Appropriate treatment of ligamentous ankle injuries is imperative to ensure full recovery and should begin immediately after the injury. Fractures and instability of the ankle mortise require immediate orthopedic surgical referral. Nonoperative management is typical of the vast majority of ankle sprains. Phase 1 care involves immediate compressive wrapping and icing to control swelling and inflammation. Protected weight bearing is encouraged as tolerated in the early phase of rehabilitation. Severe ankle sprains may benefit from a short period of treatment in a lower leg walking boot or cast. Phase 2 begins when the athlete can ambulate without pain. Supervised physical therapy prescription may be beneficial. During this time, ankle range of motion is emphasized, along with isometric contractions of the ankle dorsiflexors. Once 90% of strength has returned, active isotonic (eccentric and concentric exercises) and isokinetic exercises can be added. Phase 3 is designed to increase strength, improve proprioception, and add ballistic activity (more complex movement patterns), as well as sport-specific agility and function. The “foot alphabet”and “balance board” are excellent methods to improve ankle range of motion and proprioception. To restore range of motion, the patient is asked to actively move the ankle by drawing letters of the alphabet with the toes. To restore proprioception, the ability to maintain proper balance and control, balance exercises are performed on a balance board (or wobble board). This could also be done by having the patient stand on one leg while playing catch with a ball. This program can be effective in returning athletes to activity within a few weeks, although up to 6 weeks may be required for return to full activity. The athlete should wear a protective brace for 3–4 months, continue phase 3 home exercises, and ice after exercising.

2. Sever Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Activity-related heel pain in preadolescents.
- Pain localized to the calcaneal apophysis and Achilles insertion.
- Positive calcaneal squeeze test.

Sever disease, or calcaneal apophysitis, occurs in athletes aged 8–12 years who are typically involved in high-impact activities, such as gymnastics and soccer. Causes include overuse, improper footwear, and tightness in the calf musculature and Achilles tendon. Pain occurs about the heel and at the point of muscle tendon insertion onto the growth center of the calcaneus. The athlete presents with activity-related heel pain and examination reveals focal tenderness over the calcaneal apophysis. Tenderness created by pressing forcefully on the lateral and medial heel constitutes a positive "calcaneal squeeze test."

Treatment is symptomatic and consists of reassurance and education, relative rest, heel cord stretching, eccentric calf strengthening, ice massage, heel cups, NSAIDs for pain control, and progression to activity as tolerated based on pain level. Activity restriction is not required. Heel cups are rubber or gel infused shoe inserts that provide heel lift and cushion to decrease both tension and impact on the calcaneal apophysis. Refractory cases may benefit from brief immobilization and partial or non–weight bearing in a walking boot or cast followed by supervised physical therapy.

3. Plantar Fasciitis

Plantar fasciitis is a common problem that manifests as heel pain in the adolescent or older athlete. It typically occurs in runners who log more than 30 miles per week and in athletes who have tight Achilles tendons or wear poorly fitting shoes. It is also common in people with cavus feet and in those who are overweight. The pain is worse upon first standing up in the morning and taking a few steps. Differential diagnosis includes navicular or calcaneal stress fracture. A bone spur is often found on examination. Treatment involves local massage, stretching of the gastrocnemius-soleus-Achilles complex, NSAIDs, arch supports, and local steroid injections. Runners may need to cut back on their weekly mileage until these measures eliminate pain.

PREVENTION

As in all activities, many sports-related injuries can be prevented by education, reducing dangerous behaviors, use of protective equipment, and proper training. Early recognition of injuries, proper treatment, and appropriate rehabilitation are also crucial to ensure safe sports participation. Protective equipment should be properly fitted and maintained by an individual with training and instruction. Helmets should be used in football, baseball, hockey, bicycling, skiing, in-line skating, skateboarding, or any sport with risk of head injury. Eye protection should be used in sports that have a high incidence of eye injuries. Proper protective padding should be identified and used, including chest pads for catchers; shin guards in soccer; shoulder, arm, chest, and leg padding in hockey; and wrist and elbow protectors in skating. Other primary prevention strategies should also be addressed by coaches, parents, and physicians in order to ensure the safety of children participating in sports. These include inspecting playing fields for potential hazards, adapting rules to the developmental level of the participants, and matching opponents equally in skill level and size.

The use of the preparticipation history and physical examination can identify potential problems and allow for prevention and early intervention. Proper training techniques reduce injuries by encouraging flexibility, promoting endurance, and teaching correct biomechanics. Sports education reinforces the concepts of fitness and a healthy lifestyle along with sport-specific training. Early identification of an injury allows the athlete to modify techniques and avoid micro- and macrotrauma. Once an injury has occurred, it needs to be identified properly and appropriate measures used to minimize morbidity. Rehabilitation of the injury starts as soon as it has been identified. Early and appropriate care offers the athlete an optimal chance for full recovery and return to full participation.

28 Rehabilitation Medicine

Pamela E. Wilson, MD
Gerald H. Clayton, PhD

Rehabilitation medicine is the multispecialty discipline involved in diagnosis and therapy of individuals with congenital and acquired disabilities. The goals of rehabilitation medicine are to maximize functional capabilities and improve quality of life. Disabilities are described using the World Health Organization's International Classification of Function, Health, and Disability. Three aspects are evaluated in every patient: (1) the impact of the disability on body structure and function, (2) the impact of the disability on activity and participation in society, and (3) the environmental factors with an impact on the individual's function. These three areas are the common framework for discussion of a disabling condition and its therapy.

PEDIATRIC BRAIN INJURY

ESSENTIALS OF DIAGNOSIS

- Severe head injury: Glasgow Coma Scale (GCS) of < 9
- Moderate head injury: GCS of 9–13
- Mild head injury: GCS of 13–15

Various estimates indicate that there are up to 500,000 pediatric traumatic brain injuries in the United States every year, resulting in 37,000–50,000 hospitalizations. Mortality rates vary significantly by region (relative risk 1.19–4.2 nationally), but, overall, pediatric brain injuries result in 2000–3000 deaths annually. The cost of these injuries is significant, particularly when also considering that survivors of pediatric brain injury may have long-term deficits with lifetime needs.

» Pathogenesis

Brain injury is classically divided into two categories based upon the timing of the pathologic findings: primary and secondary injury.

Primary injury occurs at the time of trauma, causing focal and diffuse damage. Focal damage includes skull fracture, parenchymal bruising or contusion, extraparenchymal or intraparenchymal hemorrhage, blood clots, tearing of blood vessels, or penetrating injury. Diffuse damage includes diffuse axonal injury and edema. Consequences of primary injury, either focal or diffuse, include cellular disruption with release of excitatory amino acids, opiate peptides, and inflammatory cytokines.

Secondary injury is the loss of cellular function accompanying primary injury that results in loss of cerebrovascular regulation, altered cellular homeostasis, or cell death and functional dysregulation. A primary injury can initiate the processes of secondary programmed cell death (apoptosis), which further exacerbates the primary injury. Secondary injury may develop hours or days after the initial insult. It appears to be precipitated by elevated intracranial pressure, cerebral edema, and release of neurochemical mediators. Current treatment paradigms are focused on treating and preventing secondary injury.

» Clinical Findings

Classification & Assessment of Injury Severity

Traumatic brain injury is usually categorized as open or closed. Open injuries are the result of penetration of the skull by missile or sharp object or deformation of the skull with exposure of the underlying intracranial tissues. Closed injuries are the result of blunt trauma to the head, which causes movement (intracranial acceleration or deceleration and rotational forces) and compression of brain tissue. Brain contusions are referred to as coup (occurring at the site of injury) or contra-coup (occurring on the side of the brain opposite the injury). Rating the severity of injury and eventual outcomes is important in medical management. Included below are the two most commonly used scales

relevant to clinical care of these injuries in rehabilitation medicine.

A. Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is the most commonly used system to assess the depth and duration of impaired consciousness in the acute setting. The score is derived from three areas of evaluation: motor responsiveness (maximum score 6), verbal performance (maximum score 5), and eye opening to stimuli (maximum score 6). The scale has been modified for use in infants and children younger than 5 years, allowing for their lack of verbal responsiveness and understanding. Cumulative scores define injury as mild (13–15), moderate (9–12), and severe (≤ 8). The concept of posttraumatic amnesia is used to gauge severity of injury and is an adjunct to the GCS. Posttraumatic amnesia is the period of time after an injury during which new memory cannot be incorporated and the person appears confused or disoriented. Amnesia can be retrograde, anterograde, or both.

B. Rancho Los Amigos Levels of Cognitive Function

The Rancho Los Amigos Levels of Cognitive Function (LCFS or "Rancho") is used to gauge the overall severity of cognitive deficit and can be used serially during recovery as a rough gauge of improvement. The scale has 10 levels of functioning ranging from "no response" to "purposeful, appropriate."

Common Sequelae of Brain Injury

Depending on the severity of brain injury, there may be deficits in cognition and behavior, as well as physical impairments. Injuries can also produce changes in sensory and motor function, emotional stability, social behavior, speed of mental processing, memory, speech, and language. The consequences of mild brain injuries may be difficult to discern. Small intraparenchymal injuries, easily identified by computed tomographic (CT) or magnetic resonance imaging (MRI) scans, may not cause obvious signs or symptoms. The following are common problems associated with brain injury.

A. Seizures

Seizures occurring in the first 24 hours after injury are referred to as immediate seizures. Those occurring during the first week are early seizures, and those starting more than 1 week after injury are referred to as late seizures. Seizure prophylaxis with medications is recommended in the first week after brain injury in children at high risk for seizures and in very young children. Seizure prophylaxis is also recommended for 1 week after any penetrating brain trauma. Seizure prophylaxis is probably not effective for prevention of late-onset seizures; these may require long-term treatment.

B. Neuromotor Deficits/Movement Disorders

Neuromotor deficits after brain injury include movement disorders, spasticity, paralysis, and weakness. The type of disorder will be influenced by the areas damaged. The most common movement disorders are tremors and dystonias. These deficits can result in impaired ambulation, coordination, impaired ability to use upper extremities, and speech problems. Physical therapy is the primary means of treating these problems.

C. Communication Disorders

Language and communication disorders are fairly common. Aphasia, difficulty in understanding and producing written and spoken language, is categorized as fluent, nonfluent, or global. Individuals with fluent aphasia or Wernicke-type disorder can produce speech, but have little content associated. The nonfluent aphasias or Broca's type have a paucity of speech and may have word finding difficulties. Global aphasias have extensive injuries and the most severe language disorders.

D. Paroxysmal Sympathetic Hyperactivity

Severe brain injuries may be associated with excessive sympathetic outflow and results in a constellation of symptoms known as paroxysmal sympathetic hyperactivity (PSH). Symptoms of PSH are tachycardia, tachypnea, sweating, hyperthermia, hypertension, agitation, and posturing. Common medications used to treat PSH include dopamine agonists (eg, bromocriptine), β-blockers (eg, propranolol), and α-agonists (eg, clonidine).

E. Cognitive and Behavioral Deficits

After brain injury, cognitive and behavioral deficits are a frequent occurrence. Cognitive disorders depend on the location and severity of the injury. Damage to the frontal lobes can disrupt executive function along with initiation delays. Neuropsychiatric sequelae are common, and depression, anxiety disorders, and posttraumatic stress disorders (PTSD) are present in one-third of those injured. Testing by a neuropsychologist may help to identify problem areas allowing for development of accommodations in school and use of behavioral strategies.

F. Hypothalamic-Pituitary-Adrenal Axis Dysfunction

Dysfunction of the hypothalamic-pituitary-adrenal axis is common after head injury. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and diabetes

insipidus (DI) from a posterior pituitary injury can result in significant electrolyte and osmolality imbalance. Amenorrhea that typically resolves spontaneously is common in females. Injury near the onset of puberty can complicate normal development, and endocrine status should be monitored closely.

G. Cranial Nerve Injuries

The sensory and motor components of the cranial nerves are often damaged, resulting in a wide variety of deficits not centrally mediated. The most commonly injured nerves are I, IV, VII, and VIII. Hyposmia or anosmia (cranial nerve I) can occur if the shearing forces at the cribriform plate disrupt the afferent olfactory nerves. Injury to cranial nerves IV (trochlear) is common as it has the longest intracranial length. Superior oblique injuries typically cause a head tilt and vertical diplopia. Facial nerve injuries (cranial nerve VII) are common especially with temporal bone fractures. This impacts the ability to use the facial muscles, causes dryness in the eye and salivary glands along with decreasing taste in the anterior part of the tongue. The cochlear nerve (VIII) is also frequently damaged in temporal bone fractures and can result in vertigo and dizziness.

Developmental Considerations

Much of what we know of traumatic brain injury is based on adult experience. The confounding effects of age and the etiologies unique to the pediatric population (eg, child abuse) make care of the pediatric head-injured patient very complex.

The assumption that younger children will fare better than older children or adults after a brain injury is a myth. The fact that in a child a significant amount of development and synaptic reorganization has yet to occur does not guarantee an improved chance for functional recovery. Indeed, disruption of developmental processes, especially in very young infants or neonates, may be catastrophic. These processes often cannot be recapitulated.

The mechanism of injury plays an important role in determining the severity of brain injury in very young children. Mechanisms associated with non-accidental injury such as shaking often result in global diffuse damage. The weak neck musculature, large head-body mass ratio, immature blood-brain barrier, and high intracranial fluid–brain mass ratio all contribute to widespread damage.

During puberty, major hormonal changes have an impact on the outcome of brain injury. Behavioral problems may be pronounced in brain-injured adolescents. Precocious puberty and precocious development of sexual activity may occur in preadolescents and should be carefully monitored.

Careful consideration should be given to the developmental progress of the brain-injured child and adolescent. Delays can be anticipated after moderate and severe brain injuries related to abnormalities of cognition and behavior. Educational programs should include an individualized educational program (IEP) to support the child with significant remediation and assistance during their school years. Programs should also include a 504 plan (Section 504 of the Rehabilitation Act and the Americans with Disabilities Act). The 504 plan identifies the accommodations necessary in regular school settings for students with lesser disabilities so that they may be educated in a setting with their peers.

» Treatment

The primary goal of rehabilitation after childhood brain injury is to maximize functional independence. Rehabilitative care can be divided into three phases: acute, sub-acute, and long term. The acute and sub-acute phases typically occur in the inpatient setting while the long-term phase is an outpatient endeavor.

A. Acute Care

Therapy in the acute phase consists mainly of medical, surgical, and pharmacologic measures to decrease brain edema, treat increased intracranial pressure, and normalize laboratory values. Nutrition is essential in the healing process and either parenteral nutrition or supplemental enteral feedings are employed. Current research suggests that transitioning to enteral nutrition (eg, nasogastric tube feeding) as soon as possible after brain injury is associated with improved outcomes. Placement of a gastrostomy tube for supplemental enteral feeding is often performed in patients with severe brain injuries when recovery will be protracted and swallowing function is inadequate for safe oral feeding.

B. Sub-Acute Care

Therapy in the sub-acute phase is characterized by early, intensive participation in rehabilitative therapies promoting functional recovery. Treatment should be planned after consultation with physical therapy, occupational therapy, speech-language specialists, and neuropsychologists. Nursing staff members are a primary interface with the patient and often serve as educators for family-directed care. Most children and adolescents with brain injuries can be discharged home to continue with treatment on an outpatient basis.

C. Long-Term Care

Long-term follow-up starts immediately after discharge. Annual multidisciplinary evaluation, including neuropsychological testing is important as the child approaches school age so strategies to deal with noted deficits can be implemented to improve outcomes within the educational environment.

Medication is often required for cognitive and behavioral issues. Attention deficit and fatigue may be

amenable to treatment with stimulants such as methylphenidate and modafinil. Dopaminergic agents such as amantadine, levodopa, and bromocriptine can be useful in improving cognition, processing speed, and agitation. Antidepressants such as selective serotonin reuptake inhibitors can be helpful in treating depression and mood lability. Anticonvulsants can be useful as mood stabilizers and in treating agitation and aggression. Tegretol and valproic acid are typical agents for this purpose.

Attention and arousal can also be successfully addressed by utilizing behavioral techniques to reinforce desired behaviors and by identifying environmental situations to facilitate success. Gains made in the behavioral realm often have a positive impact on therapies designed to address physical issues.

» Prognosis & Outcomes

Directly after brain injury, poor pupillary reactivity, low blood pH, absence of deep tendon reflexes, and low GCS all correlate with poor outcome. Coalescing lesions noted on imaging and increased depth and duration of coma suggest more severe injury and poor functional recovery. Children younger than 1 year tend to have worse outcomes.

Functional outcome assessment is important for judging the efficacy of rehabilitation therapy. Global multidomain measures (eg, FIM/WeeFIM) are used to provide a functional "snapshot in time" of select functions—motor function and mobility, self-care, cognition, socialization, and communication. Simpler, single-domain, functional assessment tools such as the Glasgow Outcome Scale (GOS) and its pediatric cousin the Kings Outcome Scale for Childhood Head Injury (KOSCHI) may also be of use.

Outcome associated with mild brain injury is often quite favorable. Most patients recover normal function within a short time. A small percentage develop persistent problems such as chronic headache, poor focusing ability, altered memory, and vestibular abnormalities which may last for many weeks or months. Differentiating between musculoskeletal and central nervous system (CNS) etiologies of persistent symptoms such as headache is important and can influence prognosis and care planning.

In children, recovery may not be fully achieved for many months or years after the initial injury. The impact of the injury on developmental processes and its future consequences are difficult to predict. Long-term follow-up is required, particularly as the child approaches school age.

SPINAL CORD INJURY

ESSENTIALS OF DIAGNOSIS

» Spinal cord injury (SCI) is an alteration in normal motor, sensory, or autonomic function secondary to spinal insult.

» Characterized as either complete (total loss of function) or incomplete (some preservation of function below the level of lesion).

Epidemiologic studies of spinal cord injuries (SCI) suggest that there will be about 10,000 new injuries per year and that 20% will be in those younger than age 20 years. Motor vehicle accidents are the leading cause of SCI in all ages. Falls are common causes in young children. The phenomenon of SCI without obvious radiologic abnormality (SCIWORA) can be present in 20%–40% of young children. Children from birth to 2 years tend to have high-level injuries to the cervical spine because of anatomical features of their spine. The facets tend to be shallower and oriented horizontally, and the boney spine is more flexible than the spinal cord. In addition, the head is disproportionately large and the neck muscles are weak.

» Clinical Findings

A. Classification and Assessment of Injury Severity

SCI is classified using the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI), formerly known as the American Spinal Injury Association (ASIA) classification system.

This classification evaluates motor and sensory function, defines the neurologic level of the injury, and assesses the completeness (level of motor or sensory sparing) of the deficit. The 72-hour examination is used in predicting recovery. A complete lesion identified on examination at 72 hours predicts a poor recovery potential. The ISNCSCI classification is as follows:

1. Class A is a complete SCI, with no motor or sensory function in the lowest sacral segments.
2. Class B is an incomplete injury, with preserved sensory function but no motor function in the sacral segments.

3. Class C is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded less than 3/5 on manual muscle testing.
4. Class D is an incomplete lesion in which the strength of more than 50% of key muscles below the injury level is graded greater than 3/5 on manual muscle testing.
5. Class E is an injury in which full motor and sensory function is preserved.

B. Clinical Patterns of Spinal Cord Injury

1. Brown-Séquard injury—The cord is hemisected causing motor paralysis, loss of proprioception and vibration on the ipsilateral side, and loss of pain and temperature on the contralateral side.

2. Central cord syndrome—Injury is to the central part of the cord and results in greater weakness in the arms than the legs.

3. Anterior cord syndrome—Disruption of the anterior spinal artery causes motor deficits and loss of pain and temperature sensation. Proprioception and fine touch is spared.

4. Conus medullaris syndrome—Injury or tumor of the conus, the lower conical shaped end of the spinal cord, can cause minimal motor impairment but significant sensory, bowel, and bladder abnormalities.

5. Cauda equina syndrome—Injury to the nerve roots produces flaccid bilateral weakness in the legs, sensory abnormalities in the perineum, and lower motor neuron bowel and bladder dysfunction.

C. Imaging

The diagnosis and anatomic description of SCI is made mainly through imaging techniques. Initial studies should include radiographs of the entire spine (including cervical spine) and special studies for boney structures. MRI imaging is required to evaluate soft tissues. CT scans, including three-dimensional reconstructions, may be used to further define the injured elements.

» Treatment

A. Initial Management

The two primary precepts of SCI treatment are early identification and immediate stabilization of the spine. The approach used to stabilize the spine is determined by the type of injury, location of injury, and underlying condition of the spinal cord. Stabilizing the spine may prevent further damage to the spinal cord. External traction devices such as halo traction and orthotics are often used. Some injuries require internal stabilization. The benefit of methylprednisolone administration in acute SCI has recently come into question. Based on the ongoing controversy regarding efficacy and outcomes, steroids remain an option, but their administration is not considered standard of care.

B. Functional Expectations After Spinal Cord Injury

The lesions associated with SCI have a predictable impact on motor and sensory function. It is helpful to understand these concepts when discussing functional expectations with patients and parents (Table 28–1).

Table 28–1. Functional expectations related to spinal cord injury.

Level of Injury and Key Muscle Function	Functional Skills
C1–C4 (no upper extremity function)	Dependent for all skills, can use voice-activated computer, mouth stick; can drive power wheelchair with technology devices such as sip and puff, chin drive, or head array
C5 (biceps function)	Can assist with ADLs, power wheelchair with joy stick, push manual wheelchair short distances, use modified push rims
C6 (wrist extension)	More ADL skills; can push manual wheelchair indoors, perform level transfers; hand function augmented with adapted equipment
C7 (elbow extension)	ADLs independent; hand function augmented with adapted equipment; can push manual wheelchair indoor and outdoor
C8 (finger flexors)	ADLs independent; independent manual wheelchair skills; increased transfer skills
T1 (little finger abduction)	
T2–T12 (chest, abdominal and spinal extensors)[a]	ADLs independent; independent manual wheelchair skills; improved transfer; standing with braces
L1 and L2 (hip flexors)	Standing and walking with long leg braces, KAFO, and RGO; swing-through gait; manual wheelchair main form of mobility
L3 (knee extension)	Home and limited community ambulation; long leg or short leg braces
L4 (ankle dorsiflexion)	Community ambulation with short leg braces, AFO
L5 (long toe extensors)	Community ambulation; may be slower than peers and have some endurance issues
S1 (ankle plantar flexors)	

ADLs, activities of daily living; AFO, ankle-foot orthosis; KAFO, knee-ankle-foot orthosis; RGO, reciprocal gait orthosis.

C. Special Clinical Problems Associated With Spinal Cord Injury

1. Autonomic hyperreflexia or dysreflexia—This condition occurs in spinal injuries above the T6 level. Noxious stimuli in the injured patient cause sympathetic vasoconstriction below the level of injury. Vasoconstriction produces hypertension and then a compensatory, vagal-mediated bradycardia. Symptoms include hypertension, bradycardia, headaches, and diaphoresis. This response may be severe enough to be life threatening. Treatment requires identification and relief of the underlying noxious stimulus. Bowel, bladder, and skin problems are the most common stimuli. The patient should be placed in an upright position and antihypertensive medication used if conservative measures fail.

2. Hypercalcemia—Hypercalcemia, in response to immobilization, often occurs in male adolescents within the first 2 months of becoming paraplegic or tetraplegic. Patients complain of abdominal pain and malaise. Behavioral problems may occur. Initial treatment is focused on hydration and forced diuresis using fluids and furosemide to increase urinary excretion of calcium. In severe cases, especially in older children, calcitonin and etidronate may be required.

3. Thermoregulation problems—These problems are common in higher level injuries and usually result in a poikilothermic state where body temperature changes with that of the environment. The ability to vasoconstrict and vasodilate below the injury level is impaired. The person with an SCI above T6 is particularly susceptible to environmental temperature and is at risk for hypothermia and hyperthermia.

4. Deep vein thrombosis—Thrombosis is a common complication of SCI, especially in postpubescent children. Deep vein thrombosis should be suspected in children with any unilateral extremity swelling, palpable cords in the calf muscles, fevers, erythema, or leg pain. Diagnosis is confirmed by Doppler ultrasound, and full evaluation may require spiral CT scan or ventilation-perfusion scan if pulmonary embolus is suspected. Preventative measures include elastic stockings and compression devices. Anticoagulation prophylaxis may be required using medications such as low-molecular-weight heparins (eg, enoxaparin).

5. Heterotopic ossification—This complication occurs in both spinal cord and traumatic brain injuries. Ectopic calcium deposits usually appear around joints in the first 6 months after injury. They may cause swelling, decreased range of motion, pain with motion, palpable firm masses, fever, elevated sedimentation rate, and abnormal triple phase bone scan. Nonsteroidal anti-inflammatory drugs or bisphosphonates such as Etidronate should be started at the time of diagnosis. Surgical removal of ectopic deposits is controversial and usually performed only in cases of extreme loss of motion, pressure sores, or severe pain.

BRACHIAL PLEXUS LESIONS

ESSENTIALS OF DIAGNOSIS

- Upper trunk (C5 and C6) is the most common area injured and results in the classic **Erb palsy.**
- Injury to the lower trunk (C7–T1) produces a **Klumpke palsy.**
- Pan plexus lesion involves all roots.

» Pathogenesis

Brachial plexus lesions associated with delivery are related to traction applied to the nerves and is often associated with shoulder dystocia. The nerve injury can range from simple neuropraxia (stretch) to complete avulsion. Acquired brachial plexus injuries from sports, surgery, and accidents also have a mechanism which stretches or injures the plexus.

» Prevention

Identification of factors associated with shoulder dystocia, such as macrosomia, or proper positioning during surgical procedures to decrease traction on the brachial plexus may reduce the incidence of these lesions.

» Clinical Findings

Erb palsy has been described as the "waiter's tip posture" and is characterized by shoulder weakness with internal rotation and adduction of the upper arm. The elbow is extended and the wrist flexed. There is good preservation of hand function. Klumpke palsy is characterized by good shoulder function but decreased or absent hand function. Brachial plexus injuries may also cause a Horner syndrome (unilateral miosis, ptosis, and facial anhydrosis) due to disruption of cervical sympathetic nerves. The physical examination should include inspection of the humerus and clavicle for fractures. There may be injuries of the phrenic and facial nerves. The diagnosis of a brachial plexus lesion should be based on the history and clinical examination. Diagnostic testing helps confirm, localize, and classify the lesion. Electromyography is helpful 3–4 weeks after the injury. This test

not only is used diagnostically but also can track recovery. MRI, myelography, and CT scan can help to locate the lesion and determine its extent.

» Complications

The development of complications reflects the degree of nerve recovery. Severe injuries are at risk for shoulder contractures, muscle atrophy, osseous deformities, functional deficits, pain, and maladapted postures.

» Treatment & Prognosis

The treatment for brachial plexus lesions will depend on the severity of the lesion. Many will heal on their own and no interventions are needed. For persistent injuries, physical/occupational therapy is the major treatment and includes stretching, bracing, strengthening, electrical stimulation, and functional training. Primary surgery to the nerves of the plexus is indicated for children who have no spontaneous recovery of biceps function by 6–9 months. Secondary procedures to maximize function include muscle transfers and orthopedic interventions.

Many factors are used to predict recovery. The anatomic location of the lesion impacts recovery, as upper trunk lesions do better than lower trunk lesions. If a Horner syndrome is present, these injuries always have a poor recovery. Children in whom antigravity function returns within 2 months of injury will usually have a good recovery of function. If antigravity function is delayed until 6 months, recovery will probably be limited. If antigravity function is absent at 6–9 months, there will be no recovery of function and surgery should be considered.

COMMON REHABILITATION PROBLEMS

1. Neurogenic Bladder

During the first year of life, the bladder is a reflex-driven system that empties spontaneously. After the first year control begins to develop, and most children achieve continence by age 5 years. Children with damage to the central or peripheral nervous system may develop a neurogenic bladder. The diagnosis of neurogenic bladder requires a complete history and physical examination and is usually classified as noted below:

1. Uninhibited neurogenic bladder occurs after upper motor neuron injuries at the level of the brain or spinal cord that result in failure to inhibit detrusor contractions. This results in a hyperreflexive voiding pattern.
2. Reflex neurogenic bladder results from damage to the sensory and motor nerves above the S3 and S4 level. The bladder empties reflexively but coordination may not be present and dyssynergia (contraction of the bladder musculature against a closed sphincter) can occur. Increased intravesicular pressure and vesicourethral reflux may be consequences of dyssynergia.
3. Autonomous neurogenic bladder is a flaccid bladder and is associated with lower motor neuron damage. Bladder volumes are usually increased and overflow incontinence can occur.
4. Motor paralytic neurogenic bladder results from injury to the motor nerves of the S2–S4 roots. Sensation is intact but there is motor dysfunction. The child has the sensation to void but has difficulty with the voluntary contractions.
5. Sensory paralytic neurogenic bladder results when sensory roots are disrupted. Affected patients do not have sensation of the full bladder but are able to initiate voiding.

The type of neurologic damage should be identified as this will help to predict anticipated voiding issues. The upper tracts should be assessed using ultrasound, intravenous pyelogram, or renogram (isotope) studies. Lower tract testing includes urinalysis, postvoid residuals, urodynamics, cystography, and cystoscopy.

» Treatment

Treatment is geared to the type of bladder dysfunction. The simplest methods, such as timed voiding, can be effective for children with uninhibited bladders. In this technique, children are reminded verbally or use a cueing device (watch with a timer) to void every 2–3 hours before bladder capacity is reached. The Credé and Valsalva maneuvers are used in patients with an autonomous bladder to assist in draining a flaccid bladder. There is a risk of provoking vesicoureteral reflux by increasing intravesicular pressure during these maneuvers which should never be used in a patient with a reflex neurogenic bladder.

Medications are often employed to treat neurogenic bladder. Anticholinergics are commonly used to reduce detrusor contractions, decrease the sense of urgency, and increase bladder capacity. Medications include oxybutynin, tolterodine, and hyoscyamine. The side effects of these medications include sleepiness, nausea, and constipation. Absorbent pads and diapers, external catheters, indwelling catheters, and intermittent catheterization are also effective. A young child with a high-pressure bladder is at particular risk for reflux and may need medication, intermittent catheterization, or

vesicostomy to prevent hydrostatic renal damage and infection. An older child may require reconstructive bladder surgery (bladder augmentation) to increase the capacity of the bladder or an intestinal conduit from bladder to skin surface (Mitrofanoff procedure) to relieve bladder distention. If an incompetent urethral sphincter causes urinary leakage, injections, slings, or implants may be used to increase the urethral barrier. Recently, electrical stimulation of sacral roots has been used to initiate voiding. Biofeedback training is also used to improve voiding.

2. Neurogenic Bowel

Control of bowel function depends on an intact autonomic (sympathetic and parasympathetic) and somatic nervous system. Goals of treatment for patients with neurogenic bowel are to establish a predictable and reliable bowel habit, and prevent incontinence and complications. There are two types of neurogenic bowel dysfunction: upper motor and lower motor dysfunction. The upper neuron bowel results from damage above the conus. Affected patients usually have reflex bowel contractions of high amplitude, absence of sensation, and no voluntary sphincter control. Patients with the lower motor neuron bowel have no voluntary sphincter control and no reflex contraction of the external anal sphincter (anocutaneous reflex). It has been described as a flaccid bowel. In general, establishing a bowel program is easier in patients with upper motor neuron lesions.

» Treatment

Fiber intake and fluids are critical elements for maintaining a soft stool consistency, although some patients try to keep themselves constipated to prevent accidents. A predictable and scheduled bowel program is essential. Bowel movements should be scheduled to occur with meals, as the gastrocolic reflex can trigger defecation.

Laxative and stool softening medications are usually included in a comprehensive bowel program. Stool softeners such as docusate retain stool water. Mineral oil is an acceptable stool softener in patients not at risk for pulmonary aspiration. Bulking agents such as Metamucil increase fiber and water content of stool and reduce transit time. Stimulants such as senna fruit extract or bisacodyl increase peristalsis. Osmotic agents such as polyethylene glycol keep stools soft by retaining stool water. Suppositories and enemas are often used when other methods have not been successful. Upper motor neuron bowel management programs may include digital rectal stimulation. When conservative methods are ineffective, options may include surgical implantation of sacral nerve stimulators or techniques to facilitate antegrade flushing of the colon. For example, the ACE (antegrade continence enema) or Malone procedure approximates the appendix to the surface of the abdomen providing a conduit for flushing. Also, a capped cecostomy tube can be placed into the cecum through which fluids can be administered in an antegrade fashion to remove fecal matter from the colon.

3. Spasticity

Spasticity is a velocity-dependent increase in muscle tone and a loss of isolated muscle function. Whereas tone is the resistance felt in a muscle as it is moved in space, spasticity occurs when there is damage to the CNS from trauma or injury. It is included in the upper motor neuron syndrome (hyperactive and exaggerated reflexes, increased tone, clonus, positive Babinski sign). Spasticity is evaluated using the Ashworth Scale, with 0 indicating no increase in muscle tone and 4 indicating complete rigidity of the extremity.

» Treatment

Treatment is goal directed and influenced by the functional status of the client. Options for therapy range from conservative to aggressive. Children should be positioned properly and have appropriate equipment to prevent nociceptive input and facilitate physical therapy. Physical therapy can reduce the long-term effects of spasticity by use of stretching and range-of-motion exercises. Heat and cold are useful in improving tone, but their effects are not long lived. Casting of both upper and lower extremities can decrease tone and increase range of motion. Constraint therapy can be used to try to improve upper extremity function.

Pharmacologic support with medications, such as baclofen, diazepam, dantrolene, and tizanidine can be effective. Baclofen (a direct $GABA_B$ agonist) is a first-line medication, which produces effects at the spinal cord level. Side effects are primarily sleepiness and weakness. Seizure threshold may be reduced by baclofen. Baclofen, delivered directly to the CNS through an intrathecal pump, has been used successfully in children with brain injury, cerebral palsy, and SCI. Diazepam, an allosteric modulator of postsynaptic $GABA_A$ receptors in both the brain and the spinal cord, can be effective but its central CNS effects can cause drowsiness and dependence. Dantrolene inhibits excitation contraction coupling but use can result in weakness or, rarely, hepatotoxicity. Tizanidine is a newer agent and works at the α_2-adrenergic receptors presynaptically. It can cause dry mouth and sedation, and liver function tests can be elevated.

Relief of focal spasticity can be achieved by using chemodenervation techniques. Botulinum toxin A and B can be injected in selected muscles to block acetylcholine release at the neuromuscular junction and thereby improve range of motion. Enhanced function, improved hygiene, reduced pain, and deformity are the result. Botulinum toxins have also been used to treat drooling, hyperhydrosis, and chronic pain. The effects are temporary, lasting only 3–6 months, and repeat injections are often needed. Technically more challenging phenol injection denatures proteins in both myelinated and unmyelinated fibers and produces neurolysis or

myolysis, depending on the site of injection. The effects may last longer than botulinum toxins but carry a risk of sensory dysesthesia if mixed nerves are injected.

Surgical options include orthopedic procedures geared toward improving function and ambulation and alleviating deformities produced over time by spasticity. Contractures are common in the Achilles tendon, hamstrings, and adductors. Upper extremity contractures occur in the elbow, wrist, and finger flexors. Scoliosis is fairly common and bracing or surgery may be needed. Gait analysis may be helpful in evaluating the child with functional spasticity as a guide for the use of orthotics, therapy, and surgery. Neurosurgical techniques such as selective dorsal rhizotomy, sectioning afferent sensory nerve fibers, are used in a very select group of children to permanently alter spasticity patterns and improve ambulation.

QUALITY ASSURANCE/IMPROVEMENT INITIATIVES IN REHABILITATION MEDICINE

Working with the Accreditation Council for Graduate Medical Education (ACGME), the American Academy of Physical Medicine and Rehabilitation (AAPM&R) fosters acquisition of knowledge regarding the use of quality assurance/improvement techniques in its training programs. This is now one of six competencies required for board certification. The AAPM&R feels that these skills endow the practitioner with the capacity to maintain and improve the quality of care provided to the public.

29 Rheumatic Diseases

Jennifer B. Soep, MD

JUVENILE IDIOPATHIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Arthritis, involving pain, swelling, warmth, tenderness, morning stiffness, and/or decreased range of motion of one or more joints, lasting at least 6 weeks.
- May have associated systemic manifestations, including fever, rash, uveitis, serositis, anemia, and fatigue.

Juvenile idiopathic arthritis (JIA) is characterized by chronic arthritis in one or more joints for at least 6 weeks. There are four main subtypes of JIA: (1) oligoarticular, (2) polyarticular, (3) systemic, and (4) enthesitis-associated. The exact cause of JIA is not known, but there is substantial evidence that it is an autoimmune process with genetic susceptibility factors.

» Clinical Findings

A. Symptoms and Signs

The most common type of JIA is the oligoarticular form, which constitutes approximately 30%–40% of patients and is characterized by arthritis of four or fewer joints. This type of JIA often affects medium to large joints. Because the arthritis is often asymmetrical, children may develop a leg-length discrepancy in which the involved leg grows longer due to increased blood flow and growth factors. The synovitis is usually mild and may be painless. Systemic features are uncommon except for inflammation in the eye. Up to 20% of children with this type of JIA develop insidious, asymptomatic uveitis, which may cause blindness if untreated. The activity of the eye disease does not correlate with that of the arthritis. Therefore, routine ophthalmologic screening with slit-lamp examination must be performed at 3-month intervals if the antinuclear antibody (ANA) test is positive, and at 6-month intervals if the ANA test is negative, for at least 4 years after the onset of arthritis, as this is the period of highest risk.

Polyarticular disease is defined as arthritis involving five or more joints. This type of JIA affects 25% of patients. Both large and small joints are involved, typically in a symmetrical pattern. Systemic features are not prominent, although low-grade fever, fatigue, rheumatoid nodules, and anemia may be present. This group is further divided into rheumatoid factor (RF)-positive and RF-negative disease. The former resembles adult rheumatoid arthritis with more chronic, destructive arthritis.

The systemic form, previously known as Still disease, comprises 5%–10% of patients with JIA. The arthritis can involve any number of joints and affects both large and small joints, but may be absent at disease onset. One of the classic features is a high fever, often as high as 39°C–40°C, typically occurring one to two times per day. In between fever spikes, the temperature usually returns to normal or subnormal. Around 90% patients have a characteristic evanescent, salmon-pink macular rash that is most prominent on pressure areas and when fever is present. Other systemic features that may be present, but are not specific for JIA, include hepatosplenomegaly, lymphadenopathy, leukocytosis, and serositis.

Enthesitis-associated arthritis is most common in males, older than 10 years of age, and is typically associated with lower extremity, large joint arthritis. The hallmark of this form is inflammation of tendinous insertions (enthesopathy), such as the tibial tubercle or the heel. Low back pain and sacroiliitis are also commonly seen in this form of arthritis which comprises approximately 10%–20% of patients with JIA.

There are two additional subtypes of JIA. Children with psoriatic arthritis may have typical psoriasis, but may also present prior to the onset of the classic thick scaly plaques and have more subtle changes such as nail pitting (see Chapter 15). Patients with psoriatic arthritis may also present with dactylitis or "sausage digit," which is painful swelling of an entire finger or toe. Undifferentiated JIA, comprising 10% of patients, includes children with chronic arthritis that do not meet criteria for any of the other subgroups or meet more than one criterion and therefore could be classified into multiple subgroups.

B. Laboratory Findings

There is no diagnostic test for JIA. A normal erythrocyte sedimentation rate (ESR) does not exclude the diagnosis of JIA. However, patients with systemic JIA typically have significantly elevated markers of inflammation, including ESR, C-reactive protein (CRP), white blood cell count, and platelets. RF is positive in about 5% of patients, usually when the onset of polyarticular disease occurs after age 8 years. A newer test, anti-cyclic citrullinated peptide (anti-CCP) antibody, has a very high specificity for rheumatoid arthritis and may be detectable prior to the RF. ANAs are associated with an increased risk of uveitis in patients with oligoarticular disease. A positive ANA test is also fairly common in patients with the late-onset RF-positive form of the disease. Carriage of HLAB27 antigen is associated with an increased risk of developing enthesitis-associated arthritis.

Table 29–1 lists the general characteristics of joint fluid in various conditions. The main indication for joint aspiration and synovial fluid analysis is to rule out infection. A positive Gram stain or culture is the only definitive test for infection. A leukocyte count over 2000/μL suggests inflammation; this may be due to infection, rheumatologic diseases, leukemia, or reactive arthritis. A very low glucose concentration (< 40 mg/dL) or very high polymorphonuclear leukocyte count (> 60,000/μL) is highly suggestive of bacterial arthritis.

Table 29–1. Joint fluid analysis.

Disorder	Cells/μL	Glucose[a]
Trauma	More red cells than white cells; usually < 2000 white cells	Normal
Reactive arthritis	3000–10,000 white cells, mostly mononuclear cells	Normal
Juvenile idiopathic arthritis and other inflammatory arthritides	5000–60,000 white cells, mostly neutrophils	Usually normal or slightly low
Septic arthritis	> 60,000 white cells, > 90% neutrophils	Low to normal

[a]Normal value is ≥ 75% of the serum glucose value.

C. Imaging Studies

In the early stages of the disease, only soft tissue swelling and possibly periarticular osteoporosis may be seen. Magnetic resonance imaging (MRI) of involved joints may show early joint damage and, if obtained with gadolinium, can confirm the presence of synovitis. Ultrasound is now used to detect synovitis, tenosynovitis, and bony erosions without radiation and without requiring sedation. Later in the course of the disease, particularly in patients with RF-positive disease, plain films may demonstrate joint space narrowing due to cartilage thinning and erosive changes of the bone related to chronic inflammation.

» Differential Diagnosis

Table 29–2 lists the most common causes of limb pain in childhood. JIA is a diagnosis of exclusion; therefore, it is important to rule out other causes of the clinical signs and symptoms prior to settling on this diagnosis. The differential diagnosis is often quite broad, including orthopedic conditions, infectious diseases, and malignancies. A few key features can help distinguish these different entities, including the timing of the pain and associated signs and symptoms. In inflammatory conditions, patients frequently have increased symptoms in the morning with associated stiffness. In contrast, patients with an orthopedic abnormality typically have increased symptoms later in the day and with activity. Growing pains, a common cause of leg pain in childhood, are characterized by poorly localized pain at night, which frequently wakes the child from sleep; no objective signs of inflammation; and no daytime symptoms. Patients with growing pains often ask to be massaged, which is not typical of those with arthritis.

It is particularly important to establish the diagnosis in the case of monoarticular arthritis. Bacterial arthritis is usually acute and monoarticular except for arthritis associated with gonorrhea, which may be associated with a migratory pattern and hemorrhagic pustules, usually on the distal extremities. Fever, leukocytosis, and increased ESR with an acute process in a single joint demand synovial fluid examination and culture to identify the pathogen. Pain in the hip or lower extremity is a frequent symptom of childhood cancer, especially leukemia, neuroblastoma, and rhabdomyosarcoma. Infiltration of bone by tumor and a joint effusion may be seen. Radiographs of the affected site and examination of the blood smear for unusual cells and thrombocytopenia are necessary. An elevated lactate dehydrogenase value should also raise concern about an underlying neoplastic process. In doubtful cases, bone marrow examination is indicated.

Table 29–2. Differential diagnosis of limb pain in children.

Orthopedic
Stress fracture
Chondromalacia patellae
Osgood-Schlatter disease
Slipped capital femoral epiphysis
Legg-Calvé-Perthes disease
Hypermobility syndrome
Reactive arthritis
Henoch-Schönlein purpura
Transient synovitis
Rheumatic fever
Poststreptococcal arthritis
Infections
Bacterial
Lyme arthritis
Osteomyelitis
Septic arthritis
Discitis
Viral (including parvovirus, Epstein-Barr virus, and Hepatitis B)
Rheumatologic
Juvenile idiopathic arthritis
Systemic lupus erythematosus
Dermatomyositis
Chronic recurrent multifocal osteomyelitis
Neoplastic
Leukemia
Lymphoma
Neuroblastoma
Osteoid osteoma
Bone tumors (benign or malignant)
Pain syndromes
Growing pains
Fibromyalgia
Complex regional pain syndrome

Reactive arthritis is joint pain and swelling triggered by an infection. The infection is nonarticular and can be either viral or bacterial. A preceding illness is identified in approximately half of cases. Patients often have acute onset of arthritis, and there may be a migratory pattern. The duration of symptoms is a very important distinction between reactive arthritides and JIA. Symptoms associated with reactive arthritis typically resolve within 4–6 weeks. In contrast, to meet criteria for chronic arthritis, symptoms must be present for at least 6 weeks.

The arthritis of rheumatic fever is migratory, transient, and often more painful than that of JIA. Rheumatic fever is very rare in children younger than 5 years (see Chapter 20). In suspected cases, evidence of rheumatic carditis should be sought based on examination and electrocardiographic findings. Evidence of recent streptococcal infection is essential to the diagnosis. The fever pattern in rheumatic fever is low grade and persistent compared with the spiking fever that characterizes the systemic form of JIA. Lyme arthritis resembles oligoarticular JIA, but the former usually occurs as discrete, recurrent episodes of arthritis lasting 2–6 weeks and children should have a history of being in an endemic area. The typical bull's-eye rash is called erythema chronicum migrans. Approximately 70%–80% of patients have a history of a compatible rash, although it is usually resolved by the time the arthritis appears. For children suspected of having Lyme disease, testing for antibodies against Borrelia burgdorferi should be performed, with confirmatory testing by Western blot (see Chapter 42).

» Treatment

The objectives of therapy are to restore function, relieve pain, maintain joint motion, and prevent damage to cartilage and bone.

A. Nonsteroidal Anti-Inflammatory Medications

First-line therapy is nonsteroidal anti-inflammatory drugs (NSAIDs). A wide range of agents is available but only a few are approved for use in children, including naproxen (10 mg/kg per dose twice daily), ibuprofen (10 mg/kg per dose three to four times daily), and meloxicam (0.125–0.25 mg/kg once daily). NSAIDs are generally well tolerated in children, as long as they are taken with food. The average time to symptomatic improvement is 1 month, but in some patients a response is not seen for 8–12 weeks.

B. Disease-Modifying and Biologic Agents

For patients with JIA who fail to respond to NSAIDs, weekly methotrexate is the second-line medication of choice. Symptomatic response usually begins within 3–4 weeks. The low dosages used (5–10 mg/m^2/wk or up to 1 mg/kg/wk as a single dose) are generally well tolerated. Potential side effects include nausea, vomiting, hair thinning, stomatitis, leukopenia, immunosuppression, and hepatotoxicity. A complete blood count and liver function tests should be obtained every 2–3 months. Several additional disease-modifying agents are available for use in patients with persistently active disease or those intolerant to methotrexate. Leflunomide is an antipyrimidine medication that is administered orally. Side effects may include diarrhea and alopecia. Biological modifying medications that inhibit tumor necrosis factor, a cytokine known to play an important role in the pathogenesis of JIA, include etanercept, infliximab, and adalimumab. These drugs are generally quite effective in controlling disease and preventing cartilage and bone damage, and have been associated with healing based on radiologic changes. However, their potential long-term effects are unknown, they are very expensive, and require parenteral administration. Anakinra and tocilizumab, which block interleukin 1 and

6 respectively, are particularly effective for systemic JIA. Other biologic agents, including rituximab and abatacept, have demonstrated some efficacy in patients who have not responded to other treatments.

C. Corticosteroids

Local steroid joint injections may be helpful in patients who have arthritis in one or a few joints. Triamcinolone hexacetonide is a long-acting steroid that can be used for injections and is often associated with at least several months of disease control. Oral or parenteral steroids are reserved for children with severe involvement, primarily patients with systemic disease.

D. Uveitis

Inflammation of the uveal tract (uveitis or iridocyclitis) should be closely monitored by an ophthalmologist (see Chapter 16). Typically treatment is initiated with corticosteroid eye drops and dilating agents to prevent scarring between the iris and the lens. In patients who fail topical treatments, methotrexate, cyclosporine, and/or a tumor-necrosis factor inhibitor such as infliximab or adalimumab may be used.

E. Rehabilitation

Physical and occupational therapies are important to focus on range of motion, stretching, and strengthening. These exercises, as well as other modalities such as heat, water therapy, and ultrasound, can help control pain, maintain and restore function, and prevent deformity and disability. Young children with oligoarticular disease affecting asymmetrical lower extremity joints can develop a leg-length discrepancy, which may require treatment with a shoe lift on the unaffected side.

» Prognosis

The course and prognosis for JIA is variable, depending on the subtype of disease. Children with persistent oligoarticular JIA have the highest rate of clinical remission, while patients with RF-positive disease are the least likely to achieve this status and are at highest risk for chronic, erosive arthritis that may continue into adulthood. The systemic features associated with systemic arthritis tend to remit within months to years. The prognosis in systemic disease is worse in patients with persistent systemic disease after 6 months, thrombocytosis, and more extensive arthritis.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Multisystem inflammatory disease of the joints, serosal linings, skin, kidneys, blood, and central nervous system.
- Autoantibodies such as antinuclear antibodies (ANA), double-stranded DNA, and anti-Smith antibodies are present and related to the pathogenesis of disease.

» Pathogenesis

Systemic lupus erythematosus (SLE) is the prototype of immune complex diseases; its pathogenesis is related to the formation of antibody-antigen complexes that exist in the circulation and deposit in the involved tissues. The spectrum of symptoms is due to tissue-specific autoantibodies as well as to damage to tissues by lymphocytes, neutrophils, and complement evoked by the deposition of immune complexes. Autoreactive T lymphocytes that have escaped clonal deletion and unregulated B-lymphocyte production of autoantibodies may initiate the disease.

» Clinical Findings

A. Symptoms and Signs

The onset of pediatric SLE is most common in girls between the ages of 9 and 15 years. Signs and symptoms depend on the organs affected by immune complex deposition. The American College of Rheumatology has established criteria to aid in the diagnosis of SLE; four of the following 11 criteria are necessary to establish the diagnosis:

1. Malar rash—photosensitive, the so-called butterfly rash on the cheeks and nasal bridge

2. Discoid rash—annular, scaly rash on the scalp, face, and extremities that can lead to scarring
3. Photosensitivity—increased rash or other disease symptoms in response to sunlight exposure
4. Mucous membrane ulcers—painless ulcers on the hard palate and/or nasal septum
5. Arthritis—nonerosive arthritis of large and small joints, typically in a symmetrical distribution
6. Serositis—pericarditis and/or pleuritis, often associated with chest pain and difficulty breathing
7. Renal abnormalities—proteinuria (> 0.5 g/d) and/or cellular casts
8. Neurologic abnormalities—seizures and/or psychosis
9. Blood count abnormalities—low white blood cell count (< 4000/mm^3), Coombs test–positive anemia, and/or thrombocytopenia (< 100,000/mm^3)
10. Positive ANA—seen in almost 100% of patients with SLE
11. Autoantibodies—positive double-stranded DNA antibody, anti-Smith antibody, anticardiolipin antibodies, lupus anticoagulant, and/or false-positive blood test for syphilis

Other common signs and symptoms include fever, fatigue, weight loss, anorexia, Raynaud phenomenon, myositis, vasculitis, chorea, neuropathies, depression, and cognitive changes.

B. Laboratory Findings

Complete blood count abnormalities are common, including leukopenia, anemia, and thrombocytopenia. Approximately 15% of patients are Coombs test–positive, but many patients develop anemia due to other causes, including chronic disease and blood loss. Patients with significant renal involvement may have electrolyte disturbances, elevated kidney function tests, and hypoalbuminemia. The ESR is frequently elevated during active disease. In contrast, many patients with active SLE have a normal CRP. When the CRP is elevated, it is important to investigate possible infectious causes, particularly bacterial infections. It is critical to monitor the urinalysis in patients with SLE for proteinuria and hematuria, as the renal disease may be otherwise clinically silent. In immune complex diseases, complement is consumed; therefore, levels of C3 and C4 are depressed with active disease.

The ANA test is positive in almost 100% of patients, usually at titers of 1:320 or above. In patients with suspected SLE, it is important to obtain a full ANA profile—including antibodies directed against double-stranded DNA, Smith, ribonucleic protein, and Sjögren-specific antibody A and B to better characterize their serologic markers of disease. Because approximately 50%–60% of pediatric SLE patients have antiphospholipid antibodies and are therefore at increased risk of thrombosis, it is important to screen all patients with SLE for anticardiolipin antibodies and lupus anticoagulant.

» Differential Diagnosis

Because there is such a wide spectrum of disease with SLE, the differential diagnosis is quite broad, including systemic JIA, mixed connective tissue disease (MCTD), rheumatic fever, vasculitis, malignancies, and bacterial and viral infections. A negative ANA test essentially excludes the diagnosis of SLE. Anti–double-stranded DNA and Smith antibodies are very specific for SLE. The preceding diagnostic criteria, which are very helpful in establishing the diagnosis of SLE, have a specificity and sensitivity of 96%.

MCTD, an overlap syndrome with features of several collagen-vascular diseases, shares many features with SLE. The symptom complex is diverse and often includes arthritis, fever, skin tightening, Raynaud phenomenon, muscle weakness, and rash. The ANA test is typically positive in very high titers. The ANA profile is negative except for antibodies directed against ribonucleic protein.

» Treatment

The treatment of SLE should be tailored to the organ system involved so that toxicities may be minimized. Prednisone is the mainstay of treatment and has significantly lowered the mortality rate in SLE. Patients with severe, life-threatening, or organ-threatening disease are typically treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage should be adjusted using clinical and laboratory parameters of disease activity, and the minimum amount of corticosteroid to control the disease should be used. Skin manifestations, arthritis, and fatigue may be treated with antimalarials such as hydroxychloroquine, 5–7 mg/kg/d orally. Pleuritic pain or arthritis can often be managed with NSAIDs.

If disease control is inadequate with prednisone or if the dose required produces intolerable side effects, a steroid-sparing agent, such as mycophenolate mofetil, azathioprine, or cyclophosphamide, should be added. More recently, rituximab, a monoclonal antibody directed against the B-cell surface marker CD20, has been used for persistent active disease, particularly in patients with hematologic manifestations. Patients who have evidence of antiphospholipid antibodies should be treated with a baby aspirin every day to help prevent thrombosis. Thrombotic events due to these antibodies require long-term anticoagulation.

The toxicities of the regimens must be carefully considered. Growth failure, osteoporosis, Cushing syndrome, adrenal suppression, and aseptic necrosis are serious side effects of chronic use of prednisone. When high doses of corticosteroids are used (> 2 mg/kg/d), there is a high risk of

infection. Cyclophosphamide can cause bone marrow suppression, bladder epithelial dysplasia, hemorrhagic cystitis, and sterility. Azathioprine has been associated with liver damage and bone marrow suppression. Immunosuppressant treatment should be withheld if the total white blood cell count falls below 3000 mm^3 or the neutrophil count falls below 1000/mm^3μL. Retinal damage from hydroxychloroquine is generally not observed with recommended dosages, but patients typically have routine visual field testing to screen for retinal toxicity.

» Prognosis

The prognosis in SLE relates to the presence of renal involvement or infectious complications of treatment. The survival rate has improved from 51% at 5 years in 1954 to 90% today. The disease has a natural waxing and waning cycle; it may flare at any time and spontaneous remission may rarely occur.

DERMATOMYOSITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pathognomonic skin rashes.
- Weakness of proximal muscles and occasionally of pharyngeal and laryngeal groups.
- Pathogenesis related to vasculopathy.

» Clinical Findings

A. Symptoms and Signs

The predominant symptom is proximal muscle weakness, particularly affecting pelvic and shoulder girdle muscles. Tenderness, stiffness, and swelling may be found. Pharyngeal involvement, manifested as voice changes and difficulty swallowing, is associated with an increased risk of aspiration. Intestinal vasculitis can be associated with ulceration and perforation of involved areas. Flexion contractures and muscle atrophy may produce significant residual deformities. Calcinosis may follow the inflammation in muscle and skin.

Several characteristic rashes are seen in dermatomyositis. Patients often have a heliotrope rash with a reddish-purple hue on the upper eyelids, along with a malar rash that may be accompanied by edema of the eyelids and face. Gottron papules are shiny, erythematous, scaly plaques on the extensor surfaces of the knuckles, elbows, and knees. Dilated nailbed vessels are commonly seen with active disease. Thrombosis and dropout of periungual capillaries may identify patients with a more severe, chronic disease course.

B. Laboratory Findings/Imaging Studies/Special Tests

Determination of muscle enzyme levels, including aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine phosphokinase, and aldolase, is helpful in confirming the diagnosis, assessing disease activity, and monitoring the response to treatment. Even in the face of extensive muscle inflammation, the ESR and CRP may be normal. An MRI scan of the quadriceps muscle can be used in equivocal cases to confirm the presence of inflammatory myositis. Electromyography is useful to distinguish myopathic from neuropathic causes of muscle weakness. Muscle biopsy is indicated in cases of myositis without the pathognomonic rash.

» Treatment

Treatment is aimed at suppression of the inflammatory response and prevention of the loss of muscle function and joint range of motion. Acutely, it is very important to assess the adequacy of the ventilatory effort and swallowing, and to rule out intestinal vasculitis. Corticosteroids are the initial therapy of choice. Treatment is usually initiated with prednisone, 2 mg/kg/d, and continued until signs and symptoms of active disease are controlled; the dosage is then gradually tapered. In severe cases, intravenous pulse methylprednisolone for 3 days is indicated. Therapy is guided by the physical examination findings and muscle enzyme values. Methotrexate is often used concomitantly to achieve better control of the disease and minimize the steroid side effects. If patients continue to have active disease, additional steroid-sparing agents, such as cyclosporine, intravenous immunoglobulin, and, in severe cases, cyclophosphamide should be started.

Hydroxychloroquine and intravenous immunoglobulin may be particularly helpful in managing the skin manifestations. As the rashes are photosensitive, sun protection is very important. Physical and occupational therapy should be initiated early in the course of disease. Initially, passive range-of-motion exercises are performed to prevent loss of

motion. Later, once the muscle enzymes have normalized, a graduated program of stretching and strengthening exercises is introduced to restore normal strength and function.

» Prognosis

Most patients have a monocyclic course; 10%–20% of patients have more chronic or recurrent symptoms. Factors that influence the outcome include the rapidity of symptom onset, extent of weakness, presence of cutaneous or gastrointestinal vasculitis, timeliness of diagnosis, initiation of therapy, and response to treatment. Dermatomyositis in children is not associated with cancer as it is in adults.

VASCULITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cutaneous involvement with nonblanching, tender skin lesions.
- Frequent presence of systemic inflammation, particularly in the lungs and kidneys.
- Gold-standard for diagnosis is demonstration of vasculitis on biopsy.

The vasculitides are a group of conditions that involve inflammation of blood vessels. They are classified by the size of the blood vessels affected (Table 29–3). The two most common forms of vasculitis in childhood—Henoch-Schönlein purpura (HSP) (see Chapter 30) and Kawasaki disease (see Chapter 20)—are acute, self-limited forms of vasculitis. In contrast, there are idiopathic, chronic forms of vasculitis, such as granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA), which are rare in childhood.

» Clinical Findings

A. Symptoms and Signs

Signs and symptoms vary by disease, but most children with chronic vasculitis have persistent fever, fatigue, weight loss, and signs of pulmonary, renal, musculoskeletal, gastrointestinal, and/or skin inflammation.

Table 29–3. Classification of vasculitides by vessel size involved.

Large vessel
Takayasu arteritis
Giant cell arteritis
Medium vessel
Kawasaki disease
Granulomatosis with polyangiitis (previously called Wegener granulomatosis)
Polyarteritis nodosa
Churg-Strauss syndrome
Small vessel
Henoch-Schönlein purpura
Microscopic polyarteritis

Granulomatosis with polyangiitis (previously called Wegener granulomatosis) often causes nephritis and involves the lungs, manifesting as chronic cough, hemorrhage, and/or cavitating lesions. This form of vasculitis also frequently affects the upper respiratory tract, causing chronic otitis media, sinusitis, and/or inflammation of the trachea; saddle nose deformity may occur.

Children with polyarteritis nodosa (PAN) often present with skin lesions such as purpura, nodules or ulcers, and evidence of organ involvement with abdominal pain, testicular pain, hypertension, hematuria and/or neurologic symptoms. MPA typically presents with pulmonary-renal syndrome with features of pulmonary hemorrhage and rapidly progressive kidney inflammation.

B. Laboratory Findings/Imaging Studies/Special Tests

Patients with vasculitis often have elevated inflammatory markers. If they have significant renal involvement, they may have elevated renal function tests and abnormal urinary sediment. Anemia is common, due to chronic disease and/or renal insufficiency. Low hemoglobin may also be an indicator of pulmonary hemorrhage in a patient with cough, hemoptysis, respiratory distress, and/or infiltrates on chest x-ray.

Antineutrophil cytoplasmic antibodies (ANCA) may be present in patients with small vessel vasculitis. Cytoplasmic ANCA (c-ANCA), which is usually directed against proteinase 3 and is quite sensitive and specific for GPA, is positive in 80%–95% of patients with active disease. Perinuclear ANCA (p-ANCA) is typically directed against myeloperoxidase and is associated with MPA and can also be seen in HSP, Churg-Strauss, and inflammatory bowel disease.

The diagnosis is made based on a typical clinical presentation and laboratory findings. If the diagnosis remains uncertain, then attempting to definitively establish the diagnosis with a biopsy of involved tissue is warranted. A biopsy in patients with GPA typically demonstrates

necrotizing granulomatous vasculitis. Biopsies of involved areas will confirm the presence of vasculitis in small vessels in patients with MPA and small and medium arteries in PAN. If a biopsy is not feasible, additional imaging studies such as an angiogram, which can demonstrate characteristic patterns of inflammation in affected blood vessels, should be considered.

» Treatment

The treatment of the various forms of chronic vasculitis is based on the severity of illness and the organs involved. Typically, corticosteroids are the initial therapy. Patients with severe disease are usually treated with intravenous pulse methylprednisolone, 30 mg/kg per dose (maximum of 1000 mg) daily for 3 days, and then switched to 2 mg/kg/d of prednisone. The dosage is then gradually tapered as tolerated based on clinical and laboratory markers of disease activity. Patients are usually treated with other immunosuppressant medications to gain and maintain control of the disease and minimize the steroid side effects. Standard treatment has included cyclophosphamide for induction, followed by maintenance with methotrexate, azathioprine, or mycophenolate. More recent studies in patients with ANCA-positive vasculitis suggest that rituximab can be used for induction therapy with potentially fewer side effects and risks than cyclophosphamide.

» Prognosis

Immunosuppressive medications have improved survival and remission rates for patients with chronic vasculitis. Conditions such as GPA had almost always been fatal. Since introducing the regimen of high-dose steroids and cyclophosphamide (or other cytotoxic agents), patients with vasculitides have greatly improved outcomes, with 5-year survival ranging from 50% to 100%. Because relapses are common when therapy is weaned or stopped, maintenance immunosuppression is commonly required in these disorders.

Twilt M, Benseler S: Childhood antineutrophil cytoplasmic antibodies associated vasculitides. Curr Opinion Rheumatol 2014;26(1):50–55 [PMID: 24247117].

RAYNAUD PHENOMENON

Raynaud phenomenon is an intermittent vasospastic disorder of the extremities. As much as 10% of the adult population has this disorder, and onset in childhood is not uncommon. The classic triphasic presentation is cold-induced pallor, then cyanosis, followed by hyperemia, but incomplete forms are frequent. In adults older than 35 years who are ANA-positive, Raynaud phenomenon may be a harbinger of rheumatic disease. This progression is rarely seen in childhood. Evaluation should include a detailed history with review of systems relevant to rheumatic disease. Examination of the cuticle edge, using an otoscope or a special microscope called a capillaroscope, is important to screen for dilated and/or tortuous capillaries that may suggest an underlying rheumatic disease such as lupus or scleroderma. In the absence of positive findings, Raynaud phenomenon is likely to be idiopathic.

Treatment involves education about keeping the extremities and core body warm and the role of stress, which may be a precipitant. In very symptomatic patients, treatment with calcium channel blockers such as nifedipine can be effective.

NONINFLAMMATORY PAIN SYNDROMES

1. Complex Regional Pain Syndrome

Complex regional pain syndrome, previously known as reflex sympathetic dystrophy, is a painful condition that is frequently confused with arthritis. Prevalence and recognition of the condition is increasing. Severe extremity pain leading to nearly complete loss of function is the hallmark of the condition. Evidence of autonomic dysfunction is demonstrated by pallor or cyanosis, temperature differences (with the affected extremity cooler than surrounding areas), and generalized swelling. On examination, allodynia, which is marked cutaneous hyperesthesia to even the slightest touch, is often evident. Results of laboratory tests are normal, without evidence of systemic inflammation. Radiographic findings are normal except for late development of osteoporosis. Bone scans may be helpful and may demonstrate either increased or decreased blood flow to the painful extremity.

The cause of this condition remains elusive. Treatment includes physical therapy to focus on restoration of function, maintenance of range of motion, and pain relief. NSAIDs can be helpful for pain control, and in patients with more chronic disease, gabapentin, or pregabalin are frequently effective. Persistent disease may respond to local nerve blocks. Counseling is helpful to identify potential psychosocial stressors and to assist with pain management. Long-term prognosis is good if recovery is rapid; recurrent episodes imply a less favorable prognosis.

http://childhoodrnd.org/index.php.
Katholi BR, Daghstani SS, Banez GA, Brady KK: Noninvasive treatments for pediatric complex regional pain syndrome: a focused review. PM&R 2014;6(10):926–933 [PMID: 24780851].

2. Fibromyalgia

Fibromyalgia is a chronic pain syndrome characterized by diffuse musculoskeletal pain, fatigue, sleep disturbance, and chronic headaches. Weather changes, fatigue, and stress exacerbate symptoms. Patients have a normal examination except for characteristic trigger points at the insertion of muscles, especially along the neck, spine, and pelvis.

Treatment centers on physical therapy, nonnarcotic pain medications, improving sleep, and counseling. Low-dose amitriptyline or trazodone can help with sleep and may produce remarkable reduction in pain. Physical therapy should emphasize a graded rehabilitative approach to stretching and exercise and promote regular aerobic exercise. Pregabalin recently became the first medication to be approved by the Food and Drug Administration for the treatment of fibromyalgia. Use of the drug is associated with decreased pain in adults with fibromyalgia, and studies are planned to test safety and efficacy in children with the condition. The prognosis for children with fibromyalgia is not clear, and long-term strategies may be necessary to enable them to cope with the condition.

Wolfe F et al: The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. Arthritis Care Res 2010;62:600–610 [PMID: 20461783].
www.myalgia.com.

3. Hypermobility Syndrome

Ligamentous laxity, which previously was thought to occur only in Ehlers-Danlos syndrome or Down syndrome, is now recognized as a common cause of joint pain. Patients with hypermobility present with episodic joint pain and occasionally with swelling that lasts a few days after increased physical activity. Depending on the activity, almost any joint may be affected. Five criteria have been established: (1) passive opposition of the thumb to the flexor surface of the forearm, (2) passive hyperextension of the fingers so that they are parallel to the extensor surface of the forearm, (3) hyperextension of the elbow, (4) hyperextension of the knee, and (5) palms on floor with knees extended. Results of laboratory tests are normal. The pain associated with the syndrome is produced by improper joint alignment caused by the laxity during exercise. Treatment consists of a graded conditioning program designed to provide muscular support of the joints to compensate for the loose ligaments and to train patients to protect their joints from hyperextension.

Armon K: Musculoskeletal pain and hypermobility in children and young people: is it benign joint hypermobility syndrome? Arch Dis Child 2015;100(1):2–3 [PMID: 25336435].

Hematologic Disorders

30

Daniel R. Ambruso, MD
Rachelle Nuss, MD
Michael Wang, MD

NORMAL HEMATOLOGIC VALUES

The normal ranges for peripheral blood counts vary significantly with age. Normal neonates show a relative polycythemia with a hematocrit concentration of 45%–65%. The reticulocyte count at birth is relatively high at 2%–8%. Within the first few days of life, erythrocyte production decreases, and the values for hemoglobin and hematocrit fall to a nadir at about 6–8 weeks. During this period, known as physiologic anemia of infancy, normal infants have hemoglobin values as low as 10 g/dL and hematocrits as low as 30%. Thereafter, the normal values for hemoglobin and hematocrit gradually increase until adult values are reached after puberty. Premature infants can reach a nadir hemoglobin level of 7–8 g/dL at 8–10 weeks. Anemia is defined as a hemoglobin concentration two standard deviations below the mean for a normal population of the same gender and age.

Newborns have larger red cells than children and adults, with a mean corpuscular volume (MCV) at birth of more than 94 fL. The MCV subsequently falls to a nadir of 70–84 fL at about age 6 months. Thereafter, the normal MCV increases gradually until it reaches adult values after puberty.

The normal number of white blood cells (WBCs) is higher in infancy and early childhood than later in life. Neutrophils predominate in the differential white count at birth and in the older child. Lymphocytes predominate (up to 80%) between about ages 1 month and 6 years.

Normal values for the platelet count are 150,000–400,000/μL and vary little with age.

BONE MARROW FAILURE

Failure of the marrow to produce adequate numbers of circulating blood cells may be congenital or acquired and may cause pancytopenia (aplastic anemia) or involve only one cell line (single cytopenia). Constitutional and acquired aplastic anemias are discussed in this section and the more common single cytopenias in later sections. Bone marrow failure caused by malignancy or other infiltrative disease is discussed in Chapter 31. It is important to remember that many drugs and toxins may affect the marrow and cause single or multiple cytopenias.

Suspicion of bone marrow failure is warranted in children with pancytopenia and in children with single cytopenias who lack evidence of peripheral red cell, white cell, or platelet destruction. Macrocytosis often accompanies bone marrow failure. Many of the constitutional bone marrow disorders are associated with a variety of congenital anomalies.

CONSTITUTIONAL APLASTIC ANEMIA (FANCONI ANEMIA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Progressive pancytopenia.
- Macrocytosis.
- Multiple congenital anomalies.
- Increased chromosome breakage in peripheral blood lymphocytes.

General Considerations

Fanconi anemia, which is the most common inherited bone marrow failure syndrome, is characterized by defective DNA repair that is caused by a variety of genetic mutations. Inheritance is autosomal recessive, and this disease occurs in all ethnic groups; 75%–90% of affected individuals develop bone marrow failure in the first 10 years of life.

» Clinical Findings

A. Symptoms and Signs

Symptoms are determined principally by the degree of hematologic abnormality. Thrombocytopenia may cause purpura, petechiae, and bleeding; neutropenia may cause severe or recurrent infections; and anemia may cause weakness, fatigue, and pallor. Congenital anomalies are present in at least 50% of patients. The most common include abnormal pigmentation of the skin (generalized hyperpigmentation, café au lait or hypopigmented spots), short stature with delicate features, and skeletal malformations (hypoplasia, anomalies, or absence of the thumb and radius). More subtle anomalies are hypoplasia of the thenar eminence or a weak or absent radial pulse. Associated renal anomalies include aplasia, horseshoe kidney, and duplication of the collecting system. Other anomalies are microcephaly, microphthalmia, strabismus, ear anomalies, and hypogenitalism.

B. Laboratory Findings

Thrombocytopenia or leukopenia typically occurs first, followed over the course of months to years by anemia and progression to severe aplastic anemia. Macrocytosis is virtually always present; is usually associated with anisocytosis and an elevation in fetal hemoglobin levels; and is an important diagnostic clue. The bone marrow reveals hypoplasia or aplasia. The diagnosis is confirmed by demonstration of an increased number of chromosome breaks and rearrangements in peripheral blood lymphocytes. The use of diepoxybutane to stimulate these breaks and rearrangements provides a sensitive assay that is virtually always positive in children with Fanconi anemia, even before the onset of hematologic abnormalities.

Specific Fanconi genes (FANCA, B, C, and others) have been identified and transmission is generally autosomal, although FANCB is on the X chromosome.

» Differential Diagnosis

Because patients with Fanconi anemia frequently present with thrombocytopenia, the disorder must be differentiated from idiopathic thrombocytopenic purpura (ITP) and other more common causes of thrombocytopenia. In contrast to patients with ITP, those with Fanconi anemia usually exhibit a gradual fall in the platelet count. Counts less than 20,000/μL are often accompanied by neutropenia or anemia. Fanconi anemia may also be manifested initially by pancytopenia, and must be differentiated from acquired aplastic anemia and other disorders, such as acute leukemia. Examination of the bone marrow and chromosome studies of peripheral blood lymphocytes (chromosomal breakage) will usually distinguish between these disorders.

» Complications

Complications are those related to thrombocytopenia and neutropenia. Endocrine dysfunction may include growth hormone deficiency, hypothyroidism, or impaired glucose metabolism. Persons with Fanconi anemia have a significantly increased risk of developing malignancies, especially acute nonlymphocytic leukemia (800-fold), head and neck cancers, genital cancers, and myelodysplastic syndromes.

» Treatment

Attentive supportive care is critical. Patients with neutropenia who develop fever require prompt evaluation and parenteral broad-spectrum antibiotics. Transfusions are important, but should be used judiciously, especially in the management of thrombocytopenia, which frequently becomes refractory to platelet transfusions as a consequence of alloimmunization. Transfusions from family members should be discouraged because of the negative effect on the outcome of bone marrow transplant. At least 50% of patients with Fanconi anemia respond, albeit incompletely, to oxymetholone, and many recommend institution of androgen therapy before transfusions are needed. However, oxymetholone is associated with hepatotoxicity, hepatic adenomas, and masculinization, and is particularly troublesome for female patients.

The definitive treatment is a reduced intensity hematopoietic stem cell transplant, ideally from a human leukocyte antigen (HLA)–identical sibling donor, although matched unrelated and cord transplant may be considered. Before transplant, any prospective sibling donor must be screened for Fanconi anemia.

» Prognosis

Many patients succumb to bleeding, infection, or malignancy in adolescence or early adulthood. Stem cell transplant does not reduce the increased susceptibility for malignancy.

Younghoon K, D'Andrea AD: Molecular pathogenesis and clinical management of Fanconi anemia. J Clin Invest 2012;122:3799–3806 [PMID: 23114602].

ACQUIRED APLASTIC ANEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Weakness and pallor.
- Petechiae, purpura, and bleeding.
- Frequent or severe infections.
- Pancytopenia with hypocellular bone marrow.

» General Considerations

Acquired aplastic anemia is characterized by peripheral pancytopenia with a hypocellular bone marrow. Approximately 50% of cases in childhood are idiopathic. Other cases are secondary to idiosyncratic reactions to drugs such as phenylbutazone, sulfonamides, nonsteroidal anti-inflammatory drugs (NSAIDs), and anticonvulsants. Toxic causes include exposure to benzene, insecticides, and heavy metals. Infectious causes include viral hepatitis, infectious mononucleosis (Epstein-Barr virus [EBV]), and human immunodeficiency virus (HIV). In immunocompromised children, aplastic anemia has been associated with human parvovirus B19 infection. Immune mechanisms of marrow suppression are suspected in most cases.

» Clinical Findings

A. Symptoms and Signs

Weakness, fatigue, and pallor result from anemia; petechiae, purpura, and bleeding occur due to thrombocytopenia; and fevers due to generalized or localized infections are associated with neutropenia. Hepatosplenomegaly and significant lymphadenopathy are unusual.

B. Laboratory Findings

Anemia is usually normocytic, with a low reticulocyte count. The WBC count is low, with a marked neutropenia. The platelet count is typically below 50,000/μL and is frequently below 20,000/μL. Bone marrow biopsy shows a marked decrease in cellularity, typically less than 20% of normal in severe aplastic anemia.

» Differential Diagnosis

Examination of the bone marrow usually excludes pancytopenia caused by peripheral destruction of blood cells or by infiltrative processes such as acute leukemia, storage diseases, and myelofibrosis. Many of these other conditions are associated with hepatosplenomegaly. Preleukemic conditions also may present with pancytopenia and hypocellular bone marrows. Cytogenetic analysis of the marrow is helpful, because a clonal abnormality may predict the subsequent development of leukemia. Since congenital anomalies may not be apparent in some children with Fanconi anemia, patients with newly diagnosed aplastic anemia should be studied for chromosome breaks and rearrangements in peripheral blood lymphocytes.

» Complications

Acquired aplastic anemia is characteristically complicated by infection and hemorrhage, which are the leading causes of death. Other complications are those associated with therapy.

» Treatment

Comprehensive supportive care is essential. Febrile illnesses require prompt evaluation and usually parenteral antibiotics. Red blood cell (RBC) transfusions alleviate symptoms of anemia. Platelet transfusions may be lifesaving, but they should be used sparingly because many patients eventually develop platelet alloantibodies and become refractory to platelet transfusions.

Immunomodulation, usually with antithymocyte globulin and cyclosporine or tacrolimus, is associated with a high response rate and improved overall survival. However, incomplete response, relapse, and progression to myelodysplasia/leukemia may occur. Hematopoietic stem cell transplant is the treatment of choice for severe aplastic anemia when an HLA-identical sibling donor is available. Because the likelihood of success with transplant is influenced adversely by receipt of transfusions, HLA typing of family members should be undertaken at the time of diagnosis. Increasingly, patients who lack HLA-identical siblings are able to find matched donors through cord blood banks or the National Marrow Donor Program.

» Prognosis

Children receiving early bone marrow transplant from an HLA-identical sibling have a long-term survival rate of greater than 80%. Sustained, complete remissions may be seen in 65%–80% of patients receiving immunosuppressive therapy. However, both therapies are associated with an increased risk of myelodysplastic syndromes, acute leukemia, and other malignancies in long-term survivors.

Samarasinghe S et al: Excellent outcome of matched unrelated donor transplantation in paediatric aplastic anaemia following failure with immunosuppressive therapy: a United Kingdom multicentre retrospective experience. Br J Haematol 2012;157:339–346 [PMID: 22372373].

ANEMIAS

APPROACH TO THE CHILD WITH ANEMIA

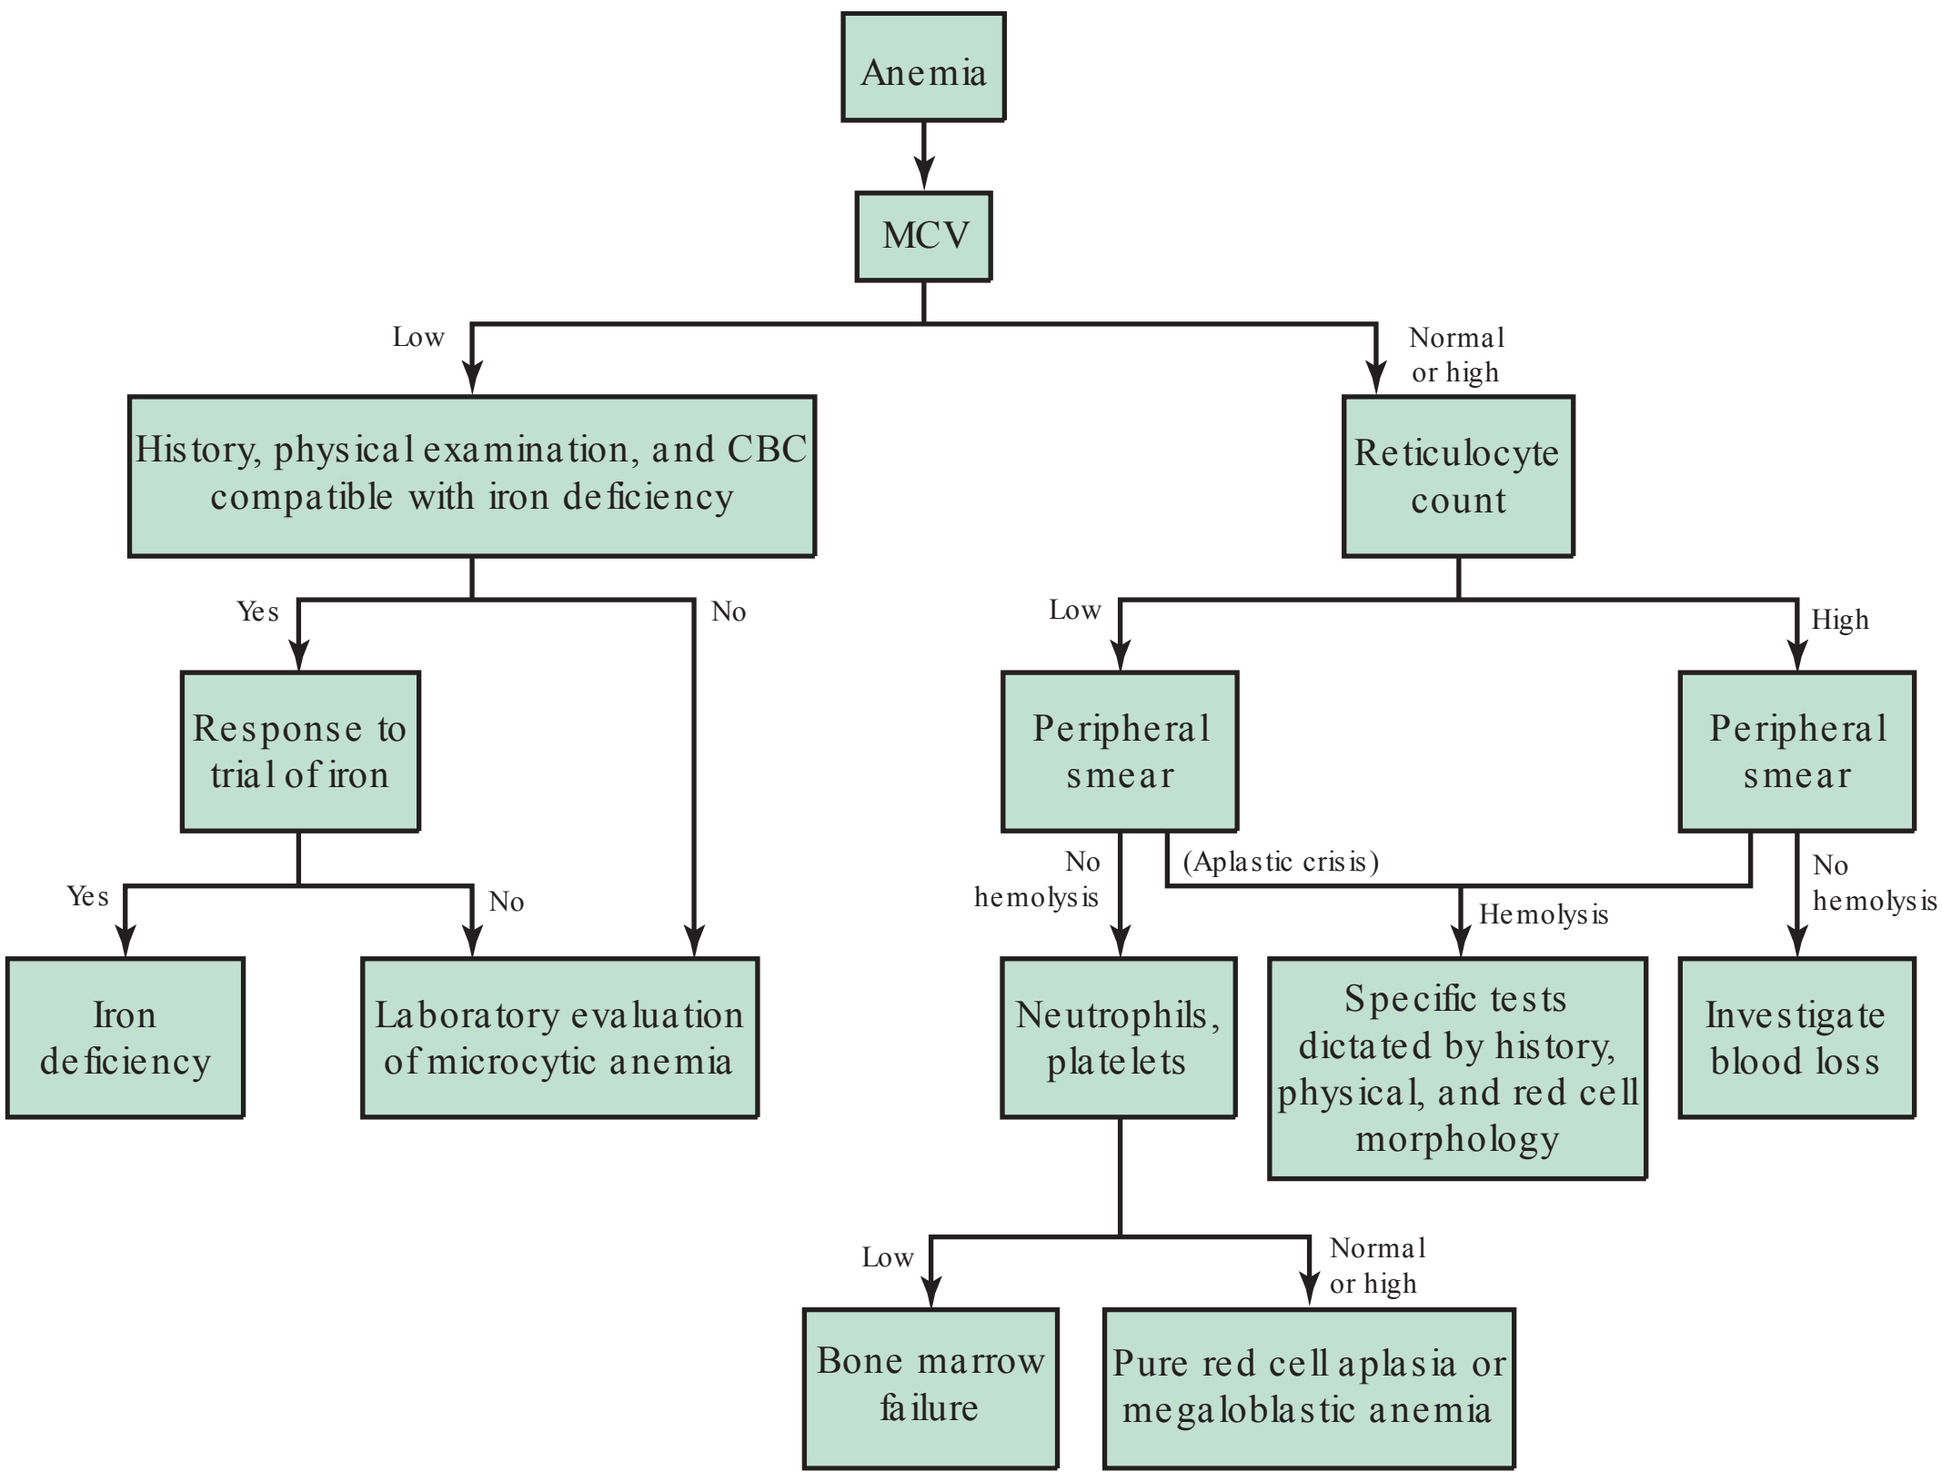
Anemia is a relatively common finding, and identifying the cause is important. Even though anemia in childhood has many causes, the correct diagnosis can usually be established with relatively little laboratory cost. Frequently the cause is identified with a careful history. Nutritional causes should be sought by inquiry about dietary intake; growth and development; and symptoms of chronic disease, malabsorption, or blood loss. Hemolytic disease may be associated with a history of jaundice (including neonatal jaundice) or by a

family history of anemia, jaundice, gallbladder disease, splenomegaly, or splenectomy. The child's ethnicity may suggest the possibility of certain hemoglobinopathies or deficiencies of red cell enzymes, such as glucose-6-phosphate dehydrogenase (G6PD). The review of systems may reveal clues to a previously unsuspected systemic disease associated with anemia. The patient's age is important because some causes of anemia are age related. For example, patients with iron deficiency anemia (IDA) and β-globin disorders present more commonly at ages 6–36 months than at other times in life.

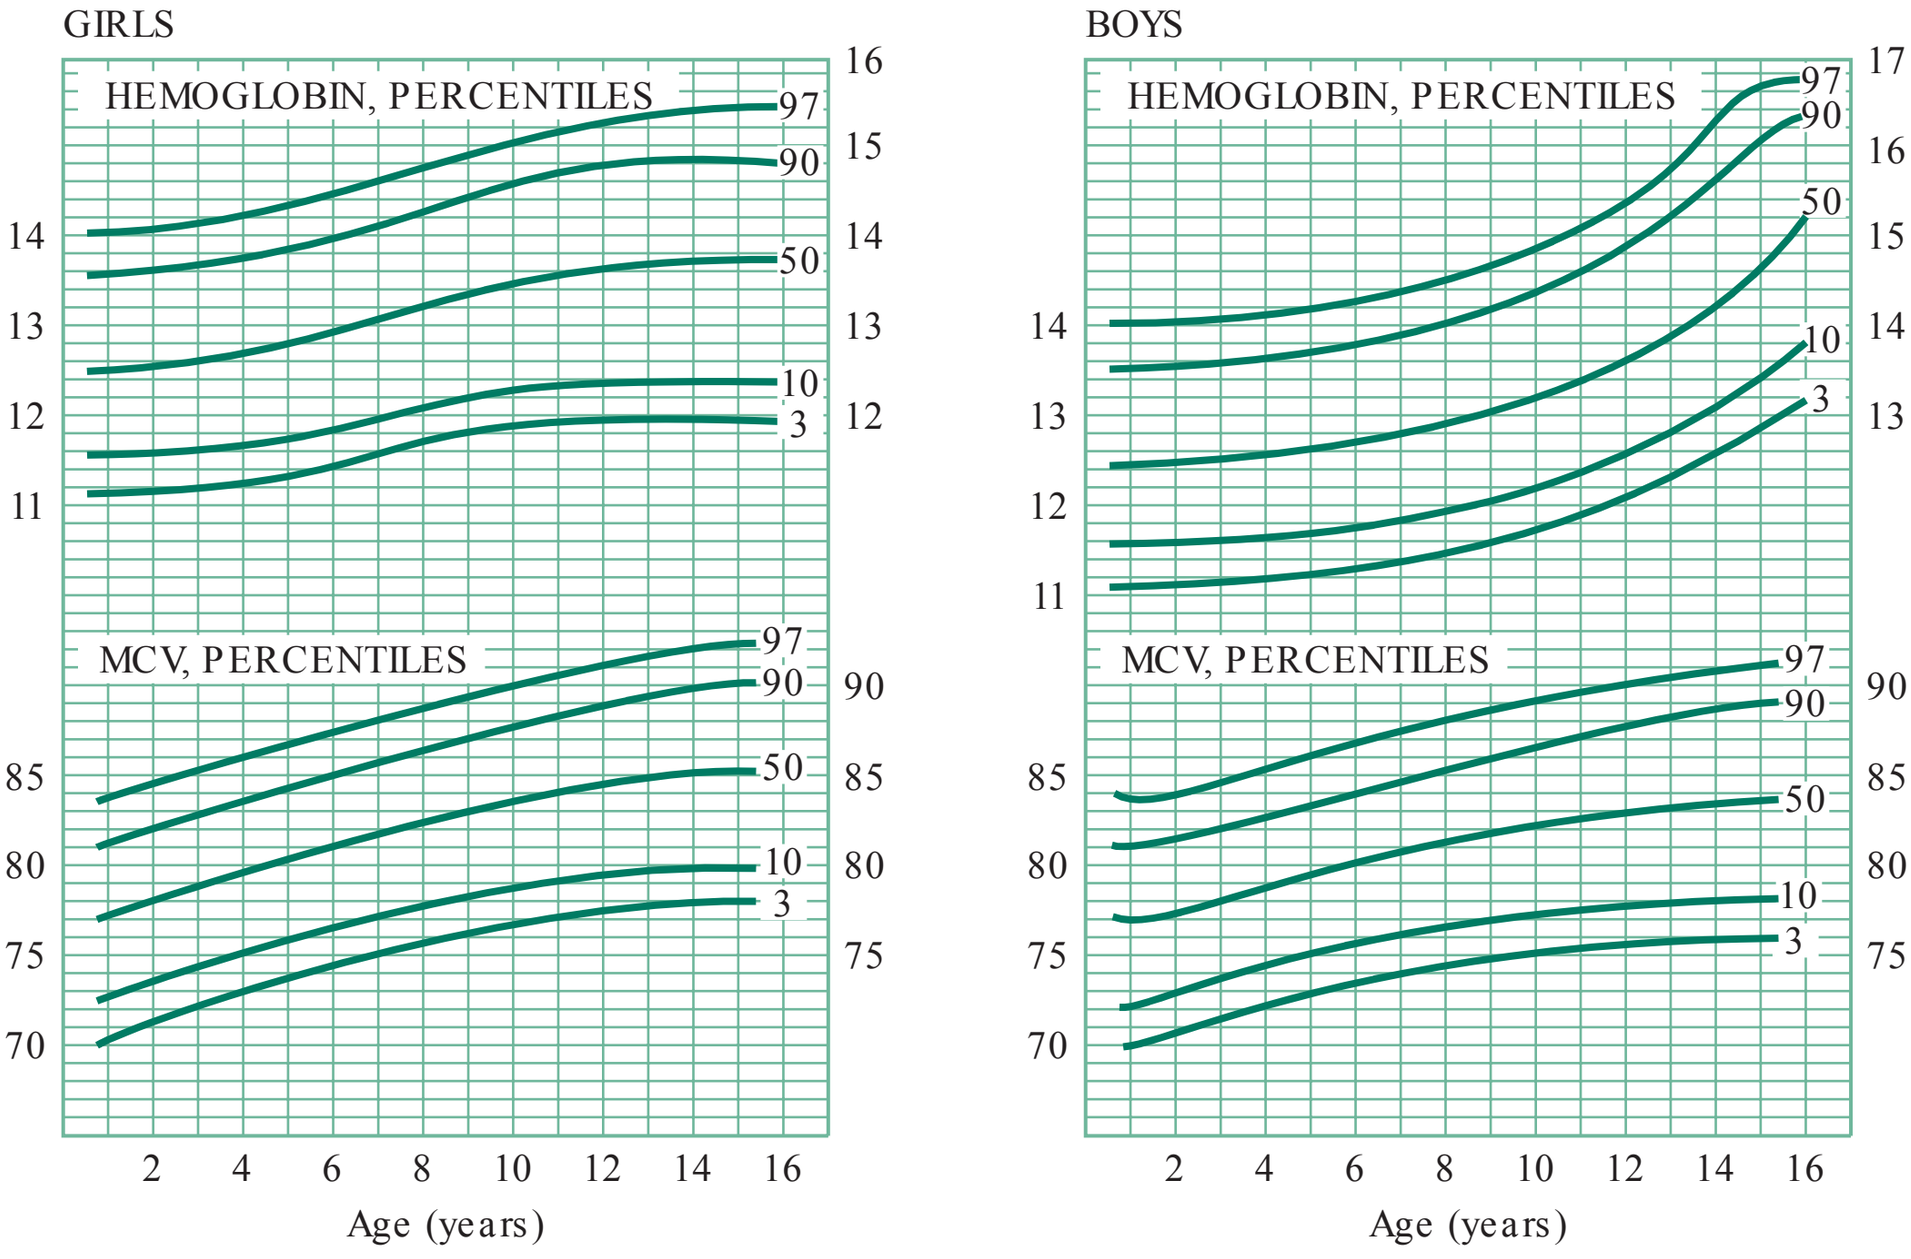
The physical examination may also reveal clues to the cause of anemia. Poor growth may suggest chronic disease or hypothyroidism. Congenital anomalies may be associated with constitutional aplastic anemia (Fanconi anemia) or with congenital hypoplastic anemia (Diamond-Blackfan anemia). Other disorders may be suggested by the findings of petechiae or purpura (leukemia, aplastic anemia, hemolytic uremic syndrome), jaundice (hemolysis or liver disease), generalized lymphadenopathy (leukemia, juvenile rheumatoid arthritis, HIV infection), splenomegaly (leukemia, sickle hemoglobinopathy syndromes, hereditary spherocytosis, liver disease, hypersplenism), or evidence of chronic or recurrent infections.

The initial laboratory evaluation of the anemic child consists of a complete blood count (CBC) with differential and platelet count, review of the peripheral blood smear, and a reticulocyte count. The algorithm in Figure 30–1 uses limited laboratory information, together with the history and physical examination, to reach a specific diagnosis or to focus additional laboratory investigations on a limited diagnostic category (eg, microcytic anemia, bone marrow failure, pure red cell aplasia, or hemolytic disease). This diagnostic scheme depends principally on the MCV to determine whether the anemia is microcytic, normocytic, or macrocytic, according to the percentile curves of Dallman and Siimes (Figure 30–2).

Although the incidence of (ID) in the United States has decreased significantly with improvements in infant nutrition, it remains an important cause of microcytic anemia, especially at ages 6–24 months. A trial of therapeutic iron is appropriate in such children, provided the dietary history is compatible with ID and the physical examination or CBC



▲**Figure 30–1.** Investigation of anemia.



▲**Figure 30–2.** Hemoglobin and red cell volume in infancy and childhood. (Reproduced, with permission, from Dallman PR, Siimes MA: Percentile curves for hemoglobin and red cell volume in infancy and childhood. J Pediatr 1979;94:26.)

does not suggest an alternative cause for the anemia. If a trial of therapeutic iron fails to correct the anemia and microcytosis, further evaluation is warranted.

Another key element of Figure 30–1 is the use of both the reticulocyte count and the peripheral blood smear to determine whether a normocytic or macrocytic anemia is due to hemolysis. Typically hemolytic disease is associated with an elevated reticulocyte count, but some children with chronic hemolysis initially present during a period of a virus-induced aplasia when the reticulocyte count is not elevated. Thus, review of the peripheral blood smear for evidence of hemolysis (eg, spherocytes, red cell fragmentation, sickle forms) is important in the evaluation of children with normocytic anemias and low reticulocyte counts. When hemolysis is suggested, the correct diagnosis may be suspected by specific abnormalities of red cell morphology or by clues from the history or physical examination. Autoimmune hemolysis is usually excluded by a negative direct antiglobulin test (DAT). Review of blood counts and the peripheral blood smears of the mother and father may suggest genetic disorders such as hereditary spherocytosis. Children with normocytic or macrocytic anemias, with relatively low reticulocyte counts and no evidence of hemolysis on the blood smear, usually have anemias caused by inadequate erythropoiesis in the bone marrow. The presence of neutropenia or thrombocytopenia in such children suggests the possibility of aplastic anemia, malignancy, or severe folate or vitamin B_{12} deficiency, and usually dictates examination of the bone marrow.

Pure red cell aplasia may be congenital (Diamond-Blackfan anemia), acquired, and transient (transient erythroblastopenia of childhood); a manifestation of a systemic disease such as renal disease or hypothyroidism; or associated with malnutrition or mild deficiencies of folate or vitamin B_{12}.

Janus J, Moerschel S: Evaluation of anemia in children. Am Fam Physician 2010;15:1462–1471 [PMID: 20540485].

PURE RED CELL APLASIA

Infants and children with normocytic or macrocytic anemia, a low reticulocyte count, and normal or elevated numbers of neutrophils and platelets should be suspected of having pure red cell aplasia. Examination of the peripheral blood smear in such cases is important because signs of hemolytic disease suggest chronic hemolysis complicated by an aplastic crisis due to parvovirus infection. Appreciation of this phenomenon is important because chronic hemolytic disease may not

be diagnosed until the anemia is exacerbated by an episode of red cell aplasia and subsequent rapidly falling hemoglobin level. In such cases, cardiovascular compromise and congestive heart failure may develop quickly.

1. Congenital Hypoplastic Anemia (Diamond-Blackfan Anemia)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Age: birth to 1 year.
- Macrocytic anemia with reticulocytopenia.
- Bone marrow with erythroid hypoplasia.
- Short stature or congenital anomalies in one-third of patients.

» General Considerations

Diamond-Blackfan anemia is a relatively rare cause of anemia that usually presents at 2–3 months of age. To date, mutations of genes encoding ribosomal proteins occurring with autosomal dominance have been recognized. Early diagnosis is important because treatment with corticosteroids results in increased erythropoiesis in 80% of patients, thus avoiding the difficulties and complications of long-term chronic transfusion therapy.

» Clinical Findings

A. Symptoms and Signs

Signs and symptoms are generally those of chronic anemia, such as pallor and congestive heart failure. Jaundice, splenomegaly, or other evidence of hemolysis are usually absent. Short stature or other congenital anomalies are present in 50% of patients. A wide variety of anomalies have been described; craniofacial and triphalangeal thumbs are the most common.

B. Laboratory Findings

Diamond-Blackfan anemia is characterized by severe macrocytic anemia and marked reticulocytopenia. The neutrophil count is usually normal or slightly decreased, and the platelet count is normal, elevated, or decreased. The bone marrow usually shows a marked decrease in erythroid precursors but is otherwise normal. In older children, fetal hemoglobin levels are usually increased and there is evidence of persistent fetal erythropoiesis, such as the presence of the i antigen on erythrocytes. In addition, the level of adenosine deaminase in erythrocytes is elevated.

» Differential Diagnosis

The principal differential diagnosis is transient erythroblastopenia of childhood. Children with Diamond-Blackfan anemia generally present at an earlier age, often have macrocytosis, and have evidence of fetal erythropoiesis and an elevated level of red cell adenosine deaminase. In addition, short stature and congenital anomalies are not associated with transient erythroblastopenia. Last, transient erythroblastopenia of childhood usually resolves within 6–8 weeks of diagnosis, whereas Diamond-Blackfan anemia is a lifelong affliction. Other disorders associated with decreased red cell production such as renal failure, hypothyroidism, and the anemia of chronic disease need to be considered.

» Treatment

Oral corticosteroids should be initiated at the time of diagnosis. Eight percent of patients respond to prednisone, 2 mg/kg/d, and many who respond subsequently tolerate significant tapering of the dose. Patients who are unresponsive to prednisone require chronic transfusion therapy, which inevitably causes transfusion-induced hemosiderosis and the need for chelation. Bone marrow transplant is an alternative definitive therapy that should be considered for transfusion-dependent patients who have HLA-identical siblings. Unpredictable spontaneous remissions occur in up to 20% of patients.

» Prognosis

The prognosis for patients responsive to corticosteroids is generally good, particularly if remission is maintained with low doses of alternate-day prednisone. Patients dependent on transfusion are at risk for the complications of hemosiderosis. There is an increased risk for the development of solid tumors.

Horos R, von Lindern M: Molecular mechanisms of pathology and treatment in Diamond Blackfan Anaemia. Br J Haematol 2012;159:514–527 [PMID: 23016900].

2. Transient Erythroblastopenia of Childhood

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Age: 6 months to 4 years.
- Normocytic anemia with reticulocytopenia.
- Absence of hepatosplenomegaly or lymphadenopathy.
- Erythroid precursors initially absent from bone marrow.

» General Considerations

Transient erythroblastopenia of childhood is a relatively common cause of acquired anemia in early childhood. The disorder is suspected when a normocytic anemia is discovered during evaluation of pallor or when a CBC is obtained for another reason. Because the anemia is due to decreased red cell production, and thus develops slowly, the cardiovascular system has time to compensate. Therefore, children with hemoglobin levels as low as 4–5 g/dL may look remarkably well. The disorder is thought to be autoimmune in most cases, because IgG from some patients has been shown to suppress erythropoiesis in vitro.

» Clinical Findings

Pallor is the most common sign, and hepatosplenomegaly and lymphadenopathy are absent. The anemia is normocytic, and the peripheral blood smear shows no evidence of hemolysis. The platelet count is normal or elevated, and the neutrophil count is normal or, in some cases, decreased. Early in the course, no reticulocytes are identified. The Coombs test is negative, and there is no evidence of chronic renal disease, hypothyroidism, or other systemic disorder. Bone marrow examination shows severe erythroid hypoplasia initially; subsequently, erythroid hyperplasia develops along with reticulocytosis, and the anemia resolves.

» Differential Diagnosis

Transient erythroblastopenia of childhood must be differentiated from Diamond-Blackfan anemia, particularly in infants younger than 1 year. In contrast to Diamond-Blackfan anemia, transient erythroblastopenia is not associated with macrocytosis, short stature, or congenital anomalies, or with evidence of fetal erythropoiesis prior to the phase of recovery. Also in contrast to Diamond-Blackfan anemia, transient erythroblastopenia is associated with normal levels of red cell adenosine deaminase. Transient erythroblastopenia of childhood must also be differentiated from chronic disorders associated with decreased red cell production, such as renal failure, hypothyroidism, and other chronic states of infection or inflammation. As with other single cytopenias, the possibility of malignancy (ie, leukemia) should always be considered, particularly if fever, bone pain, hepatosplenomegaly, or lymphadenopathy is present. In such cases, examination of the bone marrow is generally diagnostic. Confusion may sometimes arise when the anemia of transient erythroblastopenia is first identified during the early phase of recovery when the reticulocyte count is high. In such cases, the disorder may be confused with the anemia of acute blood loss or with hemolytic disease. In contrast to hemolytic disorders, transient erythroblastopenia of childhood is not associated with jaundice or peripheral destruction of red cells.

» Treatment & Prognosis

By definition, this is a transient disorder. Some children require red cell transfusions if cardiovascular compromise is present. Resolution of the anemia is heralded by an increase in the reticulocyte count, which generally occurs within 4–8 weeks of diagnosis. Transient erythroblastopenia of childhood is not treated with corticosteroids because of its short course.

NUTRITIONAL ANEMIAS

1. Iron-Deficiency Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor and fatigue.
- Poor dietary intake of iron (ages 6–24 months).
- Chronic blood loss (age > 2 years).
- Microcytic hypochromic anemia.

» General Considerations

Iron deficiency (ID) and iron deficiency anemia (IDA) are a worldwide concern. ID is defined as a state in which there is insufficient iron to maintain normal physiologic functions such that iron stores (serum ferritin or bone marrow iron content) are reduced. IDA is defined as a hemoglobin more than 2 standard deviations below normal for age and gender, which has developed as a consequence of ID.

Normal-term infants are born with sufficient iron stores to prevent ID for the first 4 months of life, whereas premature infants have reduced iron stores since iron is predominantly acquired in the last trimester. Thus premature infants, as well as those with low birth weight, neonatal anemia, perinatal blood loss, or subsequent hemorrhage may have reduced iron stores. Breast milk is low in iron relative to cow's milk and fortified formulas, and without iron supplementation, ID may develop in exclusively breast-fed children.

» Clinical Findings

A. Symptoms and Signs

Symptoms and signs vary with the severity of the deficiency. ID is usually asymptomatic. IDA may be associated with, pallor, fatigue, and irritability. A history of pica is common. It is controversial whether or not ID/IDA adversely affects long-term neurodevelopment and behavior. IDA is associated with increased lead absorption and subsequent neurotoxicity.

B. Laboratory Findings

According to the American Academy of Pediatrics (AAP) 2010 guidelines, screening for anemia should be performed at about 12 months of age with determination of hemoglobin concentration and an assessment of risk factors for ID/IDA. Risks include low socioeconomic status, prematurity or low birth weight, lead exposure, exclusive breast-feeding beyond 4 months of age without iron supplementation, weaning to whole milk or complementary foods that do not include iron, feeding problems, poor growth, and inadequate nutrition. If the hemoglobin is less than 11 mg/dL or there is a high risk for ID, an iron evaluation should be performed. There is no single measurement that will document the iron status; recommended tests include serum ferritin and C-reactive protein or reticulocyte hemoglobin concentration.

» Differential Diagnosis

The differential diagnosis is that of microcytic, hypochromic anemia. The possibility of thalassemia (α-thalassemia, β-thalassemia, and hemoglobin E disorders) should be considered, especially in infants of African, Mediterranean, or Asian ethnic background. In contrast to infants with ID, those with thalassemia generally have an elevated red cell number and are less likely, in mild cases, to have an elevated RBC distribution width (the index of the MCV divided by the red cell number is usually < 13). Thalassemias are associated with normal or increased levels of serum iron and ferritin and with normal iron-binding capacity. The hemoglobin electrophoresis in β-thalassemia minor typically shows an elevation of hemoglobin A_2 levels, but coexistent ID may lower the percentage of hemoglobin A_2 into the normal range. Hemoglobin electrophoresis will also identify children with hemoglobin E, a cause of microcytosis common in Southeast Asians. In contrast, the hemoglobin electrophoresis in α-thalassemia trait is normal. Lead poisoning has also been associated with microcytic anemia, but anemia with lead levels less than 40 mg/dL is often due to coexistent ID.

The anemia of chronic inflammation or infection is normocytic but in late stages may be microcytic. This anemia is usually suspected because of the presence of a chronic systemic disorder and an elevated CRP. Relatively mild infections, particularly during infancy, may cause transient anemia. Thus, screening tests for anemia should not be obtained within 3–4 weeks of such infections.

» Treatment

The AAP has published guidelines for routine iron intake for children. If a child has hemoglobin of 10–11 mg/dL at the 12-month screening visit, the child can be closely monitored or empirically treated with iron supplementation with a recheck of hemoglobin in one month.

If a child is found to have ID/IDA, the recommended oral dose of elemental iron is 6 mg/kg/d in three divided daily doses. Parenteral administration of iron is rarely necessary. Iron therapy results in an increased reticulocyte count within 3–5 days, which is maximal between 5 and 7 days. The rate of hemoglobin rise is inversely related to the hemoglobin level at diagnosis. Resolution of the anemia is within 4–6 weeks. Treatment is generally continued for a few additional months to replenish iron stores.

Baker RD, Greer FR; the Committee on Nutrition: Diagnosis and prevention of iron deficiency and iron-deficiency anemia in infants and young children (0–3 years of age). Pediatrics 2010;126:1040–1050 [PMID: 2093825].

Eden AN, Sandoval C: Iron deficiency in infants and toddlers in the United States. Pediatr Hematol Oncol 2012;29:704–709 [PMID: 2303474].

2. Megaloblastic Anemias

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor and fatigue.
- Nutritional deficiency or intestinal malabsorption.
- Macrocytic anemia.
- Megaloblastic bone marrow changes.

» General Considerations

Megaloblastic anemia is a macrocytic anemia caused by deficiency of cobalamin (vitamin B_{12}), folic acid, or both. Cobalamin deficiency due to dietary insufficiency may occur in infants who are breast fed by mothers who are strict vegetarians or who have pernicious anemia. Intestinal malabsorption is the usual cause of cobalamin deficiency in children and occurs with Crohn disease, chronic pancreatitis, bacterial overgrowth of the small bowel, infection with the fish tapeworm (Diphyllobothrium latum), or after surgical resection of the terminal ileum. Deficiencies due to inborn errors of metabolism (transcobalamin II deficiency and methylmalonic aciduria) also have been described. Malabsorption of cobalamin due to deficiency of intrinsic factor (pernicious anemia) is rare in childhood.

Folic acid deficiency may be caused by inadequate dietary intake, malabsorption, increased folate requirements, or some combination of the three. Folate deficiency due to dietary deficiency alone is rare but occurs in severely malnourished infants and has been reported in infants fed with goat's milk not fortified with folic acid. Folic acid is absorbed in the jejunum, and deficiencies are encountered in malabsorptive syndromes such as celiac disease. Anticonvulsion medications (eg, phenytoin and phenobarbital) and cytotoxic drugs (eg, methotrexate) also have been associated with folate

deficiency, caused by interference with folate absorption or metabolism. Finally, folic acid deficiency is more likely to develop in infants and children with increased requirements. This occurs during infancy because of rapid growth and also in children with chronic hemolytic anemia. Premature infants are particularly susceptible to the development of the deficiency because of low body stores of folate.

» Clinical Findings

A. Symptoms and Signs

Infants with megaloblastic anemia may show pallor and mild jaundice as a result of ineffective erythropoiesis. Classically, the tongue is smooth and beefy red. Infants with cobalamin deficiency may be irritable and may be poor feeders. Older children with cobalamin deficiency may complain of paresthesias, weakness, or an unsteady gait, and may show decreased vibratory sensation and proprioception on neurologic examination.

B. Laboratory Findings

The laboratory findings of megaloblastic anemia include an elevated MCV and mean corpuscular hemoglobin (MCH). The peripheral blood smear shows numerous macro-ovalocytes with anisocytosis and poikilocytosis. Neutrophils are large and have hypersegmented nuclei. The white cell and platelet counts are normal with mild deficiencies but may be decreased in more severe cases. Examination of the bone marrow is not indicated, but it typically shows erythroid hyperplasia with large erythroid and myeloid precursors. Nuclear maturation is delayed compared with cytoplasmic maturation, and erythropoiesis is ineffective. The serum indirect bilirubin concentration may be slightly elevated.

Children with cobalamin deficiency have a low serum vitamin B_{12} level, but decreased levels of serum vitamin B_{12} may also be found in about 30% of patients with folic acid deficiency. Negative results should not negate treatment if clinically compatible symptoms are present. The level of red cell folate is a better reflection of folate stores than is the serum folic acid level. Elevated serum levels of metabolic intermediates (methylmalonic acid and homocysteine) may help establish the correct diagnosis. Elevated methylmalonic acid levels are consistent with cobalamin deficiency and generally decrease with treatment, whereas elevated levels of homocysteine occur with both cobalamin and folate deficiency.

» Differential Diagnosis

Most macrocytic anemias in pediatrics are not megaloblastic. Other causes of an increased MCV include drug therapy (eg, anticonvulsants, anti-HIV nucleoside analogues), Down syndrome, an elevated reticulocyte count (hemolytic anemias), bone marrow failure syndromes (Fanconi anemia, Diamond-Blackfan anemia), liver disease, and hypothyroidism.

» Treatment

Treatment of cobalamin deficiency due to inadequate dietary intake is readily accomplished with high-dose oral supplementation that is as effective as parenteral treatment if absorption is normal. Folic acid deficiency is treated effectively with oral folic acid in most cases. Children at risk for the development of folic acid deficiencies, such as premature infants and those with chronic hemolysis, are often given folic acid prophylactically.

Stabler SP: Vitamin B_{12} deficiency. New Engl J Med 2013;368: 149–160 [PMID: 23301732].

ANEMIA OF CHRONIC DISORDERS

Anemia is a common manifestation of many chronic illnesses in children. In some instances, causes may be mixed. For example, children with chronic disorders involving intestinal malabsorption or blood loss may have anemia of chronic inflammation in combination with nutritional deficiencies of iron, folate, or cobalamin. In other settings, the anemia is due to dysfunction of a single organ (eg, renal failure, hypothyroidism), and correction of the underlying abnormality resolves the anemia.

1. Anemia of Chronic Inflammation

Anemia is frequently associated with chronic infections or inflammatory diseases. The anemia is usually mild to moderate in severity, with a hemoglobin level of 8–12 g/dL. In general, the severity of the anemia corresponds to the severity of the underlying disorder, and there may be microcytosis, but not hypochromia. The reticulocyte count is low. The anemia is thought to be due to inflammatory cytokines that inhibit erythropoiesis, and shunting of iron into, and impaired iron release from, reticuloendothelial cells. High levels of hepcidin, a peptide produced in the liver during infection or inflammation, reduce iron absorption by the duodenum and release from macrophages. Levels of erythropoietin are relatively low for the severity of the anemia. The serum iron concentration is low, but in contrast to ID, anemia of chronic inflammation is not associated with elevated iron-binding capacity and is associated with an elevated serum ferritin level. Treatment consists of correction of the underlying disorder, which, if controlled, generally results in improvement in hemoglobin level.

Ganz T: Hepcidin and iron regulation, 10 years later. Blood 2011;117:4425 [PMID: 21346250].

2. Anemia of Chronic Renal Failure

Severe normocytic anemia occurs in most forms of renal disease that have progressed to renal insufficiency. Although

white cell and platelet production remain normal, the bone marrow shows significant hypoplasia of the erythroid series and the reticulocyte count is low. The principal mechanism is deficiency of erythropoietin, a hormone produced in the kidney, but other factors may contribute to the anemia. In the presence of significant uremia, a component of hemolysis may also be present. Recombinant human erythropoietin (epoetin alfa) and iron correct the anemia, largely eliminating the need for transfusions.

3. Anemia of Hypothyroidism

Some patients with hypothyroidism develop significant anemia. Occasionally, anemia is detected before the diagnosis of the underlying disorder. A decreased growth velocity in an anemic child suggests hypothyroidism. The anemia is usually normocytic or macrocytic, but it is not megaloblastic and, hence not due to deficiencies of cobalamin or folate. Replacement therapy with thyroid hormone is usually effective in correcting the anemia.

CONGENITAL HEMOLYTIC ANEMIAS: RED CELL MEMBRANE DEFECTS

The congenital hemolytic anemias are divided into three categories: defects of the red cell membrane, hemoglobinopathies, and disorders of red cell metabolism. Hereditary spherocytosis and elliptocytosis are the most common red cell membrane disorders. The diagnosis is suggested by the peripheral blood smear, which shows characteristic red cell morphology (eg, spherocytes, elliptocytes). These disorders usually have an autosomal dominant inheritance, and the diagnosis may be suggested by family history. The hemolysis is due to the deleterious effect of the membrane abnormality on red cell deformability. Decreased cell deformability leads to entrapment of the abnormally shaped red cells in the spleen. Many patients have splenomegaly, and splenectomy usually alleviates the hemolysis.

1. Hereditary Spherocytosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Anemia and jaundice.
- Splenomegaly.
- Positive family history of anemia, jaundice, or gallstones.
- Spherocytosis with increased reticulocytes.
- Increased osmotic fragility.
- Negative DAT.

» General Considerations

Hereditary spherocytosis is a relatively common inherited hemolytic anemia that occurs in all ethnic groups, but is most common in persons of northern European ancestry, in whom the incidence is about 1:5000. The disorder is marked by variable degrees of anemia, jaundice, and splenomegaly. In some persons, the disorder is mild and there is no anemia because erythroid hyperplasia fully compensates for hemolysis. In others, symptoms and transfusion dependence may be present prior to splenectomy. The hallmark of hereditary spherocytosis is the presence of microspherocytes in the peripheral blood. The disease is inherited in an autosomal dominant fashion in about 75% of cases; the remaining cases are thought to be autosomal recessive or due to de novo mutations.

Hereditary spherocytosis is secondary to alteration of genes encoding for spectrin, band 3, ankyrin, or protein 4.2 of the red cell membrane; spectrin abnormalities are more often diagnosed in childhood and band 3 in adulthood. The vertical linkages in the membrane are impaired so that spherocytes form. These are poorly deformable resulting in a shortened life span because they are trapped in the microcirculation of the spleen and engulfed by splenic macrophages. The specific membrane defect is of no major clinical implication.

» Clinical Findings

A. Symptoms and Signs

Hemolysis causes significant neonatal hyperbilirubinemia in 50% of affected children. Splenomegaly subsequently develops in the majority and is often present by age 5 years. Jaundice is variably present and in many patients may be noted only during infection. Patients with significant chronic anemia may complain of pallor, fatigue, or malaise. Intermittent exacerbations of the anemia are caused by increased hemolysis, splenic sequestration or by aplastic crises, and may be associated with severe weakness, fatigue, fever, abdominal pain, or even heart failure.

B. Laboratory Findings

Most patients have mild chronic hemolysis with hemoglobin levels of 9–12 g/dL. In some cases, the hemolysis is fully compensated and the hemoglobin level is in the normal range. Rare cases of severe disease require frequent transfusions. The anemia is usually normocytic and hyperchromic, and many patients have an elevated MCH concentration. The peripheral blood smear shows numerous microspherocytes and polychromasia. The reticulocyte count is elevated, often higher than might be expected for the degree of anemia. WBC and platelet counts are usually normal. The osmotic fragility is increased, particularly after incubation at 37°C for 24 hours. Serum bilirubin usually shows an elevation in the unconjugated fraction. The DAT is negative.

» Differential Diagnosis

Spherocytes are frequently present in persons with immune hemolysis. Thus, in the newborn, hereditary spherocytosis must be distinguished from hemolytic disease caused by ABO or other blood type incompatibilities. Older patients with autoimmune hemolytic anemia (AIHA) frequently present with jaundice, splenomegaly, and spherocytes on the peripheral blood smear. The DAT is positive in most cases of immune hemolysis and negative in hereditary spherocytosis. Occasionally, the diagnosis is confused in patients with splenomegaly from other causes, especially when hypersplenism increases red cell destruction and when some spherocytes are noted on the blood smear. In such cases, the true cause of the splenomegaly may be suggested by signs or symptoms of portal hypertension or by laboratory evidence of chronic liver disease. In contrast to children with hereditary spherocytosis, those with hypersplenism typically have some degree of thrombocytopenia or neutropenia.

» Complications

Severe jaundice may occur in the neonatal period and, if not controlled by phototherapy, may occasionally require exchange transfusion. Intermittent or persistent splenomegaly occurs in 10%–25% of patients and may require removal. Splenectomy is associated with an increased risk of overwhelming bacterial infections, particularly with pneumococci. Gallstones occur in 60%–70% of adults who have not undergone splenectomy and may form as early as age 5–10 years.

» Treatment

Supportive measures include the administration of folic acid to prevent the development of red cell hypoplasia due to folate deficiency. Acute exacerbations of anemia, due to increased rates of hemolysis or to aplastic crises caused by infection with human parvovirus, may be severe enough to require red cell transfusions. Splenectomy may be indicated depending on clinical severity and always results in significant improvement. This increases survival of the spherocytic red cells and leads to complete correction of the anemia in most cases. Except in unusually severe cases, the procedure should be postponed until the child is at least age 5 years because of the greater risk of postsplenectomy sepsis prior to this age. All patients scheduled for splenectomy should be immunized with pneumococcal, Haemophilus influenzae type b (Hib), and meningococcal vaccines prior to the procedure, and some clinicians recommend penicillin prophylaxis afterward. Asplenic patients with fever should be promptly evaluated for severe infection. Splenectomy prevents the subsequent development of cholelithiasis and eliminates the need for the activity restrictions. However, these benefits must be weighed against the risks of the surgical procedure and the subsequent lifelong risk of postsplenectomy sepsis.

» Prognosis

Splenectomy eliminates signs and symptoms in all but the most severe cases and reduces the risk of cholelithiasis. The abnormal red cell morphology and increased osmotic fragility persist without clinical consequence.

Gallagher PG: Abnormalities of erythrocyte membranes. Pediatr Clin North Am 2013;60:1349–1362 [PMID: 24237975].

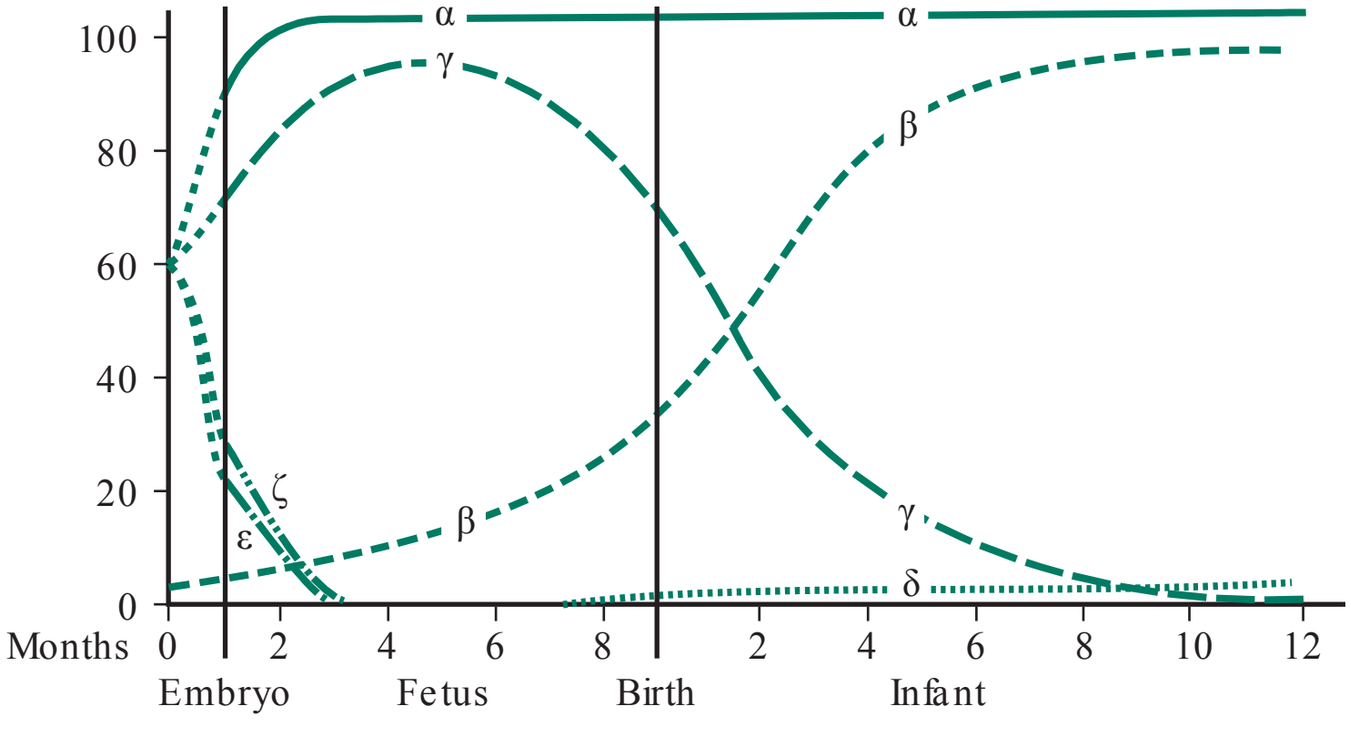
2. Hereditary Elliptocytosis

Hereditary elliptocytosis is a heterogeneous disorder that ranges in severity from an asymptomatic state with almost normal red cell morphology to about 10% having moderate to severe hemolytic anemia. Most affected persons have numerous elliptocytes on the peripheral blood smear, but mild or no hemolysis. Those with hemolysis have an elevated reticulocyte count and may have jaundice and splenomegaly. This disorder is caused by weakened horizontal linkages in the red cell membrane skeleton due either to a defective spectrin dimer-dimer interaction or a defective spectrin-actin protein 4.1R junctional complex. Inheritance is autosomal dominant. Because most patients are asymptomatic, no treatment is indicated. Patients with significant degrees of hemolytic anemia may benefit from folate supplementation or splenectomy.

Some infants with hereditary elliptocytosis present in the neonatal period with moderate to marked hemolysis and significant hyperbilirubinemia. This disorder has been termed transient infantile pyknocytosis because such infants exhibit bizarre erythrocyte morphology with elliptocytes, budding red cells, and small misshapen cells that defy description. The MCV is low, and the anemia may be severe enough to require red cell transfusions. Typically, one parent has hereditary elliptocytosis, usually mild or asymptomatic. The infant's hemolysis gradually abates during the first year of life, and the erythrocyte morphology subsequently becomes more typical of hereditary elliptocytosis.

CONGENITAL HEMOLYTIC ANEMIAS: HEMOGLOBINOPATHIES

The hemoglobinopathies are an extremely heterogeneous group of congenital disorders that occur in all ethnic groups. The relatively high frequency of these genetic variants is related to the malaria protection afforded to heterozygous individuals. The hemoglobinopathies are generally classified into two major groups. The first, the thalassemias, are caused by quantitative deficiencies in the production of globin chains. These quantitative defects in globin synthesis cause microcytic and hypochromic anemias. The second group of



▲**Figure 30–3.** Changes in hemoglobin polypeptide chains during human development. (Reproduced, with permission, from Miller DR, Baehner RL: Blood Diseases of Infancy and Childhood. 6th ed. Mosby; 1989.)

hemoglobinopathies consists of those caused by structural abnormalities of globin chains. The most important of these, hemoglobins S, C, and E, are all the result of point mutations and single amino acid substitutions in β-globin. Many, but not all, infants with hemoglobinopathies are identified by routine neonatal screening.

Figure 30–3 shows the normal developmental changes that occur in globin-chain production during gestation and the first year of life. At birth, the predominant hemoglobin is fetal hemoglobin (hemoglobin F), which is composed of two α-globin chains and two γ-globin chains. Subsequently, the production of γ-globin decreases and β-globin increases so that adult hemoglobin (two α and two β chains) predominates after 2–4 months. Because α-globin chains are present in both fetal and adult hemoglobin, disorders of α-globin synthesis (α-thalassemia) are clinically manifest in the newborn as well as later in life. In contrast, patients with β-globin disorders such as β-thalassemia and sickle cell disease are generally asymptomatic during the first 3–4 months of age and present clinically after γ-chain production and therefore fetal hemoglobin levels have decreased substantially.

1. α-Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Predominately African, Mediterranean, Middle Eastern, Chinese, or Southeast Asian ancestry.
- Microcytic, hypochromic anemia of variable severity.
- Generally Bart's hemoglobin detected by neonatal screening.

» General Considerations

Most of the α-thalassemia syndromes are the result of deletions of one or more of the four α-globin genes on chromosome 16, although nondeletional α+ mutations also occur. Excess non–α-globin chains damage the red cell membrane, causing extravascular hemolysis. The variable severity of the α-thalassemia syndromes is related to the number of gene deletions (Table 30–1). The severity of the α-thalassemia syndromes varies among affected ethnic

Table 30–1. The α-thalassemias.

Usual Genotypes[a]	α–Gene Number	Clinical Features	Hemoglobin Electrophoresis[b]	
			Birth	> 6 mo
αα/αα	4	Normal	N	N
–α/αα	3	Silent carrier	0%–3% Hb Bart's	N
–/αα or –α/–α	2	α-Thal trait	2%–10% Hb Bart's[c]	N
–/–α	1	Hb H disease	15%–30% Hb Bart's	Hb; H present
–/–	0	Fetal hydrops	> 75% Hb Bart's	—

[a]α indicates presence of α-globin gene; – α indicates deletion of α-globin gene.
[b]N = normal results, Hb = hemoglobin, Hb Bart's = γ_4, Hb H = β_4.
[c]The level of Hb Bart's does not directly correlate with the number of deleted α genes.

groups. In persons of African ancestry, α-thalassemia is usually caused by the deletion of only one of the two α-globin genes on each chromosome. Thus, in the African population, heterozygous individuals are silent carriers and homozygous individuals have α-thalassemia trait. In Asians, deletions of one or of both α-globin genes on the same chromosome are common; heterozygous individuals are either silent carriers or have α-thalassemia trait, and homozygous individuals or compound heterozygous individuals have α-thalassemia trait, hemoglobin H disease, or hydrops fetalis. Thus, the presence of α-thalassemia in a child of Asian ancestry may have important implications for genetic counseling, whereas this is not usually the case in families of African ancestry.

» Clinical Findings

The clinical findings depend on the number of α-globin genes deleted. Table 30–1 summarizes the α-thalassemia syndromes.

Persons with three α-globin genes (one-gene deletion) are asymptomatic and have no hematologic abnormalities. Hemoglobin electrophoresis in the neonatal period shows 0%–3% Bart's hemoglobin, which is a variant hemoglobin composed of four γ-globin chains. Hemoglobin electrophoresis after the first few months of life is normal. Thus, this condition is usually suspected only in the context of family studies or when a small amount of Bart's hemoglobin is detected by neonatal screening for hemoglobinopathies.

Persons with two α-globin genes (two-gene deletion) are typically asymptomatic. The MCV is usually less than 100 fL at birth. Hematologic studies in older infants and children show a normal or slightly decreased hemoglobin level with a low MCV and a slightly hypochromic blood smear with some target cells.

Persons with one α-globin gene (three-gene deletion) have a mild to moderately severe microcytic hemolytic anemia (hemoglobin level of 7–10 g/dL), which may be accompanied by hepatosplenomegaly and some bony abnormalities caused by the expanded medullary space. The reticulocyte count is elevated, and the red cells show marked hypochromia and microcytosis with significant poikilocytosis and some basophilic stippling. Incubation of red cells with brilliant cresyl blue (hemoglobin H preparation) shows inclusion bodies formed by denatured hemoglobin H.

The deletion of all four α-globin genes causes severe intrauterine anemia and results in hydrops fetalis and fetal demise or neonatal death shortly after delivery. Extreme pallor and massive hepatosplenomegaly are present. Hemoglobin electrophoresis reveals a predominance of Bart's hemoglobin with a complete absence of normal fetal or adult hemoglobin.

» Differential Diagnosis

α-Thalassemia trait (two-gene deletion) must be differentiated from other mild microcytic anemias, including ID and β-thalassemia minor (see the next section). In contrast to children with ID, children with α-thalassemia trait show normal or increased levels of ferritin and serum iron. In contrast to children with β-thalassemia minor, children with α-thalassemia trait have a normal hemoglobin electrophoresis after age 4–6 months. Finally, the history of a low MCV (96 fL) at birth or the presence of Bart's hemoglobin on the neonatal hemoglobinopathy screening test suggests α-thalassemia.

Children with hemoglobin H disease may have jaundice and splenomegaly, and the disorder must be differentiated from other hemolytic anemias. The key to the diagnosis is the decreased MCV and the marked hypochromia on the blood smear. With the exception of β-thalassemia, most other significant hemolytic disorders have a normal or elevated MCV and the RBCs are not hypochromic. Infants with hydrops fetalis due to severe α-thalassemia must be distinguished from those with hydrops due to other causes of anemia, such as alloimmunization or parvovirus.

» Complications

The principal complication of α-thalassemia trait is the needless administration of iron, given in the belief that a mild microcytic anemia is due to ID. Persons with hemoglobin H disease may have intermittent exacerbations of their anemia in response to oxidant stress or infection, which occasionally require blood transfusions. Splenomegaly may exacerbate the anemia. Women pregnant with hydropic α-thalassemia fetuses are subject to increased complications of pregnancy, particularly toxemia and postpartum hemorrhage.

» Treatment

Persons with α-thalassemia trait require no treatment. Those with hemoglobin H disease should receive supplemental folic acid and avoid the same oxidant drugs that cause hemolysis in persons with G6PD deficiency, because exposure to these drugs may exacerbate their anemia. The anemia may also be exacerbated during periods of infection, and transfusions may be required. Hypersplenism may develop later in childhood and require surgical splenectomy. Genetic counseling and prenatal diagnosis should be offered to families at risk for hydropic fetuses.

Piel FB, Weatherall DJ: The α-thalassemias. N Engl J Med 2014;13:1908–1916 [PMID: 25390741].

2. β-Thalassemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

β-Thalassemia minor:

- Normal neonatal screening test.
- Predominantly African, Mediterranean, Middle Eastern, or Asian ancestry.
- Mild microcytic, hypochromic anemia.
- No response to iron therapy.
- Elevated level of hemoglobin A_2.

β-Thalassemia intermedia:

- Ancestry as above.
- Microcytic, hypochromic anemia that usually becomes symptomatic after the first few years of life with hepatosplenomegaly.

β-Thalassemia major:

- Neonatal screening shows hemoglobin F only.
- Mediterranean, Middle Eastern, or Asian ancestry.
- Severe microcytic, hypochromic anemia with marked hepatosplenomegaly.

» General Considerations

In contrast to the four α-globin genes, only two β-globin genes are present, one on each chromosome 11. Excess non–β-globin chains damage the red cells, causing extravascular hemolysis. Individuals heterozygous for one β-thalassemia gene generally have β-thalassemia minor. Homozygous individuals generally have β-thalassemia major (Cooley anemia), a severe transfusion-dependent anemia. Individuals with β-thalassemia intermedia, which is more severe than thalassemia minor but is not generally transfusion-dependent, are usually heterozygous for two β^+ mutations (produce reduced quantities of normal A hemoglobin) or have both β^0 (production of no normal A hemoglobin) and a β+ mutation, or have an alternative mutation such as E in conjunction with a severe β^+ or β^0 mutation. Thalassemia major is the most common worldwide cause of transfusion-dependent anemia in childhood. In addition, β-thalassemia genes interact with genes for structural β-globin variants, such as hemoglobin S and hemoglobin E to cause serious disease in compound heterozygous individuals. These disorders are discussed further in the sections dealing with sickle cell disease and with hemoglobin E disorders.

» Clinical Findings

A. Symptoms and Signs

Persons with β-thalassemia minor are usually asymptomatic with a normal physical examination. The time to presentation for those with β-thalassemia intermedia is variable. Those with β-thalassemia major are normal at birth but develop significant anemia during the first year of life. If the disorder is not identified and treated with blood transfusions, such children grow poorly and develop massive hepatosplenomegaly and enlargement of the medullary space with thinning of the bony cortex. The skeletal changes (due to ineffective erythropoiesis) cause characteristic facial deformities (prominent forehead and maxilla) and predispose the child to pathologic fractures.

B. Laboratory Findings

Children with β-thalassemia minor have normal neonatal screening results but subsequently develop a decreased MCV with or without mild anemia. The peripheral blood smear typically shows hypochromia, target cells, and sometimes basophilic stippling. Hemoglobin electrophoresis performed after 6–12 months of age is usually diagnostic when levels of hemoglobin A_2, hemoglobin F, or both are elevated. β-Thalassemia major is often initially suspected when hemoglobin A is absent on neonatal screening. Such infants are hematologically normal at birth, but they develop severe anemia after the first few months of life. The peripheral blood smear typically shows a severe hypochromic, microcytic anemia with marked anisocytosis and poikilocytosis. Target cells are prominent, and nucleated RBCs often exceed the number of circulating WBCs. The hemoglobin level usually falls to 5–6 g/dL or less, and the reticulocyte count is elevated. Platelet and WBC counts may be increased, and the serum indirect bilirubin level is elevated. The bone marrow shows marked erythroid hyperplasia, but this finding is not needed for diagnosis. Hemoglobin electrophoresis shows only fetal hemoglobin and hemoglobin A_2 in children with homozygous β^0-thalassemia.

Those with β^+-thalassemia genes make a variable amount of hemoglobin A, depending on the mutation, but have a marked increase in fetal hemoglobin and hemoglobin A_2 levels. The diagnosis of homozygous β-thalassemia, intermedia or minor, may also be supported by DNA testing.

» Differential Diagnosis

β-Thalassemia minor must be differentiated from other causes of mild microcytic, hypochromic anemias, principally ID and α-thalassemia. In contrast to patients with IDA, those with β-thalassemia minor typically have an elevated number of RBCs, and the index of the MCV divided by the red cell count is under 13. Generally, the finding of an elevated hemoglobin A_2 level is diagnostic; however, the A_2 level may be

lowered by coexistent ID. Thus, in children thought to be iron-deficient, hemoglobin electrophoresis with quantitation of hemoglobin A_2 is sometimes deferred until after a course of iron therapy.

β-Thalassemia major is rarely confused with other disorders. Hemoglobin electrophoresis and family studies readily distinguish it from hemoglobin E/β-thalassemia, which is the other increasingly important cause of transfusion-dependent thalassemia.

» Complications

The principal complication of β-thalassemia minor is the unnecessary use of iron therapy in a futile attempt to correct the microcytic anemia. Children with β-thalassemia major who are inadequately transfused experience poor growth and recurrent infections and may have hepatosplenomegaly, thinning of the cortical bone, and pathologic fractures. Without treatment, most children die within the first decade of life. The principal complications of β-thalassemia major in transfused children are hemosiderosis, splenomegaly, and hypersplenism. Transfusion-related hemosiderosis requires chelation therapy to prevent cardiac, hepatic, and endocrine dysfunction. Noncompliance with chelation in adolescents and young adults may lead to death from congestive heart failure, cardiac arrhythmias, or hepatic failure. Even with adequate transfusions, many patients develop splenomegaly and some degree of hypersplenism. This may require surgical splenectomy because of the increasing transfusion requirements, but the procedure increases the risk of thrombosis, pulmonary hypertension, and overwhelming septicemia.

» Treatment

β-Thalassemia minor requires no specific therapy, but the diagnosis may have important genetic implications for the family. The time to presentation for those with β-thalassemia intermedia is variable. For β-thalassemia major, two treatments are available: chronic transfusion with iron chelation and stem cell transplant. Programs of blood transfusion are generally targeted to maintain a nadir hemoglobin level of 9–10 g/dL. This approach gives increased vigor and well-being, improved growth, and fewer overall complications. However, maintenance of good health requires iron chelation. Small doses of supplemental ascorbic acid may enhance the efficacy of iron chelation. Patients who undergo splenectomy to reduce transfusion requirements, and hence iron loading, should receive pneumococcal vaccine prior to the procedure and instructed in the use of prophylactic penicillin and urgent treatment of all febrile illness after splenectomy. Chronic transfusion therapy is infrequently indicated for individuals with β-thalassemia intermedia.

Bone marrow or umbilical cord blood transplant is an important therapeutic option for children with β-thalassemia major who have an HLA-identical sibling donor. The probability of hematologic cure is greater than 90% when transplant is performed prior to the development of hepatomegaly or portal fibrosis.

3. Sickle Cell Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Neonatal screening test usually with hemoglobins FS, FSC, or FSA (S > A).
- Predominantly African, Mediterranean, Middle Eastern, Indian, or Caribbean ancestry.
- Anemia, elevated reticulocyte count, usually jaundice.
- Recurrent episodes of musculoskeletal or abdominal pain.
- Often hepatomegaly and splenomegaly that resolves.
- Increased risk of bacterial sepsis.

» General Considerations

Sickle cell disease encompasses a family of disorders with manifestations secondary to the propensity of deoxygenated sickle hemoglobin (S) to polymerize. Polymerization of sickle hemoglobin distorts erythrocyte morphology; decreases red cell deformability; causes a marked reduction in red cell life span; increases blood viscosity; and predisposes to inflammation, coagulation activation, and episodes of vaso-occlusion. Sickle cell anemia, the most severe sickling disorder, is caused by homozygosity for the sickle gene and is the most common form of sickle cell disease. Other clinically important sickling disorders are compound heterozygous conditions in which the sickle gene interacts with genes for hemoglobins C, D_{Punjab}, O_{Arab}, C_{Harlem}, or β-thalassemia.

Overall, sickle cell disease occurs in about 1 of every 400 African-American infants. Eight percent of African Americans are heterozygous carriers of the sickle gene and thus have sickle cell trait.

» Clinical Findings

A. Symptoms and Signs

These are related to the hemolytic anemia, tissue ischemia, and organ dysfunction caused by vaso-occlusion. They are

most severe in children with sickle cell anemia or sickle β^0-thalassemia. Physical findings are normal at birth, and symptoms are unusual before age 3–4 months because high levels of fetal hemoglobin inhibit sickling. A moderately severe hemolytic anemia may be present by age 1 year. This causes pallor, fatigue, and jaundice, and predisposes to the development of gallstones during childhood and adolescence. Intense congestion of the spleen with sickled cells may cause splenomegaly in early childhood and results in functional asplenia as early as age 3 months in sickle cell anemia. This places children at great risk for overwhelming infection with encapsulated bacteria, particularly pneumococci. Up to 30% of patients experience one or more episodes of acute splenic sequestration, characterized by sudden enlargement of the spleen with pooling of red cells, acute exacerbation of anemia, and, in severe cases, shock and death. Acute exacerbation of anemia also occurs with aplastic crises, usually caused by infection with human parvovirus B19 and other viruses.

