotic instruments that articulate at the tip and are capable of precise and complex maneuvers without tremor, and better ergonomics for the surgical team. If one were to design a robotic surgical system specifically for transoral surgery, the operating system would include smaller instruments with more flexibility and better hemostatic options for removing tumors from highly vascularized areas. There are numerous robotic surgical systems that should hit the market within the next 5

to 10 years that may address many of the shortcomings of the current system. As trials continue and experience with robotic techniques increases, it is likely that robotic transoral techniques for oropharyngeal cancer resection will become more commonplace if oncologic outcomes are proven to be equivalent to the current standard.

Finally, as a lifelong fan of Major League Baseball, I would like to take up a paragraph here examining the role of chewing tobacco and snuff on oropharyngeal cancer. Babe Ruth died from nasopharyngeal carcinoma in 1948 at the age of 53. It is said that his fondness for tobacco and liquor led to his cancer. More recently, Hall of Famer Tony Gwynn who played for the San Diego Padres his entire career died of parotid cancer. Although the link between chewing tobacco and parotid cancer is not clearly defined as it is for pharyngeal cancer, Tony and his family were convinced that more than 30 years of chewing tobacco led to his cancer. Other notable major league players to develop head and neck cancer most likely due to long-term abuse of chewing tobacco include Curt Schilling, Brett Butler, and Bill Tuttle. A recently published pooled analysis of 11 US case-control studies of oral, pharyngeal, and laryngeal cancers revealed that smokeless tobacco use appears to be associated with head and neck cancer, especially oral cancers, with snuff being more strongly associated than chewing tobacco. Among people who have never smoked, the odds ratio for developing oral cavity cancer with snuff was 3.01 (95% CI: 1.63, 5.55). An estimated 25% to 30% of Major League Baseball players chew tobacco. In 2016, Major League Baseball and the players union reached a collective bargaining agreement that bans chewing tobacco for new players. Current players were grandfathered in under the ruling.

Overall, this is an excellent and informative chapter on a topic about which I previously knew relatively little. I found this chapter to be extremely interesting and relevant. I highly recommend that surgeons take the time to familiarize themselves with the content of this chapter.

30 Malignant Melanoma and Skin Cancer

Hiram C. Polk, Jr., Jane V. Carter, and Uri Netz

INTRODUCTION

An important, albeit underappreciated, part of a practicing surgeon's work is the diagnosis and treatment of skin cancers, mainly melanoma and squamous cell carcinoma. The most important change in the last 50 years has been the improvement in early diagnosis, resulting from better awareness of both patients and physicians to the results of exposure to the sun, and the importance of routine skin checkups and biopsies of suspicious lesions. This has led to an increasing number of patients being diagnosed at an earlier stage, and thus allowing more curative treatment and longer-term survival. The effect of early diagnosis has been made even more significant by a higher incidence of melanoma worldwide. This is probably related to increased exposure of the general population to the sun. The traditional victim, a family farmer who has been chronically exposed to the sun, has been altered politically and demographically to include nearly anyone. An important cause has been the increasing use of tanning beds. Indoor tanning beds, emitting mainly ultraviolet A (UV-A) radiation (>320- to 400-nm wavelengths), were previously believed to be safe, since UV-B (>280- to 320-nm wavelengths) radiations were believed to be the main risk factor for skin cancers. However, recent evidence has shown that tanning beds clearly increase the risk, especially with repeated exposure at young ages, with more than 10,000 melanoma cases and 450,000 nonmelanoma skin cancers said to be attributable to indoor tanning each year in the United States, Europe, and Australia. Although most melanomas are initially suspected and diagnosed in the offices of dermatologic specialists and family practitioners, the work-up and main treatment of potentially curative disease are in the hands of surgeons, thus stressing the importance of correct staging and treatment.

PATHOGENESIS

Some melanomas arise as changes in existing ordinary moles, while others appear to arise *de novo.* Risk factors for development of malignant melanoma are fairly well described. Particularly at risk are fair-complexioned people, often with blonde or red hair, and who typically reside between the Tropic of Capricorn and the Tropic of Cancer, predisposing them to heightened sun exposure and ultraviolet irradiation. Good examples of the prototypical high-risk population are individuals of Celtic heritage who emigrated to Australia over 100 years ago. Melanoma is more common in men who also have a worse prognosis. Another factor is the number of moles that exist in an individual patient, which may or may not be complicated by a history of sunburns. The tendency to have multiple small dark moles is frequently inherited. As such, parents as well as children of melanoma patients should be examined, not only to determine what the pattern of their moles may be, but also to look for new primary melanomas in an often unsuspecting population.

Sun exposure, particularly of the blistering type, during the period of teenage hormone bursts is especially important. Although the method by which data were collected is questionable, the reference to two or more blistering sunburns during teenage years as a causative factor has found its way into the literature, and is probably accurate. The use of sunblock containing a broad spectrum sun protection factor (SPF) protects the skin from harmful UV-A and UV-B irradiation. If sun exposure exceeds 20 minutes a day, we advise wearing sunblock of at least 30 SPF, and if used on a regular basis, may actually allow some repair of damaged skin.

It is commonly said that large birthmarks are not at risk for melanoma, including even bathing trunk nevi. This assertion is clearly untrue. An unknown proportion of these individuals acquires invasive melanoma at multiple sites within the large nevus at a later stage. When they begin to develop in such longstanding large pigmented lesions, melanomas are virtually impossible to detect by even the most attentive patients, family members, and specialist-physicians.

As stated earlier, maximum risk coincides with heightened hormonal periods, such as the teenage years and pregnancy. Pregnancy, in and of itself, has been debated as predisposing to the development or the overt clinical spread of existing melanoma. Recent data have demonstrated poorer outcomes for melanoma during pregnancy after adjustment for age and stage. The senior author has cared for at least five women who subsequently produced soon-to-be orphans, owing to progression of their

melanoma during their pregnancies. The elaboration of melanocyte-stimulating hormone (MSH) responsible for darkening of the nipple-areolar complex in pregnant women is believed to be a factor, although this remains largely unproven. This risk factor requires some very careful thought by the treating physician, particularly related to the tendency of women to have their first pregnancies at a later age, which naturally diminishes the opportunity to bear subsequent children. A current systematic review concluded that melanoma is not adversely affected by pregnancy; however, only 5 out of 304 papers were relevant and only 1 paper included melanomas beyond stage 1. Our own recommendation is that a woman who has, or had, a melanoma thicker than 1.5 mm, and/or is ulcerated or nodular, should not become pregnant during the first 5 years after such diagnosis. These alternative factors of thickness, ulceration, and conformation supervene to indicate that pregnancy avoidance or even termination becomes clinically more significant. Here lies a major test of a patient's trust in her melanoma surgeon. Fewer obstetricians are aware of this unusual risk. Whether or not pregnancy itself predisposes to melanoma is less clear. However, oral contraception is well known not to predispose to melanoma.

Overt immunosuppression, either as the result of cancer chemotherapy or as agents used to suppress host responses to solid organ or bone marrow transplants, also predisposes to new or recurrent melanoma. Obviously, physicians and patients do not undertake transplant immunosuppression lightly. However, in patients with previously diagnosed and treated melanoma, increased frequency of surveillance is warranted. Also, it appears that *de novo* melanomas can develop more readily in this scenario. The immunosuppressed patient warrants special attention, with at least annual examinations for a variety of skin cancers that include either new or recurrent melanoma and squamous cell cancer. Survivors of childhood cancers, especially those treated with radiation are also prone to develop melanoma later in life and should be screened annually.

The dysplastic nevus syndrome is a relatively rare phenomenon that generally consists of more than 100 moles, and, frequently, as many as a 1,000 on a fair-complexioned person. Here, the dominant pattern is a relentless conversion of these moles to invasive melanoma; again, these can be accentuated by the waxing and waning of hormones during teenage years or early adulthood. The optimum surgical management of these patients is unclear, although the senior author has never been able to clear

the number of lesions as rapidly as new primary melanomas appear to progress during the course of this illness once the first melanoma is detected.

CLINICAL PRESENTATION AND DIAGNOSIS

Diagnosis of melanoma has been simplified through the brilliant and imaginative work of the Queensland Melanoma Project led by the late Professor Neville Davis. “A-B-C-D” is a simple mnemonic that can be applied by virtually any physician or nurse practitioner to distinguish moles that possess malignant characteristics. Figure 30.1 demonstrates the different characteristics.

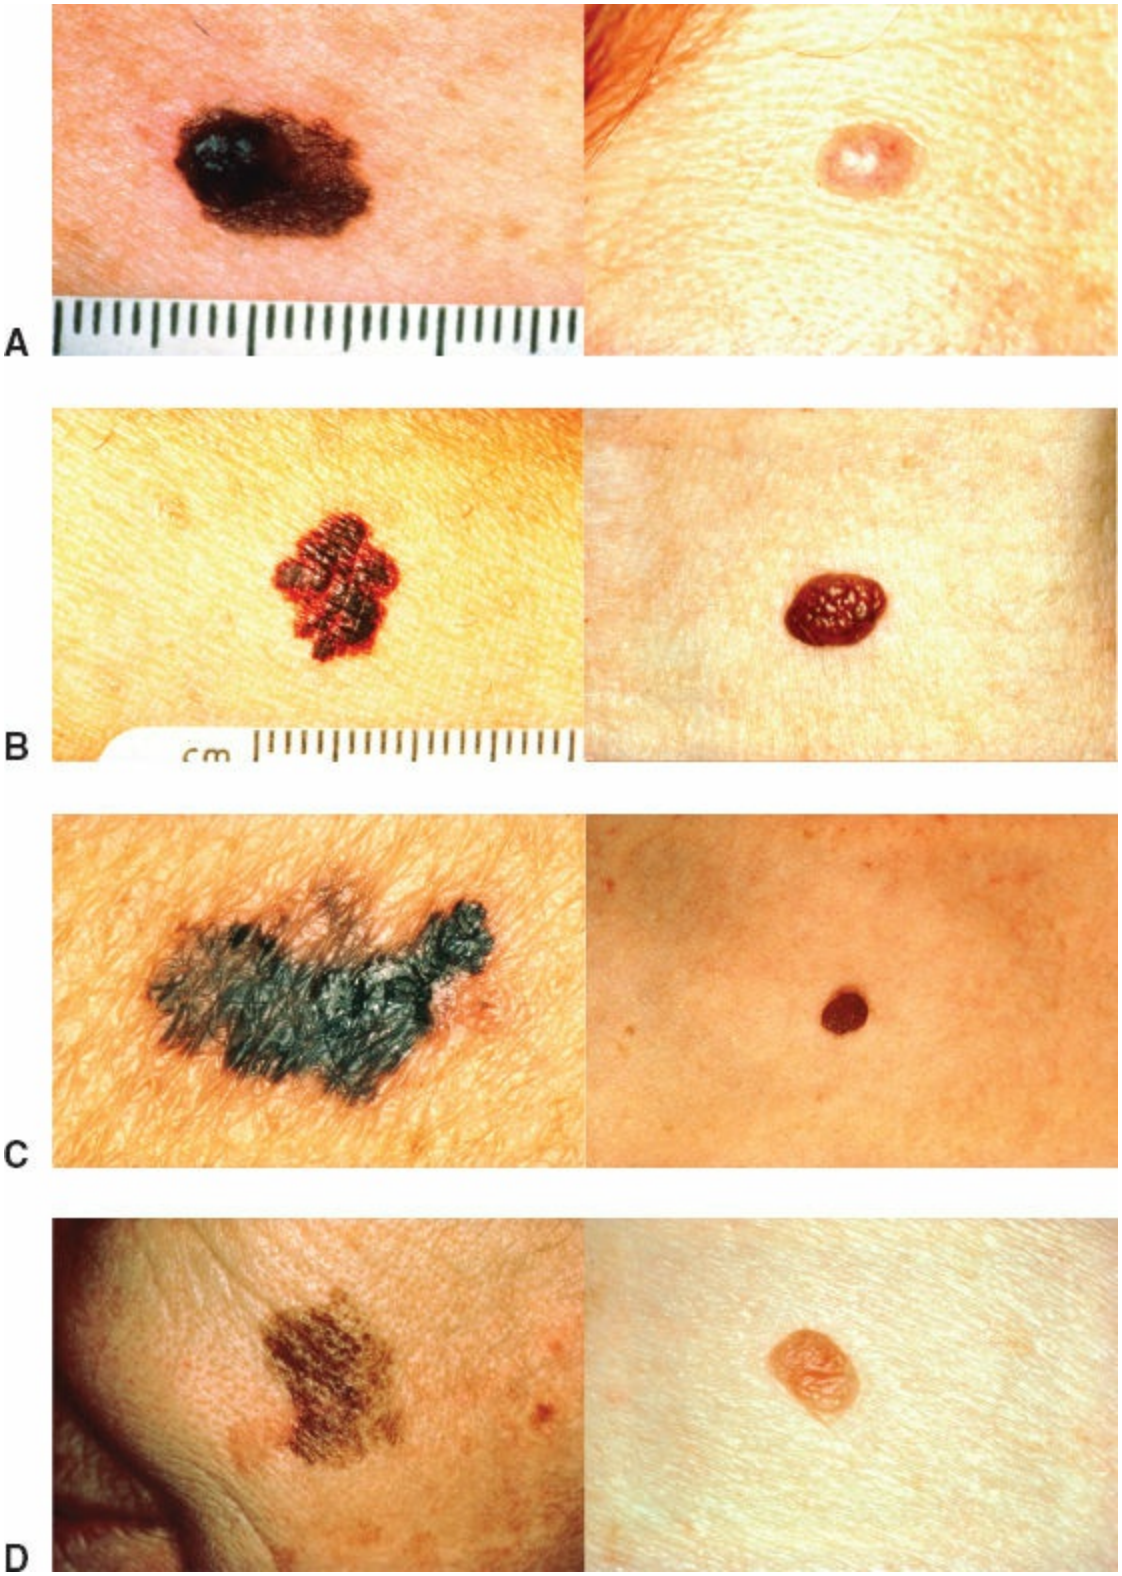

Figure 30.1. On the left are abnormal malignant melanomas as compared with benign moles for comparison on the right side. Moving from top to bottom shows asymmetry (**A**) within the malignant mole, irregular borders (**B**), different colors (**C**) within the melanoma (*black, brown,* and *tan*), and a diameter (**D**) greater than 6 mm, which is indeed suspicious.

A Asymmetry, where one half looks dissimilar to the other half.
B Irregular Borders are notched margins seen to occur in some relatively large moles.
C Uneven Coloration is especially characteristic of melanoma, with parts of the lesion often being light tan to brown to black.
D Finally, Diameters greater than 6 mm are more prone to be associated with melanoma, and are therefore suspicious.

As simple as this concept is, it is the backbone of early diagnosis by doctors, nurses, and other health care professionals. It can readily be applied to self-diagnosis through the distribution of simple patient education material. It should be part of the diagnosis for every melanoma, in both patients and their blood relatives. Since then, an **E** for Evolution has been added, inciting change in shape, size, symptoms, etc. Another useful concept is the "ugly duckling sign," implying heightened suspicion of lesions that do not match an individual's typical nevus phenotype.

There are two other variants of melanoma that remain very difficult to diagnose. The first is the amelanotic melanoma, which is difficult to differentiate among a variety of exotic dermatologic lesions, squamous cell cancer, and local fungal infections. A high degree of suspicion may be a trite word, but is virtually the only guide for any nonpigmented ulcerated skin lesion. The other lesion with this special difficulty in diagnosis is the subungual melanoma that occurs commonly on the feet. Inevitably, all patients have a history of having struck their toenails; many thoughtful physicians will have made a diagnosis of subungual hematoma. The nature of the subungual melanoma, however, is indicated by its tendency to push or elevate the nail, to bleed, and to be painful. Any question about the presence of a subungual melanoma needs to be followed by de-roofing of the lesion and an adequate incisional biopsy or curettage of the specimen.

The patient's signs or symptoms in these circumstances are enormously helpful to a physician who suspects melanoma. Lesions tend to itch, bleed, and change in size or color. Any of these is significant, particularly when combined with the observational "A-B-C-D-E" algorithm.

BIOPSY CONFIRMATION

The preferred biopsy, unless the lesion is very large, is a local excision with 1- to 2-mm margins, which will effectively deal with the occasional benign pigmented seborrheic keratosis, and, at the same time, provide an accurate thickness of melanoma and cell type, if it is present. In other

words, this should extend just into the full thickness end of the subcutaneous fat (Fig. 30.2). In part, because of the progressively earlier diagnosis of melanocytic lesions, errors of omission have begun to occur. It is sobering to recognize that nearly 2% of melanomas are not called such in North America. To some degree, the clinician can override such a potential effect by simply re-excising locally (1- to 2-mm margins) any suspicious or ambiguous lesions, and subsequently asking for a second, or even third, pathologic opinion. The minimal increase in scar or scarring is more than offset by an ultimate improved accuracy of pathologic diagnosis.

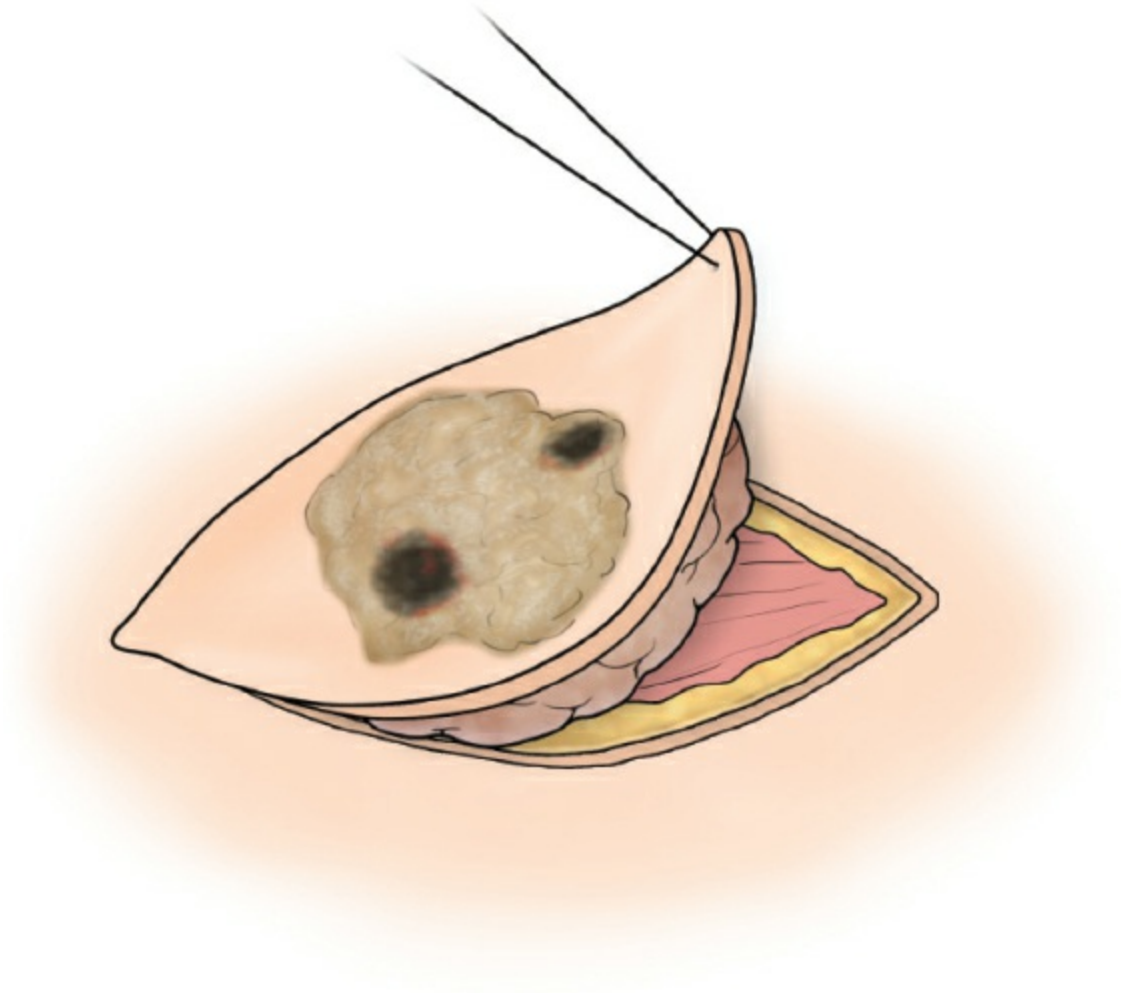

Figure 30.2. The preferred biopsy is a local excision with 1- to 2-mm margins, which will effectively deal with the occasional benign pigmented seborrheic keratosis, and, at the same time, provide an accurate depth of melanoma and cell type, if it is present. This should extend just into the full thickness end of the subcutaneous fat.

If the lesion is large or located on the face, one may opt to excise a simple 1- to 2-mm pie-shaped wedge from the edge of the lesion, choosing whichever edge by palpation is the more highly elevated. In fact, any ulcerated and/or elevated nonhealing skin lesion is at risk of being a malignant melanoma, squamous cell carcinoma, or basal cell carcinoma, and is properly treated with a 1- to 2-mm margin of excision. Depending on the location, once again, it is closed using simple closure with reconstructive methods, such as rotational flaps, used only where absolutely necessary.

Finally, the most important recommendation is take no chances; biopsy any lesion that is even remotely suspicious. The risks and discomfort are slim compared to the great advantage of early diagnosis on morbidity and mortality. For this reason, we tend to accept almost any type of tissue diagnosis, including shave biopsies. In fact, any piece of a melanoma that helps make the diagnosis is helpful. By accepting imperfect diagnoses, one helps promote an earlier biopsy on the part of practitioners, who for various reasons do not possess broader surgical skills. Actually, we have often said that the only form of biopsy that is absolutely contraindicated is cauterization; smoke under the microscope seldom looks like melanoma. As a result, this must be avoided at all costs.

LOCAL STAGING

There are three major factors affecting localized staging: depth, mitotic rate, and ulceration. The tumor-node-metastasis (TNM) system is the mainstay of clinicopathologic staging for melanoma and most other cancers. The initial observations by Clark and associates suggested that the depth of invasion of melanoma down into the skin and subcutaneous tissues was important prognostically. This observation was given much sharper focus by the work of Breslow, who simply quantified the depth of invasion, not by the various layers of the skin, but by depth of maximum melanoma invasion in millimeters. This latter figure is regularly interpreted accurately and has nearly a one-to-one relationship with prognosis. Prognostically, it is well known that melanomas less than 0.75-mm thick carry 99% cure rates with long-term survival. The senior author has only seen 2 of more than 1,000 such cases metastasize without explanation. Mitotic rate has been identified as an independent predictor of survival. In clinically localized melanoma, it has been found to be the second most powerful predictor of survival after depth. A threshold of 1

mitosis/mm^2 has been statistically correlated with decreased survival. Tumor ulceration also has a negative effect on prognosis. Survival rates of patients with an ulcerated melanoma are clearly lower per equivalent depth compared to nonulcerated cases.

TREATMENT OF THE PRIMARY LESION AND SURGICAL TECHNIQUE

The treatment of malignant melanoma focuses upon adequate local excision. In fact, this is true for most forms of cancer, but is especially important here. In general, the deeper the tumor, the wider the clinical margins needed (Table 30.1). In most cases, a peripheral margin of a centimeter per millimeter thickness is required according to the depth of the tumor. Margins of more than 2 cm have been said not to improve overall survival, regardless of the depth of the tumor; the senior author doubts this statement. It is important to measure and mark the required margins before beginning the incision in order to achieve the proper distance from the tumor in all directions. Proceeding via an elliptical incision in the line of skin creases allows for a generous wide local excision of the primary tumor and simple expansion of the resected margins as required. The elliptical wound permits simple wound closure, with or without flaps, and cosmetic defects are kept to a minimum especially when the wound can be closed in line with skin creases. Skin grafts are seldom required, unless lesions are in functionally important areas such as the hand, the ankle, and around the elbow. In general, a melanoma 1-mm thick or greater that occurs in the subungual position is best treated by digit amputation; few thin ones are detected.

TABLE 30.1 Recommended Margins of Resection According to Depth of Primary Tumor

Tumor Thickness	Recommended Excision Margins (cm)
In situ	0.5–1
≤1.0 mm	1
1.01–2 mm	1–2
2.01–4 mm	2 or more
>4 mm	2 or more

LYMPH NODE CONSIDERATIONS

As the extent of tumor invasion progressively deepens, the risk of lymphatic spread increases. Patients with involved regional lymph nodes without distant metastases benefit from regional lymphadenectomy, improving survival. Clinical palpation of lymph nodes in the hands of surgeons who care for cancer patients is a process that is approximately 80% accurate. However, that is not sufficient, as many are still missed, and a significant proportion has micrometastases, which will be missed on imaging as well.

The practice of sentinel lymph node biopsy (SLNB) has arisen for melanomas and has been shown by our unit and others to be of increasing value toward the overall care of the patient. The number of lymph nodes involved correlates with overall survival, which decreases as the number of involved nodes increases.

Any patient who has a palpable lymph node in the immediate regional distribution in which the melanoma has developed needs to be considered for a lymph node biopsy and/or often a formal node dissection (based on palpation of the nodes) at the time when the primary lesion would be excised. There is no excuse for a limited operation on lymph nodes, that is, less than a full standard radical lymphadenectomy in the relevant body part, but complete excision of the primary tumor is the most important factor in survival. This applies particularly to the neck, in which a sternocleidomastoid muscle can be preserved, to the groin in which the deeper iliac nodes should generally not be excised, and to the axilla.

Surgeons must recall that lymph node dissection should be complete to fascial plane margins as described by Spratt et al. About one fourth of such patients can still be salvaged by a delayed complete regional lymph node dissection only.

Initially, SLNB was applied to melanomas with ambiguous drainage with respect to the dorsal and ventral surfaces of the body and/or the waistline. Occasionally, more than one lymph node basin will contain sentinel nodes in the same patient. This technique and many of its ramifications were developed by Morton, and subsequently perfected in our region by Edwards and McMasters. Its importance is evident in Table 30.2. Technical issues have been discussed repeatedly. It is important to realize how valuable the SLNB can be in the overall care of the melanoma patient. Obviously, melanomas less than 1-mm thick very rarely have node involvement, and rarely require SLNB. Such thin melanomas should, however, be considered for SLNB if the biopsy is suspected of being inadequate, ulceration is found, or high mitotic rates are present. Patients with melanomas thicker than 1 mm should have an SLNB, unless there is a compelling reason to the contrary. Lymph node involvement that is recognized by SLNB and followed by completion lymphadenectomy has been shown to improve survival in comparison to watchful waiting and performing lymphadenectomy only when overtly clinically positive nodes appear.

In general, the accuracy of the SLNB, using isosulfan blue dye and technetium-99m sulfur radioisotopes, exceeds 95%, with a capacity to detect micrometastases when combined with microscopic pathologic examination (Fig. 30.3). It is never perfect; the alert clinician should always be aware that the procedure is not infallible. For example, it is infinitely less helpful with head and neck melanomas, in which the distance between the primary lesion, which must be injected with radioisotope, and the pertinent nodes is very close. This is in contrast to a melanoma on the foot, which drains to the groin in virtual uniformity.

Although seldom emphasized, an important benefit of SLNB is the one that does *not* yield microscopic-positive melanoma but permits the psychological benefit gained in a patient who can avoid a high degree of anxiety, unnecessary testing, and the considerable side effects and expense of bio-chemotherapy. An individual with a 2-mm thick nonulcerated melanoma that has been adequately excised and treated and then has negative lymph nodes simply needs to see her or his surgeon on a regular

basis and be examined for local recurrence, not only at the site, but also in the regional draining lymph nodes. Palpation of the groin, axilla, and supraclavicular spaces in the head and neck is easily done and affords a high degree of accuracy. Depending on the thickness of the melanoma, this examination needs to be done relatively frequently in the early years following excision, and progressively less frequently across a follow-up period that should last for at least 5 and, in many cases, 10 years. Such follow-up must include an examination of all skin aspects. Have the patient, wearing minimal underclothes, stand and be inspected from head to toe, paying close attention to the soles of the feet and the backs of the thighs, which are spots frequently missed by most patients. A second primary melanoma occurs in at least 8% of patients who have been successfully treated for a first primary lesion. This is especially important, because these people with an early diagnosis favorable for primary melanoma have a high likelihood that other areas will also develop disease, as these areas will also have been similarly sunburned, similarly blistered, and at similar times. Nearly one third of patients who develop a second invasive melanoma will have a third melanoma, and the rate of metachronous primary melanomas continues to rise from there.

TABLE 30.2 Multivariate Hazard Ratios for Disease Recurrence and Death Among Patients With Intermediate-Thickness Melanoma Who Underwent Sentinel-Node Biopsy, According to Prognostic Indicator

	Disease Recurrence		Death From Melanoma	
Prognostic Indicator	Hazard Ratio (95% CI)	*P*-value	Hazard Ratio (95% CI)	*P*-value
Sentinel-node status (positive vs. negative)	2.64 (1.92–3.64)	<0.001	2.40 (1.61–3.56)	<0.001
Breslow thickness (per 1-mm increase)	1.62 (1.31–2.01)	<0.001	1.59 (1.21–2.09)	<0.001
Ulceration (present vs. absent)	1.40 (1.04–1.89)	0.03	1.79 (1.24–2.58)	0.002
Site of melanoma				
Arm or leg[a]	1.00		1.00	
Trunk	1.42 (1.03–1.94)	0.03	1.91 (1.26–2.88)	0.002
Head or neck	1.20 (0.77–1.86)	0.42	1.19 (0.65–2.16)	0.58
Sex (male vs. female)	0.94 (0.70–1.26)	0.66	1.22 (0.82–1.79)	0.32
Age (per 1-yr increase)	1.01 (1.00–1.02)	0.07	1.01 (0.99–1.02)	0.33
Clark level (IV or V vs. III)	1.27 (0.94–1.71)	0.12	1.07 (0.74–1.54)	0.73

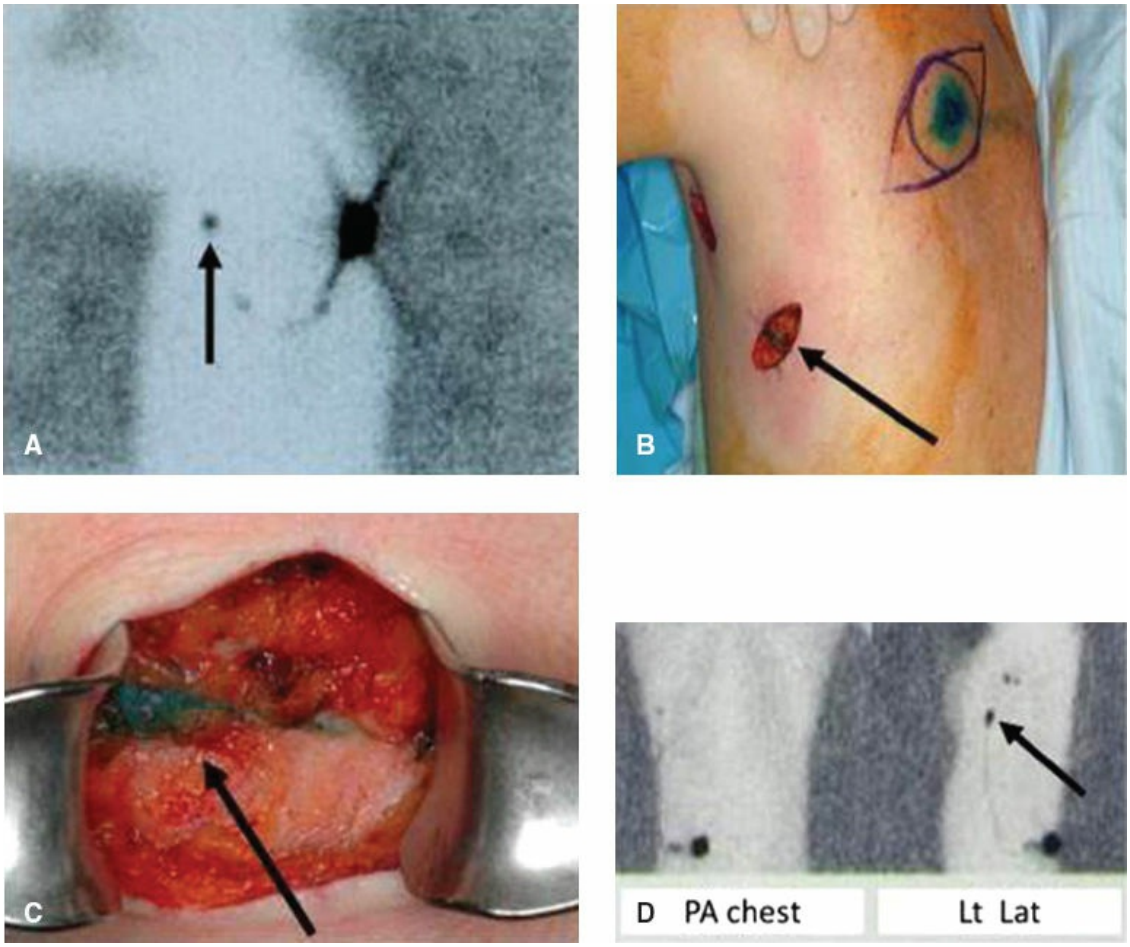

Figure 30.3. **A.** Lymphoscintigraphy demonstrating an in-transit node. **B.** Operative views demonstrate the node location in relation to the primary and draining nodal basin. **C.** With a blue node and afferent lymphatics evident on close-up view. **D.** A similar lymphoscintigraphy pattern with an in-transit node was seen in another patient. The arrow indicates blue lymphatic channels leading into a blue lymph node. (Reprinted from Ross MI, Gershenwald JE. Sentinel lymph node biopsy for melanoma: a critical update for dermatologists after two decades of experience. *Clin Dermatol* 2013;31(3):298–310. Copyright © 2013, with permission from Elsevier.)

In the current surgical literature, guidance on how to proceed with patients who have positive SLNB is not always apparent. In the first instance, understanding that these patients will require a standard or complete regional lymphadenectomy in the involved body part is critical. Once the procedure has been completed, one can, with confidence, provide pathologic data from the original lesion and regional draining nodes to medical and surgical oncologists for assessment of the need for additional systemic therapy. If there is only a single node involved, and the patient's

ability to tolerate the morbidity of therapy is impaired, then one could choose to withhold additional therapy. In general, multiple positive lymph nodes warrant systemic therapy of some sort. We continue to feel that the advantages are slightly in favor of treatment. However, the side effects of interferon alpha-2b are substantial. Many highly motivated patients do not complete their course of therapy because of significant side effects. Conversely, the value of systemic therapy in these patients continues to be debated. Systemic treatment is more frequently said to enhance 5- to 10-year survival in these patients. A recent review concisely and honestly debates the value of new and targeted systemic therapies. However, a substantial number of thoughtful patients may choose to decline such treatment and simply depend upon their surgeons for further regular follow-up, choosing to treat recurrent melanoma when and where found.

The outrageously expensive use of positron emission topography (PET) scanning for patients must be carefully considered before requesting such tests. It may become a collateral casualty of new broader health care insurance in the United States, which will inevitably pursue cost-cutting measures—a worthy casualty. PET scanning for melanoma, unless carefully applied to select genuinely, high-risk patients, yields as many false-positives as true-positives. It is well accepted that there is low yield of discovery of metastatic disease from PET in patients with stage I and II disease; however, the sensitivity and specificity of identifying metastases increase dramatically for patients with stage III or IV disease. It may also be enormously helpful in patients who have had previously positive lymph nodes, where it should be done annually initially after the primary resection. A major issue, aside from its expense, is that the positive PET scan often needs to be confirmed by tissue diagnosis, and that needs to be done in both a minimally morbid and yet definitive way. It should be assumed that the PET scan followed by biopsy confirmation creates a treatment environment that can be tolerated by the patient in order to proceed accordingly.

The majority of melanomas that recur either do so locally or in the body region initially involved and are detected on physical examination by the treating surgeon. Systemic disease occurs in well less than one third of patients treated surgically. As the tumor becomes progressively more favorable, the likelihood of systemic metastases decreases precipitously. Local recurrence, or in-transits, an “inner circle” name for intradermal lymphatic metastases, can be readily identified by physical examination.

In-transit lesions are more readily palpable than they are visible. Any nodular lesion that occurs on the body part from which the melanoma arose should be biopsied within a few weeks of its detection. When these lesions are confined to an extremity, hyperthermic isolated chemotherapeutic perfusion is a standard therapy that will stop progression permanently for about one third of patients, significantly arrest progression for another third, and have relatively little impact on the final third. We have experienced a large number of isolated extremity perfusions undertaken either for prophylaxis or for extremely unfavorable primary tumors (i.e., greater than 5-mm thick, positive regional lymph nodes, or in-transit recurrence). More than 400 such operations yielded two deaths and two amputations. One dozen patients developed significant leaks of the chemotherapeutic material, which resulted in leukopenia that required additional treatment. These patients all recovered, however. In-transit disease that is not amenable to perfusion can often be treated by simple but repeated local excision. The process through which the disease progresses is highly variable; simple local excision can allow some patients to remain lesion-free for long periods of time. There is clear evidence that the dermatotrophic variant of melanoma (i.e., those that are prone to recur in the skin or metastasize in the subdermal lymphatics) runs a very leisurely and seldom aggressive course, which adds an element of confidence to the conservative management of the patient.

NEW SYSTEMIC TREATMENTS AND ADVANCED DISEASE

Surgical excision with clear margins remains the primary curative treatment modality of melanoma. Almost all early-stage disease (in situ, I and II) and resectable stage III melanoma can be treated in this way in combination with evaluation of the regional lymph nodes. Patients who are at higher risk for recurrence, typically stage IIb and above, have been treated with adjuvant high-dose interferon alpha-2b or pegylated interferon. More recent evidence has suggested that neither of these medications improves overall survival in this group of patients, and currently newer therapies that have been shown to improve survival in recurrent and metastatic disease are being tested in clinical trials for use as adjuvant therapy. Isolated limb perfusion continues to be indicated as a treatment modality in patients with multiple lesions in a single extremity or recurrent disease in a single limb.

The treatment of more advanced disease such as unresectable stage III, stage IV, and recurrent melanoma is rapidly changing. Chemotherapy and palliative local therapy continue to be recommended as treatment for advanced or metastatic melanoma. Recent years have seen an emergence of novel therapeutic agents that show better efficacy than standard chemotherapy. Immunotherapy and signal-transduction inhibitors used as single agents, or in combination, have demonstrated increased overall survival. Currently, there are clinical trials investigating whether they can actually cure some cases of metastatic disease. An interesting dilemma, considering the heightened effectivity of the new systemic agents, is whether to treat earlier stage disease with adjuvant drugs to try to reduce recurrence or metastases. Using these drugs for cases that have had a potentially curative operation is a current subject of debate, considering their serious risks and side effects.

DISEASE RECURRENCE

There are at least two more unusual characteristics of melanoma. The first is the late recurrence of disease, which Morton called “dormant.” While unlikely, there is a variant of very late (some more than 25 years) recurrence of melanoma; in all those whom the senior author has seen, progression of disease was then rapid. This is easy to recognize and understand in patients who have been affected by systemic immunosuppression, such as that associated with organ transplantation. However, late recurrence does occur in otherwise unaltered patients and justifies some form of longer-term follow-up, either through the conscientious referring physician, or by the surgeon. Follow-up for such recurrence is, once again, easily conducted by thoroughly examining the undressed patient in good light. The other issue worthy of attention, of course, is management of a second primary. Interestingly enough, these tumors are only slightly prognostically, but not significantly, better than the first primary. One might assume that patients who have had one melanoma would demonstrate a heightened awareness to themselves using the “A-B-C-D-E” algorithms and looking for simple symptoms. One might also assume they would have the wisdom to stay out of the sun on Memorial and Labor Day holidays, with a complete avoidance of tanning beds. However, those assumptions about wise patient behavior are only infrequently true, and the informed physician’s attention to these patients is especially valuable.

What complicates this issue is the fact that 1% to 2% of all melanomas now identified in many states will have had the diagnosis missed by Board-certified pathologists. There is an ongoing argument between dermatopathologists (that is a specialty of dermatology) and pathologists skilled in skin lesions as to who identifies melanomas most accurately. In fact, as we have now advanced toward more in situ disease and the development of dysplasia, atypia, and otherwise normal moles, the pathologic landscape has become increasingly confusing. The fact that these lesions may be missed by even a good pathologist paradoxically simplifies their surgical management! If in doubt, any new lesion in a patient who had been treated for melanoma should be presumed to be a new primary, and a full-thickness local excision should be carried out by the treating surgeon, again, as guided by the body part involved and size of the lesion in question.

A further unusual characteristic relates to occasional reports that still appear about the extirpation of melanoma metastases to other viscera. In general, these are associated with a grave prognosis. Survival is approximately 100 days, and surgical approaches in treating such metastases are seldom successful. Among them are submucosal alimentary tract metastases that bleed or obstruct. Aggressive systemic therapy will arrest disease in only a few patients. However, one must also remember that malignant melanomas are on that curious list of tumors that undergo spontaneous regression for reasons that we do not understand.

THE UNKNOWN PRIMARY

From time to time, a surgeon caring for melanoma patients will see an individual who often has an isolated lymph node that, upon biopsy, shows malignant melanoma but without a visible primary lesion. Careful and detailed study of the vaginal, anal, nasopharyngeal, and oral mucosa is warranted. However, the most common unidentified primary lesions arise from the scalp, which incidentally may subsequently disappear. This is a good time to remember that melanoma may undergo spontaneous regression; it may be that there was an invasive melanoma that has regressed. A careful history about previous suspicious lesions that have either been treated or cauterized is critical in this setting.

In patients who present with single nodes associated with metastatic melanoma but without an obvious primary lesion, there is a substantial likelihood of their being cured by an isolated complete node dissection

confined to that particular body part. By doing so, at least a quarter of these patients are cured. In a self-selected way, they offer substantial salvage to the patient and to the surgeon. Systemic chemotherapy without evidence of metastases appears not to be of value in patients with unknown primary melanoma because, obviously, one simply cannot determine what is being treated.

After a diagnosis of melanoma has been made by an informed primary care physician or dermatologist, the first, second, and third consideration in the patient's care is adequate local and nodal excision and appropriate meticulous personal follow-up, with an emphasis on the potential for disease recurrence.

SQUAMOUS CELL CARCINOMA

The same sun exposure that predisposes toward melanoma appears to promote the likelihood of development of squamous cell cancer, especially in the head and neck regions. Basic lesions are usually diagnosed in doctors' offices. Biopsy strategies for squamous cell cancers are basically the same as for melanomas. Any elevated lesion or nonhealing ulcer on the skin of a patient, particularly in a patient over 50 years of age, and with sunburning, either presently or by history, warrants an excisional biopsy. In most cases, the biopsy can be a local excision with 1- to 2-mm margins, with simple repair of the wound.

In contrast to melanoma, the management of squamous cell cancer is extraordinarily simple, in that margins should generally be as noted above and consistent with the function of the body part. An adequate margin can often be as little as 1 microscopic millimeter with garden variety squamous cell cancers. In general, if the lesion is not in a functionally or cosmetically important area, somewhat wider margins are warranted; but also consistent with simple closure of the wound. Basal cell cancers or irritated seborrheic keratosis can be similarly managed. Metastases are very rare.

THE FUTURE

Whether or not one is a devotee of the "Green" movement, it is clear that the ozone layer has been impacted by some events, and it is less protective than it has been. If we continue a scenario where leisure time is enhanced, then the likelihood that more people will be exposed to the sun for longer periods of time without the protection of the natural ozone layer that benefited our generation will increase. When compounded by the liberal

use of indoor tanning beds, which today exist in an increasing variety of stores, including launderettes and gymnasiums, this leads to the inevitable conclusion that there will be more skin cancers, including both melanoma and squamous and basal cell cancer. We can only hope that the progress made in early diagnosis by dermatologists and other physicians is maintained by surgeons who respect the potential gravity of these diseases and, yet, at the same time, possess a healthy awareness of its biologic variation. The most important biologic variable in malignant melanoma is adequate excision of the primary lesion.

EDITOR'S COMMENT

With the second installment of this newly developed chapter for the seventh edition of the *Mastery of Surgery*, we were pleased Professor Polk and colleagues provided this eloquent presentation of the science, epidemiology, outcomes research, public and professional education, preventative medicine, and evolving molecular oncologic concepts for the management of skin cancers. Both melanoma and nonmelanoma skin cancers (NMSC–squamous cell carcinoma, and basal cell carcinoma) are inextricably linked to duration and intensity of sun exposure and its chronicity in the lifestyle of individual patients. Cancer of the skin remains the most frequently diagnosed cancer in America. Of epidemiologic importance, the NMSC cohort is difficult to estimate in occurrence frequency, as these neoplasms are *not* required to be reported to state cancer registries. The American Cancer Society estimated in the most recent study of NMSC (2006) that 3.5 million cases were diagnosed among 2.2 million patients. The cure rate for these NMSCs is the highest for all cancers reported. As emphasized by Dr. Polk and associates, invasive melanoma is an increasing public health liability; by 2015 the estimated lifetime risk for melanoma was 1:100,000 in blacks, 4:100,000 in Hispanics, and 25:100,000 in non-Hispanic whites. Projections estimated that new cases of melanoma would be diagnosed in nearly 73,870 patients in 2015 in the United States alone. This neoplasm has had the most rapid increase in the incidence of all cancers, which is attributed to sunlight and indoor tanning exposure, as a result of the lack of awareness and resultant risk-enhancing behavior of Americans (American Cancer Society. *Cancer Facts and Figures, 2015.* Atlanta, GA: Author; 2015). The exploitation and marketing of indoor tanning beds and their UV-A radiation emissions, formerly considered to be safe, were not only an erroneous scientific hypothesis, but together with sun exposure, have also increased the risk and the emergence of melanoma at earlier ages. Currently, over 10,000 melanoma cases and 450,000 nonmelanoma skin cancers are attributed to indoor tanning alone in Perth, Australia, and the United States. As noted by the authors, the management of melanoma with its varying anatomical, epidemiologic, and histologic presentations has remained at the core for reasoning of scientific and clinical arguments for management over multiple decades. While melanoma represents 2% of all skin cancer, it contributes as the principal cause of skin cancer-related mortality. As indicated by the authors, the management of squamous cell cancer and basal cell carcinoma is generally considerably much less complicated than that of cutaneous melanoma. Adequate margins of NMSCs are each defined in millimeters for garden variety squamous cell

carcinomas and basal cell lesions; in contrast, complex management is expected for advanced presentations of primary melanoma and subsequent recurrences.

Over the past three decades, advancing clinical, molecular, and epidemiologic research has focused intensely upon melanoma management, as advanced disease and widely metastatic melanoma predate a dismal prognosis. Furthermore, there has been a major paradigm shift over the past two decades, especially with the introduction by Morton and colleagues for the clinical implementation of intraoperative lymphatic mapping with lymphoscintigraphy and radioactive tracer introduced for early-stage melanoma at the 42nd Annual Meeting of the Society of Surgical Oncology (May, 1990). This presentation followed the original evidence for proof-of principle by the senior investigator's laboratory in 1977 (*Surg Forum* 1977;78:147–8). The technical details of intraoperative lymphatic mapping and use of vital blue dyes singularly or combined with technetium-99m sulfacolloid allowed scientific and clinical progress for management of this malignant cutaneous lesion, and the subsequent development for application in breast, and head and neck carcinomas.

Thus, the implementation of sentinel lymph node biopsy (SLNB) has dramatically shifted the method for detection and accurate pathologic staging of micro- and macrometastases within lymphatics; thereafter, the SLNB sharply impacted therapeutic management considerations for cutaneous melanoma. In what is considered current *standard* therapeutic management with biopsy and indicated dissection only for macroscopic disease, the paradigm shift from *elective* lymph node dissection (now obsolete) together with application of physical examination and radiologic (ultrasound/computed tomography [CT] diagnosis) staging, regional nodal management of melanoma has been profoundly and inextricably altered. As previously observed, fewer patients are subjected to elective nodal dissection as <1 in 5 melanoma patients (17%) will harbor nodal metastases for *lesions >1.0 mm* Breslow depth and *high-risk thin melanomas <1.0 mm depth.* In this selective cohort, high-risk is considered those melanoma lesions with ulceration, mitotic rate ≥1 per mm^2, and select histologic variants >0.75 mm but <1.0 mm (Wong SL, Balch CM, Hurley P, et al. Sentinel lymph node biopsy for melanoma: American Society of Clinical Oncology and Society of Surgical Oncology joint clinical practice guideline. *J Clin Onc* 2012(30);23:2912–8). As reiterated by Dr. Polk and the coauthors, the overwhelming majority of advanced cutaneous melanoma recurs either locally or within the anatomical body site/region initially involved by this cutaneous tumor and is usually first detected on physical examination by the treating physician/surgeon. While systemic disease occurs in *less than one third* of all patients with melanoma, systemic therapy (chemotherapy, biologic, or monoclonal) for the disorder remains largely ineffective, expensive, and often therapeutically toxic. Thus, therapeutic intervention has been principally that of aggressive surgical approaches with tumor resection and regional node dissection; this therapeutic principle provides the greatest potential for enhanced disease-free and overall survival. Moreover, in those high-risk lesions harboring

occult metastatic nodal disease, *early* intervention surgically has been shown to have measurable survival advantage over *delayed* therapeutic node dissections. To date, full (complete) lymphadenectomy in the setting of microscopic or macroscopic metastasis is considered the *standard* therapeutic approach with stage II or stage III disease. However, Bilimoria et al. (Bilimoria KY, Balch CM, Bentrem DJ, et al. Complete lymph node dissection for sentinel node-positive melanoma: assessment of practice patterns in the United States. *Ann Surg Onc* 2008;15(6):1566–76) have reported that only one half of all patients with known advanced local-regional disease receive *recommended* therapeutic approaches, which are principally surgical, with many patients being referred for other (alternative) treatment or no intervention of any type. These authors further emphasize the application of only inguinofemoral lymphadenectomy, rather than the preferred inguinopelvic nodal dissection, when clinically evident metastases are present, either clinically or radiographically (e.g., CT, MRI, PET, etc.). While the majority of surgeons consider axillary regional disease best managed with levels I, II, and III comprehensive dissection following removal of the pectoralis minor for adequate level III exposure, other surgeons limit this to incomplete therapy with dissection of levels I and II. Similar debates have been ongoing for decades and remain extant in our surgical lexicon. These debates have also emerged with the SLNB approaches, in that there is a prognostic variance between nodes that are detected clinically versus those detected by SLNB approaches. This disparity is further being defined by the *AJCC Staging System* to allow appreciation and distinction of methodologies for detection of occult nodal metastases.

In the final report of the Multicenter Selective Lymphadenectomy Trial (MSLT) Group (Morton DL, Thompson JF, Cochran AJ, et al. Final trial report of sentinel-node biopsy versus nodal observation in melanoma. *NEJM* 2014;370:599–609), no significant treatment-related differences were evident in the 10-year melanoma-specific survival rate for over 2,000 patients with primary cutaneous melanoma. Patients were randomly assigned to undergo wide excision and nodal *observation* with reservation of lymphadenectomy for nodal relapse (*observation group*), or wide excision and SLNB with *immediate lymphadenectomy* for nodal metastasis detected on biopsy (*the biopsy group*). This important work identified that biopsy-based staging of intermediate-thickness primary melanoma proved to provide prognostic data to identify patients with nodal metastases who would most appropriately benefit from *immediate* complete lymphadenectomy. This approach with biopsy-based management prolongs disease-free survival for all patients and that of distant disease-free survival and melanoma-specific survival for the patient with nodal metastasis from these intermediate-thickness lesions.

The lack of active and effective commercially developed immunotherapeutics and chemotherapeutics for the therapy of systemic melanoma has resoundingly intensified pharmacologic attention with the development and therapeutic evaluation of *new* active agents. Prior to 2011,

active therapy was limited to carboplatin, paclitaxel, interleukin-2, dacarbazine, temozolomide (Tomodar), and fotemustine. Importantly, no study confirmed any improvement in overall survival for these agents. However, the recent introduction of two FDA-approved agents, ipilimumab (Yervoy) and vemurafenab (Zelboraf), has confirmed improved survival in randomized phase III clinical trials. Of major progress with advancing biologic treatment, ipilimumab, as a fully humanized monoclonal antibody exploits signal-transduction of the immune system to eradicate primary cancer cells. This agent inhibits binding of cytotoxic T-lymphocyte antigen-4 to its ligands. This activity promotes T-cell response and antitumor immunity for melanoma. Data from phase III trials suggest that both vemurafenib and dabrafenib improve patient outcomes, with vemurafenib showing overall survival benefit together with dabrafenib. This trial confirmed improved median progression-free survival. While the immunotherapeutic ipilimumab together with the MAPK-targeted inhibitors (vemurafenib, dabrafenib, and trametinib) has considerably changed the rationale for the systemic immunotherapy of melanoma with these optimistic outcomes, these successes will likely open new vistas for therapeutic interventions. New objectives for success will require an enhancement of *durable* long-term improvement in patient outcomes. To date, traditional therapeutics as mentioned above have *not* provided sustained benefit, and have rapidly failed with time progression. Future research for this lethal neoplasm will continue on a molecular basis, and thus will yield new targeted therapeutics with more durable long-term enhancement for disease-free and overall survival (Yushak M, Kluger HM, Sznol M. Advances in the systemic treatment of metastatic melanoma. *Oncology* (Williston Park) 2013;27(5):374–81 and Olszanski. Current and future roles of targeted therapy and immunotherapy in advanced melanoma. *J Manag Care Spec Pharm* 2014;20(4):346–56).

31 Melanoma

Douglas Tyler and Kelly Olino

EPIDEMIOLOGY

According to the American Cancer Society in 2016 there were 76,380 new cases of invasive melanoma and 10,130 deaths in the United States. It currently represents 5% of all cancer in men and 4% of all cancers in women. In addition, in this same year it is estimated that there will be 63,770 cases of melanoma in situ. In contrast to many other cancers that have decreased in incidence over the past two decades, the incidence of melanoma has increased over this time.

GENETICS

Although most commonly melanoma arises out of a combination of accumulated somatic mutations, phenotypic risk factors (blue or green eyes, fair skin, red hair), and environmental exposures (sun burn, ultraviolet [UV] radiation), there are heritable genetic mutations that increase susceptibility to developing this cancer. Although rare, mutations in the CDKN2A gene are most commonly associated with familial melanoma and have a high penetrance when found. In kindreds with a member with multiple primaries or in cases where multiple (≥3) first-degree relatives are involved, consideration for genetic testing should be discussed. However, at this time there are no formal screening guidelines for this mutation given its rare occurrence. Although the relationship between the development of melanoma and multiple dysplastic nevi syndrome is currently controversial, patients with multiple dysplastic nevi are associated with having an increased risk of developing melanoma, specifically in cases of a family history of melanoma.

WORKUP OF SUSPICIOUS LESIONS

Suspicious skin lesions are usually identified using the common ABCDE method of evaluation for melanoma. A = Asymmetry; B = Border irregularity; C = Color variegation; D = Diameter >6 mm; E = Evolving

lesion. Figure 31.1 demonstrates several examples of pigmented lesions with the above characteristics that proved to be melanoma on biopsy. Once a suspicious lesion is identified, both the National Comprehensive Cancer Network (NCCN) and the American Academy of Dermatology recommend full thickness excisional biopsy (down to subcutaneous fat) with 1- to 3-mm margin. An alternative to full thickness excision is to perform a full thickness punch biopsy (as shown in Fig. 31.2) or incisional biopsy through the thickest portion of the lesion. The orientation of the incision utilized for the initial biopsy should be performed keeping re-excision or subsequent sentinel lymph node (SLN) mapping in mind. Increasingly, a shave biopsy is performed, particularly for lesions that have a low index of suspicion. Although upwards of 30% of melanoma lesions may have a positive deep margin when biopsied using this technique, shave biopsy has gained wide acceptance by dermatologists as it allows rapid, inexpensive information, and may lower the threshold to perform biopsies of suspicious lesions.

CLINICAL STAGE AND TREATMENT

Once a diagnosis of melanoma is secured, initial treatment decisions are based upon the clinical stage, which is determined by a combination of the initial biopsy results as well as evaluation of draining nodal basins by physical examination. If the initial history and physical examination suggest regional or metastatic involvement, appropriate imaging (computed tomography [CT], positron emission tomography/computed tomography [PET/CT], magnetic resonance imaging [MRI]) and biopsy should be obtained at the time of diagnosis.

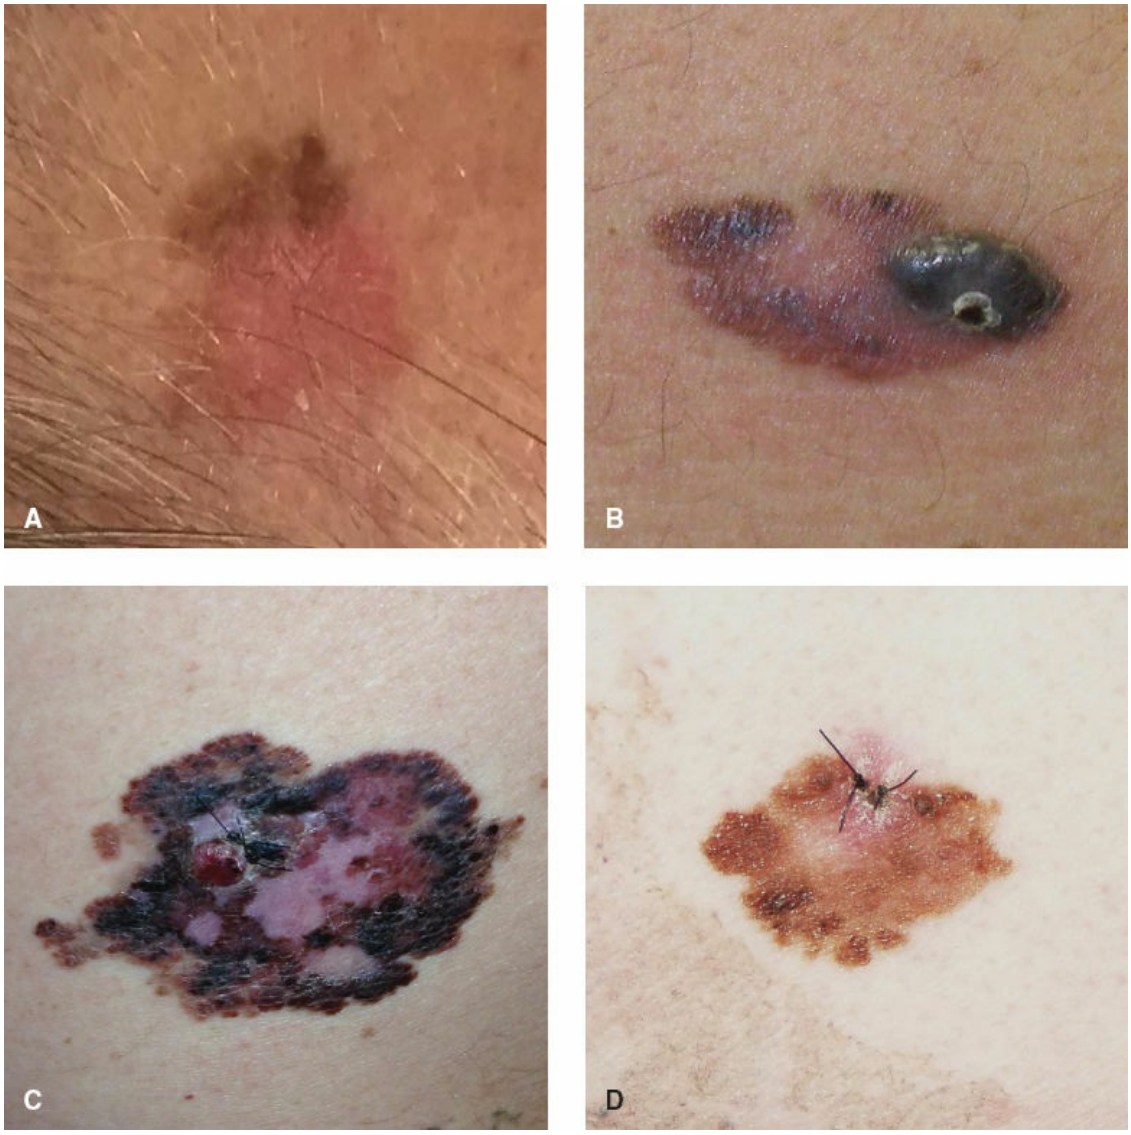

Figure 31.1. Examples of four pigmented lesions demonstrating the asymmetry, border irregularity, color variation, and size that are all concerning for melanoma. Panel **A** represents a lentigo maligna melanoma of the head and neck, Panels **B** and **C** demonstrate melanoma with nodular characteristics, and Panel **D** demonstrates a superficial spreading melanoma.

The initial biopsy specimen report should include the Breslow thickness, which as shown in Figure 31.3 is a measurement in millimeters from the top to the base of the tumor. Breslow thickness has replaced for the most part tumor staging using Clark levels, also shown in Figure 31.2, which refer to histologic levels of the skin to which the tumor has invaded. The Clark levels fell out of favor as they vary by location on the body, had more discordance among pathologists when reviewing a specimen, and were not as strongly correlated with the likelihood of metastasis as was the

Breslow classification. Other histologic characteristics that are factored into the staging system include ulceration status, margin status, and the mitotic rate. Melanoma in situ is confined to the epidermis (stage 0) and is treated by local excision with 0.5-cm margins. In some locations in situ disease may be challenging as tumor cells may extend out into the skin beyond where pigmented changes are present necessitating wider excisions to achieve negative margins. This tends to be more common with in situ disease on the sole of the foot and perianal area as well as in the head and neck area where it is frequently referred to as lentigo maligna melanoma. For invasive melanoma, the appropriate margin for re-excision of the primary site is based upon tumor thickness and has been vigorously studied in multiple randomized clinical trials (see Table 31.1). Based upon these trials, current guidelines (shown in Table 31.2) are for tumors ≤1 mm in thickness an excision with a 1-cm margin should be performed; for tumors that are 1 to 2 mm in thickness, a 1- to 2-cm margin should be obtained; and for tumors ≥2 mm in thickness, a 2-cm margin is performed. For lesions that are on the digits or under the nail bed, adequate margins are usually obtained by partial amputation of the digit at the joint space proximal to the melanoma.

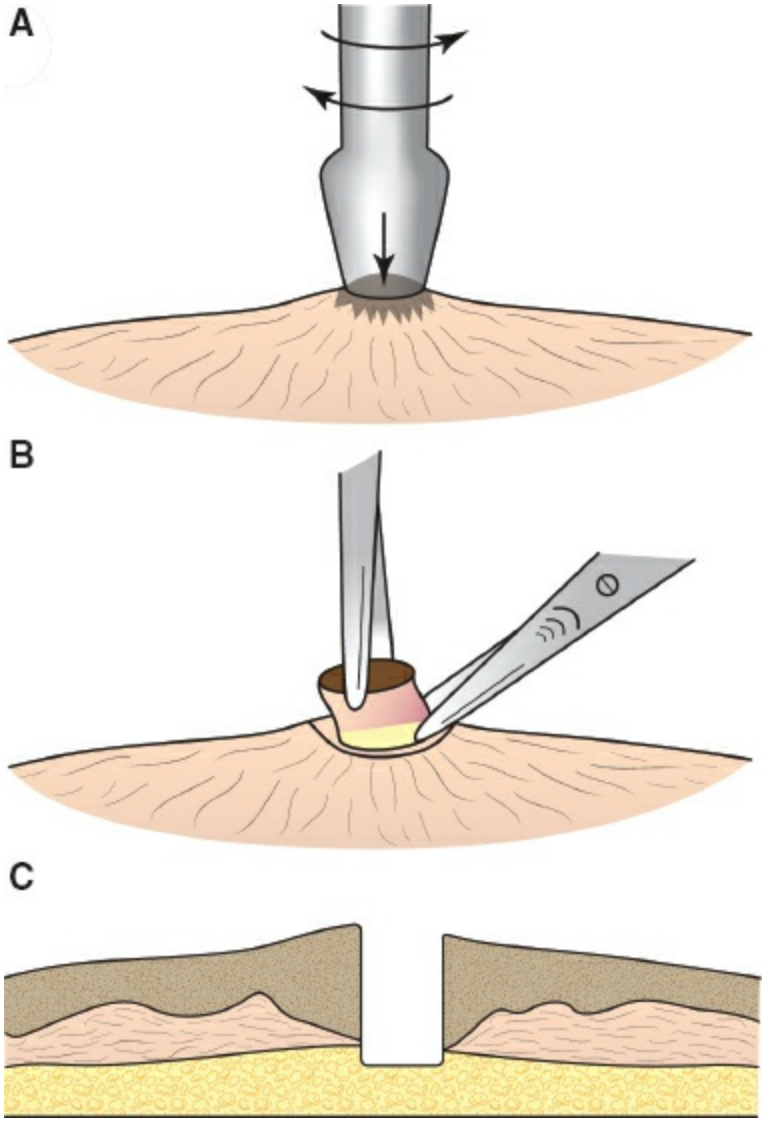

Figure 31.2. Schematic of the punch biopsy technique. Panel **A** shows the punch tool over the pigmented lesion with a twisting motion to cut through the skin. Panel **B** demonstrates the core of tissue that is elevated and cut at its base in the subcutaneous fat. Panel **C** demonstrates the full thickness skin defect left after the biopsy.

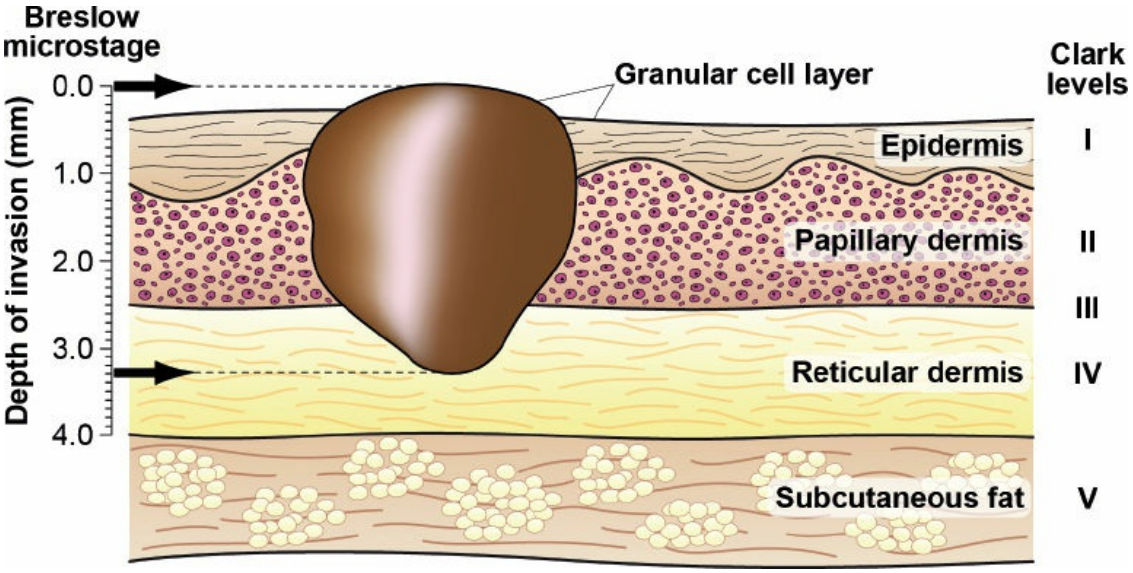

Figure 31.3. Schematic of primary tumor staging using the Breslow depth and Clark levels. The Breslow thickness is a measurement in millimeters from the top of the tumor to the base of the tumor as shown with the black arrows. The Clark level is the deepest layer that the base of the tumor invades into.

TABLE 31.1 Randomized Controlled Trials of Wide Local Excision of Melanoma

Trial	Year	N	Tumor Thickness	Arms	Outcome
WHO Melanoma Program	1988	612	<2 mm	1 cm vs. 3 cm	No difference in LR, DFS, or OS
US Intergroup Melanoma Trial	1993	486	1–4 mm	2 cm vs. 4 cm	No difference in LR, DFS, or OS
Swedish Melanoma Study Group	1996	989	0.8–2 mm	2 cm vs. 5 cm	No difference in LR, DFS, or OS
French Cooperative Study	2003	362	<2 mm	2 cm vs. 5 cm	No difference in LR, DFS, or OS
UK Melanoma Study Group	2004	900	>2 mm	1 cm vs. 3 cm	HR 1.26 for 1 cm vs. 3 cm for LR. No difference in DFS or OS
Scandinavian Study Group	2011	936	>2 mm	2 cm vs. 4 cm	No difference in LR, DFS, or OS

After determining the appropriate margin of resection, most lesions can be excised with excellent cosmesis by creating a fusiform incision with the ratio of 3:1 of the long:short axis. Small skin flaps can be created to aid in closure. For lesions on the head and neck or areas with less pliable skin, local rearrangement flaps can be used such as a rhomboid, V-Y or keystone advancement flap. For lesions on the sole of the foot, particularly in weight-bearing areas, reconstruction can be particularly challenging. Temporary placement of a VAC can be used prior to or following split thickness skin grafts. Good results have also been reported utilizing glaborous skin flap reconstruction.

Prior to the publication of the use of SLN biopsy to identify clinically occult nodes by Morton et al., management of the draining lymph node

basin in those who were clinically node negative was controversial. Although randomized controlled trials did not demonstrate a statistically significant benefit in overall survival for elective lymph node dissection, practitioners were performing the procedure based upon evidence from subgroup analysis of randomized trials and retrospective studies. After SLN biopsy became increasingly used, multiple studies were performed that correlated risk factors of the primary tumor with the risk of harboring nodal metastases. Conceptually, SLN biopsy is a technique where the primary tumor is injected with radioactive material and vital blue dye to help identify which regional draining lymph nodes drain the afferent lymphatics from the patch of skin where the tumor is located. In theory, tumor cells that leave the tumor would have followed the same channels that drain the radioactive material and vital blue dye, ending up in the first echelon or SLN in a given nodal basin as shown schematically in Figure 31.4. Figure 31.5 shows that some SLNs maybe in unusual locations such as the popliteal fossa for a posterior calf melanoma. Factors associated with an increased risk of a positive SLN include thickness of the primary tumor. For lesions <1 mm thick, there is <5% rate of a positive LN, which rises to >35% for tumors >4 mm thick. While there is general consensus for recommending SLN Bx for patients with tumors >1 mm thick, there is considerable controversy over which thin lesions might benefit from the procedure. Generally, SLN biopsy should be discussed in patients with thin melanomas that have characteristics that would push the primary tumor from being graded by AJCC criteria as a T1a (tumor <1 mm) to a T1b such as ulceration and/or high mitotic rate. These factors appear associated with a worse prognosis and a slight increase the probability of the SLN having metastatic disease.

TABLE 31.2 Recommended Surgical Margins for Local Excision of Melanoma

Tumor Thickness (mm)	Recommended Surgical Margin (cm)
In situ	0.5–1 cm (>0.5 for lentigo maligna or large in situ)
≤1.0 mm	1.0 cm
1.01–2.0 mm	1–2 cm
2.01–4.0 mm	2.0 cm
>4 mm	2.0 cm

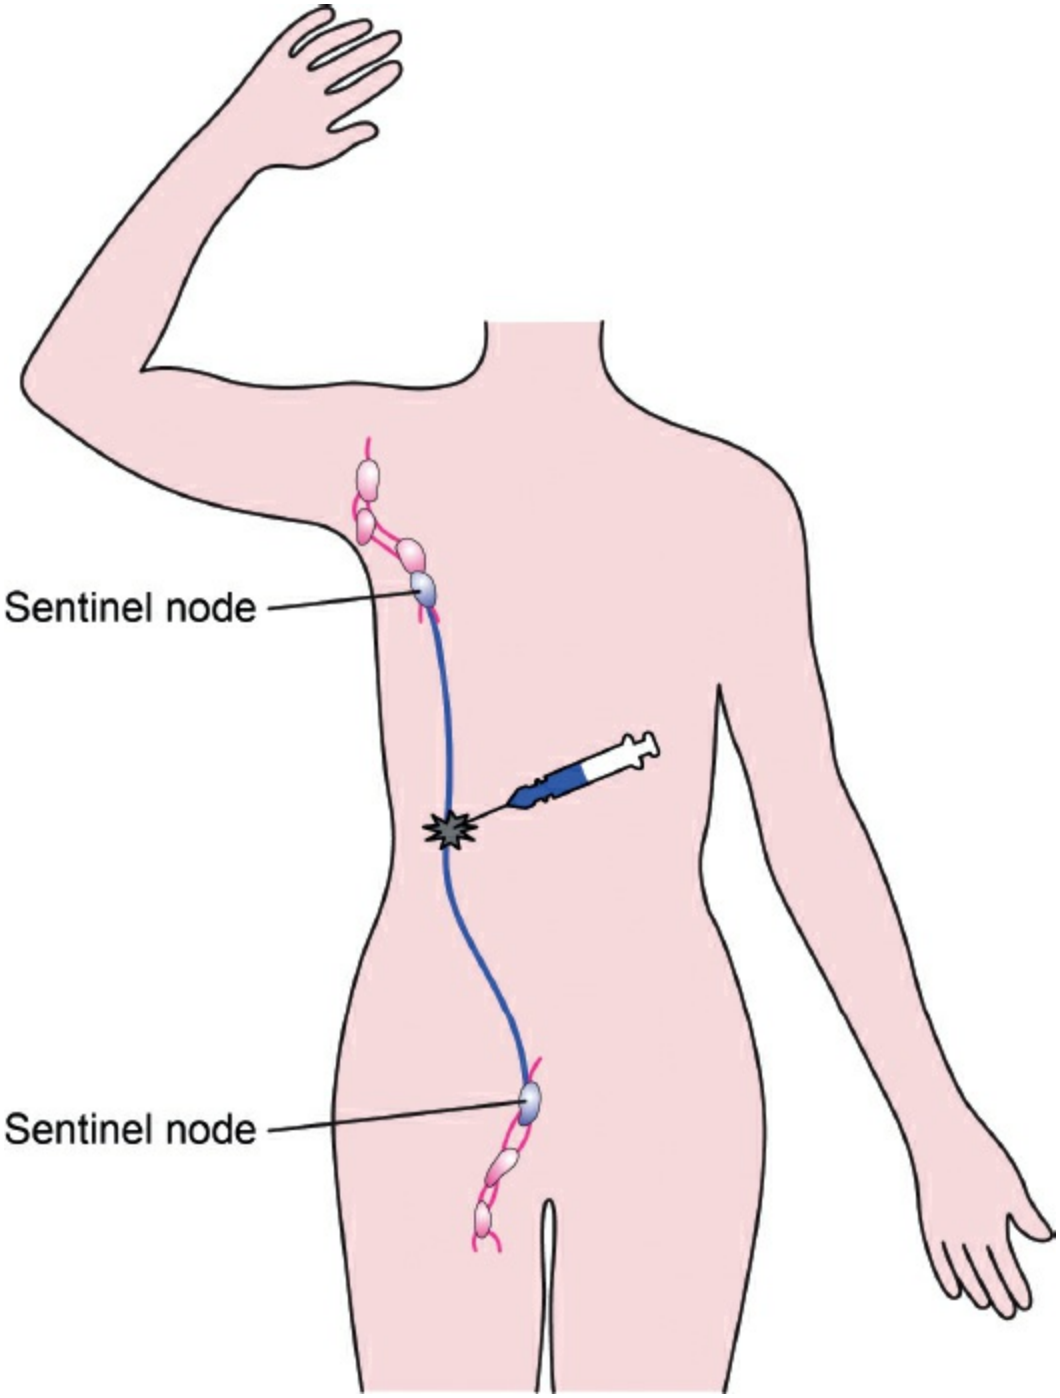

Figure 31.4. Schematic of the technique of lymphatic mapping. The blue dye is injected at the primary site, and the dye will drain to the lymph nodes that drain that area of skin. Since the lesion in the figure is in an ambiguous area of the trunk of the body, lymphatics from the primary site may drain to more than one basin. A lymphoscintigraphy that injects radiolabeled sulfa colloid at the primary site can also help facilitate identification of the sentinel lymph node.

Figure 31.5. Example of intraoperative lymphatic mapping of a posterior calf lesion that drained to a sentinel lymph node in the popliteal fossa. Panel **A** shows the operative field. Panel **B** shows the sentinel lymph node biopsy site with the nerves retracted, and Panel **C** shows the blue node that is removed.

The benefit of performing an SLN biopsy on survival was studied in a large randomized trial, the MSLT-1 Trial (Multicenter Selective Lymphadenectomy Trial). In this seminal study, 1,347 patients with melanoma 1.2 to 3.5 mm thick were randomized to undergo wide local excision with SLN Bx or wide local excision with nodal observation with clinical examination and ultrasonography. In patients who were found to have a positive SLN, a completion lymph node dissection was performed. The primary endpoint was melanoma specific survival with secondary endpoints including disease free survival and the development of nodal disease. Although there were no differences in overall melanoma specific survival between groups who underwent SLN biopsy compared to the observation-alone group, when subgroup analysis was performed there were differences seen among the intermediate thickness melanomas. For patients who had no nodal disease develop during observation, and for true negative SLN biopsies, 10-year melanoma specific survival was >85%. For patients who had a positive SLN and then underwent completion lymph node dissection, 10-year melanoma specific survival was 62%. Those who developed nodal disease in the observation arm had 10-year

melanoma specific survival of 41.5%, which was similar for those patients who were found to have a false negative SLN biopsy. Despite concerns about the validity of the subgroup analysis, these findings were interpreted to support the use of SLN biopsy. Interestingly, in this same clinical trial, for patients with thick melanoma, there was no observed difference on subgroup analysis between patients who underwent SLN biopsy followed by immediate completion LN dissection and those patients who initially underwent nodal observation and the subsequently developed nodal disease and underwent lymph node dissection.

Whereas the MSLT-1 trial has provided us with data to help shape the conversation of the benefit for performing a SLN biopsy, the MSLT-2 trial aims to answer the question whether in patients with a positive SLN, a completion lymph node dissection leads to improved melanoma specific survival when compared to observation of the nodal basin with ultrasound. This trial has completed accrual and is currently awaiting the data to mature before the first analysis is reported out. Multicenter retrospective studies have found that patients with a positive SLN who do not undergo completion lymphadenectomy that the local nodal recurrence is 15%, compared to <5% following completion lymphadenectomy. Given the morbidity associated with the extensive nodal dissection, controversy exists whether the risk is worth the potential benefit, particularly in patients with low burden of disease in a solitary lymph node.

The management of the axillae in the case of a completion lymphadenectomy requires a more extensive nodal dissection than is utilized in the management of breast cancer. Nodal dissection includes all of the nodes in levels I and II, skeletonizing the axillary vein and all fatty tissue surrounding the long thoracic and thoracodorsal bundle. For the treatment of melanoma, level III lymph nodes must also be removed following resection of level I and II nodes. The pectoris minor is retracted anteriorly in order to access the more proximal level III lymph nodes along the subclavian vein.

ADJUVANT THERAPY FOR STAGE III MELANOMA

At the current time, the prognosis for most SLN-negative patients with primary tumors <4 mm is very good and no additional therapy is recommend after surgery. Recent studies using a 31-gene expression signature have demonstrated an ability to identify patients with negative SLNs who have a high risk of distant disease recurrence. The role of this

test has yet to be determined as there are currently studies examining therapeutic interventions in those patients who have a positive test. For patients with thick primaries >4 mm or nodal metastasis, the prognosis is more guarded. High-dose interferon alpha therapy and anti-CTLA-4 therapy (Yervoy, Ipilimumab) are the only two FDA-approved adjuvant treatments for stage IIb and III disease in the United States, with low-dose interferon also approved in Europe. Interferon therapy has been evaluated in 14 separate clinical trials studying varying duration, doses including with pegylated formulations. Although most studies show a benefit in recurrence-free survival, there is no benefit in overall survival. Subgroup analysis points to patients with stage IIIa disease deriving the greatest benefit of treatment, particularly those with microscopically positive nodal disease. It also appears that the duration of treatment is related to relapse-free survival that may be due to a yet-to-be-described immunomodulatory mechanism of action, with some studies showing a benefit when continuing treatment up to 5 years. The marginal benefit of interferon treatment needs to be balanced with the high associated toxicity rates and high cost of treatment. Given this, there is a great variability among centers in the utilization of this therapy.

The success of anti-CTLA-4 treatment in the setting of metastatic disease and the lack of efficacy of other treatments in the adjuvant setting led to the EORTC 18071 trial, which equally randomized 951 stage III patients with nodal metastases following surgical resection of both the primary and regional lymph nodes to treatment with 10 mg/kg of ipilimumab (monoclonal anti-CTLA-4 antibody) or placebo. The study found an improvement in 3-year recurrence free survival of 46.5% in the ipilimumab group compared to 35% in the placebo group. Subgroup analysis revealed that patients with microscopically positive nodal disease and ulcerated primary tumors derived the greatest benefit of treatment. While the overall survival rates have yet to be reported, the marked improvement in median recurrence-free survival of 26 months for patients treated with ipilimumab compared to 17 months for patients receiving placebo has led the FDA to recently approve ipilimumab in the adjuvant setting.

Similar to treatment with adjuvant interferon alpha, the benefit of ipilimumab treatment has to be balanced with the toxicity. In this study, 54% of all patients treated with ipilimumab experienced a grade 3/4 toxicity with five treatment-related deaths. Grade 3/4 toxicity affected 25%

of the placebo group with no treatment-related deaths. Immune-associated toxicity was commonly related to colitis and hypophysitis. In this patient population when deciding whether to give adjuvant immunotherapy, great thought must be given to the potential benefit given the high toxicity as we still cannot predict who will derive benefit and whether any benefit in 3-year recurrence-free survival will translate into any benefit in overall survival.

SPECIAL SITUATIONS

Melanoma of Unknown Primary

In some situations, melanoma presents not as a pigmented lesion but as an enlarged lymph node or soft tissue mass. Despite an extensive skin exam, no obvious pigmented lesion is identified. While some feel that this may be related to the primary tumor undergoing regression, an extensive evaluation for the primary lesions needs to be undertaken before categorizing them as melanoma of unknown primary. Patients will need a careful eye exam to rule out an ocular melanoma, as well as an extensive evaluation of the nasopharynx and oropharynx to rule out mucosal melanoma. In addition to examining all the fingers and toes, an examination of the genitals for penile or vulvar/vaginal melanoma as well as the anorectal area to rule out anal melanoma is important.

If no primary is identified, and complete staging with PET/CT and brain MRI shows no additional metastatic disease, then surgical resection of the metastatic focus is indicated. If the focus is a lymph node, then a complete lymphadenectomy is recommended. If the lesion is a solitary lesion in the soft tissue that is not a lymph node, then simple surgical resection with negative margins is all that is required. In both scenarios, discussion of adjuvant therapy should take place. In general, the prognosis for patients with unknown primary is as good as those patients with a known primary, and in some cases it may be even better.

Melanoma Arising in Pregnancy

Melanoma can sometimes arise in women during pregnancy. In general, most groups currently recommend surgical excision of the primary lesion with appropriate margins under local anesthesia ideally performed in the second trimester but not totally necessary if local alone is used. The timing of the SLN biopsy if indicated for a T1b or greater lesion is more

controversial. While there are reports that lymphosyntigraphy and vital blue dye can be utilized during pregnancy especially after the first trimester, without ill effect to the mother or fetus, most surgeons still prefer to wait until after delivery to perform the SLN biopsy. In most cases, performing the wide local excision early will not impact the accuracy of the SLN biopsy. There are case reports of melanoma transmission to the fetus when mothers develop melanoma in pregnancy. As such it is important to make sure the placenta is evaluated histologically for metastatic melanoma at the time of delivery, which can be a strong predictor of spread to the child. Even in the absence of melanoma in the placenta, these children should be followed closely on the small chance metastases were missed.

Desmoplastic Melanoma

Desmoplastic melanoma is a histologic variant representing <4% of all melanomas. It commonly presents in patients >60 years old as a thick tumor, predominantly in the head and neck region. Given the heterogeneous histology associated with this diagnosis, there continues to be great difficulty in accurately securing not only the initial diagnosis but also in further delineating this diagnosis into histologic subtypes. Some centers have stratified desmoplastic melanoma into “pure” desmoplastic melanoma if >90% of the invasive melanoma was associated with stromal fibrosis, where as “mixed” or “combined” desmoplastic melanoma has >10% but <90% of invasive melanoma associated with stromal fibrosis.

Desmoplastic melanoma is thought to have a different underlying biology compared to conventional melanoma. This subtype rarely harbors BRAF mutations and when compared to similar thickness invasive melanoma, the incidence of harboring a positive SLN can be as much as 50% lower than in conventional melanoma. The decision whether to perform an SLN biopsy for staging in desmoplastic melanoma is further complicated by conflicting reports from retrospective single center case series where centers report rates ranging from 0% to 15%. Among the “pure” and “mixed” subtypes, there are also differences in reported rates of positive SLNs with “pure” ranging from 0% to 10% in various series and “mixed” ranging from 10% to 25%. Furthermore, reports also conflict as to whether the presence of a positive SLN or performing completion lymphadenectomy leads to any difference in melanoma specific survival. Given the controversy, we recommend patients with the diagnosis should

undergo pathologic re-review at an expert center to ensure appropriate diagnosis, and decisions regarding further lymph node staging be made on a case-by-case basis.

Local recurrence, particularly in thick head and neck desmoplastic melanoma, where obtaining wide local excision margins can be challenging, has led to some centers utilizing adjuvant radiation treatment either after the initial resection or in the setting of recurrent disease. Retrospective series have suggested a role for this therapy and is currently being investigated in a prospective clinical trial.

Head and Neck Melanoma Including Lentigo Maligna

Head and neck melanomas commonly arise on the face in adults over 70 years of age but can occur at all ages. The subtypes and the management of head and neck melanoma are similar to that of other locations on the body, but with additional consideration of lentigo maligna lesions that arise in pre-existing large freckles. Local excision is based upon the Breslow thickness and requires increased attention to cosmesis and reconstruction options. Several examples of melanomas in the head and neck region that highlight potential cosmetic issues and complex lymphatic drainage are shown in Figure 31.6. In the case of lentigo maligna melanoma, larger margins of resection may be required given its high incidence of subclinical involvement (see above). Lymphoscintigraphy with Technectium or a SPECT scan is vital given the variability in the location of draining SLNs in head and neck melanoma that can be bilateral, at different nodal levels in the neck, or in the parotid gland. During the operation, removal of the primary lesion is recommended to decrease the background noise as the SLN can be in close proximity. The SLN should be sent for permanent section. In the event that the SLN drains to the parotid gland, local expertise should dictate whether to perform a superficial parotidectomy or to perform a selective resection of the node alone. Following a positive SLN in the neck, selective lymphadenectomy of the involved nodal level should be performed as positive non-SLNs are usually located in close proximity. A parotidectomy is indicated in the case of a positive parotid lymph node. In the case of extensive nodal involvement, modified radical neck dissection should be performed. In the case of positive margins or extensive nodal disease, adjuvant radiation treatment should be considered.

Figure 31.6. Examples of melanoma of the head and neck region. Panel **A** is a scalp lesion, Panel **B** is a temporal area nodular melanoma, and Panel **C** is a lentigo maligna lesion of the left cheek. All of these lesions highlight some of the cosmetic issues that accompany management of head and neck melanoma lesions.

Hand and Foot Melanoma

Melanomas arising on the hands and feet can present difficult problems usually because they are usually mistaken for something else before a diagnosis is made. As a result, melanoma in these areas is usually more advanced than melanoma elsewhere on the body. The other problem with

the hands and feet is that generally the skin is not very mobile in these areas such that primary closure is usually impossible after a wide excision. Figure 31.7 shows examples of melanomas of the hands and feet. Diagnosis is made by biopsy as is elsewhere on the body but tumors arising under the nail bed require removal of the nail to gain access to the malignant tissue. Once a diagnosis is made, excision of the lesion in conjunction with a SLB biopsy is usually performed. When the tumors involve the digits, amputation at the joint space proximal to the tumor is usually the treatment of choice. Lesions on the palms and back of the hand can usually be skin grafted. Lesions involving weight-bearing parts of the foot usually need some type of tissue transfer as a skin graft may not prove durable enough especially in an active person. In some cases, tissue from a non–weight-bearing area like the arch of the plantar surface can be rotated to cover the defect and a skin graft placed on the non–weight-bearing donor site.

Figure 31.7. Examples of melanomas of the hand (Panels **A** and **B**) and foot regions (Panels **C, D,** and **E**). Reconstruction to optimize function is a challenge in these areas.

Pediatric Melanoma and Atypical Spitzoid Tumors

The incidence of pediatric melanoma is increasing in the United States, likely due to an increased awareness leading to more biopsies of atypical melanocytic lesions. Given that melanomas arise in different populations ranging from infants to older children to teenagers, the etiology underlying melanocytic lesions among these different age groups differs. Melanocytic lesions in children may not have the characteristic appearance of adult melanoma so when a suspicious lesion is identified, histopathology review of the biopsy should be sent for review at a center with experience in pediatric melanomas where molecular testing can also be performed. Several studies have demonstrated that comparative genomic hybridization can help distinguish between Spitz nevus and melanomas as melanomas will usually have significant changes in DNA copy number. Melanomas generally have frequent chromosomal aberrations whereas most melanocytic nevi, like Spitz nevi, will show no chromosomal aberrations

or have a restricted set of aberrations with no overlap with melanoma. Pediatric melanomas tend to have a lower incidence of local recurrence but higher rates of positive SLNs compared to equivalent thickness melanomas in adults. In fact, positive SLNs have also been found in atypical Spitzoid lesions despite the fact that they are unlikely to harbor distant metastases. The role of completion lymphadenectomy is controversial and should be decided on a case-by-case basis. Although there is an increased incidence of positive nodal disease, overall survival is usually better than in adults. The pediatric population, even in node negative patients, continues to have regional or distant recurrences past 5 years, so they should be followed for many years. Although there is no consensus, some centers favor the use of adjuvant interferon therapy for a year in cases of stage III disease, as the pediatric population tolerates this therapy better than in adults. The role of ipilimumab is under investigation with only one phase I clinical trial published. Given that pediatric melanomas tend not to be hypermutated, they might not be as immunogenic and may not be as responsive as adult tumors.

Anal Melanoma

Anorectal melanoma is rare, representing <1% of all cases of melanoma. It can present up to 20% of the time as an amelanotic lesion and usually presents with advanced disease at the time of diagnosis. Many times it is mistaken for a thrombosed hemorrhoid and diagnosed only after a “hemorrhoidectomy” is performed. Historically, treatment included abdominoperineal resection for loco-regional control. However, large case series showed equivalent overall and disease-specific survival for wide local excision with improved quality of life. Distant metastatic disease is common, with 5-year overall survival approaching 20%. Small case series have reported the use of adjuvant radiation therapy for local control. There is no role for prophylactic inguinal lymph node resection, with lymphadenectomy reserved for radiographic or clinically apparent disease. There are also case reports utilizing BRAF or c-kit inhibitors for targeted therapy as well as immunotherapy, but data are still lacking. Generally our practice is to locally excise small lesions and then use adjuvant radiation therapy postoperatively. For larger lesions, we treat with radiation neoadjuvantly. If the tumor shrinks, we perform a local excision; if it remains large and there is no metastatic disease, we perform a bigger circumferential operation that may require abdominoperineal resection if

the sphincters are involved. All patients with anorectal melanoma should be presented to a multidisciplinary tumor board that has expertise in managing melanoma patients.

Neoadjuvant Therapy

Increasingly, there are therapeutic options available for melanoma patients that can effectively shrink large tumors. In most solid tumors, neoadjuvant therapy is utilized to downsize a tumor to make it technically resectable or to allow preservation of an important structure like the anus. Melanoma is generally technically resectable even when it presents as a large lesion, so the reason why neo-adjuvant treatments are contemplated in melanoma is because there are concerns over the lesion having a very aggressive tumor biology. Currently, there are no systemic treatments that are approved for the neoadjuvant treatment in melanoma, and many of the reports in the literature are related to anecdotal case reports or pilot trials. Targeted agents like BRAF and MEK inhibitors as well as immunotherapy approaches targeting CTLA-4 and PD-1 (see below) have been tried with some marked responses. As such, patients with unusually large lesions or bulky lymphadenopathy should be presented at a multidisciplinary tumor board that has expertise in managing melanoma patients to consider this treatment approach.

In-Transit Disease

In-transit disease is a manifestation of dermal and subcutaneous metastasis usually related to lymphatic spread of tumor. As shown in Figure 31.8, it can present as multifocal satellite recurrences or as a single large lesion. The lesions can arise in all layers of the skin as well as in small lymph nodes that may be present outside the regional nodal basins. In-transit disease can occur secondary to melanomas that arise anywhere on the body from the scalp to the feet. Historically, the primary approach to in-transit small volume disease was surgical excision. The treatment of choice for larger volume disease confined to the extremities was treatment with regional chemotherapy using melphalan. Hyperthermic isolated limb perfusion (HILP), initially described in 1958, was the primary method used to regionally deliver melphalan (See Fig. 31.9). This technique utilized large bore vascular catheters surgically placed into the extremities, followed by isolation of the catheters with a tourniquet placed proximally on the extremity. The catheters were then connected to a pump oxygenator

allowing the drug to be circulated in the limb where acid base status and oxygenation were maintained in the physiologic range. More recently, a minimally invasive approach to deliver the chemotherapy through percutaneously placed catheters, called isolated limb infusion (ILI), has been popularized. This technique lacks a pump oxygenator, so chemotherapy circulates in a hypoxic acidotic environment (see Fig. 31.9). While HILP is more effective than ILI in achieving a complete response (50% vs. 30%), the durability of response is similar. However, HILP is associated with a higher toxicity rate, and there is no difference in overall survival in patients receiving either form of regional treatment. As such, ILI has become the preferred regional therapeutic modality in most centers that perform regional chemotherapy treatments given the increased toxicity of HILP and lack of survival benefit associated with HILP even though the complete response rate is higher. HILP is more commonly used for salvage therapy in select patients.

Although regional approaches are useful for extremity in-transit disease, they cannot be used in patients with in-transit disease on the trunk or head and neck region. Current advances in therapeutic options for melanoma patients in the last several years have changed the approach to patients with in-transit disease. There is now less consensus on the optimal way to manage patients with regionally advanced disease. Surgeons tend to have a bias toward regional treatments using surgery, intralesional therapies, or regional chemotherapy. This is mainly based on the observation that many patients can have regionally advanced disease for a prolonged period of time before it ever becomes systemic and that there appears to be a group of about 20% of patients who do exceptionally well with regional treatments such that they can be spared the toxicity of systemic therapies. Medical oncologists are more likely to consider systemic therapies early on in the course of treatment as they feel that that vast majority of patients with stage IIIB/C in-transit disease have distant micrometastatic disease. As such given the array of current treatment options and potential clinical trials that are open and available for this patient population, all individuals with in-transit disease should be discussed at a multidisciplinary melanoma tumor board. A brief summary of the various agents that are currently available are summarized below.

Regional chemotherapy: There are currently two trials exploring the combination of regional chemotherapy using ILI with ipilimumab. One trial (NCT01323517) explores the role of ipilimumab after ILI and the

other is a multicenter trial that explores the use of ipilimumab neoadjuvantly prior to ILI (NCT02115243).

Intralesional therapies: Many different intralesional therapies have been developed and generally are injected directly into the lesion as shown in Figure 31.10. While historically BCG was the intralesional treatment used by some centers, it has been replaced by newer therapeutic modalities that attempt to induce an immunogenic form of cell death that can elicit a regional and systemic immune response. These compounds include:

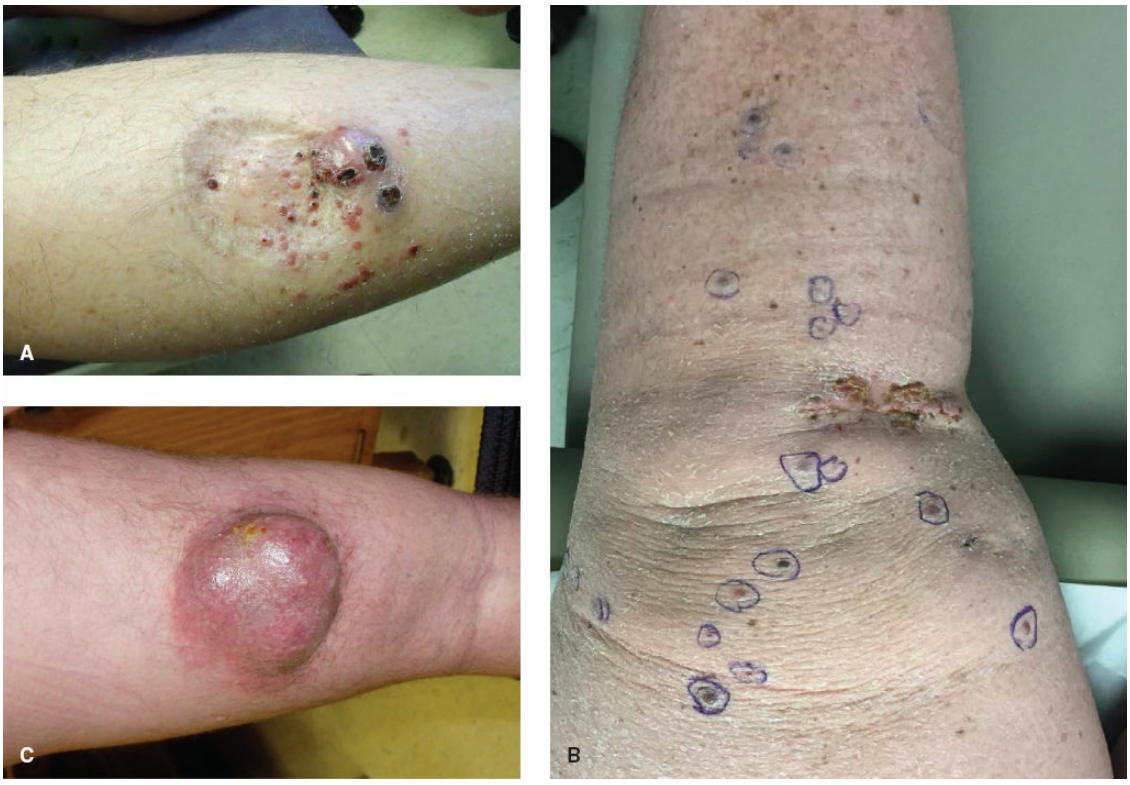

Figure 31.8. Examples of In-transit melanoma lesions that can appear as multifocal tumor deposits (Panels **A** and **B**) or large solitary lesions (Panel **C**). The size and multifocality of this pattern of disease can make management challenging.

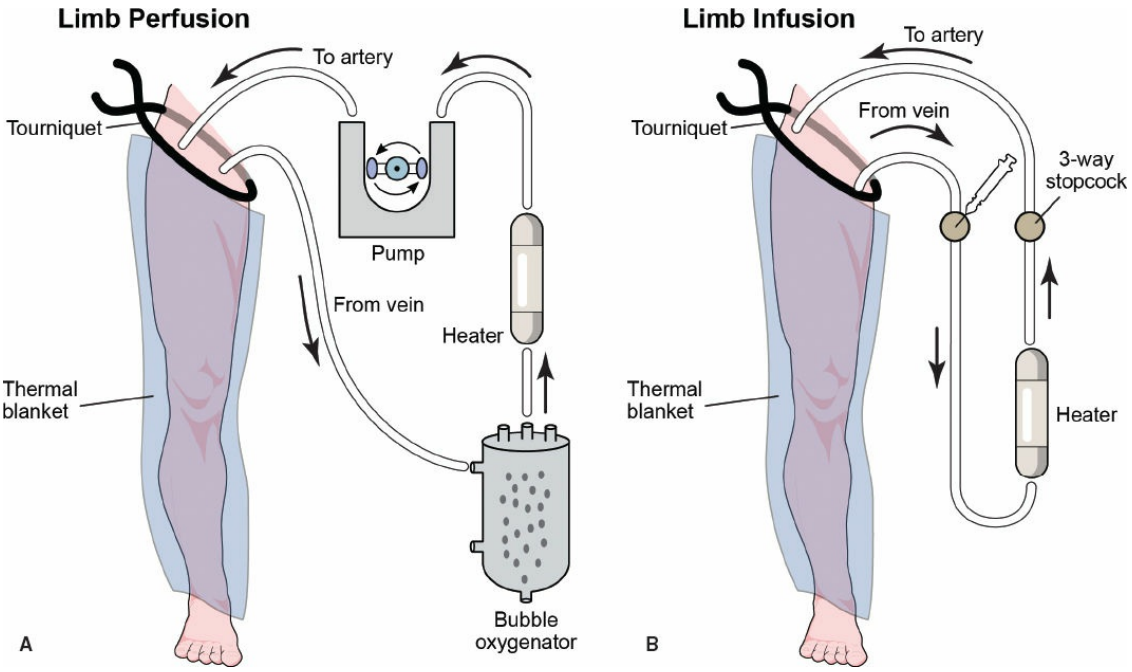

Figure 31.9. Schematic of regional chemotherapy set-ups. Panel **A** shows isolated limb perfusion (ILP) where limb oxygenation and acid/base status is maintained during chemotherapy delivery. Panel **B** shows isolated limb infusion (ILI) where the chemotherapy is delivered into a hypoxic acidotic environment.

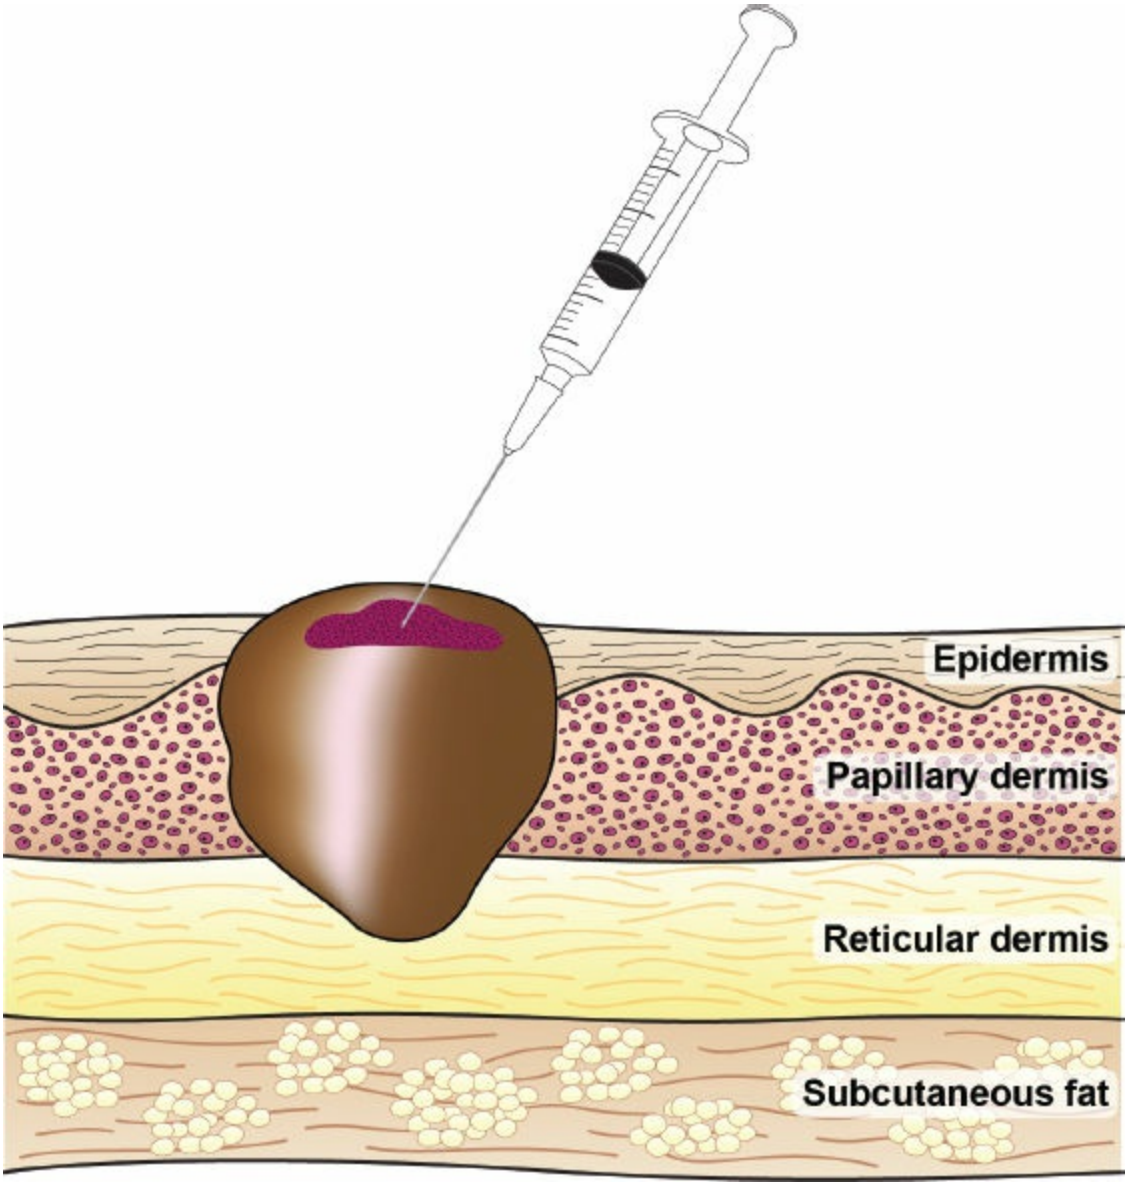

Figure 31.10. Schematic demonstrating the intralesional injection of a compound into a tumor to induce tumor cell death.

T-Vek: An oncolytic herpes virus that has been genetically altered to secrete GM-CSF. A randomized phase III trial has demonstrated improved local control but no survival advantage. The FDA recently approved this compound for the treatment of unresectable cutaneous disease.

PV-10: A vital dye that in a phase II trial has shown some ability to control disease. While these compounds have some effectiveness on their own, they are also currently being studied in trials with various combinations of agents.

Systemic therapies: Targeted and immunologic agents have revolutionized the therapeutic landscape for melanoma patients over the last 5 years. These compounds have demonstrated efficacy in stage IV

patients, and some of the trials have included patients with stage IIIB/C in transit disease.

Targeted therapies: BRAF inhibitors (vemurafenib and dabrafenib) and BRAF inhibitors plus MEK inhibitors (vemurafenib plus cobimetinib, and dafrafenib and trametinib) have proven beneficial in patients with a BRAF mutation. Response rates are in the 50% to 60% range, with progression-free survival of 6.9 months and median overall survival of 13.6 months. For combination therapy, median progression-free survival is 9.3 months and progression-free survival at 1 year ranges from 26% to 41%, depending on dose of MEK inhibitor.

Checkpoint blockade inhibitors: Ipilimumab is a checkpoint blockade inhibitor targeting the CTLA-4 protein. It is associated with a median overall survival of 10.1 months with a 24-month overall survival of 22%. Anti-PD-1 therapies include pembrolizumab, which targets the PD-1 checkpoint blockade protein and has a demonstrated objective response rate (complete plus partial responses) of approximately 20% to 25% and an overall 2-year survival rate of 49%. Nivolumab is another FDA-approved compound that targets PD-1 and has an objective response rate of 34% and an overall 2-year survival rate of 48%. Combination of anti-CTLA-4 and anti-PD-1 therapies has a very high response rate of 59% but is associated with great toxicity. As such, multiple combination regimens using different dosages and schedules are currently under investigation.

Metastatic Melanoma

Melanoma has a unique tumor biology such that selected patients can do quite well with surgical excision of their disease. While this has been recognized anecdotally for many years, it was a striking finding of Don Morton’s Canvaxin vaccine trial for patients with resected stage IV disease. In this trial, patients were randomized to receive surgery alone or surgery plus the Canvaxin vaccine. There was no difference in the survival of either group, and both groups had an approximate 50% five-year survival.

A number of case series document the survival of patients with resected disease by location. Generally surgery is reserved for patients with one to three lesions if all the disease can be removed and the morbidity of the surgery is not significant. The value of surgery is felt to decline as the number of lesions that need to be resected increases. Sites where surgical resection of solitary disease has been associated with favorable outcomes

include the brain, lung, gastrointestinal tract, and adrenal gland. Resection of metastatic disease may also be necessary for palliation secondary to significant symptoms associated with a tumor such as pain, skin ulceration, or bleeding. Surgery is also increasingly used to resect foci of metastatic disease that may not be responding to a targeted or immunologic systemic therapy especially when other lesions are responding. The current belief is that these nonresponding lesions may have tumor cells that are resistant to the targeted therapy or contain neoantigens not recognized by the immune system. Given the complexity of treatment options, patients with metastatic disease in whom surgery is being contemplated should be discussed at a multidisciplinary tumor board with expertise in managing melanoma patients.

SQUAMOUS CELL CARCINOMA

Definition

Primary cutaneous squamous cell carcinoma (SCC) is a malignant tumor that may arise from the keratinizing cells of the epidermis or its appendages. It is locally invasive and has the potential to metastasize to other organs of the body.

Incidence, Etiology, and Prevention

Actinic keratosis is the principal precursor to SCC. Actinic keratosis and SCC represent the same disease process at different stages of evolution, with neoplastic transformation of epidermal keratinocytes generally triggered by UV radiation. As the cells proliferate, they may extend into the dermis, at which point they are termed SCC. Other major risk factors for cutaneous SCC include chronically diseased or injured skin (e.g., ulcers, sinus tracts), exposure to iodizing or UV radiation, immunosuppression, and xeroderma pigmentosa. Increasingly, many SCCs are thought to be secondary to the human papillomavirus (HPV) especially in patients with depressed cell-mediated immunity. The HPV-16 and less so HPV-18 are the variants of the virus that is the most carcinogenic to humans and associated with SCCs. HPV-6 and HPV-11 are associated with most cases of genital warts. There are currently HPV vaccines that can prevent infection with these various subtypes of HPV, but there are no mature data to suggest that this leads to a decreased incidence of skin-related cancers. In addition, excessive sun exposure appears to increase

actinic keratosis that can evolve into SCC in sun-exposed areas of the skin.

Although the National Cancer Institute does not formally track the incidence and prevalence of nonmelanoma skin cancers, multiple longitudinal studies indicate that the incidence has risen sharply over the past two decades. It may develop de novo, as a result of previous exposure to ionizing radiation or arsenic, within chronic wounds, scars, burns, ulcers, or sinus tracts, and from pre-existing lesions such as Bowen's disease ("intraepidermal SCC"). Individuals with impaired immune function, for example, those receiving immunosuppressive drugs following allogeneic organ transplantation or those with lymphoma or leukemia, are at increased risk of this tumor; some SCCs are associated with HPV infection.

Clinical Presentation

SCC usually presents as an indurated nodular keratinizing papule or plaque, and may present as an ulcer without evidence of keratinization. Verrucous carcinoma is a less common but more invasive variant of SCC that often resembles a large wart.

Diagnosis

Initial tissue sampling for diagnosis of suspected nonmelanoma skin cancer is typically performed using a shave technique if the lesion is raised, or using a 2- to 4-mm punch biopsy of the most abnormal-appearing skin. Complete excision may be an appropriate initial diagnostic procedure for smaller tumors. Pigmented tumors or those eliciting any clinical suspicion of melanoma should always be evaluated using a full-thickness technique.

As part of establishing the diagnosis, the pathologist should report on the pathologic pattern; cell morphology; degree of differentiation; histologic grade; depth and the level of dermal invasion; and the presence or absence of perineural, vascular, or lymphatic invasion.

The preferred biopsy, however, unless the lesion is very large, is a local excision with 1 to 2 mm margins, which will effectively deal with the occasional benign pigmented actinic keratosis, and, at the same time, provide an accurate depth of melanoma and cell type, if it is present. The depth of the excision should extend into the subcutaneous fat. If the lesion is large, or located on the face, one may opt to excise a simple 1- to 2-mm pie-shaped wedge from the edge of the lesion, choosing whichever edge by

palpation is the more highly elevated. Given that malignant melanoma, SCC, and basal cell carcinoma are all managed in somewhat different ways, the ability to make an accurate diagnosis while preserving normal skin tissue will allow for optimal cosmetic results when definitive therapy is carried out.

Treatment

In contrast to melanoma, the management of squamous cell cancer is mainly focused on the primary lesion with the surgeon trying to obtain tissue margins that are free of tumor and consistent with the function of the body part from which the squamous cell cancer is being excised. Surgical excision, including Mohs micrographic surgery, is recommended as first-line treatment for most SCC. An adequate margin can often be as little as 1 mm with most squamous cell cancers.

Because SCC is typically sensitive to radiotherapy, this treatment option is recommended for tumors in high-risk, surgically difficult areas and offers favorable cosmetic results early on. Cosmesis can worsen with time, however, and radiotherapy usually is not considered for patients <55 years. A 2010 Cochrane Review found little evidence when comparing the effectiveness of different treatments for primary, nonmetastatic SCC.

Overall, the metastasis rate for SCC of the skin is 2% to 6%. In SCC >2 cm, the incidence of lymph node metastasis ranges from 10% to 30% and an SLN biopsy or imaging of the draining lymph node basins should to be considered. Marjolin's ulcers, aggressive ulcerating SCC that arise in the area of chronically inflamed, scarred skin such as burn wounds, post radiation scars, chronic venous ulcers, and ulcers from osteomyelitis, are also high risk for metastasis occurring 20% to 38% of the time. Therefore, an SLN biopsy is frequently performed to assess lymph node involvement.

The accumulated experience of treating cutaneous SCC by various methods has allowed some generalizations to be made about prognosis based on the original lesion. In general, SCC is highly curable when excised. Factors that influence metastatic potential include anatomical site, size, rate of growth, etiology, and degree of differentiation. Metastatic growth is most often seen at sites of chronic inflammation, the oropharynx, the nasopharynx, the genitals, and the anus. Metastatic disease isolated to nodal basins is managed by lymphadenectomy. Treatment for distant metastasis is more difficult as systemic therapies are currently not very effective.

EDITOR'S COMMENT

This is an excellent chapter on an increasingly common and in some cases devastating disease. Melanoma is the most dangerous type of skin cancer. About 9,730 people are expected to die of melanoma (approximately 6,380 men and 3,350 women). In the United States, the rates of melanoma have been rising for the last 30 years. Globally, in 2012 melanoma occurred as a new diagnosis in 232,000 people. In 2015 there were 3.1 million with active disease that resulted in 59,800 deaths. Australia and New Zealand have the highest rates of melanoma in the world.

According to the American Cancer Society, melanoma is more than 20 times more common in whites than in African Americans. Overall, the lifetime risk of getting melanoma is about 2.5% (1 in 40) for whites, 0.1% (1 in 1,000) for blacks, and 0.5% (1 in 200) for Hispanics. The risk of melanoma increases as

people age. The average age of people when it is diagnosed is 63, although melanoma is not uncommon even among those younger than 30. Melanoma is one of the most common cancers in young adult, especially young women.

Exposure to ultraviolet radiation (UVA and UVB) is one of the major contributors to the development of melanoma. Occasional extreme sun exposure resulting in sunburn is causally related to melanoma. I grew up in an era when we didn't really worry about sunscreen. Sunburns were a part of summer. An interesting and very large study conducted in Australia comparing native to Australian immigrants revealed that the risk of melanoma was related both to duration of stay in Australia and age at arrival. Immigrants had a lower rate of melanoma, and the older an immigrant at the time of arrival in Australia, the lower the melanoma risk. We now understand that exposure during childhood is a more important risk factor than exposure in adulthood. Exposure to tanning beds is also an important risk factor. Melanoma is most common in areas of sun exposure including on the back in men and on legs in women. Most melanomas arise as new lesions in the skin, although a significant fraction (25% to 40%) appears to arise from pre-existing nevi.

Lymphatic tumor spread and its implications for survival and treatment have been studied for centuries. Management of lymph nodes has been controversial since Snow first recommended elective complete lymphadenectomy for all patients with melanoma in the late 1800s. In patients without lymph node metastasis, this strategy results in overtreatment with associated morbidity and no survival advantage. Lymphatic mapping and sentinel node biopsy in melanoma were introduced in the 1990s. Sentinel node biopsy is a minimally invasive and low morbidity staging procedure performed with the use of blue dye and radiolabeled colloids. It identifies node or nodes (sentinel node(s)) in a regional node basin that receive lymph from the primary melanoma site. The tumor status of the sentinel node has been demonstrated to predict the tumor status of other nodes in the lymphatic basin. Results of a phase III trial of sentinel node biopsy versus nodal observation in melanoma was published in the *New England Journal of Medicine* in 2014 (Multicenter Selective Lymphadenectomy or MSLT-1). A total of 2001 patients with primary cutaneous melanoma were randomly assigned to undergo wide excision and nodal observation, with lymphadenectomy for nodal relapse (observation group), or wide excision and sentinel-node biopsy, with immediate lymphadenectomy for nodal metastases detected on biopsy (biopsy group). No significant treatment-related difference in the 10-year melanoma-specific survival rate was seen in the overall study population (20.8% with and 79.2% without nodal metastases). The 10-year disease-free survival rates were significantly improved in the biopsy group among patients with intermediate-thickness melanomas (1.20 to 3.50 mm) and those with thick melanomas (>3.50 mm). Biopsy-based management improved the 10-year rate of distant disease–free survival (hazard ratio for distant metastasis, 0.62; $P = 0.02$) and the 10-year rate of melanoma-specific survival (hazard ratio for death from melanoma, 0.56;

P = 0.006) for patients with intermediate-thickness melanomas and nodal metastases. The authors of this study conclude "Biopsy-based staging of intermediate-thickness or thick primary melanomas provides important prognostic information and identifies patients with nodal metastases who may benefit from immediate complete lymphadenectomy. Biopsy-based management prolongs disease-free survival for all patients and prolongs distant disease–free survival and melanoma-specific survival for patients with nodal metastases from intermediate-thickness melanomas." As discussed in the current chapter, the MSLT-2 trial aims to compare the strategies of completion lymphadenectomy versus monitoring with nodal ultrasound in patients with a positive sentinel node with regard to melanoma-specific survival. Estimated study completion date is 2022.

Significant progress has been made in adjuvant therapy for melanoma. As a surgery resident in the 1990s, I remember a patient admitted for interferon therapy for advanced melanoma. He experienced significant toxicity going through what we felt at the time was somewhat futile treatment—but really the only thing we had to offer him. In the current era, fundamental elements of the surgical, adjuvant medical, and systemic therapy of melanoma have led to improved outcomes. The intent of treatment for advanced melanoma has evolved from palliative to potentially curative. Targeted molecular therapy has been developed for many tumors including certain breast cancers, gastrointestinal stromal tumors, pancreas tumors, and melanoma. In melanoma, the cell growth signaling protein BRAF is present in an altered form (known as BRAF V600E) in many melanomas. Vemurafenib targets this mutant form of BRAF and is approved to treat patients with inoperable or metastatic melanoma that contains the altered BRAF protein. Targeted therapy, immunotherapy, chemotherapy, and neoadjuvant and adjuvant therapies for melanoma have advanced and so have the survival rates. Considering the rapid rate of progress in melanoma treatment over the past two decades, I predict we will continue to see more progress as our understanding of the disease continues to evolve. Most of these advances however are not likely to take place in the surgical approach to this disease, although surgical excision and possibly lymphadenectomy (and possibly not) will continue to occupy a central role in treatment.

Jon C. Gould

The evolution of melanoma treat which has the potential to cure is a great advance. The therapies that Dr. Gould describes is new and just the beginning. My sense is that this therapy will change the entire picture. All of us can look forward to better outcomes.

32 Inguinal Lymph Node Dissection: Indications and Surgical Technique

Steven Agle and Douglas Tyler

Dissection of the superficial inguinal lymph nodes is currently a recommended treatment for patients who have evidence of nodal metastatic disease from a variety of malignancies. Generally, it is focused on patients who are presumed through staging to have stage III disease with tumor confined to the lymph node basin. The goals of surgery are locoregional disease control with the possibility of long-term cure. The most common clinical scenarios for consideration of superficial inguinal lymph node dissection currently arise in patients with melanoma who have a positive sentinel lymph node biopsy (SLNB). There are currently data from several retrospective studies and one prospective German study to suggest that for patients with low-volume nodal involvement in a sentinel lymph node, it may be unnecessary to perform a completion lymph node dissection. The rationale is that the sentinel lymph node often is the only lymph node to contain tumor when a completion lymph node dissection is performed; and if the patient has additional lymph nodes involved, then he or she frequently will also harbor distant metastatic disease. The Multicenter Selective Lymphadenectomy Trial-2 (MSLT-2 trial) that randomized melanoma patients with a positive sentinel lymph node to completion lymphadenectomy surgery or observation has completed accrual and is awaiting maturation of the data to help us better understand the role of completion lymph node dissection in melanoma. At the current time, most surgeons will still recommend a completion lymphadenectomy for patients with a positive SLNB in melanoma. SLNB is also occasionally utilized in patients with Merkel cell carcinoma, penile carcinoma, vulvar carcinoma, anal cancers, and some sarcomas like synovial cell sarcoma where if the SLNB is positive then lymphadenectomy is recommended. There will also be patients, with all of the above malignancies, who present with clinically evident inguinal nodal disease for whom a superficial inguinal dissection is also viewed as important for disease control and to potentially limit the spread of disease.

Inguinal lymph node dissection is associated with moderate morbidity. Several large centers have reported morbidity of 50% or higher related mainly to wound healing issues in the inguinal area. Skin edge necrosis can occur if skin flaps are made too thin, and lymphedema is common more so than is seen with neck or axillary nodal dissections. Many techniques have been reported to reduce postoperative lymphedema, such as preserving the muscle fascia, pedicled omentoplasty, and saphenous vein sparing inguinal lymphadenectomy. While few studies are large enough to conclusively state, systematic reviews and meta-analysis
appear to suggest that preserving the saphenous vein has the strongest evidence to help minimize leg edema and that a sartorius transposition does not prevent complications. As such our current approach to the inguinal lymphadenectomy is to preserve the saphenous vein and muscle fascia, and to not perform a sartorius muscle transposition to cover the femoral vessels.

Inguinal lymph node dissection can be performed through a standard 6- to 10-cm incision extending from 2 to 4 cm below the inguinal ligament and parallel to it (see
Fig. 32.1). While a horizontal skin incision has the least morbidity associated with it, a vertical incision is also sometimes used if one is trying to incorporate a vertically placed SLNB incision. With either incision, an attempt should be made to encompass the incision of any previous biopsy that was performed and to try and stay out of the biopsy cavity that may be present from a previous lymph node biopsy. Flaps are raised from the skin edges deep to Scarpa fascia to the adductor longus and Sartorius muscles. The saphenous vein is identified at the junction of the sartorius and adductor muscles inferiorly with care taken to preserve it. Small branches may need to be divided especially near the saphenofemoral vein junction to clear all the nodal tissue off the vessel. If tumor or the biopsy cavity is stuck to the vein, it can be removed by ligating it as it courses over the sartorius and oversewning the saphenofemoral junction with a 5-0 prolene suture. Flaps are then raised superiorly to the inguinal ligament, and medial to the pubic tubercle. The lateral cutaneous femoral nerve is identified at this point and preserved. It usually runs under the fascia of the sartorius muscle and becomes more superficial about 10 cm below the inguinal ligament where it divides into anterior and lateral branches. The femoral nerve, artery, and vein are identified within the femoral triangle. Dissection over the femoral triangle is accomplished in a lateral to medial

direction clearing the lymph nodes from the femoral nerve and femoral artery.

All the fibrofatty tissues extending from the external oblique aponeurosis 2 cm above the inguinal ligament to the medial border of the adductor longus muscle medially and sartorius muscle laterally are removed. The femoral canal is then explored to excise Cloquet node. Cloquet node is the first node of the deep system, and to get to it one must tease apart the lacunar ligament that runs medially between the inguinal ligament and the pectineal (Cooper) ligament (Fig. 32.2). One needs to be careful to avoid injuring the femoral circumflex vessels as the node is being dissected out. Once the node is removed, the defect in the lacunar ligament is repaired by using two simple 2-0 prolene stitches to pull the inguinal ligament down to the pectineal ligament. Care is taken not to close the space in a way that compresses the femoral vein. If performing a sartorius flap, the sartorius muscle is divided in its superior aspect and transposed medially over the vessels and secured to the fascia of the external oblique. Care must be taken if doing this as the blood supply to the sartorius is segmental; and if one is not careful, devascularization of the muscle will occur. A closed suction drain is then placed within the femoral triangle.

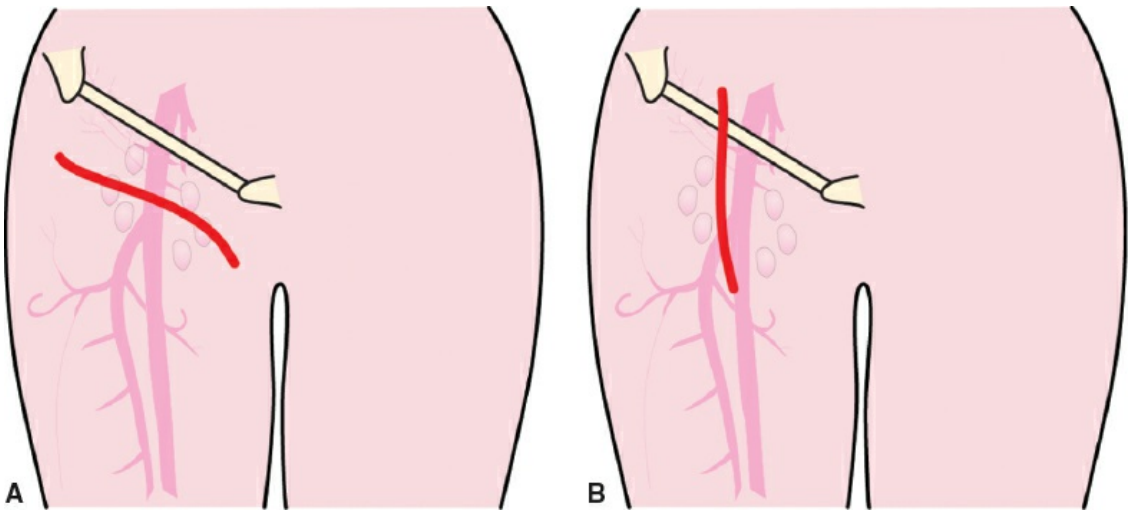

Figure 32.1. Schematic of two incision approaches to an open superficial groin dissection. Panel **A** is a horizontal incision, and Panel **B** is the vertical incision.

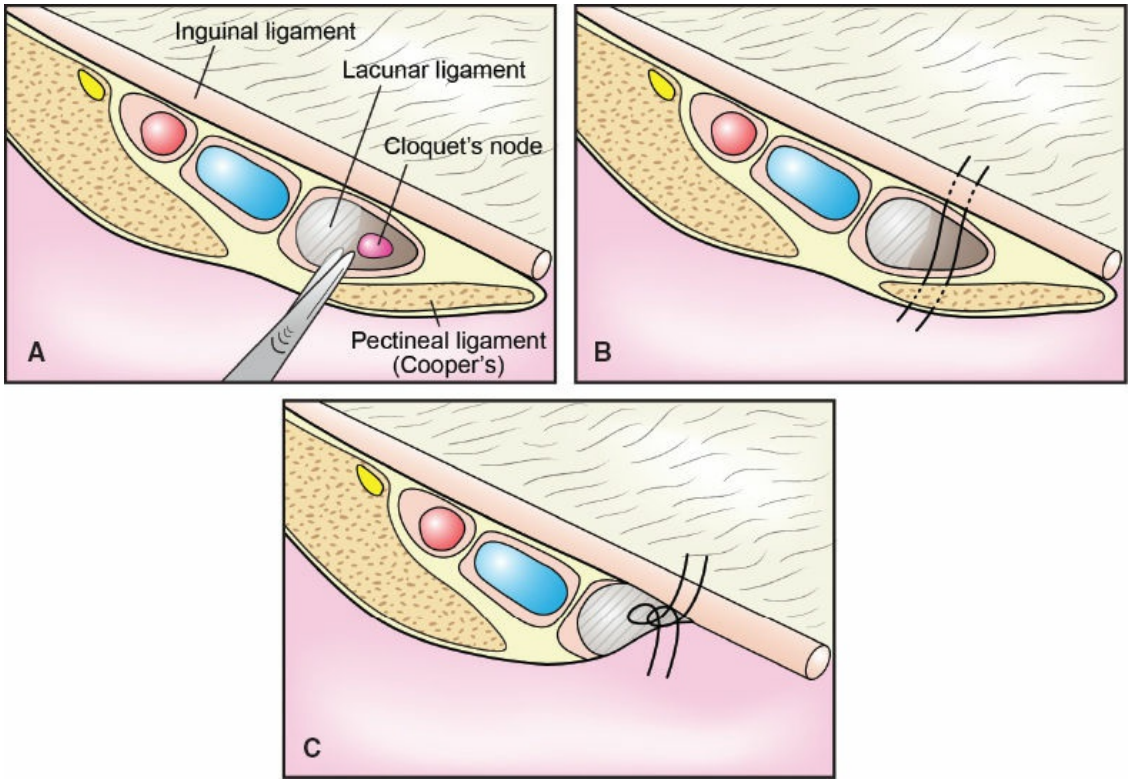

Figure 32.2. Schematic dissection of Cloquet node. Panel **A** is dissecting with a scissors to separate the lacunar ligament between the inguinal ligament and pectineal (Cooper) ligament. Panel **B** shows the node removed and two sutures placed between the inguinal ligament and Cooper ligament. Panel **C** demonstrates the sutures tied down medially to close the defect created and prevent a femoral hernia while avoiding compression on the femoral vein.

Iliac and hypogastric node dissections are generally performed for clinically or radiographically evident disease. Some individuals choose to perform a pelvic lymph node dissection if there is bulky disease in the superficial groin or four or more superficial inguinal nodes are positive due to the high incidence of pelvic nodal disease. Our preference is to only perform the deep nodal dissection if there is evidence by positron emission tomography/computed tomography (PET/CT) of disease or Cloquet node is positive. There are several ways to approach the pelvic lymph nodes. One can extend the superficial skin incision by making a lazy-S type of incision to incorporate the SLN incision en bloc. No flaps are needed on the skin overlying the pelvic dissection. Transecting the inguinal ligament is generally avoided because it increases morbidity and increases wound healing issues. Our preferred approach to provide access to the retroperitoneal space is to make a separate incision in the lower abdominal

musculature, leaving the inguinal ligament intact. External iliac vessels are exposed by blunt dissection and retraction of the peritoneum medially. Dissection of the iliac lymphatic tissue is extended up to the common iliac bifurcation. The obturator dissection is carried out by gentle mobilization of the external iliac vein medially and dissecting the obturator nodes off the obturator nerve and vessels.

Recently a new technical way of perfoming an inguinal lymphadenectomy has been described called a videoscopic inguinal lymphadenectomy. This procedure uses laparoscopic equipment to dissect out the lymph node tissue and uses very small skin incisions that are much further from the inguinal crease than the open incision. The initial studies suggest that there are significantly lower wound complications in these patients, but it comes at the expense of a longer operative procedure and longer lymphatic drainage postoperative. Given some of the technical challenges of this procedure and the decreasing incidence of nodal dissections, it remains to be seen if this method will become widely adopted.

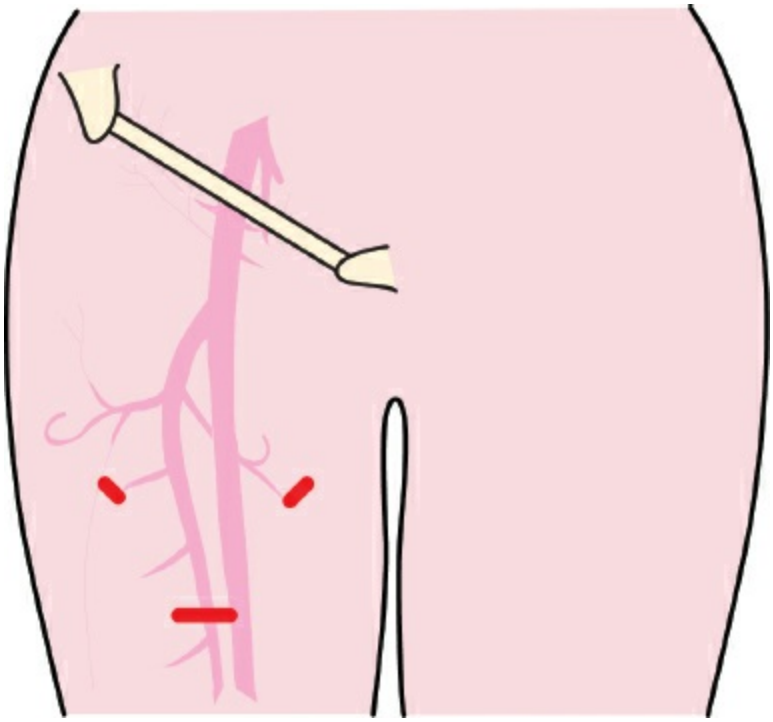

Figure 32.3. Schematic showing the location of the three incisions at the apex of the femoral triangle used when performing a videoscopic inguinal lymph node dissection.

Technically the videoscopic inguinal lympadenectomy is performed by

positioning patients supine on a split-leg table. The boundaries of the femoral triangle are mapped out with a surgical pen. The suprapubic region should be included in the field to monitor for crepitus. The surgeon is positioned between the patient's legs, and the assistant stands to the outside of the operative limb. Monitors are placed cephalad above each shoulder, with the laparoscopic tower strategically positioned on the side of the operative limb.

Trocar placement for a three-incision technique is shown in Figure 32.3 and includes a 12-mm port placed 3 cm distal to the apex of the femoral triangle. A scalpel is used to incise the skin and sharply dissect down through the Camper and Scarpa fascias. A space is then created with blunt-finger dissection, extending out 5 cm on each side from the incision. A balloon trocar is inserted into the 12-mm port site, and the dissected space is insufflated to 25 mm Hg for 10 minutes, then the pressure is decreased to 15 mm Hg to prevent end-tidal CO_2 elevation. Under direct visualization with a 0-degree scope, two 5-mm short bladeless trocars are inserted approximately a hand's breath from the visualization port. These are positioned 3 cm outside of the medial and lateral boundaries of the previously delineated femoral triangle.

At this stage, it is critical to ensure that dissection proceeds in the correct anterior plane. The dissection should be carried out just superficial to the Scarpa fascia. An energy device is generally used to complete the definition of the anterior working space between the fibrofatty node-containing packet and the superficial tissue.

Medial and lateral boundaries of the dissection consist of the adductor longus and sartorius muscle fascia, respectively, which should be correlated with the previous skin markings via transillumination. The fibrofatty packet may be rolled inward with an endoscopic sponge or Kittner continuing superiorly and inferiorly as much as possible to assist in defining the posterior tail of the node packet. Small perforating vessels and lymphatics are routinely encountered and should be divided with an ultrasonic dissecting scalpel or clipped. The deep thigh fascia constitutes the posterior boundary. Its violation is readily apparent when reddish muscle fibers are encountered.

The saphenous vein should be readily identifiable within the apex of the femoral triangle. Our practice has been to preserve it; but if it needs to be sacrificed, then it can be divided with the vascular load of an endoscopic linear cutting stapler. Careful dissection within the femoral triangle

enables identification of the femoral artery pulse as well as the medial femoral vein. Proceeding inferior to superior, the vessels are skeletonized along with all the tissue between the femoral vein and adductor longus.

Once the vascular dissection is complete, blunt dissection in the saphenofemoral junction is performed to identify the inferior edge of the saphenous vein as it enters the femoral vein. If the vein is going to be removed en bloc with the dissection, then a second vascular load of the endoscopic linear cutting stapler is then used to transect the vein at the saphenofemoral junction. Inferomedial dissection around the femoral vein will allow resection of the deep inguinal nodes (see Fig. 32.4). Complete node retrieval should be ensured by continuing the dissection to the level of the femoral canal until the pectineus muscle is visible. A biopsy of the Cloquet node can be done at this point. At this point, the nodal packet is free and is withdrawn in a laparoscopic specimen bag through the apical port. A drain is then placed through the medial port site and is usually left in place until the drainage is <30 mL over 24 hours.

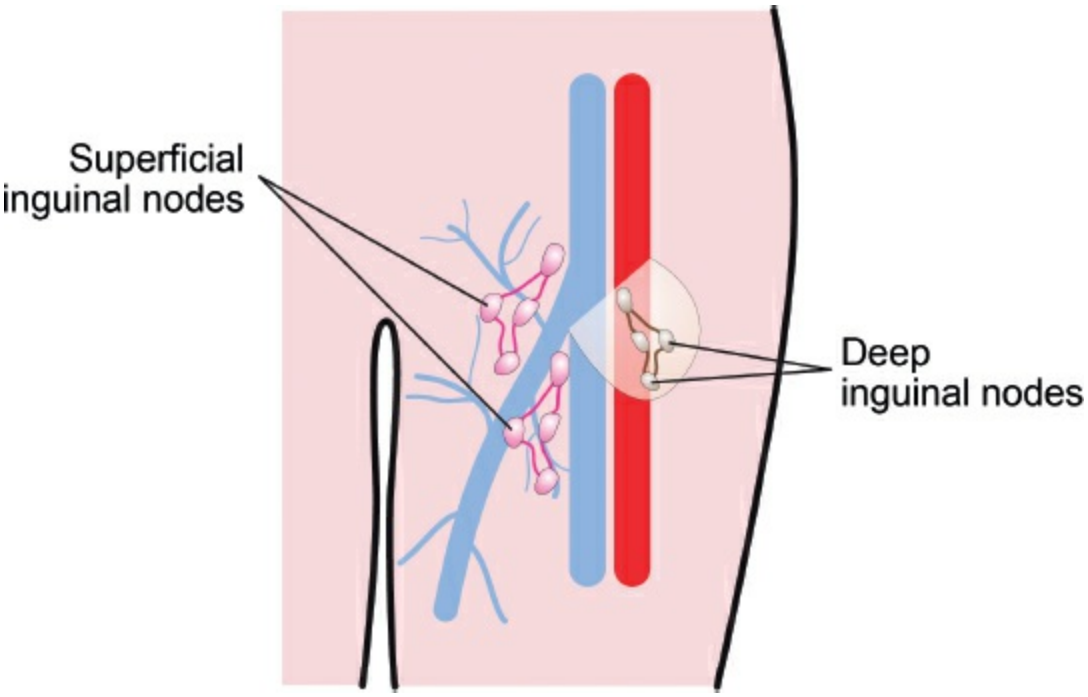

Figure 32.4. Schematic of the two levels of superficial lymph nodes present in a groin dissection. The superficial lymph nodes are generally located above the fascial layer and along branches of the saphenous vein and other tributaries of the femoral vein. The deep superficial lymph nodes are located around the anterior portion of the femoral vein and artery.

EDITOR'S COMMENT

Dr. Tyler and colleagues have nicely described the indications and their technique for groin dissection for appropriate patients with melanoma, Merkel cell carcinoma, penile carcinoma, vulvar carcinoma, anal cancers, and some sarcomas like synovial cell sarcoma. As they indicate, most surgeons will still recommend a completion lymphadenectomy for patients with a positive sentinel lymph node biopsy in melanoma. For melanoma, multiple randomized trials have failed to show any difference in overall survival for patients undergoing wide excision plus elective regional complete lymph node dissection versus wide excision plus observation, although there may be some survival benefit in certain subgroups (Balch CM, Soong S, Ross MI, et al. Long-term results of a multi-institutional randomized trial comparing prognostic factors and surgical results for intermediate thickness melanomas (1.0 to 4.0 mm). Intergroup Melanoma Surgical Trial. *Ann Surg Oncol* 2000;7:87–97). A comparison of the incidence of complications between completion lymphadenectomy undertaken immediately after identification of a positive sentinel node versus completion lymphadenectomy delayed until clinical appearance of regional node involvement has been performed (Faries MB, Thompson JF, Cochran A, et al. The impact on morbidity and length of stay of early versus delayed complete lymphadenectomy in melanoma: results of the Multicenter Selective Lymphadenectomy Trial (I). *Ann Surg Oncol* 2010;17:3324–9). Multicenter Selective Lymphadenectomy Trial-1 data showed a significant treatment-related difference in the incidence of lymphedema. Interestingly, the frequency and severity of lymphedema were greater when completion lymphadenectomy was delayed. The reason is unclear but might reflect blockage of lymphatics, or possibly a more extensive resection required for palpable nodal recurrence, although there was no difference in the number of nodes removed. Unfortunately, chronic lymphedema was seen in 20.4% of patients undergoing a delayed completion lymphadenectomy versus 12.4% of patients undergoing immediate completion lymphadenectomy.

These results are worth noting as the reported morbidity rates associated with groin dissection are significant. A recent report of a retrospective analysis of prospectively collected data in 240 patients who underwent an inguinal lymph node dissection in the University Medical Center Groningen between 1989 and 2014 analyzed four groups with different treatment protocols: A (≥10 days of bed rest with a splint), B (10 days of bed rest without a splint), C (5 days of bed rest), and D (1 day of bed rest). The effect of early mobilization, abolishment of the splint and postural restrictions, and the introduction of prophylactic antibiotics were analyzed. Of note, one or more wound complications occurred in 51.2% of the patients including wound infection (29.8%), seroma (21.5%), wound necrosis (13.6%), and hematoma (5%). In consecutive periods, respectively 44.4%, 60.3%, 44.9%, and 55.2% of the patients experienced wound complications. None of the instituted changes in protocols led to a decrease in wound complications. Furthermore, the authors demonstrated that disease-free survival and melanoma specific survival were reduced in those patients who developed a wound infection (Faut M, Heidema RM, Hoekstra HJ, et al. Morbidity after inguinal lymph node dissections: it is time for a change. *Ann Surg Onc* 2017;24:330–9).

Since changes in perioperative care protocols did not affect the rate of wound complications, it is not a large leap to infer that possibly a change in the surgical procedure itself could possibly lead to the necessary reduction of wound complications after inguinal lymph node dissection.

Replacement of the large inguinal incision by three smaller incisions away from the inguinal skinfold might offer a solution via a minimally invasive technique such as videoscopic inguinofemoral lymphadenectomy. As Dr. Tyler describes, this procedure is accompanied by a lower complication rate in some centers and has a comparable oncologic outcome (Delman KA, Kooby DA, Ogan K, et al. Feasibility of a novel approach to inguinal lymphadenectomy: minimally invasive groin dissection for melanoma. *Ann Surg Oncol* 2010:17:731–7; Jakub JW, Terando AM, Sarnaik A, et al. Safety and feasibility of minimally invasive inguinal lymph node dissection in patients with melanoma [SAFE-MILND]: report of a prospective multi-institutional trial. *Ann Surg* 2016:222:253–60; Martin BM, Etra JW, Russell MC, et al. Oncologic outcomes of patients undergoing videoscopic inguinal lymphadenectomy for metastatic melanoma. *J Am Coll Surg* 2014:218:620–6).

In the initial experience in 32 patients undergoing 45 procedures, 18 dissections (40%) were for melanoma, 19 (42%) for penile carcinoma, 4 (9%) for scrotal/urethral carcinoma, and 4 (9%) for other pathologies. The median patient age was 61 years (range, 16 to 87), and median body mass index was 30 kg/m^2 (range, 19 to 53). Eighty-nine percent of the patients with melanoma had primary disease located in the extremities, with a median Breslow depth of 2.8 mm (range, 0.6 to 9.9). Only two (4%) of the procedures were converted to an open approach. Wound complications occurred in 18% of patients. One patient (2.6%) experienced flap necrosis, which was conservatively managed with

negative pressure wound therapy. Mild to moderate lymphedema occurred in 7.8% of patients. Two of these required compressive stockings for symptomatic treatment. No episodes of wound dehiscence were noted following videoscopic inguinal lymphadenectomy (Delman KA, Kooby DA, Ogan K, et al. Feasibility of a novel approach to inguinal lymphadenectomy: minimally invasive groin dissection for melanoma. *Ann Surg Oncol* 2010;17:731–7). Although the collective clinical experience with this technique is much lower than for open inguinal lymphadenectomy, the early results reported with the videoscopic technique appear to demonstrate reduced complication. Since other adjustments in perioperative care and management have failed with the open approach, this videoscopic procedure might be a promising method for reducing wound complications after inguinal lymph node dissections.

It is possible that the results from the Multicenter Selective Lymphadenectomy Trial-2 may lead to a decrease in the need for inguinal lymph node dissection for melanoma, even in patients with a positive sentinel lymph node. Multicenter Selective Lymphadenectomy Trial-2 is a randomized phase III trial of sentinel lymph node biopsy plus regional completion lymphadenectomy versus sentinel lymph node biopsy plus ultrasound observation of the lymph nodes in patients with sentinel node metastases detected by histopathologic (H–E, immunohistochemistry [IHC]) or molecular (reverse transcriptase-polymerase chain reaction assay [RT-PCR]) techniques. The primary outcome from this trial is melanoma-specific survival, and it will generate findings that will help determine the clinical significance of sentinel node micrometastases and whether careful nodal observation enhanced by sensitive ultrasound monitoring might be an attractive alternative to complete lymphadenectomy in some patients with sentinel node metastasis (Morton DL, Cochran AJ, Thompson JF. Sentinel node biopsy in melanoma [letter]. *N Engl J Med* 2007;356:419–20; Morton DL on behalf of the MSLT-1 group. Overview and update of the Phase III Multicenter Selective Lymphadenectomy Trials [MSLT-I and MSLT-II] in melanoma. *Clin Exp Metastasis* 2012;29[7]:699–706).

33 Evaluation and Repair of Common Facial Injuries

Branko Bojovic

INTRODUCTION

Facial trauma is a common occurrence that can be due to a myriad of etiologies and result in minimal to devastating injuries. It is a fundamental skill for the general surgeon to understand the constellation of injuries that are common in the spectrum of facial trauma. The principles and well-described techniques as it relates to facial trauma evaluation and management will be discussed herein so that the broadly trained general surgeon, along with those in subspecialty disciplines, will have a thorough and clearly defined understanding of common facial injuries and how to triage, treat, and, as necessary, refer such problems for appropriate, higher-level evaluation and management. What is clear is the fact that such injures typically occur not in isolation but in concert with other injuries that may be life-threatening. As such, a requisite understanding of Basic Life Support (BLS) and Advanced Trauma Life Support (ATLS) is to be expected and multidisciplinary cooperative care the goal. Team management with the involvement of trauma surgery, plastic surgery, neurosurgery, orthopedic surgery, otolaryngology, ophthalmology, and oral and maxillofacial surgery, to name a few, is the way to insure successful global evaluation and treatment. In addition, it must be recognized that timely evaluation and management of facial traumatic injuries will establish the best likelihood for outcomes that are both functionally *and* aesthetically optimal.

This chapter will provide the reader an overview of commonly encountered facial traumatic injuries and well-described techniques for addressing such injuries that are based on fundamental principles in surgery. There will be a focus on the critical aspects of the history and physical examination that will not only alert the reader to potential injures not obvious on primary or secondary survey but will also reinforce that which radiologic evidence suggests. A careful overview of appropriate

care for the soft tissue and bony injuries commonly encountered in facial trauma will also be discussed. The reader will also have an understanding for the more serious facial fracture patterns that can be seen in high-energy blunt and ballistic injuries commonly encountered in trauma surgical practice. In addition, the appropriate operative management of such injuries will be discussed. Finally, and something new to this chapter in the Mastery of Surgery series 7th edition, is the discussion of techniques available in the state-of-the-art treatment of facial scarring that is frequently seen as a lasting sequela of the myriad of facial injuries suffered by patients and the reminder these scars serve in the psyche of these patients. We have techniques available today that, once the fundamental goals of functional and aesthetic facial injury repair have been achieved, can *almost* erase the scars that have all too long been a painful reminder of the injury or injuries suffered in the past.

INITIAL EVALUATION

As was mentioned in the Introduction, facial traumatic injuries typically occur not in isolation but in concert with other injuries that may be life-threatening. As such, facial traumatic injuries, in and of themselves, are rarely life-threatening but that should not diminish the importance of the primary and secondary surveys in evaluating these patients. In every circumstance, the American College of Surgeons' principles of ATLS should be adhered to and appropriately utilized. Once the primary survey has been completed and an assessment of airway, breathing, and circulation performed satisfactorily with adherence to BLS principles, the secondary survey may begin. This is an appropriate time not only for facial traumatic injury assessment but also an excellent opportunity to assess level of consciousness. This is performed according to the Glasgow Coma Scale (Table 33.1) and should be documented in a baseline fashion with ongoing reassessment as appropriate, especially if closed head/traumatic brain injury is a concern.

As mentioned, the secondary survey is the appropriate time for closer and dedicated evaluation of obvious or occult facial trauma. During this time, critically important observations and even life-saving interventions can be made if the examiner were to discover life-threatening concerns. Namely, in addition to devastating closed head injury, airway obstruction or evidence of aspiration and life-threatening hemorrhage; all are vitally important findings that, if recognized, may be intervened upon

expeditiously and definitively so that such factors will not be allowed to compromise the injured patient's life. A familiar example of this is the multi-injured trauma patient who despite through primary and secondary surveys is still hypotensive and unresponsive to appropriate fluid resuscitation only to discover an occult or unrecognized dependent or posterior scalp laceration causing sustained and life-threatening hemorrhage. This is an example that need not be repeated if an appropriate, systematic, and completely thorough evaluation of the facial trauma patient is performed.

From Jennet B, Teasdale G. *Management of Head Injuries.* Philadelphia, PA: FA Davis; 1981; and Oreskovich MR, Carrico CJ. Trauma: Management of the acutely injured patient. In: Sabiston DC, ed. *Textbook of Surgery,* 13th ed. Philadelphia, PA: WB Saunders, 1986:324.

One must be prepared to perform oral intubation if criteria dictate so or if concern for appropriate airway stability is apparent. In addition, if such a scenario were to present itself or develop in a rapid or deteriorating fashion, then emergent cricothyroidotomy and/or tracheostomy should be considered or performed if an oral or nasal airway cannot be established with certainty or safely. In line with this area of the evaluation, if there is evidence of concern for aspiration of a variety of things from oral secretions to blood/gastric contents to teeth or foreign bodies, then orotracheal intubation can serve as a preventive measure when clear concern or evidence for potentially compromised airway protection is

present.

Hemorrhage is also a significant concern, especially with devastating blunt or ballistic facial trauma. While there may be high index of suspicion for visceral or arteriovenous injury elsewhere, it should be noted that significant blood loss may occur from craniofacial injuries prior to and during presentation in the acute setting and as such should be evaluated and treated accordingly. Commonly encountered examples include scalp lacerations, including along the course of the superficial temporal artery and vein, facial lacerations of branches of the facial artery and vein, nasal hemorrhage that requires packing or balloon tamponade, oral cavity hemorrhage from Le Fort–type fractures, and bleeding from the cranial base or intracranial arteriovenous systems that can lead to devastating consequences if not recognized expeditiously. All the aforementioned, save the last example, may be dealt with by direct pressure or suture ligation-assisted hemostasis. However, it is important to recognize that the most appropriate place for such endeavors, in an ideal circumstance, is the operating room as critical neurologic structures may be injured iatrogenically, especially if suture ligation is performed at or near the areas of facial nerve trunks or branches. Exploration, direct visualization, and meticulous surgical technique is the safest and most predictable sequence to address many of the aforementioned hemorrhagic concerns.

It is beyond the scope of this chapter to discuss some of the more complex and infrequent occurrences of midfacial or cranial base injuries that may require temporary midfacial stabilization or possibly even interventional radiology selective arterial embolization other than to refer to some of the selected readings at the end of this chapter that discuss that thoroughly. Suffice it to say, in general, it should be at least something the reader is aware of when confronted with a scenario where thorough primary and secondary surveys have been performed and yet there is still a lacking explanation for significant hemorrhage. In such circumstances, urgent or emergent consultation with specialty colleagues in plastic surgery, otolaryngology, or oral and maxillofacial surgery should be obtained.

As discussed earlier, when the patient has been deemed to be stable and the examination now focused on careful evaluation and documentation of facial injury, the importance of a thorough and complete history during the physical examination cannot be understated. Various important facts can be obtained, if not from the patient or family members, then witnesses to

the injury or personnel present shortly thereafter, and the history can help to support the mechanism of injury suspected. In addition, important clues regarding possible substance abuse concerns can be vetted via toxicology screens and anything noted in the history including co-morbidities, allergies, medications, and immunization status will serve to complete the evaluation, so necessary interventions account for these important factors.

Careful clinical examination should begin with a thorough, reproducible, and consistent approach that will provide as much information as possible. This typically can be done by compartmentalizing the examination into soft tissue and bony considerations. In addition, if one can examine in a fashion that is consistent from patient to patient, this allows for the least likelihood that an important examination "checkbox" will be missed. Starting from the crown of the head and working in a caudal direction will typically be the easiest way to proceed. All obvious physical examination findings should be carefully noted and include ecchymosis, hematoma, puncture wounds, lacerations, asymmetry, contour irregularities, areas of tenderness to palpation or localized pain, gross visual acuity disturbances, and numbness or paresthesias, to name some of the most common findings. All soft tissue injuries encountered should be suspected to have concomitant or associated deeper, bony injuries until proven otherwise. The physical examination is a way to either raise suspicion as to what radiologic evaluation will uncover or confirm that which radiologic evaluation has already suggested or diagnosed.

As alluded to, the physical examination should be performed in a methodical and reproducible fashion. It typically is easiest to proceed with a "top-down" and "out-in" approach where careful examination starts from cephalad to caudad and from external to internal approaches. Firstly, a gross visualization of the entire craniomaxillofacial region is a very valuable way to get an initial assessment of the severity and complexity of what the presentation of injury may uncover. It should go without saying, but must be clearly understood, that part of the evaluation that frequently is done poorly or not at all is exposure and cleansing of the areas to be evaluated. Frequently, dried blood, debris, foreign bodies, or other objects such as bandages, dressings, clothing, jewelry, and so forth, can get in the way of a thorough examination. There is sometimes fear for exposing areas injured, understandably, but experience has shown that a thorough cleansing and exposure of areas of facial trauma can be safely done, unlikely to cause further injury, and will allow for a more accurate and

detailed examination that otherwise may go unnoticed by the novice examiner. It is absolutely necessary to perform an appropriate cleansing of all areas of concern and typically a warm solution of saline or a half strength solution of peroxide and warm saline functions well in that regard. A small forceps, scissors, and cotton-tipped applicator are all that is typically needed to accomplish this. Typically, most patients will tolerate this well without any need for local anesthesia as they are usually already suffering from diminished sensation at the initial evaluation and already have pain medication on board. For other areas, particularly intraorally, the use of a suction device or digital removal of debris or foreign bodies is helpful, paying particularly close attention to any loose or missing teeth, if encountered. Also, at this time, any evidence of central or midface mobility suggestive of maxillary alveolar or Le Fort–type injuries can be evaluated by bimanual palpation (Fig. 33.1). Using this technique, the maxillary alveolar ridge is manipulated with the dominant hand while the nondominant hand stabilizes the head while also being able to palpate the nasofrontal region.

Once the areas of concern have been fully exposed and cleansed, a palpation of the underlying bony structures can ensue. Generally, using the thumb or index finger, one can appreciate any irregularities, underlying foreign bodies, asymmetry, fluid collections, or what are commonly referred to as “step-offs” or focal areas where the facial skeleton may indicate evidence of fracture or displacement. Further palpation can identify loose or missing teeth, disturbances in the maxillary or mandibular dental arches, floor of mouth lacerations or hematoma, mandibular subluxation or dislocation, and presence of pain in the cervical vertebra area. All of these findings should be noted and documented carefully.

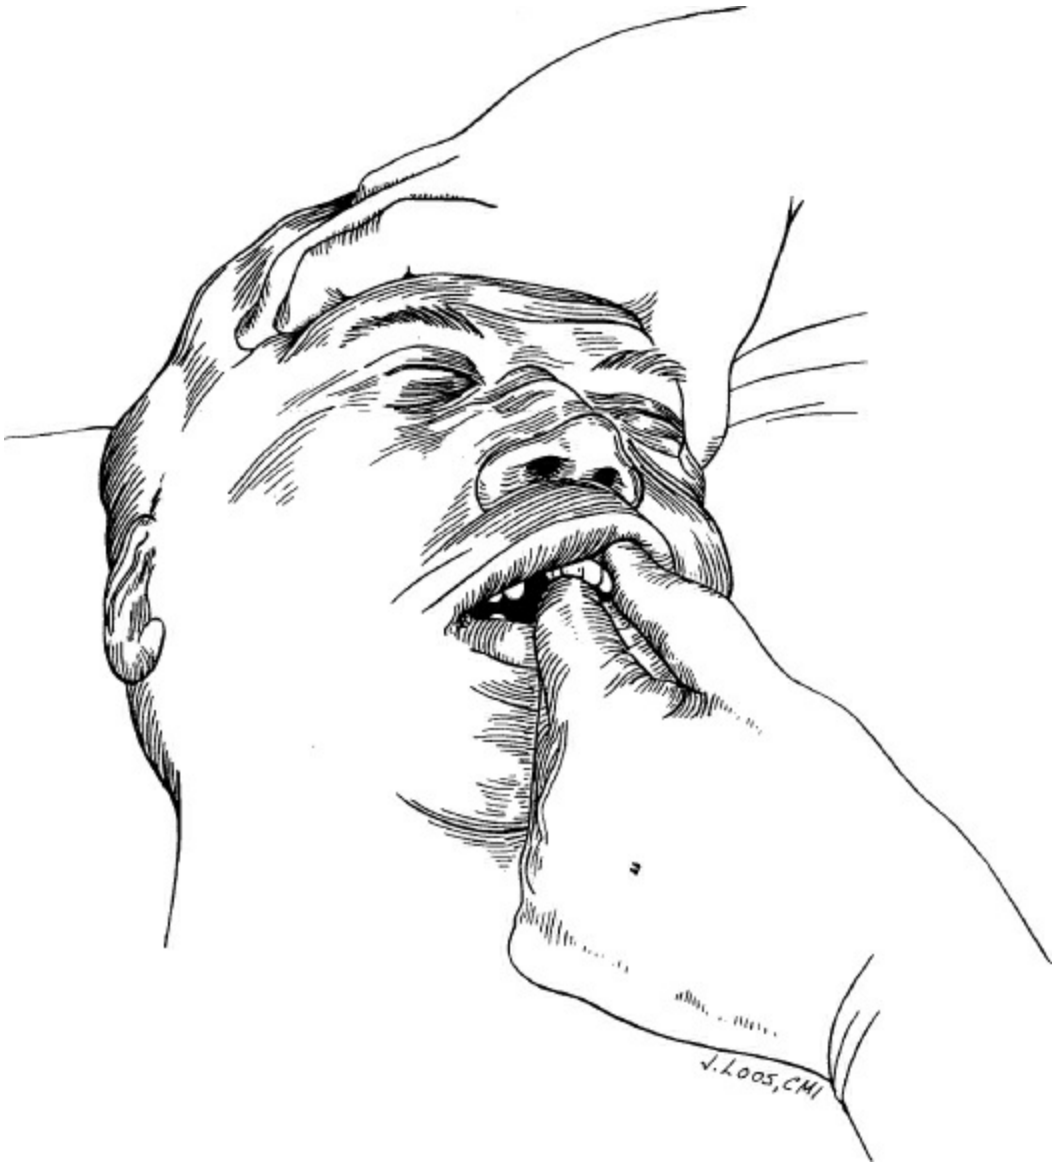

Figure 33.1. Bimanual palpation of the facial skeleton for the diagnosis of midface fractures.

Although only briefly mentioned thus far, the globe and periorbital region is of great importance and must be requisitely evaluated. If the eyelids are not swollen, then gross visual acuity and pupillary reactivity can be evaluated quickly. If needed, gentle digital or cotton-tipped applicator retraction of the eyelid(s) can be performed to facilitate the examination. Extraocular movements of the globe in all cardinal directions should be performed and any deficits noted or pain with movement documented. Ecchymosis in the periorbital region or blood in the scleroconjunctival region or anterior chamber between the cornea and iris (hyphema) will alert the examiner to high suspicion for orbital bony fractures or direct globe injury. Even with the aforementioned being

evaluated, a formal ophthalmologic evaluation should be considered when suspicion is high for periorbital injury. It should be mandatory if there is computed tomographic evidence of orbital fracture.

Once the examination has progressed to this point, it is a good time to document all relevant findings and begin thinking about adjunctive radiologic evaluation or preparing for review of any relevant radiologic imaging already performed. In addition, this is the appropriate time to start thinking about what soft tissue injuries may be able to be dealt with in the emergency room or trauma bay or whether these injures need more formal evaluation in the operating room setting.

This is especially important and relevant if there are lacerations to the periorbital region or frank trauma to the globe. Maneuvers, such as urgent or emergent lateral canthal tendon release should be considered if there is evidence of intraocular hypertension due to retrobulbar hematoma. In addition, this is also a good time to ascertain if there is evidence of injury to the lacrimal system, which will be discussed in more detail herein.

This is also an appropriate time to consider some of the deeper injuries that may not be obvious, including frontal or basilar cranial injuries. Such injuries classically present with clear fluid running out of the nose (also known as cerebrospinal fluid [CSF] rhinorrhea) or the ear (CSF otorrhea). This can be difficult to differentiate from blood or other secretions but if the index of suspicion is high, there are adjunct physical examination maneuvers that can attempt to provide clarity. One of these is the “halo” sign that can be observed when a drop or two of nasal discharge is placed onto a clean cloth and “double ring”–type effect or frank halo of CSF separates into the periphery from the center of where this fluid was placed. Additional laboratory testing in the form of serum electrophoresis can be performed to confirm the diagnosis. Furthermore, if radiologic imaging confirms pneumocephalus (air within the cranial cavity) or presence of blood in the cranial cavity then careful consideration must be given to serial neurologic examination, possible prophylactic antibiotic therapy if concern for development of meningitis is high, and close observation in an ICU-level setting to monitor progress or lack thereof. Thankfully, many of these injuries can be managed conservatively over the course of a number of days with observation.

RADIOLOGIC EVALUATION

When evaluating facial injuries, traditional radiographic workup frequently

included anteroposterior and lateral cervical spine imaging and a craniofacial imaging series with Waters view. Today, these are mostly of historic significance due to the highly sensitive and accurate rapid computed tomography (CT) scanners that are ubiquitous in most emergency or acute care facilities. In fact, CT scans provide a substantial and important amount of information and have been shown to be more cost-effective than radiographic series, especially in craniofacial trauma evaluation. In addition, superior imaging quality, the ability to have "cuts" in axial, coronal, and sagittal planes, and software available to "reconstruct" those images into three-dimensional (3D) imaging truly make craniofacial CT workup the "gold standard" for craniofacial trauma imaging. It should be noted that in most scenarios, a minimum slice size of 3 mm or less is ideal in evaluating the craniofacial trauma patient and in many cases 1-mm or 2-mm slice sizes are preferred.

It is worth mentioning that in isolated mandibular or maxillary trauma, a panoramic radiograph, also known as a Panorex, can be very valuable and in certain cases equal or superior to a CT. In these cases, injury severity and physical examination concordance with the Panorex will dictate whether further imaging is warranted. However, this is still a valuable tool and can be used with appropriate discretion.

Furthermore, 3D CT reconstructions, especially when formatted with fine slice imaging (2 mm or less/slice) can provide not only utility in operative management approaches to the surgeon repairing these injuries, but can also be used in planning of secondary reconstruction cases as more and more institutions acquire these high-speed and accurate CT scanners. It is also worth mentioning some institutions that perform a high volume of craniofacial trauma cases have intraoperative CT scanners available so that real time feedback can be obtained and intraoperative corrections made, if necessary, to areas of bony reduction and fixation, leading to fewer instances of operative revision surgery being necessary.

Even in light of the aforementioned, radiologic evaluation should serve as an adjunct to the traditional examination already discussed. "Laying on of the hands" on the patient will always be master to radiologic evaluation and a skill that will strengthen and refine over the course of a surgeon's career.

TREATMENT OF FACIAL SOFT TISSUE INJURIES

General Considerations

There is general agreement that once all of the aforementioned surveys and appropriate radiologic imaging is obtained, it is at this point in time that consideration be given to definitive management of injuries of the face. If, again, we compartmentalize these into soft tissue versus hard tissue, or both, it is obvious that there are multiple options available to provide treatment. If we look only at soft tissue injuries, then the acute setting in the emergency room, trauma bay, or even the office procedure room may serve as appropriate places for evaluation, exploration, cleansing and debridement, and meticulous closure if these injuries can be appropriately anesthetized with local anesthesia. This becomes more difficult in the highly anxious, uncooperative, or pediatric/adolescent patient and in such situations either monitored sedation or formal operative room treatment may be the best choice for the patient and the ease of management for the treating surgeon. There is consensus about tetanus prophylaxis and I refer the reader to the guidelines of the American College of Surgeons on those criteria (Table 33.2). As was mentioned earlier, it cannot be overemphasized that a commonly overlooked and frankly poorly performed initial and critical portion of any facial soft tissue injury treatment is the exposure/exploration, cleansing/debridement, and preparation of the wound(s) for definitive closure. It was once said by a plastic surgical mentor of mine “let the intern perform the flap portion of the procedure while I perform the debridement myself.” Those words underscore the importance and emphasis on appropriate wound evaluation and preparation prior to management and are just as true in the evaluation and management of common facial injuries as they are for anywhere else on the body.

Anesthesia

As alluded to, in an ideal scenario most soft tissue facial injuries are dealt with using local anesthesia optimized by utilizing well-described local nerve block techniques (Fig. 33.2). In such situations, limited amounts of local anesthesia, as little as a few milliliters, are needed and require less injection into the actual areas of injury which are already typically edematous and have areas of tissue that likely will not react favorably to the vasoconstrictive effects of epinephrine. In fact, I personally find that well-placed nerve blocks coupled with conservative placement of local anesthesia in a *topical* fashion works better than actually injecting it into the laceration or area of injury, especially when you are dealing with

aesthetically important areas including the perioral and periorbital regions.

TABLE 33.2 Recommendations for Tetanus Prophylaxis of the Committee on Trauma, American College of Surgeons

Age (Years)	Vaccination History	Clean, Minor Wounds	All Other Wounds
0–6	Unknown or not up-to-date on DTaP series based on age	DTaP	DTaP TIG
	Up-to-date on DTaP series based on age	No indication	No indication
7–10	Unknown or incomplete DTaP series	Tdap and recommend catch-up vaccination	Tdap and recommend catch-up vaccination TIG
	Completed DTaP series AND <5 years since last dose	No indication	No indication
	Completed DTaP series AND ≥5 years since last dose	No indication	Td, but Tdap preferred if child is 10 years of age
11 and older ([a]If pregnant, see footnote)	Unknown or <3 doses of tetanus toxoid containing vaccine	Tdap and recommend catch-up vaccination	Tdap and recommend catch-up vaccination TIG
	3 or more doses of tetanus toxoid containing vaccine AND <5 years since last dose	No indication	No indication
	3 or more doses of tetanus toxoid containing vaccine AND 5–10 years since last dose	No indication	Tdap preferred (if not yet received) or Td
	3 or more doses of tetanus toxoid containing vaccine AND >10 years since last dose	Tdap preferred (if not yet received) or Td	Tdap preferred (if not yet received) or Td

[a]Pregnant Women: As part of standard wound management care to prevent tetanus, a vaccine containing tetanus toxoid might be recommended for wound management in a pregnant woman if 5 years or more have elapsed since the previous Td booster. If a Td booster is recommended for a pregnant woman, healthcare professionals should administer Tdap.
From The American College of Surgeons. *The Advance Trauma Life Support Student Manual*. 10 Ed. 2017:409; an adaptation National Center for Environmental Health (NCEH)/Agency for Toxic Substances and Disease Registry (ATSDR), National Center for Injury Prevention and Control (NCIPC).

It should also be noted, and ideally already performed, that sensory (trigeminal) and motor (facial) nerve evaluation should be documented prior to local anesthetic infiltration in the face. In addition, taking advantage of anatomic nerve block techniques limits the need for direct or field block injections for the reasons mentioned. In fact, particularly in the perioral region at the vermilion border of the lips or the periorbital region of the eyebrow or eyelid, this is particularly useful so that limited distortion of these areas is performed. For example, a millimeter difference in approximation in these areas can be picked up by the human eye and it

is critical that these regions be meticulously reapproximated with limited local anesthetic infiltration if possible (Fig. 33.3).

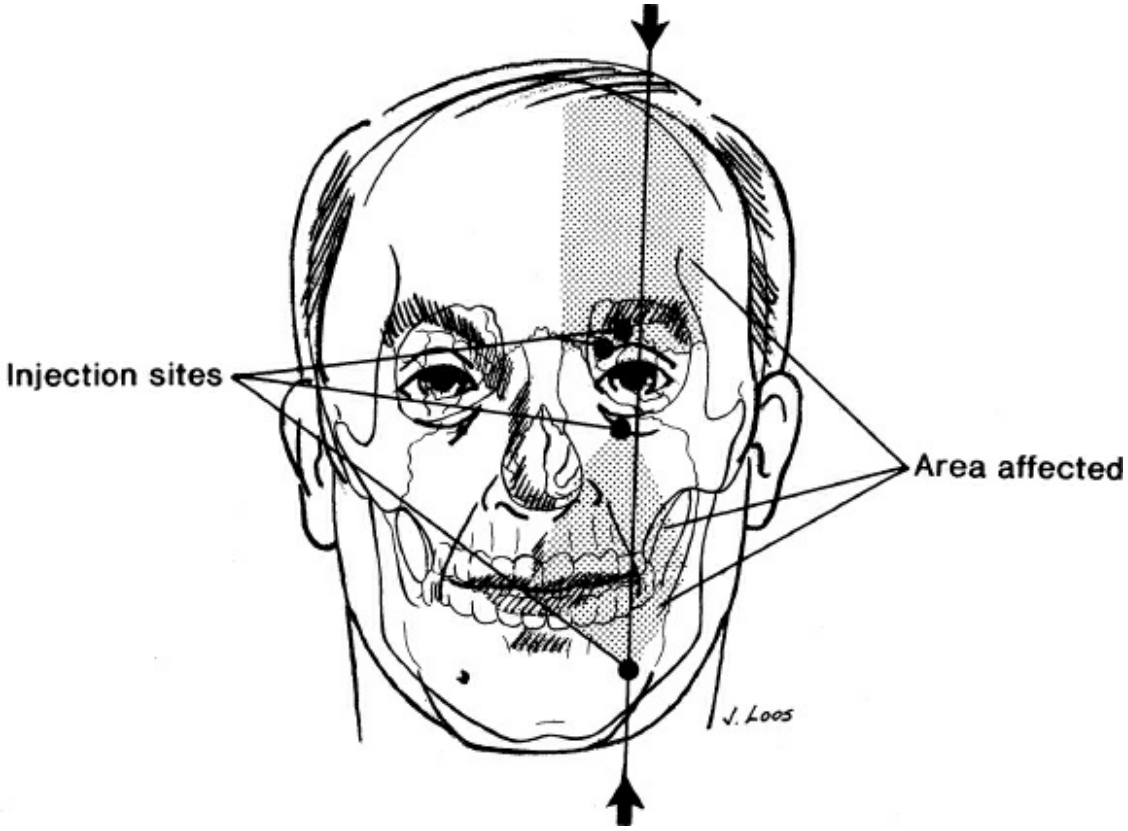

Figure 33.2. Sites for injection and affected areas for supraorbital, infraorbital, and mental nerve blocks.

Usage of bupivacaine or lidocaine is typically a personal preference but it is worth mentioning that the effects of bupivacaine can last up to 8 or more hours. This can be useful when a longer period of posttreatment pain control is needed. However, it must be remembered that accidental intravascular injection of bupivacaine can lead to asystole from its cardiotoxic effect; so when injecting using bupivacaine, use an appropriate technique with aspiration of the syringe prior to injection. In the same vein, when injecting in general, the same technique should be used to avoid inadvertent intravascular injection. There is also the potential of intraneural injection when performing the anatomic blocks mentioned. If there is extreme pain when such a block is being performed, there is a high likelihood the needle has found its way into the intraneural plane and the injection should be stopped and the needle immediately withdrawn. Finally, two areas of the facial region notoriously difficult to anesthetize without multiple areas of block or a formal ring or field block include the

nose and the ear due to overlapping regions of sensory innervation. In these cases, topical local anesthesia in the form of eutectic mixture of local anesthetics (EMLA) can be used to facilitate diminishing the pain from injecting multiple sites.

The best choice of anesthetic or the technique used can be further explored in the Suggested Readings section. Suffice it to say, that I have not personally found it useful to add sodium bicarbonate, as has been well described, to my local anesthetic of choice in attempts to make the injection less painful. While I have nothing personally against this technique, I have found the aforementioned pearls useful in limiting pain associated with injection and the additional step of adding bicarbonate practically not useful. I think that using a 1-mL tuberculin syringe with a 30-gauge needle is most effective and least painful and would encourage the reader to consider using that technique in his or her practice.

Finally, a word about conscious sedation deserves mentioning. I have found it to be very useful in some of the situations mentioned previously and feel that is an excellent option when appropriate anesthesiology or sedation-certified physician care is available with close monitoring throughout. This can sometimes save a trip to the operating room and should be used with appropriate discretion.

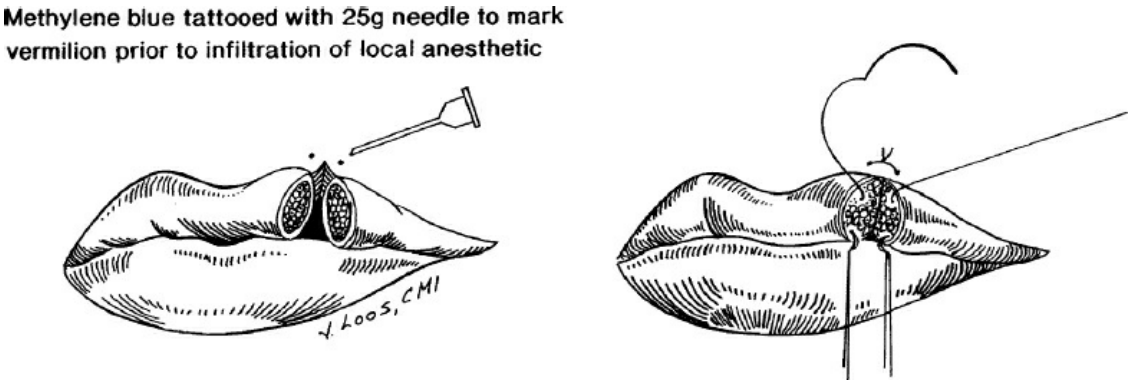

Figure 33.3. Marking the vermilion border before local infiltration of anesthetic aids precise repair of lacerations of the lip.

Wound Preparation

Wound preparation is an exercise in which multitasking is commonplace and a set routine an invaluable asset. Just as in the physical examination discussion, having a routine that one is comfortable with, reproducible, and allows for low likelihood of forgetting any steps is very useful. If the patient is awake, then wound preparation is also the time in which the

surgeon can work to calm any anxieties or fears and explain clearly, confidently, and in a step-by-step fashion what will be done.

I favor a wide exposure and preparation of the area to be intervened upon. It is extraordinarily useful to have, if possible, uninjured or contralateral landmarks available to guide your decision making and technical approach. I have found that *topically* applying local anesthesia to the wound be and giving it requisite time to take effect not only diminishes some pain the will experience with manipulating the wound prior to preparation but also leads to less local anesthesia needed overall for direct infiltration and including when anatomic blocks are performed.

Generally speaking, if overall debris or dried blood has not been removed by the time you have been asked to see the patient, please do this critical step. Then, a more formal cleansing of the wound, as has been discussed, may ensue. I do not hesitate, using clippers, to shave any areas of hair that may be obscuring the field, save for eyebrow hair which should be preserved in almost every circumstance. Solutions that are useful for cleansing include warm saline or a half-strength warm saline–hydrogen peroxide mixture. Use of betadine in the head and neck is safe and appropriate. Hibiclens solution or ChloraPrep should not be used in the head and neck under any circumstance due to mucosal and scleroconjunctival adverse effect concerns.

One of the most important things mentioned already is the concept of a thorough debridement of the areas of concern and interest. During the acute period during which most common facial injuries are suffered, this is unequivocally the best and perhaps only appropriate chance one will have to remove any foreign material, debris, devitalized tissue, and so on, that are so frequently encountered. If appropriate treatment is not able to be done under local anesthesia or even conscious sedation settings, then the operating theater should be used for definitive wound preparation, debridement, and management. The use of gentle scrub brushes can be an added asset. In addition, loupe magnification can assist with removal of small pieces of debris, especially if fine forceps are needed to individually remove various foreign bodies. Close examination of the injured areas will provide an assessment of how much, if any, sharp debridement will be necessary and if any margins of skin/subcutaneous tissue need to be removed. I would caution that, in my own experience, what may appear as marginal tissue at first many times will go onto survive and that one should be extremely conservative in debridement in the acute setting; this

is particularly important in the perioral and periorbital regions. In fact, it is easier to revise a wound months later under controlled surgical conditions once all areas have declared themselves and healed under minimal tension or stress than it is to revise a wound that has been unnecessarily or aggressively debrided, leading to increased wound tension during closure, surrounding distortion from the wound closure, and other numerous problems in the healing period that may develop under such circumstances.

With regards to closure, in general, a primary closure should be attempted when possible. Primary closure does not necessarily mean direct, linear closure. Applying a skin graft in the acute setting, for instance, is also a primary closure, just not a linear one. What matters is that when the circumstances are appropriate, direct closure is preferable for numerous reasons. However, if it is necessary to allow the wound to heal in by secondary intention or provide dressing changes as a bridge to delayed primary closure, this should be done at the discretion of the surgeon. Such circumstances are frequently encountered with animal bite wounds; deep, penetrating wounds that are difficult to thoroughly debride and drain; and in extraordinarily contaminated wounds where the risk of primary closure would predispose to a high risk of infection.

I favor layered wound closure when possible so that dead space is minimized and that multiple layers are able to serve to support the overall wound strength and stability. In the deeper layers, monofilament, absorbable sutures are preferred. In the more superficial layers, either an intradermal closure using absorbable monofilament suture or a more superficial placement of interrupted nylon or prolene suture is commonplace. For sutures in the head and neck, and certainly the face, skin sutures should be removed in 3 to 5 days, and preferably no longer than 7, to avoid the “hatching” or “track marks” so commonly seen as an iatrogenic sequela of sutures left in too long and the epithelialization of those suture tracts.

In the scalp, certainly staple usage is entirely reasonable and sometimes preferred. In the face, this is to be totally avoided. In the scalp, face, or neck, if there is dead space where concerns for postoperative fluid collection exist, either Penrose drains or closed suction drains placed for a few days can be a valuable tool to minimize such concerns. If concerns are present that critical structures of the face, including the lips or ears, are at risk for viability then subspecialty consultation should be immediately

obtained so that additional technical assistance may be provided, including microvascular repair or revascularization. In addition, if any anatomic parts are amputated, those should be wrapped in moistened-saline gauze, placed in a plastic bag, and then placed on ice while waiting for subspecialty consultation or, if not available, referral to an institution where such specialty services are available.

A quick word about adjuncts that are commonly available but frankly not that useful in facial injury repair, include the use of Histoacryl (n-Butyl-2 Cyanoacrylate) or Dermabond (2-Octyl Cyanoacrylate). While these have their unique areas of use, I have found in my practice that in the setting of craniofacial injury, they do not provide much practical help in this setting. In fact, many times they will seep into the wound and inhibit wound healing or cause an unintended reactive inflammatory response that is counterproductive. Frankly, Steri-Strips would be a more appropriate and suitable alternative if the treating surgeon feels an added amount of protection or support is needed for the area of repair and these can be placed longitudinally or perpendicularly and have the ability for fluid to egress through them as an added benefit.

Finally, a short discussion on the use of antibiotics is necessary to complete this section. In the elective setting, in clean or even clean–contaminated wounds, antibiotics are typically not used due to the robust blood supply of the face. However, an important caveat and still a controversial point of discussion is the use of antibiotics in the acute or traumatic setting. I think it is reasonable to provide at least one preprocedural/preoperative dose of appropriately selected antibiotics for skin flora coverage in these situations; typically a first-generation cephalosporin or appropriate substitute if patient allergy precludes. In fact, in cases of substantial contamination or devitalization, an additional 24 hours of antibiotic therapy is also entirely reasonable. This is especially the case in animal or human bites where multiple days of postoperative treatment may be indicated.

Special Considerations

There has already been discussion of several areas of particular importance in common facial injury management that deserve special mention. The face itself has areas of critical functional and aesthetic importance. The most important of these will be the motor and sensory nerves, which are frequently injured or at least affected to a degree in the majority of

commonly encountered facial injuries. If lacerations of the facial nerve trunk, its branches, and/or the branches of the trigeminal nerve are noted, these should be expeditiously explored in the operating room and repair attempted under the operating microscope. In addition, a frequently injured area due to lacerations in the region of a line drawn from the tragus of the ear to the lateral brow, is the frontal branch of the facial nerve. If this is unrecognized or not repaired, the frontalis muscle on the affected side will not function and lead to an inability to raise the brow and loss of rhytid lines, which can be distressing to the patient and require the use of chemodenervation on the unaffected side to restore symmetry. In fact, facial nerve injury should be suspected until proven otherwise when penetrating injuries occur on a line between the lobule of the ear and the lateral brow (Fig. 33.4). Again, physical examination and findings documentation is critical to exclude or recognize such injuries.

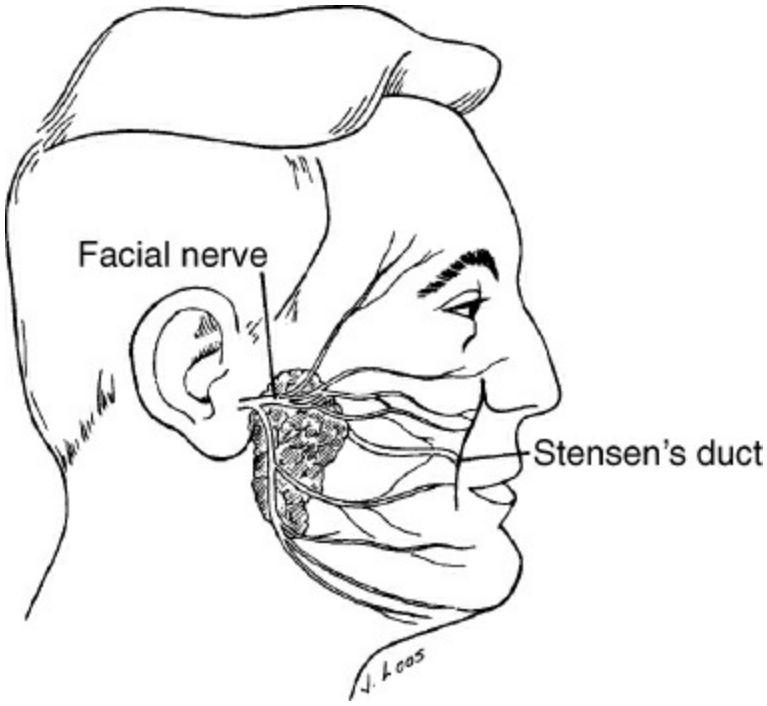

Figure 33.4. Location of the facial nerve and parotid duct (duct of Stensen).

The aforementioned is an excellent segue to discuss an injury that is not uncommonly suffered when concerns about facial nerve involvement arise. The parotid duct, also commonly referred to as the duct of Stensen, is anatomically located along the central divisions of the facial nerve as it branches from its main trunk and exits the parotid gland. Anatomically, it is located approximately 2.5 cm anterior to the tragus of the ear, at the

anterior margin of the parotid gland, to its termination intraorally visible as a small punctum near the maxillary second molar tooth. These are useful landmarks to remember as an injury along this course should alert one to parotid duct injury. If any injury is suspected, the intraoral punctum can be cannulated with a small, flexible angiocatheter and saline injected gently to see if it extravasates into a wound in that vicinity. If that is the case, exploration in the operating room should be performed to not only repair the duct but also to evaluate for high likelihood of facial nerve branch injury which can be supported by the physical examination findings. The selected readings section offers more specific information on the specifics of such evaluation and technical approaches to repair.

Fluid collections or hematomas can commonly develop in multiple areas of the face. The two most commonly encountered and important areas are the ear and the nasal septal area. If unrecognized, hematomas in these regions can lead to a disfiguring condition of the ear, commonly referred to as “cauliflower ear” or nasal septal cartilage destruction leading to a nasal septal fistula. In these cases, the fluid collection or hematoma should be incised and drained as soon as identified and the area stented or packed to prevent reaccumulation (Fig. 33.5). If other areas of the face harbor a fluid collection or hematoma, these should also be incised, drained, irrigated, and appropriately dressed with patient follow-up in the next few days to be sure that recurrence has not occurred. Occasionally, aspiration with an 18-gauge needle may be attempted but my personal experience with this has been disappointing and only as a temporizing maneuver until formal incision and drainage can be performed.

Finally, it is worth mentioning that high-energy–type wounds to the face, as is commonly seen in ballistic injures, deserve special mention. In these cases, the energy dissipation and subsequent injury may not immediately be obvious with regards to ultimate amount of tissue destruction that has declared itself. In these situations, once full BLS and ATLS, surveys, and patient clearance has been performed, it is typically necessary to perform serial examinations and debridements as the area of tissue involvement declares itself. This commonly translates into return to the operating room every 48 to 72 hours until this process has gone to completion, after which time definitive management of associated injuries can take place with lowest risk of infection or necrosis-related complications.

SOFT TISSUE INJURIES TO THE EYE, ORBIT, AND LACRIMAL APPARATUS

As was mentioned earlier, the periorbital region is of special importance for obvious reasons. I alluded to the fact that if one suspects frank globe injury or if evidence suggests orbital fracture, then consultation of ophthalmology is absolutely indicated and necessary. Once the globe(s) has(have) been appropriately evaluated and "cleared" it is then appropriate to deal with any lacerations in the periorbital region. Frequently, laceration to the eyelids is encountered and must be treated with meticulous technique (Fig. 33.6). The anatomic structures including the tarsus, eyelid margins and conjunctiva, and eyelash borders are repaired in layers. Typically, for the tarsus and conjunctival layers, a fine monofilament, absorbable suture is used in the form of 5-0, 6-0, or 7-0 suture size. The skin in these regions typically tolerates a monofilament such as nylon or polypropylene of the 6-0 or 7-0 size. In addition, noncutting, taper needles are my personal favorite in almost all situations on the face and frankly anywhere else on the body. These sutures are minimally traumatic and push nicely through delicate tissue rather than cutting through them. Once repair of the eyelid has been performed, suture ends should be protected with a fine Steri-Strip to prevent any corneal or scleroconjunctival irritation while healing occurs. As mentioned previously, leaving sutures in place for 3 to 5 days is ideal but certainly no longer than 7 days to avoid iatrogenic "hatch" or "track marks."

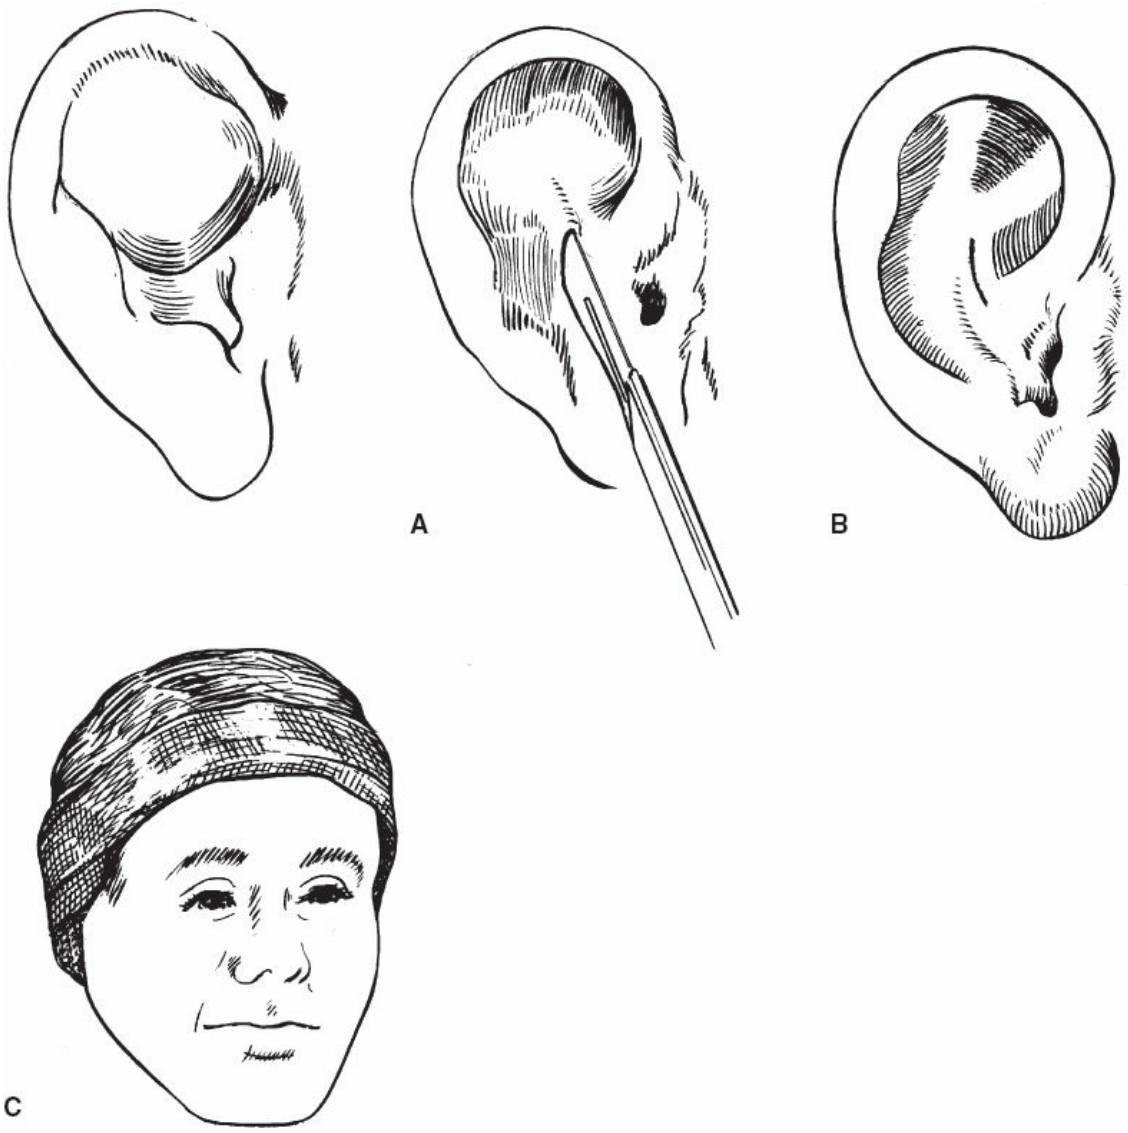

Figure 33.5. Evacuation of a hematoma of the external ear. **A.** An incision is made in a dependent position. **B.** The hematoma is evacuated and the anatomic detail of the ear is restored. **C.** A light compressive head dressing is applied.

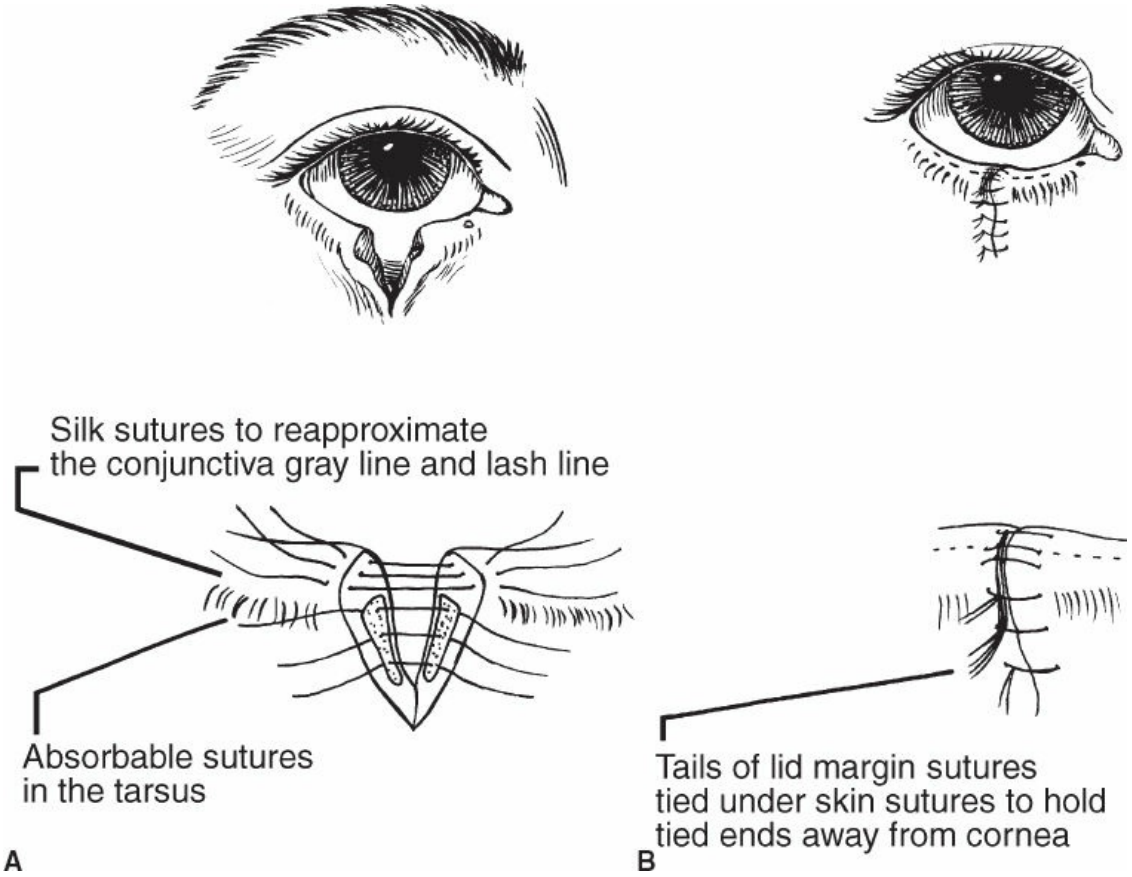

Figure 33.6. Repair of a laceration across the margin of the lower eyelid. **A.** The tarsal plate is reapproximated with fine absorbable sutures that do not penetrate the conjunctiva. **B.** The lid margin is reapproximated with fine nonabsorbable sutures anatomically. The ends of the lid margin sutures are tied under the first external suture to prevent corneal abrasion.

Another point worth discussing is lacrimal duct injury recognition, especially in the presence of lacerations in the medial eye and nasal sidewall regions (Fig. 33.7). If such injury is suspected, subspecialty consultation should be requested immediately. It is beyond the scope of this chapter to delve into the specific treatment of this injury but the selected readings section has a number of excellent resources that discuss this in great detail for those interested.

INJURIES TO THE EXTERNAL EAR AND NOSE

Much as was discussed in the previous section on eyelid repair, the same general concepts apply for the ear and its closely associated auricular cartilage (Fig. 33.8). The auricular cartilage can be approximated using absorbable, monofilament suture and the external ear skin using

nonabsorbable, monofilament suture using nylon or polypropylene in a 4-0, 5-0, or 6-0 size. The nose as well as its intimately associated cartilage and nasal septum can be also approached in a similar fashion using a similar technique and suture material (Fig. 33.9). In all cases, it is again ideal to limit any debridement, especially of cartilage, to that only necessary to preserve domain and anatomy as much as possible under presented circumstances. Much as was described already, any fluid collection or hematoma should be managed appropriately in these areas.

MANAGEMENT OF FACIAL FRACTURES

Facial fracture management has truly seen exciting and substantial advances in the last 30 years. There has been the important development and maturation of fundamental principles of management during that time as well. In the 1980s, rigid plate and screw fixation truly revolutionized facial fracture management, especially with the articulation of the concept of facial buttresses in Le Fort–type fracture management by Manson and colleagues. As time went on, the ability to perform aesthetically sound approaches to the facial skeleton for fracture management became easier due to the smaller footprint and better alloy composition of the rigid fixation materials being used, allowing for smaller incisions placed in aesthetically hidden skin creases. In 2005, facial transplantation became a reality and to date close to 40 such transplants have been performed as the ultimate reconstructive or, better stated, restorative operation for the most severely injured patients as a state-of-the-art option in select cases. In the selected readings section, there are excellent references that delve into this history further for the interested reader. What is critical to recognize is that, even in light of all the advancements made, facial fracture management still follows fundamental principles that have been shown to allow for excellent functional *and* aesthetic outcomes when followed and applied appropriately. In essence, goals of management can be listed in the following manner: (1) expeditious anatomic reduction of fracture fragments, (2) stabilization with rigid plate and screw fixation to restore anatomic fidelity and bony facial support for the soft tissues, (3) close attention paid to dental occlusal relationships and restoring as close to premorbid occlusion as possible, and (4) allowing the overlying soft tissues to heal over an appropriately reconstructed foundation of the facial bony skeleton to prevent any disfiguring secondary soft tissue abnormalities.

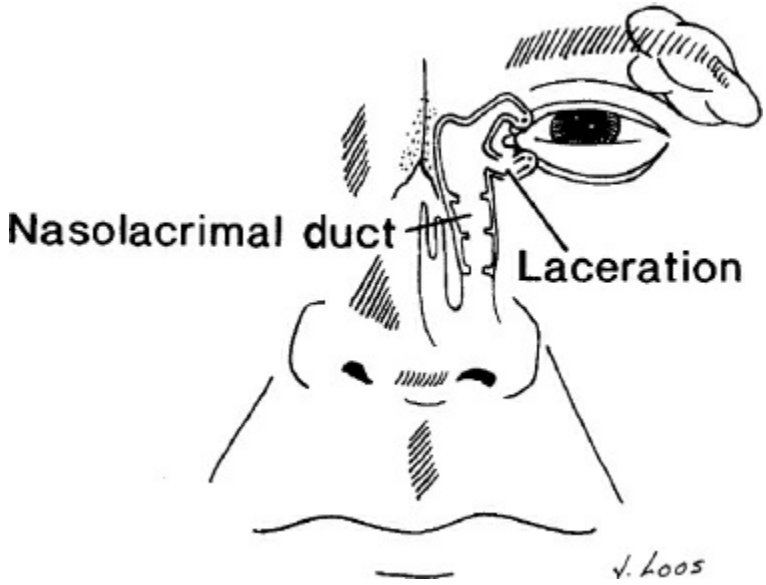

Figure 33.7. The nasolacrimal system.

A quick word about the most common facial fractures encountered is worth mentioning at this time. Nasal fractures are the most common injury seen, followed by orbitozygomaticomaxillary (OZMC) fractures, followed by mandibular fractures. Fractures of the midface (maxilla) or the frontal bones are less commonly encountered but still important to recognize. A thorough physical examination, as has been described, supplemented with appropriate radiologic imaging will allow one to essentially diagnose any facial fracture with certainty and confidence. In thinking about the facial skeleton, it is useful to divide the face into thirds: (1) upper third: frontal bone; (2) middle third: orbits, nasal bones, zygoma, and maxilla; (3) lower third: mandible. This also allows one to be systematic in his or her evaluation of the imaging obtained, so that the likelihood an injury could be missed is as low as possible. Once the constellation of facial fracture(s) is (are) identified, they may be classified and an operative plan developed to manage them. It is beyond the scope of this chapter to discuss the various classification systems that described the fracture patterns referred to previously but the selected readings section has within it the critical references that discuss the most important patterns including, frontal bone fractures, naso-orbito-ethmoid (NOE) fractures, all described Le Fort–type fractures (I, II, and III), and mandibular fractures.

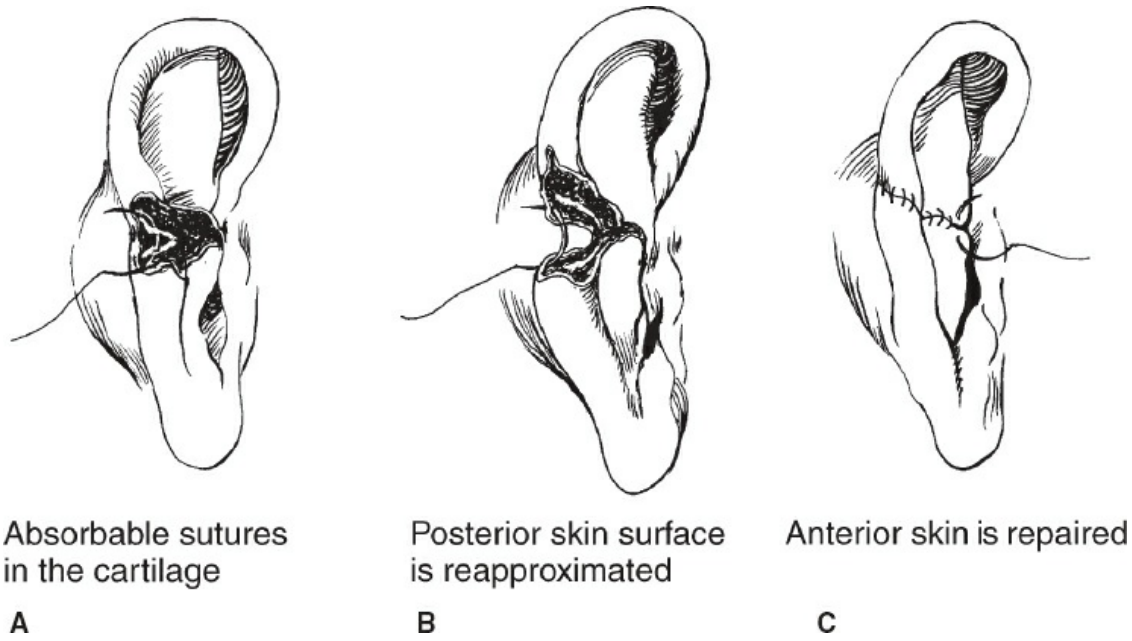

Figure 33.8. Repair of a laceration of the external ear. **A.** The cartilage is reapproximated with absorbable suture on a noncutting needle. **B,C.** The skin of the posterior and anterior surfaces is reapproximated with nonabsorbable sutures.

Figure 33.9. Repair of complex nasal laceration. **A.** The nasal mucosa is reapproximated with absorbable sutures. **B.** The cartilage is repaired with absorbable sutures on a noncutting needle. **C.** The skin is reapproximated.

As mentioned, in order of frequency, nasal fractures are the most commonly encountered and can be frequently diagnosed alone based on history and physical examination. Typically, these fractures are treated by closed reduction, ideally within the first 7 days of injury, and protected with nasal splinting (extranasal and intranasal) for about 10 to 14 days while the reduced fracture fragments heal in their anatomically reduced position. I personally do not favor attempts at nasal fracture reduction

anywhere but in the operating room with a secure airway under general anesthesia. Nasal fracture reduction can lead to a significant amount of nasal bleeding for a short period and this can be disastrous, even life-threatening, if the surgeon loses control in such situations. If there are additional nasal cartilaginous or soft tissue injuries, those can also be repaired definitively in the operating room. If elective nasal revisions are needed, waiting at least 6 months or more is appropriate due to the amount of time it takes for subtle nasal edema to resolve. In fact, it is typical that elective rhinoplasty patients have subtle edema present for up to a year after operative intervention and this fact serves as a good reference when thinking about nasal trauma after-effects.

OZMC and maxillary or Le Fort–type injuries are useful to combine in the same discussion (Fig. 33.10). The term *O*ZMC serves to alert the reader that, in fact and by definition, a zygomatic fracture involves the orbit, typically the floor, to some degree. This is important to understand not only in the anatomic sense of the fracture involvement but also that this pattern of injury always mandates a thorough globe examination and frequently ophthalmologic evaluation. There is still controversy in terms of how best to approach and treat OZMC fractures but it has become clear that the traditionally espoused 3- or 4-point fixation popularly advocated in the past is not necessary. In fact, many of these fractures can be approached from only an intraoral incision in the upper gingivobuccal sulcus and appropriately reduced and fixated with one plate with no need for an extraoral incision. In cases where the fracture is more comminuted or not easily or satisfactorily reduced via an intraoral approach, an upper blepharoplasty approach incision can be used to identify the zygomaticosphenoid articulation to confirm anatomic reduction. If needed, as some fractures will have enough orbital floor involvement that repair is needed in the orbit, a lower eyelid incision, typically transconjunctivally to avoid going through the eyelid skin and therefore avoiding a skin scar, can be used to plate the orbital rim and even place a plate to reconstitute an orbital floor defect.

Isolated orbital fractures also occur with enough frequency that a short discussion of this topic is necessary. These fractures are typically referred to as “blow-out” fractures and most commonly involve the orbital floor and medial orbital wall, as those bones are the most thin and fragile in the orbit and fracture first over the lateral and superior walls. Again, in these instances a careful evaluation of the globe is necessary and ophthalmology

consultation mandatory. Patients frequently have photophobia, diplopia, and even visual acuity abnormalities. It is paramount to be certain there are no pupillary abnormalities, there is no evidence of increased intraocular pressure, such as a retrobulbar hematoma, and that there is no restriction of any of the cardinal movements of the eye. This can all be quickly ascertained as part of the physical examination. Any of the aforementioned findings are surgical emergencies and typically mandate urgent or emergent operative intervention. The criteria for orbital fracture repair are controversial but a good rule of thumb is that if CT imaging shows orbital floor defects greater than 2 cm^2 or if the patient already has obvious muscle entrapment or a sunken in globe (enophthalmos), then operative repair should be pursued. However, many fractures of the orbit can be actually treated nonoperatively with close observation so long as the architecture surrounding the globe still maintains its “fibroligamentous sling” that will, in spite of remarkable medial orbital wall or orbital floor defects, still support the globe in its correct position, much as a hammock would function to keep its passenger in place even if the ground beneath was excavated into a deep hole. If operative intervention is pursued for the aforementioned indications, it is typically uncommon to need to do so immediately but rather it is a reasonable wait of 7 to 10 days to allow much of the orbital edema to subside so that it is technically less challenging to expose the important orbital contents. Blindness is an uncommon, but very real, risk of operative intervention on the globe and should be discussed with any patient undergoing orbital fracture repair as part of the informed consent process and as a standard of care consideration.

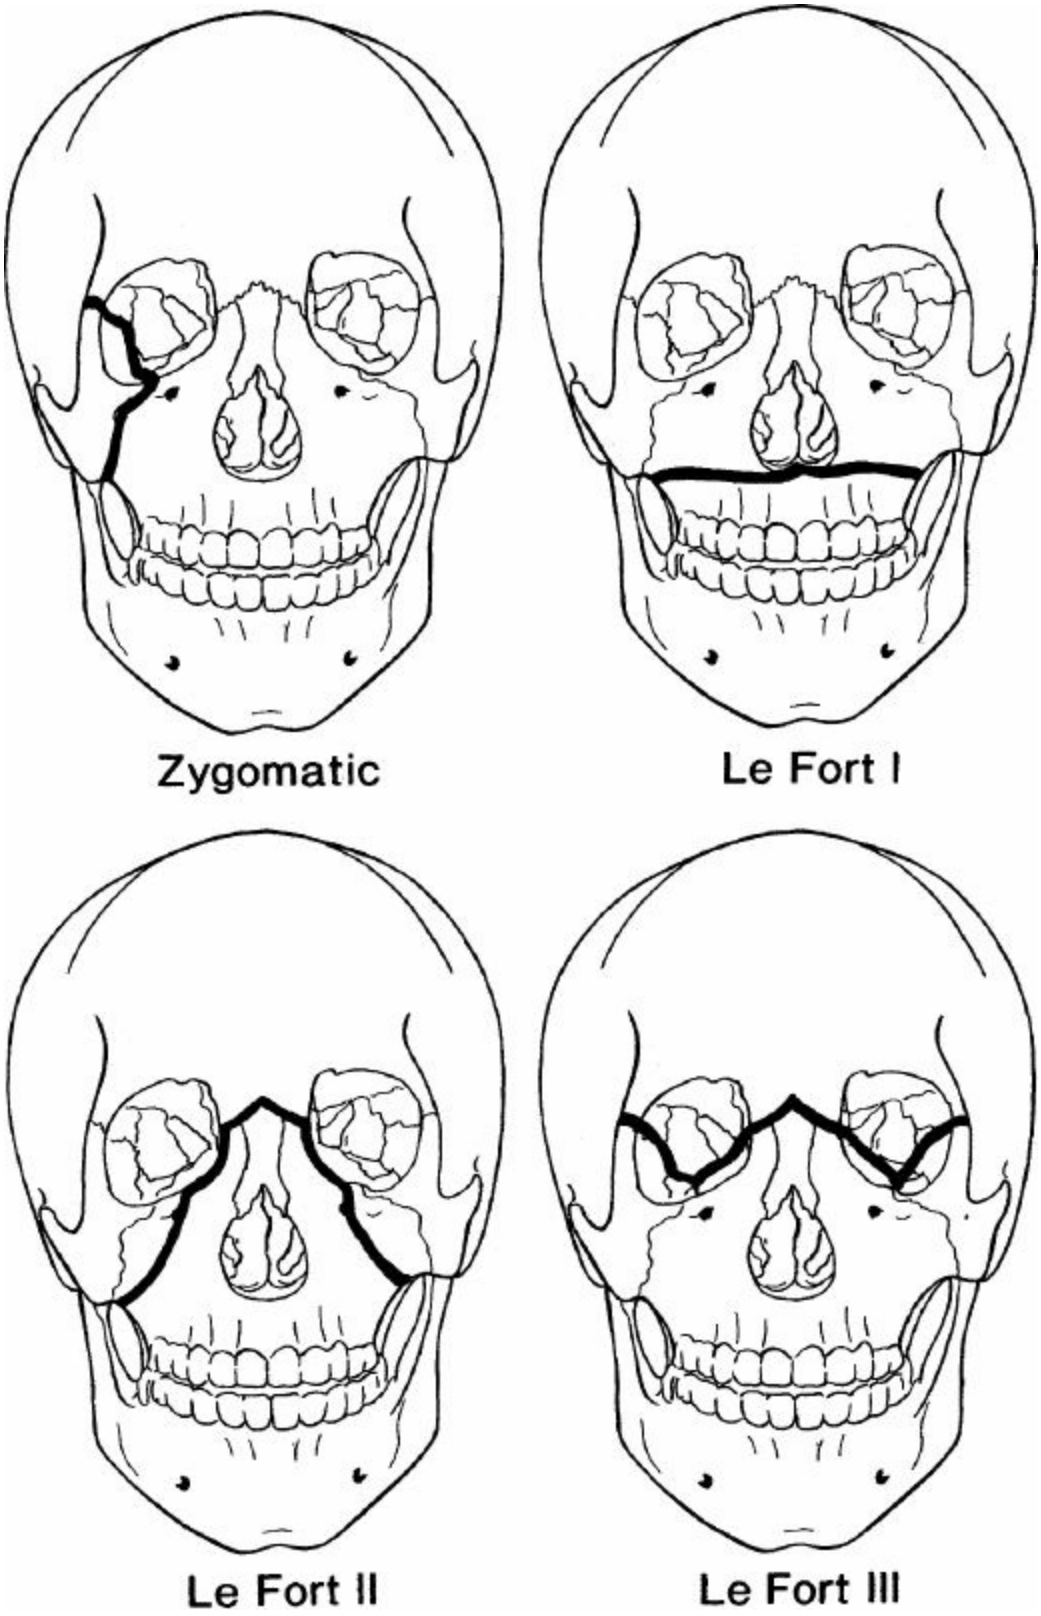

Figure 33.10. Maxillary fractures.

Mandibular fractures can occur frequently in isolation or in combination with other facial fractures and are important to recognize so that occult fractures are not missed. There are favorable and unfavorable

fracture patterns of the mandible which are useful to help guide treatment decision making (Fig. 33.11). In scenarios where there is a favorable fracture pattern and minimal to no displacement of fracture fragments, a liquid or pureed-type diet for 2 weeks may all be that is necessary to successfully treat these injuries. In more significant injuries to the mandible, including multiple fractures or involvement of the alveolar bone and teeth, these injuries frequently will need at least mandibulomaxillary fixation (MMF) to reduce the injured segments and allow for "jaw rest" so the fractures may heal. In other situations, formal operative exploration of the injuries with appropriate tooth salvage or removal, fracture debridement, and open reduction and internal fixation with rigid plates and screws is needed in addition to MMF. The selected readings section provides further information on the wide constellation of these injuries and appropriate treatment algorithms. One additional consideration that is worth mentioning with regard to mandible fractures involves fractures of the subcondylar region. These can be unilateral or bilateral and present with the classic finding on physical examination of an "open bite" wherein the patient looses mandibular height on one or both sides and has premature contact of the posterior molars and is unable to bring the anterior teeth into a normal occlusal relationship. Again, even consensus on the management of these types of fractures is controversial and is best served by subspecialty consultation, evaluation, and management.

Le Fort–type fractures were mentioned previously and deserve some further elaboration here. These fracture patterns were described in the early 1900s by a French surgeon named René Le Fort and were further characterized by Paul Manson and colleagues in 1980 by describing structural pillars of the facial skeleton and their importance in the management of Le Fort–type fractures (Fig. 33.12). There are many considerations in dealing with Le Fort-type I, Le Fort-type II, and Le Fort-type III fracture patterns but, suffice it to say, these fractures can be exposed and reduced and plated via a combination of the approaches already discussed. In fact, using gingivobuccal sulcus, upper blepharoplasty approach, and transconjunctival incisions, the surgeon can provide excellent exposure and treatment of these injuries with minimally obvious sequelae from a surgical scar perspective. Many of these injury patterns will require MMF for a period of time while all reduced and fixated fractures are allowed to heal, so it is common to use a prescription strength mouthwash on a twice or thrice daily basis as brushing of teeth

during this time is not practical and oral hygiene is of critical importance.

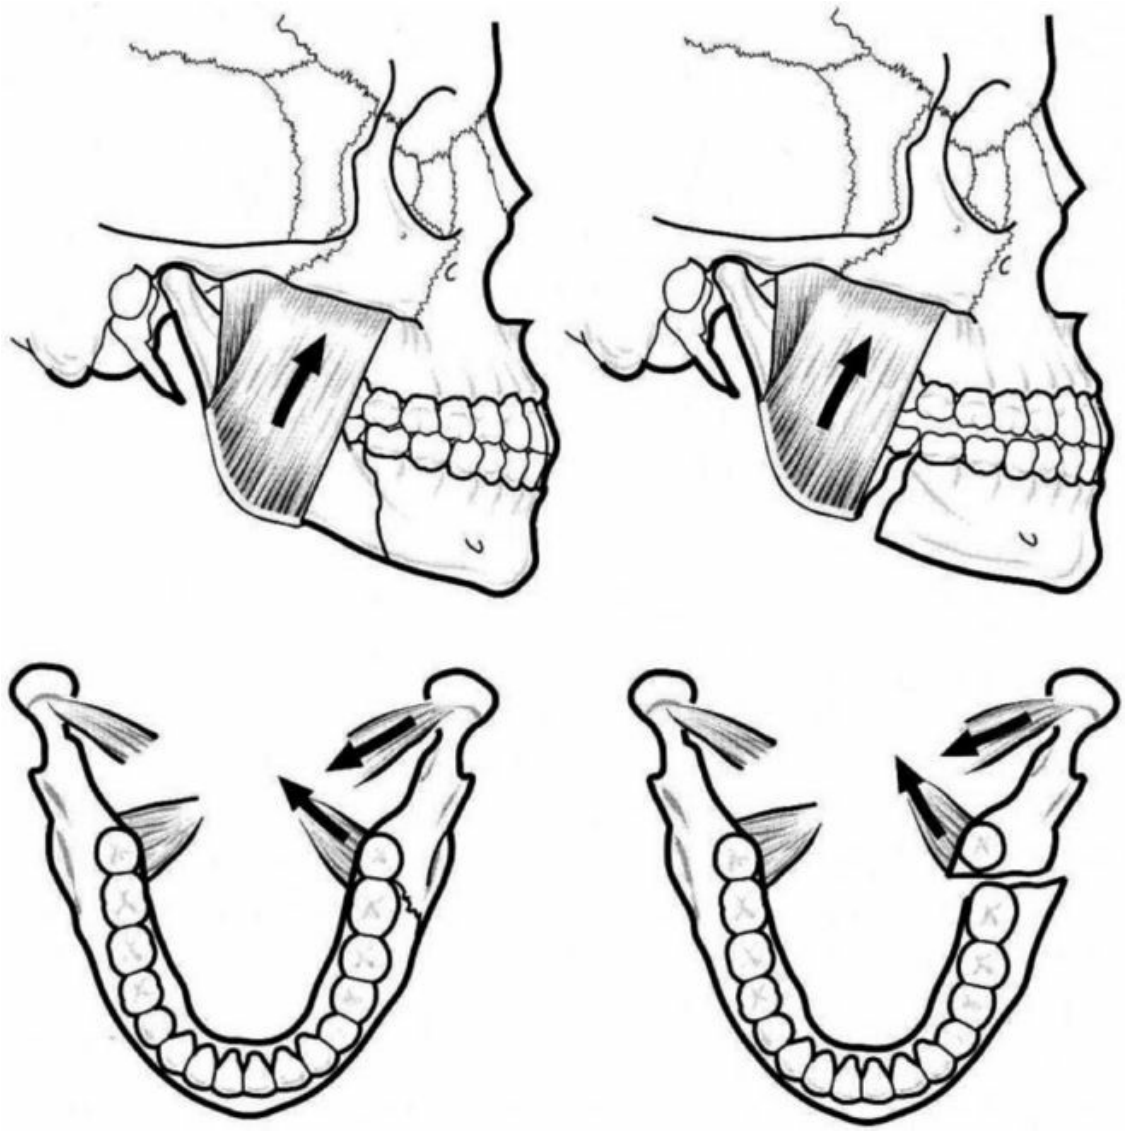

Figure 33.11. Favorable versus unfavorable mandible fractures. Favorable mandibular fractures (**left**), do not necessarily need to be plated as muscle pull impacts the fracture. In unfavorable fractures (**right**), muscle pull distracts the fracture. Rigid fixation is thus required. (From Booth PW, Schendel SA, Hausamen JE. *Maxillofacial Surgery,* 2nd ed. 2007;Vol. 1:38. Copyright © 2007 Elsevier.)

Another area mentioned in the earlier portions of this chapter was the frontal bone and its location in the upper third of the facial skeleton. It is important to recognize that injuries to the frontal bone, by definition, imply high velocity or high energy impact and should alert the surgeon to intracranial injury, cervical spine injury, and even occult carotid artery

injury that must be evaluated with CT scan evaluation of the brain, cervical spine, and even CT angiogram of the neck into the cranial base. Frontal bone injuries, also usually manifest as injuries to the anterior portion, posterior portion, or in combination. These are more frequently referred to as the anterior and posterior tables. While isolated frontal table injures can sometimes be managed nonoperatively, they can lead to significant deformities and secondary cosmetically undesirable sequelae. More importantly, frontal bone fractures, with concomitant frontal sinus involvement are a more serious and complicated matter that can lead to CSF rhinorrhea, frontal sinus mucoceles, and even meningitis depending on the amount of posterior table involvement. A general rule is that if the posterior table fracture depth of involvement exceeds the thickness of the posterior table then operative management should be considered and frequently becomes necessary. Approaches to the frontal bone can be direct, especially if an existing frontal skin laceration can be used, or via a bicoronal incision hidden in the hairline so that complete access to the frontal cranium as well as superior orbits is available for definitive surgical management. Again, it is beyond the scope of this chapter to discuss this in further detail but the selected readings by Rodriguez et al. provide a comprehensive and excellent overview of the matter.

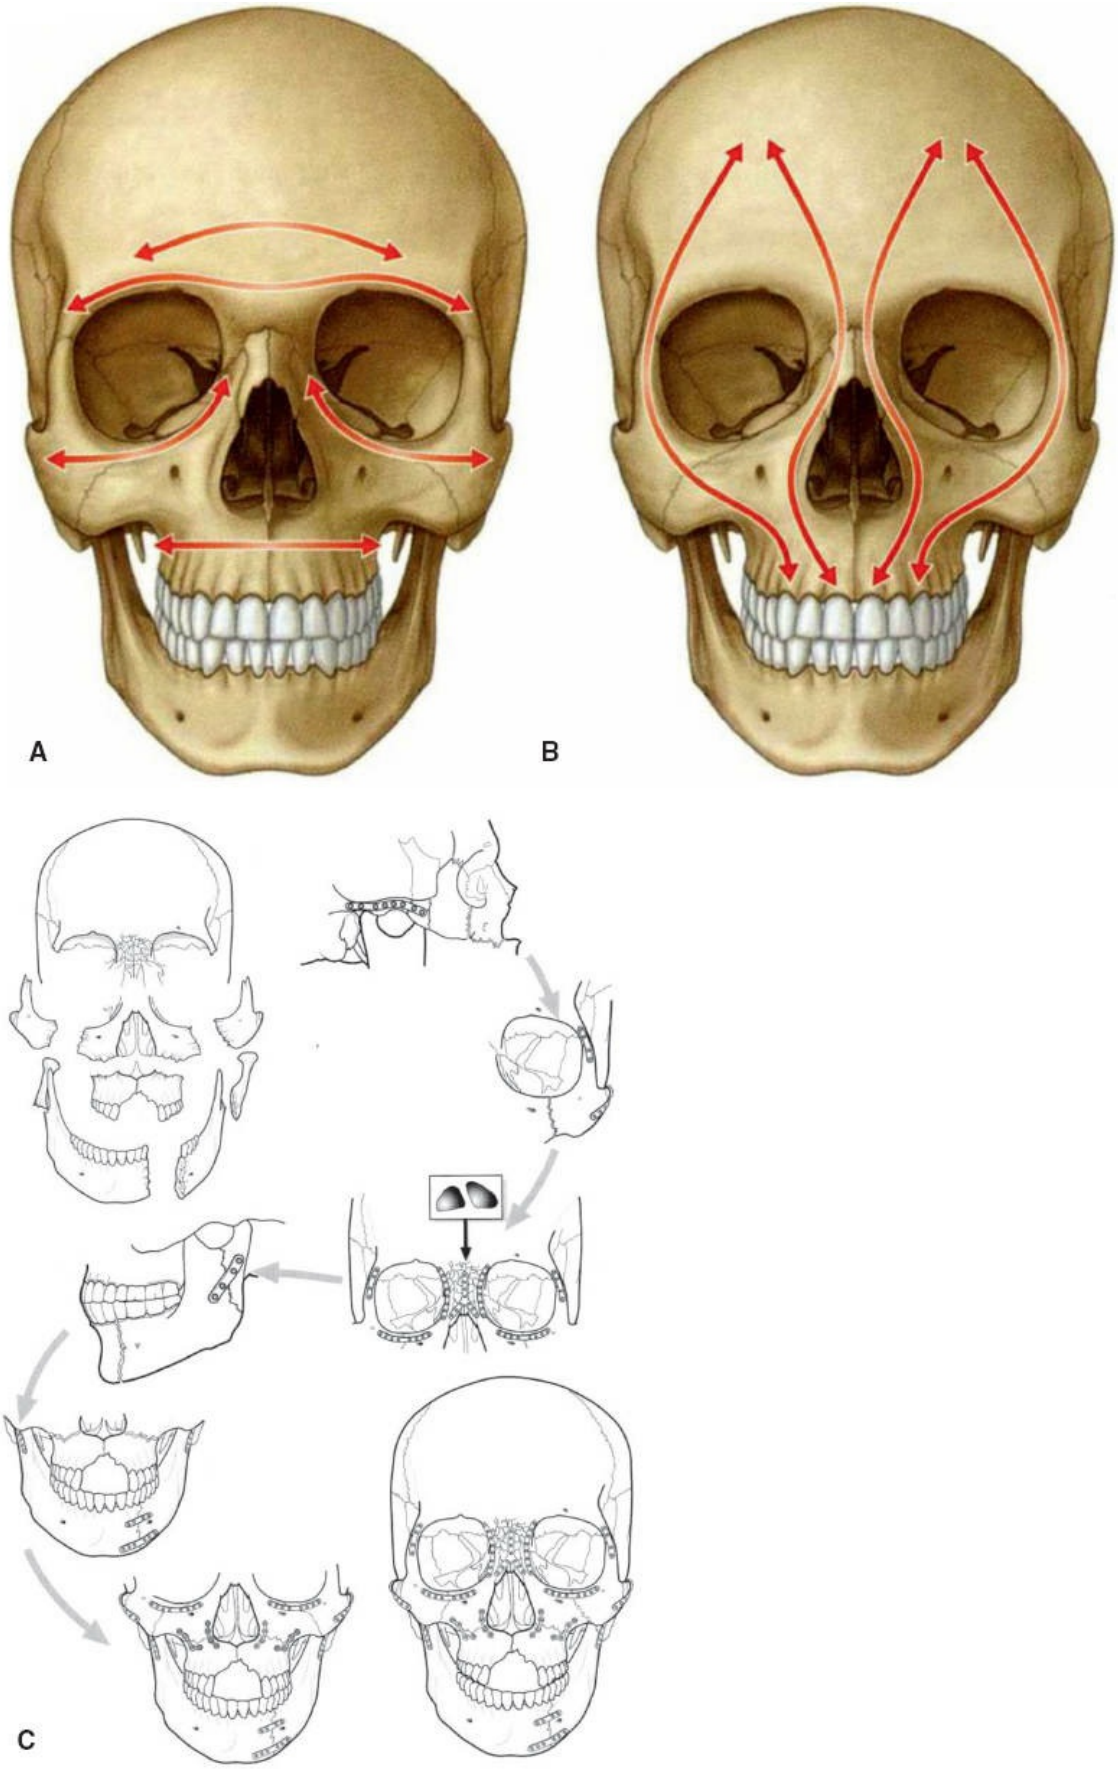

Figure 33.12. Approach to panfacial fracture management using

reconstruction of the horizontal and vertical buttresses as guiding principle. The horizontal (**A**) and vertical (**B**) facial buttresses are the support pillars of the face and overlying soft tissues. Disrupted buttresses must be reduced and reconstructed to optimize results. Nondisrupted buttresses adjacent to fracture sites serve as anchor points for fixation hardware. **C.** In panfacial fractures, buttresses are sequentially reconstructed by dividing the face into upper and lower units. Once reconstruction is complete in each unit, the two units are combined to complete reconstruction. (From Guyuron B, Eriksson E, Persing JA. *Plastic Surgery: Indications and Practice.* 2009;Vol. 1:633. Copyright © 2009 Elsevier and Booth PW, Schendel SA, Hausamen JE. *Maxillofacial Surgery.* 2nd ed. 2007;Vol. 1:38. Copyright © 2007 Elsevier.)

A final discussion about an uncommon, yet devastating, constellation of fractures is the involvement of all of the facial thirds that were defined earlier. This constellation is referred to as a “panfacial” fracture pattern. As mentioned in the frontal bone fracture section, the same high velocity and high energy impact concerns apply, even more so, in panfacial fracture patterns. This constellation is also seen in high-velocity gunshot wounds, many of which by mechanism are of the self-inflicted type. The best way to think about these injuries is a sum total of all the injury and fracture patterns discussed thus far. These types of fracture patterns are extraordinarily difficult and complicated to treat, even in skilled hands. However, it is important to recognize that the principles and fundamentals set forth thus far allow one to tackle such problems with expectations for restoring facial form, function, and appearance in a confident and high level of fidelity manner. In my personal training and, in fact, my preference is to treat panfacial fractures starting from the mandible and working my way cephalad. Using a “skull base up” approach has been a very well-described and consistent way in which panfacial fracture patterns can be dealt with appropriately and thoroughly. In such instances, subspecialty involvement is mandatory and it is frequently the case that such patients will require tracheostomy airway management and enteral access via percutaneous or open gastric tube placement as part of their immediate and postoperative course in their injury treatment.

POSTOPERATIVE MANAGEMENT

As was previously mentioned, cleansing and preparation of the wounds

commonly encountered in facial injuries was one of the important first steps in management of these patients. It needs to be reaffirmed as the completion of this chapter nears, that this is equally important in the postoperative management phase as well. In general, skin suture lines should be gently cared for on a daily basis for the first 2 to 3 days after operative intervention. Again, a half strength mixture of warm saline and hydrogen peroxide works well. Intraoral care typically involves 5 to 7 days of prescription strength oral mouth rinse and minimal instrumentation in the mouth with things like a toothbrush to allow for mucosal healing. Being observant of fluid collection or hematoma formation is also critical as these can be intervened upon easily and usually definitively if diagnosed early. Useful interventions such as head of bed elevation and cool compresses on the face facilitate edema management and resolution. Recommendations about return to activities of daily living, exercise, and recreational or contact sports are highly patient specific and individualized. I, in my own practice, have been very conservative about when I allow clearance for such activities as it makes little sense to not wait a reasonably requisite amount of time to allow the healing process to take its due course. Therefore, waiting days to weeks to even months to allow patients to resume normal activities should be a decision left to the surgeons' discretion and one that should never be hurried.

A discussion about the sequelae of facial injury apart from the many considerations already discussed would not be complete with focusing on something that many patients point out and have concerns about; namely, scarring. What we do know about the healing response and the maturation of scars is well described and frankly familiar territory, at least in the expectation we, as treating surgeons, have. Patients, understandably so, have constant reminders from their scars about the events surrounding the injuries they have suffered and anything that can be done to ameliorate or even "erase" those scars is welcome advice. I firmly believe that we do not do enough to provide counsel and assistance with this part of the postoperative management care spectrum. There are many well-described, well-documented studies that not only discuss topical treatment of scars, from high-quality topical Vitamin C or Vitamin A therapies, to facilitate their optimal maturation and healing but there is excellent, recent evidence that laser therapy of posttraumatic or hypertrophic/contracted scars is a present state-of-the art modality that is underutilized and underappreciated. In fact, for those surgeons who utilize lasers as part of their practice,

myself included, we now find very few indications, if any, for actual traditional surgical “revision” of scars. Scar revision is an oxymoron. Scars are dynamic entities not static ones, which can be stimulated and intervened upon to remodel and regenerate into a much more favorable and functionally and aesthetically pleasing state. Interventions such as z-plasties also facilitate scar improvement without the need of excising scars, rather rearranging them and releasing tension to allow more favorable conditions for ideal maturation. I have personally found lasers (of the pulsed dye and fractionated CO_2 variety) to be indispensable in my practice as it relates to traumatic and burn facial scar management. In the selected readings section, there is an excellent position paper by Anderson et al. on laser treatment of traumatic scars and should be required reading for our interns and residents in general surgical training. A paradigm shift is necessary in how we think about scars and the modalities we can offer patients today in facilitating ideal management and treatment.

CONCLUSIONS

The principles and fundamentals discussed in this chapter as it relates to evaluation and repair of common facial injuries should enable the broadly trained general or trauma surgeon to confidently and effectively manage many of the facial injuries described herein. Certainly, recommendations have been provided for instances in which subspecialty consultation is necessary and appropriate and it is my hope that the reader will understand that management of the facial injury patient is truly a team effort and facilitated certainly by the “quarterbacking” of a broadly trained and well-versed general or trauma surgeon with a fundamental, yet broad, knowledge base that will optimize patient triage, evaluation, and decision making in management and treatment. Working in a cooperative fashion and in a multidisciplinary environment will optimize outcomes for the patients we are so privileged to care for.

EDITOR'S COMMENT

Facial injuries can result from a myriad of different mechanisms and result in many different combinations of injury. As the face plays the most important roll of our interaction with the outside world it is essential to restore both form and function. While the majority of more advanced facial trauma will require management by a surgical specialist (e.g., plastic, oromaxillofacial, or otorhinolaryngologic surgery), general and trauma surgeons play a key role in the management of facial trauma as they are the first-line providers responsible for the initial evaluation and management.

The initial management of patients with facial injuries needs to follow ATLS

and BLS guidelines. It is essential that airway be adequately assessed and secured if necessary in these patients. Complex and devastating facial injuries may make it difficult to secure the airway, and the general surgeon needs to be prepared to create a surgical airway in a moment's notice. One circumstance in which orotracheal intubation may actually be easier is in the self-inflicted shotgun blast patient. Often times the mandible and soft tissues of the oral cavity have been obliterated such that the posterior oropharynx is in full view. Once an airway has been established it is important to efficiently progress to the primary and secondary surveys. A methodical approach to assessment of the craniofacial skeleton, sensory and motor nerves, and soft tissues is key to avoid missing any injuries. In the obtunded patient examination of the extraocular eye muscles is not possible. As such it is recommended that all patients undergo a forced duction test to assess for entrapment of the extraocular eye muscles. Dr. Bojovic is accurate in stating that significant blood loss can occur from the scalp and oropharynx injuries and this needs to be recognized during the initial work-up. Rapid stapled closure of scalp lacerations can be achieved to stop ongoing blood loss.

CT examination of the maxillofacial skeleton is the gold standard for assessing bony injuries, and 3D CT reconstructions are essential with more complex facial fracture patterns. In the current era of cost containment it will be important to demonstrate that the use of 3D CT reconstructions reduces operating room times to offset the increased costs associated with obtaining these images. Regarding injection of local anesthetic, I also favor the use of directed nerve blocks to avoid distorting the normal facial landmarks, particularly in the perioral and periorbital regions. However, I would disagree with Dr. Bojovic in regards to the use of a buffering agent to reduce the pain with local anesthetic. The use of a buffering agent in my experience, as well as others (Welch MN, Czyz CN, Kalwerisky K, et al. Double-blind, bilateral pain comparison with simultaneous injection of 2% lidocaine versus buffered 2% lidocaine for periocular anesthesia. *Ophthalmology* 2012;119(10):2048–52), results in much less pain when compared to unbuffered local anesthetic.

Once an operative plan is developed it is important to get the patient into the operating room as soon as the patient is adequately resuscitated and all life-threatening injuries have been addressed. There are times when the patient is not stable enough to undergo transport to the operating room, which is problematic in the setting of gross contamination. In this circumstance, a thorough washout in an ICU setting under sedation should be performed.

I agree with Dr. Bojovic that adequate surgical debridement is of the upmost importance in achieving optimal functional and aesthetic outcomes. It is important that marginal soft tissues be given time to declare themselves rather than undergoing early debridement, as tissues that originally look marginal may completely recover. Excessive debridement, particular in areas with limited skin and soft tissues (e.g., nose, ears, eyelids), can have devastating functional and aesthetic results.

After adequate debridement soft tissue closure via appropriate techniques should be performed. In the pediatric population I prefer to use tissue adhesives (e.g., Dermabond) in repair of superficial lacerations as it may avoid the need for sedation in the pediatric patients with similar aesthetic outcomes to standard suture techniques (Farion K, Osmond MH, Hartling L, et al. Tissue adhesives for traumatic lacerations in children and adults. *Cochrane Database Syst Rev* 2002;(3):CD003326). Layered wound closure is reserved for deeper injuries. One note I would add to Dr. Bojovic's comments is that in closing intraoral lacerations it is essential to obtain a watertight closure, which prevents drainage of intraoral secretions that can break down subcutaneous tissues and lead to wound-healing complications.

Once stable soft tissue coverage is achieved fracture fixation and nerve repair can be performed. It is important to remember that in patients with an injury to the facial nerve that nerve repair needs to be performed within 72 hours of injury. After this time point the distal end of the nerve will not be able to be activated with the nerve stimulator due to degeneration of the motor end plates, which can make it very difficult to find the nerve for repair. Although acute nerve repair should be performed whenever possible delayed nerve repair can be attempted up to the point at which the motor end plates atrophy, which is typically around 18 months.

I agree with Dr. Bojovic's assessment that drainage of a hematoma in the ear and nasal septum should be performed as soon as the patient is hemodynamically stable. Saddle nose deformity is a devastating occurrence in unrecognized or untreated septal hematomas, which requires extensive reconstructive surgery to correct. When draining an ear hematoma my preference is to use xeroform bolsters and through and through nylon sutures to ensure direct approximation of the overlying skin to the underlying cartilage. Particular attention should be paid reestablishing the triangular fossa, the concha symba and concha cavum.

I am in agreement with Dr. Bojovic regarding high-energy wounds to the face. These are some of the most challenging wounds to address and require multiple trips to the operating room for debridement and assessment of the tissues. Once all wounds have been debrided and the defects defined one can then proceed with a clear plan in place. Fracture fixation, soft tissue reconstruction, and free tissue transfer are all aspects that may need to be utilized in this patient population.

Injuries to the eyelid and soft tissues of the orbit should in almost all instances be managed by a specialist comfortable in the anatomy in this region. Dr. Bojovic's comments about the use of a noncutting needle I would echo. Cutting needles tend to create additional tissue damage as well as lead to the possibility of bleeding from the wound edges. Debridement of precious auricular cartilage should be limited in most circumstances. Precise repair of both cartilage and the soft tissue envelope will result in the most aesthetic outcome.

Dr. Bojovic has done an excellent review of the management of facial fractures. His goals for management give the reader a stepwise manner in which to evaluate any facial fracture. The importance of accurate fracture reduction cannot be understated. Accurate fracture fixation provides the base upon which the soft tissues are draped and provides the form and function of the human face. Inaccurate fracture fixation can lead to abnormal human facies, and repairing inappropriately reduced facial fractures in a delayed fashion is challenging and results in increased complication rates.

To this end I would disagree with Dr. Bojovic that the OZMC fracture can be effectively addressed via an oral incision only. If these fractures are displaced then it is mandatory that the zygomaticosphenoid (ZS) suture be accurately aligned, which will ensure the remainder of the tetrapod in the appropriate anatomic alignment. Fracture fixation can then proceed in a manner moving top down (zygomaticofrontal → orbital rim → lateral buttress) (Birgfeld CB, Mundinger GS, Gruss JS, et al. Evidence-based medicine: Evaluation and treatment of zygoma fractures. *Plast Reconstr Surg* 2017;139(1):168e–180e). Soft tissue suspension should be paid particular attention in order to achieve the optimal aesthetic result with any fracture repair technique.

In managing pediatric orbital floor fractures one must remember that in children the orbital floor bone has much more pliability and that the fracture may “greenstick” resulting in entrapment of the rectus muscle with nondisplaced fractures on imaging. In this patient population it is of the upmost importance to have an accurate assessment of the patient’s extraocular eye muscle movement as missed entrapment can lead to permanent injury.

With regard to mandible injuries it is imperative that the cervical spine is cleared both clinically and radiographically as the incidence of cervical spine injury is 5% with isolated mandible fractures (Mulligan RP, Mahabir RC. The prevalence of cervical spine injury, head injury, or both with isolated and multiple craniomaxillofacial fractures. *Plast Reconstr Surg* 2010;126(5):1647–51). Manipulation of the cervical spine must be avoided in these patients and neurosurgical clearance should be obtained before proceeding to surgical repair. In the management of the pan facial fracture that fracture fixation should proceed from stable to unstable. If the mandible is stable or a simple fracture starting from the mandible and proceeding cranially is the best way to proceed.

Dr. Bojovic has performed an excellent review of the key elements in the evaluation and management of facial injuries, and he should be commended for making this complex subject matter digestible for all surgeons.