Recurrent episodes of vaso-occlusion and tissue ischemia cause acute and chronic problems. Dactylitis, or hand-and-foot syndrome, is the most common initial symptom of the disease and occurs in up to 50% of children with sickle cell anemia before age 3 years. Recurrent episodes of abdominal and musculoskeletal pain may occur throughout life. Overt strokes occur in about 11% of children with sickle cell anemia and tend to be recurrent. Recurrence is significantly reduced with chronic red cell transfusions. The so-called acute chest syndrome, characterized by fever, pleuritic chest pain, and acute pulmonary infiltrates with hypoxemia, is caused by pulmonary infection, infarction, or fat embolism from ischemic bone marrow. All tissues are susceptible to damage from vaso-occlusion, and multiple organ dysfunction is common by adulthood in those with sickle cell anemia or sickle β^0-thalassemia. The common manifestations of sickle cell disease are listed in Table 30–2. Manifestations generally develop less frequently in those with SC and S β^+-thalassemia.

Table 30–2. Common clinical manifestations of sickle cell disease.

	Acute	Chronic
Children	Bacterial sepsis or meningitis[a] Splenic sequestration[a] Aplastic crisis Vaso-occlusive events Dactylitis Bone infarction Acute chest syndrome[a] Stroke[a] Priapism	Functional asplenia Delayed growth and development Avascular necrosis of the hip Hyposthenuria Cholelithiasis
Adults	Bacterial sepsis[a] Aplastic crisis Vaso-occlusive events Bone infarction Acute chest syndrome[a] Stroke[a] Priapism Acute multiorgan failure syndrome[a]	Leg ulcers Proliferative retinopathy Avascular necrosis of the hip Cholecystitis Chronic organ failure[a] Liver Lung Kidney Decreased fertility

[a]Associated with significant mortality rate.

B. Laboratory Findings

Children with sickle cell anemia generally show a baseline hemoglobin level of 7–10 g/dL. This value may fall to life-threatening levels at the time of a splenic sequestration or aplastic crisis; often this occurs in association with parvovirus B19 infection. The baseline reticulocyte count is elevated markedly. The anemia is usually normocytic or macrocytic, and the peripheral blood smear typically shows the characteristic sickle cells as well as numerous target cells. Patients with sickle β-thalassemia also generally have a low MCV and hypochromia. Those with sickle β^+-thalassemia tend to have less hemolysis and anemia. Persons with sickle hemoglobin C disease have fewer sickle forms and more target cells, and the hemoglobin level may be normal or only slightly decreased because the rate of hemolysis is much less than in sickle cell anemia.

Most infants with sickle hemoglobinopathies born in the United States are identified by neonatal screening. Results indicative of possible sickle cell disease require prompt confirmation with hemoglobin electrophoresis. Children with sickle cell anemia and with sickle β^0-thalassemia have only hemoglobins S, F, and A_2. Persons with sickle β^+-thalassemia have a preponderance of hemoglobin S with a lesser amount of hemoglobin A and elevated A_2. Persons with sickle hemoglobin C disease have equal amounts of hemoglobins S and C. The use of solubility tests to screen for the presence of sickle hemoglobin should be avoided because a negative result is frequently encountered in infants with sickle cell disease, and because a positive result in an older child does not differentiate sickle cell trait from sickle cell disease. Thus, hemoglobin electrophoresis is always necessary to accurately identify a sickle disorder. Solubility tests also will not identify hemoglobin variants other than S.

» Differential Diagnosis

Hemoglobin electrophoresis and sometimes hematologic studies of the parents are usually sufficient to confirm sickle cell disease, although DNA testing is available. It is critical to determine whether the child with only F and S hemoglobins on newborn screening has sickle cell anemia, sickle β^0 thalassemia, or is a compound heterozygote for sickle hemoglobin

and pancellular hereditary persistence of fetal hemoglobin. Such children, when older, typically have 30% fetal hemoglobin and 70% hemoglobin S, and are well.

» Complications

Repeated tissue ischemia and infarction causes damage to virtually every organ system. Table 30–2 lists the most important complications. Patients who require multiple transfusions are at risk of developing transfusion-related hemosiderosis and infections as well as red cell alloantibodies.

» Treatment

The cornerstone of treatment is enrollment in a sickle cell program involving patient and family education, comprehensive outpatient care, and appropriate treatment of acute complications. Important to the success of such a program are psychosocial services, blood bank services, and the ready availability of baseline patient information in the setting in which acute illnesses are evaluated and treated.

Management of sickle cell anemia and sickle β^0-thalassemia includes daily prophylactic penicillin, which should be initiated by age 2 months and continued to age 5 years. The routine use of penicillin prophylaxis in sickle hemoglobin C disease and sickle β^+-thalassemia is controversial. Pneumococcal conjugate and polysaccharide vaccines should be administered to all children who have sickle cell disease. Other routine immunizations, including yearly vaccination against influenza, should be provided. All illnesses associated with fever greater than 38.5°C should be evaluated promptly, bacterial cultures performed, parenteral broad-spectrum antibiotics administered, and careful inpatient or outpatient observation conducted.

Treatment of painful vaso-occlusive episodes includes the maintenance of adequate hydration (with avoidance of overhydration), correction of acidosis if present, administration of adequate analgesia, maintenance of normal oxygen saturation, and the treatment of any associated infections.

Red cell transfusions play an important role in management. Transfusions are indicated to improve oxygen-carrying capacity during acute severe exacerbations of anemia, as occurs during episodes of splenic sequestration or aplastic crisis. Red cell transfusions are not indicated for the treatment of chronic steady-state anemia or for uncomplicated episodes of vaso-occlusive pain. Simple or partial exchange transfusion to reduce the percentage of circulating sickle cells is indicated for some severe acute vaso-occlusive events and may be lifesaving. These events include stroke, moderate to severe acute chest syndrome, and acute life-threatening failure of other organs. Transfusions may be administered prior to high-risk procedures such as surgery with general anesthesia and arteriograms with high ionic contrast materials. Some patients with severe complications may benefit from chronic transfusion therapy. The most common indications for transfusions are stroke or an abnormal transcranial Doppler assessment indicating an increased risk for stroke. Extended matching for red cell antigens reduces the incidence of alloimmunization.

Successful stem cell transplant cures sickle cell disease, but to date its use has been limited because of the risks associated with the procedure, the inability to predict in young children the severity of future complications, and the paucity of HLA-identical sibling donors. Daily administration of oral hydroxyurea increases levels of fetal hemoglobin, decreases hemolysis, and reduces episodes of pain and dactylitis in young children with sickle cell anemia, as well as some evidence for a reduction in acute chest syndrome, hospitalization rates, and transfusions. The hematologic effects and short-term toxicity of hydroxyurea in children are similar to those in adults. Hydroxyurea is recommended for children and adolescents with sickle cell anemia and sickle β^0-thalassemia; efficacy in SC and β^+-thalassemia has not been formally studied.

» Prognosis

Early identification by neonatal screening, combined with sickle cell comprehensive care that includes prescription of prophylactic penicillin, instruction on splenic palpation, and education on the need to urgently seek care when fever occurs, has markedly reduced mortality in childhood. Most patients now live well into adulthood, but eventually succumb to complications.

Yawn BP et al: Management of sickle cell disease: summary of the 2014 evidence-based report by expert panel members. JAMA 2014; 312: 1033–1048 [PMID: 25203083].

4. Sickle Cell Trait

Individuals who are heterozygous for the sickle gene have sickle cell trait. Neonates are identified by neonatal screening that shows hemoglobin FAS (A > S). Accurate identification of older persons with sickle cell trait depends on hemoglobin electrophoresis, which typically shows about 60% hemoglobin A and 40% hemoglobin S. No anemia or hemolysis is present, and the physical examination is normal. Persons with sickle cell trait are generally healthy with normal life expectancy.

However, sickle trait erythrocytes are capable of sickling, with acidemia and hypoxemia. Thus, the kidney may be affected with the most common manifestation of sickle trait being hyposthenuria. Painless hematuria, usually microscopic, affects about 4% of those with sickle trait and does

not progress to significant renal dysfunction. Fewer than 40 individuals have been reported with an exceedingly rare malignancy, renal medullary carcinoma, and the majority have had sickle trait. The incidence of bacteriuria and pyelonephritis may be increased during pregnancy, but overall rates of maternal and infant morbidity and mortality are not affected by sickle cell trait.

Exertion at moderate altitudes rarely precipitates splenic infarction. Whether or not the risk of sudden unexplained death during strenuous exercise is increased in men with sickle cell trait is controversial. In general, exercise tolerance seems to be normal; the incidence of sickle cell trait in black professional football players is similar to that of the general African-American population.

There is no reason to restrict strenuous activity for individuals with sickle cell trait. As is true for all individuals performing strenuous activity, it is important to be conditioned, dress appropriately, have access to fluids, rest periodically, and perform moderate activity in extreme heat and humidity. Sickle cell trait is most significant for its genetic implications.

5. Hemoglobin C Disorders

Hemoglobin C is detected by neonatal screening. Two percent of African Americans are heterozygous for hemoglobin C and thus have hemoglobin C trait. Such individuals have no symptoms, anemia, or hemolysis, but the peripheral blood smear may show some target cells. Identification of persons with hemoglobin C trait is important for genetic counseling, particularly with regard to the possibility of sickle hemoglobin C disease in offspring.

Persons with homozygous hemoglobin C have a mild microcytic hemolytic anemia and may develop splenomegaly. The peripheral blood smear shows prominent target cells. As with other hemolytic anemias, complications of homozygous hemoglobin C include gallstones and aplastic crises.

6. Hemoglobin E Disorders

Hemoglobin E is the second most common hemoglobin variant worldwide, with a gene frequency up to 60% in northeast Thailand and Cambodia. Persons heterozygous for hemoglobin E show hemoglobin FAE by neonatal screening and are asymptomatic and usually not anemic, but they may have mild microcytosis. Persons homozygous for hemoglobin E are also asymptomatic but may have mild anemia; the peripheral blood smear shows microcytosis and some target cells.

Compound heterozygotes for hemoglobin E and β^0-thalassemia are normal at birth and, like infants with homozygous E, show hemoglobin FE on neonatal screening. Unlike homozygotes, they subsequently develop mild to severe microcytic hypochromic anemia. Such children may exhibit jaundice, hepatosplenomegaly, and poor growth if the disorder is not recognized and treated appropriately. In some cases, the anemia becomes severe enough to require lifelong transfusion therapy. Even without regular transfusions, hemosiderosis may occur. In certain areas of the United States, hemoglobin E/β^0-thalassemia has become a more common cause of transfusion-dependent anemia than homozygous β-thalassemia.

7. Other Hemoglobinopathies

At least 500 human globin-chain variants have been described. Some, such as hemoglobins D and G, are relatively common. Heterozygous individuals, who are frequently identified during the course of neonatal screening programs for hemoglobinopathies, are generally asymptomatic and usually have no anemia or hemolysis. The principal significance of most hemoglobin variants is the potential for disease in compound heterozygous individuals who also inherit a gene for β-thalassemia or sickle hemoglobin. For example, children who are compound heterozygous for hemoglobins S and D_{Punjab} ($D_{Los\ Angeles}$) have sickle cell disease.

CONGENITAL HEMOLYTIC ANEMIAS: DISORDERS OF RED CELL METABOLISM

Erythrocytes depend on the anaerobic metabolism of glucose for the maintenance of adenosine triphosphate levels sufficient for homeostasis. Glycolysis also produces the 2,3-diphosphoglycerate (2,3-DPG) levels needed to modulate the oxygen affinity of hemoglobin. Glucose metabolism via the hexose monophosphate shunt is necessary to generate sufficient reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione to protect red cells against oxidant damage. Congenital deficiencies of many glycolytic pathway enzymes have been associated with hemolytic anemias. In general, the morphologic abnormalities present on the peripheral blood smear are nonspecific, and the inheritance of these disorders is autosomal recessive or X-linked. Thus, the possibility of a red cell enzyme defect should be considered during the evaluation of a patient with a congenital hemolytic anemia in the following instances: when the peripheral blood smear does not show red cell morphology typical of membrane or hemoglobin defects (eg, spherocytes, sickle forms, target cells); when hemoglobin disorders are excluded by hemoglobin electrophoresis and by isopropanol precipitation tests; and when family studies do not suggest an autosomal dominant disorder. The diagnosis is confirmed by finding a low level of the deficient enzyme.

The two most common disorders of erythrocyte metabolism are G6PD deficiency and pyruvate kinase deficiency.

1. Glucose-6-Phosphate Dehydrogenase Deficiency

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- African, Mediterranean, or Asian ancestry.
- Neonatal hyperbilirubinemia.
- Sporadic hemolysis associated with infection or with ingestion of oxidant drugs or fava beans.
- X-linked inheritance.

» General Considerations

Deficiency of glucose-6-phosphate dehydrogenase (G6PD) is the most common red cell enzyme defect that causes hemolytic anemia. The disorder has an X-linked recessive inheritance and occurs with high frequency among persons of African, Mediterranean, and Asian ancestry. Hundreds of different G6PD variants have been characterized. In most instances, the deficiency is due to enzyme instability; thus, older red cells are more deficient than younger ones and are unable to generate sufficient nicotinamide adenine dinucleotide (NADH) to maintain the levels of reduced glutathione necessary to protect the red cells against oxidant stress. Thus, most persons with G6PD deficiency do not have a chronic hemolytic anemia; instead, they have episodic hemolysis at times of exposure to the oxidant stress of infection or of certain drugs or food substances. The severity of the disorder varies among ethnic groups; G6PD deficiency in persons of African ancestry usually is less severe than in other ethnic groups.

» Clinical Findings

A. Symptoms and Signs

Infants with G6PD deficiency may have significant hyperbilirubinemia and require phototherapy or exchange transfusion to prevent kernicterus. The deficiency is an important cause of neonatal hyperbilirubinemia in infants of Mediterranean or Asian ancestry, but less so in infants of African ancestry. Older children with G6PD deficiency are asymptomatic and appear normal between episodes of hemolysis. Hemolytic episodes are often triggered by infection or by the ingestion of oxidant drugs such as antimalarial compounds and sulfonamide antibiotics (Table 30–3). Ingestion of fava beans may trigger hemolysis in children of Mediterranean or Asian ancestry but usually not in children of African ancestry. Episodes of hemolysis are associated with pallor, jaundice, hemoglobinuria, and sometimes cardiovascular compromise.

Table 30–3. Some common drugs and chemicals that can induce hemolytic anemia in persons with G6PD deficiency.

Acetanilide	Niridazole
Doxorubicin	Nitrofurantoin
Furazolidone	Phenazopyridine
Methylene blue	Primaquine
Nalidixic acid	Sulfamethoxazole

Reproduced, with permission, from Beutler E: Glucose-6-phosphate dehydrogenase deficiency. N Engl J Med 1991;324(3):169–174.

B. Laboratory Findings

The hemoglobin concentration, reticulocyte count, and peripheral blood smear are usually normal in the absence of oxidant stress. Episodes of hemolysis are associated with a variable fall in hemoglobin. "Bite" cells or blister cells may be seen, along with a few spherocytes. Hemoglobinuria is common, and the reticulocyte count increases within a few days. Heinz bodies may be demonstrated with appropriate stains. The diagnosis is confirmed by the finding of reduced levels of G6PD in erythrocytes. Because this enzyme is present in increased quantities in reticulocytes, the test is best performed at a time when the reticulocyte count is normal or near normal.

» Complications

Kernicterus is a risk for infants with significant neonatal hyperbilirubinemia. Episodes of acute hemolysis in older children may be life-threatening. Rare G6PD variants are associated with chronic hemolytic anemia; the clinical course of patients with such variants may be complicated by splenomegaly and by the formation of gallstones.

» Treatment

The most important treatment issue is avoidance of drugs known to be associated with hemolysis (see Table 30–3). For some patients of Mediterranean, Middle Eastern, or Asian ancestry, the consumption of fava beans must also be avoided. Infections should be treated promptly and antibiotics given when appropriate. Most episodes of hemolysis are self-limiting, but red cell transfusions may be lifesaving when signs and symptoms indicate cardiovascular compromise.

2. Pyruvate Kinase Deficiency

Pyruvate kinase deficiency is an autosomal recessive disorder observed in all ethnic groups but is most common in northern Europeans. The deficiency is associated with a chronic hemolytic anemia of varying severity. Approximately one-third of those affected present in the neonatal

period with jaundice and hemolysis that require phototherapy or exchange transfusion. Occasionally, the disorder causes hydrops fetalis and neonatal death. In older children, the hemolysis may require red cell transfusions or be mild enough to go unnoticed for many years. Jaundice and splenomegaly frequently occur in the more severe cases. The diagnosis of pyruvate kinase deficiency is occasionally suggested by the presence of echinocytes on the peripheral blood smear, but these findings may be absent prior to splenectomy. The diagnosis depends on the demonstration of low levels of pyruvate kinase activity in red cells.

Treatment of pyruvate kinase depends on the severity of the hemolysis. Blood transfusions may be required for significant anemia, and splenectomy may be beneficial. Although the procedure does not cure the disorder, it ameliorates the anemia and its symptoms. Characteristically, the reticulocyte count increases and echinocytes become more prevalent after splenectomy, despite the decreased hemolysis and increased hemoglobin level.

ACQUIRED HEMOLYTIC ANEMIA

1. Autoimmune Hemolytic Anemia

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Pallor, fatigue, jaundice, and dark urine.
- Splenomegaly.
- Positive DAT.
- Reticulocytosis and spherocytosis.

» General Considerations

Acquired autoimmune hemolytic anemia (AIHA) is rare during the first 4 months of life but is one of the more common causes of acute anemia after the first year. It may arise as a primary disorder or may complicate an infection (hepatitis, upper respiratory tract infections, EBV mononucleosis, or cytomegalovirus [CMV] infection); systemic lupus erythematosus and other autoimmune syndromes; immunodeficiency states, including autoimmune lymphoproliferative syndrome (ALPS); or, very rarely, malignancies. Drugs may induce antibody-associated hemolytic anemia, and recently third-generation cephalosporins have become a common cause for this adverse event of antibiotic therapy.

» Clinical Findings

A. Symptoms and Signs

The disease usually has an acute onset manifested by weakness, pallor, dark urine, and fatigue. Jaundice is a prominent finding, and splenomegaly is often present. Some cases have a more chronic, insidious onset. Clinical evidence of an underlying disease may be present.

B. Laboratory Findings

The anemia is normochromic and normocytic and may vary from mild to severe (hemoglobin concentration < 5 g/dL). The reticulocyte count and index are usually increased but occasionally are normal or low. Spherocytes and nucleated red cells may be seen on the peripheral blood smear. Although leukocytosis and elevated platelet counts are common, thrombocytopenia occasionally occurs. Other laboratory data observed with hemolysis are increased indirect and total bilirubin, lactic dehydrogenase, aspartate aminotransferase, and urinary urobilinogen. Intravascular hemolysis is indicated by hemoglobinemia or hemoglobinuria. Examination of bone marrow shows marked erythroid hyperplasia and hemophagocytosis, but is seldom required for the diagnosis.

Serologic studies are helpful in defining pathophysiology, planning therapeutic strategies, and assessing prognosis (Table 30–4). In almost all cases, the direct and indirect antiglobulin (DAT and IAT) tests are positive. Further evaluation allows distinction into one of three syndromes. The presence of IgG and no or low level of C3 on the patient's RBCs, maximal in vitro antibody activity at 37°C, and either no antigen or an Rh-like specificity constitute warm AIHA with mostly extravascular destruction by the reticuloendothelial system. In contrast, the detection of complement alone on RBCs, optimal reactivity at 4°C, and I or i antigen specificity are diagnostic of cold AIHA with mostly intravascular and mild extravascular hemolysis. Cold agglutinins are relatively common (~10%) in normal individuals, but clinically significant cold (IgM) antibodies exhibit in vitro reactivity at 30°C or above.

Paroxysmal cold hemoglobinuria presents a third category of disease. The laboratory evaluation is identical to cold AIHA except for antigen specificity (P) and the exhibition of an in vitro hemolysis. Paroxysmal cold hemoglobinuria is almost always associated with significant infections, such as Mycoplasma, Parvovirus, Adenovirus, EBV, and CMV.

» Differential Diagnosis

AIHA must be differentiated from other forms of congenital or acquired hemolytic anemias. The DAT discriminates antibody-mediated hemolysis from other causes, such as hereditary spherocytosis. The presence of other cytopenias and antibodies to platelets or neutrophils suggests an autoimmune (eg, lupus) syndrome, immunodeficiency (eg, ALPS, congenital immunodeficiency), or Evans syndrome (AIHA and other cytopenias associated with autoantibodies). Up to one-third of patients diagnosed as Evans syndrome may have ALPS.

Table 30–4. Classification of AIHA in children.

Syndrome	Warm AIHA	Cold AIHA	Paroxysmal Cold Hemoglobinuria
Specific antiglobulin test IgG Complement	 Strongly positive. Negative or mildly positive.	 Negative. Strongly positive.	 Negative. Strongly positive.
Temperature at maximal reactivity (in vitro)	37°C.	4°C.	4°C.
Antigen specificity	May be panagglutinin or may have an Rh-like specificity.	I or i.	P.
Other		Clinically significant if agglutination occurs ≥ 30°C.	Positive biphasic hemolysin test.
Pathophysiology	Extravascular hemolysis, destruction by the RES (eg, spleen). Rarely an intravascular component early in the course.	Intravascular hemolysis (may have extravascular component).	Intravascular hemolysis (may have extravascular component).
Prognosis	May be more chronic (> 3 mo) with significant morbidity and mortality. May be associated with a primary disorder (lupus, immunodeficiency, etc).	Generally acute (< 3 mo). Good prognosis: often associated with infection.	Acute, self-limited. Associated with infection.
Therapy	Responds to RES blockade, including steroids (prednisone, 2 mg/kg/d), IMG (1 g/kg/d for 2 d), or with specific indication, splenectomy.	May not respond to RES blockade. Severe cases may benefit from plasmapheresis.	Usually self-limited. Symptomatic management.

AIHA, autoimmune hemolytic anemia; IgG, immunoglobulin G; IMG, intravenous immune globulin; RES, reticuloendothelial system.

» Complications

The anemia may be very severe and result in cardiovascular collapse, requiring emergency management. The complications of an underlying disease, such as disseminated lupus erythematosus or an immunodeficiency state, may be present.

» Treatment

Medical management of the underlying disease is important in symptomatic cases. Defining the clinical syndrome provides a useful guide to treatment. Most patients (50%–80%) with warm AIHA (in which hemolysis is mostly extravascular) respond to prednisone (2 mg/kg/d). After the initial treatment, the dose of corticosteroids may be decreased slowly. Patients may respond to 1 g of intravenous immune globulin (IVIG) per kilogram per day for 2 days, but fewer patients respond to IVIG than to prednisone. In severe cases, rituximab may be a successful alternative; however, this drug should be avoided in AIHA associated with ALPS. Although remission with splenectomy may be as high as 50%–60%, in warm AIHA, this strategy should be considered only for patients older than 5 years who are refractory or resistant to first line therapies. Short- and long-term complications are now more apparent and include infection with encapsulated organisms, increased risk for venous thromboembolism, and risk for portal and pulmonary arterial hypertension. In cases unresponsive to more conventional therapy, immunosuppressive agents such as mycophenolate, sirolimus, cyclosporine, cyclophosphamide, azathioprine, or busulfan may be tried alone or in combination with corticosteroids. The initial three exhibit less myelosuppression and risk for infection and may be helpful when hemolysis is associated with Evans syndrome or ALPS. Plasma exchange is not indicated for Warm, IgG, autoantibody diseases. Transplantation, especially when hemolysis is secondary, has been used successfully in small numbers of cases.

Patients with cold AIHA and paroxysmal cold hemoglobinuria are less likely to respond to corticosteroids or IVIG. Because these syndromes are most apt to be associated with infections and have an acute, self-limited course, supportive care alone may be sufficient. Plasma exchange may be effective in severe cold autoimmune (IgM) hemolytic anemia because the offending antibody has an intravascular distribution.

Supportive therapy is crucial. Patients with cold-reacting antibodies, particularly paroxysmal cold hemoglobinuria, should be kept in a warm environment. Transfusion may be necessary because of the complications of severe anemia but should be used only when there is no alternative. In most patients, cross-match compatible blood will not be found, and the least incompatible unit among the few tested may be transfused. Transfusion must be conducted carefully, beginning with a test dose (see Transfusion Medicine section, later in this chapter). Identification of the patient's phenotype for minor red cell alloantigens may be helpful in avoiding alloimmunization or in providing appropriate transfusions if alloantibodies arise after initial transfusions. Patients with severe intravascular hemolysis may have associated disseminated intravascular coagulation (DIC), and heparin therapy should be considered in such cases.

» Prognosis

The outlook for AIHA in childhood usually is good unless associated diseases are present (eg, congenital immunodeficiency, ALPS, AIDS, lupus erythematosus), in which case hemolysis is likely to have a chronic course. In general, children with warm (IgG) AIHA are at greater risk for more severe and chronic disease with higher morbidity and mortality rates. Hemolysis and positive antiglobulin tests may continue for months or years. Patients with cold AIHA or paroxysmal cold hemoglobinuria are more likely to have acute, self-limited disease (< 3 months). Paroxysmal cold hemoglobinuria is almost always associated with infection (eg, Mycoplasma infection, CMV, and EBV).

2. Nonimmune Acquired Hemolytic Anemia

Hepatic disease may alter the lipid composition of the red cell membrane. This usually results in the formation of target cells and is not associated with significant hemolysis.

Occasionally, hepatocellular damage is associated with the formation of spur cells and brisk hemolytic anemia. Renal disease may also be associated with significant hemolysis; hemolytic-uremic syndrome is one example. In this disorder, hemolysis is associated with the presence, on the peripheral blood smear, of echinocytes, helmet cells, fragmented red cells, and spherocytes.

A microangiopathic hemolytic anemia with fragmented red cells and some spherocytes may be observed in several conditions associated with intravascular coagulation and fibrin deposition within vessels. This occurs with DIC complicating severe infection, but may also occur when the intravascular coagulation is localized, as with giant cavernous hemangiomas (Kasabach-Merritt syndrome). Fragmented red cells may also be seen with mechanical damage (eg, associated with artificial heart valves).

POLYCYTHEMIA & METHEMOGLOBINEMIA

CONGENITAL ERYTHROCYTOSIS (FAMILIAL POLYCYTHEMIA)

In pediatrics, polycythemia is usually secondary to chronic hypoxemia. The disorder differs from polycythemia vera in that only RBCs are affected; the WBC and platelet counts are normal. It occurs as an autosomal dominant or recessive disorder. There are usually no physical findings except for plethora and splenomegaly. The hemoglobin level may be as high as 27 g/dL, and symptoms are generally limited to headache and lethargy. Treatment is not indicated unless symptoms are marked. Phlebotomy is the treatment of choice.

SECONDARY POLYCYTHEMIA

Secondary polycythemia occurs in response to hypoxemia. The most common cause of secondary polycythemia in children is cyanotic congenital heart disease, but it also occurs in chronic pulmonary disease such as cystic fibrosis. Persons living at extremely high altitudes, as well as some with methemoglobinemia, develop polycythemia. Polycythemia may occur in the neonatal period; it is particularly exaggerated in infants who are preterm or small for gestational age. It may occur in infants of diabetic mothers, in Down syndrome, and as a complication of congenital adrenal hyperplasia.

ID may complicate polycythemia and aggravate the associated hyperviscosity. This complication of polycythemia should be suspected when the MCV falls below the normal range. Coagulation and bleeding abnormalities, including thrombocytopenia, mild consumption coagulopathy, and elevated fibrinolytic activity, have been described in severely polycythemic cardiac patients. Bleeding at surgery may be severe.

The ideal treatment of secondary polycythemia is correction of the underlying disorder. When this cannot be done, phlebotomy may be necessary to control symptoms.

Iron sufficiency should be maintained. These measures help prevent the complications of thrombosis and hemorrhage.

METHEMOGLOBINEMIA

When heme iron is oxidized, it changes from the ferrous to the ferric state and methemoglobin is produced. Normally, methemoglobin is enzymatically reduced back to hemoglobin. Methemoglobin is unable to transport oxygen and causes a shift in the oxygen dissociation curve. Cyanosis is seen with methemoglobin levels greater than 15%.

1. Hemoglobin M

This designation is given to several abnormal hemoglobins associated with methemoglobinemia due to either amino acid substitutions in α- or β-globin chains. Hemoglobin M is transmitted as an autosomal dominant disorder. Hemoglobin electrophoresis at the usual pH will not always demonstrate the abnormal hemoglobin, and isoelectric focusing may be needed. Affected individuals are cyanotic, but they have normal exercise tolerance and life expectancy. No treatment is indicated.

2. Congenital Methemoglobinemia Due to Enzyme Deficiencies

Congenital methemoglobinemia is caused most frequently by congenital deficiency of the reducing enzyme diaphorase I (coenzyme factor I) and is transmitted as an autosomal recessive trait. Affected individuals may have as much as 40% methemoglobin but usually have no symptoms, although a mild compensatory polycythemia may be present. Patients with diaphorase I deficiency respond to treatment with ascorbic acid and methylene blue (see the next section), but treatment is not usually indicated.

3. Acquired Methemoglobinemia

Nitrites and nitrates, chlorates, and quinines such as aniline dyes, sulfonamides, acetanilid, phenacetin, bismuth subnitrate, and potassium chlorate generate methemoglobin. Recreational use of volatile nitrites ("poppers") and cocaine may precipitate methemoglobinemia. Poisoning with a drug or chemical containing one of these substances should be suspected with sudden onset cyanosis. Methemoglobin levels in such cases may be extremely high and can produce anoxia, dyspnea, unconsciousness, circulatory failure, and death. Because of transiently deficient NADH methemoglobin reductase, newborns are more susceptible to drug- or chemical-induced methemoglobinemia. Infants with metabolic acidosis may also develop methemoglobinemia.

Patients with acquired methemoglobinemia respond dramatically to intravenous methylene blue. Ascorbic acid administered orally or intravenously also reduces methemoglobin, but the response is slower.

DISORDERS OF LEUKOCYTES

NEUTROPENIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Increased frequency of infections.
- Ulceration of oral mucosa and gingivitis.
- Decreased absolute neutrophil count; normal numbers of red cells and platelets.

General Considerations

Neutropenia is an absolute neutrophil (granulocyte) count of less than 1500/μL in childhood, or less than 1100/μL between ages 1 month and 2 years. During the first few days of life, an absolute neutrophil count of less than 3500/μL may be considered neutropenia in term infants. Neutropenia results from absent or defective myeloid stem cells; ineffective or suppressed myeloid maturation; altered production of hematopoietic cytokines or chemokines or abnormalities in their receptors; decreased marrow release; increased neutrophil apoptosis; destruction or consumption; or, in pseudoneutropenia, from an increased neutrophil marginating pool (Table 30–5). A decrease in neutrophil mass diminishes delivery of these cells to areas where the balance favors bacterial proliferation and invasion.

The severity of neutropenia may be characterized by the level of peripheral neutrophils, the number and severity of infections, and the production of mature neutrophils in the marrow. Also important is whether the neutropenia is acute (< 3 months) or chronic (> 3 months). The most severe types of chronic neutropenia include reticular dysgenesis (congenital aleukocytosis), Kostmann syndrome or severe congenital neutropenia, SCN, (severe neutropenia with maturation defect in the marrow progenitor cells associated with specific gene defects), Shwachman syndrome (neutropenia with pancreatic insufficiency), neutropenia with immune deficiency states, cyclic neutropenia, and myelokathexis or dysgranulopoiesis. Genetic mutations for Chédiak-Higashi syndrome (LYST (CHS1), SCN 1-5 (ELANE, GFI1, HAX1, G6PC3, VPS45 as well as WASP and GCSF3R), Shwachman syndrome (SBDS), and cyclic neutropenia (ELANE) have been identified. Neutropenia may also be associated with storage (GSD-Ib) and metabolic diseases and immunodeficiency states. The most common causes of acute neutropenia are viral infection or drugs, resulting in decreased neutrophil production in the marrow, increased peripheral turnover, or both. Severe bacterial infections may be associated with neutropenia. Although not commonly identified, neonatal

Table 30–5. Classification of neutropenia of childhood.

Congenital neutropenia with stem cell abnormalities
Reticular dysgenesis
Cyclic neutropenia
Congenital neutropenia with abnormalities of committed myeloid progenitor cells
Neutropenia with immunodeficiency disorders (T cells and B cells)
Severe congenital neutropenia (Kostmann syndrome)
Chronic idiopathic neutropenia of childhood
Myelokathexis with dysmyelopoiesis
Chédiak-Higashi syndrome
Shwachman-Diamond syndrome
Cartilage-hair hypoplasia
Dyskeratosis congenital
Fanconi anemia
Organic acidemias (eg, propionic, methylmalonic)
Glucose-6-phosphatase catalytic subunit 3 deficiency
Glycogenosis Ib
Osteopetrosis
Acquired neutropenias affecting stem cells
Malignancies (leukemia, lymphoma) and preleukemic disorders
Drugs or toxic substances
Ionizing radiation
Aplastic anemia
Acquired neutropenias affecting committed myeloid progenitors or survival of mature neutrophils
Ineffective myelopoiesis (vitamin B_{12}, folate, and copper deficiency)
Infection
Immune (neonatal alloimmune or autoimmune, autoimmune, or chronic benign neutropenia of childhood)
Hypersplenism

alloimmune neutropenia can be severe and associated with infection. Autoimmune neutropenia occurs with chronic benign neutropenia of childhood, immunodeficiency syndromes, autoimmune disorders, or, in the newborn, as a result of passive transfer of antibody from the mother to the fetus. Malignancies, osteopetrosis, marrow failure syndromes, and hypersplenism usually are not associated with isolated neutropenia.

» Clinical Findings

A. Symptoms and Signs

Acute severe bacterial or fungal infection is the most significant complication of neutropenia. Although the risk is increased when the absolute neutrophil count is less than 500/μL, the actual susceptibility is variable and depends on the cause of neutropenia, marrow reserves, and other factors. The most common types of infection include septicemia, cellulitis, skin abscesses, pneumonia, and perirectal abscesses. Sinusitis, aphthous ulcers, gingivitis, and periodontal disease also cause significant problems. In addition to local signs and symptoms, patients may have chills, fever, and malaise. In most cases, the spleen and liver are not enlarged. Staphylococcus aureus and gram-negative bacteria are the most common pathogens.

B. Laboratory Findings

Neutrophils are absent or markedly reduced in the peripheral blood. In most forms of neutropenia or agranulocytosis, the monocytes and lymphocytes are normal and the red cells and platelets are not affected. The bone marrow usually shows a normal erythroid series, with adequate megakaryocytes, but a marked reduction in the myeloid cells or a significant delay in maturation of this series may be noted at various stages of myeloid maturation. Total cellularity may be decreased.

In the evaluation of neutropenia (eg, persistent, intermittent, cyclic), attention should be paid to the duration and pattern of neutropenia, the types of infections and their frequency, and phenotypic abnormalities on physical examination. A careful family history and blood counts from the parents are useful. If an acquired cause, such as viral infection or drug, is not obvious as an acute cause, no other primary disease is present, and the neutropenia is chronic, WBC counts, white cell differential, and platelet and reticulocyte counts should be completed twice weekly for 6 weeks to determine the pattern of neutropenia. Bone marrow aspiration and biopsy including cytogenetic analysis are most important to characterize the morphologic features of myelopoiesis. Measuring the neutrophil counts in response to corticosteroid infusion may document the marrow reserves. Other tests that aid in the diagnosis include measurement of neutrophil antibodies, immunoglobulin levels, antinuclear antibodies, and lymphocyte phenotyping to detect immunodeficiency states. Culture of bone marrow may define myeloid progenitors or the presence of inhibitory factors. Cytokines in plasma or mononuclear cells can be measured directly. Some neutropenia disorders have abnormal neutrophil function, but severe neutropenia may preclude collection of sufficient cells to complete assays. Analysis for gene mutations noted above may help confirm the diagnosis of a severe neutropenia syndrome. Increased apoptosis in marrow precursors or circulating neutrophils is a general characteristic described in several congenital or genetic disorders.

» Treatment

Underlying disorders should be identified and treated or associated agents should be eliminated. Infections should be aggressively assessed and treated. Prophylactic antimicrobial therapy is not indicated for afebrile, asymptomatic patients, but may be considered in rare cases with recurrent infections. Recombinant G-CSF will increase neutrophil counts in most patients; GM-CSF may be considered, but is less extensively used. For patients with neutrophil counts 500/μL or less, G-CSF (Filgrastim) may be started at 3–5 mcg/kg/d

subcutaneously or intravenously once a day. Depending on the counts, the dose may be adjusted to keep the absolute neutrophil count below 10,000/μL. Some patients maintain adequate counts with G-CSF given every other day. Treatment will decrease infectious complications but may have little effect on periodontal disease. However, not all patients with neutropenia syndromes require G-CSF (eg, chronic benign neutropenia of childhood). Patients with cyclic neutropenia may have a milder clinical course as they grow older. Immunizations should be given if the adaptive immune system is normal. Hematopoietic stem cell transplant may be considered for patients with severe complications, especially those with severe congenital neutropenia.

» Prognosis

The prognosis varies greatly with the cause and severity of the neutropenia. In severe cases with persistent agranulocytosis, the prognosis is poor in spite of antibiotic therapy; in mild or cyclic forms of neutropenia, symptoms may be minimal and the prognosis for normal life expectancy excellent. G-CSF has the potential to prolong life expectancy. Up to 50% of patients with Shwachman syndrome may develop aplastic anemia, myelodysplasia, or leukemia during their lifetime. Patients with SCNs also have a potential for leukemia, as do patients with neutropenia associated with some immune disorders. Hematopoietic stem cell transplant may be the only curative therapy for some disorders.

NEUTROPHILIA

Neutrophilia is an increase in the absolute neutrophil count in the peripheral blood to greater than 7500–8500/μL for infants, children, and adults. To support the increased peripheral count, neutrophils may be mobilized from bone marrow storage or peripheral marginating pools. Neutrophilia occurs acutely in association with bacterial or viral infections, inflammatory diseases (eg, juvenile rheumatoid arthritis, inflammatory bowel disease, Kawasaki disease), surgical or functional asplenia, liver failure, diabetic ketoacidosis, azotemia, congenital disorders of neutrophil function (eg, chronic granulomatous disease, leukocyte adherence deficiency), and hemolysis. Drugs such as corticosteroids, lithium, and epinephrine increase the blood neutrophil count. Corticosteroids cause release of neutrophils from the marrow pool, inhibit egress from capillary beds, and postpone apoptotic cell death. Epinephrine causes release of the marginating pool. Acute neutrophilia has been reported after stress, such as from electric shock, trauma, burns, surgery, and emotional upset. Tumors involving the bone marrow, such as lymphomas, neuroblastomas, and rhabdomyosarcoma, may be associated with leukocytosis and the presence of immature myeloid cells in the peripheral blood. Infants with Down syndrome have defective regulation of proliferation and maturation of the myeloid series and may develop neutrophilia. At times this process may affect other cell lines and mimic myeloproliferative disorders or acute leukemia.

The neutrophilias must be distinguished from myeloproliferative disorders such as chronic myelogenous leukemia and juvenile chronic myelogenous leukemia. In general, abnormalities involving other cell lines, the appearance of immature cells on the blood smear, and the presence of hepatosplenomegaly are important differentiating characteristics.

DISORDERS OF NEUTROPHIL FUNCTION

Neutrophils play a key role in host defenses. Circulating in capillary beds, they adhere to the vascular endothelium adjacent to sites of infection and inflammation. Moving between endothelial cells, the neutrophil migrates toward the offending agent. Contact with a microbe that is properly opsonized with complement or antibodies triggers ingestion, a process in which cytoplasmic streaming results in the formation of pseudopods that fuse around the invader, encasing it in a phagosome. During the ingestion phase, the oxidase enzyme system assembles and is activated, taking oxygen from the surrounding medium and reducing it to form toxic oxygen metabolites critical to microbicidal activity. Concurrently, granules from the two main classes (azurophil and specific) fuse and release their contents into the phagolysosome. The concentration of toxic oxygen metabolites (eg, hydrogen peroxide, hypochlorous acid, hydroxyl radical) and other compounds (eg, proteases, cationic proteins, cathepsins, defensins) increases dramatically, resulting in the death and dissolution of the microbe. Complex physiologic and biochemical processes support and control these functions. Defects in any of these processes may lead to inadequate cell function and an increased risk of infection.

» Classification

Table 30–6 summarizes congenital neutrophil function defects. Recently reported is variant CGD with p40phox deficiency manifested by inflammatory bowel disease. Also described is a syndrome of severe neutrophil dysfunction

Table 30–6. Classification of congenital neutrophil function deficits.

Disorder	Clinical Manifestations	Functional Defect	Biochemical Defect	Inheritance (Chromosome; Gene)
Chédiak-Higashi syndrome	Oculocutaneous albinism, photophobia, nystagmus, ataxia. Recurrent infections of skin, respiratory tract, and mucous membranes with gram-positive and gram-negative organisms. Many patients die during lymphoproliferative phase with hepatomegaly, fever, which may be a viral-associated hemophagocytic syndrome secondary to Epstein-Barr virus infection. Older patients may develop degenerative CNS disease.	Neutropenia. Neutrophils, monocytes, lymphocytes, platelets, and all granule-containing cells have giant granules. Most significant defect is in chemotaxis. Also milder defects in microbicidal activity and degranulation.	Gene deficit identified. Alterations in membrane fusion with formation of giant granules. Other biochemical abnormalities in cAMP and cGMP, microtubule assembly.	Autosomal recessive (1q42.1-.2; CHS1)
Leukocyte adherence deficiency I	Recurrent soft-tissue infections, including gingivitis, otitis, mucositis, periodontitis, skin infections. Delayed separation of the cord in newborn and problems with wound healing.	Neutrophilia. Diminished adherence to surfaces, leading to decreased chemotaxis.	Absence or partial deficiency of CD11/CD18 cell surface adhesive glycoproteins.	Autosomal recessive (12q22.3; ITGB2)
Leukocyte adherence deficiency II	Recurrent infections, mental retardation, craniofacial abnormalities, short stature.	Neutrophilia. Deficient "rolling" interactions with endothelial cells. Red cells have Bombay phenotype.	Deficient fucosyl transferase results in deficient sialyl Lewis X antigen, which interacts with P selectin. P selectin on endothelial cells is required for neutrophil rolling, a prerequisite for adherence and diapedesis.	Autosomal recessive (11p11.2; SLC35C1)
Chronic granulomatous disease	Recurrent purulent infections with catalase-positive bacteria and fungi. May involve skin, mucous membranes. Patients also develop deep infections (lymph nodes, lung, liver, bones) and sepsis.	Neutrophilia. Neutrophils demonstrate deficient bactericidal activity but normal chemotaxis and ingestion. Defect in the oxidase (Nox2) enzyme system, resulting in absence or diminished production of oxygen metabolites toxic to microbes.	Several molecular defects in oxidase components. Absent cytochrome b558 with decreased expression of either (1) or (2): (1) gp91-phox (2) p22-phox Absent p47-phox or p67-phox (cytosolic components).	X-linked in 60%–65% of cases (Xp21.1; CYBB) Autosomal recessive in < 5% of cases (16q24; CYBA) Autosomal recessive in 30% of cases (7q11.23; NCF1 and 1q25; NCF2, respectively)
Myeloperoxidase deficiency	Generally healthy. Fungal infections when deficiency associated with systemic diseases (eg, diabetes in poor control).	Diminished capacity to enhance hydrogen peroxide-mediated microbicidal activity. Decreased killing of Candida.	Diminished or absent myeloperoxidase; posttranslational defect in processing protein.	Autosomal recessive (17q22-23)
Specific granule deficiency	Recurrent skin and deep tissue infections.	Neutropenia. Neutrophils have band-shaped or bilobed nuclei. Decreased chemotaxis and bactericidal activity.	Failure to produce specific granules or their contents during myelopoiesis. Defect in transcription factor.	Autosomal recessive (14q11.2; CEBPε)

cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CNS, central nervous system; Nox2, NADPH oxidase 2.

and severe infections associated with a mutation in a GTPase signaling molecule, Rac2. New syndromes of innate immune dysfunction include defects in interferon and interleukin (IL)-12 receptor and signaling pathways, leading to monocyte and macrophage dysfunction and defective toll-like receptor signaling pathways (IL-1 receptor-associated kinase 4 [IRAK-4] deficiency) associated with recurrent bacterial infections. Leukocyte adhesion deficiency (LAD) III is a disorder characterized by severe bleeding, impaired leukocyte adhesion, and endothelial inflammation, and is associated with mutations of FERMT3 gene, which encodes for a protein, Kindlin-3, critical for intracellular function of β integrins and perhaps other adhesion strategies. Other congenital or acquired causes of mild to moderate neutrophil dysfunction include metabolic defects (eg, glycogen storage disease Ib, G6PC3 deficiency, diabetes mellitus, renal disease, and hypophosphatemia), viral infections, and certain drugs. Neutrophils from newborn infants have abnormal adherence, chemotaxis, and bactericidal activity. Cells from patients with thermal injury, trauma, and overwhelming infection have defects in cell motility and bactericidal activity similar to those seen in neonates.

» Clinical Findings

Recurrent bacterial or fungal infections are the hallmark of neutrophil dysfunction. Although patients will have infection-free periods, episodes of pneumonia, sinusitis, cellulitis, cutaneous and mucosal infections (including perianal or peritonsillar abscesses), and lymphadenitis are frequent. As with neutropenia, aphthous ulcers of mucous membranes, severe gingivitis, and periodontal disease are also major complications. In general, S aureus or gram-negative organisms are commonly isolated from infected sites; other organisms may be specifically associated with a defined neutrophil function defect. In some disorders, fungi account for an increasing number of infections. Deep or generalized infections, such as osteomyelitis, liver abscesses, sepsis, meningitis, and necrotic or gangrenous soft-tissue lesions, occur in specific syndromes (eg, leukocyte adherence deficiency or chronic granulomatous disease). Patients with severe neutrophil dysfunction may die in childhood from severe infections or associated complications. Table 30–6 summarizes pertinent laboratory findings.

» Treatment

The mainstays of management of these disorders are anticipation of infections and aggressive attempts to identify the foci and the causative agents. Surgical procedures to achieve these goals may be both diagnostic and therapeutic. Broad-spectrum antibiotics covering the range of possible organisms should be initiated without delay, switching to specific antimicrobial agents when the microbiologic diagnosis is made. When infections are unresponsive or they recur, granulocyte transfusions may be helpful.

Chronic management may include prophylactic antibiotics. Trimethoprim-sulfamethoxazole and some other antibiotics (eg, rifampin) enhance the bactericidal activity of neutrophils from patients with chronic granulomatous disease. Some patients with Chédiak-Higashi syndrome improve clinically when given ascorbic acid. Recombinant γ-interferon decreases the number and severity of infections in patients with chronic granulomatous disease. Demonstration of this activity with one patient group raises the possibility that cytokines, growth factors, and other biologic response modifiers may be helpful in other conditions in preventing recurrent infections. Bone marrow transplant has been attempted in most major congenital neutrophil dysfunction syndromes, and reconstitution with normal cells and cell function has been documented. Combining genetic engineering with autologous bone marrow transplant may provide a future strategy for curing these disorders.

» Prognosis

For mild to moderate defects, anticipation and conservative medical management ensure a better outlook. For severe defects, excessive morbidity and significant mortality still exist. In some diseases, the development of noninfectious complications, such as the lymphoproliferative phase of Chédiak-Higashi syndrome or inflammatory syndromes in chronic granulomatous disease, may influence prognosis.

LYMPHOCYTOSIS

From the first week up to the fifth year of life, lymphocytes are the most numerous leukocytes in human blood. The ratio then reverses gradually to reach the adult pattern of neutrophil predominance. An absolute lymphocytosis in childhood is associated with acute or chronic viral infections, pertussis,

syphilis, tuberculosis, and hyperthyroidism. Other noninfectious conditions, drugs, and hypersensitivity and serum sickness–like reactions cause lymphocytosis.

Fever, upper respiratory symptoms, gastrointestinal complaints, and rashes are clues in distinguishing infectious from noninfectious causes. The presence of enlarged liver, spleen, or lymph nodes is crucial to the differential diagnosis, which includes acute leukemia and lymphoma. Most cases of infectious mononucleosis are associated with hepatosplenomegaly or adenopathy. The absence of anemia and thrombocytopenia helps to differentiate these disorders. Evaluation of the morphology of lymphocytes on peripheral blood smear is crucial. Infectious causes, particularly infectious mononucleosis, are associated with atypical features in the lymphocytes, such as basophilic cytoplasm, vacuoles, finer and less-dense chromatin, and an indented nucleus. These features are distinct from the characteristic morphology associated with lymphoblastic leukemia. Lymphocytosis in childhood is most commonly associated with infections and resolves with recovery from the primary disease.

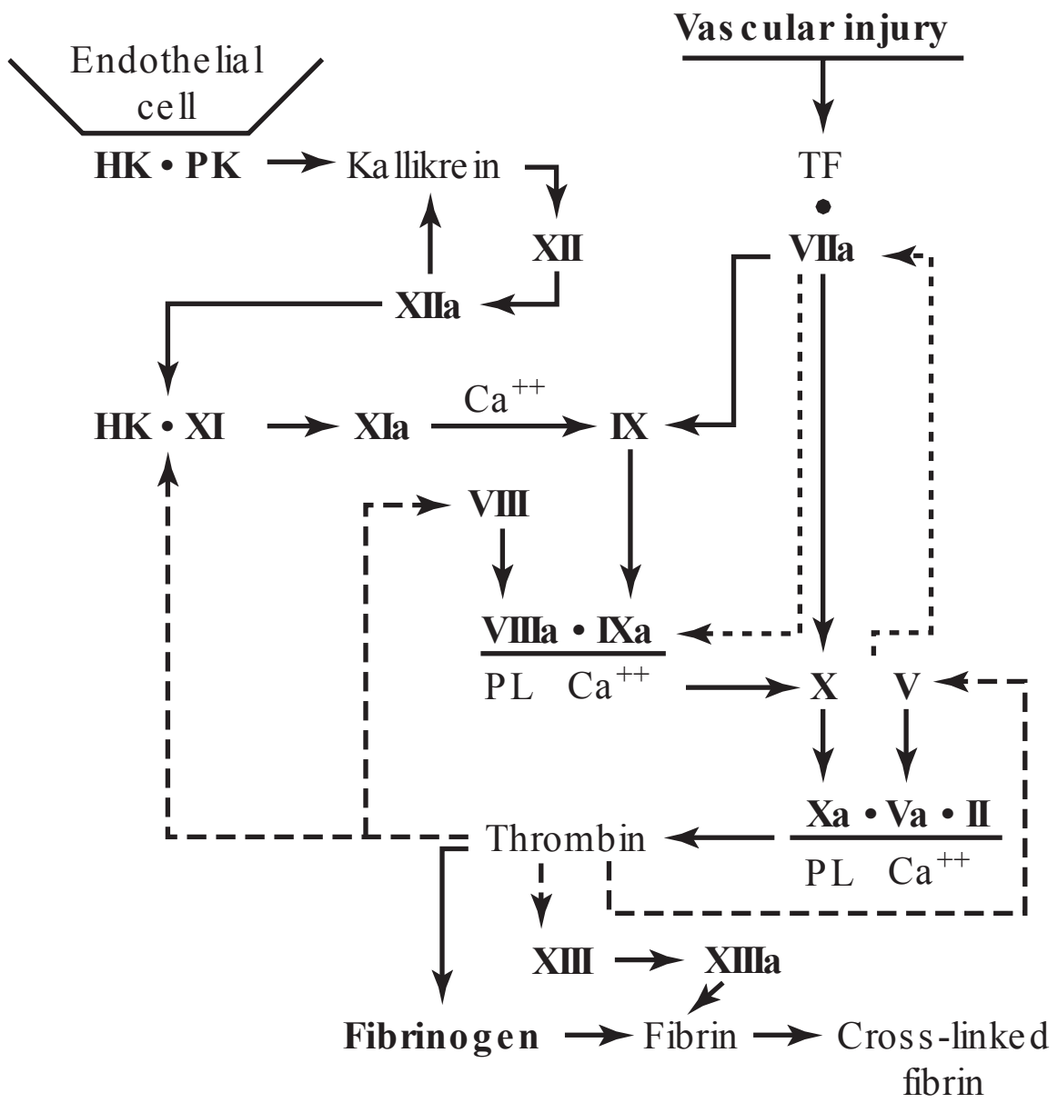
EOSINOPHILIA

Eosinophilia in infants and children is an absolute eosinophil count greater than 300/μL. Marrow eosinophil production is stimulated by the cytokine IL-5. Allergies, particularly those associated with asthma and eczema, are the most common primary causes of eosinophilia in children. Eosinophilia also occurs in drug reactions, with tumors (Hodgkin and non-Hodgkin lymphomas and brain tumors), and with immunodeficiency and histiocytosis syndromes. Increased eosinophil counts are a prominent feature of many invasive parasitic infections. Gastrointestinal disorders such as chronic hepatitis, ulcerative colitis, Crohn disease, and milk precipitin disease may be associated with eosinophilia. Increased blood eosinophil counts have been identified in several families without association with any specific illness. Rare causes of eosinophilia include the hypereosinophilic syndrome, characterized by counts greater than 1500/μL and organ involvement and damage (hepatosplenomegaly, cardiomyopathy, pulmonary fibrosis, and central nervous system injury). This is a disorder of middle-aged adults and is rare in children. Eosinophilic leukemia has been described, but its existence as a distinct entity is very rare.

Eosinophils are sometimes the last type of mature myeloid cell to disappear after marrow ablative chemotherapy. Increased eosinophil counts are associated with graft-versus-host disease after bone marrow transplant, and elevations are sometimes documented during rejection episodes in patients who have solid organ grafts.

BLEEDING DISORDERS

Bleeding disorders may occur as a result of (1) quantitative or qualitative abnormalities of platelets, (2) quantitative or qualitative abnormalities in plasma procoagulant factors, (3) vascular abnormalities, or (4) accelerated fibrinolysis. The coagulation cascade and fibrinolytic system are shown in Figures 30–4 and 30–5.



▲**Figure 30–4.** The procoagulant system and formation of a fibrin clot. Vascular injury initiates the coagulation process by exposure of tissue factor (TF); the dashed lines indicate thrombin actions in addition to clotting of fibrinogen. The dotted lines associated with VIIa indicate the feedback activation of the VII-TF complex by Xa and IXa. Ca++, calcium; HK, high-molecular-weight kininogen; PK, prekallikrein; PL, phospholipid. (Reproduced, with permission, from Goodnight SH, Hathaway WE [eds]: Disorders of Hemostasis & Thrombosis: A Clinical Guide. 2nd ed. McGraw-Hill; 2001.)

The most critical aspect in evaluating the bleeding patient is obtaining detailed personal and family bleeding histories, including bleeding complications associated with dental interventions, surgeries, suture placement and removal, and trauma. Excessive mucosal bleeding is suggestive of a platelet disorder, von Willebrand disease (vWD), dysfibrinogenemia, or vasculitis. Bleeding into muscles and joints may be associated with a plasma procoagulant factor abnormality. In either scenario, the abnormality may be congenital or acquired. A thorough physical examination should be performed with special attention to the skin, oro- and nasopharynx, liver, spleen, and joints. Screening and diagnostic evaluation in patients with suspected bleeding

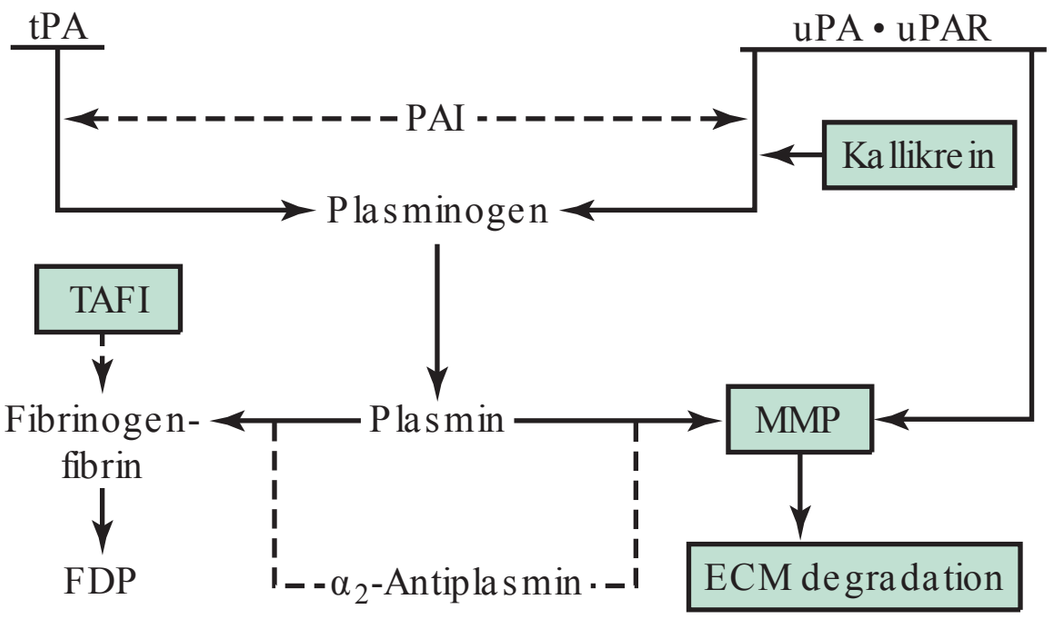


Figure 30–5. The fibrinolytic system. Solid arrows indicate activation; dashed line arrows indicate inhibition. ECM, extracellular matrix; FDP, fibrinogen-fibrin degradation products; MMP, matrix metalloproteinases; PAI, plasminogen activator inhibitor; TAFI, thrombin activatable fibrinolysis inhibitor; tPA, tissue plasminogen activator; uPA, urokinase; uPAR, cellular urokinase receptor. (Reproduced, with permission, from Goodnight SH, Hathaway WE [eds]: Disorders of Hemostasis & Thrombosis: A Clinical Guide. 2nd ed. McGraw-Hill; 2001.)

disorders may initially include the following laboratory testing:

1. Prothrombin time (PT) to assess clotting function of factors VII, X, V, II, and fibrinogen.
2. Activated partial thromboplastin time (aPTT) to assess clotting function of high-molecular-weight kininogen, prekallikrein, XII, XI, IX, VIII, X, V, II, and fibrinogen.
3. Platelet count and size determined as part of a CBC.
4. Platelet functional assessment by platelet function analyzer-100 (PFA-100), template bleeding time, or whole blood platelet aggregometry.
5. Fibrinogen functional level by clotting assay.

The following laboratory tests may also be useful:

1. Thrombin time to measure the generation of fibrin from fibrinogen following conversion of prothrombin to thrombin, as well as the antithrombin effects of fibrin-split products and heparin. The thrombin time may be prolonged in the setting of a normal fibrinogen concentration if the fibrinogen is dysfunctional (ie, dysfibrinogenemia).
2. Euglobulin lysis time (ELT), if available, to evaluate for accelerated fibrinolysis if the preceding workup is nonrevealing despite documented history of bleeding. If the ELT is shortened, assessment of plasminogen activator inhibitor-1 and α_2-antiplasmin is warranted, as congenital deficiency in these fibrinolytic inhibitors may cause hyperfibrinolysis. In ill patients, measurement of fibrin degradation products may assist in the diagnosis of DIC.

Goodnight SH, Hathaway WE (eds): Disorders of Hemostasis & Thrombosis: A Clinical Guide. 2nd ed. McGraw-Hill; 2001:41–51.

ABNORMALITIES OF PLATELET NUMBER OR FUNCTION

Thrombocytopenia in the pediatric age range is often immune-mediated (eg, ITP, neonatal auto- or alloimmune thrombocytopenia, heparin-induced thrombocytopenia), but is also caused by consumptive coagulopathy (eg, DIC, Kasabach-Merritt phenomenon), acute leukemias, rare disorders such as Wiskott-Aldrich syndrome and type 2b vWD, and artifactually in automated cytometers (eg, Bernard-Soulier syndrome), where giant forms may not be enumerated as platelets.

1. Idiopathic Thrombocytopenic Purpura

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Otherwise healthy child.
- Decreased platelet count.
- Petechiae, ecchymoses.

» General Considerations

Acute idiopathic thrombocytopenic purpura (ITP) is the most common bleeding disorder of childhood. It occurs most frequently in children aged 2–5 years and often follows infection with viruses, such as rubella, varicella, measles, parvovirus, influenza, EBV, or acute and chronic HIV. Most patients recover spontaneously within a few months. Chronic ITP (> 12 months' duration) occurs in 10%–20% of affected patients. The thrombocytopenia results from clearance of circulating IgM- or IgG-coated platelets by the reticuloendothelial system. The spleen plays a predominant role in the disease by forming the platelet cross-reactive antibodies and sequestering the antibody-bound platelets.

» Clinical Findings

A. Symptoms and Signs

Onset of ITP is usually acute, with the appearance of multiple petechiae and ecchymoses. Epistaxis is also common at presentation. No other physical findings are usually present. Rarely, concurrent infection with EBV or CMV may cause hepatosplenomegaly or lymphadenopathy, simulating acute leukemia.

B. Laboratory Findings

1. Blood—The platelet count is markedly reduced (usually < 50,000/μL and often < 10,000/μL), and platelets are frequently large on peripheral blood smear, suggesting accelerated production of new platelets. The WBC and differential are normal, and the hemoglobin concentration is preserved unless hemorrhage has been significant.

2. Bone marrow—The number of megakaryocytes is increased. Erythroid and myeloid cellularity is normal.

3. Other laboratory tests—Platelet-associated IgG or IgM, or both, may be demonstrated on the patient's platelets or in the serum. PT and aPTT are normal.

» Differential Diagnosis

Table 30–7 lists common causes of thrombocytopenia. ITP remains a diagnosis of exclusion. Family history or the finding of predominantly giant platelets on the peripheral blood smear is helpful in separating from thrombocytopenia that is hereditary. Bone marrow examination should be performed if the history is atypical (ie, the child is not otherwise healthy, or if there is a family history of bleeding), if abnormalities other than purpura and petechiae are present on physical examination, or if other cell lines are affected on the CBC. Bone marrow examination prior to using corticosteroids in the treatment for ITP remains controversial.

» Complications

Severe hemorrhage and bleeding into vital organs are the feared complications of ITP. Intracranial hemorrhage is the most serious (but rarely seen) complication, occurring in less than 1% of affected children. The most important risk factors for hemorrhage are a platelet count less than 10,000/μL and mean platelet volume less than 8 fL.

» Treatment

A. General Measures

Observation is recommended for most children in the absence of bleeding regardless of platelet count. Aspirin, other medications (eg, NSAIDs such as Advil, Naproxen, etc), and foods that compromise platelet function should be avoided. Bleeding precautions (eg, restriction from physical contact activities and use of helmets) should be observed. Platelet transfusion should be avoided except in circumstances of life-threatening bleeding, in which case emergent splenectomy may be considered. In this setting, administration of corticosteroids and IVIG is also advisable.

B. Corticosteroids

Patients with clinically significant but non–life-threatening bleeding (ie, epistaxis, hematuria, and hematochezia) and those with a platelet count of less than 10,000/μL may benefit from a short course of corticosteroids. No single dose or dosing regimen has evidence to support its use above another. A higher dose initially (3–5 mg/kg/d) for 3–7 days may lead to faster count recovery. No further prednisone is given regardless of the platelet count unless significant bleeding recurs, at which time prednisone is administered in the smallest dose that achieves resolution of bleeding episodes (usually 2.5–5 mg twice daily). Follow-up continues until the steroid can again be discontinued, spontaneous remission occurs, or other therapeutic measures are instituted. Long-term use of corticosteroids should be avoided because of toxicity.

C. Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) is the treatment of choice for severe, acute bleeding, and may also be used as an alternative or adjunct to corticosteroid treatment in both acute and chronic ITP. IVIG may be effective even when the patient is resistant to corticosteroids; responses are prompt

Table 30–7. Common causes of thrombocytopenia.

Increased Turnover			Decreased Production	
Antibody-Mediated	Coagulopathy	Other	Congenital	Acquired
Idiopathic thrombocytopenic purpura	Disseminated intravascular coagulopathy	Hemolytic-uremic syndrome	Fanconi anemia Amegakaryocytic thrombocytopenia	Aplastic anemia
Infection	Sepsis	Thrombotic thrombocytopenic purpura	Wiskott-Aldrich syndrome	Leukemia and other malignancies
Immunologic diseases	Necrotizing enterocolitis Thrombosis Cavernous hemangioma	Hypersplenism Respiratory distress syndrome Wiskott-Aldrich syndrome	Thrombocytopenia with absent radii Metabolic disorders Osteopetrosis	Vitamin B_{12} and folate deficiencies Medications

and may last for several weeks. A single dose of 0.8–1 g/kg has been recommended. Platelets may be given simultaneously during life-threatening hemorrhage but are rapidly destroyed. Side effects of IVIG are common, including transient neurologic complications in one-third of patients, (eg, headache, nausea, and aseptic meningitis) that mimic intracranial hemorrhage and necessitate radiologic evaluation. A transient decrease in neutrophil number may also be seen.

D. Anti-Rh(D) Immunoglobulin

This polyclonal immunoglobulin binds to the D antigen on RBCs. The splenic clearance of anti–D-coated red cells interferes with removal of antibody-coated platelets, resulting in improvement in thrombocytopenia. This approach is effective only in Rh(+) patients with a functional spleen who are DAT negative. At doses of 50–75 mcg/kg, approximately 80% of Rh(+) children with acute or chronic ITP respond; however, there is no clear difference between anti-D and IVIG in the time to reach the end point of achieving a platelet count of 20×10^9/L. Significant hemolysis may occur in up to 5% of patients, and the Food and Drug Administration (FDA) has provided specific monitoring requirements because of reports of fatal intravascular hemolysis. Rh(D) immunoglobulin is less expensive and infused more rapidly than IVIG, but is more expensive than corticosteroids.

E. Splenectomy

Many children with chronic ITP have platelet counts greater than 30,000/μL. Up to 70% of such children spontaneously recover with a platelet count greater than 100,000/μL within 1 year. For the remainder, corticosteroids, IVIG, and anti-D immunoglobulin are typically effective treatment for acute bleeding. Splenectomy produces a complete response in 70% and partial response in 20% of children with ITP. It should be considered only after persistence of significant thrombocytopenia for more than 12 months, and the failure of a preferred or alternative second-line therapy. The risk of overwhelming infection with encapsulated organisms is increased after splenectomy, particularly in the young child. Preoperative vaccination with polyvalent pneumococcal conjugate and polysaccharide vaccines, meningococcal C conjugate, and Hib conjugate is recommended. If possible, the procedure should be postponed, until age 5 years. For patients younger than 5 years daily penicillin prophylaxis should be started postoperatively and continued at least until 5 years of age. Postoperatively, the platelet count may rise to 1 million/μL. This reactive thrombocytosis is not associated with thrombotic complications in children. Long term, thrombosis is now recognized as a potential postsplenectomy complication.

F. Rituximab (Anti-CD20 Monoclonal Antibody)

There have been no randomized trials for rituximab in children. The efficacy of treating childhood chronic ITP in several series and case studies has demonstrated response rates between 26% and 60%. Because of significant adverse events, this therapy may be reserved for refractory cases with significant bleeding or as an alternative to splenectomy.

G. New Agents

One randomized clinical trial in children has been conducted with romiplostim, a thrombopoietin receptor agonist, with an 88% response rate and improved quality of life. In addition, as a second-line agent, they may be useful in patients where corticosteroid sparing is needed. One pitfall of this approach is that these agents require long-term administration. Further studies in more children are needed to address long-term adverse effects, efficacy, and sustained response.

» Prognosis

Eighty percent of children with ITP will achieve a remission. Predictors of the development of chronic ITP include female gender, age greater than 10 years at presentation, insidious onset of bruising, and the presence of other autoantibodies. Older child- and adolescent-onset ITP is associated with an increased risk of chronic autoimmune diseases or immunodeficiency states. Appropriate screening by history and laboratory studies (eg, antinuclear antibody) is warranted.

2. Thrombocytopenia in the Newborn

Thrombocytopenia is one of the most common causes of neonatal hemorrhage and should be considered in any newborn with petechiae, purpura, or other significant bleeding. Defined as a platelet count less than 150,000/μL, thrombocytopenia occurs in approximately 0.9% of unselected neonates; however, up to 80% of neonates in a newborn intensive care unit may have thrombocytopenia; most of these cases are transient. Several specific entities may be responsible for more severe thrombocytopenia (see Table 30–7). Many of these infants are affected by unknown mechanisms in mothers with preeclampsia. Most of these cases resolve over several days to a few weeks without treatment, but some are severe enough to warrant platelet transfusions. Infection and DIC are the most common causes of thrombocytopenia in ill full-term newborns and in preterm newborns. In the healthy neonate, antibody-mediated thrombocytopenia

(alloimmune or maternal autoimmune), viral syndromes, hyperviscosity, and major-vessel thrombosis are frequent causes of thrombocytopenia. Management is directed toward the underlying etiology.

A. Thrombocytopenia Associated With Platelet Alloantibodies (Neonatal Alloimmune Thrombocytopenia)

Neonatal alloimmune thrombocytopenia (NAIT) is the most common cause of thrombocytopenia in well, term infants, with a prevalence of 0.7 per 1000 pregnancies. Alloimmunization occurs when a platelet antigen of the infant differs from that of the mother, and the mother is sensitized by fetal platelets that cross the placenta into the maternal circulation. In Caucasians, 80% are associated with HPA-1a and 10%–15% with HPA-5b. Sensitization of a mother homozygous for HPA-1b to paternally acquired fetal HPA-1a antigen results in severe fetal thrombocytopenia in 1 in 1200 fetuses. Only 1 in 20 HPA-1a–positive fetuses of HPA-1a–negative mothers develops alloimmunization. Other platelet-specific alloantigens may be etiologic. Unlike in Rh incompatibility, 30%–40% of affected neonates are first born. Thrombocytopenia is progressive over the course of gestation and worse with each subsequent pregnancy. The presence of antenatal maternal platelet antibodies on more than one occasion and their persistence into the third trimester is predictive of severe neonatal thrombocytopenia; a weak or undetectable antibody does not exclude thrombocytopenia. Severe intracranial hemorrhage occurs in 10%–30% of affected neonates as early as 20 weeks' gestation. Petechiae or other bleeding manifestations are usually present shortly after birth. The disease is self-limited, and the platelet count normalizes within 4 weeks.

If alloimmunization is associated with clinically significant bleeding, transfusion of platelets harvested from the mother is more effective than random donor platelets in increasing the platelet count. Transfusion with HPA-matched platelets from unrelated donors or treatment with IVIG or methylprednisolone to acutely block macrophage uptake of sensitized platelets has also been successful in raising the platelet count and achieving hemostasis. If thrombocytopenia is not severe and bleeding is absent, observation alone is often appropriate.

Intracranial hemorrhage in a previous child secondary to alloimmune thrombocytopenia is the strongest risk factor for severe fetal thrombocytopenia and hemorrhage in a subsequent pregnancy. Amniocentesis or chorionic villus sampling to obtain fetal DNA for platelet antigen typing is sometimes performed if the father is heterozygous for HPA-1a. If alloimmunization has occurred with a previous pregnancy, irrespective of history of intracranial hemorrhage, screening cranial ultrasound for hemorrhage should begin at 20 weeks' gestation and be repeated regularly. In addition, cordocentesis should be performed at approximately 20 weeks' gestation, with prophylactic transfusion of irradiated, leukoreduced, maternal platelet concentrates. If the fetal platelet count is less than 100,000/μL, the mother should be treated with weekly IVIG. Delivery by elective cesarean section is recommended if the fetal platelet count is less than 50,000/μL to minimize the risk of intracranial hemorrhage associated with birth trauma.

B. Thrombocytopenia Associated With ITP in the Mother (Neonatal Autoimmune Thrombocytopenia)

Infants born to mothers with ITP or other autoimmune diseases (eg, antiphospholipid antibody syndrome or systemic lupus erythematosus) may develop thrombocytopenia as a result of transfer of antiplatelet IgG from the mother to the infant. Unfortunately, maternal and fetal platelet counts and maternal antiplatelet antibody levels are unreliable predictors of bleeding risk. Antenatal corticosteroid administration to the mother is generally instituted once maternal platelet count falls below 50,000/μL, with or without a concomitant course of IVIG.

Most neonates with autoimmune thrombocytopenia do not develop clinically significant bleeding, and thus treatment for thrombocytopenia is not often required. The risk of intracranial hemorrhage is 0.2%–2%. If diffuse petechiae or minor bleeding are evident, a 1- to 2-week course of oral prednisone, 2 mg/kg/d, may be helpful. If the platelet count remains consistently less than 20,000/μL or if severe hemorrhage develops, IVIG should be given (0.8–1 g/kg daily for 1–2 days). Platelet transfusions are only indicated for life-threatening bleeding, and may only be effective after removal of antibody by exchange transfusion. The platelet nadir is typically between the fourth and sixth day of life and improves significantly by 1 month; full recovery may take 2–4 months. Platelet recovery may be delayed in breast-fed infants because of transfer of IgG to the milk.

C. Neonatal Thrombocytopenia Associated With Infections

Thrombocytopenia is commonly associated with severe generalized infections during the newborn period. Between 50% and 75% of neonates with bacterial sepsis are thrombocytopenic. Intrauterine infections such as rubella, syphilis, toxoplasmosis, CMV, herpes simplex (acquired intra- or postpartum), enteroviruses, and parvovirus are often associated with thrombocytopenia. In addition to specific treatment for the underlying disease, platelet transfusions may be indicated in severe cases.

D. Thrombocytopenia Associated With Kaposiform Hemangioendotheliomas (Kasabach-Merritt Syndrome)

A rare but important cause of thrombocytopenia in the newborn is kaposiform hemangioendotheliomas, a benign

neoplasm with histopathology distinct from that of classic infantile hemangiomas. Intense platelet sequestration in the lesion results in peripheral thrombocytopenia and may rarely be associated with a DIC-like picture and hemolytic anemia. The bone marrow typically shows megakaryocytic hyperplasia in response to the thrombocytopenia. Corticosteroids, α-interferon, vincristine, and sirolimus are all useful for reducing the size of the lesion, and are indicated if significant coagulopathy is present, the lesion compresses a vital structure, or the lesion is cosmetically unacceptable. If consumptive coagulopathy is present, heparin or an antifibrinolytic agent may be useful. Depending on the site, embolization may be an option. Surgery is often avoided because of the high risk of hemorrhage.

Kaplan RN: Differential diagnosis and management of thrombocytopenia in childhood. Pediatr Clin North Am 2004;51:1109 [PMID: 15275991].

3. Disorders of Platelet Function

Individuals with platelet function defects typically develop abnormal bruising and mucosal bleeding similar to that occurring in persons with thrombocytopenia. Historically, platelet function has been screened by measuring the bleeding time. If this is prolonged, in vitro platelet aggregation is studied using agonists, such as adenosine diphosphate, collagen, arachidonic acid, and ristocetin. While labor-intensive, platelet aggregometry remains important in selected clinical situations. The PFA-100 that can evaluate platelet dysfunction and vWD has replaced the template bleeding time in many institutions. Unfortunately, none of these screening tests of platelet function is uniformly predictive of clinical bleeding severity.

Platelet dysfunction may be inherited or acquired, with the latter being more common. Acquired disorders of platelet function may occur secondary to uremia, cirrhosis, sepsis, myeloproliferative disorders, congenital heart disease, and viral infections. Many pharmacologic agents decrease platelet function. The most common offending agents in the pediatric population are aspirin and other NSAIDs, synthetic penicillins, and valproic acid. In acquired platelet dysfunction, the PFA-100 closure time is typically prolonged with collagen-epinephrine, while normal with collagen-ADP.

The inherited disorders are due to defects in platelet-vessel interaction, platelet-platelet interaction, platelet granule content or release (including defects of signal transduction), thromboxane and arachidonic acid pathway, and platelet-procoagulant protein interaction. Individuals with hereditary platelet dysfunction generally have a prolonged bleeding time with normal platelet number and morphology by light microscopy. PFA-100 closure time, in contrast to that in acquired dysfunction, is typically prolonged with both collagen-ADP and collagen-epinephrine.

Congenital causes of defective platelet–vessel wall interaction include Bernard-Soulier syndrome, which is characterized by increased platelet size and decreased platelet number. The molecular defect in this autosomal recessive disorder is a deficiency or dysfunction of glycoprotein Ib-V-IX complex on the platelet surface resulting in impaired von Willebrand factor (vWF) binding, and hence impaired platelet adhesion to the vascular endothelium.

Glanzmann thrombasthenia is an example of platelet-platelet dysfunction. In this autosomal recessive disorder, glycoprotein IIb-IIIa is deficient or dysfunctional. Platelets do not bind fibrinogen effectively and exhibit impaired aggregation. As in Bernard-Soulier syndrome, acute bleeding is treated by platelet transfusion, and more recently with recombinant factor VIIa.

Disorders involving platelet granule content include storage pool disease and Quebec platelet disorder. In individuals with storage pool disease, platelet-dense granules lack adenosine dinucleotide phosphate and adenosine trinucleotide phosphate and are often found to be low in number by electron microscopy. These granules are also deficient in Hermansky-Pudlak, Chédiak-Higashi, and Wiskott-Aldrich syndromes. Whereas deficiency of a second granule class, α-granules, results in the gray platelet syndrome, Quebec platelet disorder is characterized by a normal platelet α-granule number, but with abnormal proteolysis of α-granule proteins and deficiency of platelet α-granule multimerin. α-Granule abnormality in this disorder also results in increased serum levels of urokinase-type plasminogen activator. Epinephrine-induced platelet aggregation is markedly impaired.

Platelet dysfunction has also been observed in other congenital syndromes, such as Down and Noonan syndromes, without a clear understanding of the molecular defect.

» Treatment

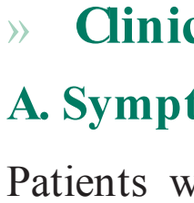
Acute bleeding in many individuals with acquired or selected congenital platelet function defects responds to therapy with desmopressin acetate, likely due to an induced release of vWF from endothelial stores and/or upregulated expression of glycoprotein Ib-V-IX on the platelet surface. If this therapy is ineffective, or if the patient has Bernard-Soulier syndrome or Glanzmann syndrome, the mainstay of treatment for bleeding episodes is platelet transfusion, possibly with HLA type-specific platelets. Recombinant VIIa has variable efficacy and may be helpful in platelet transfusion-refractory patients, and now has an FDA-approved indication for patients with Glanzmann syndrome.

Israels S: Platelet disorders in children: a diagnostic approach. Pediatr Blood Cancer 2011;56:975 [PMID: 21294245].

INHERITED BLEEDING DISORDERS

Table 30–8 lists normal values for coagulation factors. The more common factor deficiencies are discussed in this section. Individuals with bleeding disorders should avoid exposure to medications that inhibit platelet function. Participation in contact sports should be considered in the context of the severity of the bleeding disorder.

1. Factor VIII Deficiency (Hemophilia A)



ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bruising, soft-tissue bleeding, hemarthrosis.
- Prolonged aPTT.
- Reduced factor VIII activity.

» General Considerations

Factor VIII activity is reported in units per milliliter, with 1 U/mL equal to 100% of the factor activity found in 1 mL of normal plasma. The normal range for factor VIII activity is 0.50–1.50 U/mL (50%–150%). Hemophilia A occurs predominantly in males as an X-linked disorder. One-third of cases are due to a new mutation. The incidence of factor VIII deficiency is 1:5000 male births.

» Clinical Findings

A. Symptoms and Signs

Patients with severe hemophilia A (< 1% plasma factor VIII activity) have frequent spontaneous bleeding episodes involving skin, mucous membranes, joints, muscles, and viscera in the absence of factor VIII. In contrast, patients with mild hemophilia A (5%–40% factor VIII activity) mainly bleed at times of trauma or surgery. Those with moderate hemophilia A (1% to < 5% factor VIII activity) typically have intermediate bleeding manifestations. The most crippling aspect of factor VIII deficiency is the tendency to develop recurrent hemarthroses that incite joint destruction.

B. Laboratory Findings

Individuals with hemophilia A have a prolonged aPTT, except in some cases of mild deficiency. The PT is normal. The diagnosis is confirmed by finding decreased factor VIII activity with normal vWF activity. In two-thirds of families of hemophilic patients, the females are carriers and some manifest symptomatic bleeding. Carriers of hemophilia can be suspected by determination of the ratio of factor VIII activity to vWF antigen and definitively diagnosed by molecular genetic techniques. In a male fetus or newborn with a family history of hemophilia A, cord blood sampling for factor VIII activity is accurate and important in subsequent care.

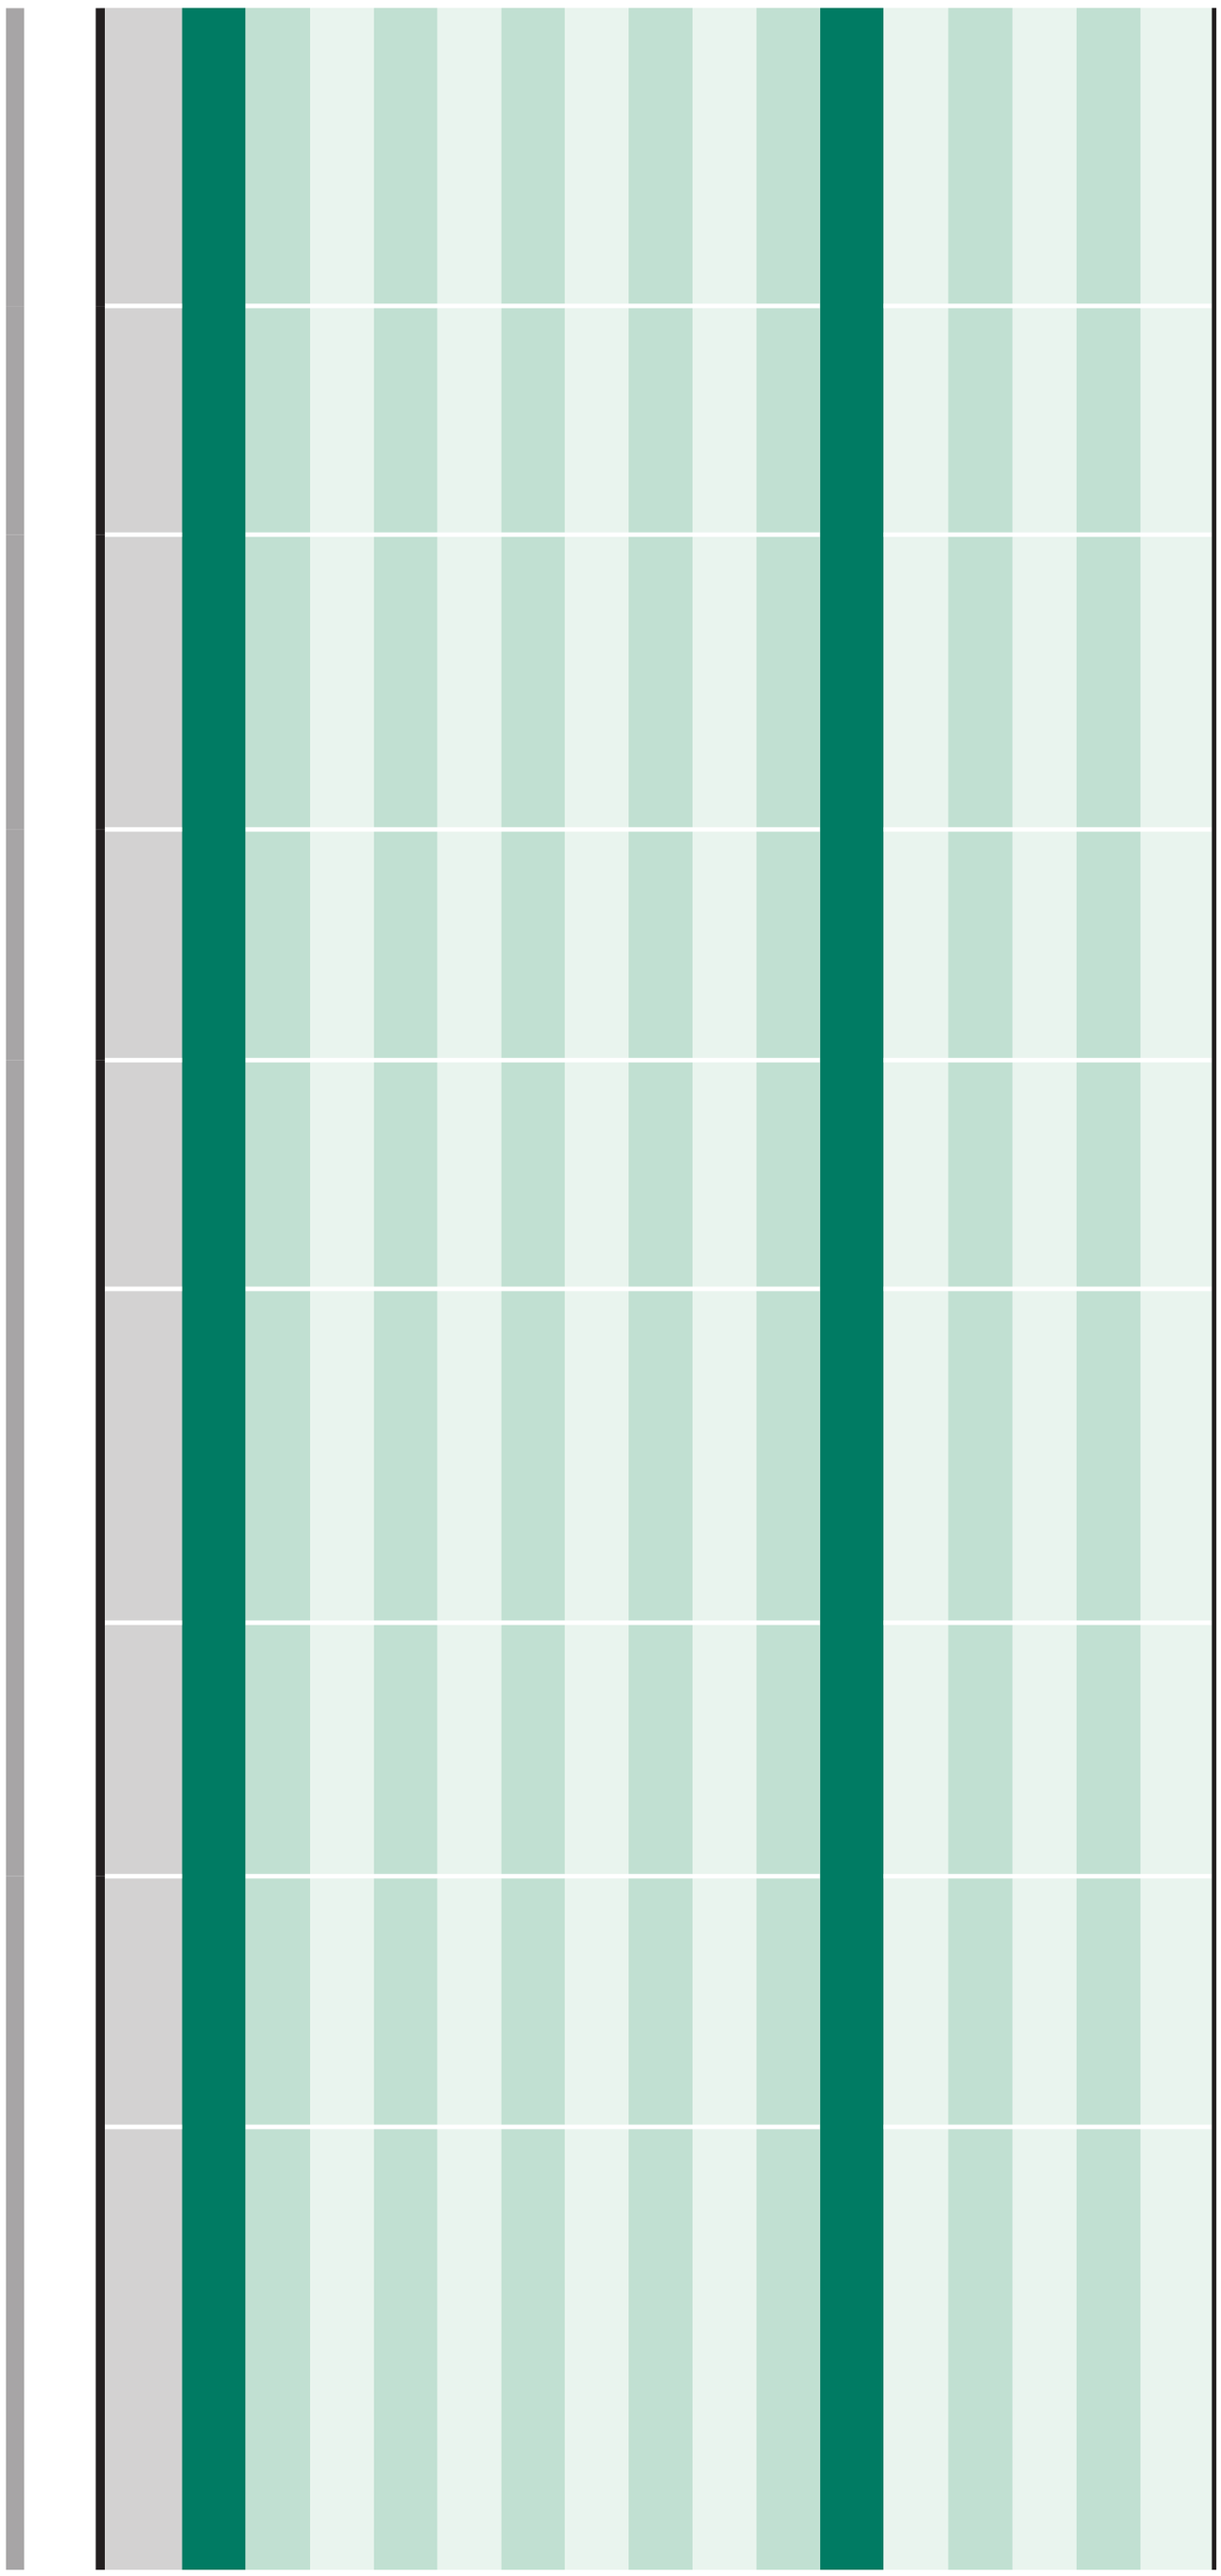
» Complications

Intracranial hemorrhage is the leading disease-related cause of death among patients with hemophilia. Most intracranial hemorrhages in moderate to severe deficiency are spontaneous (ie, not associated with trauma). Hemarthroses begin early in childhood and, particularly when recurrent, can result in joint destruction (ie, hemophilic arthropathy). Large intramuscular hematomas can lead to a compartment syndrome with resultant neurologic compromise. Although these complications are most common in severe hemophilia A, they may be experienced by individuals with moderate or mild disease. Acquired circulating antibodies to factor VIII is a potential serious complication after treatment with factor VIII concentrate. These antibodies develop in up to 30% of patients with severe hemophilia A, and especially in patients with large deletions in the factor VIII gene. Inhibitors may be amenable to desensitization with regular factor VIII infusion (immune tolerance therapy) with or without immunosuppressive therapy. Bypassing agent therapy with recombinant factor VIIa and/or FEIBA has become standard treatment of acute hemorrhage in patients with hemophilia A and a high-titer inhibitor.

In prior decades, therapy-related complications in hemophilia A have included infection with HIV, hepatitis B virus, and hepatitis C virus. Through stringent donor selection, the implementation of sensitive screening assays, the use of heat or chemical methods for viral inactivation, and the development of recombinant products, the risk of these infections is effectively minimized. Inactivation methods do not eradicate viruses lacking a lipid envelope; however, so that transmission of parvovirus and hepatitis A remains a concern with the use of plasma-derived products. Immunization with hepatitis A and hepatitis B vaccines is recommended for all hemophilia patients.

» Treatment

The general aim of management is to raise the factor VIII activity to prevent or stop bleeding. Some patients with mild factor VIII deficiency may respond to desmopressin via release of endothelial stores of factor VIII and vWF into plasma; however, most patients require administration of exogenous factor VIII to achieve hemostasis. The in vivo half-life of factor VIII is generally 8–12 hours but may vary considerably among individuals. Non–life-threatening, non–limb-threatening hemorrhage is treated initially with 20–30 U/kg of factor VIII, to achieve a rise in plasma factor VIII activity to 40%–60%. Large joint hemarthrosis and life- or limb-threatening hemorrhage is treated initially with



approximately 50 U/kg of factor VIII, targeting a rise to 100% factor VIII activity. Subsequent doses are determined according to the site and extent of bleeding and the clinical response. In circumstances of suboptimal clinical response, recent change in bleeding frequency, or comorbid illness, monitoring the plasma factor VIII activity response may be warranted. For most instances of non–life-threatening hemorrhage in experienced patients with moderate or severe hemophilia A, treatment can be administered at home, provided adequate intravenous access and close contact with the hemophilia clinical team.

Prophylactic factor VIII infusions (eg, two or four times weekly) may prevent the development of arthropathy in severe hemophiliacs, and this approach is the standard of care in pediatric hemophilia. Extended half-life factor VIII concentrates have been approved by the FDA with the hope of decreasing infusions and improving clinical outcomes caused by bleeding.

» Prognosis

The development of safe and effective therapies for hemophilia A has resulted in improved long-term survival in recent decades. In addition, more aggressive management and the coordination of comprehensive care through hemophilia centers have greatly improved quality of life and level of function.

Blanchette VS: Meeting unmet needs in inhibitor patients. Haemophilia 2010;16(Suppl 3):46–51 [PMID: 20586802].

Srivastava A: Guidelines for the management of hemophilia. 2012;19(1):1–47 [PMID: 22776238].

2. Factor IX Deficiency (Hemophilia B, Christmas Disease)

The mode of inheritance and clinical manifestations of factor IX deficiency are the same as those of factor VIII deficiency. Hemophilia B is 15%–20% as prevalent as hemophilia A. Factor IX deficiency is associated with a prolonged aPTT, but the PT and thrombin time are normal. However, the aPTT is slightly less sensitive to factor IX deficiency than factor VIII deficiency. Diagnosis of hemophilia B is made by assaying factor IX activity, and severity is determined similar to hemophilia A. In general, clinical bleeding severity correlates less well with factor activity in hemophilia B than in A.

The mainstay of treatment in hemophilia B is exogenous factor IX. Unlike factor VIII, about 50% of the administered dose of factor IX diffuses into the extravascular space. Therefore, 1 U/kg of plasma-derived factor IX concentrate or recombinant factor IX is expected to increase plasma factor IX activity by approximately 1%. Factor IX typically has a half-life of 20–22 hours in vivo, but because of variability, therapeutic monitoring may be warranted. As for factor VIII products, viral-inactivation techniques for plasma-derived factor IX concentrates appear effective in eradicating enveloped viruses. Only 1%–3% of persons with factor IX deficiency develop an inhibitor to factor IX, but patients may be at risk for anaphylaxis when receiving exogenous factor IX. The prognosis for persons with factor IX deficiency is comparable to that of patients with factor VIII deficiency. Gene therapy research efforts are ongoing for both hemophilias.

Aledort LM: Optimizing the treatment of haemophilia B: laboratory and clinical perspectives. Haemophilia 2010;16(Suppl 6): 1–2 [PMID: 20561350].

Santagostino E: Prophylaxis in haemophilia B patients: unresolved issues and pharmacoeconomic implications. Haemophilia 2010;16(Suppl 60):13–17 [PMID: 20561353].

3. Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a genetic, autosomally transmitted coagulopathy, typically of mild to moderate clinical severity. Cases of factor XI deficiency account for less than 5% of all hemophilia patients. Homozygotes generally bleed at surgery or following severe trauma and at hyperfibrinolytic sites, but do not commonly have spontaneous hemarthroses. In contrast to factor VIII and IX deficiencies, factor XI activity is least predictive of bleeding risk. Although typically mild, pathologic bleeding may be seen in heterozygous individuals with factor XI activity as high as 60%. The aPTT is often considerably prolonged. In individuals with deficiency of both plasma and platelet-associated factor XI, the PFA-100 may also be prolonged. Management typically consists of perioperative prophylaxis and episodic therapy for acute hemorrhage. Treatment includes infusion of fresh frozen plasma (FFP); platelet transfusion may also be useful for acute hemorrhage in patients with deficiency of platelet-associated factor XI. Desmopressin has been used in some cases, and antifibrinolytic therapy is common. The prognosis for an average life span in patients with factor XI deficiency is excellent.

Gomez K: Factor XI deficiency. Haemophilia 2008;14(6):1183–1189 [PMID: 18312365].

4. Other Inherited Bleeding Disorders

Other hereditary single clotting factor deficiencies are rare. Transmission is generally autosomal. Homozygous individuals with a deficiency or structural abnormality of prothrombin, factor V, factor VII, or factor X may have excessive bleeding.

Persons with dysfibrinogenemia (ie, structurally or functionally abnormal fibrinogen) may develop recurrent venous thromboembolic episodes or bleeding. Immunologic assay of fibrinogen is normal, but clotting assay may be low and the

thrombin time prolonged. The PT and aPTT may be prolonged. Cryoprecipitate, which is rich in fibrinogen, has been the treatment of choice. Fibrinogen concentrates are available in the United States, but the clinical experience is limited.

Afibrinogenemia resembles hemophilia clinically but has an autosomal recessive inheritance. Affected patients can experience a variety of bleeding manifestations, including mucosal bleeding, ecchymoses, hematomas, hemarthroses, and intracranial hemorrhage, especially following trauma. Fatal umbilical cord hemorrhage has been reported in neonates. The PT, aPTT, and thrombin time are all prolonged. A severely reduced fibrinogen concentration in an otherwise well child is confirmatory of the diagnosis. As in dysfibrinogenemia, fibrinogen concentrate or cryoprecipitate infusion is used for surgical prophylaxis and for acute hemorrhage.

Todd T: A review of long-term prophylaxis in the rare inherited coagulation factor deficiencies. Haemophilia 2010;16(4): 569–583 [PMID: 19906159].

VON WILLEBRAND DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Easy bruising and epistaxis from early childhood.
- Menorrhagia.
- Prolonged PFA-100 (or bleeding time), normal platelet count, absence of acquired platelet dysfunction.
- Reduced amount or abnormal activity of vWf.

» General Considerations

von Willebrand disease (vWD) is the most common inherited bleeding disorder among Caucasians, with a prevalence of 1%. vWF is a protein present as a multimeric complex in plasma, which binds factor VIII and is a cofactor for platelet adhesion to the endothelium. An estimated 70%–80% of all patients with vWD have classic vWD (type 1), which is caused by a partial quantitative deficiency of vWF. vWD type 2 involves a qualitative deficiency of (ie, dysfunctional) vWF, and vWD type 3 is characterized by a nearly complete deficiency of vWF. The majority (> 80%) of individuals with type 1 disease are asymptomatic. vWD is most often transmitted as an autosomal dominant trait, but it can be autosomal recessive. The disease can also be acquired, developing in association with hypothyroidism, Wilms tumor, cardiac disease, renal disease, or systemic lupus erythematosus, and in individuals receiving valproic acid. Acquired vWD is most often caused by the development of an antibody to vWF or increased turnover of vWF.

» Clinical Findings

A. Symptoms and Signs

A history of increased bruising and excessive epistaxis is often present. Prolonged bleeding also occurs with trauma or at surgery. Menorrhagia is often a presenting finding in females.

B. Laboratory Findings

PT is normal, and aPTT is sometimes prolonged. Prolongation of the PFA-100 or bleeding time is usually present since vWF plays a role in platelet adherence to endothelium. Platelet number may be decreased in type 2b vWD. Factor VIII and vWF antigen are decreased in types 1 and 3, but may be normal in type 2 vWD. vWF activity (eg, ristocetin cofactor or collagen binding) is decreased in all types. Since normal vWF antigen levels vary by blood type (type O normally has lower levels), blood type must be determined. Complete laboratory classification requires vWF multimer assay. The diagnosis requires confirmation of laboratory testing and bleeding history is often helpful when present.

» Treatment

The treatment to prevent or halt bleeding for many patients with vWD types 1 and 2 is desmopressin acetate, which causes release of vWF from endothelial stores. Desmopressin may be administered intravenously or subcutaneously, and typically elicits a three- to fivefold rise in plasma vWF. A high-concentration desmopressin nasal spray (150 mcg/spray), different from the preparation used for enuresis, may be used. Because response to vWF is variable among patients, factor VIII and vWF activities are typically measured 30–60 minutes before and 4 hours after infusion, to document the adequacy of the response. Desmopressin may cause fluid shifts, hyponatremia, and seizures; therefore, fluid restriction should be discussed, especially in children younger than 2 years. Because release of stored vWF is limited, tachyphylaxis often occurs with desmopressin.

If further therapy is indicated, vWF-replacement therapy (eg, plasma-derived concentrate) is recommended; such therapy is also used in patients with type 1 or 2a vWD who exhibit suboptimal laboratory response to desmopressin, and for all individuals with type 2b or 3 vWD. Antifibrinolytic agents (eg, ε-aminocaproic acid) may be useful for control of mucosal bleeding. Topical thrombin and fibrin glue may also be of benefit, although antibodies that inhibit these clotting proteins occur and therefore limit the affect of the glue. Estrogen-containing contraceptive therapy may be helpful for menorrhagia.

» Prognosis

With the availability of effective treatment and prophylaxis for bleeding, life expectancy in vWD is normal.

Branchford BR, Di Paola J: Making a diagnosis of VWD. Hematology Am Soc Hematol Educ Program 2012;2012:161 [PMID: 23233576].

ACQUIRED BLEEDING DISORDERS

1. Disseminated Intravascular Coagulation

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Presence of a disorder known to trigger DIC.
- Evidence for consumptive coagulopathy (prolonged aPTT, PT, or thrombin time; increase in FSPs [fibrin-fibrinogen split products]; decreased fibrinogen or platelets).

» General Considerations

Disseminated intravascular coagulation (DIC) is an acquired pathologic process characterized by tissue factor–mediated coagulation activation in the host. DIC involves dysregulated, excessive thrombin generation, with consequent intravascular fibrin deposition and consumption of platelets and procoagulant factors. Microthrombi, composed of fibrin and platelets, may produce tissue ischemia and end-organ damage. The fibrinolytic system is frequently activated in DIC, leading to plasmin-mediated destruction of fibrin and fibrinogen; this results in fibrin-fibrinogen degradation products (FDPs) that exhibit anticoagulant and platelet-inhibitory functions. DIC commonly accompanies severe infection and other critical illnesses in infants and children. Conditions known to trigger DIC include endothelial damage (eg, endotoxin, virus), tissue necrosis (eg, burns), diffuse ischemic injury (eg, shock, hypoxia acidosis), and systemic release of tissue procoagulants (eg, certain cancers, placental disorders).

» Clinical Findings

A. Symptoms and Signs

Signs of DIC may include (1) signs of shock, often including end-organ dysfunction, (2) diffuse bleeding tendency (eg, hematuria, melena, purpura, petechiae, persistent oozing from needle punctures or other invasive procedures), and (3) evidence of thrombotic lesions (eg, major vessel thrombosis, purpura fulminans).

B. Laboratory Findings

Tests that are most sensitive, easiest to perform, most useful for monitoring, and best reflect the hemostatic capacity of the patient are the PT, aPTT, platelet count, fibrinogen, and FSPs. The PT and aPTT are typically prolonged and the platelet count and fibrinogen concentration may be decreased. However, in children, the fibrinogen level may be normal until late in the course. Levels of FSPs are increased, and elevated levels of d-dimer, a cross-linked fibrin degradation byproduct, may be helpful in monitoring the degree of activation of both coagulation and fibrinolysis. However, d-dimer is nonspecific and may be elevated in the context of a triggering event (eg, severe infection) without concomitant DIC. Often, physiologic inhibitors of coagulation, especially antithrombin III and protein C, are consumed, predisposing to thrombosis. The specific laboratory abnormalities in DIC may vary with the triggering event and the course of illness.

» Differential Diagnosis

DIC can be difficult to distinguish from coagulopathy of liver disease (ie, hepatic synthetic dysfunction), especially when the latter is associated with thrombocytopenia secondary to portal hypertension and hypersplenism. Generally, factor VII activity is decreased markedly in liver disease (due to deficient synthesis of this protein, which has the shortest half-life among the procoagulant factors), but only mildly to moderately decreased in DIC (due to consumption). Factor VIII activity is often normal or even increased in liver disease, but decreased in DIC.

» Treatment

A. Therapy for Underlying Disorder

The most important aspect of therapy in DIC is the identification and treatment of the triggering event. If the pathogenic process underlying DIC is reversed, often no other therapy is needed for the coagulopathy.

B. Replacement Therapy for Consumptive Coagulopathy

Replacement of consumed procoagulant factors with FFP and of platelets via platelet transfusion is warranted in the setting of DIC with hemorrhagic complications, or as periprocedural bleeding prophylaxis. Infusion of 10–15 mL/kg FFP typically raises procoagulant factor activities by approximately 10%–15%. Cryoprecipitate can also be given as a rich source of fibrinogen; one bag of cryoprecipitate per 3 kg in infants or one bag of cryoprecipitate per 6 kg in older children typically raises plasma fibrinogen concentration by 75–100 mg/dL.

C. Anticoagulant Therapy for Coagulation Activation

Continuous intravenous infusion of unfractionated heparin is sometimes given in order to attenuate coagulation activation and consequent consumptive coagulopathy. The rationale for heparin therapy is to maximize the efficacy of, and minimize the need for, replacement of procoagulants and platelets; however, clinical evidence demonstrating benefit of heparin in DIC is lacking. Prophylactic doses of unfractionated heparin or low-molecular-weight heparin (LMWH) in critically ill and nonbleeding patients with DIC may be considered for prevention of venous thromboembolism. Unfractionated heparin dosing and monitoring is listed on page 934.

D. Specific Factor Concentrates

A nonrandomized pilot study of antithrombin concentrate in children with DIC and associated acquired antithrombin deficiency demonstrated favorable outcomes, suggesting that replacement of this consumed procoagulant may be of benefit. Protein C concentrate has also shown promise in two small pilot studies of meningococci-associated DIC with purpura fulminans. Activated protein C has reduced mortality in septic adults in a large randomized multicenter trial; in additional studies, efficacy in adults and pediatrics is increasingly controversial.

2. Liver Disease

The liver is the major synthetic site of prothrombin; fibrinogen; high-molecular-weight kininogen; and factors V, VII, IX, X, XI, XII, and XIII. In addition, plasminogen and the physiologic anticoagulants (antithrombin III, protein C, and protein S) are hepatically synthesized. α_2-Antiplasmin, a regulator of fibrinolysis, is also produced in the liver. Deficiency of factor V and the vitamin K–dependent factors (II, VII, IX, and X) is most often a result of decreased hepatic synthesis, and is manifested by a prolonged PT and often a prolonged aPTT. Extravascular loss and increased consumption of clotting factors may contribute to PT and aPTT prolongation. Fibrinogen production is often decreased, or an abnormal fibrinogen (dysfibrinogen) containing excess sialic acid residues may be synthesized, or both. Hypofibrinogenemia or dysfibrinogenemia is associated with prolongation of thrombin time and reptilase time. FDPs and d-dimers may be present because of increased fibrinolysis, particularly in the setting of chronic hepatitis or cirrhosis. Thrombocytopenia secondary to hypersplenism may occur. DIC and coagulopathy of liver disease also mimic vitamin K deficiency; however, vitamin K deficiency has normal factor V activity. Treatment of acute bleeding in the setting of coagulopathy of liver disease consists of replacement with FFP and platelets. Desmopressin may shorten the bleeding time and aPTT in patients with chronic liver disease, but its safety has not been well established. Recombinant VIIa also is efficacious for life-threatening hemorrhage.

3. Vitamin K Deficiency

The newborn period is characterized by physiologically depressed activity of the vitamin K–dependent factors (II, VII, IX, and X). If vitamin K is not administered at birth, a bleeding diathesis previously called hemorrhagic disease of the newborn and now termed vitamin K deficiency bleeding (VKDB) may develop. Outside of the newborn period, vitamin K deficiency may occur as a consequence of inadequate intake, excess loss, inadequate formation of active metabolites, or competitive antagonism.

One of three patterns is seen in the neonatal period:

1. Early VKDB of the newborn occurs within 24 hours of birth and is most often manifested by cephalohematoma, intracranial hemorrhage, or intra-abdominal bleeding. Although occasionally idiopathic, it is most often associated with maternal ingestion of drugs that interfere with vitamin K metabolism (eg, warfarin, phenytoin, isoniazid, and rifampin). Early VKDB occurs in 6%–12% of neonates born to mothers who take these medications without receiving vitamin K supplementation. The disorder is often life threatening.
2. Classic VKDB occurs at 24 hours to 7 days of age and usually is manifested as gastrointestinal, skin, or mucosal bleeding. Bleeding after circumcision may occur. Although occasionally associated with maternal drug usage, it most often occurs in well infants who do not receive vitamin K at birth and are solely breast fed.
3. Late neonatal VKDB occurs on or after day 8. Manifestations include intracranial, gastrointestinal, or skin bleeding. This disorder is often associated with fat malabsorption (eg, in chronic diarrhea) or alterations in intestinal flora (eg, with prolonged antibiotic therapy). Like classic VKDB, late VKDB occurs almost exclusively in breast-fed infants.

The diagnosis of vitamin K deficiency is suspected based on the history, physical examination, and laboratory results. The PT is prolonged out of proportion to the aPTT (also prolonged). The thrombin time becomes prolonged late in the course. The platelet count is normal. This laboratory profile is similar to the coagulopathy of acute liver disease, but with normal fibrinogen level and absence of hepatic transaminase elevation. The diagnosis of vitamin K deficiency is confirmed by a demonstration of noncarboxylated proteins in the absence of vitamin K in the plasma and by clinical and laboratory responses to vitamin K. Intravenous or subcutaneous treatment with vitamin K should be given immediately and not withheld while awaiting test results. In the setting of severe bleeding, additional acute treatment with FFP or recombinant factor VIIa may be indicated.

4. Uremia

Uremia is frequently associated with acquired platelet dysfunction. Bleeding occurs in approximately 50% of patients with chronic renal failure. The bleeding risk conferred by platelet dysfunction associated with metabolic imbalance may be compounded by decreased vWF activity and procoagulant deficiencies (eg, factor II, XII, XI, IX) due to increased urinary losses of these proteins in some settings of renal insufficiency. In accordance with platelet dysfunction, uremic bleeding is typically characterized by purpura, epistaxis, menorrhagia, or gastrointestinal hemorrhage. Acute bleeding may be managed with infusion of desmopressin acetate, factor VIII concentrates containing vWF, or cryoprecipitate with or without coadministration of FFP. Red cell transfusion may be required. Prophylactic administration of erythropoietin before the development of severe anemia appears to decrease the potential for bleeding. Recombinant VIIa may be useful in refractory bleeding.

VASCULAR ABNORMALITIES ASSOCIATED WITH BLEEDING

1. Henoch-Schönlein Purpura (Anaphylactoid Purpura)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purpuric cutaneous rash.
- Migratory polyarthritis or polyarthralgias.
- Intermittent abdominal pain.
- Nephritis.

» General Considerations

Henoch-Schönlein purpura (HSP), the most common type of small vessel vasculitis in children, primarily affects boys 2–7 years of age. Occurrence is highest in the spring and fall, and upper respiratory infection precedes the diagnosis in two-thirds of children.

Leukocytoclastic vasculitis in HSP principally involves the small vessels of the skin, gastrointestinal tract, and kidneys, with deposition of IgA immune complexes. The most common and earliest symptom is palpable purpura, which results from extravasation of erythrocytes into the tissue surrounding the involved venules. Antigens from group A β-hemolytic streptococci and other bacteria, viruses, drugs, foods, and insect bites have been proposed as inciting agents.

» Clinical Findings

A. Symptoms and Signs

Skin involvement may be urticarial initially, progresses to a maculopapules, and coalesces to a symmetrical, palpable purpuric rash distributed on the legs, buttocks, and elbows. New lesions may continue to appear for 2–4 weeks, and may extend to involve the entire body. Two-thirds of patients develop migratory polyarthralgias or polyarthritis, primarily of the ankles and knees. Intermittent, sharp abdominal pain occurs in approximately 50% of patients, and hemorrhage and edema of the small intestine can often be demonstrated. Intussusception may develop. From 25% to 50% of those affected develop renal involvement in the second or third week of illness with either a nephritic or, less commonly, nephrotic picture. Hypertension may accompany the renal involvement. In males, testicular torsion may also occur, and neurologic symptoms are possible due to small vessel vasculitis.

B. Laboratory Findings

The platelet count is normal or elevated, and other screening tests of hemostasis and platelet function are typically normal. Urinalysis frequently reveals hematuria, and sometimes proteinuria. Stool may be positive for occult blood. The antistreptolysin O (ASO) titer is often elevated and the throat culture positive for group A β-hemolytic streptococci. Serum IgA may be elevated.

» Differential Diagnosis

The rash of septicemia (especially meningococcemia) may be similar to skin involvement in HSP, although the distribution tends to be more generalized. The possibility of trauma should be considered in any child presenting with purpura. Other vasculitides should also be considered. The lesions of thrombotic thrombocytopenic purpura (TTP) are not palpable.

» Treatment

Generally, treatment is supportive. NSAIDs may be useful for the arthritis. Corticosteroid therapy may provide symptomatic relief for severe gastrointestinal or joint manifestations but does not alter skin or renal manifestations. If

culture for group A β-hemolytic streptococci is positive or if the ASO titer is elevated, a therapeutic course of penicillin is warranted.

» Prognosis

The prognosis for recovery is generally good, although symptoms frequently (25%–50%) recur over a period of several months. In patients who develop renal manifestations, microscopic hematuria may persist for years. Progressive renal failure occurs in less than 5% of patients with HSP, with an overall fatality rate of 3%.

McCarthy HJ: Clinical practice: diagnosis and management of Henoch-Schönlein purpura. Eur J Pediatr 2010;169:643–650 [PMID: 20012647].

2. Collagen Disorders

Mild to life-threatening bleeding occurs with some types of Ehlers-Danlos syndrome, the most common inherited collagen disorder. Ehlers-Danlos syndrome is characterized by joint hypermobility, skin extensibility, and easy bruising. Coagulation abnormalities may sometimes be present, including platelet dysfunction and deficiencies of coagulation factors VIII, IX, XI, and XIII. However, bleeding and easy bruising, in most instances, relates to fragility of capillaries and compromised vascular integrity. Individuals with Ehlers-Danlos syndrome types 4 and 6 are at risk for aortic dissection and spontaneous rupture of aortic aneurysms. Surgery should be avoided for patients with Ehlers-Danlos syndrome, as should medications that induce platelet dysfunction.

Key NS, DE Paepe A, Malfait F, Shovlin CL: Vascular hemostasis. Haemophilia 2010 Jul;16(Suppl 5):146 [PMID: 20590874].

° THROMBOTIC DISORDERS

» General Considerations

Although uncommon in children, thrombotic disorders are being recognized with increasing frequency, particularly with heightened physician awareness and improved survival in pediatric intensive care settings. Several clinical conditions have a potential association with thrombotic events in childhood.

» Clinical Findings

Initial evaluation of the child who has thrombosis includes an assessment for potential triggering factors, as well as a family history of thrombosis and early cardiovascular or cerebrovascular disease.

A. Clinical Risk Factors

Clinical risk factors are present in more than 90% of children with acute venous thromboembolism (VTE). These conditions include the presence of an indwelling vascular catheter, cardiac disease, infection, trauma, surgery, immobilization, collagen-vascular or chronic inflammatory disease, renal disease, sickle cell anemia, and malignancy. Prospective findings employing serial radiologic evaluation as screening indicate that the risk of VTE is nearly 30% for short-term central venous catheters placed in the internal jugular veins.

Retrospective data suggest that approximately 8% of children with cancer develop symptomatic VTE.

1. Inherited Thrombophilia (Hypercoagulable) States

a. Protein c deficiency—Protein C is a vitamin K–dependent protein that is normally activated by thrombin bound to thrombomodulin and inactivates activated factors V and VIII. In addition, activated protein C promotes fibrinolysis. Two phenotypes of hereditary protein C deficiency exist. Heterozygous individuals with autosomal dominant protein C deficiency often present with VTE as young adults, but the disorder may manifest during childhood or in later adulthood. In mild protein C deficiency, anticoagulant prophylaxis is typically limited to periods of increased prothrombotic risk. Homozygous or compound heterozygous protein C deficiency is rare but phenotypically severe. Affected children generally present within the first 12 hours of life with purpura fulminans (Figure 30–6) and/or VTE. Prompt protein C replacement by infusion of protein C concentrate (if unavailable) or FFP every 6–12 hours, along with therapeutic heparin administration, is recommended. Subsequent management requires chronic anticoagulation with warfarin, sometimes along with routine protein C concentrate infusion in order to permit lower warfarin dosing. Recurrent VTE is common, especially during periods of subtherapeutic anticoagulation or in the presence of conditions associated with increased prothrombotic risk.

b. Protein s deficiency—Protein S is a cofactor for protein C. Neonates with homozygous protein S deficiency have a course similar to those with homozygous or compound heterozygous protein C deficiency. Lifelong warfarin therapy is indicated in homozygous/severe deficiency, or in heterozygous individuals who have experienced recurrent VTE. Efforts must be made to distinguish these conditions from acquired deficiency, which can be antibody-mediated or secondary to an increase in C4b-binding protein induced by inflammation.

c. Antithrombin deficiency—Antithrombin, which is the most important physiologic inhibitor of thrombin, also

▲**Figure 30–6.** Purpura fulminans in an infant with severe protein C deficiency.

inhibits activated factors IX, X, XI, and XII. Antithrombin deficiency is transmitted in an autosomal dominant pattern and is associated with VTE, typically with onset in adolescence or young adulthood. Therapy for acute VTE can involve replacement with antithrombin concentrate in addition to therapeutic anticoagulation. The efficiency of heparin may be significantly diminished in the setting of severe antithrombin deficiency and it often requires supplementation of antithrombin via concentrate. Patients with homozygous/severe deficiency or recurrent VTE are maintained on lifelong warfarin.

d. Factor v leiden mutation—An amino acid substitution in the gene coding for factor V results in factor V Leiden, a factor V polymorphism that is resistant to inactivation by activated protein C. The most common cause of activated protein C resistance in Caucasians, factor V Leiden is present in approximately 5% of the Caucasian population, 20% of Caucasian adults with deep vein thrombosis, and 40%–60% of those with a family history of VTE. VTE occurs in both heterozygous and homozygous individuals. In the former case, thrombosis is typically triggered by a clinical risk factor (or else develops in association with additional thrombophilia traits), whereas in the latter case, it is often spontaneous. Population studies suggest that the risk of incident VTE is increased two- to sevenfold in the setting of heterozygous factor V Leiden, 35-fold among heterozygous individuals taking the oral contraceptives, and 80-fold in those homozygous for factor V Leiden.

e. Prothrombin mutation—The 20210 glutamine to alanine mutation in the prothrombin gene is a relatively common polymorphism in Caucasians that enhances its activation to thrombin. In heterozygous form, this mutation is associated with a two- to threefold increased risk for incident VTE. This mutation also appears to modestly increase the risk for recurrent VTE.

f. Other inherited disorders—Qualitative abnormalities of fibrinogen (dysfibrinogenemias) are usually inherited in an autosomal dominant manner. Most individuals with dysfibrinogenemia are asymptomatic. Some patients experience bleeding, while others develop venous or arterial thrombosis. The diagnosis is suggested by a prolonged thrombin time with a normal fibrinogen concentration. Hyperhomocysteinemia can be an inherited or an acquired condition and is associated with an increased risk for both arterial and venous thromboses. In children, it may also serve as a risk factor for ischemic arterial stroke. Hyperhomocysteinemia is quite uncommon in the setting of dietary folate supplementation (as in the United States) and is observed almost uniquely in cases of renal insufficiency or metabolic disease (eg, homocystinuria). Methylene tetrahydrofolate reductase receptor mutations do not appear to constitute a risk factor for thrombosis in US children if homocysteine is not elevated.

Lipoprotein(a) is a lipoprotein with homology to plasminogen. In vitro studies suggest that lipoprotein(a) may both promote atherothrombosis and inhibit fibrinolysis. Some evidence to date suggests that elevated plasma concentrations of lipoprotein(a) are associated with an increased risk of VTEs and recurrent ischemic arterial stroke in children.

Increased factor VIII activity is a risk factor for incident and recurrent VTE and is common among children with acute VTE. Elevation in factor VIII may persist in the long-term follow-up of these patients, and can be inherited.

2. Acquired Disorders

a. Antiphospholipid antibodies—The development of antiphospholipid antibodies is the most common form of acquired thrombophilia in children. Antiphospholipid antibodies, which include the lupus anticoagulant, anticardiolipin antibodies, and β_2-glycoprotein-1 antibodies (among others), are common in acute childhood VTE. The lupus anticoagulant is demonstrated in vitro by its inhibition of phospholipid-dependent coagulation assays (eg, aPTT and dilute Russell viper venom time), whereas immunologic techniques (eg, enzyme-linked immunosorbent assays) are often used to detect anticardiolipin and β_2-glycoprotein-1 antibodies. Although common in persons with autoimmune

diseases such as systemic lupus erythematosus, antiphospholipid antibodies may also develop following certain drug exposures, infection, acute inflammation, and lymphoproliferative diseases. Sometimes VTE and antiphospholipid antibodies may predate other signs of lupus for long periods of time. Viral illness is a common precipitant in children, and in many cases, the inciting infection may be asymptomatic.

If an antiphospholipid antibody persists for 12 weeks following the acute thrombotic event, the diagnosis of antiphospholipid syndrome is confirmed. Optimal duration of anticoagulation in this setting is unclear, such that current pediatric treatment guidelines recommend a 3-month to lifelong course.

b. Deficiencies of intrinsic anticoagulants—Acquired deficiencies of proteins C and S and antithrombin may occur in the clinical context of antibodies (eg, protein S antibodies in acute varicella), excessive consumption, including sepsis, DIC, major-vessel or extensive VTE, and post–bone marrow transplant sinusoidal obstruction syndrome (formerly termed hepatic veno-occlusive disease), or excessive loss, such as inpatients with nephrotic syndrome, protein-losing enteropathy or liver failure.

c. Acute phase reactants—As part of the acute phase response, elevations in plasma fibrinogen concentration, plasma factor VIII, and platelet count may occur, all of which may contribute to an acquired prothrombotic state.

Reactive thrombocytosis is rarely associated with VTEs in children when the platelet count is less than 1 million/μL.

B. Symptoms and Signs

Presenting features of thrombosis vary with the anatomic site, extent of vascular involvement, degree of vaso-occlusion, and presence of end-organ dysfunction. The classic presentation of deep venous thrombosis of an upper or lower extremity is painful acute or subacute extremity swelling, while that for pulmonary embolism commonly involves dyspnea and pleuritic chest pain, and in cerebral sinovenous thrombosis (CSVT) often includes severe or persistent headache, with or without neurologic deficit in otherwise well children. Arterial thrombosis of the lower extremity (eg, neonatal umbilical artery catheter–associated), as well as vasospasm without identified thrombosis, often manifests with diminished distal pulses and dusky discoloration of the limb.

C. Laboratory Findings

A comprehensive laboratory investigation for thrombophilia (ie, hypercoagulability) was recommended in 2002 by the International Society on Thrombosis and Haemostasis in order to disclose possible underlying congenital or acquired abnormalities that may affect acute or long-term management; however, there remains controversy and wide variation of practice. Recent trends favor thrombophilia testing in adolescents with spontaneous thrombosis, and in neonates/children with non–catheter-related thrombosis and stroke. There are insufficient data to recommend routine thrombophilia testing in neonates/children with catheter-related thrombosis. When indicated, thrombophilia testing includes evaluation for intrinsic anticoagulant deficiency (proteins C and S and antithrombin), procoagulant factor excess (eg, factor VIII), proteins and genetic mutations mediating enhanced procoagulant activity or reduced sensitivity to inactivation (antiphospholipid antibodies; factor V Leiden and prothrombin 20210 polymorphisms), biochemical mediators of endothelial damage (homocysteine), and markers or regulators of fibrinolysis (eg, d-dimer, plasminogen activator inhibitor-1, and lipoprotein[a]). Interpretation of procoagulant factor and intrinsic anticoagulant levels should take into account the age dependence of normal values for these proteins. Among these VTE risk factors, antiphospholipid antibodies and elevated levels of homocysteine and lipoprotein(a) have also been demonstrated as risk factors for arterial thrombotic and ischemic events.

D. Imaging

Appropriate radiologic imaging is essential to objectively document the thrombus and to delineate the type (venous vs arterial), occlusiveness, and extent (proximal and distal termini) of thrombosis. Depending on site, typical imaging modalities include compression ultrasound with Doppler, computed tomographic (CT) venography, magnetic resonance venography, and conventional angiography.

» Treatment

Current guidelines for the treatment of first-episode VTE in children have been largely based on adult experience and include therapeutic anticoagulation for at least 3 months. During the period of anticoagulation, bleeding precautions should be followed, as previously described (see Treatment under Idiopathic Thrombocytopenic Purpura, earlier). In CVST, presentation with postthrombotic hemorrhage often does not necessarily preclude anticoagulant therapy. Initial therapy for acute VTE employs continuous intravenous unfractionated heparin or subcutaneous injections of LMWH) for at least 7 days, monitored by anti-Xa activity level to maintain anticoagulant levels of 0.3–0.7 or 0.5–1.0 IU/mL, respectively. Subsequent extended anticoagulant therapy is given with LMWH or daily oral warfarin, the latter agent monitored by the PT to maintain an international normalized ratio (INR) of 2.0–3.0. During warfarin treatment, the INR optimally should be within the therapeutic range for 2 consecutive days before discontinuation of heparin.

Warfarin pharmacokinetics are affected by acute illness, numerous medications, and changes in diet, and can necessitate frequent monitoring. In children, warfarin dose is determined by age and weight. LMWH offers the advantage of infrequent need for monitoring but is far more expensive than warfarin. Anatomic contributions to venous stasis (eg, mastoiditis or depressed skull fracture as risk factors for CVST; congenital left iliac vein stenosis in DVT of proximal left lower extremity with May-Thurner anomaly) should be addressed to optimize response to anticoagulation. In cases of limb- or life-threatening VTEs, including major proximal pulmonary embolus, and in cases of progressive VTE despite therapeutic anticoagulation, thrombolytic therapy (eg, tissue-type plasminogen activator) may be considered. Whether thrombolytic therapy may also reduce the risk of the postthrombotic syndrome (PTS) in children with veno-occlusive deep venous thrombosis of the proximal limbs in whom adverse prognostic biomarkers (ie, elevated factor VIII and D-dimer levels) are present at diagnosis needs further prospective evaluation. In adolescent females, estrogen-containing contraceptives are relatively contraindicated in those with prior VTE, particularly if an additional genetic cause for impairment of protein C pathway is disclosed.

» Prognosis

Registries and cohort studies have suggested that recurrent VTE occurs in approximately 10% of children within 2 years. Persistent thrombosis is evident following completion of a standard therapeutic course of anticoagulation in up to 30% of children, with unclear clinical importance. Approximately one in four children with deep venous thrombosis involving the extremities develops postthrombotic syndrome, a condition of venous insufficiency of varying severity characterized by chronic skin changes, edema, and dilated collateral superficial venous formation, and often accompanied by functional limitation (pain with activities or at rest). Complete veno-occlusion and elevated levels of factor VIII and d-dimer at VTE diagnosis have been identified as prognostic factors for PTS among children with deep venous thrombosis affecting the limbs. The presence of homozygous anticoagulant deficiencies, multiple thrombophilia traits, or persistent antiphospholipid antibodies following VTE diagnosis has been associated with increased risk of recurrent VTE, leading to consideration of extended anticoagulation in these instances. In CSVT, failure to provide antithrombotic therapy has been associated with adverse neurologic outcome.

° SPLENIC ABNORMALITIES

SPLENOMEGALY & HYPERSPLENISM

The differential diagnosis of splenomegaly includes the general categories of congestive splenomegaly, chronic infections, leukemia and lymphomas, hemolytic anemias, reticuloendothelioses, and storage diseases (Table 30–9).

Splenomegaly due to any cause may be associated with hypersplenism and the excessive destruction of circulating red cells, white cells, and platelets. The degree of cytopenia is variable and, when mild, requires no specific therapy. In other cases, the thrombocytopenia may cause life-threatening bleeding, particularly when the splenomegaly is secondary to portal hypertension and associated with esophageal varices or the consequence of a storage disease. In such cases, treatment with surgical splenectomy or with splenic embolization may be warranted. Although more commonly associated with acute enlargement, rupture of an enlarged spleen can be seen in more chronic conditions such as Gaucher disease.

Thomas AS, Mehta A, Hughes DA: Gaucher disease:; hematological presentations and complications. Br J Haematol 2014;165:427–440 [PMID: 24588457].

ASPLENIA & SPLENECTOMY

Children who lack normal splenic function are at risk for sepsis, meningitis, and pneumonia due to encapsulated bacteria such as pneumococci, meningococcus, and H influenzae. Such infections are often fulminant and fatal because of inadequate antibody production and impaired phagocytosis of circulating bacteria.

Congenital asplenia is usually suspected when an infant is born with abnormalities of abdominal viscera and complex cyanotic congenital heart disease. Howell-Jolly bodies are usually present on the peripheral blood smear, and the absence of splenic tissue is confirmed by technetium radionuclide scanning. The prognosis depends on the underlying cardiac lesions, and many children die during the first few months. Prophylactic antibiotics, usually penicillin, and pneumococcal conjugate, Hib, and meningococcal vaccines are recommended.

The risk of overwhelming sepsis following surgical splenectomy is related to the child's age and to the underlying disorder. Because the risk is highest when the procedure is

Table 30–9. Causes of chronic splenomegaly in children.

Cause	Associated Clinical Findings	Diagnostic Investigation
Congestive splenomegaly	History of umbilical vein catheter or neonatal omphalitis; signs of portal hypertension (varices, hemorrhoids, dilated abdominal wall veins); pancytopenia; history of hepatitis or jaundice	Complete blood count, platelet count, liver function tests, ultrasonography
Chronic infections	History of exposure to tuberculosis, histoplasmosis, coccidiomycosis, other fungal disease; chronic sepsis (foreign body in bloodstream; subacute infective endocarditis)	Appropriate cultures and skin tests, ie, blood cultures; PPD, fungal serology and antigen tests, chest film; HIV serology
Infectious mononucleosis	Fever, fatigue, pharyngitis, rash, adenopathy, hepatomegaly	Atypical lymphocytes on blood smear, monospot, EBV antibody titers
Leukemia, lymphoma, Hodgkin disease	Evidence of systemic involvement with fever, bleeding tendencies, hepatomegaly, and lymphadenopathy; pancytopenia	Blood smear, bone marrow examination, chest film, gallium scan, LDH, uric acid
Hemolytic anemia	Anemia, jaundice; family history of anemia, jaundice, and gallbladder disease in young adults	Reticulocyte count, Coombs test, blood smear, osmotic fragility test, hemoglobin electrophoresis
Reticuloendothelioses (histiocytosis X)	Chronic otitis media, seborrheic or petechial skin rashes, anemia, infections, lymphadenopathy, hepatomegaly, bone lesions	Skeletal radiographs for bone lesions; biopsy of bone, liver, bone marrow, or lymph node
Storages diseases	Family history of similar disorders, neurologic involvement, evidence of macular degeneration, hepatomegaly	Biopsy of liver or bone marrow in search for storage cells
Splenic cyst	Evidence of other infections (postinfectious cyst) or congenital anomalies; peculiar shape of spleen	Radionuclide scan, ultrasonography
Splenic hemangioma	Other hemangiomas, consumptive coagulopathy	Radionuclide scan, arteriography, platelet count, coagulation screen

EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; LDH, lactic dehydrogenase; PPD, purified protein derivative.

performed earlier in life, splenectomy is usually postponed until after age 5 years. The risk of postsplenectomy sepsis is also greater in children with malignancies, thalassemias, and reticuloendothelioses than in children whose splenectomy is performed for ITP, hereditary spherocytosis, or trauma. Prior to splenectomy, children should be immunized against Streptococcus pneumoniae, H influenzae, and Neisseria meningitidis. Additional management should include penicillin prophylaxis and prompt evaluation for fever 38.8°C or above or signs of severe infection.

Children with sickle cell anemia develop functional asplenia during the first year of life, and overwhelming sepsis is the leading cause of early deaths in this disease. Prophylactic penicillin reduces the incidence of sepsis by 84%.

TRANSFUSION MEDICINE

DONOR SCREENING & BLOOD PROCESSING: RISK MANAGEMENT

Minimizing the risks of transfusion begins by screening volunteer donors with a universal donor questionnaire that will protect the recipient from transmission of infectious agents as well as other risks of transfusions. In addition, information defining high-risk groups whose behavior increases the possible transmission of HIV, hepatitis, and other diseases is provided, with the request that persons in these groups not

donate blood. Positive responses may result in temporary or permanent deferral from donation.

Before blood components can be released for transfusion, donor blood is screened for hepatitis B surface antigen; antibodies to hepatitis B core antigen, hepatitis C, HIV-1 and 2, and human T-cell lymphotropic virus (HTLV) I and II; and a serologic test for syphilis (Table 30–10). Screening donor blood for viral genome (nucleic acid amplification [NAT] testing) was mandated for HIV, HCV, and West Nile virus. NAT testing for other viruses may be added in the future, and screening for Chagas disease was accepted in 2007 and is routine in the Southwest. Positive tests are repeated.

Upon confirmation of a positive test, the unit in question is destroyed and the donor is notified and deferred from future donations. Many of the screening tests used are very sensitive and have a high rate of false-positive results. As a result, confirmatory tests have been developed to check the initial screening results and separate the false positives from the true positives, allowing for donors with repeat reactive screening tests on a specific donation to be reentered into

Table 30–10. Transmission risks of infectious agents for which screening of blood products is routinely performed.

Disease Entity	Transmission	Screening and Processing Procedures	Approximate Risk of Transmission
Syphilis	Low risk: fresh blood drawn during spirochetemia can transmit infection. Organism not able to survive beyond 72 h during storage at 4°C.	Donor history. RPR or VDRL.	< 1:100,000
Hepatitis A	Units drawn during prodrome could transmit virus. Because of brief viremia during acute phase, absence of asymptomatic carrier phase, and failure to detect transmission in multiple transfused individuals, infection by this agent is unlikely.	Donor history.	1:1,000,000
Hepatitis B	Prolonged viremia during various phases of the disease and asymptomatic carrier state make HBV infection a significant risk of transfusion. Incidence has markedly decreased with screening strategies. Also, an increasing number of blood recipients have been vaccinated.	Donor history, education, and self-exclusion. HBsAg. Surrogate test for non-A, non-B hepatitis (hepatitis-B core antibody) has helped screen out population at risk for transmitting HBV.	1:500,000–1:200,000
Hepatitis C	Most cases of posttransfusion hepatitis in the past have been related to this virus.	Donor history. Surrogate tests: hepatitis B core antibody (anti-HBc), anti-HCV. Nucleic acid testing for viral genome required.	1:2,000,000
Non-A, non-B, non-C hepatitis	Agents other than HAV, HBV, HCV, EBV, and CMV, which can cause posttransfusion hepatitis.	Donor history. Surrogate tests: anti-HBc.	Undefined
Human immunodeficiency virus (HIV-1, HIV-2) infection	Retroviruses spread by sexual contact, parenteral (including transfusion) and vertical routes.	Donor history, education, and self-exclusion. Anti-HIV by EIA screening test. Western blot confirmatory. Nucleic acid testing for viral genome required.	1:2,000,000
Human T-cell lymphotropic virus I and II (HTLV-I and II) infection	Retroviruses spread by sexual contact, parenteral (including transfusion) and vertical modes.	Donor history. Anti-HTLV-I and II by enzyme immunoassay screening test. Western blot confirmatory.	1:3,000,000
Chagas disease	Transmitted by insect vector, blood transfusion (all components), organ transplant, food contaminated with parasites, and mother to fetus.	History (especially country of origin), detection of antibody in donor serum or plasma.	< 1:25,000
West Nile virus	Seasonal transmission through mosquito vector. Transmitted by blood transfusion and organ transplant.	History, nucleic acid testing for viral genome.	1:350,000

CMV, cytomegalovirus; EBV, Epstein-Barr virus; EIA, enzyme-linked immunosorbent assay; HAV, HBV, HCV, hepatitis A virus, hepatitis B virus, hepatitis C virus, respectively; HIV, human immunodeficiency virus; HBsAg, hepatitis B surface antigen; HTLV, human T-cell lymphotropic virus; RPR, rapid plasma reagin; VDRL, syphilis test.

the donor pool in the future if they meet other requirements. Recently, bacterial culture of apheresis or pooled platelet concentrates was added to the testing paradigm.

With these approaches, the risk of an infectious complication from blood components has been minimized (see Table 30–10). Autologous donation is recognized by some centers as a safe alternative to homologous blood. Issues of donor size limit the use of autologous donation difficult to apply to the pediatric population.

Primary CMV infections are significant complications of blood transfusion in transplant recipients, neonates, and immunodeficient individuals. Transmission of CMV can be avoided by using seronegative donors, apheresis platelet concentrates collected by techniques ensuring low numbers of residual white cells, or red cell or platelet products leukocyte-depleted by filtration (< 5 million WBCs per packed red cell unit or apheresis platelet concentrate equivalent).

STORAGE & PRESERVATION OF BLOOD & BLOOD COMPONENTS

Whole blood is routinely fractionated into packed red cells, platelets, and FFP or cryoprecipitate for most efficient use of all blood components. The storage conditions and biologic characteristics of the fractions are summarized in Table 30–11. The conditions provide the optimal environment to maintain appropriate recovery, survival, and function, and are different for each blood component. For example, red cells undergo dramatic metabolic changes during their 35- to 42-day storage, with a virtual disappearance of 2,3-DPG by day 14 of storage, a decrease in adenosine triphosphate, a gradual loss of intracellular potassium, but in vivo recovery of greater than or equal to 80% transfused cells in red cells by day of storage outdate. Fortunately, these changes are reversed readily in vivo within hours to days after the red cells are transfused. However, in certain clinical conditions, these effects may define the type of components used. For example, blood less than 7 days old would be preferred for exchange transfusion in neonates, red cell exchanges in older patients, or replacement of red cells in persons with severe cardiopulmonary disease to ensure adequate oxygen-carrying capacity. Storage time is not an issue when administering transfusions to those with chronic anemia.

If extracellular potassium in older packed red cells may present a problem, one may use blood less than 10 days old, making packed cells out of an older unit of whole blood or washing blood stored as packed cells.

Platelets are stored at 22°C for a maximum of 5 days; criteria for 7-day storage are being developed. At the extremes of storage, there should be at least a 60% recovery, a survival time that approximates turnover of fresh autologous platelets, and normalization of the bleeding time or PFA-100 in proportion to the peak platelet count. Frozen components, red cells, FFP, and cryoprecipitate are outdated at 10 years, 1 year, and 1 year, respectively. Frozen red cells retain the same biochemical and functional characteristics as the day they were frozen. FFP contains 80% or more of all of the clotting factors of fresh plasma. Factors VIII and XIII, vWF, and fibrinogen are concentrated in cryoprecipitate.

PRETRANSFUSION TESTING

Both the donated blood and the recipient are tested for ABO and Rh(D) antigens and screened for auto- or alloantibodies in the plasma. The cross-match is required on any component that contains red cells. In the major cross-match, washed donor red cells are incubated with the serum from the patient, and agglutination is detected and graded. The antiglobulin phase of the test may then be performed; Coombs reagent, which will detect the presence of IgG or complement on the surface of the red cells, is added to the mixture, and agglutination is evaluated. In the presence of a negative antibody screen in the recipient, a negative immediate spin cross-match test confirms the compatibility of the blood and antiglobulin phase is not required. Further testing is required if the antibody screen or the cross-match is positive, and blood should not be given until the nature of the reactivity is delineated. An incompatible cross-match is evaluated first with a DAT or Coombs test to detect IgG or complement on the surfaces of the recipient's red cells. The indirect antiglobulin test is also used to determine the presence of antibodies that will coat red cells or activate complement, and additional studies are completed to define the antibody.

TRANSFUSION PRACTICE

General Rules

Several rules should be observed in administering any blood component:

1. In final preparation of the component, no solutions should be added to the bag or tubing set except for normal saline (0.9% sodium chloride for injection, USP), ABO-compatible plasma, or other specifically approved expanders. Hypotonic solutions cause hemolysis of red cells, and, if these are transfused, a severe reaction will occur. Any reconstitution should be completed by the blood bank.
2. Transfusion products should be protected from contact with any calcium-containing solution (eg, lactated Ringer); recalcification and reversal of the citrate effect will cause clotting of the blood component.
3. Blood components should not be warmed to a temperature greater than 37°C. If a component is incubated in a water bath, it should be enclosed in a watertight bag to prevent bacterial contamination of entry ports.

4. Whenever a blood bag is entered, the sterile integrity of the system is violated, and that unit should be discarded within 4 hours if left at room temperature or within 24 hours if the temperature is 4–6°C.
5. Transfusions of products containing red cells should not exceed 4 hours. Blood components in excess of what can be infused during this time period should be stored in the blood bank until needed.
6. Before transfusion, the blood component should be inspected visually for any unusual characteristics, such as the presence of flocculent material, hemolysis, or clumping of cells, and mixed thoroughly.
7. The unit and the recipient should be identified properly.
8. The administration set includes a standard 170- to 260-μm filter. Under certain clinical circumstances, an additional microaggregate filter may be used to eliminate small aggregates of fibrin, white cells, and platelets that will not be removed by the standard filter.
9. The patient should be observed during the entire transfusion and especially during the first 15 minutes. With the onset of any adverse symptoms or signs, the transfusion should be stopped, an evaluation initiated immediately, and the reaction reported promptly to the transfusion service.
10. When cross-match–incompatible red cells or whole blood unit(s) must be given to the patient (as with AIHA), a test dose of 10% of the total volume (not to exceed 50 mL) should be administered over 15–20 minutes; the transfusion is then stopped and the patient observed. If no changes in vital signs or the patient's condition are noted, the remainder of the volume can be infused carefully.
11. Blood for exchange transfusion in the newborn period may be cross-matched with either the infant's or the mother's serum or plasma. If the exchange is for hemolysis, 500 mL of whole blood stored for less than 7 days will be adequate. If replacement of clotting factors is a key issue, packed red cells (7 days old) reconstituted with ABO type-specific FFP may be considered. Based on posttransfusion platelet counts, platelet transfusion may be considered. Other problems to be anticipated are acid-base derangements, hyponatremia, hyperkalemia, hypocalcemia, hypoglycemia, hypothermia, and hypervolemia or hypovolemia.

Choice of Blood Component

Several principles should be considered when deciding on the need for blood transfusion. Indications for blood or blood components must be well defined, and the patient's medical condition, not just the laboratory results, should be the basis for the decision. Specific deficiencies exhibited by the patient (eg, oxygen-carrying capacity, thrombocytopenia) should be treated with appropriate blood components and the use of whole blood minimized. Information about specific blood components is summarized in Table 30–11. In general, very little is known about specific indications for blood component transfusion and outcomes. In recent years the criteria have become more restrictive for transfusion of any component. A recent review evaluates what is known and presents fertile areas for investigation (see Josephson et al).

A. Whole Blood

See Table 30–11.

B. Packed Red Blood Cells

See Table 30–11.

C. Platelets

The decision to transfuse platelets depends on the patient's clinical condition, the status of plasma phase coagulation, the platelet count, the cause of the thrombocytopenia, and the functional capacity of the patient's own platelets. In the face of decreased production, clinical bleeding, and platelet counts less than 10,000/μL, the risk of severe, spontaneous bleeding is increased markedly. In the presence of these factors and in the absence heparin-induced thrombocytopenia, TTP, or antibody-mediated thrombocytopenia, transfusion may be considered. Under certain circumstances, especially with platelet dysfunction or treatment that inhibits the procoagulant system, transfusions at higher platelet counts may be necessary.

Transfused platelets are sequestered temporarily in the lungs and spleen before reaching their peak concentrations, 45–60 minutes after transfusion. A significant proportion of the transfused platelets never circulate but remain sequestered in the spleen. This phenomenon results in reduced recovery; under best conditions, only 60%–70% of the transfused platelets are accounted for when peripheral platelet count increments are used as a measure of response.

In addition to cessation of bleeding, two variables indicate the effectiveness of platelet transfusions. The first is platelet recovery, as measured by the maximum number of platelets circulating in response to transfusion. The practical measure is the platelet count at 1 hour after transfusion. In the absence of immune or drastic nonimmune factors that markedly decrease platelet recovery, one would expect a 7000/μL increment for each random donor unit and a 40,000–70,000/μL increment for each single-donor apheresis unit in a large child or adolescent. For infants and small children, 10 mL/kg of platelets will increase the platelet count by at least 50,000/μL. The second variable is the survival of transfused platelets. If the recovery is greater than 50,000/uL, transfused platelets will approach a normal

Table 30–12. Adverse events following transfusions.

Event	Pathophysiology	Signs and Symptoms	Management
Acute hemolytic transfusion reaction	Preformed alloantibodies (most commonly to ABO) and infrequently autoantibodies cause rapid intravascular hemolysis of transfused cells with activation of clotting (DIC), activation of inflammatory mediators, and acute renal failure.	Fever, chills, nausea, chest pain, back pain, pain at transfusion site, hypotension, dyspnea, oliguria, hemoglobinuria.	The risk of this type of reaction overall is low (1:70,000–1:30,000), but the mortality rate is high (up to 40%). Stop the transfusion; maintain renal output with intravenous fluids and diuretics (furosemide or mannitol); treat DIC with heparin; and institute other appropriate supportive measures.
Delayed hemolytic transfusion reaction	Formation of alloantibodies after transfusion and resultant destruction of transfused red cells, usually by extravascular hemolysis.	Jaundice, anemia. A small percentage may develop chronic hemolysis.	Detection, definition, and documentation (for future transfusions). Supportive care. Risk, < 5% of transfused patients may develop alloantibody; hemolysis, 1:11,000–1:2500.
Febrile reactions	Usually caused by leukoagglutinins in recipient, cytokines, or other biologically active compounds.	Fever. May also involve chills.	Supportive. Leukocyte-reduced products decrease reactions. Risk per transfusion, 1:100 transfusions.
Allergic reactions	Most causes not identified. In IgA-deficient individuals, reaction occurs as a result of antibodies to IgA.	Itching, hives, and occasionally chills and fever. In severe reactions, may see signs of anaphylaxis: dyspnea, pulmonary edema.	Mild to moderate reactions: diphenhydramine. More severe reactions: epinephrine subcutaneously and steroids intravenously. Risk for mild to moderate allergic reactions, 1:100. Severe anaphylactic reactions, 1:50,000—1:20,000.
Transfusion-related acute lung injury	Acute lung injury occurring within 6 h after transfusion. Two sets of factors interact to produce the syndrome. Patient factors: infection, surgery, cytokine therapy. Blood component factors: lipids, antibodies, cytokines. Two groups of factors interact during transfusion to result in lung injury indistinguishable from ARDS.	Tachypnea, dyspnea, hypoxia. Diffuse interstitial markings. Cardiac evaluation normal.	May consider younger products: packed red blood cells ≤ 2 wk, platelets ≤ 3 d, washing components to prevent syndrome. Management: supportive care. Risk, 1:2000–1:3000 per transfusion. Current preventive procedures include avoiding donors at risk for alloimmunization: use of male-only FFP or white blood cell antibody-negative apheresis FFP or platelet products.
Dilutional coagulopathy	Massive blood loss and transfusion with replacement with fluids or blood components and deficient clotting factors.	Bleeding.	Replacement of clotting factors or platelets with appropriate blood components.
Bacterial contamination	Contamination of units results in growth of bacteria or production of clinically significant levels of endotoxin.	Chills, high fever, hypotension, other symptoms of sepsis or endotoxemia.	Stop transfusion; make aggressive attempts to identify organism; provide vigorous support. Sepsis in 1:500,000–1:75,000
Graft-versus-host disease	Lymphocytes from donor transfused in an immunoincompetent host.	Syndrome can involve a variety of organs, usually skin, liver, gastrointestinal tract, and bone marrow.	Rare. Preventive management: irradiation (> 1500 cGy) of cellular blood components transfused to individuals with congenital or acquired immunodeficiency syndromes, intrauterine transfusion, very premature infants, and when donors are relatives of the recipient.
Iron overload	There is no physiologic mechanism to excrete excess iron. Target organs include liver, heart, and endocrine organs. In patients receiving red cell transfusions over long periods of time, there is an increase in iron burden.	Signs and symptoms of dysfunctional organs affected by the iron.	Significant risk with chronic transfusions. Treated with chronic administration of iron chelator such as deferoxamine given intravenously or Exjade given orally.

ARDS, adult respiratory distress syndrome; DIC, disseminated intravascular coagulation; FFP, fresh frozen plasma; IgA, immunoglobulin A.

half-life in the circulation. In the presence of increased platelet destruction, the life span may be shortened to a few days or a few hours. Frequent platelet transfusions may be required to maintain adequate hemostasis.

A particularly troublesome outcome in patients receiving long-term platelet transfusions is the development of a refractory state characterized by poor (≤ 20%) recovery or no response to platelet transfusion (as measured at 1 hour). Most (70%–90%) of these refractory states result from the development of alloantibodies directed against HLA antigens on the platelet. Platelets have class I HLA and i antigens, and the antibodies are primarily against HLA A or B determinants. A smaller proportion of these alloantibodies (< 10%) may be directed against platelet-specific alloantigens. The most effective approach to prevent HLA sensitization is to use leukocyte-depleted components (< 5 million leukocytes per unit of packed red cells or per apheresis or 6–10 random donor unit concentrates). For the alloimmunized, refractory patient, the best approach is to provide HLA-matched platelets for transfusion. Reports have suggested that platelet crossmatching procedures using HLA-matched or unmatched donors may be helpful in identifying platelet concentrates most likely to provide an adequate response.

D. Fresh Frozen Plasma

See Table 30–11.

E. Cryoprecipitate

See Table 30–11.

F. Granulocytes

With better supportive care over the past 20 years, the need for granulocytes in neutropenic patients with severe bacterial infections has decreased. Indications still remain for severe bacterial or fungal infections unresponsive to vigorous medical therapy in either newborns or older children with bone marrow failure, or patients with neutrophil dysfunction. Newer mobilization schemes using G-CSF and steroids in donors result in granulocyte collections with at least 50 billion neutrophils. This may provide a better product for patients requiring granulocyte support.

G. Apheresis Products and Procedures

Apheresis equipment allows one or more blood components to be collected while the rest are returned to the donor. Apheresis platelet concentrates, which have as many platelets as 6–10 units of platelet concentrates from whole blood donations, are one example; granulocytes are another. Apheresis techniques can also be used to collect hematopoietic stem cells that have been mobilized into the blood by cytokines (eg, G-CSF) given alone or after chemotherapy or mononuclear cells for immunotherapy. Stem cells are used for allogeneic or autologous bone marrow transplantation. Blood cell separators can be used for the collection of single-source plasma or removal of a blood component that is causing disease. Examples include red cell exchange in sickle cell disease and plasmapheresis in Goodpasture syndrome or in Guillain-Barré syndrome.

Adverse Effects

The noninfectious complications of blood transfusions are outlined in Table 30–12. Most complications present a significant risk to the recipient.

Each year approximately 150 out of every 1 million children younger than 20 years are diagnosed with cancer. For children between the ages of 1 and 20 years, cancer is the fourth leading cause of death, behind unintentional injuries, homicides, and suicides. However, combined-modality therapy, including surgery, chemotherapy, and radiation therapy, has improved survival dramatically, such that the overall 5-year survival rate of pediatric malignancies is now greater than 75%. It is estimated that by the year 2020, 1 in 600 adults will be a survivor of childhood cancer.

Because pediatric malignancies are rare, cooperative clinical trials have become the mainstay of treatment planning and therapeutic advances. The Children's Oncology Group (COG), representing the amalgamation of four prior pediatric cooperative groups (Children's Cancer Group, Pediatric Oncology Group, Intergroup Rhabdomyosarcoma Study Group, and the National Wilms Tumor Study Group), offers current therapeutic protocols and strives to answer important treatment questions. A child or adolescent newly diagnosed with cancer should be enrolled in a cooperative clinical trial whenever possible. Because many protocols are associated with significant toxicities, morbidity, and potential mortality, treatment of children with cancer should be supervised by a pediatric oncologist familiar with the hazards of treatment, preferably at a multidisciplinary pediatric cancer center.

Advances in molecular genetics, cell biology, and tumor immunology have contributed and are crucial to the continued understanding of pediatric malignancies and their treatment. Continued research into the biology of tumors will lead to the identification of targeted therapy for specific tumor types with, it is hoped, fewer systemic effects.

Research in supportive care areas, such as prevention and management of infection, pain, and emesis, has improved the survival and quality of life for children undergoing cancer treatment. Long-term studies of childhood cancer survivors are yielding information that provides a rationale for modifying future treatment regimens to decrease morbidity. A guide for caring for childhood cancer survivors is now available to medical providers as well as families and details suggested examinations and late effects by type of chemotherapy received.

MAJOR PEDIATRIC NEOPLASTIC DISEASES

ACUTE LYMPHOBLASTIC LEUKEMIA

General Considerations

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for about 25% of all cancer diagnoses in patients younger than 15 years. The worldwide incidence of ALL is about 1:25,000 children per year, including 3000 children per year in the United States. The peak age at onset is 4 years; 85% of patients are diagnosed between ages 2 and 10 years. Children with Down syndrome have a 14-fold increase in the overall rate of leukemia.

ALL results from uncontrolled proliferation of immature lymphocytes. Its cause is unknown, and genetic factors may play a role. Leukemia is defined by the presence of more than 25% malignant hematopoietic cells (blasts) in the bone marrow aspirate. Leukemic blasts from the majority of cases of childhood ALL have an antigen on the cell surface called the common ALL antigen (CALLA). These blasts derive from B-cell precursors early in their development, called B-precursor ALL. Less commonly, lymphoblasts are of T-cell origin or of mature B-cell origin. Over 70% of children receiving aggressive combination chemotherapy and early

presymptomatic treatment to the central nervous system (CNS) are now cured of ALL.

» Clinical Findings

A. Symptoms and Signs

Presenting complaints of patients with ALL include those related to decreased bone marrow production of red blood cells (RBCs), white blood cells (WBCs), or platelets and to leukemic infiltration of extramedullary (outside bone marrow) sites. Intermittent fevers are common, as a result of either cytokines induced by the leukemia itself or infections secondary to leukopenia. Many patients present due to bruising or pallor. About 25% of patients experience bone pain, especially in the pelvis, vertebral bodies, and legs.

Physical examination at diagnosis ranges from virtually normal to highly abnormal. Signs related to bone marrow infiltration by leukemia include pallor, petechiae, and purpura. Hepatomegaly and/or splenomegaly occur in over 60% of patients. Lymphadenopathy is common, either localized or generalized to cervical, axillary, and inguinal regions. The testes may occasionally be unilaterally or bilaterally enlarged secondary to leukemic infiltration. Superior vena cava syndrome is caused by mediastinal adenopathy compressing the superior vena cava. A prominent venous pattern develops over the upper chest from collateral vein enlargement. The neck may feel full from venous engorgement. The face may appear plethoric, and the periorbital area may be edematous. A mediastinal mass can cause tachypnea, orthopnea, and respiratory distress. Leukemic infiltration of cranial nerves may cause cranial nerve palsies with mild nuchal rigidity. The optic fundi may show exudates of leukemic infiltration and hemorrhage from thrombocytopenia. Anemia can cause a flow murmur, tachycardia, and, rarely, congestive heart failure.

B. Laboratory Findings

A complete blood count (CBC) with differential is the most useful initial test because 95% of patients with ALL have a decrease in at least one cell type (single cytopenia): neutropenia, thrombocytopenia, or anemia with most patients having a decrease in at least two blood cell lines. The WBC count is low or normal (= 10,000/μL) in 50% of patients, but the differential shows neutropenia (absolute neutrophil count < 1000/μL) along with a small percentage of blasts amid normal lymphocytes. In 30% of patients the WBC count is between 10,000/μL and 50,000/μL; in 20% of patients it is over 50,000/μL, occasionally higher than 300,000/μL. Blasts are usually readily identifiable on peripheral blood smears from patients with elevated WBC counts. Peripheral blood smears also show abnormalities in RBCs, such as teardrops. Most patients with ALL have decreased platelet counts (< 150,000/μL) and decreased hemoglobin (< 11 g/dL) at diagnosis. In approximately 1% of patients diagnosed with ALL, CBCs and peripheral blood smears are entirely normal, but patients have bone pain that leads to bone marrow examination. Serum chemistries, particularly uric acid and lactate dehydrogenase (LDH), are often elevated at diagnosis as a result of cell breakdown.

The diagnosis of ALL is made by bone marrow examination, which shows a homogeneous infiltration of leukemic blasts replacing normal marrow elements. The morphology of blasts on bone marrow aspirate can usually distinguish ALL from acute myeloid leukemia (AML). Lymphoblasts are typically small, with cell diameters of approximately two erythrocytes. Lymphoblasts have scant cytoplasm, usually without granules. The nucleus typically contains no nucleoli or one small, indistinct nucleolus. Immunophenotyping of ALL blasts by flow cytometry helps distinguish precursor B-cell ALL from T-cell ALL or AML. Histochemical stains specific for myeloblastic and monoblastic leukemias (myeloperoxidase and nonspecific esterase) distinguish ALL from AML. About 5% of patients present with CNS leukemia, which is defined as a cerebrospinal fluid (CSF) WBC count greater than 5/μL with blasts present on cytocentrifuged specimen.

C. Imaging

Chest radiograph may show mediastinal widening or an anterior mediastinal mass and tracheal compression secondary to lymphadenopathy or thymic infiltration, especially in T-cell ALL. Abdominal ultrasound may show kidney enlargement from leukemic infiltration or uric acid nephropathy as well as intra-abdominal adenopathy. Plain radiographs of the long bones and spine may show demineralization, periosteal elevation, growth arrest lines, or compression of vertebral bodies. Although these findings may suggest leukemia, they are not diagnostic.

» Differential Diagnosis

The differential diagnosis, based on the history and physical examination, includes chronic infections by Epstein-Barr virus (EBV) and cytomegalovirus (CMV), causing lymphadenopathy, hepatosplenomegaly, fevers, and anemia. Prominent petechiae and purpura suggest a diagnosis of immune thrombocytopenic purpura. Significant pallor could be caused by transient erythroblastopenia of childhood, autoimmune hemolytic anemias, or aplastic anemia. Fevers and joint pains, with or without hepatosplenomegaly and lymphadenopathy, suggest juvenile rheumatoid arthritis (JRA). The diagnosis of leukemia usually becomes straightforward once the CBC reveals multiple cytopenias and leukemic blasts. Serum LDH levels may help distinguish JRA from leukemia, as the LDH is usually normal in JRA. An elevated WBC count with lymphocytosis is typical of pertussis; however, in pertussis the lymphocytes are mature, and neutropenia is rarely associated.

» Treatment

A. Specific Therapy

Intensity of treatment is determined by specific prognostic features present at diagnosis, the patient's response to therapy, and specific biologic features of the leukemia cells. The majority of patients with ALL are enrolled in clinical trials designed by clinical groups and approved by the National Cancer Institute; the largest group is COG. The first month of therapy consists of induction, at the end of which over 95% of patients exhibit remission on bone marrow aspirates by morphology. The drugs most commonly used in induction include oral prednisone or dexamethasone, intravenous vincristine, daunorubicin, intramuscular or intravenous asparaginase, and intrathecal methotrexate.

Consolidation is the second phase of treatment, during which intrathecal chemotherapy along with continued systemic therapy and sometimes cranial radiation therapy are given to kill lymphoblasts "hiding" in the meninges. Several months of intensive chemotherapy follows consolidation, often referred to as intensification. This intensification has led to improved survival in pediatric ALL.

Maintenance therapy can include daily oral mercaptopurine, weekly oral methotrexate, and, often, monthly pulses of intravenous vincristine and oral prednisone or dexamethasone. Intrathecal chemotherapy, either with methotrexate alone or combined with cytarabine and hydrocortisone, is usually given every 2–3 months.

Chemotherapy has significant potential side effects. Patients need to be monitored closely to prevent drug toxicities and to ensure early treatment of complications. The duration of treatment ranges between 2.2 years for girls and 3.2 years for boys in COG trials. Treatment for ALL is tailored to prognostic, or risk, groups. A child aged 1–9 years with a WBC count below 50,000/μL at diagnosis of pre B ALL and without poor biologic features [t(9;22) or an 11q23 rearrangement)] is considered to be at "standard risk" and receives less intensive therapy than a "high-risk" patient who has a WBC count at diagnosis over 50,000/μL or is 10 years of age or greater. An infant less than 1 year at diagnosis would be considered very high risk and receive even more intensive chemotherapy. Also important is the patient's response to treatment determined by minimal residual disease (MRD) monitoring. This risk-adapted treatment approach has significantly increased the cure rate among patients with less favorable prognostic features by allowing for early intensification while minimizing treatment-related toxicities in those with favorable features. Bone marrow relapse is usually heralded by an abnormal CBC, either during treatment or following completion of therapy.

The CNS and testes are sanctuary sites of extramedullary leukemia. Currently, about one-third of all ALL relapses are isolated to these sanctuary sites. Systemic chemotherapy does not penetrate these tissues as well as it penetrates other organs. Thus, presymptomatic intrathecal chemotherapy is a critical part of ALL treatment, without which many more relapses would occur in the CNS, with or without bone marrow relapse. The majority of isolated CNS relapses are diagnosed in an asymptomatic child at the time of routine intrathecal injection, when CSF cell count and differential show an elevated WBC with leukemic blasts. Occasionally, symptoms of CNS relapse develop: headache, nausea and vomiting, irritability, nuchal rigidity, photophobia, changes in vision, and cranial nerve palsies. Currently, testicular relapse occurs in less than 5% of boys. The presentation of testicular relapse is usually unilateral painless testicular enlargement, without a distinct mass. Routine follow-up of boys both on and off treatment includes physical examination of the testes.

Bone marrow transplantation, now called hematopoietic stem cell transplantation (HSCT), is rarely used as initial treatment for ALL, because most patients are cured with chemotherapy alone. Patients whose blasts contain certain chromosomal abnormalities, hypodiploidy (< 44 chromosomes), and patients with a very slow response to therapy may have a better cure rate with early HSCT from a human leukocyte antigen (HLA)-DR–matched sibling donor, or perhaps a matched unrelated donor, than with intensive chemotherapy alone. HSCT cures about 50% of patients who relapse, provided that a second remission is achieved with chemotherapy before transplant. Children who relapse more than 1 year after completion of chemotherapy (late relapse) may be cured with intensive chemotherapy without HSCT.

Several new biologic agents, including tyrosine kinase inhibitors and immunotoxins, are currently in various stages of research, development, and in chemotherapeutic trials. Some of these therapies may prove relevant for future treatment of poor risk or relapsed ALL.

Several years ago, Imatinib, a tyrosine kinase inhibitor (TKI), directed against the Philadelphia chromosome (Ph+) protein product, was combined in a backbone of intensive ALL therapy for Ph+ ALL in pediatric patients. The preliminary results of this trial showed a 3-year event-free survival (EFS) of 78% compared to about 50% in historical controls. An ongoing trial for COG in Ph+ ALL is incorporating a newer, more targeted TKI, Dasatinib, into a very similar intensive chemotherapy background with the goal of improving EFS further for this select group of patients. As more is understood about the biology of ALL, further therapy will likely include more of these targeted agents.

B. Supportive Care

Tumor lysis syndrome, which consists of hyperkalemia, hyperuricemia, hyperphosphatemia, should be anticipated when treatment is started. Maintaining brisk urine output

with intravenous fluids plus/minus alkalinization of urine with intravenous sodium bicarbonate and treating with oral allopurinol are appropriate steps in managing tumor lysis syndrome. Rasburicase is indicated for severe tumor lysis syndrome with initial high uric acid values or high WBC at presentation. Serum levels of potassium, phosphorus, and uric acid should be monitored. If superior vena caval or superior mediastinal syndrome is present, general anesthesia is contraindicated temporarily and until there has been some decrease in the mass. If hyperleukocytosis (WBC count > 100,000/μL) is accompanied by hyperviscosity with symptoms of respiratory distress and/or mental status changes, leukophoresis may be indicated to rapidly reduce the number of circulating blasts and minimize the potential thrombotic or hemorrhagic CNS complications. Throughout the course of treatment, all transfused blood and platelet products should be irradiated to prevent graft-versus-host disease (GVHD) from the transfused lymphocytes. Whenever possible, blood products should be leuko-depleted to minimize CMV transmission, transfusion reactions, and sensitization to platelets.

Due to the immunocompromised state of the patient with ALL, bacterial, fungal, and viral infections are serious and can be life-threatening or fatal. During the course of treatment, fever (temperature = 38.3°C) and neutropenia (absolute neutrophil count < 500/μL) require prompt assessment, blood cultures from each lumen of a central line, and prompt treatment with empiric broad-spectrum antibiotics. Patients receiving ALL treatment must receive prophylaxis against Pneumocystis jiroveci (formerly Pneumocystis carinii). Trimethoprim-sulfamethoxazole given twice each day on 2 or 3 consecutive days per week is the drug of choice. Patients nonimmune to varicella are at risk for very serious—even fatal—infection. Such patients should receive varicella-zoster immune globulin (VZIG) within 72 hours after exposure and treatment with intravenous acyclovir for active infection.

» Prognosis

Cure rates depend on specific prognostic features present at diagnosis, biologic features of the leukemic blast, and the response to therapy. Two of the most important features are WBC count and age. Children aged 1–9 years whose diagnostic WBC count is less than 50,000/μL, standard risk ALL, have an EFS in the 90% range, while children 10 years or older have an EFS of approximately 88%. MRD measurements are now frequently used to determine both the rapidity of response as well as the depth of remission attained at the end of induction (first 4–6 weeks of therapy). Patients with very low levels of MRD at the end of induction will likely have a superior EFS as compared to other patients with similar initial risk factors but a higher MRD level. On the flip side, by identifying patients with higher MRD at end induction, more intensified therapy can be delivered in order to reduce the MRD and thus, improve the EFS.

Certain chromosomal abnormalities present in the leukemic blasts at diagnosis influence prognosis. Patients with t(9;22), the Philadelphia chromosome, had a poor chance of cure in the past but as discussed earlier in this chapter, now have improved outcome with the incorporation of a directed TKI. Likewise, infants younger than 6 months with 11q23 rearrangements have a poor chance of cure with conventional chemotherapy. In contrast, patients whose blasts are hyperdiploid (containing > 50 chromosomes instead of the normal 46) with trisomies of chromosomes 4, and 10, and patients whose blasts have a t(12;21) and ETV6-AML1 rearrangement have a greater chance of cure, approaching 95%–97% EFS, than do children without these characteristics.

ACUTE MYELOID LEUKEMIA

» General Considerations

Approximately 500 new cases of AML occur per year in children and adolescents in the United States. Although AML accounts for only 25% of all leukemias in this age group, it is responsible for at least one-third of deaths from leukemia in children and teenagers. Congenital conditions associated with an increased risk of AML include Diamond-Blackfan anemia; neurofibromatosis; Down syndrome; Wiskott-Aldrich, Kostmann, and Li-Fraumeni syndromes; as well as chromosomal instability syndromes such as Fanconi anemia. Acquired risk factors include exposure to ionizing

radiation, cytotoxic chemotherapeutic agents, and benzenes. However, the vast majority of patients have no identifiable risk factors. Historically, the diagnosis of AML was based almost exclusively on morphology and immunohistochemical staining of the leukemic cells. AML has eight subtypes (M0–M7) according to the French-American-British (FAB) classification (Table 31–1). Immunophenotypic, cytogenetic, and molecular analyses are increasingly important in confirming the diagnosis of AML and subclassifying it into biologically distinct subtypes that have therapeutic and prognostic implications. Recently the World Health Organization (WHO) classification was published to describe AML as AML with recurrent genetic abnormalities with a list of genetic abnormalities sufficient to diagnose AML and then AML not otherwise specified with morphologic descriptions of AML including similar to the FAB classification. Cytogenetic clonal abnormalities occur in 80% of patients with AML and are often predictive of outcome.

Aggressive induction therapy currently results in a 75%–85% complete remission rate. However, long-term survival has improved only modestly to approximately 50%, despite the availability of several effective agents, improvements in supportive care, and increasingly intensive therapies.

» Clinical Findings

The clinical manifestations of AML commonly include anemia (44%), thrombocytopenia (33%), and neutropenia (69%). Symptoms may be few and innocuous or may be life threatening. The median hemoglobin value at diagnosis is 7 g/dL, and platelets usually number fewer than 50,000/μL. Frequently the absolute neutrophil count is under 1000/μL, although the total WBC count is over 100,000/μL in 25% of patients at diagnosis.

Hyperleukocytosis may be associated with life-threatening complications. Venous stasis and sludging of blasts in small vessels cause hypoxia, hemorrhage, and infarction, most notably in the lung and CNS. This clinical picture is a medical emergency requiring rapid intervention, such as leukophoresis, to decrease the leukocyte count. CNS leukemia is present in 5%–15% of patients at diagnosis, a higher rate of initial involvement than in ALL. Certain subtypes, such as M4 and M5, have a higher likelihood of meningeal infiltration than do other subtypes. Additionally, clinically significant coagulopathy may be present at diagnosis in patients with M3, M4, or M5 subtypes. This problem manifests as bleeding or an abnormal disseminated intravascular

Table 31–1. FAB subtypes of acute myeloid leukemia.

FAB Classification	Common Name	Distribution in Childhood (Age)		Cytogenetic Associations	Clinical Features
		< 2 y (%)	> 2 y (%)		
M0	Acute myeloid leukemia, minimally differentiated	1		inv (3q26), t(3;3)	
M1	Acute myeloblastic leukemia without maturation	17	23		
M2	Acute myeloblastic leukemia with maturation	26		t(8;21), t(6;9); rare	Myeloblastomas or chloromas
M3	Acute promyelocytic leukemia	4		t(15;17); rarely, t(11;17) or (5;17)	Disseminated intravascular coagulation
M4	Acute myelomonoblastic leukemia	30	24	11q23, inv 3, t(3;3), t(6;9)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M4Eo	Acute myelomonoblastic leukemia with abnormal eosinophils			inv16, t(16;16)	
M5	Acute monoblastic leukemia	46	15	11q23, t(9;11), t(8;16)	Hyperleukocytosis, CNS involvement, skin and gum infiltration
M6	Erythroleukemia	2			
M7	Acute megakaryoblastic leukemia	7	5	t(1;22)	Down syndrome frequent (< age 2 y)

CNS, central nervous system; FAB, French-American-British classification.

coagulation screen and should be at least partially corrected prior to initiation of treatment, which may transiently exacerbate the coagulopathy.

» Treatment

A. Specific Therapy

AML is less responsive to treatment than ALL and requires more intensive chemotherapy. Toxicities from therapy are common and likely to be life threatening; therefore, treatment should be undertaken only at a tertiary pediatric oncology center.

Current AML protocols rely on intensive administration of anthracyclines, cytarabine, and etoposide for induction of remission. After remission is obtained, patients who have a matched sibling donor undergo allogeneic HSCT, while those without an appropriate related donor are treated with additional cycles of aggressive chemotherapy for a total of four to five cycles. Inv16 and t(8;21) herald a more responsive subtype of AML. In patients with a rapid response to induction chemotherapy, intensive chemotherapy alone may be curative in patients whose blasts harbor these cytogenetic abnormalities. Additional recognized genetic risk factors that carry a poor outcome for children with AML include monosomy 7 and FLT3 internal tandem duplications (ITDs). HSCT is recommended for all these patients, using either a related or unrelated donor. Trials with risk grouping are ongoing as more is understood about the varying biologic factors.

The biologic heterogeneity of AML is becoming increasingly important therapeutically. The M3 subtype, associated with t(15;17) demonstrated either cytogenetically or molecularly, is currently treated with all trans-retinoic acid in addition to chemotherapy with high-dose cytarabine and daunorubicin. All trans-retinoic acid leads to differentiation of promyelocytic leukemia cells and can induce remission, but cure requires conventional chemotherapy as well. The use of arsenic trioxide has also been investigated in the treatment of this subtype of AML with favorable results. This subtype has an increased EFS over other AML subtypes.

Another biologically distinct subtype of AML occurs in children with Down syndrome, M7, or megakaryocytic AML. Using less intensive treatment, remission induction rate and overall survival of these children are dramatically superior to non–Down syndrome children with AML. It is important that children with Down syndrome receive appropriate treatment specifically designed to be less intensive due to their increased rate of toxicity with chemotherapeutic agents.

As with ALL, newer biologic agents with more specific targeting are available and undergoing clinical trails. One such agent, sorafenib, appears to be active against AML with Flt3 ITDs. Combining sorafenib with AML therapy has been useful in relapsed disease and is now being studied in to upfront trials.

Clofarabine, a newer nucleoside analogue, also has activity in AML and is currently undergoing trials in relapsed and refractory patients with promising results.

B. Supportive Care

Tumor lysis syndrome rarely occurs during induction treatment of AML. Nevertheless, when the diagnostic WBC cell count is greater than 100,000/μL or significant adenopathy or organomegaly is present, one should maintain brisk urine output, and follow potassium, uric acid, and phosphorous laboratory values closely. Hyperleukocytosis (WBC > 100,000/μL) is a medical emergency and, in a symptomatic patient, requires rapid intervention such as leukophoresis to rapidly decrease the number of circulating blasts and thereby decrease hyperviscosity. Delaying transfusion of packed RBCs until the WBC can be decreased to below 100,000/μL avoids exacerbating hyperviscosity. It is also important to correct the coagulopathy commonly associated with M3, M4, or M5 subtypes prior to beginning induction chemotherapy. As with the treatment of ALL, all blood products should be irradiated and leukodepleted; Pneumocystis prophylaxis must be administered during treatment and for several weeks afterward; and patients not immune to varicella must receive VZIG within 72 hours of exposure and prompt treatment with intravenous acyclovir for active infection.

Onset of fever (temperature ≥ 38.3°C) or chills associated with neutropenia requires prompt assessment, blood cultures from each lumen of a central venous line, other cultures such as throat or urine as appropriate and prompt initiation of broad-spectrum intravenous antibiotics. Infections in this population of patients can rapidly become life-threatening. Because of the high incidence of invasive fungal infections, there should be a low threshold for initiating antifungal therapy. Filgrastim (granulocyte colony-stimulating factor) may be used to stimulate granulocyte recovery during the treatment of AML and results in shorter periods of neutropenia and hospitalization. It must be stressed that the supportive care for this group of patients is as important as the leukemia-directed therapy and that this treatment should be carried out only at a tertiary pediatric cancer center.

» Prognosis

Published results from various centers show a 50%–60% survival rate at 5 years following first remission for patients who do not have matched sibling hematopoietic stem cell donors. Patients with matched sibling donors fare slightly better, with 5-year survival rates of 60%–70% after allogeneic HSCT.

As treatment becomes more sophisticated, outcome is increasingly related to the subtype of AML. Currently, AML in patients with t(8;21), t(15;17), inv 16, or Down syndrome has the most favorable prognosis, with 65%–75% long-term

survival using modern treatments, including chemotherapy alone. The least favorable outcome occurs in AML patients with monosomy 7 or 5, 7q, 5q–, 11q23 cytogenetic abnormalities, or FLT 3 mutations or ITD.

MYELOPROLIFERATIVE DISEASES

Myeloproliferative diseases in children are relatively rare. They are characterized by ineffective hematopoiesis that results in excessive peripheral blood counts. The three most important types are chronic myelogenous leukemia (CML), which accounts for less than 5% of the childhood leukemias, transient myeloproliferative disorder in children with Down syndrome, and juvenile myelomonocytic leukemia (Table 31–2).

1. Chronic Myelogenous Leukemia

» General Considerations

CML with translocation of chromosomes 9 and 22 (the Philadelphia chromosome, Ph+) is identical to adult Ph+CML. Translocation 9;22 results in the fusion of the BCR gene on chromosome 22 and the ABL gene on chromosome 9. The resulting fusion protein is a constitutively active tyrosine kinase that interacts with a variety of effector proteins and allows for deregulated cellular proliferation, decreased adherence of cells to the bone marrow extracellular matrix, and resistance to apoptosis. The disease usually progresses within 3 years to an accelerated phase and then to a blast crisis. It is generally accepted that Ph+ cells have an increased susceptibility to the acquisition of additional molecular changes that lead to the accelerated and blast phases of disease.

» Clinical Findings

Patients with CML may present with nonspecific complaints similar to those of acute leukemia, including bone pain, fever, night sweats, and fatigue. However, patients can also be asymptomatic. Patients with a total WBC count of more than 100,000/μL may have symptoms of leukostasis, such as dyspnea, priapism, or neurologic abnormalities. Physical findings may include fever, pallor, ecchymoses, and hepatosplenomegaly. Anemia, thrombocytosis, and leukocytosis are frequent laboratory findings. The peripheral smear is

Table 31–2. Comparison of JMML, CML, and TMD.

	CML	TMD	JMML
Age at onset	> 3 y	< 3 mo	< 2 y
Clinical presentation	Nonspecific constitutional complaints, massive splenomegaly, variable hepatomegaly	DS features, often no or few symptoms; or hepatosplenomegaly, respiratory symptoms	Abrupt onset; eczematoid skin rash, marked lymphadenopathy, bleeding tendency, moderate hepatosplenomegaly, fever
Chromosomal alterations	t(9;22)	Constitutional trisomy 21, but usually no other abnormality	Monosomy or del (7q) in 20% of patients
Laboratory features	Marked leukocytosis (> 100,000/μL), normal to elevated platelet count, decreased to absent leukocyte alkaline phosphatase, usually normal muramidase	Variable leukocytosis, normal to high platelet count, large platelets, myeloblasts	Moderate leukocytosis (> 10,000/μL), thrombocytopenia, monocytosis (> 1000/ μL), elevated fetal hemoglobin, normal to diminished leukocyte alkaline phosphatase, elevated muramidase

CML, chronic myelogenous leukemia; DS, Down syndrome; JMML, juvenile myelomonocytic leukemia; TMD, transient myeloproliferative disorder.

usually diagnostic, with a characteristic predominance of myeloid cells in all stages of maturation, increased basophils and relatively few blasts.

» Treatment & Prognosis

Historically, hydroxyurea or busulfan has been used to reduce or eliminate Ph+ cells and HSCT was the only consistently curative intervention. Reported survival rates for patients younger than 20 years transplanted in the chronic phase from matched-related donors are 70%–80%. Unrelated stem cell transplants result in survival rates of 50%–65%.

The understanding of the molecular mechanisms involved in the pathogenesis of CML has led to the rational design of molecularly targeted therapy. Imatinib mesylate (Gleevec) is a tyrosine kinase inhibitor that has had dramatic success in the treatment of CML, with most adults and children achieving cytogenetic remission. There are now newer, more targeted TKIs including dasatinib, erlotinib, nilotinib, and ponatinib. These medications in adults have an increased incidence of molecular remissions and may be all that is required for long-term survival in adults. The durability of the remission for children with TKIs therapy alone is unclear but is now the accepted upfront therapy.

2. Transient Myeloproliferative Disorder

Transient myeloproliferative disorder is unique to patients with trisomy 21 or mosaicism for trisomy 21. It is characterized by uncontrolled proliferation of blasts, usually of megakaryocytic origin, during early infancy and spontaneous resolution. The pathogenesis of this process is not well understood, although mutations in the GATA1 gene have recently been implicated as initial events.

Although the true incidence is unknown, it is estimated to occur in up to 10% of patients with Down syndrome. Despite the fact that the process usually resolves by 3 months of age, organ infiltration may cause significant morbidity and mortality.

Patients can present with hydrops fetalis, pericardial or pleural effusions, or hepatic fibrosis. More frequently, they are asymptomatic or only minimally ill. Therefore, treatment is primarily supportive. Patients without symptoms are not treated, and those with organ dysfunction receive low doses of chemotherapy or leukophoresis (or both) to reduce peripheral blood blast counts. Although patients with transient myeloproliferative disorder have apparent resolution of the process, approximately 30% go on to develop acute megakaryoblastic leukemia (AML M7) within 3 years.

3. Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML) accounts for approximately one-third of the myelodysplastic and myeloproliferative disorders in childhood. Patients with neurofibromatosis type 1 (NF-1) are at higher risk of JMML than the general population. It typically occurs in infants and very young children and is occasionally associated with monosomy 7 or a deletion of the long arm of chromosome 7.

Patients with JMML present similarly to those with other hematopoietic malignancies, with lymphadenopathy, hepatosplenomegaly, skin rash, or respiratory symptoms. Patients may have stigmata of NF-1 with neurofibromas or café au lait spots. Laboratory findings include anemia, thrombocytopenia, leukocytosis with monocytosis, and elevated fetal hemoglobin.

The results of chemotherapy for children with JMML have been disappointing, with estimated survival rates of less than 30%. Approximately 40%–45% of patients are projected to survive long term using HSCT, although optimizing conditioning regimens and donor selection may improve these results.

BRAIN TUMORS

» General Considerations

The classic triad of morning headache, vomiting, and papilledema is present in fewer than 30% of children at presentation. School failure and personality changes are common

in older children. Irritability, failure to thrive, and delayed development are common in very young children with brain tumors. Recent-onset head tilt can result from a posterior fossa tumor.

Brain tumors are the most common solid tumors of childhood, accounting for 1500–2000 new malignancies in children each year in the United States and for 25%–30% of all childhood cancers. In general, children with brain tumors have a better prognosis than do adults. Favorable outcome occurs most commonly with low-grade and fully resectable tumors. Unfortunately, cranial irradiation in young children can have significant neuropsychological, intellectual, and endocrinologic sequelae.

Brain tumors in childhood are biologically and histologically heterogeneous, ranging from low-grade localized lesions to high-grade tumors with neuraxis dissemination. High-dose systemic chemotherapy is used frequently, especially in young children with high-grade tumors, in an effort to delay, decrease, or completely avoid cranial irradiation. Such intensive treatment may be accompanied by autologous HSCT or peripheral stem cell reconstitution.

The causes of most pediatric brain tumors are unknown. The risk of developing astrocytomas is increased in children with neurofibromatosis or tuberous sclerosis. Several studies show that some childhood brain tumors occur in families with increased genetic susceptibility to childhood cancers in general, brain tumors, or leukemia and lymphoma. A higher incidence of seizures has been observed in relatives of children with astrocytoma. The risk of developing a brain tumor is increased in children who received cranial irradiation for treatment of meningeal leukemia. All children with gliomas and meningiomas should be screened for NF-1. In children with meningiomas, without the skin findings of NF-1, neurofibromatosis type 2 and von Hippel-Lindau syndrome should be considered. Inherited germline mutations are possible in atypical teratoid/rhabdoid tumors (AT/RTs) and in choroid plexus carcinomas. Careful family histories should be taken in these tumors and genetic counseling considered.

Because pediatric brain tumors are rare, they are often misdiagnosed or diagnosed late; most pediatricians see no more than two children with brain tumors during their careers.

» Clinical Findings

A. Symptoms and Signs

Clinical findings at presentation vary depending on the child's age and the tumor's location. Children younger than 2 years more commonly have infratentorial tumors. Children with such tumors usually present with nonspecific symptoms such as vomiting, unsteadiness, lethargy, and irritability. Signs may be surprisingly few or may include macrocephaly, ataxia, hyperreflexia, and cranial nerve palsies. Because the head can expand in young children, papilledema is often absent. Measuring head circumference and observing gait are essential in evaluating a child for possible brain tumor. Eye findings and apparent visual disturbances such as difficulty tracking can occur in association with optic pathway tumors such as optic glioma. Optic glioma occurring in a young child is often associated with neurofibromatosis.

Older children more commonly have supratentorial tumors, which are associated with headache, visual symptoms, seizures, and focal neurologic deficits. Initial presenting features are often nonspecific. School failure and personality changes are common. Vaguely described visual disturbance is often present, but the child must be directly asked. Headaches are common, but they often will not be predominantly in the morning. The headaches may be confused with migraine.

Older children with infratentorial tumors characteristically present with symptoms and signs of hydrocephalus, which include progressively worsening morning headache and vomiting, gait unsteadiness, double vision, and papilledema. Cerebellar astrocytomas enlarge slowly, and symptoms may worsen over several months. Morning vomiting may be the only symptom of posterior fossa ependymomas, which originate in the floor of the fourth ventricle near the vomiting center. Children with brainstem tumors may present with facial and extraocular muscle palsies, ataxia, and hemiparesis; hydrocephalus occurs in approximately 25% of these patients at diagnosis.

B. Imaging and Staging

In addition to the tumor biopsy, neuraxis imaging studies are obtained to determine whether dissemination has occurred. It is unusual for brain tumors in children and adolescents to disseminate outside the CNS.

Magnetic resonance imaging (MRI) has become the preferred diagnostic study for pediatric brain tumors. MRI provides better definition of the tumor and delineates indolent gliomas that may not be seen on computed tomography (CT) scan. In contrast, a CT scan can be done in less than 10 minutes—as opposed to the 30 minutes required for an MRI scan—and is still useful if an urgent diagnostic study is necessary or to detect calcification of a tumor. Both scans are generally done with and without contrast enhancement. Contrast enhances regions where the blood-brain barrier is disrupted. Postoperative scans to document the extent of tumor resection should be obtained within 48 hours after surgery to avoid postsurgical enhancement.

Imaging of the entire neuraxis and CSF cytologic examination should be part of the diagnostic evaluation for patients with tumors such as medulloblastoma, ependymoma, and pineal region tumors. Diagnosis of neuraxis drop metastases (tumor spread along the neuraxis) can be accomplished by gadolinium-enhanced MRI incorporating sagittal and axial views. MRI of the spine should be obtained

preoperatively in all children with midline tumors of the fourth ventricle or cerebellum. A CSF sample should be obtained during the diagnostic surgery or, if that is not possible, 7–10 days after the surgery. Lumbar CSF is preferred over ventricular CSF for cytologic examination. Levels of biomarkers in the blood and CSF, such as human chorionic gonadotropin and α-fetoprotein, may be helpful in diagnosis and follow-up. Both human chorionic gonadotropin and α-fetoprotein should be obtained from the blood preoperatively for all pineal and suprasellar tumors.

The neurosurgeon should discuss staging and sample collection with an oncologist before surgery in a child newly presenting with a scan suggestive of brain tumor.

C. Classification

About 50% of the common pediatric brain tumors occur above the tentorium and 50% in the posterior fossa. In the very young child, posterior fossa tumors are more common. Most childhood brain tumors can be divided into two categories according to the cell of origin: (1) glial tumors, such as astrocytomas and ependymomas, or (2) nonglial tumors, such as medulloblastoma and other primitive neuroectodermal tumors. Some tumors contain both glial and neural elements (eg, ganglioglioma). A group of less common CNS tumors does not fit into either category (ie, craniopharyngiomas, AT/RTs, germ cell tumors, choroid plexus tumors, and meningiomas). Low- and high-grade tumors are found in most categories. Table 31–3 lists the locations and frequencies of the common pediatric brain tumors.

Table 31–3. Location and frequency of common pediatric brain tumors.

Location	Frequency of Occurrence (%)
Hemispheric	**37**
Low-grade astrocytoma	23
High-grade astrocytoma	11
Other	3
Posterior fossa	**49**
Medulloblastoma	15
Cerebellar astrocytoma	15
Brainstem glioma	15
Ependymoma	4
Midline	**14**
Craniopharyngioma	8
Chiasmal glioma	4
Pineal region tumor	2

Astrocytoma is the most common brain tumor of childhood. Most are juvenile pilocytic astrocytoma (WHO grade I) found in the posterior fossa with a bland cellular morphology and few or no mitotic figures. Low-grade astrocytomas are in many cases curable by complete surgical excision alone. Chemotherapy may be effective in about 40%–50% of low-grade astrocytomas and even in those who will fail chemotherapy eventually; it may delay time to radiation.

Medulloblastoma and related primitive neuroectodermal tumors are the most common high-grade brain tumors in children. These tumors usually occur in the first decade of life, with a peak incidence between ages 5 and 10 years and a female-male ratio of 2.1:1.3. The tumors typically arise in the midline cerebellar vermis, with variable extension into the fourth ventricle. Neuraxis dissemination at diagnosis affects from 10% to 46% of patients. Prognostic factors are outlined in Table 31–4. Determination of risk using histology may soon be replaced by molecular classifications.

Brainstem tumors are third in frequency of occurrence in children. They are frequently of astrocytic origin and often are high grade. Children with tumors that diffusely infiltrate the brainstem and involve primarily the pons (diffuse intrinsic pontine gliomas) have a long-term survival rate of less than 5%. There has been considerable biological discovery, largely from autopsy samples, in diffuse pontine gliomas in the very recent past; it is hoped this will result in new, better targeted therapies. Brainstem tumors that occur above or below the pons and grow in an eccentric or cystic manner have a somewhat better outcome. Exophytic tumors in this location may be amenable to surgery. Generally, brainstem tumors are treated without a tissue diagnosis.

Other brain tumors such as ependymomas, germ cell tumors, choroid plexus tumors, and craniopharyngiomas are less common, and each is associated with unique diagnostic and therapeutic challenges.

» Treatment

A. Supportive Care

Dexamethasone should be started prior to initial surgery (0.5–1.0 mg/kg initially, then 0.25–0.5 mg/kg/d in four divided doses). Anticonvulsants should be started if the

Table 31–4. Prognostic factors in children with medulloblastoma.

Factor	Favorable	Unfavorable
Extent of disease	Nondisseminated	Disseminated
Histologic features	Undifferentiated, desmoplastic	Large cell, anaplastic
Age	≥ 4 y	< 4 y

child has had a seizure or if the surgical approach is likely to induce seizures. Keppra is now the preferred anticonvulsant in this population as it does not induce liver enzymes. Because postoperative treatment of young children with high-grade brain tumors incorporates increasingly more intensive systemic chemotherapy, consideration should also be given to the use of prophylaxis for prevention of oral candidiasis and Pneumocystis infection. Dexamethasone potentially reduces the effectiveness of chemotherapy and should be discontinued as soon after surgery as possible.

Optimum care for the pediatric patient with a brain tumor requires a multidisciplinary team including subspecialists in pediatric neurosurgery, neuro-oncology, neurology, endocrinology, neuropsychology, radiation therapy, and rehabilitation medicine, as well as highly specialized nurses, social workers, and staff in physical therapy, occupational therapy, and speech and language science.

B. Specific Therapy

The goal of treatment is to eradicate the tumor with the least short- and long-term morbidity. Long-term neuropsychological morbidity becomes an especially important issue related to deficits caused by the tumor itself and the sequelae of treatment. Meticulous surgical removal of as much tumor as possible is generally the preferred initial approach. Technologic advances in the operating microscope, the ultrasonic tissue aspirator, and the CO_2 laser (which is less commonly used in pediatric brain tumor surgery); the accuracy of computerized stereotactic resection; and the availability of intraoperative monitoring techniques such as evoked potentials and electrocorticography have increased the feasibility and safety of surgical resection of many pediatric brain tumors. Second-look surgery after chemotherapy is increasingly being used when tumors are incompletely resected at initial surgery.

Radiation therapy for pediatric brain tumors is in a state of evolution. For tumors with a high probability of neuraxis dissemination (eg, medulloblastoma), craniospinal irradiation is still standard therapy in children older than 3 years. For tumors, such as medulloblastomas, there are ongoing trials aimed at further reducing the craniospinal dose. In others (eg, ependymoma), craniospinal irradiation has been abandoned because neuraxis dissemination at first relapse is rare. Conformal radiation and the use of three-dimensional treatment planning are now in routine.

Chemotherapy is effective in treating low-grade and malignant astrocytomas and medulloblastomas. There is an initial report supporting the effectiveness of chemotherapy in AT/RTs. The therapy used in this study was prolonged and intensive. The utility of chemotherapy in ependymoma is being reexplored in national trials. A series of brain tumor protocols for children younger than 3 years involved administering intensive chemotherapy after tumor resection and delaying or omitting radiation therapy. The results of these trials have generally been disappointing but have taught valuable lessons regarding the varying responses to chemotherapy of different tumor types. Superior results seem to have been obtained in the very young with high-dose chemotherapy strategies with stem cell rescue often followed by conformal radiotherapy. Conformal techniques allow the delivery of radiation to strictly defined fields and may limit side effects.

Perhaps the most exciting development in pediatric neuro-oncology is the development of biologically and clinically relevant subclassifications in both medulloblastoma and ependymoma. This development will drive a new generation of targeted therapy aimed at these biologically defined groups. The consensus definition of four biologically defined entities in medulloblastoma, including the Wnt and SHH groups, is the best example of this. New studies are in the planning stage based on this new defined biology.

In older children with malignant glioma, the current approach is surgical resection of the tumor and combined-modality treatment with irradiation and intensive chemotherapy. It has recently been realized there is considerable heterogeneity in pediatric high-grade gliomas. Some, such as the congenital tumors, may do well with relatively modest therapy. Others, such as epithelioid glioblastomas may harbor Braf mutations and may be targetable with specific agents. Generally, however, the prognosis is poor for children with high-grade gliomas and there has been little progress in finding better chemotherapeutic agents and strategies for most children with these devastating tumors.

The treatment of low-grade astrocytomas, which cannot be completely excised, has likewise shown only disappointing progress. The chemotherapy agents currently in use have high failure rates and some children suffer multiple, neurologically damaging, relapses. Radiotherapy with its improved conformational techniques is perhaps being delayed too long in some children.

» Prognosis

Despite improvements in surgery and radiation therapy, the outlook for cure remains poor for children with high-grade glial tumors. For children with high-grade gliomas, an early CCG study showed a 45% progression-free survival rate for children who received radiation therapy and chemotherapy, but this may have been due to the inclusion of low-grade patients. More recent studies would suggest survival rate of less than 10%. The major exception to this is congenital glioblastomas which appear to have a much more favorable prognosis. Biologic factors that may affect survival are being increasingly recognized. The prognosis for diffuse pontine gliomas remains very poor, with the standard therapy of radiation alone, being only palliative.

The 5- and even 10-year survival rate for low-grade astrocytomas of childhood is 60%–90%. However, prognosis depends on both site, grade and, it is increasingly realized,

on biology. A child with a pilocytic astrocytoma of the cerebellum has a considerably better prognosis than a child with a fibrillary astrocytoma of the cerebral cortex. Pilomyxoid astrocytomas have been recently designated a grade II tumor and have a worse prognosis. For recurrent or progressive low-grade astrocytoma of childhood, relatively moderate chemotherapy may improve the likelihood of survival.

Conventional craniospinal irradiation for children with low-stage medulloblastoma results in survival rates of 60%–90%. Ten-year survival rates are lower (40%–60%). Chemotherapy allows a reduction in the craniospinal radiation dose while improving survival rates for average-risk patients (86% survival at 5 years on the most recent COG average-risk protocol). However, even reduced-dose craniospinal irradiation has an adverse effect on intellect, especially in children younger than 7 years. Five-year survival rates for high-risk medulloblastoma have been 25%–40%, but this may be improved with the introduction of more chemotherapy during radiation although this still awaits the results of formal trials.

The previously poor prognosis for children with AT/RTs seems improved by intensive multimodality therapy. A single-center study suggests an improved outcome for ependymoma using conformational radiation techniques. This awaits confirmation by a national study.

Major challenges remain in treating brain tumors in children younger than 3 years and in treating brainstem gliomas and malignant gliomas. The increasing emphasis is on the quality of life of survivors, not just the survival rate.

LYMPHOMAS & LYMPHOPROLIFERATIVE DISORDERS

The term lymphoma refers to a malignant proliferation of lymphoid cells, usually in association with and arising from lymphoid tissues (ie, lymph nodes, thymus, spleen). In contrast, the term leukemia refers to a malignancy arising from the bone marrow, which may include lymphoid cells. Because lymphomas can involve the bone marrow, the distinction between the two can be confusing. The diagnosis of lymphoma is a common one among childhood cancers, accounting for 10%–15% of all malignancies. The most common form is Hodgkin disease, which represents nearly half of all cases. The remaining subtypes, referred to collectively as non-Hodgkin lymphoma (NHL), are divided into four main groups: lymphoblastic, small noncleaved cell, large B-cell, and anaplastic large cell lymphomas.

In contrast to lymphomas, lymphoproliferative disorders (LPDs) are quite rare in the general population. Most are polyclonal, nonmalignant (though often life-threatening) accumulations of lymphocytes that occur when the immune system fails to control virally transformed lymphocytes. However, a malignant monoclonal proliferation can also arise. The posttransplant LPDs arise in patients who are immunosuppressed to prevent solid organ or bone marrow transplant rejection, particularly liver and heart transplant patients. Spontaneous LPDs occur in immunodeficient individuals and, less commonly, in immunocompetent persons.

1. Hodgkin Lymphoma

» General Considerations

Children with Hodgkin lymphoma have a better response to treatment than do adults, with greater than 90% 5- to 10-year overall survival rate when all stages are evaluated. Although adult therapies are applicable, the management of Hodgkin lymphoma in children younger than 18 years frequently differs. Because excellent disease control can result from several different therapeutic approaches, selection of staging procedures (radiographic, surgical, or other procedures to determine additional locations of disease) and treatment are often based on the potential long-term toxicity associated with the intervention.

Although Hodgkin lymphoma represents 50% of the lymphomas of childhood, only 15% of all cases occur in children aged 16 years or younger. Children younger than 5 years account for 3% of childhood cases. There is a 4:1 male predominance in the first decade. Notably, in underdeveloped countries the age distribution is quite different, with a peak incidence in younger children.

Hodgkin disease is subdivided into four histologic groups, and the distribution in children parallels that of adults: lymphocyte-predominant (10%–20%); nodular sclerosing (40%–60%) (increases with age); mixed cellularity

(20%–40%); and lymphocyte-depleted (5%–10%). Prognosis is independent of subclassification, with appropriate therapy based on stage (see section Staging).

» Clinical Findings

A. Symptoms and Signs

Children with Hodgkin lymphoma usually present with painless cervical adenopathy. The lymph nodes often feel firmer than inflammatory nodes and have a rubbery texture. They may be discrete or matted together and are not fixed to surrounding tissue. The growth rate is variable, and involved nodes may wax and wane in size over weeks to months.

As Hodgkin lymphoma nearly always arises in lymph nodes and spreads to contiguous nodal groups, a detailed examination of all nodal sites is mandatory. Lymphadenopathy is common in children, so the decision to perform biopsy is often difficult or delayed for a prolonged period. Indications for consideration of early lymph node biopsy include lack of identifiable infection in the region drained by the enlarged node, a node greater than 2 cm in size, supraclavicular adenopathy or abnormal chest radiograph, and lymphadenopathy increasing in size after 2 weeks or failing to resolve within 4–8 weeks.

Constitutional symptoms occur in about one-third of children at presentation. Symptoms of fever greater than 38.0°C, weight loss of 10% in the previous 6 months, and drenching night sweats are defined by the Ann Arbor staging criteria as B symptoms. The A designation refers to the absence of these symptoms. B symptoms are of prognostic value, and more aggressive therapy is usually required for cure. Generalized pruritus and pain with alcohol ingestion may also occur.

Half of patients have asymptomatic mediastinal disease (adenopathy or anterior mediastinal mass), although symptoms due to compression of vital structures in the thorax may occur. A chest radiograph should be obtained when lymphoma is being considered. The mediastinum must be evaluated thoroughly before any surgical procedure is undertaken to avoid airway obstruction or cardiovascular collapse during anesthesia and possible death. Splenomegaly or hepatomegaly is generally associated with advanced disease.

B. Laboratory Findings

The CBC is usually normal, although anemia, neutrophilia, eosinophilia, and thrombocytosis may be present. The erythrocyte sedimentation rate and other acute-phase reactants are often elevated and can serve as markers of disease activity. Immunologic abnormalities occur, particularly in cell-mediated immunity, and anergy is common in patients with advanced-stage disease at diagnosis. Autoantibody phenomena such as hemolytic anemia and an idiopathic thrombocytopenic purpura–like picture have been reported.

C. Staging

Staging of Hodgkin lymphoma determines treatment and prognosis. The most common staging system is the Ann Arbor classification that describes extent of disease by I–IV and symptoms by an A or a B suffix (eg, stage IIIB). A systematic search for disease includes chest radiography; CT scan of the chest, abdomen, and pelvis; and bilateral bone marrow aspirates and biopsies. Technetium bone scanning may show bony involvement and is usually reserved for patients with bone pain, as bone involvement is rare. In recent years, positron emission tomography (PET) is increasingly used in the staging and follow-up of patients with Hodgkin disease, often replacing gallium scanning.

The staging laparotomy in pediatrics is rarely performed because almost all patients are given systemic chemotherapy rather than radiation therapy. This shift in favored therapy is due to the toxicities of high-dose, extended-field radiation in children and the complications of laparotomy, including postsplenectomy sepsis.

D. Pathologic Findings

The diagnosis of Hodgkin lymphoma requires the histologic presence of the Reed-Sternberg cell or its variants in tissue. Reed-Sternberg cells are germinal-center B cells that have undergone malignant transformation. Nearly 20% of these tumors in developed countries are positive for EBV. EBV has been linked to Hodgkin disease and the large portion of Hodgkin patients with increased EBV titers suggests that EBV activation may contribute to the onset of Hodgkin lymphoma.

» Treatment & Prognosis

Treatment decisions are based on presence of B symptoms, stage, tumor bulk, and number of involved nodal regions. To achieve long-term disease-free survival while minimizing treatment toxicity, Hodgkin disease is increasingly treated by chemotherapy alone—and less often by radiation therapy.

Several combinations of chemotherapeutic agents are effective, and treatment times are relatively short compared with pediatric oncology protocols for leukemia. Clinical trials have addressed whether only 9 weeks of therapy with AV-PC (Adriamycin [doxorubicin], vincristine, prednisone, and cyclophosphamide) is sufficient to induce a complete response in patients with low-risk Hodgkin lymphoma. Two additional drugs, bleomycin and etoposide, are currently added in the treatment of intermediate-risk patients for a total of 4–6 months of therapy for patients with intermediate-risk disease. The removal of involved field irradiation in patients with intermediate-risk Hodgkin lymphoma who respond early to chemotherapy is being investigated. Combined-modality therapy with chemotherapy and irradiation is used in advanced disease.

Current treatment gives an overall 5 year survival of 90%–95% to children with stages I and II Hodgkin lymphoma. Two-thirds of all relapses occur within 2 years after diagnosis, and relapse rarely occurs beyond 4 years. Although patients with advanced disease (stages III and IV) have slightly lower overall survival, more patients are becoming long-term survivors of Hodgkin disease. As a result, the risk of secondary malignancies, both leukemias and solid tumors, is becoming more apparent and is higher in patients receiving radiation therapy. Therefore, elucidating the optimal treatment strategy that minimizes such risk should be the goal of future studies.

Patients with relapsed Hodgkin lymphoma are often salvageable using chemotherapy and radiation therapy. An increasingly popular alternative is autologous HSCT, which may improve survival rates. Allogeneic HSCT is also used, but carries increased risks of complications and may not offer added survival benefit.

Targeted therapies are being tested for children with high-risk Hodgkin lymphoma, including antibody conjugates targeting CD30, a transmembrane receptor highly expressed in Hodgkin lymphoma. A current COG trial is investigating if an anti-CD30 murine/human chimeric monoclonal antibody linked to monomethyl auristatin E is able to target the Reed-Stenberg cell in newly diagnosed high-risk Hodgkin Lymphoma. Other agents being considered in the high-risk group are histone deacetylase inhibitors and mTOR inhibitors.

2. Non-Hodgkin Lymphoma

» General Considerations

Non-Hodgkin lymphomas (NHLs) are a diverse group of cancers accounting for 5%–10% of malignancies in children younger than 15 years. About 500 new cases arise per year in the United States. The incidence of NHLs increases with age. Children aged 15 years or younger account for only 3% of all cases of NHLs, and the disease is uncommon before age 5 years. There is a male predominance of approximately 3:1. In equatorial Africa, NHLs cause almost 50% of pediatric malignancies.

Most children who develop NHL are immunologically normal. However, children with congenital or acquired immune deficiencies (eg, Wiskott-Aldrich syndrome, severe combined immunodeficiency syndrome, X-linked lymphoproliferative syndrome, human immunodeficiency virus (HIV) infection, immunosuppressive therapy following solid-organ or marrow transplantation) have an increased risk of developing NHLs. It has been estimated that their risk is 100–10,000 times that of age-matched control subjects.

Animal models suggest a viral contribution to the pathogenesis of NHL, and there is evidence of viral involvement in human NHL as well. In equatorial Africa, 95% of Burkitt lymphomas (BLs) contain DNA from the EBV. But in North America, less than 20% of Burkitt tumors contain the EBV genome. The role of other viruses (eg, human herpesviruses 6 and 8), disturbances in host immunologic defenses, chronic immunostimulation, and specific chromosomal rearrangements as potential triggers in the development of NHL is under investigation.

Unlike adult NHL, virtually all childhood NHLs are rapidly proliferating, high-grade, diffuse malignancies. These tumors exhibit aggressive behavior but are usually very responsive to treatment. Nearly all pediatric NHLs are histologically classified into four main groups: lymphoblastic lymphoma (LL), small noncleaved cell lymphoma (BL and Burkitt-like lymphoma [BLL]), large B-cell lymphoma (LBCL), and anaplastic large cell lymphoma (ALCL). Immunophenotyping and cytogenetic features, in addition to clinical presentation, are increasingly important in the classification, pathogenesis, and treatment of NHLs. Comparisons of pediatric NHLs are summarized in Table 31–5.

» Clinical Findings

A. Symptoms and Signs

Childhood NHLs can arise in any site of lymphoid tissue, including the lymph nodes, thymus, liver, and spleen. Common extralymphatic sites include bone, bone marrow, CNS, skin, and testes. Signs and symptoms at presentation are determined by the location of lesions and the degree of dissemination. Because NHL usually progresses very rapidly, the duration of symptoms is quite brief, from days to a few weeks. Nevertheless, children present with a limited number of syndromes, most of which correlate with cell type.

Children with LL often present with symptoms of airway compression (cough, dyspnea, orthopnea) or superior vena cava obstruction (facial edema, chemosis, plethora, venous engorgement), which are a result of mediastinal disease. These symptoms are a true emergency necessitating rapid diagnosis and treatment. Pleural or pericardial effusions may further compromise the patient's respiratory and cardiovascular status. CNS and bone marrow involvement are not common at diagnosis. When bone marrow contains more than 25% lymphoblasts, patients are diagnosed with ALL.

Most patients with BL and BLL present with abdominal disease. Abdominal pain, distention, a right lower quadrant

Table 31–5. Comparison of pediatric non-Hodgkin lymphomas.

	Lymphoblastic Lymphoma	Small Noncleaved Cell Lymphoma (BL and BLL)	Large B-Cell Lymphoma	Anaplastic Large Cell Lymphoma
Incidence (%)	30–40	35–50	10–15	10–15
Histopathologic features	Indistinguishable from ALL lymphoblasts	Large nucleus with prominent nucleoli surrounded by very basophilic cytoplasm that contains lipid vacuoles	Large cells with cleaved or noncleaved nuclei	Large pleomorphic cells
Immunopheno-type	Immature T cell	B cell	B cell	T cell or null cell
Cytogenetic markers	Translocations involving chromosome 14q11 and chromosome 7; interstitial deletions of chromosome 1	t(8;14), t(8;22), t(2;8)	Many	t(2;5)
Clinical presentation	Intrathoracic tumor, mediastinal mass (50%–70%), lymphadenopathy above diaphragm (50%–80%)	Intra-abdominal tumor (90%), jaw involvement (10%–20% sporadic BL, 70% endemic BL), bone marrow involvement	Abdominal tumor most common; unusual sites: lung, face, brain, bone, testes, muscle	Lymphadenopathy, fever, weight loss, night sweats, extranodal sites including viscera and skin
Treatment	Similar to ALL therapy; 24 mo duration	Intensive administration of alkylating agents and methotrexate; CNS prophylaxis; 3–9 mo duration	Similar to therapy for BL/BLL	Similar to therapy for lymphoblastic lymphoma or BL/BLL

ALL, acute lymphoblastic leukemia; BL, Burkitt lymphoma; BLL, Burkitt-like lymphoma; CNS, central nervous system.

mass, or intussusception in a child older than 5 years suggests the diagnosis of BL. Bone marrow involvement is common (~65% of patients). BL is the most rapidly proliferating tumor known and has a high rate of spontaneous cell death as it outgrows its blood supply. Consequently, children presenting with massive abdominal disease frequently have tumor lysis syndrome (hyperuricemia, hyperphosphatemia, and hyperkalemia). These abnormalities can be aggravated by tumor infiltration of the kidney or urinary obstruction by tumor. Although similar histologically, numerous differences exist between cases of BL occurring in endemic areas of equatorial Africa and the sporadic cases of North America (Table 31–6).

Large cell lymphomas are similar clinically to the small noncleaved cell lymphomas, although unusual sites of involvement are quite common, particularly with ALCL. Skin lesions, focal neurologic deficits, and pleural or peritoneal effusions without an obvious associated mass are frequently seen.

B. Diagnostic Evaluation

Diagnosis is made by biopsy of involved tissue with histology, immunophenotyping, and cytogenetic studies. If mediastinal disease is present, general anesthesia must be avoided if the airway or vena cava is compromised by tumor. In these cases samples of pleural or ascitic fluid, bone marrow, or peripheral nodes obtained under local anesthesia

Table 31–6. Comparison of endemic and sporadic Burkitt lymphoma.

	Endemic	Sporadic
Incidence	10 per 100,000	0.9 per 100,000
Cytogenetics	Chromosome 8 breakpoint upstream of c-myc locus	Chromosome 8 breakpoint within c-myc locus
EBV association	≥ 95%	≤ 20%
Disease sites at presentation	Jaw (58%), abdomen (58%), CNS (19%), orbit (11%), marrow (7%)	Jaw (7%), abdomen (91%), CNS (14%), orbit (1%), marrow (20%)

CNS, central nervous system; EBV, Epstein-Barr virus.

(in the presence of an anesthesiologist) may confirm the diagnosis. Major abdominal surgery and intestinal resection should be avoided in patients with an abdominal mass that is likely to be BL, as the tumor will regress rapidly with the initiation of chemotherapy. The rapid growth of these tumors and the associated life-threatening complications demand that further studies be done expeditiously so that specific therapy is not delayed.

After a thorough physical examination, a CBC, liver function tests, and a biochemical profile (electrolytes, calcium, phosphorus, uric acid, renal function) should be obtained. An elevated LDH reflects tumor burden and can serve as a marker of disease activity. Imaging studies should include a chest radiograph and chest CT scan, an abdominal ultrasound or CT scan, and possibly a PET scan. Bone marrow and CSF examinations are also essential.

» Treatment

A. Supportive Care

The management of life-threatening problems at presentation is critical. The most common complications are superior mediastinal syndrome and acute tumor lysis syndrome. Patients with airway compromise require prompt initiation of specific therapy. Because of the risk of general anesthesia in these patients, it is occasionally necessary to initiate corticosteroids or low-dose emergency radiation therapy until the mass is small enough for a biopsy to be undertaken safely. Response to steroids and radiation therapy is usually prompt (12–24 hours).

Tumor lysis syndrome should be anticipated in all patients who have NHL with a large tumor burden. Maintaining a brisk urine output (> 5 mL/kg/h) with intravenous fluids and diuretics is the key to management. Allopurinol will reduce serum uric acid, and alkalinization of urine will increase its solubility. Rasburicase is an effective intravenous alternative to allopurinol and is increasingly used for patients with high risk of tumor lysis based on tumor burden or in patients who do not have an optimal response to allopurinol. Because phosphate precipitates in alkaline urine, alkali administration should be discontinued if hyperphosphatemia occurs. Renal dialysis is occasionally necessary to control metabolic abnormalities. Every attempt should be made to correct or minimize metabolic abnormalities before initiating chemotherapy; however, this period of stabilization should not exceed 24–48 hours.

B. Specific Therapy

Systemic chemotherapy is the mainstay of therapy for NHLs. Nearly all patients with NHL require intensive intrathecal chemotherapy for CNS prophylaxis. Surgical resection is not indicated unless the entire tumor can be resected safely, which is rare. Partial resection or debulking surgery has no role. Radiation therapy does not improve outcome, so its use is confined to exceptional circumstances.

Therapy for LL is generally based on treatment protocols designed for ALL and involves dose-intensive, multiagent chemotherapy. Current trials are testing whether the addition of bortezomib to the current multiagent chemotherapy regimen will decrease the risk of relapse for patients with T-cell LL. The duration of therapy is 2 years. Treatment of BL and BLL using alkylating agents and intermediate- to high-dose methotrexate administered intensively but for a relatively short time produce the highest cure rates. LBCL is treated similarly, whereas ALCL has been treated with both BL and LL protocols.

Monoclonal antibodies such as rituximab (anti-CD20) allow for more targeted therapy of lymphomas and have been successful in improving outcomes in adults. Studies employing this type of therapy in children are underway in those with newly diagnosed as well as relapsed or refractory B-cell NHL. Additionally, inhibitors against the ALK oncogene are being explored as novel therapy for specific subsets of patients with NHL. Specifically, the ALK oncogene (activated by a 2;5 translocation leading to juxtaposition of NPM N-terminal region to the intracellular part of ALK) is the defining genetic lesions in ALK-positive ALCL and in rare variants of LBCL. Molecular profiling of pediatric lymphomas has identified other potential biologic targets. Current trials are testing the efficacy of oral small molecule inhibitors of ALK in children with relapsed/refractory ALCL.

» Prognosis

A major predictor of outcome in NHL is the extent of disease at diagnosis. Ninety percent of patients with localized disease can expect long-term, disease-free survival. Patients with extensive disease on both sides of the diaphragm, CNS involvement, or bone marrow involvement in addition to a primary site have a 70%–80% failure-free survival rate. Relapses occur early in NHL; patients with LL rarely have recurrences after 30 months from diagnosis, whereas patients with BL and BLL very rarely have recurrences beyond 1 year. The cure rate for patients with relapsed T-cell lymphoblastic leukemia/lymphoma is particularly poor (3-year EFS rates < 20%). Patients who experience relapse may have a chance for cure by autologous or allogeneic HSCT.

3. Lymphoproliferative Disorders

Lymphoproliferative disorders (LPDs) can be thought of as a part of a continuum with lymphomas. Whereas LPDs represent inappropriate, often polyclonal proliferations of nonmalignant lymphocytes, lymphomas represent the development of malignant clones, sometimes arising from recognized LPDs.

A. Posttransplantation Lymphoproliferative Disorders

Posttransplantation lymphoproliferative disorders (PTLDs) arise in patients who have received substantial immunosuppressive medications for solid organ or bone marrow transplantation. In these patients, reactivation of latent EBV infection in B cells drives a polyclonal proliferation of these cells that is fatal if not halted. Occasionally a true lymphoma develops, often bearing a chromosomal translocation.

LPDs are an increasingly common and significant complication of transplantation. The incidence of PTLD ranges from approximately 2% to 15% of transplant recipients, depending on the organ transplanted and the immunosuppressive regimen.

Treatment of these disorders is a challenge for transplant physicians and oncologists. The initial treatment is reduction in immunosuppression, which allows the patient's own immune cells to destroy the virally transformed lymphocytes. However, this is only effective in approximately half of the patients. For those patients who do not respond to reduced immune suppression, chemotherapy of various regimens may succeed. The use of anti–B-cell antibodies, such as rituximab (anti-CD20), for the treatment of PTLDs has been promising in clinical trials. More recently, T-cell–based immune therapies, such as donor lymphocyte infusions and adoptive transfer of EBV-specific cytotoxic T lymphocytes, have also been explored as novel approaches.

B. Spontaneous Lymphoproliferative Disease

Immunodeficiencies in which LPDs occur include Bloom syndrome, Chédiak-Higashi syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, congenital T-cell immunodeficiencies, and HIV infection. Treatment depends on the circumstances, but unlike PTLD, few therapeutic options are often available. Castleman disease is an LPD occurring in pediatric patients without any apparent immunodeficiency. The autoimmune lymphoproliferative syndrome (ALPS) is characterized by widespread lymphadenopathy with hepatosplenomegaly, and autoimmune phenomena. ALPS results from mutations in the Fas ligand pathway that is critical in regulation of apoptosis.

NEUROBLASTOMA

» General Considerations

Neuroblastoma arises from neural crest tissue of the sympathetic ganglia or adrenal medulla. It is composed of small, fairly uniform cells with little cytoplasm and hyperchromatic nuclei that may form rosette patterns. Pathologic diagnosis is not always easy, and neuroblastoma must be differentiated from the other "small, round, blue cell" malignancies of childhood (Ewing sarcoma, rhabdomyosarcoma, peripheral neuroectodermal tumor, and lymphoma).

Neuroblastoma accounts for 7%–10% of pediatric malignancies and is the most common solid neoplasm outside the CNS. Fifty percent of neuroblastomas are diagnosed before age 2 years and 90% before age 5 years.

Neuroblastoma is a biologically diverse disease with varied clinical behavior ranging from spontaneous regression to progression through very aggressive therapy. Unfortunately, despite significant advances in our understanding of this tumor at the cellular and molecular level, the overall survival rate in advanced disease has changed little in 20 years, with 3-year EFS being less than 15%.

» Clinical Findings

A. Symptoms and Signs

Clinical manifestations vary with the primary site of malignant disease and the neuroendocrine function of the tumor. Many children present with constitutional symptoms such as fever, weight loss, and irritability. Bone pain suggests metastatic disease, which is present in 60% of children older than 1 year at diagnosis. Physical examination may reveal a firm, fixed, irregularly shaped mass that extends beyond the midline. The margins are often poorly defined. Although most children have an abdominal primary tumor (40% adrenal gland, 25% paraspinal ganglion), neuroblastoma can arise wherever there is sympathetic tissue. In the posterior mediastinum, the tumor is usually asymptomatic and discovered on a chest radiograph obtained for other reasons. Patients with cervical neuroblastoma present with a neck

mass, which is often misdiagnosed as infection. Horner syndrome (unilateral ptosis, myosis, and anhidrosis) or heterochromia iridis (differently colored irises) may accompany cervical neuroblastoma. Paraspinous tumors can extend through the spinal foramina, causing cord compression. Patients may present with paresis, paralysis, and bowel or bladder dysfunction.

The most common sites of metastases are bone, bone marrow, lymph nodes (regional as well as disseminated), liver, and subcutaneous tissue. Neuroblastoma has a predilection for metastasis to the skull, in particular the sphenoid bone and retrobulbar tissue. This causes periorbital ecchymosis and proptosis. Liver metastasis, particularly in the newborn, can be massive. Subcutaneous nodules are bluish in color and associated with an erythematous flush followed by blanching when compressed, probably secondary to catecholamine release.

Neuroblastoma may also be associated with unusual paraneoplastic manifestations. Perhaps the most striking example is opsoclonus-myoclonus, also called dancing eyes/dancing feet syndrome. This phenomenon is characterized by the acute onset of rapid and chaotic eye movements, myoclonic jerking of the limbs and trunk, ataxia, and behavioral disturbances. This process, which often persists after therapy is complete, is thought to be secondary to cross-reacting antineural antibodies. Intractable, chronic watery diarrhea is associated with tumor secretion of vasoactive intestinal peptides. Both of these paraneoplastic syndromes are associated with favorable outcomes.

B. Laboratory Findings

Anemia is present in 60% of children with neuroblastoma and can be due to chronic disease or marrow infiltration. Occasionally, thrombocytopenia is present, but thrombocytosis is a more common finding, even with metastatic disease in the marrow. Urinary catecholamines (vanillylmandelic acid and homovanillic acid) are elevated in at least 90% of patients at diagnosis and should be measured prior to surgery.

C. Imaging

Plain radiographs of the primary tumor may show stippled calcifications. Metastases to bone appear irregular and lytic. Periosteal reaction and pathologic fractures may also be seen. CT scanning provides more information, including the extent of the primary tumor, its effects on surrounding structures, and the presence of liver and lymph node metastases. Classically, in tumors originating from the adrenal gland, the kidney is displaced inferolaterally, which helps to differentiate neuroblastoma from Wilms tumor. MRI is useful in determining the presence of spinal cord involvement in tumors that appear to invade neural foramina.

Technetium bone scanning is obtained for the evaluation of bone metastases, because the tumor usually takes up technetium. Metaiodobenzylguanidine (MIBG) scanning is also performed to detect metastatic disease.

D. Staging

Staging of neuroblastoma is performed according to the International Neuroblastoma Staging System (INSS) (Table 31–7). A biopsy of the tumor is performed to determine the biologic characteristics of the tumor. In addition, bilateral bone marrow aspirates and biopsies must be performed to evaluate marrow involvement.

Tumors are classified as favorable or unfavorable based on histologic characteristics. Amplification of the MYCN protooncogene is a reliable marker of aggressive clinical behavior with rapid disease progression. Tumor cell DNA content is also predictive of outcome. Hyperdiploidy is a favorable finding, whereas diploid DNA content is associated with a worse outcome.

Table 31–7. International Neuroblastoma Staging System.

Stage	Description
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically.
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement. The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs, except as defined for stage 4S.
4S	Localized primary tumor, as defined for stage 1, 2A, or 2B, with dissemination limited to skin, liver, or bone marrow, and limited to infants age < 1 y. Marrow involvement should be < 10% of nucleated cells.

» Treatment & Prognosis

Patients are treated based on a risk stratification system adopted by the COG based on INSS stage, age, MYCN status, histology, cytogenetic findings, and DNA index. The mainstay of therapy is surgical resection coupled with chemotherapy. The usually massive size of the tumor often makes primary resection impossible. Under these circumstances, only a biopsy is performed. Following chemotherapy, a second surgical procedure may allow for resection of the primary tumor. Radiation therapy is sometimes also necessary. Effective chemotherapeutic agents in the treatment of neuroblastoma include cyclophosphamide, doxorubicin, etoposide, cisplatin, vincristine, and topotecan. About 80% of patients achieve complete or partial remission, although in advanced disease, remission is seldom durable.

For low-risk disease (stages 1 and 2, with good biologic features), surgical resection alone may be sufficient to affect a cure. Infants younger than 1 year with stage 4S disease may need little if any therapy, although chemotherapy may be initiated because of bulky disease causing mechanical complications. In intermediate-risk neuroblastoma (subsets of patients with stages 3 and 4 disease), the primary treatment approach is surgical combined with chemotherapy. High-risk patients (the majority with stages 3 and 4 disease) require multimodal therapy, including surgery, irradiation, chemotherapy, and autologous HSCT. The administration of cis-retinoic acid, a differentiating agent, was shown to prolong disease-free survival in advanced-stage neuroblastoma when administered in the setting of MRD after HSCT.

A recent cooperative clinical trial concluded that administration of ch14.18 (a monoclonal antibody specific for the predominant antigen on neuroblastoma cells) and cytokines improves outcome in the high-risk population following HSCT. All patients with high-risk disease are offered this therapy, with the 2-year EFS being around 75%. The current COG trial for high-risk patients is investigating whether addition of radiolabeled MIBG to the induction regimen will improve outcome.

For children with stage 1, 2, or 4S disease, the 5-year survival rate is 80%–100%. Infants younger than 547 days have a greater than 80% likelihood of long-term survival.

WILMS TUMOR (NEPHROBLASTOMA)

» General Considerations

Approximately 460 new cases of Wilms tumor occur annually in the United States, representing 5%–6% of cancers in children younger than 15 years. After neuroblastoma, this is the second most common abdominal tumor in children. The majority of Wilms tumors are of sporadic occurrence. However, in a few children, Wilms tumor occurs in the setting of associated malformations or syndromes, including aniridia, hemihypertrophy, genitourinary malformations (eg, cryptorchidism, hypospadias, gonadal dysgenesis, pseudohermaphroditism, and horseshoe kidney), Beckwith-Wiedemann syndrome, Denys-Drash syndrome, and WAGR syndrome (Wilms tumor, aniridia, ambiguous genitalia, mental retardation).

The median age at diagnosis is related both to gender and laterality, with bilateral tumors presenting at a younger age than unilateral tumors, and males being diagnosed earlier than females. Wilms tumor occurs most commonly between ages 2 and 5 years; it is unusual after age 6 years. The mean age at diagnosis is 4 years.

» Clinical Findings

A. Symptoms and Signs

Most children with Wilms tumor present with increasing size of the abdomen or an asymptomatic abdominal mass incidentally discovered by a parent and/or health care provider. The mass is usually smooth and firm, well demarcated, and rarely crosses the midline, though it can extend inferiorly into the pelvis. About 25% of patients are hypertensive at presentation. Gross hematuria is an uncommon presentation, although microscopic hematuria occurs in approximately 25% of patients.

B. Laboratory Findings

The CBC is usually normal, but some patients have anemia secondary to hemorrhage into the tumor. Blood urea nitrogen and serum creatinine are usually normal. Urinalysis may show some blood or leukocytes.

C. Imaging and Staging

Ultrasonography or CT of the abdomen should establish the presence of an intrarenal mass. It is also essential to evaluate the contralateral kidney for presence and function as well as synchronous Wilms tumor. The inferior vena cava needs to be evaluated by ultrasonography with Doppler flow for the presence and extent of tumor propagation. The liver should be imaged for the presence of metastatic disease. Chest CT scan should be obtained to determine whether pulmonary metastases are present. Approximately 10% of patients will have metastatic disease at diagnosis. Of these, 80% will have pulmonary disease and 15% liver metastases. Bone and brain metastases are extremely uncommon and usually associated with the rarer, more aggressive renal tumor types, such as clear cell sarcoma or rhabdoid tumor; hence, bone scans and brain imaging are not routinely performed. The clinical stage is ultimately decided at surgery and confirmed by the pathologist.

» Treatment & Prognosis

In the United States, treatment of Wilms tumor begins with surgical exploration of the abdomen via an anterior surgical approach to allow for inspection and palpation of the contralateral kidney. The liver and lymph nodes are inspected and suspicious areas biopsied or excised. En bloc resection of the tumor is performed. Every attempt is made to avoid tumor spillage at surgery as this may increase the staging and treatment. Because therapy is tailored to tumor stage, it is imperative that a surgeon familiar with the staging requirements perform the operation.

In addition to the staging, the histologic type has implications for therapy and prognosis. Favorable histology (FH; see later discussion) refers to the classic triphasic Wilms tumor and its variants. Unfavorable histology (UH) refers to the presence of diffuse anaplasia (extreme nuclear atypia) and is present in 5% of Wilms tumors. Only a few small foci of anaplasia in a Wilms tumor give a worse prognosis to patients with stage II, III, or IV tumors. Loss of heterozygosity of chromosomes 1p and 16q are adverse prognostic factors in those with favorable histology. Following excision and pathologic examination, the patient is assigned a stage that defines further therapy.

Improvement in the treatment of Wilms tumor has resulted in an overall cure rate of approximately 90%. The National Wilms Tumor Study Group's fourth study (NWTS-4) demonstrated that survival rates were improved by intensifying therapy during the initial treatment phase while shortening overall treatment duration (24 vs 60 weeks of treatment).

Table 31–8 provides an overview of the current treatment recommendations in NWTS-5. Patients with stage III or IV Wilms tumor require radiation therapy to the tumor bed and to sites of metastatic disease. Chemotherapy is optimally begun within 5 days after surgery, whereas radiation therapy should be started within 10 days. Stage V (bilateral Wilms tumor) disease dictates a different approach, consisting of possible bilateral renal biopsies followed by chemotherapy and second-look renal-sparing surgery. Radiation therapy may also be necessary.

Table 31–8. Treatment of Wilms tumor.

Stage/Histologic Subtype	Treatment
I–II FH and I UH	18 wk (dactinomycin and vincristine)
III–IV FH and II–IV focal anaplasia	24 wk (dactinomycin, vincristine, and doxorubicin) with radiation
II–IV UH (diffuse anaplasia)	24 wk (vincristine, doxorubicin, etoposide, and cyclophosphamide) with radiation

FH, favorable histology; UH, unfavorable histology.

Using these approaches, 4-year overall survival rates through NWTS-4 are as follows: stage I FH, 96%; stages II–IV FH, 82%–92%; stages I–III UH (diffuse anaplasia), 56%–70%; and stage IV UH, 17%. Patients with recurrent Wilms tumor have a salvage rate of approximately 50% with surgery, radiation therapy, and chemotherapy (singly or in combination). HSCT is also being explored as a way to improve the chances of survival after relapse.

» Future Considerations

Although progress in the treatment of Wilms tumor has been extraordinary, important questions remain to be answered. Questions have been raised regarding the role of prenephrectomy chemotherapy in the treatment of Wilms tumor. Presurgical chemotherapy seems to decrease tumor rupture at resection but may unfavorably affect outcome by changing staging. Future studies will be directed at minimizing acute and long-term toxicities for those with low-risk disease and improving outcomes for those with high-risk and recurrent disease.

BONE TUMORS

Primary malignant bone tumors are uncommon in childhood with only 650–700 new cases per year. Osteosarcoma accounts for 60% of cases and occurs mostly in adolescents and young adults. Ewing sarcoma is the second most common malignant tumor of bony origin and occurs in toddlers to young adults. Both tumors have a male predominance.

The cardinal signs of bone tumor are pain at the site of involvement, often following slight trauma, mass formation, and fracture through an area of cortical bone destruction.

1. Osteosarcoma

» General Considerations

Although osteosarcoma is the sixth most common malignancy in childhood, it ranks third among adolescents and young adults. This peak occurrence during the adolescent growth spurt suggests a causal relationship between rapid bone growth and malignant transformation. Further evidence for this relationship is found in epidemiologic data showing patients with osteosarcoma to be taller than their peers, osteosarcoma occurring most frequently at sites where the greatest increase in length and size of bone occurs, and osteosarcoma occurring at an earlier age in girls than boys, corresponding to their earlier growth spurt. The metaphyses of long tubular bones are primarily affected. The distal femur accounts for more than 40% of cases, with the proximal tibia, proximal humerus, and mid and proximal femur following in frequency.

» Clinical Findings

A. Symptoms and Signs

Pain over the involved area is the usual presenting symptom with or without an associated soft tissue mass. Patients generally have symptoms for several months prior to diagnosis. Systemic symptoms (fever, weight loss) are rare. Laboratory evaluation may reveal elevated serum alkaline phosphatase or LDH levels.

B. Imaging and Staging

Radiographic findings show permeative destruction of the normal bony trabecular pattern with indistinct margins. In addition, periosteal new bone formation and lifting of the bony cortex may create a Codman triangle. A soft tissue mass plus calcifications in a radial or sunburst pattern are frequently noted. MRI is more sensitive in defining the extent of the primary tumor and has mostly replaced CT scanning. The most common sites of metastases are the lung (≤ 20% of newly diagnosed cases) and the additional boney sites (10%). CT scan of the chest and bone scan are essential for detecting metastatic disease. PET-CT may be a consideration in monitoring response to therapy. Bone marrow aspirates and biopsies are not indicated.

Despite the rather characteristic radiographic appearance, a tissue sample is needed to confirm the diagnosis. Placement of the incision for biopsy is of critical importance. A misplaced incision could preclude a limb salvage procedure and necessitate amputation. The surgeon who will carry out the definitive surgical procedure should perform the biopsy. A staging system for osteosarcoma based on local tumor extent and presence or absence of distant metastasis has been proposed, but it has not been validated.

» Treatment & Prognosis

Historical studies showed that over 50% of patients receiving surgery alone developed pulmonary metastases within 6 months after surgery. This suggests the presence of micrometastatic disease at diagnosis. Adjuvant chemotherapy trials showed improved disease-free survival rates of 55%–85% in patients followed for 3–10 years.

Osteosarcomas are highly radioresistant lesions; for this reason, radiation therapy has no role in its primary management. Chemotherapy is often administered prior to definitive surgery (neoadjuvant chemotherapy). This permits an early attack on micrometastatic disease and may also shrink the tumor, facilitating a limb salvage procedure. Preoperative chemotherapy also makes detailed histologic evaluation of tumor response to the chemotherapy agents possible. If the histologic response is poor (> 10% viable tumor tissue), postoperative chemotherapy can be changed accordingly but a recently completed COG Group study showed increased toxicity with no additional benefit. Chemotherapy may be administered intra-arterially or intravenously, although the benefits of intra-arterial chemotherapy are disputed. Agents having efficacy in the treatment of osteosarcoma include doxorubicin, cisplatin, high-dose methotrexate, ifosfamide, and etoposide.

Definitive cure requires en bloc surgical resection of the tumor with a margin of uninvolved tissue. Amputation, limb salvage, and rotationplasty (Van Ness rotation) are equally effective in achieving local control of osteosarcoma. Contraindications to limb-sparing surgery include major involvement of the neurovascular bundle by tumor; immature skeletal age, particularly for lower extremity tumors; infection in the region of the tumor; inappropriate biopsy

site; and extensive muscle involvement that would result in a poor functional outcome.

Postsurgical chemotherapy is generally continued until the patient has received 1 year of treatment. Relapses are unusual beyond 3 years, but late relapses do occur. Histologic response to neoadjuvant chemotherapy is an excellent predictor of outcome. Patients with localized disease having 90% or greater tumor necrosis have a 70%–75% long-term, disease-free survival rate. Other favorable prognostic factors include distal skeletal lesions, longer duration of symptoms, age older than 20 years, female gender, and near-diploid tumor DNA index. Patients with metastatic disease at diagnosis or multifocal bone lesions do not fair well, despite advances in chemotherapy and surgical techniques.

2. Ewing Sarcoma

» General Considerations

Ewing sarcoma accounts for only 30% of primary malignant bone tumors; fewer than 200 new cases occur each year in the United States. It is a disease primarily of white males, almost never affects blacks, and occurs mostly in the second decade of life. Ewing sarcoma is considered a "small, round, blue cell" malignancy. The differential diagnosis includes rhabdomyosarcoma, lymphoma, and neuroblastoma. Although most commonly a tumor of bone, it may also occur in soft tissue (extraosseous Ewing sarcoma or peripheral neuroectodermal tumor [PNET]).

» Clinical Findings

A. Symptoms and Signs

Pain at the site of the primary tumor is the most common presenting sign, with or without swelling and erythema. No specific laboratory findings are characteristic of Ewing sarcoma, but an elevated LDH may be present and is of prognostic significance. Associated symptoms include fevers and weight loss.

B. Imaging and Staging

The radiographic appearance of Ewing sarcoma overlaps with osteosarcoma, although Ewing sarcoma usually involves the diaphyses of long bones. The central axial skeleton gives rise to 40% of Ewing tumors. Evaluation of a patient diagnosed as having Ewing sarcoma should include an MRI of the primary lesion to define the extent of local disease as precisely as possible. This is imperative for planning future surgical procedures or radiation therapy. Metastatic disease is present in 25% of patients at diagnosis. The lung (38%), bone (particularly the spine) (31%), and the bone marrow (11%) are the most common sites for metastasis. CT scan of the chest, bone scan, and bilateral bone marrow aspirates and biopsies are all essential to the staging workup. PET-CT may be a consideration in helping to monitor therapy response.

A biopsy is essential in establishing the diagnosis. Histologically, Ewing sarcoma consists of sheets of undifferentiated cells with hyperchromatic nuclei, well-defined cell borders, and scanty cytoplasm. Necrosis is common. Electron microscopy, immunocytochemistry, and cytogenetics may be necessary to confirm the diagnosis. A generous tissue biopsy specimen is often necessary for diagnosis but should not delay starting chemotherapy.

A consistent cytogenetic abnormality, t(11;22), has been identified in Ewing sarcoma and PNET and is present in 85%–90% of tumors. These tumors also express the protooncogene c-myc, which may be helpful in differentiating Ewing sarcoma from neuroblastoma, in which c-myc is not expressed.

» Treatment & Prognosis

Therapy usually commences with the administration of chemotherapy after biopsy and is followed by local control measures. Depending on many factors, including the primary site of the tumor and the response to chemotherapy, local control can be achieved by surgery, radiation therapy, or a combination of these methods. Following local control, chemotherapy continues for approximately 6 months. Effective treatment for Ewing sarcoma uses combinations of dactinomycin, vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Recent data showed that giving chemotherapy every 2 weeks, rather than every 3 weeks, improved the EFS for localized Ewing sarcoma. The current COG nonmetastatic Ewing sarcoma study is looking at whether the addition of topotecan to the present five-drug regimen will improve survival.

Patients with small localized primary tumors have a 70%–75% long-term, disease-free survival rate. For patients with metastatic disease survival is poor. Autologous HSCT may be considered as part of the treatment of these high-risk patients. Patients with pelvic tumors have an intermediate prognosis of around 50% long-term, disease-free survival.

RHABDOMYOSARCOMA

» General Considerations

Rhabdomyosarcoma is the most common soft tissue sarcoma occurring in childhood and accounts for 10% of solid tumors in childhood. The peak incidence occurs at ages 2–5 years; 70% of children are diagnosed before age 10 years. A second smaller peak is seen in adolescents with extremity tumors. Males are affected more commonly than females.

Rhabdomyosarcoma can occur anywhere in the body. When rhabdomyosarcoma imitates striated muscle and cross-striations are seen by light microscopy, the diagnosis is straightforward. Immunohistochemistry, electron microscopy, or chromosomal analysis is sometimes necessary to make the diagnosis. Rhabdomyosarcoma is further classified into subtypes based on pathologic features: embryonal (60%–80%), of which botryoid is a variant; alveolar (~15%–20%); undifferentiated sarcoma (8%); pleomorphic, which is seen in adults (1%); and other (11%). These subtypes occur in characteristic locations and have different metastatic potentials and outcomes.

Although the pathogenesis of rhabdomyosarcoma is unknown, in rare cases a genetic predisposition has been determined. Li-Fraumeni syndrome is an inherited mutation of the p53 tumor suppressor gene that results in a high risk of bone and soft tissue sarcomas in childhood plus breast cancer and other malignant neoplasms before age 45 years. Two characteristic chromosomal translocations [t(2;13) and t(1;13)] have been described in alveolar rhabdomyosarcoma. The t(1;13) translocation appears to be a favorable prognostic feature in patients with metastatic alveolar rhabdomyosarcoma, whereas t(2;13) is associated with poor outcomes.

» Clinical Findings

A. Symptoms and Signs

The presenting symptoms and signs of rhabdomyosarcoma result from disturbances of normal body function due to tumor growth (Table 31–9). For example, patients with orbital rhabdomyosarcoma present with proptosis, whereas patients with rhabdomyosarcoma of the bladder can present with hematuria, urinary obstruction, or a pelvic mass.

B. Imaging

A plain radiograph and a CT and/or MRI scan should be obtained to determine the extent of the primary tumor and to assess regional lymph nodes. A chest CT scan is obtained to rule out pulmonary metastasis, the most common site of metastatic disease at diagnosis. A skeletal survey and a bone scan are obtained to determine whether bony metastases are present. Bilateral bone marrow biopsies and aspirates are obtained to rule out bone marrow infiltration. Additional studies may be warranted in certain sites. For example, in parameningeal primary tumors, a lumbar puncture is performed to evaluate CSF for tumor cells.

» Treatment

Optimal management and treatment of rhabdomyosarcoma is complex and requires combined modality therapy. When feasible, the tumor should be excised, but this is not always possible because of the site of origin and size of tumor. When only partial tumor resection is feasible, the operative procedure is usually limited to biopsy and sampling of lymph nodes. Debulking of unresectable tumor may

Table 31–9. Characteristics of rhabdomyosarcoma.

Primary Site	Frequency (%)	Symptoms and Signs	Predominant Pathologic Subtype
Head and neck	**35**		Embryonal
Orbit	9	Proptosis	
Parameningeal	16	Cranial nerve palsies; aural or sinus obstruction with or without drainage	
Other	10	Painless, progressively enlarging mass	
Genitourinary	**22**		Embryonal (botryoid variant in bladder and vagina)
Bladder and prostate	13	Hematuria, urinary obstruction	
Vagina and uterus	2	Pelvic mass, vaginal discharge	
Paratesticular	7	Painless mass	
Extremities	**18**	Adolescents, swelling of affected body part	Alveolar (50%), undifferentiated
Other	25	Mass	Alveolar, undifferentiated

improve outcomes by decreasing the assigned stage/group. Chemotherapy can often convert an inoperable tumor to a resectable one. A second-look procedure to remove residual disease and confirm the clinical response to chemotherapy and radiation therapy is generally performed at about week 20 of therapy.

Radiation therapy is an effective method of local tumor control for both microscopic and gross residual disease. It is generally administered to all patients, the only exception being those with a localized tumor that has been completely resected. All patients with rhabdomyosarcoma receive chemotherapy, even when the tumor is fully resected at diagnosis. The exact regimen and duration of chemotherapy are determined by primary site, group, and tumor node metastasis classification. Vincristine, dactinomycin, and cyclophosphamide have shown the greatest efficacy in the treatment of rhabdomyosarcoma. Irinotecan is now being studied in upfront treatment of metastatic rhabdomyosarcoma based on good responses in relapsed disease. Newer treatment strategies for high-risk patients include different drug combinations, including the use of temozolomide and cixutumumab (monoclonal antibody against IGF-IR) in a current COG randomized trial.

» Prognosis

The age of the patient, the extent of tumor at diagnosis, the primary site, the pathologic subtype, and the response to treatment all influence the long-term, disease-free survival rate from the time of diagnosis. Children with localized disease at diagnosis have a 70%–75% 3-year disease-free survival rate, whereas children with metastatic disease at presentation have a worse outcome (39% 3-year disease-free survival).

RETINOBLASTOMA

» General Considerations

Retinoblastoma is a neuroectodermal malignancy arising from embryonic retinal cells that accounts for 3% of malignant disease in children younger than 15 years. It is the most common intraocular tumor in pediatric patients and causes 5% of cases of childhood blindness. In the United States, 200–300 new cases occur per year. This is a malignancy of early childhood, with 90% of the tumors diagnosed before age 5 years. Bilateral involvement occurs in 20%–30% of children and typically is diagnosed at a younger age (median age 14 months) than unilateral disease (median age 23 months).

Retinoblastoma is the prototype of hereditary cancers due to a mutation in the retinoblastoma gene (RB1), which is located on the long arm of chromosome 13 (13q14). This gene is a tumor-suppressor gene that normally controls cellular growth. When the gene is inactivated, as in retinoblastoma, cellular growth is uncontrolled. Uncontrolled cell growth leads to tumor formation. Inactivation of both RB1 alleles within the same cell is required for tumor formation.

Retinoblastoma is known to arise in heritable and nonheritable forms. Based on the different clinical characteristics of the two forms, Knudson proposed a "two-hit" hypothesis for retinoblastoma tumor development. He postulated that two independent events were necessary for a cell to acquire tumor potential. Mutations at the RB1 locus can be inherited or arise spontaneously. In heritable cases, the first mutation arises during gametogenesis, either spontaneously (90%) or through transmission from a parent (10%). This mutation is present in every retinal cell and in all other somatic and germ cells. Ninety percent of persons who carry this germline mutation will develop retinoblastoma. For tumor formation, the loss of the second RB1 allele within a cell must occur; loss of only one allele is insufficient for tumor formation. The second mutation occurs in a somatic (retinal) cell. In nonheritable cases (60%), both mutations arise in a somatic cell after gametogenesis has taken place.

» Clinical Findings

A. Symptoms and Signs

Children with retinoblastoma generally come to medical attention while the tumor is still confined to the globe. Although present at birth, retinoblastoma is not usually detected until it has grown to a considerable size. Leukocoria (white pupillary reflex) is the most common sign (found in 60% of patients). Parents may note an unusual appearance of the eye or asymmetry of the eyes in a photograph. The differential diagnosis of leukocoria includes Toxocara canis granuloma, astrocytic hamartoma, retinopathy of prematurity, Coats disease, and persistent hyperplastic primary vitreous. Strabismus (in 20% of patients) is seen when the tumor

involves the macula and central vision is lost. Rarely (in 7% of patients), a painful red eye with glaucoma, a hyphema, or proptosis is the initial manifestation. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Bilateral involvement occurs in 20%–30% of children.

B. Diagnostic Evaluation

Suspected retinoblastoma requires a detailed ophthalmologic examination under general anesthesia. An ophthalmologist makes the diagnosis of retinoblastoma by the appearance of the tumor within the eye without pathologic confirmation. A white to creamy pink mass protruding into the vitreous matter suggests the diagnosis; intraocular calcifications and vitreous seeding are virtually pathognomonic of retinoblastoma. A CT scan of the orbits and MRI of the orbits/brain detects intraocular calcification, evaluates the optic nerve for tumor infiltration, and detects extraocular extension of tumor. A single focus or multiple foci of tumor may be seen in one or both eyes at diagnosis. Metastatic disease of the marrow and meninges can be ruled out with bilateral bone marrow aspirates and biopsies plus CSF cytology.

» Treatment

Each eye is treated according to the potential for useful vision, and every attempt is made to preserve vision. The choice of therapy depends on the size, location, and number of intraocular lesions. Absolute indications for enucleation include no vision, neovascular glaucoma, inability to examine the treated eye, and inability to control tumor growth with conservative treatment. External beam irradiation has been the mainstay of therapy. A total dose of 35–45 Gy is administered. However, many centers are investigating the role of systemic chemotherapy for the treatment of retinoblastoma confined to the globe and the elimination of external beam radiotherapy is now accepted. Cryotherapy, photocoagulation, and radioactive plaques can be used for local tumor control. Patients with metastatic disease receive chemotherapy.

Children with retinoblastoma confined to the retina (whether unilateral or bilateral) have an excellent prognosis, with 5-year survival rates greater than 90%. Mortality is correlated directly with extent of optic nerve involvement, orbital extension of tumor, and massive choroid invasion. Patients who have disease in the optic nerve beyond the lamina cribrosa have a 5-year survival rate of only 40%. Patients with meningeal or metastatic spread rarely survive, although intensive chemotherapy and autologous HSCT have produced long-term survivors.

Patients with the germline mutation (heritable form) have a significant risk of developing second primary tumors. Osteosarcomas account for 40% of such tumors. Second malignant neoplasms occur in both patients who have and those who have not received radiation therapy. The 30-year cumulative incidence for a second neoplasm is 35% in patients who received radiation therapy and 6% in those who did not receive radiation therapy. The risk continues to increase over time. Although radiation contributes to the risk, it is the presence of the retinoblastoma gene itself that is responsible for the development of nonocular tumors in these patients.

HEPATIC TUMORS (SEE ALSO CHAPTER 22)

Two-thirds of liver masses found in childhood are malignant. Ninety percent of hepatic malignancies are either hepatoblastoma or hepatocellular carcinoma. Hepatoblastoma accounts for the vast majority of liver tumors in children younger than 5 years, hepatocellular carcinoma for the majority in children aged 15–19 years. The features of these hepatic malignancies are compared in Table 31–10. Of the benign tumors, 60% are hamartomas or vascular tumors such as hemangiomas. There is mounting evidence for a strong association between prematurity and the risk of hepatoblastoma.

Children with hepatic tumors usually come to medical attention because of an enlarging abdomen. Approximately 10% of hepatoblastomas are first discovered on routine examination. Anorexia, weight loss, vomiting, and abdominal pain are associated more commonly with hepatocellular carcinoma. Serum α-fetoprotein is often elevated and is an excellent marker for response to treatment.

Imaging studies should include abdominal ultrasound, CT scan, or MRI. Malignant tumors have a diffuse hyperechoic pattern on ultrasonography, whereas benign tumors are usually poorly echoic. Vascular lesions contain areas with varying degrees of echogenicity. Ultrasound is also useful for imaging the hepatic veins, portal veins, and inferior vena

Table 31–10. Comparison of hepatoblastoma and hepatocellular carcinoma in childhood.

	Hepatoblastoma	Hepatocellular Carcinoma
Median age at presentation	1 y (0–3 y)	12 y (5–18 y)
Male-female ratio	1.7:1	1.4:1
Associated conditions	Hemihypertrophy, Beckwith-Wiedemann syndrome, prematurity, Gardner syndrome	Hepatitis B virus infection, hereditary tyrosinemia, biliary cirrhosis, α_1-antitrypsin deficiency
Pathologic features	Fetal or embryonal cells; mesenchymal component (30%)	Large pleomorphic tumor cells and tumor giant cells
Solitary hepatic lesion	80%	20%–50%
Unique features at diagnosis	Osteopenia (20%–30%), isosexual precocity (3%)	Hemoperitoneum, polycythemia
Laboratory features		
Hyperbilirubinemia	5%	25%
Elevated AFP	> 90%	50%
Abnormal liver function tests	15%–30%	> 30%–50%

AFP, α-fetoprotein.

cava. CT scanning and, in particular, MRI are important for defining the extent of tumor within the liver. CT scanning of the chest should be obtained to evaluate for metastatic spread. Because bone marrow involvement is extremely rare, bone marrow aspirates and biopsies are not indicated.

The prognosis for children with hepatic malignancies depends on the tumor type and the resectability of the tumor. Complete resectability is essential for survival. Chemotherapy can decrease the size of most hepatoblastomas. Following biopsy of the lesion, neoadjuvant chemotherapy is administered prior to attempting complete surgical resection. Monitoring the rate of decline of the α-fetoprotein levels can help indicate favorable versus poor responders to chemotherapy. Chemotherapy can often convert an inoperable tumor to a completely resectable one and can also eradicate metastatic disease. Approximately 50%–60% of hepatoblastomas are fully resectable, following preoperative chemotherapy, whereas only one-third of hepatocellular carcinomas can be completely removed. Even with complete resection, only one-third of patients with hepatocellular carcinoma are long-term survivors. A recent CCG/Pediatric Oncology Group trial has shown cisplatin, fluorouracil, and vincristine to be as effective as but less toxic than cisplatin and doxorubicin in treating hepatoblastoma. The current open COG trial is using cisplatin, fluorouracil, vincristine, and doxorubicin along with the cardioprotectant dexrazoxane in intermediate-risk patients with the addition of temsirolimus in high-risk patients. Other drug combinations that have demonstrated benefit include carboplatin plus etoposide and doxorubicin plus ifosfamide. Liver transplantation has been shown to be a successful surgical option in patients whose tumors are considered to be unresectable.

LANGERHANS CELL HISTIOCYTOSIS

» General Considerations

Langerhans cell histiocytosis (LCH; formerly called histiocytosis X) is a rare and poorly understood spectrum of disorders. It can occur as an isolated lesion or as widespread systemic disease involving virtually any body site.

Eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease are all syndromes encompassed by this disorder. LCH is not a true malignancy, but instead is a clonal, reactive proliferation of normal histiocytic cells, perhaps resulting from an immunoregulatory defect.

The distinctive pathologic feature is proliferation of histiocytic cells beyond what would be seen in a normal inflammatory process. Langerhans histiocytes have typical features: on light microscopy, the nuclei are deeply indented (coffee bean–shaped) and elongated, and the cytoplasm is pale, distinct, and abundant. Additional diagnostic characteristics include Birbeck granules on electron microscopy, expression of CD1 on the cell surface, and positive immunostaining for S-100 protein.

» Clinical Findings

Because LCH encompasses a broad spectrum of diseases; its presentation can be variable, from a single asymptomatic lesion to widely disseminated disease. Skin and bone lesions are the most frequent sites of disease.

Patients with localized disease present primarily with lesions limited to bone. Occasionally found incidentally on radiographs obtained for other reasons, these lesions are well-demarcated and frequently found in the skull, clavicles, ribs, and vertebrae. These lesions can be painful. Patients can also present with localized disease of the skin, often as a diaper rash that does not resolve.

Bony lesions, fever, weight loss, otitis media, exophthalmos, and diabetes insipidus (in 10%–15% of patients) occur in a fewer number of children with the disease. Children with this multifocal disease, formerly called Hand-Schüller-Christian disease, commonly present with generalized symptoms and organ dysfunction, mainly of the liver and lungs.

Children with disseminated LCH (formerly called Letterer-Siwe disease) typically present before age 2 years with a seborrheic skin rash, fever, weight loss, lymphadenopathy, hepatosplenomegaly, and hematologic abnormalities.

Diagnosis is made with biopsy of the involved organ. The workup should include a CBC, liver and kidney function tests, a skeletal survey or technetium bone scan, and a urinalysis with specific gravity to rule out diabetes insipidus.

» Treatment & Prognosis

The outcome in LCH is extremely variable and may spontaneously resolve. Isolated lesions may need no therapy at all. Intralesional corticosteroids, curettage, and low-dose radiation therapy are useful local treatment measures for symptomatic focal lesions. Patients with localized disease have an excellent prognosis, nearing 100%.

Multifocal disease is often treated with systemic chemotherapy. Prednisone and vinblastine are used for multifocal disease or disease involving other organs such as liver, spleen, hematopoietic system. The agents are given repeatedly or continuously until lesions heal; the drugs can then be reduced and finally stopped. A common therapeutic protocol for LCH is LCH III. Other active chemotherapeutic agents include 6-mercaptopurine, methotrexate, and etoposide. HSCT can also be used with some success in refractory cases. "High-risk" LCH has approximately 85% 5-year overall survival.

Multifocal disease is less predictable, but most cases resolve without sequelae. Age, degree of organ involvement, and response to therapy are the most important prognostic factors. Infants with disseminated disease tend to do poorly, with mortality rates approaching 50%. New treatment approaches for patients who do not respond to conventional chemotherapy have been evaluated in small studies. With some success, 2-Chlorodeoxyadenosine (2-CDA) has been used. Therapeutic strategies targeting the dysregulated immune response using interferon-α or etanercept (anti–tumor necrosis factor-α) have also been reported.

HEMATOPOIETIC STEM CELL TRANSPLANT

GENERAL CONSIDERATIONS

Hematopoietic stem cell transplant (HSCT) is considered standard therapy for a variety of malignancies, hematologic disorders (aplastic anemia, hemoglobinopathies), storage diseases, and severe immunodeficiencies. In most instances, high doses of chemotherapy and/or radiation are given to the HSCT patient for myeloablation prior to infusion of stem cells that rescue hematopoietic and lymphoid function.

HSCT can be divided into two main categories: autologous, infusion of the patient's own hematopoietic stem cells, or allogeneic, infusion of another individual's (donor) hematopoietic stem cells. Stem cells can be obtained from bone marrow, peripheral blood, or umbilical cord blood.

The rationale for HSCT in patients with nonmalignant disorders is to use the transplanted donor stem cells to replace the absent or defective hematopoietic or lymphoid elements of the recipient. For children with oncologic disorders, the rationale for HSCT is multifaceted. High doses of chemotherapy and/or radiation are used to optimize tumor cell kill by overcoming cancer cell resistance. Additionally, in allogeneic HSCT (stem cells from another person), the donor lymphoid cells may recognize the cancer as foreign and provide an immunologic attack on the malignancy, a concept known as the graft-versus-tumor (GVT) effect.

Autologous transplantation, often referred to as "stem cell rescue," is restricted to the treatment of certain pediatric malignancies: neuroblastoma, lymphoma, selected brain tumors, germ cell tumors, and Ewing sarcoma. Relapse of the malignancy continues to be the greatest obstacle to successful autologous transplantation, likely due to limitations in achieving systemic cancer control prior to transplant, resistance to pretransplant chemotherapy and/or radiation, and lack of GVT effect.

Allogeneic transplantation rescues hematopoiesis with stem cells from another person, either within the immediate family or an unrelated individual from a volunteer bank. Allogeneic HSCT recipients require potent pre-HSCT immunosuppressive treatment to prevent rejection of donor cells. Posttransplant medications such as cyclosporine, tacrolimus, mycophenolate, and methotrexate are needed to reduce the risk of GVHD. The selection of a suitable donor who matches the recipient most closely at key HLA (human leukocyte antigen) loci, HLA-A, B, C, and DR, is critical, as disparities mediate graft rejection and GVHD. Every child expresses one set of paternal and one set of maternal HLA antigens. Thus, the probability of one child inheriting any specific combination and matching another full sibling for an allogeneic transplant is one in four. Large worldwide registries of unrelated bone marrow and umbilical cord blood donors have been developed; however, finding a closely matched unrelated donor can be challenging, especially for underrepresented minorities.

Supportive care in the initial weeks after transplant includes management of chemotherapy side effects, prevention and treatment of infection, nutritional support, and immunosuppressive medications to lessen the potential for development of GVHD in allogeneic HSCT recipients. Until their new donor cells engraft, patients require blood product support for several weeks following preparative therapy. These blood products should be leukocyte reduced to decrease the risk of CMV transmission and irradiated to prevent GVHD from residual lymphocytes that remain even in leukocyte-reduced blood products.

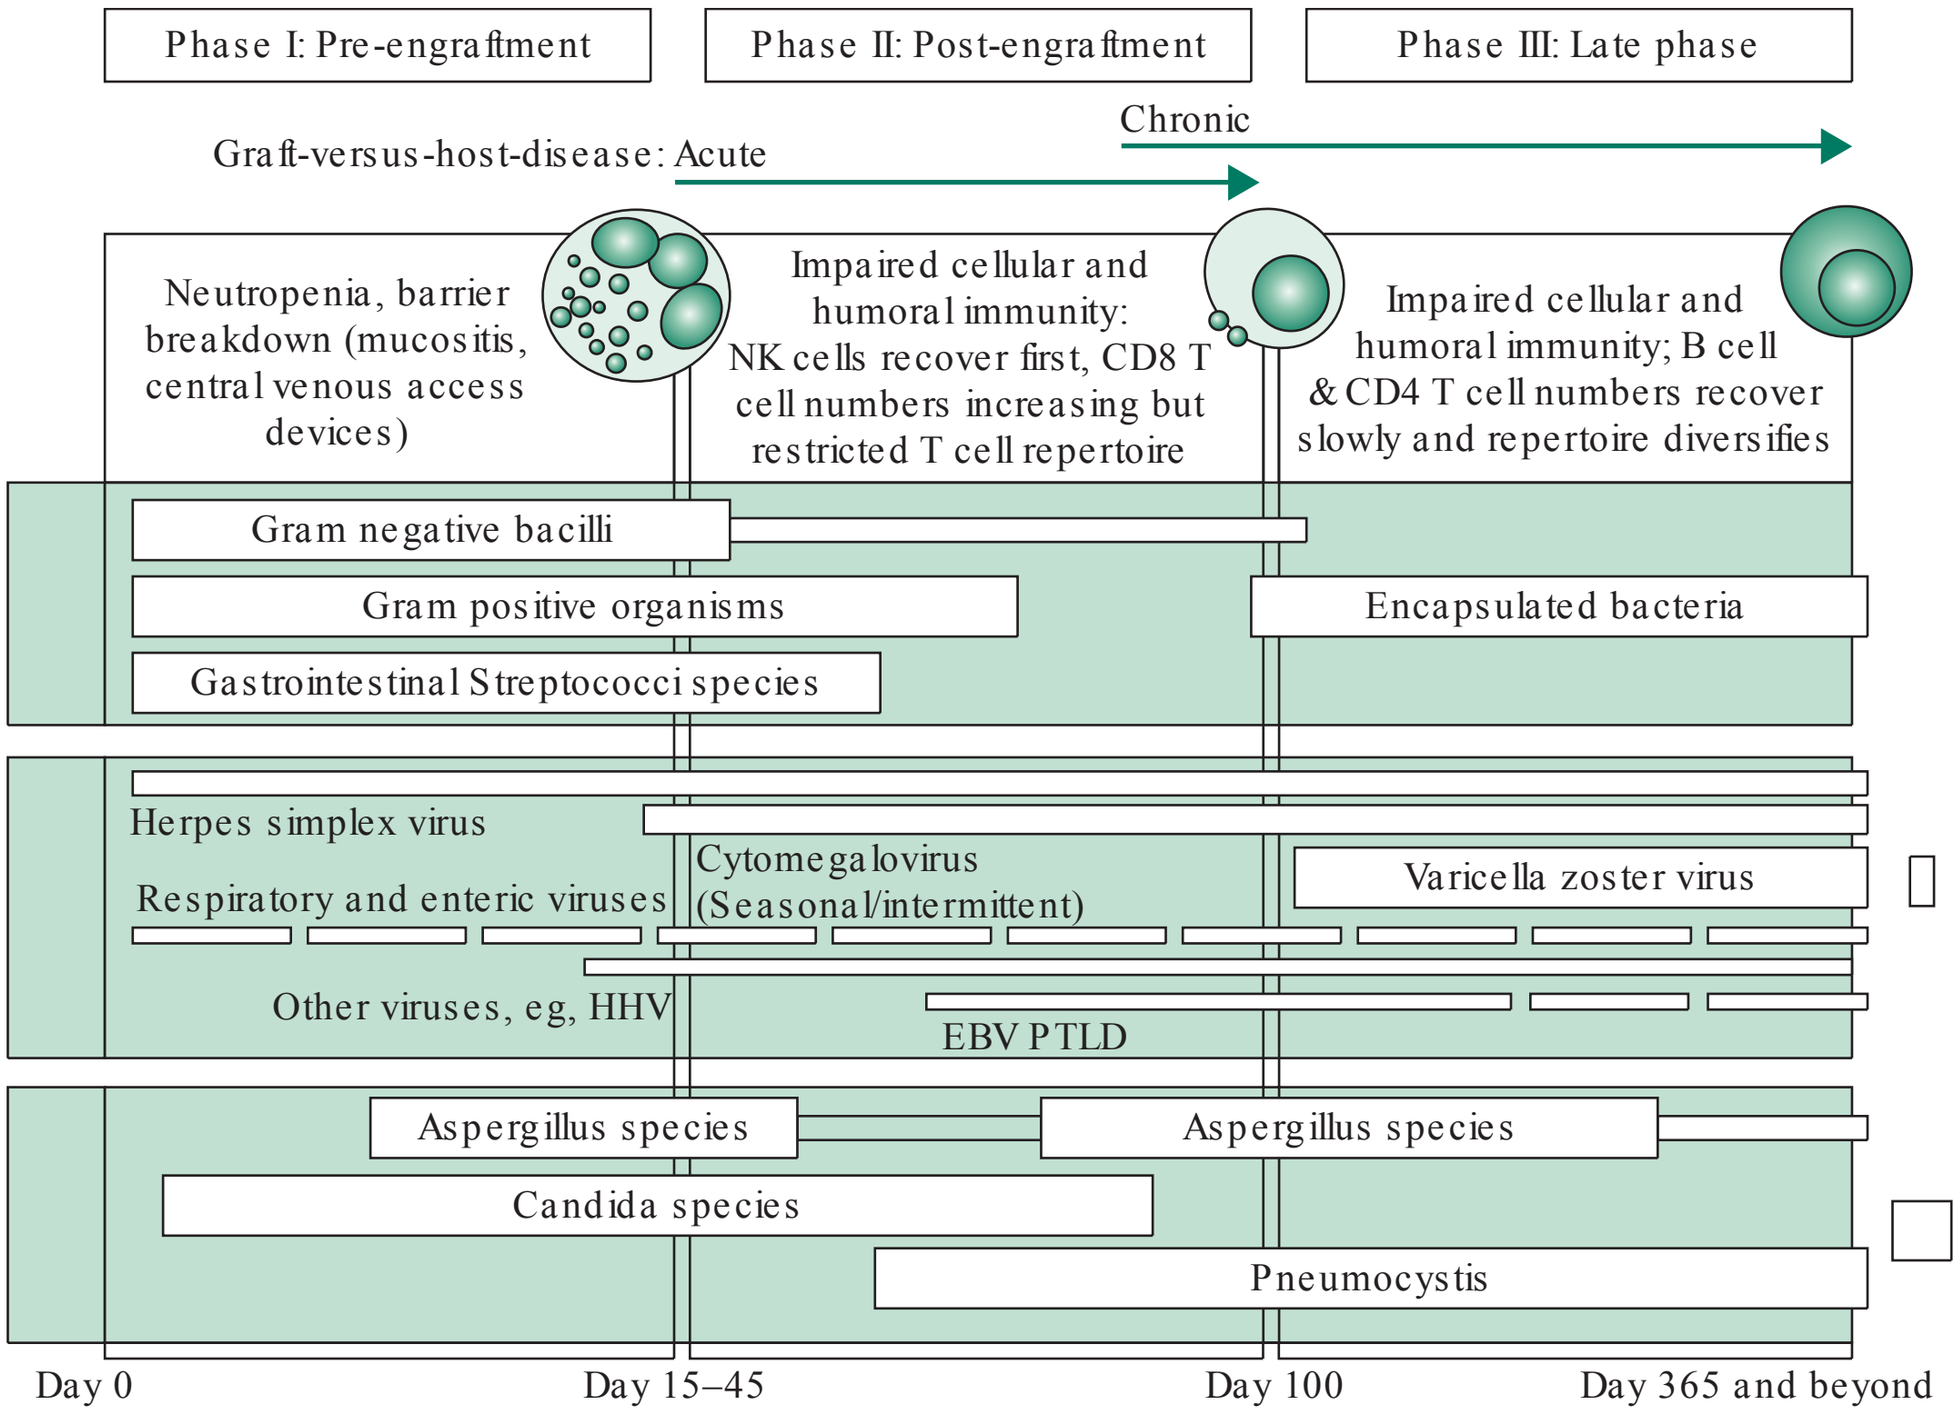
» HSCT COMPLICATIONS

HSCT patients are profoundly immunocompromised for many months following transplantation. Consequently, infections from bacteria, viruses, fungi, and protozoa can account for significant morbidity and mortality. During the early phase (0–1 month after transplant), when there is severe neutropenia and mucosal disruption, bacteria from the patient's aerodigestive tract are common culprits in bacteremia. Additionally, the presence of a central venous catheter makes gram-positive bacteremia an important consideration. Therefore, empiric or prophylactic antibiotic coverage and intravenous immune globulin supplementation are commonly used to decrease the risk of bacterial sepsis. Acyclovir prophylaxis is used to prevent the reactivation of herpes simplex virus that may occur early in up to 70% of seropositive patients, and antifungal agents are routinely used to prevent infections from Candida and Aspergillus (Figure 31–1).

In the intermediate phase (1–6 months after transplant), the HSCT patient usually has adequate neutrophil counts yet remains significantly compromised due to reduced T-lymphocyte number and function. Because of this relative T-cell defect, a child after transplant is susceptible to sudden, overwhelming illness from viral pathogens. CMV reactivation or de novo infection is relatively common and can result in retinitis, enteritis, and pneumonia. Treatment with foscarnet or ganciclovir is usually successful if CMV infection is recognized early particularly when preventive or preemptive approaches to control viremia are used. Common community-acquired viruses, such as respiratory syncytial virus, adenovirus, influenza, parainfluenza, and human metapneumovirus, can also be life threatening; therefore, prevention is critical. The use of frequent hand washing, contact restriction, and early treatment with available antiviral therapies, such as inhaled ribavirin, can be lifesaving in this population. Prophylactic administration of acyclovir helps limit reactivation of herpes simplex virus and varicella-zoster virus (shingles). Trimethoprim-sulfamethoxazole, dapsone, atovaquone, or pentamidine reduces prophylaxis, but does not eliminate P jiroveci pneumonia.

The late phase (6–12 months after transplant) is characterized by dysfunction of the reticuloendothelial system, leading to infections from encapsulated bacteria such as pneumococcus, and ongoing inadequate lymphocyte function, resulting in poor control of new or reactivated viral infection. Patients on immunosuppressive treatment for GVHD have an increased and protracted risk of all types of infections.

GVHD occurs after allogeneic HSCT when donor lymphocytes recognize the recipient tissues as foreign and mount an immunologic attack. Despite the use of immunosuppressive agents, anti–T-cell antibodies, and T-cell depletion of the donor graft, 20%–70% of allogeneic HSCT patients



▲**Figure 31–1.** Phases of opportunistic infections among allogeneic HCT recipients. EBV, Epstein-Barr virus; HHV6, human herpesvirus 6; PTLD, posttransplant lymphoproliferative disease. (Reproduced with permission from: Tomblyn M et al: Guidelines for preventing infectious complications among hematopoietic cell transplantation recipients: a global perspective. Biol Blood Marrow Transplant. 2009 Oct;15(10):1143–1238 [Review].)

experience some degree of acute GVHD. Factors influencing GVHD risk include the degree of HLA match, stem cell source, patient age, and donor sex. Acute GVHD generally occurs within the first 100 days after transplant but, on occasion, may occur later. Acute GVHD typically presents with a maculopapular skin rash, secretory diarrhea, and/or cholestatic jaundice. Chronic GVHD generally occurs after day 100 and may involve multiple organ systems; sclerotic skin, malabsorption, weight loss, keratoconjunctivitis sicca, oral mucositis, chronic lung disease, and cholestatic jaundice are common manifestations. Prevention and treatment of GVHD involves use of immunosuppressive agents.

Long-term follow-up of HSCT patients is essential. Patients are at risk for numerous complications, including pulmonary disease, cataracts, endocrine dysfunction affecting growth and fertility, cardiac dysfunction, avascular necrosis of bone, developmental delay, and second malignancies. Although HSCT has many challenges, it represents an important advance in curative treatment for a variety of serious pediatric illnesses.

LATE EFFECTS OF PEDIATRIC CANCER THERAPY

Late effects of treatment by surgery, radiation, and chemotherapy have been identified in survivors of pediatric cancer. Current estimates are that 1 in every 640 adults between the ages of 20 and 39 years is a pediatric cancer survivor. Recently it was reported that the prevalence of poor health status in this group is higher among adult survivors of pediatric cancer than siblings and increases rapidly with age, particularly among female survivors. One recent study found that 60% of survivors of pediatric cancer diagnosed between 1970 and 1986 have at least one chronic condition. Virtually any organ system can demonstrate sequelae related to previous cancer therapy. This has necessitated the creation of specialized oncology clinics whose function is to identify and provide treatment to these patients.

The Childhood Cancer Survivor Study, a pediatric multiinstitutional collaborative project, was designed to investigate the various aspects of late effects of pediatric cancer therapy in a cohort of over 13,000 survivors of childhood cancer.

GROWTH COMPLICATIONS

Children who have received cranial irradiation are at highest risk of developing growth complications. Growth complications of cancer therapy in the pediatric survivor are generally secondary to direct damage to the pituitary gland, resulting in growth hormone deficiency. However, new evidence in children treated for ALL suggests that chemotherapy alone may result in an attenuation of linear growth without evidence of catch-up growth once therapy is discontinued. Up to 90% of patients who receive more than 30 Gy of radiation to the CNS will show evidence of growth hormone deficiency within 2 years. Approximately 50% of children receiving 24 Gy will have growth hormone problems. The effects of cranial irradiation appear to be age-related, with children younger than 5 years at the time of therapy being particularly vulnerable. These patients usually benefit from growth hormone therapy. Currently, there is no evidence that such therapy causes a recurrence of cancer.

Spinal irradiation inhibits vertebral body growth. In 30% of treated children, standing heights may be less than the fifth percentile. Asymmetrical exposure of the spine to radiation may result in scoliosis.

Growth should be monitored closely, particularly in young survivors of childhood cancer. Obesity may become an issue for selected survivors who are young at diagnosis and have received whole brain radiation. Follow-up studies should include height, weight, growth velocity, scoliosis examination, and, when indicated, growth hormone testing.

ENDOCRINE COMPLICATIONS

Thyroid dysfunction, manifesting as hypothyroidism, is common in children who received total body irradiation, cranial irradiation, or local radiation therapy to the neck and/or mediastinum. Particularly at risk are children with brain tumors who received more than 3000 cGy and those who received more than 4000 cGy to the neck region. The average time to develop thyroid dysfunction is 12 months after exposure, but the range is wide. Therefore, individuals at risk should be monitored yearly for at least 7 years from the completion of therapy. Although signs and symptoms of hypothyroidism may be present, most patients will have a normal thyroxine level with an elevated thyroid-stimulating hormone level. These individuals should be given thyroid hormone replacement because persistent stimulation of the thyroid from an elevated thyroid-stimulating hormone level may predispose to thyroid nodules and carcinomas. In a recent report from the Childhood Cancer Survivor Study, thyroid cancer occurred at 18 times the expected rate for the general population in pediatric cancer survivors who received radiation to the neck region. Hyperthyroidism, although rare, also occurs in patients who have received neck irradiation.

Precocious puberty, delayed puberty, and infertility are all potential consequences of cancer therapy. Precocious puberty, more common in girls, is usually a result of cranial irradiation causing premature activation of the hypothalamic-pituitary axis. This results in premature closure of the epiphysis and decreased adult height. Luteinizing hormone (LH) analogue and growth hormone are used to halt early puberty and facilitate continued growth.

Gonadal dysfunction in males is usually the result of radiation to the testes. Patients who receive testicular irradiation as part of their therapy for ALL, abdominal irradiation for Hodgkin disease, or total body irradiation for HSCT are at highest risk. Radiation damages both the germinal epithelium (producing azoospermia) and Leydig cells (causing low testosterone levels and delayed puberty). Alkylating agents such as ifosfamide and cyclophosphamide can also interfere with male gonadal function, resulting in oligospermia or azoospermia, low testosterone levels, and abnormal follicle-stimulating hormone (FSH) and LH levels. Determination of testicular size, semen analysis, and measurement of testosterone, FSH, and LH levels will help identify abnormalities in patients at risk. When therapy is expected to result in gonadal dysfunction, pretherapy sperm banking should be offered to adolescent males.

Exposure of the ovaries to abdominal radiation may result in delayed puberty with a resultant increase in FSH and LH and a decrease in estrogen. Girls receiving total body irradiation as preparation for HSCT and those receiving craniospinal irradiation are at particularly high risk for delayed puberty as well as premature menopause. In patients at high risk for development of gonadal complications, a detailed menstrual history should be obtained, and LH, FSH, and estrogen levels should be monitored if indicated.

No studies to date have confirmed an increased risk of spontaneous abortions, stillbirths, premature births,

congenital malformations, or genetic diseases in the offspring of childhood cancer survivors. Women who have received abdominal irradiation may develop uterine vascular insufficiency or fibrosis of the abdominal and pelvic musculature or uterus, and their pregnancies should be considered high risk.

CARDIOPULMONARY COMPLICATIONS

Pulmonary dysfunction generally manifests as pulmonary fibrosis. Therapy-related factors known to cause pulmonary toxicities include certain chemotherapeutic agents, such as bleomycin, the nitrosoureas, and busulfan, as well as lung or total body irradiation. Pulmonary toxicity due to chemotherapy is related to the total cumulative dose received. Pulmonary function tests in patients with therapy-induced toxicity show restrictive lung disease, with decreased carbon monoxide diffusion and small lung volumes. Individuals exposed to these risk factors should be counseled to refrain from smoking and to give proper notification of the treatment history if they should require general anesthesia.

Cardiac complications usually result from exposure to anthracyclines (daunorubicin, doxorubicin, and mitoxantrone), which destroy myocytes and lead to inadequate myocardial growth as the child ages, and eventually result in congestive heart failure. The incidence of anthracycline cardiomyopathy increases in a dose-dependent fashion. A recent report indicates that survivors receiving cumulative doses larger than 360 mg/m^2 were more than 40 times more likely to die of cardiac disease. In a recent study, complications from these agents appeared 6–19 years following administration of the drugs. Pregnant women who have received anthracyclines should be followed closely for signs and symptoms of congestive heart failure, as peripartum cardiomyopathy has been reported.

Radiation therapy to the mediastinal region, which is a common component of therapy for Hodgkin disease, has been linked to an increased risk of coronary artery disease; chronic restrictive pericarditis may also occur in these patients.

Current recommendations include an echocardiogram and electrocardiogram every 1–5 years, depending on the age at therapy, total cumulative dose received, and presence or absence of mediastinal irradiation. Selective monitoring with various modalities is indicated for those who were treated with anthracyclines when they were younger than 4 years or received more than 500 mg/m^2 of these drugs. Biomarkers such as cardiac troponins and brain natriuretic peptides may be useful in assessing cardiotoxicity of anthracyclines.

RENAL COMPLICATIONS

Long-term renal side effects stem from therapy with cisplatin, alkylating agents (ifosfamide and cyclophosphamide), or pelvic irradiation. Patients who have received cisplatin may develop abnormal creatinine clearance, which may or may not be accompanied by abnormal serum creatinine levels, as well as persistent tubular dysfunction with hypomagnesemia. Alkylating agents can cause hemorrhagic cystitis, which may continue after chemotherapy has been terminated and has been associated with the development of bladder carcinoma. Ifosfamide can also cause Fanconi syndrome, which may result in clinical rickets if adequate phosphate replacement is not provided. Pelvic irradiation may result in abnormal bladder function with dribbling, frequency, and enuresis.

Patients seen in long-term follow-up who have received nephrotoxic agents should be monitored with urinalysis, appropriate electrolyte profiles, and blood pressure. Urine collection for creatinine clearance or renal ultrasound may be indicated in individuals with suspected renal toxicity.

NEUROPSYCHOLOGICAL COMPLICATIONS

Pediatric cancer survivors who have received cranial irradiation for ALL or brain tumors appear to be at greatest risk for neuropsychological sequelae. The severity of cranial irradiation effects varies among individual patients and depends on the dose and dose schedule, the size and location of the radiation field, the amount of time elapsed after treatment, the child's age at therapy, and the child's gender. Girls may be more susceptible than boys to CNS toxicity because of more rapid brain growth and development during childhood.

Auditory complications can be seen in childhood cancer survivors exposed to platinum-based chemotherapy and/or temporal or posterior fossa radiation. Difficulty hearing sounds, tinnitus, or hearing loss requiring an aid have been reported.

The main effects of CNS irradiation appear to be related to attention capacities, ability with nonverbal tasks and mathematics, and short-term memory. Recent studies support the association between treatment with high-dose systemic methotrexate, triple intrathecal chemotherapy, and, more recently, dexamethasone and more significant cognitive impairment.

Additionally, pediatric cancer patients have been reported as having more behavior problems and as being less socially competent than a sibling control group. Adolescent survivors of cancer demonstrate an increased sense of physical fragility and vulnerability manifested as hypochondriasis or phobic behaviors.

A recent report from Childhood Cancer Survivor Study noted that, when compared to population norms, childhood cancer survivors and siblings report positive psychological health, good health-related quality of life, and life satisfaction. There are, however, subgroups that could be targeted for intervention.

SECOND MALIGNANCIES

Approximately 3%–12% of children receiving cancer treatment will develop a new cancer within 20 years of their

first diagnosis. This is a 10-fold increased incidence when compared with age-matched control subjects. Particular risk factors include exposure to alkylating agents, epipodophyllotoxins (etoposide), and radiation therapy, primary diagnosis of retinoblastoma or Hodgkin disease, or the presence of an inherited genetic susceptibility syndrome (Li-Fraumeni syndrome or NF). In a recent report, the cumulative estimated incidence of second malignant neoplasms for the cohort of the Childhood Cancer Survivor Study was 3.2% at 20 years from diagnosis.

Second hematopoietic malignancies (acute myelogenous leukemia) occur as a result of therapy with epipodophyllotoxins or alkylating agents. The schedule of drug administration (etoposide) and the total dose may be related to the development of this secondary leukemia.

Children receiving radiation therapy are at risk for developing second malignancies, such as sarcomas, carcinomas, or brain tumors, in the field of radiation. A recent report examining the incidence of second neoplasms in a cohort of pediatric Hodgkin disease patients showed the cumulative risk of a second neoplasm to be as high as 8% at 15 years from diagnosis. The most common solid tumor was breast cancer (the majority located within the radiation field) followed by thyroid cancer. Girls aged 10–16 years when they received radiation therapy were at highest risk and had an actuarial incidence that approached 35% by age 40 years. Secondary gastrointestinal cancer is also increased in pediatric cancer survivors and is related to radiation exposure as well as to certain types of chemotherapeutic agents (procarbazine, platinums).

32 Pain Management & Pediatric Palliative & End-of-Life Care

Brian S. Greffe, MD
Jeffrey L. Galinkin, MD, FAAP
Nancy A. King, MSN, RN, CPNP

Children experience pain to at least the same level as adults. Multiple studies have shown that neonates and infants perceive pain and have memory of these painful experiences. Frequently, children are underprescribed and underdosed for opioid and nonopioid analgesics due to excessive concerns of respiratory depression and/or poor understanding of the need for pain medications in children. Few data are available to guide the dosing of many pain medications and the majority of pain medications available on the market today are unlabeled for use in pediatric patients.

Taddio A, Katz J: The effects of early pain experience in neonates on pain responses in infancy and childhood. Pediatr Drugs 2005;7:245–257 [PMID: 16118561].

PAIN ASSESSMENT

Standardizing pain measurements require the use of appropriate pain scales. At most institutions, pain scales are stratified by age (Table 32–1) and are used throughout the institution from operating room to medical floor to clinic, creating a common language around a patient's pain. Pain assessment by scales has become the "5th vital sign" in hospital settings and is documented at least as frequently as heart rate and blood pressure at many pediatric centers around the world. There are many pain scales available, all of which have advantages and disadvantages (e.g., Figures 32–1 and 32–2, and Table 32–2). It is less important what type of scale is used, but that they are used on a consistent basis.

Special Populations

Noncommunicative patients such as neonates and the cognitively impaired are often difficult to assess for pain. For these patients using an appropriate assessment tool (see Table 32–1) on a frequent basis (every 1–2 hours) is essential in ensuring adequate pain control. For these populations, increasing pain score trends are often a sign of discomfort.

Bieri D et al: The Faces Pain Scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for ratio scale properties. Pain 1990;41:139–150 [PMID: 2367140].

ACUTE PAIN

» Definition Etiology

Acute pain is caused by an identifiable source. In most cases, it is self-limiting and treatment is a reflection of severity and type of injury. In children, the majority of acute pain is caused by trauma or, if in a hospital setting, an iatrogenic source such as surgery.

» Treatment

Treatment of acute pain is dependent on the disposition of the individual patient. For outpatient care the mainstay of treatment is nonsteroidal anti-inflammatory drugs (NSAIDs) (Table 32–3). Acetaminophen is the most commonly used NSAID. Acetaminophen is administered via the oral or rectal routes. Acetaminophen is more predictable in its effects as an oral dose. It has also been found that round-the-clock administration (oral 10–15 mg/kg, rectal 20 mg/kg) is better than PRN dosing for both minor pain or as an adjunct for major pain. The toxicity of acetaminophen is low in clinically used doses. However, the use of acetaminophen combined with many over-the-counter and prescription combination products has been a frequent cause of toxicity. Liver damage or failure can occur with doses exceeding 200 mg/kg/d. Other oral analgesics available in suspension are ibuprofen (10–15 mg/kg) and naproxen (10–20 mg/kg).

Table 32–1. Pain scales—description and age-appropriate use.

Name of Scale	Type	Description	Age Group
Numeric	Self-report	Verbal 0–10 scale; 0 = no pain, 10 = worst pain you could ever imagine	Children who understand the concept of numbers, rank, and order; approximately > 8 y
Bieri and Wong-Baker scales	Self-report	6 faces that range from no pain to the worst pain you can imagine	Younger children who have difficulty with numeric scale; cognitive age 3–7 y
FLACC	Behavioral observer	5 categories: face, legs, activity, cry, and consolability; range of total score is 0–10; score ≤ 7 is severe pain. Figure 32–1 and 32–2 and Table 32–2	Nonverbal children > 1 y
CRIES, NIPS, PIPP	Behavioral observer	Rates a set of standard criteria and gives a score	Nonverbal infant < 1 y

When pain is more severe, oral opioids can be added for short-term use (Table 32–4). Many of these opioids come formulated with an NSAID, that is, oxycodone/acetaminophen (Percocet) and hydrocodone/acetaminophen (Lortab). When using these combination drugs, the dose of drug is based on the opioid component. Other concomitantly administered similar NSAIDs should be discontinued. The most commonly used oral opioids are oxycodone, hydrocodone, and codeine. The use of codeine is least recommended due to its metabolism. Codeine is metabolized to morphine via the cytochrome P-450 2D4 isoenzyme. From 1% to 10% people (Asians 1%–2%, African Americans 1%–3%, Caucasians 5%–10%) are poor metabolizers as a result of a genetic polymorphism. Thus, patients with this defect get no effect from this drug. A very small percentage of patients (primarily from East Africa) are ultrarapid metabolizers. These patients convert 10–15 times the amount of parent drug to active compound which can result in clinical toxicity. Morphine, oxycodone, and hydrocodone are all available as suspensions, are active as administered, and are metabolized by multiple routes.