Ryan Gobble

34 Resection and Reconstruction of the Trachea

Natalie Lui, Harald C. Ott, and Douglas J. Mathisen

INTRODUCTION

Etiology

Tracheal resection is a relatively uncommon operation. The most common indication for surgical resection is tracheal stenosis resulting as a complication of prolonged intubation or as a consequence of tracheostomy. The injury from intubation results from an overinflated endotracheal cuff causing excessive pressure on the trachea and reducing blood supply. The ischemic injury can be mucosal or full thickness of the airway depending on the severity. Tracheostomy stomal injuries occur as a result of excessive damage of the trachea from technique, excessive traction on the tracheostomy tube or infection.

Symptoms

Patients with tracheal stenosis present with symptoms of shortness of breath of varying degrees. The degree of shortness of breath depends upon the diameter of the stenosis. Slow growing tumors may have an insidious onset with shortness of breath only noticed with extremes of exertion. Over time this progresses to symptoms at rest and frank stridor. Postintubation injuries usually present within days to weeks after extubation or decannulation. Recently extubated or decannulated patients who present with shortness of breath should be suspected of tracheal stenosis.

Those initially treating patients with tracheal stenosis are responsible for diagnosis, initial management and stabilizing the airway. In the nonemergent airway computerized axial, sagittal and coronal views of the trachea should establish the diagnosis in most patients. Initial management should include humidified oxygen and elevation of the head of the bed. Heliox administration can be effective in some patients who remain symptomatic. When a more urgent situation exists, it is best to secure the

airway in the operating room. Control of the airway can be achieved by balloon dilation of structures or dilation with bougies and rigid bronchoscopes. If a tumor exists, debridement may be required to establish a safe airway. Tracheostomy is a last resort. Care must be taken to place it in the proper position. Ideally through the damaged stenotic segment after dilation has been successfully achieved. This is to allow the most trachea for subsequent reconstruction. Ideally a thoracic surgeon is best suited to control the airway in a combination of anesthesiologists, pulmonologists, and general surgeons. Once stabilized, the patient should be transferred to a facility to deal with the problem.

INDICATIONS

The indications for tracheal reconstructive operations are (a) primary tumors, principally adenoid cystic and squamous cell carcinoma, and a wide variety of malignant, low-grade malignant, and benign tumors; and (b) secondary tumors, primarily thyroid carcinoma, bronchogenic, and, rarely, esophageal carcinoma. Benign conditions include (c) postintubation lesions, including cuff and stomal stenosis, tracheomalacia, tracheoesophageal fistula (TEF), and brachiocephalic arterial fistula, plus proximal stenosis including the subglottic larynx; and (d) stenosis of many causes, including trauma, prior surgery, tuberculosis, amyloidosis, relapsing polychondritis, congenital malformation, mediastinal fibrosis, idiopathic stenosis, and Wegener granulomatosis.

PREOPERATIVE PLANNING

Simple posteroanterior and lateral x-rays of the neck are satisfactory for seeing proximal lesions. The entire airway can be imaged with computed tomography (CT) and 3D reconstruction. Sagittal, coronal, and axial images are quite helpful in assessing the airway and are becoming the norm. CT adds data about potential mediastinal invasion by tumors. Knowing the extent of the uninvolved airway left for reconstruction is as important as defining the lesion itself.

Bronchoscopy is essential but can be performed at resection unless the problem is unusually complicated. When laryngeal abnormality is suspected, the examination is often carried out concurrently with an otolaryngologist. Rigid bronchoscopy with general anesthesia provides better visualization of anatomy, superior biopsy specimens, and the potential for airway management and improvement through maneuvers

such as dilatation or coring out of obstructive tumors. Furthermore, measurements that can be used in planning an operative procedure can be made using the rigid bronchoscope. These measurements are the distance from the carina to the bottom of the lesion, the length of the lesion, and distance from the top of the lesion to the vocal cords. The quality of mucosal inflammation can also be assessed. Care must be exercised in the outpatient setting when using flexible bronchoscopy to evaluate tracheal stenosis because of the possibility of precipitating airway obstruction.

Emergency tracheal resection is rarely performed. Critical obstruction can be relieved by dilatation of benign stenosis under anesthesia using rigid pediatric bronchoscopes and dilators. Tracheal obstruction by neoplasm requires removal of tissue via the rigid bronchoscope and biopsy forceps. An internal stent or T tube can also provide relief. Laser techniques have little use in the management of carcinoma except to debride tumor and relieve obstruction. Once the acute obstruction is relieved, careful diagnostic studies and examinations can be performed.

Patients must be in optimal preoperative condition to ensure a successful operation and recovery. Patients with postobstructive pneumonia or active mucosal inflammation, or those receiving high-dose steroids should undergo dilatation, and the condition should be allowed to improve. Repeated dilatations may be necessary in some circumstances. The need for mechanical ventilatory support would constitute a contraindication to resection. If the decision is made that a tracheostomy tube or T tube must be inserted to control the airway, placing the tube through the most damaged portion of the tracheal stenosis is mandatory to preserve the maximal amount of normal trachea for subsequent reconstruction.

ANESTHESIA

The maintenance of anesthesia can be achieved either with inhalational agents or with total intravenous anesthesia. Inhalational anesthesia in tracheal surgery is limited by the open airway during the procedure and periods when no anesthesia can be delivered. With total intravenous anesthesia, ventilation and anesthesia are uncoupled and there is the continuous delivery of anesthetic agents making it well suited for airway resections. This has become our preferred technique.

Prolonged paralysis of respiration is avoided because the desire is that the patient resume spontaneous respiration postoperatively without the

need for ventilatory support. After the trachea has been divided by either the anterior or intrathoracic approach, a sterile, flexible endotracheal tube with attached connecting tubing is introduced into the distal trachea for maintenance of ventilation. In carinal resections, ventilation is usually maintained through the opposite (usually the left) lung after the resection of the carina. With experience, the use of such tubes is not cumbersome. The alternative of high-frequency jet ventilation through a catheter works well and is used preferentially in special instances. Extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass can be used for complicated carinal operations, but extensive manipulation of the lung while heparinized can lead to intrapulmonary hemorrhage and must be considered.

SURGICAL TECHNIQUE

Basic Principles

Although not all problems have been solved, standard and reliable methods for resection and reconstruction of the trachea have been developed. Because few patients with lesions requiring such operations are likely to be seen by one thoracic surgeon, close attention must be paid to basic principles and the special techniques of this type of operation. The rates of failure and complications in tracheal surgery remain unacceptably high when surgeons who only occasionally operate on the airway perform these operations.

Close attention to the basic principles of tracheal reconstruction will avoid many serious complications.

1. The trachea that is to remain must remain well vascularized. Extensive circumferential dissection of the trachea should not extend beyond the level of the resection. Preferably, no more than 1 cm of trachea should be circumferentially freed from lateral attachments beyond the line of resection.
2. Approximation must be performed without excessive tension. Levels of tension in grams beyond which dehiscence can be expected to occur have been measured precisely in the laboratory. Skilled surgeons, however, know whether they are attempting to pull the ends of the trachea together under excessive tension. Surgeons operating on the trachea must be familiar with all available techniques for mobilization of the trachea to lessen tension. They must also make a mature judgment in advance of resection as to whether sufficient trachea will

be left to construct a safe anastomosis.

3. Precise anastomotic technique is required. Lines of resection should be cut cleanly. Fine absorbable suture material must be used. We use 4-0 polyglycolic acid polymer (Vicryl, Ethicon, Inc., Piscataway, NJ) suture for all anastomoses in adults, and 5-0 polyglycolic acid polymer in small children. Stay sutures are 2-0 polyglycolic acid polymer and are usually left in place after tying to reduce anastomotic tension. All sutures are oiled to promote sliding of the suture through tissues.
4. A second layer of tissue coverage is required of all intrathoracic anastomoses, especially after carinal resection when the pulmonary artery is adjacent. The anastomosis should be airtight when tested under saline before coverage with a pedicled tissue flap.
5. The airway reconstruction should function satisfactorily at the conclusion of the operation. Internal stenting or protection by tracheostomy above, below, or through the anastomosis should not be required. If the anastomosis is not adequate at the conclusion of the operation, it is not likely to improve with time, with the exception of edema. If edema is suspected, a small, uncuffed endotracheal tube should be left in place for 48 hours. The patient should be given steroids for 24 hours, kept upright in bed, lasix, and fluid restricted to reduce edema. After 48 hours, the patient is returned to the operating room and extubation is attempted. If the patient is still stridorous, a small tracheostomy tube is placed two rings below the anastomosis and a pedicled strap muscle flap is placed over the anastomosis to protect it. Another exception is the traumatically divided cervical trachea in which both recurrent laryngeal nerves have been made dysfunctional and the glottic aperture is inadequate. In this case, a tracheostomy placed below the anastomosis is necessary. This will provide an adequate airway until the vocal cords recover function or further interventions are performed.

Anterior Approach

The anterior approach to the trachea is used for most benign strictures, even at the supracarinal level, and also for tumors of the upper and middle trachea. The patient is positioned supine with an inflatable thyroid bag beneath the shoulders, which allows for easy neck flexion during the case. The knee and hips are flexed to position the neck for the surgeon. A low collar incision is used and the upper flap is elevated to a point above the cricoid cartilage if no laryngeal involvement is present (Fig. 34.1). The

lower flap is carried to the sternal notch. The anterior surface of the trachea is exposed. The dissection may be difficult and tedious in postintubation stricture with prior or existing tracheostomies, or when prior operative procedures have been performed. The strap muscles are elevated. The thyroid isthmus is dissected away from the trachea, divided, and retracted laterally with sutures. An important principle is to keep dissection close to the trachea so that the operator does not injure the recurrent laryngeal nerves while working laterally around the area of disease, where scar tissue and inflammation are maximal. No effort is made to expose the nerves in instances of inflammation as this would likely lead to their injury. Circumferential dissection is carried only a short distance above and below the lesion to preserve the lateral blood supply of the proximal and distal trachea. The anterior surface of the trachea is freed bluntly as far as the carina to provide mobility.

With tumors, the dissection is not carried as close to the trachea as it is for other lesions. When the operation is for carcinoma, the recurrent laryngeal nerves are identified distal to the lesion and followed to the area around the lesion to provide a greater margin around the tumor. If the nerve is involved, it must be sacrificed, although at least one recurrent nerve should be preserved. Adjacent tissue occasionally has to be resected with the specimen to provide adequate margins. This may include a lobe of the thyroid gland or part of the esophageal wall. Adjacent lymph nodes should be removed with the specimen, but an extensive mediastinal node dissection cannot be performed without possible injury to the blood supply of the residual trachea.

With an upper tracheal lesion, it is important to identify the lesion. This can be obvious but if doubt exists the oral endotracheal tube should be pulled back, flexible bronchoscope inserted, the lesion identified by placing a needle through the suspected location and marked with a suture. I prefer to open the airway through the lesion so as not to sacrifice any usable trachea.

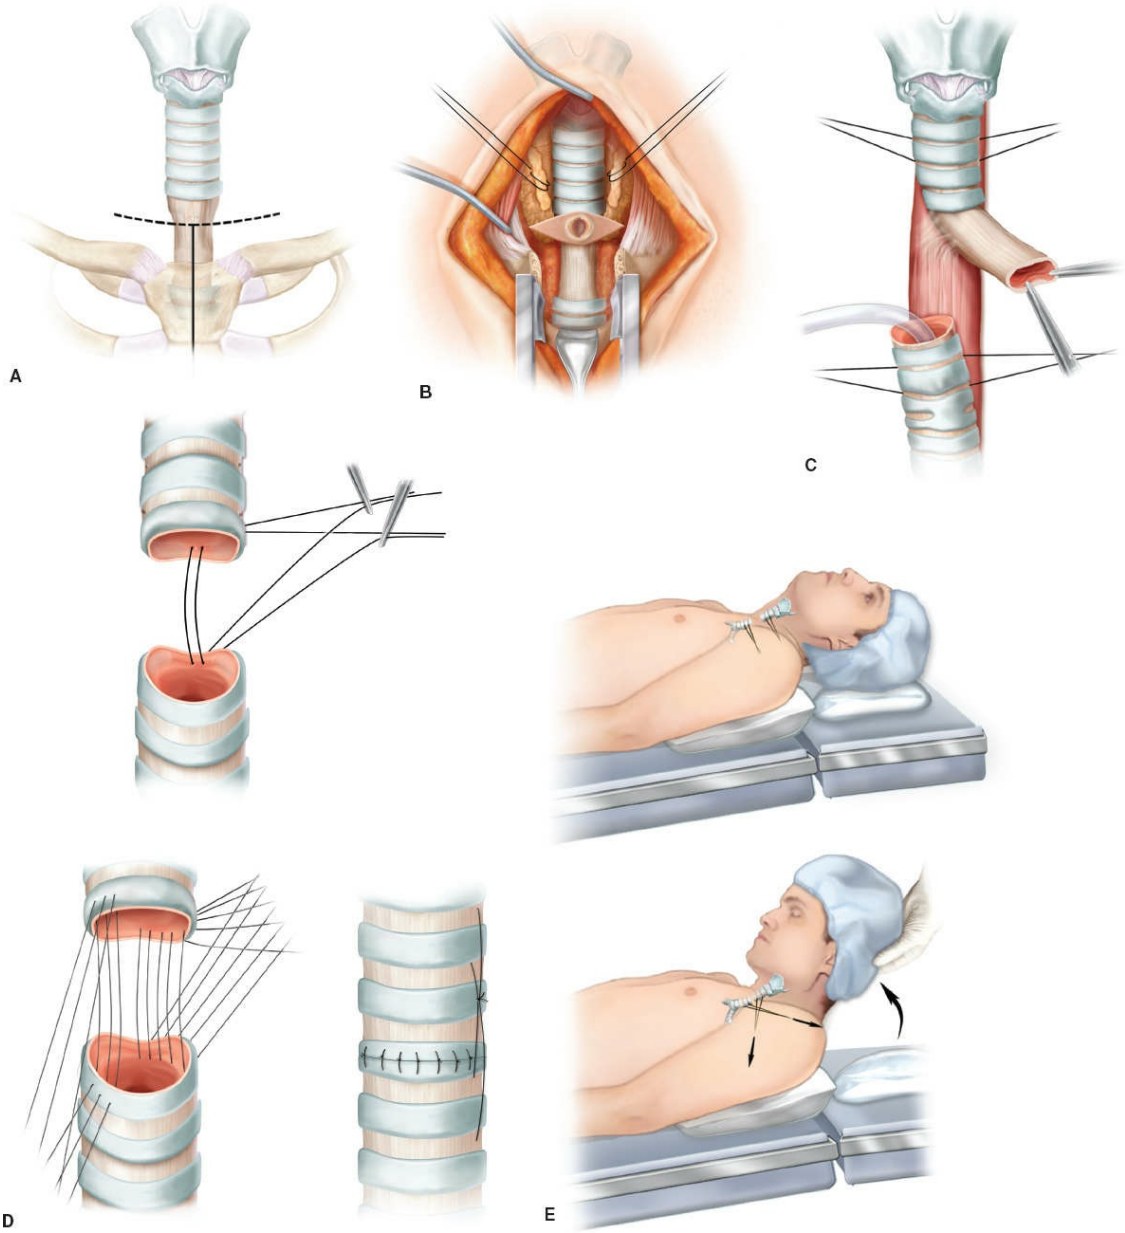

Figure 34.1. Reconstruction of the upper trachea. **A.** Collar incision and extension for upper sternotomy. Essentially, all benign strictures and upper tracheal neoplasms can be most easily resected through this approach. **B.** Dissection is carried anteriorly to the level of the carina. Nothing is gained by dividing the brachiocephalic vein. The brachiocephalic artery can be gently retracted downward. **C.** Circumferential dissection has been carried out only immediately beneath the lower-most level of the lesion, and the trachea has been divided. Traction sutures are in place and the patient has been intubated distally. The lesion is being retracted upward to facilitate dissection from the underlying esophagus. **D.** Details of anastomotic technique. The sutures are placed beginning posteriorly and working anteriorly. All the sutures are placed before the endotracheal tube is

advanced from above into the distal trachea. All the knots are on the outside. The diagram must be recognized as not indicating the complete circumferential dissection of the lengths of trachea shown. **E.** A greater amount of approximation is obtained by cervical flexion rather than upward traction on the carina in the anterior approach. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections.* 2014; Wolters Kluwer.)

Traction sutures (2-0 polyglycolic acid polymer [Vicryl]) are placed at the midlateral position of the trachea on both sides through the full thickness of the tracheal wall and at least 1 cm below the projected level of division. The trachea is divided and the oral endotracheal tube is withdrawn above the lesion. The distal trachea is intubated across the operative field with a flexible endotracheal tube and sterile anesthesia tubing. An assistant holds this tube in position by arrangement of the lateral traction sutures, which can be drawn on to pull the distal trachea away from the field of dissection. The specimen is grasped with forceps and elevated, which makes the dissection of benign stenosis from the esophagus much easier. It also gives access to tumors that have posterior extension. If the esophageal wall is involved, either the muscular portion can be resected or the muscular and mucosal layers removed. The esophageal wall is then closed with two layers of interrupted sutures. The narrowed esophagus can be dilated later, although it frequently dilates itself with the passage of food.

Lateral traction sutures are placed on either side of the trachea proximal to the level of the upper resection, and the specimen is removed. With upper tracheal stenoses or tumors, this means the lateral traction sutures are frequently placed in the substance of the cricoid. If the tracheal division is very high, a catheter is usually sutured to the end of the endotracheal tube so that it can be withdrawn out of the larynx to remove it from the field. The catheter remains as an aid for replacement of the endotracheal tube later in the operation.

In low lesions, division of the trachea is usually done as previously described. When the specimen has been fully dissected, distal traction sutures are placed and the specimen is divided inferiorly. If the lesion is a tight stenosis, it is dilated under direct vision after the trachea has been divided superiorly, and the endotracheal tube is placed through the

stenosis.

The surgeon and the assistant now pull the lateral traction sutures together on either side while the anesthetist flexes the patient's neck. This maneuver determines whether the ends can be approximated without excessive tension. If the ends can be approximated, the neck is allowed to fall back into extension and the anastomosis is begun. If the tension is excessive, a suprahyoid laryngeal release is performed. Although the skin flap can be elevated to the level of the hyoid bone, we find it more cosmetic and convenient to make a second transverse incision directly over the hyoid bone to perform the suprahyoid release. We have noted fewer early postoperative difficulties with deglutition and aspiration when this procedure is chosen in preference to the thyrohyoid release. After completion of the release, the upper incision should be closed with appropriate drainage because it becomes inaccessible when the neck is flexed later.

Anastomosis is performed with interrupted 4-0 polyglycolic acid polymer sutures placed approximately 3 to 4 mm back from the cut edge of the trachea and approximately 3 to 4 mm distant from each other. The sutures are placed so the knots can be tied outside the lumen. We prefer to place all the sutures before completing the anastomosis. We begin with the most posterior suture in the membranous wall in the midline, placing each successive suture until the lateral traction suture is reached on that side. This step is repeated on the opposite side to the level of the opposite lateral traction suture. The sutures are individually clipped with a hemostat, and further clipped to the drapes with a second hemostat in an orderly manner. The most posterior suture is clipped cephalad and each successive one follows. Care must be taken not to confuse the placement of the sutures. The sutures anterior to the lateral traction sutures are placed next, and these are fanned out on the operative drapes over the chest.

The divided distal trachea is suctioned frequently to prevent blood from seeping past the occluding cuff, which increases the risk of postoperative atelectasis and the need for ventilation. After all the sutures are placed, the tracheobronchial tree is suctioned thoroughly, the distal endotracheal tube is removed, and the endotracheal tube from above is passed into the distal trachea. The patient's neck is flexed and supported by blankets beneath the head. Next, the surgeon and the assistant tie the lateral traction sutures simultaneously so that the ends of the trachea are approximated. This permits the anastomotic sutures to be tied without tension.

The sutures are tied in the opposite order in which they are placed, with the anterior sutures between the two lateral traction sutures being tied first. The excess of each suture is cut after tying. As the assistant gently pulls one lateral traction suture to one side, the surgeon proceeds to tie the sutures posterior to the traction sutures down to the posterior midline in order. Again, each suture is cut after being tied. This procedure is repeated on the opposite side. The anastomosis is now complete. It can be tested for adequacy under saline solution. If the anastomosis is distal to the occluding cuff, the anesthetist can provide 30 cm of pressure to test the anastomosis. If the anastomosis is proximal, the airway cannot easily be occluded, and instead, the cuff of the endotracheal tube is deflated and the anesthetist provides 30 cm of pressure. Gas escapes through the larynx, but at that pressure the anastomosis should demonstrate an air leak under saline solution if there is a problem. The anastomosis should be airtight.

We leave the traction sutures in place even though they penetrate the wall of the trachea. We have observed no difficulty with absorbable sutures. The thyroid isthmus can be reapproximated and the strap muscles sutured over the trachea. A second layer is preferable over the cervical and mediastinal tracheal anastomosis to protect the anastomosis and provide coverage if superficial infection develops. If the brachiocephalic artery lies directly over the anastomosis, viable tissue must be interposed. We avoid exposing the artery and attempt to dissect on the surface of the trachea rather than on the surface of the artery. In reoperations in which the artery is necessarily exposed, or in tumors in which the arterial surface has been exposed, one of the strap muscles is sutured between the two structures.

Transthoracic Approach

The transthoracic approach is used for tumors of the lower trachea and carina (Fig. 34.2). We prefer a posterolateral right thoracotomy, entering the chest through the fourth interspace. The azygos vein is divided, the pleura is opened, and the trachea is exposed. The vagus nerve is divided as it crosses obliquely over the trachea. If the dissection is carried high in the chest, care must be taken not to injure the right recurrent laryngeal nerve as it courses around the subclavian artery. In the dissection of the lower trachea, care must be taken not to injure the left recurrent nerve as it passes on the other side of the trachea over the aortic surface. The principles of resection are the same as for the upper trachea. If the distal trachea is resected, cross-field intubation is generally done through the lower trachea

into the left main bronchus. This has the added advantage of collapsing the right lung. High-frequency ventilation can also be used. If intubation is used and partial pressure of oxygen (PO_2) begins to fall, a shielded vascular clamp can be placed on the right pulmonary artery to eliminate shunting through the unventilated lung. This is rarely necessary. An alternative is to continue high-frequency ventilation because this does not massively inflate the lung.

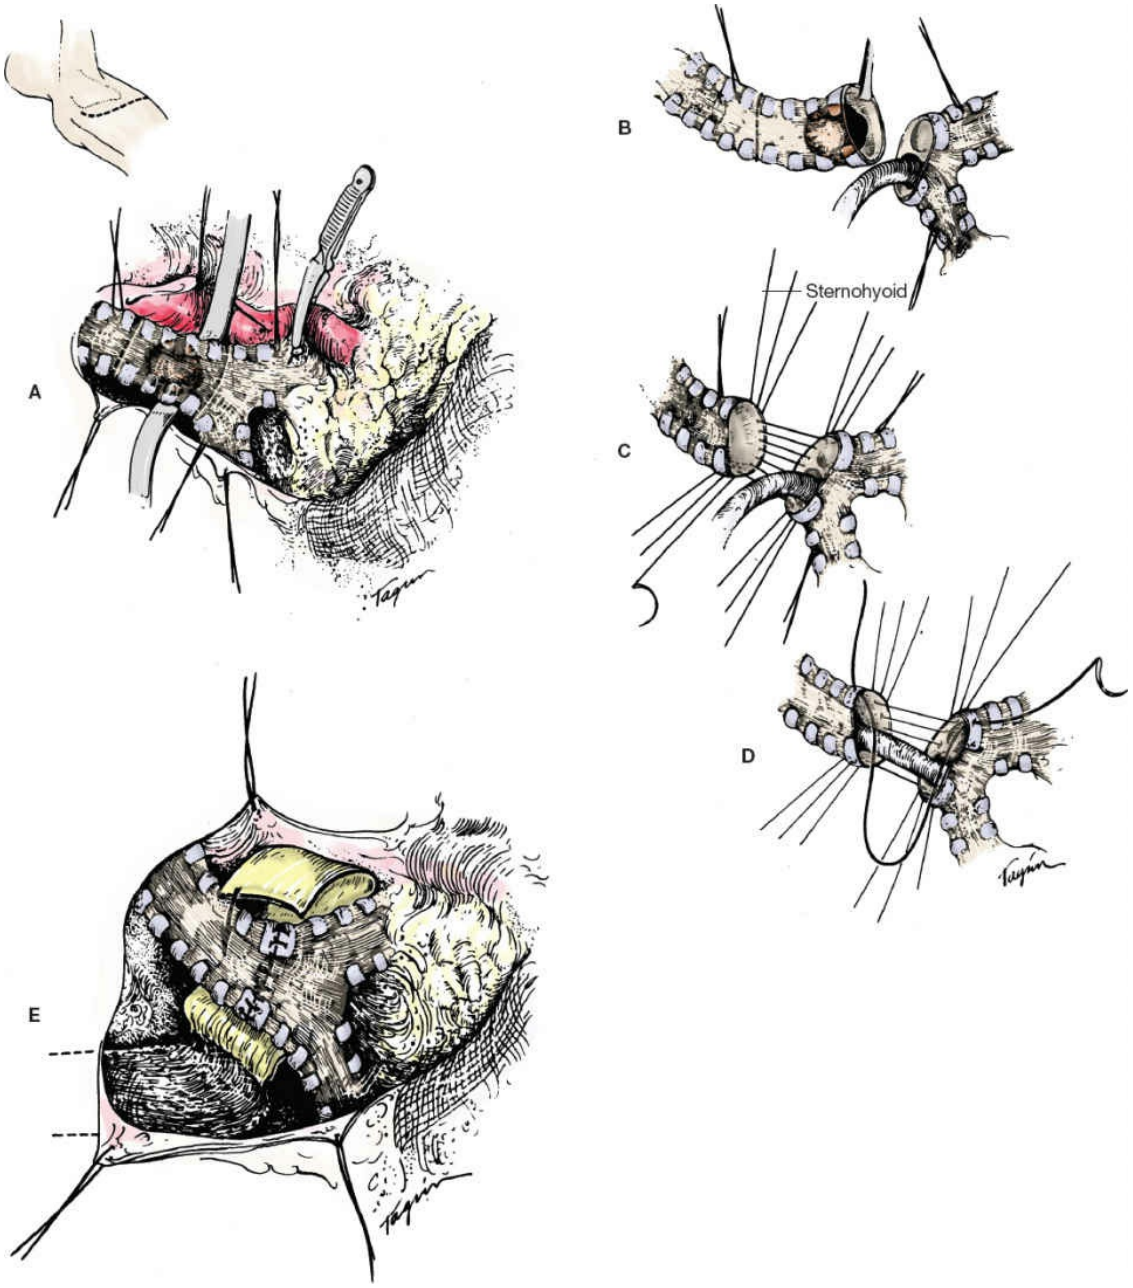

Figure 34.2. Transthoracic approach to resection of the lower trachea. **A.** As much mobilization as is thought to be necessary is done before division of the trachea. The drawing shows the placement of a clamp on the pulmonary artery, but clamps are not placed routinely. Proximal and distal traction sutures are placed as in the cervical procedure. **B.** The trachea has been divided just above the carina, and the left main bronchus has been intubated. **C.** Detail of anastomotic suture placement. **D.** The endotracheal tube from above is advanced distally and the balance of the sutures are placed. **E.** Once the anastomosis has been demonstrated to be airtight, a pedicled pleural flap or pericardial fat pad is placed on the anastomosis for security. (Reprinted from Grillo HC. Surgery of the trachea. *Curr Probl*

Surg 1970;7(7):3–59. Copyright © 1970, with permission from Elsevier.)

If it appears that tension will be excessive when the ends of the trachea are drawn together despite cervical flexion, intrathoracic intrapericardial mobilization should be used (Fig. 34.3). If this measure is required, it is easier to perform before resection of the tracheal lesion. The inferior pulmonary ligament is divided. A U-shaped incision is made in the pericardium just below and around the lower portion of the inferior pulmonary vein, the structure that most tethers the hilum. Often this degree of release is all that is required to provide sufficient upward movement of the hilum for anastomosis. If this release is not adequate, complete circumferential division of the pericardium around the hilum of the right lung can be performed. When the pericardium is so divided, we attempt to save the pedicle of vessels and lymphatics in the posterior hilum by looping a tape around them. Salvage of these lymphatics may be important for the early postoperative function of that lung. One must remember that the neck should be flexed during the anastomosis because this delivers a considerable amount of cervical trachea into the mediastinum. Laryngeal release does not help free the trachea for distal tracheal or carinal reconstruction.

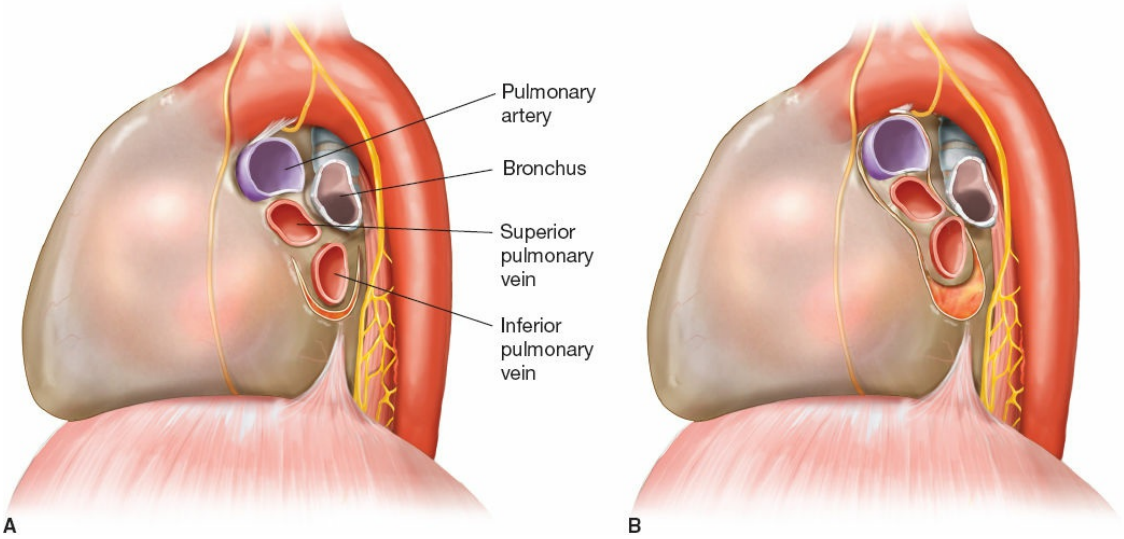

Figure 34.3. The left-side intrapericardial hilar release technique, showing the U-shaped pericardial incision, which allows 1 to 2 cm of upward hilar mobility to facilitate the creation of a tension-free anastomosis. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections.*

After the reconstruction is complete and tested under saline solution, second-layer coverage is provided with a broad-based pleural flap or pedicled pericardial fat carried in a circular manner around the anastomosis and sutured into place.

The distal trachea can also be approached through a median sternotomy using Perelman variation of the Abruzzini incision, in which the lower trachea and carina are exposed between the aorta and vena cava, and the pulmonary artery and the brachiocephalic artery are retracted. The pericardium is opened front and back. This is not a truly adequate incision for difficult or larger tumors, especially those that might involve the esophagus posteriorly. The exposure is also inadequate for complex anastomoses, such as those required for carinal reconstruction. It has the advantage, however, of allowing bilateral intrapericardial release if this is needed.

In complex procedures, such as operations for large tumors of the middle and lower trachea, we have sometimes used a “trap-door” incision, which consists of a collar incision and median sternotomy that angle to open the right fourth interspace. This incision provides access to the entire airway from the hyoid bone to the carina. In such circumstances, hyoid release and intrapericardial release both may be necessary.

Carinal Resection

Our preferred approach for resection and reconstruction of the carina is a right posterolateral thoracotomy. Anesthesia and dissection are carried out as described previously. The origin of the left main bronchus is easily accessible through the right hemithorax. The anatomical method of reconstruction is determined by the extent of the tumor and the amount of tissue removed. In a few instances, the medial walls of the right and left main bronchi can be sutured together to form a new carina, with this anastomosed to the distal trachea (Fig. 34.4). This procedure is rarely possible because fixing the right and left main bronchi together below the level of the aortic arch prevents upward movement. All the necessary length has to come from cervical flexion with downward devolvement of the trachea.

When more trachea has to be removed, we usually anastomose the trachea end-to-end to the left main bronchus (Fig. 34.5). The right main

bronchus is elevated and sutured into a side opening made in the trachea 1.0 cm above the end-to-end anastomosis. An ovoid opening is made in the lateral cartilaginous wall so that cartilage is all the way around the margin of the anastomosis. The anastomosis must be done with precision. Pericardial mobilization is often necessary to permit elevation of the right main bronchus.

If a greater amount of trachea has to be sacrificed, the trachea and left main bronchus will not reach one another. Under these circumstances, with full intrapericardial mobilization, the right main bronchus is elevated to the stump of the trachea and an end-to-end anastomosis is made. The end of the left main bronchus is anastomosed to an opening in the medial wall of the bronchus intermedius (Fig. 34.6).

In cases in which the right upper lobe also has been sacrificed because of tumor extension, or if a localized bronchogenic carcinoma of the right upper lobe extends to the carina, the bronchus intermedius or lower-lobe bronchus can be anastomosed to the trachea (Fig. 34.7) or to the left main bronchus, if it fails to reach the trachea.

In patients who have had prior pneumonectomies and who require carinal resection for residual or recurrent tumor in the bronchial stump, resection is usually done through the right chest, unless there is a long left mainstem bronchial stump (Fig. 34.8). After a left pneumonectomy, care is taken to maintain ventilation in the right lung. The surgeon retracts the lung gently to provide access to the carina without collapsing the lung. The anterior approach may be useful in some circumstances.

In a small number of patients, the approach has been made from the left side when a tumor involves a large length of left main bronchus but a small portion of the carina. In this situation, the left lung cannot be salvaged by any current technique. Tapes are placed around the base of the trachea and the right main bronchus to gain enough access to excise the carina and left lung. A direct end-to-end anastomosis of trachea to right main bronchus is done from the left side. We have tried dividing intercostal vessels and approaching the carina from the left posterior aspect to the aortic arch, but this has not proved to be of much help.

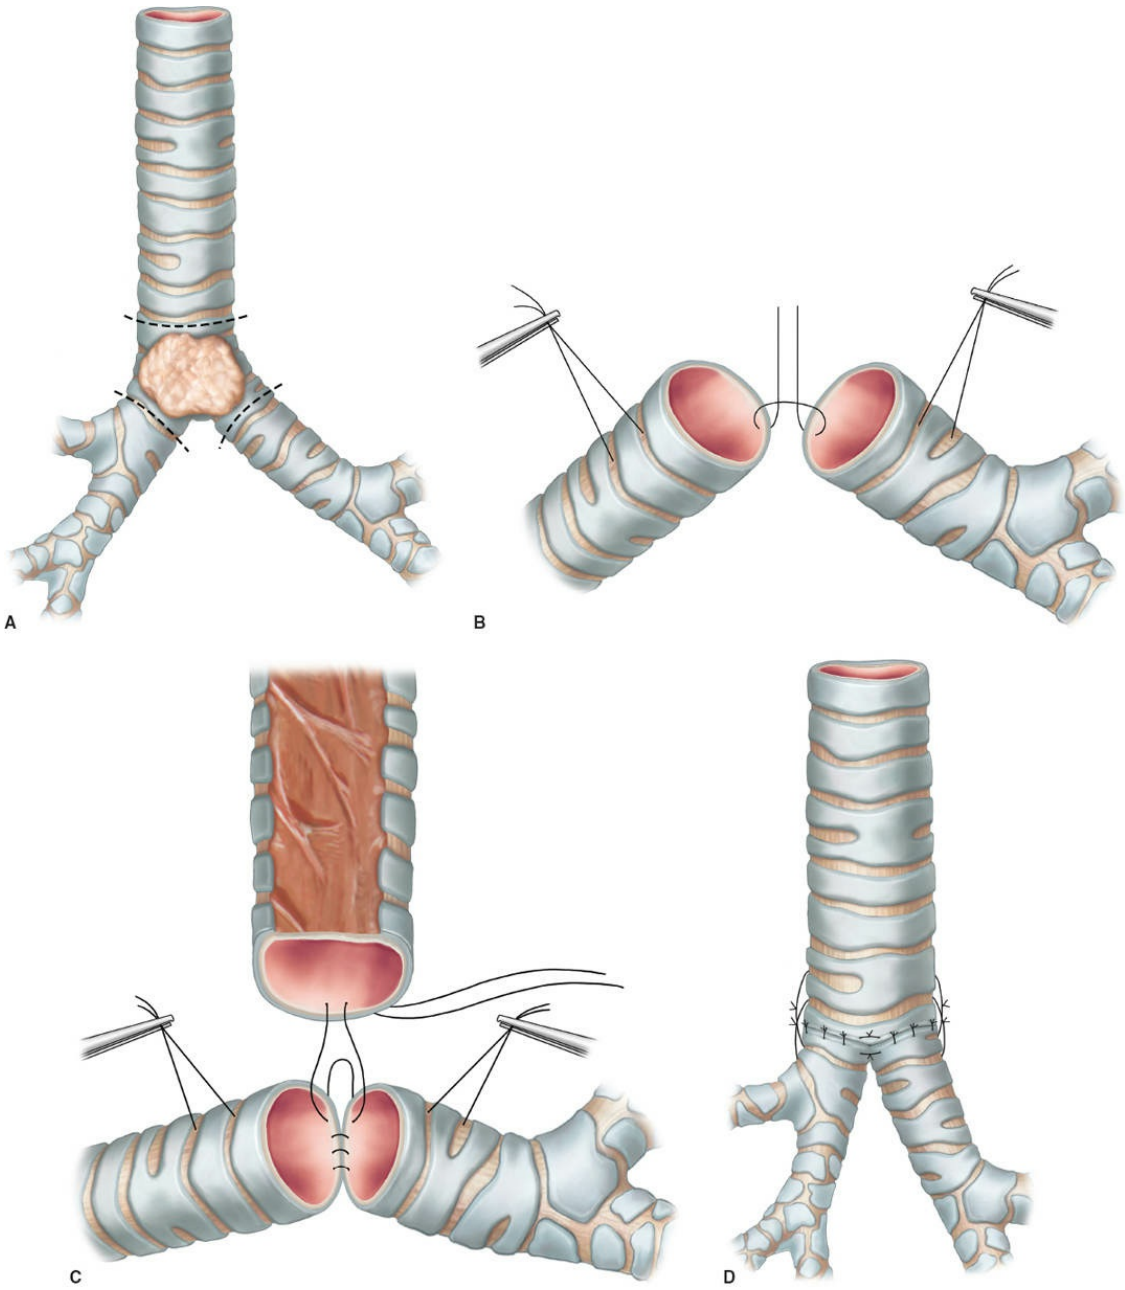

Figure 34.4. Resection with restitution of the carina. This technique is applicable only for small, centrally placed tumors. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Lung Resections, Bronchoplasty.* 2014; Wolters Kluwer.)

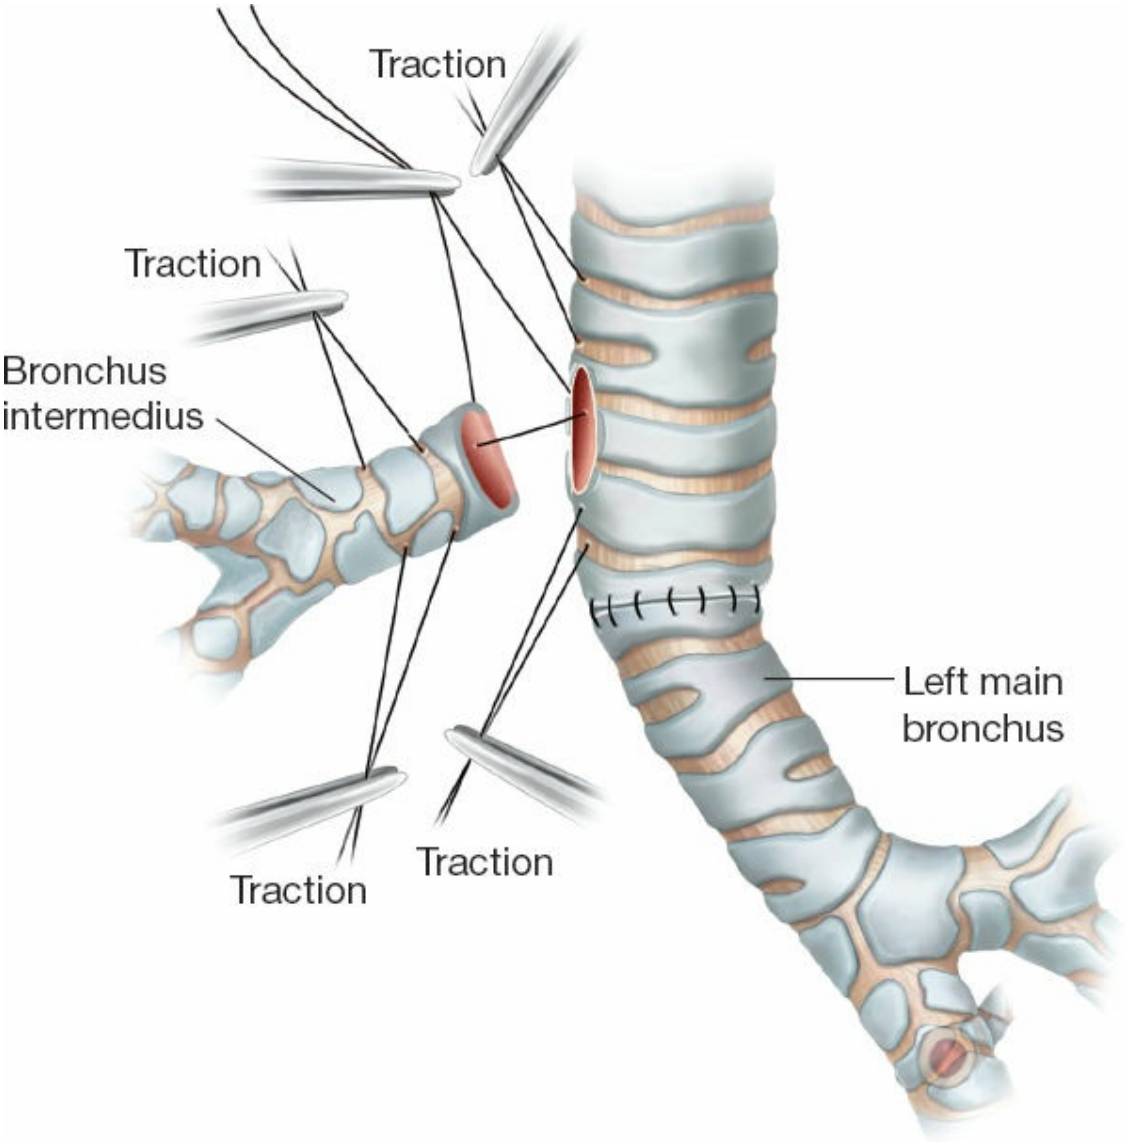

Figure 34.5. Carinal reconstruction after resection. The trachea is anastomosed end-to-end to the left main bronchus, and the right bronchus is placed into the lateral wall of the trachea above the first anastomosis. (Modified from Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Lung Resections, Bronchoplasty.* 2014; Wolters Kluwer.)

A problem that has not been satisfactorily solved is how to approach a tumor involving a large amount of carina and a long segment of left main bronchus. If the approach is through the right chest alone, the tumor can be excised and the left main bronchus stapled off from the right side. Perelman proposed this procedure along with ligation of the left pulmonary artery to avoid shunting in the nonfunctional left lung. A left pneumonectomy can be done later. Another approach is bilateral thoracotomy. In patients who have satisfactory pulmonary reserve, the

approach has been through a bilateral anterior clamshell thoracotomy, crossing the sternum in the fourth interspace. This approach provides excellent exposure for resection, the anastomosis of the right main bronchus to the trachea, and the left pneumonectomy. However, bilateral thoracotomy is a physiologically demanding approach and may require postoperative ventilation in selected patients. An alternative is median sternotomy, which allows access for left pneumonectomy. Cardiopulmonary bypass or ECMO has been useful in certain large central tumors.

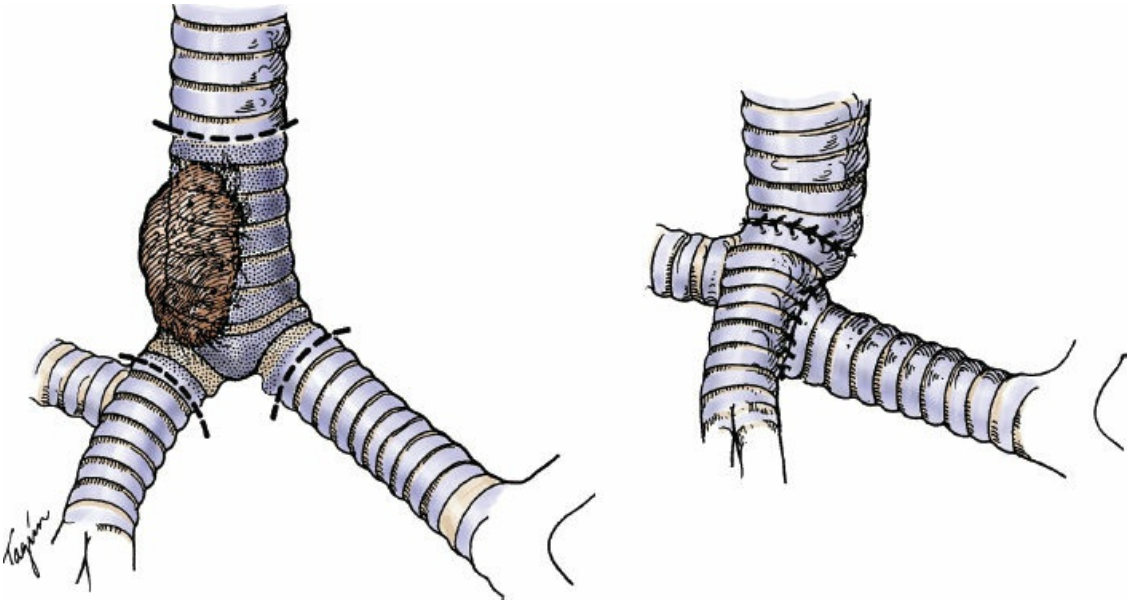

Figure 34.6. More extensive tracheal resection, with advance of the right main bronchus to the end of the trachea and implantation of the left main bronchus into the bronchus intermedius. (Reprinted from Grillo HC. Carinal reconstruction. *Ann Thorac Surg* 1982;34(4):356–73, with permission of the Society of Thoracic Surgeons.)

All suture lines are covered with flaps (pleural or pericardial fat) in carinal reconstructions. If a patient needs postoperative ventilation, it can be done safely with the cuff placed well above the anastomosis. The anastomosis can tolerate gas pressures but should not have a foreign body resting against it, which may cause injury. If secretions cannot be cleared by physiotherapy, flexible bronchoscopy should be used freely.

Laryngotracheal Resection in Benign Stenosis

If a subglottic stenosis stops short of the vocal cords so that a space exists

beneath the cords to which the trachea can be sutured, many of these lesions can be corrected while salvaging recurrent laryngeal nerve function. The lower anterior portion of the larynx involved by the stenosis is resected with the specimen. The line of resection begins inferior to the lower border of the midline of the thyroid cartilage (Fig. 34.9). The vocal cords are just above this level. The line of resection sweeps laterally downward on either side through the cricothyroid membrane in the line of the inferior margin of the thyroid cartilage. It then transects the lateral laminae of the cricoid cartilage and angles posteriorly, just below the inferior margin of the posterior plates of the cricoid cartilage. Dissection must be made with extreme care and must be very close to the cricoid cartilage to avoid injury to the recurrent laryngeal nerves, which enter the larynx medial to the inferior cornua of the thyroid cartilage.

If the intralaryngeal portion of the stenosis is entirely anterior, as it often is in stomal lesions because of either cricothyroidotomy or erosion by a high tracheostomy, the mucosa overlying the posterior plate of the cricoid cartilage may be intact. If, on the other hand, the stenosis is circumferential, as occurs from pressure secondary to a large endotracheal tube, then the scar that overlies the posterior plate also must be removed. The scar is excised down to the surface of the posterior cricoid plate leaving the cartilage intact. The upper line of mucosal division may lie just below the arytenoid cartilages. This bared cartilage must be resurfaced with the membranous wall of the distal trachea.

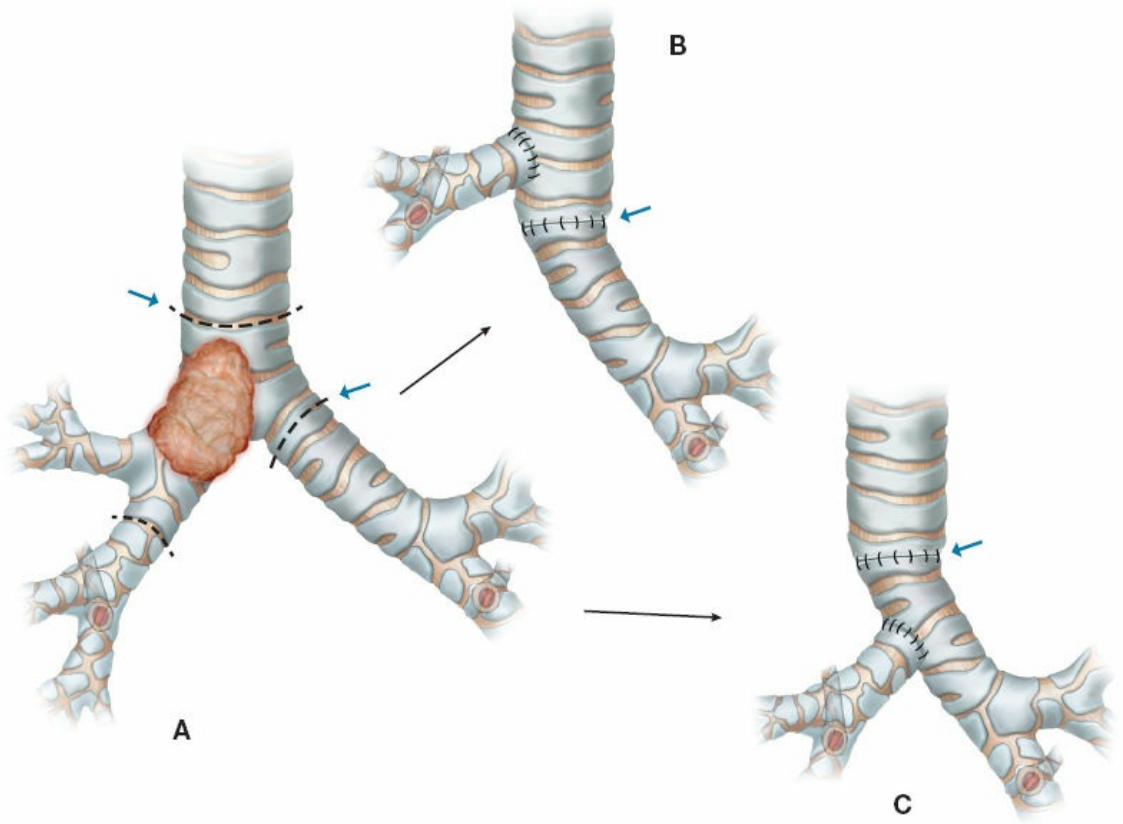

Figure 34.7. Carinal resection with right upper lobectomy. With mobilization, the bronchus intermedius is advanced to the side of the trachea and implanted above the anastomosis of the trachea and the left main bronchus. If it fails to reach the trachea, it is implanted into the side of the left main bronchus. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Lung Resections, Bronchoplasty.* 2014; Wolters Kluwer.)

Distally, the line of resection of the trachea is beveled backward along the thickness of just one cartilaginous ring so that a prow is formed. Posteriorly, the membranous wall can be transected horizontally if a mucosal flap is not needed to resurface the posterior plate of the cartilage. If the posterior plate has been bared by removal of scar, a broad-based flap of membranous wall is preserved, as indicated in Figure 34.9.

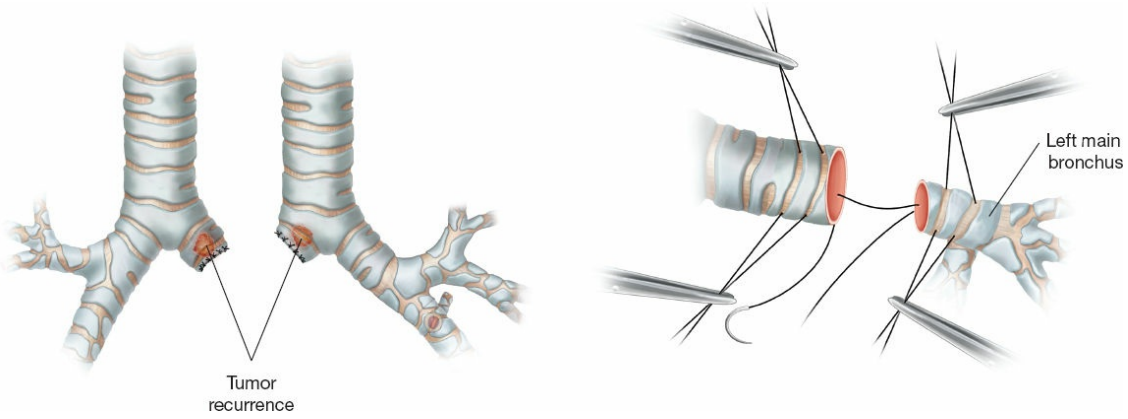

Figure 34.8. Carinal resection after prior pneumonectomy. Except in a patient who has a long residual left main bronchial stump, the procedures are carried out through the right hemithorax. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Lung Resections, Bronchoplasty.* 2014; Wolters Kluwer.)

When no posterior flap is to be inserted, the anastomosis is done in the conventional manner. When a flap must be inserted, we first place four sutures from the inferior margin of the posterior cricoid plate to a point approximately 5 mm down on the back of the membranous wall of the trachea so that the flap is free to cover the bared cartilage inside. These sutures are carefully marked but are not tied. The sutures on the membranous wall are placed in a vertical mattress fashion so that the knots are on the outside. After this step, all of the posterior anastomotic mucosal sutures are placed from the margin of the membranous wall flap to the mucosa within the posterior wall of the larynx. These sutures are placed so that the knots lie inside the lumen. The first few lateral anastomotic sutures go through the full thickness of the cartilage and mucosa of the trachea, and the mucosa and some of the cartilage of the lateral laminae of the cricoid. The lateral traction sutures are tied. The first four fixing sutures are tied and cut. The mucosal sutures inside the larynx are tied with the larynx open so that the surgeon’s finger can go into the larynx. After the posterior mucosal flap has been sutured into place, the balance of the lateral and anterior anastomotic sutures are placed in the usual manner and tying is continued.

In some patients with inflammatory disease, a considerable amount of submucosal thickening and edema remains in the subglottic larynx all the way to the undersurface of the vocal cords. In these instances, reconstruction has to accept a narrowed airway. If the airway is inadequate

after the reconstruction because of edema, a small, uncuffed endotracheal tube is placed well below the anastomosis for 48 to 72 hours. If airway obstruction is still present after the tube is removed, a small tracheostomy is placed in a previously marked area well below the anastomosis. With time, the edema usually regresses and the tracheostomy tube is removed.

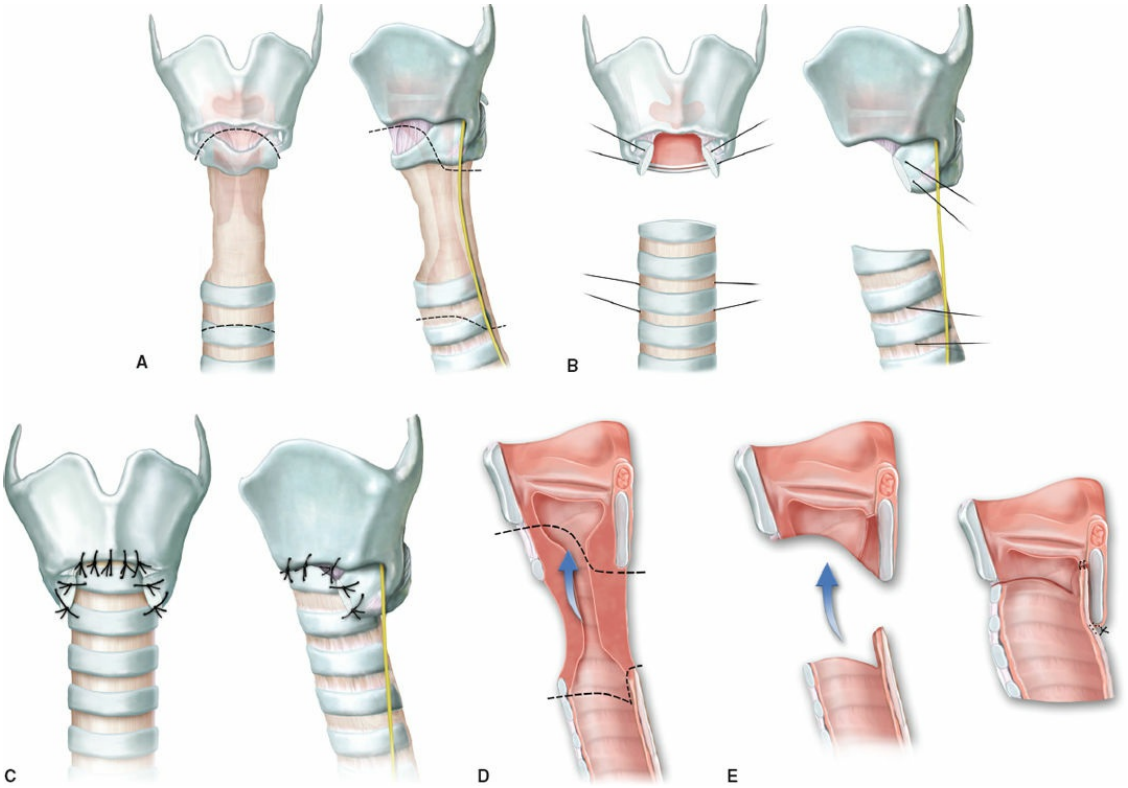

Figure 34.9. Operative repair of anterolateral stenosis of the subglottic larynx and upper trachea. **A.** Anteroposterior and lateral views showing the extent of disease and the ultimate lines of transection. **B.** Larynx and trachea after removal of the specimen. Recurrent nerves have been left intact. The mucous membrane of the larynx has been transected sharply at the same level of division as the cartilage. **C.** Anteroposterior and lateral views of the reconstruction. **D.** Resection and reconstruction of circumferential stenosis of the subglottic larynx and upper trachea. The external line of cartilaginous division of both the larynx and trachea is the same as in anterolateral stenosis. Interior view of the larynx and trachea demonstrate modifications necessary when stenosis involves mucosa and submucosa just in front of the cricoid plate. Superior *dotted line* indicates external cartilaginous division of the larynx. *Dashed line* against the anterior wall of the cricoid plate indicates that the mucosa with its scarring will be cut back to within a short distance of the arytenoid cartilage, if necessary. Inferiorly, the posterior

membranous wall has been retained as a broad-based flap. **E.** Resected specimen, leaving the bare area of the intraluminal portion of the lower part of the cricoid lamina. The flap of the membranous wall of the trachea is fitted into the defect to provide complete mucosal coverage, shown at the right. The mucosa of the larynx has been anastomosed to the mucosa of the membranous wall of the trachea. External to the lumen, connective tissue of the membranous wall has been fixed with four sutures to the inferior margin of the cricoid cartilage to assure that the flap stays firmly applied to the surface. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections.* 2014; Wolters Kluwer.)

Idiopathic subglottic stenosis is becoming a common reason for subglottic resection. Almost all patients are female and Caucasian. They present with progressive dyspnea on exertion that develops into stridor over several years. Possible etiologies such as gastroesophageal reflux, Wegener granulomatosis, and connective tissue disorders must be excluded. Typically there is a short stenosis that involves the first two or three tracheal rings, the cricoid cartilage, and the posterior cricoid mucosa. Patients will often undergo several procedures for palliation, such as tracheostomy, balloon dilatation, laser debridement, and cryotherapy. We prefer instead definitive treatment with single-stage resection and reconstruction, which almost always involves a buttressed anastomosis between the trachea and thyroid cartilage. Patients are almost always extubated immediately after the procedure, and rarely is a protecting tracheostomy required.

Laryngotracheal Resection for Tumor

Occasionally, a high primary tumor, such as adenoid cystic carcinoma, or a secondary tumor, such as differentiated but invasive thyroid carcinoma, involves the lower larynx. Often, one recurrent laryngeal nerve is already paralyzed. The line of resection is tailored to the particular tumor (Fig. 34.10). On the involved side, this line may lie beneath the vocal cord with a variable portion of the cricoid cartilage resected. The recurrent laryngeal nerve on the opposite side must remain functional. On the uninvolved side, the resection line is just below the lower margin of the cricoid cartilage. Frozen sections are used to check completeness of resection. The line of

tracheal resection is made to correspond to the line of laryngeal division so that the two structures can be mortised together. A protective tracheostomy usually is not necessary in these patients.

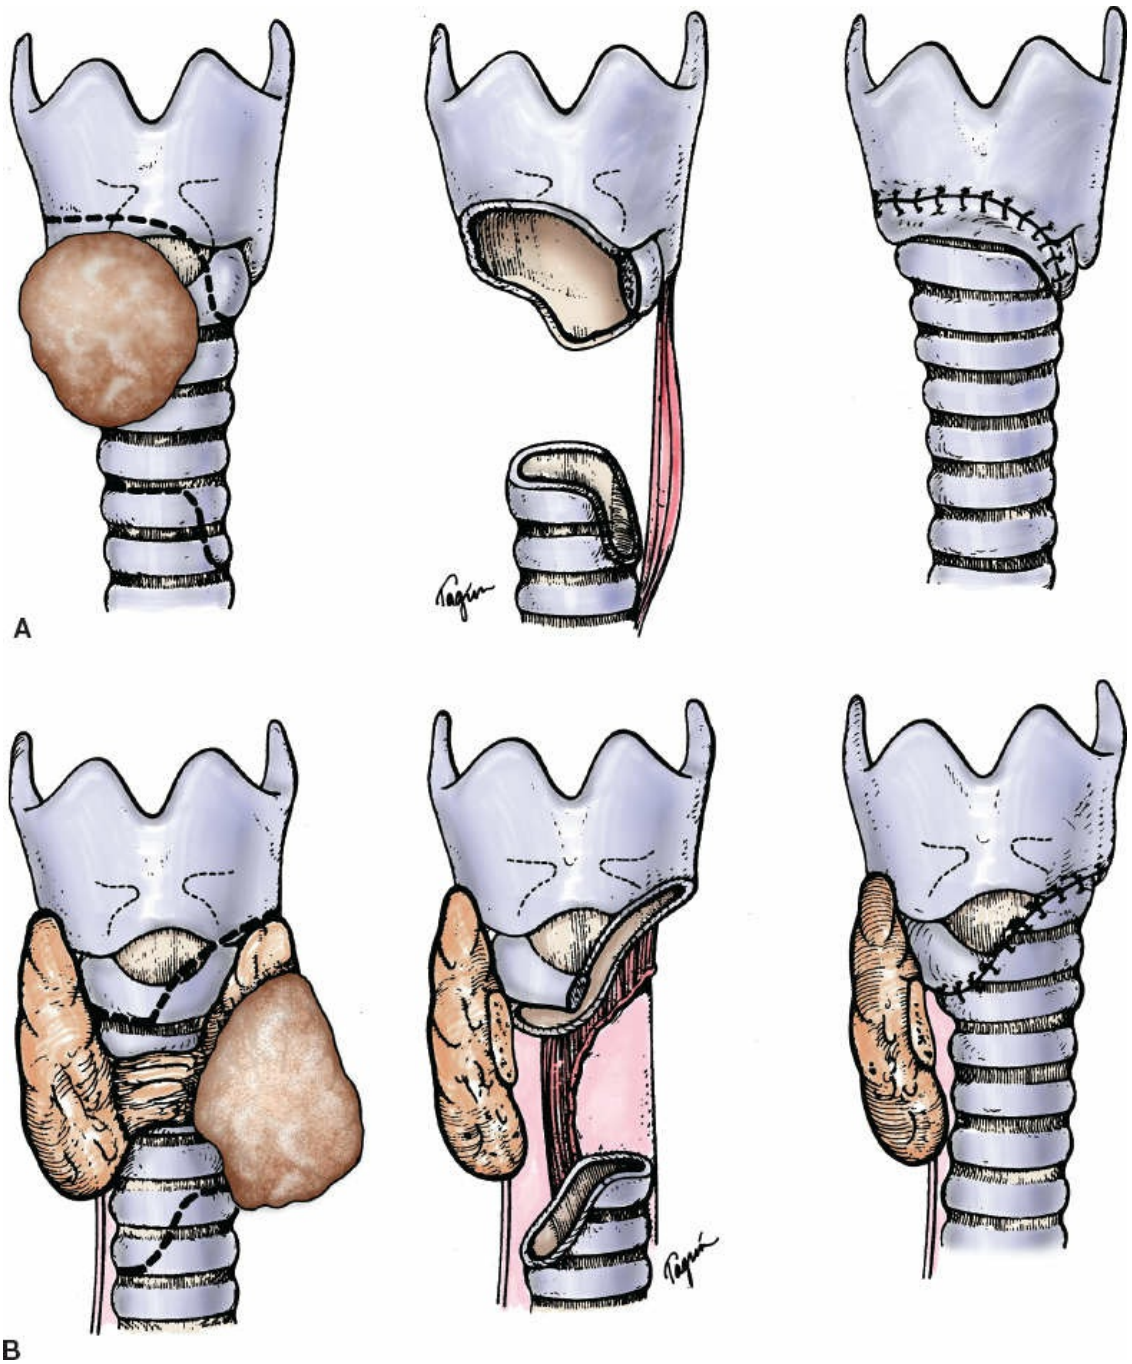

Figure 34.10. **A.** Resection of mixed papillary and follicular carcinoma after recurrence following total thyroidectomy. **B.** Mixed papillary and follicular carcinoma, not previously treated, is managed by complex resection, including removal of the anterolateral muscular wall of the esophagus. (Reprinted from Grillo HC, Zannini P. Resectional management of airway invasion by thyroid carcinoma. *Ann Thorac Surg* 1986;42(3):287–98, with permission of the Society of Thoracic Surgeons.)

Tracheoesophageal Fistula

TEF can arise from malignancy or mechanical causes. The most common location for tumor is the esophagus, but the precipitating carcinoma can arise from lung, trachea, or thyroid. The most common cause of nonmalignant TEFs is erosion by tracheostomy tubes that press against an in-lying, hard nasogastric tube. The common wall of the trachea and esophagus is destroyed between the two foreign bodies (Fig. 34.11A). However, because circumferential injury to the trachea is caused by the endotracheal cuff, simple tracheal repair is usually not sufficient, and adequate treatment involves a tracheal resection and reconstruction. We advocate a single-stage repair once the patient no longer depends on mechanical ventilation. However, the initial steps following the recognition of a TEF include removing the esophageal foreign body, using a low-pressure cuff in the distal trachea, and placing the cuff below the fistula. A gastrostomy tube is placed to drain the stomach and prevent reflux through the fistula, and a feeding jejunostomy is placed. Because of the location of most TEFs, proximal esophageal diversion is not feasible or practical. When the patient has been weaned from ventilation, a single-stage operation is performed via the anterior approach. The majority of TEFs that result from intubation can be repaired through a low-collar incision. If a tracheostomy stoma is present, it can be incorporated into the incision and resected. If the fistula is located near the carina, a right posterolateral thoracotomy may be used. The injured tracheal segment is resected along with the esophageal fistula (Fig. 34.11B). The esophagus is closed in two layers with fine interrupted sutures (Fig. 34.11C) and a pedicled muscle flap is placed over the esophageal repair (Fig. 34.11D). With a small fistula and otherwise normal trachea, tracheal resection may not be required. In this case, the fistula is dissected and divided from a lateral approach, cautiously avoiding the recurrent laryngeal nerves. The trachea is closed with fine absorbable sutures and the esophagus is closed in two layers. Again, a muscle flap is sutured over the esophageal closure to interpose healthy tissue between the esophageal and tracheal closures.

A TEF caused by malignancy has a particularly dismal prognosis, with few patients surviving more than 1 year. In the setting of continuous soiling of the tracheobronchial tree, a variety of treatment alternatives are available, including esophageal stenting, esophageal exclusion and palliative chemoradiotherapy.

Laryngotracheal Trauma

After the diagnosis of laryngotracheal trauma is made, control of the airway is critical. If any doubt exists about the status of the airway, emergency tracheostomy should be performed. Repeated attempts at oral intubation should be avoided for fear of losing airway control altogether. Examination of the traumatized airway is best done in the operating room with a flexible bronchoscope over which a small endotracheal tube has been passed to allow for intubation by using the flexible bronchoscope as a guide. Patients should be scrupulously examined for associated injuries, such as laryngeal, vascular, esophageal, and spine injuries. The presence of these injuries may influence management of the airway injury.

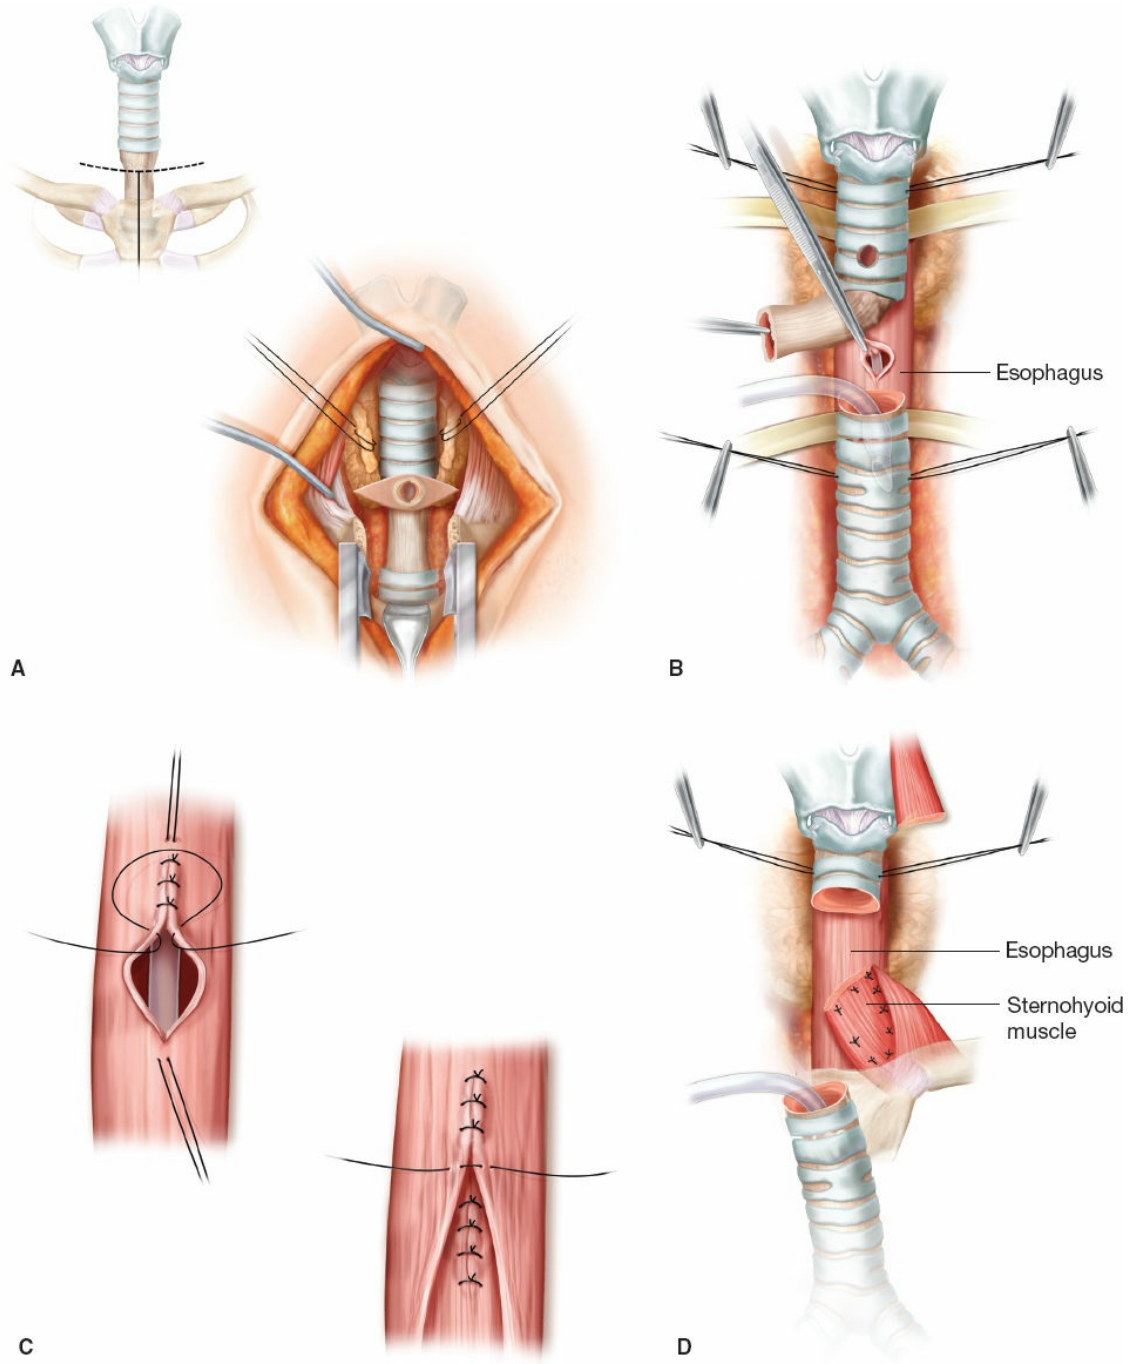

Figure 34.11. A. With tracheoesophageal fistulas, the common wall of the trachea and esophagus is destroyed. **B.** Because of circumferential tracheal damage, the injured tracheal segment is resected along with the esophageal fistula. **C.** The esophagus is closed in two layers with fine interrupted sutures. **D.** A pedicled muscle flap is placed over the esophageal repair. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections.* 2014; Wolters Kluwer.)

Simple lacerations should be repaired by interrupted, simple 4-0

polyglycolic acid sutures. Complex injuries require individual solutions. Placing a tracheostomy tube through damaged trachea to secure the airway with repair of associated injuries may be appropriate in some cases. One should stress that all viable trachea should be preserved for further reconstruction. Concomitant esophageal injuries should be repaired in two layers and covered by a pedicled strap muscle to separate the esophageal and tracheal suture lines (Fig. 34.12). Laryngeal injuries are best managed in conjunction with an otolaryngologist and often require a protecting tracheostomy. Complete transections of the airway are almost always accompanied by damage to one or both laryngeal nerves. A protecting tracheostomy is needed after repair of such injuries because of the risk of adduction of the vocal cords.

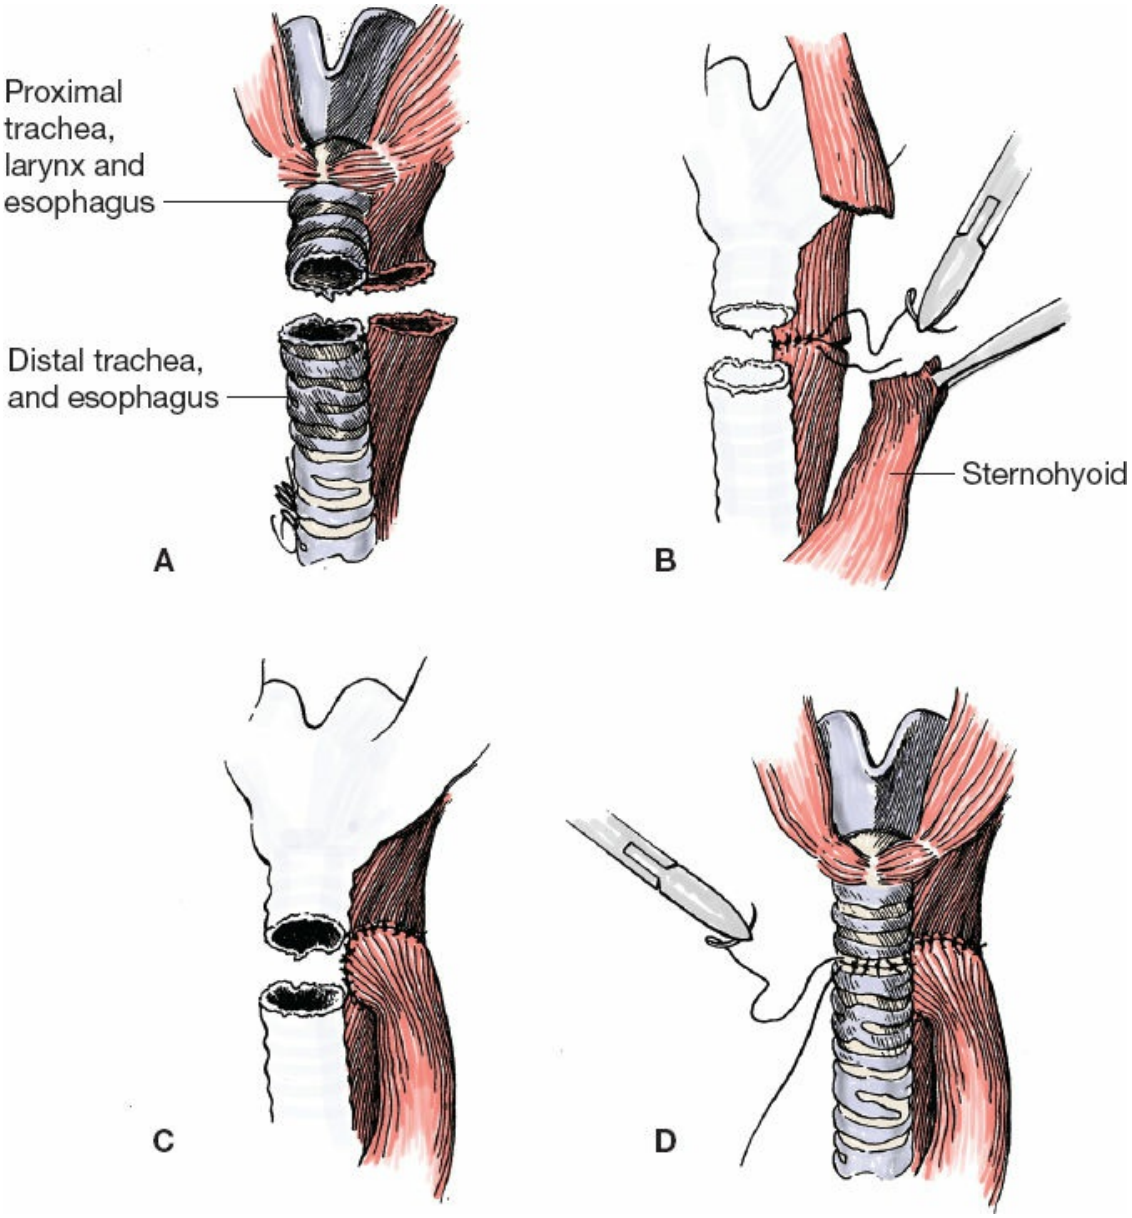

Figure 34.12. A. View of transected trachea and esophagus. **B.** Esophagus closed in two layers. **C.** Strap muscle interposed between the esophageal and tracheal suture lines. **D.** Completed repair.

Pediatric Tracheal Stenosis

Tracheal stenosis in children is an uncommon problem. When present, if the child is of sufficient size, resection and end-to-end anastomosis is the procedure of choice for correction. If the child is deemed too small, a tracheostomy or T tube is preferable until the child attains sufficient size. Congenital tracheal stenosis is even more uncommon. Short-segment tracheal stenosis is best managed by resection and end-to-end anastomosis. If long-segment stenosis exists and respiratory distress develops, two options are available. One option involves incising the stenosis (O rings) and inserting a pedicled pericardial patch. The second method, described by Goldstraw and Grillo, has been dubbed *slide tracheoplasty*. It involves dividing the stenosis at its midpoint. The anterior surface is incised in the distal segment and the posterior surface in the proximal segment (Fig. 34.13). The proximal and distal segment slide over one another and an anastomosis is performed, as described for tracheal reconstruction.

Reoperative Tracheal Surgery

Failure of primary tracheal resection and reconstruction may occur despite attention to technical details, and early restenosis poses a difficult challenge. Most important is the establishment of a secure airway. Dilatation is a temporary measure, as restenosis will occur within days to weeks, but it may be appropriate in some patients. Placement of a tracheostomy or T tube through the most damaged or stenotic portion of the trachea is the safest procedure. For definitive repair, the best approach is to wait 4 to 6 months before another attempt at reconstruction. This allows the inflammatory changes from surgery to subside and improves the mobility of tissues. Every effort should be made to discern the reason for failure and to correct any identifiable causes. Prior to any reconstruction, repeat bronchoscopy is essential to determine the amount of available airway and the condition of the tracheal mucosa. Surgery requires the same careful attention to detail. A laryngeal release is much more likely to be needed the second time around (25% of second operations vs. 6% of primary operations). Careful evaluation of patients, proper management of

the airway, correct timing of the operation, and strict attention to technical details can achieve success in more than 90% of patients selected for reoperation.

Subtotal Tracheal Resection

We do not recommend the use of tracheal prostheses or staged tracheal reconstructions using skin tubes or other tissues. Although success has been seen with both techniques, the number of complications and hazards are so great that these procedures seem unjustified. For a benign stenosis to require a resection that cannot be managed by primary reconstruction is extraordinarily rare unless the patient has had an inappropriate tracheal operation previously. In such situations, a safely placed silicone tracheal T tube performs the same function as a silicone prosthesis placed surgically, which has considerably more hazard.

Tissue-engineered tracheal replacement has gained some interest. Many problems still exist with this concept and cannot be recommended at present.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS OF TRACHEAL RESECTIONS

Following a tracheal resection, all patients have a “guardian suture” placed from the submental location to the angle of Louis. The suture is a reminder for the patient to maintain neck flexion, taking tension off the anastomosis. The patients are initially kept from food by mouth, but a diet is advanced slowly over the first several days. Warm, humidified oxygen helps mobilize secretions. Vomiting is best avoided in the early phase of recovery by the use of antiemetics. All patients are kept in the hospital until postoperative day 7, when repeat bronchoscopy is performed. At that time, if the anastomosis is intact with minimal edema, the guardian suture is cut and the patient is discharged. Edema when present is treated with 24 hours of dexamethasone. We use 10 mg IV initially, then 4 mg IV every 6 hours. This is often supplemented with heliox and diuresis. If stridor develops at any time postoperatively, the patient needs to be emergently evaluated and likely undergo bronchoscopy.

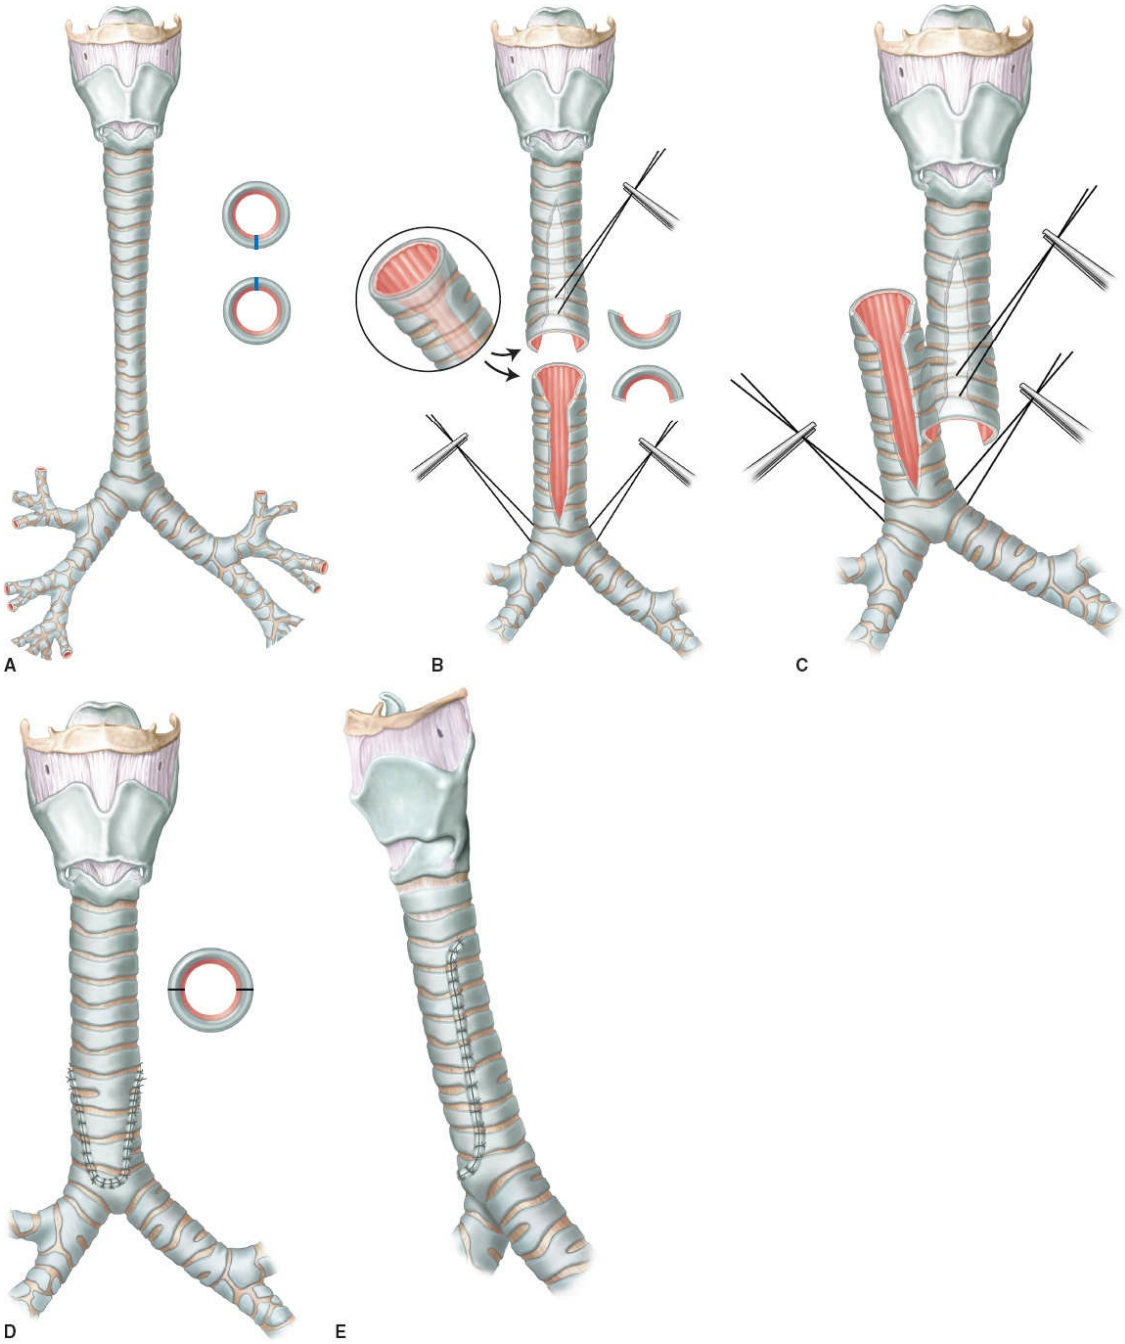

Figure 34.13. Technique of slide tracheoplasty. **A.** The extent of the stenosis is precisely identified. The stenotic segment is divided transversely in its midpoint after circumferential dissection at that locus only. The upper stenotic segment is incised vertically posteriorly and the lower segment is incised anteriorly for the full length of stenosis. **B.** The right-angled corners produced by these divisions are trimmed above and below. A stay suture near the top of the superior flap is helpful, as are traction sutures at the tracheobronchial angles or the main bronchi below. Minimal dissection of the lateral blood supply is performed. **C.** The two ends are slid together after placement of individual anastomotic sutures around the entire oblique circumference of the

tracheoplasty. **D, E.** The circumference is doubled, which results in quadrupled cross-sectional area. (From Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections.* 2014; Wolters Kluwer.)

Anastomotic complications are rare following tracheal resections. Edema, granulation tissue, and complete separation of the anastomosis are all potential problems. Early diagnosis and intervention is important in the management of complications. With an unstable airway, the patients should be intubated from above with a small endotracheal tube and bronchoscopic guidance. If the airway is stable, a CT scan of the neck may be obtained to look for extraluminal air and fluid collections. Bronchoscopy can then be performed to evaluate the anastomosis. It is rare that an anastomotic separation can be repaired primarily, and these are best managed by either a T tube or tracheostomy. A T tube is preferred because it allows for speech and for the patient to clear secretions with humidification of air through the nose. As mentioned previously, one should wait at least 6 months before considering reoperation to allow for the resolution of swelling and edema.

In a small number of patients we have used hyperbaric oxygen therapy for partial necrosis of the tracheal cartilage. Fifteen to 20 treatments has been the norm. It has been used successfully to date. Patients must have a secure airway.

RESULTS

Careful patient selection and strict attention to technical details should result in very good results. First time tracheal resection and reconstruction should achieve a good to excellent result in over 90% of patients. Resection for tracheal tumors should have similar postoperative results. Carinal resection continues to pose technical challenges, but mortality rates are consistently less than 10% as extent of resection, better patient selection and better understanding of postoperative care have improved outcomes. Management of laryngotracheal trauma has improved as understanding of initial airway management and principles of repair have become more widely understood. Even the paralyzed larynx can be salvaged to provide an adequate airway and functional voice. TEFs are among the most challenging airway problems. The goal of fistula closure

can be achieved in over 90% of patients if principles of management and repair are observed. For more detailed analysis of results readers are referred to the selected readings.

EDITOR'S COMMENT

We are honored to have Professor Mathisen contribute this chapter. He is an international leader in this field. It is fitting that he holds the Hermes C. Grillo Professor of Thoracic Surgery, as we cannot talk about surgery of the trachea without mentioning Dr. Grillo. It is appropriate to digress at this point and share some facts concerning Professors Grillo and Mathisen.

Dr. Grillo was a great thoracic surgeon, who may have invented and popularized extensive resections of the trachea including the carina. He was born in Boston in 1923 and died at age 83 in Italy on October 14, 2006. He is considered the father of tracheal surgery. While in doing and working out the technique of resection of trachea and reanastomosis it became clear that 5 cm was the limit even with the Montgomery release, which he used to bring down the laryngeal structures and chin stitch, which I remember as a resident, that kept elevation of the chin from stretching the anastomosis. Dr. Grillo and I became very good friends.

Dr. Mathisen has been Chief of Thoracic Surgery at MGH since 1994 and was Chief of Cardiac Surgery during 2007–2011, and Program Director in Cardiothoracic Surgery since 1995. He has carried on the Grillo legacy.

Grillo successfully introduced and popularized tracheal resection and spawned a number of offspring, as it were, of which the senior author is one. It is only natural that attention would turn from being able to do tracheal repair to not being dependent on native trachea. Since the last edition, there have been substantial improvements or at least initial attempts, some successful, and improvement in substitutes for trachea.

One of the problems with trachea is that it has little in the way of specific vascular supply that one can identify and perform a microsurgical anastomosis. Thus, the reconstruction of a long segmental tracheal defect requires a vascularized allograft. The vascularity needs to be induced. In order to do so, the Belgium surgeon Delaere et al., from the KU Leuven Tracheal Transplant

Group (Tracheal allotransplantation after withdrawal of immunosuppressive therapy. Tracheal allotransplantation after withdrawal of immunosuppressive therapy *N Engl J Med* 2010;362:138–45), detail a profusely illustrated tracheal allograft, which was wrapped in the recipient's forearm fascia. At 4 months the tracheal chimera, which was now fully lined with mucosa that consisted of respiratory epithelium from the donor and buccal mucosa from the recipient, had begun to be placed once "revascularization was achieved." The recipient had been placed on immunosuppressive therapy, which was then withdrawn and then the tracheal allograft was moved to its correct anatomical position with an intact blood supply. This is a surgical tour de force. The patient reported was a 55-year-old woman who had been involved in a car accident and had undergone a tracheotomy with a long history of long tracheal stenosis. The fact that she is a woman and the cadaver donor was a male made it relatively easy to tell which cells in the allograft were which and indeed the 8-cm tracheal allograft from the recipient's forearm could be traced to having male donor respiratory cells as well as the tracheal allograft. Delaere's most recent review publication gave a state of art update and is offered as a resource to the reader (Delaere PR. Tracheal transplantation. *Curr Opin Pulm Med* 2012;18:313–20).

Replacing the trachea is not a new idea. In 1979, Rose et al. (Tracheal allotransplantation in man. *Lancet* 1979;1:433) reported the first allogenic tracheal transplant in a human. The donor trachea was originally implanted heterotopically, very much as here, in the sternocleidomastoidal recipient and transferred to the orthotopic position 3 weeks later. The recipient was not given immunosuppressive therapy, however. The report did not document the viability of the allograft, and no information has been made available about the long-term outcome. In addition, Klepetko et al. (Heterotopic tracheal transplantation with omentum wrapping in the abdominal position preserves functional and structural integrity of a human tracheal allograft. *Journal of Thoracic Cardiovascular Surgery* 2004;127:862–7) reported a preserved viability of a heterotopically revascularized allograft, which was revascularized in the omentum of a patient who ultimately received a lung transplant from the same donor. However, the tracheal transplant was not utilized but its viability was documented for at least 60 days.

There has also been some controversy surrounding tracheal replacement since the 6e. Debate and scrutiny surrounded the reports of the development of an artificial trachea created in a bioreactor and its implantation. At the present time this debate can be simply summed up that such techniques are not ready for prime time.

Another way of approaching the same problem is to use a scaffold of inert material. Janssen et al. (Tracheal reconstruction: mucosal survival on porous titanium. *Arch Otolaryngol Head Neck Surg* 2009;135:472–8) used a porous titanium scaffold and mucosa on a pedicled fascia flap created in rabbits utilizing a two-stage procedure. They noted normal mucosa in a submucosal layer and vital cells on top of the titanium. They also noted multiple blood

vessels from the muscle layer through the titanium strut. Cytokeratin expression was present in the suprabasal and basal layers of the mucosal epithelium. All animals survived the reconstruction. As far as I am aware, this type of experiment has not been tried in humans.

Another approach was tried by Hodjati et al. (Tracheal reconstruction by reinforced Gore-Tex in esophageal submuscular tunneling: An experimental study. *Ann Thorac Med* 2011;17–21) in which 10 adult mongrel dogs had a segment of seven tracheal rings resected circumferentially and a submuscular tunnel was induced between the muscular layers of the adjacent esophagus right next to the trachea. Implanted Gore-Tex passed through reinforcing the trachea and the anastomosis was made between distal ends of Gore-Tex and the trachea. Their criteria and end points were air tightness, good reepithelialization, and no limitation on esophageal length, which were all important. The Gore-Tex grafts were implanted and harvested 12 weeks after the implantation and the epithelialization that resulted was with mixed squamous/mucociliary metaplasia. It does seem as if this is another model that can be used for this important work.

Some newer experimental approaches which are being tested in animal models and in vitro include the use of cryopreserved tracheal allograft (Candas F, Gorur R, Haholu A, et al. Is tracheal transplantation possible with cryopreserved tracheal allograft and hyperbaric oxygen therapy? An experimental study. *Ann Thorac Surg* 2016;101:1139–44), the vacuum seeding BM-MNCs on nanofiber scaffolds for immediate implantation as tracheal interposition grafts to generate tissue engineered tracheal grafts in the lab of Chris Breuer (Clark ES, Best C, Onwuka E, et al. Effect of cell seeding on neotissue formation in a tissue engineered trachea. *J Pediatr Surg* 2016:49–55) and applications of chondrocyte-based cartilage engineering (Phull A, Eon S, Abbas Q, et al. Applications of chondrocyte-based cartilage engineering: an overview. *Biomed Res Int* 2016;2016:1879837).

Finally, in patients with tracheostomies, other than stenosis, a well-recognized complication is trachea-innominate arterial fistula. Tracheo-innominate artery fistula (TIF) is an uncommon but life-threatening complication after a tracheostomy. Rates between 0.1% and 1% after surgical tracheostomy have been reported, with a peak incidence at 7 to 14 days post procedure. Initial case reports of TIF resulted from surgically performed tracheostomies. This results in acute exsanguinating hemorrhage sometimes heralded by a sentinel bleed. I do not know how many of the readers have ever seen the rupture of a trachea-innominate artery fistula, but it is impressive. It is usually fatal unless treatment is instituted immediately. It may occur after percutaneous tracheostomy as well as a surgical tracheostomy. The literature describes methods of air way control, tamponade, and emergent ligation of the innominate artery. More recent publications describe percutaneous stenting as a way to provide initial treatment.

Prevention is the key as treatment outcomes are poor. To this end Sung et al.

(Is computerized tomography angiographic surveillance valuable for prevention of tracheoinnominate artery fistula, a life-threatening complication after tracheostomy? *J Korean Neurosurg Soc* 2011;49:107–11) focused on different measurements by CT angiography on 22 patients who had tracheostomies. They wished to evaluate the relationship between the tracheostomy tube and the innominate artery utilizing the proximal tube position on the cervical vertebra, the distal tube position, and the course of innominate artery and the gap between the tube and the innominate artery. After some complicated measurements they came to the conclusion that a low tracheostomy tube departure level was an indicator that some potential complication. Only 6 of the 22 patients were free of difficulties in these observations. These writings suggest that if one is concerned about this disastrous complication, there may be a way to avoid it.

Tracheal resection, reanastomosis, and the elimination of tracheostomy and tracheal stenosis are excellent advances in thoracic surgery. American surgery is pleased to have been able to call Dr. Hermes Grillo a friend and we are secure in the knowledge that Dr. Mathisen will carry on the tradition.

> Book 22: The Death of Hector, The Iliad

ANATOMY

Few areas of the body concentrate vital anatomy as in the neck. Notable structures include the pharynx; larynx; trachea; esophagus; common carotid artery; internal carotid artery; external carotid artery and its branches; the vertebral and subclavian arteries; the internal and external jugular veins and their tributaries; cranial nerves IX to XII (glossopharyngeal, vagus, spinal accessory, and hypoglossal); thyroid, parathyroid, and submandibular glands, and the bony spine and spinal cord. Thorough knowledge of the anatomy of this region is essential.

The platysma muscles spread subcutaneously as a sheet across the entire length of the lower border of the mandible down to and across the entire length of the clavicle below, distinguishing superficial from deep layers. Deeper fasciae envelope the infrahyoid “strap” muscles (sternohyoid, omohyoid, and sternothyroid) laterally and encircle the esophagus and trachea centrally. Palpable landmarks along the midline of the neck, which is not covered by platysma muscle, include the thyroid cartilage superiorly, the cricoid cartilage more caudally, and the suprasternal notch at the base of the neck between the clavicles.

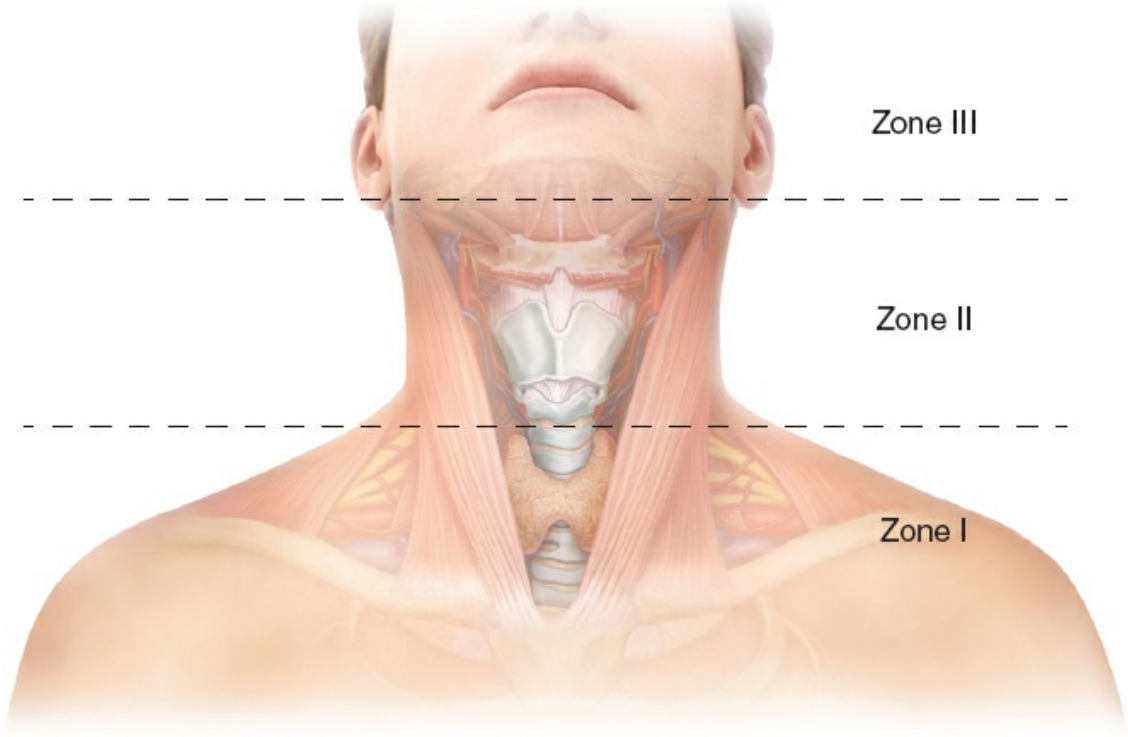

Figure 35.1. Anatomic zones of the neck.

Traditionally, anatomists divide the neck into triangular areas (Fig. 35.1), bordered by musculature and bony landmarks, while surgeons refer to Monson's three "zones" of the neck. The dominant muscular landmark of the lateral neck is the sternocleidomastoid muscle. Coursing obliquely from the skull base to the sternum and medial clavicle, the sternocleidomastoid separates anterior and posterior triangles. The anterior triangle is further bounded by the midline and lower border of the mandible and contains the "carotid bundle" (carotid artery and bifurcation, internal jugular vein, and vagus nerve) (Fig. 35.2). Zone I of the neck extends from the clavicle to the cricoid cartilage, zone II from the cricoid to the angle of the mandible, and zone III from the angle of the mandible to the skull base. Surgeons have historically favored the zone classification because it is useful to predict operative access. Injuries within zone II are readily exposed and repaired (Fig. 35.3); access to injury within zone I (the thoracic outlet) (Fig. 35.4) or III (the skull base) is far more challenging (Fig. 35.5).

CLINICAL PRESENTATION AND DIAGNOSIS

Patients who are in shock, have airway compromise, or other "hard signs" of visceral injury should undergo immediate exploration after penetrating

injury to the neck (Table 35.1). Without these hard signs on admission, the approach to penetrating neck injury has changed dramatically over the past several decades. Mandatory surgical exploration of injuries in zone II as practiced for decades traded ease and reliability for a high rate of negative and nontherapeutic operation. Over time, a more selective operative approach, based on findings from various arteriography or gastrografin/barium swallow and endoscopic studies, replaced this one-time standard. With the advancements in technology associated with the multislice helical CT, CT angiography (CTA) has emerged as the screening modality of choice for penetrating neck wounds in patients without hard signs for immediate exploration. CTA is the next step after history, physical examination, and chest radiograph—irrespective of the zone of injury (Fig. 35.6). It is easily accessible, well tolerated with minimal risk, sensitive for defining trajectory, and reliable for excluding significant arterial injury. Venous injuries which are not apparent on physical examination, meaning no evidence of active bleeding, generally do not require an operation (low pressure system). Nearly all tracheal injuries will have obvious signs or symptoms revealing their presence on admission (crepitance, sucking wound, etc.). Fortunately, aerodigestive tract injuries are uncommon, but are easily missed, and may not be apparent on clinical assessment alone. Abnormalities identified on CTA or trajectory suspicious for aerodigestive tract injury should be further evaluated with surgical exploration, laryngoscopy, tracheobronchoscopy, catheter-based arteriography, esophagoscopy, or esophagography as suggested by CTA, symptoms, or other findings. Soft signs mandate further evaluation of the patient with penetrating neck injury (Table 35.2).

Shock
Pulsatile bleeding
Expanding hematoma
Signs of stroke/cerebral ischemia
Unilateral extremity pulse deficit
Airway compromise
Extensive subcutaneous emphysema or bubbling wound
Stridor, hoarseness
Audible bruit/thrill (CTA first, if stable)

Several studies have reported that many of the patients who are asymptomatic after penetrating neck injury can be admitted and observed without further evaluation beyond history, physical examination, and chest radiograph (neck films if indicated). However, physical examination is unreliable to exclude aerodigestive tract injuries in the asymptomatic patient with penetrating neck wounds deep to the platysma muscle. A comprehensive literature review by the Practice Management Guidelines Committee of the Eastern Association for the Surgery of Trauma in 2008 concluded that “either contrast esophagography or esophagoscopy can be

used to rule out an esophageal perforation that requires operative repair." Furthermore, patients admitted for observation without further workup should be reexamined frequently by the same surgeon; this is labor intensive, difficult in a busy center, and may require a mean hospital stay up to 2.5 days. This may be useful in areas where technology is limited. In a busy trauma center with the resources, screening CTA allows more rapid triage, identification of injuries, and definitive treatment—this is our approach.

Hematoma of the neck
Peripheral neurologic abnormality

Primary Survey

As always, the principles set forth by Advanced Trauma Life Support guide the initial assessment of the patient with penetrating neck injury. Important historical information includes mechanism of injury and blood loss at the scene. Gunshot wounds have a significantly higher likelihood of vital-structure injury than stab wounds. The primary survey will identify patients in shock or with clear signs of vital-structure injury such as airway compromise, massive subcutaneous emphysema, sucking wound, active hemorrhage, expanding or pulsatile hematoma, carotid bruit or thrill (CTA may be helpful in a stable patient), neurologic defect, or absent/decreased radial pulse in the ipsilateral upper extremity. Immediate surgical intervention is indicated when any of these “hard” signs are documented (see Table 35.1).

Airway Management

Impending airway occlusion can occur with any tracheal or laryngeal injury, with compression from a large or expanding hematoma, or from intraoral hemorrhage. Control of the airway is a priority in these patients and may be accomplished by oral endotracheal intubation, cricothyroidotomy, or formal tracheotomy. If time allows, these airways are best managed in the operating room with full access to good lighting and surgical equipment. While blind nasotracheal intubation is contraindicated in this setting, fiberoptic bronchoscopy-assisted nasotracheal intubation can be helpful when tracheal deviation from large hematoma is present. Patients with significant intraoral hemorrhage often need to remain sitting rather than in the supine position to avoid essentially drowning in their own blood. Recognize these patients who are staying alive breathing on their own, but may not be able to be intubated after

rapid sequence intubation—and are now apneic. This uncommon patient will require awake intubation, or at times, a surgical airway with sedation.

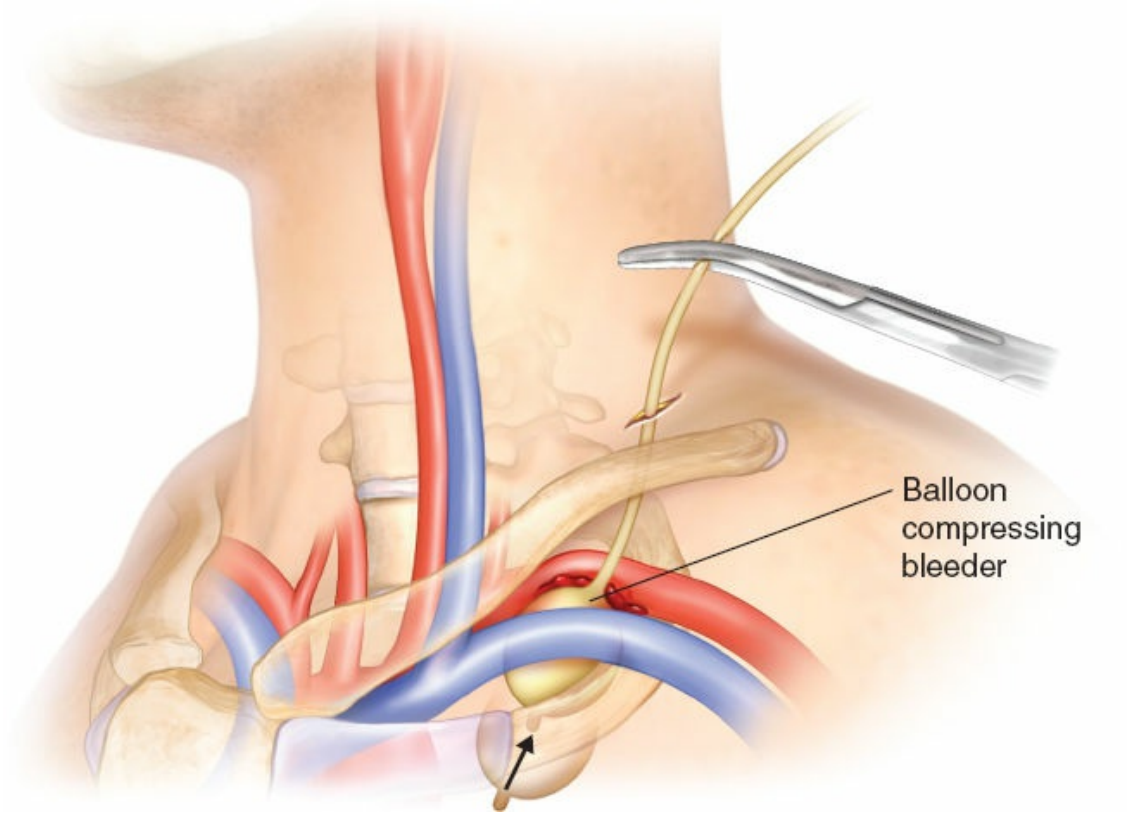

Figure 35.7. Balloon tamponade for bleeding control from the subclavian vessels. It can also be used for bleeding control from other zones in the neck.

Cricothyroidotomy is the quickest and most efficient way to access and secure the airway when oral intubation is unsuccessful. Understand that this operation is conducted with palpation more than visualization. Stay in the midline to avoid bleeding from the anterior jugular veins. If they are injured during the procedure, complete cannulation of the trachea and then control the venous bleeding. The operator should be on the patient's right side and should begin by palpating the superior and inferior aspects of the thyroid cartilage and securing this structure with the left hand between the thumb and middle fingers, leaving the index finger free to palpate the membranous space between the thyroid and cricoid cartilages. A vertical or transverse incision is made at this level, and the subcutaneous tissues are separated bluntly with a straight or curved clamp to the cricothyroid membrane, which is then incised with a No. 11 or 15 knife blade for direct access to the subglottic space. (Avoid cutting too deeply to protect the

posterior membranous trachea and more deeply located esophagus.) This should allow entry of the left index finger for control and dilatation. Alternatively, one can use the knife handle to dilate the space. A No. 6 endotracheal tube can then be positioned and secured. When a cricothyroidotomy is required, it should be converted to a tracheotomy at the earliest safe opportunity.

Circulatory Support

Large-bore peripheral venous catheters are adequate for circulatory support; however, avoid the ipsilateral upper extremity as an access site in patients with zone I (thoracic outlet) entry or trajectory. A plain radiograph of the chest should be obtained to assess for hemopneumothorax. Active hemorrhage from a wound in the neck in any zone is best managed by digital compression until the airway is controlled and surgical access can be obtained. If digital pressure fails to control the bleeding, insertion of a balloon catheter (Foley catheter) to control hemorrhage in the oral cavity or through the gunshot wound at the thoracic outlet may be necessary for temporary control of hemorrhage (Fig. 35.7).

PREOPERATIVE PLANNING

In the symptomatic patient who requires surgery without prior diagnostic testing, zone of entry and likely trajectory are important to plan exposure (see Fig. 35.5). The patient should be positioned supine, with arms tucked, neck extended, and head deviated slightly away from the side of injury; some surgeons find the beach chair position or reverse Trendelenburg helpful. A towel roll placed beneath the shoulders will extend the neck. The sterile preparation should include both sides of the neck from the temporomandibular joint to the lower lip down to and including the entire anterior chest. Zone II injuries are best approached via an oblique incision along the anterior border of the sternocleidomastoid muscle from the angle of the jaw to the clavicular head. With zone I entry, the surgeon should be prepared to perform a median sternotomy for access to and repair of structures in the thoracic outlet or base of the neck. In this circumstance the ipsilateral arm should be free and prepped to the elbow. A horizontal incision along the superior aspect of the clavicle will supply access to the proximal subclavian vessels and innominate vessels on the right. This incision may be independent or can extend an anterior sternocleidomastoid or median sternotomy incision when necessary. Clavicle resection may be

required on occasion. Access to the left subclavian artery at its origin can be difficult through a median sternotomy because of its posterior position on the aortic arch. Exposure here may require a third interspace left anterior thoracotomy (Fig. 35.8). Wounds in zone III may require a curvilinear posterior extension over the mastoid process to allow exposure of the distal internal carotid artery to the skull base. A horizontal "collar" incision can offer excellent exposure to multiple zones when subplatysmal flaps are developed. This incision is most useful for isolated laryngotracheal injuries that require a surgical airway or axial traverse gunshot wounds that require bilateral exploration.

SURGICAL TECHNIQUE

Standard Exposure (Zone II)

Injuries in zone II are both more frequent and more accessible than those at the skull base (zone III) or thoracic outlet (zone I). An incision along the anterior border of the sternocleidomastoid muscle offers the best access to all of the important vascular and aerodigestive structures of the neck (Fig. 35.4). As described above, this incision can also be extended to allow exposure to the thoracic outlet and skull base if needed (see preoperative planning). We prefer the semi-Fowler position with the neck extended and turned slightly away from the surgeon. The anterior chest should be prepared and accessible but may be draped. The ear lobe, chin, and entire lateral neck should be in the surgical field for easy orientation. On the left side we pay particular attention to trajectories that suggest zone I involvement as these patient will also have their left arm prepared to the elbow with the forearm and hand in a sterile wrap (i.e., self-adhesive Coban), so that the entire arm is free and mobile in the surgical field. With a towel roll elevating the shoulder, this preparation will facilitate exposure to the proximal left subclavian via a high anterolateral thoracotomy should that be necessary for control or repair (see exposure of the thoracic outlet). Separate right and left incisions may be made when bilateral exploration is required.

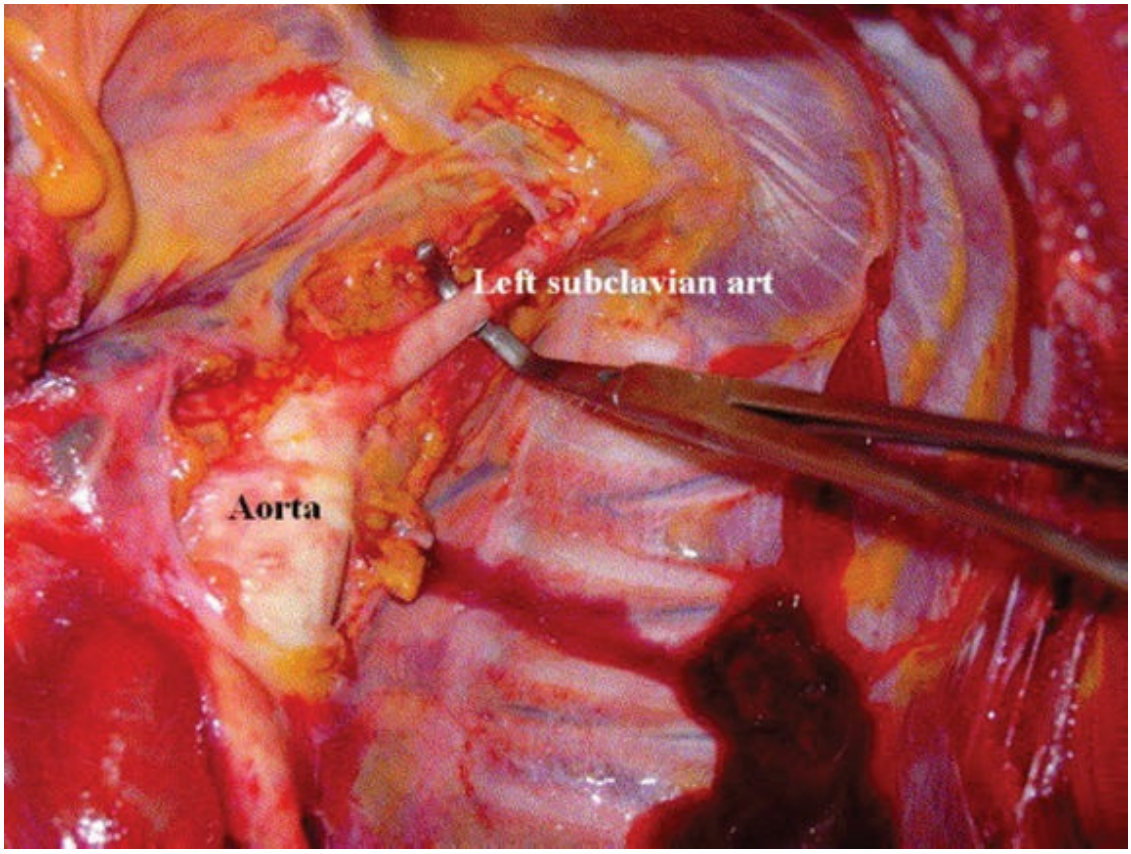

Figure 35.8. Bleeding from the left subclavian artery may be controlled in the apex of the hemithorax through a left thoracotomy. (Reprinted from Demetriades D, Salim A, Brown C, et al. Neck injuries. *Curr Problem Surg* 2007;44(1); Figure 19, page 64, with permission from Elsevier.)

The skin incision should begin near the angle of the jaw and extend down to the sternum. After incising the platysma muscle, a layer of investing fascia is encountered and taken (in line with the skin and platysma incisions) along with two cutaneous nerves (the greater auricular and anterior cervical) and the transverse portion of the anterior jugular vein. This vessel connects the external jugular (posterolateral) to the anterior jugular (anteromedial), is variable in location, and lies intimate to the undersurface of the platysma. It can be prominent and should be ligated when encountered. The plane along the anterior border of the sternocleidomastoid is now further developed, allowing posterolateral retraction and access to the carotid bundle. Two blunt Weitlaner self-retaining retractors positioned at the ends of the wound will open this space adequately. Alternatively, two right-angle retractors similarly positioned with retraction laterally by an assistant is sometimes less cumbersome. The internal jugular vein lies most prominently in this space

and obscures the carotid artery, which at this point in the dissection should be easily palpable. An injured internal jugular vein will stain this space and surrounding tissues with dark blood and clot but will also aid in the dissection. Digital manual pressure is the most effective initial maneuver, followed by ligation of the facial vein, which courses to the internal jugular directly over the carotid bifurcation from the midline, serving as a landmark for the surgeon (Fig. 35.2). The internal jugular vein can then be repaired or ligated as indicated (see treatment). Lateral retraction of the internal jugular will now reveal the carotid artery and vagus nerve and repositioning of the self-retaining or manual retractors will maintain exposure. The vagus nerve travels between the carotid and jugular and care must be taken when retracting the vein to protect this cranial nerve from injury.

As with any vascular injury, proximal and distal control should be obtained prior to entering a hematoma. However, this is often difficult in the tight confines of the lateral neck and proximal access alone will frequently suffice along with digital compression. Exposure of the proximal common carotid artery requires incision of the intermediate tendon of the omohyoid muscle (separating the superior and inferior bellies) along with the enveloping fascial sheath that tethers this muscle to the clavicle below (Fig. 35.2). A Kelly clamp introduced beneath the intermediate tendon along the course of the jugular vein facilitates development of this space allowing an assistant to incise the tendon without injury to the contents of the sheath. At a negligible cost to patient function, this release allows a more complete lateral eversion of the sternocleidomastoid muscle and should be a standard part of the dissection of the lateral neck for trauma. The proximal exposure can be even further enhanced by liberating the sternal head of sternocleidomastoid muscle. This muscular attachment can be freed from the bony sternum with electrocautery and serves as an excellent interposition muscle flap should one be required. The release of the sternal head of the sternocleidomastoid muscle also offers exposure to the proximal vertebral artery for ligation when required (see treatment). To this end, dissection is along the lateral border of the internal jugular vein with retraction of the bundle medially. This repositioning allows dissection into the posterior triangle to encounter the supraclavicular fat pad. Careful blunt dissection here will reveal the first stage of the vertebral artery deep in the thoracic outlet.

Exposure at the Skull Base (Zone III)

To expose the internal carotid artery at the skull base, a “hockey stick” extension curves the superior aspect of the skin incision toward the back of the ear along the mastoid process. Anatomy in this region is dense with cranial nerves that should be preserved. The glossopharyngeal nerve (cranial nerve IX) coursing anteriorly, and spinal accessory nerve (cranial nerve XI) coursing posteriorly, depart quite high, while the hypoglossal nerve (cranial nerve XII), as it swings down beneath the occipital branch of the external carotid artery en route to the tongue, is most vulnerable (Fig. 35.9A). The dissection here should begin with division of the posterior belly of the digastric muscle. The occipital branch of the external carotid and the less important ansa cervicalis (innervation to the strap muscles) can be sacrificed to preserve the hypoglossal nerve, which can now be retracted anteriorly (Fig. 35.9B). This maneuver alone can free up to 2 cm of internal carotid artery. Further exposure at the skull base can best be accomplished via a vertical ramus osteotomy, a procedure familiar to maxillofacial surgeons as a method to correct prognathism (extreme under-bite). Kumins et al. describe several advantages to this procedure over a temporomandibular subluxation. They describe it as follows:

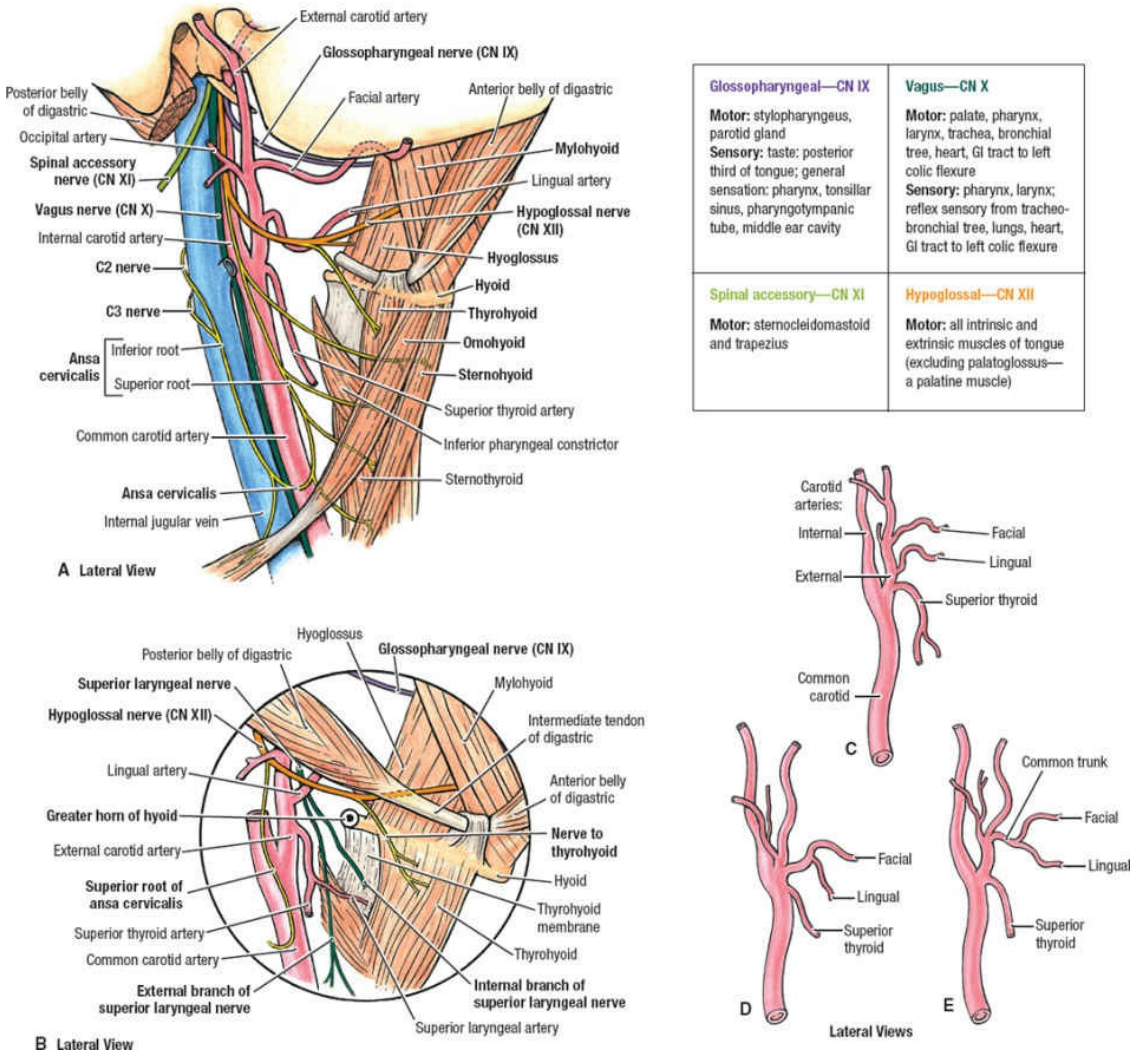

Figure 35.9. Anatomy pertinent to internal carotid artery exposure.

The ramus is approached by dissecting in a plane anterior to the masseter muscle and deep to the parotid gland. This exposure avoids injury to the branches of the facial nerve. The masseter muscle is elevated laterally from the mandibular angle to the sigmoid notch. A mark identifying the planned osteotomy is made with a small reciprocating saw. The osteotomy is designed to lie posterior to the entrance of the inferior alveolar nerve into the mandible. The bony transection courses vertically from the depth of the sigmoid notch to the angle of the mandible (Kumins et al., 2001).

Once the osteotomy is completed, the posterior segment is rotated anteriorly and superiorly. This provides access to the distal internal carotid artery up to the skull base. The mandible is repaired with miniature titanium plates that are positioned prior to the osteotomy to ensure realignment.

Hemorrhage Control at the Skull Base

Clearly, dissection at the skull base is a challenge even when structures are not obscured by active bleeding or hematoma. A more practical approach to exsanguinating hemorrhage from injury at this level of the internal carotid is to place a small thrombectomy catheter into the vessel through an arteriotomy in the common or proximal internal carotid artery and inflate the balloon at various levels until the bleeding is controlled. This technique can also control unrelenting bleeding from the vertebral artery when proximal ligation is insufficient. Dissection can then proceed, or, in the case of hemodynamic instability, the catheter can be left in place, sutured to the vessel and secured at the skin, for 48 hours. This approach is essentially equivalent to ligation of the internal carotid and should be reserved as damage control for patients in extremis.

Exposure at the Thoracic Outlet (Zone I)

Vascular injuries in the superior mediastinum often require exposure at the aortic arch. Again, an understanding of anatomy in this region is critical to obtain adequate access and exposure and avoiding iatrogenic injury. Important nerves to preserve include the vagus, phrenic, and recurrent laryngeal. On the right side, median sternotomy as an extension of the sternocleidomastoid incision will grant excellent access for control and repair of the brachiocephalic trunk (innominate artery), proximal subclavian artery, and first portion of the vertebral artery. On the left side, the left subclavian artery's posterior orientation as it emerges from the aortic arch renders it difficult to access and debate persists as to the optimal approach.

Patients in extremis with a zone I trajectory and massive ipsilateral hemothorax should have a Foley catheter placed into the wound and the balloon inflated for tamponade. If this is difficult or unsuccessful, they should undergo anterolateral thoracotomy in the emergency department and bimanual compression of the thoracic outlet with one hand inside the chest and the other outside at the base of the neck until optimal exposure can be achieved in the operating room. More often, thoracic outlet vascular injuries are contained in the superior mediastinum and some time is available to plan and optimize an approach. As described above, the ipsilateral arm should be prepared and freely mobile when approaching zone I injuries.

When a median sternotomy extends the standard neck incision (Fig.

35.5), the musculature attachments to the sternoclavicular joint (sternal head of the sternocleidomastoid, sternohyoid, and sternothyroid) are released at their insertion and the thymus and innominate vein are divided with suture ligature. A contained hematoma in the superior mediastinum should never be violated until proximal and distal control are achieved. For proximal control, this is accomplished by incising the pericardium to gain access to the arch of the aorta. The brachiocephalic trunk (innominate artery) can then be controlled with a vessel loop for injuries to the right side. For injuries to the left, the left common carotid artery is similarly encircled. Dissection can then proceed from the neck incision cephalad. With the innominate vein ligated, the right internal jugular vein is retracted laterally to further expose the vagus nerve, which at this level emerges from its posterior lie to cross the proximal subclavian artery anteriorly. Veins (brachiocephalic, innominate, right and left subclavian) reside more anteriorly in the thoracic outlet and like the internal jugular (see treatment), can be repaired if small and simple or ligated if large and complex. On the left, the thoracic duct joins the confluence of the left subclavian and left internal jugular veins and should be ligated when injured. The anterior scalene muscle is another important anatomical landmark in this area. The subclavian artery travels deep to it and the important phrenic nerve courses diagonally from lateral to medial just on top of it. If the anterior scalene muscle requires ligation the phrenic nerve must be identified and retracted away. The muscle should be divided sharply rather than with electrocautery as these important structures are intimate to the muscle and at risk for thermal injury. Release of the anterior scalene will grant access to the more distal subclavian artery, where the vertebral and internal mammary arteries emerge.

On the left side, a posterolateral thoracotomy offers the best exposure to the posterior aortic arch and origin of the left subclavian artery but requires lateral positioning, which is ill-advised in the trauma patient because zone II and the distal subclavian and axillary arteries become inaccessible. Consensus favors a left anterolateral thoracotomy incision (third interspace) for access to the take-off of the left subclavian artery paired with a separate supraclavicular, standard neck, or infraclavicular incision for access to the remainder of the left subclavian artery depending on what needs to be accomplished (Fig. 35.8). The proximal supraclavicular incision offers access via the anterior scalene release while the more distal infraclavicular incision is an excellent option if the axillary artery is

needed for distal anastomosis of an interposition graft. The laterally oriented pectoralis major musculature is split and retracted to reveal vertically oriented pectoralis minor muscle near its origin at the coracoid process. The pectoralis minor is then divided to expose the second portion of the axillary artery. Alternatively, a clavicle resection can be performed. A median sternotomy with left supraclavicular extension (Fig. 35.5) has also been described as a reliable option. Following the muscle release and ligation of the innominate vein, the left common carotid artery can then be retracted medially to expose the first stage of the left subclavian artery at a depth of 5 to 7 cm. The oft-mentioned "trapdoor" exposure joins an anterolateral thoracotomy to a supraclavicular incision via a limited sternotomy. We prefer the median sternotomy with supraclavicular extension for its ease and versatility; an additional anterolateral thoracotomy extension improves the traditional trapdoor. Although the subclavian artery has many branches, none besides the vertebral are essential. Relative to other arteries of similar size, the subclavian wall is thin and easily damaged. Important nerves are dense in this area. The brachial plexus forms from cervical nerve roots and travels through the thoracic outlet deep to the vasculature, while the phrenic and vagus nerves cross much more anteriorly. The recurrent laryngeal nerve (a branch of the vagus nerve) loops the subclavian on the right and the aortic arch on the left from anterior to posterior.

TREATMENT

Carotid Artery

Carotid artery injuries should be repaired except in rare circumstances. Primary repair, patch angioplasty, and interposition grafting are all options depending on the nature of the injury (Fig. 35.9). Small, clean wounds (i.e., stab wounds <2 cm) that can be approximated without significant narrowing should be repaired with nonabsorbable, monofilament suture (4-0, 5-0, or 6-0 polypropylene). Saphenous vein or polytetrafluoroethylene (PTFE) can be used for patch repair in cases where primary closure would narrow the vessel or as an interposition conduit when segmental resection is required and end-to-end repair is restricted by tension. PTFE as a conduit has not been shown to increase the incidence of thrombosis or infection when compared to saphenous vein (Table 35.3).

Common carotid artery injuries are usually easy to access and repair even when complex; however, they may be ligated in the extreme case that

associated injuries or severe hemodynamic instability prevent repair—although a temporary shunt would be preferable. Antegrade flow to the internal carotid via the external carotid is possible, and patients with adequate collateral cerebral blood flow (intact circle of Willis) will tolerate unilateral common carotid artery occlusion. External carotid artery injuries and injuries at the carotid bifurcation can be repaired when simple, but complex injuries can be ligated because collateral supply from the face and scalp is reliably ample. Injuries involving the internal carotid artery should be repaired when simple and the patient's condition permits, especially when patency is preserved. Controversy persists with regard to treatment of the injured and occluded internal carotid artery in the face of focal neurologic deficit or coma. The theoretical risk of reinstituting antegrade flow to the brain in the setting of cerebral ischemia is that of hemorrhage into the ischemic or infarcted area, aggravating brain injury. A reasonable approach to this dilemma is to base the decision to repair on the presence or absence of back bleeding from the distal internal carotid or obvious evidence of clot. Brisk blood flow from the distal end confirms adequate collateral cerebral flow, in which case repair should be safe. Aside from coma, which carries a dismal prognosis, neurologic deficits identified in patients with penetrating neck injury preoperatively are more likely to improve or remain unchanged with repair than with ligation.

TABLE 35.3 Principles of Repair of the Carotid Artery

- Systemic heparinization (100 U/kg) if complex repair (resection with end-to-end anastomosis or interposition graft) or repair at base of skull will be necessary
- No intraluminal shunt unless inadequate back-bleeding or prolonged repair at base of skull will be necessary
- Interrupted 6-0 polypropylene repair in children or in internal carotid artery in all patients
- Flushing sequence after verifying back-bleeding is externally, and then into the external carotid artery, and finally flow is reestablished into the internal carotid artery

From Feliciano DV, Vercruysse GA. In: Mattox KL, Moore EE, Feliciano DV, eds. *Trauma*. 7th ed. New York: McGraw-Hill; 2013:414–29. Copyright McGraw-Hill Education.

A heparin bolus, either systemic (5,000 or 10,000 units) or regional (10 to 15 mL of 50 units/mL concentration injected proximally and distally), should be administered when repair requires vascular occlusion. A completion angiogram should be obtained following interposition grafting. Internal shunting (Javid) will decrease arterial occlusion time and should

be considered as an adjunct during any interposition grafting that includes the internal carotid artery.

Injuries to the carotid artery that demonstrate contrast extravasation (pseudoaneurysm or arteriovenous fistula) on imaging studies are best repaired surgically when accessible (zone II). When similar injuries occur at the skull base or thoracic outlet, endovascular interventions, such as stent placement or embolization, should be considered. A tear or dissection of the intima that does not limit flow (as with blunt force injury) can be observed with repeat imaging after a 2-week interval on anticoagulation.

Internal Jugular Vein

Any venous structure in the neck can be safely ligated. Small, simple lacerations to the internal jugular vein should be repaired with a 4-0 nonabsorbable, monofilament suture. Larger lacerations can be repaired as well, provided the patient's clinical condition permits. When both internal jugular veins are injured, an attempt at repair of one should be made. Any neck-vein ligation should be done with a suture ligature to avoid postoperative bleeding from pressure-induced slippage of a simple tie.

Vertebral Artery

Vertebral artery injuries are much less common than carotid artery injuries and the vast majority are diagnosed by angiography (CT or catheter-based) in hemodynamically stable patients. Optimal treatment is coil or gel-foam occlusion via catheter-based angioembolization with repeat angiography at 2 weeks to rule out pseudoaneurysm or arteriovenous fistula formation. In the rare instance where active hemorrhage and associated shock prevent angiography, hemorrhage control must take place in the operating room. The vertebral artery travels within the bony transverse foramen of the cervical spine, and this portion of the posterior triangle is difficult to expose (Fig. 35.10). If packing the wound can decrease bleeding enough to achieve hemodynamic stability (we have found bone wax to be most effecting in this setting), the patient may be taken to angiography for embolization. Alternatively, control must be obtained by proximal ligation of the vessel at the thoracic outlet.

Subclavian Artery

Subclavian artery injuries diagnosed by angiography (CT or catheter-

based) in hemodynamically stable patients should be considered for endovascular repair. The vessel and injury may be accessed via the femoral artery and aortic arch (catheter-based angiography) or retrograde via a brachial artery cut-down (following CTA) for stent deployment. If hemodynamic stability becomes compromised during endovascular access, a balloon catheter can be inflated at or proximal to the injury for hemorrhage control until surgical exposure is obtained. Subclavian artery injuries should be repaired with PTFE interposition grafting. In the case of exsanguination and extremis, ligation may be considered as a life-saving option with a high risk of significant ischemic complications.

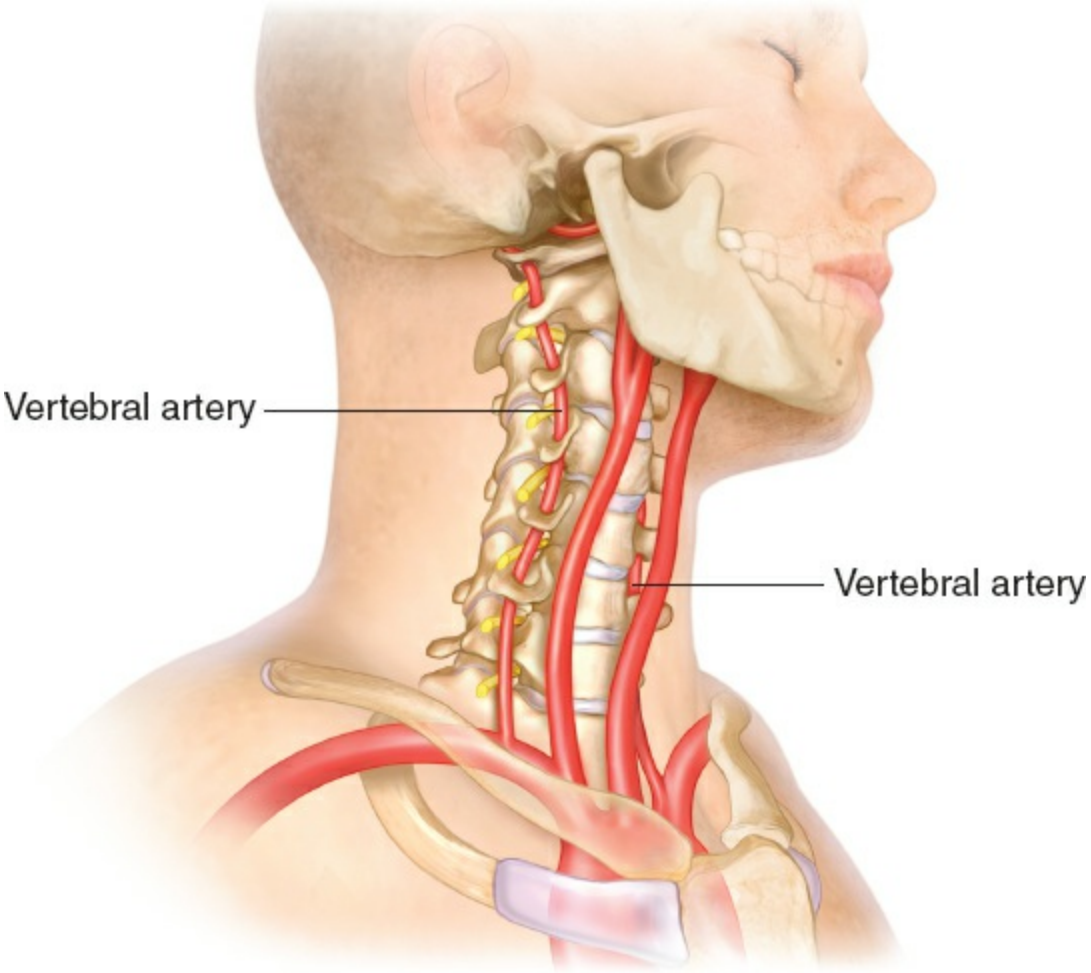

Figure 35.10. The vertebral artery (VA) is the first branch of the subclavian artery. Its takeoff is on the dorsosuperior aspect of the ascending subclavian artery.

Aerodigestive Injury

When considering injury to the pharynx or cervical esophagus, the importance of early diagnosis and repair cannot be overstated. A delay of

several hours can significantly increase the incidence of mediastinitis and empyema. All injuries should undergo repair as soon as diagnosed. All repairs should be drained with a closed-suction drain, which is left in place until a contrast esophagram at 1 week shows no extravasation and the patient is tolerating a diet. Inadequate or leaking repairs can heal without additional surgery as long as adequate drainage is maintained. Enteral nutrition can be administered via a soft feeding tube placed during surgery. Antibiotics appropriate for oral flora should be given postoperatively.

Esophageal Injury

Following exploration and repair of the carotid sheath structures, attention is next turned to evaluation of the aerodigestive tract. Begin with repositioning retractors so as to achieve displacement of the entire carotid bundle laterally. This will expose the pharynx and esophagus as well as the larynx, thyroid gland, and trachea inferiorly. This space has its own enveloping fasciae as well as many small perforating vessels, requiring careful dissection. The recurrent laryngeal branch of the vagus nerve travels in the groove between the esophagus and trachea and is an essential nerve. It should be identified and preserved as it is vulnerable to injury during dissection (Fig. 35.11).

Often flat and with a lie off-center to the left, the esophagus is best evaluated with a dilator, bougie, or rigid nasogastric tube inserted orally by the anesthesiologist. The esophagus is without a serosal layer and any necrotic muscle or mucosa should be debrided—but not excessively. Healthy tissue is then approximated with absorbable 3-0 or 4-0 suture in one or two layers (knots outside the mucosa) as needed to establish a watertight closure. The repair should then be reinforced with a buttress of muscle, usually the detached sternal head of the sternocleidomastoid muscle (Table 35.4). Ipsilateral superficial strap muscles (sternohyoid and the anterior belly of the omohyoid) are easily liberated and may be also be useful as interposition or reinforcement flaps. The blood supply to the strap muscles originates from cephalad origins; divide the strap muscle inferiorly and rotate them up as a muscular flap. As mentioned above, digestive tract repairs always require drainage. We prefer closed-suction drains (fully perforated Jackson-Pratt or Blake). Care must be taken to direct drains away from associated vital structure repairs as salivary enzymes are quite corrosive. Clean, uninjured muscle should interpose repairs and drain tracts.

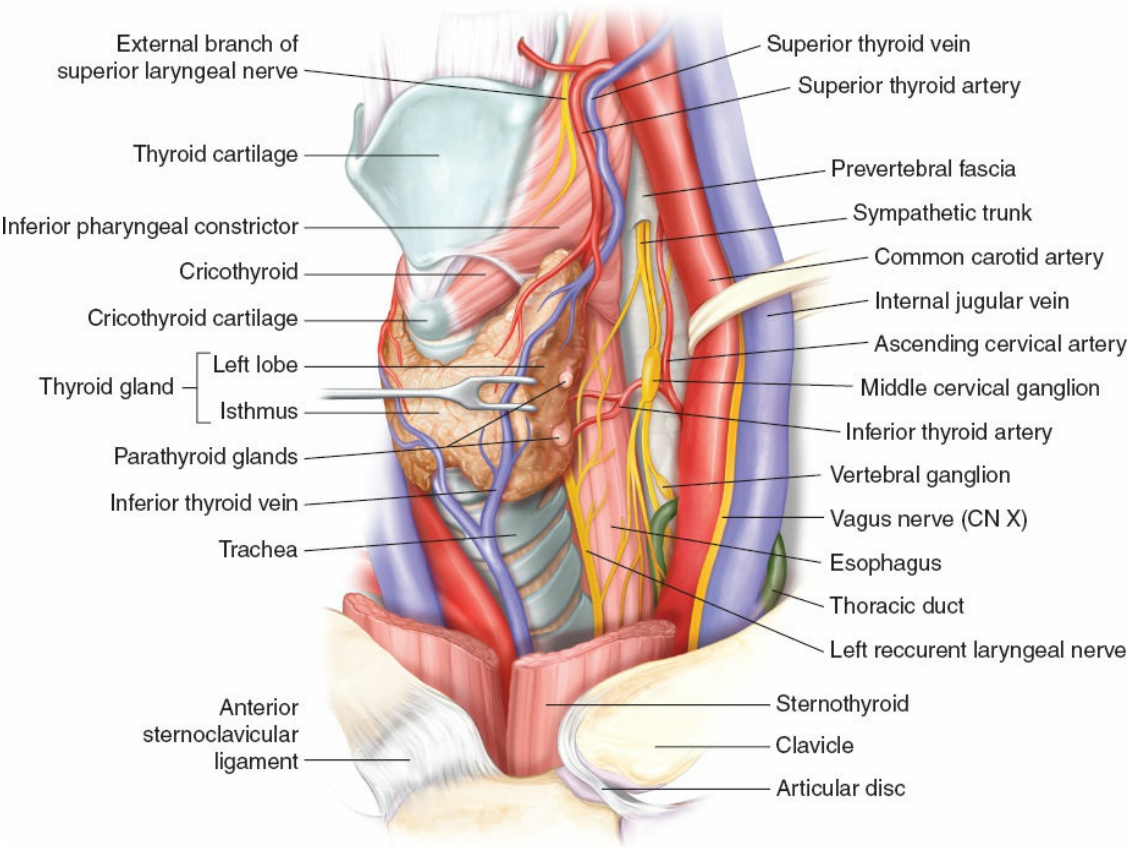

Figure 35.11. Alimentary layer of the visceral compartment.

TABLE 35.5 Principles of Repair of the Trachea

- No debridement is necessary.
- One-layer repair with absorbable suture if small or moderate-sized hole.
- When there is loss of a portion of the anterior or lateral wall, a tracheostomy tube is inserted into the defect. The sternocleidomastoid muscle is then detached inferiorly, mobilized, and sewn in an airtight fashion to the defect after the tracheostomy tube is removed.
- When there is loss of a portion of the membranous trachea, a three-sided rectangular longitudinal flap of pericardium based superiorly is sewn to the defect to create an airtight seal.

From Feliciano DV, Vercruysse GA. In: Mattox KL, Moore EE, Feliciano DV, eds. *Trauma*. 7th ed. New York: McGraw-Hill; 2013:414–29. Copyright McGraw-Hill Education.

Occasionally it is not possible (extensive tissue injury) or prudent (operative delay) to primarily repair the esophagus at the initial operation. Generally, these injuries are best treated with a large T-tube through the injury to create a controlled lateral esophageal fistula. A second option, if mobile enough, is to deliver the injured esophagus through the skin as an esophagostomy. (If needed, the efferent limb can be closed with a TA-

stapler.) A blind cervical esophageal stump should never be left in place. Either one of these treatments allows simple repair of the esophagus at a later date. Whenever possible, avoid esophagectomy, as ultimate reconstruction will be far more difficult. Cervical esophagostomy is always performed on the left side. If an end-esophagostomy is required, a subcutaneous tunnel should be developed over the sternocleidomastoid muscle, clavicle, and pectoralis so as to reach the anterior chest wall where an ostomy appliance can rest comfortably. The end is externalized through a 2-cm disc-shaped skin excision and sutured, full-thickness to the skin edges with interrupted absorbable sutures.

Tracheal Injury

Tracheal injuries require repair. Anterior injuries of appropriate size and location may be converted to tracheotomy. Exploration and repair of tracheal injuries may require division or retraction of the ipsilateral thyroid lobe for access. Formal lobectomy is rarely required, but division of the isthmus is generally necessary. For repair of tracheal injuries larger than 4 cm (three to four tracheal rings), mobilization of the trachea at the thoracic outlet inferiorly or the laryngeal complex superiorly may be required.

Head flexion is the simplest tension releasing maneuver; this may require suturing the chin to the chest wall for 10 to 14 days postoperatively. Minimize mobilization of the trachea to only what is essential. The blood supply to the trachea is at 3 o'clock and 9 o'clock positions and must be preserved. Thus, mobilization is safe only anterior and posterior to the trachea. To mobilize the trachea inferiorly, care should be taken to stay adjacent to the tracheal wall to avoid injury to the recurrent laryngeal nerve. The thyroid isthmus is divided along with the midline strap muscles (sternohyoid and sternothyroid). Blunt dissection is then all that is needed to separate the superficial and deep strap muscles and develop the pretracheal plane into the mediastinum. The suprahyoid release is a fairly complex procedure for the general surgeon and is ideally performed by otolaryngologists. It requires a separate, transverse incision over the hyoid bone followed by division of the superior muscular attachments and transection of the hyoid itself. Tracheal repair is performed in a single layer, using absorbable 3-0 or 4-0 monofilament suture, placed transversely (knot outside the lumen), in an interrupted fashion and incorporating the tracheal ring above and below the injury. A "protective" tracheostomy should be avoided, as there is little proven

benefit, as well as introducing a higher risk of infection (Table 35.5).

Larynx

When significant enough to compromise the airway, laryngeal injuries are typically discovered at surgical exploration during the creation of a tracheotomy or during the conversion of a cricothyroidotomy to a formal tracheotomy. Patients with less complex injuries found on CT scan or laryngoscopy should undergo tracheotomy to protect the airway. Laryngeal injuries often need reconstruction, internal fixation, or stent placement and are best treated semielectively by otolaryngologists. The surgeon should resist the temptation to widely debride these wounds when encountered at initial exploration. Although definitive treatment is usually deferred, consultation to otolaryngology at the time of exploration is important.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Patients who have undergone vascular repair should be monitored closely for hemorrhage and neurologic deficit in the immediate postoperative period. Any signs of bleeding or arterial thrombosis should prompt rapid return to the operating room for reexploration. Blood pressure and heart rate should be monitored particularly if there has been dissection or injury near the carotid bifurcation. A chest radiograph should be obtained to assess for pneumothorax. Antibiotics in the postoperative period should be reserved for esophageal injuries, and drains left routinely can be removed after 48 hours if the output is low (<20 mL). Injuries to the various cranial nerves can result in the following predictable deficits: facial droop (facial), aspiration (glossopharyngeal), dysphagia/dysarthria (hypoglossal), and vocal cord paralysis (recurrent laryngeal branch of vagus).

TABLE 35.4 Principles of Repair of the Esophagus

- Either one- or two-layer with absorbable sutures is acceptable, preferably in a transverse direction
- Loss of a portion of the wall in zone II and some patients with delayed diagnosis of perforation should be treated with a loop esophagostomy over a rod rather than an acute tenuous repair that is likely to dehisce
- Combined injuries with the trachea or carotid artery mandate a vascularized muscle buttress/separator such as sternocleidomastoid muscle

EDITOR'S COMMENT

Dr.'s Corcos and Peitzman have written an incredibly detailed and comprehensive chapter on penetrating neck injuries. Penetrating neck trauma represents approximately 5% to 10% of all trauma cases that present to the emergency department. About 30% of these cases are accompanied by injury outside of the neck zones as well. The current mortality rate in civilians with penetrating neck injuries ranges from 3% to 6%. Higher mortality rates occur with injuries to large vessels, such as the carotid or subclavian arteries and veins. A recent review of the National Trauma Data Bank revealed that in children less than 14 years old, the incidence of penetrating neck trauma is 0.28%. Mortality rate in children was 5.6% in this NTDB review, and vascular injury and hypotension on presentation to the ED were both associated with an increased risk of mortality.

Penetrating neck trauma is an important area of trauma care that has undergone evolution in the recent past. Many changes have occurred in the treatment paradigm as new technologies have developed, and as surgeons have explored the outcomes from different treatment protocols. Therapy has evolved from no treatment (before effective anesthesia and instrumentation) to nonoperative management, routine exploration, selective exploration, and adjunctive invasive or noninvasive assessment. Penetrating neck injuries remain challenging, as there are a number of important structures in a small area, and injury to any of these structures may not be readily apparent.

Patients with penetrating wounds to the neck present with overt symptoms and signs of injury or are asymptomatic/mildly symptomatic. When there are overt signs and symptoms of injury, resuscitation and immediate operation is appropriate. In asymptomatic and mildly symptomatic patients, observation or a diagnostic evaluation is appropriate to avoid what is an approximately 45% rate of negative exploration in this cohort of patients. Asymptomatic patients with penetration of the platysma muscle but no signs of a visceral or vascular injury should undergo serial physical examinations for 24 to 36 hours before discharge. Noncontrast CT does not add to the accuracy of serial physical examinations. In stable patients with a variety of symptoms or signs possibly related to an injury to the carotid artery, CT-arteriography has become the diagnostic modality of choice. Patients with possible injuries to the cervical esophagus are often still evaluated with a Gastrografin swallow and a thin barium swallow prior to fiberoptic endoscopy. The addition flexible endoscopy to contrast studies can increase the diagnostic accuracy of detecting an injury to the cervical esophagus. Initial concerns about air insufflation during visualization for flexible endoscopy contributing to bacterial contamination in a perforation have waned. CT-esophagram is an evolving diagnostic modality that may replace the above tests in the screening algorithm in the near future. An unrecognized cervical esophageal injury can result in devastating complications

in a relatively short period of time. An intense necrotizing inflammatory response can result in the neck in the first 12 hours and worse if the mediastinum is involved. Unrecognized esophageal injuries significantly increase the mortality of these injuries.

Injuries to the trachea are usually apparent on presentation (over 85% present with overt symptoms and signs). In questionable cases, laryngoscopy and fiberoptic bronchoscopy can help confirm or rule out the diagnosis. These lesions should be repaired when identified. As for esophageal injuries, CT may replace bronchoscopy and laryngoscopy as diagnostic tests.

The optimal surgical management of the carotid artery injury is another controversy. The issues involve whether severe neurologic deficits (coma for example) and demonstrated absence of antegrade flow in the internal carotid artery contraindicate repair. In several studies, reestablishing antegrade flow has been suggested to be hazardous because it may convert an ischemic infarction into a hemorrhagic infarction. Many authors recommend repair of an injured carotid artery rather than ligation in all patients with a Glasgow Coma Scale >9. Patients with a GCS of 8 and below generally have an unfavorable outcome whether the carotid artery is revascularized or ligated. Options for management of a carotid artery injury include observation with or without anticoagulation, ligation, operative repair, or endovascular repair depending on the nature of the injury (and associated injuries) and the patient's neurologic status.

The utility of the traditional classification of neck injuries using the anatomic zones I through III has recently been questioned. In a recently published article, patients who sustained penetrating neck trauma from December 2008 to March 2011 were analyzed. All patients underwent structured clinical examination documenting the external zone where the wound(s) were located. All internal injuries were then correlated with the external wounds. An internal injury was defined as "unexpected" if it was located outside the borders of the neck zone corresponding to the external wound. In total, 146 patients sustaining a penetrating neck injury were analyzed. The mechanism of injury was stab wounds in 74 (51%) and gunshot wounds in 69 (47%). There was a high incidence of noncorrelation between the location of the external injury and the internal structures that were damaged in patients with hard signs of vascular or aerodigestive injury. The authors of this study concluded that the use of the anatomic zones and their role in the workup of penetrating neck injury are questionable. Another recently published discussion on the "no-zone" approach to management and evaluation of penetrating neck injury concludes that a comprehensive physical examination, combined with CT angiogram (CTA), is adequate for triage to effectively identify or exclude vascular and aerodigestive injury after penetrating neck trauma. "Zone-based algorithms lead to an increased reliance on invasive diagnostic modalities (endoscopy and angiography) with their associated risks and to a higher incidence of nontherapeutic neck exploration. Therefore, surgeons evaluating hemodynamically stable patients with penetrating neck injuries should consider

departing from antiquated, invasive algorithms in favor of evidence-based screening strategies that use physical examination and CTA."

Finally, recent military conflicts have led to an experience with penetrating neck injuries from bullets as well as blast injuries that have helped informed modern management of these injuries. Ramasamy et al. performed a retrospective medical record review of British military casualties from Iraq and Afghanistan who sustained penetrating neck injuries to determine the need for prehospital cervical immobilization, given current ATLS protocols requiring spinal precautions when a significant mechanism of injury may damage the cervical spine. Of 90 patients with a penetrating neck injury, 66 (73%) were from explosions and 24 (27%) were from gunshot wounds. In 20 (22%) patients, cervical spine injuries were present; only 6 (7%) survived to reach the hospital, and 4 of these 6 died within 72 hours of their injuries. Of 56 survivors that reached a surgical facility, only 1 (1.8%) had an unstable cervical spine injury requiring surgical stabilization, and this patient subsequently died due to a concomitant head injury. The investigators determined that it is unlikely that survivors of penetrating ballistic trauma to the neck will have unstable cervical spines; therefore, "not only is the risk/benefit ratio of mandatory spinal immobilization unfavorable, but cervical collars may also hide potential life-threatening conditions, in addition to putting medical teams at prolonged personal risk."

Penetrating neck injury is a potentially devastating problem. Surgeons who care for these patients need an in-depth knowledge of the neck anatomy and a clear understanding of the current approach to diagnosis and management. With modern diagnostic modalities, most of these injuries in stable patients can be managed nonoperatively. This chapter is an excellent review of a very important topic, whose management continues to evolve even today.

TRAUMATIC AND NONTRAUMATIC HEAD AND BRAIN INJURY

Traumatic Brain Injury: Blunt versus Penetrating Trauma

Epidemiology of Traumatic Brain Injury (TBI)

Before we are committing ourselves to reviewing the management of traumatic brain injury (TBI), we need to understand that this problem remains a major public health issue in our times. To illustrate this point, I want to reiterate some facts about TBI in the United States as an introduction to the topic as reported by the Brain Trauma Foundation (www.BTF.org):

Brain injuries are most often caused by motor vehicle crashes, assaults, sports injuries, or even simple falls on the playground, at work or in the home. An estimated 1.5 million moderate to severe head injuries occur every year in the United States, and an additional estimated 1.6 million to 3.8 million sports-related TBIs occur each year. Every year, approximately 52,000 deaths occur from TBI. It is the leading cause of death and disability in children and adults from ages 1 to 44, and at least 5.3 million Americans (i.e., 2% of the U.S. population) currently live with disabilities resulting from TBI. In addition, moderate and severe head injuries are associated with an increased risk of developing Alzheimer's disease.

Males are about two times as likely as females to experience TBI, and hospitalization rates had increased from 79 per 100,000 in 2002 to 87.9 per 100,000 in 2003. Blasts are a leading cause of TBI among active duty military personnel in war zones, and veterans' advocates believe that between 10% and 20% of Iraq veterans, or 150,000 and 300,000 service members, have some level of TBI. Of note, 30% of soldiers admitted to Walter Reed Army Medical Center have suffered TBI.

Traumatic Head Injury Basics

What are the unique features of brain anatomy and physiology, and how do they affect patterns of brain injury?

The head is a rigid compartment filled with brain, cerebrospinal fluid (CSF), and blood.
Cerebral blood flow (CBF) in the healthy individual is autoregulated for SBP 80 to 160 to generate an adequate cerebral perfusion pressure (CPP).
If autoregulation is intact, CBF is maintained constant via a mean BP adjustment to generate a CPP of 50 to 60 mm Hg.
In moderate or severe brain injury cases, autoregulation is disrupted in a way that CBF varies greatly with mean BP.
The injured brain is more vulnerable to episodes of hypotension and metabolic imbalance that may cause secondary brain injury.

Intracranial Pressure (ICP)

Besides hemodynamic parameters and confining metabolic conditions, intracranial pressure (ICP) is the single most important determinant of neurologic function of the brain (Table 36.1).

Normal ICP is defined as the pressure (in cm H_2O) that is measured within the skull, either in subarachnoid fluid, ventricles, or parenchyma. It corresponds to the hydrostatic pressure that must be applied to prevent the emergence of fluid through a puncture needle from the CSF in the horizontal body position. Normal ICP should reside below 15 cm H_2O. An increase in ICP occurs when one of the intracranial compartments within the rigid skull is increased (1,500 to 1,700 mL total volume, which is made of ca. 80% brain parenchyma and 10% CSF and 10% blood). An acute increase in ICP above tolerance is fatal.

TABLE 36.1 Intracranial Pressure

Infants	0.5–2 mm H_2O
Children	2–10 mm H_2O
Adults	6–200 mm H_2O = Normal >200 mm H_2O = Abnormal >400 mm H_2O = Severe increase

Physiologic variations occur and show age dependence, with children having lower values than adults, fluctuation with each pulse-pressure wave, fluctuation with respiration, and a correlation with body weight (obese patient showing higher values).

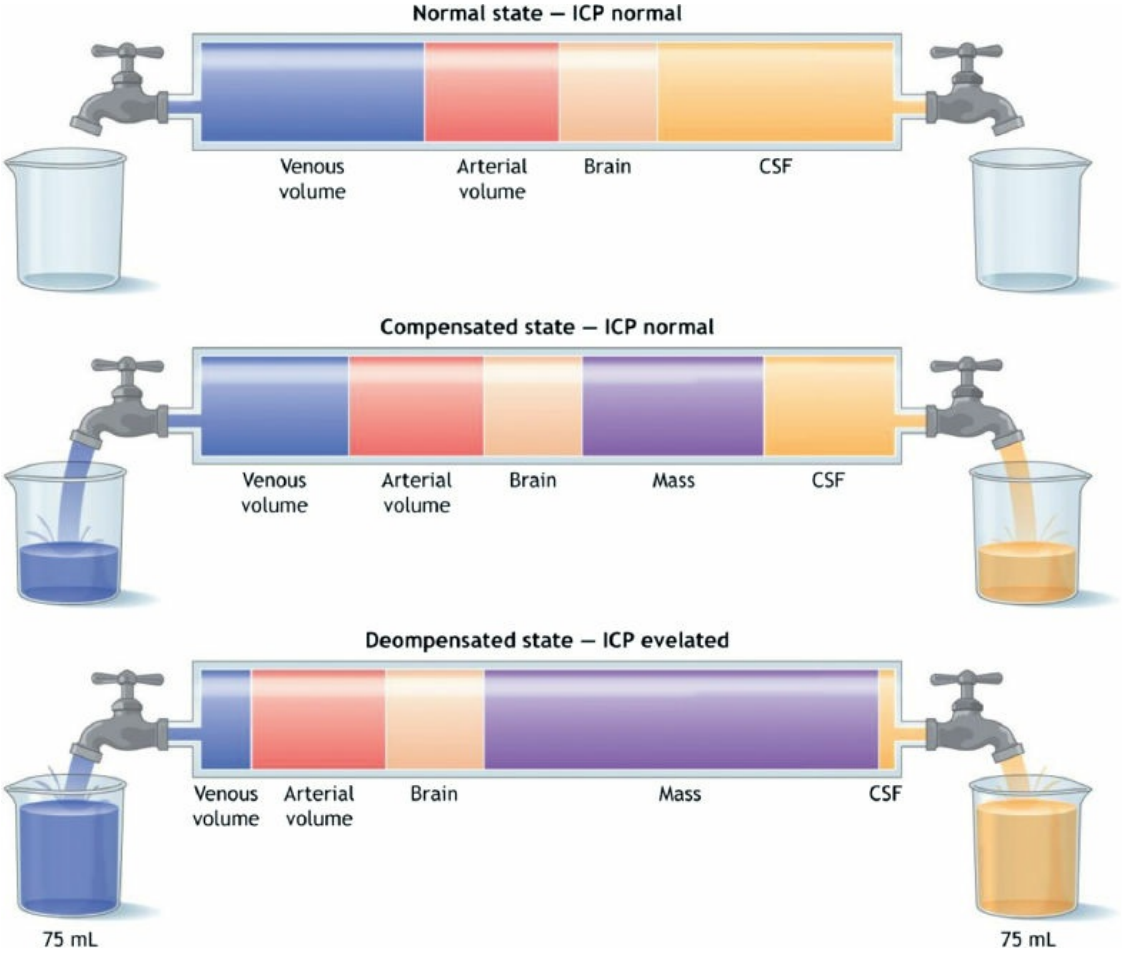

Figure 36.1. Monro–Kellie doctrine.

It must be noted that ICP can*not* be predicted based on imaging (head computed tomography [CT] or magnetic resonance imaging [MRI]).

The ***Monro–Kellie doctrine*** (Figs. 36.1 and 36.2) states that *the sum of all intracranial volumes will remain constant* and that *any increase in one of them or adding an intracranial mass will be offset by an equal decrease in one of its other components*; otherwise, it will cause an increase in ICP at the expense of the brain. *(This concept was introduced by both Monro and Kellie in the early 1800s.)*

ICP Impact

- In TBI, resulting increased ICP leads to decreased brain function and

poor outcome.

- Systemic hypotension and low O_2-saturation adversely affect outcome via poor CPP and hypoxia (Table 36.2).

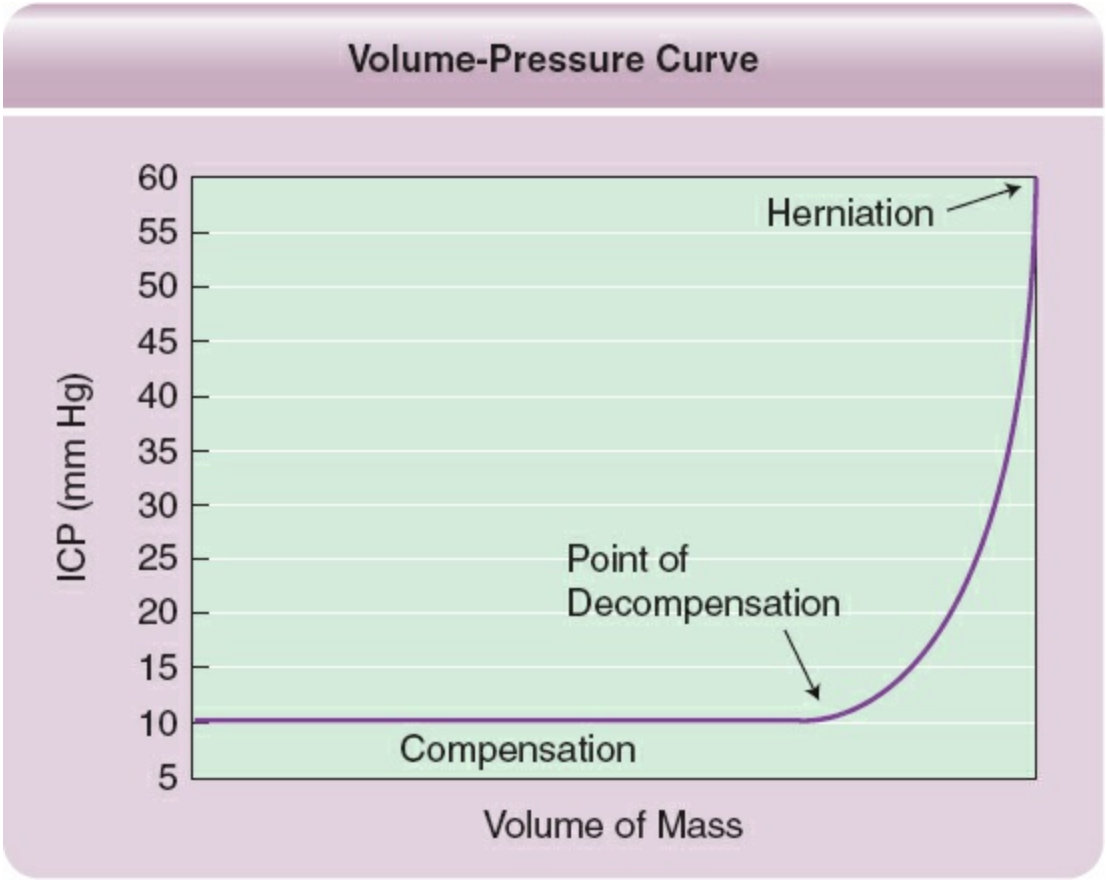

Figure 36.2. Volume–pressure curve.

TABLE 36.2 Cerebral Perfusion Pressure (CPP)

	MAP	– ICP	= CPP
Normal	90	10	80
Cushing Response	100	20	80
Hypotension	50	20	30

Primary and Secondary Brain Injury

Primary and secondary brain injuries are terms to classify brain injury processes. In TBI, primary injury occurs during the initial insult and results from the physical impact and energy transfer causing structural damage to the brain. Secondary injury is a consequence thereof. Its time

course is more gradual, reflecting the involvement of distinct cellular processes to which both primary and secondary injuries respectively will contribute. Primary and secondary injuries occur in other brain insults such as spontaneous hemorrhage, stroke, or mass lesions too.

In TBI, primary injury (Table 36.3) happens from energy transfer at the moment of trauma and it manifests as concussion (injury without visible correlate on CT), contusion (with damage to tissue and vessels), or diffuse axonal shear injury. Normal physiologic barriers (the blood brain barrier and connective tissue such as the meninges) can be damaged, and cells may die in a nonspecific manner. Certain areas of the brain are more susceptible to injury either by location (fronto-basis and temporal tip in head-on collision deceleration injuries) or by structural features (myelinated fiber tracts versus nonmyelinated fibers), and this type of structural injury is thought to be irreversible.

Since primary injury occurs at the moment of trauma, there is little that can be done for it; efforts to reduce disability and death from TBI are thought to be best aimed at secondary injury.

Secondary injury (Table 36.4) is delayed and results indirectly from the impact and comes via cellular processes as a consequence of the trauma. It is a well-known observation that many TBI victims do not die right away at the scene, but almost half of TBI patients deteriorate during their hospitalization as a result of secondary injury, which ultimately may cause raised ICP and brain herniation.

TABLE 36.3 Examples of Primary Brain Injury in TBI

Primary
■ Subarachnoidal hemorrhage ■ Epidural hemorrhage ■ Subdural hemorrhage ■ Parenchymal Hemorrhage ■ Concussion ■ Contusion ■ Diffuse axonal injury/or ■ Axonal stretch injury

TABLE 36.4 Causes for Secondary Brain Injury

Secondary
■ Edema ■ Change in cerebral blood flow (CBF) ■ Hypercapnia ■ Acidosis ■ Altered metabolism (free radical formation) ■ Change in neurotransmitters ■ Change in receptor activity ■ Excitotoxicity ■ Infection/abscess formation

Since secondary injury occurs over time, it can be prevented in part by taking measures to prevent complications and researchers are working actively to find drug therapies to limit or prevent the damage.

INITIAL DATA EVALUATION

It is crucial to obtain as much of the history upon arrival of the emergency medical services, and particular attention must be paid to mechanism of injury, initial on scene-exam, and time course of developing symptoms of concern.

Whenever there is significant impact, the index of suspicion of a life-threatening injury should be very high, even if the patient was doing rather well at the scene and looks good on arrival! Whenever there was significant injury to the head (e.g., enough to cause a fracture or bleed), the concern for associated cervical spine injury should be high. So actively search for neck pain and signs of radiculopathy or myelopathy! If the patient has sustained multisystem injury, the extent of injury and its initial management matter greatly for prognostic purposes.

Specific scenarios: In cases of motor vehicle accidents (MVA), questions about mechanism of injury should include a detailed account of vehicle speed (high/low), direction of impact (head on, rear ended, side/oblique impact), extend of external damage, possible passenger ejection, and death of or injuries to other participants. In cases of penetrating or blunt injury, ask about type of assault weapon (e.g., firearm versus golf club). Get as much information as possible from bystander accounts. It is important not

to miss the body temperature in this assessment since hypothermia may depress neurologic functions.

Examination

It may be of vital importance to obtain a description of the scenario and vital signs plus the first examination at the scene. When a patient is "found down," ask about circumstantial evidence (alcohol, drugs, observed blood loss). How long was the patient unaccounted for? Was there loss of consciousness (+LOC), evidence of seizure activity, or progressive obtundation? Did the patient act abnormally? Did the patient develop headache, nausea, vomiting, blurred vision, hearing loss, altered speech, or any other progressive symptom en route? If the patient became unconscious and arrives with a "blown pupil," ask when it happened. If bilaterally, ask which side went up first and when.

As in all other trauma case, a *full survey = primary trauma team assessment of ABC must be conducted first!*

Observe the primary survey by the trauma team as they gather vital signs and make sure all initial measures to limit secondary brain injury are being implemented (oxygen administered, adequate ventilation secured, and SBP >90 mm Hg maintained at all times).
Check for bradycardia, changes in breathing frequency, and hypertension (signs for increased ICP and Cushing's Response).
Make sure the patient is being treated with full spine precautions, a hard board is used, and the cervical spine is correctly immobilized with a hard collar or taped to the trauma board. Only in the setting of hypovolemic systemic shock (scalp blood loss can be massive!) and in cases of spinal cord injuries with florid neurogenic shock, you will see hypotensive responses despite increased ICP.

During the trauma-team assessment, get information about medications given during transport (paralytics, narcotics, sedatives).

Have a quick look at the pupils and check for size and reactivity. A side-difference >1 mm is considered nonphysiologic, unless caused by a preexisting condition. Classify the status of the pupils since *any newly dilated pupil >6 mm defines a neurosurgical emergency.* Rapid acquisition of head *CT-imaging in this setting* (e.g., penetrating Glasgow Coma Score (GCS) to the head) *takes precedence over a detailed secondary trauma survey!*

TABLE 36.5 TBI and GCS Scoring Table

Severity Level	GCS Score
Mild TBI (Concussion)	GCS 14–15 with LOC <5 min; impaired alertness or memory
Moderate TBI	GCS >9; focal neurologic deficit; possibly reversible; some residual possible
Severe TBI	GCS 5–8
Critical TBI	GCS 3–4; poor prognosis

Traumatic Brain Injury: The Glasgow Coma Scale

Once the trauma survey has been conducted, evaluate the patient rapidly yourself before other diagnostic studies are done: Check the patient's initial GCS to evaluate the patient's level of consciousness via motor response, eye opening, and verbal response. This score has predictive and prognostic value (Table 36.5).

If the patient is stable and in reasonable neurologic condition, obtain a focused exam:

1. *HEAD:* Observe the patient for external signs of trauma (*raccoon's eyes* = periorbital edema and hematoma, retro-auricular hematoma and ecchymosis = *Battle's sign* indicating a skull base injury). Check head and neck for wounds such as lacerations, abrasions, contusions, and palpate for possible fractures. *Do not probe lacerations concerning for open fractures* until in the OR and after adequate imaging has been obtained. Inspect and palpate the globes to assess possible rupture. Corneal reflexes can be used to assess CN 5/7 function in the comatous patient. A fundoscopic/ophtalmoscopic exam is less valuable in the adult, since ICP increase does not cause immediate optic nerve pallor and it is unlikely that one picks up a decrease in retinal venous pulsations in this ER setting. However, in pediatric patients and unclear mechanism of injury, evidence of retinal hemorrhage may point to abuse. *Pharmacologic dilatation must be avoided until ICP*

elevation has been ruled out. Check the external auditory canal (EAC) for hematotympanon and otorrhoea/liquorrhoea. Inspect also the nares for blood or CSF leakage/rhinorrhoea. Lower cranial nerve injury is rare in the acute trauma patients, and if noticed later during hospitalizations it needs attention to assess the risk of aspiration.

2. *BODY:* Check for motor response in all four extremities; if the patient has decreased level of consciousness, painful stimuli are applied to elicit an adequate response. Learn to recognize the posturing responses to be able to distinguish: decerebrate, decorticate, tripleflexion-withdrawal.

TABLE 36.6 Classification of Injury Patterns

- Concussion = mild TBI
  Altered MS with closed head injury
  Fully reversible
- Contusion = (e.g., deceleration injury)
  Structural changes; ME/MLS/swelling
  Possibly reversible, some residual
- Contre-Coup injury/second impact syndrome
- Diffuse axonal injury (DAI or shear injury)
  Microscopic/multiple structural lesions/+LOC severe; poor prognosis

In conversant patients also check the sensation from the head toward the toes and mark any possible level that correlates with a spinal cord injury. Check tactile stimulation as well as pain. You *must perform a rectal exam* to assess sphincter tone. In the comatous patient, this may be the only evidence for spinal cord injury. If the bulbo-cavernosus reflex is missing (reflecting acute myelopathy), the patient may show signs of spinal shock.

Check biceps and patellar reflexes as well as plantar responses (Babinski's). In acute spinal cord injury, the patient will present with dropped reflexes and mute toes. Only in rare cases of brain stem shear injury one can find hyperreflexia in the acute setting.

Serial neurologic examinations and serial imaging are necessary to diagnose delayed neurologic status change and deterioration from

secondary brain injury (Table 36.6).

INITIAL TREATMENT PLAN IN THE ER

Since TBI is a rather heterogeneous group of incidents, it has been extremely difficult to gather prospective randomized trial data and treatment recommendations from clinical studies in this scenario. However, a few fundamental and basic recommendations were derived from detailed analysis of retrospective data and prospective collection of data from cohorts that were followed long term.

Some priorities in guidelines are intuitive; for example, the systemically unstable patient needs to be treated first since systemic hypotension from hypovolemic shock in the multitrauma patient carries a poor prognosis in neurotrauma. Also, if there are any concerns for raised ICP or the GCS is <9, the patient should have treatment initiated *before* further and time-consuming diagnostic studies are undertaken (see below).

ICP Treatment
After systemic stabilization (make sure only isotonic solutions are used) administer mannitol (ca. 1 g/kg BW), Lasix (10–20 mg IV) and hyperventilate the patient (increase frequency and volume for goal pCO_2 = 30) before you run off to radiology/CT for further studies.

The current existing guidelines for management of acute head trauma are contained by a publication of the Brain Trauma Foundation and the American Association of Neurological Surgeons (AANS) and can be obtained from the AANS or found via web-link under:

http://www.guideline.gov/summary/summary.aspx?doc_id=10995

Some points of interest need to be described when accepting or signing out a patient: single versus multiple wounds; LOC at the scene, GCS at the scene, downtime until patient was found and treatment was initiated, seizures at the scene, any accompanying systemic injury. Then, focus on the actual neurologic injury.

Document mechanism of injury as *nonpenetrating blunt trauma* where the bony confinements remain intact (e.g., strike with a baseball bat) versus *penetrating trauma* where the bony integrity has been violated (GSW and stabs). It is helpful to realize that the energy transfer accounts for the devastation, so one should specify *"high-energy" versus "low-energy" injury*. Based on the initial GCS you can stratify the injury into

mild, moderate and severe (see Table 36.6 above).

Document morphology: **Surface and vault injuries:** *open versus closed, depressed versus nondepressed*, with and without translocated fragments. **Basilar injuries:** *with or without CSF leak*, with or without cranial nerve palsy.

Once a CT of the head as been obtained, classify the injury pattern into bony and parenchymal: epidural/subdural/subarachnoid/intracerebral/focal or diffuse (see below).

Upon arrival, the patient will undergo some ER-management in the hospital. Here are some conservative measures that can be initiated quickly and efficiently (Tables 36.7, 36.8 and 36.9).

TABLE 36.7 First Set of Conservative TBI Treatment Measures (Before Imaging)

- Optimize positioning: *elevate the head* of bed above the level of the heart to improve venous return and choose a level of ca. 30 degrees; if the spine is not cleared, *tilt the entire bed* into *reverse Trendelenburg position*; make sure the neck is not compressed by tapes from intubation or tight collars resulting in compromise to jugular venous return. Keep even the mild TBI patient initially at *bedrest* until the assessment has been completed
- Administer warm isotonic fluids (ns + 20 mM KCl) for volume resuscitation and give maintenance fluid to avoid secondary injury
- Avoid hypotension (SBP >90 at all times for sufficient CPP)
- Avoid hypothermia = cover the patient with warm blankets
- Intubation in all patients with GCS <8 who cannot protect their airway at all times; since facial and skull base fractures may be present, orotracheal intubation is the method of choice
- Keep the patient NPO and insert NGT for intubated patients
- Prior to imaging, provide assisted ventilation/hyperventilation
- If the patient arrives in poor neurologic condition and with a high suspicion for increased ICP, initiate osmoherapy (100 g mannitol + 20 mg Lasix) as you go to the CT-scanner, since it buys you time

Strategy in the Trauma Bay:

- Early intervention is the goal for all treatable conditions
  - Each patient with a significant impact or unclear story MUST be studied with imaging.
  - Comatous patients TBI patients (GCS 8 or less) with NORMAL CT scans: may be watched during further workup
  - All comatous TBI patients (GCS 8 or less) with ABNORMAL CT scans should receive invasive ICP monitoring

- This algorithm helps with earlier detection of intracranial lesions, to prognosticate recovery and it improves outcome

DIAGNOSTIC STUDIES

CT of the head is the study of choice in head trauma patients. All patients with a GCS of <15 should obtain a CT scan for proper assessment. Patients who look perfect, but had a significant mechanism of injury should also be imaged as well as patients on systemic anticoagulation and patients with syncopal events. *In all patients with a lateralizing or localizing sign, the radiographic workup must be obtained emergently*, since it is highly specific and sensitive for bony injuries as well as blood and gives a chance to assess intracranial injuries in a timely fashion. (Timely means: a significant head injury should be imaged within 15 minutes after arrival in the ER.) Most indications for surgical intervention can be made based on CT results alone and do not require MRI, which is only superior for prognostic purposes in patients with shear injuries and diffuse axonal injury (DAI) (Fig. 36.3; Tables 36.10 and 36.11).

TABLE 36.8 Second Set of Conservative TBI Treatment Measures (After Imaging)

A. *Invasive ICP monitoring* is indicated in all patients with a GCS <8 and/or signs of raised ICP on imaging (the only exception being the intoxicated patient with a normal head CT who has an obvious reason for depressed mental status and may recover in a short period of time in the ICU under constant observation); each patient should have an immediate repeat CT after placement of an EVD or ICPB to assess success and r/o complications. If the GCS is <8, but the patient shows 2 out of the 3 following signs: posturing, hypotension or age >45, monitoring is also recommended
B. *Anticonvulsants:* Once intracranial imaging has revealed a superficial focus of injury OR blood products, load the patient with prophylactic medication such as phosphophenytoin = dilatin 10–15 mg/kg BW = which equals about 1 g per adult load followed by 100 mg TID maintenance-dose for a blood serum level of 10–20 for a minimum of 10 days. Overall risk of seizures is low, even in severe TBI (ca. 1%) and less in mild TBI (ca. 0.1%), but their consequences can be dramatic, especially because they can exacerbate secondary damage. Newer data support the use of Leviracetam (Keppra) 1,000 mg p.o. BID, but the drug is still being evaluated
C. *Steroids:* Currently there is no indication for routine application of steroid therapy in trauma
D. *Antibiotics:* In patients with an obvious open scalp injury, provide skin flora coverage (e.g., Cephalosporin = Ancef 1 g Q8h × 3); if there is an obvious CSF leak or exposed brain tissue, provide triple coverage (gram+/gram– anaerobes; e.g., Vanco/Gent/Flagyl)
E. *Analgetics, sedatives, antiemetics* should be prescribed prn; mind you not to cloud your neuroexam by oversedation. See Table 36.9 for a guide on dosing

Plain XRT films are still acquired in some trauma patient for the initial series and in patient with possible cervical spine injury, patients presenting with myelopathy or focal spine symptoms, and in all comatous patients if a CT is unavailable. For any patient who is diagnosed with a traumatic spine fracture, a full spine assessment with CT is mandatory, since 15% of patients have one or multiple associated fractures. In any case of myelopathy with or without observed bony abnormality, an immediate MRI must be arranged for to rule out canal compromise from traumatic disc herniation, hematoma, tumor, or any other source.

A CT/*CTA of the head* is recommended in settings where the distribution of the blood does not match the mechanism of injury, or if the patient has experienced a thunderclap headache up to the trauma, since subarachnoidal hemorrhage (SAH) may well be caused by an underlying vascular lesion leading to a syncopal event that then presents as a trauma.

Other diagnostic studies such as MRI, conventional angiograms, electromyography (EMG), electroencephalography (EEG), and nuclear medicine studies are warranted in special circumstances only and go beyond the scope of this chapter. The interested reader should study publications related to the definition of brain death and high cervical spinal

injuries such as atlanto-occipital dislocations.

INDICATIONS FOR SURGICAL INTERVENTION

Any patient, who has a chance of recovery from TBI, who presents on imaging with a focal lesion that exerts mass effect, an expanding lesion that will predictably cause further damage, or a global injury that raises ICP or and puts the patient at risk *quo ad vitam* should undergo emergent intervention.

Surgical Goals for Craniotomy or Craniectomy

Debridement and closure for open wounds
Evacuation of hematoma and relief of pressure/MLS
Decompression for edema = craniectomy + duroplasty
Decrease in ICP
Bullet/bone fragment retrieval
Wound closure for CSF leak
Sinus repair

TABLE 36.9 Dosing Table for Medications

Medication	Mechanism	Dosage	Indication	Evidence Level
Mannitol	Osmotic	1 g/kg IV	GCS <9 in patients with a lateralizing motor deficit or unequal pupils	III
Dilantin	Antiepileptic	ca. 1 g IV load	Seizure prohylaxis ca. 100 mg TID for serum level	I
Kefzol	Antibiotic	1 g Q8h IV	Prophylaxis for G+ infections; scalp lacerations and open fractures	III

Possible Sources for CSF Leak

Traumatic CSF leaks occur in ca. 3% of all patients with significant head injury and up to 50% in penetrating injuries. Two thirds appear within days of the insult, 95% manifest within 3 months. Ca. two thirds of leaks stop spontaneously within 72 hours, most cease within 6 months. The incidence of associated meningitis is 5% to 10% in closed head injuries and its incidence increases with the length of a persisting leak.

The treatment recommendation remains controversial. We recommend

coverage for 72 hours post trauma to minimize the risk of meningitis until most leaks close spontaneously.

If a CSF leak persists for >2 weeks, surgical intervention is indicated.

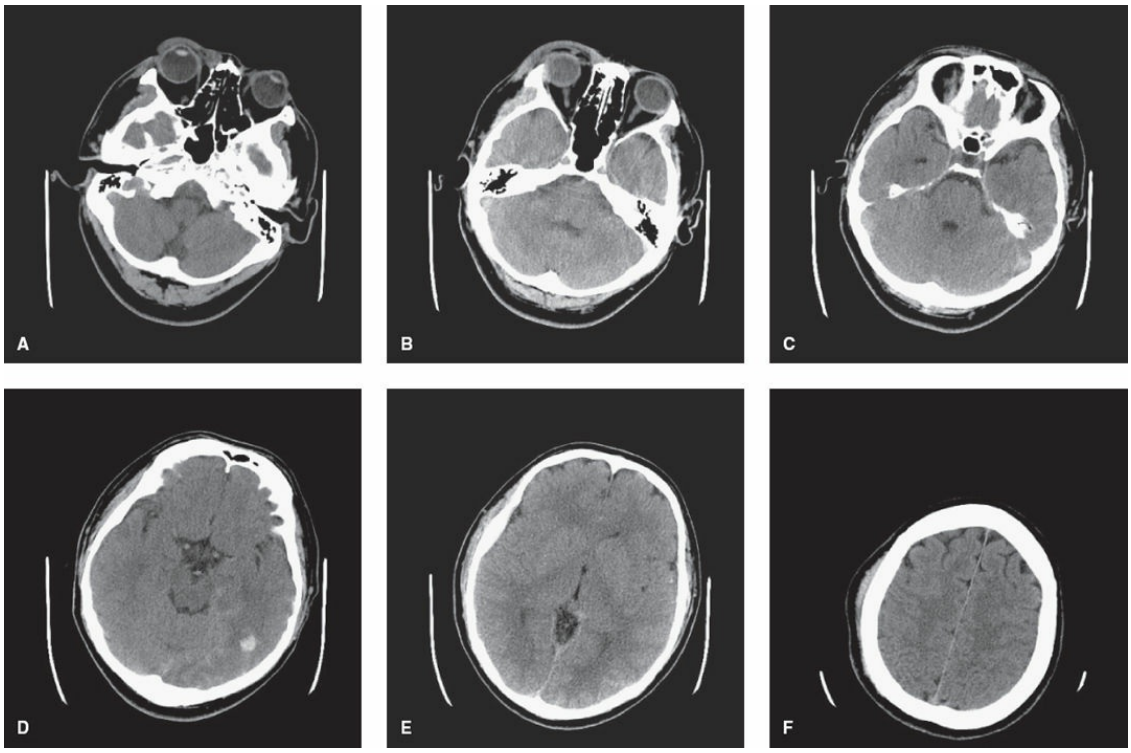

Figure 36.3. Slices of an emergent CT. **A.** Foramen-Magnum. **B.** 4th ventricle. **C.** Temporal lobe. **D.** Sylvian fissure. **E.** Midline/Ventricles. **F.** Superficial sulci.

Illustration of Specific Cases

Increased ICP From Global Injury; Emergent ICP-Bolt or EVD Placement (Fig. 36.4A–C)

Indicated in all comatous TBI patients with a GCS of 8 or less and an abnormal CT scan. The ICPB or EVD is placed in the ER/ICU/OR at Kocher's point (10 cm posterior and 3 cm lateral from the nasion).

It subsequently requires a management protocol written for ICP >20 cm >5 min

f/u CT needed immediately after placement

Epidural Hematoma (Fig. 36.5)

Characterized by convex, extra-axial, hyperdense mass, confined by sutures

Incidence among all TBI is about 3%

1/3 to 1/2 of patients are in coma on admission

50% present with classic lucid interval
Peak incidence: patients aged 20 to 30 years
Most frequently from meningeal arteries or veins, fx, or from sinus
10% require open surgery
Imaging shows incipient mass effect
Outcome correlates with Clot-location, Clot-thickness, Clot-volume, and MLS

- May be managed conservatively if: patient noncomatous, no focal deficits, thickness <15 mm, volume <30 cc, and MLS <5 mm or in a nontemporal location
- Indication for surgery: GCS <9 and/or volume >30 cc

Be aware: Time from deterioration to decompression correlates with outcome!

TABLE 36.10 Checklist for Interpreting a Trauma Head CT

A. Soft tissue windows

- Start at the level of the foramen magnum and work your way up to the vault
- Is the Foramen magnum open or crowded?
- Are the cisterns around the brainstem visible?
- Is the 4th ventricle visible? open? blood filled? in the midline?
- Is there a mass in the posterior fossa or cerebellum? is there a bleed or a stroke?
- Is the temporal lobe displaced medially? (pressing on the 3rd nerve?)
- Is the Sylvian fissure visible and open?
- Are the ventricles visible and midline (measure shift at the level of the Foramen Monroi)?
- Is there blood in the ventricles (check occipital horns in the supine pt)?

- Is there visible blood around the brain?
- Are there changes in the brain parenchyma (fronto-basal/ temporal tip contusions)
- Does the surface show visible sulci (indicating SAH or assessing ICP)

B. Bone windows

- Check for fractures. If at the surface, are they depressed? How much in mm? Is there a petrous apex/skull base fracture through the carotid canal (requires CTA)?
- Check the sinus and whether they are air-filled or opacified (= fluid-filled)
- Check for intracranial air indicating a CSF leak
- Check the orbit for fractures rule out compression of the optic nerve

TABLE 36.11 Radiologic Facts

1. Approximately 10% of initial head CT scans in patients with severe TBI do NOT show any abnormality
2. Significant new lesions and increased ICP may develop in 40% of patients with an initially normal head CT
3. Approximately 15% of patients with significant head injury may develop delayed deterioration (from hemorrhage or edema)

Clinical Case Vignette

- 26-year-old female patient s/p MVA with HA and dizziness and

intermittent confusion; transferred from OSH with initial CT: negative! Repeat Imaging for increased HA about 2 hours later showed a temporal fracture, and a new left 12 mm temporal EDH with incipient mass effect + uncal herniation

- Emergent L craniotomy for evacuation performed.

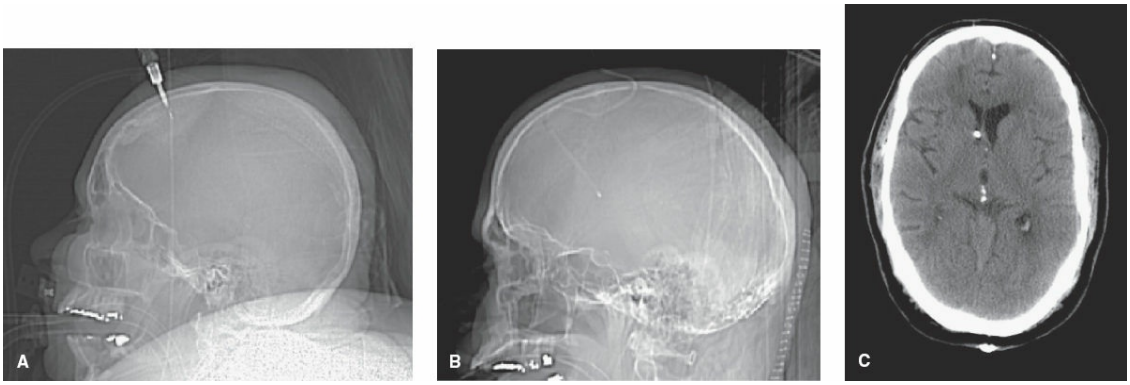

Figure 36.4. **A.** ICP-bolt insertion position on lateral XRT. **B.** Right frontal EVD placement. **C.** Postplacement CT scan: the soft tissue window shows the tip of the catherted at the level of the Foramen Monro.

Figure 36.5. Epidural hematoma.

Subdural Hematoma

Characterized as a crescentic, extra-axial, hyperdense mass on native head CT (Fig. 36.6), not confined by suture lines
Incidence among severe TBI patient is about 12% to 30%
1/3 to 1/2 of those patients are in coma on admission
Rarely patients present with a lucid interval
Peak incidence lies with patients aged 31 to 47 years, mainly men
Frequently from MVA, falls, fractures, assaults
35% to 80% of patients will present with GCS <9;
Poor outcome >age 60
Imaging shows incipient mass effect
Outcome correlates with clot-location, clot-thickness, clot-volume, and MLS
May be managed conservatively if: patient is noncomatous, without focal deficits, thickness <10 mm, volume <30 cc, and MLS <5 mm, nontemporal location; with ICPB
Indication for surgery: GCS <9, clot-thickness >10 mm, MLS >5 mm and/or volume >30 cc
Remember: Time from deterioration to decompression correlates with outcome!

Figure 36.6. Subdural hematoma.

Clinical Case Vignette

- 42-year-old male s/p fall from standing prior to admit and progressive hemi-paresis; h/o HTN and significant EtOH intoxication; Imaging revealed a Right acute SDH (Fig. 36.7)

Subarachnoidal Hemorrhage

Characterized as diffuse bleeding in the CSF space (looks like "sugar spilling" of extra-axial, hyperdense material on native head CT) not confined by suture lines. It is best visible in the sulci and fissures and in the occipital horns of the ventricles.

Figure 36.7. Right osteoplastic craniotomy for evacuation of hematoma.

Incidence among severe TBI patient is very high.
Patients may be in coma on admission (depends on mechanism of injury and impact), but it is very important to get a precise PMH.
Rarely patients present with a lucid interval.
Frequently from MVA, falls, fractures, assaults.
Imaging shows very little mass effect, if it occurs as an isolated injury.

Look carefully at the distribution of the blood and especially the basilar

cisterns and the Sylvian fissure. If there is any suspicion, that it could be aneurysmal in nature and the story does not make sense, it is mandatory to rule out that the SAH did not precede the TBI.

Intraparenchymal Hematoma

Traumatic parenchymal lesions occur in 10% of all TBI patients and in up to 30% of severe TBI patients

Smaller lesion may not require aggressive operative treatment, but additive mass effect may result in secondary brain injury and puts the patient at risk for deficit or death (Fig. 36.8)

All comatous patients with temporal or frontal lesions >20 cc or MLS >5 mm or any larger lesions >50 cc should be treated surgically

Early intervention is advocated with progressive neurologic deterioration

The threshold for decompression is a medically refractory ICP increase >25

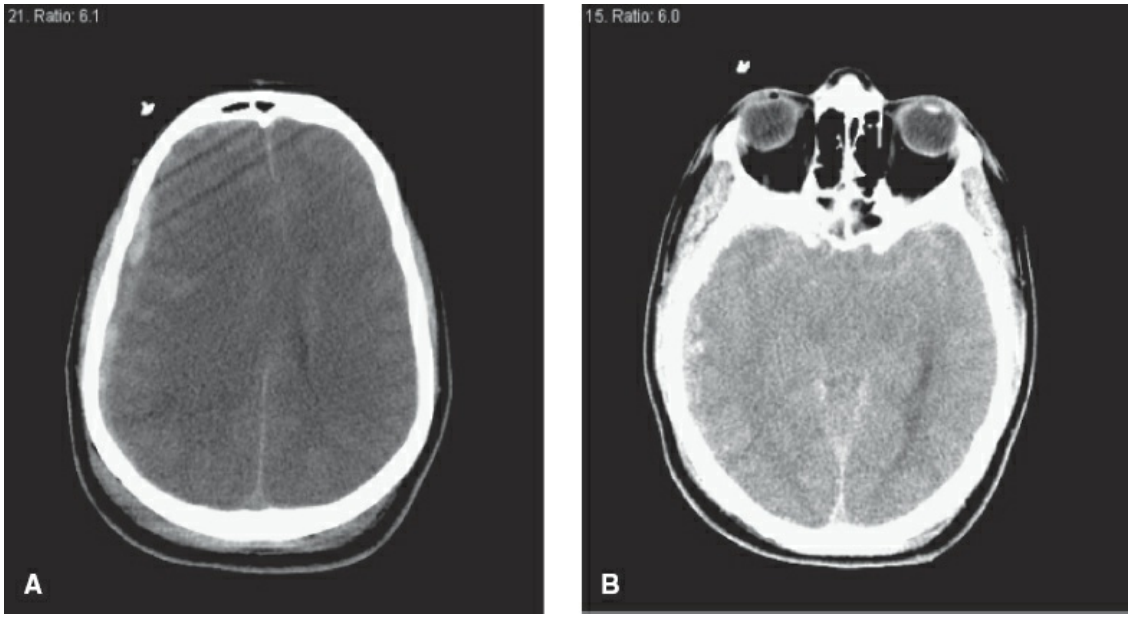

Figure 36.8. **A.** Small R SDH with global swelling. **B.** Right temporal hemorrhagic contusion adding mass effect.

Clinical Case Vignette

- 22-year-old male presented s/p snow board crash against brick wall; upon arrival he had a GCS 8 and a R 3rd palsy; Emergent CT revealed a small R acute SDH with a nondisplaced skull fracture, significant midline shift and multiple bilateral hemorrhagic contusions adding up to significant mass effect.

- Emergent R craniectomy, evacuation of SDH, and temporal lobectomy performed (Fig. 36.9)

Skull Fracture

Characterized by bone destruction to the skull and possible displacement, forming an extra-axial mass, not confined by sutures (Fig. 36.10)
Incidence among all TBI is about 6%
Because of the high impact, it is associated with high risk for intracranial hemorrhage and a significant neurologic deficit thus causing a poor outcome
Closed fractures can be fixed intraoperatively in one setting with craniotomy for exploration and bone fragment elevation and repair
All open fractures require a craniectomy with discarding of the bone, followed by delayed allograft cranioplasty. Most patients have to receive long-term antibiotics

Indications for surgery: if the depressed bone segment is thicker than the thickness of the overlying skull, they are unstable and require surgery.

Gun Shot Wounds (GSW)

GSW are the most frequent penetrating injuries (other are stabs/nailguns/falls into sharps) and account for one third of TBI trauma deaths in patients <45 years. The overall "proximal mortality" remains >90% (Fig. 36.11 and Table 36.12).

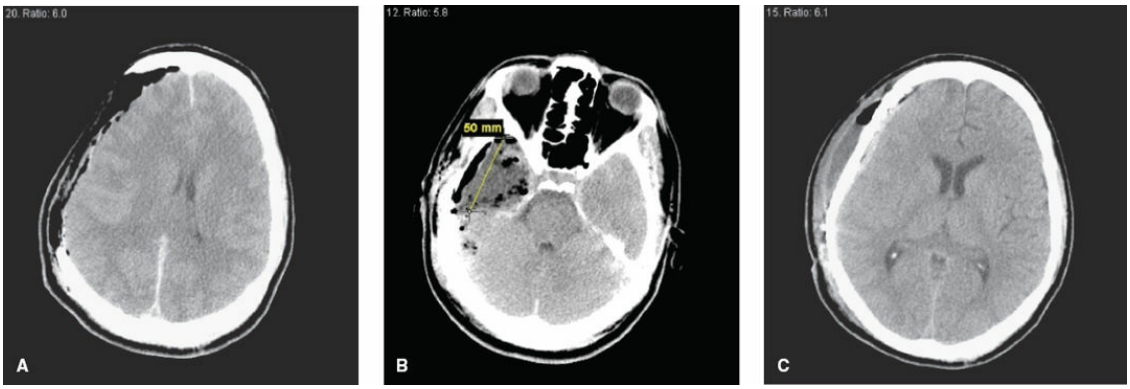

Figure 36.9. A. Right hemicraniectomy and evacuation of a SDH. **B.** R temporal lobectomy for performed to create space. **C.** Second stage R cranioplasty performed 8 weeks post trauma.

Hospital Course: Cardiopulmonary resuscitation (CPR) is likely to be performed in the field as necessary. Most patients will arrive per

emergency medicine services (EMS) in the hospital intubated and sedated. An expeditious trauma survey must be performed and additional injuries need to be identified and treated accordingly. Control bleeding from the scalp and other sites. DO NOT PROBE WOUNDS. Remember to keep MAP high during rescuscitation and avoid excessive hydration to avoid cerebral edema; standard spine precautions apply. Important: Describe entrance and exit wounds, unilateral injuries versus bullets crossing midline (very poor prognosis). Get 3D reformats from the CT done right away. If you have any chance to save the patient, act proactively and apply mannitol, lasix, hyperventilation as outlined and get the patient to the OR swiftly for decompression above.

Late complications: If the patient survives the initial insult and finally goes to rehab, a scheduled follow-up with full imaging is necessary to rule out delayed issues such as traumatic aneurysms, hydrocephalus, infections, and abscess. Keep the patient on anticonvulsants until reevaluation to protect him from secondary damage from seizures.

Outcome: GCS score and LOC (or the level of consciousness) at the scene and upon arrival in the hospital are the most relevant predictors of outcome. Most victims die at the scene. If the patient shows + LOC at the scene and upon arrival, 94% die and 3% survive with severest disabilities. Suicide attempts are more likely to be fatal. As in most TBI, young age and physical status are advantageous for improved recovery during rehabilitation, which should happen at an experienced TBI center.

NONTRAUMATIC EMERGENCIES

Mass Effect and Herniation

Background: Irrespective of detailed etiology and pathology, many CNS diseases directly or indirectly threat the patient's neurologic status and life by exerting force to functionally important and/or vital cerebral centers. Among the most dangerous conditions is brain herniation and its most critical final route of brainstem compression with consecutive death.

Brain herniation (Fig. 36.12) occurs when brain tissue inside the rigid skull is displaced or shifted by local pressure from its normal position toward another location with less pressure. It frequently happens as a direct consequence of hemorrhage (secondary to blood volume) or perifocal brain edema following ischemic stroke, CNS trauma, infection,

or inflammation, but is also commonly seen as vasogenic edema in the context of both primary and metastatic CNS tumors. It can also be caused by “global” problems such as hydrocephalus or generalized edema such as in malignant hypertension.

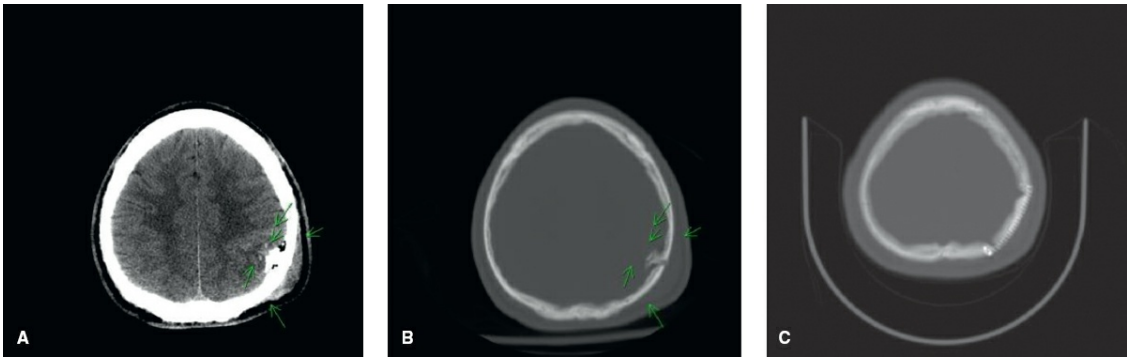

Figure 36.10. **A.** L frontal depressed skull fracture from a golf club assault. **B.** Bone window demonstrating internally displaced fragment. **C.** Post-OP CT of elevated calvarial fracture, which was repaired and augmented with titanium mesh.

TABLE 36.12 TBI From GSW Fall Into Two Categories: Primary and Secondary Injuries

Primary injury: Injury to soft tissue (scalp/face; bacteria translocation; pressure wave or gas); comminuted fracture to the bone; cerebral injury from missiles (direct path/ricochet/ fragments/coup & contrecoup)
Secondary injury (Early): Edema (ICP); cardiac output (MAP); DIC; hemorrhage; **(Late):** abscess/infection; Traumatic aneurysms; seizures; migrating fragments

Symptomatology: Any surgeon should know about the risks of herniation and anticipate and recognize the signs of impending or incipient herniation inherent to CNS disease potentially causing acute or delayed mass effect.

While the attribution of certain clinical signs to types and stages of herniation is puzzling, key symptoms of brainstem functional impairment in a patient at risk are as follows:

Dynamic decrease of the level of consciousness: somnolence → sopor → coma

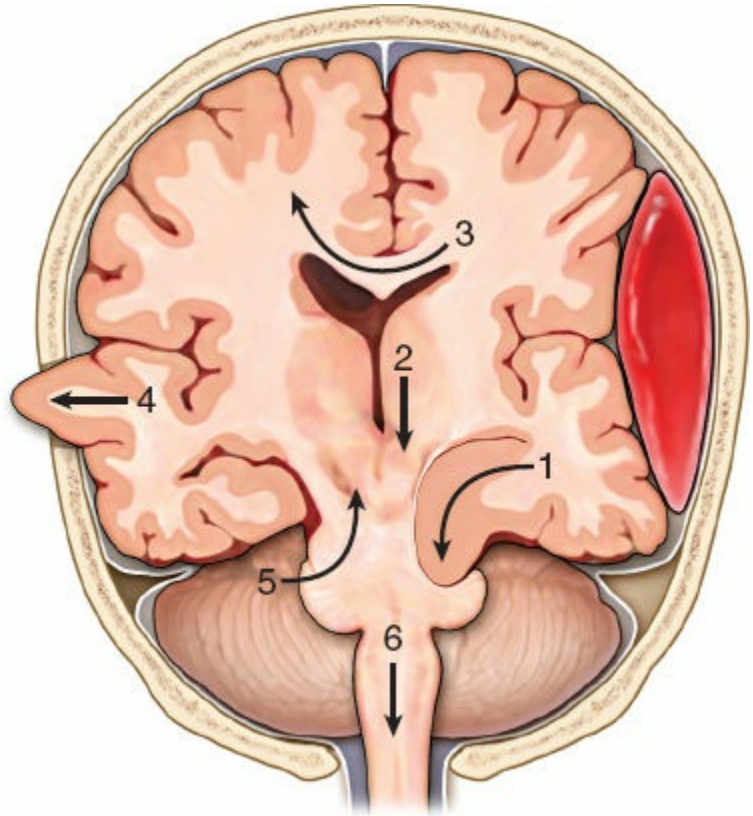

Figure 36.12. Brain herniation can occur from one compartment to another inside the skull. Subfalcine (3), uncal (1) and transtentorial herniation (2), upward herniation from posterior fossa (5), through a natural opening (tonsillar herniation at the foramen magnum (6)) or through bony defects such as the ones created during brain surgery (craniectomy sites (4)) or natural defects (encephaloceles).

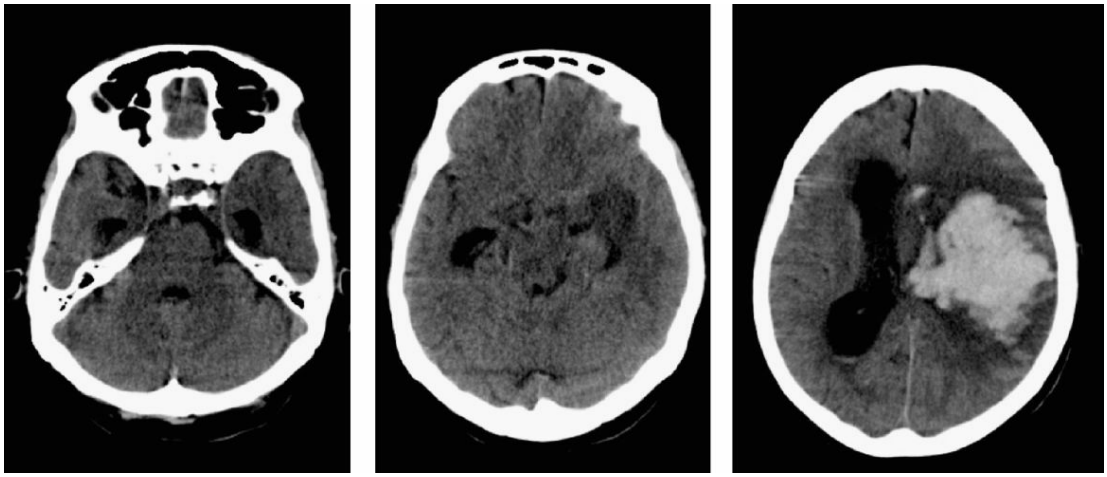

Figure 36.13. Hemorrhage into a left subtotal MCA infarction: Note radiographic signs b. to d. of transtentorial herniation as mentioned in the text. Note apparent shift of pons and associated changes in perimesencephalic cisterns.

Pupillary changes: especially bilateral small pupils, anisocoria, bilateral wide pupils
Pyramidal signs (especially Babinski group of signs)
Abnormal breathing patterns: pausing, hyperventilation, “machine breath”
Abnormal body posturing such decortication and decerebration
Abnormal motor reaction to painful stimuli
Development of hemiparesis

While often a developing hemiparesis is contralateral to the causative lesion (due to axial downward stress to ipsilateral peduncular long tracts before their decussation), an ipsilateral hemiparesis can develop by displacement of the upper brainstem leading to tentorial force on the contralateral cerebral peduncle (*Kernohan notch*). Thus, in case of a patient with primary left supratentorial mass lesion developing a left hemiparesis, Kernohan notch pressure during incipient herniation is the likely mechanism. Another traumatic mechanism leading to secondary damage is hemorrhage at the site of shearing force (*Durette hemorhage*).

Imaging features: CT and MRI need to be checked for signs related to early stages of progressive parenchymal shift indicating the risk of developing transtentorial herniation.

Noteworthy are the following: (a) principal basal cistern narrowing, (b) ipsilateral ambient cistern widening, (c) contralateral ambient cistern narrowing, and (d) contralateral temporal horn widening. Typical complications from herniation syndromes are usually detected on routine follow-up scans and include: anterior cerebral artery (ACA) infarction from transfalcine herniation in case of frontal lobe midline shift, or posterior vcerebral artery (PCA)-infarction due to transtentorial herniation (which may also occur from posterior masses). See Fig. 36.13.

Therapy: Intervention for increased ICP is either medical or surgical. Goal is to provide treatment that shrinks the brain and reduces associated tissue pressures. This includes such measures as improving venous outflow via elevation of the head, hyperventilation for vasoconstriction, osmotica for volume contraction, and steroids to decrease vasogenic edema in nontraumatic cases.

Surgical options depend on the scenario and patient eligibility and are aimed at: (a) eliminating the offending mass that creates such pressure and (b) forming a space by creating a skull defect to allow brain expansion to

occur and thus significantly lowering the resulting net tissue pressure and reducing midline shift and herniation.

Neurosurgical strategy, approach, and technique for decompression hence depend on the nature of the underlying lesion, the actual patient systemic status, and relevant imaging findings. One classic example is decompressing craniectomy for ischemic stroke, which will be discussed in detail below.

Ischemic Stroke (Malignant Media Infarction)

Acute occlusion of any major cerebral artery will result in significant ischemia to the brain secondary to the lack of adequate perfusion given that there is no functional collateral circulation. Resulting tissue death leads to the breakdown of the blood-brain barrier causing significant edema and raised ICP, which may result in herniation. Among strokes, large middle cerebral artery (MCA) territory or hemispheric infarction is often characterized by early and rapid clinical deterioration (*"malignant MCA infarction"*) and impending death unless a life-saving intervention is performed.

The clinical picture of total MCA infarction is characterized by severe sensorimotor hemisymptoms, head and eye deviation to lesion side, hemi-inattention and global aphasia (dominant hemisphere), accompanied by an early deterioration of conciousness and need of mechanical ventilation. Main causes are thromboembolic and atherothrombotic occlusion of proximal MCA or internal carotid artery (ICA). Such complete MCA infarction represents about 1% to 10% of all supratentorial ischemic strokes and occurs at an incidence of 10 to 20 per 1,000,000 per year; compared to other stroke types, it tends to affect women more likely and to occur at younger ages. It is associated with a significant mortality and morbidity rate of up to 80%.

Early diagnosis and initiation of aggressive therapy are determinants of outcome. In most cases, developing brain edema cannot be adequately treated by conservative means alone. Parenchymal edema is mainly due to ischemia resulting in cytotoxic cellular reaction. Its effect peaks approximately 1 to 5 days after the insult. The term "malignant" is used for such cases when brain swelling is starting early (within 24 to 48 hours) and results in significant mass effect. Extensive edema and marked elevation of ICP may cause secondary brain damage via ischemia of neighboring brain areas and can lead to "bystander-infarction," for

example, ACA-occlusion by transfalcian herniation or PCA-occlusion from transtentorial herniation.

The primary goal of surgical intervention is to save the patient's life, but also to limit the functional deficit. Several studies indicate that decompressive craniectomy limits the progressive evolution of effects on adjacent areas (e.g., secondary cerebral ischemia in the penumbra). For supratentorial strokes, it has been shown that early decompressive hemicraniectomy with durotomy/duroplasty is the most effective intervention in such circumstances, ultimately resulting in interruption of this vicious cycle. It not only reduces mortality, but it also improves outcome and reduces infarction size. It generates space, decreases ICP, alleviates mass effect, and increases cerebral perfusion to the penumbra allowing for perfusion via leptomeningeal collaterals. Metabolically compromised but viable parenchyma may thus survive. Optimal patient selection remains to be determined but preoperative clinical signs and timing of surgery seem to influence the prognosis.

Many retrospective clinical reports have indicated the significant effect of hemicraniectomy on survival of MCA infarction patients, several of them also pointing to positive results concerning functional outcome.

Data of several randomized controlled trials are currently available, i.e., DECIMAL, DESTINY, and HAMLET. All of them show significant rates of survival with respect to surgical versus nonsurgical treatment. According to a *pooled* analysis of these trials, the case fatality rate was significantly reduced comparing decompression (29%) versus conservative treatment (78%), the absolute risk reduction was 50%, and the functional outcome was significantly better. Age appears as the most important predictor of mortality, disability, and long-term functional dependence; further studies are running (DESTINY-2).

Currently there are only limited data reported as to the *optimal* time point for surgical intervention, but it shall be discussed early. More recently available imaging techniques, such as perfusion and diffusion MRI, may help to determine the time course of cerebral ischemia early after symptom onset, thereby allowing the clinician to decide on indication for surgical intervention. A similar approach needs consideration for expanding posterior fossa infarction, i.e, large cerebellar stroke.

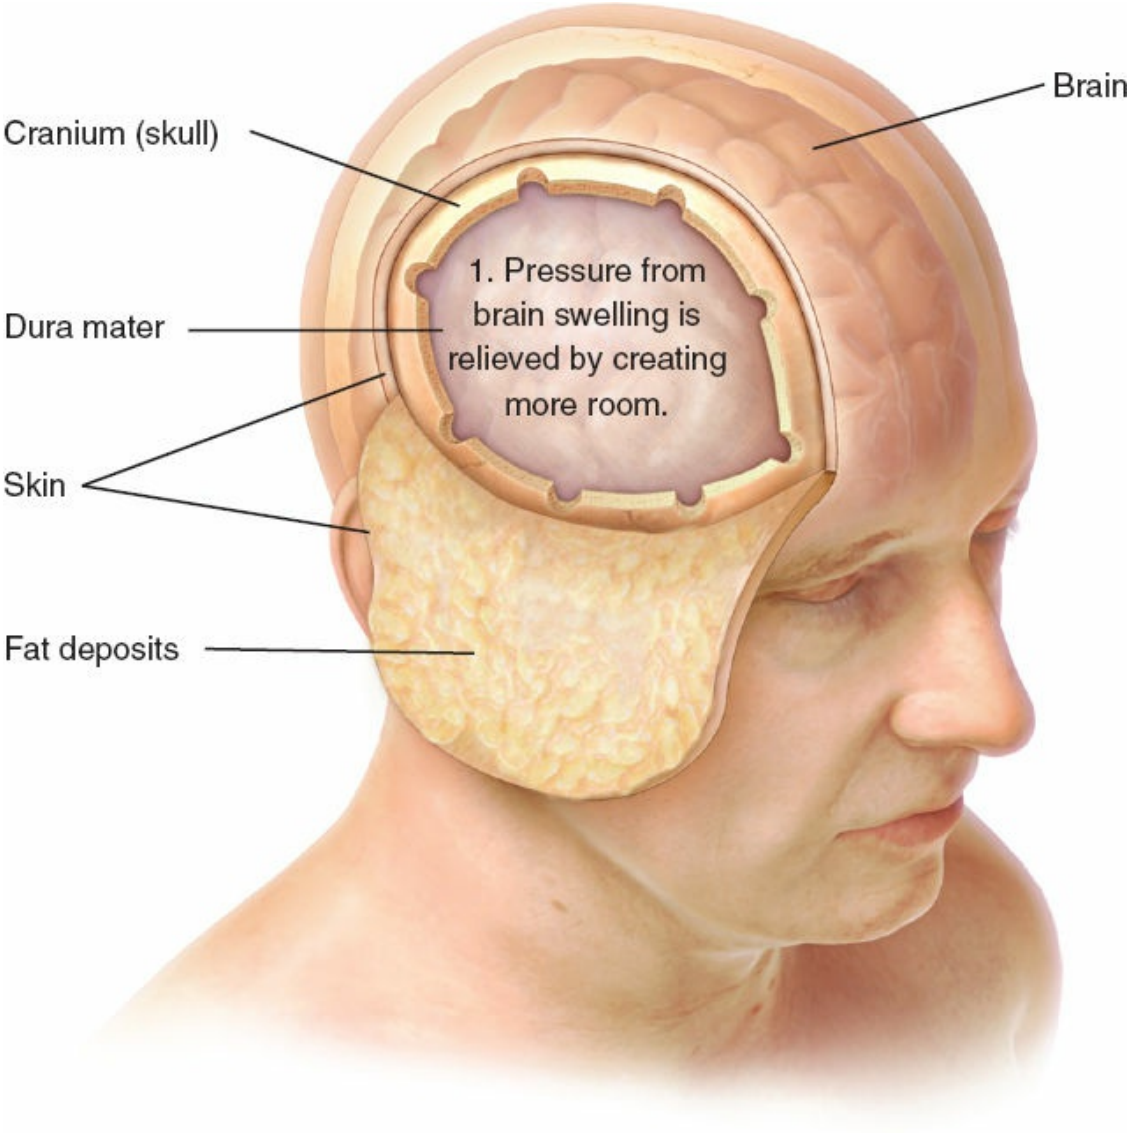

Figure 36.14. Hemicraniectomy.

Technical Considerations Concerning Hemicraniectomy

In order to give the brain parenchyma the maximum space for swelling and allowing for maximum decompression, the primary goal in a standard hemicraniectomy for MCA infarction is to remove a large bone fragment over one hemisphere (Fig. 36.14):

Trauma flap: fronto-parieto-temporal
Margins:
Anteriorly: superior border of orbital rim, avoiding frontal sinus
Posteriorly: 2 cm posterior to external meatus
Medially: 2 cm lateral to midline, avoiding superior sagittal sinus
Inferiorly: just above the ear cartilage = floor of middle fossa
Reflect temporal muscle anteriorly

Place several burr holes
Bone fragment can be stored in abdominal pouch or cryo-conservated
Remove sphenoid wing
Tack up dural edges to bony margins
Open dura via stellate or C-shaped incision
Perform duraplasty (periostium, temporal fascia)

This generates a 10 × 15 cm calvarial defect with a lower margin that should be extending <1 cm to the floor of the middle cranial fossa. If the bony opening is too small (<8 × 8 cm), it can lead to parenchymal injury from persistent pressure at the craniectomy margins with subsequent infarction. It must be emphasized that this type of emergent surgery is a dramatic event and only justified as a life-saving measure. It is to be noted that secondary to the significant compromise most of these patients sustained from their TBI, only 55% of the survivors answered "yes" to the question, "whether they would have liked the surgery being performed on them in this setting." Once the craniectomy has been successfully performed, one should plan on elective repair 8 to 12 weeks thereafter to reconstruct the calvarial defect.

Seizures: Status Epilepticus (SE)

Background

"Status epilepticus (SE)" is a term describing any type of prolonged, sustained or fast repetitive seizure activity and can occur in the setting of TTBI or not. It does represent a life-threatening emergency in many cases. Most relevant status types are as follows:

Generalized convulsive status epilepticus (GCSE, "Grand Mal"-Status)
Nonconvulsive SE (NCSE) and subtle status—SE without major motor activity; important cause of pronlonged impairment of conciousness or unexplained coma; often developing out of a GCSE, when epileptic activity on EEG outlasts the end of clinical motor activity. Special type: Absence Status
Simple partial SE—most frequently associated with certain conditions, for example, chronic focal encephalitis or other lesion. A special variant is Epilepsia partialis continua.

The International League Against Epilepsy (ILAE) classification of SE does not include a definite duration criterion for SE. GCSE has often been defined as >30 minutes seizure activity or a series of seizures without

return to full consciousness between the individual seizures. Notably, even a short period of seizure activity may cause neuronal injury and self-limitation is really rare after 5 minutes.

Epidemiology and Etiology

SE incidence is estimated to be 10 to 20 per 100,000 per year and is increasing with age. Approximately 50,000 to 200,000 cases occur per year in the United States. Males and females are affected nearly equally. SE affects all age groups but more frequently at the extremes of age (i.e., in neonates related to hypoxic injury or metabolic disease and in elderly people related to stroke).

Overall mortality rate is as high as 20%, but may exceed 50% in prolonged SE cases. Death often relates to underlying cause, unsuccessful treatment or SE complications.

Systemic SE complications are: (a) excessive catecholamine release leading to hypertension, tachycardia, cardiac arrhythmia, hyperglycemia and lactic acidosis; (b) hyperpyrexia promoted by excessive muscular activity; (c) hypoxia from impaired ventilation, pulmonary edema; (d) myoglobinemia due to muscular destruction with danger of renal failure.

Causes of SE may be roughly divided into three groups (Table 36.13):

Exacerbation of a known seizure disorder (irrespective of known or unknown etiology) occurs in up to 50% of the cases. Triggering factors include noncompliance; antiepileptic drug (AED) serum level drop caused by intercurrent disease (e.g., gastrointestinal) or pharmacologic interaction (after prescription of an interacting drug), intercurrent infection/febrile disease; complication acquired during a preceding seizure (intracranial hemorrhage, CNS trauma). So do not miss a new acute/subacute cause unrelated to pre-existing epilepsy!

TABLE 36.13 Causes for Status Epilepticus

Infection (e.g., meningitis, encephalitis, brain abscess)
Ischemic stroke
Subarachnoid hemorrhage
Neoplastic lesion (primary CNS tumor, metastasis)

Trauma
Systemic disease affecting the CNS, e.g., eclampsia
Toxic etiology (e.g., amphetamines)
Metabolic encephalopathies (e.g., hyponatremia, hepatic encephalopathy)

Hypoglycemia
A variety of medications, notably sympath-omimetics
Alcohol withdrawal
Hypoxic injury

First manifestation of an idiopathic/cryptogenic seizure disorder
Acute and subacute symptomatic CNS disease

Notably, any CNS disease may be associated with the development of acute seizures, including SE, which can be the first symptom also.

Given that such causes might also occur as secondary change (e.g., infarction due to vasospasms due to SAH, or intracranial infection after any open surgery, or generalized edema due to metabolic derangement due to sodium loss due to diuretic treatment) any of these scenarios must be considered regardless of primary cause of hospitalization.

Important Notes

Classic GCSE is easily recognizable at the bedside by the typical rhythmic tonic-clonic activity. Rarely, SE presents as persistent tonic seizure (postural, versive fits).
Rapid repeated and prolonged extensor and/or flexor movements or posturing may be confused with clonic activity, but rather characterizes nonepileptic attacks (“psychogenic status”). Typical is the “waxing and waning” character of motor symptoms. EEG is normal during the attack

(monitoring!).
Suspect persisting SE in any patient not regaining consciousness within the regular timescale after a witnessed grand mal seizure (subtle status or NCSE); here EEG is mandatory within 30 minutes (Fig. 36.15).
Suspect NCSE in all otherwise unexplained coma or significant disturbance of consciousness regardless of underlying primary cause, especially in the ICU. *NCSE not rarely is the cause of unexplained coma, especially in TBI patients.*

Figure 36.15. Characteristic rhythmic epileptic EEG activity from a case of NCSE.

Repetitive generalized myoclonus in a comatose patient following diffuse hypoxic brain injury may mimic generalized seizures; it poorly responds to AED treatment because its pathophysiology is likely not pure epileptic; it usually carries a poor prognosis.
Important seizure and SE-related injuries may include: severe tongue bites with the need of surgical therapy; joint dislocations and fractures (especially shoulder and spine); head and/or facial trauma;

rhabdomyolysis with danger of renal failure; and aspiration.

Since prolonged GCSE will cause severe CNS damage, it is paramount to diagnose and aggressively treat this condition from the very beginning in the general surgical population until a root cause has been identified or excluded.

Treatment

GCSE is a condition needing an intensive care setting.

General Notes

Determine and correct glucose level if necessary; consider substituting thiamine and folate (especially in alcohol withdrawal); optimize supportive care (blood pressure, oxygen); establish cardiovascular monitoring; measure AED levels in cases of preexisting epilepsy prior to acute treatment, perform extensive laboratory testing *early*, and consider CSF analysis.

Medical

It is recommended to establish a specific in-house standard algorithm. The general principles of SE, especially GCSE, drug treatment can be summarized as follows:

First line	benzodiazepines IV, especially lorazepam > diazepam > midazolam
Second/ Third line	phenytoin/fos-phenytoin versus valproate, levetiracetame, lacosamide; phenobarbital, propofol
Ultima ratio:	general anesthesia

Guidelines differ between countries and the United States and Europe, and, of course, strategies can incorporate the type of SE. Applying “third-line drugs” can be reasonable at stage 2; this field is in evolution. Notably, there is increasing usage of intranasal or intramuscular applications, for example, for midazolam.

Surgical Treatment

Besides surgical treatment of the primary cause of seizures, if necessary, and AED pharmacotherapy, a surgical intervention can be discussed in selected cases of refractory SE, for example in Rasmussen's encephalitis or malformation of cortical development. Repeatedly, successful surgical SE treatment has been reported, usually from partial epilepsy with strong semiologic, imaging, and electroclinical signs indicating the active area.

EDITOR'S COMMENT

Traumatic brain injury (TBI) is a major cause of morbidity and mortality worldwide. TBI accounts for nearly one third of all injury-related mortality and 2.2% of all deaths in the United States alone (Taylor CA, Bell JM, Breiding MJ, et al. Traumatic brain injury–related emergency department visits, hospitalizations, and deaths—United States, 2007 and 2013. *MMWR Surveill Summ 2017.* 2017;66(9):1–19). Data from the Centers for Disease Control and Prevention reveal that the number of TBI-associated deaths in the United States is increasing and over 70% of TBI-associated hospital admissions were due to falls (50.4%) or motor vehicle accidents (21.5%). TBI frequently occurs with and complicates the management of multisystem peripheral injuries. Nearly two thirds of multisystem trauma deaths have an associated brain injury. TBI in the context of multisystem trauma is associated with a significant increase in mortality (doubling of expected mortality for multisystem trauma patients with an associated moderate brain injury) (McMahon CG, Yates DW, Campbell FM, et al. Unexpected contribution of moderate traumatic brain injury to death after major trauma. *J Trauma* 1999;47(5):891–5). Consequently, it is critical to optimize TBI management in the multisystem trauma patient, as detailed by E. Kasper and colleagues.

Understanding of the mechanism of TBI through direct patient, first responder, and/or eye witness reports is essential to the evaluation and management of the patient (see the *Case Vignettes* demonstration of various injury mechanisms). Significant mechanisms of injury may result in delayed complications, suboptimal management, and impaired prognostication in patients. Careful assessment of vital signs before, at, and after admission can provide additional insight into intracranial complications and determine management strategy. Initial (after patient stabilization) and serial neurologic examinations are essential to the evaluation, management, and outcome estimation in all TBI patients. The Glascow Coma Scale (GCS) provides a succinct and broadly recognized grading scale for TBI patients that supplements the focused neurologic and physical examination. TBI severity based on GCS includes *mild* (GCS 13 to 15), *moderate* (9 to 12), and *severe* injury (3 to 8).

Computed tomography (noncontrast) provides the most efficient imaging assessment of intracranial injury. Early computed tomography scanning is critical in the assessment of the brain-injured patient immediately after stabilization, as well as for those patients with neurologic decline over their course of management. Magnetic resonance imaging can be used to supplement and better define subtle brain parenchymal injury (e.g., diffuse axonal injury) and the extent of edema/infarction as clinically indicated in patients. Patients with penetrating (e.g., gunshot wounds, knife wounds, other penetrating objects) or other nonpenetrating head injuries (e.g., skull fractures, anoxia, arterial dissection) that can be associated with possible vascular injury are assessed after stabilization/resuscitation with conventional angiography, computed tomography angiography, and/or magnetic resonance angiography.

Management strategies in TBI frequently follow injury severity as defined by the GCS. *Mild* injuries are typically managed by in-hospital or at-home observation (in *concussed* individuals). Signs and symptoms most often associated with mild head injury include headaches, nausea/vomiting, dizziness, forgetfulness/memory problems, blurred vision, fatigue, photophobia, and balance problems. Adult patients with *mild* injuries often improve at variable rates. While signs and symptoms frequently resolve in 2 weeks, some patients can remain symptomatic for several months. Symptomatic treatment and rehabilitation are used to manage refractory signs and symptoms. *Moderate* to *severe* injuries require hospitalization and careful serial observation in an intensive care unit until exam/imaging stabilize. *Severe* TBI patients require intracranial pressure monitoring and additional directed medical/surgical management to minimize TBI sequelae (see below) (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15).

Pathologic mechanisms of brain injury are defined as *primary* and *secondary* injury processes. Primary brain injury occurs at the time of the brain insult and is a result of the mechanical forces associated with the injury. The mechanism of primary injury can cause reversible and/or irreversible physiologic and anatomic changes. Because primary injury occurs at the time of injury, the treating physician cannot mitigate its effects. Secondary injury processes occur hours to days after injury and are due to cellular, physiologic, and anatomic alterations associated with the primary injury. Secondary processes frequently underlie delayed morbidity and mortality and can include hypoperfusion, increased intracranial pressure, hemorrhage, metabolic changes, excitotoxic injury, edema, infection, seizure, and hypercapnia. Because these processes can be minimized through careful management, they are the focus of care and guidelines development (see Guidelines for the Management of Severe Traumatic Brain Injury, Fourth Edition, 2017) (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15).

Two critical physiologic processes essential to mitigating secondary injury in

the *severe* TBI patient include optimizing cerebral perfusion (cerebral blood flow) and intracranial pressure. Cerebral perfusion pressure guidelines recommend a target of 60 to 70 mm Hg (cerebral perfusion pressure = mean arterial pressure − intracranial pressure) but target perfusion pressure can depend on patient autoregulatory status. (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15) Systolic blood pressure thresholds of 100 mm Hg or more in patients 15 to 49 years or over 70 years and 110 mm Hg or more in patients 50 to 69 years are recommended. Intracranial pressure guidelines recommend treating intracranial pressure greater than 22 mm Hg. (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15) Methods to reduce patient intracranial pressure can be patient specific (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15; Hutchinson PJ, Kolias AG, Timofeev IS, et al. Trial of decompressive craniectomy for traumatic intracranial hypertension. *N Engl J Med* 2016;375(12):1119–30) and include drainage of cerebrospinal fluid, removal of mass-occupying lesions (hematoma), diuretics/hyperosmolar therapy, decompressive craniectomy, short-term hyperventilation (to acutely reduce pressure), and barbiturates.

Other management guidelines (Carney N, Totten AM, O'Reilly C, et al. Guidelines for the management of severe traumatic brain injury, fourth edition. *Neurosurgery* 2017;80(1):6–15) that are critical parts of the multidisciplinary management of TBI patients with multisystem trauma, include nutritional and ventilator care. Latest TBI guidelines recommend caloric intake at replacement levels optimally by day 5 after injury and day 7 after injury at the latest. For patients unable to safely take oral nutrition, transgastric jejunal feeding is recommended to reduce risk of ventilator-associated pneumonia. Early tracheostomy is recommended in patients to minimize mechanical ventilation complications. The decision to place a tracheostomy in a TBI patient is made after weighing the procedural risk against the benefit. Steroids do not have a role in treating TBI-associated edema. Taken together, these medical and surgical management guidelines for TBI are continually evolving but provide a framework based on best available evidence.

E. Kasper and colleagues provide an expert review of TBI management in their chapter. The authors cover critical areas of exam, assessment, imaging, and management (including indications for surgical intervention). Surgeons frequently encounter trauma patients who have associated multisystem injuries that include the brain. These patients necessitate complex individualized multidisciplinary care to maximize outcome. The pathophysiologic features of the brain injury require strategies to minimize secondary injury. Further research remains critical to better define management strategies and develop new therapeutics.

37 Tracheotomy

Ryan Little and Jonathan M. Bock

INTRODUCTION

Surgical access to the airway follows three distinct approaches depending on the patient status and clinical situation. These are the open surgical tracheotomy, the emergency tracheotomy or cricothyrotomy, and the percutaneous dilatational tracheotomy (PDT). The first two have a wide range of described techniques each with advocates and detractors. Open surgical tracheotomy is often performed in cases of prolonged intubation and mechanical ventilation, or when the native airway is somehow obstructed or impaired above the level of the trachea. Narrowing of the airway at the level of a prior endotracheal tube (ETT) cuff or scarring of structures above this point can be seen after prolonged oral or nasal endotracheal intubation. An open surgical tracheotomy may also be utilized in preparation for major head and neck surgery or in the event of massive maxillofacial trauma.

Emergency airway access techniques include cricothyrotomy and “slash” tracheotomy, each done as quickly as possible in the context of an arrest with the single-minded indication being the preserving of the patient’s life. This technique is utilized when attempts to definitively secure the airway or temporize the situation are unsuccessful, including failed noninvasive ventilation, positioning techniques, oral or nasal airway, or transtracheal needle jet ventilation. Indications for securing a definitive airway include: apnea, inability to maintain a patent airway by other means, protection of the lower airway from aspiration of blood or vomitus (GCS <8), impending or potential compromise of the airway, inhalation injury, facial fractures, sustained seizure activity, closed head injury requiring hyperventilation, and failure to maintain adequate oxygenation despite supplemental oxygen via masking. While the surgical anatomy is relevant in the general sense, it is far less of an issue than getting a tube into the airway by whatever means as quickly as humanly possible. The main role of the surgeon in the emergency setting is to obtain access to the trachea for ventilation as quickly as possible, while being mindful and

protective of the laryngeal anatomy as much as possible.

PDT is a technique that has gained increased attention over the last three decades, and generally is performed at the bedside within the intensive care unit (ICU) with minimal surgical instrumentation and simple surface anatomy guidance. The process generally requires direct visualization of the airway with rigid or flexible endoscopic guidance to guide proper placement of the tracheotomy. It is indicated for any critically ill ventilated patient who would otherwise have to be taken to the operating room (OR) for an open surgical tracheotomy. Enthusiasm for PDT is tempered by some reports of increased bleeding risk and other complications, although evolving data in this regard is mixed.

OPEN SURGICAL TRACHEOTOMY

General Issues and Indications

The primary indication for tracheotomy is the bypassing of the larynx when prolonged intubation is necessary to reduce the risk of airway stenosis and secure airway access. Additional indications include definitive treatment of airway obstruction due to masses or obstructive sleep apnea, and protection of the airway in anticipation of extensive head and neck surgery or maxillofacial trauma. The timing of when to consider this operation in the context of prolonged intubation is fairly well established. Data support a 10- to 14-day window of intubation as the target for converting from orotracheal intubation to tracheotomy access, as risk of glottic and subglottic stenosis increases markedly on a daily basis after this time.

There are some areas of debate and variability in the timing of tracheotomy. Traumatic brain injury patients who are mobile and fighting their intubation can cause significant glottic injury. The pure physical erosion of the ETT against the posterior glottis can be very damaging to the larynx by causing granulation, mucosal erosion, cricoarytenoid joint inflammation and fixation, and subsequent posterior glottic stenosis. These patients may require tracheotomy in a timely fashion to prevent these devastating laryngeal injuries. Conversely, the comatose patient who needs no sedation and who has some chance of spontaneous recovery may have little endolaryngeal inflammation or injury even after 2 or 3 weeks of orotracheal intubation because they do not cough or swallow. Though these findings are common in these scenarios, it is our experience that laryngeal and tracheal injuries related to prolonged orotracheal intubation

remain quite variable, and the general maxim remains to perform tracheotomy early when prolonged intubation requirements are expected.

Patient medical factors can also influence the risk of glottic stenosis during periods of prolonged intubation. Laryngopharyngeal reflux (LPR) is known to contribute markedly to the potential laryngeal damage of prolonged intubation. Very short periods of intubation in patients with severe LPR can result in profound ulcerative laryngitis and edema which can increase rates of scarring and joint fixation. Other factors that can increase risk of airway edema and subsequent intubation-related injury are: immunosuppression; microvascular disease; diabetes mellitus; and history of recent airway instrumentation. In the context of these additional risks and unsuccessful attempts to wean or extubate, early tracheotomy to protect the larynx from further insult is highly recommended.

The surgically matured tracheostomy is useful in several specific clinical scenarios. The first is in a patient whose neurologic condition is so devastated that there is no reasonable chance for future removal of the tracheostomy tube, known as decannulation. Examples of such conditions include massive strokes, extensive brain injury, or high quadriplegia. Patients with intractable aspiration and laryngeal diversion surgery may need a permanent stoma to avoid airway obstruction if the cannula ever fell out or became plugged and had to be removed. Surgically maturing a tracheostomy may also be considered in cases of advanced head and neck cancer, wherein there is very advanced local invasion of the upper aerodigestive tract. In this scenario, a surgically matured stoma may be prudent in patients that are known to be a difficult orotracheal intubation should tracheostomy tube dislodgement or accidental decannulation occur in the immediate postoperative period. In addition, depending on the site of the primary tumor and staging, these patients may have a protracted course with multiple treatment modalities including surgery and/or chemoradiation, which may also have adverse effects on the airway. Lastly, a fully matured stoma is often appropriate for the morbidly obese patient or obstructive sleep apnea patient with significant pretracheal adipose tissue, as accidental decannulation in these patients can lead to life-threatening airway collapse and marked difficulty in the identification of the tracheal incision. In all of these cases, this technique allows a low maintenance stoma and the safety of a channel that will remain open for hours to days with no cannula at all in many cases. The main risk of a fully matured stoma is that if the clinical assessment is incorrect and the

person's condition does improve allowing for decannulation, the stoma will have most likely have to be surgically closed.