For severe pain not amenable to oral analgesics, an intravenous opioid can be titrated to effect; options for pain relief are dependent on severity and location of pain and age. Intravenous opioids used as bolus dose, continuous infusion, and as part of a patient-controlled analgesia (PCA) infusion have a long track record of both safe and efficacious use in children. Often the NSAID ketorolac 0.5–1.0 mg/kg is used as an adjunct for severe pain. Side effects of ketorolac are the same as for adults: renal insufficiency, gastric irritability, and prolonged bleeding times due to decreased platelet adhesiveness. Patients with bleeding concerns should not receive ketorolac.

PCA pumps can be used in children as young as 6 years with proper instruction and coaching (Table 32–5). Morphine and hydromorphone are the most commonly used drugs for PCA management in the United States. Whenever PCA is used, it is imperative to assess patients frequently (at least hourly) to ensure adequate pain relief.

CHRONIC PAIN MANAGEMENT

» Assessment

Chronic pain is a pain that persists past the usual course of an acute illness or beyond the time that is expected for an acute injury. In children this is an increasingly recognized problem. It is estimated that chronic pain may affect as much as 10%–15% of the population. The most common problems include headache, chronic abdominal pain, myofascial pain, fibromyalgia, juvenile rheumatoid arthritis, complex regional pain syndrome, phantom limb pain, and pain associated with cancer. Chronic pain in children often has multiple other contributing factors, including psychological issues, psychosocial factors, sociologic factors, and family dynamics. Associating pain with a single physical cause can lead the physician to investigate the patient with repeated invasive testing, laboratory tests, and procedures and to overprescribe medications. A multidimensional assessment to chronic pain is optimal and often required.

» Treatment

When possible, a multidisciplinary team approach is standard of care for treating chronic pain in children. All children evaluated for chronic pain should be seen on their initial visit by all primary members of the team to establish a management strategy. Team members should include a pain physician, a pediatric psychologist and/or a psychiatrist, occupational and physical therapists (OT/PT), advanced pain nurses (APNs), and a social worker. The majority of

Table 32–2. FLACC pain assessment tool.

Categories	Score 0	Score 1	Score 2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractible	Difficult to console or comfort

Table 32–3. Suggested doses for nonopioid analgesics.

	Route	Dosage Guidelines	Half-Life	Duration
Acetaminophen	PO	10–15 mg/kg/dose every 4–6 h, maximum dose 4000 mg/d	Neonates: 2–5 h Adults: 2–3 h	4 h
	PR	40 mg/kg loading dose, followed by 10–20 mg/kg/dose every 6 h		
Ibuprofen	PO	4–10 mg/kg/dose every 6–8 h, maximum dose 40 mg/kg/d, no > 2400 mg/d	Children: 1–7 y: 1–2 h Adults: 2–4 h	6–8 h
Ketorolac	IV	0.5 mg/kg/dose every 6 h, maximum of 30 mg/dose, maximum course of 8 doses	Children: ~ 6 h Adults: ~ 5 h	4–6 h

pediatric chronic pain management programs in the United States base their approach on combined intensive rehabilitation and intensive psychotherapy relying minimally on invasive procedures and pharmacotherapy.

A. Tolerance, Dependence, and Addiction

Physiologic and psychological responses to opioids are similar between adults and children. A consensus paper by the American Academy of Pain Medicine, American Pain Society, and American Society of Addiction Medicine defined important differences between normal and pathologic responses to opioids. The definitions of tolerance dependence and addiction are listed as follows.

1. Tolerance—A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. Tolerance develops at

Table 32–4. Suggested doses of oral and intravenous opioids in infants and children.

Opioid Drug	Route	Dosage Guidelines	Onset	Duration
Fentanyl	IV intermittent	0.5–1 mcg/kg/dose (best for intermittent short duration analgesia; titrate to effect)	1–3 min	30–60 min
Hydromorphone	IV	Children: 0.015 mg/kg/dose every 3–6 h Adolescent: 1–4 mg every 3–6 h	15 min	4–5 h
Methadone	IV	0.1 mg/kg/dose every 4 h for 2–3 doses, then every 6–12 h	10–20 min	6–8 h (22–48 h after repeated doses)
Morphine	IV intermittent	0.05–0.1 mg/kg/dose every 2–4 h	Neonates: 7–8 h 1–3 mo: 6 h 6 mo–2.5 y: 3 h 3–19 y: 1–2 h Adults: 2–4 h	2–4 h
Codeine	PO	0.5–1 mg/kg/dose every 4–6 h, maximum of 60 mg/dose	30–60 min	4–6 h
Hydromorphone	PO	Children: 0.03–0.1 mg/kg/dose every 4–6 h Adolescents: 1–4 mg every 3–4 h	15–30 min	4–5 h
Hydrocodone (in Vicodin, Lortab elixir)	PO	Children: 0.15–0.2 mg/kg/dose every 4–6 h Adolescents: 1–2 tabs every 4–6 h (limited due to acetaminophen content; see acetaminophen recommendations in text)	10–20 min	3–6 h
Methadone	PO	0.1 mg/kg/dose every 4–6 h for 2–3 doses, then every 6–12 h	30–60 min	6–8 h (22–48 h after repeated doses)
Morphine	PO-IR	0.2–0.5 mg/kg/dose every 4–6 h	15–60 min	3–5 h
	PO-ER	0.3–0.6 mg/kg/dose every 12 h	1–2 h	8–12 h

Data from Perkins RM et al (eds): Pediatric Hospital Medicine. 2nd ed. Lippincott Williams and Wilkins, 2008:743–754.

Table 32–5. PCA dosing recommendations.

	Morphine	Fentanyl	Hydromorphone
Solution	1 mg/mL	Solution 10 mcg/mL	0.1 mg/mL or 1 mg/mL
Initial dose	15–20 mcg/kg (max 1.5 mg)	0.25 mcg/kg	3–4 mcg/kg (max 0.3 mg)
Lockout time	8–10 min	8–10 min	8–10 min
Basal infusion	0–20 mcg/kg/h	0–1 mcg/kg/h	0–4 mcg/kg/h
Maximum starting dose (for non-opioid tolerant patients)	100 mcg/kg/h	1–2 mcg/kg/h	20 mcg/kg/h

different rates for different opioid effects, that is, tolerance to sleepiness and respiratory depression occurs earlier than that to constipation and analgesia.

2. Dependence—A state of adaptation that is manifested by a drug class–specific **withdrawal** syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.

3. Addiction—A primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following:

- Loss of **C**ontrol over use of drug
- **C**raving and **C**ompulsive use of drug
- Use despite adverse **C**onsequences

Addiction is rare when opioids are used appropriately for acute pain on both inpatient and outpatient settings. It should be emphasized that tolerance and dependence do not equal addiction.

Heit HA: Addiction, physical dependence, and tolerance: precise definitions to help clinicians evaluate and treat chronic pain patients. J Pain Palliat Care Pharmacother 2003;17:15–29 [PMID: 14640337].

B. Withdrawal

1. Recognition—Withdrawal symptoms can be expected to occur for all patients after 1 week of opioid treatment. Signs of withdrawal in older children include agitation, irritability, dysphoria, tachycardia, tachypnea, nasal congestion, temperature instability, and feeding intolerance. In neonates with withdrawal (neonatal abstinence syndrome), common symptoms include neurologic excitability, gastrointestinal dysfunction, autonomic signs (increased sweating, nasal stuffiness, fever, mottling, poor weight gain), and skin excoriation secondary to excessive rubbing.

2. Treatment

- Make a schedule/plan in conjunction with patient and family.
- Factor in duration of time on opioid.
- Consider switching to once-a-day opioid (see methadone dosing in Table 32–4).
- Decrease the dose by 10–25% every 1–2 days.
- Look for signs of withdrawal.
- Consider adding lorazepam 0.05–0.1 mg/kg every 6–8 hours.
- Consider adding clonidine patch 0.1 mg/d (changed every fifth day).

Richard J et al: A prospective evaluation of opioid weaning in opioid-dependent pediatric critical care patients. Anesth Analg 2006;102:1045–1050 [PMID: 16551896].

PEd iATRiC PAl l iATiv E & End -o f -l if E CARE

INTRODUCTION

It has been estimated that almost 55,000 children die each year in the United States. At least 50% of these children die during the newborn period or within the first year of life. Many of these children, particularly those older than 1 year of age, suffer from illnesses that are clearly life-limiting. Thousands more children are diagnosed with life-limiting illnesses, resulting in a chronic condition that may last for many years, even decades. Furthermore, children who are diagnosed with life-threatening illnesses that may be curable, such as cancer, continue to live with the potential of a recurrence of their malignancy for many years. The above populations are those where palliative and end-of-life care could play an important role during the illness of these patients.

Although commonly used interchangeably, palliative care and end-of-life care are not synonymous terms. Palliative

care aims to prevent, relieve, reduce, or soothe the symptoms produced by potential life-limiting illnesses or their treatments and to maintain the patient's quality of life along the entire continuum of treatment. Provision of palliative care does not imply imminent death nor does it prohibit aggressive curative treatment modalities. Rather, it acknowledges the uncertainty and potential for suffering inherent in a potentially life-limiting condition such as cancer. Understanding how a family defines quality of life and suffering for their child is imperative and provides a framework for decision making between care provider and the family throughout treatment.

While a child is doing well with treatment, the primary focus will be on achieving cure or stabilization of the disease. Palliative care goals at this time focus on promoting quality of life in preparation for survivorship in the face of a potentially life-limiting illness. Some of these goals include helping a family come to terms with the diagnosis, addressing issues of treatment-related pain and distress, facilitating reintegration into the social realms of school and community, and promoting as much normalcy in the child's life as possible. When it becomes clear that the chances for cure are poor or present an unreasonable cost to the child's quality of life, the goals of palliative care will shift toward end-of-life care. The focus will still be on promoting quality of life but now in preparation for a comfortable and dignified end of life with increasingly less attention given to the treatment or cure of the disease itself.

Palliative care not only comprises support in the pain and symptom management of the disease but also addresses equally the psychosocial, emotional, and spiritual needs of the patient with a potential life-limiting illness and their family.

CHILDREN WHO MAY BENEFIT FROM PALLIATIVE CARE INTERVENTIONS

In a recent review by Himelstein et al, conditions that are appropriate for palliative care were divided into four groups as follows:

- Conditions for which curative treatment is possible but may fail such as advanced or progressive cancer and complex and severe congenital or acquired heart disease
- Conditions requiring intensive long-term treatment aimed at maintaining the quality of life such as HIV/AIDS, cystic fibrosis, and muscular dystrophy
- Progressive conditions in which treatment is exclusively palliative after diagnosis such as progressive metabolic disorders and certain chromosomal abnormalities
- Conditions involving severe, nonprogressive disability, causing extreme vulnerability to health complications such as severe cerebral palsy and anoxic brain injury

The United States Congress mandated in 2010 that palliative care will be covered concurrently with curative therapies for children with terminal conditions who are receiving Medicaid. Based on the Patient Protection and Affordable Care Act, a voluntary election to receive hospice care for a child does not constitute a waiver of any rights of the child to be provided with, or to have payments made for services that are related to the treatment of the child's condition. This significant milestone in pediatric palliative care should open the door to concurrent care being covered by private insurance companies in the future.

PAIN MANAGEMENT IN PEDIATRIC PALLIATIVE CARE

Optimal pain management is critical when providing pediatric palliative care. (See the section on Pain Management earlier for definitions and guidelines for treatment). As end of life approaches, dosing of comfort medications may eventually exceed normally prescribed doses. The goal at all times must be to achieve and maintain comfort. When pain management at the end of life is provided with this goal at the forefront and in concert with careful ongoing assessment and documentation of the child's symptoms, there should be no reason to fear that this action is tantamount to euthanasia which is a conscious action intended to hasten death.

QUALITY-OF-LIFE ADJUNCTS & SYMPTOM MANAGEMENT IN PEDIATRIC PALLIATIVE CARE

When offering treatment to children with a life-limiting illness particularly at the end of life, certain nonpain symptoms and signs may develop more quickly in children when compared to the adult population. A thorough and complete history and physical examination should be obtained. It is critical to determine how much distress the symptom causes the child and how much it interferes with child and his/her family's routine when deciding upon treatment. Areas of management should include drug treatment, nursing care, and psychosocial support. Symptoms that commonly occur during disease progression and at the end of life in children with a life-limiting condition are listed in Table 32–6, with suggestions for management.

Complementary & Alternative Modalities

It is not unusual for families seek complementary or alternative modalities (CAM) for their child when mainstream treatment has failed or is unavailable. Children with chronic conditions such as cancer, asthma, sickle cell disease, and epilepsy have a higher incidence of CAM usage compared to the general pediatric population (Post-White, 2009). As children approach end of life, many families opt to try some

Table 32–6. Symptom management in pediatric palliative care.

Symptom	Etiology	Management
Nausea and vomiting	Chemotherapy, narcotics, metabolic	Diphenhydramine, hydroxyzine, 5-HT_3 inhibitors, prokinetic agents for GI motility
Anorexia	Cancer, pain, abnormal taste, GI alterations, metabolic changes, drugs, psychological factors	Treat underlying condition, exercise, dietary consultation, appetite stimulants (dronabinol, megestrol, steroid)
Constipation/diarrhea	Narcotics, chemotherapy, malabsorption, drug related	Laxatives (must be initiated whenever starting narcotics), loperamide for diarrhea, peripheral opioid antagonists (methylnaltrexone, alvimopan)
Dyspnea	Airway obstruction; decrease in functional lung tissue due to effusion, infection, metastases; impaired chest wall movement; anemia	Treatment of specific cause (surgery to alleviate obstruction, red blood cell transfusion, chemotherapy/radiation therapy for metastatic disease), nonpharmacologic management (reassurance, position of comfort, improvement of air circulation using electric fan, oxygen, and relaxation therapy), pharmacologic management with opioids given IV/SQ as continuous infusion, nebulized morphine in older patients, concomitant use of anxiolytics (lorazepam, midazolam) if agitation
Terminal respiratory congestion	Airway/oral secretions at the end of life, resulting in rattling, noisy, gurgling breath sounds	Repositioning, anticholinergics such as hyoscine IV/SQ/PO or transdermal scopolamine
Pressure sores	Direct tissue damage, tissue fragility, immobility, diminished response to pain or irritation	Prevention (avoidance of trauma, relieve pressure, good hygiene), treatment with local hygiene, debridement, use of appropriate wound dressings, antibiotics, analgesics
Bone pain	Bony metastases, leukemic infiltration of bone marrow	Palliative radiation, bone-seeking isotopes, bisphosphonates, chemotherapy, analgesics
Agitation	Present in conjunction with pain, dyspnea, terminal phase of illness	Benzodiazepines (midazolam), barbiturates to achieve complete sedation in terminal restlessness
Pruritus	Urticaria, postherpetic neuralgia, cholestasis, uremia, opioids	Antihistamines (cholestasis, uremia, opioids), 5-HT_3 receptor antagonists (cholestasis, opioids)
Hematologic	Marrow infiltration by malignant cells (leukemia) Coagulopathy Bleeding from erosive or ulcerative processes	Transfusions (red blood cells, platelets) to relieve symptoms, hemostatics (aminocaproic acid) Dark bath towel (black, burgundy, or dark purple) to help absorb and camouflage blood
Intractable pain	Various	Chronic pain team consult; consider palliative sedation in very selected cases

form of CAM. Most often, these treatments are aimed at improving physical or spiritual quality of life, Sometimes the goal is a desperate hope to find a treatment when other options have failed or an attempt to find something perceived as less toxic than mainstream treatments to induce remission, support the child's ability to fight the disease, or prolong life. Parents report using CAM gives them a sense of control and hope. The most common modalities reported in pediatrics are prayer/meditation, relaxation techniques, massage, chiropractic care including acupuncture, and nutritional supplements (Post-White et al, 2009). The use of CAM in children is influenced primarily by parental use and acceptance of CAM. Culturally accepted beliefs and practices also play an important role. In Asia, the use of meditation and prayer as a method to control pain is well supported by the medical community. In Europe, the use of homeopathic remedies is commonplace.

Studies of the effectiveness of CAM use in children have been small and the data is often conflicting. There is generally an acceptance for the lack of harm associated with mind-body techniques such as prayer, meditation, touch and sensory modalities, and relaxation. Acupuncture and acupressure are gaining more acceptance in the Western medical community and may be beneficial in some children for relief of pain, nausea, and other symptoms. Touch and sensory modalities such as massage, healing touch, and

aromatherapy can induce a relaxation response in some children which can be very helpful. The use of supplements including botanicals and vitamins has been of more concern due to the lack of dosing information for pediatrics, lack of standardization of products, and the potential for serious drug interactions and toxicities. Treatments touted as alternative "cures" are likely not beneficial and can have very dangerous consequences. The cost of CAM, particularly botanicals and alternative medicine treatments, can be prohibitive and the cost is rarely covered by insurance. Hospice providers frequently incorporate relaxation and mind/body/spirit modalities into their programs.

It is important for the health care provider to ask parents and adolescents about CAM usage and to be open to discussion with the family about modalities they are using or may wish to consider. Parents consistently have reported in studies their desire to inform and discuss CAM with their health care provider, but may be reluctant to do so if they are unsure what response they will get from the provider. Providing families with clear information about the treatment they are considering or using and any contraindications is key. In some cases, recommendation of complementary techniques such as massage, mind/body modalities, and acupuncture/acupressure may be appropriate.

PSYCHOSOCIAL ASPECTS OF PEDIATRIC PALLIATIVE CARE

Pediatric palliative care is unique in that caregivers must be familiar with children's normal emotional and spiritual development. Working with a child at his or her level of development through the use of both oral and expressive communication will allow the child to be more open with respect to hopes, dreams, and fears. A child's understanding of death will depend also on his or her stage of development. Children understand death as a changed state by 3 years of age, universality by 5–6 years of age, and personal mortality by 8–9 years of age. Table 32–7 gives a broad overview of children's concepts of death and offers some helpful interventions.

CHILDREN'S CONCEPT OF DEATH

As end of life approaches, psychosocial support is invaluable to the child and family. Children may need someone to talk to outside of the family unit who can respond to their questions and concerns openly and honestly. Parents may need guidance and support in initiating discussions with or responding to questions from their child about death and dying. Children and adolescents may have specific tasks they wish to complete before they die. Some want to have input into funeral and memorial service plans and disposition of their body. Parents often need support in making funeral arrangements, handling financial concerns, talking with siblings and other family members, and coping with their own grief.

It is important to recognize that grief is not an illness but a normal, multidimensional, unique, dynamic process presenting as pervasive distress due to a perceived loss. Once parents have accepted the reality of the loss of the child, they must then complete the other tasks of grief such as experiencing the pain of their loss and adjusting to an environment without their child in order to move on with their lives. Parents who lose a child are at high risk for complicated grief reactions such as absent grief, delayed grief, and prolonged or unresolved grief. Siblings are also at risk for complicated grief and require special attention.

SPIRITUAL & CULTURAL SUPPORT

Health care decisions are often intertwined with a family's culture and belief system. Understanding the influences of a family's beliefs and culture allows the practitioner to provide sensitive, appropriate care, particularly at the end of life. Interaction with members of the family's faith and cultural communities can often be instrumental in helping both the care team and the community support of the family. Allowance for specific prayers, rituals, or other activities may help facilitate procedures and discussions.

Families who speak a foreign language probably suffer from inadequate support the most. Every effort should be made to find and utilize a qualified interpreter, particularly for any discussion that involves delivering difficult news or making critical decisions. Many times, the role of interpreter is imposed upon a bilingual family member or friend who may not understand medical terminology well enough to translate clearly or who may deliberately translate the information inaccurately in an attempt to protect the family.

WITHDRAWAL OF MEDICAL LIFE SUPPORT

Medical technology has enabled many children with serious health conditions to enjoy a good quality of life. When technological support no longer enables a child's quality and enjoyment of life or there are no viable options to restore quality of life to the child, it may be appropriate to discontinue it. Feeding tubes, ventilators, dialysis, parenteral nutrition and implanted cardiac pacemakers are examples of medical modalities that may need to be re-evaluated when a child's condition deteriorates or in the case of a catastrophic injury.

There are five circumstances in which withdrawal of medical support and technology can be considered in children (Tournay, 2000). (See the following table.)

Table 32–7. Children's concepts of death.

Age Group and Cognitive Development	Cognitive Understanding of Death	Response to Stress	Helpful Interventions
Infancy: Sense of self is directly related to having needs met	None	Lethargy, irritability, failure to thrive	Maintain routines Prompt response to physical and emotional caretaking needs Cuddling, holding, rocking
Toddler: Egocentric, concrete thinking; see objects and events in relationship to their usefulness to self	None but beginning to perceive implications of separation	Irritability, change in sleep-wake patterns, clinginess, regression, tantrums	Maintain routines Keep familiar people and objects at hand Prompt response to physical and emotional caretaking needs Accept need for increased physical and emotional comfort but continue to encourage acquisition of developmental skills
Preschool: Beginning to understand concept of time but limited sense of time permanence, curious, still quite concrete in thinking	View death as deliberately caused Magical thinking about causes of illness and death Death is not a permanent state	Oppositional behaviors, regression, sleep-wake changes, nightmares, somatic complaints Beginning to identify meaning and context of emotions	Simple, concrete explanations to questions—find out what it is they want to know Reassurance that death and illness are not the result of their thoughts or wishes Keep familiar people and objects at hand Play is a powerful tool to help children process events and emotions and as distraction from stressful situations
School age: Beginning of ability to apply logic; accept points of view other than their own	Death is seen in context of experience (pets, grandparents, what is seen on TV or in movies) Can understand that death is permanent	Oppositional behaviors, nightmares, sleep disruption, withdrawal, sadness Can verbally identify own feelings of fear, sadness, happiness	Ascertain how they perceive and understand what is happening and respond accordingly to their questions Acknowledge that feelings of sadness, fear, and anger are normal Allow age-appropriate control whenever possible Maintain as much normalcy in routine as possible Play is very important for expression of emotions and release of stress, amenable to directed play
Preadolescence and adolescence: Gaining mastery over themselves as individuals by exploring their own moral, ethical, and spiritual beliefs; increased reliance on peers for emotional support and information	Adult awareness of death but still may be highly experiential in understanding	Anger, withdrawal, sadness, depression, somatic complaints May have difficulty asking for emotional help	Set the tone for open, honest communication Allow the young person as much control as possible in decisions about his or her own health care Be willing to discuss and respect wishes and desires for disposition of belongings, funeral planning, what happens to his or her body Assist the young person in accomplishing important life tasks and activities that gives meaning to his or her existence or leaves behind a legacy

Brain death	All reversible causes excluded, meets established criteria for determination of brain death
Persistent vegetative state (PVS)	Child totally dependent for all cares, has no ability to interact meaningfully with his environment. Lack of cortical peaks in the somatosensory evoked potential may be helpful in making prognosis of PVS (Tournay, 2000)
Treatment will delay death without significantly relieving the suffering caused by the condition	No chance for cure, invasiveness of the treatment may prolong life but does not diminish or increases suffering
Child's life may be saved, but at the cost of physical and mental impairment that makes life intolerable for the child	Important to understand how child and family defines "intolerable life"
Additional treatment with potential benefit will cause further suffering	Burden of suffering outweighs the potential for benefit.

At these times, it will be necessary to have a gentle but frank discussion with the family that includes eliciting their understanding of the child's situation and prognosis. Helping them identify and define what quality of life means to their child and to the family and what would be an intolerable life for the child is important. It is critical to present in a clear and understandable format the child's medical condition, test results, and the treatments that have been tried, what the expectations are for the child's ability to survive or function and interact with his environment, and why it is believed that current or additional interventions will be futile or induce further suffering. These discussions should be conducted with sensitivity and without need for an immediate answer from the parents. It often takes several such discussions for families to come to a decision that they themselves will be able to live with and families should not be rushed into decision making. The family may request additional testing or retesting to assure themselves they are making the right decision for their child. When feasible, these requests should be honored. Spiritual support may be very helpful to families during this process and should be offered.

Once the family has made the decision to withdraw support, it is helpful to explain what the anticipated course will be following withdrawal, what the child will likely look like during that time and what the plan of care will be to ensure comfort. Create a plan with the family for time and place of withdrawal, who they would like to be there with them, any specific requests for environment such as music, a favorite movie playing, or a book being read, and who they would like to perform the withdrawal. Offering the opportunity for rituals, prayer, or private time prior to or during the withdrawal is appropriate. If death is anticipated to happen quickly after withdrawal, any specific religious requirements for the body after death should be arranged in advance. In all cases of withdrawal, the family should be offered support during the process and after the death occurs.

ADVANCE CARE PLANNING

Advance care planning allows patients and families to make known their wishes about what to do in care of serious or life-threatening problems. Himelstein et al describe advance care planning as a four-step process. First, those individuals considered decision makers are identified and included in the process. Second, an assessment of the patient's and family's understanding of the illness and prognosis is made and the impending death is described in terms that the child and family can understand. Third, on the basis of their understanding of the illness and prognosis, the goals of care are determined regarding current and future intervention—curative, uncertain, or primarily focused on providing comfort. Finally, shared decisions about the current and future use or abandonment of life-sustaining techniques and aggressive medical interventions are made. In the event of a disagreement between parents or parents and their patient regarding these techniques or interventions, it may be prudent to involve the hospital's ethics committee in order to resolve these issues.

Some states permit parents to sign an advanced directive that asserts their decision not to have resuscitative attempts made in the event of a cardiac or respiratory arrest outside of the hospital. When an advanced directive is in place, emergency responders are not required to provide cardiopulmonary resuscitation (CPR) if called to the scene. Some school districts will respect an advanced directive on school property, many will not. If a child with an advanced directive in place wishes to go to school, a discussion between the medical team and school officials should be arranged to determine the best plan should the child have a cardiac or respiratory arrest at school.

Parents and, occasionally, the child may bring up the possibility of donating organs or body tissues after death. Although the tissues that may be donated by a child may be limited in some instances by the type of disease (eg, cancer), some parents find immense comfort in knowing their child was able to benefit another. If the parents have not discussed donation with the physician by the time of death and donation is possible, the physician should offer the opportunity to the family.

Autopsy is another subject many physicians find difficult to approach with a family, but it is an important option to discuss. In cases of anticipated death from natural causes, autopsies are generally not mandatory; however,

information obtained from an autopsy may be useful for parental peace of mind or medical research. If death at home is to be followed by an autopsy, special arrangements for transporting and receiving the body will need to be made with the mortuary or the coroner.

33 Immunodeficiency

Jordan K. Abbott, MD
Pia J. Hauk, MD

Immune deficiencies that present in childhood comprise rare disorders that have been characterized by a combination of clinical patterns, immunologic laboratory tests, and often molecular identification of the mutant gene. Children with primary immunodeficiency (PID) commonly present with recurrent and/or severe bacterial infections, failure to thrive, and/or developmental delay as a result of infection. Immunodeficiency should be considered when infections are recurrent, severe, persistent, resistant to standard treatment, or caused by opportunistic organisms. Because delayed diagnosis of PIDs is common, heightened diagnostic suspicion is warranted.

The human immune system consists of the phylogenetically more primitive innate immune system and the adaptive immune system. For the purpose of clinical categorization, PIDs are commonly divided into four main groups: antibody deficiencies, combined T- and B-cell immunodeficiencies, phagocyte disorders, and complement deficiencies. Understanding the role each part of the immune system plays in host defense allows critical evaluation for possible immunodeficiency as the cause of recurrent infections.

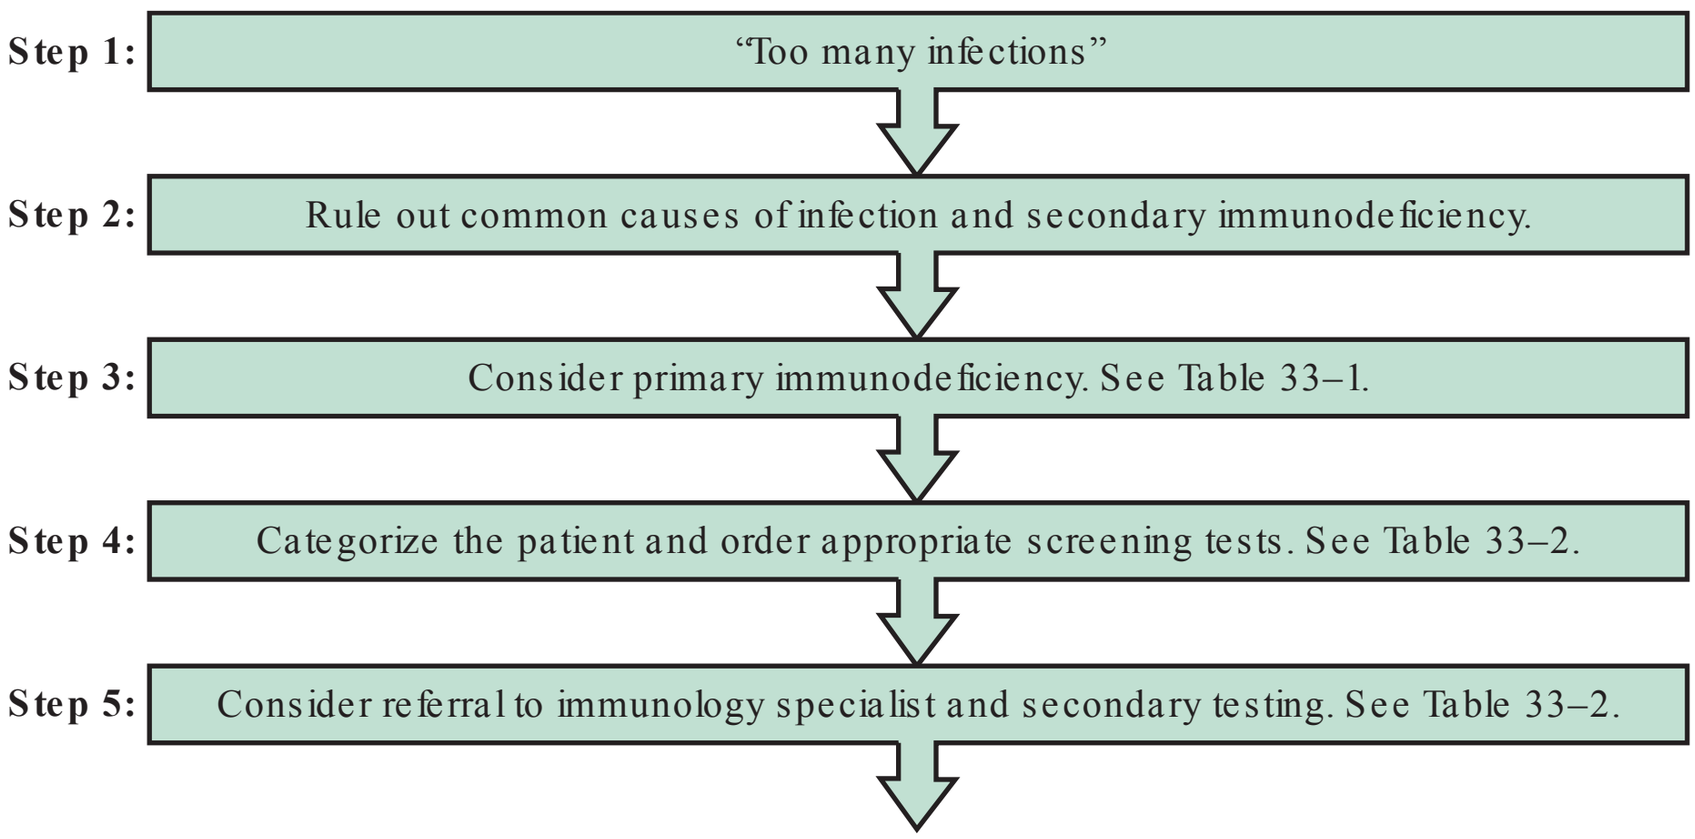
Picard C et al: Primary immunodeficiency diseases: an update on the classification from the international union of immunological societies expert committee for primary immunodeficiency. J Clin Immunol 2015;35:696–726 [PMID: 26482257].

IMMUNODEFICIENCY EVALUATION: PRIMARY CONSIDERATIONS

When evaluating for a possible PID, other conditions that increase susceptibility to infections have to be considered, such as allergic rhinitis, asthma, cystic fibrosis, foreign body aspiration, and conditions that interfere with skin barrier function. Common causes of secondary or acquired immunodeficiency need to be excluded. These include malnutrition, aging, certain drugs (chemotherapy, immunosuppressive medications, glucocorticoids, disease-modifying antirheumatic drugs, rituximab), protein loss via gastroenteropathy or kidney disease, and other diseases associated with impaired immunity (bone marrow and blood cell malignancies, and certain chronic infections, including AIDS). If a single site is involved, anatomic defects and foreign bodies may be present. Figure 33–1 outlines when PIDs should be considered.

Key clinical patterns can indicate the presence of a PID and the category of immune impairment. PID should be considered in patients with frequent, severe, or unusual infections. When the infection history suggests PID, the type of infections can help guide the initial workup. Antibody, complement, and phagocyte defects predispose mainly to bacterial infections, but diarrhea, superficial candidiasis, opportunistic infections, and severe herpesvirus infections are more characteristic of T-lymphocyte immunodeficiency. Location of infection can provide important clues. Additional features such as the presence of autoimmunity, poor wound healing, lymphoproliferative disease, age of disease onset, and failure to thrive can help further categorize the PID. Table 33–1 classifies PID into four main host immunity categories based on age of onset, infections with specific pathogens, affected organs, and other special features. Frequently seen clinical features of PID are shown in Figure 33–2.

Initial laboratory investigation should be directed by the clinical presentation and the suspected category of host immunity impairment. If antibody deficiency is suspected, a complete blood cell (CBC) count with cell differential and measurement of quantitative immunoglobulins (Igs) will identify the majority of patients. If T-cell deficiency is suspected, lymphocyte phenotyping to quantify blood T cells, B cells, and natural killer (NK) cells should be sent. For phagocyte defects, testing of oxidative burst in stimulated granulocytes should be performed. For complement deficiency, testing of the function of the classical and alternative pathway should be performed. Table 33–2 summarizes the approach to laboratory evaluation of PID.



▲**Figure 33–1.** General approach to primary immunodeficiencies.

Antibodies & Immunoglobulins

The initial laboratory screening for antibody deficiency includes the measurement of serum Igs: IgG, IgM, IgA, and IgE, which have age-dependent normal ranges (Table 33–3). Normal IgG, IgM, and IgA, and increased IgE levels are indicative of atopy. Some patients may have normal Ig levels but fail to make protective antibodies to certain microbes; other patients have subnormal Ig levels but make protective antibodies. Specific antibodies include isohemagglutinins, naturally occurring IgM antibodies that are detectable by age 6 months except in children with blood group AB. Specific IgG antibodies to protein antigens (tetanus, diphtheria, rubella, mumps) and polysaccharide antigens (Streptococcus pneumoniae) can be measured after immunization. The response to polysaccharide antigens develops during the second year of life, but protein-conjugated vaccines elicit an earlier response in immunocompetent children. Assessing the antibody response to pneumococcal polysaccharide antigens can be helpful in the face of repeated pneumococcal infections. The gold standard is comparison of pre- and postimmunization titers.

If an initial screen reveals very low concentrations of Ig isotypes, further studies are aimed at identifying the cause of immunoglobulin deficiency. Certain types of hypogammaglobulinemia are characterized by low levels of or absent B lymphocytes, such as X-linked Bruton agammaglobulinemia. Serum albumin should be measured in patients with hypogammaglobulinemia to exclude secondary deficiencies due to protein loss through bowel or kidneys. IgG or IgA subclass measurements may be abnormal in patients with varied immunodeficiency syndromes, but they are rarely helpful in an initial evaluation.

T Lymphocytes

The initial laboratory screening for a T-lymphocyte deficiency includes a CBC with cell differential to evaluate for a decreased absolute lymphocyte count (< 1000/μL) and enumeration of absolute numbers of T cells and their subsets, B cells, and NK cells (see Table 33–2). T-cell function can be analyzed by in vitro lymphocyte proliferation assays to mitogens that stimulate all T cells and by specific antigens that stimulate only antigen-specific T cells. Borderline function must be interpreted based on clinical correlation. T-lymphocyte function is often also studied in vivo by delayed hypersensitivity skin tests to specific antigens, including Candida albicans, tetanus, or mumps, but a negative result is not helpful, as it may be due to young age, chronic illness, vitamin D deficiency, or poor test technique. T-lymphocyte deficiencies will often not manifest as skin-test anergy until the impairment is severe, for example, as in AIDS. It is important to evaluate a patient's specific antibody production because proper B-lymphocyte function and antibody production are dependent on adequate T-lymphocyte function. Therefore, most T-lymphocyte deficiencies manifest as combined T- and B-lymphocyte deficiencies.

Phagocyte Immunity

The initial laboratory screening for phagocyte disorders, mainly impaired neutrophil function, should include a CBC and cell differential to look for neutropenia. A blood smear can detect Howell-Jolly bodies in erythrocytes, indicative of asplenia, and abnormalities in lysosomal granules in neutrophils. An abnormality of the neutrophil respiratory burst, which would lead to impaired neutrophil bactericidal

Table 33–1. Clinical features of primary immunodeficiencies.

Characteristic	Combined Deficiency (T- and B-Lymphocyte Defect)	Antibody Deficiency (B-Lymphocyte Defect)	Phagocyte Defect	Complement Defect
Age at onset of infections	Early onset, usually before 6 mo	Onset after maternal antibodies decline, usually after 3–6 mo; some later in childhood or adults	Early onset	Any age
Specific pathogens	**Bacteria**: Streptococcus pneumoniae, Campylobacter fetus, Staphylococcus aureus, Haemophilus influenzae, Pseudomonas aeruginosa, Mycoplasma hominis, Ureaplasma urealyticum, Listeria monocytogenes, Salmonella spp, enteric flora, atypical mycobacteria, and BCG **Viruses:** CMV, EBV, varicella, RSV, enterovirus, rotavirus **Fungi/protozoa:** Candida albicans, Aspergillus fumigatus, Toxoplasma gondii **Other:** Pneumocystis carinii, Cryptosporidium	**Bacteria:** Spneumoniae, Cfetus, Hinfluenzae, Paeruginosa, Uurealyticum, Saureus, Mhominis **Viruses:** Enteroviruses **Fungi/protozoa:** Giardia lamblia	**Bacteria:** Saureus, enteric flora, Burkholderia spp, Aspergillus spp, Paeruginosa, Salmonella spp, Serratia spp, Nocardia asteroides, Klebsiella spp, nontuberculous mycobacteria, and BCG **Viruses:** None **Fungi/protozoa**: Calbicans, Afumigatus	**Bacteria:** Neisseria meningitidis and gonorrhoeae, Spneumoniae, Saureus, Paeruginosa, Hinfluenzae **Viruses:** None **Fungi/protozoa:** None Common
Affected organs and infections	**General:** Failure to thrive **Infections:** Severe infections (meningitis, septicemia, sinopulmonary), recurrent candidiasis, protracted diarrhea	**Infections:** Recurrent sinopulmonary, pneumonia, meningitis **GI:** Chronic malabsorption, IBD-like symptoms **Other**: Arthritis	**Skin:** Dermatitis, abscesses, cellulitis **Lymph nodes:** Suppurative adenitis **Oral cavity:** Periodontitis, ulcers **Lungs:** Pneumonia, abscesses **Other:** Liver and brain abscesses, osteomyelitis	**Infections:** Meningitis, disseminated gonococcal infection, septicemia, pneumonia
Special features	GVHD from maternal T cells or blood product transfusion Disseminated infection after BCG or live polio immunization Absent lymphoid tissue Absent thymic shadow on chest radiograph	Autoimmunity Lymphoreticular malignancy Postvaccination polio Chronic enteroviral encephalitis	Poor wound healing Pyloric and urethral stenosis, IBD	**Autoimmune disorders:** SLE, vasculitis, dermatomyositis, scleroderma, glomerulonephritis **Other:** Hereditary angioedema, aHUS

aHUS, atypical hemolytic uremic syndrome; BCG, bacille Calmette-Guérin; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; IBD, inflammatory bowel disease; RSV, respiratory syncytial virus; SLE, systemic lupus erythematosus.

activity, can be tested by nitroblue tetrazolium (NBT) reduction. The dihydrorhodamine (DHR) flow cytometry assay assesses the same function more quantitatively. Leukocyte adhesion molecules can be studied by flow cytometry. Assays to study neutrophil phagocytosis of bacteria and phagocytic microbicidal activity are available in specialized laboratories. The clinical symptom pattern that suggests a possible defect of phagocytic cell function should dictate which tests are used.

Complement Pathways (Figure 33–3)

Testing for total hemolytic complement activity with the CH50 assay screens for most of the diseases of the complement system. A normal CH50 titer depends on the ability of all 11 components of the classic pathway and membrane attack complex to interact and then lyse antibody-coated sheep erythrocytes. Alternative complement pathway deficiencies are identified by subnormal lysis of

10 Warning signs of primary immunodeficiency

Primary immunodeficiency (PID) causes children and young adults to have infections that come back frequently or are unusually hard to cure. In America alone, up to 1/2 million people suffer from one of the 100 known PID diseases. If you or someone you know are affected by two or more of the following warning signs, speak to a physician about the possible presence of an underlying PID.

1. Four or more new ear infections in 1 y
2. Two or more serious sinus infections within 1 y
3. Two or more months on antibiotics with little effect
4. Two or more pneumonias within 1 y
5. Failure of an infant to gain weight or grow normally
6. Recurrent, deep skin, or organ abscesses
7. Persistent thrush in mouth or fungal infection of skin
8. Need for intravenous antibiotics to clear infections
9. Two or more deep-seated infections, including septicemia
10. A family history of primary immunodeficiency

▲**Figure 33–2.** Warning signs of primary immunodeficiency. (Data from the Jeffrey Modell Foundation.)

Table 33–2. Laboratory evaluation for primary immunodeficiency.

Suspected Defect	Screening Evaluation	Specialist Evaluation
B lymphocyte	• CBC with differential • Quantitative immunoglobulins	• T-cell, B-cell, and NK-cell enumeration • Extended phenotyping of B cells • IgG levels to immunization antigens • DNA analysis for specific genetic mutations
T lymphocyte	• CBC with differential • Quantitative immunoglobulins • T-cell, B-cell, and NK-cell enumeration	• Extended phenotyping of T cells • Lymphocyte proliferation to mitogens and antigens • Delayed-type hypersensitivity skin test • Cytotoxicity studies • ADA or PNP levels of RBC • DNA analysis for specific genetic mutations
Phagocyte	• CBC with differential	• DHR flow cytometry assay, • Nitroblue tetrazolium reduction assay • Bactericidal assays • CD11/18 analysis • Chemotaxis assay
Complement	• CH50 • AH50	• Complement component levels • Complement component function • Complement antibodies

ADA, adenosine deaminase; CBC, complete blood cell count; CD, cluster of differentiation; DHR, dihydrorhodamine; HIV, human immunodeficiency virus; NK, natural killer; PNP, purine nucleoside phosphorylase; RBC, red blood cell; WBC, white blood cell.

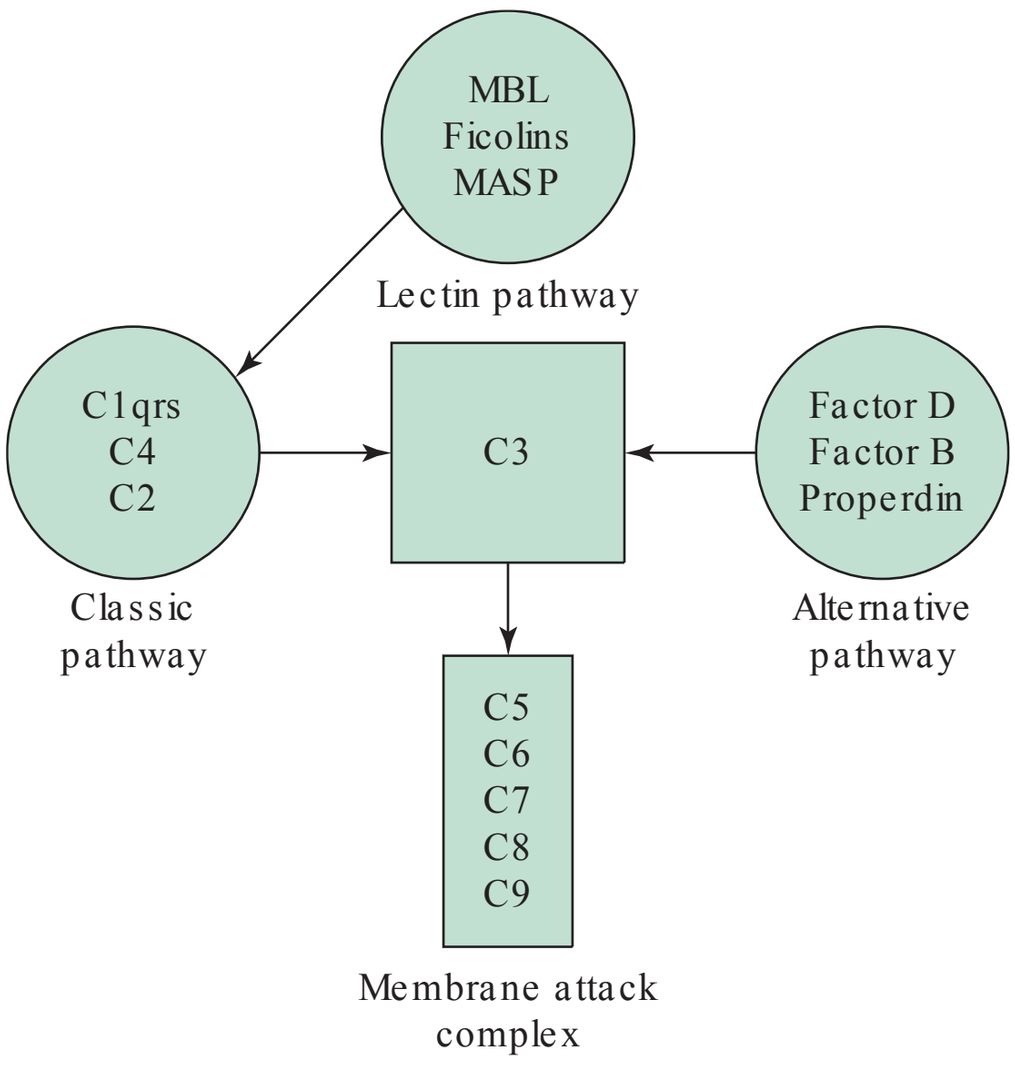
rabbit erythrocytes in the AH50 assay. For both assays, the patient's serum must be separated and frozen at –70°C within 30–60 minutes after collection to prevent loss of activity. Measuring levels of individual components is not necessary when both CH50 and AH50 are normal. If both the CH50 and AH50 are low, a deficiency in their shared terminal pathway (C3, C5, C6, C7, C8, or C9) would be the most common explanation. If the CH50 is low but the AH50 is normal, the deficiency must affect C1, C4, C2, or components of the lectin pathway. If the AH50 is low but the CH50 is normal, a deficiency in factors D or B or properdin should be suspected.



▲**Figure 33–3.** Pathways of complement activation and the central functional role of C3. MASP, MBL-associated serine protease; MBL, mannose-binding lectin.

Pattern-Recognition Receptors

Selected laboratories offer tests to assess Toll-like receptor (TLR) function upon stimulation with ligands for different TLRs that have been identified. Mannose-binding lectin levels can be measured in clinical laboratories. However, expression or function of pattern recognition receptors and associated gene mutations are studied mostly in a research setting at the current time.

SEVERE COMBINED IMMUNODEFICIENCY DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Onset in first year of life.
- Recurrent infections caused by bacteria, viruses, fungi, and opportunistic pathogens.
- Chronic diarrhea and failure to thrive.
- Absent lymphoid tissue.

» General Considerations

Severe combined immunodeficiency disease (SCID) is a group of rare immunologic disorders with the defining characteristic of severe deficiency of T-cell function and/or number. Due to the centrality of T cells in the immune system, the severity of T-cell deficit results in widespread immunologic dysfunction and broad susceptibility to infection. Left untreated, SCID uniformly results in death before the first year of life. The treatment approach varies depending on the underlying molecular defect, but for the majority of patients with SCID, the optimal treatment is hematopoietic stem cell transplant (HSCT). Transplant outcomes are favorable if performed within the first 3 months of life, or if performed prior to the onset of SCID-associated chronic infections. Newborn screening efforts have therefore been implemented to identify and transplant these patients soon after birth. Suspected SCID is a medical emergency, and both the necessary steps to confirm diagnosis and the initiation of treatment must be performed rapidly.

» Clinical Findings

A. Symptoms and Signs

SCID frequently presents with opportunistic, unusual, and persistent infection. Common organisms include but are not limited to Pneumocystis jiroveci, candidiasis, and cytomegalovirus. In the absence of an identified microorganism, SCID may present with any combination of the following: failure to thrive, chronic diarrhea, or unexplained chronic respiratory illness. Physical examination is notable for a lack of lymphoid tissue, including tonsils and lymph nodes. A chest radiograph usually demonstrates an absent thymic shadow.

B. Laboratory Findings

The characteristic feature of SCID is the deficiency in production of T cells by the host. Endogenous production of T cells can be verified by quantifying T-cell receptor rearrangement excision circles (TRECs) in blood or by measuring the expression of CD31 on peripheral blood T cells. The presence of normal numbers of lymphocytes in a CBC or even normal numbers of CD4 T cells does not rule out SCID because of the possibility of either maternally derived T-cell populations or abnormally expanded endogenous T-cell populations with severely limited diversity. Associated laboratory findings can include decreases in numbers of NK cells and B cells, poor lymphocyte proliferative response to mitogens, and low immunoglobulin levels. Genetic testing should be pursued to confirm the diagnosis; although, treatment should not be delayed while awaiting results of genetic testing. Known genetic etiologies of SCID are listed in Table 33–4.

» Differential Diagnosis

The differential diagnosis of SCID must be carefully considered as misdiagnosis could potentially result in unwarranted HSCT. Disorders that result in either the abnormal loss or compartmentalization of lymphatic fluid such as chylothorax, lymphangiectasia, gastroschisis, and omphalocele can result in the apparent absence of endogenously generated T cells even though they are actually being normally produced. HIV disease can result in severe deficiency of CD4 T cells and the same infections seen in SCID. Prematurity can be associated with abnormally low TREC levels but these levels ultimately increase with increasing gestational age.

» Treatment

A variety of therapies are used in the treatment of SCID. These therapies include HSCT, gene therapy, thymus transplant, and enzyme replacement. Choice of therapy depends upon the specific genetic defect, age at diagnosis, access to a suitable HSCT donor, and comorbidities. To optimize the outcome of any chosen definitive therapy, concerted effort must be made to prevent clinical deterioration in the waiting period. Antimicrobial prophylaxis should be initiated with the aim of preventing pulmonary infection with Pneumocystis, as well as other fungal pathogens. Antiviral prophylaxis can be considered as well. Replacement Ig therapy should be initiated. Patients with suspected SCID should only be transfused with CMV-negative, irradiated blood products, and they should not receive any live vaccines. If the patient has received BCG vaccination, specific therapy should be considered. Isolation precautions should be initiated, and if the mother is CMV-positive, breast-feeding should be discouraged. Additional precautions can be tailored based on the individual risk factor of the patient.

SCID Classification

» Defective T-cell Development

T cells develop in a multiple stage process fostered by supporting cells and directive cytokines. Problems with the production or sensing of these developmental signals can result in a severe deficit of T-cell number. T-cell intrinsic developmental defects include genetic deficiency in components of the IL-7R signaling complex, including IL2RG, IL7RA, and JAK3. Defective integration of signals present in the thymus can be seen in ZAP-70 deficiency, CD45 deficiency, and deficiency of the delta-epsilon, and gamma-subunits of the CD3 complex.

Deficiency in the RAG recombination machinery and nonhomologous end joining machinery (NHEJ) prevent the formation of a functionally rearranged T-cell receptor and result in absence of T cells with the NHEJ-caused deficiency also being associated with radiation sensitivity. Primary absence of the thymus prevents development of mature T cells in severe presentations of 22q11 deletion syndrome, CHARGE syndrome, and deficiency of FOXN1.

» Impaired T-cell Survival

Impaired T-cell survival is seen in deficiency of both adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP), as well as reticular dysgenesis and dyskeratosis congenita. ADA and PNP are components of purine salvage in lymphocytes, and loss of theses enzymes results in buildup of toxic purine by-products. Dyskeratosis congenita results from abnormal telomere maintenance and results in survival defects in hematologic cells. Reticular dysgenesis is possibly the most severe form of combined immunodeficiency, resulting from deficient adenylate kinase 2 (AK2), an enzyme involved in apoptosis. Defects in the one-carbon pathway, including defects in TCN2 and defects in MTHFD1 can result in severe deficiency of hematopoietic cells.

» Impaired T-cell Function

Few syndromes have been identified where T cells mature normally despite a residual impairment in T-cell receptor

Table 33–4. Severe combined immunodeficiency classification.

	Genes Containing Defects	Likely Etiology	Characteristic Features
Defective T-cell development			
• **Defective IL7R signaling**	IL2RG, IL7RA, JAK3	IL-7 signaling is essential for T-cell development.	• IL2RG- and JAK3-deficiency have associated absence of NK cells and functional B-cell deficiency.
• **Defective T-cell receptor (TCR) signaling**	ZAP70, PTPRC, CD3D, CD3G, CD3E	TCR signaling is essential for T-cell development.	• ZAP70 has apparent deficiency of only CD8 T cells but CD4 T cells are also nonfunctional. • B cells are not affected.
• **RAG-recombination defect**	RAG1, RAG2	Functional TCR is not formed.	• Both B and T cells are deficient. NK cells are unaffected.
• **NHEJ-recombination defect**	LIG4, NHEJ1, DCLRE1C, PRKDC	Functional TCR is not formed.	• Both B and T cells are deficient. NK cells are unaffected. • Body wide sensitivity to radiation toxicity • Can be associated with microcephaly and other syndromic features
• **Absent thymus function**	22q11 deletion, CHARGE syndrome, FOXN1	Thymus is essential for T-cell development.	• B cell counts generally are not affected. • FOXN1 deficiency is associated with nail dysplasia.
Impaired T-cell Survival			
• **Impaired purine salvage**	ADA, PNP	Toxic metabolites	• B cell, T cell, and NK cells deficient
• **Dyskeratosis congenita** (Hoyeraal-Hreidarsson Syndrome)	DKC1, ACD (TPP1), TINF2, TERT, RTEL1	Telomere maintenance is severely defective.	• Associated IUGR and cerebellar hypoplasia
• **Reticular dysgenesis**	AK2	Possible cellular energy imbalance	• Associated with agranulocytosis and deficiency of all lymphocytes, but normal erythrocyte and platelet formation
• **One-Carbon Pathway**	TCN2, MTHFD1	Unclear	• Associated neurodegenerative defect • Megaloblastic anemia • Patients improve with adequate supplementation.
• **Ribosomal Defect**	RMRP	Unclear	• Associated with short-limb dwarfism
Impaired T-cell function			
• **Ca^{2+}-signaling defect**	STIM1, ORAI1	IL-7 signaling is essential for T-cell development.	• IL2RG- and JAK3-deficiency have associated absence of NK cells and functional B-cell deficiency.
• **Antigens to cells**	CD3G, CD3E	Impaired T-cell development and signal transduction	• B cells are not affected.

(TCR) signaling that results in susceptibility to infections typically seen in T-cell deficiency syndromes. In STIM1 and ORAI1 deficiency, defective mobilization of store-operated calcium channels results in inadequate activation of peripheral T cells despite normal numbers. In MHC Class II deficiency, normal T cells are unable to respond to antigen because it is not presented by antigen presenting cells.

Omenn Syndrome

Omenn syndrome is a presentation of SCID caused by residual autoreactive T cells in the absence of T-cell immune competence. The syndrome can include severe rash, failure to thrive, splenomegaly, diarrhea, eosinophilia, and elevated IgE in association with typical infections seen in conventional SCID. T-cell numbers are elevated, but detailed phenotyping reveals the majority of T cells to have a memory phenotype (CD45RO-positive). Omenn syndrome has been tied to mutations in genes known to cause conventional SCID, arising in part due to mutation-specific factors and partly due to the individual susceptibility of the patient. A similar clinical presentation occurs in SCID patients who have engrafted maternal T cells.

ANTIBODY DEFICIENCY SYNDROMES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent bacterial infections, typically due to encapsulated pyogenic bacteria.
- Low immunoglobulin levels.
- Inability to make specific antibodies to vaccine antigens or infections.

» General Considerations

Antibody deficiency syndromes include both congenital and acquired forms of hypogammaglobulinemia with low levels of one or more of the immunoglobulins IgM, IgG, and IgA. As a group, antibody deficiencies represent nearly half of all PIDs. They can be divided into (1) defects of B-cell development; (2) defects in Ig class switching; (3) and functional B-cell deficiency. Table 33–5 outlines primary antibody deficiency syndromes, laboratory findings, and genetic inheritance in these disorders.

» Clinical Findings

A. Symptoms and Signs

For patients with antibody deficiency, specific infectious susceptibility and other features of immune dysregulation are dependent upon the specific cause of antibody deficiency. In isolated early B-cell development defects, such as X-linked agammaglobulinemia, infections are limited to encapsulated bacteria, mycoplasma species, and enterovirus species. In the class-switching defect caused by defective CD40L, infectious susceptibility can include Pneumocystis and Cryptosporidium, whereas class switching defects caused by absence of AICDA or UNG can include lymphoproliferation and autoimmunity. Functional defects in B cells or B-cell activation, such as in combined immunodeficiency syndromes or common variable immunodeficiency (CVID) syndromes will include infectious susceptibility dependent on the underlying molecular defect. Antibody deficiency therefore represents a broad and somewhat heterogeneous grouping whose individual features depend on the root cause of immune abnormality.

Independent of underlying cause, untreated antibody deficiency results in typical infections. Pulmonary infection can be severe and chronic, resulting in bronchiectasis or other permanent lung damage. Severe pulmonary infections are generally preceded by chronic, recurrent middle ear and sinus infections. Additional infections can include bacteremia, bacterial meningitis, skin infection, and joint infection. Other sites of infection can arise depending on the underlying genetic defect.

B. Laboratory Findings

Numerous blood tests are available for the investigation of antibody production. Serum immunoglobulin levels are routinely tested and reference values are widely accessible. Antibodies to a particular antigen are measured to ensure that antibody production is specific. For instance, the amount of antibody to tetanus toxoid is frequently measured because the tetanus toxoid vaccine is routinely administered in developed countries. Vaccine titers to pneumococcal serotypes are frequently measured following vaccination with the unconjugated polysaccharide S pneumoniae vaccine. The increase in titers represents the ability of B cells to form antibodies in the absence of T-cell costimulation. Production of allo-specific IgM to red cell antigens is also a measure of T-cell independent antibody formation. When abnormalities are detected in immunoglobulin levels or antibody production, lymphocyte surface phenotyping may reveal additional aspects of the underlying abnormality, such as B- or T-cell deficiency.

The characteristic feature of antibody deficiency is the absence or severe deficiency of one of the three predominant immunoglobulins found in blood, IgG, IgA, or IgM. All three immunoglobulin isotypes are severely reduced in early B-cell development defects; although, IgG deficiency is rarely seen in children younger than 4 months due to the presence of placentally transferred maternal IgG. In class switching defects, IgM production can be normal or elevated, whereas production of IgG and IgA is deficient. In functional B-cell deficiencies, a combination of antibody production abnormalities may be detected. For instance, CVID is defined by

Table 33–5. Antibody deficiency disorders.

	Genes Containing Defects	Likely Etiology	Characteristic Features
Defects in B-cell development			
• **Defect in developmental signal**	TCF3, IKZF1, LRRC8A	Commitment to B-cell lineage affected	• Peripheral B cells < 2% of lymphocyte count
• **Defect in pre–B-cell receptor (BCR)**	IGHM, IGLL1, CD79A, CD79B,	B-cell development requires functional pre-BCR	• Peripheral B cells < 2% of lymphocyte count
• **Defect in pre-BCR downstream signaling**	BLNK, BTK	Pre-BCR signaling inadequate to support further development	• Peripheral B cells < 2% of lymphocyte count
• **Block at Transitional B-cell stage**	CARD11	Unclear	• Normal total B-cell numbers with decreased maturation beyond the transitional B-cell stage • Regulatory T-cell numbers reduced
Class-switching defects			
• **Defect in CD40L-CD40 interaction**	CD40L, CD40	CD40L signal initiates class switching	• Typically high IgM levels • No germinal centers • Susceptible to some typical T-cell deficiency-associated infections such as pneumocystis pneumonia and cryptosporidial infection • Associated with biliary malignancy possibly from chronic infection
• **Defect in genomic rearrangement**	AICDA, UNG	Rearrangement of the IgH constant region is defective	• Normal B-cell numbers • Associated with significant autoimmunity • Large germinal center reactions because proliferative signaling remains intact
• **Varied**	IKBKG, IKBA, PIK3CD	Unclear	• Usually associated with predominant T-cell abnormalities
Functional antibody deficiency			
• **Common variable immunodeficiency (CVID)**	Unknown	Heterogeneous	• Normal or low IgM, low IgG, low IgA, poor specific antibody production
• **Monogenetic syndromes previously characterized as CVID**	TACI, BAFFR, ICOS, CD19, TNFRSF13C, CD20, CD81, CD225	Impaired signaling through B-cell coreceptors	• Normal or low IgM, low IgG, low IgA, poor specific antibody production
• **Combined immunodeficiency syndromes**	CD21, CD27, PIK3D gain of function	Impaired signaling through molecules present in B and T cells	• Normal or low IgM, low IgG, low IgA, poor specific antibody production • T-cell dysfunction
Selective immunoglobulin deficiencies			
• **IgG subclass deficiency**	IGHG1, IGHG2, IGHG3, IGHG4	Defects of isotype differentiation	• Decrease in one or more IgG isotypes
• **IgA deficiency**	IGAD1	Defect in IgA production	• Decrease or absent IgA
• **Specific antibody deficiency**	Unknown	Unclear	• Deficient antibody response to polysaccharide antigens

the combination of poor vaccine response and a decrease in blood levels of IgG in conjunction with a severe decrease in levels of either IgM or IgA, or a decrease of both.

Blood cell abnormalities also vary according to the underlying cause of antibody deficiency. The majority of early B-cell development defects are limited to the B-cell compartment, and as a result, B-cell numbers are severely reduced, but levels of other blood cells are usually within normal limits. In class switching defects, peripheral B-cell numbers will also approach normal levels. On the other hand, functional antibody deficiency can arise in any combination of deficiency of specific lymphocyte subsets and other blood cells. For these deficiencies, the underlying genetic abnormality is most relevant to understand the resulting hematologic abnormality.

» Differential Diagnosis

The differential diagnosis of antibody deficiency includes secondary causes of decreased amount of immunoglobulin in the peripheral blood. Several medications are known to specifically decrease immunoglobulin levels in the blood. For some of these medications, the mechanism is idiosyncratic. For others, low immunoglobulin levels result from inhibition of normal B-cell development processes, such as in chronic prednisone use, or they result from direct effects on the B-cell compartment, such as with rituximab therapy. Additional secondary causes of low immunoglobulin include protein-losing states, malnutrition, and autoimmune conditions.

» Treatment

Treatment of antibody syndromes is primarily directed at preventing bacterial infection. The primary intervention in achieving this goal is replacing deficient IgG. There are no formulations of isolated IgM or IgA used in clinical practice. Some centers advocate the use of prophylactic antibiotic therapy. In combined immunodeficiency or antibody deficiency syndromes with associated autoimmunity, immunosuppressive therapy or even hematopoietic stem cell transplantation may be required.

Antibody Deficiency Classification

» Defective B-cell Development

Aborted B-cell development can occur at multiple developmental stages. Initially, B cells develop from precursors in the bone marrow in a process that is dependent on the generation of a functioning rearranged B-cell receptor. In the absence of the ability to transmit signals through a B-cell receptor, B cells do not continue development. Consistent with this model of B-cell development, congenital defects in several of the proteins essential for the formation and signaling of the B-cell receptor have been identified as causes of severe B-cell deficiency. Additional blocks in B-cell development have been identified prior to the expression of the B-cell receptor and also later in development as cells approach the naïve B-cell stage.

Patients with defects in B-cell development are generally immunologically normal with the exception of a severe reduction of B cells in the blood and infections that result from their absence. Patients with early defects have little detectable lymphoid tissue, and upon physical examination, one may find an absence of tonsils or palpable lymph nodes. Patients with later defects may have palpable lymphoid tissue. In both groups, the spleen is generally normal in size.

» Class Switching Defects

Normal immunoglobulin isotype class switching occurs in germinal centers in response to antigenic and T-cell costimulatory signals, and the class switching defects involve severe dysfunction of this process. Defects in either T-cell surface CD40L or B-cell surface CD40 impair the initial step in the class-switching cascade, and as a result, no class switching occurs. Further downstream, defects in either AICDA or UNG impair class switching by preventing the formation of double stranded breaks that are essential for the genomic rearrangement required to switch isotypes. Defects in RAG proteins and NHEJ proteins impair this process at an earlier step, preventing B-cell development, so are not considered to result in class switching abnormalities. Additional defects in class switching can be seen with genetic abnormalities in the NF-κB and also PIK3D activating mutations, but in either case, the class switching phenotype can be variable.

Class switching presents with various associated features depending on the genetic cause. Defects in CD40L and CD40 can have risk of associated opportunistic infection with Pneumocystis and Cryptosporidium, and they have hypoplastic lymphoid tissue. Patients with defective AICDA can have associated autoimmunity, including ITP, hemolytic anemia, autoimmune hepatitis, inflammatory bowel disease, arthritis, and interstitial lung disease. Both AICDA and UNG deficient patients suffer from lymphoid hyperplasia.

Transient Hypogammaglobulinemia

Serum IgG levels normally decrease during an infant's first 4–6 months of life as maternal IgG transmitted in utero is metabolized. Transient hypogammaglobulinemia represents a delay in the onset of immunoglobulin synthesis that results in a prolonged nadir. Symptomatic patients present with recurrent infections, including upper respiratory tract infections, otitis, and sinusitis. The diagnosis is suspected in infants and young children with low levels of IgG and IgA (usually two standard deviations below normal for age), but normal levels of IgM and normal numbers of circulating B lymphocytes. Most affected children have normal specific antibody responses and T-lymphocyte function. Apart from appropriate antibiotics, no treatment is required. Infants

with severe infections and hypogammaglobulinemia could be given Ig replacement, but benefits and risk must be considered and this is rarely necessary. Recovery occurs between 18 and 30 months of age, and the prognosis for affected children is excellent provided infections are treated promptly and appropriately.

Functional Antibody Deficiency

The group of functional antibody deficiency disorders includes any disorder in which a persistent deficiency in immunoglobulin production has been identified, and the deficiency is not the result of a secondary cause. This group includes genetic syndromes, combined immunodeficiency syndromes, CVID, and monogenetic syndromes previously classified as CVID. As expected, this group contains highly variable phenotypes, in part due to the variety of associated non-B–cell immune abnormalities, and also due to modifying factors in the individual. If possible, understanding the underlying genetic defect of the individual syndrome dramatically improves the ability to anticipate additional complications and decide on treatment approaches. Even the need for immunoglobulin G replacement therapy will vary from individual to individual.

» Monogenetic Causes of Functional Antibody Deficiency

A number of monogenetic causes of functional antibody deficiency have been identified in scattered individuals that had previously been diagnosed with CVID. These syndromes encompass the range of phenotypes conventionally included in the broad category of CVID. Severe defects in the classic B-cell coreceptor complex, including CD19, CD21, CD81, and CD225 have been identified in individuals mainly with poor antibody response and infections that would be expected to follow. These defects presumably arise from an impaired germinal center reaction to foreign antigens in lymph nodes. Similar phenotypes were shown to result both with defects in other B-cell coreceptors such as BAFFR or TACI and also with defects in molecules that signal through these receptors such as ICOS. Additional syndromes that include involvement of T-cell dysfunction as well as functional antibody deficiency have been identified in molecules that function in both cell types. These syndromes include, but are not limited to, CD27 deficiency, PIK3D gain of function, and IL-21 deficiency. Additional syndromes with predominant features outside of functional antibody deficiency are discussed later in the chapter.

» CVID

Common variable immunodeficiency is a heterogeneous category of functional antibody deficiencies in which no other more appropriate classification is available. CVID is defined by the combination of poor vaccine response and a decrease in blood levels of IgG in conjunction with a severe decrease in levels of either IgM or IgA, or a decrease of both (see Table 33–5). Associated cellular abnormalities can include reduced numbers of memory B-cell subsets in the blood, as well as T-cell lymphopenia. Patients have recurrent infections, most often of the sinopulmonary tract, but chronic gastrointestinal infections may manifest with recurrent diarrhea. Patients with CVID are at risk for developing bronchiectasis, autoimmune diseases (idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, rheumatoid arthritis, and inflammatory bowel disease), and malignancies (especially gastric carcinoma and lymphoma).

Selective Immunoglobulin Deficiencies

Deficiency of an IgA or an IgG subclass can be seen in the presence of both recurrent infections and other immune abnormalities; however, these deficiencies are often seen in the absence of any other identifiable immune abnormality. With an incidence of 1:700, isolated IgA deficiency is a common laboratory finding. The majority of patients with isolated IgA deficiency are asymptomatic, but associations also exist with inflammatory bowel disease, allergic disease, asthma, and autoimmune disorders (thyroiditis, arthritis, vitiligo, thrombocytopenia, and diabetes). Deficiency of IgG subclasses 2–4 can be identified in the absence of other laboratory immune abnormalities; whereas, severe deficiency of IgG1 universally presents with an overall decrease in total IgG levels because it makes up the majority of IgG detectable in the blood. Deficiency of IgG2 can be seen in association with decreased IgA, and in that context, it is suggestive of an underlying functional antibody deficiency with a possibly identifiable genetic cause. IgG3 and IgG4 make up the smallest fraction of the total IgG pool, and in the absence of any other immune abnormality, deficiency of either of these IgG subclasses is generally not considered to cause increased susceptibility to infection. IgG replacement is not indicated in either IgA deficiency or IgG subclass deficiency when no other quantitative or functional immune abnormality has been identified. When other immune abnormalities are seen, antibody deficiency syndromes listed elsewhere in this chapter should be considered.

Durandy A, Kracker S, Fischer A: Primary antibody deficiencies. Nat Rev Immunol 2013;13:519033 [PMID: 23830147].

OTHER COMBINED IMMUNODEFICIENCY DISORDERS

Combined immunodeficiencies include defects that directly impair both T and B lymphocytes, as well as T-lymphocyte–specific defects, because proper B-lymphocyte function and antibody production are dependent on T-lymphocyte help.

Therefore, most T-lymphocyte deficiencies manifest as combined impairments.

1. Wiskott-Aldrich Syndrome

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Immunodeficiency with recurrent infections.
- Microplatelet thrombocytopenia.
- Eczema.
- Occurs only in males.

General Considerations

Wiskott-Aldrich syndrome (WAS) is an XL recessive disease characterized by immunodeficiency, microplatelet thrombocytopenia, and eczema. The syndrome results from mutations of the gene encoding WAS protein (WASP) at X11p. WASP is a protein involved in the rearrangement of actin and is important in interactions between T lymphocytes and antigen-presenting cells.

Clinical Findings

A. Symptoms and Signs

Common presenting symptoms include mucosal bleeding, bloody diarrhea, cerebral hemorrhage, and severe infections with polysaccharide-encapsulated bacteria, but the clinical presentation can vary from classic severe WAS to mild thrombocytopenia without immunodeficiency, or X-linked thrombocytopenia (XLT), depending on the mutation. Early deaths are due to bleeding and infections, but malignancies and autoimmune syndromes can develop over time. Survival beyond adolescence is rare in patients not receiving treatment, although XLT is sometimes diagnosed in adults.

B. Laboratory Findings

Laboratory findings that suggest the diagnosis are a low platelet count, small platelets, low or absent isohemagglutinins, and reduced antibody responses to polysaccharide antigens (S pneumoniae and H influenzae). IgM may be low; IgG is usually normal; and IgA and IgE are often high. The diagnosis can be confirmed by genetic testing for a mutation of the WASP gene or by assessing WASP expression. Genetic testing can also be used for carrier screening.

Differential Diagnosis

In addition to WAS and XLT, the differential diagnosis in a patient with a low platelet count must include other causes of platelet consumption, destruction, and abnormal production, such as idiopathic thrombocytopenic purpura, leukemia or myelodysplasia, drug adverse effect, and infection. WAS can be differentiated from these other conditions by small-sized platelets on smear evaluation, the presence of eczema and other atopic features, and documented immune dysfunction. Additionally, there is a continuous spectrum between WAS and XLT that lacks immunodeficiency. Subsequently, a scoring system has been developed to help clinicians distinguish WAS from XLT.

Treatment

Treatment includes infection prophylaxis with antibiotics (including trimethoprim-sulfamethoxazole for Pneumocystis carinii pneumonia) and IVIG-replacement therapy for patients with deficient antibody responses. Splenectomy to reduce thrombocytopenia has been helpful in some patients with XLT, but it must be followed by antibiotic prophylaxis because of the increased risk of septicemia and sudden death. Platelet transfusions should be avoided unless severe bleeding has occurred. Finally, BMT using the best-matched donor offers the possibility of a definitive cure, but it is associated with morbidity and mortality.

2. 22q11.2 Deletion Syndrome (DiGeorge Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Congenital heart defects.
- Hypocalcemia and seizures.
- Distinctive craniofacial features.
- Thymic hypoplasia.

General Considerations

DiGeorge syndrome or 22q11.2 deletion syndrome is an AD syndrome, resulting in defective development of the third and fourth pharyngeal pouches. There is considerable variability in phenotype based on the location and extent of the deletion, but deletions that include the TBX1 gene appear relevant. Overlapping syndromes include velocardiofacial syndrome and Shprintzen syndrome. The incidence is about 1:4000 births, and the abnormal chromosome is usually inherited from the mother. The associated immunodeficiency is secondary to the aplastic or hypoplastic thymus, where T-lymphocyte maturation occurs. Surprisingly, most patients have no or only mild immune defects. The term

partial DiGeorge syndrome is commonly applied to these patients with impaired rather than absent thymic function.

» Clinical Findings

A. Symptoms and Signs

Clinical characteristics include congenital heart defects, hypocalcemia due to hypoparathyroidism, distinctive craniofacial features, renal anomalies, and thymic hypoplasia. Presentation usually results from cardiac failure or from hypocalcemia 24–48 hours postpartum. The diagnosis is sometimes made during the course of cardiac surgery when no thymus is found in the mediastinum. Infections commonly present as recurrent ENT (ear-nose-throat) infections. Additional important clinical issues include delayed speech, cognitive impairment, and behavioral problems. Patients have an increased risk to develop schizophrenia and autoimmune disorders.

B. Laboratory Findings

Laboratory evaluation typically reveals normal to decreased numbers of T lymphocytes with preserved T-lymphocyte function and normal B-lymphocyte function. In the rare patient with absent or dysfunctional T lymphocytes, B-lymphocyte function and antibody production may be abnormal. Over time, T-lymphocyte numbers normalize in the majority of patients who have low numbers of T lymphocytes at initial presentation. The diagnosis is confirmed via fluorescence in situ hybridization (FISH) chromosomal analysis for the microdeletion on chromosome 22, or microarray-based comparative genomic hybridization.

» Treatment

Treatment of the 22q11.2 deletion syndrome may require surgery for cardiac defects, and vitamin D, calcium, or parathyroid hormone replacement to correct hypocalcemia and treat seizures. Transfusion products should be irradiated. Both thymic grafts and BMT have been used successfully in patients with absent T-lymphocyte immunity. Prior to giving live vaccines, T-cell numbers and function should be assessed if not done earlier, to prevent vaccine-related side effects.

3. Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T) is a rare, neurodegenerative, AR-inherited disorder caused by mutations in the ataxia-telangiectasia–mutated (ATM) gene located on chromosome 11q22–23 that encodes the ATM protein, a protein kinase involved in repair of double-stranded DNA and cell cycle regulation. A-T is characterized by progressive cerebellar ataxia, telangiectasia, and variable immunodeficiency. Children usually present as toddlers with slurred speech and balance problems, and also with sinopulmonary infections. Telangiectasias of the conjunctivae and exposed areas (eg, nose, ears, and shoulders) follow later during childhood. Respiratory tract infections promoted by respiratory muscle weakness, swallowing dysfunction and recurrent aspirations, and malignancies, including carcinomas and lymphomas, are the major causes of death between the second and fourth decade of life. Abnormal findings in A-T include elevated serum α-fetoprotein levels that increase over time and are used diagnostically; immunoglobulin deficiencies, including low levels of IgA, IgE, or IgG; and defective ability to repair radiation-induced DNA fragmentation. There is no definitive treatment, although Ig replacement and aggressive antibiotics have been used with limited success. Heterozygotes have an increased risk for breast cancer.

Similarly to A-T, the **Nijmegen breakage** syndrome is a disorder associated with impaired DNA repair and mutations in the NBS1 gene that shows more severe clinical features, including microcephaly and facial dysmorphisms, small stature, immunodeficiency, and increased risk for lymphoid malignancies.

4. X-Linked Hyper-IgM Syndrome

X-linked hyper-IgM (HIGM) syndrome or CD40L deficiency is the most common and most severe form of HIGM syndrome and involves a mutation in the gene encoding for CD40L (CD154). CD40L is expressed on activated T lymphocytes and necessary for T cells to induce immunoglobulin isotype switching in B cells. Unlike the AR forms of HIGM syndrome, the mutation results in both antibody- and cell-mediated deficiencies, as the interaction between CD40L on T cells and CD40 on B cells and antigen-presenting cells is important for both antibody production and T-cell activation. Affected males have normal numbers of B lymphocytes, low levels of IgG and IgA, but normal or elevated levels of IgM. Typically, male infants present with recurrent bacterial and opportunistic infections such as P carinii pneumonia or Cryptosporidium diarrhea. Additionally, affected males have a high frequency of sclerosing cholangitis, increased liver and biliary tract carcinomas, neutropenia, and autoimmune syndromes, including thrombocytopenia, arthritis, and inflammatory bowel disease. Conservative treatment includes Ig replacement and antibiotic prophylaxis. Because the prognosis is still quite poor, BMT has been used with initial success.

5. NF-κB Signaling defects

Immunodeficiency due to mutations in the gene for nuclear factor-κB (NF-κB)–essential modulator (NEMO; IKBKG gene) is an XL syndrome in which male patients manifest ectodermal dysplasia (abnormal, conical teeth, fine sparse hair, and abnormal or absent sweat glands) and defects of T and B lymphocytes. NF-κB is involved in signaling through

CD40 on B cells, and NEMO mutations result in abnormal immunoreceptor signaling. Many mutations are fatal in utero for male infants. Female carriers may have incontinentia pigmenti. Surviving males present with early serious infections, including opportunistic infections with P carinii and atypical mycobacteria. Laboratory evaluation reveals hypogammaglobulinemia that may present as HIGM syndrome and poor specific antibody production, but normal numbers of T and B lymphocytes. Functional evaluation of lymphocytes demonstrates variable response. Because patients with confirmed NEMO mutations are quite rare, the best treatment course is unknown, but aggressive antibiotic therapy in combination with Ig replacement as well as BMT has been used. The prognosis is dependent on the severity of immunodeficiency, with most deaths due to infection. Mutations in the NF-κBIA gene that encodes IκBα (nuclear factor of kappa light polypeptide gene enhancer in B-cell inhibitor alpha) result in an AD-inherited defect with similar clinical presentation.

6. Combined Immunodeficiency With Defective Expression of MHC I & II

Major histocompatibility complex class I (MHC I) deficiency or bare lymphocyte syndrome type I is an AR-combined immunodeficiency. Affected patients have abnormal expression of the transporter associated with antigen processing (TAP). TAP proteins are important for intracellular transport and expression of MHC I on cell surfaces. Patients with bare lymphocyte syndrome type I present with recurrent sinopulmonary and skin infections. The diagnosis is confirmed by demonstrating an absence of MHC I expression.

Major histocompatibility complex class II (MHC II) deficiency or bare lymphocyte syndrome type II is a rare AR-combined immunodeficiency in which cells lack MHC II expression due to mutations in CIITA, RFX-5, RFXAP, or RFXANK genes. Clinical presentation includes recurrent viral, bacterial, and fungal infections. Patients with bare lymphocyte syndrome type II have normal numbers of T and B lymphocytes, but low $CD4^+$ lymphocyte numbers, abnormal lymphocyte function, and hypogammaglobulinemia. They also have a high incidence of sclerosing cholangitis. When this diagnosis is suspected, demonstration of absent MHC II molecules confirms the disorder. Severe cases are fatal without BMT, but milder phenotypes may be managed with Ig replacement and aggressive use of antibiotics.

Kersseboom R et al: Educational paper: syndromic forms of primary immunodeficiency. Eur J Pediatr 2011;170:295–308 [PMID: 21337117].

PHAGOCYTE DISORDERS

Phagocyte defects include abnormalities of both numbers (neutropenia) and function of polymorphonuclear neutrophils. Functional defects consist of impairments in adhesion, chemotaxis, bacterial killing, or, less often, of combinations of these.

1. Neutropenia

The presence of neutropenia should be considered when evaluating recurrent infections. The diagnosis and treatment of neutropenia is discussed in Chapter 30. Additionally, some PID syndromes are associated with neutropenia (eg, XLA).

2. Chronic Granulomatous Disease

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent infections with catalase-positive bacteria and fungi.
- XL and AR forms.
- Caused by abnormal phagocytosis-associated generation of microbicidal oxygen metabolites (respiratory burst) by neutrophils, monocytes, and macrophages.

» General Considerations

Chronic granulomatous disease (CGD) is caused by a defect in any of several genes encoding proteins in the enzyme complex nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which results in defective superoxide and hydrogen peroxide generation during ingestion of microbes. Most cases (probably 75%) are inherited as an XL recessive trait; the rest are AR in inheritance.

» Clinical Findings

A. Symptoms and Signs

The typical clinical presentation is characterized by recurrent abscess formation in subcutaneous tissue, lymph nodes, lungs, and liver, and by pneumonia and eczematous and purulent skin rashes. Infecting organisms are typically catalase-positive bacteria, which can break down their own hydrogen peroxide and thus avoid death when captured in a CGD phagocytic vacuole. (Streptococci, pneumococci, and H influenzae lack catalase and are not unusually pathogenic in CGD.) Aspergillosis is also common and a frequent cause of death. Lymphadenopathy and hepatosplenomegaly are found on physical examination, and granulomas are seen in histopathologic sections. Granulomatous inflammation can narrow the outlet of the stomach or bladder in these patients, leading to vomiting or urinary obstruction.

B. Laboratory Findings

Patients typically present with serious infection, positive microbial cultures, and neutrophilia. The most common infecting organisms are S aureus, Aspergillus species, Burkholderia cepacia, and Serratia marcescens. (Culture of either of the last two should suggest this diagnosis.) Patients also present with granulomas of lymph nodes, skin, liver, and genitourinary tract. The erythrocyte sedimentation rate may be elevated without obvious infection. The diagnosis is confirmed by demonstrating lack of hydrogen peroxide production using the DHR flow cytometry assay or lack of superoxide production using the NBT test. Both tests can demonstrate carrier status of XL disease.

» Differential Diagnosis

The differential diagnosis includes other phagocyte abnormalities or deficiencies described in this section, as well as the rare neutrophil granule deficiency. Other immunodeficient states leading to severe bacterial or fungal infections should be considered, but none have the striking abscess formation and deficient phagocytosis-associated respiratory burst that characterize CGD.

Treatment

Daily intake of an antimicrobial agent such as trimethoprim-sulfamethoxazole is indicated in all patients; an oral antifungal agent like itraconazole and regular subcutaneous injections of interferon-γ can greatly reduce the risk of severe infections. BMT has been successful in some cases, but the risk of death is high unless the patient's condition is stable. Gastric or GU obstruction can be relieved by short-term steroid therapy.

3. Leukocyte Adhesion Defects Types I & II

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Recurrent serious infections.
- "Cold" abscesses without pus formation.
- Poor wound healing.
- Gingival or periodontal disease (or both).

» General Considerations

The ability of phagocytic cells to enter peripheral sites of infection is critical for effective host defense. In leukocyte adhesion defect (LAD), defects in proteins required for leukocyte adherence to and migration through blood vessel walls prevent these cells from arriving at the sites of infection.

LAD I is an AR disease caused by mutations in the common chain of the β_2 integrin family (CD18) located on chromosome 21q22.3. These mutations result in impaired neutrophil migration, adherence, and antibody-dependent phagocytosis. LAD II is a rare AR disease caused by an inborn error in fucose metabolism that results in abnormal expression of leukocyte Sialyl-Lewis X (CD15s), which binds to selectins on the vessel endothelium. The resulting phenotype is similar to LAD I, with recurrent infections, lack of pus formation, poor wound healing, and periodontal disease. LAD II patients also have developmental delays, short stature, dysmorphic facies, and the Bombay (hh) blood group.

» Clinical Findings

A. Symptoms and Signs

Patients present with variably severe phenotypes, including recurrent serious infections, lack of pus formation, poor wound healing, and gingival and periodontal disease. The hallmark is little inflammation and absent neutrophils on histopathologic evaluation of infected sites (ie, "cold" abscesses), especially when concurrent with neutrophilia, and expression of poor adherence to vessel walls. The most severe phenotype manifests with infections in the neonatal period, including delayed separation of the umbilical cord with associated omphalitis.

» B. Laboratory Findings

Laboratory evaluation often demonstrates a striking neutrophilia. Diagnosis of suspected cases is confirmed by flow cytometry analysis for CD18 (LAD I) or CD15s (LAD II).

» Treatment

Treatment includes aggressive antibiotic therapy. Fucose supplementation in LAD II has been reported with some success.

4. Glucose-6-Phosphate Dehydrogenase Deficiency

Rare forms of XL glucose-6-phosphate dehydrogenase deficiency with associated hemolytic anemia affect leukocytes as well as erythrocytes and result in recurrent infections due to an abnormal neutrophil respiratory burst, probably due to NAD/NADPH deficiency.

Marciano BE et al: Common severe infections in chronic granulomatous disease. Clin Infect Dis 2015;60:1176–1183 [PMID: 25537876].

COMPLEMENT DEFICIENCIES

Complement contributes to innate immunity and facilitates antibody-mediated immunity through opsonization, lysis of

target cells, and recruitment of phagocytic cells. The complement system includes three interactive pathways of enzymatic reactions: classic, alternative, and lectin (see Figure 33–3). All three pathways generate cleavage of C3 and result in promotion of inflammation, elimination of pathogens, and enhancement of the immune response. Activation of the complement system occurs through microbial products, tissue enzymes, and surface-bound IgG and IgM antibodies or pentraxins, for example, C-reactive protein.

» Complement Component Deficiencies

Deficiencies of individual complement components (C1–C9) are inherited as autosomal codominant traits, each parent contributing one null gene. Serum levels of the deficient component are about half normal in the parents and zero or almost zero in the patients. Deficiencies of C1, C2, or C4 predispose to increased infections but are particularly associated with autoimmune disorders such as systemic lupus erythematosus. Patients with homozygous C2 deficiency can present at any age in childhood with bacteremia or meningitis due to S pneumoniae or H influenzae. Primary C3 deficiency presents with severe pyogenic infections since C3 is critical for opsonization in both the classic and alternative pathways. Deficiency of the control protein factor I, which acts to break up the C3-cleaving complex formed in the classic or alternative pathway, leads to unbridled consumption of C3 and, thereby, severe bacterial infections. Deficiency of a terminal complement component in the membrane attack complex (C5, C6, C7, C8, and C9) or of properdin (an XL alternative pathway control protein) results in recurrent neisserial meningitis or disseminated gonococcal infection. Survivors of either of these serious neisserial infections should be screened for complement deficiency, first with a CH50.

Degn SE, Jensenius JC, Thiel S: Disease-causing mutations in genes of the complement system. Am J Hum Genet 2011;88:689–705 [PMID: 21871896].

OTHER WELL-DEFINED IMMUNODEFICIENCY SYNDROMES

1. Hyper-IgE Syndrome

Hyper-IgE syndrome (HIES), also known as Job syndrome, is a rare PID characterized by elevated levels of IgE (> 2000 IU/mL), neonatal eczematoid rash, recurrent infections with S aureus, recurrent pneumonia with pneumatocele formation, and typical facies. Mutations in a specific transcription factor, signal transducer and activator of transcription 3 (STAT3), underlie sporadic and AD forms of HIES. Additional clinical findings of HIES include retained primary teeth, scoliosis, hyperextensibility, high palate, and osteoporosis. In addition to staphylococcal infections, affected patients also have increased incidence of infections due to Streptococcus spp, Pseudomonas spp, C albicans, and even opportunistic infections with P carinii. AR HIES is associated with mutations in dedicator of cytokinesis 8 (DOCK8) and tyrosine kinase 2 (TYK2) genes. Patients with AR HIES have an increased susceptibility to viral infections, including recurrent molluscum contagiosum, warts, and herpes simplex infections. Increased susceptibility to mycobacterial infections is found in patients with TYK2 mutations. Laboratory evaluation reveals normal to profoundly elevated levels of IgE and occasionally eosinophilia. However, atopic dermatitis and parasite infection are much more common causes of elevated IgE. Diagnosis is often difficult due to variable presentation, which may become progressively severe with increasing age, but genetic testing for STAT3, DOCK8, and TYK2 mutations will help confirm the diagnosis of HIES particularly at a young age. All patients with HIES have impaired T_H17 cell function, and measurement of T_H17+ cells in the peripheral blood can be used as screening test if HIES is suspected. The mainstay of treatment is prophylactic and symptomatic antibiotic use in combination with good skin care. Ig replacement has been used with some success to decrease infections and possibly modify IgE levels. Successful stem cell transplants have been conducted in DOCK8 deficiency.

2. Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare disease that usually manifests with severe diarrhea and insulin-dependent diabetes mellitus within the first months of life. Affected males also have severe eczema, food allergy, autoimmune cytopenias, lymphadenopathy, splenomegaly, and recurrent infections. Most die before 2 years of age due to malnutrition or sepsis. IPEX syndrome results from mutations in the FOXP3 gene that encodes a protein essential for developing regulatory T lymphocytes. Leukocyte counts and immunoglobulin levels are generally normal. Immunosuppression and nutritional supplementation produce temporary improvements, but the prognosis is poor and most cases result in early death. BMT has been attempted with variable success. More recently, IPEX-like syndromes have been described as associated with mutations of the gene encoding CD25, the high affinity IL-2 receptor (IL2R) which is constitutively expressed on regulatory T cells. If IPEX or IPEX-like syndromes are suspected, the presence of $FOXP3^+/CD25^+$ regulatory T cells should be assessed not only in affected boys but also in girls. Genetic testing for FOXP3 mutations will be helpful to identify affected patients and carriers of the gene mutation.

3. X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome is an immunodeficiency that usually develops following EBV infection. Affected males develop fulminant infectious mononucleosis with hemophagocytic syndrome, multiple organ system failure, and bone marrow aplasia. The mutated gene (SH2D1A/SAP/DSHP)

encodes a signaling protein used by T lymphocytes and NK cells called SLAM-adapter protein (SAP). Affected boys are immunologically normal prior to EBV infection and during acute infection, they produce antibody to EBV. In most instances, infection with EBV is fatal. Patients who survive the initial episode or who are never infected with EBV in childhood develop lymphomas, vasculitis, hypogammaglobulinemias (with elevated IgM), or CVID in later life. Genetic analysis for a mutation of the SAP (SH2D1A) gene and testing for SAP protein expression are available. Mutations in the genes encoding for the X-linked inhibitor of apoptosis (XIAP), a potent regulator of lymphocyte homeostasis, and for IL-2–inducible T-cell kinase (ITK) have been described to present as an XLP-like syndrome. Testing for mutations of the gene encoding for XIAP (BIRC4) and XIAP protein expression will help establish the diagnosis. A decreased number of naïve, $CD45RA^+$ T cells are indicative of ITK deficiency, and further genetic analysis can establish the diagnosis.

4. Chronic Mucocutaneous Candidiasis

Several gene defects have been associated with chronic mucocutaneous candidiasis (CMC), a disorder characterized by isolated candidal infections of the skin, nails, and mucous membranes. Systemic disease is not characteristic, but case reports of intracranial mycotic aneurysms exist. Primary CMC most commonly occurs as an isolated syndrome, but it can be associated with endocrine or autoimmune disorders. Mutations in the signal transducer and activator of transcription 3 (STAT3) gene and gain-of-function mutations in STAT1 can lead to defective T_H17 responses, susceptibility to CMC, and S aureus infections. Mutations in IL17F and IL17R, C-type lectin–associated 7 (CLEC7A or DECTIN1) or caspase recruitment domain-containing protein 9 (CARD9) cells have also been associated with CMC. An AR form of CMC with associated autoimmunity, also known as autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia (APECED) syndrome, is characterized by recurrent candidal infections, abnormal T-lymphocyte response to Candida, autoimmune endocrinopathies, and ectodermal dystrophies. APECED is caused by mutations in the gene for an important transcription regulator protein called autoimmune regulator (AIRE) that is critical for normal thymocyte development. In APECED, autoantibodies against IL17A and IL17F impair the T_H17 response and contribute to CMC. Treatment of CMC includes antifungal therapy in combination with therapy for associated endocrinopathies.

5. Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) results from mutations of genes important for regulating programmed lymphocyte death (apoptosis). Most commonly, the defect is in Fas (CD95) or Fas ligand, but other defects in the Fas pathway have also been described (eg, caspase 10). Clinical presentation includes lymphadenopathy, splenomegaly, and autoimmune disorders (autoimmune hemolytic anemia, neutropenia, thrombocytopenia, and sometimes arthritis). Occasionally, patients have frequent infections. The diagnosis is suspected when T-lymphocyte subsets by flow cytometry demonstrate elevated numbers of $CD3^+CD4^-CD8^-$ (double negative) T lymphocytes. Several different types of ALPS are distinguished by the response of lymphocytes to Fas-induced apoptosis. Patients are often heterozygous, and inheritance is mostly autosomal dominant. Treatment with prednisone often controls the lymphadenopathy. Infections should be treated appropriately. In some cases, BMT has been curative. Affected patients are also at risk for lymphoma. Mutations affecting another apoptosis-related protein, caspase 8, cause an ALPS variant syndrome in which the susceptibility to infection by herpes simplex virus also increases.

6. WHIM Syndrome

WHIM (warts, hypogammaglobulinemia, infection, myelokathexis) syndrome is a rare AD immunodeficiency caused by gain-of-function mutations in the gene encoding the chemokine receptor CXCR4. Patients have an increased susceptibility to viral infections (including HPV, EBV, and HSV) and recurrent bacterial infections. Laboratory evaluation reveals peripheral blood neutropenia with bone marrow hypercellularity, decreased B-cell numbers and hypogammaglobulinemia, and T-cell lymphopenia with normal $CD4^+/CD8^+$ ratio.

7. Diseases Due to Defects in Interferon-γ & Interleukin-12 Pathways

IL-12 is a powerful inducer of interferon-γ (IFN-γ) production by T cells and NK cells. IFN-γ, and therefore the IFN-γ –IL-12 axis, is critical for macrophage activation and resistance to mycobacterial infections. Individuals with inherited deficiency in IL-12, macrophage receptors for IFN-γ, lymphocyte receptors for IL-12, or STAT1 signaling suffer a profound and selective susceptibility to infection by nontuberculous mycobacteria such as Mycobacterium avium complex or bacille Calmette-Guérin (BCG). About half of these patients have had disseminated salmonellosis. Treatment with supplemental IFN-γ is effective unless the IFN-γ receptor is not functional. Long-term mycobacterial prophylaxis should be considered in these individuals.

8. MonoMAC Syndrome

Disseminated infection by nontuberculous mycobacteria, viruses (ie, HPV), and fungi were recently described in association with GATA2 mutations or MonoMAC (sporadic monocytopenia and mycobacterial infection) syndrome.

Patients usually become symptomatic during adulthood, but younger patients may also be affected. Patients have peripheral blood monocytopenia, but presence of macrophages at sites of infections. B-lymphocyte and NK cell numbers are reported low with variable T-cell numbers. This is an autosomal dominant inherited disease with an increased risk for malignancies, especially myelodysplasia and leukemia.

9. Pattern-Recognition Receptor Defects

Pattern-recognition receptor (PRR) defects are associated with altered cytokine production and increased susceptibility to specific microbes. The clinical presentation of affected patients is most severe during infancy and early childhood with improvement of infections while patients get older, suggesting that adaptive immune responses compensate for defects in innate immunity. TLRs and members of the interleukin-1 receptor (IL-1R) family signal through IL-1R–associated kinases (IRAK) 1 and 4 while using the adaptor molecule MyD88, leading to activation of NF-κB and inflammatory cytokine production. Patients with AR deficiencies in MyD88 and IRAK-4 are predisposed to severe bacterial infections that are not associated with a high fever or significant increase in C-reactive protein at the beginning of infection. Laboratory results may reveal a decreased antibody response to polysaccharide antigens, increased IgG and IgG_4 concentrations, and decreased IL-6 production upon whole blood stimulation through most TLR and IL-1R agonists. TLR3 deficiency increases susceptibility to infections with herpes simplex infections, while polymorphisms of TLR5 predispose to legionella pneumonia infections. Chronic mucocutaneous fungal infections have been linked to defects in the dectin-1/CARD9 pathway. Bacterial infections, specifically with Neisseria meningitis, but also viral and fungal infections can occur in context of mannose-binding lectin deficiency.

GENETIC SYNDROMES ASSOCIATED WITH IMMUNODEFICIENCY

Several described genetic syndromes have associated immunodeficiency that is often identified after the syndrome has been diagnosed. Usually, the immune defect is not the major presenting clinical problem.

1. Bloom Syndrome

Characteristics of Bloom syndrome include growth retardation, sunlight sensitivity, and telangiectasias of the face. The syndrome results from mutations in the Blm gene that encodes a RecQ-helicase involved in DNA repair. Affected patients present with growth retardation, microcephaly, and sun-sensitive rashes. They have an increased risk of malignancy and life-threatening infections. B- and T-cell numbers are low. Serum Igs are decreased, and T-lymphocyte function is abnormal.

2. Immunodeficiency, Centromeric Instability, Facial Anomalies Syndrome

Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome is a rare AR condition caused by abnormal DNA methyltransferase. In half of the patients, a mutation can be detected in the DNMT3B gene. Unlike other chromosome instability syndromes, ICF syndrome does not have an associated hypersensitivity to sunlight. Affected patients have severe respiratory, gastrointestinal, and skin infections due to low or absent immunoglobulins and abnormal T-lymphocyte numbers and function.

3. Trisomy 21

Patients with trisomy 21 or Down syndrome have increased susceptibility to respiratory infection. Immunodeficiency is variable, and abnormal numbers and function of T and B lymphocytes have been reported. Additionally, patients have an increased incidence of autoimmune diseases.

4. Turner Syndrome

Turner syndrome (partial or complete absence of one X chromosome) is associated with increased risk of otitis media, respiratory infections, and malignancies. Immune defects are variable but may include abnormal T-lymphocyte numbers and function and hypogammaglobulinemia.

5. Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare AR disease caused by mutations in a lysosomal trafficking regulator (LYST) gene. The neutrophils of affected individuals have giant lysosomes, impaired chemotaxis, neutropenia, and abnormal NK-cell cytotoxicity. Patients present with recurrent infections (particularly periodontitis), partial oculocutaneous albinism, and neuropathy. Most patients progress to generalized lymphohistiocytic infiltration syndrome, which is a common cause of death. Treatment strategies address infections and neuropathy, and the use of immunosuppression attempts to slow lymphoproliferative progression.

6. Griscelli Syndrome

Characterized by partial albinism, neutropenia, thrombocytopenia, and lymphohistiocytosis, Griscelli syndrome is a rare AR syndrome resulting from mutations in the myosin

VA gene. Affected patients have recurrent and serious infections caused by fungi, viruses, and bacteria. Immunologic evaluation demonstrates variable immunoglobulin levels and antibody function with impaired T-lymphocyte function. BMT can correct the immunodeficiency. Griscelli syndrome is distinguished from Chédiak-Higashi syndrome by the lack of granules in white blood cells.

7. Netherton Syndrome

Patients with the AR Netherton syndrome present with trichorrhexis (brittle hair), ichthyosiform rash, and allergic diseases. A subset of patients develops recurrent infections. Immune function is variable but may include hypo- or hypergammaglobulinemia, abnormal T-lymphocyte function, or abnormal phagocyte function. The disease results from mutations in a serine protease inhibitor encoded on the SPINK5 gene.

8. Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia is an AR form of chondrodysplasia manifesting with short-limbed short stature, hypoplastic hair, defective immunity, and poor erythrogenesis. The immune defect is characterized by mild to moderate lymphopenia and abnormal lymphocyte function, but normal antibody function. Affected patients have increased susceptibility to infections and increased risk of lymphoma. The disorder results from mutation in the RMRP gene that encodes the RNA component of an RNase MRP complex. BMT can restore cell-mediated immunity but does not correct the cartilage or hair abnormalities.

34 Endocrine Disorders

Megan Moriarty Kelsey, MD, MS
Jennifer M. Barker, MD
Sarah Bartz, MD
Christine M. Chan, MD
Michael S. Kappy, MD, PhD
Sharon H. Travers, MD
Philip S. Zeitler, MD, PhD

GENERAL CONCEPTS

The classic concept that endocrine effects are the result of substances secreted into the blood with effects on a distant target cell has been updated to account for other ways in which hormonal effects occur. Specifically, some hormone systems involve the stimulation or inhibition of metabolic processes in neighboring cells (eg, within the pancreatic islets or cartilage). This phenomenon is termed paracrine. Other hormone effects reflect the action of hormones on the same cells that produced them. This action is termed autocrine. The discoveries of local production of ghrelin, somatostatin, cholecystokinin, incretins, and many other hormones in the brain and gut support the concept of paracrine and autocrine processes in these tissues.

Another significant discovery in endocrine physiology was an appreciation of the role of specific hormone receptors in target tissues, without which the hormonal effects cannot occur. For example, in nephrogenic diabetes insipidus (DI), affected children have defective vasopressin or receptor function, and show the metabolic effects of DI despite more-than-adequate vasopressin secretion. Alternatively, abnormal activation of a hormone receptor leads to the effects of the hormone without its abnormal secretion. Examples of this phenomenon include McCune-Albright syndrome (precocious puberty and hyperthyroidism), testotoxicosis (familial male precocious puberty), and hypercalciuric hypocalcemia.

HORMONE TYPES

Hormones are of three main chemical types: peptides and proteins, steroids, and amines. The peptide hormones include the releasing factors secreted by the hypothalamus; the hormones of the anterior and posterior pituitary gland; pancreatic islet cells; parathyroid glands, lung (angiotensin II), heart, and brain (atrial and brain natriuretic hormones); and local growth factors such as insulin-like growth factor 1 (IGF-1). Steroid hormones are secreted primarily by the adrenal cortex, gonads, and kidney (active vitamin D [1,25$(OH)_2$ D3]). The amine hormones are secreted by the adrenal medulla (epinephrine) and the thyroid gland (triiodothyronine [T_3] and thyroxine [T_4]).

Peptide hormones and epinephrine act through cell surface receptors. The metabolic effects of these hormones are usually stimulation or inhibition of the activity of preexisting enzymes or transport proteins (posttranslational effects). The steroid hormones, thyroid hormone, and active vitamin D, in contrast, act more slowly and bind to cytoplasmic receptors inside the target cell and subsequently to specific regions on nuclear DNA, where they direct a read-out of specific protein(s). Their metabolic effects are generally caused by stimulating or inhibiting the synthesis of new enzymes or transport proteins (transcriptional effects).

Metabolic processes that require rapid response, such as blood glucose or calcium homeostasis, are usually controlled by peptide hormones and epinephrine, while processes that respond more slowly, such as pubertal development and metabolic rate, are controlled by steroid hormones and thyroid hormone. The control of electrolyte homeostasis is intermediate and is regulated by a combination of peptide and steroid hormones (Table 34–1).

FEEDBACK CONTROL OF HORMONE SECRETION

Hormone secretion is regulated by feedback in response to changes in the internal environment. When the metabolic imbalance is corrected, stimulation of the hormone secretion ceases and may even be inhibited. Overcorrection of the imbalance stimulates secretion of a counterbalancing hormone or hormones, so that homeostasis is maintained within relatively narrow limits.

Table 34–1. Hormonal regulation of metabolic processes.

First Level (Most Direct)			
Metabolite or Other Parameter	Stimulus	Endocrine Gland	Hormone
Glucose	Hyperglycemia	Pancreatic beta cell	Insulin
Glucose	Hypoglycemia	Pancreatic alpha cell	Glucagon
Glucose	Hypoglycemia	Adrenal medulla	Epinephrine
Calcium	Hypercalcemia	Thyroid C cell	Calcitonin (?)
Calcium	Hypocalcemia	Parathyroid	PTH
Sodium/plasma osmolality	Hypernatremia/hyperosmolality	Hypothalamus with posterior pituitary gland as reservoir	ADH
Plasma volume	Hypervolemia	Heart	ANH
Second Level: Sodium and Potassium Balance			
Metabolite or Other Parameter	**Abnormality**	**Endocrine Gland**	**Hormone**
Sodium/potassium	Hyponatremia	Kidney	Renin (an enzyme)
	Hyperkalemia	Liver and others	Angiotensin I
	Hypovolemia	Lung	Angiotensin II
		Adrenal cortex	Aldosterone
Third Level (Most Complex)			
Hypothalamic-Releasing Hormone	**Trophic Hormone (Pituitary Gland)**	**Endocrine Target Tissue**	**Endocrine Gland Hormone**
CRH	ACTH	Adrenal cortex	Cortisol
GHRH	GH	Liver and other tissues	IGF-1
GnRH	LH	Testis	Testosterone
GnRH	FSH/LH	Ovary	Estradiol/progesterone
TRH	TSH	Thyroid gland	T_4 and T_3

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; ANH, atrial natriuretic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; PTH, parathyroid hormone; T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

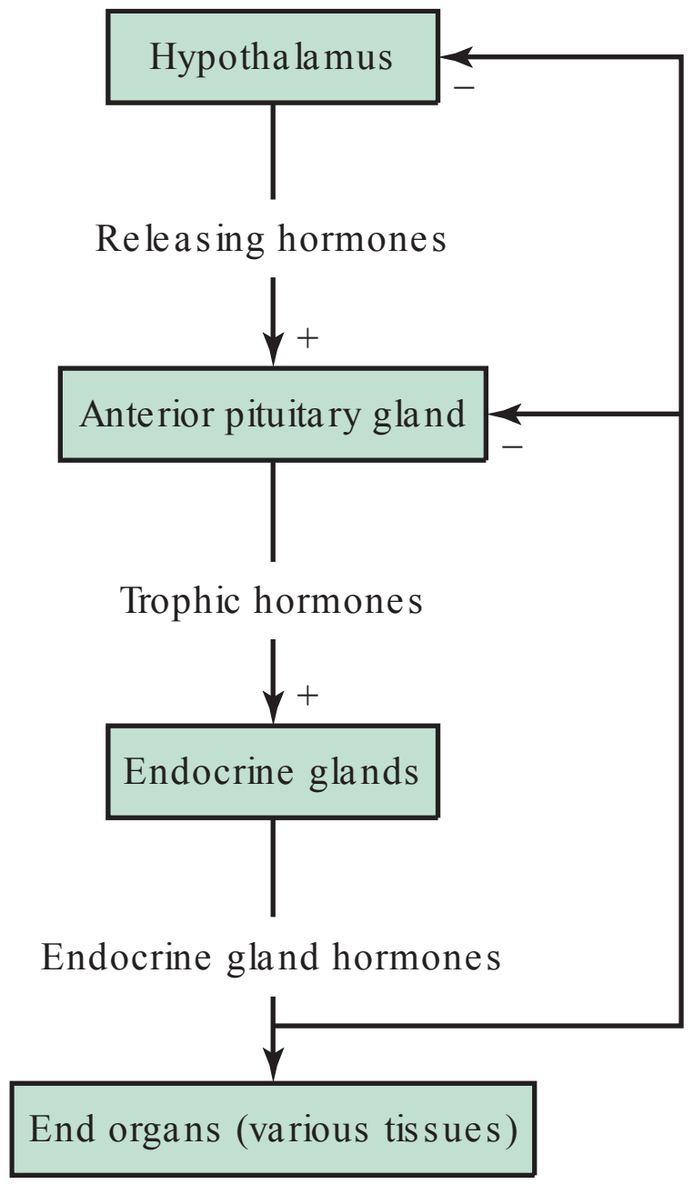
Hypothalamic-pituitary control of hormonal secretion is regulated by feedback. End-organ failure (endocrine gland insufficiency) leads to decreased circulating concentrations of endocrine gland hormones and increased secretion of the respective hypothalamic releasing and pituitary hormones (see Table 34–1; Figure 34–1). If restoration of normal circulating concentration of hormones occurs, feedback inhibition at the pituitary and hypothalamus results in cessation of the previously stimulated secretion of releasing and pituitary hormones and restoration of their circulating concentrations to normal.

Similarly, if there is autonomous endocrine gland hyperfunction (eg, McCune-Albright syndrome, Graves disease, or adrenal tumor), the specific hypothalamic releasing and pituitary hormones are suppressed (see Figure 34–1).

Bethin K, Fuqua JS: General concepts and physiology. In: Kappy MS, Allen DB, Geffner ME (eds): Pediatric Practice-Endocrinology. McGraw Hill; 2010:1–22.

DISTURBANCES OF GROWTH

Disturbances of growth and development are the most common problems evaluated by a pediatric endocrinologist. While most cases represent normal developmental variants, it is critical to identify abnormal growth patterns, as



▲**Figure 34–1.** General scheme of the hypothalamus-pituitary-endocrine gland axis. Releasing hormones synthesized in the hypothalamus are secreted into the hypophyseal portal circulation. Trophic hormones are secreted by the pituitary gland in response, and they in turn act on specific endocrine glands to stimulate the secretion of their respective hormones. The endocrine gland hormones exert their respective effects on various target tissues (end organs) and exert a negative feedback (feedback inhibition) on their own secretion by acting at the level of the pituitary and hypothalamus. This system is characteristic of those hormones listed in Table 34–1 (third level).

deviations from the norm can be the first or only manifestation of an endocrine disorder. Height velocity is the most critical parameter in evaluating a child's growth. A persistent increase or decrease in height percentiles between age 2 years and the onset of puberty always warrants evaluation. Similarly, substantial deviations from target (midparental) height may be indications of underlying endocrine or skeletal disorders. It is more difficult to distinguish normal from abnormal growth in the first 2 years of life, as infants may have catch-up or catch-down growth during this period. Similarly, the variable timing of the onset of puberty makes early adolescence another period during which evaluation of growth abnormalities may require careful consideration.

Appropriate standards must be used to evaluate growth. The National Center for Health Statistics provides standard cross-sectional growth charts for North American children (see Chapter 2) and the World Health Organization (WHO) growth charts use an ethnically more diverse sample. Normal growth standards may vary with country of origin. Growth charts are available for some ethnic groups in North America and for some syndromes with specific growth disturbance such as Turner or Down syndromes.

TARGET HEIGHT & SKELETAL MATURATION

A child's height potential is determined largely by genetic factors. The target height of a child is calculated from the mean parental height plus 6.5 cm for boys or minus 6.5 cm for girls. This calculation helps identify a child's genetic growth potential. Most children achieve an adult height within 8 cm of the target height. Another parameter that determines growth potential is skeletal maturation or bone age. Beyond the neonatal period, bone age is evaluated by comparing a radiograph of the child's left hand and wrist with the standards of Greulich and Pyle. Delayed or advanced bone age is not diagnostic of any specific disease, but the extent of skeletal maturation allows determination of remaining growth potential as a percentage of total height and allows prediction of ultimate height.

SHORT STATURE

It is important to distinguish normal variants of growth (familial short stature and constitutional growth delay) from pathologic conditions (Table 34–2). Pathologic short stature is more likely in children who have a low growth velocity (crossing major height percentiles on the growth curve) or who are significantly short for their family. Children with chronic illness or nutritional deficiencies may have poor linear growth, but this is typically associated with inadequate weight gain and low body mass index (BMI). In contrast, endocrine causes of short stature are usually associated with normal or excessive weight gain.

1. Familial Short Stature & Constitutional Growth Delay

Children with familial short stature typically have normal birth weight and length. In the first 2 years of life, their linear growth velocity decelerates as they near their genetically determined percentile. Once the target percentile is reached, the child resumes normal linear growth parallel to the growth curve, usually between 2 and 3 years of age. Skeletal maturation and timing of puberty are consistent with chronologic age. The child grows along his/her own growth percentile and the final height is short but appropriate for the family (Figure 34–2).

Children with constitutional growth delay do not necessarily have short parents but have a growth pattern similar to those with familial short stature with a decline in linear

Table 34–2. Causes of short stature.

NORMAL
A. Genetic-familial short stature
B. Constitutional growth delay
PATHOLOGICAL
C. Endocrine disturbances
1. Growth hormone (GH) deficiency
a. Hereditary
b. Idiopathic—with and without associated abnormalities of midline structures of the central nervous system
c. Acquired
(1) Transient—eg, psychosocial short stature
(2) Organic—tumor, irradiation of the central nervous system, infection, or trauma
2. GH resistance/insulin-like growth factor 1 (IGF-1) deficiency
3. Hypothyroidism
4. Excess cortisol—Cushing disease and Cushing syndrome
5. Diabetes mellitus (poorly controlled)
6. Pseudohypoparathyroidism
7. Rickets
D. Intrauterine growth restriction
1. Intrinsic fetal abnormalities—chromosomal disorders
2. Syndromes (eg, Russell-Silver, Noonan, Bloom, de Lange, Cockayne)
3. Congenital infections
4. Placental abnormalities
5. Maternal abnormalities during pregnancy
E. Inborn errors of metabolism
F. Intrinsic diseases of bone
1. Defects of growth of tubular bones or spine (skeletal dysplasias)
2. Disorganized development of cartilage and fibrous components of the skeleton
G. Short stature associated with chromosomal defects
1. Autosomal (eg, Down syndrome, Prader-Willi syndrome)
2. Sex chromosomal (eg, Turner syndrome–XO)
H. Chronic systemic diseases, congenital defects, and cancers
I. Psychosocial short stature (deprivation dwarfism)

growth velocity between ages 2 and 3 years and then maintenance of a normal growth velocity prior to puberty. The difference is that children with constitutional growth delay have a delay in skeletal maturation and a delay in the onset of puberty. In these children, growth continues beyond the time the average child stops growing, and final height is appropriate for target height (Figure 34–3).

2. Growth Hormone Deficiency

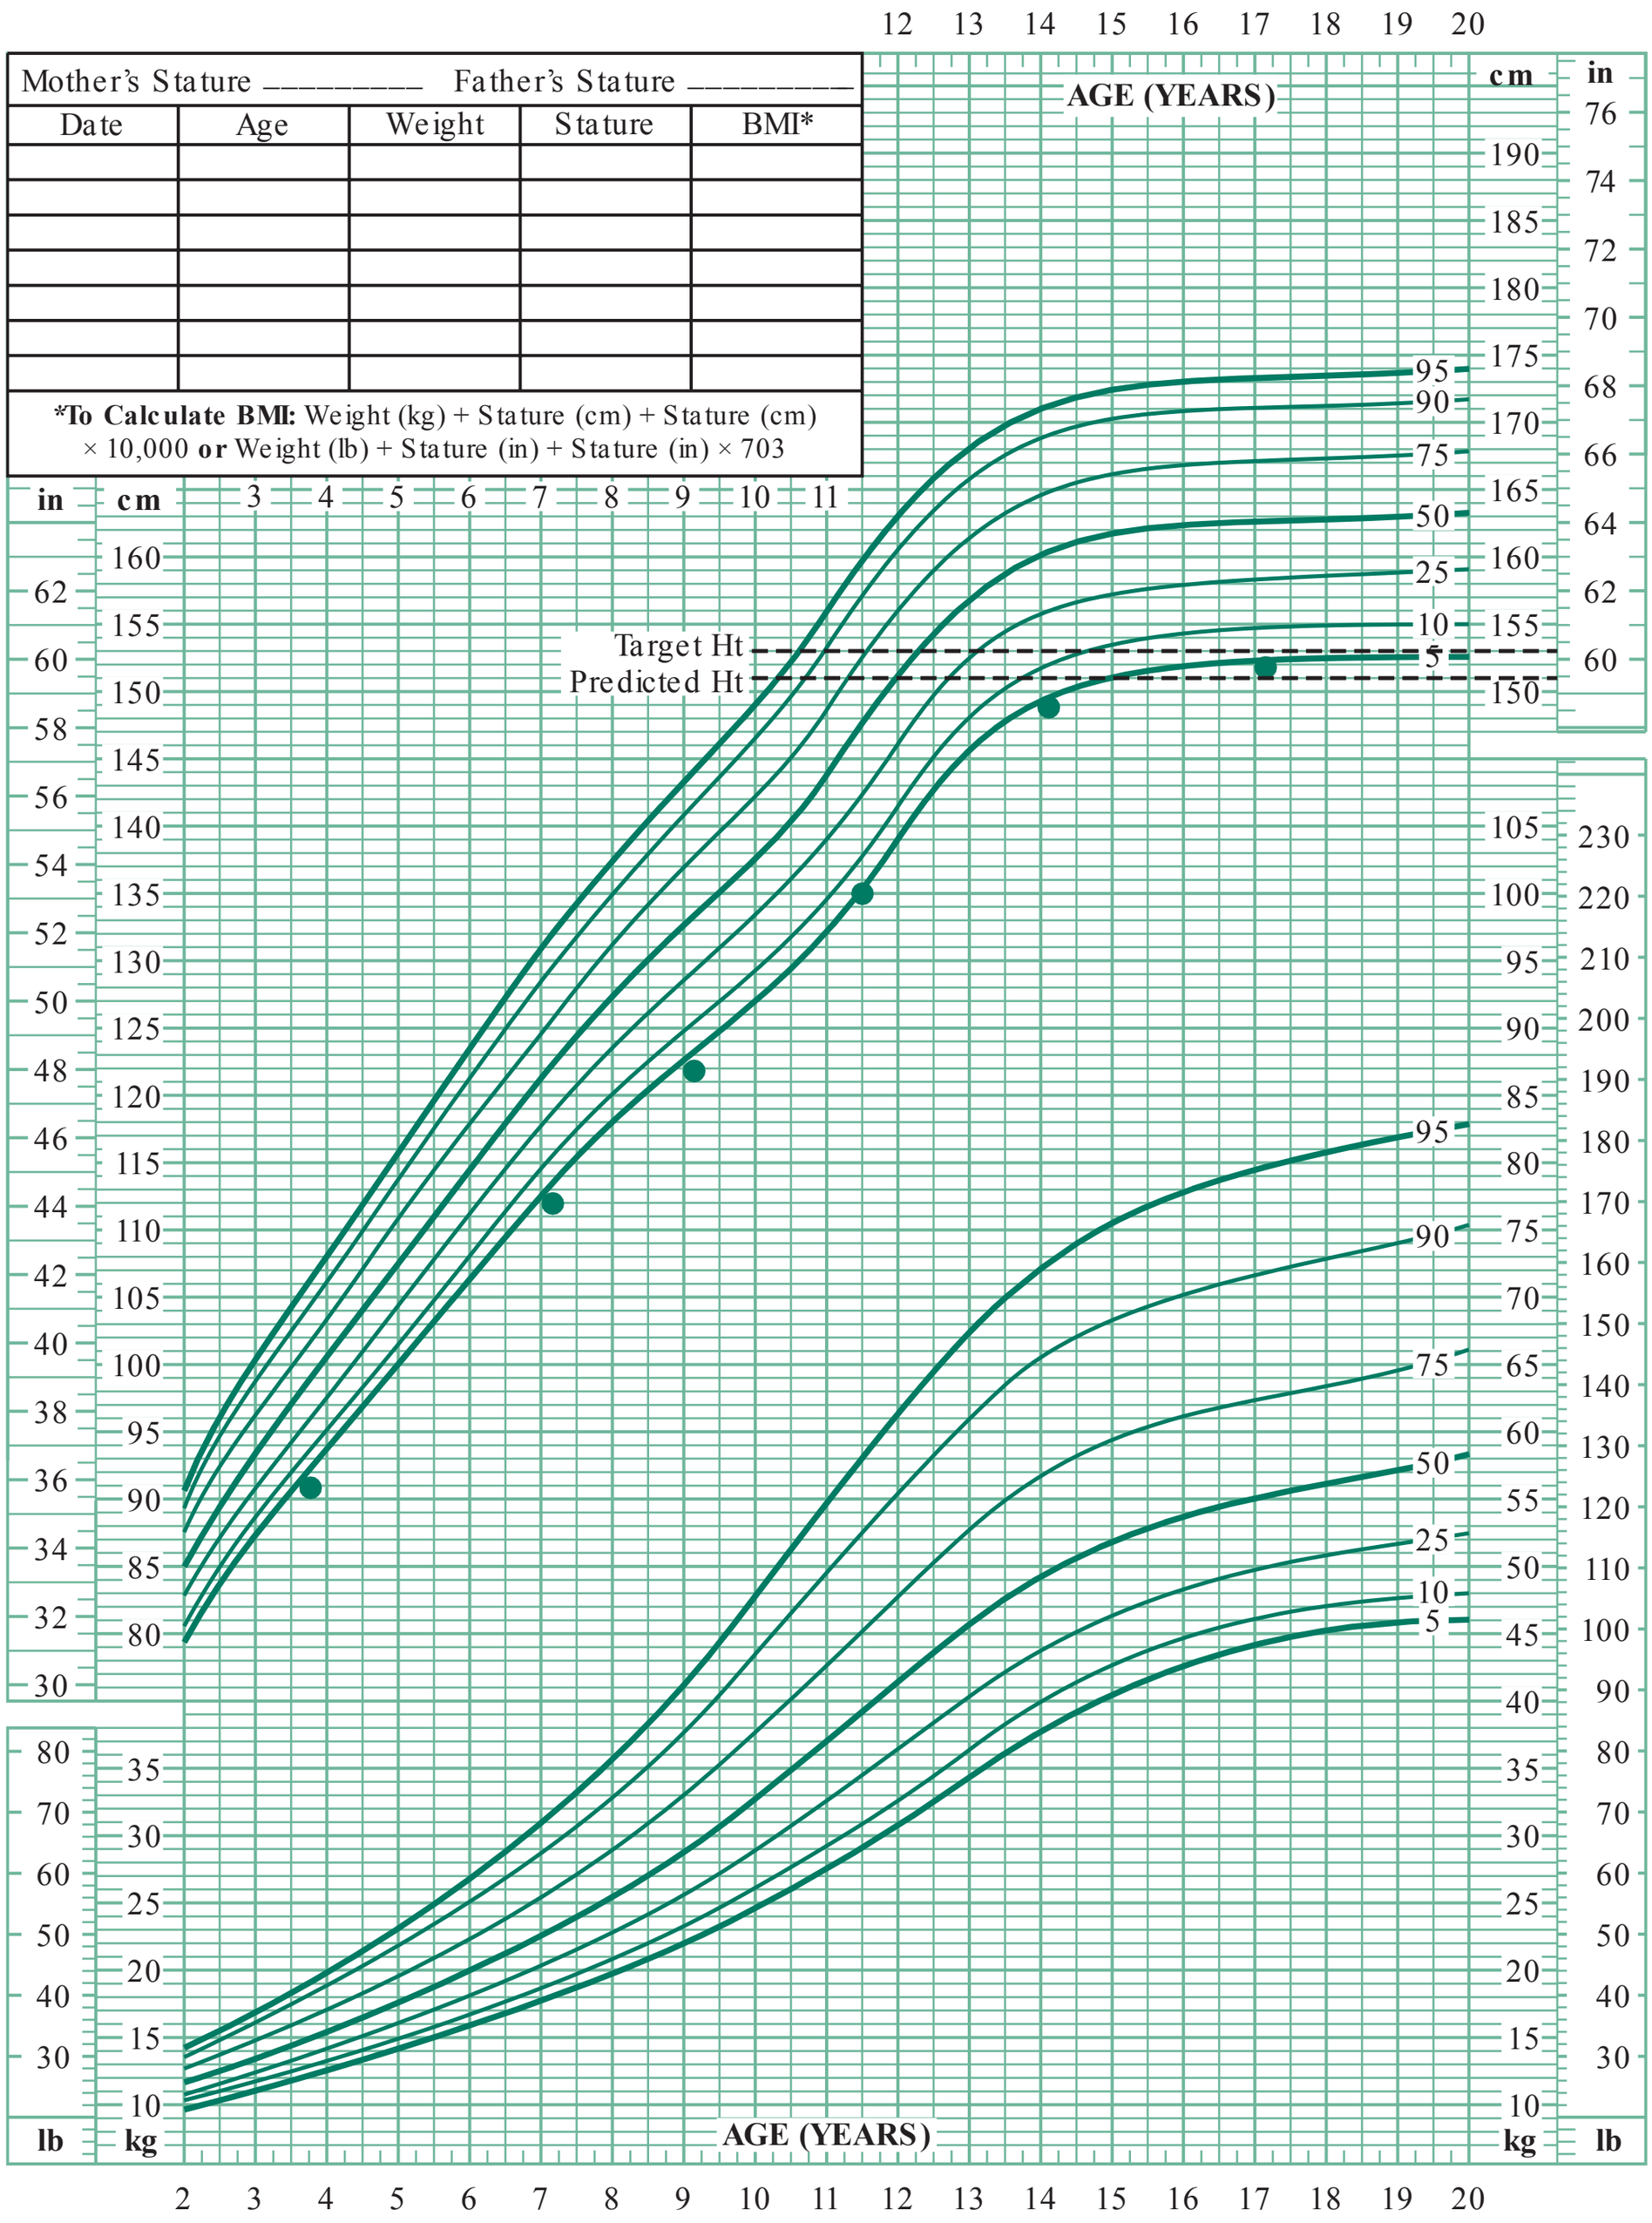
Human growth hormone (GH) is produced by the anterior pituitary gland. Secretion is stimulated by growth hormone–releasing hormone (GHRH) and inhibited by somatostatin. GH is secreted in a pulsatile pattern in response to sleep, exercise, and hypoglycemia, and has direct growth-promoting and metabolic effects (Figure 34–4). GH also promotes growth indirectly by stimulating production of insulin-like growth factors, primarily IGF-1.

Growth hormone deficiency (GHD) is characterized by decreased growth velocity and delayed skeletal maturation in the absence of other explanations (Figure 34–5). Because GH promotes lipolysis, many GH deficient children have excess truncal adiposity. GHD may be isolated or coexist with other pituitary hormone deficiencies and may be congenital (septo-optic dysplasia or ectopic posterior pituitary), genetic (GH or GHRH gene mutation), or acquired (craniopharyngioma, germinoma, histiocytosis, or cranial irradiation). Idiopathic GHD is the most common deficiency state with an incidence of about 1:4000 children. Patients have also been described with congenital GH resistance syndromes. The presentation of GH resistance is similar to that of GHD, but short stature is often severe, with little or no response to GH therapy and may be accompanied by dysmorphic features.

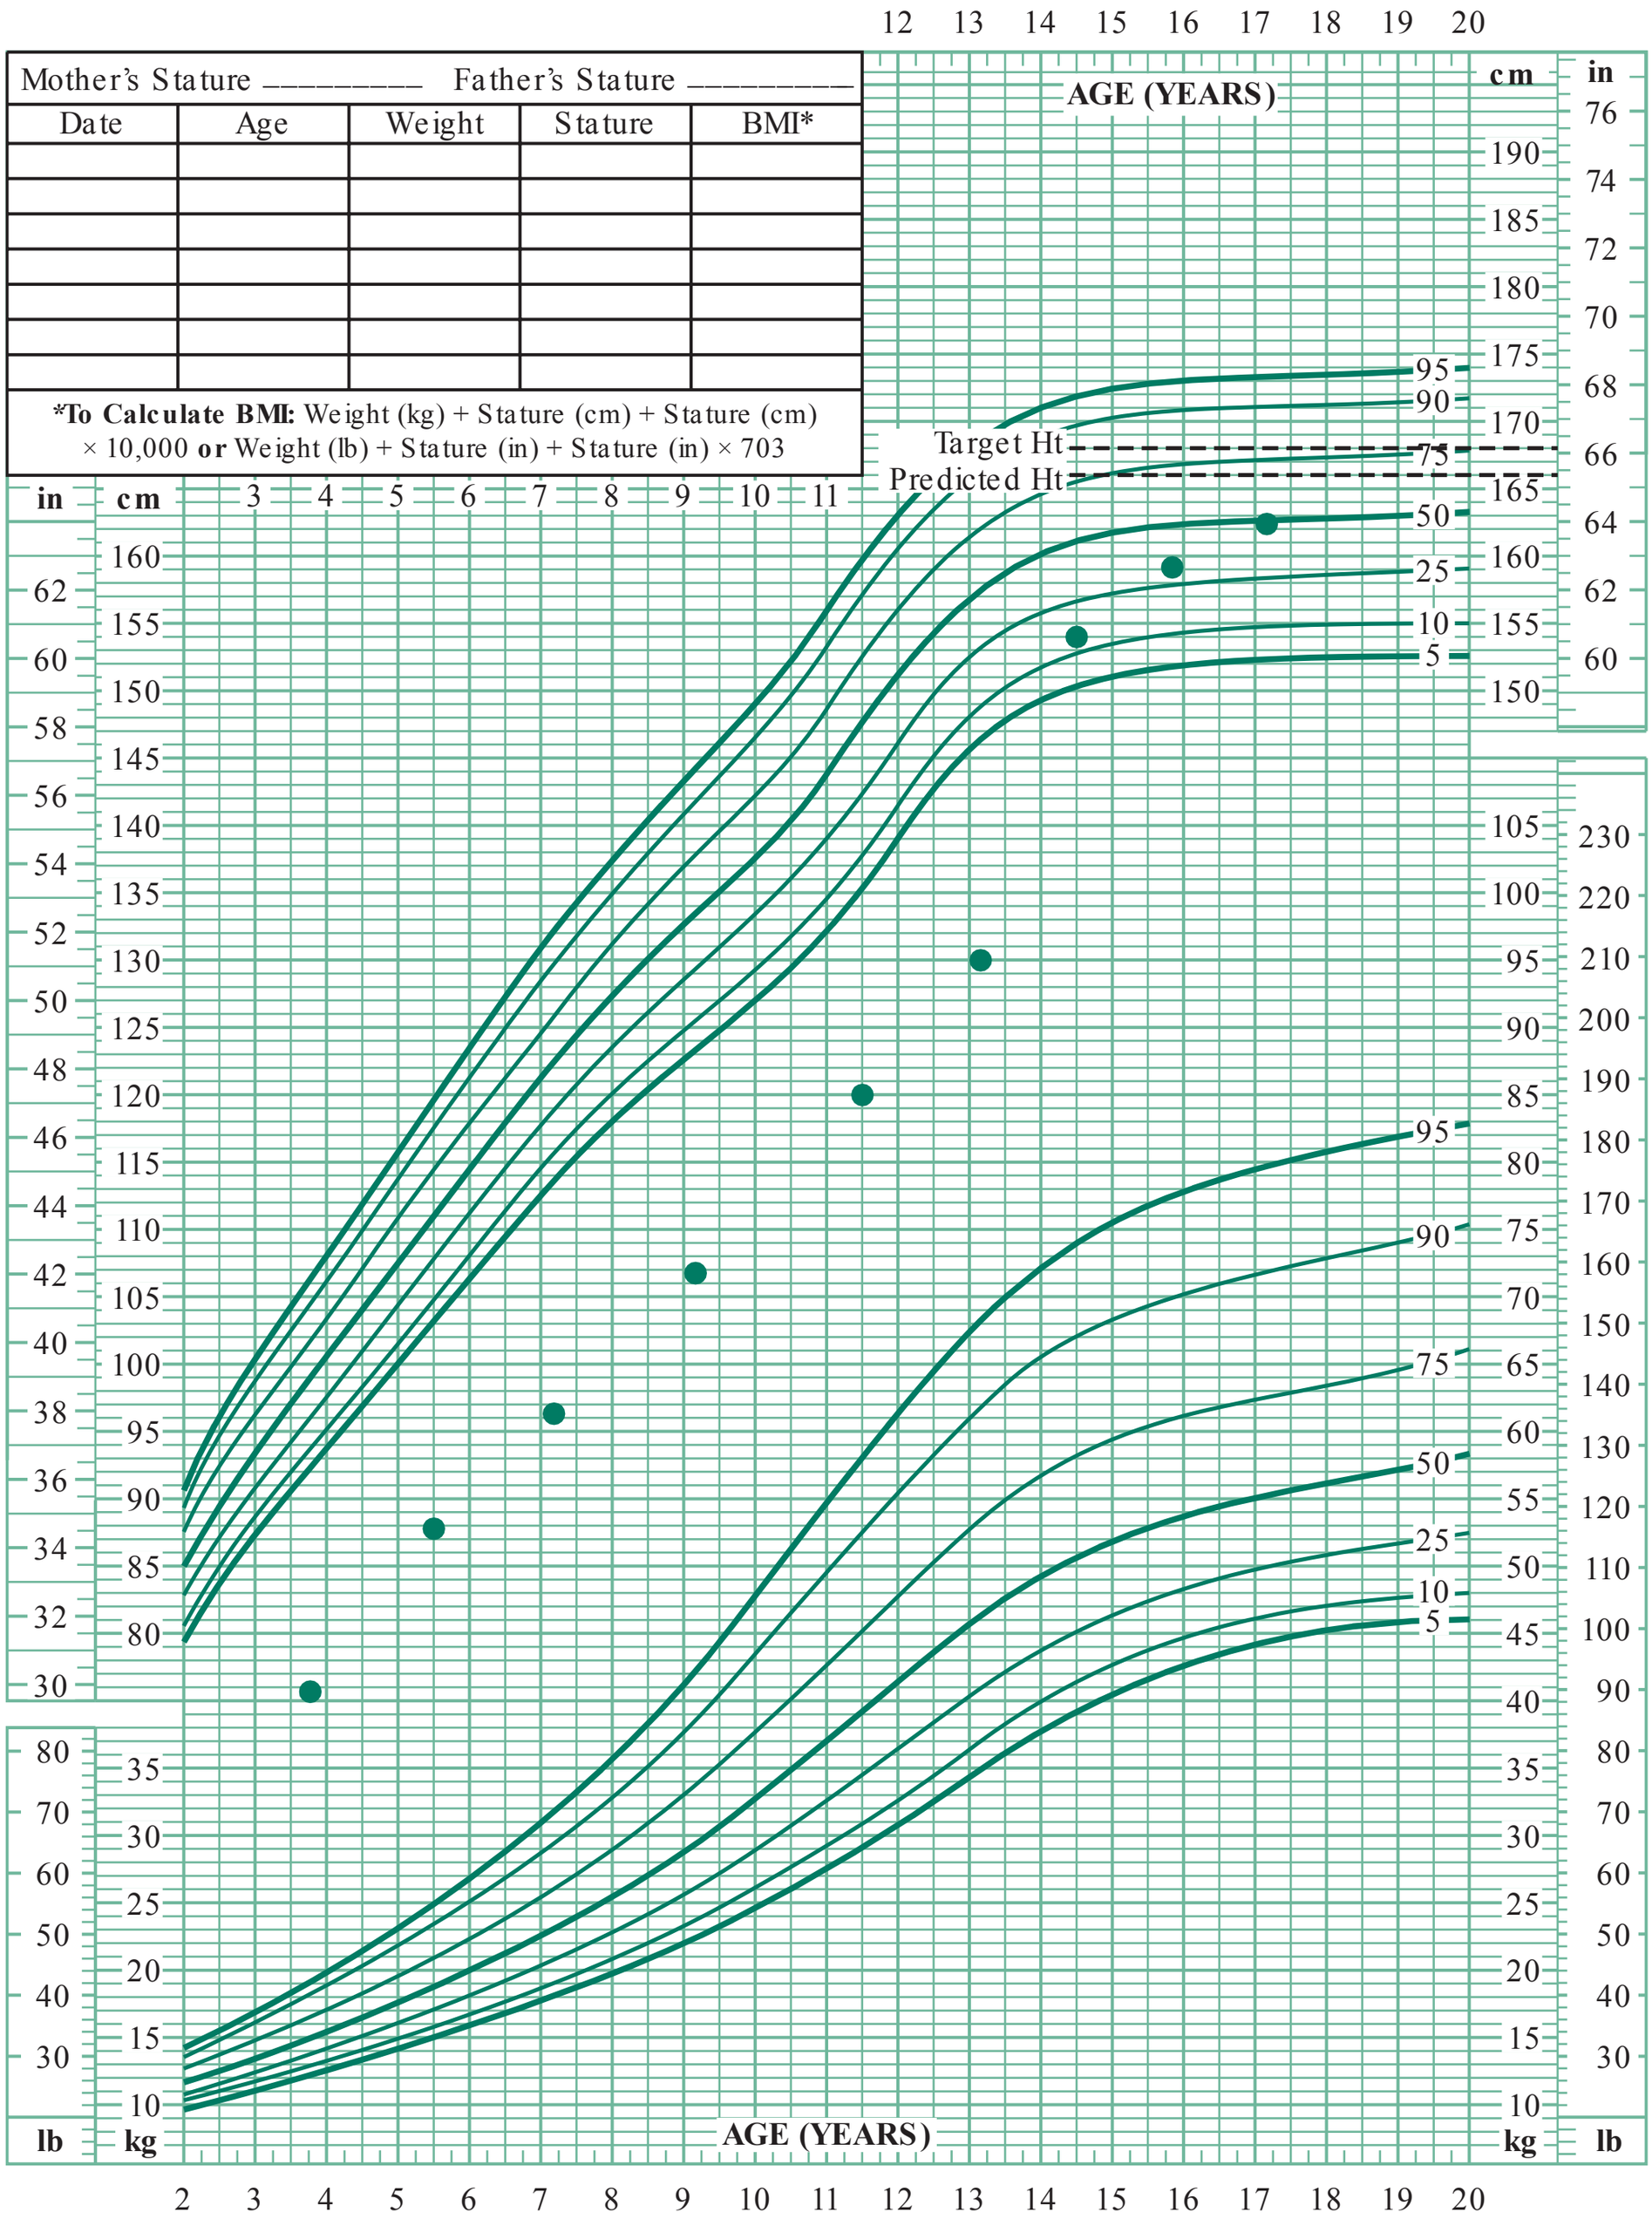
Features of infantile GHD include normal birth weight and slightly reduced length, hypoglycemia (if accompanied by adrenal insufficiency), micropenis (if accompanied by gonadotropin deficiency), and conjugated hyperbilirubinemia (if other pituitary hormone deficiencies present). Growth retardation in isolated GHD and hypopituitarism may not present until late in infancy or childhood.

Laboratory tests to assess GH status may be difficult to interpret because there is significant overlap in GH secretion between normal and GH-deficient children. GH secretion is pulsatile, so random samples for measurement of serum GH are of no value in the diagnosis of GHD. Serum concentrations of IGF-1 give reasonable estimations of GH secretion and action in the adequately nourished child (see Figure 34–4), and are often used as a first step in the evaluation for GHD. IGF-binding protein 3 (IGFBP-3) is a much less sensitive marker of GH deficiency, but may be useful in the underweight child or in children younger than 4 years, since it is less affected by age or nutritional status. Provocative studies using such agents as insulin, arginine, levodopa, clonidine, or glucagon are traditionally done to clarify GH secretion, but are not physiologic and are often poorly reproducible, ultimately limiting their value in the clarification of GH secretion. Currently, the recommended treatment schedule for GHD is subcutaneous recombinant GH given subcutaneously 7 days per week with total weekly dose of 0.15–0.3 mg/kg. All patients diagnosed with GHD should have an MRI of the hypothalamus and pituitary gland.

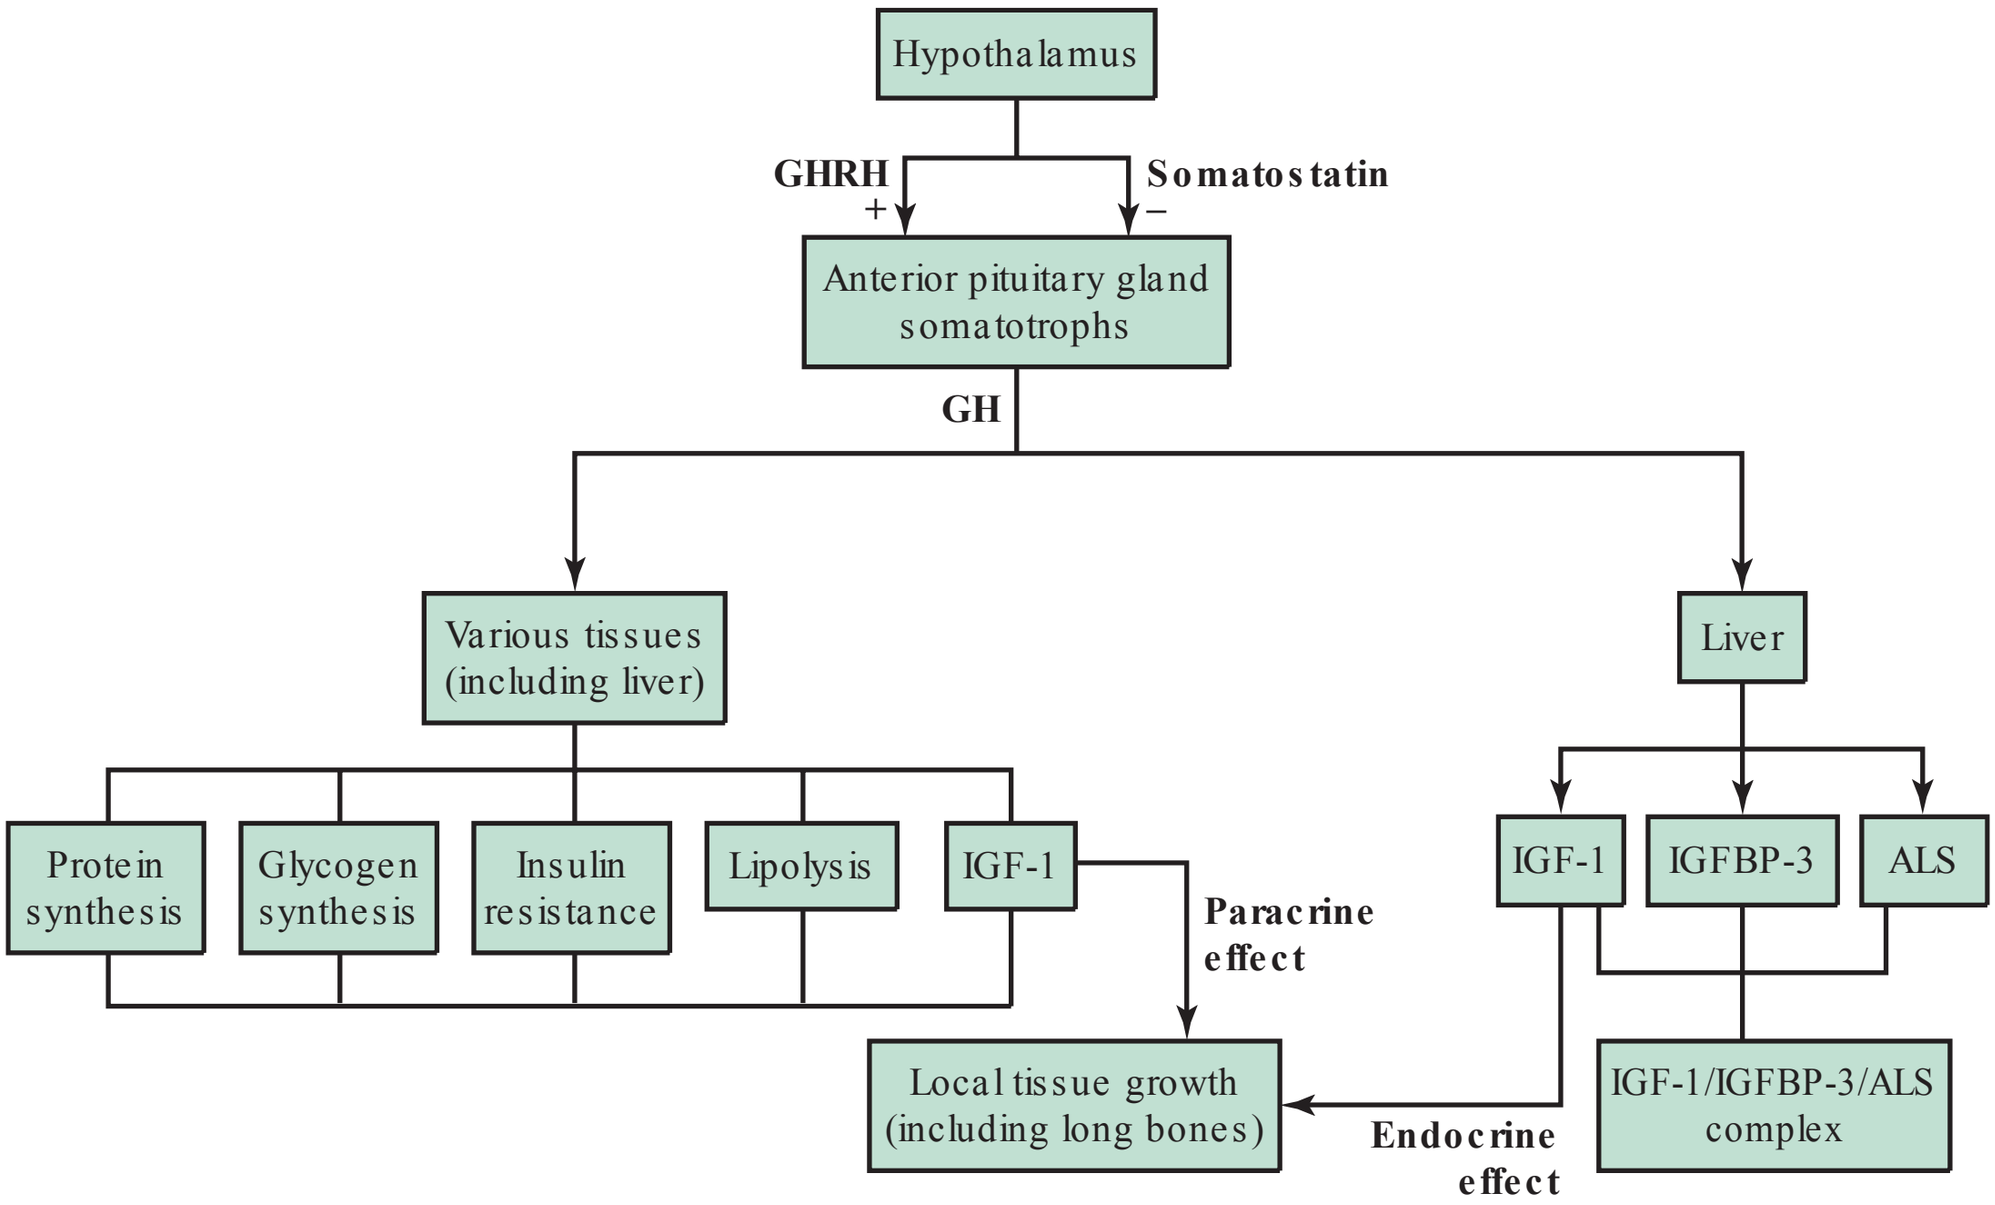
GH therapy is approved by the U.S. Food and Drug Administration (FDA) in children for: GHD; growth restriction associated with chronic renal failure; Turner, Prader-Willi, and Noonan syndromes; children born small for gestational age (SGA) who fail to demonstrate catch-up growth by age 4; and SHOX gene mutations. GH therapy has also been approved for children with idiopathic short stature whose current height is more than 2.25 standard deviations below the normal range for age. With GH treatment, final



▲**Figure 34–2.** Typical pattern of growth in a child with familial short stature. After attaining an appropriate percentile during the first 2 years of life, the child will have normal linear growth parallel to the growth curve. Skeletal maturation and the timing of puberty are consistent with chronologic age. The height percentile the child has been following is maintained, and final height is short but appropriate for the family.



▲**Figure 34–3.** Typical pattern of growth in a child with constitutional growth delay. Growth slows during the first 2 years of life, similarly to children with familial short stature. Subsequently the child will have normal linear growth parallel to the growth curve. However, skeletal maturation and the onset of puberty are delayed. Growth continues beyond the time the average child has stopped growing, and final height is appropriate for target height.



▲**Figure 34–4.** The GHRH/GH/IGF-1 system. The effects of growth hormone (GH) on growth are partly due to its direct anabolic effects in the muscle, liver, and bone. In addition, GH stimulates many tissues to produce insulin-like growth factor 1 (IGF-1) locally, which stimulates the growth of the tissue itself (paracrine effect of IGF-1). The action of GH on the liver results in the secretion of IGF-1 (circulating IGF-1), which stimulates growth in other tissues (endocrine effect of IGF-1). The action of growth hormone on the liver also enhances the secretion of IGF-binding protein 3 (IGFBP-3) and acid-labile subunit (ALS), which form a high-molecular-weight complex with IGF-1. The function of this complex is to transport IGF-1 to its target tissues, but the complex also serves as a reservoir and possible inhibitor of IGF-1 action. In various chronic illnesses, the direct metabolic effects of GH are inhibited; the secretion of IGF-1 in response to GH is blunted, and in some cases IGFBP-3 synthesis is enhanced, resulting in marked inhibition in the growth of the child. GHRH, growth hormone–releasing hormone.

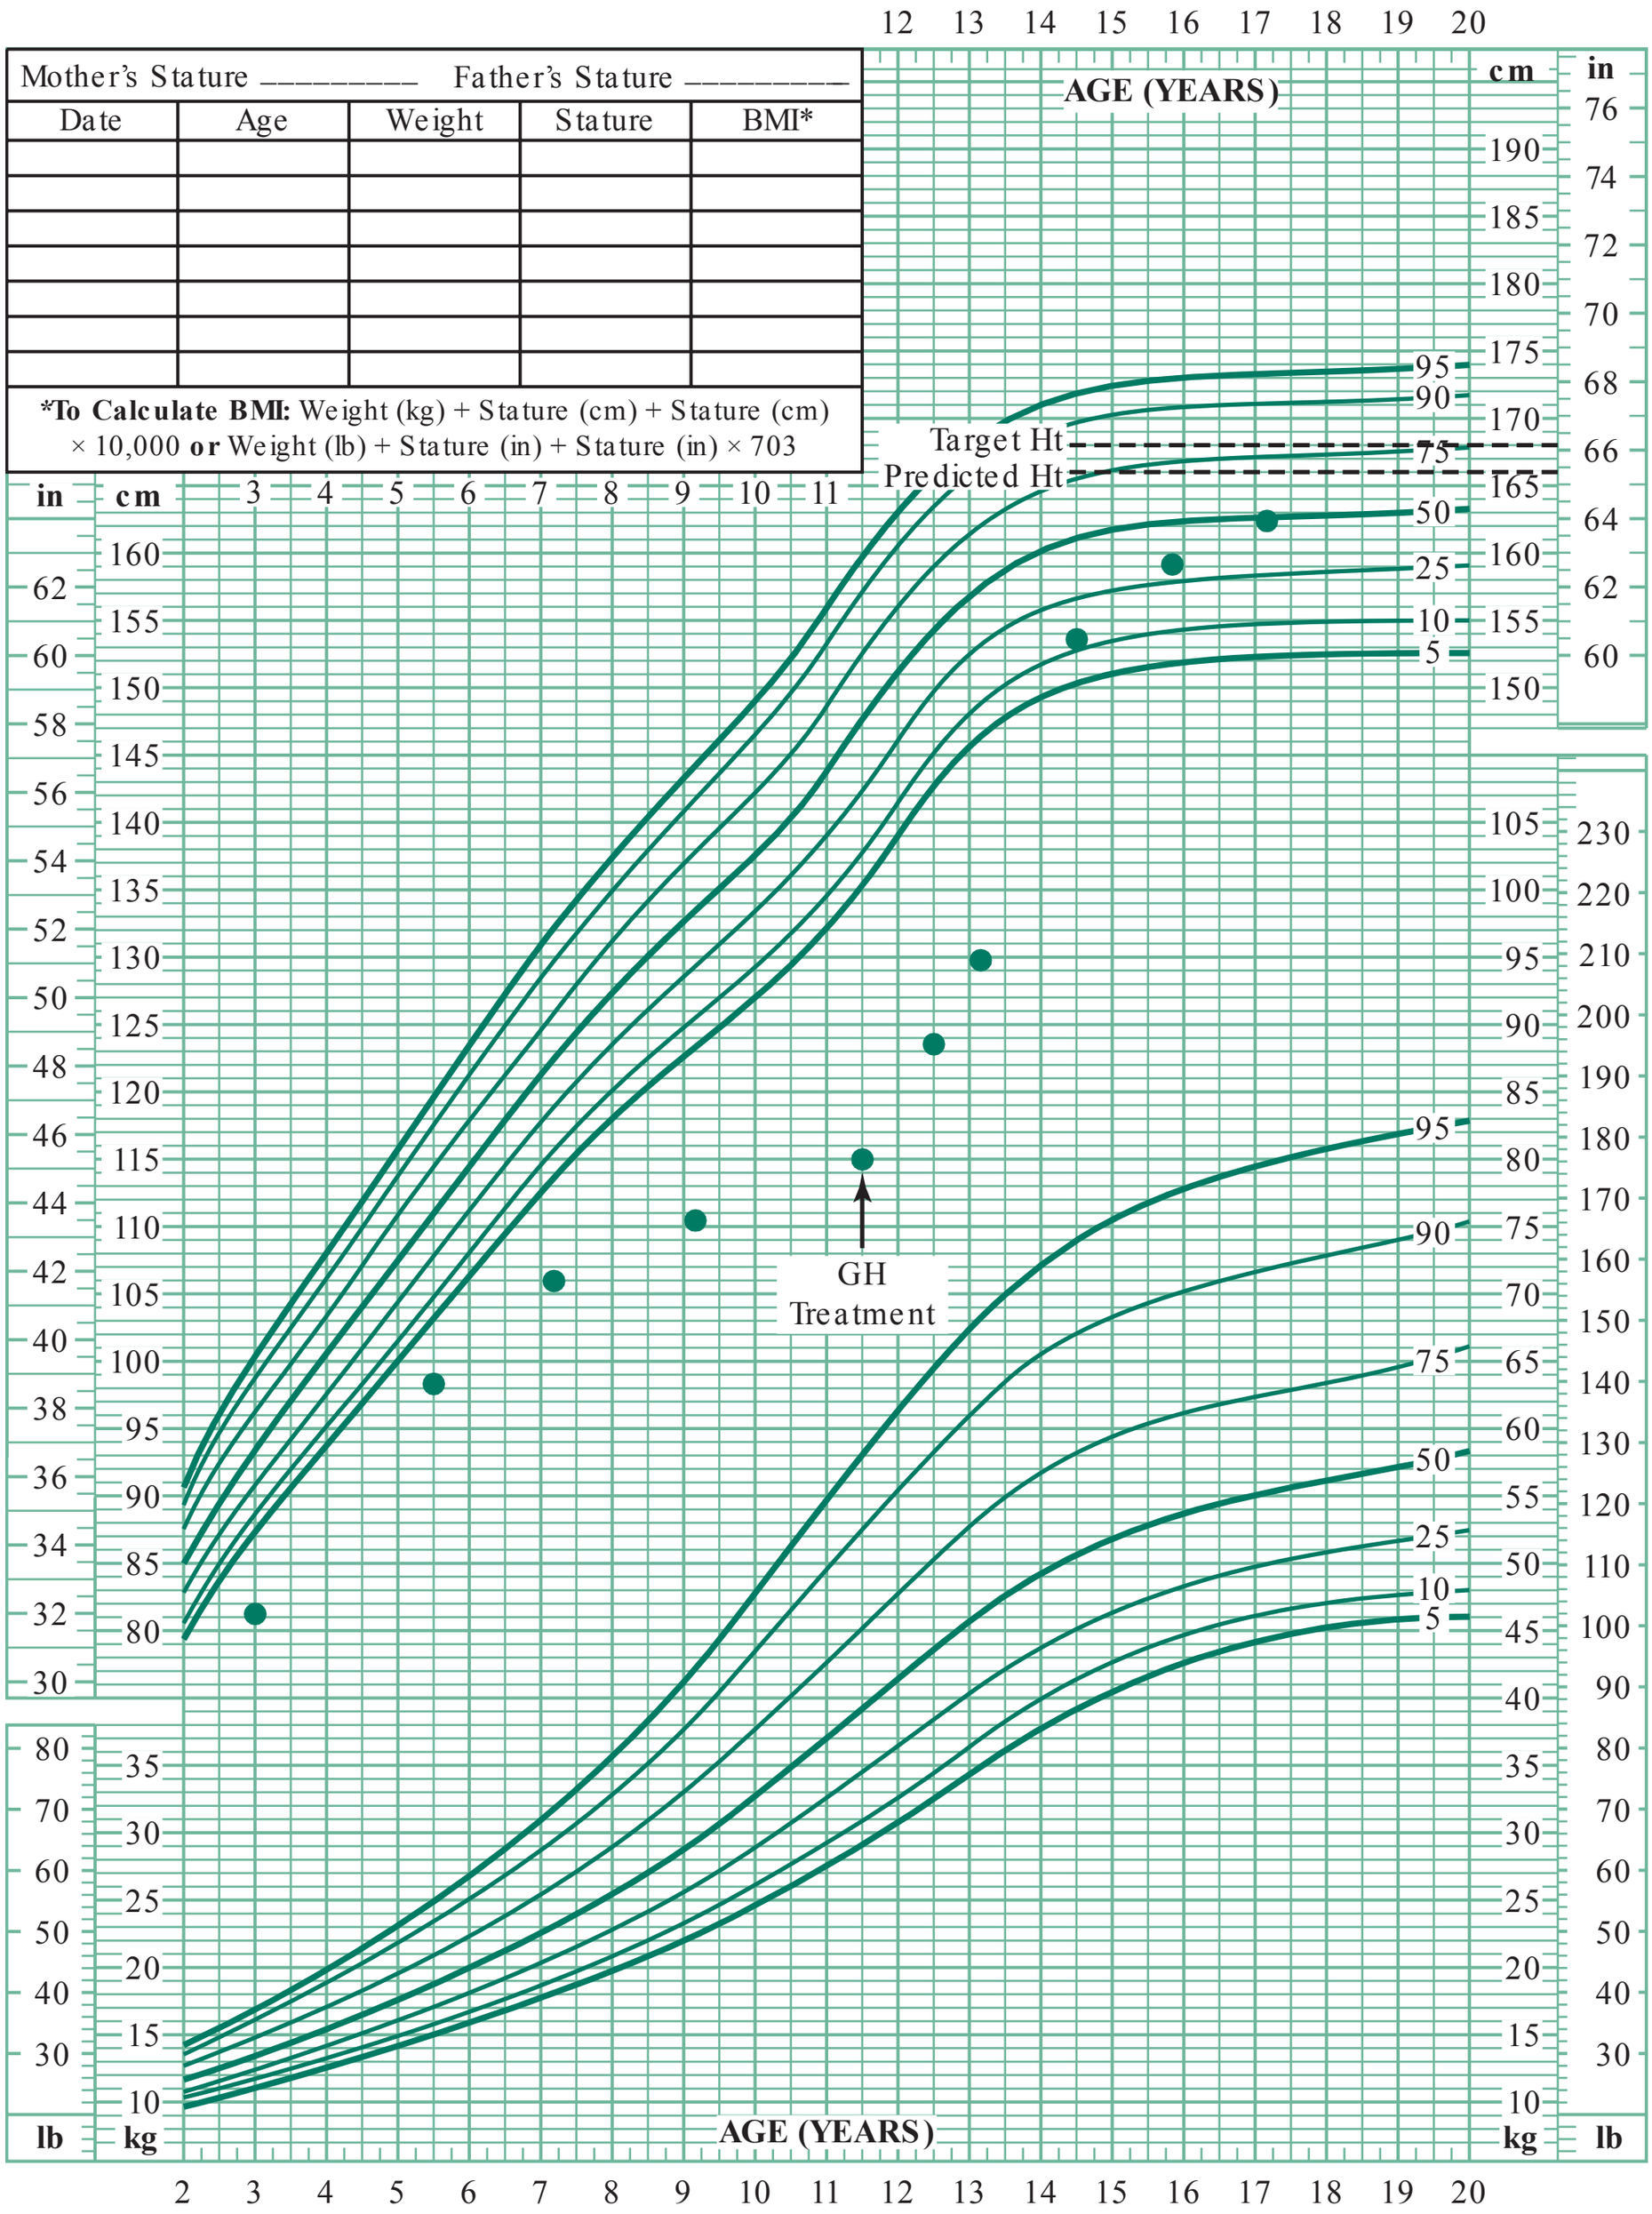
height may be 5–7 cm taller in this population. The role of GH for idiopathic short stature is still unclear, especially due to the expense, long duration of treatment, and unclear psychological consequences. Side effects of recombinant GH are uncommon but include benign intracranial hypertension and slipped capital femoral epiphysis. With early diagnosis and treatment, children with GHD reach normal or near-normal adult height. Recombinant IGF-1 injections may be used to treat children with GH resistance or IGF-1 deficiency, but improvements in growth are not as substantial as seen with GH therapy for GH deficiency.

3. Small for Gestational Age/Intrauterine Growth Restriction

Small for gestational age (SGA) infants have a birth weight and/or length below the 10th percentile for the population's birth weight–gestational age relationship. SGA infants include constitutionally small infants and infants with intrauterine growth restriction (IUGR). Many children with mild SGA/IUGR and no intrinsic fetal abnormalities exhibit catch-up growth during the first 3 years, but 15%–20% remain short throughout life. Catch-up growth may also be inadequate in preterm SGA/IUGR infants with poor postnatal nutrition. Children who do not show catch-up growth may have normal growth velocity but follow a lower height percentile than expected for the family. In contrast to children with constitutional growth delay, those with SGA/IUGR have skeletal maturation that corresponds to chronologic age or is only mildly delayed. GH therapy for SGA/IUGR children with growth delay is FDA-approved and appears to increase growth velocity and final adult height.

4. Disproportionate Short Stature

There are more than 200 sporadic and genetic skeletal dysplasias that may cause disproportionate short stature. Measurements of arm span and upper-to-lower body segment



▲**Figure 34–5.** Typical pattern of growth in a child with acquired growth hormone deficiency (GHD). Children with acquired GHD have an abnormal growth velocity and fail to maintain height percentile during childhood. Other phenotypic features (central adiposity and immaturity of facies) may be present. Children with congenital GHD will cross percentiles during the first 2 years of life, similarly to the pattern seen in familial short stature and constitutional delay, but will fail to attain a steady height percentile subsequently.

ratio are helpful in determining whether a child has normal body proportions. If disproportionate short stature is found, a skeletal survey may be useful to detect specific radiographic features characteristic of some disorders. The effect of GH on most of these rare disorders is unknown.

5. Short Stature Associated With Syndromes

Short stature is associated with many genetic syndromes, including Turner, Down, Noonan, and Prader-Willi. Girls with Turner syndrome often have recognizable features such as micrognathia, webbed neck, low posterior hairline, edema of hands and feet, multiple pigmented nevi, and an increased carrying angle. However, short stature can be the only obvious manifestation of Turner syndrome. Consequently, any girl with unexplained short stature for family warrants a chromosomal evaluation. Although girls with Turner syndrome are not usually GH deficient, GH therapy can improve final height by an average of 6.0 cm. Duration of GH therapy is a significant predictor of long-term height gain; consequently, it is important that Turner syndrome be diagnosed early and GH started as soon as possible.

GH is approved for treatment of growth failure in Prader-Willi syndrome–associated GHD. GH improves growth, body composition, and physical activity. A few deaths have been reported in Prader-Willi children receiving GH, all of which occurred in very obese children, children with respiratory impairments, sleep apnea, or unidentified respiratory infections. The role of GH in these deaths is unknown, but it is recommended that all patients with Prader-Willi syndrome be evaluated for upper airway obstruction and sleep apnea prior to starting GH therapy.

Children with Down syndrome should be evaluated for GHD only if their linear growth is abnormal compared with the Down syndrome growth chart.

6. Psychosocial Short Stature (Psychosocial Dwarfism)

Psychosocial short stature refers to growth retardation associated with emotional deprivation. Undernutrition probably contributes to growth retardation in some of these children. Other symptoms include unusual eating and drinking habits, bowel and bladder incontinence, social withdrawal, and delayed speech. GH secretion in children with psychosocial short stature is diminished, but GH therapy is usually not beneficial. A change in the psychological environment at home usually results in improved growth and improvement of GH secretion, personality, and eating behaviors.

» Clinical Evaluation

Laboratory investigation should be guided by the history and physical examination, including history of chronic illness and medications, birth weight and height, pattern of growth since birth, familial growth patterns, pubertal stage, dysmorphic features, body segment proportion, and psychological health. In a child with poor weight gain as the primary disturbance, a nutritional assessment is indicated. The following laboratory tests may be useful as guided by history and clinical judgment: (1) radiograph of left hand and wrist for bone age; (2) karyotype (girls) and/or Noonan syndrome testing; (3) thyroid function tests: thyroxine (T_4) and thyroid-stimulating hormone (TSH); (4) IGF-1 (IGFBP-3 is an alternative for children < 4 or in malnourished individuals); (5) complete blood count (to detect chronic anemia or leukocyte markers of infection); (6) erythrocyte sedimentation rate (often elevated in collagen-vascular disease, cancer, chronic infection, and inflammatory bowel disease); (7) urinalysis, blood urea nitrogen, and serum creatinine (occult renal disease); (8) serum electrolytes, calcium, and phosphorus (renal tubular disease and metabolic bone disease); (9) stool examination for fat, or measurement of serum tissue transglutaminase (malabsorption or celiac disease).

TALL STATURE

Although growth disturbances are usually associated with short stature, potentially serious pathologic conditions may also be associated with tall stature and excessive growth (Table 34–3). Excessive GH secretion is rare, particularly in children, and generally associated with a functioning pituitary adenoma. GH excess leads to gigantism if the epiphyses are open and to acromegaly if the epiphyses are closed. The diagnosis is confirmed by finding elevated random GH and IGF-1

levels and failure of GH suppression during an oral glucose tolerance test. Precocious puberty can also cause tall stature for age or rapid growth, but would be associated with early signs of puberty and an advanced bone age. Obese youth are also often tall for age, but they do not achieve a taller final height.

DISORDERS OF THE POSTERIOR PITUITARY GLAND

The posterior pituitary (neurohypophysis) is an extension of the ventral hypothalamus. Its two principal hormones—oxytocin and arginine vasopressin—are synthesized in the supraoptic and paraventricular nuclei of the ventral hypothalamus. These peptide hormones are packaged in granules with specific neurophysins and transported via the axons to their storage site in the posterior pituitary. Vasopressin is essential for water balance; it acts primarily on the kidney to promote reabsorption of water from urine. Oxytocin is most active during parturition and breast feeding and is not discussed further here.

ARGININE VASOPRESSIN (ANTIDIURETIC HORMONE) PHYSIOLOGY

Vasopressin release is controlled primarily by serum osmolality and intravascular volume. Release is stimulated by minor increases in plasma osmolality (detected by osmoreceptors in the anterolateral hypothalamus) and large decreases in intravascular volume (detected by baroreceptors in the cardiac atria). Disorders of vasopressin release and action include (1) central (neurogenic) DI, (2) nephrogenic DI (see Chapter 24), and (3) the syndrome of inappropriate secretion of anti-diuretic hormone (see Chapter 45).

CENTRAL DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polydipsia, polyuria (> 2 L/m^2/d), nocturia, dehydration, and hypernatremia.
- Inability to concentrate urine after fluid restriction (urine specific gravity < 1.010; urine osmolality < 300 mOsm/kg).
- Plasma osmolality greater than 300 mOsm/kg with urine osmolality less than 600 mOsm/kg.
- Low plasma vasopressin with antidiuretic response to exogenous vasopressin.

» General Considerations

Central diabetes insipidus (DI) is an inability to synthesize and release vasopressin. Without vasopressin, the kidneys cannot concentrate urine, causing excessive urinary water loss. Genetic causes of central DI are rare and include mutations in the vasopressin gene and the WFS1 gene that causes DI, diabetes mellitus, optic atrophy, and deafness (Wolfram or DIDMOAD syndrome). The most common causes of pediatric central DI are midline defects (septo-optic dysplasia, holoprosencephaly); trauma (surgery, injury); infiltrative/neoplastic disease (tumors such as craniopharyngioma, germinoma, Langerhans cell histiocytosis, sarcoidosis); infectious (meningitis); and idiopathic.

Traumatic DI often has three phases. Initially, transient DI is caused by edema in the hypothalamus or pituitary area. In 2–5 days, unregulated release of vasopressin from dying neurons causes the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Finally, permanent DI occurs if a sufficient number of vasopressin neurons are destroyed. Of note, germinomas often present with DI, whereas DI in craniopharyngioma is more often the result of neurosurgical intervention. Germinomas and other infiltrative diseases are often associated with pituitary stalk thickening on magnetic resonance imaging (MRI).

» Clinical Findings

Onset of DI is characterized by polyuria, nocturia, enuresis, and intense thirst, usually with a preference for cold water. Hypernatremia, hyperosmolality, and dehydration occur if insufficient fluid intake does not keep up with urinary losses. In infants, symptoms may also include failure to thrive, vomiting, constipation, and unexplained fevers. Some infants may present with severe dehydration, circulatory collapse, and seizures. Vasopressin deficiency may be masked in patients with panhypopituitarism due to the impaired excretion of free water associated with adrenal insufficiency; treatment with glucocorticoids may unmask DI in these patients.

DI is confirmed when serum hyperosmolality is associated with urine hypo-osmolarity. If the history indicates that the child can go through the night comfortably without drinking, outpatient testing is appropriate. Oral fluid intake is prohibited after midnight. Osmolality, sodium, and specific gravity of the first morning void are obtained. This can also be done as a water deprivation test in the hospital if screening results are unclear or if symptoms preclude safely withholding fluids at home. See "Essentials" box for diagnostic criteria. Children with central DI should have an MRI of the head with contrast to look for tumors or infiltrative processes.

Primary polydipsia must be distinguished from DI. Children with primary polydipsia tend to have lower serum sodium levels and usually can concentrate their urine with

overnight fluid deprivation. Some may have secondary nephrogenic DI due to dilution of the renal medullary interstitium and decreased renal concentrating ability, but this resolves with restriction of fluid intake.

» Treatment

Central DI is treated with oral or intranasal desmopressin acetate (DDAVP). The aim of therapy is to provide antidiuresis that allows uninterrupted sleep and approximately 1 hour of diuresis before the next dose. It is important to note that postsurgical DI can be associated with disruption of thirst mechanism, and for these patients, a prescribed volume of fluid intake needs to be determined. Children hospitalized with acute-onset DI can be managed with intravenous or subcutaneous vasopressin. Due to the amount of antidiuresis, electrolytes should be closely monitored to avoid water intoxication. Infants with DI should not be treated with DDAVP, since their primary source of nutrition is through liquid calories and this combination can result in water intoxication. For this reason, infants are treated with extra free water to maintain normal hydration. A formula with a low renal solute load and chlorothiazides may be helpful in infants with central DI.

THYROID GLAND

FETAL DEVELOPMENT OF THE THYROID

As early as the 10th week of gestation, the fetal thyroid synthesizes thyroid hormone, which appears in the fetal serum by the 11th week of gestation and progressively increases throughout gestation. The fetal pituitary-thyroid axis functions largely independently of the maternal pituitary-thyroid axis because maternal TSH cannot cross the placenta. However, maternal thyroid hormone can cross the placenta in limited amounts.

At birth, there is a TSH surge peaking at about 70 mU/L within 30–60 minutes. Thyroid hormone serum level increases rapidly during the first days of life in response to this TSH surge. The TSH level decreases to childhood levels within a few weeks. The physiologic neonatal TSH surge can produce a false-positive newborn screen for hypothyroidism (ie, high TSH) if the blood sample for the screen is collected on the first day of life.

PHYSIOLOGY

Hypothalamic thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary gland to release TSH. In turn, TSH stimulates the thyroid gland to take up iodine and synthesize and release T_4 and T_3. This process is regulated by negative feedback involving the hypothalamus, pituitary, and thyroid (see Figure 34–1).

T_4 is the predominant thyroid hormone secreted by the thyroid gland. Most circulating T_3 and T_4 are bound to thyroxine-binding globulin (TBG), albumin, and prealbumin. Less than 1% of thyroxine exists in the free form. T_4 is deiodinated in the tissues to T_3, which binds to high-affinity nuclear thyroid hormone receptors in the cytoplasm and translocates to the nucleus, exerting its biologic effects by modifying gene expression. Causes of low T_4 are hypothyroidism (central or primary), prematurity, malnutrition and severe illness, and following therapy with T_3.

Total T_4 is also low in situations that decrease TBG, such as familial TBG deficiency, nephrosis, and in patients receiving androgens. In sepsis, TBG cleavage is increased. Treatment with certain medications (heparin, furosemide, salicylates, and phenytoin) results in abnormal binding to TBG. However, since these effects primarily involve TBG, TSH and free T_4 (FT_4) levels remain in the normal range. Conversely, total T_3 and T_4 levels may be elevated in conditions associated with increased TBG levels (congenital TBG excess, pregnancy, estrogen therapy) and increased thyroid hormone binding to transport proteins. Again, patients are clinically euthyroid in this circumstance.

HYPOTHYROIDISM (CONGENITAL & ACQUIRED)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Growth retardation, decreased physical activity, weight gain, constipation, dry skin, cold intolerance, and delayed puberty.
- Untreated congenital hypothyroidism: thick tongue, large fontanels, poor muscle tone, hoarseness, umbilical hernia, jaundice, and intellectual retardation.
- T_4, FT_4, and T_3 resin uptake are low; TSH levels are elevated in primary hypothyroidism.

» General Considerations

Thyroid hormone deficiency may be congenital or acquired (Table 34–4). It can be due to defects in the thyroid gland (primary hypothyroidism) or in the hypothalamus or pituitary (central hypothyroidism).

Table 34–4. Causes of hypothyroidism.

A. Congenital
1. Aplasia, hypoplasia, or maldescent of thyroid
2. Inborn errors of thyroid hormone synthesis, secretion, or recycling
3. Maternal antibody-mediated (inhibit TSH binding to receptor)
4. TSH receptor defect
5. Thyroid hormone receptor defect
6. In utero exposures
a. Radioiodine therapy
b. Goitrogens (propylthiouracil, methimazole)
c. Iodine excess
7. Iodide deficiency
B. Acquired (juvenile hypothyroidism)
1. Autoimmune (lymphocytic) thyroiditis
2. Thyroidectomy or radioiodine therapy
3. Irradiation to the thyroid
4. Thyrotropin deficiency
5. TRH deficiency due to hypothalamic injury or disease
6. Medications
a. Iodides
(1) Excess (eg, amiodarone)
(2) Deficiency
b. Lithium
c. Cobalt
7. Large hemangiomas
8. Idiopathic

T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Congenital hypothyroidism occurs in about 1:3000–1:4000 infants. Untreated, it causes severe neurocognitive impairment. Most cases are sporadic resulting from hypoplasia or aplasia of the thyroid gland or failure of the gland to migrate to its normal anatomic location (ie, lingual or sublingual thyroid gland). Other causes are listed in Table 34–4. In severe maternal iodine deficiency, both the fetus and the mother are T_4-deficient, with irreversible brain damage to the fetus. Acquired hypothyroidism, particularly if goiter is present, is usually a result of chronic lymphocytic (Hashimoto) thyroiditis.

Several hundred patients with resistance to thyroid hormone have been described and present with elevations in T_4 and/or FT_4, with normal TSH. There is often a family history of the disorder. Clinical manifestations are highly variable due to differential expression of thyroid hormone receptor isoforms in different tissues.

» Clinical Findings

A. Symptoms and Signs

Even when the thyroid gland is completely absent, most newborns with congenital hypothyroidism appear normal. However, because congenital hypothyroidism is associated with intellectual impairment, thyroid testing is included in the newborn screen and treatment must be initiated as early as possible. Jaundice associated with an unconjugated hyperbilirubinemia may be present in newborns with congenital hypothyroidism.

Features of juvenile hypothyroidism include short stature, abnormal weight gain; delayed bone age and retarded dental eruption; skin changes (dry, thick, scaly, coarse, pale, cool, or mottled, or have a yellowish tinge); hair changes (dry, coarse, or brittle), hair loss; lateral thinning of the eyebrows; musculoskeletal findings (hypotonia and a slow relaxation component of deep tendon reflexes); physical and mental sluggishness; nonpitting myxedema; constipation; cold temperature intolerance; bradycardia; puberty may be delayed; occasional pseudopuberty.

In hypothyroidism resulting from enzymatic defects, ingestion of goitrogens, or chronic lymphocytic thyroiditis, the thyroid gland may be enlarged. Thyroid enlargement in children is usually symmetrical, and the gland is moderately firm and not nodular. In chronic lymphocytic thyroiditis, however, the thyroid frequently has a cobblestone surface (see the following text).

B. Laboratory Findings

In primary hypothyroidism, the total T_4 and FT_4 may be normal or decreased and the serum TSH is elevated. Circulating autoantibodies to thyroid peroxidase and thyroglobulin may be present. In central hypothyroidism, the TSH is usually inappropriately normal and associated with a low total T_4 and FT_4. Serum prolactin may be elevated, resulting in galactorrhea. Other pituitary deficiencies may be present, as central hypothyroidism may be associated with congenital or acquired disorders of the hypothalamus or pituitary gland.

C. Imaging

Thyroid imaging, while helpful in establishing the cause of congenital hypothyroidism, does not affect the treatment plan and is not necessary. Bone age is delayed. Cardiomegaly is common. Long-standing primary hypothyroidism may be associated with thyrotrophic hyperplasia characterized by an enlarged sella or pituitary gland.

D. Screening Programs for Neonatal Hypothyroidism

All newborns should be screened for congenital hypothyroidism shortly after birth. Depending on the state, the newborn screen measures either the total T_4 or TSH level. Abnormal newborn screening results should be confirmed immediately with a venous T_4 and TSH level. Treatment should be started as soon as possible. Initiation of treatment

in the first month of life and good compliance during infancy usually results in a normal neurocognitive outcome.

» Treatment

Levothyroxine (75–100 mcg/m^2/d) is the drug of choice for acquired hypothyroidism. In neonates with congenital hypothyroidism, the initial dose is 10–15 mcg/kg/d. Serum total T_4 or FT_4 concentrations are used to monitor the adequacy of initial therapy because the high neonatal TSH may not normalize for weeks. Subsequently, T_4 and TSH are monitored in combination.

THYROIDITIS

1. Chronic Lymphocytic Thyroiditis (Chronic Autoimmune Thyroiditis, Hashimoto Thyroiditis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Firm, freely movable, nontender, diffusely enlarged thyroid gland.
- Thyroid function is usually normal but may be elevated or decreased depending on the stage of the disease.

» General Considerations

Chronic lymphocytic thyroiditis is the most common cause of goiter and acquired hypothyroidism in childhood. It is more common in girls, and the incidence peaks during puberty. The disease is caused by an autoimmune attack on the thyroid. Increased risk of thyroid autoimmunity (and other endocrine autoimmune disorders) is associated with certain histocompatibility alleles. The following conditions are associated with increased risk for autoimmune (Hashimoto) thyroiditis: Down syndrome, Turner syndrome, celiac disease, vitiligo, alopecia, and type 1 diabetes.

» Clinical Findings

A. Symptoms and Signs

The thyroid is characteristically enlarged, firm, freely movable, nontender, and symmetrical. It may be nodular. Onset is usually insidious. Occasionally patients note a sensation of tracheal compression or fullness, hoarseness, and dysphagia. No local signs of inflammation or systemic infection are present. Most patients are euthyroid. Some patients are symptomatically hypothyroid, and few patients are symptomatically hyperthyroid. A detailed family history may reveal the presence of multiple autoimmune diseases in family members. Individuals at a high risk based on a chromosomal disorder or other autoimmune disease benefit from careful monitoring of growth and development, routine screening (in the case of Down syndrome, Turner syndrome, and type 1 diabetes), and a low threshold for measurement of thyroid function.

B. Laboratory Findings

Laboratory findings vary. Serum concentrations of TSH, T_4, and FT_4 are usually normal. Some patients are hypothyroid with an elevated TSH and low thyroid hormone levels. A few patients are hyperthyroid with a suppressed TSH and elevated thyroid hormone levels. Thyroid antibodies (antithyroglobulin, antithyroid peroxidase) are frequently elevated. Thyroid uptake scan adds little to the diagnosis. Surgical or needle biopsy is diagnostic but seldom necessary.

» Treatment

There is controversy about the need to treat chronic lymphocytic thyroiditis with normal thyroid function. Full replacement doses of thyroid hormone may decrease the size of the thyroid, but may also result in hyperthyroidism. Hypothyroidism commonly develops over time. Consequently, patients require lifelong surveillance. Children with documented hypothyroidism should receive thyroid hormone replacement.

2. Acute (Suppurative) Thyroiditis

Acute thyroiditis is rare. The most common causes are group A streptococci, pneumococci, Staphylococcus aureus, and anaerobes. Thyroid abscesses may form. The patient is toxic with fever and chills. The thyroid gland is enlarged and exquisitely tender with associated erythema, hoarseness, and dysphagia. Thyroid function tests are typically normal. Patients have a leukocytosis, "left shift," and elevated erythrocyte sedimentation rate. Specific antibiotic therapy should be administered.

3. Subacute (Nonsuppurative) Thyroiditis

Subacute thyroiditis (de Quervain thyroiditis) is rare. It is thought to be caused by viral infection with mumps, influenza, echovirus, coxsackievirus, Epstein-Barr virus, or adenovirus. Presenting features are similar to acute thyroiditis—fever, malaise, sore throat, dysphagia, and thyroid pain that may radiate to the ear. The thyroid is firm and enlarged. Sedimentation rate is elevated. In contrast to acute thyroiditis, the onset is generally insidious and serum thyroid hormone concentrations may be elevated.

HYPERTHYROIDISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nervousness, emotional lability, hyperactivity, fatigue, tremor, palpitations, excessive appetite, weight loss, increased perspiration, and heat intolerance.
- Goiter, exophthalmos, tachycardia, widened pulse pressure, systolic hypertension, weakness, and smooth, moist, warm skin.
- TSH is suppressed. Thyroid hormone levels (T_4, FT_4, T_3, T_3 resin uptake [T_3RU]) are elevated.

» General Considerations

In children, most cases of hyperthyroidism are due to Graves disease, caused by antibodies directed at the TSH receptor that stimulate thyroid hormone production. Other causes include thyroiditis (acute, subacute, or chronic); autonomous functioning thyroid nodules; tumors producing TSH; McCune-Albright syndrome; exogenous thyroid hormone excess; and acute iodine exposure.

» Clinical Findings

A. Symptoms and Signs

Hyperthyroidism is more common in females than males. In children, it most frequently occurs during adolescence. The course of hyperthyroidism tends to be cyclic, with spontaneous remissions and exacerbations. Symptoms include poor concentration, hyperactivity, fatigue, emotional labiality, personality disturbance/unmasking of underlying psychosis, insomnia, weight loss (despite increased appetite), palpitations, heat intolerance, increased perspiration, increased stool frequency, polyuria, and irregular menses. Signs include tachycardia, systolic hypertension, increased pulse pressure, tremor, proximal muscle weakness, and moist, warm, skin. Accelerated growth and development may occur. Thyroid storm is a rare condition characterized by fever, cardiac failure, emesis, and delirium that can result in coma or death. Most cases of Graves disease are associated with a diffuse firm goiter. A thyroid bruit and thrill may be present. Many cases are associated with exophthalmos.

B. Laboratory Findings

TSH is suppressed. T_4, FT_4, T_3, and free T_3 (FT_3) are elevated except in rare cases in which only the serum T_3 is elevated (T_3 thyrotoxicosis). The presence of thyroid-stimulating immunoglobulin (TSI) or thyroid eye disease confirms the diagnosis of Graves disease. TSH receptor–binding antibodies (TRaB) are usually elevated.

C. Imaging

Radioactive iodine uptake by the thyroid is increased in Graves disease, whereas in subacute and chronic thyroiditis it is decreased. An autonomous hyperfunctioning nodule takes up iodine and appears as a "hot nodule" while the surrounding tissue has decreased iodine uptake. In children with hyperthyroidism, bone age may be advanced. In infants, accelerated skeletal maturation may be associated with premature fusion of the cranial sutures. Long-standing hyperthyroidism causes osteoporosis.

» Treatment

A. General Measures

Strenuous physical activity should be avoided in untreated hyperthyroidism.

B. Medical Treatment

1. β-Adrenergic blocking agents—These are adjuncts to therapy. They can rapidly ameliorate symptoms and are indicated in severe disease with tachycardia and hypertension. β_1-Specific agents such as atenolol are preferred because they are more cardioselective. Propranolol also decreases conversion of T_4 to active T_3, so is preferred in severe cases/thyrotoxicosis.

2. Antithyroid agents (methimazole)—Antithyroid agents are frequently used in the initial treatment of childhood hyperthyroidism. These drugs interfere with thyroid hormone synthesis, and usually take a few weeks to produce a clinical response. Adequate control is usually achieved within a few months. If medical therapy is unsuccessful, more definitive therapy, such as radioablation of the thyroid or thyroidectomy, should be considered.

Although methimazole is the drug of choice, propylthiouracil (PTU) is still available. However, there are reports of severe hepatotoxicity related to PTU.

a. Initial dosage—Methimazole is initiated at a dose of 10–60 mg/d (0.5–1 mg/kg/d) given once a day. Initial dosing is continued until FT_4 or T_4 have normalized and signs and symptoms have subsided.

b. Maintenance—The optimal dose of antithyroid agent for maintenance treatment remains unclear. Recent studies suggest that 10–15 mg/d of methimazole provides adequate long-term control in most patients with a minimum of side effects. If the TSH becomes elevated, many providers decrease the dose of the antithyroid agent; others continue the same dose of antithyroid agent and add exogenous thyroid hormone replacement. Treatment usually continues for 2 years with the goal of inducing remission. If thyroid hormone levels are stable at that point, a trial off medication could be considered.

c. Toxicity—If vasculitis, arthralgia, arthritis, granulocytopenia, or hepatitis occur, the drug must be discontinued. Urticarial rash can sometimes be treated symptomatically.

3. Iodide—Large doses of iodide usually produce a rapid but short-lived blockade of thyroid hormone synthesis and release. This approach is recommended only for acute management of severely thyrotoxic patients.

C. Radiation Therapy

Radioactive iodine ablation of the thyroid is usually reserved for children with Graves disease who do not respond to antithyroid agents, develop adverse effects from the antithyroid agents, fail to achieve remission after several years of medical therapy, or have poor medication adherence. Antithyroid agents should be discontinued 4–7 days prior to radioiodine treatment to allow radioiodine uptake by the thyroid. ^{131}I is administered orally, concentrating in the thyroid and resulting in decreased thyroid activity. In the first 2 weeks following radioiodine treatment, hyperthyroidism may worsen as thyroid tissue is destroyed and thyroid hormone is released and temporary therapy with a β-adrenergic antagonist or methimazole may be necessary. In most cases, hypothyroidism develops and thyroid hormone replacement is needed. Long-term follow-up studies have not shown any increased incidence of thyroid cancer, leukemia, infertility, or birth defects when ablative doses of ^{131}I were used.

D. Surgical Treatment

Subtotal and total thyroidectomies are infrequently used in children with Graves disease. Surgery is indicated for extremely large goiters, goiters with a suspicious nodule, very young or pregnant patients, or patients refusing radioiodine ablation. Before surgery, a β-adrenergic blocking agent is given to treat symptoms, and antithyroid agents are given for several weeks to minimize the surgical risks associated with hyperthyroidism. Iodide (eg, Lugol solution, one drop every 8 hours, or saturated solution of potassium iodide, one to two drops daily) is given for 1–2 weeks prior to surgery to reduce thyroid vascularity and inhibit release of thyroid hormone. Surgical complications include severe hypocalcemia due to hypoparathyroidism and recurrent laryngeal nerve damage. An experienced thyroid surgeon is crucial to good surgical outcome. After thyroidectomy, patients become hypothyroid and need thyroid hormone replacement.

» Course & Prognosis

Partial remissions and exacerbations may continue for several years. Treatment with an antithyroid agent results in prolonged remissions in one-third to two-thirds of children.

» Neonatal Graves Disease

Transient congenital hyperthyroidism (neonatal Graves disease) occurs in about 1% of infants born to mothers with Graves disease. It occurs when maternal TSH receptor antibodies cross the placenta and stimulate excess thyroid hormone production in the fetus and newborn. Neonatal Graves disease can be associated with irritability, intrauterine growth retardation (IUGR), poor weight gain, flushing, jaundice, hepatosplenomegaly, and thrombocytopenia. Severe cases may result in cardiac failure and death. Hyperthyroidism may develop several days after birth. Thyroid studies should be obtained at birth and repeated within the first week. Immediate management should focus on the cardiac manifestations. Temporary treatment may be necessary with iodide, antithyroid agents, β-adrenergic antagonists, or corticosteroids. Hyperthyroidism gradually resolves over 1–3 months as maternal antibodies decline. As TSH receptor antibodies may still be present in the serum of previously hyperthyroid mothers after thyroidectomy or radioablation, neonatal Graves disease should be considered in all infants of mothers with a history of hyperthyroidism.

THYROID CANCER

Thyroid cancer is rare in childhood. Children usually present with a thyroid nodule or an asymptomatic asymmetrical neck mass. Dysphagia and hoarseness are unusual

symptoms. Thyroid function tests are usually normal. A "cold" nodule is often seen on a technetium or radioiodine uptake scan of the thyroid. Fine-needle aspiration biopsy of the nodule assists in the diagnosis.

The most common thyroid cancer is papillary thyroid carcinoma, a well-differentiated carcinoma arising from the thyroid follicular cell. Children frequently present with local metastases to the cervical lymph nodes and occasionally with pulmonary metastases. Despite its aggressive presentation, children with papillary thyroid carcinoma have a relatively good prognosis, with a 20-year survival rate greater than 90%. Treatment consists of total thyroidectomy and removal of all involved lymph nodes, usually followed by radioiodine ablation to destroy residual thyroid remnant and metastatic tissue left behind after surgery. Thyroid hormone replacement is started to suppress TSH stimulation of residual thyroid tissue and to treat the hypothyroidism that results from surgical removal of the thyroid gland. Since papillary thyroid carcinoma in children is associated with a high recurrence rate, regular follow-up with serum thyroglobulin levels (a tumor marker), neck ultrasound, and radioiodine whole body scan are required.

Follicular thyroid carcinoma, medullary thyroid carcinoma, anaplastic carcinoma, and lymphoma are less common thyroid malignancies. Medullary thyroid carcinoma, due to autosomal dominant mutations in the RET proto-oncogene, arises from the thyroid C cells, which secrete calcitonin, and it is associated with elevated serum calcitonin levels. It can occur sporadically or be inherited in multiple endocrine neoplasia (MEN) type 2 and familial medullary thyroid carcinoma. In affected families, all members should be screened for the mutation, and those identified with the mutation should be treated with prophylactic thyroidectomy in early childhood.

DISORDERS OF CALCIUM & PHOSPHORUS METABOLISM

Serum calcium concentration is tightly regulated by the coordinated actions of the parathyroid glands, kidney, liver, and small intestine. Low serum calcium concentrations, detected by calcium-sensing receptors on the surface of parathyroid cells, stimulate parathyroid hormone (PTH) release. PTH in turn promotes release of calcium and phosphorus from the bone, reabsorption of calcium from the urinary filtrate, and excretion of phosphorus in the urine. Another essential cofactor in calcium homeostasis is 1,25-dihydroxy vitamin D (calcitriol). The first step in production of this active form of vitamin D occurs in the liver where dietary vitamin D is hydroxylated to 25-hydroxy vitamin D. The final step in formation of calcitriol is 1-hydroxylation, which takes place in the kidney under control of PTH. The primary effect of calcitriol is to promote the absorption of calcium from the intestines. In concert with PTH, however, it also facilitates calcium and phosphorus mobilization from bones. Deficiencies or excesses of PTH or calcitriol, abnormalities in their receptors, or abnormalities of vitamin D metabolism lead to clinically significant aberrations in calcium homeostasis. Although calcitonin, released from the thyroid gland C cells, also reduces serum calcium concentration, changes in its serum concentration rarely cause clinically relevant disease.

HYPOCALCEMIC DISORDERS

A normal serum calcium concentration is approximately 8.9–10.2 mg/dL. The normal concentration of ionized calcium is approximately 1.1–1.3 mmol/L. Serum calcium levels in newborns, which are slightly lower than in older children and adults, may be as low as 7 mg/dL in premature infants. Fifty to sixty percent of calcium in the serum is protein-bound and metabolically fairly inactive. Thus, measurement of ionized serum calcium, the metabolically active form, is helpful if serum proteins are low or in conditions such as acidosis that cause abnormal calcium binding to protein.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Tetany with facial and extremity numbness, tingling, cramps, spontaneous muscle contractures, carpopedal spasm, positive Trousseau and Chvostek signs, loss of consciousness, and convulsions.
- Diarrhea, prolongation of electrical systole (QT interval), and laryngospasm.
- In hypoparathyroidism or pseudohypoparathyroidism (PHP): defective nails and teeth, cataracts, and ectopic calcification in the subcutaneous tissues and basal ganglia.

General Considerations

Hypocalcemia is a consistent feature of conditions such as hypoparathyroidism, PHP, transient neonatal hypoparathyroidism, and severe vitamin D deficiency rickets, and may

be present in rare disorders of vitamin D action (receptor defects). Causes of rickets are outlined in Table 34–5. Other causes of hypocalcemia include the following:

- Intestinal malabsorption of calcium (may be exacerbated by malabsorption of vitamin D, magnesium)
- Chronic renal disease
- Tumor lysis syndrome, rhabdomyolysis (due to cellular destruction that liberates large amounts of intracellular phosphate that complex with serum calcium)
- Activating mutation in the calcium-sensing receptor of the parathyroid glands and kidneys (hypercalciuric hypocalcemia)
- Hypoparathyroidism

Deficient PTH secretion may be due to deficient parathyroid tissue (DiGeorge syndrome), autoimmunity, or sometimes, magnesium deficiency. Decreased PTH action may be due to magnesium deficiency, vitamin D deficiency, or defects in the PTH receptor (PHP). Occasionally, PTH deficiency is idiopathic. Table 34–6 summarizes the clinical and laboratory characteristics of disorders of PTH secretion and action.

Autoimmune parathyroid destruction with subsequent hypoparathyroidism may be isolated, or associated with other autoimmune disorders in the APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, or APS-1) syndrome. Hypoparathyroidism may also result from unavoidable surgical removal in patients with thyroid cancer. Autosomal dominant hypocalcemia, also called familial hypercalciuric hypocalcemia, is associated with a gain-of-function mutation in the calcium receptor, which causes a low serum PTH despite hypocalcemia, and excessive urinary loss of calcium. A family history of hypocalcemia may be the clue that differentiates this condition from other causes of hypocalcemia.

Transient neonatal hypoparathyroidism is caused both by a relative deficiency of PTH secretion and PTH action (see Table 34–6). In the early form, associated hypomagnesemia often aggravates hypoparathyroidism due to magnesium's role in facilitating PTH secretion. The late form of neonatal hypoparathyroidism (after 2 weeks of age) occurs in infants receiving high-phosphate formulas (whole cow's milk is a well-known example) due to intestinal calcium-phosphate binding, resulting in decreased absorption.

Rickets describes characteristic clinical and bony radiologic features associated with hypophosphatemia (see Chapter 11). Vitamin D deficiency, caused by lack of sunlight exposure or dietary deficiency, is the most common cause of rickets. Recently, high rates of occult vitamin D deficiency have formed the basis for the 2008 recommendation by the American Academy of Pediatrics that breast-fed infants receive vitamin D supplementation of at least 400 IU/d. See Table 34–5 for features of other causes of rickets.

Familial hypophosphatemic rickets occurs due to abnormal renal phosphate loss related to abnormal fibroblast growth factor 23 (FGF23) regulation.

» Clinical Findings

A. Symptoms and Signs

Prolonged hypocalcemia from any cause is associated with tetany, photophobia, blepharospasm, and diarrhea. Symptoms of tetany include numbness, muscle cramps, twitching of the extremities, carpopedal spasm, and laryngospasm. Tapping the face in front of the ear causes facial spasms (Chvostek sign). Some patients with hypocalcemia exhibit bizarre behavior, irritability, loss of consciousness, and convulsions. Headache, vomiting, increased intracranial pressure, and papilledema may occur. In early infancy, respiratory distress may be a presenting finding.

B. Laboratory Findings

Tables 34–5 and 34–6 outline the specific laboratory findings in various causes of hypocalcemia. Magnesium levels may also be low. Measurement of urinary excretion of calcium (calcium-creatinine ratio) can assist in diagnosis and monitoring of therapy in children on calcitriol therapy.

C. Imaging

Soft tissue and basal ganglia calcification may occur in idiopathic hypoparathyroidism and PHP. Various skeletal changes are associated with rickets, including cupped and irregular long bone metaphyses. Torsional deformities can result in genu varum (bowleg). Accentuation of the costochondral junction gives the rachitic rosary appearance seen on the chest wall.

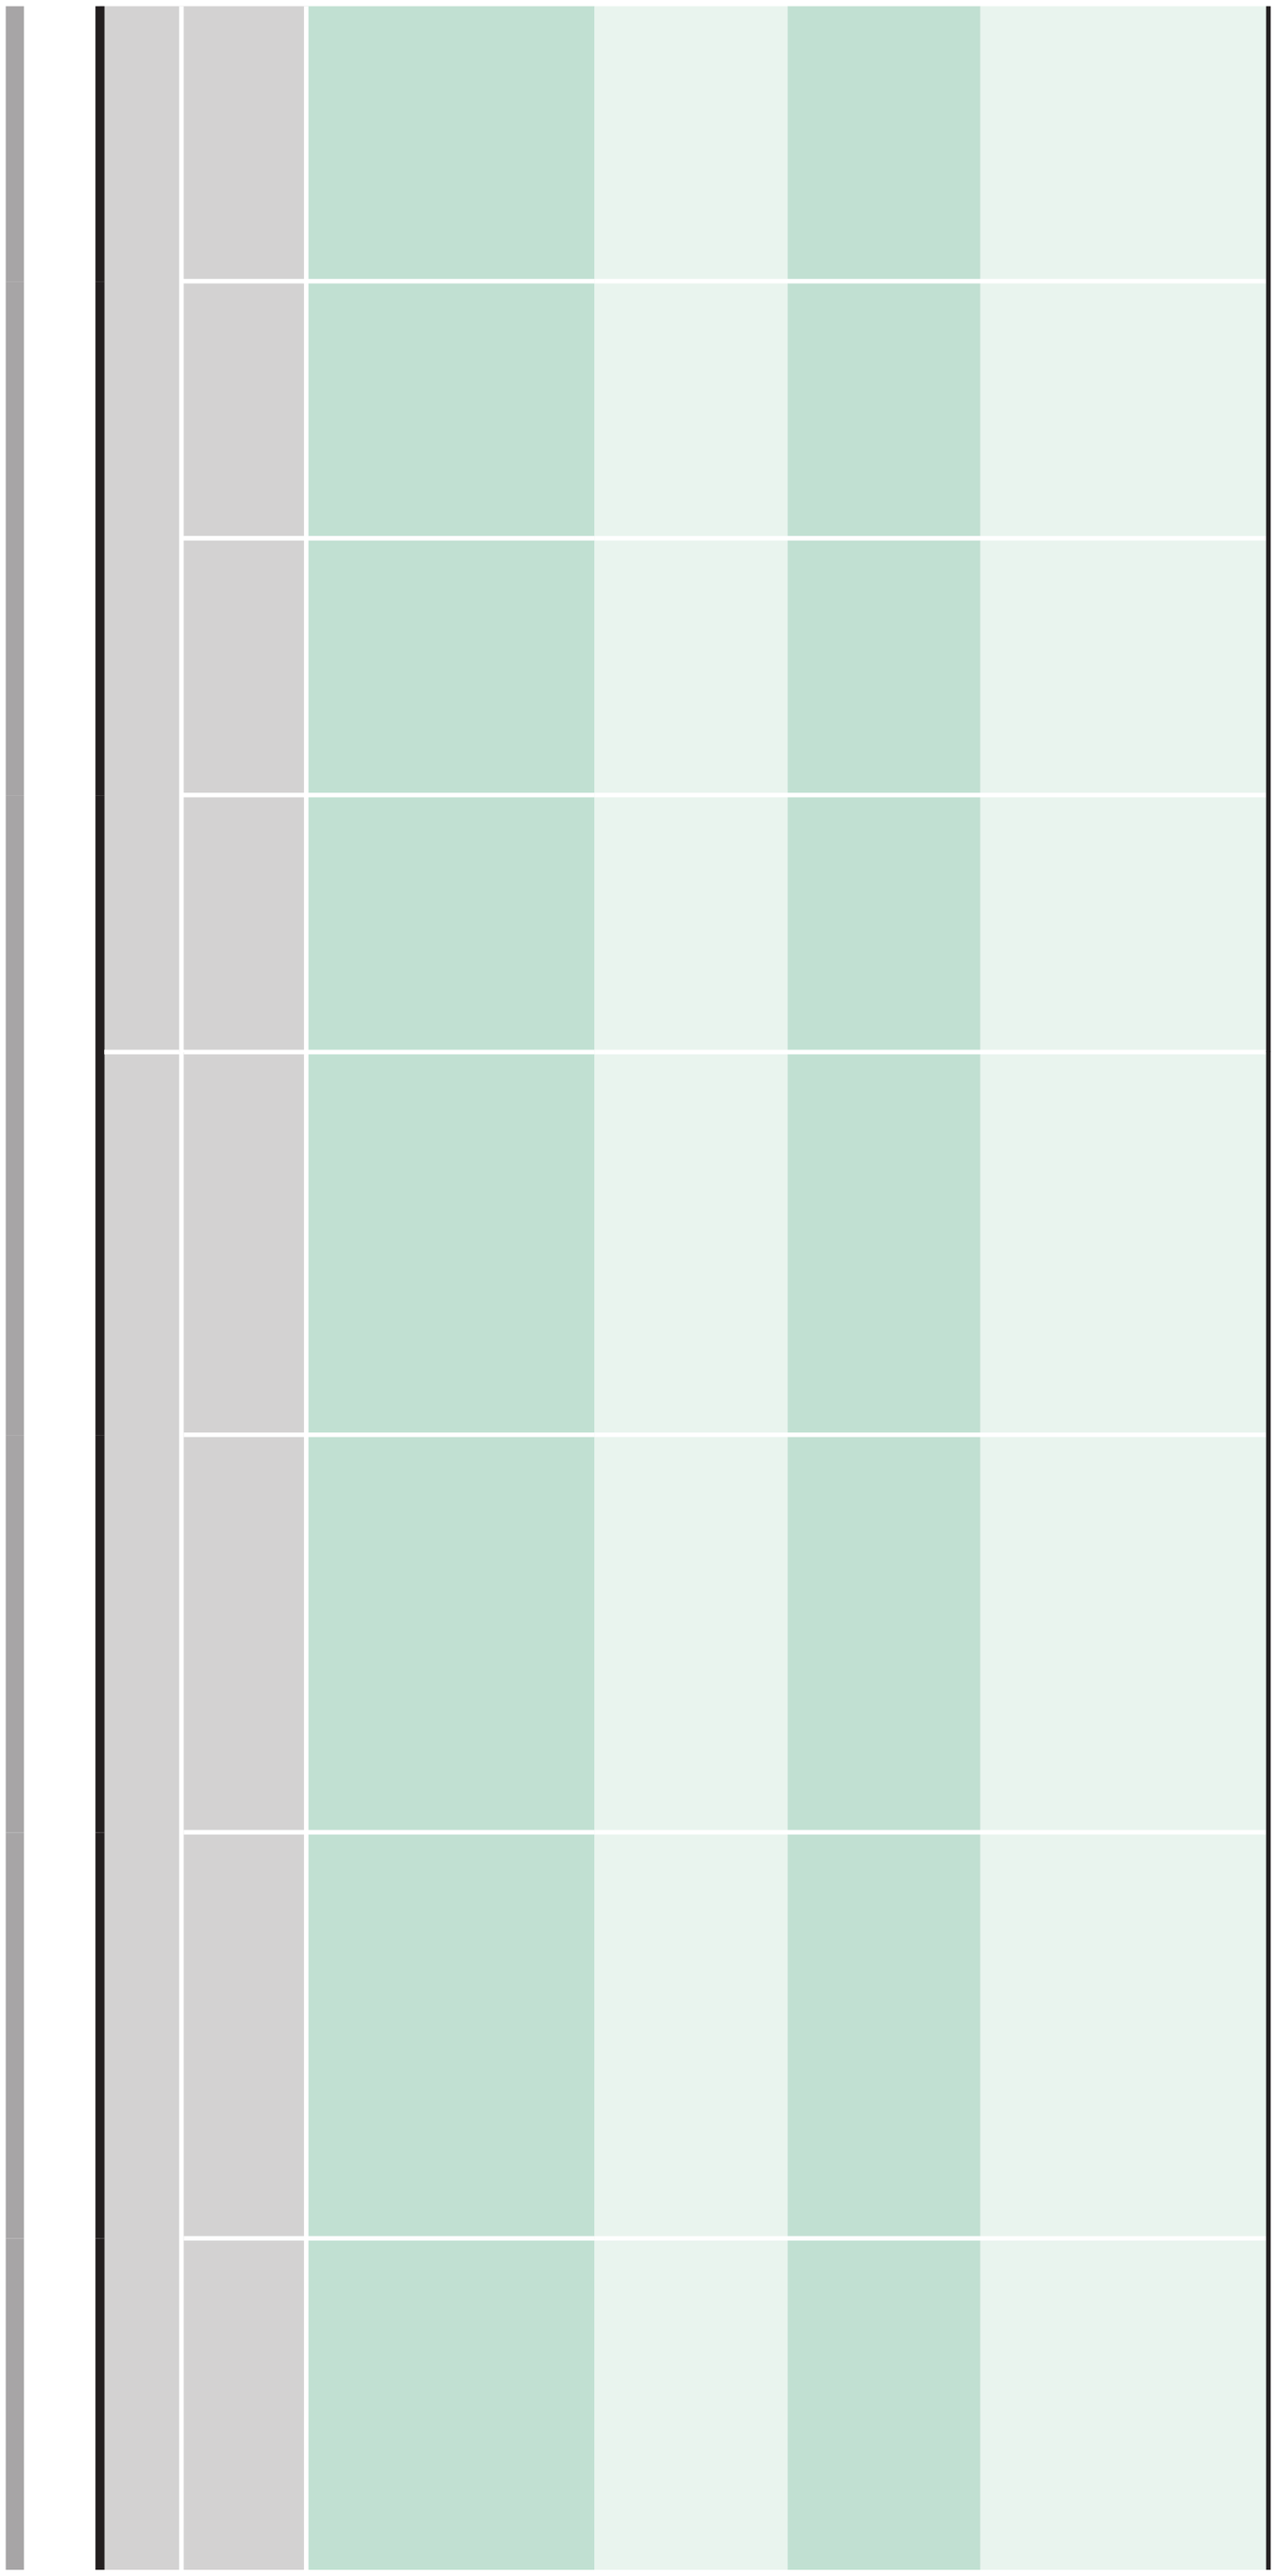
» Differential Diagnosis

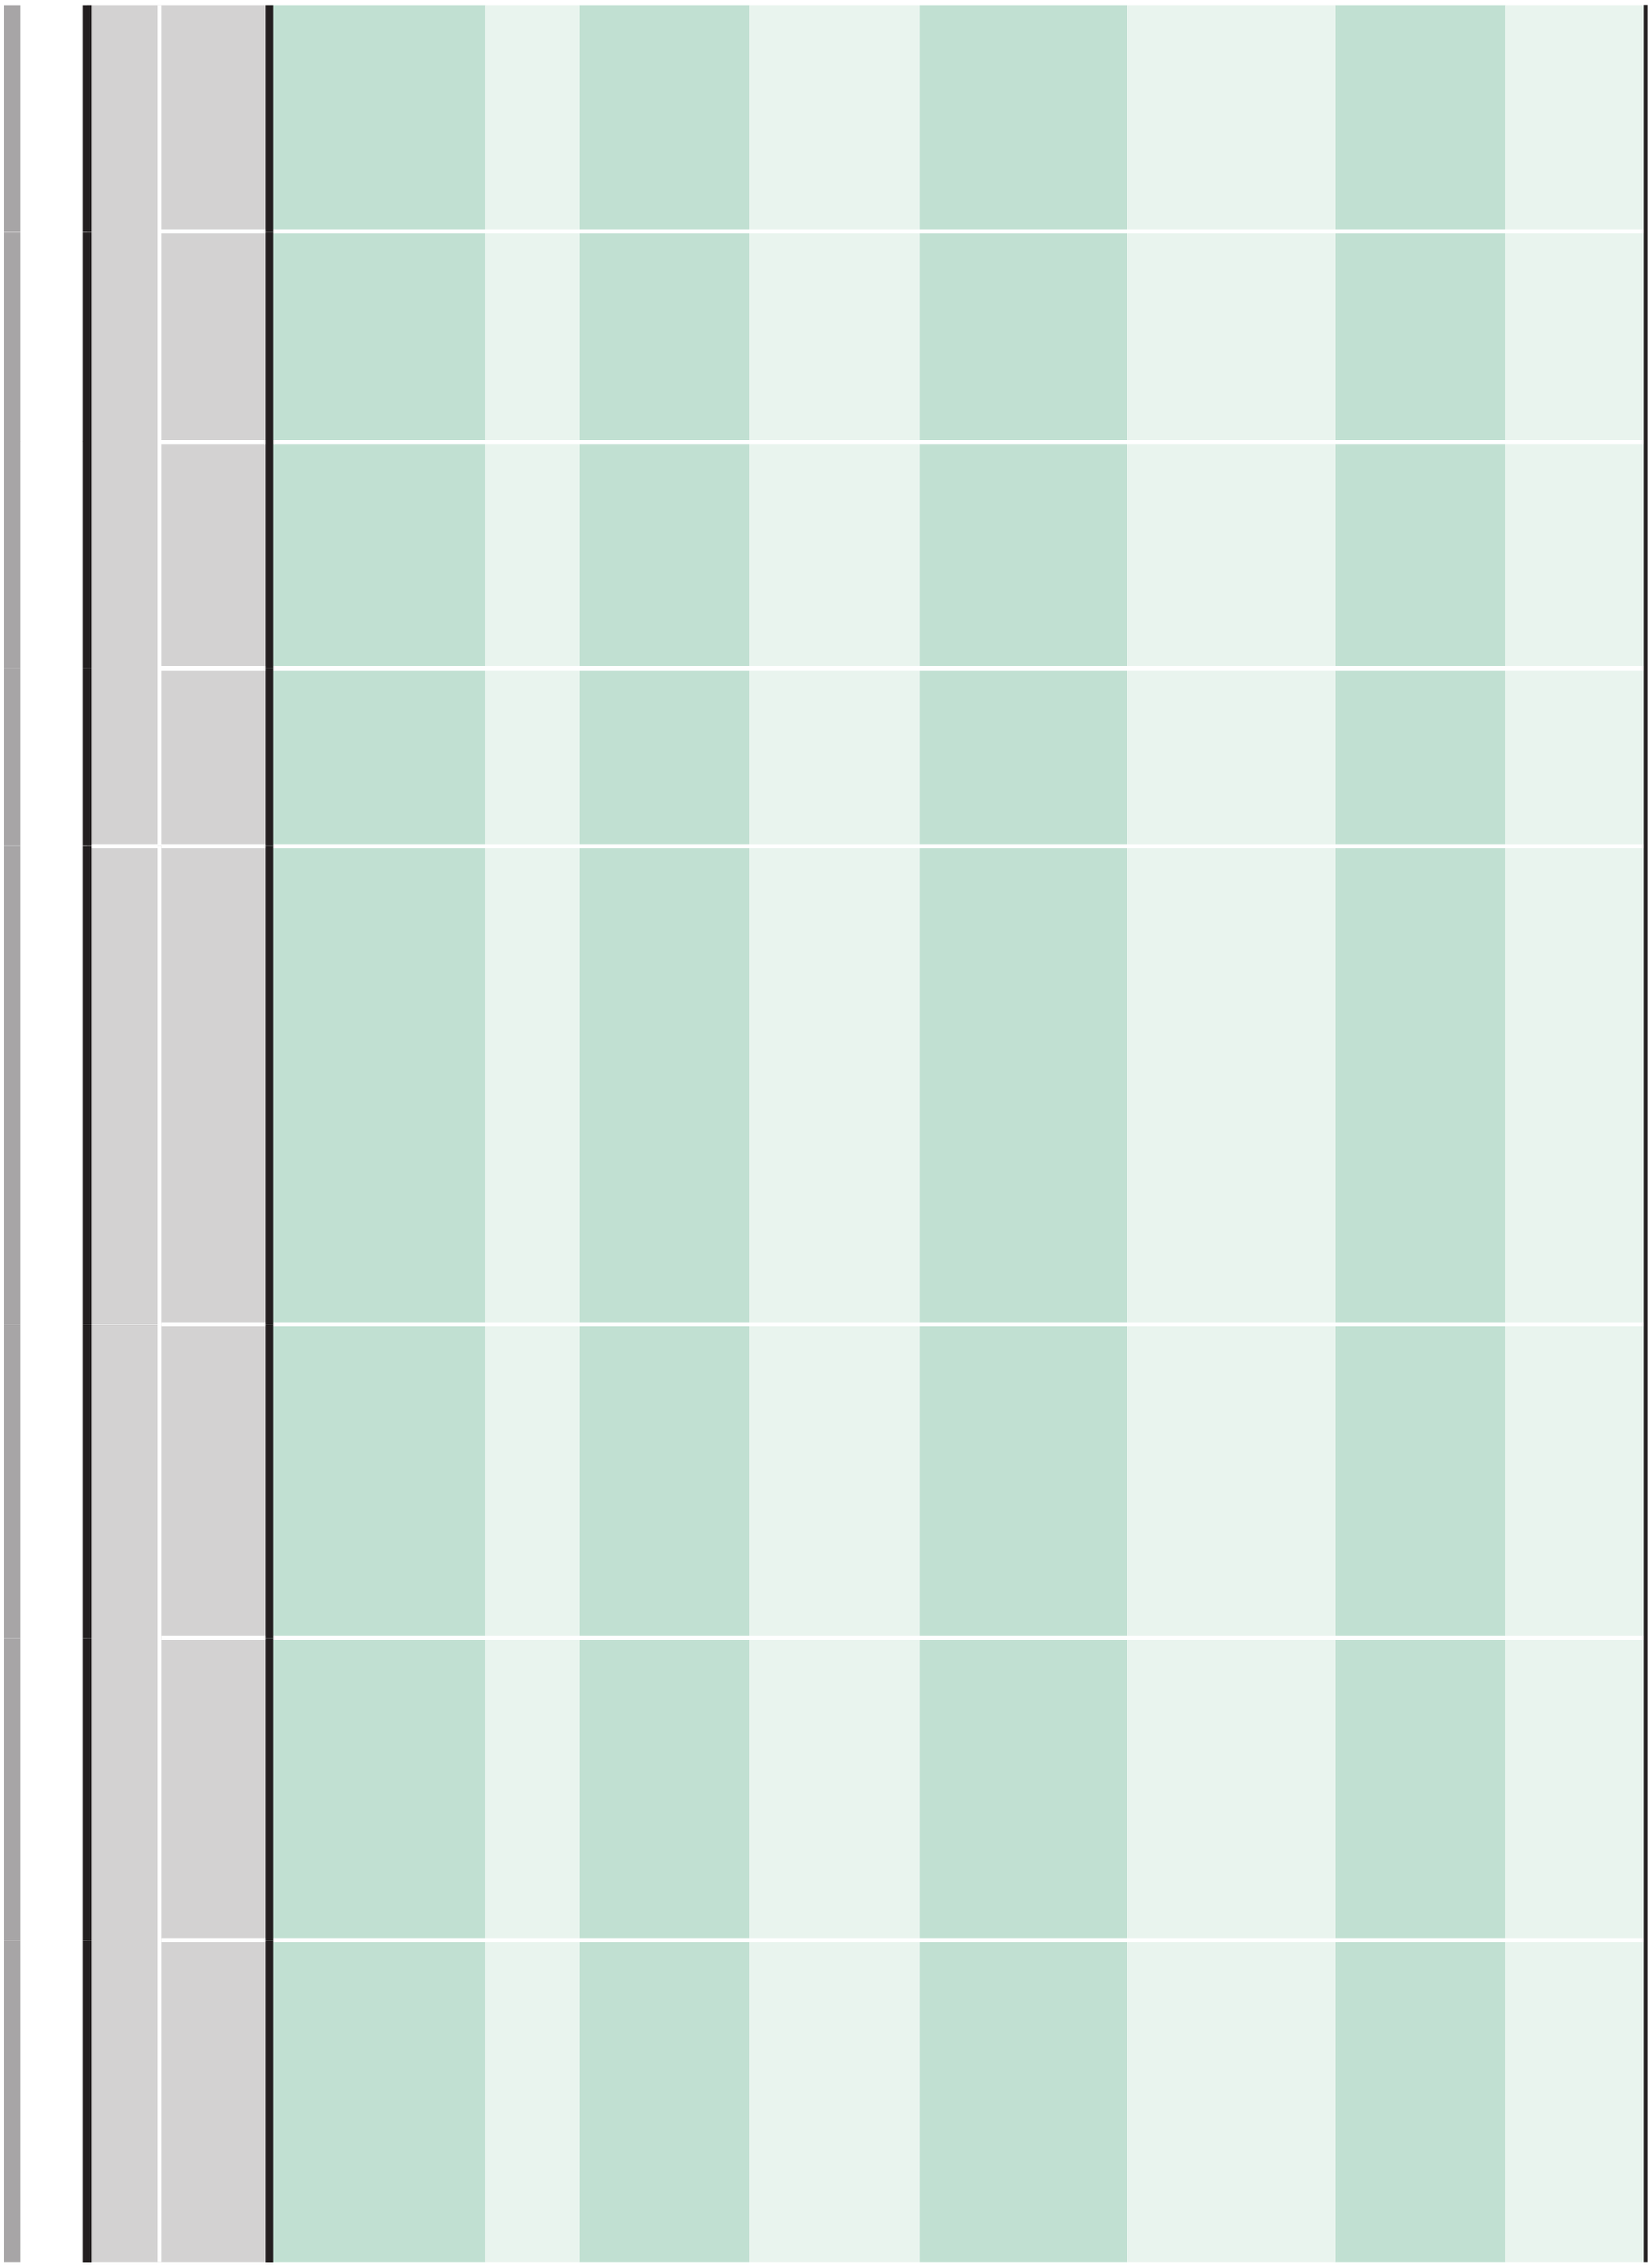
Tables 34–5 and 34–6 outline the features of disorders associated with hypocalcemia. In individuals with hypoalbuminemia, the total serum calcium may be low and yet the functional serum ionized calcium is normal. Ionized calcium is the test of choice for hypocalcemia in patients with low serum albumin.

» Treatment

A. Acute or Severe Tetany

Symptoms are treated acutely by administration of intravenous calcium gluconate or calcium chloride at a dose of 10 mg/kg. Intravenous calcium infusions should not exceed 50 mg/min because of possible cardiac arrhythmia. Cardiac monitoring should be performed during calcium infusion.





B. Maintenance Management of Hypoparathyroidism or Chronic Hypocalcemia

The objective of treatment is to maintain the serum calcium and phosphate at near-normal levels without excess urinary calcium excretion.

1. Diet—Calcium supplementation should start at a dose of 50–75 mg of elemental calcium per kilogram per day divided in three to four doses. Supplemental calcium can often be discontinued in patients with rickets after vitamin D therapy has stabilized.

2. Vitamin D supplementation—Ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) are the most commonly used oral vitamin D preparations. Cholecalciferol is slightly more active than ergocalciferol. Calcitriol (1,25-dihydroxy vitamin D_3) supplementation is recommended for impaired metabolism of dietary vitamin D to 25-OH vitamin D as seen in hepatic dysfunction, or to its active end product, 1,25-dihydroxy vitamin D, or impaired PTH function. Selection and dosage of vitamin D supplements varies with the underlying condition and the response to therapy.

3. Monitoring—Dosage of calcium and vitamin D must be tailored for each patient. Monitoring serum calcium, urine calcium, and serum alkaline phosphatase levels at 1- to 3-month intervals is necessary to ensure adequate therapy and to prevent hypercalcemia, hypercalciuria/nephrocalcinosis, and vitamin D toxicity.

The major goals of monitoring in vitamin D deficiency are to ensure: (1) maintenance of serum calcium and phosphorus concentrations within normal ranges; (2) normalization of alkaline phosphatase activity for age; (3) regression of skeletal changes; (4) maintenance of an age-appropriate urine calcium-creatinine ratio. The ratio should be less than 0.8 in newborns, 0.3–0.6 in children, and less than 0.25 in adolescents (when using creatinine and calcium measured in milligrams per deciliter).

Monitoring goals are somewhat different in hypophosphatemic rickets. Serum calcium and alkaline phosphatase, and urinary calcium to creatinine ratio should be maintained within normal limits. Monitoring of serum PTH is necessary to ensure that secondary hyperparathyroidism does not develop from excessive phosphate treatment or inadequate calcitriol replacement.

PSEUDOHYPOPARATHYROIDISM (RESISTANCE TO PARATHYROID HORMONE ACTION)

In PHP, PTH production is adequate, but target organs (renal tubule, bone, or both) fail to respond because of receptor resistance. Resistance to PTH action is due to a heterozygous inactivating mutation in the stimulatory G protein subunit associated with the PTH receptor, which leads to impaired signaling. Resistance to other G protein–dependent hormones such as TSH, GHRH, and follicle-stimulating hormone (FSH)/luteinizing hormone (LH), may also be present.

There are several types of PHP with variable biochemical and phenotypic features (see Table 34–6). Biochemical abnormalities in PHP (hypocalcemia and hyperphosphatemia) are similar to those seen in hypoparathyroidism, but the PTH levels are elevated. PHP may be accompanied by a characteristic phenotype known as Albright hereditary osteodystrophy (AHO), which includes short stature; round, full facies; irregularly shortened fourth metacarpal; a short, thick-set body; delayed and defective dentition; and mild mental retardation. Corneal and lenticular opacities and ectopic calcification of the basal ganglia and subcutaneous tissues (osteoma cutis) may occur with or without abnormal serum calcium levels. Treatment is the same as for hypoparathyroidism.

Pseudo-pseudohypoparathyroidism (PPHP) describes individuals with the AHO phenotype, but normal calcium homeostasis. PHP and PPHP can occur in the same cohort. Genomic imprinting is probably responsible for the different phenotypic expression of disease. Heterozygous loss of the maternal allele causes PHP and heterozygous loss of the paternal allele causes PPHP.

HYPERCALCEMIC STATES

Hypercalcemia is defined as a serum calcium level greater than 11 mg/dL. Severe hypercalcemia is a level greater than 13.5 mg/dL.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal pain, polyuria, polydipsia, hypertension, nephrocalcinosis, failure to thrive, renal stones, intractable peptic ulcer, constipation, uremia, and pancreatitis.
- Bone pain or pathologic fractures, subperiosteal bone resorption, renal parenchymal calcification or stones, and osteitis fibrosa cystica.
- Impaired concentration, altered mental status, mood swings, and coma.

» General Considerations

More than 80% of hypercalcemic children or adolescents have either hyperparathyroidism or a malignant tumor. Table 34–7 summarizes the differential diagnosis of childhood hypercalcemia.

Hyperparathyroidism is rare in childhood and may be primary or secondary. The most common cause of primary hyperparathyroidism is parathyroid adenoma. Familial hyperparathyroidism may be an isolated disease, or it may be associated with MEN type 1, or rarely type 2A. Hypercalcemia of malignancy is associated with solid and hematologic malignancies and is due either to local destruction of bone by tumor or to ectopic secretion of PTH-related protein. When ectopic PTH-related protein is present, calcium is elevated, serum PTH is suppressed, and serum PTH–related protein is elevated. Chronic renal disease with impaired phosphate excretion is the most common secondary cause of hyperparathyroidism.

Belcher R, Metrailer AM, Bodenner DL, Stack BC Jr: Characterization of hyperparathyroidism in youth and adolescents: a literature review [Review]. Int J Pediatr Otorhinolaryngol 2013 Mar;77(3):318–322 [PMID: 23313432].

Table 34–7. Hypercalcemic states.

A. Primary hyperparathyroidism
1. Parathyroid hyperplasia
2. Parathyroid adenoma
3. Familial, including MEN types 1 and 2
4. Ectopic PTH secretion
B. Other hypercalcemic states resulting from increased intestinal or renal absorption of calcium
1. Hypervitaminosis D (including idiopathic hypercalcemia of infancy)
2. Familial hypocalciuric hypercalcemia
3. Lithium therapy
4. Sarcoidosis
5. Phosphate depletion
6. Aluminum intoxication
7. Subcutaneous fat necrosis (due to vitamin D activation)
C. Other hypercalcemic states resulting from increased mobilization of bone minerals
1. Hyperthyroidism
2. Immobilization
3. Thiazides
4. Vitamin A intoxication
5. Malignant neoplasms
a. Ectopic PTH secretion or PTH-related protein (PTHRP)
b. Prostaglandin-secreting tumors
c. Tumors metastatic to bone
d. Myeloma

MEN, multiple endocrine neoplasia; PTH, parathyroid hormone.

» Clinical Findings

A. Symptoms and Signs

1. Due to hypercalcemia—Manifestations include hypotonicity and muscle weakness; apathy, mood swings, and bizarre behavior; nausea, vomiting, abdominal pain, constipation, and weight loss; hyperextensibility of joints; and hypertension, cardiac irregularities, bradycardia, and shortening of the QT interval. Coma occurs rarely. Calcium deposits occur in the cornea or conjunctiva (band keratopathy) and are detected by slit-lamp examination. Intractable peptic ulcer and pancreatitis occur in adults but rarely in children.

2. Due to Increased calcium and phosphate excretion—Loss of renal concentrating ability causes polyuria, polydipsia, and calcium phosphate deposition in renal parenchyma or as urinary calculi with progressive renal damage.

3. Due to changes in the skeleton—Initial findings include bone pain, osteitis fibrosa cystica, subperiosteal bone absorption in the distal clavicles and phalanges, absence of lamina dura around the teeth, spontaneous fractures, and moth-eaten appearance of the skull on radiographs. Later, there is generalized demineralization with high risk of subperiosteal cortical bone.

B. Imaging

Bone changes may be subtle in children. Technetium sestamibi scintigraphy is preferred over conventional procedures (ultrasound, computed tomography, and MRI) for localizing parathyroid tumors.

» Treatment

A. Symptomatic

Initial management is vigorous hydration with normal saline and forced calcium diuresis with a loop diuretic such as furosemide (1 mg/kg given every 6 hours). If response is inadequate, glucocorticoids or calcitonin may be used. Bisphosphonates, standard agents for the management of acute hypercalcemia in adults, are being used more often in refractory pediatric hypercalcemia.

B. Chronic

Treatment options vary with the underlying cause. Resection of parathyroid adenoma or subtotal removal of hyperplastic parathyroid glands is the preferred treatment.

Postoperatively, hypocalcemia due to the rapid remineralization of chronically calcium-deprived bones may occur. A diet high in calcium and vitamin D is recommended immediately postoperatively and is continued until serum calcium concentrations are normal and stable. Treatment of secondary hyperparathyroidism from chronic renal disease is primarily directed at controlling serum phosphorus levels with phosphate binders. Pharmacologic doses of calcitriol are used to suppress PTH secretion. Long-term therapy for hypercalcemia of malignancy is the treatment of the underlying disorder. There is also an increasing role for bisphosphonates in treatment of chronic hypercalcemia.

» Course & Prognosis

The prognosis after resection of a single adenoma is excellent. The prognosis following subtotal parathyroidectomy for diffuse hyperplasia or removal of multiple adenomas is usually good and depends on correction of the underlying defect. In patients with multiple sites of parathyroid adenoma or hyperplasia, MEN is likely, and other family members may be at risk. Genetic counseling and DNA analysis to determine the specific gene defect are indicated.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA (FAMILIAL BENIGN HYPERCALCEMIA)

Familial hypocalciuric hypercalcemia is distinguished by low to normal urinary calcium excretion as a result of high renal reabsorption of calcium. PTH is normal or slightly elevated. In most cases, the genetic defect is a mutation in the membrane-bound calcium-sensing receptor expressed on parathyroid and renal tubule cells. It is inherited as an autosomal dominant trait with high penetrance. There is a low rate of new mutations. Most patients are asymptomatic, and treatment is unnecessary. A severe form of symptomatic neonatal hyperparathyroidism may occur in infants homozygous for the receptor mutation.

HYPERVITAMINOSIS D

Vitamin D intoxication is almost always the result of ingestion of excessive amounts of vitamin D. Signs, symptoms, and treatment of vitamin D–induced hypercalcemia are the same as those in other hypercalcemic conditions. Treatment depends on the severity of hypercalcemia. Severe hypercalcemia requires hospitalization and aggressive intervention. Due to the storage of vitamin D in the adipose tissue, several months of a low-calcium, low–vitamin D diet may be required.

IDIOPATHIC HYPERCALCEMIA OF INFANCY (WILLIAMS SYNDROME)

Williams syndrome is an uncommon disorder of infancy characterized by elfin-appearing facies and hypercalcemia in infancy. Other features include failure to thrive, mental and motor retardation, cardiovascular abnormalities (primarily supravalvular aortic stenosis), irritability, purposeless movements, constipation, hypotonia, polyuria, polydipsia, and hypertension. A gregarious and affectionate personality is the rule in children with the syndrome. Hypercalcemia may not appear until several months after birth. Treatment consists of restriction of dietary calcium and vitamin D (Calcilo formula) and, in severe cases, moderate doses of glucocorticoids or even bisphosphonates.

A defect in the metabolism of, or responsiveness to, vitamin D is postulated as the cause of Williams syndrome. Elastin deletions localized to chromosome 7 have been identified in more than 90% of patients and is generally identified by fluorescent in situ hybridization (FISH) analysis. The risk of hypercalcemia generally resolves by age 4.

IMMOBILIZATION HYPERCALCEMIA

Abrupt immobilization, particularly in a rapidly growing adolescent, may cause hypercalcemia and hypercalciuria. Abnormalities often appear 1–3 weeks after immobilization. Medical or dietary intervention may be required in severe cases.

HYPOPHOSPHATASIA

Hypophosphatasia is a rare autosomal recessive condition characterized by deficiency of alkaline phosphatase activity in serum, bone, and tissues, resulting from mutations in the gene for tissue-nonspecific isozyme of alkaline phosphatase (TNSALP). Enzyme deficiency leads to poor skeletal mineralization with clinical and radiographic features similar to rickets. Severity ranges from severe skeletal deformity and perinatal death to milder skeletal findings (including craniosynostosis), reduced bone mineral density, and motor delays. Serum calcium levels may be elevated. The diagnosis of hypophosphatasia is made by demonstrating elevated urinary phosphoethanolamine associated with low serum alkaline phosphatase. Standard therapy is supportive care; enzyme-replacement therapy shows promise for improved prognosis.

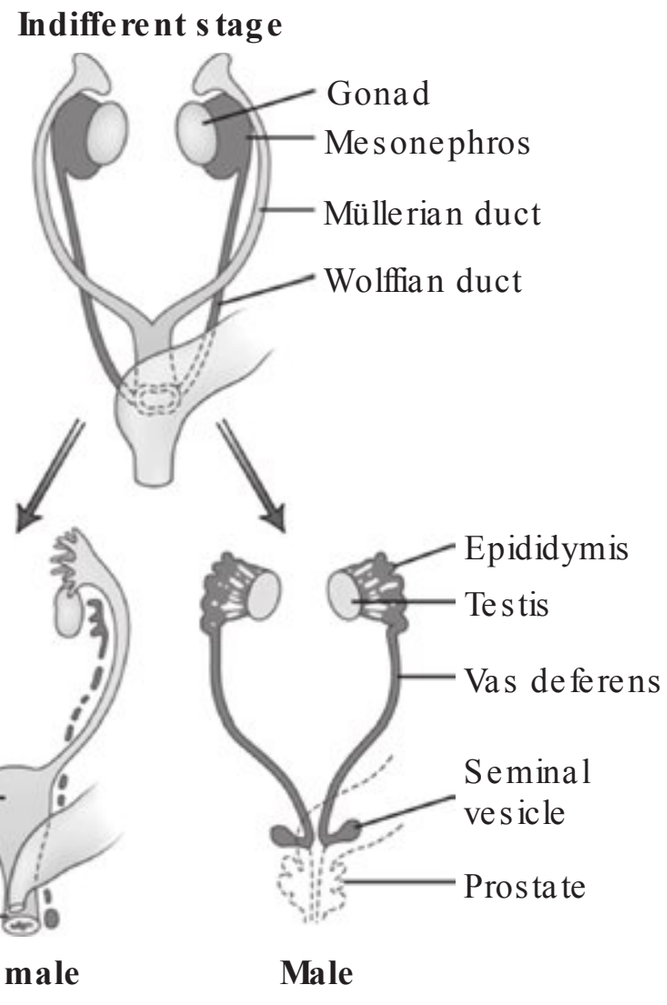
GONADS (OVARIES & TESTES)

DEVELOPMENT

Sex development is a complex process beginning with the differentiation of the bipotential gonad into either a testis or ovary. In an infant with a Y chromosome, expression of the transcription factor SRY initiates a cascade of gene expression that directs the formation of testes. Without expression of SRY, ovaries develop; however, a 46,XX complement of chromosomes, in addition to several unique genes, is necessary for the development of normal ovaries. Secretion of testosterone and antimüllerian hormone (AMH) by the testes results in the development of male internal ducts (epididymis, seminal vesicle, and vas deferens) and regression of the müllerian ducts, which are the precursors of the female internal genital structures (fallopian tubes, uterus, and vagina) (Figure 34–6).

The external genitalia develop from sexually indifferent structures called the genital tubercle, the urethral folds, and the labioscrotal swellings (Figure 34–7). Development of typical male external genitalia depends on an adequate circulating concentration of testosterone and its metabolite dihydrotestosterone (DHT). Sexual differentiation of the external genitalia is completed at about 12 weeks of gestation.



▲**Figure 34–6.** Differentiation of internal reproductive ducts. (Reproduced with permission from Kronenberg H (ed): Williams Textbook of Endocrinology, 11th ed. Saunders Elsevier; 2008.)

DISORDERS OF SEXUAL DEVELOPMENT

Disorders of sex development (DSDs) can arise from alterations in three main processes: gonadal differentiation, steroidogenesis, or androgen action. Many DSDs will be evident in the newborn period, but some will not manifest until later with abnormal pubertal development. In disorders of gonadal differentiation, the testes or ovaries do not develop normally, which results in either ambiguous genitalia or sex reversal. As an example, individuals with 46,XY complete gonadal dysgenesis do not develop normal gonadal tissue (ie have streak gonads), and this results in typical female internal and external reproductive structures. XY partial gonadal dysgenesis is associated with incomplete testes development and usually results in a phenotype of ambiguous genitalia. Mutations in genes important for gonadal differentiation have been demonstrated in many patients with both complete and partial gonadal dysgenesis. Mixed gonadal dysgenesis is usually due to presence of both 45,XO and 46,XY cell lines in the same individual. There is typically a testis on one side and a streak gonad on the contralateral side. Ovotesticular DSD occurs when there is both ovarian and testicular tissue. Steroidogenesis refers to steroid hormone biosynthesis and depends on the function of multiple enzymes (Figure 34–8). Enzymatic defects in this pathway can result in decreased or absent testosterone synthesis and in affected XY individuals, there will be reduced or lack of androgen effects resulting in ambiguous genitalia. Since the gonad and adrenal gland share common enzymes of steroid hormone production, some of the enzymatic defects associated with male undervirilization may also affect production of cortisol and aldosterone, leading to cortisol deficiency and salt wasting. Deficiency of 21-hydroxylase, an enzyme in the cortisol and aldosterone pathways, leads to overproduction of adrenal androgens and the most common form of congenital adrenal hyperplasia. In the classic salt-losing form of this disorder, 46,XX infants present with genital ambiguity due to the excess of adrenal androgen production, but have normal uterus and ovaries.

Disorders of androgen action include the diagnosis of androgen insensitivity syndrome (AIS) which is caused by an inactivating mutation in the androgen receptor gene located on the proximal long arm of the X chromosome. In complete AIS (CAIS), there is no androgen action; thus, 46,XY affected individuals have normal appearing female external genitalia with a short vagina, absent müllerian structures and absence or rudimentary wolffian structures. Gonads are located either intra-abdominally or in the inguinal canal. Many of these individuals present when surgery for an inguinal hernia reveals a testis in the hernia sack. With partial AIS (PAIS), the degree of virilization and ambiguity depends on the degree of abnormality in androgen binding.

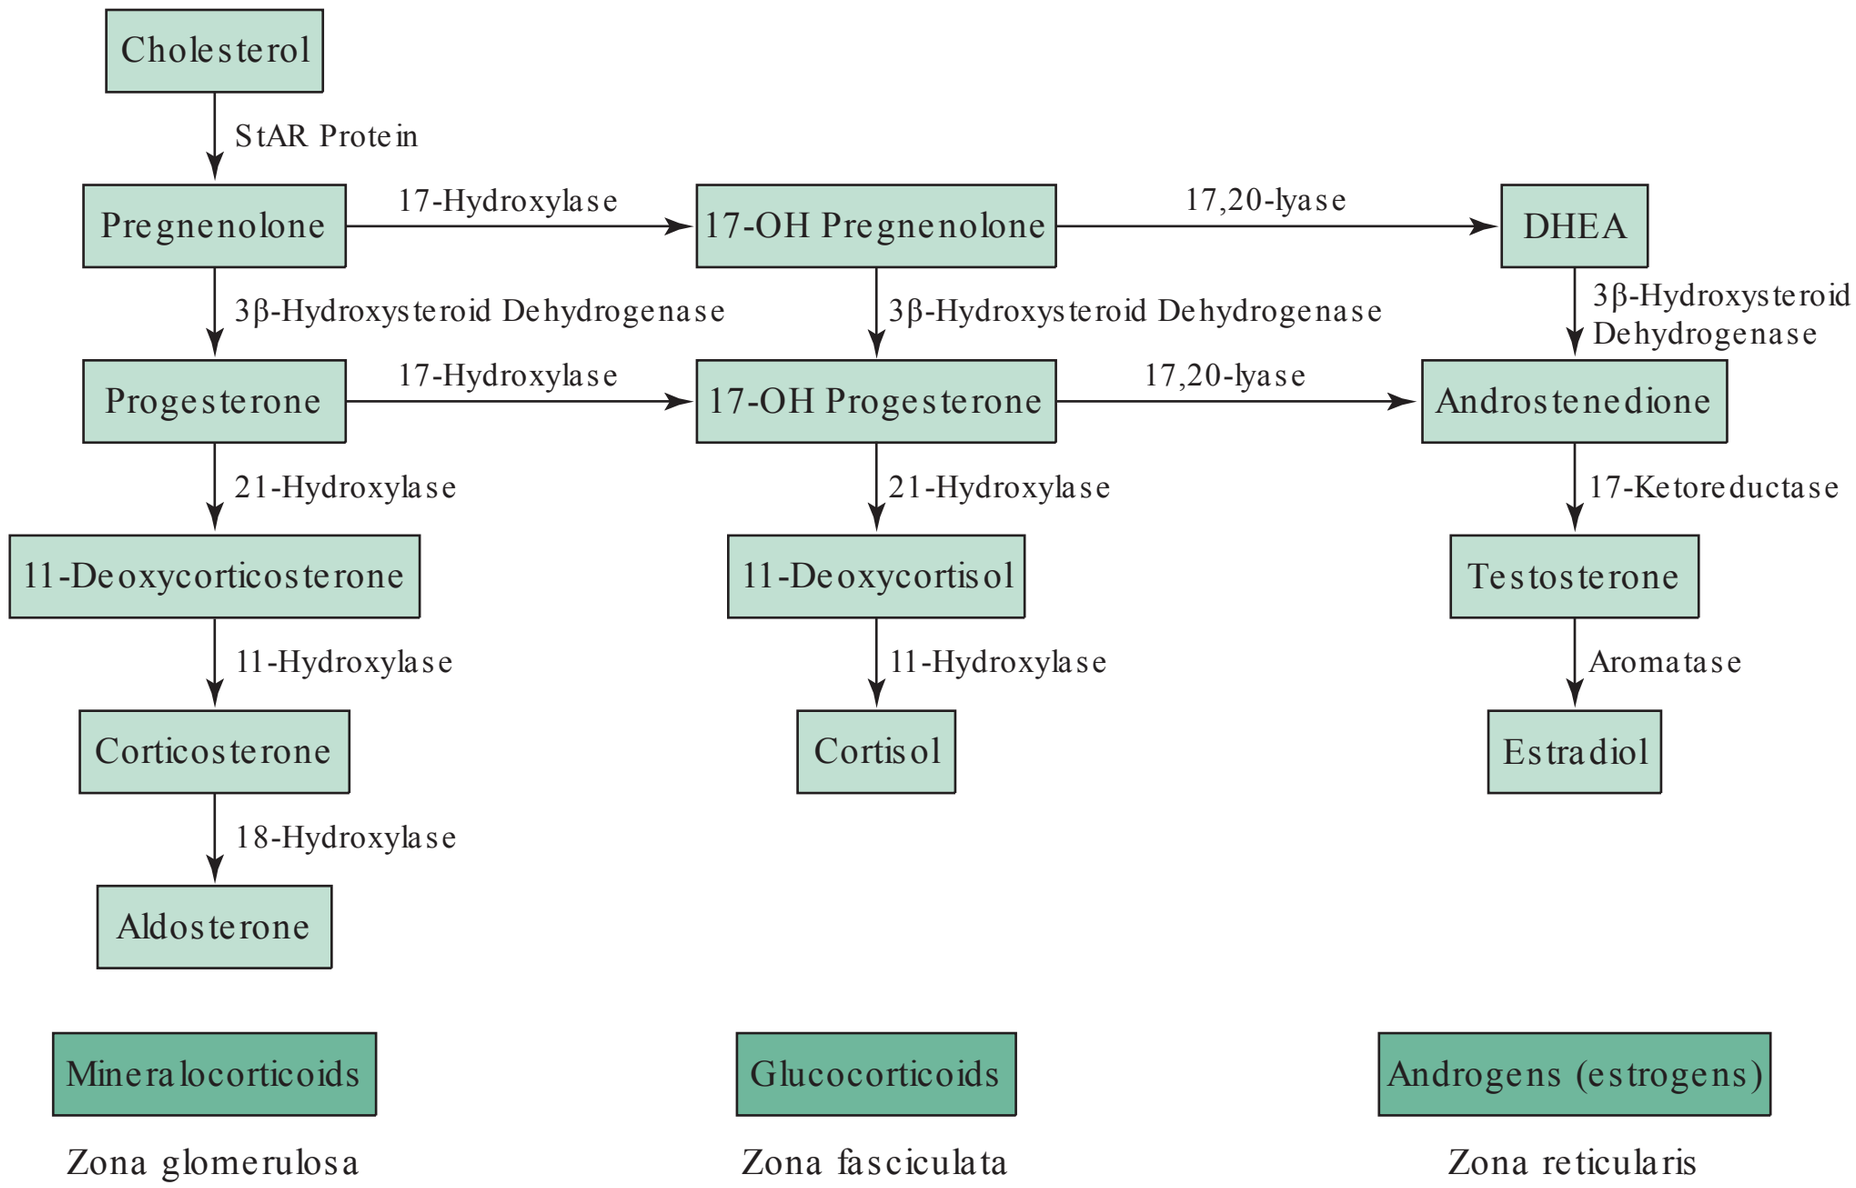
Evaluation

On physical examination, dysmorphic features and other congenital anomalies should be noted. The genital examination should include measuring the width and length of the stretched phallus and noting the position of the urethral meatus as well as degree of labioscrotal fusion. The normal stretched penile length (SPL) is greater than 2.0 cm in term male infants. The labioscrotal and inguinal regions should be palpated for presence of gonads. Since ovaries and streak gonads do not typically descend, the presence of a palpable gonad is suggestive of a 46,XY or 45X/46,XY karyotype. In all infants, laboratory studies should be done within the first 24 hours of life and include a FISH for SRY/X-centromere, chromosomal analysis or microarray, electrolytes, LH, FSH, testosterone, and 17-hydroxyprogesterone. Additional laboratory evaluation is usually based on these results. A pelvic ultrasound can be helpful to evaluate for the presence of a uterus; however, ultrasound findings can be unreliable so should be done in an institution which has expertise in pediatric imaging. Many times, laparoscopic examination is necessary to delineate internal structures. It is important



▲**Figure 34–8.** The corticosteroid hormone synthetic pathway. The pathways illustrated are present in differing amounts in the steroid-producing tissues: adrenal glands, ovaries, and testes. In the adrenal glands, mineralocorticoids from the zona glomerulosa, glucocorticoids from the zona fasciculata, and androgens (and estrogens) from the zona reticularis are produced. The major adrenal androgen is androstenedione, because the activity of 17-ketoreductase is relatively low. The adrenal gland does secrete some testosterone and estrogen, however. The pathways leading to the synthesis of mineralocorticoids and glucocorticoids are not present to any significant degree in the gonads; however, the testes and ovaries each produce both androgens and estrogens. Further metabolism of testosterone to dihydrotestosterone occurs in target tissues of the action of the enzyme 5α-reductase. DHEA, dehydroepiandrosterone.

that gender assignment be avoided until expert evaluation by a multidisciplinary team is performed. Ideally this team includes pediatric specialists from endocrinology, urology, gynecology, genetics, psychology, and nursing. The team should develop a plan for diagnosis, gender assignment, and treatment options before making any recommendations. Open communications with the parents is essential and their participation in decision making encouraged.

ABNORMALITIES IN FEMALE PUBERTAL DEVELOPMENT & OVARIAN FUNCTION

1. Precocious Puberty in Girls

Precocious puberty is defined as pubertal development occurring below the age limit set for normal onset of puberty. Puberty is considered precocious in girls if the onset of secondary sexual characteristics occurs before age 8 years in Caucasian girls and 7 years for African-American and Hispanic girls. Precocious puberty is more common in girls than in boys. Many girls showing signs of puberty between 6 and 8 years of age have a benign, slowly progressing form that requires no intervention. The age of pubertal onset may be advanced by obesity.

Table 34–8. Causes of precocious pubertal development.

A. Central (GnRH-dependent) precocious puberty
1. Idiopathic
2. Central nervous system abnormalities
a. Acquired—abscess, chemotherapy, radiation, surgical trauma
b. Congenital—arachnoid cyst, hydrocephalus, hypothalamic hamartoma, septo-optic dysplasia, suprasellar cyst
c. Tumors—astrocytoma, craniopharyngioma, glioma
B. Peripheral (GnRH-independent) precocious puberty
1. Congenital adrenal hyperplasia
2. Adrenal tumors
3. McCune-Albright syndrome
4. Familial male-limited gonadotropin independent precocious puberty
5. Gonadal tumors
6. Exogenous estrogen—oral (contraceptive pills) or topical
7. Ovarian cysts (females)
8. HCG-secreting tumors (eg, hepatoblastomas, choriocarcinomas) (males)

GnRH, gonadotropin-releasing hormone; HCG, human chorionic gonadotropin.

Central (gonadotropin-releasing hormone [GnRH]–dependent) precocious puberty involves activation of the hypothalamic GnRH pulse generator, an increase in gonadotropin secretion, and a resultant increase in production of sex steroids (Table 34–8). The sequence of hormonal and physical events in central precocious puberty is identical to that of normal puberty. Central precocious puberty in girls is generally idiopathic but may be secondary to a central nervous system (CNS) abnormality that disrupts the prepubertal restraint on the GnRH pulse generator. Such CNS abnormalities include, but are not limited to, hypothalamic hamartomas, CNS tumors, cranial irradiation, hydrocephalus, and trauma. Peripheral precocious puberty (GnRH-independent) occurs independent of gonadotropin secretion. In girls, peripheral precocious puberty can be caused by ovarian or adrenal tumors, ovarian cysts, late-onset congenital adrenal hyperplasia, McCune-Albright syndrome, or exposure to exogenous estrogen. McCune-Albright syndrome is a triad of irregular café au lait lesions, polyostotic fibrous dysplasia, and GnRH-independent precocious puberty. It is caused by an activating mutation in the gene encoding the α-subunit of Gs, the G protein that stimulates adenyl cyclase. Endocrine cells with this mutation have autonomous hyperfunction and secrete excess amounts of their respective hormones.

» Clinical Findings

A. Symptoms and Signs

Female central precocious puberty usually starts with breast development, followed by pubic hair growth and menarche. However, the order may vary and girls younger than 5 years may not have pubic hair development. Girls with ovarian cysts or tumors generally have signs of estrogen excess such as breast development and possibly vaginal bleeding. Adrenal tumors and CAH produce signs of androgen excess which include pubic hair, axillary hair, acne, and increased body odor. Children with precocious puberty usually have accelerated growth and skeletal maturation, and may temporarily be tall for age. However, because skeletal maturation advances at a more rapid rate than linear growth, final adult stature may be compromised.

B. Laboratory Findings

An estradiol level can be drawn to rule out an ovarian tumor or cyst. If the bone age is advanced, further laboratory evaluation is warranted. In central precocious puberty, random FSH and LH concentrations may still be in the prepubertal range. If so, documentation of the maturity of the hypothalamic-pituitary axis depends on demonstrating a pubertal LH response after stimulation with a GnRH agonist. In peripheral precocious puberty, the LH response to GnRH stimulation is suppressed by feedback inhibition of the hypothalamic-pituitary axis by the autonomously secreted gonadal steroids (see Figure 34–1). In girls with an ovarian cyst or tumor, estradiol levels will be markedly elevated. In girls who present with pubic and/or axillary hair but no breast development, androgen levels (testosterone, androstenedione, dehydroepiandrosterone-sulfate) and 17-hydroxyprogesterone should be measured.

C. Imaging

One of the first steps in evaluating a child with early pubertal development is obtaining a radiograph of the left hand and wrist to determine skeletal maturity (bone age). When a diagnosis of central precocious puberty is made, an MRI of the brain should be done to evaluate for CNS lesions. In girls whose laboratory tests suggest peripheral precocious puberty, an ultrasound of the ovaries and/or adrenal gland may be indicated.

» Treatment

Girls with central precocious puberty can be treated with GnRH analogues that downregulate pituitary GnRH receptors and thus decrease gonadotropin secretion. Currently, the two most common GnRH analogues used are (1) leuprolide, which is given as a monthly intramuscular injection or (2) histrelin subdermal implant, which is replaced annually. With treatment, physical changes of puberty regress or cease to progress and linear growth slows to a prepubertal rate. Projected final heights often increase as a result of slowing

of skeletal maturation. After stopping therapy, pubertal progression resumes, and ovulation and pregnancy have been documented.

Treatment of peripheral precocious puberty is dependent on the underlying cause. In a girl with an ovarian cyst, intervention is generally not necessary, as the cyst usually regresses spontaneously. Serial ultrasounds are recommended to document this regression. Surgical resection and possibly chemotherapy are indicated for the rare adrenal or ovarian tumor.

In McCune-Albright syndrome, therapy with aromatase inhibitors, which block the production of estrogen, may be effective. Regardless of the cause of precocious puberty or the medical therapy selected, attention to the psychological needs of the patient and family is essential.

2. Benign Variants of Precocious Puberty

Benign premature thelarche (benign early breast development) occurs most commonly in girls younger than 2 years of age. Girls present with isolated breast development without other signs of puberty such as linear growth acceleration and pubic hair development. The breast development is typically present since birth and often waxes and wanes in size. It may be unilateral or bilateral. Treatment is parental reassurance regarding the self-limited nature of the condition. Observation of the child every few months is also indicated. Onset of thelarche after age 36 months or in association with other signs of puberty requires evaluation.

Benign premature adrenarche (benign early adrenal maturation) is manifested by early development of pubic hair, axillary hair, acne, and/or body odor. Benign premature adrenarche is characterized by normal linear growth and no or minimal bone age advancement. Laboratory tests (see above) will differentiate benign premature adrenarche from late-onset CAH and adrenal tumors. It is recognized that approximately 15% of girls with benign premature adrenarche will go on to develop polycystic ovarian syndrome.

3. Delayed Puberty

Delayed puberty in girls should be evaluated if there are no pubertal signs by age 13 years or menarche by 16 years.

Table 34–9. Cause of delayed puberty or amenorrhea.

A. Constitutional growth delay
B. Hypogonadism
1. Primary ovarian insufficiency
a. Gonadal dysgenesis (Turner syndrome, true gonadal dysgenesis)
b. Premature ovarian failure
(1) Autoimmune disease
(2) Surgery, radiation, chemotherapy
c. Galactosemia
2. Central hypogonadism
a. Hypothalamic or pituitary tumor, infection, irradiation
b. Congenital hypopituitarism
c. Kallmann syndrome
d. Functional (chronic illness, undernutrition, exercise, hyperprolactinemia
C. Anatomic
1. Müllerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome)
2. Complete androgen resistance

Primary amenorrhea refers to the absence of menarche, and secondary amenorrhea refers to the absence of menses for at least 6 months after regular menses have been established. The most common cause of delayed puberty is constitutional growth delay (Table 34–9). This growth pattern, characterized by short stature, normal growth velocity, and a delay in skeletal maturation, is described in detail earlier in this chapter. The timing of puberty in children with constitutional growth delay is commensurate to the bone age, not the chronologic age. Girls may also have delayed puberty from any condition that delays growth and skeletal maturation, such as hypothyroidism and GHD.

Primary hypogonadism in girls refers to a primary abnormality of the ovaries. The most common diagnosis in this category is Turner syndrome, in which the lack of or an abnormal second X chromosome leads to early loss of oocytes and accelerated stromal fibrosis. Other types of primary ovarian insufficiency include 46,XY gonadal dysgenesis and 46,XX gonadal dysgenesis, galactosemia, autoimmune ovarian failure, radiation, and chemotherapy. Premutation carriers for fragile X syndrome are also at increased risk of premature ovarian failure.

Central hypogonadism refers to a hypothalamic or pituitary deficiency of GnRH or FSH/LH, respectively. Central hypogonadism can be functional (reversible), caused by stress, undernutrition, prolactinemia, excessive exercise, or chronic illness. Permanent central hypogonadism is typically associated with conditions that cause multiple pituitary hormone deficiencies, such as congenital hypopituitarism, CNS tumors, or cranial irradiation. Isolated gonadotropin deficiency is rare but may occur in Kallmann syndrome,

which is also characterized by hyposmia or anosmia. There are many genes that have been implicated in both isolated gonadotropin deficiency and Kallmann syndrome. In either primary or central hypogonadism, signs of adrenarche are generally present.

Delayed menarche or secondary amenorrhea may result from primary ovarian failure or central hypogonadism, or may be the consequence of hyperandrogenism, anatomic obstruction precluding menstrual outflow, or müllerian agenesis. This latter disorder is called Mayer-Rokitansky-Küster-Hauser syndrome and is characterized by underdevelopment of the vagina and uterus, with or without renal and skeletal anomalies.

Girls with complete AIS (androgen receptor defect) typically present with primary amenorrhea, breast development, and absence of sexual hair (see DSD section). At puberty, if the gonads have not been removed, testosterone produced in the testes is aromatized to estrogen resulting in breast development.

» Clinical Evaluation

The history should ascertain whether and when puberty commenced, level of exercise, nutritional intake, stressors, sense of smell, symptoms of chronic illness, and family history of delayed puberty. Past growth records should be assessed to determine if height and weight velocity have been appropriate. Physical examination includes body proportions, breast and genital development, and stigmata of Turner syndrome. Pelvic examination or pelvic ultrasonography should be considered, especially in girls with primary amenorrhea.

A bone age radiograph should be obtained first. If the bone age is lower than that consistent with pubertal onset (< 12 years in girls), evaluations should focus on finding the cause of the bone age delay. If short stature and normal growth velocity are present, constitutional growth delay is likely. If growth rate is abnormal, evaluation for causes of growth delay is warranted. Measurement of FSH and LH may not be helpful in the setting of delayed bone age since prepubertal levels are normally low.

If the patient has attained a bone age of more than 12 years and there are minimal or no signs of puberty on physical examination, FSH and LH levels will distinguish between primary ovarian failure (elevated FSH/LH) and central hypogonadism (low FSH/LH). If gonadotropins are elevated, a karyotype should be performed to evaluate for Turner syndrome. Central hypogonadism is characterized by low gonadotropin levels, and evaluation is geared toward determining if the hypogonadism is functional or permanent. Laboratory tests should be directed toward identifying chronic disease and hyperprolactinemia. Cranial MRI may be helpful.

In girls with adequate breast development and amenorrhea, a progesterone challenge may be helpful to determine if sufficient estrogen is being produced and to evaluate for anatomical defects. Girls who are producing estrogen have a withdrawal bleed after 5–10 days of oral progesterone, whereas those who are estrogen-deficient or have an anatomical defect have little or no bleeding. The most common cause of amenorrhea in girls with sufficient estrogen is polycystic ovarian syndrome. Girls who are estrogen-deficient should be evaluated similarly to those who have delayed puberty.

» Treatment

Replacement therapy in hypogonadal girls begins with estrogen alone at the lowest available dosage. Oral preparations such as estradiol or topical patches are used. Cyclic estrogen–progesterone therapy is started 18–24 months later, and eventually the patient may be switched over to a birth control pill for convenience. Progesterone therapy is needed to counteract the effects of estrogen on the uterus, as unopposed estrogen promotes endometrial hyperplasia. Estrogen is also necessary to promote bone mineralization and prevent osteoporosis.

4. Secondary Amenorrhea

See discussion of amenorrhea in Chapter 4.

ABNORMALITIES IN MALE PUBERTAL DEVELOPMENT & TESTICULAR FUNCTION

1. Precocious Puberty in Boys

Puberty is considered precocious in boys if secondary sexual characteristics appear before age 9 years. While the frequency of central precocious puberty is much lower in boys than girls, boys are more likely to have an associated CNS abnormality (see Table 34–8). In addition, several types of gonadotropin-independent (peripheral) precocious puberty occur in boys (see Table 34–8).

» Clinical Findings

A. Symptoms and Signs

Increased linear growth rate and growth of pubic hair are the most common presenting signs. Testicular size differentiates central precocity, in which the testes enlarge, from gonadotropin-independent causes, in which the testes usually remain small (< 2 cm in the longitudinal axis). In

familial male precocious puberty and HCG-mediated precocious puberty, there may be some testicular enlargement. Tumors of the testis are associated with either asymmetrical or unilateral testicular enlargement.

B. Laboratory Findings

Elevated testosterone levels verify early pubertal status but do not differentiate the source. Basal high-sensitivity serum LH and FSH concentrations will be in the pubertal range in boys with central precocious puberty and the LH response to GnRH stimulation testing is pubertal. Sexual precocity caused by CAH is usually associated with abnormal plasma adrenal androgens. Serum β-HCG concentrations signify the presence of an HCG-producing tumor (eg, CNS dysgerminoma or hepatoma) in boys who present with precocious puberty and testicular enlargement but suppressed gonadotropins following GnRH testing.

C. Imaging

In all boys with central precocious puberty, cranial MRI should be obtained to evaluate for a CNS abnormality. If testing suggests peripheral precocious puberty and laboratory studies are not consistent with CAH, imaging may be useful in detecting hepatic, adrenal, and testicular tumors.

» Treatment

Treatment of central precocious puberty in boys entails treatment of the underlying cause and the use of GnRH analogues. Boys with McCune-Albright syndrome or familial testotoxicosis can be treated with agents that block steroid synthesis (ketoconazole), or with a combination of antiandrogens (spironolactone) and aromatase inhibitors (anastrozole or letrozole) that block the conversion of testosterone to estrogen.

2. Delayed Puberty

Boys should be evaluated for delayed puberty if they have no secondary sexual characteristics by 14 years of age or if more than 5 years have elapsed since the first signs of puberty without completion of genital growth.

The most common cause of delayed puberty in boys is constitutional growth delay, a normal variant of growth described in detail earlier in this chapter. Hypogonadism in boys may be primary, due to absence, malfunction, or destruction of testicular tissue, or central, due to pituitary or hypothalamic insufficiency.

Primary testicular insufficiency may be due to: anorchia; Klinefelter syndrome (47,XXY) or other sex chromosome abnormalities; enzymatic defects in testosterone synthesis; inflammation or destruction of the testes following infection (mumps), autoimmune disorders, radiation, trauma, or tumor.

Central hypogonadism may accompany panhypopituitarism, hypogonadotropic hypogonadism with (Kallmann syndrome) or without abnormalities in smell, hyperprolactinemia, isolated LH or FSH deficiency, destructive lesions in or near the anterior pituitary (especially craniopharyngioma and glioma), infection, Prader-Willi syndrome, and Laurence-Moon syndrome (Bardet-Biedl syndrome).

Deficiencies in gonadotropins may be partial or complete. Functional or reversible gonadotropin may occur with chronic illness, malnutrition, hyperprolactinemia, hypothyroidism, or excessive exercise.

» Clinical Evaluation

The history should focus on whether and when puberty started, testicular descent, symptoms of chronic illness, nutritional intake, sense of smell, and family history of delayed puberty. Physical examination should include body proportions, height and weight, pubertal stage, and testicular location, size, and consistency. Testes less than 2 cm in length are prepubertal; testes more than 2.5 cm in length suggest early pubertal growth.

A radiograph of the left hand and wrist to assess bone age should be the first step in evaluating a boy with delayed puberty. If bone age is delayed (< 12 years) and growth velocity is normal, constitutional growth delay is the most likely diagnosis.

Laboratory evaluation includes measurement of LH and FSH levels (if bone age is > 12 years). Elevated gonadotropins indicate primary hypogonadism or testicular failure. Low gonadotropins on a sensitive assay are consistent with central hypogonadism and further evaluation should focus on looking for pituitary hormone deficiencies, chronic disease, undernutrition, hyperprolactinemia, or CNS abnormalities.

» Treatment

Boys with simple constitutional delay may be offered a 4- to 6-month course of low-dose depot testosterone (50–100 mg/mo) to stimulate their pubertal appearance and "jump-start" their endogenous development. In adolescents with permanent hypogonadism, treatment with depot testosterone is initiated with 50–100 mg intramuscularly each month and gradually increased over 3–4 years to adult dosing (200 mg every 2–4 weeks). Testosterone gel, either in single-dose packets or in a pump set to dispense a preset dose, is an alternative that is applied daily.

3. Cryptorchidism

Cryptorchidism (undescended testis) affects 2%–4% of full-term male newborns and up to 30% of premature infants. After 6 months of age, spontaneous descent occurs only very rarely. Consequently, intervention is typically considered beginning at this time.

Infertility and testicular malignancy are major risks of cryptorchidism. Fertility is impaired by approximately 33% after unilateral cryptorchidism and by 66% after bilateral disease. The cancer risk for adults after cryptorchidism in childhood is reported to be 5–10 times greater than normal. However, histologic changes clearly occur as early as age 6 months in children with undescended testes.

The cause of most cases of cryptorchidism is not completely understood. Cryptorchidism can occur in an isolated fashion or associated with other findings. Abnormalities in the hypothalamic-pituitary-gonadal axis and androgen biosynthesis or receptor defects predispose to cryptorchidism.

The diagnosis of bilateral cryptorchidism in an apparently normal male newborn should never be made until the possibility that the child is actually a fully virilized female with potentially fatal salt-losing CAH has been considered.

» Clinical Findings

In infants between 2 and 6 months of age, measurement of LH, FSH, inhibin B, and testosterone can help determine whether testes are present. After this time, an HCG stimulation test can be done to confirm the presence or absence of functional abdominal testes. Ultrasonography, CT scanning, and MRI may detect testes in the inguinal region, but these studies are not completely reliable in finding abdominal testes.

» Differential Diagnosis

During examination, the cremasteric reflex may cause the testis to retract into the inguinal canal or abdomen (pseudocryptorchidism). To prevent retraction, the fingers are placed across the abdominal ring and the upper portion of the inguinal canal. Examination in the squatting position or in a warm bath is helpful. No treatment for retractile testes is necessary.

» Treatment

Surgical orchidopexy should be performed if descent has not occurred by 6–12 months of age. The recommended timing of surgical intervention is based on the assumption that early surgery will allow normal germ cell development and decrease the risk for future infertility and cancer. However, in some cases, a primary abnormality of the testis may be responsible for both the undescent and future risks. Therapy with HCG to induce descent of the testis has a success rate of about 20%, and even less when retractile testes are excluded. HCG doses range from 250 to 1000 international units and are given twice weekly for 5 weeks.

4. Gynecomastia

Gynecomastia is a common, self-limited condition that occurs in up to 75% of normal pubertal boys. Adolescent gynecomastia typically resolves within 2 years but may not totally resolve if the degree of gynecomastia is extreme (> 2 cm of tissue). Gynecomastia may also occur in male hypogonadism, such as Klinefelter syndrome, and as a side effect of some medications. Medical therapy using antiestrogens and aromatase inhibitors may be beneficial if initiated early, but generally results are not satisfying. Surgical intervention should be considered promptly for prolonged and/or severe cases (see Chapter 4).

ADRENAL CORTEX

The adult adrenal cortex consist of three zones responsible for synthesis of different steroids:

- Outermost zona glomerulosa—aldosterone.
- Middle zona fasciculata—cortisol and small amounts of mineralocorticoids.
- Innermost zona reticularis—androgens and estrogens.

A fetal zone, or provisional cortex, predominates during fetal development and produces glucocorticoids, mineralocorticoids, androgens, and estrogens. The fetal zone is relatively deficient in 3β-hydroxysteroid dehydrogenase (see Figure 34–8); hence placental progesterone is the major precursor for fetal adrenal production of cortisol and aldosterone.

The adrenal cortical production of cortisol is under the control of pituitary adrenocorticotropic hormone (ACTH; see Figure 34–1 and Table 34–1), which is in turn regulated by hypothalamic corticotropin-releasing hormone (CRH). ACTH concentration is greatest during the early morning hours with a smaller peak in the late afternoon and a nadir at night. The pattern of serum cortisol concentration follows this pattern with a lag of a few hours. In the absence of cortisol feedback, there is dramatic CRH and ACTH hypersecretion.

Glucocorticoids are critical for gene expression in a many cell types. Glucocorticoids also help maintain blood pressure by promoting peripheral vascular tone and sodium and water retention. In excess, glucocorticoids are both catabolic and antianabolic; they promote the release of amino acids from muscle and increase gluconeogenesis while decreasing incorporation of amino acids into muscle protein. They also antagonize insulin activity and facilitate lipolysis.

Mineralocorticoids (primarily aldosterone in humans) promote sodium retention and stimulate potassium excretion in the distal renal tubule. The predominant regulator of aldosterone secretion is the volume- and sodium-sensitive renin-angiotensin-aldosterone system. Hyperkalemia also directly stimulates aldosterone release.

Androgen (dehydroepiandrosterone and androstenedione) production by the zona reticularis is insignificant before puberty. At the onset of puberty, androgen production increases and is an important contributor to pubertal development in both sexes; the adrenal gland is the major source of androgen in females.

ADRENOCORTICAL INSUFFICIENCY (ADRENAL CRISIS, ADDISON DISEASE)

Adrenal insufficiency may be primary—due to disorders of the adrenal gland itself, or central—due to disorders of CRH and/or ACTH secretion.

The causes of primary adrenal insufficiency include the following:

- Hereditary enzyme defects (congenital adrenal hyperplasia)
- Autoimmune destruction of the glands (Addison disease)—Addison disease may be familial and can be isolated or associated with hypoparathyroidism, mucocutaneous candidiasis, hypothyroidism, pernicious anemia, hypogonadism, and diabetes mellitus in one of the polyglandular autoimmune syndromes.
- Destruction of the gland by tumor, calcification, or hemorrhage (Waterhouse-Friderichsen syndrome).
- Adrenal disease secondary to opportunistic infections (fungal or tuberculous) is reported in immunocompromised patients
- Rare forms of familial adrenal insufficiency occur in association with cerebral sclerosis and spastic paraplegia (adrenoleukodystrophy) or with achalasia and alacrima in the triple A (Allgrove) syndrome
- Salt-losing disorders can occur due to homozygous mutations of aldosterone synthase (CYP11B2) or from partial or complete unresponsiveness of the mineralocorticoid receptor to aldosterone (pseudohypoaldosteronism). A transient autosomal dominant form of pseudohypoaldosteronism has been reported in infancy.

The causes of central adrenal insufficiency include the following:

- Intracranial neoplasm or its treatment.
- Congenital midline defects associated with optic nerve hypoplasia (septo-optic dysplasia).
- Chronic iatrogenic exposure to exogenous glucocorticoids.
- Central adrenal insufficiency due to anterior pituitary tumor is rare.

Acute illness, surgery, trauma, or hyperthermia may precipitate an adrenal crisis in patients with adrenal insufficiency. Patients with primary adrenal insufficiency are at greater risk for life-threatening crisis than patients with central ACTH deficiency because mineralocorticoid secretion and low-level autonomous cortisol secretion remain intact in central ACTH deficiency.

» Clinical Findings

A. Symptoms and Signs

1. Acute form (adrenal crisis)—Nausea, vomiting, diarrhea, abdominal pain; dehydration; fever (sometimes followed by hypothermia); weakness; hypotension and circulatory collapse; confusion and coma.

2. Chronic form—Fatigue; hypotension; weakness; weight loss or failure to gain weight; salt craving (primary insufficiency); vomiting and dehydration; recurrent hypoglycemia; a small heart on chest radiograph. Diffuse tanning occurs with increased pigmentation over pressure points, scars, and mucous membranes primary adrenal insufficiency due to melanocyte stimulating activity of alternate products of hypersecreted pro-opiomelanocortin, the parent molecule of ACTH.

B. Laboratory Findings

1. Suggestive of adrenocortical insufficiency

- Primary adrenal insufficiency
  - Decreased—serum sodium, serum bicarbonate, arterial partial pressure of carbon dioxide, blood pH, and blood volume.
  - Increased—serum potassium, urea nitrogen levels.
  - Urinary sodium and the ratio of urinary sodium to potassium are inappropriate for the degree of hyponatremia.
- Central adrenal insufficiency—serum sodium levels may be mildly decreased as a result of impaired water excretion.
- Eosinophilia and moderate lymphopenia occur in both forms of insufficiency.

2. Confirmatory tests

a. ACTH (cosyntropin) stimulation test

- primary adrenal insufficiency—plasma cortisol less than 18 mcg/dL 30 and 60 minutes after 250 mcg of cosyntropin given intravenously and aldosterone fails to rise above baseline
- central adrenal insufficiency—plasma cortisol less than 18 mcg/dL 30 and 60 minutes after 1 mcg of cosyntropin given intravenously

b. Baseline serum ACTH concentration—Elevated in primary adrenal failure and low in central adrenal insufficiency.

c. Urinary free cortisol—Decreased.

d. CRH test—After administration of ovine CRH, serum concentrations of ACTH and cortisol are measured over 2 hours. Localization of the site of impairment is possible based on careful interpretation of results.

» Differential Diagnosis

Acute adrenal insufficiency must be differentiated from sepsis diabetic coma, CNS disturbances, and acute poisoning. In the neonatal period, adrenal insufficiency may be clinically indistinguishable from respiratory distress, intracranial hemorrhage, or sepsis. Chronic adrenocortical insufficiency must be differentiated from anorexia nervosa, certain muscular disorders (myasthenia gravis), salt-losing nephritis, and chronic debilitating infections.

» Treatment

A. Acute Insufficiency (Adrenal Crisis)

1. Hydrocortisone sodium succinate—Hydrocortisone sodium succinate (50 mg/m^2 intravenously over 2–5 minutes or intramuscularly) is given initially followed by 12.5 mg/m^2, every 4–6 hours until stabilization is achieved and oral therapy can be tolerated. Cortisol replacement is critical because pressor agents may be ineffective in adrenal insufficiency.

2. Fluids and electrolytes—In primary adrenal insufficiency, 5%–10% glucose in normal saline, 10–20 mL/kg intravenously, is given over the first hour and repeated if necessary to reestablish vascular volume. Normal saline is continued thereafter at 1.5–2 times the maintenance fluid requirements. In central adrenal insufficiency, routine fluid management is generally adequate after restoration of vascular volume and institution of cortisol replacement.

3. Fludrocortisone—When oral intake is tolerated, fludrocortisone, a mineralocorticoid agonist is started, 0.05–0.15 mg daily, and continued every 12–24 hours for primary adrenal insufficiency.

4. Waterhouse-friderichsen syndrome with fulminant Infections—Corticosteroids should be considered if there is possible adrenal insufficiency, particularly if there is hypotension and circulatory collapse.

B. Maintenance Therapy

1. Glucocorticoids—A maintenance dosage of 6–10 mg/m^2/d of hydrocortisone (or equivalent) is given orally in two or three divided doses. The dosage of all glucocorticoids is increased to 30–50 mg/m^2/d during intercurrent illnesses or other times of stress. Overtreatment should be avoided as it causes obesity, growth retardation, and other cushingoid features

2. Mineralocorticoids—In primary adrenal insufficiency, fludrocortisone is given, 0.05–0.15 mg orally daily as a single dose or in two divided doses. Periodic monitoring of blood pressure is recommended to avoid overdosing.

3. Salt—Children should be given ready access to table salt. In the infant, supplementation of breast milk or formula with 3–5 mEq Na^+/kg/d is generally required until table foods are introduced.

C. Corticosteroids in Patients With Adrenocortical Insufficiency Who Undergo Surgery

1. Before operation—Hydrocortisone sodium succinate, 30–50 mg/m^2 IM or intravenously 1 hour before surgery.

2. During operation—Hydrocortisone sodium succinate, 25–100 mg intravenously with 5%–10% glucose in saline as a continuous drip throughout surgery.

3. During recovery—Hydrocortisone sodium succinate, 12.5 mg/m^2 intravenously every 4–6 hours until oral doses are tolerated. The oral stress hydrocortisone dose (30–50 mg/m^2) is continued until the acute stress is over, at which time the patient can be returned to the maintenance dose.

» Course & Prognosis

The course of acute adrenal insufficiency is rapid and death may occur within a few hours, particularly in infants, unless adequate treatment is given. Spontaneous recovery is unlikely. Patients who have received long-term treatment with glucocorticoids may exhibit adrenal collapse if they undergo surgery or other acute stress. Pharmacologic doses of glucocorticoids during these episodes may be needed throughout life. In all forms of acute adrenal insufficiency, the patient should be observed carefully once the crisis has passed and evaluated with laboratory tests to assess the degree of permanent adrenal insufficiency. Patients with chronic adrenocortical insufficiency who receive adequate therapy can lead normal lives.

CONGENITAL ADRENAL HYPERPLASIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES–CONGENITAL

- Adrenal hyperplasia: 21-OHase Deficiency.
- Genital virilization in females, with labial fusion, urogenital sinus, enlargement of the clitoris, or other evidence of androgen action.
- Salt-losing crises in infant males or isosexual precocity in older males with infantile testes.
- Increased linear growth and advanced skeletal maturation.
- Elevation of plasma 17-hydroxyprogesterone concentrations in the most common form; may be associated with hyponatremia, hyperkalemia, and metabolic acidosis, particularly in newborns.

General Considerations

Autosomal recessive mutations in the enzymes of adrenal steroidogenesis cause impaired cortisol biosynthesis with increased ACTH secretion. ACTH excess subsequently results in adrenal hyperplasia with increased production of adrenal hormone precursors that are metabolized through the unblocked androgen pathway. Increased pigmentation, especially of the scrotum, labia majora, and nipples, is common due to excessive ACTH secretion. CAH is most commonly (> 90% of patients) the result of homozygous or compound heterozygous mutations in the cytochrome P-450 C21 (CYP21A2) gene causing 21-hydroxylase deficiency (see Figure 34–8). The defective gene is present in 1:250–1:100 people and the worldwide incidence of the disorder is 1:15,000, with increased incidence in certain ethnic groups. In its severe form, excess adrenal androgen production starting in the first trimester of fetal development causes virilization of the female fetus and life-threatening hypovolemic, hyponatremic shock (adrenal crisis) in the newborn, if untreated. There are also other enzyme defects that less commonly result in CAH. The clinical syndromes associated with these defects are shown in Figure 34–8 and Table 34–10.

Prenatal diagnosis is now possible and newborn screening by measurement of serum 17-hydroxyprogesterone has been established in all 50 US states and many other countries worldwide.

In nonclassic presentations of 21-hydroxylase deficiency, affected individuals have a normal phenotype at birth but develop virilization during later childhood, adolescence, or early adulthood. Hormonal studies are characteristic of 21-hydroxylase deficiency, with cosyntropin stimulated

Table 34–10. Clinical and laboratory findings in adrenal enzyme defects resulting in congenital adrenal hyperplasia.

Enzyme Deficiency[a]	Elevated Plasma Metabolite	Plasma Androgens	Aldosterone	Hypertension/ Salt Loss	External Genitalia
StAR Protein	-	↓↓↓	↓↓↓	-/+	Males: ambiguous Females: normal
3β-Hydroxysteroid -dehydrogenase	17-OH pregnenolone (DHEA)	↑ (DHEA)	↓↓↓	-/+	Males: ambiguous Females: possibly virilized
17α-Hydroxylase/17-20 lyase	Progesterone	↓↓	(↑ DOC)	+/-	Males: ambiguous Females: normal, absent puberty

P450 oxidoreductase	17-OHP (mild elevation)	↓↓	Normal or mildly elevated	+/-	Males: ambiguous Females: ambiguous

DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone; 17-OHP, 17-hydroxyprogestrone.
[a]Children with "simple virilizing (non–salt-wasting)" forms of 21-hydroxylase deficiency congenital adrenal hyperplasia (CAH) may have normal aldosterone production and serum electrolytes, but some children have normal aldosterone production and serum electrolytes at the expense of elevated plasma renin activity and are, by definition, compensated salt-wasters. These children usually receive mineralocorticoid as well as glucocorticoid treatment. Children with 21-hydroxylase deficiency CAH should therefore have documented normal plasma renin activity in addition to normal serum electrolytes before they are considered non–salt-wasters.

17-OHP levels intermediate between those of nonaffected individuals and those with the classic form of the disease. Individuals with the nonclassic form of the disease may be asymptomatic or only mildly symptomatic, but they can carry a severe CYP21A2 mutation resulting in offspring with the classic form.

» Clinical Findings

A. Symptoms and Signs

1. In females—Abnormality of the external genitalia varies from mild enlargement of the clitoris to complete fusion of the labioscrotal folds, forming an empty scrotum, a penile urethra, a penile shaft, and clitoral enlargement sufficient to form a normal-sized glans (see Figure 34–7). Signs of adrenal insufficiency (salt loss) typically appear 5–14 days after birth. With milder enzyme defects, clinically apparent salt loss may not occur and virilization predominates with accelerated growth and skeletal maturation. Pubic hair appears early, acne may be excessive, and the voice may deepen. Excessive pigmentation may develop. Isosexual central precocious puberty may occur if treatment is not initiated before the bone age is significantly advanced. Final adult height is often compromised.

2. In males—The male infant usually appears normal at birth but may present with salt-losing crisis in the first weeks of life. In milder forms, salt-losing crises may not occur and virilization predominates, with enlargement of the penis and increased pigmentation, as well as other symptoms and signs similar to those of affected females. The testes are not enlarged unless there are rare adrenal rests in the testes producing asymmetrical enlargement. In some rare enzyme defects, ambiguous genitalia may be present due to impaired androgen production (see Figure 34–8).

B. Laboratory Findings

1. Blood—Hormonal studies are essential for accurate diagnosis. Findings characteristic of the enzyme deficiencies are shown in Table 34–10.

2. Genetic studies—Rapid assessment of genetic sex should be obtained in any newborn with ambiguous genitalia since 21-hydroxylase deficiency is the most common cause of ambiguity in females.

3. Urine—Assessment of urinary steroid metabolites is no longer routine, but is reserved for rare forms of CAH.

C. Imaging

Imaging is generally not required to make the diagnosis of CAH. Ultrasonography, CT scanning, and MRI may be useful in defining pelvic anatomy or to exclude an adrenal tumor.

» Treatment

A. Medical Treatment

Treatment goals in CAH are to provide the smallest dose of glucocorticoid that will adequately suppress excess androgen precursors and produce normalization of growth velocity and skeletal maturation; excessive glucocorticoids cause the undesirable side effects of Cushing syndrome. Mineralocorticoid replacement sustains normal electrolyte homeostasis, but excessive mineralocorticoids cause hypertension and hypokalemia.

1. Glucocorticoids—Supraphysiologic doses of hydrocortisone are often needed to suppress androgen excess in CAH. Initially, parenteral or oral hydrocortisone (30–50 mg/m^2/d) is provided until suppression of abnormal adrenal steroidogenesis has been accomplished, as evidenced by normalization of serum 17-hydroxyprogesterone. Subsequently, patients are placed on maintenance doses of 10–15 mg/m^2/d in three divided doses. Dosage is adjusted to maintain normal growth rate and skeletal maturation. Various serum and urine androgens have been used to monitor therapy, including 17-hydroxyprogesterone and androstenedione; however, no one test is universally accepted. In pregnant females with CAH, suppression of adrenal androgen secretion is critical to avoid virilization of the fetus, particularly a female fetus. Hydrocortisone is the preferred choice for glucocorticoid replacement therapy in pregnant women with CAH because it does not cross the placenta.

2. Mineralocorticoids—Fludrocortisone, 0.05–0.15 mg, is given orally once a day or in two divided doses. Periodic monitoring of blood pressure and plasma renin activity are recommended to avoid overdosing.

B. Surgical Treatment

For affected females, consultation with an urologist or gynecologist experienced in female genital reconstruction should be arranged as soon as possible during infancy.

» Course & Prognosis

When initiated in early infancy, treatment with glucocorticoids permits normal growth, development, and sexual maturation. If not adequately controlled, CAH results in sexual precocity and masculinization throughout childhood. Affected individuals will be tall as children but short as adults because of rapid skeletal maturation and premature closure of the epiphyses. If treatment is delayed or inadequate, true central precocious puberty may occur in males and females.

Patient education stressing lifelong therapy is important to ensure compliance in adolescence and later life. Virilization and multiple surgical genital reconstructions may be

associated with risk of psychosexual disturbances in female patients and ongoing psychological evaluation and support is a critical component of care.

Speiser PW et al: Congenital adrenal hyperplasia due to steroid 21-hydroxylase deficiency: an Endocrine Society clinical practice guideline. J Clin Endocrinol Metab 2010;95:4133–4160 [PMID: 20823466].

ADRENOCORTICAL HYPERFUNCTION (CUSHING DISEASE, CUSHING SYNDROME)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Truncal adiposity, thin extremities, moon facies, muscle wasting, weakness, plethora, easy bruising, purple striae, decreased growth rate, and delayed skeletal maturation.
- Hypertension, osteoporosis, and glycosuria.
- Elevated urinary free cortisol, elevated midnight salivary cortisol.

» General Considerations

Cushing syndrome may result from excessive autonomous secretion of adrenal steroids (adrenal adenoma or carcinoma), excess pituitary ACTH secretion (Cushing disease), ectopic ACTH or CRH secretion, or chronic exposure to exogenous glucocorticoids. In children younger than 12 years, Cushing syndrome is usually iatrogenic. It is less commonly due to adrenal tumor, adrenal hyperplasia, pituitary adenoma, or extrapituitary ACTH-producing tumor.