Open Tracheostomy Techniques

There are innumerable techniques for performing a tracheotomy and a tracheostomy (Fig. 37.1). The distinction between the two is of a surgically mature stoma in the latter, though both involve an opening or "otomy" into the trachea as an intrinsic feature of the operation. Vertical or transverse skin incisions are often debated. The vertical is more easily made with little risk of needing to ligate large anterior jugular veins but heals less well than a transverse incision that can be put into a skin crease. In an open surgical tracheotomy, most prefer to perform a transverse skin incision and simply ligate the anterior jugular veins if necessary. These vessels can be extensive in some patients, especially in those with a history of congestive heart failure. The deep dissection often includes the need to either divide or reposition the thyroid isthmus. Dividing the isthmus provides broad access to the trachea; however this may slightly increase the risk of bleeding postoperatively. Suture-ligation with a running baseball stitch or division with monopolar cautery is usually sufficient to control any potential hemorrhage. Another option if the isthmus is small and without cystic or nodular lesions is to move this above or below the tracheotomy entry site.

It is often wise to ask the anesthesia team to lower the ETT cuff pressure and advance the tube further into the airway prior to incision into the trachea. This allows for the tracheal incision to be made without damaging the ETT pressure cuff, which can cause significant respiratory compromise in patients who require large amounts of positive pressure to maintain appropriate ventilation. This allows for measured and careful stomal maturation prior to removal of the ETT under direct vision and placement of the tracheotomy cannula. The tube can even be advanced into the right mainstem bronchus temporarily if needed, as most patients can tolerate this for a minute or two while the stoma is developed. The type of tracheal incision is also an area of great controversy and varies between authors. Our recommendation is to perform an anteriorly based Björk flap wherein a wide transverse incision is made between the second and third tracheal rings, followed by parallel inferolateral vertical cuts to create an inferiorly based flap (Fig. 37.2). The free end of the cut tracheal ring is then secured to the dermis of the lower skin flap with 3-0 vicryl or chromic

sutures. This approach stabilizes the inferior aspect of the stoma to the neck skin, allowing for easier visualization of the tracheal airway in the event of accidental decannulation. Leaving one or two undisturbed rings below the cricoid is also beneficial to increase the protection to the cricoid, as inflammation of the cricoid ring can lead to cricoarytenoid joint fixation and subsequent airway compromise. A vertical incision is often done in children as the tracheal diameter is more narrow and floppy, and does not allow easy maturation of a Björk flap. Vertical tracheal incisions are also sometimes performed in an emergency situation as they allow for faster entry into the airway.

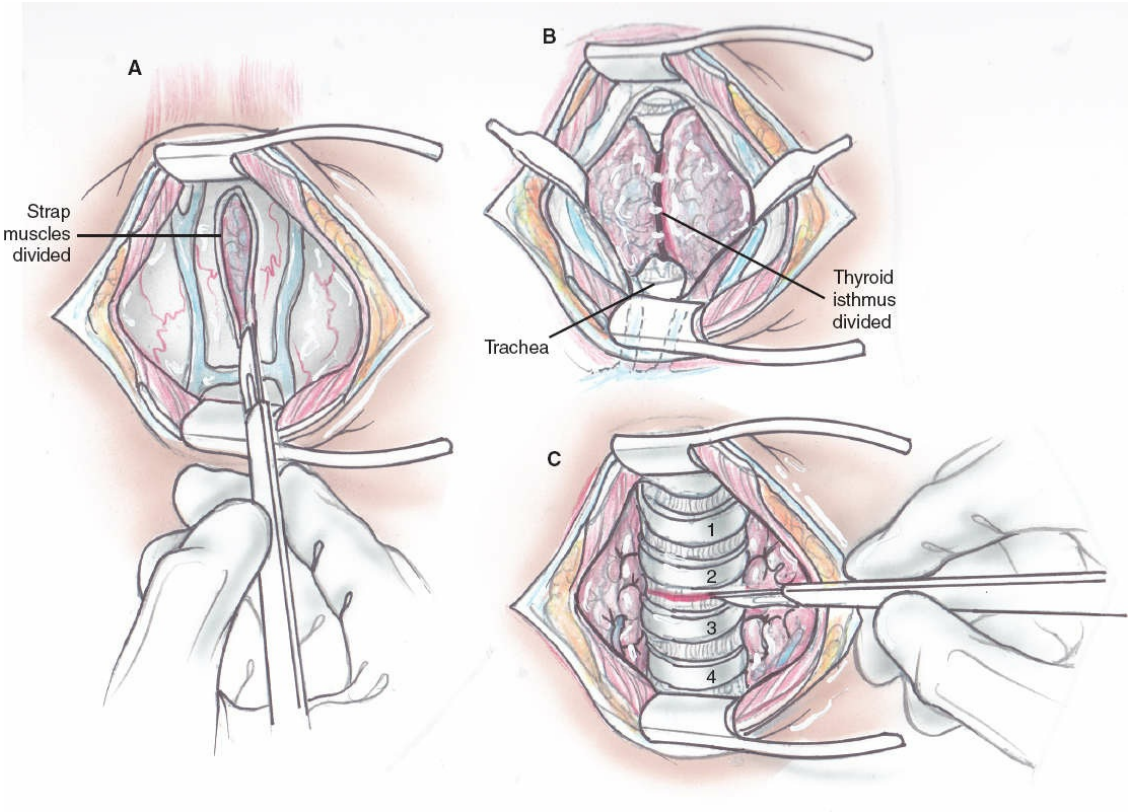

Figure 37.1. Steps of a typical open tracheotomy. The division of the thyroid isthmus is a common part of the procedure, though this may be avoided by mobilizing the isthmus and retracting it superiorly or inferiorly. This results in less potential for bleeding and tissue necrosis within the tracheotomy wound and less malodorous drainage. The hazard of preserving the isthmus is that you may not enter the airway in an ideal position, resulting in a stoma position that may make for a greater tendency for stenosis of the subglottis by injuring the cricoid cartilage. **A.** The strap muscles are divided along the midline raphe and retracted laterally. The trachea and thyroid gland are identified. **B.** The thyroid isthmus is retracted superiorly or divided, as required. **C.**

The first three or four tracheal rings are exposed. The trachea is entered between the second and third tracheal rings. (Modified from Kost KM. Advanced airway management—Intubation and tracheotomy. In: Johnson JT, Rosen CA, Bailey BJ, eds. *Head and Neck Surgery—Otolaryngology*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2014.)

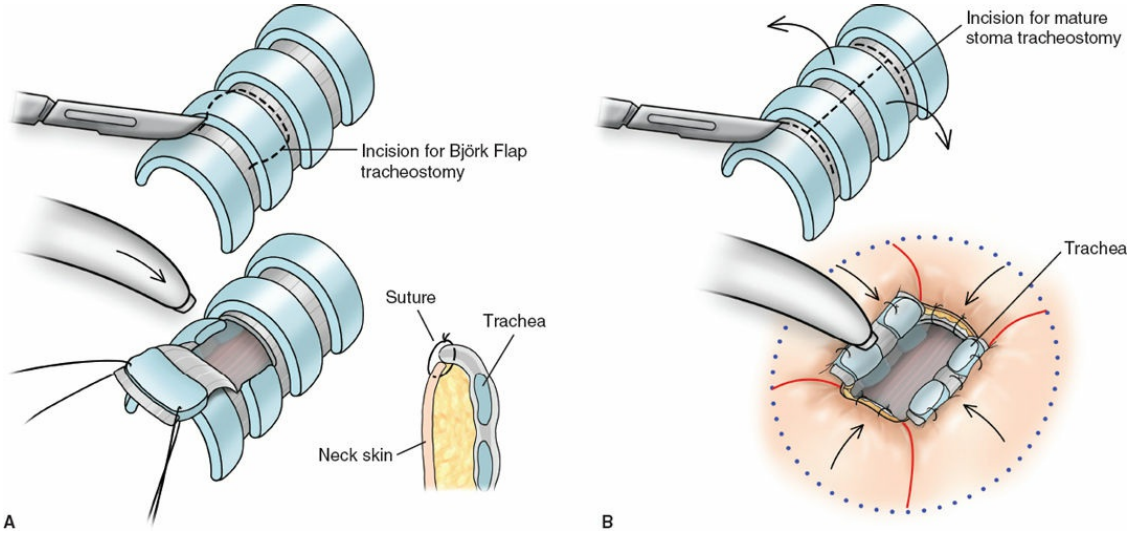

Figure 37.2. A. Generation of the "Björk Flap." **B.** The skin from the neck can be advanced to the trachea instead of the other way around, if additional security against the dislodgement of the cannula is needed. It takes only a small amount of additional effort to enable this. In fact, the same maneuver can be extended in the circumference of the tracheotomy to generate an appropriately named "tracheostomy" by advancing flaps of skin on the three sides of the opening suturing each to the corresponding part of the trachea with slowly absorbing buried monofilament sutures. (Modified from Weissler MC, Couch ME. Tracheotomy and intubation. In: Bailey BJ, Johnson JT, Newlands SD, eds. *Head and Neck Surgery—Otolaryngology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Obese patients or those with very short necks often have eventual issues with upward displacement of the tracheotomy tube after surgery. These body types promote the development of stenosis by the vertical upward force on the tracheostomy tube from their cervical pannus with consequent irritation of the anterior tracheal wall. These patients often develop a tracheotomy site with a dense vertical scar beneath it indicating that the initial entry point into the airway was far lower than it ended up (Fig. 37.3). A higher cannula placement point can therefore be justified in these

patients to help avoid this complication, although placement preference should always avoid contact with the cricoid cartilage if at all possible. Extensive anterior cervical defatting can allow for the tracheostomy tube to lay more flush against the skin, and development of skin flaps above and below the tracheotomy site can further facilitate this. Obese patients also are at increased risk of subglottic stenosis due to inappropriate ETT sizing prior to tracheotomy. Aggressive trach mask trials to remove the patients from ventilation and plugging trials to progress to decannulation as quickly as possible are highly recommended in the obese patient population.

The “mature stoma” tracheostomy in-volves the generation of laterally based cartilage flaps sewn to the skin by multiple buried absorbable sutures (PDS, chromic, or vicryl) (Fig. 37.4). A vertical incision through two rings in the midline of the trachea can be connected above and below by a generous transverse incision. This is termed an “I” flap by virtue of the shape of the capital letter “I.” The cartilage of each flap is supported by lateral axial blood and mucosa. An alternative approach is to make a tracheal window by simply excising the median portion of two tracheal rings. All the suture materials used to mature to stoma to the skin should be absorbable so as to avoid the need for suture removal from this difficult to access area. All sutures to mature the stoma are generally placed while the patient is still intubated to facilitate placement without a tube in the way of the surgeon (Fig. 37.5; see also Figs. 37.2 and 37.4).

Complications of Tracheotomy

There is no single technique that enables one to avoid all of the common complications of tracheotomy. These include inadvertent decannulation, or the loss of the airway from the separation of the trachea from the tracheotomy cannula; postoperative hemorrhage; local infection; stenosis or cicatricial scarring above, within, or below the airway entry point; cartilaginous or membranous tracheomalacia; and the potential of injury to the critical neighboring structures such as the esophagus posteriorly and the innominate artery anteriorly. The tracheotomy tube itself is a foreign body and can place pressure on the anterior or posterior tracheal wall, depending on the angle of placement and the patient’s neck anatomy. Erosion into the anterior or posterior wall may therefore occur over time, thus entering the adjacent structures including the esophagus or innominate artery (Fig. 37.6). The dilation that occurs, even in the absence

of erosion, can be its own disease in the form of tracheomalacia. This can make the process of decannulation laborious, long, and potentially unsuccessful. Other factors such as the patient's overall state of nutrition, the ventilatory pressures being used, and patient movements like repeated swallowing and coughing play a role in this erosive and dilatational process. Because of these host factors, potentially dire complications can occur even under the most meticulous attention. Severe and life-threatening complications of tracheostomy can be reduced by careful monitoring of the tracheotomy tube cuff pressure, maintaining it at the lowest possible pressure that allows proper ventilation. A slow increase in necessary cuff pressure and minute volume may indicate a gradual dilation of the trachea and may herald the damage that leads to complications. Proper sizing of the airway appliance can also be facilitated by flexible endoscopic evaluation of the airway through the tracheotomy tube.

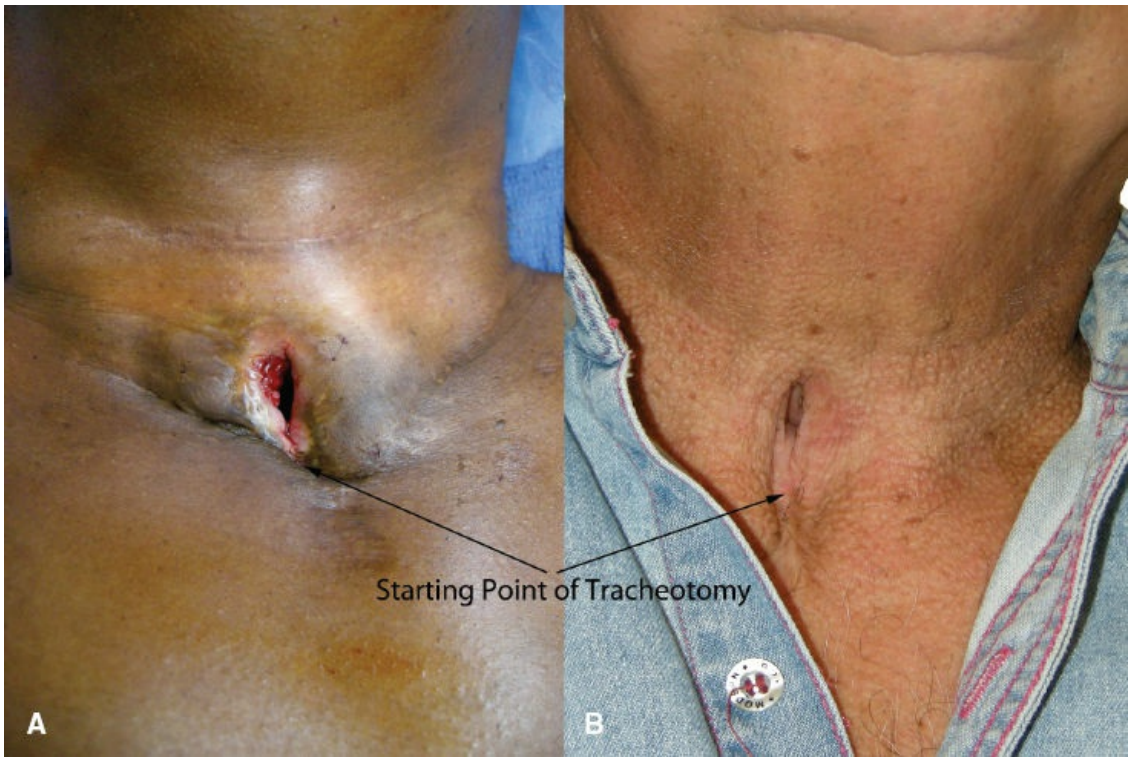

Figure 37.3. A. This stoma began at the level of the transverse scar and eroded upward. The jagged edges are made up of granulation tissue and cartilage that has lost it circular shape. **B.** This very old tracheostomy lacks obvious granulation tissue but clearly has eroded up from its original starting point near the thoracic inlet up to its ending spot below the larynx. Both patients experienced severe airway complications from the tracheotomies. "**A**" required a segmental tracheal resection prior to being able to be decannulated. "**B**" was able to be decannulated after a series

of minimally invasive procedures to widen his airway from the inside.

Figure 37.4. Incisions and dissection that are needed for a surgically matured tracheostomy, in the truest meaning of the term. The four divided skin segments sewn down to the airway on each of four sides bring them to the mucosa circumferentially. This promotes the generation of an “ostomy” that will be secure, require little local care, and will have to be surgically closed if it is ever no longer needed.

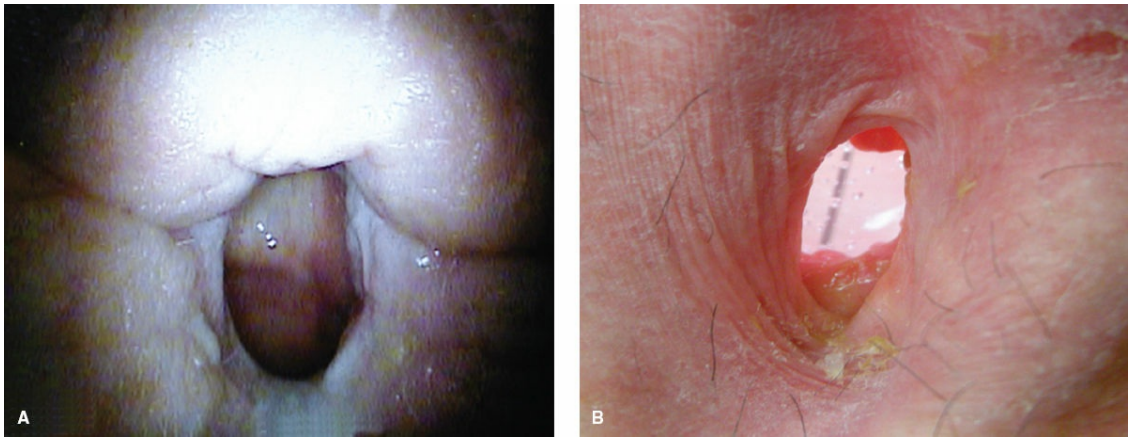

Figure 37.5. A. Video image of a stoma surgically "matured," in that skin flaps were sewn to the trachea to accomplish what can happen to a tracheotomy after it has had a cannula in place for several years depicted in "B." **B.** This image, taken during an endoscopy, provides internal illumination allowing the detection of the granulation tissue evident within the stoma that persists despite the fact that this stoma has been in place for several years. See Figure 37.4.

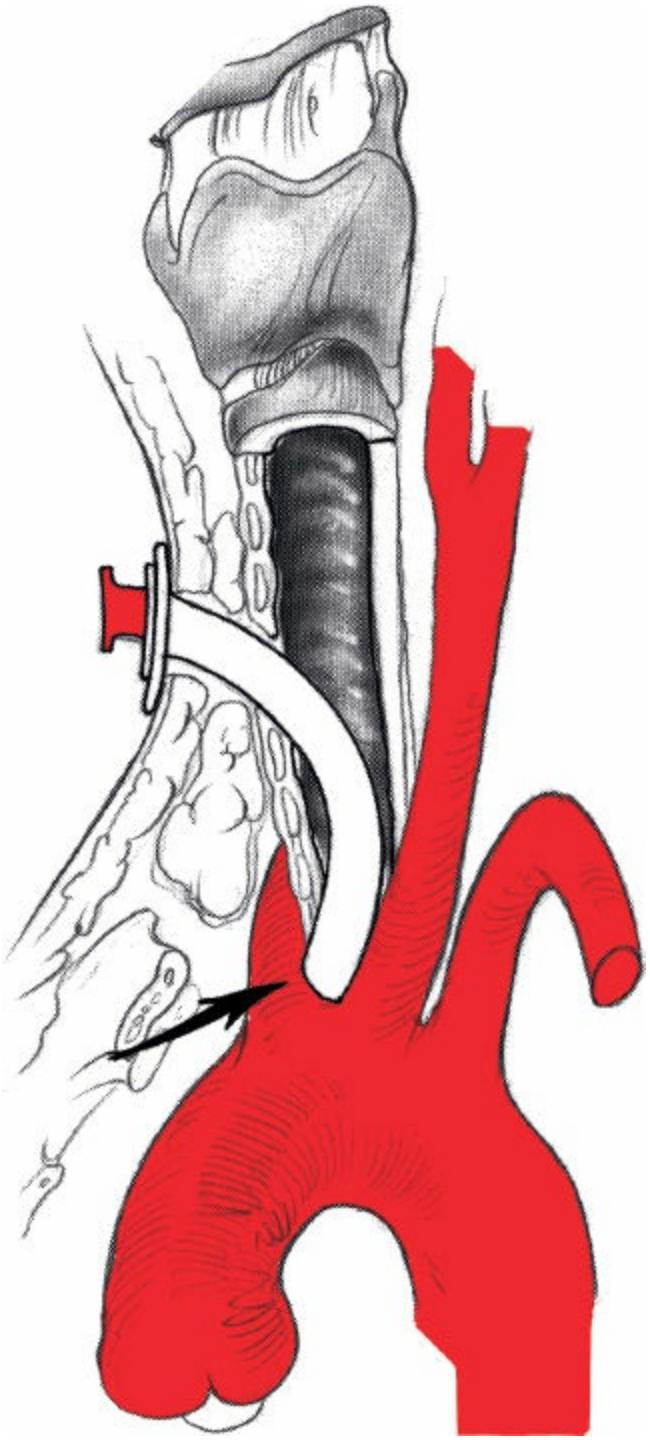

Figure 37.6. Diagrammatic rendering of the anatomical basis of tracheal erosion through the wall into the innominate artery. The curved shape of common tracheotomy cannulas is a common fit for most patients but not all. Common bleeding may indicate a poor shape match for a given patient. A brisk arterial bleed that stops spontaneously may be the so-called sentinel bleed of an innominate artery fistula. This is commonly a fatal complication of tracheotomy. (Modified from Weissler MC, Couch ME. Tracheotomy and intubation. In: Bailey BJ, Johnson JT,

Newlands SD, eds. *Head and Neck Surgery—Otolaryngology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Inadvertent decannulation warrants special mention as it the most likely cause of postoperative mortality in the tracheotomy patient. It tends to occur early after the procedure has been performed and before scar has formed to maintain the trachea in contact with the skin incision. This enables the tip of the cannula to fall out of the tracheostomy tract entirely or to sit within a false passage anterior to the tracheal lumen. The patient may be able to breathe, in the latter situation, through or around the cannula for a short time but loss of tidal volumes and decreased gas exchange will likely indicate the problem. If the driving pressures are increased or "bag ventilation" is employed enabling far higher air pressure and volume delivery, a pneumothorax soon follows and a dire downward spiral can result. A quick evaluation of the position of the tracheotomy tube with flexible endoscopy can confirm a view of the tracheal airway, and can also be used to advance the tracheotomy tube into the trachea using the Seldinger technique. The cannula can sometimes be replaced by "feel," if the problem is caught early and the tracheal wall is still widely open. If not, manipulating the cannula can fully close off the communication between the skin and the trachea. Intubation from above should be considered under such circumstances. If intubation from above is not successful, possible, or the patient has arrested, removal of the existing cannula and digital exploration of the wound should be attempted. The anterior tracheal wall may be palpated and the opening into the trachea found. If so, a small ETT (5.0 or less) can be used to reintubate the airway and provide for some degree of ventilation while chest tubes are being placed. The tracheotomy cannula can then be passed by Seldinger technique over a tube exchanger once the situation is stabilized. If the airway is not able to be cannulated but the tracheal opening is palpable, oxygen or Heliox can also supplied by high flow or jet through the open cervical incision into the distal trachea using a needle, IV catheter, or flexible suction. Depending on why the cannula became dislodged in the first place, it may be reasonable to introduce an extra-long cannula such as the Shiley XLT that comes with a proximal or distal extra-long segment (Mallinckrodt, St. Louis, MO). Stay sutures at all four corners of the tracheotomy tube can fixate the cannula base to the neck to secure it against inadvertent removal until the track has matured for 5 days, and also

decrease the rate of postoperative hemorrhage.

The most fearsome complications from tracheotomy, including tracheoesophageal fistula formation (TEF) and innominate artery fistula (IAF), should be mentioned but cannot be addressed definitively in a work of this scope. The critical issue is to avoid a tracheostomy in the context of a known TEF unless the fistula is very high and unlikely to be at or below the level of the entry point of the tracheotomy itself. It is possible that the cannula could be placed into the fistula and the esophagus will be intubated. Repositioning can be hazardous and ineffective. Dire scenarios are common in this setting. Esophageal stenting and rotational flaps in concert with thoracic surgery assistance are usually necessary to correct this problem, and decannulation can be challenging. IAF is highly morbid with over 50% mortality, and requires emergent intervention by cardiothoracic surgical intervention.

Infection is a known risk of tracheotomy but rarely causes life-threatening complications. The tracheotomy wound is open to the airway and by default contaminated with oral flora. The head and neck is famous for tolerating a high degree of contamination without infection because of the excellent blood supply and the vigor of the immune system built into our design. Nonetheless, tracheotomy sites are often oozing with foul mucopurulent secretions and blood caused by pooling of oropharyngeal secretions. Reflux of stomach acid including digestive enzymes and bile from the GI tract may also induce inflammation and a favorable environment for worsened scarring and stenosis of the larynx and subglottis. Prevention or reduction of reflux can be achieved by postural means with head of bed elevation, the use of gastrojejunostomy technology for post pyloric feeding, use of proton pump inhibitors, and vigorous irrigation and suctioning of the aerodigestive tract including the mouth and trachea if at all possible.

Another complication of tracheotomy or tracheostomy worthy of mention is an unwanted persistent opening into the trachea following decannulation, known as a tracheocutaneous fistula (TCF). When a stoma has been surgically matured as described in the technique section above, or when the cannula has been left in place for a prolonged period of time, a mucosalized tract forms between the surface skin and the trachea that may not spontaneously close. The TCF should be evaluated with flexible endoscopy by an airway clinician through the larynx and through the TCF, if it is wide enough. The surgery needed to repair airway stenosis of the

trachea is out of the scope of this work, but many options exist including minimally invasive techniques that could enable a safe and effective widening of the airway to restore adequate patency for ongoing decannulation. Following such care, the fistula could be closed as described below. Until such surgery is performed, it may be safest to replace a small cannula through the fistula tract to secure the patients airway. In some patients with a borderline airway, a persistent TCF may actually be favorable as even a tiny TCF can be dilated under local anesthesia to accommodate a small metal or cuffless plastic tracheotomy cannula.

If the airway is not narrowed on endoscopic evaluation, the TCF can be closed in a variety of ways. An initial attempt at treatment can include thorough cautery of the tract in clinic with silver nitrate, which can induce inflammation in the tissues and remodeling that can at times lead to TCF closure. Our surgical technique involves dissection around the TCF tract in a circular pattern down to the entry into the airway, followed by a Connell-type stitch to invert a small cuff of skin into the airway. The wound is then closed over three layers with reapproximation of the strap muscles to midline, deep dermal closure, followed by skin closure. It is our practice to perform these procedures under MAC with the patient spontaneously breathing, and to always place a small rubber band drain into the wound that remains in until follow-up in clinic. This drain functions as a pressure release valve if the patient should cough or sneeze, allowing egress of air out of the wound and preventing subcutaneous emphysema and possible pneumothorax. If a pinpoint TCF persists at the drain site in follow-up, this can often be treated with silver nitrate of simple suture overclosure.

Emergency Airway Surgery—Tracheotomy and Cricothyrotomy

Multiple techniques exist for emergency airway access, all with the expressed goal of stabilizing the emergent airway while minimizing laryngeal injury. It is certainly appropriate to perform an urgent awake or sedated tracheotomy under emergency circumstances in order to avoid cricothyrotomy and potential laryngeal injury. In an emergent airway scenario, the patient’s anatomy, overall condition, and/or surgeon experience may preclude tracheotomy and therefore emergent cricothyrotomy is an acceptable alternative for securing the airway in this circumstance. This decision is often based on the ability to maintain a mask airway during patient stabilization. Time lost in getting the airway

secured can cause profound anoxia and subsequent dire consequences. The finest operation in the world to gain access to the airway that is clean and well dissected but too slow to maintain a life is of no value in this circumstance. There is one goal and one goal only: to sustain the patient's life. The one which gets the clinician to that goal fast enough is the right choice.

Surgical neck access can be very challenging in the emergency airway patient. The maxim passed down from surgeon to surgeon in this situation is first to "take your own pulse," and keep a calm and deliberate demeanor. Once the decision has been made to establish a surgical airway, the airway surgeon should be able to obtain it in 1 to 2 minutes. The situation usually dictates that the patient is at points being mask ventilated, going through repeated efforts at intubation, and getting chest compressions. The surgeon may want to place their nondominant hand on the neck with the palm under the patient's chin to extend the head and draw the trachea out of the chest (Fig. 37.7). The same hand may then be used to stabilize the airway by putting the index and third fingers on either side of the trachea/larynx so as to put pressure on the paralaryngeal soft tissues and establish the midline of the neck. This also reduces the disruptive effect of the compressions on defining the surface landmarks of the airway. Once the airway is identified a midline vertical cut is used to open the skin over the CTM. This midline incision tends to avoid the anterior jugular vessels and may lessen hemorrhage. This also splays the edges of the incision laterally because of the pressure of the fingers of the nondominant hand applied to trap the airway. The dominant hand can then be used to palpate the laryngeal landmarks to verify what was felt through the skin. Note that in a male, the thyroid notch is the most prominent anterior laryngeal landmark, while in a female it is often the cricoid cartilage. The next knife cut is into the airway either through the trachea or the CTM. The channel is palpated and when performing a tracheotomy, the nondominant index finger is placed into the airway guiding the tube caudad. A hemostat is also very useful to open the airway widely and facilitate passage of a small ETT (5.0) into the airway. If passing the tube through the CTM is difficult, a tube exchanger or stylet can be used to accomplish this. The opening into the trachea or CTM can also be enlarged using a tracheal spreader or hemostat to allow the ETT to pass. In most emergency circumstances, a small ETT will be placed at the time of intervention, and the patient will be taken to the OR immediately for conversion to a standard tracheotomy.

In any emergency situation, the actions of the surgeon and anesthesia team are truly life-saving, and any subsequent injury or damage to the larynx in this situation are absolutely allowable secondary to preserving life.

Percutaneous Dilatational Tracheotomy

PDT is a newer technique in tracheotomy that is minimally invasive and kit based (Fig. 37.8). It is indicated for nonemergency situations and designed for bedside care in an ICU setting. It is commonly performed with bronchoscopic airway lumen visualization through the existing ETT. This approach has dramatically altered bedside airway care in many parts of the world and is rapidly gaining popularity in the United States and Asia. Regardless of the technique, taking a critically ill patient to the OR for a tracheotomy not only removes them from the location where he/she is best cared for, but also adds additional risks related to the need to transport them some distance away, rolling their IV pole(s) and their ventilator with them. The costs associated with OR tracheotomy are very high when OR time is taken into account along with the personnel costs of the transport team and those in the OR for the surgery itself. Bedside tracheotomy has the advantage of being performed in the ICU obviating all of the costs unrelated to the procedure itself. If done in the ICU by the open technique, there is the disadvantage of needing to essentially bring the OR to the bedside. With head lights and OR trays, a cautery device, and drapes; tracheotomy can be performed in a manner similar to that which is performed in the OR itself. According to the advocates of this approach, this is done in the event that a deep exploration of the neck is needed to control a bleeder that might retract into the surrounding tissues. There are some clinicians who also perform PDT in the operative setting due to the convenience and decreased operative time.

Kit-based PDT techniques, by contrast, are based on the surface incision of skin with the blunt dissection of the superficial tissues to gain access to the tracheal wall. The operating clinician navigates through the procedure by seeing on a video monitor the effect of the manipulation of the soft tissues overlying the airway. When performed by the typical PDT technique or T-PDT, a bronchoscope is used to get the existing ETT repositioned so that the tip of the tube is at or just above the likely entry point of the trachea as viewed from within the lumen of the airway. This is in reality, a controlled partial extubation and will limit the minute ventilation of some patients significantly. Most patients with high positive

end expiratory pressure (PEEP) needs or high minute ventilation needs will not tolerate this procedure due to this, and it may therefore be a contraindication to PDT. Inadvertent complete extubation can occur and may be followed by difficulty in finding the airway and the potential for dire consequences, even death. While complications on this scale are rare, the potential for this scale of adverse outcome has made the adoption of this otherwise safe and effective technique slow. This has been particularly the case by the one specialty most commonly involved in tracheotomy, the Otolaryngologists.

Figure 37.7. Emergency airway surgery handhold technique. **A.** Side view of the neck anatomy with markings indicating the relevant anatomy such as the thyroid notch, the cricoid, and the thoracic inlet. The vertical mark above the thoracic inlet is the planned skin incision. **B.** Lateral view of the handhold placed on the airway to stabilize it and isolate the trachea in the context of a resuscitation procedure. **C.** Oblique view identical to "B." **D.** *En face* view of the procedure as it could be performed with the scalpel ready to incise the trachea. The left hand could sit over a bag mask being used to ventilate the patient.

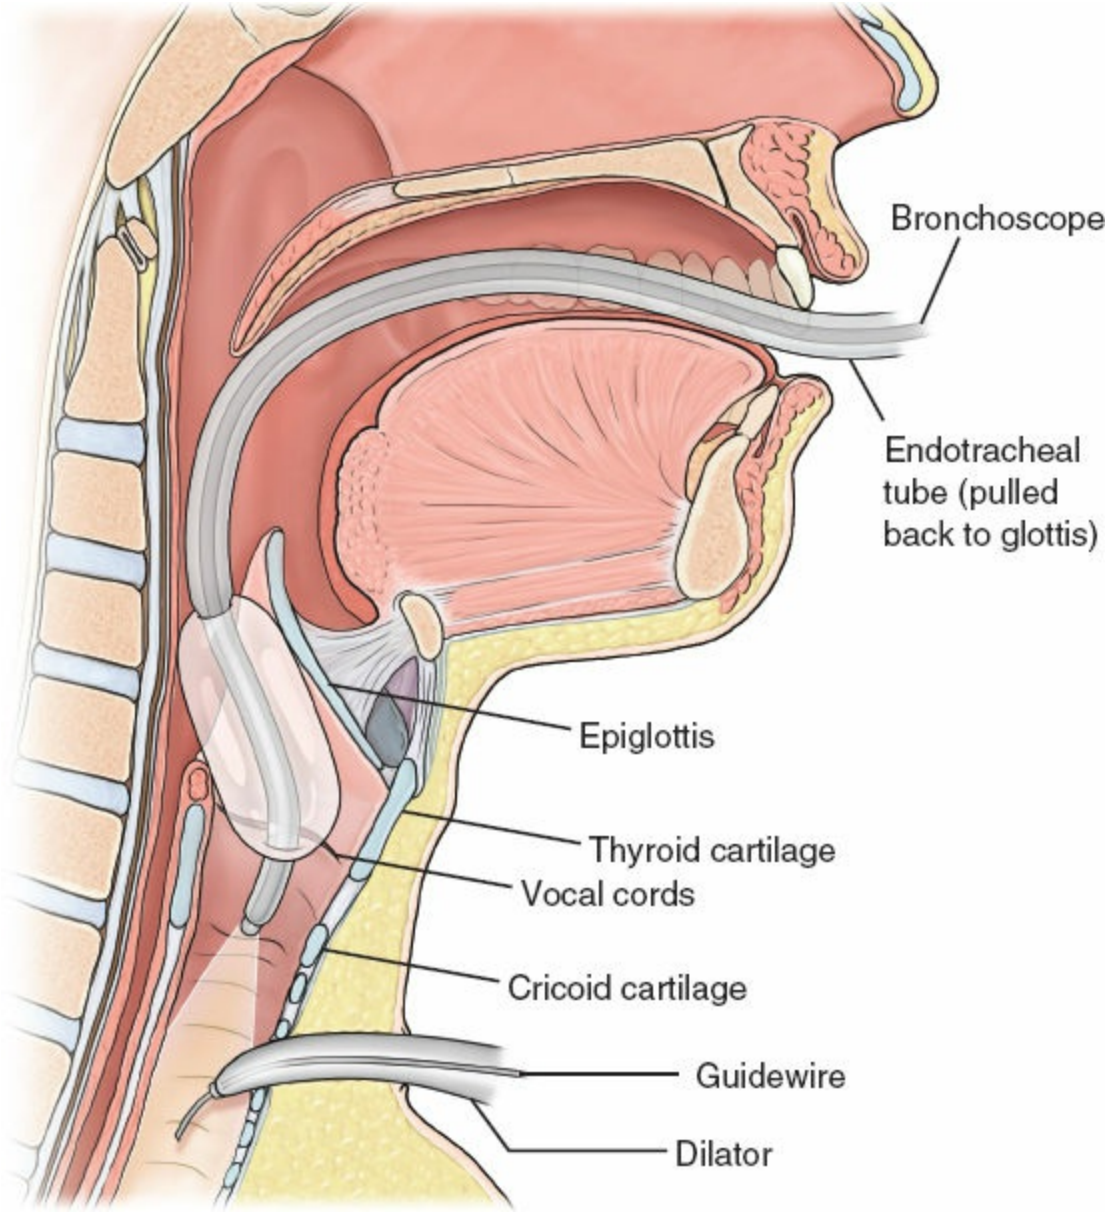

Figure 37.8. Anatomy and instrumentation of the typical or "traditional" percutaneous dilatational tracheotomy technique with the flexible bronchoscopic image of the inside of the airway, the guide wire entering the airway ahead of the dilator in the area that is transilluminated. (Modified from Weissler MC, Couch ME. Tracheotomy and intubation. In: Bailey BJ, Johnson JT, Newlands SD, eds. *Head and Neck Surgery—Otolaryngology*, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Numerous prospective cohort studies and randomized controlled trials have investigated the safety and efficacy of open surgical tracheotomy versus PDT techniques in critically ill patients. A recent Cochrane systematic review concluded that there appears to be some benefit in terms of PDT effectiveness and safety specifically as it relates to number of peri-

and postoperative non–life-threatening adverse events, rates of wound infection, and unfavorable scarring. There is no compelling evidence that PDT offers any advantage over traditional open techniques with respect to postoperative mortality, rates of serious postoperative life-threatening events, and rates of major bleeding. Unfortunately, many studies exclude patients with unfavorable anatomy or "difficult" anatomy, prior airway problems, coagulopathies, and those requiring emergent tracheostomy therefore limiting how generalizable these findings are for critically ill adults in an ICU setting. In practice, PDT is often reserved for patients who are assumed to be an "easy" tracheotomy due to body habitus, airway anatomy, and ventilator settings, and it is perhaps best used for that patient population.

Recently, a new approach to PDT known as suspension laryngoscopy-assisted PDT (SL-PDT) has been introduced to the Otolaryngology community (Fig. 37.9). This technique differs from T-PDT in that a suspension laryngoscopy system is used to secure the airway such that there is no way for the airway to be lost or the patient inadvertently extubated because of the very nature of suspension laryngoscopy. The airway is trapped by the orifice of a rigid laryngoscope and elevated with a device designed to fulcrum the scope against the maxilla and a second surface, commonly the patient's tray table. A new foreshortened (cut off at 20 cm) ETT is then passed into the airway through the rigid laryngoscope and the balloon is inflated within the scope and the upper larynx so as to seal the airway within the ventilatory circuit. This enables the delivery of the requisite tidal flow with the entire PEEP the patient needs. The internal view of the airway is accomplished by a 30 cm × 5 mm rigid telescope. Thus, the whole operation can be performed with the patient adequately ventilated. There is, therefore, no rush to locate the ideal position through which to enter the airway since there is no significant potential for desaturation. In addition, should the patient become unstable for any reason, the procedure can be safely aborted without any undue risk to the patient. A fresh full-length ETT can simply be placed into the laryngoscope beyond the airway entry point even if the airway has already been opened through the skin.

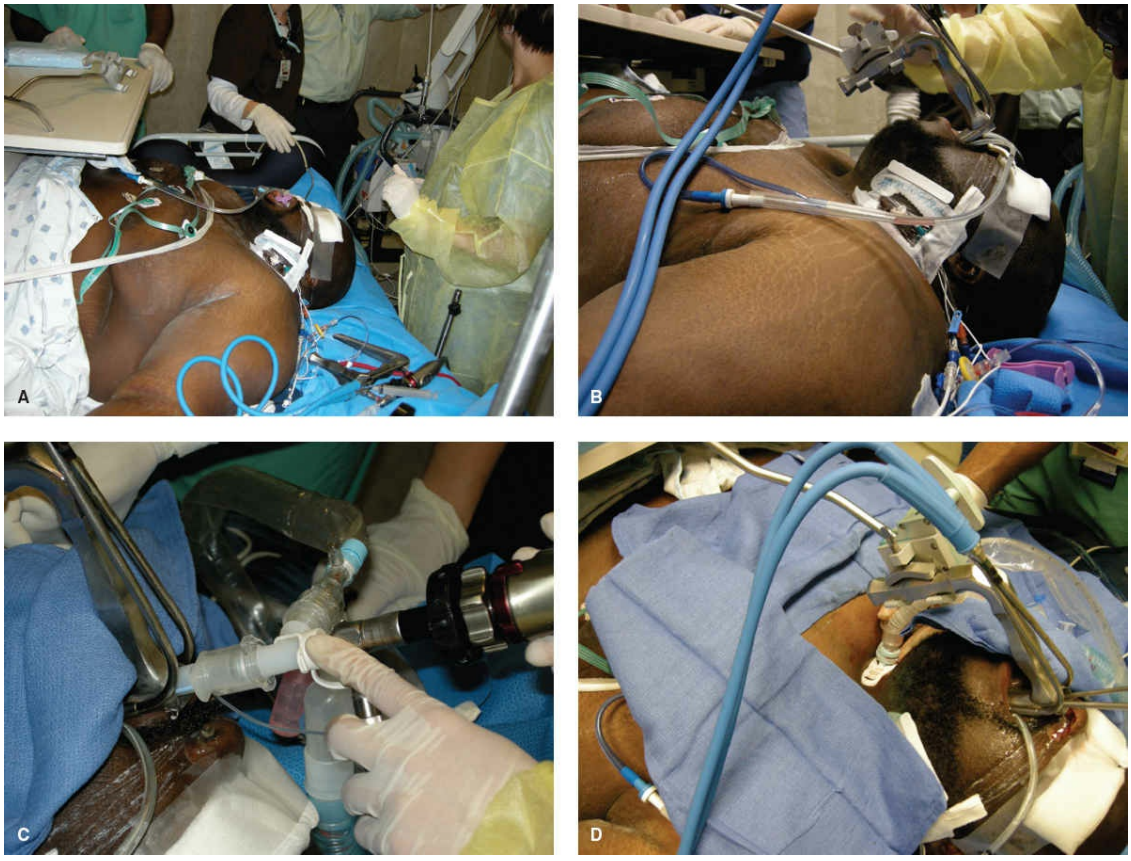

Figure 37.9. These images are of a morbidly obese patient, the type of whom who can be treated safely with this technique given sufficient expertise with the rigid laryngoscopy part of the procedure. This particular male was mechanically ventilated for several weeks but considered too unstable to be transported to the OR for his tracheotomy. It was performed uneventfully at bedside using the SL-PDT technique. **A.** The general view of his body habitus at bedside. **B.** The Storz Dedo laryngoscope in place and extending his neck backward and his airway closer to the surface. **C.** A close-up view of the laryngoscope, telescope, and ventilating endotracheal tube assembly. **D.** The #8 Shiley XLT Proximal extra length cannula in place ventilating the patient while the Dedo laryngoscope is still in place to make sure that there is no internal airway bleeding or other problems that need to be dealt with prior to the conclusion of the procedure.

Both the T-PDT and the SL-PDT techniques may have a role to play in a comprehensive multispecialty ICU airway program; T-PDT applying to roughly half of ICU patients who need a tracheotomy but have no special ventilatory needs such as high PEEPs, have easy-to-feel landmarks, have an easily accessible segment of trachea, and no history of challenging airway anatomy. The remainder of patients, including those with high

BMIs, poor landmarks, low larynges, prior neck surgery, and even neck tumors, anasarca, or other types of generalized edema and high/challenging ventilator may benefit from SL-PDT or referral to the OR for formal operative tracheotomy. The contraindications to SL-PDT include patients with trismus, uncertain C-spine disease or kyphoscoliosis, and/or the inability to tolerate a general anesthetic.

The main complications of PDT are well known, and have lessened ongoing enthusiasm for this approach among many otolaryngologists. The anterior jugular venous network can be extensive in some patients, and marked hemorrhage can be induced by PDT techniques requiring operative intervention. This is often due to repositioning of the PDT dilator or "second attempts" at passing the dilator wires into the trachea. Hemorrhage is also common from injury during transection of the thyroid isthmus without ability to provide direct cautery or vascular control. In addition, perforation through the posterior tracheal wall into the esophagus or nonmidline tracheal placement causing eccentric stenosis is also a possible issue. Careful visualization of the dilators and tracheotomy tube using either T-PDT or SL-PDT technique is of paramount importance to avoid these issues.

In conclusion, tracheotomy is a very important intervention to protect or establish the airway and there are many approaches, each of which has its advantages and risks. Open surgery in the OR is the best way to fashion a surgically matured tracheal "stoma." Emergency airway surgery has to be performed as quickly as it is performed effectively. The technique presented here is one that will enable this result. Tracheotomy in an ICU patient is best done at the bedside with a kit-based system and without leaving the unit. ICU patients with contraindications to T-PDT can safely have an SL-PDT operation and get a thorough airway evaluation in the process.

EDITOR'S COMMENT

Almost any surgeon could be called upon to perform an emergency airway. About once a year or so I find myself in a room watching an anesthesiologist struggle to attain and to maintain the airway of a recently induced patient about to undergo surgery. These patients are often obese, and I find my mind wandering to recall what I know about the surgical landmarks of the neck and the best way to attain a surgical airway without haste. These are anxiety-provoking situations to say the least. While the vast majority of us will never need to perform an emergency airway, it is a great idea to be familiar with the techniques and pitfalls described so eloquently in the chapter by Dr.'s Bock and Little.

As a GI surgeon who deals mostly with patients undergoing elective surgery for benign disease, I rarely care for patients who have or ultimately need a tracheostomy. Most of my patients for whom we ultimately need to have a discussion about a new tracheostomy have experienced some sort of significant postoperative complication and will likely require prolonged intubation and ventilation as a result. For a surgeon dealing with the stress and anxiety that comes with a major complication in one of your patients, it can be difficult to wrap one's head around the fact that things are bad enough that a tracheostomy is the next step. In this chapter there is some excellent information and data to help those of us who occasionally struggle with these issues to understand the importance of considering and moving forward with a tracheostomy at the appropriate point in time.

The data on early versus late tracheostomy in critically ill patients is mostly equivocal. There have been quite a number of randomized, controlled clinical trials and several subsequent systematic reviews and meta-analysis of these trials. Metrics often evaluated in these trials include mortality, ventilator-associated pneumonia rates, duration of mechanical ventilation, and length of

ICU stay. Early versus late tracheostomy is variably defined, and 7 or 10 days are the most commonly used time points after laryngeal intubation used as cutoffs. A systematic review and meta-analysis published in 2015 in the Lancet Respiratory Medicine journal examined 13 trials in more than 2,400 patients to undergo early (<7 days), late (>7 days), or no tracheostomy. The primary outcome of interest was mortality and pneumonia. While an effect on mortality was not observed, the incidence of ventilator-associated pneumonia was lower in mechanically ventilated patients assigned to the early versus the late or no tracheostomy group (Odds Ratio 0.60, 95% CI 0.41–0.90; $p = 0.01$). Another systematic review and meta-analysis including nine trials and more than 2,000 patients published in 2016 used 7 days as the cutoff for early versus late tracheostomy. The results of this meta-analysis suggested that early tracheostomy might be able to reduce the duration of sedation but did not significantly alter the mortality, incidence of ventilator-associated pneumonia, the duration of mechanical ventilation, or the length of ICU stay. A Cochrane Database Systematic Review published in 2015 included eight randomized trials and nearly 2,000 patients. Early tracheostomy was defined as tracheostomy within 10 days. The authors of this review concluded "The whole findings of this systematic review are no more than suggestive of the superiority of early over late tracheostomy because no information of high quality is available for specific subgroups with particular characteristics." In other words, there are likely certain patients much more likely to benefit from early tracheostomy than others. There are several additional systematic reviews and meta-analysis examining this issue published between 2014 and 2016. For the most part, these studies found little difference in outcomes for early versus late tracheostomy.

Tracheostomy is one of the most frequently performed surgical procedures in ICU patients. As many as 10% of patients requiring at least 3 days of mechanical ventilation will eventually receive a tracheostomy for prolonged mechanical ventilation or airway support. In addition to minimizing the risk of laryngeal trauma as well as glottic and subglottic stenosis by converting an ETT to a tracheostomy, there is some data to support that a tracheostomy is more comfortable for patients, requires less sedation, and is easier to maintain. Nonverbal communication can prove frustrating for patients with prolonged respiratory failure. Patient communication can be greatly enhanced following tracheostomy by use of specialized appliances that utilize an additional small diameter tube that expels gas above the cuff of the tracheostomy tube when the proximal end has been manually occluded. Limitations of this device include the requirement for manual occlusion and the frequent inability to speak in complete sentences.

Otolaryngologists and general surgeons most often perform open tracheostomy. Many patients who require a tracheostomy are also ideal candidates for a percutaneous endoscopic gastrostomy (PEG) tube placement. Concurrent placement of a tracheostomy and a PEG tube is often performed in the OR to decrease the cost, anesthesia time, and procedural time that would

otherwise be associated with performing both of these procedures in a staged manner in the same patient. For this reason, in many institutions general surgeons perform the majority of the open tracheostomies. The option of a percutaneous dilatational tracheotomy (PDT) has led a variety of specialists in nonsurgical disciplines to perform tracheostomy. In some hospitals, anesthesiologists, pulmonologists, and cardiac surgeons routinely perform PDT on their patients.

Although there are concerns that PDT is essentially a "blind" tracheal tube placement and associated with an increased risk of bleeding and other serious complications, these concerns have not been validated in the published literature. In a recently published Cochrane review on PDT versus open surgical tracheostomy, 20 trials from 1990 to 2011 enrolling 1,652 participants fulfilled the inclusion criteria. When compared to surgical tracheostomy, PDTs significantly reduced the rate of wound infection/stomatitis (moderate quality evidence) and the rate of unfavorable scarring (low-quality evidence due to imprecision and heterogeneity). In terms of mortality and the rate of serious adverse events, there was low quality evidence favoring PDT. In terms of the rate of major bleeding, there was very low-quality evidence that nonsignificant positive effects exist for PDT. "However, because several groups of participants were excluded from the included studies, the number of participants in the included studies was limited, long-term outcomes were not evaluated, and data on participant-relevant outcomes were either sparse or not available for each study, the results of this meta-analysis are limited and cannot be applied to all critically ill adults."

A tracheostomy is one of the earliest described procedures, having first appeared in Egyptian artifacts dating to 3600 BC. As our capacity to keep sicker patients alive has improved in recent decades, tracheostomy has become more commonplace. Recent advances in tracheostomy include new techniques for percutaneous access to the trachea that can be performed safely at the bedside in many patients. This chapter on tracheostomy outlines the challenges, pitfalls, pros, and cons of several different options in a highly informative and well-organized fashion. Even those surgeons who do not perform routine tracheostomy should familiarize themselves with the content in this book chapter.

SECTION IV

ENDOCRINE SURGERY

38 Surgical Anatomy of the Thyroid, Parathyroid, and Adrenal Glands

Clive S. Grant

Success in the surgical management of a patient can be conveniently divided into three phases: preoperative, intraoperative, and postoperative. Vitally important is the preoperative decision making and planning; an expertly performed operation for a wrong reason is still a bad operation. However, if the preoperative process is correctly conceived, at least in an elective procedure, a perfectly executed operation guarantees a smooth postoperative course in a high percentage of patients. The foundation for this operative success is a thorough knowledge of surgical anatomy. Anatomy to anatomists or pathologists is different from surgical anatomy. Because surgeons operate through limited incisions and must preserve function wherever possible, as well as control or prevent bleeding, the "anatomist's anatomy" must be applied from the surgeon's perspective. An attempt has been made to amalgamate the two forms of anatomy in the following sections to give a broad perspective (the anatomist's view as well as the perspective of the surgeon).

The surgical anatomy of the thyroid and parathyroid glands is so closely interrelated that much of what is important to one proves equally important to the other. Because of this overlap, the overall anatomic relationships of the region are covered in the Thyroid section, and the differences or additions as they relate specifically to parathyroid disease are noted in the Parathyroid section.

EMBRYOLOGY

From a median entodermal diverticulum on the ventral wall of the pharyngeal gut, in approximately the fourth week of embryologic development, the thyroid descends from the posterior tongue (foramen cecum) in front of the pharynx as a bilobed diverticulum. It initially remains attached to the pharynx by a hollow tube, the thyroglossal duct, which attaches to the foramen cecum. At the end of the second month, the

thyroid reaches its final position in front of the trachea; and the thyroglossal duct tissue, which has become solid, usually breaks up and disappears. Distal persistence of the solid duct is represented by the pyramidal lobe of the thyroid. If parts of the ductal epithelium persist, the secretion of the epithelium expands the remnant tube, which is closed at both ends, into a cystic mass filled with a colloid-like material—a thyroglossal duct cyst. It rarely has a connection either to the skin or the tongue unless it has been infected and drained or previously operated on. Cysts can develop anywhere along the course of the thyroglossal duct but are most typically found overlying the hyoid bone in the midline just above the thyroid cartilage. Adjacent to the primary persistent thyroglossal duct remnants, other smaller duct and mucus-secreting gland remnants are often found.

To prevent cyst recurrence, the duct and remnants can be encompassed in a core of tissues that should be excised from the cyst through the mylohyoid muscle to the base of the tongue, the site of the foramen cecum (Fig. 38.1). In addition, because the hyoid bone fuses in the midline in close proximity to the thyroglossal duct, the duct can pass either anterior or posterior, or even course through the bone. The central portion of the hyoid bone should, therefore, be excised as part of the operation for a thyroglossal duct cyst. Ectopic normal thyroid tissue or papillary thyroid carcinoma (PTC) can develop in a thyroglossal duct cyst or anywhere along the tract of the thyroglossal duct. Lingual thyroid represents a total failure of thyroid descent, in which the entire thyroid is located at the foramen cecum of the tongue, under the mucosa.

Contributing perhaps less than 1% of the eventual thyroid mass, yet critically important in considering thyroid malignancy, are the lateral thyroid anlagen. Originating from the fourth pharyngeal pouches, corresponding to the ultimobranchial bodies, they are responsible for production of calcitonin from the parafollicular or C cells. They fuse with the posterior and medial aspect of each thyroid lobe. Medullary thyroid carcinomas evolve from these small parts of the thyroid.

ANATOMY

An overall view of the anatomy relevant to thyroid and parathyroid operations is shown in Figure 38.2. For optimal surgical exposure, the patient is positioned with a small pillow placed between the scapulae, and the neck is hyperextended, bringing the thyroid gland as far anterior as

possible. The skin incision follows Langer lines transversely, optimally in a skin crease.

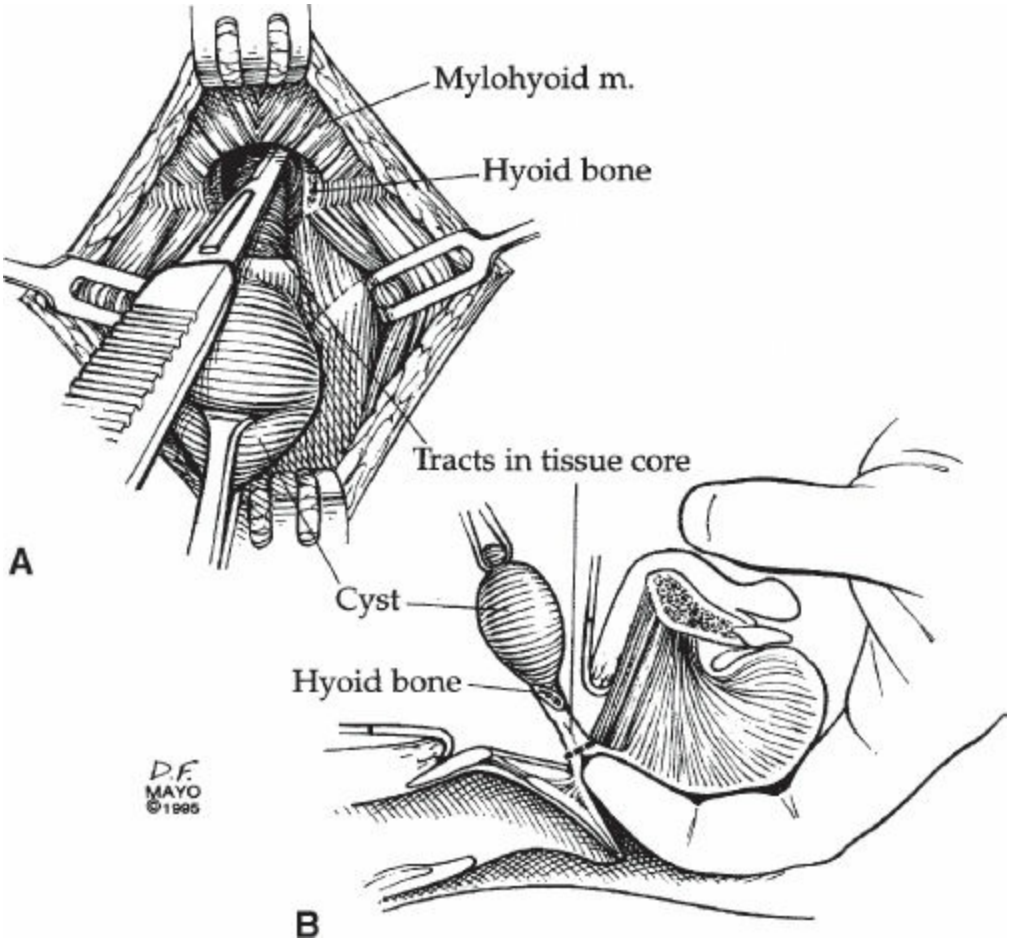

Figure 38.1. A: A thyroglossal duct cyst is excised from its usual location just above the thyroid cartilage, in the midline, overlying, or just inferior to the hyoid bone. The central portion of the hyoid bone is excised with the specimen, as is a core of muscle tissue encompassing duct tracts that lead to the former foramen cecum at the base of the posterior tongue. **B:** Lateral view showing the surgeon's finger through the patient's mouth positioned to assist excision of the tract at its origin.

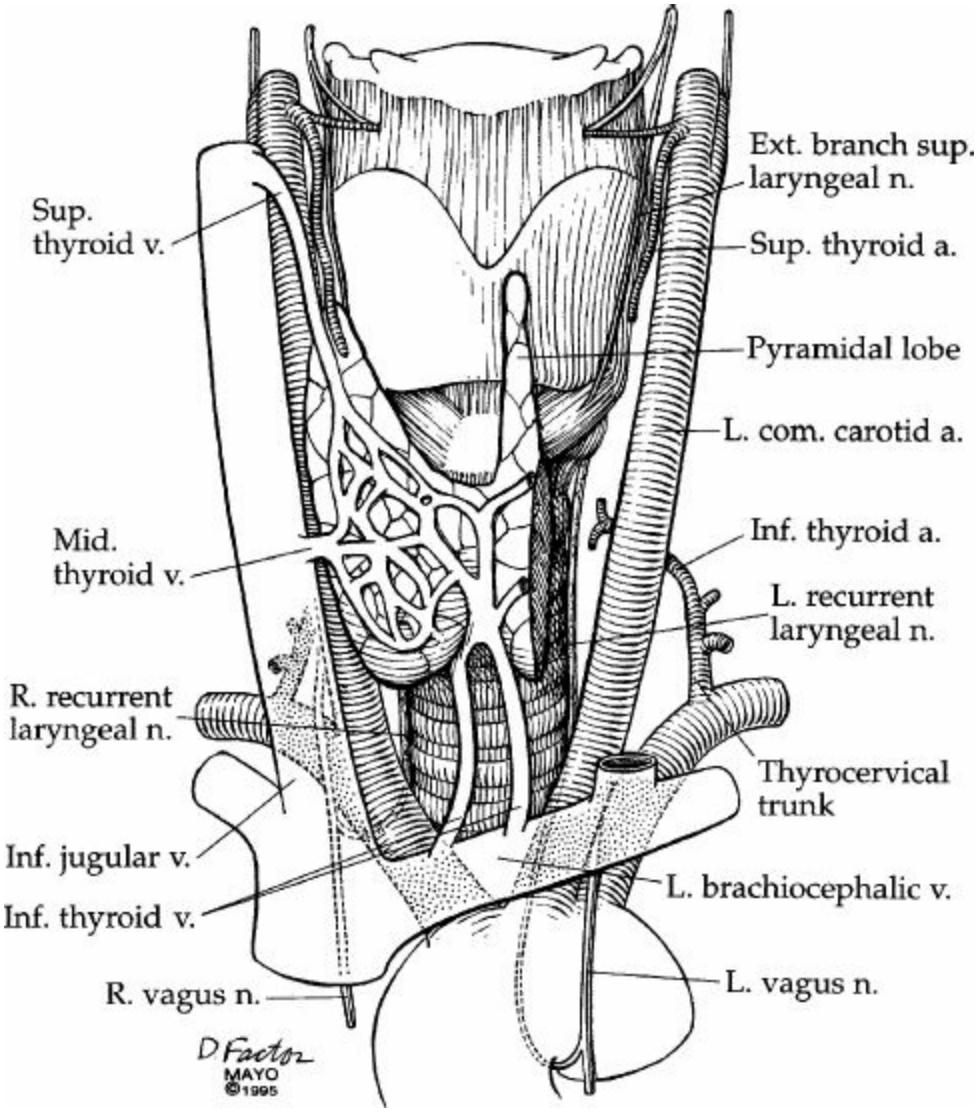

Figure 38.2. Overall anatomic relationships of the thyroid and surrounding structures. Note the course of the inferior thyroid artery, behind and perpendicular to the carotid artery. The superior thyroid artery and external branch of the superior laryngeal nerve run in close approximation.

Dissection of Muscles

Beneath the skin and subcutaneous tissue is the thin platysma muscle, under which is a relatively avascular plane. In this plane, the superior and inferior flaps can be raised with minimal blood loss. Once the flaps have been developed, the strap muscles—the sternohyoid and sternothyroid muscles—are exposed. The more anterior sternohyoid muscles lie close together, but the midline between them can be identified as a thin line of fat and avascular fascia. Dissection along this line to separate these muscles is facilitated by lifting the muscles anteriorly so as to avoid the

inferior thyroid veins, which course just below, running longitudinally over the trachea. Often bordering the midline along these muscles are the anterior jugular veins. These veins can be avoided but can be ligated as the need arises.

As the sternohyoid muscle is elevated, the underlying sternothyroid muscles are exposed. The fascia between these two muscles can be dissected for improved exposure. With the sternohyoid muscles retracted, as the sternothyroid muscle is dissected from the underlying thyroid lobes, care is taken to avoid the widely interconnecting venous network in the thyroid capsule. This caution is of particular importance in a larger goiter because the strap muscles can be thinned and splayed out across the bulging thyroid lobes and the large veins are in jeopardy. The insertion of the sternothyroid muscle into the thyroid cartilage can obscure the superior pole of the thyroid gland and can be partially transected for better exposure. Both the sternohyoid and sternothyroid muscles (as well as the omohyoid muscle) are innervated by the ansa cervicalis, derived from the hypoglossal nerve and C1 through C3. These muscles can be partially or completely removed as necessary for cancer operations without any significant disability. The cricothyroid muscles run obliquely from the cricoid cartilage to the thyroid cartilage and are innervated by the external branch of the superior laryngeal nerve. This muscle and nerve should be carefully preserved because they serve the important function of fine-tuning the voice.

VASCULAR ANATOMY

The principal arterial blood supply of the thyroid gland comes from the paired superior and inferior thyroid arteries, and, to a much lesser degree, the thyroidea ima (Fig. 38.2). Even when all these arteries are ligated, remnants of thyroid often survive from other small branches derived from laryngeal and tracheoesophageal arteries. The superior thyroid artery is the first branch of the external carotid artery and courses inferiorly to reach the superior pole of the thyroid gland. It often branches at this point, with the main branch running over the anterior surface of the superior pole of the thyroid and the other smaller branches entering more posteriorly. The inferior thyroid artery usually arises from the thyrocervical trunk, runs superiorly behind the carotid artery, and then arches medially to the thyroid gland, coursing either perpendicular to or in a recurrent path to the thyroid gland. The thyroidea ima artery is encountered in less than 10% of

patients and is almost never a relevant vessel except to ligate.

Dissection of Thyroid Lobe

Once the strap muscles have been dissected laterally, the thyroid gland is elevated anteriorly and medially, opening an areolar plane overlying the carotid artery and traversed by one or more small middle thyroid veins (Fig. 38.3). These veins are ligated and transected, and the space anterior to the carotid from the thyroid cartilage inferiorly to the base of the neck can be dissected safely. This step exposes the transversely directed inferior thyroid artery and the obliquely coursing recurrent laryngeal nerve (RLN), a branch of the vagus nerve, which, on the right, wraps around the subclavian artery and passes behind the carotid artery to ascend in the tracheoesophageal groove (Fig. 38.4). On the left, the RLN crosses the arch of the aorta, loops under it, adjacent and lateral to the ligamentum arteriosum, and ascends in the tracheoesophageal groove. Adjacent and mostly anterior to the RLN are the tracheoesophageal lymph nodes, which are a common site of metastasis in PTC and medullary thyroid carcinoma. Removal of these nodes requires care to protect the RLN; it should preserve not only the inferior parathyroid gland but also its blood supply, which usually crosses anterior to the RLN. Damage to the RLN on one side causes vocal cord paralysis and hoarseness and prevents complete closure of the vocal cords to protect the trachea. This incomplete closure results in choking, especially when the patient consumes fluids. Bilateral nerve injury jeopardizes the airway and usually requires at least a temporary tracheostomy. When the right subclavian artery anomalously originates directly from the aortic arch as its fourth branch, it passes behind the trachea and esophagus. The right recurrent nerve, therefore, does not recur around this artery and takes a direct course from the vagus nerve to the larynx (Fig. 38.5). In this instance, although it emerges posterior to the carotid artery, its perpendicular course mimics the usual course of the inferior thyroid artery and must be distinguished from it.

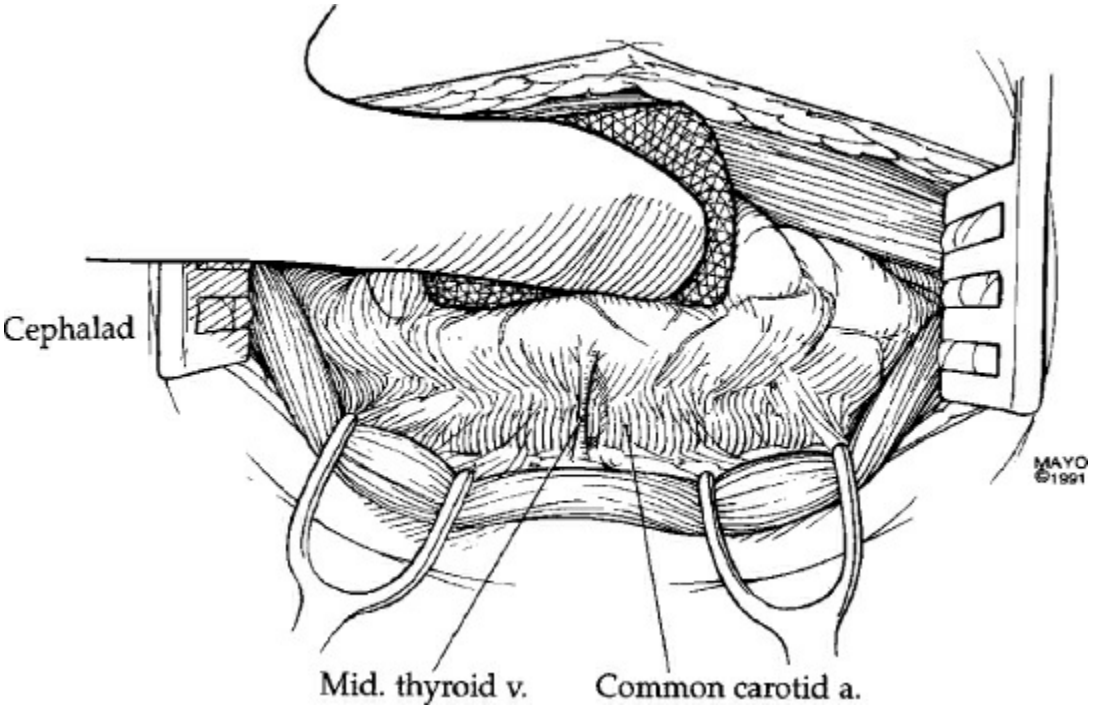

Figure 38.3. With traction laterally on the strap muscles that have been separated in the midline, but not transected, and countertraction on the thyroid medially, the middle thyroid vein is exposed. It runs anterior to the carotid artery and should be transected. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

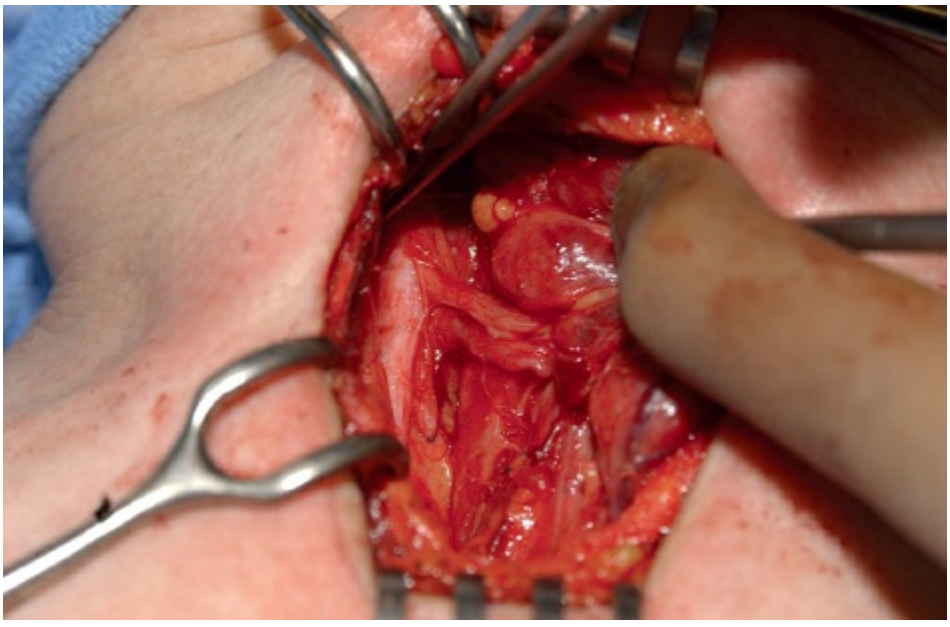

Figure 38.4. A nonrecurrent, recurrent laryngeal nerve (on the

patient's right side) courses directly from the vagus to its insertion at the cricothyroid membrane.

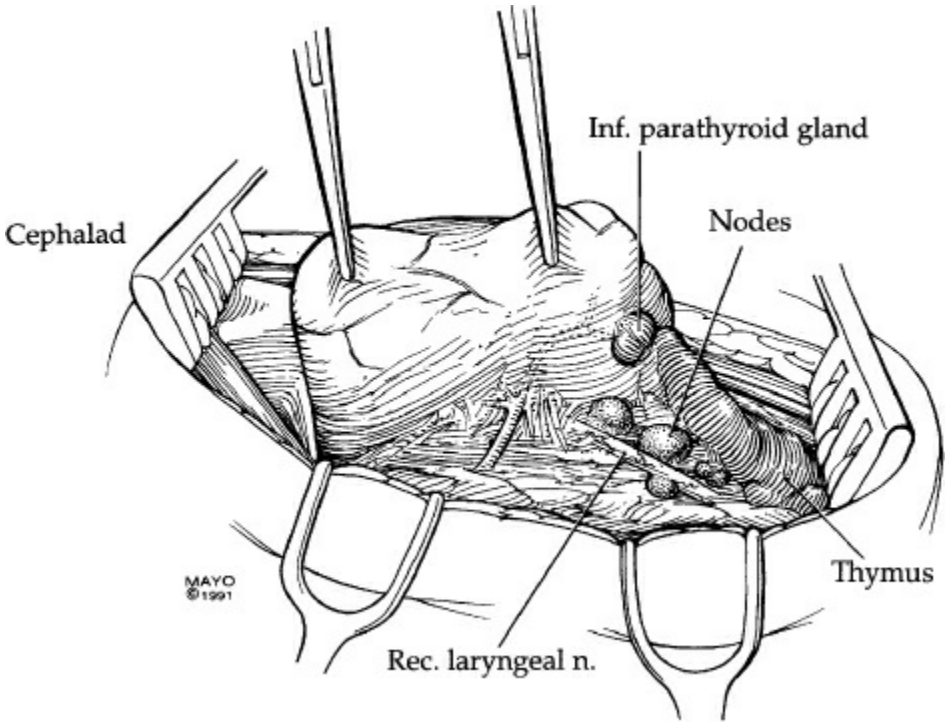

Figure 38.5. The right thyroid lobe is retracted anteriorly and medially, and the recurrent laryngeal nerve is exposed, coursing obliquely in the tracheoesophageal groove and surrounded by lymph nodes. The thymus lies anterior to the nerve and nodes and can contain or point to the inferior parathyroid gland. The superior parathyroid gland is not yet adequately exposed. The intersection of the inferior thyroid artery and the recurrent (rec.) laryngeal nerve is marked by branches of the artery, one crossing the nerve that serves the inferior parathyroid gland. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

The inferior thyroid artery is usually the principal blood supply to both the superior and inferior parathyroid glands. These feeding vessels are small and fragile, often traveling in a course parallel, if not slightly anterior, to the parathyroid glands before reaching the vascular hila (Fig. 38.6). As the inferior thyroid artery intersects with the RLN, it usually branches into superior and inferior trunks. The superior trunk typically divides again with one branch anterior and another posterior to the RLN.

The inferior thyroid veins run vertically, anterior to the trachea, and are easily identified and controlled during the course of thyroidectomy. Accompanying these veins are the pretracheal lymph nodes, both infra- and supraisthmic (Delphian), which often contain metastatic thyroid cancer.

The superior thyroid artery and vein, which are sacrificed during thyroidectomy, must be separated from the external branch of the superior laryngeal nerve. Placing inferior and lateral traction on the superior pole of the thyroid gland usually distracts the artery away from the nerve, and the artery can be cleanly isolated and individually ligated (Fig. 38.7).

Once the vascular branches to the thyroid lobe have been transected and the nodes cleared, the posterior capsule of the thyroid is all that remains before the lobe is completely removed. To re-emphasize, a small vessel regularly courses in this dense posterior capsule (Berry ligament), and the RLN is also commonly tethered anteriorly. Gentle dissection will expose the vessel for ligation and push the RLN down and out of danger before the ligament is transected.

In addition to the pretracheal and tracheoesophageal lymph nodes already mentioned, thyroid cancer often metastasizes to lateral nodes. The routes of spread roughly follow the venous drainage. Cancers of the upper lobe, in addition to the primary drainage to the supraisthmic nodes, can involve the midjugular nodes, both anterior and lateral to the internal jugular vein (IJV), and occasionally extend superiorly along the vein to the base of the skull. Cancers of the mid- and lower thyroid lobes drain initially into the pretracheal and tracheoesophageal nodes, then to the mid- and lower jugular nodes and anterior mediastinal nodes.

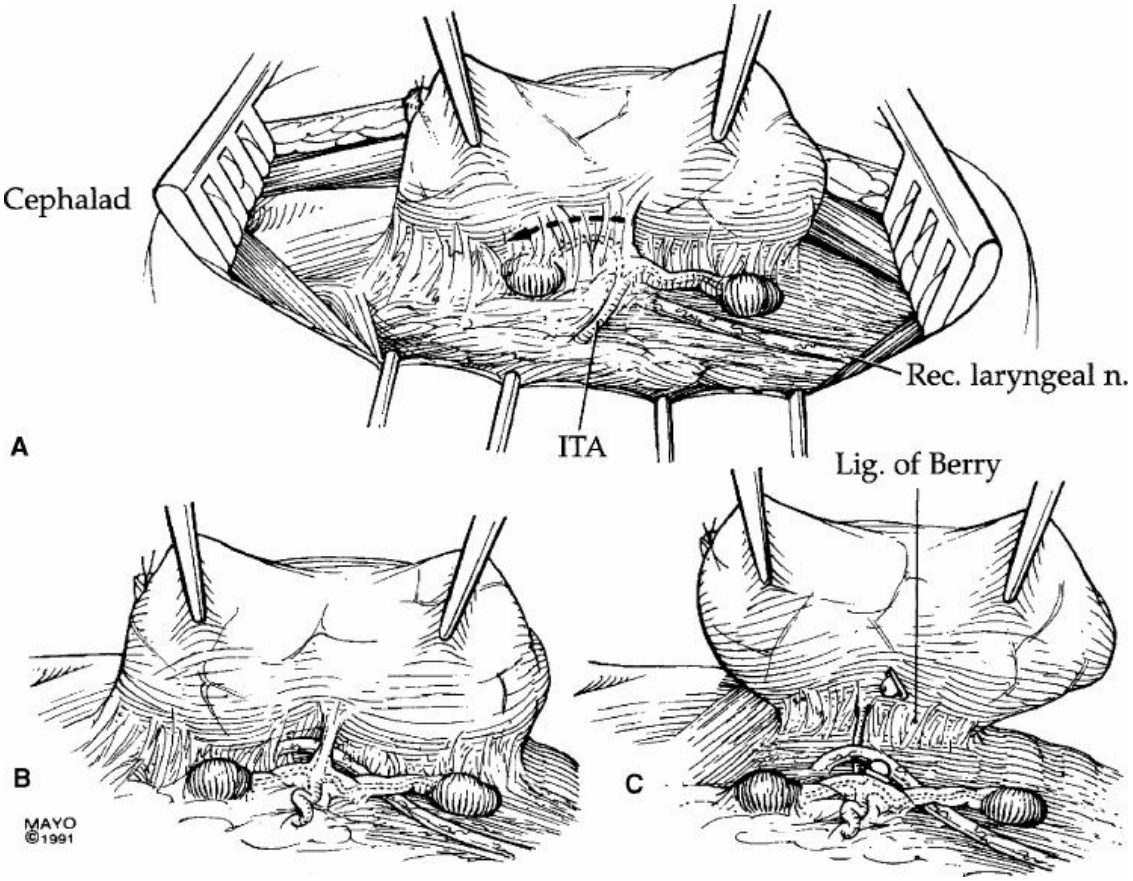

Figure 38.6. A: The small vessels feeding the parathyroid glands often run at least parallel if not slightly anterior to the glands. **B:** The surgeon can usually preserve these vessels by gently dissecting them and the parathyroid glands from the surface of the thyroid gland. **C:** Two significant branches of the inferior thyroid artery (ITA) are routinely present, one traveling anterior and the other posterior to the recurrent (rec.) laryngeal nerve. The coalescence of the dense posterior thyroid capsule constitutes Berry ligament (lig.), through which the posterior arterial branch courses. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

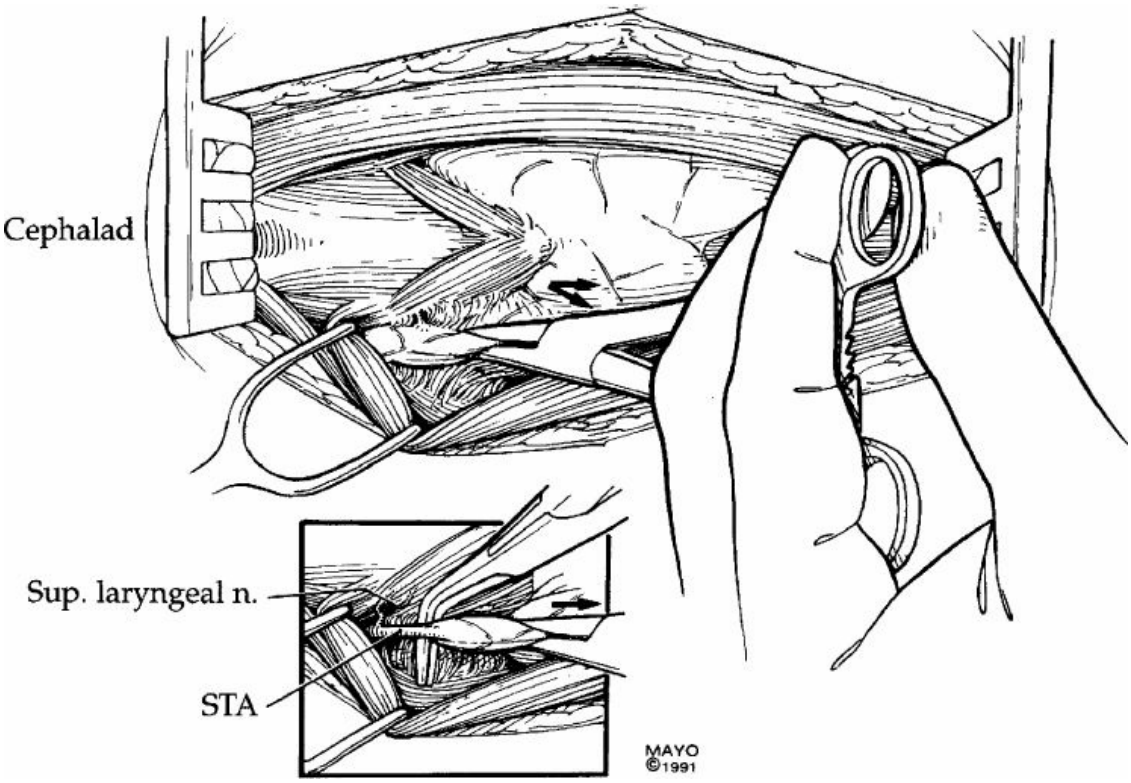

Figure 38.7. With traction inferiorly and laterally on the thyroid lobe, the superior thyroid artery (STA) can be displaced from its closely associated external branch of the superior laryngeal nerve. The artery is thereby transected individually, and the nerve is preserved (*inset*). (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

Modified Radical Neck Dissection

Important in the surgical management of papillary, medullary, and in some Hürthle cell carcinomas, lymph node metastases to the lateral internal jugular lymph nodes will necessitate a lymphadenectomy. Depending upon the extent of the dissection, various descriptive terms have been applied including regional, functional, selective, and modified radical neck dissection. Perhaps more important is the thorough, *en bloc* approach, and the neck *compartments* dissected. The anatomic boundaries of Compartments I to VI are summarized in Table 38.1, and graphically illustrated in Figure 38.8. Rarely used in thyroid cancer surgery is the classic radical neck dissection that implies sacrifice of the sternocleidomastoid muscle (SCM), IJV, and the spinal accessory nerve. In

addition, the submandibular triangle is virtually never dissected for thyroid cancer. Whereas in medullary thyroid carcinoma and node-positive Hürthle cell carcinoma, thorough dissection of Compartment VI is advised, controversy exists as to the extent and indications for this compartment dissection in papillary cancer.

Whether a standard collar incision is extended vertically along the anterior border of the SCM, or a separate transverse incision is made higher in the neck, extensive subplatysmal flaps are developed.

Compartments III, IV, and the Anterior Aspect of Compartment V

The dissection proceeds with dissecting the plane between the SCM and the strap muscles exposing the omohyoid muscle that is conveniently sacrificed (Figs. 38.9 and 38.10). This uncovers the lower aspect of the IJV and adjacent carotid sheath structures (carotid artery medially, IJV laterally, and vagus nerve posteriorly between the other two). The lymph nodes to be removed extend from the base of the neck inferiorly, behind the clavicle and slightly behind the IJV anteriorly, and laterally behind the SCM. Retracting the IJV anteriorly and medially (protecting the adjacent vagus nerve), areolar tissue is easily dissected laterally down to the floor of the neck onto the prevertebral fascia extending laterally as the fascia overlying the anterior scalene muscle (Figs. 38.11 and 38.12). Running vertically on the anterior scalene muscle is the phrenic nerve that is crossed low in the neck by the transverse cervical artery (Fig. 38.13A,B), a branch of the thyrocervical trunk. This artery may be sacrificed, but care must be taken to preserve the phrenic nerve. The lateral border of the IJV may be used as a guide to dissect inferiorly, but it will join the subclavian vein, and on the left side, the thoracic duct. This duct runs adjacent to the esophagus in the chest, coursing up behind the carotid sheath structures, and loops up a short distance from medial to lateral behind the IJV, and then enters the subclavian vein near its junction with the IJV. Nodes near the clear-fluid–containing duct are commonly involved in thyroid cancer, and the duct is very vulnerable to injury. In adults, if injured, the thoracic duct may be ligated without harm. The dissection across the base of Compartment IV at the level of the clavicle is usually safe with only relatively small veins requiring control. After releasing the inferior attachments, and with dissection superiorly along the lateral border of the IJV, and safely elevating the packet of lymph nodes from the anterior scalene muscle, the packet of nodes and soft tissue can be retracted anteriorly, putting tension on the posterior attachments behind the SCM.

Dissecting from inferior to superior, the cutaneous cervical plexus nerves (C2 to 4) will be encountered as substantial nerves coursing obliquely down behind the SCM (Fig. 38.14A,B). With care, these nerves can be preserved without jeopardizing a good nodal dissection. Deeply situated at the inferior and lateral aspect of the dissection, coursing from behind the anterior scalene and in front of the middle scalene muscles are the brachial plexus trunks. The superior border of Compartment III is defined as the level of the hyoid bone or carotid bifurcation. Not infrequently, lymph nodes, located anterior to the carotid artery at the level of the bifurcation, are metastatically involved and may be overlooked if not intentionally sought.

TABLE 38.1 Compartments of Neck and Levels of Cervical Lymph Nodes

Level (Compartment)	Location
I (Submandibular triangle)	Bounded by anterior and posterior bellies of digastric muscle and inferior ramus of mandible.
II (Upper jugular)	Extending from base of skull to bifurcation of carotid artery or hyoid bone. The posterior border of IA is the spinal accessory nerve (C. XI), and of IB is the sternocleidomastoid muscle. Anterior border of compartment is sternohyoid muscle.
III (Middle jugular)	Inferior border of Level II to omohyoid muscle or cricoid cartilage; anterior borders same as II.
IV (Lower jugular)	Inferior border of Level III to clavicle; anterior and posterior borders same as II and III.
V (Posterior triangle)	Bounded by clavicle inferiorly, trapezius muscle posteriorly, sternocleidomastoid anteriorly and medially.

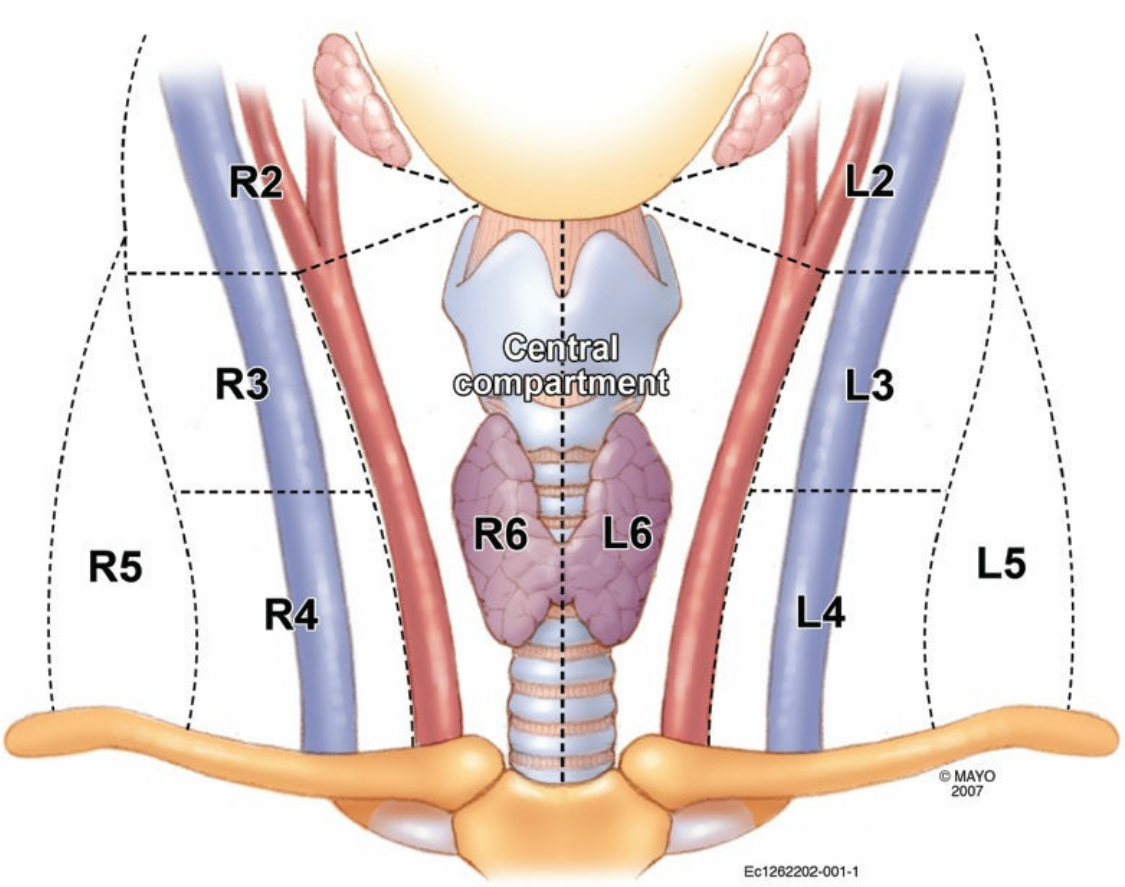

Figure 38.8. Anatomic compartments of the neck.

Compartment II

Superior to the cervical plexus nerves, coursing obliquely inferiorly and laterally from under the posterior belly of the digastric muscle is the spinal accessory nerve (Nerve XI). If dissection is carefully conducted with low-power cautery, stimulation of the nerve will cause contraction of the SCM and trapezius muscles with sudden movement of the shoulder. Further dissection with standard instruments will uncover the nerve where it can be traced cephalad and the associated lymph nodes cleared from Compartments IIA (anterior to the nerve) and IIB (posterior to the nerve), if necessary. At this level, several important structures emerge deep to the posterior belly of the digastric muscle. These include the carotid sheath structures, Nerve XI, the sympathetic chain behind the carotid artery, and the hypoglossal nerve (C XII) turning anteriorly, hooking under the arterial branch to the SCM off of the occipital artery. If dissection is kept along the lateral border of the IJV, C XII should not be encountered. Its descending branch, the ansa cervicalis (innervating strap muscles), descends anterior to the carotid artery and may be identified and sacrificed lower in the neck

(level of the omohyoid muscle).

EMBRYOLOGY

The parathyroid glands develop from Branchial Pouches III and IV. The superior parathyroid glands develop from Pouch IV, travel a shorter distance than the inferior glands, and are typically located along the posterior border of the thyroid gland at approximately 1 cm superior to the entrance of the inferior thyroid artery (Fig. 38.6A). Because of this location, when the superior glands descend further, they almost always remain posterior, in the tracheoesophageal groove or retroesophageal space (Fig. 38.15). Even when located quite low in the posterior superior mediastinum, they can still be retrieved through a collar incision.

In conjunction with the thymus, the inferior parathyroid glands develop from Pouch III and descend to the posterior aspects of the lower pole of the thyroid gland. This long descent gives rise to a much more variable position for the inferior parathyroid than for the superior gland. The location of the inferior gland can range from being high, anterior to the carotid artery (the so-called undescended parathymus), to being in the anterior mediastinum within the thymus, necessitating sternotomy for retrieval (Fig. 38.15). Inferior glands associated with the thyroid gland usually remain ventral to the RLN, whereas the superior glands are found dorsal to the nerve. The usual home for the inferior glands is on the posterolateral surface of the thyroid gland, just above, at, or within the attached remnant of the cervical thymus, the so-called thyrothymic ligament (Fig. 38.4). Rarely, this combined descent of parathyroid and thymus can be trapped within the carotid sheath, which might become relevant and evident only when the parathyroid gland is enlarged and hyperfunctioning. Moreover, because of the relationship between the thymus and the developing heart, these aberrant parathyroid glands can be located adjacent to the origin of the great vessels from the aorta.

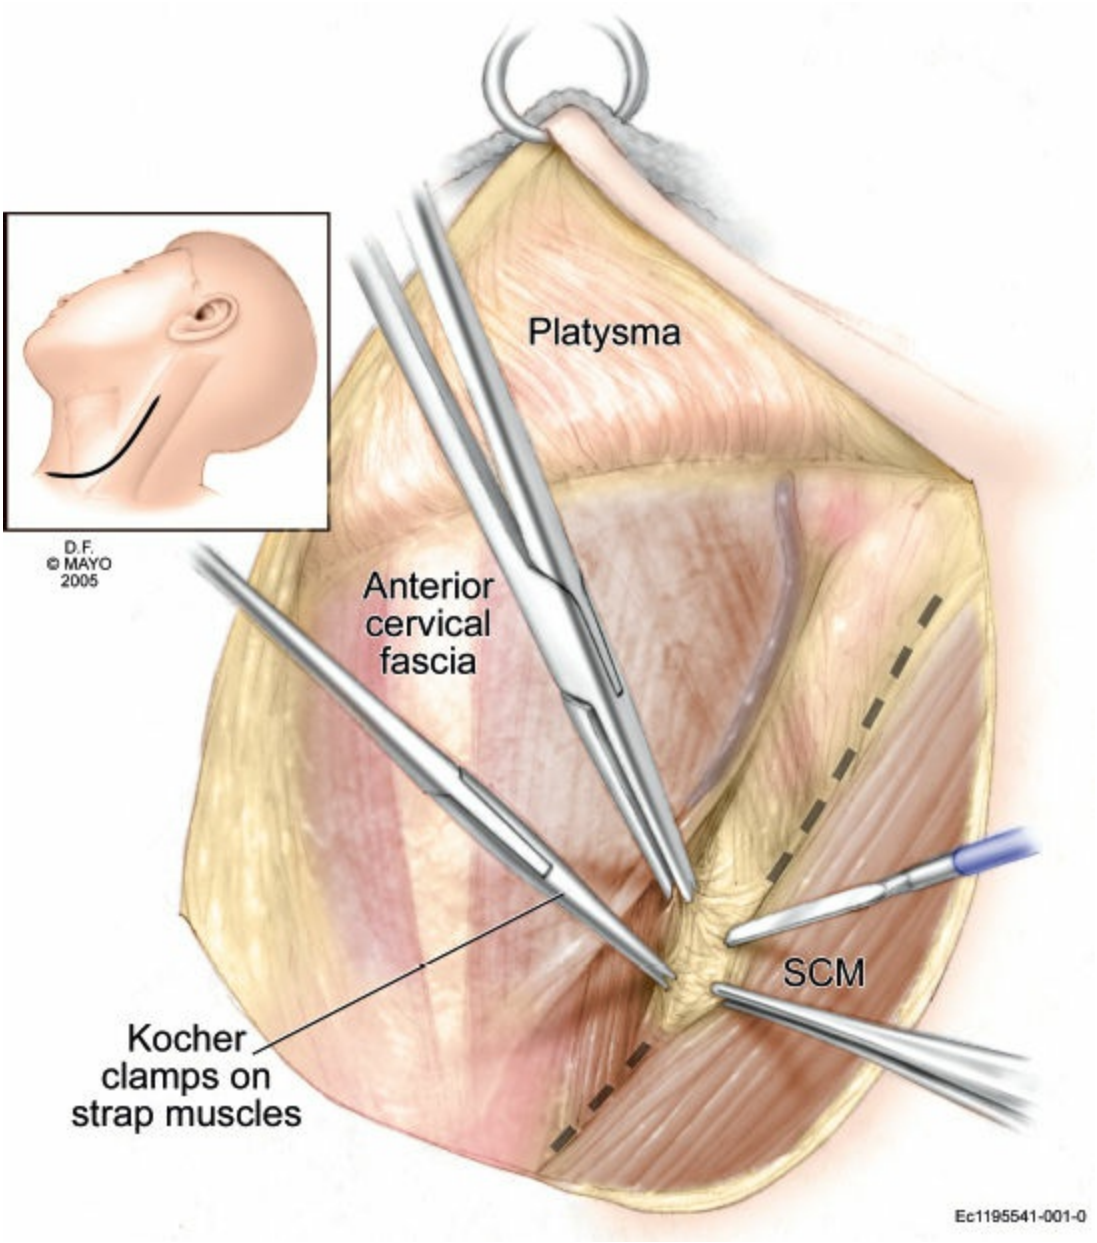

Figure 38.9. Modified radical neck dissection incision and dissection between sternocleidomastoid muscle (SCM) and strap muscles.

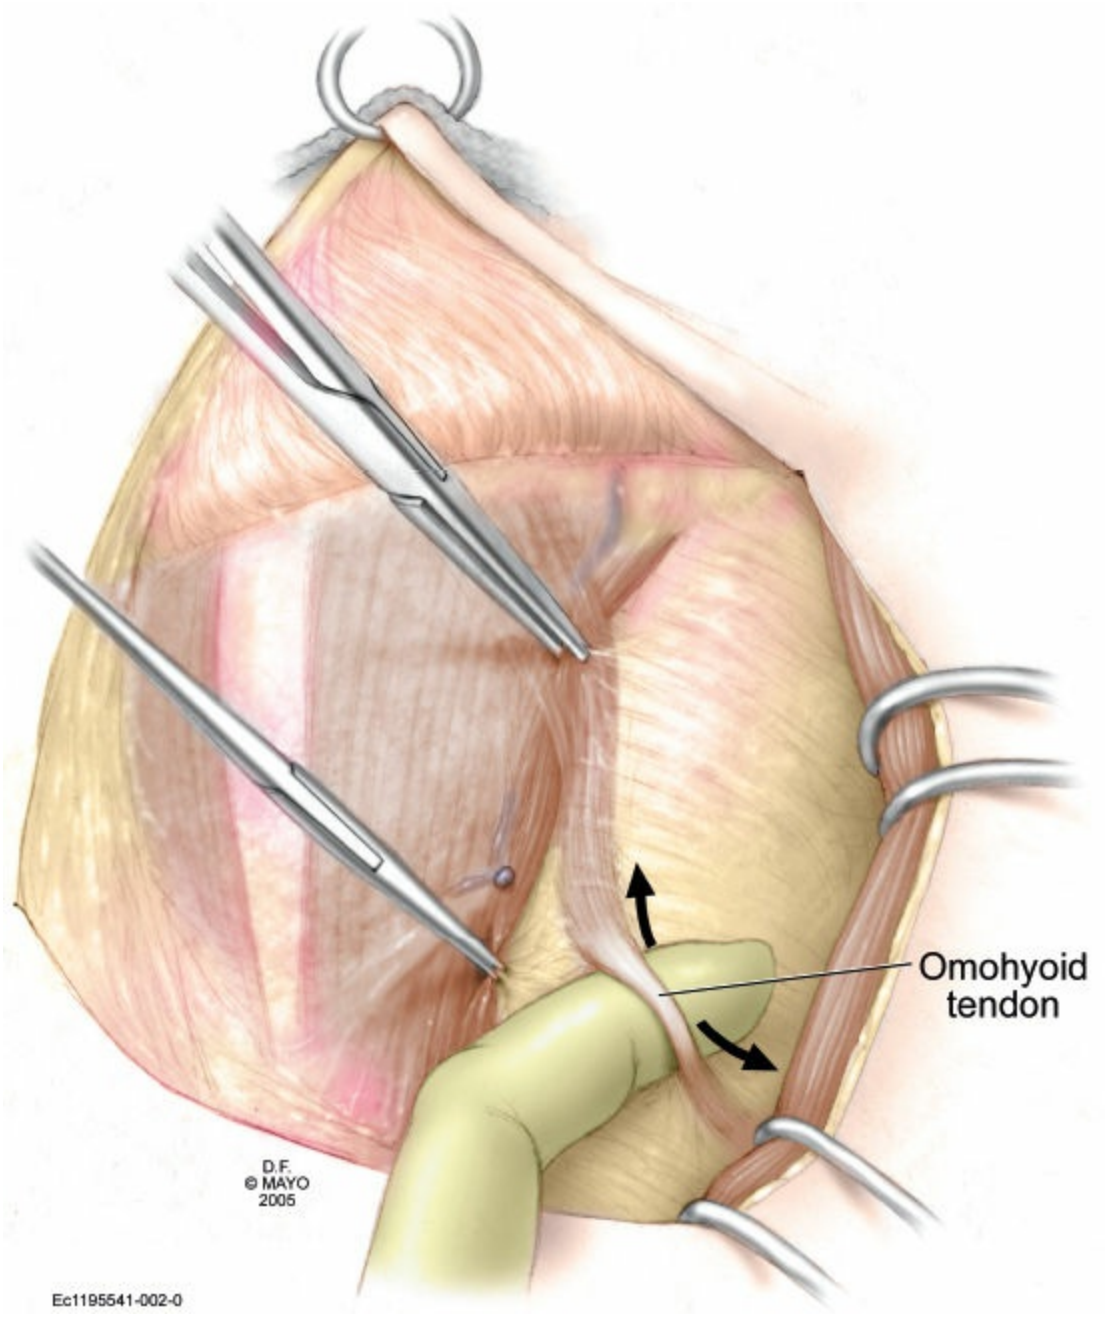

Figure 38.10. Isolation and resection of omohyoid muscle.

In very rare instances, the parathyroid glands can be found to be completely intrathyroidal. More commonly, they can be located on the surface of the thyroid gland, under the capsule but in clefts of the thyroid parenchyma. This location can seem intrathyroidal, particularly during reoperative parathyroid surgery, when the thyroid capsule is thickened with scar.

SURGICAL ANATOMY

Virtually everyone has at least four parathyroid glands, but at least 13% of the population has supernumerary glands. However, only one half of these supernumerary glands are proper glands; the others are tiny, rudimentary bits of parathyroid tissue, usually located near another normal gland. Supernumerary glands become important surgically in four situations: (a) hyperparathyroidism (HPT) caused by multiple endocrine neoplasia (MEN), especially type 1, and familial HPT, when all glands are abnormal; (b) secondary HPT, most typically that results from chronic renal failure, in which all glands are stimulated to enlarge and hyperfunction; (c) sporadic cases in which the four usual glands are normal and only the supernumerary gland is abnormally enlarged and responsible for hyperfunction; and (d) cases in which the supernumerary gland is enlarged in addition to another normal gland, which represents a double-adenoma situation.

Dissection of Parathyroid Glands

There are three important goals in parathyroid surgery: (a) recognition of normal parathyroid glands as well as removal of the abnormal glands; (b) safe searches in *predictable* locations for missing parathyroid glands; and (c) the preservation of parathyroid glands during thyroidectomy or the removal of other abnormal parathyroid glands.

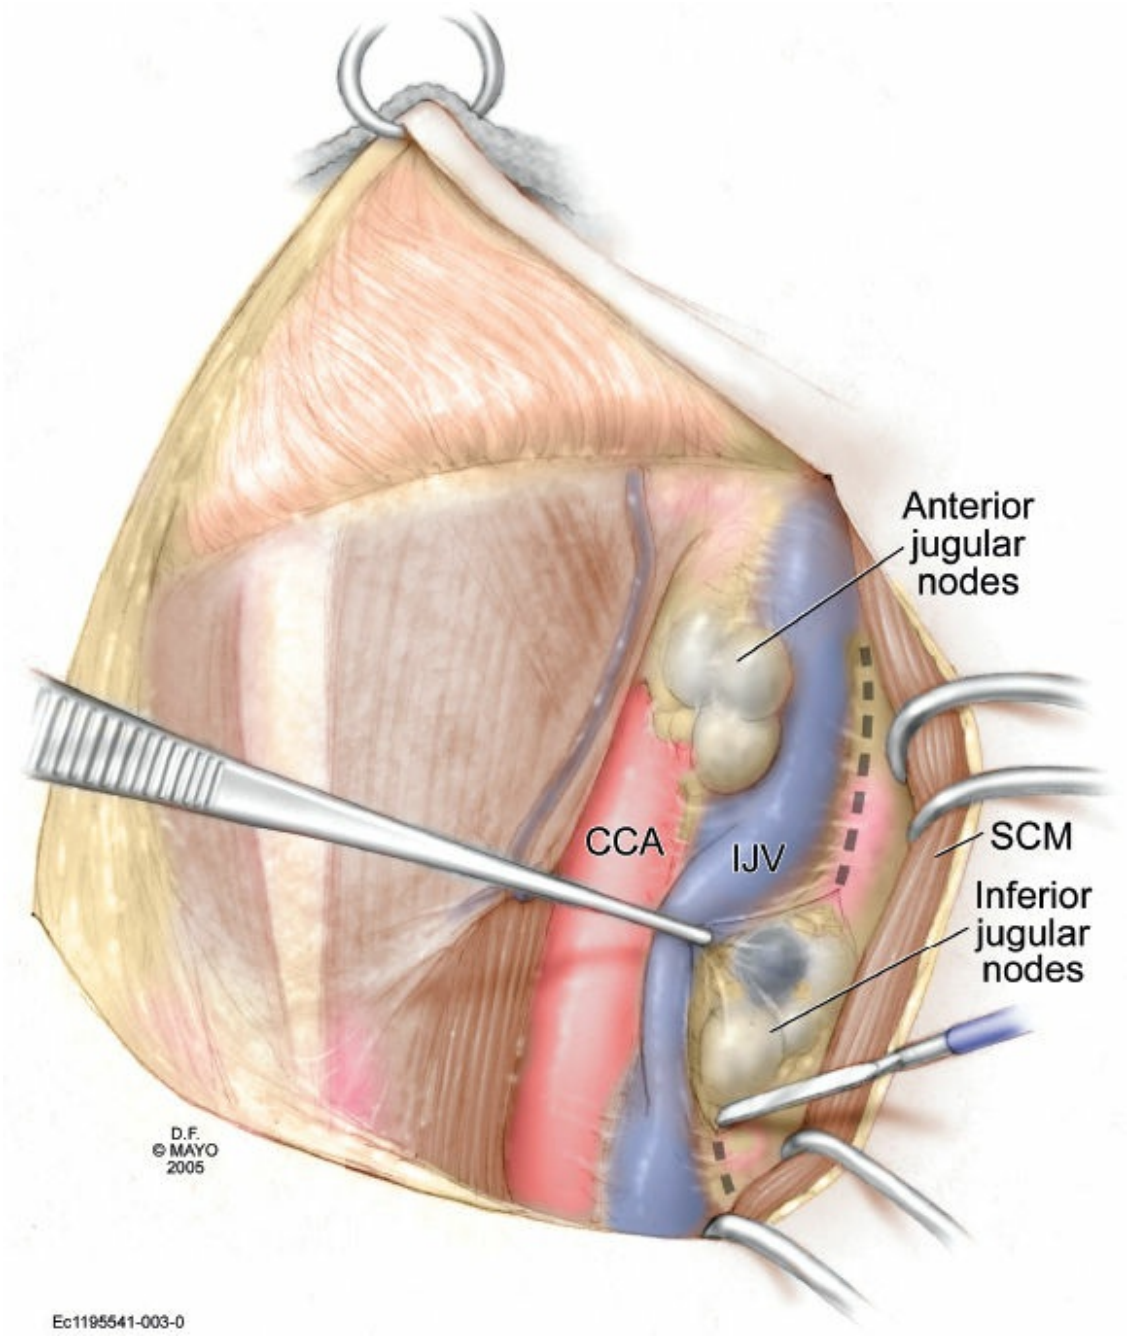

Figure 38.11. Initial dissection along lateral border of internal jugular vein (IJV) above level of clavicle. CCA, common carotid artery; SCM, sternocleidomastoid muscle.

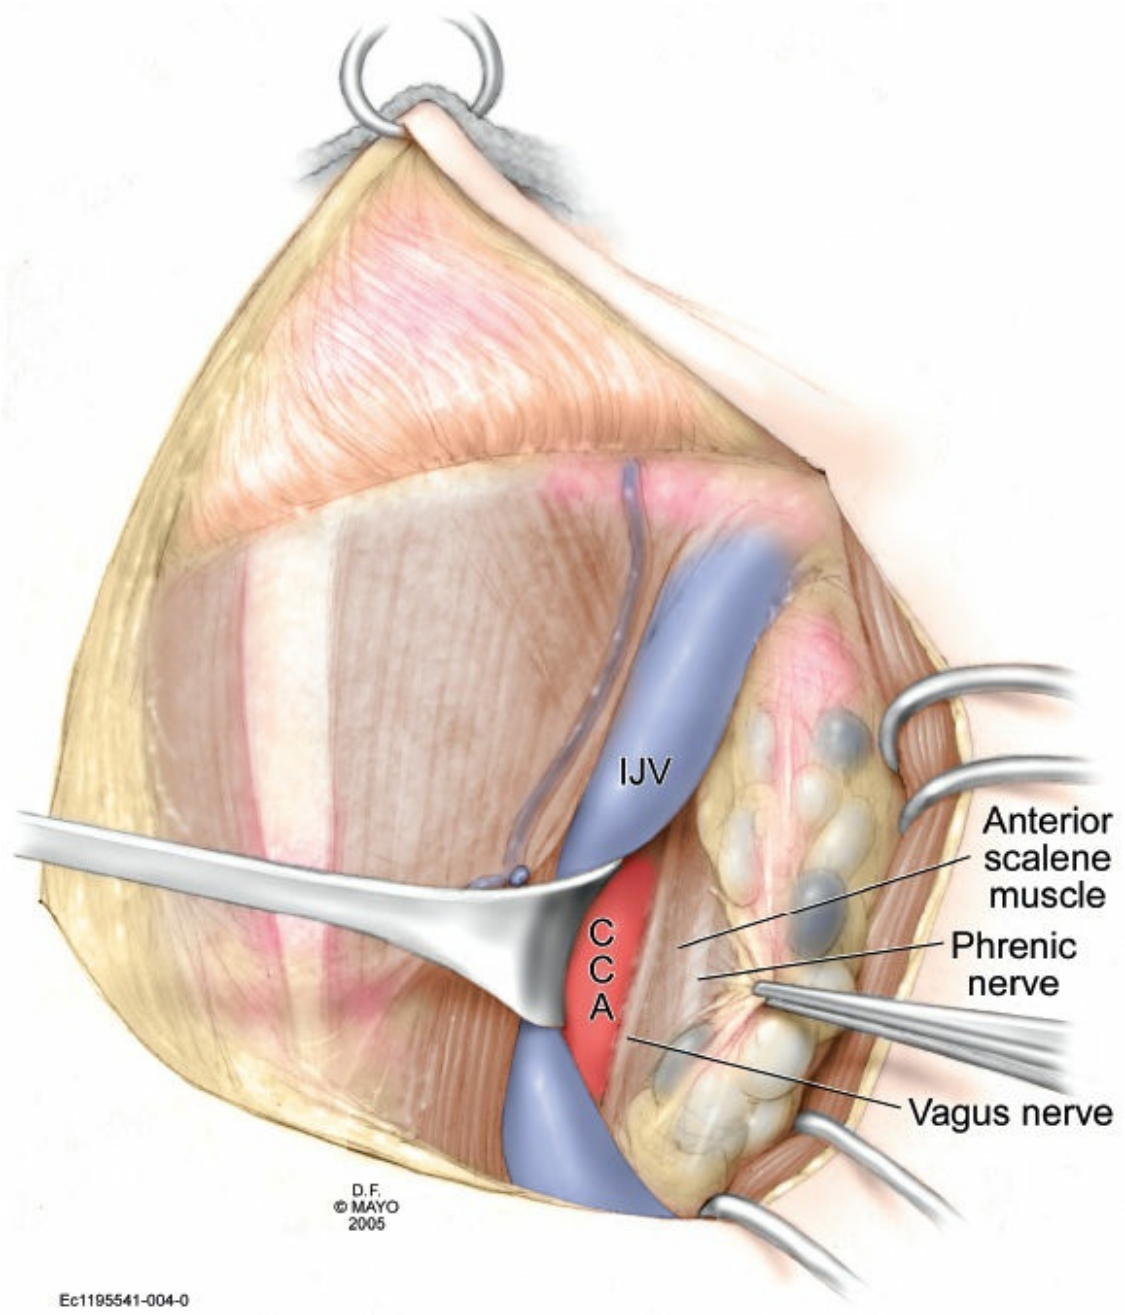

Figure 38.12. Exposure of anterior scalene muscle and phrenic nerve. CCA, common carotid artery; IJV, internal jugular vein.

The dissection of parathyroid glands proceeds similarly to the mobilization of a thyroid lobe, as described previously. In contrast, when HPT is the indication for operation, the arterial supply of the thyroid is usually preserved. Once the thyroid gland has been elevated (Fig. 38.4), the inferior parathyroid gland is usually sought first. It usually resides either on the posterolateral surface of the lower pole of the thyroid gland or at the tip of the cervical thymus or thyrothymic ligament. In fact, this ligament can be used to point to the gland or conceal it within its variably

atrophic and fat-replaced thymic substance. Similar to the superior gland, the inferior gland is often located in a lobule of fat, from which it can be distinguished by its reddish-yellow or yellowish-brown color. Normal glands are soft, pliable, and virtually nonpalpable, and can be present in differing shapes depending on whether the fascial layer that flattens it against the thyroid has been teased away to yield a more globular shape. When a tiny biopsy has been taken from the *nonhilar* portion of the gland, the entire parenchymal surface bleeds from pinpoint capillaries (in contrast to fat with its single bleeding vessel). Thyroid nodules and normal or diseased lymph nodes are firmer, not soft and pliable like normal parathyroid glands. The thymus can usually be distinguished by its pale, off-white color. If an inferior parathyroid adenoma is not found in the usual locations, it has almost universally migrated along an anterior path, following the course of or located within the cervical or mediastinal thymus. The sequence of searching for inferior glands not in the usual locations proceeds as follows: (a) the cervical and mediastinal thymus are drawn into the wound and searched or excised for pathologic review; (b) dissection is carried anterior to the carotid artery at least to its bifurcation to search for an undescended parathymus, as described previously; (c) the carotid sheath is opened, particularly if the cervical thymus is seen to deviate toward it; and (d) the lower pole of the thyroid is excised to exclude an intrathyroidal location.

The superior parathyroid glands are in a more constant location but are somewhat more difficult to expose than the inferior glands. They are usually found within a globule of fat located along the posterior border of the thyroid gland, 1 to 2 cm superior to where the inferior thyroid artery enters the thyroid gland (Fig. 38.6). Gentle dissection to strip thin fascial layers overlying the gland causes it to pop out directly, or the surrounding fat can be manipulated to expose the parathyroid gland. Initially, to identify probable locations for this gland, gentle prodding with an instrument causes the fat and contained parathyroid gland to float within the fascial envelope. They often directly overlie the RLN, although they are separated by a delicate fascial space. When a superior gland is not in the usual position, it tends to migrate posteriorly, behind the inferior thyroid artery, drawing its blood supply with it and descending in the potential space called the *tracheoesophageal groove*, which is almost the same as the retroesophageal or prevertebral space. Because the RLN is closely applied to the trachea and is located anterior to this dissection

plane, the retroesophageal space can be entered and widely dissected from the level of the larynx superiorly almost to as low as the tracheal bifurcation inferiorly. The only critical structure that crosses this plane is the inferior thyroid artery, which can be protected as it enters the thyroid gland or transected. Occasionally, exposure of the superior gland can be facilitated by mobilizing the superior pole of the thyroid gland by transecting the superior thyroid artery. Very rarely is a superior gland located within the thyroid gland. Superior and inferior glands are remarkably symmetric in their locations. Even in ectopic locations, with the exception of an inferior gland located low in the cervicomediastinal thymus, symmetry is often preserved.

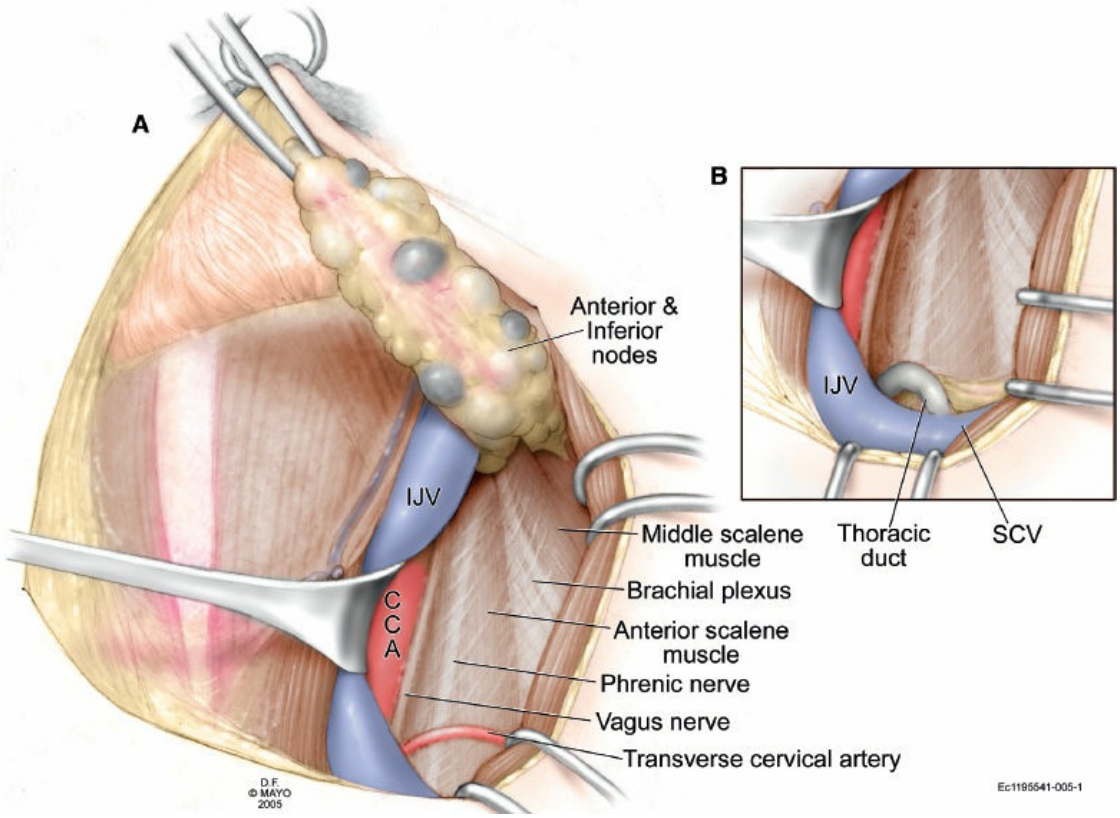

Figure 38.13. *En bloc* dissection of internal jugular vein (IJV) lymph nodes and exposure of floor of neck. CCA, common carotid artery.

Although the principal arterial blood supply to the superior and inferior parathyroid glands originates from the inferior thyroid arteries, other anastomotic vessels certainly provide a supplementary supply in most patients. However, when a total thyroidectomy has been performed, these supplementary sources are often interrupted. As a general rule during a

thyroidectomy, the inferior thyroid artery should be transected distal to the branches that supply the parathyroid glands. When an inferior gland is located within the substance of the thymus, it usually derives a satisfactory blood supply from thymic vessels.

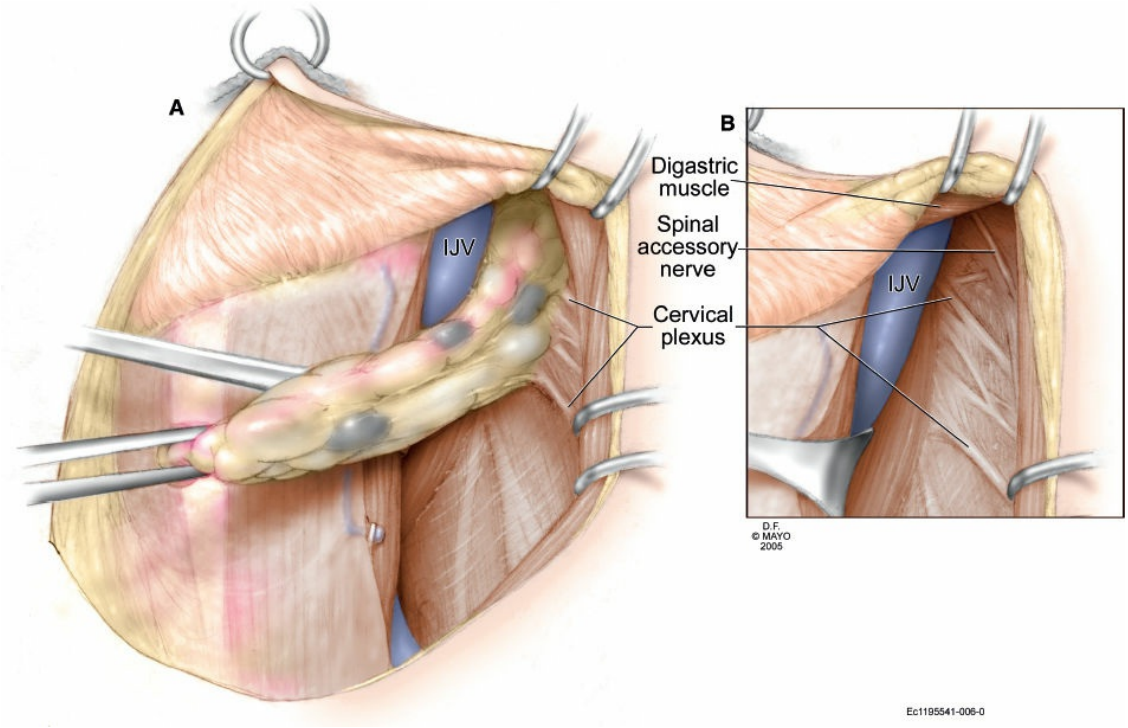

Figure 38.14. Cervical plexus (CP) and spinal accessory nerve dissection (extending to Level II). IJV, internal jugular vein.

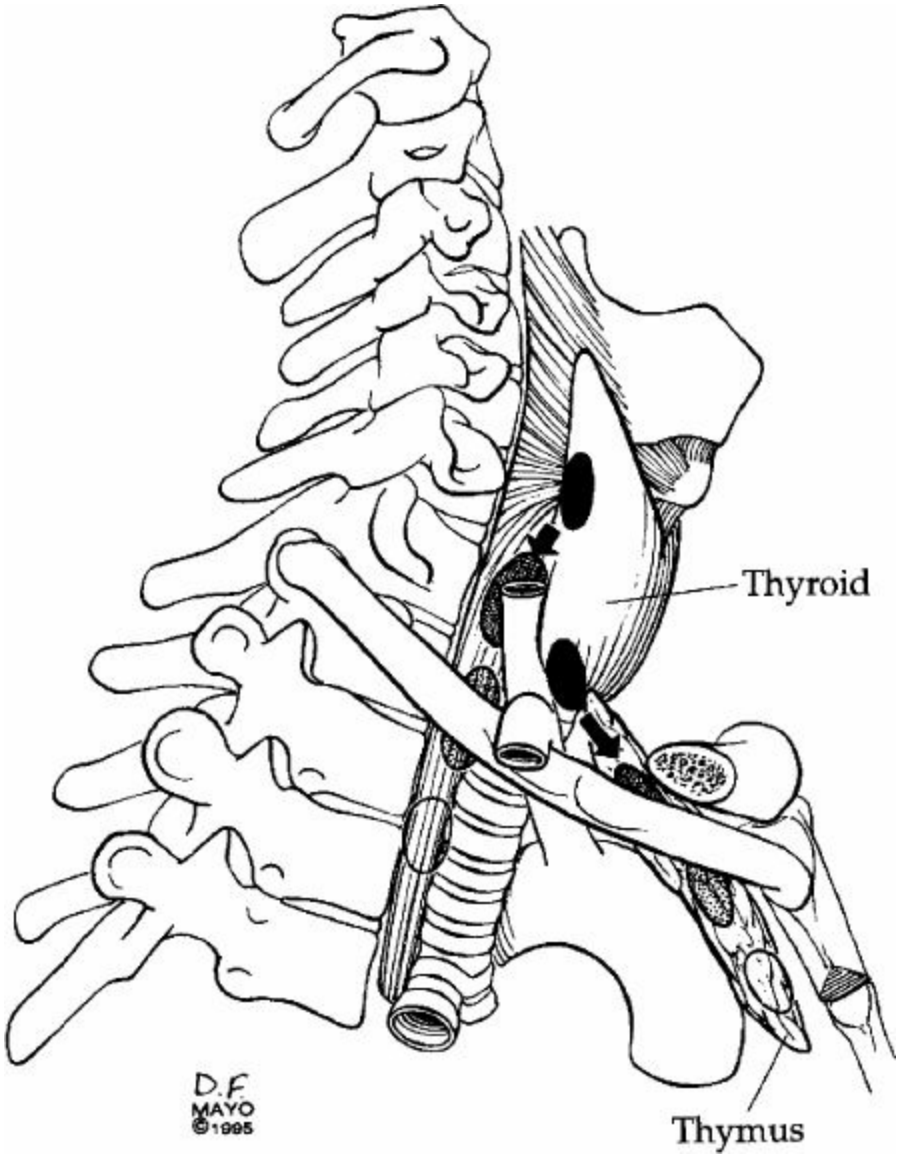

Figure 38.15. Owing to their embryologic origins, the parathyroid glands, particularly when enlarged, follow different, but often predictable, courses. The superior glands descend posteriorly in the contiguous tracheoesophageal groove or retroesophageal space, or into the posterior superior mediastinum. The inferior glands are less predictable but are usually found anteriorly in association with the thymus gland, either in the neck or in the anterior superior mediastinum.

Minimal-Access Parathyroidectomy

Application of minimal-access techniques that have swept across all disciplines of surgery have been applied to parathyroidectomy and, to a lesser degree, thyroidectomy. Two distinct methodologies have emerged: First, an open technique, which uses local anesthesia and a small incision and is directed by preoperative imaging and sometimes by intraoperative

rapid parathyroid hormone determination; and second, microendoscopic techniques. The feasibility of both techniques has been solidly established in the hands of experts, and the ultimate use of either or both awaits the assessment of the safety, cost-effectiveness, and, perhaps most important, the demands of patients.

Although perhaps only two thirds of patients with HPT are actually suitable for a limited exploration using present localization modalities, the surgeon must understand not only the anatomy of the parathyroid glands, but also the critical importance of his or her ability to interpret localization studies accurately.

Sestamibi Parathyroid Scan

Up to 80% of patients with sporadic HPT are demonstrated by sestamibi scan to have a single "hot spot" that represents a single enlarged parathyroid adenoma. This is probably the single most effective preoperative localization method currently available. Even if the hot spot is located as far inferior as the lower pole of the thyroid gland, it can still be a superior parathyroid gland, located posteriorly in the tracheoesophageal groove. Conversely, a hot spot superior to the superior pole of the thyroid gland is almost certainly an inferior gland—the undescended parathymus. Oblique views should be included in the scan technique to distinguish an anterior hot spot, which is most likely an inferior gland and rotates with the inferior pole of the thyroid gland (Fig. 38.16A). A posterior hot spot—a superior gland—moves to the midline in the opposite oblique view (Fig. 38.16B). Also, the level of the sternal notch should be noted, as the gland may reside within the mediastinal thymus in the anterior-superior mediastinum yet to be easily retrievable from a cervical incision. These ectopic but not unusual locations have been recognized for decades but need to be carefully considered to place a limited incision properly or to opt for a standard open exploration.

EMBRYOLOGY

The adrenal glands can be separated into two distinct areas, both histologically and physiologically: the cortex and the medulla. The cortex develops from mesodermic celomic epithelium of the posterior abdominal wall, at the cranial end of the mesonephros. The medulla develops from the neural crest in conjunction with the sympathetic ganglia. This group of neural cells migrates along the adrenal vein to invade the cortex and

becomes the completed adrenal gland. Other small masses of these cells, which stain brown with chromic acid (thus the name *chromaffin* or *pheochrome cells*), can persist throughout the life along the sympathetic chain as paraganglia. The most common location of a tumor (or paraganglioma) is at the origin of the inferior mesenteric artery on either side of the aorta, near the Zuckerkandl organ. Accessory adrenal tissue can be found occasionally in the connective tissue adjacent to the main gland but can also occur near a gonad, either ovary or testis.

ANATOMY

Because the adrenal glands are situated deeply in the retroperitoneum, and because primary diseases that require adrenalectomy are rare, surgeons tend to be less familiar with the anatomic relationships of these glands (Fig. 38.17). In addition, adrenal tumors can distort these relationships. On both sides, they cap the kidneys and derive arterial blood supply from the aorta and the inferior phrenic and renal arteries.

On the right, the upper part of the gland lies partially behind the inferior vena cava (IVC), against the bare area of the liver (to which it can seem somewhat adherent), and on the diaphragm. The principal venous drainage is through the adrenal vein, which is short and wide and which exits the gland just below its apex to enter the IVC on its posterior surface and is the only vein to enter the IVC posteriorly along its retrohepatic course.

The left adrenal gland lies on the diaphragm and is covered on its anterior surface by peritoneum superiorly and on its lower portion by the nonperitoneally covered pancreas. The adrenal *vein* exists near the lower border of the gland, often to join with the inferior phrenic vein to empty into the renal vein.

ANATOMY IMPORTANT TO VARIOUS SURGICAL APPROACHES

Anterior (Transabdominal)

Right

After the abdominal incision is made, the posterior edge of the liver should be dissected from the posterior peritoneum, which allows the liver to be lifted anteriorly and superiorly. This maneuver is also facilitated by transecting one or two small branches from the anterior surface of the IVC coursing to the caudate lobe of the liver. Neither the hepatic flexure of the

colon nor the duodenum usually needs to be mobilized unless the tumor is quite large. The arterial branch from the inferior phrenic artery is often located at the extreme superomedial aspect of the gland, higher than the adrenal vein, and requires careful control. Once this artery and the adrenal vein have been transected and the posterior peritoneal layer that covers the superior aspect of the adrenal gland has been incised, the gland can be retracted laterally as the IVC is retracted medially, which separates the plane between the two (Fig. 38.18). Control of the vessels from the aorta and renal vessels completes the dissection. With reasonable frequency, at least one small but significant accessory adrenal vein drains from the inferior aspect of the gland (especially important when large tumors are present that enlarge these veins) into the right renal vein. This situation is easily controlled when recognized. Care must be taken on this side as well as on the left to avoid ligating or injuring a small polar branch of the renal artery.

Figure 38.16. **A:** The single “hot spot” is located at the inferior pole of the right lobe of the thyroid and moves with it in oblique views, indicating a right inferior parathyroid adenoma. **B:** The “hot spot” is located at the inferior pole of the right lobe of the thyroid, but moves into the midline in the left oblique view, indicating a right superior parathyroid adenoma (RS, left oblique view).

Left

Access to the left adrenal gland can be gained by dissecting the omentum from the colon, elevating the stomach, and dissecting the avascular plane under the pancreas to elevate it off the adrenal gland. The spleen does not need to be mobilized in this approach, but this exposure is adequate only for small to moderate tumors. For larger tumors, including adrenal cancers, the splenic flexure of the colon can be dissected and the spleen and pancreas mobilized from their bed (including ligation of short gastric vessels) to the patient’s right side (Fig. 38.19). This step exposes the adrenal gland or tumor inferomedially and eventually the most critical area of dissection on the left side. The adrenal vein and the arterial branches from the aorta and renal artery course in this space (Fig. 38.20).

Laparoscopic (Transperitoneal)

The laparoscopic approach has rapidly been adopted as the procedure of choice for removing all benign tumors, both functioning and nonfunctioning, with the upper size limit varying from 6 to 10 cm. Obviously, larger tumors require enlarging one of the trocar sites to accommodate removal, but most tumors “mold” somewhat into an oblong shape, allowing a much smaller transabdominal hole than might be expected. However, at present, most authors reporting a series of laparoscopic adrenalectomies prefer to remove adrenal malignancies using an anterior, open approach.

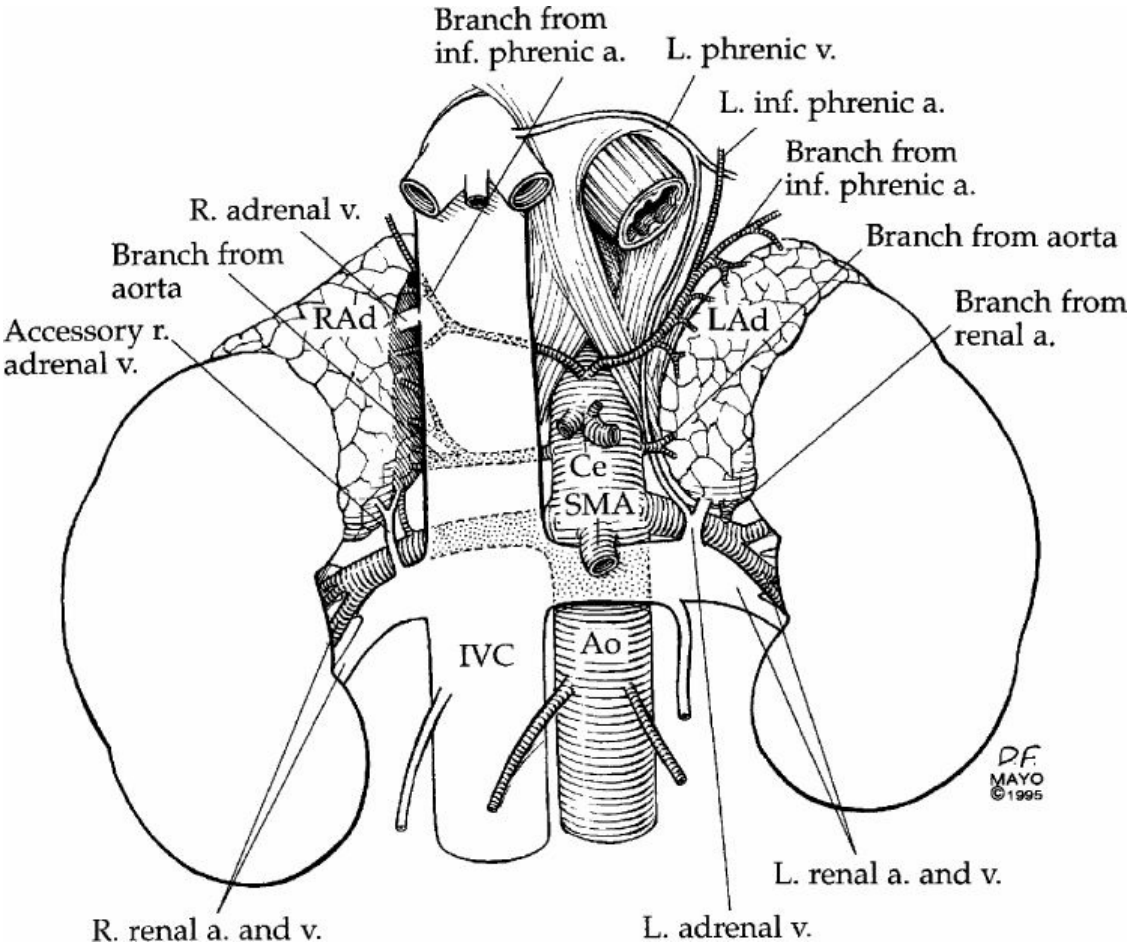

Figure 38.17. Overall anatomic relationships of the adrenal glands. Note the origins of the three main arteries: the inferior phrenic, aortic, and renal branches. Note also the single draining veins (except a small accessory right adrenal vein): the right, located superior and medial; and the left, found inferior and medial. Ao, aorta; Ce, celiac; IVC, inferior vena cava; LAd, left adrenal gland; RAd, right adrenal gland.

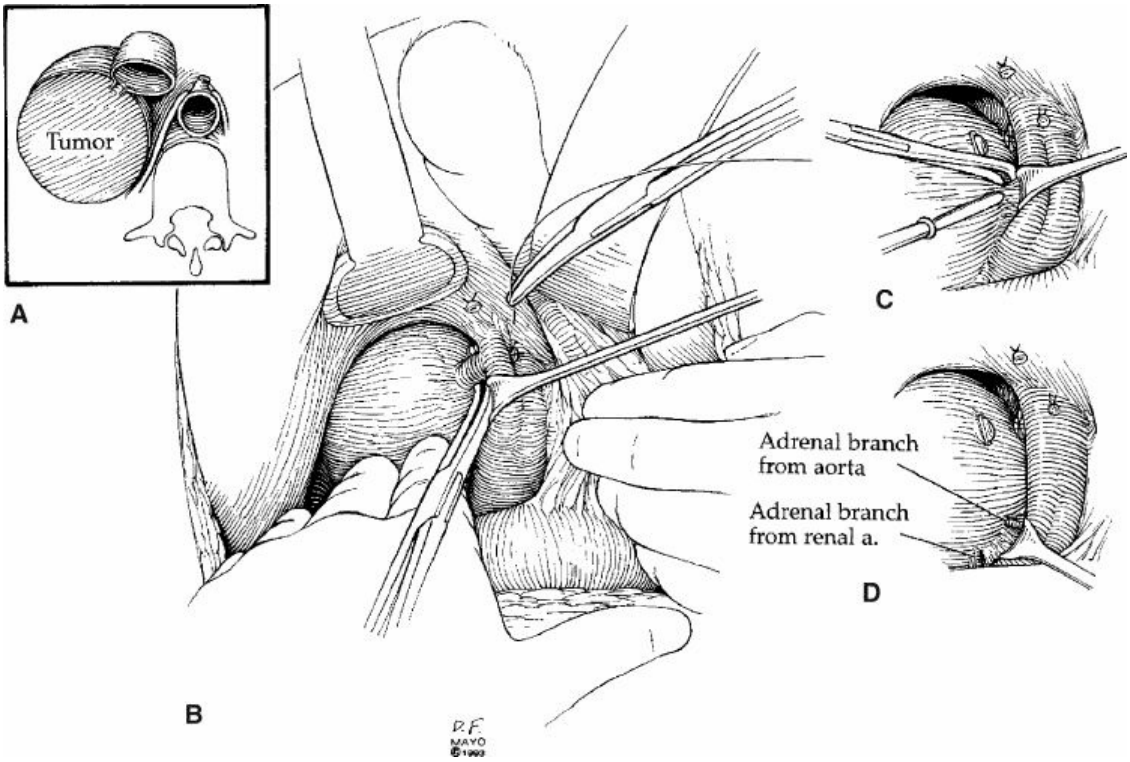

Figure 38.18. A: Cross-section of the anatomic relationships of the adrenal tumor, the inferior vena cava (IVC), and the right adrenal vein. **B:** With the liver elevated and the IVC retracted medially, the short, fat, right adrenal vein is exposed, coursing from the adrenal tumor to the posterior surface of the IVC. **C:** The vein has been clipped or ligated and transected, and the minimally vascular areolar tissues between the tumor and the IVC below the level of the vein are dissected. **D:** Along the medial inferior aspect of the tumor, the aortic and renal arterial branches that need to be controlled are found. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

At least three different laparoscopic approaches have been described, including directly anterior with the patient positioned supine; retroperitoneal with the patient prone; and, most commonly, transperitoneal with the patient positioned laterally, with the side to be operated on elevated. “Breaking” the operating room table to distract and enlarge the distance from the costal margin to the iliac crest allows maximal space for placement of the trocars. Moreover, the most lateral trocar should be placed so as to avoid restriction of its inferior rotation by

the iliac crest. The anatomic considerations for a laparoscopic approach are not substantially different from the open operations, but some deserve special emphasis.

Right Adrenalectomy

Although the right side is potentially more dangerous of the two sides due to the short adrenal vein, the exposure is more direct and often easier than the left side. Four trocar sites are used, starting a few centimeters inferior to the right costal margin, somewhat medial to the midclavicular line, and coursing laterally. As much space as possible should be allowed between trocar sites to prevent the camera and instruments inserted through the cannulae from interfering with each other. The most medial cannula is used for retracting the liver, and the right triangular ligament should be divided to allow retraction of the liver, both medially and anteriorly, off the retroperitoneum. The retroperitoneal attachments to the liver should be lysed, exposing the IVC. The camera is usually best placed in the second cannula, and the two lateral cannulae are used for dissection and retraction by the surgeon. As the retroperitoneal covering is incised adjacent to the IVC, lateral retraction is placed on the adrenal gland to distract it from the IVC. Although the space between the gland and the IVC is limited, the camera magnification allows precise cautery dissection of the small vessels proceeding from the inferior border of the gland superiorly. We have not required direct retraction of the IVC. The incision in the retroperitoneal covering is curved laterally above the superior border of the adrenal gland, which allows further mobilization. Care must be taken to avoid unintentional trauma to the adrenal vein or the moderate-sized inferior phrenic artery, which can be transected at this stage. Gentle dissection of the adrenal vein, ensuring circumferential clearance, permits safe and precise control with endoscopic clips.

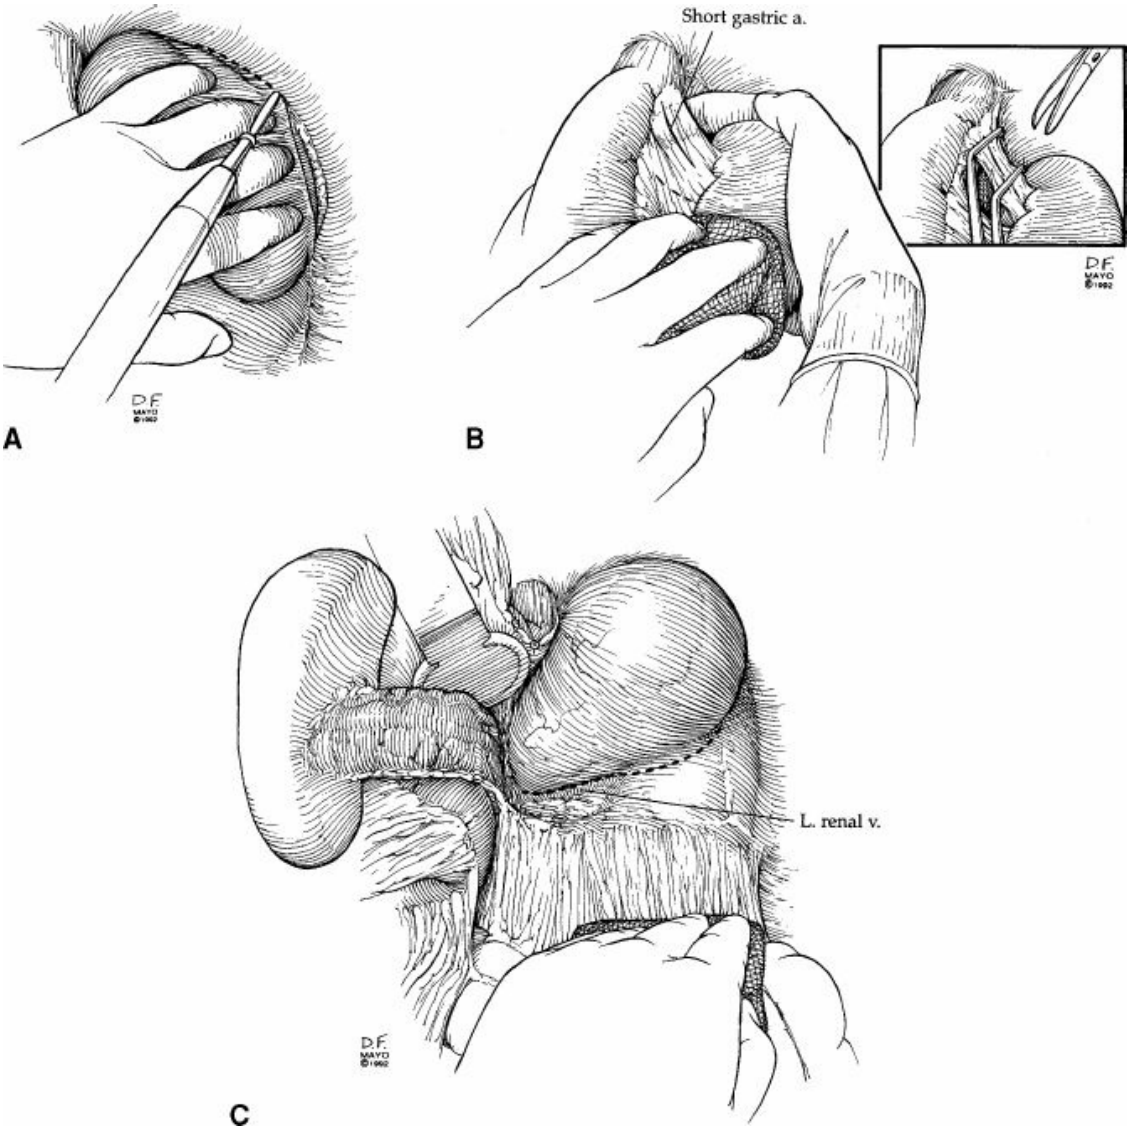

Figure 38.19. A: Retracting the spleen medially and inferiorly, the lateral peritoneal attachments are incised. **B:** The short gastric vessels are individually transected. **C:** With omentum dissected from the left transverse colon, the spleen and pancreas mobilized from their bed, and the short gastric vessels transected, these organs can be retracted into the patient's right upper quadrant, exposing a large adrenal tumor. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

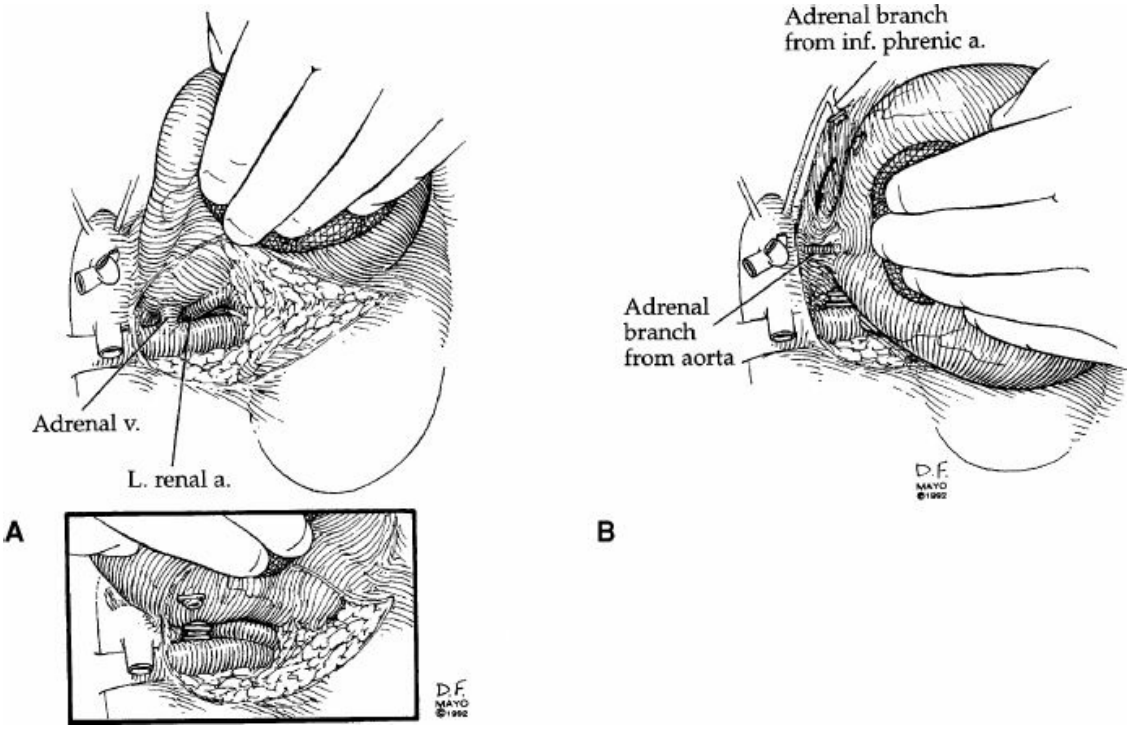

Figure 38.20. A: Along the inferomedial aspect of the adrenal tumor, the adrenal vein is identified, somewhat shorter than usual in the situation depicted. Care must be taken not to injure renal arterial branches coursing close by the vein as it is transected. **B:** The adrenal branches from the inferior phrenic and aorta can be seen in their typical locations. (Republished with permission of John Wiley & Sons, Inc. from Grant CS, van Heerden JA. Technical aspects of thyroidectomy. In: Donohue JH, van Heerden JA, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge: Blackwell Science; 1995:81–6; permission conveyed through Copyright Clearance Center, Inc.)

As the dissection is carried around the inferior border of the gland, a thicker layer of fat is commonly encountered, and special attention must be taken, as in the open operation, not only to clip and transect the arterial branches to the adrenal gland but also to protect the arteries coursing to the underlying kidney. Particularly true of laparoscopic procedures, visualization is enhanced considerably by traction, and elevating the adrenal gland to facilitate dissection of the posterior attachments is most helpful. Placement of the adrenal gland into an endoscopic bag and withdrawal through one of the trocar sites completes the operation.

Left Adrenalectomy

Often, only three trocars are necessary for left adrenalectomy, because

once the spleen is mobilized, it usually does not require ongoing retraction. Trocar placement is planned in mirror image to the right side described previously. Before the third trocar is placed, the splenic flexure may need mobilization, sometimes extensively, to facilitate not only the placement of the trocar, but also the "dropping" of the transverse colon to gain exposure to the left adrenal vein later. The camera is usually placed in the lateral cannula (or third cannula if four are used—the most lateral to aid in retracting the kidney to expose the medial aspect where the adrenal vein drains into the left renal vein), but placement can be switched to another trocar as needed for optimal visualization. A blunt instrument is used to tip the spleen away from its retroperitoneal attachments; these then are incised relatively close to the spleen coursing superiorly, curving around the superior margin, and looking for and protecting the stomach as the dissection proceeds medially. The characteristic "fuzzy" areolar tissue posterolateral to the spleen that extends to the pancreas can be opened widely, exposing a variable thickness of fat and the adrenal gland. Locating the adrenal gland may be the most difficult portion of the procedure. During an operation for Cushing adrenal hyperplasia, with considerable overall obesity but particularly generous amounts of fat in the retroperitoneum, the marginally enlarged adrenal gland sometimes is engulfed by the fat. Along the medial border of the gland, as noted in the open procedure, the inferior phrenic vein may prove to be a valuable landmark. We often initially dissect the medial, superior, and lateral borders before visualizing and transecting the left adrenal vein, which is longer and generally more slender than its right-sided counterpart, and, when dissected, is easily clipped.

SPECIAL CONSIDERATIONS

There are several hot topics that have generated considerable interest and controversy relating to thyroid, parathyroid, and adrenal aspects of endocrine surgery that deserve special consideration. Without delving into great depth on these subjects or attempting to "answer" the controversies, the intent here is to highlight these contemporary issues, anticipating that perhaps a new set of topics will be covered in subsequent editions of Mastery of Surgery.

Thyroid

Papillary Thyroid Cancer

With the turn of the millennium, the goal of the endocrinologist seemed to be eradication of all evidence of disease, even down to molecular amounts. Facilitated by three new technologic advances—recombinant human TSH (rhTSH), high-resolution real-time cervical ultrasonography (US), and highly sensitive thyroglobulin (Tg)—postoperative disease as small as only a few millimeters, even submicroscopic size, could be discovered, that prompted either additional surgical intervention or administration of radioactive iodine (RAI). Of course patient's anxiety levels surged with discovery of this additional disease. Surgeons responded by obtaining preoperative US to identify subtle suspicious lymphadenopathy which was often combined with routine central neck (Compartment VI) lymphadenectomy. The result was a significant spike in recognizing either small volume metastatic disease preoperatively, or similar minimal disease residual postoperatively. Apart from these perioperative investigations, but closely related to the discovery of small volume disease, was an exponential rise in the diagnosis of thyroid cancer, specifically PTC. In large part attributed to increased use of sensitive imaging studies such as US, CT, and MRI, this explosive rise in the frequency of incidentally discovered PTC was principally comprised of papillary thyroid microcarcinoma (defined as ≤1 cm in largest size). Inevitably, questions arose as to the appropriateness of such exhaustive and expensive efforts to first identify then treat even minimal volume PTC surgically or with RAI ablation.

It appears that the pendulum of aggressive combined medical and surgical management is swinging back to a more moderate approach.

Japanese literature has convincingly demonstrated that the overwhelming majority of PTMC behave in a very indolent manner. In fact, in one large study, the Japanese have withheld treatment entirely, opting for only observation with ongoing US surveillance, and this management course has been shown convincingly to be safe.

Whereas the American Thyroid Association guidelines for therapy of PTC call for total or near-total thyroidectomy for all tumors >1 cm, data from large institutions indicate equivalent survival for lobectomy only in T1 to T2/N0 patients. Recent very large studies lend further support for lobectomy only to treat localized PTC even up to 4 cm.

Even though strong international data verify the safety and reduced lymph node recurrence rates of PTC following routine central neck lymphadenectomy, this is counterbalanced by more frequent temporary

hypoparathyroidism, and raises the very basic question of whether residual millimeter-sized PTC even requires any treatment. As a result, more recently, a greater tolerance for serial observation rather than intervention has evolved for mildly elevated postoperative Tg or image-detected, probable lymph node metastases <8 mm in the central compartment.

Following demonstrated lack of value of routine postoperative RAI in stage 1 PTC, its use nationally has finally turned on a downslope.

Intraoperative Neural Monitoring of the Recurrent Laryngeal Nerve

Following feasibility studies of intraoperative neural monitoring (IONM) prior to the year 2000, there has been increased investigation, modifications, enthusiasm, and usage of these techniques. The entire effort is directed to prevent unilateral and importantly bilateral RLN paralysis. The most important study on this topic was a multi-institutional, prospective, nonrandomized study of 16,448 patients with 29,998 nerves at risk. Comparing patients with routine visual identification of the RLN to those with both visual identification and IONM, there was no statistical difference in RLN injuries. While multiple studies and reports have been published on this topic, only a single major study has found IONM to improve outcome compared to visualization only, and that was only in rates of transient but not permanent RLN paresis. Even though its popularity has increased, given these data, IONM would certainly not be considered standard of care at this time.

Outpatient Thyroidectomy

In the last 10 years, increasing emphasis has been placed on outpatient surgery, including thyroidectomy. For this discussion, outpatient means same-day dismissal from the hospital or ambulatory surgical center (not to include 23-hour observation). Although a number of potential advantages have been cited, including potential to reduce hospital-acquired infections or management errors, the dominant reasons are patient-preference of a more familiar environment outside the hospital that is conducive to comfort and support, and cost reduction. However, these need to be balanced against the potential risk of postoperative complications that might be disastrous outside the prompt care available within a monitored hospital setting. When assessed by experts on behalf of the British Association of Endocrine and Thyroid Surgeons, they declared their opposition to the change: “Any financial benefits may be outweighed by

the exposure of patients to an increased risk of an adverse outcome." In the United States, several reports of safe outpatient thyroidectomy have been published, and the American Thyroid Association commissioned a task force to define eligibility criteria, preoperative, intraoperative, and postoperative factors to optimize safe outpatient thyroidectomy. As requested, thoughtful eligibility criteria, relative contraindications, operative surgical and anesthetic considerations, postoperative management, and discharge criteria were all enumerated. Perhaps paramount to this entire process would be a required clinical pathway incorporating all of the recommendations, necessitating adherence to it by all members of the team caring for the patient. Particularly highlighted were discharge assessment for any evidence of bleeding/hematoma, and 2-hour postoperative rapid PTH measurement or routine calcium and vitamin D supplementation to avoid these most significant potential complications. A cautionary note was emphasized in an editorial by Dr. Steward, "Outpatient thyroidectomy is clearly not for every patient, and perhaps not for every surgeon."

Parathyroid

Minimal Access Parathyroidectomy

Over the recent 15 to 20 years, "minimal access parathyroidectomy (MAC)" has become the favored approach by many if not most surgeons who perform this operation. This was facilitated by the development of technologic advances of high-quality Sestamibi scan to preoperatively localize parathyroid adenomas (sometimes augmented by the use of a γ-probe for intraoperative localization), and intraoperative parathyroid hormone (IOPTH) monitoring to verify cure. Coincidentally, across the nation and pertaining to all surgical disciplines, strong emphasis was being placed on "patient-centered" outcomes such as pain management, short-stay or outpatient procedures, small incisions, and local anesthesia. The convergence of these factors was further fueled by the explosion of information on the internet, readily accessible to patients, and particularly relevant to MAC—surgeon internet marketing. Over this time period, further attempts have been introduced to refine these techniques, trying to edge closer to perfection in surgical success for HPT. The nemesis has been the known occurrence in primary HPT of multiple gland disease. But strangely, even today, the frequency of this potential Achilles' heal of parathyroid localization and surgical success is still debated, and not

merely a few percentage point controversy. The original force behind use of IOPTH, George Irvin, found the frequency of single-adenoma to be nearly 95%, and surgical cure following single adenoma excision when postexcision IOPTH values dropped >50% from the pre-excision baseline. In contrast, an equally reputable leader in endocrine surgery, Allan Siperstein at the Cleveland Clinic, has pegged the multiple gland rate near 30%, with the use of IOPTH failing to detect 16% of abnormal parathyroid glands. He advocates bilateral, four-gland exploration as routine. Dr. James Norman, quoting exponentially greater surgical volume of parathyroid surgery than anyone else in the United States, and certainly the most powerful initial driving force in the use of MAP, initially touted success of nearly 100% with this technique. Recently, Norman has reversed his stance, now virtually never using a unilateral approach, preferring to explore all 4 glands, and finding multiple gland disease in 25%. Graphing his >15,000 case experience, he depicts improving his success rate from about 94% to >99% in his most recent 5,000 cases. He does utilize the γ-probe, but only a single planar Sestamibi scan preoperatively, and never uses IOPTH. To paraphrase his surgical strategy, he still performs the operation through a 2.5-cm incision, usually without intubation, never using nerve-monitoring, without need for SPECT, CT, 4D-CT, MRI, US, IOPTH, closing the incision in an average of 18 minutes, rarely keeping the patient more than 1 to 2 hours postoperatively. Most academic parathyroid surgeons continue to advocate a unilateral approach when preoperative localization and IOPTH indicate single-gland disease. Despite the initial simple “50% rule,” the details of IOPTH measurement are sometimes subtle but important.

Surgical Indication—Bone Mineral Density

A satisfying trend has emerged with increased acceptance and strong support favoring parathyroidectomy for patients with HPT, not only by surgeons, but also endocrinologists. Perhaps the most recent, persuading indication for recommending parathyroidectomy rather than observation, even in the “asymptomatic” patient, are the data regarding bone mineral density (BMD). Previously, at a 10-year follow-up of a prospective observational study of the natural history of PHP with and without surgical intervention, the unoperated, asymptomatic patients were found not to suffer a decline in BMD. In surgical patients, despite the 12% increase in lumbar spine BMD and 14% increase in femoral neck BMD at 10 years following surgical cure, observation was considered a reasonable option

for asymptomatic patients. However, the “permission” not to surgically intervene on the basis of stable BMD at 10 years seemed to crumble, as did the bones when the 15-year follow-up study was published. Cortical site (femoral neck and distal radius) BMD fell from 10% to 35%, and 37% of patients manifested BMD decline. From prior consensus conferences, women younger than 50 already had been recommended to undergo parathyroidectomy. Add to them a surgical recommendation for women older than 50 with osteoporosis, and it would seem with these newer data that we are on track in the future to add surgical recommendation for women not only with osteopenia, but any woman with declining BMD who has HPT.

Adrenal

Adrenal Incidentalomas

Although small adrenal tumors have been well recognized since they were first appreciated as a consequence of newly introduced CT imaging in the early 1980s, the management still remains somewhat controversial. Defined as an adrenal tumor >1 cm in size, without any obvious clinical evidence of hormonal hyperfunction, the prevalence increases with age, reaching about 7% in patients over 70 years of age. Once identified, the evaluation is intended to determine (1) if there is subclinical hormonal hypersecretion that would justify surgical resection, and (2) if the tumor represents a meaningful threat of malignancy. Measurement of simultaneous serum aldosterone and plasma renin activity (PRA) assesses for primary aldosteronism (abnormal aldosterone to PRA ratio is >20:1); a 1-mg overnight dexamethasone suppression test evaluates for subclinical Cushing syndrome (normal serum cortisol the following morning is <5 μg/dL); and a 24-hour urine collection for fractionated metanephrines and catecholamines to assess for pheochromocytoma. These tests have been quite well accepted as sensitive and cost-effective for assessment of hormonal hyperfunction. Criteria for assessing risk of malignancy have been weighted heavily on diameter size of the tumors. However, quite valuable in addition to tumor size are the imaging characteristics—the “imaging phenotype.” Adenomas are usually <3 cm, round or oval with smooth margins, homogeneous in texture, have a density on CT ≤10 Hounsfield units, have low-level vascularity and ≥50% washout of contrast medium at 10 minutes after injection. Their growth rate is slow, <1 cm/yr. In contrast, the small but real percentage of small adrenocortical

carcinomas (ACC) are usually >4 cm, with irregular margins, heterogeneous in texture with areas of necrosis and possibly calcification, >10 Hounsfield units in density with high vascularity and slower washout <50% at 10 minutes and hyperintense on T2-weighted image on MRI. Their growth rate is usually >2 cm/yr. Even though adrenalectomy now performed laparoscopically is quite safe, often requiring only an overnight hospitalization, used indiscriminately without careful attention to the imaging phenotype can be costly and unnecessary.

Laparoscopic Adrenalectomy for Small Adrenocortical Carcinomas

Only rarely are ACC smaller than 8 to 10 cm in size with no imaging evidence of surrounding tumor invasion—a situation that would seem suitable for potential laparoscopic resection. Between 1998 and 2004, 11 investigators had reported only 25 cases of primary ACC resected laparoscopically, with local recurrence or intraperitoneal dissemination in 40% of the patients. Subsequently, however, in the largest study of 152 patients, the German Adrenocortical Carcinoma Registry Group failed to demonstrate inferiority of the laparoscopic approach compared to open adrenalectomy either by matched pair or multivariate analysis. Consequently, the European Society of Endocrine Surgeons issued a position statement endorsing laparoscopic adrenalectomy for ACC with careful stipulations including an R0 resection, without capsule rupture, for tumors <10 cm in diameter. In sharp disagreement, citing increased frequency and more prompt local recurrence and peritoneal carcinomatosis, surgeons from the University of Michigan, MD Anderson, and France opposed the laparoscopic approach. Most of these studies have been small, including patients whose operations were performed somewhere other than the reporting institution, and many of the key operative and pathology details have been lacking. More information would be potentially beneficial, comparing patients matched for demographics and oncologic aspects of their cancers, but different only in the surgical approach. In retrospective review of our experience at Mayo Clinic of nearly 1,000 adrenalectomies, restricting ACA to <10 cm by imaging, with no surrounding soft tissue or organ invasion, only 20 were operated by open resection, and only 7 by laparoscopic or hand-assisted techniques. On follow-up, 5 of the 7 laparoscopically resected, and 5 of the 20 having undergone open resection were alive with no disease. Therefore, we would cautiously feel safe in initiating a laparoscopic approach, but convert to an open approach if necessary. While at first glance this overall

situation might seem to apply only to a tiny fraction of adrenalectomy patients, it actually must be considered in all patients undergoing adrenalectomy when the specific indication is to determine if a nonfunctioning adrenal tumor is benign or malignant—a significant proportion of adrenal resection patients.

Partial Adrenalectomy—Hereditary Pheochromocytoma

Hereditary forms of pheochromocytoma are rare, including MEN type 2 (MEN2) and von Hippel–Lindau disease (VHL), and often have bilateral but rarely malignant adrenal tumors. Particularly in MEN2 patients, the classic operation has been bilateral total adrenalectomies, since virtually 100% of the adrenal medullae are abnormal, featuring tumors which are frequently multicentric as well as bilateral, and associated with extratumoral medullary hyperplasia. Strong consideration has been given to preserve a portion of adrenal gland to avoid a permanent Addisonian state that can evolve into crisis in as many as 23% of patients. Furthermore, noncrisis symptoms of anxiety and mild adrenal insufficiency causes patients to restrict their activities resulting from the risk or actual need for supplemental cortisone. Even if a recurrent pheochromocytoma developed in an adrenal remnant, this could be discovered early—given the diligent follow-up necessary for associated conditions of either MEN2 or VHL—and reoperation could be performed safely. Two recent studies provide strong endorsement for partial adrenalectomy. When operating on small pheochromocytomas, cortical-sparing adrenalectomy showed only a 4% to 7% recurrence rate (12% after laparoscopic approach), no reduction in survival, and 57% to 64% of patients were steroid independent long term. Ideally, it is recommended to preserve 30% of the adrenal parenchyma to ensure cortical function, but less may still be successful, even sacrificing the adrenal vein. Interestingly, some of the strongest proponents of this advanced surgical method favor a posterior, retroperitoneal approach.

EDITOR'S COMMENT

Dr. Grant has written an exceptional chapter on the surgical anatomy of the thyroid, parathyroid, and the adrenal gland. New in this addition of the chapter are some special considerations that highlight some very contemporary and evolving issues in the field of Endocrine Surgery. Endocrine Surgery as a defined surgical specialty has exploded in popularity over the past 20 years. It continues to amaze me that there are so many innovations and advances that have occurred recently in a field so focused on three very small endocrine

organs. The number of endocrine procedures being performed in the United States has been steadily increasing. In 2004, there were 80,505 endocrine surgery cases performed representing a 25% increase at the time in a span of 4 years. It has been estimated that 98,000 to 174,000 procedures will be performed annually by 2020. The steady increase in volume is attributable to improved imaging modalities, a rise in minimally invasive techniques and technologies, and an evolving understanding of the indications for surgery and the ramifications of leaving conditions like hyperparathyroidism undertreated.

High-volume endocrine surgeons are performing a large proportion of these surgical procedures, as are otolaryngologists. Unfortunately, the operative experience of endocrine surgery cases in a general surgical residency may not be adequate to properly prepare general surgeons to make endocrine surgery a routine part of their practice after training. This has contributed to the increase in endocrine surgery fellowship trained surgeons in recent years. A recent survey queried department chairs and determined that the average number of endocrine surgeons in their department increased from 1.3 to 2.2 over a 10-year period. A recognized endocrine surgery section exists in about half of all departments, and 39% of department chairs felt a likely need to recruit another endocrine surgeon in the next 2 years when this study was published in 2013. This is important because a clear volume outcome relationship has been demonstrated for endocrine surgical procedures in multiple studies. A review of the Nationwide Inpatient Sample over the years 2003–2009 stratified surgeons into low-, intermediate-, and high-volume categories for adrenalectomies. Surgeries performed by low-volume surgeons were associated with a higher risk of postoperative complications. Costs were greater for low-volume surgeons as well. An analysis from the same data source on thyroidectomy revealed that thyroidectomy procedures performed by low-volume surgeons were associated with a higher risk of postoperative complications compared with high-volume surgeons and that mean hospital cost was significantly associated with surgeon volume. Another meta-analysis showed that patients who received thyroidectomies performed by high-volume hospitals and surgeons had shorter length of stay and lower costs compared with those treated by low-volume hospitals and surgeons. In addition, in-hospital survival rates were better in patients treated by high-volume surgeons. A larger cross-sectional study using the NIS to examine thyroidectomy revealed a significant increase in cases during 2001–2008 compared to 1993–2000. The proportion of procedures performed for thyroid cancer increased from 28% to 34%. Cases performed by high-volume surgeons increased from 12% to 25% whereas cases performed by very–low-volume surgeons decreased from 51% to 34%. Review of practice patterns and outcomes revealed that high-volume surgeons were significantly more likely to perform total thyroidectomy and had a lower incidence of recurrent laryngeal nerve injury, hypocalcemia, and in-hospital death.

Dr. Grant discussed the evolving trend of outpatient or same-day thyroidectomy in his chapter. To investigate the practice patterns and outcomes

for same-day thyroidectomy in New York State, investigators recently turned to the 2004 New York State Inpatient and ambulatory surgery databases. A total of 6,762 thyroidectomies were identified; 17% were same-day thyroidectomies. Patients undergoing same-day surgery compared to thyroidectomy with admission were more often white, with private insurance and fewer comorbid medical conditions. Same-day surgery was performed more often by high-volume surgeons and at high-volume hospitals. Rehospitalization rates were similar for both approaches. In multivariate analysis, thyroidectomy by a high-volume surgeon was associated with a higher chance of same-day discharge. The authors conclude that there seem to be a few high-volume surgeons and centers with extensive same-day thyroidectomy experience, and that "*more research is needed to explore optimized patient triage and patterns of referral to centers of excellence*." As Dr. Grant discusses in his chapter, this is a controversial practice that should be selectively applied. In the current era of Milliman guidelines as well as payer and hospital pressure to convert procedures to outpatient and move them to low-cost ambulatory surgery centers, surgeons need to be acutely aware of the potential drawbacks to this approach.

Minimally invasive endocrine surgery is discussed at length in this chapter. Robotic thyroidectomy is not described in great detail however. The robotic approach to thyroid resection was pioneered in South Korea, primarily out of a desire to avoid a neck incision. In 2009, Intuitive Surgical began promoting the da Vinci robotic surgical system for use in thyroid surgery in the United States. In October 2011, the company announced in that it would withdraw promotion, training, and support in reaction to reports of complications and concern about whether Intuitive had received appropriate FDA approval for use of the device in thyroid surgery. Robotic thyroid surgery has not as of yet caught on in the United States, accounting for less than 1% of all thyroidectomies. Most of the published outcomes literature on this topic is from Asia. A recently published systematic review and meta-analysis of robotic thyroidectomy included 5,200 cases from 23 publications. Robotic thyroidectomy was associated with equivalent adverse event and complication rates. The "completeness" of surgical resection was also equivalent. Robotic thyroidectomy was demonstrated to be associated with less blood loss, fewer retrieved nodes, and better cosmetic satisfaction. In contrast, open thyroidectomy was associated with shorter operative time. The authors of this systematic review conclude "*robotic thyroidectomy is as safe as open thyroidectomy for the treatment of thyroid cancer. Based on the long-time follow-up and surgical completeness, the adverse events and complications, and recurrence rate of robotic thyroidectomy were comparable with open thyroidectomy.*"

An American Thyroid Association Statement on Remote-Access Thyroid Surgery sought to develop a simple classification of these approaches to thyroidectomy that are designed to avoid a neck incision, to describe the optimal patient selection criteria, to evaluate the outcomes objectively, and to define the barriers to adoption. Remote-access thyroid procedures can be

categorized into endoscopic or robotic. Approaches can include breast, bilateral axillo-breast, axillary, and facelift approaches. The experience in the United States involves the latter two techniques. Expert consensus was that in appropriate hands remote access thyroidectomy could be a viable option for patients with unilateral small nodules who wish to avoid a neck incision. "*These approaches require an additional level of expertise, and therefore should be done by surgeons performing a high volume of thyroid and robotic surgery.*"

A thorough understanding of the surgical anatomy described in this chapter is essential for surgeons who perform these operations. In the case of the thyroid and parathyroid, the critical anatomy is packed into a very small area and the potential for patient morbidity in surgeons who do not understand the nuances is high.

39 Biopsy, Lobectomy, Total Thyroidectomy, and Lymph Node Dissection for Thyroid Cancer

Randall Scheri, Sanziana Roman, and Julie Ann Sosa

ETIOLOGY AND PATHOPHYSIOLOGY

Patients may be seen in the surgery clinic for the evaluation of either structural (nodule, goiter, or malignancy) or functional (Graves' disease, toxic adenoma, or toxic multinodular goiter) thyroid disease. Thyroid nodules are very common and are present in approximately 50% of patients on screening ultrasound or autopsy studies. The overwhelming majority of thyroid nodules are benign and include colloid nodules, pseudonodules of thyroiditis, follicular, and Hürthle cell adenomas. However, thyroid cancer is the fastest increasing cancer in American men and women, with an incidence that has risen approximately 270% over the last three decades; malignant diagnoses include papillary, follicular, Hürthle cell, medullary and anaplastic thyroid cancers, primary thyroid lymphoma or (rarely) metastases to the thyroid, typically from breast, lung, or kidney primaries.

The etiology of benign nodules is unknown, but risk factors have been identified, including female gender, increasing age, and pre-existing thyroiditis. Thyroid goiters are described as endemic or nonendemic. Endemic goiters are secondary to iodine insufficiency. The etiology of nonendemic goiter is unknown; however, dietary and other environmental factors have been implicated. Family history of thyroid disease and radiation exposure particularly in childhood and adolescence from either therapeutic external beam radiation or environmental sources is well-established risk factors for papillary and anaplastic thyroid cancers. The thyroid cancer genetic analysis for well-differentiated thyroid cancer has identified BRAF, RAS, RET, NTRK1, and PAX8-PPAR mutations as potential driver mutations for thyroid cancer. Germline mutations responsible for familial thyroid cancer syndromes also have been identified. The RET proto-oncogene is responsible for multiple endocrine

neoplasia type 2 (MEN2A and B) syndrome and familial medullary thyroid cancer, conferring a nearly 100% risk of developing medullary thyroid cancer. The PTEN mutation is responsible for Cowden's syndrome, which is associated with a higher risk of nodular thyroid disease, follicular and papillary thyroid carcinomas. Adenomatous polyposis coli (APC) mutation is responsible for familial adenomatous polyposis, which is associated with a higher risk of developing the cribriform variant of papillary thyroid cancer.

Graves' disease is an autoimmune disease of the thyroid that is marked by the development of thyroid-stimulating hormone receptor antibodies (TRAb) that stimulate thyroid hormone synthesis and thyroid growth leading to hyperthyroidism. In addition to hyperthyroidism, patients with Graves' disease may experience ophthalmopathy, with periorbital edema and exophthalmos, as well as infiltrative dermopathy with pretibial myxedema. These features are also thought to be secondary to the TRAb. Risk factors for Graves' disease include a family history, female gender, patient age <40 years, and a history of autoimmune disease, pregnancy, and/or smoking. Toxic adenoma and toxic multinodular goiter are caused by hyperplasia of thyroid follicular cells that have become autonomous and are no longer regulated by thyroid-stimulating hormone (TSH).

CLINICAL PRESENTATION

History

A detailed patient history should evaluate for symptoms of hyper- and hypothyroidism, risk factors for thyroid cancer, family history of thyroid disease or other abnormalities of the adrenal, pancreas, pituitary, and parathyroid glands, and symptoms of local compression in the anterior neck. Symptoms of hyperthyroidism include weight loss, hair loss, anxiety, heat intolerance, palpitations, and increased frequency of bowel movements. Symptoms of hypothyroidism include weight gain, fatigue, cold intolerance, and constipation. Many patients with a thyroid nodule or thyroid cancer are asymptomatic, and the nodule is identified on physical exam or incidentally after radiologic imaging conducted for another indication. Risk factors for thyroid cancer include radiation exposure (for papillary and anaplastic thyroid cancers), a family history of thyroid cancer, or history concerning for a familial thyroid cancer syndrome, such as MEN 2. Symptoms of local compression, including a globus sensation, dysphagia, dysphonia, or dyspnea, can be related to large goiters or

nodules that compress surrounding structures. In the setting of a known or suspected cancer, these symptoms are concerning for locally advanced disease and should raise concern for invasion into surrounding structures. The rapid onset of symptoms or nodule growth is concerning for an aggressive, malignant disease process, such as primary thyroid lymphoma or anaplastic thyroid cancer. Pain over the thyroid is most likely related to thyroiditis, but an aggressive malignancy also should be on the differential.

Physical Examination

Physical examination should include a focused exam of the neck, including the thyroid and cervical lymph nodes. The thyroid gland is best palpated by standing behind the patient and asking the patient to swallow from a glass of water. The thyroid moves with swallowing, facilitating palpation of subtle thyroid nodules. Substernal extension of a goiter should be suspected if the inferior aspect of the thyroid gland cannot be defined, or there is a positive Pemberton's sign (facial congestion and respiratory distress with elevation of both arms above the head). Firm nodules and those with irregular borders are concerning for malignancy. Fixed nodules are concerning for a locally advanced malignancy, and enlarged lymph nodes are suspicious for metastases. The patient should also be evaluated for signs of hyper- and hypothyroidism. Signs of hyperthyroidism include tachycardia, tremor/tremulousness, muscle weakness, orbital edema, and exophthalmos. Signs of hypothyroidism include dry skin, coarse hair, and nonpitting edema.

SURGICAL INDICATIONS AND CONTRAINDICATIONS

Indications for thyroid surgery include indeterminate thyroid nodules, thyroid cancer, symptomatic nodules or goiters, Graves' disease, toxic adenoma, and toxic multinodular goiter. A TSH should be obtained to screen all patients for hyperthyroidism. For patients with hyperthyroidism, a thyroid uptake scan can be obtained to determine the etiology. Patients with Graves' disease will have diffuse increased uptake within the thyroid, while a toxic adenoma will demonstrate a solitary focus of increased uptake, with suppression of the remainder of the gland, and a toxic multinodular goiter will have increased uptake that is heterogeneous. Thyroid scan is not indicated for patients who are euthyroid. Thyroid ultrasound should be performed for all patients with a suspected nodule or goiter identified on physical exam or incidentally noted on other radiologic

imaging modality. Sonographic features of thyroid nodules that are suspicious for malignancy include microcalcifications, hypoechoic appearance, irregular margins, taller than wide nodule shape, rim calcifications with extrusive component, and evidence of extrathyroidal extension. Fine-needle aspiration (FNA) biopsy under ultrasound guidance is the procedure of choice for the evaluation of thyroid nodules and selection of patients who should undergo diagnostic or therapeutic surgery for a suspected or confirmed thyroid cancer.

FNA is a safe procedure that easily can be performed in the outpatient clinic. Ultrasound guidance is essential for nonpalpable nodules and is preferred in general because it improves accuracy and reduces the rate of nondiagnostic cytology. The patient is placed in a supine position with a pillow placed beneath the shoulder to slightly extend the neck (Fig. 39.1). The skin is prepped with an alcohol-based solution and the area is draped. A high-resolution (7.5 to 15 MHz) transducer is placed in a sterile cover and used for ultrasound. The nodule to be biopsied is identified with ultrasound, and 1% lidocaine is injected into the skin and subcutaneous tissue of the planned biopsy site. The transducer is placed directly over the nodule with the nondominant hand. Using the dominant hand, a 23- or 25-gauge needle with an attached 10 mL syringe is placed next to the transducer and advanced into the nodule perpendicular to the plane of the transducer. Once the needle is identified within the nodule, the FNA is performed using an aspiration or nonaspiration technique. The nonaspiration technique is preferred because it is less bloody. Using this method, the needle is moved back and forth within the nodule while rotating the needle on its axis until material is noted within the needle hub. For the aspiration technique, the needle is placed into various areas of the nodule and moved back and forth with suction applied; suction is released before the needle leaves the nodule. For cystic lesions, the aspirated fluid is sent for cytology, and repeat ultrasound is performed to evaluate for a solid component which, if present, should be aspirated. After the biopsy is completed, pressure is placed on the puncture site for 5 minutes, and a dressing is applied.

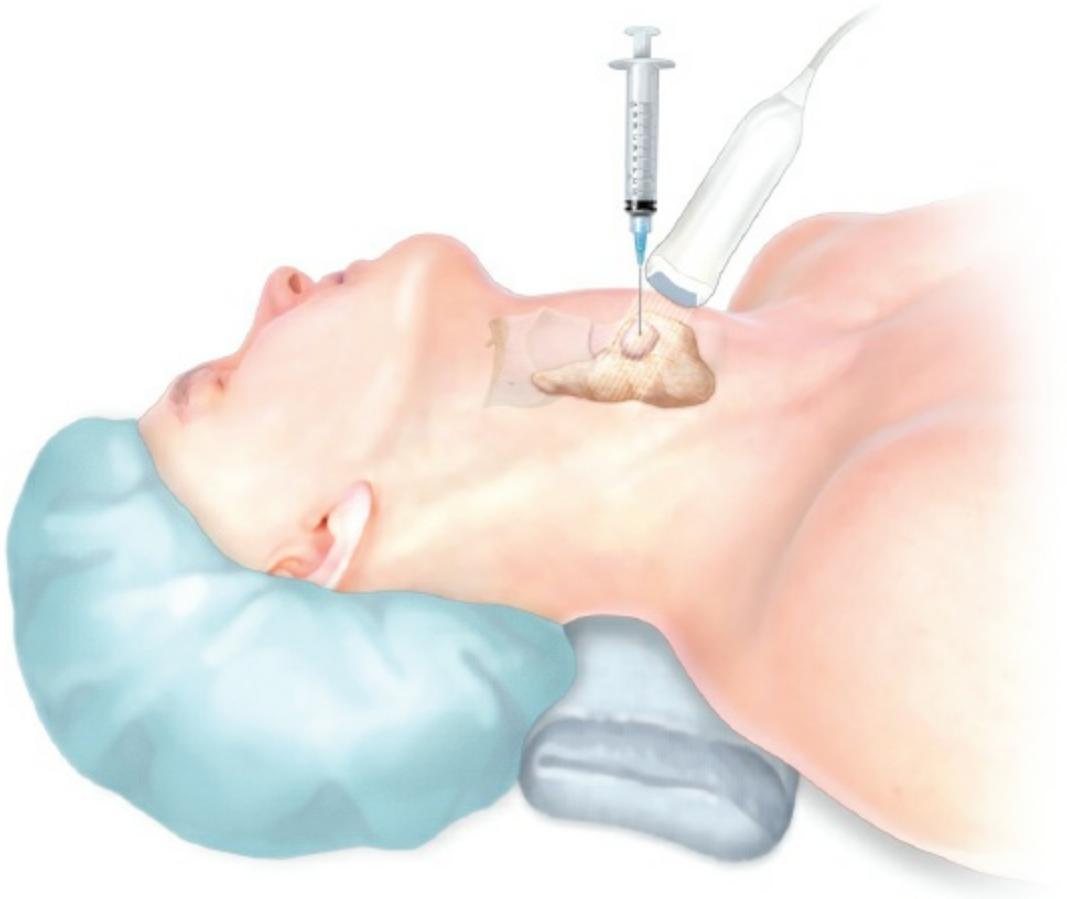

Figure 39.1. FNA biopsy with neck extended, nondominant hand holding ultrasound probe, and needle in dominant hand.

After the FNA is performed, the needle is detached from the syringe and reattached after the syringe is filled with air so that the needle contents can be expelled onto a glass microscope slide. A second slide is placed on top of the slide with the cellular contents, and the slides are pulled in opposite directions, thus creating two slides for evaluation. The slides can be placed in 95% ethyl alcohol or sprayed with fixative for Papanicolaou staining or air-dried for Giemsa staining. The specimen should be evaluated for adequate cellularity (if possible in the ultrasound suite in order to avoid the need for the patient to undergo a second ultrasound in the setting of an inadequate collection), and repeat FNA should be performed if the specimen is deemed to be inadequate. Typically, at least three passes are required. Complications from FNA are rare and primarily limited to bleeding or hematoma formation.

The results of the FNA should be reported using the Bethesda criteria. The possible results of FNA include a specimen that is nondiagnostic (Bethesda category I) for 2% to 3% of nodules, benign (Bethesda category

II) for 70% of nodules, indeterminate (Bethesda category II to V) for 20% to 25% of nodules, and malignant (Bethesda category VI) for 5% of nodules. A repeat FNA should be performed for nondiagnostic nodules. The cytologic results of the FNA guide therapy and surgical management for nodular disease.

Indeterminate and Benign FNA (Bethesda Criteria I and II)

Benign thyroid nodules do not typically require surgical resection unless they are symptomatic with associated symptoms of compression, or associated with hyperthyroidism. Asymptomatic benign nodules should be followed with serial ultrasound to evaluate for nodule growth. If the nodule increases in size significantly (2 mm in 2+ dimensions, or 50% increase in nodule volume), FNA should be repeated. Surgical resection of benign nodules is recommended if the nodules are symptomatic due to compressive symptoms, such as dysphagia or dyspnea, or for cosmetic reasons in the setting of very large nodules and patient preference. Surgery also should be considered for large thyroid nodules because FNA may be less accurate due to the greater potential for "sampling error." Several studies have shown that nodules >4 cm have a 10% to 15% risk of malignancy on final pathology after surgical resection. For nodules that have nondiagnostic cytology (Bethesda criteria I) after two biopsies, a diagnostic thyroid lobectomy should be done, as the risk of malignancy is similar to that of indeterminate nodules.

Suspicious or Indeterminate FNA (Bethesda Criteria III–V)

Indeterminate nodules are reported as follicular/Hürthle cell neoplasm or suspicious for follicular/Hürthle cell neoplasm (Bethesda category IV) or follicular/Hürthle cell lesion of undetermined significance or atypia of undetermined significance (Bethesda category III). Approximately 15% to 30% of FNAs that are reported as follicular neoplasm/suspicious for follicular neoplasm are follicular thyroid carcinomas or the follicular variant of papillary thyroid cancer (FVPTC). The FVPTC is more common than follicular thyroid cancer and is associated with a better prognosis. The encapsulated FVPTC is especially associated with an excellent prognosis, with a very low risk of metastases or recurrence. The diagnosis of follicular thyroid cancer is based on capsular or vascular invasion, so a final histologic diagnosis cannot be predicted by cytology alone, while the FVPTC has follicular architecture and cytologic features of papillary

thyroid cancer, sometimes permitting a diagnosis of malignancy based on cytology. The likelihood of follicular thyroid cancer versus FVPTC can be predicted based on patient and tumor characteristics. Follicular thyroid cancer is more likely in elderly male patients with large tumors. Patients with nodules suspicious for follicular thyroid cancer should be treated with a diagnostic lobectomy without frozen section, which is not helpful since it cannot assess well for capsular and vascular invasion, which are characteristics that separate benign from malignant follicular neoplasms; however, for patients likely to have a FVPTC, intraoperative assessment with frozen section/touch prep cytology may confirm malignancy, allowing a single stage thyroidectomy. A completion thyroidectomy would be indicated if final pathology revealed a follicular cancer/FVPTC with intermediate- or high-risk features. The completion thyroidectomy should be done either within 2 weeks of the initial surgery or after 2 to 3 months from the original surgery to avoid the worst inflammation and scar tissue. While surgery with a diagnostic lobectomy is the “gold-standard” for indeterminate nodules, molecular testing may be used to further differentiate these nodules into those that are likely malignant and should have surgery and those that are likely benign and can be safely observed. The ultrasound characteristics of the nodule, patient history and physical exam findings, and patient preference all should be taken into consideration when deciding whether to obtain molecular testing, and the type of molecular test to use. Two distinct types of molecular testing are available and can be classified as either a “rule out” or a “rule in” test. Molecular testing with the Afirma gene expression classifier (GEC) has been shown to effectively “rule out” malignancy. For negative test results on the Afirma GEC, the risk of malignancy is similar to that of a benign nodule, thereby potentially avoiding the need for diagnostic surgery. For results deemed to be “suspicious” on the GEC, the risk of malignancy is reported to be approximately 40%, so these patients frequently go on to a diagnostic thyroid lobectomy. It is important to note that long-term results have not been published demonstrating durability of the “benign” GEC result in thyroid nodules that have been surveilled. The “rule-in” test evaluates for a panel of somatic mutations and rearrangements. A commercially available 7 gene panel (BRAF V600E, BRAF K601E, KRAS, NRAS, HRAS, RET/PTC, PAX8/PPARG) is available which is highly specific, but lacks sensitivity to rule out thyroid cancer. If a mutation is identified, there is a high likelihood of malignancy (100%

BRAF or RET/PTC and 85% BRAF K601E, RAS or PAX8/PPARG), and definitive surgery should be performed. A diagnostic lobectomy can still be performed for a negative test, since malignancy is not excluded with the same confidence. Newer versions of the “rule in” test with a larger gene panel have been developed with a reported improved sensitivity and specificity, but additional validation studies are necessary. In the end, patients should be counseled about the strengths and weaknesses of molecular testing, as patient preference is critical in decision making regarding its use in specific cases.

An FNA revealing a Hürthle cell neoplasm/suspicious for Hürthle cell neoplasm implies a 15% to 45% risk of malignancy. Similar to follicular neoplasms, the diagnosis of malignancy is based on capsular or vascular invasion, such that cytology cannot reliably distinguish malignant from benign tumors. Accordingly, Hürthle cell neoplasms are treated similarly to follicular neoplasms, with a diagnostic thyroid lobectomy without frozen section analysis followed by completion thyroidectomy if an intermediate- or high-risk malignancy is found on final pathology. Unlike follicular neoplasms, large Hürthle cell neoplasms are more likely to be malignant than small Hürthle cell neoplasms, particularly in elderly patients. The risk of malignancy for tumors >4 cm exceeds 50%, so an upfront total thyroidectomy is often recommended for these large tumors. Molecular testing also may be employed for these nodules, but appears to be less effective than for follicular neoplasms.

A 5% to 15% risk of malignancy is implied when an FNA reveals a follicular/Hürthle cell lesion of undetermined significance or atypia of undetermined significance (Bethesda category III). For these patients, a repeat FNA with/without molecular testing or upfront diagnostic lobectomy is recommended. Upfront lobectomy should be considered for nodules with concerning imaging features or based on patient preference. If a repeat FNA is performed, recommendations are based on these results. Thyroid lobectomy is recommended for repeat indeterminate cytology or positive (“suspicious”) molecular testing. Alternatively, for patients with small nodules with indeterminate cytology that do not have suspicious ultrasound features, surveillance with serial ultrasound may be reasonable.

A nodule suspicious for papillary thyroid cancer (Bethesda category V) implies a 60% to 75% risk of malignancy; however, this may vary between institutions. Due to the high risk of malignancy, these patients may be treated similarly to patients with FNA diagnostic for papillary thyroid

cancer and have upfront thyroidectomy for any clinical or patient features that may indicate an intermediate- or high-risk tumor. A thyroid lobectomy may be planned as the definitive operation for patients with suspicious nodules anticipated to be at a low risk of malignancy. Alternatively, a diagnostic lobectomy with frozen section and touch prep analysis may be performed. If frozen section is positive for papillary thyroid cancer (which is typically a cytologic diagnosis), a total thyroidectomy can be performed during the same operation. If the intraoperative assessment is indeterminate, the operation should be terminated, and final recommendations for completion thyroidectomy are made based on permanent pathology.

Malignant FNA (Bethesda Category VI)

Patients with an FNA diagnostic of papillary thyroid cancer should be treated with either thyroid lobectomy or total thyroidectomy. The 2015 American Thyroid Association (ATA) guidelines for thyroid nodules and differentiated thyroid cancer recommend an individualized approach, taking into consideration patient and tumor characteristics and surgeon experience to determine the extent of surgery. Patients with intermediate- or high-risk tumors (including extrathyroidal extension/locally advanced disease, tumors >4 cm, multifocality, aggressive histologies, vascular invasion, nodal and distant metastatic disease) and patient-specific factors (e.g., history of familial thyroid cancer and head and neck irradiation) should be treated with total thyroidectomy to facilitate radioactive iodine treatment and close surveillance due to higher risk of recurrence. Tumors that are at low risk of recurrence and do not require treatment with radioactive iodine may be treated with thyroid lobectomy or total thyroidectomy. This recommendation is based on recent studies by our group and others showing that patients with 1 to 4 cm tumors have equivalent overall survival following either lobectomy or total thyroidectomy. Contralateral thyroid nodules, a history of cervical radiation exposure, family history of thyroid cancer, and patient choice may be criteria used to justify total thyroidectomy. Unifocal tumors <1 cm should be treated with thyroid lobectomy except if there is a history of cervical radiation, a family history of thyroid cancer, evidence of extrathyroidal extension, lymph node/distant metastases, or clear indications to remove the contralateral lobe. Emerging evidence suggests that surveillance with serial ultrasound might represent a nonoperative

alternative for a subset of patients with tumors <1 cm who are at low risk of developing tumor progression. A therapeutic level VI compartmental central lymph node dissection should be performed for patients when abnormal central lymph nodes are identified during surgery or preoperatively on physician examination, ultrasound, or other radiologic imaging. A prophylactic central compartment (level VI) lymph node dissection can be considered for high-risk tumors (T3, T4), clinically involved lateral compartment lymph nodes, or if the information would be helpful to plan further therapy. If suspicious lateral compartment cervical lymph nodes are identified, an ultrasound-guided FNA should be performed, and if it is positive for malignancy, a selective lateral compartment lymph node dissection of levels IIA, III, IV, and VB should be performed (Fig. 39.2).

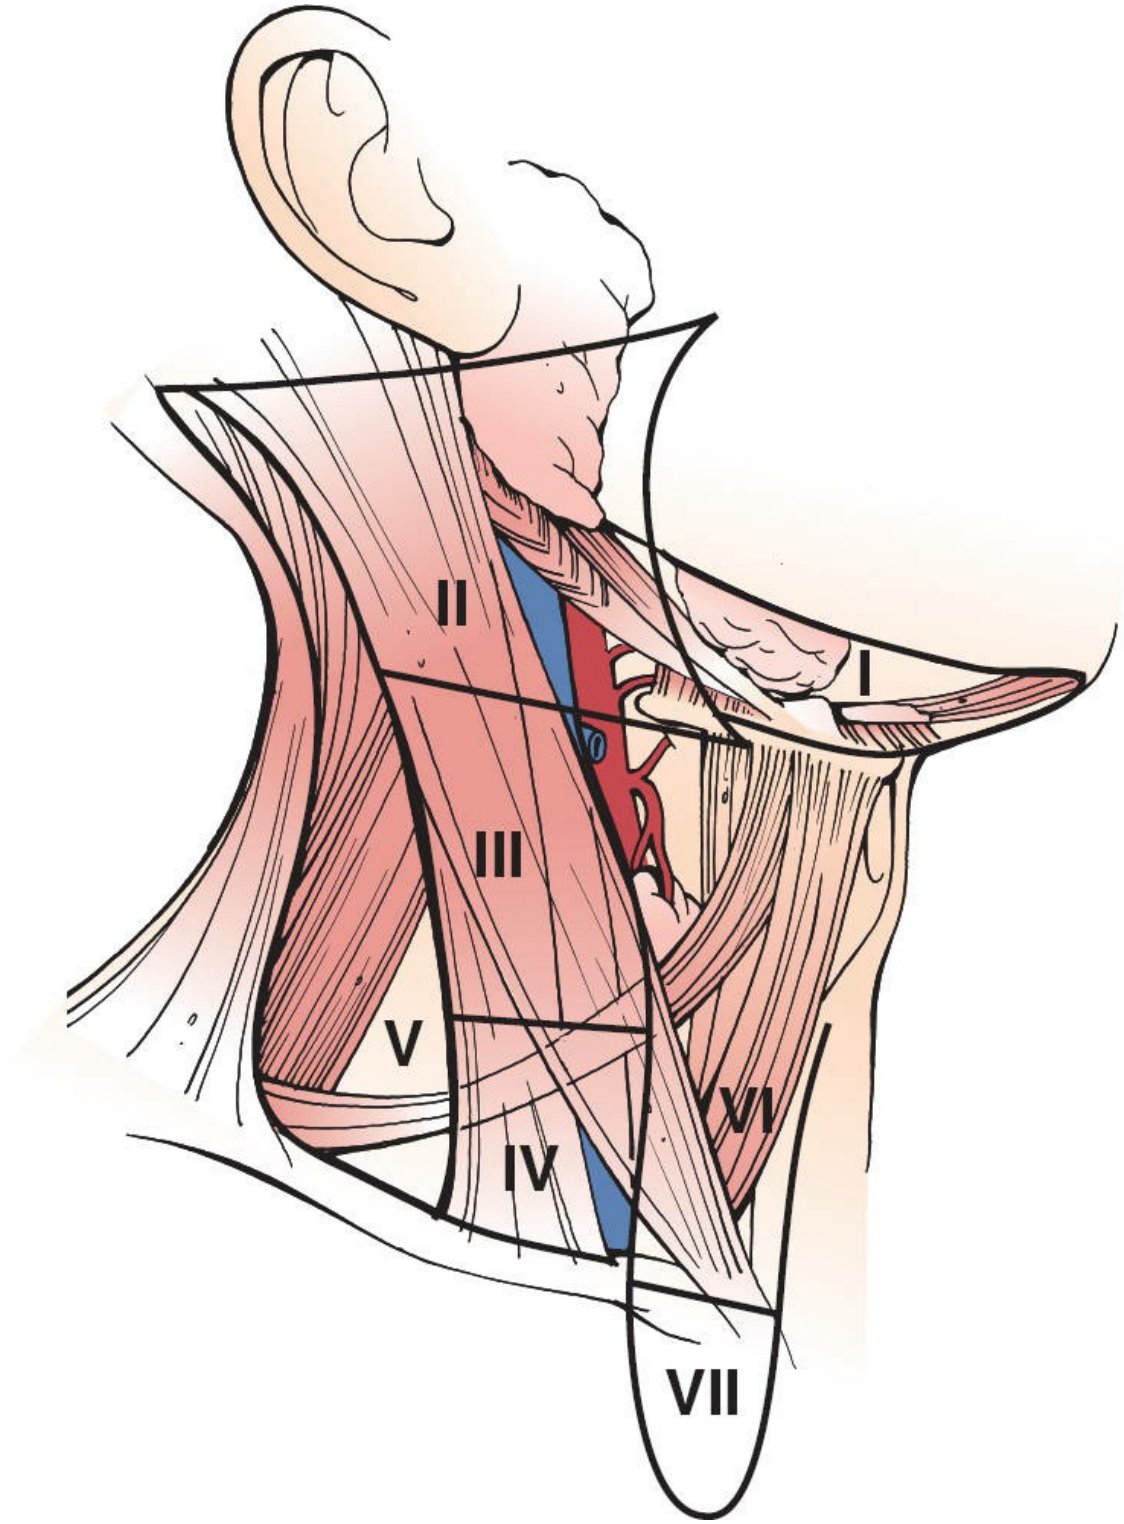

Figure 39.2. Nodal levels and their numbered compartments in the neck (I to VII).

Patients with an FNA diagnostic for medullary thyroid cancer should be treated with a total thyroidectomy and bilateral level VI central compartment lymph node dissection due to the frequency of lymph node metastases and the lack of effective adjuvant treatment. A selective lateral

compartment (levels II to V) should be performed for biopsy-proven lymph node metastases. The role of prophylactic lateral compartment lymph node dissection for patients with elevated calcitonin levels is controversial and is neither recommended for nor against by the 2015 ATA medullary thyroid cancer guidelines.

Patients with an FNA diagnostic for anaplastic thyroid cancer are usually not treated with surgery. They typically present with primary tumors that are locally advanced with/out extensive distant metastases and are treated with chemotherapy and external beam radiation. On rare occasions, anaplastic thyroid cancer is localized to the thyroid gland without local invasion or distant metastases (Stage IVA disease), such that thyroidectomy can be performed prior to chemotherapy and external beam radiation. Also, thyroidectomy can be performed to optimize local disease control in the setting of distant metastases if it may be accomplished with minimal morbidity and would not delay further treatment.

Primary thyroid lymphoma is uncommon but should be suspected with a rapidly expanding thyroid mass/goiter. The majority of these tumors are diffuse B-cell non-Hodgkin lymphomas. Symptoms of dysphagia, dyspnea, dysphonia, neck pain, and facial edema are common. Some patients may have systemic symptoms of lymphoma, including fever, night sweats, and weight loss. On physical exam, the thyroid is typically enlarged, firm, fixed, and may be tender to palpation; cervical lymphadenopathy is common. If primary thyroid lymphoma is suspected, FNA with flow cytometry should be performed to obtain a diagnosis. If FNA is nondiagnostic but suggestive of lymphoma or the clinical suspicion for lymphoma is high, a core biopsy is recommended to obtain sufficient tissue to confirm the diagnosis. Multiple core biopsies may be required if extensive tumor necrosis is present. An excisional biopsy is rarely necessary. Primary thyroid lymphoma is typically treated with chemotherapy and radiation; thyroidectomy is not recommended.

Hyperthyroidism

Hyperthyroidism can be treated with medication (thionamides), radioactive iodine, or surgery. The decision for the treatment should be individualized based on patient factors, disease process, and patient preference. Patients treated with thionamides should be reconsidered for radioactive iodine or surgery if hyperthyroidism persists after treatment for 12 to 18 months. In the special situation when hyperthyroidism is diagnosed during pregnancy,

thionamides are recommended (propylthiouracil 1st trimester, methimazole thereafter). Radioactive iodine is contraindicated, and surgery is only recommended for patients who fail medical management. In the United States, the majority of patients with Graves' disease are treated with radioactive iodine. However, surgery is the preferred treatment of some patients. Surgery is recommended for children, pregnant patients, nodules concerning or diagnostic of cancer, symptomatic or large goiters (>80 g), moderate-to-severe Graves' ophthalmopathy, or patient preference. Toxic multinodular goiter (Plummer's disease) may be treated with surgery or radioactive iodine. Surgery is recommended for patients with large goiters, evidence of low radioactive iodine uptake on thyroid scan, concern for malignancy, or patient choice. Total thyroidectomy is the surgical procedure of choice for Graves' and Plummer's disease because subtotal thyroidectomy is associated with a higher risk of recurrence with similar surgical morbidity. A toxic adenoma may be treated with radioactive iodine or an ipsilateral thyroid lobectomy. Both methods are effective; however, thyroid lobectomy offers rapid control of the hyperthyroidism and a lower recurrence rate than radioactive iodine.

Multinodular Goiter

Surgery is recommended for goiters that are symptomatic due to local compression, concern for malignancy, or for cosmetic reasons. Large goiters can compress the trachea and esophagus, leading to dyspnea or dysphagia. FNA of thyroid nodules may be indeterminate for malignancy, or innumerable nodules may be present that meet the criteria for biopsy, such that despite benign FNA of the most suspicious nodules, the patient or clinician may prefer surgery rather than undergo frequent/repeat FNAs indefinitely. Thyroidectomy also should be considered for mediastinal extension due to an inability to definitively rule out malignancy or since the mediastinal component may increase in size over time, making cervical excision more difficult; this would be a particular concern in a younger patient. Lastly, patients may be concerned about the cosmetic appearance of large goiters and elect for surgery.

Remedial Thyroid Surgery

Remedial thyroid surgery may be required for recurrent goiter, Graves' disease, or thyroid cancer. Prior medical records including operative reports and pathology slides should be obtained and carefully reviewed.

For patients with thyroid cancer, recurrence should be confirmed with FNA, and the extent of disease evaluated with imaging prior to initiating treatment. The decision for surgery is best derived after multidisciplinary evaluation, taking into consideration extent of disease and risk of complication, patient preference, and surgeon experience. Even in experienced hands, the risk of complication is significantly higher with remedial surgery. The majority of patients with thyroid cancer develop recurrence within regional cervical lymph nodes which are best treated with compartment-oriented central or lateral compartment lymph node dissection to remove all cervical disease. For patients with a prior compartment-oriented dissection by an experienced surgeon, a more selective approach using intraoperative ultrasound or wire localization of the disease may be used. Observation for patients with low volume disease is another option, especially in a reoperative field. For patients with distant metastases, surgical resection may be considered to protect the airway or facilitate radioactive iodine treatment directed to the extracervical disease. Prior to surgery, laryngoscopy and imaging with cervical ultrasound and selective use of CT are recommended to facilitate surgical planning and inform risk stratification. For patients who are not operative candidates due to medical comorbidities, high-risk disease location or a challenging reoperative field may be treated with radioactive iodine (if still iodine avid), ethanol ablation, radio frequency ablation, external beam radiation, or systemic therapy with tyrosine kinase inhibitors.

Contraindications

There are few contraindications to thyroid surgery, as long as the patient's overall health does not preclude general anesthesia. Surgery is not recommended for primary thyroid lymphoma and should be performed selectively for patients with anaplastic thyroid cancer when it can be performed with acceptable patient morbidity, as noted above. For differentiated thyroid cancer or medullary thyroid cancer, extensive invasion into the trachea, larynx, or esophagus is a relative contraindication for surgery, particularly in the setting of distant metastases. A limited resection of the trachea is well tolerated, and a more extensive resection to remove all disease in a young healthy patient may be warranted. Tumor involvement of the carotid artery or bilateral internal jugular veins is unresectable, while unilateral sacrifice of an internal jugular vein generally can be accomplished safely. The decision for

surgery in these complicated patients is best made in a multidisciplinary team setting, taking into consideration the patient's overall health, extent of metastatic disease, extent of surgery with attendant morbidity, underlying pathology, and the patient's goals. Distant metastases are not an absolute contraindication to surgery; indeed, palliative debulking surgery might be recommended to protect the aerodigestive tract, and in well-differentiated thyroid cancer facilitates more efficient radioactive iodine treatment.

PREOPERATIVE PLANNING

Preoperative Testing

All patients should have a TSH drawn to evaluate thyroid function. A calcium level should be obtained to evaluate for hyperparathyroidism. If hyperparathyroidism is identified, parathyroidectomy should be performed at the same time as thyroid surgery. Patients with medullary thyroid cancer should have calcitonin and carcinoembryonic antigen (CEA) tumor markers drawn, as well as a rearranged during transfection (RET) proto-oncogene tested, since one quarter of incident cases of medullary thyroid cancer will be inherited. Patients with unknown or positive genetic testing should also have biochemical testing to rule out pheochromocytoma (plasma fractionated metanephrines or 24 hour urinary catecholamines and metanephrines), and primary hyperparathyroidism (serum calcium and intact parathyroid hormone [PTH] levels) prior to surgery. Calcitonin and CEA levels correlate well with volume and extent of disease and can provide important prognostic information. Patients with locally advanced medullary thyroid cancer or serum calcitonin levels >500 pg/mL should have cross-sectional imaging to evaluate for extracervical metastatic disease, including neck/chest CT, liver MRI, and bone scan.

If not already performed, all patients should have a dedicated thyroid ultrasound to determine the size of the thyroid gland, size, number, and appearance of thyroid nodules, and the association of the nodules to surrounding structures. The 2015 ATA guidelines for thyroid nodules and differentiated thyroid cancer stratify nodules into risk categories by sonographic appearance. High-risk nodules are hypoechoic solid or partially cystic nodules with a solid hypoechoic component with one or more of the following features: microcalcifications, irregular margins, taller than wide nodule shape, rim calcifications with extrusive component, and evidence of extrathyroidal extension. Nodules with these features have

a 70% to 90% risk of malignancy. Intermediate-risk nodules are hypoechoic without any of the suspicious features mentioned above and have a 10% to 20% risk of malignancy. Low-risk nodules are hyper- or isoechoic and partially cystic nodules without suspicious features; they have a 5% to 10% risk of malignancy. Very low-risk nodules are spongiform in appearance and have a <3% risk of malignancy; finally, purely cystic nodules have a <1% risk of malignancy. Lymph node mapping with ultrasound to evaluate for lymph node metastases in the central and lateral neck compartments should be performed for all patients with cytologic or molecular findings diagnostic or suspicious for thyroid cancer. FNA of any suspicious appearing (cystic, microcalcifications, round shape, or peripheral vascularity) or significantly enlarged lymph nodes should be performed to evaluate for metastatic disease. Thyroglobulin or calcitonin washout of the FNA aspirate can be done for indeterminate cytology in order to increase the accuracy of FNA for differentiated or medullary thyroid cancers, respectively. CT with contrast is recommended for patients with suspected locally advanced disease, including advanced primary tumors or bulky/extensive lymph node involvement, ultrasound findings revealing posterior extension of tumor, inferior extension of tumor or inability to visualize the inferior extent of the tumor, voice changes, or vocal cord paralysis. CT with intravenous contrast is useful to identify invasion into surrounding structures, including the trachea, larynx, esophagus, muscle, major vascular structures, including the carotid artery and internal jugular vein, and extension into the mediastinum. Preoperative identification of any of these findings would significantly alter the surgical plan. The iodinated contrast from CT scanning should not delay radioactive iodine treatment of patients with normal renal function, since the iodine should be cleared prior to planned treatment. If there is any concern, urinary iodine concentration can be measured to assess for adequate clearance.

The 2015 ATA guidelines for differentiated thyroid cancer recommend preoperative voice assessment for all patients prior to thyroid surgery by the patient and physician. All patients with subjective or objective voice changes, a prior history of cervical or chest surgery, or locally advanced cancer (particularly with posterior extension) should be evaluated with laryngoscopy to assess vocal cord function. A paralyzed vocal cord significantly increases the risk of surgery and may alter surgical planning. Surgery on the side contralateral to the paralyzed vocal cord should be

undertaken with extreme caution because the patient would be placed at risk of bilateral recurrent laryngeal nerve (RLN) injury and potential tracheostomy.

Hyperthyroidism

Prior to thyroidectomy, a euthyroid state needs to be restored in patients with hyperthyroidism in order to avoid increased risk of thyroid storm during surgery. Treatment with methimazole, a thionamide, can typically accomplish this within 4 to 6 weeks. Propylthiouracil is no longer recommended due to a higher risk of side effects, including fulminant hepatic failure, except during the first trimester of pregnancy due to birth defects associated with the use of methimazole by the mother during that time. Methimazole is usually started with a dose of 10 mg one to two times/day and tapered based on patient response. Beta blockers can be added to control symptoms of tachycardia and tremor. Thyroidectomy can be safely performed once the patient's free T3 and T4 levels are normal; the TSH level usually lags behind and does not need to be normal at the time of surgery. For Graves' disease, super saturated sodium iodine (SSKI) with two drops three times daily should be started 7 to 10 days prior to surgery to decrease the vascularity of the thyroid gland and facilitate thyroidectomy by reducing blood loss. Patients who do not tolerate or are resistant to thionamides or who require urgent surgery can be prepared for the operating room within 1 week using a combination or SSKI (five drops every 6 hours), corticosteroids (300 mg loading dose then 100 mgs every 8 hours), and beta blockers (60 to 80 mg propranolol every 4 hours).

Patients with Graves' disease are at higher risk of postoperative hypoparathyroidism and hypocalcemia. To avoid this complication, patients can be started on calcitriol 0.5 mcg twice/daily 3 days prior to surgery. Alkaline phosphatase and 25OH vitamin D levels are obtained for risk stratification. For patients that are severely vitamin D insufficient or deficient or who have an elevated alkaline phosphatase level, surgery may be delayed to permit repletion of vitamin D and stabilization of bone disease. Preoperative calcium supplementation with 1,000 mg three times/day for 2 weeks prior to surgery also has been shown to decrease the incidence of postoperative hypocalcemia.

Informed Consent

Thyroidectomy is a well-tolerated procedure with infrequent complications

when performed by an experienced (high-volume) surgeon. Complications include the risk of an injury to the RLN which may result in hoarseness, change in voice, and/or aspiration. A bilateral RLN injury can result in loss of the airway, stridor, and even the need for tracheostomy. Injury to the external branch of the superior laryngeal nerve injury can lead to the patient's inability to reach high pitch and decreased voice volume. In some patients, nerve injury can be occult. The risk of transient and permanent nerve injury/hoarseness is 5% and 1%, respectively, for high-volume thyroid surgeons, but on average appears to be significantly more frequent for low-volume surgeons. Hypoparathyroidism may occur following total thyroidectomy, but not lobectomy, since only two parathyroid glands are at risk of injury. The risk of transient and permanent hypoparathyroidism is 10% to 20% and 1% to 2%, respectively. Transient hypoparathyroidism usually resolves within 1 to 2 weeks, but may take longer for some patients. Postoperative bleeding and hematoma are rare complications (<1%); however, they can be life threatening, with a rapid loss of the airway. Wound infection or other wound complications are uncommon. Complications of lateral compartment neck dissection include injury to the vagus nerve causing hoarseness; phrenic nerve leading to dyspnea and a weak cough; sympathetic chain injury leading to Horner's syndrome; spinal accessory nerve leading to shoulder weakness; brachial plexus leading to hand and arm weakness; marginal branch of the facial nerve injury leading to asymmetric smile; great auricular nerve, ansa cervicalis, and cervical plexus injury leading to numbness of the ear, neck, face, and upper chest; and lymphatic leak and thoracic duct injury potentially necessitating drainage, amendment of diet, or even reoperation.

Lifelong thyroid hormone replacement is required after total thyroidectomy and may be required after thyroid lobectomy. Only about 20% to 30% of patients will require thyroid hormone replacement after thyroid lobectomy. Risk factors for developing hypothyroidism following lobectomy include a high normal TSH preoperatively, a heterogeneous gland on ultrasound imaging, and a history of thyroiditis.

Anticoagulants should be stopped prior to thyroidectomy to minimize the risk of postoperative hematoma. For patients who are at increased risk of thromboembolic events, anticoagulation should be bridged with an agent with a short half-life and started cautiously after surgery. Antiplatelet therapy including aspirin should be stopped if possible before surgery; however, for patients who are at higher risk of thrombosis, low

dose aspirin may be continued.

A single dose of intraoperative corticosteroids prior to the start of surgery can be given to decrease postoperative pain, nausea, and vomiting. It may also improve postoperative voice function; however, studies have shown conflicting results leading to no recommendation for or against its use by the American Academy of Otolaryngology guidelines to optimize voice quality after thyroid surgery.

SURGICAL TECHNIQUE

Thyroid Lobectomy and Total Thyroidectomy

General anesthesia is induced, and the patient is intubated. The patient is kept in a supine position and centered on the operating table. A shoulder roll is placed lengthwise between the shoulders to extend the neck and permit adequate exposure to the thyroid. It is important to ensure that the neck is not overextended which can lead to postoperative discomfort and a slight risk of spinal cord injury. Patients with known cervical spine disease may need to be evaluated by neurosurgery or orthopedic surgery prior to thyroidectomy. A gel head ring should be placed to secure the head. The arms are tucked at the patient's side, and all bony protuberances padded, including the elbows, to prevent a nerve injury. The bed is placed in a beach-chair (semi-Fowler) position to reduce venous pressure/distention within the neck and minimize bleeding. Sequential compression devices are used for deep venous thrombosis prophylaxis. Perioperative antibiotics are not required, since thyroidectomy is a clean procedure. The surgical field is prepped with a Betadine- or chlorhexidine-based solution, and sterile drapes are applied. A surgical headlight improves visualization through small-sized thyroidectomy incisions.

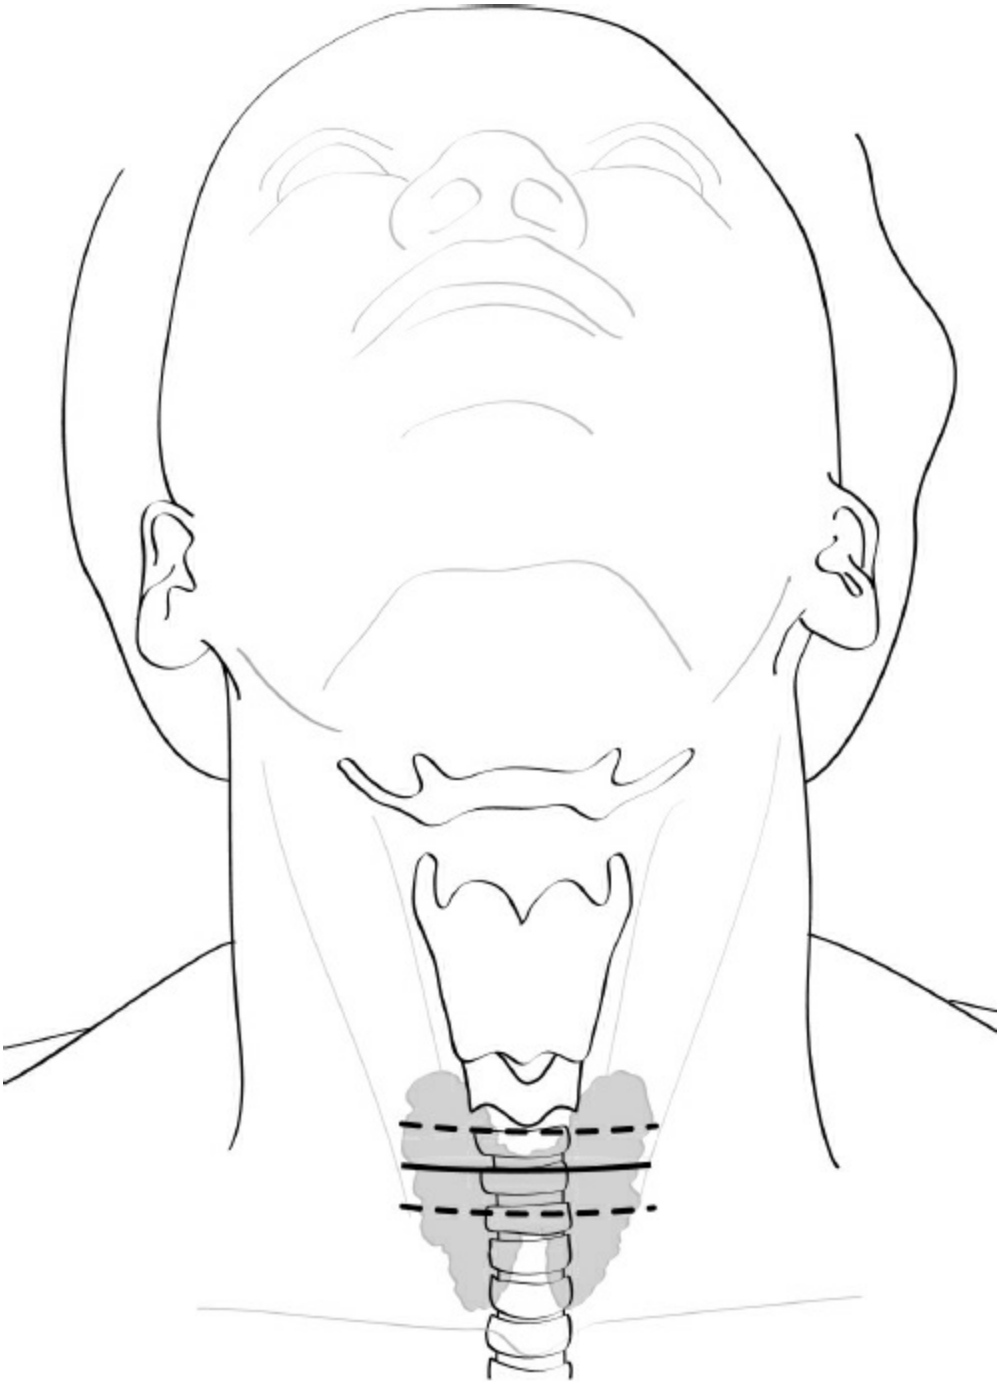

Figure 39.3. Site of incision in a skin fold about 1 cm below the cricoid. Surface anatomy with underlying anatomy shown to demonstrate why this location is optimal for thyroid surgery.

A slightly curved transverse incision is placed within a skin crease approximately 1 cm below the cricoid cartilage (Fig. 39.3). The length of the incision is based on the size of the thyroid gland, the patient's body habitus, and extent of surgery. A 3 to 4 cm incision is adequate for a normal-sized thyroid gland and small nodules. The incision should be created with a scalpel, deepened into the subcutaneous tissue and through

the platysma with electrocautery. Subplatysmal flaps are created using electrocautery. The superior flap is created by grasping the platysma and incising the natural bloodless plane posterior to the platysma and anterior to the anterior jugular veins and sternohyoid muscle (Fig. 39.4). The flap is extended to the thyroid cartilage. The inferior aspect of the platysma is grasped, and the inferior flap is created in a similar fashion in a caudal direction to the sternal notch. A self-retaining retractor can be placed to facilitate exposure (Fig. 39.5).

The sternohyoid muscles are separated in the midline raphe using electrocautery, exposing the anterior surface of the thyroid. The incision should be extended from the thyroid notch to the sternal notch to facilitate exposure. The ipsilateral strap muscles (sternothyroid and sternohyoid) are grasped, retracted laterally and dissected off the anterior aspect of the thyroid gland using blunt dissection with a Kitner or right angle clamp down to the level of the internal jugular vein along the entire length of the thyroid from the superior to inferior pole. If present, the middle thyroid vein is identified between the lateral aspect of the thyroid gland and internal jugular vein and divided between ties (Fig. 39.6). The strap muscles can be divided to provide additional exposure for large goiters. This should be done at the level of the cricoid cartilage to preserve the nerve supply, which enters inferiorly.

After thyroid exposure, the initial step is to divide the superior pole vessels in order to mobilize the superior thyroid pole. The superior thyroid pole is retracted in a lateral and inferior direction to facilitate exposure to the superior thyroid pole vessels. A retractor is used to retract the strap muscles laterally. Using a fine clamp, the cricothyroid space is opened, and the superior pole vessels are individually divided with either ties or a thermal sealing device close to the surface of the thyroid gland (Fig. 39.7) to prevent injury to the external branch of the superior laryngeal nerve. The nerve is very small and usually passes medially to the superior thyroid vessels; it can take a number of varied paths. Care should be taken not to injure the superior parathyroid gland, which may lie directly posterior to the superior thyroid pole. Thermal sealing devices have been shown to be safe and effective for thyroid surgery and may reduce operative time.

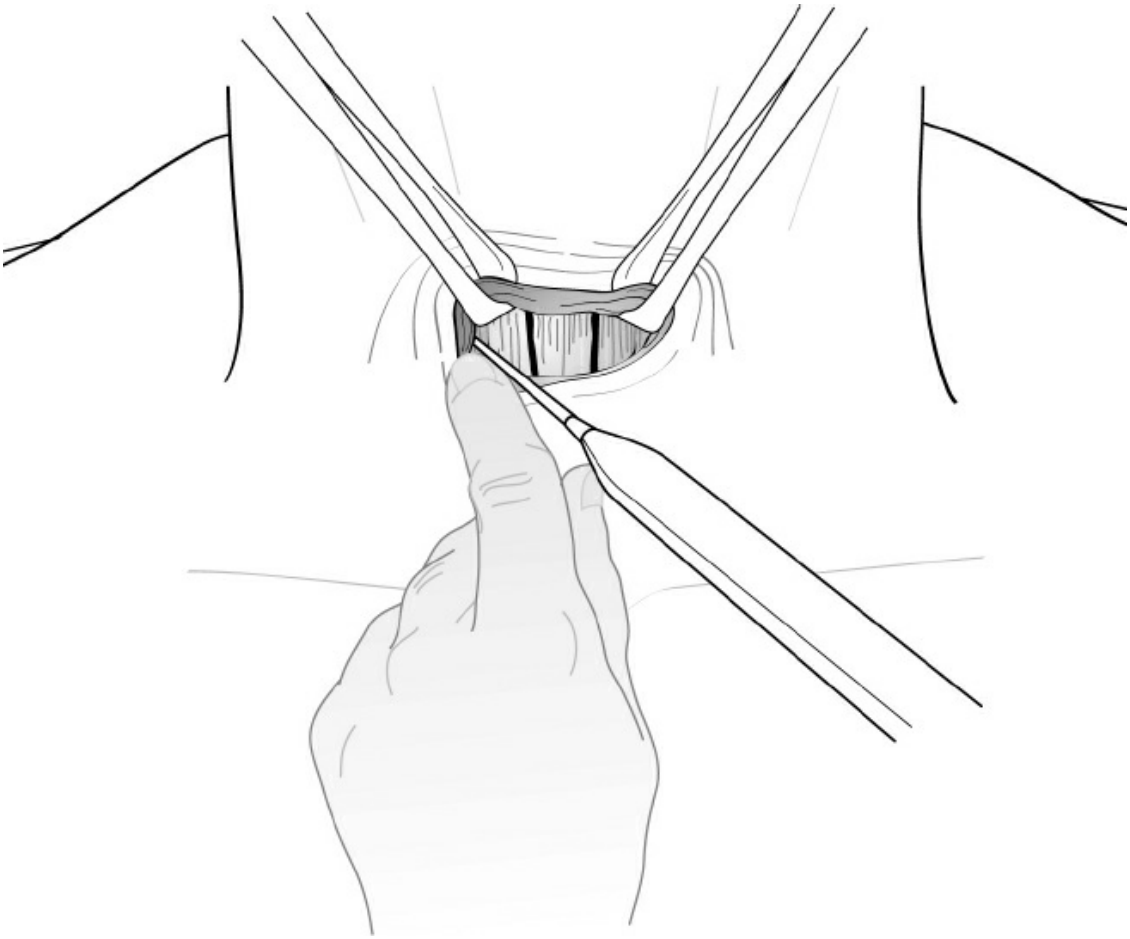

Figure 39.4. Creating superior flap—Allis clamps on platysma, countertraction with the surgeon's finger, and electrocautery, also demonstrating anterior jugular veins.

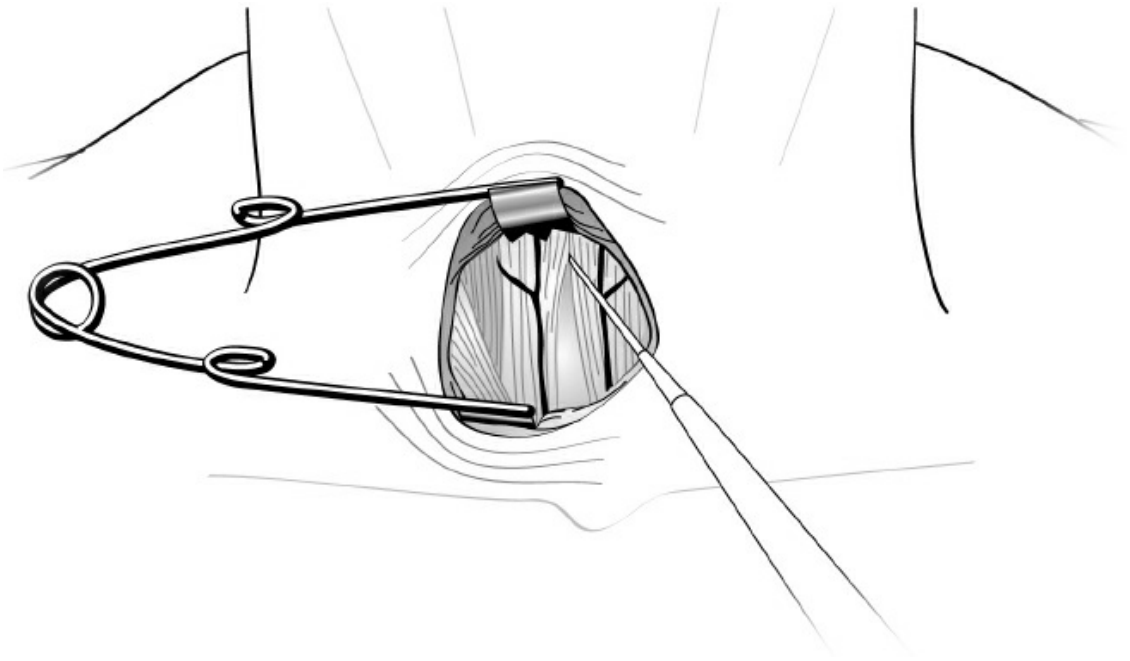

Figure 39.5. Dividing the strap muscles with electrocautery.

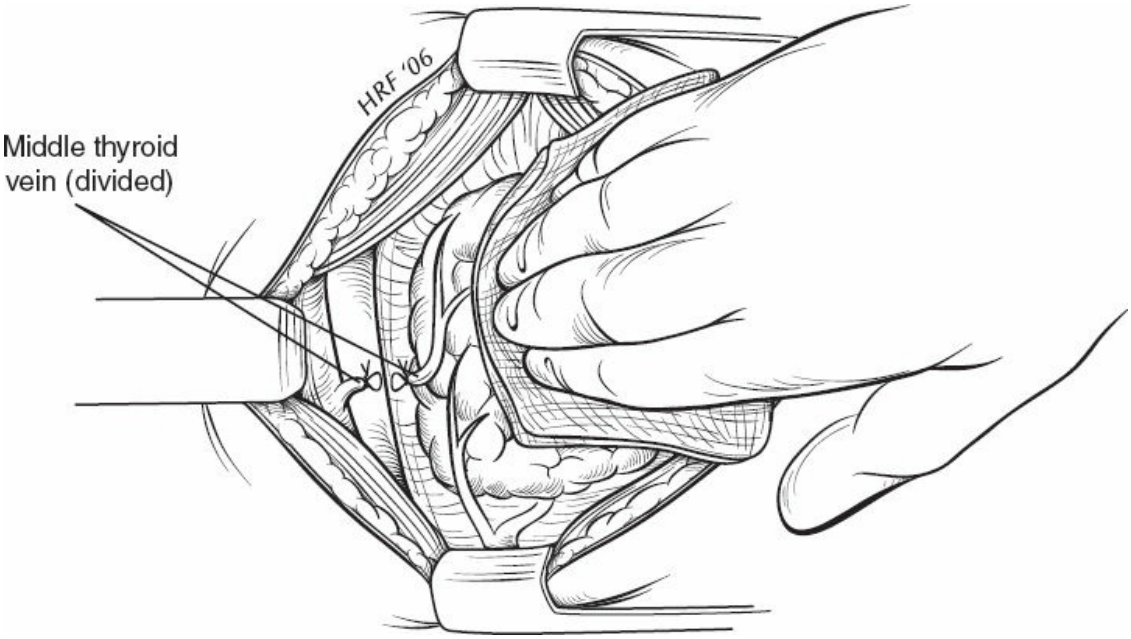

Figure 39.6. Medial retraction of thyroid with fingers covered with surgical sponge after division of the middle thyroid vein.

Once the superior pole is fully mobilized, the thyroid gland can be mobilized anteriorly and medially out of the operative wound. The thyroid is held in this position for the remainder of the procedure. In this position, the RLN and parathyroid glands can be identified, as the tracheoesophageal groove is well exposed (Fig. 39.8).

The parathyroid glands are usually within 1 cm of where the RLN crosses the inferior thyroid artery. The superior gland is typically located in a position that is superior and posterior to the RLN, and the inferior gland is usually inferior and anterior to the RLN. The superior parathyroid gland is frequently adherent to the posterior capsule of the thyroid near the tubercle of Zuckerkandl. A plane between the thyroid capsule and the superior parathyroid gland should be created, permitting the parathyroid gland to be swept off the thyroid out of the operative field while preserving its blood supply, which typically comes from the inferior thyroid artery.

The RLN should always be clearly identified and traced along its course during thyroidectomy. Routine visualization of the nerve has been shown to reduce the incidence of nerve injury. The left RLN travels in the tracheoesophageal groove throughout its entire course. The right RLN enters the neck more laterally and has an oblique course. The most reliable place to identify the nerve is just caudal to the inferior thyroid artery. If there is significant inflammation or scar in this area, the nerve can be

identified in a more caudal location. The RLN may pass posteriorly, anteriorly, or between branches of the inferior thyroid artery. A non-RLN coming directly from the vagus nerve may occur (right side) and should be suspected in patients with known aortic arch anomalies. Dissecting immediately anterior and parallel to the proposed course of the RLN facilitates identification. Branches of the inferior thyroid artery should not be ligated until the RLN and any of its branches are clearly identified to avoid inadvertent injury. Extreme caution should be exercised when dissecting the RLN to prevent inadvertent traction injury or division of the RLN or any branches that may occur prior to entering the cricothyroid muscle. Also, electrocautery should be used sparingly in proximity to the RLN to minimize the risk of a thermal injury. Once the RLN is clearly identified and protected, the end branches of the inferior thyroid artery are divided on the capsule of the thyroid gland to preserve the blood supply to the parathyroid glands. The inferior parathyroid gland is typically located in proximity to the inferior thyroid lobe and should be identified and preserved. Division of end branches of the inferior thyroid artery along the inferior surface of the thyroid gland permits the inferior parathyroid gland to drop away from the thyroid gland, thereby helping to preserve its blood supply. The final dissection through the ligament of Berry is where the RLN is most prone to injury (Fig. 39.9). The RLN should be visualized throughout the entire dissection to minimize the risk of injury. Once the anterior surface of the trachea is exposed, typically in an avascular plane, the thyroid can be dissected from the trachea with electrocautery. If a thyroid lobectomy is planned, the thyroid isthmus can be oversewn with a running suture, or divided with a sealant device (Fig. 39.10).

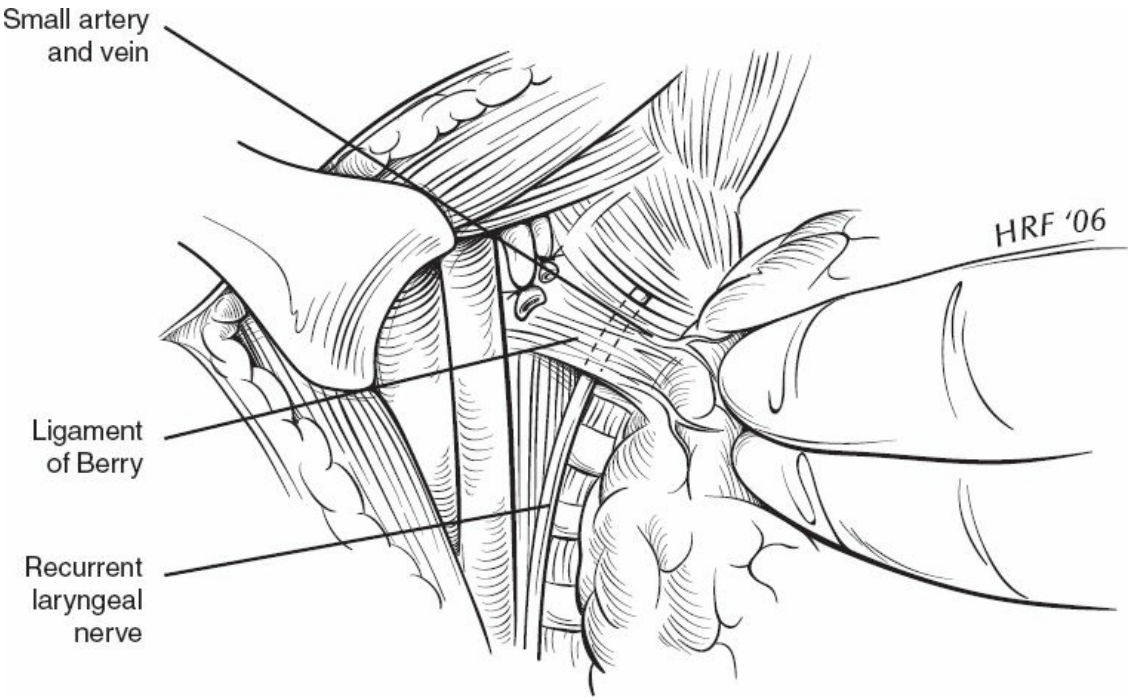

Figure 39.9. Dissection of the ligament of Berry depicting the course of the recurrent laryngeal nerve.

Intraoperative RLN monitoring may be employed during thyroidectomy; however, its use has not been shown to decrease the rate of permanent nerve injury. Proponents of nerve monitoring have advocated that it facilitates nerve identification, particularly for remedial surgery or challenging anatomy, such as advanced cancer or large goiters. Another perceived benefit of nerve monitoring is the ability to prognosticate nerve function at the conclusion of surgery. This would permit identification of a traction or blunt nerve injury and avoid the possibility of a bilateral nerve injury if surgery is terminated. Routine nerve monitoring may also be helpful because unusual anatomy and difficult surgery cannot always be predicted, and increased use permits improved familiarity with the device and potentially greater ability to troubleshoot problems. The American Academy of Otolaryngology and Head and Neck Surgery has published guidelines for improving voice outcomes after thyroid surgery. Based on an intermediate level of evidence from one randomized trial and multiple observational studies, the guidelines state that it is reasonable for surgeons to consider intraoperative nerve monitoring due to established benefit in complex and remedial cases, avoidance of bilateral nerve injury, and reduced operating time negating increased cost, suggesting value for bilateral surgery, remedial surgery, and surgery in the setting of pre-existing nerve injury.

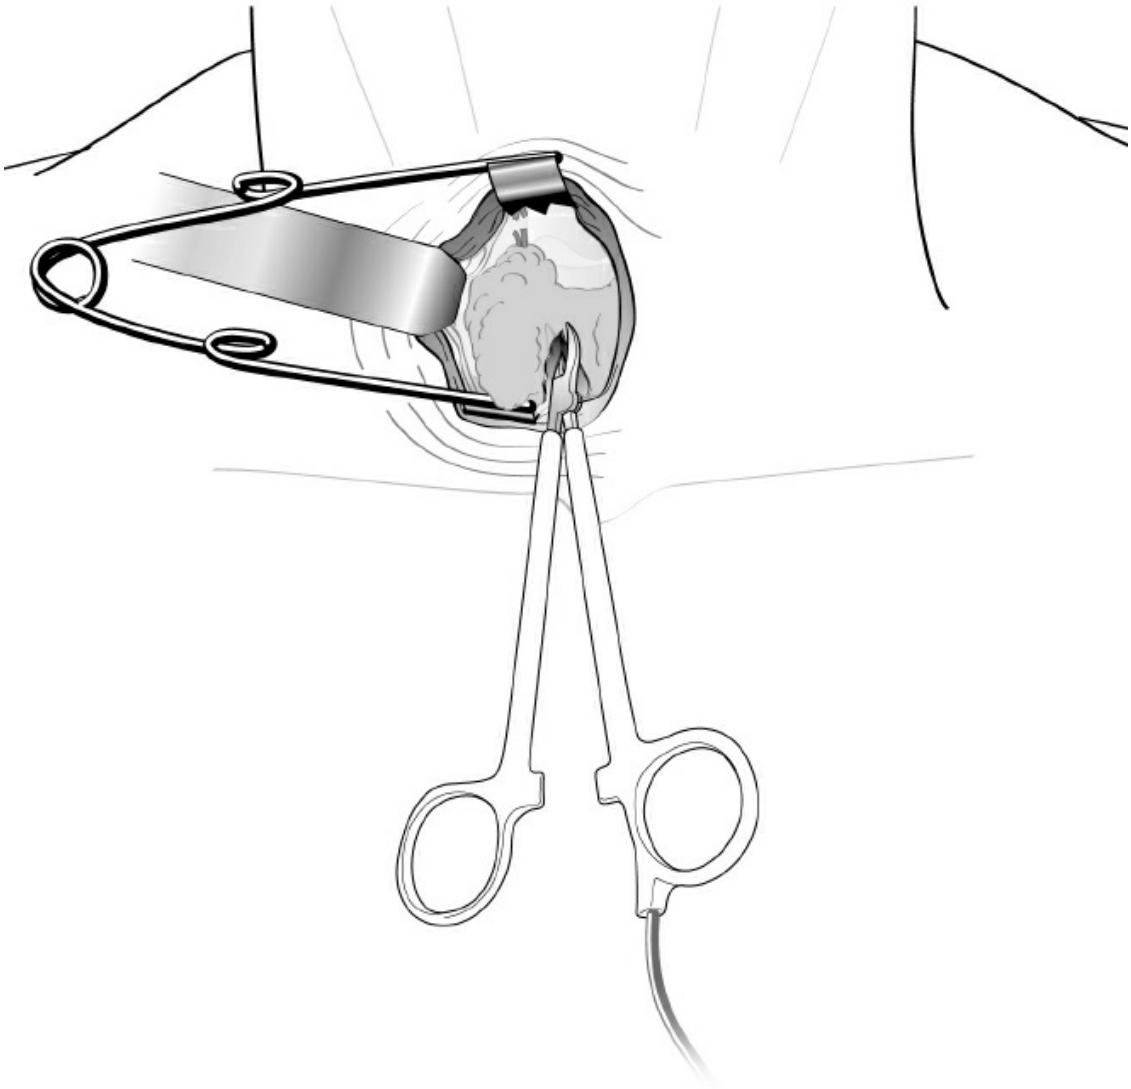

Figure 39.10. Dividing the thyroid isthmus with Ligasure during thyroid lobectomy.