» Clinical Findings

A. Symptoms and Signs

1. Excess glucocorticoid—Adiposity, most marked on the face, neck, and trunk—a fat pad (buffalo hump) in the interscapular area is characteristic but not diagnostic; fatigue; plethoric facies; purplish striae; easy bruising; osteoporosis and back pain; hypertension and glucose intolerance; muscle wasting and weakness; retardation of growth and skeletal maturation.

2. Excess mineralocorticoid—Hypokalemia and mild hypernatremia; increased blood volume; edema; hypertension.

3. Excess androgen—Hirsutism; acne; virilization; and menstrual irregularities.

B. Laboratory Findings

1. Blood

a. Plasma cortisol—Values are generally elevated, with loss of normal diurnal variation. Determination of cortisol level at the expected nadir between midnight and 2 am is a sensitive indicator of the loss of diurnal variation.

b. Serum electrolytes—Serum sodium and bicarbonate are mildly elevated, with metabolic alkalosis, while potassium may be low.

c. Serum acth—Morning ACTH concentration is decreased in adrenal tumors and increased with ACTH- or CRH-producing pituitary or extrapituitary tumors.

2. Salivary cortisol—Salivary cortisol obtained at midnight is a noninvasive but highly specific and sensitive test for hypercortisolism.

3. 24-Hour urinary free cortisol excretion—Measurement of urinary free cortisol/creatinine ratio is a useful way to document hypercortisolism, though midnight salivary cortisol is now considered a more practical and specific alternative.

4. Response to dexamethasone suppression testing—Suppression of adrenal function by a small dose (0.5–1.0 mg) of dexamethasone is seen in children who may have elevated urinary free cortisol excretion due to obesity, but not in children with an ACTH-secreting tumor or adrenal tumor. Larger doses (4–16 mg/d in four divided doses) of dexamethasone cause suppression of adrenal activity when the disease is due to ACTH hypersecretion by a pituitary tumor, whereas hypercortisolism due to adrenal adenomas or adrenal carcinomas is rarely suppressed.

5. CRH test—The CRH stimulation test, in conjunction with petrosal sinus sampling, is used to distinguishing pituitary and ectopic sources of ACTH excess and to assess lateralization prior to surgery.

C. Imaging

Pituitary imaging may demonstrate a pituitary adenoma. Adrenal imaging by CT scan may demonstrate adenoma or bilateral hyperplasia. MRI and nuclear medicine studies of the adrenals may be useful in complex cases. Skeletal maturation is usually delayed.

» Differential Diagnosis

Children with exogenous obesity accompanied by striae and hypertension are often suspected of having Cushing syndrome. However, children with Cushing syndrome have

a poor growth rate, relatively short stature, and delayed skeletal maturation, while those with exogenous obesity usually have a normal or slightly increased growth rate, normal to tall stature, and advanced skeletal maturation. The color of the striae (purplish in Cushing syndrome, pink in obesity) and the distribution of the obesity may assist in differentiation. The urinary-free cortisol excretion (in milligrams per gram of creatinine) may be mildly elevated in obesity, but midnight salivary cortisol is normal and cortisol secretion is suppressed by a relatively small dose of dexamethasone.

» Treatment

In all cases of primary adrenal hyperfunction due to tumor, surgical removal is indicated if possible. Glucocorticoids should be administered parenterally in pharmacologic doses during and after surgery until the patient is stable. Supplemental oral glucocorticoids, potassium, salt, and mineralocorticoids may be necessary until the suppressed contralateral adrenal gland recovers, sometimes over a period of several months. Mitotane, a DDT derivative toxic to the adrenal cortex is often used as adjuvant therapy, but increases glucocorticoid requirements. Similarly, pituitary adenomas and ectopic sources of ACTH or CRH are generally treated surgically. Recurrent adenomas may respond to irradiation.

» Prognosis

If the adrenal tumor is malignant, the prognosis is poor if it cannot be completely removed. If it is benign, cure is to be expected following proper preparation and surgery. The prognosis in pituitary adenoma is generally good, though the occurrence of pituitary hormone deficiencies is variable, depending on the extent of the surgery and additional therapies. Prognosis in Cushing syndrome caused by ectopic ACTH or CRH secretion depends on the nature of the tumor of origin.

Stratakis CA: Cushing syndrome in pediatrics. Endocrinol Metab Clin North Am 2012 Dec;141(4):793–803 [PMID: 23099271].

PRIMARY HYPERALDOSTERONISM

Primary hyperaldosteronism may be caused by an adrenal adenoma or adrenal hyperplasia. It is characterized by paresthesias, tetany, weakness, periodic paralysis; nocturnal enuresis; hypokalemia, hypernatremia, metabolic alkalosis, alkaline urine; hypertension; glucose intolerance; elevated plasma and urinary aldosterone; and suppressed plasma renin activity.

Primary hyperaldosteronism is rare in pediatrics. However, there are three recognized genetic causes (types I–III). Type I (glucocorticoid remediable hyperaldosteronism) is due to a hybrid of the genes encoding 11β-hydroxylase and aldosterone synthase. Type III results from mutations in the KCNJ5 gene encoding a K^+ channel. Somatic mutations of this gene are also seen in later onset hyperaldosteronism. The cause for type II is unknown.

Treatment is with glucocorticoids (type I), spironolactone (type II), or subtotal or total adrenalectomy for hyperplasia or tumor.

Chao CT et al: Diagnosis and management of primary aldosteronism: an updated review. Ann Med 2013 Jun;45(4):375–383 [PMID: 23701121].

USES OF GLUCOCORTICOIDS & ADRENOCORTICOTROPIC HORMONE IN TREATMENT OF NONENDOCRINE DISEASES

Glucocorticoids are used for their anti-inflammatory and immunosuppressive properties in a variety of conditions in childhood. Pharmacologic doses are necessary to achieve these effects, and side effects are common. Numerous synthetic preparations possessing variable ratios of glucocorticoid to mineralocorticoid activity are available (Table 34–11).

When prolonged use of pharmacologic doses of glucocorticoids is necessary, clinical manifestations of Cushing syndrome are common. Side effects may occur with the use of synthetic exogenous agents by any route, including inhalation and topical administration, or with the use of ACTH. Alternate-day therapy lessens the incidence and severity of some of the side effects (Table 34–12).

» Tapering of Pharmacologic Doses of Steroids

Prolonged use of pharmacologic doses of glucocorticoids causes suppression of ACTH secretion and consequent adrenal atrophy; the abrupt discontinuation of glucocorticoids may result in adrenal insufficiency. ACTH secretion generally does not restart until the administered steroid has been given in subphysiologic doses (< 6 mg/m^2/d orally) for several weeks.

If pharmacologic glucocorticoid therapy has been given for less than 10–14 days, the drug can be discontinued abruptly because adrenal suppression will be short-lived. However, it is advisable to educate the patient and family about the signs and symptoms of adrenal insufficiency in case problems arise.

If tapering is necessary in treating the condition for which the glucocorticoid is prescribed, a reduction of 25%–50% every 2–7 days is sufficiently rapid to permit observation of clinical symptomatology. An alternate-day schedule (single dose given every 48 hours) will allow for a 50% decrease in the total 2-day dosage while providing the desired pharmacologic effect. If tapering is not required for

Table 34–11. Potency equivalents for adrenocorticosteroids.

Adrenocorticosteroid	Trade Names	Potency/mg Compared with Cortisol (Glucocorticoid Effect)	Potency/mg Compared with Cortisol (Sodium-Retaining Effect)
Glucocorticoids			
Hydrocortisone (cortisol)	Cortef	1	1
Cortisone	Cortone Acetate	0.8	1
Prednisone	Meticorten, others	4–5	0.8
Methylprednisolone	Medrol, Meprolone	5–6	Minimal
Triamcinolone	Aristocort, Kenalog Kenacort, Atolone	5–6	Minimal
Dexamethasone	Decadron, others	25–40	Minimal
Betamethasone	Celestone	25	Minimal
Mineralocorticoid			
Fludrocortisone	Florinef	15–20	300–400

the underlying disease, the dosage can be safely decreased to the physiologic range. Although a rapid decrease in dose to the physiologic range will not lead to frank adrenal insufficiency (because adequate exogenous cortisol is being provided), some patients may experience a steroid withdrawal syndrome, characterized by malaise, insomnia, fatigue, and loss of appetite. These symptoms may necessitate a two- or three-step decrease in dose to the physiologic range.

Once a physiologic equivalent dose (8–10 mg/m^2/d hydrocortisone or equivalent) is achieved and the patient's underlying disease is stable, the dose can be decreased to 4–5 mg/m^2/d given only in the morning. This will allow the adrenal axis to recover. After this dose has been given for 4–6 weeks, endogenous adrenal activity is assessed by obtaining fasting plasma cortisol concentrations between 7 and 8 am prior to the morning steroid dose. When an alternate-day

Table 34–12. Side effects of glucocorticoid use.

A. Endocrine and metabolic effects
1. Hyperglycemia and glycosuria (chemical diabetes)
2. Cushing syndrome
3. Persistent suppression of pituitary-adrenal responsiveness to stress with resultant hypoadrenocorticism

B. Effects on electrolytes and minerals
1. Marked retention of sodium and water, producing edema, increased blood volume, and hypertension (more common in endogenous hyperadrenal states)
2. Potassium loss with symptoms of hypokalemia
3. Hypocalcemia, tetany

C. Effects on protein metabolism and skeletal maturation
1. Negative nitrogen balance, with loss of body protein and bone -protein, resulting in osteoporosis, pathologic fractures, and aseptic bone necrosis
2. Suppression of growth, retarded skeletal maturation
3. Muscular weakness and wasting
4. Osteoporosis
5. Avascular necrosis

D. Effects on the gastrointestinal tract
1. Excessive appetite and intake of food
2. Activation or production of peptic ulcer
3. Gastrointestinal bleeding from ulceration or from unknown cause (particularly in children with hepatic disease)
4. Fatty liver with embolism, pancreatitis, nodular panniculitis

E. Lowering of resistance to infectious agents; silent infection; decreased inflammatory reaction
1. Susceptibility to bacterial, fungal, and parasitic infections
2. Activation of tuberculosis; false-negative tuberculin reaction
3. Reactivation and poor containment of herpesviruses

F. Neuropsychiatric effects
1. Euphoria, excitability, psychotic behavior, and status epilepticus with electroencephalographic changes
2. Increased intracranial pressure with pseudotumor cerebri -syndrome

G. Hematologic and vascular effects
1. Bleeding into the skin as a result of increased capillary fragility
2. Thrombosis, thrombophlebitis, cerebral hemorrhage

H. Miscellaneous effects
1. Myocarditis, pleuritis, and arteritis following abrupt cessation of therapy
2. Cardiomegaly
3. Nephrosclerosis, proteinuria
4. Acne (in older children), hirsutism, amenorrhea, irregular menses
5. Posterior subcapsular cataracts; glaucoma

schedule is followed, plasma cortisol is measured the morning before treatment. Plasma cortisol concentration in the physiologic range (> 10 mg/dL) indicates return of basal physiologic adrenal rhythm. Exogenous steroids may then be discontinued safely, although it is advisable to continue giving stress doses of glucocorticoids when appropriate until recovery of the response to stress has been documented.

After basal physiologic adrenal function returns, the adrenal reserve or capacity to respond to stress and infection can be estimated by the low-dose ACTH stimulation test, in which 1 mcg of synthetic ACTH (cosyntropin) is administered intravenously. Plasma cortisol is measured 45–60 minutes after the infusion. A plasma cortisol concentration greater than 18 mg/dL indicates a satisfactory adrenal reserve. Even if the results of testing are normal, careful monitoring and the use of stress doses of glucocorticoids should be considered during severe illnesses and surgery.

Wildi-Runge S et al: A search for variables predicting cortisol response to low-dose corticotropin stimulation following supraphysiological doses of glucocorticoids. J Pediatr 2013 Aug;163(2):484–488 [PMID: 23414662].

ADRENAL MEDULLA PHEOCHROMOCYTOMA

Pheochromocytoma is an uncommon tumor, but up to 10% of reported cases occur in pediatric patients. The tumor can be located wherever chromaffin tissue (adrenal medulla, sympathetic ganglia, or carotid body) is present. It may be multiple, recurrent, and sometimes malignant. Familial forms include pheochromocytomas associated with the dominantly inherited neurofibromatosis type 1, MEN type 2, and von Hippel-Lindau syndromes, as well as mutations of the succinate dehydrogenase genes. Neuroblastomas, ganglioneuromas, and other neural crest tumors, as well as carcinoid tumors, may secrete pressor amines and mimic pheochromocytoma.

The symptoms of pheochromocytoma are caused by excessive secretion of epinephrine or norepinephrine: headache; sweating; tachycardia, hypertension, vasomotor instability (flushing and postural hypotension); anxiety; dizziness, weakness; nausea, vomiting, diarrhea; dilated pupils, blurred vision; abdominal and precordial pain.

Laboratory diagnosis is possible in more than 90% of cases. Serum and urine catecholamines are elevated, but abnormalities may be limited to periods of symptomatology or paroxysm. Plasma-free metanephrine is the most sensitive and specific test, though phenoxybenzamine, tricyclic antidepressants, and β-adrenoreceptor blockers can cause false-positive results. Levels three times the normal range are diagnostic. Intermediate values may require additional testing with serum and urine catecholamines. After demonstrating a tumor biochemically, imaging methods including CT or MRI are used to localize the tumor and nuclear medicine using functional ligands such as (123)I-MIBG, [^{18}F]DA positron emission tomography scanning, and somatostatin receptor scintigraphy (with either [^{123}I]Tyr3-octreotide or [^{111}In] DTPA-octreotide) are useful in further diagnostic evaluation.

Laparoscopic tumor removal is the treatment of choice; however, the procedure must be undertaken with great caution and with the patient properly stabilized. Oral phenoxybenzamine or intravenous phentolamine is used preoperatively. Profound hypotension may occur as the tumor is removed but may be controlled with an infusion of norepinephrine, which may have to be continued for 1–2 days.

Unless irreversible secondary vascular changes have occurred, complete relief of symptoms is to be expected after recovery from removal of a benign tumor. However, prognosis is poor in patients with metastases, which occur more commonly with large, extra-adrenal pheochromocytomas.

Waguespack SG et al: A current review of the etiology, diagnosis, and treatment of pediatric pheochromocytoma and paraganglioma. J Clin Endocrinol Metab 2010;95(5):2023–2037 [PMID: 20215394].

Diabetes Mellitus

Marian Rewers, MD, PhD
H. Peter Chase, MD

35

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Polyuria, polydipsia, and weight loss; respiratory distress, heavy diapers in infants.
- Hyperglycemia and glucosuria often with ketonemia/ketonuria.

GENERAL CONSIDERATIONS

Type 1 diabetes (T1D) is the most common type of diabetes mellitus in people younger than 20 years but can develop at any age and most cases are diagnosed after age 20. The classical presentation includes increased thirst (polydipsia), urination (polyuria), and weight loss; the patient may be overweight or even obese. T1D is further divided into T1a (autoimmune) (~95% of the cases) and T1b (idiopathic) diabetes. T1a diabetes is marked by presence of autoantibodies to islet cell autoantigens (insulin, GAD65, IA-2, and ZnT8) and high-risk HLA (human leucocyte antigen) haplotypes (DR4-DQ8 and DR3-DQ2). Insulin production, measured by fasting or stimulated C-peptide levels, is usually low. In the United States, T1D affects an estimated 1.5 million people, including more than 200,000 patients younger than 20 years (~25,000 diagnosed annually).

Type 2 diabetes (T2D) is a heterogeneous phenotype diagnosed most often in persons older than age 40 who are usually obese and initially not insulin-dependent. T2D is rare before age 10 but has increased in frequency in older children as a consequence of the epidemic of obesity. The vast majority of the 29 million patients with diabetes in the United States have T2D, but less than 20,000 patients are younger than age 20 (~5000 diagnosed annually).

Monogenic forms of diabetes can be diagnosed at any age. They account for less than 1% of childhood diabetes, but form the majority of cases diagnosed before the ninth month of life. Neonatal diabetes is transient in about half of the cases; if persistent, it presents a significant clinical challenge. Some infants respond better to sulfonylurea than insulin. Maturity-onset diabetes of the young (MODY) presents as a nonketotic and usually non–insulin-dependent diabetes in the absence of obesity or islet autoantibodies. A strong family history of early-onset diabetes is common. The most frequent forms are due to mutations in glucokinase or hepatic nuclear factor 1 or 2 genes. Glucokinase mutations rarely require therapy; other forms respond to oral hypoglycemic agents or insulin. Commercial and research-oriented genotyping services are available to aid correct diagnosis.

» Pathogenesis

A. Type 1 Diabetes

Type 1 diabetes results from autoimmune destruction of the insulin-producing β cells of the pancreatic islets. This destruction occurs over months or years, and symptoms do not appear until most of the pancreatic islets have been destroyed.

The incidence is the highest in children of European ancestry, followed by African Americans and Hispanics; the rates are low in Asians and Native Americans.

About 6% of siblings or offspring of persons with T1D also develop diabetes (compared with prevalence in the general population of 0.2%–0.3%). However, fewer than 10% of children newly diagnosed with T1D have a parent or sibling with the disease. More than 90% of children with T1D carry at least one of the two high-risk HLA haplotypes—DR4/DQ8 or DR3/DQ2—and 40% of US children diagnosed before age 10 years have both (one from each parent), compared with only 2.5% of the general population. Over 50 non-HLA genetic variants have also been implicated.

B. Type 2 Diabetes

Type 2 diabetes has a strong genetic component, although the inherited defects of insulin secretion vary in different families. Obesity, particularly central, and lack of exercise contribute, but are rarely sufficient alone to cause diabetes in youth. Many pediatric patients come from low socioeconomic strata and dysfunctional families; some present with psychiatric disorders. T2D and associated insulin resistance adversely affect cardiovascular health. Acanthosis nigricans, a thickening and darkening of the skin over the posterior neck, armpits, or elbows, is present in many obese children and not specific for the diagnosis of T2D.

» Prevention

A. Type 1 Diabetes

Since the 1950s, the incidence of T1D has increased worldwide, doubling every 20 years. Despite much research of early childhood infections and diet, the environmental factor(s) responsible for this epidemic are poorly defined. There is no effective prevention as of 2015; however, screening of high-risk groups for islet autoantibodies and intensive follow-up reduces the severity of the presentation. Islet autoantibodies do not mediate β-cell destruction, but offer a useful screening tool as they are usually present for years prior to diagnosis. Free antibody screening is now available for families having a relative with type 1 diabetes (1-800-425-8361). The β-cell damage is mediated by T lymphocytes. Immunosuppression at different checkpoints of the autoimmune process can slow down the damage, but has no durable effect when stopped. Immunomodulation, including induction of tolerance to islet autoantigens, with or without immunosuppression, is an area of intensive research.

B. Type 2 Diabetes

The Diabetes Prevention Program in adults with impaired glucose tolerance found that 30 minutes of exercise per day (5 d/wk) and a low-fat diet reduced the risk of diabetes by 58%. Taking metformin also reduced the risk of T2D by 31%.

» Clinical Findings

A combination of polyuria, polydipsia, and weight loss in a child is unique to diabetes. Unfortunately, these symptoms are often missed by parents and primary care providers. The frequency of diabetic ketoacidosis (DKA) in US children has not decreased in the past 20 years and is approximately 40%, a sign of poor provider and poor community awareness. More than half of DKA patients were seen by a provider in days preceding diagnosis and obvious symptoms and signs were missed. In contrast, only 10%–20% of newly diagnosed children in Scandinavia or Canada present with DKA. The correct diagnosis could be improved with better history taking and point-of-care urine analysis. Initial diagnosis can be easily confirmed by blood glucose and ketones measurement using widely available and inexpensive meters.

The clinical presentation of DKA includes abdominal pain, nausea, and vomiting that can mimic an acute abdomen. The patients are mildly to moderately dehydrated (5%–10%), may have Kussmaul respiration, and become progressively somnolent and obtunded. The age of diagnosis has shifted lower; infants, toddlers, and preschool age children are at particular risk. They often have symptoms of minor infection or gastrointestinal upset. A heavy diaper in a dehydrated child without diarrhea should always flash an alarm. A blood or urine glucose test could be lifesaving.

Blood glucose higher than 200 mg/dL in a child is always abnormal and must be promptly and meticulously followed in consultation with a pediatric endocrinology service. If the presentation is mild and an outpatient diabetes education service is available, hospitalization is usually not necessary.

In the presence of typical symptoms, a random blood glucose level above 200 mg/dL (11 mmol/L) (confirmed on a CLIA [Clinical Laboratory Improvement Amendments]-certified instrument) is sufficient to make the diagnosis of diabetes. An oral glucose tolerance test is rarely necessary in children. In borderline or asymptomatic cases, a fasting plasma glucose level more than 125 mg/dL (7 mmol/L) or a plasma glucose level above 200 mg/dL (11.1 mmol/L) 2 hours after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g) on 2 separate days confirms the diagnosis. Impaired (not yet diabetic) fasting glucose values are 100–125 mg/dL (5.5–6.9 mmol/L) and impaired 2-hour values are 140–200 mg/dL (7.8–11.1 mmol/L). Children with impaired fasting glucose or impaired glucose tolerance and no islet autoantibodies are at high risk of T2D and require careful follow-up and lifestyle modification with weight loss, if obese.

» Differential Diagnosis

A combination of polyuria, polydipsia, and weight loss in a child is unique to diabetes.

Transient, "stress-" or steroid-induced hyperglycemia can occur with illness. In a well-child, the diagnosis must not be based on a single plasma glucose test or a borderline result obtained using a glucose meter. Our center routinely tests such children for islet autoantibodies to rule out ongoing islet autoimmunity. Absence of the three most available autoantibodies (to insulin, GAD, and IA-2) provides 80% negative predictive value. If HbA_{1c} is normal, we recommend home monitoring of blood glucose for several days. In children progressing to overt diabetes, hyperglycemia after dinner is usually the initial abnormality, while fasting hyperglycemia develops much later.

» Complications

A. Diabetic Ketoacidosis

Acidosis (venous blood pH < 7.30 or bicarbonate < 15 mEq/L) is unfortunately still a frequent acute complication in patients with newly diagnosed T1D.

In established T1D, acidosis may occur in those who miss insulin injections, do not check blood or urine ketone levels, or fail to seek help when ketones are elevated. Repeated episodes of ketoacidosis signify that counseling may be indicated, and that a responsible adult must take over the diabetes management. If for any reason this is not possible, a change in the child's living situation may be necessary.

Treatment of DKA is based on four physiologic principles: (1) restoration of fluid volume; (2) intravenous insulin to inhibit lipolysis and return to glucose utilization; (3) replacement of electrolytes; and (4) correction of acidosis. Mild DKA is defined as a venous blood pH of 7.2–7.3; moderate DKA, a pH of 7.10–7.19; and severe DKA, a pH below 7.10. Patients with severe DKA should be hospitalized in a pediatric intensive care unit, if available. Laboratory tests at the start of treatment should include venous blood pH, glucose, and an electrolyte panel. More severe cases may benefit from determination of blood osmolality, calcium, phosphorus, and urea nitrogen levels. Severe and moderate episodes of DKA generally require hourly determinations of serum glucose, electrolytes, and venous pH levels, whereas these parameters can be measured every 2 hours if the pH level is 7.20–7.30.

1. Restoration of fluid volume—Dehydration is judged by estimated loss of body weight, dryness of oral mucous membranes, low blood pressure, and tachycardia. Initial treatment is with normal saline (0.9%), 10–20 mL/kg during the first hour (can be repeated in severely dehydrated patients during the second hour). The total volume of fluid in the first 4 hours of treatment should not exceed 20–40 mL/kg because of the danger of cerebral edema. After initial expansion, 0.45%–0.9% saline is given at 1.5 times maintenance to replace losses over 24–36 hours. When blood glucose level falls below 250 mg/dL (13.9 mmol/L), 5% dextrose is added to the intravenous fluids. If blood glucose level falls below 120 mg/dL (6.6 mmol/L), 10% dextrose can be added.

2. Inhibition of lipolysis and return to glucose utilization—Insulin turns off fat breakdown and ketone formation. Regular insulin is given after completion of the initial fluid bolus, as a continuous drip at a rate of 0.05–0.1 U/kg/h to achieve a drop in blood glucose of approximately 100 mg/dL/h. An IV insulin bolus is not recommended as it may increase the risk of brain edema. Fast-acting insulin analogues have no advantage over regular insulin when given intravenously. The insulin solution should be administered by pump and can be made by diluting 30 units of regular insulin in 150 mL of 0.9% saline (1 U/5 mL). If necessary, the insulin dosage can be reduced, but it should not be discontinued before the venous blood pH reaches 7.30 and there is sufficient level of insulin from subcutaneous injections. We recommend continuing intravenous insulin for at least 30 minutes after the initial subcutaneous injection of short-acting insulin.

3. Replacement of electrolytes—In patients with DKA, both sodium and potassium are depleted. Serum sodium concentrations may be corrected for hyperglycemia. Sodium is usually replaced adequately by the use of 0.45%–0.9% saline in the rehydration fluids.

Serum potassium levels may be elevated initially because of inability of potassium to stay in the cell in the presence of acidosis (even though total body potassium is low). Potassium should not be given until the serum potassium level is known to be less than 5 mEq/L and urine output is confirmed. It is then usually given in replacement fluid at a concentration of 40 mEq/L, with half of the potassium (20 mEq/L) either as potassium acetate or potassium chloride and the other half as potassium phosphate (20 mEq/L). Hypocalcemia can occur if all of the potassium is given as the phosphate salt; hypophosphatemia occurs if none of the potassium is of the phosphate salt.

4. Correction of acidosis—Acidosis corrects spontaneously as the fluid volume is restored and insulin facilitates aerobic glycolysis and inhibits ketogenesis. Bicarbonate is generally not recommended.

5. Management of cerebral edema—Some degree of cerebral edema has been shown by computed tomography to occur commonly in DKA. Associated clinical symptoms are rare, unpredictable, and may be associated with demise. Cerebral edema may be related to the degree of dehydration, cerebral hypoperfusion, acidosis, and hyperventilation at the time of presentation. In general, it is recommended that no more than 40 mL/kg of fluids be given in the first 4 hours of treatment and that subsequent fluid replacement not exceed 1.5 times maintenance. Cerebral edema is more common when the serum sodium is noted to be falling rather than rising. Early neurologic signs may include headache, excessive drowsiness, and dilated pupils. Prompt initiation of therapy should include elevation of the head of the bed, mannitol (1 g/kg over 30 minutes), and fluid restriction. If the cerebral edema is not recognized and treated early, over 50% of patients will die or have permanent brain damage.

B. Hypoglycemia

Hypoglycemia (or "insulin reaction") is defined as a blood glucose level below 60 mg/dL (3.3 mmol/L). For preschool children, values below 70 mg/dL (3.9 mmol/L) should be cause for concern. The common symptoms of hypoglycemia are hunger, weakness, shakiness, sweating, drowsiness (at an unusual time), headache, and behavioral changes. Every year, 10%–25% of children with T1D experience one

or more severe hypoglycemic episodes (loss of consciousness or seizure). If low blood glucose is not treated immediately with simple sugar, the hypoglycemia may result in loss of consciousness and seizures; brain damage or death can occur with prolonged hypoglycemia.

Children learn to recognize hypoglycemia at different ages but can often report "feeling funny" as young as age 4–5 years. School personnel, sports coaches, and babysitters must be trained to recognize and treat hypoglycemia. Consistency in daily routine, correct insulin dosage, regular blood glucose monitoring, controlled snacking, compliance of patients and parents, and good education are all important in preventing severe hypoglycemia. In addition, insulin should not be injected prior to getting into a hot tub, bath, or shower as the heat may cause more rapid insulin uptake. The use of insulin analogues, insulin pumps, and continuous glucose monitoring (CGM) has helped to reduce the occurrence of hypoglycemia.

The treatment of mild hypoglycemia involves giving 4 oz of juice, a sugar-containing soda drink, or milk, and waiting 10 minutes. If the blood glucose level is still below 60 mg/dL (3.3 mmol/L), the liquids are repeated. If the glucose level is above 60 mg/dL, solid foods are given. Moderate hypoglycemia, in which the person is conscious but incoherent, can be treated by squeezing one-half tube of concentrated glucose (eg, Insta-Glucose or cake frosting) between the gums and lips and stroking the throat to encourage swallowing.

Families are advised to have glucagon in the home and in their travel pack to treat severe hypoglycemia by giving subcutaneous or intramuscular injections of 0.3 mL (30 units in an insulin syringe) for children younger than 5 years; 0.5 mL (50 units) to those older than age 5 years; and 1 mL (100 units) to those heavier than 100 lb. Smaller doses of glucagon (two units + number of units equal to the age of the child, eg, 2 + 10 = 12 units in a 10-year-old) up to a maximum of 15 units can be used to prevent severe hypoglycemia during nondiabetic illness (gastroenteritis, respiratory infections).

Some patients, usually those who have had diabetes for more than 10 years or those tolerating routinely blood glucose 50–80 mg/dL, fail to recognize the symptoms of low blood glucose (hypoglycemic unawareness). For these individuals, glucose control must be liberalized to prevent severe hypoglycemia and CGM should be considered.

C. Long-Term Complications

Table 35–1 summarizes routine tests helpful in preventing long-term complications.

1. Hypertension—Elevated blood pressure is prevalent among children with diabetes and strongly predicts micro- and macrovascular complications. Treatment of blood pressure is critical in reducing these complications in adults with diabetes and presumably in children and adolescents as well. Blood pressure should be checked and reviewed at each clinic visit. Hypertension is defined as systolic or diastolic blood pressure (measured on at least 3 separate days) above the 95th percentile for the child's age, sex, and height. If elevated blood pressure is confirmed, nondiabetic causes should first be excluded. Angiotensin-converting enzyme inhibitors are the first-line agents; if not tolerated well, angiotensin II receptor blockers can be used.

2. Lipid abnormalities—Lipid profiles are generally favorable in children with T1D. The screening for dyslipidemia should commence after the age of 2 years and, if normal, should be repeated every 5 years. Good glycemic control should be established in newly diagnosed patients prior to screening, but screening should not be delayed more than 1 year after diagnosis. Children with LDL levels of 130–159 mg/dL (3.4–4.1 mmol/L) should receive dietary and exercise counseling for 6 months, with consideration of pharmacologic therapy if this fails. Statin therapy in addition to diet

Table 35–1. Checklist of good diabetes management in children and adolescents.

Variable	Frequency of Measurement	Tests and Values
Blood glucose	At least four times daily	See Table 35–2
Hemoglobin A_{1c}	Every 3 mo	< 7.5%
Blood pressure	Every 3 mo	< 95th percentile for age
Blood lipid panel	Within 1 y after diagnosis (age ≥ 2 y); if normal, repeat q 5 y	LDL < 100 mg/dL (2.6 mmol/L), HDL > 35 mg/dL(0.9 mmol/L), triglycerides < 150 mg/dL(1.7 mmol/L).
Urine—microalbumin	Annually after 3–5 y of diabetes (age ≥ 10 y)	AER < 20 mcg/min A/C ratio < 30 mg/g
Ophthalmology referral	Annually after 3–5 y of diabetes (age ≥ 10 y)	Retinal photographs
Signs of other endocrinopathy	Evaluate thyroid at least annually Autoantibody screening every 1–2 y • Celiac disease • Addison disease	TSH: 0.5–5.0 IU/mL T4: 4.5–10 mcg/dL TPO Ab Transglutaminase IgA Ab 21-hydroxylase Ab

Ab, antibody; A/C, albumin/creatinine; AER, albumin excretion rate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; T4, thyroxine; TPO, thyroid peroxidase autoantibodies; TSH, thyroid-stimulating hormone.

and lifestyle changes is recommended if LDL is more than 160 mg/dL (4.1 mmol/L). The treatment goals are LDL less than 100 mg/dL (2.6 mmol/L), HDL more than 35 mg/dL (0.9 mmol/L), and triglycerides less than 150 mg/dL (1.7 mmol/L). The use of lipid-lowering drugs in children has been the subject of much discussion. The American Heart Association recommends initiating therapy with statins at the lowest dose at age more than 10 years in boys, Tanner stage II or higher, and preferably after menarche in girls.

3. Nephropathy—Rapid decline of the glomerular filtration rate (GFR) is the first clinical manifestation of diabetic kidney disease and may be reversible with diligent glycemic and blood pressure control. Microalbuminuria is an established risk factor, defined as: urinary albumin excretion rate between 20 and 200 μg/min or urinary albumin/creatinine ratio 2.5–25 mg/mmol or 30–300 mg/g (spot urine) in males and 3.5–25 mg/mmol in females. Screening for microalbuminuria with a random spot urine sample should occur annually in children once they are 10 years of age and have had diabetes for more than 3–5 years. If values are abnormal or borderline, two timed overnight collections should occur. The diagnosis of microalbuminuria requires documentation of two out of three abnormal samples over a period of 3–6 months. Once persistent microalbuminuria is confirmed, nondiabetic causes of renal disease should be excluded. Following this evaluation, treatment with an ACE inhibitor should be started, even if the blood pressure is normal. Patients should be counseled about the importance of glycemic control and smoking cessation, if applicable. Patients with T2D should have microalbuminuria assessed soon after diagnosis and then annually.

4. Retinopathy—The first dilated ophthalmologic examination should be obtained by an ophthalmologist or optometrist trained in diabetes-specific retinal examination once the child is ≥ 10 year old and has had diabetes for 3–5 years. The frequency of subsequent examination is generally every 1–2 years, depending on the patient risk profile and advice of the eye care provider. While rare in children, proliferative retinopathy does occur in adolescents with long duration and poor control of diabetes. Laser treatment to coagulate proliferating capillaries prevents bleeding and leakage of blood into the vitreous fluid or behind the retina. This treatment preserves useful vision.

5. Associated autoimmune diseases—Thyroid-stimulating hormone (TSH) level should be measured every 1–2 years in all patients. Thyroid peroxidase autoantibody (TPO) is usually the first test to become abnormal in the autoimmune thyroiditis affecting up to 20% of children with T1D. If TPO is positive, we recommend screening with TSH every 6–12 months.

Transglutaminase autoantibodies offer a sensitive and specific screening test for celiac disease affecting up to 10% of children with T1D. Risk of celiac disease is most strongly associated with the HLA-DR3-DQ2 haplotype. We recommend routine screening at diagnosis of diabetes and, if negative, retesting every 1–2 year. About half of celiac disease cases develop several years after diagnosis of T1D. Most of the biopsy-confirmed children are "asymptomatic," but report improved health status upon initiation of gluten-free diet. Untreated celiac disease may lead to severe hypoglycemia, increased bone turnover, and decreased bone mineralization, among many other long-term complications (see Chapter 21).

The 21-hydroxylase autoantibody, a marker of increased risk of Addison disease, is present in approximately 1% of patients with T1D, although Addison disease develops (usually slowly) in only about one-third of these antibody-positive individuals.

» Treatment

A. Treatment of Type 1 Diabetes

1. Treatment goals—The overarching goals of therapy in T1D include prevention of acute and long-term complications by reducing chronic hyperglycemia, along with preventing hypoglycemia and maximizing quality of life. The HbA_{1c} level reflects the average blood glucose levels over the previous 3 months. Each child should have targets individually determined to aim for the lowest HbA_{1c} that can be sustained without severe hypoglycemia or frequent moderate hypoglycemia.

In the seminal DCCT trial, HbA_{1c} values of 7%, compared to 9%, resulted in greater than 50% reductions in the eye, kidney, cardiovascular, and neurologic complications of T1D. At present, the safest recommendation for glycemic control in children is to achieve an HbA_{1c} less than 7.5%; unfortunately less than 30% of the US children and youth meet this goal.

2. Patient and family education—All caregivers need to learn about diabetes, how to give insulin injections, perform home blood glucose monitoring, and handle acute complications. While teenagers can be taught to perform many of the tasks of diabetes management, they do better when supportive, not overbearing, parents continue to be involved in management of their disease. The use of an educational book (see Understanding Diabetes and Understanding Insulin Pumps and Continuous Glucose Monitors) can be very helpful to the family.

3. Home blood glucose monitoring—All families must be able to monitor blood glucose levels at least four times daily—and more frequently in patients who have glucose-control problems or intercurrent illnesses. Blood glucose levels can be monitored using any downloadable meter. Target levels when no food has been eaten for 2 or more hours vary according to age (Table 35–2).

Table 35–2. Ideal glucose levels after 2 or more hours of fasting.

Age (y)	Glucose Level
≤ 4	80–200 mg/dL (4.6–11 mmol/L)
5–11	70–180 mg/dL (3.9–10 mmol/L)
≥ 12	70–150 mg/dL (3.9–8.3 mmol/L)

The frequency of self-monitoring of blood glucose correlates with improved HbA_{1c}. Blood glucose results, insulin dosage, and events, for example, illness, parties, exercise, menses, and episodes of hypoglycemia or ketonuria/ketosis should be recorded in a logbook or downloaded. Regular evaluation by the family helps to see patterns, adjust insulin dosage and, if needed, communicate with health care providers. If more than 50% of the values are above the desired range for age or more than 15% below the desired range, the insulin dosage needs to be adjusted.

Some families are able to make these changes independently, whereas others need help from the health care provider by telephone, fax, or email to optimize insulin dose between visits. Children with diabetes should be evaluated by a diabetes provider every 3 months to check compliance, adjust insulin dose according to growth, measure HbA_{1c}, and review blood glucose patterns, as well as for routine review of systems, physical examination, and laboratory tests (see Table 35–1).

Continuous glucose monitoring (CGM) is now routinely available and can tremendously improve diabetes management if used most of the time. Subcutaneous glucose levels are obtained every 1–5 minutes from a sensor placed under the skin. The sensor must be replaced every 7–10 days. A transmitter sends glucose levels via radio waves from the sensor to a receiver that can be inside an insulin pump. As with insulin pump therapy, intensive education and follow-up is required, usually at a specialty diabetes center. The user is trained on how to keep the real-time displayed blood glucose "between the lines," that is, in the personalized range. Low and high blood glucose alarms can be set and in some systems they may change insulin pump delivery rate. At the time of consultation, data from CGM devices and pumps are routinely downloaded for analysis of patterns.

4. Insulin—Insulin has three key functions: (1) it allows glucose to pass into the cell for oxidative utilization; (2) it decreases the physiologic production of glucose, particularly in the liver; and (3) it turns off lipolysis and ketone production.

a. Insulin treatment of new-onset type 1 diabetes—In children who present without DKA and have adequate oral intake, the initial insulin dose can be administered subcutaneously as 0.2 U/kg of short-acting insulin (regular) or, preferentially, rapid-acting analogue: lispro (Humalog), aspart (NovoLog), or glulisine (Apidra). At the same time, 0.2–0.3 U/kg of long-acting insulin analogue—glargine (Lantus) or detemir (Levemir)—can be administered subcutaneously to provide the "basal" level of insulin. This usually suffices for the initial 12–24 hours preceding systematic diabetes education.

The dose is adjusted with each injection during the first week. The rule of thumb is to start insulin at the low end of the estimated daily requirement and titrate it up based on frequent (q2–4h) blood-glucose monitoring. The initial daily dose of insulin is higher in the presence of ketosis, infection, obesity, or steroid treatment. It also varies with age and severity of onset. A total subcutaneous daily dose of 0.3–0.7 U/kg/d may suffice in prepubertal children, while pubertal or overweight children and those with initial HbA_{1c} more than 12% commonly require 1–1.5 U/kg/d of insulin during the initial week of treatment. Children younger than 12 years cannot reliably administer insulin without adult supervision because they may lack fine motor control and/or may not understand the importance of accurate dosage.

The insulin dose peaks about 1 week after diagnosis and decreases slightly with the waning of glucotoxicity and voracious appetite. Approximately 3–6 weeks after diagnosis, most school-children and adolescents experience a partial remission or "honeymoon period." Temporary decrease in the insulin dose during this period is necessary to avoid severe hypoglycemia. The remission tends to last longer in older children, but is rarely complete and never permanent. Other types of diabetes should be considered in patients with unusually low insulin requirements.

b. Long-term insulin dosage—Children usually receive a rapid-acting insulin to cover food intake or correct high blood glucose and a long-acting insulin to suppress endogenous hepatic glucose production. This is achieved by combining insulins with different desired properties. Understanding the onset, peak, and duration of insulin activity is essential (see Table 35–3).

Nearly all children diagnosed with T1D at our center receive insulin from a pump or through basal-bolus multiple daily injections (MDI). This usually consists of injections (boluses) of rapid-acting analogue before meals (ie, three to four times daily) and one to two injections of long-acting analogue insulin. The dose of premeal rapid-acting insulin is calculated based on anticipated carbohydrate content of the meal and additional insulin to correct for high blood glucose, if needed. Sliding scales for dosing of rapid-acting insulin (based only on current blood glucose level) are helpful initially, while families learn carbohydrate counting. This shortcut assumes that the content of carbohydrates, for example in dinner, does not vary from day to day, this may lead to significant under- and overdosing.

Table 35–3. Kinetics of insulin action.

Type of Insulin	Begins Working	Main Effect	All Gone
Rapid-acting			
Regular	30 min	95 min	6–9 h
Humalog (lispro) NovoLog (aspart) Apidra (glulisine)	10–15 min	55 min	4 h
Intermediate-acting			
NPH (neutral protamine Hagedorn)	2–4 h	6–8 h	12–15 h
Long-acting			
Lantus (glargine) Levemir (detemir)	3–4 h	6–18 h	18–26 h
Tresiba (degludec)	4 h	no peak	24- 40 h
Premixed (available in various combinations)			
NovoLog 75/25 (75% NPH + 25% lispro)	15 min	1–8 h	12–15 h
Humulin 70/30 (70% NPH+30% Regular)	30 min	Variable	12–18 h

Children younger than 4 years usually need one or two units of rapid-acting insulin to cover carbohydrate intake. Children aged 4–10 years may require up to four units of rapid-acting insulin to cover breakfast and dinner, whereas 4–10 units of rapid-acting insulin are used in older children. These estimates do not include correction for high blood glucose.

Families gradually learn to make small weekly adjustments in insulin dosage based on home blood glucose testing. Rapid-acting analogue insulin is given 10–20 minutes before eating to account for delay in insulin action. If slower human regular insulin is used, the injections should be given 30–60 minutes before meals—rarely a practical option. In young children who eat unpredictably, it is often necessary to wait until after the meal to decide on the appropriate dose of rapid-acting insulin, which is a compromise between avoiding hypoglycemia and tolerating hyperglycemia after meals.

A long-acting analogue insulin glargine (Lantus) or detemir (Levemir) is given once or twice a day to maintain basal insulin levels between meals. Daily adjustments in long-acting insulin dose usually are not needed. However, decreases should be made for heavy activity (eg, sports, hikes, or overnight events).

In the past, most children would receive two injections per day of rapid-acting insulin and an intermediate-acting insulin (NPH), often mixed just before injection. About two-thirds of the total dosage would be given before breakfast and the remainder before dinner. This regimen has been shown to be inferior in achieving recommended HbA_{1c} levels and avoiding hypoglycemia, compared with the basal-bolus regimen described previously. Analogue insulin (glargine, detemir) works more efficiently than NPH. When changing a patient from NPH insulin to an analogue, initially only 50% of the daily units of long-acting insulin is recommended.

c. Insul in pump t r eat ment —Continuous subcutaneous insulin (insulin pump) therapy is currently the best way to restore the body's physiologic insulin profile. The pump delivers a variable programmed basal rate that corresponds to the diurnal variation in insulin needs. Prepubertal children require higher basal rate in the early part of night, while postpubertal patients who experience the "dawn phenomenon" require higher rates in the morning. Lower rates are set for periods of vigorous activity. The user initiates bolus doses before meals and to correct hyperglycemia. Most pumps can receive wireless transmission of test results from glucose meters, but the patient or caregiver must still manually enter the amount of carbohydrate being consumed. The pump calculates the amount of insulin needed for a meal or correction based on previously entered parameters which include: insulin-to-carbohydrate ratios, insulin sensitivity factor, glycemic target, and duration of insulin action (set at 3–4 hours to protect from accumulating too much insulin). The user may override the suggestion or press a button to initiate the bolus.

Most clinical trials have demonstrated better HbA_{1c} and less severe hypoglycemia with pump therapy, compared to MDI. Pump therapy can improve the quality of life in children who have trouble with or fear of injections or who desire greater flexibility in their lifestyle; for example, with sleeping in, sports, or irregular eating. Insulin pumps can be particularly helpful in young children or infants who have multiple meals and snacks and require multiple small doses of rapid-acting insulin. The newer generation of insulin pumps can deliver as little as 0.025 U/h, but higher rates using diluted insulin may be needed for uninterrupted flow.

Compliance problems include infrequent blood glucose testing, not reacting to elevated blood glucose, incorrect carbohydrate counting, or missing the boluses altogether. Side effects of insulin pump treatment include failures of insulin delivery because of a displaced or obstructed infusion set. Insulin pump treatment is significantly more expensive than regimens based on injections. For some patients, pumps may be too difficult to operate; some cannot comply with the multiple testing and carbohydrate counting requirements, or the pump is unacceptable because of body image issues or extreme physical activity (swimming, contact sports). Disposable pumps are already available and much smaller "patch" pumps are in development.

5. "Closed-loop" systems—In the near future, insulin pumps will be directed automatically by a continuous glucose sensor with minimal human input. Simple systems are already available that feature, for instance, sensor-initiated automatic suspension of insulin delivery at a predetermined low-glucose level and automatic resumption of the delivery at a safe level. Other systems that react to predicted, rather than current, low or high blood glucose are in clinical trials. A number of issues remain to be solved, for example, the accuracy and biocompatibility of the sensors and infusion sets, limitations (lag time) of the systemic versus intraportal administration of insulin, lack of counterbalancing delivery of glucagon, and optimal delivery algorithms for various meals and activities.

6. Sick day management—Families must be educated to check blood or urine ketone levels during any illness, when a fasting blood glucose level is above 240 mg/dL (13.3 mmol/L), or a randomly measured glucose level is above 300 mg/dL (16.6 mmol/L). The health care provider should be called in presence of moderate or significant ketonuria or ketonemia (blood β-hydroxybutyrate > 1.0 mmol/L, by Precision Xtra meter). Usually 10%–20% of the total daily insulin dosage is given subcutaneously as rapid-acting analogue or regular insulin every 3–4 hours until blood glucose normalizes. This prevents progression to ketoacidosis and allows most patients to receive treatment at home. Water is the oral fluid of choice if blood glucose is more than 250 mg/dL; at lower levels of glycemia, one should switch to Gatorade/Poweraid or other glucose-containing beverages.

Mild ketonuria/ketonemia secondary to fasting or acute gastrointestinal upset and associated with normal or low blood glucose does not require supplemental insulin treatment. Of note, the brain uses β-hydroxybutyrate as the alternate fuel to glucose in the setting of hypoglycemia. Overtreatment with insulin during a sick day that begins with hyperglycemia and ketosis may lead to severe hypoglycemia resulting in loss of consciousness and/or seizures.

7. Diet—A thorough dietary history should be obtained, including the family's dietary habits and traditions, the child's typical meal times, and patterns of food intake. Nutritional management in children with diabetes does not require a restrictive diet; just a healthy dietary regimen that benefits the children and their families. Insulin pump and MDI therapy utilize carbohydrate counting in which the grams of carbohydrate to be eaten are counted and a matching dose of insulin is administered. This plan allows for the most freedom and flexibility in food choices, but it requires expert education and commitment and may not be suitable for many families or situations, such as for school lunches and teenagers. Alternatively to a precise carbohydrate counting, "exchanges" are taught to estimate 10- or 15-g servings of carbohydrate.

A constant carbohydrate meal plan was used often in the past with insulin regimens based on NPH and regular insulin, where carbohydrate intake and the amount of insulin were kept relatively constant from day to day. This is now perceived as too restrictive and a potential source of conflict that will lead to poor control.

8. Exercise—Regular aerobic exercise is important for children with diabetes. Exercise fosters a sense of well-being; helps increase insulin sensitivity (a drop in glycemia in response to insulin); and helps maintain proper weight, blood pressure, and HDL-cholesterol levels.

Hypoglycemia during exercise or in the 2–12 hours after exercise can be prevented by careful monitoring of blood glucose before, during, and after exercise; reducing the dosage of the insulin active at the time of (or after) the exercise; and by providing extra snacks. Fifteen grams of glucose usually covers about 30 minutes of exercise. The use of drinks containing 5%–10% dextrose, such as Gatorade, during the period of exercise is often beneficial. Insulin dose for meals as well as the basal insulin pump rate should be reduced before, during, and sometimes after the exercise; the longer and more vigorous the activity, the greater the reduction in insulin dose.

9. Psychological care—The diagnosis of T1D changes lives of the affected families and brings on relentless challenges. It is impossible to take "vacation" from diabetes without some unpleasant consequences. The stress imposed on the family around the time of initial diagnosis may lead to feelings of shock, denial, sadness, anger, fear, and guilt. Meeting with a counselor to express these feelings at the time of diagnosis helps with long-term adaptation. Children with T1D and their parents often experience difficult adjustment. Persisting adjustment problems may indicate underlying dysfunction of the family or psychopathology of the child or caregiver. Young people with T1D are more frequently diagnosed with and treated for psychiatric disorders, disordered eating, neurocognitive, learning problems, and poor coping skills than the general population.

Routine assessment should be made of developmental adjustment to and understanding of diabetes management, including diabetes-related knowledge, insulin adjustment skills, goal setting, problem-solving abilities, regimen adherence, and self-care autonomy and competence. This is especially important during late childhood and prior to adolescence. General and diabetes-related family functioning such as communication, parental involvement and support, and roles and responsibilities for self-care behaviors need to be assessed. Teaching parents effective behavior management skills, especially at diagnosis and prior to adolescence, emphasizes involvement and support, effective problem-solving, self-management skills, and realistic expectations. Adolescents should be encouraged to assume increased responsibility for diabetes management, but with continued, mutually agreed parental involvement and support. The transition to adult diabetes care should be negotiated and

planned between adolescents, their parents, and the diabetes team well in advance of the actual transfer.

B. Treatment of Type 2 Diabetes

Treatment of type 2 diabetes in children varies with the severity of the disease. If the HbA_{1c} is still near normal, modification of lifestyle (preferably for the entire family) is the first-line therapy. This must include reducing caloric intake and increasing exercise. With mildly elevated HbA_{1c} (6.2%–8%) and no ketosis, metformin is usually started at a dose of 500 mg twice daily along with modification of lifestyle. If needed, and if gastrointestinal adaptation has occurred, the dose can be gradually increased to 1 g twice daily. If the presentation is more severe, with ketosis, the initial treatment is similar to that of T1D, including IV or subcutaneous insulin. Of note, 10% of children with T2D present in DKA. Oral hypoglycemic agents may be tried at a later date, particularly if weight loss has been successful.

» Prognosis

The long-term prognosis of children diagnosed with T1D has improved tremendously over the past 20 years, primarily due to better control of blood glucose and blood pressure. While life expectancy is now only slightly shorter in these patients, compared to the general population, the risk of cardiovascular disease is still 4–10 times higher, especially in diabetic women.

Modern diabetes care generally leads to excellent health outcomes. Tremendous progress in biotechnology (insulin analogues), insulin pumps, and continuous glucose sensing has made the prevention of acute and long-term complications achievable. However, comprehensive and continuing education of patients and their families remains the foundation of healthy and quality life with diabetes.

Inborn Errors of Metabolism

Janet A. Thomas, MD
Johan L.K. Van Hove, MD, PhD, MBA

Disorders in which single gene defects cause clinically significant blocks in metabolic pathways are called inborn errors of metabolism. Once considered rare, the number of recognized inborn errors has increased dramatically and they are now recognized to affect 1:1500 children. Many of these disorders can be treated effectively. Even when treatment is not available, correct diagnosis permits parents to make informed decisions about future offspring.

The pathology in metabolic disorders usually results from accumulation of enzyme substrate behind a metabolic block, or from deficiency of a reaction product. In some cases, the accumulated enzyme substrate is diffusible and has adverse effects on distant organs; in other cases, as in lysosomal storage diseases, the substrate primarily accumulates locally. The clinical manifestations of inborn errors vary widely with both mild and severe forms of virtually every disorder. Many patients do not match the classic phenotype because mutations are not identical in different patients, even though they occur in the same gene.

A first treatment strategy is to enhance the reduced enzyme activity. Gene replacement is a long-term goal, but problems of gene delivery to target organs and control of gene action make this an unrealistic option at present. Enzyme-replacement therapy using intravenously administered recombinant enzyme has been developed as an effective strategy in lysosomal storage disorders. Organ transplantation (liver or bone marrow) can provide a source of enzyme for some conditions. Pharmacologic doses of a cofactor such as a vitamin can sometimes be effective in restoring enzyme activity. Residual activity can be increased by pharmacologically promoting transcription (transcriptional upregulation) or by stabilizing the protein product through therapy with chaperones. Alternatively, some strategies are designed to cope with the consequences of enzyme deficiency. Strategies used to avoid substrate accumulation include restriction of precursor in the diet (eg, low-phenylalanine diet for phenylketonuria), avoidance of catabolism, inhibition of an enzyme in the synthesis of the precursor (eg, NTBC in tyrosinemia type I (see section Hereditary Tyrosinemia), or removal of accumulated substrate pharmacologically (eg, glycine therapy for isovaleric acidemia) or by dialysis. An inadequately produced metabolite can also be supplemented (eg, glucose administration for glycogen storage disease type I).

Inborn errors can manifest at any time, can affect any organ system, and can mimic many common pediatric problems. This chapter focuses on when to consider a metabolic disorder in the differential diagnosis of common pediatric problems. A few of the more important disorders are then discussed in detail.

DIAGNOSIS

SUSPECTING INBORN ERRORS

Inborn errors must be considered in the differential diagnosis of critically ill newborns, children with seizures, neurodegeneration, recurrent vomiting, Reye-like syndrome, parenchymal liver disease, cardiomyopathy, unexplained metabolic acidosis, hyperammonemia, and hypoglycemia. Mental retardation, developmental delay, and failure to thrive are often present but have little specificity. Inborn errors should be suspected when (1) symptoms accompany changes in diet, (2) the child's development regresses, (3) the child shows specific food preferences or aversions, or (4) the family has a history of parental consanguinity or problems suggestive of inborn error such as retardation or unexplained deaths in first- and second-degree relatives.

Physical findings associated with inborn errors include alopecia or abnormal hair, retinal cherry-red spot or retinitis pigmentosa, cataracts or corneal opacity, hepatomegaly or splenomegaly, coarse features, skeletal changes (including gibbus), neurologic regression, and intermittent or progressive ataxia or dystonia. Other features that may be important

in the context of a suspicious history include failure to thrive, microcephaly, rash, jaundice, hypotonia, and hypertonia.

Finding an immediate cause of symptoms does not rule out an underlying inborn error. For example, renal tubular acidosis and cirrhosis may be due to an underlying inborn error. Acute crises may be brought on by intercurrent infections in some inborn errors. Some inborn errors suggest a diagnosis of nonaccidental trauma (eg, glutaric acidemia type I) or poisoning (eg, methylmalonic acidemia). In addition, children with inborn errors may be at higher risk for child abuse or neglect because of their frustrating irritability.

LABORATORY STUDIES

Laboratory studies are almost always needed for the diagnosis of inborn errors. Serum electrolytes and pH should be used to estimate anion gap and acid-base status. Serum lactate, pyruvate, and ammonia levels are available in most hospitals, but care is needed in obtaining samples appropriately. Amino acid, acylcarnitine, and organic acid studies must be performed at specialized facilities to ensure accurate analysis and interpretation. An increasing number of inborn errors are diagnosed with DNA sequencing, but interpretation of private mutations, that is, mutations only seen in a particular family, can be problematic. Knowing the causative mutation in the family allows prenatal diagnosis to be done by molecular analysis. This can be done on any material that contains fetal DNA such as chorionic villi, amniotic cells, or fetal blood obtained through umibilical cord blood sampling. Large scale next generation sequencing such as exome or genome sequencing has been very useful in identifying disorders with nonspecific symptoms that are not readily recognized by routine metabolite screening, such as mental retardation. Specific metabolite or enzyme assays are used for confirmation.

The physician should know what conditions a test can detect and when it can detect them. For example, urine organic acids may be normal in patients with medium-chain acyl-CoA dehydrogenase deficiency or biotinidase deficiency; glycine may be elevated only in cerebrospinal fluid (CSF) in patients with nonketotic hyperglycinemia. A result that is normal in one physiologic state may be abnormal in another. For instance, the urine of a child who becomes hypoglycemic upon prolonged fasting should be positive for ketones. In such a child, the absence of ketones in the urine suggests a defect in fatty acid oxidation.

Samples used to diagnose metabolic disease may be obtained at autopsy. Samples must be obtained in a timely fashion and may be analyzed directly or stored frozen until a particular analysis is justified by the results of postmortem examination, new clinical information, or developments in the field. Studies of other family members may help establish the diagnosis of a deceased patient. It may be possible to demonstrate that parents are heterozygous carriers of a particular disorder or that a sibling has the condition.

COMMON CLINICAL SITUATIONS

1. Mental Retardation

Some inborn errors can cause mental retardation without other distinguishing characteristics. Measurements of plasma amino acids, urine organic acids, and serum uric acid should be obtained in every patient with nonspecific mental retardation. Urine screens for mucopolysaccharides and succinylpurines and serum testing for carbohydrate-deficient glycoproteins are useful because these disorders do not always have specific physical findings. Absent speech can point to disorders of creatine. Abnormalities of the brain detected by magnetic resonance imaging can suggest specific groups of disorders (eg, cortical migrational abnormalities in peroxisomal biogenesis disorders).

2. Acute Presentation in the Neonate

Acute metabolic disease in the neonate is most often a result of disorders of protein or carbohydrate metabolism and may be clinically indistinguishable from sepsis. Prominent symptoms include poor feeding, vomiting, altered mental status or muscle tone, jitteriness, seizures, and jaundice. Acidosis, alkalosis, or altered mental status out of proportion to systemic symptoms should increase suspicion of a metabolic disorder. Laboratory measurements should include electrolytes, ammonia, lactate, glucose, blood pH, urine ketones, and urine carbohydrate analysis. Amino acids in CSF should be measured if nonketotic hyperglycinemia is suspected. Plasma and urine amino acid, urine organic acid, and serum acylcarnitine analysis should be performed urgently. Neonatal cardiomyopathy or ventricular arrhythmias should be investigated with serum acylcarnitine analysis and carnitine levels.

3. Vomiting & Encephalopathy in the Infant or Older Child

Electrolytes, ammonia, glucose, urine pH, urine carbohydrate analysis, and urine ketones should be measured in all patients with vomiting and encephalopathy before any treatment affects the results. Samples for plasma amino acids, serum acylcarnitine profile, and urine organic acid analysis should be obtained early. In the presentation of a Reye-like syndrome (ie, vomiting, encephalopathy, and hepatomegaly), amino acids, acylcarnitines, carnitine levels, and organic acids should be assessed immediately. Hypoglycemia with inappropriately low urine or quantitative serum ketones suggests the diagnosis of fatty acid oxidation or ketogenesis defects.

4. Hypoglycemia

Duration of fasting, presence or absence of hepatomegaly, and Kussmaul breathing provide clues to the differential diagnosis of hypoglycemia. Serum insulin, cortisol, and growth hormone should be obtained on presentation. Urine ketones, urine organic acids, plasma lactate, serum acylcarnitine profile, carnitine levels, ammonia, triglycerides, and uric acid should be measured. Ketone body production is usually not efficient in the neonate, and ketonuria in a hypoglycemic or acidotic neonate suggests an inborn error. In the older child, inappropriately low urine ketone levels suggest an inborn error of fatty acid oxidation. Assessment of ketone generation requires simultaneous measurements of quantitative serum 3-hydroxybutyrate, acetoacetate, and free fatty acids in relation to a sufficient duration of fasting and age. Metabolites obtained during the acute episode can be very helpful and avoid the need for a formal fasting test.

5. Hyperammonemia

Symptoms of hyperammonemia may appear and progress rapidly or insidiously. Decreased appetite, irritability, and behavioral changes appear first with vomiting, ataxia, lethargy, seizures, and coma appearing as ammonia levels increase. Tachypnea inducing respiratory alkalosis due to a direct effect on respiratory drive is characteristic. Physical examination cannot exclude the presence of hyperammonemia, and serum ammonia should be measured whenever hyperammonemia is possible. Severe hyperammonemia may be due to urea cycle disorders, organic acidemias, or fatty acid oxidation disorders (such as carnitine-acylcarnitine translocase deficiency) or, in the premature infant, transient hyperammonemia of the newborn. The cause can usually be ascertained by measuring quantitative plasma amino acids (eg, citrulline), plasma carnitine and acylcarnitine esters, and urine organic acids and orotic acid. Respiratory alkalosis is usually present in urea cycle defects and transient hyperammonemia of the newborn, while acidosis is characteristic of hyperammonemia due to organic acidemias.

6. Acidosis

Inborn errors may cause chronic or acute acidosis at any age, with or without an increased anion gap. Inborn errors should be considered when acidosis occurs with recurrent vomiting or hyperammonemia and when acidosis is out of proportion to the clinical status. Acidosis due to an inborn error can be difficult to correct. The main causes of anion gap metabolic acidosis are lactic acidosis, ketoacidosis (including abnormal ketone body production such as in β-ketothiolase deficiency), methylmalonic aciduria or other organic acidurias, intoxication (ethanol, methanol, ethylene glycol, and salicylate), and uremia. Causes of nonanion gap metabolic acidosis include loss of base in diarrhea or renal tubular acidosis (isolated renal tubular acidosis or renal Fanconi syndrome). If renal bicarbonate loss is found, a distinction must be made between isolated renal tubular acidosis and a more generalized renal tubular disorder or renal Fanconi syndrome by testing for renal losses of phosphorus and amino acids. Inborn errors associated with renal tubular acidosis or renal Fanconi syndrome include cystinosis, tyrosinemia type I, carnitine palmitoyltransferase I, galactosemia, hereditary fructose intolerance, Lowe syndrome, and mitochondrial diseases. Tests indicated for anion gap metabolic acidosis include urine organic acids, serum lactate and pyruvate, serum 3-hydroxybutyrate and acetoacetate, and plasma amino acids, in addition to a toxicology screen.

° MANAGEMENT OF METABOLIC EMERGENCIES

Patients with severe acidosis, hypoglycemia, and hyperammonemia may be very ill; initially mild symptoms may worsen quickly, and coma and death may ensue within hours. With prompt and vigorous treatment, however, patients can recover completely, even from deep coma. All oral intake should be stopped. Sufficient glucose should be given intravenously to avoid or minimize catabolism in a patient with a known inborn error who is at risk for crisis. Most conditions respond favorably to glucose administration, although a few (eg, primary lactic acidosis due to pyruvate dehydrogenase deficiency) do not. After exclusion of fatty acid oxidation disorders, immediate institution of intravenous fat emulsions (eg, intralipid) can provide crucial caloric input. Severe or increasing hyperammonemia should be treated pharmacologically or with dialysis (see section Disorders of the Urea Cycle), and severe acidosis should be treated with bicarbonate. More specific measures can be instituted when a diagnosis is established.

° NEWBORN SCREENING

Criteria for screening newborns for a disorder include its frequency, its consequences if untreated, the ability of therapy to mitigate consequences, the cost of testing, and the cost of treatment. With the availability of tandem mass spectrometry, newborn screening has expanded greatly to now include 20 core conditions and multiple secondary conditions screened by most states. In general, amino acidopathies, organic acidurias, and disorders of fatty acid oxidation are the disorders for which screening now occurs. Most states also screen for hypothyroidism, congenital adrenal hyperplasia, hemoglobinopathies, biotinidase deficiency, galactosemia, and cystic fibrosis. Screening for severe combined immune deficiency and congenital heart disease has been recently added. A few states have begun screening for some of the lysosomal and peroxisomal storage disorders.

Screening should occur for all infants between 24 and 72 hours of life or before hospital discharge.

Some screening tests measure a metabolite (eg, phenylalanine) that becomes abnormal with time and exposure to diet. In such instances, the disease cannot be detected reliably until intake of the substrate is established. Other tests measure enzyme activity and can be performed at any time (eg, for biotinidase deficiency). Transfusions may cause false-negative results in this instance, and exposure of the sample to heat may cause false-positive results. Technologic advances have extended the power of newborn screening but have brought additional challenges. For example, although tandem mass spectrometry can detect many more disorders in the newborn period, consensus on diagnosis and treatment for some conditions is still under development.

Screening tests are not diagnostic, and diagnostic tests must be undertaken when an abnormal screening result is obtained. Further, because false-negative results occur, a normal newborn screening test does not rule out a condition.

The appropriate response to an abnormal screening test depends on the condition in question and the predictive value of the test. For example, when screening for galactosemia by enzyme assay, complete absence of enzyme activity is highly predictive of classic galactosemia. Failure to treat may rapidly lead to death. In this case, treatment must be initiated immediately while diagnostic studies are pending. In phenylketonuria, however, a diet restricted in phenylalanine is harmful to the infant whose screening test is a false-positive, while diet therapy produces an excellent outcome in the truly affected infant if treatment is established within the first weeks of life. Therefore, treatment for phenylketonuria should only be instituted when the diagnosis is confirmed. Physicians should review American College of Medical Genetics recommendations, state laws and regulations, and consult with their local metabolic center to arrive at appropriate strategies for each hospital and practice.

GLYCOGEN STORAGE DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Types 0, I, III, VI, and IX manifest with hypoglycemia in infants.
- Types II, V, and VII manifest with rhabdomyolysis or muscle weakness.
- Types IV and IX manifest with hepatic cirrhosis.

Glycogen is a highly branched polymer of glucose that is stored in liver and muscle. Different enzyme defects affect its biosynthesis and degradation. The hepatic forms of the glycogenoses cause growth failure, hepatomegaly, and severe fasting hypoglycemia. They include glucose-6-phosphatase deficiency (type I; von Gierke disease), debrancher enzyme deficiency (type III), hepatic phosphorylase deficiency (type VI), and phosphorylase kinase deficiency (type IX), which normally regulates hepatic phosphorylase activity. Glycogen synthase deficiency (GSD; glycogen storage disease type 0) causes hypoglycemia, usually after about 12 hours of fasting, and can cause mild postprandial hyperglycemia and hyperlactatemia. There are two forms of glucose-6-phosphatase deficiency: in type Ia, the catalytic glucose-6-phosphatase is deficient and there is pronounced lactic acidosis, hyperuricemia, and hyperlipidemia in addition to hypoglycemia, and in type Ib, the glucose-6-phosphate transporter is deficient and neutropenia also occurs. Glycogenosis type IV, brancher enzyme deficiency, usually presents with progressive liver cirrhosis, as do some rare forms of phosphorylase kinase deficiency. The gluconeogenesis disorder fructose-1,6-bisphosphatase deficiency presents with major lactic acidosis and delayed hypoglycemia on fasting.

The myopathic forms of glycogenosis affect skeletal muscle. Skeletal myopathy with weakness or rhabdomyolysis may be seen in muscle phosphorylase deficiency (type V), phosphofructokinase deficiency (type VII), and acid maltase deficiency (type II; Pompe disease). The infantile form of Pompe disease also has hypertrophic cardiomyopathy and macroglossia.

» Diagnosis

Initial tests include glucose, lactate, triglycerides, cholesterol, uric acid, transaminases, and creatine kinase. Functional testing includes responsiveness of blood glucose

and lactate to fasting; for myopathic forms, an ischemic or nonischemic exercise test is helpful. Most glycogenoses can now be diagnosed by molecular analysis, including next-generation panels. Other diagnostic studies include enzyme assays of leukocytes, fibroblasts, liver, or muscle. Disorders diagnosable from analysis of red blood cells include deficiency phosphorylase kinase (type IX) in half the cases. Pompe disease can usually be diagnosed by assaying acid maltase in a blood spot with confirmation in fibroblasts.

» Treatment

Treatment is designed to prevent hypoglycemia and avoid secondary metabolite accumulations such as elevated lactate in glycogenosis type I. In GSD1, the special diet must be strictly monitored with restriction of free sugars and measured amounts of uncooked cornstarch, which slowly releases glucose in the intestinal lumen. Good results have been reported following continuous nighttime carbohydrate feeding or uncooked cornstarch therapy. Late complications even after years of treatment include focal segmental glomerulosclerosis, hepatic adenoma or carcinoma, and gout. Enzyme-replacement therapy in Pompe disease corrects the cardiomyopathy, but the response in skeletal myopathy is variable with optimal results seen in patients treated early and who have mutations that allow formation of some residual protein which is detected as cross-reacting material on Western blotting. Immunomodulation is used for patients whose treatment response declines due to antibodies to the recombinant enzyme. In glycogen storage diseases with intact gluconeogenesis (GSD III, VI, IX), a high-protein diet improves glucose control and reduces late complications.

GALACTOSEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severely deficient neonates present with vomiting, jaundice, and hepatomegaly on initiation of lactose-containing feedings.
- Renal Fanconi syndrome, cataracts of the ocular lens, hepatic cirrhosis, and sepsis occur in untreated children.
- Delayed, apraxic speech and ovarian failure occur frequently even with treatment. Developmental delay, tremor, and ataxia occur less frequently.

Classic galactosemia is caused by almost total deficiency of galactose-1-phosphate uridyltransferase. Accumulation of galactose-1-phosphate causes hepatic parenchymal disease and renal Fanconi syndrome. Onset of the severe disease is marked in the neonate by vomiting, jaundice (both direct and indirect), hepatomegaly, and rapid onset of liver insufficiency after initiation of milk feeding. Hepatic cirrhosis is progressive. Without treatment, death frequently occurs within a month, often from Escherichia coli sepsis. Cataracts usually develop within 2 months in untreated cases but usually reverse with treatment. With prompt institution of a galactose-free diet, the prognosis for survival without liver disease is excellent. Even when dietary restriction is instituted early, patients with galactosemia are at increased risk for speech and language deficits and ovarian failure. Some patients develop progressive mental retardation, tremor, and ataxia. Milder variants of galactosemia with better prognosis exist.

The disorder is autosomal recessive with an incidence of approximately 1:40,000 live births.

» Diagnosis

In infants receiving foods containing galactose, laboratory findings include liver dysfunction, particularly PT prolongation, together with proteinuria and aminoaciduria. Galactose-1-phosphate is elevated in red blood cells. When the diagnosis is suspected, galactose-1-phosphate uridyltransferase should be assayed in erythrocytes. Blood transfusions give false-negative results and sample deterioration false-positive results.

Newborn screening by demonstrating enzyme deficiency in red cells or by demonstrating increased serum galactose allows timely institution of treatment. Some patients identified on newborn screening have a genotype that results in sufficient residual activity (Duarte allele) and treatment is not always required.

» Treatment

A galactose-free diet should be instituted as soon as the diagnosis is made. Compliance with the diet must be monitored by following galactose-1-phosphate levels in red blood cells. Appropriate diet management requires not only the exclusion of milk but an understanding of the galactose content of foods. Avoidance of galactose should be lifelong with appropriate calcium replacement, intake of which tends to be low due to the restriction of dairy products.

HEREDITARY FRUCTOSE INTOLERANCE

Hereditary fructose intolerance is an autosomal recessive disorder in which deficient activity of fructose-1-phosphate aldolase causes hypoglycemia and tissue accumulation of fructose-1-phosphate on fructose ingestion. Other abnormalities include failure to thrive, vomiting, jaundice, hepatomegaly, proteinuria, and renal Fanconi syndrome. The untreated condition can progress to death from liver failure.

» Diagnosis

The diagnosis is suggested by finding fructosuria or an abnormal transferrin glycoform in the untreated patient. Diagnosis is made by sequencing the HFI gene. An alternative method for diagnosis is enzyme assay of fructose-1-phosphate aldolase in liver biopsy.

» Treatment

Treatment consists of strict dietary avoidance of fructose. Vitamin supplementation is usually needed. Drugs and vitamins dispensed in a sucrose base should be avoided. Treatment monitoring can be done with transferrin glycoform analysis. If diet compliance is poor, physical growth retardation may occur. Growth will resume when more stringent dietary restrictions are reinstituted. If the disorder is recognized early, the prospects for normal development are good. As affected individuals grow up, they may recognize the association of nausea and vomiting with ingestion of fructose-containing foods and selectively avoid them.

DISOr DEr S Of ENEr GY MEt AbOl ISM

The most common disorders of central mitochondrial energy metabolism are pyruvate dehydrogenase deficiency and deficiencies of respiratory chain components. Disorders of the Krebs cycle include deficiencies in fumarase, 2-ketoglutarate dehydrogenase, and succinyl-CoA ligase. In many, but not in all, patients lactate is elevated in either blood or CSF. In pyruvate dehydrogenase deficiency, the lactate-pyruvate ratio is normal, whereas in respiratory chain disorders the ratio is often increased. Care must be taken to distinguish an elevated lactate level that is due to these conditions (called primary lactic acidoses) from elevated lactate that is a consequence of hypoxia, ischemia, or sampling problems. Table 36–1 lists some causes of primary lactic acidosis.

Table 36–1. Causes of primary lactic acidosis in childhood.

Defects of the pyruvate dehydrogenase complex
E_1 (pyruvate decarboxylase) deficiency
E_2 (dihydrolipoyl transacetylase) deficiency
E_3 (lipoamide dehydrogenase) deficiency
E_3-binding protein Xdeficiency
Pyruvate decarboxylase phosphate phosphatase deficiency
Thiamine pyrophosphokinase deficiency
Disorders of lipoate biosynthesis
Mitochondrial pyruvate carrier
Abnormalities of gluconeogenesis
Pyruvate carboxylase deficiency
Isolated
Biotinidase deficiency
Holocarboxylase synthetase deficiency
Fructose-1,6-diphosphatase deficiency
Glucose-6-phosphatase deficiency (von Gierke disease)
Defects in the mitochondrial respiratory chain
Complex I deficiency
Complex IV deficiency (cytochrome C oxidase deficiency; frequent cause of Leigh disease)
Complex V (ATPase) deficiency (frequent cause of Leigh disease)
Complex II deficiency
Complex III deficiency
Combined deficiencies: due to defects in mitochondrial DNA maintenance (deletions or depletion) or in mitochondrial translation (eg, mitochondrial tRNA defects)
Coenzyme Q10 deficiency
Other respiratory chain disorders
Defects in the Krebs cycle
Succinyl-CoA ligase deficiency

Patients with a defect in the pyruvate dehydrogenase complex often have agenesis of the corpus callosum or Leigh syndrome (lesions in the globus pallidus, dentate nucleus, and periaqueductal gray matter). They can have mild facial dysmorphism. Recurrent altered mental status, recurrent ataxia, and recurrent acidosis are typical of many disturbances of pyruvate metabolism. The most common genetic defect is in the X-linked $E_1\alpha$ component, with males carrying milder mutations and females carrying severe mutations leading to periventricular cystic brain lesions.

The respiratory chain disorders are frequent (1:5000) and involve a heterogenous group of genetic defects that produce a variety of clinical syndromes (now > 50) of varying severity and presentation. The disorders can affect multiple organs. The following set of symptoms (not intended as a comprehensive listing) can indicate a respiratory chain disorder:

1. General: Failure to thrive
2. Brain: Progressive neurodegeneration, Leigh syndrome, myoclonic seizures, brain atrophy, movement disorders, cerebellar atrophy, and subcortical leukodystrophy
3. Eye: Optic neuropathy, retinitis pigmentosa, progressive external ophthalmoplegia, and cataracts
4. Ears: Nerve deafness
5. Muscle: Myopathy with decreased endurance or rhabdomyolysis
6. Kidney: Renal Fanconi syndrome, proteinuria (in CoQ deficiency)
7. Endocrine: Diabetes mellitus and hypoparathyroidism
8. Intestinal: Pancreatic or liver insufficiency or pseudoobstruction
9. Heart: Cardiomyopathy, conduction defects, and arrhythmias

Respiratory chain disorders are among the more common causes of static, progressive, or self-limited neurodevelopmental problems in children. Patients may present with nonspecific findings such as hypotonia, failure to thrive, or renal tubular acidosis, or with more specific features such as ophthalmoplegia or cardiomyopathy. Symptoms are often combined in recognizable clinical syndromes with ties to specific genetic causes. Ragged red fibers and mitochondrial abnormalities may be noted on histologic examination of muscle. Thirteen of the more than 100 genes that control activity of the respiratory chain are part of the mitochondrial genome. Therefore, inheritance of defects in the respiratory chain may be mendelian or maternal.

» Diagnosis

Pyruvate dehydrogenase deficiency is diagnosed by enzyme assay in leukocytes or fibroblasts. Confirmation can be obtained by molecular analysis. Diagnosis of respiratory chain disorders is based on a convergence of clinical, biochemical, morphologic, enzymatic, and molecular data. Classic pathologic features of mitochondrial disorders are the accumulation of mitochondria, which produces ragged red fibers in skeletal muscle biopsy, and abnormal mitochondrial shapes and inclusions inside mitochondria on electron microscopy. However, these findings are only present in 5% of children. Enzyme analysis on skeletal muscle or liver tissue is complicated by an overlap between normal and affected range. Blue native polyacrylamide gel electrophoresis (PAGE) analyzes the assembly of the respiratory chain enzyme complexes. Mitochondrial DNA (mtDNA) analysis in blood or tissue may identify a diagnostic mutation. A rapidly increasing number of nuclear genes (now > 300) causing respiratory chain defects are recognized. Children with defects in mtDNA maintenance (such as mtDNA polymerase γ, POLG1 gene) often present with liver disease and neurodegeneration and are diagnosed by sequencing the causative nuclear genes. Next-generation sequencing of panels of genes or exome sequencing is increasingly used due to the large number of genes involved, but functional testing is often required for confirmation of the pathogenicity of identified mutations. Although diagnostic criteria have been published, the cause of respiratory chain defects still cannot be defined in many patients. In some instances, the genetics and prognosis may be clear, but in many cases neither prognosis nor genetic risk can be predicted. Because of the high complexity of this group of disorders, many patients require a high degree of expertise and multiple studies to arrive at a final diagnosis.

» Treatment

A ketogenic diet is useful in pyruvate dehydrogenase deficiency. In rare patients with primary coenzyme Q deficiency, coenzyme Q treatment is very effective. Other treatments are of theoretical value, with little data on efficacy. Thiamine and lipoic acid have been tried in patients with pyruvate dehydrogenase complex deficiencies, and coenzyme Q and riboflavin have been helpful in some patients with respiratory chain defects. Dichloroacetic acid has limited clinical response in pyruvate dehydrogenase deficiency and has adverse effects. Avoidance of catabolism and of medications that impair mitochondrial function is an important component of treating patients with respiratory chain defects. Transcriptional upregulation in partial deficiencies of nuclear origin and new antioxidants such as EPI-743 offer new hope for the treatment of respiratory chain defects.

DISOr DEr S Of AMINO ACID MEt AbOl ISM

DISORDERS OF THE UREA CYCLE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Typical presentation is infantile encephalopathy; later onset presentations are common with cyclic vomiting or encephalopathy with illness or protein load.

» Diagnosis is suspected with the finding of hyperammonemia frequently with minimal other laboratory findings.

Ammonia is derived from the catabolism of amino acids and is converted to an amino group in urea by enzymes of the urea cycle. Patients with severe defects (often those enzymes early in the urea cycle) usually present in infancy with severe hyperammonemia, vomiting, and encephalopathy, which is rapidly fatal. Patients with milder genetic defects may present with vomiting, encephalopathy, or liver failure after increased protein ingestion or infection. Although defects in argininosuccinic acid synthetase (citrullinemia) and argininosuccinic acid lyase (argininosuccinic acidemia) may cause severe hyperammonemia in infancy, the usual clinical course is chronic with mental retardation. Ornithine transcarbamylase deficiency is X-linked; the others are autosomal recessive. Age at onset of symptoms varies with residual enzyme activity, protein intake, growth, and stresses such as infection. Even within a family, males with ornithine transcarbamylase deficiency may differ by decades in the age of symptom onset. Many female carriers of ornithine transcarbamylase deficiency have protein intolerance. Some develop migraine-like symptoms after protein loads, and others develop potentially fatal episodes of vomiting and encephalopathy after protein ingestion, infections, or in the postpartum period. Trichorrhexis nodosa is common in patients with argininosuccinic aciduria.

» Diagnosis

Blood ammonia should be measured in any acutely ill newborn in whom a cause is not obvious. In urea cycle defects, early hyperammonemia is associated with hyperventilation and respiratory alkalosis. Plasma citrulline is low or undetectable in carbamoyl phosphate synthetase and ornithine transcarbamylase deficiency, high in argininosuccinic acidemia, and very high in citrullinemia. Large amounts of argininosuccinic acid are found in the urine of patients with argininosuccinic acidemia. Urine orotic acid is increased in infants with ornithine transcarbamylase deficiency. Prenatal diagnosis is most commonly done by molecular methods, but citrullinemia and argininosuccinic acidemia can also be diagnosed in utero by appropriate enzyme assays in uncultured chorionic villus sample (CVS) material or in amniocytes. Other causes of severe neonatal hyperammonemia, which have a different prognosis and treatment, include: liver failure; blood shunting to bypass the liver as seen in transient hyperammonemia of the neonate; and the metabolic disorders pyruvate carboxylase deficiency and mitochondrial carbonic anhydrase deficiency.

» Treatment

During treatment of acute hyperammonemic crisis, protein intake should be stopped, and glucose and lipids should be given to reduce endogenous protein breakdown from catabolism. Careful administration of essential amino acids facilitates protein anabolism. Arginine is given intravenously. It is an essential amino acid for patients with urea cycle defects and increases the excretion of waste nitrogen in citrullinemia and argininosuccinic acidemia. Sodium benzoate and sodium phenylacetate are given intravenously to increase excretion of nitrogen as hippuric acid and phenylacetylglutamine. Additionally, hemodialysis or hemofiltration is indicated for severe or persistent hyperammonemia, as is usually the case in the newborn. Peritoneal dialysis and exchange transfusion are ineffective. Long-term treatment includes low-protein diet, oral administration of arginine

or citrulline, and sodium benzoate or sodium phenylbutyrate (a prodrug of sodium phenylacetate). Symptomatic heterozygous female carriers of ornithine transcarbamylase deficiency should also receive such treatment. Liver transplantation may be curative and is indicated for patients with severe disorders.

The outcome of urea cycle disorders depends on the genetic severity of the condition (residual activity) and the severity and prompt treatment of hyperammonemic episodes. Brain damage depends on the duration and the degree of elevation of ammonia and glutamine. Many patients with urea cycle defects, no matter what the enzyme defect, develop permanent neurologic and intellectual impairments, with cortical atrophy and ventricular dilation seen on computed tomographic scan. Rapid identification and treatment of the initial hyperammonemic episode is critical in improving outcome.

PHENYLKETONURIA & THE HYPERPHENYLALANINEMIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mental retardation, hyperactivity, seizures, light complexion, and eczema characterize untreated patients.
- Newborn screening for elevated plasma phenylalanine identifies most infants.
- Disorders of cofactor metabolism also produce elevated plasma phenylalanine level.
- Early diagnosis and treatment with phenylalanine-restricted diet prevents mental retardation.

Probably the best-known disorder of amino acid metabolism is the classic form of phenylketonuria caused by decreased activity of phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine. In classic phenylketonuria, there is little or no phenylalanine hydroxylase activity. In the less severe hyperphenylalaninemia there may be significant residual activity. Rare variants can be due to deficiency of dihydropteridine reductase or defects in biopterin synthesis.

Phenylketonuria is an autosomal recessive trait, with an incidence in Caucasians of approximately 1:10,000 live births. On a normal neonatal diet, affected patients develop hyperphenylalaninemia. Patients with untreated phenylketonuria exhibit severe mental retardation, hyperactivity, seizures, a light complexion, and eczema.

Success in preventing severe mental retardation in phenylketonuric children by restricting phenylalanine starting in early infancy led to screening programs to detect the disease early. Because the outcome is best when treatment is begun in the first month of life, infants should be screened during the first few days. A second test is necessary when newborn screening is done before 24 hours of age, and should be completed by the third week of life.

» Diagnosis & Treatment

The diagnosis of phenylketonuria is based on finding elevated plasma phenylalanine and an elevated phenylalanine/tyrosine ratio in a child on a normal diet. The condition must be differentiated from other causes of hyperphenylalaninemia by examining pterins in urine and dihydropteridine reductase activity in blood. Determination of carrier status and prenatal diagnosis of phenylketonuria or pterin defects is possible using molecular methods.

A. Phenylalanine Hydroxylase Deficiency: Classic Phenylketonuria and Hyperphenylalaninemia

In phenylketonuria, plasma phenylalanine levels are persistently elevated above 1200 μM (20 mg/dL) on a regular diet, with normal or low plasma levels of tyrosine, and normal pterins. Poor phenylalanine tolerance persists throughout life. Treatment to decrease phenylalanine levels is always indicated. Hyperphenylalaninemia is diagnosed in infants whose plasma phenylalanine levels are usually 240–1200 μM (4–20 mg/dL), and pterins are normal while receiving a normal protein intake. Treatment to reduce phenylalanine levels is indicated if phenylalanine levels consistently exceed 360 μM (6 mg/dL). In contrast, in the rare case of transient hyperphenylalaninemia, plasma phenylalanine levels are elevated early but progressively decline toward normal. Dietary restriction is only temporary, if required at all.

Treatment of all forms of phenylketonuria is aimed at maintaining phenylalanine levels less than 360 μM (6 mg/dL). Treatment can consist of dietary restriction of phenylalanine,

increasing enzyme activity with pharmacologic doses of R-tetrahydrobiopterin, or new methods to interfere with phenylalaine absorption or to breakdown phenylalanine.

Dietary restriction of phenylalanine intake to amounts that permit normal growth and development is the most common therapy and results in good outcome if instituted in the first month of life and carefully maintained. Metabolic formulas deficient in phenylalanine are available but must be supplemented with normal milk and other foods to supply enough phenylalanine to permit normal growth and development. Plasma phenylalanine concentrations must be monitored frequently while ensuring that growth, development, and nutrition are adequate. This monitoring is best done in experienced clinics. Children with classic phenylketonuria who receive treatment promptly after birth and achieve phenylalanine and tyrosine homeostasis will develop well physically and can be expected to have normal or near-normal intellectual development.

Phenylalanine restriction should continue throughout life. Patients who discontinued diet after treatment for several years have developed subtle changes in intellect and behavior, and risk neurologic damage. Counseling should be given during adolescence particularly to girls about the risk of maternal phenylketonuria (see as follows), and women's diets should be monitored closely prior to conception and throughout pregnancy. Late treatment may still be of benefit in reversing behaviors such as hyperactivity, irritability, and distractibility, but it does not reverse the mental retardation.

Treatment with R-tetrahydrobiopterin results in improved phenylalanine tolerance in up to 50% of patients with a deficiency in phenylalanine hydroxylase. The best results and the most frequent responsiveness are seen in patients with hyperphenylalaninemia. Provision of high doses of large neutral amino acids results in a moderate reduction in phenylalanine and is used as an adjunctive treatment in some adults with phenylketonuria. Treatment trials with pegylated phenylalanine ammonia lyase administration to decrease phenylalanine levels show promise.

B. Biopterin Defects: Dihydropteridine Reductase Deficiency and Defects in Biopterin Biosynthesis

In these patients, plasma phenylalanine levels vary. The pattern of pterin metabolites is abnormal. Clinical findings include myoclonus, tetraplegia, dystonia, oculogyric crises, and other movement disorders. Seizures and psychomotor regression occur even with diet therapy, probably because the enzyme defect also causes neuronal deficiency of serotonin and dopamine. These deficiencies require treatment with levodopa, carbidopa, 5-hydroxytryptophan, and folinic acid. Tetrahydrobiopterin may be added for some biopterin synthesis defects.

C. Tyrosinemia of the Newborn

Plasma phenylalanine levels are lower than those associated with phenylketonuria and are accompanied by marked hypertyrosinemia. Tyrosinemia of the newborn usually occurs in premature infants and is due to immaturity of 4-hydroxyphenylpyruvic acid oxidase, resulting in increase in tyrosine and its precursor phenylalanine. The condition resolves spontaneously within 3 months, almost always without sequelae.

D. Maternal Phenylketonuria

Offspring of mothers with phenylketonuria may have transient hyperphenylalaninemia at birth. Elevated maternal phenylalanine during pregnancy causes mental retardation, microcephaly, growth retardation, and often congenital heart disease or other malformations in the offspring. The risk to the fetus is lessened considerably by maternal phenylalanine restriction with maintenance of phenylalanine levels below 360 μM (6 mg/dL) throughout pregnancy and optimally started before conception.

HEREDITARY TYROSINEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Consider in a child presenting with liver disease with or without accompanying renal disease or bone disease.
- Elevated urinary succinylacetone is diagnostic of tyrosinemia, type 1.

Type I hereditary tyrosinemia is an autosomal recessive condition caused by deficiency of fumarylacetoacetase. It presents with acute or progressive hepatic parenchymal damage with elevated α-fetoprotein, renal tubular dysfunction with generalized aminoaciduria, hypophosphatemic rickets, or neuronopathic crises. Tyrosine and methionine are increased in blood and tyrosine metabolites and δ-aminolevulinic acid in urine. The key diagnostic metabolite is elevated succinylacetone in urine. Liver failure may be rapidly fatal in infancy or somewhat more chronic, with a high incidence of liver cell carcinoma in long-term survivors. Tyrosinemia type II presents with corneal ulcers and keratotic lesions on palms and soles and very high plasma tyrosine levels (> 600 μM), and patients with tyrosinemia type III can also have developmental delays and ataxia.

» Diagnosis

Similar clinical and biochemical findings may occur in other liver diseases such as galactosemia and hereditary fructose intolerance. Increased succinylacetone occurs only in fumarylacetoacetase deficiency and is diagnostic, and is increasingly used in newborn screening. Diagnosis is confirmed by mutation analysis or by enzyme assay in liver tissue. Prenatal diagnosis is possible. Tyrosinemia type II and type III are diagnosed by molecular methods.

» Treatment

A diet low in phenylalanine and tyrosine ameliorates liver disease, but it does not prevent carcinoma development. Pharmacologic therapy to inhibit the upstream enzyme 4-hydroxyphenylpyruvate dehydrogenase using 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) decreases the production of toxic metabolites, maleylacetoacetate and fumarylacetoacetate. It improves the liver disease and renal disease, prevents acute neuronopathic attacks, and greatly reduces the risk of hepatocellular carcinoma. Liver transplantation is effective therapy. Tyrosinemia types II and III respond well to dietary tyrosine restriction.

Thimm E et al: Neurocognitive outcome in patients with hypertyrosinemia type I after long-term treatment with NTBC. J Inherit Metab Dis 2012;35(2);263 [PMID: 22069142].

MAPLE SYRUP URINE DISEASE (BRANCHED-CHAIN KETOACIDURIA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Typical presentation is infantile encephalopathy.
- Diagnosis suspected with elevated plasma branched chain amino acids plus alloisoleucine.

Maple syrup urine disease is due to deficiency of the enzyme that catalyzes the oxidative decarboxylation of the branched-chain keto acid derivatives of leucine, isoleucine, and valine. Accumulated keto acids of leucine and isoleucine cause the characteristic sweet odor. Only leucine and its corresponding keto acid have been implicated in causing central nervous system (CNS) dysfunction. Many variants of this disorder have been described, including mild, intermittent, and thiamine-dependent forms. All are autosomal recessive traits.

Patients with classic maple syrup urine disease are normal at birth, but after about 1 week they develop feeding difficulties, coma, and seizures. Unless diagnosis is made and dietary restriction of branched-chain amino acids is begun, most will die in the first month of life. Nearly normal growth and development may be achieved if treatment is begun before about age 10 days, which is facilitated by newborn screening.

» Diagnosis

Amino acid analysis shows marked elevation of branched-chain amino acids including alloisoleucine, a diagnostic transamination product of the keto acid of isoleucine. Urine organic acids demonstrate the characteristic keto acids. The magnitude and consistency of metabolite changes are altered in mild and intermittent forms. Prenatal diagnosis is possible by enzyme assay in cultured amniocytes or chorionic villi, and by molecular analysis if the mutation is known.

» Treatment

Dietary leucine restriction and avoidance of catabolism are the cornerstones of treatment. Infant formulas deficient in branched-chain amino acids must be supplemented with normal foods to supply enough branched-chain amino acids to permit normal growth. Plasma levels of branched-chain amino acids must be monitored frequently to deal with changing protein requirements. Acute episodes must be aggressively treated to prevent catabolism and negative nitrogen balance. Very high leucine levels require hemodialysis. Liver transplantation corrects the disorder.

HOMOCYSTINURIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Consider in a child of any age with a marfanoid habitus, dislocated lenses, or thrombosis.
- Diagnosis is suggested by elevated total homocysteine and methionine.
- Newborn screening allows early diagnosis and treatment resulting in a normal outcome.

Homocystinuria is most often due to deficiency of cystathionine β-synthase (CBS), but may also be due to deficiency of methylenetetrahydrofolate reductase (MTHFR) or to defects in the biosynthesis of methyl-B_{12}, the coenzyme for methionine synthase. All inherited forms of homocystinuria are autosomal recessive traits.

About 50% of patients with untreated CBS deficiency are mentally retarded, and most have arachnodactyly, osteoporosis, and a tendency to develop dislocated lenses and thromboembolic phenomena. Mild variants of CBS deficiency present with thromboembolic events. Patients with severe remethylation defects usually exhibit failure to thrive and a variety of neurologic symptoms, including brain atrophy, microcephaly, hydrocephalus, and seizures in infancy and early childhood.

» Diagnosis

Diagnosis is made by demonstrating elevated total serum homocysteine or by identifying homocystinuria in a patient who is not severely deficient in vitamin B_{12}. Plasma methionine levels are usually high in patients with CBS deficiency and often low in patients with remethylation defects. Cystathionine levels are low in CBS deficiency. When the remethylation defect is due to deficiency of methyl-B_{12}, megaloblastic anemia or hemolytic uremic syndrome may be present and an associated deficiency of adenosyl-B_{12} may cause methylmalonic aciduria. Mutation analysis or studies of cultured fibroblasts can make a specific diagnosis.

» Treatment

About 50% of patients with CBS deficiency respond to large oral doses of pyridoxine. Pyridoxine nonresponders are treated with dietary methionine restriction and oral administration of betaine, which increases methylation of homocysteine to methionine and improves neurologic function. Early treatment prevents mental retardation, lens dislocation, and thromboembolic manifestations, which justifies the screening of newborn infants. Large doses of vitamin B_{12} (eg, 1–5 mg hydroxocobalamin administered daily intramuscularly or subcutaneously) are indicated in some patients with defects in cobalamin metabolism.

Diekman EF, de Koning TJ, Verhoeven-Duif NM, Rovers MM, van Hasselt PM: Survival and psychomotor development with early betaine treatment in patients with severe methylenetetrahydrofolate reductase deficiency. JAMA Neurol 2014;71(2):188 [PMID: 2432304].

Schiff M, Blom HJ: Treatment of inherited homocystinurias. Neuropediatrics 2012;43(6):295 [PMID: 23124942].

NONKETOTIC HYPERGLYCINEMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severely affected newborns present with apnea, hypotonia, lethargy, myoclonic seizures, and hiccups and develop severe mental and motor retardation.
- Mildly affected children have developmental delay, hyperactivity, mild chorea, and seizures.
- Electroencephalography (EEG) shows burst suppression.
- CSF glycine is elevated.

Inherited deficiency of various subunits of the glycine cleavage enzyme causes nonketotic hyperglycinemia, also called glycine encephalopathy. Glycine accumulation in the brain may disturb neurotransmission of the glycinergic receptors and the N-methyl-D-aspartate type of glutamate receptor. In its most severe form, the condition presents in the newborn as hypotonia, lethargy proceeding to coma, myoclonic seizures, and hiccups, with a burst suppression pattern on EEG. Respiratory depression may require ventilator assistance in the first 2 weeks, followed by spontaneous recovery. Patients

develop severe mental retardation and therapy-resistant seizures. Some patients have agenesis of the corpus callosum or posterior fossa malformations. All patients have restricted diffusion on MRI in the already myelinated long tracts at birth. Some patients with an attenuated form present with seizures, varying developmental delay, and chorea, and half of these may present later in infancy or in childhood. All forms of the condition are autosomal recessive.

» Diagnosis

Nonketotic hyperglycinemia should be suspected in any neonate or infant with seizures, particularly those with burst suppression pattern on EEG. Diagnosis is confirmed by demonstrating a large increase in glycine in nonbloody CSF, with an abnormally high ratio of CSF glycine to plasma glycine. Molecular analysis is diagnostic in more than 98% of cases. Variant cases are caused by defects in biosynthesis of the cofactor lipoate. Enzyme analysis on liver tissue can confirm the diagnosis. Prenatal diagnosis is possible by molecular analysis if both mutations are known or by enzyme assay on uncultured CVS.

» Treatment

In patients with mild disease, treatment with sodium benzoate (to normalize plasma glycine levels) and dextromethorphan or ketamine (to block N-methyl-D-aspartate type of glutamate receptors) controls seizures and improves outcome. Treatment of severely affected patients is generally unsuccessful. High-dose benzoate therapy can aid in seizure control but does not prevent severe mental retardation. Ketogenic diet reduces glycine levels, but the impact on outcome is very limited.

Hennermann JB, Berger JM, Grieben U, Scharer G, Van Hove JL: Prediction of long-term outcome in glycine encephalopathy: a clinical survey. J Inherit Metab Dis 2012;35(2);253 [PMID: 22002442].

Swanson MA et al.: Biochemical and molecular predictors for prognosis in nonketotic hyperglycinemia. Ann Neurol 2015;78(4):606–618 [PMID: 26179960].

ORGANIC ACIDEMIAS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Consider in any child presenting with metabolic acidosis and ketosis in early infancy.
- Urine organic acid analysis is usually diagnostic.

Organic acidemias are disorders of amino and fatty acid metabolism in which nonamino organic acids accumulate in serum and urine. These conditions are usually diagnosed by examining organic acids in urine, a complex procedure that requires considerable interpretive expertise and is usually performed only in specialized laboratories. Table 36–2 lists the clinical features of organic acidemias, together with the urine organic acid patterns typical of each. Additional details about some of the more important organic acidemias are provided in the sections that follow.

PROPIONIC & METHYLMALONIC ACIDEMIA (KETOTIC HYPERGLYCINEMIAS)

The oxidation of threonine, valine, methionine, and isoleucine results in propionyl-CoA, which propionyl-CoA carboxylase converts into L-methylmalonyl-CoA, which is metabolized through methylmalonyl-CoA mutase to succinyl-CoA. Gut bacteria and the breakdown of odd-chain-length fatty acids also substantially contribute to propionyl-CoA production. Propionic acidemia is due to a defect in the biotin-containing enzyme propionyl-CoA carboxylase, and methylmalonic aciduria is due to a defect in methylmalonyl-CoA mutase, in either the mutase apoenzyme or in defects of its cofactor, adenosyl-B_{12} coenzyme. Some disorders of intracellular vitamin B_{12} metabolism affect only the synthesis of adenosyl-B_{12} (Cbl A, B, or D), whereas in others (Cbl C, D, F, J, X), the synthesis of methyl-B_{12} is also blocked, and hence homocysteine is also elevated in blood in addition to methylmalonic acid.

Clinical symptoms vary according to the location and severity of the enzyme block. Children with severe blocks present with acute, life-threatening metabolic ketoacidosis, hyperammonemia, coma, and bone marrow depression in early infancy or with metabolic acidosis, vomiting, and failure to thrive during the first few months of life. Most patients with severe disease have mild or moderate mental retardation. Late complications include pancreatitis, cardiomyopathy, basal ganglia stroke, and most commonly in methylmalonic aciduria, interstitial nephritis.

All forms of propionic and methylmalonic acidemia are autosomal recessive traits (except for X-linked Cbl X) and can be diagnosed in utero.

» Diagnosis

Laboratory findings consist of increases in urinary organic acids derived from propionyl-CoA or methylmalonic acid (see Table 36–2). Hyperglycinemia can be present. In some forms of abnormal vitamin B_{12} metabolism, homocysteine can be elevated. Confirmation is by molecular analysis or by assays in fibroblasts.

Table 36–2. Clinical and laboratory features of organic acidemias.

Disorder	Enzyme Defect	Clinical and Laboratory Features
Isovaleric academia	Isovaleryl-CoA dehydrogenase	Acidosis and odor of sweaty feet in infancy, or growth retardation and episodes of vomiting, lethargy, and acidosis. Persistent isovalerylglycine and intermittent 3-hydroxyisovaleric acid in urine.
3-Methylcrotonyl-CoA carboxylase deficiency	3-Methylcrotonyl-CoA carboxylase	Usually asymptomatic. Acidosis and feeding problems in infancy, or Reye-like episodes in older child. 3-Methylcrotonylglycine and 3-hydroxyisovaleric acid in urine.
Combined carboxylase deficiency	Holocarboxylase synthetase	Hypotonia and lactic acidosis in infancy. 3-Hydroxyisovaleric acid in urine, often with small amounts of 3-hydroxypropionic and methylcitric acids. Often biotin-responsive.
Biotinidase deficiency	Biotinidase	Alopecia, seborrheic rash, seizures, and ataxia in infancy or childhood. Urine organic acids as above. Always biotin-responsive.
3-Hydroxy-3-methylglutaric acidemia	3-Hydroxy-3-methylglutaryl-CoA lyase	Hypoglycemia and acidosis in infancy; Reye-like episodes with nonketotic hypoglycemia or leukodystrophy in older children. 3-Hydroxy-3-methylglutaric, 3-methylglutaconic, and 3-hydroxyisovaleric acids in urine.
3-Ketothiolase deficiency	3-Ketothiolase	Episodes of vomiting, severe metabolic acidosis (hyperketosis), and encephalopathy. 2-Methyl-3-hydroxybutyric and 2-methylacetoacetic acids and tiglylglycine in urine, especially after isoleucine load.
Propionic acidemia	Propionyl-CoA carboxylase	Hyperammonemia and metabolic acidosis in infancy; ketotic hyperglycinemia syndrome later. 3-Hydroxypropionic and methylcitric acids in urine, with 3-hydroxy- and 3-ketovaleric acids during ketotic episodes.
Methylmalonic academia	Methylmalonyl-CoA mutase	Clinical features same as in propionic acidemia. Methylmalonic acid in urine, often with 3-hydroxypropionic and methylcitric acids.
	Defects in vitamin B_{12} biosynthesis	Clinical features same as above when only adenosyl-B_{12} synthesis is decreased; early neurologic features prominent when accompanied by decreased synthesis of methyl-B_{12}. In latter instance, hypomethioninemia and homocystinuria accompany methylmalonic aciduria.
Pyroglutamic acidemia	Glutathione synthetase	Acidosis and hemolytic anemia in infancy; chronic acidosis later. Pyroglutamic acid in urine.
Glutaric acidemia type I	Glutaryl-CoA dehydrogenase	Progressive extrapyramidal movement disorder in childhood, with episodes of acidosis, vomiting, and encephalopathy. Glutaric acid and 3-hydroxyglutaric acid in serum and urine.
Glutaric acidemia type II	ETF:ubiquinone oxidoreductase (ETF dehydrogenase) and ETF	Hypoglycemia, acidosis, hyperammonemia, and odor of sweaty feet in infancy, often with polycystic and dysplastic kidneys. Later onset may be with episodes of hypoketotic hypoglycemia, liver dysfunction, or slowly progressive skeletal myopathy. Glutaric, ethylmalonic, 3-hydroxyisovaleric, isovalerylglycine, and 2-hydroxyglutaric acids in urine, often with sarcosine in serum.
4-Hydroxybutyric acidemia	Succinic semialdehyde dehydrogenase	Seizures, ataxia, and developmental retardation. 4-Hydroxybutyric acid in urine.

CoA, coenzyme A; ETF, electron transfer flavoprotein.

Treatment

Patients with enzyme blocks in B_{12} metabolism usually respond to pharmacologic doses of vitamin B_{12} given subcutaneously or intramuscularly. Vitamin B_{12} nonresponsive methylmalonic acidemia and propionic acidemia require amino acid restriction, strict prevention of catabolism, and carnitine supplementation to enhance propionylcarnitine excretion. Intermittent metronidazole can help reduce the propionate load from the gut. In the acute setting, hemodialysis or hemofiltration may be needed. Combined liver-renal transplantation is an option for patients with renal insufficiency, and liver transplantation has shown promise for patients with life-threatening cardiomyopathy.

CARBOXYLASE DEFICIENCY

Isolated pyruvate carboxylase deficiency presents with lactic acidosis and hyperammonemia in early infancy. Even if biochemically stabilized, the neurologic outcome is dismal. Isolated 3-methylcrotonyl-CoA carboxylase deficiency is frequently recognized on newborn screening using acylcarnitine analysis. It is usually a benign condition that sometimes causes symptoms of acidosis and neurologic depression. All carboxylases require biotin as a cofactor. Holocarboxylase synthetase covalently binds biotin to the apocarboxylases for pyruvate, 3-methylcrotonyl-CoA, and propionyl-CoA; biotinidase releases biotin from these proteins and from proteins in the diet. Recessively inherited deficiency of either enzyme causes deficiency of all three carboxylases (ie, multiple carboxylase deficiency). Patients with holocarboxylase synthetase deficiency usually present as neonates with hypotonia, skin problems, and massive acidosis. Those with biotinidase deficiency present later with a syndrome of ataxia, seizures, seborrhea, and alopecia. Untreated patients can develop mental retardation, hearing loss, and optic nerve atrophy. Newborn screening is justified because the neurologic sequelae of the disorder in many patients are preventable if treated early.

Diagnosis

This diagnosis should be considered in patients with typical symptoms or in those with primary lactic acidosis. Urine organic acids are usually but not always abnormal (see Table 36–2). Diagnosis is made by enzyme assay of carboxylase activities in fibroblasts or leucocytes. Biotinidase can be assayed in serum, and holocarboxylase synthetase in leukocytes or fibroblasts.

Treatment

Oral administration of pharmacologic doses of biotin reverses the organic aciduria within days and the clinical symptoms within days to weeks. Hearing loss can occur in patients with profound biotinidase deficiency despite treatment.

GLUTARIC ACIDEMIA TYPE I

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Suspect in children with acute basal ganglia necrosis, macrocrania with subdural bleeds, and acute or progressive dystonia.
- Presymptomatic diagnosis by newborn screening and treatment reduces the incidence of acute encephalopathic crises.

Glutaric acidemia type I is due to deficiency of glutaryl-CoA dehydrogenase. Patients have frontotemporal atrophy with enlarged sylvian fissures and macrocephaly. Sudden or chronic neuronal degeneration in the caudate and putamen causes an extrapyramidal movement disorder in childhood with dystonia and athetosis. Children with glutaric acidemia type I may present with retinal hemorrhages and intracranial bleeding, and may thus be falsely considered victims of child abuse. Severely debilitated children often die in the first decade, but many patients have had only mild neurologic abnormalities. Symptoms almost always develop in the first 6 years of life, which represents the vulnerable period. The condition is autosomal recessive and prenatal diagnosis is possible.

» Diagnosis

Glutaric acidemia type I should be suspected in patients with acute or progressive dystonia in the first 6 years of life. Magnetic resonance imaging of the brain is highly suggestive. The diagnosis is supported by finding glutaric, 3-hydroxyglutaric acid, and glutarylcarnitine in urine or serum or by finding two mutations in the GCDH gene. Demonstration of deficiency of glutaryl-CoA dehydrogenase in fibroblasts can confirm the diagnosis. Prenatal diagnosis is by mutation analysis, enzyme assay, or quantitative metabolite analysis in amniotic fluid.

» Treatment

Strict catabolism prevention during any intercurrent illness is critically important. Supplementation with large amounts of carnitine and provision of a lysine and tryptophan restricted diet reduces the risk of degeneration of the basal ganglia. Early diagnosis does not prevent neurologic disease in all patients, but it clearly reduces the risk, warranting newborn screening. Neurologic symptoms, once present, do not resolve. Symptomatic treatment of severe dystonia is important for affected patients.

Kölker S et al: Complementary dietary treatment using lysine-free, arginine-fortified amino acid supplements in glutaric aciduria type I—a decade of experience. Mol Genet Metab 2012; 107(1-2):72 [PMID: 22520952].

o DISOr DEr S Of f At t Y ACID OXIDAt ION & CAr NIt INE

FATTY ACID OXIDATION DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Obtain an acylcarnitine profile for any child with hypoglycemia to evaluate for a fatty acid oxidation defect.
- Early diagnosis and treatment can prevent morbidity and mortality in affected children, and avoidance of prolonged fasting is of paramount importance for long-term management.

Deficiencies of very-long-chain and medium-chain acyl-CoA dehydrogenase (VLCAD, MCAD) and long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), three enzymes of fatty acid β-oxidation, usually cause Reye-like episodes of hypoketotic hypoglycemia, mild hyperammonemia, hepatomegaly, and encephalopathy. Sudden death in infancy is a less common presentation. The long-chain defects, which also include carnitine palmitoyltransferase deficiency I and II and carnitine-acylcarnitine translocase deficiency, often also cause skeletal myopathy with hypotonia, episodic rhabdomyolysis, cardiomyopathy, and ventricular arrhythmias. Symptoms specific to LCHAD deficiency include progressive liver cirrhosis, peripheral neuropathy, and retinitis pigmentosa, and a high incidence of acute fatty liver of pregnancy or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) during pregnancy in mothers of affected infants. Mild carnitine palmitoyltransferase I deficiency may cause renal tubular acidosis and hypertriglyceridemia. MCAD deficiency is most common, occurring in perhaps 1:9000 live births. Reye-like episodes may be fatal or cause residual neurologic damage. Episodes tend to become less frequent and severe with time. After the diagnosis is made and treatment instituted, morbidity decreases and mortality is avoided in MCAD deficiency.

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency is characterized by the presence of ethylmalonic acid in the urine. Most patients are asymptomatic. Glutaric acidemia type II results from defects in the transfer of electrons from fatty acid oxidation and some amino acid oxidation into the respiratory chain. Some patients with glutaric acidemia type II have a clinical presentation resembling MCAD deficiency. Patients with a severe neonatal presentation also have renal cystic disease and dysmorphic features. The least affected patients can present with late-onset myopathy and be riboflavin responsive. Some develop cardiomyopathy or leukodystrophy. Deficiency of the ketogenic enzyme 3-hydroxymethylglutaryl-CoA synthase presents with hypoketotic hypoglycemia. These conditions are autosomal recessive.

» Diagnosis

All disorders of fatty acid oxidation have reduced ketogenesis in response to fasting. The analysis of acylcarnitine esters is a first-line diagnostic test used in neonatal screening because it reveals diagnostic metabolites regardless of clinical status. A typical pattern can be recognized for each disorder; for instance, MCAD deficiency is characterized by elevated octanoylcarnitine. Some disorders have elevated acylglycine esters which can be identified on urine organic acids or on a specific quantitative analysis. Further confirmation can be obtained from molecular analysis or analysis of fatty acid oxidation in fibroblasts; enzyme assays are only rarely available.

Treatment

Management involves prevention of hypoglycemia by avoiding prolonged fasting (> 8–12 hours). This includes providing carbohydrate snacks before bedtime and vigorous treatment of fasting associated with intercurrent infections. Because fatty acid oxidation can be compromised by associated carnitine deficiency, young patients with MCAD deficiency usually receive oral carnitine when carnitine levels are low. Restriction of dietary long-chain fats is not necessary in MCAD deficiency but is required for severe VLCAD and LCHAD deficiencies. Medium-chain triglycerides are contraindicated in MCAD deficiency but are an essential energy source for patients with severe VLCAD and LCHAD deficiencies or carnitine-acylcarnitine translocase deficiency. Riboflavin may be beneficial in some patients with glutaric acidemia type II. Outcome in MCAD deficiency is excellent but is more guarded in patients with the other disorders.

CARNITINE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Primary carnitine deficiency manifests as cardiac disease including cardiomyopathy and sudden death or as hypoketotic hypoglycemia.
- Treatment of primary carnitine deficiency with carnitine improves outcome and prognosis.
- There are many causes of secondary carnitine deficiency.

Carnitine is an essential nutrient found in highest concentration in red meat. Its primary function is to transport long-chain fatty acids into mitochondria for oxidation. Primary defects of carnitine transport may manifest as Reye syndrome, cardiomyopathy, or skeletal myopathy with hypotonia. These disorders are rare compared with secondary carnitine deficiency, which may be due to diet (vegan diet, intravenous alimentation, or ketogenic diet), renal losses, drug therapy (especially valproic acid), and other metabolic disorders (especially disorders of fatty acid oxidation and organic acidemias). The prognosis depends on the cause of the carnitine abnormality. Primary carnitine deficiency is one of the most treatable causes of dilated cardiomyopathy in children.

Free and esterified carnitine can be measured in blood. If carnitine insufficiency is suspected, the patient should be evaluated to rule out disorders that might cause secondary carnitine deficiency.

Oral or intravenous L-carnitine is used in carnitine deficiency or insufficiency in doses of 25–100 mg/kg/d or higher. Treatment is aimed at maintaining normal carnitine levels. Carnitine supplementation in patients with some disorders of fatty acid oxidation and organic acidurias may also augment excretion of accumulated metabolites, although supplementation may not prevent metabolic crises in such patients.

PURINE METABOLISM DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Lesch-Nyhan syndrome is classically described in boys with spasticity, dystonia, and self-mutilating behaviors.
- Urinary uric acid to creatinine ratio or urine succinylpurines are useful screening tests.

Hypoxanthine-guanine phosphoribosyltransferase is an enzyme that recycles the purine bases hypoxanthine and guanine to inosine monophosphate and guanosine monophosphate, respectively. Hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome) is an X-linked recessive disorder. The complete deficiency is characterized by CNS dysfunction and purine overproduction with hyperuricemia and hyperuricosuria. Depending on the residual activity of the mutant enzyme, male hemizygous individuals may be severely disabled by choreoathetosis, spasticity, and compulsive, mutilating lip and finger biting,

or they may have only gouty arthritis and urate ureterolithiasis. Adenylosuccinate lyase deficiency involves a defect in the synthesis of purines. Patients present with static mental retardation, hypotonia, and seizures.

» Diagnosis

Diagnosis of Lesch-Nyhan syndrome is made by demonstrating an elevated uric acid-creatinine ratio in urine, followed by demonstration of enzyme deficiency in red blood cells or fibroblasts or by molecular analysis. Screening for adenylosuccinate lyase deficiency is by measurement of succinylpurines in urine, with confirmation by further metabolite and molecular assays.

» Treatment

Hyperhydration and alkalinization are essential to prevent kidney stones and urate nephropathy. Allopurinol and probenecid may be given to reduce hyperuricemia and prevent gout but do not affect the neurologic status. Physical restraints are often more effective than neurologic medications for automutilation. No effective treatment exists for adenylosuccinate lyase deficiency.

1 YSOSOMA1 DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Lysosomal storage disorders may present clinically with multisystem involvement including hepatosplenomegaly, cardiac disease, and skeletal features, with or without neurologic involvement.
- Brain imaging, skeletal survey, and urinary mucopolysaccharide or oligosaccharide screen may be helpful initial screening studies; most diagnoses are made by enzyme assay.
- Therapy may be available for many of these previously untreatable disorders.

Lysosomes are cellular organelles in which complex macromolecules are degraded by specific acid hydrolases. Deficiency of a lysosomal enzyme causes its substrate to accumulate in the lysosomes, resulting in a characteristic clinical picture. These storage disorders are classified as mucopolysaccharidoses, lipidoses, or mucolipidoses, depending on the nature of the stored material. Two additional disorders, cystinosis and Salla disease, are caused by defects in lysosomal proteins that normally transport material from the lysosome to the cytoplasm. Table 36–3 lists clinical and laboratory features of these conditions. Most are inherited as autosomal recessive traits, and all can be diagnosed in utero.

» Diagnosis

The diagnosis of mucopolysaccharidosis is suggested by certain clinical and radiologic findings (dysostosis multiplex, which includes enlarged sella turcica, scaphocephaly, broad ribs, hook-shaped vertebrae [L1 and L2 most affected], and prominent pointing of the metacarpals and broad phalanges). Urine screening tests can detect increased mucopolysaccharides and further identify which specific mucopolysaccharides are present. Diagnosis must be confirmed by enzyme assays of leukocytes or cultured fibroblasts. Analysis of urinary oligosaccharides indicates a specific disorder prior to enzymatic testing. Lipidoses present with visceral symptoms or neurodegeneration. The pattern of the leukodystrophy associated with many lipidoses can indicate a specific condition. Diagnosis is made by appropriate enzyme assays of peripheral leukocytes or cultured skin fibroblasts. Molecular analysis is also available for most conditions.

» Treatment

Most conditions cannot be treated effectively, but new avenues have given hope in many conditions. Hematopoietic stem cell transplantation can greatly improve the course of some lysosomal diseases and is first-line treatment in some, such as infantile Hurler syndrome. Several disorders are treated with infusions of recombinant modified enzyme. Treatment of Gaucher disease is very effective, and long-term data suggest excellent outcome. Similar treatments have been developed for Fabry disease, several mucopolysaccharidoses, Wolman, and Pompe disease. Substantial improvements in these conditions have been reported but with limitations. New avenues for treatment through substrate inhibition and chaperone therapy are being developed. Treatment of cystinosis with cysteamine results in depletion of stored cystine and prevention of complications including renal disease.

Table 36–3. Clinical and laboratory features of lysosomal storage diseases.

Disorder	Enzyme Defect	Clinical and Laboratory Features	Available Therapies
I. Mucopolysaccharidoses			
Hurler syndrome	α-Iduronidase	Autosomal recessive. Mental retardation, hepatomegaly, umbilical hernia, coarse facies, corneal clouding, dorsolumbar gibbus, severe heart disease. Heparan sulfate and dermatan sulfate in urine.	HSCT ERT
Scheie syndrome	α-Iduronidase (incomplete)	Autosomal recessive. Corneal clouding, stiff joints, normal intellect. Clinical types intermediate between Hurler and Scheie common. Heparan sulfate and dermatan sulfate in urine.	ERT
Hunter syndrome	Sulfoiduronate sulfatase	X-linked recessive. Coarse facies, hepatomegaly, mental retardation variable. Corneal clouding and gibbus not present. Heparan sulfate and dermatan sulfate in urine.	HSCT ERT
Sanfilippo syndrome: Type A Type B Type C Type D	Sulfamidase α-N-Acetylglucosaminidase Acetyl-CoA: α-glucosaminide-N-acetyltransferase α-N-acetylglucosamine-6-sulfatase	Autosomal recessive. Severe mental retardation and hyperactivity, with comparatively mild skeletal changes, visceromegaly, and facial coarseness. Types cannot be differentiated clinically. Heparan sulfate in urine.	
Morquio syndrome	N-Acetylgalactosamine-6-sulfatase	Autosomal recessive. Severe skeletal changes, platyspondylisis, corneal clouding. Keratan sulfate in urine.	
Maroteaux-Lamy syndrome	N-Acetylgalactosamine-4-sulfatase	Autosomal recessive. Coarse facies, growth retardation, dorsolumbar gibbus, corneal clouding, hepatosplenomegaly, normal intellect. Dermatan sulfate in urine.	HSCT ERT
B-Glucuronidase deficiency	β-Glucuronidase	Autosomal recessive. Varies from mental retardation, dorsolumbar gibbus, corneal clouding, and hepatosplenomegaly to mild facial coarseness, retardation, and loose joints. Hearing loss common. Dermatan sulfate or heparan sulfate in urine.	HSCT
II. Oligosaccharidoses			
Mannosidosis	α-Mannosidase	Autosomal recessive. Varies from severe mental retardation, coarse facies, short stature, skeletal changes, and hepatosplenomegaly to mild facial coarseness and loose joints. Hearing loss common. Abnormal oligosaccharides in urine.	HSCT
Fucosidosis	α-Fucosidase	Autosomal recessive. Variable: coarse facies, skeletal changes, hepatosplenomegaly, occasional angiokeratomas. Abnormal oligosaccharides in urine.	HSCT

(Continued)

Table 36–3. Clinical and laboratory features of lysosomal storage diseases. (Continued)

Disorder	Enzyme Defect	Clinical and Laboratory Features	Available Therapies
I-cell disease (mucolipidosis II)	N-Acetylglucosaminylphosphotransferase	Autosomal recessive; severe and mild forms known. Very short stature, mental retardation, early facial coarsening, clear cornea, and stiffness of joints. Increased lysosomal enzymes in serum. Abnormal sialyl oligosaccharides in urine.	HSCT
Sialidosis	Neuraminidase (sialidase)	Autosomal recessive. Mental retardation, coarse facies, skeletal dysplasia, myoclonic seizures, macular cherry-red spot. Abnormal sialyl oligosaccharides in urine.	
III. Lipidoses			
Niemann-Pick disease	Sphingomyelinase	Autosomal recessive. Acute and chronic forms known. Acute neuronopathic form common in eastern European Jews. Accumulation of sphingomyelin in lysosomes of RE system and CNS. Hepatosplenomegaly, developmental retardation, macular cherry-red spot. Death by 1–4 y in severe type A; mild type B develops respiratory insufficiency usually in adulthood.	HSCT[a]
Metachromatic leukodystrophy	Arylsulfatase A	Autosomal recessive. Late infantile form, with onset at 1–4 y, most common. Accumulation of sulfatide in white matter with central leukodystrophy and peripheral neuropathy. Gait disturbances (ataxia), motor incoordination, absent deep tendon reflexes, and dementia. Death usually in first decade.	HSCT[a]
Krabbe disease (globoid cell leukodystrophy)	Galactocerebroside α-galactosidase	Autosomal recessive. Globoid cells in white matter. Onset at 3–6 mo with seizures, irritability, retardation, and leukodystrophy. Death by 1–2 y. Juvenile and adult forms are rare.	HSCT
Fabry disease	α-Galactosidase A	X-linked recessive. Storage of trihexosylceramide in endothelial cells. Pain in extremities, angiokeratoma and (later) poor vision, hypertension, and renal failure.	ERT
Farber disease	Ceramidase	Autosomal recessive. Storage of ceramide in tissues. Subcutaneous nodules, arthropathy with deformed and painful joints, and poor growth and development. Death within first year.	HSCT[a]
Gaucher disease	Glucocerebroside β-glucosidase	Autosomal recessive. Accumulation of glucocerebroside in lysosomes of RE system and CNS. Acute neuronopathic form: retardation, hepatosplenomegaly, macular cherry-red spot, and Gaucher cells in bone marrow. Death by 1–2 y. Chronic form common in eastern European Jews. Hepatosplenomegaly and flask-shaped osteolytic bone lesions. Consistent with normal life expectancy.	ERT SIT

(Continued)

Table 36–3. Clinical and laboratory features of lysosomal storage diseases. (Continued)

Disorder	Enzyme Defect	Clinical and Laboratory Features	Available Therapies
G_{M1} gangliosidosis	G_{M1} ganglioside β-galactosidase	Autosomal recessive. Accumulation of G_{M1} ganglioside in lysosomes of RE system and CNS. Infantile form: abnormalities at birth with dysostosis multiplex, hepatosplenomegaly, macular cherry-red spot, and death by 2 y. Juvenile form: normal development to 1 y of age, then ataxia, weakness, dementia, and death by 4–5 y. Occasional inferior beaking of vertebral bodies of L1 and L2.	HSCT[a]
G_{M2} gangliosidoses Tay-Sachs disease Sandhoff disease	β-N-Acetylhexosaminidase A β-N-Acetylhexosaminidase A and B	Autosomal recessive. Tay-Sachs disease common in eastern European Jews; Sandhoff disease is panethnic. Clinical phenotypes are identical, with accumulation of G_{M2} ganglioside in lysosomes of CNS. Onset at age 3–6 mo, with hypotonia, hyperacusis, retardation, and macular cherry-red spot. Death by 2–3 y. Juvenile and adult onset forms of Tay-Sachs disease are rare.	
Wolman disease	Acid lipase	Autosomal recessive. Accumulation of cholesterol esters and triglycerides in lysosomes of reticuloendothelial system. Onset in infancy with gastrointestinal symptoms and hepatosplenomegaly, and death in the first year. Adrenals commonly enlarged and calcified.	HSCT ERT
Niemann-Pick disease type C	NPC1 gene (95%), NPC2 gene (5%)	Autosomal recessive. Blocked transport of lipids and cholesterol from late endosomes to lysosomes. Infantile cholestatic liver disease or later neurodegeneration with vertical supranuclear gaze palsy, ataxia, seizures, spasticity and loss of speech. Some have splenomegaly.	SIT

CNS, central nervous system; ERT, enzyme-replacement therapy; HSCT, hematopoietic stem cell transplantation; RE, reticuloendothelial; SIT, substrate inhibition therapy.

PEr OXISOMAl DISEASES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dysmorphic features, hypotonia, hearing loss, seizures, cataracts, retinopathy, liver disease and renal disease are characteristic findings of severe peroxisomal disease.
- Change in behavior or school failure in a young boy may suggest X-linked adrenoleukodystrophy and warrants a brain MRI with contrast.
- Very-long-chain fatty acid analysis is a good screening test for most, but not all, peroxisomal disorders.

Peroxisomes are intracellular organelles that contain a large number of enzymes, many of which are oxidases linked to catalase. The enzyme systems in peroxisomes include β-oxidation of very-long-chain fatty acids, phytanic acid, and bile acids and the biosynthesis of plasmalogens. In addition, peroxisomes contain oxidases for d- and l-amino acids, pipecolic acid, and phytanic acid, and an enzyme (alanine-glyoxylate aminotransferase) that affects transamination of glyoxylate to glycine.

In peroxisomal biogenesis disorders, multiple enzymes are deficient. They present with Zellweger (cerebrohepatorenal) syndrome spectrum of varying severity. Patients present as neonates or infants with seizures, hypotonia, characteristic facies with a large forehead and fontanel, cholestatic hepatopathy, retinal dystrophy, and hearing loss. At autopsy, renal cysts, brain neuronal migration abnormalities, and absent or empty peroxisomes are seen. Patients with milder biochemical and clinical phenotype have ataxia, developmental delay, and hearing and vision loss.

In other peroxisomal diseases, only a single enzyme is deficient. Primary hyperoxaluria (alanine-glyoxylate aminotransferase deficiency) causes renal stones and nephropathy. Mutations in the X-linked very-long-chain fatty acid transporter gene, ABCD1, cause either a rapid leukodystrophy with loss of function (adrenoleukodystrophy), or a slowly progressive spasticity and neuropathy (adrenomyeloneuropathy), or adrenal insufficiency. Defective phytanic acid oxidation in adult Refsum disease causes ataxia, leukodystrophy, cardiomyopathy, neuropathy, and retinal dystrophy. Other isolated enzyme deficiencies can mimic Zellweger syndrome.

Abnormalities of plasmalogen synthesis are clinically associated with rhizomelic chondrodysplasia punctata. Except for adrenoleukodystrophy, all peroxisomal diseases are autosomal recessive and can be diagnosed in utero.

Diagnosis

The best screening test for Zellweger syndrome spectrum is determination of very-long-chain fatty acids in plasma. Urine bile acids are abnormal in other peroxisomal disorders. Phytanic acid and plasmalogens can also be measured. Together, these studies identify most peroxisomal diseases. Fibroblast enzyme assays and molecular analysis provide confirmation, especially when prenatal diagnosis is sought.

Treatment

Bone marrow transplantation may be an effective treatment at the early stages of adrenoleukodystrophy, and close monitoring of affected males is necessary. Newborn screening is being trialed. Adrenal insufficiency requires hydrocortisone substitution. Lorenzo's oil, a mixture of glyceryl-trierucate and glyceryl-trioleate that suppresses endogenous very-long-chain fatty acid synthesis, in combination with a very-low-fat diet and essential fatty acid supplementation, is ineffective in patients with established symptoms but may reduce the incidence of neurologic symptoms in presymptomatic males with adrenoleukodystrophy. Dietary treatment is used and effective for adult Refsum disease. Liver transplantation protects the kidneys in severe primary hyperoxaluria.

CONGENITAL DISORDERS OF GLYCOSYLATION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Analysis of glycosylation of marker glycoproteins such as transferrin (N-linked glycosylation) and apolipoprotein C (O-linked glycosylation) are initial screening tests for these broad-spectrum, multisystem disorders.

Many proteins, including many extracellular and lysosomal proteins, require glycosylation for normal function. The carbohydrate-deficient glycoprotein syndromes are an ever-increasing family of disorders that result from defects in the synthesis of glycans or in the attachment of glycans to other compounds. N-linked, O-linked, and combined N- and O-linked glycosylation defects have been described. The most common N-linked defect is phosphomannomutase-2 deficiency or congenital disorders of glycosylation type Ia (CDG-Ia). Children with type Ia disease usually present with prenatal growth disturbance, often with abnormal fat distribution, cerebellar hypoplasia, typical facial dysmorphic features, and mental retardation. The typical course includes chronic liver disease, peripheral neuropathy, endocrinopathies, retinopathy, and in some patients, acute life-threatening events. Patients with type Ib disease have a variable combination of liver fibrosis, protein-losing enteropathy, and hypoglycemia. More than a dozen other forms are characterized by additional key symptoms, including coloboma, cutis laxa, severe epilepsy, ichthyosis, immunoglobulin deficiency, and Dandy-Walker malformation. Biochemical differences and variations in clinical course (eg, the absence of peripheral neuropathy) characterize the other types. Pathophysiology probably relates to defects of those biochemical pathways that require glycosylated proteins. Recently, O-linked glycosylation defects have been found to underlie more classically described genetic syndromes such as multiple exostoses syndrome, Walker-Warburg syndrome, muscle-eye-brain disease, and a number of α-dystroglycanopathies. The syndromes appear to be inherited in an autosomal recessive manner with the exception of multiple exostoses syndrome which is autosomal dominant. The frequency of N-linked glycosylation defects is estimated to be as high as 1:20,000 in northern Europe.

Diagnosis

Diagnosis is supported by finding altered levels of glycosylated enzymes or other proteins such as transferrin, thyroxine-binding globulin, lysosomal enzymes, and clotting factors (IX, XI, antithrombin III, and proteins C and S). However, these levels may be normal in carbohydrate-deficient glycoprotein syndromes or abnormal in other conditions. Diagnosis is confirmed by finding typical patterns of abnormal glycosylation of selected proteins. Most diagnostic laboratories examine serum transferrin to screen for N-linked defects and apoCIII for O-linked defects. Confirmatory diagnosis is by assaying enzyme activity, analysis of lipid-linked oligosaccharides in fibroblasts, and mutation analysis. Genomic diagnostic methods are increasingly used to identify these disorders.

Treatment

Treatment is supportive, including monitoring and providing early treatment for expected clinical features. Mannose treatment is curative for patients with type Ib deficiency only.

SMITH-LEMLI-OPITZ SYNDROME & DISORDERS OF CHOLESTEROL SYNTHESIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Elevated 7- and 8-dehydrocholesterol in serum is diagnostic in Smith-Lemli-Opitz (SLO) syndrome, which presents with developmental delay and malformations.
- Chondrodysplasia punctata, skin defects, and neurological symptoms can indicate other cholesterol synthetic defects.

Several defects of cholesterol synthesis are associated with malformations and neurodevelopmental disability. SLO syndrome is an autosomal recessive disorder caused by a deficiency of the enzyme 7-dehydrocholesterol Δ7-reductase. It is characterized by microcephaly, poor growth, mental retardation, typical dysmorphic features of face and extremities (particularly two- to three-toe syndactyly), and often malformations of the heart and genitourinary system. It is further described in Chapter 37. Other cholesterol synthetic

defects are seen in Conradi Hünermann syndrome, which includes chondrodysplasia punctata and atrophic skin. Cholestanolosis (cerebrotendinous xanthomatosis) manifests with progressive ataxia and cataracts, or, in young children, with intestinal intolerance.

» Diagnosis

In SLO, elevated 7- and 8-dehydrocholesterol in serum or amniotic fluid is diagnostic. Serum cholesterol levels may be low or in the normal range. Enzymes of cholesterol synthesis may be assayed in cultured fibroblasts or amniocytes, and mutation analysis is possible.

» Treatment

Although postnatal treatment does not resolve prenatal injury, supplementation with cholesterol in SLO improves growth and behavior. The role of supplemental bile acids is controversial.

DISOr DEr S Of NEUr Ot r ANSMIt t Er MEt AbOl ISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Consider in children with movement disorders, especially dystonia and oculogyric crises.
- Severe seizures, abnormal tone, ataxia, and mental retardation, autonomic instability occur in severely affected infants.
- Mildly affected patients have dopa-responsive dystonia with diurnal variability.
- Deficient serine synthesis causes microcephaly, seizures, and failure of myelination in neonates.
- Deficient glucose transporter causes seizures and a movement disorder. Identifiable on CSF analysis and treatable with a ketogenic diet.

Abnormalities of neurotransmitter metabolism are increasingly recognized as causes of significant neurodevelopmental disabilities. These disorders typically affect the biosynthesis of the neurotransmitters dopamine and serotonin. Affected patients may present with movement disorders (especially dystonia and oculogyric crises), seizures, abnormal tone, or mental retardation, and are often considered to have cerebral palsy. Patients may be mildly affected (eg, dopa-responsive dystonia with diurnal variation) or severely affected (eg, intractable seizures with profound mental retardation). Deficient serine synthesis leads to congenital microcephaly, infantile seizures, and failure of myelination.

Pyridoxine-dependent epilepsy manifests as a severe seizure disorder in the neonatal or early infantile period that responds to high doses of pyridoxine. The disorder is caused by deficient activity of the enzyme α-amino adipic semialdehyde dehydrogenase resulting from mutations in the antiquitin (ALDH7A1) gene. Pyridoxal-phosphate–responsive encephalopathy manifests as a severe seizure disorder in infancy that responds to pyridoxal-phosphate. This disorder is caused by mutations in the PNPO gene encoding pyridox(am)ine oxidase, which is necessary for activation of pyridoxine.

» Diagnosis

Although some disorders can be diagnosed by examining plasma amino acids or urine organic acids (eg, 4-hydroxybutyric aciduria), in most cases, diagnosis requires analysis of CSF. Spinal fluid samples for neurotransmitter analysis require special collection and handling, as the neurotransmitter levels are graduated along the axis of the CNS. A phenylalanine loading test can be diagnostic for mild defects in GTP-cyclohydrolase deficiency, in which neurotransmitter analysis may be insufficiently sensitive. Analysis of CSF shows elevated threonine and decreased pyridoxal-phosphate in pyridoxal-phosphate–responsive disease, and decreased serine and glycine in serine biosynthetic defects. Urine or plasma α-aminoadipic acid and piperideine-6-carboxylate best identifies infants with pyridoxine-dependent seizures.

» Treatment

Biosynthesis defects of dopamine and serotonin are usually treated with a combination of levodopa, 5-hydroxytryptophan, and carbidopa. Pyridoxine-dependent epilepsy is treated with pyridoxine in high doses and can benefit from a lysine-restricted diet, whereas pyridoxal-phosphate–responsive encephalopathy requires pyridoxal-phosphate. Supplementation with serine and glycine can substantially improve outcome in serine deficiency. For several conditions, such as pyridoxine-responsive seizures, pyridoxal-phosphate–responsive encephalopathy, or dopa-responsive dystonia, response to treatment is dramatic. For others, response to therapy is less satisfactory in part because of poor penetration of the blood-brain barrier.

° CREATINE SYNTHESIS DISORDERS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Consider in children with seizures, movement disorders, autistic features, and developmental delay especially with severe expressive language delay.

Creatine and creatine phosphate are essential for storage and transmission of phosphate-bound energy in muscle and brain. They spontaneously convert to creatinine. The disorders arginine:glycine amidinotransferase (AGAT) deficiency and guanidinoacetate methyltransferase (GAMT) deficiency are autosomal recessive, whereas creatine transporter (CrT1) deficiency is X-linked. All patients demonstrate developmental delay, mental retardation, autistic behavior, seizures, and severe expressive language delay. Patients may also show developmental regression and brain atrophy. Patients with GAMT deficiency have more severe seizures and an extrapyramidal movement disorder. The seizure disorder is mild in male CrT1-deficient patients, and some female heterozygotes may show learning disabilities.

» Diagnosis

The common feature of all creatine synthesis defects is a severe depletion of creatine and creatine phosphate in the brain demonstrable by reduction to absence of signal on magnetic resonance spectroscopy. In GAMT deficiency, guanidinoacetate accumulates, whereas it is reduced in AGAT deficiency. Guanidinoacetate seems to be responsible for the severe seizures and movement disorder found in GAMT deficiency. Blood, urine, and CSF creatine levels are decreased in GAMT deficiency but normal in AGAT deficiency. Urine excretion of creatine is elevated in CrT1 deficiency. Enzyme and molecular analyses are available for diagnostic confirmation.

» Treatment

Treatment with oral creatine supplementation is in part successful in GAMT and AGAT deficiencies. Treatment with combined arginine restriction and ornithine substitution in GAMT deficiency can decrease guanidinoacetate concentrations and improve the clinical course. Combined therapy using arginine, glycine, and creatine supplementation in CrT1 deficiency is effective in approximately one-third of affected males, specifically improving seizure control and gross motor delays. Improvement is correlated with higher initial cerebral creatine peaks on magnetic resonance spectroscopy (MRS) and early initiation of therapy.

° QUALITY INITIATIVES IN THE FIELD OF METABOLIC DISEASE

Expanded newborn screening has had a large impact on the field of metabolic disorders. Patients are being diagnosed earlier, and for some patients, this dramatically reduces the disease burden. Expanded newborn screening, also revealed unexpected consequences. For example, the clinical spectrum of many disorders is being expanded to include mildly affected or asymptomatic patients. This raises care questions particularly in regard to the need for aggressive management in the more mildly affected patients or if, for some patients, therapy is needed at all. It is unclear whether some patients on the milder end of a disease spectrum would have ever become symptomatic. These additionally recognized milder patients have increased the disease incidence. In addition, newborn screening for several conditions has brought to light our ability to detect maternal disease. Disorders such as maternal B_{12} deficiency and maternal carnitine uptake deficiency pose management as well as risk questions for this largely asymptomatic or presymptomatic population. Further, owing to limitations in diagnostic testing, patients

who may be carriers for a condition are now being treated, as the carrier status cannot be entirely confirmed nor the condition, with severe health risks, entirely excluded. This is particularly true for disorders such as glutaric acidemia, type I and VLCAD deficiency. This not only adds to parental anxiety, but treatment of an unaffected child may entail risk to the child or to family dynamics.

Improvement in diagnostic testing, especially the sensitivity of molecular and enzymatic testing, may help improve the diagnostic conundrum. National initiatives are underway in an attempt to clarify other issues. Initiated under regional programs and now under the guidance of the American College of Medical Genetics and the Newborn Screening Translational Research Network (NBSTRN), uniform clinical data sets for disorders diagnosed via newborn screening have been developed. A national database for data collection integrating clinical care, public health, and state laboratories is being constructed. The overall goal is to track the long-term outcome of individuals diagnosed with inborn errors of metabolism, to define best practice guidelines, and to determine the benefit of newborn screening. In addition, the NBSTRN seeks to stimulate research in newborn screening, advocate pilot screening programs, and establish a national, virtual dried blood spot repository for research. This national initiative is inclusive of all disorders for which newborn screening occurs, not just inborn errors of metabolism.

Another national focus is the expansion of newborn screening to other genetic disorders. Currently, some states are beginning to implement newborn screening for severe combined immunodeficiency (SCID) and for lysosomal and peroxisomal storage disorders. As technology for early detection and treatment strategies advance, more disorders will likely be considered candidates for newborn screening. Additionally, some conditions being considered for screening affect an individual after the newborn period. Second-tier, childhood screening for such late-onset disorders may be a consideration in the future. Careful consideration will need to be given regarding the risks and benefits to screening for such conditions. The U.S. Secretary for Health and Human Services' Advisory Committee on Heritable Disorders in Newborns and Children has established a rigorous process for disease review before recommending a disorder be considered for nationwide screening.

37 Genetics & Dysmorphology

Margarita Sifuentes Saenz, MD
Naomi J.L. Meeks, MD
Anne Chun-Hui Tsai, MD, MSc
Ellen R. Elias, MD

Genetics is an exciting and rapidly evolving field that has significant relevance to the understanding of human embryology, physiology, and disease processes. Tremendous advances in molecular biology and biochemistry are allowing more comprehensive understanding of mechanisms inherent in genetic disorders as well as improved diagnostic tests and management options. Many of the newer technologies and terms may be unfamiliar to the clinician in practice. Thus, the topics in the first part of the chapter serve as an introduction and review of the basic principles of genetics, including basic knowledge of cytogenetics and molecular biology. The second part discusses principles of inherited human disorders, encompassing different genetic mechanisms as well as how to obtain a genetic history and pedigree. Topics in the third part of the chapter focus on applied clinical genetics, which include dysmorphology, teratology, and perinatology. Common clinical disorders with descriptions of the diseases and discussion of their pathogenesis, diagnosis, and management are also included.

FOUNDATIONS OF GENETIC DIAGNOSIS

CYTOGENETICS

Cytogenetics is the study of genetics at the chromosome level. Chromosomal anomalies occur in 0.4% of all live births and are a common cause of intellectual disabilities and congenital anomalies. The prevalence of chromosomal anomalies is much higher among spontaneous abortions and stillbirths.