A total thyroidectomy is essentially performing a thyroid lobectomy on each side. The thyroid should be resected as one specimen; however, the isthmus may be divided to facilitate exposure in large goiters. When a total thyroidectomy is planned, lobectomy should be done on the most abnormal side first. If there is an injury to the RLN during the first side, surgery should be stopped in order to preserve the contralateral RLN and prevent a bilateral nerve injury.

After the specimen is excised, it is carefully examined to determine if a parathyroid gland was inadvertently excised. If a parathyroid gland is present, it should be autotransplanted after confirmation that it is indeed parathyroid tissue (see parathyroid autotransplantation below). The operative wound is copiously irrigated, a Valsalva procedure is performed,

and hemostasis ensured. A small amount of topical hemostatic agent may be placed if there is oozing in proximity to the RLN, and pressure applied. The strap muscles are reapproximated with interrupted suture. The platysma is reapproximated with running suture, and the skin is closed with a running subcuticular monofilament suture and steri-strips.

Parathyroid Autotransplantation

Parathyroid glands should be treated as if each gland is the patient's last. If a parathyroid gland cannot be preserved in situ with ample blood supply, it should be excised, and a biopsy submitted for frozen section to confirm the presence of parathyroid tissue. While waiting, the parathyroid tissue should be placed in chilled saline. After confirmation, the parathyroid tissue is minced into small pieces and placed into pockets in the ipsilateral sternocleidomastoid or strap muscle. The pockets are closed with nonabsorbable suture and marked with clips to facilitate future localization if necessary.

Central Compartment Neck Dissection

A central compartment, level VI lymph node dissection should extirpate all prelaryngeal, pretracheal, and unilateral or bilateral paratracheal lymph nodes. A unilateral or bilateral compartment dissection may be performed. The anatomic boundaries of the central (level VI) compartment are the hyoid bone superiorly, the innominate artery inferiorly, and the carotid arteries laterally (Fig. 39.2). A standard thyroidectomy incision provides ample access to the central compartment. The entire course of the RLN should be identified from insertion into the cricothyroid muscle to where it enters the mediastinum. All lymphatic tissue should be carefully excised from around the RLN, and all lymphatic tissue within the central compartment excised. The parathyroid glands should be identified and preserved in situ if possible. Identification and preservation of the inferior parathyroid glands may be difficult. If all parathyroid glands cannot be readily identified, the excised lymphatic tissue should be carefully examined. Any parathyroid tissue that cannot be preserved in situ should be confirmed as parathyroid tissue and autotransplanted into the ipsilateral sternocleidomastoid or strap muscle.

Lateral Compartment Neck Dissection

The anatomic boundaries of the lateral compartment (levels II to V) are the base of the skull superiorly, the clavicle inferiorly, the carotid artery medially, and the medial border of the trapezius muscle laterally (Fig. 39.2). A lateral compartment lymph node dissection can be accomplished through a collar incision that is extended laterally to the lateral border of the sternocleidomastoid muscle on the affected side. Subplatysmal flaps are created superiorly to the hyoid bone and inferiorly to the clavicle. The marginal mandibular branch of the facial nerve is preserved along the superior flap. Heavy suture is placed through the platysma and secured to the drapes to provide exposure. The external jugular vein is identified and divided at the base and superior aspect of the neck dissection so that all lymphatic tissue may be removed. The dissection can be begun along the lateral border in the posterior triangle. The spinal accessory nerve is identified where it enters the trapezius using a nerve stimulator. The spinal accessory nerve is skeletonized of all lymphatic tissue from the insertion into the trapezius to the insertion at Erb's point under the sternocleidomastoid muscle. The greater auricular nerve and all sensory nerves emanating from Erb's point should be preserved if possible to avoid numbness of the ipsilateral ear lobe.

Attention is drawn to the medial border of the neck dissection. The plane between the sternocleidomastoid and the strap muscles is incised and extended inferiorly to the base of the neck and superiorly to the angle of the mandible. The sternocleidomastoid muscle is skeletonized of all fascia and lymphatic tissue and encircled with a Penrose drain to facilitate exposure. In muscular patients, the sternal and clavicular heads of the sternocleidomastoid muscle can be divided to permit visualization of the carotid sheath beneath. The omohyoid muscle is identified, dissected superiorly and laterally, skeletonized of all investing fascia and lymphatic tissue, and encircled with a Penrose drain, permitting exposure of the internal jugular vein, vagus nerve, and common carotid artery. The dissection along the lateral border of the internal jugular vein is initiated by incising the fascia just lateral to the vein approximately 2 to 3 cm cephalad to the clavicle. The internal jugular vein, carotid artery, and vagus nerve are encircled with a Penrose drain, and all lymphatic tissue surrounding these structures is extirpated. The sympathetic chain is identified posteriorly and preserved. The dissection is taken inferiorly and superiorly, such that the internal jugular vein can be retracted medially, exposing areolar tissue that extends down to the anterior scalene muscle.

Small branches of the internal jugular vein should be identified and ligated to prevent hemorrhage. The space between the lymphatic packet and the anterior scalene can be easily entered, and all lymphatics bluntly swept away from the jugular vein and anterior scalene muscle, thereby facilitating exposure of the phrenic nerve. The identity of the phrenic nerve can be confirmed with a nerve stimulator by eliciting movement of the diaphragm. The transverse cervical artery is identified on the anterior surface of the anterior scalene muscle and preserved. The dissection along the internal jugular vein is taken inferiorly to the base of the neck to where it joins the subclavian vein. On the left side, injury to the thoracic duct should be avoided where it loops up into the base of the neck and enters at the confluence of the internal jugular vein and subclavian vein. If injured, it should be ligated to prevent a chyle leak. Alternatively, it may be ligated routinely in adults. The dissection is taken from medial to lateral along the base of the neck just superior to the subclavian vein. The lymphatic tissue is divided between ties to prevent lymphatic leak. This will fully expose the anterior scalene muscle, and with further blunt anterior dissection of the lymphatic packet, the brachial plexus can be identified and protected.

The entire lymphatic packet is retracted anteriorly and medially. The phrenic nerve, brachial plexus, transverse cervical artery, accessory nerve, and vagus nerve should be easily visualized at this point and preserved (Fig. 39.11). Branches of the cervical plexus should be individually identified and preserved. Lymph nodes posterior to these nerves should be separated from posterior attachments and delivered in between branches. The spinal accessory nerve is identified and protected along its course deep and medial to the sternocleidomastoid muscle. The dissection is taken superiorly above the level of the carotid bifurcation, preserving the facial vein to the level of the posterior belly of the digastric muscle and salivary glands. Once the lymphatic packet is free, it is delivered from the operative field, oriented, and sent to pathology (Fig. 39.12A,B). For patients with differentiated thyroid cancer, excision of levels IIA, III, IV and VB is recommended. However, excision of levels IIB and VA lymphatic tissue superior to the spinal accessory nerve is recommended for medullary thyroid cancer, or patients with known involvement at these levels.

After the specimen is excised, the operative wound is copiously irrigated, a Valsalva procedure is performed, and hemostasis ensured. A small amount of topical hemostatic agent may be placed, and pressure applied if there is oozing. A closed suction drain is placed in the surgical

bed that exits below the clavicle. The cervical motor nerves should be assessed with the nerve stimulator at the conclusion of surgery to confirm their function is preserved. The anterior border of the sternocleidomastoid muscle is reapproximated to the lateral border of the sternothyroid muscle with interrupted suture. The platysma is reapproximated with running suture, and the skin is closed with a running monofilament subcuticular suture and steri-strips.

POSTOPERATIVE CARE

Thyroid Lobectomy

Thyroid lobectomy is frequently performed as an outpatient procedure. In 2013, the ATA published a statement on outpatient thyroidectomy. The statement recommended that patients should be observed in the recovery room for at least 2 hours and meet specific criteria prior to discharge, including the ability to take liquids, adequate pain control, and satisfactory postoperative evaluation without concern for hematoma, dysphonia, dysphagia, or dyspnea. Postoperative hematomas usually occur shortly after surgery, but may occur up to 3 days later, so patients should be counseled regarding symptoms of hematoma so that they can seek medical attention early in their postoperative course if necessary. If these criteria for discharge are not met, the patient should be admitted for overnight observation. Patients may be advanced from a clear liquid to regular diet as long as the patient is not nauseated. Postoperative pain is usually minimal and requires only a mild narcotic, such as acetaminophen with codeine, for no more than 1 to 2 days after surgery; frequently, acetaminophen alone is adequate. The dressing should be removed the day after surgery, and steri-strips left in place until they fall off. Patients may shower 2 to 3 days after surgery. Driving is permitted once the patient is no longer taking narcotic pain medication, and they can turn their neck without hesitating; this usually occurs 4 to 5 days after surgery. Normal activity may be resumed after surgery; however, patients should refrain from strenuous activity, including bending over and heavy lifting for 1 week. A postoperative appointment should be arranged 1 to 2 weeks after surgery to evaluate the patient for any voice changes, wound problems, and to review pathology with the patient. The half-life of levothyroxine is 7 days, so TSH is not obtained until 4 to 6 weeks after surgery to assess thyroid function. Communication between surgeon and endocrinologists/internal medicine physicians after surgery is imperative. It is essential to communicate operative findings, pathology, and intra- and postoperative events to facilitate transitions of care and treatment after surgery.

Total Thyroidectomy

After total thyroidectomy, most patients are admitted for 23-hour overnight observation. In select patients, some high-volume centers

perform thyroidectomy as an outpatient procedure. As mentioned above, the ATA published a statement for outpatient thyroidectomy in 2013. Relative contraindications to outpatient thyroidectomy were identified, including massive goiter, extensive substernal goiter, locally advanced cancer, challenging hemostasis, Graves' disease, severe thyroiditis, significant medical comorbidities, and social barriers to care. It is imperative that patients who have an outpatient thyroidectomy meet strict discharge criteria and can be easily evaluated for postoperative problems that require immediate attention should they arise.

Postoperative pain management, activity, wound care, and diet are similar for patients who undergo a thyroid lobectomy or total thyroidectomy. However, unlike thyroid lobectomy, hypoparathyroidism and hypocalcemia may occur after total thyroidectomy. Postoperative calcium levels usually nadir 3 days after surgery, so hypocalcemia should be identified early and supplemented prior to this time before symptoms occur. Selective or routine supplementation with calcium and calcitriol should be implemented to avoid this complication. Both methods have been shown to be effective for preventing postoperative hypocalcemia. Selective supplementation is based on either postoperative calcium or PTH levels. For selective supplementation based on calcium levels, serum calcium is checked in the evening after surgery and the following morning. Supplementation is based on the calcium value and change in the evening and morning values. Ionized calcium or calcium corrected for albumen more accurately reflect active calcium levels and may be useful in select patients. For selective supplementation based on PTH levels, serum PTH is obtained in the recovery room, and if >10 pg/mL, patients are given 1,000 mg calcium carbonate twice/day for 1 week; for PTH <10 pg/mL, patients are given 0.25 mcg calcitriol twice/day in addition to 1,000 mg of calcium carbonate three times/day. Our group and others have advocated routine supplementation for all patients following thyroidectomy, with calcitriol 0.25 mcg twice/day and 1,000 mg calcium carbonate three times/day, since routine supplementation has been shown to be more cost-effective than selective supplementation. All patients should be counseled to contact the surgeon for symptoms of hypocalcemia, such as perioral or distal extremity paraesthesias. If these symptoms occur, the supplementation may need to be increased. Calcitriol and calcium are titrated down over 1 to 2 weeks after surgery, as long as the patient does not experience symptoms of hypocalcemia.

After thyroidectomy, patients should be started on 1.6 mg/kg levothyroxine taken as a single dose on an empty stomach. Antithyroid medications for patients with hyperthyroidism should be stopped immediately after surgery and beta blockers weaned to off over 1 week. A TSH should be obtained 6 weeks after surgery to determine whether the patient is on adequate supplementation. The goal TSH should be within normal limits for patients with benign disease or low-risk thyroid cancer. A suppressive dose of thyroid hormone supplementation is recommended for patients with intermediate- or high-risk thyroid cancer.

Patients with differentiated thyroid cancer should be evaluated for radioactive iodine ablation (RAI). Treatment is selective and should be based on the risk of recurrence. The 2015 ATA guidelines for the management of differentiated thyroid cancer recommend RAI for patients with evidence of extrathyroidal extension or distant metastasis, regardless of tumor size. The guidelines also recommend that RAI be considered for other intermediate or high-risk tumor features, such as tumor size 1 to 4 cm with regional lymph node involvement or a combination of other high-risk features, such as larger tumor size, metastatic lymph nodes, and aggressive subtypes (tall cell, insular, diffuse sclerosing variants) of papillary thyroid cancer. RAI can be accomplished with either traditional thyroid hormone withdrawal or recombinant human TSH (rhTSH; Thyrogen). Both methods have been shown to be equally effective for the purpose of remnant ablation in randomized controlled trials. Thyrogen avoids the side effects of thyroid hormone withdrawal, improving quality of life for patients, so it should be used preferentially.

Lateral Compartment Neck Dissection

After lateral neck dissection with or without thyroidectomy, patients are observed in the hospital for one to two nights. Postoperative diet and wound management are similar to patients who have thyroidectomy. Patients may have more pain and require a stronger narcotic pain medication than acetaminophen with codeine. A drain in the surgical bed can be removed when there is less than 20 to 30 mL/day, typically after 2 to 4 days. Return to normal activities and driving may take longer due to increased pain or a sensation of tightness and neck stiffness. Occupational and physical therapy consultation and exercises can be beneficial to speed patients' recovery to baseline activity.

COMPLICATIONS AND THEIR MANAGEMENT

Hematoma

Hematoma requiring emergent surgical evacuation is a rare complication after thyroidectomy. Cervical hematomas can occur up to 72 hours after surgery and are characterized by a large firm mass directly posterior to the skin incision; they may be only mildly symptomatic when first identified. These are surgical emergencies, because symptoms may progress rapidly, leading to respiratory compromise. The patient should remain awake to protect the airway and be taken to the operating room emergently. The neck should be prepped, and the surgeon should be prepared to evacuate the hematoma or perform a surgical airway if the patient cannot be intubated. Once the airway is secured, the wound is opened and copiously irrigated to identify any bleeding source. It is important to use electrocautery carefully to avoid an inadvertent injury to the RLN or parathyroid glands. Overnight intubation and perioperative steroid treatment may be necessary to allow airway edema to resolve prior to extubation. A drain should be placed to evacuate any postoperative seroma or potentially identify a recurrent bleed.

Hypoparathyroidism

Hypoparathyroidism leading to hypocalcemia is the most common complication after thyroidectomy. Transient hypoparathyroidism is seen in 10% to 20% of patients, and permanent hypoparathyroidism is seen in 1% to 2% of patients after total thyroidectomy. Transient hypoparathyroidism usually resolves within 1 to 2 weeks, but may take as long as 6 months to evolve. Symptoms of hypocalcemia include perioral or distal extremity paraesthesias, with mild hypocalcemia progressing to muscle cramps and tetany with severe hypocalcemia. The threshold where patients experience hypocalcemic symptoms is highly variable and cannot be predicted based on calcium levels alone. Patients that experience symptoms usually can be managed with oral calcium and vitamin D supplementation with calcium carbonate or citrate and calcitriol. For patients already on supplementation, a dose increase may alleviate symptoms. For patients with persistent symptoms from hypocalcemia, treatment with intravenous calcium gluconate is required. The infusion should be started at 1 mg/kg/hour for 24 hours. The drip is slowly titrated off as long as the serum calcium level remains stable. At this point, the patient can be discharged home on an oral

supplementation regimen. The calcium and vitamin D supplementation can be weaned off as long as the patient does not experience symptoms of hypocalcemia.

Nerve Injury/Hoarseness

Postoperative voice changes may be due to irritation from the endotracheal tube, vocal cord edema/hematoma and arytenoid dislocation from intubation, or RLN injury. Transient RLN injury is seen in 5% of patients, and permanent RLN injury is seen in 1% of patients after thyroidectomy performed by experienced (high-volume) thyroid surgeons. Complication rates, on average, are higher when thyroidectomy is performed by less experienced, low-volume thyroid surgeons. An RLN injury should be suspected in patients with hoarseness, dyspnea, coughing, or symptoms concerning for aspiration that persist for more than 48 hours after surgery. Patients with significant dyspnea or symptoms concerning for aspiration should be immediately referred for laryngoscopy to evaluate for vocal cord paresis. These patients may require early intervention to prevent aspiration.

Most RLN injuries are transient and due to stretch or compression of the nerve, so they should resolve. Evaluation and treatment by a speech therapist can improve voice quality and reduce voice strain and patient anxiety until nerve function recovers. If vocal cord paralysis does not resolve by 6 months, it is usually permanent. Patients who have significant symptoms may undergo collagen injection into the paralyzed vocal cord, thereby medializing the cord. Medialization allows the contralateral cord to close the larynx during swallowing and phonation. If vocal cord function does not recover after 6 months and the patient remains symptomatic, a permanent medialization of the vocal cord may be performed.

Bilateral vocal cord paralysis is an uncommon but dreaded complication after total thyroidectomy. Patients typically present with difficulty breathing and stridor after extubation. Immediate intubation should be attempted, but may not be possible if the vocal cords are in a closed/adducted position. The surgeon must be prepared to perform a tracheostomy if the patient cannot be intubated or is unable to maintain an adequate airway.

Injury to the external branch of the laryngeal nerve may lead to inability to reach high pitches, voice fatigue, and decreased voice projection. These

injuries can be difficult to diagnose, except with electromyography. Most of these injuries are transient and should recover with time. Voice therapy is the mainstay of the treatment of permanent injury.

Spinal Accessory Nerve Injury

The spinal accessory nerve may be injured with a lateral compartment neck dissection. This leads to winging of the scapula, drooped shoulder, and shoulder weakness. Treatment focuses on physical therapy to strengthen the shoulder and improve range of motion.

Chyle Fistula

Chyle leaks and fistulas are caused by injury to the thoracic duct where it enters the junction of the left subclavian vein and internal jugular vein at the base of the left neck during a left lateral compartment neck dissection. Milky-appearing chylous drainage into the closed suction drain, or bulging of the left supraclavicular fossa with erythema over the area, are physical examination findings suspicious for leak. Most fistulas are low volume and can be treated conservatively with nonoperative management by placing the patient on a low fat diet, or NPO with TPN. High output fistulas (>500 mL/day) or those that are refractory may require surgical intervention.

OUTCOMES

In experienced hands, outcomes from thyroid surgery are superb. Surgery is well tolerated, and complications are infrequent. Recurrence of benign goiter and Graves' disease are rare after total thyroidectomy. The prognosis for patients with differentiated thyroid cancer is excellent, with a 5-year overall survival rate exceeding 95%. However, more than 30% of patients will develop recurrent disease. The most common site of recurrence is regionally in the cervical lymph nodes; it usually occurs within 10 years after initial diagnosis, but may recur later, thereby necessitating long-term surveillance. Treatment of patients with benign or malignant thyroid disease should be individualized and directed by easily assessed evidence-based guidelines published by professional societies in order to optimize patient outcomes. In areas where evidence is lacking, patient preference regarding treatment is essential. Overall, there is a trend toward less aggressive treatment of low-risk differentiated thyroid cancer with a careful consideration weighing the benefits against the real potential

risk of surgery and radioactive iodine. Treatment of patients continues to evolve, requiring a contemporary understanding of current literature.

EDITOR'S COMMENT

The incidence of thyroid nodules increases with age and is increased in women, in people with iodine deficiency, pre-existing thyroiditis, and after radiation

exposure. Many studies suggest a prevalence of 2% to 6% with palpation, 19% to 35% with ultrasound, and 8% to 65% in autopsy data. With widespread use of sensitive imaging in clinical practice, incidental thyroid nodules are being discovered with increasing frequency. As pointed out by the authors, ultrasonography is the most accurate and cost-effective method for evaluating and observing thyroid nodules. Current ultrasonography machines are relatively inexpensive, sensitive, and easy to operate. Most endocrinologists are now using ultrasound examination in the initial evaluation of a patient with known or suspected thyroid nodule. While the overwhelming majority of thyroid nodules are benign, the management of thyroid incidentalomas is a matter of controversy, particularly as the incidence of thyroid cancer has increased some 270% in the last three decades (Dean DS, Gharib H. Epidemiology of thyroid nodules. *Best Pract Res Clin Endocrinol Metab* 2008;22(6):901–11). It is the fifth most common cancer. In 2015, an estimated 64,300 adults (14,950 men and 49,350 women) in the United States will be diagnosed with thyroid cancer. As noted in the commentary in the 6th edition by Dr. Fischer, there was skepticism expressed by early endocrine surgeons (in particular Dr. Oliver Cope), in the mid-20th century about whether papillary thyroid cancer in particular was “a real cancer.” This was largely based on the indolent nature of some of the tumors. The 5-year survival for papillary thyroid cancer is: Stage 1 near 100%, Stage 2 near 100%, Stage 3 93%, and Stage IV 51%. The 5-year survival for follicular thyroid cancer is nearly 100% for Stage 1 and 2, and 71% for Stage 3, and 50% for Stage 4. For medullary carcinoma the survival is: Stage 1 near 100%, Stage 2 98%, Stage 3 81%, and Stage 4 28%. As evident in this chapter, we now appreciate the full malignant potential of thyroid cancer, have evolving evidence-based treatment guidelines and an understanding of specific sporadic and familial genetic mutations in the pathogenesis of this disease.

For the best outcomes, the surgeon must apply clearly defined evidence-based algorithm for the management of the incidental thyroid nodule. After screening for hyper- and hypothyroidism, fine-needle aspiration (FNA) biopsy under ultrasound guidance is the procedure of choice for the evaluation of thyroid nodules and selection of patients who should undergo surgery for a suspected or confirmed thyroid cancer. The technique has variable accuracy and that depends on the size of the lesion, skill of the person performing the biopsy, and the skill of the cytologist. FNA is recommended for nodules 1 cm or greater in size. In addition, there is difficulty in distinguishing some benign cellular adenomas, particularly follicular adenomas from their malignant counterparts. For nodules greater than 4 cm, the accuracy of the technique decreases presumably because of sampling error. Up to 15% of large thyroid nodules will contain a thyroid cancer. Analysis of recent data suggests a false-negative rate of thyroid FNA 1% to 11%, a false-positive rate of 1% to 8%, a sensitivity of 65% to 98%, and a specificity of 72% to 100%. The introduction of FNA has had a substantial effect on the management of patients with thyroid nodules.

The percentage of patients undergoing thyroidectomy has decreased by 25%, and the yield of carcinoma in patients who undergo surgery has increased from 14% to nearly 50%. In early series, FNA has been reported to decrease the cost of care by 25% (Gharib H, Goeliner JR. Fine-needle aspiration biopsy of the thyroid: an appraisal. *Ann Intern Med* 1993;118:282–9).

In this chapter, the authors describe the technique clearly. Using a 23 or 25 gauge needle will give superior sampling and accuracy. Although the technique may be done with or without aspiration, most thyroid surgeons favor the less traumatic nonaspiration technique.

"It is critical that cytopathologists communicate thyroid FNA interpretations to referring physicians in terms that are succinct, unambiguous, and clinically helpful" (Cibas ES, Syed ZA. The Bethesda System For Reporting Thyroid Cytopathology. *Am J Clin Pathol* 2009;132:658–65). Historically, the terminology used to describe the findings for thyroid FNA had been variable creating confusion in some cases.

The authors refer to using the Bethesda System for Reporting Thyroid Cytopathology (Bethesda Criteria) for categorizing thyroid nodules. In order to address terminology and other issues related to thyroid FNA, the National Cancer Institute (NCI) hosted the NCI Thyroid FNA State of the Science Conference: October 22–23, 2007. The conclusions regarding terminology and morphologic criteria from the NCI meeting led to the Bethesda Thyroid Atlas Project and formed the framework for the Bethesda Criteria. For clarity of communication, the Bethesda Criteria recommend that each report begin with one of six general diagnostic categories (Table 39.1).

As the authors point out, molecular tests are relatively new tools for further assessing nodules with atypical, suspicious, or indeterminate FNA cytology results. Combining cytology and molecular results may improve diagnosis. These tests can detect molecular alterations involved in the pathogenesis of thyroid cancer. Nodules with indeterminate cytology lacking these alterations are less likely to be malignant. Alternatively, more than 70% of papillary thyroid carcinomas have a point mutation in BRAF or RAS or a RET/PTC rearrangement, and >70% of follicular thyroid carcinomas (FTCs) harbor either RAS mutations or PAX8/PPARγ rearrangements. If a point mutation is identified, then definitive surgery is indicated. However, the reader is cautioned that RAS mutations may be found in benign thyroid lesions and hence may not be specific. In addition, sporadic and hereditary medullary thyroid carcinoma (MTC) are associated with point mutations in the RET gene.

In Chapter 39, the authors outline the appropriate treatment based on the Bethesda Criteria. For a lesion that has a high likelihood of malignancy, treatment depends on the cell type, patient and tumor characteristics as recommended by the 2015 American Thyroid Association guidelines (Haugenm BR, Alexnader EK, Bible, KC, et al. 2015 American Thyroid Association Guidelines for adult patients with thyroid nodules and differentiated thyroid cancer. *Thyroid* 2016;26:1–133). This evidence-based compendium of treatment

options for thyroid nodules is a phenomenal resource. It is clear that operations need to be individualized.

Lymph node metastases occur in 20% to 50% of patients with papillary thyroid carcinoma. Microscopic metastases are even more common and may be found in 90% of patients (Mazzaferri EL, Doherty GM, Steward DL. The pros and cons of prophylactic central compartment lymph node dissection for papillary thyroid carcinoma. *Thyroid* 2009;19:683–9). The central compartment of the neck (level VI) is most commonly involved. It is well documented that regional lymph node involvement is associated with increased rates of tumor recurrence and recurrence is more frequent in node-positive patients over the age of 45 years (Chisholm EJ, Kulinskaya E, Tolley NS. Systematic review and meta-analysis of the adverse effects of thyroidectomy combined with central neck dissection as compared with thyroidectomy alone. *Laryngoscope* 2009;119:1135–9). As the authors point out "a therapeutic level VI compartmental central lymph node dissection should be performed for patients when abnormal central lymph nodes are identified during surgery or preoperatively on physician examination, ultrasound, or other radiologic imaging. A prophylactic central compartment (level VI) lymph node dissection can be considered for high-risk tumors (T3, T4), clinically involved lateral compartment lymph nodes, or if the information would be helpful to plan further therapy. If suspicious lateral compartment cervical lymph nodes are identified preoperatively, an ultrasound-guided FNA should be performed, and if it is positive for malignancy, a selective lateral compartment lymph node dissection of levels IIA, III, IV, and VB should be recommended." In these situations, determination of FNA cytology thyroglobulin measurements may enhance the accuracy of FNA in diagnosing metastatic disease (Boi F, Baghino G, Atzeni F, et al. The diagnostic value for differentiated thyroid carcinoma metastases of thyroglobulin (Tg) measurement in washout fluid from fine-needle aspiration biopsy of neck lymph nodes is maintained in the presence of circulating anti-Tg antibodies. *J Clin Endo Metab* 2006;91:1364–9).

TABLE 39.1 The Bethesda System for Reporting Thyroid Cytopathology

Recommended Diagnostic Categories

I. Nondiagnostic or Unsatisfactory
- Cyst fluid only
- Virtually acellular specimen
- Other (obscuring blood, clotting artifact, etc.)

II. Benign
- Consistent with a benign follicular nodule (includes adenomatoid nodule and colloid nodule)
- Consistent with lymphocytic (Hashimoto) thyroiditis in the proper clinical context
- Consistent with granulomatous (subacute) thyroiditis
- Other

III. Atypia of Undetermined Significance or Follicular Lesion of Undetermined Significance

IV. Follicular Neoplasm or Suspicious for a Follicular Neoplasm
- Specify if Hürthle cell (oncocytic) type

V. Suspicious for Malignancy
- Suspicious for papillary carcinoma
- Suspicious for medullary carcinoma
- Suspicious for metastatic carcinoma
- Suspicious for lymphoma
- Other

VI. Malignant
- Papillary thyroid carcinoma
- Poorly differentiated carcinoma
- Medullary thyroid carcinoma
- Undifferentiated (anaplastic) carcinoma
- Squamous cell carcinoma
- Carcinoma with mixed features (specify)
- Metastatic carcinoma
- Non-Hodgkin lymphoma
- Other

The reader must be cautioned that the value of prophylactic central neck dissection is controversial in the absence of imaging showing abnormally enlarged nodes or palpable lymph nodes. Although regional lymph node metastases in papillary thyroid carcinoma do increase regional recurrence rates, they do not negatively impact survival rates. Pointing out the high risk of positive lymph nodes, better outcomes, and a lower morbidity rate associated with this as an initial operation some surgeons recommend prophylactic central neck dissection in order to prevent recurrence. Others argue that this procedure increases the risk of injury to the parathyroid glands and RLNs, without any demonstrable benefits in terms of long-term survival (Carling T, Long WD, Udelsman R. Controversy surrounding the role for routine central lymph node dissection for differentiated thyroid cancer. *Curr Opin Oncol* 2010;22:30–34). Central neck dissection does permit more accurate pathologic staging of the lymph nodes and treatment of the microscopic metastases. It is also argued that recurrence in this compartment is difficult to treat, while central lymph node dissection during the initial thyroidectomy can be performed within the standard collar incision.

Safely limiting hospitalization after thyroid surgery will reduce costs. The ATA guidelines refer to ambulatory thyroidectomy and specify contraindications to this approach. In this regard, of interest as is the role of PTH assay in the postoperative recovery unit in predicting the need for postoperative calcium supplementation.

Postoperative follow-up after surgery for thyroid cancer is necessary. Monitoring of serum thyroglobulin after thyroid surgery/ablation is a crucial part of follow-up for papillary thyroid cancer, follicular thyroid cancer, and Hürthle cell carcinoma. However, circulating antithyroglobulin autoantibodies may make these measurements unreliable in 20% to 30% of patients. Patients with medullary thyroid cancer are monitored to detect residual and recurrent disease using serum calcitonin and carcinoembryonic antigen measurements.

40 Comprehensive Parathyroidectomy for the Treatment of PHPT, Including Intraoperative Parathyroid Hormone Assay–Guided Parathyroidectomy

Azadeh A. Carr and Tracy S. Wang

INTRODUCTION

The diagnosis and management of primary hyperparathyroidism (PHPT) has evolved considerably over the past several decades. From a once obscure disease, PHPT has become the most common cause of hypercalcemia in the outpatient population. A recent study of a large multiracial population in the United States identified an incidence of 66 per 100,000 person-years among women and 25 per 100,000 person-years among men. The reasons for the increased incidence of PHPT are multifactorial; first, the introduction of automated routine calcium testing in the 1970s led to a significant increase in the identification of hypercalcemia. Second, osteoporosis screening has also increased and practitioners have become more aware of the association of both osteoporosis and nephrolithiasis to PHPT, prompting additional evaluation in patients with these conditions.

Surgery remains the only curative treatment for PHPT. However, there is still wide variability in management of PHPT, with a high frequency of underreferral and undertreatment. Recent studies have shown that potentially less than 40% of patients with PHPT will undergo parathyroidectomy. This may be due to lack of recognition of diagnosis, lack of referral to endocrinology, lack of referral to surgery (especially if imaging obtained is nonlocalizing), as well as locoregional access issues. Due to this variability in evaluation and treatment recommendations for PHPT, several multidisciplinary committees have established standardized guidelines on the management of PHPT to guide providers on establishing the diagnosis of PHPT, and indications and timing of surgery.

Bilateral exploration of all four parathyroid glands, which will be referred to as comprehensive parathyroidectomy, was previously the standard method for parathyroidectomy. With the introduction of improved imaging techniques and intraoperative parathyroid hormone monitoring (IPM), there has been a shift in the technique of parathyroid surgery to minimally invasive techniques, which have become the preferred method when these intraoperative adjuncts are available. However, all surgeons performing parathyroid surgery must have knowledge and experience in comprehensive parathyroidectomy, as it may be required in patients with nonlocalizing preoperative imaging, when intraoperative adjuncts fail or are unavailable, and in patients with multigland PHPT. This chapter will focus on the method for comprehensive parathyroidectomy as well as introduce the use of IPM, which may be useful for both minimally invasive parathyroidectomy (MIP) and comprehensive parathyroidectomy.

ANATOMY AND PATHOPHYSIOLOGY

There are typically four parathyroid glands in most individuals, although autopsy study has identified five or more glands in up to 13% of people. Supranumerary parathyroids are most often located in the thymus. The possibility of having an unusual number or location of parathyroid glands has direct impact on the success of parathyroid surgery and the potential need for comprehensive parathyroidectomy.

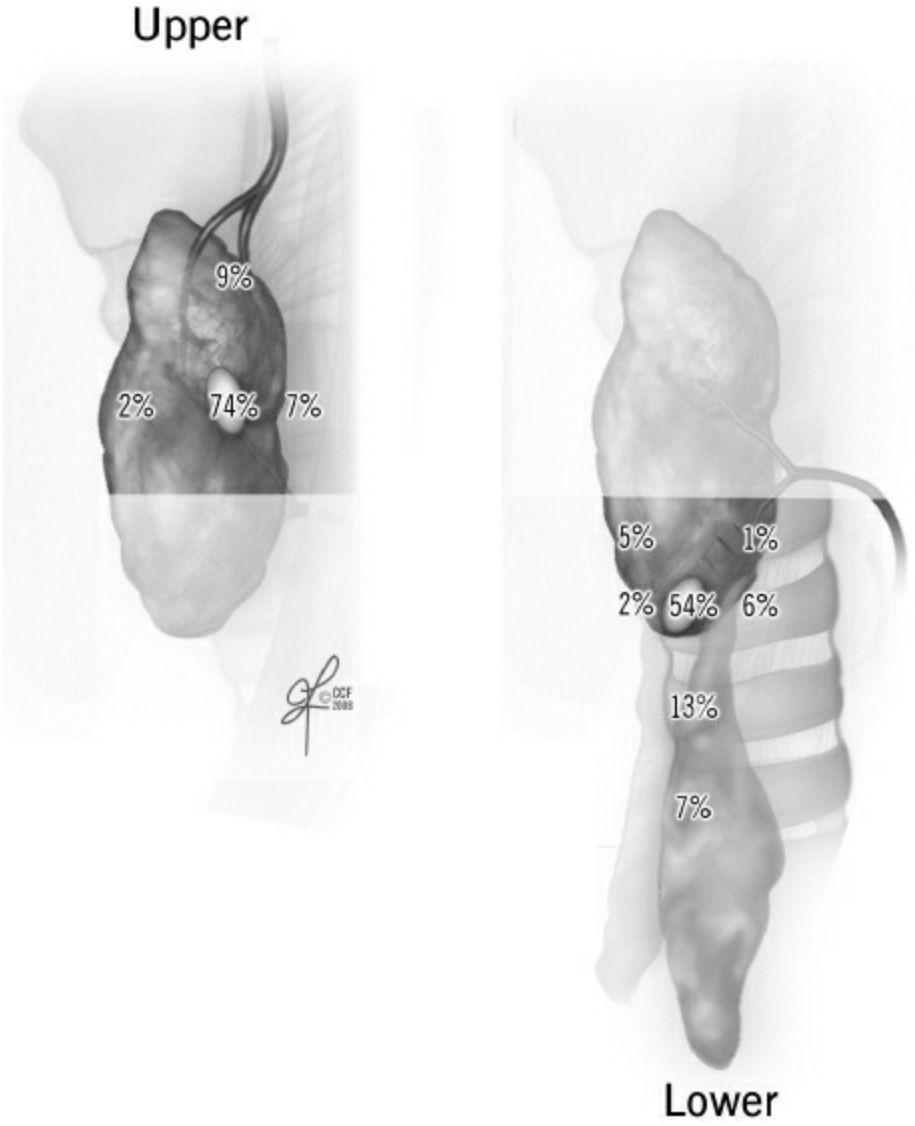

Figure 40.1. Normally expected distribution of upper and lower parathyroid glands. (Reprinted from Ritter H, Milas M. Parathyroidectomy: bilateral neck exploration. In: Terris D, ed. *Operative Techniques in Otolaryngology*. St. Louis, MO: Elsevier; 2009. Copyright © 2009, with permission from Elsevier.)

Embryologically, the upper parathyroids develop from the fourth branchial pouch and migrate caudally with the thyroid, while the lower parathyroid glands derive from the third branchial pouch and migrate with the thymus. The upper parathyroid glands have a narrow area of distribution and are fairly reliably positioned in the perithyroidal fat posterior to the superior pole of the thyroid gland and near the path of the recurrent laryngeal nerve as it enters the cricothyroid muscle. In contrast, the lower parathyroids are in an anterior plane with a long descent and more variable location around the lower pole of the thyroid gland,

thyrothymic ligament, and pretracheal fat. Symmetry is usually present between parathyroid locations in the left and right sides of the neck (Fig. 40.1). Migratory distribution of the parathyroids can lead to ectopic locations within the thymus, within the sheath encompassing the carotid artery, jugular vein, and vagus nerve even in high cervical locations, retroesophageally and even intrathyroidally (Fig. 40.2).

Calcium levels are closely regulated by interactions between parathyroid hormone (PTH) and vitamin D targeting bone, kidney, and gastrointestinal tract. In the normal state, PTH is released from chief cells in the parathyroid gland in response to low levels of ionized serum calcium, leading to resorption of calcium by the kidneys, hyperphosphaturia, increased renal synthesis of 1,25-dihydroxyvitamin D_3 (calcitriol) which increases interstitial calcium resorption, increased intestinal absorption of calcium and phosphate, and increased resorption of bone. PHPT refers to the inappropriate or unregulated secretion of PTH leading to abnormal calcium levels.

PHPT may be due to parathyroid adenomas, parathyroid hyperplasia, or rarely, parathyroid carcinoma. Parathyroid adenomas are most common, causing approximately 80% of cases of PHPT. Parathyroid adenomas are caused by a somatic DNA mutation in a parathyroid cell that provides a proliferative advantage and ultimately undergoes clonal expansion to produce the adenoma. Double adenomas may have an incidence of 2% to 15%, but may also represent a subset of patients with parathyroid hyperplasia. Parathyroid hyperplasia, present in 10% to 15% of patients with PHPT, is due to an increase in proliferation of parenchymal cells in all parathyroid glands. In PHPT, there is no biochemical stimulus for proliferation; this is in contrast to patients with secondary hyperparathyroidism, in whom parathyroid hyperplasia may be due to chronic low calcium levels or low vitamin D levels.

Most cases of PHPT are sporadic; however, PHPT may be associated with inherited syndromes in 3% to 5% of patients. These include familial isolated PHPT, multiple endocrine neoplasia type 1 (MEN1), multiple endocrine neoplasia type 2 (MEN2A), and hyperparathyroidism-jaw tumor syndrome (HPT-JT). PHPT is also linked to lithium use as it decreases the sensitivity of the parathyroid gland to circulating calcium and may also reduce urinary calcium excretion, which may ultimately lead to parathyroid hyperplasia. A history of radiation exposure, either environmental or cervical or whole body radiation for benign or malignant

conditions, is also a risk factor for developing PHPT. Parathyroid carcinoma is a very rare (<1%) cause of PHPT. It usually presents with significant hypercalcemia (>14.0 mg/dL) and frequently involves invasion of tumor into blood vessels, perineural spaces, soft tissue, or thyroid gland.

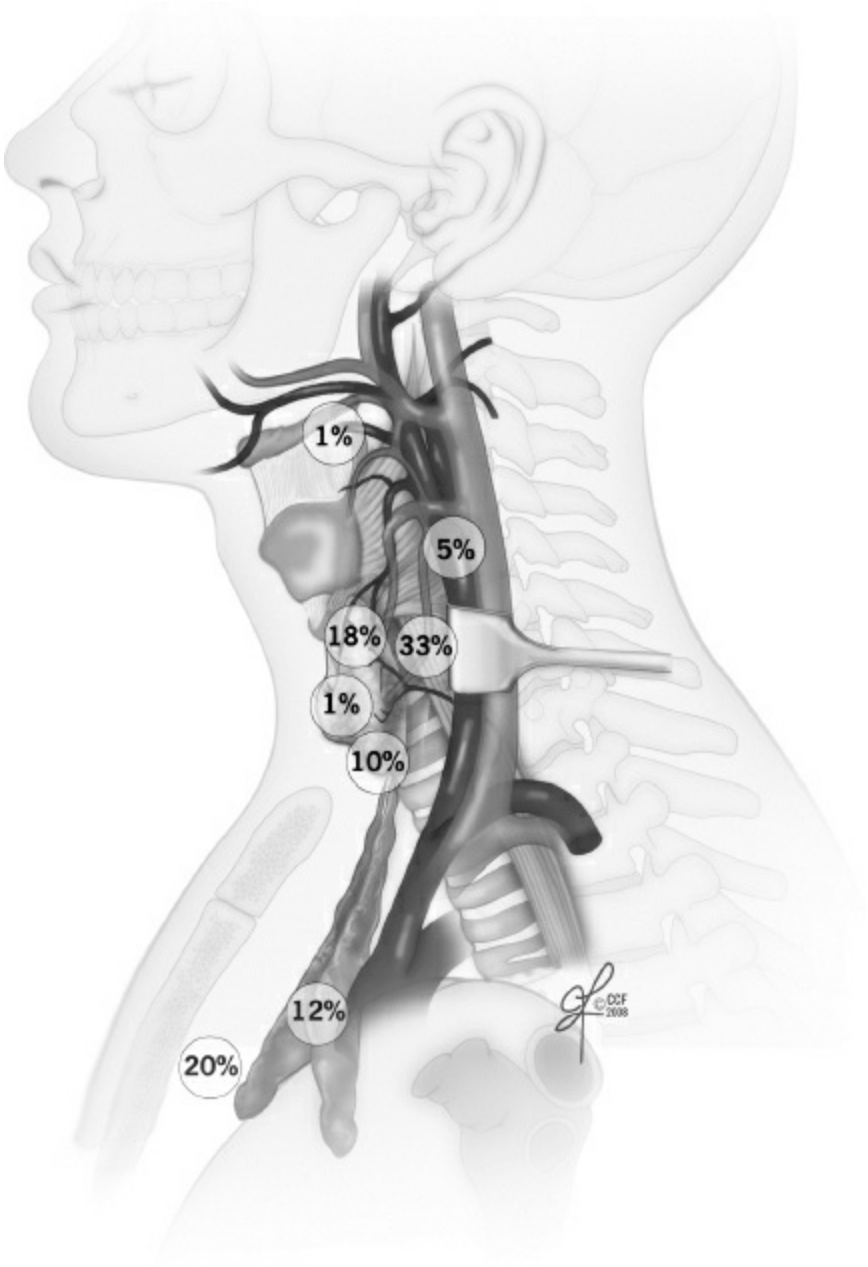

Figure 40.2. Distribution of ectopic parathyroid glands. (Reprinted from Ritter H, Milas M. Parathyroidectomy: bilateral neck exploration. In: Terris D, ed. *Operative Techniques in Otolaryngology*. St. Louis, MO: Elsevier; 2009. Copyright © 2009, with permission from Elsevier.)

TABLE 40.1 Signs and Symptoms of Primary Hyperparathyroidism

	Classical Signs and Symptoms	Potentially Unrecognized Signs and Symptoms
Neurologic	Lethargy Psychosis Coma	Anxiety Confusion Forgetfulness Fatigue Depression Poor sleep
Cardiovascular	Arrhythmia	Hypertension Ventricular hypertrophy
Musculoskeletal	Severe weakness Osteitis fibrosa cystica	Muscle weakness Bone pain Fractures Osteopenia/osteoporosis
Renal	Nephrolithiasis Renal insufficiency	Polyuria Polydipsia Nocturia
Gastrointestinal	Peptic ulcer disease Pancreatitis	Anorexia Constipation

CLINICAL PRESENTATION AND DIAGNOSIS

PHPT was first recognized as associated to parathyroid glands by Felix Mandl, who performed the first successful parathyroidectomy in 1925 in Vienna, Austria. At that time, patients often presented with advanced disease, and PHPT typically manifested as osteitis fibrosa cystica, characterized by generalized demineralization of bone, subperiosteal resorption, bone cysts, and brown tumors, or recurrent nephrolithiasis and kidney dysfunction. Patients also often presented with significant gastrointestinal symptoms including abdominal pain, peptic ulcer disease, and pancreatitis. Significant psychiatric and cognitive symptoms were also present, including generalized weakness, depression, and even coma. With the development of routine serum chemistry testing in the 1970s, the diagnosis of calcium abnormalities became more common and patients with few or no symptoms began to be diagnosed with PHPT. In the modern era, most patients do not present with advanced symptoms. However, many patients may have some unrecognized signs and symptoms related to the disease (Table 40.1).

In many patients, biochemical evaluation of PHPT is prompted by an incidentally identified elevated serum calcium level. In any patient with suspected PHPT, biochemical evaluation should include a serum total

calcium with simultaneous PTH, 25-hydroxyvitamin D, creatinine, albumin, and 24-hour urine calcium and creatinine levels. Table 40.2 details the recommended diagnostic studies. Calcium within plasma exists in the ionized (unbound) state, which is physiologically active and bound to other molecules, primarily albumin. Total serum calcium levels are a measure of bound calcium and are affected by albumin levels; therefore, total serum calcium should be corrected for albumin levels. In certain patients it may also be useful to obtain a simultaneous ionized calcium level, as some patients may have elevated ionized calcium levels but normal uncorrected total calcium levels. These patients are still considered to have PHPT. Vitamin D deficiency will increase PTH production, which is a type of secondary hyperparathyroidism; therefore 25-hydroxyvitamin D levels should be measured. However, patients with vitamin D deficiency alone will usually have normal or low calcium levels.

Some patients with PHPT may have elevated calcium levels with PTH levels within a normal range but inappropriately elevated in relation to calcium level. These patients should be considered to have PHPT and other workup and indications for surgery should be similar to classic PHPT. Another subset of patients may have normocalcemic PHPT, which is defined as consistently elevated PTH values and normal total and ionized serum calcium concentration without any secondary cause for the elevated PTH. Normocalcemic PHPT requires multiple measurements of total and ionized serum calcium and PTH values. The natural progression of normocalcemic PHPT is not certain although it has been suggested that normocalcemic PHPT may progress to classical PHPT with elevated serum and ionized calcium levels.

TABLE 40.2 Diagnostic Workup for Primary Hyperparathyroidism

Suspected PHPT

- Hypercalcemia or conditions related to PHPT (osteopenia, osteoporosis, kidney stones)
- History and Physical examination
  - Symptoms, prior head and neck irradiation, prior neck surgery, medication, other endocrine disorders, family history
- Laboratory testing: serum total calcium, serum ionized calcium, intact PTH, serum phosphate, 25-hydroxyvitamin D, 24-hour urine collection of urinary volume, creatinine, and calcium
- Diagnosis confirmed by: elevated serum total or ionized calcium or both with inappropriately elevated PTH and normal or elevated 24-hour calcium
  - If urine calcium is low (<100 mg/24 hrs) consider possible FHH, calculate urine calcium/creatinine ratio
    - Calcium Creatinine Clearance Ratio <0.01 suggestive of FHH

Suspected Normocalcemic PHPT

- Obtain multiple serum biochemical profiles—serum total calcium, ionized calcium, and PTH should be from same blood draw

- Correct vitamin D deficiency if present
- Eliminate other causes of secondary hyperparathyroidism

Other Causes of Hypercalcemia

- Bony metastases
- Sarcoidosis
- Multiple myeloma (check serum protein electrophoresis)
- PTH-RP-producing tumors such as breast, lung (squamous), head and neck (squamous), kidney, bladder, cervix, uterus, and ovary (check PTH-RP)
- Ectopic PTH-producing tumors (extremely rare)

Family History Present:

- Obtain genetic counseling/testing (Genes to be tested may include menin for MEN1, RET for MEN2, and CDC73 for HPT-JT)

PHPT, primary hyperparathyroidism; PTH, parathyroid hormone; FHH, familial hypercalcemic hypocalciuria; PTHrp, parathyroid hormone related protein; MEN1, multiple endocrine neoplasia type 1; MEN2, multiple endocrine neoplasia type 2; HPT-JT, hyperparathyroidism-jaw tumor syndrome.

Other causes for hypercalcemia or elevated PTH levels should be considered in patients undergoing evaluation for PHPT. Except for the rare case of ectopic PTH production, nonparathyroid causes of hypercalcemia will have suppressed PTH levels. The most common other cause of hypercalcemia is malignancy; if a malignancy is suspected, a parathyroid hormone-related peptide (PTH-RP) level can be obtained. Urine calcium levels are essential to exclude the rare condition of benign familial hypercalcemic hypocalciuria (FHH). Patients with this disorder have an inactivating mutation in the calcium-sensing receptor (CaSR) gene resulting in hypercalcemia with low urine calcium. These patients will not

benefit from parathyroidectomy. In patients with elevated PTH levels, medications and conditions associated with secondary causes of elevated PTH levels must be ruled out or accounted for. These may include the use of thiazide diuretics, bisphosphonates and lithium, malabsorption syndromes (including gastric bypass), and vitamin D deficiency (<20 μg/L) and insufficiency (20 to 30 μg/L).

A comprehensive family history must be obtained and patients with a family history should be considered for genetic counseling and/or testing. Current recommendations are for genetic counseling for patients <40 years of age with PHPT, those with multigland disease (MGD) (any age), and those with a family history or other disease processes associated with known syndromes such as jaw fibromas and uterine cancer (HPT-JT); pituitary and pancreatic tumors (MEN1); medullary thyroid cancer, and pheochromocytoma (MEN2A).

INDICATIONS FOR PARATHYROIDECTOMY

For patients with specific signs and symptoms related to PHPT such as kidney stones or fragility fractures, surgery is recommended. For patients with asymptomatic disease, in the current International Workshop on the Management of Asymptomatic Primary Hyperparathyroidism, a consortium of endocrinologists and endocrine surgeons, surgery is recommended for patients with: (a) serum calcium >1.0 mg/dL above the normal range; (b) osteoporosis (bone mineral density with T-score <−2.5 at lumbar spine, total hip, femoral neck, or distal 1/3 radius); (c) vertebral fracture; (d) nephrolithiasis by x-ray, ultrasound, or CT; (e) 24-hour urine calcium >400 mg/day and increased stone risk by biochemical stone risk analysis; or (f) age <50. Surgery may also be considered for patients for whom medical surveillance is not desired or not possible without any other contraindications. Parathyroidectomy is strictly contraindicated in patients with FHH as hypercalcemia will not improve. Patients with significant medical comorbidities who may have limited long-term benefit from parathyroidectomy may be considered poor candidates for parathyroidectomy.

Neurocognitive symptoms such as difficulty with concentration, cognition changes, sleep disturbances, depression, and reduced quality of life were not included in these guidelines, as indications for surgery in otherwise asymptomatic patients. However, studies have demonstrated that patients with PHPT suffer from these symptoms, although the symptoms

may overlap with other common diseases. Recent prospective studies using psychosocial assessment indices have found that patients may have improvement in symptoms within weeks after surgery with durable long-term effects. There have also been several randomized controlled trials of surgery versus observation which have found improvement in quality of life including lower anxiety and bodily pain, and improved general health after curative parathyroidectomy. However, the degree and area of improvement in neurocognitive symptoms have been varied among different studies; therefore, patients must be realistically counseled on potential benefits of surgery on neurocognitive symptoms.

Patients with otherwise asymptomatic disease may have unrecognized indications for surgery. Additional testing that should be performed include imaging to detect renal calculi, either abdominal x-ray, renal ultrasound, or noncontrast computed tomography (CT). Bone mineral density should also be evaluated by dual energy x-ray absorptiometry due to the increased bone turnover in PHPT. This should include evaluation of the forearm as it contains primarily cortical bone, which is most at risk for bone loss.

PREOPERATIVE PLANNING

Imaging

Once the diagnosis of PHPT has been established, imaging tests are recommended to attempt to identify abnormal gland or glands, if a MIP is planned. Nonlocalizing imaging studies do not preclude proceeding to parathyroidectomy, but may change the technique of parathyroidectomy. Cervical ultrasonography is the recommended initial test due to its cost effectiveness, lack of ionizing radiation, and its ability to assess concomitant thyroid disease (Fig. 40.3A). Evaluation of thyroid nodules, including fine needle aspiration, should follow current guidelines for evaluation of thyroid nodules. Cervical ultrasonography, whether performed by radiologists, endocrinologists, or surgeons, should be performed by a skilled ultrasonographer with knowledge of parathyroid anatomy. Ultrasonography is not as effective in identifying retroesophageal lesions and mediastinal parathyroid glands, secondary to depth of gland and poor transmission through gas-containing structures such as the trachea or esophagus. Meta-analyses have shown a sensitivity of 76% to 79% by trained ultrasonographers and a specificity of up to 96%. However, when MGD is present, sensitivity of ultrasonography to

identify all abnormal parathyroid glands does decrease significantly. Fine needle aspiration of suspected parathyroid glands is not recommended, as there have been concerns regarding potential seeding of parathyroid tissue (causing parathyromatosis) or that postbiopsy changes would affect interpretation of final histopathology.

Other imaging options include ^{99}Tmc-Sestamibi scan, preferably with single photon emission computed tomography (SPECT). ^{99}Tmc-sestamibi is normally distributed to the parotid and submandibular salivary glands, thyroid gland, heart, and liver, and not visualized in normal parathyroid glands. The rate of washout from hyperfunctioning parathyroid glands is slower; therefore, with delayed imaging the abnormal glands may be identified. Standard imaging obtains two-dimensional planar imaging with anterior views and possibly anterior oblique and lateral views. SPECT displays three-dimensional images with improved sensitivity, which may be even further improved when fused with CT. This allows for the combination of the three-dimensional physiologic information from SPECT with the anatomic information from CT (Fig. 40.3B). Sestamibi imaging has varied reported sensitivity and specificity due to institutional variability and use of varied protocols. A recent meta-analysis found the sensitivity of Sestamibi to be as high as 79%, while single institutions have reported sensitivities ranging from 45% to 92%. Sensitivity decreases significantly in patients with MGD and smaller parathyroid glands.

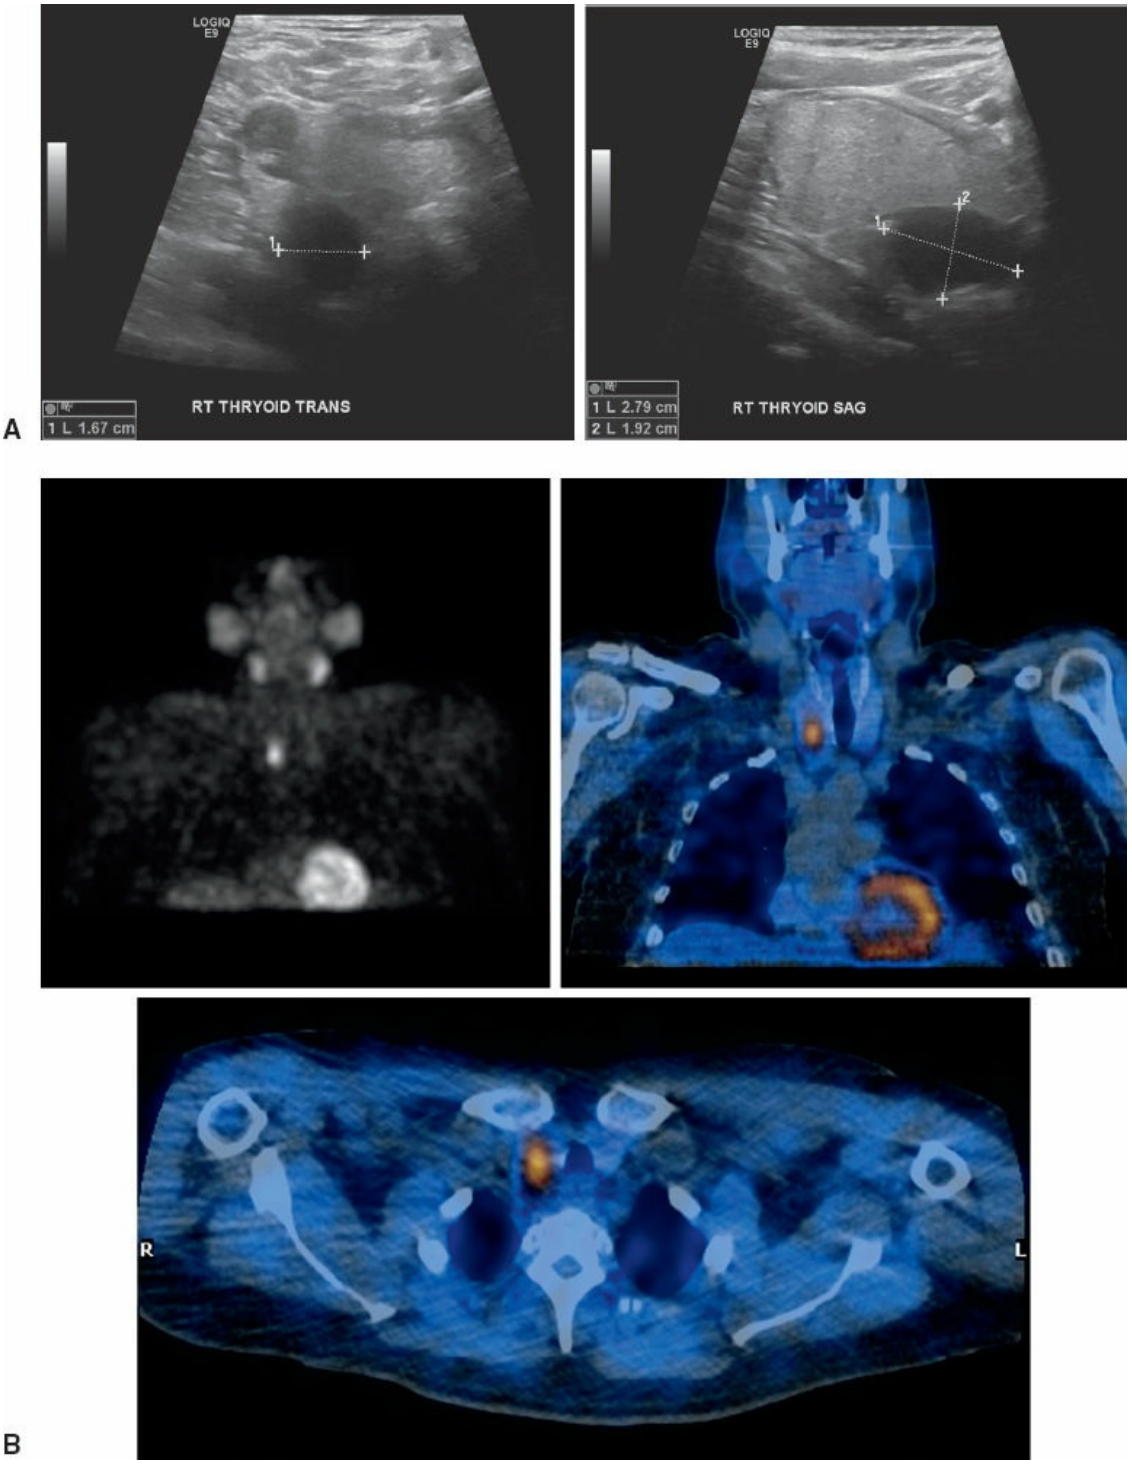

Figure 40.3. Preoperative imaging. **A.** Cervical ultrasound shows a 1.7 × 2.8 × 1.9 cm suspected parathyroid adenoma posterior to mid right thyroid lobe. **B.** The 99-Tc Sestamibi image shows an abnormality on the right side that is more precisely seen on the color SPECT.

4D-CT is a multiphase detector CT examination that combines the three-dimensional CT scanning with an added dimension from changes in

perfusion of contrast over time (Fig. 40.4). Parathyroid adenomas generally demonstrate a rapid uptake and washout compared to thyroid and adjacent tissue. On meta-analysis, 4D-CT has been found to have sensitivity as high as 89% and positive predictive value of 93.5%. Obtaining images does require having the appropriate imaging protocol as standard neck CT does not use thin sections or multiphase acquisition and may not yield equivalent results. Disadvantages include radiation exposure and need for iodinated contrast.

Preoperative ultrasound-guided differential jugular venous sampling may aid in localization of parathyroid disease in certain patients, especially in patients with persistent or recurrent disease. Whole blood is collected from each internal jugular vein and sent to the laboratory for PTH measurement. If the jugular venous PTH level on one side of the neck is 10% higher than the opposite side, the test is considered positive (localizing). Reported accuracy of this technique for abnormal parathyroid glands is 71% to 81% and may be a useful adjunct to other anatomical localization studies.

Overall, which imaging modality is obtained is generally based on surgeon preference and availability. The diagnosis of PHPT is based on biochemical evaluation and is not dependent on imaging. Imaging may be used to aid in preoperative planning but should not be used to select patients for surgical referral. For patients selected to undergo comprehensive parathyroidectomy, based on surgeon preference or other considerations, it is valid to consider whether imaging is necessary. However, preoperative imaging may help in comprehensive parathyroidectomy by allowing focused early dissection on the region of greatest suspected abnormality as well as the ability to identify concomitant thyroid disease, which may be addressed in the same procedure.

Other Considerations for Preparation for Surgery

In the evaluation and preoperative period, patients do not need to restrict their calcium intake and should maintain an intake in accordance with the Institute of Medicine guidelines, (1,000 to 1,200 mg calcium daily, via diet and supplements). It is not uncommon for patients to have low 25-hydroxyvitamin D levels; deficiency is typically defined as <20 ng/mL. There has been concern that vitamin D repletion in patients with PHPT may worsen hypercalcemia. However, this is rare and recent studies have

demonstrated that patients may be safely repleted without risk of hypercalcemia. Caution should be taken in patients with marked hypercalciuria, as this may be aggravated by vitamin D supplementation.

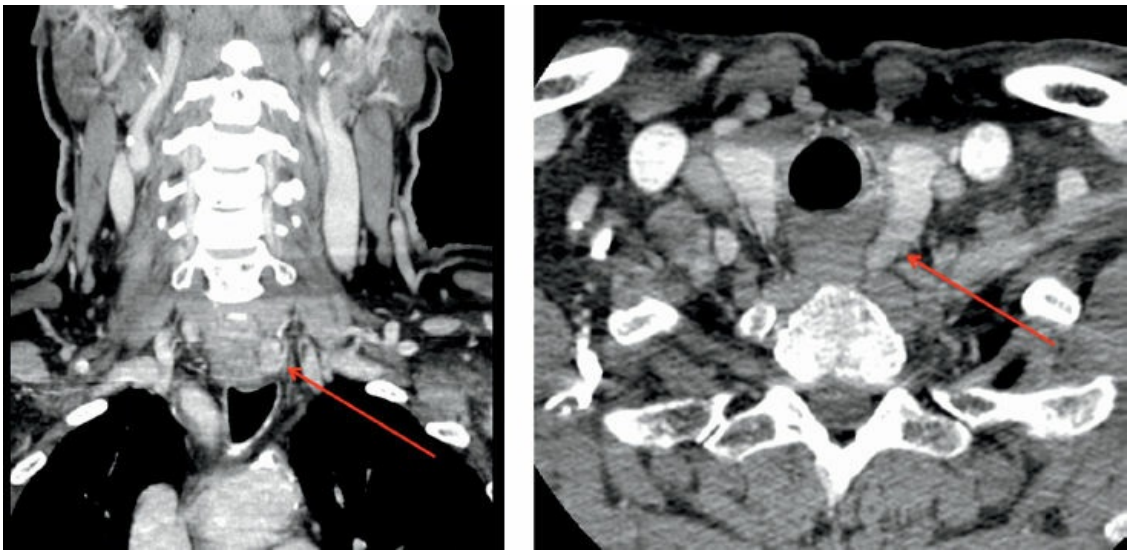

Figure 40.4. Preoperative imaging. 4D CT shows a 1.6 × 0.9 cm soft tissue lesion posterior and medial to the left inferior thyroid lobe consistent with parathyroid adenoma.

One of the most feared complications of parathyroid surgery is recurrent laryngeal nerve injury, although the incidence of permanent injury in parathyroid and thyroid surgery is <1%. The patient's voice should be examined as part of routine examination and in cases where subjective changes in the patients' voice, either by the patient or by the surgeon, are present or prior anterior cervical surgery (including thyroidectomy, previous parathyroidectomy, carotidectomy, cervical fusion, and/or thoracic procedures) has been performed with risk to the vagus or recurrent laryngeal nerves additional evaluation may be indicated. This may include indirect/direct laryngoscopy, sonographic evaluation of vocal cord motion, and/or videostroboscopy.

SURGICAL TECHNIQUE

Parathyroidectomy can be accomplished with minimal invasiveness and morbidity, gentle dissection. Most surgeons currently perform parathyroid surgery with general anesthesia, while some use local anesthetics supplemented by deep cervical nerve block and sedation. No antibiotics are needed except in reoperative cases, or in patients with other indications for prophylaxis. For prophylaxis of deep vein thrombosis, sequential

compression devices are adequate for most patients.

Traditional comprehensive parathyroidectomy requires bilateral cervical exploration with the identification of all four parathyroid glands and excision of all grossly enlarged glands, based on the surgeon's judgment. Normal parathyroid glands should be kept in situ. This method has been shown in large series to have success rates of 95% to 99% when performed by experienced parathyroid surgeons. However, curative rates are lower and risk of complications are higher when performed by inexperienced surgeons. Although comprehensive parathyroidectomy is a necessary skill for parathyroid surgeons, with contemporary techniques for preoperative imaging and the use of intraoperative adjuncts, such as IPM, operative cure can be obtained by directing the procedure to only the abnormal gland, MIP. Comprehensive parathyroidectomy may be performed based on surgeon preference, nonlocalizing imaging, suspicion for MGD, or when intraoperative PTH levels do not appropriately fall. Table 40.3 shows indications for comprehensive parathyroidectomy.

TABLE 40.3 Indications for Comprehensive Parathyroidectomy as the Initial Surgery for PHPT

Absolute Indications

- Coexisting thyroid cancer or bilateral goiter requiring total thyroidectomy
- Failure to find diseased gland at location indicated by imaging studies
- Intraoperative PTH fails to drop after resection of suspected single adenoma
- Imaging studies suggest multiple sites of disease
- Known or suspected multiple endocrine neoplasia syndromes (initial surgery)
- Finding more than one abnormal parathyroid during intended focal or unilateral neck exploration

Advisable Indications

- Negative or discordant parathyroid imaging studies
- Unavailability or malfunction of intraoperative PTH measurement
- Lithium-induced PHPT
- Non-MEN familial hyperparathyroidism
- Surgeon preference or experience

Comprehensive parathyroid exploration can be performed without the use of intraoperative adjuncts, although these may be helpful depending on the complexity of surgical findings, assessment of usefulness by the individual surgeon, or experience of the surgeon. Numerous intraoperative adjuncts have been described. Most notably IPM has become a fundamental part of modern parathyroid surgical practice and may be used

to confirm complete excision of hyperfunctioning glands. Other adjuncts include frozen section histology and needle aspiration of excised tissue for measurement of PTH as means of distinguishing parathyroid from nonparathyroid tissue. It is useful to recall that frozen section examination and permanent histology both cannot distinguish between single adenomas and multigland hyperplasia. Intraoperative gamma probe has been applied to in vivo localization of abnormal parathyroids and ex vivo measurement of radiotracer counts as markers of normal versus abnormal parathyroids. Near-infrared autofluorescence with use of a fluorescence system to distinguish parathyroid tissue is a newer method that is under investigation. These different methods may require specific equipment and have varying efficacy that has been documented or continuing to be elucidated in the literature. Ultimately the use of these different adjuncts may be surgeon and institution dependent and perhaps more often applied to MIP.

Technique

Once anesthetized, the patient is positioned with arms tucked at the side and head gently hyperextended, facilitated by placement of a roll or inflatable pressure infuser bag under the shoulders. Both arms are tucked and bed is placed in semi-Fowler position with the knees bent. Care to have vertical alignment of the patient’s chin, suprasternal notch, and center of the thyroid cartilage aids a symmetric incision. It may be useful to take note of natural skin creases when patient is awake and sitting upright to use as a site of incision. The authors prefer chlorhexidine for sterile prep because it is nonflammable and avoids potential irritation and staining of the face and neck.

A transversely oriented incision is made according to the optimal site marked. In most patients, this is 1.5 to 2 fingerbreadths above the suprasternal notch. The length of the incision varies with surgeon preference, and usually does not need to be longer than 4 to 6 cm. The incision is carried down by electrocautery through the platysma muscle that is about 2 to 3 mm thick (more visible in men) and relatively free of blood vessels. Deep to the platysma is an avascular plane just above the anterior jugular veins that should be developed to aid exposure, using a combination of electrocautery and blunt dissection. This subplatysmal plane is developed until the thyroid cartilage is palpable superiorly and the sternal notch inferiorly, but can be dissected less in thin patients.

Mobilizing these flaps offers optimal exposure through small incisions by increasing the ease of retraction.

The avascular midline raphe of the strap muscles is opened vertically along the midline to separate the muscles and expose the thyroid. Electrocautery is generally sufficient for tiny branches that may cross the midline. If preoperative imaging was obtained and a potential abnormal gland was identified on imaging, exploration should first begin on that side. Fine instruments based on surgeon's preference can be used for the dissection with the goal of maintaining a bloodless field with minimal manipulation of potential parathyroid tissue. If no imaging was obtained or it was nonlocalizing, laterality may not matter, although a systematic order of exploration, particularly if comprehensive parathyroidectomy is planned, can be useful. For comprehensive parathyroidectomy, a convenient strategy is to target exposure of the most abnormal parathyroid first, then the ipsilateral parathyroid, and finally explore the contralateral side. When all parathyroids have been identified, assessment about the disease process (single adenoma, double adenoma, or multigland hyperplasia) can be made and a decision about which parathyroids to remove and in what order can be determined.

Irrespective of planned extent of exploration, careful dissection should be performed staying close to the thyroid gland in expected location for superior and inferior glands. The sternothyroid muscle is bluntly separated from the undersurface of the sternohyoid muscle for a short distance, again to aid mobility in lateral retraction. The loose areolar tissue between the sternothyroid muscle and thyroid is taken down with cautery at low settings or with blunt dissection. It is important to separate these tissues or any pretracheal fat at the very edge of the sternothyroid muscle, to avoid unintentionally displacing parathyroid tissue laterally. Traction is exerted on the thyroid lobe by using a peanut or manually with 4 × 4 sponges, in order to elevate and medially rotate the lobe. This exposes the lateral and posterior thyroid surface, and brings the middle thyroid vein into view. This vein is always above the plane of the carotid artery, which should now be visible or palpable. The vein courses in a medial to lateral direction, similar and often parallel to the inferior thyroid artery, which in contrast, is always situated deep to the carotid artery. The middle thyroid vein can be isolated, ligated, and divided if necessary to facilitate exposure.

When an area of likely parathyroid abnormality is seen, careful blunt

dissection is done using a fine curved hemostat or right angle to separate the overlying fatty tissue looking for subtle color changes of the parathyroid. Normal parathyroid glands are small in size, weighing less than 50 mg. They generally have a yellow-brown color and are not detectable by preoperative imaging. A normal parathyroid will appear flattened and have a leaf-like vascular pattern absent in simple fat or thymus. It can be gently coaxed out of the areolar or fatty covering to determine its entire size and that it does not hide an enlarged segment (a "cap of normal" disguising an underlying parathyroid tumor).

Abnormal or enlarged parathyroid glands may display more prominent variable morphologic changes in size, shape, texture, and firmness. Abnormal parathyroid glands are generally fuller in all dimensions, have a darker brown or reddish-brown color, and do not compress easily or are significantly firm when gently probed. They will often appear as a mass bulging below thicker tissue, or have a sliding motion back and forth beneath a film of thin areolar cover ("float sign"). They may also have an irregular and knobby shape, more prominent vascular pedicles, or a plexus of vasculature. Glands of patients with secondary and tertiary hyperparathyroidism may be sclerotic and light in color from fibrosis. The abnormal parathyroid should also be separated from the encasing thin areolar tissue so that its only attachment is the vascular pedicle. Ideally, the dissection should free the enlarged parathyroid along its lateral and posterior aspects first, leaving the medially located pedicle along the thyroid last. Single or double adenomas should be treated with simple excision of the abnormal gland(s). We will discuss below the use of IPM.

Multigland hyperplasia is suspected when all four glands are enlarged and should be ideally treated with subtotal parathyroidectomy and parathyroid cryopreservation if available. Subtotal parathyroidectomy consists of removing 3.5 parathyroid glands. The most normal appearing of the four glands should be chosen and the remnant should be created first. This should preferably be an inferior gland as these are easier to approach in the future if reoperation is needed. The remnant should be about one to two times the size of a normal parathyroid gland, have a good vascular pedicle, and is ideally anteriorly located. It should be marked with a nonabsorbable suture or surgical clip. It is always easier to remove more tissue than to deal with a small remnant and potential hypoparathyroidism. This is where IPM can also be useful. More elongated or oval parathyroids with a discrete identifiable vascular pedicle are better suited for the

remnant. Subsequently the remaining hyperplastic parathyroid glands may be resected. Prior to resecting the final gland the remnant should be inspected. If there is concern that the remnant does not appear viable a remnant may be fashioned from the remaining gland.

If the initial examination of eutopic locations does not identify all four parathyroid glands or if the IPM reveals the presence of additional abnormal parathyroid tissue, then further exploration is needed. Important areas to examine are summarized in Figure 40.5. The most commonly missed location is a retroesophageal parathyroid that has sunken into the deep posterior space behind the tracheoesophageal groove, often lying on the anterior surface of the spine and below the main trunk of the inferior thyroid artery. This parathyroid is embryologically derived from the upper gland, although it often appears to have a position more inferior than the actual lower gland, both intraoperatively and on imaging studies (Fig. 40.6). The thymus should be retracted out of the mediastinum as far as possible without avulsion, carefully examined, palpated, and removed. The middle thyroid vein should be ligated and divided, if not already done, as this provides greater exposure of the trachea and esophagus. Mobilizing the upper thyroid pole as during thyroidectomy can occasionally disclose ectopic parathyroids without devascularizing the thyroid gland. Thyroid lobectomy on the side of the missing abnormal parathyroid may be justifiable even when no palpable abnormalities exist, but this circumstance can potentially be avoided if preoperative ultrasound describes a normal thyroid without nodules. Examination of the path along the carotid artery and jugular vein can be performed as widely as the incision allows. The skin incision can be enlarged to permit adequate exposure of any of these regions.

Parathyroid gland location is generally symmetrical and can aid in contralateral neck exploration. A parathyroid located at the posterior midpoint of the thyroid lobe could represent either a lower gland that sits higher than usual, or an upper gland that is more inferior than usual. Finding the other ipsilateral gland should take into account both possibilities. Double parathyroid adenomas, reported in 3% to 15% of patients, have a nonuniform distribution that favors enlargement of both upper parathyroids.

During parathyroidectomy, care should be taken to avoid injury to the recurrent laryngeal nerve, which may be found in the tracheoesophageal groove; the surgeon should note that the course of the recurrent laryngeal

nerve on the right side may be more variable than on the left. Its entire course does not need to be exposed but adequate identification should be performed to ensure its safety and as a potential guide to identification of parathyroid glands.

After exploration and resection are completed, the neck is irrigated with sterile water, which provides a clearer view of the surgical field than saline. Hemostasis is achieved. Each gland or remnant should be re-evaluated for viability. Some mild bruising and discoloration of the parathyroids is acceptable. If remaining parathyroid tissue has become completely black from ischemia or has questionable viability, it can be reimplanted into the ipsilateral sternocleidomastoid muscle. This is done by mincing the normal parathyroid tissue using a fresh blade and inserting the entire sample into a small window created within the sternocleidomastoid muscle. This window is sutured closed with a permanent prolene suture and can also marked with a clip in case there is need for identification and removal in the future. The strap muscles and platysma are reapproximated with absorbable suture, and the skin incision is closed. Drains are seldom, if ever, necessary. Our preferred technique uses a 5-0 prolene subcuticular stitch with long tails left in place and steristrips applied. The suture is removed on postoperative day 1. Absorbable monofilament (monocryl) may also be used.

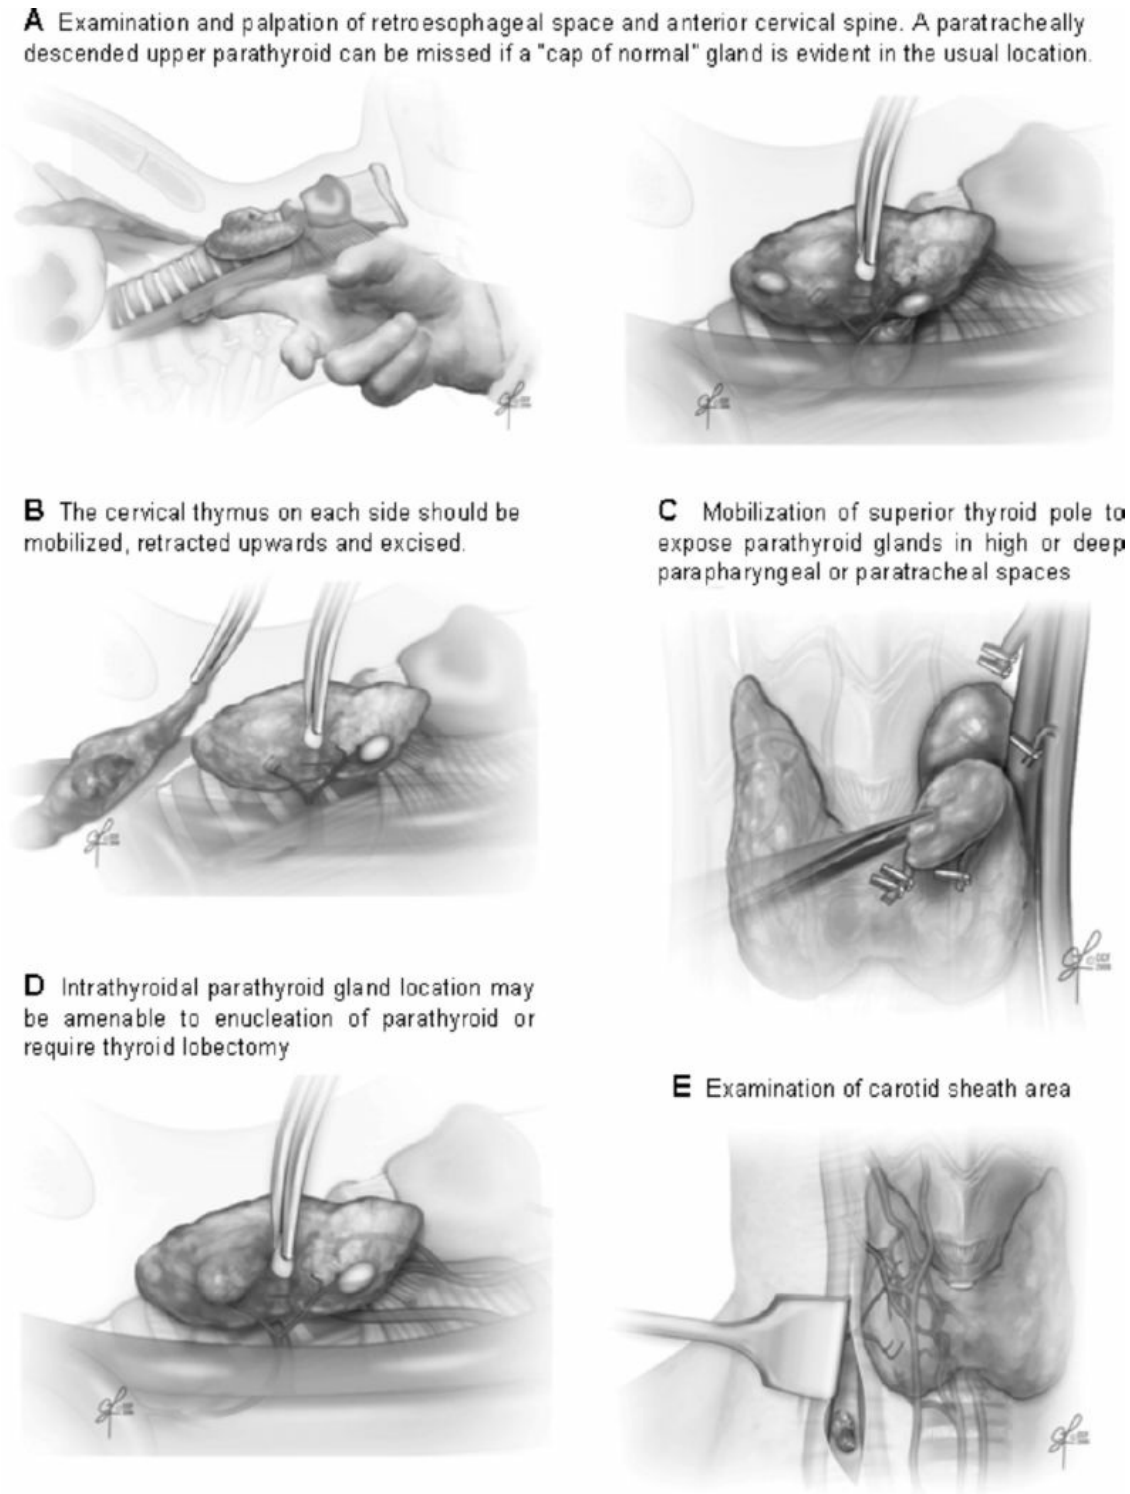

Figure 40.5. Secondary parathyroid survey examines areas of atypical or ectopic parathyroid location when initial exploration fails to reveal all pathologic glands.

Intraoperative Parathyroid Hormone Monitoring

IPM may be used as an intraoperative adjunct to confirm the complete excision of all hyperfunctioning parathyroid tissue. IPM is possible due to

the short half-life of PTH (3 to 5 minutes) and the use of a rapid immunochemiluminescence assay technique that runs for 8 to 20 minutes. Turnaround time may also be decreased by close proximity of the testing equipment to the operating room. A standard protocol should be used that the operating room staff and laboratory team are all well-informed of. It requires multiple blood collection samples that may be obtained from peripheral venous or arterial access. A central neck vein may also be used for blood samples although studies have shown levels may be higher then systemic levels and take longer to decrease. Central neck veins may be used to aid in lateralization as discussed below.

There are several intraoperative criteria that may be used to predict removal of a hyperfunctioning parathyroid tissue. The initially described protocol was developed at the University of Miami by George L. Irvin III, MD, and requires a “>50% drop in PTH” 10 minutes after resection of hyperfunctioning tissue to predict postoperative eucalcemia. Samples should be drawn at specific times during parathyroidectomy. The intravenous access is kept open with a slow infusion of saline, which must be discarded from the line before any blood sample is measured to prevent dilution. During the procedure, the anesthesiologist collects 4 mL of whole blood in an EDTA tube at specific times: (a) a “preincision” level before skin incision, (b) a “pre-excision” level collected after dissection and just before clamping the abnormal gland’s blood supply, (c) a 5-minute level, and (d) 10-minute level after excision of the suspected abnormal gland. When peripheral PTH values drop more than 50% from the highest either preincision or pre-excision level 10 minutes after the excision of all abnormal parathyroid gland(s), this criterion predicts normal or low calcium levels postoperatively with an overall accuracy of 98%. After this sufficient decrease occurs, the procedure may be terminated without any need for further parathyroid tissue excision. Conversely, if the hormone level fails to drop at the 10-minute interval following excision of a suspected hyperfunctioning parathyroid gland, the PTH assay signals that more hypersecreting tissue is likely to be present. Thus, the surgeon is directed to continue the exploration as a comprehensive parathyroidectomy with the above described protocol applied to each removed gland.

Other IPM criteria have also been developed. Our preferred criteria is the Normal range (or Dual Criteria) Protocol. Intraoperative criteria for a biochemical cure is met when the PTH level drops >50% from the highest value (preincision or preexcision) and falls into the normal range.

Additional levels beyond 10 minutes may be necessary to meet both criteria. If both criteria are not met this indicates residual hyperfunctioning parathyroid tissue and additional exploration is required. PTH levels are obtained as described above. We prefer to obtain the preincision level before entering the operating room to avoid any potential elevation from manipulation of parathyroid glands, particularly anteriorly located glands, during intubation or surgical prep. If comprehensive parathyroidectomy is planned and a clear adenoma is identified during initial exploration, either aided by imaging or not, resection of gland may be performed and levels obtained while completing exploration for remaining glands. However, if the initial gland appears only slightly enlarged or normal it is recommended to proceed with systematic exploration as described before resection of any glands.

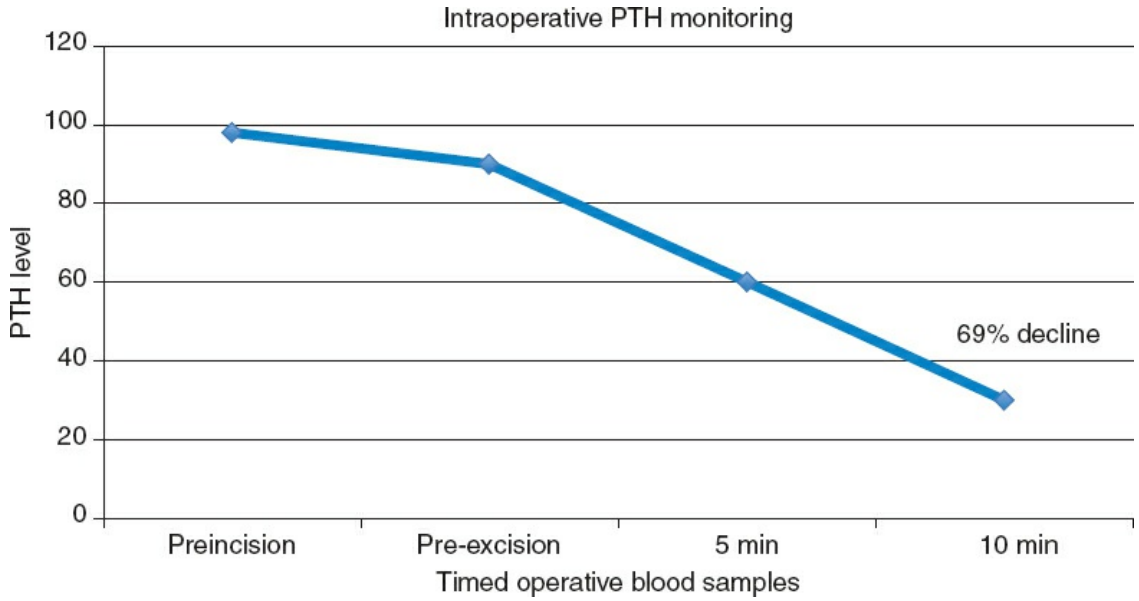

Figure 40.6. Intraoperative parathyroid hormone (PTH) dynamics after removal of a single parathyroid adenoma. At 10 minutes there was a 69% decline in PTH level from highest level (preincision), which is consistent with biochemical cure.

As an example, Figure 40.6 shows the PTH levels in a patient after excision of a single hypersecreting gland. The hormone dynamic shows an adequate >50% PTH drop at 10 minutes from gland excision from the preincision level, which was higher than pre-excision level, and into normal range. Conversely, if the hormone level fails to drop at the 10-minute interval after excision of a right inferior parathyroid adenoma, the persistently elevated PTH assay indicates that additional hypersecreting

tissue is likely present. Upon further exploration after identifying the three remaining glands, an additional adenoma is identified—a left inferior parathyroid adenoma (Fig. 40.7). Levels are obtained in a similar fashion starting with the pre-excision level and the IPM drops at the 10-minute interval appropriately indicating all hypersecreting tissue has been removed.

IPM criteria are not as effective when both preincision and pre-excision levels are not obtained. The pre-excision level may increase ("spike") significantly due to manipulation of abnormal gland(s) during exploration or dissection. In these instances, if only a preincision level is obtained, the PTH level may not drop >50% from this level at the 10-minute interval. This may lead to the need for additional PTH levels, potential prolongation of the procedure and occasionally unnecessary additional tissue excision. However, in some patients even when all hypersecreting tissue has been excised and all parathyroid glands have been identified, the dual criteria may not be met at 10 minutes. This may be more common when there is a PTH spike that is especially high (greater than three times the baseline). Recent analysis has shown that in these cases it may not be necessary to wait until the final PTH level is within a normal range as long as an appropriate decline of >50% has occurred. Ultimately the surgeon must use his/her best judgment and analysis of the hormone dynamics in deciding when to terminate the procedure.

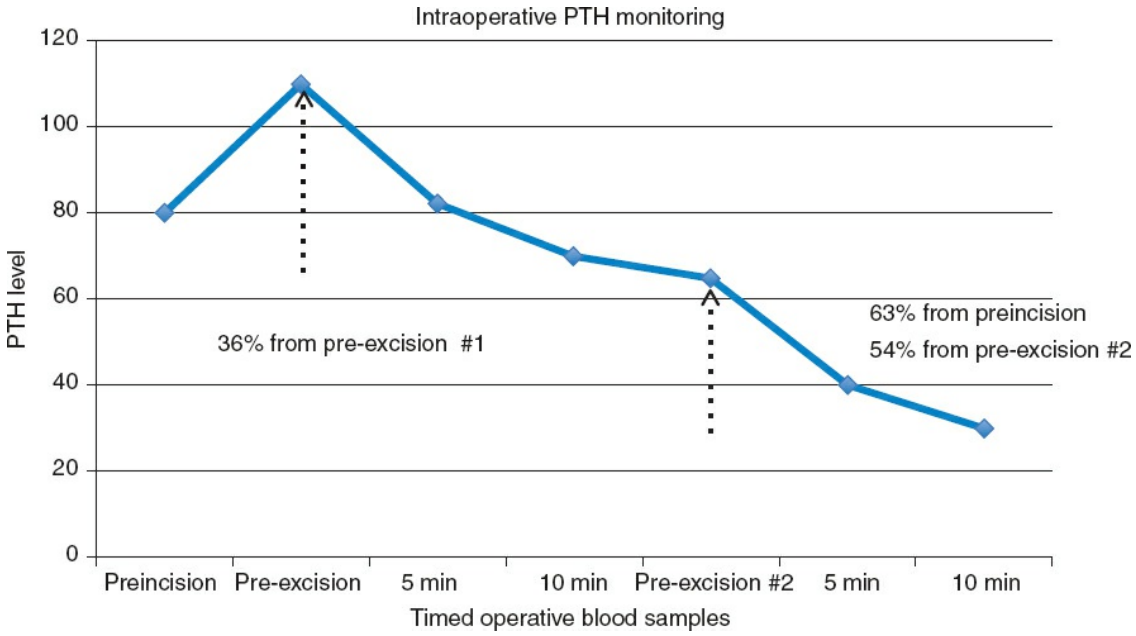

Figure 40.7. Intraoperative parathyroid hormone (PTH) dynamics in a patient with multigland disease. At time of right inferior gland

excision there is a mild increase (spike) in PTH level to 110 pg/mL. At 10 minutes there is only a 36% decline from highest value (pre-excision) indicating there is remaining hypersecreting parathyroid tissue. A left inferior parathyroid adenoma is also identified and repeat levels are obtained. At 10 minutes from the second gland excision the PTH level has dropped to 30 pg/mL which is a 64% decline from the preincision value and consistent with removal of all hypersecreting parathyroid tissue. The *dotted lines* indicate time of gland removal.

In certain situations, internal jugular venous vein sampling may aid in identifying the laterality of the abnormal parathyroid glands if initial bilateral cervical exploration does not demonstrate abnormal appearing parathyroid tissue or when one of the glands cannot be identified. If performed for this reason, samples should be taken from both right and left internal jugular veins, preferably as low as possible in the neck to account for all possible drainage, at the same time as a peripheral level is obtained. Lateralization is indicated by a PTH level 10% or higher than the opposite side. Further exploration may be further directed on the appropriate side. If both glands have been identified on the lateralizing side a supernumerary gland may be present. If both glands are not identified and PTH levels suggest lateralization, thyroid lobectomy or thymectomy should be considered.

Confirming Parathyroid Tissue

Intraoperative confirmation that the resected tissue is parathyroid tissue is recommended, especially if IPM is not being performed. The most frequently used method is frozen section. This has varied accuracy and may lengthen operative time and incur additional costs. However, it is widely available and most commonly used. Ex vivo aspiration of parathyroid and analysis for PTH levels is a point-of-care method that allows for rapid results where IPM is available with specificity and positive predictive values of up to 100%. In this method, presumed parathyroid tissue is aspirated with multiple passes of a 3 mL syringe prefilled with 1 mL of normal saline, using a 22-gauge needle. After aspiration an additional 1 mL of normal saline is aspirated directly through the needle to allow all aspirate material to be drawn into the syringe. Then the syringe may be passed off the sterile field to be tested for PTH level. Based on a recent study, a level of at least >1.5× above baseline is

indicative of parathyroid tissue, with typical levels being >5,000 pg/mL. Weight is a reliable distinguishing factor and should be part of the pathology report as well. Several studies have suggested that when the initial gland excised is <200 mg in size, it is more likely that MGD is present. Finally, the IPM results can help guide the surgeon in confirming that parathyroid tissue has been removed.

Reoperative Parathyroidectomy

Reoperative parathyroidectomy may result in unexpected challenges. Reoperative cases may be due to persistent or recurrent PHPT, or to initial parathyroidectomy in patients that have had prior thyroidectomy. In these cases, it is essential to obtain as much information as possible by study of prior operative and pathology reports. These will provide information on what, if any parathyroid tissue or other tissue was identified and/or resected. Without histologic confirmation of parathyroid tissue that was not removed, one cannot assume that the reported gland was actually identified. In the case of previous thyroidectomy, review of previous operative notes and pathology reports are critical to determining the status of the remaining parathyroid glands. It may be possible that the only functioning parathyroid gland is an abnormal gland in these situations and this must be considered intraoperatively.

Surgery in the reoperative field is more challenging due to tissue fibrosis, distortion of anatomy, and loss of natural tissue planes. The cure rates in reoperation, 82% to 98%, are lower than for initial parathyroidectomy and risk of complications are higher, with reported rates of 5% to 8% for postoperative hypoparathyroidism and up to 15% for recurrent laryngeal nerve injury. Therefore, most surgeons will apply stricter indications for surgery for these patients with more significant symptomatology and hypercalcemia. Imaging is essential in these cases and comprehensive parathyroidectomy is generally not recommended as the initial approach for reoperation. Surgery should be directed toward glands identified on imaging if possible. IPM may be useful in these cases to allow for monitoring of PTH levels after excision of identified abnormal gland. If PTH levels drop too low (<10 pg/mL), reimplantation of parathyroid tissue may be required. For this reason, all excised tissue should be kept on the operative field until the end of the procedure.

POSTOPERATIVE CARE

There are a number of essential issues in the immediate and long-term postoperative care of patients after parathyroidectomy. These include appropriate documentation of operative findings, observation for postoperative complications of hematoma or recurrent laryngeal nerve injury, calcium supplementation, monitoring for hypocalcemia and hypoparathyroidism, and long-term follow-up. Documentation of operative findings should be detailed and include specific description of all visualized glands including the relation to the recurrent laryngeal nerve, appearance, and management of the gland (removed, biopsied, transected, left viable in situ); all areas explored, any additional procedures (thyroidectomy, thymectomy, etc.), and results of IPM. These key points are essential for communication to other members of the care team and if there is need for future cervical or parathyroid surgery.

Complications from parathyroidectomy include hematoma, recurrent laryngeal nerve injury, transient or permanent hypoparathyroidism, and operative failure (persistent PHPT). Infections from parathyroid surgery are very rare. The rate of neck hematomas requiring operative evacuation is low at approximately 0.3%, while MIP has not reported to require reoperation for hematoma. Several large institutional studies have found that almost all cervical hematomas will be identified within 4 to 6 hours postoperatively. However, overnight observation is not essential for comprehensive parathyroidectomy; if multiple glands are removed we recommend one night observation. Signs and symptoms of postoperative hematoma include increasing swelling, neck pain, difficulty swallowing, respiratory distress, and voice changes. This is a potentially life-threatening complication and the treatment for neck hematomas should be immediate operative evacuation. The rates of permanent recurrent laryngeal nerve injury for initial parathyroidectomy are reportedly lower than with thyroidectomy (0.3% to 1.0%). Rates do increase with reoperative parathyroidectomy (2% to 9%). If nerve transection is noted during the procedure reinnervation should be attempted. For all patients if voice abnormalities are noted after procedure, formal evaluation by fiberoptic laryngoscopy or transcutaneous laryngeal ultrasound should be performed.

There is currently no standard for postoperative calcium management after parathyroidectomy. We recommend starting all patients on calcium supplementation postoperatively as relative and/or symptomatic hypocalcemia is common. This may be more frequent in patients with

vitamin D deficiency and/or malabsorption, and after comprehensive parathyroidectomy, especially with MGD. Calcium supplementation may vary based on preoperative calcium levels, adenoma size, rate of drop of IPM levels, and calcium levels in the perioperative period. Regimens may include calcium supplementation of 1,000 mg twice daily up to 2,500 mg three times daily, with as needed supplementation for symptoms. Additional activated vitamin D supplementation (calcitriol) may be necessary in patients with significant drops in PTH levels, calcium levels, or significant symptoms. IV calcium supplementation may be very infrequently necessary for parathyroidectomy for PHPT. The rate of permanent hypoparathyroidism for initial parathyroid surgery is low, 0% to 3.6%.

Patients should be seen in postoperative visit within 1 to 2 weeks after procedure. Laboratory testing including calcium and PTH levels should be obtained and calcium supplementation may be weaned down as needed. Subsequent testing may be obtained as needed. Patients should ultimately continue calcium and vitamin D intake levels according to the Institute of Medicine dietary recommendations. Successful parathyroidectomy is defined by normocalcemia at 6 months post procedure. Therefore, it is critically important that the patient have at least 6 months of postoperative follow-up, by either the surgeon or a member of the multidisciplinary team. Recommended laboratory tests at the 6-month timepoint include calcium, PTH, and 25-hydroxyvitamin D levels.

OUTCOMES

When performed by experienced parathyroid surgeons, the expected cure rate for initial operation for sporadic PHPT is >95% and for reoperation is >90%. With improved imaging modalities and the implementation of IPM, comprehensive parathyroidectomy is now one of two options for definitive treatment of PHPT. Comprehensive parathyroidectomy with bilateral neck exploration has a >95% success rate and low complication rates. All surgeons performing parathyroidectomy must be prepared for comprehensive parathyroidectomy in the situation of nonlocalizing imaging, suspicion for MGD, or when IPM levels do not appropriate fall during MIP. Recent observational studies have found that surgeon volume of cervical endocrine procedures inversely correlates with complications, cost, and length of stay. Hospital volume of parathyroidectomy has also been linked to outcome with low volume sites having higher rate of

complications, failed surgery, and need for reoperation.

With MIP, there is concern that even with meeting IPM criteria, there may be unrecognized enlarged glands that are identified and resected. Studies have identified increased incidence of MGD in comprehensive parathyroidectomy compared to planned MIP. Overall studies have shown conflicting results with some studies suggesting that MIP may not be as effective in identifying MGD and a trend to increased long-term recurrence rates with MIP. Cure of PHPT requires resection of all hyperfunctioning parathyroid tissue. Since in the immediate postoperative period there may be fluctuations in serum calcium and patients may be on higher doses of calcium supplementation, the long-established definition of cure of PHPT is normocalcemia at 6 months after surgery. Normalization of PTH levels is not required although preferred. There have been several studies showing PTH levels may continue to be elevated in patients cured of PHPT, potentially for varied reasons including vitamin D deficiency, mild renal insufficiency, and increased bone mineralization. However, due to the possible risk of recurrence, patients with normal calcium levels but elevated PTH postoperatively should be monitored at least annually for recurrence.

CONCLUSIONS

PHPT is an increasingly recognized disease that may only be cured by parathyroidectomy. The technique for comprehensive parathyroidectomy is an essential procedure that all surgeons performing parathyroidectomy should be prepared to perform. In skilled hands, comprehensive parathyroidectomy has an extremely high success rate. IPM is essential for MIP and may also aid in decision making and confirmation of findings during comprehensive parathyroidectomy. A careful approach to parathyroidectomy with understanding of the nuances of parathyroid location and analysis of IPM is essential to success.

EDITOR'S COMMENT

Drs. Carr and Wang have done a commendable job in detailing a comprehensive and in-depth review of "Comprehensive Parathyroidectomy for the Treatment of PHPT, Including Intraoperative Parathyroid Hormone Assay–Guided Parathyroidectomy." I would like to highlight some key points.

The recognition of PHPT increased in the 1970s with automated routine calcium testing, and prevalence continues to increase today. Incidence appears to increase with age and is two to three times higher in women. Primary hyperparathyroidism remains underdiagnosed and undertreated (Marcocci C, Cetani F. Primary hyperparathyroidism. *N Engl J Med* 2011;365:2389–97).

Genetic counseling should be performed for patients younger than 40 years with PHPT and MGD and considered for those with a family history or syndromic manifestations. Lithium-associated PHPT occurs in up to 15% of long-term users, with increased rates of MGD. Molecular alterations also affect the pathophysiologic mechanisms and rates of MGD. Germline-inactivating mutation of the *MEN1* gene causes multiple endocrine neoplasia type 1, and somatic events occur in sporadic tumors; germline-activating mutations of the *RET* proto-oncogene result in multiple endocrine neoplasia type 2; the somatic *PRAD1* rearrangement upregulates cyclin D1 in sporadic adenomas; and inactivating mutations of *CDC73* (formerly *HRPT2*) occur as germline alterations in hyperparathyroidism–jaw tumor syndrome and familial isolated hyperparathyroidism and as somatic events in sporadic parathyroid cancer (PCA) (Wilhelm SM, Wang TS, Ruan DT, et al. The American association of endocrine surgeons guidelines for definitive management of primary hyperparathyroidism. *JAMA Surg* 2016;151(10):959–68).

Imaging has no utility in confirming or excluding the diagnosis of PHPT. Imaging results should not be used to select patients for surgical referral. Patients with negative imaging results remain candidates for parathyroidectomy. There is a marked regional variability in imaging accuracy. When imaging with initially negative results is performed again at high volume centers, the sensitivity of localization improves to as high as 92%. Imaging is performed after deciding to proceed with parathyroidectomy and is performed for operative planning. Parathyroid imaging is significantly less accurate for MGD.

Four-dimensional computerized tomography (4D CT) combined with ultrasound is the imaging modality of choice at our institution. The ultrasound is more sensitive and specific to rule out any coexisting thyroid pathology. Our data and others have shown significantly higher positivity and accurate localization rate in single-gland parathyroid disease, significantly higher predictive value in multigland parathyroid disease, and significantly higher overall accuracy rate when compared with sestamibi. In addition, 4D CT minimizes unnecessary opposite-side exploration, provides excellent 3D reconstruction images, superior surgical planning, especially with ectopic glands (Kukar M, Platz TA, Schaffner TJ, et al. The use of modified four-dimensional computed tomography in patients with primary hyperparathyroidism: an argument for the abandonment of routine sestamibi single-positron emission computed tomography (SPECT). *Ann Surg Oncol* 2015;22(1):139–45).

Cohort data have demonstrated reductions in the risk of all fractures postparathyroidectomy. Surgery has also been shown to reduce the risk of renal

stones and offers a cure if successful. Similar benefits have not yet been demonstrated with the existing medical options available. Medical monitoring appears to be safe for individuals who do not meet surgical guidelines and is required for those with contraindications for surgery or who are unwilling to undergo surgery. Targeted medical therapy includes aminobisphosphonates for skeletal protection and cinacalcet for lowering serum calcium. There are no data showing fracture risk reduction with either antiresorptive therapy or with cinacalcet.

Future research should focus on the effects of PHPT on skeletal strength as well as pharmacologic approaches to lowering fracture risk. The effects of PHPT on cognition and the cardiovascular, gastrointestinal, and musculoskeletal systems in patients with mild asymptomatic disease require further evaluation with well-designed prospective cohort studies.

41 Minimally Invasive Parathyroidectomy

Robert Udelsman and Tobias Carling

BACKGROUND

Approximately, 85% of patients with primary hyperparathyroidism (pHPT) harbor a single adenoma and are cured by excision of the incident gland. The remaining patients display double adenoma (3% to 5%) or four-gland hyperplasia (10% to 15%). Thus, with accurate preoperative localization, targeted surgery using unilateral neck exploration under regional or local anesthesia has been developed, evaluated over the past 10 to 20 years and has become the standard of care in an ever-increasing number of specialized centers. Unilateral surgery for pHPT was advocated in 1975, and the side to be explored was chosen based on palpation, esophageal imaging, venography, or arteriography.[1] If both an enlarged and normal gland were found on the initial side, then contralateral cervical exploration was obviated. Other authors advocated a similar approach, arguing that bilateral exploration increased the risk, cost, and morbidity of surgery for pHPT.[2] The Lund University surgeons advocated unilateral parathyroidectomy, which they defined as the removal of both an adenoma and ipsilateral normal parathyroid gland.[3] The excised tissue was studied microscopically during surgery with oil-red-O, and the decision to stop the operation at this stage was based on demonstration of a reduction in intracytoplasmic fat droplets in the excised adenomatous parathyroid tissue. Both techniques would fail, however, in the setting of a double adenoma on the contralateral side and if the essentially "random" choice of which side to explore was incorrect. Today, minimally invasive parathyroidectomy (MIP) is performed after preoperative parathyroid localization usually with high-quality sestamibi scans, ultrasonography, or four-dimensional CT (4DCT) scans, often under cervical block anesthesia during which a focused exploration is performed, and a rapid intraoperative parathyroid hormone (PTH) assay is employed to confirm an adequate resection.[4] These procedures are now often performed on an

outpatient basis.[4]

INDICATIONS

The indications for MIP are the same as those for traditional cervical exploration, that is, symptomatic patients or those with asymptomatic pHPT fulfilling the criteria established by the most recent consensus meeting.[5,6] In addition, there are now significant data to support more liberal use of parathyroidectomy for pHPT, since the disease has been associated with a number of "nonclassical" morbidities, some of which seem to improve postoperatively. These include neurocognitive impairments and cardiovascular abnormalities (extensively reviewed in reference).[6] Patients with persistent disease (previously failed parathyroidectomy) as well as other reoperative cases can also successfully be performed using the MIP techniques.[7,8] Minimally invasive techniques are rarely employed when preoperative localization of the parathyroid tumor was not performed, is negative, or is consistent with multiglandular enlargement. The role of MIP in the setting of familial HPT (i.e., multiple endocrine neoplasia type 1 [MEN1], MEN2A, the hyperparathyroidism-jaw tumor syndrome [HPT-JT], familial isolated hyperparathyroidism [FIHPT], and HPT occurring in patients with an underlying mutation in the calcium sensing receptor [CASR] gene) is evolving.[9] A conventional cervical exploration should be performed in the vast majority of these cases, although MIP may prove to have a limited role in specific instances of familial HPT. For instance, in HPT associated with MEN2A, HPT-JT, and FIHPT where uniglandular uptake is noted on preoperative imaging, MIP may be considered when combined with employment of an intraoperative PTH assay to confirm the adequacy of resection.[9,10] In rare cases when parathyroid carcinoma is diagnosed or suspected, a radical resection at the initial operation is required for optimal results.[11,12]

PREOPERATIVE PLANNING

The development and refinement of parathyroid imaging have been essential for the development of MIP techniques. Several noninvasive preoperative localization methods are available, including sestamibi-technetium-99m scintigraphy, ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and thallium-201-technetium (Tc)-99m pertechnetate scanning. The most commonly used modality remains sestamibi with single photon emission computed tomography

(SPECT), which generates three-dimensional localization.[13–16] In 1989, it was first reported that the new agent Technetium-99m used for cardiac imaging also was avidly taken up by parathyroid tissue.[17] Parathyroid cells have a large number of mitochondria, which take up sestamibi/Tc-99m.[18] Sestamibi, a monovalent lipophilic cation, diffuses passively across cell membranes, concentrates in mitochondria, and accumulates in adenomatous parathyroid tissue because of increased blood supply, higher metabolic activity, and an absence of p-glycoprotein on the cell membrane.[19] Sestamibi imaging can be performed preoperatively to plan an MIP or on the morning of operation in combination with the use of a gamma probe in the operating room to guide the surgeon during surgery.[20] The sensitivity of sestamibi is limited in multiglandular disease. In a large study, scintigraphy localized at least one gland in all patients, but only 62% of the total number of hyperplastic glands.[21] SPECT, which allows localization of structures in the anterior/posterior plane, is particularly helpful in detecting smaller lesions and adenomas located posterior to the thyroid gland. The overall sensitivity for localizing adenomas <500 mg varies, from 53% to 92%.[22,23] A major limitation of sestamibi scans is related to the coexistence of thyroid nodules or other metabolically active tissues (e.g., lymph nodes, thyroid nodules, and metastatic thyroid cancer) that can mimic parathyroid adenomas, thereby causing false-positive results on sestamibi scans. This limitation can be overcome in part by using the double-tracer subtraction technique of sestamibi, in which both thyroid and parathyroid nodular abnormalities can be diagnosed simultaneously, or in combination with a neck ultrasound to preoperatively distinguish between thyroid lesions and parathyroid enlargement.[16,24] Sestamibi with SPECT does not provide detailed anatomical depiction, and can only detect double adenomas and multiglandular hyperplasia in a minority of cases.

Ultrasound is effective, noninvasive, and inexpensive, but its limitations include both operator dependency and being limited to application in the neck because it cannot image mediastinal adenomas. The normal parathyroid gland is generally too small to be visualized sonographically, whereas parathyroid enlargement seen in pHPT is often identified as a homogeneously hypoechoic extrathyroidal ovoid mass. Parathyroid adenomas are typically vascular, and an arterial branch can often be followed to the superior or inferior pole of the lesion.[25,26] An additional advantage of ultrasound is the ability to perform fine needle aspirates with

rapid PTH measurements of the aspirates. This technique should be reserved for select patients undergoing re-exploration.[13,27] By itself, ultrasound has approximately a 50% to 75% true-positive rate, with generally better rates for larger glands.[25,26] However, when combined with sestamibi, the true-positive rate approaches 90%, with few false-positives.[28] The ability of both ultrasound and sestamibi with SPECT to detect the parathyroid abnormality is reduced in milder forms of pHPT (i.e., only mildly elevated PTH and calcium levels) and in obese patients.[16]

The 4DCT scan is a promising, more novel parathyroid imaging technique. It is similar to CT angiography. The term is derived from 3-dimensional CT scanning with an added dimension referring to the changes in perfusion of contrast over time. Exquisitely detailed, multiplanar images are obtained that accentuate the differences in the perfusion characteristics of hyperfunctioning parathyroid glands (i.e., rapid uptake and washout), compared with normal parathyroid glands and other structures in the neck. The images provide both anatomic information and functional information (based on changes in perfusion) in a single study that the operating surgeon can easily interpret. In a recent series, 4DCT displayed improved sensitivity (88%) over sestamibi imaging (65%) and ultrasonography (57%), when the imaging studies were used to localize (lateralize) hyperfunctioning parathyroid glands to one side of the neck. Moreover, when used to localize parathyroid tumors to the correct quadrant of the neck (i.e., right inferior, right superior, left inferior, or left superior), the sensitivity of 4DCT (70%) was significantly higher than sestamibi imaging (33%) and ultrasonography (29%).[29] In a prospective consecutive cohort, the results at Yale University are similar. Moreover, 4DCT predicted multiglandular disease in 85.7% (6/7) patients.[30] Compared to sestamibi with SPECT, 4DCT is significantly less expensive but associated with higher exposure to ionizing radiation and thus should be used cautiously in children and young adults due to the theoretic risk of inducing thyroid carcinoma.[16,31] Moreover, because of the use of intravenous contrast it should be avoided in patients with renal insufficiency as well as in patients with concomitant well-differentiated thyroid carcinoma.[16,31] With the development of improved CT scanning, MRI is rarely used. However, since it does not involve the use of radiation it may be employed in select cases such as during pregnancy. Parathyroid adenomas may appear very intense on T_2-weighted images.

A subset of patients who require re-exploration will have negative,

discordant, or nonconvincing noninvasive localization studies. Current guidelines recommend that these patients undergo invasive localization procedures in the form of selective venous sampling (SVS) with measurements of PTH. Rapid PTH measurement is now being used in the angiography suite, because results are rapidly available on-site, and interventional radiologists can obtain additional samples from a region in which a subtle but potentially significant PTH gradient is detected.[32,33] In a recent study, we demonstrated that superselective SVS had a sensitivity of 90% for the correct localization of a parathyroid adenoma in remedial cases where other imaging was negative or inconclusive. All patients underwent reoperative parathyroidectomy and were cured.[33]

REGIONAL BLOCK ANESTHESIA TECHNIQUE

The majority of parathyroidectomies are performed under general anesthesia using either an endotracheal tube (ETT) or a laryngeal mask airway (LMA). We prefer local and regional block anesthesia with monitored anesthesia care (MAC). The regional block is performed by the surgeon in the operating room, and intravenous supplementation is administered by the anesthesia staff (Fig. 41.1). In most patients, 1% lidocaine containing 1:100,000 epinephrine is used and supplemented during the operation as required. Care is taken to aspirate before delivering the anesthetic to avoid intravascular administration. We have found that by also infiltrating along the anterior border of the sternocleidomastoid muscle, as well as a local field block, excellent analgesia is obtained in virtually every case (Fig. 41.2). The total cumulative volume of lidocaine administered is typically 18 to 25 mL. Intravenous sedation is used to minimize patient anxiety while maintaining an awake, conscious patient who can phonate. Propofol was thought to possibly interfere with the PTH assay, but a recent randomized trial has shown that the PTH assay can be employed during propofol sedation.[34]

Regional anesthesia avoids complications associated with general anesthesia, including endotracheal intubation, which has been reported to cause vocal cord changes in up to 5% of patients.[35] Furthermore, exploring a conscious patient permits intraoperative assessment of the superior and recurrent laryngeal nerve functions because the patient can vocalize during the procedure. We recently demonstrated that laryngeal physiology and voice acoustics are maintained after MIP.[36]

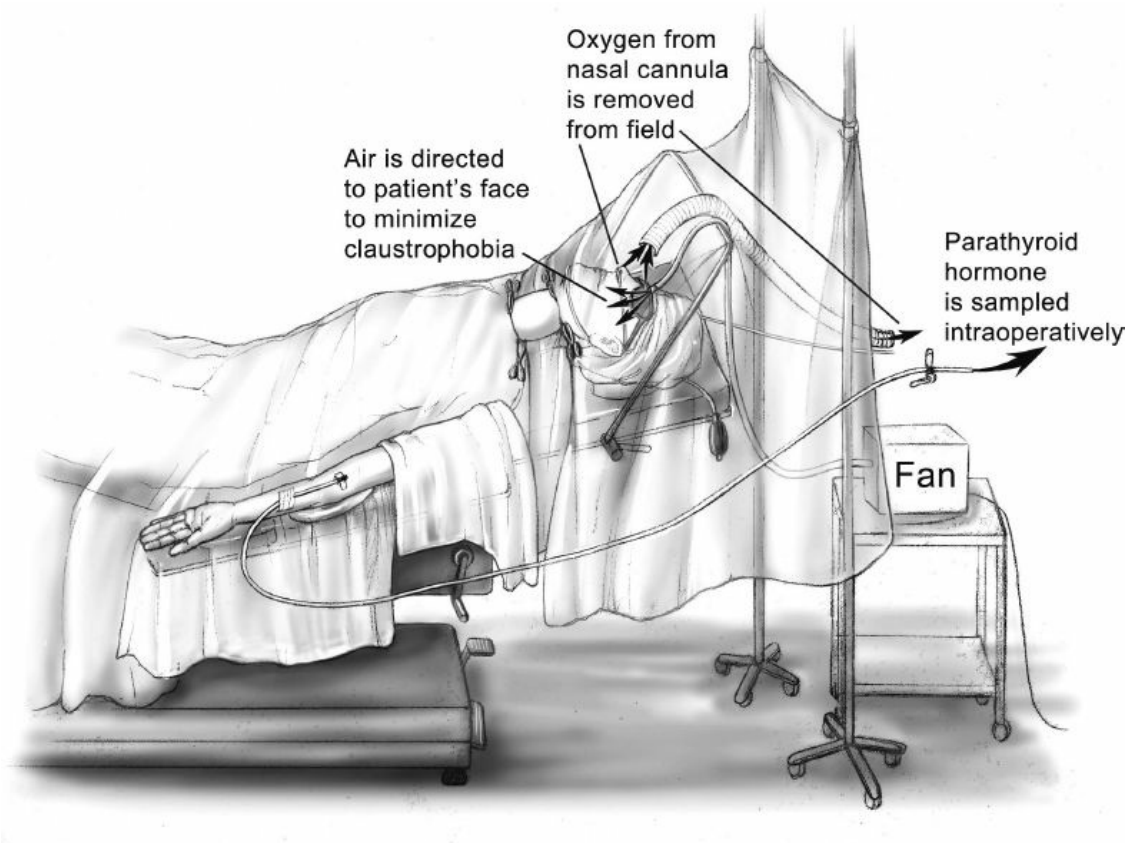

Figure 41.1. The patient has a large-bore peripheral intravenous line inserted, which is used for medication and fluid administration as well as sampling for parathormone (PTH) levels. The patient is awake, wearing protective eye glasses, and a fan is used to circulate room air gently toward his or her face to minimize the sensation of claustrophobia.

LoGerfo and colleagues have shown that bilateral neck exploration under regional anesthesia can be performed safely and effectively in patients with coexisting thyroid disease and a nonlocalized adenoma. In a series of 236 patients undergoing MIP, 62% had a nonlocalizing sestamibi scan preoperatively or no scan at all, but only 4 required conversion to general anesthesia. Twenty-three percent had a simultaneous procedure performed for thyroid disease, and 85% underwent a bilateral neck exploration.[37] We reported in 441 consecutive patients that 47 (10.6%) required conversion to general anesthesia.[38] In all instances, conversion was performed in a controlled fashion using neuromuscular blockade, endotracheal intubation, and maintenance of the original surgical field preparation. Table 41.1 summarized the reasons for conversion from regional block to general endotracheal anesthesia.

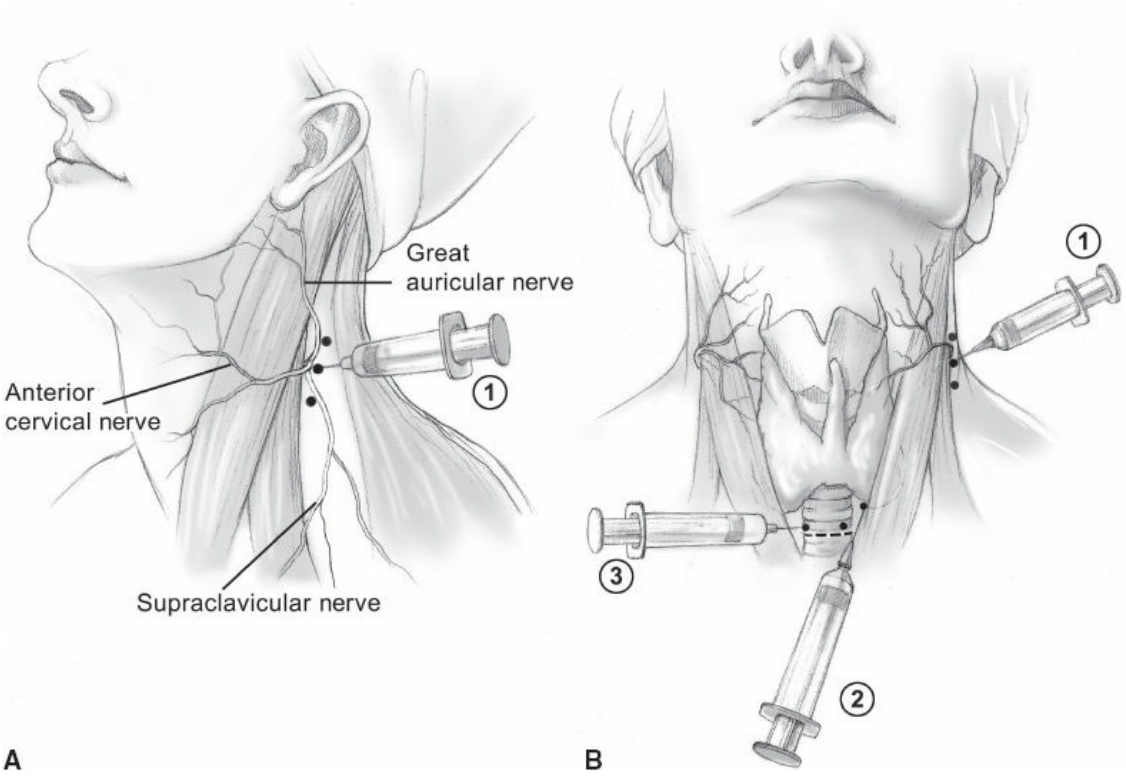

Figure 41.2. Cervical block anesthesia. **A.** A superficial cervical block is administered posterior and deep to the sternocleidomastoid muscle (SCM) (1). **B.** Local infiltration is also performed along the anterior border of the SCM (2), and a local field block (3) is performed.

SURGICAL TECHNIQUE AND RESULTS

No preoperative imaging modality will replace the need for a well-trained, thoughtful parathyroid surgeon. Surgeons performing MIP must understand the embryology and anatomy of the parathyroid glands. The embryonic development and descent into the cervical neck of the parathyroids lead to a highly variable anatomy. Ectopic parathyroid tissue is commonly encountered within the thyroid, thymus, mediastinum, carotid sheath, and tracheoesophageal groove. Nondescended glands can be located along the carotid bifurcation or along the larynx.

The MIP technique used at our institution is individualized after the parathyroid adenoma has been localized. Typically, a 2.5 to 3.5-cm abbreviated Kocher incision is made, and the parathyroid adenoma is identified and excised after the creation of limited subplatysmal flaps and mobilization of the ipsilateral strap muscles (Figs. 41.3 and 41.4). Parathyroid surgery is a meticulous procedure and operative experience correlates with rates of recurrence and persistence as well as complications. The procedure is guided by intraoperative PTH measurements, which is used routinely.

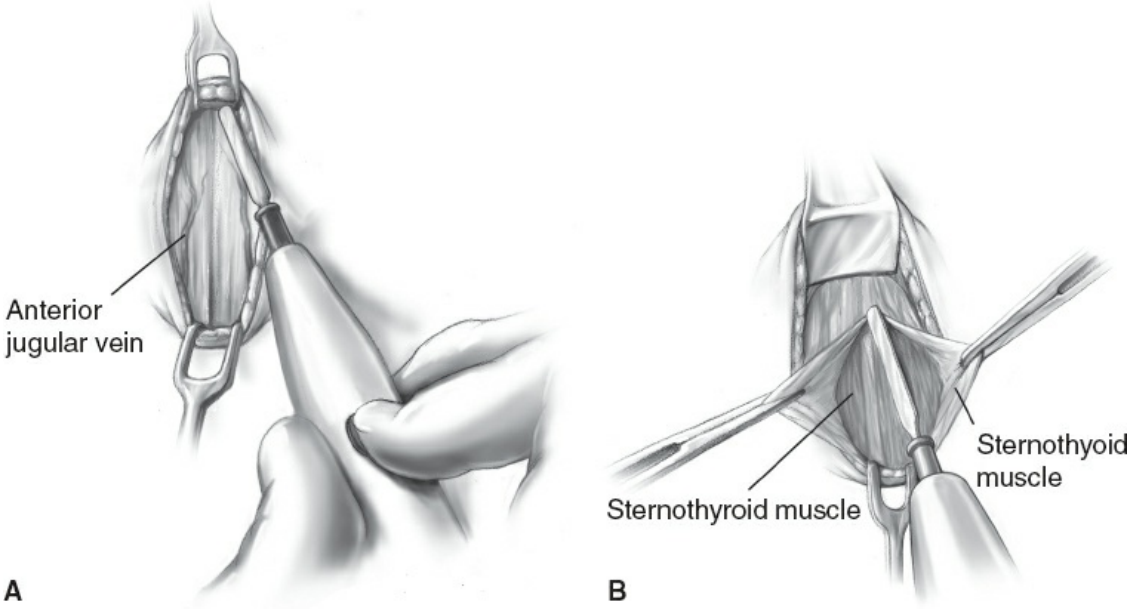

Figure 41.3. A. An abbreviated Kocher incision is made, the platysma is divided, and (**B**) the strap muscles are separated.

INTRAOPERATIVE PTH

Intraoperative PTH measurement is employed because although preoperative imaging can be sensitive for single adenomas, they fail to

identify 17% of a second (double) adenoma and 55% of hyperplastic glands. The circulating half-life of PTH is 3.5 to 4 minutes, and thus PTH levels are obtained prior to and 5 and 10 minutes after tumor extraction. Since the remaining normal parathyroid glands are suppressed by the hyperfunctioning parathyroid adenoma, a decline (>50%) in PTH is usually seen by 5 or 10 minutes, and the patient requires no additional exploration. Failure of the peripheral venous PTH level to adequately decline suggests remaining hyperfunctioning parathyroid tissue and additional surgery is indicated under either regional or general anesthesia.

Chapuis in France (1990) and Irvin in Miami (1991) independently described the use of intraoperative PTH monitoring to guide the surgeon during parathyroid surgery in patients with successful preoperative imaging.[39,40] These pioneers both concluded that intraoperative PTH monitoring could be reliably used during surgery to influence the extent of surgery and to determine the need for exploration of the contralateral side of the neck. At our institution, we have laboratory personnel and the analytical assay in the operating room, providing near real-time feedback to the surgeon.

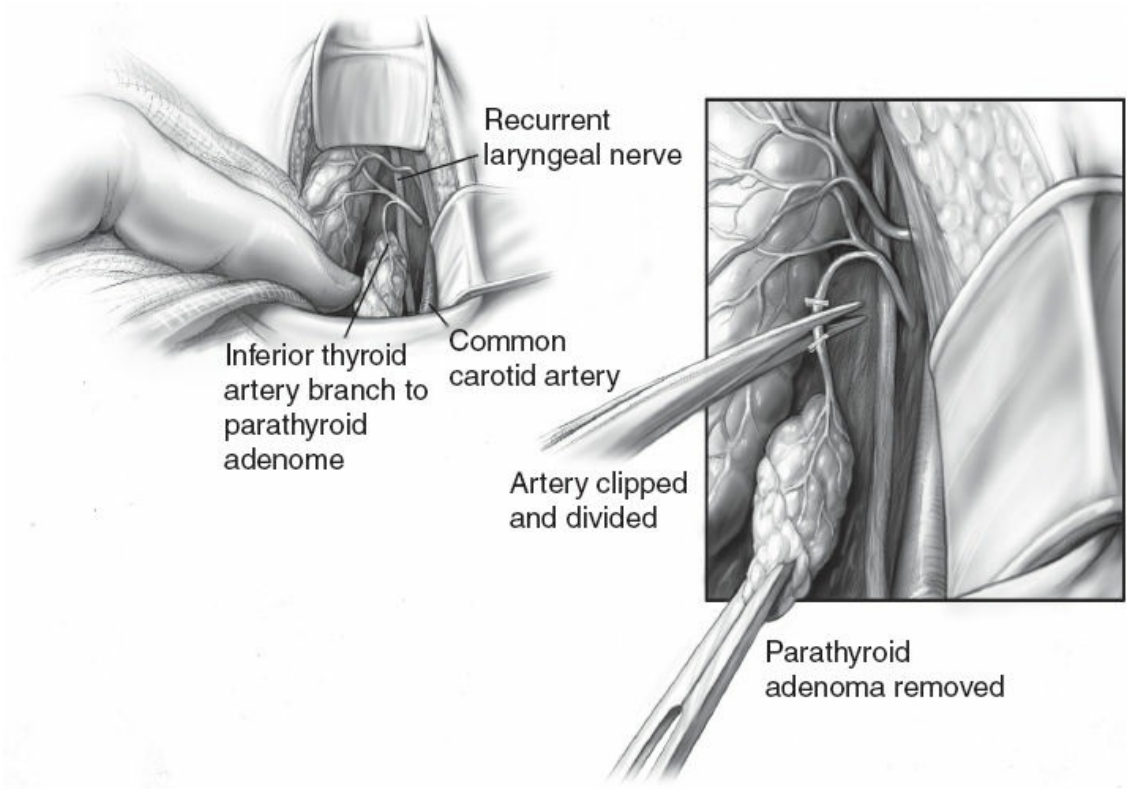

Figure 41.4. The parathyroid adenoma is identified, its end-arterial blood supply is ligated, the recurrent laryngeal nerve is protected, and the adenoma is removed.

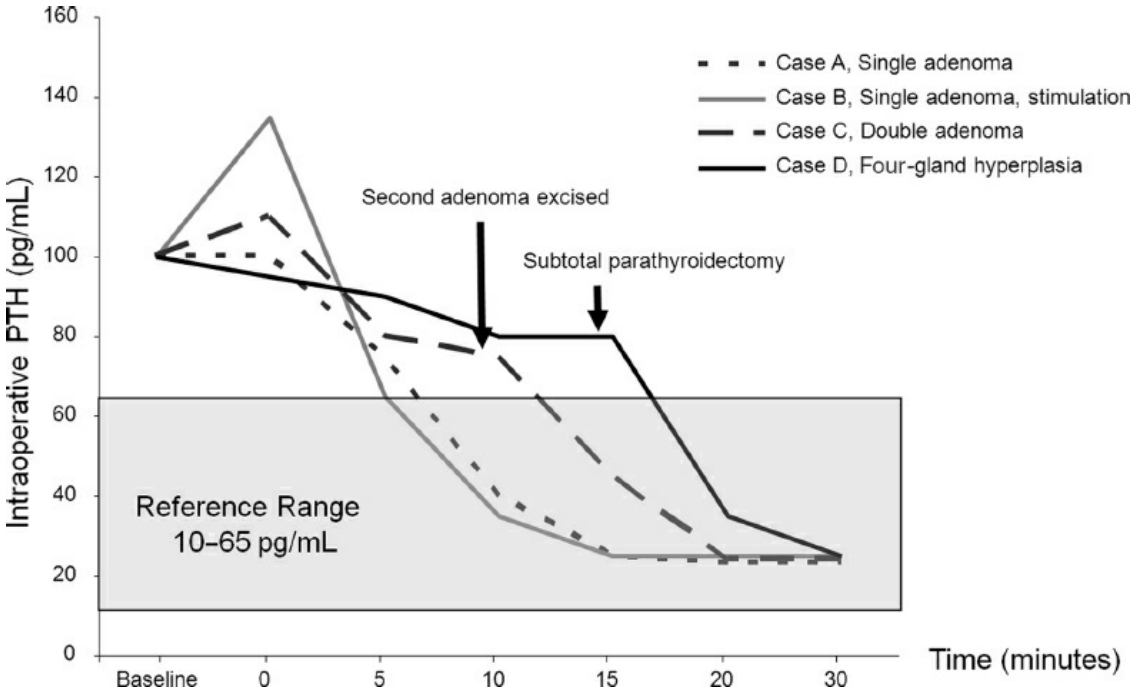

Figure 41.5. Interpretation of intraoperative PTH measurements. The graph illustrates typical findings in intraoperative PTH levels in four different scenarios. Case A shows the typical fall in PTH levels to below 50% of the preoperative baseline after excision of a single parathyroid adenoma, whereas case B illustrates an initial rise in PTH levels at time 0 minutes after resection, which is due to surgical manipulation. The patient in case C has pHPT due to double adenomas. Thus, although there is a slight reduction in PTH levels after the removal of the initial parathyroid gland at time 0 minutes, the PTH levels normalize only after excision of the second adenoma 10 minutes later. Case D shows typical findings of patients with pHPT due to hyperplasia of all four glands, and biochemical cure is not achieved until after subtotal parathyroidectomy.

Blood is collected from a peripheral vein, such as the antecubital vein, as blood sampled from the anterior or inferior jugular veins may not yield accurate results, because of their proximity to the parathyroid glands. To date, no standardized guidelines have been formulated regarding the timing and the number of PTH levels to measure during parathyroidectomy. It is important to measure a pre-incision baseline level as well as an immediate post-excision level, because frequently there will be a significant increase in PTH levels during surgical manipulation of the gland. If the manipulation level is not measured, the post-excision values may be difficult to interpret due to operative stimulation. Additional PTH levels are measured 5, 10, and occasionally 20 or 30 minutes following

excision of the targeted gland, the latter specimen being collected only if there is not an appropriate reduction in PTH levels at 5 and 10 minutes.

There is no universally adopted algorithm for interpreting the results of intraoperative PTH measurements. We advocate more stringent criteria than most, with a >50% reduction from the baseline with an absolute normalization of the PTH levels (Fig. 41.5). However, some surgeons advocate using a >50% reduction after parathyroidectomy, using the higher of either the pre-incision or the manipulation value. The rationality to use a more stringent criterion relates to the fact that patients may have multiglandular disease. We and others have advocated obtaining delayed measurements selectively (20 minutes or more after excision), especially in the setting of renal insufficiency, cystic parathyroid tumors, a significant manipulatory rise in the intact PTH, and multiglandular hyperplasia.[9,41] In the setting of familial HPT (especially MEN 1), a reduction in PTH levels >80% may be advocated prior to accepting adequate excision of parathyroid tissue.[9] Recently a computer algorithm has been developed to aid the surgeon in interpretation of intraoperative PTH data.[42]

In addition to being a valuable adjunct to confirming the completeness of parathyroid resection, the rapid PTH assay has been shown to be a useful adjunct to other aspects in the treatment of pHPT. We routinely perform, ex vivo, fine needle aspirations of tissue excised during parathyroid surgery with measurement of PTH. A positive aspirate will demonstrate PTH levels >1,000 pg/mL. This has eliminated the need for frozen section analysis in the vast majority of cases and saves time and expenses.

Although we rely heavily on the intraoperative PTH assay, it does not replace clinical judgment and the assay should be interpreted in this context.

CHALLENGING PATIENTS

Equivocal Imaging

Although the preoperative imaging of patients with pHPT has improved, approximately 10% to 15% of patients still present with equivocal or negative imaging results. We do not routinely perform additional imaging in the previously unexplored patients; rather, these patients are explored under cervical block anesthesia, or if the patients prefers, general anesthesia. Additional imaging techniques using ultrasound-guided fine needle aspiration (FNA) or SVS are reserved for patients undergoing

remedial cervical exploration.[32,33] Multiglandular parathyroid enlargement appears to be more common in patients with negative imaging studies. The intraoperative rapid PTH assay has been validated in the setting of multiglandular parathyroid disease in patients with either primary and secondary HPT.[43]

Static PTH Post-Excision

In about 85% of the cases, the rapid PTH assay demonstrates a >50% drop in the intact PTH level after excision of a single enlarged parathyroid gland, which is consistent with a diagnosis of a single parathyroid adenoma. In the remaining patients, failure of the PTH decrement suggests additional disease and further exploration is mandatory. Continued exploration unilaterally as well as bilaterally can be done under regional block in the vast majority of cases, but conversion to general anesthesia is sometimes needed.[38] Since the most advantageous time to cure pHPT is during the first surgical exploration, it is the obligation of the initial surgeon to perform a meticulous exploration evaluating both eutopic and ectopic sites. This exploration includes the retroesophageal space, thymus gland, carotid sheaths, and submandibular region for undescended glands. If the occult gland is still not identified, additional intraoperative adjuncts are used, including ultrasound and bilateral internal jugular vein sampling to determine if an ipsilateral PTH gradient is present. This technique has guided us to explore upstream and locate occult undescended or partially descended glands. Partial or complete thyroid lobectomy can be performed depending on the suspected location of the missing gland. We do not recommend sternotomy at the initial exploration unless imaging strongly suggests mediastinal disease that is not accessible by less invasive routes.[44] Despite all of these maneuvers, there still remains a subset of patients in whom the elusive parathyroid is not identified. In this setting, ligation of the blood supply to the missing parathyroid gland is performed. This usually involves ligation of the ipsilateral inferior thyroid artery but may also involve devascularization of other arterial branches.[7]

Coexistent Thyroid Disease

Coexistent thyroid disease is relatively common and may range from benign nodules to thyroid cancer. In patients undergoing a preoperative ultrasound showing thyroid lesions, appropriate work-up should be done prior to parathyroid exploration. In cases where a preoperative ultrasound

has not been performed, intraoperative recognition of coexistent thyroid disease is sometimes encountered. A thyroid lobectomy can be performed under regional block, but for more extensive thyroid resections conversion to general anesthesia is sometimes needed.[38] Patients with Hashimoto's thyroiditis, Graves' disease, or sarcoidosis often display significant cervical lymphadenopathy, which may cause difficulty in distinguishing enlarged lymph nodes from hypercellular parathyroid glands.

Previously Operated Patients

Despite the success rate of parathyroidectomy in the modern era, surgeons still encounter three groups of patients representing challenging management issues: (a) patients with persistent pHPT having failed initial exploration, (b) patients who develop recurrent pHPT having sustained a period of eucalcemia for >6 months after their initial operation, and (c) patients who have undergone previous neck explorations, particularly total thyroidectomy, who then develop pHPT. In each of these settings, remedial cervical explorations are associated with decreased success and increased complication rates.[7,45] Recently, we reported the experience with remedial surgery over the past 15 years in 130 consecutive operations (Fig. 41.6). Although the explorations were performed under general anesthesia in the majority of patients, MIP was employed in 23 patients. The cure rate was similar in the two groups, 94% and 96%, respectively. Again, meticulous preoperative imaging enhances the chance of operative success, and may include sestamibi scanning, ultrasound, 4DCT, venous localization, ultrasound combined with FNA of suspected enlarged parathyroid glands, or superselective SVS with rapid PTH measurements.

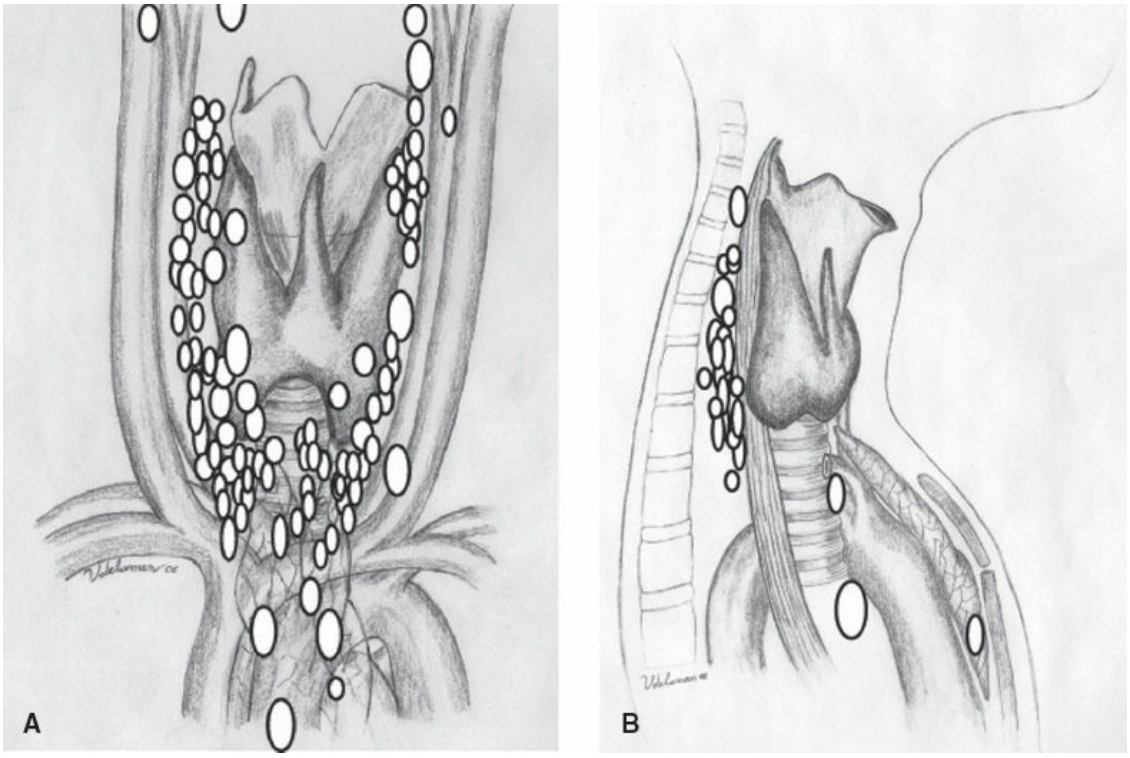

Figure 41.6. Location of enlarged parathyroid glands resected during remedial cervical exploration. Because of overlapping glands, the parathyroid glands are not drawn to scale. Some patients had more than one enlarged gland. Individual glands are depicted on one illustration only. **A:** Anteroposterior projection. **B:** Lateral projection.

POSTOPERATIVE CARE

Approximately 90% of cases are performed under regional cervical block anesthesia in the ambulatory setting at our institution. However, the patients are counseled that an overnight stay is a possibility. The most common reasons for admission to the hospital are multiglandular disease requiring subtotal parathyroidectomy, significant comorbidity, advanced age, or the lack of support at home. The majority of patients are monitored for 1 to 2 hours postoperatively, mainly to ensure absence of a neck hematoma. After curative parathyroidectomy, the patient is placed on oral calcium carbonate in the immediate postoperative period (2 to 4 weeks) to avoid symptoms of transient relative hypocalcemia. Since many patients suffer vitamin D deficiency as well, they are advised to adhere to current recommendations for calcium/vitamin D supplementation.

RESULTS AND COMPLICATIONS

The success of MIP has been confirmed by evidence of cure and complication rates that are at least as good as those achieved by conventional bilateral exploration. Specifically, in a series of 656 consecutive parathyroidectomies (of which 401 were performed in the standard fashion and 255 were performed with MIP) between 1990 and 2001, there were no significant differences in complication (3.0% and 1.2%, respectively) or cure rates (97% and 99%, respectively).[46] MIP was associated with an approximately 50% reduction in operating time (1.3 hours for MIP vs. 2.4 hours for standard operation), a seven-fold reduction in length of hospital stay (0.24 days vs. 1.64 days, respectively), and a mean savings in terms of charges of $2,693 per procedure. This represents a reduction by nearly one half in total hospital charges. A prospective randomized controlled trial comparing unilateral to bilateral neck exploration was recently published.[47] In this study of 91 patients, comparison was made between patients assigned to preoperative sestamibi localization and unilateral neck exploration with the rapid PTH assay versus patients assigned to bilateral neck exploration. Patients who underwent unilateral neck exploration had a lower incidence of early postoperative hypocalcemia necessitating calcium supplementation. There were no statistical differences between complication rates, costs, and operative time between the two groups. The study, which was not blinded, was encumbered by a high-crossover rate; only 62% of patients assigned to unilateral exploration actually underwent this operation. This may relate to the relatively low sensitivity (71%) of the sestamibi imaging in this population.

The complication rate of MIP is similar or lower compared to standard cervical approach. Recurrent laryngeal nerve injury may occur in 0.5% to 1.0% of the cases.[48] The risk of permanent hypoparathyroidism is absent if a single gland is explored and removed, but remains a concern in patients undergoing subtotal parathyroidectomy for multiglandular disease.

EDITOR'S COMMENT

Minimally invasive parathyroidectomy (MIP) has gained worldwide acceptance in the surgical treatment of sporadic hyperparathyroidism, replacing the gold standard of bilateral neck exploration in patients with a presumed solitary parathyroid adenoma. A survey distributed among members of the International Association of Endocrine Surgeons (IAES) found that MIP was offered to patients by almost two thirds of endocrine surgeons worldwide in 2002. (Sackett WR, Barraclough B, Reeve TS, et al. Worldwide trends in the surgical treatment of primary hyperparathyroidism in the era of minimally invasive parathyroidectomy. *Arch Surg* 2002;137:1055–9.) It is likely if queried today a greater percentage would opt for this techniques as the results are comparable to bilateral neck dissection. The contribution by Udelsman and Carling reviews the indications for the procedure, the use of various preoperative imaging

modalities, the type of anesthesia including an extensive discussion of application of regional block to parathyroid surgery, the role of intraoperative parathyroid hormone (IOPTH) assay, challenging patients, and outcomes.

What is MIP? The term means different things to different people. James et al. (James BC, Kaplan EL, Grogan RH, et al. What's in a name?: Providing clarity in the definition of minimally invasive parathyroidectomy. *World J Surg* 2015;39(4):975–80) try to provide some insight into a definition of minimally invasive parathyroid surgery. They performed a PubMed search using the terms: parathyroidectomy, minimally invasive, localized, focused, unilateral, radio-guided, video-assisted, and endoscopic. They analyzed 443 (44%) articles after applying specific exclusion criteria and identified 18 words that were used in 75 different combinations to describe MIP. The finding that there were 75 different definitions for MIP confirms that their hypothesis that the term is too generic to be useful. They established that there were four categories that encompassed all 75 definitions: (1) operative approach (incision size, including the specific technique as open; endoscopic; robotic; or video-assisted), (2) number of glands explored, (3) operative adjuncts, and (4) anesthesia type and recommend that these categories be used to specify an operation as MIP. They cite as an example "2-cm, single gland parathyroidectomy using IOPTH measurement, under general anesthesia" rather than using the generic MIP. This more granular approach will enhance the clarity of the operative report and provide better definition for subsequent patient care and data collection. In the United States, there is no specific CPT code for MIP. Rather the CPT code 60500 is currently used as a one size fits all. When guided by IOPTH assay, the 36500 code represents blood sampling for the PTH assay. For the use of adjunctive measures, it is recommended the 22 modifier be used.

The primary imaging modality for parathyroid localization is sestamibi-technicium-99m scintigraphy. Some surgeons use an intraoperative radioguided approach using a small gamma probe. The success of radioguided MIP is 96% to 98%. In this technique, the patient is injected with technetium sestamibi 1 to 2 hours prior to surgery. During the operation, a gamma probe is used to identify counts of the enlarged parathyroid gland relative to background counts. After excision of the parathyroid gland, the tissue is scanned and ex vivo counts are expressed as a percentage of background counts. According to Norman et al. if the ex vivo parathyroid count is >20% of the background, then frozen section is not needed. (Murphy C, Norman J. The 20% rule: a simple, instantaneous radioactivity measurement defines cure and allows elimination of frozen sections and hormone assays during parathyroidectomy. *Surgery* 1999;126:1023–28.) Inabet and colleagues reported that intraoperative radioguidance is not necessary (Inabet WB, Kim CK, Haber RS, et al. Radioguidance is not necessary during parathyroidectomy. *Arch Surg* 2002;137:967–70). Radioguidance is helpful but may not be necessary. Ultrasound may prove to be an important adjunct and may be used as the sole localizing test. Butt and colleagues (Butt HZ, Husainy MA, Bolia A, et al.

Ultrasonography alone can reliably locate parathyroid tumours and facilitates minimally invasive parathyroidectomy. *Ann R Coll Surg Engl* 2015;97(6):420–4) present an 8-year experience using ultrasonography alone to guide parathyroidectomy. Between April 2004 and December 2012, 100 patients with proven hyperparathyroidism underwent parathyroidectomy performed by a single surgeon. All patients underwent ultrasonography as the only localization test. The procedure included preoperative marking of the lesion by a single radiologist. The median age of all cases was 58 years (range: 19 to 90 years). Of the 100 patients (69% female) who underwent parathyroidectomy, 93 had MIP. Conventional surgery was indicated in 7 patients owing to the need for concurrent thyroidectomy. The median operative time was 30 minutes (range: 10 to 130 minutes). Ultrasonography localized the parathyroid adenoma correctly in 98% of patients. Outcome analysis at 6 to 8 weeks demonstrated that 86% of open cases (6/7) and 94% of MIP cases (87/93) were rendered normocalcemic. Although there is variability in the results of ultrasound owing to user experience and the quality of ultrasound probes, it is likely to gain increasing use as it may be more cost-effective and ultrasound is being more integrated into graduate medical education and clinical practice. In addition as pointed out ultrasound-directed FNA for parathyroid hormone (PTH) assay may facilitate parathyroid adenoma localization for recurrent disease or a failed operation.

The majority of procedures are performed under general anesthesia with an endotracheal tube for airway control and oxygenation. Udelsman and the Yale group have an extensive experience with parathyroidectomy under local anesthesia that was reported in 2006 (Carling T, Donovan P, Rinder C, et al. Minimally invasive parathyroidectomy using cervical block: reasons for conversion to general anesthesia. *Ann Surg* 2006;141:401–4). The advantages are readily apparent particularly in the elderly population, and it avoids voice changes caused by the effect of the endotracheal tube on the vocal cords. Adopting this technique requires a well-delineated protocol and a dedicated team.

If the localization procedures are so accurate, then why would one need to do IOPTH assays to guide the success of the procedure? As the authors note, double adenomas may occur in 3% to 5% of patients and 10% to 15% have parathyroid hyperplasia. Sestamibi scans are very sensitive for single adenomas, however fail to identify 17% of double adenomas and 55% of hyperplastic glands. Hence without IOPTH assay, there is a potentially greater risk of a failed operation. Kim and colleagues compared outcomes in 53 patients undergoing MIP with and without IOPTH assay. The overall cure rate of group 1 (without IOPTH) was 94.9% and that of group 2 (with IOPTH) was 100%. Hence as this study shows even though the localization studies are successful, IOPTH monitoring is essential to avoid a surgical failure in MIP. A paper by Vaid and Pandelidis (Vaid S, Pandelidis S. Minimally invasive parathyroidectomy: a community hospital experience. *Arch Surg* 2011;146:876–

8) ascertained the outcomes of MIP performed in a community hospital without the expense of measuring PTH intraoperatively. This was a retrospective review of 188 parathyroidectomies including 111 MIRP. The success rate of MIP was 98% with two failures. The authors indicate that higher preoperative PTH levels and gland weights had a direct correlation with the success of MIP. It is possible that patients with lower PTH levels and possible microadenomas underwent conventional parathyroidectomy. The safest course of action is to perform IOPTH assays. The goal is avoid failure and the need for a second operation.

What is the role of video-assisted parathyroid surgery? It is no surprise that video-assisted techniques have been applied to parathyroidectomy (Miccoli P, Materazzi G, Bonari G, et al. Minimally invasive video-assisted parathyroidectomy. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:22–5). Barczynski and colleagues report a retrospective case-controlled study of video-assisted versus open MIP (Barczyn´ski M, Papier A, Kenig J, et al. A retrospective case-controlled study of video-assisted versus open minimally invasive parathyroidectomy. *Videosurg Miniinv* 2014;9:537–47). Of 455 patients with primary hyperparathyroidism and a solitary parathyroid adenoma on preoperative imaging, 151 underwent video-assisted MIP using the technique of Miccoli and 304 had open MIP. They reported that the following outcomes were superior for video-assisted versus open MIP: lower pain intensity during 24 hours postoperatively ($p < 0.001$), lower analgesia request rate ($p < 0.001$), lower analgesics consumption ($p < 0.001$), higher recurrent laryngeal nerve identification rate ($p < 0.001$), shorter scar length ($p < 0.001$), and better cosmetic satisfaction at 1 month ($p = 0.013$) and at 6 months ($p = 0.024$) after surgery. However, the video-assisted procedures had longer duration of surgery ($p < 0.001$), and were more expensive ($p < 0.001$) than the open technique. There were no differences noted in the conversion rate, length of hospital stay, and morbidity (including recurrent laryngeal nerve injury; 3/151 in the video-assisted group and 8/304 in the open group).

Robotic-assisted transaxillary parathyroidectomy using the da Vinci Si surgical system (Intuitive Surgical, Sunnyvale, CA) has been described recently in several case reports and small series, as well as robotic-assisted retroauricular parathyroidectomy. Overall, the data with robotic transaxillary parathyroidectomy in the literature are very limited. The robotic approach is more technically demanding than open or video-assisted MIP and will likely add unnecessary expense. A few series report that this procedure can be performed by surgeons experienced in robotic and conventional surgery safely, but with longer operating times compared to conventional approaches (Okoh AK, Sound S, Berber E. Robotic parathyroidectomy. *J Surg Onc* 2015;112:240–42). The candidates for this procedure are patients with a diagnosis of primary hyperparathyroidism and a single gland localized on ultrasound and/or sestamibi scan. Similar to robotic thyroidectomy, candidates should be thin (BMI <30) with an axillary to sternal notch distance of <17 cm, in order to facilitate transaxillary access. Absolute contraindications include previous neck

surgery, significant thyroiditis, or bulky thyroid disease. Based on the limited experience with this technique, more analysis is needed before the robotic approach can be widely applied.

There are some special considerations for the application of MIP. First is the reoperative neck. In these situations, MIP is not contraindicated as long as there is clearly identified single adenoma. These procedures are best performed under general anesthesia as the difficulty of the planned dissection and hence the time of the procedure is hard to predict. Although head and neck irradiation should not be considered a contraindication for MIP with single gland hyperparathyroidism, the surgeon should beware of the routine application in these inpatients. Wilson and colleagues (Wilson SD, Doffek KM, Wang TS, et al. Primary hyperparathyroidism with a history of head and neck irradiation: the consequences of associated thyroid tumors. *Surgery* 2011;150:869–77) found in 49 patients with hyperparathyroidism with previous head and neck irradiation that patients presenting for parathyroidectomy had marked increase in nodular thyroid disease: nearly one in two had concurrent thyroidectomy, and nearly one in four had thyroid carcinoma. High-resolution ultrasound prior to parathyroidectomy detects associated thyroid pathology and allows the surgeon to plan the extent of thyroid resection. MIP is likely not be appropriate if there is associated thyroid pathology.

E. Christopher Ellison

42 Secondary and Tertiary Hyperparathyroidism

Richard A. Prinz, Kaare J. Weber, and Shalini Arora

Secondary hyperparathyroidism is a physiologic attempt to maintain calcium homeostasis when calcium absorption is diminished. Its causes are varied and are related to gastrointestinal, genetic, vitamin D, and renal deficiencies (Table 42.1). Secondary hyperparathyroidism develops in nearly all patients with chronic renal failure undergoing long-term dialysis. These are the patients who may require surgery for secondary hyperparathyroidism. This discussion will focus on the etiology, diagnosis, and management of renal hyperparathyroidism. Even with the improvements that have been made in the medical management of chronic renal failure as many as 10% to 15% of patients with this problem may eventually require parathyroidectomy.

ETIOLOGY

Parathyroid hormone (PTH) and the active form of vitamin D (1,25-dihydroxy D_3) are the chief regulators of calcium metabolism. Their main target organs are the bones, intestines, and kidneys. As renal function decreases as reflected by a declining glomerular filtration rate, circulating levels of active vitamin D_3 decrease because of diminished hydroxylation by the kidney of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. The resulting decreased intestinal absorption of calcium leads to a relative hypocalcemia. The calcium-sensing receptor which is highly expressed in parathyroid cells detects the change in calcium and causes a compensatory secretion of PTH to raise circulating calcium levels. Concurrently, hyperphosphatemia occurs due to impaired renal phosphate excretion. Both hypocalcemia and hyperphosphatemia stimulate the parathyroid glands to secrete PTH. Persistent stimulation leads to hyperplasia of all parathyroid glands in a compensatory attempt to raise serum calcium levels by increasing PTH levels. Continued stimulation results in polyclonal cell proliferation and enlargement of the parathyroid glands. As

the parathyroid glands enlarge, the parathyroid cells show a decreased expression of the vitamin D and calcium-sensing receptors. This causes resistance to medical treatment with vitamin D analogs and calcimimetics. With prolonged stimulation, the parathyroid glands may develop autonomous production of PTH which can persist even after the physiologic stimulus has been removed. This autonomous condition is termed tertiary hyperparathyroidism. Like primary hyperparathyroidism symptomatic tertiary hyperparathyroidism is treated with parathyroidectomy. A successful renal transplant should reverse the pathophysiologic effects of chronic renal failure on calcium metabolism so the parathyroid glands and PTH secretions should return to normal. However, if the parathyroid glands have become autonomous, a return to normal calcium metabolism does not occur. The incidence of this type of tertiary hyperparathyroidism that persists after renal transplantation and requires parathyroidectomy ranges from 0.5% to 5.6%.

TABLE 42.1 Differential Diagnosis of Secondary Hyperparathyroidism

Gastrointestinal/ Malabsorption	Gastric bypass
	Cystic fibrosis
	Pancreatic disease
	Calcium deficiency
	Liver/biliary disease
Kidney related	Chronic kidney disease
Vitamin D deficiency	Lack of sunlight exposure
	Inadequate dietary intake
Genetic	Pseudohypopara-thyroidism

CLINICAL MANIFESTATIONS

Secondary hyperparathyroidism can lead to a spectrum of bone disease referred to as renal osteodystrophy. The most common finding that patients with chronic kidney disease will have is low bone mineral mass. This increases the risk of fractures which are associated with substantial morbidity and even mortality. Patients can also present with generalized

weakness, myopathy, and bone pain. The extreme clinical manifestation of renal osteodystrophy is termed leontiasis ossea. The hyperostotic changes in the facial bones cause an expansion of the malar processes, a reduced nasomaxillary angle, widening of the nares, flattening of the nasal bridge and an increase of the interdental spaces. This gives the patient's face a characteristic lion-like appearance.

Uremic pruritus can have a major effect on quality of life and be quite debilitating. Its etiology is multifactorial. Secondary changes in calcium phosphate metabolism can lead to extra osseous calcium deposition in the dermis and sub-dermal tissue. Other factors include increased circulating PTH levels, anemia, and elevated aluminum levels. A high calcium phosphate product can also cause extraosseous calcification of the joints, soft tissue, and viscera that may cause pain and functional impairment.

Renal hyperparathyroidism is associated with an increase in cardiovascular morbidity and mortality. Hypertension, cardiomyopathy and hypertrophy, insulin resistance, and calcium phosphate deposition in small and large vessel walls all contribute to this accelerated development of cardiovascular complications.

Calciphylaxis is a rare but life-threatening complication of secondary hyperparathyroidism. Excessive calcium in the microvasculature causes ischemia and ulceration in atypical areas of the body. The ulcers can be quite painful and difficult to treat. Debridement and local wound care alone are often insufficient. When these wounds become secondarily infected the risk of sepsis and death are high.

Tertiary hyperparathyroidism is described as persistent hyperparathyroidism with hypercalcemia despite reversal of secondary hyperparathyroidism from chronic renal failure with kidney transplantation. The average time for PTH levels to return to normal after renal transplantation is 3 to 6 months but can continue for over a year. Most patients with tertiary hyperparathyroidism are asymptomatic. Symptoms of tertiary hyperparathyroidism are similar to those of primary hyperparathyroidism and include osteoporosis, nephrolithiasis, fatigue, and neuropsychiatric complaints. High calcium may also cause deterioration of graft function.

MEDICAL MANAGEMENT

In the United States, total Medicare expenditures for end-stage renal disease (ESRD) reached $34.3 billion in 2011 accounting for 6.3% of the

Medicare budget. About 1.4% of Medicare patients had ESRD in 2011. This accounted for 7.2% of Medicare spending. Medicare costs for ESRD were "$75,670 per patient per year."

The goal of medical treatment of secondary hyperparathyroidism is to inhibit excess parathyroid secretion by correcting vitamin D deficiency, hypocalcemia, and hyperphosphatemia. Calcium and vitamin D supplements, phosphate binders and dietary restrictions, and a calcimimetic are all used usually in combination. Calcimimetics limit the effect of extracellular calcium on the parathyroid glands. By occupying the calcium-sensing receptor on the parathyroid cells, they downregulate PTH release. Cinacalcet improves blood levels of PTH, calcium, and phosphorous. It has reduced the frequency of parathyroidectomy in ESRD patients from 5% to 1% per year. However, it has not improved overall cardiovascular mortality in secondary hyperparathyroidism. Cinacalcet increases the risk of nausea, vomiting, and hypocalcemia and patients may require more frequent testing of blood calcium levels. With calcimimetics there is a progressive decrease in the calcium-sensing receptors and vitamin D receptors which results in treatment resistance.

Tertiary hyperparathyroidism is characterized by the inappropriate autonomous hypersecretion of PTH. As such it does not respond to the treatments for secondary hyperparathyroidism. Calcimimetics are not approved for long-term treatment of tertiary hyperparathyroidism. Parathyroidectomy is the only proven treatment option for tertiary hyperparathyroidism.

INDICATIONS FOR SURGERY

Guidelines have been developed to improve the clinical outcomes for dialysis patients with metabolic bone disease from secondary hyperparathyroidism. The Kidney Disease Improving Global Outcomes (KDIGO) group proposed revised practice guidelines in 2009 which defined target ranges for serum calcium, phosphorous, and PTH levels. Calcium and phosphorous levels should be maintained within their normal ranges and PTH levels should be maintained within two to nine times the upper limit of the assay. When these targets are not obtained with maximal medical therapy, parathyroidectomy is recommended. Parathyroidectomy is generally advised when serum levels of PTH are greater than 800 pg/mL in association with hypercalcemia or hyperphosphatemia. A calcium × phosphate product of 55 or greater also implies failed medical treatment

and carries a risk of extraosseous precipitation of calcium salts. When the calcium and phosphate product exceeds 55, despite appropriate medical management, parathyroidectomy is indicated.

Parathyroidectomy is also indicated to relieve patient symptoms. These include bone and joint pain, muscle pain and weakness, intractable pruritus, progressive bone mineral loss, extra skeletal calcifications, and tissue loss from vascular calcifications.

There is controversy concerning the treatment of calciphylaxis. Because mortality rates can be as high as 90% once secondary infection of the ulcers and sepsis occurs, calciphylaxis seems best managed by parathyroidectomy which will promptly control the secondary hyperparathyroidism. After the biochemical abnormalities are reversed, the ischemic tissue and ulcerations are then managed with local wound care and systemic antibiotics as needed. Medical management with bisphosphonate therapy or sodium thiosulfate, a calcium chelator, has also been used to reverse arterial calcification in calciphylaxis. Hyperbaric oxygen has been used with some reported success in healing the ulcerations.

After successful renal transplantation, up to 5% of patients may ultimately need parathyroidectomy for tertiary hyperparathyroidism. The indications for parathyroidectomy in tertiary hyperparathyroidism include persistently elevated serum calcium, symptomatic hypercalcemia, increasing PTH levels, hypophosphatemia, decrease in bone mineral density, or a decline in kidney function associated with hyperparathyroidism. Generally parathyroidectomy is delayed for a year after the transplant. However, surgery can be performed as early as 3 months because most patients should recover or be moving toward normal parathyroid function by that time.

PREOPERATIVE IMAGING

Preoperative imaging has not been a standard recommendation for secondary and tertiary hyperparathyroidism. Unlike primary hyperparathyroidism, these diseases are usually not due to a single adenoma. Since all the glands have been affected by the adverse changes in calcium metabolism a bilateral neck exploration to identify all the abnormal glands is required. Routine imaging with SPECT 99mTc-sestamibi and cervical ultrasound identifies some but not all the abnormal glands in these patients with hyperplasia. Even though up to 10% of

patients with renal hyperparathyroidism can have supernumerary glands and up to 40% can have ectopic glands, most of these can be found and removed with a thorough cervical exploration including a thymectomy. We do recommend preoperative ultrasound to identify any associated thyroid pathology in these patients. Nodular thyroid disease is present in at least 10% to 20% of all patients with secondary hyperparathyroidism. The presence of thyroid pathology should be evaluated preoperatively using clinical parameters, ultrasound, and ultrasound-guided fine needle aspiration biopsy to determine if an associated thyroidectomy is necessary at the time of the parathyroidectomy.

For patients with persistent or recurrent secondary hyperparathyroidism preoperative localization studies are essential. At least two imaging studies should confirm and pinpoint the location of the missing gland or glands before undertaking a second operation. We start the localization process with ultrasound which is the least invasive and least expensive study. Ultrasound-guided fine needle aspiration biopsy for cytology and/or measurement of PTH can be done for conclusive identification of parathyroid tissue. We usually reserve this if the other noninvasive studies are not confirmatory. SPECT 99mTc-sestamibi scanning can provide both a functional and anatomic localization of an enlarged parathyroid gland. It is useful for identifying ectopic glands especially those in the chest and mediastinum. MRI and 4D CT scanning can also be helpful in localizing ectopic glands in the thorax. Selective venous sampling is rarely necessary for localization.

SURGICAL APPROACHES

There are three surgical procedures that are utilized for patients with secondary hyperparathyroidism who require parathyroidectomy. These include subtotal parathyroidectomy with 3½ gland removal, total parathyroidectomy with autotransplantation, and total parathyroidectomy alone. Surgical thymectomy should be included with all three approaches because of the high likelihood of ectopic and supernumerary glands in the thymus. Likewise, cryopreservation of parathyroid tissue should be considered with all three operations in case the remnant or transplant do not function or the patient develops difficulty to control hypoparathyroidism after total parathyroidectomy. All three techniques have achieved good and comparable results. There are no randomized prospective trials comparing the three approaches. Surgeons treating these

patients usually favor one method based on their experience and training. It is important to remember that parathyroidectomy does not cure secondary hyperparathyroidism. It is a temporizing procedure intended to control the pathophysiologic response that chronic renal failure has induced in the patient's calcium metabolism. Only a functioning kidney transplant can bring about normal calcium metabolism and parathyroid function.

Each operation utilizes a Kocher incision placed in a natural skin line in the mid to lower neck to achieve an optimal cosmetic result. A meticulous technique is needed to identify all the parathyroid glands and to avoid injury to the recurrent laryngeal nerves. Nerve monitoring should be considered but there is no proof that it decreases the rate of recurrent nerve injury with these operations. If all four glands are not identified the surgeon should perform a complete neck exploration guided by the knowledge of the embryologic development of the parathyroid glands. The carotid sheath should be opened, intrathyroid lesions can be evaluated with ultrasound, and the retroesophageal areas should be explored. A cervical thymectomy should be done even if all four glands have been found. The surgeon should do everything to ensure that no parathyroid tissue remains in the neck after their exploration except for the remnant if they are doing a 3½ gland subtotal parathyroidectomy. Care should be taken to avoid rupturing the capsule of the individual parathyroid glands when removing them. This can cause shedding of cells which can seed into the surrounding tissue. The implantation of parathyroid cells with resulting parathyromatosis is very difficult to treat. The surgeon should not rely on visual inspection alone to identify the parathyroid glands but should obtain frozen section confirmation by taking a small incisional biopsy from each. This is especially true for the gland that will serve as the remnant in a 3½ gland parathyroidectomy or will be transplanted or cryopreserved in the other procedures. All four parathyroid glands should first be identified before removing any.

The most normal appearing gland should be used as the remnant for a subtotal parathyroidectomy. A 30- to 50-mg well-vascularized portion of the gland should be left in place. There is a tendency to leave too much tissue for fear of hypoparathyroidism. The surgeon should remember that the operation does not reverse the pathophysiologic effects of renal failure and its continued stimulation, so hyperplasia of the remnant parathyroid tissue is likely over time. The remnant should be fashioned first before any

of the other parathyroid glands are removed. If the initial remnant does not look viable, another gland can then be used. The remnant is marked with a metallic clip or nonabsorbable suture in order to help locate it if a subsequent reexploration would ever be required. Another factor to consider when choosing which gland will be the remnant is the ease of subsequent removal if persistent or recurrent hyperparathyroidism develops. In other words the risk of injury to the recurrent laryngeal nerve or other structures at potential reexplorations should be considered. If too large a remnant or supernumerary glands are left in the neck, persistent or recurrent disease would necessitate a reoperation in a neck. During any future exploration, the surgeon will have to deal with the extensive scarring that potentially increases the morbidity especially for recurrent laryngeal nerve injury. We do use nerve monitoring when doing these reexplorations.

To minimize the chance of reoperative neck surgery, a total parathyroidectomy, transcervical thymectomy, and autotransplantation of normal parathyroid tissue is favored by some surgeons. Again the surgeon should select the most normal appearing parathyroid gland for autotransplantation. A biopsy should be taken for frozen section confirmation before any tissue is transplanted or cryopreserved. Preparation of the tissue and the site of the implant vary among surgeons. We mince a 30- to 50-mg piece of the chosen parathyroid gland with a fine scissors and place the resulting slurry in a pocket in the brachioradialis muscle. When possible the nondominant forearm is chosen especially if it does not contain the dialysis access site. A small skin incision is made and the muscle fascia is opened. The muscle fibers are gently spread apart being careful to avoid bleeding and hematoma formation which can jeopardize the viability of the transplant. The graft is placed in this pocket and the overlying fascia is closed with two metallic clips which also identify the site of the graft if reexcision of it is needed in the future. The advantage of this approach is that no parathyroid tissue should remain in the neck. If recurrence does occur, PTH levels can be sampled from both antecubital fossae. If the graft is the source of the persistent or recurrent disease there will be a marked gradient with very high levels above the transplant site. If there is no meaningful gradient, the graft is not the source of the recurrence so localization studies are needed to determine whether a supernumerary or ectopic gland is present in the neck or the chest. Other areas that have been used for placing the graft include the

subcutaneous and muscle tissue in the neck and in the upper chest. Some surgeons also place 1-mm pieces in individual pockets so that they can remove the individual pieces if recurrence occurs.

Total parathyroidectomy and cervical thymectomy alone without autotransplantation is advocated by some surgeons. Most patients who are managed this way do not seem to be hypoparathyroid. It is the exceptional patient who does develop difficult to manage hypoparathyroidism. Because there is concern about this possibility most surgeons favor leaving some parathyroid tissue either as a remnant in the neck or as a transplant elsewhere.

Permanent hypoparathyroidism occurs in up to 10% of all patients who have parathyroidectomy for renal hyperparathyroidism regardless of which of the three methods is used. Therefore, cryopreservation of parathyroid tissue, which can be done by the blood bank at most hospitals, is recommended with all three approaches. Success rates for autotransplantation at the initial operation with fresh parathyroid tissue exceed 90%, but only 50% to 60% of patients who receive cryopreserved tissue will have adequate parathyroid function.

The development of persistent or recurrent disease requires a thorough evaluation of the patient to determine if a reoperation is necessary. Localization of the abnormal gland is essential before considering reoperation. Imaging using ultrasound, parathyroid scanning, MRI, and 4D CT scanning is used as needed. Venous sampling is rarely necessary but can be helpful in select patients. At least two imaging studies should confirm the same exact location of the missing gland. If the gland is in the neck, a focused approach should be done to avoid unnecessary dissection that risks morbidity. If the gland has been located in the chest or mediastinum, it can be removed with a minimally invasive thoracoscopic approach. Intraoperative PTH monitoring is useful to limit and stop the dissection when performing these reoperations.

A subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to the forearm has been the traditional surgical approach for tertiary hyperparathyroidism. Since normal calcium metabolism has been restored by the normalization of renal function with the kidney transplant, it is desirable that the patient have functioning parathyroid tissue. Consequently total parathyroidectomy is not recommended in this situation. Again, parathyroid tissue should be cryopreserved in case postoperative hypoparathyroidism develops.

Because one third or more of patients with tertiary hyperparathyroidism have been reported to have a single or double adenoma as the cause of their disease, some surgeons are utilizing a minimally invasive focused approach. To avoid increased recurrence rates with the focused approach, intraoperative PTH monitoring should be used to guide the extent of resection for tertiary hyperparathyroidism. This technique has led to success rates that seem to be equivalent to the traditional four-gland exploration.

INTRAOPERATIVE PARATHYROID HORMONE MONITORING

PTH has a serum half-life of 2 to 4 minutes. Measurement of intraoperative PTH levels in primary hyperparathyroidism is routinely used to determine the complete removal of abnormal parathyroid glands. In primary hyperparathyroidism, a drop of the intraoperative PTH level of greater than 50% and to within normal limits 5 to 15 minutes after excision is indicative of a cure in greater than 95% to 98% of patients. This criteria for intraoperative PTH monitoring is well accepted for primary hyperparathyroidism.

The interpretation of intraoperative PTH monitoring in secondary hyperparathyroidism is complicated by the altered clearance of PTH breakdown products in renal failure patients. PTH is a single chain polypeptide consisting of 84 amino acids. The intact PTH assay measures both the 1 through 84 PTH and large C-terminal degradation products which are cleared by the kidneys. These products have a half-life that is five to ten times longer than that of the 1 to 84 PTH and may interfere with the assay interpretation. Newer bioactive assays measure only the active PTH and not the inactive C-terminal fragments and seem to be more specific in patients with renal failure.

The criteria to interpret intraoperative PTH levels in secondary hyperparathyroidism are not as clear cut as in primary hyperparathyroidism. We have reported a drop of 90% from baseline or return to normal level as an indication of a successful operation with removal of all parathyroid glands. Nephrologists prefer an absolute drop of a postoperative PTH level to 200 pg/mL or less postoperatively. Some surgeons have suggested that thymectomy may not be needed if the intraoperative PTH levels indicate an adequate resection before this is done. Again the assay can be quite helpful in guiding the extent and

success of parathyroidectomy in reoperations for secondary hyperparathyroidism and in primary operations for tertiary hyperparathyroidism.

Preoperative management of these patients requires a multidisciplinary approach. Patients should undergo dialysis the day prior to or on the day of the operation. There is a risk of intraoperative hyperkalemia especially in males who are younger than 40 years of age. The anesthesiologist should be aware of the potential complications of hyperkalemia. The PTH level should drop markedly with a successful operation with a resulting profound decrease in serum calcium postoperatively. Hypocalcemia is the intended effect of the procedure and should not be considered a complication. Both the surgeon and the nephrologist must be prepared to deal with possible life-threatening hypocalcemia. Patients can require up to 18 g or even 20 g of intravenous calcium in a 24-hour period. An intravenous calcium drip may be required in order to maintain serum calcium at a safe level in patients with severe bone hunger. Calcium must be given according to the patient's needs. Postoperative supplementation should include large amounts of oral calcium as well as the active form of vitamin D, calcitriol, since the lack of kidney function will not convert the 25-hydroxy vitamin D to its active form. Calcitriol is essential for maximizing intestinal calcium absorption. These patients should be dialyzed with a high calcium bath to prevent symptomatic hypocalcemia and maintain their serum calcium levels.

Platelet dysfunction in renal failure patients as well as the need for heparin during dialysis postoperatively raises the concern for hematoma formation. The patient should be monitored closely for any swelling in their neck during the postoperative period. Life-threatening hypocalcemia and airway compromise must be identified early to avert disaster. Patients will require hospitalization until they can maintain their serum calcium at a safe level for 24 hours with only oral calcium and vitamin D.

Patients who have had aluminum-containing phosphate binders may develop high circulating aluminum levels. Aluminum toxicity is associated with reduced symptom improvement in patients having parathyroidectomy for secondary hyperparathyroidism. The surgeon and nephrologist caring for these patients must be aware that serum aluminum levels should be kept lower than 20 μg/L.

EDITOR'S COMMENT

Dr. Prinz and colleagues have written an excellent chapter describing an increasingly prevalent disease complex. According to the National Kidney Foundation, Chronic Kidney Disease affects 14.5% of the US population. Biochemical abnormalities including chronic kidney disease, mineral and bone disorder, and renal osteodystrophy are common in patients with advanced kidney disease. It was estimated in 2007 that between 2 and 4.7 million people with chronic kidney disease had elevated parathyroid hormone (PTH) levels and were candidates for treatment. It was further estimated that these treatments would cost up to $122 billion dollars per year. Although secondary hyperparathyroidism is a frequent complication of chronic kidney disease (some would state that this condition eventually develops in all dialysis patients), it remains underrecognized and undertreated in early kidney disease. The prevalence of secondary hyperparathyroidism increases rapidly with decreasing glomerular filtration rate. When detected in an advanced stage, secondary hyperparathyroidism is more resistant to dietary and medical therapy, and may persist following kidney transplantation (tertiary hyperparathyroidism).

The distinction between primary (autogenous secretion of PTH, most often by a parathyroid adenoma) and secondary hyperparathyroidism is important as these conditions are treated differently. As it turns out, primary and secondary hyperparathyroidism can be confused in certain circumstances. A parathyroid tumor can contribute to kidney damage. Chronically elevated calcium levels from primary hyperparathyroidism can lead to nephrocalcinosis and kidney failure. It is important to remember that early stage kidney disease (Stage III or less) is highly unlikely to lead to secondary hyperparathyroidism. Patients with secondary hyperparathyroidism are typically on dialysis or have had kidney

failure for years. Their calcium level is low normal or low. A patient with kidney disease not on dialysis, high PTH levels, and a high calcium level has primary hyperparathyroidism and needs resection of the parathyroid lesion.

Historically, approximately 5% of patients with secondary hyperparathyroidism undergo parathyroidectomy. With advances in medical management, this rate has steadily declined. As discussed in this chapter, medical treatments such as intravenous vitamin D analogues and cinacalcet has led to the steady decline in parathyroidectomy for secondary hyperparathyroidism over the past 10 years. A recent study conducted using data from the international Dialysis Outcomes and Practice Patterns Study (DOPPS) examined trends in PTH levels and secondary hyperparathyroidism therapies over the past 15 years. The association between PTH levels and clinical outcomes were reported in more than 35,000 patients on dialysis. The median PTH levels increased over time, the number of prescriptions for Vitamin D analogues and cinacalcet increased, and parathyroidectomy rates declined over time. Compared to PTH levels of 150 to 300 pg/mL, in adjusted models all-cause mortality risk was higher for patients with PTH levels between 301 and 450 (hazard ratio, 1.09; 95% confidence interval, 1.01 to 1.18) and 600 pg/mL (hazard ratio, 1.23; 95% confidence interval, 1.12 to 1.34). PTH levels over 600 pg/mL were also associated with higher risk of cardiovascular mortality as well as all-cause and cardiovascular hospitalizations. The authors of this study concluded, “In the absence of definitive evidence in support of a specific PTH target, there is an urgent need for additional research to inform clinical practice.” In the current day, parathyroidectomy rates for secondary hyperparathyroidism remain at around 1% to 2%. One of the factors that prevent a more routine approach to parathyroid resection for secondary hyperparathyroidism is the fact that mortality rates following surgery are between 1% and 3%. The single most preventable cause of death in the first 30 days following parathyroid resection is hyperkalemia. Acute hypocalcemia, cardiac complications, and respiratory complications can also lead to early postoperative mortality. Based on my reading, this remains a controversial topic with regards to secondary hyperparathyroidism. A very nice review on this topic published in Langenbeck’s Archives of Surgery concludes “*Specialized endocrine surgery offers efficient metabolic correction of renal hyperparathyroidism with very low surgical morbidity. The summarized data reveals that infrequently surgical treatment remains the last choice, a negative selection of severely comorbid patients with advanced intractable cardiovascular manifestation and calciphylaxis are offered surgery too late to benefit. From the surgical perspective, earlier cooperation between nephrologists and endocrine surgeon in the management of renal hyperparathyroidism is desirable and cooperative studies without industrial influence are needed to establish interdisciplinary consented guidelines for the role of surgery in renal hyperparathyroidism.*”

Tertiary hyperparathyroidism is an interesting disease. A kidney transplant

often cures secondary hyperparathyroidism. Only about 0.6% to 5.6% of patients to undergo a kidney transplant eventually require a parathyroidectomy for tertiary hyperparathyroidism. As I review the surgical literature on this topic, there appears to be a prevailing opinion that the actual rate of parathyroidectomy in this patient population should perhaps be higher. The rate of tertiary hyperparathyroidism necessitating surgery is directly related to how long a patient is on dialysis prior to receiving a kidney transplant. I completed my residency at a program with a very high volume of kidney transplants and in the era prior to the introduction of calcimimetics in this population. A review from this institution revealed 618 kidney transplant recipients over an 8-year period with tertiary hyperparathyroidism. Only 41 (6.6%) underwent parathyroidectomy. Patients with higher levels of serum calcium and PTH posttransplant were more likely to be referred for parathyroid resection. Importantly, those who underwent parathyroidectomy had serum calcium and PTH values distributed more closely to the normal range. After transplantation, poor follow-up of parathyroid function is common because normalization of parathyroid function is expected and there are other medical management issues in the first year after transplant that take precedence. Given the fact that persistent hyperparathyroidism in a posttransplant patient can be associated with significant morbidity and even allograft dysfunction, this is a topic that requires further investigation in the opinion of several authors.

Calciphylaxis is a devastating condition that can develop in patients with secondary and tertiary hyperparathyroidism. Between 1% and 4% of patients on chronic hemodialysis or peritoneal dialysis develop calciphylaxis. Calciphylaxis involves cutaneous gangrene and extremely painful skin ulcerations. I do not routinely care for patients with hyperparathyroidism, but I can vividly recall a patient with calciphylaxis I cared for in the burn unit when I was a resident. I am not sure I have ever seen a patient quite as miserable and uncomfortable as this patient. Besides renal hyperparathyroidism, obesity, systemic corticosteroids, and vitamin K antagonists have been identified as predisposing risk factors for calciphylaxis.

The rising prevalence of kidney disease, kidney transplants, and now calcimimetics has led to dramatic changes in the field of surgery for secondary and tertiary hyperparathyroidism in the past 10 years. This is a very interesting, detailed, and well-written chapter by some of the world’s experts on the topic. This chapter is a “must read” for surgical residents, general surgeons who perform parathyroidectomy, nephrologists, endocrinologists, and even endocrine surgeons.

43 Transsternal, Transcervical, and Minimally Invasive Thymectomy for Benign and Malignant Disease

Daniel P. McCarthy and Malcolm M. DeCamp

Thymectomy is one of the most common mediastinal procedures performed by thoracic surgeons. Myasthenia gravis (MG), an autoimmune disease characterized by weakness and fatigability following repetitive exercise, is the most common indication for thymectomy. Regardless of the etiology, malignant, benign, or autoimmune, complete resection of all thymic tissue is the key to state-of-the-art thymectomy. Thymectomy can be performed via a variety of operative approaches. The purpose of this chapter is to analyze the pathophysiology of thymic diseases, the indications for surgery in their treatment, and the available techniques of resection to achieve acceptable and durable outcomes.

HISTORY OF SURGERY OF THE THYMUS GLAND

The word *thymus* originates from the Greek word *thymos*, which has dual meaning. Although it is synonymous with heroic character and is associated with soul, spirit, courage, power, will, heart, and anger, it is also related to the herb thyme and to the thyme flower. Rufus (98 to 117 CE), who lived in Ephesus, a center of learning on the western shore of modern-day Turkey, is acknowledged as the first person to refer to the thymus gland in humans.

The thymus gland gained clinical importance once it was linked by the Swiss physician Platter in 1614 to the sudden death of a 5-month-old boy from suffocation. An autopsy was performed at the request of the father as two other sons had died similarly. This revealed a highly vascular mass compressing the mediastinal structures. This condition was subsequently called “mors thymica or thymic death.” More than two centuries later, Sir Astley Cooper in 1832 described the death of a 19-year-old woman from a malignant thymic tumor invading the major veins of the superior mediastinum and compressing the trachea.

The finding of thymic tumors in autopsies in 1889 by Oppenheim and in 1901 by Weigert first suggested an interrelation between the thymus and MG. Contemporaneous invention of X-rays by Wilhelm Roentgen in 1895 allowed diagnostic imaging of enlarged mediastinal structures. The first thymectomy for MG was performed in 1911 by Ernst Ferdinand Sauerbruch from Zurich. He used a radiogram to diagnose thymic enlargement, associated it with the patient's MG symptoms, and performed a successful transcervical thymectomy on a 19-year-old woman.

In 1936, Alfred Blalock became the first person to perform a transsternal thymectomy in a 19-year-old woman with persistent, severe MG and an anterior–superior mediastinal tumor that had only partially responded to three courses of radiotherapy. Beginning with this case, and encouraged by the neurologist Ford, Blalock also demonstrated the relation between MG and nonthymomatous thymus glands.

Sir Geoffrey Keynes followed Blalock in 1942 when he performed a thymectomy and completion thyroidectomy on one of his previous patients with severe MG and recurrent thyrotoxicosis 12 years after removal of a goiter. The subsequent smooth postoperative period encouraged Keynes, who reported a series of 281 thymectomies by 1956. His contributions to the evolution of thymectomy included the separate evaluation of the operative results of patients with thymomatous and nonthymomatous glands, and the precise documentation of surgical thymic anatomy.

The transsternal approach remained the "gold standard" for thymectomy until the early 1960s. After Carlens described mediastinoscopy in 1959, Crile in 1964 and Akakura in 1965 reported their experience with 24 cases of transcervical thymectomy. In addition to MG, the indications for thymectomy were extended to resection of thymic cysts or suppression of rejection in renal transplant recipients. In 1969, Kirschner reported on 21 cases with only 1 death, and suggested that transcervical thymectomy be adopted as the preferred approach to resection, exclusive of thymomas.

Other clinicians remained skeptical regarding completeness of transcervical thymectomy. Reported clinical failures following cervical excisions, in some cases necessitating a reresection, fueled the ongoing debate of the optimal approach to thymectomy for MG. These discussions became more complicated after the reports of Masaoka et al. in 1975 and Jaretzki in 1988 demonstrating the presence of extra glandular thymic

tissue in 74% of the cases. Investigators at the University of Pennsylvania have reported comparable results with transcervical thymectomy to transsternal thymectomy after using a specially designed sternal retractor that allowed extended dissection through the limited cervical incision. With this report, the scale again tipped in favor of less-invasive surgery in the debate of thymectomy for MG. The controversy continues with increased vigor in the modern era, as thoracoscopic and robotic approaches add to the available minimally invasive options for treating nonthymomatous disease.

ETIOLOGY AND PATHOPHYSIOLOGY

Embryology

The thymus gland, together with the inferior parathyroid glands, arises from the third pair of pharyngeal pouches (Fig. 43.1). Although the fourth pharyngeal pouches also give rise to a small amount of thymic tissue, these are usually vestigial masses and these latter primordia in humans are usually either absent or rudimentary. In the 6th week of gestation, epithelium of the third pouch proliferates to form a dorsal bulbar component, later becoming the inferior parathyroid gland, and an elongated ventral portion, which is destined to become a thymic lobe. The entire third pouch separates from the pharynx during the 7th week. These thymic primordia migrate in a caudal and medial direction. Originally hollow, thymic primordia rapidly become solid epithelial bars, and during the 8th week, the caudal ends of the paired components of the thymus fuse together to form what is generally a four-lobed gland that attaches to the anterior pericardium. The organ, then being attached to the growing pericardium, descends into the mediastinum behind the sternum and anterior to the great vessels. Incomplete migration may potentially leave islands of thymus anywhere along the course of the primordia. The lower capsule tends to be less distinct, and thymic corpuscles, as well as abundant lymphocytes, trail off into the surrounding mediastinal fat and nodal tissue. Because of either premature arrest of migration or deviation from its natural tract, the thymus gland itself may be found anywhere between the hyoid bone cranially and the xiphoid process of sternum caudally.

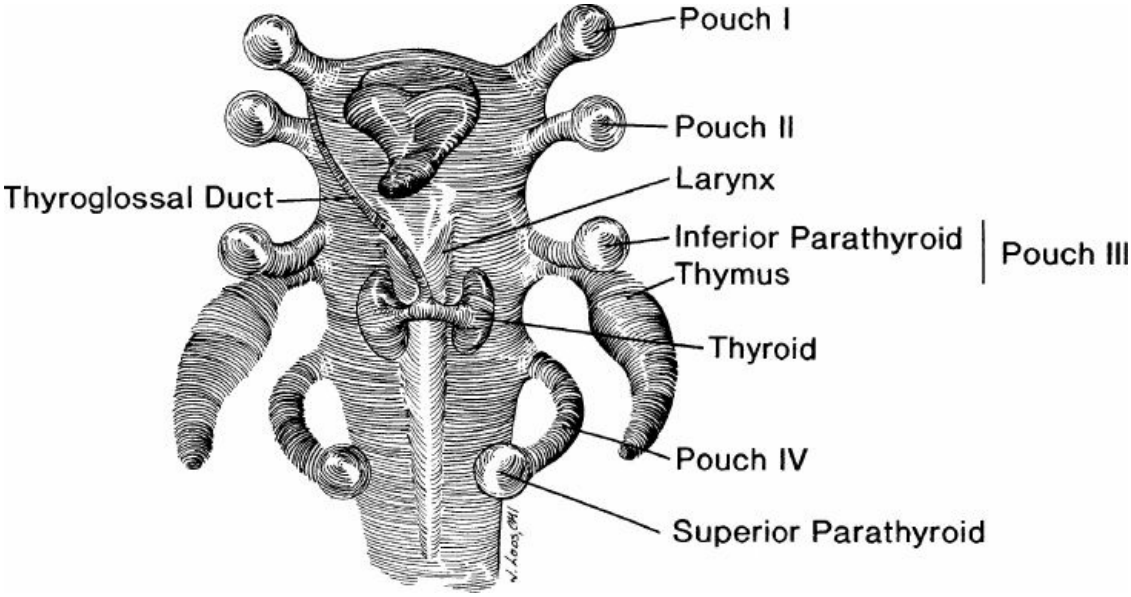

Figure 43.1. Embryologic development of the thymus and parathyroid glands from the third and fourth pharyngeal pouches.

Embryologic Development

Although the thyroid, parathyroid, and thymus glands arise from the pouches of the same primordial pharynx, they separate in later stages of embryonic life. As the thymus descends caudally, the parathyroid glands normally remain settled at the same level with and posterior to the lower poles of thyroid. The parathyroid glands are also called *parathymic* glands. In autopsy studies, as many as 20% of inferior parathyroid glands are found within the thymic capsule in the neck or in the mediastinum. Although more common for parathyroid tissue, thyroid tissue may also be present within the thymus gland.

Anatomy

In the newborn, the thymus weighs 10 to 12 g and continues to grow until puberty. Steinmann reported an average weight of 27.3 g with a standard deviation of 16.4 g within the 1st year of life. At puberty, the gland reaches its maximum weight of 20 to 50 g. Thereafter, it enters a gradual involution state, decreasing in mass to only 5 to 15 g in the elderly. At this time, the parenchyma is mostly replaced by fibro fatty tissue.

The thymus is a bilobed glandular structure; however, its two lobes are rarely symmetrical. The thymus is located predominantly in the anterior–superior mediastinum, where it anteriorly covers the great vessels, pericardium, and the base of the heart. It is also in close proximity with the

anterior surface of the innominate vein as it runs obliquely across the superior mediastinum to join the right brachiocephalic vein to form the superior vena cava (SVC; Fig. 43.2). The thymus may sometimes lie adjacent to either SVC on the right or the pulmonary artery on the left. One or both lobes may also lie behind the left innominate vein instead of in front of it. The two thymic lobes are fused in the midline, giving the gland its H-shaped configuration. The upper poles of each lobe reach into the neck where they join the thyroid gland by the thyrothymic ligaments on both sides. The lower poles lie on the pericardium anterior to the heart.

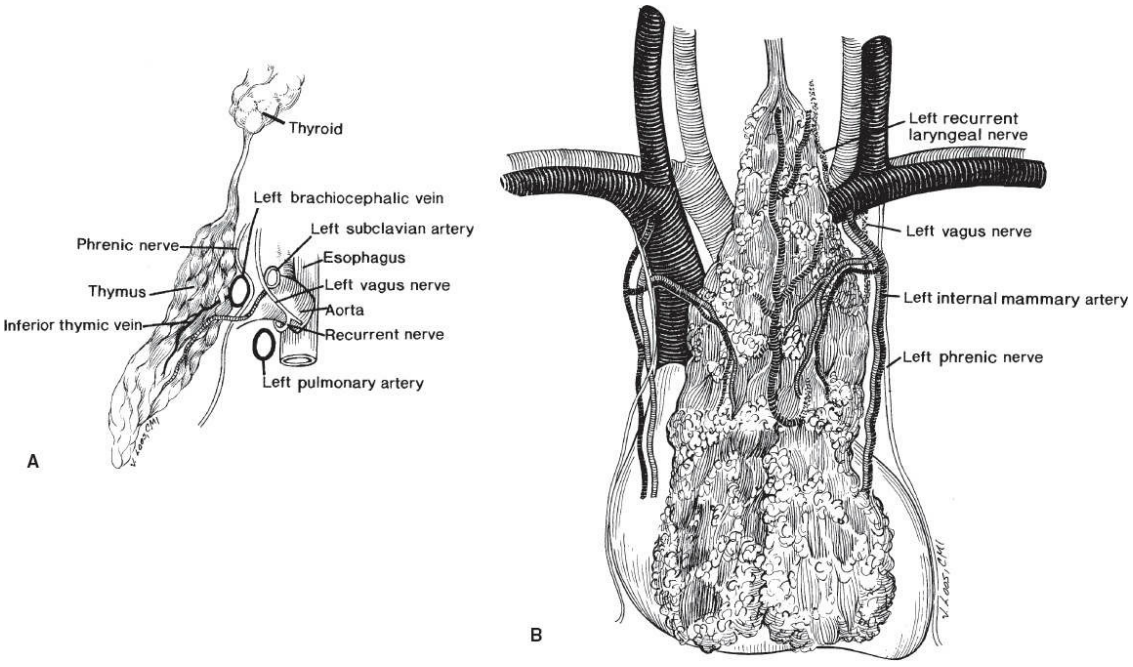

Figure 43.2. Anatomy of the thymus gland. **A.** Lateral view, showing the relationship to the left brachiocephalic vein, the inferior aspect of the thyroid gland, and the phrenic and recurrent laryngeal nerves. **B.** Anterior view, showing the relationship to the pericardium and great vessels. The major arterial supply originates from the internal thoracic (internal mammary) arteries, and the major venous drainage empties posteriorly into the left brachiocephalic vein.

Anatomy

The arterial supply of the thymus is chiefly derived from the internal thoracic arteries, although it receives branches from inferior thyroid arteries and pericardiophrenic arteries as well. There may be small draining veins traveling with the arteries from any of the three sources. However, the main venous drainage is through one or two major trunks,

formed by convergence of multiple tributaries from both lobes, running posteriorly between the lobes and draining into the anterior surface of the innominate vein. Although it is a major lymphatic tissue, unlike a lymph node, the thymus gland lacks afferent lymph channels. There are efferent lymph channels, which only drain the capsule and fibrous septa of the gland and drain into anterior mediastinal, pulmonary hilar, and internal mammary lymph nodes. Both sympathetic and parasympathetic nerve fibers are found in the thymus.

Numerous islets of thymic tissue, both macroscopic and microscopic, may be found in the neck, middle mediastinum, pulmonary hila, aortopulmonary window, retrocarinal fat, diaphragm, and even within the pulmonary parenchyma. Masaoka et al. reported 72% of cases had extracapsular microscopic collections of thymic tissue in the anterior mediastinum in 1975, and Fukai et al. came up with the same findings in 51.8% of cases in 1991. Jaretzki documented the variations of extra glandular thymic tissue found in different mediastinal locations in 1997 (Fig. 43.3). These publications form the basis for the ongoing debate on completeness and adequacy of thymectomy via various incisions.

Thymic Physiology

The thymus is a complex organ with epithelial and lymphoid components. During infancy, the thymus is essential for the development of cellular immunity. It is the main site for maturation of null lymphocytes into T cells. The majority of cells in the thymus are T lymphocytes and epithelial cells. These cells comprise the two main structural layers of the gland, the cortex and the medulla, respectively. Occasional lymphoid follicles with B cells and germinal centers can also be found. Although rare, myoid cells may also arise in the thymus. These cells act like skeletal muscle cells, including expression of the acetylcholine receptors (AChRs), and may be involved in the pathophysiology of MG.

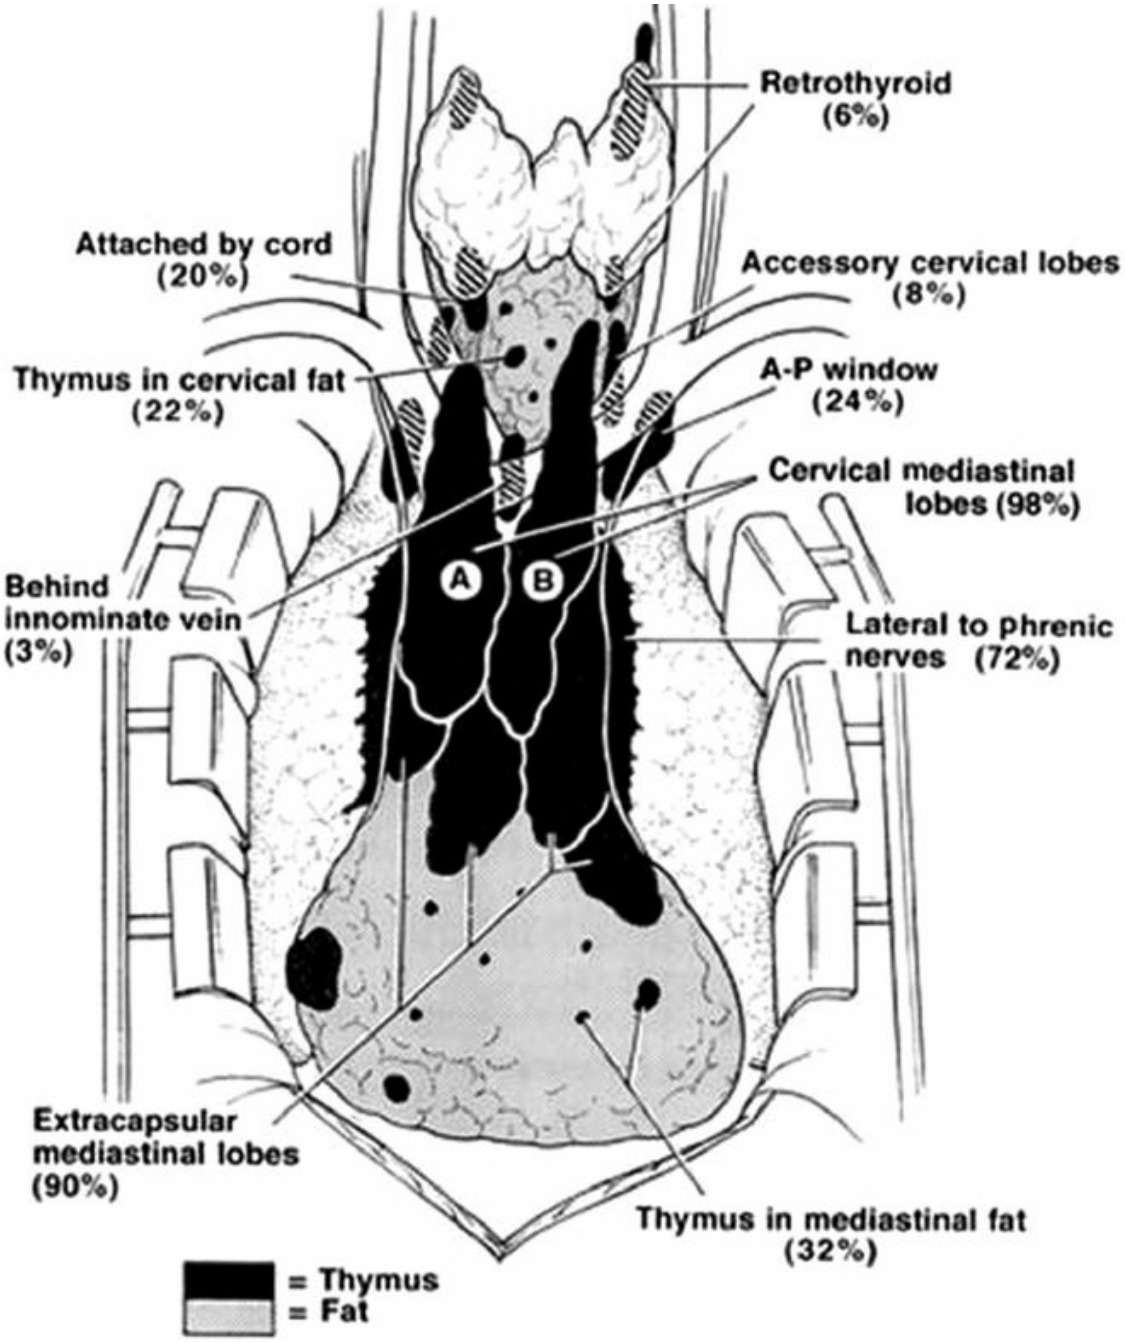

Figure 43.3. Locations of extraglandular thymic tissue. (Reprinted from Jaretzki A, Barohn RJ, Ernstoff RM, et al. Myasthenia gravis: recommendations for clinical research standards. *Ann Thorac Surg* 2000;70(1):327–34. Copyright © 2000, with permission from Elsevier.)

The proper function of the immune system depends on the normal simultaneous development of cellular and humoral components, and normal interaction between them. Thymus-centered T cells are responsible for differentiating self-antigens from intruders and producing cell-mediated immune reactions, as seen in delayed hypersensitivity reactions.

The bursa-dependent system, formed by the bursa, lymphoid follicles, and plasma cells, is responsible for the production of immunoglobulins (A, G, and M) and specific antibodies. Any disturbance in development of either system may lead to one of the various immunologic deficiency syndromes. Interestingly, some of these syndromes have been associated with various neoplasms of the thymus as well as with congenital thymic hyperplasia and agenesis. Some morphologic changes that the thymus can display have also been linked to hyperplasia, abnormal development, and infections.

Thymic Neoplasms

The epithelial subset of thymic neoplasms, namely, thymoma, is the most common tumor of the anterior mediastinum. It is fundamental in oncology that a successful therapeutic approach to a neoplasm be based on a definitive and prognostically reproducible classification and staging system. However, the classification of thymic tumors has been one of the most debated subjects of modern thoracic pathology, surgery, and oncology. There have been several classification proposals, focusing on one or more of histology, embryology, and biology of the tumors, in an attempt to establish an agreed-on nomenclature. Although lymphomas are far more common than thymomas in children and adolescents, the only role for surgery in their treatment is for diagnostic and staging purposes. Mesenchymal and germ cell tumors of the thymus are uncommon. The most common type is teratoma. Seminomas and nonseminomatous germ cell tumors also occur in the thymus, almost exclusively in men. Thymic carcinoids are extremely rare, often associated with endocrinopathies such as Cushing syndrome or inappropriate secretion of the antidiuretic hormone. They are typically invasive, often recur, are associated with extrathoracic metastases, and have a poor prognosis. The thymus can rarely be a site for metastasis as well.

Thymoma

Thymomas are rare tumors. Despite this, they account for 20% of all mediastinal neoplasms and comprise half of all primary tumors found in the anterior compartment. They may also be encountered in other areas of the neck and the thorax: along the pleura, inside the pericardial sac, over the diaphragm, within the lung parenchyma, and even as a polypoid lesion in the trachea. Thymomas are slow-growing tumors; however, they exhibit malignant potential as some demonstrate local invasion, pleural

dissemination, and systemic metastases without overt cytologic features of malignancy. They are more common between ages 40 and 60 and do not show predilection for either sex.

The clinical presentation of thymoma is extremely varied. In up to 50% of instances, these neoplasms are entirely asymptomatic, discovered incidentally on chest imaging or at autopsy. Approximately 30% of patients present with local symptoms related to pressure or direct invasion. In 20% to 70% of patients, thymoma is associated with systemic disorders that are primarily of autoimmune origin. When present, these concomitant diseases worsen the prognosis. The most common autoimmune disease associated with thymoma is MG. However, up to 28% of thymoma patients will present with an immune disorder other than MG. The most common disorders include pure red cell aplasia, lupus erythematosus, polymyositis, and hypogammaglobulinemia.

All thymomas originate from the thymic epithelial cells; however, only about 4% of them consist of a pure population of epithelial cells. Most have mixed populations of lymphoid cells, to a varying extent. There have been two major approaches to histologic classification of thymomas. In the 1960's Bernatz et al. from the Mayo Clinic divided thymomas into lymphocytic, epithelial, mixed, and spindle subtypes according to the lymphocyte-to-epithelial cell ratio in tumors. At that time, thymic carcinomas were not distinctly segregated, but grouped with thymomas. In 1978, Levine and Rosai proposed a new classification that proved to be of high clinical relevance. In this report, they divided the thymomas into benign (circumscribed) and malignant (invasive) types. Wick et al. in 1982 and Lewis et al. in 1987 proposed the separation of thymic epithelial cell neoplasms into thymomas and thymic carcinomas, which is now well accepted. Mixed thymoma cases with islets of thymic carcinoma behave clinically like typical thymomas more than thymic carcinomas. These findings support the theory that thymomas carry the potential for malignant transformation into malignant thymic carcinoma.

The Bernatz system remained the mainstay of thymoma classification until the mid-1980s. In 1985, Marino and Müller-Hermelink proposed a classification system based on the origin of the cells more than the cell type (i.e., cortical, medullary, or mixed subtypes). They differentiated the origin of epithelial cells found in the thymoma according to their resemblance to the normal epithelial cells in other parts of the thymic lobule and classified the tumor accordingly. This classification was

suggested to have independent prognostic implications. In their 80-patient series in 1990, Pescarmona and colleagues found that the Müller-Hermelink (M-H) classification reliably predicted prognosis. Medullary thymomas tended to be more encapsulated and clinically acted benign, but cortical ones were invasive and malignant in nature. When a modification of the Bernatz classification was used in the same 80-patient series, there was no correlation found between the subtypes and their prognosis. Wilkins (1995) also confirmed the M-H results, as he noted only a few recurrences in patients with medullary or mixed tumors, whereas the recurrence rate was much higher in cortical tumors.

The World Health Organization's (WHO) "Histological Typing of Tumors of the Thymus," reported by Rosai in 1999, reflected the consensus of the pathologists specializing in thymic tumors (Table 43.1). The cellular origins of the various neoplasms are emphasized in this classification, which is a successful synthesis of the most widely used classifications and resembles more the M-H classification. Currently, the WHO classification is the preferred classification method in thymic neoplasms. In this classification, type A represents atrophic adult-life thymic cells that are spindle or oval in shape, and type B represents bioactive thymic cells, of fetus and infants, with dendritic or epithelioid appearance. Type B thymomas are further divided into B1, B2, and B3 on the basis of increasing epithelial-to-lymphoid ratio and the emergence of atypia of the epithelial cells. Type AB thymomas display the common features of type A and type B lesions. Type C tumors are frankly malignant cells, and these lesions correspond to thymic carcinomas. There are at least nine subtypes of type C tumors, and they may be further subdivided into low-grade and high-grade malignant tumors.

TABLE 43.1 World Health Organization (WHO) Histologic Classification of Thymomas and Carcinomas of the Thymus

WHO Histologic Type	Previous Corresponding Terminology
A	Medullary thymomas; spindle cell thymoma
AB	Mixed thymoma
B1	Predominantly cortical thymoma; organoid thymoma; lymphocyte-predominant thymoma; lymphocytic thymoma
B2	Cortical thymoma
B3	Well-differentiated thymic carcinoma; epithelial; predominant epithelial; squamoid thymoma
C	Thymic carcinoma (with nine subtypes)

Besides the efforts of classifying the thymomas according to their histologic or morphologic features, Masaoka et al. in the 1980's proposed an anatomic classification based on the presence or absence of gross or microscopic invasion of the tumor capsule as well as its metastatic status. Medullary and mixed histology tumors are usually not invasive and therefore correspond to Masaoka stages I or II, whereas cortical thymomas are more commonly invasive and more likely to be Masaoka stages of III or IV. Later modifications of the Masaoka classification, as suggested by Koga et al. in the 1990's and Nakagawa et al. in the early 2000's have been more widely adopted (Table 43.2). These systems incorporated microscopic incomplete capsular invasion into stage I, leaving only transcapsular invasion in stage II.

As part of the WHO thymoma classification effort, it was suggested that a TNM scheme be used in staging of all malignant thymomas and thymic carcinomas. Because there has been so much controversy regarding tumor classification during the past four decades, no authorized TNM system has been adopted. The proposed WHO TNM schema is similar to the Modified Masaoka system but remains tentative, pending validation of its reliability, reproducibility, and predictive power.

To further enhance our understanding of thymic malignancies and provide support to patients and families with thymic cancer, the Foundation for Thymic Cancer Research (FTCR) organized meetings of international leaders in the field, resulting in collaborative initiatives. These efforts include several published meta-analyses, National Comprehensive Cancer Network (NCCN) guidelines for the management of thymic malignancies, and the creation of the International Thymic Malignancy Interest Group (ITMIG). The NCCN and ITMIG currently identify the Masaoka-Koga classification as the most widely used system for staging, and endorse the WHO system for histologic classification.

Myasthenia Gravis

The original description of MG dates back to the case report of the physiologist Sir Thomas Willis in 1672. The real recognition of the clinical syndrome came after the report by Wilks in 1877, in which he described a young woman who died of a respiratory paralysis. Autopsy did not reveal any central nervous system pathology that would explain the problem. In 1895, Jolly described the test now bearing his name, disclosing the easy fatigability in the affected muscle following repetitive stimuli. He then proposed the name *myasthenia gravis pseudoparalytica* for the disease. In 1899, the Berlin Society for Neurology and Psychiatry shortened the name to myasthenia gravis. However, only during the last two decades has the pathophysiology of this disorder become well elucidated as the experiments revealed the microstructure, physiology, and molecular composition of the nicotinic AChR.

TABLE 43.2 Modified Masaoka Clinical Staging of Thymoma and Thymic Carcinoma

I	Fully encapsulated tumor (a thymoma completely surrounded by a fibrous capsule of varying thickness that is not infiltrated by tumor growth in its full thickness)
II	Tumor infiltrates beyond the capsule into the thymus or mediastinal fatty tissue. Adhesion to the mediastinal pleura may be present
III	Macroscopic invasion into neighboring organs (i.e., pericardium, great vessels, or lung)
IVa	Pleural or pericardial dissemination
IVb	Lymphogenous or hematogenous metastasis

Thymoma: A clinicopathologic study based on the new World Health Organization classification. *J Thorac Cardiovasc Surg* 2003;126:1134–40.

Pathophysiology of Myasthenia Gravis

The process of neuromuscular transmission in synapses is initiated with influx of calcium into the motor neuron, which in turn leads to release of acetylcholine (ACh) into the synaptic space. These ACh molecules diffuse across the synaptic cleft and bind to postsynaptic ACh receptors on the endplate of the muscle cell. In MG patients, this mechanism is blocked by an antibody-mediated attack on nicotinic AChRs on the muscle endplate. Clinically and physiologically, MG should be differentiated from the "myasthenic syndrome," which is also known as the Eaton–Lambert syndrome. It is a rare defect of neuromuscular transmission and is usually

associated with bronchogenic carcinoma. It is characterized by weakness and easy fatigability of proximal muscles of the extremities, with minimal or no bulbar symptoms and decreased or absent deep tendon reflexes.

The autoimmune attack on the AChRs appears to involve both cellular and humoral immune systems. Approximately 80% to 90% of MG patients have serum antibodies to the AChR. B-lymphocytes, which secrete anti-AChR immunoglobulin G, have been found in circulating blood as well as intrathymic germinal centers. Anti-AChR antibody and AChR interaction may occur in one of three ways: by accelerating the degradation of AChR through a cross-linking phenomenon, by directly blocking the receptor site, or by complement-mediated degradation of the receptor sites. Besides the amplified production of B cells in MG, antigen-specific T-helper cells are increased as well. AChR-specific T cells accumulate in myasthenic thymus glands regardless of the presence or absence of thymomas. The peripheral blood of myasthenic patients contains an increased amount of these autoreactive T cells, which in turn activate AChR-reactive B cells stimulating the anti-AChR antibody production.

Treatment is aimed at decreasing the circulating antibody levels, using either immunosuppression or plasmapheresis. This will result in clinical improvement in affected individuals as long as the treatment continues. In appropriately selected patients, the treatment that offers the best chance of complete remission is thymectomy. In this way, the source of autoimmunization is removed, depleting the specific T-helper cell population and normalizing T-cell function. B cells and helper T cells primed before thymectomy would theoretically remain in circulation, thus accounting for incomplete recovery in many patients who have undergone thymectomy as well as the relatively prolonged period (up to 2 years) between operation and remission in many patients.

CLINICAL PRESENTATION

Symptoms related to thymic disease are categorized as arising directly from the thymic lesion by either compression or invasion, symptoms associated with a previously described clinical syndrome (i.e., MG, red cell aplasia, or hypogammaglobulinemia), or nonspecific systemic symptoms such as anorexia and fatigue. Developmental anomalies can involve the location of the thymus or its structure. Failure of the thymus to descend into the anterior mediastinum might account for cervical thymic tissue, which can be mistaken for neoplasm, lymphadenopathy, or an

enlarged parathyroid. This aberrant tissue can cause compressive symptoms such as stridor or dysphagia. Lymphocyte count and tests of immunologic capacity may be diminished by thymectomy; however, no particular clinical problems have developed to correlate with these laboratory observations.

MG is the most common syndromic presentation of thymic disease. The prevalence of MG has been estimated at 43 to 64 per million persons. It has a predilection for females with a ratio of 3:2. Its peak age is 20 to 30 in women and more than 50 years in men. The disease is usually nonfamilial. The common presenting symptom of the disease is an insidious onset of generalized weakness. This is seen in 85% of the patients. It is usually symmetrical and becomes more intense at the end of the day. Muscles innervated by cranial nerves are often the first to be affected; however, any striated muscle in the body may be involved. Some patients may present with external ocular symptoms only, such as ptosis and diplopia. These symptoms may either spread to other muscle groups or remain confined to the eye, and may be so subtle that patients may go through several eyeglass prescriptions before they are diagnosed with MG. The worst type of disease occurs when the bulbar muscles are involved. The symptoms may include dysarthria with nasal tones caused by palatal paresis, diminished voice, and dysphonia. Often, patients can bite on the food but as they continue to eat, the mastication muscles weaken until they can no longer chew or close their jaws. Dysphagia may be associated with nasal regurgitation of liquids. Weakening of neck and back muscles may necessitate manual support of the head. Pelvic weakness may result in waddling gait. The most dreaded complication, however, is respiratory involvement. Weakness of respiratory muscles with paresis of intercostal muscles and the diaphragm may necessitate emergent medical attention. The Osserman and Genkins classification of MG is still very useful and widely adopted (Table 43.3). Standardized preoperative clinical staging has been recommended by applying the Myasthenia Gravis Foundation of America (MGFA) clinical classification (Table 43.4). Postoperative outcome can be characterized again in a standardized schema by following the De Filippi classification (Table 43.5).

Approximately 75% of patients with MG have thymic abnormalities; the majority having thymic hyperplasia. Although thymomas are present in 10% to 25% of MG patients, a higher proportion (30% to 60%) of patients with thymoma manifest some features of MG.

INDICATIONS AND CONTRAINDICATIONS

Thymectomy is indicated for the treatment of a resectable thymic neoplasm. Recent NCCN guidelines identify a “likely” thymic tumor as a well-defined anterior mediastinal mass in the expected location the thymus, with negative tumor markers, no mediastinal lymphadenopathy, and no continuity with the thyroid gland. Resectability must be defined by a thoracic surgeon and individualized to patient comorbidity. En bloc resections of pleura, pericardium, lung parenchyma, and even unilateral phrenic nerve may be safely performed. Innominate and SVC may be resected and reconstructed in appropriately selected patients. Direct myocardial involvement is rare but is a relative contraindication. Bilateral phrenic nerve involvement is generally avoided due to severe pulmonary morbidity.

Thymectomy is also indicated for nonthymomatous myasthenia gravis. The ideal patient for thymectomy is young with a short duration of symptoms and with significant disability and poor control with anticholinesterase medications. Conversely, elderly patients with nonthymomatous MG are generally not helped by thymectomy. In general, patients with mere ocular symptoms, or those whose condition is well controlled with acceptable medical treatment, are usually not first-line candidates for thymectomy. On the other hand, Shrager et al. reported an actual 50% complete remission, with a 5-year Kaplan–Meier estimate of complete remission of 57%, in patients with pure ocular MG. They also noted that as many as 50% of pure ocular MG patients historically deteriorate or develop generalized MG. In their ocular myasthenic patient group that had undergone thymectomy, the incidence of MG progression was zero.

TABLE 43.3 Osserman and Genkins Classification System of Myasthenia Gravis (MG)

I. Pediatric MG

A. Neonatal MG (1%)
- Seen in offspring of myasthenic mothers
- Self-limited (<6 weeks)
- Caused by transplacental transfer of circulating AChR antibodies
- Progression to juvenile or adult form is rare

B. Juvenile MG (9%)
- Onset any time between birth and puberty
- Tends to be permanent
- Nonmyasthenic mother
- MG disability is classified as in adult MG
- Familial involvement

II. Adult MG

Group I: Ocular MG (20%)
- Disease limited to ocular muscles
- 40% ultimately develop clinically generalized disease
- Electromyographic results may be positive in peripheral muscles
- Rarely progresses after 2 years of isolated ocular symptoms

Group IIA: Mild generalized disease (30%)
- Initial ocular symptoms progress gradually to generalized symptoms and involve cranial, limb, and truncal muscles
- Respiratory muscles are spared
- Good response to medical therapy, with low mortality

Group IIB: Moderately generalized disease (20%)
- More severe generalized involvement
- Bulbar symptoms are common, such as dysarthria, dysphagia, feeding problems
- Relative sparing of respiratory muscles
- Less responsive to medical therapy

Group III: Acute fulminating MG (11%)
- Rapid onset of severe generalized weakness
- Prominent respiratory symptoms
- Severe bulbar, limb, and truncal weakness
- Poor response to therapy
- High association with thymoma
- High mortality rate

Group IV: Late severe MG (9%)
- Patients with severe symptoms developing >2 years after onset of ocular or mild MG
- High incidence of thymoma
- Poor response to therapy

TABLE 43.4 Myasthenia Gravis Foundation of America Clinical Classification

Class	Description
Class I	Any ocular muscle weakness, other muscle strength normal
Class II	(IIa, IIb) Mild muscle weakness affecting limb, axial, oropharyngeal or respiratory muscles; any degree of ocular muscle weakness
Class III	(IIIa, IIIb) Moderate muscle weakness affecting limb, axial, oropharyngeal or respiratory muscles; any degree of ocular muscle weakness
Class IV	(IVa, IVb) Severe muscle weakness affecting limb, axial, oropharyngeal or respiratory muscles; any degree of ocular muscle weakness
Class V	Defined by intubation, with or without mechanical ventilation, except when employed during routine postoperative management

TABLE 43.5 De Filippi Postoperative Classification

Class	Description
Class 1	Complete remission, no medication
Class 2	Asymptomatic, decreased medication
Class 3	Improved, decreased symptoms or decreased medication
Class 4	No change
Class 5	Worsening symptoms

MG is unusual in childhood; however, one would expect the thymus to have a critical role in immunologic development. Although no deleterious effects of thymectomy have been shown in children older than 3 years of age, it is usually advisable to postpone pediatric thymectomies until puberty. In patients with MG and thymoma, the clinical course is influenced favorably by smaller tumor size.

PREOPERATIVE PLANNING

Comprehensive preoperative work-up for thymectomy includes attention to disease-specific considerations. Patients are screened for signs or symptoms of paraneoplastic syndrome. Serologic markers of germ-cell tumors, thyroid function tests, and anti-AChR antibodies may be useful.

Every candidate for thymectomy should undergo a preoperative contrast-enhanced computerized tomographic (CT) scan of mediastinum to accurately assess vascular relationships. CT defines the anatomic location, size, density, and extent of mediastinal tumors; identifies pulmonary and/or pleural-based metastases; and evaluates the status of contiguous mediastinal lymph nodes. Multidetector CT with multiplanar reconstructive capability may suggest local invasion of other mediastinal structures such as the chest wall, heart, pericardium, great vessels, central airways, or diaphragm and assists in surgical planning. Dedicated cardiac imaging protocols may be necessary when evaluating thymic tumors in close proximity to the pericardium. Most centers agree that magnetic resonance imaging (MRI) does not add much additional information to an optimally performed and reformatted contrast-enhanced CT. Rarely MRI may be used to better characterize soft tissue planes in an effort to discriminate between compression and local invasion. The utility of positron emission tomography in thymoma management is unknown. Additional neck imaging, and even thyroid scintigraphy, may be necessary to differentiate true thymic neoplasm from substernal goiter or ectopic thyroid tissue. A preoperative tissue biopsy is usually unnecessary, and a transpleural approach is contraindicated because of the risk of seeding the pleural space. Percutaneous core needle biopsy or surgical biopsy may occasionally be useful in the setting of significant diagnostic uncertainty with concern for a neoplasm that does not require surgical intervention (e.g., lymphoma). Fit patients who present with localized but marginal or unresectable disease should undergo core needle biopsy to confirm the histology followed by induction chemoradiotherapy in an attempt to allow subsequent resection. Unresectable thymic neoplasms should be biopsied prior to initiating definitive chemotherapy and/or radiation treatment.

Patients undergoing thymectomy for MG should not be rushed into the operating room until their medical condition is optimized. MG surgery is usually safe and well tolerated provided that a systematic, meticulous preoperative evaluation and preparation is performed. A team approach involving the anesthesiologist, neurologist, pulmonologist, respiratory therapist, intensivist, and thoracic surgeon is mandatory to minimize risk and achieve the desired outcome. The primary neurologist is charged with establishing an optimal medical regimen of anticholinesterases and immune-modulating drugs including corticosteroids. A preoperative spirometric workup is essential to forecast possible perioperative

respiratory complications. Various parameters including forced vital capacity, negative inspiratory force, maximum expiratory force, and maximum voluntary ventilation should be measured, both before and after application of cholinesterase inhibitors. Maximum expiratory force is useful for predicting an efficacious cough, and a measurement of less than 40 to 50 cm H_2O indicates a higher risk of postoperative respiratory complications. Vital capacity less than 2 L is another indicator of possible ventilatory compromise. Simple spirometric measures may be followed postoperatively as early indicators of impending respiratory compromise. Although data are limited in the perioperative population, forced vital capacity of less than 20 mL/kg and negative inspiratory force less than 30 cm H_2O have been identified as potential thresholds for elective intubation in patients with myasthenic crisis.

If the MG patient is unstable and/or symptoms are poorly controlled despite maximal maintenance therapy, intravenous immunoglobulin infusion or plasmapheresis is performed to diminish the circulating antibody levels. Plasmapheresis is also advisable prior to thymectomy in patients with bulbar symptoms even if they are well controlled on their current medical regimen. Three to five plasma exchanges, typically performed every other day, provide good preoperative preparation. As plasmapheresis is a nonspecific plasma exchange, other serum proteins such as clotting factors are depleted. To allow sufficient time for their resynthesis, surgery should be scheduled 2 to 3 days after the final pheresis session.

Anticholinesterase agents (pyridostigmine) should be discontinued 8 hours before the surgery. If these medications are discontinued any earlier, especially in severe cases, it may result in a myasthenic crisis. On the other hand, continuing the medications up until the time of surgery, especially in patients with mild symptoms, may cause a postoperative cholinergic crisis. Premedication in the operating room is usually minimal, consisting of atropine and a mild sedative. Long-acting muscle relaxants are avoided and deep anesthesia is maintained by inhalational agents and short-acting narcotics. Use of succinylcholine at induction is controversial. If possible, it is better to avoid it, but one should not hesitate to use it in case of a difficult intubation. First-generation cephalosporins are optimal for perioperative antibiotic prophylaxis. Aminoglycosides are to be avoided as they may increase neuromuscular blockade.

SURGICAL TECHNIQUE

Thymectomy is performed for benign and malignant thymic pathology. Thymectomy for MG, with or without thymoma, must be complete in order to obtain drug-free remission or at least significant improvement. This principle has fueled the endless debate between the enthusiastic proponents of the most extensive thymus and mediastinal fat resection and the defenders of thymic resection through a minimal incision.

Development of fiberoptic surgical tools, video applications in mediastinal and thoracic surgery, and specially designed sternal elevators improved direct mediastinal vision and the completeness of removed thymus from a small cervical incision. This in turn allowed the proponents of limited-incision approaches to improve the scope of their resections and report outcomes that had remission rates comparable with those of open extended or maximal thymectomies. The 1990s saw the advent of video-assisted thoracic surgery (VATS) followed by robotic-assisted thoracic surgery (RATS) a decade later, providing additional minimally invasive approaches to thymic surgery.

In the presence of clinical and radiologic evidence for a resectable thymoma, the surgical approach should be a full median sternotomy in order to obtain complete resection. There are, however, reports of video-assisted and robotic surgery approaches to resection of small thymomas (stages I and II). The goal of surgery remains a complete (R0) resection with inclusion *en bloc* of any adjacent structures involved by tumor such as pericardium, pleura, lung, or major vessels. Margins of resection include the thyroid gland superiorly, diaphragm inferiorly, and both phrenic nerves laterally. Microscopic (R1) and macroscopic (R2) incomplete resections are to be avoided but if unavoidable should be treated with adjuvant radiotherapy with consideration of chemotherapy as indicated by the NCCN guidelines.

Given the paucity of comparative studies, each of these approaches is in use today and will be discussed here.

Standard and Extended Transsternal Thymectomy

A standard thymectomy can be accomplished via either a full or partial sternotomy. For nonthymomatous MG, a partial sternotomy provides sufficient exposure. If a partial sternotomy is chosen, a T-shaped sternal incision through the fourth intercostal space facilitates excision of the inferior thymic poles. The technique used in standard thymectomy is the

same as for extended thymectomy except that there is a limitation in reaching caudally to the lower-most part of the anterior mediastinum and above the diaphragm because of the intact lower sternum. Extended transsternal thymectomy involves complete anterior mediastinal fat exenteration. This approach requires a full median sternotomy through either a midline or transverse submammary skin incision. It overcomes the shortcomings of standard thymectomy in removing all of the thymic tissue, beginning at the diaphragm and extending cranially together with any extraglandular thymic tissue found within the anterior mediastinal fat. It only lacks the accessory cervical incision used in the transsternal–transcervical (maximal) thymectomy. The patient is positioned supine with a transverse shoulder roll behind the scapulae and with the head in extension. A standard midline incision is made starting from one fingerbreadth below the suprasternal notch, extending down to below the xiphoid process. In the case of standard thymectomy, the incision is prematurely ended at the level of the fourth intercostal space. Because many of the patients are young women, either the transverse submammary or Y-shaped incision for sternotomy might be cosmetically preferable (Fig. 43.4). The presternal soft tissue and the fascia overlying the sternum are cut in the midline with electrocautery. Once the cleido-cleido ligament is divided with caution to avoid the vascular structures that may lie posterior to it, the space posterior to the manubrium is developed from the mediastinal tissues with blunt finger dissection. Similar digital dissection is carried out inferiorly behind the xiphoid process and the lower end of the sternum. The sternum is vertically split in the midline with a reciprocating or oscillating saw.

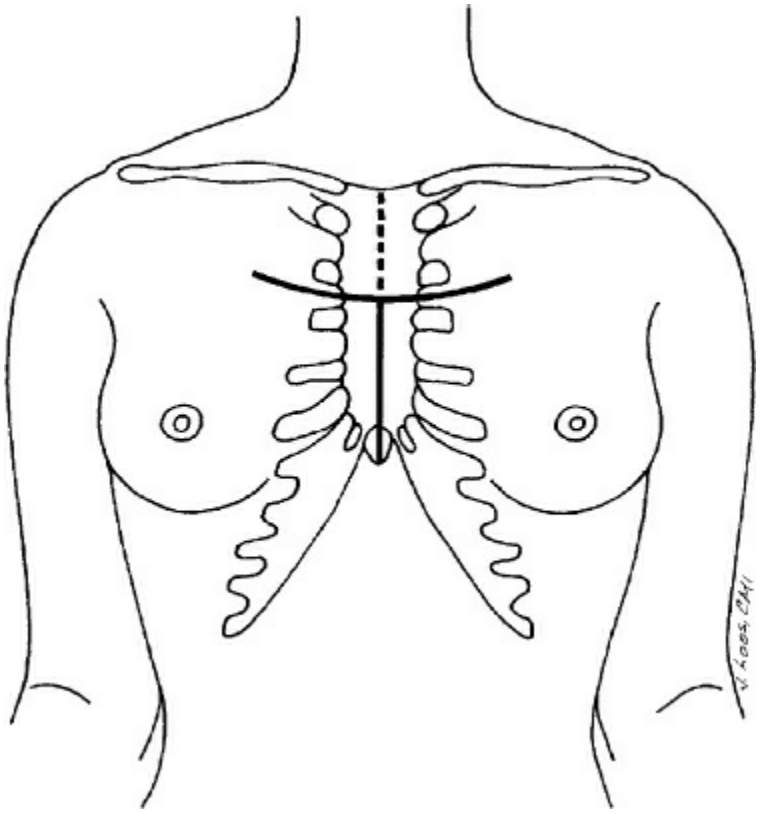

Figure 43.4. The Y-shaped skin incision, with a cephalad skin/subcutaneous flap, allows access to the entire sternum for midline sternotomy while maintaining cosmesis (especially in females) of the upper chest area.

Y-Shaped Incision

Because of its involution and since it is mostly filled with fibro fatty tissue, the thymus gland is often hard to distinguish from mediastinal fat in the adult. This is especially true in patients with long-term steroid use and in the presence of abundant mediastinal fat. *En bloc* resection of all mediastinal fat tissue, including both mediastinal pleural sheets, will ensure the inclusion of all of the thymic remnants in the resected specimen. Initially, both pleural spaces are opened and the phrenic nerves identified. Then, by using sharp and blunt dissection, the overlying mediastinal pleurae are pushed to the sides to bring the thymus and left innominate vein into view. Once the anterior surface of the gland is exposed, the mobilization starts at the diaphragm. The mediastinal fat, including the anterior pericardiophrenic fat pad, is elevated bilaterally and continued superiorly with the lower lobes of the thymus. The phrenic nerves should always be kept under direct vision to avoid injury. The lymph nodes and fat that course along the nerves are also separated and

included with the specimen. As the dissection moves cranially, the specimen should be elevated off the pericardium and sharp dissection should be carried strictly on the pericardium.

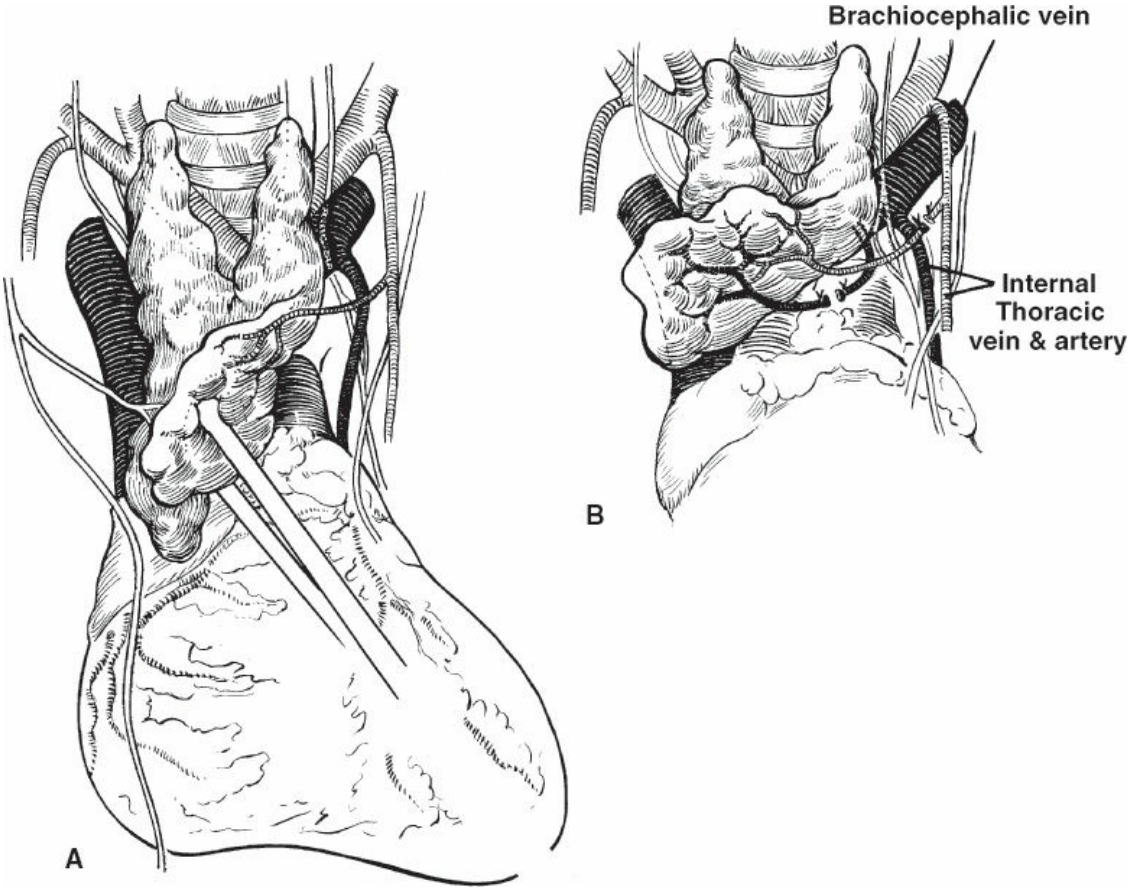

Figure 43.5. A. Division of the branches from the internal thoracic arteries allows the *en bloc* specimen to be rotated upward, exposing the undersurface of the gland and the draining veins. **B.** The brachiocephalic vein is exposed and the thymic veins are isolated and divided between ligatures or clips.

The arterial blood supply to the thymus gland extends laterally from the internal thoracic arteries. These branches are isolated and ligated appropriately. Once these anchoring vascular structures are divided, the gland can be rotated upward, exposing its posterior surface (Fig. 43.5). The thymic veins draining into the innominate vein are easily identified and safely divided as the inferior lobes are elevated. Once the dissection is completed on both sides up to the anterior borders of phrenic nerves, and the specimen is separated from the anterior surface of the innominate vein, the only attachment that remains would be the superior horns of the gland. This part of the dissection is carried out cautiously to avoid premature

disruption as the superior horns may be very delicate and extend well up into the cervical planes. Inferior parathyroid glands should be avoided and left with their blood supply intact if they are visualized. Venous tributaries between the thymic horns and inferior thyroid plexus should be ligated and divided. The fatty tissue between the SVC and aorta is swept anteriorly toward the mobilized thymus. Similarly, the lymphatic areolar tissue within the aortopulmonary window deep under the innominate vein is included with the specimen, completing the excision. Extra caution is needed during this radical anterior mediastinal lymph node dissection to avoid the left phrenic, vagus, and recurrent laryngeal nerves within the aortopulmonary window and along the left upper part of the dissection as such an injury would be devastating for a myasthenic patient.

En Bloc Resection

The presence of a thymoma mandates a thorough evaluation of resectability prior to embarking on thymectomy. The surgeon's assessment of local invasion is critical in defining the precise Masaoka stage, which in turn influences decisions regarding adjuvant treatments. A complete exploration includes inspection and palpation of both pleural spaces, the lung parenchyma, and the diaphragmatic and pericardial surfaces. Any tissue or organ involved by direct invasion with the thymoma should be included in the *en bloc* resection. Dense adherence of a thymoma to the pericardium requires that a portion of the parietal pericardium be included with the specimen. Direct invasion of the myocardium is rare. Droplet metastases along the pericardium and/or pleura should also be excised. In an adult, one but not both phrenic nerves can be resected if necessary. If the patient also suffers from MG, every effort to preserve diaphragmatic innervation should be made. Invasion of the innominate vein or SVC may require local resection. When possible, defects in these low-pressure vessels should be reconstructed with autologous tissue patches, transposition of the SVC or innominate vein to the right atrial appendage, or interposition with native vein or prosthetic grafts. If the right brachiocephalic to the SVC connection and the left jugulo-subclavian confluence remain intact, then an isolated resection of the innominate vein can be left unreconstructed.

Following resection of the gland, meticulous hemostasis is performed. Patients who underwent plasmapheresis prior to surgery may tend to bleed more postoperatively. A chest tube placed from the right inframammary

chest wall, across the mediastinum, and extended to the contralateral apex usually provides adequate postoperative drainage. For more extensive resections, the pleural spaces can be drained separately. The sternum is reapproximated with stainless-steel wires and the soft tissues with absorbable sutures in layers. Postoperatively, the patient is extubated in the operating room, the recovery room, or intensive care unit and is closely followed by the surgery, anesthesia, and neurology teams for signs of myasthenic crisis.

Patients are usually maintained on their preoperative medications as MG response to thymectomy is usually slow to evolve. Although the majority of myasthenic patients who undergo thymectomy experience significant improvement in their symptoms, drug-free remission is achieved predominantly in patients with earlier Osserman classes. This observation supports the recommendation for early thymectomy, as progression of symptoms was associated with an incomplete response to thymectomy.

TRANSCERVICAL THYMECTOMY

The original transcervical thymectomy described in the early 1970s involved removal of only the intracapsular thymus gland. Such a technique will not suffice as acceptable therapy for MG. In recurrent cases following basic transcervical thymectomy, transsternal reoperations revealed 2 to 60 g of retained thymic tissue, including thymomas. With specialized retraction, improved instrumentation, and illumination, the technique used in selected patients with thymic hyperplasia only has achieved results comparable with those of transsternal approaches. Moreover, proponents argued that patients with MG may choose transcervical removal of the thymus earlier in the course of their disease owing to its superior cosmetic results and lower morbidity. Because the duration of symptoms has an adverse effect on the MG response to thymectomy, an earlier commitment to surgery could provide better outcomes. Major contraindications to transcervical thymectomy are suspicion of thymoma and the patient's inability to fully extend the neck. Previous sternotomy or mediastinal surgery also precludes the transcervical approach.

Following the same preoperative preparation as for transsternal thymectomy, the patient is positioned supine on the operating table, with a roll behind the shoulders and the neck extended. Anesthesia equipment is positioned laterally in relation to the patient's head as the surgeon is seated

at the head of the bed. As there is always the possibility to convert to an open sternotomy in case of an emergency or unexpected finding (thymoma), the surgical field should be wide enough to expose such anatomic landmarks to allow this surgical conversion. The incision is a transverse curvilinear incision approximately 2 cm above the sternal notch. After the skin incision, the platysma is cut and both superior and inferior skin flaps are raised by electrocautery dissection. The strap muscles are separated and retracted laterally on both sides. The upper poles of the thymus gland are usually located at this tissue plane lying superficial to inferior thyroid vessels. Initially, the upper portion of the thymus gland and surrounding fat tissue is dissected off of the trachea, thyroid gland up to its isthmus, and inferiorly to the sternal notch (Fig. 43.6A). Ectopic thymus tissue should always be expected and searched for, deep to and superior to the upper horns on both sides. The recurrent laryngeal nerves and the inferior parathyroid glands are usually identified and preserved. If it becomes difficult to differentiate inferior parathyroid glands from the thymus tissue, or the ectopic thymus tissue, a frozen section can be sent for analysis and confirmation.

Cervical Dissection

Following the true cervical portion of the dissection, the cleido-cleido ligament is cut vertically and the prethymic plane is separated from posterior sternal plate by blunt finger dissection. The gland is palpated for nodular or invasive characteristics. A special narrow right-angled retractor is placed behind the sternum and attached to a self-retaining apparatus for upward traction (Fig. 43.6B). With the help of headlight illumination, the anterior mediastinum is then well visualized. The already mobilized upper half of the gland is lifted up and dissection is carried down posterior to the thymus until the innominate vein is exposed and the thymic venous branches isolated where they drain into the innominate vein. These branches are ligated and divided under direct vision. After this is accomplished, the remaining attachments of the gland and pericardial fat pad are dissected caudally with the combination of sharp and blunt dissection, as well as cranial traction, off of the pericardium and bilateral pleural surfaces. Although the dissection technique is almost identical to that of transsternal thymectomy, the major difference is the inability to keep the phrenic nerves under direct vision at all times. Therefore, utmost care should be paid to the anatomic landmarks and to staying away from

the possible course of the phrenic nerves. If there is any invasion of pleura, it should be resected *en bloc* with the specimen and may necessitate conversion to a sternotomy or VATS approach.

After removal of the specimen, the anterior mediastinum should carefully be inspected for satisfactory hemostasis. Unless the pleural spaces are opened, no chest tube is required. A red rubber catheter is placed into the mediastinum through the incision during closure of the layers. Once the strap muscles and platysma layers are approximated with absorbable sutures, and the lungs are fully expanded, the red rubber catheter is placed on suction and removed. The skin is closed with a running absorbable subcuticular suture.

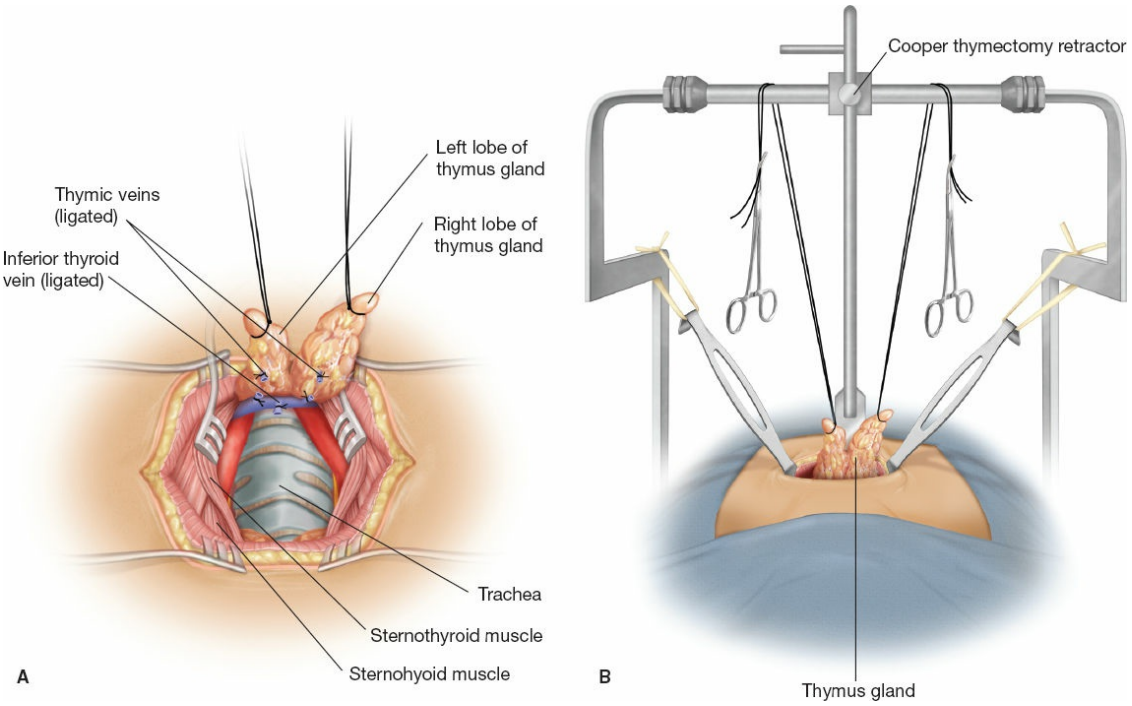

Figure 43.6. A. The cervical poles of the thymus gland have been dissected off the trachea, and are used to deliver the thymus up into the cervical incision and off of the posterior structures. **B.** After completion of the cervical dissection, a self-retaining retractor is used to bring the sternum anteriorly and facilitate better exposure of the anterior mediastinum. (Reproduced from Mulholland MW, Albo D, Dalman RL, et al. *Operative Techniques in Surgery*. Volume 1. Philadelphia, PA: Wolters Kluwer Health; 2015.)

VIDEO-ASSISTED THORACOSCOPIC THYMECTOMY

Thymectomy can be accomplished using VATS using a variety of

approaches. These include right- or left-sided VATS thymectomy, bilateral VATS thymectomy, bilateral VATS combined with a cervical approach for extended thymectomy (video-assisted thoracoscopic extended thymectomy [VATET]), bilateral VATS combined with a subxiphoid approach, and VATS thymectomy with sternal and anterior chest wall elevation. Both right- and left-sided approaches have their advantages and limitations. In left video-assisted thoracic thymectomy, it is easier to mobilize the left inferior pole and pericardial fat tissue lying laterally along the left ventricle. The aortopulmonary window is also more directly visualized. On the other hand, dissection along the innominate vein and visualization of the SVC can be quite challenging. The proponents of right-sided VATS thymectomy use the SVC as a helpful landmark, and can more easily identify the innominate vein. Combinations of transcervical, subxiphoid, and bilateral VATS thymectomy may allow for more extended thymic resection. Despite this, the complexity of multiple incisions is cumbersome, associated with postoperative pain similar to that following sternotomy, and lacks any evidence for therapeutic benefit. Currently, only right or left VATS approaches to thymectomy are performed with significant frequency to warrant a detailed description.

Technique for Right-Sided VATS Thymectomy

Following the initiation of general anesthesia with a double-lumen endotracheal tube, the patient is positioned in full left lateral decubitus position with the bed rotated 30 degrees to the right to allow the lung to fall away posteriorly. The port for a 0-degree or a 30-degree telescope is made at the fifth intercostal space along the posterior axillary line. The remaining working ports are located at the third intercostal space in the midaxillary line and fifth intercostal space in the anterior axillary line. If needed, another posterior port can be placed for lung retraction. The entire hemithorax is carefully examined for metastatic disease or for direct mediastinal pleural involvement. In case of a large thymoma or invasive disease, conversion to open sternotomy is recommended. The mediastinal incision starts from just anterior to the SVC, which is the cardinal landmark in the right chest. Once the pleura is opened longitudinally, the thymus is exposed. The plane between the anterior surface of the thymus and mediastinal fat pad and the posterior table of the sternum is dissected across the mediastinum to the contralateral side. The right inferior horn of the thymus is identified and dissected off the pericardium and aorta,

beginning at the diaphragm inferiorly and extending cranially to the innominate vein. Often, simple blunt dissection with anterior and cephalad retraction of the gland is sufficient. The thymic venous branches draining into the innominate vein are isolated, doubly clipped, and divided. The left inferior horn is dissected free using the same gentle combination of blunt dissection and cephalad retraction.

Once the two inferior poles are freed up to the isthmus and venous branches are divided, traction is applied anteriorly and inferiorly to allow the dissection of superior horns from the surrounding mediastinal and cervical tissue. If one or both superior horn(s) of the thymus gland pass behind the innominate vein, it/they should be carefully dissected off the vein before they can be freed safely from the neck. The descending blood supply within the inferior thyroid plexus may require clips for adequate hemostasis. Cautery should be avoided here to prevent injury to the recurrent laryngeal nerves. Once the thymus gland is completely free, it is removed in an endobag through the most anterior trocar incision, as this is usually the widest intercostal space.

In case of a clinical stage I or II thymoma, the dissection may be modified according to its size and location. If it is located to the left of the midline and is large, a left VATS thymectomy may also be performed. However, VATS thymectomy for thymoma is suggested only for stage I thymomas. After removal of the specimen, the bed is closely examined for bleeding and completeness of the resection. The brachiocephalic veins are skeletonized, and the junction where they form the SVC is clearly visualized. The pleural space is drained with a small chest tube or silastic drain and the port incisions are closed in layers.

Technique for Left-Sided VATS Thymectomy

Under general anesthesia via a double-lumen endotracheal tube, the patient is rotated 45 degrees toward the right lateral decubitus position. Typically, three or four thoracoscopic ports are used. The ports are located in the fourth intercostal space along the midclavicular line, a camera port in the fifth intercostal space at the anterior axillary line, and the other working ports in the fourth intercostal space approximately 2 cm lateral to the anterior axillary line, and in the sixth intercostal space between the anterior axillary and the midclavicular lines. The entire left hemithorax is examined to locate the important structures, such as aorta, subclavian artery, and phrenic nerve, and to look for tumor or thymic deposits on

pericardial, pleural, and diaphragmatic surfaces. If an invasive thymoma is found, the procedure is converted to a median sternotomy.

The dissection begins with left inferior horn and the pericardial fat pad, which is separated from the diaphragm inferiorly. The mediastinal pleura is incised along the course of the left phrenic nerve, leaving 1 cm of margin anteriorly. The adjuvant use of pneumomediastinum performed preoperatively or low-level (5 to 10 mm Hg) carbon dioxide insufflation intraoperatively has been reported to facilitate separation of the gland from the pericardium and posterior sternum. The dissection is then continued cephalad bluntly with pledget dissectors to the level of the innominate vein. Before proceeding above the innominate vein, it is advisable to dissect the thymus off the sternum anteriorly and complete the mobilization of the right lower horn. Utmost care should be given to avoid an injury to the contralateral phrenic nerve or to opening the opposite pleural space. The thymic veins draining into the innominate vein are then isolated, clipped, and divided. This is followed by the dissection of the superior horns up to the level of fascial attachments to the thyroid gland low within the neck. The intact thymus gland is extracted from the chest in an endobag through the most anterior access port. The surgical field is policed for bleeding, and any extra pericardial fat tissue is removed from the pericardiophrenic angles, aortopulmonary window, and aortocaval groove. Once the dissection is complete, the junction of both brachiocephalic veins where they form the SVC should be clearly visualized. The pleural space is appropriately drained and the port incisions are closed in simple layers.

Regardless of which VATS approach to thymectomy is used, there are shared benefits such as less postoperative discomfort, a shorter hospital stay, superior cosmesis, and acceptance of surgery by the patient earlier in the disease course. The thoracoscopic procedure is generally more time-consuming and requires additional technical expertise. The patient must be able to tolerate single-lung ventilation for a prolonged period of time. Although the response rates reported with VATS approaches are comparable with the results of more invasive approaches, the complete remission rates are still somewhat lower, at least partly because of shorter follow-up and limited accrual in reported series. The variety of approaches to resection and inconsistent use of adjunctive measures, such as pneumomediastinum or carbon dioxide insufflation, has hindered adoption of a standard approach to VATS thymectomy.

ROBOTIC THYMECTOMY

Incorporation of robotic surgical systems has been proposed by some to enhance maneuverability of instruments and precision of surgical dissection of the thymus when compared with conventional VATS thymectomy. While the feasibility and safety of RATS thymectomy has been proven, no additional benefits have been demonstrated over the VATS approach. Proponents of RATS suggest that robotic surgery is more suitable than VATS for either complete or extended thymectomy because of easier dissection of the upper horns, better control of the upper thymic veins, and improved unilateral access to the entire anterior mediastinum. Disadvantages of RATS include the initial expense of the equipment, lack of formal training, and a steep learning curve. Several groups have reported their experience with RATS, mostly for MG. The median operating time for the entire group of approximately 200 patients was 2 hours, with a range from 1 to 5.2 hours. The mortality for the group was 0%, the morbidity was 2% to 10%, and the length of stay was a median of 2 to 5 days. RATS has also been utilized for resection of small thymomas.

Technique of Robotic Thymectomy

RATS thymectomy can be performed through a right- or left-sided approach. Advantages of the left-sided approach include better access to the aortopulmonary window and lower possibility of phrenic nerve injury. The left-sided approach may allow a more extensive resection of ectopic thymic tissue than the right-sided approach and gives remission rates similar to maximal thymectomy in an early, highly selected clinical review. Advantages of the right-sided approach include easier identification of the innominate vein and a larger operative space for improved maneuverability of the instruments.

Placement of the incisions is, however, similar for both approaches. The patient is intubated with a double-lumen endotracheal tube for selective single-lung ventilation. For a left RATS thymectomy, the patient is positioned left side up at a 30-degree angle with a bean bag or with a roll along the left paraspinal area. The camera port for the 0-degree stereo endoscope is introduced through a 15-mm incision in the fifth intercostal space on the midaxillary line. Carbon dioxide insufflation is utilized to aid with exposure (6 to 10 mm Hg). Two additional ports are placed: one in the third intercostal space in the midaxillary region and another in the fifth intercostal space on the midclavicular line. Two arms of the robotic system

are then attached to the two access ports and a third arm is attached to the endoscope. The left arm controls an instrument for grasping of the thymus and the right arm has an endoscopic dissection device with an electrosurgical device (e.g., hook cautery). The dissection starts inferiorly at the left pericardiophrenic angle and continues along the anterior border of the phrenic nerve (Fig. 43.7). Care is taken to avoid current injury to the phrenic nerve by staying several millimeters away from the nerve. The dissection is continued cephalad toward the thoracic inlet at the point where the phrenic nerve crosses behind the left innominate vein. The thymic tissue is dissected from the pericardium by grasping the thymus and dividing the areolar tissue with electrocautery from the phrenic nerve toward the retrosternal area. At this point, the retrosternal plane of dissection is established by gently grasping the thymus downward and electrocautery is utilized to incise the mediastinal pleura away from the internal mammary vessels. This plane of dissection is carried from the midsternum toward the thoracic inlet until the prior plane of dissection is reached in front of the innominate vein. Retrosternal dissection is continued until the contralateral pleura is visualized and the underlying lung identified. The pleura is gently incised and entry to the contralateral pleural space is achieved. At this point, the dissection moves toward the thoracic inlet and the fat covering the innominate vein is dissected. The left innominate vein is identified and the dissection continues along the border of the vein to the point where the thymic veins are identified. These veins can be controlled and divided with electrocautery or clipped and divided. The left superior thymic horn is then identified and dissection performed by applying traction and gentle electrocautery until the entire horn is dissected from the thyroid attachments. Care is taken to avoid injury to the innominate vein or avulsing thymic venous branches. The right thymic horn is dissected in a similar fashion. The plane of dissection in the right hemithorax is then carried cephalad until the innominate vein is reached at the confluence with the SVC. The right phrenic nerve is usually protected by the SVC and care should be taken not to pull the nerve into the field of dissection (Fig. 43.8). The entire thymus gland, fatty mediastinal tissue, and the cervical extensions are resected and the specimen is placed in a bag. Following extraction of the specimen and complete hemostasis, a 24-Fr or 28-Fr chest tube is inserted through the lower port and directed transmediastinally so that the tip of the tube is in the right pleural space. The lung is reinflated and the incisions closed. The

patient is extubated in the operating room and after a period of observation in the recovery room, the patient is admitted to a regular surgical floor. The chest tube is typically removed the following day and the patient discharged on postoperative day 1 to 3.

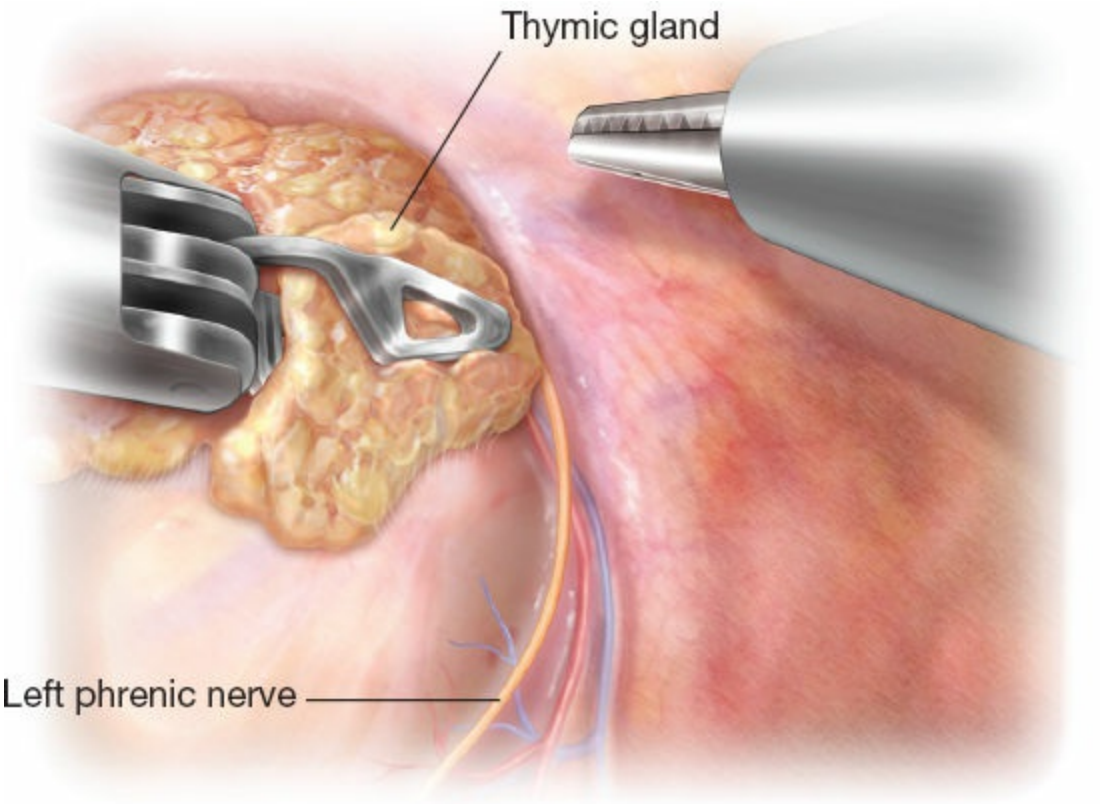

Figure 43.7. The thymus is mobilized along the left phrenic nerve from the pericardiophrenic fat pad to the level of the innominate vein. (Reproduced from Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections*. 1st ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2014.)

POSTOPERATIVE CARE

Following thymectomy, the majority of the patients can be extubated in the operating room or in the recovery area within a few hours. Frequent evaluations of the myasthenic patient by the anesthesiologist, surgeon, and/or neurologist with periodical measurements of negative inspiratory force and forced vital capacity may allow the extubated patient to be cared for on a standard postsurgical ward. Some authors strongly recommend that these patients be followed in an intensive care setting for at least 24

hours. Postoperative analgesia is maintained by administering small doses of intravenous morphine or by patient-controlled analgesia. It is advisable to start oral intake cautiously and slowly. Once the patient tolerates liquids without symptoms of choking, cough, or aspiration, the diet can be advanced. Following drain removal, parenteral analgesia is converted to an oral agent. Most patients are able to return to normal activity and work within 2 to 4 weeks following transsternal thymectomy and 1 to 2 weeks following transcervical, robotic, or video-assisted thymectomy.

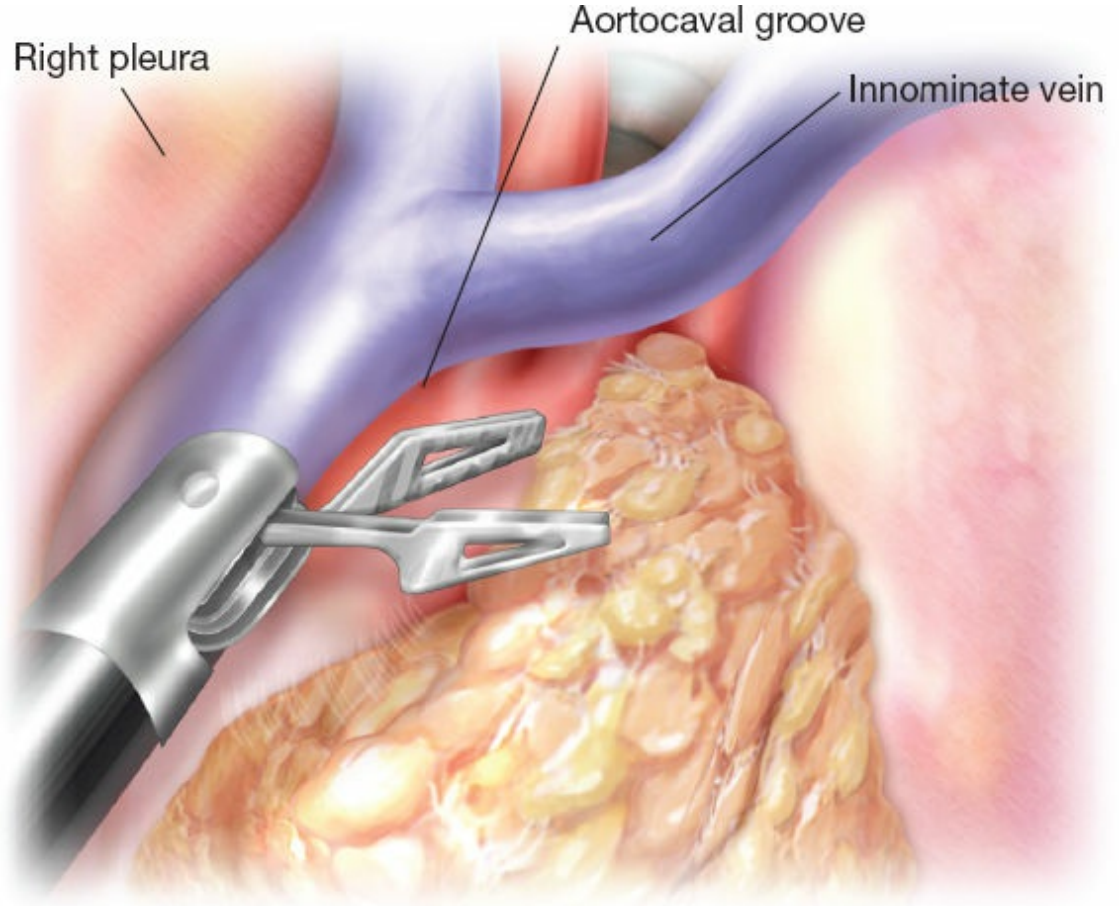

Figure 43.8. The right side of the gland is mobilized out of the aortocaval groove. The phrenic nerve is typically protected in its position lateral to the superior vena cava, but may inadvertantly be brought into the field with excessive traction. (Reproduced from Mathisen DJ, Morse C. *Master Techniques in Surgery: Thoracic Surgery: Transplantation, Tracheal Resections, Mediastinal Tumors, Extended Thoracic Resections*. 1st ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2014.)

The care of a myasthenic patient requires teamwork, with an experienced neurologist involved throughout the perioperative period.

Immunosuppressive medications, such as azathioprine, mycophenolate, or cyclosporine, are usually continued in the postoperative period; however, the continuation of corticosteroids is controversial. In some centers, it is preferred to discontinue the steroids after surgery, whereas they may be given and weaned over varying durations in others. Most patients will not be completely asymptomatic soon after surgery. Typically, weaning of MG medications happens over time through close outpatient follow-up by a neurologist, and, for some patients, this may require years.

The most feared complication after thymectomy is myasthenic crisis with acute respiratory failure. It may be caused by weakness and fatigability of the respiratory muscles limiting ventilation or from oropharyngeal muscle dysfunction with inability to maintain an open airway free of secretions. Myasthenic crisis should be differentiated from other postoperative causes of respiratory failure such as phrenic nerve injury. The latter can be suspected by the presence of an elevated diaphragmatic contour in full inspiration on an upright chest radiograph. Phrenic nerve conduction studies or fluoroscopic or ultrasound evaluation of diaphragmatic movements may confirm isolated phrenic dysfunction. In the absence of some anatomic explanation for ventilator dependence, and if reinitiation of cholinesterase inhibitors and stress dose steroids does not stabilize the patient, plasmapheresis should be instituted and continued daily. Proper preoperative preparation of MG patients, especially those with bulbar symptoms, coupled with meticulous surgical and anesthetic management has vastly reduced the incidence of myasthenic crisis following thymectomy. When it does occur, consideration of early tracheostomy is appropriate.

OUTCOMES

Several series have reported acceptable outcomes with videoscopic, robotic, and transcervical approaches. Ye et al. retrospectively evaluated short-term outcomes in 125 VATS thymectomies and 137 transsternal thymectomies. They found similar complications rates, with reduced length of pleural drainage and shorter hospital length of stay in the VATS group. Ruckert et al. compared their VATS and RATS experience in a retrospective cohort study. With 42-month median follow-up, the cumulative complete remission rates were 39% for RATS thymectomy and 20% for VATS thymectomy. Longer outcome data are available for transcervical thymectomy. Cooper et al., in three different reports on the

transcervical approach, have presented complete remission rates of 52% at 3.6-year follow-up, 35% at 5 years, and 44% in 8.4 years. In the report by Shrager et al. on extended transcervical thymectomy, the actuarial complete remission rate was 43% at 4.6 years.

The most important criticism against minimally invasive techniques for MG is the higher likelihood of incomplete resection of the thymus tissue and, accordingly, a lower rate of complete remission. Jaretzki's report of combined, maximal transcervical–transsternal thymectomies demonstrated a 50% actuarial complete remission rate at 5 years. Masaoka reported a 46% remission rate at 5 years, 67% at 15 years, and 90% overall palliation for their nonthymomatous group. The same investigators noted only a 32% remission rate and 82% palliation rate for their thymomatous patient group.

Unfortunately, there are no definitive data establishing one thymectomy technique as the standard of care. There are no randomized trials comparing operative approach for either thymic neoplasia or myasthenia gravis. It is very difficult to make meaningful comparisons between the existing retrospective studies due to differences in technique, patient population (e.g., severity of disease, symptom duration, presence of thymoma), and definitions of outcomes (e.g., complete remission, medication reduction, symptom improvement).

EDITOR'S COMMENT

Thymectomy is often performed by thoracic surgeons for management of myasthenia gravis or surgical resection of a thymic neoplasm, such as thymoma or thymic carcinoma. Drs. DeCamp and McCarthy have written a very comprehensive chapter describing the history of thymic surgery and the current operative approaches utilized for resection of the thymus gland. The authors also cogently reviewed the embryology and physiology of the thymus gland. This commentary will focus on a very controversial and vigorously debated topic regarding thymic surgery. As reported in the chapter, Alfred Blalock performed the first transsternal thymectomy for a severe case of myasthenia gravis, which was the first time that myasthenia gravis was associated with the thymus gland. He reported a series of six patients who underwent transsternal thymectomy for nonthymomatous myasthenia gravis. Sir Geoffrey Keynes reported a series of 218 thymectomies in 1954 for patients with myasthenia gravis (Keynes G. Surgery of the thymus gland; second (and third) thoughts. *Lancet* 1954;263:1197–202).

In recent years there has been a proliferation of minimally invasive techniques for thymic surgery, such as VATS, RATS, and transcervical thymectomy. There is ample controversy regarding the use of these minimally invasive techniques for thymectomy in patients with myasthenia gravis which requires complete extirpation of all thymic tissues as well as extraglandular thymic tissues to achieve a clinical remission. As the authors describe, complete resection of the thymus gland requires dissection of all thymic tissues from phrenic nerve laterally to phrenic nerve down to the diaphragm and up to the inferior poles of the thyroid gland. There remains skepticism that minimally invasive thymectomy techniques can effectively achieve complete extirpation of all thymic and extrathymic tissues as described by Masoka and cited by the authors.

The transcervical approach for thymectomy was described my Kirschner in 1969 (Kirschner P, Osserman KE, Kark AE. Studies in myasthenia gravis. Transcervical total thymectomy. *JAMA* 1969; 209:906–10). This procedure involves the complete excision of the thymus gland through a cervical neck incision and requires extreme elevation of the sternum with customized

retractors (Cooper JD, Al-Jilaihawa AN, Pearson FG. An improved technique to facilitate transcervical thymectomy for myasthenia gravis. *Ann Thorac Surg* 1988;45:242–7).

The technique obviates the need for a sternotomy since the operation is performed in the retrosternal space. Shrager and colleagues reported a 35% remission rate for patients undergoing transcervical thymectomy for myasthenia gravis (Shrager JB, Nathan D, Brinster CJ, et al. Outcomes after 151 extended transcervical thymectomies for myasthenia gravis. *Ann Thorac Surg* 2006;82:1863–9).

VATS can be performed from a bilateral approach or unilateral approach. There are numerous nonrandomized single-institution studies reporting the results of VATS thymectomy. The authors all describe the advantages of the VATS technique over median sternotomy, which include less postoperative pain and shorter hospital length of stay. Ruckert and colleagues reported a series of 79 patients with myasthenia gravis who underwent a left VATS thymectomy with minimal morbidity (Ruckert JC, Swierzy M, Ismail M. Comparison of robotic and nonrobotic thoracoscopic thymectomy: a cohort study. *J Thorac Cardiovasc Surg* 2011;141:673–7). The complete stable remission rate was reported to be 20%. Tomulescu and colleagues reported a series of 107 patients with myasthenia gravis who underwent a bilateral VATS thymectomy (Tomulescu V, Ion V, Kosa A. Thoracoscopic thymectomy mid-term results. *Ann Thorac Surg* 2006;82:1003–7). The reported complete stable remission rate was 15%. Youssef and colleagues reviewed the results of minimally invasive thymectomy compared to sternotomy (Youssef SJ, Louie BE, Farivar AS, et al. Comparison of open and minimally invasive thymectomies at a single institution. *Am J Surg* 2010;199(5):589–93). The study had a small sample size with eight patients in each group. The average hospital stay for the minimally invasive thymectomy group was 2.4 days compared to 4.3 days for the sternotomy group. This study did not offer any results regarding the remission rates or symptom improvement after thymectomy.

In recent years, the prevalence of RATS has increased and proponents of the technology report that the three-dimensional optics of the DaVinci robot is superior to the VATS technique and is similar to the open median sternotomy approach. There are currently no randomized studies comparing the robotic-assisted thymectomy to the VATS or transsternal approach. There are numerous single-institution reports describing the results of robotic-assisted approach for thymectomy in patients with myasthenia gravis. Marulli and colleagues reported a series of 100 patients undergoing left robotic thymectomy for myasthenia gravis (Marulli G, Schiavon M, Perissinotto E, et al. Surgical and neurologic outcomes after robotic thymectomy in 100 consecutive patients with myasthenia gravis. *J Thorac Cardiovasc Surg* 2013;145:730–5). The reported complete stable remission rate was 28.5%. Ruckert and colleagues reported a series of 74 patients undergoing left robotic-assisted thymectomy for myasthenia gravis. The reported complete stable remission rate was 39.3% which was higher than

the remission rate reported for VATS thymectomy in the same study.

The Myasthenia Gravis Thymectomy Trial (MGTX) is a randomized prospective clinical trial published in the New England Journal of Medicine in 2016 (Wolfe GI, Kaminski HJ, Aban IB, et al. Randomized trial of thymectomy in myasthenia gravis. *N Eng J Med* 2016;375:511–22). A total of 126 patients with nonthymomatous myasthenia gravis were randomized to prednisone therapy alone or transsternal thymectomy with prednisone therapy. The inclusion criteria for this clinical trial were very rigorous and included a duration of myasthenia gravis symptoms for less than 5 years and serum acetylcholine receptor antibody levels greater than 1.0 nmol/L. The primary outcomes of the study were clinical status measured by the quantitative myasthenia gravis score and the time-weighted average required dose of prednisone over a 3-year period. The trial mandated that surgeons perform an extended transsternal thymectomy (median sternotomy) to insure that there would not be any variability in thymectomy technique. The results in this clinical trial demonstrated that extended transsternal thymectomy significantly improved the symptoms of patients with generalized myasthenia gravis. The patients who were randomized to extended transsternal thymectomy had significantly lower quantitative myasthenia scores and a significantly lower dose of prednisone was needed maintain improved neurologic symptoms. The importance of the MGTX cannot be overemphasized. The clinical trial provided level 1A evidence that extended transsternal thymectomy objectively improves the symptoms for patients with nonthymomatous myasthenia gravis. The results of the study also establish transsternal thymectomy as the gold standard approach for thymectomy in patients with myasthenia gravis.

In conclusion, the debate regarding the efficacy of minimally invasive techniques for thymectomy for myasthenia gravis will continue despite the paucity of randomized level 1A evidence to support their use in myasthenia gravis. Regardless of the surgical approach for thymectomy, the clinical efficacy of thymectomy for myasthenia gravis requires the complete excision of the thymus gland as well as all extra glandular thymic tissue within the anterior mediastinum.

Robert E. Merritt

44 Adrenalectomy—Minimally Invasive and Open

L. Michael Brunt and Arghavan Salles

Tumors of the adrenal gland may present in a variety of clinical manifestations depending on the underlying pathophysiology. Surgical resection is the preferred treatment for a primary adrenal mass that is hormonally functional or malignant. Accurate diagnosis and localization through a systematic approach with biochemical testing and imaging techniques are essential in selecting patients for operation. Several open and laparoscopic approaches are available to remove the adrenal gland, each with its own advantages in terms of exposure, degree of invasiveness, ability to explore the entire abdomen, and patient outcomes. Tumor size, functionality, bilaterality or extra-adrenal location, malignant potential, individual patient characteristics, and surgeon experience all play an important role in determining the type of procedure utilized. Patients with hormonally functional tumors should undergo adequate preoperative preparation to minimize intraoperative complications. Proper selection of patients for operation, a thorough knowledge of adrenal anatomy, and a meticulous and hemostatic extra-adrenal dissection technique are imperative to optimize outcomes, especially in the minimally invasive setting.

ETIOLOGY AND PATHOPHYSIOLOGY

The adrenal glands are retroperitoneal organs immediately superior to the kidneys. These glands are slightly nodular with a firm texture and are surrounded by a layer of areolar connective tissue. Each gland weighs approximately 4 to 5 g in the adult and has a golden yellow-orange color distinct from the pale yellow retroperitoneal fat. The left adrenal gland is bordered inferiorly by the left kidney and left renal vein, superiorly and posteriorly by the diaphragm, anteriorly by the tail of the pancreas, and medially by the spleen and aorta. The right adrenal gland is bordered inferiorly by the right kidney; superiorly, posteriorly, and laterally by the

diaphragm; anteriorly by the liver; and medially by the inferior vena cava (IVC; Fig. 44.1).

The arterial blood supply to the adrenal gland is derived mainly from the inferior phrenic and renal arteries as well as directly off the aorta. Occasionally, intercostal and ovarian vessels may contribute as well. Rather than one or two main arteries, the distribution is primarily one of multiple small branches that enter the superior, medial, and inferior aspects of the gland (Fig. 44.2). Venous drainage of the left adrenal is via the left adrenal vein, which arises from the inferomedial aspect of the gland and empties into the left renal vein. The inferior phrenic vein usually joins the left adrenal vein above its entry into the renal vein. Blood from the right adrenal gland empties directly into the IVC via the short central adrenal vein that arises from the medial aspect of the gland. Accessory adrenal veins entering the vena cava or hepatic veins may be present on the right side. Lymphatic drainage from the adrenal gland is into adjacent pericaval and periaortic lymph nodes, which is important during resection of a malignant tumor.

The adrenal gland is divided into two distinct components: the cortex and the medulla. The adrenal cortex is the site of production of mineralocorticoids (aldosterone), glucocorticoids (cortisone), and sex steroids. The medulla contains chromaffin cells that secrete the catecholamines epinephrine and norepinephrine and also dopamine.

CLINICAL PRESENTATION

Adrenal tumors may come to attention because of clinical signs and symptoms of hormone hypersecretion, because of local symptoms of pain due to a large mass, or as a lesion discovered incidentally during cross-sectional imaging done for other reasons. Appropriate diagnosis and localization are imperative for successful operative planning and treatment. The various indications for adrenalectomy are given in Table 44.1. Algorithms for biochemical testing as well as radiographic imaging are available for differentiating the various causes of adrenal lesions, including aldosteronoma, Cushing syndrome, pheochromocytoma, adrenal cortical carcinoma, metastatic disease of the adrenal glands, and adrenal incidentaloma. A summary of the biochemical evaluation and preoperative preparation used for the treatment of these adrenal lesions is described in Table 44.2.

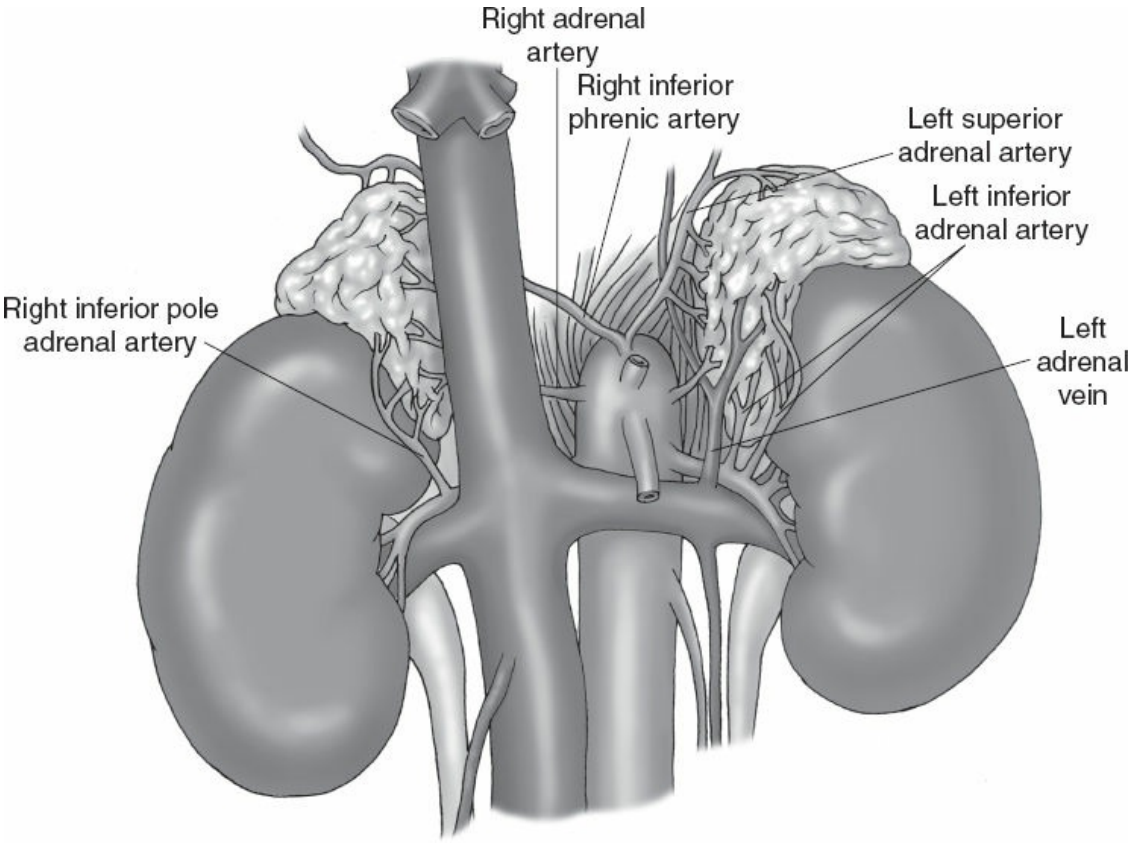

Figure 44.2. Blood supply to the adrenals.

TABLE 44.1 Indications for Adrenalectomy

Unilateral Adrenalectomy
Aldosteronoma
Cortisol-secreting adenoma (Cushing syndrome or subclinical Cushing's)
Unilateral pheochromocytoma (sporadic or familial)
Virilizing or feminizing tumors
Nonfunctioning unilateral tumor
Size >4–5 cm
Imaging features atypical for adenoma, myelolipoma, or cyst
Adrenocortical carcinomas
Solitary unilateral adrenal metastasis
Bilateral Adrenalectomy
Bilateral pheochromocytomas
Cushing syndrome from
Bilateral nodular adrenal hyperplasia
Ectopic ACTH-producing tumor unresponsive to primary therapy
Cushing disease (pituitary tumor) unsuccessfully treated by surgery or radiation

ACTH, adrenocorticotropic hormone.

Aldosteronoma

Primary hyperaldosteronism is the most common cause of secondary hypertension and has a much higher prevalence rate in the population than previously appreciated, occurring in 8% to 12% of hypertensive patients. Although the classic findings in primary hyperaldosteronism are hypertension and hypokalemia, many patients with this diagnosis have a normal serum potassium level. Therefore, any patient who has hypertension, with an early age of onset or that is difficult to control or refractory to medical management (especially if the hypertension is predominantly diastolic) should be considered for this diagnosis, regardless of the serum potassium level. Because endogenous

hyperaldosteronism suppresses renin secretion, biochemical screening entails simultaneous measurement of both plasma aldosterone and renin levels. A plasma aldosterone concentration (PAC)–to–plasma renin activity (PRA) ratio >20 to 25 in the setting of an absolute PAC >15 ng/dL is consistent with this diagnosis and should be evaluated further. Confirmatory testing consists of demonstrating elevated 24-hour urine aldosterone levels (>12 μg/24 h) while on a high-sodium diet or after intravenous saline loading. Other biochemical findings include an elevated urinary potassium excretion rate (>30 mEq/24 h).

TABLE 44.2 Diagnosis and Preoperative Preparation of Common Adrenal Tumors

Tumor Type	Biochemical Diagnosis	Preoperative Preparation
Pheochromocytoma	Plasma fractionated metanephrines and/or 24-h urinary catecholamines and metanephrines	Alpha-receptor blockade; hydration; beta-blockade only if persistent tachycardia or epinephrine-secreting tumor
Aldosteronoma	PAC and PRA; urinary aldosterone and potassium (on high-salt diet)	Replete hypokalemia, control hypertension
Cushing syndrome from cortical adenoma	24-h urine-free cortisol; overnight low-dose DMST; plasma ACTH	Perioperative stress steroids
Adrenal cortical carcinoma	24-h urine cortisol, plasma DHEA level	None unless tumor is cortisol secreting
Incidentaloma	Low-dose DMST, plasma fractionated	None unless biochemical screen positive metanephrines or urine catecholamines and metanephrines; PAC and PRA if hypertensive or hypokalemic

ACTH, adrenocorticotropic hormone; DHEA, dehydroepiandrosterone; DMST, dexamethasone suppression test; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

The most common causes of primary hyperaldosteronism are aldosterone-producing adenoma (65%) and idiopathic cortical adrenal hyperplasia (35%). Aldosterone-secreting adrenal carcinomas are rare. Differentiation of these causes is critical in directing therapy since the preferred treatment of an aldosteronoma is adrenalectomy, whereas idiopathic hyperaldosteronism from cortical hyperplasia is treated medically with the aldosterone antagonist spironolactone. Adrenal cross-

sectional imaging with thin-cut (3-mm image slices) computed tomography (CT) is indicated once primary aldosteronism has been confirmed biochemically. Younger patients (under age 40 to 50) with a discrete unilateral macroadenoma (>1 cm) and a normal contralateral adrenal may undergo adrenalectomy without further testing. All other patients should undergo adrenal vein sampling for cortisol and aldosterone to determine if there is a lateralizing source of increased aldosterone production.

Most aldosteronomas are small (≤1 to 2 cm in size), with a golden orange color. These tumors are rarely malignant and can almost always be removed laparoscopically. Spironolactone may be given preoperatively to control hypertension but should not be administered until the biochemical evaluation, including adrenal vein sampling, is complete because it interferes with any subsequent testing including adrenal vein sampling. Patients should also have potassium levels repleted and, in long-standing cases, cardiac function and renal insufficiency should be assessed prior to surgery.

Cushing Syndrome

Cushing syndrome results from excessive cortisol secretion from a variety of pathologic processes that are not controlled by normal regulatory mechanisms. Overproduction of glucocorticoids may lead to development of characteristic features, such as truncal obesity, moon facies, plethora, hirsutism, abdominal striae, acne, and the presence of a “buffalo hump.” One of the most telling features that are distinct from patients with morbid obesity is prominence of the supraclavicular fat pads. Hypertension and diabetes are also commonly present.

Causes of Cushing syndrome can be divided into those that are adrenocorticotropic hormone (ACTH)-dependent and those that are ACTH-independent. Most ACTH-dependent cases are related to Cushing disease (due to excessive pituitary production of ACTH), while other cases may result from ectopic production of ACTH by other tumors. ACTH-independent causes include primary adrenocortical diseases, such as cortisol-producing adenoma, adrenocortical carcinoma, and adrenal hyperplasia. Suspected Cushing syndrome should be evaluated with measurement of 24-hour urine-free cortisol levels. A single-dose dexamethasone test can also be used to screen for Cushing syndrome. In this test, 1 mg of dexamethasone is given at 11:00 PM, and a morning (8:00

AM) cortisol level is obtained. Normal individuals are able to suppress plasma cortisol to <3 μg/dL, whereas patients with Cushing syndrome fail to suppress. Late-night (11:00 PM) salivary cortisol levels are also highly sensitive and specific in screening for Cushing syndrome and are increasingly being used by some groups.

Once Cushing syndrome is confirmed biochemically, plasma ACTH levels should be measured to differentiate ACTH-dependent from ACTH-independent causes. A low plasma ACTH suggests adrenocortical disease and should be evaluated further with CT. Patients with normal or elevated plasma ACTH levels should have pituitary imaging (pituitary magnetic resonance imaging [MRI], inferior petrosal sinus sampling) to evaluate for Cushing disease as the cause and to localize the tumor. Adrenalectomy is the treatment for Cushing syndrome from an adrenocortical tumor. Patients with Cushing disease who fail treatment of the pituitary lesion may benefit from bilateral adrenalectomy. It is important to administer stress doses of steroids to these patients in the preoperative period since they may not be physiologically capable of responding to stress with endogenous glucocorticoids. Patients undergoing bilateral adrenalectomy should also be given replacement mineralocorticoids postoperatively.

Subclinical Cushing Syndrome

Subclinical Cushing syndrome (SCS) is a condition in which there is autonomous secretion of cortisol but without the typical clinical signs of classic Cushing syndrome. SCS is most commonly identified in the setting of an adrenal incidentaloma. Laboratory findings include lack of suppressibility of cortisol secretion with dexamethasone, loss of the diurnal variation in cortisol secretion, low or suppressed plasma ACTH levels, and a blunted response of ACTH to corticotropin-releasing hormone. Elevation of 24-hour urine-free cortisol levels is seen in up to 50% of patients with SCS, but the degree of elevation is usually mild. Although patients with subclinical Cushing have a higher incidence of hypertension, obesity, and diabetes than controls, the natural history is not well characterized. In one study, progression to overt Cushing syndrome at 1-year follow-up was 12.5%. In the only randomized clinical trial to date comparing surgery to nonoperative management in patients with SCS, over the course of 15 years none of the patients managed nonoperatively developed overt Cushing syndrome. However, patients treated with surgical resection had higher rates of resolution or improvement of

diabetes, hypertension, and obesity than those treated nonoperatively, and those treated nonoperatively tended to have stabilization or worsening of their conditions.

Adrenalectomy is indicated for patients with this condition who are an acceptable risk for surgery. SCS is important to recognize in the setting of adrenal incidentaloma as these patients may develop adrenal insufficiency after adrenalectomy if glucocorticoid replacement is not administered.

Pheochromocytoma

Pheochromocytomas are rare tumors that arise from the chromaffin cells of the adrenal medulla. Approximately 10% of tumors in adults (up to 35% in children) arise in extra-adrenal locations, such as the area of the renal hilum, organ of Zuckerkandl, bladder, or rarely elsewhere along the sympathetic chain. While most pheochromocytomas are unilateral and benign, approximately 10% are bilateral in location (seen more commonly in hereditary endocrine syndromes) and up to 10% may be malignant. These tumors secrete excessive catecholamines including epinephrine, norepinephrine, and dopamine. Patients often present with symptoms of episodic spells consisting of headaches, diaphoresis, and palpitations in association with marked hypertension, although in recent years approximately 30% to 40% of pheochromocytomas have presented as incidentalomas.

Screening for pheochromocytoma consists of measurement of either plasma fractionated metanephrines or 24-hour urinary metanephrines and catecholamines (epinephrine, norepinephrine, and dopamine). Indications for screening for pheochromocytoma include refractory or accelerated hypertension, labile hypertension, hypertensive paroxysms during anesthesia or sedation, adrenal incidentaloma, paradoxic hypertension in response to beta-blockers, and familial screening for hereditary endocrinopathies. Patients with biochemical evidence suggestive of pheochromocytoma should undergo cross-sectional imaging. T2-weighted MRI sequences often show a bright appearance of the tumor that is characteristic for pheochromocytoma (adrenal mass/liver image intensity ratio >3.0). ^{123}I-metaiodobenzylguanidine (MIBG) scanning may occasionally be useful in localizing functional, extra-adrenal, or metastatic tumors. ^{123}I-MIBG is not warranted in patients with uncomplicated pheochromocytomas that are localized on CT or MRI, as it is expensive and rarely alters treatment in this setting.

Once the diagnosis of a pheochromocytoma is made, the patient should be placed on alpha-blockade with phenoxybenzamine to control hypertension and dilate the intravascular space and should be instructed to drink ample fluids. Alternatively, patients may be prepared with other selective alpha-1 blocking agents such as prazosin, terazosin, or doxazosin that blocks conversion of tyrosine to dihydroxyphenylalanine (dopa); metyrosine that inhibits catecholamine synthesis; and calcium channel blockers. Beta-blockade may be added if the patient develops tachycardia on phenoxybenzamine or has a predominantly epinephrine-secreting tumor. For further details, see the section on Patient Preparation below.

Adrenocortical Carcinoma

Adrenocortical carcinoma is a rare malignancy with an annual incidence of less than two cases per million individuals. It carries a poor prognosis as many patients (up to 40%) have advanced or metastatic disease at the time of presentation. Adrenocortical cancers are usually large tumors with an average diameter of around 12 cm and may be functional or nonfunctional. Malignancy should be suspected in any adrenal cortical tumor >6 cm in diameter, as the incidence of malignancy increases with increasing tumor size. Nonfunctional tumors may present with abdominal or back pain, weight loss, malaise, or hematuria. A majority of adrenal cancers (approximately 60%) are functional, however, with symptoms of Cushing syndrome, virilization, or both.

Preoperative considerations and preparation are similar to those for other functioning adrenal tumors. CT scanning or MRI is necessary to fully evaluate the extent of disease as well as possible involvement of major vascular structures and regional or distant metastases. Surgical resection remains the only potentially curative treatment.

Adrenal Incidentaloma

The most common adrenal mass encountered by the clinician is the adrenal incidentaloma discovered during abdominal imaging for a non–adrenal-related workup. The incidence of finding an adrenal mass on abdominal CT scanning ranges from 0.4% to 4.4%. The key factors in evaluating an adrenal incidentaloma are to characterize its size, functionality, and risk of malignancy. Functional masses should be removed regardless of size. Nonfunctional tumors 4 to 5 cm or larger (except for myelolipomas) should be removed, as should lesions in which the imaging characteristics

are atypical for an adenoma. The biochemical evaluation of the adrenal incidentaloma should include measurement of plasma fractionated metanephrines to exclude a pheochromocytoma and a single low-dose (1-mg) dexamethasone test to evaluate for subclinical hypercortisolism. Plasma aldosterone and renin levels should be done only if the patient is hypertensive or hypokalemic.

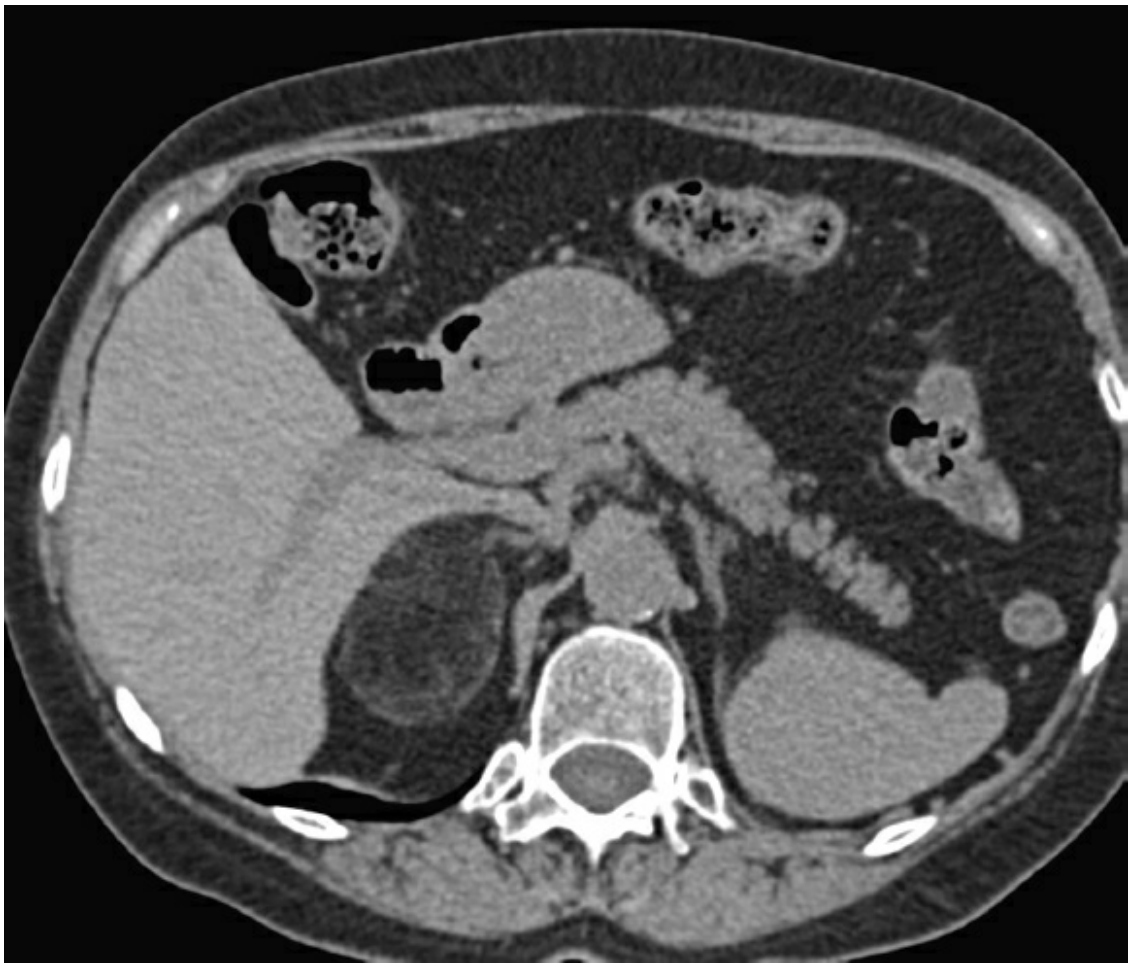

Figure 44.3. The typical radiographic appearance of an adrenal myelolipoma.

The most common adrenal lesion discovered as an incidentaloma is a nonfunctioning cortical adenoma. Adrenal myelolipomas are benign lesions composed of fat and bone marrow elements that can be diagnosed by their typical radiographic appearance (Fig. 44.3). They do not need to be removed unless they are enlarging or become symptomatic, such as from hemorrhage into the lesion. Nonfunctioning tumors <4 to 5 cm should be followed with serial imaging at 4 to 6 months initially and then at 12 months.

Occasionally other primary tumors such as lung cancer, breast cancer, renal cell carcinoma, and melanomas metastasize to the adrenal glands. In addition to CT or MRI, positron emission tomography (PET) should be done in potentially resectable cases to exclude metastatic disease in other sites. Surgical resection may be indicated for selected patients with an isolated adrenal metastasis. Percutaneous biopsy of suspected adrenal metastases should be reserved for patients who are not candidates for surgical resection and in whom the results of biopsy will impact therapy.

PREOPERATIVE PLANNING

Prior to adrenalectomy, patients should have electrolyte abnormalities such as hypokalemia corrected. Hypertension should be controlled medically, and patients with pheochromocytomas should receive 7 to 10 days of preoperative alpha-receptor blockade with phenoxybenzamine to avoid hypertensive exacerbations intraoperatively. Phenoxybenzamine is typically started in a dose of 10 mg twice daily and the dose is increased by 10 to 20 mg/day every 2 to 3 days until the blood pressure is well controlled and the patient is mildly orthostatic. Some patients with symptomatic pheochromocytomas in hypertensive crisis will need to be blocked while in the hospital, but for most patients the blockade can be managed on an outpatient basis. During this time, patients should be instructed to drink ample fluids to allow volume expansion as the alpha-blockade proceeds. Patients who are blocked while in the hospital should have monitoring of orthostatic vital signs and urinary output. A total dose of phenoxybenzamine of 60 to 80 mg/day is sufficient to block most patients. Intraoperatively, patients with vasoactive pheochromocytomas should have continuous blood pressure monitoring via an arterial line. Intraoperative fluid resuscitation is crucial to avoid hypotension after the tumor has been removed.

Patients with Cushing syndrome should receive intravenous steroids perioperatively and will require maintenance doses of steroids for 6 months or longer postoperatively. Mechanical bowel cleansing is not routinely given prior to adrenalectomy.

Indications and Contraindications

The retroperitoneal location of the adrenals makes them accessible via a variety of surgical approaches: transabdominal, retroperitoneal, or through the flank, and using either laparoscopic or open techniques. The choice of

surgical approach in a given patient depends on the size and functionality of the lesion, the degree of exposure needed, the likelihood that the tumor is malignant, and the surgeon's experience (Table 44.3). For most patients with an adrenal tumor, laparoscopic adrenalectomy should be the preferred approach. This approach has been associated with less pain, a shorter hospitalization, faster return to unrestricted activities, and less morbidity than open adrenalectomy. Late complications such as incisional hernia and chronic incisional pain are also less common with the laparoscopic approach.

Currently, the presence of local tumor invasiveness is the only absolute contraindication to laparoscopic adrenalectomy (Table 44.3). Large tumors >8 to 10 cm in size are more difficult to manipulate and remove laparoscopically and are associated with an increased rate of conversion to an open operation. Large pheochromocytomas are often benign and may be resected laparoscopically by highly experienced adrenal surgeons. In contrast, adrenal cortical tumors larger than 6 to 7 cm are likely to be adrenal cortical cancers and should be approached with great caution as some groups have reported higher local recurrence rates after laparoscopic excision. However, since the vast majority of patients with adrenal tumors have lesions that are <6 cm in size and have low malignant potential, open adrenalectomy is not often indicated. Prior major upper abdominal surgery on the planned side of the adrenalectomy, such as previous splenectomy, liver resection, or renal procedures, does not contraindicate a laparoscopic approach but does make the procedure more difficult. Laparoscopic adrenalectomy may also be more difficult in patients with large pheochromocytomas (because of the bulk and vascularity of these tumors) and in patients who have significant obesity, including those with Cushing syndrome.

TABLE 44.3 Indications for Various Surgical Approaches to Adrenalectomy

Laparoscopic

Nonmalignant primary unilateral or bilateral adrenal tumors <8–10 cm in size

Solitary unilateral adrenal metastasis[a]

Small adrenocortical carcinomas[a]

Retroperitoneal Endoscopic[b]

Previous upper abdominal surgery on affected side

Small adrenal tumor ≤5 cm

Bilateral adrenalectomy

Open Anterior

Any tumor with extra-adrenal extension or local invasion

Tumors with suspected regional lymph node metastases

Thoracoabdominal

Large tumor with major vascular invasion (e.g., inferior vena cava) that cannot be controlled intra-abdominally

[a]Controversial; depends on imaging features and laparoscopic surgical experience.
[b]More difficult in high BMI patients (≥35).

SURGICAL TECHNIQUE

The most common approach to laparoscopic adrenalectomy is the transabdominal lateral flank approach described by Gagner in 1992. The other laparoscopic approach that has been used increasingly is the retroperitoneal endoscopic approach. The retroperitoneal approach is the most direct route to the adrenals and avoids entry into the abdominal cavity. However, it has a smaller working space, which can present difficulties in patients with large tumors or significant amounts of retroperitoneal fat. It may also be more difficult to learn and to maintain orientation in the retroperitoneal space. Robotic posterior adrenalectomy has also been reported and may offer some potential advantages of using

wristed instruments for working in such a small space. In experienced hands, it can also be done in less time than a laparoscopic retroperitoneal adrenalectomy, although data on this approach are limited.

The transabdominal lateral flank approach carries several advantages, including good exposure and access to the superior retroperitoneum and a large working space. Because this approach is transperitoneal, the adjacent organs and anatomic landmarks are clearly identifiable even though the patient is in a lateral position.

Open adrenalectomy may be carried out via one of four approaches: anterior transabdominal, dorsal or posterior retroperitoneal, lateral flank, and thoracoabdominal approach. The anterior approach can be performed through a bilateral, subcostal, or midline incision. The benefit of this technique is that it allows for complete exploration of the abdomen and en bloc resection of the adrenal and contiguous structures in patients with large adrenal malignancies. The posterior approach gives more direct access to the adrenals, and although it has been associated with low morbidity, this approach has been completely supplanted by laparoscopic techniques. The flank approach provides reasonable exposure and access to major vessels, but it may be difficult to remove larger tumors or to perform en bloc cancer resections, and is also not commonly utilized. The thoracoabdominal approach provides the greatest exposure for difficult cases and large tumors. However, it potentially carries additional morbidity and increased patient discomfort; it is the rare tumor that cannot be resected via an abdominal incision.

Laparoscopic Adrenalectomy

Patient Positioning and Setup

The patient is placed supine on the operating table on a padded beanbag mattress. A urinary catheter is often used but may be unnecessary for uncomplicated cases and patients with small tumors. The patient is then turned into the lateral decubitus position with the affected side facing upward. The torso, the extremities, all pressure points, and the head are well padded, and the patient is secured with safety straps and the beanbag mattress. The table is then placed in reverse Trendelenburg position to allow abdominal contents to fall away from the upper abdomen and is flexed at the waist to lengthen the space between the costal margin and the iliac crest (Fig. 44.4). It can be helpful to mark the anterior and posterior axillary lines before draping the patient as these landmarks are useful in

determining initial port placement. The patient is prepped and draped with the midline of the abdomen exposed so that conversion to an open procedure can be performed if necessary. Monitors are placed at both sides of the head of the table.

A 5-mm incision is placed somewhat medial to the anterior axillary line, two fingerbreadths below the costal margin. Initial access to create the pneumoperitoneum can be achieved with a closed technique using a Veress needle through this incision or under direct vision via a larger open incision with a Hasson- or balloon-type cannula. Our preference is to use the closed Veress needle technique since open access through the overlapping muscle layers in the flank is more cumbersome. After establishing adequate pneumoperitoneum, a 5-mm optical trocar to directly visualize the insertion is placed at this site. The remaining ports are then placed under direct laparoscopic visualization at 5- to 7-cm intervals across the subcostal and flank region (Fig. 44.5). We generally use four ports for both right and left adrenalectomy, but the left side can be done with only three ports if the operating surgeon is experienced. One 12-mm port is used for insertion of a clip applier and for specimen extraction. The remaining ports can all be 5 mm in size. Additional ports may be added if needed for difficult cases. Care should be taken in determining port placement to allow enough spacing (minimum 5-cm apart) so that the instruments can move without impedance from the other port sites.

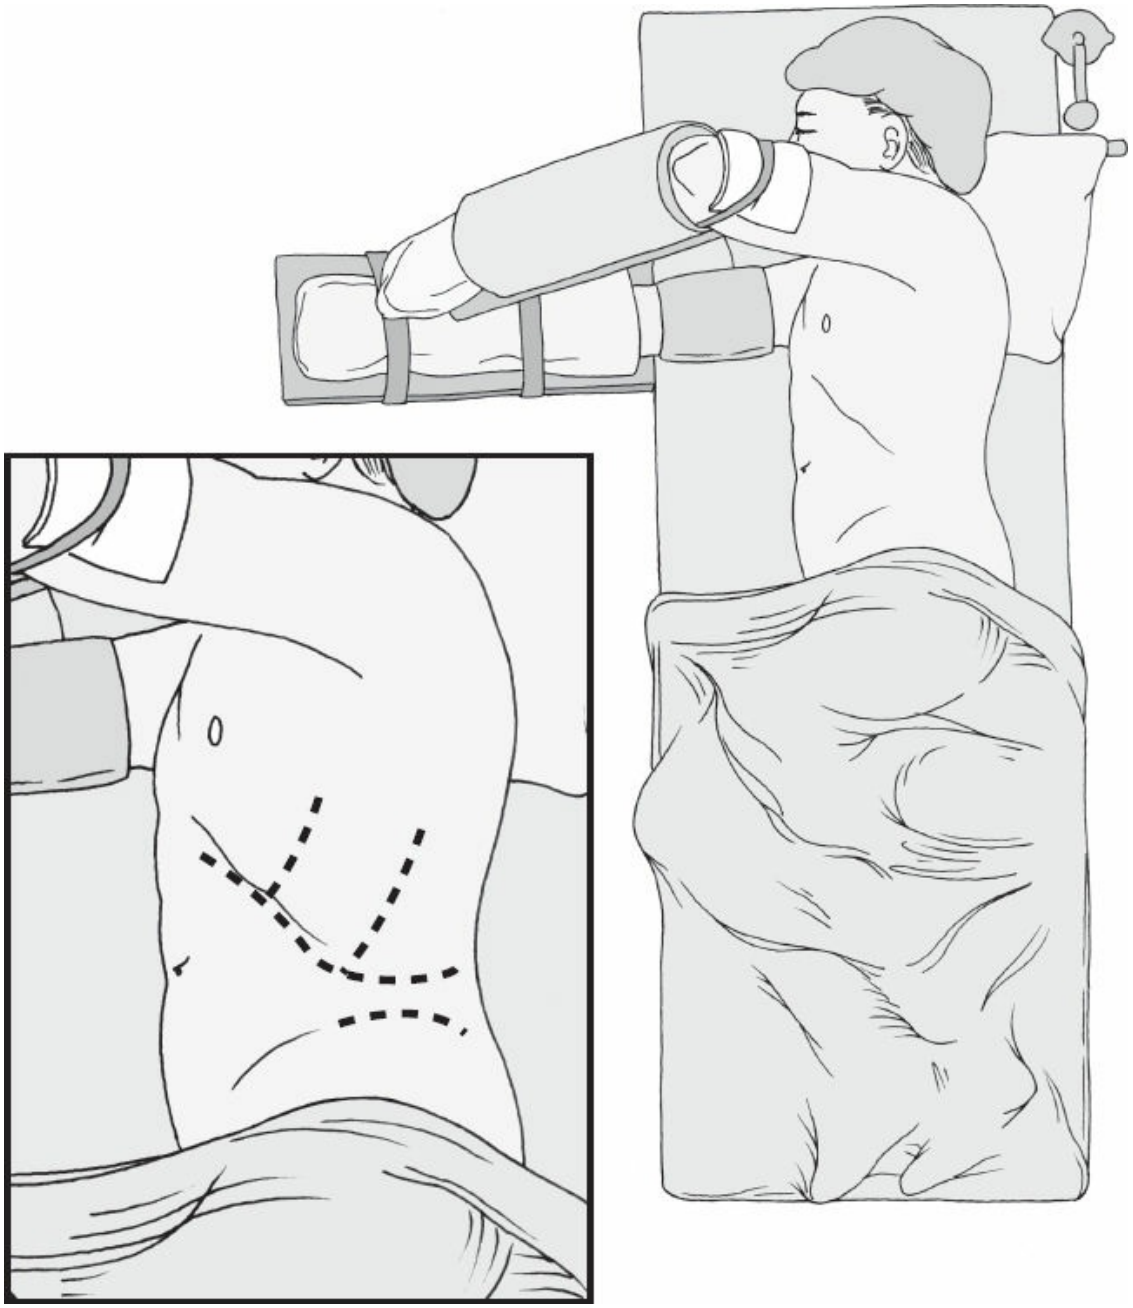

Figure 44.4. Patient position for laparoscopic adrenalectomy, left side.

Right Adrenalectomy

For right adrenalectomy, the patient is placed in the lateral decubitus position with the right side upward. The surgeon stands facing the patient's back (right side of the table), and the assistant and laparoscopic camera operator stand on the opposite side of the table. The sequential steps in the dissection are illustrated in Figure 44.6. After placement of all laparoscopic ports, the liver is first mobilized by incising the right triangular ligament. The hepatic flexure of the colon does not typically

need to be mobilized or retracted. It is key that the entire length of the triangular ligament be divided from the inferior border of the liver all the way to the diaphragm.

Once the liver has been mobilized, it is retracted medially with a 5-mm instrument placed through the most medial port. The adrenal gland and IVC should be visible at this point in the dissection (Fig. 44.6). The plane between the adrenal and IVC is then developed by incising the overlying peritoneum at the lateral border of the vena cava with an L-hook electrosurgical instrument. After identification of the gland, it is gently dissected away from the vena cava beginning along the medial border of the adrenal and continuing superiorly and inferiorly. Most of the arterial branches that enter the superior, medial, and inferior aspects of the adrenal are small and can be divided with monopolar electrosurgery, but there are often two or three larger branches that should be clipped. Alternatively, these vessels along with the remaining attachments can be taken with an ultrasonic or bipolar coagulating device.

The right adrenal vein is usually identifiable early in the dissection and is typically located at about the midportion of the adrenal; it enters the posterolateral aspect of the IVC. This vein should be carefully isolated with blunt dissection with a right-angle instrument and should be doubly ligated with clips. Alternatively, if the vein is large or if the tumor encroaches on it, a vascular stapler can be used to divide the vein taking the lateral “shoulder” of the IVC. Excessive traction on the adrenal vein is to be avoided as it may tear along the vena cava with resultant brisk hemorrhage. If there is major or uncontrolled bleeding from the vena cava, the patient should be immediately converted to an open procedure. Once the vein has been ligated and divided, the adrenal can be retracted away from the vena cava and all remaining medial attachments and small vessels can be divided. At this point, the diaphragm should be visible posteriorly and the dissection should stay on top of that plane. The dissection then continues along the inferomedial border of the adrenal and out laterally along the superior pole of the kidney. Some arterial branches are encountered here that may require ligation with clips or an advanced energy device. The dissection should not extend too low into the area of the renal hilum because of the risk of injuring a superior polar renal artery. Finally, the relatively avascular posterior and lateral attachments are divided.

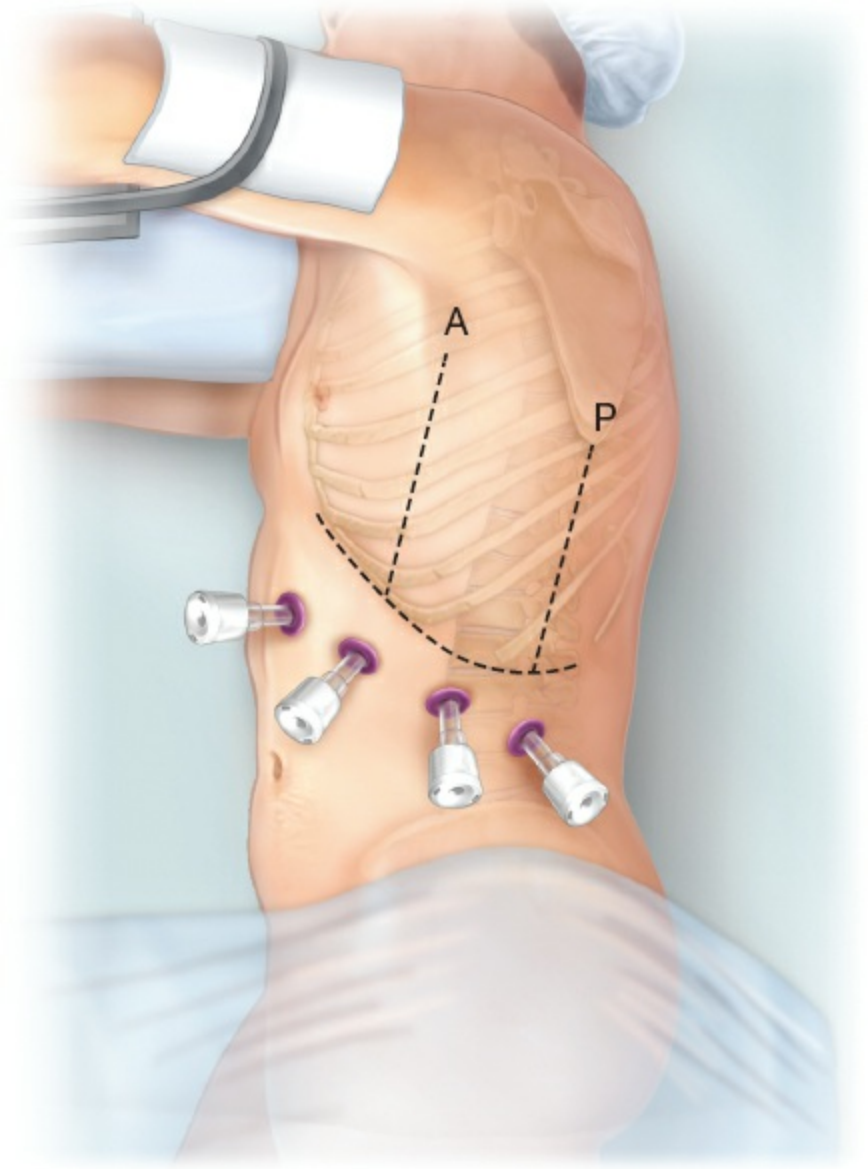

Figure 44.5. Port site placement for laparoscopic left adrenalectomy. The *dashed lines* indicate the anterior and posterior axillary lines and costal margin. The initial Veress needle access is usually achieved just medial to the anterior axillary line about two fingerbreadths below the costal margin. In most cases, a fourth port placed medial to the anterior axillary line is also used. A, anterior axillary line; P, posterior axillary line.

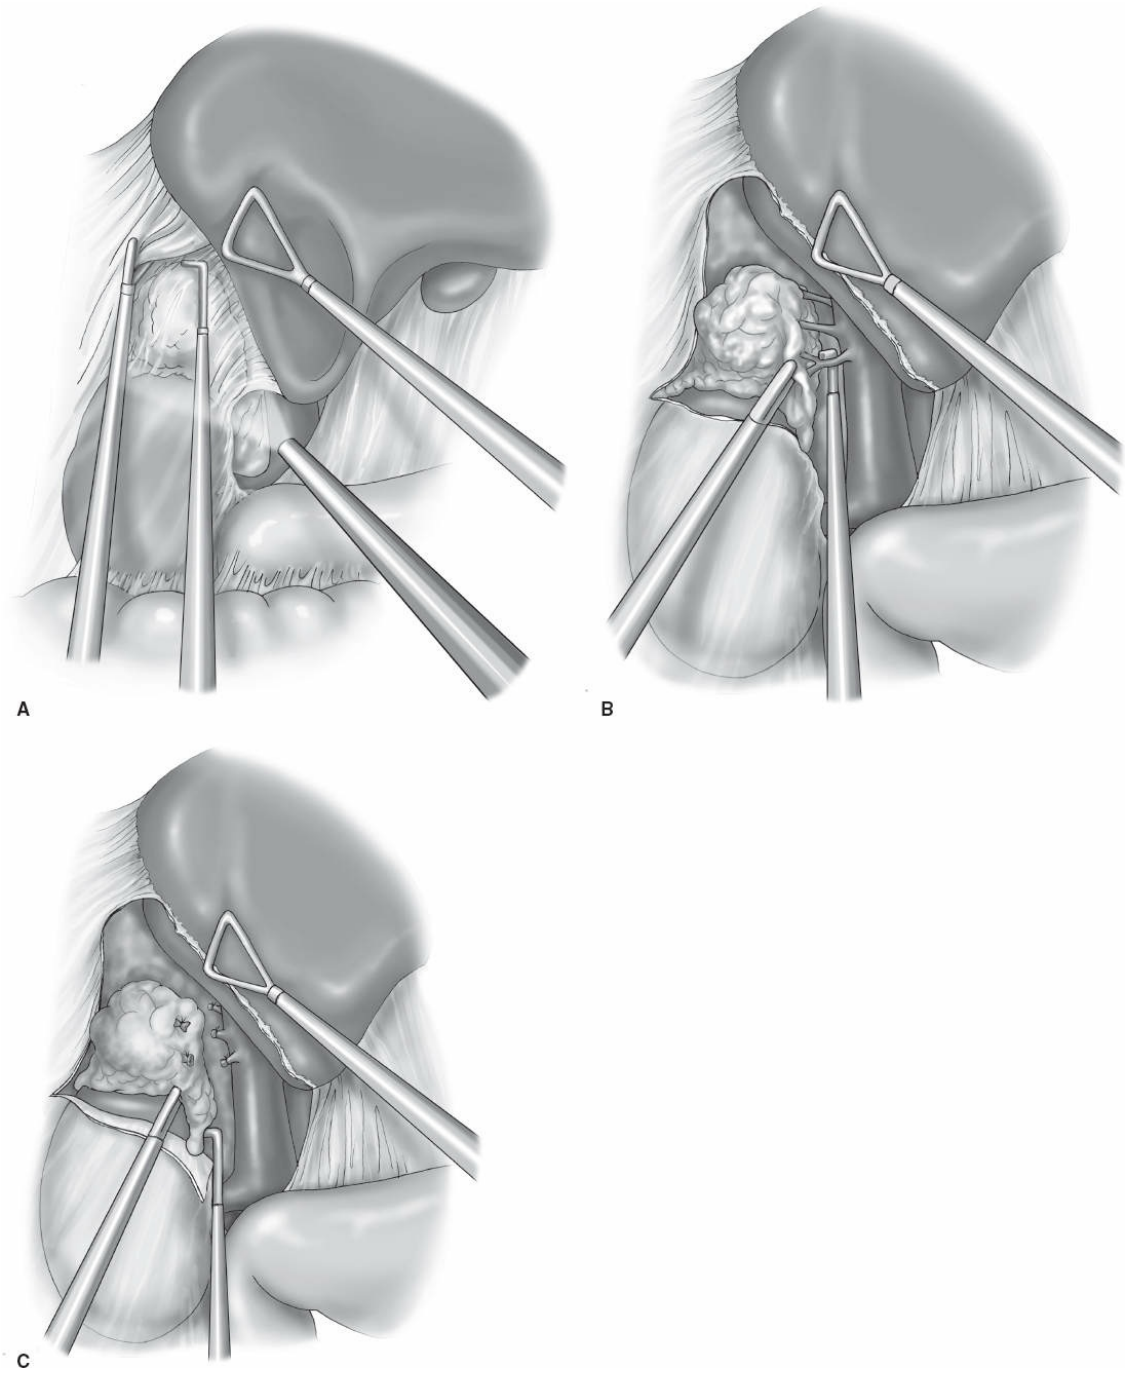

Figure 44.6. Sequential steps in laparoscopic right adrenalectomy. **A.** Mobilization of the right triangular ligament of the liver. A hook cautery is used to divide this ligament. **B.** Dissection of the plane between the adrenal and vena cava. The adrenal vein is ligated with clips and divided. **C.** Dissection of the inferior and posterior attachments of the adrenal. Note the exposure of the superior pole of the kidney.

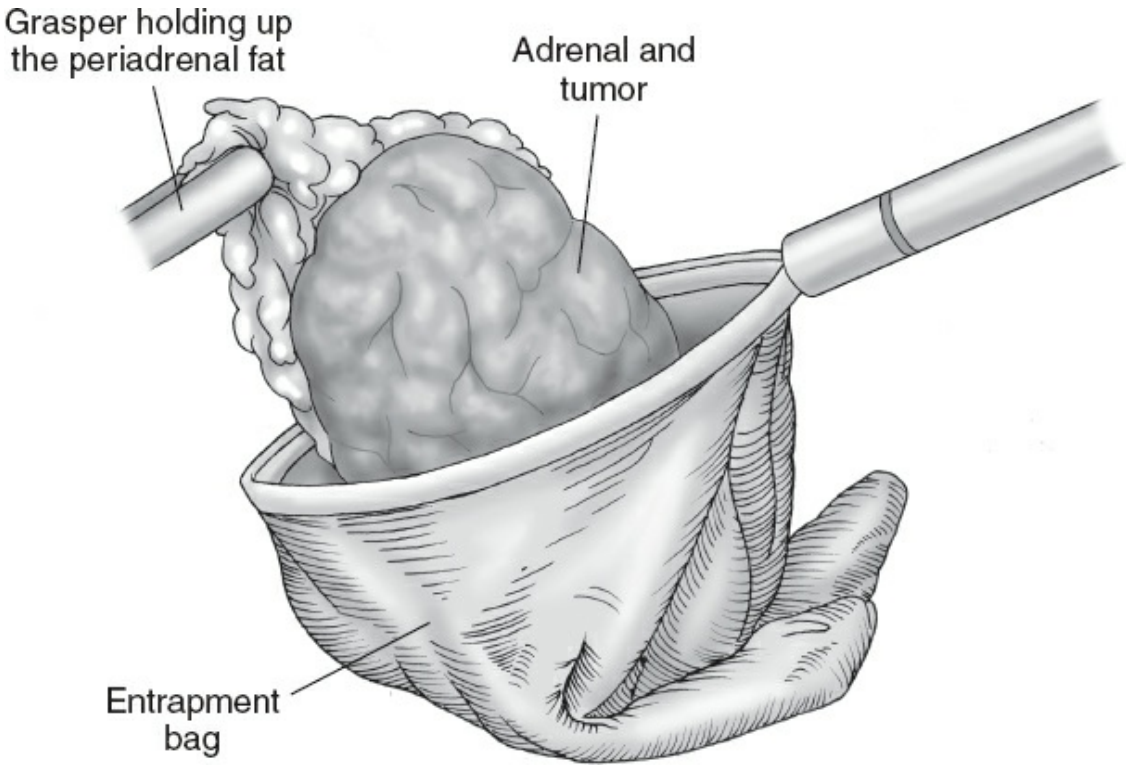

Figure 44.7. Specimen removal. The adrenal is placed in a secure entrapment bag for removal.

Care should be taken throughout the dissection to handle the adrenal and surrounding tissue in a gentle fashion, as aggressive retraction and blunt dissection can lead to bleeding or trauma to the adrenal gland or tumor with risk of tumor spillage. Direct grasping of the adrenal and tumor should also be avoided, but one can grasp the peri-adrenal fat and use that to elevate and move the gland around. Minimizing any retraction or pressure on the tumor may also serve to limit the release of catecholamines by a pheochromocytoma. Meticulous hemostasis is important to prevent blood from obscuring the visual field of dissection. Once the gland is free, it is placed into an impermeable bag for removal from the abdomen, and the retroperitoneum (Fig. 44.7) is irrigated and inspected for hemostasis and for security of the clipped vein pedicle on the vena cava. The gland is then removed at the 12-mm port incision, which usually will need to be enlarged somewhat. For large pheochromocytomas and other large noncortical tumors, the specimen may be morcellated within the entrapment bag to facilitate extraction. However, it is preferable to extract most cortical tumors and metastases intact for complete pathologic assessment. Finally, after the specimen is out, the abdomen is reinflated and the operative bed is reinspected. The extraction site is then closed in

two layers of 0-gauge absorbable suture for the fascia and an absorbable subcuticular layer or tissue glue for the skin. Steri-strip tapes are sufficient to approximate the other incision sites.

Left Adrenalectomy

For left adrenalectomy, the patient is placed in the lateral decubitus position with the left side facing upward. The surgeon and camera operator both stand on the side of the table facing the patient's abdomen and the assistant stands on the opposite side. The landmarks used for port placement are the same as for the right side. The key steps in left adrenalectomy are illustrated in Figure 44.8. After port placement, the splenic flexure of the colon is taken down from its lateral reflection to the inferior pole of the spleen to allow it to fall away inferiorly. The majority of the dissection is done with an advanced bipolar energy device, but an ultrasonic coagulator or electrosurgical scissors can be used alternatively. It is usually necessary to mobilize the splenic flexure before the most dorsal fourth port is placed. The length of the splenorenal ligament can then be divided to the diaphragm. This allows the spleen to be rotated medially with gravity using minimal retraction. A key step at this stage is to develop the plane between the tail of the pancreas and the left kidney using blunt dissection and cautery or an ultrasonic coagulator. The splenic artery and vein should be visible at this point as should the salmon-colored pancreas to the left side of the operative field (Fig. 44.9). This maneuver should lead directly to the adrenal gland, which is found in the perinephric fat in close proximity to the superior pole of the kidney, just superior and lateral to the pancreas and splenic vessels and cephalad to the renal vessels. It is important to positively identify the pancreas at this stage in order to avoid mistaking it for the adrenal.

In patients with small tumors or with large amounts of retroperitoneal fat, the left adrenal can sometimes be difficult to find. In such cases, laparoscopic ultrasound can be useful to image the adrenal and to identify its relationship to the kidney and renal vessels. The dissection starts along the medial and lateral borders to define those limits of the adrenal and then progresses inferiorly to locate the adrenal vein (Fig. 44.8C). On the left side, arterial branches enter the gland at the lateral–inferior aspect along the superior pole of the kidney, and also medially. The inferior border of the adrenal often sits adjacent to the renal vein and should be carefully dissected away from that structure. It is helpful to use the electrosurgical L-hook instrument for this part of the dissection because it allows

elevation and division of small amounts of tissue. The left adrenal vein courses along the inferomedial aspect of the gland to drain into the left renal vein and should be doubly ligated. The inferior phrenic vein empties into the adrenal vein just above this and may need to be ligated separately. Once the vein has been divided, the inferior border of the gland is elevated and the posterior attachments and remaining lateral and superior attachments are divided with advanced bipolar energy or an ultrasonic coagulator. Care must be taken to avoid injury to the superior pole renal arterial branches, which run cephalad to the renal vein and at the lateral aspect of the adrenal. The gland is then placed in an impermeable sac and removed as described for right adrenalectomy.

Hand-Assisted Laparoscopic Adrenalectomy

A hand-assisted laparoscopic approach to adrenalectomy may be considered for cases of large tumors or those in which there are intraoperative difficulties such as bleeding or failure to progress with the laparoscopic dissection. Access for hand port placement is usually carried out in the subcostal region or upper midline medial to the other ports. The hand port often replaces the most medial 5-mm port depending on where the incision is located. Although experience with this technique in patients with adrenal tumors is limited, its use in difficult splenectomy cases suggests that it may be of value in selected cases of adrenalectomy. Another benefit of this approach is that it greatly facilitates extraction of larger tumor specimens.

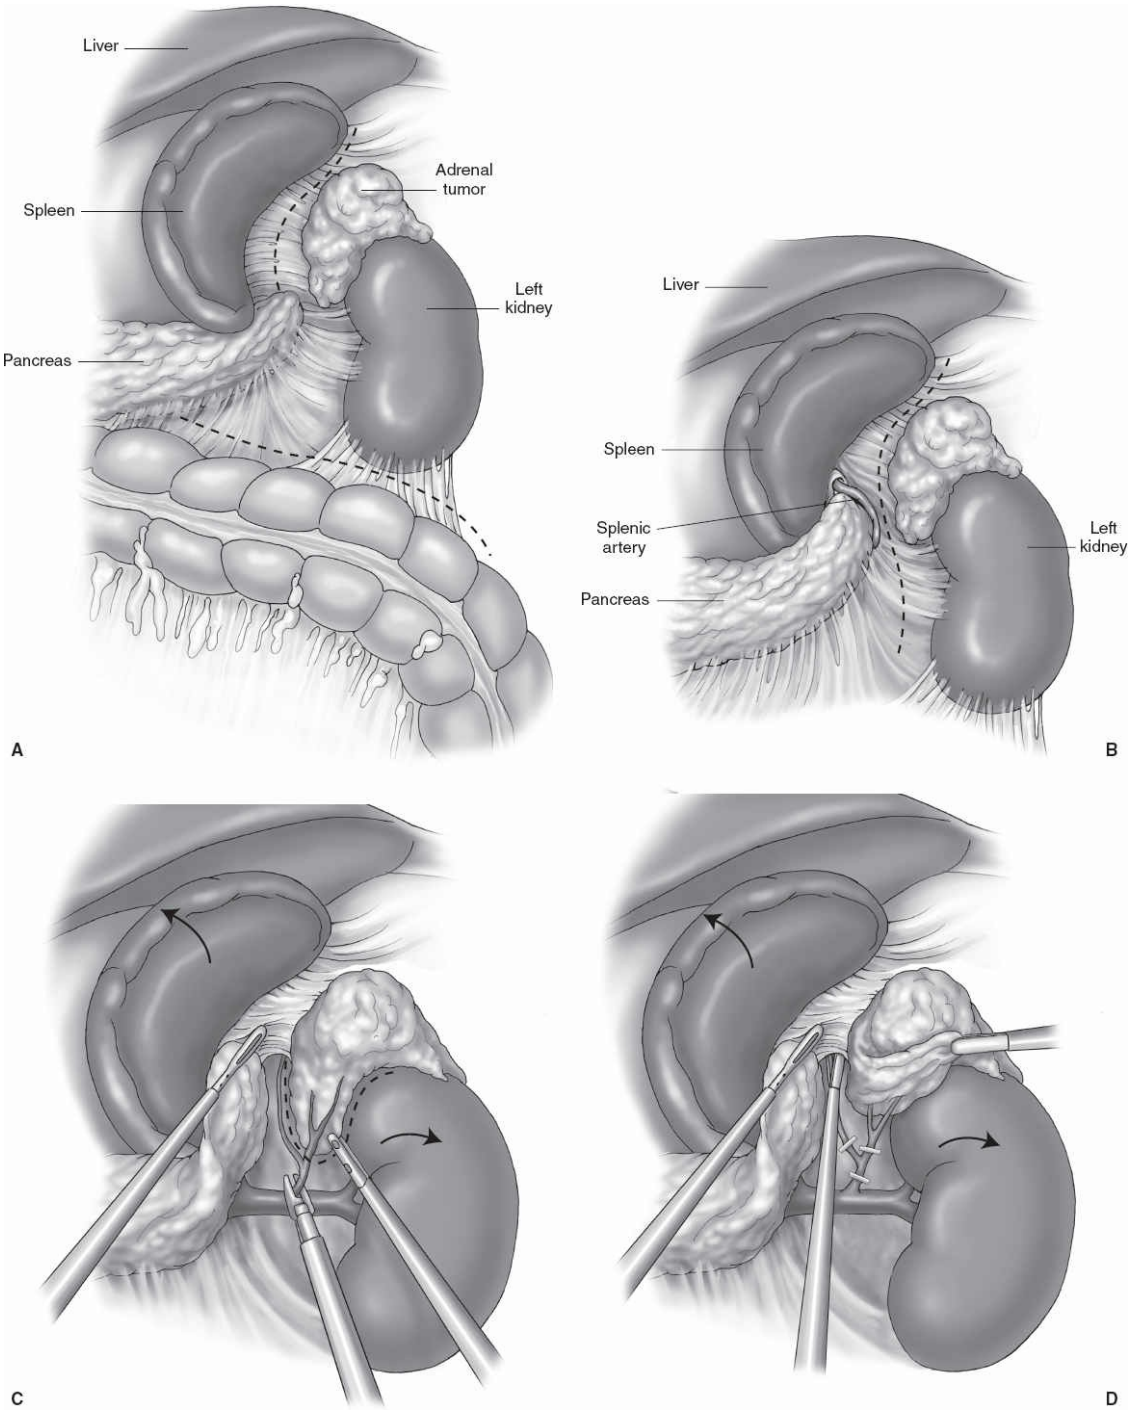

Figure 44.8. Sequential steps in laparoscopic left adrenalectomy. **A.** The splenic flexure of the colon is taken down, and the splenorenal ligament is divided (*dashed line*). **B.** The plane between the tail of the pancreas and kidney is developed to expose the adrenal gland. **C.** The medial, inferior, and lateral borders of the adrenal are dissected to expose the adrenal vein, which is clipped and divided. **D.** The posterior and superior attachments are divided to free the gland.

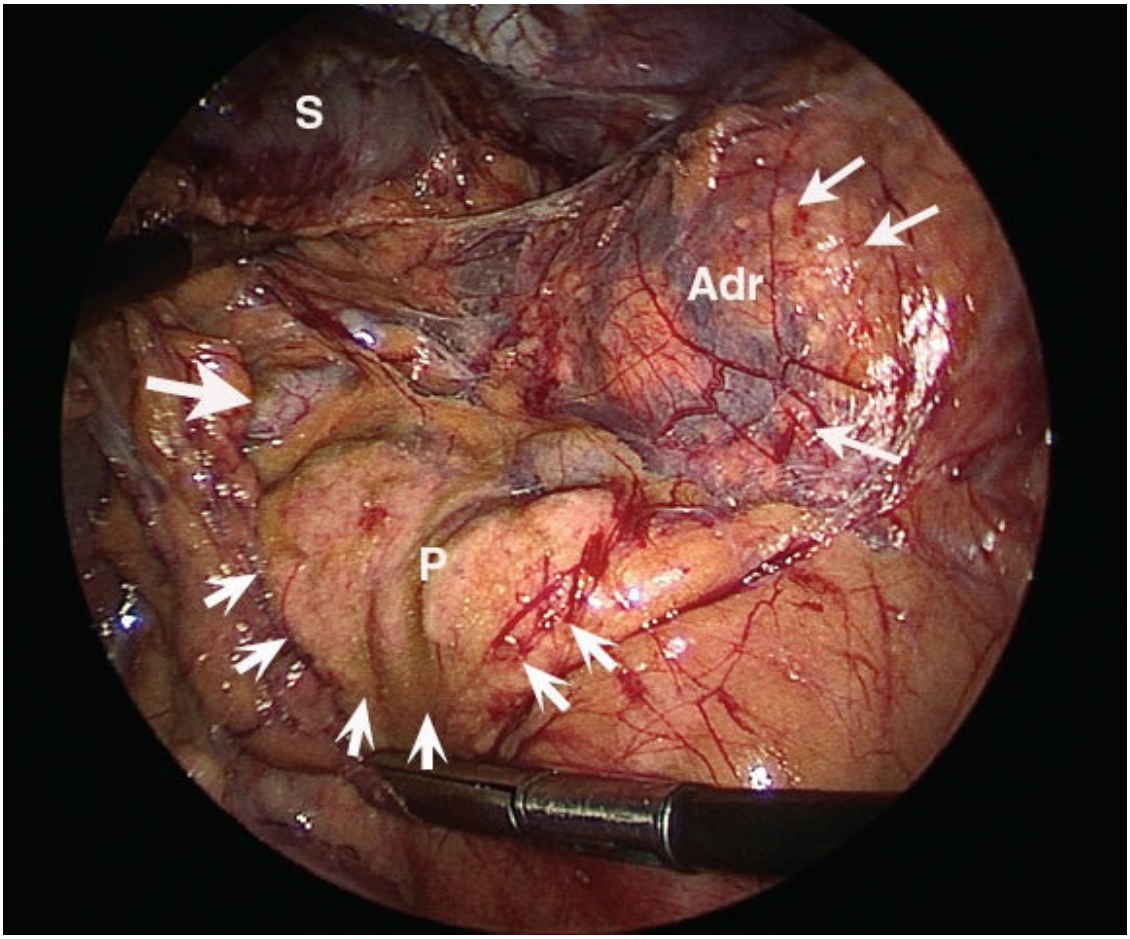

Figure 44.9. Operative photograph that demonstrates the relationships between the spleen (S), splenic artery (*large single arrow*), tail of pancreas (P and *arrows*), and left adrenal gland (Adr and *smaller arrows*) is shown.

Retroperitoneal Endoscopic Approach

The retroperitoneal approach to adrenalectomy is the most direct route to the adrenal glands and is becoming more popular for a number of reasons. Its advantages include avoiding intraperitoneal adhesions from prior operations, eliminating manipulation or retraction of intra-abdominal organs, and diminished bleeding due to the higher CO_2 pressures used. With experience, this approach can result in faster operating times; Walz has reported 560 adrenalectomies with this technique with average operating times of only 67 minutes. With the prone position, bilateral adrenalectomy can be performed without the need to reposition the patient between sides. The disadvantage of this approach includes a smaller working space, which makes removal of tumors >5 cm more difficult; also, the working space can be compromised if the peritoneum is opened. In addition, this approach can be more difficult to learn initially because

the anatomic landmarks and orientation are unfamiliar to most abdominal surgeons.

The retroperitoneal approach is carried out with the patient in a prone jack-knife position, although a lateral decubitus approach has also been described. In the prone jack-knife position, the patient is lying on a rectangular support, which allows the abdominal wall to hang freely to open up the retroperitoneal space (Fig. 44.10). Initial access to the retroperitoneal space is by direct visualization just below the tip of the 12th rib. The incision is extended through the muscle layers by blunt dissection with scissors into the retroperitoneal space, and this space is further developed with blunt finger dissection. A second trocar is placed under direct finger guidance 4 to 5 cm laterally below the 11th rib and a third trocar is placed 5 cm medially to the first port about 3 cm below the 12th rib (Fig. 44.10). A blunt balloon-tipped trocar is used at the open insertion site and the other ports may be 5 mm in size. Pneumoretroperitoneum of 20 to 25 mmHg is achieved, which increases the working space and decreases bleeding. The retroperitoneal fat beneath the diaphragm is pushed down bluntly to expose the upper pole of the kidney. The dissection should proceed lateral to medially to expose the adrenal gland. Laparoscopic ultrasonography can be used if there is difficulty locating the kidney and adrenal, but with experience, this is rarely necessary. The diaphragmatic and medial arterial branches are ligated with a bipolar energy device (or ultrasonic coagulator) as encountered during dissection. For right adrenalectomy, the vena cava is identified and dissected off the adrenal to expose the adrenal vein, which is ligated. For left adrenalectomy, the adrenal is elevated to expose the inferomedial aspect of the gland where the vein is identified and ligated. One should keep in mind that the orientation of the surgeon to the major vessels and the adrenal vein relative to the tumor is reversed compared with the conventional anterior approach (i.e., the right adrenal vein will be coming off the surgeon's left-handed view of the adrenal to enter the posterolateral vena cava). After the vein is taken, the adrenal gland is retracted caudally and the remaining attachments are divided. The gland is extracted and the incisions closed in the usual manner.

Open Adrenalectomy

Anterior Approach

Open adrenalectomy is most commonly carried out using an extended

subcostal incision. This incision can also be extended cephalad in the midline up to the xiphoid to allow better exposure for mobilization of the liver and other upper abdominal viscera, which is often necessary for very large (>10 cm) or invasive tumors. This incision also provides the exposure needed to perform periaortic lymph node dissection and en bloc resection of contiguous structures in patients with adrenocortical carcinoma. Exposure for this approach for right adrenalectomy may be facilitated by elevating the right flank somewhat and by placing a roll under the right side (Fig. 44.11). A midline incision is an option for the rare patient who requires bilateral open adrenalectomy.

Figure 44.10. Patient position and port site placement for the retroperitoneal approach to adrenalectomy.

After entering the abdomen, the liver and peritoneal surfaces are inspected for the presence of metastatic disease. On the right side, the liver is fully mobilized by dividing the triangular ligament as for the laparoscopic approach. With a large tumor, it may be necessary to mobilize the hepatic flexure of the colon and retract it inferiorly. The duodenum is also mobilized using a Kocher maneuver to expose the IVC (Fig. 44.11B). Inferior traction on the kidney exposes the adrenal gland. The dissection begins medially to develop the plane between the tumor

and the vena cava and to assess resectability. Periaortic lymph nodes should be assessed for involvement as well. The right adrenal vein is ligated, and the tumor is dissected away from the vena cava. A portion of the lateral wall of the vena cava may be taken along with the tumor if it appears involved. Once the medial side of the adrenal and the tumor are free, the dissection proceeds as described for the laparoscopic approach. For adrenocortical carcinomas that have invaded the kidney or liver, it may be necessary to perform an en bloc resection of the tumor along with these structures.

On the left side, the open operative approach is as described for the laparoscopic technique. The splenic flexure of the colon is mobilized from its attachments and the splenorenal ligament is divided. The tail of the pancreas and spleen are together reflected medially to expose the adrenal (Fig. 44.11C). If the spleen and pancreas cannot be mobilized away from the adrenal because of tumor involvement, then the lesser sac should be opened and the pancreas and splenic hilum accessed anteriorly. Large malignant tumors on the left may require en bloc resection of the spleen, tail of the pancreas, and even the kidney. These tumors should be removed along with a generous margin of retroperitoneal fat and Gerota fascia. In cases of primary adrenal cortical malignancies, periaortic lymph nodes medial to the adrenal should be removed along with the tumor.

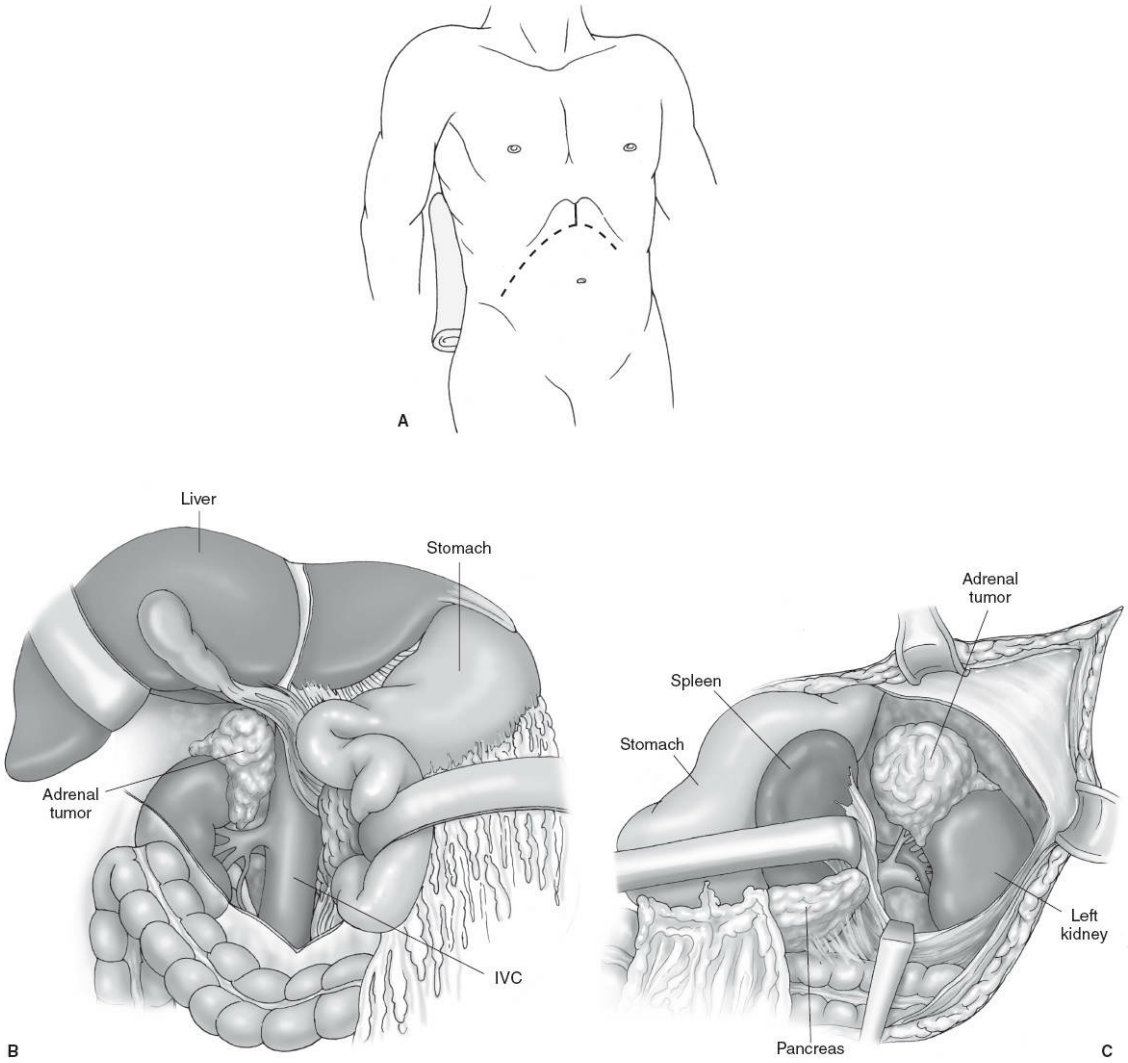

Figure 44.11. Incision and exposure for open adrenalectomy. **A.** Incision location. The incision can be extended into a bilateral subcostal incision or superiorly in the midline to improve exposure. **B.** Exposure for right adrenalectomy. **C.** Exposure for left adrenalectomy. IVC, inferior vena cava. (**B, C:** Modified from Scott HW Jr. Anatomy of the adrenal glands and bilateral adrenalectomy. In: Nyhus LM, Baker RJ, eds. *Mastery of Surgery*. Boston, MA: Little, Brown and Co.; 1992:1374.)

Posterior Approach

The posterior approach is rarely used today because there are fewer patients in whom this approach would be indicated who are not also candidates for laparoscopic adrenalectomy.

In the past, this approach was used primarily for bilateral adrenalectomy for Cushing disease or for small unilateral tumors. The patient is placed prone on two chest rolls with a pillow or roll under the hips and pillows under the legs and the table is flexed. A hockey stick–

shaped incision is made from the 10th rib extending first inferiorly and then laterally to the iliac crest (Fig. 44.12). The latissimus dorsi muscle is divided and the 12th rib is resected, preserving the intercostal nerve. Next the diaphragm with the pleura along its superior surface is exposed. The pleura is dissected off the diaphragm and reflected superiorly and the diaphragm is incised to expose the Gerota fascia. The adrenal gland is exposed by bluntly reflecting the fat away and retracting the kidney inferiorly. The remainder of the dissection is then as previously described for the endoscopic retroperitoneal approach. Once the adrenal is free, the wound is closed in layers with absorbable sutures, with care to avoid the neurovascular bundles of the ribs. If a pleural opening is created during the dissection, it can be treated by closing the incision over a small red rubber catheter placed in the pleural space and removing the tube as positive pressure ventilation is delivered after the space has been closed. A chest radiograph is obtained postoperatively to ensure that there is no residual pneumothorax.

Thoracoabdominal Approach

The thoracoabdominal approach is reserved for advanced adrenal malignancy with major vessel involvement (e.g., IVC) that requires exposure of the supradiaphragmatic vena cava. The options for access to the chest are to extend the bilateral subcostal incision in the midline into a median sternotomy or to make a classic thoracoabdominal incision. For the latter, the patient is placed supine and a roll is placed under the thorax to be incised. Either a midline or subcostal abdominal incision can be carried onto the chest for this approach. The thoracic portion of the incision is made along the 9th or 10th rib. The costal margin is divided and a portion of the costal cartilage is excised to prevent the costal margin edges from rubbing together after the incision is closed. The chest is entered through the 8th or 9th interspace, and the diaphragm is incised as the lung is retracted superiorly. Exposure of the vena cava above and below the tumor as well as the hepatic veins should be carried out. The dissection then proceeds as described above.

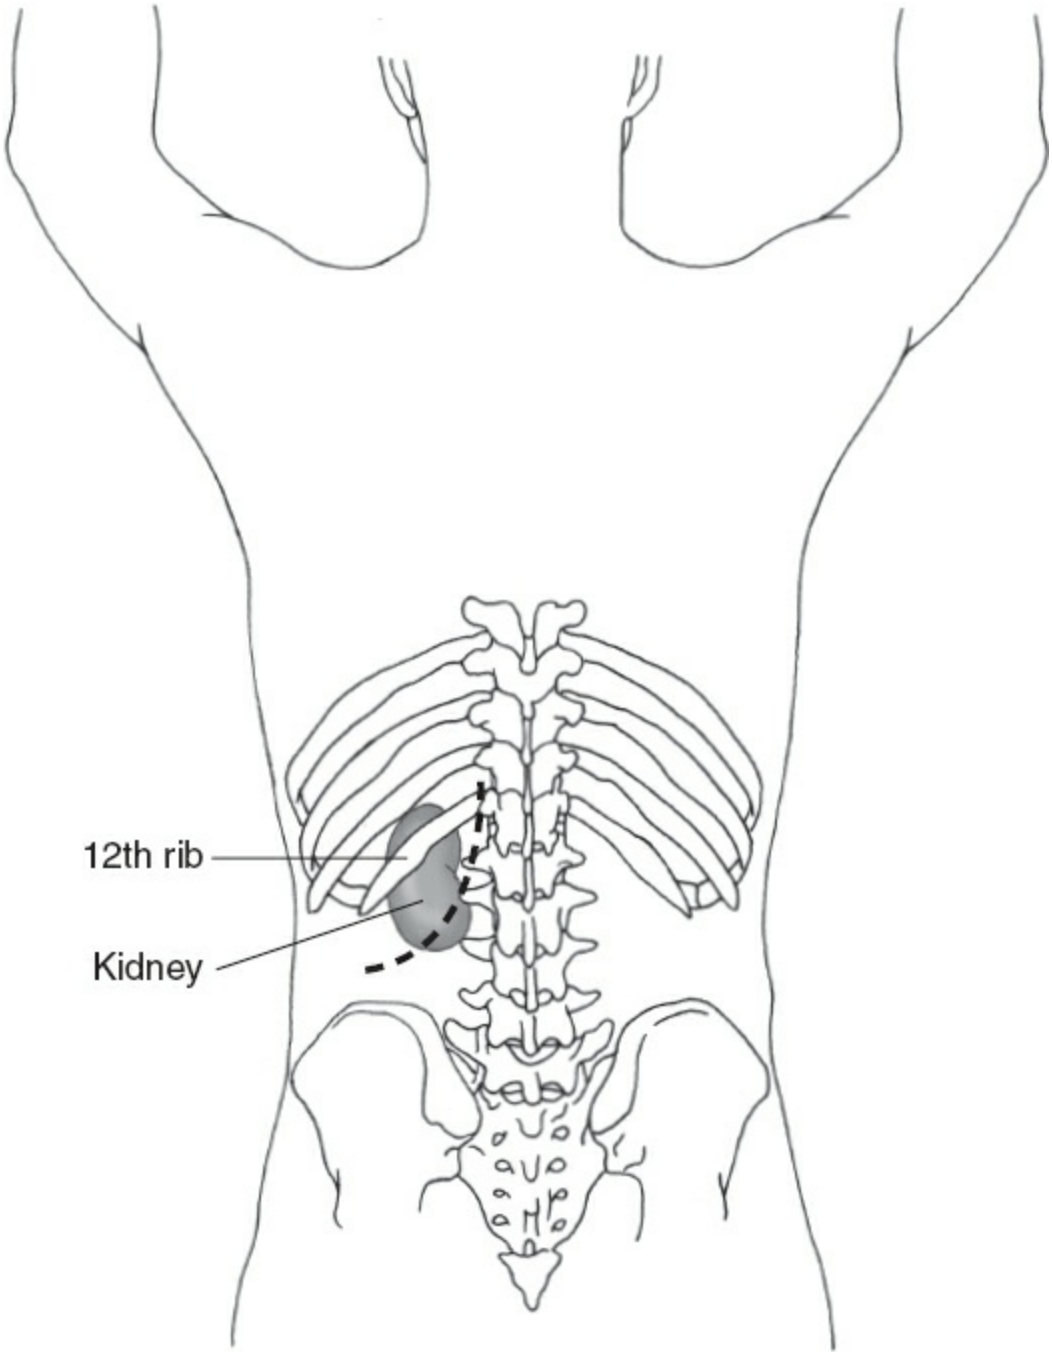

Figure 44.12. Schematic of incision for open posterior adrenalectomy.

POSTOPERATIVE CARE

A principal benefit of the laparoscopic approach compared with open adrenalectomy has been a reduction in the incidence of adrenalectomy-related complications. This lower complication rate has primarily been a result of fewer wound, pulmonary, and infectious complications with the laparoscopic approach. Although several complications can occur as a result of adrenalectomy, many of these can be avoided with careful

dissection principles, good hemostasis, and thorough knowledge of the surgical anatomy in this region. The most common operative complication is hemorrhage, which can occur from the adrenal vein, small arteries to the adrenal, the adrenal gland or tumor, hepatic veins, renal vessels, and the IVC or adjacent solid organs (spleen, pancreas, kidney, liver). Bleeding has also been the most common reason for conversion from the laparoscopic approach to open adrenalectomy. Minor bleeding during the procedure can usually be managed with tamponade of the area and then direct control of the bleeding site with an energy device or clips. Prompt conversion to an open procedure should be carried out if the bleeding is from a major vessel that cannot be immediately controlled. In addition to hemorrhage, vascular occlusion can also occur by inadvertent ligation of a renal artery branch or other visceral vessels. Other organs and structures in the vicinity of the dissection that may be injured (e.g., by electrosurgery) include the colon, spleen, pancreas, liver, stomach, kidney, and ureter, and these should be inspected carefully prior to closure. If there is any concern that the pancreatic parenchyma has been injured, a closed-suction drain should be placed. The diaphragm and pleura can also be injured with any of the various approaches, although this complication is less common with the laparoscopic approach.

The patient with a pheochromocytoma is at risk for intraoperative hypertensive crisis and arrhythmias if there has not been adequate preparation pharmacologically for surgery. Patients with an adrenal tumor causing Cushing syndrome should receive glucocorticoids as a stress dose in the perioperative period, which can then be tapered to an oral maintenance steroid dose until their hypothalamic–pituitary–adrenal axis has recovered, which may take up to 12 to 18 months. Patients undergoing bilateral adrenalectomy will require lifelong supplementation with both glucocorticoid and mineralocorticoid replacement.

Following resection of a pheochromocytoma, additional intravenous fluids may be required postoperatively due to intravascular volume expansion from phenoxybenzamine. These patients may also become hypoglycemic postoperatively due to loss of inhibition of insulin secretion by high levels of circulating catecholamines. Plasma-fractionated metanephrines or 24-hour urinary catecholamine levels should be checked at follow-up and on a yearly basis to evaluate for recurrence. Close follow-up is also required for patients with adrenocortical malignancy including periodic measurement of hormone levels and imaging with CT or MRI.

Local recurrences or solitary metastases may be treated with surgical resection in select cases.

Patients undergoing laparoscopic adrenalectomy usually require minimal parenteral analgesia and are often on oral pain medication on the first postoperative day, whereas patients undergoing an open procedure have a greater parenteral analgesia requirement often lasting more than 48 hours. Laparoscopic patients are started on a liquid diet early postoperatively and often can be discharged within 24 hours unless a longer period of observation is needed for blood pressure management or hormone replacement. Most patients can return to unrestricted activity within 7 to 10 days of operation.

EDITOR'S COMMENT

The authors have made a nice outline of how to handle varied scenarios of known diseases and syndromes. Because of the frequent use or overuse of computerized tomography (CT) and positron emission tomography (PET) scans, the incidental finding of adrenal masses of unknown etiology has become all too frequent. These are the so-called incidentalomas, and this occurs about 4% of the time being less common in the younger than older patient (1% to 10%). Nonendocrine surgeons frequently have to deal with these as a part of their regular practice. The differential diagnosis requires a working knowledge of possible syndromes, their pathophysiology and biochemistry, and associated abnormalities. Bilateral cases occur about 10% of the time but are more common with genetic syndromes.

In my oncology practice, CTs are common place in the metastatic work-up. As with any patient, a thorough history and physical examination are the key to determining the origin of an adrenal mass(es) focusing on uncontrolled hypertensive and/or flushing episodes, a history of tachycardia, virilization or feminization, and pain. The presentation could be one of metastatic disease versus a functioning or nonfunctioning adrenal tumor. Pain and virilization are more often than not associated with malignancy where constitutional symptoms may be a sign of a functioning adrenal tumor. Even in the presence of a tumor, e.g., breast cancer, a functioning adrenal tumor must be ruled out. Serum metanephrines, cortisol, aldosterone, and renin (in presence of hypertension) are the initial biochemical tests. Often, however, these may come back high but in an equivocal range. In the setting of neoadjuvant chemotherapy, the surgeon cannot be sure what that means. If equivocal, then the next biochemical test would be 24-hour urine metanephrines.

CT scans can help elucidate the possibility of malignancy, size, and invasion into contiguous structures and possibility for resection. Pheochromocytomas have distinctive washout characteristics from intravenous contrast on fine-cut multi-phase CTs and require special alpha-blockade prior to any surgery. About 20% of pheochromocytomas will have intralesional calcifications. Pheochromocytomas also require work-up for associated tumors and genetic

mutations. Size makes a difference as well. Four centimeters is the cut-off because >4 cm has a proportional increased risk of malignancy. A nonfunctioning incidentaloma <4 cm in size with a Hounsfield unit (HU) of <10 and/or intralesional fat needs to be watched with serial CTs for growth but is almost never malignant. A HU >10 in a nonfunctional incidentaloma but with a washout >50% is also going to benign. Chemical shift magnetic resonance can also confirm malignancy with a sensitivity of >80% and a specificity of >90%. PET scans often the source of identification of incidentalomas should not be relied on to rule out malignancy as they have a false negative rate of >10%. Needle biopsy of an adrenal mass should only be performed for a nonfunctioning mass that is highly suspicious for metastatic disease. Primary adrenal tumors and benign adrenal cells are indistinguishable under the microscope when obtained by fine need aspiration and therefore should be avoided. Metastatic lesions to the adrenal should be referred back to the medical oncologists for appropriate treatment. Primary adrenal cancer can be suggested by local invasion or when presenting as distant metastases. In addition, bilateral nonfunctioning adrenal tumors should prompt consideration of hemorrhage (especially with associated pain), lymphoma, infection, and amyloidosis.

Nonfunctioning benign tumors need to be followed long term as up to 47% will become hormonally active within a 5-year period and 29% of cases will demonstrate worrisome imaging growth or characteristics requiring investigation for carcinoma. Recommendations are for yearly biochemical follow-up for a period of 5 years. Repeat imaging should be performed at 3 to 6 months, 1 year, and 2 years. An increase in size of greater or equal to 0.8 cm should prompt surgical intervention.

Functioning benign tumors can be managed by surgery. In the setting of an elsewhere primary malignancy (e.g., breast) especially with pheochromocytomas, the patient will need alpha blockade followed by beta blockade then adrenalectomy and fluid resuscitation. If bilateral (10%), an adrenalectomy of one side should be performed along with a cortical-sparing adrenalectomy on the contralateral side. Pheochromocytomas can recur and progress to a malignant pheochromocytoma and as such will need yearly biochemical follow-up.

Subclinical cortisol-producing adenomas are rare as 95% of cortisol-producing adrenal tumors will present as Cushing syndrome. Again a careful history and physical examination can help pick up this rare syndrome. However, this can be confusing because 70% of citizens in the United States are overweight, ~30% have diabetes (estimate of diagnosed and undiagnosed), hypertension (~29%), and osteoporosis (one tenth aged 60, one fifth aged 70, two fifths aged 80, and two thirds aged 90). The key is to consider this subclinical presentation and get the appropriate biochemical tests—a cortisol suppression test and baseline serum ACTH level. Surgery can alleviate the effects of hypercortisolemia especially in the young and as such should be pursued. Adrenalectomy should be considered for those presenting with a

primary cancer, especially, breast as cortisol may exacerbate tumor growth.

In the case of functioning aldosteromas, they can be quite small. Patients present with hypertension and chronic hypokalemia. A plasma aldosterone to renin level >20 is considered diagnostic. However, a falsely high ratio can be calculated if the plasma renin level is very low. A confirmatory saline suppression test can be used in a case like this. Nonsupression of aldosterone with administration of a 2-liter normal saline bolus confirms the diagnosis. Adrenalectomy can be curative.

The authors have described nicely the three main approaches to adrenalectomy, including open, laparoscopic, and retroperitoneal. Each technique has its own advantages and disadvantages. The open approach is recommended when cancer is known to be present as lymphadenectomy is required and it has the lowest rate of positive margins (including contiguous structures) and as such as the best chance for cure. Transabdominal laparoscopic cases have significantly less blood loss, better time to ambulation, postoperative pain, resumption of normal diet, and normal activities and length of stay compared to open. The retroperitoneal approach avoids the abdomen altogether and potential complication and also allows a bilateral approach. However, the retroperitoneal approach doesn't allow assessment of the peritoneal space, and if necessary the patient will need to be flipped, intraoperatively. A recent meta-analysis demonstrated statistically significant decreases in operative time, intraoperative blood loss, operative duration, length of hospital stay but not complications for the retroperitoneal approach over the laparoscopic approach.

45 Pancreatic Neuroendocrine Tumors

Michael P. Kim and Brian D. Badgwell

Pancreatic neuroendocrine tumors (PanNETs) comprise approximately 10% of all pancreatic lesions and represent a rare and heterogeneous subset of pancreatic tumors marked by indolence and latent presentation. Nonfunctioning PanNETs (NF-PanNETs) do not exhibit endogenous hormone secretion and comprise 40% to 91% of all PanNETs. Functioning PanNETs secrete hormones native to endogenous tissues; approximately 22% of patients with PanNETs have secretory disease symptoms. Among all functioning PanNETs, insulinomas are the most common and comprise 70%, whereas glucagonomas comprise approximately 15% of all functioning PanNETs. Less-common tumors include gastrinomas, VIPomas, and somatostatinomas, which together comprise approximately 5% to 10% of all functioning PanNETs. Primary considerations for surgical resection include tumor function, the presence of symptoms, size/mass effect, and the propensity for metastasis. The decision for formal surgical intervention should be made on an individual basis; patients with functioning PanNETs should generally proceed to surgical resection in the absence of clear contraindications or substantial risk of morbidity and/or mortality. Very small NF-PanNETs (<1 cm) may be selectively monitored in the absence of symptoms; most functioning PanNETs should be strongly considered for resection if location or mass effects are likely to result in anticipated complications such as an onerous or infeasible resection. Diagnosis of one or more PanNETs should also elicit consideration for an occult inherited genetic disorder such as multiple endocrine neoplasia-1 (MEN-1).

ETIOLOGY AND PATHOPHYSIOLOGY

The landscape of genetic mutations associated with sporadic PanNETs continues to evolve, but firm insight into the genetic nature of this disease is evident from their associations with genetic syndromes, e.g., MEN-1,

neurofibromatosis type 1, tuberous sclerosis, Von Hippel Lindau syndrome, and Li-Fraumeni syndrome. Somatic mutations in genes responsible for chromatin remodeling such as menin (MEN1), death-domain-associated protein (DAXX), and α thalassemia/mental retardation syndrome X-linked (DAXX) have been identified in substantial numbers of patients with PanNETs, indicating a possible role in disease development. NF-PanNETs largely exert deleterious effects by distorting native anatomy via anatomic involvement and compromised organ function at primary and metastatic sites. Because of aberrant hormone production, functioning PanNETs may result in profound symptoms despite a diminutive size that is often not amenable to localization despite highly detailed imaging.

PanNET STAGING

The clinical management of PanNETs largely depends on the location(s) and extent of tumor burden. Accordingly, staging of PanNETs is determined by criteria composed of tumor size and extension (T), tumor involvement of regional lymph nodes (N), and the presence of distant metastasis (M). Surgical management hinges on the ability to accurately identify and characterize primary lesion(s), and to assess regional and distant sites for disease. Initially, high-resolution CT or MRI should be obtained to accomplish these upfront goals. If insufficient, adjunct imaging modalities such as EGD/endoscopic ultrasound (EUS), somatostatin scintigraphy, and positron emission tomography (PET) may be employed to diagnose and stage PanNETs.

Somatostatin Scintigraphy

The majority of neuroendocrine tumor cells, including nonfunctioning tumors, express high levels of somatostatin receptors on the cell surface. High expression of somatostatin receptors on tumor cells may therefore help to identify PanNETs through the selective binding and detection of radio-labeled somatostatin analogs to somatostatin receptors. While advancements in the resolution and contrast timing protocols of CT and MRI have largely obviated the use of somatostatin scintigraphy, it does retain well-defined roles in: (1) the identification of small lesions not detected by other imaging modalities, (2) predictive value in the therapeutic response to the clinical administration of somatostatin analogs, and (3) to establish a baseline of tumor burden for monitoring of disease

progression. Ongoing treatment with somatostatin analogs should be suspended prior to somatostatin scintigraphy as they exhibit competitive binding to somatostatin receptors and can attenuate or obfuscate positive signals.

EGD/Endoscopic Ultrasound

The primary benefit of EGD/EUS is to identify and enumerate PanNETs, and to obtain a tissue diagnosis prior to surgical decision making. This aspect of preoperative planning is arguably the most important as the degree and nature of any intended resection may be completely altered by the presence of additional lesions not appreciated prior to surgical exploration and/or resection. Among PanNETs, gastrinomas are notorious for being multifocal and elusive; EGD/EUS may provide a powerful adjunct to high-resolution imaging to clarify imaging abnormalities or to discern anatomic relationships between tumors and critical structures. In nonfunctioning PanNETs, EGD/EUS may readily secure a histologic diagnosis of pancreatic lesions and significantly affect clinical management.

METASTATIC DISEASE

The decision to surgically resect metastatic PanNETs is directed by the feasibility of curative resection, control of symptoms, and/or the progressive nature of disease. Oligometastases that would permit an R0 resection along with the primary tumor should undergo upfront surgical resection with curative intent. Patients in whom all disease may be removed at the time of operation have the greatest potential for long-term and disease-free survival and therefore benefit from an aggressive surgical approach, including en bloc resections with other organs and/or sound vascular resection and reconstruction. Generally, patients with oligometastatic disease tend to require a lesser extent of resection with fewer postoperative complications. Patients with more extensive metastatic disease that precludes R0 resection may selectively undergo debulking operations to alleviate symptoms related to mass effect or associated hormonal syndromes. However, such debulking should be undertaken under careful consideration of the benefits derived from surgery versus systemic therapies. Ideally, surgical candidates with extensive metastatic disease will have tumors that are symptomatic and unresponsive to medical therapies, i.e., hormonal syndromes, and demonstrate stable, slow-

growing tumors. Following tumor debulking, symptom improvement and a prolonged period of disease progression may justify the risks associated with surgery and incomplete tumor resection. Accordingly, patients with large-volume, rapidly progressive metastatic disease are not likely to derive benefit from surgical resection and should undergo treatment with nonsurgical therapies.

Nonsurgical Therapies

Somatostatin Analogs

All patients with symptoms related to excessive hormone secretion by PanNETs should undergo treatment with somatostatin analogs. The two most common somatostatin analogs are octreotide and lanreotide; mechanistically, both bind and activate somatostatin receptors, thereby dampening the secretion of hormones from normal glands and from PanNETs. Somatostatin analogs are widely considered first-line agents to treat symptomatic hormone hypersecretion and have less side effects than other drug therapies. Notably, patients who receive somatostatin therapy are at high risk for gallstone and gallbladder sludge formation due to delayed emptying of the gallbladder. If long-term treatment with somatostatin analogs is anticipated for remnant disease or anticipated recurrence, a cholecystectomy should be performed at the time of surgical resection or debulking of primary and metastatic PanNETs to mitigate the chances of cholecystitis or symptoms related to diminished gallbladder contractility.

Cytotoxic Chemotherapy

Optimal chemotherapeutic regimens for PanNETs continue to be defined but are largely reserved for patients with unresectable, metastatic, or rapidly progressive disease. Toxicity of cytotoxic therapy is prevalent among patients commonly experiencing renal toxicity and myelosuppression. The use of streprozocin plus 5-FU or doxorubicin has led to objective responses and stabilization of disease. Dacarbazine and its less toxic analog, temozolomide, have also been shown to effect responses in patients with PanNETs, although toxicity continues to limit its use. Bevacizumab and everolimus have been administered in conjunction with temozolomode with a 33% and 40% response rate in PanNETs, respectively. FOLFOX plus bevacizumab have also demonstrated an overall response rate of 50%, with 50% of patients also demonstrating

stable disease.

Targeted Therapies

Preclinical studies in PanNETs have demonstrated the activation of signaling pathways downstream of numerous growth factors and their cognate receptors. Tyrosine kinase receptors including those belonging to the vascular endothelial growth factor (VEGF) receptor family and the mammalian target of rapacmyin-Akt (mTOR-Akt) have been targeted in PanNETs with some degree of success. Sunitinib, a tyrosine kinase inhibitor with broad inhibitory activity against VEGFR 1, 2, and 3 as well as PDGFRs (alpha and beta) and c-KIT, demonstrated an overall response rate of 9.3% but resulted in numerous toxicities and no improvement in overall survival. Everolimus, an mTOR inhibitor, has been shown to improve the median progression free survival (11 months from 4.6 months) with an increase in partial responses compared to placebo (5% vs. 2%). Overall, targeted therapies in PanNETs demonstrate less overall and partial responses compared to cytotoxic chemotherapy and are generally administered in conjunction with octreotide or lanreotide in patients with progressive metastatic disease.

INSULINOMAS

Insulinomas are the most common PanNET and represent approximately 70% of all functioning PanNETs. However, they are quite rare with an estimated occurrence in only 4/1,000,000 people. Approximately 10% of insulinomas demonstrate a proclivity for metastasis, and the vast majority are considered benign. Generally, insulinomas are distributed evenly throughout the head, body, and tail of the pancreas. Most sporadic insulinomas are solitary tumors (～87%); 7% are multifocal and approximately 6% are malignant with metastases. The spectrum of symptoms related to insulin overproduction ranges from the absence of symptoms to the necessity for continuous intravenous glucose administration in extreme cases. The presence of synchronous lesions should be ruled out preoperatively and at the time of surgical exploration. If multiple lesions are encountered, the possibility of MEN-1 should be strongly considered since insulinomas are among the commonest PanNETs encountered in patients with MEN-1.

Clinical Presentation

The majority of patients with insulinomas present with neuroglycopenic symptoms: diaphoresis, palpitations, anxiety, confusion, and behavioral changes. The median age of affected patients is approximately 50 years with a slight predilection for females (57% to 70%). The disease should be confirmed via biochemical evaluation, and exogenous insulin administration should be excluded prior to an extensive workup. A formal diagnosis of insulinoma is rendered from a 72-hour fast during which patients are monitored for neuroglycopenic symptoms. The development of hypoglycemia (serum glucose <40 mg/dL) in the presence of neuroglycopenic symptoms and high insulin levels (>5 μU/mL) confirms the diagnosis. C-peptide and proinsulin levels should also be tested, as subsets of insulinomas produce large amounts of proinsulin with attenuated symptomatology relative to insulin-secreting tumors.

Preoperative Planning

Once a diagnosis of insulinoma has been rendered, high-resolution computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to localize tumors and to stage active disease. Pancreas protocol imaging may reveal small lesions and inform anticipated operations and patient counseling. If tumors are not identified or well-characterized on cross-sectional imaging, we recommend proceeding with EUS, which is highly successful in identifying PanNETs (82% of cases). However, proceeding with EUS for initial localization is not recommended, as high-resolution CT or MRI is required for staging and may adequately localize tumors without the need for EUS. Patients with a biochemical diagnosis of insulinoma without identifiable tumors by conventional imaging modalities may undergo selective arterial calcium stimulation for localization. Calcium gluconate is sequentially injected into the superior mesenteric artery, gastroduodenal artery, and splenic artery, and hepatic venous outflow is sampled, and insulin levels are measured. Arteriography is also performed and used to establish specific perfusion to different regions of the pancreas. As calcium gluconate selectively stimulates insulin secretion from insulinomas, the general region of the pancreas containing the tumor may be identified through increases in detected insulin (>2-fold increase) when each source of arterial inflow undergoes calcium infusion. If all attempts at preoperative tumor localization are unsuccessful, laparotomy with careful inspection and palpation of the pancreas, coupled with intraoperative ultrasound, may be

needed to localize the tumor(s).

GASTRINOMAS

Gastrinomas secrete supra-physiologic levels of the hormone gastrin, resulting in a clinical syndrome (Zollinger-Ellison syndrome [ZES]), whereby the hypersecretion of gastric acid results in peptic ulcer disease and diarrhea. Common locations for gastrinomas are in the pancreatic head and duodenum, although extra-anatomic tumors may arise in 5% to 15% of cases. The gastrinoma triangle, defined by the junctions of the (1) cystic common bile duct, (2) neck and body of the pancreas, and (3) second and third portions of the duodenum, therefore encompasses the majority of gastrinomas (Fig. 45.1). Pancreatic gastrinomas comprise 25% of all gastrinomas, and most (50% to 88%) arise in the duodenum, most often in the first portion of the duodenum. There is a predilection for males with ZES; approximately 20% of cases occur in association with MEN-1, and the remaining 80% are sporadic.

Clinical Presentation

Patients typically present between the ages of 20 and 50 years with complaints of abdominal pain and chronic diarrhea. Sources of abdominal pain include reflux and peptic ulcer disease from acid hypersecretion; gastrointestinal bleeding may also occur in up to 25% of patients. Persistent acid hypersecretion into the gastrointestinal tract may also result in the inactivation of pancreatic enzymes with resultant steatorrhea and diarrhea. When persistent acid hypersecretion is refractory to treatments with H2-blockers or proton pump inhibitors, a diagnosis of gastrinoma should be considered, and additional workup should be planned.

Preoperative Planning

The diagnosis of gastrinoma is primarily established from elevated fasting gastrin levels in the setting of a gastric pH less than 4. Other clinical entities related to antral cell hyperplasia, prior gastrectomy, gastric outlet obstruction, proton pump inhibitor therapy, etc. may also result in an elevated serum gastrin level and should be excluded. Most patients (～2/3 of patients), however, have a serum gastrin level less than 1,000 pg/mL, requiring additional diagnostic evaluation in the form of a secretin stimulation test. During this test, secretin is administered intravenously

and serum gastrin levels are measured. Gastrinoma cells inappropriately secrete gastrin in response to secretin stimulation. Caution should be used in administering this test in patients with profound symptoms from suspected ZES and maintenance on proton pump inhibitor therapy. Sudden discontinuation of proton pump inhibitors may lead to gastrointestinal hemorrhage and profound diarrhea with subsequent dehydration. Localization of gastrinomas should initially be performed with high-resolution imaging focused within the gastrinoma triangle. Pancreas protocol, triple-phase CT imaging should be performed to identify suspicious lesions. Co-localization with somatostatin receptor scintigraphy and/or endoscopy/EUS may further confirm the diagnosis. In the absence of demonstrable lesions on imaging, selective arterial stimulation with secretin may assist in identifying the relative location of gastrinomas. Biochemical tests that strengthen the diagnosis of gastrinoma in questionable cases include serum chromogranin A. Last, exploratory laparotomy, manual palpation of the duodenum, intraoperative ultrasound, and endoscopic trans-illumination may be employed to identify and resect gastrinomas. The duodenum may be opened to facilitate visual and manual inspection if difficulty is encountered in the identification and localization of tumor(s).

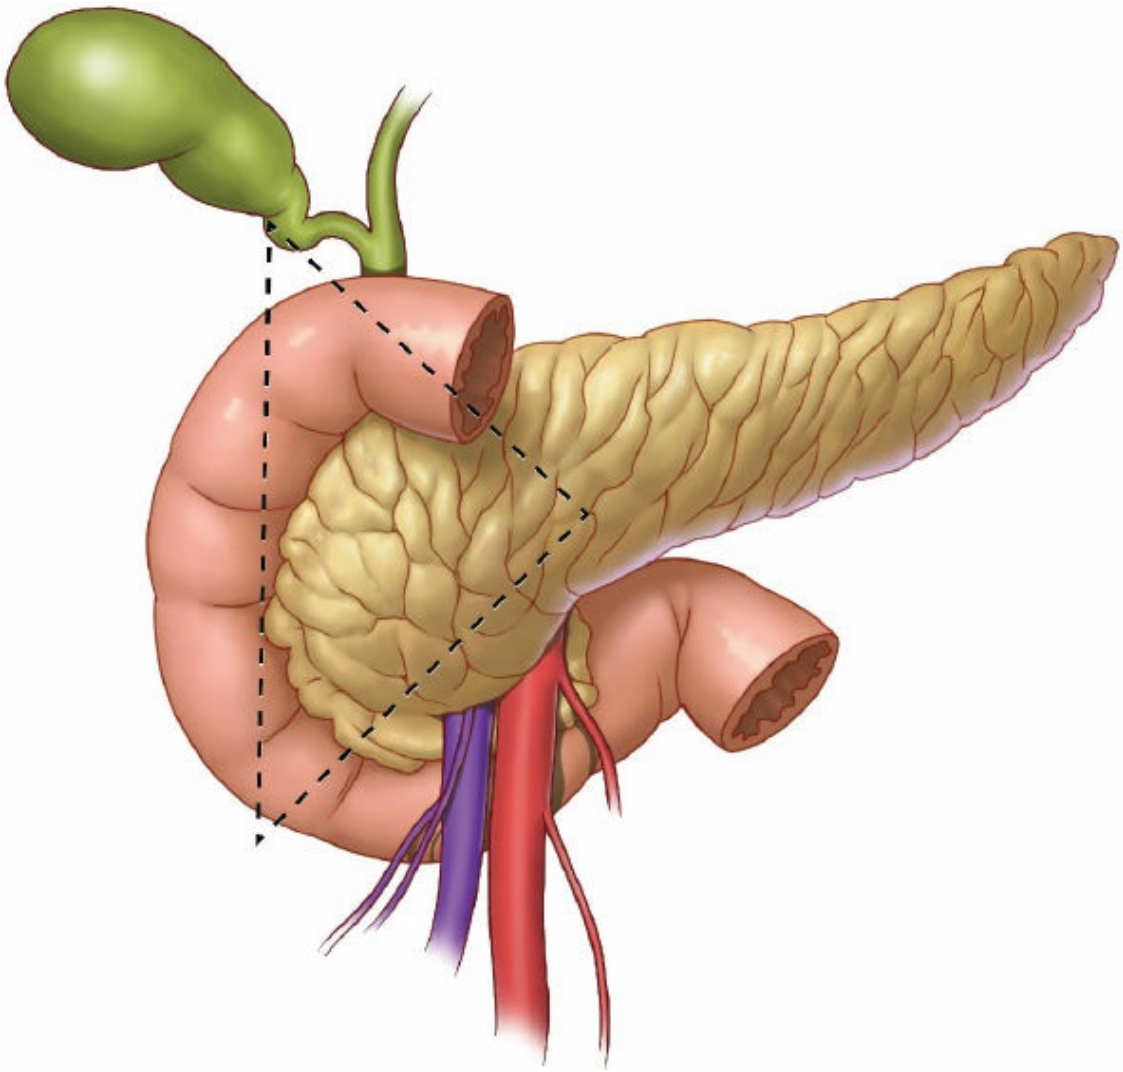

Figure 45.1. The gastrinoma triangle is defined by the junctions of the (1) cystic common bile duct, (2) neck and body of the pancreas, and (3) second and third portions of the duodenum. The vast majority (80%) of gastrinomas may be found within the anatomic confines of this triangle. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

GLUCAGONOMAS

Glucagonomas are rare tumors marked by high metastatic proclivity; 50% to 80% of patients have metastatic disease at the time of diagnosis. Glucagonomas comprise 15% of all functional PanNETs, and the lesions are confined to the pancreatic tail in the majority of patients. Most glucagonomas present as solitary lesions in the fifth decade of life without a predilection for males or females. Owing to the malignant behavior of the majority of glucagonomas, surgical resection is strongly recommended when clearance of all tumor may be achieved. Up to 20% of patients with

a diagnosis of glucagonoma may have MEN-1 and therefore should be thoroughly evaluated within the context of management and surgical planning, if indicated.

Clinical Presentation

Two clinical features largely characterize patients with glucagonoma: weight loss and necrolytic migratory erythema (NME). Autonomous glucagon secretion produces nonspecific symptoms but promotes catabolic processes that result in significant weight loss. Approximately 80% of patients display weight loss at the time of presentation. Hyperglycemia and glucose intolerance are present at equal frequencies, although formal diabetes mellitus is present in approximately 40% of patients. NME is present in 70% of glucagonoma patients and manifests as painful, pruritic, erythematous papules/plaques on the face, perioral region, mucous membranes, and extremities. Formal diagnosis of NME is made through serial biopsies that show necrolysis of the epidermis and infiltration with lymphocytes. Last, deep venous thrombosis and/or pulmonary embolism may occur in up to 33% of glucagonoma patients, requiring treatment with anti-coagulants even prior to surgery and thereafter.

Preoperative Planning

Many glucagonomas present in late stages as sizable primary lesions. As such, diagnosis is usually made in the majority of cases via the presence of a pancreatic mass in the setting of elevated serum glucagon levels. Serum gastrin levels of >1,000 pg/mL are virtually diagnostic of glucagonoma, although levels above 500 pg/mL strongly indicate the diagnosis. Dedicated triple-phase CT imaging should be performed to identify suspicious lesions, intrapancreatic and otherwise, with a sensitivity of almost 100%. MRI may be employed to further characterize suspicious lesions or to confirm the presence of metastases, a finding that may drastically alter clinical management. In rare cases in which glucagonoma is suspected but not visualized on high-resolution, multiphase imaging, EUS, somatostatin receptor scintography, and angiography may be used to identify small lesions leading up to laparotomy, pancreatic palpation, and intraoperative ultrasound.

NONFUNCTIONING PanNETS

The majority of PanNETs are nonfunctioning and therefore do not produce symptomatic, hypersecretory, hormonal syndromes. Consequently, patients may present with advanced disease with latent onset of symptoms that may signal the presence of an underlying tumor. NF-PanNETs do secrete minute quantities of hormones such as pancreatic polypeptide, chromogranin, neuron-specific enolase, and ghrelin, which should be measured at presentation and used to monitor patients for recurrence and/or disease progression. Patients with NF-PanNETs commonly present with abdominal pain (35% to 78%), nausea/vomiting, and significant weight loss. At least a third of patients have metastatic disease at the time of diagnosis. Initial efforts should focus on ruling out active hormone secretion, alleviating symptoms, and staging disease prior to consideration for surgical resection. Owing to the occult nature of NF-PanNETs, patients often present with imaging studies demonstrative of a pancreatic mass. Once extensive biochemical workups fail to reveal hormonal hypersecretion, endoscopic biopsy should be performed to confirm the histologic diagnosis of a tumor of pancreatic endocrine origin. Distinguishing NF-PanNETs from pancreatic adenocarcinomas via tissue diagnosis is imperative, as both diseases may have similar patient presentations and imaging characteristics. High-resolution CT or MRI imaging should also be obtained prior to surgical resection to delineate anatomic relationships between tumors and critical, surrounding structures, particularly in cases of large, bulky NF-PanNETs.

SURGICAL MANAGEMENT OF PanNETS

The decision to proceed with surgical resection of PanNETs depends on the presence of resectable lesions in patients in whom the risks associated with surgery are justified and adequately mitigated. Patients with other malignancies in their family or personal history in whom genetic syndromes may be suspected should be adequately screened, and synchronous tumors should be excluded. This is particularly true for MEN-1 patients as the sequence of surgeries if multiple lesions are found directly affects the scope or sequencing of surgery.

Laparotomy for lesions of the pancreas is dictated by the anticipated operation, patient body habitus, location of the lesion(s), and surgeon preference. Generally, an upper midline incision that is extended inferiorly past the umbilicus, if needed, is adequate for exposure of the entire pancreas. A subcostal incision extended medially past the midline or into a

bilateral subcostal (chevron) incision may be particularly efficient for exposure and to mitigate wound complications in significantly obese patients. Laparoscopic resection of PanNETs may be considered in clinical settings with adequate volume and experience; enucleation of lesions may also be attempted for smaller lesions with low malignant potential. It should be emphasized that the surgical management of PanNETs rests almost entirely on their identification. Therefore, intraoperative exposure and uninhibited access to all indicated aspects of the pancreas are mandatory to evaluate the tumor involvement and extent of required resection and to exclude synchronous lesions.

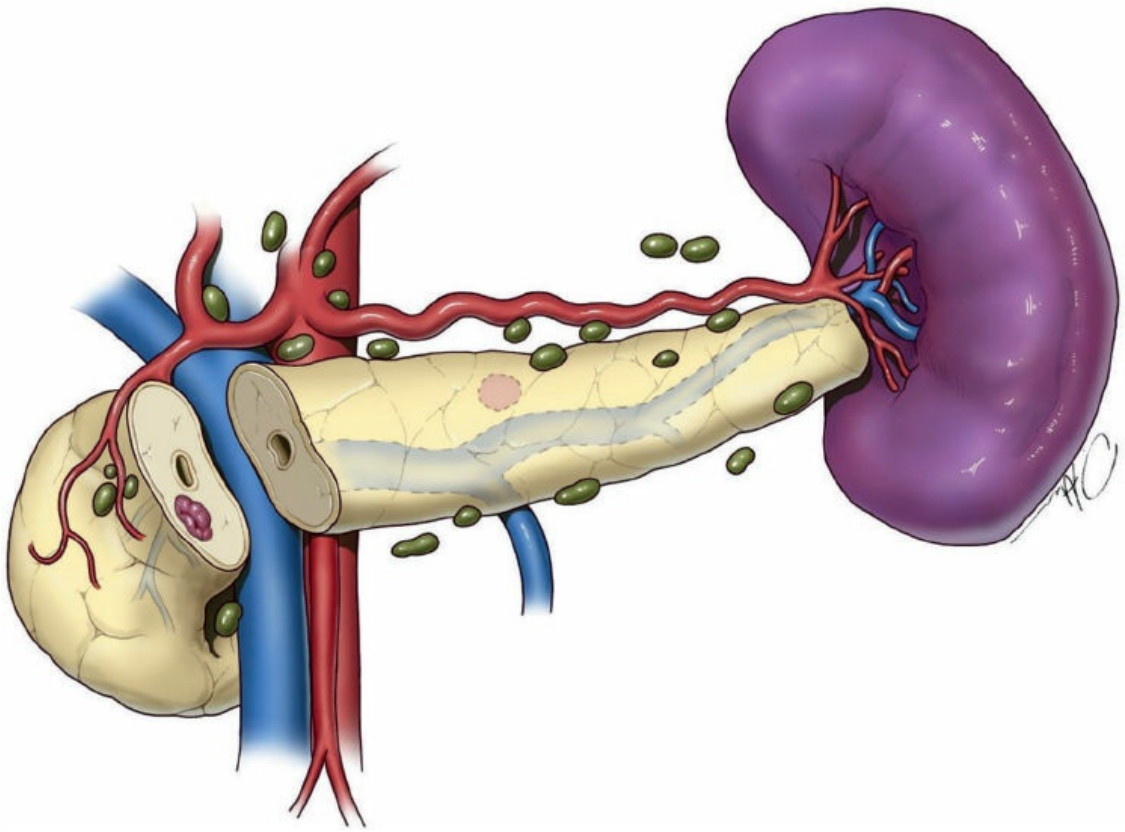

Figure 45.2. The planned operation to resect PanNETs depends on the location of tumor within the pancreas and its proximity to the pancreatic duct. Tumors located next to the pancreatic duct or that displace a significant volume of pancreatic parenchyma (>2 cm largest dimension) are not amenable to enucleation and require formal pancreatic resection. In such cases, PanNETs located with within the head of the pancreas require a pancreaticoduodenectomy and associated regional lymphadenectomy. PanNETs located within the pancreatic neck, body, or tail require a distal pancreatectomy and possibly a splenectomy, depending on the identity of the primary tumor. The

pancreas is typically divided along the pancreatic neck following the establishment of a clear plane between the posterior aspect of the pancreatic neck and the superior mesenteric vein. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

The surgical approach to the resection of PanNETs is dictated by the physical location of the lesion(s) within the pancreas. Adherence to sound oncologic principles to maximally excise disease burden, obtain staging information, and dictate additional adjuvant therapies is mandatory to optimize patient outcomes. PanNETs deep within the pancreatic head or of sufficient size (generally >2 cm) require pancreaticoduodenectomy with lymphadenectomy of peri-pancreatic lymph nodes for regional clearance of disease. PanNETs located within the pancreatic neck or body require distal pancreatectomy and splenectomy (Fig. 45.2); regional lymphadenectomy is inherently achieved with this operation to control any potential locoregional disease. A central pancreatectomy, involving resection of the pancreatic neck and a small volume of adjacent pancreatic parenchyma, may also be performed in patients intolerant of the complications associated with formal pancreaticoduodenectomy or in whom removal of the majority of pancreatic parenchyma entailed in distal pancreatectomy is not desired. However, if locoregional disease is suspected, a central pancreatectomy does not permit significant lymphadenectomy and should be avoided except with the most benign of lesions. When possible, enucleation of PanNETs may be performed, usually when the lesion is smaller and the main pancreatic duct is not involved. As leakage of pancreatic fluid may result from enucleation(s), intraoperative drains should be strategically positioned to evacuate dependent fluid that may accumulate in the postoperative period (Fig. 45.3).

The entire length of the pancreas may be visualized when exposed through the lesser sac (Fig. 45.4). Access to the lesser sac is achieved either through direct division of the gastrocolic ligament or through division of the avascular fusion plane between the posterior surface of the omental apron and the transverse colon. In the latter approach, the stomach and omentum are reflected cephalad with a retractor, offering abundant access to the lesser sac. In cases where inspection or resection of the pancreatic head is required, the hepatic flexure may be mobilized and extended with a Cattell and Braasch maneuver to expose the pancreatic head, duodenum, and superior mesenteric vessels up to the ligament of

Treitz (Fig. 45.5). The duodenum and pancreatic head may then be thoroughly inspected following an extended Kocher maneuver that entails the division of the peritoneum overlying the C-loop of the duodenum (Fig. 45.6). Physical palpation and intraoperative ultrasound may be performed to identify PanNETs within the pancreatic head parenchyma (Fig. 45.7). Manual palpation and ultrasound assessment of the pancreatic body and tail may be performed once the pancreas is identified in the lesser sac. However, posterior tumors located within the deep substance of the pancreas are most thoroughly assessed following the division of the peritoneum along the superior and inferior borders of the pancreas and partial mobilization of the distal pancreas (Fig. 45.4).

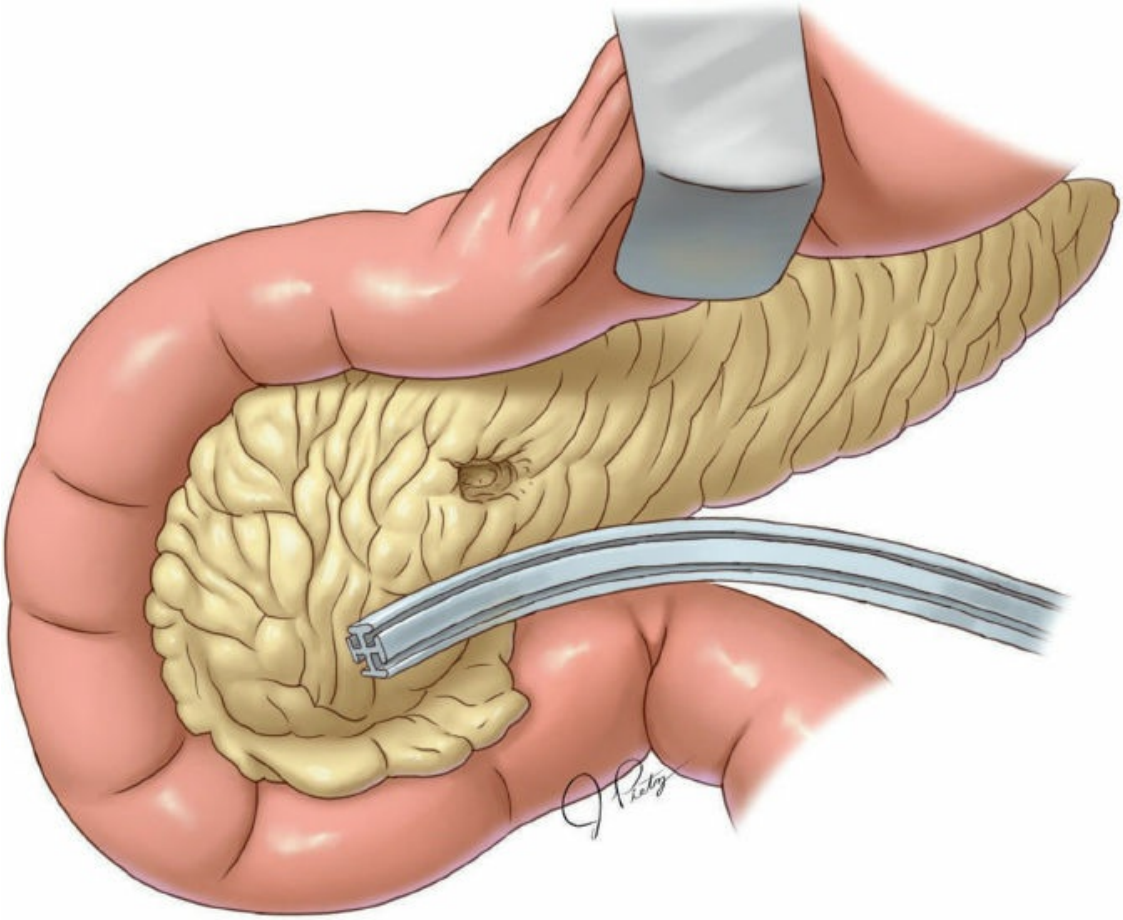

Figure 45.3. Placement of a closed suction drain to evacuate accumulated fluid following enucleation of PanNETs is recommended to prevent an uncontrolled pancreatic fistula or formation of a pancreatic abscess. The drain should be placed along the inferior border of the pancreas to optimally remove dependent fluid. Postoperatively, suspicion for a pancreatic leak may be supported through evaluation of closed drain suction fluid for amylase. (Image © 2015 The University of Texas MD

Anderson Cancer Center.)

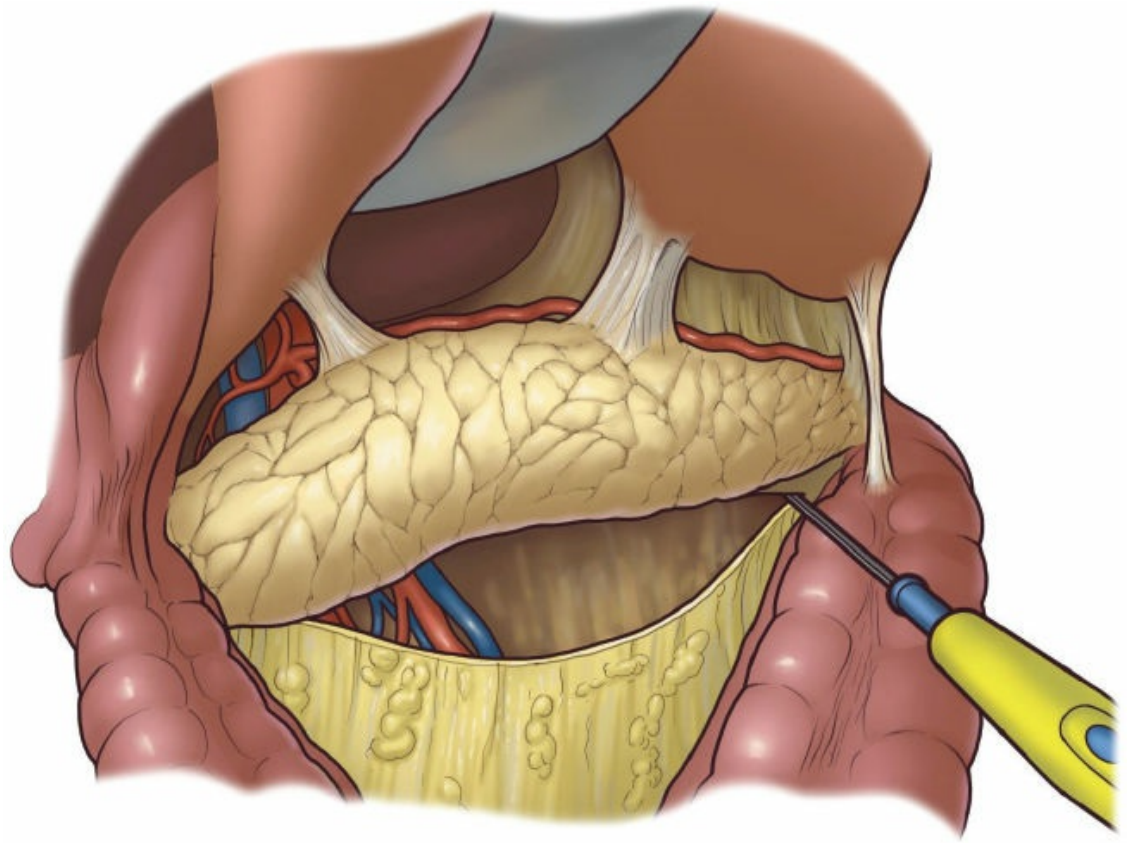

Figure 45.4. The length of the pancreas may be visualized and exposed for anticipated procedures through the lesser sac. Entrance into the lesser sac is commonly achieved following the division of the gastrocolic ligament with cephalad retraction of the stomach and caudad retraction of the omentum/transverse colon. Alternatively, dissection may proceed through the avascular fusion plane between the omental apron and transverse colon with subsequent cephalad retraction of the greater omentum and stomach and caudad retraction of the transverse colon. The latter approach offers unfettered access to the entire pancreas and facilitates subsequent mobilization of the pancreatic head without ligation of the gastroepiploic vessels. Consequently, we favor this approach when close evaluation or resection of the pancreatic head is anticipated. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

Access to the pancreatic neck for division is required when performing either a pancreaticoduodenectomy or a distal pancreatectomy. The gastrocolic trunk and middle colic veins identified during operative exposure of the pancreatic head may be ligated to enhance exposure or to

prevent inadvertent avulsion and blood loss. Peritoneum covering the infrapancreatic neck may be carefully incised to mobilize and gain access to the posterior portion of the pancreatic neck. Likewise, removal of the hepatic artery lymph node provides an access point through the peritoneum that may be extended to the posterior aspect of the superior pancreatic neck. A dissection plane may then be slowly developed between the posterior aspect of the pancreatic neck and the anterior surface of the superior mesenteric vessels. Depending on the location of the tumor(s) and the ability to obtain negative margins, the pancreatic neck may be divided and the indicated operation performed.

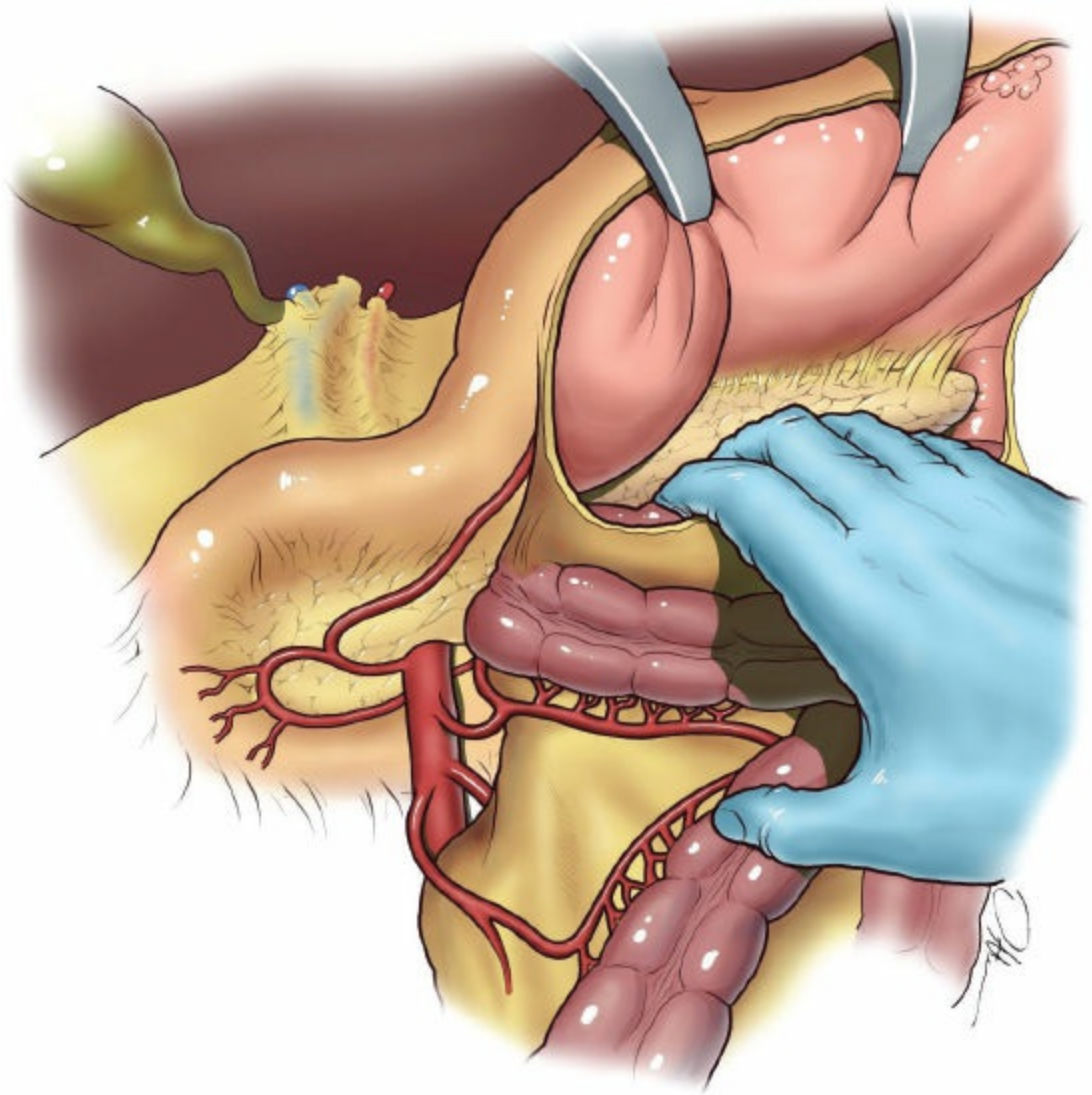

Figure 45.5. Complete exposure of the pancreatic head and mesenteric vessels is achieved following mobilization of the hepatic flexure and completion of a Cattell and Braasch maneuver. Controlled division of the gastrocolic trunk and/or middle colic veins, located along the anterior surface of the

infrapancreatic superior mesenteric vein, may be performed to prevent inadvertent rupture or to facilitate additional access to the pancreas or mesenteric vessels. Extended exposure of the pancreatic head and duodenum further facilitates their subsequent mobilization, if needed. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

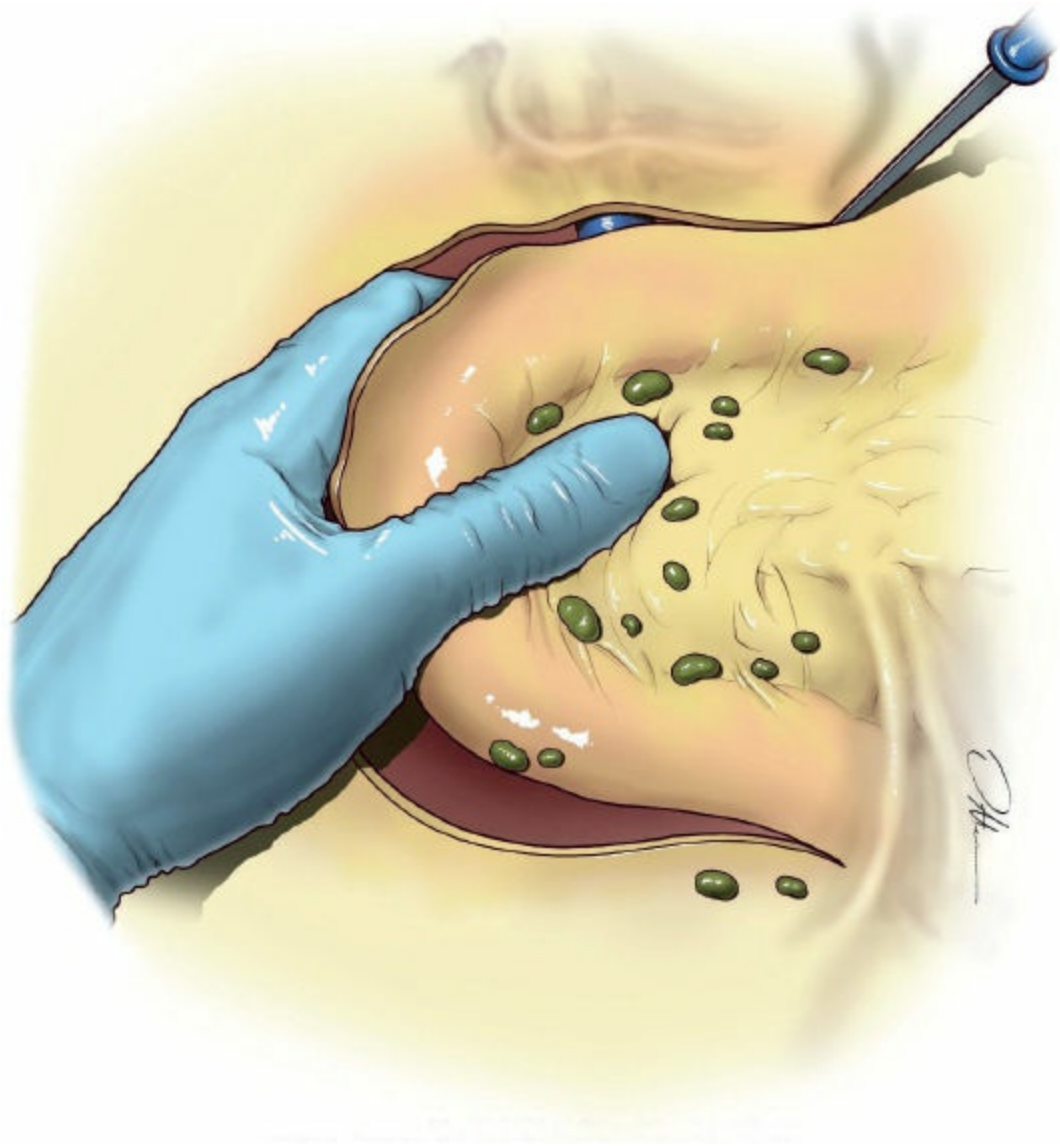

Figure 45.6. An extended Kocher maneuver is performed through incision of the peritoneum overlying the duodenum. Gentle retraction of the duodenum and pancreatic head in an anterolateral direction, to the left of the patient, exposes the underlying, avascular plane between the posterior aspects of the pancreatic head/neck and the inferior vena cava/aorta. Dissection should proceed until the left renal vein is visualized. Generous mobilization of the pancreatic head greatly enhances visual, manual, and ultrasound evaluation of the pancreatic head and

duodenum for PanNET identification and greatly facilitates subsequent dissection and/or resection of the pancreatic head and duodenum. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

Special Considerations for Insulinomas

The vast majority (90%) of functional insulinomas are benign and therefore may be enucleated largely without fear of metastasis or recurrence. In familial syndromes, insulinomas are also commonly multifocal; in such cases, the liberal mobilization and assessment of the pancreas by palpation and intraoperative ultrasound are requisite to identify and remove all tumors. Three factors dictate whether an insulinoma may be enucleated: (1) involvement with surrounding structures, (2) tumor size, and (3) proximity to the pancreatic duct. As tumor size increases, so too does its involvement with normal pancreatic parenchyma and proximity to the pancreatic duct, necessitating a formal pancreatic resection. Tumors that are exophytic or located in the periphery of the pancreas, as evident on intraoperative ultrasound, may be enucleated regardless of their location along the length of the pancreas. Tumors located adjacent to the pancreatic duct should undergo a formal pancreatectomy. Likewise, formal pancreatectomy should be performed when enucleation of superficial tumors that extend deep into the pancreatic parenchyma might result in pancreatic duct damage or extensive disruption of pancreatic parenchyma. Intraoperative, closed-suction drains should be placed in locations where dependent drainage from enucleation sites might occur.

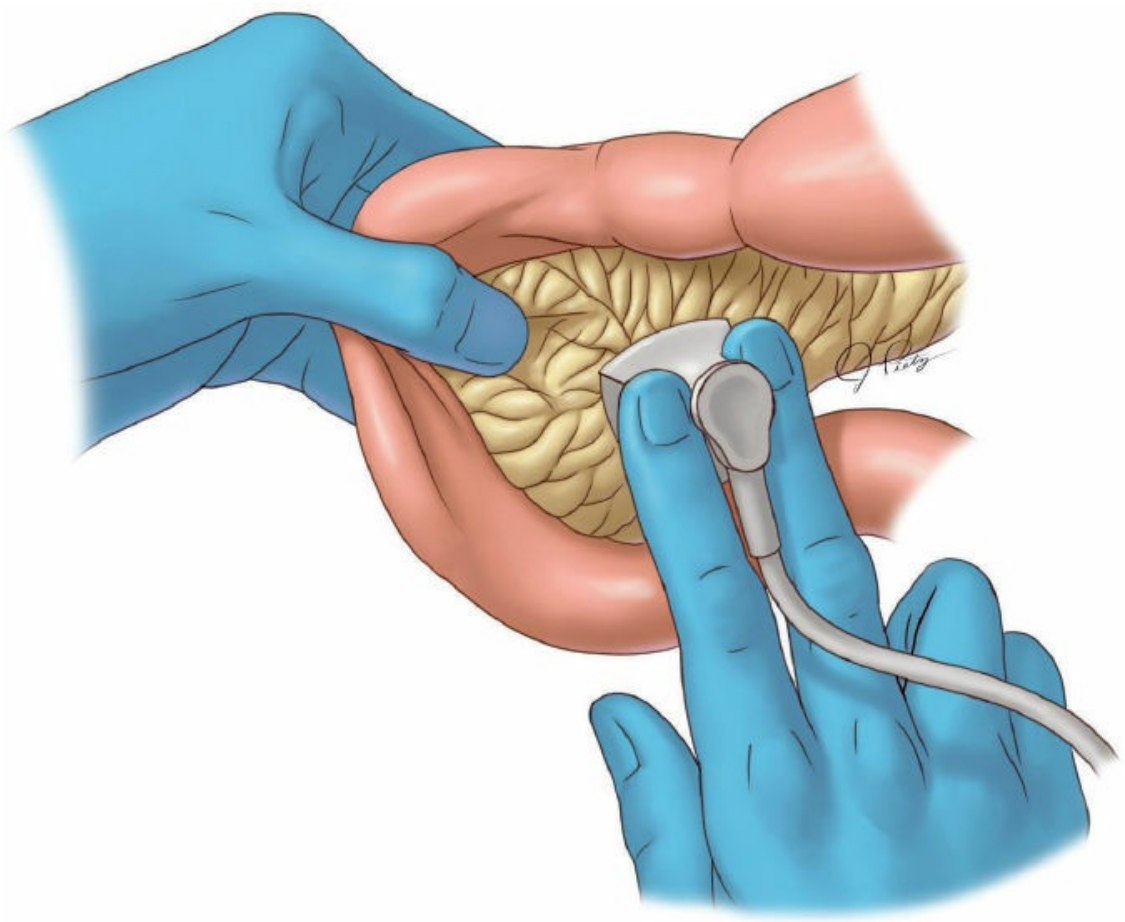

Figure 45.7. Intraoperative ultrasound may be utilized to localize PanNETs within the pancreatic parenchyma and to evaluate their proximity to the pancreatic duct. Many PanNETs may be enucleated when located in the peripheral pancreatic parenchyma and not adjacent to the pancreatic duct. Mobilization of the pancreatic head greatly enhances inspection and ultrasound evaluation of PanNETs, particularly for tumors located in the posterior pancreatic head or deep within the pancreatic parenchyma. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

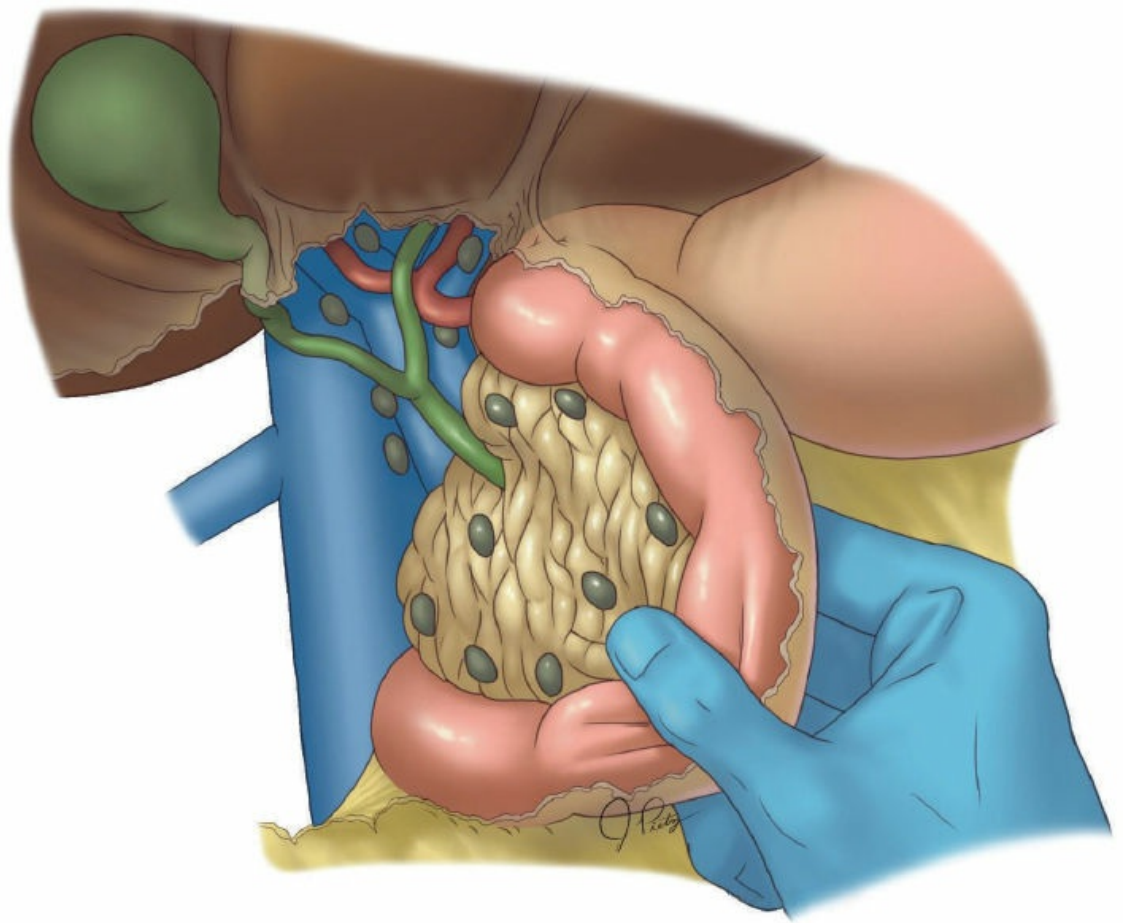

Figure 45.8. Regional lymphadenectomy is a critical technical point in the resection of PanNETs with a high propensity for metastasis. During pancreaticoduodenectomy, peripancreatic and periduodenal lymph nodes are largely adherent to the resected pancreatic head and duodenum. Extension of the lymphadenectomy into the porta hepatis is necessary to achieve complete clearance of periportal and perihepatic lymph nodes that may contain nodal disease. However, skeletonization or aggressive lymphadenectomy of structures far up the porta hepatis is not recommended and can result in devascularization of the common bile duct. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

Special Considerations for Gastrinomas

Distinguishing factors that inform the resection of gastrinomas are their small size and frequent location in the duodenum. Metastatic disease should be excluded both radiographically and by visual inspection of the peritoneal cavity, liver, and diaphragm. Similar to insulinomas, enucleation may be performed for pancreatic head lesions that are peripheral and located away from the pancreatic duct. Regional lymph

node dissection inclusive of periportal, periduodenal, perihepatic, and celiac lymph nodes should be performed for all lesions in the head of the pancreas that undergo enucleation or pancreaticoduodenectomy (Fig. 45.8). Tumors in the distal pancreas are managed with distal pancreatectomy, with or without splenectomy, as this also provides an adequate lymphadenectomy for clearance of disease and prognostic information. This fundamental surgical concept is necessary given the frequency of regional nodal metastasis (~50%) associated with gastrinomas.

The most common primary site of gastrinomas is the duodenum. As such, mobilization of the duodenum with an extended Kocher maneuver is important to fully palpate and identify gastrinomas that may be located in the duodenum. Intraoperative ultrasound may be combined with manual palpation of the duodenum to localize gastrinomas for resection. If no tumors can be located at the time of laparotomy, intraoperative esophagogastroduodenoscopy may be performed to evaluate the duodenal mucosa for suspicious lesions. As light is less able to penetrate tumor and specifically tumors thicker than the surrounding bowel wall, trans-illumination of the duodenum with an endoscope may also assist in the identification of gastrinomas (Fig. 45.9). If the tumor(s) cannot be identified via transmural palpation, intraoperative ultrasound, and endoscopic evaluation/trans-illumination, some groups advocate incising the duodenal wall to facilitate palpation of the mucosal surface and bowel wall to better palpate and identify tumors. Typically, intramural gastrinomas of the duodenum are locally resected with a margin of normal tissue, and the defect is primarily repaired. A keen awareness of the location of the ampulla is necessary to prevent injury during duodenotomy and subsequent resection of the tumor.

Special Considerations for Glucagonomas

Surgical management of glucagonomas is based largely on their biologic propensity for metastasis, requiring thorough lymphadenectomy for disease clearance and staging. Accordingly, enucleation or formal pancreatectomy must be coupled with regional lymph node dissection. As most glucagonomas are located in the distal pancreas, distal pancreatectomy and splenectomy should be performed with lymphadenectomy of the celiac and perisplenic lymph nodes (Fig. 45.2). Small lesions in the distal pancreas are uncommon but may be enucleated

if they are smaller than 2 cm and located in the peripheral pancreas. Glucagonomas in the head of the pancreas are rare but almost always require formal pancreaticoduodenectomy owing to their size and the need for appropriate removal of periduodenal, retroperitoneal, perihepatic/celiac, and periportal lymph nodes.

Special Considerations for Nonfunctioning PanNETs

Most NF-PanNETs should undergo surgical resection, although lesions smaller than 1 cm may be closely monitored for patients who have relative or strict contraindications or unacceptable surgical risk. Small NF-PanNETs have a relatively small risk for metastasis; tumors 1 to 2 cm should undergo enucleation or formal pancreatectomy with or without regional lymphadenectomy. In cases of distal pancreatectomy, the spleen may be conserved. NF-PanNETs larger than 2 cm should undergo surgical resection, either pancreaticoduodenectomy or distal pancreatectomy and splenectomy, with corresponding regional lymphadenectomy similar to gastrinomas and glucagonomas.

POSTOPERATIVE CARE/COMPLICATIONS

Postoperative mortality for patients undergoing enucleation is lower than that of patients undergoing pancreaticoduodenectomy or distal pancreatectomy, owing in part to the preservation of pancreatic tissue and the avoidance of complications of pancreatic and bowel anastomoses. The morbidity rate of enucleation, however, is similar to that of formal pancreatic resection owing to the equivalent frequency of pancreatic fistula. Pancreatic fistulas associated with enucleation tend to be less severe. Moreover, blood loss is lower and hospitalization duration is shorter in patients undergoing enucleation. Closed-suction drains are helpful in patients who undergo enucleation to identify and manage postoperative pancreatic leaks, although postoperative drain placement is an area of active controversy in pancreatic surgery. Other complications include pseudocyst formation, abscesses, and the typical risks of major abdominal procedures. Laparoscopic resection is associated with reduced pain and shorter hospital stays but does not appear to provide benefit over open surgery for the risk of pancreatic fistula. The use of octreotide and, more recently, pasireotide to prevent pancreatic fistula formation varies among surgeons. Drains, if placed, should be maintained until the patient can tolerate a regular diet with no evidence of pancreatic leak.

Figure 45.9. Intramural PanNETs, specifically gastrinomas, may be identified and biopsied through preoperative endoscopic evaluation. Intraoperatively, an endoscope may be passed into the duodenum to trans-illuminate the duodenal wall to aid in the localization of small tumor(s). Because of their increased density and attenuated transmittance of light, tumors identified in this manner will appear as dark spots surrounded by illuminated, pink bowel. Localized resection of tumor may then proceed, limiting the resection of involved bowel wall. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

OUTCOMES

Pan-NETs have a diverse range of outcomes based on their clinical and histologic features. As outcomes are classified according to stage, the inherent diversity and wide spectrum of clinical behavior of islet cell

tumors can represent a challenge in applying a universal staging system to these tumors. Pan-NETs are not included in the American Joint Committee on Cancer (AJCC) Neuroendocrine Tumor staging system. Pan-NETs are rather included in the AJCC Exocrine and Endocrine Pancreas category. Although survival rates are much better for patients with endocrine tumors than for those with exocrine histology, inclusion in this category has been shown to have good discrimination among stages and to correlate well with overall survival. In addition, inclusion within the pancreas stage group allows for improved data collection and hopefully for the identification of future prognostic factors. The 5-year overall survival rates for patients in the National Cancer Database who underwent resection of Pan-NETs, classified according to AJCC stage, were 61% for stage I, 52% for stage II, 41% for stage III, and 16% for stage IV. A similar staging system has been proposed by the European Neuroendocrine Tumor Society and also has demonstrated good prognostic differentiation among stages for overall survival.

Single-institution reports, from tertiary centers, of patients with Pan-NETs have reported higher rates of 5-year overall survival, on the order of 90%, 85%, 80%, and 60% for AJCC stages I, II, III, and IV, respectively. Grade is also highly prognostic for survival. When patients are categorized according to grade alone, 5-year survival rates are approximately 75%, 60%, and 10% for low-, intermediate-, and high-grade tumors, respectively. The outcomes for these tumors are perhaps best categorized according to their function, although their rarity limits cohort size to relatively small numbers of patients. In reports from high-volume centers, the 10-year disease-specific survival rate for patients with insulinoma who undergo resection approaches 100%. Gastrinomas have a lower cure rate with 5-year survival rates of approximately 40%. Patients with nonfunctional pancreatic NETs and localized disease who undergo resection can obtain 5-year survival rates of 70% to 80%. Accurate survival predictions for the rarest functioning tumors are even more difficult. Patients with VIPomas have a 5-year survival rate of approximately 70%, whereas patients with glucagonoma have lower rates of survival, approximately 50% to 60%.

EDITOR'S COMMENT

The authors present an up-to-date overview of neuroendocrine tumors. Pancreatic neuroendocrine tumors are very rare. As a surgeon, you may see a patient or two in your life time. They have an incidence of 1 to 5 per million per year and make up only 1% to 2% of pancreatic neoplasms. Autopsy studies suggest a greater frequency, occurring in 0.5% to 1.5% of the population. They are categorized as functional and nonfunctional. From the most to the least frequent, the order of frequency of these tumors is nonfunctional, insulinoma, gastrinoma, glucagonoma, VIPoma, somatostatinoma, and others (Metz DC, Jensen RT. Gastrointestinal neuroendocrine tumors: pancreatic endocrine tumors. *Gastroenterol* 2008;135:1469–92 and Grozinsky-Glasberg S, Mazeh H, Gross DJ. Clinical features of pancreatic neuroendocrine tumors. *J*

Hepatobiliary Pancreat Sci 2015;22:578–85). Functional pancreatic neuroendocrine tumors are so classified on the presence of a specific clinical syndrome and measurement of the related hormone in the serum. It is not based on immunocytohistochemical staining. Both the functional and nonfunctional tumors may secrete peptides. Some such as pancreatic polypeptide cause no associated syndrome. The peptides secreted from rare pancreatic endocrine tumors include luteinizing hormone, erythropoietin, insulin-like growth factor II, enteroglucagon, renin, glucagon-like peptide, and secretin.

After establishing the biochemical diagnosis, initial treatment should be directed at the clinical syndrome. For gastrinoma acid hypersecretion may be controlled with proton pump inhibitors. Somatostatin analogs may be effective in eliminating diarrhea and hence hypokalemia in VIPoma and the metabolic effects of glucagonoma. Somatostatin is frequently ineffective in insulinoma as these tumors do not predominantly express the somatostatin 2 receptor. Somatostatin is not a first-line therapy in gastrinoma, but has been shown to decrease serum gastrin levels and reduce acid hypersecretion.

Tumor localization is critical for the initial surgical management. The U.S. Food and Drug Administration approved Netspot® on June 1, 2016. This was the first kit for the preparation of gallium Ga 68 dotatate injection, a radioactive diagnostic agent for positron emission tomography (PET) imaging. This radioactive probe will help localize somatostatin receptor positive neuroendocrine tumors. DOTA-TATE is an amide of the acid DOTA, which acts as a chelator for a radionuclide, and (Tyr3)-octreotate, a derivative of octreotide. The latter binds to somatostatin receptors, which are found on the cell surfaces of a number of neuroendocrine tumors.

A recent study evaluated the diagnostic and management role of 68Ga-DOTATATE PET imaging in patients with neuroendocrine tumors and negative or equivocal findings on standard somatostatin scintigraphy (Srirajaskanthan J, Srirajaskanthan R, Kayani I, et al. The role of 68Ga-DOTATATE PET in patients with neuroendocrine tumors and negative or equivocal findings on 111In-DTPA-octreotide scintigraphy. *Nucl Med* 2010;51:875–82). The authors reported that 68Ga-DOTATATE PET was positive in 41 of these 47 patients (87.2%). No false-positive lesions were identified. 68Ga-DOTATATE PET identified significantly more lesions than 111In-DTPA-octreotide scintigraphy (168 vs. 27 respectively, $p < 0.001$). Another group reported the impact of 68Ga-DOTATATE PET/CT for imaging neuroendocrine and other somatostatin expressing tumors and compared it to Octreoscan and conventional imaging. They demonstrated that 88% of 68Ga-DOTATATE PET/CT studies were abnormal and in 83% of patients provided additional information not available on standard imaging (Hofman MS, Kong G, Neels OC, et al. High management impact of Ga-68 DOTATATE (GaTate) PET/CT for imaging neuroendocrine and other somatostatin expressing tumours. *J Med Imaging Radiat Oncol* 2012;56:40–7).

Insulinomas are usually benign as noted by the authors and are amendable to

enucleation unless the pancreatic duct is involved or in close proximity in which case resection is warranted. Enucleation is facilitated by using a bipolar device or ultrasonic energy. The tumors are very vascular and use of energy will allow better control of bleeding.

Whereas prior to 1980, total gastrectomy was the only certain way to control the ulcer diathesis associated with the Zollinger-Ellison syndrome, today gastric surgery of any kind is rarely indicated as the acid hypersecretion can be controlled with pharmacologic inhibition with proton pump inhibitors(preferred) or H2 antagonists. Gastrinomas are unique in that the primary may be in the duodenum or pancreas. It is critical to perform duodenotomy in all patients who are explored to accurately identify primary duodenal gastrinomas. At least 50% of such tumors will go unrecognized if the duodenum is not opened. This technique was championed by Norm Thompson and Jeff Norton. The authors note a 5-year survival of 40% in gastrinoma. This is low compared to our experience and that of Norton and colleagues at the National Institutes of Health and the University of Michigan group. In our experience, disease-specific survival is 60% to 80% at 10 years and is related to stage and whether an R0 resection was carried out. Long-term survival is independent of biochemical cure. Patients who are initially cured with gastrinoma resection have a recurrence rate of about 30% within 8 years after surgery. Hence, careful follow-up must be undertaken.

Glucagonomas are rare F-PNETs, with an incidence of 0.04 to 0.12 per million per year. Glucagonomas are typically diagnosed in the fifth decade and are equally distributed between the sexes. All glucagonomas occur in the pancreas, but are most frequently identified in the tail of the pancreas. The tumors are invariably malignant and frequently metastatic at diagnosis. The glucagonoma syndrome has been called the 4-D Syndrome (dermatitis, diabetes, depression, and deep vein thrombosis).

VIPoma is another rare tumor, with an incidence of 1 per 10 million per year. VIPomas are most often sporadic, solitary lesions usually larger than 3 cm. Eighty-five percent to 95% are located in the pancreas, with 75% found in the pancreatic tail. VIP-secreting tumors have also been found in the bronchus, colon, adrenals, and liver. In children, VIPomas occur as extrapancreatic ganglioneuromas. In adults 70% to 90% are malignant, and 60% to 80% are metastatic at diagnosis. Regardless of the location, VIPomas produce a clinical syndrome known as Verner-Morrison syndrome, WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria), or the pancreatic cholera syndrome. The hallmark of the syndrome is secretoty diarrhea with stool volumes from 700 to 3,000 cc/day. This is associated with profound hypokalemia that may result in temporary paralysis and dehydration. Achlorhydria is present in 30% to 75% of patients. Metabolic acidosis may occur. Although VIP is the dominant hormonal cause of the syndrome, secretin may also be the causal agent as suggested by Robert Zollinger (Zollinger RM, Tompkins RK, Amerson JR, et al. Identification of the diarrheogenic hormone associated with non-beta islet

cell tumors of the pancreas. *Ann Surg* 1968;168:502–18) and later verified by William Chey (Chey WY, Frankel WL, Roy S, et al. Primary pancreatic secretinoma: further evidence supporting secretin as a diarrheogenic hormone. *Ann Surg* 2016. [Epub ahead of print]). The syndrome responds well to somatostatin analogs.

Somatostatinomas are exceedingly rare, occurring in less than one in 40 million people. About 50% of the reported tumors are in the duodenum or jejunum. The other half are in the pancreas. And these are more likely to cause the characteristic syndrome of gall bladder disease, weight loss, diarrhea, steatorrhea, and anemia. Periampullary tumors may occur in neurofibromatosis. If a duodenal somatostatinoma is found, then genetic screening for Neurofibromatosis 1 is suggested as this syndrome accounts for >40% of all duodenal somatostatinomas.

An interesting phenomenon may occur with highly malignant tumors. Although most tumors in this class have a dominant hormone and syndrome, it is known that highly malignant lesions may produce multiple hormones. ACTH is one such hormone, and it may induce a Cushing-like state.

Although these tumors are rare, the surgeon should be aware of their peculiar nature and generally better survival than adenocarcinoma of the pancreas. In addition, about 20% to 25% of these tumors may occur in multiple endocrine neoplasm type 1 syndrome. Hence genetic screening may be warranted particularly in gastrinoma.

SECTION V

THE BREAST, CHEST, AND MEDIASTINUM

46 Embryology and Anatomy of the Breast

Kirby I. Bland

With embryonic development in utero, primordially derived breast tissue anatomically matures as a modified sweat gland. The maturation of mammary parenchyma (ductal, lobular, and connective tissues), represents a unique feature of the mammalian species. Embryologically, the paired mammary glands synchronously develop within the “milk line” (Fig. 46.1); this anatomical linear plane which extends between the limb buds of the primordial axilla distally to the inguinal area. The number of paired glands varies widely among the various mammalian species, but in humans and most primates, a single pair of glands normally develops in the pectoral region, one gland on each side. In approximately 1% of the female population, supernumerary breasts (polymastia) or nipples (polythelia) may develop. Supernumerary appendages principally develop anatomically within the milk lines. While there is normally minimal additional development of the mammary gland during postnatal life in the male, extensive growth and development are evident secondary to hormonal stimuli in the female. Postnatal development of the female mammary gland is related to pubertal development of the organ and is principally regulated by hormones (estrogens and progesterones) which also regulate reproductive function. The greatest development of the breast is attained by the age of 20 years, and atrophy begins premenopausally at approximately the age of 40 to 45 years with waning estrogenic support of ductal–lobular matrix of the breast. During pregnancy and lactation, striking variants occur in both the amount (volume) of glandular tissue and the functional activity of the breast. Structural changes are also observed during menstrual cycles that result from variations in ovarian hormone levels (estrogens/progesterone). During menopause, with reduction in the hormonal secretory activity of ovarian function, the mammary gland undergoes involution and is primarily replaced by fat and connective tissue, and thereafter, diminishes its structural volume, form, and contour.

Figure 46.1. Mammary Milk line. After development of the milk bud in the pectoral area of ectodermal thickening, the “milk streak” extends from the axilla to the inguinal areas. At week 9 of intrauterine development, atrophy of the bud has occurred except for the presence of the supernumerary nipples of breast.

FUNCTIONAL ANATOMY OF THE BREAST

The glands of the breast are located within the superficial fascial compartment of the anterior chest wall. This organ consists of 15 to 20 lobes of tubuloalveolar glandular tissue, fibrous connective stroma that supports the lobules, and the adipose tissue that resides within parenchyma that intercalates between the lobules. Subcutaneous connective tissue typically does not possess a distinctive capsule around breast components;

rather, this tissue surrounds the gland and extends as septa between the lobes and lobules, providing longitudinal and gravitational support to the glandular elements. The deep layers of the superficial fascia that lie upon the posterior surface of the breast fuse with the deep (pectoral) fascia of the chest wall. A distinct space, the *retromammary bursa*, can be identified anatomically on the posterior aspect of the breast and resides between the deep layer of the superficial fascia and the deep investing fascia of the pectoralis major and the contiguous muscles of the thoracic wall (Fig. 46.2). The retromammary bursa contributes to the laxity and mobility of the breast on the rigid chest wall. Fibrous thickenings of supportive connective tissue interdigitate between the parenchymal tissue of the breast and extend from the deep layer of the superficial fascia to attach to the dermis of the skin. These dense fibrous suspensory structures, known as *Cooper ligaments*, are located perpendicular to the delicate superficial fascial layers of the dermis. These ligaments allow remarkable mobility of the gland while providing structural support and breast contour.

The postpubertal mature female breast extends from the level of the 2nd or 3rd rib inferiorly to the inframammary fold that is located at the level of the 6th or 7th rib interspaces. Laterally, the breast extends from the lateral border of the sternum to the anterior or midaxillary line. Breast parenchyma extends commonly into the anterior axillary fold as the axillary tail of Spence. The upper half of the breast, principally the upper outer quadrant, contains a greater volume of glandular tissue than the remainder of the breast. The posterior or deep surfaces of the breast reside upon portions of the fasciae of the pectoralis major, serratus anterior, and external oblique muscles; the gland also resides on upper portions of the anterior rectus sheath.

ANATOMY OF THE AXILLA

The anatomical boundaries of the axilla represent a pyramidal compartment that is tightly invested between the upper extremity and the thoracic wall; this structure has four boundaries inclusive of a base and an apex (Fig. 46.3). The curved oblong base consists of dense axillary fascia which is an investure of the axillary musculature. The apex of the axilla represents an aperture that extends into the posterior triangle of the neck via the cervicoaxillary canal. Most structures that course between the neck and the upper extremity enter this anatomic passage, that is bounded anterior/cephalad by the clavicle, medially by the 1st rib, and posteriorly

by the lateral margin of the scapula. The anterior wall of the axilla is composed of the pectoralis major and minor muscles and their associated fasciae. The posterior wall is formed primarily of the subscapularis muscle, located on the anterior surface of the scapula; the floor of this boundary is the teres major and latissimus dorsi muscles. The lateral wall of the axilla is the bicipital groove, a thin strip of condensed muscular tissue between the insertion of the musculature of the anterior and posterior compartments. The medial wall is composed of the serratus anterior muscle.

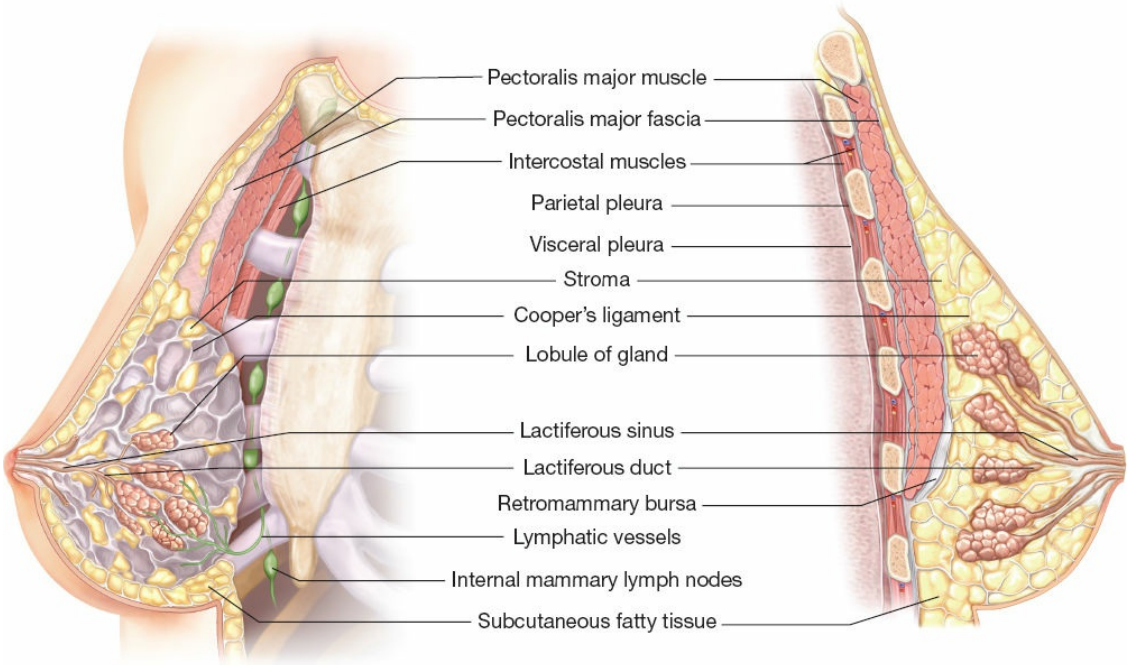

Figure 46.2. A tangential view of the breast on the chest wall and a sectional (sagittal) view of the breast and associated chest wall. The breast lies in the superficial fascia just deep to the dermis. It is attached to the skin by the suspensory ligaments of Cooper and is separated from the investing fascia of the pectoralis major muscle by the retromammary bursa. Cooper ligaments form fibrosepta in the stroma that provide support for the breast parenchyma. From 15 to 20 lactiferous ducts extend from lobules comprising the glandular epithelium to openings located on the nipple. A dilation of the duct, the lactiferous sinus, is present near the opening of the duct in the subareolar tissue. Subcutaneous fat and adipose tissue distributed around the lobules of the gland give the breast its smooth contour and, in the nonlactating breast, account for most of its mass. Lymphatic vessels pass through the stroma surrounding the lobules of the gland and convey lymph to collecting ducts. Lymphatic channels ending in the intercostal

muscles. The parietal pleura, attached to the endothoracic fascia, and the visceral pleura, covering the surface of the lung are shown.

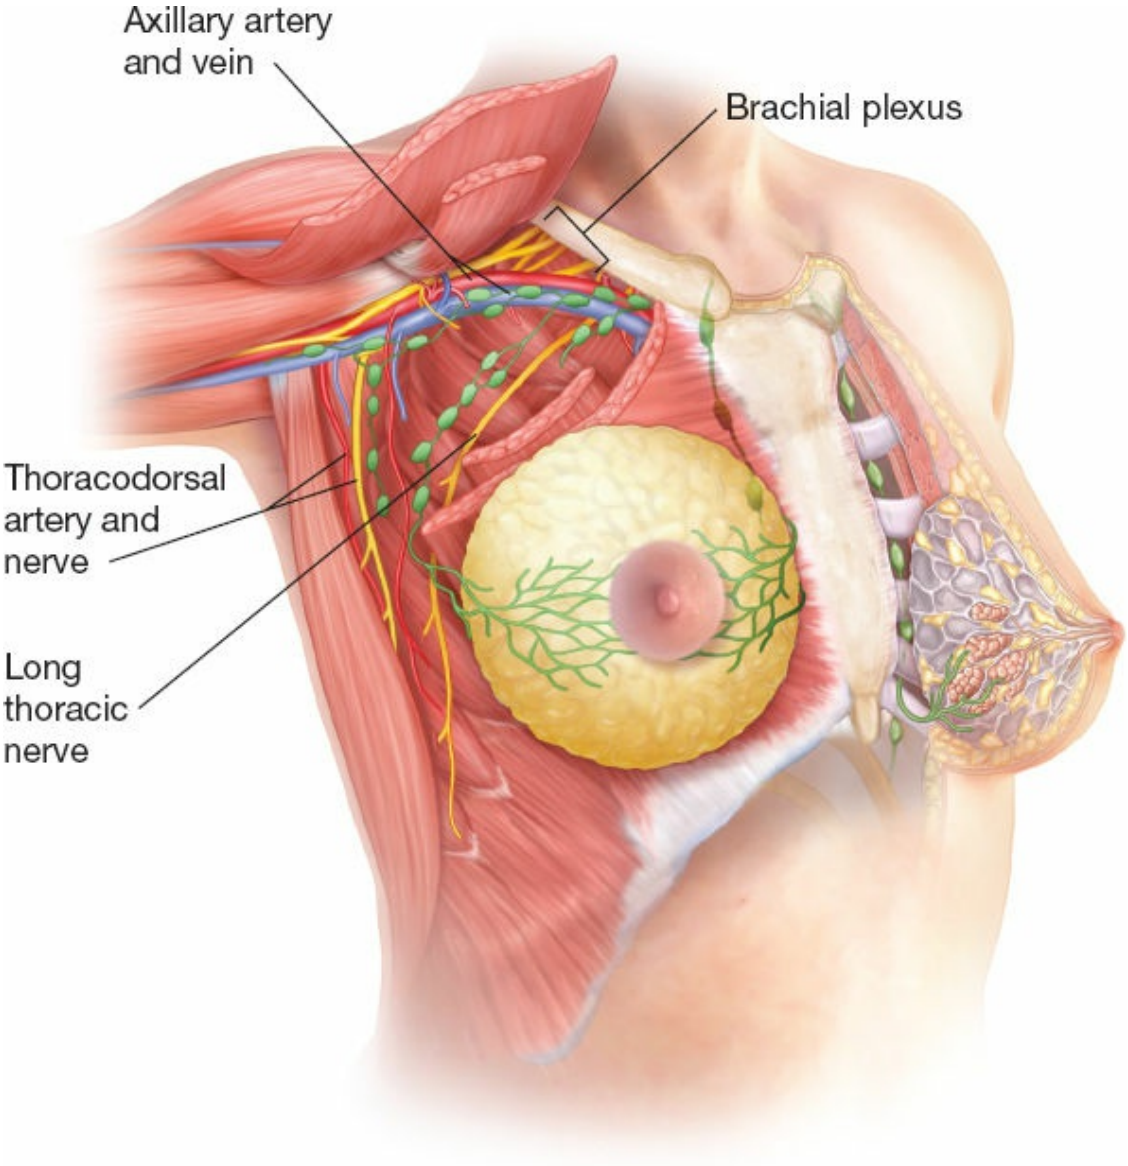

Figure 46.3. The anterior chest illustrating the structure of the chest wall, breast, and axilla. See text for details of the structure of the axilla and a description of its contents. On the right side, the pectoralis major muscle has been cut lateral to the breast and reflected laterally to its insertion into the crest of the greater tubercle of the humerus. This exposes the underlying pectoralis minor muscle and the other muscles forming the walls of the axilla. The contents of the axilla, including the axillary artery and vein, components of the brachia plexus, and axillary lymph node groups and lymphatic channels, are exposed. On the left side, the breast is cut to expose its structure in sagittal view. The

lactiferous ducts and sinuses can be seen. Lymphatic channels passing to parasternal lymph nodes are also shown.

The fascia of the pectoralis major and minor muscles are evident in two distinct planes: the superficial layer, called the *pectoral fascia*, invests the pectoralis major muscle; whereas the deep layer, called the *clavipectoral* or *costocoracoid fascia*, extends from the clavicle to the axillary fascia in the floor of the axilla and encloses the subclavius and the pectoralis minor muscle (Fig. 46.4).

The costocoracoid membrane represents the upper portion of the clavipectoral fascia and is pierced by the cephalic vein, the lateral pectoral nerve, and branches of the thoracoacromial trunk. The *medial pectoral nerve*, whose origin is the medial cord of the brachial plexus, does not penetrate the costocoracoid membrane, but rather, enters the deep surface of the pectoralis minor and passes through the anterior investing fascia of the pectoralis minor to innervate the pectoralis major muscle. Caudad portions of the clavipectoral fascia, which are anatomically inferior to the pectoralis minor, are sometimes referred to as the *suspensory ligament of the axilla* or the *coracoaxillary fascia*. Many surgeons refer to this anatomic landmark as *Halsted ligament*, which represents a dense condensation of the clavipectoral fascia that extends from the medial aspect of the clavicle, attaches to the 1st rib, and invests the subclavian artery and vein as each traverse the first rib. Surgical division intraoperatively is essential to complete the level III (cephalad) axillary dissection and allows full, safe exposure of the axillary vein anatomically.

Within the axilla are the great vessels and nerves of the upper extremity, which, together with the other axillary contents, are encircled by loose connective tissue. These vessels and nerves are anatomically contiguous and are enclosed within an investing layer of fascia referred to as the axillary sheath. The *axillary artery* can be divided into three anatomical segments within the axilla proper:

1. Located medial to the pectoralis minor muscle, the *first* segment gives rise to one branch, the *supreme thoracic*, which supplies the upper thoracic wall inclusive of the first and second intercostal spaces.
2. The *second* segment of this artery, located immediately posterior to the pectoralis minor, gives rise to two branches, the *thoracoacromial trunk* and the *lateral thoracic artery*. Pectoral branches of the thoracoacromial and lateral thoracic arteries supply the pectoralis

major and minor muscles (Fig. 46.5). Identification of these vessels during surgical dissection of the axilla is imperative to provide safe conduct of the procedure. The lateral thoracic artery gives origin to the lateral mammary branches.

3. The *third* segment of this vessel, located lateral to the pectoralis minor muscle, gives rise to three branches. These include the *anterior and posterior humeral circumflex arteries* that supply the upper arm, and the *subscapular artery*, which is the largest branch within the axilla. After a short course, the subscapular artery gives origin to its terminal branches, the *subscapular circumflex* and the *thoracodorsal arteries.* The thoracodorsal artery, which courses with its corresponding nerve and vein, crosses the subscapularis muscle, providing its substantial blood supply, as well as that of the serratus anterior and latissimus dorsi muscles.

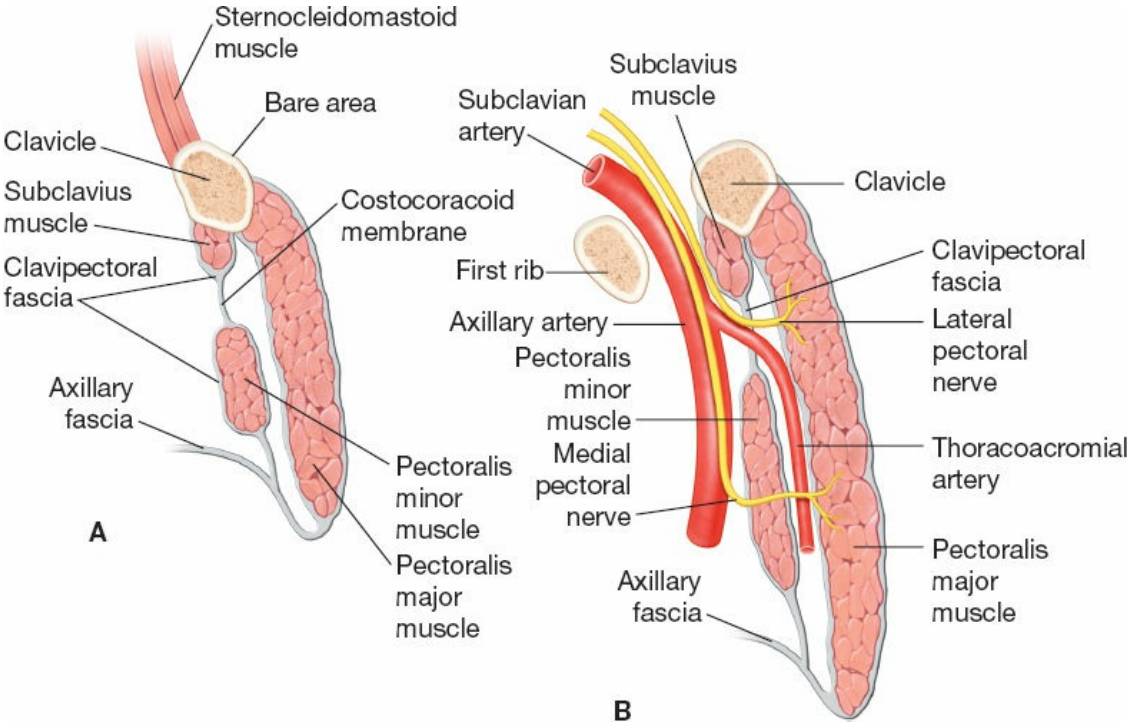

Figure 46.4. Sagittal sections of the chest wall in the axillary region. **A:** The anterior wall of the axilla. The clavicle and three muscles inferior to it are shown. **B:** Section through the chest wall illustrating the relationship of the axillary artery and medical and lateral pectoral nerves to the clavipectoral fascia. The clavipectoral fascia is a strong sheet of connective tissue that is attached superiorly to the clavicle and envelops the subclavius and pectoralis minor muscles. The fascia extends from the lower border of the pectoralis minor to become continuous with the axillary fascia in the floor of the axilla.

Tributaries of the axillary vein follow the course of the branches of the axillary artery, usually in the form of venae comitantes, paired veins that follow the course of the artery. The cephalic vein passes in the groove between the deltoid and pectoralis major muscles, and thereafter enters the axillary vein after piercing the clavipectoral fascia.

The *axillary artery* is anatomically contiguous with various portions of the brachial plexus throughout its course in the axilla. The cords of the *brachial plexus* are named according to their structural and positional relationship with the axillary artery—medial, lateral, and posterior—rather than their anatomic position in the axilla or on the chest wall. Thus, the *medial pectoral* nerve is laterally positioned; the *lateral pectoral* nerve is medial in the axilla.

There are three nerves of principal interest to surgeons that are located in the axilla (Fig. 46.3). Preservation of the *long thoracic nerve*, located on the medial wall of the axilla is imperative with axillary dissection. This nerve arises in the neck from the 5th, 6th, and 7th cervical roots (C5, C6, and C7) with entry in the axilla via the cervicoaxillary canal. This medially placed nerve lies on the lateral-most surface of the serratus anterior muscle and is invested by the serratus fascia such that it might be accidentally divided together with resection of the fascia during surgical dissection (sampling) of lymphatics of the axilla. The long thoracic nerve, although diminutive in size, courses a considerable anatomic distance to supply the serratus anterior muscle; injury or division of this nerve results in the "winged scapula" deformity with subsequent denervation of the muscle group and the inability to provide shoulder fixation. The *thoracodorsal nerve* takes origin from the posterior cord of the brachial plexus and innervates the laterally placed latissimus dorsi muscle. Injury or division is inconsequential to primary shoulder function; however, preservation of this nerve is essential to allow transfer survival and motor function preservation for the myocutaneous flap used for the latissimus dorsi musculocutaneous reconstruction. The *intercostobrachial nerve* is formed by the merging of the lateral cutaneous branch of the *second intercostal nerve* with the medial cutaneous nerve of the arm; this nerve provides sensory innervation of the skin of the apex and lateral axilla and the upper medial and inner aspect of the arm. The second intercostobrachial nerve may sometimes merge with an anterior branch of the *third lateral cutaneous nerve*.

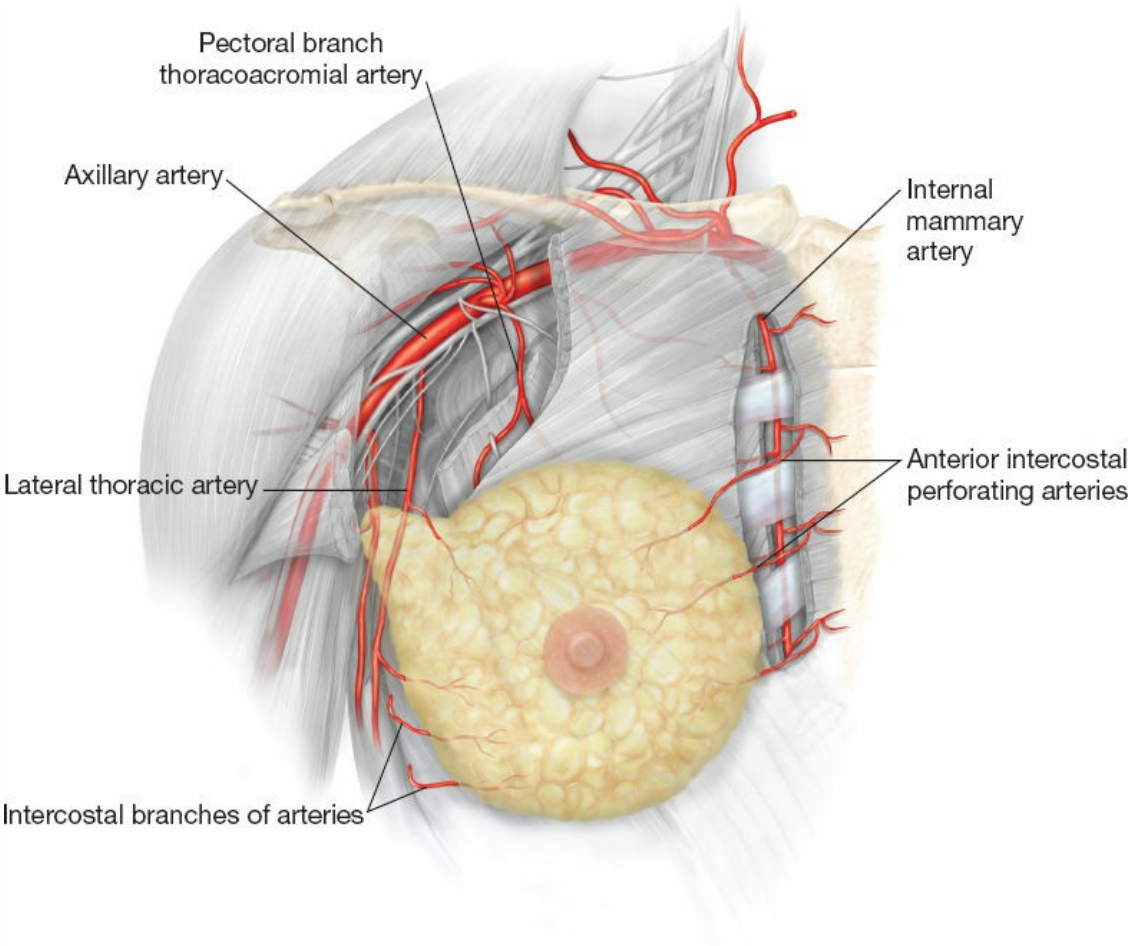

Figure 46.5. Arterial distribution of blood to the breast, axilla, and chest wall. The breast receives its blood supply via three major arterial routes: (a) medially from anterior perforating intercostal branches arising from the internal thoracic artery; (b) laterally from either pectoral branches of the thoracoacromial trunk or branches of the lateral thoracic artery (the thoracoacromial trunk and the lateral thoracic arteries are branches of the axillary artery); and (c) from lateral cutaneous branches of the intercostals arteries that are associated with the overlying breast. The arteries indicated with a *dashed line* lie deep to the muscles of the thoracic wall and axilla. Many of the arteries must pass through these muscles before reaching the breast.

BLOOD SUPPLY OF THE BREAST

Blood supply to the mammary gland is derived from perforating branches of the *internal mammary artery*, lateral branches of the *posterior intercostal arteries*, and several branches of the *axillary artery*. The latter vessels include the highest thoracic, lateral thoracic, and pectoral branches of the *thoracoacromial artery* (Figs. 46.4 and 46.5). Branches from the

second, third, and fourth anterior perforating arteries pass to the breast as medial mammary arteries.

The *lateral thoracic artery* branches allow perfusion to the serratus anterior muscle, both the pectoralis muscles, and the subscapularis muscle, and also supply the axillary lymphatics and supporting fatty tissues. The posterior intercostal arteries give rise to mammary branches in the 2nd, 3rd, and 4th intercostal spaces.

Although the *thoracodorsal branch of the subscapular artery* does not contribute to the primary blood supply of the breast *per se*, this vessel is intimately associated with the *central, subscapular, and lateral lymph node groups* of the axilla as it courses through the axilla. This fact should be taken into consideration during axillary node dissection, as postoperative bleeding can result when unidentified penetrating branches of this vessel are severed.

Principal venous outflow of the gland has preferential directional flow toward the axilla, with the veins principally paralleling the path of the arterial distribution. The superficial venous plexus of mammary parenchyma has extensive anastomoses that may be evident through the overlying skin. Circumscribing the nipple, superficial veins form an anastomotic circle, the *circulus venosus.* Veins from this circle and from deeper aspects of the gland converge to drain blood to the periphery of the breast, and thereafter into vessels that terminate in the *internal mammary, axillary, and internal jugular veins.*

Venous return from the gland is derived from three principal groups of veins providing drainage of the breast and the thoracic wall and include (a) perforating branches of the *internal mammary vein*, (b) tributaries of the *axillary vein*, and (c) perforating branches of *posterior intercostal veins.* The posterior intercostal veins lie in direct continuity with the *vertebral plexus of veins (Batson plexus)* that surround the vertebrae and extend from the base of the skull to the sacrum. This plexus has great importance clinically, as these veins may provide an important conduit for hematogenous dissemination of breast cancer. This vertebral venous plexus may physiologically account for metastases to the skull, vertebrae, pelvic bones, and central nervous system in the absence of pulmonary metastases.

INNERVATION OF THE BREAST

Neurosensory innervation of the gland is primarily supplied by the lateral

and anterior cutaneous branches of the 2nd through the 6th *intercostal nerves* (Fig. 46.6). These sensory nerves of the breast originate *principally* from the 4th, 5th, and 6th intercostal nerves, although the 2nd and 3rd intercostal nerves may provide cutaneous branches to the cephalad aspect of the breast. Cutaneous sensory supply is further augmented by nerves arising from the cervical plexus, specifically the anterior or medial branches of the supraclavicular nerve; these nerves supply a limited region of the skin of the upper portion of the breast. Collectively, these nerves convey sympathetic fibers for innervation to the breast and the overlying skin.

The *lateral branches* of the intercostal nerves exit the intercostal space via the attachment sites of the slips of the serratus anterior muscle. These nerves divide into anterior and posterior branches as they exit the muscle. Anterior branches of the intercostal also supply the anterolateral thoracic wall. The third through the sixth branches, known as the *lateral mammary branches*, supply the majority of the surface of the breast. As noted above, the *intercostal brachial nerve*, a large and constant sensory nerve, takes origin from the lateral branch of the second intercostal nerve. The intercostal brachial nerve courses through the fascia of the floor of the axilla to commonly join the *medial cutaneous nerve* of the arm. This nerve is of little functional significance; however, with injury to the intercostal brachial nerve during axillary dissection, the principal consequence for the patient is modest loss of cutaneous sensation in the upper medial aspect of the arm and axilla. No motor loss is evident after injury or division of the intercostal brachial nerve but prolonged hypoesthesia and/or paresthesia can be expected. This physiologic consequence is the genesis of principle somatic morbidity in the postoperative patient.

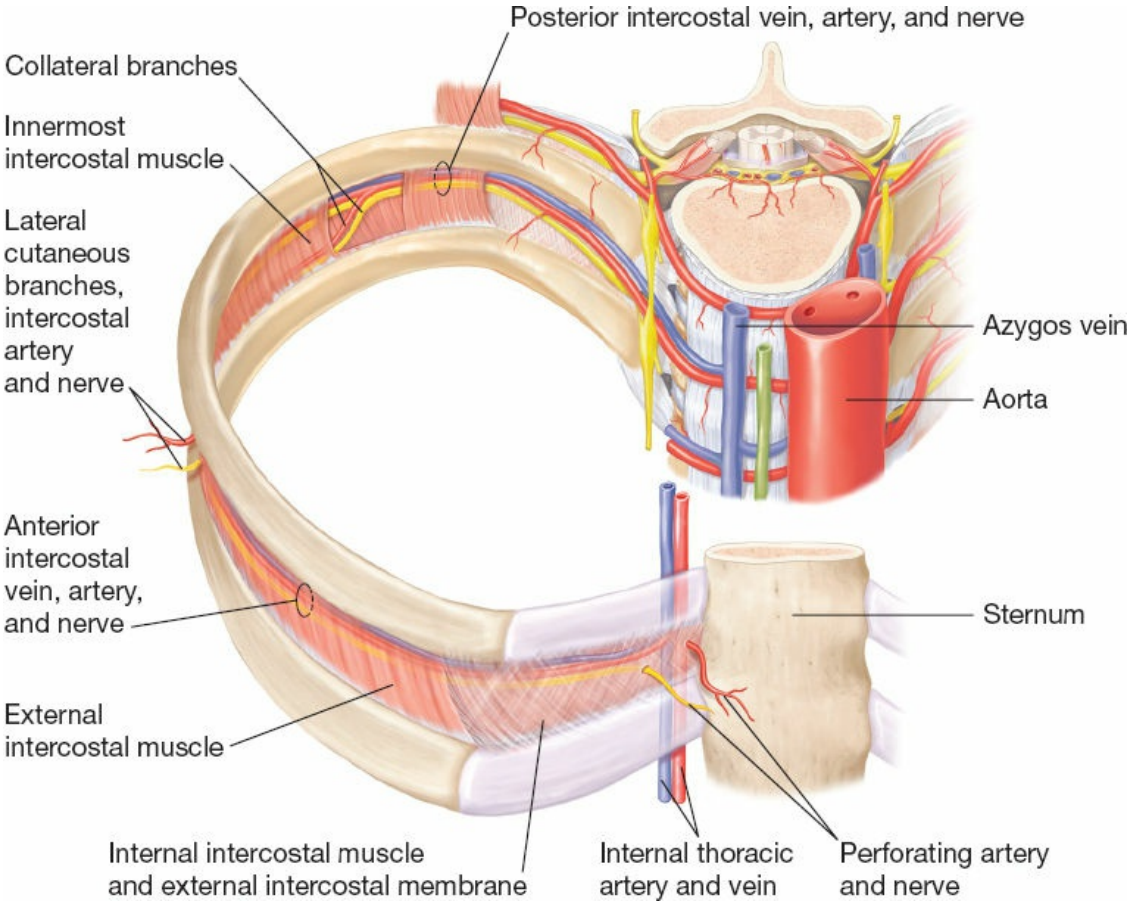

Figure 46.6. A segment of the body wall illustrating the relationship of structures to the ribs. Two ribs are shown as they extend from the vertebrae to attach to the sternum. The orientation of the muscle and connective tissue fibers is shown. The external intercostal muscle extends downward and forward. The muscle layer extends forward from the rib tubercle to the costochondral junction, where the muscle is replaced by the aponeurosis, called the external intercostal membrane. The internal intercostal muscle fibers with the opposite orientation can be seen through this layer. The innermost intercostal muscle fibers are present along the lateral half of the intercostal space. The intercostal nerve and vessels pass through the intercostal space in the plane between the internal and innermost (or intima of the internal) intercostal muscle layers. Anterior intercostal arteries arise from the internal thoracic artery; anterior intercostal veins join the internal thoracic vein. Posterior intercostal arteries arise from the aorta; posterior intercostal veins join the azygos venous system on the right and the hemiazygos system on the left. Lymphatics follow the path of the blood vessels. Anteriorly, lymphatics pass to parasternal (or internal mammary) nodes that are located along the internal mammary vessels; posteriorly, they pass to intercostal nodes located in the intercostal space near the

vertebral bodies.

The anterior branches of the intercostal nerves exit the intercostal space near the lateral border of the sternum to allow arborization of branches medially and laterally over the thoracic wall. The branches that course laterally innervate the medial aspect of the breast and are referred to as *medial mammary branches.*

LYMPHATIC DRAINAGE OF THE BREAST

Lymphatic drainage of the breast is primarily via the laterally positioned axillary lymph node groups, (levels I, II, III) (Fig. 46.7). There have been considerable variations in nomenclature for the lymph node groups of the axilla as the boundaries of these nodal groups are not well demarcated. These variations are particularly evident in level I nodal groups. Historically, anatomists have described four principal levels (groups) of axillary lymph nodes; whereas, surgeons typically identify six groups inclusive of three anatomic levels. The most commonly used terms to describe the axillary nodes are as follows:

1. The *axillary vein group,* usually identified by anatomists as the *lateral group,* consists of four to six lymph nodes that lie lateral and posterior to the axillary vein and at level I. This group is well identified at the anatomic confluence of the lateral vein with the latissimus dorsi. These nodes receive the majority of lymphatic contents from the upper extremity and ipsilateral back with the exception of lymph that drains into the deltopectoral lymph nodes, a group also referred to as the *infraclavicular nodes* (Fig. 46.8).
2. The external mammary group (Fig. 46.8), usually identified by anatomists as the *anterior or pectoral group,* consists of four or five lymph nodes positioned along the lower and lateral border of the pectoralis minor muscle contiguously associated with the lateral thoracic vessels. These nodes receive the principal volume of lymph drainage from the breast parenchyma and are positioned, as well, at level I. From these nodes, lymph drains primarily into the central lymph nodes (see below). However, lymphatics may interconnect with direct passage from the external mammary nodes, to the subclavicular lymph nodes, and to Rotter's (interpectoral) nodal group (all level II).
3. The *scapular group* (Figs. 46.7 and 46.8), usually identified by anatomists as the *posterior or subscapular group,* consists of six or

seven lymph nodes positioned near the posterior wall of the axilla in juxtaposition to the lateral border of the scapula and contiguous with the subscapular vessels near the "axillary floor." This group also occupies level I nodal group. These nodes receive lymph primarily from the lower aspects of the neck, the posterior skin and subcutaneous tissues of the trunk (as low as the iliac crest), and posterior portions of the shoulder region. Lymph from the (sub)scapular nodes drains into the central and subclavicular nodes.

4. The *interpectoral* or *Rotter's group* (Figs. 46.7 and 46.8), usually identified by surgeons but not by anatomists, consists of one to four small lymph nodes located *between* the pectoralis major and minor muscles. This group in level II is contiguous with pectoral branches of the thoracoacromial vessels. Lymph from these nodes enters the central and subclavicular nodes.
5. The *central group* (Figs. 46.8 and 46.9), considered to be centrally positioned by both anatomists and surgeons at level II, and consists of three or four large lymph nodes that are embedded in the fat of the axilla, usually behind the pectoralis minor muscle. These level II nodes receive lymph from the preceding nodal groups (lateral axillary, external mammary, and (sub)scapular nodal sites; all level I) and may also receive afferent lymphatic vessels directly from the breast parenchyma. Lymph from the central group, which may lie directly upon the ventral and anterior aspects of the axillary vein, and thereafter, drain directly into the *subclavicular* (apical, level III) nodes. This group is often placed superficially beneath the skin and the fascia of the mid axilla, and it is centrally located between the posterior and anterior axillary folds. This *superficial* nodal group is the most easily palpable with evident axillary adenopathy. This is the most numerous of axillary lymphatics; anatomically its superficial position may provide accurate clinical assessment of metastatic disease.
6. The subclavicular group, identified by anatomists as the apical group, consists of 6 to 12 lymph nodes that are located in part posterior and partially above the upper border of the pectoralis minor muscle. This nodal group extends into the apex of the axilla along the medial aspect of the axillary vein and is anatomically a level III group (Figs. 46.8 and 46.9). These nodes receive lymph from all other axillary lymph node groups. Thereafter, these efferent lymphatic vessels from the subclavicular lymph nodes unite to form the subclavian trunk. The course of the *subclavian trunk* is highly variable anatomically. It may join and directly enter the internal jugular vein or the subclavian vein,

or their junction. On the right side of the subclavian trunk, the right lymphatic duct may enter this structure, whereas on the left side confluence with the *thoracic duct* is common. Efferent vessels from the subclavicular lymph nodes may also pass to the deep cervical lymph nodes.

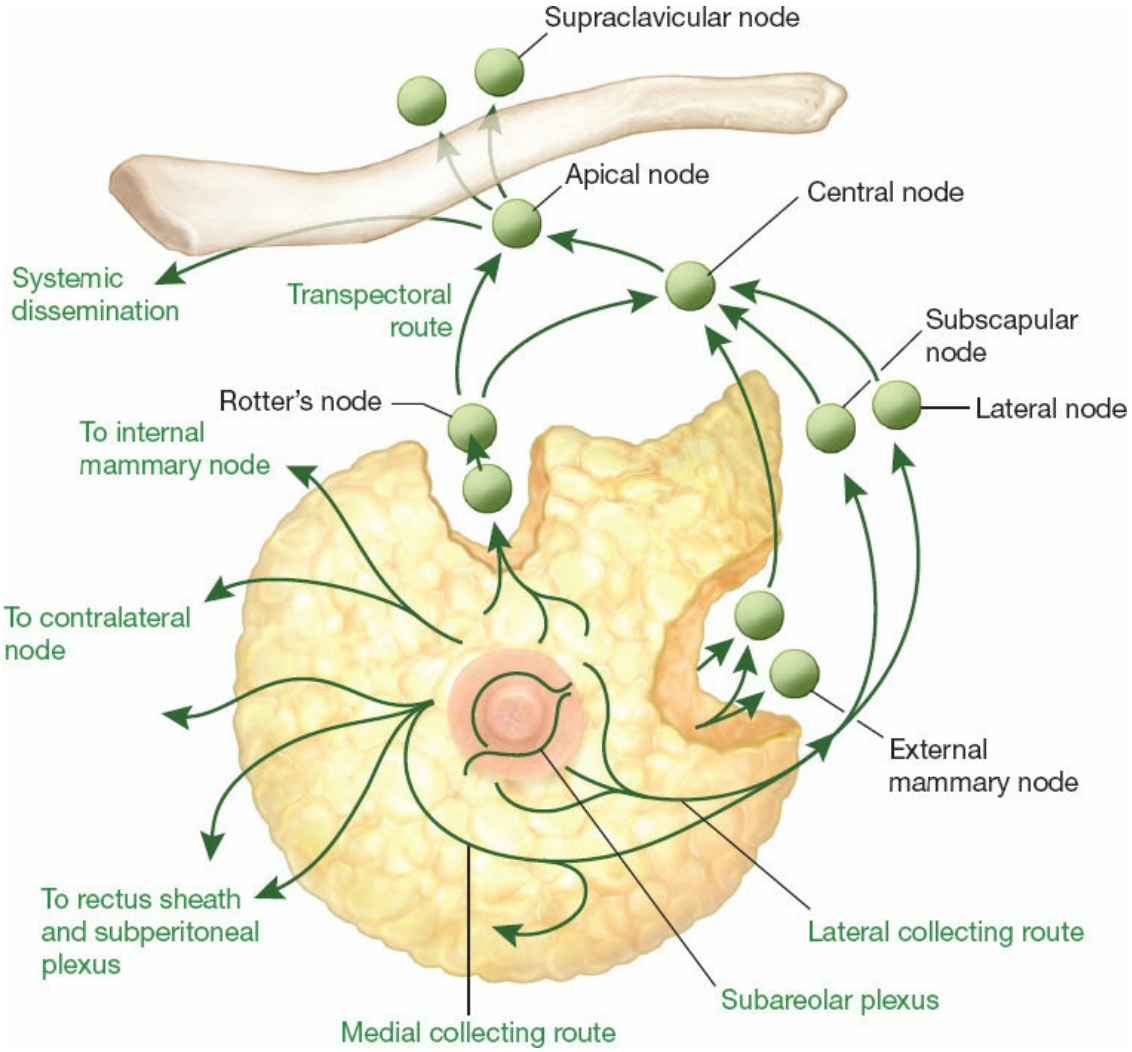

Figure 46.7. Schematic drawing of the breast identifying the position of lymph nodes relative to the breast and illustrating routes of lymphatic drainage. The clavicle is indicated as a reference point. See the text and Figure 8 to identify the group or level to which the lymph nodes belong. Level I lymph nodes include the external mammary (or anterior), axillary vein (or lateral), and scapular (or posterior) groups; level II, the central group; and level III, the subclavicular (or apical). The *arrows* indicate the routes of lymphatic drainage (see text).

As detailed above, axillary lymphatics are divided into three distinct levels according to their lateral and medial (surgical) anatomic

relationships with the pectoralis minor muscle. These nodal groups are identified as *levels I through III* (Figs. 46.8 to 46.10). *Level I nodes* are located lateral to or below the inferior border of the pectoralis minor; this level includes the *external mammary*, the *lateral axillary vein*, and the *scapular lymph node groups. Level II nodes* are located deep upon the ventral/caudad surface of the axillary vein *OR* behind the pectoralis minor and include the *central lymph node group* and possibly the lateral *subclavicular* lymph node group. *Level III nodes* are located superomedial to the upper margin of the pectoralis minor and include the *subclavicular (apical) lymph node group* (Figs. 46.7 to 46.10). This nodal group is contiguous with the axillary venous entry into the subclavian vein, entering between the 1st and 2nd ribs, bilaterally.

The British surgeon W. Sampson Handley is credited with the recognition of metastatic spread of breast carcinoma to the *internal mammary nodes* as a primary route of systemic lymphatic dissemination. As an anatomist, Handley provided extensive clinical and anatomic research to confirm that central and medial breast lymphatics pass medially and parallel to the course of major blood vessels, to perforate the pectoralis major muscle, and terminate in the internal mammary nodal chain.

Internal mammary nodes are located within the retrosternal interspaces between the costal cartilages, approximately 2 to 3 cm within the sternal margin (Figs. 46.7 to 46.10). This nodal group traverses and parallels the internal mammary vasculature and is invested by endothoracic fascia. The internal mammary lymphatic trunks terminate in the subclavicular nodal groups (Figs. 46.6 to 46.10). The right internal mammary nodal group drains into the right lymphatic duct, whereas the left enters the main thoracic duct (Fig. 46.11).

There are three *interconnecting groups* of lymphatic vessels that drain the breast:

1. A primary set of vessels originate as channels within the gland in the interlobular spaces and parallel the robust accumulation of lactiferous ducts of the breast parenchyma.
2. The vessels draining the glandular tissue and the overlying skin of the central part of the gland pass directly into the subareolar plexus, an interconnecting network of vessels located beneath the areola.
3. The rich lymphatic plexus lies upon the deep surface of the breast to communicate with minute vessels that parallel the deep fascia

underlying the breast. Along the medial border of the breast, lymphatic vessels within the substance of the gland anastomose with vessels that pass to parasternal nodes.

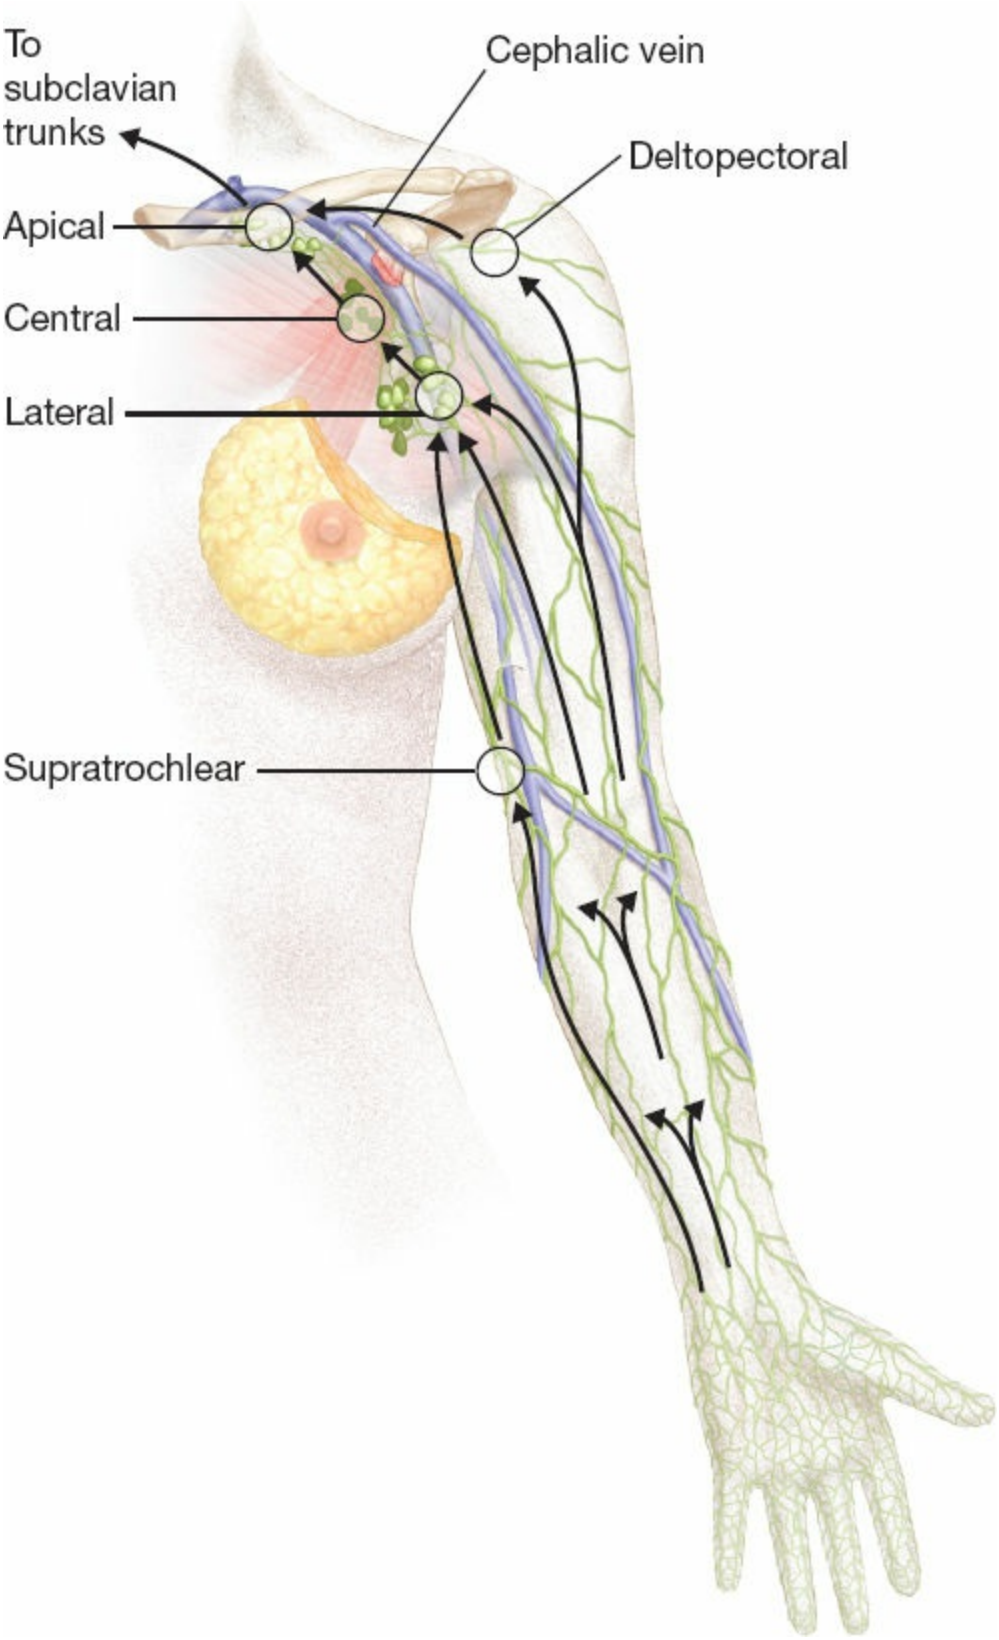

Figure 46.8. Schematic drawing illustrating the route of lymphatic drainage in the upper extremity. The relationship of the drainage to the major axillary lymph node groups is indicated by the *arrows.* All the lymph vessels of the upper extremity drain directly or indirectly through outlying lymph node groups into the axillary lymph nodes. The outlying lymph nodes are few in number and are organized into three groups: (a) supratrochlear lymph nodes (one or two, located above the medial epicondyle of the humerus adjacent to the basilic vein); (b) deltopectoral lymph nodes (one or two, located beside the cephalic vein where it lies between the pectoralis major and deltoid muscle just below the clavicle); and (c) variable small isolated lymph nodes (few and variable in number: may be located in the cubital fossa or along the medial side of the brachial vessels). Note that the deltopectoral lymph node group drains directly into the subclavicular, or apical, lymph nodes of the axillary group.