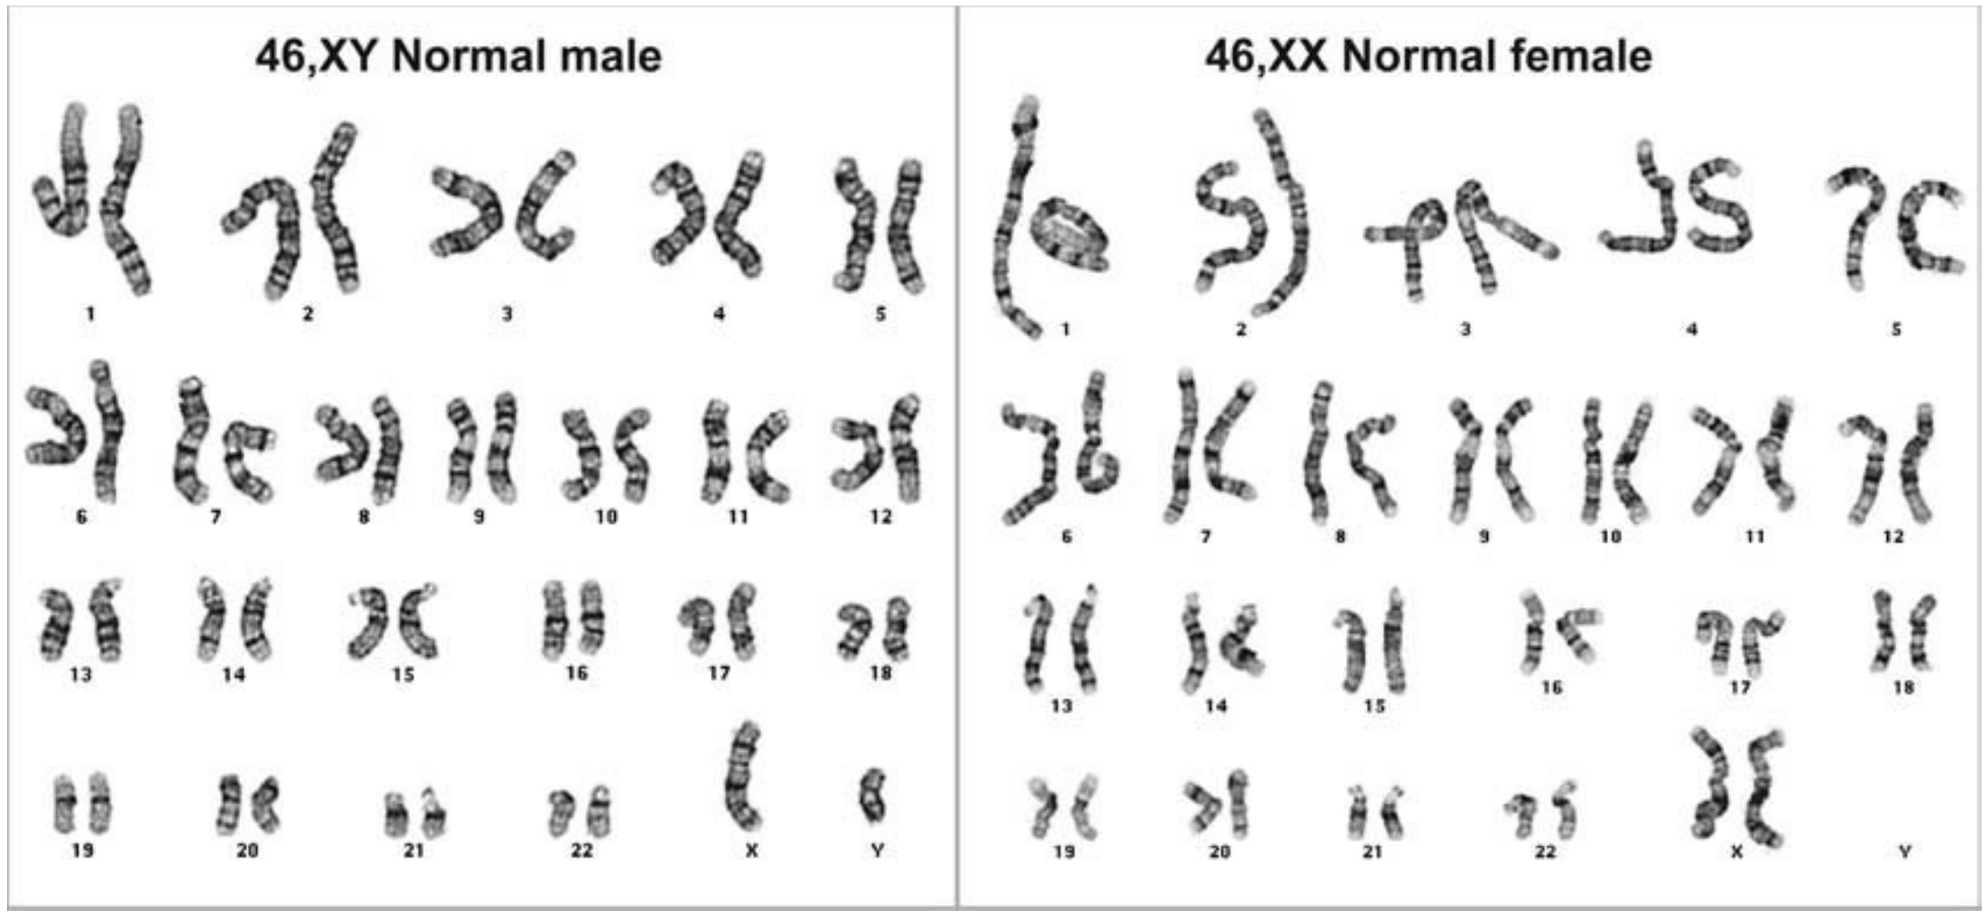
Chromosomes

Human chromosomes consist of DNA (the blueprint of genetic material), specific proteins forming the backbone of the chromosome (called histones), and other chromatin structural and interactive proteins. Chromosomes contain most of the genetic information necessary for growth and differentiation. The nuclei of all normal human cells, with the exception of gametes, contain 46 chromosomes, consisting of 23 pairs (Figure 37–1). Of these, 22 pairs are called autosomes. They are numbered according to their size; chromosome 1 is the largest and chromosome 22 the smallest. In addition, there are two sex chromosomes: two X chromosomes in females and one X and one Y chromosome in males. The two members of a chromosome pair are called homologous chromosomes. One homolog of each chromosome pair is maternal in origin (from the egg); the second is paternal (from the sperm). The egg and sperm each contain 23 chromosomes (haploid cells). During formation of the zygote, they fuse into a cell with 46 chromosomes (diploid cell).

Chromosome Preparation & Analysis

Chromosome structure is visible only during mitosis, most often achieved in the laboratory by stimulating a blood lymphocyte culture with a mitogen for 3 days. Cells processed for routine chromosome analysis are stained on glass slides to yield a light-and-dark band pattern across the arms of the chromosomes (see Figure 37–1). This band pattern is characteristic and reproducible for each chromosome, allowing the chromosomes to be identified. A karyotype is the arrangement of chromosomes in homologous pairs in numerical order. High-resolution chromosome analysis is the study of more elongated chromosomes and can detect smaller imbalances than routine chromosome analysis. Although the bands can be visualized in greater detail, subtle chromosomal rearrangements less than 5 million base pairs (5 Mb) can still be missed.

Fluorescence in situ hybridization (FISH) is a powerful technique that labels a known chromosome sequence with DNA probes attached to fluorescent dyes, thus enabling visualization of specific regions of chromosomes by fluorescent microscopy. FISH can detect submicroscopic structural



▲ **Figure 37–1.** Normal male and female human karyotype. (Used with permission from the Colorado Genetics Laboratory.)

rearrangements undetectable by classic cytogenetic techniques and can identify marker chromosomes. (For pictures of FISH studies, go to http://www.kumc.edu/gec/prof/cytogene.html.)

Interphase FISH allows noncultured cells (lymphocytes, amniocytes) to be rapidly screened for numerical abnormalities such as trisomy 13, 18, or 21, and sex chromosome anomalies. However, because of the possible background or contamination of the signal, the abnormality must be confirmed by conventional chromosome analysis in aneuploidy cases. Two hundred–cell FISH can also be used to ascertain mosaicism.

Chromosomal Microarray Analysis (CMA) or Array Comparative Genomic Hybridization (aCGH)

Advances in computer technology and bioinformatics have led to the development of genetic testing using comparative genomic hybridization with microarray technique. This technique allows detection of very small genetic imbalances anywhere in the genome. It is used to detect interstitial and submicroscopic imbalances, to characterize their size at the molecular level, and to define the breakpoints of translocations. This test has replaced high resolution chromosomes as the first-line test in evaluating children with developmental delays and multiple congenital anomalies. The principle behind chromosomal microarrays is comparison of a patient's genome at hundreds of thousands of locations against a reference genome. Current CMAs are designed to screen the entire genome but the oligonucleotide probes are particularly targeted toward known disease-causing regions. In some cases, the resolution in disease-related genes may be as small as several hundred base pairs. However, this technology is not able to detect very small deletions, duplications, or single nucleotide changes. Most newer CMA platforms use single nucleotide polymorphisms (SNPs) in addition to or instead of oligonucleotide probes. This has the advantage of also being able to pick up cases of uniparental disomy or cases of consanguinity.

Wiszneiwska J et al: Combined array CGH plus SNP genome analyses in a single assay for optimized clinical testing. Eur J Hum Genet 2014 Jan;22(1):79–87 [PMID: 23695279].

Chromosome Nomenclature

Visible under the microscope is a constriction site on the chromosome called the centromere, which separates the chromosome into two arms: p, for petite, refers to the short arm, and q, the letter following p, refers to the long arm. Each arm is further subdivided into numbered bands visible using different staining techniques. The use of named chromosome arms and bands provides a universal method of chromosome description. Common symbols include del (deletion), dup (duplication), inv (inversion), ish (in situ hybridization), i (isochromosome), pat (paternal origin), mat (maternal origin), and r (ring chromosome). These terms are further defined in the section Chromosomal Abnormalities.

Chromosomal Abnormalities

There are two types of chromosomal anomalies: numerical and structural.

A. Abnormalities of Chromosomal Number

When a human cell has 23 chromosomes, such as human ova or sperm, it is in the haploid state (n). After conception, in cells other than the reproductive cells, 46 chromosomes are present in the diploid state (2n). Cells deviating from the multiple of the haploid number are called aneuploid, indicating an abnormal number of chromosomes. Trisomy, an example of aneuploidy, is the presence of three of a particular chromosome rather than two. It results from unequal division, called nondisjunction, of chromosomes into daughter cells. Trisomies are the most common numerical chromosomal anomalies found in humans (eg, trisomy 21 [Down syndrome], trisomy 18, and trisomy 13). Monosomies, the presence of only one member of a chromosome pair, may be complete or partial. Complete monosomies may result from nondisjunction or anaphase lag. All complete autosomal monosomies appear to be lethal early in development and only survive in mosaic forms. Sex chromosome monosomy, however, can be viable.

B. Abnormalities of Chromosomal Structure

Many different types of structural chromosomal anomalies exist. Figure 37–2 displays the formal nomenclature as well as the ideogram demonstrating chromosomal anomalies. In clinical context, the sign (+) and (-) preceding the chromosome number indicate increased and decreased number, respectively, of that particular whole chromosome in a cell. For example, 47, XY+21 designates a male with three copies of chromosome 21. The sign (+) and (-) after the chromosome number signify extra material and missing material, respectively, on one of the arms of the chromosome. For example, 46, XX, 8q- denotes a deletion on the long arm of chromosome 8. Detailed nomenclature, such as 8q11, is required to further demonstrate a specific missing region so that genetic counseling can be provided.

1. Deletion (del) (see Figure 37–2A)—This refers to an absence of normal chromosomal material. It may be terminal (at the end of a chromosome) or interstitial (within a chromosome). The missing part is described using the code "del," followed by the number of the chromosome involved in parentheses, and a description of the missing region of that chromosome, also in parentheses, for example, 46, XX, del(1) (p36.3). This chromosome nomenclature describes the loss of genetic material from band 36.3 of the short arm of chromosome 1, which results in 1p36.3 deletion syndrome.

2. Duplication (dup) (see Figure 37–2B)—An extra copy of a chromosomal segment can be tandem (genetic material present in the original direction) or inverted (genetic material present in the opposite direction). A well-described duplication of chromosome 22q11 causes Cat eye syndrome, resulting in iris coloboma and anal or ear anomalies.

3. Inversion (inv) (see Figure 37–2C)—In this aberration, a rearranged section of a chromosome is inverted. It can be paracentric (not involving the centromere) or pericentric (involving the centromere).

4. Ring chromosome (r) (see Figure 37–2D)—Deletion of the normal telomeres (and possibly other subtelomeric sequences) leads to subsequent fusion of both ends to form a circular chromosome. Ring chromosomal anomalies often cause growth retardation and intellectual disability.

5. Translocation (trans) (see Figure 37–2E)—This interchromosomal rearrangement of genetic material may be balanced (the cell has a normal content of genetic material arranged in a structurally abnormal way) or unbalanced (the cell has gained or lost genetic material as a result of chromosomal interchange). Balanced translocations may further be described as reciprocal, the exchange of genetic material between two nonhomologous chromosomes, or Robertsonian, the fusion of two acrocentric chromosomes.

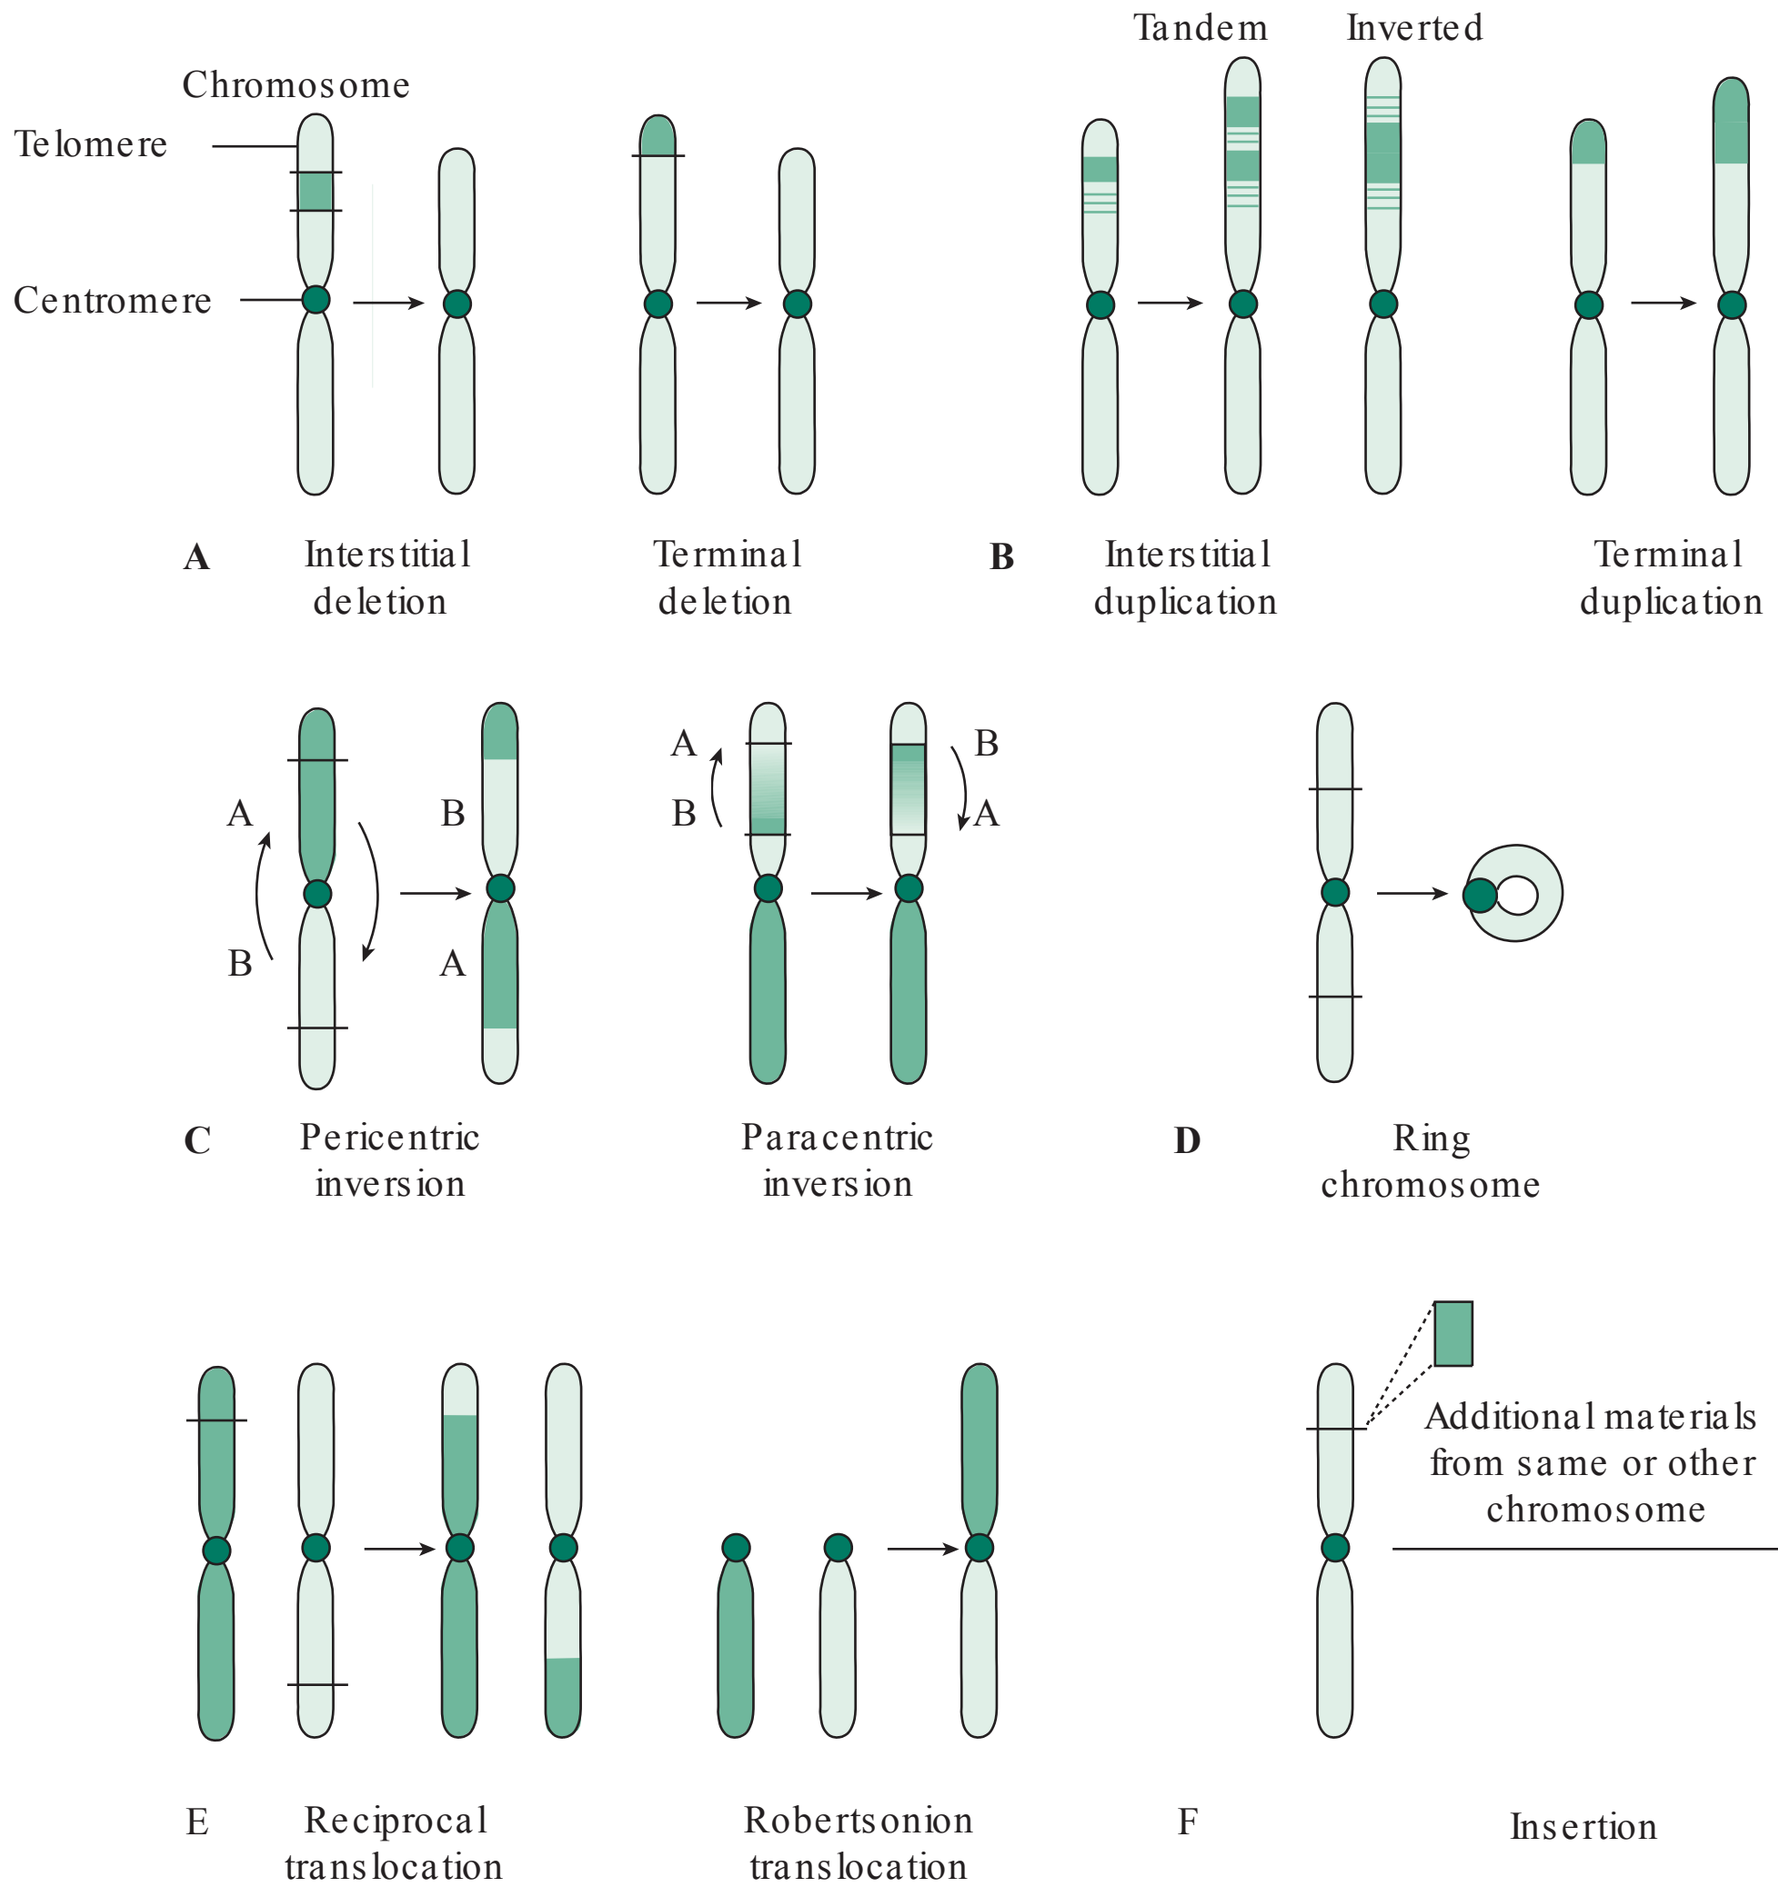
6. Insertion (ins) (see Figure 37–2F)—Breakage within a chromosome at two points and incorporation of another piece of chromosomal material is called insertion. This requires three breakpoints and may occur between two chromosomes or within the same chromosome. The clinical presentation or phenotype depends on the origin of the inserted materials.

C. Sex Chromosomal Anomalies

Abnormalities involving sex chromosomes, including aneuploidy and mosaicism, are relatively common in the general population. The most common sex chromosome anomalies include 45,X (Turner syndrome), 47,XXX, 47,XXY (Klinefelter syndrome), 47,XYY, and different mosaic states. (See later text for clinical discussion.)

D. Mosaicism

Mosaicism is the presence of two or more different chromosome constitutions in different cells of the same individual. For example, a patient may have some cells with 47 chromosomes and others with 46 chromosomes (46,XX/47,XX,+21 indicates mosaicism for trisomy 21; similarly, 45,X/46,XX/47,XXX indicates mosaicism for a monosomy and a trisomy X). Mosaicism should be suspected if clinical symptoms are milder than expected in a non-mosaic patient with the same chromosomal abnormality, or if the patient's skin shows unusual pigmentation. The prognosis is frequently better for a patient with mosaicism than for one with a corresponding chromosomal abnormality without mosaicism. In general, the smaller the proportion of the abnormal cell line, the better the prognosis. In the same patient, however, the proportion

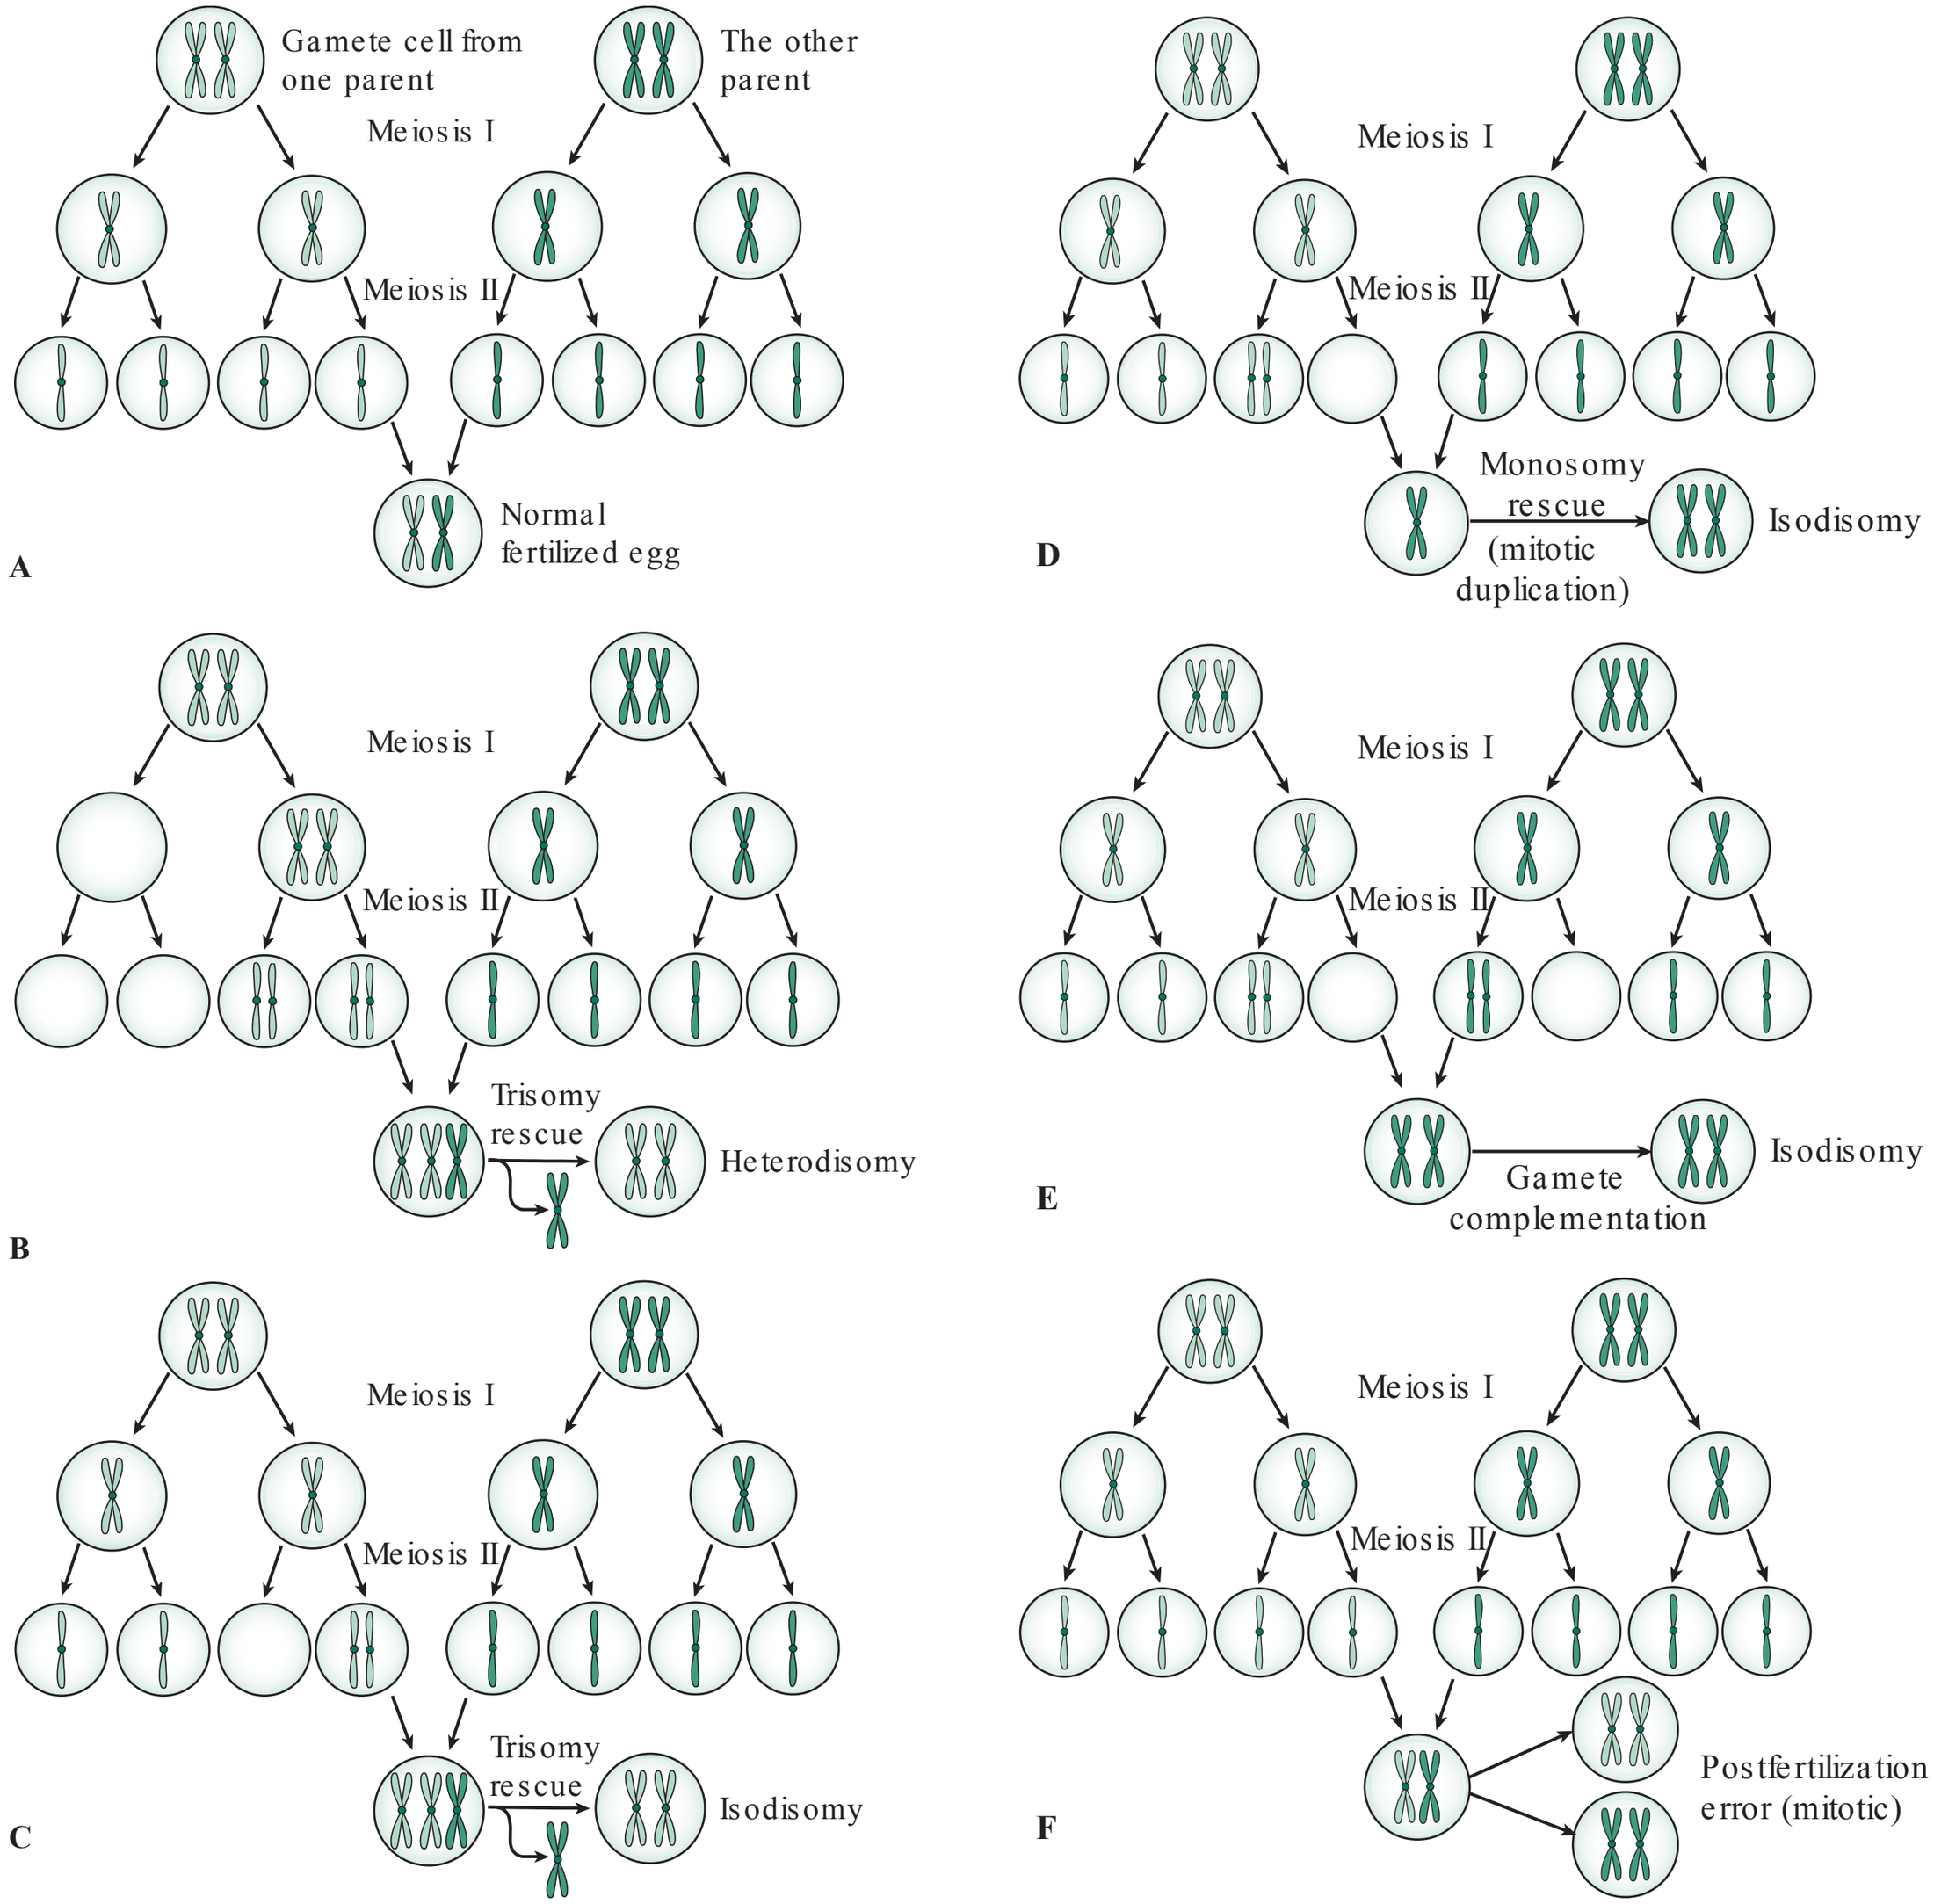


▲**Figure 37–2.** Examples of structural chromosomal abnormalities: deletion, duplication, inversion, ring chromosome, translocation, and insertion.

of normal and abnormal cells in various tissues, such as skin, brain, internal organs, and peripheral blood, may be significantly different. Therefore, the prognosis for a patient with chromosomal mosaicism can seldom be assessed reliably based on the karyotype in peripheral blood alone.

E. Uniparental Disomy

Under normal circumstances, one member of each homologous pair of chromosomes is of maternal origin from the egg and the other is of paternal origin from the sperm (Figure 37–3A). In uniparental disomy (UPD), both copies of a particular chromosome pair originate from the same parent. If UPD is caused by an error in the first meiotic division, both homologous chromosomes of that parent will be present in the gamete—a phenomenon called heterodisomy (Figure 37–3B). If the disomy is caused by an error in the second meiotic division, two copies of the same chromosome will be present through the mechanism of rescue, duplication, and complementation (Figure 37–3C through 37–3E)—a phenomenon called isodisomy. Isodisomy may also occur as a postfertilization error (Figure 37–3F).



▲**Figure 37–3.** The assortment of homologous chromosomes during normal gametogenesis and uniparental disomy. **A:** Fertilization of normal gametes. **B:** Heterodisomy by trisomy rescue. **C:** Isodisomy by trisomy rescue. **D:** Isodisomy by monosomy rescue. **E:** Isodisomy by complementation. F: Isodisomy by mitotic error.

Possible mechanisms for the adverse effects of UPD include homozygosity for deleterious recessive genes and the consequences of imprinting (see discussion in the section Imprinting). It is suspected that UPD of some chromosomes is lethal.

UPD has been documented for certain human chromosomes, including chromosomes 7, 11, 14, 15, and X, and has been found in patients with Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes (BWS). In addition, cystic fibrosis with only one carrier parent (caused by maternal

isodisomy) has been reported. UPD may cause severe prenatal and postnatal growth retardation.

F. Microdeletion and Microduplication Syndromes

Microdeletion and microduplication syndromes result when there is a loss or gain of small regions of a chromosome. These are frequently referred to as copy number variants (CNVs). These may include one gene, multiple genes, or noncoding regions of the genome. Though high-resolution chromosomes can detect some copy number variants, most are detected or confirmed by FISH or CMA. These copy number variants may be familial (passed on by a parent) or may occur de novo. Many copy number variants are now known to be associated with specific syndromes (discussed in Chromosomal Abnormalities: Abnormal Structure). However some are not totally understood and may be classified as a Variant of Uncertain Significance (VOUS) or may be benign changes. Therefore, special caution and parental studies are often required in interpreting the results.

H. Chromosomal Abnormalities in Cancer

Numerical and structural chromosomal abnormalities are often identified in hematopoietic and solid-tumor neoplasms in individuals with otherwise normal chromosomes. These cytogenetic abnormalities have been categorized as primary and secondary. In primary abnormalities, their presence is necessary for initiation of the cancer; an example is 13q- in retinoblastoma. Secondary abnormalities appear de novo in somatic cells only after the cancer has developed, for example, Philadelphia chromosome, t(9;22)(q34;q11), in acute and chronic myeloid leukemia. Primary and secondary chromosomal abnormalities are specific for particular neoplasms and can be used for diagnosis or prognosis. For example, the presence of the Philadelphia chromosome is a good prognostic sign in chronic myelogenous leukemia and indicates a poor prognosis in acute lymphoblastic leukemia. The sites of chromosome breaks coincide with the known loci of oncogenes and tumor suppressor genes.

MOLECULAR GENETICS

Advances in molecular biology have revolutionized human genetics, as they allow for the localization, isolation, and characterization of genes that encode protein sequences. Molecular genetics can help explain the complex underlying biology involved in many human diseases.

Molecular diagnosis on a clinical basis can be achieved using the following technologies: **Southern blot analysis** uses electrophoresis and specific DNA probes to look for changes in genomic DNA, most often trinucleotide repeats. The **polymerase chain reaction (PCR)** replicates fragments of DNA between predetermined primers so that sufficient DNA is obtained for characterization or sequencing in the space of a few hours. **Quantitative fluorescent PCR** combines PCR amplification with fluorescent DNA probes to provide real-time replication and rapid determination of gene copy number and dosage effects. **DNA sequencing** is the process of determining the nucleotide order of a given DNA fragment. **aCGH** can also be used to look for small deletions or duplications (as small as one exon) on the gene level. **Methylation** analysis can look for uniparental disomy or imprinting defects (discussed below). **Next generation sequencing (NextGen)** or massively parallel sequencing allows the sequencing of many genes quickly and accurately, and for less expense per gene than traditional DNA sequencing. This technology has allowed the screening of dozens or hundreds of genes at one time with targeted panel testing. This technology is also being used to perform **whole-exome sequencing (WES)** where all genes in the entire genome are sequenced at one time. Prices for WES in commercial laboratories run around $7000 per patient with a 25%–30% diagnostic hit rate. The same technology will be applied to Whole Genome Sequencing, which is technically possible but not widely clinically available yet due to the lack of ability to interpret results on a clinical basis.

Desai AN, Jere A: Next-generation sequencing: ready for the clinics? Clin Genet 2012:81;6, 503–510 [PMID: 22375550].

Genetics and Its Clinical Applications

There are multiple reasons a patient may undergo genetic testing, and it's important for families to receive genetic counseling prior to testing to understand how that result may impact the patient and other family members.

Patients are often referred for genetic testing if they present with specific features of a known condition, if they have clinical characteristics but an unknown cause for those characteristics or because of a family history of a specific genetic condition. Genetic testing may confirm or identify a specific diagnosis, which can then be used to target specific treatments or interventions. Many families also feel a pressing need to know "why" a child has the condition they do; in some cases this may help alleviate feelings of guilt experienced by parents worrying there may have been something they did to cause a condition in their child. Even in cases where a genetic diagnosis does not alter treatments and interventions, some patients or families are seeking information about recurrence risks or information to allow prenatal or preimplantation genetic diagnosis.

In some genetic diagnoses, confirmation of a specific diagnosis results in additional recommendations for screening (laboratory and/or imaging studies) for additional medical complications. This can be seen in 22q11.2 deletion syndrome where those children are at risk for developmental

delays, speech and palate problems, cardiac malformations, immune dysfunction, hormone imbalances, and growth delays/short stature among many others. In other diagnoses, specific medical treatments are indicated which do not impact the gene itself, but are designed to minimize complications of the disorder. An example of this is Marfan syndrome where diagnosis indicates treatment with beta-blockers or an angiotensin-receptor blocker to prevent complications related to aortic dilation. In some inborn errors of metabolism, organ transplant can treat the disorder if the affected gene is expressed primarily in one organ (ie, liver transplantation in Ornithine transcarbamylase deficiency). Finally, in rare genetic diagnoses, trials are underway to actually alter gene expression itself to ameliorate effects of the disease. An example of this is Duchenne muscular dystrophy, where treatment to induce exon skipping and help restore normal protein function is under investigation.

Pharmacogenomics is a new field offering enormous promise for predicting drug response in patients. For example, by DNA analysis of two specific genes, CYP2C9 and VKORC1, it is now possible to predict response to warfarin anticoagulation therapy and to individualize the dose, saving the patient multiple blood tests and dosage adjustments. It is also possible to predict which patients would be at risk for hearing loss after receiving aminoglycoside treatment, based on mutations in the mitochondrial 12S rRNA gene.

Personalized medicine is an advancing field of medicine that offers increased precision and effectiveness than traditional medicine. A patient's genomic information offers insight into the individual aspects of one's medical management. The goal is to optimize care and overall outcomes, one example being the aforementioned area of pharmacogenomics and potential therapeutic responses.

Genetic testing allows practitioners to test patients for a wide variety of genetic conditions. Advances in this area of medicine have included the advent of parents requesting testing for adult onset disease, carrier status, and disease susceptibility in their children. There are significant ethical and legal issues surrounding this topic. The American College of Medical Genetics and Genomics and American Society of Human Genetics formed a consensus statement on the topic that educates families and health care providers on the potential negative impacts of such testing. In the face of whole exome or genome sequencing, single-gene analysis, and microarray analysis, carrier status for conditions may be revealed and this requires detailed genetic counseling. The decision-making capacity of the minor should also be taken into account where applicable.

MENDELIAN INHERITANCE

Autosomal single-gene disorders follow the principles explained by Gregor Mendel's observations. The inheritance of genetic traits through generations relies on segregation and independent assortment. **Segregation** is the process through which gene pairs are separated during gamete formation. Each gamete receives only one copy of each gene (allele). **Independent assortment** refers to the idea that the segregation of different alleles occurs independently.

Victor McKusick's catalog, Mendelian Inheritance in Man, lists more than 10,000 entries in which the mode of inheritance is presumed to be autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. Single genes at specific loci on one or a pair of chromosomes cause these disorders. An understanding of inheritance terminology is helpful in approaching Mendelian disorders. Analysis of the pedigree and the pattern of transmission in the family, identification of a specific condition, and knowledge of that condition's mode of inheritance usually allow for explanation of the inheritance pattern.

Terminology

1. Dominant and Recessive—Concepts for dominant and recessive refer to the **phenotypic expression** of alleles and are not intrinsic characteristics of gene loci. Therefore, it is incorrect to discuss "a dominant locus."

2. Genotype—Genotype means the genetic status, that is, the alleles an individual carries.

3. Phenotype—Phenotype is the expression of an individual's genotype including appearance, physical features, organ structure, and biochemical and physiologic nature. It may be modified by environment.

4. Pleiotropy—Pleiotropy refers to the phenomenon whereby a single mutant allele can have widespread effects or expression in different tissues or organ systems. In other words, an allele may produce more than one effect on the phenotype. For example, Marfan syndrome has manifestations in different organ systems (skeletal, cardiac, ophthalmologic, etc) due to a single mutation within the fibrillin gene.

5. Penetrance—Penetrance refers to the proportion of individuals with a particular genotype that express the same phenotype. Penetrance is a proportion that ranges between 0 and 1 (or 0 and 100%). When 100% of mutant individuals express the phenotype, penetrance is **complete**. If some mutant individuals do not express the phenotype, penetrance is said to be **incomplete**, or **reduced**. Dominant conditions with incomplete penetrance, therefore, are characterized by "skipped" generations with unaffected, obligate gene carriers.

6. Expressivity—Expressivity refers to the variability in degree of phenotypic expression (severity) seen in different individuals with the same mutant genotype. Expressivity may be extremely variable or fairly consistent, both within and between families. Intrafamilial variability of expression may be due to factors such as epistasis, environment, genetic anticipation, presence of phenocopies, mosaicism, and chance (stochastic factors). Interfamilial variability of expression may be due to the previously mentioned factors, but may also be due to allelic or locus genetic heterogeneity. Expansion of this concept is frequently seen in newly described microdeletion and microduplication syndromes.

7. Genetic heterogeneity—Several different genetic mutations may produce phenotypes that are identical or similar enough to have been traditionally considered as one diagnosis. "Anemia" or "intellectual disability" are examples of the above concept. There are two types of genetic heterogeneity: locus heterogeneity and allelic heterogeneity.

a. Locus heterogeneity—Locus heterogeneity describes a phenotype caused by mutations at more than one genetic locus; that is, mutations at different loci cause the same phenotype or a group of phenotypes that appear similar enough to have been previously classified as a single disease, clinical "entity," or diagnostic spectrum. An example would be Sanfilippo syndrome (mucopolysaccharidosis types IIIA, B, C, and D), in which the same phenotype is produced by four different enzyme deficiencies.

b. Allelic heterogeneity—A phenotype causing different mutations at a single-gene locus. As an example, cystic fibrosis may be caused by many different genetic changes, such as homozygosity for the common Δ F508 mutation, or ΔF508 and an R117H mutation. The latter example represents **compound heterozygosity**.

8. Phenotypic heterogeneity or "clinical heterogeneity"—This term describes the situation in which more than one phenotype is caused by different allelic mutations at a single locus. For example, different mutations in the FGFR2 gene can cause different craniosynostosis disorders, including Crouzon syndrome, Jackson-Weiss syndrome, Pfeiffer syndrome, and Apert syndrome. These syndromes are clinically distinguishable and are due to the presence of a variety of genetic mutations within a single gene.

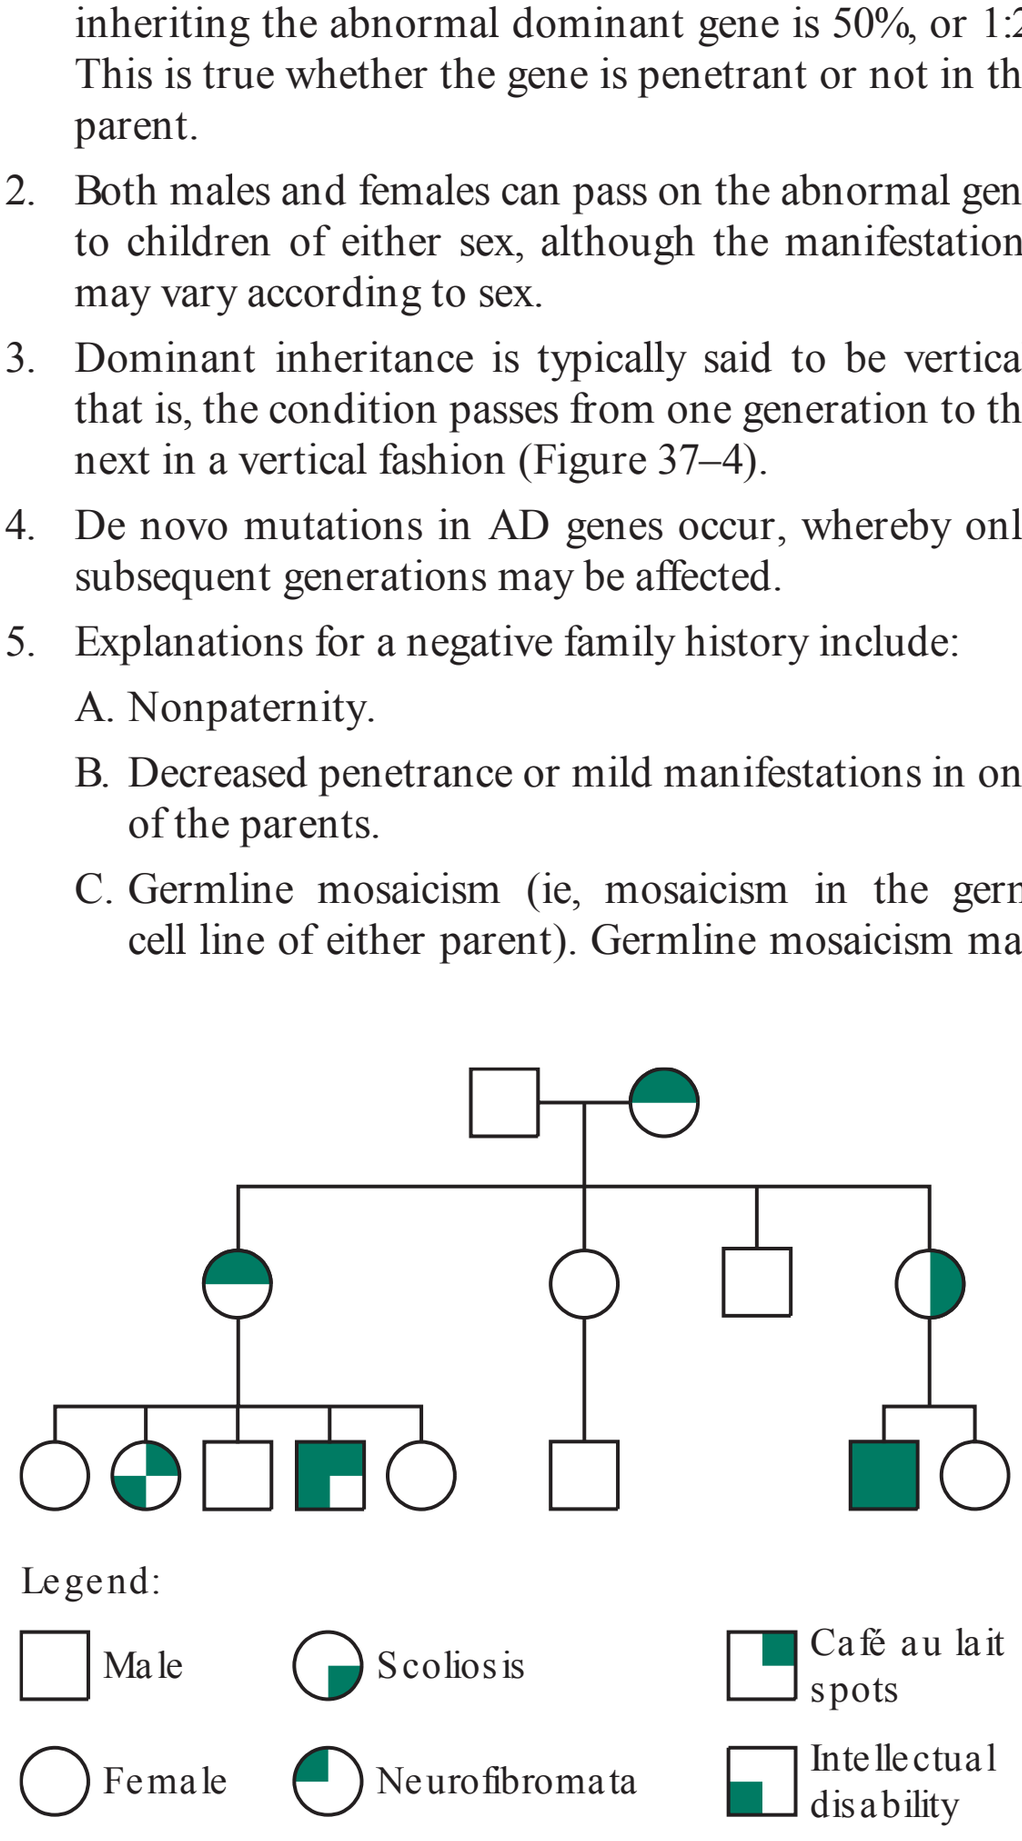
9. Homozygous—A cell or organism that has identical alleles at a particular locus is said to be homozygous. For example, a cystic fibrosis patient with a ΔF508 mutation on both alleles would be called homozygous for that mutation.

10. Heterozygous—A cell or organism that has nonidentical alleles at a genetic locus is said to be heterozygous. In autosomal dominant conditions, a mutation of only one copy of the gene pair is all that is necessary to result in a disease state. However, an individual who is heterozygous for a recessive disorder will not manifest symptoms.

Hereditary Patterns

A. Autosomal Dominant Inheritance

1. If a parent is affected, the risk for each offspring of inheriting the abnormal dominant gene is 50%, or 1:2. This is true whether the gene is penetrant or not in the parent.
2. Both males and females can pass on the abnormal gene to children of either sex, although the manifestations may vary according to sex.
3. Dominant inheritance is typically said to be vertical, that is, the condition passes from one generation to the next in a vertical fashion (Figure 37–4).
4. De novo mutations in AD genes occur, whereby only subsequent generations may be affected.
5. Explanations for a negative family history include:
   A. Nonpaternity.
   B. Decreased penetrance or mild manifestations in one of the parents.
   C. Germline mosaicism (ie, mosaicism in the germ cell line of either parent). Germline mosaicism may



▲**Figure 37–4.** Autosomal dominant inheritance. Variable expressivity in neurofibromatosis type 1.

mimic autosomal recessive inheritance, because it leads to situations in which two children of completely normal parents are affected with a genetic disorder. Recurrence risks are in the range of 1%–7%.

D. The abnormality present in the patient may be a phenocopy, or it may be a similar but genetically different abnormality with a different mode of inheritance.

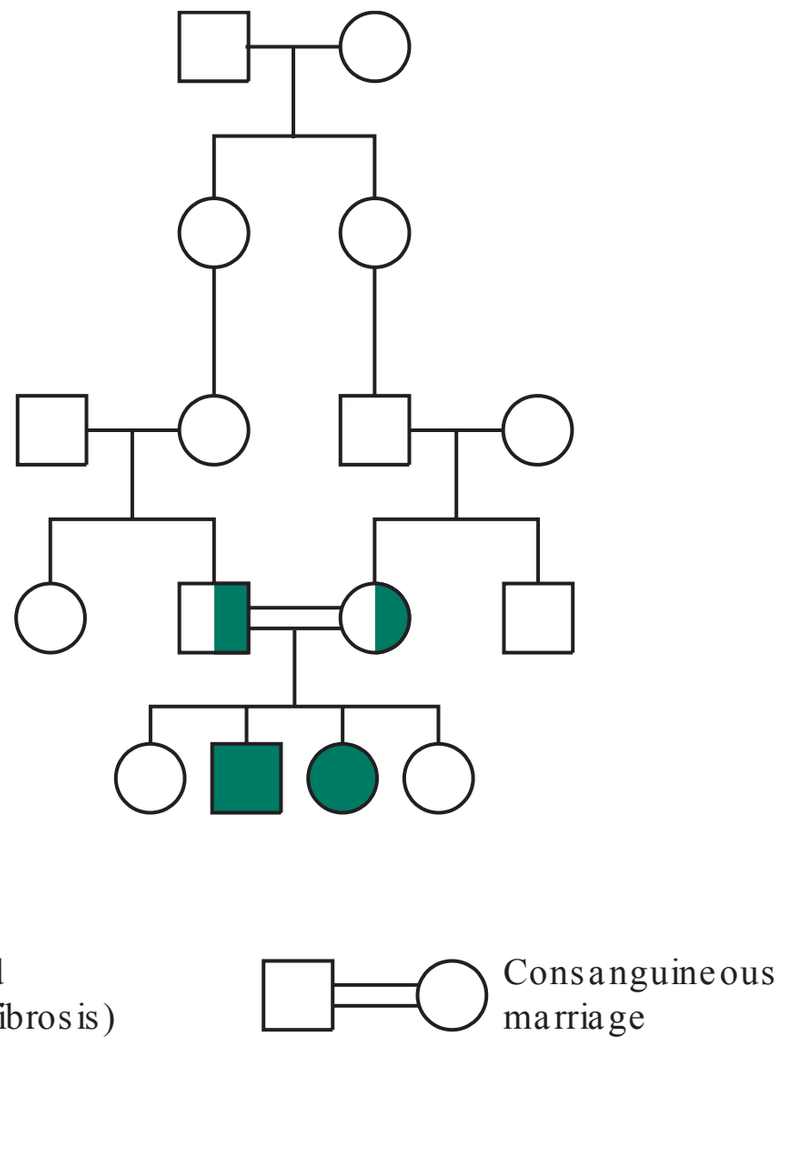
6. If an abnormality represents a new mutation of a dominant trait, the parents of the affected individual run a low risk during subsequent pregnancies. The risk for an affected sibling is still slightly increased over the general population, because of the possibility of germline mosaicism.

B. Autosomal Recessive Inheritance

1. The recurrence risk for parents of an affected child is 25%, or 1:4 for each pregnancy. The gene carrier frequency in the general population can be used to assess the risk of having an affected child with a new partner, for unaffected siblings, and for the affected individuals themselves.
2. Parents are carriers and are clinically normal. (There are, however, exceptions to this rule. For example, carriers of sickle cell trait may become symptomatic if they become hypoxic.)
3. Males and females are affected equally.
4. Inheritance is horizontal; siblings may be affected (Figure 37–5).
5. The family history is usually negative, with the exception of siblings.
6. In rare instances, a child with a recessive disorder and a normal karyotype may have inherited both copies of the abnormal gene from one parent and none from the other. The topic of uniparental disomy was addressed earlier in the chapter.

C. X-Linked Inheritance

When a gene for a disorder is on the X chromosome, the condition is said to be X-linked. Females may be either homozygous or heterozygous, because they have two X chromosomes. Males have only one X, and are hemizygous for any gene on his X chromosome. The severity of an X-linked disorder is generally greater in males than in females. According to the Lyon hypothesis, because one of the two X chromosomes in each cell is inactivated, and this inactivation is random, the clinical picture in females depends on the percentage of mutant versus normal alleles inactivated. The X chromosome is not inactivated until about 14 days of gestation, and parts of the short arm remain active throughout life.

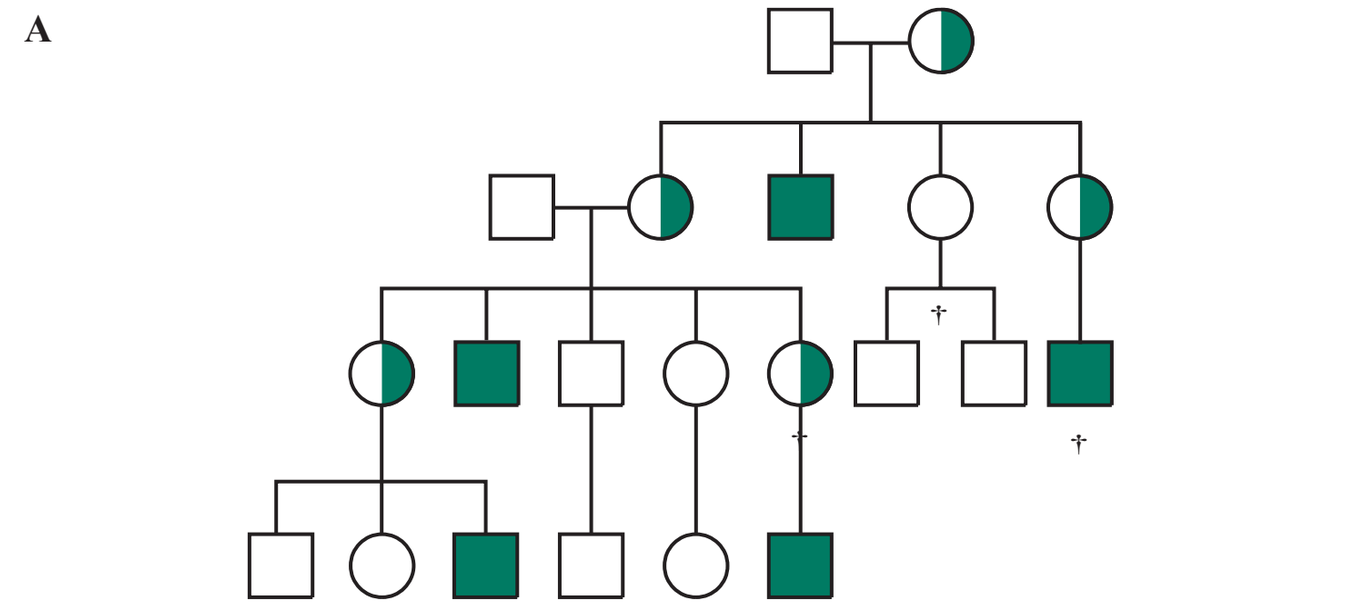


▲**Figure 37–5.** Autosomal recessive inheritance: cystic fibrosis.

1. X-linked recessive inheritance—The following features are characteristic of X-linked recessive inheritance:

1. Males are affected, and heterozygous females are either normal or have mild manifestations.
2. Inheritance is diagonal through the maternal side of the family (Figure 37–6A).
3. A female carrier has a 50% chance that each daughter will be a carrier and a 50% chance that each son will be affected.
4. All of the daughters of an affected male are carriers, and none of his sons are affected.
5. Occasionally a female may be fully affected. Several possible mechanisms may account for a fully affected female: (aa.) skewed X-inactivation; (bb.) 45,X karyotype; (cc.) homozygosity for the abnormal gene; (dd.) an X-autosome translocation, or other structural abnormality of one X chromosome, in which the X chromosome of normal structure is preferentially inactivated; (ee.) UPD; and (ff.) nonrandom inactivation, which may be controlled by an autosomal gene.

2. X-linked dominant inheritance—The X-linked dominant inheritance pattern is less common than the X-linked recessive type. Examples include incontinentia pigmenti and hypophosphatemic or vitamin D–resistant rickets. The following features are characteristic of X-linked dominant inheritance:



▲**Figure 37–6.** **A**: X-linked recessive inheritance. **B:** X-linked dominant inheritance.

1. The heterozygous female is symptomatic, and the disease is twice as common in females.
2. Clinical manifestations are more variable in females than in males.
3. The risk for the offspring of heterozygous females to be affected is 50% regardless of sex.
4. All of the daughters but none of the sons of affected males will have the disorder (Figure 37–6B).
5. Although a homozygous female is possible (particularly in an inbred population), she would be severely involved. All of her children would also be affected.
6. Some disorders (eg, incontinentia pigmenti) are lethal in males (and in homozygous females). Affected women have twice as many daughters as sons and an increased incidence of miscarriages, because affected males will be spontaneously aborted. A 47,XXY karyotype has allowed affected males to survive.

D. Y-Linked Inheritance

In Y-linked inheritance, also known as "holandric" inheritance, a disorder is caused by genes located on the Y chromosome. These conditions are relatively rare with only

about 40 entries listed in the McKusick's catalog. Male-to-male transmission is seen in this category, with all sons of affected males being affected and no daughters or females being affected.

MULTIFACTORIAL INHERITANCE

Many general population attributes, such as height, are familial and are the result of the actions of multiple rather than single genes. Inheritance of these traits is described as **polygenic** or **multifactorial**. The latter term recognizes that environmental factors such as diet also contribute to these traits. Genetic testing for these conditions is not available.

Many disorders and congenital abnormalities that are clearly familial but do not segregate as Mendelian traits (eg, autosomal dominant, recessive) show polygenic inheritance. For the most part, these conditions become manifest when thresholds of additive gene actions or contributing environmental factors are exceeded. Many common disorders ranging from hypertension, stroke, and thrombophlebitis to behavioral traits such as alcoholism demonstrate multifactorial (polygenic) inheritance. Some common birth defects, including isolated congenital heart disease, cleft lip and palate, and neural tube defects, also demonstrate polygenic inheritance. Polygenic or multifactorial inheritance has several distinctive characteristics:

1. The risk for relatives of affected persons is increased. The risk is higher for first-degree relatives (those who have 50% of their genes in common) and lower for more distant relations, although the risk for the latter is higher than for the general population (Table 37–1).
2. The risk is higher if the defect is more severe. In Hirschsprung disease, the longer the aganglionic segment, the higher the recurrence risk.
3. Sex ratios may not be equal. If a marked discrepancy exists, the recurrence risk is higher if a child of the less commonly affected sex has the disorder. This assumes that more genetic factors are required to raise the more resistant sex above the threshold. For example, pyloric stenosis is more common in males. If the first affected child is a female, the recurrence risk is higher than if the child is a male.

NONMENDELIAN INHERITANCE

Epigenetic Regulation

Although development is regulated by genes, it is initiated and sustained by nongenetic processes. Epigenetic events are functionally relevant changes to the genome that are independent of changes in the primary DNA sequence. Genetic imprinting and DNA methylation are examples of epigenetic processes that affect development. Certain genes important in regulation of growth and differentiation are themselves

Table 37–1. Empiric risks for some congenital disorders.

Anencephaly and spina bifida: incidence (average) 1:1000	
One affected child: 2%–3%	
Two affected children: 10%–12%	
One affected parent: 4%–5%	
Hydrocephalus: incidence 1:2000 newborns	
Occasional X-linked recessive	
Often associated with neural tube defect	
Some environmental etiologies (eg, toxoplasmosis)	
Recurrence risk, one affected child	
Hydrocephalus: 1%	
Some central nervous system abnormality: 3%	
Nonsyndromic cleft lip and/or palate: incidence (average) 1:1000	
One affected child: 2%–4%	
One affected parent: 2%–4%	
Two affected children: 10%	
One affected parent, one affected child: 10%–20%	
Nonsyndromic cleft palate: incidence 1:2000	
One affected child: 2%	
Two affected children: 6%–8%	
One affected parent: 4%–6%	
One affected parent, one affected child: 15%–20%	
Congenital heart disease: incidence 8:1000	
One affected child: 2%–3%	
One affected parent, one affected child: 10%	
Clubfoot: incidence 1:1000 (male:female = 2:1)	
One affected child: 2%–3%	
Congenital dislocated hip: incidence 1:1000 (female > male) with marked regional variation	
One child affected: 2%–14%	
Pyloric stenosis: Incidence, males: 1:200; females: 1:1000	
Male index patient	
Brothers	3.2%
Sons	6.8%
Sisters	3.0%
Daughters	1.2%
Female index patient	
Brothers	13.2%
Sons	20.5%
Sisters	2.5%
Daughters	11.1%

regulated by chemical modification that occurs in specific patterns in gametes. Certain techniques developed to assist infertile couples (advanced reproductive technology) may affect epigenetic processes and lead to genetic disorders in the offspring conceived via these methods.

Storey KB: Regulation of hypometabolism: insights into epigenetic controls. J Exp Biol 2015 Jan 1;218(Pt 1):150–159 [PMID: 25568462].

Imprinting

The parental origin of chromosome pairs can affect which genes are actually transcribed and which are inactivated. The term imprinting refers to the process by which preferential transcription of certain genes takes place. Certain chromosomes, particularly chromosome X, 15, 11, and 7, have imprinted regions where some genes are only read from one homolog (ie, either the maternal or paternal allele) under normal circumstances, and the gene on the other homolog is typically inactivated. Errors in imprinting may arise because of UPD (in which a copy from one parent is missing), chromosomal deletion causing loss of the gene normally transcribed, mutations in the imprinting genes that normally code for transcription, or inactivation of other genes downstream. A good example of how imprinting may affect human disease is Beckwith-Wiedemann syndrome, the gene for which is located on chromosome 11p15.

Ko JM: Genetic Syndromes Associated with Overgrowth in Childhood. Ann Pediatr Endocrinol Metab 2013 Sep;18(3):101–105 [PMID: 2494861].

Genetic Anticipation

Geneticists coined the term "anticipation" to describe an unusual pattern of inheritance in which symptoms became manifest at earlier ages and with increasing severity as traits are passed to subsequent generations. Mapping of the genes responsible for these disorders led to the discovery that certain repeat sequences of DNA at disease loci were not stable when passed through meiosis. Repeated DNA sequences, in particular triplets (eg, CGG and CAG), tended to increase their copy number. As these runs of triplets expanded, they eventually affect the expression of genes and produce symptoms. Disorders undergoing triplet repeat expansion detected thus far produce primarily neurologic symptoms. Most conditions are progressive. The size of the triplet expansion is roughly correlated with the timing and severity of symptoms. The reasons for the meiotic instability of these sequences are not yet understood. The mechanisms appear to involve interactions between DNA structure (eg, formation of hairpin loops) and replication enzymes (DNA polymerase complexes) during meiosis.

Triplet repeat instability can modify the inheritance of autosomal dominant, autosomal recessive, and X-linked traits. Autosomal dominant disorders include several spinal cerebellar atrophies, Huntington disease, and myotonic dystrophy. Unstable triplet repeat expansion contributes to at least one autosomal recessive disorder, Friedreich ataxia. The most common X-linked disorder demonstrating triplet repeat instability and expansion is Fragile X syndrome.

Mitochondrial Inheritance

Mitochondrial disorders can be caused by both nuclear and mitochondrial genes. The former would follow Mendelian inheritance, either AR, AD, or X-linked, while the latter demonstrates mitochondrial inheritance. Mitochondrial DNA is double-stranded, 16,569 base pair, circular, and smaller than nuclear DNA, and is found in the cytoplasm. It codes for 13 gene products involved in oxidative phosphorylation and electron transport.

Mitochondrial DNA (mtDNA) can sustain pathogenic point mutations, deletions, or duplications. However, there is a threshold effect depending on the heteroplasmy. Due to the difficulty in diagnosing mitochondrial DNA disorders, and the variability of the clinical course, it is often difficult to calculate specific recurrence risks.

Mitochondrial disorders related to mtDNA have the following characteristics:

1. Remarkable phenotypic variability.
2. Maternally inheritance (only the egg has any cytoplasmic material, and during early embryogenesis any sperm-born mitochondrial material will be eliminated).
3. In most mitochondrial disorders, cells are heteroplasmic: cells contain both normal and mutated or abnormal mtDNA (Figure 37–7). The proportion of normal

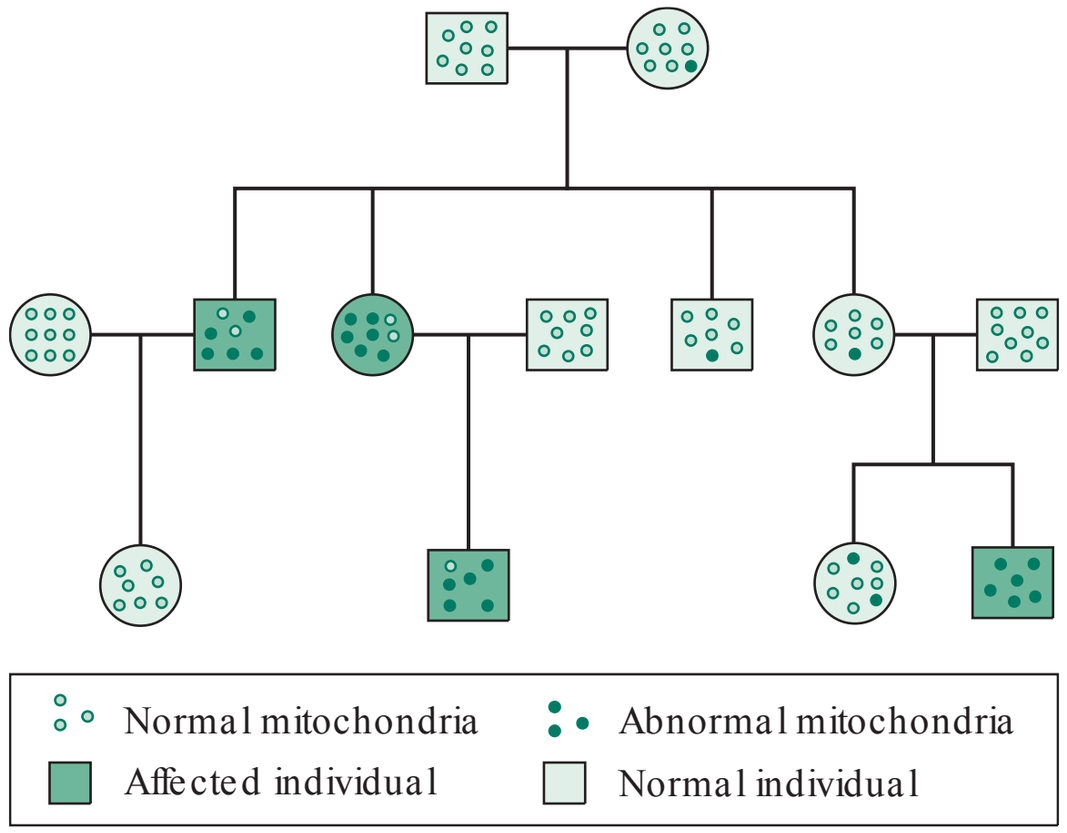


Figure 37–7. Mitochondrial inheritance. Mutations are transmitted through the maternal line.

to abnormal mtDNA in the mother's egg seems to determine the severity of the offspring's disease and the age at onset in most cases.

4. Those tissues with the highest adenosine triphosphate/energy requirements—specifically, central nervous system (CNS) and skeletal muscle—appear most susceptible to mutations in mtDNA.
5. Somatic cells show an increase in mtDNA mutations and a decline in oxidative phosphorylation function with age. This explains the later onset of some of these disorders and may indeed be a clue to the whole aging process.

FAMILY HISTORY & PEDIGREE

Critical in the evaluation of a potential genetic condition is the construction of a family tree, also known as a pedigree. Underused by most medical personnel, the pedigree is a valuable record of genetic and medical information, which is much more useful in visual form than in list form. Tips for pedigree preparation include the following:

- Start with the proband—the patient's siblings and parents, and obtain a three-generational history at minimum, when possible.
- Always ask about consanguinity in a nonjudgmental manner.
- Obtain data from both sides of the family.
- Ask about spontaneous abortions, stillbirths, infertility, children relinquished for adoption, and deceased individuals.

In the course of taking the family history, one may find information that is not relevant in elucidating the cause of the patients' problem but may indicate a risk for other important health concerns. Conditions unrelated to the chief complaint should be directed for follow-up care. Examples of the latter scenario include: an overwhelming family history of early-onset breast and ovarian cancer, or multiple pregnancy losses.

DYSMORPHOLOGY & HUMAN EMBRYOLOGY

Birth defects are the leading cause of death in the first year of life. They are evident in 2%–3% of newborn infants and in up to 7% of adults. Many are detected by prenatal ultrasound. Clinical investigation of the causes and consequences of birth defects is called dysmorphology.

MECHANISMS

Developmental Biology

Cell proliferation and programmed cell death (apoptosis) both contribute to embryonic structural formation. Products of other genes establish regulatory pathways in which positive and negative signaling loops initiate and maintain cell differentiation with precise timing. Further understanding of these mechanisms may lead to interventions that could prevent birth defects or potentially provide treatment prenatally. An example of the evolution of the aforementioned process is fetal surgery for neural tube defects.

Cellular Interactions

The picture emerging from experimental studies of morphogenesis is one of a hierarchy of gene expression during development. Morphogenesis begins with expression of genes encoding transcription factors. These proteins bind to DNA in undifferentiated embryonic cells and recruit them into developmental fields, groups of cells primed to respond to specific signals later in development. The recruitment also establishes spatial relationships and orients cells with respect to their neighbors. As fields differentiate into identifiable tissues (eg, ectoderm, mesoderm, and endoderm), cellular proliferation, migration, and further differentiation are mediated through genes-encoding cell-signaling proteins.

Signaling proteins include growth factors and their receptors, cellular adhesion molecules, and extracellular matrix proteins that both provide structure and position signals to developing tissues. Genetic mutations that alter these pathways can yield genetic disease.

Environmental Factors

The effects of exogenous agents during development are also mediated through genetically regulated pathways. At the cellular level, compounds foreign to nature cause birth defects either because they disrupt cell signaling and thereby misdirect morphogenesis, or because they are cytotoxic and lead to cell death in excess of the usual developmental program.

In general, drug receptors expressed in embryos and fetuses are the same molecules that mediate pharmacologic effects in adults. However, effector systems may be different, reflecting incomplete morphogenesis and differences between fetal and postnatal physiology. These circumstances allow prediction of dose-response relationships

during development on the one hand, but call for caution about predicting effects on the other.

Over-the-counter, prescribed, and abused drugs that are pharmacologically active in mothers will be active across the placenta. Exposure to agents achieving cytotoxic levels in adults are likely to be teratogenic (ie, cause birth defects). Abused substances such as alcohol that are toxic to adults are predictably toxic to embryos and fetuses. Drugs generally safe in adults will be generally safe for fetuses. An exception is ibuprofen with its prostaglandin blocking properties that can affect fetal circulation, which is prostaglandin dependent. It is important to keep in mind that embryonic and fetal physiology may differ from that of an adult with respect to drug action.

Effects of toxic environmental contaminants on the embryo and fetus are dose-dependent. Thus, the level of exposure to a toxin frequently becomes the primary determinant of its risk.

Transplacental pharmacologic effects can be therapeutic. The potential for embryonic and fetal drug therapies during pregnancy is increasing. Folic acid supplementation can lower risks for birth defects such as spina bifida, and maternally administered corticosteroids can induce fetal synthesis and secretion of pulmonary surfactants prior to delivery.

Mechanical Factors

Much of embryonic development and all of fetal growth occurs normally within the low pressure and space provided by amniotic fluid. Loss or inadequate production of amniotic fluid can have disastrous effects, as can disruption of placental membranes. Disruption of placental membranes in early gestation leads to major structural distortion and most often lethal. Later, deformation or even amputation of fetal extremities (amniotic band sequence) can occur.

Movement is also important for morphogenesis. Fetal movement is necessary for normal development of joints and is the principal determinant of folds and creases present at birth in the face, hands, feet, and other areas of the body. Clubfoot is an etiologically heterogeneous condition in which the foot is malpositioned at birth. It more often results from mechanical constraint secondary to intrauterine crowding, weak fetal muscles, or abnormal neurologic function than from primary skeletal development.

Lung and kidney development are particularly sensitive to mechanical forces. Constriction of the chest through malformation of the ribs, lack of surrounding amniotic fluid, or lack of movement (fetal breathing) leads to varying degrees of pulmonary hypoplasia in which lungs are smaller than normal and develop fewer alveoli. The presentation at birth is respiratory distress and may be lethal.

Cystic renal dysplasia is frequently associated with obstruction ureters or bladder outflow. As pressure within obstructed renal collecting systems increases, it distorts cell interactions and alters histogenesis. Developing kidneys exposed to increased internal pressures for long periods eventually become nonfunctional.

CLINICAL DYSMORPHOLOGY

An important task for the clinician presented with an infant with a birth defect is to determine whether the problem is isolated or part of a larger embryopathy (or syndrome).

Terminology

Classification of dysmorphic features strives to reflect mechanisms of abnormal development. Birth defects are referred to as **malformations** when they result from altered genetic or developmental processes. When physical forces interrupt or distort morphogenesis, their effects are termed **disruptions** and **deformations**, respectively. The term **dysplasia** is used to denote abnormal histogenesis. Malformations occurring together more frequently than would be expected by chance alone may be classified as belonging to **associations**. Those in which the order of maldevelopment is understood may be referred to as **sequences**. For example, Robin sequence (or Pierre Robin anomaly) is used to describe cleft palate that has occurred because poor growth of the jaw (retrognathia) has displaced the tongue and prevented posterior closure of the palate. **Syndromes** are simply recurrent patterns of maldevelopment, with a known genetic cause.

Evaluation of the Dysmorphic Infant

History and physical examinations provide most of the clues to diagnosis. Special aspects of these procedures in a clinical genetics setting are outlined in the following sections. The extent of an infant's abnormalities may not be immediately apparent, and parents who feel grief and guilt are often desperate for information.

A. History

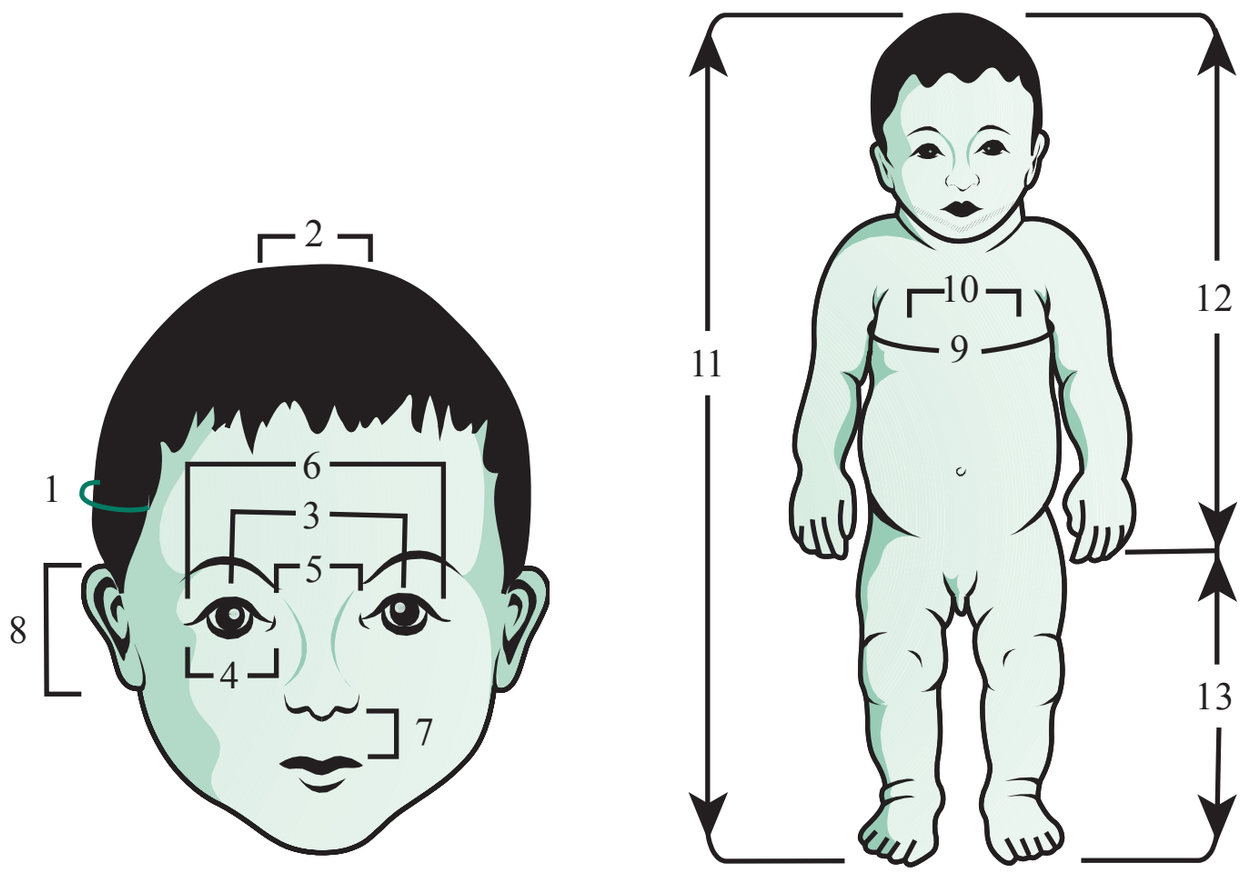
Pregnancy histories are a critical part of the history intake. Review of gestational age, intrauterine drug exposure, prenatal complications, and prenatal testing is important. Family histories are preferred in pedigree formation. Environmental histories should include descriptions of parental habits and work settings. Targeted histories, based on chief complaint should be obtained with past medical and surgical histories, developmental history, and review of systems.

B. Physical Examination

Meticulous physical examination is crucial for accurate diagnosis in dysmorphic infants and children. In addition to the routine procedures described in Chapter 2, special attention should be paid to the patient's physical measurements (Figure 37–8). Photographs are helpful and should include a consistent method of measurement for reference.

C. Imaging and Laboratory Studies

Radiologic investigation is fundamental in the assessment and management of dysmorphic patients. A series of 9 plain



Measurement	Range (cm)	
	Term (38–40 wk)	Preterm (32–37 wk)
1 Head circumference	32–37	27–32
2 Anterior fontanelle $\left(\frac{L-W}{2}\right)$	0.7–3.7	. . .
3 Interpupillary distance	3.3–4.5	3.1–3.9
4 Palpebral fissure	1.5–2.1	1.3–1.6
5 Inner canthal distance	1.5–2.5	1.4–2.1
6 Outer canthal distance	5.3–7.3	3.9–5.1
7 Philtrum	0.6–1.2	0.5–0.9
8 Ear length	3–4.3	2.4–3.5
9 Chest circumference	28–38	23–29
10 Internipple distance[a]	6.5–10	5–6.5
11 Height	47–55	39–47
12 / 13 Ratio $\frac{\text{Upper body segment}}{\text{Lower body segment}}$	1.7	. . .
14 Hand (palm to middle finger)	5.3–7.8	4.1–5.5
15 Ratio of middle finger to hand	0.38–0.48	0.38–0.5
16 Penis (pubic bone to tip of glans)	2.7–4.3	1.8–3.2

[a]Internipple distance should not exceed 25% of chest circumference.

▲**Figure 37–8.** Neonatal measurements.

radiographs, called a skeletal survey, is useful in the evaluation of patients with suspected skeletal dysplasia. Magnetic resonance imaging (MRI), with or without angiogram, venogram, or spectroscopy, contributes to diagnostic evaluation when clinically indicated. Computed tomography (CT) is useful for bony structure assessment, but less so for deep tissue evaluation in comparison to MRI. Ultrasonography also has case-dependent utility for noninvasive imaging. Evaluation of high risk sacral dimpling is generally performed via ultrasound in infants 3–6 months of age. Institutions vary on the cutoff age. Consultation with a radiologist is encouraged if there is any question about which imaging modality would serve the patient best.

Traditional cytogenetic analysis provides specific diagnoses in approximately 5% of dysmorphic infants who survive the neonatal period. Chromosomal abnormalities are recognized in 10%–15% of infants who die. With the availability of chromosomal microarray, at least 10%–15% additional subtle chromosomal anomalies have been identified. Of note, many copy number variations (CNVs) exist in different individuals; therefore, interpretation is sometimes difficult and may require parental samples for clarification. Common disorders such as trisomies 21, 13, and 18 can be determined rapidly (48–72 hours) through use of FISH, but this technique should be accompanied by a complete karyotype. As a rule, a normal karyotype does not rule out the presence of significant genetic disease. Any case requiring rapid diagnosis should be discussed with an experienced clinical geneticist.

Benachi A, Sarnacki S: Prenatal counseling and the role of the paediatric surgeon. Semin Pediatr Surg 2014 Oct;23(5):240–243 [PMID: 25459006].

Chromosomal Disorders: Abnormal Number

TRISOMIES

1. Trisomy 21 (Down Syndrome)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Characteristic features include upslanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae.
- Generalized hypotonia.
- Cognitive disabilities (usually mild to moderate).
- Associated with congenital heart disease and gastrointestinal anomalies.

Down syndrome occurs in about 1:700 newborns. Cognitive disabilities in the mild/moderate range are characteristic of Down syndrome, as is generalized hypotonia. The affected newborn may have prolonged physiologic jaundice, and transient blood count abnormalities. Feeding problems and constipation are common during infancy. Problems which may develop during childhood include thyroid dysfunction, visual issues, hearing loss, obstructive sleep apnea, celiac disease, atlanto-occipital instability, and autism. Leukemia is 12–20 times more common in patients with Down syndrome.

Clinical Findings

The principal physical findings include a flattened occiput, characteristic facies (upslanting palpebral fissures, epicanthal folds, midface hypoplasia, and small, dysplastic pinnae), and minor limb abnormalities. About one-third to one-half of children with Down syndrome have congenital heart disease, most often endocardial cushion defects or other septal defects. Anomalies of the gastrointestinal tract, including esophageal and duodenal atresias, are seen in about 15% of cases.

Clinical Report: Health Supervision for Children with Down Syndrome, Marilyn Bull and the Committee on Genetics. Pediatrics 2011:128;393–406 [PMID: 21788214].

Information regarding healthcare guidelines for patients with Down syndrome. http://www.downsyn.com/guidelines/healthcare.html.

2. Trisomy 18 Syndrome

The incidence of trisomy 18 syndrome is about 1:4000 live births, and the ratio of affected males to females is approximately 1:3. Trisomy 18 is characterized by prenatal and postnatal growth retardation, which is often severe, and hypertonicity. Complications are related to associated anomalies. Death is often caused by heart failure or pneumonia and usually occurs in infancy or early childhood, although a small percentage of patients reach adulthood. Surviving children show significant cognitive disabilities.

Clinical Findings

Infants with trisomy 18 are often small for gestational age and have dysmorphic features including a characteristic facies and extremities (overlapping fingers and rocker-bottom feet) and congenital heart disease (often ventricular septal defect or patent ductus arteriosus). To see clinical pictures of patients with trisomy 18, visit the following website: http://medgen.genetics.utah.edu/photographs/pages/trisomy_18.htm.

3. Trisomy 13 Syndrome

The incidence of trisomy 13 is about 1 per 12,000 live births, and 60% of affected individuals are female. Most infants with trisomy 13 have congenital anomalies that are incompatible with survival. Surviving children demonstrate failure to thrive, cognitive disabilities, apneic spells, seizures, and deafness. Death usually occurs in early infancy or by the second year of life, commonly as a result of heart failure or infection.

» Clinical Findings

The symptoms and signs include characteristic features, often a normal birth weight, CNS malformations, eye malformations, cleft lip and palate, polydactyly or syndactyly, and congenital heart disease. The facies of an infant with trisomy 13 can be viewed at the following website: www.trisomy.org.

» Treatment of Trisomies

A. Medical Therapy

Trisomy 21: Interventions for specific issues such as surgical intervention for cardiac and GI anomalies, screening for autoimmune disorders such as hypothyroidism and celiac disease, developmental supports such as infant stimulation programs, special education, and physical, occupational, and speech therapies are all indicated. The goal of treatment is to help affected children develop to their full potential. Parents' participation in support groups such as the local chapter of the National Down Syndrome Congress should be encouraged. See the following website: http://www.ndss.org/.

There is no treatment other than general supportive care for Trisomy 13 or 18. Rapid confirmation of suspected Trisomy 13 or 18 can be made by FISH. A support group for families of children with trisomies 13 and 18 who survive beyond infancy is called SOFT. See the following website: http://www.trisomy.org/.

B. Genetic Counseling

Most parents of trisomic infants have normal karyotypes. The risk of having a child affected with a trisomy increases with maternal age. For example, age-specific risks are approximately 1 per 1500 for mothers aged 25 years; and 1 per 100 for mothers at age 40. The recurrence risk for trisomy in future pregnancies is equal to 1 per 100 plus the age-specific maternal risk.

If the child has a trisomy resulting from a translocation, and the parent has an abnormal karyotype, the risks are increased. When the mother is the carrier of a balanced Robertsonian translocation, there is a 10%–15% chance that the child will be affected and a 33% chance that the child will be a balanced translocation carrier. When the father is the carrier, there is a smaller than 0.5% chance of having another affected child. If the child has a 21/21 translocation and one parent has the translocation, the recurrence risk is 100%.

SEX CHROMOSOME ABNORMALITIES

1. Turner Syndrome (Monosomy X, Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Webbed neck, triangular facies, short stature, wide-set nipples, amenorrhea, and absence of secondary sex characteristics.
- » Associated with coarctation of the aorta and genitourinary malformations.
- » IQ is usually normal but learning disabilities are common.
- » Mosaic individuals may manifest only short stature and amenorrhea.

The incidence of Turner syndrome is 1 per 10,000 females. However, it is estimated that 95% of conceptuses with monosomy X are miscarried and only 5% are liveborn.

» Clinical Findings

Newborns with Turner syndrome may have webbed neck, edema of the hands and feet, coarctation of the aorta, and a characteristic triangular facies. Other findings in older girls may include short stature, a shield chest with wide-set nipples, streak ovaries, amenorrhea, absence of secondary sex characteristics, and infertility. Some affected girls, particularly those with mosaicism, have only short stature and amenorrhea, without dysmorphic features. Learning disabilities are common, secondary to difficulties in perceptual motor integration.

» Treatment

Academic supports for learning issues perceptual difficulties are important. Hormonal treatment includes estrogen therapy, which permits development of secondary sex characteristics and normal menstruation, and prevents osteoporosis. Growth hormone therapy is also used to increase the height of affected girls. Females with 45,X or 45,X mosaicism have a low fertility rate, and those who become pregnant have a high risk of fetal wastage (spontaneous miscarriage, ~30%; stillbirth, 6%–10%). Furthermore, their liveborn offspring

have an increased frequency of chromosomal abnormalities involving either sex chromosomes or autosomes and congenital malformations. Thus, prenatal ultrasonography and chromosome analysis are indicated for the offspring of females with sex chromosome abnormalities.

2. Klinefelter Syndrome (XXY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diagnosis is rarely made before puberty.
- Key findings include microorchidism; lack of libido; minimal facial hair; and tall, eunuchoid build.
- IQ can vary (normal to borderline with a small percentage showing cognitive disabilities).

The incidence of Klinefelter syndrome in the newborn population is roughly 1 per 1000, but it is about 1% among intellectual disabilities males and about 3% among males seen at infertility clinics. The maternal age at birth is often advanced. Unlike Turner syndrome, Klinefelter syndrome is rarely the cause of spontaneous abortions. The diagnosis is seldom made before puberty except as a result of prenatal diagnosis, because prepubertal boys have a normal phenotype.

» Clinical Findings

The characteristic findings after puberty include small testicles associated with otherwise normal external genitalia, azoospermia, sterility, gynecomastia, normal to borderline IQ, diminished facial hair, and a tall, eunuchoid build. In chromosome variants with three or four X chromosomes (XXXY and XXXXY), intellectual disabilities may be severe, and skeletal and genital anomalies may be present. In general, the physical and mental abnormalities associated with Klinefelter syndrome increase as the number of sex chromosomes increases.

» Treatment

Males with Klinefelter syndrome require testosterone replacement therapy. The presence of the extra X chromosome may allow expression of what might normally be a lethal X-linked disorder to occur.

3. XYY Syndrome

Newborns with XYY syndrome in general are normal. Affected individuals may on occasion exhibit an abnormal behavior pattern from early childhood and may have mild intellectual disabilities. Fertility may be normal. Many males with an XYY karyotype are normal. There is no treatment.

4. XXX Syndrome

The incidence of females with an XXX karyotype is approximately 1 per 1000. Females with XXX are phenotypically normal. However, they tend to be taller than usual and to have lower IQs than their normal siblings. Learning and behavioral issues are relatively common. This is in contrast to individuals with XXXX, a much rarer condition causing more severe developmental issues, and a dysmorphic phenotype reminiscent of Down syndrome.

Jones KL: Smith's Recognizable Patterns of Human Malformation. 7th ed. Philadelphia, PA: Elsevier; 2013.

o Chr OmOSOmAl ABNOr mAl ITIES: ABNOr mAl STr UCTUr E

Chromosomal abnormalities most often present in newborns as multiple congenital anomalies in association with intrauterine growth retardation. In addition to trisomies as just described, other more subtle chromosomal abnormalities are also common. In some cases, a chromosomal rearrangement is too subtle to be detected by karyotype. The current technology, comparative genomic hybridization array (microarray), enables screening for multiple submicroscopic chromosomal abnormalities simultaneously, and is a very helpful tool in evaluating the child with a suspected chromosomal abnormality.

Although most cases of severe chromosomal abnormality such as trisomy are lethal, some individuals may survive if the abnormality exists in mosaic form. Two examples of this include trisomy 8 and Cat eye syndrome, caused by extra genetic material, which is derived from a portion of chromosome 22.

Miller DT et al: Consensus statement: chromosomal microarray is a first-tier clinical diagnostic test for individuals with developmental disabilities or congenital anomalies. Am J Hum Genet 2010;86:749–764 [PMID: 20466091].

Moeschler JB, Shevell M; Committee on Genetics: Comprehensive evaluation of the child with intellectual disability or global developmental delays. Pediatrics 2014; 134(3):e903–e918 [PMID: 25157020].

o Chr OmOSOmE DEl ETION DISOr DEr S

Three common chromosomal deletion disorders that were previously detected on routine karyotype analysis, and

confirmed via FISH assay, but are now detected with microarray, are 1p36- syndrome, Wolf-Hirschhorn syndrome (4p-), and cri du chat syndrome (5p-). Microdeletion or contiguous gene syndrome are referring to those small deletion not readily picked up by karyotype but detected by microarray or FISH.

1. Deletion 1p36 Syndrome

Microcephaly and a large anterior fontanelle are characteristic features of 1p36- syndrome. Cardiac defects are common, and dilated cardiomyopathy may present in infancy. Intellectual disability, hypotonia, hearing loss, and seizures are usually seen.

2. Wolf-Hirschhorn Syndrome

Also known as 4p- (deletion of 4p16), this syndrome is characterized by microcephaly and unusual development of the nose and orbits that produces an appearance suggesting an ancient Greek warrior's helmet. Other anomalies commonly seen include cleft lip and palate and cardiac and renal defects. Seizure disorders are common, and the majority of patients have severe intellectual disability.

3. Cri du Chat Syndrome

Also known as 5p- (deletion of terminal chromosome 5p), this disorder is characterized by unique facial features, growth retardation, and microcephaly. Patients have an unusual catlike cry. Most patients have major organ anomalies and significant intellectual disability.

Contiguous Gene Disorders

Three common contiguous gene disorders which are usually suspected on the basis of an abnormal phenotype and then confirmed via microarray are Williams syndrome, Smith-Magenis syndrome, and Velocardiofacial syndrome. The meiotic mechanisms responsible for interstitial chromosomal deletions causing these disorders also result in duplications. We now understand that interstitial chromosomal duplications in the following regions also produce abnormal phenotypes:

1. Williams Syndrome

Williams syndrome is a contiguous gene disorder that deletes the gene for elastin and other neighboring genes at 7q11.23. It is characterized by short stature; congenital heart disease (supravalvular aortic or pulmonic stenosis); coarse, elfin-like facies with prominent lips; hypercalcemia or hypercalciuria in infancy; developmental delay; and neonatal irritability evolving into an overly friendly personality. Calcium restriction may be necessary in early childhood to prevent nephrocalcinosis. The hypercalcemia often resolves during the first year of life. The natural history includes progression of cardiac disease and predisposition to hypertension and spinal osteoarthritis in adults. Most patients have mild to moderate intellectual deficits.

Duplication of chromosome 7q11.23 results in a syndrome that includes speech delay and features of autistic spectrum disorders. Physical features are less consistent than in Williams syndrome.

Pober BR: Williams-Beuren Syndrome. N Engl J Med 2010;362:239–252 [PMID: 20089974].
Van der Aa et al: Fourteen new cases contribute to the characterization of the 7q11.23 microduplication syndrome. Europ J Med Genet 2009;52:94 [PMID: 19249392].

2. Smith-Magenis Syndrome

This syndrome is associated with microdeletion of 17p11 and is characterized by prominent forehead, deep-set eyes, cupid-shaped upper lip, self-mutilating behavior, sleep disturbance, and intellectual disabilities. Some patients also have seizure disorders, hearing loss, thyroid disease, and immunological and lipid abnormalities.

Duplication of 17p11 produces Potocki-Lupski syndrome that is characterized by growth failure, variable levels of cognitive deficiencies, autistic features, and, occasionally, structural abnormalities of the heart.

De Leersnyder H: Smith Magenis syndrome. Handb Clin Neurol 2013;111:295–296 [PMID: 23622179].
Magoulas PL et al. Inherited dup(17)(p11.2p11.2): expanding the phenotype of the Potocki-Lupski syndrome. Am J Med Genet A. 2014 Feb;164A(2):500–504 [PMID: 24311450].

3. Velocardiofacial Syndrome (Deletion 22q11 Syndrome)

Also known as DiGeorge syndrome, this condition was originally described in newborns presenting with cyanotic congenital heart disease, usually involving great vessel abnormalities; thymic hypoplasia leading to immunodeficiency; and hypocalcemia due to absent parathyroid glands. This chromosomal abnormality is associated with a highly variable phenotype. Characteristics include mild microcephaly, palatal clefting or incompetence, speech and language delays, and congenital heart disease (Great vessel abnormalities, tetralogy of Fallot, and a variety of other abnormalities). Some affected individuals are predisposed to psychosis.

Duplication of the 22q11 region produces a mild and highly variable phenotype that ranges from developmental delays and learning disabilities to functionally normal.

Chen CP et al: Chromosome 22q11.2 deletion syndrome: prenatal diagnosis, array comparative genomic hybridization characterization using uncultured amniocytes and literature review. Gene 2013 Sep 15;527(1):405–409 [PMID: 23791650].

mENDEl IAN DISOr DEr S

AUTOSOMAL DOMINANT DISORDERS

Neurofibromatosis, Marfan syndrome, achondroplasia, osteogenesis imperfecta, and the craniosynostoses are among the most well-known autosomal dominant disorders. There are many other common autosomal dominant disorders, including Treacher-Collins syndrome, associated with a distinct craniofacial phenotype including malar and mandibular hypoplasia, and Noonan syndrome, which has a phenotype similar to Turner syndrome and is characterized by short stature and a webbed neck. Two other common genetic disorders whose causative genes were recently identified and found to be dominant mutations are CHARGE syndrome and Cornelia de Lange syndrome.

1. Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF-1) is one of the most common autosomal dominant disorders, occurring in 1 per 3-4000 births and seen in all races and ethnic groups. In general, the disorder is progressive, with new manifestations appearing over time. Neurofibromatosis type 2 (NF-2), characterized by bilateral acoustic neuromas, with minimal or no skin manifestations, is a different disease caused by a different gene.

The gene for NF-1 is on the long arm of chromosome 17 and codes for a protein with properties similar to a tumor suppresser factor. NF results from many different mutations of this gene. Approximately half of all NF cases are caused by new mutations. Careful evaluation of the parents is necessary to provide accurate genetic counseling. Recent evidence suggests that penetrance is close to 100% in those who carry the gene if individuals are examined carefully.

Café au lait macules may be present at birth, and the majority of individuals with NF-1 will have more than six by age 1 year. Neurocutaneous findings are declarative by age 8 years. Neurofibromas are benign tumors consisting of Schwann cells, nerve fibers, and fibroblasts; they may be discrete or plexiform. The incidence of Lisch nodules, which can be seen with a slit lamp, also increases with age. Affected individuals commonly have a large head, bony abnormalities on radiographic studies, scoliosis, and a wide spectrum of developmental problems. Although the average IQ is within the normal range, half of NF1 patients will experience some form of intellectual delay. (For more details of medical evaluation and treatment, see Chapter 25 of this book.) Useful information is provided on the following website: http://www.nfinc.org.

Hyperpigmented macules can occur in other conditions such as Albright, Noonan, Leopard, Russell-Silver, and Banayan-Riley-Ruvalcaba (BRR) syndromes. The genes for NF-1, Noonan, and Leopard syndromes are molecules which control cell cycling through the RAS-MAPK signal transduction pathways; therefore, it is not surprising that some features can be shared.

2. Marfan Syndrome

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Skeletal abnormalities (Ghent criteria).
- Lens dislocation.
- Dilation of the aortic root.
- Dural ectasia.
- Positive family history in some cases.

» Clinical Findings

Genetic testing is available for Marfan syndrome, but the diagnosis remains largely clinical and is based on the Ghent criteria (available at: http://www.genereviews.org). Children can present with a positive family history, suspicious skeletal findings, or ophthalmologic complications. Motor milestones are frequently delayed due to joint laxity. Adolescents are prone to spontaneous pneumothorax. Dysrhythmias may be present. The characteristic facies is long and thin, with down-slanting palpebral fissures, malar flattening and retrognathia. The palate is high arched, and dentition is often crowded. Mutations in the gene for fibrillin-1 (FBN1), an extracellular matrix protein (ECM), are causative.

» Differential Diagnosis

Homocystinuria should be excluded through metabolic testing in all individuals with Marfanoid skeletal features. An X-linked recessive disorder, **Lujan syndrome**, combines Marfanoid habitus with cognitive disability. Other connective tissue disorders, **Ehlers-Danlos syndrome**, and **Stickler syndrome** should also be considered.

Mutations in (FBN2) and in transforming growth factor β (TGFβ) pathway) can also produce phenotypes that fit criteria for a clinical diagnosis of Marfan syndrome. Beals syndrome (FBN2), Shprintzen-Goldberg syndrome (SKI1), aneurysm-osteoarthritis syndrome, syndromic thoracic aortic aneurysms, and Loeys-Dietz syndromes (TGFβ pathway)

are distinct connective tissue disorders with different medical management and prognostic implications. The reader is referred to reviews available at http://www.genereviews.org for descriptions of these disorders.

» Complications

The skeletal problems including scoliosis are progressive. Astigmatism and myopia are very common and regular ophthalmologic surveillance for lens dislocation is necessary.

The most serious associated medical problems involve the heart. Although many patients with Marfan syndrome have mitral valve prolapse, the most serious concern is progressive aortic root dilation, which may lead to aneurysmal rupture and death, and progressive or acute valvular (aortic more frequently than mitral) incompetency.

Families and practitioners seeking additional information about Marfan syndrome can be referred to the National Marfan Foundation (http://www.marfan.org).

» Treatment

A. Medical Therapy

Medical treatment for patients with Marfan syndrome includes surveillance for and appropriate management of the ophthalmologic, orthopedic, and cardiac issues. Serial echocardiograms are indicated to diagnose and follow the degree of aortic root enlargement, which can be managed medically or surgically, in more severe cases. Prophylactic Δ-adrenergic blockade can slow the rate of aortic dilation and reduce the development of aortic complications.

Interest in the effects of deficient extracellular fibrillin-1 has led to the discovery that the mild myopathy in Marfan syndrome reflects excessive signaling by transforming growth factor β (TGFβ), an inhibitor of myoblast differentiation. Animal studies suggest that aortic aneurysm can be prevented by TGFβ antagonists, including blockers of angiotensin II type 1 receptors. Clinical studies are currently underway using this approach in human patients.

B. Genetic Counseling

Genetic testing for mutations in genes associated with aortopathy in patients with arterial dilatation should be considered in all individuals with Marfan syndrome as penetrance is variable and apparently unaffected family members can carry and pass on mutations.

Kumar A, Agarwal S: Marfan syndrome: an eyesight of syndrome. Meta Gene 2014 Jan 14;2:96–105 [PMID: 25606393].

3. Achondroplasia

Achondroplasia, the most common form of skeletal dysplasia, is caused by a mutation in FGFR3.

» Clinical Findings

The classic phenotype includes relative macrocephaly, midface hypoplasia, short-limbed dwarfism, and trident-shaped hands. The phenotype is apparent at birth. Individuals with achondroplasia are cognitively normal.

» Treatment

A. Medical Therapy

Orthopedic intervention is necessary for spinal problems including severe lumbar lordosis and gibbus deformity. Long bone lengthening surgery may help to improve upper extremity function.

Head circumference during infancy must be closely monitored and plotted on a diagnosis-specific head circumference chart. Bony overgrowth at the level of the foramen magnum may lead to progressive hydrocephalus and brainstem compression and may warrant neurosurgical intervention.

Many patients find support through organizations such as the Little People of America at the following website: http://www.lpaonline.org.

B. Genetic Counseling

The vast majority of cases (approximately 90%) represent a new mutation. Two hemizygous parents with achondroplasia have a 25% risk of having a child homozygous for FGFR3 mutations, which is a lethal disorder.

4. Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), or brittle bone disease, is a relatively common disorder. The more common forms are caused by mutations in type I collagen.

» Clinical Findings

A number of types of OI have now been described, and molecular testing in blood is now used to confirm the diagnosis. The four most common types of OI, caused by dominant mutations in COL1A1 and COL1A2, are

1. Type I, a mild form, with bony fractures after birth and blue sclerae.
2. Type II, usually lethal in the newborn period with multiple congenital fractures and severe lung disease.
3. Type III, a severe form causing significant bony deformity secondary to multiple fractures (which are both congenital and after birth), blue sclerae, short stature, and mild restrictive lung disease.
4. Type IV, another mild form with increased incidence of fracturing after birth; dentinogenesis imperfecta is common.

» Treatment

A. Medical Therapy

Geneticists and endocrinologists are now treating OI patients with Pamidronate, a bisphosphonate compound, which can reduce incidence of fracture and improve bone density. Patients should also be followed by an experienced orthopedist, as rodding of long bones and surgery to correct scoliosis are often required. Hearing assessments are indicated, because of the association between OI and deafness, as is close dental follow-up.

B. Genetic Counseling

DNA analysis in blood can confirm mutations in COL1 which cause OI. The milder forms are often inherited as a dominant trait, while the more severe forms of OI generally result from new mutations.

5. Craniosynostosis Syndromes

The craniosynostosis disorders are common dominant disorders associated with premature fusion of cranial sutures. This class of disorders is usually caused by mutations in FGFR genes.

Crouzon syndrome is the most common of these disorders and is associated with multiple suture fusions, but with normal limbs. Other craniosynostosis disorders have limb as well as craniofacial anomalies and include Pfeiffer, Apert, Jackson-Weiss, and Saethre-Chotzen syndromes.

Patients with craniosynostosis often have shallow orbits, midface narrowing that may result in upper airway obstruction (choanal atresia and pyriform aperature stenosis are not uncommon), and hydrocephalus that may require shunting. Children with craniosynostosis may require multiple-staged craniofacial and neurosurgical procedures to address these issues, but usually have normal intelligence.

6. CHARGE Syndrome

CHARGE syndrome is a common genetic disorder presenting with unusual features, birth defects, intellectual disabilities, and abnormalities in vision and hearing. The acronym CHARGE serves as a mnemonic for associated abnormalities that include **C**olobomas, congenital **H**eart disease, choanal **A**tresia, growth **R**etardation, **G**enital abnormalities (hypogenitalism), and **E**ar abnormalities, with deafness. Facial asymmetry is a common finding. CHARGE is caused by mutations in the CHD7 gene on chromosome 8q. A website with information on CHARGE syndrome is available at http://www.chargesyndrome.org/.

Bergman JE et al: CHD7 mutations and CHARGE syndrome: the clinical implications of an expanding phenotype. J Med Genet 2011 May; 48(5):334–342 [Epub 2011 Mar 4] [PMID: 21378379].

7. Cornelia de Lange Syndrome

Cornelia de Lange syndrome is characterized by severe growth retardation; limb, especially hand, reduction defects (50%); congenital heart disease (25%); and stereotypical facies with hirsutism, medial fusion of eyebrows (synophrys), and thin, down-turned lips. The course and severity are variable, and milder presentations may be inherited as a dominant trait.

Heterozygous mutations in the cohesin regulator, NIPBL, or the cohesin structural components SMC1A and SMC3, have been identified in approximately 65% of individuals with CdLS. Cohesin regulates sister chromatid cohesion during mitotis and meiosis. In addition, cohesin has been demonstrated to play a critical role in the regulation of gene expression. Furthermore, multiple proteins in the cohesin pathway are also involved in additional fundamental biological events such as double-stranded DNA break repair, chromatin remodeling, and maintaining genomic stability.

Jones KL: Recognizable Patterns of Human Malformation. 6th ed. Philadelphia, PA: Elsevier; 2006. * new edition

Liu J et al: Cornelia de Lange syndrome. Adv Exp Med Biol 2010;685:111–123 [PMID: 20687500].

8. Noonan Syndrome

Noonan syndrome is a common autosomal dominant disorder characterized by short stature, congenital heart disease, webbed neck, down-slanting palpebral fissures, hearing loss, and low-set ears. Feeding problems are common. The presentation evolves with age and may be difficult to recognize in older patients. Mild developmental delays are often present, but intelligence may be normal. Noonan syndrome and Noonan-like disorders are caused by mutations in the RAS-mitogen-activated protein kinase (MAPK) pathway, and thus are often called "RASopathies." Noonan syndrome is the most common of these disorders. Other related disorders include Cardiofacial Cutaneous syndrome and Costello syndromes. A blood test that screens for the approximately 12 genes in this pathway is called a Noonan chip and can help confirm a diagnosis.

Because mutations in NF-1 causing neurofibromatosis, also affect RAS proto-oncogene signaling, it is not surprising that there is an NF-1 subtype with an associated Noonan phenotype.

Zenker M: Clinical manifestations of mutations in RAS and related intracellular signal transduction factors. Curr Opin Pediatr 2011 Aug;23(4):443–451 [PMID: 21750428].

AUTOSOMAL RECESSIVE DISORDERS

1. Cystic Fibrosis

The gene for cystic fibrosis, CFTR, is found on the long arm of chromosome 7. Approximately 1 in 22 persons are

carriers. Many different mutations have been identified; the most common mutation in the Caucasian population is ΔF508.

Molecular analysis of CFTR is widely available in the pre- and postnatal settings. The sweat chloride assay still plays a role in confirming the diagnosis in some cases.

The identification of the mutation in the cystic fibrosis gene has also raised the issue of mass newborn screening, because of the high frequency of this gene in the Caucasian population. Some states, such as Colorado, have offered newborn screening by trypsinogen assay, which can detect 70% of patients with cystic fibrosis. Although early detection can ensure good nutritional status starting at birth, newborn screening is controversial as there is no cure for cystic fibrosis. (For more details of medical management, see Chapters 19 and 22.)

2. Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is a common disorder, caused by a metabolic error in the final step of cholesterol production, resulting in low cholesterol levels and accumulation of the precursor 7-dehydrocholesterol (7-DHC). Because cholesterol is a necessary precursor for sterol hormones and CNS myelin, and cholesterol content is crucial for the integrity of all cell membranes, the medical consequences of both cholesterol deficiency and 7-DHC accumulation are complex and severe. Also, 7-DHC is oxidized into substances called oxysterols, which are toxic to the retinal and brain.

» Clinical Findings

Patients with Smith-Lemli-Opitz syndrome present with a characteristic phenotype, including dysmorphic facial features (Figure 37–9), multiple congenital anomalies, hypotonia, growth failure, and intellectual disability. The diagnosis can be confirmed via a blood test looking for the presence of the precursor, 7-DHC in special laboratories. DNA analysis of mutations in the DHR7 gene is also available, as is prenatal testing.

» Treatment

Treatment with cholesterol can ameliorate the growth failure and lead to improvement in medical issues, although treatment does not cure this complex disorder. Antioxidant treatment is being used to prevent progressive retinal degeneration caused by oxysterol accumulation.

3. Sensorineural Hearing Loss

Approximately 50% of hearing loss is thought to be caused by genetic factors, many of which have not yet been identified. There is marked genetic heterogeneity in causes of sensorineural hearing loss including: dominant, recessive, mitochondrial, and X-linked inheritance patterns. Several

▲**Figure 37–9.** Child with Smith-Lemli-Opitz syndrome, featuring bitemporal narrowing, upturned nares, ptosis, and small chin.

hundred genes are known to cause hereditary hearing loss and deafness. Nonsyndromic recessively inherited deafness is the predominant form in severe genetic childhood deafness. The genetic forms of hearing loss are diagnosed by otologic, audiologic, and physical examination; family history; ancillary testing (such as CT examination of the temporal bone); and molecular genetic testing. Mutations in connexin 26 are present in 49% of cases of prelingual deafness.

Edi Lúcia Sartorato, Karen Friderici, Ignacio Del Castillo: Genetics of deafness. Genet Res Int 2012;2012:562848. doi:10.1155/2012/562848 [PMID: 22567392].

4. Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive neuromuscular disorder in which anterior horn cells in the spinal cord degenerate. The mechanism for the loss of cells appears to involve apoptosis of neurons in the absence of the

product of the SMN1 (survival motor neuron) gene located on chromosome 5q. Loss of anterior horn cells leads to progressive atrophy of skeletal muscle. The disorder has an incidence of approximately 1 in 12,000, with the majority of the cases presenting in infancy. Carrier frequencies approach 1 in 40 in populations with European ancestry.

» Clinical Findings

Three clinical subtypes are recognized based on age of onset and rate of progression. SMA I is the most devastating. Mild weakness may be present at birth but is clearly evident by 3 months and is accompanied by loss of reflexes and fasciculations in affected muscles. Progression of the disorder leads to eventual respiratory failure, usually by age 1 year. Symptoms of SMA II begin later, with weakness and decreased reflexes generally apparent by age 2 years. Children affected with SMA III begin to become weak as they approach adolescence.

Homozygous deletion of exon 7 of SMN1 is detectable in approximately 95%–98% of cases of all types of SMA and confirms the diagnosis. The SMN1 region on chromosome 5q is complex and variability in presentation of the disorder involves expression of up to three copies of the neighboring SMN2 gene. More severe phenotypes have fewer SMN2 copies. Approximately 2%–5% of patients affected with SMA will be compound heterozygotes in whom there is one copy of SMN1 with exon 7 deleted and a second copy with a point mutation.

Prenatal diagnosis is available through genetic testing, but careful molecular analysis of the proband and demonstration of carrier status in parents is advised since, in addition to the problem of potential compound heterozygosity, 2% of cases occur as a result of a de novo mutation in one SMN1 allele. In this case, one of the parents is not a carrier and recurrence risks are low. Carrier testing is further complicated by a duplication of SMN1 in 4% of the population that results in there being two SMN1 genes on one of their chromosomes. Hence, reproductive risk assessment, carrier testing, and prenatal diagnosis of SMA are best undertaken in the context of careful genetic counseling.

X-LINKED DISORDERS

1. Duchenne & Becker Muscular Dystrophies

Duchenne muscular dystrophy (DMD) results from failure of synthesis of the muscle cytoskeletal protein dystrophin. The DMD gene is located on the X chromosome, at position Xp21.1-p21.2. Approximately 1 in 4000 male children is affected. Mutations in the same gene that result in partial expression of the dystrophin protein produce a less severe phenotype, Becker muscular dystrophy (BMD). In both DMD and BMD, progressive degeneration of skeletal and cardiac muscle occurs. Boys with DMD exhibit proximal muscle weakness and pseudohypertrophy of calf muscles by age 5–6 years. Patients become nonambulatory by age 13 years. Serum creatine kinase levels are markedly elevated. Boys with DMD frequently die in their twenties of respiratory failure and cardiac dysfunction. The prognosis for BMD is more variable. Although corticosteroids are useful in maintaining strength, they do not slow progression of the disorder. Evolution of the natural history of dystrophinopathies in females is demonstrating an increased incidence of serious cardiovascular disease, including cardiomyopathy and arrhythmias. The gene for dystrophin is largest gene found in nature and is a common target for mutation. Large deletions or duplications can be detected in the gene for dystrophin in 65% of cases. Molecular analysis has largely replaced muscle biopsy for diagnostic purposes.

One-third of DMD cases presenting with a negative family history are likely to be new mutations. Genetic counseling is complicated by the fact that germline mosaicism for mutations in the dystrophin gene occur in approximately 15%–20% of families, which is among the highest rates for this otherwise rare phenomenon. It is also necessary to look for mutations in all sisters of affected boys. Since mutations are now detected in the great majority of DMD cases, there is considerably less need for estimating carrier risks based on creatine kinase levels. Nonetheless, counseling and prenatal diagnosis remain difficult in some families. (Additional information about muscular dystrophies is included in Chapter 25.)

2. Hemophilia A

Hemophilia A is an X-linked, recessive, bleeding disorder caused by a deficiency in the activity of coagulation factor VIII. Affected individuals develop a variable phenotype of hemorrhage into joints and muscles, easy bruising, and prolonged bleeding from wounds. The disorder is caused by heterogeneous mutations in the factor VIII gene (F8), which maps to Xq28. The detection rate in molecular testing is approximately 98%. Carrier detection and prenatal diagnosis are possible. Replacement of factor VIII is done using a variety of preparations derived from human plasma or recombinant techniques. Although replacement therapy is effective in most cases, 10%–15% of treated individuals develop neutralizing antibodies that decrease its effectiveness. (See Chapter 30 for additional discussion.)

Hemophilia B, also X-linked in inheritance is caused by mutation in the gene F9. It is clinically indistinguishable from hemophilia A. Diagnosis is based on a factor IX clotting activity and/or molecular analysis.

DISORDERS OF IMPRINTING

1. Beckwith-Wiedemann Syndrome

The association of macrosomia (enlarged body size), macroglossia (enlarged tongue), and omphalocele constitutes the Beckwith-Wiedemann syndrome (BWS), now known to be related to abnormal expression of imprinted genes located on chromosome 11p15. Other associated findings include hypertelorism, unusual ear creases, infantile hypoglycemia due to transient hyperinsulinemia, multiple congenital anomalies (cleft palate and genitourinary anomalies common), and increased risk for certain malignancies, especially Wilms tumor (7%–10%).

Chromosomal abnormalities such as duplication of the paternal 11p15 region, or paternal UPD, are associated with BWS. Reading two copies of a growth factor gene IGF2, rather than one is felt to lead to the macrosomia. Paternal UPD may also lead to loss of expression of a tumor suppressor gene (H19), normally read from the maternal homolog, contributing to the increased predisposition to cancer seen in this disorder. Children affected with BWS should undergo tumor surveillance protocols, including an abdominal ultrasound every 3 months until they reach age 8 years, as diagnosing malignancy at early stages leads to a significant improvement in outcome.

2. Prader-Willi Syndrome

Prader-Willi syndrome results from lack of expression of several imprinted genes, including SNRPN, located on chromosome 15q11. Clinical characteristics include severe hypotonia in infancy, often necessitating placement of a feeding gastrostomy tube. In older children, characteristic facies include almond-shaped eyes, and strabismus. Obstructive sleep apnea is common as are short stature, obesity, hypogenitalism, and small hands and feet. Growth hormone treatment is now offered to PWS patients, which improves the above symptoms. Obsessive hyperphagia (usual onset 3–4 years) is the hallmark of this disorder.

Deletion of the paternally inherited allele of chromosome 15q11 (detected by FISH or microarray) is the most common chromosomal abnormality causing Prader-Willi syndrome, followed by maternal UPD, diagnosed by DNA methylation studies.

3. Angelman Syndrome

Angelman syndrome also involves imprinting and results from a variety of mutations that inactivate a ubiquitin-protein ligase gene, UBE3A, located in the same region of chromosome 15 as SNRPN, the gene involved in Prader-Willi syndrome (see the preceding section). The classic phenotype includes severe intellectual disability with prognathism, seizures, and marked delay in motor milestones, abnormal gait and posturing, poor language development, autism, and paroxysmal laughter and tongue thrusting.

Angelman syndrome is most commonly caused when sequences detectable by microarray or FISH on 15q11 are deleted from the maternal homolog. Uniparental paternal disomy 15 is the least common cause. Mutations in UBE3A cause the disorder in about one-fourth of cases. Imprinting errors, which may be associated with advanced reproductive techniques, may also result in Angelman syndrome.

Iliadou AN, Janson PC, Cnattingius S: Epigenetics and assisted reproductive technology. J Intern Med 2011;270(5):414–420 [PMID: 21848664].

DISORDERS ASSOCIATED WITH ANTICIPATION

1. (Autosomal Dominant) Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant condition characterized by muscle weakness and tonic muscle spasms (myotonia). Additional features include: respiratory dysfunction, hypogonadism, frontal balding, developmental delay, myopathic facies, cardiac conduction abnormalities, and cataracts. This disorder occurs when a CTG repeat in the DMPK gene on chromosome 19 expands to 50 or more copies. Normal individuals have from 5 to 35 CTG repeat copies. Individuals carrying 35–49 repeats are generally asymptomatic, but repeat copies greater than 35 are meiotically unstable and tend to further expand when passed to subsequent generations. Individuals with 50–100 copies may be only mildly affected (eg, cataracts). Most individuals with repeat copies greater than 100 will have symptoms or electrical myotonia as adults.

As unstable alleles continue to expand and copy numbers approach 400, symptoms become evident in children. Expansion from greater than 1000 copies produces fetal and neonatal disease that can be lethal. This occurs most frequently when the unstable repeats are passed through an affected mother. Therefore, an important component in the workup of the floppy or weak infant is a careful neurologic assessment of both parents for evidence of weakness or myotonia. Molecular testing that measures the number of CTG repeats is diagnostic clinically and prenatally. (See Chapter 25 for additional discussion.)

2. (Autosomal Recessive) Friedreich Ataxia

Symptoms of Friedreich ataxia include dysarthria, muscle weakness, lower limb spasticity, bladder dysfunction, absent lower limb reflexes, with both motor and sensory findings beginning in preadolescence and typically progressing through the teenage years. The gene involved, FXN, is

located on chromosome 9. Unaffected individuals typically carry 7–33 GAA repeats at this locus. Close to 96% of affected patients are homozygous for repeat expansions that exceed 66 copies. Point mutations in the gene also occur. Meiotic instability for GAA repeats is more variable than for others and contractions occur more frequently than do expansions. Relationships between genotype and phenotype are also more complex. Molecular diagnostic testing requires careful interpretation with respect to prognosis and reproductive risks. (See Chapter 25 for additional discussion.)

3. (X-Linked) Fragile X Syndrome

Fragile X syndrome, present in approximately 1 in 1000 males, is the most common cause of cognitive disabilities in males. The responsible gene is FMR1, which has unstable CGG repeats at the 5′ end. Normal individuals have up to 50 CGG repeats. Individuals with 51–200 CGG repeats have a premutation and may manifest symptoms including developmental, and behavioral, traits; premature ovarian failure in a subset of females; and a progressive, neurologic deterioration in older males called FXTAS (Fragile X–associated tremor-ataxia syndrome). Affected individuals with Fragile X syndrome (full mutation) have more than 200 CGG repeats and also have hypermethylation of both the CGG expansion and an adjacent CpG island. This methylation turns off the FMR1 gene. DNA analysis, rather than cytogenetic testing, is the method of choice for confirming the diagnosis of Fragile X syndrome.

» Clinical Features

Most males with Fragile X syndrome present with intellectual disabilities, oblong facies with large ears, and large testicles after puberty. Other physical signs include hyperextensible joints and mitral valve prolapse. Many affected individuals are hyperactive and exhibit behaviors along the autism spectrum.

Unlike other X-linked disorders where female heterozygotes are asymptomatic, females with a full mutation may exhibit a phenotype ranging from normal IQ to intellectual disability, and may show behaviors along the autism spectrum.

Clinical expression of Fragile X differs in male and female offspring depending on which parent is transmitting the gene. The premutation can change into the full mutation only when passed through a female. DNA analysis is a reliable test for prenatal and postnatal diagnosis of Fragile X syndrome and facilitates genetic counseling. (Management considerations for patients with Fragile X syndrome are described in Chapter 3.)

Hersh JH, Saul RA; Committee on Genetics. Health Supervision for Children with Fragile X Syndrome. Pediatrics May 2011;127(5):994–1006 [PMID: 21518720].

MITOCHONDRIAL DISORDERS

More than 100 point mutations and rearrangements of mtDNA have been identified, which are associated with a large number of human diseases. Symptoms of mitochondrial disorders are secondary to deficiency in the respiratory chain enzymes of oxidative phosphorylation, which supply energy to all cells. Mitochondrial diseases are usually progressive disorders with neurologic dysfunction including hypotonia, developmental delay, and seizures. Ophthalmologic issues, hearing loss, gastrointestinal tract dysfunction with growth failure, and renal, endocrine, cardiac, and autonomic dysfunction are some of the many issues which can affect patients with mitochondrial diseases. The following disorders are three of the more common ones.

1. MELAS

MELAS is an acronym for Mitochondrial Encephalopathy, Lactic Acidosis, and Strokelike episodes. Symptoms occur in the pediatric age group and include recurrent episodes resembling stroke (blindness, paralysis), headache, vomiting, weakness of proximal muscles, and elevated blood lactate. (Note: Lactate may be falsely elevated secondary to technical difficulties in obtaining a free-flowing blood specimen or delay in laboratory measurement.) The most common mutation causing MELAS is in the $tRNA^{Leu}$ gene (A3243G). Many patients are treated with l-arginine or citrulline supplementation for alleviation of symptoms.

2. MERRF

MERRF is an acronym for Myoclonus Epilepsy with Ragged Red Fibers. Children with MERRF present with a variety of neurologic symptoms, including myoclonus, deafness, weakness of muscles, and seizures. Eighty percent of cases are due to a missense mutation in the mitochondrial $tRNA^{Lys}$ gene (A8344G).

3. Leigh Subacute Necrotizing Encephalomyelopathy

Multiple different abnormalities in respiratory chain function lead to Leigh disease, a very severe disorder associated with progressive loss of developmental milestones, along with extrapyramidal symptoms and brainstem dysfunction. Episodes of deterioration are frequently associated with an intercurrent febrile illness. Symptoms include hypotonia, choreoathetoid hand movements, feeding dysfunction with failure to thrive, and seizures. Focal necrotic lesions of the brainstem and thalamus are hallmarks on MRI scan. Mitochondrial mutations affecting the respiratory chain, especially complexes I, II, and IV, and nuclear DNA mutations affecting complex II have been identified as causing Leigh disease.

Wong LJ, Scaglia F, Graham BH, Craigen WJ: Current molecular diagnostic algorithm for mitochondrial disorders. Mol Genet Metab 2010 Jun;100(2):111–117 [PMID: 20359921].

Disorders of Multifactorial Inheritance

Cleft Lip & Cleft Palate

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cleft lip is more common in males, cleft palate in females.
- Cleft lip and palate may be isolated defects (nonsyndromic) or associated with other anomalies as part of a genetic disorder (syndromic).
- Pierre Robin sequence, the association of cleft palate, micrognathia, and glossoptosis may lead to severe airway complications in young infants, necessitating tracheostomy.

General Considerations

From a genetic standpoint, cleft lip with or without cleft palate is distinct from isolated cleft palate. Although both can occur in a single family, particularly in association with certain syndromes, this pattern is unusual. Racial background is a factor in the incidence of facial clefting. The prevalence of facial clefting per 10,000 births is 10.2 in the United States, 12.1 in Western Europe, and 20.0 in Japan.

Findings

A cleft lip may be unilateral or bilateral and complete or incomplete. It may occur with a cleft of the entire palate or just the primary (anterior and gingival ridge) or secondary (posterior) palate. An isolated cleft palate can involve only the soft palate or both the soft and hard palates. It can be a V-shaped or a U-shaped cleft. When the cleft palate is associated with micrognathia and glossoptosis (a tongue that falls back and causes respiratory or feeding problems), it is called the **Pierre Robin sequence**. Among individuals with facial clefts—more commonly those with isolated cleft palate—the incidence of other congenital abnormalities is increased, with up to a 60% association with other anomalies or syndromes. The incidence of congenital heart disease, for example, is 1%–2% in liveborn infants, but among those with Pierre Robin sequence it can be as high as 15%. Associated abnormalities should be looked for in the period immediately after birth and before surgery.

Differential Diagnosis

A facial cleft may occur in many different circumstances. It may be an isolated abnormality or part of a more generalized syndrome. Prognosis, management, and accurate determination of recurrence risks all depend on accurate diagnosis. In evaluating a child with a facial cleft, the physician must determine if the cleft is nonsyndromic or syndromic.

A. Nonsyndromic

In the past, nonsyndromic cleft lip or cleft palate was considered a classic example of polygenic or multifactorial inheritance. Several recent studies have suggested that one or more major autosomal loci, both recessive and dominant may be involved. Empirically, however, the recurrence risk is still in the range of 2%–3% because of nonpenetrance or the presence of other contributing genes.

B. Syndromic

Cleft lip, with or without cleft palate, and isolated cleft palate may occur in a variety of syndromes that may be environmental, chromosomal, single gene, or of unknown origin (Table 37–2). Prognosis and accurate recurrence risks depend on the correct diagnosis.

Complications

Problems associated with facial clefts include early feeding difficulties, which may be severe; airway obstruction necessitating tracheostomy; recurrent serous otitis media associated with fluctuating hearing and language delays;

Table 37–2. Syndromic isolated cleft palate (CP) and cleft lip with or without cleft palate (CL/CP).

Environmental

AD, autosomal dominant; AR, autosomal recessive.

speech problems, including language delay, hypernasality, and articulation errors; and dental and orthodontic complications.

A. Medical Therapy

Long-term management ideally should be provided through a multidisciplinary cleft palate clinic.

B. Genetic Counseling

Accurate counseling depends on accurate diagnosis and the differentiation of syndromic from nonsyndromic clefts. A complete family history must be taken, and the patient and both parents must be examined. The choice of laboratory studies is guided by the presence of other abnormalities and clinical suspicions and may include microarray analysis and metabolic and DNA studies. Clefts of both the lip and the palate can be detected on detailed prenatal ultrasound.

Watkins SE, Meyer RE, Strauss RP, Aylsworth AS: Classification, epidemiology and genetics of orofacial clefts. Clin Plast Surg 2014 Apr;41(2):149–163 [PMID: 24607185].

NEURAL TUBE DEFECTS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Various defects, ranging from anencephaly to open or skin-covered lesions of the spinal cord, may occur in isolation or as part of a syndrome.
- Myelomeningocele is usually associated with hydrocephalus, Arnold-Chiari II malformation, neurogenic bladder and bowel, and congenital paralysis in the lower extremities.
- Anomalies of the CNS, heart, and kidneys may also be seen.
- MRI helps determine the extent of the anatomic defect in skin covered lesions.

» General Considerations

Neural tube defects comprise a variety of malformations, including anencephaly, encephalocele, spina bifida (myelomeningocele), sacral agenesis, and other spinal dysraphisms. Evidence suggests that the neural tube develops via closure at multiple closure sites and that each closure site is mediated by different genes and affected by different teratogens. Hydrocephalus associated with the Arnold-Chiari type II malformation commonly occurs with myelomeningocele. Sacral agenesis, also called the caudal regression syndrome, occurs more frequently in infants of diabetic mothers.

» Clinical Findings

At birth, neural tube defects can present as an obvious open lesion, or as a more subtle skin-covered lesion. In the latter case, MRI should be conducted to better define the anatomic defect. The extent of neurologic deficit depends on the level of the lesion and may include clubfeet, dislocated hips, or total flaccid paralysis below the level of the lesion. Hydrocephalus may be apparent at birth or may develop after the back has been surgically repaired. Neurogenic bladder and bowel are commonly seen.

» Differential Diagnosis

Neural tube defects may occur in isolation (nonsyndromic) or as part of a genetic syndrome. They may result from teratogenic exposure to alcohol or the anticonvulsant valproate. Any infant with dysmorphic features or other major anomalies in addition to a neural tube defect should be evaluated by a geneticist, and a microarray analysis should be performed.

» Treatment

A. Neurosurgical Measures

Infants with an open neural tube defect should be placed in prone position, and the lesion kept moist with sterile dressing. Neurosurgical closure should occur within 24–48 hours after birth to reduce risk of infection. The infant should be monitored closely for signs of hydrocephalus. Shunts are required in about 85% of cases of myelomeningocele and are associated with complications including malfunction and infection. Symptoms of the Arnold-Chiari II malformation include feeding dysfunction, abducens nerve palsy, vocal cord paralysis with stridor, and apnea. Shunt malfunction may cause an acute worsening of Arnold-Chiari symptoms that may be life-threatening.

B. Orthopedic Measures

The child's ability to walk varies according to the level of the lesion. Children with low lumbar and sacral lesions walk with minimal support, while those with high lumbar and thoracic lesions are rarely functional walkers. Orthopedic input is necessary to address foot deformities and scoliosis. Physical therapy services are indicated.

C. Urologic Measures

Neurogenic bladders have variable presentations and therefore urological studies are recommended early on to define bladder function and guide management. Continence can sometimes be achieved by the use of medications, clean

intermittent catheterization, and a variety of urologic procedures. Renal function should be monitored regularly, and an ultrasound examination should be periodically repeated. Symptomatic infections should be treated.

Symptoms of neurogenic bowel include incontinence and chronic constipation and are managed with a combination of dietary modifications, laxatives, stool softeners, and rectal stimulation. A surgical procedure called ACE (antegrade continence enema) may be recommended for patients with severe constipation that is unresponsive to conservative management.

D. Genetic Counseling

Most isolated neural tube defects are polygenic, with a recurrence risk of 2%–3% in future pregnancies. The recurrence risk for siblings of the parents and siblings of the patient is 1%–2%. A patient with spina bifida has a 5% chance of having an affected child. Prenatal diagnosis is possible. Screening includes measurement of maternal serum α-fetoprotein levels at 16–18 weeks' gestation and prenatal ultrasound. Elevated α-fetoprotein and acetylcholine esterase levels in amniotic fluid can be detected via amniocentesis.

Prophylactic folic acid can significantly lower the incidence and recurrence rate of neural tube defects, if the intake of the folic acid starts at least 3 months prior to conception and continues for the first month of pregnancy, at a dose of 4 mg/d for women at increased risk. For women of childbearing age without a family history of neural tube defects, the dose is 0.4 mg of folic acid daily. Folic acid supplementation prior to conception may also lower the incidence of other congenital malformations such as conotruncal heart defects.

» Special Issues & Prognosis

All children requiring multiple surgical procedures (ie, patients with spina bifida or urinary tract anomalies) have a significant risk for developing hypersensitivity type I (IgE-mediated) allergic reactions to latex. For this reason, nonlatex medical products are now routinely used when caring for patients with neural tube defects.

Most individuals with myelomeningocele are cognitively normal, but learning disabilities are common. Individuals with closed spinal cord abnormalities (eg, sacral lipomas) have more mild issues in general, and intelligence is normal. Individuals with encephalocele or other CNS malformations, however, have a much poorer intellectual prognosis. Spinal cord tethering may present later with symptoms of back pain, progressive scoliosis, and changes in bowel or bladder function. This often requires neurosurgical intervention.

Individuals with neural tube defects have lifelong medical issues, requiring the input of a multidisciplinary medical team. A good support for families is the National Spina Bifida Association, at the following website: http://www.sbaa.org.

» Common Recognizable Disorders With Variable or Unknown Cause

The text that follows describes several important and common human malformation syndromes. The best illustrations of these syndromes are found in Smith's Recognizable Patterns of Human Malformation. An excellent Internet site at the University of Kansas Medical Center can be consulted for further information: http://www.kumc.edu/gec/support.

1. Arthrogryposis Multiplex

The term arthrogryposis is often used as shorthand to describe multiple congenital contractures that affect two or more different joint groups. Arthrogryposis is not a specific diagnosis, but rather a clinical finding, and it is a characteristic of more than 300 different disorders. Causes most often involve constraint, CNS malformation or injury, and neuromuscular disorders. Polyhydramnios is often present as a result of lack of fetal swallowing. Pulmonary hypoplasia may also be present, reflecting lack of fetal breathing. The workup includes brain imaging, evaluation for metabolic disease, neurologic consultation, and, in some cases, electrophysiologic studies and/or muscle biopsy. The parents should be examined. Family history review for findings such as: muscle weakness or cramping, cataracts, and early-onset heart disease, suggesting myotonic dystrophy is important. Mutations in at least five genes (TNNI2, TNNT3, TPM2, MYH3, and MYH8) that encode components of the contractile apparatus of fast-twitch myofibers can cause distal arthrogryposis.

Darras B, Jones, Jr. HR, Ryan M, De Vivo D. Neuromuscular Disorders of Infancy, Childhood, and Adolescence. A Clinician's Approach; Chapter 7 Hall JG, Vincent A. 2nd ed. Elsevier 2015: 96–114.

2. Goldenhar Syndrome

Goldenhar syndrome, also known as vertebro-auriculo-facial syndrome, is an association of multiple anomalies involving the head and neck. The classic phenotype includes hemifacial microsomia (one side of the face smaller than the other) and abnormalities of the pinna on the same side with associated deafness. Ear anomalies may be quite severe and include anotia. A characteristic benign fatty tumor in the outer sclera, called an epibulbar dermoid, is frequently present, as are preauricular ear tags. Vertebral anomalies, particularly of the cervical vertebrae, are common. The Arnold-Chiari type I malformation (herniation of the cerebellum into the cervical spinal canal) is a common associated anomaly. Cardiac anomalies and hydrocephalus are seen in more severe cases. Most patients with Goldenhar syndrome have normal intelligence. The cause is unknown; however, there is significant overlap with the Townes-Brocks syndrome, caused by mutations in the SALL1 gene. This condition has an undetermined

association with chronically elevated maternal blood glucose levels in pregnancy. (See Craniofacial Microsomia Overview, GeneReviews, www.genereviews.org for an excellent discussion and differential diagnosis.)

3. Oligohydramnios Sequence (Potter Sequence)

This condition presents in newborns as severe respiratory distress due to pulmonary hypoplasia in association with positional deformities of the extremities, usually bilateral clubfeet, and typical facies consisting of suborbital creases, depressed nasal tip and low-set ears, and retrognathia. The sequence may be due to prolonged lack of amniotic fluid. Most often it is due to leakage, renal agenesis, or severe obstructive uropathy.