The key and operative word for lymphatic flow in this organ is *multidirectional* however, greater than 75% of lymph flow directly enters the axillary lymph nodes. The residual medial (nonaxillary) lymph will egress to parasternal nodes, following the course of the internal mammary artery and vein. This anatomic feature provides support for the rationale of the sentinel lymph node biopsy (sampling) of the axilla, popularized and scientifically advanced by Donald L. Morton in the 1990s, to determine the (accurate) histologic status of these nodes and, hence, valid pathologic staging. Although some authorities have suggested that the parasternal nodes receive lymph primarily from the medial part of the breast, others report that both the axillary and the parasternal lymph node groups receive lymph from all quadrants of the breast, with no definitive probability for any quadrant to drain medially or laterally. This observation allows surgeons to use sentinel nodes procured in the axilla to be the principal determinate of pathologic staging, regardless of the quadrant of anatomic presentation of the index tumor. The skin of the breast also drains via the superficial lymphatic vessels to the axillary lymph nodes. The anterolateral chest and the upper abdominal wall cephalad to the umbilicus show a striking unidirectional flow of lymph toward the axilla. Lymphatic vessels near the lateral margin of the sternum pass through intercostal spaces to the parasternal lymph nodes that course with the internal thoracic vessels. In the upper pectoral region, small numbers of lymphatic vessels pass over the clavicle to inferior deep cervical lymph nodes.

Within the fascial and muscular structures of the thoracic wall, lymphatics drain primarily into three groups of lymph nodes: the *parasternal, intercostal,* and *diaphragmatic lymphatics.* The *parasternal (internal thoracic) lymph nodes* are a group of smaller lymphatics positioned approximately 1 cm lateral to the sternal border in the intercostal spaces along the internal mammary vessels. These nodes reside in the areolar tissue just beneath the endothoracic fascia bordering the space between the adjacent costal cartilages.

The *intercostal lymph nodes* (Fig. 46.11) represent a small group located in the posterior portion of the thoracic cavity within the intercostal spaces near the origin of the ribs. One or more nodes are found in each intercostal space with contiguous relationship to the intercostal vessels. These nodes receive deep lymphatics from the posterolateral thoracic wall, including lymphatic channels from the breast. Upper efferent lymphatics from the intercostal lymph nodes on the right side terminate in the right lymphatic duct, whereas the efferent lymphatics from the corresponding nodes on the left side terminate in the thoracic duct.

The *diaphragmatic lymph nodes* consist of three groups of small lymph nodes located upon the thoracic surface on the diaphragm. The anterior group includes two or three small lymph nodes, also known as *prepericardial nodes,* located behind the sternum at the base of the xiphoid process. The efferent lymphatics from the anterior diaphragmatic nodes pass to the parasternal nodes. The lateral set of diaphragmatic lymph nodes is composed of two or three small nodes on each side of the diaphragm, adjacent to the pericardial sac, where the phrenic nerve innervates the diaphragm. These nodes lie near the vena cava on the right side and near the esophageal hiatus on the left. The posterior set of diaphragmatic nodes consists of a few lymph nodes located near the crura of the diaphragm. These nodes receive lymph from the posterior aspect of the diaphragm and convey the same to posterior mediastinal and lateral aortic nodes.

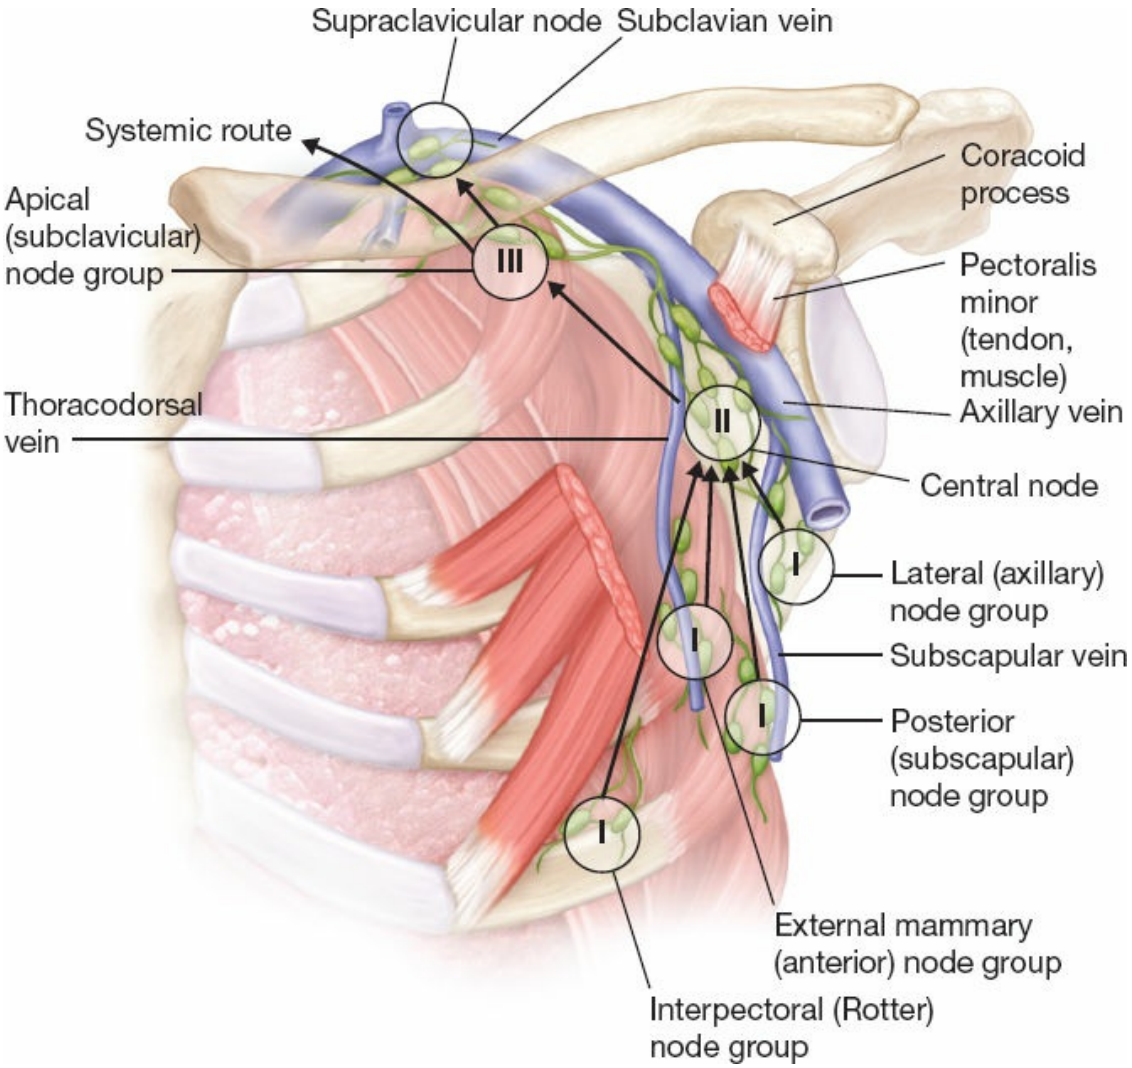

Figure 46.9. Schematic drawing illustrating the major lymph node groups associated with the lymphatic drainage of the breast. The roman numerals indicate three levels or groups of lymph nodes that are defined by their location relative to the pectoralis minor. Level I includes lymph nodes located lateral to the pectoralis minor; level II, lymph nodes located deep to the muscle; and level III, lymph nodes located medial to the muscle. The *arrows* indicate the general direction of lymph flow. The axillary vein and its major tributaries associated with the pectoralis minor are included.

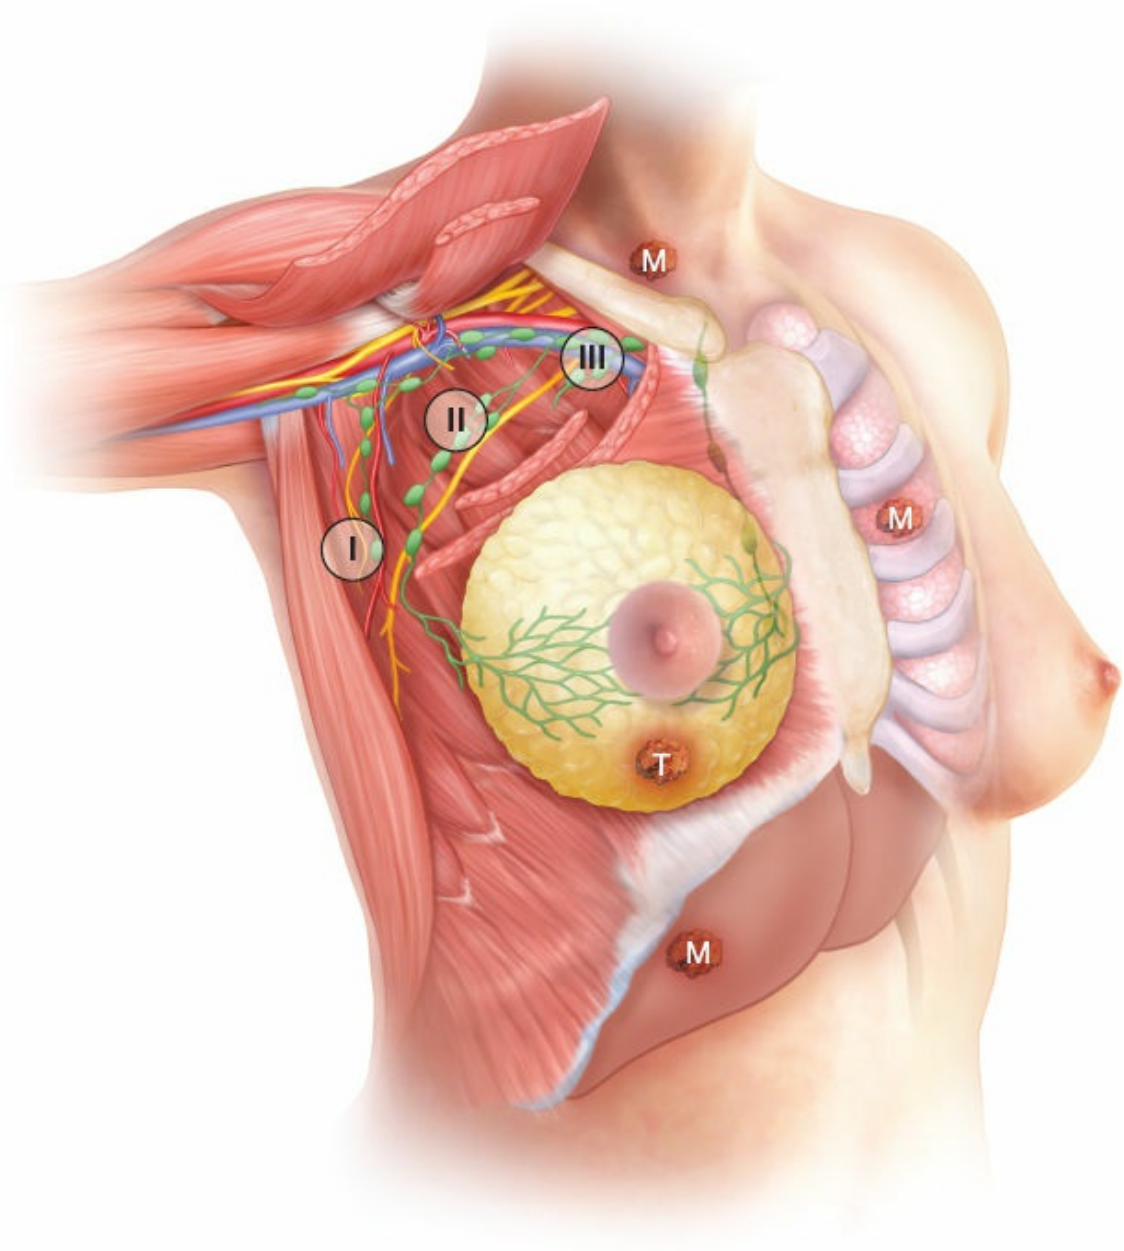

Figure 46.10. Lymphatic drainage of the breast. The pectoralis major and minor muscles, which contribute to the anterior wall of the axilla, have been cut and reflected. This exposes the medial and posterior walls of the axilla, as well as the basic contents of the axilla. The lymph node groups of the axilla and the internal mammary nodes are depicted. Also shown is the location of the long thoracic nerve on the surface of the serratus anterior muscle (on the medial wall of the axilla). The scapular lymph node group is closely associated with the thoracodorsal nerve and vessels. The roman numerals indicate lymph node groups defined in Figure 46.9. M, metastases; T, tumor.

MICROSCOPIC ANATOMY OF THE BREAST

Embryologically, the parenchyma of the mature mammary gland is composed of 15 to 20 irregular lobes of branched tubuloalveolar glands. These lobes, separated by fibrous bands of connective tissue, radiate from the mammary papilla (or nipple) and are further subdivided into multiple lobules. The fibrous bands that support the parenchyma and attach to the cutis reticularis of the dermis are termed the *suspensory ligaments of Cooper*. These tubuloalveolar glands lie within the subcutaneous tissues. Each lobe of the primary gland terminates in the lactiferous duct, 2 to 4 mm in diameter, and empties into the subareolar ampulla via a constricted orifice at the terminus of the nipple (Fig. 46.1). Beneath the areola at the termination of each duct is a dilated portion that is termed the lactiferous sinus. These lactiferous ducts are populated near their openings with stratified squamous epithelium. The epithelial lining of the duct has evidence of gradual transition to two layers of cuboidal cells in the lactiferous sinus, thereafter becoming a single layer of columnar or cuboidal cells distributed throughout the remainder of the ductal system.

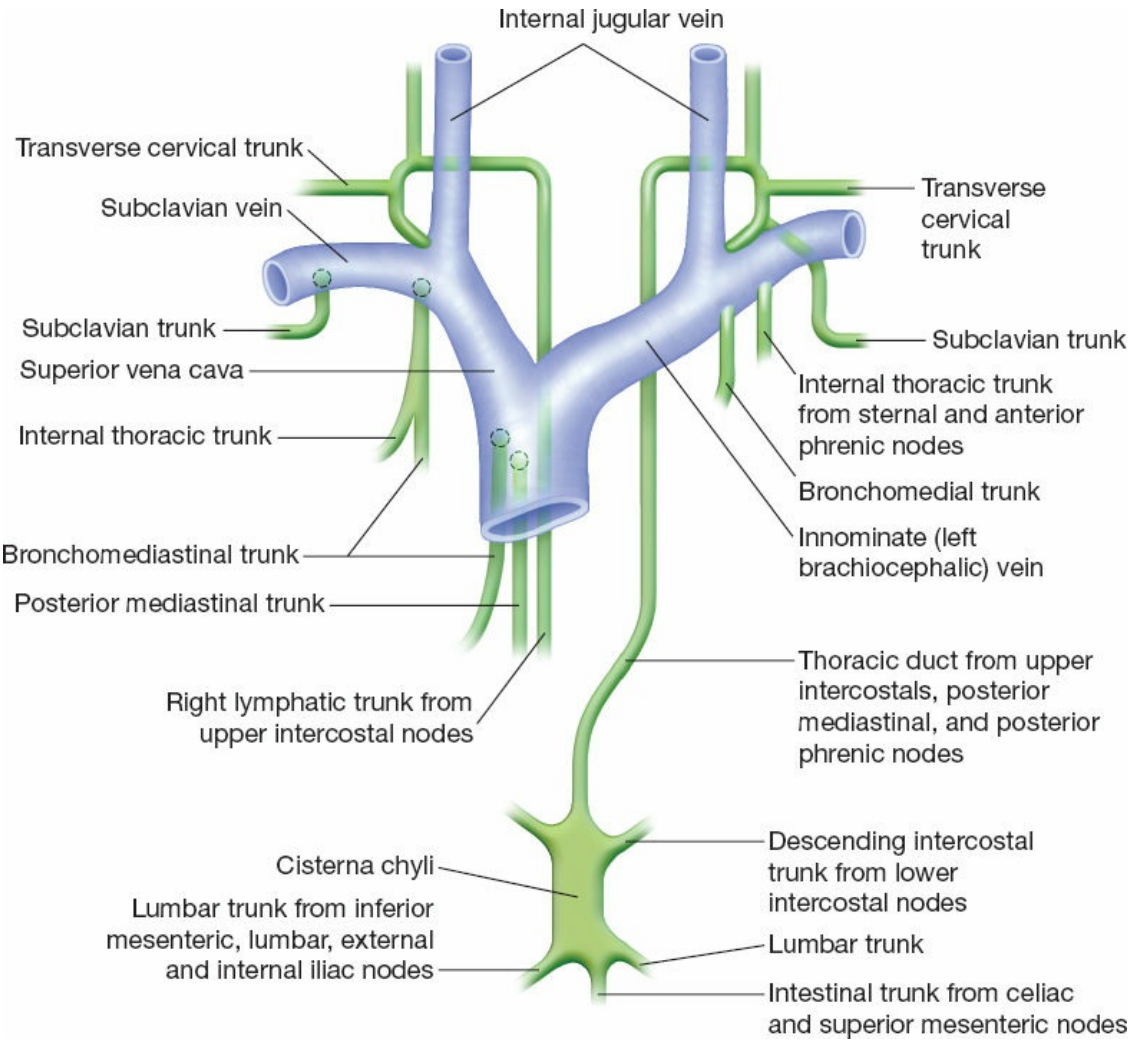

Figure 46.11. Schematic of the major lymphatic vessels of the thorax and the root of the neck. The thoracic duct begins at the cisterna chyli, a dilated sac that receives drainage from the lower extremities and the abdominal and pelvic cavities via the lumbar and intestinal trunks. Lymph enters the systemic circulation via channels that join the great veins of the neck and superior mediastinum. The lymphatic vessels demonstrate considerable variation as to their number and pattern of branching. A typical pattern is illustrated here. Most of the major trunks, including the thoracic and right lymphatic ducts, end at or near the confluence of the internal jugular with the subclavian veins.

Morphology of the secretory portion of the mammary gland varies significantly with patient age and has physiologic and anatomic variance with pregnancy and lactation. The glandular component of the breast is sparse in the inactive (nonpregnant) premenopausal gland and consists predominantly of duct elements. The inactive organ undergoes slight cyclical changes throughout the menstrual cycle. During pregnancy, the gland is altered in size and secretory function with dramatic proliferation inclusive of cellular hypertrophy, lactation, and development. These physiologic events are accompanied by relative diminution in the volume of connective and adipose tissue. With pregnancy, the epidermis of the nipple and areola becomes deeply pigmented and somewhat corrugated. It is covered thereafter with keratinized, stratified squamous epithelium. The areola contains sebaceous glands, sweat glands, and *accessory areolar glands of Montgomery*, which are intermediate between true mammary glands and sweat glands in their structure. These accessory areolar glands present as small elevations on the surface of the areola. Sebaceous and sweat glands are distributed along the margin of the areola. The apex of the nipple contains numerous free sensory nerve endings and Meissner (tactile) corpuscles in the dermal papillae, whereas the areola contains few of these terminal sensory structures. Neuronal plexuses are also present around hair follicles in the skin peripheral to the areola. Pacinian (pressure) corpuscles are present in the dermis and in the glandular tissue. Anatomically and functionally, the rich sensory innervation of the nipple–areolar complex is of great significance to allow lactation and breast feeding.

EDITOR'S COMMENT

Dr. Bland has superbly described the embryologic development of and the anatomical relationships of the tissue, vasculature, and lymphatics of the breast and axilla. Recent developments in oncoplastic procedures of the breast make breast anatomy more important than ever. One of the first of these that I would like to emphasize is total or nipple skin sparing mastectomy (NSSM). When developing flaps for this relatively new procedure, the surgeon must stay in the correct subcutaneous plane. If too thin the surgeon will strip the subcutaneous plexus that lies below the dermis along with the blood supply and the skin flaps will become necrotic. If too thick one risks leaving breast parenchyma behind. The surgeon wants to be right at the level of the superficial fascia of the breast. As this layer is of different thickness dependent on body habitus, Boneti and colleagues have described a dilation technique to determine this layer for the individual patient and consistently achieve viable flaps. The other anatomical consideration in NSSM is the preservation of the blood supply to the skin of the nipple areola as the nipple areolar complex (NAC) proper is removed. This is dependent on preserving the interconnecting network of vessels surrounding the areola within the subcutaneous tissue to feed the otherwise devascularized skin of the nipple and areola. In addition, when taking the NAC it is removed down to the dermis of the nipple. As Dr. Bland has pointed out the lactiferous ducts here are lined with squamous epithelium making the risk of leaving cancer behind in the ducts very low and ultimately assuring that NSSM is safe.

The other point of anatomy that I would like to bring out and that is less understood is the lymphatic anatomy of the axilla. Dr. Bland has done a superb job of describing the traditional concept of where and how the breast drains and similarly the upper extremity. However, it is less clear how the respective lymphatics intermingle within the axilla. This becomes important as we evolve our treatment of the axilla toward mitigating the complication of lymphedema. Using the concept of axillary reverse mapping (ARM), Boneti and colleagues have described variations in the location of the lymphatics draining the arm that include sling and apron patterns that are as much as 4 cm below the vein and in harm’s way during an axillary lymph node dissection or even a sentinel lymph node biopsy. The issue is how often do these coalesce with the lymphatics draining the breast and can they be separated and preserved. ARM is a technique of split mapping (mapping the breast with radiocolloid and mapping the arm with blue dye) and has shown an extremely low rate of coalescence which only occurs in patients with N2 or higher disease. Using this technique, Ochoa and colleagues have shown an extremely low incidence of lymphedema when ARM is added to sentinel lymph node biopsy or axillary lymph node dissection with an equally low rate of axillary recurrence. Further, Ochoa and colleagues describe reanastomosing/reapproximating lymphatics severed during lymphadenectomy with great success and an extremely low rate of lymphedema.

47 Benign Disease and Breast Pain

Amy C. Degnim and Karthik Ghosh

WHAT IS BENIGN BREAST DISEASE

A woman is diagnosed with benign breast disease (BBD) when a radiologic or palpable abnormal area in the breast is subject to biopsy and the pathology is benign. BBD presents clinically with one of two scenarios: (1) a screening breast imaging test shows an abnormality that leads to a benign breast biopsy, or (2) a patient may present with a palpable finding in the breast (with or without suspicious imaging findings) and a biopsy shows benign results. If the findings are benign and concordant with imaging, the woman is diagnosed with BBD. Understanding BBD is important for patient care because multiple studies have reported elevated risk of breast cancer for these women, with varying levels of risk depending on the specific histologic findings that are present (see below). The risk associated with various BBD lesions is an important piece of information to include when estimating a woman's long-term risk of developing breast cancer, which is also influenced by other factors such as family history/genetics, hormonal exposures, mammographic density, and lifestyle factors.

Core Biopsy Is the Standard of Care for Diagnostic Approach

National Comprehensive Cancer Network (NCCN) guidelines indicate that if an abnormality is noted in the breast that warrants diagnostic tissue biopsy, the preferred approach to obtain tissue is with percutaneous core needle breast biopsy. Generally, this is an image-guided biopsy performed under ultrasound, stereotactic, or magnetic resonance imaging guidance. In the uncommon situation of a suspicious palpable abnormality and negative imaging findings, freehand core needle biopsy can be performed. Excisional biopsies are rarely performed as the initial diagnostic procedure, because the majority of mammographic lesions are benign, reducing healthcare costs and risks of surgical excision while still achieving excellent diagnostic accuracy. Furthermore, if cancer is

diagnosed by core needle biopsy, there is a far greater chance of successful treatment with only one operation compared to cases where cancer is diagnosed with surgical excision.

Imaging and Pathology Concordance

All percutaneous needle biopsies should be followed by imaging-pathology concordance evaluation. Assessment of concordance involves review of the clinical and imaging findings to determine if they are consistent with the pathology features of the tissue, in which case concordance is established. In other words, the pathology findings must be plausible to explain the imaging features of the lesion in that individual case. This concordance review and assessment requires multidisciplinary input from the treating clinician (usually a surgeon), the radiologist, and the pathologist. If discordant, such as when the imaging suggests a "suspicious finding" classified as Breast Imaging Reporting and Data System (BI-RADS) 4 or 5 but the pathology is benign, concern exists that the targeted lesion may have been missed at biopsy. Surgical excision of the lesion is the recommended approach to manage discordant breast lesions, as well as other benign lesions diagnosed on core needle biopsy that are shown to have an increased risk that cancer may be present within the lesion but can only be diagnosed accurately with complete surgical excision (so-called "borderline" or "high-risk" lesions). In these situations where adequate diagnosis is best made with complete surgical excision of the lesion, there is a significant risk that cancer will be found at the time of surgical excision and thus the diagnosis will be "upgraded" to cancer (see section below on Management of Benign Breast Disease). The term "high-risk lesion" has also been used to describe breast lesions that confer a long-term increased risk of breast cancer (generally atypical ductal hyperplasia [ADH], atypical lobular hyperplasia [ALH], and lobular carcinoma in situ [LCIS]). Information is presented below for various types of noncancerous breast lesions, along with their management.

Benign Breast Lesions—Histopathology, Management After Core Needle Biopsy, and Long-Term Associations With Breast Cancer Risk

Here we define categories and specific histologic entities of BBD, as well as their management. In order to understand how these benign lesions differ, some basic terminology is necessary regarding the microscopic

anatomy of breast tissue. Breast tissue consists of a branching series of ductal structures designed to channel the flow of milk from the milk-producing units of the breast, called the terminal duct lobular units (TDLUs) also referred to as lobules. This ductal and glandular structure is supported within a stroma of fibrous tissue. Like a cluster of grapes at the end of a vine, the TDLUs contains microscopic sacs called acini (singular form is *acinus*) that are lined with epithelium surrounding a central lumen. In the lactating state, the epithelium produces milk that flows into the central lumen and via the ductal system out the lactiferous ducts of the nipple. BBD includes abnormalities of both epithelial and stromal elements, although most BBD is classified according to the degree of the epithelial abnormality (which also correlates with long-term breast cancer risk).

The three major categories of BBD lesions are based on the degree of epithelial proliferation and abnormality as follows: (1) nonproliferative disease (NPD), (2) proliferative disease without atypia (PDWA), or (3) atypical hyperplasia (AH), as described by Dupont and Page. Multiple studies have demonstrated increasing risk associations across these three categories, with relative risk (RR) increased minimally for women with NPD (RR, 1.3), twofold for women with PDWA (RR, 1.9), and fourfold for women with AH (RR, 4.2) (see Table 47.1).

TABLE 47.1 Classification of Benign Breast Disease

Benign Breast Disease Category	Specific Lesions	Relative Risk of Breast Cancer
Nonproliferative disease	Mild duct hyperplasia Cysts Fibroadenomas Columnar cell change Apocrine metaplasia Duct ectasia Benign phyllodes Pseudoangiomatous stromal hyperplasia	1.2
Proliferative disease without atypia	Ductal hyperplasia (more than mild) Radial scar Sclerosing adenosis Flat epithelial atypia Papillary lesions	1.8
Atypical hyperplasia	Atypical ductal hyperplasia Atypical lobular hyperplasia	4.2
Lobular carcinoma in situ		10

Nonproliferative disease: Includes breast tissue changes such as cysts, fibroadenomas, pseudoangiomatous stromal hyperplasia (PASH), columnar cell change, and mild ductal hyperplasia.

Proliferative disease without atypia: Includes moderate and florid duct hyperplasia, papilloma, radial scar, sclerosing adenosis, columnar cell hyperplasia, and flat epithelial atypia (FEA).

Atypical hyperplasia: Includes ADH and ALH. *Lobular neoplasia* is a term that refers globally to both ALH and LCIS.

Nonproliferative Disease

This group of lesions indicates only mildly increased risk (RR, 1.3) of breast cancer and includes cysts, fibroadenomas, columnar cell change, and mild ductal hyperplasia.

Fibroadenoma

Fibroadenomas are common breast tumors that may present as a palpable mobile, well-defined breast mass or they may be incidentally detected as a mass on mammography. On ultrasound, they are round to oval circumscribed masses with homogenous echotexture, often without posterior shadowing. Histologically, fibroadenomas are predominantly stromal lesions, composed of collagenous stroma containing compressed epithelium that is not proliferative. Fibroadenomas are either simple or

complex, with the latter being based on the finding of sclerosing adenosis, calcifications, or papillary hyperplasia within the fibroadenoma.

Management

Fibroadenomas can sometimes be diagnosed presumptively based upon benign appearing imaging features in a young woman who may elect to follow the lesion rather than undergo diagnostic needle biopsy. However, once diagnosed by core needle biopsy, these lesions do not need to be surgically excised unless there is discordance with imaging or AH identified, in which case surgical excision is recommended to rule out malignancy. Fibroadenomas diagnosed presumptively (without core biopsy) need to be followed clinically every 6 to 12 months and excised in the event of rapid growth, generally defined as a doubling in size over 6 to 12 months. In general, fibroadenomas that are proven on core needle breast biopsy do not require any further evaluation or treatment. However, surgical excision is recommended for a fibroadenoma that is symptomatic, or enlarging, or measures over 2 cm.

Pseudoangiomatous Stromal Hyperplasia

PASH is a benign breast entity that is often noted clinically as a breast mass or on imaging as an asymmetric density or breast mass, leading to a core needle breast biopsy. Histologically, PASH is a stromal abnormality without epithelial proliferation, seen as a diffuse dense fibrosis between lobular units, where the proliferation of fibroblasts results in slit-like spaces resembling blood vessels. PASH is not associated with a significant increase in long-term breast cancer risk.

Management

If the imaging lesion has been adequately sampled, a finding of PASH is considered concordant with imaging and no further intervention is needed. However, if further clinical growth of the breast mass occurs, this suggests a possible sampling error in which case the lesion should be surgically excised.

Columnar Cell Change

Columnar cell change (also called columnar cell alteration) describes an abnormality of the breast epithelium in which the cells exhibit a columnar shape. Although the acini within lobules may enlarge in size and demonstrate larger lumens, there is very little to no epithelial proliferation,

as this condition is defined by only one or two layers of epithelial cells.

Management

Unless discordance or atypia are present (see Flat Epithelial Atypia below), columnar cell change identified on core biopsy does not require surgical excision. Columnar cell change without hyperplasia and without atypia does not confer an increase in long-term risk of breast cancer.

Mild Ductal Hyperplasia

Mild ductal hyperplasia (also called “usual ductal hyperplasia”) refers to an increase in the number of epithelial cells above the basement membrane within the TDLU acini, with the epithelial cells having a normal appearance. In mild usual duct hyperplasia, there are three to four layers and the cells do not completely fill or cross the lumen of the involved acinus.

Management

Mild or usual ductal hyperplasia found on core biopsy does not require surgical excision unless there is concern of discordance. This change is considered NPD and is associated with no significant increase in breast cancer risk.

Proliferative Disease

This group of lesions indicates an approximate twofold increased long-term risk (RR, 1.9) of breast cancer and includes moderate/florid ductal hyperplasia, radial scar, complex sclerosing lesion, sclerosing adenosis, papillary lesions, columnar cell hyperplasia, and FEA.

Moderate/Florid Ductal Hyperplasia

Moderate or florid hyperplasia is similar to usual ductal hyperplasia, with overgrowth of normal appearing epithelial cells that completely fill the lumen of the ductal structure and portray a streaming pattern microscopically. Despite the overgrowth of epithelial cells, the cells have a normal cytologic appearance.

Management

Moderate ductal hyperplasia found on core biopsy does not require surgical excision unless there is concern of discordance. However, this change is considered proliferative disease and is associated with an

approximate twofold increase in breast cancer risk.

Radial Scar/Complex Sclerosing Lesion

Radial scar and complex sclerosing lesions are the same histologically and distinguished only by their size, with lesions >1 cm termed complex sclerosing lesions. This is a benign breast lesion that may present as a palpable mass or on breast imaging and radiologically mimics breast cancer due to its spiculated appearance, prompting diagnostic core needle biopsy. It is composed of a dense collagenous core with epithelial components trapped in this core, mostly benign epithelium, but in some instances there can be atypical epithelium within the radial scar.

Management

Radial scar can often be an incidental histologic finding seen with benign proliferative breast changes on core needle biopsy. In that case, surgical excision is not warranted. However if atypia is present within a radial scar, these lesions should be excised due to an approximate 30% risk of upgrade to cancer. In addition, if the lesion is >1 cm in size, if there is discordance, or the sampling of the lesion is judged to be inadequate, surgical excision should also be performed. Alternately, if radial scar was biopsied with a larger gauge (11-gauge) vacuum biopsy technique with 12 or more cores obtained at biopsy, and no atypia is present, the upgrade rate is likely 5% or less and short-term follow-up mammogram in 6 months is reasonable to assure stability. In the long-term, radial scar and complex sclerosing lesions (without atypia) confer a twofold increased risk of breast cancer.

Sclerosing Adenosis

Sclerosing adenosis is a benign breast condition that is characterized by an increase in the number of lobular acini and myoepithelial cells. This lesion may present as a mammographically detected mass or architectural distortion with calcifications leading to a core needle biopsy.

Management

If the imaging is highly suspicious, and the finding of sclerosing adenosis is discordant with imaging, surgical excision would be advised to rule out malignancy. However, if concordant with imaging, no further work-up would be needed, and routine breast screening recommended. As a proliferative breast lesion, the long-term risk of breast cancer is increased approximately twofold.

Papillary Lesions

Papillomas are a heterogeneous group of lesions that include benign solitary intraductal papillomas, atypical papillomas, and papillary cancer. These are lesions with an epithelium-lined, branching, fibrovascular stalk. They may present clinically with nipple discharge or a breast mass that may be noted radiologically. Imaging often may demonstrate an intraductal mass that is then evaluated with core needle biopsy.

Management

Papillary lesions can be challenging to diagnose with percutaneous core needle biopsy. If atypia is present, then surgical excision is required due to an upgrade rate of approximately 25% to 30%. In addition, papillary lesions that present as a mass over 1.0 cm in size, or if there is imaging and pathology discordance, are also managed with surgical excision. In situations with imaging and pathology concordance and no atypia or associated high-risk lesion, observation is reasonable with a low risk of missed cancer. If observation is planned, clinical and radiologic follow-up in the short term is recommended to assess stability of the finding. Papillary lesions without atypia are a form of proliferative breast disease and are associated with an approximately twofold increase in long-term breast cancer risk. There is a fourfold increased risk of breast cancer for women with papillary lesions containing AH, similar to the risk associated with ADH or ALH alone.

Columnar Cell Hyperplasia and Flat Epithelial Atypia

Columnar cell hyperplasia refers to an abnormality of the breast epithelium in which the cells exhibit a columnar shape and appearance, with hyperplasia defined as more than two cell layers thick. When this is also accompanied by cytologic atypia in the epithelial cells, the condition is termed FEA. FEA is an uncommon entity that is seen in about 5% of percutaneous breast biopsies.

Management

Columnar cell hyperplasia found on core needle biopsy does not require surgical excision, and as a proliferative lesion carries a twofold increase in the long-term risk of breast cancer. The management of FEA is more controversial. Published studies on upgrade rates for FEA diagnosed on core needle biopsy show that at surgical excision approximately 8% to 10% of women are found to have cancer. In addition, approximately 20%

to 25% are found to have AH. Therefore, due to the risk of finding either cancer or AH at excision, both of which would change management compared to FEA alone, surgical excision is recommended for FEA diagnosed on core needle biopsy. As always, surgical excision should be performed in any case of discordant findings. Regarding long-term risk and FEA, due to its cytologic atypia, concern exists that it may portend an increase in long-term breast cancer risk similar to AH. However, a recent study of 282 women in the Mayo Clinic Benign Breast Disease cohort showed that FEA has a risk similar to other proliferative lesions without atypia. However, approximately half of the women with FEA also had AH. In these women with both FEA and AH, their risk was defined by the presence of AH (RR, 4), and the FEA did not further increase risk. In general, women with FEA and no AH or malignancy are not offered chemoprevention on the basis of the FEA finding alone, as the risk elevation is not considered large enough to justify the side effects of the medication. At this time, the recommendation is that if surgical excision shows no evidence of AH or malignancy, the patient can resume yearly breast screening with mammography.

Atypical Hyperplasia and Lobular Carcinoma In Situ

Atypical Hyperplasia (Atypical Ductal Hyperplasia and Atypical Lobular Hyperplasia)

AH refers to both ADH and ALH, lesions characterized by an epithelial proliferation with atypical cytologic changes in the TDLU. In ADH, there is a monomorphic epithelial proliferation that fills the acinar lumens, often with cribriform architecture and secondary “punched out” lumens. The cytologic atypia and architectural changes of ADH are similar to ductal carcinoma in situ (DCIS), but unlike ductal carcinoma in situ, ADH involves only 1 to 2 ducts and measures less than 2 mm. As a result, core needle biopsy can result in underdiagnosis of cancer (especially ductal carcinoma in situ) in 10% to 30% of cases. In ALH, the atypical epithelial cells have a monomorphic and discohesive appearance and distend and enlarge the lobules.

Management

Due to the frequent finding of cancer at surgical excision of ADH found on core needle biopsy, surgical excision is the standard of care. For ALH found on core needle biopsy, the need for surgical excision is less clear,

with multiple published papers showing widely varying rates of cancer upgrade. Although current NCCN guidelines recommend surgical excision of ADH and ALH lesions diagnosed by core needle biopsy, several recent publications suggest that an approach of selective excision may be safe with a low risk of missed cancer. This is more accepted in cases of ALH on core needle biopsy where the ALH was an incidental finding, there is radiologic-pathologic concordance, and no other high-risk lesion is seen microscopically. In that event, an observation approach is reasonable with imaging follow-up at 6 and 12 months. For ADH on core needle biopsy, criteria for avoiding excision are still in evolution but will likely include a lesion size less than 1 cm, near complete removal of the lesion mammographically, and only 1 or 2 foci of ADH microscopically.

Women with AH have a significantly increased risk of future breast cancer, estimated as an absolute risk of breast cancer of 1% to 2% per year, and risk is similar for ADH and ALH. Research suggests that long-term risk in these women is stratified by the number of separate foci of AH found at the time of biopsy, with risk increasing in stepwise fashion for 1, 2, and 3 or more foci of AH. In these women, closer screening is warranted, with annual mammography starting at age 40 (possibly earlier depending on other risk factors for breast cancer such as family history and mammographic density). Similarly, supplemental screening can be considered with breast magnetic resonance imaging if overall lifetime risk is estimated to be at least 25%. Furthermore, women with ADH or ALH should be counseled about lifestyle changes to reduce risk (see below) and the use of prevention medications, which reduce breast cancer risk by 50% to 70%.

Lobular Carcinoma In Situ

LCIS most often presents as an incidental finding seen on breast biopsy. Histologically it is similar to ALH with expanded acini in the TDLUs and a monomorphic discohesive cytologic appearance. LCIS differs from ALH in that the TDLUs is completely involved (LCIS) instead of partially involved (ALH), and the degree of expansion of the acini and the TDLUs itself is much greater with LCIS. Studies of mastectomy specimens have shown that LCIS is often multifocal in nature and can be present in both breasts.

Management

The need for surgical excision is controversial for LCIS observed on core

needle breast biopsy. Published studies show wide variation in upgrade rates to cancer, but similar to ALH, recent studies support an approach for imaging surveillance rather than surgical excision with a <5% risk of missed cancer with the following criteria: LCIS is an incidental finding, radiologic-pathologic concordance is confirmed, and there are no other high-risk lesions that would indicate surgical excision. Long-term risk of breast cancer is substantial in women with LCIS, estimated as an eightfold increase in RR. In terms of absolute risk estimation, recent data show that women with LCIS have a long-term risk of ~2% per year. Therefore, long-term management of women with LCIS should include more intensive imaging surveillance, as well as thorough discussion of risk reduction options, including prevention medications as well as surgical risk reduction with bilateral mastectomy (see below).

Phyllodes Tumors

Phyllodes tumors of the breast present most commonly as a palpable breast mass and less commonly as circumscribed, lobulated masses on mammography. They are also known to increase in size over time and often present as large masses, sometimes up to 20 cm in diameter. Histologically, phyllodes tumors have a hypercellular stroma that is out of proportion to the epithelium. These lesions generally do not have proliferative epithelial changes and therefore are not classified according to the typical range of BBD categories. Phyllodes tumors are categorized as benign, borderline, and malignant based on World Health Organization (WHO) classification that accounts for stromal cellularity and atypia, stromal overgrowth, mitotic activity, and tumor margin.

Management

For phyllodes tumors diagnosed on core needle biopsy, wide local excision remains the mainstay of surgical management of phyllodes tumors, whether benign, borderline, or malignant. For benign phyllodes tumors, complete surgical excision to negative margins is adequate treatment with a low risk of local recurrence, with larger margins desired for borderline and malignant lesions. Local recurrence occurs in about 15% of patients with phyllodes tumors and is more common after inadequate excision. Studies have shown that local recurrence is lower for women who have wide local excision with >1 cm margin compared to resection with less than 1 cm margin for all types of phyllodes tumors. However, this is more important for women with borderline and malignant tumors. Margin over 1

cm may not be necessary for women with benign phyllodes especially if wide excision will be disfiguring for the patient. For patients with borderline and malignant phyllodes, local recurrence was reduced when margin-negative excision was followed by radiation therapy when compared to excision alone.

Risk Reduction Strategies

Lifestyle

A healthy lifestyle with regular exercise, healthy low fat diet, maintaining a healthy weight, avoiding smoking, and avoiding or limiting alcohol are measures that can be associated with up to 25% reduction in breast cancer risk.

Medications

Medications including tamoxifen, raloxifene, exemestane, and anastrozole have been studied and demonstrated to have benefit in reducing breast cancer risk. These agents are offered to women with a 5-year breast cancer risk over 1.66% as estimated by various risk prediction models, and also should be offered to women with AH or LCIS on breast biopsy. Risk reduction of 50% is noted for most women, with up to 70% risk reduction in women with AH. In addition to the benefits, the side effects and precautions have to be clarified with the patient. Discussing the pros and cons and taking a shared decision-making approach based on risk assessment and patient preferences is the recommended approach.

Risk Reduction Mastectomy

Risk reducing mastectomies are not generally required for women with BBD as the lifetime risk of breast cancer is not as high as noted with for women with deleterious breast cancer susceptibility gene germline mutations. However, in select cases, based on patient values and preferences, risk-reducing surgery may be offered to women with AH or LCIS who have had multiple breast biopsies, or for women who have a strong family history of breast cancer. When considering bilateral mastectomy, women need to be well informed that this is a personal decision that needs to be made with complete information of the pros and cons of the procedure, changes in body image and sexuality, risks of the intervention itself, as well as other options for risk reduction, so that they are satisfied with the ultimate outcome.

Summary of Benign Breast Disease

Women diagnosed with BBD have a wide range in long-term risk of breast cancer, with some lesions associated with no increased risk such as benign cysts or fibroadenomas to others with substantially increased risk such as women with LCIS or multiple foci of AH. Surgical excision needs to be considered for some lesions diagnosed with core needle biopsy in order to ensure that cancer is not missed. Clarifying the pathology finding, ensuring imaging and pathology concordance, and multidisciplinary approach is needed to guide management. Tailoring therapy based on these features, the patient's other risk factors for breast cancer, and taking into account the patient's preferences will ensure the most optimal management of this condition.

BREAST PAIN

Breast pain (or mastalgia) is a common concern for women and may necessitate a clinical visit for evaluation. In a 10-year study of a health maintenance organization, breast pain was the indication for 47% of breast-related clinical visits.

Etiology/Pathophysiology

Breast pain may often be physiologically related to hormone effects on breast tissue. However, evaluation is needed to determine whether the cause is due to a benign condition or malignancy. Mastalgia can be classified as cyclic or noncyclic based on its relationship with the menstrual cycle. Cyclic mastalgia occurs in premenopausal women, who experience mastalgia most prominently in the second half of the menstrual cycle and that resolves with the onset of menstruation. Noncyclic mastalgia is unrelated to the menstrual cycle and may be related to conditions such as breast infection or mastitis, breast lumps such as fibroadenomas, or hematoma from breast trauma. An uncommon entity, thrombophlebitis of the breast (Mondor disease), can present with mastalgia. Other conditions that can present as mastalgia but are nonbreast related include chest wall pain from costochondritis, radiculopathy, cardiac etiology, or gastro-esophageal reflux disease (GERD). Although there are many benign conditions that can cause mastalgia, breast cancer is in the differential diagnosis for breast pain and is the primary diagnosis that should be ruled out. When pain is due to breast malignancy it is usually

noncyclic in nature, but there can be a cyclic component in premenopausal women.

Clinical Presentation

A detailed history and examination are important components of the evaluation. The patient history should include location of pain, duration, intensity, timing related to the menstrual cycle, radiation of pain to or from another site, aggravating or relieving factors, recent trauma, and medication changes especially related to hormone use; these can all provide clues to the etiology of pain (Table 47.2). On examination, it is important to pinpoint the location of the pain, especially focal pain such as in a specific breast location, or parasternal pain as with costochondritis, or pectoral muscle pain.

TABLE 47.2 Benign Causes of Breast Pain

Cyclic:
Fibrocystic changes
Use of hormones: oral contraceptives, post-menopausal estrogen therapy
Noncyclic:
Mastitis
Superficial thrombophlebitis (Mondors disease)
Hematoma from breast trauma
Breast lumps—fibroadenoma, lipomas
Chest wall pain such as costochondritis, pectoral myalgia
Coronary artery disease
Gastrointestinal—related to hiatal hernia, gall bladder disease
Neurologic such as radiculopathy

Evaluation

Breast imaging with mammography and targeted ultrasound is reasonable for patients aged 30 or older with a palpable abnormality or focal breast

pain to rule out an underlying cyst or mass contributing to the symptom. For women younger than 30 years, targeted ultrasound alone is reasonable.

Persistent breast pain despite treatment also warrants reassessment.

Management

Women with mastalgia and no abnormality on examination or imaging can be reassured of the absence of malignancy and for many patients, no further intervention is needed. In addition, conservative management approaches can be discussed.

Use of a fitted bra has been offered for patients with breast pain as breast tissue can pull on the chest wall if the tissue is unsupported or inadequately supported. Using a well-fitting bra for physical activity such as running is also recommended.

Methylxanthines including caffeine found in coffee, tea, chocolates, and some respiratory medications have been thought to cause breast pain. However, research in this area does not provide strong evidence of an association. Although controversial, many patients report benefits with discontinuation of caffeine, and being an inexpensive and noninvasive therapy, it is reasonable for the patient to try to see if it helps symptoms. A low fat diet has also been reported to help symptoms. Gentle massages, stretching exercises for upper body, and use of nonsteroidal anti-inflammatory medications may also be helpful.

A few research studies have evaluated the use of medications to help with breast pain. For women on postmenopausal estrogen therapy, stopping the medication can result in pain relief. Another approach to reduce estrogen stimulation on the breast tissue is to use tamoxifen, a selective estrogen receptor modulator, which has been shown to provide relief of breast pain. Benefits of tamoxifen have to be assessed keeping the side effects in perspective, and it should be used only for short periods such as 3 to 6 months for symptom relief. Side effects include hot flashes, vaginal symptoms, and more serious but infrequent concerns of deep vein thrombosis, pulmonary embolism, stroke risk, and uterine cancer risk. The only medication that has been Food and Drug Administration (FDA) approved for breast pain is danazol. However, the significant androgenic side effects of the medication make it a less attractive option for symptom management unless the patient is refractory to all other nonsurgical options. The dopamine agonist, bromocriptine has also been studied for breast pain management. Although therapeutically effective, the

medication is rarely used due to the significant side effects of nausea and vomiting, and headache. Evening oil of primrose and vitamin E have been reported to relieve breast pain symptoms but a randomized, double blind, placebo-controlled study failed to report benefit of either of these agents when compared with placebo. In a meta-analysis report on agents used for treatment of mastalgia, bromocriptine, danazol, and tamoxifen were shown to result in significant pain relief while evening primrose oil had no benefit.

Surgical procedures, such as excisional biopsy of a tender area or mastectomy for mastalgia, should only be done as a last option and if requested by the patient, ensuring that the patient is well informed and understands that the surgery may not relieve the pain symptom.

Summary of Breast Pain

In summary, a detailed history and examination, targeted imaging as needed, and if no abnormality, conservative management with plan for reassessment for persistent or worsening pain is recommended.

EDITOR'S COMMENT

Degnim and colleagues have given a very detailed explanation on benign and high-risk lesions with advice on when further surgical investigation is necessary. A few clarifications are necessary. Any lesion with atypia in the name should be treated as any other atypia. Surgical excision should be performed secondary to the risk of associated breast cancer. When dealing with small (less than 2 cm) probable benign lesions, every attempt should be made to percutaneously excise them making close follow-up unnecessary. Percutaneous excision of such a mass can be done at the time of the core biopsy for diagnosis and takes only a few minutes more to completely excise such a mass at no extra cost.

Breast pain often does not receive the attention it should. After all, it is one of the most common presenting complaints of women. In a recent survey two thirds of women complained of breast pain with one fifth of these cases being severe. It can be normal up to 5 days prior to the start of the menstrual cycle if mild. As with most of medicine a good history and physical can help sort out not only the cause of mastalgia but determine how to treat it. Severity can be

assessed by how much the mastalgia affects the patient's habits of daily living including work, sex, and sleep. Dietary intake of caffeine, fats, and medication should be assessed including cardiac and antihypertensives (digoxin, methyldopa, minoxidil, spironolactone, and other diuretics), hormone replacement therapy, psychiatric medications (selective serotonin reuptake inhibitors, venlafaxine, haloperidol, and other antipsychotics), antimicrobials (ketoconazole, metronidazole), antacids (e.g., cimetidine and related medicines), cyclosporine, domperidone, penicillamine, and methadone. A recent history of stress or trauma should lead one to consider the very common cause of breast pain, shoulder bursitis. This is especially true in the postmenopausal patient where endogenous hormones would not play a factor. Mild cases are easily treated with heat to the scapulothoracic bursa and analgesics. More severe cases can be treated with steroid trigger point injections. Because stress itself can raise prolactin levels mild cases can be treated with obtaining a normal mammogram and reassurance.

Age appropriate work-up should be undertaken of the breast pain patient because as much as 22% of breast cancer is associated with pain and as much as 7% of breast cancer can present as pain alone. The old myth that breast cancer does not hurt is simply false. However, no study has reported an increased risk of breast cancer with cyclical mastalgia. Cysts can be diagnosed with ultrasound and can cause severe pinpoint pain which can be treated with aspiration when small or percutaneous excision when large.

As might be predictable, there is a long list of suggested treatments for such a pervasive and variable symptom whose cause is, most of the time, unknown and whose relationship to benign and cancerous breast disease is so poorly understood. There are many treatments for mastalgia that have been proven by randomized clinical trials to be moderately effective for mastalgia including abstinence from methylxanthines like caffeine (83% effective), analgesics (92% effective), danazol (an attenuated androgen, 64% to 92% effective, 30% side effects), luteinizing hormone releasing hormone (LHRH) agonist (67% effective, 37% side effects), thyroid replacement (73% effective), molecular iodine (65% effective, 11% side effects), and tamoxifen (56% to 90% effective, 65% side effects). Placebo-controlled trials are necessary to prove the effectiveness of such agents as breast pain has a high spontaneous resolution as well as a high placebo effect. What has not been well controlled for in these studies is the cause of the breast pain. For example, if the cause of breast pain is bursitis then abstinence from caffeine is not helpful but as your bursitis improves over time it may appear to work. However, dietary changes including decreased caffeine ingestion and a low fat diet have been shown to decrease the fibrocystic changes in the breast as assessed with mammography as well as breast pain. An unfaultable, prospective study that accurately assesses methylxanthine intact paired with reliable dependent variables to assess pain has yet to be performed. Dietary manipulation is difficult to achieve but costs nothing to try. Ineffective treatments include diuretics, progesterone, vitamins

E, AB1, and B6.

Initial studies indicated that women with mastalgia have abnormally low blood levels of gamolenic acid, an essential fatty acid which can affect prolactin levels. Early clinical experience with evening primrose oil (EPO), a source of gamolenic acid, produced a good response rate. However, two more recent multicenter randomized controlled trials have not supported or contradicted this earlier evidence of the efficacy of EPO or antioxidants in the treatment of breast pain. A meta-analysis reviewing the data from all randomized controlled trials using EPO revealed no significant beneficial effect over placebo.

The exact influence of iodine on breast tissue is not understood. Eskin and colleagues demonstrated that iodine is involved particularly in the breast which has receptors for iodine. Absence of iodine may render the epithelium of the terminal intralobular ducts more sensitive to estrogen stimulation. Objective improvement was noted in 72% of those receiving molecular iodine as first-line therapy. Molecular iodine was found to be nonthyrotropic, without side effects, and beneficial for breast pain. Thyroid hormones may work in a similar way and may antagonize the effects of estrogen at the pituitary receptor levels of thyroid releasing hormone (TRH), although there is no conclusive support for this. Relative estrogen dominance is suggested as a cause for the increase in prolactin responsiveness to TRH in patients with mastalgia. Testing for hypothyroidism and replacement as necessary may also be helpful in some patients and relatively innocuous. Bromocriptine is effective through an antiprolactin mechanism and has been associated with a significant clinical response in patients with cyclic mastalgia. However, its use has been associated with seizure and death and is no longer recommended for mastalgia.

It is clear that estrogen and progesterone play a causative role in premenopausal breast pain. Therefore, various androgen formulations have been tried to treat mastalgia. The major problem has been side effects. Danazol is an attenuated androgen and therefore has less side effects. Danazol competitively inhibits estrogen and progesterone receptors in the breast, hypothalamus, and pituitary; multiple enzymes of ovarian steroidogenesis; the midcycle surge of LH in premenopausal women; and reduces gonadotropin levels. It is the only medication approved by the FDA for the treatment of breast pain. Danazol is usually started at 200 to 400 mg/day in divided doses. To prevent androgen-related side effects, danazol is weaned within a few months or even given only in the second half of the menstrual cycle. Eventually, danazol can be discontinued in those women with a complete response. Gestrinone is another androgen derivative with less data and is similarly effective to danazol with perhaps less side effects.

For those with severe mastalgia LHRH agonist can be tried to induce ovarian ablation and extremely low levels of ovarian hormones. Monthly injections of an LHRH analog can result in an overall response rate of more than 81% in patients with both cyclic and noncyclic mastalgia. Because LHRH can induce osteoporosis only short courses of LHRH analogs should be used and only for

severe refractory cases of mastalgia. Likewise tamoxifen, an estrogen agonist–antagonist, 20 mg per day were associated with a 75% reduction in mean pain scores in patients with cyclic mastalgia in a double-blind, controlled, crossover trial. However, tamoxifen is associated with major side effects including hot flashes, vaginal dryness, and rarely uterine cancer. Because of side effects tamoxifen as well as toremifene, 4-hydroxytamoxifen, centchroman, and other selective estrogen receptor modulators should only be used for refractory mastalgia.

Breast pain can present as a referred pain from the shoulder or other spinal abnormalities. When pain is mild heat on the scapula and nonsteroidal analgesics may be effective. Trigger points can be found along the medial scapular border. Injections containing a mix of lidocaine, bupivacaine, and steroids are used in the trigger point(s). The short-acting lidocaine is diagnostic if at least some relief occurs within 15 minutes. Relief is continued because of the long-acting bupivacaine allowing time for the steroid to decrease inflammation in the scapulothoracic bursa. Daily heat to the scapula and nonsteroidal analgesics accentuate the anti-inflammatory effect and result in long-acting relief. Patients should become aware of what caused the bursitis (e.g., heavy lifting) and avoid it.

In summary, a good history and physical is key to the accurate diagnosis of pain and ultimately its treatment.

48 Diagnostic Approach to Breast Abnormalities

Catherine Caldwell Parker, Heidi Umphrey, Helen Krontiras, and Kirby I. Bland

Breast cancer accounts for 26% of all female cancers (excluding nonmelanoma skin cancer and in situ cancers). Despite significant strides in the treatment of breast cancer, 232,340 women were diagnosed with invasive breast cancer and 39,620 women died of the disease in 2013 alone. The highest incidence rates of breast cancer occur in non-Hispanic white females; however, the death rates for breast cancer are highest among African-American females. Breast cancer awareness has increased dramatically over the years. Therefore, women presenting with breast complaints are anxious about the possibility of being diagnosed with breast cancer. Clinicians evaluating these women should provide a comprehensive, efficient, and timely consultation in order to relieve anxiety with either a benign diagnosis or initiate an appropriate treatment plan should a cancer be diagnosed.

HISTORY AND PHYSICAL EXAMINATION

A thorough history and physical examination are essential components of the diagnostic evaluation of a breast abnormality. Key features of the history include details about the presenting symptom, history of previous breast disease or prior breast surgery, as well as, risk factors for breast cancer including a menstrual history and other contributing past medical history. Initial questions should focus on the presenting symptom, which could include a breast mass, nipple discharge, palpable adenopathy, pain, or abnormal imaging. As in any history, questions should be asked regarding the length of time the abnormality has been present, associated pain, change in size or texture of the breast or overlying skin over time, and the relationship of the pain or change in size of the breast or mass to the menstrual cycle. In addition, it is important to ascertain whether the patient has noticed any associated nipple discharge, nipple changes or

inversion, axillary adenopathy, or skin changes. If the patient reports nipple discharge, it is important to inquire whether the discharge is spontaneous or occurs only with manipulation, as well as, the color of the discharge, clear, green, white, or bloody. A patient may also notice staining of spontaneous discharge on her bra or bedclothes.

Identification of risk factors responsible for increasing a woman's likelihood of developing breast cancer is important in the daily practice of clinicians caring for women of all ages. Risk factors for developing breast cancer can be divided into several categories: gender, age, endocrine factors, family history, Ashkenazi Jewish heritage, genetic or inherited factors, breast density, and previous breast disease. Female gender is the most common risk factor for breast cancer. A woman living in the United States has 12.3% or 1 out of 8 lifetime risk of being diagnosed with breast cancer. Male breast cancer accounts for less than 1% of all breast cancer. A patient's risk for developing breast cancer increases with age. A woman in the sixth decade has a 1 in 24 chance of developing breast cancer, compared with 1 in 257 for a woman in her third decade. Endocrine risk factors for breast cancer include endogenous estrogen exposure as well as exogenous exposure to estrogen and progesterone. Early menarche, late menopause, late parity, and nulliparity all increase exposure to endogenous estrogen. In women posthysterectomy, documentation of concomitant oophorectomy should be obtained. It may be difficult to accurately determine the date of menopause, and often questions about menopausal symptoms may be helpful. Studies have indicated that long-term hormone replacement therapy (with estrogen and progesterone) can increase risk for breast cancer.

Previous personal history of breast cancer increases risk for subsequent breast cancer by approximately 0.7% per year. A previous breast biopsy also increases risk although to a much smaller extent, and this risk is further elevated if the pathology includes atypical hyperplasia or lobular carcinoma in situ. Table 48.1 lists the pathologic classification of benign breast disease and the risk associated with each category. A family history of breast or ovarian cancer consistent with genetic or inherited breast cancer significantly increases risk. A history of prior thoracic irradiation in women in their second and third decades of life carries a risk of subsequent breast cancer of approximately 35% by age 40. A summary of risk factors is listed in Table 48.2. It is important to note, however, that 60% of women with newly diagnosed breast cancer have no identifiable

risk factors. Thus, the decision to evaluate a breast abnormality should not depend on the presence or absence of risk factors. Moreover, the presence or absence of risk factors does not influence the probability that a breast abnormality is malignant.

TABLE 48.1 Pathologic Classification of Benign Breast Disease and Associated Risk

Lesion	Relative Risk
Nonproliferative Breast Disease (No Increased Risk)	**None**
Cysts and apocrine metaplasia	
Duct ectasia	
Mild ductal epithelial hyperplasia	
Calcifications	
Fibroadenoma	
Proliferative Breast Disease (Mild Increased Risk)	**1.5–2.0-fold**
Sclerosing adenosis	
Radial and complex sclerosing lesions	
Florid ductal hyperplasia	
Benign intraductal papilloma without atypia	
Flat epithelial atypia	
Proliferative Disease with Atypia (Moderate Increased Risk)	**4.0-fold**
Atypical ductal hyperplasia	
Atypical lobular hyperplasia	
Lobular carcinoma in situ	**6–10-fold**

The physical examination should be performed with respect for patient privacy and comfort without compromising the complete evaluation. The examination begins with inspection. The breasts are visually observed and compared with the patient upright for any obvious masses, asymmetries, or skin changes. The nipples are also inspected for the presence of retraction,

inversion, or excoriation. Thereafter, patients are then asked to place their hands on their hips and then raise their arms above their head for a more careful inspection of the lower half of the breasts. This maneuver also highlights any subtle skin retraction that is not readily visible with the arms in the relaxed position. Palpation of the regional nodes should then follow to include the cervical, supraclavicular, infraclavicular, and axillary nodal basins bilaterally. Finally, the breast is palpated in a systematic manner with the patient upright with arms relaxed and then again in the supine position with the ipsilateral arm raised above the head.

TABLE 48.2 Risk Factors for Breast Cancer

Gender

Age

Genetic risk factors
- *BRCA1* or *BRCA2* gene mutation
- Bannayan–Riley–Ruvalcaba syndrome
- Li–Fraumeni syndrome
- Cowden syndrome

Family history of breast cancer

Personal history of breast cancer

Previous breast biopsy
- Proliferative breast disease without atypia
- Atypical hyperplasia
- Lobular carcinoma in situ

Previous thoracic radiation

Endocrine risk factors
- Early menarche
- Late menopause
- Late parity
- Nulliparity
- Long-term hormone replacement with estrogen and progesterone

Lifestyle factors
- Alcohol
- Obesity

A dominant mass is defined as being three-dimensional (3D), distinct from surrounding tissues, and asymmetric relative to the contralateral breast. True masses will persist throughout the menstrual cycle. If a dominant mass is identified, it should be measured, and its location, mobility, and character should be documented in the medical record. If uncertainty remains regarding the significance of an area of nodularity in the absence of a dominant mass in a premenopausal woman, a repeat examination at a different point in the menstrual cycle may clarify the issue.

In patients who present with nipple discharge, the nipple discharge is

often elicited during palpation of the breast. The character, color, and location of the discharging duct or ducts should be documented. If the discharge is not grossly bloody, a Hemoccult test may be used to detect occult blood. Pathologic discharge, which is defined as unilateral, uniduct, spontaneous, and/or bloody discharge, should be evaluated initially with breast imaging and followed by surgical duct excision.

Male breast cancer is uncommon, accounting for less than 1% of all breast cancers. The most common male breast complaint is gynecomastia. Gynecomastia is a benign hypertrophy of breast tissue. In older men, the hypertrophy is often unilateral. The patient usually presents with a discoid mass symmetrically placed beneath the areola, which may be tender to palpation. There are a myriad of benign causes of gynecomastia. Many medications are associated with gynecomastia. Gynecomastia is easily distinguished from breast cancer in that breast cancer is asymmetrically located beneath or next to the areola, and may be fixed to the overlying dermis or the pectoral fascia (Fig. 48.1). If breast cancer is suspected, imaging followed by biopsy should be pursued.

IMAGING

Patients referred from another facility should provide prior imaging so that the consulting surgeon may examine the images as part of the complete patient evaluation. Imaging of inadequate quality should be repeated, and additional images should be performed as necessary depending on the specific complaint.

Mammography

Breast cancer incidence increased between 1980 and 1987 due to the widespread use of screening mammography. Since mammography can detect lesions too small to be palpated, cancers can be diagnosed 1 to 3 years earlier than would have been in the absence of screening.

Mammography allows for a description of breast density defined by the Breast Imaging Reporting and Data System (BI-RADS) outlined in Table 48.3. Breast density is not discernable by palpation on physical examination. Instead, density is a mammographic indicator of the amount of glandular and connective tissue relative to fatty tissue in the breast. Breast density is relevant since it is a risk factor for developing breast cancer. Women with very high breast density (BI-RADS Category D) (Fig. 48.2A) have a 4- to 6-fold increased risk of breast cancer compared to

women with the least dense breasts (BI-RADS Category A) (Fig. 48.2B). A number of factors influence breast density, such as age, menopausal status, the use of certain drugs (hormone replacement therapy), pregnancy, and genetics. The percentage of breast density is generally lower among women with higher body weight due to the higher proportion of fatty tissue, and usually breast density decreases with age. While women with denser breasts have been shown to be at increased risk for breast cancer, the etiology remains unclear and researchers often disagree. It is acknowledged that the sensitivity of a mammographic examination for the detection of breast cancer is decreased in patients with dense breast tissue. Due to this, some states have laws requiring that women be informed if they have heterogeneously (Category C) or extremely dense (Category D) breast compositions. At this time, however, there is no expert consensus on what other imaging tests, if any, should be done in addition to annual screening mammography for breast cancer screening in average risk women with dense breasts.

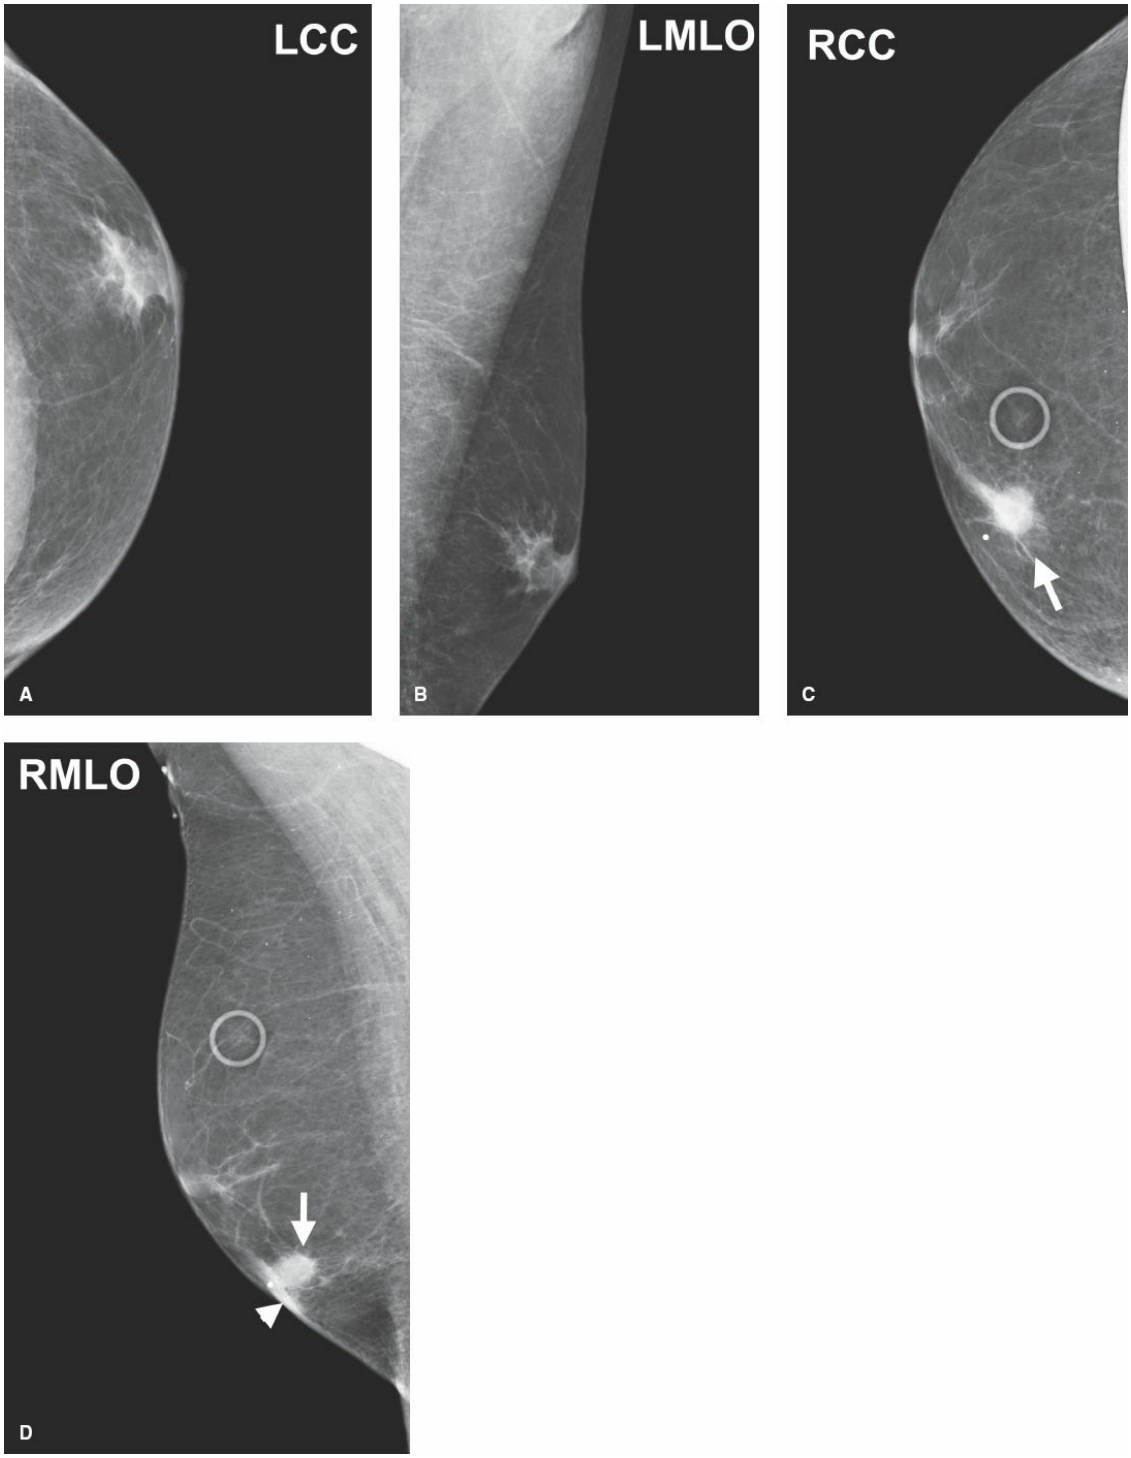

Figure 48.1. Left craniocaudal (LCC) (**A**) and left mediolateral oblique (LMLO) (**B**) views demonstrate left subareolar focal asymmetry, male gynecomastia. Right CC (RCC) (**C**) and right MLO (RMLO) (**D**) views demonstrate a well-circumscribed hyperdense round mass (*arrows*) with associated skin thickening (*arrowhead*), invasive ductal carcinoma. Radiopaque skin markers denote nevi.

TABLE 48.3 BI-RADS Breast Composition Categories

	Description
A	The breasts are almost entirely fatty.
B	There are scattered areas of fibroglandular density.
C	The breasts are heterogeneously dense, which may obscure small masses.
D	The breasts are extremely dense, which lowers the sensitivity of mammography.

Reprinted with permission of the American College of Radiology (ACR). No other representation of this material is authorized without expressed, written permission from the ACR. Refer to the ACR website at www.acr.org/Quality-Safety/Resources/BIRADS for the most current and complete version of the BI-RADS® Atlas.

Screening mammography is used to detect cancer in asymptomatic women when cancer is not suspected. It usually consists of at least two views of each breast in the craniocaudal (CC) and mediolateral oblique (MLO) projections (Fig. 48.3).

The American Cancer Society recommendations on breast cancer screening include:

Annual mammograms starting at age 40
Clinical breast examination (CBE) about every 3 years for women in their 20s and 30s and annually for women 40 and over
Breast self-examination (BSE)—Women should have baseline knowledge of how their breasts normally look and feel in order to report any breast changes to a health care provider right away.
Diagnostic mammography is used to evaluate patients with breast symptoms or complaints, such as nipple discharge or a palpable mass. It is also valuable in the work-up of patients who have had abnormal results on screening mammography. The diagnostic mammographic examination is tailored to the patient's specific abnormality. The

radiologist is present on site during performance of diagnostic mammography to facilitate the assessment process.

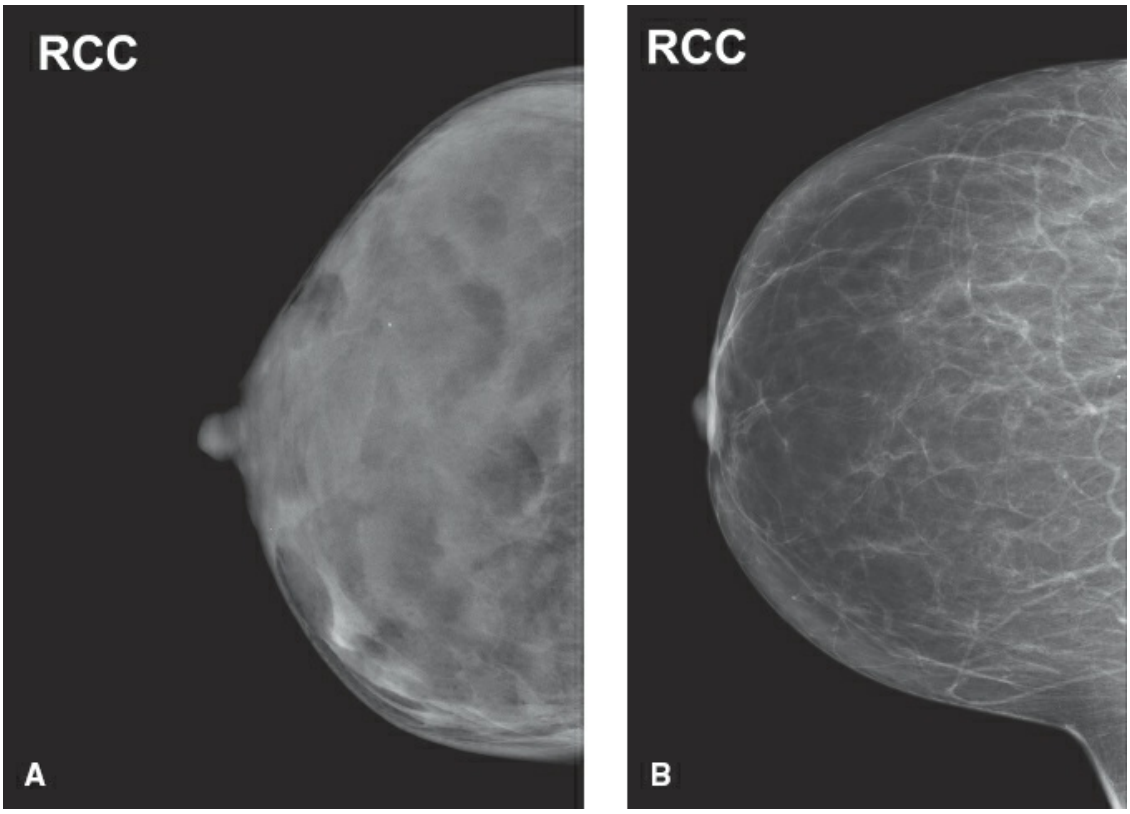

Figure 48.2. A. Right craniocaudal (CC) view demonstrates an extremely dense breast. **B.** Right CC view demonstrates an almost entirely fatty breast.

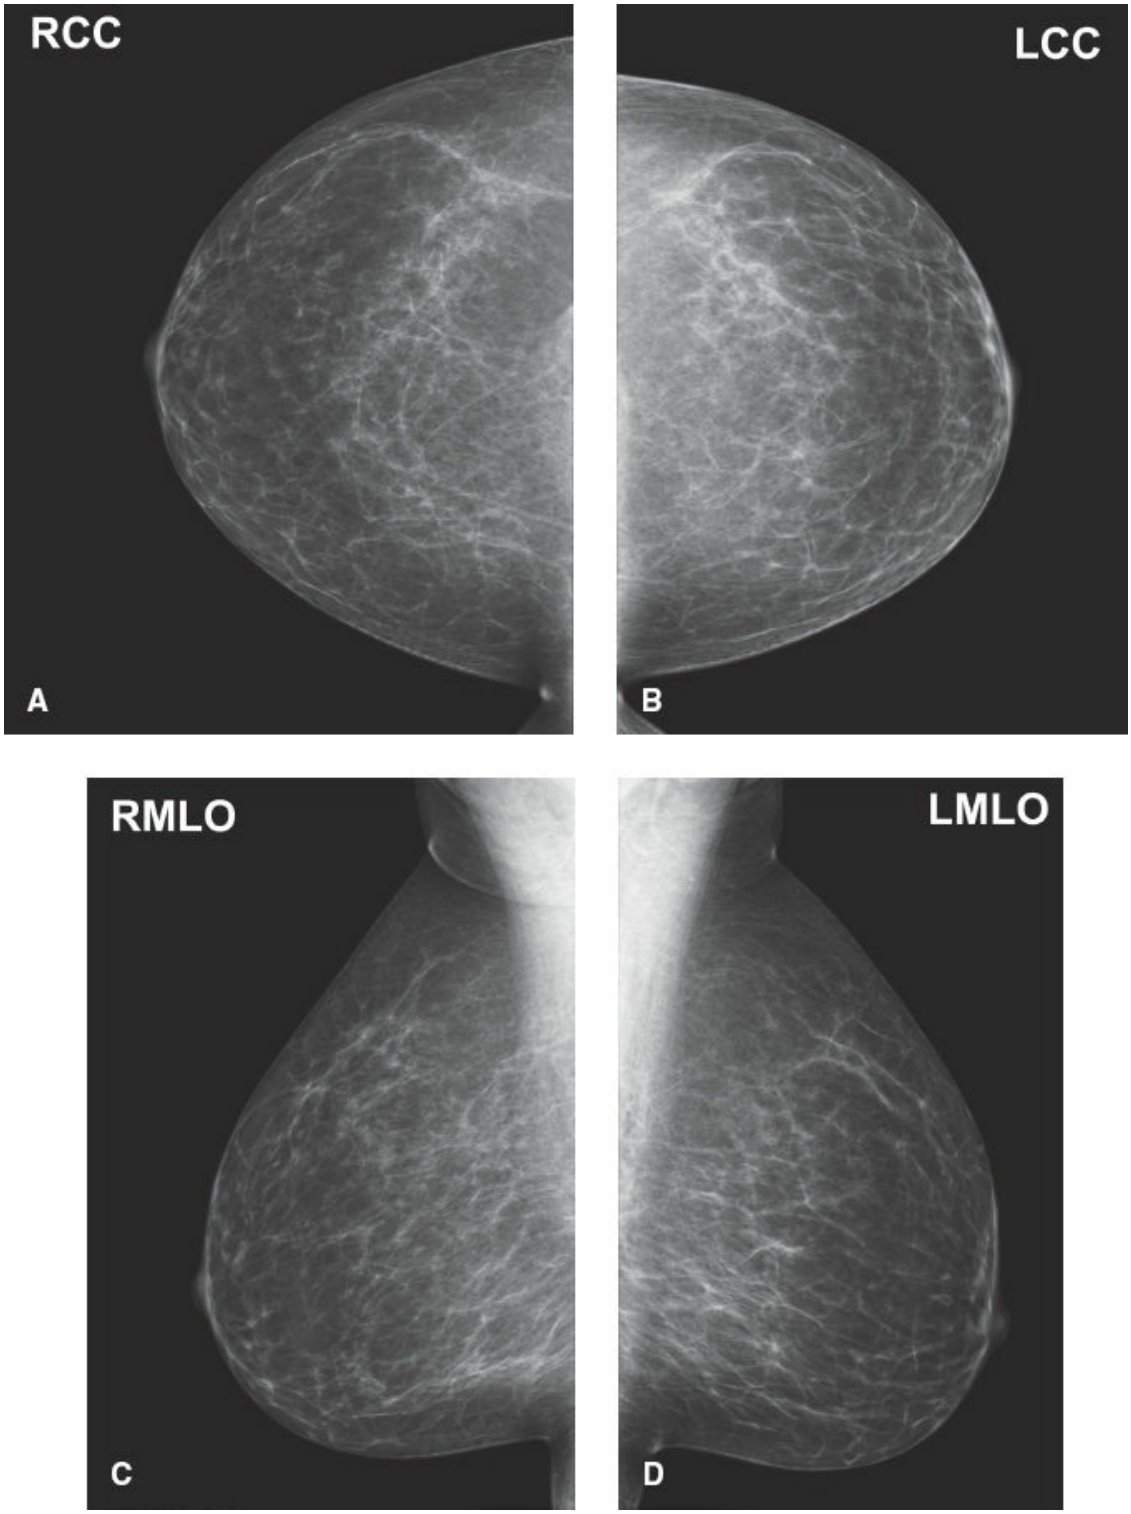

Figure 48.3. Screening mammography consists of craniocaudal (CC) (**A, B**) and mediolateral oblique (MLO) (**C, D**) views. Markers denoting view and laterality are placed near the axilla.

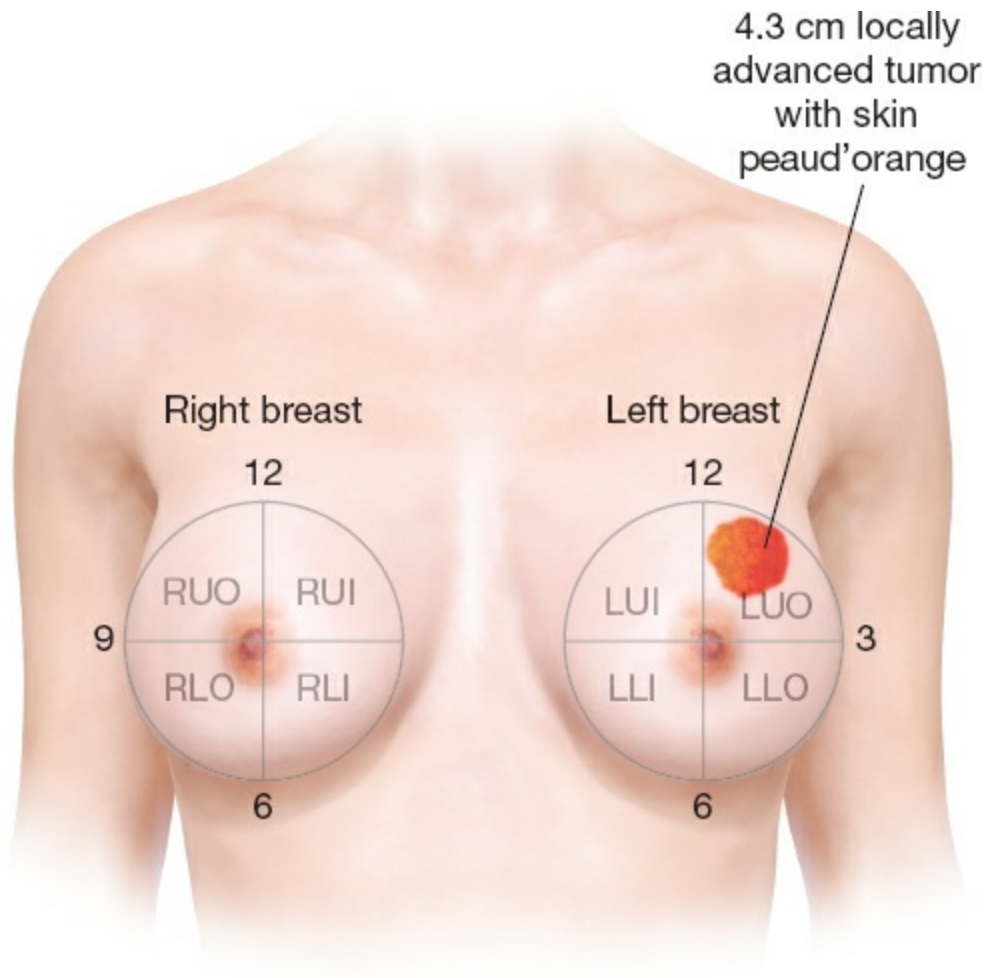

Figure 48.4. Lesions are localized by an o'clock designation with the physician facing the patient.

Screen-film mammography records the image on film, and digital mammography records the image in digital format that can be archived in a picture archiving and communication system (PACS). Images are reviewed for masses, asymmetries, calcifications and changes over time when temporal data is available. Right and left views are examined side by side so that asymmetries can be detected. A magnifying glass or magnification tool may be necessary for a thorough evaluation. The description of the abnormality should include the location of the lesion including laterality, quadrant, (o'clock) position (with the physician facing the patient) (Fig. 48.4), distance from the nipple, and depth.

After analyzing the mammographic images, radiologists describe the finding and subsequently classify the finding into a final assessment category. The BI-RADS final assessment classification was developed by the American College of Radiology to standardize mammographic reporting. The BI-RADS classification is listed in Table 48.4. Follow-up

recommendations are made based on the final assessment category. BI-RADS 0 or “incomplete” final assessments require additional imaging to further assess an abnormality seen on screening examinations. Magnification views, spot compression views, or other additional views are used to define or resolve the abnormality. Spot compression may be used to differentiate an area of summation artifact from a true abnormal lesion. Magnification views may be used to more clearly evaluate calcifications (Fig. 48.5). These techniques may also be used together.

Most mammographically visible cancers present as masses, calcifications, architectural distortion, or a combination of the three. Masses and calcifications account for about 90% of all breast cancers. A mass is a space-occupying lesion that can be detected in two projections. If a finding is only seen on one projection, and has concave margins it is referred to as an asymmetry. An asymmetry may or may not prove to be a real finding after directed diagnostic imaging. Masses are characterized by their shape, margin, density, and associated features (calcifications, distortion, and skin or nipple findings) to determine the probability of malignancy.

The shape of a mass can be described as round, oval, or irregular (Fig. 48.6A–C). Round or oval masses are usually benign. Masses that are irregular imply a greater probability of malignancy. Margin assessment is important because of the infiltrative nature of most breast cancers. Margins can be described as circumscribed, obscured, microlobulated, indistinct, or spiculated. A circumscribed margin that sharply delineates a mass from the surrounding tissue is commonly a benign finding, as seen in a fibroadenoma (Fig. 48.7) or a cyst. A mass with spiculated margins is highly suspicious for malignancy (Fig. 48.8).

TABLE 48.4 BI-RADS Assessment Categories

Assessment	Management	Likelihood of Cancer
Category 0: Need additional imaging evaluation and/or prior mammograms for comparison	Recall for additional imaging and/or comparison with prior examination(s)	N/A
Category 1: Negative	Routine mammography screening	Essentially 0% likelihood of malignancy
Category 2: Benign	Routine mammography screening	Essentially 0% likelihood of malignancy
Category 3: Probably benign	Short-interval (6-month) follow-up or continued surveillance mammography	>0% but ≤2% likelihood of malignancy
Category 4: Suspicious	Tissue diagnosis	>2% but <95% likelihood of malignancy
Category 5: Highly suggestive of malignancy	Tissue diagnosis	≥95% likelihood of malignancy
Category 6: Known biopsy-proven malignancy	Surgical excision when clinically appropriate	N/A

Reprinted with permission of the American College of Radiology (ACR). No other representation of this material is authorized without expressed, written permission from the ACR. Refer to the ACR website at www.acr.org/Quality-Safety/Resources/BIRADS for the most current and complete version of the BI-RADS® Atlas.

Calcifications are a common mammographic finding. Most calcifications are not associated with malignancy. When identified, the shape or morphology, location, number, and distribution of the calcifications should be noted. Malignant-appearing calcifications are usually fine linear branching or fine pleomorphic. Malignant-appearing calcifications are usually in a grouped, linear, or segmental distribution (Fig. 48.5). Benign calcifications are more likely round, milk of calcium, rim or coarse popcorn-like calcifications (Fig. 48.9).

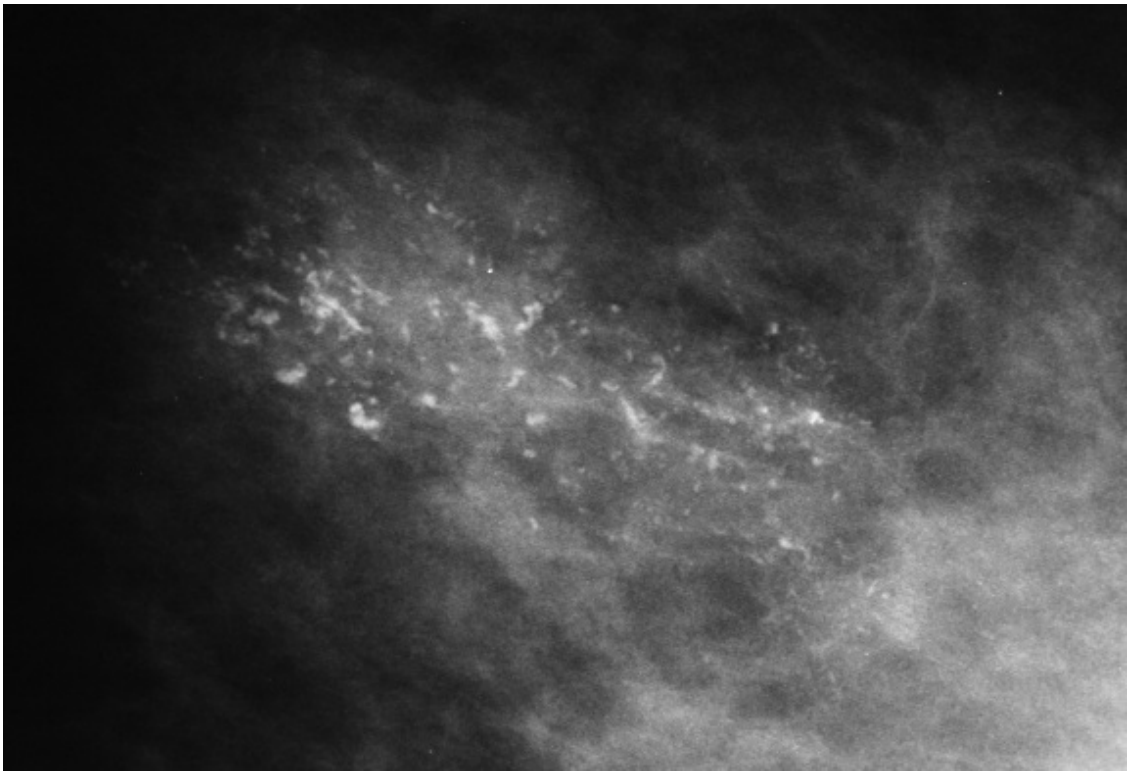

Figure 48.5. Magnification mediolateral (LMML) view reveals fine-linear branching and fine pleomorphic calcifications in a segmental distribution, ductal carcinoma in situ (DCIS).

Fat necrosis is becoming more common and can potentially pose a challenge to clinicians and breast imagers. Fat necrosis results from accidental breast trauma or most commonly seen after surgery (lumpectomy, breast augmentation, or reduction) or radiation therapy. Fat necrosis can present as oil cysts, rim or dystrophic calcifications, focal asymmetries, calcifications, or even spiculated masses (Fig. 48.10). Early evolution of fat necrosis may prove challenging and prompt a biopsy or short-term follow-up.

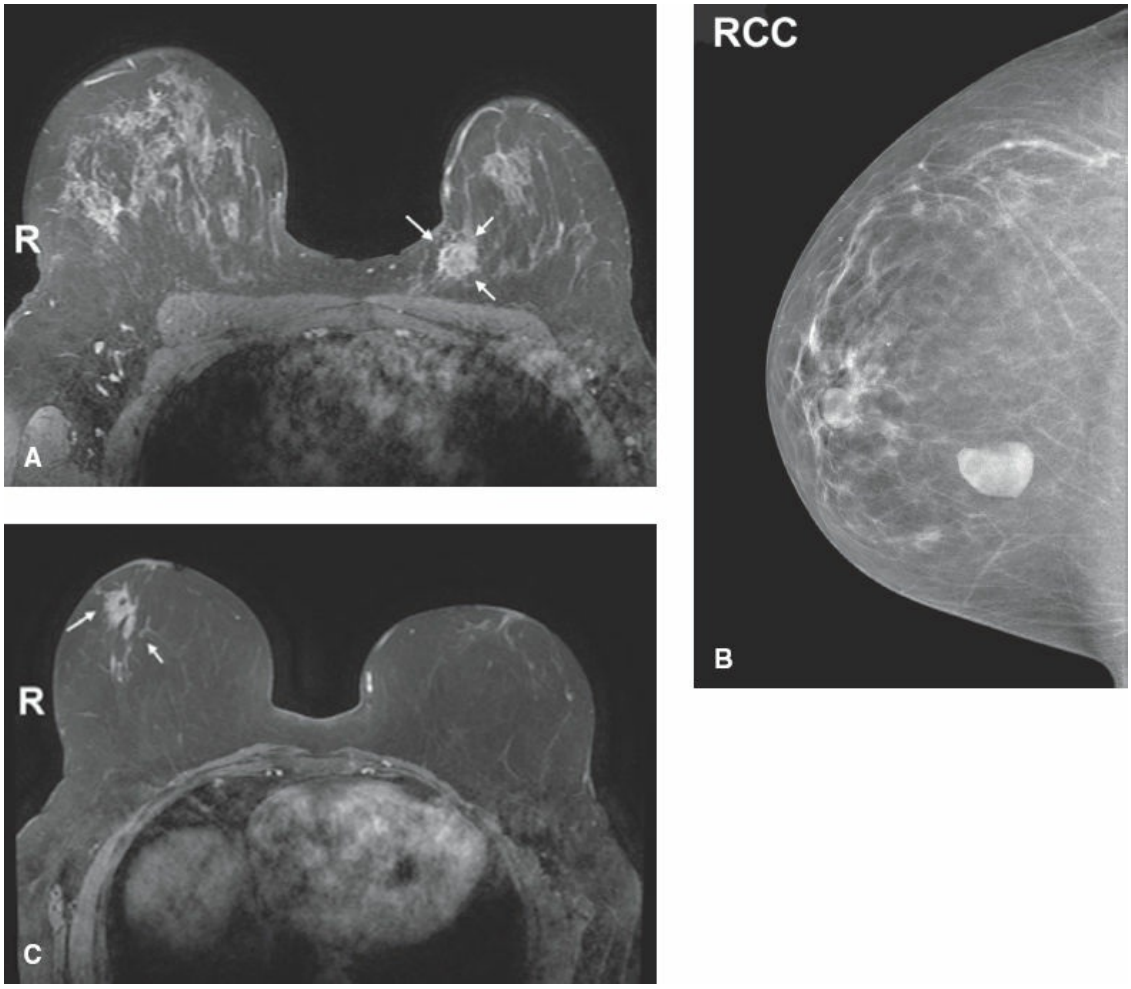

Figure 48.6. Mass shape classification. **A.** Axial T1 fat saturated image demonstrates a round mass in the left upper inner breast with microlobulated margins, invasive medullary carcinoma. **B.** Right craniocaudal (CC) view demonstrates an oval low density mass in the right medial breast with circumscribed margins, pseudoangiomatous stromal hyperplasia (PASH). **C.** Axial T1 fat saturated image demonstrates an irregular enhancing mass with spiculated margins, invasive ductal carcinoma.

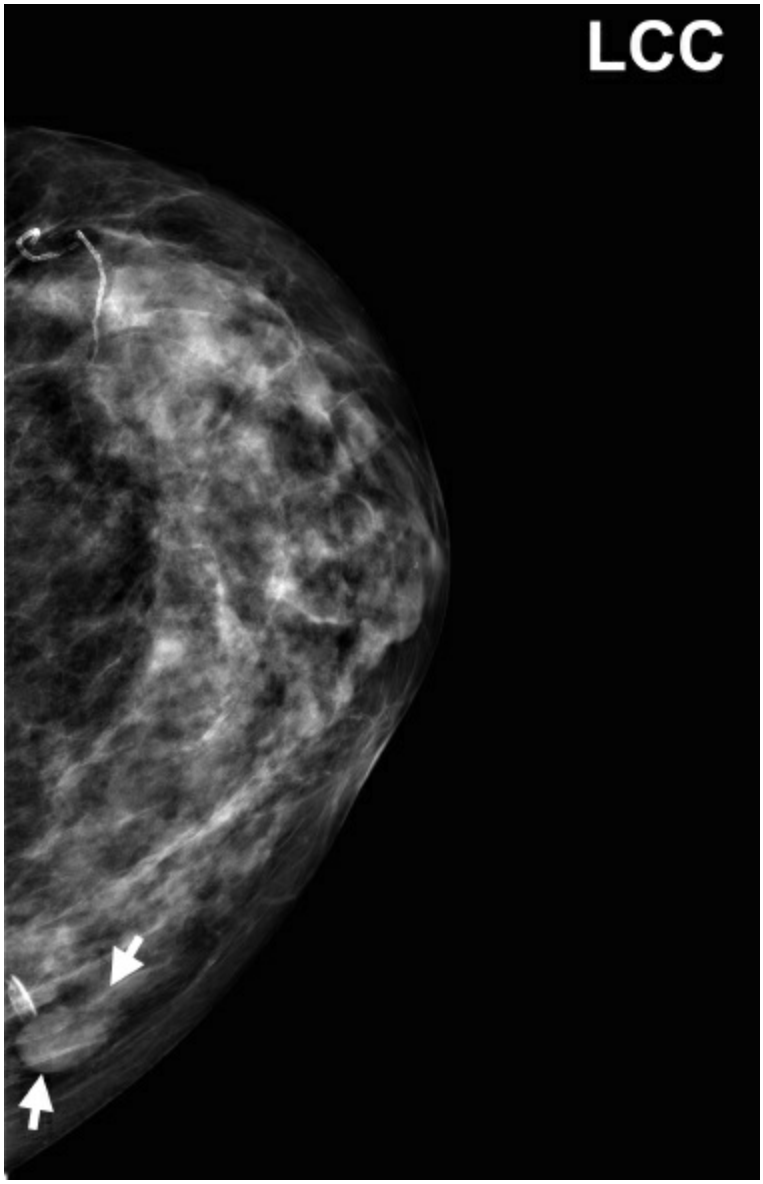

Figure 48.7. Left craniocaudal (CC) view shows an equal dense oval circumscribed mass (*arrows*) in the medial breast, fibroadenoma.

Ultrasound

Ultrasound was initially used to differentiate solid masses from cystic masses, but it has become an important adjunct to mammography and is an excellent method for guiding interventional procedures. Accurate breast ultrasonography requires high-resolution real-time ultrasound equipment that is properly maintained and calibrated. A 7-MHz linear array transducer is the minimum frequency that can be used for ultrasound of the breast, although 10- to 15-MHz linear transducers are preferable. Operators should be trained in breast anatomy and pathology, as well as

basic ultrasound technology and mammography. The patient is positioned so that the depth of tissue penetration needed for imaging by the ultrasound beam is minimized.

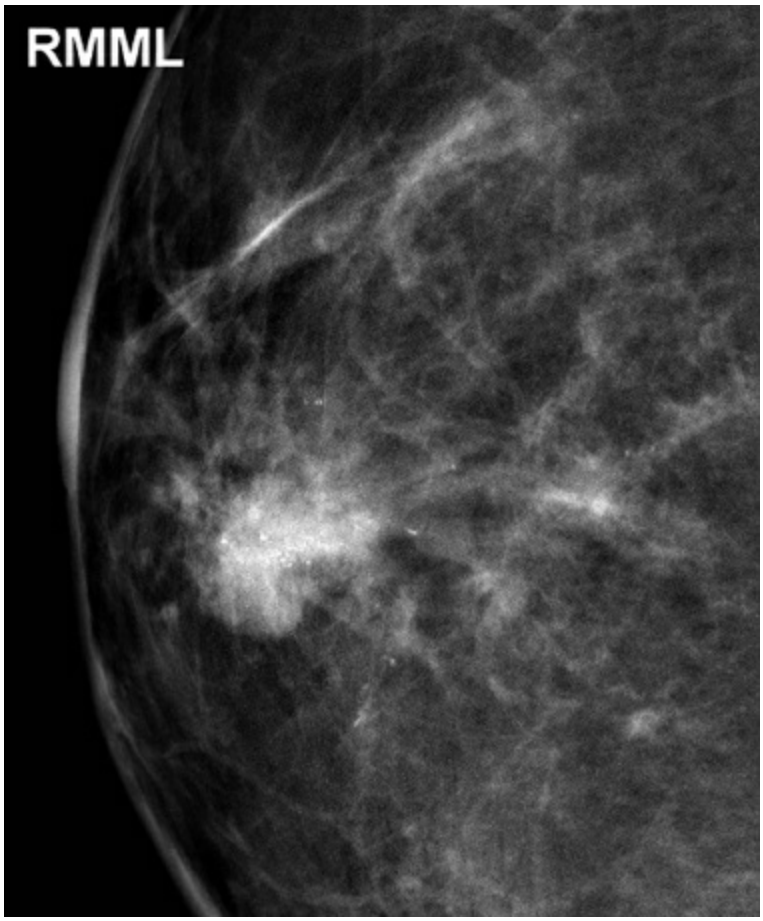

Figure 48.8. Right magnification mediolateral (RMML) view demonstrates a round hyperdense mass with spiculated margins and associated pleomorphic calcifications, invasive ductal carcinoma (IDC).

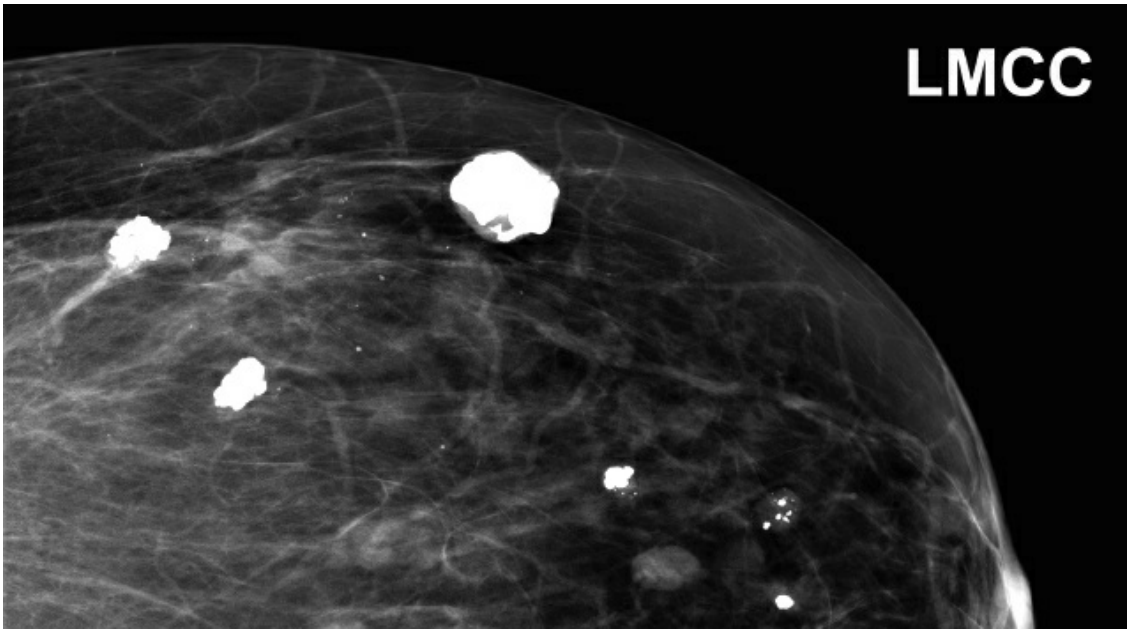

Figure 48.9. Left magnification craniocaudal (LMCC) view demonstrates multiple oval, well-circumscribed masses some with coarse-popcorn calcifications, hyalized fibroadenomas. Additional scattered round benign calcifications are noted.

Cystic masses are readily identified with ultrasound. Cysts are anechoic, oval, or round lesions with well-circumscribed margins that lack internal vascularity (Fig. 48.11). Because the cyst contents will transmit the ultrasound wave, posterior acoustic enhancement is frequently visualized. When the above features are present, the diagnostic accuracy of ultrasound in evaluating a simple cyst approximates 100%. Solid masses may have benign or malignant features. Malignant features of a solid mass on ultrasound include irregular margins, hypoechoic to the surrounding fatty lobules, and posterior acoustic shadowing. Malignant-appearing masses usually have a vertical growth pattern that disrupts the tissue planes (“taller than wide”) (Fig. 48.12). Benign features include ellipsoid shape, hyperechogenicity, and smooth, well-circumscribed margins (Fig. 48.13).

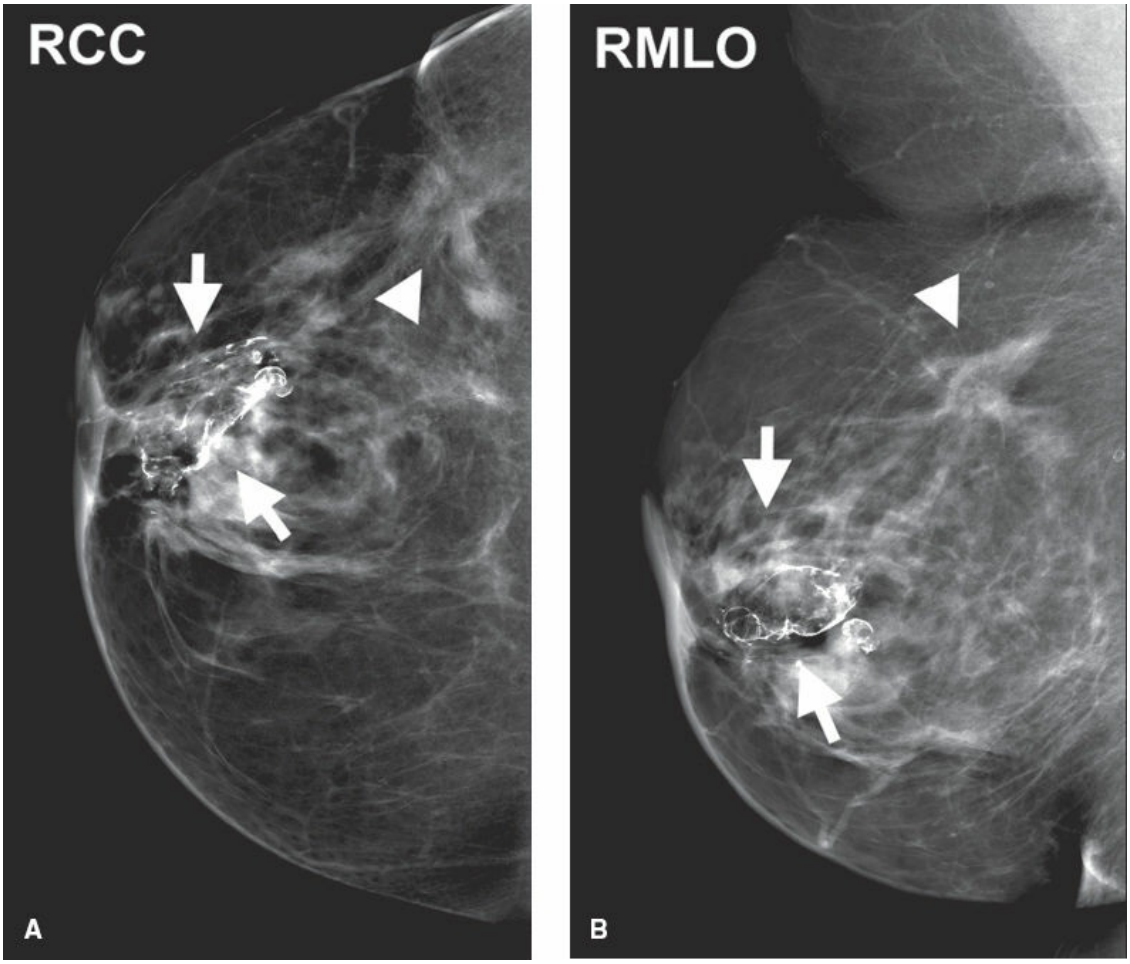

Figure 48.10. Right craniocaudal (CC) (**A**) and mediolateal oblique (MLO) (**B**) views demonstrate architectural distortion consistent with prior lumpectomy site (*arrowheads*) in the upper outer right breast and fat-containing architectural distortion with rim and dystrophic calcifications in the right subareolar breast, fat necrosis.

Ductography

Ductography is the injection of contrast into a discharging duct to identify a filling defect or other intraductal irregularity (Fig. 48.14). It can be useful in those presenting with nipple discharge without an underlying mass or mammographic or sonographic abnormality. If an abnormality is found, it may enable a directed excision of the presumed abnormality causing the discharge. A negative ductogram does not obviate the need for surgical excision of pathologic discharge.

Digital Tomosynthesis

Tomosynthesis is similar to mammography; however, it creates a 3D

picture of the breast using various projections obtained. In 2011, digital tomosynthesis was approved by the U.S. Food and Drug Administration (FDA) in combination with standard digital mammography; however, this radiographic technique is not yet considered the standard of care for breast cancer screening. Full field digital mammography depicts the breasts in two views; thus allowing for two-dimensional (2D) imaging that may allow for summation artifact that may increase recall rates and for tissue overlap that increases false-negative rates in patients with dense breasts. Digital tomosynthesis attempts to address some of these limitations. Multiple images of each breast are taken from several angles. The breast is positioned in the same way as conventional mammogram with appropriate compression. The tube moves in an arc around the breast while several images are taken over time. The information is then sent to a computer, where it is assembled to produce clear, highly focused 3D images throughout the breast. Single-institution studies have shown that adding tomosynthesis to mammography increases cancer detection and reduces false-positive results; however, there are limitations with tomosynthesis. Total radiation dose when tomosynthesis is added is approximately two times the current dose for digital mammography though still below the limits defined by the FDA.

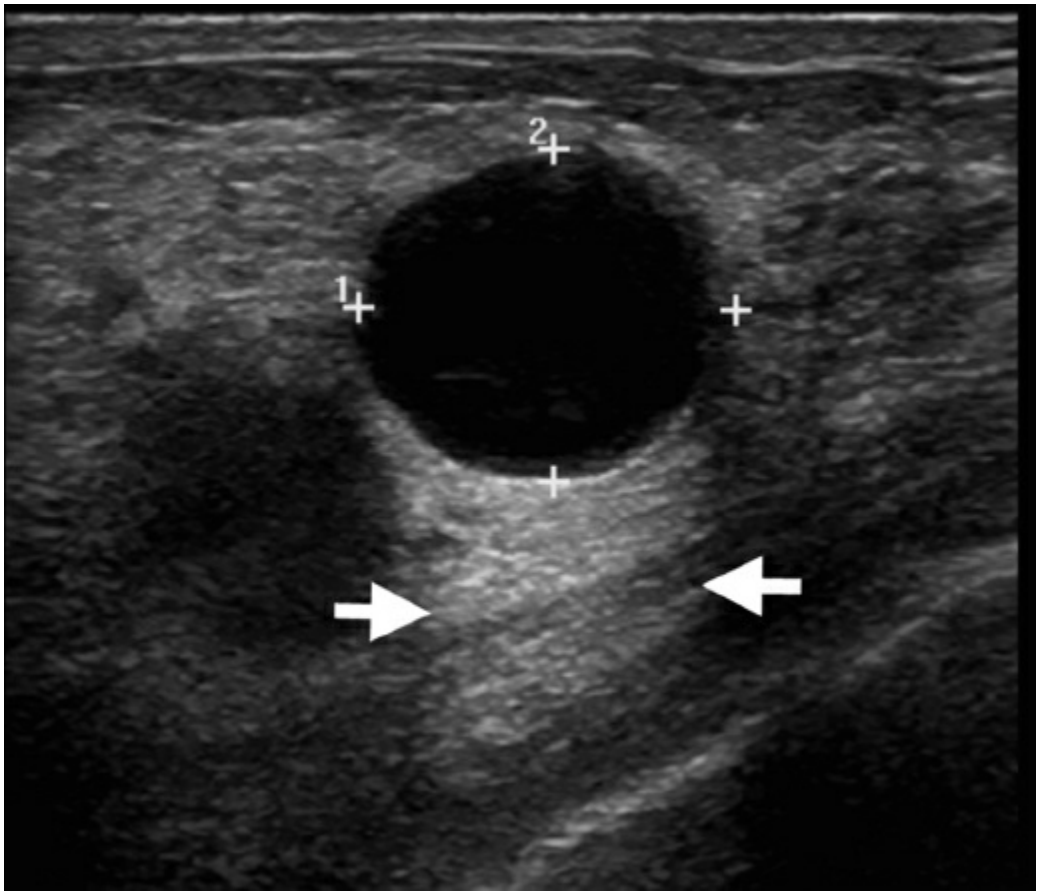

Figure 48.11. Grayscale ultrasound image demonstrates an anechoic round lesion with circumscribed margins (designated by calipers) and posterior acoustic enhancement (*arrows*), simple cyst.

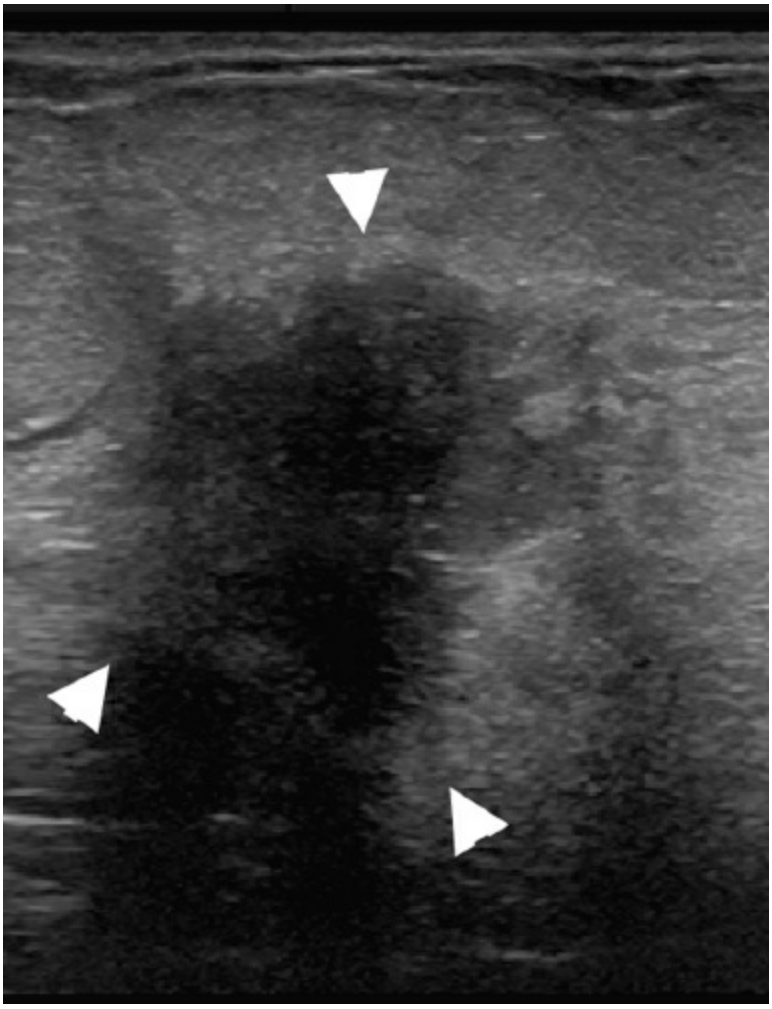

Figure 48.12. Grayscale ultrasound image demonstrates a hypoechoic irregular mass, taller than wide with posterior acoustic shadowing, invasive mammary carcinoma.

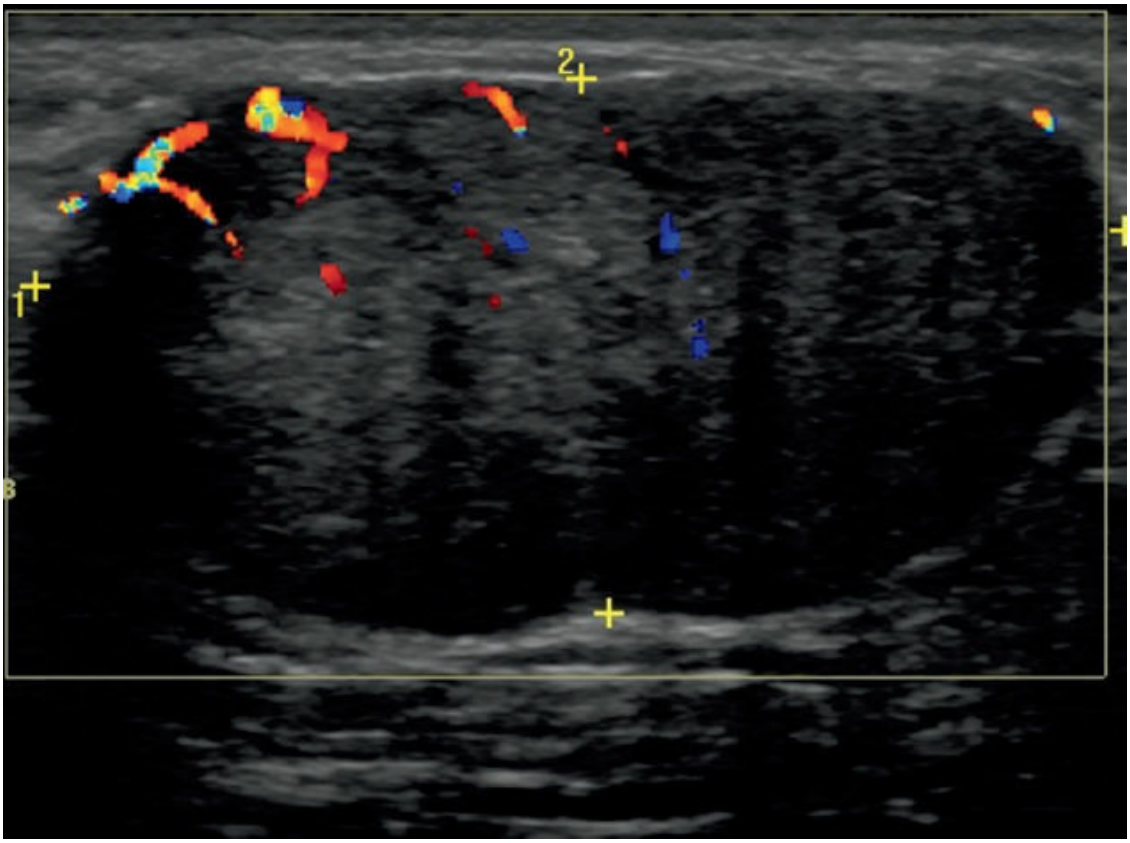

Figure 48.13. Color Doppler ultrasound image demonstrates an oval well-circumscribed hypoechoic mass with internal vessels, fibroadenoma.

Molecular Breast Imaging

Molecular breast imaging (MBI) is a nuclear medicine technique that utilizes small semiconductor-based γ-cameras in a mammographic configuration in order to provide high-resolution functional images of the breast. Current studies with MBI have used Tc-99m sestamibi, which is an approved agent for breast imaging. The scan procedure includes a single injection of 20 mCi Tc-99m sestamibi with imaging of the breast starting about 5 minutes postinjection. The breast is lightly compressed between two detectors, then two 10-minute images are obtained of each breast in the CC and MLO projections, total imaging time of 40 minutes or greater depending on breast size. MBI has shown promise with potential applications ranging from evaluation of the extent of disease to a role as an adjuvant in screening patients with dense breasts and or high-risk patients. The disadvantages of MBI, however, include the long imaging time and the radiation dose associated with the injection of the Tc-99m sestamibi.

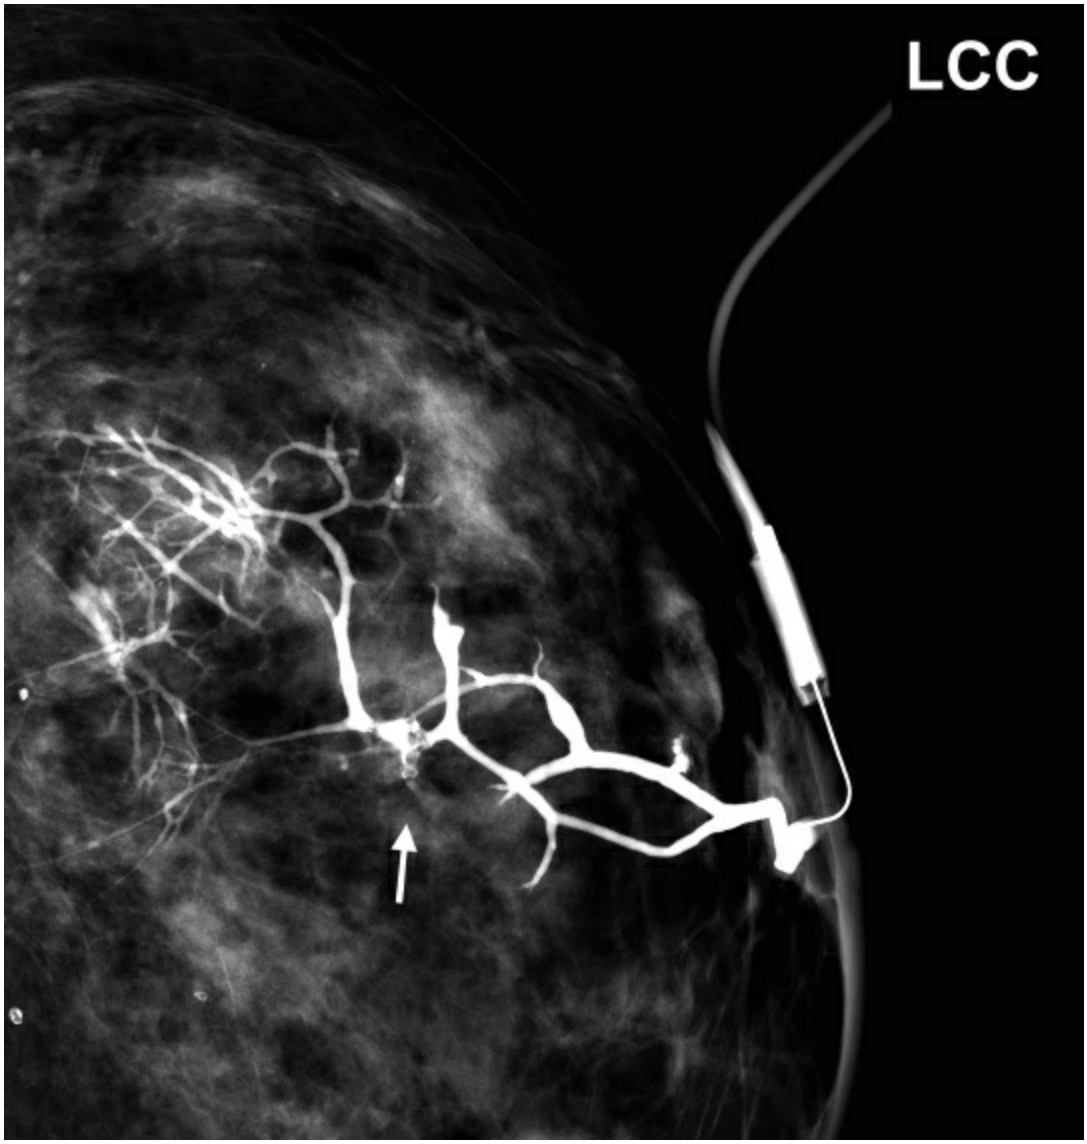

Figure 48.14. Left ductogram demonstrates an opacified ductal system with an intraductal filling detect (*arrow*), intraductal papilloma.

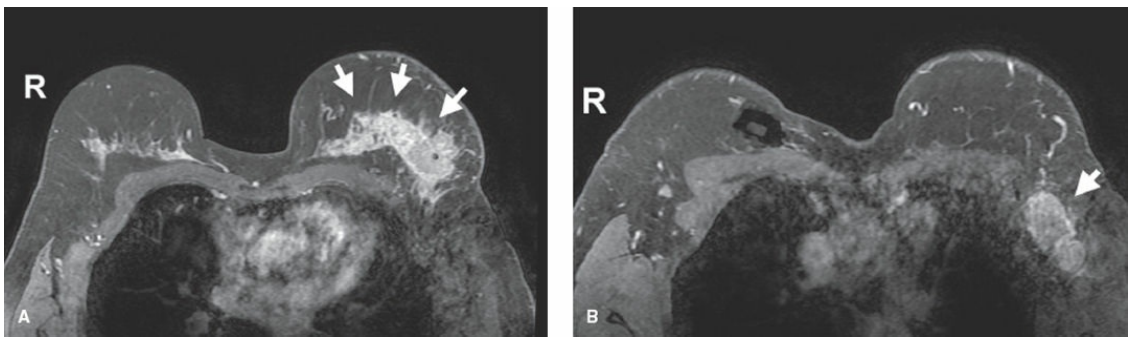

Figure 48.15. **A.** Axial T1 postcontrast fat saturated image demonstrates an enhancing irregular mass with indistinct margins and heterogeneous internal enhancement involving the left upper inner and upper outer quadrants (*arrows*), multicentric invasive

ductal carcinoma. **B.** Image through the axillary region demonstrates left axillary nodal involvement with extracapsular extension (*arrows*).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is being used with increasing frequency for screening and diagnosis of breast cancer in certain cases. While mammography remains the "gold standard," MRI is emerging as an important modality for evaluating breast disease. MRI has several advantages. There is no ionizing radiation to the patient with MRI. MRI is not limited by breast density and is an excellent tool for the screening of young women with increased risk for the development of breast cancer. Breast MRI is useful is determining extent of disease (Fig. 48.15) in certain patients with breast cancer and may also be a valuable tool in determining response to neoadjuvant therapy in certain patients. MRI allows for assessment of silicone implant integrity. In patients with indeterminate mammographic or ultrasonographic findings, MRI may be used for problem solving or clarification of imaging but should not replace biopsy for clinically suspicious lesions. Disadvantages of MRI are cost, limited availability, and specificity resulting in false positive biopsies. Patients with MRI-incompatible implantable devices, certain metallic clips, or prostheses may not undergo MRI. MRI should be performed in a breast imaging center with a 1.5-T magnet or greater. Patients lie prone with the breasts suspended in a dedicated breast imaging coil. Patients who are claustrophobic may require sedation prior to examination. Images are obtained before and after the administration of gadolinium, an MRI-contrast agent. The images are then evaluated for breast abnormalities with evaluation of enhancement and kinetic curves. Lesions suspicious for cancer will have malignant morphologic features with suspicious enhancement characteristics (Fig. 48.16).

DIAGNOSTIC BIOPSY

Nonpalpable Lesions

The widespread use of mammography and other breast imaging has resulted in the detection of increasing numbers of suspicious but clinically occult lesions of the breast. Such lesions represent more than half of the detected cancers in screening clinics and account for a substantial

proportion of breast tumors investigated with biopsy. Nonpalpable breast lesions are generally discovered on routine screening mammography, or incidentally with computed tomography or MRI performed for other reasons. Biopsy of these nonpalpable lesions can be performed utilizing various methods of image guidance.

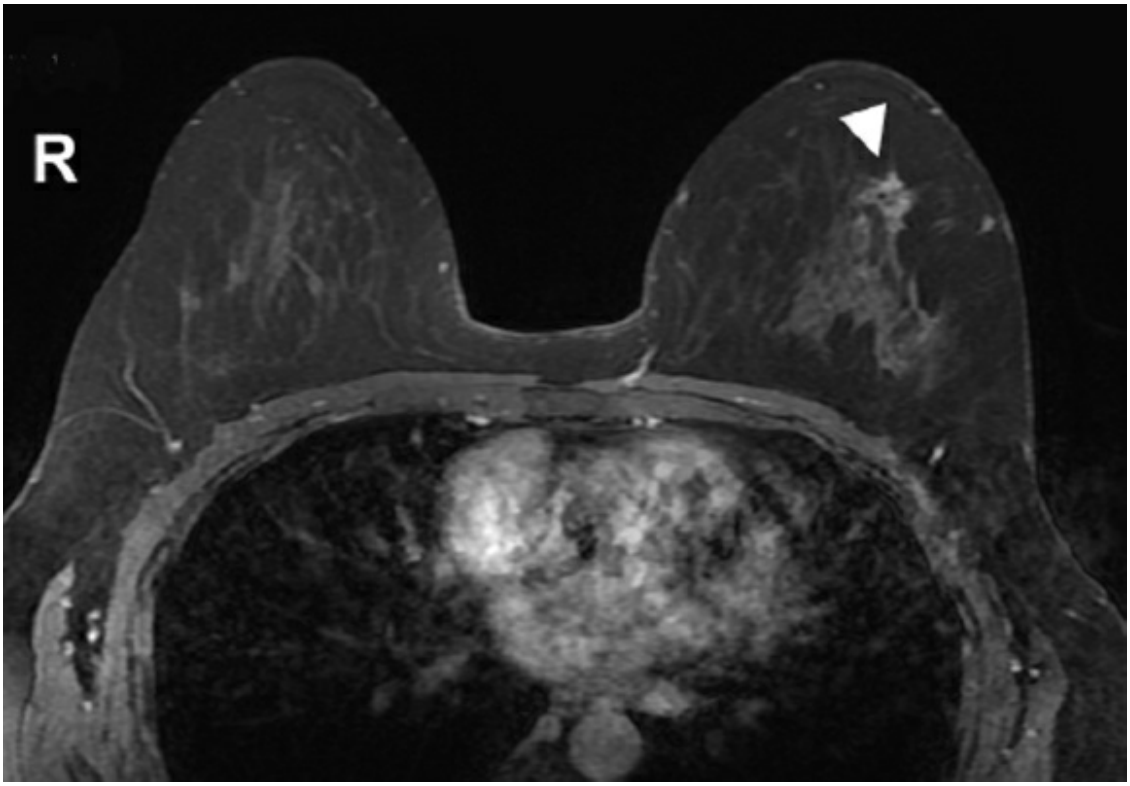

Figure 48.16. Axial T1 postcontrast fat saturated image demonstrates a heterogeneously enhancing irregular mass with indistinct margins in the left upper outer breast (*arrowhead*), invasive ductal carcinoma.

Aspiration

A simple cyst is a common finding and thought to arise from dilation of the terminal duct lobular units. Simple cysts diagnosed with ultrasound need not be aspirated unless the cyst causes the patient pain or anxiety regarding the finding. If the fluid aspirated is greenish or yellow-brown and the mass resolves sonographically, a benign diagnosis can be virtually confirmed and the fluid may be discarded. Follow-up is necessary within 4 to 6 weeks to ensure that the cyst has not recurred. Biopsy may be indicated if the cyst recurs. If the fluid aspirated is bloody, cytologic analysis should be performed to rule out malignancy, which occurs in a very small percentage of cases. Cysts that yield bloody fluid should not be

aspirated completely as the cyst may be difficult to localize either by physical examination or by imaging localization as histologic sampling is usually required in this situation. Complicated cysts, as defined by thin septations, debris within the cyst, rim enhancement (Fig. 48.17), or a cluster of microcysts may require short-term follow-up or aspiration for cytology or histologic biopsy as indicated. A solid component may indicate a papillary lesion and a cystic-solid lesion should undergo tissue diagnosis with biopsy. In addition, a presumed simple or complicated cyst that does not resolve with aspiration necessitates tissue diagnosis as well.

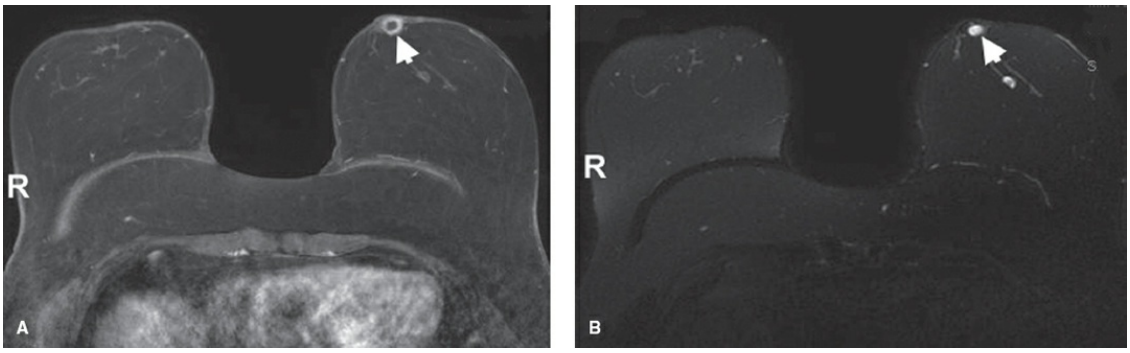

Figure 48.17. A. Axial T1 postcontrast fat saturated image demonstrates a rim-enhancing fluid collection at the base of the nipple suggesting inflammatory cyst versus abscess. **B.** Axial T2 image reveals increased T2 signal centrally consistent with fluid. Aspiration revealed an acute abscess.

Fine Needle Aspiration Biopsy

Cytologic analysis of a solid mass by fine needle aspiration (FNA) biopsy can be obtained rapidly, and often the patient can be informed of the results the same day (Fig. 48.18). The technique can be performed using imaging guidance or by palpation. The diagnostic accuracy of FNA biopsy of breast masses approximates 80%. When the specimen is properly prepared and reviewed by an experienced cytopathologist, the false-positive result is rare. False-negative results occur in approximately 15% of cases and thus a lesion that is suspicious clinically or by imaging must be further investigated with core biopsy. When physical examination, imaging, and FNA yield benign concordant results, the probability of a lesion being benign approaches 95%. Suspicious axillary lymph nodes may also be assessed with FNA during a breast cancer staging evaluation.

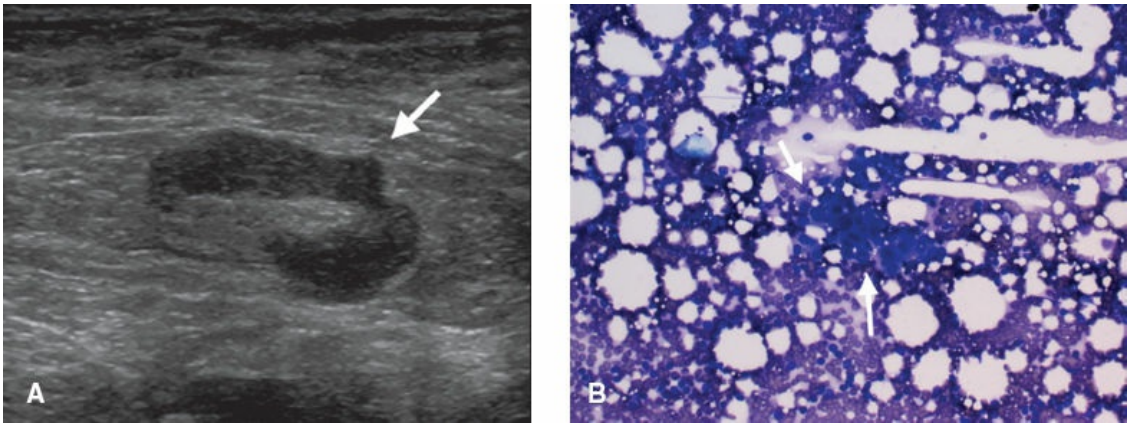

Figure 48.18. A. Grayscale ultrasound image reveals an axillary lymph node with focal nodularity (*arrow*). **B.** Cytologic specimen from ultrasound-guided fine needle aspiration revealed metastatic carcinoma (*arrows*).

Core Needle Biopsy

Core biopsy is the preferred method of evaluating an indeterminate or suspicious solid mass. Core biopsy obtains several tissue specimens for histologic evaluation. This can be performed using a variety of image-guided techniques or by palpation. The value of a core biopsy over an FNA is the ability to obtain hormone receptor and HER2 status, which is essential for personalized medicine.

Stereotactic Core Biopsy

Stereotactic mammographic devices use the principle of triangulation, which allows the precise location of a breast lesion to be determined in three dimensions. The procedure consists of placing the patient sitting upright or prone on the stereotactic table with the breast suspended through an opening in the table. The breast is compressed within the mammographic unit. A scout image is obtained and subsequently, two images are obtained and displayed on a digital monitor. The views obtained are taken at +15-degree and −15-degree angles from the plane perpendicular to the image receptor. These views are evaluated by the radiologist and the lesion is marked in both views. The needle is calibrated to the coordinates determined by the computer. The skin of the breast is sterilized, and the skin and underlying soft tissue are anesthetized with local anesthesia. A small incision is made in the skin using an 11-blade scalpel. A vacuum-assisted device is used to obtain several cores of breast tissue. Stereotactic biopsies performed for calcifications should be

evaluated with a specimen radiograph of the cores obtained to confirm the presence of the calcification within the sampled tissue (Fig. 48.19). A biopsy clip is then placed at the biopsy site via a hollow biopsy needle to facilitate locating the area should all of the imaging abnormality be removed with the biopsy. A postprocedure mammogram should be obtained to document clip placement and satisfactory sampling of the targeted lesion. Pathology results should be reviewed to determine concordance and appropriate follow-up. Patients who cannot lie prone or cannot tolerate breast compression may not be candidates for stereotactic breast biopsy. In addition, if the breast compresses to less than 3.5 cm, as in women with very thin breasts, stereotactic biopsy may not be technically feasible due to the possibility of piercing the opposite edge of the breast with the needle. The complication rate is low and most patients tolerate the procedure quite well. Most procedures can be completed within 30 minutes.

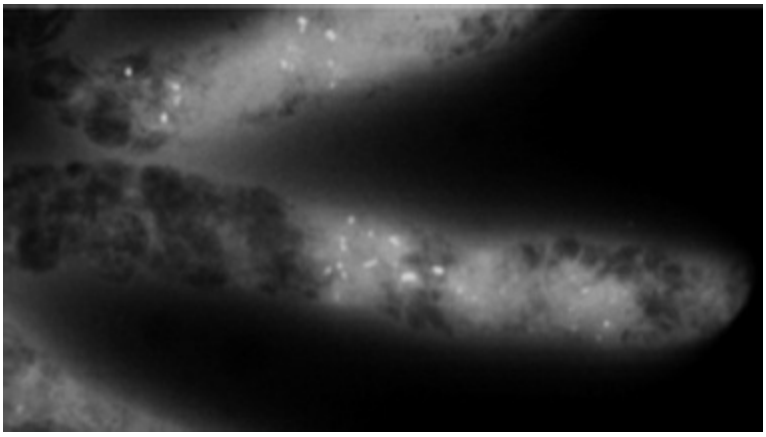

Figure 48.19. Specimen radiograph demonstrates vacuum-assisted core biopsies containing fine pleomorphic calcifications, ductal carcinoma in situ (DCIS).

Ultrasound-Guided Biopsy

Ultrasound-directed biopsy is performed for those lesions that are identified with ultrasound. Ultrasound-guided core biopsy is technically easier than stereotactic-guided biopsy as real-time imaging allows the surgeon or radiologist to visualize the biopsy as it occurs. Using sterile technique and local anesthesia, a small skin incision is made with an 11-blade scalpel and the needle is inserted into or abutting the lesion parallel to the chest wall. The position of the needle is visualized by ultrasound (Fig. 48.20). Once again, a handheld 11- or 8-gauge vacuum-assisted

needle or an 18- to 14-gauge spring-loaded automated large-core biopsy gun is used to remove several cores of tissue and in some instances completely remove the lesion. A biopsy clip is then placed at the biopsy site to facilitate locating the area should all of the visible abnormality be removed with the biopsy.

MRI-directed biopsy allows those lesions seen only with MRI to be biopsied under MRI guidance usually with vacuum assistance, and once again, it is important to place a postbiopsy clip to facilitate localization if surgical excision is indicated based on pathology.

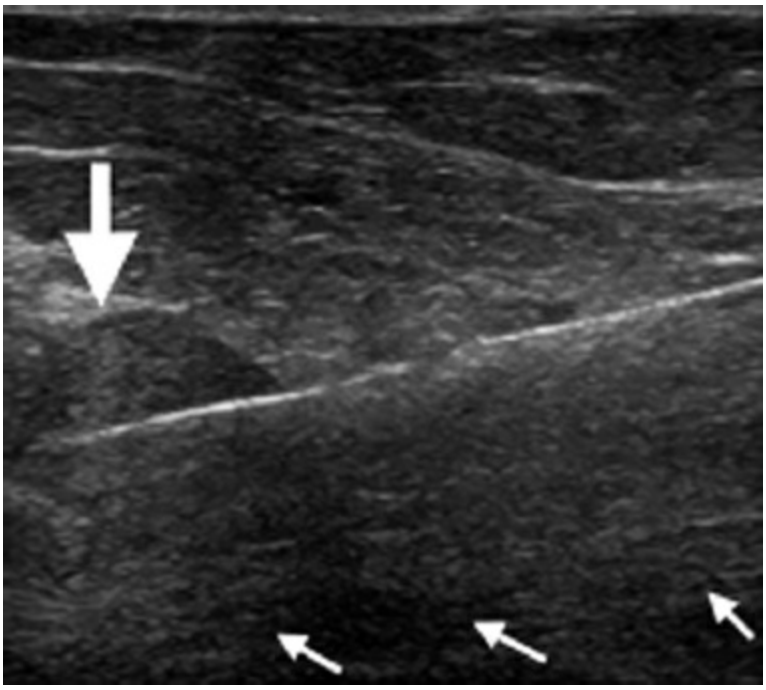

Figure 48.20. Grayscale ultrasound image demonstrates 16G needle through round hypoechoic mass (*large arrow*). Note needle is parallel to chest wall (*small arrows*).

If the core biopsy result is benign and is concordant with imaging findings, continued surveillance is acceptable. If the result is indeterminate or image-discordant, surgical excision is indicated to rule out malignancy. In addition, surgical excision is indicated for a core biopsy that demonstrates certain high-risk lesions including atypical hyperplasia (and some advocate for lobular carcinoma in situ as well) as the incidence of coexisting ductal carcinoma in situ or invasive carcinoma may be as high as 50% because of potential undersampling. Additional lesions requiring excisional biopsy also include atypical papillary lesions, mucocele-like lesions to exclude mucinous carcinoma, and cellular fibroepithelial lesions

to exclude phyllodes tumor.

Needle Localization Biopsy

Despite the frequency and simplicity of mammographic identification of suspicious lesions, intraoperative localization with subsequent adequate excision presents challenging technical problems because the shape and position of the breast during compression mammography may be quite different from that seen by the surgeon in the operating room. This has led to the development of several methods for preoperative localization of nonpalpable lesions. The aim of these methods is to facilitate complete removal of the lesion at first attempt excision while simultaneously minimizing the size of the resected specimen and shortening the duration of anesthesia. Radiologically guided, invasive preoperative localization of nonpalpable lesions is a safe, simple, and established procedure that allows for accurate and expeditious biopsy or excision. A specimen radiograph is mandatory to document the removal of the suspected area and to facilitate histologic examination because often these lesions remain nonpalpable even upon examination of the resected specimen.

The self-retaining wire localization was first described by Frank, Hall, and Steer. This technique utilizes a flexible, hooked wire within the localizing needle (Fig. 48.21). The hook lodges, ideally, within or adjacent to the suspicious lesion. The hook prevents dislodgement of wire within the breast prior to excision. The wire may be placed in most circumstances using mammography or ultrasound guidance, although MR-guided wire localization can also be performed. Mammographic images are obtained with the wire in place and are transported with the patient to the operating room for surgical excision. Incisions should be cosmetically placed using the natural skin lines, or Langer lines (Fig. 48.22). Utilizing the mammographic images, the surgeon begins the dissection. Some wires are labeled with regard to length or possess a change in caliber to direct the excision. The direction of the dissection and dimensions of the specimen are determined by the lesion size and the relative proximity of the wire to the lesion. If the incision does not pass though the entry site of the wire, it is necessary to identify the shaft of the wire proximal to the lesion and retract it into the wound (Fig. 48.23).

Once the specimen is removed, it should be oriented for the pathologist. A variety of orienting techniques can be used, including sutures or indelible ink (paint). The specimen is then sent for specimen radiograph to

conclusively confirm full excision of the suspicious/malignant lesion. The presence of the lesion within the specimen is documented mammographically and immediately relayed to the surgeon (Fig. 48.15B). The specimen should then be sent for pathologic analysis.

Radioactive Seed Localization

Radioactive seed localization (RSL) is an alternative for guiding surgical excision of nonpalpable breast lesions. The RSL uses radioactive seeds previously approved for the treatment of other cancers. Typically, iodine-125 and palladium-103 seeds between 200 and 300 μCi/seed are implanted into the breast lesion using a standard 18-gauge needle. The seeds can be implanted using mammography or ultrasound guidance, but seeds are not MRI compatible. The seeds are then surgically removed between 1 and 5 days postimplantation. In the operating room, radioactive seeds are located with appropriate instrumentation and removed with similar techniques surgeons use for sentinel lymph node biopsy. The advantages of RSL over wire implantation includes the bracketing of lesions and the postlocalization of mammograms is not impeded by wires, and procedure can be performed up to 5 days before surgery, minimizing schedule conflicts. The amount of radiation is similar to a screening mammogram. The seed or seeds are then disposed of in accordance with 10 CFR 35.92 or the equivalent Agreement State regulations. A successful radioactive seed program requires the combined efforts across multiple disciplines including surgery, pathology, radiology, radiation safety, and nuclear medicine.

(Reproduced with permission from Bland KI, Edward M. *The Breast: Comprehensive Management of Benign and Malignant Diseases.* 4th ed. Philadelphia, PA: WB Saunders, 2009.)

Palpable Masses

Ultrasound evaluation is the preferred method of evaluation of a palpable mass, but practitioners without ultrasound readily available may use aspiration to distinguish a solid mass from a benign cystic lesion. Details

of cyst aspiration were discussed previously. If a solid mass is confirmed, FNA biopsy may be performed to obtain a cytologic diagnosis (Fig. 48.24). An FNA, however, does not distinguish between in situ and invasive disease. Obtaining a core biopsy prior to proceeding to the operating room for a breast lesion is preferred and accepted as standard today. In 2003, the National Comprehensive Cancer Network identified core needle biopsy as “preferred” over surgical excision for breast diagnosis, and more recently the National Accreditation Program for Breast Centers established “palpation-guided or image-guided needle biopsy as the initial diagnostic approach rather than open biopsy” as a clinical management standard by which breast centers are measured. Obtaining a cancer diagnosis via core biopsy allows for better planning of the cancer treatment by obtaining hormone receptor status and avoiding multiple surgeries.

Punch Biopsy

While the diagnosis of inflammatory breast cancer is made largely clinically, histologic confirmation of cancer cells within the dermal lymphatics is pathognomonic for inflammatory breast cancer. In patients who present with skin changes, including erythema and/or peau d'orange, a 3- to 5-mm punch biopsy can be performed in the office using local anesthesia. The biopsy should be full thickness through the most suspicious area. Most inflammatory breast cancers do not present with a palpable mass, but if present, a core biopsy can then be obtained through the punch biopsy site to provide more tissue for receptor assays.

SUMMARY

The use of mammography and developing technology has revolutionized our ability to diagnose and treat breast abnormalities. While in the past most patients underwent surgical excision, we now have the capability to

perform less invasive procedures for both diagnosis and treatment of benign disease. In addition, a cancer diagnosis from an image-guided core biopsy allows for optimal patient management in this time of precision medicine.

Nearly 8 billion is spent on diagnostic breast biopsies each year. Nearly half of that cost is the result of false-positive biopsies. Nearly 80% of biopsied lesions result in negative pathology. However, it is the standard of care to get a preoperative diagnosis before going to the operating room. First it allows for planned staging of the patient prior to surgery and of the axilla at surgery. It is also well documented that knowing the presence of cancer at surgery results in obtaining a higher likelihood of negative margins. Occasionally, one can get a significant bleed from an ultrasound-guided or stereotactic-guided core needle biopsy. In such a case, we use a pediatric Foley inserted in the needle track. A Doppler US can see the bleeder and the balloon can be inflated to produce tamponade. It can save the patient a huge hematoma.

In addition, the diagnostic procedure allows marking of the lesion for removal by a number of different methods. It is standard of care to leave a marker behind at the biopsy site. This is especially true in the case of neoadjuvant chemotherapy as a complete pathologic response may make the original lesion difficult or impossible to localize. In addition to the standard titanium clips of all shapes and sizes, innovations in markers have proliferated with coils, gels, radio-guided and magnetic markers which have added greatly to the cost and complexity of breast surgery localization. Wires and special clips and radio-markers all require an additional procedure to mark the site for lumpectomy while the patient is awake. However, there are a couple of situations when a second procedure is not necessary. The first instance is that of a lesion that is visible on ultrasound.

The fully developed technique of US-guided excision has evolved and been developed over time by multiple researchers. Breast ultrasonography is performed intraoperatively using a 7.5- or 10-MHz linear array transducer while the arm is abducted. After sterile preparation, the abnormality is localized in the standard two planes, longitudinal and transverse. After the incision was made, the transducer was placed inside the incision and the lesion was again visualized. Dissection is performed using a “line-of-sight” technique. This technique was adapted from and mimics the use of the gamma probe in sentinel lymph node surgery. The transducer is then placed perpendicular to the lesion and parallel to the chest wall to assess the adequacy of the deep margin. Tissue is excised around the lesion in a block fashion down to the ascertained depth. Ex vivo ultrasonography is performed on the specimen. Margins felt to be inadequate on specimen ultrasonography are reexcised at the time of the initial surgery. The remaining cavity is reassessed for residual disease both by palpation and ultrasonography.

A recent development presented at the 2017 American Society of Breast Surgeons is another localization procedure that does not require a second localizing procedure to remove the index lesion. We developed *F*luoroscopic *I*ntraoperative *N*eoplasia and *N*ode *D*etection or FIND after a needle from an NLBB was inadvertently removed at surgery. Barring waking the patient up and relocalizing the lesion, we used the fluoroscope which easily found the clip. We

wondered why no one had used this before as all surgeons are familiar with the use of fluoroscopy whether it be with placing a central line or performing and intraoperative cholangiogram. As it turns out not all clips are visible by fluoroscopy. The ribbon clips and collagen clips don't show up well at all. The bar clips and the newer circular clips are easily seen. We cut the dose of the fluoroscopy by three-fourths and we still easily saw the clips. Probably the most cumbersome thing about this procedure is the need to wear protective lead aprons. This innovation can easily be implemented in practice. In fact, walking out of the auditorium where we presented our work, a surgeon stopped us and said they'd already called their operating room and posted a case utilizing FIND. This allows cases to be done without a second localization and obviates scheduling issues. Care must be taken to note any post-clip placement migration. The surgeon can bill for the utilization of fluoroscopy as intraoperative interpretation. You will also be your mammographer's new best friend as (s)he will no longer have to get up early and torture patients with an NLBB. They hate them as much as the patients and we do.

Recent developments in oncoplastic procedures of the breast make breast texture and anatomy and localization technique more important than ever. In determining how to approach the breast, location, location, location is all important. For nearly any lesion in the breast a Benelli or donut deepithelialization can be performed and a flap raised over the index lesion. The closure produces a periareolar scar and if warranted the deepithelialization can be widened to perform a lift or a reduction. In a very large-breasted women (e.g., 54H) a bat-wing reduction can be performed to remove an upper quadrant lesion. Radial incision should be avoided in the upper pole of the breast but work well in the lower pole especially if they are tangential to the areola. Excision of lesions can be incorporated into a wise pattern reduction incision. With upper pole lesion, the nipple can emanate from an inferior pedicle. In the case of a lower pole lesion, the nipple should be on a superior pedicle. Both of these should come from the medial side as the blood supply to the nipple is based mainly on the internal mammary perforators.

When choosing a localization technique or procedure, it is best to choose one that does not require second preoperative localizations.

49 Breast-Conserving Surgery

J. Michael Dixon

BREAST-CONSERVING SURGERY IN INVASIVE BREAST CANCER

The aim of local treatment of breast cancer is to achieve long-term local disease control with the minimum of local morbidity. The majority of women presenting symptomatically to breast clinics or who are diagnosed as having breast cancer through screening programs have small breast cancers that are suitable for breast-conserving surgery (BCS). Breast-conserving treatment (BCT) consists of BCS followed by whole breast radiotherapy. The major advantages of BCT are that it produces

an acceptable cosmetic appearance in the majority of women.
lower levels of psychological morbidity with less anxiety, depression, improved body image, sexuality, and self-esteem than mastectomy.
equivalence in terms of disease outcome for BCT and mastectomy, as shown by two systematic reviews.

One of these reviews analyzed data from six randomized controlled trials comparing BCT with mastectomy. A meta-analysis of data from five of these six trials, which included 3,006 women, found no significant difference in the risk of death at 10 years (odds ratio, 0.91, 95% confidence interval [CI], 0.78 to 1.05). The sixth randomized trial used different protocols. In the second systematic review, nine randomized control trials involving 4,981 women randomized to mastectomy or BCT were included in the analysis. A meta-analysis of these nine trials found no significant difference in the risk of death over 10 years (relative risk reduction [RRR] for BCS when compared with mastectomy was 0.02, 95% CI −0.05 to +0.09). There was also no difference in the rates of local recurrence in the six randomized control trials involving 3,107 women for whom data were available (RRR mastectomy vs. BCT, 0.04, 95% CI −0.04 to +0.12). The Milan Group published their 20-year follow-up results and, although they showed a significant difference in local recurrence within the ipsilateral breast of 2.3% in the mastectomy group

and 8.8% in the BCT group, the disease-specific survival was similar between the two groups, with rates of death from breast cancer being 24.3% in the mastectomy group and 26.1% in the BCT group.

Originally it was thought that local therapy had little influence on overall survival, but it is becoming clear that local therapy is responsible, at least in part, for some patients developing metastatic disease. It is thus important to minimize local recurrence and at the same time achieve a good cosmetic outcome.

More recent studies have confirmed the safety of BCT. One large cohort study from California indicated that BCT was associated with superior survival in all groups compared with mastectomy alone. Two other large European studies confirmed that women treated with BCT do better than women treated by mastectomy. A study from New York showed equivalent outcomes for BCT and mastectomy in triple negative breast cancer. Another study showed event free and overall survival is equivalent when comparing BCT and mastectomy in young women.

INDICATIONS AND CONTRAINDICATIONS TO BREAST-CONSERVING TREATMENT

Traditionally single cancers measuring 4 cm or less, without signs of involvement of skin or chest wall, have been managed by BCT (Table 49.1). Different units have different size criteria, and many units have a tumor size cut off for BCS of 3 cm. Increasing tumor size, however, does not mean increasing local recurrence rates, and this approach is therefore illogical. Clinical tumor size overestimates actual tumor size. There is a better correlation between pathologic tumor size and the size measured on imaging, with magnetic resonance imaging (MRI) assessment being more accurate than ultrasound or mammographic measurements. MRI has not been shown to be of value in improving the rate of successful BCT or reducing rates of recurrence (COMICE). It is the balance between tumor size as assessed by imaging and breast volume that determines whether a patient is suitable for BCT. Patients with tumors measuring clinically larger than 4 cm can be treated by BCT if the patient has large breasts. Conversely, in a patient with small breasts, excision of even a 1-cm tumor may produce an unacceptable cosmetic result. Options for patients with tumors considered too large relative to the size of the breast for BCT include neoadjuvant systemic therapy to shrink the tumor or an oncoplastic procedure, involving either transfer of tissue into the breast or surgery to

reduce the size of the breast usually combined with synchronous contralateral reduction.

Because of an initially high reported incidence of in breast recurrence, patients with multiple tumors in the same breast had not been previously considered good candidates for BCT. This view has changed and provided that the cancers can be excised to clear margins even if they are far apart and a satisfactory cosmetic outcome produced, then BCT is feasible. In some patients who have large areas of the breast involved, BCT may be possible if one or both breasts are made smaller by a mammaplasty procedure. If there is widespread ductal carcinoma in situ (DCIS) alone or associated with an invasive cancer, then most of these women are best treated by mastectomy, combined with immediate reconstruction in appropriate patients. Patients with two tumors close to each other on mammograms, or who have multisite disease identified only by the pathologist, are good candidates for BCT provided that all disease can be excised and the cosmetic outcome is not compromised. Patients with bilateral small cancers can also be treated by bilateral breast conservation.

TABLE 49.1 Indications and Contraindications for Breast-Conserving Surgery

Indications
- T1, T2 (<4 cm), N0, N1, M0
- T2 >4 cm in large breasts
- Single clinical and mammographic lesion

Contraindications
- T4, N2, or M1 (some localized T4 disease and some patients with limited metastatic disease may be suitable for breast-conserving surgery)
- Patients who prefer mastectomy

Relative contraindications
- Large or central tumors in small breasts[a]
- Clinically evident multifocal/multicentric disease[a]
- Collagen vascular disease
- Women with a strong family history of breast cancer or BRCA1 and BRCA2 mutation carriers

[a]Now common for these women to be offered BCS (see below).

CLINICAL AND PATHOLOGIC FACTORS

Clinical and pathologic factors have previously influenced selection of patients for BCT because of their perceived impact on local recurrence. They are no longer considered as contraindications for BCT. These include young age (<35 to 39 years), the presence of an extensive in situ component associated with an invasive tumor, grade 3 histology, and widespread lymphatic/vascular invasion (LVI). Another relative contraindication to BCT has been the presence of a collagen vascular disease, as radiotherapy may create problems in such women. Experience is emerging that most of these women can be treated by BCT without significant problems. Central tumors were initially considered a relative contraindication to BCT as the cosmetic result can be suboptimal. Most patients with small central tumors, however, are candidates for wide local

excision with or without nipple/areolar excision and/or rotational flap advancement as described later in this chapter.

Young women with a strong family history of breast cancer or known carriers of BRCA1 or BRCA2 mutations are probably better served by bilateral mastectomy instead of BCT as they are at higher risk of developing either a recurrent cancer or a new cancer in the treated or opposite breast. Young women without a gene mutation can be managed by BCT, and their outcomes are not improved by mastectomy.

PREOPERATIVE PLANNING

Patients are currently staged according to the International Union against Cancer TNM (Tumor, Nodes, Metastasis) classification, but this method of staging is of no real value in breast cancer. Clinical assessment of tumor size usually overestimates tumor size, although there is some correlation between clinical tumor size and final pathologic measurement. Decisions on treatment are thus best based on size estimated by imaging. Clinical examination is unreliable in determining whether the axillary nodes are involved with metastatic breast cancer. For this reason, in most units nodes are assessed by ultrasound.

In early operable breast cancer (Tl to 2, N0 to 1), there is no current evidence to support routine screening for metastatic disease in asymptomatic women. Patients with symptoms suggestive of metastases at a particular site require appropriate investigation. The incidence of asymptomatic metastases increases as the T and N stage increases. If it will affect treatment, patients with more advanced but operable disease (T3 and multiples N1 nodes or N2 disease clinically or on imaging) should be considered for investigations to exclude distant metastases.

All patients with a breast mass should have a careful clinical examination, and the mass should be measured accurately and recorded. The presence or absence of any signs of local advancement such as inflammation, peau d’orange, ulceration, satellite nodules, direct chest wall involvement, and fixed axillary nodes should be noted and recorded. All patients should have good-quality bilateral mammograms with magnification views of any visible indeterminate calcification. Ultrasound of the whole breast is recommended to assess the extent and size of the tumor, and ultrasound of the axilla should be performed to assess the presence of any metastatic lymph nodes and ultrasound-guided fine-needle aspiration biopsy or core biopsy performed of any lymph nodes with

features suggestive of metastatic spread. Routine use of breast MRI is unnecessary, but in certain patients it can provide useful clinical information on disease extent.

Patients should be informed prior to surgery that there is up to a 35% chance that BCS will not remove all disease and that these women need reexcision or sometimes a mastectomy to obtain clear margins and excise all disease. Patients should also be informed of other common complications, including bleeding, infection, scars, skin healing issues (two to three times more common in smokers), and of the likelihood of seromas. Prior to operation, patients should sign a consent form that includes these complications and have the side and site of surgery marked with an indelible pen.

The patient's imaging should be inspected before operation and excision planned to include the whole of the abnormal area. Some invasive carcinomas have surrounding noninvasive disease that is visible as microcalcification on mammograms. These microcalcifications should be excised and may require preoperative localization.

SURGICAL TECHNIQUE OF WIDE LOCAL EXCISION

Two breast-conservation surgical procedures have been studied extensively and described: quadrantectomy and wide local excision. Quadrantectomy is based on the belief that the breast is organized into segments, with each segment draining into its own major duct, and that invasive cancer spreads down the duct system toward the nipple. The evidence is that both of these premises are incorrect. Studies have also shown that both invasive and noninvasive diseases are no more likely to extend toward the nipple than in any other direction. One of the early studies of BCT randomized patients to lumpectomy or quadrantectomy. A significantly greater number of patients who had lumpectomy had incomplete local excisions. Not surprisingly, therefore, local recurrence was greater after lumpectomy than after the more extensive quadrantectomy, although survival was no different. Other nonrandomized studies have shown similar rates of local recurrence for quadrantectomy and wide local excision, provided margins of excision are clear. Quadrantectomy is no longer advocated because it removes substantially more breast tissue and produces a significantly poorer cosmetic outcome than wide local excision. The consensus view is that the majority of patients having BCT can be adequately treated by wide local excision.

The majority of wide excisions of palpable and impalpable cancers are performed under general anesthesia, although it is possible to perform wide excision under local anesthesia with or without sedation. A meta-analysis of studies of prophylactic antibiotics in breast surgery has shown a small but significant reduction in postoperative infections if intravenous antibiotics are administered during induction of general anesthesia, so many surgeons give a dose of intravenous antibiotics to cover the operative period. Our practice is to use 1.2 g of co-amoxiclav or a cephalosporin. The lack of a clear advantage for antibiotics in randomized studies means that not all surgeons give them.

Incisions

The aim of wide local excision is to remove all invasive and any DCIS with a 1-cm macroscopic margin of normal surrounding breast tissue. It is important to place the incision in a position that will obtain the optimal cosmetic result. Langer described the predominant orientation of collagen fibers in the skin and around the breast, and these lines are essentially circular (Fig. 49.1A). Kraissl later demonstrated that the lines of maximum resting skin tension run in a more transverse orientation across the breast (Fig. 49.1B). In general, scars placed in the lines of maximum resting skin tension (parallel to Kraissl lines) produce the best cosmetic incisions with least hypertrophy and keloid formation. Incisions that are at right angles to both the orientation of collagen fibers and the lines of maximum resting skin tension, such as radial incisions in the upper outer quadrant, generally produce the worst cosmetic results. Circumareolar incisions heal well. Radial incisions can produce a satisfactory cosmetic result in some circumstances, and a vertical incision at 6 o'clock that is used as part of most therapeutic mammaplasty procedures usually gives a reasonable scar. Radiation reduces the rate of hypertrophic scars, so most incisions used for breast-conserving incision produce satisfactory cosmetic results. Increasingly, remote incisions, including submammary, circumareolar, and axillary incisions, are used as they produce the best cosmetic outcomes. Excising skin directly overlying a cancer is only necessary if the carcinoma is very superficial and/or the skin is tethered. Skin should not be excised routinely.

Figure 49.3. After having dissected around three sides of the cancer, it is grasped with finger and thumb of the nondominant hand before completing the excision at the other margins.

The cosmetic result after BCT is influenced by the amount of skin excised. The poorest outcomes are seen in those patients who have the most skin removed. Limiting the length of the incision is important as in general the longer the incision the poorer the cosmetic outcome. The length of the scar is less of an issue if the scar is hidden as for example in a sub- or inframammary incision.

Excising the Cancer

After making a skin incision, the skin and subcutaneous fat are dissected off the breast tissue. This can be facilitated by injecting a 1 in 500,000 adrenaline (epinephrine) solution in saline into the plane between the breast and subcutaneous fat. This solution should be left a few minutes for the epinephrine to work and restrict local blood flow. When elevating skin, it is important not to disrupt the subcutaneous fat as thin skin flaps give a poor cosmetic result. The skin flaps should be elevated 1 to 2 cm beyond the edge of the cancer. This allows the fingers of the nondominant hand to be placed over the palpable cancer and the breast tissue can then be divided beyond the fingertips (Fig. 49.2); the line of incision through the

breast tissue should be 1 cm beyond the limit of the palpable mass. The breast tissue is divided 1 cm deep to the deepest aspect of the tumor and then breast tissue under the cancer is divided. It is usual but not always necessary to remove full thickness of breast tissue because this ensures that there is an adequate clearance deep to the cancer. In the majority of patients, in order to completely excise the cancer at the deep margin, it is necessary to continue the dissection through the breast tissue down to the pectoral fascia. The cancer and surrounding breast tissue are then lifted off the pectoral fascia. It is not necessary to excise pectoral fascia unless it is tethered to the tumor. If a carcinoma is infiltrating a chest wall muscle, then a portion of the affected muscle can be removed beneath the tumor in order to get clear tissue at the deep margin. For very superficial cancers in parts of the breast with significant depth, it is possible to clear the deep margins without removing full thickness of breast tissue.

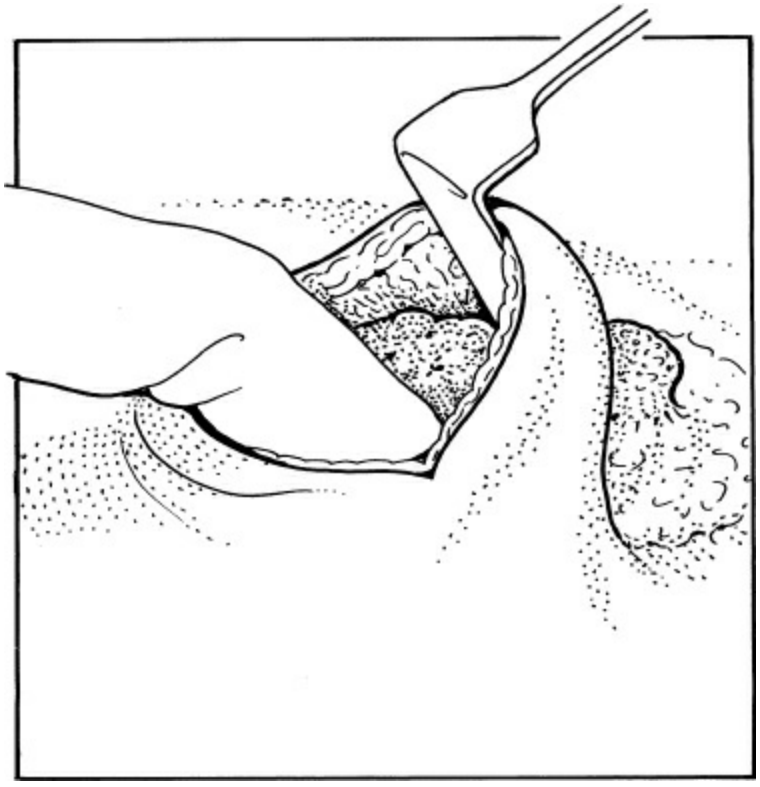

Figure 49.2. Finger of nondominant hand is placed over palpable cancer and breast tissue is divided beyond the fingertips.

Having lifted the tumor and surrounding breast tissue off the chest wall muscles, the cancer and surrounding tissue can then be grasped between the finger and the thumb of the nondominant hand and excision is completed at the other margins (Fig. 49.3). The specimen is immediately

orientated with sutures, ligaclips, or metal markers (Fig. 49.4). Using metal markers and ligaclips or attaching the specimen to an orientated grid has the advantage of allowing orientated anteroposterior-intraoperative specimen radiography to be performed. This helps the surgeon to determine first that the target lesion has been excised and second allows assessment of completeness of excision at the radial margins (medial, lateral, superior, and inferior). If inspection of the specimen radiograph shows that the cancer or any associated microcalcification is close to a radial margin, then the surgeon should remove further tissue from the margin of concern. Having excised this extra tissue, the surgeon should orientate this tissue, and send it for pathologic evaluation (Fig. 49.5A,B).

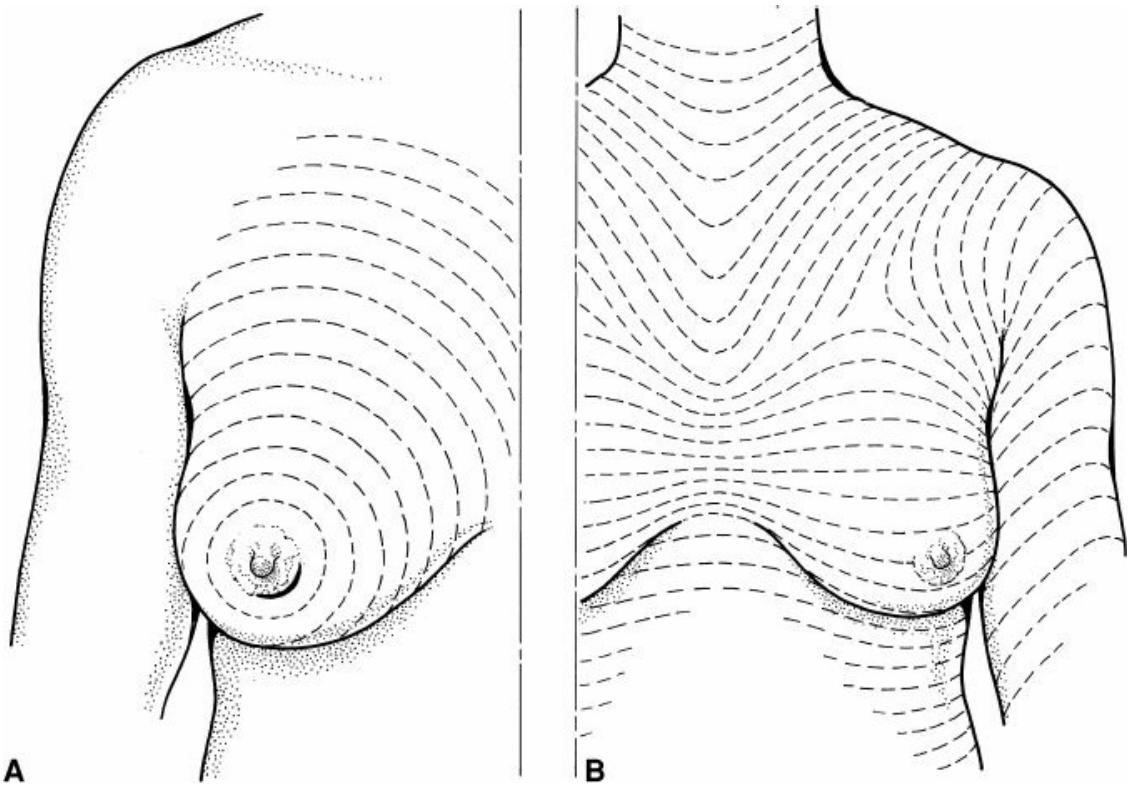

Figure 49.1. The direction of Langer lines (**A**) and the lines of maximum resting skin tension in the breast (the so-called dynamic lines of Kraissl) (**B**).

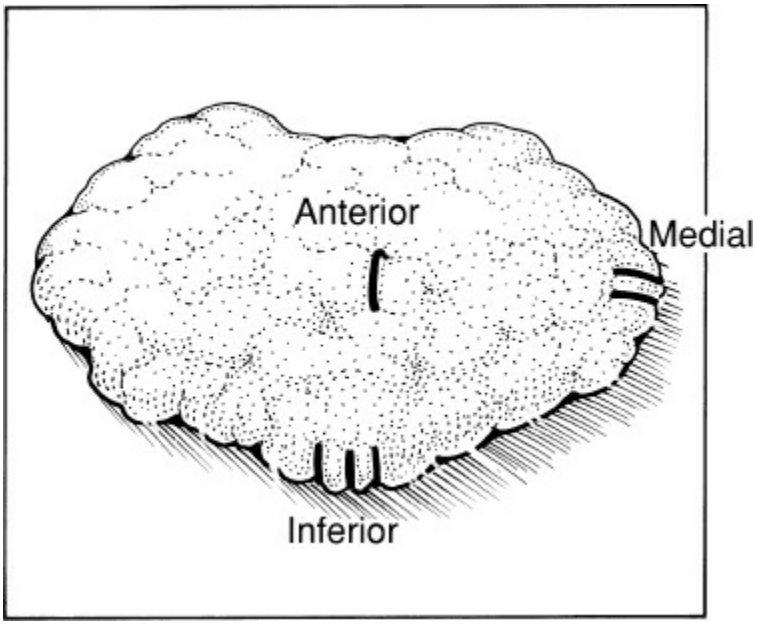

Figure 49.4. Orientation of the specimen. In our unit, we use one ligaclip for the anterior margin, two ligaclips for the medial margin, and three ligaclips at the inferior margin.

Controversy surrounds the use of routine cavity shavings or margin reexcision. Studies have demonstrated that the major factor that increases incomplete excision rates is DCIS out with the invasive cancer not imaged by mammography and ultrasound. The greater the volume of tissue excised, the more likely the margins will be clear. A recent study showed that shaving the margins can marginally reduce the rate of reexcision but the volume of excision increased from 74.2 cm^3 to 1115.1 cm^3 as a result of shaving of all margins. This is consistent with the view that the more tissue you excise, however you do it, the lower the rate of incomplete excisions, but larger excisions yield poorer cosmetic outcomes. It is difficult to believe that routine shaving of all margins is justified. Selective shaves of margins of concern is more logical. New devices in clinical trials are being used to assess margins intraoperatively, and these show promise but are not yet suitable for routine use.

Having excised the cancer from the breast, suturing the defect in the breast without mobilization of breast tissue usually results in distortion of the breast contour. Small defects (<5% breast volume) can be left open and can produce a good final cosmetic result. Larger defects in the breast should if possible be closed by mobilizing the surrounding breast tissue from the overlying skin and subcutaneous tissue. I do not usually find it necessary to undermine tissue from the chest wall unless the defect is

large. If such large defects (>10% breast volume) are not closed, they fill with seroma, which later absorbs; and as scar tissue forms, this contracts, often producing an ugly, distorted breast. The extent to which breast tissue can be mobilized depends on breast density. Soft fatty breast tissue cannot be mobilized extensively and fatty breast tissue cannot be easily sutured. Extensive mobilization of fatty breasts thus produces a very poor final cosmetic result. In contrast, dense fibrous breast tissue can be mobilized widely to allow defects to be closed and heals well. Having mobilized breast tissue from the subcutaneous tissue and if necessary the chest wall, it is usually possible to close the defect in the breast with a series of interrupted absorbable sutures. Larger defects can be filled by local flaps, or more major breast reshaping as part of a unilateral or bilateral therapeutic mammaplasty. Immediate lipofilling is being used in a few units, but it remains experimental and its use cannot as yet be recommended.

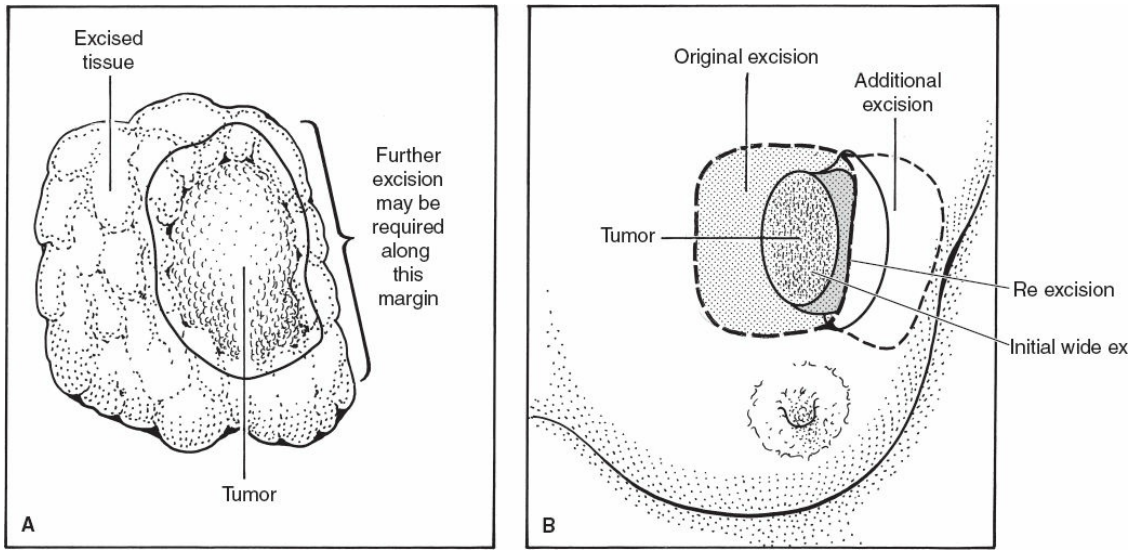

Figure 49.5. A. Specimen after removal and inspection showing that the cancer is close to a margin. **B.** A further excision is required to obtain clear margins.

Drains are not necessary following wide local excision and should not be used routinely. They do not protect against hematoma formation and increase infection rates. Breast skin wounds should be closed in layers with absorbable sutures, finishing with a subcuticular suture. Staples and interrupted sutures are not an acceptable method of wound closure in the breast. Long-acting local anesthetic should be infiltrated into the wound as it reduces postoperative pain, unless other anesthetic nerve blocks are

used.

PLACING MARKERS AFTER BREAST-CONSERVING SURGERY

Most young patients and selected older patients treated by radiation after BCS will have a local tumor bed boost. To help facilitate this boost and as an aid in further follow-up, most surgeons place four clips at the superior, inferior, medial, and lateral margins of the wide excision cavity.

AVAILABLE TECHNIQUES FOR WIDE LOCAL EXCISION OF CENTRAL TUMORS

Central cancers, if they are close to but do not involve the nipple, can be removed by a standard wide excision preserving the overlying nipple skin. If the lesion is very superficial and there is tethering, inversion, or invasion of the nipple, then the nipple and/or areolar complex needs to be excised. The nipple may need to be removed, but in some all or part of the areola can be preserved. Not all women with blood-stained nipple discharge require excision of the nipple. In between 25% and 50% of patients, the nipple can be preserved as the margin under the nipple will be clear on histologic assessment. A preoperative biopsy or an initial duct excision can be used to assess the safety of nipple preservation in such women. In women with large breasts, the nipple–areolar complex can be incorporated into a vertical wedge mammaplasty incision and the cancer excised in continuity with the nipple/areolar skin. Although this does alter the breast shape, acceptable results can be obtained in women with larger breasts. Following nipple–areolar excision, one option is to close the circular wound with a purse-string closure, or a series of radiating scars. The final cosmetic result is variable but can sometimes produce an excellent long-term cosmetic outcome. An alternative approach for such cancers involves removal of the nipple–areolar complex with underlying breast tissue and reconstructing the defect with a skin and breast tissue flap rotated in from the lower outer quadrant of the breast. To do this, an island of skin is identified and marked (Fig. 49.6A). The flap of tissue to be rotated to fill the defect is defined and, apart from the circle of skin that will close the central cutaneous defect, the rest of the skin is deepithelialized (Fig. 49.6B). The breast tissue is incised and divided (Fig. 49.6C) so that the flap can rotate and allow the island of skin to lie in the position of the

areola (Fig. 49.6D). The flap is sutured in situ with absorbable sutures. In patients with large breasts, a skin and breast flap can be advanced from tissue and skin that would normally be excised as part of a breast reduction.

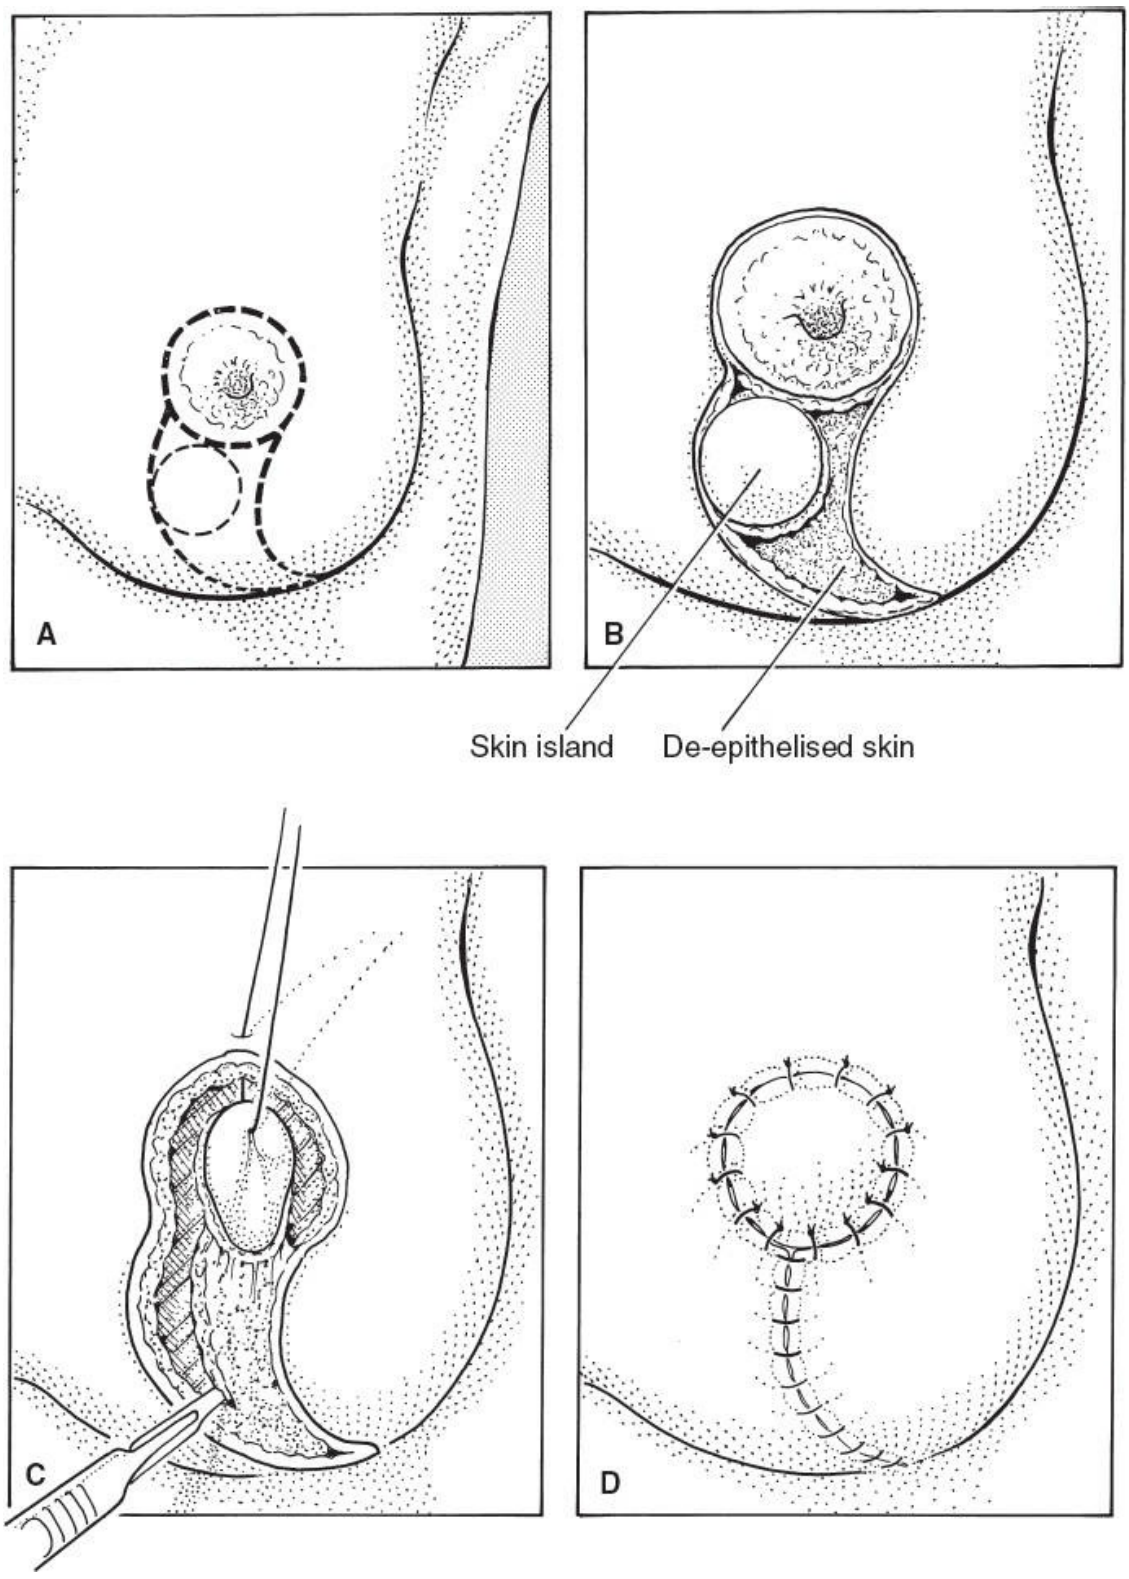

Figure 49.6. How to excise a central cancer under the nipple and get a satisfactory cosmetic outcome without major breast distortion. This procedure has also been called a *central quadrantectomy.* **A.** The nipple–areolar complex is excised and a portion of skin inferior to it is marked out. **B.** An incision around the circular skin island is made, and the remaining skin around

the island is deepithelialized. **C.** A full-thickness incision is the made in the breast, and the skin island is rotated to fill the central defect. Staples are useful to position the flap. **D.** When the flap is deemed to be in an optimal position, the staples are removed and the wound is closed in two layers with absorbable sutures.

TECHNIQUE OF EXCISING IMPALPABLE CANCERS

Impalpable lesions can be localized prior to surgery using a number of different techniques, including skin marking, injection of blue dye, carbon, or radioisotope, radioactive seed, or insertion of a hook wire with postlocalization mammograms (Fig. 49.7), or use of intraoperative ultrasound by the surgeon. Excising an impalpable cancer is easier if the skin incision is placed close to the cancer. Increasingly however such lesions are being excised through remote excisions. If the lesion is being localized by ultrasound, the skin directly over the cancer should be marked along with an indication of the depth of the cancer below the skin by the radiologist or radiographer performing the localization. If the lesion is only visible on a radiograph, then from a true lateral and craniocaudal mammogram, it is usually possible for the surgeon to estimate the likely position in the breast. An appropriate-sized skin incision is made and deepened (Fig. 49.8). If a wire is in place, dissection continues toward the wire so that it can be located where it enters the breast (Fig. 49.9).

If a remote incision is being used, hydrodissection with elevation of the skin and subcuteaneous fat allows identification and delivery of the wire through the skin into the breast. Localization wires with markings, which change diameter or have a guide that can be placed over the wire, help the surgeon know exactly how far down the wire the lesion is situated. Some surgeons use multiple wires to bracket a lesion. This can be helpful and improves the rate of complete excision in more difficult widespread calcifications. The direction of the wire on the preoperative mammograms is only a guide to the actual path of the wire through the breast, and can be misleading. Having found the wire as it enters the breast, do not cut it at its entry into the breast but deliver some of the wire outside the breast and only then cut the wire. This ensures sufficient wire is palpable and can be seen entering the surface of the breast. The aim is to remove the mammographic lesion with a clear radiologic margin (Figs. 49.10 and 49.11). Many so-called impalpable lesions can be palpated once it is clear where the lesion is situated within the breast parenchyma. Be cautious

when placing tissue forceps on the breast tissue. They distort the breast and can affect histologic assessment, and if used they are best placed at the edge of the lesion to be excised. Radio-guided occult lesion localization is a newer technique for localization of impalpable lesions. Under mammogram or ultrasound control, technetium-labeled human serum albumin, sulfur colloid, or an iridium seed is injected into the tumor. The surgeon then uses a handheld gamma-detecting probe intraoperatively to locate the lesion to guide excision. There is some evidence that this technique may be easier than hook wire localization, but no evidence to show it increases the rate of complete excision or reduces the volume excised. Radio iodine seeds are showing promise as they can be inserted days or even weeks prior to surgery. Iron is also being used to localize breast masses and to locate sentinel nodes. The iron in the cancer or the node is located with an intraoperative magnetometer. The use of intraoperative ultrasound has been evaluated in a number of studies. It has been used for removal of both palpable and impalpable lesions. Ultrasound performed by the surgeon during operation allows greater surgical autonomy and obviates the need for radiologist-led tumor localization, although it is greatly dependent on the training and experience of the surgeon. Most, but not all, studies using intraoperative ultrasound have reported high rates of complete excision and low rates of reexcision. It is clear that the major factor in incomplete excision is the presence of DCIS out with the invasive cancer that is not visualized by current imaging techniques. It is difficult based on this observation to believe that application of a technique to image disease that is not visualized by preoperative ultrasound will increase excision rates. Perhaps by ensuring that the lesion is more centrally situated and optimizing the excision with a consistent margin width all around the cancer will allow some of those patients with DCIS around the invasive cancer to have a complete excision. Newer techniques employing newer technologies to assess margins of excision during operation are showing promise.

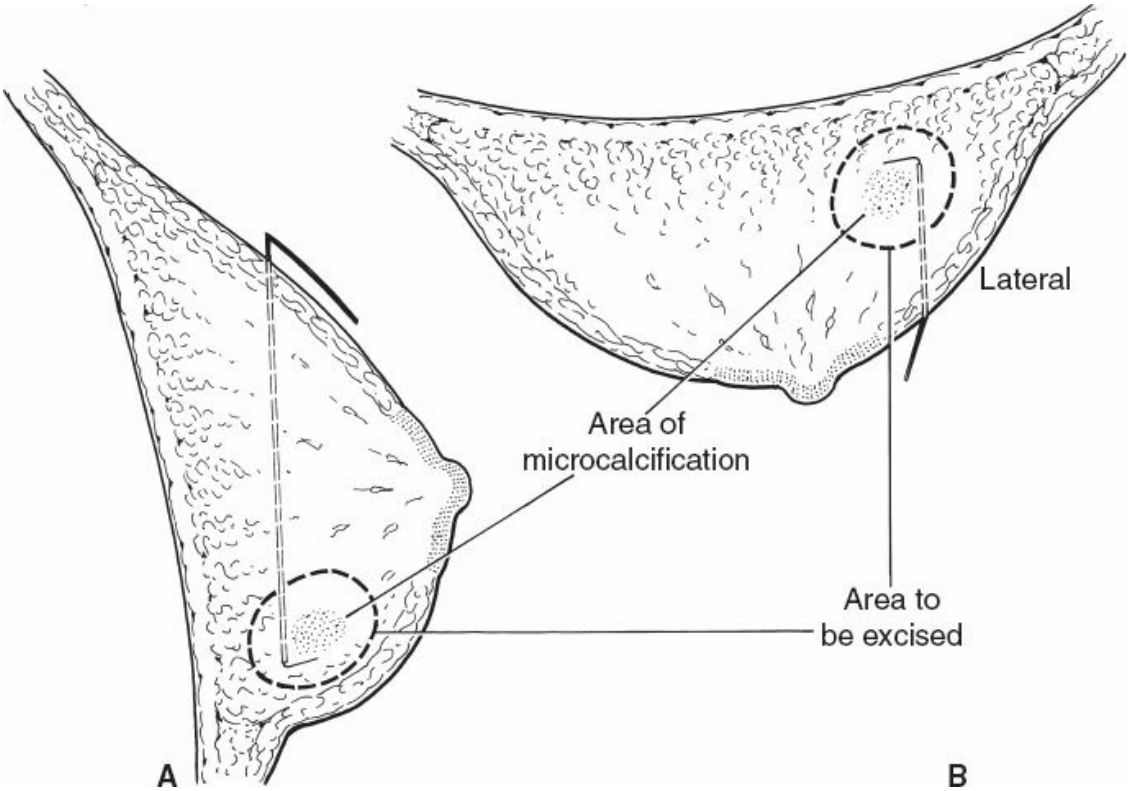

Figure 49.7. Diagrammatic representation of mammograms illustrating the position of a hook wire in relation to the area of microcalcification. **A.** Lateral view. **B.** Craniocaudal view.

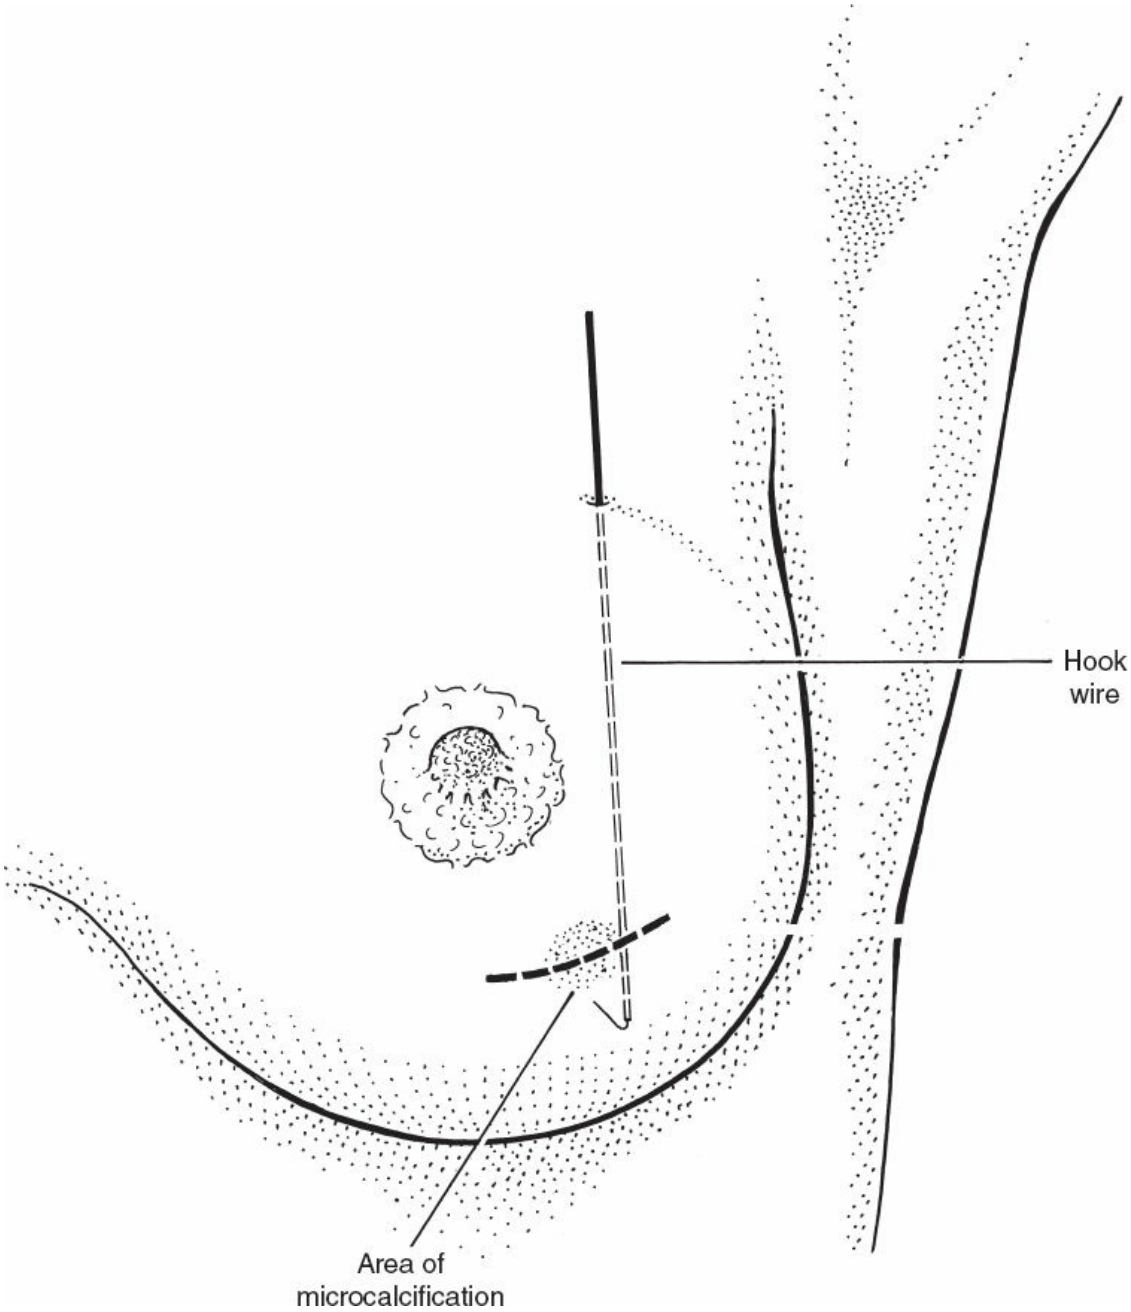

Figure 49.8. Planned incision over area of microcalcification.

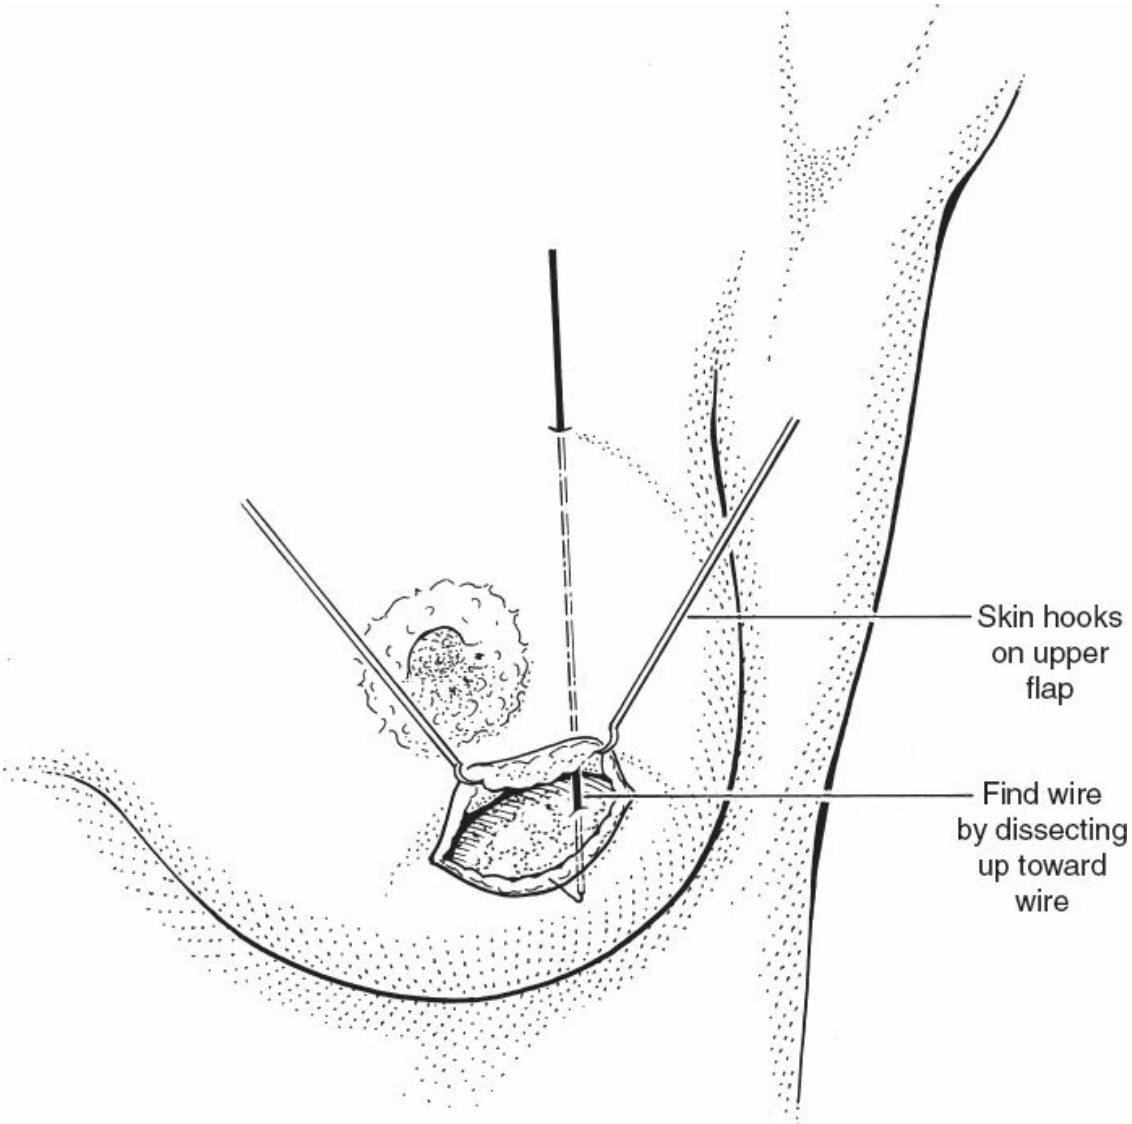

Figure 49.9. Dissection toward the hook wire to locate its entry site into the lesion.

Core biopsy itself causes a hematoma in some patients, although the hematoma is not always directly surrounding the cancer. So-called hematoma-directed and ultrasound-guided wide excisions have been reported. This has the potential to avoid wire localization in some patients. Hematomas do result in increased blood flow, so whereas some prefer to operate early, others wait until the hematoma and any increased blood flow to subside.

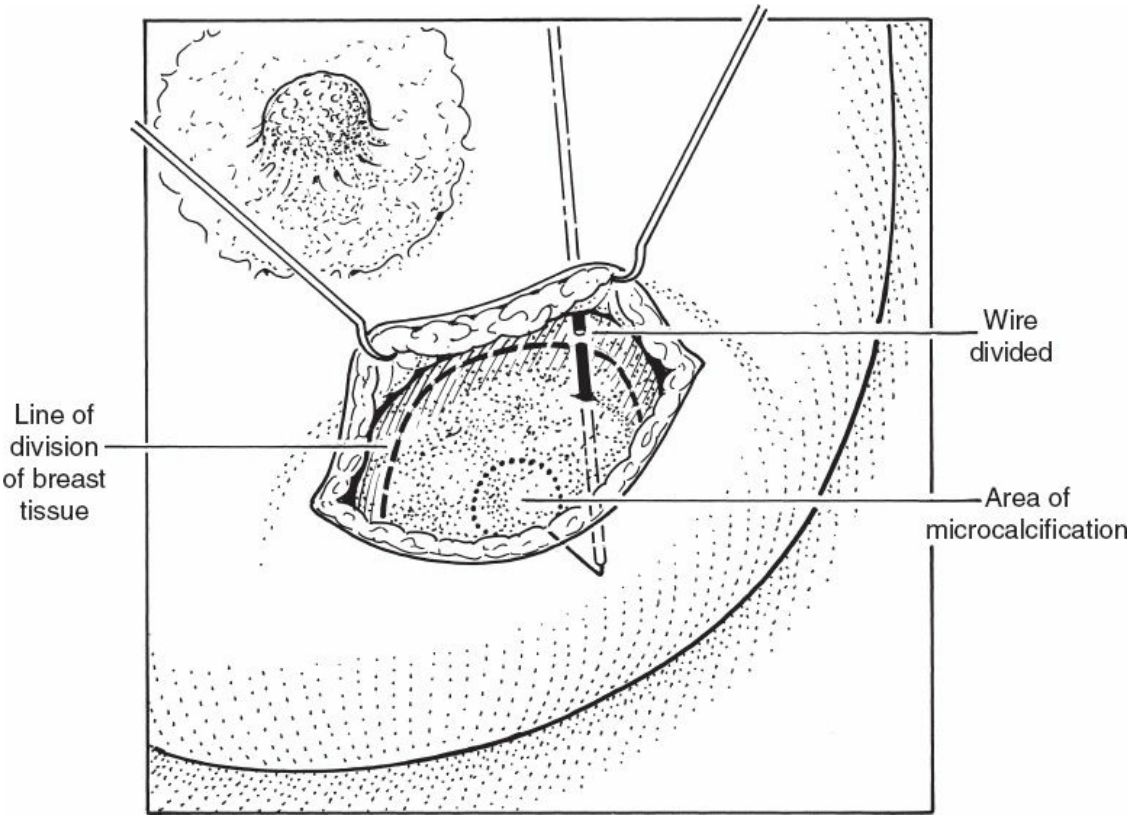

Figure 49.10. The goal of excision is to remove the lesion with a 1-cm clear radiologic margin.

Once the specimen has been excised, it should be orientated with ligaclips or metal markers, or secured to an orientated grid so that an orientated-specimen radiograph can be obtained. Orientated-specimen radiographs improve the rate of complete excision of impalpable cancers. The patient should remain anesthetized until the specimen radiograph has been reviewed and it has been confirmed that all radiologically visible suspicious areas have been removed before the patient.

BREAST-CONSERVING SURGERY AFTER NEOADJUVANT THERAPY

Significant numbers of patients with large and locally advanced breast cancers are treated with neoadjuvant chemotherapy (NAC) and then become suitable for BCS. Surgeons are poor at assessment of disease extent after NAC, and decisions on operability should be based on imaging. All patients having NAC should have all areas of disease marked at diagnosis with radiopaque markers or radioactive seeds. Up to 40% of patients with triple negative breast cancers, up to 60% with HER2 positive cancers, but only 10% of patients with ER-rich (Estrogen Receptor [ER])

breast cancers achieve a complete pathology response. More patients after chemotherapy than after endocrine therapy have a diffuse pattern of response and have a reduction in cellularity but little reduction in volume. Patients undergoing NAC should be warned of this.

The aim of BCS after NAC should be to excise the clip or clips and any palpable disease or disease marked by calcifications or visible on imaging. The surgery should focus on what is left, not what was present at diagnosis (Fig. 49.12A,B). Large volume excisions defeat the whole purpose of using NAC. Limit the surgery to the disease visible on imaging or palpable at surgery.

POSTOPERATIVE COMPLICATIONS

Breast Conservation

Complications of wide excision include bleeding with hematoma formation, infection, incomplete excision, and poor cosmetic results. Incomplete excision rates vary between 15% and 40% depending on what is defined as an involved margin. Hematoma requiring evacuation should be rare and occurs in less than 2% of patients. Rates will be higher in patients who have had greater tissue mobilization. Infection requiring treatment affects up to 5% of patients and is more common when BCS is combined with an axillary dissection. A common problem following BCS is a poor cosmetic result. Factors influencing cosmetic outcome are listed in Table 49.2.

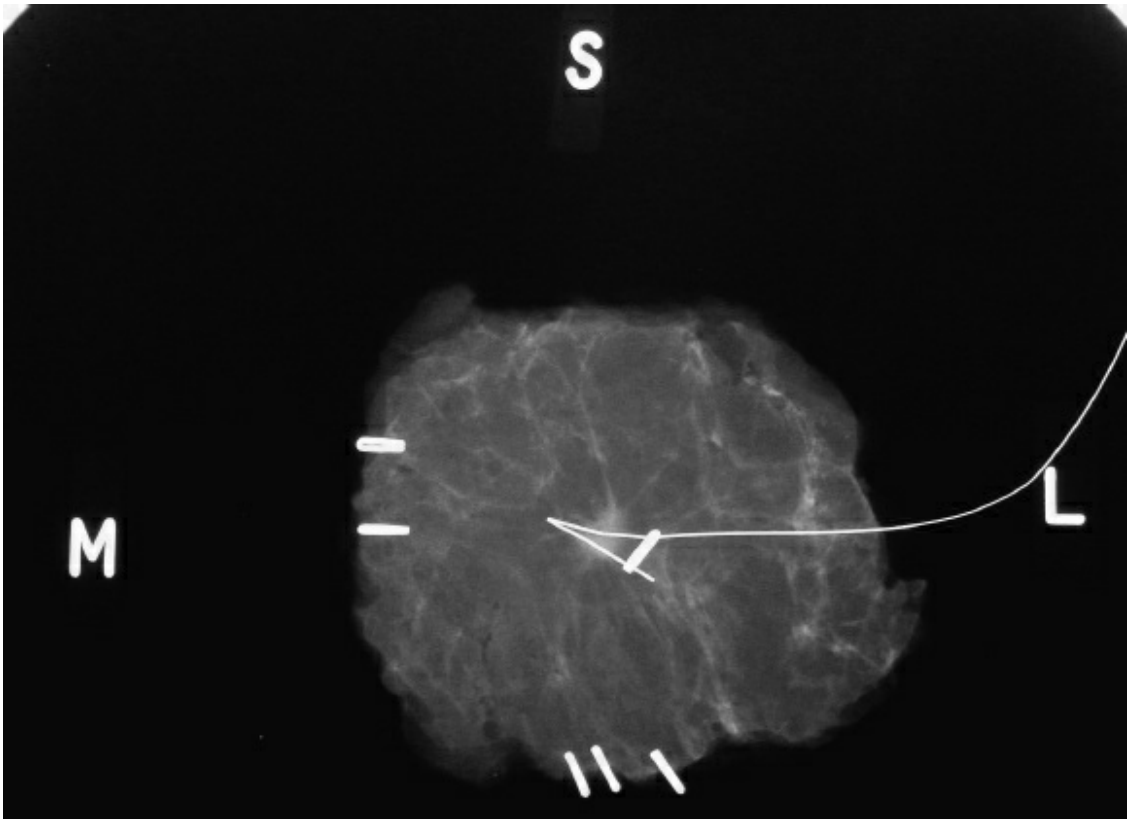

Figure 49.11. Specimen x-ray of small cancer. Note the clips orienting the specimen. Two clips are medial and three inferior.

There is a variation in different series in the number of patients getting good to excellent cosmetic results after BCT. The importance of good cosmetic results is demonstrated in a study from Nottingham, which showed that there was a significant correlation between cosmetic outcome and levels of anxiety, depression, body image, sexuality, and self-esteem. The extent of surgical excision (weight of excision) or the volume of resected breast tissue is the single most important factor affecting cosmesis. The inferior cosmetic results obtained with quadrantectomy compared with wide excision, even in the most experienced hands, are well documented. Even more critical is the percentage of the breast excised. Excisions less than 10% of breast volume are generally associated with a good cosmetic outcome in 95% of patients, whereas excisions of more than 10% produce poor cosmetic results in up to 50% of patients. When more than 10% of the breast volume needs to be excised to remove the cancer completely, then reshaping or volume replacement using local flaps, lipofilling, an oncoplastic reduction procedure, neoadjuvant drug therapy, or a mastectomy with or without immediate reconstruction should be considered.

INDICATIONS FOR REEXCISION

The current surgical practice is to aim for microscopically disease-free margins. In the United States, this is defined as no ink on tumor, but in other countries 1 mm is defined as a free margin based on the finding of two meta-analyses. What is clear is that there is no advantage in terms of local recurrence in having wide margins. Anterior and posterior margins matter much less than radial margins if full thickness of breast tissue has been excised. Regardless of how a negative margin is defined (no ink on tumor or ≥1 mm), there is an increased rate of local recurrence in patients with positive or involved margins. There remains controversy on the use of shaving of margins. Taking shavings reduces reexcision rates but does so at the expense of removing more tissue.

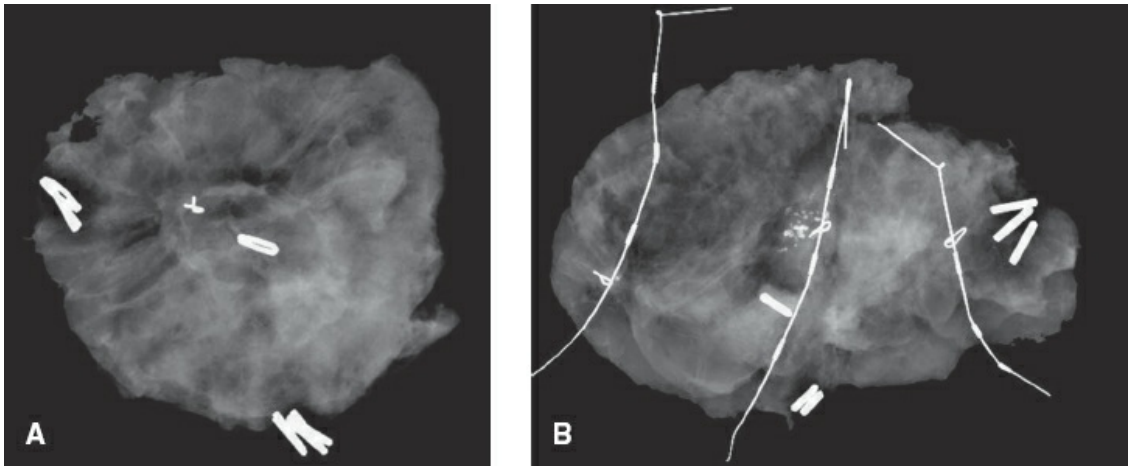

Figure 49.12. **A.** Specimen x-ray. Mass had disappeared after chemotherapy but no mass lesion leaving clip and this was localized. Pathology showed scar tissue with a complete pathologic response. **B.** Specimen x-ray. Patient had three masses adjacent with calcification in central mass. Clips were placed before chemotherapy. All three clips were localized and excised. Pathology showed all three cancers had a complete pathology response.

TABLE 49.2 Factors Resulting in Poor Cosmetic Outcome After Breast-Conserving Surgery

Large breasts
Increasing tumor size
Central tumor position
Increasing volume of breast tissue removed
Reexcision procedure
Increasing scar length
Postoperative complications
Associated axillary dissection
Increasing dose of radiotherapy, especially use of a boost
Chemotherapy

Neither lobular carcinoma in situ (LCIS) nor atypical ductal hyperplasia (ADH) at the margins increases local recurrence rates; consequently, there is thus no need for a surgeon to reexcise if the pathologist reports these features alone at any of the margins of excision. Patients with a positive radial (medial, lateral, superior, or inferior) margin for DCIS or pleomorphic LCIS should have a reexcision. Patients with a positive anterior or posterior margin do not appear to require reexcision providing full thickness of breast tissue has been taken and a radiotherapy boost is given.

Surgical Technique: Reexcision

When performing a reexcision, the old scar is opened and there is no need to excise the scar. The breast is opened and the site of the previous wide excision is identified. The involved margin is then excised to a thickness of approximately 1 cm. The outer margin of the reexcision is marked for the pathologist (we use a ligaclip) and the tissue is sent for pathology. A specimen radiograph of the reexcision is performed if there is a residual mammographic abnormality. Postoperative bleeding can be a problem following reexcision, so meticulous attention to hemostasis is required. The breastplate can be mobilized in patients with dense breast tissue from the subcutaneous fat +/− chest wall and the defect closed with absorbable sutures if at all possible. The wound is then closed as described previously in layers with absorbable sutures and infiltrated with local anesthetic. Drains are not required.

RECURRENCE AFTER BREAST-CONSERVING SURGERY

Local recurrence rates following BCS and adjuvant radiotherapy for invasive carcinoma of the breast vary widely between different centers but nowadays should be less than 0.5% per annum. Approximately half of in breast tumor recurrences are new primary cancers, and the remainder are true recurrences. The rate of true in breast local recurrence has fallen dramatically over the last two decades. Factors that affect local recurrence rates after BCT can be divided into patient-, tumor-, and treatment-related factors.

Patient-Related Factors

In breast tumor recurrence (IBTR) in the treated breast following BCT can be either a true recurrence (at the site of the previous cancer) or a second primary (usually elsewhere in the breast). IBTR is significantly more common in younger patients and is much less of a problem in older patients (>65 years). This may be because women who develop breast cancer at a young age are more likely to carry a mutated gene that predisposes them to develop another cancer in the treated breast. Family history of breast cancer, and, in particular, carriage of a mutation in one of the known breast cancer predisposing genes, is associated with a significantly increased rate of in breast tumor recurrence. If these women undergo a prophylactic oophorectomy, then local recurrence rates fall close to that of the general population.

Tumor-Related Factors

Tumor Grade

A number of studies have looked at the relationship between tumor grade and local recurrence. Grade 1 tumors have the lowest rates of local recurrence. Some series, although not all, report a higher recurrence rate in grade 3 compared with grade 2 cancers. The relative risk of local recurrence between grade 1 and grades 2 and 3 cancer is approximately 1.5.

Histologic Type

A few studies have correlated histologic tumor type and in breast recurrence. Data indicate that invasive lobular cancer is not associated

with a higher recurrence rate than invasive ductal carcinoma. Patients with invasive lobular cancer are more likely however to have incomplete excision than patients with invasive ductal carcinoma of no special-type, so patients with invasive lobular cancer identified on core biopsy should be warned of this.

Lymphatic/Vascular Invasion

Local failure rates were reported in many, but not all, early series to be higher in patients with histologic evidence of LVI. Recent studies have shown that LVI is a marker for recurrence after mastectomy but now is associated with little increased in patients having BCS and whole breast radiotherapy.

Extensive In Situ Component

Early reports indicated that local recurrence rates were higher in patients who had cancers with an extensive in situ component, but the majority of these studies undertook simple tumor excision rather than a wide local excision. If clear margins are obtained, there appears to be no increased rate of local recurrence in patients with an extensive in situ component.

Multiple Tumors

A patient with macroscopic multiple cancers (multisite disease) was until recently considered to be more likely to develop local recurrence following BCT than a patient with a unifocal cancer. It has long been recognized that if multisite disease is identified only by the pathologist or there are two cancers that are adjacent, then acceptable local recurrence rates can be obtained by BCT, provided that all margins of excision are clear of disease. More recent data indicate that multisite cancers can be treated safely by BCS provided all disease can be excised to clear margins and that any BCS performed will produce an acceptable cosmetic outcome. Multisite disease may be associated with a small increase in the risk of local recurrence, but is no longer a contraindication to breast conservation.

Tumor Size

Tumor size is not considered important in relation to local recurrences.

Other Factors

Tumor location, the presence of skin or nipple retraction, the presence or absence of axillary node involvement, and hormone receptor status of the

cancer have not been consistently shown to exert any influence on breast recurrence after BCT.

Treatment-Related Factors

The most important treatment-related factors are completeness of excision and the use of systemic therapy and appropriate doses of radiotherapy. Margins need to be clear of both in situ and invasive disease. In the United States, no ink on tumor is accepted, whereas in other countries ≥1 mm is defined as a clear margin. Some use a margin index to determine whether reexcision is required. Margin index is defined as the margin in millimetres multiplied by 100, divided by the tumor size in millimeters. When the index is ≥5, residual disease is present in less than 3% of reexcisions. This suggests that the bigger the tumor the bigger the margin needed. However, not all studies support this and reexcising based on margin status alone independent of the size of the cancer does not seem to be unreasonable based on the literature. Radiotherapy significantly reduces the rates of local recurrence and improves overall survival. Ongoing studies are evaluating whether localized radiotherapy delivered either during or within a few days of surgery is as effective as whole-breast radiotherapy. Following whole-breast radiotherapy, increasing the local dose of radiotherapy by giving a dose to the tumor bed reduces local recurrence rates, particularly in younger women (<50 years). There are a group of older patients with low-risk cancers (completely excised, node-negative, hormone receptor-positive on hormone treatment) in whom the rates of local recurrence without radiotherapy are low.

Adjuvant tamoxifen, chemotherapy, and trastuzumab all reduce local recurrence after BCT. In the absence of radiotherapy, however, tamoxifen or chemotherapy alone does not provide satisfactory local control. The interval between surgery and both radiotherapy and systemic therapy may be important, and there are suggestions that the rates of local recurrence are increased if radiotherapy or systemic therapy is delayed for many months.

Treatment of in Breast Tumor Recurrence

In breast tumor recurrence rates vary widely in the literature, but rates of less than 0.5% per year after BCT should be achievable by all units. Approximately half of in breast recurrences are second primaries. Although an isolated local breast recurrence does not appear to affect

survival, breast recurrence can be a predictor of distant disease. Isolated recurrences in the breast can be treated by excision or mastectomy. Excision alone is associated with a greater rate of subsequent local recurrence if the initial recurrence develop within the first 5 years of treatment. Local recurrence within the first 5 years is also associated with a worse long-term survival than recurrence thereafter. Ninety percent of local recurrences following BCT are invasive. The majority of in breast events that develop in the treated breast after 5 years represent a second primary cancer rather than a true local recurrence. Mastectomy is the most commonly used treatment for in breast recurrence after BCT and can be combined with immediate breast reconstruction. Excision of the recurrence combined with a change of systemic therapy or excision together with further radiation are also options. Care is needed when performing a further excision or mastectomy after breast radiotherapy as the complications of wound healing problems, necrosis of the skin flap edges, and development of postoperative seromas are more common following prior radiotherapy than in untreated patients.

MANAGEMENT OF CARCINOMA IN SITU AND PROLIFERATIVE LESIONS OF THE BREAST

Classification of noninvasive and proliferative lesions is difficult and challenging. Carcinoma in situ is separated into two groups: DCIS and LCIS based on cell type and pattern of disease. DCIS is the most common form of noninvasive disease and represents a heterogeneous group of neoplastic lesions confined to breast lobules and ducts. DCIS diagnoses have increased in frequency as a consequence of the widespread use of screening mammography. DCIS makes up 3% to 4% of symptomatic and 20% to 25% of screen-detected breast cancers.

Epidemiology

The overall incidence of DCIS increased from 5.8 per 100,000 women in the 1970s to 32.5 per 100,000 in 2004 and then reached a plateau. The risk of developing DCIS, like invasive cancer, increases with age. Death following a diagnosis of DCIS is rare and is less than 3% at 20 years. Risk factors for DCIS include family history, increased breast density, obesity, and late age at first birth. DCIS is seen in BRCA1 and 2 mutation carriers and tends to occur at a younger age in these women. Tamoxifen given to

high-risk women reduces the number of women who develop DCIS.

Clinical Presentation

Prior to mammographic screening, most women with DCIS presented with a mass, nipple discharge or Paget disease of the nipple. Now more women with DCIS are diagnosed following mammography. Ninety percent of women with DCIS have microcalcifications, and DCIS accounts for 80% of all cancers that have microcalcification without a mass lesion or distortion. Linear branching or segmental pleomorphic calcifications are characteristic of high-grade DCIS. Fine granular calcifications are seen more commonly with low- and intermediate-grade DCIS. Mammography often underestimates the size of DCIS, particularly in low-grade disease. The role of MRI in DCIS is unclear. It can visualize DCIS, particularly high-grade disease but can underestimate and overestimate size. There is no role for the routine use of MRI in DCIS management.

Diagnosis and Histology

The diagnosis is established by core biopsy typically guided using stereotaxis. Large core vacuum-assisted devices are favored as they remove more tissue and are more likely to sample sufficient calcification to establish the diagnosis. It is essential when performing core biopsy to ensure that adequate numbers of calcifications are retrieved and that these are identified by the pathologist in the histologic sections. For large lesions, core biopsies should be performed from each end of the lesion to establish the extent of disease. After core biopsy marker clips should be placed because sometimes most or all the calcifications are removed by the biopsy. Check films should be performed after marker deployment to check that markers are on target.

Histology

DCIS is classified into three main groups based on nuclear grade: high, intermediate, and low grade. Pathologists often separate DCIS into different patterns, such as solid, cribriform, micropapillary, and comedo, but these descriptions have little direct clinical significance. The presence of necrosis is a feature that has some prognostic significance. Approximately 50% of high-grade DCIS and 75% of low- and intermediate-grade DCIS overexpress the estrogen receptor and are classified as ER-positive. Approximately 40% of DCIS overexpress HER2

and are classed as HER2 positive.

Natural History

Approximately 30% to 40% of women with untreated low-grade lesions were reported to develop an invasive cancer over a 30-year period in studies performed almost 40 years ago. Newer evidence indicates that many low-grade DCIS lesions are indolent and some may not need any treatment and that the rate of breast cancer development if untreated is much lower than that reported in older studies and is closer to 10% to 20%. The rate of progression of high-grade DCIS to invasive cancer is much higher with a 30% or greater lifetime risk.

Treatment

The objective of treatment is to prevent recurrence or progression of DCIS to invasive cancer.

Surgery

The options are BCS or mastectomy.

Breast-Conserving Surgery

Outcomes with BCS are improving, and local recurrence rates have fallen over time and are now less than 0.5% per year. There is no size limit for offering BCS other than the balance between the extent of disease and breast size. When over 10% of the breast volume is excised, the cosmetic outcome is more frequently poor than when lower volumes are excised. In general, it is difficult to excise lesions over 5 cm except in women with larger breasts when a mammaplasty is an option. In such women once the the DCIS is excised, the breast is reshaped and made smaller, and usually the opposite breast is reduced to match. Wide excision is performed in an identical manner to that for invasive breast cancer. As DCIS is usually impalpable, the disease needs to be localized by one or more hooked wires or another method of localization such as using isotopes. As for invasive cancer, DCIS needs to be excised to clear margins. There is less uniformity in what constitutes a negative margin; ≥1 mm or ≥2 mm is the most frequently used margin, but some try to excise DCIS with wide margins ≥10 mm. There seems little scientific basis for using different margins for invasive cancer and DCIS given that most recurrences after BCS for invasive cancer is from residual DCIS. Up to 20% of excisions for DCIS show the presence of invasive cancer on histologic assessment. Such

patients usually require a later sentinel node biopsy. Rates of upgrade to invasive cancer are less if lesions have been sampled with a large core vacuum-assisted device.

Preoperative Assessment

This is similar to that for invasive cancer. Patients need to be warned of the 20% risk that invasive cancer may be diagnosed after excision and warned that if invasion is diagnosed they may need a subsequent sentinel lymph node biopsy (SLNB). Surgical Technique is similar for excision of impalpable invasive cancers. Complications are similar to that for invasive cancer.

Mastectomy

Mastectomy is a highly effective treatment for DCIS, but may be overtreatment for many women particularly those with small low- and intermediate-grade lesions that may never have become symptomatic within a patient's lifetime. Most women with DCIS are suitable for a skin sparing mastectomy approach with immediate breast reconstruction. While recurrence rates have been traditionally low after standard mastectomy, in younger patients with high-grade DCIS who have close margins much higher rates of recurrence of invasive cancer have been reported. Patients who have mastectomies for DCIS should have the breast X-rayed to assist the pathologist in localizing the disease. Studies have shown high rates of recurrence in young women with high-grade DCIS who have margins less than 1 to 2 mm after mastectomy. For this reason, in skin-sparing mastectomies particular care must be taken when dissecting the area over the DCIS. Taking extra tissue from the flaps and sending this separately for assessment increase the likelihood of obtaining a clear anterior margin. Given the 20% rate of invasive cancer evident on histologic assessment after excision of patients diagnosed on core as DCIS, sentinel node biopsy is often combined with mastectomy. The isotope +/− blue dye is injected centrally.

Radiotherapy

Multiple randomized trials have shown that radiotherapy reduces the rate of in breast tumor recurrence following BCS for DCIS by approximately 50%. In an overview of randomized trials radiotherapy reduced the absolute 10-year risk of any ipsilateral event (i.e., recurrent DCIS or invasive cancer) by 15.2% (SE 1.6%, 12.9% vs. 28.1% $p < 0.001$). The

proportional reduction in events was greatest for younger women. Even for women with negative margins and small low-grade lesions, radiotherapy showed a significant reduction in local events (12% vs. 30% $p = 0.02$). Despite this large effect, there is no current evidence that radiotherapy improves survival.

Not all women following BCS for DCIS require radiotherapy. A variety of algorithms and a new genomic index have been used to identify those who are most likely to benefit from radiotherapy. Younger women, with more extensive high-grade DCIS with comedo necrosis that is close to margins appear at greater risk of local recurrence and so these women may benefit from radiotherapy. In contrast, older women with small low- and intermediate-grade DCIS, excised adequately appear to benefit least and so many of these women can potentially avoid radiotherapy. A new genomic index that measures RNA for seven tumor genes and five reference genes has been developed and validated. In the first cohort patients classed as low risk had a 10.6% rate at 10 years of any in breast event and a 3.7% rate of invasive breast cancer development at 10 years. The figures for intermediate risk lesions were 26.7% and 12.3% for DCIS and invasive cancer, and for high-risk DCIS 25.9% developed further DCIS and 19.2% developed invasive cancer. This index does potentially identify a low-risk group who can potentially avoid radiotherapy after excision.

Endocrine Therapy

Two studies have shown a benefit of tamoxifen in reducing both the rates of DCIS recurrence and invasive cancer development following BCS. The effects were greatest in women with ER-positive DCIS with up to a 60% reduction in the number of in breast events. Studies with aromatase inhibitors have also shown reductions in the number of in breast events. Raloxifene has also been shown to reduce DCIS and invasive cancer events but appears less effective than tamoxifen.

The issue surrounding the use of endocrine therapy is how much benefit is necessary to justify their use. There is no evidence that any of these agents improve survival and all are associated with significant morbidity. Endocrine treatment is an option for both pre- and postmenopausal women following excision of DCIS and appears of greatest value in younger women with ER-positive DCIS where not only the rates of recurrence are higher, but the reductions in events with endocrine therapy have been greatest in the studies published to date.

Treatment for Low-Grade DCIS

A recent study has suggested that surgery for low-grade DCIS has no effect on subsequent outcomes. There is clear evidence from screening studies that between 11% and 19% of screen-detected cancers (including many DCIS lesions) are overdiagnosed and thus overtreated. Over diagnosis means that if left untreated they would never have caused problems in the patient's lifetime. Studies are now these studies are investigating doing less for low-grade DCIS and treating such patients without initial surgery and investigating the role of observation or endocrine therapy rather than surgical excision +/- radiotherapy.

Atypical Ductal Hyperplasia

ADH is defined as a localized intraductal proliferation having some but not all microscopic features of (low-grade) DCIS. It is usually seen most commonly in biopsies for calcification seen on breast screening. ADH is part of a spectrum and poses a challenge for the pathologist because it can be difficult to distinguish usual duct hyperplasia from ADH and low-grade DCIS. Histologically ADH is an architecturally complex proliferation of monotonous luminal-type cells forming bridging structures and "crisp" secondary lumens. ADH is distinguished from low-grade DCIS using a combination of qualitative and quantitative criteria: generally, there is less cytologic atypia in ADH than in DCIS. ADH is limited to fewer than three contiguous ducts or a size less than 0.2 cm. As sampling by core biopsy produces small fragments of tissue, it is not always possible to distinguish ADH from low-grade DCIS. On average 10% to 20% of ADH cases diagnosed on core needle biopsy are "upgraded" to DCIS or invasive carcinoma on subsequent excision, although the reported upstaging rates to DCIS or invasive carcinoma vary from 11.5% to 62%. If ADH is diagnosed on a core biopsy, then more tissue needs to be sampled at that site either by large bore vacuum-assisted biopsy or open surgical biopsy.

The relative risk of atypical hyperplasia for development breast cancer is between 3.9 and 13.0. Most have reported relative risks at the lower end of this range between 3.1 and 4. Risk increases in women with a strong family history of breast cancer. Various risk models are available to calculate individual risk. In the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 study, there was a 57% increase in invasive cancer compared to patients without atypical hyperplasia (10.11 events per 1,000 patients vs. 6.44 events per 1,000 patients) at a mean follow-up of

47.7 months (Fisher).

ADH is a risk lesion, and options for management include chemoprevention with tamoxifen or raloxifene in premenopausal women and tamoxifen, raloxifene, or an aromatase inhibitor in postmenopausal women. Tamoxifen reduced the risk of breast cancer in patients with atypical hyperplasia patients by 86% in the NSABP P-1 prevention study. The other main option is regular breast screening with mammography with or without MRI. Performing risk reducing mastectomies based on ADH alone is not recommended.

Lobular Carcinoma *In Situ* and Atypical Lobular Hyperplasia

LCIS is rare. It was first described in 1941 and was originally treated in a similar way to invasive cancer by mastectomy. LCIS is a proliferative lesion of the terminal duct lobular unit characterized by lobules expanded by neoplastic cells that are regular in shape and size and have regular rounded nuclei. LCIS-like invasive lobular cancers lock e-cadherin—an adhesion molecule. Between 0.5% and 2% of all core biopsies contain LCIS, and it is seen most commonly in postmenopausal women and is often an incidental finding.

Atypical lobular hyperplasia (ALH) is a histologic continuum with LCIS and has similar but less developed features. The lobules are expanded with the same cell type with the cells having lost e-cadherin but not all the spaces in the lobule are expanded. Because of the difficulties in distinguishing between ALH and LCIS, the term *lobular intraepithelial neoplasia* (*LIN*) has been introduced to include both LCIS and ALH. Like LCIS, ALH is often an incidental finding and is most commonly diagnosed in core biopsies performed for calcification even though the ALH is not often associated with calcification.

Management

Studies of patients with LCIS on core biopsy have reported upgrade rates to invasive carcinoma or DCIS following surgical excision of between 25% and 38% of patients. Little data exist on upgrade rates for ALH alone, but studies of LIN (LCIS and ALH) have reported upgrade rates of 13% to 20%. Current NCCN and UK guidelines recommend that patients who have LCIS or ALH on core biopsy should have surgical excision. There are however huge problems with studies that have reported upgrade rates of LCIS and ALH on core biopsy. All such studies have contained small

numbers of patients, and there has been a wide reported variation in the upgrade rate. More recently, there has been an attempt to correlate radiology and pathology, and two groups have been identified. The first group is the concordant group where the histologic findings on the core biopsy are consistent with the radiology. The second is the discordant group where the findings on core biopsy do not adequately explain the radiology findings. A recent prospective study enrolled 79 patients, and of these 74 had LIN as the worst histologic lesion. The histology and radiology were concordant in all these 74 patients. There was no upgrade on surgical excision in 73 (73/74) of these concordant cases with just one upgrade to DCIS on excision. This is consistent with findings in the literature where a total of 335 cases combined from 5 different publications had histologic and radiologic concordance. In these 335, there were just six upgrades (1.8%). Of these six, five were upgraded to DCIS and one was a 2-mm grade 1 cancer. There is now growing evidence that it is possible to avoid excision biopsy in women diagnosed by LIN on core biopsy where there is concordance between pathology and imaging. As yet this change has not been incorporated into guidelines.

Pleomorphic LCIS

The clinical significance of pleomorphic lobular carcinoma in situ (PLCIS) is unclear. Currently management is inconsistent. One review analyzed nine studies involving a total of 176 patients and included five management guidelines (from United Kingdom, United States, Australia, and pan-European). This review found that 46 of 93 (49%) patients had PLCIS associated with concurrent invasive disease. They reported that 11 of 117 (9.4%) patients developed a recurrence of PLCIS, although no patient developed invasive disease or DCIS when they recurred. There were no studies assessing long-term outcomes of PLCIS. The Association of Breast Surgery (United Kingdom) and the National Breast and Ovarian Cancer Care (Australia) do not mention PLCIS. The National Comprehensive Cancer Network (United States) indicates that PLCIS should be excised to negative margins. The NHS Breast Screening Programme (United Kingdom) and the European Society of Medical Oncology (pan-European) recommend PLCIS should be treated in an identical manner to DCIS. Although high-quality evidence to guide management of PLCIS is lacking, the current consensus is to treat PLCIS in a similar manner to DCIS. If PLCIS is found on core biopsy, then

excision is required as the rate of upgrade to invasive cancer or DCIS is reported as between 17% and 46% in three small series.

AXILLARY SURGERY

The two main aims of axillary surgery in patients with operable breast cancer are to stage the axilla by SLNB and to treat any axillary disease by axillary clearance or axillary dissection. The presence or absence of axillary lymph node involvement is an important predictor of survival in patients with breast cancer, and important treatment decisions are based on it. The number of involved lymph nodes and the level of lymph node involvement are predictors of survival of patients with breast cancer. Figures 49.13 and 49.14 illustrate the levels of the axillary lymph nodes.

Indications for SLNB:

operable breast cancer (T1, T2)
clinically node-negative
imaging axillary node negative.[1]

Indications for axillary dissection[2]:

patients with histologically or cytologically proven involved axillary lymph nodes after freehand or ultrasound-guided fine-needle aspiration biopsy/core biopsy or after sentinel node biopsy.

MANAGEMENT OF THE INVOLVED AXILLA

For patients with involved axillary nodes in whom it is considered that the axilla requires treatment, there are two options: axillary dissection and axillary radiotherapy. A randomized trial AMAROS (After Mapping of the Axilla: Radiotherapy Or Surgery) showed after an average of 6.1 years an axillary recurrence rate of 0.43% after axillary lymph node dissection (n = 744) versus 1.19% after axillary radiotherapy (n = 681). There was no difference in disease-free or overall survival but an approximate doubling of the lymphoedema rates for lymph node dissection compared with axillary radiotherapy.

Sentinel Lymph Node Biopsy

The aim of SLNB is to identify patients who are node-negative or who have limited volume axillary disease. The premise behind SLNB is that the sentinel lymph node(s) is the first lymph node(s) to drain the cancer. If

sentinel lymph nodes are identified and removed and these do not contain metastatic disease, then the remainder of the axilla is likely to be negative, and complete axillary dissection and its sequelae can be avoided.

In the 1830s, Sappey injected mercury into the lymphatic channels of the breast. From these experiments, he concluded that breast tissue drains centripetally into the subareolar plexus before draining into the axilla. More recent studies of lymphatic channels in mastectomy specimens found no common subareolar plexus, but did identify one or two major lymphatic channels that drained the breast terminating in lymph nodes in the lower axilla. Tracer to identify sentinel nodes can be injected into the subareolar region, intradermally into the skin overlying the tumor, or around the tumor. The density of lymphatics is greater in the skin than in breast parenchyma, so uptake in the axillary nodes is greater with intradermal injection than other sites. Injection into skin can allow visualization of lymphatic channels, which may aid sentinel lymph node identification and can help to distinguish between first-echelon and higher-echelon lymph nodes. Peritumoral injection of tracer is preferred by some but the “shine-through” effect of injecting radio isotope in upper outer quadrant cancers can impede detection of the sentinel lymph node in the axilla. One study showed a 100% concordance between intradermal patent blue dye injection and peritumoral radioactive tracer injection. Intradermal injection has a higher rate of identification of the sentinel lymph node and a comparable false-negative rate when compared with peritumoral injection of tracer. Subareolar injection of tracer has advantages over peritumoral injection in patients with multisite or nonpalpable cancers. One review of 3,961 patients found that with subareolar and periareolar injection, the sentinel lymph node identification rate was 99.3% and 95.6%, respectively, compared with 91.1% for patients with peritumoral tracer injections. They concluded that subareolar and periareolar injection was superior, and this adds support to the hypothesis that lymphatic drainage of the breast, regardless of the site of injection, is through the same sentinel lymph nodes.

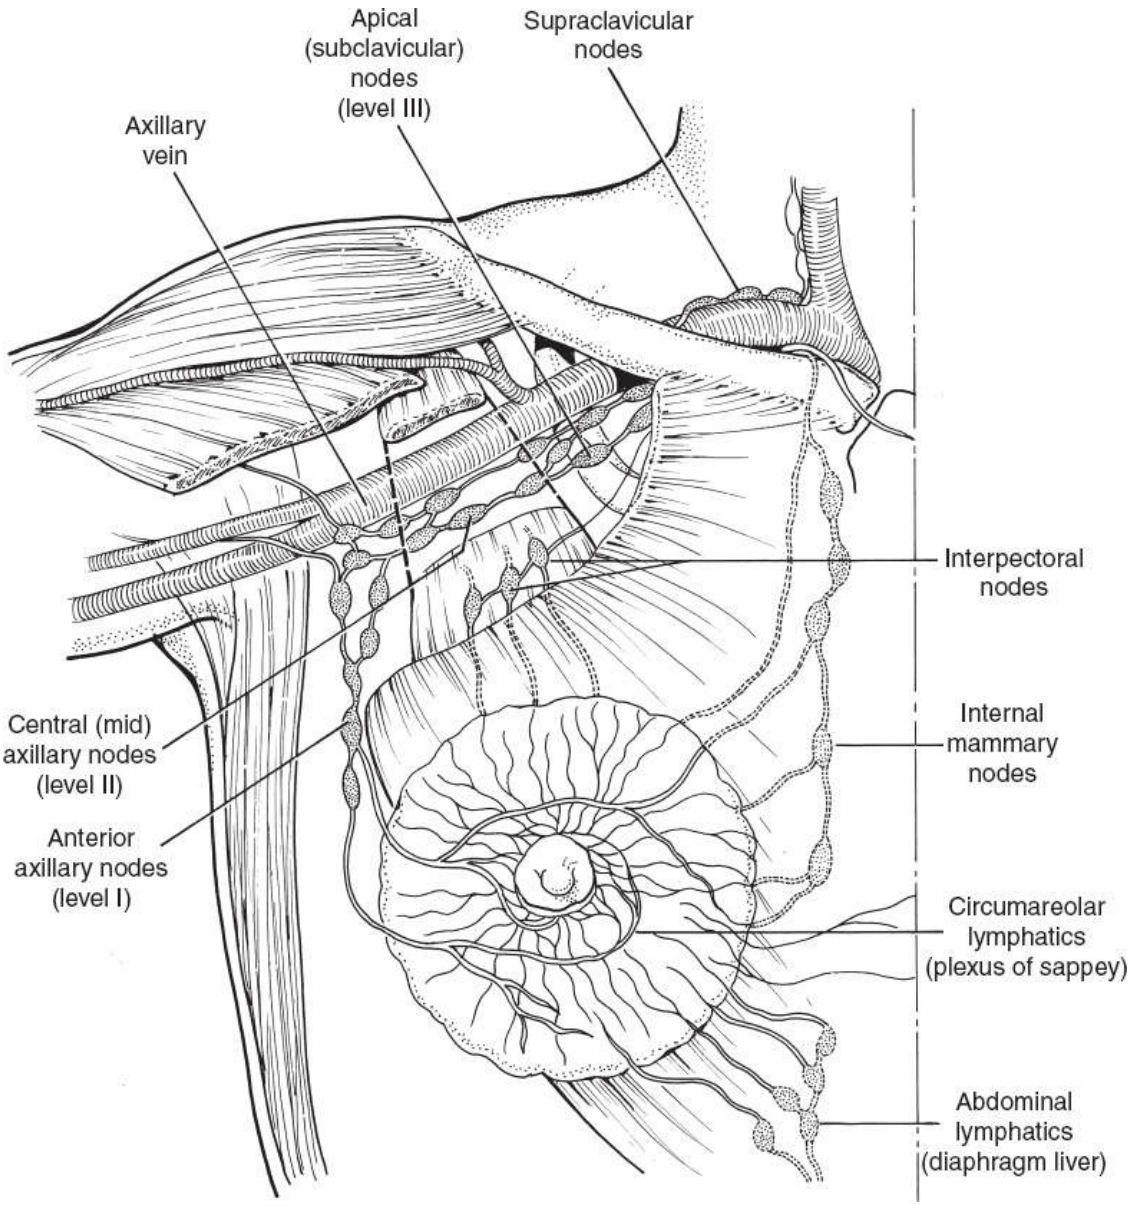

Figure 49.13. Lymph nodes and lymphatic drainage of the breast.

The two tracers in common use are technetium-99M-labeled albumin or sulfur colloid, and a blue supravital dye such as patent blue V, isosulfan blue, or methylene blue. Early studies of sentinel lymph nodes in breast cancer used a blue dye alone. In these studies, the rate of sentinel node identification was 66%, and no sentinel lymph nodes outside the axilla were identified with blue dye alone. The blue color appears in the axillary lymphatics and nodes within a few minutes of injection and can be visualized during operation. Injecting a gamma-emitting radiopharmaceutical around the primary tumor, into the skin over the tumor, or into the subareolar or periareolar area allows preoperative

visualization of any draining nodes using a gamma camera. The sentinel lymph node identified on scintiscans is in the internal mammary chain in up to 6% of patients. Internal mammary node uptake is dependent on the site and depth of injection. Peritumoral injections, particularly if placed deep in the breast, are more likely to drain to the internal mammary nodes. Using a handheld gamma probe, the surgeon can locate the node with the highest uptake of radioisotope and allow the surgeon to make a skin incision directly over it. This limits dissection and the associated morbidity of SLNB.

Following injection of a radioisotope, radioactivity can be identified in sentinel lymph nodes within a few minutes. Results from Milan demonstrated a 97.5% accuracy of SLNB using radioisotope alone. In their series of 250 women, only 10 patients did not have a sentinel lymph node identified. The average number of sentinel nodes was 2 (range 1 to 5) with less nodes being identified when larger colloid particles were used. Of the 240 patients who had sentinel lymph nodes removed, 108 had involved sentinel lymph nodes and 132 had negative sentinel lymph nodes. Of the 132 patients with a negative sentinel lymph node, 126 were node-negative following a full axillary clearance. The remaining 6 patients had a negative sentinel lymph node but had other involved nodes identified in the full axillary dissection specimen, a false negative rate of 6/108 (6%). The group from Memorial Sloan Kettering Cancer Center reported a detection rate with blue dye of 90%, compared with 98% for radioactive colloid. They recommended using both modalities to enhance sentinel lymph node detection.

Currently, radioactive colloid is used in most women with blue dye being used only for patients who do not have a sentinel node visualized on scan or nodes detectable by a handheld gamma probe. There are a range of reasons why blue dye is not used in all patients. First, and most importantly, blue dye is associated with a small but not insignificant rate of severe anaphylaxis. Allergic reaction to isosulfan blue or patent blue V has been reported in between 0.07% and 2.7% of patients. Methylene blue appears safer with no cases of anaphylaxis identified by one literature review. A second reason to avoid blue dye is that regardless of where it is injected the breast can remain discolored for months and even years after surgery. Other options are being explored including fluorescent tracers such as indocyanine green and injection of iron particles. The fluorescent tracers can be visualized intraoperatively in subcutaneous lymphatic

channels by ultraviolet light. Iron injected in the breast, like isotope and blue dye, migrates to nodes, and this iron can be identified by a handheld intraoperative magnetic device known as a magnetometer.

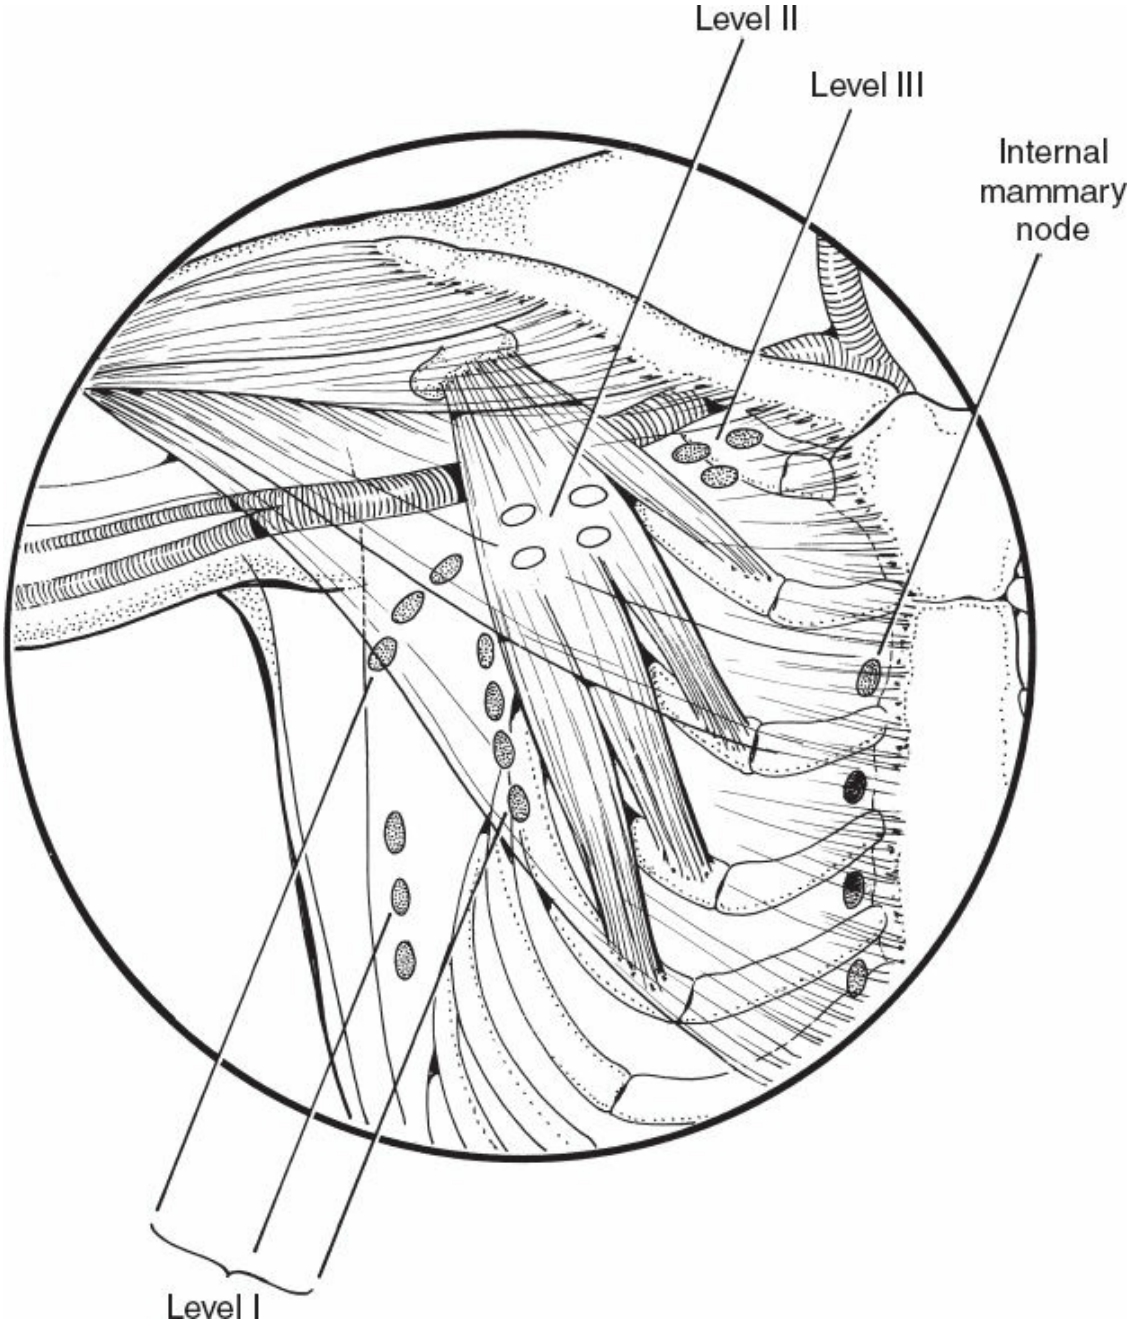

Figure 49.14. Levels I to III of the axillary lymph nodes.

Numbers of Sentinel Nodes

The false negative rate depends on the tracer used and the number of nodes retrieved. The false negative rate varies from 8.6% for dye alone, 7.5% for radioactive tracer alone, and 5.9% when both are used. There is no significant difference related to location in the breast. The false negative

rate in the largest study published to date (NSABP B-32) was 17.7% if one sentinel node was removed, 10% for two sentinel nodes, 6.9% for 3 nodes, and 5.5% for four nodes. Given that anatomical studies show the majority have two draining lymphatics ending at either the pectoral node, situated medially behind the pectoralis major muscle, or a second node laterally situated just above the axillary tail, then the average number of sentinel nodes a surgeon should be removing to limit the false negative rate is between two and three, and should include nodes at these two locations.

Despite the apparent high false negative rate overall in NSABP B-32 of 9.8%, the numbers of patients who developed axillary recurrence over the next decade was small validating the safety of this technique.

Technique of Sentinel Lymph Node Biopsy

The technique used in Milan is to inject 1 mCi of technetium-99M-labeled albumin around the tumor into the breast parenchyma on the day prior to surgery. This is equivalent to approximately 37 MBq of technetium. Most American studies have used technetium-labeled sulfur colloid. Doses of between 450 mCi and 1 Ci have been injected 1 to 6 hours before the operative procedure. Although the optimum volume has yet to be found, when using radioactivity, between 0.5 and 6 mL of technetium-labeled albumin or sulfur colloid in saline is used. The dose I use is 25 to 28 mBq of technetium on the day of surgery or 40 mBq if injected the day before. When using dye, between 2.0 and 7.5 mL of isosulfan blue, patent blue V, or methylene blue is injected just before the skin is prepared for surgery.

My practice is to inject a radioactive tracer together with blue dye into the breast in the anesthetic room following induction of anesthesia. The isotope is injected either intradermally or in the subareolar region. I dilute 2 mL of patent blue V with 3 mL of saline, making a total of 5 mL, and inject this into the subareolar region in those patients in whom a handheld gamma probe does not detect a sentinel node in the axilla. The injection site is then massaged for 1 minute. During surgery, the gamma-detecting probe is used to identify the site of the sentinel lymph node in the axilla. I do not perform scintigraphy and the UK Training Program recommends scintigrams only in the learning phase. A skin crease incision is made over the site of maximal radioactivity and this is deepened. The sound emitted by the probe is used as a guide to find a node, and the tissues are divided down through the fascia anterior to the axillary fat and then the fat of the axilla is separated to the point of maximum impulse intensity. Where there is no radioactive node visible on scan or detected by the probe, then a skin

crease incision is made in the lower axilla between the edges of the pectoralis major muscle anteriorly and the latissimus dorsi muscle posteriorly (Fig. 49.15). During dissection, blue lymphatics are usually visible and the tissue around these lymphatics is divided and the blue lymphatic is followed to a sentinel lymph node. The two classical sites for sentinel nodes are in the subpectoral region—low and medial—and in the low lateral axilla just above the axillary tail of the breast. Two or more sentinel nodes are usually evident, and all the nodes identified with the handheld probe containing significant isotope (10% or more of the radioactivity of the hottest node) or stained blue should be removed and sent for histologic evaluation. Routine intraoperative assessment of nodes is no longer recommended. Some units still use intraoperative assessment by frozen section or one stop nucleic acid amplification (OSNA) for patients having mastectomy. Given the alternative options of no further treatment for low volume axillary nodal disease or axillary radiation in patients with more extensive disease, intraoperative assessment of nodes is rarely indicated in patients having BCS.

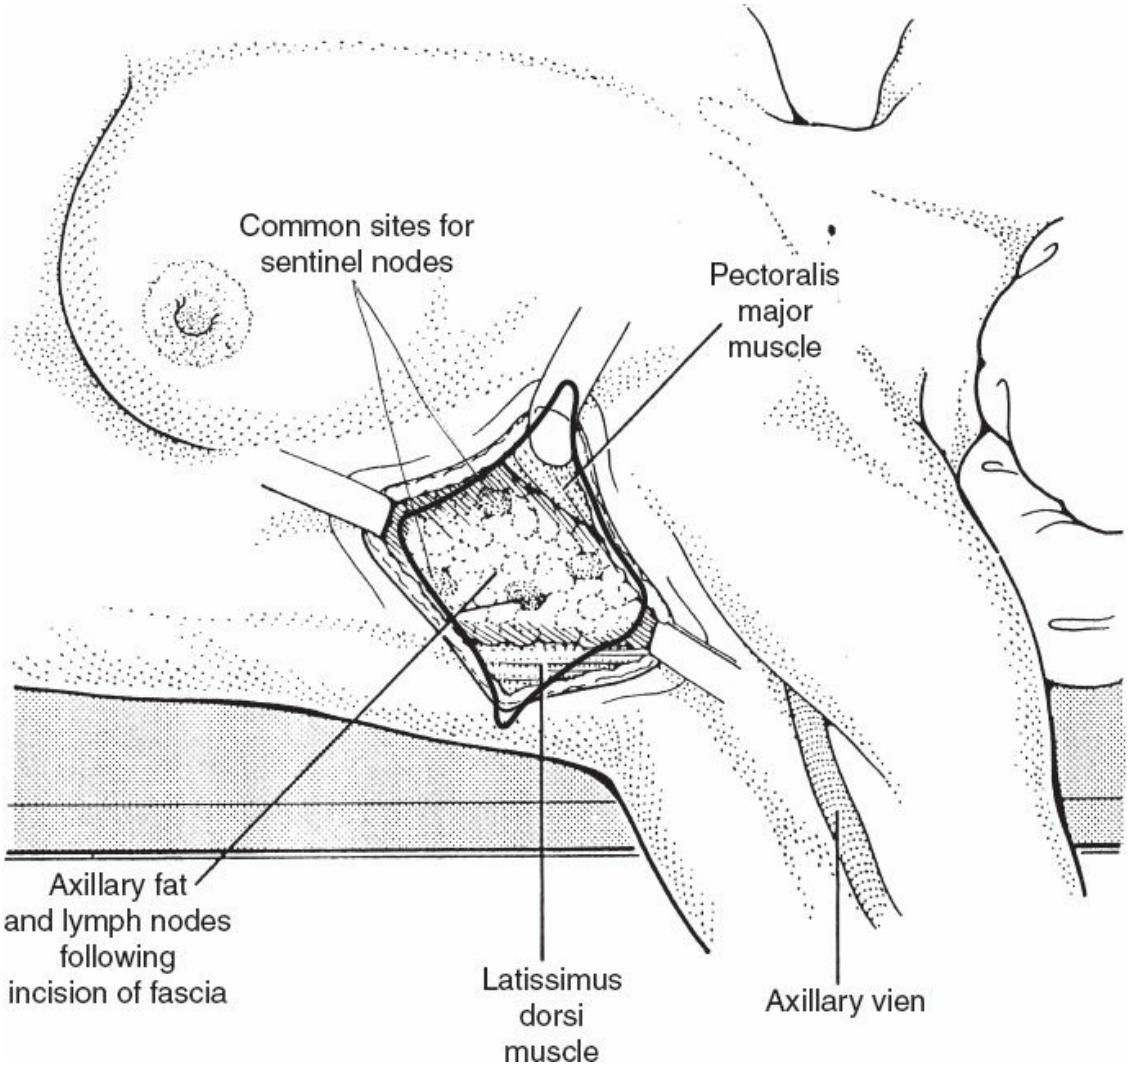

Figure 49.15. Diagram showing lower axilla, where sentinel lymph node(s) is commonly found.

Following a check to ensure that all nodes with residual isotope >10% of the hottest node and all blue nodes have been removed then, the wound is closed in layers with absorbable sutures before infiltration of the axilla with local anesthetic. Some slim women have a large number of nodes containing isotope and/or blue dye. In these patients, I remove only the three or four hottest and bluest nodes; these are usually the closest nodes to the breast. The most widely used method of assessing sentinel lymph nodes is by paraffin-section histology. Studies from the American College of Surgeons and the NSABP have not shown any advantage to staining nodes using immunohistochemistry to detect metastases not evident on routine H&E staining.

Axillary Reverse Mapping (ARM)

The lymphatics of the arm can be mapped with blue dye at the same time as the sentinel nodes are mapped with radioisotope during axillary lymph node dissection. Blue dye is injected into the upper arm and during axillary surgery lymphatics and lymph nodes draining the arm can be identified because they are stained blue and these lymphatics and nodes can be preserved providing there is no evidence that these nodes are clinically involved by metastatic disease or that they contain isotope indicating they are a sentinel node of the breast. Fluorescent dyes are an alternative to blue dye. The success of ARM has not yet been determined in randomized trials, but it seems logical.

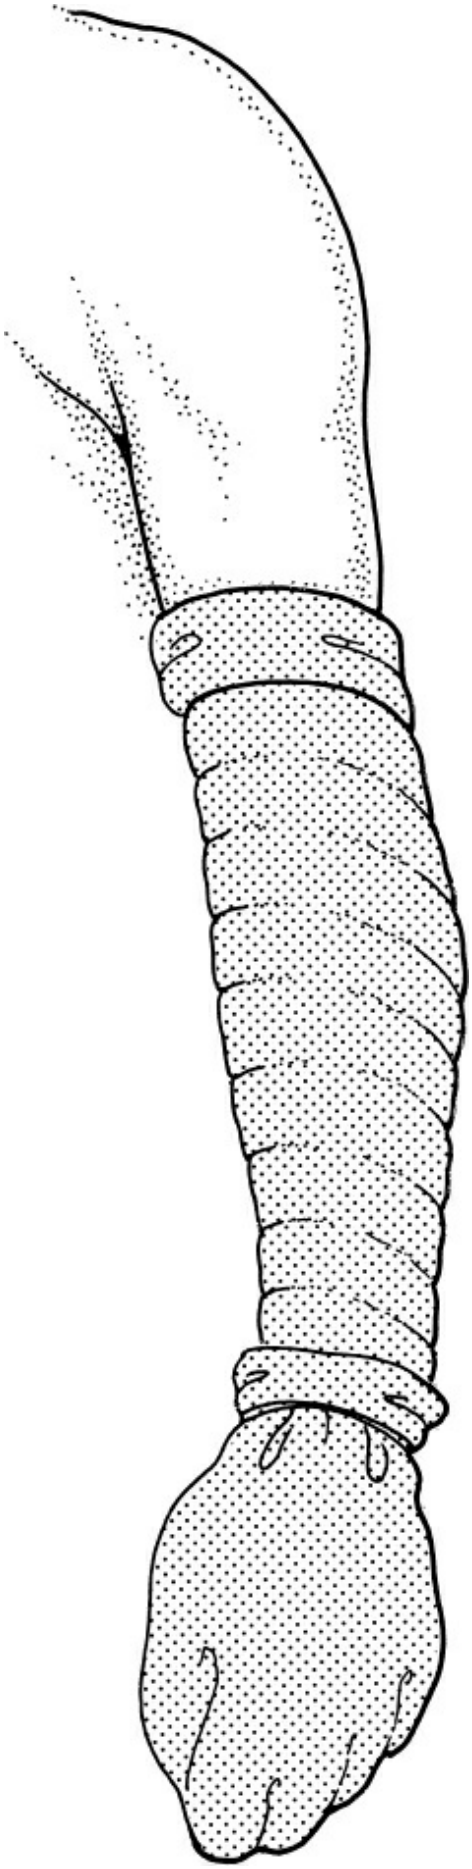
Internal Mammary Node Biopsy

In patients who have a preoperative scintiscan, there is drainage to the internal mammary chain in 6% or more depending on exactly where in the breast and how deep the isotope was injected. There is no consensus as to whether these nodes should be excised if visualized on scintiscan. It is true that a small number of women do have involved internal mammary nodes in the absence of axillary node involvement but the exact percentage remains a topic of discussion. Recent studies of internal mammary node and supraclavicular node irradiation have shown a small survival advantage (82.3% 10-year survival with radiation vs. 80.7% without radiation [$p = 0.056$]), although the rate of skin and lung toxicity was higher with radiation. The role of preoperative scintigraphy and excision of all nodes visualized on the scan is best established for patients having a sentinel node biopsy performed when excising a recurrence, be that after mastectomy or BCS, in patients who have had a prior SLNB.

Technique of Axillary Dissection

Exposure is facilitated by placing a wedge or sandbag under the ipsilateral shoulder so as to elevate the axilla. The ipsilateral arm can be prepared and draped separately, and this allows the arm to be moved above the patient's head during surgery. The skin of the arm up to and above the elbow is prepared, and the lower arm and hand are wrapped in a sterile drape and secured with a stockinette (Fig. 49.16). A skin crease incision just distal to the hair-bearing skin of the axilla is made (Fig. 49.17A). This allows satisfactory exposure in patients with an adequate anteroposterior diameter, but in very small or thin patients, the length of this incision may be inadequate. A lazy S incision is an alternative, placed between the

pectoralis major and latissimus dorsi muscles (Fig. 49.17B). An anterior axillary fold incision can also be used (Fig. 49.17C). The skin incision is deepened through the superficial fascia, and skin flaps are developed deep to the superficial fascia. The axilla is protected by an anterior layer of fascia, and this should be identified. Dissection is anterior to this axillary fascia, and using skin hooks it is possible to elevate superior, medial, and inferior skin flaps in the plane deep to the subcutaneous fat but in front of this axillary fascia fat. Dissection continues with the aid of gentle retraction with a swab. Medially the edge of the latissimus dorsi is identified and laterally the pectoralis major muscle is palpable and dissection should continue to it.



1889

Figure 49.16. Skin of the arm up to and above the elbow is prepared, and the lower arm and hand are wrapped in a sterile drape and secured with a stockinette.

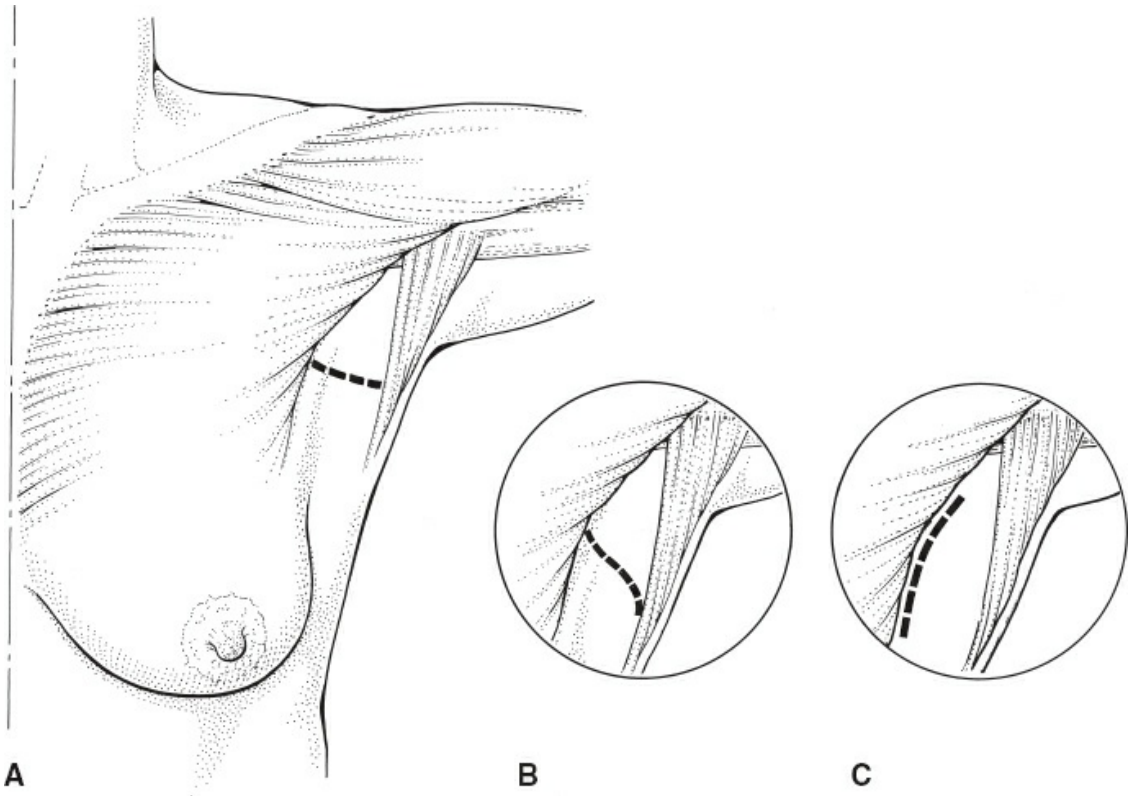


Figure 49.17. Incisions for axillary dissection. **A.** Skin crease incision distal to the hair-bearing skin of the axilla. **B.** Lazy S incision placed between pectoralis major and latissimus dorsi muscles. **C.** Anterior axillary fold incision (*dashed line*) placed parallel and posterior to lateral border of the pectoralis major muscle.

Retractors replace skin hooks, and the lateral edge of the pectoralis major is carefully cleared. Care is taken to identify and preserve the medial pectoral nerve and vessels that pass into the lateral border of the pectoralis minor muscle from the pectoralis major: these innervate both and supply the pectoralis minor and the lower lateral third of the pectoralis major muscle (Fig. 49.18). While retracting the pectoralis major and minor muscles, the elbow can be bent and the arm moved upward behind the patient's head (Fig. 49.19). This makes retraction of the pectoral muscles easier. Care must be taken when the arm is retracted not to overstretch the brachial plexus. With the pectoralis major and minor muscles retracted medially, it is possible to identify the nodes under the pectoralis minor

muscle. Beyond the medial margin of the pectoralis minor muscle and covered by the stretched clavipectoral fascia lies a small conical depression of adipose tissue containing a small number of lymph nodes. The upper limit of this depression is defined by the axillary vein, and the subclavius muscle forms its medial limit. Nodes in this adipose tissue comprise the third axillary level, as described by Berg. There remains conflict as to what comprises an adequate axillary dissection. Some surgeons perform a level I/II dissection, others remove levels I and II, and some remove all nodes to level III routinely. An empirical approach based on the findings at operation seems reasonable. Fewer patients require removal of level III nodes and only where there is obvious involvement of nodes up to level III should they be removed.

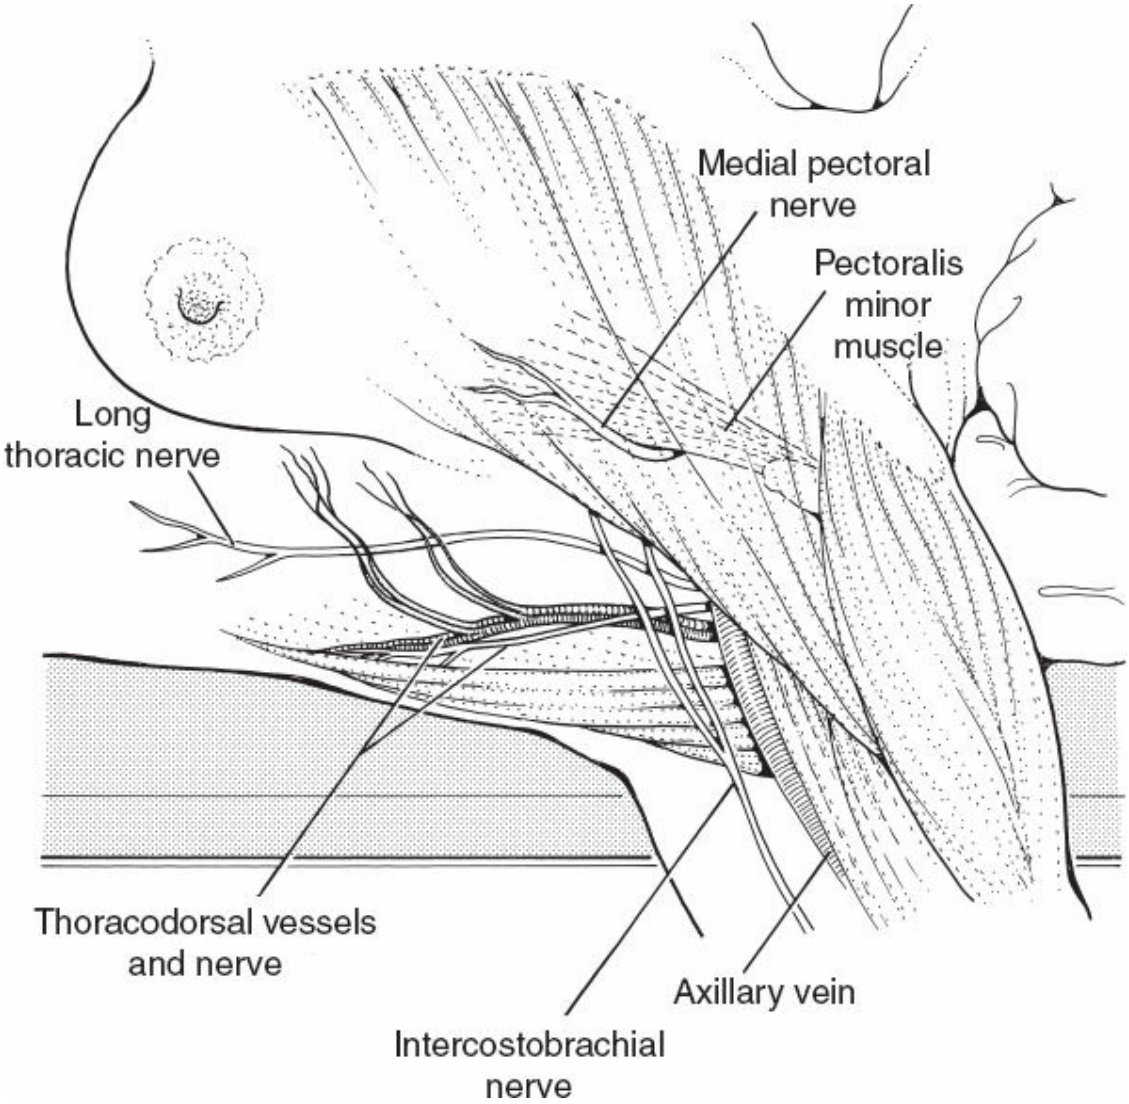

Figure 49.18. Major neurovascular structures to be preserved in an axillary clearance/dissection.

There are two surgical approaches to removing potentially involved nodes at level III, depending on whether the pectoralis minor muscle is spared or divided. This muscle should only be divided if there is extensive node involvement evident at surgery and a more radical dissection is to be performed. If the muscle is to be divided, then the lateral edge of the pectoralis minor is identified and a finger placed around the pectoralis minor as it passes over the axillary vein. The muscle can be traced up to the coracoid process and, with a finger around the pectoralis minor muscle, the tendon is divided from the coracoid process without damaging surrounding structures. Once the muscle has been divided, the pectoral fascia that covers the vein is also divided and swept downward. Care should be taken to divide and ligate the small vessels that drain into the axillary vein at level III as bleeding from these vessels high in the axilla is not easy to stop. If the pectoralis minor muscle is spared, as is now usual practice, the muscle is elevated and retracted. When elevating the muscle, care should be taken not to damage the medial pectoral nerve and vessels. Branches from these vessels pass laterally, and these branches should be divided and clipped or coagulated. The axillary vein, as it passes to the apex of the axilla, can then be dissected free from the adipose tissue containing lymph nodes. Sometimes, the vein is partially covered by fat or lymph nodes are adherent to the adventitia of the vein and it may be necessary to strip away this adventitia.

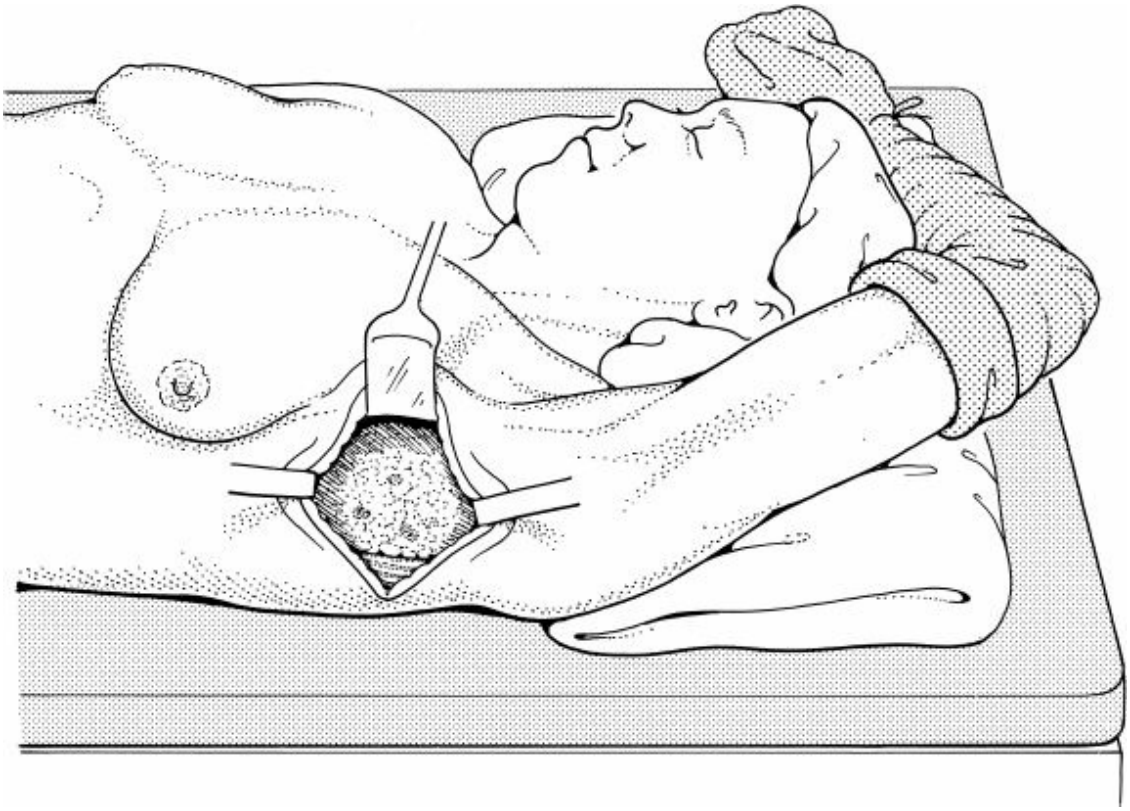

Figure 49.19. The ipsilateral elbow is flexed and the arm is moved over the patient's head to facilitate retraction of pectoral muscles and exposure of the axilla.

Dissection should continue until the vein meets the tendon of subclavius, which marks the medial limit of a level III dissection. In most patients, lymphatic vessels passing beyond the apex of the axilla can be seen, and these should be divided and ligaclipped or coagulated. At the end of this level III dissection, the apex of the axilla should be completely clean. As outlined above, care should be taken to preserve the vessels supplying the pectoralis major muscle (Fig. 49.20). When all the tissue from level III has been removed, the pectoralis major muscle should be lifted with a retractor and the thoracoacromial vessels, which supply the pectoralis major muscle, identified and palpated. Along these vessels lie the interpectoral nodes, and any palpable nodes in this area should be removed by incising the fascia on the undersurface of the pectoralis major muscle, and individual lymph nodes should be dissected out separately. Having removed all the tissue at level III, dissection then continues underneath the pectoralis minor muscle to remove the level II nodes. If level III nodes are not being removed and only level I and II nodes are being removed, then the medial border of the dissection is the medial border of the pectoralis minor muscle. Having cleared the nodes from

under pectoralis minor up to the axillary vein dissection on the medial wall continues inferiorly. This defines the medial margin of the dissection. Dissecting medially the inferior limit is the axillary tail of the breast. The edge of the latissimus dorsi muscle defines the lateral border of dissection. The intercostobrachial nerve traverses the axilla and passes from the chest wall and crosses the lateral edge of the latissimus dorsi muscle and can be damaged if the lateral edge of the latissimus dorsi muscle is dissected with cautery or a knife up to the level of the axillary vein, so the lateral dissection should not be performed until this nerve has been identified.

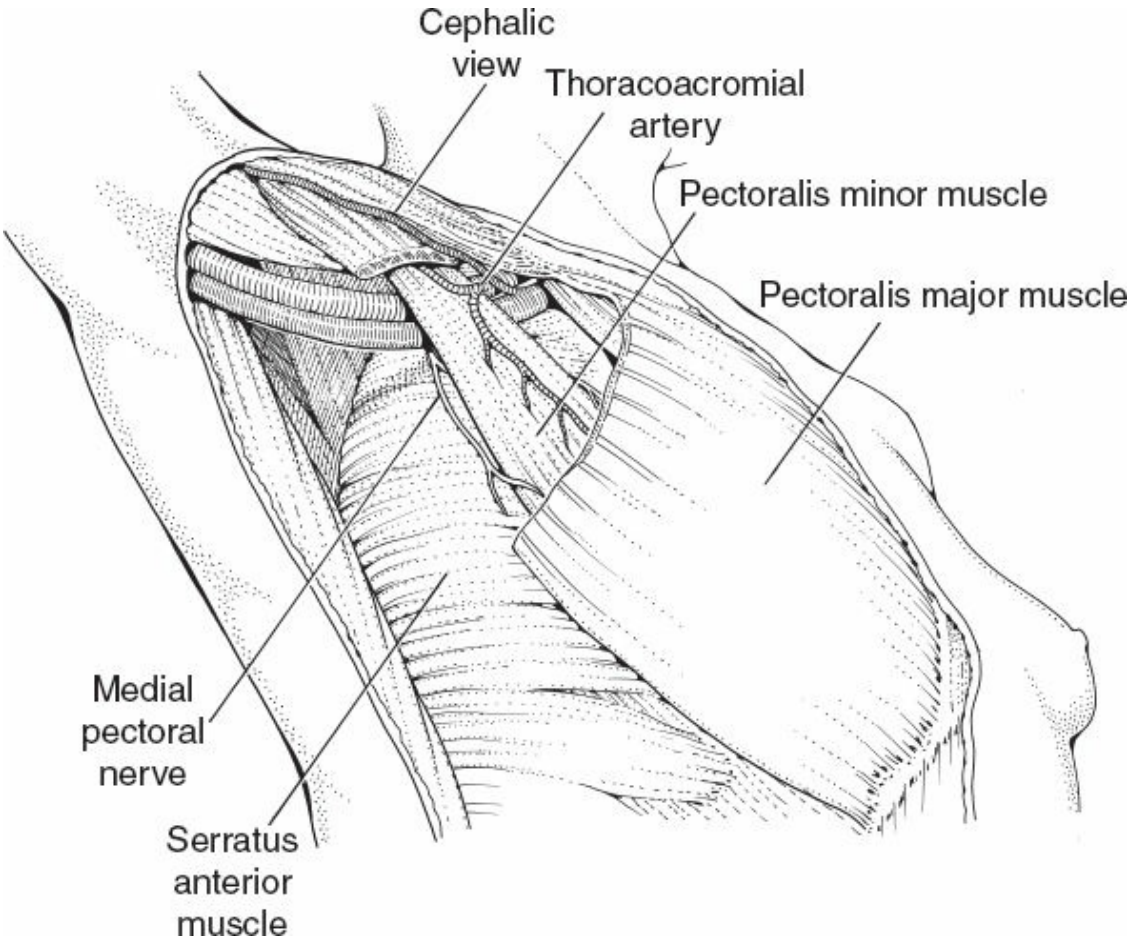

Figure 49.20. Vessels supplying the pectoralis major muscle.

By this point of the operation, the medial border, the inferior border, and the lower half of the lateral border have been defined. The next step is to develop dissection from the pectoralis minor laterally by a combination of sharp and blunt dissection and clear the tissue inferior to the central part of the axillary vein. The lower border of the axillary vein represents the superior limit of the dissection. The tissue below the axillary vein is dissected from the vein all the way to the edge of the latissimus dorsi

muscle. Veins that drain into the axillary vein on its anterior surface are divided between ties and ligaclips. The fat and lymph nodes are teased away by blunt dissection, and the intercostobrachial nerve is identified as it leaves the chest wall medially. This is usually in the second intercostal space but can be in the first. Dissecting out the whole of this nerve as it courses across the axilla can be tedious, but it is worthwhile as it avoids the annoying numbness and occasional pain or hyperesthesia that affects the skin of the upper inner arm when this nerve has been divided.

The anatomy of the intercostobrachial nerve is variable. Although there is usually one major intercostobrachial nerve that comes out of the chest wall, it divides laterally into a number of branches. Some of these branches pass into the axillary tail of the breast and can be sacrificed. Once this nerve is identified passing across the axilla and dissected from surrounding structures, it can be retracted superiorly. The next step is to identify and preserve the long thoracic nerve. This nerve can be identified by retracting the axillary contents laterally, although the long thoracic nerve has a tendency to be pulled out laterally with the axillary contents. It is situated approximately 2 cm posterior to the intercostobrachial nerve. Blunt dissection in the valley between the serratus anterior muscle and the axillary contents usually identifies this nerve. Once it has been identified, it is freed and pushed medially toward the chest wall and preserved. Certain identification and protection of this nerve is one of the most important principles in this operation. Vessels run with the nerve, and these should not be damaged as this can interfere with nerve function.

Dissection along the lower border of the axillary vein continues in a deeper plane in a medial-to-lateral direction. The next structures to be identified are the thoracodorsal nerve and vessels. The thoracodorsal vessels are situated posteriorly about two thirds of the way across the axilla from medial to lateral. The vein is often the first structure to be identified as it drains into the posterior aspect of the axillary vein; the nerve is the most medial structure of this neurovascular bundle. Having identified and protected the thoracodorsal vessels, the valley on the subscapularis muscle between the long thoracic and thoracodorsal nerves is cleaned with a cranial-to-caudad dissection. As fat, lymphatic vessels, and blood vessels pass underneath the axillary vein, these structures are divided and ligated or cauterized. Dissection then continues inferiorly, and branches passing from the thoracodorsal vessels into the axillary fat are identified; these vessels can cause troublesome bleeding, so they should be

identified and ligated or ligaclipped ensuring that the main vessels are not narrowed. Dissection continues laterally, removing tissue lateral to and around the thoracodorsal vessels to the lateral margin of the latissimus dorsi muscle. This allows completion of the lateral part of the operation. Care should be taken not to stray beyond the latissimus dorsi. Nodes at the top of the arm should be preserved to reduce the chances of lymphedema. If the arm lymphatics and lymph nodes have been mapped with blue dye, then care should be taken during dissection to preserve lymphatics and lymph nodes stained blue, ensuring that at the same time all pathologic nodes are removed.

The valley between the thoracodorsal vessels and the long thoracic nerve is cleared, taking care not to damage any branches from the thoracodorsal vessels that pass across to the serratus anterior muscle as damage results in troublesome bleeding. The thoracodorsal vessels and the long thoracic nerves remain in the axilla, while the axillary nodes and fat are retracted anteriorly. The inferior margin of the dissection is completed by dividing the axillary tail of the breast under direct vision. Any vessels passing into the tail of the breast should be cauterized or ligated. A single suction drain can be placed into the cavity and brought out through a separate stab incision. If possible, the skin flaps are sutured to the chest wall as results from small trials of axillary quilting have shown that this decreases the subsequent seroma rate. Finally, the wound is closed in layers with absorbable sutures before infiltration with local anesthetic.

POSTOPERATIVE COMPLICATIONS

Axillary Surgery

Complications of SLNB and axillary node sampling include bleeding, hematoma, and wound infection. Seroma formation requiring aspiration develops in 5% to 10% of patients after sentinel node biopsy. Lymphedema was reported after SNLB in 8% in NSABP B-32. Damage to the intercostobrachial nerve is rare after SLNB (0% at 6 months in the UK ALMANAC study with SLNB compared with 48% after axillary lymph node dissection). With careful attention to technique therefore, damage to the nerve can usually be avoided in SLNB.

Complications of axillary dissection/clearance include those mentioned for SLNB. Seroma formation is more of a problem with axillary clearance. Factors known to be related to increased or prolonged drainage include obesity, involved axillary nodes, a recent breast biopsy, and an extensive

axillary dissection. The results of studies investigating the effects of early shoulder mobilization are confusing. There is early evidence that there is less seroma formation in patients who do not perform early shoulder exercises after surgery and patients who have prolonged high-volume drainage generally have been more active in their shoulder movement. Early shoulder exercises, however, protect against frozen shoulder, which can develop as a consequence of decreased shoulder movement following axillary surgery. I encourage early shoulder mobility as I believe frozen shoulder is a worse problem than seroma. Patients who develop shoulder problems should be seen urgently by the physical therapist. Some patients after axillary surgery are said to develop scapulothoracic bursitis. Studies have shown improvement with local anesthetic and steroid injections. Despite looking for this, I have not found this problem in a significant number of patients.

Lymphedema develops in up to 40% of patients who undergo axillary dissection, and can develop many years after axillary clearance. In AMAROS, lymphedema rates were twice as common after axillary dissection than after axillary radiotherapy. At 5 years, observed or treated lymphedema was present in 28% of the axillary dissection group versus 13.6% after SLNB and radiotherapy. Lymphedema can occur following infection in the soft tissues of the ipsilateral arm. Infections in treated arms are usually caused by Gram-positive cocci and require prompt treatment. No adequate remedy exists for chronic lymphedema. Paresthesiae of the upper, inner arm from division of the intercostobrachial nerve is present in at least half of patients having axillary lymph node dissection and produces annoying symptoms. If neuroma formation develops, this can result in acutely painful areas that are difficult to manage. Sparing of this nerve, although tedious, is worthwhile. Damage to the thoracodorsal nerve resulting in atrophy of the latissimus dorsi muscle may cause problems if this muscle is to be used later for breast reconstruction, but otherwise has little or no functional consequence. The most significant injury is that to the long thoracic nerve, which, if damaged, results in a winged scapula. This results in a functional deficit and a cosmetic deformity.

POSTOPERATIVE MANAGEMENT FOLLOWING BREAST-CONSERVING SURGERY OR AXILLARY SURGERY

If the patient is feeling well and is mobile after BCS, she can be

discharged home on the same day. For patients having an axillary clearance, they may need education on drain management. Some units keep some mastectomy patients and those having an axillary clearance in overnight. A community nurse can visit the patient daily to record 24-hourly output from the drain and to check the wound. One option is to remove the drain at a fixed time after surgery, regardless of volume, as studies have shown that the rate of infection increases if drains are left in longer than 1 week. Some surgeons do not use drains. Patients should see a physical therapist and be given shoulder exercises to carry out several times a day. A surgical follow-up visit is organized for 1 to 2 weeks after operation, when the wounds are checked and the histologic evaluation report is available. Seromas may occur particularly if a significant defect has been left in the breast and are common after mastectomy or extensive axillary surgery. Aspiration is usually not painful and is performed using a needle attached to a nonreturn valve and a syringe. Repeat aspirations may be necessary until there is no more fluid accumulation. Persistent seromas can occur particularly in patients who have had extensive surgery. Recurrent seromas can be treated by aspiration to dryness and instilling 10 to 40 mg of triamcinolone acetonide (Kenalog).

FOLLOW-UP

Regular clinical examination after BCS or mastectomy has not been shown to be of value. Patients should be seen for 1 to 2 years to check the wound has healed and the cosmetic result is acceptable. Defects at the site of wide excision can be improved with lipofilling or lipomodelling. There is evidence that annual mammography is cost-effective and worthwhile. Regular MRI screening in younger women and women whose cancer was not visible on mammography also appears cost-effective.

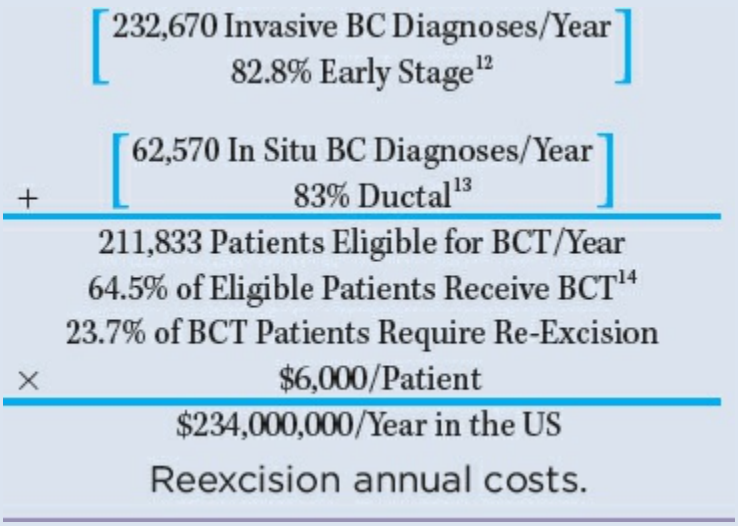
EDITOR'S COMMENT

The current standard of care is to offer breast conservation therapy (BCT) to patients with early-stage disease. BCT includes excision of the tumor with a rim of normal tissue (i.e., lumpectomy) and adjuvant treatments including radiation therapy, most commonly whole breast radiation therapy (WBXRT), to treat residual disease. BCT offers equivalent survival to mastectomy (removal of the whole breast) with similar local recurrence rates. Furthermore, BCT is less invasive and has favorable cosmetic and psychological outcomes compared to mastectomy.

However, BCT has limitations. Approximately 24% of BCT patients undergo at least one additional surgery due to inadequate negative margins on the initial lumpectomy (83.2% of these additional surgeries are mastectomies) at a total cost of $234 million per year to the US healthcare system. In addition, BCT patients undergo 25 to 30 adjuvant WBXRT sessions over 6 to 7 weeks, introducing adverse effects, high costs, and inconvenience. The Canadians have championed a hypofractionated regimen that completes the radiation in 3 weeks. With WBXRT patients may experience burns, breast shrinkage, pneumonitis/pulmonary fibrosis, edema, secondary solid cancers, and ischemic heart disease. Patients also often endure lengthy travel and significant expenses ($13,000 to $47,000) to access WBXRT facilities, leading many that may prefer breast conservation to elect mastectomy. Unfortunately, 36% of women who elect mastectomy are actually eligible for BCT.



Because of the challenges of WBXRT, 14% to 26% of BCT patients skip WBXRT entirely. Patients refusing completion radiation lead to trials testing whether older patients (>70 years old) with favorable tumors received significant benefit from radiation. While the initial results looked favorable, the most recent follow-up of the CALGB (Cancer and Leukemia Group B) 9343 demonstrated that at 10 years that 98% of patients receiving tamoxifen plus WBXRT were free from local and regional recurrence compared to only 90% of those receiving tamoxifen alone. Survival was equivalent. This is tempered, however, with the fact that the Early Breast Cancer Trialist Group that reviewed data from over 42,000 women from 78 randomized studies demonstrated that at 15-year follow-up, for every four recurrences there was an associated increase of one death that could be avoided.

Issues surrounding WBXRT have led to the development of several alternative partial breast irradiation (APBI) technologies that are able to deliver biologically equivalent doses of radiation twice daily for 5 days to the approximate 1-cm region around the lumpectomy site where up to 90% of recurrences occur. These technologies can be divided into applicator-based brachytherapy devices and external-beam XRT. In addition, single-dose intraoperative radiation has become a viable option, although the cost of running such a program is untenable for many centers. All of these techniques will make BCT much more attractive. These will be reviewed in the Chapter 50.

It is my feeling that incorporating intraoperative ultrasound (US) techniques will allow even more patients to be eligible for BCT with increasingly better cosmetic results. The fully developed technique of US-guided excision has evolved and been developed over time by multiple researchers. Breast ultrasonography is performed intraoperatively using a 15 MHz linear array transducer while the arm is abducted. After sterile preparation, the abnormality is localized in the standard two planes, longitudinal and transverse. After the incision is made, the transducer was placed inside the incision and the lesion is again visualized. Dissection is performed using a “line-of-sight” technique. This technique was adapted from and mimics the use of the gamma probe in sentinel lymph node surgery. The transducer is then placed perpendicular to the lesion and parallel to the chest wall to assess the adequacy of the deep margin. Tissue is excised around the lesion in a block fashion down to the ascertained depth. Ex vivo ultrasonography is performed on the specimen to confirm adequacy of margins. Margins felt to be inadequate on specimen ultrasonography are reexcised at the time of the initial surgery. The remaining cavity is reassessed for residual disease both by palpation and ultrasonography. Recent studies show that if the margins from the main mass are greater than 1 cm, then 90% of excisions are successful. Advantages touted for intraoperative US include immediate documentation of removal of the suspect lesion, no additional discomfort to the patients, and no need for preoperative localization. It allows the entire procedure to be performed in the operating room, does not require radiation, and can be used to immediately assess margin status. With the use of

intraoperative US, the incision at the time of surgery is always closer to the lesion and the cosmetic results may be improved. Disadvantages include the equipment and additional required expertise on the part of the surgeon. As Dr. Dixon comments, in most series, positive margins were attributed to ductal carcinoma in situ (DCIS). DCIS is not commonly visualized by US. A specimen mammogram should be performed in addition to US in all lesions especially those with microcalcifications or spiculations that go beyond as well as to confirm clip removal. Use of intraoperative stand-alone surgical specimen radiography systems is now available in the operating room that have much improved visualization of specimen calcifications and can help direct reexcision. Most importantly, the specimen should be marked by the surgeon with pathological ink. Marking with sutures or clips is just not adequate. As most breast specimens don't hold their shape, the surgeon should immediately mark all sides for the most reliable pathology assessment.

Intraoperative US can also be used in localizing and guiding the excision of post-core or stereotactic biopsies viz a viz the hematoma-filled biopsy cavities. Needle-localization has been the most widely used tool available for excising lesions that require further evaluation after performing stereotactic core needle biopsy (SCNB). However, now there are a variety of methods that have been developed that can assist in removing nonpalpable lesions. All but one requires a second localization procedure to place a clip that can be visualized by ultrasound or that is radio-opaque. Traumatic hematomas after SCNB can be seen by US most of the time and utilized to locate the lesion, thus making the stereotactic procedure not only a diagnostic procedure but a localizing procedure as well. This has been deemed the HUG procedure (Hematoma-directed US-guided).

Oncoplastic techniques have become more widely used as surgeons are taken bigger margins and submitting shaved margins and certainly have allowed more patients to undergo BCT. These techniques range from the very simple such as using a parallelogram to improve simple excisions to those that incorporate reduction mammoplasties. Most oncoplastic surgeries can be performed by all surgeons without specific plastic surgery training. Cadaver courses are now actively training surgeons on how to incorporate more advanced procedures into their practice. These procedures are needed when excising excess skin and reshaping the breast.

Finally, I would like to comment on the addition of axillary reverse mapping (ARM) to lymphadenectomy whether it be sentinel lymph node biopsy (SLNB) or axillary lymph node dissection (ALND). As we developed this technique, we hypothesized that mapping the lymphatic drainage of the arm with blue dye (ARM) during axillary lymphadenectomy decreases the likelihood of disruption of lymphatics and subsequent lymphedema. The technique uses lymphazurin in the upper inner volar surface of the index arm at the time of surgery. Using ARM, we have identified significant lymphatic variations draining the upper extremities and have used ARM to facilitate preservation. Metastases in ARM-

identified lymph nodes were acceptably low indicating that ARM is safe. We also found in our single-institution trial that we could lower lymphedema rates with SLNB from 8% to less than 1.7%. During ALND, we could lower rates from 23% to 2.4%% in our most recent 18-month median follow-up. Although slightly more tedious and time-consuming, ARM can be safely accomplished and affords the patient the reduced risk of lymphedema. To date we have seen only one axillary recurrence in our single institution prospective trial of breast cancer patients giving credence that ARM adding to lymphadenectomy is a safe staging and therapeutic procedure.

50 Radiation Treatment, Whole and Partial Breast and Intraoperative Irradiation

Julia White

OVERVIEW AND HISTORICAL PERSPECTIVE

Of the nearly 260,000 breast cancers diagnosed within the next year, more than half will be considered eligible for breast-conserving therapy and the majority of these will receive radiation. Numerous phase III randomized clinical trials with over 25 years of outcome data have established that overall survival is equivalent for women treated with breast conservation compared to mastectomy. Over the past three decades, there has been extensive clinical research focused on improving the results of breast conservation that included defining the ideal suitable patient population, proper surgical resection margins, best systemic therapy, and optimal use of radiation. Advancements in surgical and radiation methods as well as more effective systemic therapy agents have now resulted in a gradual decline in local regional recurrence rates. Large registry-based analyses that have used propensity risk-based analysis to minimize bias now reflect that breast-conserving therapy delivered in a more modern era may even have improved cancer outcomes compared to mastectomy. This is good news for women with breast cancer who otherwise are good candidates for breast-conserving therapy but are considering mastectomy for "peace of mind" about their cancer control.

For invasive cancer, roughly 70% receive breast radiation following lumpectomy and somewhat less for those who have a ductal carcinoma in situ (DCIS) diagnosis. Radiation to the entire breast using 25 to 28 fractions (or treatments) of 1.8 to 2 Gray (Gy) of radiation to a total dose of 45 to 50.4 Gy was the conventional standard for decades (see Table 50.1 for common radiation terms). Often, a "boost" or additional dose of radiation is focused just on the breast tissue in the vicinity of the surgical cavity anticipated to be at a higher risk of recurrence. The boost delivers 5 to 8 fractions of 2 Gy to a total dose of 10 to 16 Gy so that this region

receives a cumulative total dose of 60 to 66 Gy over 30 to 33 fractions. This is the method of breast radiation used in the landmark clinical trials that established breast conservation therapy in invasive disease and DCIS. The other hallmark of conventional whole breast radiotherapy is that treatment planning was two-dimensional (2D), based on a single axial plane representing the patient external breast contour at about the longitudinal mid-plane of the treatment field that was established with fluoroscopy. This conventional approach to breast radiation has decades of documented efficacy and was technically simple so that all levels of radiation centers could become equally competent in its delivery.

Conventional whole breast radiation therapy also has known limitations. The protracted treatment time is one of the major drawbacks. Radiotherapy is delivered Monday through Friday, 5 days a week so that the 30 to 33 fractions for whole breast treatment require 6 to 7 weeks. Not long after breast conservation became validated as an effective treatment it was noted that its adoption into clinical practice varied widely across the United States and abroad; in part because of communities where women lived a far distance from a radiotherapy facility. A recent analysis of the National Cancer Database (NCDB) from 1998 to 2011 confirms this barrier persists as utilization for breast conservation was higher for woman residing within a 27.8 km vicinity of a treatment facility. Conventional whole breast radiotherapy also resulted in significant toxicity in some patient populations. In particular, women with large body mass index or pendulous breasts had higher rates of poor cosmetic results due to excess breast scarring or fibrosis attributed to dose heterogeneity. Finally, conventional breast radiation provided only an approximated means of assessing the extent of radiation delivered to the ipsilateral lung or heart.

TABLE 50.1 Commonly Used Terms in Radiation Therapy for Breast Cancer

Radiation Term	Definition
LINAC	Linear Accelerator delivers external beam radiation
CT Simulation	Establishes treatment position and acquires CT images for planning
Verification Simulation	Confirms that the virtually designed radiation plan is clinically reproducible
CTV	Clinical Target Volume: tissue at risk for cancer recurrence
PTV	Planning Target Volume: margin around the CTV for setup variation
OAR	Organ at risk for radiation toxicity
Gy, cGy	1 Gray = 100 centiGray: units of radiation dose
MV	MegaVoltage or million volt photon beam
kV	KiloVoltage or thousand volt photon beam
MeV	Megaelectronvoltage or million volt electron beam
Fraction	One radiation treatment
DVA	Dose Volume Analysis: quantifies dose distribution to organs

The desire to reduce the burden and toxicity of treatment led to investigating alternatives to conventional whole breast radiation delivered over several weeks for breast conservation. As a result, there are now multiple effective options for breast radiation. This progress is due in large part to scientific advances in technology and radiobiology that occurred over the same time period that the biologic heterogeneity of breast cancer became better appreciated and its impact on cancer recurrence established. It is clear that while there are now multiple methods of breast radiation available for post lumpectomy treatment, the specific method to be used depends on the type and stage of breast cancer as well as the needs of the individual patient.

WHOLE BREAST IRRADIATION

Radiation of the whole breast remains the most common treatment method for breast conservation. However, conventional whole breast radiation has been modified significantly over the past decade through a series of clinical trials demonstrating that (1) computed tomography (CT)-based three-dimensional conformal radiation (3DCRT) or intensity modulated radiation therapy (IMRT) planning reduces toxicity, and (2) the use of moderate hypofractionation— meaning, 260 to 270 cGy per fraction—is safe and effective so that the overall treatment duration can be reduced to 3 to 4.5 weeks.

The introduction of CT dramatically changed the approach to radiation therapy. The American College of Radiology documented through a series

of surveys that CT simulation for whole breast radiotherapy planning was about 5% in 1994, 17% in 1999, and jumped to >90% by 2007. The use of CT for treatment planning individualizes the radiation to each patient. Once the CT of a patient in treatment position is acquired, it is loaded into a software program for modeling the radiation treatment. The breast to be targeted and organs at risk (OAR) of injury from radiation, such as the lung and heart, are delineated onto each axial (cross-sectional) CT image (Fig. 50.1). These can then be used to create reconstructed three-dimensional volumes. The optimal radiation beam direction and energy are selected, and the treatment field is shaped to conform to the breast target volumes and to provide shielding of OAR. Radiation plans are approved for patient treatment using a set of standardized quantifiable measures of target dose coverage (typically aim for 95% of the dose to cover 95% of the target), dose homogeneity (keep "hot spots" <108% to 110%), and that the minimal constraint dose to the smallest volume of the OAR was met with a Dose Volume Analysis (DVA). Prior to starting treatment, a verification simulation is performed on the linear accelerator (LINAC) confirming that the computer model is reproducible. Radiation treatment is delivered with a LINAC typically using 6 to 15 megavoltage (MV) photon beams. For daily treatment, patients are on the treatment table ~15 to 20 minutes and the beam on-time for the radiation treatment is on average 6 to 8 minutes. Using modern methods, 10-year local recurrence rates for lumpectomy and breast radiation range from 4% to 7% and grade 3 toxicity rates are <2% to 3%.

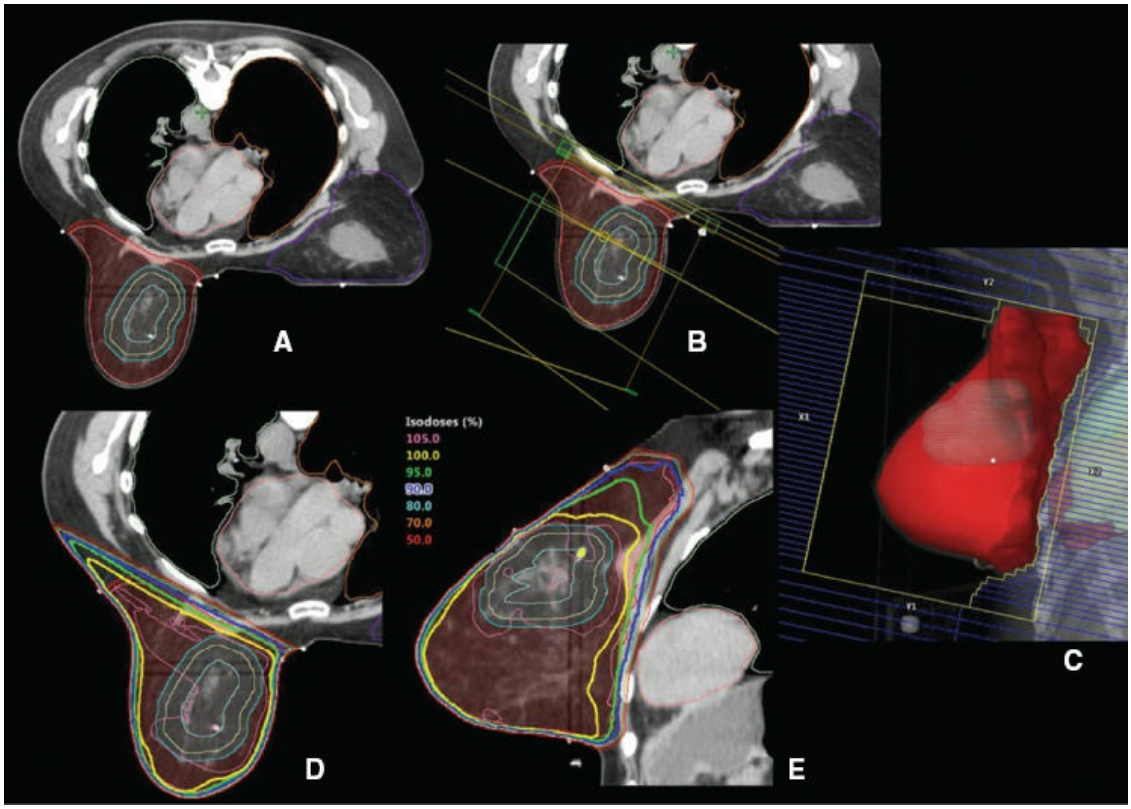

Figure 50.1. Steps in CT-based treatment planning for a left breast in the prone position. **A.** Targets and OAR are delineated after CT images are acquired at Simulation in the treatment position. **B.** Optimal beam arrangement is established. **C.** Treatment fields conform to targets and exclude OAR. **D.** Dose distribution in the axial. **E.** The sagittal reconstructions. A DVA will be reviewed and approved prior to Verification Simulation.

Several clinical trials have demonstrated reduced acute skin toxicity, less palpable firmness or fibrosis in the breast, and improved cosmetic outcomes when whole breast radiotherapy is delivered with CT-based 3DCRT or IMRT planning versus the simplified 2D approach. Despite the improved toxicity outcomes from integration of advanced treatment planning technology, large breast size has remained at relatively more risk for toxicity. One solution for this population is to treat in the prone position. In the prone position, gravity elongates and narrows the breast creating a more regular shape that has improved radiation dose homogeneity with fewer “hot spots” compared to the conical shape the breast takes in the supine position. In a clinical trial at the University of Ghent, Belgium, women with a C-cup bra or larger randomized to receive post lumpectomy breast radiation with IMRT in the prone position had significantly reduced desquamation, dermatitis, edema, and pain during

radiation, and a better cosmetic outcome was observed at 2 years.

Conventional fractionation for whole breast radiotherapy using 1.8 to 2 Gy per fraction for 25 to 28 treatments was based on the radiobiologic assumption that breast cancer is less sensitive to changes in the dose per fraction than the adjacent dose-limiting normal tissues. Therefore, delivery of a small dose per fraction such as 2 Gy or less to a higher total dose over several weeks was intended to spare the healthy tissues while effectively treating the breast cancer. On reevaluation, adenocarcinomas such as breast cancer appeared much more sensitive to changes in radiotherapy dose per fraction providing the opportunity to define a new larger fraction size that could preserve or improve cancer control, still minimize late toxicity, and shorten the treatment course. Three randomized trials have confirmed this shift in radiobiology to larger fewer fractions (hypofractionation) for whole breast radiation: the United Kingdom (UK) Standardization of Breast Radiotherapy (START) A (n = 2,236) and B (n = 2,215) trials, and the Ontario Clinical Oncology Group (OCOG) (n = 1,234) trial. Each of these trials demonstrated equivalent local regional cancer control and toxicity at 10 years from whole breast radiotherapy delivered with the shorter treatment course using moderate hypofractionation versus the conventional fractionation over several weeks. With adoption of hypofractionation, the treatment course for whole breast radiation becomes ~3 instead of 5 weeks. A sequential radiotherapy boost to the surgical cavity region still uses the conventional 2 Gy per fraction for 5 to 8 fractions to 10 to 16 Gy, but nevertheless the entire treatment course is reduced to 4.5 weeks instead of 6 to 7 weeks.

Indications and Recommendations

Whole breast radiotherapy is indicated for breast conservation in all cases of invasive disease or DCIS post lumpectomy. It is the treatment of choice in the following populations of breast cancer patients who have undergone lumpectomy: (1) triple-negative and HER2-positive breast cancer subtypes, (2) young premenopausal women (age <40) with invasive cancer or DCIS, (3) positive axillary lymph nodes from sentinel node biopsy or axillary dissection, or (4) those who received neoadjuvant chemotherapy prior to surgery. Standard treatment planning for whole breast radiotherapy should be based on CT scans using 3DCRT or IMRT and the dose distribution to contoured target and OAR volumes should be assessed with DVA. Hypofractionated whole breast radiotherapy post lumpectomy using

either 16 fractions of 2.66 Gy to a total dose of 42.56 Gy (OCOG) or 15 fractions of 2.67 Gy to a total dose of 40.05 Gy (START B) is indicated for most patients with node-negative invasive breast cancer. Increasingly, DCIS patients post lumpectomy are treated with hypofractionated whole breast radiation given the supporting radiobiologic and clinical outcome data for invasive disease. Young premenopausal patients ≤40 years of age comprised only 5% of the START A and B population and were not reported separately in the OCOG Trial. While deductively these women should be acceptable for hypofractionated radiotherapy, it is reasonable to treat them with conventional fractionation as well until more data are reported in this age group. So far, the protracted conventional fractionation (23 to 25 fractions of 2 Gy to a total dose of 46 to 50 Gy) for whole breast radiotherapy remains indicated for when the regional nodes (axilla, supraclavicular, and internal mammary) are simultaneously irradiated.

Many women receiving whole breast radiation post lumpectomy have indications for a “boost” or an additional few radiation treatments focused on a 1 to 2 cm expansions of breast tissue around the surgical cavity. The European Organization for Research and Treatment of Cancer (EORTC) Boost trial that enrolled 5,569 women reported that at 20 years after treatment those who were randomized to receive a boost had a 4% absolute improvement in cancer control in the breast and were less likely to undergo subsequent mastectomy by a similar percentage. The improvement in local control derived by a boost dose was largest in younger patients, or specifically in those ≤50 years of age where the boosted cases had 6% to 9% improvement in local control. The use of a boost resulted in a higher cumulative incidence of severe fibrosis at 20 years, 1.8% in the no boost group versus 5.2% in the boost group ($p < 0{\cdot}0001$). Typically, the boost portion of treatment is delivered with external beam radiation using either photons or electrons. Electrons are less penetrating than photons and are a good choice for when the lumpectomy cavity is in a more superficial location or within 3 to 4 cm from the skin surface. One of the challenges that arise is the identification of the surgical cavity if there is no seroma or other persistent postoperative changes present on CT treatment planning. The ability to target the boost is improved when surgeons mark the cavity with clips. Other radiation methods that have been successfully used to deliver the boost include brachytherapy, which is treatment with radioactive sources inserted into temporary implants or devices located in the breast, and intraoperative

radiotherapy (IORT), which is a single radiation fraction delivered in the operating room once the tumor has been removed and prior to surgical closure.

PARTIAL BREAST IRRADIATION

Rationale and Background

Shortly after breast conservation therapy was adopted, clinical patterns of failure emerged documenting that cancer recurrences in the breast after treatment were found in the vicinity of the original primary in roughly 75% to 90% of cases. This supported that recurrence risk is not constant across the entire breast post lumpectomy and that the breast tissue immediately adjacent to the surgical cavity is at the highest risk for cancer recurrence. This concept has had two important implications on radiation practice. First, this recurrence pattern serves as the scientific rationale for why a “boost” dose to the surgical cavity after whole breast radiation can improve local control. Second, it suggests that the major effect of post lumpectomy breast radiotherapy for many cases may really be from treating the high-risk breast tissue adjacent to the surgical cavity with much less gained from irradiating the remainder of the breast at lower risk. This is the underlying principle of partial breast irradiation (PBI) which delivers radiation solely to the high-risk breast tissue around the surgical cavity instead of the entire breast.

The first prospective trials evaluating PBI as the sole radiation method post lumpectomy yielded disappointing results with 19% to 37% 5-year local recurrence rates. On closer examination, the patients enrolled in these initial PBI trials had many adverse clinical pathologic features, including positive surgical margins, large tumors, positive nodes, and no systemic therapy. With more careful patient selection, the next generation of prospective trials studying brachytherapy for PBI yielded acceptable local recurrence rates of 5% at 10 years in 199 women treated at William Beaumont hospital and 2% at 7 years in 51 women treated at Oschner Clinic. Over the next decade, robust clinical investigation ensued and two approaches to PBI have been established: (1) accelerated partial breast irradiation (APBI) is delivered after lumpectomy when the final pathology is known, typically using 5 to 10 fractions of 3.4 to 6 Gy given once or twice a day over 5 to 10 elapsed days and (2) intraoperative partial breast irradiation (IPBI) delivers a single fraction of 18 to 21 Gy during surgery once the tumor has been removed and prior to surgical closure. Multiple

methods of APBI and IPBI have been developed, and each has advantages and disadvantages that are important to understand so that their use appropriately achieves acceptable outcome from breast conservation therapy.

ACCELERATED PARTIAL BREAST IRRADIATION

There are multiple methods for APBI post lumpectomy using either brachytherapy or external beam radiation that have been well-studied and are currently in clinical practice. Brachytherapy for APBI means the temporary insertion of either multiple narrow hollow catheters (multicatheter implant) around the surgical cavity or a device (single entry) into the surgical cavity (Fig. 50.2). Radiation is delivered internally by "after loading" the brachytherapy catheters or device with a radioactive source, typically Iridium 192. Initially, APBI with brachytherapy was with low dose rate (LDR) radiation using radioactive ribbons that were left in place in an implant for a few days to deliver a dose of 45 to 50 Gy at 0.5 Gy/hour while the patient remained in the hospital. This method has been replaced with the use of a high dose rate (HDR) radiation using single radioactive source that measures about 3 × 1 mm that robotically enters the implant or device and dwells for a matter of minutes to deliver the prescribed dose and can be delivered as an outpatient. The dose prescribed is commonly 10 fractions of 3.4 Gy HDR radiation given two times per day to deliver APBI as an outpatient. Prior to initiating treatment, CT-based treatment planning with DVA is done for brachytherapy to confirm dose distribution to targets and avoidance of OAR. The brachytherapy implant or device is removed after APBI is completed. External beam methods for APBI were developed after brachytherapy methods and are dominated by 3DCRT or IMRT. The steps for treatment planning of external beam APBI are similar to those outlined above for whole breast irradiation. There are multiple other external beam methods for APBI that are under investigation, including the use of protons, gamma rays, and stereotactic body radiotherapy for which mature data are pending.

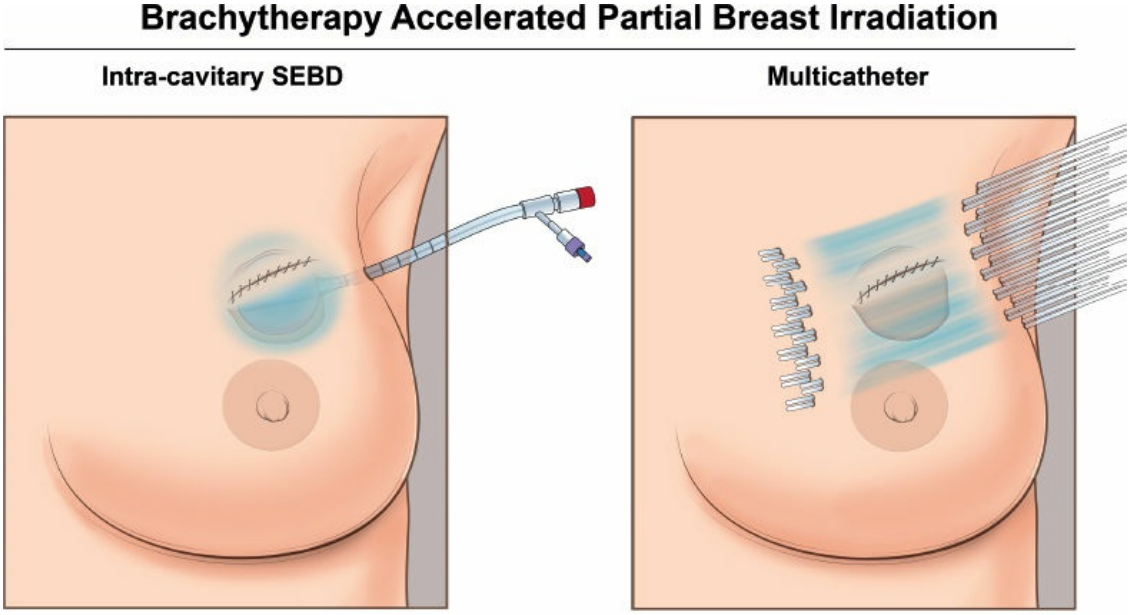

Figure 50.2. Brachytherapy methods for APBI are the multicatheter implant (**right**) and the single entry device (**left**). Each method has a characteristic radiation dose distribution (*blue*).

Multicatheter Brachytherapy APBI

Multicatheter (MCT) brachytherapy is one of the earliest methods of APBI developed and as a result has the longest track record documenting clinical outcome. When using MCT brachytherapy for APBI, the area targeted for radiation is the lumpectomy cavity plus a 1 to 2 cm expansion of breast tissue surrounding it comprises the clinical target volume (CTV). Rigid hollow needles are inserted into the breast under either ultrasound or CT guidance in 1 to 3 parallel planes to cover the extent of the CTV. An average size implant uses ~15 to 17 needles, typically within each plane are 5 to 7 needles set about 1.5 cm apart (Fig. 50.2). The distance between each plane of needles is also 1.5 to 2 cm to achieve optimal dose distribution. Once the total implant is completed, the rigid needles are replaced by narrow hollow flexible tubes that remain in place until the treatment is completed. A CT for treatment planning is done after the MCT implant is inserted and the dose distribution is confirmed by DVA. Treatment is outpatient and commonly the prescribed radiation dose with HDR is 34 Gy delivered in 10 fractions of 3.4 Gy twice daily, with a minimum of 6 hours between fractions. Each fraction lasts ~8 to 15 minutes depending on the Iridium 192 source strength. After the last fraction is delivered, the flexible tubes are removed.

Numerous clinical trials have reported local recurrence rates in the breast following MCT APBI of 2% to 6% at 5 to 10 years in the mostly stage 1 and hormone sensitive (i.e., tumor estrogen [ER] or progesterone [PR] receptors are positive) breast cancer cases that were enrolled. The durable local control results that are achievable are seen in an early phase II trial, RTOG 9517, where the median follow-up is 12 years for 100 women treated post lumpectomy with MCT APBI from 1997 to 2000 and the 10-year local recurrence is 6.2%. Similarly, a phase II German-Austrian Trial treated 274 women from 2000 to 2005 with MCT APBI resulting in a 5% 10-year local recurrence rate at 9.6 years median follow-up. Two phase III randomized trials have documented no difference in local control in women treated with MCT APBI versus standard whole breast irradiation post lumpectomy. The largest of these, the Groupe Européen de Curiethérapie of the European Society for Radiotherapy and Oncology (GEC-ESTRO) trial randomized 1,184 women with stage 1, 95% hormone sensitive breast cancer to MCT APBI versus whole breast irradiation post lumpectomy and reported 5-year in-breast recurrence risks of 1.42% and 0.92% respectively (p = 0.42) with a median follow-up of 6.6 years.

In addition to its established efficacy, the advantage of MCT brachytherapy for APBI is its technical adaptability to fit nearly any position or thickness of the breast by adjusting the number of planes or catheters used. The disadvantage of this method is that it is invasive, technically complicated, and requires significant training. As a result, it has limited availability in the United States, being practiced at only a minority of radiation facilities. This is reflected by the NSABP B39/RTOG 0413 phase III clinical trial that randomized 2,107 women to the APBI arm, of which only 5% were treated with MCT HDR brachytherapy.

Single Entry Device Brachytherapy (SEBD) ABPI

The emergence of single entry brachytherapy devices (SEBD) for APBI overcame the technical barriers of MCT brachytherapy. These are catheter-like devices inserted into the surgical cavity post lumpectomy through a single puncture site and once placed deliver HDR radiation through a single or multiple channels (Fig. 50.2). The first of these developed commercially (MammoSit) had a single central channel for radiation delivery that was enclosed in an expandable balloon used to secure the device in position within the cavity. There is a separate port on the catheter

to expand the balloon (typically with normal saline) after placement to fill the cavity and then radiation is delivered from the central channel to treat breast tissue that is within 1 cm from the balloon surface. The radiation CTV for this method of APBI is defined as an expansion of 1 cm from the surgical cavity edge. The most commonly used dosing is also 34 Gy in 10 fractions of 3.4 Gy HDR radiation delivered twice daily with a minimum of 6 hours between fractions, although investigation is ongoing to reduce this to 3 to 4 fractions over 2 days. It is important that the device fits well within the cavity so that the radiation reaches the targeted breast tissue. After the SEBD is placed, a CT is done to ensure it fits the cavity well and for radiation treatment planning. The radiation dose distribution, particularly to the skin and chest wall, is confirmed by DVA prior to starting treatment.

The initial SEBD (MammoSite) was approved by the Federal Drug Administration in 2001 and the prospective trial evaluating its safety for ABPI post lumpectomy included 42 node-negative breast cancer patients with a median tumor size of 1 cm that had no local breast recurrence events through 5 years of follow-up. The largest clinical experience is from the American Society of Breast Surgeons (ASBS) registry that includes 1,440 women from 93 institutions who were treated with APBI post lumpectomy from 2002 to 2004 using the one radiation channel SEBD (MammoSite). With a median follow-up of 5.4 years, it reported a 5-year rate for in-breast recurrence of 3.7% in 1,249 invasive breast cancer cases that were 97% node negative, 87% hormone sensitive with a median tumor size of 1 cm, and a 4.1% in-breast recurrence in 194 cases of DCIS with an average size of 9 mm. Despite the improved ease of use, the single channel SEBD for APBI delivery created a very heterogeneous dose distribution and prevented individualized dose adjustments resulting in excess toxicity when the balloon surface is too close (within 7 to 8 mm) to the skin or chestwall. Additional brachytherapy devices with more radiation channels were developed to overcome this limitation. Multichannel SEBD models have a central radiation channel and either three (MammoSiteML) or four (Contura) fixed surrounding radiation channels that expand after placement allowing more individualized modulation of the radiation dose at 1 cm from the balloon edge (Fig. 50.3). Another SEBD designed to more closely approximate the dose distribution of MCT brachytherapy is not encompassed in a balloon but instead has a central catheter with 6, 8, or 10 peripheral catheters (Fig. 50.3) that expand

to fill the cavity after insertion and permit even more individualized dose adjustment at 1 cm from the edge of the surgical cavity (Strut-Adjusted Volume Implant, SAVI). Early experience using the multichannel and multicatheter SEBD for APBI has demonstrated reduced dose to the skin and chest wall and similar efficacy. The various brachytherapy devices commercially available can accommodate a good fit in a range of lumpectomy cavity sizes, shapes, and locations.

Figure 50.3. Multichannel (**left**) and Multicatheter (**right**) Single Entry Brachytherapy Devices (SEBD) allow more modification of the dose to protect adjacent uninvolved normal tissue, like the

chestwall and skin.

The development of the SEBD really led to the broader utilization of APBI for breast conservation and acceptance in the surgical community. Examination of the National Cancer Database from 2003 through 2010 reveals that the use of APBI post lumpectomy increased from 3.4% in 2003 to 12.4% in 2010, and the largest increase was in brachytherapy methods (8.9% by 2010) likely reflecting the emergence of single entry devices. Surgeons place SEBD for APBI in the majority of cases, typically in an outpatient setting with the use of ultrasound guidance and local anesthesia. Initially the SEBD was placed at the time of lumpectomy, but insertion transitioned quickly to postoperative closed-cavity placement that permitted review of final pathology and was associated with fewer toxicity outcomes. Most often the entry site for the SEBD is separate in the lateral aspect of the breast, but some surgeons have entered through the prior lumpectomy scar if the cavity location is sufficiently deep. If APBI with a SEBD is an option, performing the lumpectomy in a way that will facilitate fit of the device should be considered. This includes bearing in mind cavity shape so that crevasses and irregular cavity walls are avoided when feasible to minimize poor device fit. There is a need for close cooperation between the surgeon who performs the lumpectomy and postoperatively places the SEBD and the treating radiation oncologist to ensure optimal cancer and cosmetic outcomes. The use of SEBD for APBI still has the drawback of being invasive and requiring the treating facility to have HDR radiation capability. Furthermore, so far there are no randomized data comparing SEBD APBI to standard whole breast irradiation post lumpectomy.

3DCRT and IMRT APBI

External beam radiation methods for APBI using 3DCRT or IMRT were developed after those using brachytherapy. When external beam radiation is used for APBI, the CTV to be irradiated is the surgical cavity plus a 1 to 1.5 cm expansion. In contrast to brachytherapy that is internally secured to the CTV, patient motion and set-up error must be taken into account for external beam radiation, so another 0.5 to 1.0 cm expansion is necessary for a planning target volume (PTV); this means the total expansion from the surgical cavity for this method is 1.5 to 2.5 cm. The most commonly used dosing regimen for 3DCRT or IMRT APBI is 38.5 Gy in 10 fractions

delivered twice daily with a minimum of 6 hours between fractions. The dosing scheme of 30 Gy in 5 nonconsecutive daily fractions at 6 Gy per fraction over 2 weeks of treatment has also been successfully used.

Several single institutions have completed phase II prospective trials evaluating 3DCRT APBI for breast conservation in predominantly stage 1 hormone sensitive breast cancer demonstrating in-breast recurrence rates of 1% to 5% at 5 years. A phase II multi-institution trial, RTOG 0319, studied 3DCRT APBI and reported a 5.9% rate of isolated local recurrence in the treated breast at 7 years with an 8-year median follow-up. A phase III randomized trial conducted at the University of Florence compared IMRT APBI versus whole breast irradiation in 520 women after lumpectomy who nearly all had stage 1, hormone sensitive breast cancer and with a median follow-up of 5 years reported very low rates of local recurrence at 5 years that were not significantly different by arm—1.5% versus 1.4%, respectively ($p = 0.86$).

The advantage of 3DCRT or IMRT APBI for breast conservation is its broad availability as every radiation facility has the technical capability to deliver external beam radiation. In fact, ~70% of the 2,107 women randomized post lumpectomy to the APBI Arm on the NSABP B39/RTOG 0413 clinical trial were treated using 3DCRT. Despite its accessibility, there is some caution with its acceptance as 10% to 15% higher rates of adverse cosmesis have been reported from 3DCRT APBI in comparison to whole breast radiation by the Ontario Clinical Oncology Group RAPID randomized trial. In contrast, the University of Florence trial reported improved physician assessed cosmetic outcomes at 5 years for women randomized to IMRT APBI compared to whole breast irradiation, $p = 0.045$. One of the main criticisms of external beam APBI is the extent of variation within this method—there are multiple definitions for the CTV and how much of the breast should be irradiated yet still be considered “partial”—in addition to inherent variation due to patient movement or technical set-up. It is likely that this variability explains the different toxicity and cosmetic outcomes reported so far from external beam APBI methods and will be addressed as clinical trial data mature and are more fully reported.

Indications and Recommendations

APBI is indicated for breast conservation in women with stage 1 hormone sensitive breast cancer who intend to complete the recommended adjuvant

endocrine therapy. Across all the clinical trials, registry, and cohort research that have reported efficacy of the different APBI methods, there has been an exceedingly consistent population of breast cancer patients studied. Nearly uniformly the population studied is breast cancer that has undergone lumpectomy with negative surgical margins, is node negative, hormone sensitive, with a tumor size <2 cm. Invasive cancers up to 3 cm have been included in these studies, but the prevalence of those >2 cm in size has been typically <10%. Similarly, the median age of women studied has been consistently 60 years or older with very few women <40 years evaluated. Endocrine therapy is likely an important component of the success of APBI in this population. This is illustrated well by the phase II German-Austrian MCT APBI trial where the 5-year local recurrence for hormone-sensitive patients (n = 264) with adjuvant endocrine therapy was 1.1%, and without was 12% (p = 0.0087).

Treatment outcomes from APBI for breast conservation in other breast cancer subtypes, including HER2 and triple negative, or with other adverse pathologic features have been reported relatively infrequently but in general have yielded poorer results. In particular, early-stage triple-negative breast cancer cases treated with APBI have had significantly higher in-breast recurrence at 5 years of up to 20% to 33% in prospective phase II trials. Other features that have been associated with significantly higher local recurrence after APBI, particularly when there are multiple present, include: estrogen receptor negative, grade III histology, involved surgical margins, age <50 years, and being premenopausal. The pending results of the NSABP B39-RTOG 0413 randomized trial may be able to clarify in the future the safety of APBI in other populations as it uniquely enrolled among its 4,216 accrued 19% who had triple-negative disease and 39% who were younger than 50 years old.

Numerous treatment guidelines and consensus statements have emerged to counsel when APBI is indicated for breast conservation therapy while data from the randomized trials are pending. The updated American Society of Radiation Oncologists (ASTRO) consensus statement identifies suitable candidates for APBI as women older than 50 years of age who have undergone lumpectomy with negative margins with either unicentric invasive breast cancers <2 cm in size, with negative nodes, estrogen receptor-positive disease, or low-risk DCIS. A detailed list of “cautionary” or “unsuitable” characteristics for APBI is also detailed by the ASTRO guidelines. The ASBS guidelines for women to be considered for APBI

include those age 45 years old or older for invasive cancer, age 50 years or older for DCIS, invasive carcinoma or DCIS, total tumor size (invasive and DCIS) ≤3 cm in size, negative surgical margins, and sentinel lymph node negative.

INTRAOPERATIVE PARTIAL BREAST IRRADIATION

IPBI refers to the delivery of a single fraction of radiation in a dose range of 18 to 21 Gy to the breast tissue surrounding the lumpectomy cavity following the removal of the tumor and prior to surgical closure. Delivery of IORT after surgical excision adds ~20 to 45 minutes to the case in the operating room. Currently, IPBI is delivered with either 4 to 12 mega-electron voltage (MeV) electrons delivered through a cone from a specialized mobile LINAC, or with low energy kilo voltage (kV) photons through a spherical applicator inserted into the cavity (Fig. 50.4). Brachytherapy methods for IORT are available but less commonly used.

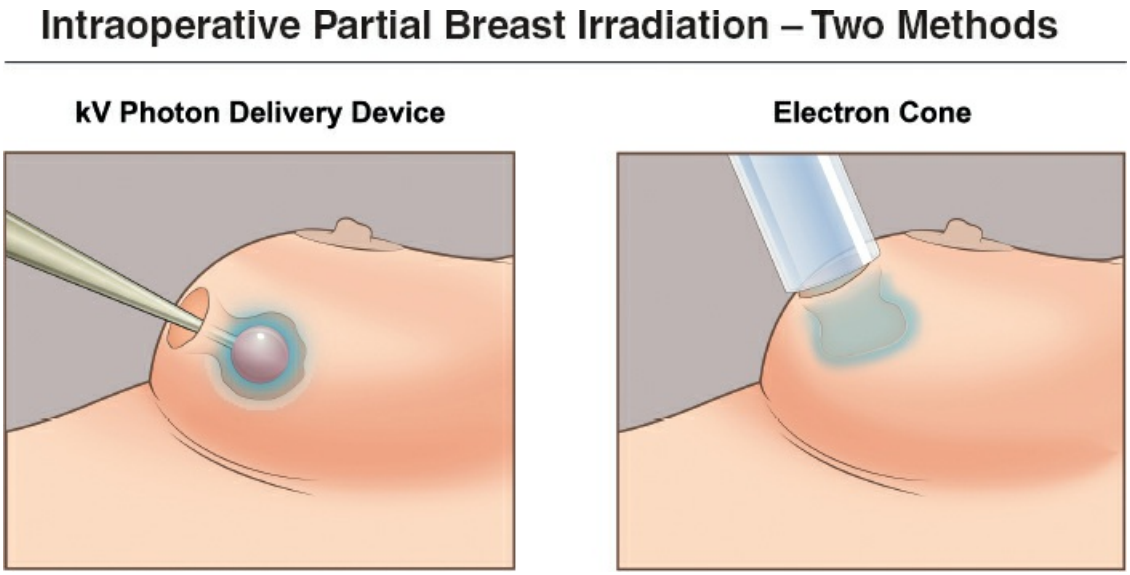

Figure 50.4. Methods for IPBI include the use of electrons (**right**) delivered via a cone from a small LINAC and kV photons delivered through a spherical applicator connected to a miniature LINAC. Each method has a characteristic radiation dose distribution (*blue*).

Electron IORT

The delivery of IORT became more feasible in the late 1990s with the development of small, mobile LINACS capable of delivering electron therapy in the 4 to 12 MeV range. These units can be moved into the

surgical suite and include self-shielding, so minimal modification to the operating room is required. Intraoperative PBI is delivered after the sentinel node biopsy and lumpectomy are completed. Following removal of the breast cancer, the tumor bed is identified and the depth of breast tissue to be irradiated measured. The skin is mobilized from the breast tissue in the affected region to allow entry of the LINAC cone and to exclude it from the radiation. The breast tissue can also be mobilized from the muscle fascia to allow a disc of aluminum-lead or Lucite to be placed below the glandular breast for radioprotection of the chestwall and intrathoracic organs. The edges of the lumpectomy cavity are approximated by sutures to bring it into the radiotherapy target volume deep to the cone. Based on the size and depth of the surgical cavity, the appropriate electron cone and energy for treatment are selected. Cones of 5 to 8 cm diameter and 6 to 8 MeV electrons (4 to 15 MeV) are commonly used to deliver the prescribed dose of 21 Gy to the cavity plus 1.5 to 2 cm of adjacent breast tissue and a depth of 1 to 3 cm.

Mature outcome date from electron IPBI for breast conservation is available from phase II and III trials. Two phase II trials have reported a range of local recurrence rates: 0.4% from the University of Verona trial of 227 women with a mean follow-up of 46 months and 9.2% at 6 years median follow-up in the Montpellier phase II trial that enrolled 96 women. The European Institute of Oncology (EIO) in Milan, instrumental in developing the electron methods for IORT (termed ELIOT) in breast cancer, conducted a phase III trial that randomized 1,305 women to receive either IPBI of 21 Gy during surgery versus standard adjuvant whole breast irradiation. Eligible cases had a clinical tumor size <2.5 cm and were between the ages of 48 and 75 years. On final pathology, 85% were T1 tumors, 90% were estrogen receptor positive, and 26% had positive nodes. An axillary dissection was performed in all cases with positive nodes. At a median follow-up of 5.8 years, the 5-year rate of local recurrence following IPBI was 4.4% versus 0.4% for standard adjuvant breast radiation (p = 0.001). The 5-year local recurrence rate exceeded 10% in the IPBI arm when there was a tumor size >2 cm, positive lymph nodes, grade 3 histology, ER negative, or triple-negative breast cancer. In a separate analysis, 1,822 cases in the ELIOT database that received IPBI were retrospectively categorized into the ASTRO APBI Consensus Groups of Suitable, Cautionary, or Unsuitable and were determined to have corresponding local recurrence risks of 1.5%, 4.4%, and 8.8%,

respectively ($p = 0.0003$).

kV IORT

For this form of IPBI, a miniature LINAC delivers low-energy x-ray radiation through a spherical applicator fitted into the cavity after the breast cancer has been removed (Fig. 50.4). The miniature LINAC accelerates the electrons to 50 kV and guides them through a narrow tube that ends within the spherical applicator. The electrons impinge on a gold target at the end of the narrow tube resulting in the generation of low-energy x-rays that distribute around the applicator surface. The spherical applicator is available in several sizes ranging from 15 mm through 50 mm diameter to accommodate a range of cavity sizes. The applicator should fit snugly within the cavity and one or two purse-string sutures are placed through the breast tissue around the cavity to appose it to the applicator. Care needs to be taken to prevent the skin from being too close to the applicator surface to minimize the radiation it receives. After positioning the appropriately sized applicator into the cavity, the radiation is delivered. A dose of 20 Gy is delivered to the surface of the applicator giving 5 to 7 Gy at 1 cm from the applicator surface.

The primary outcome data from kV IPBI are from a large phase III multi-institution trial, TARGIT A that randomized 3,451 women to receive either 20 Gy kV IPBI during surgery or standard adjuvant whole breast radiation therapy. For those randomized to the kV IPBI arm, radiation was considered “risk adapted,” meaning that adjuvant whole breast radiation was allowed if adverse pathologic features were present on final pathology and this indeed occurred in 15%. In addition, while 2,298 (66.5%) received kV IPBI after the cancer was removed during the first surgery or “pre pathology,” the other 1,153 (33.5%) had a second surgical procedure after initial lumpectomy or “post pathology” to specifically receive kV IPBI. On final pathology, 87% had tumors <2 cm, 93% were hormone sensitive, and 16% had positive nodes. With a median follow-up of 2.4 years, the 5-year risk for local recurrence in the conserved breast for kV IPBI was 3.3% versus 1.3% for standard adjuvant breast radiation ($p = 0{\cdot}042$). Patients treated with kV IPBI who received it “pre-pathology” had a 1% local risk at 5 years but 22% also received whole breast radiation, and those in the “post-pathology” group had a 3.7% local recurrence rate at 5 years with 3% also receiving whole breast radiation. The 2.4-year median follow-up on this trial is relatively short, and additional follow-up

is needed to confirm efficacy.

Indications and Recommendations

IPBI is best considered for breast conservation in those who are 50 years of age or older whose invasive tumor is <2 cm in size, hormone sensitive, HER2 negative, and expected to be node negative. Adherence to the ASTRO consensus guideline "suitable" category for patient selection is recommended. Careful workup of the axilla is warranted to reduce the likelihood of positive nodes at sentinel node biopsy.

The main advantage of IPBI is the convenience and efficiency of completing surgery and breast radiation by the time the patient exits the operating room. However, the main disadvantage is the risk of overtreatment and undertreatment as a result of not knowing the final surgical pathology. The IPBI could be considered medically pointless if the patient needs to undergo external beam radiation to the breast or regional nodes anyway due to adverse features on final pathology as seen in 22% and 5% respectively in the TARGIT-A and ELIOT phase III randomized trials. On the other hand, potential undertreatment can occur if patients with adverse pathologic features are treated with IPBI alone. Further research is warranted to improve patient selection that minimizes inclusion of high-risk features. Finally, the other disadvantage of IPBI is that it is not possible to confirm that the radiation dose distribution is being delivered accurately through individual treatment planning. Many of these issues will be addressed by additional follow-up from the large randomized trials and careful monitoring of outcome data as IPBI is used in practice.

EDITOR'S COMMENT

Professor White of the Department of Radiation Oncology, the Ohio State University Comprehensive Cancer Center, has included a technical and comprehensive overview of the role of whole and partial breast irradiation, as well as the intraoperative irradiation choices, available to the surgeon managing breast cancer. As Dr. White would embrace, radiation science is an art and technical feat that is not considered an exact science. The advancement of radiation technology and tools capable of delivering precise energy photons, electrons, and rads continues to be an emerging technical advance with increasing options for management of breast cancer patients as noted in the commentary made by Dr. White. All disciplines managing breast cancer require

advanced quality imaging inclusive of: ultrasonography, mammography, magnetic resonant imaging, and confirmatory CTs and staging, including positron emission tomography (PET) scans.

As noted, the original investigation by Agarwal et al. (Agarwal S, Pappas L, Neumayer L, et al. Effect of breast conservation therapy vs mastectomy on disease-specific survival for early-stage breast cancer. *JAMA Surg* 2014;149(3):267–74) provides emerging data that compare breast cancer-specific survival of patients who are undergoing breast conservation therapy (BCT) to mastectomy alone or mastectomy with radiation using contemporary cohorts in the investigation. Agarwal and associates confirm that patients undergoing BCT have a higher breast cancer-specific survival when compared with individuals treated with mastectomy alone or with mastectomy and irradiation. There are nearly four decades of data that date back with the NSABP of the 1970s that confirm BCT has equivalent cancer-specific survival to modified or radical mastectomies. Moreover, contemporary data suggest that BCT plus radiotherapy has an improved 10-year overall and relative survival when compared to mastectomy of these earlier era treatment protocols. Furthermore, 10-year distant metastases-free survival was enhanced with BCT plus RT when compared with mastectomy and the T1N0 subgroup cohorts. It would therefore be a conservative statement that BCT with radiotherapy is at least equivalent to mastectomy with respect to the overall survival and may influence therapeutic decisions (van Maaren MC, de Munck L, de Bock GH, et al. 10 year survival after breast-conserving surgery plus radiotherapy compared with mastectomy in early breast cancer in the Netherlands: a population-based study. *Lancet Oncol* 2016;17:1158–70). *This is a very important point. -JEF*

Mukesh et al. of Cambridge University Hospital National Health Service Foundation Trust, UK, reiterate that within the current era use of intensity-modulated radiotherapy (IMRT) clearly decreases late breast tissue toxicity; thus, control rates and cosmesis are enhanced as an additional equivalent in current radiation therapy protocols, and these outcomes are “practice-changing” parameters that will encourage university centers and population growth centers to increasingly utilize simple IMRT technology with two-dimensional RT to implement breast IMRT. (Mukesh MB, Barnett GC, Wilkinson JS, et al. Randomized controlled trial of intensity-modulated radiotherapy for early breast cancer: 5-year results confirm superior overall cosmesis. *J Clin Oncol* 2013;31:4488–95).

The European Organization for Research and Treatment of Cancer Radiation Oncology and Breast Cancer Groups suggested that the most commonly utilized techniques in postop whole-breast techniques with irradiation boost had no effect on long-term survival, but was implemented to confirm local control with the largest absolute benefit in the younger patient. It should be noted that this randomized controlled trial (Bartelink H, Maingon P, Poortmans P, et al. Whole-breast irradiation with or without a boost for patients treated with breast-conserving surgery for early breast cancer: 20-year follow-up of a randomised

phase 3 trial. *Lancet Oncol* 2015;16:47–56) confirmed this technology can improve local control with the largest absolute benefit in the younger patient, although the technique increases relative risk of moderate to severe fibrosis in these patients. Addition of a radiation dose was noted to possibly be avoided for the older patient (>60 years).

In the original dated trials that confirmed the value of whole-breast irradiation following BCT, 20 fractions of radiation at 50.0 Gy were given over an interval of over 5 weeks with daily fractions of 2.0 Gy. Whelan et al. (Whelan TJ, Pignol JP, Levine MN, et al. Long-term results of hypofractionated radiation therapy for breast cancer. *N Engl J Med* 2010;362:513–20) reported the 5-year results of a randomized trial with whole-breast therapy at this dose over a period of 35 days when compared to accelerated hypofractionated whole-breast radiation (42.5 Gy in 16 fractions over 22 days) following BCT with axillary lymph node-negative breast cancer. Of note, radiation-induced toxicity related to large doses per fraction that increased with time raises dubious concerns regarding the universal approach for hypofractionated radiation. Whelan and associates, thus, provide support for the use of accelerated hypofractionated whole-breast RT for select women who are node-negative following BCT. This abbreviated course of treatment was considered to be potentially less costly than standard therapy and could have an additional benefit to enhance the number of women who receive breast RT following breast-conserving surgery.

In the phase III randomized, noninferiority trial, by Strnad et al. of the European Society of Radiotherapy and Oncology (GEC-ESTRO) (Strnad V, Ott OJ, Hildebrandt G, et al. 5-year results of accelerated partial breast irradiation using sole interstitial multicatheter brachytherapy versus whole-breast irradiation with boost after breast-conserving surgery for low-risk invasive and in-situ carcinoma of the female breast: a randomised, phase 3, non-inferiority trial. *Lancet* 2016;387:229–38), the authors report this a phase III randomized trial for APBI with stages 0, I, and IIA breast cancer, which were compared with whole-breast irradiation. In finality of the report, the difference between treatments was below a relevance margin of 3 percentage points. Using multicatheter brachytherapy following BCT in patients with early breast cancer is *not inferior* to adjuvant whole-breast radiation relative to the 5-year occurrence of this patient population relative to overall survival, disease-free survival, and local control. Therefore, adjuvant APBI that utilized multicatheter brachytherapy was virtually identical to whole-breast irradiation and the risk of severe fibrosis at 5 years was 0.2% with whole-breast irradiation and 0% with APBI ($p = 0.46$).

The European Institute of Oncology (Milan, Italy) randomized trial with Intraoperative Radiotherapy versus External Radiotherapy for Early Breast Cancer (ELIOT) was a controlled equivalence trial. Veronesi et al. (Veronesi U, Orecchia R, Maisonneuve P, et al. Intraoperative radiotherapy versus external radiotherapy for early breast cancer (ELIOT): a randomised controlled

equivalence trial. *Lancet Oncol* 2013;14:1269–77) in this trial of 1,305 patients randomized to receive either external radiotherapy or intraoperative RT observed fewer skin effects in the intraoperative RT group than in the external RT group (p = 0.0002); although the result was within this pre-specified equivalence margin, the rate was significantly greater with external RT. Overall survival did *not* differ between the groups, and the authors conclude that improved patient selection could reduce the rate of ipsilateral breast tumor recurrence (IBTR) with intraoperative RT with electrons.

In the reported systematic search for the National Library of Medicine PubMed Database by Smith et al. (Smith B, Arthur D, Buchholz T, Accelerated partial breast irradiation consensus statement from the American Society for Radiation Oncology (ASTRO). *Int J Radiation Oncology Biol Phys* 2009;74[4]:987–1001), this multi-institutional trial report yielded 645 candidate research articles applicable to APBI versus whole-breast radiation. With his dated publication, taskforce proposed three patient groups: "*suitable*" group for whom APBI was acceptable outside a clinical trial, a "*cautionary group*" in whom concern should be applied when considering APBI outside a clinical trial and an "*unsuitable*" group where it is not generally considered warranted. The conclusion states that these patients in whom APBI therapy is being considered must be informed of the long-term database experience with whole-breast irradiation as an established therapy with known safeguards and effectiveness.

Finally in the randomized prospective phase III controlled trial from the University of Florence reported by Livi et al. (Livi L, Meattini I, Marrazzo L, et al. Accelerated partial breast irradiation using intensity modulated radiotherapy versus whole breast irradiation: 5-year survival analysis of a phase 3 randomised controlled trial. *Euro J Cancer* 2015;51:451–63), women older than 40 years affected with early breast cancer and tumor size that did not exceed 25 mm were randomized 1:1 with APBI using IMRT technique followed BCT to that of conventional whole-breast irradiation. Patients in the APBI arm received a total dose of 30 Gy to the tumor bed in 5 daily fractions; the whole breast irradiation (WBI) group received 50 GY in 25 fractions, following with boost to the tumor bed of 10 Gy in 5 fractions. Of 520 randomized patients equally divided between the two arms, this randomized study using IMRT for APBI delivery, no significant differences in terms of in-breast tumor reoccurrence (IBTR) and overall survival between the modalities were evident. Moreover, APBI had evidence of a significantly better toxicity profile than WBI.

These techniques and emerging RT technology embrace the improved outcomes with equivalent survival rates and superior cosmesis than the dated whole-breast irradiation technology.

Kirby I. Bland

EDITOR'S COMMENT

The current standard of care is to offer breast conservation therapy (BCT) to patients with early stage disease. BCT includes excision of the tumor with a rim of normal tissue (i.e., lumpectomy) and adjuvant treatments including radiation therapy, most commonly whole breast radiation therapy (WBXRT), to treat residual disease. BCT that is less invasive offers improved cosmesis, well-being, and equivalent survival to mastectomy (removal of the whole breast) with similar local recurrence rates. However, because of the challenges of WBXRT (time, travel, cost, and complications), 14% to 26% of BCT patients skip WBXRT entirely, and an additional 22% of women do not complete their treatment. This despite the knowledge that the risk of local recurrence is five times greater without the addition of radiation. Patients refusing completion radiation led to trials testing whether older patients (>70 years old) with favorable tumors received significant benefit from radiation. While the initial results looked favorable, the most recent follow-up of the CALGB (Cancer and Leukemia Group B) 9343 demonstrated a recurrence of 2% at 10 years in patients receiving Tamoxifen plus WBXRT and 10% in those receiving tamoxifen alone. Importantly, survival remained equivalent. On the other hand, most patients who get XRT don't benefit from it. That is, for example, in the CALGB study 90% of patient who didn't get radiation didn't recur. So that on 8 patients out of the 100 who got XRT actually benefited from it. One could conclude that we are vastly overtreating the majority of patients. Yet, recurrence remains important. The Early Breast Cancer Trialist Group, in review of data from over 42,000 women from 78 randomized studies, demonstrated that at 15-year follow-up, for every four recurrences there was an associated increase of one death that could be avoided.

Thirty-six percent of women who elect mastectomy are actually eligible for BCT. With variable rates of positive margins, a majority of women elect mastectomy after a failed first attempt at lumpectomy. Others fear the complications of radiation to the chest wall, including radiation dermatitis, breast shrinkage (moderate or greater decrease in size of the breast in 50%), pneumonitis/pulmonary fibrosis, edema, ischemic heart disease, and rare second lethal cancers like angiosarcoma. Rural patients and others cannot spare the time and/or cost of travel for treatment. These issues have been partially alleviated by the development of brachytherapy and accelerated partial breast irradiation (APBI) of which Dr. White nicely outlines the history. These techniques include a surfeit of devices and techniques developed for delivery of shorter courses of radiation administered only to the pericavitary breast tissue, including interstitial catheters, applicator-based brachytherapy, and external-beam XRT.

Partial breast irradiation (PBI) when added to lumpectomy demonstrates nearly equivalent local recurrence and equal survival when compared to whole

breast radiation. However, PBI can be delivered in much shorter time (5 days as compared to 3 to 6 weeks) and even intraoperatively as a one-time dose. This chapter describes the many alternative techniques available for delivering PBI.

One option for avoiding whole breast irradiation after breast conserving surgery is the use of three-dimensional conformal external beam radiation therapy (3DCRT) to deliver noninvasive APBI. This modality may be advantageous to brachytherapy in comparison due to its noninvasive nature, widespread availability of necessary resources, knowledge of final pathology at the time of treatment planning, and potential decrease in seroma formation and infection associated with catheter-based treatment. APBI is most commonly administered in a 38.5 Gy regimen divided into 10 fractions given twice per day for 5 days. Rodriguez et al. reported on the 5-year outcomes of 102 patients with early-stage breast cancer randomized to receive WBXRT or APBI. A median follow-up of 5 years found no local recurrences in either group, and physician assessment reported that >75% of patients had excellent or good cosmesis and remained stable over time. An interim analysis of the RAPID (Randomized Trial of Accelerated Partial Breast Irradiation) trial was performed by Peterson and colleagues to evaluate cosmetic outcomes of APBI compared to WBRT. The RAPID trial enrolled 1,108 patients; 539 were randomized to 3D external beam APBI and 569 were randomized to WBRT. Baseline posttreatment nurse assessment for adverse cosmesis was 19% in the APBI arm and 17% in the WBRT arm with 3-year evaluations increased to 29% with adverse cosmetic outcomes for APBI, but remained 17% for WBRT ($p < 0.001$). The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-39/Radiation Therapy Oncology Group (RTOG) 0413 trial that randomized 3,000 patients to WBXRT or PBI has not yet matured. Most of the patients on the non-WBXRT arm have received 3DCRT.

In 2012, the consensus statement recommendations by the American Society for Radiation Oncology (ASTRO, 2009) that Dr. White reviewed delineating who was suitable for APBI was reviewed by a group examining 2,127 cases of APBI and comparing them with 206 of those patients having 3DCRT. At a median follow-up of 6.7 years, the recurrence rate in the tumor bed was 1.1% in the suitable group, 1.2% in the cautionary group, and 1.2% in the unsuitable group ($p = 0.2$). 3DCRT is easier on the patient, doesn't require an external device or device placement, and is readily accepted by the patient and physician alike. In addition, dose homogeneity can be assured. The complication rates tend to be less than with whole breast; but in my experience, when they do occur they tend to be worse with block fibrosis and pain. APBI has been associated with a fourfold higher rate of patients developing a palpable mass at the lumpectomy site and a 42% incidence of telangiectasia and/or other side effects. Dr. White is the PI for the phase III National Surgical Breast and Bowel Project (NSABP) B-39 comparing APBI and brachytherapy techniques with who breast radiation. Although the results of this trial are pending maturity, most of the patients in this trial receiving partial breast XRT did so via APBI.

The MammoSite (Hologic, Marlborough, MA) (the first balloon-based catheter) Registry of the American Society of Breast Surgeons has the largest collection of data with this device, which demonstrates comparable results to historical controls receiving WBXRT. The Registry has 1,449 patients with a median follow-up of 63.1 months with an actuarial ipsilateral breast tumor recurrence (IBTR) rate of 3.8% and axillary recurrence rate of 0.6%, which compares favorably to WBXRT. Cosmetic results are reported to be good to excellent in about 90% of the patients. Contura (SenoRx, Inc. Aliso Viejo, CA) makes a balloon that has multiple catheters as well as a vacuum port within the balloon with a total of 40 dwell positions. The multiplicity of catheters allows better treatment planning and is particularly useful in patients where the skin distance to the balloon is <7 mm. Multiple catheters make this and other balloons a bit stiffer and more uncomfortable for the patient. Most catheters have to be scanned with each treatment as they can rotate leading to incorrect dosing. The SAVI (Cianna Medical, Inc., Aliso Viejo, CA) device that also has multicatheters and has the advantage that it can be locked in place and comes in sizes such that the catheter can be custom-fitted to the lumpectomy cavity. ClearPath (Renata Medical, Irvine, CA) makes a similar device with multiple catheters that has the advantageous of laying flush with the skin and is a bit better-tolerated by the patient. Xoft, Inc (Sunnyvale, CA) has developed the Axxent electronic brachytherapy system that is an iridium seed-based single catheter radiolucent balloon impregnated with barium that emits low energy and can be turned on and off in the office setting. The EXIBT Electronic Xoft Intersocietal Brachytherapy Trial (EXIBT) registry recruited 400 patients and at 1- and 2-year follow-up demonstrated the safety and efficacy of Xoft as an adjuvant radiation therapy for early-stage breast cancer reporting no recurrences in 69 patients.

The major advantage of brachytherapy APBI is that the radiation therapy can be completed prior to systemic therapy. However, one must be careful. Starting chemotherapy too soon (<3 weeks) can result in the rare case of radiation recall that can be so severe as to necrose the overlying skin of the cavity.

As Dr. White discussed intra-operative radiation therapy (IORT) can provide effective long-term local control with equivalent recurrence rates to WBRT. IORT delivers a single large fraction over 2 minutes directly into the wound for increased dose delivery and decreased normal tissue exposure. IORT is more expensive because it requires radiation delivery equipment not available at most hospitals.

Using the Mobetron IORT device is a self-shielded, magnetron-driven, X-band linear accelerator Philippson and colleagues recruited 200 patients to a phase II trial who had favorable breast cancer ≤2 cm and no lymph node involvement, lymphovascular invasion or extensive ductal carcinoma in situ (DCIS). The patients received 21 Gy or intraoperative XRT. At a median follow-up of 23 months, the local regional recurrence was 0.5%, acute toxicity was 5.4%, and the late toxicity was 17.1%. Cosmetic outcome was good or very

good in 92.5% of patients. This technology is extremely expensive, and requires dedicated operating rooms and time and multidisciplinary interactive teams. The other disadvantage is the uncertainty of margins at the time of delivery of the dose.

The European ELIOT trial used a linear accelerator to deliver 21 Gy to the tumor bed via a collimator (4 to 9 cm) placed into the tumor bed after excision. The ELIOT trial compared WBXRT to intraoperative XRT comparing 1,205 patients presented with tumors 2.5 cm or smaller. In the intent-to-treat analysis, the 5-year ipsilateral breast tumor recurrence (IBTR) was 4.7% for ELIOT versus 0.5% for WBXRT. In subgroup analysis, low-risk women had a 5-year IBTR was 1.7%. ELIOT did report a higher rate of regional failure (1.0% vs. 0.3%, $p = 0.03$), but the overall survival was the same between the two arms at 5 years.

Zeiss (Carl Zeiss Meditec, Jena, Germany) has developed a low-cost low-energy electronic radiation source (IntraBeam) for intraoperative partial breast irradiation (IPBI) that requires minimal shielding and is much less expensive than other intraoperative devices. The applicators are solid and rounded and come in different sizes to place into the wound (2 to 5 cm). The appropriate size catheter is placed in the wound and the tissue cinched up around the catheter. The radiation oncologist must calculate an ~20 Gy one-time dose to be delivered at the surface of the applicator such that a dose of 5 Gy is delivered at a depth of 1cm from the cavity. The IntraBeam shares some of the same disadvantages as the IOERT devices but is much less expensive and has long-term data demonstrating noninferiority to WBXRT as well as a 2% survival advantage for cardiac events thought attributable to radiation. Silverstein and colleagues recently published a critical analysis and comparison of the two studies.

There is no doubt that radiation therapy reduces the risk of recurrence but only in the peri-cavitary bed and not for the majority of patients to whom it is given. Thus, future endeavors will minimize the treatment to the whole breast and develop better less toxic and less expensive methods to prevent recurrence at the tumor cavity site.

V. Suzanne Klimberg

This chapter has two commentaries and rightly so. Preservation of the breast (as much as possible) is extremely important to the female patient, thus the two commentaries. I have intentionally allowed this because of the importance of leaving as much breast as possible. Experienced breast surgeons know how important this is.

51 Ablative Techniques for Benign and Malignant Breast Tumors

Sheldon Feldman and Margaret Chen

INTRODUCTION

Medical science and technology are rapidly progressing toward the goal of providing personalized, minimally invasive treatments, which are becoming increasingly effective and safe. An area of growth is the investigative use of thermal ablative techniques to treat breast tumors, either as a replacement for or as an adjunct to open surgical resection.

Thermal ablation of tumors is the in situ destruction of tumorous tissue by the local application of heat or cold. Heat-based modalities include radiofrequency ablation (RFA), interstitial laser therapy (ILT), microwave ablation (MWA), and high-intensity focused ultrasound (HIFU). Cryotherapy uses low temperature to ablate tissue.

Hyperthermia has been used to destroy tumor masses for over 4,000 years. Hippocrates describes that “if a tumor cannot be cut, it should be burned. If it cannot be burned, then it is incurable.” This concept is largely true today!

Hippocrates treated superficial tumors with direct ablative therapy. Around the middle ages, instruments were designed with shapes that would allow direct application of heat to kill tumors or cauterize bleeding. It was reported in 1900 that the first curative electrosurgery for cancer occurred when a man with a cutaneous carcinoma accidentally touched an electrical wire. Shortly thereafter, William T. Bovie and Harvey Cushing developed an electrosurgical device (The Bovie) that uses heat to reduce blood loss during surgery. This is used on a daily basis by surgeons around the world.

Hyperthermia has been used in combination with chemotherapy during isolated limb perfusion for melanoma and sarcoma. Targeted hyperthermia for tumor ablation has been used with increasing frequency for treating hepatic, pulmonary, renal, cervical and prostate disease. The use of hypothermia or cryotherapy has a much shorter history with evidence of

efficacy in treating prostate, liver, and renal tumors. It is a potentially very important modality for treating breast tumors as recent clinical trials have demonstrated.

This chapter showcases the most widely studied ablative techniques to treat breast tumors. Lumpectomy with radiation has a long history with excellent oncologic and esthetic outcomes, particularly with application of oncoplastic techniques. It is a low-risk, outpatient procedure with minimal associated complications, which allows for pathologic assessment of the completeness of resection. This experience sets the bar quite high for tumor ablation to perform as well, particularly in terms of safety, recurrence risk, and cost analysis. However, as technology advances ablation is becoming increasingly relevant. Patients are increasingly drawn to minimally invasive methods, which minimizes visible scars while maintaining normal appearance. Patient reported outcomes and patient satisfaction have becoming increasingly important measures of the success of therapy. In fact, there are patients who fear and thus procrastinate or decline traditional surgical treatment of breast cancer due to concern about scars and breast deformity. This often results in devastating outcomes. Nonsurgical ablation treatment may be particularly relevant to provide a less threatening option for this group. It is becoming increasingly clear that ablation techniques will become an important component to our armamentarium of local therapy tools.

The increased use of mammogram screening worldwide has enabled the diagnosis of smaller tumors. Breast conservation surgery remains the preferred approach for the majority of these patients. Screen-detected breast cancers are the most feasible for ablation since smaller tumor volumes can be more effectively treated in relatively shorter time, compared with larger tumors.

Advances made in breast imaging allow more precise targeting for nonoperative ablation. Presently, image-guided needle biopsy can fully characterize tumor biology and genomics. This information increasingly informs systemic therapy decision. Therefore, for most patients, it is no longer important to have tissue analyzed from tumor excisional procedures, such as lumpectomy, to guide subsequent management.

The role of axillary node evaluation for decision making in patients with small favorable subtype tumors is rapidly diminishing. Improved pretreatment axillary imaging with ultrasound allows many patients with nodal metastases to be identified. Thus, selecting out patients most likely

to be node negative will improve patient selection for a nonsurgical ablative approach.

Systemic therapy and radiation recommendations are increasingly be made based on tumor biology and genomics. Thus, it is likely in the near future that many patients will be fully staged and treated without any surgical intervention including sentinel node biopsy. The key to advancing nonsurgical ablation will depend on our ability to choose optimal patients and defining compete ablation without surgical excision.

In the breast, ablative approaches have been studied to treat benign fibroadenoma and cancer, as well as to extend lumpectomy margins intraoperatively. Compared with surgical excision, thermal ablation has the potential advantages of minimal scarring, decreased infection and bleeding, shorter recovery time, better cosmetic outcome, and treatment of patients who are not surgical candidates. Intracavitary hyperthermia using RFA to treat margins during lumpectomy adds an additional tumor-free zone and may reduce reexcision rate as well as obviate the need for radiation therapy. Disadvantages may include thermal injury, palpability, incomplete ablation, residual tumor, inability to assess margin, and disease recurrence.

There are no randomized trials comparing the outcomes of thermal ablation and surgical resection and radiation. Reports of spontaneous regression of untreated distant metastases after local thermal ablation of the primary tumor are generating research in immunomodulation, and may have implications for enhanced combinatorial treatment. There is growing evidence that ablation (whether hyperthermia or cryoablation) may have the additional benefit of altering the local tumor microenvironment and cause autovaccination against tumor antigens. This biologic effect may ultimately be exploited as a strategy to enhance the systemic benefit initiated by ablative local therapy, particularly with tumors with unfavorable biology.

TABLE 51.1 Comparison of Ablative Therapies of Breast Tumors

Characteristics	Radiofrequency Ablation	Cryotherapy	Laser	Microwave	High-Intensity Focused Ultrasound
Energy type	Heat	Cold	Heat	Heat	Heat
Invasiveness	Minimal	Minimal	Minimal	Minimal	Noninvasive
Image guidance	Ultrasound, open lumpectomy	Ultrasound	Ultrasound	Ultrasound	MRI, ultrasound
Target ablation temperature (°C)	100	−40	60	90	60–90
Ablation time (min)	<30	<30	<30	<30	≤120
Real-time monitoring	Yes	Yes	Yes	No	Yes
Procedural pain	Variable	Minimal	Variable	Variable	Variable
Complete tumor ablation rate (%)	44–100	36–93	13–91	0–90	24–100
Postablation MRI correlation with residual disease			High		High
Morbidity with breast and other tumor ablation (%)	2–10				
Mortality with breast and other tumor ablation (%)	0.3–0.8				
Postprocedural palpable breast mass	Yes	Yes	Yes	Yes	Yes
Unique features		Cryoshock phenomenon, immunostimulation, and paradoxical immunosuppression			

INDICATIONS AND CONTRAINDICATIONS

Data from ablative therapies of breast tumors are accumulating, and appear to demonstrate that each technique has a wide range of effectiveness, with low morbidities in appropriate patients. Each ablative technique has advantages and disadvantages, and currently, it is unknown whether one method is superior (Table 51.1). The selection of using a specific technique is determined by each patient's case and the vailable resources and experience with the modality.

Overall, clinical and pathologic criteria determine the selection of patients for thermal ablation (Table 51.2). Ablation is most successful when treating tumors measuring 2 cm or less in diameter, and is at least 5 mm away from the skin and chest wall to minimize thermal injury. Larger tumors have been treated and may require multiple treatments for complete ablation. Tumors are ablated using image guidance, and must, therefore, be well visualized on mammogram, ultrasound, or MRI. Prior to ablation, core needle biopsy is performed to establish definitive tissue diagnosis. It is critically important that adequate tissue be obtained by core biopsy so that complete evaluation of the tumor biology including genomic profiling is available. For cancer, most studies have treated small, well-characterized unifocal, invasive ductal carcinoma without extensive ductal carcinoma in situ, and excluded lobular neoplasm, recurrent, and uncommon malignancies.

PREABLATION PLANNING

Ablation of breast cancer is investigative and should be performed in the setting of a clinical trial. Trials require approval from institutional review board prior to starting treatment. For the ablation of benign fibroadenoma, laser ablation and cryoablation have received United States Food and Drug Administration 501 (k) clearance, and may be performed without trial participation. Prospective outcomes data are encouraged to share results and continually improve technique and patient selection.

TABLE 51.2 Indications and Contraindications for Thermal Ablation of Breast Tumors

Indications

- Patients 18 years of age or older
- Tumor measuring 2 cm or less
- Tumor at least 5 mm away from the skin and chest wall
- Tumor well visualized on imaging (mammogram, ultrasound, or MRI)
- Preablation pathologic diagnosis established by needle biopsy
- Benign fibroadenoma
- Invasive duct cancer
- No extensive ductal carcinoma in situ (<25% intraductal component)

Contraindications

- Pregnancy or breast feeding
- Women with strong family history of breast cancer or BRCA mutation carrier
- Large tumor measuring >2 cm in diameter
- Tumor not well visualized by imaging
- Phyllodes tumor
- Lobular neoplasm, metastatic cancer to breast, sarcoma, Paget's disease
- Recurrent breast cancer
- Neoadjuvant therapy

Appropriate patient selection is the key to successful ablation of breast tumors. Core needle biopsy of the tumor is required prior to any ablation procedure to establish diagnosis. A marker is often placed at the time of biopsy for localization. All patients should be carefully examined, and all imaging and pathology should be reviewed to ensure eligibility for inclusion.

ABLATIVE TECHNIQUES AND OUTCOMES

Patients who meet inclusion criteria and are eligible for ablation are treated, after discussion and informed consent. Treatment can be performed in the office or at an outpatient facility, under local anesthesia, conscious sedation, or general anesthesia depending on patient-related

factors.

Radiofrequency Ablation

Technique

RFA is a technology based on the principle of heating tumors or tumor margins to destroy tumor cells with heat. The RFA procedure was initially used for ablation of aberrant conduction pathways to treat cardiac arrythymias. It has evolved into use for ablation of solid tumors, since it causes a reproducible pattern of cell death in a predicable volume of tissue. For solid tumors, it was initially used for ablation of unresectable tumors, primarily in the liver and lung. Technical advances in RFA have led to increased ablation volumes, which have led to use for primary tumor ablation in the breast. None of the currently available devices have been specifically designed for use in the breast. They have been adapted for use in the breast.

RFA is usually performed under ultrasound guidance. Local anesthesia with mild sedation is generally adequate. There are several RFA devices commercially available. Newer bipolar cool-tip devices are being evaluated for ease of use and potentially reduce heat-related complications. The RFA device is percutaneously guided into the target tissue, and radiofrequency energy is transmitted into the target tissue where it produces heat and either shrinks or kills tumor cells depending on the size of the tumor. Following RFA, the ablated tissue shrinks and forms an internal scar. The ablation is monitored with duplex ultrasound so that the ablation zone can be identified.

While most studies involve ablation followed by surgical resection, some studies have investigated the safety of ablation only in patients who are poor surgical candidates or who have small well-defined tumors with favorable biology (Luminal A). RFA converts radiofrequency waves into heat by ionic vibration. The ionic vibration is created by passing a high-frequency alternating current from an electrode into surrounding tissues, which causes ions to vibrate as they attempt to follow the change in the alternating current. This vibration generates frictional heat. The heat causes coagulation necrosis and cell death in the tissue. The procedure is performed by placing the RF probe (which is connected to a generator) into the center of a tumor or the tumor bed under ultrasound guidance. The RF probe itself contains a small electrode, and a larger electrode grounding pad is placed on the patient’s thigh.

Figure 51.1. RFA cold water circulated in probe (2 different sizes).

Under imaging guidance, the RF probe is advanced with ultrasound guidance into the center of the tumor after local anesthesia has been administered. The goal is to obtain uniform temperatures throughout the tumor. Both multiprong and single needle probes are available (Figs. 51.1 and 51.2). The single needle probe has internal electrode cooling with circulating water or saline, to cool the tissue surrounding the electrode. The multiprong device has tines that are deployed within the tumor. The ablation involves activating the probe over at least 5 minutes to a target temperature of 100°C for 15 minutes. There is a 1-minute cool-down period before the probe is removed. Some protocols allow for repeat RFA if the cool down is too rapid. Temperature is monitored by sensors during the entire ablation. Thermal injury begins at temperatures above 42°C. Actual cell necrosis is identified at temperatures above 46°C. Irreversible cell death occurs above 60°C.

The ablation zone is most frequently visualized with ultrasonography with spectral Doppler. Doppler ultrasound signals can detect the creation of gas bubbles from tissue boiling. Doppler has the ability to record and visualize the “off gassing” of microbubbles that occurs when the tissue is heated by the RFA to 100°C (Fig. 51.3). Doppler ultrasound is used to determine the width and depth of ablation as well as to make sure that the skin is not injured. The RF probe should be maintained 1 cm away from any structure that is to be protected from ablation (skin or chest wall.) For percutaneous ablations, an aqueous solution can be injected between the skin and tumor or tumor and chest wall in order to achieve this 1 cm

distance.

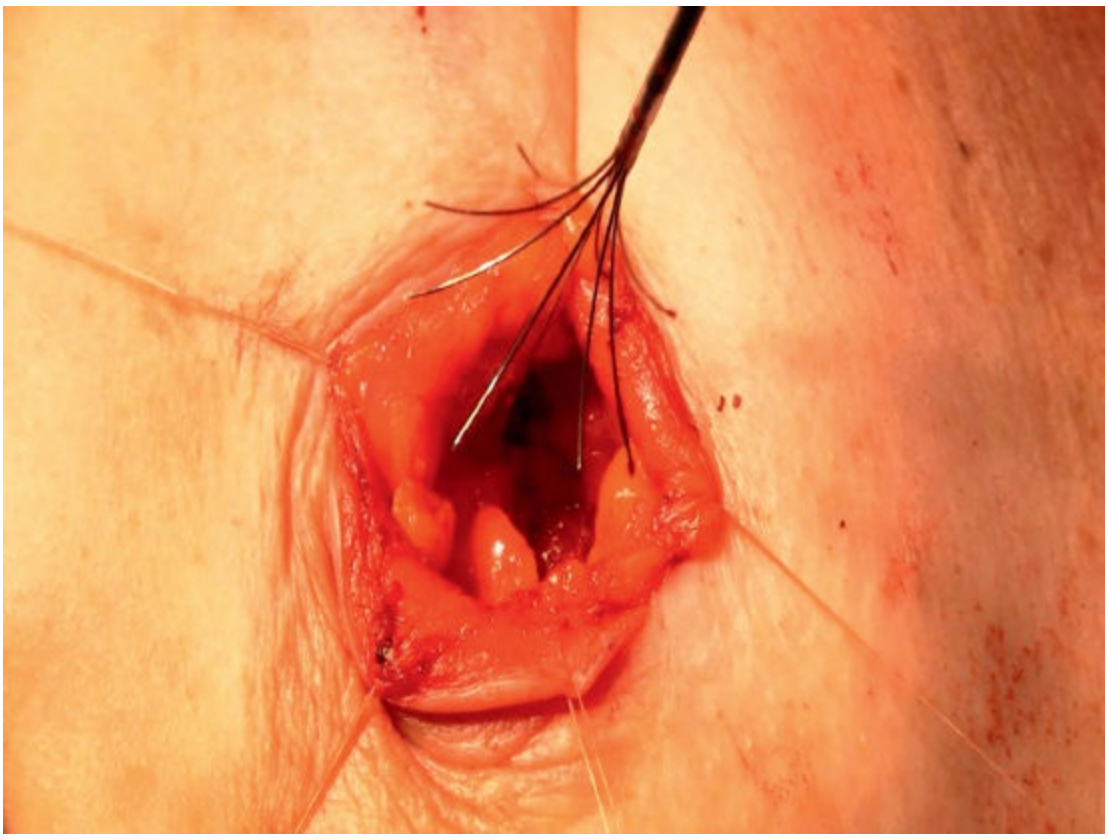

Figure 51.2. Starburst multi-tined RFA device.

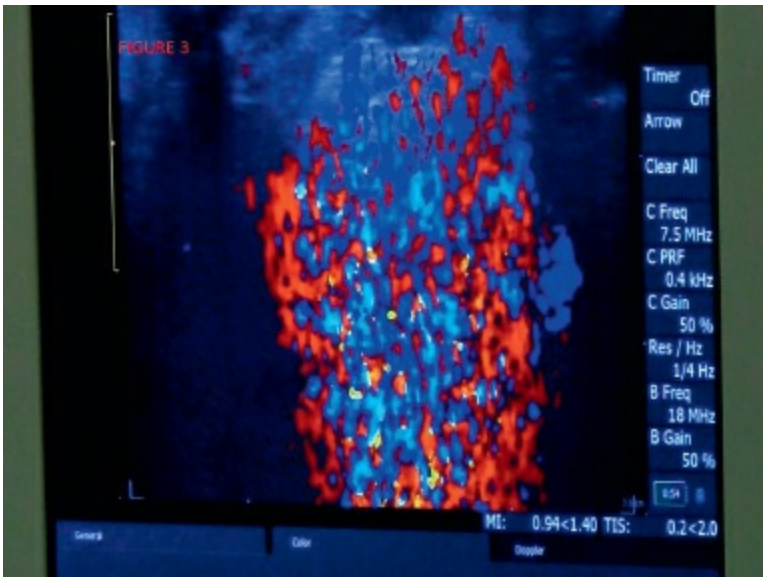

Figure 51.3. Dopplar ultrasound ablation zone.

A novel intraoperative approach is to use RFA for intracavitary ablation after surgical resection of a tumor. In fact RFA is FDA-approved for soft tissue ablation. This application has resulted in a trial known as the

ABLATE I and II Trials (RFA after Breast Lumpectomy Added To Extend intraoperative margins in the treatment of breast cancer). The goal is to assess intracavitary RFA to decrease surgical reexcision rates by extending the final margin after lumpectomy (Fig. 51.4). Primary goals are to estimate reexcision rate for close or positive margins, and to decrease local recurrence rates. Secondary goals of the trial include assessment of cosmesis and quality of life, monitoring the peri-cavitary zone of Doppler enhancement, monitoring complications and side effects, and monitoring ablation effects on postoperative imaging. Other potential benefits of RFA may be to obviate the need for postoperative radiation in the setting of breast conservation. This protocol included women with age ≥50 with invasive cancer or ductal carcinoma in situ (DCIS) with tumor <3 cm and clinically negative axillary nodes. A standard breast lumpectomy is performed with the incision placed over the tumor site. After achieving hemostasis, a purse string suture is placed in the cavity at the level of the previous tumor and brings the cavity together so that the opening is ~1 cm in diameter. A Starburst RFA probe is deployed in the tumor bed so that the tines enter the tumor bed to a depth of 1 cm. Skin is retracted with stay sutures (D). RF probe is activated to 100°C for 15 minutes (Fig. 51.5). Wait for 30 seconds and if the temperature goes below 55°C, an additional ablation at 100°C is performed for 5 minutes. Doppler ultrasound is used to determine the width of ablation zone (Fig. 51.3) and to monitor possible thermal injury to the skin. If necessary, the tines on the RF probe can be retracted to protect the skin. Once the ablation is complete, the RF probe is removed after a cool-down period. If the ablation is intraoperative in a lumpectomy cavity, the cavity is irrigated, hemostasis is obtained, and the cavity is closed.

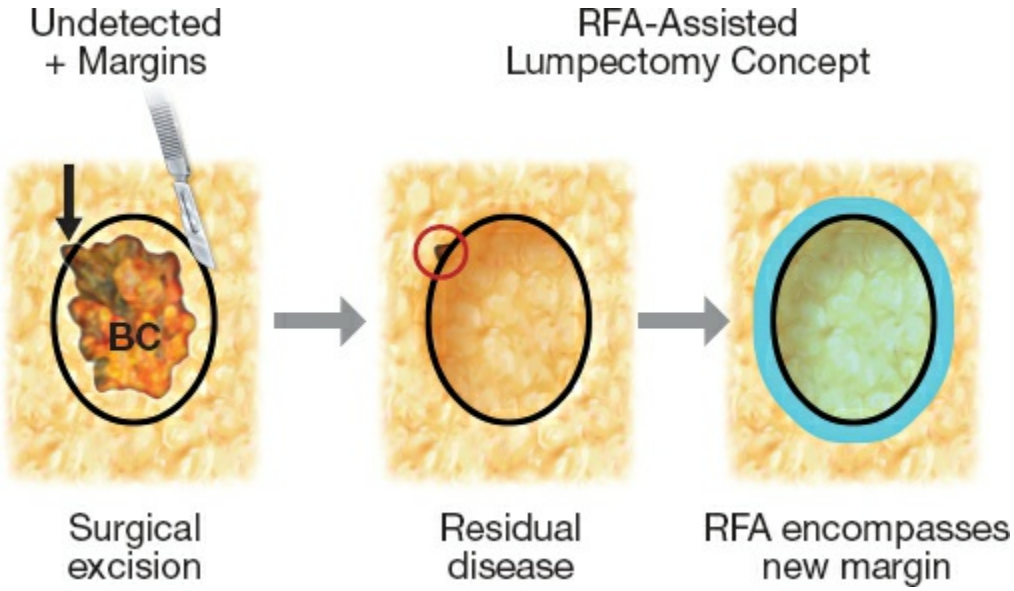

Figure 51.4. RFA-assisted lumpectomy concept.

The role of RFA for benign lesions has not been well-studied. In benign lesions, issues including margins or incomplete ablation are not as concerning and therefore RFA may be an alternative to surgical excision. However, the persistence of a palpable lump that may occur post RFA can be problematic for patients presenting for treatment with a palpable fibroadenoma.

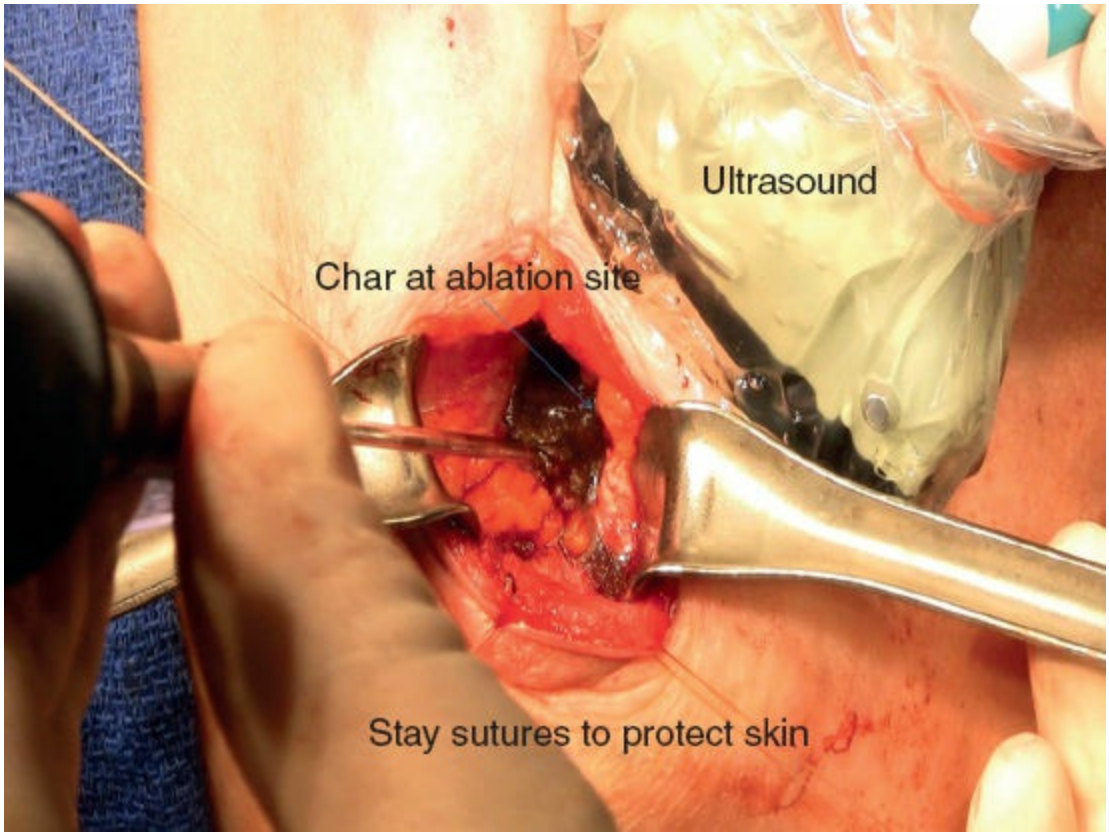

Figure 51.5. Intraoperative radiofrequency ablation of lumpectomy cavity.

Outcomes

Published studies of RFA for breast cancer involve RF for ablation of the tumor followed by either immediate or delayed surgical resection, or ablation of the primary tumor with clinical follow-up only. Some centers have performed RF and followed it with percutaneous biopsy techniques. The first clinical study regarding RFA of breast tumors was published in 1999 by Jeffrey et al. and consisted of 5 patients with locally advanced breast cancer (T3 lesions) who underwent RFA prior to immediate mastectomy. A portion of the tumor was treated, in order to evaluate the zone of RF ablation and the margin between ablated and nonablated tissue. This study was the first to demonstrate that RF ablation caused invasive breast cancer cell death. Subsequent studies (Table 51.2) investigated RF ablation followed by resection. Endpoints were either extent of ablation of target zone, which ranged from 90% to 96%, or extent of cell necrosis, which ranged from 61% to 100%. Cell viability can be assessed with nicotinamide adenine dinucleotide-diaphorase (NADPH) staining or proliferating cell nuclear antigen (PCNA) stains that enable detection of actively replicating DNA, so that absence of PCNA staining confirms cell death. These studies demonstrated that in appropriately selected patients, RF ablation could be done safely with minimal side effects. The patients with residual tumor cells at the tumor site were noted to have preoperative underestimation of tumor size on imaging studies. The efficacy of tumor ablation is dependent on tumor size, with RFA more likely to completely ablate tumors <2 cm. Tumors with extensive intraductal component (EIC) are more difficult to completely ablate. Preoperative MRI helps to select patients who are optimal for ablation. A number of investigators have performed RFA of small breast cancers without resection (Table 51.3). Patients underwent breast imaging follow-up with percutaneous needle biopsy of the ablation zone to assess residual disease or recurrence. Patients selectively received postablation radiation and systemic therapy. Local recurrence detected in 5 out of 125 patients with 15 to 50 months of follow-up. Cosmesis was described as excellent in 83% of cases, good in 12%, and fair in 6%. A palpable hard lump at the ablation site is noted in most patients, which gradually resolves. Infrequent complications of skin or muscle burn, pain, bruising, and pneumothorax have been reported.

Overall RFA outcomes are promising, and there is substantial research developing breast-specific RFA devices that likely will continue to advance this approach.

TABLE 51.3 Studies of Percutaneous RFA Without Resection (With or Without Radiation) and Periodic Biopsy of Cavity

Author/ Year	*N*	Patient Characteristics	RFA-Electrode	Assessment Ablated Lesion	Follow-Up	Outcome	Complications
Susni 2006	3	T1 >75 yo No adjuvant rx	Cool-Tip	US-guided core biopsy	18 months	No local recurrence	None
Marcy 2007	5	T1–2 >70 yo Endocrine and RT	Elecktrotom	Core biopsy	29 months	1 local recurrence	1 abscess
Oura 2007	52	T1 systemic therapy + RT	Cool-Tip	Fine needle aspiration 3–4 weeks postablation	15 months	No local recurrence	1 skin burn
Earashi 2007	7	T1 RT, some systemic Rx	Starburst	Core biopsy	4 months	No local recurrence	None
Brkljacic 2010	7	T1–2, elderly inoperable Endocrine and radiation	Bipolar	Core biopsy	29 months	No local recurrence	2 unrelated deaths
Yamamoto 2010	30	T1 RT and systemic some	Cool-Tip	Core biopsy	17 months	2 patients with viable tumor on core biopsy	None
Palous-siere 2012	21	T1–2, >70 yo Endocrine, no RT	LeVeen	Imaging only-core biopsy if finding	50 months	3 recurrences 2 breast cancer related deaths	None

Klimberg and colleagues published results of the ABLATE I trial in 2014. This was a prospective phase II trial where 100 patients with early-stage breast cancer underwent intraoperative RFA as an adjunct to lumpectomy. Of these, 15 patients had close or focally positive margins of which only 1 was reexcised, and 23 patient received adjuvant radiation. There were six postop complications, including hematoma and infection. With a median follow-up of 68 months, there were five local recurrences (three at the core biopsy site), two elsewhere, and one contralateral recurrence. These results suggest that a portion of breast conservation patients could potentially be managed without surgical reexcision for close margins and avoid radiation. Mammography follow-up (Figs. 51.6 and 51.7) demonstrates how the ablation zone appears post RFA and largely resolves with time and normal breast volume is maintained compared to post adjuvant radiation. The ABLATE trial II is planned that will include genomic profiling with Oncotype recurrence score to help define low-risk patients for this approach.

Cryoablation

Technique

Cryoablation is generally performed with ultrasound guidance in the outpatient setting with local anesthesia under sterile technique. Oral sedation may be necessary for some patients. There is limited experience with MRI-guided cryoablation. The key to successful ablation is having a well-defined visible mass by ultrasound. The long axis of the mass is identified with ultrasound and a 2-mm dermotomy is made with a No. 11 blade after local anesthesia is administered. A cosmetic location, either periarolar or inframammary or lateral skin crease, is chosen for the skin incision if possible. The entire track of breast tissue from the entry site to the mass is infiltrated with local anesthesia. Usually 10 to 20 ccs is adequate. Additional sterile normal saline can also be injected to separate the mass from the skin and/or chest wall if needed to avoid cold injury to those structures. The key to successful ablation is having a clearly visible mass by ultrasound. There has been limited experience with MRI-guided cryoablation. The probe is placed in the tumor under ultrasound guidance (Fig. 51.8), and positioning is confirmed by scanning in multiple planes. Final probe position is determined by the length of the cooling segment. Generally the tip of the cryoprobe will extend beyond the tumor depending on whether treating cancer or a fibroadenoma. The probe is insulated with the exception of the active tip, so there is no risk of cold injury to the skin at the insertion site. The current commercially available cryotherapy systems use liquid nitrogen for cooling, which circulates through a hollow, closed-end cryoprobe. The typical ablation protocol algorithm now involves a rapid freeze–thaw–rapid freeze protocol with target temperature of −160°C. Duration of the procedure depends on the tumor size, but generally is <30 minutes. It is important that the entire lesion is engulfed by the iceball that is confirmed by ultrasound. The treatment time can be extended during the procedure if the mass does not appear to be fully engulfed. The technique of cryoablation is similar for treating fibroadenomas or cancer. However, unlike cryoablation of fibroadenomas, where the engulfment of the lesion while minimizing ablation of surrounding tissue is the goal, protocols for cancer treatment involve treating the lesion and an additional 1 cm margin of normal tissue. Once the ablation is completed, the cryoprobe is removed and the entry site is compressed for 5 minutes. A steristrip is applied. The postprocedure bruising and discomfort are generally mild as the iceball provides some anesthesia and hemostasis. Patients are discharged with oral analgesics with office follow-up in 2 weeks. Imaging follow-up may include

ultrasound for ablated fibroadenomas or MRI and mammography for cancer if surgical resection is not performed.

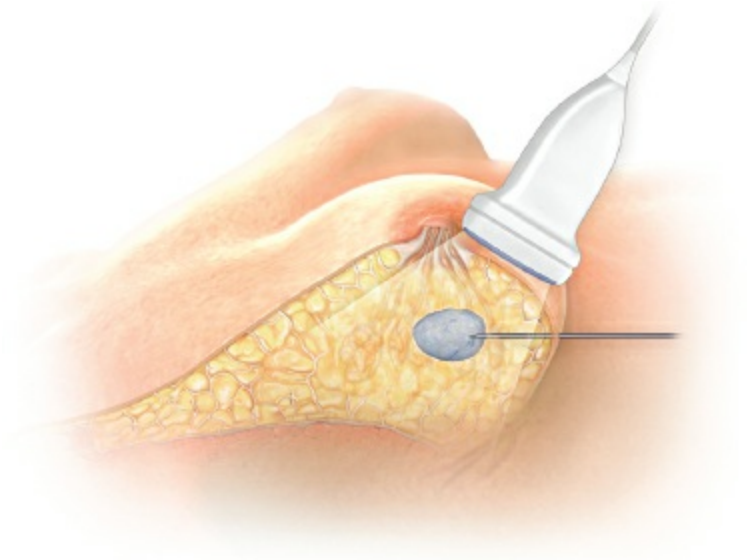

Figure 51.8. Cryoablation of fibroadenoma. **A.** Cryoprobe with ice ball. **B.** Ultrasound image ice ball.

Outcomes

Cryoablation causes cell death by several mechanisms. Closest to the probe, where the temperature is the lowest, there is intracellular ice

formation, cell membrane disruption, and intracellular ice formation. Further away from the probe, there is extracellular ice crystal formation with the increased osmotic concentration causing cell rupture with rehydration. In addition, freezing causes blood vessel endothelial cell, leading to vascular stasis and tissue ischemia, extracellular osmotic imbalance with cell lysis upon thawing, and blood vessel damage and ischemia. Many studies have shown that cells of various organs including breast tissue exposed to at least –40°C during two subsequent freeze thaw cycles are uniformly ablated. Cryoablation for breast cancer was described as feasible in mice by Rand in 1985. Subsequent case reports followed, suggesting that this could be an effective viable method for breast cancer treatment in humans. Sabel in 2004 reported the results of 29 patients treated by cryoablation using a single treatment probe. Tumor destruction was complete in cancers <1.0 cm in size. For tumors >1.5 cm, cryoablation was not reliable. Niu in 2007 reported similar results in 27 patients. In all series, residual DCIS was the most common reason for incomplete ablation. Morin in 2004 demonstrated a 52% complete ablation rate in 25 patients using an MRI-guided ablation approach. Manetti in 2011 reported complete ablation (confirmed by excision) in 14 of 15 patients with unifocal subcentimeter breast cancers. His patients underwent concomitant sentinel node mapping and node excision at the time of ablation to obviate potential concern about accuracy of lymphatic mapping as a secondary procedure after ablation.

Dr. Eisuke Fukuma from Kameda Medical Center in Japan reported his experience with nonsurgical cryoablation in 38 patients with luminal A phenotype, subcentimeter tumors at the American Society of Breast Surgeons meeting in 2012. All patients received whole breast radiation and antiestrogen therapy. At median 29-month follow-up, there were no local or distant recurrences or treatment-related adverse events. In addition, the preliminary results of a phase II ACOSOG Z1072 trial of cryoablation of breast cancer followed by resection were reported at the American Society of Breast Surgeons meeting in 2014 by Simmons et al. This was an ablate and subsequent resection protocol with the patients undergoing MRIs (Fig. 51.9) pre- and postablation. This was a multicenter trial with 87 patients treated at 19 centers. Overall complete ablation was achieved in 63% of patients. A 94% complete ablation rate was obtained in patients with tumors <1 cm. MRI correctly predicted the final ablation status in 75% of the patients.

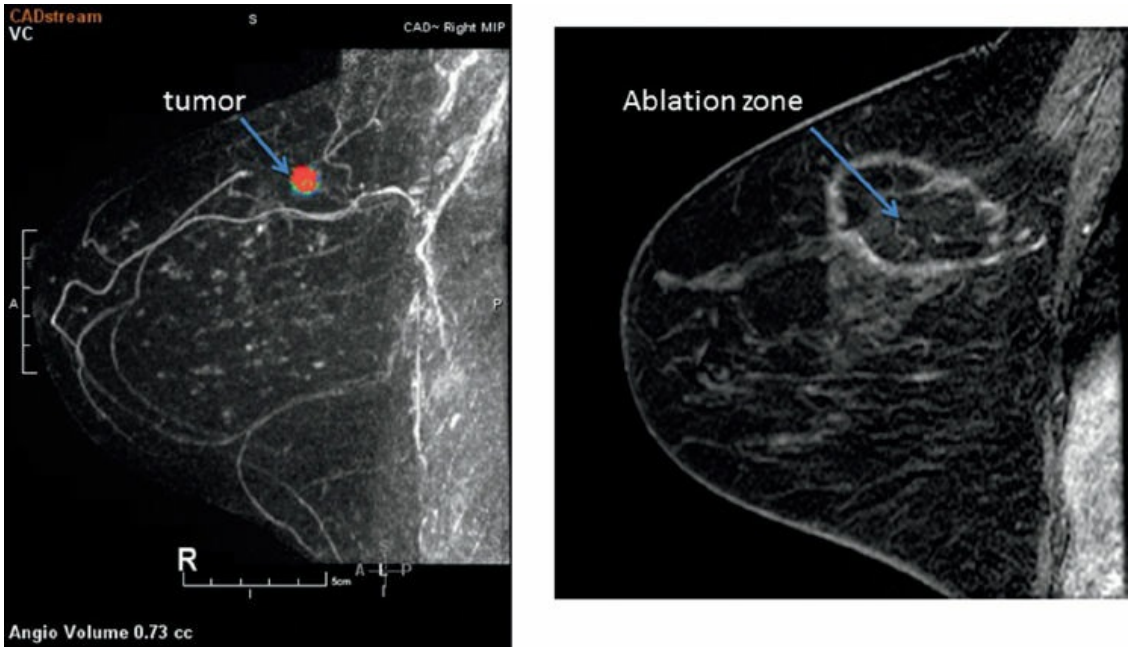

Figure 51.9. Cryoablation cancer (MRI).

There has been more extensive experience with cryoablation of fibroadenomas. Reported experience treating fibroadenomas up to 4 cm in diameter and multiple fibroadenomas shows a high degree of success. Series by Edwards, Caleffi, Kaufman, and Littrup with a total over 500 patients combined demonstrate a 73% to 97% volume reduction by ultrasound at 12 months postablation. Patient satisfaction was reported at >90%. Palpability of a fibroadenoma is often the reason that patients may seek treatment for a fibroadenoma. Postcryoablation there are some patients who do not have complete resolution of the palpable mass. This is more common with fibroadenomas over 2 cm. Ultrasound may demonstrate an ongoing cryolesion. A small number of patients request surgical excision due to ongoing concern about the mass.

Laser Ablation

Technique

Ultrasound-guided ILT (Novilase, Chicago, IL) is performed as follows. The patient is positioned supine or lateral decubitus on the examination table with ipsilateral arm raised and a roll under the chest, similar to positioning for needle biopsy. Ultrasound is performed to visualize the mass, measure maximal dimensions of the mass in both transverse and sagittal axes, measure the skin to mass distance to ensure a safe zone, and identify any neighboring blood vessels for potential heat sink effect.

The skin is sterilized using povidone-iodine; 1% lidocaine is infiltrated into the skin and along the track of the needle for prolonged anesthesia. Care must be taken not to inject excessive amount of lidocaine, which may obscure optimal visualization of the mass. A small incision is made. Under ultrasound guidance, the laser trocar needle is inserted into the breast and mass, with the needle tip at the center of the mass (Fig. 51.10). Its position is verified in both transverse and sagittal views. The trocar is replaced with a laser fiber that extends 2 mm beyond the laser needle tip. There is a thermal sensor at the tip that measures laser temperature. Normal saline tubing is connected to the laser needle, and saline is infused at a rate of 1 mL per minute to cool the laser tip, preventing extreme heating and charring, and to facilitate uniform heat radiation. A second incision is made. A temperature probe containing five evenly spaced sensors is inserted under ultrasound, alongside the needle probe, at the peripheral edge of the mass. The temperature probe measures and monitors peripheral temperatures throughout the ablation procedure to achieve complete tumor ablation.

Laser energy is activated, starting at the power output of 4 watts, and can increase to 8 watts. The rate of saline infusion is increased proportionally as power is increased. Additional lidocaine may be injected if the patient experiences pain. Ablation progress is monitored in real time using ultrasound and temperature readings. Temperature at the laser tip may rise up to 100°C, and shuts off automatically above 100°C for safety. Bubbling may be seen at the laser tip, indicating active heating. As the temperature rises, the tumor, initially appearing hypoechoic, becomes progressively replaced with hyperechoic ablation changes until the tumor outlines are no longer visible. Completion of ablation is determined by both ultrasound visual changes of tumor obliteration, formation of an ablation zone, and temperature criteria. Tissue necrosis is achieved when all five peripheral temperature readings show 60°C or higher, or 50°C for 2 minutes. With currently technology, laser ablation generally takes 1 minute per 1 mm of tumor and thus only small tumors can be ablated.

After ablation, both the laser and temperature probes are withdrawn. The patient remains for 30 minutes for monitoring, and is discharged on a regimen of ice packs and oral analgesics. Patients with ablated cancer return according to trial protocol. Patients who have ablation of fibroadenomas return for clinical examination and ultrasound assessment after 1 week, and at 1, 3, 6, and 12 months.

Outcomes

ILT is a newer technology compared to other ablative techniques, and thus has fewer reports. ABLATE (American Breast Laser Ablation Therapy Evaluation), a Web-based registry, was developed to monitor the effectiveness and safety of ultrasound guided ILT of fibroadenoma in the communities. As part of the registry, we performed laser ablation of biopsy-proven fibroadenoma among 39 patients at New York Hospital Queens, between 2009 and 2011: 56% Asian, 18% White, 5% Black, 18% other, and 3% unknown race. The mean tumor diameter was 10.5 (6 to 18.9) mm. Average treatment time was 14.2 minutes, at an average laser temperature of 60.3°C. Patients were followed for 1 year. Ablation was well-tolerated with a median pain score of 2/10. The median return time to normal activities was 24 hours. Thirty-seven of the 39 patients (94.9%) had complete ablation of fibroadenomas after one treatment as determined by ultrasound imaging. One patient with residual tumor was successfully treated after a second ablation. A second patient appeared to have a possible scar suggestive of residual tumor, which resolved without additional treatment. The most common patient's symptom after ablation was a painless, palpable lump, becoming less noticeable during the ensuing 6 months. Two patients had mild skin scalding, which resolved without significant scarring. Patient satisfaction was recorded on a scale of "Excellent," "Good," "Fair," and "Poor." On evaluation at 1 year, 100% patients reported Excellent-Good overall satisfaction, and 96.8% were satisfied with the cosmesis.

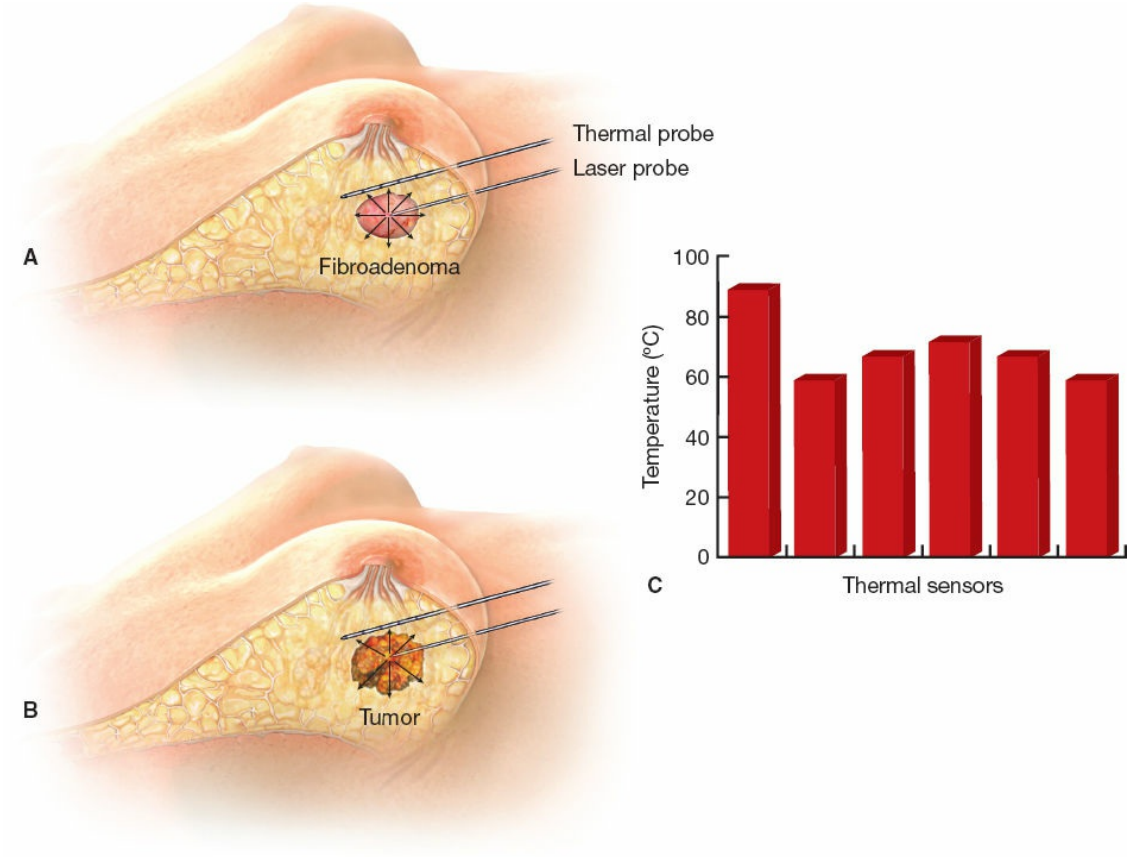

Figure 51.10. Laser ablation therapy of breast fibroadenoma (**A**) and cancer (**B**). Under ultrasound guidance, a laser probe is inserted into the center of the tumor. A thermal probe, containing evenly spaced thermal sensors (*dots*), is placed alongside the laser probe, at the peripheral edge of the tumor. Laser energy is activated and ablates tumor through heat radiation (*arrows*). Ablation progress and completion are determined in real time by observing ultrasound morphologic changes and temperature levels (**C**).

In 2002, Dowlat et al. reported stereotatically guided ILT for breast cancer among 54 patients—50 invasive and 4 in situ cancers, mean diameter 12 (5 to 23) mm. Forty-eight patients underwent excision following ILT. Overall complete tumor ablation was 70%. Incomplete tumor ablation was attributed to technical and procedural challenges during learning curve, such as inadequate laser energy, patient motion, malfunctioning thermal probes and fluid pump, suboptimal target visualization due to excessive fluid infusion or hematoma, and large tumor (2 cm). There were 2 patients who did not have excision and developed oil cysts 6 to 24 months after ILT that were aspirated.

We performed laser ablation of breast cancer at New York-

Presbyterian/Columbia University Medical Center as part of a multicenter trial. Collectively from all centers, 49 of the 61 patients treated had complete data for analysis. The mean tumor size was 11.3 mm, with mean laser time 15.7 minutes. Patients eligible for ILT had pre- and postablation mammograms, ultrasounds, and MRIs, followed by excision for pathologic correlation. Postablation tumor cell viability was determined by MRI and changes in CK8/18, Ki67, and ER. Seventy-three percent patients had complete tumor ablation, with 92% concordance between postablation MRI and pathology. Postablation MRI had 6% false negative with residual tumor <2 mm, and 2% false positive. ILT appears to be a promising method to treat breast tumors.

Microwave Ablation

Microwave Thermotherapy

Microwaves are a form of nonionizing electromagnetic radiation with a frequency higher than radio waves but lower than infrared light. Microwave ovens for heating food were first developed in 1947. Two methods of using microwave energy for breast tumor ablation have been described: focused microwave thermotherapy (FMT) and percutaneous microwave coagulation (PMC).

Focused Microwave Thermotherapy (FMT)

An FMT ablation system consists of three components: a generator, a power distribution system, and antennas. A cooling system is a crucial component of microwave systems to avoid thermal skin injury. MWA utilizes dielectric hysteresis to produce heat. Tissue destruction occurs when tissues are heated to lethal temperatures from an applied electromagnetic field, typically at 900 to 2,500 MHz. Polar molecules in tissue (primarily H_2O) are forced to continuously realign with the oscillating electric field, increasing their kinetic energy and, hence, the temperature of the tissue. Tissues with a high percentage of water (as in solid organs and tumors) are most conducive to this type of heating. Breast tumors have a much higher water content (mean, 74.3%) than benign fibrofatty breast tissue (19.1% to 58.5%) and thus microwave may preferentially destroy tumor cells.

Dooley et al. (2010) reviewed the clinical trials of FMT for preoperative treatment of invasive breast cancer. This method utilized a two-channel 915-MHz adaptive phased-array FMT system (model APA-

1000; Medifocus, Inc) (Fig. 51.11). An investigational device exemption (IDE) was obtained from the FDA for these studies. Using sterile technique, local anesthesia is injected into the breast skin and a 16-gauge catheter is placed percutaneously with ultrasound guidance into the center of the tumor to be treated. A single-use disposable (1.12-mm OD) combination electromagnetic-field focusing sensor and fiber-optic temperature sensor is inserted into the catheter to focus the microwaves and measure the tumor temperature during thermotherapy. The combination sensor has the fiber-optic temperature sensor at the probe tip, and the electromagnetic sensor is 1.5 cm from the tip. The patient is positioned prone with the breast dependent through a hole in the treatment table and the breast is compressed to a thickness of between about 4 and 8 cm, similar to a prone stereotactic biopsy table (Fig. 51.12). Temperature sensors are taped to the breast skin to monitor surface temperature during thermotherapy. Cooling the breast compression plates and skin with room-temperature airflow during FMT treatments helps reduce the potential for skin-surface hot spots. Compression immobilizes the breast tissue to avoid motion. The compression plates are composed of microwave-transparent acrylic plastic material (Fig. 51.13). This system uses transcutaneous opposing microwave waveguide applicators and produces a phase-focused microwave field in the compressed breast to heat and destroy high-water high-ion-content tumor tissue. The effective microwave radiation field encompasses an ~6 cm × 8 cm area in the breast tissue in a plane parallel to the breast compression plates. In the compressed breast thickness dimension, the effective microwave field extends ~1.5 cm on either side of the focal (target) point in the tumor. During treatment, the amount of breast compression, focused microwave power, and air cooling of the skin are adjusted from a computer console to provide patient comfort. Average ablation time is ~30 minutes. Experimental studies support the concept that tumor cell heating for 60 minutes at 43°C is tumoricidal. The period of time to kill tumor cells decreases by a factor of 2 for each 1°C increase in temperature above about 43°C. The cumulative equivalent minutes (CEM) thermal dose relative to 43°C is calculated from the measured temperatures recorded by the sensor in the tumor and also from the sensors on the skin and nipple. Once the desired tumor temperature range and target thermal dose are achieved during active microwave heating, the microwave power is reduced to zero and breast compression is maintained during a 5-minute cool-down period. Ultrasound images are obtained

postablation to assess for tumor shrinkage.

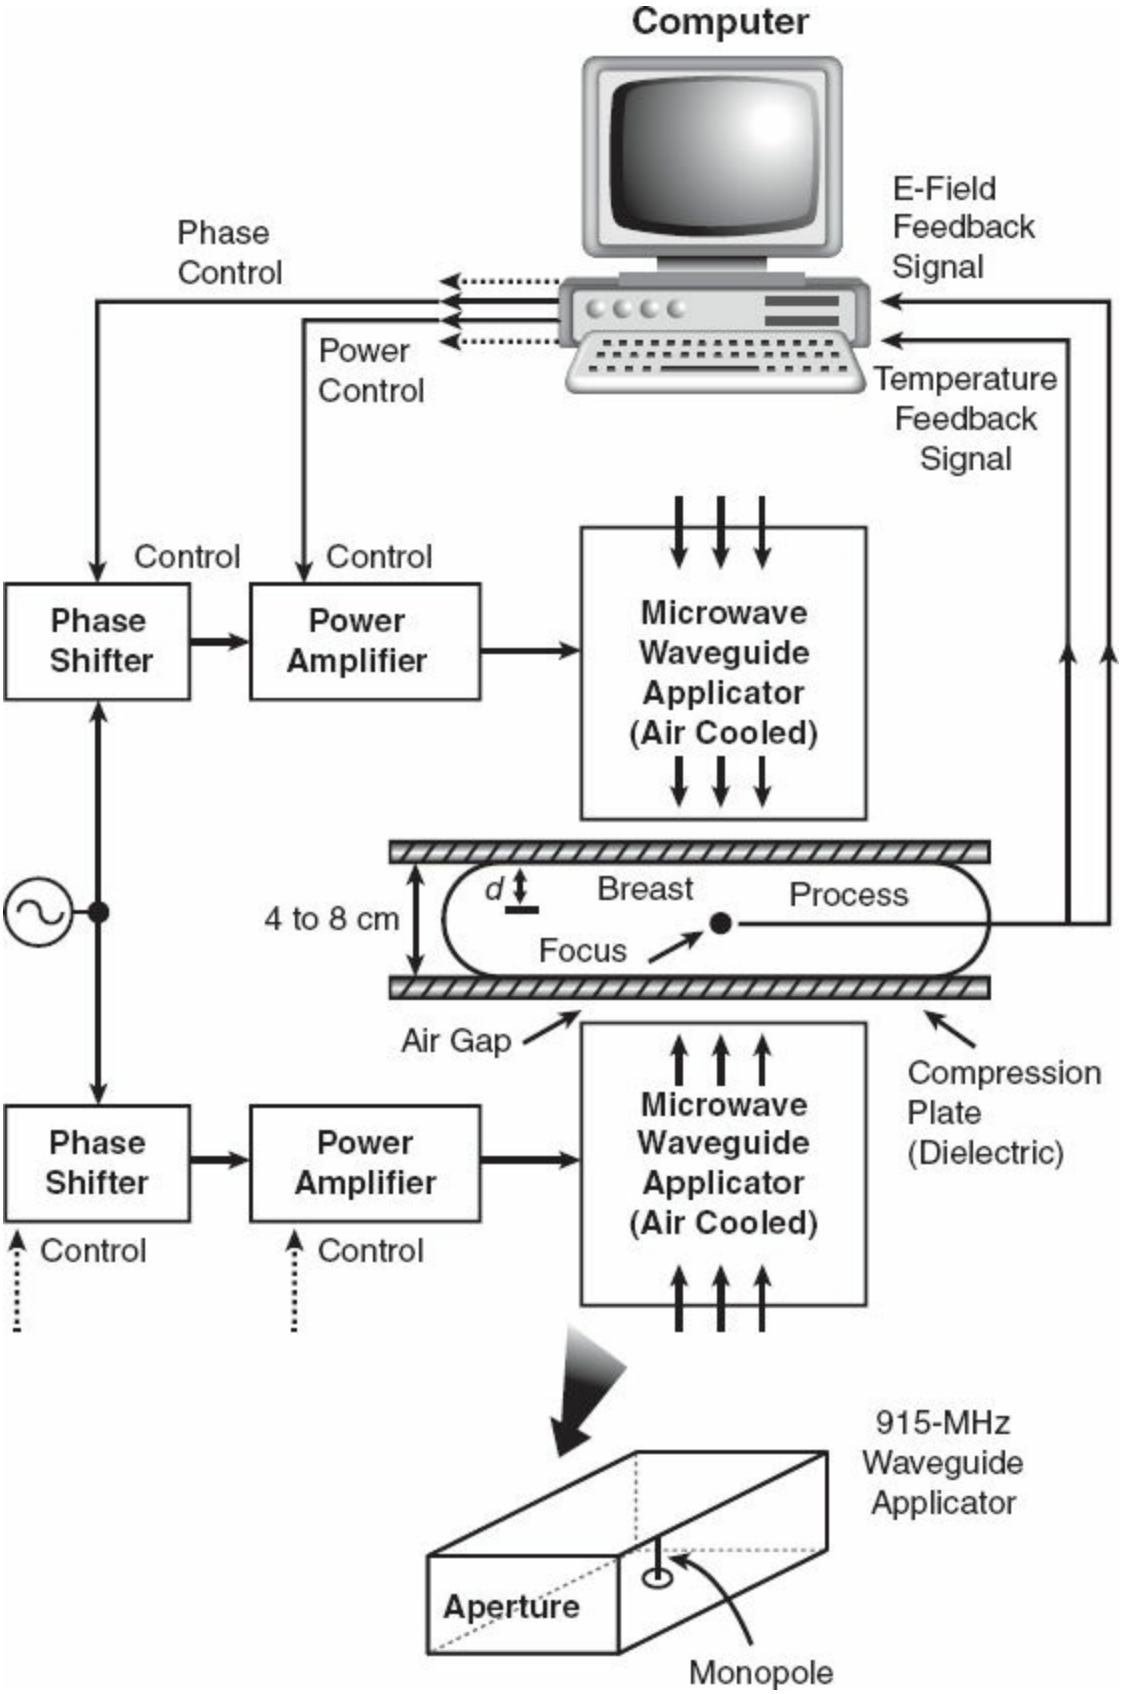

Figure 51.11. Diagram for a dual-channel adaptive microwave

phased-array thermotherapy system for treating breast cancer. The breast-compression plates are made of an acrylic material transparent to microwaves. Air cooling through the rectangular waveguide applicators is used to reduce the skin temperatures. The applicators generate a focused electric-field radiation pattern that will treat a large volume of breast tissue. (From Gardner RA, Vargas HI, Block JB, et al. Focused microwave phased array thermotherapy for primary breast cancer. *Ann Surg Oncol* 2002;9(4):326–32; with permission of Springer.)

Figure 51.12. Patient position on modified stereotactic biopsy table for microwave thermotherapy treatment.

In the first trial of FMT, this technique was used preoperatively prior to mastectomy. In this phase I study, 8 of 10 (80%) of patients with tumors 0.8 cm to 8.0 cm had a partial response as measured by ultrasound or pathology. For the second study, patients were randomized to preoperative FMT versus no preoperative ablation. The FMT thermal dose was increased, and patients were treated prior (5 to 27 days) to breast conservation surgery for early-stage breast cancer (average tumor size 1.7 cm). The results showed that 0 of 34 patients with preop FMT had

involved tumor margins compared to 4 of 41 (9.8%). Three of 34 patients (8.5%) experienced skin burns (<3 cm), and 8 of 34 patients (26%) experienced moderate to severe procedure-related discomfort. The final trial was a study of patients with larger tumors, who were randomized to FMT and neoadjuvant chemotherapy versus neoadjuvant chemotherapy alone. This demonstrated based on ultrasound measurements that there was a median tumor volume reduction of 88.4% (n = 14) for patients receiving FMT and neoadjuvant chemotherapy compared to 58.8% (n = 10) reduction in neoadjuvant chemotherapy alone arm. These studies have demonstrated that FMT can be safely administered with some evidence to support improvement in margin clearance and tumor volume reduction. Prospective randomized trials are required to further evaluate the safety and effectiveness of this promising experimental approach.

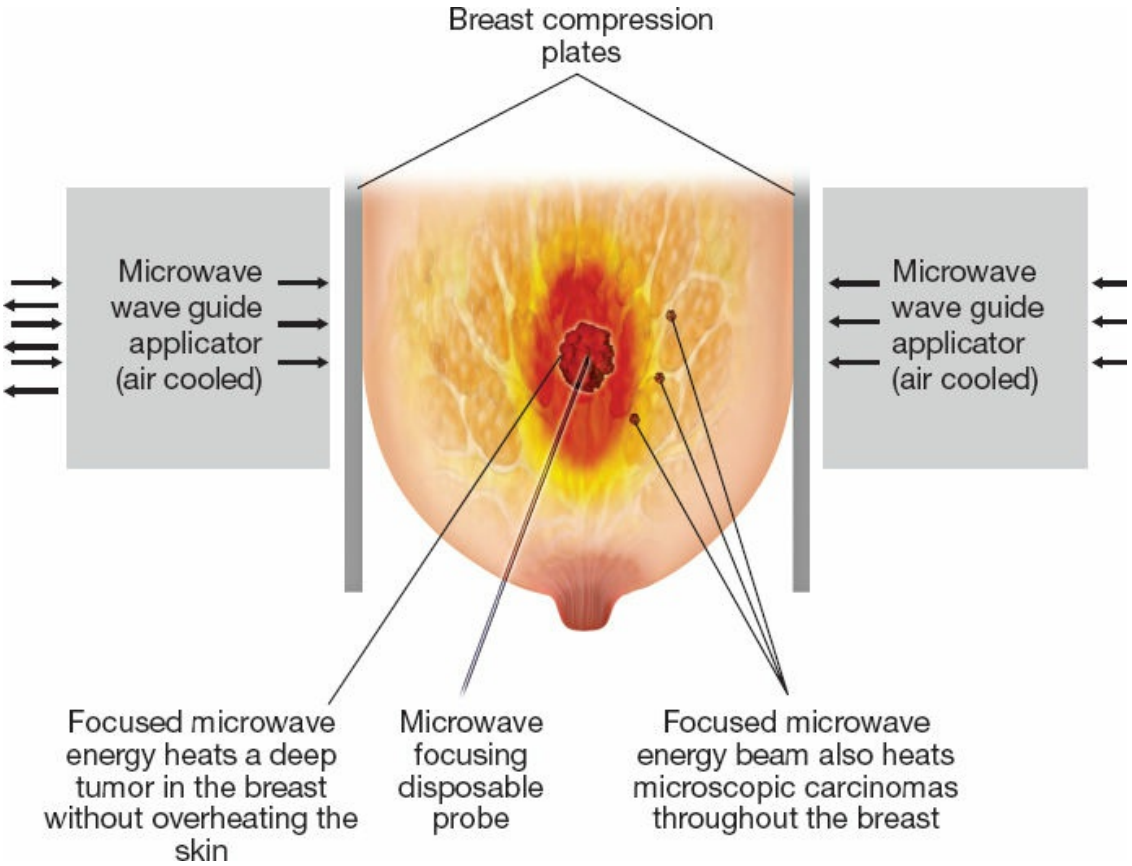

Figure 51.13. APA microwave breast thermotherapy concept.

Percutaneous Microwave Coagulation (PMC)

PMC has been described as an effective approach for the treatment of liver tumors and uterine myomas. It is an appealing method for tumor ablation since it potentially results larger ablation zones with shorter ablation times.

Zhou et al. from Nanjing, China, published the first experience with this method for breast cancer in 2012. This is a nonrandomized study of 41 with ultrasound-guided core biopsy-proven invasive ductal carcinoma <3 cm (mean 2 cm) in maximum diameter. Tumor must have an ultrasound distance of at least 1 cm from the skin and chest wall with patient in supine position. The procedure was performed in the operating room with patients under general anesthesia who underwent PMC followed immediately by mastectomy. A microwave generator with 2,450 megahertz irradiation frequency and 40 watt power output was used. A 2-mm coaxial cable with a water-cooled shaft antenna is inserted percutaneously along the long access of the tumor with ultrasound guidance into the center of the tumor (Fig. 51.14). It is a 2-lumen catheter that allows cooling water (4°C) circulation during the ablation. Peak temperature averages 91°C with completeness of ablation determined by ultrasound monitoring (Figs. 51.15 and 51.16). Ablation time was 3 to 10 minutes (mean 4.48 minutes). Completeness of ablation was determined using alpha NADH-diaphorase staining. Their results demonstrated that 37 of 41 pts (90%) had complete tumor ablation. It is noted that of the 4 patients with incomplete ablation, 2 had extensive DCIS and 2 had suboptimal positioning of the ablating antenna. One patient was noted to have a 1.5-cm skin burn and 2 patients had thermal injury to the underlying pectoralis muscle. Breast MRI was not used for patient selection and potentially could help select patients to avoid issue related to DCIS. Limitation of the study is that patient tolerability and long-term effects concerning pain, fibrosis, recurrence, and ongoing imaging artifacts could not be assessed. This study supports the feasibility of PMC ablation of small unicentric breast cancers. PMC appears to perform quite well compared to the other tumor ablation methods, including FMT, laser, cryo, RFA, and HIFU. Prospective randomized trials will be critical to further evaluate the safety and efficacy of PMC.

High-Intensity Focused Ultrasound Ablation

Technique

HIFU ablates tumors by two mechanisms. HIFU focuses acoustic waves onto a specific point within the tumor, causing focal tissue vibration, thus creating heat and coagulative necrosis. HIFU also causes acoustic cavitation that expands and contracts the gaseous nuclei in cells, leading to the collapse of cells and cell death (Fig. 51.17).

HIFU can be performed under MRI or ultrasound guidance. For MRI-guided ablation, an ultrasound transducer is fitted onto the MRI table top, and generates ultrasound beams that focus onto specific areas of tumor.

Compared with ultrasound, MRI has the advantage of producing more precise and reproducible images of breast tumors, thus facilitating better procedural planning and tumor targeting during ablation. MRI thermometry can also provide temperature measurements to monitor ablation progress. Disadvantages of MRI-guided HIFU include limited real-time imaging, injection of gadolinium, imaging complexity, and high cost that prohibit many surgeons from performing the procedure.

Ultrasound-guided HIFU (Echopulse, Paris, France) has been developed to treat breast fibroadenoma and thyroid and parathyroid nodules in Europe. This technology is currently being reviewed by the FDA for use in the United States.

For ultrasound-guided HIFU ablation of biopsy-proven fibroadenoma, the patient is positioned on the treatment table similar to other ultrasound-guided ablations (Fig. 51.11). An extracorporeal probe (Visualization Treatment Unit [VTU]), containing ultrasound imaging, acoustic treatment, and cooling systems, is applied to the patient's breast. The fibroadenoma mass is visualized. Full 3D treatment volume is calculated using both radial and antiradial slices through the tumor. Acoustic energy level is selected to begin ablation at the center of the tumor, and can range from 102 joules to 249 joules.

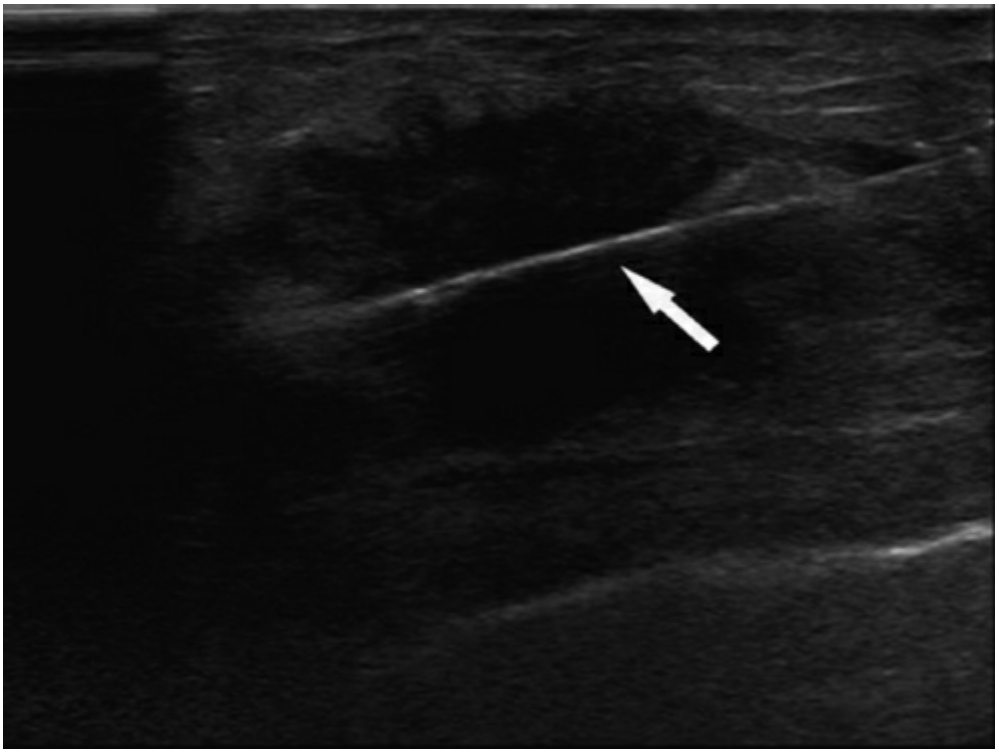

Figure 51.14. Longitudinal sonogram shows centrally placed antenna (*arrow*) in the tumor. (From Zhou W, Zha X, Liu X, et al. US-guided percutaneous microwave coagulation of small breast cancers: a clinical study. *Radiology* 2012;263:364–73. DOI: 10.1148/radiol.12111901.)

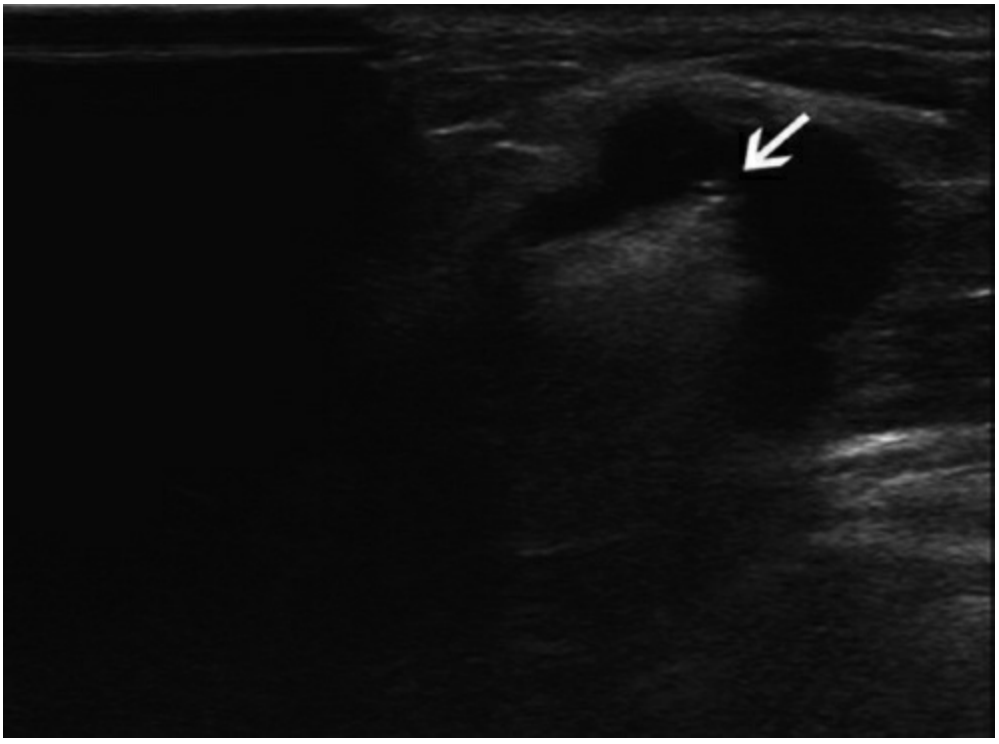

Figure 51.15. Sonogram shows the area with increased echogenicity covering approximately one half of the tumor (*arrow*)

in the middle of PMC session. (From Zhou W, Zha X, Liu X, et al. US-guided percutaneous microwave coagulation of small breast cancers: a clinical study. *Radiology* 2012;263:364–73. DOI: 10.1148/radiol.12111901.)

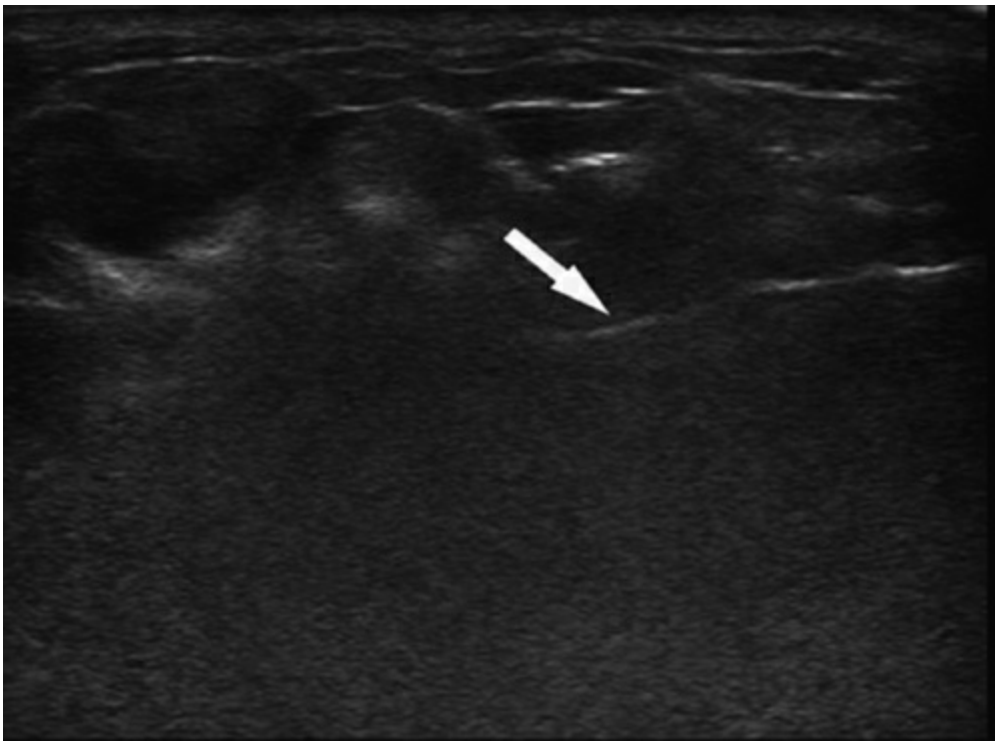

Figure 51.16. Sonogram shows the tumor obscured by an echogenic area, with the antenna (*arrow*) still clearly visible at the end of the PMC session. The sonograms show a gradual and diffuse increase in the echogenicity of the tumor from the irradiating segment to the whole tumor. (From Zhou W, Zha X, Liu X, et al. US-guided percutaneous microwave coagulation of small breast cancers: a clinical study. *Radiology* 2012;263:364–73. DOI: 10.1148/radiol.12111901.)

HIFU energy is activated and delivers the first pulses of treatment, and gradually increases until a hyperechoic mark (HEM) appears on ultrasound image corresponding to the localized boiling point of 100°C. Focal ablation endpoint is achieved by observing both HEM and reinforced interference pattern generated by the HIFU pulse on ultrasound image. Under computer control, the VTU repositions and successively treats other foci until the entire defined tumor volume has been ablated.

Outcomes

Similar to laser ablation, HIFU is a newer technology that is less well-

studied. Initial feasibility studies demonstrated variable complete ablation rates, ranging from 24% to 100%.[6] HIFU is the truly noninvasive treatment modality among all thermal ablations, and thus has the theoretical advantage of no risk of tumor seeding along the needle track, and no risk of bleeding.[7]

Complications of HIFU include burn, pain, and palpability associated with other hyperthermic ablations. Unlike other techniques, HIFU has technical limitations that require patients to be sedated consciously and remain motionless for the long procedure times.[3]

For treating breast cancer using HIFU, Peek et al. performed a systematic review of nine studies up to 2013 that showed complete cancer ablation rate of 46% (range 17% to 100%) on subsequent excision. Twenty-nine percent (range 0% to 53%) had <10% residual tumor, and 23% (range 0% to 60%) had residual tumor between 10% and 90%. Pre- and postablation MRI was found to successfully predict residual disease, with 82% (range 50% to 100%) patients whose posttreatment MRI showed no enhancement. Complications included pain (40%), edema (17%), skin burns (4%), and pectoralis major injury (4%).

Sheng et al. reviewed MRI- and ultrasound-guided HIFU in treating breast cancer between 2002 and 2010. A total of 173 patients whose tumors ranged from 0.5 cm to 6 cm were treated. Complete ablation was achieved in 71% patients determined by excision, 59% by MRI guidance, and 96% by ultrasound. These studies were small, and larger, prospective studies are needed.

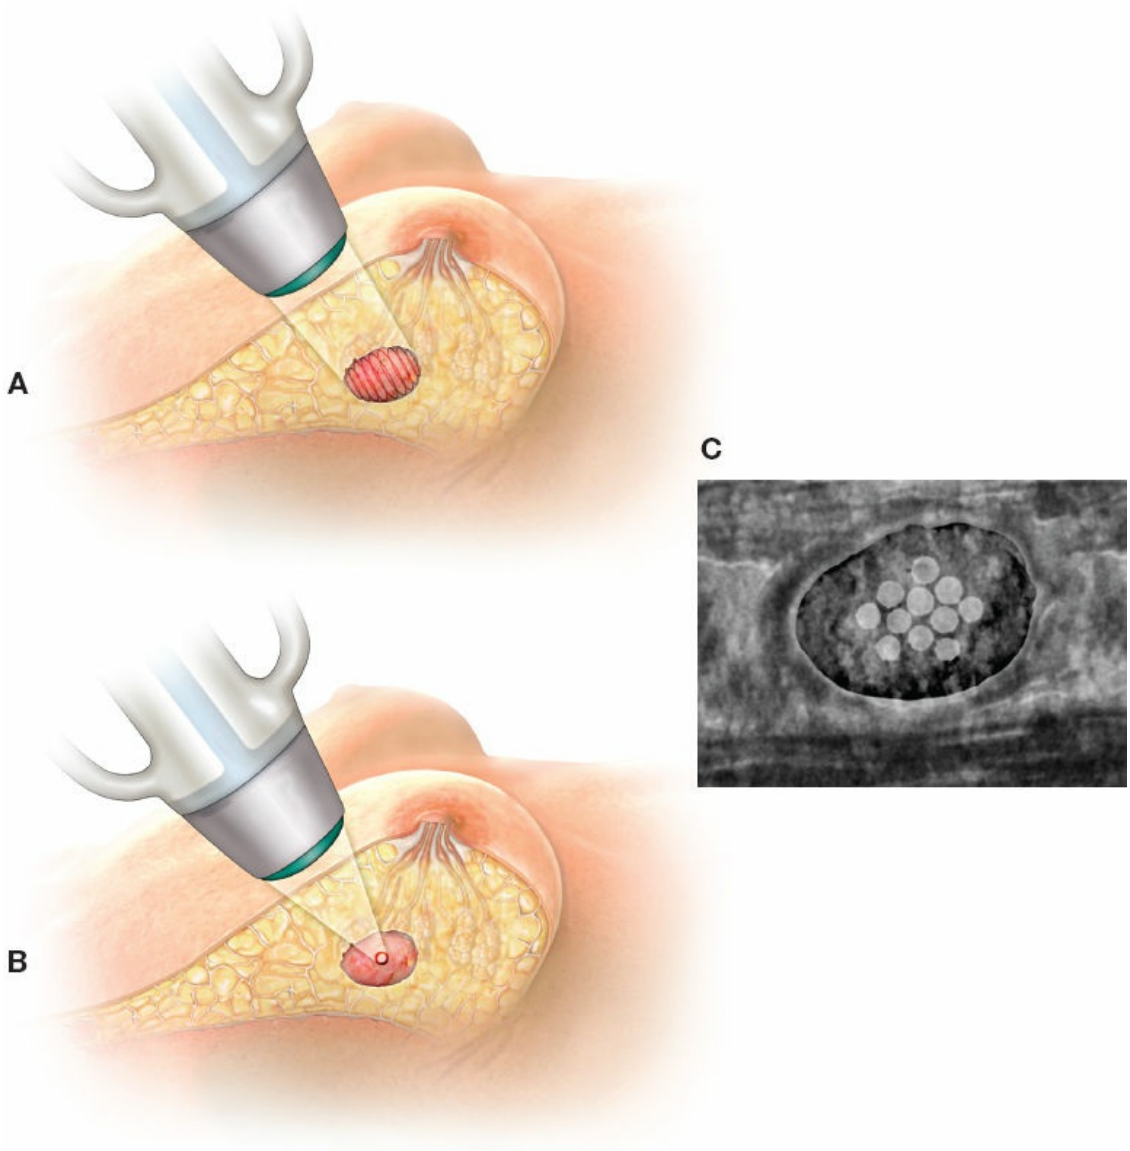

Figure 51.17. High-intensity focused ultrasound ablation of fibroadenoma. **A.** The Visualization Treatment Unit (VTU), containing ultrasound imaging, acoustic treatment, and cooling systems, is applied to the patient's breast to visualize the fibroadenoma. 3D treatment volume of the tumor is determined using both radial and antiradial slices (*ellipses*). **B.** Acoustic energy is focused at the center of the tumor, and is activated to cause tissue ablation. **C.** A hyperechoic mark (*white spot*) appears on ultrasound image after focal ablation. This process is repeated until the entire tumor volume is treated.

Like other ablative techniques, HIFU ablation of breast tumor seems feasible and safe. However, treatment time is longer, and complete ablation rate is variable, possibly due to occult multifocal disease, inadequate tumor volume calculation, and ablation margin imaging.

Continued research is needed to advance this technology and have wider applicability to potentially treat breast cancer.

SUMMARY AND FUTURE DIRECTIONS

The ablation techniques presented in this chapter represent a great deal of work by many dedicated researchers and clinicians toward the goal of improving treatment options for our patients. There is regulatory approval for the use of laser ablation and cryotherapy for the treatment of fibroadenomas in the United States. HIFU has been approved to treat fibroadenomas in Europe. The experience of using ablation to treat fibroadenomas has been as a proving ground toward using ablative methods for cancer. However, unlike fibroadenomas, most breast cancers do not have very well-defined borders and the implication of incomplete treatment can have serious consequences. If ablation fails, then the treatment of a selected favorable small tumor is compromised, so extreme caution in the attempt to advance ablation approaches is warranted. There are no randomized trials comparing ablation with lumpectomy. At the present time, all patients who are treated for breast cancer with ablative methods must be enrolled in clinical trials with informed consent and well-validated outcome measures. Refinement of patient selection criteria and adjunctive postablation therapies including radiation and systemic therapies need to be defined. The ultimate ablation method must be highly effective, well-tolerated by patients, cost-effective, and result in local recurrence rates at least as low as those achieved with breast conservation surgery. The modalities described in this chapter are incrementally moving toward this goal. Combination approaches such as intraoperative ablation to expand margins at the time of lumpectomy and prelumpectomy ablation supplemented with immunomoduling agents may have unique advantages. There is a great deal of work to do to optimize and ultimately define the role of ablation in the treatment of breast cancer. Long-term studies are needed to assess these growing techniques.

EDITOR'S COMMENT

Breast conservation therapy (BCT) is the ideal, yet 35.5% of women choose mastectomy over BCT despite being eligible; 14% to 26% of women receiving BCT but never start XRT; and up to an additional 22% of women receiving BCT but not completing the XRT regimen. The successful demonstration of local therapy alternatives to whole breast radiation therapy (WBXRT) opens new opportunities for BCT patients to achieve positive outcomes without the cost, inconvenience, and morbidities associated with WBXRT or accelerated partial breast irradiation (APBI). APBI and intraoperative radiation therapy that aim to address whole breast XRT's limitations by giving a concentrated radiation dose to a local region, specifically the 1 cm region around the original lumpectomy site, where up to 90% of recurrences occur in a shorter amount of time, have limitations including high cost limiting outreach to smaller communities, variable results, and side effects. Because of this, many have

sought to use ablative tools to improve BCT and/or replace adjuvant radiation. The fact is, for patients with favorable tumors, 84% of patients do not benefit from radiation therapy. In the National Surgical Breast and Bowel Project (NSABP) B-21 patients were randomized to lumpectomy plus tamoxifen, lumpectomy plus WBXRT, or lumpectomy plus both WBXRT and tamoxifen. In the group that received lumpectomy plus tamoxifen and that did not receive WBXRT, the local recurrence rate at 8 years was only 16%. The local recurrence rate was lowered to about 4% if they received both tamoxifen and radiation. Thus, for every 100 women taking radiation, only a few benefit.

Of BCT patients, ~20% to 40% undergo at least one reexcision because an adequate negative margin was not achieved during the initial lumpectomy. Our group hypothesized that radiofrequency ablation (RFA) of breast tissue around the postlumpectomy cavity would reduce reexcision rates for patients with close or positive margins, as well as potentially provide local tumor control without radiation. Used for local control, RFA of the margin avoids damage to nearby organs including the heart and the lung that can occur with WBXRT. RFA is a method of inducing thermal tissue necrosis by using an applied sinusoidal voltage, oscillating between 400 and 800 kHz between electrodes and a dispersive grounding pad (in monopolar RFA) to generate ionic heating, and is currently utilized for the treatment of liver, lung, kidney, and bone tumors.

We initially investigated our RFA by performing lumpectomies in donor mastectomy samples, followed with RFA of the cavity to temperatures of 100°C. The procedure involves purse-string suturing the cavity to a ~1.0-cm volume, then the electrode tines of the radiofrequency probe are deployed into the cavity walls to achieve a circumferential ablation zone that after 15 minutes averages 10 mm in depth from the cavity wall. This preliminary investigation led to a 5-year 100-patient pilot trial including 22 patients with close or positive margins. Of these, 15 (two thirds) did not require reexcision per protocol. Upon follow-up, 2 of 68 patients who received a wide excision followed by RFA alone had a true in-breast recurrence (i.e., two elsewhere recurrences) and 3 had needle biopsy skin recurrences at the core entrance that were not classified as in-breast recurrence, but there were no tumor bed recurrences. Of these skin recurrences, all were successfully resected and WBXRT given. The 5-year disease-free survival rate was 88%. The postoperative complication rate was 6% (wound dehiscence, hematomas, or infection), and the cosmetic outcome on four-point scale was graded as excellent or good in 92% of patients. What was of the greatest interest is the high level of pain documented by patients even 5 years out who did receive WBXRT. This was virtually absent in the RFA-only group. Recently, we have just completed a 250-patient multicenter trial in patients with favorable tumors. An 18-month interval report demonstrated no recurrences with excellent cosmetic results. Final results will be reported as the trial matures.

During cryoablation, the size of the ablation as judged by the “ice ball” that develops can be judged by US. This ice ball has been used as an adjunct to

lumpectomy to try and improve margin excision but in a randomized trial showed no improvement over standard needle localization biopsy. One of the issues that had limited adoption of RFA in breast was the initial inability to determine the progression and size of the ablation zone. We developed a method of Doppler ultrasound that is currently utilized to observe nitrogen off-gassing from tissue motion in the tissue during ablation and therefore gives an estimation of the ablated zone. This is an essential component to the success of breast tumor ablation both primarily and secondarily that is excision followed by ablation. Accurate imaging of the ablated region is necessary for evaluating the clinical endpoint of these procedures, which is achieving a 1 cm region of necrosis around a tumor to avoid reexcision in case of close or focally positive margins as well as to mirror the equivalent area of radiation given during brachytherapy or APBI.

There is a desire to eventually be able to percutaneously ablate tumors. Promising yet experimental percutaneous techniques include RFA, cryoablation, laser, microwave therapy, focused microwave thermotherapy, percutaneous microwave coagulation, and high-intensity focused ultrasound ablation (HIFU). Most trials have <100% ablation of whole breast tumors and especially larger lesions and those that contain DCIS. RFA of breast cancer tumors without surgical removal has also been enthusiastically investigated. However, percutaneous RFA of primary breast tumors has met resistance and has found limited adoption by oncologists, breast surgeons, and patients because ablation of the primary tumor does not allow for complete histologic examination of the tumor and its margin, essentially eliminating tissue banking for molecular profiling and other future therapeutic and prevention options. In a different vain, my group used percutaneous excision of lesions ≤1.5 cm by vacuum-assisted device followed by percutaneous RFA versus laser as an alternative treatment to open lumpectomy. Twenty-one patients were enrolled onto a NIH pilot trial with 15 receiving RFA after percutaneous excision. In this manor, 100% ablation and negative margins were achieved. However, the laser arm was stopped secondary to unreliable ablation zones. Further follow-up studies are planned to determine if percutaneous excision followed by ablation is a reliable option for small favorable breast cancers. The main obstacle to this approach is the skill needed to accomplish both percutaneous excision and ablation and the select group of patients in which it can be accomplished.

Finally ablative techniques have found much more use for the time being in the management of bone disease in women with breast cancer and those with hepatic metastases.

52 Sentinel Lymph Node Biopsy in Breast Cancer

Anthony Lucci, Sarah M. DeSnyder, and Oluwadamilola (Lola) Fayanju

INTRODUCTION

While there is some disagreement on the timing of the first description of the sentinel lymph node concept, there is general consensus that the first report of the modern technique of sentinel lymph node biopsy (SLNB) was made in 1992 by Alistair Cochran and Donald Morton as a less morbid alternative to full lymph node dissection in the staging of patients with early melanoma. It was subsequently adapted to and validated in the axillary staging of breast cancer by Armando Giuliano and colleagues at John Wayne Cancer Center, who published their experience in 1994. For breast cancer, SLNB relies on the principle that the breast drains predictably and preferentially to the axilla, and that within the axilla, there exist guardian or "sentinel" nodes that are the first to receive metastatic tumor cells in the case of dissemination beyond the breast mound (Fig. 52.1). Thus, these sentinel nodes may be seen as reliable surrogates for extent of disease in the axillary lymph node basin, thereby providing accurate axillary staging information without the associated morbidity of an axillary lymph node dissection (ALND). The accuracy of SLNB in the staging of early breast cancer has now been demonstrated in many trials, with false negative rates of <5% and rates of >95% for sentinel node identification reported in the literature. It remains the standard of care for axillary staging in patients with clinically node-negative breast cancer. But even in patients with SLNBs demonstrating metastatic disease, ALND is not always performed: the American College of Surgeons Oncology Group [ACOSOG] Z0011 trial demonstrated that ALND can be safely omitted in clinically node-negative patients found to have only 1 to 2 involved lymph nodes on SLNB, provided they go on to receive post-lumpectomy radiation as part of breast conservation therapy.

Furthermore, clinical determination of node-negative status has moved

beyond physical examination to also include image-guided axillary sampling techniques. Routine use of axillary ultrasound (AUS) has improved detection of microscopic metastatic disease in the axilla of patients with nonpalpable axillary disease. At our institution, sonographically abnormal lymph nodes are subjected to needle biopsy at the time of initial breast cancer diagnosis, thereby facilitating early assessment of nodal involvement that can inform decisions about neoadjuvant systemic therapy without the need for SLNB. However, the availability and accuracy of AUS remain heterogeneous, and SLNB is still recommended for axillary staging in patients with node-negative breast cancer based on physician examination in the absence of reliable axillary imaging.

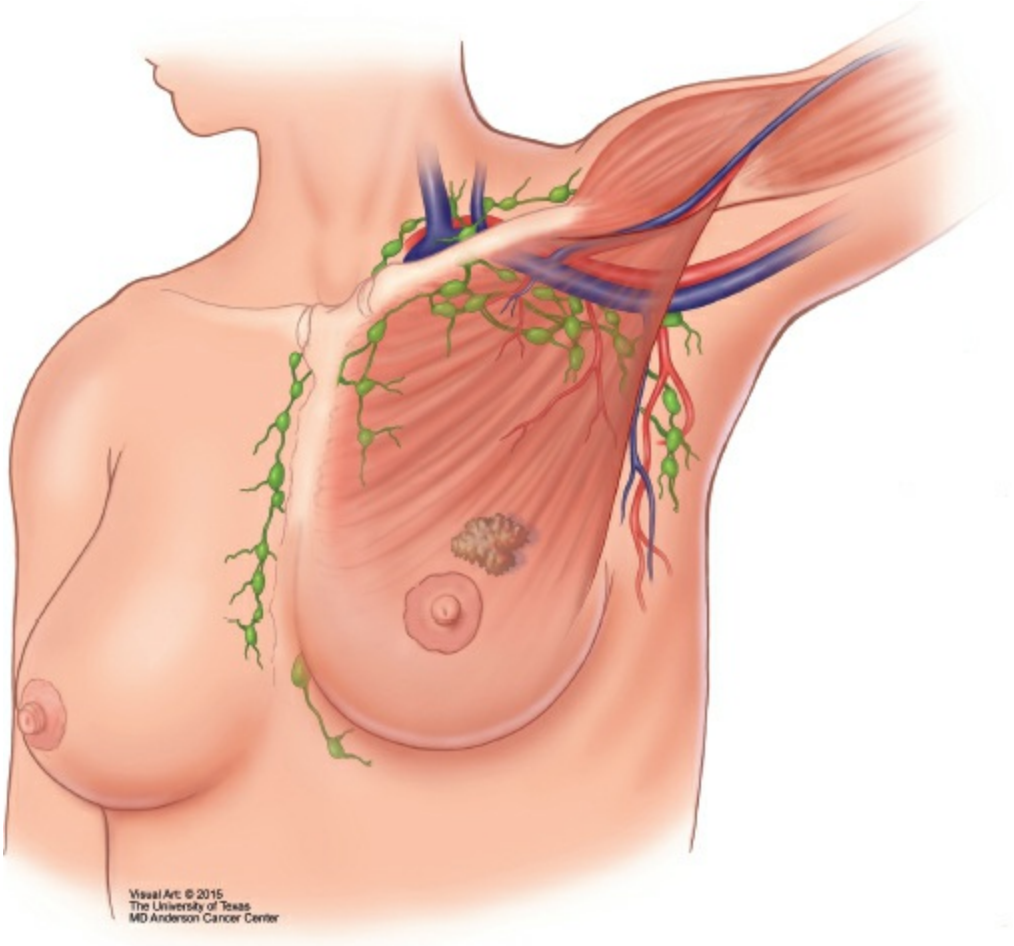

Figure 52.1. Illustration of axillary anatomy demonstrating lymphatic drainage of the breast. (Image © 2015 The University of Texas MD Anderson Cancer Center.)

INDICATIONS AND CONTRAINDICATIONS

SLNB is indicated for patients with nonmetastatic, T1-T3 breast cancer and no palpable lymphadenopathy. It is contraindicated in patients with inflammatory breast cancer or clinically palpable nodal disease regardless of response to neoadjuvant chemotherapy (NACT), though the timing of SLNB relative to systemic therapy remains controversial. At our institution, most patients with node-positive breast cancer receive NACT, but the accuracy of post-NACT SLNB continues to be investigated. Both the ACOSOG Z1071 trial in the United States and the SENTINA study from Austria and Germany demonstrated false-negative rates of >10% in patients with N1 disease prior to NACT, indicating that SLNB alone is not a reliable alternative to ALND in axillary staging after NACT. At institutions where ultrasound-guided needle biopsy of axillary lymph nodes is routinely performed, the results of needle-biopsy prior to NACT can guide therapy without the need for SLNB. If AUS-guided sampling is not available, SLNB can be performed prior to initiation of NACT to determine the likelihood of needing post-NACT ALND. Although there are ongoing trials to improve the selection of post-NACT patients with node-positive breast cancer who might be able to forego post-NACT ALND (see below under “Future Directions”), we continue to recommend that all patients with either needle- or sentinel-node biopsy-proven axillary disease prior to NACT undergo ALND after the completion of systemic therapy.

SLNB can be used in the work-up of early-stage, node-negative male breast cancer, though men are still more likely to undergo ALND as a result of later stage at presentation. There is also some evidence that men with positive SLNBs are more likely than women to harbor metastatic disease in the rest of the axilla. Neither previous augmentation nor prior mammoplasty is a contraindication to SLNB, though lymphatic drainage may be more aberrant, especially if either procedure is performed relatively soon prior to breast cancer diagnosis. Although sentinel node identification may be more challenging after previous axillary surgery due to scarring and aberrant drainage, SLNB can still be performed in patients who have undergone previous SLNB. This approach is associated with low false negative rates. In pregnant women, SLNB has usually been performed with radiocolloid only. Perioperative fetal exposure to radiation —which is already estimated to be very low with radiocolloid—can be further minimized by day-of-surgery injection with low-dose (0.5 mCi) isotope rather than high-dose (2.5 mCi) injection the day before surgery.

Both isosulfan blue and methylene blue are Class C (i.e., unknown teratogenic potential) drugs with regards to pregnancy, but there has been no clear linkage of birth defects associated with the use of either reported in the literature. However, because of the unknown teratogenic potential of the blue dyes, currently at our institution we use radiocolloid only for SLNB in pregnant patients. Pregnant women with breast cancer who are otherwise eligible for SLNB should, therefore, be offered SLNB in the context of extensive counseling as to the theoretical but as yet undemonstrated risks to the fetus.

SURGICAL TECHNIQUE

Successful mapping of the sentinel lymph node(s) is critical to ensuring identification of the sentinel lymph node(s) with minimal morbidity. When SLNB was first described for breast cancer by Giuliano and colleagues in 1994, intraoperative lymphatic mapping was performed using vital blue dye (1% isosulfan blue in the United States; patent blue V in Canada, Europe, or Australia). This blue dye was injected in the peritumoral location of the breast, and the lymphatic channels were identified and tracked to the sentinel lymph node(s). Lymphatic mapping can also be performed using radiocolloid material, most commonly technetium (^{99}Tc)-labeled sulfur colloid. In contrast to blue dye, injection of radiocolloid may occur either in the nuclear medicine suite on the day before or day of surgery or in the operating room on the day of surgery. If injection is performed in the nuclear medicine suite, lymphoscintigraphy can be performed using a gamma camera to document the presence of a “hot” node representing a sentinel lymph node. Infrequently, a sentinel node will localize only to the internal mammary position; given the difficulty of exposure at this site and the risks associated with this dissection, internal mammary SLNB should only be performed by surgeons experienced with this procedure, though in current practice many surgeons find this step unnecessary. Intraoperatively, a handheld gamma probe is used to transcutaneously localize the sentinel lymph node within the axilla. Dual agent mapping has been clearly demonstrated to improve the accuracy of SLNB, but some surgeons utilize these agents selectively. It is important to recognize that surgeon experience is critical to successful SLNB, and in the hands of a surgeon experienced in this technique, dual agent mapping may not be as critical as it would be to a less experienced surgeon. We believe that dual agent mapping is especially important for those patients

who have undergone neoadjuvant systemic therapy, patients who have undergone prior breast or axillary surgery, and patients with recurrent breast cancer.

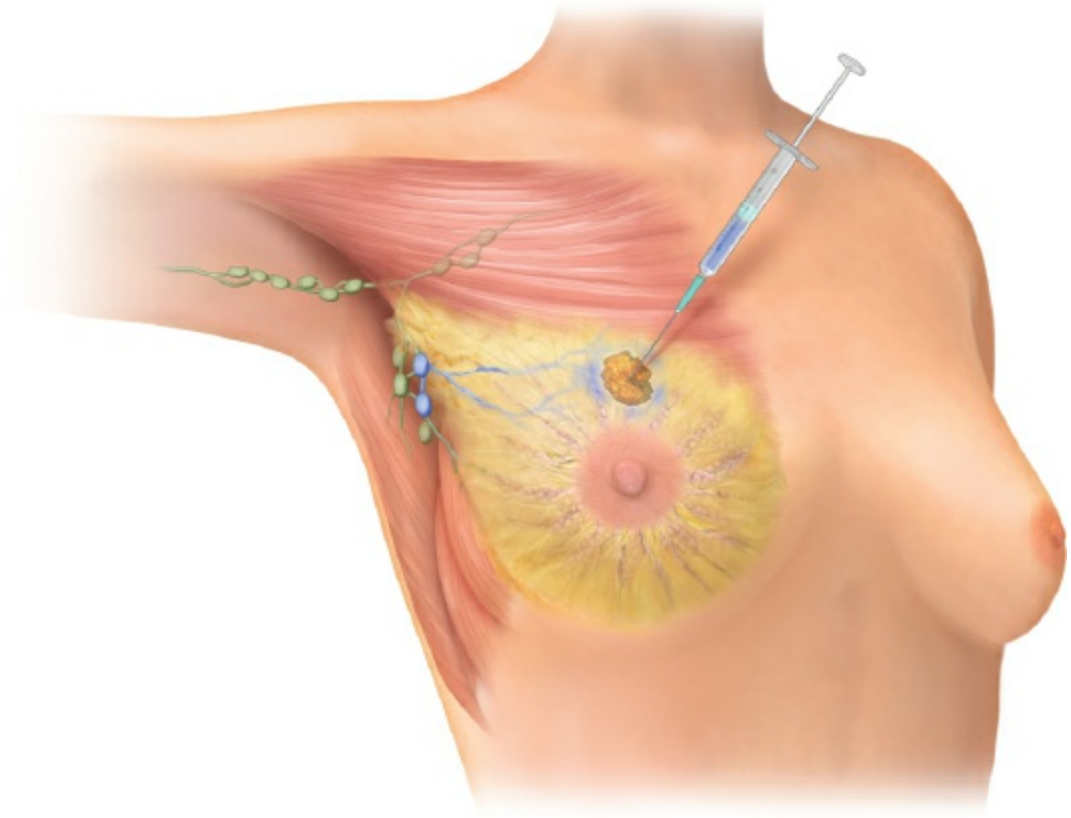

Figure 52.2. Peritumoral injection of blue dye using 25-guage needle.

General anesthesia is utilized for SLNB in our practice. However, this procedure can be performed using monitored anesthesia care consisting of local anesthesia with sedation and analgesia. Prior to injection of isosulfan blue (which is the preferred dye at our institution), the patient is administered a glucocorticoid, diphenhydramine (Benadryl), and famotidine as a prophylactic measure to minimize the severity of any allergic response the patient might have to the blue dye. After the patient is induced with general anesthesia, the breast, chest wall, and upper extremity are prepped and draped in standard sterile fashion with the arm in the field. If radiocolloid was not injected in the nuclear medicine suite, a 25-gauge needle is used to inject low dose ^{99}Tc-labeled sulfur colloid in divided aliquots around the peritumoral position. We use another 25-gauge needle to inject an additional 5 mL of blue dye in the peritumoral position (Fig. 52.2). It is important to inject the blue dye into the breast

parenchyma, as injection into the dermis may tattoo the skin. The breast is then massaged for 5 minutes to facilitate movement through the lymphatic channels to the sentinel node(s).

A small (~2 to 3 cm) transverse incision is made just below the axillary hairline, over the transcutaneous "hot spot" (Fig. 52.3). Dissection through the subcutaneous tissue is carried out using electrocautery and the clavipectoral fascia is opened. If blue dye is used, the blue superficial lymphatics are used as a guide to find the blue sentinel lymph node(s) (Fig. 52.4). A right angle clamp is used to dissect along the blue lymphatic. Care is taken to avoid disruption of the blue lymphatics and thus disruption of the blue guide. A lymph node is considered blue if the blue channel terminates at the node, if the hilum of the node is blue, or if the entire node is blue. When radiocolloid is used as a mapping agent, the gamma probe is used to detect the node(s) with the highest level of radioactivity, that is, the "hot" sentinel lymph node(s) within the axilla (Fig. 52.5). Care must be taken to focus the probe on the axilla and to direct it away from the breast so as to avoid shine-through from the site of peritumoral injection in the breast. The handheld probe is then used to guide the dissection within the axilla. In the event that the sentinel node(s) is located inferiorly or medially within the axilla, it may be helpful to raise the arm over the patient's head to bring the axillary contents to a more superficial position.

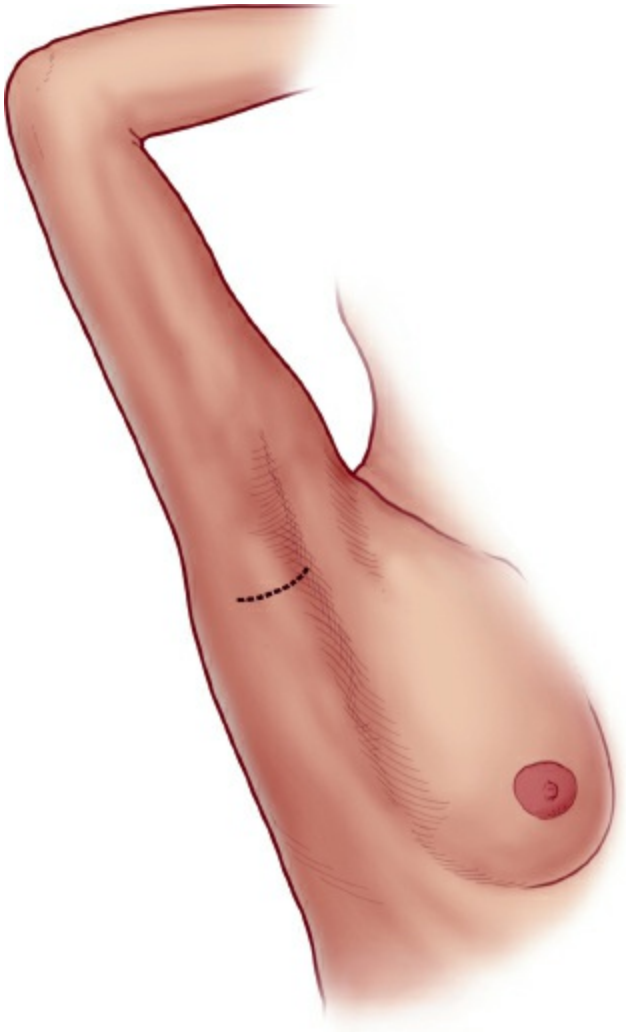

Figure 52.3. Ipsilateral arm is raised over the patient’s head. The incision site is represented by the dotted line.

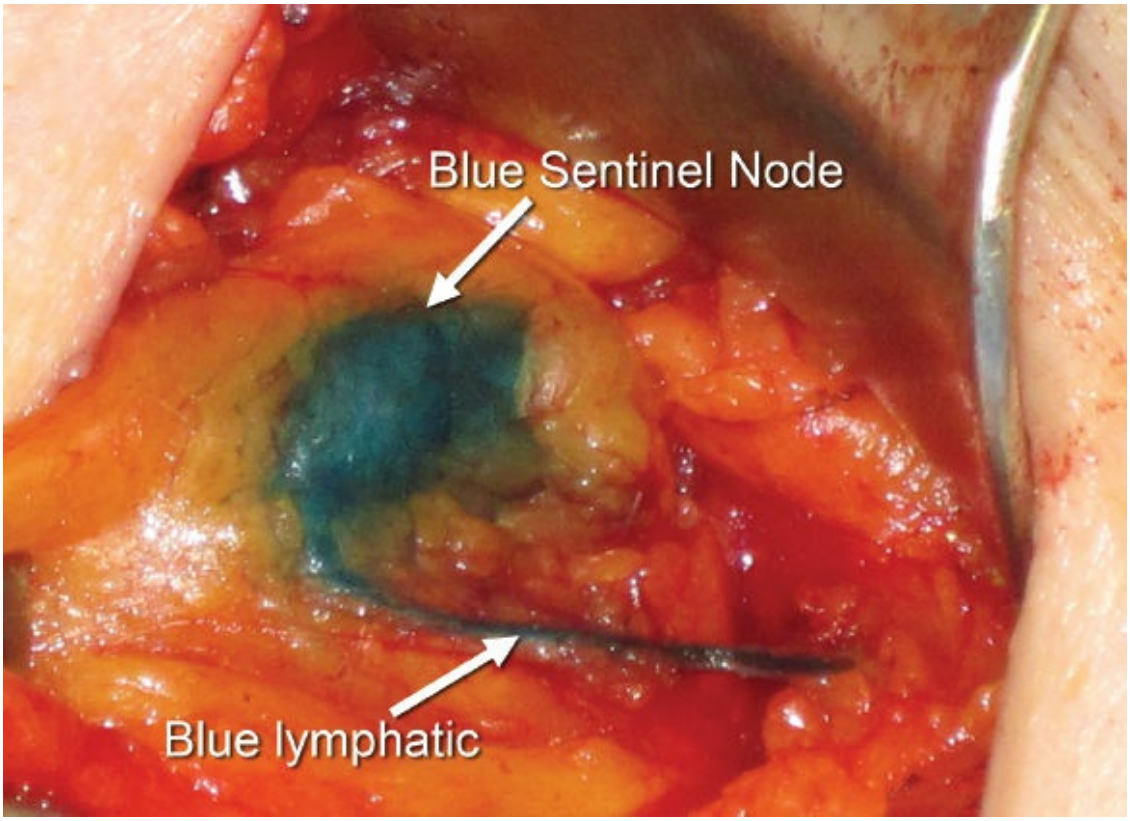

Figure 52.4. Visualization of blue-stained lymphatic traveling to the blue-stained sentinel node.

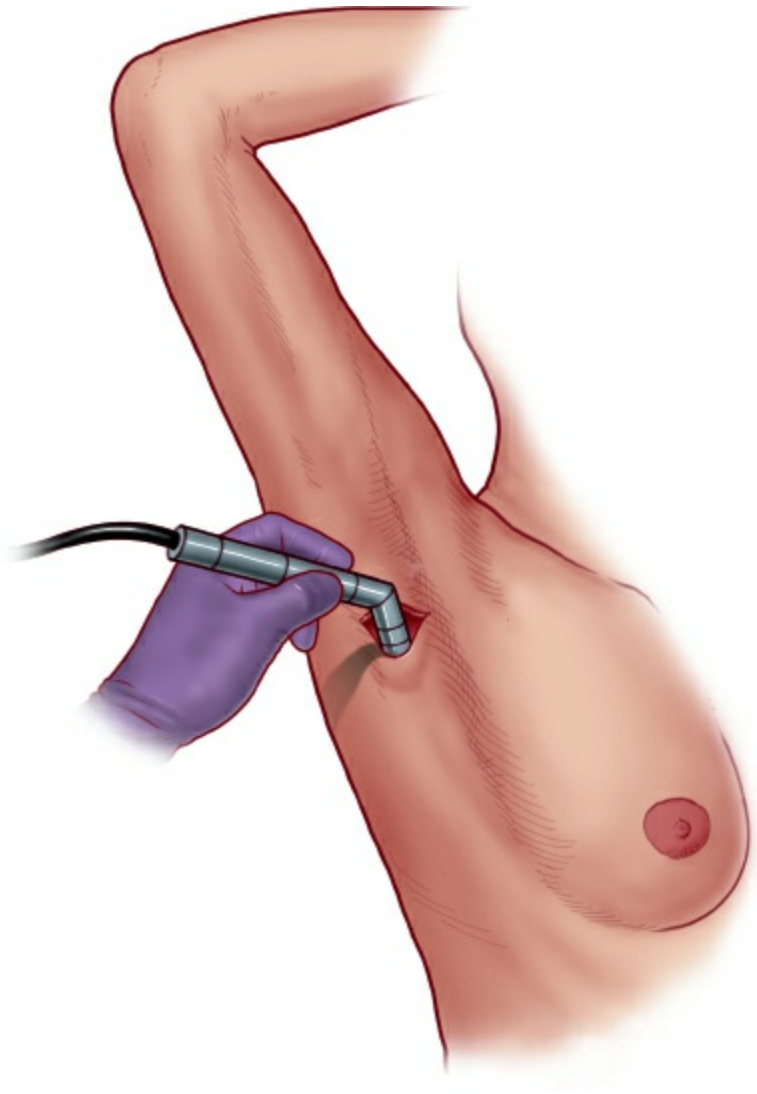

Figure 52.5. Handheld probe detects gamma rays and guides localization of sentinel nodes.

Sentinel node(s) are defined as those nodes that are either “hot” or blue. Nodes that are <10% of the highest ex vivo count with the gamma probe are not considered sentinel nodes. Palpable nodes that are neither “hot” nor blue are not usually considered sentinel lymph nodes, though at our institution we do remove and submit for pathologic evaluation any suspicious palpable nodes identified during the SLNB procedure. After all sentinel lymph nodes have been harvested, the axillary cavity is irrigated and checked carefully for hemostasis. The authors prefer to close the opened clavipectoral fascia with interrupted 3-0 vicryl sutures. The remainder of the incision is closed using 3-0 vicryl in an interrupted deep dermal fashion followed by 4-0 monocryl in a running subcuticular fashion. Dermabond is placed over the incision to complete the closure.

For patients undergoing breast-conserving therapy (and who will

receive whole breast irradiation), sentinel lymph nodes are sent for permanent pathologic examination. For patients with invasive carcinoma undergoing mastectomy, sentinel lymph nodes are sent to pathology for frozen section examination. In pathology, sentinel lymph nodes are bisected and examined by frozen section (for rapid intraoperative assessment) or embedded in paraffin (for permanent assessment), stained with hematoxylin and eosin, and examined for metastasis. If the sentinel lymph nodes are negative, no further surgery is needed. If metastases are identified, the size of metastasis may dictate the need for additional surgery. Nodal metastasis is reported as isolated tumor cells (<0.2 mm), micrometastasis (0.2 to 2 mm), or macrometastasis (>2 mm). Patients with isolated tumor cells require no further axillary surgery as this is considered N0(i+) disease in the American Joint Committee on Cancer staging system. For patients with T1/T2 primary tumors undergoing breast-conserving therapy with whole breast irradiation, patients with either micrometastases or macrometastases in one or two lymph nodes do not require additional axillary surgery as long as extranodal extension is absent. For patients undergoing breast-conserving therapy, patients with either micrometastases or macrometastases and extranodal extension present should undergo completion ALND. Patients undergoing mastectomy who have either micrometastases or macrometastases should undergo completion ALND. Many surgeons utilize a nomogram to determine the risk of additional nodal metastasis when counseling patients and making a decision about the need for additional axillary surgery.

COMPLICATIONS

Although SLNB confers significantly less morbidity when compared with ALND, it is, as with all surgical procedures, associated with some complications. Patients enrolled in the ACOSOG Z0010 trial who underwent SLNB alone had fewer complications, which included anaphylaxis after receiving blue dye for lymphatic mapping (0.1%), axillary wound infection (1%), axillary seroma (7.1%), axillary hematoma (1.4%), axillary paresthesias (8.6%), decreased upper extremity range of motion (3.8%), and objectively measured proximal upper extremity lymphedema (6.9%). Analysis of patients enrolled in the ACOSOG Z0011 trial revealed that patients who underwent SLNB alone had significantly fewer wound infections, axillary seromas, paresthesias, and subjectively reported lymphedema when compared with those who underwent

completion ALND. The Sentinel Node Biopsy versus Axillary Clearance (SNAC-1) trial from Australia and New Zealand also examined the morbidity of SLNB. Complications resulting from SLNB were similar to those seen in previous trials, but patients also had significant recovery from these complications. Notably, this trial included both subjective and objective measurements of arm swelling. The reported rate of lymphedema for patients undergoing SLNB in the SNAC-1 trial was 2.5%. Although the risk of developing it after SLNB is low, lymphedema is a dreaded sequela of any axillary surgery. It is important for patients to be educated not only about the signs and symptoms of lymphedema but also about who to contact if they develop them, as earlier diagnosis of lymphedema is associated with better outcomes after therapy. Stage 0 lymphedema occurs when patients experience symptoms of fluid build-up, such as fatigue, discomfort, and a sensation of heaviness in the absence of swelling. Stage I lymphedema is when swelling is noted, but the swelling can be alleviated with elevation of the arm. Stage II lymphedema is when swelling is present that cannot be relieved by arm elevation. Patients with stage II lymphedema also develop fibrosis of the tissue of the arm. Stage III lymphedema, also known as elephantitis, is when massive swelling is present with fibrosis of the arm tissue and thickening of the skin. The current standard of care for lymphedema is complete decongestive therapy. It is important to note that treatment of lymphedema is intensive, and care of the affected extremity requires a lifelong commitment for afflicted patients. Studies have been undertaken examining the role of axillary reverse mapping (ARM) in the prevention of lymphedema. The ARM technique involves injection of blue dye into the arm to determine if arm lymphatics can be successfully identified and spared during axillary surgery in an attempt to decrease the risk of lymphedema.

FUTURE DIRECTIONS

Preliminary studies are ongoing to determine if localization of the sentinel lymph node using radiocolloid and/or microbubbles followed by image-guided excision of the sentinel lymph node using vacuum-assisted core needle biopsy could provide accurate axillary staging. In addition, the possibility of omitting SLNB in patients with small breast tumors and a negative AUS is also being evaluated in the Sentinel Node versus Observation after Axillary UltrasouND (SOUND) trial.

SLNB remains the standard of care in patients with clinically node-

negative breast cancer, but controversy exists as to its accuracy following NACT, particularly in patients who convert from clinically node-positive to clinically node-negative after systemic treatment. ACOSOG Z1071 showed a false negative rate of 12.6% for SLNB in patients with clinical N1 disease after NACT. This trial resulted in much debate as to how the technique of SLNB in this subset of patients might be improved. Investigators at the University of Texas MD Anderson Cancer Center have published the results of a trial exploring the real-world accuracy of an enhanced form of selective, post-NACT axillary staging called targeted axillary dissection (TAD). Patients with axillary disease at presentation undergo placement of a clip within the node containing metastasis as determined by image-guided needle biopsy. Preoperatively, a radioactive I^{125} seed is placed within the clipped lymph node to facilitate localization at the time of surgery. During surgery, SLNB is performed in standard fashion and the clipped lymph node is also targeted for excision using a gamma probe. In patients who underwent TAD followed by completion axillary surgery, the false negative rate of this approach was 2%. This technique may allow for those whose systemic therapy eradicates their nodal disease to undergo a minimally invasive axillary operation that avoids the significant morbidity of completion ALND.

SUMMARY

SLNB biopsy is an accurate method of staging the axilla in patients with early-stage breast cancer. Patients who are found to have metastasis in the sentinel node(s) are then selected for additional axillary surgery as clinically indicated. Compared with ALND, SLNB is less invasive and associated with significantly less morbidity. Thus, SLNB has replaced ALND as standard of care for axillary staging in clinically node-negative patients. Ongoing studies may result in enhanced techniques that will allow SLNB to become an important component of axillary staging in patients with nodal metastasis at diagnosis who undergo neoadjuvant systemic therapy.

EDITOR'S COMMENT

Sentinel lymph node biopsy (SLNB) was originally described by Krag et al. with unfiltered Technetium 99m sulfur colloid and then by Giuliano using blue dye. Since that time the injectate, method, timing, and patient selection have been a moving target and vary from country to country. Variation of ^{99}Tc includes filtered or unfiltered, nanocolloid or albumin. Isosulfan versus methylene blue dye have been used in Europe and the United States, and indigo carmine has been used in Asia. Lymphoseek® (technetium Tc99m tilmanocept) is a conjugation of the radioisotope and blue dye and seems to work well in small trials (Wallace AM, Han LK, Povoski SP, et al. Comparative evaluation of [(99m)Tc]tilmanocept for sentinel lymph node mapping in breast cancer patients: results of two phase 3 trials. *Ann Surg Oncol* 2013;20(8):2590–9). Others have successfully used fluorescent dyes that require near-infrared fluorescence imaging (just recently FDA-approved) and magnetic particles for sentinel lymph node (SLN) localization (SentiMag® in the United Kingdom, which is not yet FDA-approved). As yet the ideal injectate is not settled, nonradioactive methods will continue to be the subject of development.

Originally, peritumoral injection of radiotracer was used at least 30 minutes and up to 8 hours before surgery. Lymphoscintigraphy is not routinely performed in the United States and does not appear to be particularly valuable, although researchers have developed an intraoperative handheld camera (hybrid single-photon emission computed tomography/computed tomography [SPECT/CT]) that can be used for detecting intraoperative SLN drainage (Serrano-Vicente J, Rayo-Madrid JI, Domínguez-Grande ML, et al. Role of SPECT-CT in breast cancer sentinel node biopsy when internal mammary chain drainage is observed. *Clin Transl Oncol* 2016;18(4):418–25). I use ultrasound of the internal mammary lymph node chain when there is potential for significant aberrant drainage as is seen in recurrent tumors and large inner quadrant tumors with positive axillary nodes. Internal mammary node positivity

is rare when the axillary nodes are negative. Vital blue dye had the advantage of injection after induction of anesthesia. The original multicenter trial, using both blue dye and radioisotope methods, showed that all of the false negatives were in the upper outer quadrant of the breast. So we developed a subareolar injection that would avoid overlap with the zone of diffusion and decrease false negatives and showed it to be accurate and could be injected intraoperatively as well (Johnson CB, Boneti C, Korourian S, et al. Intraoperative injection of subareolar or dermal radioisotope results in predictable identification of sentinel lymph nodes in brest cancer. *Ann Surg* 2011;254(4):612–8). Others have injected dermally or intratumorally and up to the day prior to surgery. After a learning curve period and with experience of the surgeon, it appears that almost anything will work well. Thus, the drainage of the breast itself seems to be more important than where the tumor is sitting within the breast. We have also used axillary reverse mapping (ARM) or split mapping of the arm and the breast so that we can protect the arm lymphatics while performing an axillary lymphadenectomy with extremely low lymphedema rates (Tummel E, Ochoa D, Korourian S, et al. Does axillary reverse mapping prevent lymphedema after lymphadenectomy? *Ann Surg* 2016, May 9. (Epub ahead of print)).

Eleven quality indicators for the performance of SLNB have been identified by a consensus group and include: pathologic evaluation protocol, pathologic reporting by the American Joint Committee on Cancer (AJCC) guideline, protocol for injection of radiocolloid, proper identification of SLN, SLNB performance in eligible patients, SLNB concurrent with lumpectomy/mastectomy, completion of ALND for positive SLNB, SLNB performance in ineligible patients, axillary node positivity rate, number of nodes removed, and axillary recurrence rate (Quan ML, Wells BJ, McCready D, et al. Beyond the false negative rate: development of quality indicators for sentinel lymph node biopsy in breast cancer. *Ann Surg Oncol* 2010;17(2):579–91).

Since the first trials of SLNB, there has been ever-changing parameters of patient selection. According to the updated 2014 American Society of Clinical Oncology (ASCO) guidelines, SLNB is recommended with a limited or good level of evidence for DCIS (with mastectomy), T1 or T2 and multicentric tumors, pregnancy, older age, obesity, male breast cancer, evaluation of internal mammary nodes, prior excisional or percutaneous breast or axillary biopsy, prior nononcologic breast surgery (reduction or augmentation mammoplasty, breast reconstruction), and before or after preoperative systemic therapy. ASCO does not recommend SLNB for T3 or T4 tumors (as there is insufficient evidence although our group routinely uses it), inflammatory breast cancer, DCIS without mastectomy except for large DCIS (>5 cm) on core biopsy or with suspected or proven microinvasion, suspicious, or palpable axillary nodes. Although not mentioned by ASCO, there are just insufficient data on patients with lymphedema precox, extensive injuries or burns or extensive surgeries for hidradenitis who are not good candidates for SLNB. There are minimal data on patients with local recurrence especially in an irradiated field and most

recommend lymphoscintigraphy as this is the circumstance when abberant drainage is most likely to be seen. The risk of nodal metastasis in patients who are clinically node negative is 40%, ~60% if palpable but not suspicious, and ~85% if clinically palpable and suspicious. In my practice, patients with clinically palpable nodes undergo ultrasound and core needle biopsy if suspicious and are not considered candidates for SLNB until after neoadjuvant chemotherapy.

I do not recommend performance of SLNB during prophylactic mastectomies either for genetic mutation or for contralateral mastectomies. In a recent meta-analysis of 14 studies and 2,708 patients undergoing prophylactic mastectomy with accompanying SLNB, the frequency of occult invasive cancer was 1.8% and the rate of positive SLNs was 1.2% (Nagaraja V, Edirimanne S, Eslick GD. Is sentinel lymph node biopsy necessary in patients undergoing prophylactic mastectomy? A systematic review and meta-analysis. *Breast J* 2016;22(2):158–65). The rate of lymphedema for such a group would be 5% to 8% if everyone received an SLNB. The rate for selective ALND after a prophylactic mastectomy for an actual diagnosis of breast cancer would be <1% (1.8% × 11% = 0.198%). In addition, you should only put those patients at risk for lymphedema who might benefit from knowledge of nodal involvement or in prevention of axillary recurrence.

The future will bring additional changes regarding who will benefit from an SLNB only or not at all. Clinically node negative but SLNB positive patients may now be candidates for SLNB only when coupled with breast conservation whole breast irradiation. Ongoing is the Alliance 111202 trial in which patients who are node positive by core needle biopsy and have undergone neoadjuvant chemotherapy are randomized (if still node positive) to radiation versus axillary node dissection. In patients who are node negative, after chemotherapy they receive SLNB alone. Further in an European trial, in those patients who are node negative by palpation as well as ultrasound, the SOUND trial randomizes patients to SLNB versus follow-up alone without surgical intervention. The role of axillary surgery continues to evolve.

53 Lymphedema—Pathophysiology, Prevention, and Treatment

Sarah A. McLaughlin

Lymphedema is a dreaded, poorly understood, underestimated, and understudied long-term complication of surgery and cancer care. It occurs when protein-rich lymphatic fluid accumulates in the interstitial tissue causing swelling generally in an upper or lower extremity. Clinicians caring for cancer patients should understand the clinical manifestations, diagnosis, and treatment of lymphedema because of its relatively high frequency and significant negative impact on the overall patient functional status and quality of life. Lymphedema and other long-term consequences of cancer care remain key issues for the Institute of Medicine as the National Cancer Institute estimates the number of cancer survivors in the United States will increase by 31% from 14.5 to 19 million by 2024.

ETIOLOGY AND PATHOPHYSIOLOGY

The lymphatic system includes both lymphatic vessels and lymphatic tissue. Interstitial fluid composed of protein, water, fatty acids, cellular debris, and micro-organisms is absorbed from the interstitial space into the lymphatic vessels and transported to the venous system as lymph fluid. The superficial lymphatic system drains the skin and subcutaneous tissues and connects with perforating vessels to the deep lymphatic system, which course with the main arterial and venous vasculature. The lymphatic capillaries of the superficial system are larger and more permeable than blood vessel capillaries allowing absorption of interstitial macromolecules. These capillaries cover the entire skin surface but lack valves, therefore propelling fluid only in the direction of lower pressure gradients. The lymphatic fluid is transported via capillaries to pre-collector vessels that may have valves, to collector vessels that are similar in structure to veins, to lymph nodes or lymphatic trunks to the central veins or thoracic duct. The regional lymph nodes of the head and neck, thoracic and abdominal cavities, retroperitoneum, axilla, and groin are considered the major

regional lymphatic basins. The lymph nodes aim to filter and process lymphatic fluid and then produce an immune response.

In the normal state, the function of the lymphatic vessels is dependent on the relationship between lymphatic fluid volume and the vessel transport capacity. When transport volumes exceed capacity or lymphatic vessels are dysfunctional and capacity cannot be maintained, interstitial edema develops. Mechanical insufficiency prevents reabsorption of the interstitial protein and macromolecules leading to the progressive accumulation of fluid and thus lymphedema. Prolonged presence of increased interstitial fluid results in inflammatory skin changes, tissue fibrosis, and adipogenesis. Patients with chronic lymphedema are at risk for recurring soft tissue infections due to stagnant fluid accumulation and cutaneous angiosarcoma due to chronic skin changes.

Primary lymphedema, or Milroy's disease, results from a mutation in *VEGFR3* affecting initial lymphatic fluid absorption and drainage. Secondary lymphedema implies an external stimulus (surgery, radiation, trauma, parasitic infection) has interrupted the drainage pathways. Cancer treatment remains the most common cause of lymphedema in the developed world. Mechanistic obstruction however may be simplistic as the sole etiologic factor for lymphedema as research has demonstrated that women with lymphedema have higher peripheral lymphatic flow (not lower as expected) and this increased flow is witnessed even in the contralateral upper extremity after surgery. Together, these events suggest the development of lymphedema may be systematically driven. Regardless, other genes that may influence lymphedema development include *SOX18, CCBE1, GJC2, GATA2, KIF11,* and VEGFC; however, little is known about genetic influences or predisposition to lymphedema after mechanical trauma.

Advancements in molecular science and lymphedema pathogenesis currently focus on lymphatic endothelial cell specific targets and receptors like VEGF-C, VEGF-D, VEGFR-3, LYVE1, PROX1, and Podoplanin (D2–40). These markers have provided insight into how lymphatic vessels function. Whether these endothelial targets can become therapeutically beneficial or direct lymphangiogenesis remains unclear, but several animal models have exhibited promising results. A further relationship between lymphatic function, immunity, inflammation, fibrosis, and fat is suspected with extensive research into IL-6, CD4, fibroblast growth factor-2, and adipogenesis demonstrating alterations in lymphatic flow and vasculature

function, but the exact mechanisms are also unclear.

Incidence

The precise risk of developing lymphedema has been difficult to ascertain. This problem is complicated by the fact that lymphedema has prolonged periods of latency, months to years, requiring diligent follow-up and consistent reporting among patients and clinicians. In addition, as only a fraction of patients will develop lymphedema, large numbers of patients must be followed. The heterogenous body of literature addressing lymphedema incidence after breast cancer treatment highlights these specific limitations and inconsistencies. In general, the incidence of lymphedema after breast cancer treatment is primarily dependent on the extent of axillary surgery performed. A recent pooled analysis of 6,711 breast cancer patients undergoing sentinel lymph node biopsy (SLNB) found the incidence of lymphedema to be 6.3% with a range of 0% to 23%. A similar analysis of 5,354 patients undergoing axillary lymph node dissection (ALND) found a pooled incidence of 28% (range 11% to 57%).

The variations in incidence are also reflected in several recent therapeutic breast cancer randomized controlled trials. These trials were designed to evaluate disease-free survival and overall survival with respect to differing axillary management strategies. As secondary endpoints though, they each sought to evaluate the incidence of lymphedema (Table 53.1). The National Surgical Adjuvant Breast and Bowel Project B-32 trial identified lymphedema in 8% SLNB and in 14% ALND patients. The After Mapping of the Axilla: Radiotherapy Or Surgery? (AMAROS) trial reported lymphedema in 13% to 23% of patients after ALND and 5% to 11% after axillary radiation therapy when defined by objective or subjective measures, respectively. The National Cancer Institute of Canada-Clinical Trials Group MA.20 trial reported a much lower incidence of lymphedema with only 4.5% of patients developing lymphedema after ALND + standard whole breast radiation while 8.4% of patients having ALND + both whole breast irradiation and comprehensive regional nodal radiation therapy (RNI) developed lymphedema. The EORTC RNI trial had a design similar to MA.20 and found lymphedema rates of 10.5% and 12% respectively in the control and intervention RNI arms. Finally, the American College of Surgeons Oncology Group Z0010 trial found lymphedema in 12% to 24% of SLNB patients and 40% to 41% of ALND patients when using objective and subjective measures

respectively. Collectively, these trials outline the persisting controversies in lymphedema research and lack of consensus with respect to follow-up, diagnostic criteria, and objective and subjective measures as reviewed in Table 53.1.

TABLE 53.1 Incidence and Definition of Lymphedema in Recent Randomized Controlled Trials With Lymphedema as a Secondary Endpoint

	B-32	AMAROS	MA.20(12)	Z10
Definition	>10% RVC	Subjective or >10% RVC	unclear	Symptoms or 2 cm
Length of follow-up (yrs)	3	5	5	5
SLNB	8%		4.5%	Sx: 12% Obj: 24%
ALND	14%	Sx: 23% Obj: 13%		Sx: 41% Obj: 40%
Ax XRT		Sx: 11% Obj: 5%		
ALND and RNI			8.4%	

AMAROS, after mapping of the axilla: radiotherapy or surgery?; SLNB, sentinel lymph node biopsy; ALND, axillary lymph node dissection; AX XRT, axillary radiation; ALND+RNI, axillary lymph node dissection and regional nodal radiation; RVC, relative volume change; Sx, subjective; Obj, objective.

The strong advocacy movements surrounding breast cancer have pushed issues of survivorship like lymphedema to the forefront of clinicians' minds. It has also led to the inaccurate assumption that the risk of developing lymphedema is synonymous only with breast cancer treatment. In fact, lymphedema may occur anytime a lymph node basin is disturbed. Cormier et al. published the most comprehensive review on the incidence of secondary lymphedema after treatment for non-breast cancers. Table 53.2 highlights the incidence of lymphedema according to cancer type. Several conclusions can be made in reviewing these data. First, the incidence of lymphedema varies with cancer type even if the affected nodal basin is consistent. For example, the risk of lymphedema appears to be less after melanoma treatment in the upper extremity than after similar axillary surgery for breast cancer. Second, there seems to be a

higher incidence of lymphedema when the at-risk limb is a lower extremity but again rates differ between cancer types. Third, the overall number of subjects and published manuscripts on this subject matter is far fewer than those addressing breast cancer-related lymphedema (BCRL). As a result, they generally lack large numbers or long-term follow-up, both of which are imperative to accurately determining lymphedema incidence.

A large body of data regarding lymphedema after melanoma does exist and suggests a pooled incidence of lymphedema of 4.1% after SLNB, 3% after ALND, and 18% after inguinofemoral lymph node dissection. Hyngstrom et al. recently published the most contemporary prospective assessment of 182 melanoma patients followed for 12 months after therapeutic lymph node surgery. Using both objective and subjective assessment, similar to breast cancer data they found lymph node dissection resulted in an increased likelihood for lymphedema over SLNB (OR 3.18, $p < 0.01$) and evidence of borderline significance suggesting lower extremity lymph node procedures resulted in a higher risk for lymphedema than upper extremity procedures (OR 1.72, $p = 0.07$). When compared with patients with <5% volume change in their limb, those with >10% difference demonstrated seven to nine times increase in lymphedema-related symptoms of swelling, tightness, and tenderness. Data from the Multicenter Selective Lymphadenectomy Trial I (MSLT 1) prospectively randomized patients undergoing wide excision of a primary melanoma to SLNB or observation alone with the plan that those with a positive SLNB would complete immediate or early lymph node dissection. Those developing regional nodal recurrence would undergo delayed completion lymph node dissection. Again, results from this prospective trial suggest the timing and anatomical site of completion ALND may influence lymphedema risk. With a median follow-up of 5 years, the authors found patients proceeding with immediate/early lymph node dissection experienced less lymphedema than those undergoing delayed lymph node dissection (12.4% vs. 20%, $p = 0.04$). In addition when stratified according to lymph node basin, inguinofemoral dissection was significantly more likely to result in lymphedema than ALND (26% vs. 9%, $p < 0.001$).

TABLE 53.2 Prevalence of Lymphedema in Non-Breast Cancers

Cancer Site	No. of Studies	Incidence (Range)
Head/neck	3	4% (0–8)
Genitourinary	8	11% (1–23)
Gynecologic	22	25% (0–73)
Melanoma	15	9% (1–66)
Sarcoma	1	30%

RISK FACTORS

The etiology of lymphedema remains unclear. As a result, multitudes of studies have attempted to determine risk factors after breast cancer treatment but unfortunately they lack agreement regarding the exact factors and the strength of the association between the specific risk factor and the risk of lymphedema. The extent of nodal surgery, radiation, obesity, infection, and injury remain the most commonly reported risk factors. The ensuing discussion focuses primarily on patients treated for breast cancer as there is a paucity of robust data on lymphedema risk factors in non-breast malignancies. However, it is assumed that many of these principles can be extrapolated to those malignancies as well.

Tsai et al. have reviewed 98 studies and found that lymphedema was more likely after mastectomy compared to lumpectomy (RR, 1.42; CI, 1.15–1.76), ALND compared to no dissection (RR, 3.47; CI, 2.34–5.15), ALND compared to SLNB (RR, 3.07; CI, 2.20–4.29), radiation versus no radiation therapy (RR, 1.92; CI, 1.61–2.28), and for positive versus negative axillary lymph nodes (RR, 1.54; CI, 1.32–1.80). DiSipio et al. also performed a systematic review and meta-analysis of 72 studies published between 2000 and 2012 assessing lymphedema of which 29 met inclusion criteria for risk factor review. Similarly, extensive surgery such as mastectomy, ALND, greater number of nodes removed, or obesity exhibited strong level evidence supporting a relationship with lymphedema development. Collectively these studies used 11 different definitions of lymphedema and exhibited a wide range of follow-up (1 month to 30 years) both of which should temper enthusiasm for the results. Nevertheless, this serves as the most contemporary assessment.

The randomized controlled trials evaluating the efficacy of SLNB to accurately stage the axilla in breast cancer also clearly demonstrate the reductions in lymphedema after SLNB when compared to ALND reporting

rates of 0% to 7% and 12% to 16%, respectively. While the extent of axillary surgery may be the most commonly cited risk factor, this explanation may be overly simplistic. Data by Goldberg et al. suggest it may be the relative degree of lymphatic destruction of each patient's lymphatic anatomy that is more influential in lymphedema development. They prospectively followed 600 SLNB patients and stratified them by mean, median, or range of number of nodes excised and found no difference in the rates of lymphedema ($p = 0.93$) even when >10 nodes were excised at SLNB. Interestingly, when the subset of SLNB patients with >10 nodes removed was compared to women having 10 to 17 nodes removed at ALND, they identified 11% of the ALND and none of the SLNB patients had lymphedema ($p = 0.04$), suggesting that the relative extent of lymphatic damage may have been greater in the ALND group over the SLNB group despite a similar number of nodes removed.

Given that radiation frequently couples with nodal surgery for optimal oncologic treatments and that few studies include detailed descriptions of the radiation treatment fields, it can be difficult to extract the individual or incremental risk of radiation alone. The variations in lymphedema incidence seen in AMAROS and MA.20 (Table 53.1) attest to this fact. When reviewing simply radiation tangets alone, Cormier et al. performed a systematic literature review and reported the risk of lymphedema to be 14.5% after breast or chest wall radiation, 31.5% after breast/chest wall plus supraclavicular radiation, and 41.4% when a posterior axillary boost was added. Shah et al. also evaluated the impact of radiation on 1,861 breast cancer patients who completed breast conserving surgery and whole breast radiation. They found the risk of lymphedema was less than that reported by Cormier ranging from 8.3% to 14.7% according to whether supraclavicular, posterior axillary, or internal mammary nodes were treated. However, patients were significantly more likely to develop lymphedema if they had more nodes removed, extracapsular extension, advanced nodal status, grade III disease, or received adjuvant systemic therapy (all $p < 0.02$).

Less robust data suggest obesity and its associated comorbid conditions may increase the risk for lymphedema. A study of 455 patients treated for breast cancer found an overall rate of lymphedema of 27%. Among those with lymphedema, 92% were found to have an elevated body mass index (BMI) >25 kg/m^2 and their data concluded that obesity was an important risk factor for lymphedema ($p < 0.001$). Ridner et al. evaluated 138

patients with preoperative and postoperative measures in a prospective longitudinal study with 30-month follow-up. They found that breast cancer survivors who had a BMI >30 at the time of cancer treatment were 3.6 times more likely to develop lymphedema by 6 months than those with a BMI <30 (OR 3.6, 1.42–9.04, p = 0.007). Interestingly however, those with an increase in BMI to 30 or greater over the survivorship follow-up period were no more likely to develop lymphedema than those who maintained a BMI <30.

Many of the recommended and practiced preventative measures detailed below focus on reducing the risk of injury or infection to the at-risk extremity in an effort to reduce the future risk of lymphedema. Unfortunately injury and infection after nodal surgery have been difficult to capture and stratify as clear risk factors. Data evaluating patient injury or infection are primarily based on the patient's ability to recall an inciting event. Unfortunately this recall bias subjects the reported data to significant limitations as those affected with lymphedema are more likely to recall infection or injury.

While clinicians acknowledge many risk factors for lymphedema, it is clear that the development of lymphedema is likely multifactorial and includes not only clinical risk factors but also anatomical and genetic predispositions. Little effort has been put forth to individualize patient lymphedema risk, and therefore most preventative measures are widely applied to all at risk and more likely to be applied to those women with a history of breast cancer over other malignancies.

DIAGNOSING LYMPHEDEMA

Diagnosing lymphedema begins with a history and physical examination followed by one or a combination of the following objective and/or subjective measures. Many objective tools exist to measure lymphedema. The ideal tool would be easy to use, cost and time efficient, hygienic, reproducible, and noninvasive. Water displacement is the historic gold standard for limb volume measurement, and the tools are relatively inexpensive. However, it is cumbersome to incorporate into a busy clinical setting given infection control guidelines. More importantly, water displacement while considered sensitive and specific is unable to localize the lymphedema to a particular portion of the extremity (hand, forearm, upperarm, foot, calf, thigh).

Worldwide circumferential limb measurements are the most widely

used method of quantifying lymphedema. A nonstretch, flexible tape measure should be used to perform circumferential measures at specific anatomic points. These measurements are then used to calculate limb volumes using equations for a truncated cone or frustrum. There is no agreement as to the number of or distance between points needing to be measured or what constitutes a key measurement difference between limbs. The literature reports a heterogeneous collection of definitions ranging from 1 cm, 2 cm, and 3 cm differences at a specific point or 100 cc, 200 cc volume differences between limbs or relative volume changes of >10%, >20%. While inexpensive, this method suffers from significant inter-rater and intra-rater variability. As a result, it is ideal to limit the number of clinicians performing the measurements and ensure they undergo consistent training and quality assessment.

Perometry uses infrared light to measure the limb volume at various points. The machine is mounted on a table allowing for the open frame to be moved along the length of the extremity producing output points then creating a volumetric image of the limb. It allows for efficient segmental identification of the limb swelling with minimal to no patient discomfort.

Bioimpedance spectroscopy uses resistance to electrical currents to measure and compare the composition of extracellular compartments within affected and unaffected limbs. Elevations in extracellular fluid volume (including lymph fluid) result in a decrease in the impedance in the affected limb. The commercially available L-Dex device marketed by Impedimed is FDA-approved for the assessment of unilateral upper extremity lymphedema. Small EKG-like gel electrodes are placed on the skin between the areas of interest. The L-Dex device produces a ratio normalizing the contralateral/normal limb. An increase by >10 L-dex units from baseline measurement or a value outside of the normal range may suggest the diagnosis of early-stage lymphedema. The role for bioimpedance remains unclear, but it may be best suited for diagnosing early subclinical lymphedema as circumferential arm measurements or water displacement may have difficulty in detecting subtle changes in arm volumes <150 cc. However, a recent study suggests little correlation between volume displacement and bioimpedance ratios. Other imaging modalities have been suggested to aid in the diagnosis of lymphedema and include lymphoscintigraphy for assessment of lymphatic flow rates and high-frequency ultrasound; however, studies validating these techniques include very small numbers of patients and are generally used only in

research settings. Early data of lymphoscintigraphy suggest it may be reliable reporting sensitivity and specificity of 73% and 100%, respectively.

Several studies use patient-reported symptoms of heaviness or swelling to define and diagnose of lymphedema. Unfortunately little work demonstrates clear correlations between symptoms and objective measures. Patients may report a symptom without meeting a set objective measurement threshold or have measurements beyond the threshold and remain asymptomatic. Arm dominance and weight may contribute to this discordance. However, it could be argued that the patient's symptoms are the most important indicator of lymphedema as it may be these perceptions that will negatively impact quality of life.

Armer et al. sought to determine the best diagnostic method and definition for diagnosing lymphedema. She measured 118 women after breast cancer treatment with perometry, circumferential measures at 4 cm increments, and subjective assessment using validated questionnaires. She used four different definitions of lymphedema, including: 200-mL perometry limb volume change, 10% limb volume change, 2-cm circumferential arm increase, and subjective report of heaviness or swelling "now" or within the "past year" to define lymphedema. At 60-month follow-up, the incidence of lymphedema ranged from 43% to 94% with signs or symptoms or a 10% limb volume change being the most conservative definitions and 2-cm difference being the most liberal definition. These findings and the frequent lack of baseline findings in reported studies support the inability to identify one consistent "best" diagnostic technique or definition. Currently, the National Lymphedema Network does not recommend one measurement technique or definition over another but supports circumferential measures, bioimpedance, or perometry and emphasizes that baseline and follow-up ipsilateral and contralateral measures are critical.

Clearly choosing the method for lymphedema diagnosis can be challenging. Furthermore, clinicians must understand the advantages and limitations to the diagnostic modality chosen. Regardless, it is imperative that measurements begin preoperatively or pretreatment and continue at standardized intervals post treatment. In addition, measurements must be taken in both the ipsilateral and contralateral extremities for appropriate comparisons to be made and account for arm dominance and weight changes that may occur over time.

STAGING AND EARLY DETECTION

Various staging systems are in use to evaluate the severity of lymphedema in the limbs, but the Foldi scale and the International Society of Lymphology (ISL) scale are most commonly cited (Table 53.3). Figure 53.1 demonstrates severe clinical lymphedema. In general, the staging systems agree on the clinical signs and symptoms as well as on the presence of a latent or subclinical stage, whereby lymphatic transport is altered but does not result in clinical symptoms. Many researchers debate the significance of the stage 0 classification as this group may simply represent those at risk for the development of lymphedema. The surge in research devoted to identifying patients with stage 0 lymphedema underscores the trend in lymphedema specialists' perpetual effort to identify patients at the earliest stage possible. Several hypothesis generating studies suggest early diagnosis and intervention may halt or even reverse lymphedema progression. First, Stout-Gergich prospectively followed 196 women after breast cancer treatment setting an arbitrary threshold of 3% difference between arms. If a woman reached this threshold, she was treated with a compression garment for 4 weeks. This resulted in a >50% volume reduction in the affected arm at a mean of 4.8 months. Second, Bar Ad reported on the importance of mild lymphedema demonstrating that 48% of women with mild lymphedema were likely to progress to a more severe form within 5 years if not treated. The best way to diagnose subclinical or early lymphedema remains debatable. Barrio et al. prospectively followed 223 women treated for breast cancer for lymphedema assessing by both volume displacement and bioimpedance. At a median of 18.2 months, 4/25 women with abnormal biopimedance ratios developed lymphedema while 9 additional women developed lymphedema without a prior bioimpedance abnormality. The researchers found poor correlations between volume displacement measures and bioimpedance at 3 (r = 0.31) and 6 (0.21) months and acknowledge that most women with lymphedema did not have a prior abnormal bioimpedance value. As patients rarely exhibit symptoms in this latent phase, diagnosis of subclinical lymphedema without subjecting patients to a more invasive test like lymphoscintigraphy to document lymphatic flow rates is difficult.

TABLE 53.3 Common Staging Systems to Evaluate the Severity of

Lymphedema

Foldi Scale		International Society of Lymphology Scale		
	Clinical signs and symptoms		Clinical signs and symptoms	Severity
0	■ Latency ■ Asymptomatic	0	■ Latent; swelling not evident but altered lymphatic transport	Subclinical
I	■ Spontaneously reversible ■ Pitting edema	I	■ Early accumulation of fluid ■ May subside with extremity elevation	Minimal; <20% volume increase
II	■ Spontaneously irreversible ■ Extensive fibrosclerosis ■ Proliferation of adipose tissue ■ Not reduced with elevation	II	■ Limb elevation no longer reduces swelling ■ Pitting edema ■ Tissue fibrosis in late stage II	Moderate; 20%–40% volume increase
III	■ Elephantiasis	III	■ Lymphostatic elephantiasis ■ Tropchi skin changes ■ Acanthosis ■ Fat deposits ■ Wart-like overgrowths	Severe >40% increase in limb volume

Figure 53.1. Severe lymphedema right arm.

Specialized grading scales exist for the staging of head and neck lymphedema. These have been prospectively validated and similar to the extremity grading scales aim to categorize patients by the extent of swelling and fibrosis but also add the palpable consistency of the tissue as well.

PREVENTION

Prediction

As evidenced by the multitude of studies reporting various risk factors, diagnostic modalities, and definitions for lymphedema, it is no surprise that clinicians are unable to accurately predict which patients will develop lymphedema. As a result, women worry about lymphedema out of proportion to reported risks and long practiced risk-reducing strategies including avoidance of blood pressure, needle sticks, flying, heavy lifting, or tight clothing continue to be recommended to all patients without regard to their individual risk. Furthermore, clinicians lack high-quality evidence supporting or refuting the efficacy of these intuitive, well-intentioned physiologically based activities. The highest quality data regarding risk-reducing strategies come from a subanalysis of the prospectively randomized Physical Activities and Lymphedema (PAL) trial, which reviewed 30 different prevention practices and found only sauna use to be significantly associated with lymphedema risk on multivariate analysis. Regardless, educational strategies focus on all patients treated for breast cancer but are rarely discussed in the context of lymph node removal for non-breast malignancies creating further patient and clinician confusion.

In an attempt to refine and optimize delivery of prevention strategies, several studies have evaluated mathematical models to augment prediction. Bevilacqua et al. developed a nomogram after prospectively following 1,054 women who had ALND for treatment of breast cancer. Concordance indices for the three models when compared to the validation set were 0.70, 0.72, and 0.73 suggesting this may be useful. The nomogram is available for free at www.lymohedemarisk.com. Kim et al. identified the number of nodes removed, adjuvant chemotherapy, and supraclavicular radiation as the key independent risk factors for the development of lymphedema. Using these factors, they created a simple model to aid prediction showing that patients with 0–1 risk factors had a 5-year probability of 3%, 2 risk factors had a 19% probability, while 3 risk factors had a 38% probability of developing lymphedema at 5 years.

Campanholi et al. developed a similar model based in melanoma patients assigning points to individual risk factors, such as graft reconstruction, Breslow thickness >4 mm, ilioinguinal lymphadenectomy, and wound infection. The model score was found to have an area under the curve of 0.82 (95% CI 0.71–0.93) with a sensitivity of 70.8% and specificity of 80%. Although hypothesis generating, none of these models have been widely adopted in clinical practice.

Clinical Trials

The realization that modern systemic therapies reduce locoregional recurrences in addition to distant disease risk has fostered a new era in clinical trial development with respect to axillary surgery. Given that ALND seems to be the biggest driver for lymphedema, these recent clinical trials hypothesize that a tailored approach to axillary surgery or radiation may reduce axillary morbidity and specifically lymphedema without negatively affecting survival. The SLNB randomized trials reviewed above certainly attest to this movement. More recently, the ACOSOG Z0011 trial prospectively randomized women undergoing breast conserving surgery with one or two positive sentinel lymph nodes (SLNs) to either completion ALND or no further axillary surgery. They reported regional recurrence rates <1% in both arms and no differences between the overall survival (91.8% vs. 92.5%) and the disease-free survival (82.2% vs. 83.9%) between cohorts, concluding that SLNB alone in this population was not inferior to ALND. The ACOSOG 1071, SENTINA, and SN FNAC trials evaluated the accuracy and false negative rates of SLNB after neoadjuvant chemotherapy in patients with a positive axillary node at presentation. Collectively these trials find SLNB to be accurate with a false negative rate <10% when dual tracer mapping (blue dye and nuclear injection) is used and more than three SLNs are removed. Based on these data, the ALLIANCE 11202 and NRG B 51cooperative group trials are actively evaluating the role of selective ALND +/- axillary radiation in patients treated with neoadjuvant chemotherapy. Lymphedema is a secondary endpoint. Interestingly however, to date data from Z0011 have not demonstrated a difference in lymphedema rates between treatment arms.

Surgery

Emerging surgical techniques performed at the time of initial axillary

surgery seek to prevent lymphedema. The most widely reported is axillary reverse mapping (ARM), which hypothesizes that the upper extremity has lymphatic drainage pathways separate from the breast and that sparing the arm lymphatics will reduce lymphedema. By isolating the lymph nodes draining the breast with technetium and those draining the arm with blue dye, the surgeon attempts to preserve those draining the arm. Pioneering work done by Klimberg and Boneti has demonstrated variations in arm lymphatic pathways and their relationship to breast sentinel nodes (Fig. 53.2). To date nine studies with more than 50 patients published since 2011 have reported on ARM of which seven reported lymphedema rates, although the follow-up and definition of lymphedema vary (Tables 53.4 and 53.5). Concerns surrounding ARM have been focused on ARM identification rates and the risk of crossover lymph nodes/lymphatics where the breast SLNB is also an ARM node. Salvage of the efferent blue ARM lymphatics is critical to maintain drainage but may be challenging in axillae with heavy tumor burden. Review of the current literature suggests increasing rates of ARM node identification with ALND likely secondary to increased exposure and dissection when compared to SLNB. Currently reported ARM node crossover rates in ALND patients range from 7% to 49%. Most importantly, however, the rate of lymphedema appears to be <10% after ALND when the ARM nodes can routinely be saved. Although longer follow-up is critical to validate these findings, these results are optimistic.

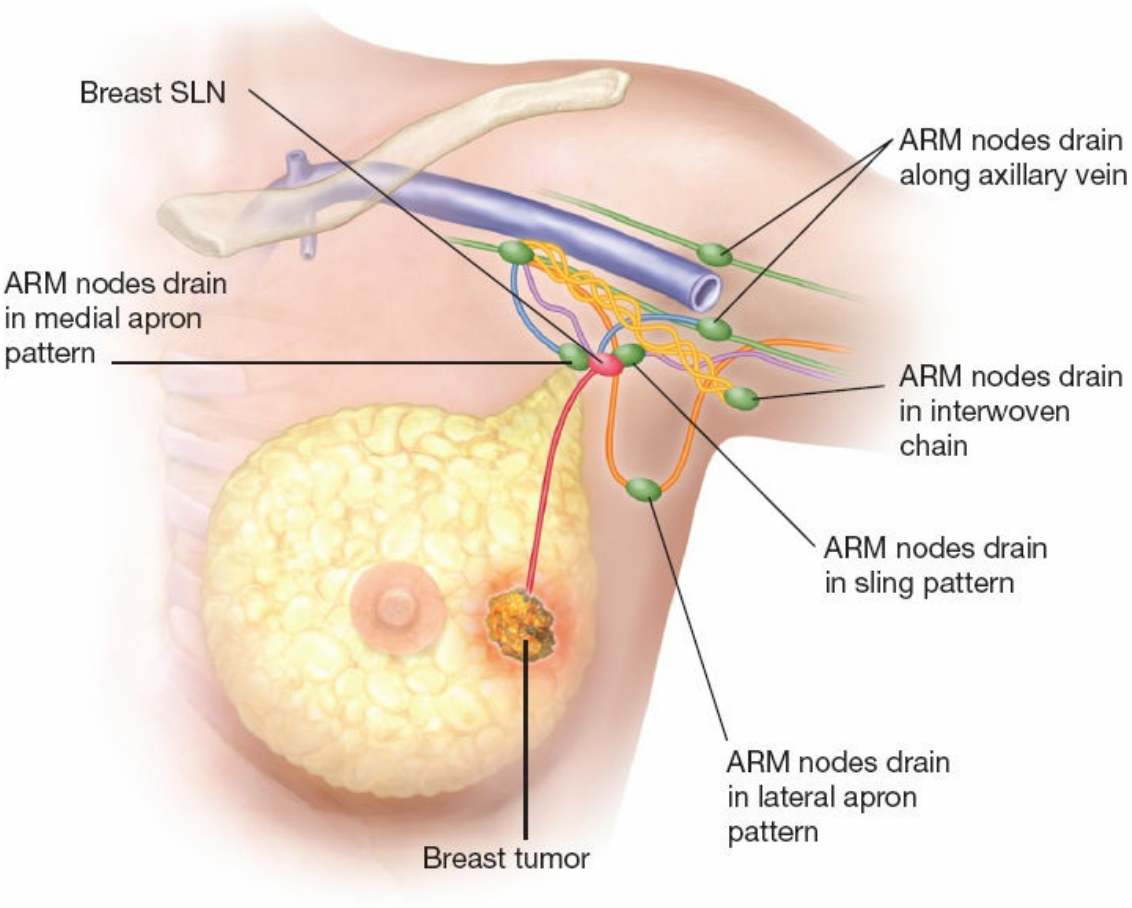

Figure 53.2. Five variations in upper extremity lymphatic drainage as demonstrated by axillary reverse mapping (ARM) and their relationship to the breast sentinel lymph node (SLN).

TABLE 53.4 Summary of Axillary Reverse Mapping (ARM) Outcomes in Patients Undergoing Axillary Lymph Node Dissection

Study	N	ARM Node Identification Rate	Crossover Rate[a]	Metastatic Disease in ARM Node	Lymphedema Rate[b]	Definition of Lymphedema	Follow-up (mos)
Ikeda	60	48/60 (80%)	NR	7/48 (15%)	NR	NR	NR

While ARM aims to preserve arm lymphatics, surgeons performing lymphatic microsurgical preventive healing approach (LYMPHA) seek to identify arm lymphatics in the ALND field, then perform lymphatic to venous anastomoses via “dunking” microsurgical techniques in the presence of a competent venous valve (Fig. 53.3). Boccardo et al. first published this method in 2009 and recently reported their 4-year follow-up. Defining lymphedema volumetrically and with lymphoscintography, they demonstrated an ongoing lymphedema rate of 4% (3/74 patients) at 4 years follow-up after ALND that increased to 10.5% when they expanded their definition to include patients with transient postoperative lymphedema. Interestingly, lymphoscintography performed postoperatively demonstrated patent lymphovenous anastomoses in the remaining 71 patients at 1 to 4 years follow-up. Feldman et al. successfully completed LYMPHA in 24 patients and followed them for 26 months. They performed an average of 1.5 anastomoses per ALND patient and defined lymphedema as a combination of abnormal L-Dex bioimpedance ratios, arm measurements, and clinical symptoms. They reported an ongoing lymphedema rate of 8%, which increased to 12.5% when those with transient lymphedema were included. Regardless, this rate is much improved when compared to their own institutional historical cohort where 30% of women were diagnosed with lymphedema after ALND. Together, these studies suggest a benefit to immediate lymphovenous anastomosis (LVA) during ALND; however, the added cost, impact on operative time, and need for specialized microsurgical training must be considered for LYMPHA if the technique is to be adopted for all ALND patients.

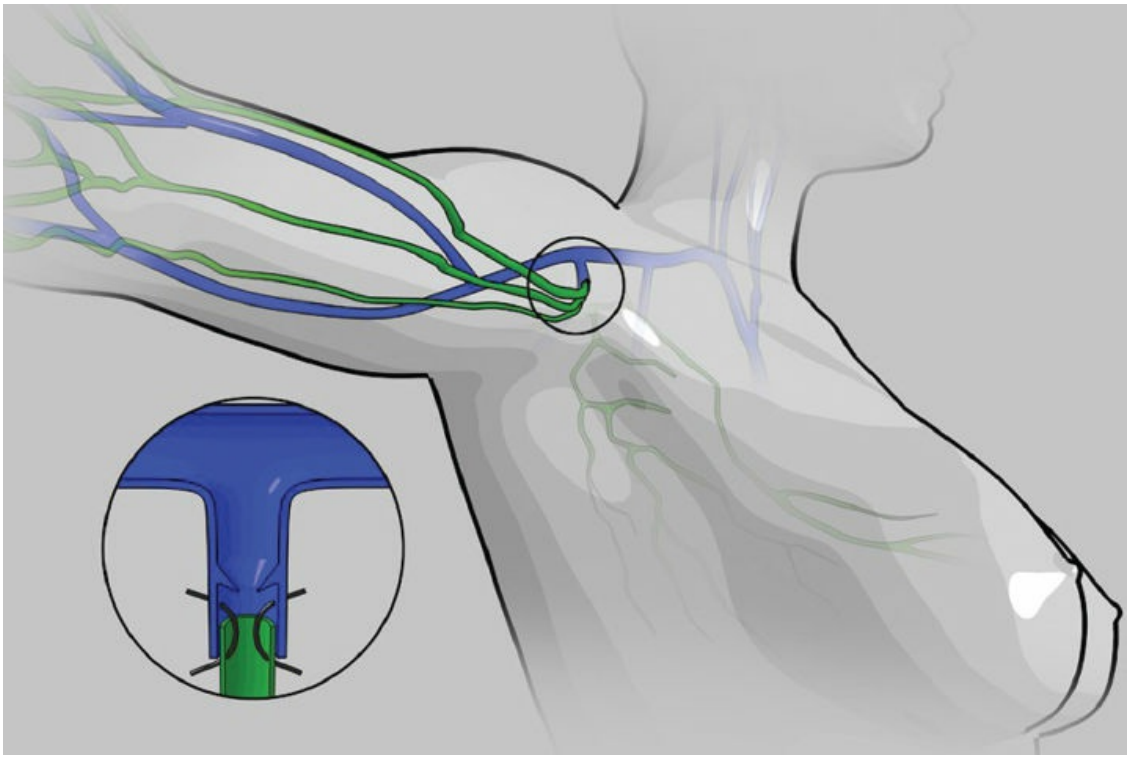

Figure 53.3. Technical aspects of lymphatic microsurgical preventative healing. The functioning lymphatics (green) draining the upper extremity are collectively gathered in the axilla and "dunked" and fixed into a vein tributary (blue) draining into the axillary vein. Illustrated by Peter Kuempel, Courtesy of Sheldon Feldman, MD Columbia University Medical Center.

The influence of breast reconstruction on the risk of lymphedema has been controversial with some purporting reconstruction to decrease risk of lymphedema. Review of five studies each with >300 patients compared subsequent lymphedema rates after any type of reconstruction (immediate or delayed, implant or autologous) finding significantly lower rates of lymphedema in the setting of breast reconstruction (3% to 9%) when compared to no reconstruction (9% to 18%). Unfortunately, these studies are limited by vague study design, short follow-up, and inability to stratify according to axillary surgery performed or other treatment characteristics. The most contemporary data however challenge these findings. Basta et al. performed a propensity matched analysis of breast reconstruction on the subsequent development of lymphedema. Using matched cohorts of 239 patients each, they found lymphedema in 19.2% of reconstruction patients and in 20.1% in no-reconstruction patients (p = 0.82) at >55 months follow-up. The authors concluded breast reconstruction did not appear to influence lymphedema rates either positively or negatively. Further study

into the relationship between breast reconstruction and lymphedema is warranted, although at present collective data suggest that breast reconstruction should not be withheld from patients based on concern for lymphedema.

TREATMENT

Complex Decongestive Therapy (CDT)

While treatment for lymphedema remains controversial and should be individualized, it is safe to say that the cornerstone of lymphedema therapy is still complex decongestive therapy (CDT). CDT is composed of manual lymphatic drainage (MLD), compression (both bandages and garments), skin care, and exercise. The first phase of CDT aims to reduce swelling, while the second phase aims to maintain limb volume reduction.

MLD aims to encourage lymphatic transport by rerouting lymphatic flow away from the obstructed lymphatics and toward normally functioning lymphatic basins. MLD is provided by a specially trained therapist who uses light massage strokes applying tension to the skin which in turn stimulates stretch in the superficial lymphatics and contraction in the deeper lymphatic channels. Patients then practice remedial exercises, and then compression bandages are applied to the arm. MLD is performed 5 days per week in the reduction phase. This cycle continues for 1 to 4 weeks until limb volume plateaus, then the maintenance phase begins. In the maintenance phase, patients wear compression bandages at night and compression garments during the day and continue to practice good skin care and remedial exercises daily. In an effort to standardize MLD and CDT treatments, the Lymphology Association of North America has established a standardized examination to certify lymphedema therapists. A list of certified therapists according to zip code can be found on the LANA Web site.

Compression bandaging and garments are key components to CDT and long-term lymphedema treatment maintenance. Compression bandages are short stretch bandages applied in multiple layers and designed to maintain volume reductions achieved through lymphatic drainage. These short stretch bandages have a low resting pressure and are therefore comfortable for patients to wear, but with increased muscular contraction these bandages maintain their integrity (high working pressure) enhancing lymphatic pumping, reducing capillary filtration, and preventing refilling of the tissue spaces cleared through MLD. Compression garments are the

most widely used form of compression as they are simpler to apply than bandages. They aim to limit re-accumulation of edema following reductions gained with MLD and bandaging. Their mechanism of action is unclear, but physiology suggests they may maintain an increased interstitial pressure and therefore interstitial fluid homeostasis.

A systematic review of 26 studies evaluating lymphedema management strategies supports the benefits of both MLD and compression bandaging with the greatest limb reductions identified when both therapies were used in combination. MLD alone for the specific intent of limb volume reduction is ineffective when used independently from CDT. A review published by Mosely et al. also supports these findings concluding that intensive treatment provided by health care professionals produced larger volume reductions than therapies performed solely by the patient. Overall it is estimated that CDT reduces limb volume by 30% to 70% with degree of volume reductions primarily linked to the baseline extremity volume, edema severity, and number of CDT sessions completed. MLD also significantly contributed to reductions in patient perceived symptoms of limb heaviness and tension especially when used in a palliative setting. Finally, MLD may be the best treatment option in patients with head and neck, genital or breast lymphedema when compression bandaging is not an option.

Despite significant gains in volume reduction achieved by CDT, recent randomized trials may temper enthusiasm for CDT. McNeelly et al. randomized women to 4 weeks of CDT versus compression garments alone. Patients participating in either study arm demonstrated significant limb volume reductions; however, the maximum volume reduction did not differ between trial arms (CDT: 46% vs. compression: 39%, $p = 0.22$). With a similar trial design, Andersen et al. also randomly assigned women to CDT or compression and also showed no significant difference in volume reductions between the two trial arms ($p = 0.66$). Finally, Dayes et al. performed the most rigorous randomized trial randomly assigning 103 women to CDT or compression bandaging but also standardized arm measurement techniques, required maintenance of diary logs, and actively performed monitoring to ensure treatment compliance. The groups were well-balanced with respect to BMI, duration of lymphedema, and oncologic treatments, although the CDT group did have a higher percentage of patients with larger limb volumes at commencement of treatment. They found no significant difference in percent volume

reduction at 6 weeks with a mean 29% reduction in the CDT and 23% in the compression groups, $p = 0.34$. This outcome was sustained to 52 weeks follow-up. Importantly, the authors also reported no difference in quality of life or symptoms between the groups. While these trials are limited by relatively small numbers and short follow-up, they provide enough evidence to establish the controversy surrounding the added value of CDT for first-line lymphedema therapy. That said, the impact of untreated lymphedema is significant and overall all these treatment strategies provide minimal morbidity.

Maintenance of volume reduction can be challenging as it requires strict adherence to treatment strategies with daily care performed by the patient or caregiver. Adherence with therapist-prescribed self-care modalities among women with breast care-related lymphedema has been documented to be variable. Brown et al. questioned 141 breast cancer survivors about their self-care practices of physical therapy exercises, bandaging, self-administered lymphatic drainage, pneumatic compression pump usage, compression garments, and taping. Over 12 months, they reported decreased prescriptions for therapist-administered treatments but still found 39% of women followed <50% of the recommendations with the trend of high adherence to low adherence over time. They concluded that adherence to self-care is suboptimal for this lifelong condition. Reasons for noncompliance may include patient difficulty with application of compression bandages, prolonged time commitment required for adequate daily therapy, or discomfort with bandaging in warm or humid climates. In addition, pumps, bandages, and sleeves can interfere with sleep or be cumbersome to use during daily activities. Finally, bandages and supplies must be replaced on a regular basis (at least twice annually). These costs frequently are not covered by private insurance or Medicare, which may deter adherence.

Exercise

Historically, patients with lymphedema have been discouraged from exercise and those at risk for lymphedema have been cautioned against certain sports or lifting activities fearing those behaviors may increase cellular waste products and lead to subsequent extracellular fluid accumulation causing lymphedema. However, as rates of obesity rise in cancer survivors and the acknowledgment that obesity may increase cancer recurrence in some settings, the NCCN has embarked on a campaign to

encourage healthy lifestyles in survivors, including maintenance of physical activity. Patients with lymphedema are considered at moderate risk of an exercise induced adverse event. Kwan et al. published a systematic review of 19 studies evaluating resistance and aerobic exercises in women at risk for or affected with BCRL. Evidence from this review suggests exercise can be safe in both populations when appropriately supervised and does not cause or exacerbate lymphedema. The largest randomized controlled trial evaluating exercise in women with lymphedema randomized 141 women to twice weekly weight training with compression garment or standard activity. The authors found no increase in lymphedema and interestingly found fewer and less severe exacerbations in the intervention cohort. The NCCN supports the concept that women with lymphedema should wear compression garments during exercise and begin supervised programs starting with low weights, low repetitions with gradual increases. Controversy remains surrounding the role of prophylactic use of compression garments during exercise in at-risk women and should be individualized.

Unfortunately little data exist regarding the risks or benefits of exercise in non-breast cancer survivors at risk for or affected by lymphedema. Specifically, data regarding lower limb lymphedema are sparse. One cross-sectional study of 213 uterine cancer survivors reported that patients with at least 18 MET hours per week of physical activity were less likely to develop lower limb lymphedema when compared with those with <3 MET hours (OR 0.32, 95% CI 0.15–0.6, p = 0.003). Given the paucity of additional validating studies, the authors concluded these findings should be viewed as preliminary but nonetheless can be viewed with cautious optimism. Clinicians should embrace exercise as being safe when performed under appropriate supervision in patients at risk for or affected by lymphedema.

Surgery

Advancements in microsurgical techniques have brought about the resurgence in interest of exploring surgery as a cure for lymphedema. While the concept of cure is enticing for such a chronic debilitation complication like lymphedema, enthusiasm for these surgical interventions should be tempered by the overwhelming lack of consensus surrounding lymphedema etiology, pathophysiology, definition, and diagnostic modalities worldwide. As a result of these limitations, the published

literature addressing surgery for lymphedema patients is very heterogeneous with regard to surgical timing and indications, hindered by short follow-up and small numbers, inconsistent reporting on quality-of-life outcomes, and frequently does not eliminate the need for CDT and/or compression to maintain volume reduction gains. Broadly, surgical procedures can be categorized as excisional or reductive, reconstructive, or tissue transfer.

Historically, surgeons performed the Charles procedure excising large areas of the affected fibrotic lymphatic tissues. In the modern era, specialized liposuction cannulas can be used to reduce limb bulk. This technique has been popularized by Brorson et al. Both techniques result in over 100% limb volume reduction, but strict adherence to posttreatment compression garments and therapy regimens is critical to maintaining reduced limb size. More importantly, excisional procedures fail to alter the underlying etiologic cause of lymphedema.

Surgeons performing lympholymphatic and lymphovenous anastomosis (LVA) use microsurgery to connect severed lymphatics or to divert lymphatic flow to the venous system. The technique requires multiple microsurgical anastomoses as targeted vessels range from 0.2 to 0.6 mm in diameter and surgeons seek to perform as many anastomoses as possible. Lymphoscintography is variably used to demonstrate functionality. Alternatively patient symptoms can be followed. Lymph node transfer (LNT) requires harvest of a small flap of lymphatic tissue containing lymph nodes, the vascular supply, and surrounding fat. The tissue is transferred to the affected lymphatic basin or extremity. Researchers hypothesize transferred lymphatic tissue promotes VEGF-C production encouraging lymphatic collateralization and regeneration. Animal studies support this hypothesis as transferred lymph nodes have demonstrated rapid infiltration of functional host lymphatics correlating with elevated endogenous VEGF C expression in the perinodal fat. Both LVA and LNT are likely most effective in early lymphedema as patients tend to have some remaining functional lymphatics.

Cormier et al. reviewed 8 LVA studies evaluating 990 patients and found a weighted limb reduction of 54%. They also reviewed 4 tissue transfer studies evaluating 61 patients and found a weighted limb reduction of 48%. However, little to no data are presented on the potential morbidity of the donor site in the LNT patients. Basta et al. reviewed 27 studies offering level III or IV evidence of which 22 studies evaluated LVA and 5

LNT. Overall, excess volume was reduced 56%, 91% reported subjective improvement, and 65% reported discontinuation of their compression garments. Unfortunately, 11.8% of patients had no change in their lymphedema and 35% experienced some kind of complication with the surgery. Many clinicians point to the largest LVA study to date to support surgery for lymphedema. This study reports on 1,800 patients treated with LVA over a 10-year period of time and notes a 56% limb reduction and 85% discontinuation of compression garments. While these results are exceedingly good, the methods and results section for this manuscript is shockingly brief limiting interpretation, not to mention that the authors fail to acknowledge the vast changes in surgical technique over the 10 years of the study.

The enthusiasm for surgery in lymphedema is growing in both the prevention and treatment arenas. Early data are encouraging. However, small numbers, short follow up, nonstandardized indications, techniques, and evaluation parameters hinder the ability to draw clear evidenced based conclusions. Finally, none of these procedures obviate the need for post-surgical compression therapy or CDT.

EDITOR'S COMMENT

The newly added chapter for the Seventh Edition of the *Mastery of Surgery* by Dr. McLaughlin of Mayo Clinic Florida was included in this edition to acknowledge the important morbidity of lymphedema, and its therapeutic expense, created as a consequence of surgical and radiation therapy management for neoplasms of the breast, extremities, and head and neck. Historically, etiologic factors that contribute to lymphedema of various organ sites are inclusive of (1) extent of the surgical resection of lymph node-bearing tissues and/or contiguous musculature, (2) irradiation, (3) obesity, (4) age, (5) inflammation and cellulitis, and (6) the anatomical length and site of the

surgical incision. Age is included in the aforementioned etiologic factors as lymphedema may be influenced by a relative lack of collateral lymphovenous anastomoses in older women. This process of neovascularization may be more evident in younger women postoperatively bridging lymphatic and vascular structures. Such lymphovascular anastomoses are less frequently observed in the aging population, especially those who are less physically active. Moreover, the occurrence of postoperative wound complications (e.g., infection, seroma/hematoma, flap necrosis) can be identified as independent variables that initiate early and late lymphedema of the ipsilateral neck or extremity. The extent of regional node dissection, that is, radical versus modified head and neck lymphadenectomy; levels I–II versus level III axillary LND for breast carcinoma, melanoma, and non-melanoma neoplasms; and superficial lymph node dissection versus combination with deep inguinal (radical) dissection each recognize that *extent of the dissection* is an important contributing factor, especially when combined with radiation therapy. The latter modality alone will increase the incidence of lymphedema from 20% to 52% (Sauter ER, Eisenberg BL, Hoffman JP, et al. Postmastectomy morbidity after combination preoperative irradiation and chemotherapy for locally advanced breast cancer. *World J Surg* 1993;17:237 and Copeland, *5th Annual General Surgery Forum Telluride, Colorado*). In dated publications authors have reported the risk of arm lymphedema to be as great as 37% for therapy of breast cancer when full axillary lymph node dissection (ALND) (levels I–III) was completed versus 8% when dissection was limited to levels I–II ALND. (Larson D, Weinstein M, Goldberg I, et al. Edema of the arm as a function of the extent of axillary surgery in patients with stage I-II carcinoma of the breast treated with primary radiotherapy. *Int J Rad Oncol Biol Phys* 1986;12:1575–82). This in-depth analysis found a correlation between the risk of lymphedema formation and the number of removed nodes; when >10 lymph nodes were removed in dissection, the risk of lymphedema is 28% versus 9% in the 1 to 10 nodal group resections.

The ascribed adverse observation of posttreatment weight gain and obesity (Petrek JA, Senie RT, Peters M, et al. Lymphedema in a cohort of breast carcinoma survivors 20 years after diagnosis. *Cancer* 2001;92:1368–77) suggests that this observation is an independent risk factor for lymphedema formation as well.

In the superb and detailed chapter included by Dr. McLaughlin, the incidence and even the definition of lymphedema in contemporary randomized controlled trials vary (Table 53.1). Implied in this context of the definition of risk/incidence is the variation of the prevalence for surgically induced lymphedema for non-breast cancers of four different sites (head/neck, genitourinary, gynecologic, extremity) and variable tumor types for management (melanoma, sarcoma, squamous cell, urinary tract epithelium, endometrial, and ovarian) (Table 53.2). Francis and Ahghari (Francis WP1, Abghari P, Du W, et al. Improving surgical outcomes: standardizing the reporting of incidence and severity of acute lymphedema after sentinel lymph

node biopsy and axillary lymph node dissection. *Am J Surg* 2006;192:636–9) describe common terminology criteria for adverse events (CTCAE) 3.0, which are detailed by the National Cancer Institute and have standardized reporting of adverse events and their inclusion to grade outcomes in clinical trials. These include lymphedema for extremities: levels I–IV that progress from: 5% to 10% (level I), 10% to 30% (level II), >30% (level III), and progression to malignancy (level IV). This incidence and the severity of post-op acute lymphedema were observed within the 1st year following sentinel lymph node biopsy (SLNB) and ALND. The incidence of lymphedema was 16.8% following SLNB and 47.1% after ALND. Acute lymphedema of severity level I was evident in 65% following SLNB and level II severity in 35%. This frequency for level II lymphedema escalated to 60% in the ALND group.

A large NSABP B-32 trial (Ahikaga T, Krag DN, Land SR, et al. Morbidity results from the NSABP B-32 trial comparing sentinel lymph node dissection versus axillary dissection. *J Surg Onc* 2010;102[2]:111–8) for postsurgical morbidity with treatment of breast cancer between patients with negative SLNB alone versus negative SLND and negative ALND confirms arm differences >10% at 36 months with reduction advantage with limited tumor burden for the SLND groups (8%) and ALND groups(14%). Numbness and paresthesias peaked at 6 months following ALND (49%, 23%) and for the SLND groups were 15% and 10%, respectively. Thus, in the node negative groups, the superiority of SLND was evident when compared with ALND groups to alleviate postsurgical morbidity with outcomes over a 3-year interval. This advantage is further emphasized in the radiotherapy or surgery of the axilla following positive sentinel lymph nodes in breast cancer (EORTC 10981–22023 AMAROS) (Donker M, van Tienhoven G, Straver ME, et al. Radiotherapy or surgery of the axilla after a positive sentinel node in breast cancer (EORTC 10981-22023 AMAROS): a randomised, multicentre, open-label, phase 3 non-inferiority trial. *Lancet Oncol* 2014;15[12]:1303–10) and was designed concurrently with the Z-0011 protocol of the American College of Surgeons Oncology Group (ACOSOG) trial for the evaluation and outcomes with ≤2 *positive* breast cancer lymph nodes. In the EORTC study, assessment of axillary radiotherapy to provide comparable regional control, together with its side effects, was evaluated. Axillary recurrence following axillary irradiation versus ALND were virtually equivalent; recurrence was evident in 4/744 patients in the ALND and 7/681 in the axillary RT group but appears to be statistically underpowered because of the low number of adverse events in the cohorts. Of interest, lymphedema in the ipsilateral arm was noted significantly more often following ALND (13% to 23%) than following axillary RT (5% to 11%) at 1 year, 3 years, and 5 years post treatment.

Whelan et al. (Whelan TJ, Olivotto IA, Parulekar WR, et al. Regional Nodal Irradiation in Early-Stage Breast Cancer. *N Engl J Med* 2015;373[4]:307–16) reported on the multi-institutional Canadian study for the National Cancer Institute of Canada (CT Group MA.20 trial). In this 10-year follow-up study of

1,832 women assigned to nodal-irradiation group or the control group (each arm = 916 patients), there was no significant difference in these groups for survival (82.8%) in the RT and in the control group (81.8%) (p = 0.38). The rate of disease-free survival was superior in the nodal RT (82.0%) group versus the control arm (77.0%) (p = 0.01). Nodal irradiation had higher rates of grade 2 or greater frequency of acute pneumonitis (1.2% vs. 0.2%, p = 0.01) and lymphedema was evident in 8.4% in the irradiated group versus 4.5% in the control (p = 0.001). Thus, the addition of whole breast irradiation to the ALND group for those receiving comprehensive regional nodal irradiation essentially doubled the frequency of lymphedema. While this approach of combination modality does not improve overall survival, this therapeutic methodology reduces the frequency of local-regional failure to enhance disease-free survival. This trend was further evident in the American College of Surgeons Oncology Group Z0010 trial (Teshome et al. 67th Symposium, Society of Surgical Oncology, March 2014) to confirm the considerable reduction in lymphedema for SLNB patients (20% to 24%) versus ALND patients (40% to 41%) combining both objective and subjective parameters. These data are detailed in Table 53.1 by the author of this chapter.

Since the original formulation of the physiologic principles of the sentinel node concept by Ramon Cabanas for penile carcinoma in 1977 (Cabanas RM. An approach for the treatment of penile carcinoma. *Cancer* 1977;456–66) with lymphangiograms and the technological progression with use of the technetium 99m pertechnetate and vital blue dye for the SLNB by Donald Morton in 1992 (Morton DL, Wen DR, Wong JH, et al. Technical details of intraoperative lymphatic mapping for early stage melanoma. *Arch Surg* 1992;127:392–9) for melanoma, the aforementioned articles apply the same considerations for breast SLNB. Guiliano et al. (Giuliano AE, Kirgan DM, Guenther JM, et al. Lymphatic mapping and sentinel lymphadenectomy for breast cancer. *Ann Surg* 1994;220:391–401) began development for adoption of these principles for breast lymphatic mapping in 1991. As melanoma requires a more comprehensive nodal dissection for axillary metasteses (levels I, II, III) versus breast (levels I, II), the extent of radical nodal resection is enlarged in the melanoma population for the axilla and in the groin. In addition, should Cloquet's femoral node be positive, deep ilioinguinal resection is recommended. Interval CT staging with contrast to evaluate subsequent development of deep ilioinguinal nodal progression is programmatically a follow-up recommendation. Hyngstrom et al. at UT MD Anderson Cancer Center (Hyngstrom JR, Chiang YJ, Cromwell KD, et al. Prospective assessment of lymphedema incidence and lymphedema-associated symptoms following lymph node surgery for melanoma. *Melanoma Res* 2013;23[4]:290–7) evaluated 182 patients at 12 months following therapeutic axillary inguino-femoral dissection with observation that there was a seven- to nine-fold increase in symptoms for patients with a significant limb volume change (LVC) >10% compared with those with LVC <5% (p < 0.05). With multivariant regression

analysis, therapeutic lymph node dissections at *both* anatomical sites versus SLND were more injurious with enhanced probability for lymphedema ($p < 0.01$); this was borderline significant for lower versus upper extremity procedures ($p = 0.07$) when associated with LVC >5%. These authors conclude that LVC >5% is common at 12 months following node dissection for melanoma and the risk of postoperative lymphedema should be an important component of informed consent for postsurgical morbidity.

In the meta-analysis for treatment factors for the risk of developing arm lymphedema in breast cancer survivors, Tsai et al. (Tsai RJ, Dennis LK, Lynch CF, et al. The risk of developing arm lymphedema among breast cancer survivors: a meta-analysis of treatment factors. *Ann Surg Onc* 2009;16:1959–72) further emphasize that the extent of the axillary dissection with irradiation and the presence of positive nodes increase the risk of developing arm lymphedema following breast cancer surgery treatment. This incidence of lymphedema after axillary surgery apparently increases up to 2 years following diagnosis of breast cancer, and the frequency increases in all studies in which preoperative direct measurements versus the control group arm dimensions were measured. DiSipio et al. (DiSipio T, Rye S, Newman B, et al. Incidence of unilateral arm lymphoedema after breast cancer: a systematic review and meta-analysis. *Lancet Oncology* 2013;14:500–15) also suggest that risk factors that enhance the frequency of lymphedema include: (1) extensive surgery with comprehensive nodal dissection, (2) greater number of lymph nodes procured with dissection at mastectomy, and (3) being overweight or obese are contributory. In the Phase III noninferiority Z-0011 trial of ACOSOG, Guiliano et al. (Giuliano AE, Hunt KK, Ballman KV, et al. Axillary dissection vs no axillary dissection in women with invasive breast cancer and sentinel node metastasis: a randomized clinical trial. *JAMA* 2011;305[6]:569–75) randomized patients with clinical T1–T2 invasive cancer and no palpable adenopathy between breast conservation surgery with one to two positive sentinel nodes following completion ALND versus no further axillary surgery. The authors concluded that there were no differences between overall survival (91.8%, 92.5%) and disease-free survival (82.2% vs. 83.9%), and that outcomes for SLNB are equivalent to ALND with two or fewer positive sentinel lymph nodes. Now beyond 6 years follow-up to date, the Z0011 trial has not demonstrated evidence of differences in lymphedema between the two randomized cohorts.

An important emphasis and therapeutic principle enunciated by Dr. McLaughlin includes that of complex decongestive physiotherapy (CDP). CDP in the treatment of lymphedema was studied by Kim and Park (Kim SJ, Park YD. Effects of complex decongestive physiotherapy on the oedema and the quality of life of lower unilateral lymphoedema following treatment for gynecological cancer. *Eur J Cancer Care* 2008;17:463–8) to determine quality-of-life (QOL) issues for lower extremity lymphedema following the therapy of gynecologic cancers. CDP was inclusive of manual lymphatic drainage, skin

care, remedial exercises, compression garments, pneumatic pumps, mercury compression, oral and topical benzopyrones, elevation, and microwave and laser therapies. These approaches have been emphasized by *The International Society of Lymphology* as objective measures that enhance control of lymphedema. In the analysis by Kim and Park, 57 gynecologic patients with unilateral lymphedema resulted in measurable change in edema and QOL; the percent excess volume correlated with change in QOL, and was significantly reduced following CDP ($p < 0.05$). QOL was significantly improved ($p < 0.05$) over baseline scores indicating that evident improvement of QOL was associated with enhanced physiologic function, social function, physical strength, body pain, and general health over parameters at baseline within 1 month ($p < 0.05$).

When the lymphatic system is partially or completely obliterated by either result of infection, malignancy, radiation or surgery, lymphatic fluid transport capacity is reduced. This consequence leads to the production of interstitial fluid that exceeds the rate of lymphatic return and therefore the stagnation of high-molecular-weight proteins leak into the interstitium. Kim and Park provide parameters for the patient's history and the measurement and documentation of lymphedema with the inherent problem for making objective and subjective assessments for improvement over baseline. This is particularly evident in those who have minimal lymphedema in the ipsilateral extremity.

The role of micro-surgery for lymphedema has periodically been approached by various international clinics and the largest series to date is that by Campisi et al. at San Martino, University of Genoa, Italy, in which 1,800 patients with peripheral lymphedema of various organ sites had treatment that was managed with microsurgical techniques. In this evolution of lymphonodal-venous microsurgery, surgeons used direct anastomoses with microvascular techniques for lymphatic vessel anastomoses directly to axillary and inguinal veins (Campisi C, Bellini C, Campisi C, et al. Microsurgery for lymphedema: clinical research and long-term results. *Microsurgery* 2010;30:256–60). The objective assessment was taken by water volumetry and lymphoscintigraphy. Objective volume changes confirmed an improvement in 83%, with an average volume reduction of 67% of excess volume. In follow-up, 85% have been able to continue use of conservative measures with an average follow-up of >10 years and an average reduction success limb volume of 69%. These results are not reproducible in all clinics and require an intensive long investment in the cost of expertise and experience to achieve these exceptional results.

The surgeon must be cognizant of the need for recognition of *early* lymphedema in the post-mastectomy and post-inguinal node dissection patient. Recurrent and detailed examination of the extremities and head and neck sites post therapy is essential to pre-empt progression of lymphedema. Implementation of the CDP measures enumerated above should be considered early in therapy. While salt restriction is appropriate in the elderly people, especially with heart failure, diuretics are of minimal benefit in the therapy of chronic lymphedema. Compression pumps, together with CDP measures,

currently represent the principle treatments that are the most beneficial medical management strategies. Together with physical massage taught by qualified therapists and compression sleeves “measured-to-fit” the extremity, advanced lymphedema may be avoided.

Kirby I. Bland

54 Modified Radical Mastectomy and Radical Mastectomy

Kirby I. Bland

HISTORY OF BREAST CANCER SURGERY

The anatomist, physiologist, and surgeon, Claude Galen, stated in the second century AD with his classical clinical observation of breast carcinoma: “We have often seen in the breast a tumor exactly resembling the animal, *the crab*. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab’s legs. We have cured this disease in its early stages, but after it has reached a large size, no one has cured it.” As advocated in the 18th century by Morgagni, father of modern pathology, surgical resections were more frequently undertaken, including early attempts at mastectomy and axillary dissection. Also in the 18th century, the surgeon Henri le Dran postulated that breast cancer was initially a local disease that progressed in stages to spread via skin and breast lymphatics to axillary lymph nodes. With surgery for breast cancer, le Dran routinely removed *en bloc* any enlarged axillary lymph nodes.

In the late 19th century, C.H. Moore, of the Middlesex Hospital, London, reemphasized complete resection of the breast for cancer and stated that palpable axillary lymph nodes should also be removed. In a presentation before the British Medical Association in 1877, Banks supported Moore’s concepts and advocated the routine resection of axillary lymph nodes even when palpable lymphadenopathy was *not evident*, recognizing that occult involvement of axillary lymph nodes was frequent. In 1894, William S. Halsted and Willy Meyer reported their operations for the radical treatment of breast cancer. By demonstrating superior locoregional control rates with radical resection, these surgeons established radical mastectomy (RM) as the benchmark procedure for that era. Both Halsted and Meyer advocated complete dissection of all levels of axillary lymph node levels (I, II, and III). Resection of the long thoracic nerve and the thoracodorsal neurovascular bundle with the axillary

contents was routine. This technical maneuver contributed significantly to the surgical management of the disease while enhancing surgical morbidity and limitation of postoperative function.

However, in 1943, Haagensen and Stout described the “grave-signs” of breast cancer, which included (a) edema of the skin of the breast, (b) skin ulceration, (c) chest wall fixation, (d) an axillary lymph node >2.5 cm in diameter, and/or (e) fixed axillary lymph nodes. Women with two or more signs had a 42% local recurrence rate and only a 2% 5-year disease-free survival. Based upon these observations, these investigators declared that patients with grave signs were beyond cure by radical surgery. Advocating this principle, approximately 25% of women were excluded from surgery based upon the criteria of inoperability. Presently, with comprehensive mammographic screening, approximately 10% of women are found to have advanced breast cancers.

The “modified radical” mastectomy was proposed in 1948, when Patey and Dyson of the Middlesex Hospital, London, provided a major technical and aesthetic advancement for the management of operable breast cancer. The technique espoused by Patey and Dyson included removal of the breast and axillary lymph nodes with preservation of the pectoralis major muscle. These surgeons confirmed that removal of the pectoralis minor muscle allowed access to and the anatomical dissection of axillary lymph node levels I to III (Patey modification). Today, the modification is frequently limited to severance of the origin of the pectoralis major muscle at the coracoid process of the scapula. Subsequent to the description of the Patey modification, Madden advocated a modified RM that preserved *both* the pectoralis major and minor muscles even though this approach prevented thorough dissection of the apical (level III) axillary lymph nodes.

The performance of the technique with frequency in the 1980s, allowed the modified RM to become the most frequently used procedure by American surgeons for the therapy of breast cancer. The transition from the Halsted RM to the modified RM acknowledged that (a) extirpation of the pectoralis major muscle was *not* essential for locoregional control in stage I and stage II breast cancer and (b) neither the modified RM nor Halsted RM procedures consistently achieved locoregional control of stage III disease. The National Surgical Adjuvant Breast and Bowel Project B-04 (NSABP B-04) conducted by Bernard Fischer and coinvestigators, thereafter, compared local and regional treatments of breast cancer. Life

table estimates were obtained for 1,665 women enrolled and followed for a mean of 120 months. This study randomized clinically node-negative women into three groups: (a) Halsted RM, (b) total mastectomy plus radiation therapy (TM+RT), and (c) total mastectomy alone (TM). Clinically node-positive women were treated with RM or TM+RT. With median follow-up of 10 years, there were *no differences in survival* between the three groups of node-negative women or between the two groups of node-positive women.

Additional prospective clinical trials comparing Halsted RM to the modified RM were the Manchester Trial, reported by Turner and colleagues, and the University of Alabama Trial, reported by Maddox and colleagues. In both studies, the *type* of surgical procedure did not influence recurrence rates for stage I and stage II breast cancer patients. Criteria for accrual to the Alabama Breast Cancer Project (1975 to 1978) included T1 to T3 breast cancers (Table 54.1) with absence of clinically apparent distant metastases. Patients underwent a radical or a modified RM. Node-positive patients received adjuvant cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy or adjuvant melphalan. With median follow-up of 15 years, neither type of surgery, nor type of chemotherapy, was shown to affect locoregional disease-free or overall survival. Since the 1970s, considerable progress has been made in the integration of surgery, radiation therapy, and chemotherapy to control locoregional disease, to enhance survival, and to increase the possibility of breast conservation. Locoregional control is now achieved for approximately 80% of women with advanced breast cancers, following neoadjuvant chemotherapy.

TABLE 54.1 Definition of TNM

Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. The telescoping method of classification can be applied. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic, are used, the telescoped subsets of T1 can be used

Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/of LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the site and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted
T1	Tumor ≤2 cm in greatest dimension
T1mi	≤0.1 cm or less in greatest dimension
T1a	Tumor ≥0.1 but ≤0.5 cm in greatest dimension
T1b	Tumor ≥0.5 cm but ≤1 cm in greatest dimension
T1c	Tumor ≥1 cm but ≤2 cm in greatest dimension
T2	Tumor ≥2 cm but ≤5 cm in greatest dimension
T3	Tumor ≥5 cm in greatest dimension
T4	Tumor of any size with direct extension to chest wall and/or skin (ulceration of skin nodules)
T4a	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma.
T4c	Both (T4a and T4b)
T4d	Inflammatory carcinoma

Regional Lymph Nodes (N)

Clinical

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary level I, II lymph node(s)
N2	Metastasis to ipsilateral level I, II axillary lymph node(s) that are clinically fixed or matted; or in clinically detected* ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases.
N2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically detected* ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases.
N3	Metastases to ipsilateral internal mammary lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected* ipsilateral internal mammary lymph nodes(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement.
N3a	Metastases in ipsilateral intraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph nodes(s)
NOTES	*"Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.

Pathologic Classification (pN)

pNX	Regional lymph nodes cannot be assessed (e.g., previously removed, or not removed for pathologic study)
pN0	No regional lymph node metastasis identified histologically
pN0(i–)	No regional lymph node metastases histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) no >0.2 mm (detected by H&E or IHC including ITC)
pN0(mol–)	No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
pN0(mol+)	Positive molecular findings (RT-PCR)**, but no regional lymph node metastases detected by histology or IHC
pN1	Micrometastases; or metastases in 1–3 axillary lymph nodes; and/or in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected***
pN1mi	Micrometastases (>0.2 mm and/or >200 cells, but none >2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis >2.0 mm.
pN1b	Metastasis in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected***
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected

pN2	Metastases in 4–9 axillary lymph nodes; or in clinically detected****internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastases in clinically detected****internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases to 10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected****ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but no clinically detected***, or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit >2.0 mm); or metastases to the infraclavicular (level III axillary lymph) nodes
pN3b	Metastases in clinically detected****ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected***
pN3c	Metastases in ipsilateral supraclavicular lymph nodes
NOTES	*Classification is based on axillary lymph node dissection with or without sentinel lymph node biopsy. Classification based solely on sentinel lymph node biopsy without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," for example, pN0(sn) **RT-PCR: reverse transcriptase/polymerase chain reaction. ***"Not clinically detected" is defined as not detected by imaging studies (excluding lymphoscintigraphy) or not detected by clinical examination ****"Clinically detected" is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.
Distant Metastasis (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases.
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven >0.2 mm

MASTECTOMY INDICATIONS

In contemporary surgical oncology, the type of therapy offered to the breast cancer patient is determined by the stage of the disease (Table 54.2). Survival rates for women diagnosed with breast cancer between 2003 and 2009 have been calculated based on Surveillance, Epidemiology and End Results (SEER) Program Data. The 5-year survival rate is diminished among women with advanced stage at diagnosis. Considering *all races*, 5-year relative-survival rate is 99% for *localized* disease, 84% for *regional* disease, and 24% for *distant* stage disease (Table 54.3). Race is highly correlative for the adverse effect and decreased survival of the underserved populations of American culture (Table 54.4).

Women at High Risk for Breast Cancer

Retrospective studies of women at high risk for breast cancer have found that prophylactic mastectomy can reduce their risk by >90%. Studies involving women who were carriers of BRCA-1 or BRCA-2 mutations found that the benefit of prophylactic mastectomy differed according to the breast cancer risk conferred by the individual mutations. For women with an estimated lifetime risk of 40% (approximately four times the population

risk), prophylactic mastectomy added almost 3 years of life, whereas for women with an estimated lifetime risk of 85%, prophylactic mastectomy added >5 years to survival based on genetic/familial risk of disease.

TABLE 54.2 TNM Breast Cancer Stages

Stage Grouping			
Stage 0	Tis	N0	M0
Stage IA	T1*	N0	M0
Stage IB	T0	N1mi	M0
Stage IIA	T0	N1**	M0
	T1*	N1**	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1*	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1
NOTES	T1 includes T1mi **T0 and T1 tumors with nodal micrometastases only are excluded from Stage IIA and are classified Stage 1B

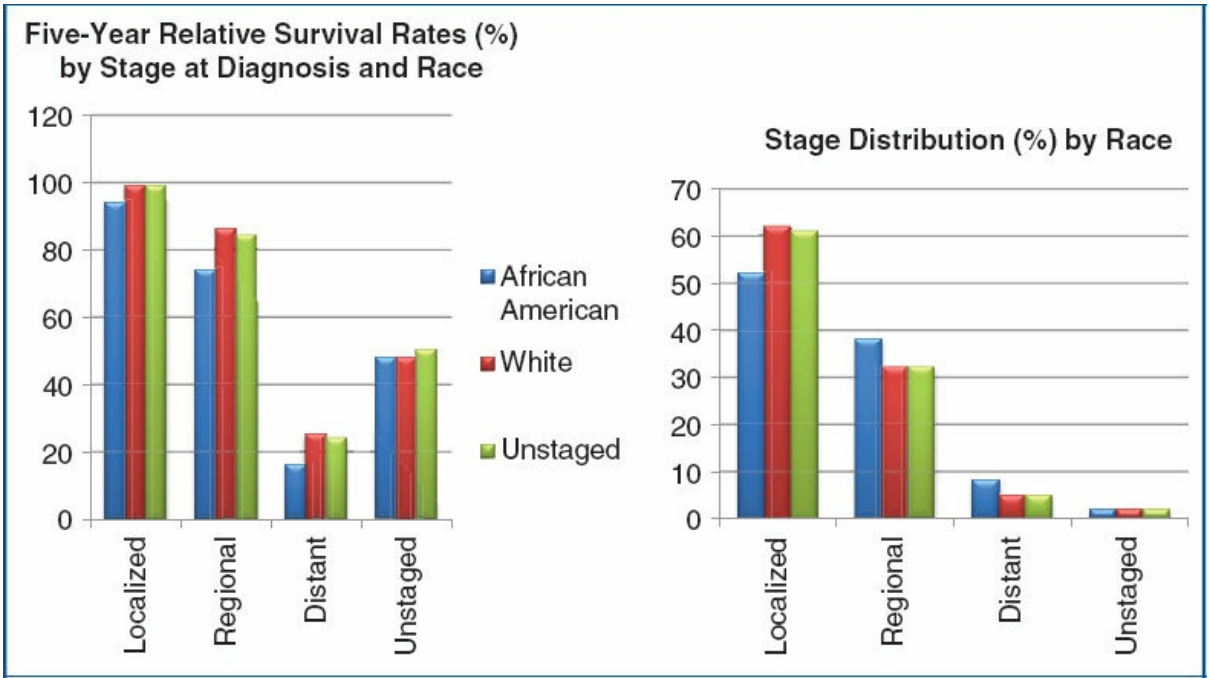
TABLE 54.3

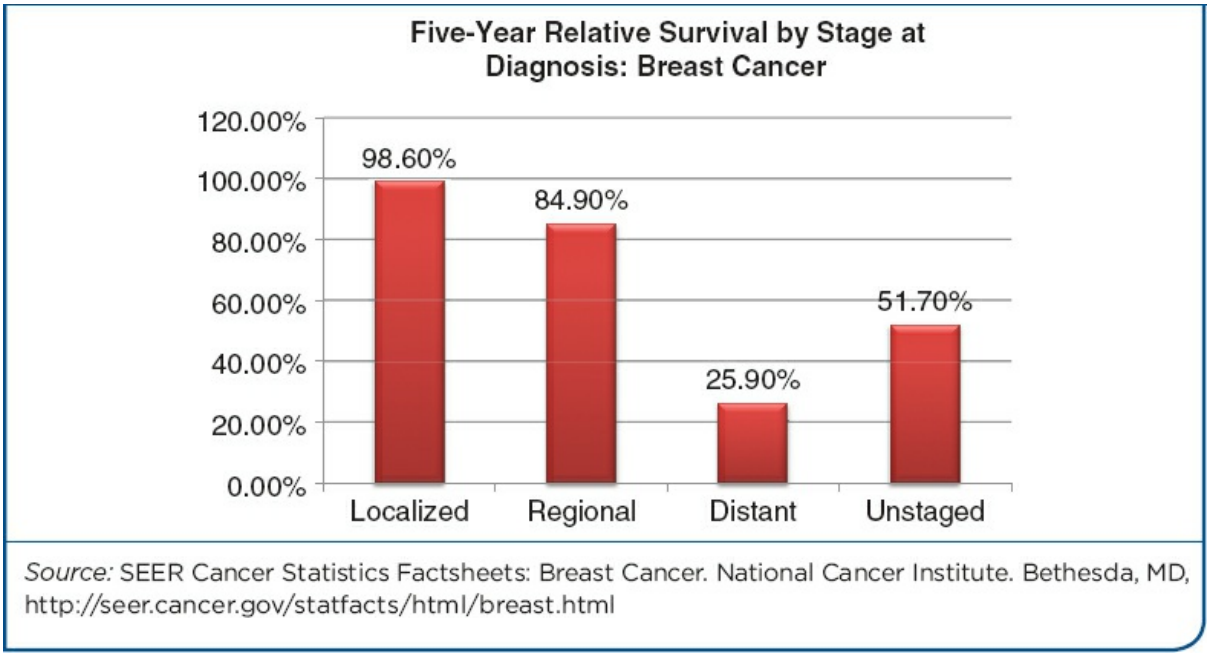


Source: Howlader N, Noone AM, Krapcho M, et al., eds. SEER Cancer Statistics Review, 1975–2010. Bethesda, MD: National Cancer Institute; 2013: http://seer.cancer.gov/csr/1975_2012/ based on November 2012 SEER data submission.

Variants of In Situ Breast Cancer (Stage 0)

Pathologists are cognizant that, on occasion, both lobular carcinoma in situ (LCIS) and ductal carcinoma in situ (DCIS) may be pathologically difficult to distinguish from atypia, atypical hyperplasia or from cancers with micro-invasion. Expert pathologic review is required in all cases. Since LCIS is considered a "marker" for increased risk rather than an inevitable precursor of invasive disease, the current treatment of LCIS is surveillance observation with or without antiestrogen therapy. The goal of treatment is to prevent or detect at an early stage the invasive cancer that subsequently develops in 25% to 35% of these women. Women with multifocal DCIS that is not amenable to lumpectomy and women with multicentric disease (involvement of two or more quadrants of the breast) require mastectomy. For women with limited disease, lumpectomy and radiation therapy is recommended. Sentinel lymph node biopsy is recommended for women with (a) multifocal DCIS, (b) multicentric DCIS, and (c) DCIS with comedonecrosis and tumor size ≥2.5 cm. In all cases, antiestrogen therapy is considered.

TABLE 54.4



Source: SEER Cancer Statistics Factsheets: Breast Cancer. National Cancer Institute. Bethesda, MD, http://seer.cancer.gov/statfacts/html/breast.html

Early Invasive Breast Cancer (Stage I, IIa, or IIb)

NSABP B-06 represented a large, randomized prospective trial that compared TM with lumpectomy with or without radiation therapy for the treatment of stage I and II breast cancer. With 12 and 20 years of follow-up, the disease-free, distant disease-free, and overall survival rates for lumpectomy with or without radiation therapy were statistically equivalent to those observed after TM. However, the incidence of ipsilateral breast cancer recurrence (in breast recurrence) was higher in the lumpectomy group not receiving radiation therapy. The observations from this trial supported the routine recommendation of lumpectomy and radiation in the treatment of stage I and II breast cancer. Currently, (a) breast conservation (lumpectomy and radiation therapy with sentinel lymph node biopsy and/or axillary lymph node dissection) or (b) mastectomy with sentinel lymph node biopsy and/or axillary lymph node dissection should be the recommended treatments for stage I and II breast cancer. Breast conservation should be considered primarily for all patients because of the important cosmetic and functional advantages without compromise of overall cancer-related survival.

Relative contraindications to breast conservation therapy include: (a) *prior radiation therapy* to the breast or chest wall, (b) *involved surgical margins or unknown margin status* following reexcision, (c) *multicentric disease*, and (d) *scleroderma or other connective tissue disorders.* This recommendation pertains to the likely inability to utilize postoperative radiation therapy. In cases with three or more positive nodes,

lymphadenopathy or metastatic disease in a sentinel lymph node necessitates an axillary lymph node dissection (levels I, II) and/or regional node radiotherapy for disease control; both adjuvant techniques may apply in extranodal axillary metastases. In all cases with tumor size >0.5 cm, adjuvant chemotherapy and/or antiestrogen therapy is routinely considered.

Locoregionally Advanced Regional Breast Cancer (Stage IIIa or IIIb)

The patient presenting with stage IIIa and IIIb breast cancer has advanced locoregional breast cancer but does not have clinically or radiographically detected distant metastases (M0). In an effort to enhance optimal locoregional disease-free as well as distant disease-free survival for these women, surgery is integrated with radiation therapy and chemotherapy. Stage IIIa patients are divided into those who have operable disease and those who have inoperable disease (Fig. 54.1). Surgical therapy for women with operable stage IIIa disease is usually a modified RM, followed by adjuvant chemotherapy and adjuvant radiation therapy. Adjuvant chemotherapy is used to maximize distant disease-free survival, while radiation therapy is used to maximize locoregional control for disease-free survival. In *select stage IIIa* patients, initial (neoadjuvant) chemotherapy is increasingly utilized to enhance cytoreduction of the primary cancer and permit conservation surgery. For *inoperable stage IIIa* and for *stage IIIb* breast cancer, neoadjuvant chemotherapy is considered to decrease the locoregional cancer burden and may permit subsequent surgery to establish locoregional control. In this clinical scenario, the modified RM with/without the Patey modification or the infrequent (<2%) Halsted RM is followed by adjuvant chemotherapy and adjuvant radiation therapy.

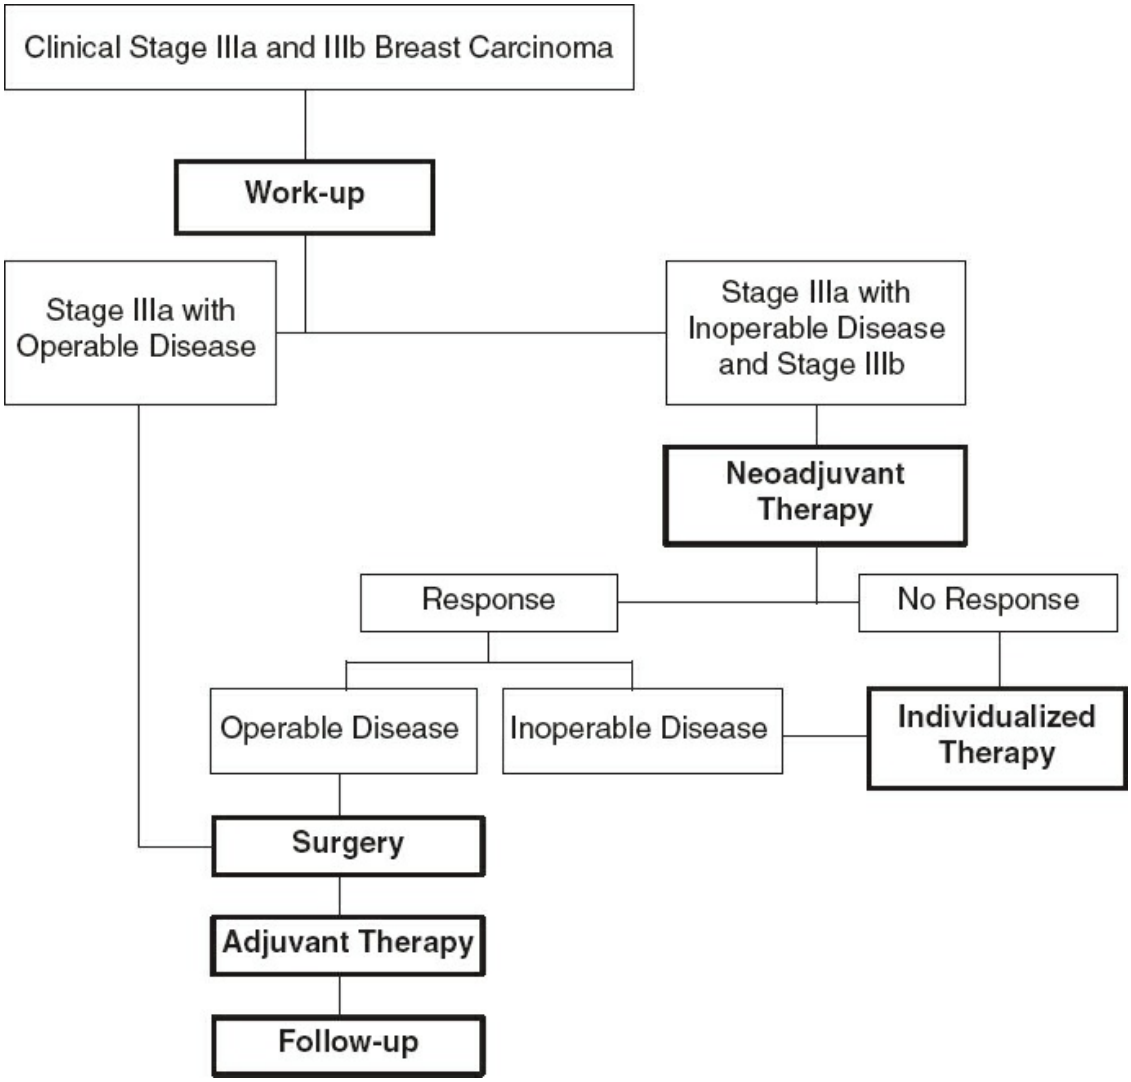


Figure 54.1. Treatment pathways for stage IIIa and stage IIIb breast cancer. (Adapted from Bland KI, ed. *The Practice of General Surgery*. Philadelphia, PA: WB Saunders; 2002. Copyright © 2002 Elsevier.)

Locoregional Recurrence of Breast Cancer

Therapeutic options for the patient with local recurrence of breast cancer is best separated into two groups: (a) those having had mastectomy completion and (b) those having had conservation surgery (lumpectomy). Patients who had prior mastectomy should undergo surgical resection of the recurrence and appropriate reconstruction. Chemotherapy and/or antiestrogen therapy are considered and adjuvant radiation therapy is given if the ipsilateral chest wall has not previously received breast irradiation. For patients having previous breast conservation, therapy should include mastectomy and appropriate reconstruction. Chemotherapy and/or antiestrogen therapy are considered. Women with recurrent disease

involving the axillary lymph nodes (regional recurrence) require axillary lymph node dissection followed by adjuvant chemotherapy.

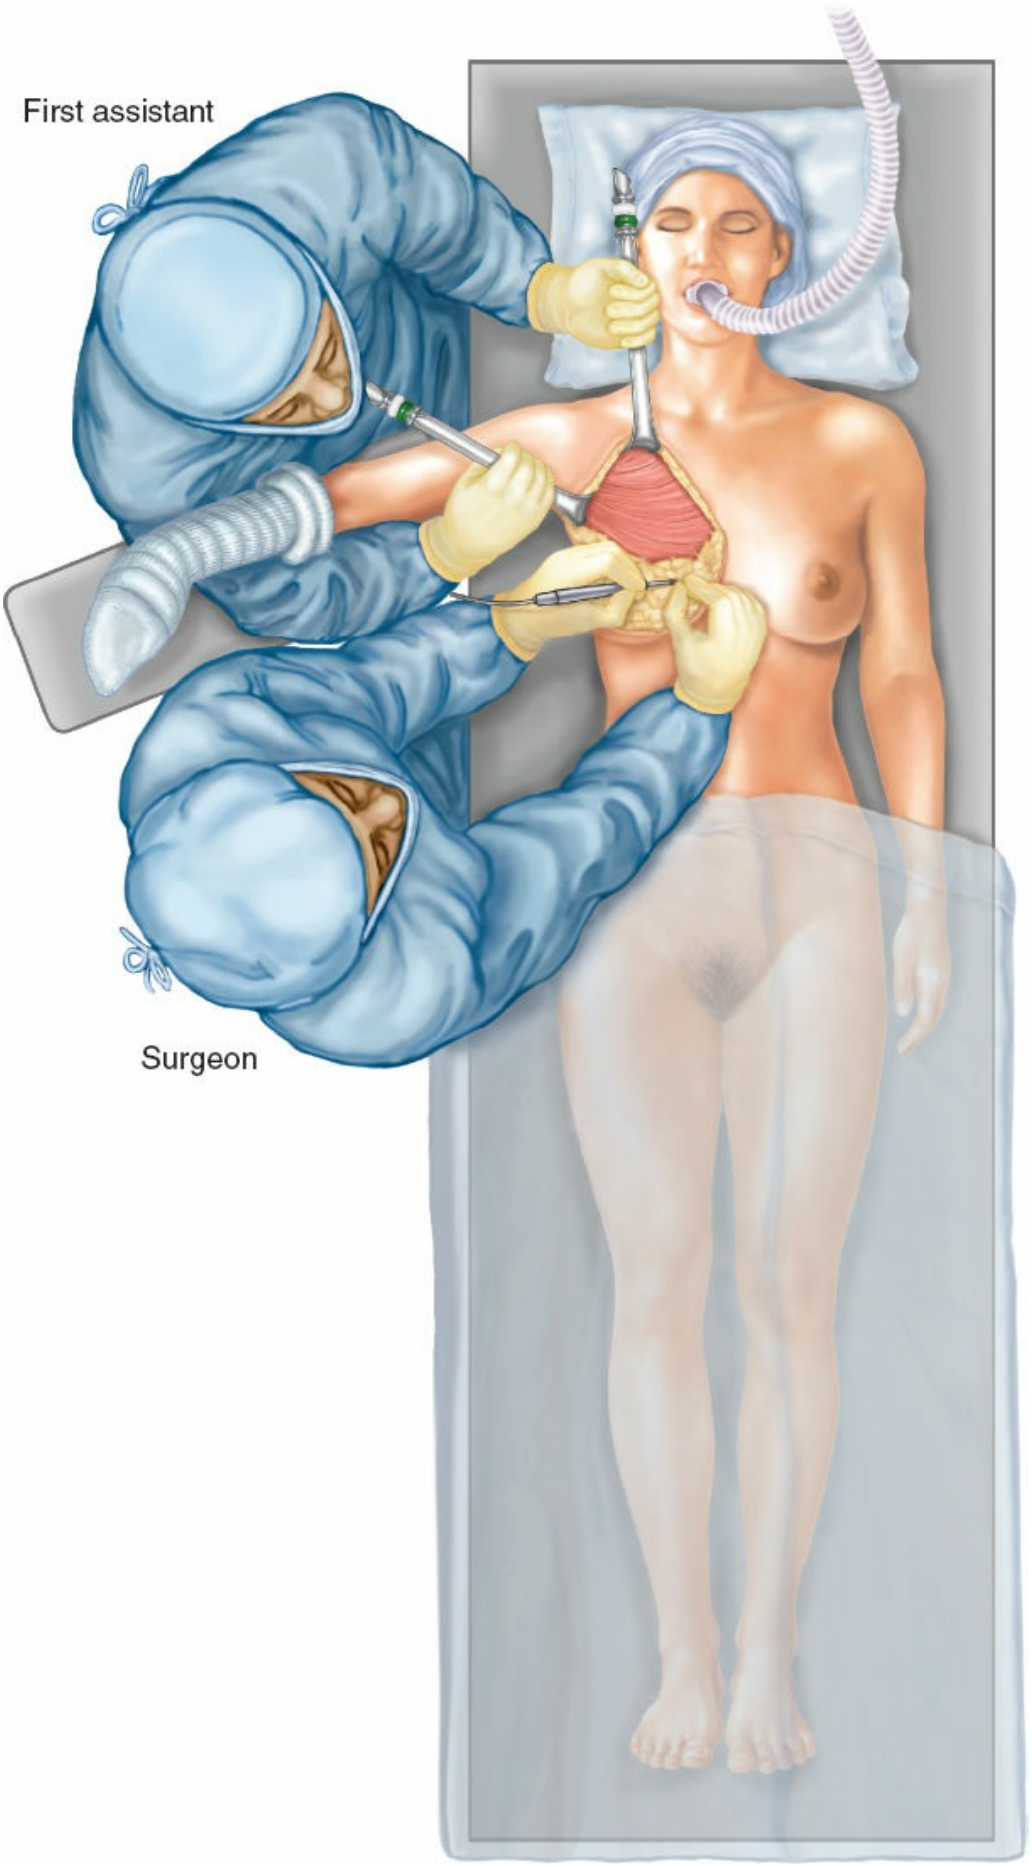
MODIFIED RADICAL MASTECTOMY: SURGICAL TECHNIQUE

The increasingly popular *skin-sparing mastectomy* removes all breast tissue, the nipple–areola complex, and <1 cm of skin around excised scars. There is a recurrence rate of <2% to 4% when skin-sparing mastectomy is used for T1 to T3 cancers. A *total (simple) mastectomy* removes all breast tissue, the nipple–areola complex, and necessary skin without axillary sampling/dissection. An *extended simple mastectomy* removes all breast tissue, the nipple–areola complex, necessary skin, and the level I axillary lymph nodes. The *modified RM* removes all breast tissue, the nipple–areola complex, extensive skin, and the level I and II axillary lymph nodes. The *Patey modified RM* also removes the pectoralis minor muscle, to provide access for complete dissection of the apical (level III) axillary lymph nodes. *The Halsted RM* removes all breast tissue, the nipple–areola complex, necessary skin, the pectoralis major and (optionally) the pectoralis minor muscles, and the level I to III axillary lymph nodes. Currently, early diagnostic imaging and education—together with chemotherapy, hormone therapy, and radiation therapy—have existentially eliminated the need for the classical Halsted RM.

Positioning

The patient is positioned on the operating table in the supine position for induction of general endotracheal anesthesia (Fig. 54.2). Folded towels provide modest nonrestrictive elevation of the ipsilateral hemithorax and shoulder so that shoulder movement is not compromised. Positioning the patient at the edge of the operating table affords the surgeon and the surgical assistant ample access to the breast and axilla and avoids undue retraction on the pectoralis muscle groups or the brachial plexus. The arm and shoulder must be prepped into the surgical field to allow unrestricted access for dissection of the axilla. The ipsilateral breast, neck, shoulder, and hemithorax are prepped down to the operating table and across the midline of the chest. Folded towels are used to expose the prepped operative field, which includes the shoulder, lower neck, sternum, and upper abdominal musculature. The towels are secured in place with towel

clips or surgical staples. In addition, the ipsilateral axilla, arm, and hand are fully prepared within the operative field and the arm is positioned on an arm board that is placed perpendicular to the operating field. While alternative methods exist for including the arm and hand in the operative field, isolation of the hand and forearm with an occlusive cotton dressing (stockinette) is preferred. The stockinette is secured in place by applying an elastic or cotton bandage distal to the ipsilateral elbow, thereby ensuring free mobility of the ipsilateral elbow, arm, and shoulder.



First assistant
Surgeon

Figure 54.2. Position of patient for left modified radical mastectomy at margin of operative table. The first assistant is cephalad to the arm board and shoulder of the patient to allow access to the axillary contents without undue traction on major muscle groups. Depicted is the preferential isolation of the hand and forearm with an occlusive Stockinette cotton dressing secured distal to the elbow. This technique allows free mobility of the elbow, arm, and shoulder to avoid undue stretch of the brachial plexus with muscle retraction. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

Prior to commencement of the procedure, the first surgical assistant is positioned cephalad to the shoulder of the ipsilateral breast, cephalad to the arm board (Fig. 54.2). This position permits the assistant to position the arm and shoulder and retract the pectoral muscles appropriately at the time of the axillary dissection. In an obese patient with large breasts, a second surgical assistant can be positioned on the contralateral side of the operating table to assist with exposure of the axilla during axillary dissection.

Planned incisions appropriate for cancers occupying various locations in the breast are depicted in Figures 54.3 to 54.9. The elliptical incision of the breast skin incorporates the nipple–areolar complex and skin overlying the breast cancer en bloc with skin margins that lie 1 to 2 cm from the cephalad and caudad extents of the cancer.

Utilizing electrocautery, “cold” or “harmonic” scalpel, all flaps are developed that extend to the boundaries of dissection for the modified RM and include: (a) the anterior margin of the latissimus dorsi muscle laterally; (b) the midline of the sternum medially; (c) the subclavius muscle superiorally; and (d) the caudal extension of the breast, which is 3 to 4 cm inferior to the inframammary fold, inferiorly (Fig. 54.10, *inset*). The skin edges are elevated at a right angle to the chest wall to adequately expose the superficial fascia (Fig. 54.10). Skin flaps include the skin and tela subcutanea and vary in thickness depending upon body habitus (Fig. 54.11A). The fascial envelope plane for skin flap elevation is variable and deep to the subcutaneous vasculature and superficial to the larger end-artery vessels of the breast parenchyma. The surgeon elevates the skin flap with consistent thickness to avoid creation of devascularized subcutaneous

tissues, which can contribute to wound seroma, skin necrosis, and flap retraction (Fig. 54.11B).

With development of skin flaps, the breast parenchyma and pectoralis major fascia are elevated from the underlying pectoralis major muscle in a plane consistently parallel with the muscle bundles as they course from their medial origin (ribs 2 to 6) to their lateral insertion on the humerus (Fig. 54.11B). Perforating vessels from the *lateral thoracic or anterior intercostal arteries* are end-arteries that supply the pectoralis major and minor muscles and breast parenchyma, are regularly encountered during elevation of the breast parenchyma and pectoralis major fascia. These vessels are individually identified and ligated with 2-0 or 3-0 nonabsorbable sutures. Elevation of the breast parenchyma and pectoralis major fascia is continued laterally until the lateral edge of the pectoralis major muscle and the underlying pectoralis minor muscle are exposed. The surgeon is aware of the anatomic location of the *lateral neurovascular bundle* in which the *medial pectoral nerve* (laterally placed with origin from the medial cord) courses to innervate the pectoralis major and minor muscles. If possible, this nerve is routinely preserved to prevent atrophy of the lateral head of the pectoralis major—a significant cosmetic and functional deficit (Table 54.5).

Following elevation of the breast parenchyma and pectoralis major muscle fascia from the underlying pectoralis major muscle, an incontinuity axillary lymph node dissection is performed (Figs. 54.12 and 54.13). The investing fascia of the axillary space is sharply divided (Fig. 54.12), the pectoralis minor muscle is defined, and lymph nodes, which may lie between the pectoralis muscles (Rotter's nodes), are cleared. As the axillary lymph node dissection proceeds, the loose areolar tissue of the lateral axillary space is elevated with identification of the lateral extent of the axillary vein in its course anterior and caudad to the brachial plexus and axillary artery (Fig. 54.12). (The axillary contents can also be removed in a medial to lateral direction.) The investing layer of the axillary vein is dissected sharply, with dissection allowing complete visualization of the anterior and ventral surfaces of the vein.

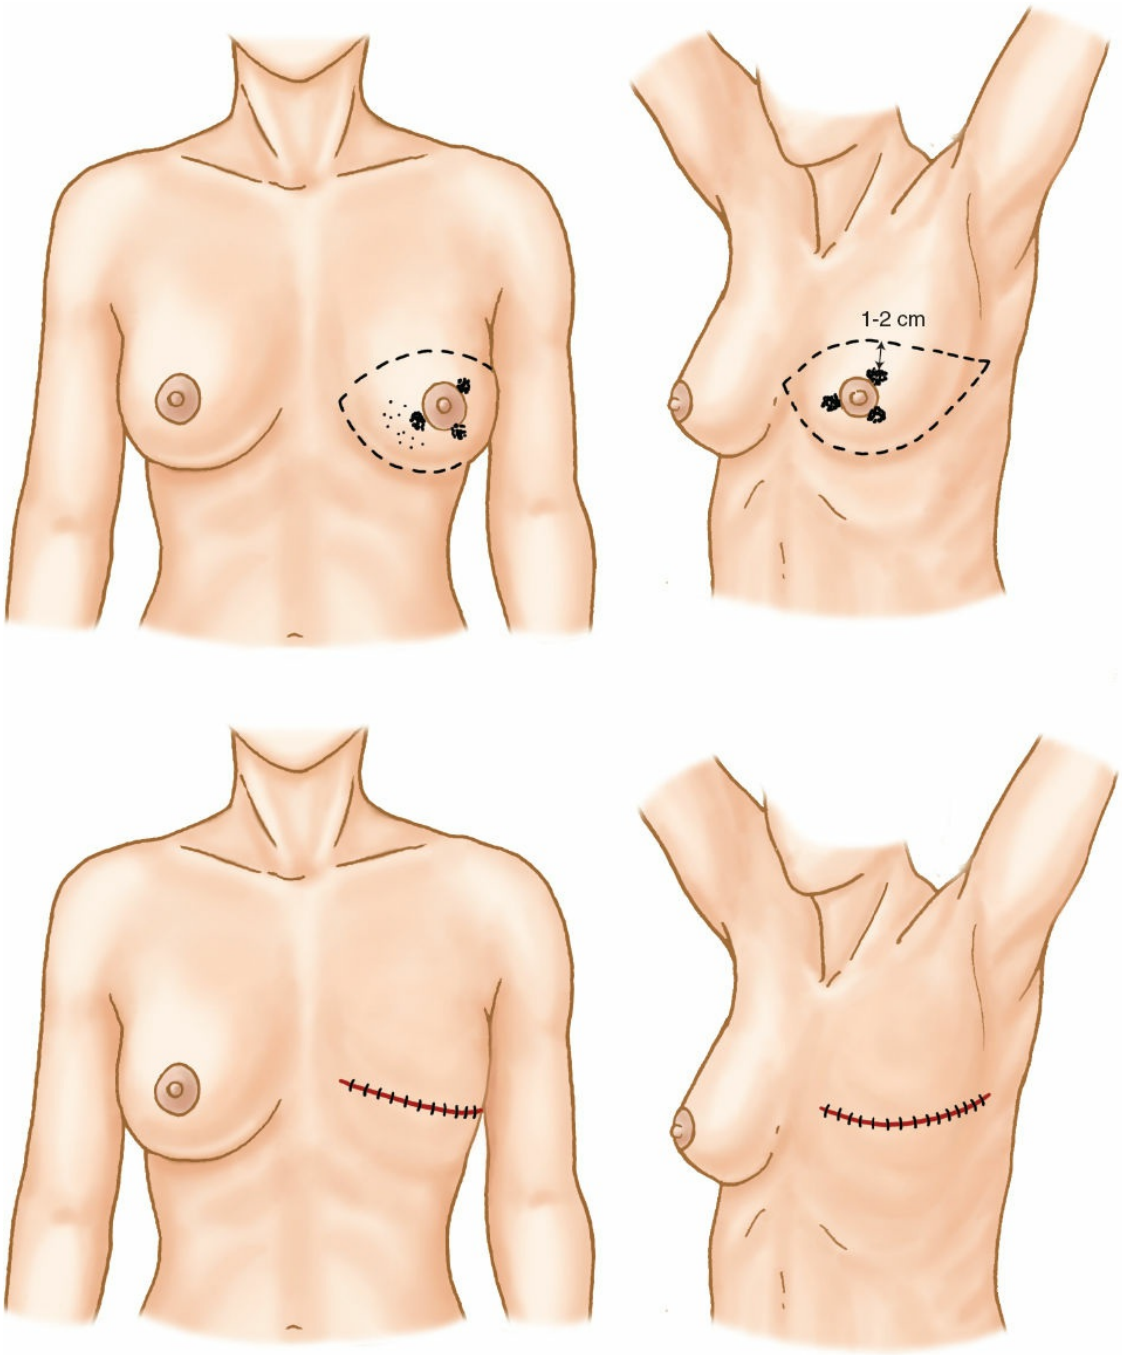


Figure 54.3. Design of the classic Stewart elliptical incision for central and subareolar primary lesions of the breast. The medial extent of the incision ends at the margin of the sternum. The lateral extent of the skin incision should overlie the anterior margin of the latissimus dorsi. The design of the skin incision should incorporate the primary neoplasm en bloc with margins that are 1 to 2 cm from the cranial and caudal edges of the tumor. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

Division and ligation of intervening venous tributaries is performed. Retraction of the superomedial aspect of the pectoralis major muscle exposes the lateral pectoral nerve, which originates from the lateral cord, and is protected to preserve innervation to the medial heads of the pectoralis major muscle (Figs. 54.12 and 54.13; Table 54.5). Dissection continues medially on the anteroventral surface of the axillary vein and the loose areolar tissue at the juncture of the axillary vein with the anterior margin of the latissimus dorsi muscle is swept inferomedially to include the lateral group of axillary lymph nodes (level I, see Fig. 54.12). The intercostobrachial nerves are infrequently visualized, except for the superior trunk that commonly divides close to the chest wall and courses through the level II axillary lymph nodes that lie below the axillary vein. Generally, no attempt is made to salvage the superior trunk and branches of the intercostobrachial nerve (Table 54.5).

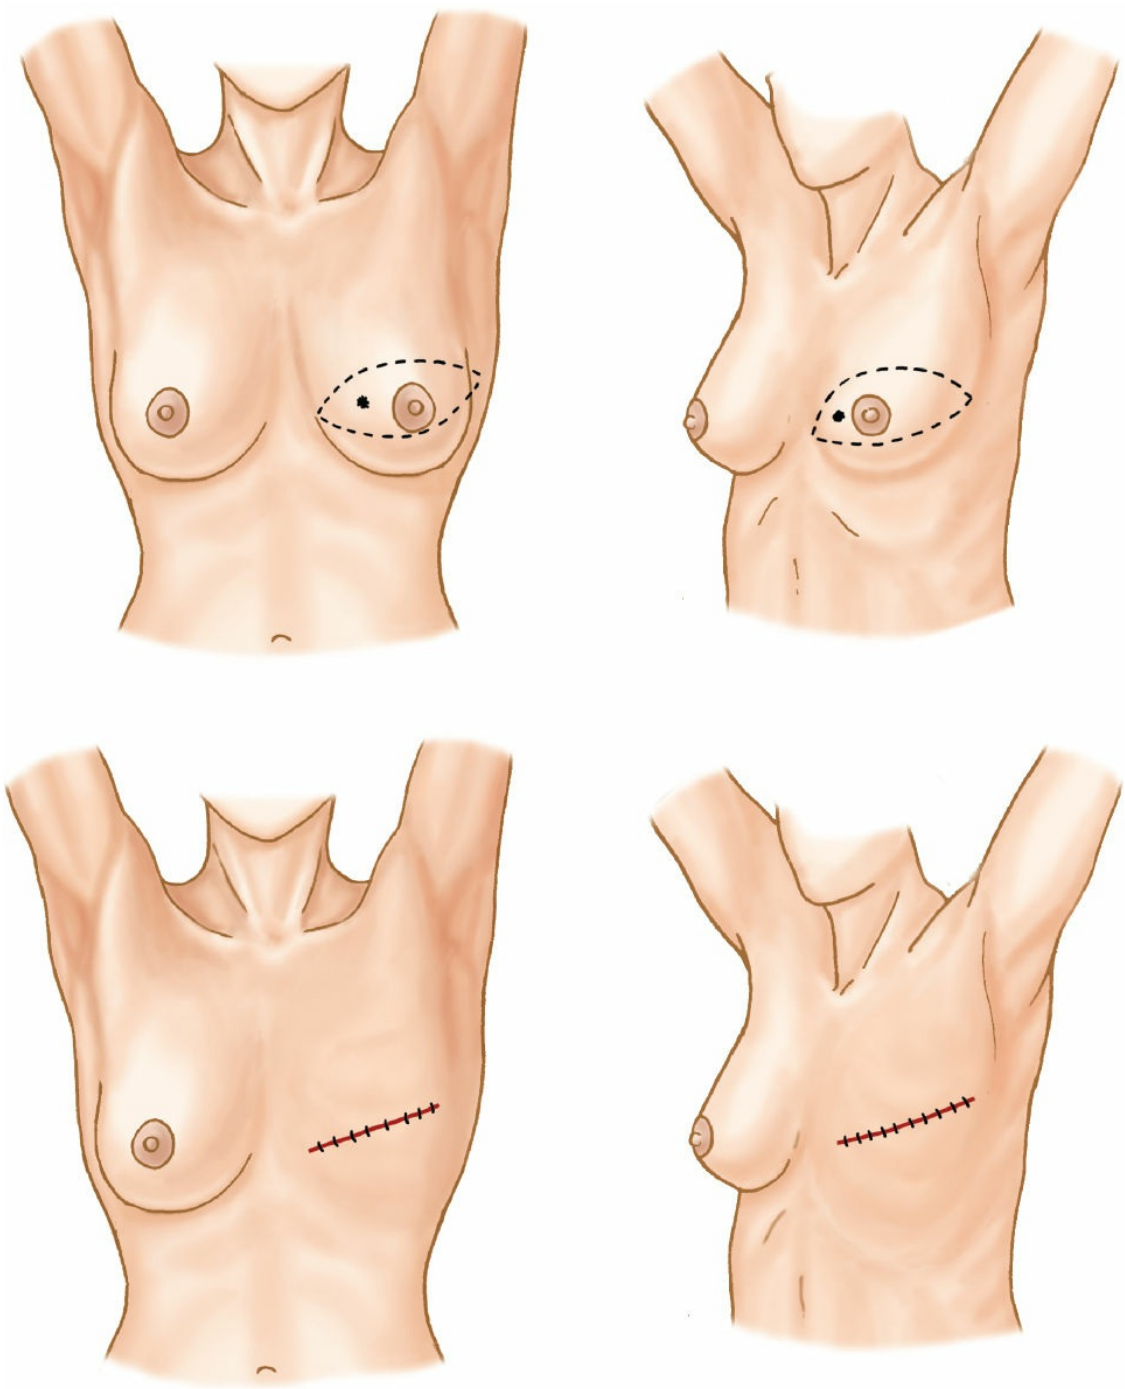

Figure 54.4. Design of the obliquely placed modified Stewart incision for cancer of the inner quadrant of the breast. The medial extent of the incision must often incorporate skin to the midsternum to allow a 1- to 2-cm margin in all directions from the edge of the tumor. Lateral extent of the incision ends at the anterior margin of the latissimus. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

The surgeon should be cognizant of preservation of the thoracodorsal artery, nerve, and vein, located deeply in the axillary space; this maneuver is advocated as these structures are invested with loose areolar tissue and the axillary lymph nodes of the lateral and subscapular groups (Figs. 54.12 and 54.13). The thoracodorsal nerve originates from the posterior cord medial to the thoracodorsal artery and vein and is visualized and protected along its variable inferolateral course en route to its distal innervation of the latissimus dorsi muscle. The lateral axillary lymph node group (Fig. 54.12) is retracted inferomedially and anterior to the thoracodorsal neurovascular bundle and dissected en bloc with the subscapular group of axillary lymph nodes (level I), which are medially located between the thoracodorsal nerve and the lateral chest wall. Dissection of the posterior contents of the axillary space exposes the posterior boundary of the axilla, allowing visualization of the heads of the teres major muscle laterally and the subscapularis muscle medially. Dissection then proceeds medially with extirpation of the central axillary lymph node groups (level II, see Fig. 54.12, *inset*). The superomedial aspect of the dissection specimen can be identified with a metallic marker or suture to provide anatomic orientation for the pathologist. The surgeon continues the dissection en bloc to avoid separation of nodal groups and disruption of lymphatic vessels in the axilla. With medial dissection, the surgeon encounters the chest wall deep in the medial axillary space and is able to identify and preserve the long thoracic nerve (Bell's respiratory nerve), which is constant in its location, anterior to the subscapularis muscle, and is closely applied to the investing serratus fascial compartment of the chest wall. The diminutive long thoracic nerve is meticulously dissected from cephad to caudad longitudinal to its course; dissection is terminated at the point of innervation of the serratus anterior muscle (Figs. 54.12 and 54.13). Damage to the nerve initiates permanent disability with a "winged scapula" deformity secondary to denervation of the serratus anterior muscle (Table 54.3). The axillary contents anterior and medial to the long thoracic nerve are then swept inferomedially with the dissection specimen. The surgeon ensures that the long thoracic and thoracodorsal nerves are completely visualized prior to division of the inferior extent of the axillary dissection contents.

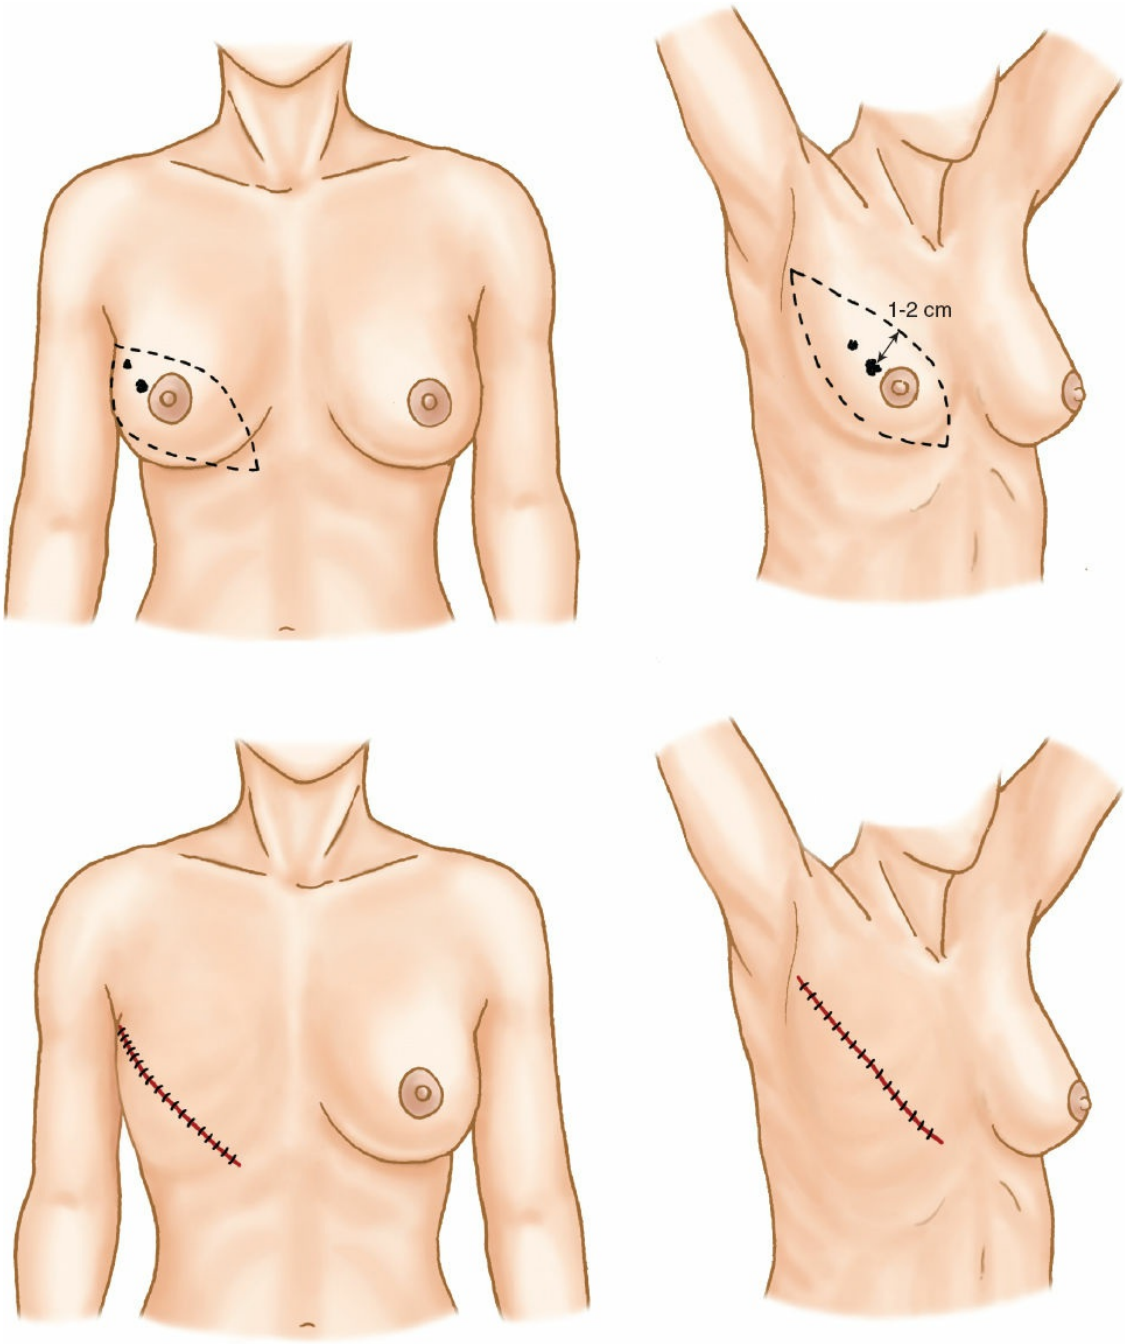

Figure 54.5. Design of the classic Orr oblique incision for carcinoma of the upper outer quadrants of the breast. The skin incision is placed 1 to 2 cm from the margin of the tumor in an oblique plane that is directed cephalad toward the ipsilateral axilla. This incision is a variant of the original Greenough, Kocher, and Rodman techniques for flap development. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

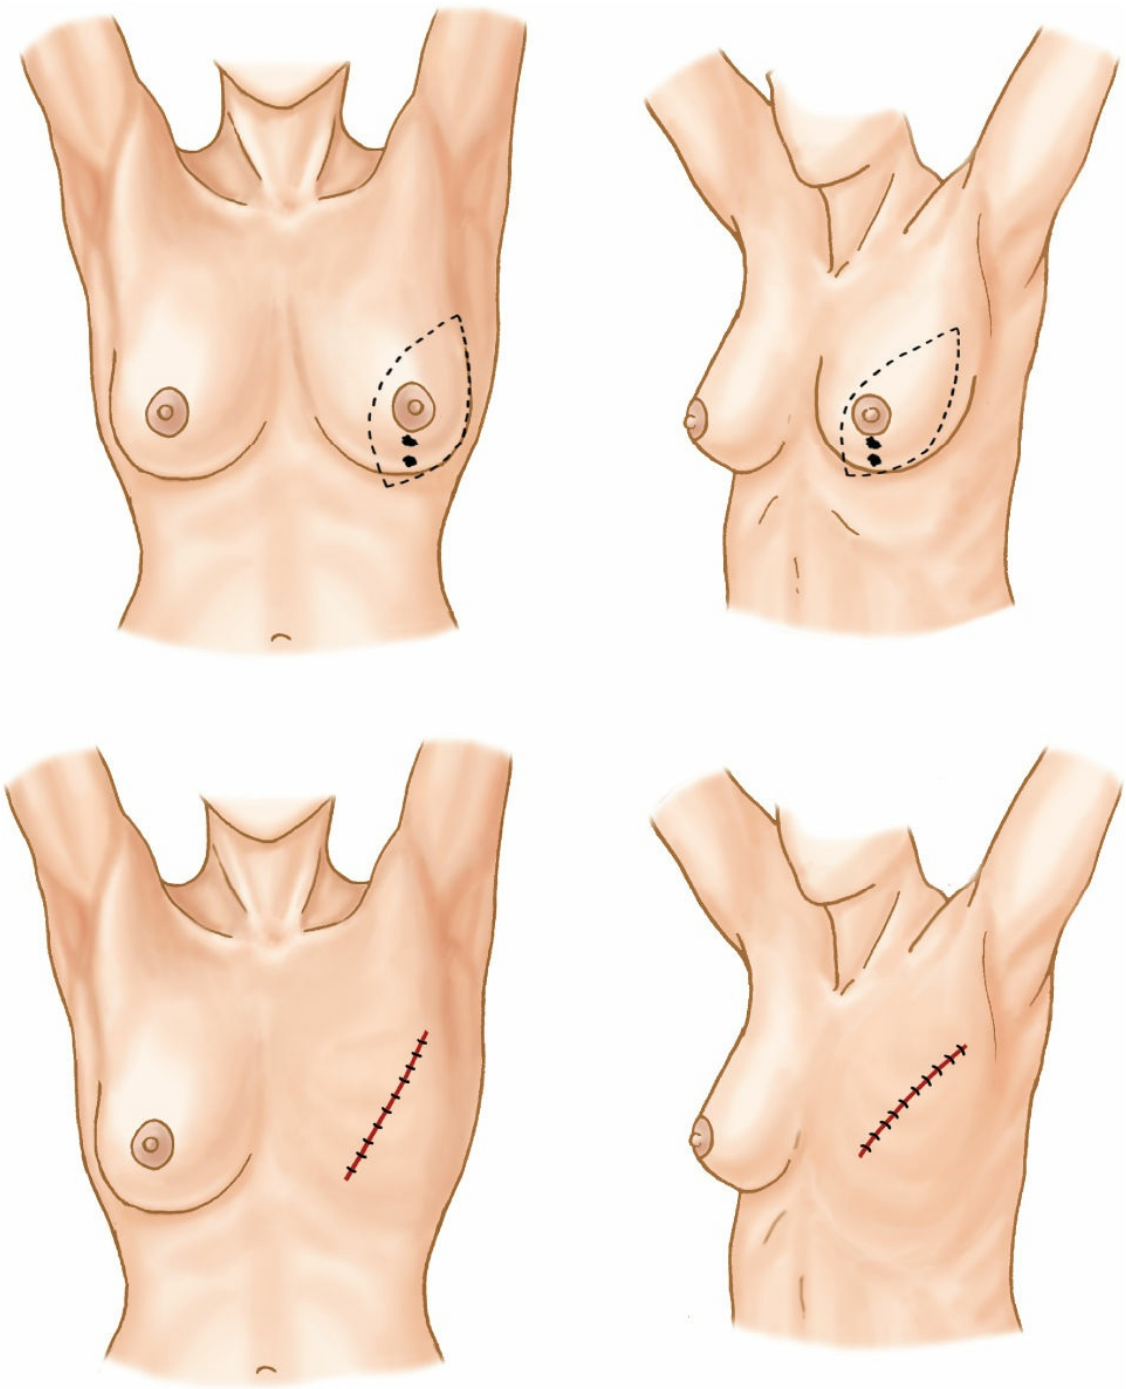

Figure 54.6. Variation of the Orr incision for lower inner and vertically placed (6 o'clock) lesions of the breast. The design of the skin incision is identical to that of Figure 20.4, with attention directed to margins of 1 to 2 cm. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

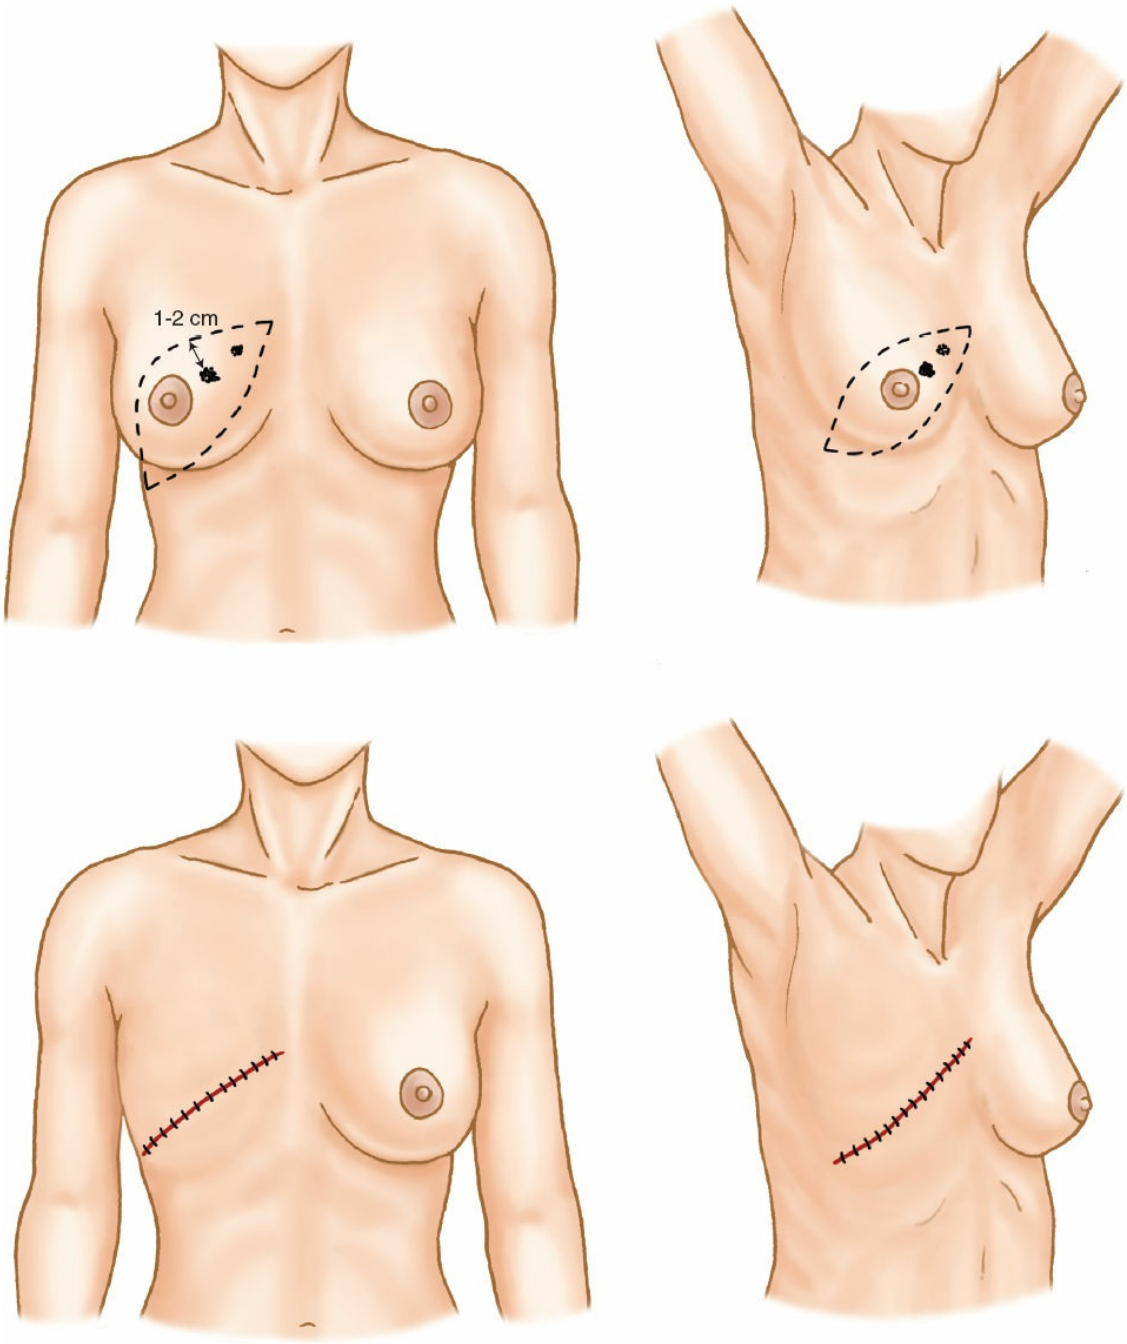

Figure 54.7. Design of skin flaps for upper inner quadrant primary tumors of the breast. The cephalad margin of the flap must be designed to allow access for dissection of the axilla. With flap margins 1 to 2 cm from the tumor, variation in the medial extent of the incision is expected and may extend beyond the edge of the sternum. On occasion, the modified Stewart incision can incorporate the tumor en bloc, provided that the cancer is not too high on the breast and craniad from the nipple/areola complex. All incision designs must be inclusive of the nipple/areola complex when total mastectomy is planned with primary therapy. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*.

Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

With the presence of level III lymphadenopathy, the Patey modification of the modified RM is employed to enhance locoregional control (Fig. 54.13). As the surgeon proceeds medially to complete dissection along the lateral margin of the pectoralis major muscle, abduction of the shoulder and extension of the arm along with finger dissection at the lateral margin of the pectoralis major muscle allow visualization of the insertion of the pectoralis minor muscle on the coracoid process of the scapula. The Patey modification involves division of the tendinous portion of the pectoralis minor muscle (Fig. 54.12) near its insertion on the coracoid process with/without removal of the muscle, which permits access to the apical axillary lymph nodes (level III) and visualization of the full extent of the axillary vein as it courses beneath the pectoralis minor muscle to its confluence with the subclavian vein beneath the costoclavicular ligament (Halsted ligament).

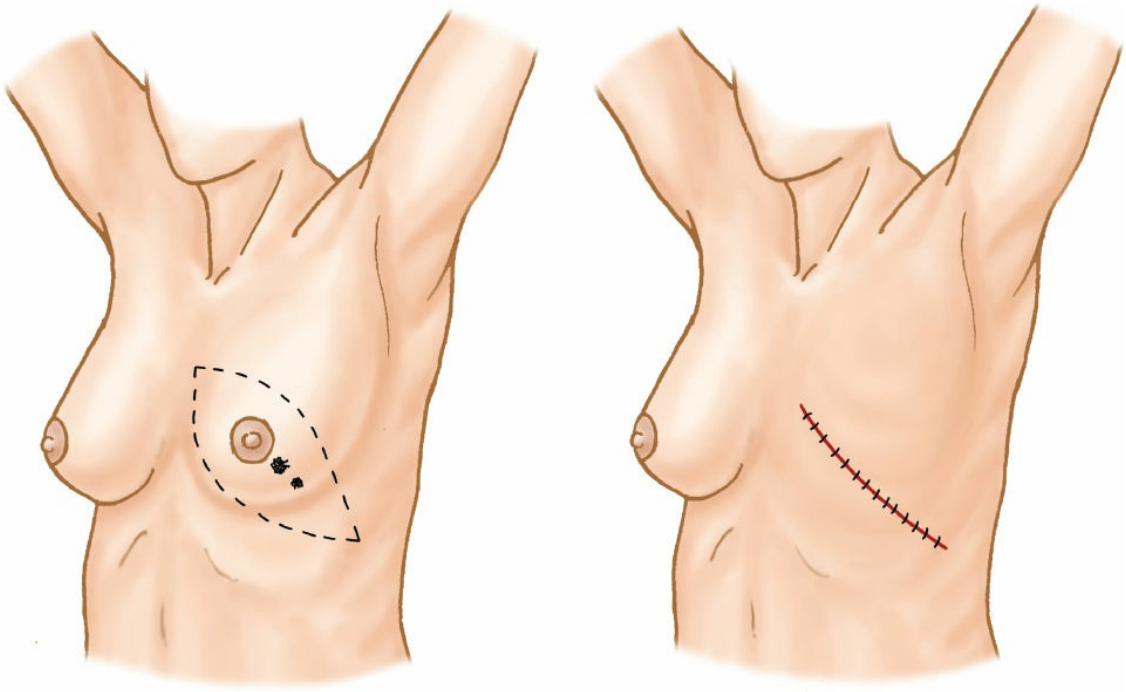

Figure 54.8. Incisions for cancer of the lower outer quadrants of the breast. The surgeon should design incisions that achieve margins of 1 to 2 cm from the tumor with cephalad margins that allow access for dissection of the axilla. The medial extent is the margin of the sternum. Laterally, the inferior extent of the incision is the latissimus. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*.

Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

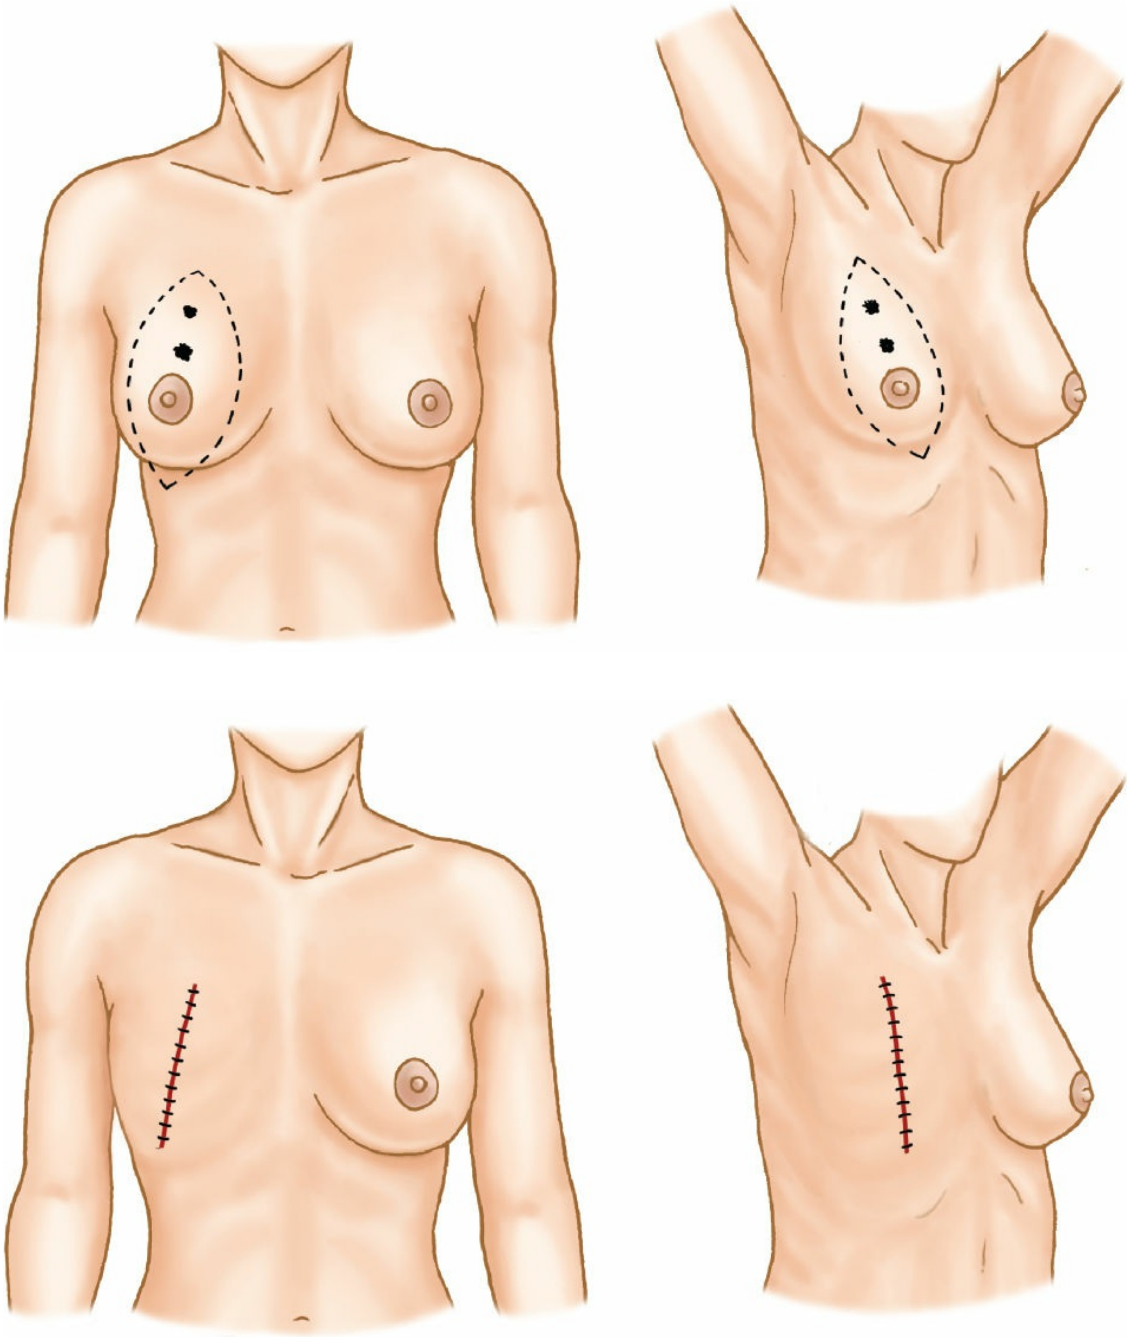

Figure 54.9. Depiction of skin flaps for lesions of the breast that are high lying, infraclavicular, or fixed to the pectoralis major muscle. Fixation to the muscle and/or chest wall necessitates Halsted radical mastectomy with skin margins of at least 2 cm. Skin grafting is necessary when large margins of skin are resected for T_3 and T_4 cancers. Primary closure for T_1 and some T_2 tumors is often possible. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with

permission.)

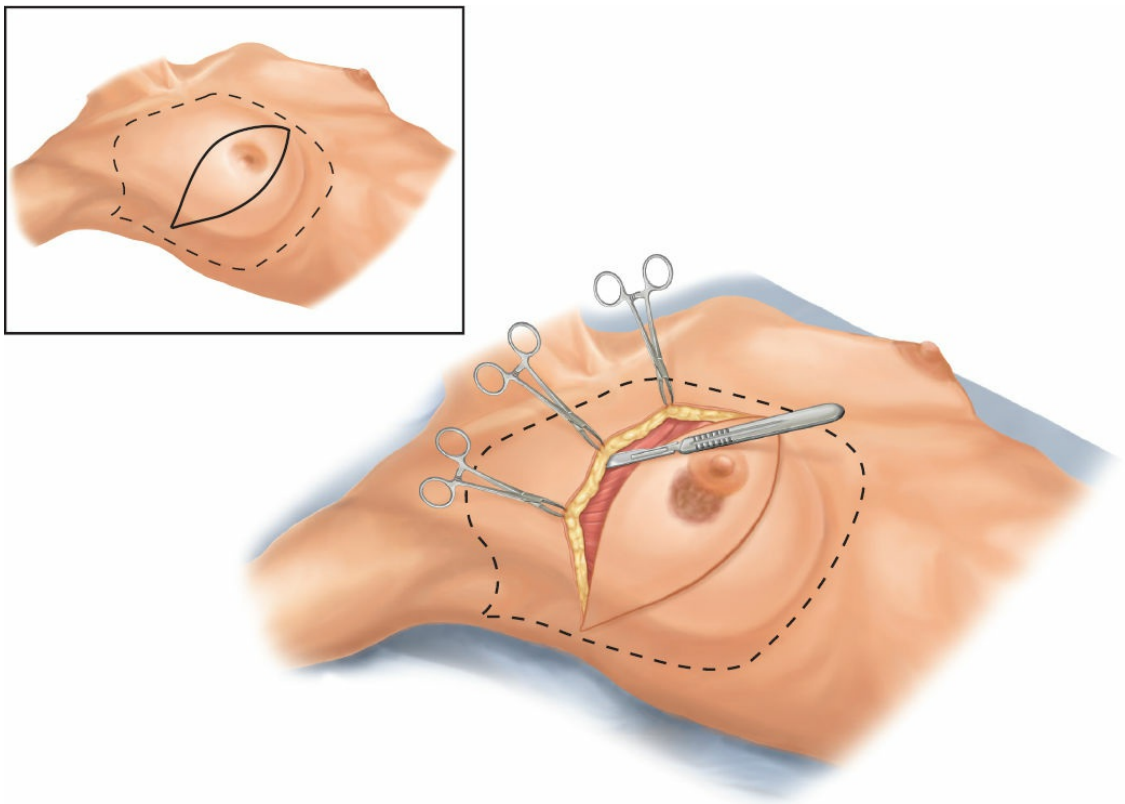

Figure 54.10. *Inset:* Limits of the modified radical mastectomy are delineated laterally by the anterior margin of the latissimus dorsi muscle, medially by the sternal border, superiorly by the subclavius muscle, and inferiorly by the caudal extension of the breast approximately 3 to 4 cm inferior to the inframammary fold. Skin flaps for the modified radical technique are planned with relation to the quadrant in which the primary neoplasm is located. Adequate margins are ensured by developing skin edges 3 to 5 cm from the tumor margin. Skin incisions are made perpendicular to the subcutaneous plane. Flap thickness should vary with patient body habitus but ideally should be 7 to 8 mm thick. Flap tension should be perpendicular to the chest wall with flap elevation deep to the cutaneous vasculature, which is accentuated by flap retraction. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

TABLE 54.5 Anatomical Complications of the Modified RM

Vascular Injury	The first and second perforating vessels are too large for cautery. They are ligated. The axillary vein, if torn, is repaired. Ligation may cause chronic edema.
Nerve Injury	
Intercostobrachial nerve	When cut, circumscribed numbness of the medial aspect of the ipsilateral upper arm results.
Long thoracic nerve	If cut, a "winged scapula" deformity results.
Medial and lateral thoracic nerves	If cut, the pectoralis muscles atrophy.
Thoracodorsal nerve	If cut, internal rotation and abduction of the shoulder is weakened.

Following completion of axillary node dissection (Fig. 54.13), the resection specimen is sent for histologic examination and for immunohistochemistry (ER, PR, Ki67, Her2-neu and appropriate prognostic genomic/proteomic analyses). The surgical bed is irrigated with sterile saline to evacuate residual tissue, blood clots, and serum. Bleeding points are identified, clipped, cauterized, or ligated. After this, the surgeon, surgical assistant, and scrub nurse don fresh surgical gloves and utilize clean surgical instruments to avoid implantation of exfoliated cancer cells in the surgical bed. Just prior to closure, closed suction silastic catheters are placed in the surgical bed and are brought out through separate stab wounds inferiorly (Fig. 54.13, *inset*). The laterally placed silastic catheter is positioned in the axillary space approximately 2 cm inferior to the axillary vein on the ventral surface of the latissimus dorsi muscle to provide drainage of the axilla. The medially placed silastic catheter is positioned under the skin flaps. Both catheters are secured to the skin with a 3-0 nylon suture and are maintained on low-pressure suction. The wound is closed in two layers with 3-0 absorbable sutures placed in the subcutaneous tissues, while the skin edges are approximated with staples or with 4-0 absorbable subcuticular sutures, in which case, short Steri-strips are applied perpendicular to the skin to closely approximate the skin edges. Noncompressive dressings can be applied.

Wound dressings are removed after 24 to 48 hours. The silastic catheters remain in place until drainage becomes serous or serosanguinous in character and decreases to ≤20 mL per 24 hours for a 48-hour period. Generally, the catheters are removed between postoperative days 5 and 7, but, when necessary for continued high-volume drainage, can remain until postoperative day 10. Range-of-motion shoulder exercises begin 24 hours

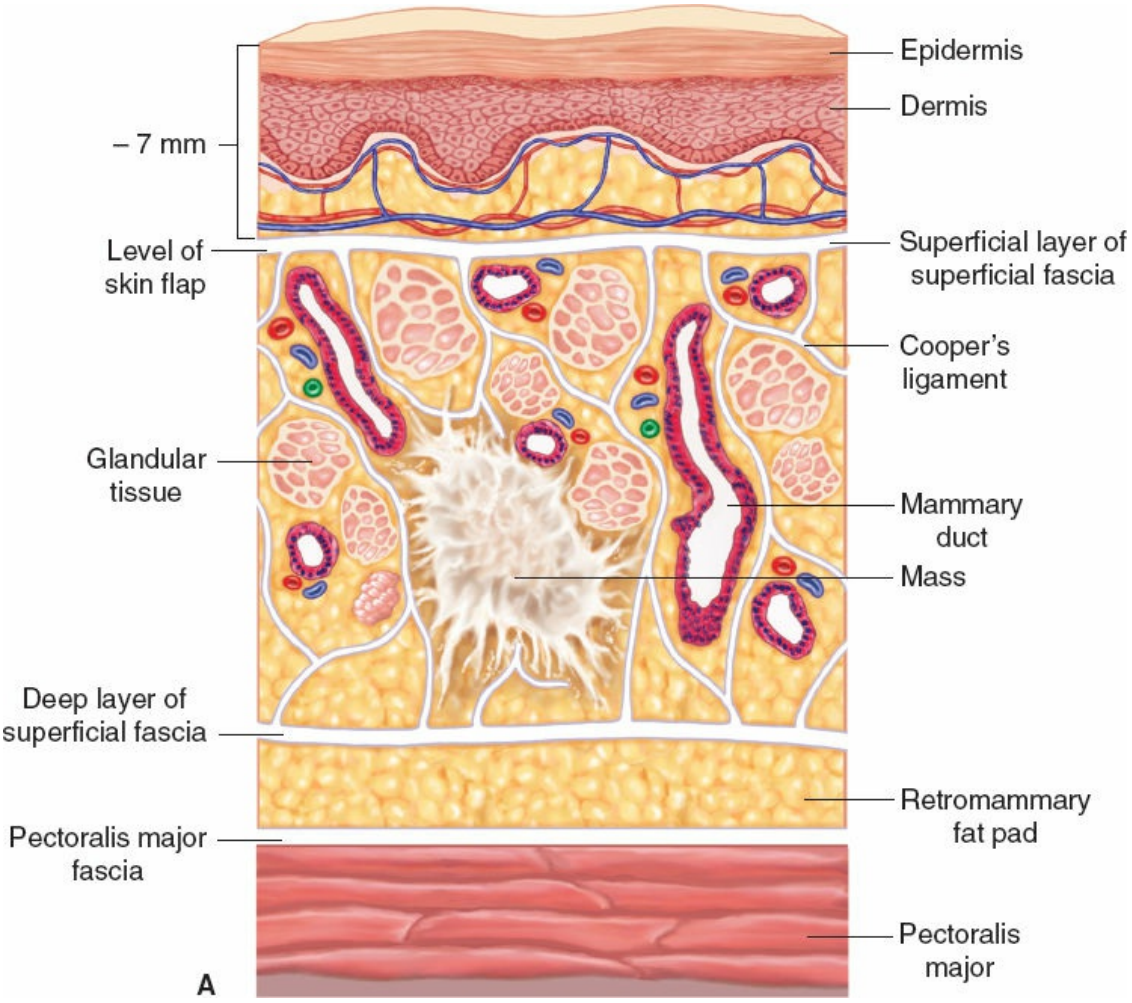
after surgery but are suspended for the 24-hour period following drain removal.

Development of a seroma beneath the skin flaps or in the axilla represents the most frequent complication of mastectomy and axillary lymph node dissection, reportedly occurring in as many as 30% of cases. Wound infections occur infrequently after a mastectomy and the majority occurs secondary to skin flap necrosis. Culture of the infected wound for aerobic and anaerobic organisms, debridement, and antibiotics are effective management. Moderate or severe hemorrhage in the postoperative period is rare and is best managed by return to the operating room with early wound exploration for control of hemorrhage and reestablishment of closed system suction drainage. The incidence of functionally *significant lymphedema* after modified RM is ≤10%. Extended axillary lymph node dissection (levels I to III), adjuvant radiation therapy, the presence of pathologic lymph nodes, and obesity contribute to an increased incidence of lymphedema. Individually fitted compression sleeves and intermittent compression devices considerably reduce the extent and palliate the symptoms of lymphedema.

RECONSTRUCTION OF THE BREAST AND CHEST WALL FOLLOWING MRM

The options for reconstructive surgery following mastectomy for breast cancer include: primary wound closure and prosthetic expanders/implants with transfer of skin and subcutaneous tissues for breast reconstruction. These techniques are either *initiated immediately* (Fig. 54.14) or *delayed* (Figs. 54.15 and 54.16). Reconstruction following prophylactic mastectomy or after mastectomy for *early invasive disease may be* performed concurrent with surgical resection of the neoplasm; however, reconstruction following surgery for *advanced breast cancer* is optimally delayed for 6 to 18 months after completion of adjuvant therapy to ensure that locoregional control of disease has been established. For most women, wound closure after mastectomy is accomplished with simple approximation of the wound margins. When more radical removal of skin and subcutaneous tissue is necessary, the split-thickness skin graft provides functional coverage but allows poor tolerance for adjuvant radiation therapy when required with more advanced disease. Thus, creation of large soft tissue defects should be covered with mycocutaneous flaps. Implants placed beneath the pectoralis muscle can be utilized for

reconstruction with or without the concomitant use of myocutaneous flaps. Various types of myocutaneous flaps may be employed, but the latissimus dorsi and the transverse rectus abdominis myocutaneous (TRAM) flaps are most frequently utilized and favored by the reconstructive plastic surgeon.



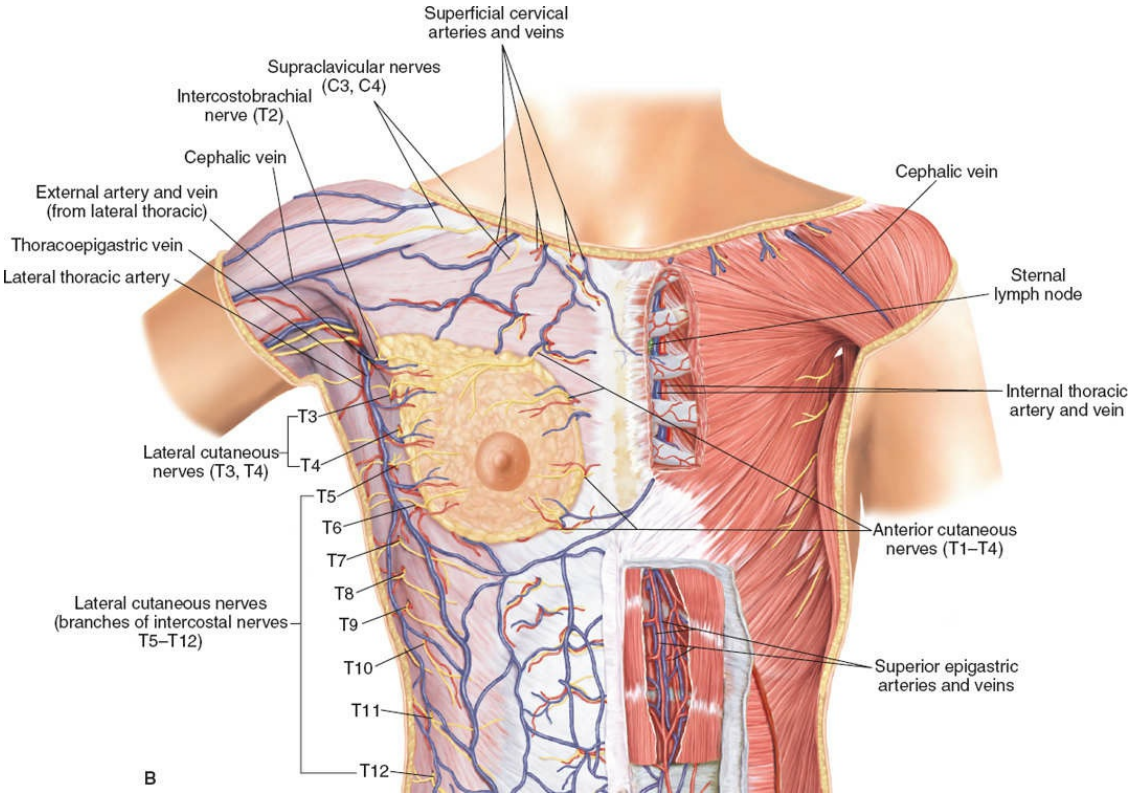


Figure 54.11. Development of the skin flaps. **A.** The skin flaps incorporate skin and the tela subcutanea and are elevated deep to the subcutaneous vasculature. The anterior border of the latissimus dorsi muscle and the innervation of the skin of the lateral chest and axilla by the lateral cutaneous branches of the intercostobrachial nerves are illustrated. **B.** Branches of these nerves also innervate the skin of the medial aspect of the arm. The intercostobrachial nerves are commonly divided during the axillary dissection. Elevation of the breast parenchyma and pectoralis major muscle fascia. The breast parenchyma and pectoralis major fascia are elevated en bloc from the underlying pectoralis major muscle in a plane parallel to the muscle bundles as they course from their medial origin (ribs 2 to 6) to their lateral insertion on the humerus. Perforating vessels from the lateral thoracic or anterior intercostal arteries, which are end arteries that supply the pectoralis major and minor muscles and breast parenchyma, are regularly encountered during elevation of the breast parenchyma and pectoralis major fascia. These vessels are individually identified and secured with 2-0 or 3-0 nonabsorbable sutures. Elevation of breast parenchyma and fascia continue until the full length of the lateral edge of the pectoralis major muscle is exposed. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

In the absence of metastic disease with bony chest wall invasion by locoregional disease, or with pretreated recurrent/primary disease, resection of portions of the bony chest wall en bloc is indicated. When one or two ribs are resected en bloc with the specimen, myocutaneous flap coverage is provided; reconstruction of the bony defect is usually not necessary as scar tissue will stabilize the chest wall. When more than two ribs are sacrificed, it is advisable to stabilize the chest wall with Marlex or other prosthetic mesh, which is thereafter covered with autologous soft tissues utilizing either the latissimus dorsi or TRAM myocutaneous flap.

For purposes of simplicity and function, the most pragmatic procedure for immediate breast reconstruction includes the placement of an implant beneath the pectoralis major muscle (Fig. 54.14). Candidates for this technique include patients with (a) early-stage breast cancer who require minimal skin excision, (b) a small-diameter nipple–areola complex, and (c) small- to moderate-sized breasts without ptosis. After completion of the mastectomy, an incision is made at the inframammary crease and a musculofascial flap involving the pectoralis major, serratus anterior, external oblique, and rectus abdominis muscles is elevated. An implant of appropriate size is then placed on the chest wall beneath the musculofascial flap and the incision closed with absorbable sutures. Capsular contraction is a complication of implant placement and can require reoperation.

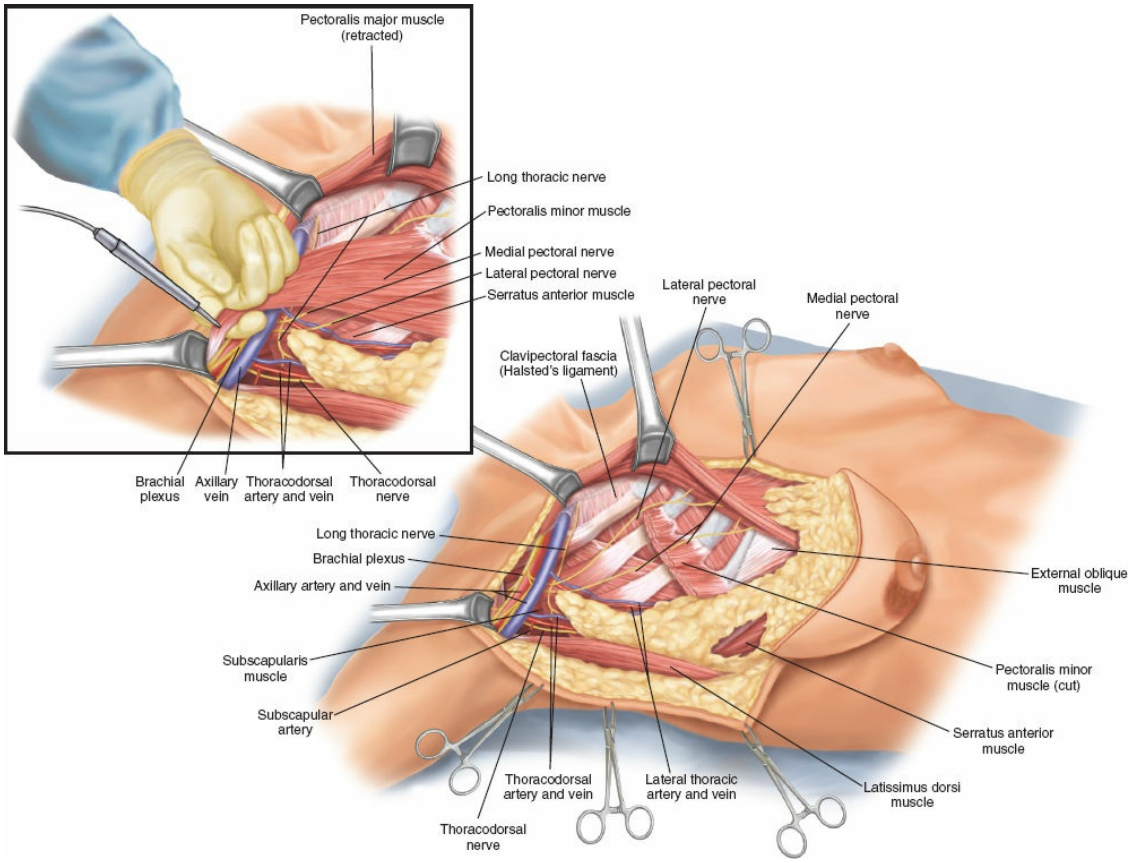

Figure 54.12. Exposure of the pectoralis minor muscle and incision of the investing fascia of the axilla. Upward retraction of the pectoralis major muscle reveals the underlying pectoralis minor muscle and an intervening compartment (Rotter's space), which may contain lymph nodes (Rotter's nodes). *Inset:* After incision of the investing fascia of the axillary space, the tendinous portion of the pectoralis minor muscle and underlying structures (axillary artery and vein, brachial plexus) are readily identified. Digital protection of the brachial plexus for division of the insertion of the pectoralis minor muscle on the coracoid process. All loose areolar and lymphatic tissues are swept en bloc with the axillary contents. Dissection commences superior to inferior with complete visualization of the anterior and ventral aspects of the axillary vein. Dissection craniad to the axillary vein is inadvisable, for fear of damage to the brachial plexus and the infrequent observation of gross nodal tissue cephalic to the vein. Investing fascial dissection of the vein is best completed with the cold scalpel following exposure, ligation, and division of all venous tributaries on the anterior and ventral surfaces. Caudal to the vein, loose areolar tissue at the junction of the vein with the anterior margin of latissimus is swept inferomedially inclusive of the lateral (axillary) nodal group (level 1). Care is taken to preserve the neurovascular thoracodorsal artery, vein, and nerve

in the deep axillary space. The thoracodorsal nerve is traced to its innervation of the latissimus dorsi muscle laterally. Lateral axillary nodal groups are retracted inferomedially and anterior to this bundle for dissection en bloc with the subclavicular (level 3) group. The superomedial most extent of the dissection is the clavipectoral fascia (Halsted ligament). This level of dissection with the Patey technique allows the surgeon to mark, with metallic clip or suture, the superiormost extent of dissection. All loose areolar tissue just inferior to the apical nodal group is swept off the chest wall, leaving the fascia of the serratus anterior intact. With dissection parallel to the long thoracic nerve (respiratory nerve of Bell), the deep investing serratus fascia is incised. This nerve is closely applied to the investing fascial compartment of the chest wall and must be dissected in its entirety, cephalic to caudal, to ensure innervation of the serratus anterior and avoidance of the “winged scapula” disability. Axillary lymph node dissection. The loose areolar tissue of the axillary space is elevated and the investing layer of the axillary vein is dissected sharply, with dissection continuing to allow complete visualization of the anterior and ventral surfaces of the vein, as well as ligation and division of intervening venous tributaries. The loose areolar tissue at the juncture of the axillary vein with the anterior margin of the latissimus dorsi muscle laterally is swept inferomedially to include the lateral group of axillary lymph nodes (level I). The thoracodorsal artery and vein, which are located deep in the axillary space and are invested with loose areolar tissue and the axillary lymph nodes of the lateral and subscapular groups, are preserved. The lateral axillary lymph node group is retracted inferomedially and anterior to the thoracodorsal neurovascular bundle and dissected en bloc with the subscapular group of axillary lymph nodes (level I), which is located medially between the thoracodorsal nerve and the lateral chest wall. Dissection then proceeds medially with extirpation of the central axillary lymph node groups (level II). The long thoracic nerve (Bell’s respiratory nerve), which is constant in its location anterior to the subscapularis muscle, and is closely applied to the investing fascial compartment of the chest wall, is identified and preserved. The axillary contents anterior and medial to the long thoracic nerve are then swept inferomedially with the dissection specimen. *Inset:* When level III lymphadenopathy is present, a Patey modification of the axillary dissection is performed, which involves division of the tendinous portion of the pectoralis minor muscle near its insertion on the coracoid process with/without removal of the muscle. This modification provides exposure for

dissection of the apical axillary lymph nodes (level III). Digital protection of the brachial plexus prior to division of the tendinous insertion of the pectoralis minor muscle at the corocoid process is illustrated.

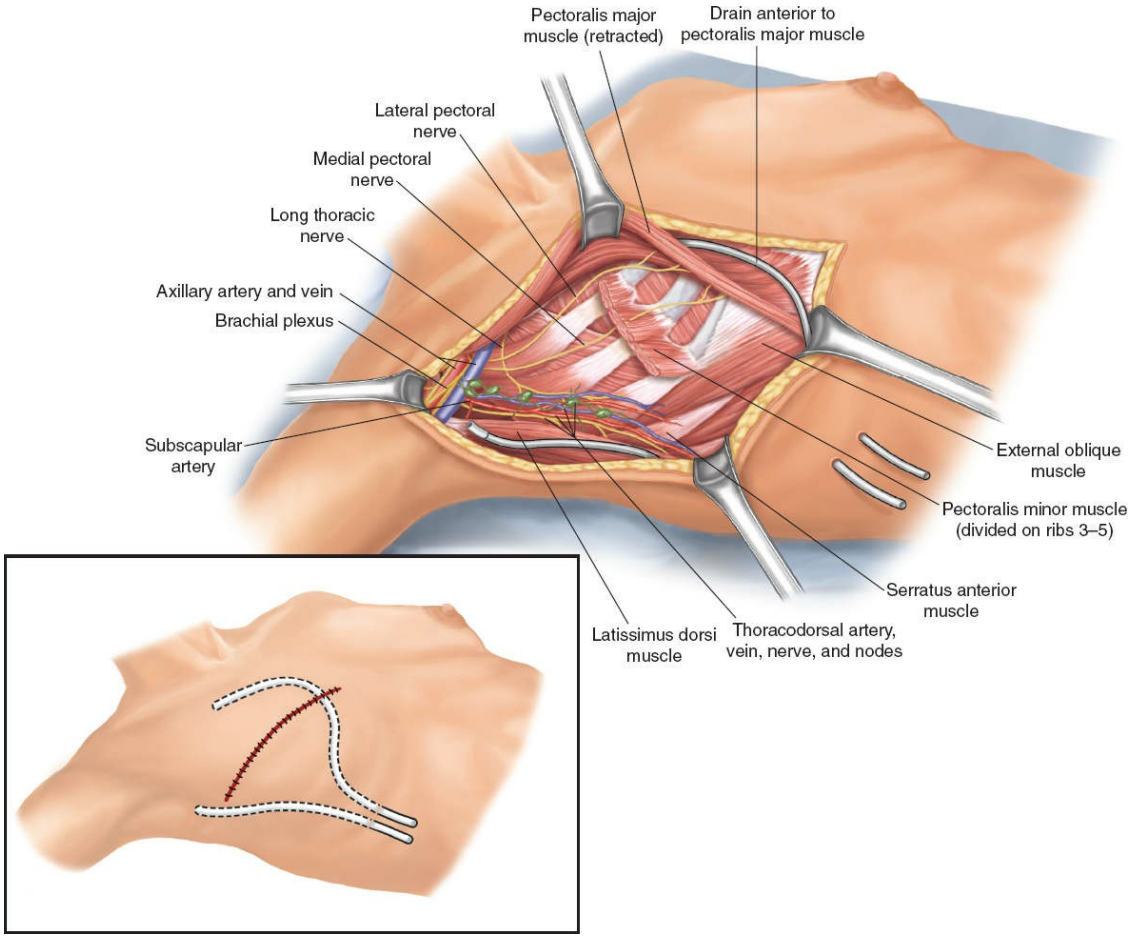

Figure 54.13. The completed Patey axillary dissection variant of the modified radical technique. The dissection is inclusive of the pectoralis minor muscle from origin to insertion on ribs 2 to 5. Both medial and lateral pectoral nerves are preserved to ensure innervation of pectoralis major. With completion of the procedure, remaining portions of this muscle are swept en bloc with the axillary contents to be inclusive of Rotter's interpectoral and the retropectoral groups. *Inset:* Following copious irrigation with saline, closed suction Silastic catheters (10 French) are positioned via stab incisions placed in the inferior flap at the anterior axillary line. The lateral catheter is placed approximately 2 cm inferior to the axillary vein. The superior, longer catheter placed via the medial stab wound is positioned in the inferomedial aspect of the wound bed anterior to the pectoralis major muscle beneath the skin flap. The wound is closed in two layers with 3-0 absorbable synthetic sutures placed in subcutaneous planes. Undue tension on margins of the flap must be avoided; it may necessitate undermining of tissues to reduce mechanical forces. The skin is closed with subcuticular 4-0 synthetic absorbable or nonabsorbable sutures. After completion of wound closure, both catheters are connected to bulb suction.

Light, bulky dressings of gauze are placed over the dissection site and taped securely in place with occlusive dressings. The surgeon may elect to place the ipsilateral arm in a sling to provide immobilization. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

The myocutaneous latissimus dorsi flap is appropriate for immediate breast reconstruction as a result of its favorable donor site and predictable wound repair (Figs. 54.15 and 54.16). The flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. Alternatively, placement of an implant below the pectoralis major muscle may also be necessary to achieve a breast mound of adequate size and symmetry.

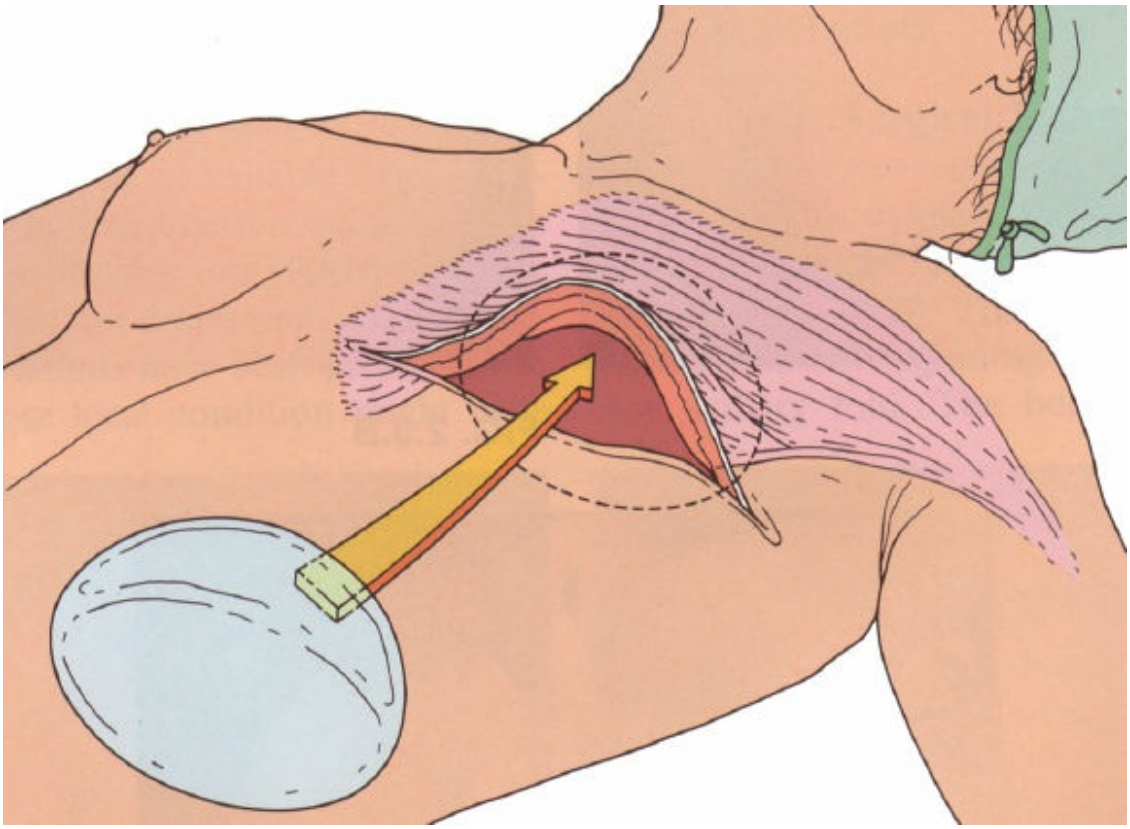

Figure 54.14. Implant placement beneath the pectoralis major muscle. An incision is made at the inframammary crease and a musculofascial flap involving the pectoralis major, serratus anterior, external oblique, and rectus abdominis muscles is elevated. An implant of appropriate size is then placed on the chest wall beneath the musculofascial flap (subpectoral flap) and

the incision closed with absorbable sutures. (From Bland KI, Copeland EM III, eds. *The Breast: Comprehensive Management of Benign and Malignant Disorders*. 4th ed. Philadelphia, PA: WB Saunders; 2009. Copyright © 2009 Elsevier.)

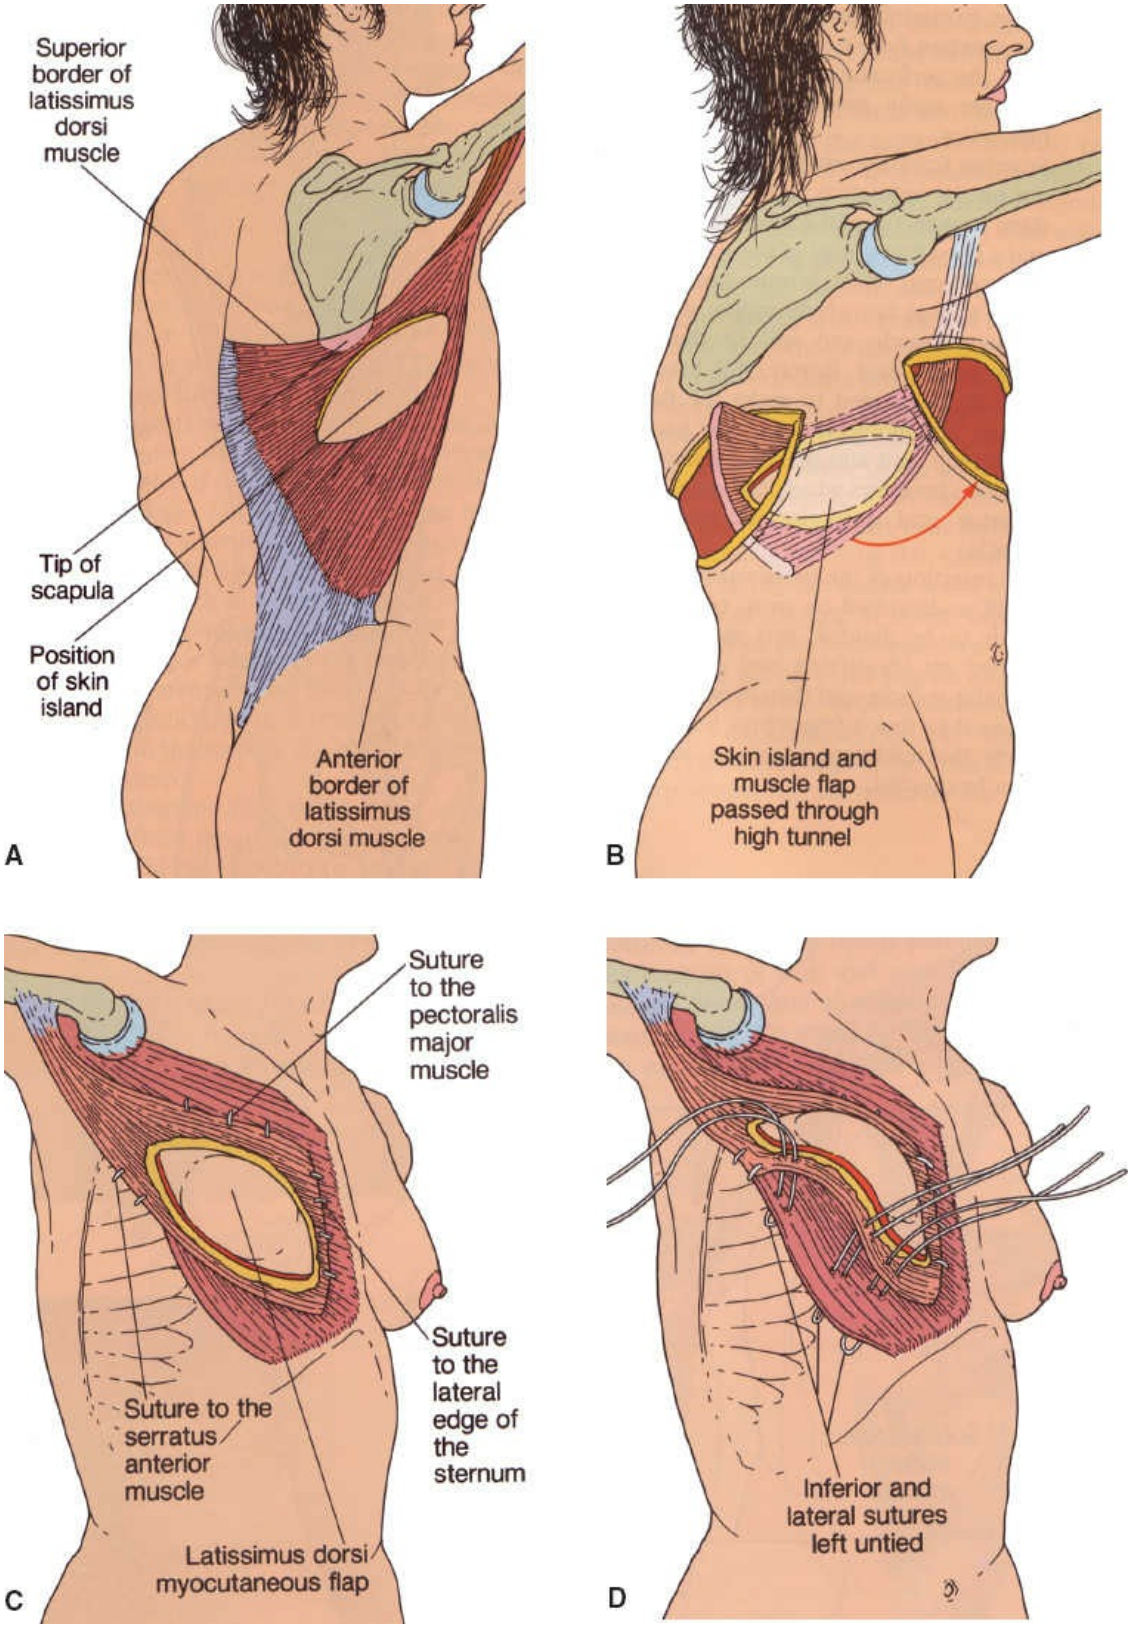

Figure 54.15. Anatomic relations of the latissimus dorsi myocutaneous flap. The latissimus dorsi myocutaneous flap consists of a skin paddle based on the underlying latissimus dorsi muscle, which is supplied by the thoracodorsal artery with contributions from the posterior intercostal arteries. **A.** Latissimus

dorsi muscle flap with skin island paddle delineated. **B.** The latissimus dorsi flap is being passed through a subcutaneous tunnel anteriorly to the breast defect. **C.** Inset of latissimus dorsi myocutaneous flap to reconstruct breast defect. **D.** Surgical dissection delineating elevated latissimus dorsi flap and its pedicle. (From Bland KI, Copeland EM III, eds. *The Breast: Comprehensive Management of Benign and Malignant Disorders*. 4th ed. Philadelphia, PA: WB Saunders; 2009. Copyright © 2009 Elsevier.)

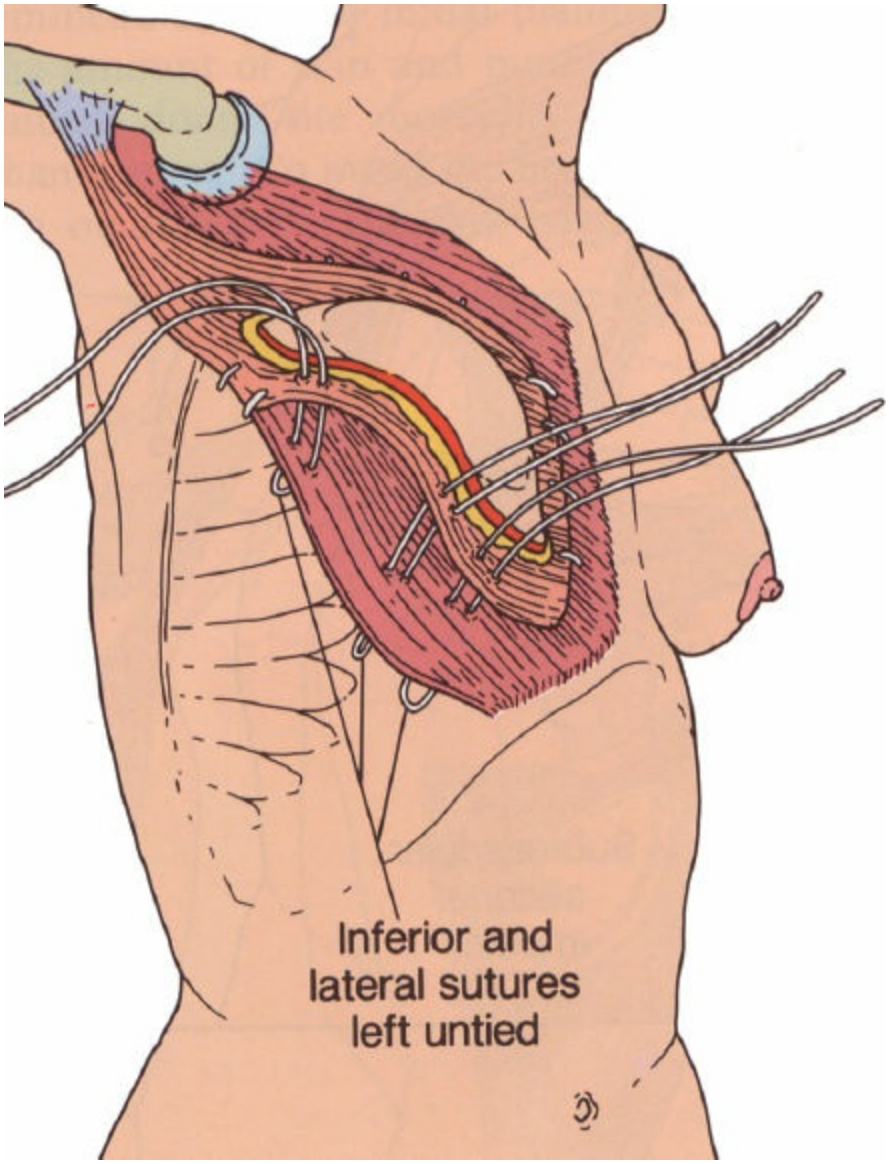

Figure 54.16. Inset of the latissimus dorsi myocutaneous flap for breast reconstruction. Breast reconstruction with a latissimus dorsi myocutaneous flap is appropriate for immediate reconstruction because of the favorable donor site and predictable wound healing. Occasionally, placement of an implant below the pectoralis major muscle may also be necessary to

achieve a breast mound of adequate size. (From Bland KI, Copeland EM III, eds. *The Breast: Comprehensive Management of Benign and Malignant Disorders*. 4th ed. Philadelphia, PA: WB Saunders; 2009. Copyright © 2009 Elsevier.)

The TRAM flap is internationally utilized for breast reconstruction and provides excellent symmetry relative to the contralateral breast. The TRAM flap can be pedicled or can utilize microvascular anastomosis to establish blood supply. It is composed of the rectus abdominis musculature, which is supplied by vessels from the deep superior and inferior epigastric arteries (Fig. 54.17), and the redundant skin and adipose tissue of the lower abdominal wall. After elevation from its bed, a pedicled flap (or two pedicled flaps for bilateral reconstruction; Figs. 54.17 and 54.18) can be rotated on its vascular pedicle and passed cephalad to the site of breast reconstruction through a subcutaneous tunnel where it is tailored for conformity with the contralateral breast and sutured to the pectoralis major muscle. The abdominal wall defect is closed in layers. Utilization of microvascular anastomotic techniques has made the free TRAM flap an excellent choice for immediate and delayed breast reconstruction. The harvested TRAM flap is tailored for conformity to the contralateral breast and receives its blood supply via microvascular anastomoses between the deep inferior epigastric vessels and the ipsilateral latissimus dorsi or internal mammary vessels. Utilization of the free TRAM frequently allows for one-stage breast reconstruction, but results in increased operative time, prolonged hospitalization, and more lengthy convalescence.

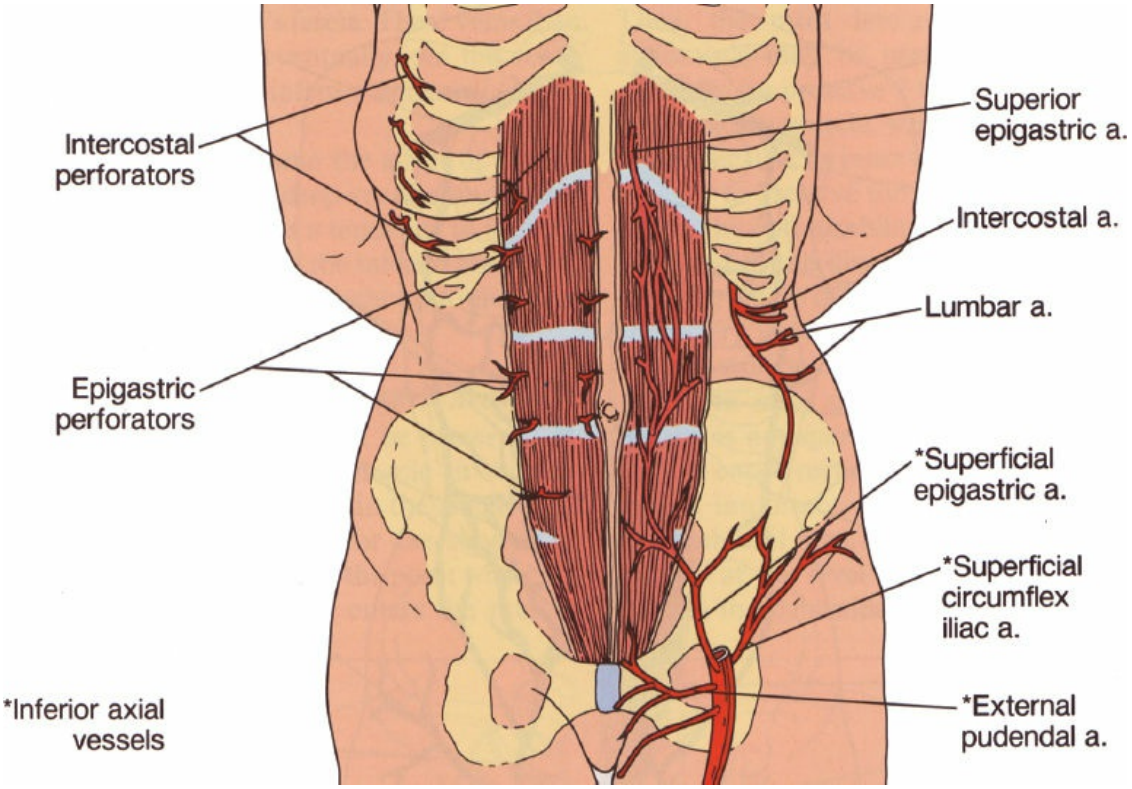

Figure 54.17. Superior and inferior epigastric artery axial blood supply to the rectus abdominus muscle and overlying skin. The transverse rectus abdominis myocutaneous (TRAM) flap is composed of the rectus abdominis musculature, which is supplied by vessels from the deep superior and inferior epigastric arteries, and the redundant skin and adipose tissue of the lower abdominal wall. (From Bland KI, Copeland EM III, eds. *The Breast: Comprehensive Management of Benign and Malignant Disorders*. 4th ed. Philadelphia, PA: WB Saunders; 2009. Copyright © 2009 Elsevier.)

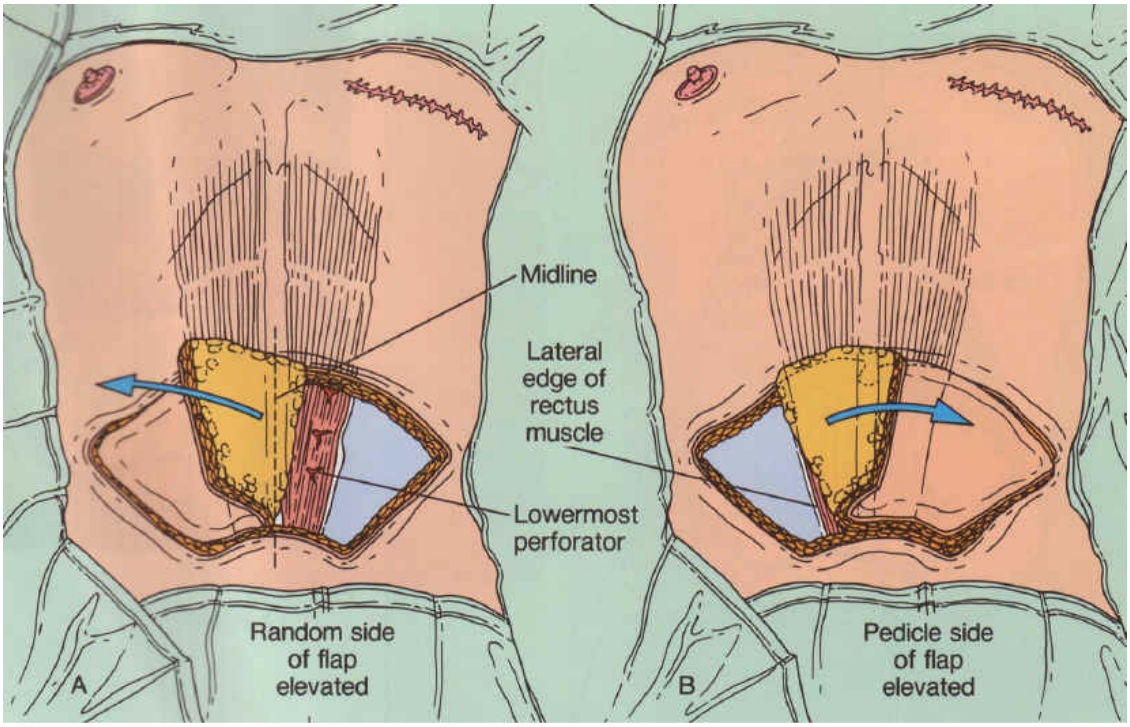
HALSTED RADICAL MASTECTOMY

INTRODUCTION

In 1894 William Stewart Halsted of Johns Hopkins Hospital was credited with the tenets and development of RM. However, this result was the consolidated synthesis with the development and writings of multiple surgeons who preceded him and allowed Halsted to achieve unprecedented local and regional recurrence rates of 6% and 22%, respectively, with this innovative *en bloc* approach. Meyer noted similar reductions in local recurrence rates to 6% comparative to the extraordinarily elevated rates of 54% to 82% that were evident among European surgeons of the 19th century. The procedure was a masterful contribution to treatment of this

organ, as >80% of the patient population was stage III/IV in this time in surgical history. Moreover, only a radical surgical procedure was effectively therapeutic in the era, with absence of the advances in adjuvant chemo-hormonal and radiotherapy. Table 54.6 is a compilation of data provided by Hutchison which compares these operations completed by European surgeons during the Halstedian era. These data provide an accompanying 3-year estimated “cure rate” for breast cancer by surgeon, year, and case volume. The Halstedian procedure more than doubled the international 3-year “cure rates” of prior eras.



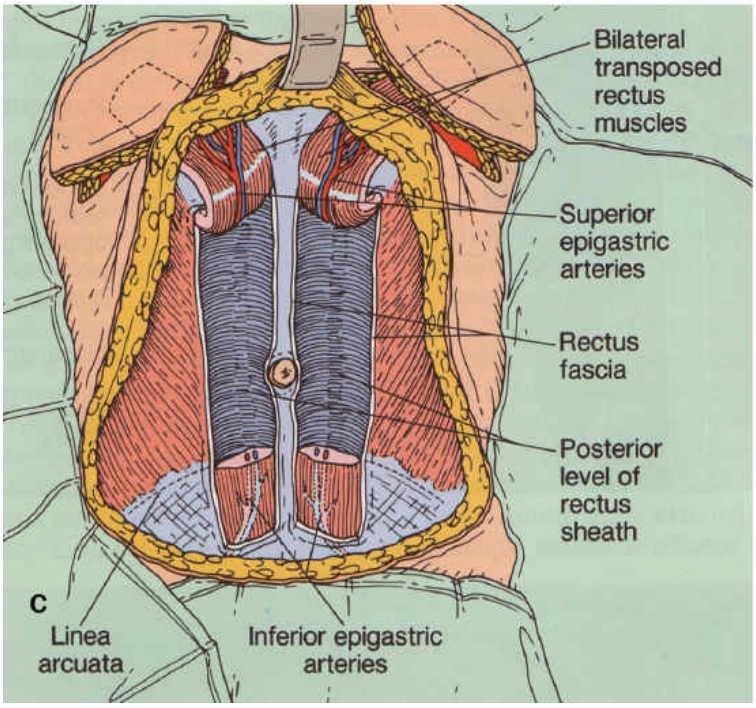


Figure 54.18. The TRAM flap. **A/B.** After elevation from the beds, two pedicled flaps are rotated on their vascular pedicles and passed cephalad to the sites of breast reconstruction through subcutaneous tunnels where they are tailored for conformity and sutured to the pectoralis major muscle. The abdominal wall defect is closed in layers. **C.** Diagrammatic depiction of bilateral transverse rectus abdominis myocutaneous (TRAM) flaps transposed on their superior epigastric pedicles. (From Bland KI, Copeland EM III, eds. *The Breast: Comprehensive Management*

of Benign and Malignant Disorders. 4th ed. Philadelphia, PA: WB Saunders; 2009. Copyright © 2009 Elsevier.)

Importantly, the advancement of *en bloc* resection techniques espoused in the Halstedian radical procedure by both Halsted and Meyer embodied the following tenets:

wide excision of the skin, covering the defect with Thiersch grafts;
routine resection of *both* pectoral muscles;
routine axillary dissection (levels I, II, III); and
resection of all tissues en bloc, providing wide skin and surgical margins for all margins of tumor growth.
Routine sacrifice of the long thoracic nerve and the thoracodorsal artery, nerve, and vein.

TABLE 54.6 Chronology of the Mastectomy for Treatment of Breast Cancer With Expectant (Average) 3-Year "Cure Rates"

Type of Operation	Study	Year	No. of Cases	3-Year Cures (%)
Simple mastectomy	Winiwarter (Billroth)[a]	1867–1875		4.7
Mean				4.7
Complete mastectomy and axillary dissection in most cases	Oldekop[b]	1850–1878	229	11.7
	Dietrich (Lucke)[c]	1872–1890	148	16.2
	Horner[d]	1881–1893	144	19.4
	Poulsen[e]	1870–1888	110	20
	Banks[f]	1877	46	20
	Schmid (Kuster)[g]	1871–1885		21.5
Mean				**18.1**
Complete (total) mastectomy, axillary dissection, removal of pectoral fascia, and greater or lesser amounts of pectoral muscle	Sprengel (Volkmann)[h]	1874–1878	200	11
	Schmidt[i]	1877–1886	112	18.8
	Rotter[j]	1887–1897	30	20
	Mahler[k]	1887–1893	150	21
	Joerss[l]		98	28.5
Mean				**19.9**
Modern radical mastectomy	Halsted[m]	1889–1894	76	45
	Halsted[n]	1907	232	38.3
	Hutchison[o]	1910–1933		39.4
Mean				**40.9**

INDICATIONS/CONTRAINDICATIONS FOR THE

HALSTED RADICAL MASTECTOMY

Modern medical pharmacology allows application of cytoreduction of the advanced primary mammary neoplasm to provide the medical oncologists and surgeons a vast increase in the latitude of application of less radical procedures in the therapy of carcinoma of this organ. Although modern pharmacology and breast irradiation enhance the probability of these cytoreductive events, especially with the combinations of targeted chemotherapeutic agents, Halsted RM is only occasionally (<2%) indicated to achieve local–regional control of the breast, axilla, and chest wall. Quite simply put, contemporary adjuvant therapeutic advancements are the principle scientific tenets that allow *less radical* procedures to achieve enhanced local–regional control and survival without application of the Halstedian or modified radical techniques.

OPERATIVE PLANNING

Current indications for the use of the Halsted RM for patients presenting with advanced local–regional disease are depicted in Table 54.7. Historical developmental progress in breast cancer therapy has allowed a paradigm shift in application of more aggressive approach management tenets that replace contemporary management suggest:

Major transitions from the Halstedian approach for breast cancer therapy have occurred as a result of the equivalent local–regional control that is evident with alternative breast conservation principles.

With the increasing application of appropriate breast conservation surgery in eligible patients, there has been a redefinition for indications of the Halsted procedure.

RM may be indicated when disease *invades* the *pectoralis major* muscle and has been unresponsive to neoadjuvant therapy. Surgical dogma suggests that the Halstedian procedure represents a “salvage mastectomy” necessary for large, bulky recurrences, especially for posterior lesions that recur with fascial or muscle fixation. In the contemporary practice of surgical oncology, the medical or surgical oncologist should expect this event to occur in <2% to 5% of presenting patients following neoadjuvant approaches.

The radical surgical procedure may be the only available technique for local–regional control of locally advanced (fixed, ulcerated) disease, especially in patients who have received prior therapy with total breast irradiation and/or multimodality cytotoxic therapy.

Formerly advocated for medial quadrant lesions, *extended* RM (with internal mammary nodal dissection) has no indication in the contemporary practice of breast surgery.

TABLE 54.7 Relative Indications for the Halsted RM

Advanced locoregional disease with fixation to pectoralis major muscle (T_2, T_3, T_{4a-c}; stages IIIA, IIIB, IIIC), when refractory to induction chemotherapy and irradiation
Advanced locoregional disease with skin ulceration (T_{4b}; stage IIIb) unresponsive to radiochemotherapy
Recurrent advanced, locoregional disease (T_2, T_3, T_4) after partial (segmental) mastectomy with tumor fixation to pectoralis major muscle ("salvage" mastectomy)
For completion of the radical procedure with locoregional recurrence after modified/segmental mastectomy when tumor invades chest wall and is refractory to cytoinduction chemotherapy
High-lying advanced peripheral lesions near clavicle/sternum with tumor fixation to muscle (stages IIA, IIB; stages IIIA, IIIB)
All presentations of advanced locoregional disease should receive induction cytotoxic drug therapy, radiotherapy, or both before radical mastectomy. Staging to rule out systemic disease should precede induction therapy.

SURGERY POSITIONING

Following induction of general endotracheal anesthesia, the patient is carefully positioned with a cooperative anesthesiologist and surgeon to ensure that the patient is positioned supine on the operating table near its margin.

The ipsilateral and involved arm should have careful inspection such that the shoulder contour overlies the placement of a padded arm board and allows the ipsilateral hemithorax and shoulder to be slightly elevated on a sheet roll. This latter maneuver ensures avoidance of subluxation and abduction of the shoulder with potential stretch of the brachial plexus. Such stretch injury to the brachial plexus may initiate motor denervation (transient or prolonged) of the shoulder and arm. This complication is best avoided by padding the arm board to allow elevation of the forearm and hand, as well as by providing a relaxed anatomical position (Fig. 54.19).

The operator should confirm that the ipsilateral arm and shoulder have free mobility for adduction across the chest wall; moreover, the elbow should be easily flexed and extended without undue tension (Fig. 54.20).

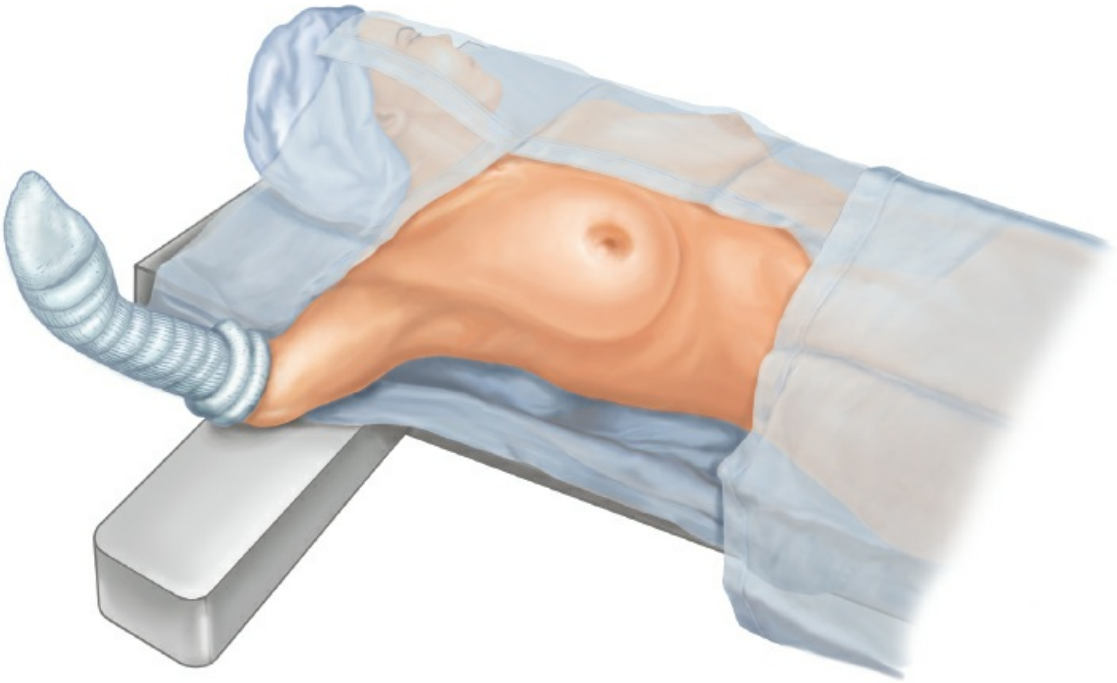

Figure 54.19. Typical position for draping patient for operations of cancer of the right breast. The ipsilateral hemithorax is positioned at the margin of the operative table with a sheet roll that provides slight elevation to the ipsilateral shoulder and hemithorax. This position potentially prevents subluxation and abduction of the shoulder with stretch of the brachial plexus. Draping of the periphery of the breast is inclusive of the supraclavicular fossa and the entire shoulder to allow adequate mobility for adduction of the shoulder and arm across the chest wall. The elbow should be easily flexed and extended without undue tension. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

TECHNIQUE

Prior to commencement of the surgical incision, the ipsilateral arm is placed in a relaxed, extended position on the arm board to allow proper planning of the incision. Incisions are made based upon the guidelines discussed in this chapter. The two most common incisions employed for Halsted RM are the *classical Orr* and *Stewart incisions* illustrated previously in Figures 54.6 and 54.7 of this chapter. Planned tissue dissections and flap elevations may be completed with electrocautery, cold scalpel, or aluminum garnet (Nd:YAG) laser scalpel.

The Halsted RM has decreasing usage in American surgery as noted in Table 54.8; this results from the increasing application of neoadjuvant

chemotherapy with tumor cytoreduction. However, tumors that are T2, T3, or T4 with gross fixation (involvement) of muscle and the skin overlying the pectoralis major muscle (Fig. 54.21), or peripheral high-lying lesions that are fixed near the clavicle to the pectoralis major, that are not otherwise candidates for radiation therapy, would be considered for the procedure. Furthermore, stages IIIa, IIIb, and IIIc would be candidates for Halsted RM when *refractory to induction chemotherapy and/or irradiation.* It is uncommon in conventional medical oncology to present with advanced local–regional disease and skin ulceration (T4b; stage IIIb) and tumors that are unresponsive to chemotherapy as replete publications in the dated medical literature suggest. Advanced local–regional disease with tumor fixation to the pectoralis major following segmental mastectomy and whole breast irradiation is an unusual presentation. Clinical and/or radiographic fixation to the pectoralis major muscle in this circumstance should have planned partial or total resection of the pectoralis major, even when radiographic evidence (mammogram, MRI) confirms evidence of cytoreduction.

The identification and exposure of the craniolateral humeral insertion of the pectoralis major muscle, with continuation of the dissection in a central superiomedial direction with muscular elevation, provide exposure of the pectoralis minor. The insertion of the pectoralis major on the humerus is transected and rotated medially. This muscle has origin on ribs 1 to 6 near the sternocostal junction. The surgeon must thereafter be aware of the anatomical position of the cephalic vein and the relationship to the deltopectoral triangle. Thereafter, the dissection commences medially with resection of the pectoralis major at its cranial clavicular attachments. This maneuver allows the surgeon direct exposure to the axilla. Thereafter, the tendinous portion of the pectoralis minor may be identified, encircled digitally, and stripped back to its insertion on the coracoid process of the scapula (Fig. 54.22). The pectoralis minor is similarly elevated digitally from the axilla with careful elevation from the axilla, taking care to avoid injury to the axillary vein. Division and ligature of perforating muscular branches from the thoracoacromial artery and vein must be ensured. The *medial* (anterior thoracic) *pectoral nerve* commonly penetrates the pectoralis minor en route to innervation of the pectoralis major and should be ligated and divided on its posterior surface of origin below the medial cord of the brachial plexus.

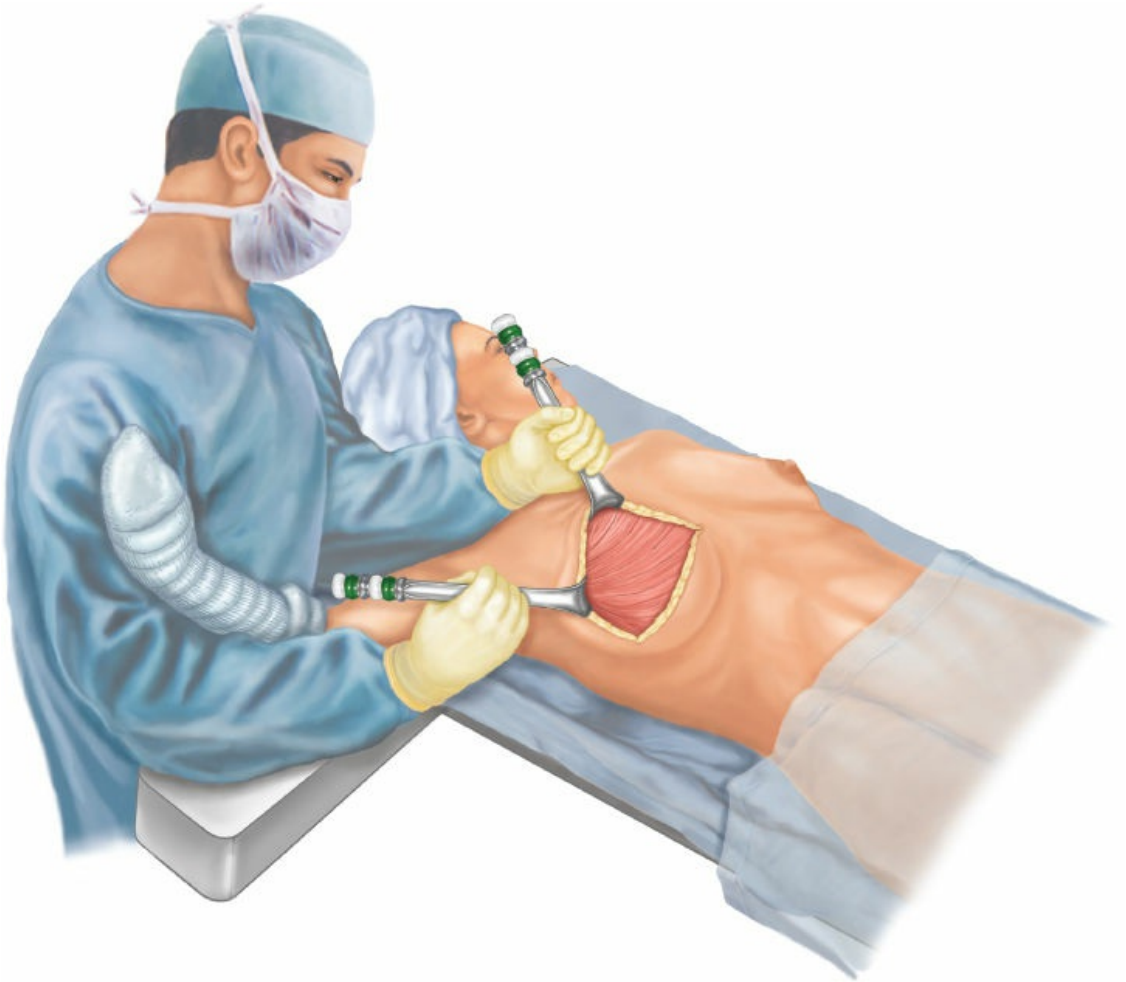

Figure 54.20. Position of the first assistant for right radical mastectomy. The surgical assistant, positioned cephalad to the arm board and shoulder, is able to provide traction, control, and protection of the arm and shoulder. Undue traction of chest wall musculature with potential damage to the brachial plexus can be avoided by ensuring free mobility of the shoulder and elbow that is being controlled by the first assistant. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

TABLE 54.8 Percentage of Breast Cancer Cases by Type of Surgery by Year of Diagnosis

Operation	1985	1988	1990
Radical mastectomy	1.9	1.5	0.6
Modified radical mastectomy	63.2	64.8	59.7
Total mastectomy	3.4	3.8	2.8
Partial (segmental) mastectomy	18.4	22.2	28.4
Subcutaneous mastectomy	0.5	0.5	0.5
Surgery type unknown	3.5	1	1.1
No surgery	7	5.4	4.5
Unknown if surgery done	2.1	0.8	2.4
Total	100	100	100
No. of cases	14,509	26,465	39,869

Thereafter, medial rotation and resection of the pectoralis major and minor from the chest wall *en bloc* follow. As medial resection of the pectoralis major continues, the *lateral* (anterior thoracic) *pectoral nerve* with origin from the lateral cord (and is located medially in the neurovascular bundle) should be identified and ligated. We prefer to continue the dissection in the superiomedial aspect of the elevated flap such that the pectoralis major is divided from its medial origin at the costosternal junction of ribs 2 to 6 (Fig. 54.23). Resection of pectoralis musculature invariably allows the surgeon to encounter multiple perforator vessels (lateral thoracic, anterior, intercostal arteries) at its periphery and presents end arteries of the pectoralis major and minor muscles. Perforator branches from the intercostal muscles that take origin from the intercostal arteries and vein are also encountered. It is essential that the operator individually clamp and ligate with nonabsorbable 2-0 or 3-0 suture all divided tributaries with division of the pectoral muscles. With inferomedial traction of the specimen and the operator's hand posterior to the specimen lying on the chest wall, the axillary contents may be fully exposed. The origin of the pectoralis minor on ribs 2 to 5 is thereafter visualized and is divided, ideally with electrocautery, at its insertion into the sternocostal junction. With this maneuver, *Rotter's interpectoral nodes* are swept en bloc into the specimen and allow full visualization of the course of the axillary vein to the level of *Halsted ligament* (*costoclavicular*), which is recognized as a condensation of the *clavipectoral fascia.* Thereafter, *level III* (*apical, subclavicular*) *nodes* are dissected at this level and should be individually clipped or tagged to indicate the highest level of dissection.

With identification of the tendinous insertion of the latissimus dorsi muscle, the surgeon recognizes the anatomical juncture at which the dissection of the axillary vein commences; all tissues in this plane must be cleared of the *lateral* (*axillary*) *nodal group* (level I). Care is taken to preserve the thoracodorsal artery, nerve, and vein. The surgeon must be aware of the origin of the *thoracodorsal nerve,* which is uniformly medial to the thoracodorsal artery and vein. This nerve originates from the posterior cord and may run a variable course in the central axillary space and on occasion crosses anterior or posterior to the thoracodorsal artery and vein as it courses inferolaterally to innervate the latissimus dorsi muscle in its central muscular portion. As the axillary dissection commences, the operator will often encounter, at a minimal, two branches of the intercostobrachial nerves that traverse the axillary space at right angles to the latissimus and chest wall. These nerves, which are sensory to the medial arm and axilla with fibers from the lateral cutaneous branches of the second and third intercostal nerves, may be sacrificed without prolonged morbidity aside from paresthesia and hypesthesia of the axilla and medial arm skin.

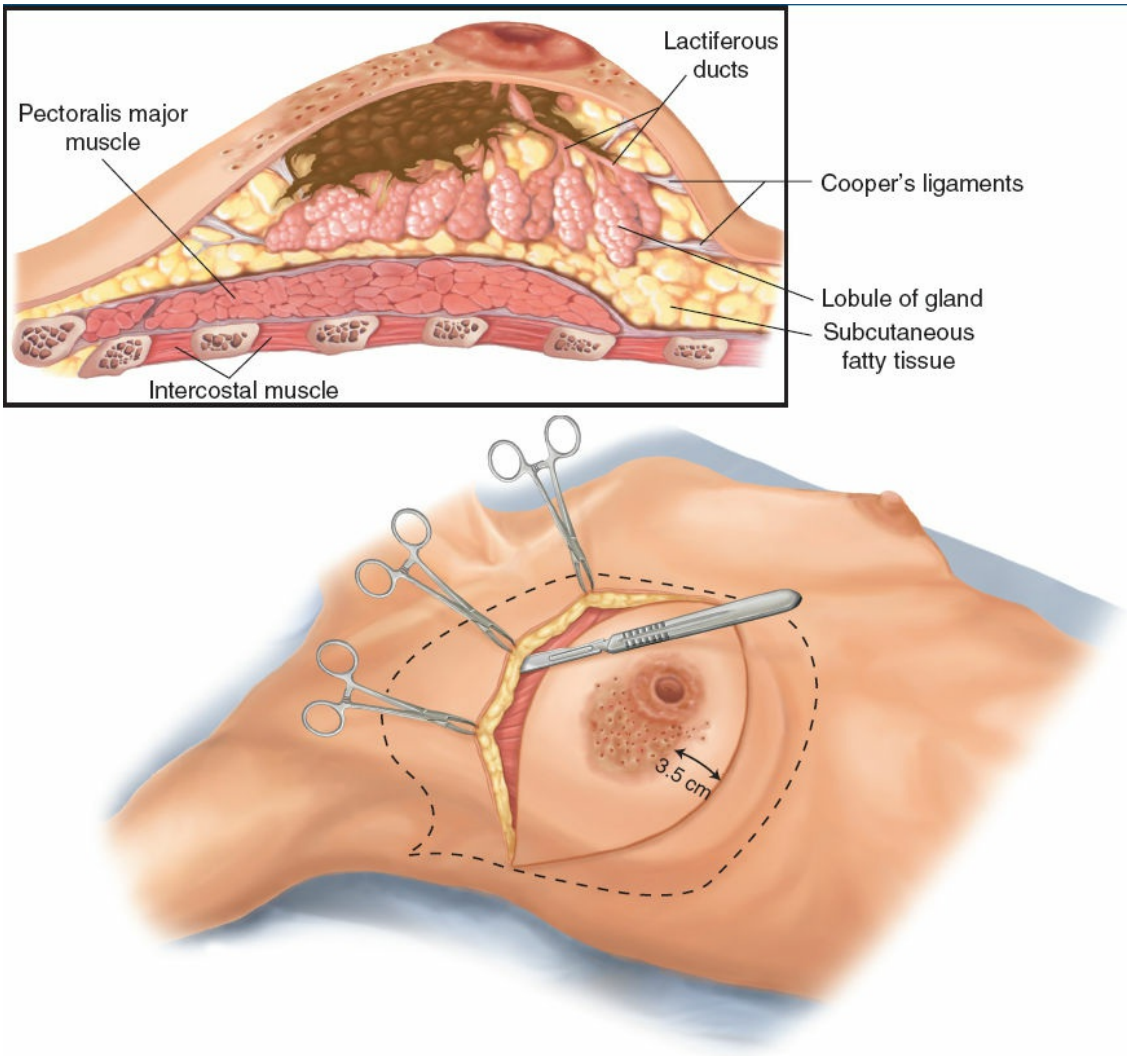

Figure 54.21. *Inset:* Large breast lesions (T2, T3, T4) may present with gross fixation to the skin and/or pectoralis major musculature. The radical mastectomy is designed to encompass wider skin flaps than the modified technique. The margins designed and developed should encompass normal skin and breast parenchyma 3 to 5 cm from the periphery of the tumor. This wider margin ensures tumor clearance and facilitates skin closure without redundancy of tissue flaps. The design of elevated flaps is inclusive of skin margins at the periphery of the breast on the chest wall. The broken line indicates the limits of the dissection and includes the following: superior, the inferior border of the clavicle at the subclavius muscle; lateral, the anterior margin of the latissimus dorsi muscle; medial, midline of the sternum; and inferior, the inframammary fold with extension of dissection to the cephalic extension of the aponeurosis of the rectus abdominis tendon. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with

permission.)

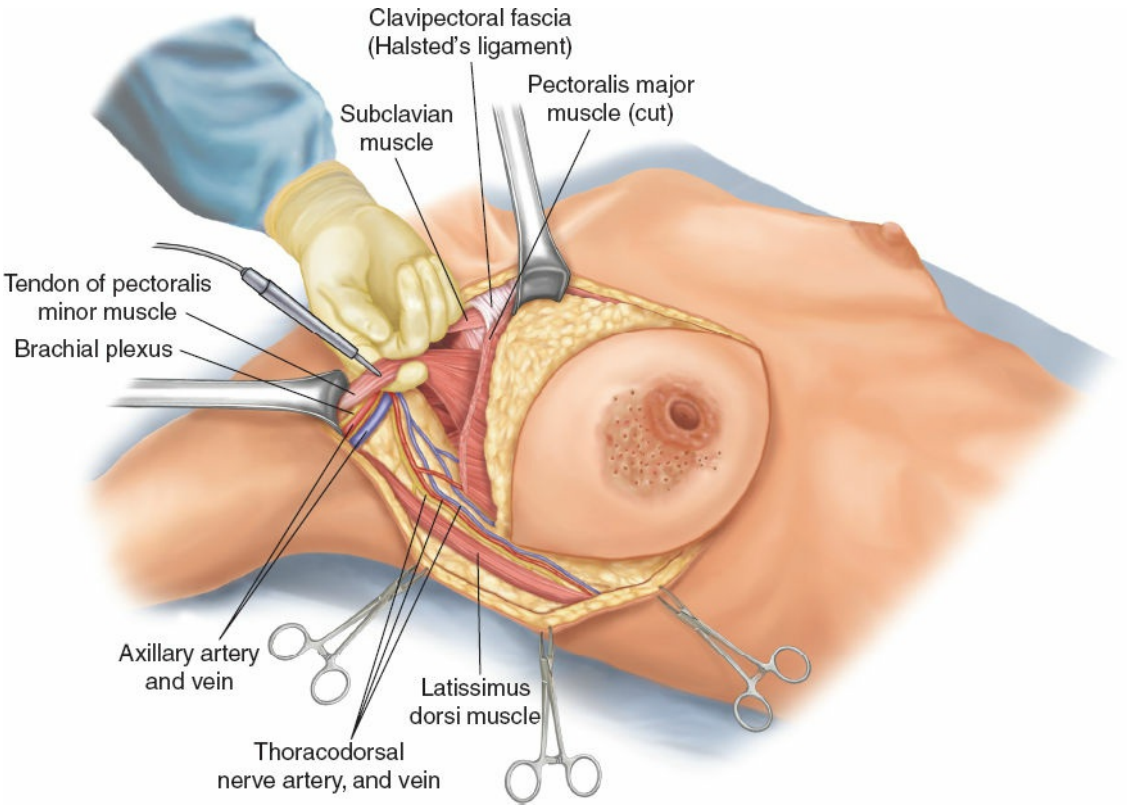

Figure 54.22. Exposure of the superolateral aspect of the mastectomy wound following division of the humeral insertion of the pectoralis major muscle. The insertion of the pectoralis minor on the coracoid process of the scapula is transected and rotated medially with en bloc dissection of Rotter's interpectoral nodes. Technically, the dissection commences on the anterior and ventral aspects of the axillary vein to incorporate level I to III nodes. Division of the pectoralis major and minor tendons allows the surgeon direct access to the floor of the axilla. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

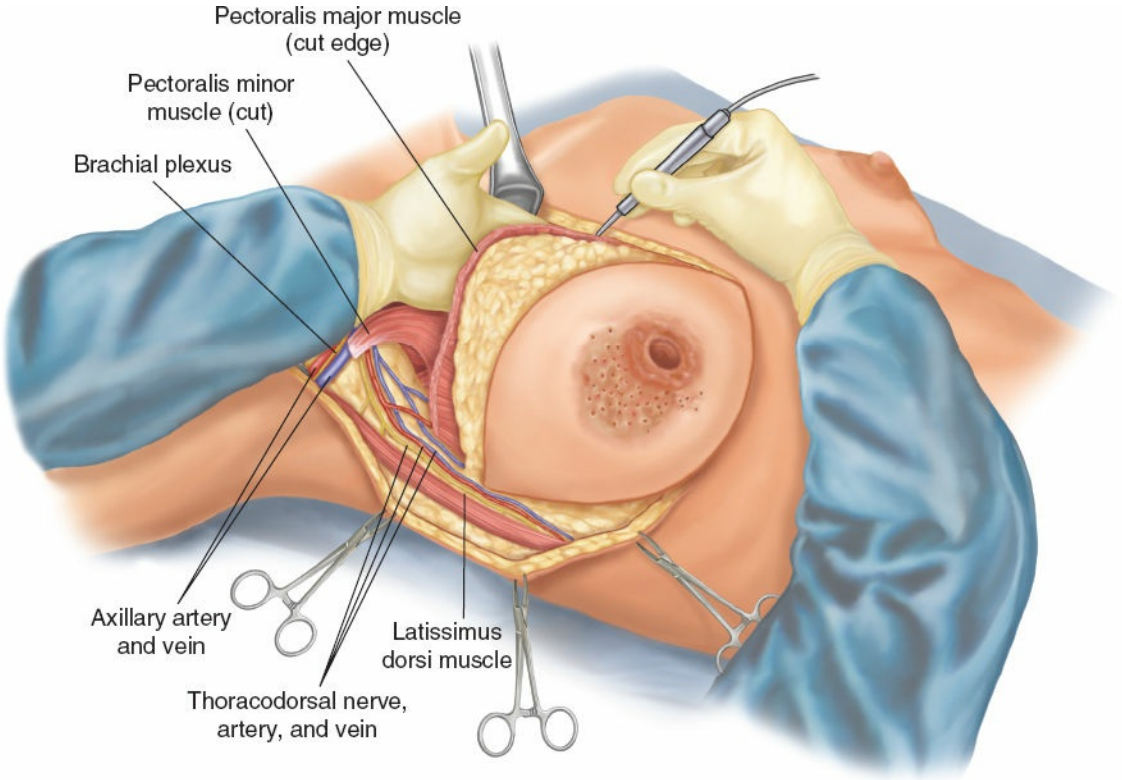

Figure 54.23. Superomedial dissection of the elevated pectoralis minor and pectoralis major muscles en bloc with the breast. The breast parenchyma remains intact with the pectoralis major fascia. Illustrated is the medial extent of the dissection along the costoclavicular margin with division of insertion of the pectoralis major on ribs 2 through 6 and the pectoralis minor on ribs 2 through 5. Multiple perforator branches from the intercostal muscles are encountered at the origin of the intercostal arteries and veins. Following superomedial and inferomedial dissection, the axillary contents are fully exposed to allow completion of the Patey axillary dissection of level I to III nodes. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

I recommend dissection of the *lateral* (*axillary*) *nodal group* in a caudad and parallel direction to the thoracodorsal neurovascular bundle and to be incorporated en bloc with the *subscapular nodal group* (*level I*), which is medially placed between the thoracodorsal nerve and the lateral chest wall. With dissection of these two nodal basins and its investing areolar tissues, the posterior boundary of the axillary space is delineated with exposure of the teres major and subscapular muscles. Medial dissection with clearing of the ventral surface of the axillary vein further

allows direct visualization of the subscapularis muscle, which is medially placed near the chest wall and medial to the teres. Inferior dissection of the *external mammary nodal group* of *level I* is deferred until completion of dissection of the *central nodal group* (*level II*) and the *apical* or *subclavicular level III nodes.*

Following clearance of the superiomedial nodal contents, the costoclavicular (Halsted ligament) area allows these nodal groups to be retracted inferiorly with the dissected muscles. Thereafter, nodal dissection begins on the chest wall with en bloc dissection of the *external mammary nodal group* (*level I*) that is medial and contiguous with the tail of Spence of the breast. The operator is reminded to dissect in the cephalad to caudad direction, parallel with the thoracodorsal neurovascular bundle, sweeping all contents en bloc. This maneuver is important in dissection to prevent neural injury and allows direct access to the venous tributaries posterior to the axillary vein. Thereafter, the surgeon will encounter the chest wall and exposure of the fascia of the serratus anterior. This maneuver is essential to allow high-level identification below the axillary vein of the *long thoracic nerve* (*respiratory nerve of Bell*), which provides motor innervation to the serratus anterior. This nerve courses consistently along the lower lateral chest wall, just superficial to the teres major over the subscapularis musculature. Following incision of the serratus anterior fascia, this nerve is dissected throughout its course in the medial axillary space from its superiormost origin near the chest wall to its innervation of the serratus anterior following proper exposure.

Following these maneuvers, the axillary contents anterior and medial to the long thoracic nerve are swept inferomedially en bloc with the specimen. The surgeon should defer division of the inferior boundary of the axillary content dissection until the preserved innervation of the long thoracic and the thoracodorsal nerves is definitively visualized.

Any points of origin of the pectoralis major from the first through the sixth ribs are left intact with the medial dissection are completely divided such that an en bloc resection of the pectoralis major is accomplished over the retromammary bursa. The surgeon continues the dissection in an avascular plane to sweep the breast and axillary contents toward the aponeurosis of the rectus abdominis muscle to complete extirpation of the specimen as an en bloc procedure (Fig. 54.24).

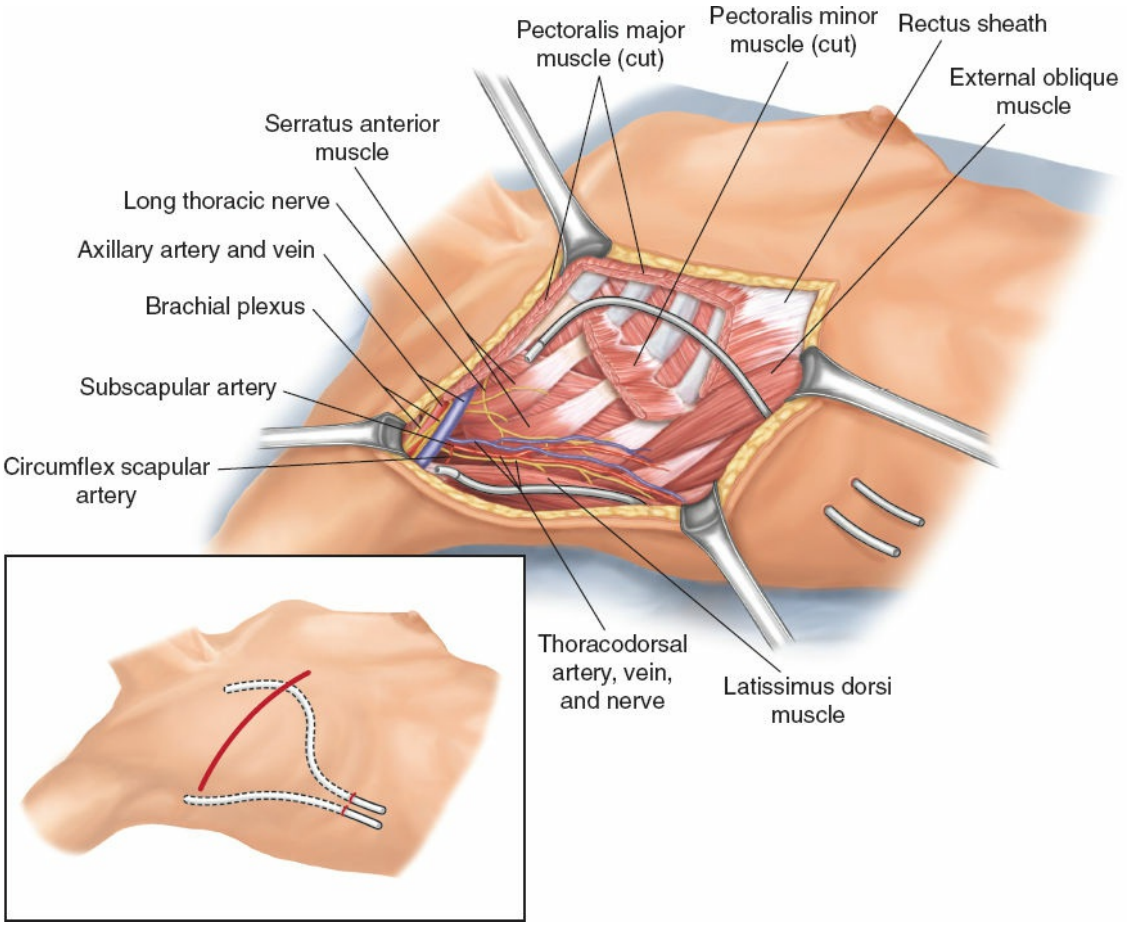

Figure 54.24. The complete Halsted RM with residual margins of the pectoralis major and minor muscles. Ideally, preservation of the long thoracic nerve ensures innervation of the serratus anterior. Innervation of the latissimus dorsi muscle is ensured with preservation of the thoracodorsal nerve that accompanies the neurovascular bundle of the posterior axillary space. Inset depicts position of closed suction catheters (18 to 20 French) placed through separate stab wounds that enter the inferior margin of the flap at approximately the anterior axillary lines. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

WOUND CLOSURE: Two closed suction catheters (flat 10-mm Jackson-Pratt) are placed via separate incisions that enter the inferior margin of the flap at approximately the anterior axillary line with the second lateral catheter placed approximately 2 cm below the axillary vein. Drains are secured at skin level with 3-0 nonabsorbable nylon sutures. Suction catheters should not be secured to the chest wall to abrogate the potential for muscle injury and hemorrhage with removal.

Before the surgeon initiates flap closure, skin margins are carefully inspected to evaluate for devascularization that results from trauma of dissection or tangential incisions that contribute to skin necrosis and wound dehiscence. We prefer closure with interrupted 2-0 absorbable synthetic sutures placed in subcutaneous tissues with purchase of the cutis reticularis of the skin without tension. Optionally, the skin may be closed with running subcuticular 4-0 synthetic absorbable sutures or stainless-steel staples. Steri-strips are applied across (perpendicular to) the incision when subcuticular sutures are used in closure. After irrigation, the closed suction catheters are connected and maintained on continuous low to moderate suction with large plastic vacuum reservoirs. Closure of dead space by suturing of skin flaps to underlying muscle combined with early removal of closed suction drainage has been reported to diminish incidence of seroma formation. We prefer to use light, bulky dressings applied with adherent sealed closure of the surgical incision. Typically, wound catheters may be removed when drainage becomes predominantly serous and each has decreased to a maximum of 20 to 25 cc during a 24-hour interval. Shoulder exercises are initiated on the day following removal of the drainage catheters.

ALTERNATIVE CLOSURE OF FLAP DEFECTS

Following completion of the classical Halstedian operation and sacrifice of large volumes of skin centrally, alternative measures are essential to close the central defect. However, with the conventional cytoreductive chemotherapeutic neoadjuvant principles used today, such maneuvers are rarely necessary and flap closure can usually be accomplished as a primary procedure. However, should defects be sizable and alternative closure essential, one could consider using either myocutaneous flaps (latissimus dorsi or rotational flaps) or the placement of skin grafts. In the latter circumstance, the defect may be grafted with split-thickness skin grafts (0.018 to 0.02 in) procured with a dermatome from the anterolateral thigh or buttock (Fig. 54.25).

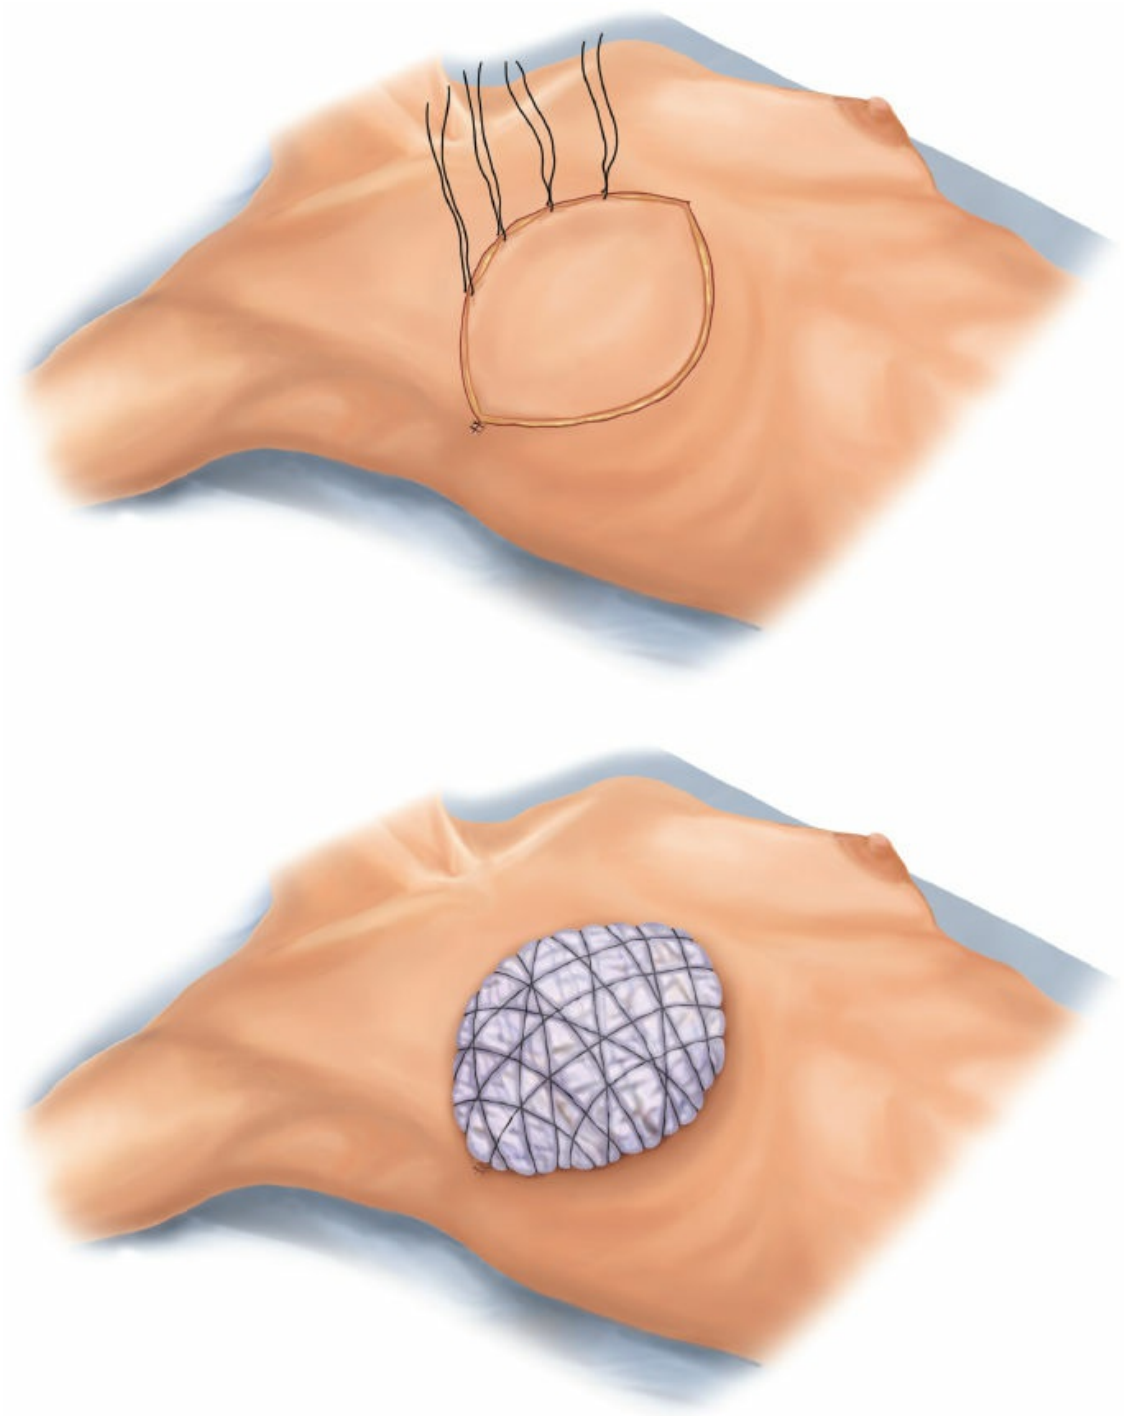

Figure 54.25. *Top,* Large defect that is expected with creation of large skin flaps inclusive of the periphery of the breast for T3 and T4 lesions with fixation to the pectoralis major. Such large defects must be grafted with split-thickness skin (0.018 to 0.020 in) that is preferably obtained through a dermatome from skin of the anterior/lateral thigh or buttock. An additional option for closure is the myocutaneous latissimus dorsi flap. *Bottom,* The partial-thickness skin graft held in position with a compression stent created with cotton gauze mesh. These large skin defects do not require catheter drainage. Alternatively, compression foam mesh

as the stent may be applied over the split-thickness skin graft. Foam mesh may be stapled in place at the margin of the skin defect. (Bland KI, Klimberg VS, eds. Breast surgery. In: Fischer JE, ed. *Master Techniques in General Surgery: a Series*. Philadelphia, PA: Wolters Kluwer; 2010, with permission.)

The surgeon should be cognizant of the necessity for immobilization of the skin graft to enhance the probability of adherence (with "graft take" to the chest wall); the partial-thickness graft is stented with bolsters (Fig. 54.25) or compression-foamed mesh, which may be stapled to the peripheral wound edges. In such closures, catheters are not necessary when skin grafts are applied to the defect. The stents placed over the split-thickness skin graft are not removed until day 5 or 6 postoperatively, unless undue drainage (serum, blood, suppuration) from beneath the grafts is evident. This practice increases the probability of graft adherence, which is further enhanced when postoperative shoulder immobilization for large defects is ensured.

Should postoperative irradiation be required following review of the operative pathology report, these patients may be offered breast reconstruction 6 to 18 months following the radical procedure. Breast reconstruction allows for cosmetic enhancement of the patient with maintenance of form and functional restoration. This alternative is being applied more commonly internationally. With the presence of adverse biologic features and the inexact probability of positive margins, the surgeon must often defer the reconstruction. Nonetheless, the Wells prospective trial conducted by Patel and associates with follow-up over 10 years suggests that an immediate reconstruction is widely applicable, technically feasible, and can be conducted with long-term outcomes that are not detrimental to local recurrence of metastatic disease. With the advancement and utility of myocutaneous reconstruction, with or without implants, the use of immediate reconstruction has increased between 1985 and 1995 from 3.4% to 8.3%. Considerations of the patient's decisions for reconstructive surgery include income, age, geographic location, hospital size and type, as well as tumor stage. Reports emphasize the importance of patient education as an essential component to address and provide proper patient consultation and information for options that include risk of reconstruction recurrence and projected morbidity.

EDITOR'S COMMENT

Dr. Bland not only presents us with superb anatomical descriptions and diagrams but also provides us with a splendid historical account of surgical breast cancer treatment. The surgical evolution continues today as many advances in screening and early detection have led to innovations in the indications for and the way in which we perform mastectomies, lymphadenectomies, and reconstruction.

It is uncommon but not rare (especially in rural states) that there is an indication for radical mastectomy and usually only in the most advanced and/or resistant disease. Morbidity can be minimized by avoiding the use of a skin graft. In my practice, it is rare that one cannot rotate a skin flap in to cover the

defect. Often in these situations the defect is large and several rotational flaps can be performed for coverage. These types of flaps heal well as long as attention is paid to optimizing the nutritional status of the patient which is often poor. In my view anything is better than a skin graft. Skin grafts may or may not take and they do not radiate well at all. As an alternative a variety of pedicle or free flaps can be brought in for coverage. Healing with TRAM, DIEP, or Latissimus flaps are usually more slow and the complication rate higher than with rotational skin flaps but may be the only choice if the defect is large enough.

For locally advanced disease T4, especially T4d (inflammatory), one should consider neoadjuvant XRT as well as neoadjuvant chemotherapy as resection alone often results in recurrence if there is slow wound healing. Having said that radiation upfront will be met with decreased wound healing and prolonged seroma but less of a chance for chest wall recurrence.

Modified Radical is appropriately named because everyone has their own modification of it. Changes in this procedure continue even today. One of the major issues with a modified radical mastectomy as with a radical mastectomy is the occurrence of upper extremity lymphedema. One of the easy ways to mitigate some lymphedema is to try when possible to spare the intercostobrachial nerves as they have lymphatics that run with them. Taking these nerves can cause increased lymphedema particularly of the back. The best way to reduce lymphedema of the upper extremity is to add to the modified radical mastectomy the additional procedure of axillary reverse mapping (ARM). This procedure entails dual mapping of the breast with radioactivity and the upper extremity with vital blue dye. In doing so one can delineate what is draining the upper extremity from those lymphatics that drain the breast. This can be done via intraoperative injection making the procedure easy on the patient. Subareolar injection of the breast localizes within minutes as does the blue dye from the arm. This dual mapping is necessary as about 4% of the time the drainage colocalizes. In a case like this the so localized lymph node can be removed and the afferent and efferent lymphatics can be reapproximated or reanastomosed. The point is to keep incontinuity the lymphatics draining the arm and thus prevent lymphedema. We have shown in over 600 patients that lymphedema after axillary lymph node dissection is about 6% and nil if cut lymphatics are reanastomosed. Yu and colleagues have performed the only randomized trial of ALND with or without ARM and have similar shown upper extremity lymphedema rate of 6% with ARM and 33% without it.

Both chemotherapy and XRT increase the risk of lymphedema. Obesity, hypertension, and infection all increase the risk of lymphedema by 50%. Intermittent compression devices have now been shown not to be effective. Complete decongestive therapy with specialized upper extremity massage, compressive wrapping, and fitted sleeves is effective but constitutes a lifelong effort. Lymphovenous anastomosis and lymph node transfer may also be effective in treating lymphedema although more experience with these

techniques is needed.