4. Overgrowth Syndromes

Overgrowth syndromes typically present at birth and are characterized by macrocephaly, motor delays (cerebral hypotonia), and occasional asymmetry of extremities. Bone age may be advanced and diagnosed in the older child. The most common overgrowth syndrome is **Sotos syndrome**. Patients with Sotos syndrome have a characteristic facies with a prominent forehead, prominent chin, elongated nasal bridge, and down-slanting palpebral features. Mutations in NSD1 cause Sotos syndrome. Patients have a small but increased risk of cancer.

Other overgrowth syndromes include BWS (described earlier), and two single-gene disorders, Simpson-Golabi-Behmel syndrome and somatic overgrowth syndromes like megalocephaly-capillary malformation syndrome (MCAP). Patients with **Simpson-Golabi-Behmel syndrome** exhibit a BWS-like phenotype, but with additional anomalies, including polydactyly and more severe facial dysmorphism. Unlike patients with BWS, who have normal intelligence, patients with Simpson-Golabi-Behmel syndrome often have cognitive impairment. It is inherited as an X-linked disorder. Patients with **Bannayan-Riley-Ruvalcaba syndrome** have macrosomia, macrocephaly, and unusual freckling of the penis. They may present with autism. They may develop hemangiomatous or lymphangiomatous growths and have a predisposition to certain malignancies (thyroid, breast, colon cancer). The cause of Bannayan-Riley-Ruvalcaba syndrome is a mutation of the PTEN gene implicated in Cowden syndrome, the association of intestinal polyposis with malignant potential. Proteus syndrome was recently found to be caused by mosaic AKT-1 mutation.

The **PI3K/AKT/mTOR pathway** is critical in regulating cellular proliferation, mobility, and survival. Variation in genes of this pathway can result in several disorders characterized by a wide range of phenotypes including MCAP. MCAP is defined by the following characteristics: megalencephaly or hemimegalencephaly, hypotonia, seizures, intellectual disability, and cutaneous capillary malformations with focal or generalized somatic overgrowth. Cortical malformation is not uncommon. Molecular analysis is most successful in affected tissue samples versus buccal swab or blood sample.

Keppler-Noreuil KM et al: Clinical delineation and natural history of the PIK3CA-related overgrowth spectrum. Am J Med Genet A 2014 Jul;164(7):1713–1733 [PMID: 24782230].

Lindhurst MJ et al: A mosaic activating mutation in AKT1 associated with the Proteus syndrome. N Engl J Med 2011 Aug 18;365(7):611–619 [Epub 2011 Jul 27] [PMID: 21793738].

5. Syndromic Short Stature

Short stature is an important component of numerous syndromes, or it may be an isolated finding. In the absence of nutritional deficiencies, endocrine abnormalities, evidence of skeletal dysplasia (disproportionate growth with abnormal skeletal films), or a positive family history, intrinsic short stature can be due to UPD. The phenotype of Russell-Silver syndrome—short stature with normal head growth (pseudohydrocephalus), normal development, and minor dysmorphic features (triangular facies, body asymmetry and fifth finger clinodactyly)—has been associated in some cases with maternal UPD7.

6. VACTERL Association

The disorder is sporadic, and some of the defects may be life-threatening. The prognosis for normal development is good. The cause is unknown, but a high association with monozygotic twinning suggests a mechanism dating back to events perhaps as early as blastogenesis.

Careful examination and follow-up are important, because numerous other syndromes have overlapping features. Microarray studies and genetic consultation are warranted. VACTERL is a diagnosis of exclusion.

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

VACTERL association is described by an acronym denoting the association of the following:

- Vertebral defects (segmentation anomalies).
- Imperforate anus.
- Cardiac malformation (most often ventricular septal defect).
- Tracheoesophageal fistula.
- Renal anomalies.
- Limb (most often radial ray) anomalies.

7. Kabuki syndrome

Kabuki syndrome (KS) is characterized by typical facial features (elongated palpebral fissures with eversion of the lateral third of the lower eyelid; arched and broad eyebrows; short columella with depressed nasal tip; large, prominent, or cupped ears), minor skeletal anomalies, persistence of fetal fingertip pads, mild to moderate intellectual disability, and postnatal growth deficiency. Other findings may include: congenital heart defects, genitourinary anomalies, cleft lip and/or palate, gastrointestinal anomalies including anal atresia, ptosis, and strabismus, and widely spaced teeth and hypodontia. Functional differences can include increased susceptibility to infections and autoimmune disorders, seizures, endocrinologic abnormalities including isolated premature thelarche in females, feeding problems, and hearing loss. Molecular genetic testing for MLL2 and KMT2D, the only genes in which mutations are known to cause KS, are available on a clinical basis.

Adam MP et al: Kabuki syndrome. GeneReviews. www.ncbi.nlm.nih.gov/books/.

Genetic Evaluation of the Child with Developmental Disabilities

Cognitive disabilities or developmental delays affect 8% of the population. There are thousands of genes associated with developmental and intellectual disabilities, and determining an underlying genetic diagnosis may require consultation with a geneticist. Table 37–3 lists the main features of developmental delay, emphasizing the major clinical and genetic considerations. (See Chapter 3 for additional information about developmental delay and intellectual disability.)

Obtaining a detailed history, including pertinent prenatal and perinatal events, is critical. Feeding issues and slow growth velocity are seen in many genetic disorders causing developmental delay. Rate of developmental progress and particularly a history of loss of skills are important clues, as the latter might suggest a metabolic disorder with a neurodegenerative component. Family history can provide clues to suggest possible genetic etiologies, particularly if there is a history of consanguinity or a family pattern of other affected individuals.

Physical examination provides helpful clues. Referral to a clinical geneticist is indicated whenever unusual features are encountered. Neurologic, ophthalmologic, and audiologic consultation should be sought when indicated. Brain imaging (MRI) should be requested in cases involving unexplained deviations from normal head growth. Neuroimaging and skeletal studies may also be indicated when dysmorphic features are present.

Metabolic and genetic testing procedures other than those listed in the Table 37–3 may also be indicated.

Table 37–3. Evaluation of the child with developmental delay.

History
Pregnancy history
Growth parameters at birth
Neonatal complications
Feeding history
History of somatic growth
Motor, language, and psychosocial milestones
Seizures
Loss of skills
Abnormal movements
Results of previous tests and examinations
Family history
Developmental and educational histories
Psychiatric disorders
Pregnancy outcomes
Medical history
Consanguinity
Physical examination
General pediatric examination, including growth parameters
Focused dysmorphologic evaluation including measurement of facial features and limbs
Complete neurologic examination
Parental growth parameters (especially head circumferences) and dysmorphic features should also be assessed
Imaging studies
See text
Laboratory assessment
Microarray analysis (this has replaced chromosome analysis and FISH testing in most cases)
Fragile X testing (analysis of FMR1 gene for triplet repeats)
Other blood analyses: comprehensive metabolic panel, acylcarnitine profile, creatinine kinase (CK), lactate, pyruvate (this testing is helpful in the case of hypotonia)
Other metabolic tests may be helpful as second tier tests, including:
Serum amino acid analysis
Urine amino and organic acid analysis
Urine analysis for mucopolysaccharides (if coarse features and organomegaly)

Interpretation & Follow-Up

Clinical experience indicates that specific diagnoses can be made in approximately half of patients evaluated according to the protocol presented here. With specific diagnosis comes prognosis, ideas for management, and insight into recurrence risks.

Follow-up is important both for patients in whom diagnoses have been made and for those patients initially lacking a diagnosis. Genetic testing is advancing rapidly and can be translated into new diagnoses and better understanding with periodic review of clinical cases.

Autism

Autism is a developmental disorder comprising abnormal function in three domains: language development, social development, and behavior. Many patients with autism also have cognitive disabilities and might be appropriately evaluated according to the recommendations above. However, given the enormous increase in prevalence of autism in the past decade (1 in 68 children per latest CDC report), it is worth discussing the genetic evaluation of autism separately.

There are multiple known genetic causes of autism. Advances in molecular diagnosis, understanding of metabolic derangements, and technologies such as microarray are allowing more patients with autism to be identified with specific genetic disorders. This allows more accurate genetic counseling for recurrence risk, as well as diagnosis-specific interventions which may improve prognosis.

With this in mind, recommendations for the genetic evaluation of a child with autism include the following:

1. Genetic referral if dysmorphic features or cutaneous abnormalities are present (ie, hypopigmented spots such as those seen in patients with **tuberous sclerosis**).
2. Laboratory testing to include the following:
   A. Microarray.
   B. Molecular testing for **Fragile X syndrome**.
   C. Methylation testing for UPD15 if phenotype is suggestive of **Angelman syndrome**.
   D. Measurement of cholesterol and 7-DHC if syndactyly is present between the second and third toes to rule out a mild form of **Smith-Lemli-Opitz syndrome**.
   E. MECP2 testing if clinical course is suggestive of **Rett syndrome** (ie, little to no functional hand use, progressive microcephaly, and seizures in a female patient).
   F. PTEN molecular testing if the head circumference is greater than 2 standard deviations above the mean, plus evidence of penile freckling, lipomatous lesions, or a strong family history of certain malignancies.

Autism spectrum disorders are discussed in more detail in Chapter 3.

° pEr INATAl GENETICS

TERATOGENS

1. Drug Abuse & Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) results from excessive exposure to alcohol during gestation and affects 30%–40% of offspring of mothers whose daily intake of alcohol exceeds 3 ounces. Features of the syndrome include: short stature, poor head growth (may be postnatal in onset), developmental delay, and midface hypoplasia characterized by a poorly developed philtrum, thin upper lip, narrow palpebral fissures, and short nose with anteverted nares. Facial findings may be subtle, but careful measurements and comparisons with standards are helpful. Structural abnormalities occur in half of affected children. Cardiac anomalies and neural tube defects are commonly seen. Genitourinary tract anomalies are frequent. Neurobehavioral effects in FAS include: poor judgment and inappropriate social interactions, and lack of stranger anxiety in toddlers. Cognitive deficiencies and behavioral problems may occur without other classic physical characteristics of fetal alcohol syndrome and constitute an alcohol-related neurological disorder (ARND). One of the most challenging aspects in evaluating these children is there is no blood test to confirm or rule out this diagnosis; it is strictly based on maternal history and clinical findings.

Maternal abuse of psychoactive substances is also associated with increased risks for adverse perinatal outcomes including miscarriage, preterm delivery, growth retardation, and increased risk for injury to the developing CNS. Methamphetamine and crack cocaine are particularly dangerous. Maternal abuse of inhalants, such as glue, appears to be associated with findings similar to those of fetal alcohol syndrome.

Careful evaluation for other syndromes and chromosomal disorders should be included in the workup of exposed infants. Behavioral abnormalities in older children may be the result of maternally abused substances, poor early social circumstances but they may also reflect evolving psychiatric disorders. Psychiatric disorders, many recognized as heritable, affect large numbers of men and women with substance abuse problems. Fetal alcohol spectrum disorders are discussed in more detail in Chapter 3.

2. Maternal Anticonvulsant Effects

Anticonvulsant exposure during pregnancy is associated with adverse outcomes in approximately 10% of children born to women treated with these agents. A syndrome characterized by small head circumference, anteverted nares, cleft lip and palate (occasionally), and distal digital hypoplasia was first described in association with maternal use of phenytoin but also occurs with other anticonvulsants.

Risks for spina bifida are increased, especially in pregnancies exposed to valproic acid.

3. Retinoic Acid Embryopathy

Vitamin A and its analogs have considerable teratogenic potential. Developmental toxicity occurs in approximately one-third of pregnancies exposed in the first trimester to the synthetic retinoid isotretinoin, commonly prescribed to treat acne. Exposure produces CNS malformation, especially of the posterior fossa; ear anomalies (often absence of pinnae); congenital heart disease (great vessel anomalies); and tracheoesophageal fistula. It is now recognized that vitamin A itself, when taken as active retinoic acid in doses exceeding 25,000 IU/d during pregnancy, can produce similar fetal anomalies. Vitamin A intake is limited to 10,000 IU/d of retinoic acid. Maternal ingestion of large amounts of vitamin A taken as retinol during pregnancy, however, does not increase risks, because conversion of this precursor to active retinoic acid is internally regulated.

ASSISTED REPRODUCTION

Assisted reproductive technologies including in vitro fertilization are now utilized in a significant number of pregnancies. Although healthy live births are accepted as the usual outcomes resulting from successful application of these procedures, the actual number of viable embryos is limited and questions about the risks of adverse effects continue to be raised. Increased rates of twinning, both monozygotic and dizygotic, are well recognized, while the possibility of increased rates of birth defects remains controversial. Abnormal genetic imprinting appears to be associated with in vitro fertilization. Evidence supports increased prevalence of Beckwith-Wiedemann and Angelman syndromes among offspring of in vitro pregnancies.

PRENATAL DIAGNOSIS

Prenatal screening for birth defects is now routinely offered to pregnant women of all ages. Prenatal diagnosis introduces options for management.

Prenatal assessment of the fetus includes techniques that screen maternal blood, fetal imaging by ultrasound or MRI, fetal DNA analysis via maternal blood samples, and samples of fetal and placental tissues.

» Maternal Blood Analysis

Several options now exist to evaluate the fetus and pregnancy by obtaining a maternal blood sample. In the first trimester, measurements of PAPA (pregnancy-associated plasma protein A) and the free β-subunit of human chorionic gonadotropin (hCG) screen for trisomies 21 and 18. In the second trimester, maternal α-fetoprotein (AFP), hCG, unconjugated estradiol, and inhibin ("quad screen") combine to estimate risks for trisomies 21 and 18. Low estradiol levels can also predict cases of Smith-Lemli-Opitz syndrome. Noninvasive prenatal testing using NextGen sequencing, via maternal blood sample (also known as cell free fetal DNA), can detect specific chromosome imbalances and typically tests for the presence of sex chromosomes as well as Trisomy 13, 18, and 21. Some newer test platforms are starting to look for common microdeletion sequencing as well. It is important to note that this testing is a screening test and diagnoses always need to be confirmed by another method as described in the next section.

» Analysis of Fetal Samples

A. Amniocentesis

Amniocentesis samples fluid surrounding the fetus; the cells obtained are cultured for cytogenetic, molecular, or metabolic analyses. α-Fetoprotein and other chemical markers can also be measured. This is a safe procedure with a complication rate (primarily for miscarriage) of less than 0.01% in experienced hands.

B. Chorionic Villus Sampling (Placental)

Chorionic villus sampling is generally performed at 10–12 weeks' gestation. Tissue obtained by chorionic villus sampling provides DNA for molecular analysis and contains dividing cells that can be rapidly evaluated by FISH. However, direct cytogenetic preparations may be of poor quality and placental fibroblasts must be routinely grown and analyzed. In addition, chromosomal abnormalities detected by this technique may be confined to the placenta (**confined placental mosaicism**) and be less informative than amniocentesis.

C. Fetal Blood and Tissue

Fetal blood can be sampled directly in late gestation through ultrasound-guided percutaneous umbilical blood sampling (PUBS). A wide range of diagnostic tests ranging from biochemical to aCGH can be applied. Fetal urine sampled from the bladder or dilated proximal structures can provide important information about fetal renal function.

It is occasionally necessary to obtain biopsy specimens of fetal tissues such as liver or muscle for accurate prenatal diagnosis. These procedures are available in only a few perinatal centers.

D. Preimplantation Genetic Diagnosis

With the advent of single-cell PCR techniques as well as interphase, FISH it is now possible to make genetic diagnoses in preimplantation human embryos by removing and analyzing blastocyst cells. Using this procedure, parents can

now consider selecting pregnancies for positive attributes such as becoming donors for transplantation of tissues to siblings affected by genetic disorders.

» Fetal Imaging

Fetal ultrasonography has become routine and MRI imaging is becoming increasingly common during pregnancy, while fetal x-rays are rarely employed. Ultrasonography has joined maternal blood sampling as a screening technique for common chromosomal aneuploidies, neural tube defects, and other structural anomalies. Pregnancies at increased risk for CNS anomalies, skeletal dysplasias, and structural defects of the heart and kidneys should be monitored by careful ultrasound examinations. Fetal MRI has become routine in the workup of suspected fetal CNS abnormalities as well as in an increasing number of other fetal anomalies.

38 Allergic Disorders

Ronina A. Covar, MD
David M. Fleischer, MD
Christine Cho, MD
Mark Boguniewicz, MD

Allergic disorders are among the most common problems seen by pediatricians and primary care physicians, affecting over 25% of the population in developed countries. In the most recent National Health and Nutrition Examination Survey, 54% of the population had positive test responses to one or more allergens. According to a recent National Center for Health Statistics survey, the prevalence of food and skin allergies has increased over the past decade; with prevalence in 2009–2011 of 5% and 12.5%, respectively. While the prevalence of respiratory allergies has been stable, it is still the highest among children (17% in 2009–2011). In children, asthma, allergic rhinitis, and atopic dermatitis have been accompanied by significant morbidity and school absenteeism, with adverse consequences for school performance and quality of life, as well as economic burden measured in billions of dollars. In this chapter, atopy refers to a genetically determined predisposition to develop IgE antibodies found in patients with asthma, allergic rhinitis, and atopic dermatitis.

ASTHMA

» General Considerations

The Global Strategy for Asthma Management and Prevention 2014 (www.ginasthma.org) report offers a new definition for asthma as "a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness, and cough that vary over time and in intensity, together with variable expiratory limitation."

Asthma is the most common chronic disease of childhood, affecting over 7 million children in the United States. While current prevalence rates for asthma have increased in the past decade (most recent estimate of 10%), the rate of asthma attack in the past year has been stable. Gender, race, and socioeconomic disparities in the prevalence of asthma exist: (1) More boys than girls are affected in childhood; (2) Higher percentage affected among black children compared to Hispanic and non-Hispanic white children; (3) Children belonging to poor families are more likely to be affected.

There is still a disproportionately higher health care utilization for asthma among children compared to adults affected by this disease. Asthma health care encounters in primary care settings have increased over time; death rates and emergency department (ED) visits related to asthma have declined, and hospitalizations due to asthma have been steady. Hospitalizations and emergency department or urgent ambulatory or office visits, all indicators of asthma severity, impose significant costs to the health care system and to families, caretakers, schools, and parents' employers. Indirect costs primarily from loss of productivity due to school/work absences are harder to measure, yet considerable. Asthma remains a potentially life-threatening disease for children; the rate of asthma deaths was 28 per 1 million children with current asthma. Similar to disparities in prevalence, morbidity and mortality rates for asthma are higher among minority and inner city populations. The reasons for this are unclear but may be related to a combination of more severe disease, poor access to health care, lack of asthma education, delay in use of appropriate controller therapy, and environmental factors (eg, irritants including smoke and air pollutants, and perennial allergen exposure).

Up to 80% of children with asthma develop symptoms before their fifth birthday. Atopy (personal or familial) is the strongest identifiable predisposing factor. Sensitization to inhalant allergens increases over time and is found in the majority of children with asthma. The principal allergens associated with asthma are perennial aeroallergens such as dust mite, animal dander, cockroach, and Alternaria (a soil mold). Rarely, foods may provoke isolated asthma symptoms.

About 40% of infants and young children who have wheezing with viral infections in the first few years of life

will have continuing asthma through childhood. Viral infections (eg, respiratory syncytial virus [RSV], rhinovirus, parainfluenza and influenza viruses, metapneumovirus) are associated with wheezing episodes in young children. RSV may be the predominant pathogen of wheezing infants in the emergency room setting, but rhinovirus can be detected in the majority of older wheezing children. It is uncertain if these viruses contribute to the development of chronic asthma, independent of atopy. Severe RSV bronchiolitis in infancy has been linked to asthma and allergy in childhood. Although speculative, individuals with lower airways vulnerability to common respiratory viral pathogens may be at risk for persistent asthma.

In addition to atopy and infections being associated with the development of asthma, observational studies have also demonstrated an increased risk of asthma attributed to acetaminophen exposure during prenatal periods, infancy, childhood, and even adulthood. Acetaminophen is the most commonly used antipyretic medication for children in the United States. Furthermore, there is evidence from secondary analyses suggesting that acetaminophen exposure increases the risk for subsequent asthma exacerbations or wheeze compared to ibuprofen; and that a dose dependent elevated risk of asthma symptoms could be found.

There are several mechanisms which have been proposed: acetaminophen interfering with glutathione (a tripeptide antioxidant that is involved in free radical scavenging and xenobiotic detoxification) pathway and impairing respiratory antioxidant defenses; presence of genetic polymorphisms in the glutathione pathway that are associated with increased susceptibility to asthma; and acetaminophen causing a switch to a TH2 from a TH1 response. Stronger pieces of evidence such as prospectively designed studies primarily addressing the questions of whether acetaminophen exposure truly increases the risk of the development of chronic asthma or even triggers acute asthma are needed.

Exposure to tobacco smoke is also a risk factor and a trigger for asthma. Other triggers include exercise, cold air, pollutants, strong chemical odors, and rapid changes in barometric pressure. Aspirin sensitivity is uncommon in children. Psychological factors may precipitate asthma exacerbations and place the patient at high risk from the disease.

Pathologic features of asthma include shedding of airway epithelium, edema, mucus plug formation, mast cell activation, and collagen deposition beneath the basement membrane. The inflammatory cell infiltrate includes eosinophils, lymphocytes, and neutrophils, especially in fatal asthma exacerbations. Airway inflammation contributes to airway hyperresponsiveness, airflow limitation, and disease chronicity. Persistent airway inflammation can lead to airway wall remodeling and irreversible changes.

» Clinical Findings

A. Symptoms and Signs

The diagnosis of asthma in children, especially among preschool aged, is based largely on clinical judgment and an assessment of symptoms, activity limitation, and quality of life. For example, if a child with asthma refrains from participating in physical activities so as not to trigger asthma symptoms, their asthma would be inadequately controlled but not detected by the standard questions.

Wheezing is the most characteristic sign of asthma, although some children may have recurrent cough and shortness of breath. Complaints may include "chest congestion," prolonged cough, exercise intolerance, dyspnea, and recurrent bronchitis or pneumonia. Chest auscultation during forced expiration may reveal prolongation of the expiratory phase and wheezing. As the obstruction becomes more severe, wheezes become more high-pitched and breath sounds diminished. With severe obstruction, wheezes may not be heard because of poor air movement. Flaring of nostrils, intercostal and suprasternal retractions, and use of accessory muscles of respiration are signs of severe obstruction. Cyanosis of the lips and nail beds may be seen with underlying hypoxia. Tachycardia and pulsus paradoxus also occur. Agitation and lethargy may be signs of impending respiratory failure.

B. Laboratory Findings

Bronchial hyperresponsiveness, reversible airflow limitation, and airway inflammation are key features of asthma. Documentation of all these components is not always necessary, unless the presentation is rather atypical.

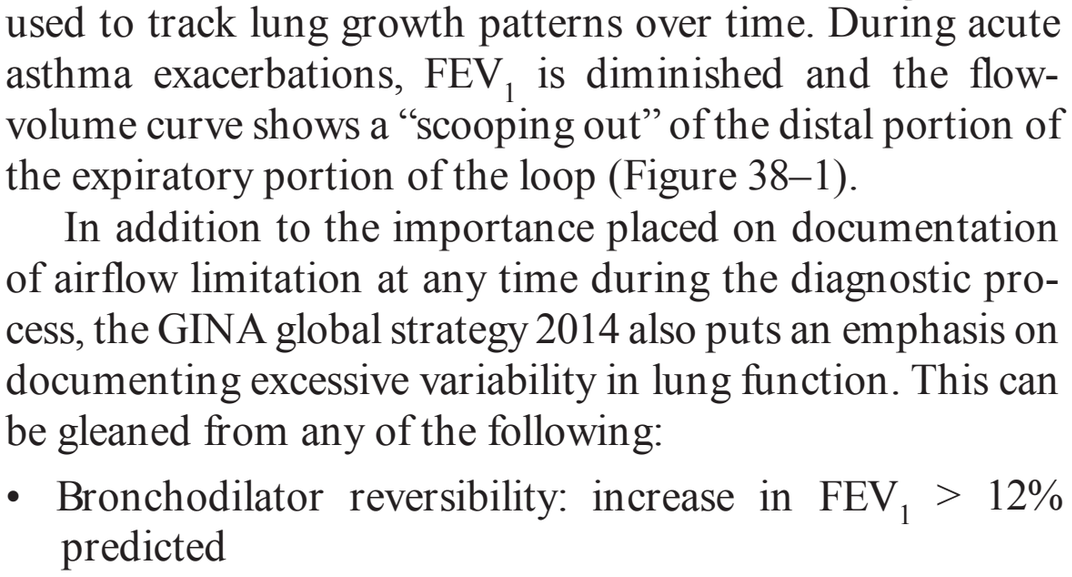
Bronchial hyperresponsiveness to nonspecific stimuli is a hallmark of asthma. These stimuli include inhaled pharmacologic agents such as histamine, methacholine, and mannitol, as well as physical stimuli such as exercise and cold air. Mannitol (Aridol) bronchoprovocation has been approved by the U.S. Food and Drug Administration (FDA) and is simpler and easier to administer in the office. It is available as a dry powder inhalation kit and takes less time to complete. Unlike methacholine and histamine challenges and similar to exercise challenge, it is considered an indirect challenge, that is, it simulates airway responses to specific physiologic situations, by creating an osmotic effect within the airway that subsequently leads to an inflammatory response. Airways may exhibit hyperresponsiveness or twitchiness even when baseline pulmonary function tests are normal. Giving increasing concentrations of a bronchoconstrictive agent to induce a decrease in lung function (usually a 20% drop in forced expiratory volume in 1 second [FEV_1] for histamine and methacholine and a 15% reduction for mannitol) and doing an exercise challenge are ways to determine airway responsiveness. Hyperresponsiveness

in normal children younger than age 5 years is greater than in older children. Bronchoprovocation challenges are not always available in a clinical setting but they help to establish a diagnosis of asthma when the history, examination, and pulmonary function tests are not definitive.

The National Asthma Education and Prevention Program Expert Panel Report 3 (NAEPP3) reinforces the use of spirometry over peak expiratory flow rate (PEFR) measurements in the evaluation of airflow limitation in asthma. This can be measured by reduction in FEV_1 and FEV_1/FVC (forced vital capacity) values compared to reference or predicted values. By itself, it is not adequate in establishing a diagnosis, but it can be an important parameter to monitor asthma activity and treatment response. In children, FEV_1 may be normal, despite frequent symptoms. Spirometric measures of airflow limitation can be associated with symptom severity, likelihood of exacerbation, hospitalization, or respiratory compromise. Regular monitoring of prebronchodilator (and ideally postbronchodilator) FEV_1 can be used to track lung growth patterns over time. During acute asthma exacerbations, FEV_1 is diminished and the flow-volume curve shows a "scooping out" of the distal portion of the expiratory portion of the loop (Figure 38–1).

In addition to the importance placed on documentation of airflow limitation at any time during the diagnostic process, the GINA global strategy 2014 also puts an emphasis on documenting excessive variability in lung function. This can be gleaned from any of the following:

- Bronchodilator reversibility: increase in FEV_1 > 12% predicted
- Excessive variability in twice daily peak flow readings over 2 weeks: average daily diurnal PEF variability > 13% ([Day's highest PEF minus day's lowest PEF)]/mean of day's highest and lowest), averaged over 1 week
- Significant increase in lung function after 4 weeks of anti-inflammatory treatment (FEV1 > 12% and 200 mL (or PEF > 20%)
- (+) Exercise challenge test: fall in FEV_1 > 12% predicted or PEF > 15%
- (+) Bronchoprovocation challenge test
- Excessive variation in lung function between visits: variation in FEV1 of 12% or PEF > 15%



▲**Figure 38–1.** Representative flow-volume loops in persons with normal lung function, asthma, and vocal cord dysfunction.

PEFR monitoring can be a simple and reproducible tool to assess asthma activity in children with moderate or severe asthma, a history of severe exacerbations, or poor perception of airflow limitation or worsening condition. Significant changes in PEFR may occur before symptoms become evident. In more severe cases, PEFR monitoring enables earlier recognition of suboptimal asthma control.

Lung function assessment using body box plethysmography to determine lung volume measurements can also be informative. The residual volume, functional residual capacity, and total lung capacity are usually increased, while the vital capacity is decreased. Reversal or significant improvement of these abnormalities in response to inhaled bronchodilator therapy or with anti-inflammatory therapy can be observed.

Infant pulmonary function can be measured in sedated children with compression techniques. The forced oscillation technique can be used to measure airway resistance even in younger children.

Hypoxemia is present early with a normal or low PCO_2 level and respiratory alkalosis. Hypoxemia may be aggravated during treatment with a β_2-agonist due to ventilation-perfusion mismatch. Oxygen saturation less than 91% is indicative of significant obstruction. Respiratory acidosis and increasing CO_2 tension may ensue with further airflow obstruction and signal impending respiratory failure. Hypercapnia is usually not seen until the FEV_1 falls below 20% of predicted value. Metabolic acidosis has also been noted in combination with respiratory acidosis in children with severe asthma and indicates imminent respiratory failure. PaO_2 less than 60 mm Hg despite oxygen therapy and $PaCO_2$ over 60 mm Hg and rising more than 5 mm Hg/h are relative indications for mechanical ventilation in a child in status asthmaticus.

Pulsus paradoxus may be present with moderate or severe asthma exacerbation. In moderate asthma exacerbation in a child, this may be between 10 and 25 mm Hg, and in severe asthma exacerbation between 20 and 40 mm Hg. Absence of pulsus paradoxus in a child with severe asthma exacerbation may signal respiratory muscle fatigue.

Clumps of eosinophils on sputum smear and blood eosinophilia are frequent findings. Their presence tends to reflect disease activity and does not necessarily mean that allergic factors are involved. Leukocytosis is common in acute severe asthma without evidence of bacterial infection and may be more pronounced after epinephrine administration. Hematocrit can be elevated with dehydration during prolonged exacerbations or in severe chronic disease.

Noninvasive measures of airway inflammation include exhaled nitric oxide concentrations, serum eosinophil cationic protein levels, and induced sputum. Each test has its strengths and weaknesses.

C. Imaging

Evaluation of asthma usually does not need chest radiographs (posteroanterior and lateral views) since they often appear normal, although subtle and nonspecific findings of hyperinflation (flattening of the diaphragms), peribronchial thickening, prominence of the pulmonary arteries, and areas of patchy atelectasis may be present. Atelectasis may be misinterpreted as the infiltrates of pneumonia. Some lung abnormalities, such as bronchiectasis, which may point to a different diagnosis implicating an asthma masquerader, such as cystic fibrosis, allergic bronchopulmonary mycoses (aspergillosis), ciliary dyskinesias, or immune deficiencies, can be better appreciated with high-resolution, thin-section chest computed tomography (HRCT) scans. It is primarily useful clinically in ruling out certain diagnoses in patients with difficult to manage asthma but radiation exposure should be considered when ordering HRCT.

Allergy testing is discussed in the section General Measures under Treatment, Chronic Asthma.

» Differential Diagnosis

Diseases that may be mistaken for asthma are often related to the patient's age (Table 38–1). Congenital abnormalities must be excluded in infants and young children. Asthma can be confused with croup, acute bronchiolitis, pneumonia, and pertussis. Immunodeficiency may be associated with cough and wheezing. Foreign bodies in the airway may cause dyspnea or wheezing of sudden onset, and on auscultation, wheezing may be unilateral. Asymmetry of the lungs secondary to air trapping may be seen on a chest radiograph, especially with forced expiration. Cystic fibrosis can be associated with or mistaken for asthma.

Vocal cord dysfunction is an important masquerader of asthma, although the two can coexist. It is characterized by the paradoxic closure of the vocal cords that can result in dyspnea and wheezing. Diagnosis is made by direct visualization of the vocal cords. In normal individuals, the vocal cords abduct during inspiration and may adduct slightly during expiration. Asthmatic patients may have narrowing of the glottis during expiration as a physiologic adaptation to airway obstruction. In contrast, patients with isolated vocal cord dysfunction typically show adduction of the anterior two-thirds of their vocal cords during inspiration, with a small diamond-shaped aperture posteriorly. Because this abnormal vocal cord pattern may be intermittently present, a normal examination does not exclude the diagnosis. Bronchial challenges using exercise or methacholine can precipitate symptoms of vocal cord dysfunction. The flow-volume loop may provide additional clues to the diagnosis of vocal cord dysfunction. Truncation of the inspiratory portion can be demonstrated in most patients during an acute episode, and some patients continue to show this pattern even when they are asymptomatic (see Figure 38–1). Children with vocal cord dysfunction, especially adolescents, tend to be overly competitive, primarily in athletics and scholastics. A psychiatric consultation may help define underlying psychological issues and provide appropriate therapy. Treatment of isolated vocal cord dysfunction includes education regarding the condition and appropriate breathing exercises. Hypnosis, biofeedback, and psychotherapy have been effective for some patients.

» Conditions That May Increase Asthma Severity

Chronic hyperplastic sinusitis is frequently found in association with asthma. Upper airway inflammation has been shown to contribute to the pathogenesis of asthma, and asthma may improve after treatment of sinusitis. However, sinus surgery is usually not indicated for initial treatment of chronic mucosal disease associated with allergy. In older children, rarely, hyperplastic sinusitis and polyposis and severe refractory asthma can be associated with aspirin sensitivity, known as aspirin-exacerbated respiratory disease (AERD).

A significant correlation has been observed between nocturnal asthma and gastroesophageal reflux. Patients may not complain of burning epigastric pain or have other reflux symptoms—cough may be the only sign. For patients with poorly controlled asthma, particularly with a nocturnal component, investigation for gastroesophageal reflux may be warranted even in the absence of suggestive symptoms.

Population studies have demonstrated associations between obesity and asthma. Obesity has been linked not only to the development of asthma but also with asthma

control and severity. What contributes to these associations or to what extent inflammation or physiologic impairment relates to both obesity and asthma is less established. It becomes difficult to determine if a child's trouble breathing is a result of obesity itself, its comorbidities (eg, gastroesophageal reflux or obstructive sleep apnea), and/or asthma. A management approach targeting weight reduction in obese children is encouraged to improve asthma control or its assessment.

The risk factors for death from asthma include psychological and sociological factors. They are probably related to the consequences of illness denial, poor coping or self-management skills, as well as to nonadherence with prescribed therapy. Recent studies have shown that less than 50% of inhaled asthma medications are taken as prescribed and that compliance does not improve with increasing severity of illness. Moreover, children requiring hospitalization for asthma, or their caregivers, have often failed to institute appropriate home treatment.

» Complications

With acute asthma, complications are primarily related to hypoxemia and acidosis and can include generalized seizures. Pneumomediastinum or pneumothorax can be a complication in status asthmaticus. With chronic asthma, recent studies point to airway wall remodeling and loss of pulmonary function with persistent airway inflammation. Childhood asthma independent of any corticosteroid therapy has been shown to be associated with delayed maturation and slowing of prepubertal growth velocity.

» Treatment

A. Chronic Asthma

1. General measures—The NAEPP EPR3 and the GINA 2014 global strategy offer slightly different management approaches. Both include an assessment and regular monitoring of disease activity, education and partnership to improve the child's and his/her family's knowledge and skills for self-management, identification and management of triggers and conditions that may worsen asthma, and appropriate medications selected to address the patient's needs. The objective of asthma management is the attainment of the best possible asthma control.

The NAEPP EPR3 stepwise approach is based on an assessment of severity and control. An assessment of asthma severity (ie, the intrinsic intensity of disease) is generally most accurate in patients not receiving controller therapy. Hence, assessing asthma severity directs the level of initial therapy. For those already on treatment, asthma severity can be classified according to the level of medication requirement to maintain adequate asthma control. The two general categories are intermittent and persistent asthma, the latter further subdivided into mild, moderate, and severe (Table 38–2). In contrast, asthma control refers to the degree to which symptoms, ongoing functional impairments, and risk of adverse events are minimized and goals of therapy are met. Assessment of asthma control should be done at every visit as this is important in adjusting therapy. It is categorized as "well controlled," "not well controlled," and "very poorly

Table 38–2. Assessing severity and initiating treatment for patients who are not currently taking long-term control medications.

Components of Severity		Classification of Asthma Severity			
			Persistent		
		Intermittent	Mild	Moderate	Severe
Impairment	Daytime symptoms	≤ 2 d/wk	> 2 d/wk but not daily	Daily	Throughout the day
	Nighttime awakenings				
	Age 0–4 y	0	1–2 ×/mo	3–4 ×/mo	> 1 ×/wk
	Age ≥ 5 y	≤ 2 ×/mo	3–4 ×/mo	> 1 ×/wk but not nightly	Often 7 ×/wk
	SABA use for symptoms (not prevention of EIB)	≤ 2 d/wk	> 2 d/wk but not daily, and not more than 1 × on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function				

(Continued)

Table 38–2. Assessing severity and initiating treatment for patients who are not currently taking long-term control medications. (Continued)

Components of Severity		Classification of Asthma Severity			
		Intermittent	Persistent		
			Mild	Moderate	Severe
	FEV_1% predicted	Normal FEV_1 between exacerbations			
	Age ≥ 5 y	> 80% predicted	≥ 80% predicted	60%–80% predicted	< 60% predicted
	FEV_1/FVC ratio				
Normal FEV_1/FVC: 8–19 y, 85% 20–39 y, 80%	Age 5–11 y	> 85%	> 80%	75%–80%	< 75%
	Age ≥ 12 y	Normal	Normal	Reduced 5%	Reduced > 5%
Risk	Exacerbations requiring systemic corticosteroids				
	Age 0–4 y	0–1/y (see Notes)	≥ 2 exacerbations in 6 mo requiring systemic corticosteroids OR ≥ 4 wheezing episodes/year lasting > 1 d and risk factors for persistent asthma		
	Age ≥ 5 y	0–1/y (see Notes)	≥ 2/y (see Notes)		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV_1.			
Recommended step for initiating therapy		Step 1	Step 2	Age 0–4 y	
				Step 3	Step 3
				Age 5–11 y	
				Step 3, medium-dose ICS option	Step 3, medium-dose ICS option, OR step 4
				Age ≥ 12 y	
				Step 3	Step 4 or 5
				Consider a short course of systemic corticosteroids	
		In 2–6 wk, evaluate level of asthma control that is achieved and adjust therapy accordingly. If no clear benefit is observed within 4–6 wk, consider adjusting therapy or alternative diagnoses.			

EIB, exercise-induced bronchospasm; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; SABA, short-acting β_2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether a patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥ 4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Adapted with permission from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

controlled" (Table 38–3). Responsiveness to therapy is the ease with which asthma control is attained by treatment. It can also encompass monitoring for adverse effects related to medication use.

The NAEPP EPR3 classification of either asthma severity or control is based on the domains of current impairment and risk, recognizing that these domains may respond differently to treatment. The level of asthma severity or control is established upon the most severe component of impairment or risk. Generally, the assessment of impairment is symptom based, except for the use of lung function for school-aged children and youths. Impairment includes an assessment of the patient's recent symptom frequency and intensity and functional limitations (ie, daytime symptoms, nighttime awakenings, need for short-acting β_2-agonists for quick relief, work or school days missed, ability to engage in normal or desired activities, and quality-of-life assessments) and airflow compromise preferably using spirometry. Numerous validated instruments and questionnaires for assessing health-related quality of life and asthma control have been developed. The Asthma Control Test (ACT, www.asthmacontrol.com), the Asthma Control Questionnaire (ACQ, www.qoltech.co.uk/Asthma1.htm), and the Asthma Therapy Assessment Questionnaire (ATAQ, www.ataqinstrument.com) for children 12 years of age and older, and the Childhood ACT for children 4–11 years of age are examples of self-administered questionnaires that have been developed with the objective of addressing multiple aspects of asthma control such as frequency of daytime and nocturnal symptoms, use of reliever medications, functional status, missed school or work, and so on. A five-item caregiver-administered instrument, the Test for Respiratory and Asthma Control in Kids (TRACK), has been validated as a tool to assess both impairment and risk presented in the NAEPP Expert Panel Report 3 (EPR3) guidelines in young children with recurrent wheezing or respiratory symptoms consistent with asthma.

Table 38–3. Assessing asthma control and adjusting therapy in children.

		Classification of Asthma Control		
Components of Control		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤ 2 d/wk but not more than once on each day	> 2 d/wk or multiple times on ≤ 2 d/wk	Throughout the day
	Nighttime awakenings			
	Age 0–4 y	≤ 1 × /mo	> 1 × /mo	> 1 × /wk
	Age 5–11 y	≤ 1 × /mo	≥ 2 × /mo	≥ 2 × /wk
	Age ≥ 12 y	≤ 2 × /mo	1–3 × /wk	≥ 4 × /wk
	SABA use for symptoms (not EIB pretreatment)	≤ 2 d/wk	> 2 d/wk	Several times per day
	Interference with normal activity	None	Some limitation	Extremely limited
	Lung function			
	Age 5–11 y			
	FEV_1% predicted or peak flow	> 80% predicted or personal best	60%–80% predicted or personal best	< 60% predicted or personal best
	FEV_1/FVC	> 80%	75%–80%	< 75%
	Age ≥ 12 y			
	FEV_1% predicted or peak flow	> 80% predicted or personal best	60%–80% predicted or personal best	< 60% predicted or personal best
	Validated questionnaires			
	Age ≥ 12 y			
	ATAQ	0	1–2	3–4
	ACQ	≤ 0.75[a]	≥ 1.5	N/A
	ACT	≥ 20	16–19	≤ 15
Risk	Exacerbations requiring systemic corticosteroids			
	Age 0–4 y	0–1 y	2–3/y	> 3/y
	Age ≥ 5 y	0–1 y	≥ 2/y (see Notes)	
	Consider severity and interval since last exacerbation.			

(Continued)

Table 38–3. Assessing asthma control and adjusting therapy in children. (Continued)

Components of Control		Classification of Asthma Control		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
	Treatment-related adverse effects.	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
	Reduction in lung growth or progressive loss of lung function.	Evaluation requires long-term follow-up care.		
Recommended action for treatment.		• Maintain current step. • Regular follow-up every 1–6 mo to maintain control. • Consider step-down if well controlled for at least 3 mo.	• Step up (1 step). • Reevaluate in 2–6 wk. • If no clear benefit in 4–6 wk, consider alternative diagnoses or adjusting therapy. • For side effects, consider alternative options.	• Consider short course of oral corticosteroids. • Step up (1–2 steps). • Reevaluate in 2 wk. • If no clear benefit in 4–6 wk, consider alternative diagnoses or adjusting therapy. • For side effects, consider alternative options.

EIB, exercise-induced bronchospasm; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥ 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated questionnaires for the impairment domain (the questionnaires do not assess lung function or the risk domain):
  a. ATAQ = Asthma Therapy Assessment Questionnaire
  b. ACQ = Asthma Control Questionnaire
  c. ACT = Asthma Control Test
  d. Minimal Important Difference: 1.0 for ATAQ; 0.5 for the ACQ; not determined for ACT; [a]ACQ values of 0.76–1.40 are indeterminate regarding well-controlled asthma.
- Before step-up therapy:
  a. Review adherence to medications, inhaler technique, and environmental control.
  b. If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

Adapted with permission from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

"Risk" refers to an evaluation of the patient's likelihood of developing asthma exacerbations, reduced lung growth in children (or progressive decline in lung function in adults), or risk of untoward effects from medications. The GINA 2014 strategy also cites risk factors for poor asthma outcomes (ie, exacerbations, fixed airflow limitation, and medication side effects). Potentially modifiable risk factors for exacerbations include uncontrolled asthma symptoms; excessive short-acting beta-agonist use (> 1 200-dose canister/month); inadequate or lack of inhaled corticosteroid; poor adherence; incorrect inhaler technique; low FEV1, especially if < 60% predicted; major psychological or socioeconomic problems; presence of smoking or allergen exposure; having comorbidities (obesity, rhinosinusitis, confirmed food allergy); sputum or blood eosinophilia; and pregnancy. Considered major independent risk factors for flare ups are history of intubation or ICU admission for asthma; and ≥1 severe exacerbation in last 12 months. Risk factors for developing fixed airflow limitation are lack of inhaled corticosteroid treatment; exposures to tobacco smoke, noxious chemicals, occupational exposures; low initial FEV_1; and chronic mucus hypersecretion, sputum or blood eosinophilia. Frequent oral corticosteroid use, long-term high dose and/or potent inhaled corticosteroid, and intake of P450 inhibitors are risk

factors for systemic medication side effects; while high-dose or potent inhaled corticosteroid and poor inhaler technique are also risk factors for local side effects.

Education is important and partnership with the child's family is a key component in the management to improve adherence and outcomes. The patient and family must understand the role of asthma triggers, the importance of disease activity even without obvious symptoms, how to use objective measures to gauge disease activity, and the importance of airway inflammation—and they must learn to recognize the warning signs of worsening asthma, allowing for early intervention. A stepwise care plan should be developed for all patients with asthma. Providing asthma action plans is currently a requirement that is tracked by many hospitals and others to document that educational instruction for chronic disease management has been given. Asthma action plans should be provided to school personnel and all those who care for children with asthma.

Because the degree of airflow limitation is poorly perceived by many patients, peak flow meters can aid in the assessment of airflow obstruction and day-to-day disease activity. Peak flow rates may provide early warning of worsening asthma. They are also helpful in monitoring the effects of medication changes. Spacer devices optimize delivery of medication from metered-dose inhalers (MDIs) to the lungs and, with inhaled steroids, minimize side effects. Large-volume spacers are preferred. Poor understanding by patients and families of proper device use can lead to inadequate delivery and treatment with inhaled medications, especially inhaled controllers. Short instructive videos for device use can be provided to educate families and other caregivers (URL: http://www.thechildrenshospital.org/conditions/lung/asthmavideos.aspx).

Patients should avoid exposure to tobacco smoke and allergens to which they are sensitized, exertion outdoors when levels of air pollution are high, β-blockers, and sulfite-containing foods. Patients with persistent asthma should be given the inactivated influenza vaccine yearly unless they have a contraindication.

For patients with persistent asthma, the clinician should use the patient's history to assess sensitivity to seasonal allergens and Alternaria mold and in vitro testing (either by skin or blood test) to assess sensitivity to perennial indoor allergens, to assess the significance of positive tests in the context of the patient's history, and to identify relevant allergen exposures. For dust mite–allergic children, important environmental control measures include encasing the pillow and mattress in an allergen-impermeable cover and washing the sheets and blankets on the patient's bed weekly in hot water. Other measures include keeping indoor humidity below 50%, minimizing the number of stuffed toys, and washing such toys weekly in hot water. Children allergic to furred animals or feathers should avoid indoor exposure to pets, especially for prolonged periods of time. If removal of the pet is not possible, the animal should be kept out of the bedroom with the door closed. Carpeting and upholstered furniture should be removed. While a high-efficiency particle-arresting filter unit in the bedroom may reduce allergen levels, symptoms may persist if the pet remains indoors. For cockroach-allergic children, control measures need to be instituted when infestation is present in the home. Poison baits, boric acid, and traps are preferred to chemical agents, which can be irritating if inhaled by asthmatic individuals. Indoor molds are especially prominent in humid or damp environments. Measures to control dampness or fungal growth in the home may be of benefit. Patients can reduce exposure to outdoor allergens by staying in an air-conditioned environment. Allergen immunotherapy may be useful for implicated aeroallergens that cannot be avoided. However, it should be administered only in facilities staffed and equipped to treat life-threatening reactions.

Patients should be treated for rhinitis, sinusitis, or gastroesophageal reflux, if present. Treatment of upper respiratory tract symptoms is an integral part of asthma management. Intranasal corticosteroids are recommended to treat chronic rhinosinusitis in patients with persistent asthma because they reduce lower airway hyperresponsiveness and asthma symptoms. Intranasal cromolyn reduces asthma symptoms during the ragweed season but less so than intranasal corticosteroids. Treatment of rhinosinusitis includes medical measures to promote drainage and the use of antibiotics for acute bacterial infections (see Chapter 18). Medical management of gastroesophageal reflux includes avoiding eating or drinking 2 hours before bedtime, elevating the head of the bed with 6- to 8-in blocks, and using appropriate pharmacologic therapy.

2. Pharmacologic therapy—A revised stepwise approach to pharmacologic therapy, broken down by age categories, is recommended in the NAEPP EPR3 (http://www.nhlbi.nih.gov) (Table 38–4). This approach is based on the concepts of asthma severity and asthma control. A separate set of recommendations for younger children is provided given the lack of tools which can be used to assess lung function and quality of life otherwise available for older children. Treatment recommendations for older children and adults are better supported by stronger evidence from available clinical trials, whereas those for younger children have been extrapolated from studies in older children and adults.

The choice of initial therapy is based on assessment of asthma severity. For patients who are already on controller therapy, treatment can be adjusted based on assessment of asthma control and responsiveness to therapy. The goals of therapy are to reduce the components of both impairment (eg, preventing chronic and troublesome symptoms, allowing infrequent need of quick-relief medications, maintaining "normal" lung function, maintaining normal activity levels including physical activity and school attendance, meeting

Table 38–4. Stepwise approach for managing asthma in children.

	Intermittent[a]	Persistent Asthma: Daily Medication					
		Step 2	Step 3	Step 4	Step 5	Step 6	Step down if possible (and asthma is well controlled at least 3 mo)
Age 0–4 y	Step 1 Preferred SABA PRN	Preferred Low-dose ICS Alternative Cromolyn or montelukast	Preferred Medium-dose ICS	Preferred Medium-dose ICS + either LABA or LTRA	Preferred High-dose ICS + either LABA or LTRA	Preferred High-dose ICS + either LABA or LTRA AND oral corticosteroid	**Assess Control** Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid condition)
Age 5–11 y	Preferred SABA PRN	Preferred Low-dose ICS Alternative Cromolyn, LTRA, nedocromil, or theophylline	Preferred EITHER Low-dose ICS + either LABA, LTRA, or theophylline OR medium-dose ICS	Preferred Medium-dose ICS + LABA Alternative Medium-dose ICS + either LTRA or theophylline	Preferred High-dose ICS + LABA Alternative High-dose ICS + either LTRA or theophylline	Preferred High-dose ICS + LABA AND oral corticosteroid Alternative High-dose ICS + either LTRA or theophylline AND oral corticosteroid	
Age ≥ 12 y	Preferred SABA PRN	Preferred Low-dose ICS Alternative Cromolyn, LTRA, nedocromil, or theophylline	Preferred Low-dose ICS + LABA OR medium-dose ICS Alternative Low-dose ICS + either LTRA, theophylline, or zileuton	Preferred Medium-dose ICS + LABA Alternative Medium-dose ICS + either LTRA or theophylline or zileuton	Preferred High-dose ICS + LABA AND consider omalizumab for patients with allergies	Preferred High-dose ICS + LABA + oral corticosteroid AND consider omalizumab for patients with allergies	

Each step: Patient education, environmental control, and management of comorbidities.
Age ≥ 5 y: Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma.
Quick-Relief Medication for All Patients

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to three treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.
- Caution: Use of SABA > 2 d/wk for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.
- For ages 0–4 years: With viral respiratory infection: SABA q4-6h up to 24 hours (longer with physician consult). Consider short course of systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.

ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2-agonist; LTRA, leukotriene receptor antagonist; prn, as needed; SABA, inhaled short-acting β_2-agonist.
[a]Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.

(Continued)

Table 38–4. Stepwise approach for managing asthma in children. (Continued)

	Intermittent[a]	Persistent Asthma: Daily Medication

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children aged 0–4 years are limited. Step 2 therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.
- For age 5–11 years, steps 1 and 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- For ages ≥ 12 years, steps 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR-1 1997) and Evidence B for omalizumab. In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Zileuton is less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function.
- Immunotherapy for steps 2–4 is based on Evidence B for house dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.

Adapted with permission from the National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR3): Guidelines for the Diagnosis and Management of Asthma—Summary Report 2007. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

families' expectations and satisfaction with asthma care) and risk (eg, preventing recurrent exacerbations, reduced lung growth, and medication adverse effects).

1. The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
2. In the absence of persistent symptoms, the new clinical guidelines recommend considering initiation of long-term controller therapy for infants and younger children who have risk factors for asthma (ie, modified asthma predictive index: parental history of asthma, physician-diagnosed atopic dermatitis, or sensitization to aeroallergens or two of the following: wheezing apart from colds, sensitization to foods, or peripheral eosinophilia) and four or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep or two or more exacerbations in 6 months requiring systemic corticosteroids.
3. Inhaled corticosteroids, either as monotherapy or in combination with adjunctive therapy, are preferred treatment for all levels of persistent asthma.
4. Along with medium-dose inhaled corticosteroids, combination therapy with inhaled corticosteroids plus any of the following adjunctive therapies—long-acting inhaled β_2-agonists (LABAs), leukotriene modifying agents, cromones, and theophylline—is recommended as step 3 treatment for moderate persistent asthma, or as step-up therapy for uncontrolled persistent asthma for school-aged children and youths. In children aged 0–4 years, medium-dose inhaled corticosteroids as monotherapy remain the step 3 therapy, and combination therapy to be initiated only as a step 4 treatment. A rescue course of systemic corticosteroids may be necessary at any step.

The GINA global strategy has a different and maybe simplified set of recommend options for initiation of controller therapy (Table 38–5). In their stepwise approach (Table 38–6), emphasis on maximizing benefit from available medications, inhaler technique, and adherence before step-up treatment is pursued.

Asthma medications are classified as long-term controller medications and quick-relief medications. The former includes anti-inflammatory agents, leukotriene modifiers, and long-acting bronchodilators. Although LABAs (salmeterol, formoterol) are β-agonists, they are considered to be daily controller medications, but unlike the other asthma controller medications with primarily anti-inflammatory properties, LABAs cannot be administered as monotherapy.

Inhaled corticosteroids are the most potent inhaled anti-inflammatory agents currently available. Although recommended as daily controller therapy, recent studies have shown their efficacy even for intermittent use for rescue or at the onset of acute respiratory illnesses. Different inhaled corticosteroids are not equivalent on a per puff or microgram basis (Table 38–7). Early intervention with inhaled corticosteroids can improve asthma control and prevent exacerbations during treatment, but they do not prevent

Table 38–5. Recommended options for initial controller treatment in adults and adolescents.

Presenting symptoms	Preferred initial controller
Asthma symptoms or need for SABA <2 x/month; no waking due to asthma in last month; and no risk factors for exacerbations, including no exacerbations in the last year	Step 1: No controller
Infrequent asthma symptoms, but the patient has ≥ 1 risk factors for exacerbations; eg, low lung function, or exacerbation requiring OCS in the last year, or has ever been in ICU for asthma	Step 2: Low dose ICS
Asthma symptoms or need for SABA between twice a month and twice a week, or patient wakes ≥1 a month	Step 2: Low dose ICS
Asthma symptoms or need for SABA more than twice a week	Step 2: Low dose ICS; alternative options (LTRA or theophylline)
Troublesome asthma symptoms most days; or waking due to asthma ≥ 1 a week, especially if any risk factors exist	Step 3: Medium/high dose ICS or Low dose ICS/LABA*
Initial asthma presentation is with severely uncontrolled asthma, or with an acute exacerbation	Short course of oral CS AND Start regular controller treatment; options are: High dose ICS OR Moderate dose ICS/LABA

*Not recommended for initial treatment in children 6–11 years

the development of persistent asthma nor do they alter its natural history. Long-term inhaled corticosteroids may be associated with early slowing of growth velocity in children, and although this can impact the final adult height by a minimum degree, it is not a cumulative effect. Possible risks from inhaled corticosteroids need to be weighed against the risks from undertreated asthma. The adverse effects from inhaled corticosteroids are generally dose and duration dependent, so that greater risks for systemic adverse effects are expected with high doses. The various inhaled corticosteroids are delivered in different devices such as MDI (beclomethasone, ciclesonide, fluticasone propionate, flunisolide, mometasone, and triamcinolone), dry powder inhaler (DPI) (fluticasone propionate [Diskus], fluticasone furoate [Ellipta], budesonide [Flexhaler], and mometasone [Twisthaler]), and nebulized aerosol suspensions (budesonide respules). Inhaled medications delivered in MDI now use the more ozone friendly hydrofluoroalkane (HFA) propellant,

Table 38–6. GINA 2014 Stepwise approach to control symptoms and minimize future risk.

Preferred Controller Choice	STEP 1	STEP 2 Low dose ICS	STEP 3 *Children 6-11 yr: Medium dose ICS Low dose ICS/LABA	STEP 4 Medium/high ICS/LABA	STEP 5 Refer to add-on treatment, eg, anti-IgE
Other controller options	Consider low Dose ICS	LTRA Low Dose theophylline	Medium/High dose ICS Low dose ICS+LTRA (or +theophylline for adolescents and adults)	High dose ICS+LTRA (or +theophylline for adolescents and adults)	Add low dose OCS
Reliever	As needed SABA		As needed SABA (all children) or Low dose ICS/formoterol		
Assess Diagnosis Symptom control &Risk factors (including lung function) Inhaler technique &adherence Patient preference		Adjust Treatment Asthma medications Nonpharmacologic strategies Treat modifiable risk factors		Review Response Symptoms Exacerbations Side effects Patient satisfaction Lung function

which has replaced chlorofluorocarbons (CFC). See instructions for different device use at the following URL: http://www.thechildrenshospital.org/conditions/lung/asthmavideos.aspx.

Only inhaled corticosteroids have been shown to be effective in long-term clinical studies for infants. Nebulized budesonide is approved for children as young as 12 months. The suspension (available in quantities of 0.25 mg/2 mL, 0.5 mg/2 mL, and 1.0 mg/2 mL) is usually administered either once or twice daily in divided doses. For effective drug delivery, it is critical that the child has a mask secured on the face for the entire treatment, as blowing it in the face is not effective and yet a common practice by parents. Notably, this drug should not be given by ultrasonic nebulizer. Limited data suggest that inhaled corticosteroids may be effective even in very young children when delivered by MDI with a spacer and mask.

Fewer data are available with nedocromil, although data from the Childhood Asthma Management Program study showed that an inhaled corticosteroid was superior to nedocromil with respect to several efficacy parameters, including rate of hospitalization, symptom-free days, need for albuterol rescue, and longer time to treatment with prednisone, when each was compared to a placebo.

Theophylline is rarely used. Sustained-release theophylline, an alternative long-term control medication for older children, may have particular risks of adverse effects in infants, who frequently have febrile illnesses that increase theophylline concentrations. Hence, if theophylline is used, it requires monitoring of serum concentration to prevent numerous dose-related acute toxicities.

For school-aged children whose asthma is uncontrolled on low-dose inhaled corticosteroid (ie, requiring step 3 guidelines therapy), majority are likely to respond to a step-up combination therapy with a long-acting β_2-agonist bronchodilator (eg, salmeterol and formoterol), although some respond best either to an increased dose of inhaled corticosteroid or to an addition of a leukotriene receptor antagonist. LABAs should not be used for treatment of acute symptoms, nor should they be used without any inhaled corticosteroid therapy, even if the patient feels better. Salmeterol is available as an inhalation powder (one inhalation twice daily for patients aged 4 years and older). It is also available combined with fluticasone (50 mcg salmeterol with 100, 250,

or 500 mcg fluticasone in a DPI or 21 mcg salmeterol with 45, 115, or 230 mcg fluticasone in an MDI). For children 12 years and older, one inhalation DPI or two inhalations MDI can be taken twice daily. (Note: The 100/50 fluticasone/salmeterol combination is approved in children aged 4 and older.) Salmeterol can also be used 30 minutes before exercise (but not in addition to regularly used LABAs). Formoterol has a more rapid onset of action and is available singly either as a DPI (Aerolizer, 12 mcg) or a nebulized solution approved only for COPD (Perforomist); or combined with an inhaled steroid (formoterol fumarate, either 4.5 mcg with budesonide [80 or 160 mcg] or 5 mcg with mometasone [100 or 200 mcg], in an MDI). Formoterol DPI is approved for use in children 5 years and older, one inhalation (12 mcg) twice daily, while the combination product is approved for children 12 years and older, two inhalations twice daily. For long-term control, formoterol should be used in combination with an anti-inflammatory agent. It can be used for exercise-induced bronchospasm in patients 5 years and older, one inhalation at least 15 minutes before exercise (but not in addition to regularly used LABAs). An even longer acting LABA, vilanterol, with a 24-hour activity, combined with fluticasone furoate (Breo) is available for asthma in patients 18 years and older. Of note, FDA has requested the manufacturers of Advair Diskus and HFA (salmeterol and fluticasone), Serevent Diskus (salmeterol xinafoate), Foradil Aerolizer (formoterol fumarate), Symbicort HFA, and Brovana (arformoterol tartrate inhalation solution, a LABA approved for chronic obstructive pulmonary disease) to update their product information warning sections regarding an increase in severe asthma episodes associated with these agents. This action is in response to data showing an increased number of asthma-related deaths in patients receiving LABA therapy in addition to their usual asthma care as compared with patients not receiving LABAs. This notice is also intended to reinforce the appropriate use of LABAs in the management of asthma. Specifically, LABA products should not be initiated as first-line asthma therapy, used with worsening wheezing, or used for acute control of bronchospasm. No data are available regarding safety concerns in patients using these products for exercise-induced bronchoconstriction. Additional information, including copies of the Patient and Healthcare Professional information sheets, can be found at: http://www.fda.gov/cder/drug/infopage/LABA/default.htm.

Montelukast and zafirlukast are leukotriene-receptor antagonists available in oral formulations. Montelukast is given once daily and has been approved for treatment of chronic asthma in children aged 1 year and older, as an alternative step 2 monotherapy and add-on therapy for steps 3–6. It is also indicated for seasonal allergic rhinitis in patients 2 years and older, and for perennial allergic rhinitis in patients 6 months and older. To date, no drug interactions have been noted. The dosage is 4 mg for children 1–5 years (oral granules are available for children aged 12–23 months), 5 mg for children aged 6–14 years, and 10 mg for those aged 15 years and older. The drug is given without regard to mealtimes, preferably in the evening. Zafirlukast is approved for patients aged 5 years and older. The dose is 10 mg twice daily for those 5–11 years and 20 mg twice daily for those 12 years and older. It should be taken 1 hour before or 2 hours after meals. Zileuton is a 5-lipoxygenase inhibitor indicated for chronic treatment in children 12 years of age and older, available in regular 600 mg dose tablet four times a day or extended release 600 mg dose tablet, 2 tablets twice a day. Patients need to have hepatic transaminase levels evaluated at initiation of therapy, then once a month for the first 3 months, every 2–3 months for the remainder of the first year, and periodically thereafter if receiving long-term zileuton therapy. Rare cases of Churg-Strauss syndrome have been reported in adult patients with severe asthma whose steroid dosage was being tapered during concomitant treatment with leukotriene-receptor antagonists (as well as inhaled corticosteroids), but no causal link has been established. Both zafirlukast and zileuton are microsomal P-450 enzyme inhibitors that can inhibit the metabolism of drugs such as warfarin and theophylline. The FDA has requested that manufacturers include a precaution in the drug prescribing information (drug labeling) regarding neuropsychiatric events (agitation, aggression, anxiousness, dream abnormalities and hallucinations, depression, insomnia, irritability, restlessness, suicidal thinking and behavior, and tremor) based on postmarket reports of patients taking leukotriene-modifying agents. Of note, in a study of children with mild to moderate persistent asthma that looked at whether responses to an inhaled corticosteroid and a leukotriene-receptor antagonist are concordant for individuals or whether asthmatic patients who do not respond to one medication respond to the other, response to fluticasone and montelukast were found to vary considerably. Children with low pulmonary function or high levels of markers associated with allergic inflammation responded better to the inhaled corticosteroid.

Children with persistent asthma who remain uncontrolled on inhaled corticosteroid monotherapy are more likely to respond to a combination treatment of an inhaled corticosteroid and a LABA; however, there are children who can respond best to a higher dose of inhaled corticosteroid, or even a low-dose inhaled corticosteroid plus montelukast. It has not been definitely determined what clinical features would be helpful in selecting the most appropriate medication for any one patient. Recent studies in adults have also shown the efficacy of a long-acting antimuscarinic agent, tiotropium (Spiriva respimat [1.25 mcg] has now been approved as once daily maintenance treatment for asthma in patients 12 years and older), as an add-on therapy to inhaled corticosteroids.

Quick-relief medications include short-acting inhaled β_2-agonists (SABAs) such as albuterol, levalbuterol, pirbuterol, or terbutaline. Albuterol can be given by nebulizer, 0.05 mg/kg (with a minimal dose of 0.63 mg and a maximum

of 5 mg) in 2–3 mL saline (although it is also available in a 2.5 mg/3 mL single vial or 5 mg/mL concentrated solution) or by MDI (90 mcg/actuation) or by breath-actuated DPI (Respiclick). It is better to use SABAs as needed rather than on a regular basis. Increasing use, including more than one canister per month, may signify inadequate asthma control and the need to step up or revise controller therapy. Levalbuterol, the (R)-enantiomer of racemic albuterol, is available in solution for nebulization in patients aged 6–11 years, 0.31 mg every 8 hours, and in patients 12 years and older, 0.63–1.25 mg every 8 hours. It has recently become available in an HFA formulation for children 4 years and older, two inhalations (90 mcg) every 4–6 hours as needed. Anticholinergic agents such as ipratropium, 1–3 puffs or 0.25–0.5 mg by nebulizer every 6 hours, may provide additive benefit when used together with an inhaled SABA. Systemic corticosteroids such as prednisone, prednisolone, and methylprednisolone can be given in a dosage of 1–2 mg/kg, usually up to 60 mg/d in single or divided doses for 3–10 days. There is no evidence that tapering the dose following a "burst" prevents relapse.

Anti-IgE (omalizumab) is a recombinant DNA-derived humanized IgG_1 monoclonal antibody that selectively binds to human IgE. It inhibits the binding of IgE to the high-affinity IgE receptor (FcεRI) on the surface of mast cells and basophils. Reduction in surface-bound IgE on FcεRI-bearing cells limits the degree of release of mediators of the allergic response. Treatment with omalizumab also reduces the number of FcεRI receptors on basophils in atopic patients. Omalizumab is indicated for patients 12 years of age and older with moderate to severe persistent asthma who have a positive skin test or in vitro reactivity to a perennial aeroallergen with total serum IgE of 30–700 IU/mL, and whose symptoms are inadequately controlled with medium- to high-dose inhaled corticosteroids. Omalizumab has been shown to decrease the incidence of asthma exacerbations and improve asthma control in these patients. Dosing is based on the patient's weight and serum IgE level and is given subcutaneously every 2–4 weeks. The FDA has ordered a black box warning to the label because of new reports of serious and life-threatening anaphylactic reactions (bronchospasm, hypotension, syncope, urticaria, and angioedema of the throat or tongue) in patients after treatment with omalizumab (Xolair). Based on pre-marketing clinical trials in patients with asthma, anaphylaxis occurred with 0.1% of patients; in a postmarketing spontaneous reports based on an estimated exposure of about 57,300 patients from June 2003 through December 2006, the frequency of anaphylaxis attributed to Xolair use was estimated to be at least 0.2% of patients. From a case control study, patients with a history of anaphylaxis from whatever are considered at increased risk of anaphylaxis with Xolair, compared to those with no prior history of anaphylaxis. Although these reactions occurred within 2 hours of receiving a omalizumab subcutaneous injection, they also included reports of serious delayed reactions 2–24 hours or even longer after receiving the injections. Anaphylaxis occurred after any dose of omalizumab (including the first dose), even in patients with no allergic reaction to previous doses. Omalizumab-treated patients should be observed in the facility for an extended period after the drug is given, and medical providers who administer the injection should be prepared to manage life-threatening anaphylactic reactions. Patients who receive omalizumab should be fully informed about the signs and symptoms of anaphylaxis, their chance of developing delayed anaphylaxis following each injection, and how to treat it, including the use of autoinjectable epinephrine. Malignancy (e.g., breast, non-melanoma skin, prostate, melanoma, and parotid, etc.) was observed in 20 of 4127 (0.5%) Xolair-treated patients compared with 5 of 2236 (0.2%) control patients in clinical studies of adults and adolescents with asthma and other allergies. A more recent observational study of 5007 Xolair-treated and 2829 non-Xolair-treated patients with moderate to severe persistent allergic asthma followed for up to 5 years showed similar incidence rates (per/1000 patient years) of primary malignancies among Xolair-treated (12.3) and non-Xolair-treated patients (13.0).

New biologics or immunomodulators directed against specific type 2 helper T-cell cytokines have been studied to target the inflammatory component of asthma. The US FDA has recently recommended approval of both anti-IL-5 antibodies—mepolizumab (Nucala, monoclonal antibody IgG1K, administered 100 mg subcutaneously every 4 weeks) for patients 12 years and older; and reslizumab (Cinquil™, monoclonal antibody IgG4K, given 3 mg/kg intravenously monthly) for adult patients aged 18 years and older. Both drugs are targeted biologic therapy for the treatment of poorly controlled asthma in patients with elevated blood eosinophils, shown to be effective at reducing exacerbations and improving lung function and symptom control.

Immunotherapy (discussed in more detail in section Immunotherapy) can be considered for children 5 years and older with allergic asthma who require steps 2, 3, and 4 therapy.

Continual monitoring is necessary to ensure that control of asthma is achieved and sustained. Once control is established, gradual reduction in therapy is appropriate and may help determine the minimum amount of medication necessary to maintain control. Regular follow-up visits with the clinician are important to assess the degree of control and consider appropriate adjustments in therapy. At each step, patients should be instructed to avoid or control exposure to allergens, irritants, or other factors that contribute to asthma severity.

Referral to an asthma specialist for consultation or comanagement is recommended if there are difficulties in achieving or maintaining control. For children younger than age 5 years, referral is recommended for moderate persistent asthma or if the patient requires step 3 or 4 care and should be considered if the patient requires step 2 care. For children 5 years and

older, consultation with a specialist is recommended if the patient requires step 4 care or higher and should be considered at step 3. Referral is also recommended if allergen immunotherapy or anti-IgE therapy is being considered.

3. Exercise-induced bronchospasm—Exercise-induced bronchospasm should be anticipated in all asthma patients. It typically occurs during or minutes after vigorous activity, reaches its peak 5–10 minutes after stopping the activity, and usually resolves over the next 20–30 minutes. Participation in physical activity should be encouraged in children with asthma, although the choice of activity may need to be modified based on the severity of illness, presence of other triggers such as cold air, and, rarely, confounding factors such as osteoporosis. Poor endurance or exercise-induced bronchospasm can be an indication of poorly controlled persistent asthma. If symptoms occur during usual play activities, either initiation of or a step-up in long-term therapy is warranted. However, for those with exercise-induced bronchospasm as the only manifestation of asthma despite otherwise being "well-controlled," treatment immediately prior to vigorous activity or exercise is usually effective. SABAs, leukotriene receptor antagonists, cromolyn, or nedocromil can be used before exercise. The combination of a SABA with either cromolyn or nedocromil is more effective than either drug alone. Salmeterol and formoterol may block exercise-induced bronchospasm for up to 12 hours (as discussed earlier). However, decreased duration of protection against exercise-induced bronchospasm can be expected with regular use. Montelukast may be effective up to 24 hours. An extended warm-up period may induce a refractory state, allowing patients to exercise without a need for repeat medications.

B. Acute Asthma

1. General measures—The most effective strategy in managing asthma exacerbations involves early recognition of warning signs and early treatment. For patients with moderate or severe persistent asthma or a history of severe exacerbations, this should include a written action plan. The latter usually defines the patient's green, yellow, and red zones based on symptoms (and PEFR for patients with poor symptom perception) with corresponding measures to take according to the state the patient is in. PEFR cut-off values are conventionally set as > 80% (green), 50%–80% (yellow), and < 50% (red) of the child's personal best. Prompt communication with the clinician is indicated with severe symptoms or a drop in peak flow or with decreased response to SABAs. At such times, intensification of therapy may include a short course of oral corticosteroids. The child should be removed from exposure to any irritants or allergens that could be contributing to the exacerbation.

2. Management at home—Early treatment of asthma exacerbations may prevent hospitalization and a life-threatening event. Initial treatment should be with a SABA such as albuterol or levalbuterol; 2–6 puffs from an MDI can be given every 20 minutes up to three times, or a single treatment can be given by nebulizer (0.05 mg/kg [minimum dose, 1.25 mg; maximum, 2.5 mg] of 0.5% solution of albuterol in 2–3 mL saline; or 0.075 mg/kg [minimum dose, 1.25 mg; maximum, 5 mg] of levalbuterol). If the response is good as assessed by sustained symptom relief or improvement in PEFR to over 80% of the patient's best, the SABA can be continued every 3–4 hours for 24–48 hours. Patients should be advised to seek medical care once excessive doses of bronchodilator therapy are used or for prolonged periods (eg, > 12 puffs/d for > 24 hours). Doubling the dose of inhaled corticosteroids is not proven sufficient to prevent worsening of exacerbations; however, recent evidence indicates that quadrupling the inhaled corticosteroid dose at the early sign of deterioration might be effective. If the patient does not completely improve from the initial therapy or PEFR falls between 50% and 80% predicted or personal best, the SABA should be continued, an oral corticosteroid should be added, and the patient should contact the physician urgently. If the child experiences marked distress or if PEFR persists at 50% or less, the patient should repeat the SABA immediately and go to the emergency department or call 911 or another emergency number for assistance.

3. Management in the office or emergency department—Functional assessment of the patient includes obtaining objective measures of airflow limitation with PEFR or FEV_1 and monitoring the patient's response to treatment; however, very severe exacerbations and respiratory distress may prevent the execution of lung function measurements using maximal expiratory maneuver. Flow-volume loops should be obtained to differentiate upper and lower airway obstruction, especially in patients with atypical presentation. Other tests may include oxygen saturation and blood gases. Chest radiographs are not recommended routinely but should be considered to rule out pneumothorax, pneumomediastinum, pneumonia, or lobar atelectasis. If the initial FEV_1 or PEFR is over 40%, initial treatment can be with a SABA by inhaler (albuterol, 4–8 puffs) or nebulizer (0.15 mg/kg of albuterol 0.5% solution; minimum dose, 2.5 mg), up to three doses in the first hour. Oxygen should be given to maintain oxygen saturation at greater than 90%. Oral corticosteroids (1–2 mg/kg/d in divided doses; maximum of 60 mg/d for children aged ≤ 12 years and 80 mg/d for those > 12 years) should be instituted if the patient responds poorly to therapy or if the patient has recently been on oral corticosteroids. Sensitivity to adrenergic drugs may improve after initiation of corticosteroids. For severe exacerbations or if the initial FEV_1 or PEFR is under 40%, initial treatment should be with a high-dose SABA plus ipratropium bromide, 1.5–3 mL every 20 minutes for 3 doses (each 3 mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol), then as needed by nebulizer. Continuous

albuterol nebulized treatments (0.5 mg/kg/hour for small and 10–15 mg/hour for older children) can be administered for evidence of persistent obstruction. Oxygen should be given to maintain oxygen saturation at greater than 90%, and systemic corticosteroids should be administered. For patients with severe exacerbation having no response to initial aerosolized therapy, or for those who cannot cooperate with or who resist inhalation therapy, adjunctive therapies such as intravenous magnesium sulfate (25–75 mg/kg up to 2 g in children) and heliox-driven albuterol nebulization should be considered. Epinephrine 1:1000 or terbutaline 1 mg/mL (both 0.01 mg/kg up to 0.3–0.5 mg) may be administered subcutaneously every 20 minutes for three doses; although the use of intravenous β_2-agonists is still unproven. For impending or ongoing respiratory arrest, patients should be intubated and ventilated with 100% oxygen, given intravenous corticosteroids, and admitted to an intensive care unit (ICU). Potential indications for ICU admission also include any FEV_1 or PEFR less than 25% of predicted that improves less than 10% after treatment or values that fluctuate widely. (See Asthma [life-threatening] in Chapter 14.) Further treatment is based on clinical response and objective laboratory findings. Hospitalization should be considered strongly for any patient with a history of respiratory failure.

4. Hospital management—For patients who do not respond to outpatient and emergency department treatment, admission to the hospital becomes necessary for more aggressive care and support. The decision to hospitalize should also be based on presence of risk factors for mortality from asthma, duration and severity of symptoms, severity of airflow limitation, course and severity of previous exacerbations, medication use at the time of the exacerbation, access to medical care, and home and psychosocial conditions. Fluids should be given at maintenance requirements unless the patient has poor oral intake secondary to respiratory distress or vomiting, because overhydration may contribute to pulmonary edema associated with high intrapleural pressures generated in severe asthma. Potassium requirements should be kept in mind because both corticosteroids and β_2-agonists can cause potassium loss. Moisturized oxygen should be titrated by oximetry to maintain oxygen saturation above 90%. Inhaled β_2-agonist should be continued by nebulization in single doses as needed or by continuous therapy, along with systemic corticosteroids (as discussed earlier). Ipratropium is no longer recommended during hospitalization. In addition, the role of methylxanthines in hospitalized children remains controversial. Antibiotics may be necessary to treat coexisting bacterial infection. Sedatives and anxiolytic agents are contraindicated in severely ill patients owing to their depressant effects on respiration. Chest physiotherapy is usually not recommended for acute exacerbations.

5. Patient discharge—Criteria for discharging patients home from the office or emergency department should include a sustained response of at least 1 hour to bronchodilator therapy with FEV_1 or PEFR greater than 70% of predicted or personal best and oxygen saturation greater than 90% in room air. Prior to discharge, the patient's or caregiver's ability to continue therapy and assess symptoms appropriately needs to be considered. Patients should be given an action plan for management of recurrent symptoms or exacerbations, and instructions about medications should be reviewed. The inhaled SABA and oral corticosteroids should be continued, the latter for 3–10 days. Finally, the patient or caregiver should be instructed about the follow-up visit, typically within 1 week. Hospitalized patients should receive more intensive education prior to discharge. Referral to an asthma specialist should be considered for all children with severe exacerbations or multiple emergency department visits or hospitalizations.

» Prognosis

Since the 1970s, morbidity rates for asthma have increased, but mortality rates may have stabilized. Mortality statistics indicate that a high percentage of deaths have resulted from underrecognition of asthma severity and undertreatment, particularly in labile asthmatic patients and in asthmatic patients whose perception of pulmonary obstruction is poor. Long-term outcome studies suggest that children with mild symptoms generally outgrow their asthma, while patients with more severe symptoms, marked airway hyperresponsiveness, and a greater degree of atopy tend to have persistent disease. Data from an unselected birth cohort from New Zealand showed more than one in four children had wheezing that persisted from childhood to adulthood or that relapsed after remission. Recent evidence suggests that early intervention with anti-inflammatory therapy does not alter the development of persistent asthma, and it is also unclear if such intervention or environmental control measures influence the natural history of childhood asthma. Nonetheless, the pediatrician or primary care provider together with the asthma specialist has the responsibility to optimize control and, it is hoped, reduce the severity of asthma in children. Interventions that can have long-term effects such as halting progression or inducing remission are necessary to decrease the public health burden of this common condition.

ALLERGIC RHINOCONJUNCTIVITIS

» General Considerations

Allergic rhinoconjunctivitis is the most common allergic disease and significantly affects quality of life as well as school performance and attendance. It frequently coexists with asthma, can impact asthma control, and is a risk factor for subsequent development of asthma. Over 80% of patients with asthma have rhinitis and 10%–14% of patients with rhinitis have asthma. About 80% of individuals with allergic rhinitis develop their symptoms before age 20 years. It is estimated that 13% of children have a physician diagnosis of allergic rhinitis. Prevalence of this disease increases during childhood, peaking at 15% in the postadolescent years. Although allergic rhinoconjunctivitis is more common in boys during early childhood, there is little difference in incidence between the sexes after adolescence. Race and socioeconomic status are not considered to be important factors.

The pathologic changes in allergic rhinoconjunctivitis are chiefly hyperemia, edema, and increased serous and mucoid secretions caused by mediator release, all of which lead to variable degrees of nasal obstruction and conjunctival injection, nasal and ocular pruritus, or nasal and ocular discharge. Ocular allergies can occur in isolation, but more commonly, they are in conjunction with nasal symptoms. This process may involve other structures, including the sinuses and possibly the middle ear. Inhalant allergens are primarily responsible for symptoms, but food allergens can cause symptoms as well. Children with allergic rhinitis seem to be more susceptible to—or at least may experience more symptoms from—upper respiratory infections, which, in turn, may aggravate the allergic rhinitis.

Allergic rhinoconjunctivitis has been classified as perennial, seasonal (hay fever), or episodic; however, there are areas where pollens and soil molds may be present year round while exposure to typical perennial allergens such as indoor furred animals may be intermittent. For this reason, the preferred terms are intermittent (ie, symptoms present < 4 days a week or for < 4 weeks) and persistent (ie, symptoms present > 4 days a week and for > 4 weeks). In addition, severity should be noted as mild (ie, without impairment or disturbance of sleep, daily activities, leisure, sport, school, or work, or without troublesome symptoms) or moderate-severe (ie, presence of one or more of the aforementioned). The major pollen groups in the temperate zones include trees (late winter to early spring), grasses (late spring to early summer), and weeds (late summer to early fall), but seasons can vary significantly in different parts of the country. Mold spores also cause seasonal allergic rhinitis, principally in the summer and fall. Seasonal allergy symptoms may be aggravated by coincident exposure to perennial allergens.

» Clinical Findings

A. Symptoms and Signs

Patients may complain of itching of the nose, eyes, palate, or pharynx and loss of smell or taste. Nasal itching can cause paroxysmal sneezing and epistaxis. Repeated rubbing of the nose (so-called allergic salute) may lead to a horizontal crease across the lower third of the nose. Nasal obstruction is associated with mouth breathing, nasal speech, allergic salute, and snoring. Nasal turbinates may appear pale blue and swollen with dimpling or injected with minimal edema. Typically, clear and thin

nasal secretions are increased, with anterior rhinorrhea, sniffling, postnasal drip, and congested cough. Nasal secretions often cause poor appetite, fatigue, and pharyngeal irritation. Conjunctival injection, tearing, periorbital edema, and infraorbital cyanosis (so-called allergic shiners) are frequently observed. Increased pharyngeal lymphoid tissue ("cobblestoning") from chronic drainage and enlarged tonsillar and adenoidal tissue may be present.

B. Laboratory Findings

Eosinophilia often can be demonstrated on smears of nasal secretions or blood. This is a frequent but nonspecific finding and may occur in nonallergic conditions. Although serum IgE may be elevated, measurement of total IgE is a poor screening tool owing to the wide overlap between atopic and nonatopic subjects. Skin testing to identify allergen-specific IgE is the most sensitive and specific test for inhalant allergies; alternatively, the Phadia ImmunoCAP assay, radioallergosorbent test (RAST), or other in vitro tests can be done for suspected allergens.

» Differential Diagnosis

Disorders that need to be differentiated from allergic rhinitis include infectious rhinosinusitis. Foreign bodies and structural abnormalities such as choanal atresia, marked septal deviation, nasal polyps, and adenoidal hypertrophy may cause chronic symptoms. Overuse of topical nasal decongestants may result in rhinitis medicamentosa (rebound congestion). Use of medications such as propranolol, clonidine, and some psychoactive drugs may cause nasal congestion. Illicit drugs such as cocaine can cause rhinorrhea. Spicy or hot foods may cause gustatory rhinitis. Nonallergic rhinitis with eosinophilia syndrome is usually not seen in young children. Vasomotor rhinitis is associated with persistent symptoms but without allergen exposure. Less common causes of symptoms that may be confused with allergic rhinitis include pregnancy, congenital syphilis, hypothyroidism, tumors, and cerebrospinal fluid rhinorrhea.

As in the differential diagnoses for allergic rhinitis, infectious conjunctivitis (secondary to viral, bacterial, or chlamydial etiology) can mimic allergic eye disorders. In this case, it typically develops in one eye first, and symptoms include stinging or burning sensation (rather than pruritus) with a foreign body sensation and eye discharge (watery, mucoid, or purulent). Nasolacrimal duct obstruction, foreign body, blepharoconjunctivitis, dry eye, uveitis, and trauma are other masqueraders of ocular allergy.

The other conditions which comprise allergic eye diseases, presenting with bilateral conjunctivitis, include atopic keratoconjunctivitis, vernal conjunctivitis, and giant papillary conjunctivitis. Except for giant papillary conjunctivitis, the three (allergic conjunctivitis, atopic keratoconjunctivitis, and vernal conjunctivitis) are associated with allergic sensitization. Atopic keratoconjunctivitis and vernal conjunctivitis are both vision-threatening. Atopic keratoconjunctivitis is rarely seen before late adolescence and it most commonly involves the lower tarsal conjunctiva. Ocular symptoms (itching, burning, and tearing) are more severe than in allergic conjunctivitis and persist all year round, with accompanying eyelid eczema with erythema and thick, dry scaling skin, which can extend to the periorbital skin and cheeks. Vernal conjunctivitis is characterized by giant papillae, described as cobblestoning, seen in the upper tarsal conjunctiva. It affects boys more often than girls and patients of Asian and African descent are more predisposed. It affects individuals in temperate areas, with exacerbations in the spring and summer months. In addition to severe pruritus which can be exacerbated by exposure to irritants, light, or perspiration, other accompanying signs and symptoms include photophobia, foreign body sensation, lacrimation, and presence of stringy or thick, ropey discharge, transient yellow-white points in the limbus (Trantas dots) and conjunctiva (Horner points), corneal "shield" ulcers, Dennie lines (prominent skin folds that extend in an arc form from the inner canthus beneath and parallel to the lower lid margin), and prominently long eyelashes. Giant papillary conjunctivitis is associated with exposure to foreign bodies such as contact lenses, ocular prostheses, and sutures. It is characterized by mild ocular itching, tearing, and mucoid discharge especially on awakening. Trantas dots, limbal infiltration, bulbar injection, and edema may also be found. One eye condition, contact allergy, which can also involve the conjunctivae especially when associated with use of topical medications, contact lens solutions, and preservatives, typically affects the eyelids.

» Complications

Sinusitis may accompany allergic rhinitis. Allergic mucosal swelling of the sinus ostia can obstruct sinus drainage, interfering with normal sinus function and predisposing to chronic mucosal disease. Nasal polyps due to allergy are unusual in children, and cystic fibrosis should be considered if they are present. Unlike vision-threatening complications associated with atopic keratoconjunctivitis and vernal conjunctivitis, allergic conjunctivitis manifests primarily with significant pruritus and discomfort affecting the patients' quality of life.

» Treatment

A. General Measures

The value of identification and avoidance of causative allergens cannot be overstated. Reducing indoor allergens through environmental control measures as discussed in the section on asthma can be very effective. Nasal saline irrigation may be useful. For ocular allergies, cold compresses and lubrication are also important.

B. Pharmacologic Therapy

Evidence-based clinical practice guidelines such as the Allergic Rhinitis and its Impact on Asthma (ARIA) which include the pharmacologic management of allergic rhinitis have been developed based on the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach. While ARIA recommends the use of intranasal corticosteroids for adults with allergic rhinitis, the use of the topical corticosteroids over oral antihistamines for children is suggested.

The treatment of mild intermittent rhinitis includes oral or intranasal H_1 antihistamines and intranasal decongestants (for < 10 days and not to be repeated more than twice a month). Oral decongestants are not usually recommended in children. Options for moderate-severe intermittent rhinitis are oral or intranasal antihistamines, oral H_1 antihistamines and decongestants, intranasal corticosteroids, and cromones. The same medication options are available for persistent rhinitis, but a stepwise approach is proposed both for treatment of mild and moderate-severe persistent rhinitis. For mild persistent rhinitis, reassessment after 2–4 weeks is recommended and treatment should be continued, with a possible reduction in intranasal corticosteroids, even if the symptoms have abated. If, however, the patient has persistent mild symptoms while on H_1 antihistamines or cromones, an intranasal corticosteroid is appropriate. For moderate-severe persistent disease, use of intranasal corticosteroids as first-line therapy is recommended. For severe nasal congestion, either a short 1- to 2-week course of an oral corticosteroid or an intranasal decongestant for less than 10 days may be added. If the patient improves, the treatment should last for at least 3 months or until the pollen season is over. If the patient does not improve within 2–4 weeks despite adequate compliance and use of medications, comorbidities such as nasal polyps, sinusitis, and significant allergen exposure should be considered, as well as the possibility of misdiagnosis. Once these are ruled out, options include increasing the dose of the intranasal corticosteroid, combination therapy with an H_1 antihistamine (particularly if major symptoms are sneezing, itching, or rhinorrhea), ipratropium bromide (if major symptom is rhinorrhea), or an oral H_1 antihistamine and decongestant. Referral to a specialist may be considered if the treatment is not sufficient.

For allergic rhinoconjunctivitis, topical nasal corticosteroids also reduce ocular symptoms, presumably through a naso-ocular reflex. For ocular allergies which persist or occur independent of rhinitis, pharmacologic treatment includes use of oral or topical antihistamines, topical decongestants, mast cell stabilizers, and anti-inflammatory agents. In general, topical ophthalmic drops should not be used with contact lenses. Topical decongestants relieve erythema, congestion, and edema but do not affect the allergic response. Combined therapy with an antihistamine and a vasoconstrictive agent is more effective than either agent alone. Topical medications with both antihistamine and mast cell blocking-properties provide the most benefits which incorporate fast-acting symptom relief and anti-inflammatory action. Refrigerating ophthalmic drops before use can provide soothing relief as well. However, children can get wary of eye drops and prefer oral preparations. Avoiding contamination by preventing the applicator tip from touching the eye or eyelid is important. Severe ocular allergy can be treated with topical, or rarely, oral corticosteroids. In such a case, a referral to an ophthalmologist is warranted, as these treatments can be associated with elevation of the intraocular pressure, viral infections, and cataract formation.

Allergen immunotherapy can be very effective in allergic rhinoconjunctivitis and may decrease the requirement for medications to control the symptoms in the long term.

1. Antihistamines—Antihistamines help control itching, sneezing, and rhinorrhea. Sedating antihistamines include diphenhydramine, chlorpheniramine, hydroxyzine, and clemastine. Sedating antihistamines may cause daytime somnolence and negatively affect school performance and other activities, especially driving. Second-generation antihistamines include loratadine, desloratadine, cetirizine, and fexofenadine. Cetirizine is approved for use in children aged 6–23 months (2.5 mg daily), 2–5 years (2.5–5.0 mg/d or 2.5 mg twice a day), and 6 years or older (5–10 mg/d). It is now available without a prescription. Loratadine is approved for use in children aged 2–5 years (5 mg/d) and 6 years or older (10 mg/d), and is available without prescription in tablet, rapidly disintegrating tablet, and liquid formulations. Desloratadine is approved for use in children aged 6–11 months (1 mg/d), 1–5 years (1.25 mg/d), and for 12 years and older (5 mg/d). Fexofenadine is approved for children aged 6–23 months (15 mg twice a day), 2–11 years (30 mg twice a day), and 12 years or older (60 mg twice a day or 180 mg once daily), and is also now available without a prescription. Levocetirizine (5 mg/d) is approved for children aged 6 years and older. Loratadine, fexofenadine, and cetirizine are available in combination with pseudoephedrine for patients aged 12 years or older, although regular use of these combination products is not recommended. Azelastine is available in nasal and ophthalmic formulations. Levocabastine and emedastine are available as ophthalmic preparations. They should not be used for treatment of contact lens–related irritation and caution should be implemented with concomitant use of soft contact lenses.

2. Mast cell stabilizers—Intranasal ipratropium can be used as adjunctive therapy for rhinorrhea. Intranasal cromolyn may be used alone or in conjunction with oral antihistamines and decongestants. It is most effective when used prophylactically, one to two sprays/nostril, four times a day. This dose may be tapered if symptom control is achieved. Rarely, patients complain of nasal irritation or burning. Most patients find complying with four-times-daily dosing difficult. Cromolyn is

also available in an ophthalmic solution. It can be used to treat giant papillary and vernal conjunctivitis. Other ophthalmic mast cell stabilizers include lodoxamide 0.1% solution (can be used for vernal keratoconjunctivitis as well), one to two drops four times a day; nedocromil sodium 2%, one to two drops two times a day; and pemirolast potassium 0.1%, one to two drops four times a day.

3. Decongestants and vasoconstrictor agents—Nasal α-adrenergic agents help to relieve nasal congestion and ophthalmic vasoconstrictors relieve ocular erythema, edema, and congestion. Topical nasal decongestants such as phenylephrine and oxymetazoline should not be used for more than 4 days for severe episodes because prolonged use may be associated with rhinitis medicamentosa. As with nasal decongestants, a rebound phenomenon (ie, conjunctivitis medicamentosa with hyperemia and stinging/burning) can occur with chronic use of ophthalmic vasoconstrictive agents such as naphazoline and tetrahydrozoline. Oral decongestants, including pseudoephedrine, phenylephrine, and phenylpropanolamine, are often combined with antihistamines or expectorants and cough suppressants in over-the-counter (OTC) cold medications, but there are no convincing data to support the use of oral decongestants for upper respiratory illnesses in children nor for regular use in patients with allergic rhinitis. They may cause insomnia, agitation, tachycardia, and, rarely, cardiac arrhythmias. Of note, the FDA has recommended the removal of phenylpropanolamine from all drug products due to a public health advisory concerning the risk of hemorrhagic stroke associated with its use.

4. Corticosteroids—Intranasal corticosteroid sprays are effective in controlling allergic rhinitis if used chronically. They are minimally absorbed in usual doses and are available in pressurized nasal inhalers and aqueous sprays. Mometasone and fluticasone furoate nasal sprays have been approved for use in children as young as age 2 years (one spray in each nostril once daily) and in children 12 years or older (two sprays/nostril once daily). Fluticasone propionate nasal spray is approved for children 4 years or older, and budesonide and triamcinolone nasal sprays are approved for those 6 years or older (one to two sprays/nostril once daily). Flunisolide is approved for ages 6–14 years (one spray/nostril three times a day or two sprays/nostril twice a day). Ciclesonide is approved for seasonal allergic rhinitis in children 6 years and older and those with perennial allergic rhinitis for children 12 years and older, two sprays in each nostril once daily. Side effects include nasal irritation, soreness, and bleeding, although epistaxis occurs commonly in patients with allergic rhinitis if corticosteroids are used chronically. Rarely, these drugs can cause septal perforation. Excessive doses may produce systemic effects, especially if used together with orally inhaled steroids for asthma. Onset of action is within hours, although clinical benefit is usually not observed for a week or more. They may be effective alone or together with antihistamines.

Use of oral or topical (eg, loteprednol etabonate) corticosteroids for the treatment of ocular allergy should be worked out in conjunction with an ophthalmologist due to potential complications mentioned in the preceding section.

5. Other pharmacologic agents—Montelukast is approved for perennial allergic rhinitis in children aged 6 months and older (4 mg/d for ages 6–23 months) and seasonal allergic rhinitis in children 2 years and older in doses as discussed in section Pharmacologic Therapy under Treatment, Chronic Asthma. Oral antihistamines are also available in combination with a decongestant. Ketorolac, a nonsteroidal anti-inflammatory drug (NSAID), is available as an ophthalmic solution but should be avoided in patients with aspirin or NSAID sensitivity and should be used with caution in those with complicated eye surgeries, corneal denervation or epithelial defects, ocular surface diseases, diabetes mellitus, or rheumatoid arthritis. Combination ophthalmic preparations are available. Both antazoline and pheniramine are antihistamine/vasoconstrictor formulations. Olopatadine 0.1%, epinastine 0.05% and ketotifen 0.025% ophthalmic solutions have antihistamine and mast cell–stabilizing actions and can be given to children older than age 3 years as one drop twice a day (8 hours apart) for olopatadine and every 8–12 hours for ketotifen, respectively. Ketotifen fumarate 0.025% is now available as an OTC ophthalmic medication. Olopatadine 0.2% is the first once-daily ophthalmic medication available for the treatment of ocular pruritus associated with allergic conjunctivitis.

C. Surgical Therapy

Surgical procedures, including turbinectomy, polypectomy, and functional endoscopic sinus surgery, are rarely indicated in allergic rhinitis or chronic hyperplastic sinusitis.

D. Immunotherapy

Allergen immunotherapy should be considered when symptoms are severe and due to unavoidable exposure to inhalant allergens, especially if symptomatic measures have failed. Immunotherapy is the only form of therapy that may alter the course of the disease. It should not be prescribed by sending the patient's serum to a laboratory where extracts based on in vitro tests are prepared for the patient (ie, the remote practice of allergy). Subcutaneous immunotherapy should be done in a facility where a physician prepared to treat anaphylaxis is present. Patients with concomitant asthma should not receive an injection if their asthma is not under good control (ie, peak flows preinjection are below 80% of personal best), and the patient should wait for 25–30 minutes after an injection before leaving the facility. Outcomes with single allergen immunotherapy show success

rates of approximately 80%. The optimal duration of therapy is unknown, but data suggest that immunotherapy for 3–5 years may have lasting benefit.

Sublingual immunotherapy has been developed for treatment of allergic rhinitis caused by pollens in both adults and children, and for allergic rhinitis caused by dust mites only in adults. (in other countries). Two recently FDA-approved sublingual immunotherapy are GRASTEKTM and RAGWITEKTM. GRASTEK may be prescribed for children (as young as 5 years) and adults who are allergic to grass pollen, while RAGWITEK may be prescribed for persons 18 through 65 years of age who are allergic to ragweed pollen. They are recommended to be taken daily for about 12 weeks before and throughout the grass or ragweed pollens season, respectively, over a period of at least 3 years for sustained effects.

» Prognosis

Allergic rhinoconjunctivitis associated with sensitization to indoor allergens tends to be protracted unless specific allergens can be identified and eliminated from the environment. In seasonal allergic rhinoconjunctivitis, symptoms are usually most severe from adolescence through mid-adult life. After moving to a region devoid of problem allergens, patients may be symptom-free for several years, but they can develop new sensitivities to local aeroallergens.

ATOPIC DERMATITIS

» General Considerations

Atopic dermatitis is a chronically relapsing inflammatory skin disease typically associated with respiratory allergy. Over half of patients with atopic dermatitis will develop asthma and allergic rhinitis. A subset of patients with atopic dermatitis has been shown to have mutations in the gene encoding filaggrin, a protein essential for normal epidermal barrier function. These patients have early-onset, more severe, and persistent disease. Mutations in filaggrin have also been associated with allergic sensitization as well as increased risk for asthma, but only in patients with atopic dermatitis. Atopic dermatitis may result in significant morbidity, leading to school absenteeism, occupational disability, and emotional stress. The disease presents in early childhood, with onset prior to age 5 years in approximately 90% of patients.

» Clinical Findings

A. Symptoms and Signs

Atopic dermatitis has no pathognomonic skin lesions or laboratory parameters. Diagnosis is based on the clinical features, including severe pruritus, a chronically relapsing course, and typical morphology and distribution of the skin lesions. Acute atopic dermatitis is characterized by intensely pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate; subacute atopic dermatitis by erythematous, excoriated, scaling papules; and chronic atopic dermatitis by thickened skin with accentuated markings (lichenification) and fibrotic papules. Patients with chronic atopic dermatitis may have all three types of lesions present concurrently. Patients usually have dry, "lackluster" skin. During infancy, atopic dermatitis involves primarily the face, scalp, and extensor surfaces of the extremities. The diaper area is usually spared. When involved, it may be secondarily infected with Candida. In older patients with longstanding disease, the flexural folds of the extremities are the predominant location of lesions.

B. Laboratory Findings

In patients with persistent disease despite appropriate treatment, consideration should be given for irritant, allergic, or infectious triggers. Elevated serum IgE levels can be demonstrated in 80%–85% of patients with atopic dermatitis, but have little clinical utility, although they may be helpful in interpreting specific IgE tests. Identification of allergens involves taking a careful history and performing selective immediate hypersensitivity skin tests or in vitro tests when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms in suspected food allergen–induced atopic dermatitis and should be confirmed with double-blind, placebo-controlled food challenges unless there is a coincidental history of anaphylaxis to the suspected food. Alternatively, specific IgE levels to milk, egg, peanut, and fish proteins have been established with the Phadia ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction. It is important for the clinician to understand that sIgE levels determine probability of reaction, but not type of reaction or severity. Clinicians should avoid extensive testing, as results may reflect elevated total serum with no clinical significance.

Exacerbation of atopic dermatitis can occur with exposure to aeroallergens such as house dust mites, and environmental control measures have been shown to result in clinical improvement. Patients can make specific IgE

directed at Staphylococcus aureus toxins secreted on the skin. Peripheral blood eosinophilia is a common finding. Routine skin biopsy does not differentiate atopic dermatitis from other eczematous processes but may be helpful in atypical cases. Tests for the most common filaggrin gene mutations may identify patients who would be at increased risk for more severe, persistent atopic dermatitis and be more likely to develop allergic sensitizations and asthma.

» Differential Diagnosis

Scabies can present as a pruritic skin disease. However, distribution in the genital and axillary areas and the presence of linear lesions as well as skin scrapings may help to distinguish it from atopic dermatitis. Seborrheic dermatitis may be distinguished by a lack of significant pruritus; its predilection for the scalp (so-called cradle cap); and its coarse, yellowish scales. Allergic contact dermatitis may be suggested by the distribution of lesions with a greater demarcation of dermatitis than in atopic dermatitis. Allergic contact dermatitis superimposed on atopic dermatitis may appear as an acute flare of the underlying disease. Nummular eczema is characterized by coin-shaped plaques. Although unusual in children, mycosis fungoides or cutaneous T-cell lymphoma has been described and is diagnosed by skin biopsy. Eczematous rash has been reported in patients with human immunodeficiency virus (HIV) infection. Other disorders that may resemble atopic dermatitis include Wiskott-Aldrich syndrome, severe combined immunodeficiency disease, hyper-IgE syndrome, immunodeficiency with DOCK8 mutations, IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome, zinc deficiency, phenylketonuria, and Letterer-Siwe disease (see Chapter 33).

» Complications

Ocular complications associated with atopic dermatitis can lead to significant morbidity. Atopic keratoconjunctivitis is always bilateral, and symptoms include itching, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis, and may result in visual impairment from corneal scarring (see Chapter 16). Keratoconus in atopic dermatitis is believed to result from persistent rubbing of the eyes in patients with atopic dermatitis and allergic rhinitis. Anterior subcapsular cataracts may develop during adolescence or early adult life.

Patients with atopic dermatitis have increased susceptibility to infection or colonization with a variety of organisms. These include viral infections with herpes simplex, molluscum contagiosum, and human papillomavirus. Of note, even a past history of atopic dermatitis is considered a contraindication for receiving the current smallpox (vaccinia) vaccine. Superimposed dermatophytosis may cause atopic dermatitis to flare. S aureus can be cultured from the skin of more than 90% of patients with atopic dermatitis, compared with only 5% of normal subjects. S aureus toxins can act as superantigens, contributing to persistent inflammation or exacerbations of atopic dermatitis. Community-acquired methicillin resistant S aureus (MRSA) has become an increasing problem, especially in patients treated with frequent antibiotics. Although recurrent staphylococcal pustulosis can be a significant problem in atopic dermatitis, invasive S aureus infections occur rarely and should raise the possibility of an immunodeficiency.

Patients with atopic dermatitis often have a nonspecific hand dermatitis. This is frequently irritant in nature and aggravated by repeated wetting.

Nutritional disturbances may result from unwarranted and extensive dietary restrictions imposed by providers or parents.

Poor academic performance and behavioral disturbances may be associated with uncontrolled itching, sleep loss, and poor self-image. Severe disease may lead to problems with social interactions and self-esteem.

» Treatment

A. General Measures

Avoidance of irritants such as detergents, chemicals, and abrasive materials as well as extremes of temperature and humidity is important in managing this disease. New clothing should be washed to reduce the content of formaldehyde and other chemicals. Because residual laundry detergent in clothing may be irritating, using a liquid rather than a powder detergent and adding an extra rinse cycle is beneficial. Occlusive clothing should be avoided in favor of cotton or cotton blends. Temperature in the home should be controlled to minimize sweating. Swimming is usually well tolerated; however, patients should shower and use a mild cleanser to remove chemicals such as chlorine or bromine, then apply a moisturizer or occlusive agent. Sunlight may be beneficial to some patients with atopic dermatitis, but nonsensitizing sunscreens should be used to avoid sunburn. Prolonged sun exposure can cause evaporative losses, overheating, and sweating, all of which can be irritating.

In children who have undergone controlled food challenges, milk, eggs, peanuts, wheat, soy, and fish account for approximately 90% of the food allergens that exacerbate atopic dermatitis. Avoidance of foods implicated in controlled challenges can lead to clinical improvement. Extensive elimination diets are almost never warranted.

In dust-mite allergic patients, environmental control measures aimed at reducing dust mite load may improve atopic dermatitis. These include use of dust mite–proof covers on pillows and mattresses, washing linens weekly in hot water, decreasing indoor humidity levels, minimizing dust collectors, and in some cases removing bedroom carpeting.

Evaluation by a behavioral health clinician may be of benefit when dealing with a pruritic, relapsing disease.

Relaxation, behavioral modification, or biofeedback training may help patients with habitual scratching. Patients with severe or disfiguring disease may require psychotherapy.

Clinicians should provide the patient and family with both general information and specific written skin care recommendations. The patient or parent should demonstrate an appropriate level of understanding to help ensure a good outcome. Educational pamphlets and a video about atopic dermatitis can be obtained from the National Eczema Association, a national nonprofit, patient-oriented organization, at: (800) 818-7546; http://www.nationaleczema.org.

B. Hydration

Patients with atopic dermatitis have evaporative losses due to a defective skin barrier, so soaking the affected area or bathing for 10–15 minutes in warm water, then applying an occlusive agent to retain the absorbed water, is an essential component of therapy. Oatmeal or baking soda added to the bath may feel soothing to certain patients but does not improve water absorption. Atopic dermatitis of the face or neck can be treated by applying a wet facecloth or towel to the involved area. The washcloth may be more readily accepted by a child if it is turned into a mask and also allows the older patient to remain functional (eg, reading during bath). Lesions limited to the hands or feet can be treated by soaking in a basin. Daily baths may be needed and increased to several times daily during flares of atopic dermatitis, while showers may be adequate for patients with mild disease. It is important to use an occlusive preparation within a few minutes after soaking the skin to prevent evaporation, which is both drying and irritating.

C. Moisturizers and Occlusives

An effective emollient combined with hydration therapy will help skin healing and can reduce the need for topical medications. Moisturizers are available as lotions, creams, and ointments. Lotions can be drying because of their evaporative effect especially in a non-humid climate. Preservatives and fragrances in lotions and creams may cause skin irritation. Moisturizers often need to be applied several times daily on a long-term basis and should be obtained in the largest size available. Crisco shortening can be substituted as an inexpensive alternative. Petroleum jelly (Vaseline) is an effective occlusive agent when used to seal in water after bathing. There are several topical nonsteroidal creams (eg, Atopiclair, MimyX, EpiCeram, Eletone) approved as medical devices (thus, currently requiring prescriptions) for relief and management of signs and symptoms of dermatoses. Their potential benefits need to be weighed against their cost.

D. Corticosteroids

Corticosteroids reduce the inflammation and pruritus in atopic dermatitis. Topical corticosteroids can decrease S aureus colonization. Systemic corticosteroids, including oral prednisone, should be avoided in the management of this chronic relapsing disease as the rapid clinical improvement may be associated with an equally dramatic disease flaring following discontinuation. Topical corticosteroids are available in a variety of formulations and range in potency, ranging from extremely high- to low-potency preparations (see Table 15–3). Choice of a particular product depends on the severity and distribution of skin lesions. Patients need to be counseled regarding the potency of their corticosteroid preparation and its potential side effects. In general, the least potent agent that is effective should be used. However, choosing a preparation that is too weak may result in persistence or worsening of the atopic dermatitis. Side effects include thinning of the skin, telangiectasias, bruising, hypopigmentation, acne, and striae, although these occur infrequently when low- to medium-potency topical corticosteroids are used appropriately. In contrast, use of potent topical corticosteroids for prolonged periods—especially under occlusion—may result in atrophic changes as well as systemic side effects. The face (especially the eyelids) and intertriginous areas are especially sensitive to corticosteroid side effects, and only low-potency preparations should be used routinely on these areas. Perioral dermatitis may occasionally be worsened by use of topical steroids. Because topical corticosteroids are commercially available in a variety of bases, including ointments, creams, lotions, oil, solutions, gels, foams, and even tape, there is no need to compound them. Ointments are most occlusive and in general provide better delivery of the medication while preventing evaporative losses. However, in a humid environment, creams may be better tolerated than ointments because the increased occlusion may cause itching or even folliculitis. Lotions, while easier to spread, can contribute to skin dryness and irritation. Solutions can be used on the scalp and hirsute areas, although they can be irritating, especially to open lesions. With clinical improvement, a less potent corticosteroid should be prescribed and the frequency of use decreased. Topical corticosteroids can be discontinued when inflammation resolves, but hydration and moisturizers need to be continued. Several topical steroids including fluticasone 0.05% cream and desonide 0.05% hydrogel have been approved in infants as young as 3 months of age for up to 28 days. Undertreatment remains a common problem due to caregiver concerns about potential side effects of topical corticosteroids along with inadequate prescription size.

E. Topical Calcineurin Inhibitors

Tacrolimus and pimecrolimus are non-steroidal immunomodulatory agents that are available in topical formulations. Tacrolimus ointment—0.03% for children 2–15 years of age and 0.1% for older patients—is approved for twice-daily short-term and intermittent long-term use in moderate to severe atopic dermatitis. Pimecrolimus 1% cream is

approved for patients 2 years of age or older who have mild to moderate atopic dermatitis. Local burning at the site of application, which occurs more frequently with tacrolimus ointment, has been the most common side effect, although this is usually a transient problem. As a precaution, patients should wear sunscreen with these medications drugs. In Europe, tacrolimus ointment is approved as twice weekly maintenance therapy for patients 2 years and older with a relapsing course after clearing up eczema with reevaluation of need for continued therapy after 12 months.

Although there is no evidence of a causal link between the use of topical calcineurin inhibitors and malignancy, in 2006, the FDA issued a boxed warning for these medications because of a lack of long-term safety data (see U.S. package inserts for Elidel [Novartis] and Protopic [Astellas]). The labeling states that these drugs are recommended as second-line treatment for short-term and noncontinuous chronic treatment and that their use in children younger than the age of 2 years is currently not recommended. Long term surveillance registries have been established for pediatric patients who had been treated with both topical tacrolimus and pimecrolimus.

F. Tar Preparations

Tar preparations are used primarily in shampoos and rarely as bath additives. Side effects associated with tar products include skin dryness or irritation, especially if applied to inflamed skin, and, less commonly, photosensitivity reactions and folliculitis.

G. Wet Dressings

Wet dressings are used together with hydration and topical corticosteroids for the treatment of severe atopic dermatitis. They can serve as an effective barrier against the persistent scratching that often undermines therapy. Total body dressings can be applied by using wet pajamas or long underwear with dry pajamas or a sweat suit on top. Hands and feet can be covered by wet tube socks with dry tube socks on top. Alternatively, wet gauze with a layer of dry gauze over it can be used and secured in place with an elastic bandage. Dressings can be removed when they dry out, usually after several hours, and are often best tolerated at bedtime. They should be considered an acute, not chronic intervention as overuse can result in chilling, skin maceration, or secondary infection.

H. Anti-Infective Therapy

Systemic antibiotic therapy may be important when treating atopic dermatitis secondarily infected with S aureus. For limited areas of involvement, a topical antibiotic such as mupirocin or retapamulin ointment may be effective. A first- or second-generation cephalosporin or semisynthetic penicillin is usually the first choice for oral therapy, as erythromycin-resistant organisms are fairly common. Overuse may result in colonization by methicillin-resistant S aureus. Bleach baths (6% sodium hypochlorite, ½ cup in a full tub of water) two times per week in combination with nasal mupirocin (twice daily for 5 consecutive days per month) may be helpful for patients with recurrent methicillin-resistant S aureus, although some patients find this treatment irritating.

Disseminated eczema herpeticum usually requires treatment with systemic acyclovir. Patients with recurrent cutaneous herpetic lesions can be given prophylactic oral acyclovir. Superficial dermatophytosis and Malassezia sympodialis infection can be treated with topical or (rarely) systemic antifungal agents.

I. Antipruritic Agents

Pruritus is usually the least well-tolerated symptom of atopic dermatitis. Oral antihistamines and anxiolytics may be effective owing to their tranquilizing and sedating effects and can be taken mostly in the evening to avoid daytime somnolence. Nonsedating antihistamines may be helpful for associated allergic symptoms, but are not usually effective in treating pruritus. Use of topical antihistamines and local anesthetics should be avoided because of potential sensitization.

J. Recalcitrant Disease

Patients who are erythrodermic or who appear toxic may need to be hospitalized. Hospitalization may also be appropriate for those with severe disease who fail outpatient management. Marked clinical improvement often occurs when the patient is removed from environmental allergens or stressors. In the hospital, compliance with therapy can be monitored, the patient and family can receive in-depth hands-on education, and controlled challenges can be conducted to help identify triggering factors.

Limited published data are available on use of cyclosporine in children treated with both continuous and intermittent therapy (5 mg/kg daily) for up to 1 year. Patients treated with this agent should have their dose titrated to the lowest effective dose after the disease is brought under control with appropriate monitoring, under the care of a specialist familiar with the drug. Mycophenolate mofetil has also been shown to be safe and effective in children with severe atopic dermatitis although this was a retrospective case series. Ultraviolet light therapy can be useful in a subset of patients with chronic recalcitrant atopic dermatitis under the supervision of a dermatologist.

K. Experimental and Unproved Therapies

Subcutaneous desensitization to dust mite allergen has been shown to improve atopic dermatitis in adult patients and one blinded, placebo-controlled study of sublingual desensitization in dust mite allergic children showed benefit in mild-moderate atopic dermatitis (currently not

FDA approved); however, further controlled trials are needed before this form of therapy can be recommended for atopic dermatitis in children. Treatment of atopic dermatitis with high-dose intravenous immunoglobulin and omalizumab is currently investigational. Although disturbances in the metabolism of essential fatty acids have been reported in patients with atopic dermatitis, controlled trials with fish oil and evening primrose have shown no clinical benefit.

» Prognosis

While many children, especially those with mild disease will outgrow their atopic dermatitis, patients with filaggrin gene mutations are more likely to have more persistent and severe disease. In addition, these patients appear to be the ones at greater risk for developing asthma and allergic sensitizations.

URTICARIA & ANGIOEDEMA

» General Considerations

Urticaria and angioedema are common dermatologic conditions, occurring at some time in up to 25% of the population. Urticarial lesions are arbitrarily designated as acute, lasting less than 6 weeks, or chronic, lasting more than 6 weeks. A history of atopy is common with acute urticaria or angioedema. In contrast, atopy does not appear to be a factor in chronic urticaria. Note that bradykinin-mediated hereditary angioedema is discussed in the immunodeficiency chapter (Chapter 33).

Mast cell degranulation, dilated venules, and dermal edema are present in most forms of urticaria or angioedema. The dermal inflammatory cells may be sparse or dense depending on the chronicity of the lesions. Mast cells are thought to play a critical role in the pathogenesis of urticaria or angioedema through release of a variety of vasoactive mediators. Mast cell activation and degranulation can be triggered by different stimuli, including cross-linking of Fc receptor–bound IgE by allergens or anti-FcεRI antibodies. Non–IgE-mediated mechanisms have also been identified, including complement anaphylatoxins (C3a, C5a), radiocontrast dyes, and physical stimuli. Chronic urticarial lesions have greater numbers of perivascular mononuclear cells, consisting primarily of T cells, and cutaneous mast cells.

The cause of acute urticaria can be identified in about half of patients and includes infectious allergens agents, including streptococci, mycoplasmas, hepatitis B virus, and Epstein-Barr virus and allergies to foods, aeroallergens, latex, drugs, or insect venoms. Urticaria or angioedema can occur after the administration of blood products or immunoglobulin from immune complex formation with complement activation, vascular alterations, and triggering of mast cells by anaphylatoxins. Opiate analgesics, polymyxin B, tubocurarine, and radiocontrast media can induce acute urticaria by direct mast cell activation. Urticaria and angioedema can also occur following ingestion of aspirin or nonsteroidal anti-inflammatory agents (see section Adverse Reactions to Drugs & Biologicals).

Inducible (physical) urticarias represent a heterogeneous group of disorders in which urticaria or angioedema is triggered by physical stimuli, including pressure, cold, heat, water, or vibrations. Dermographism is the most common form of physical urticaria, affecting up to 4% of the population and occurring at skin sites subjected to mechanical stimuli. Many physical urticarias are considered to be acute because the lesions are usually rapid in onset, with resolution within hours. However, symptoms can recur for months to years.

The cause of chronic spontaneous urticaria is usually not due to allergies and typically cannot be determined. It can be associated with autoimmunity, such as autoimmune thyroid disease, or the presence of basophil-activating IgG autoantibodies directed at the high-affinity receptor for IgE or at IgE.

» Clinical Findings

A. Symptoms and Signs

Cold-induced urticaria or angioedema can occur within minutes of exposure to a decreased ambient temperature or as the skin is warmed following direct cold contact. Systemic features include headache, wheezing, and syncope. If the entire body is cooled, as may occur during swimming, hypotension and collapse can occur. Two forms of dominantly inherited cold urticaria have been described. The immediate form is known as familial cold urticaria, in which erythematous macules appear rather than wheals, along with fever, arthralgias, and leukocytosis. The delayed form consists of erythematous, deep swellings that develop 9–18 hours after local cold challenge without immediate lesions.

In solar urticaria, which occurs within minutes after exposure to light of appropriate wavelength, pruritus is followed by morbilliform erythema and urticaria.

Cholinergic urticaria occurs after increases in core body and skin temperatures and typically develops after a warm bath or shower, exercise, or episodes of fever. Occasional episodes are triggered by stress or the ingestion of certain foods. The eruption appears as small punctate wheals surrounded by extensive areas of erythema. Rarely, the urticarial lesions

become confluent and angioedema develops. Associated features can include one or more of the following: headache, syncope, bronchospasm, abdominal pain, vomiting, and diarrhea. In severe cases, systemic anaphylaxis may develop.

In pressure urticaria or angioedema, red, deep, painful swelling occurs immediately or 4–6 hours after the skin has been exposed to pressure. The immediate form is often associated with dermographism. The delayed form, which may be associated with fever, chills, and arthralgias, may be accompanied by elevated erythrocyte sedimentation rate and leukocytosis. Lesions are frequently diffuse, tender, and painful rather than pruritic. They typically resolve within 48 hours.

B. Laboratory Findings

Laboratory tests are selected on the basis of the history and physical findings. Testing for specific IgE antibody to food or inhalant allergens or infections may be helpful in implicating a potential cause in acute urticaria particularly if the history is suggestive. Specific tests for inducible urticarias, such as an ice cube test or a pressure test, may be indicated. Intradermal injection of methacholine reproduces clinical symptoms locally in about one-third of patients with cholinergic urticaria. In chronic spontaneous urticaria, diagnostic tests should be limited and guided by the history. Evaluation for underlying disease may be indicated, including a complete blood count, erythrocyte sedimentation rate, biochemistry panel, or antithyroid antibodies. Intradermal testing with the patient's serum has been suggested as a method of detecting histamine-releasing activity, including autoantibodies (autologous serum skin test). In patients with well-characterized autoimmune urticaria, donor basophil and mast cell activation markers including CD63 and CD203c have been shown to be upregulated in patient serum. If the history or appearance of the urticarial lesions suggests vasculitis, a skin biopsy for immunofluorescence is indicated. Patient diaries occasionally may be helpful to determine the cause of recurrent hives. A trial of food or drug elimination may be considered.

» Differential Diagnosis

Urticarial lesions are usually easily recognized—the major dilemma is the etiologic diagnosis. Lesions of urticarial vasculitis typically last for more than 24 hours. "Papular urticaria" is a term used to characterize multiple papules from insect bites, found especially on the extremities, and is not true urticaria. Angioedema can be distinguished from other forms of edema because it is transient, asymmetrical, and nonpitting and does not occur predominantly in dependent areas. Hereditary angioedema is a rare autosomal dominant disorder caused by a quantitative or functional deficiency of C1-esterase inhibitor and characterized by episodic, frequently severe, nonpruritic angioedema of the skin, gastrointestinal tract, or upper respiratory tract (discussed in Chapter 33). Life-threatening laryngeal angioedema may occur. Rare autoinflammatory disorders with urticaria or urticaria-vasculitic-like lesions include cold-induced autoinflammatory syndrome, Muckle-Wells syndrome, and Schnitzler syndrome.

» Complications

In severe cases of cholinergic urticaria, systemic anaphylaxis may develop. In cold-induced disease, sudden cooling of the entire body as can occur with swimming can result in hypotension and collapse.

» Treatment

A. General Measures

The most effective treatment is identification and avoidance of the triggering agent. Underlying infection should be treated appropriately. Patients with inducible urticarias should avoid the relevant physical stimulus. Patients with cold urticaria should be counseled not to swim alone and prescribed autoinjectable epinephrine in case of generalized mast cell degranulation with immersion in cold water or other widespread cold exposures.

B. Antihistamines

For the majority of patients, H_1 antihistamines given orally or systemically are the mainstay of therapy. Antihistamines are more effective when given on an ongoing basis rather than after lesions appear. Second-generation H_1 antihistamines (discussed previously under Allergic Rhinoconjunctivitis) are long acting, show good tissue levels, are non- or minimally sedating at usual dosing levels, and lack anticholinergic effects. They are the preferred first line treatment for urticaria. If refractory at the recommended dose, second line treatment is increasing the dose up to 4-fold.

C. Corticosteroids

Although corticosteroids are usually not indicated in the treatment of acute or chronic urticaria, severe recalcitrant cases may require alternate-day or low-dose therapy in an attempt to diminish disease activity or short-term use to facilitate control with antihistamines, particularly in the setting of acute urticaria. High-dose chronic steroid use should be avoided. Systemic corticosteroids may also be needed in the treatment of urticaria or angioedema secondary to necrotizing vasculitis, an uncommon occurrence in patients with serum sickness or collagen-vascular disease.

D. Other Pharmacologic Agents

Third-line treatment for chronic spontaneous urticarial is the addition of a leukotriene-receptor antagonist, cyclosporine A, or omalizumab. Limited studies suggest that some patients may benefit from treatment with a leukotriene-receptor antagonist. Cyclosporine has been shown to be effective in multiple trials of severe chronic urticaria, but

it requires blood pressure and renal function monitoring. Omalizumab has been demonstrated to be effective in antihistamine resistant urticaria in case series and in a double-blind placebo-controlled trial. It obtained FDA approval for chronic urticaria in patients 12 years old or older in 2014. Dosing is 150 mg or 300 mg subcutaneously every 4 weeks. Treatment of chronic urticaria with hydroxychloroquine, azathioprine, sulfasalazine, dapsone, colchicine, and intravenous immune globulin should be considered investigational.

» Prognosis

Spontaneous remission of urticaria and angioedema is frequent, but some patients have a prolonged course, especially those with inducible urticaria. Reassurance is important, because this disorder can cause significant frustration. Periodic follow-up is indicated, particularly for patients with laryngeal edema, to monitor for possible underlying cause.

Maurer Saini SS et al: Efficacy and safety of omalizumab in patients with chronic idiopathic/spontaneous urticaria who remain symptomatic on h1 antihistamines: a randomized, placebo-controlled study. J Invest Dermatol 2015;135:67–75 [PMID: 25046337].

ANAPHYLAXIS

» General Considerations

Anaphylaxis is an acute life-threatening clinical syndrome that occurs when large quantities of inflammatory mediators are rapidly released from mast cells and basophils after exposure to an allergen in a previously sensitized patient. Anaphylactoid reactions mimic anaphylaxis but are not mediated by IgE antibodies. They may be mediated by anaphylatoxins such as C3a or C5a or through nonimmune mast cell degranulating agents. Some of the common causes of anaphylaxis or anaphylactoid reactions are listed in Table 38–8. Idiopathic anaphylaxis by definition has no recognized external cause. The clinical history is the most important tool in making the diagnosis of anaphylaxis.

» Clinical Findings

A. Symptoms and Signs

The history is the most important tool to determine whether a patient has had anaphylaxis. The symptoms and signs of anaphylaxis depend on the organs affected. Onset typically occurs within minutes after exposure to the offending agent and can be short-lived, protracted, or biphasic, with recurrence after several hours despite treatment.

Table 38–8. Common causes of systemic allergic and pseudoallergic reactions.

Causes of anaphylaxis
Drugs
Antibiotics
Anesthetic agents
Foods
Peanuts, tree nuts, shellfish, and others
Biologicals
Latex
Insulin
Allergen extracts
Antisera
Blood products
Enzymes
Monoclonal antibodies (eg, omalizumab)
Insect venoms
Radiocontrast media
Aspirin and other nonsteroidal anti-inflammatory drugs
Anesthetic agents
Idiopathic

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (eg, generalized hives, pruritus or flushing, swollen lips-tongue-uvula) and at least one of the following:
   a. Respiratory compromise (eg, dyspnea, wheeze, bronchospasm, stridor, reduced peak expiratory flow, hypoxemia)
   b. Reduced blood pressure or associated symptoms of end-organ dysfunction (eg, hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
   a. Involvement of the skin-mucosal tissue (eg, generalized urticaria, itch-flush, swollen lips-tongue-uvula)
   b. Respiratory compromise (eg, dyspnea, wheeze, bronchospasm, stridor, reduced PEFR, hypoxemia)
   c. Reduced blood pressure or associated symptoms (eg, hypotonia [collapse], syncope, incontinence)
   d. Persistent gastrointestinal symptoms (eg, crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to a known allergen for that patient (minutes to several hours):
   a. Infants and children: low systolic blood pressure (age specific) or greater than 30% decrease in systolic pressure
   b. Low systolic blood pressure in children, defined as less than 70 mm Hg in those aged from 1 month to 1 year, less than (70 mm Hg + [2 × age]) in those 1–10 years of age, and less than 90 mm Hg in those 11–17 years

B. Laboratory Findings

An absence of laboratory findings does not rule out anaphylaxis. Tryptase released by mast cells can be measured in the serum within 3 hours of onset of the reaction and may be helpful when the diagnosis of anaphylaxis is in question. However, tryptase levels are often normal, particularly in individuals with food-induced anaphylaxis. Elevation of serum creatine kinase, aspartate aminotransferase, and lactic dehydrogenase may be seen with myocardial involvement. Electrocardiographic abnormalities may include ST-wave depression, bundle branch block, and various arrhythmias. Arterial blood gases may show hypoxemia, hypercapnia, and acidosis. The chest radiograph may show hyperinflation.

» Differential Diagnosis

Although shock may be the only sign of anaphylaxis, other diagnoses should be considered, especially in the setting of sudden collapse without typical allergic findings. Other causes of shock along with cardiac arrhythmias must be ruled out (see Chapters 12 and 14). Respiratory failure associated with asthma may be confused with anaphylaxis. Mastocytosis, hereditary angioedema, scombroid poisoning, vasovagal reactions, vocal cord dysfunction, and anxiety attacks may cause symptoms mistaken for anaphylaxis.

» Complications

Depending on the organs involved and the severity of the reaction, complications may vary from none to aspiration pneumonitis, acute tubular necrosis, bleeding diathesis, or sloughing of the intestinal mucosa. With irreversible shock, heart and brain damage can be terminal. Risk factors for fatal or near-fatal anaphylaxis include age (adolescents and young adults), reactions to peanut or tree nuts, associated asthma, strenuous exercise, and use of medications such as β-blockers.

» Prevention

Strict avoidance of the causative agent is extremely important, and effort to determine its cause should be made, beginning with a thorough history. Typically, there is a strong temporal relationship between exposure and onset of symptoms. With exercise-induced anaphylaxis, patients should be instructed to exercise with another person and to stop exercising at the first sign of symptoms. If prior ingestion of food has been implicated, eating within 4 hours—perhaps up to 12 hours—before exercise should be avoided. Patients with a history of anaphylaxis should carry epinephrine for self-administration, preferably in the form of an autoinjector (eg, Auvi-Q or EpiPen in 0.15- and 0.3-mg doses), and they and all caregivers should be instructed on its use. When epinephrine autoinjectors are unavailable or unaffordable, some patients have been provided with unsealed syringes containing premeasured epinephrine doses, but this is not the recommended form since it needs to be replaced every few months due to lack of stability and the use of a syringe is more unwieldy in an emergent situation. They should also carry an oral antihistamine such as diphenhydramine or cetirizine, preferably in liquid or chewable preparation to hasten absorption, but epinephrine should be considered as the first-line treatment of anaphylaxis. Patients with idiopathic anaphylaxis may require prolonged treatment with oral corticosteroids. Specific measures for dealing with food, drug, latex, and insect venom allergies as well as radiocontrast media reactions are discussed in the next sections.

» Treatment

A. General Measures

Anaphylaxis is a medical emergency that requires rapid assessment and treatment. Exposure to the triggering agent should be discontinued. Airway patency should be maintained and blood pressure and pulse monitored. Simultaneously and promptly, emergency medical services or a call for help to a resuscitation team should be made. The patient should be placed in a supine position with the legs elevated unless precluded by shortness of breath or emesis. Oxygen should be delivered by mask or nasal cannula with pulse oximetry monitoring. If the reaction is secondary to a sting or injection into an extremity, a tourniquet may be applied proximal to the site, briefly releasing it every 10–15 minutes.

B. Epinephrine

Epinephrine is the treatment of choice for anaphylaxis. Epinephrine 1:1000, 0.01 mg/kg to a maximum of 0.5 mg in adults and 0.3 mg in children, should be injected intramuscularly in the midanterolateral thigh without delay. This dose may be repeated at intervals of 5–15 minutes as necessary for controlling symptoms and maintaining blood pressure. If the precipitating allergen has been injected intradermally or subcutaneously, absorption may be delayed by giving 0.1 mL of epinephrine subcutaneously at the injection site unless the site is a digit. There is no precisely established dosing regimen for intravenous epinephrine in anaphylaxis, but a 5–10 mcg intravenous bolus for hypotension and 0.1–0.5 mg intravenously for cardiovascular collapse has been suggested.

C. Antihistamines

Diphenhydramine, an H_1-blocker, 1–2 mg/kg up to 50 mg, can be given orally, intramuscularly or intravenously. Intravenous antihistamines should be infused over a period of 5–10 minutes to avoid inducing hypotension. Alternatively in young patients, cetirizine 0.25 mg/kg to a maximum dose of 10 mg could be given orally, as it was shown to have a longer duration of action and reduced sedation profile.

Addition of ranitidine, an H_2-blocker, 1 mg/kg up to 50 mg intravenously, may be more effective than an H_1-blocker alone, especially for hypotension, but histamine blockers should be considered second-line treatment for anaphylaxis.

D. Fluids

Treatment of persistent hypotension despite epinephrine requires restoration of intravascular volume by fluid replacement, initially with a crystalloid solution, 20–30 mL/kg in the first hour.

E. Bronchodilators

Nebulized β_2-agonists such as albuterol 0.5% solution, 2.5 mg (0.5 mL) diluted in 2–3 mL saline, or levalbuterol, 0.63 mg or 1.25 mg, may be useful for reversing bronchospasm. Intravenous methylxanthines are generally not recommended because they provide little benefit over inhaled β_2-agonists and may contribute to toxicity.

F. Corticosteroids

Although corticosteroids do not provide immediate benefit, when given early they may prevent protracted or biphasic anaphylaxis. Intravenous methylprednisolone, 50–100 mg (adult) or 1 mg/kg, maximum 50 mg (child), can be given every 4–6 hours. Oral prednisone, 1 mg/kg up to 50 mg, might be sufficient for less severe episodes.

G. Vasopressors

Hypotension refractory to epinephrine and fluids should be treated with intravenous vasopressors such as noradrenaline, vasopressin, or dopamine (see Chapter 14).

H. Observation

The patient should be monitored after the initial symptoms have subsided, because biphasic or protracted anaphylaxis can occur despite ongoing therapy. Biphasic reactions occur in 1%–20% of anaphylactic reactions, but no reliable clinical predictors have been identified. Observation periods should be individualized based on the severity of the initial reaction, but a reasonable time for observation is 4–6 hours in most patients, with prolonged observation or admission for severe or refractory symptoms.

» Prognosis

Anaphylaxis can be fatal. In two reports describing children, adolescents, and adults who died from food-induced anaphylaxis (eg, from peanuts, tree nuts, fish, shellfish, and milk) over the past 12 years, treatment with epinephrine was delayed for more than 1 hour after reaction onset, as it was not readily accessible in the majority of subjects. The prognosis, however, is good when signs and symptoms are recognized promptly and treated aggressively, and the offending agent is subsequently avoided. Exercise-induced and idiopathic anaphylaxis may be recurrent. Because accidental exposure to the causative agent may occur, patients, parents, and caregivers must be prepared to recognize and treat anaphylaxis (have an anaphylaxis action plan).

ADVERSE REACTIONS TO DRUGS & BIOLOGICALS

Patients or caregivers often label any adverse drug reaction as an "allergy." Adverse drug reactions are any undesirable and unintended response elicited by a drug. Allergic or hypersensitivity drug reactions are adverse reactions involving immune mechanisms. Although hypersensitivity reactions account for only 5%–10% of all adverse drug reactions, they are the most serious, with 1:10,000 resulting in death. Other causes of adverse drug reactions include idiosyncratic reactions, overdosage, pharmacologic side effects, nonspecific release of pharmacologic effector molecules, or drug interactions. Clinicians can report adverse drug reactions and get updated information on drugs, vaccines, and biologics at the FDA's MedWatch website.

1. Antibiotics

Antibiotics constitute the most frequent cause of allergic drug reactions. Amoxicillin, trimethoprim–sulfamethoxazole, and ampicillin are the most common causes of cutaneous drug reactions.

The penicillins and other β-lactam antibiotics, including cephalosporins, carbacephems, carbapenems, and monobactams, share a common β-lactam ring structure and a marked propensity to couple to carrier proteins. Penicilloyl is the predominant allergenic metabolite of penicillin and is called the major determinant. The other penicillin metabolites are present in low concentrations and are referred to as minor determinants. Sulfonamide reactions are mediated presumably by a reactive metabolite (hydroxylamine) produced by cytochrome P-450 oxidative metabolism. Slow acetylators appear to be at increased risk. Other risk factors for drug reactions include previous exposure, previous reaction, age (20–49 years), route (parenteral), and dose of administration (high, intermittent). Atopy does not predispose to development of a reaction, but atopic individuals have more severe reactions.

Immunopathologic reactions to antibiotics include type I (IgE-mediated) reactions, Type II (cytotoxic) reactions such as drug-induced hemolytic anemia or thrombocytopenia,

Type III (immune complex) reactions such as serum sickness, and Type IV (T-cell–mediated) reactions such as allergic contact dermatitis. Immunopathologic reactions not fitting into the types I–IV classification include interstitial nephritis, pneumonitis, hepatitis, eosinophilia, fixed drug eruption, acute generalized exanthematous pustulosis (AGEP), Stevens-Johnson syndrome, exfoliative dermatitis, and maculopapular exanthemas. The prevalence of morbilliform rashes in patients given ampicillin increases significantly during Epstein-Barr virus and cytomegalovirus infections or with acute lymphoblastic anemia, 69%–100% compared to 5%–9%. Serum sickness–like reactions resemble type III reactions, although immune complexes are not documented; β-lactams, especially cefaclor, and sulfonamides have been implicated most often. The incidence of "allergic" cutaneous reactions to trimethoprim–sulfamethoxazole in patients with AIDS has been reported to be as high as 70%. The mechanism is thought to relate to severe immune dysregulation, although it may be due to glutathione deficiency resulting in toxic metabolites.

» Clinical Findings

A. Symptoms and Signs

IgE-mediated reactions can cause pruritus, erythema, urticaria, angioedema, bronchospasm, or anaphylaxis within 1 hour of the dose. Serum sickness is characterized by fever, rash, lymphadenopathy, myalgias, and arthralgias. Cytotoxic drug reactions can result in symptoms and signs associated with the underlying anemia or thrombocytopenia. Delayed-type hypersensitivity may cause contact dermatitis.

B. Laboratory Findings

Skin testing is useful for evaluation of IgE-mediated drug allergies, particularly of beta-lactam antibiotics where it has been most validated. Approximately 80% of patients with a history of penicillin allergy will have negative skin tests. Use of both the major determinant, Pre-Pen (penicilloyl-polylysine) and penicillin G or suspect penicillin, increases sensitivity to about 95%. Not using the minor determinant mixture, which is not commercially available, in skin testing can result in failure to predict potential anaphylactic reactions in up to 20% of those who test negative to both. Therefore, all patients who have negative skin testing should undergo drug provocation test for the final diagnosis. Regarding cross-reactivity between penicillins and cephalosporins, the R-side chains of the penicillins and cephalosporins have been implicated in most allergic reactions to these medications. Skin prick testing can be performed to cephalosporins, but as a negative skin test would not exclude sensitivity to a potentially relevant metabolite, drug provocation test would need to be performed. Carbacephems (loracarbef) and carbapenems (imipenem) are thought to have a high degree of cross-reactivity with penicillin, although recent prospective studies suggest an incidence of cross-reactivity on skin testing of approximately 1%. Skin testing can be performed and, if negative, drug provocation test should be performed. Monobactams (aztreonam) contain a monocyclic rather than bicyclic ring structure, and limited data suggest that aztreonam can be safely administered to most penicillin-allergic subjects. In contrast, administration of aztreonam to a patient with ceftazidime allergy may be associated with increased risk of allergic reaction due to similarity of side chains.

Skin testing for non–β-lactam antibiotics is less reliable, because the relevant degradation products are for the most part unknown or multivalent reagents are unavailable.

Solid-phase in vitro immunoassays for IgE to penicillins are available for identification of IgE to penicilloyl, but are considerably less sensitive than skin testing and the predictive values are not known.

For nonimmediate reactions, skin testing can be performed, but with an additional late intradermal reading before proceeding to drug provocation test. In the case of contact sensitivity reactions to topical antibiotics, a 48-hour patch test can be useful.

» Treatment

A. General Measures

Withdrawal of the implicated drug is usually a central component of management. Acute IgE-mediated reactions such as anaphylaxis, urticaria, and angioedema are treated according to established therapeutic guidelines that include the use of epinephrine, H_1- and H_2-receptor blocking agents, volume replacement, and systemic corticosteroids. Antibiotic-induced immune cytopenias can be managed by withdrawal of the offending agent or reduction in dose. Drug-induced serum sickness can be suppressed by drug withdrawal, antihistamines, and corticosteroids. Contact allergy can be managed by avoidance and treatment with antihistamines and topical corticosteroids. Reactions such as toxic epidermal necrolysis and Stevens-Johnson syndrome require immediate drug withdrawal and supportive care.

B. Alternative Therapy

If possible, subsequent therapy should be with an alternative drug that has therapeutic actions similar to the drug in question but with no immunologic cross-reactivity.

C. Desensitization

Administering gradually increasing doses of an antibiotic either orally or parentally over a period of hours to days may be considered if alternative therapy is not acceptable. This should be done only by a physician familiar with desensitization, typically in an intensive care setting. Of note,

desensitization is only effective for the course of therapy for which the patient was desensitized, unless maintained on a chronic prophylactic dose of the medication as patients revert from a desensitized to allergic state after the drug is discontinued. In addition, desensitization does not reduce or prevent non–IgE-mediated reactions. Patients with Stevens-Johnson syndrome should not be desensitized because of the high mortality rate.

» Prognosis

The prognosis is good when drug allergens are identified early and avoided. Stevens-Johnson syndrome and toxic epidermal necrolysis may be associated with a high mortality rate.

2. Latex Allergy

» General Considerations

Allergy to latex and rubber products is common among health care workers and children with spina bifida. The combination of atopy and frequent exposure seems to synergistically increase the risk of latex hypersensitivity. Latex sensitization and reactions decrease with the use of latex-free gloves and medical equipment.

Nonmedical sources of latex are also common and include balloons, toys, rubber bands, erasers, condoms, and shoe soles. Pacifiers and bottle nipples have also been implicated as sources of latex allergen, although these products are molded rather than dipped, and allergic reactions to molded products are less common. Latex-allergic patients and their caregivers must be continuously vigilant for hidden sources of exposure.

» Clinical Findings

A. Symptoms and Signs

Localized pruritus and urticaria occur after cutaneous contact; conjunctivitis and rhinitis can result from aerosol exposure or direct facial contact. Systemic reactions, including bronchospasm, laryngospasm, and hypotension, may occur with more substantial exposure or in extremely sensitive individuals. Finally, vascular collapse and shock leading to fatal cardiovascular events may occur. Intraoperative anaphylaxis represents a serious manifestation of latex allergy.

Allergic contact dermatitis to rubber products typically appears 24–48 hours after contact. The primary allergens include accelerators and antioxidants used in the manufacturing process. The diagnosis is established by patch testing. Shoe soles are an important source of exposure. The skin lesions appear primarily as a patchy eczema on exposed surfaces, although reactions can become generalized.

B. Laboratory Findings

Epicutaneous prick testing is a rapid, inexpensive, and sensitive test that detects the presence of latex-specific IgE on skin mast cells although a standardized antigen is not yet commercially available. Reports of life-threatening anaphylactic events have been associated with skin testing to latex, and intradermal testing may be especially dangerous.

When compared with a history of latex-induced symptoms or positive skin tests, the sensitivity of immunoassays testing for latex antigens ranges from 50% to 100% with specificity between 63% and 100%. These broad ranges may reflect the patient population studied and the source of latex antigen as well as the assay employed. A positive immunoassay test to latex in the presence of a highly suggestive latex allergy history is useful and may circumvent the potential concerns associated with prick skin testing in certain patients. Patch testing with standardized T.R.U.E. Test or other sources of antigens can identify antigens used in the manufacturing of latex products that can cause allergic contact dermatitis.

Cross-reactivity has been demonstrated between latex and a number of other antigens such as foods. Banana, avocado, kiwi, and chestnut have been found to be antigenically similar to latex both immunologically and clinically.

» Treatment

Avoidance remains the cornerstone of treatment for latex allergy. Patients identified as being allergic to latex may need to have a personal supply of vinyl or latex-free gloves for use when visiting a physician or dentist. “Hypoallergenic gloves” are poorly classified with respect to their ability to induce IgE-mediated reactions; the FDA currently uses this term to designate products that have a reduced capacity to induce contact dermatitis. Nonlatex gloves include nitrile and vinyl ones. A glove made from guayule latex has been approved by the FDA. Autoinjectable epinephrine and medical identification bracelets may be prescribed for latex-allergic patients along with avoidance counseling.

Prophylactic premedication of latex-allergic individuals has been used in some surgical patients at high risk for latex allergy. The rationale for this therapy is derived from the pretreatment protocols developed for iodinated radiocontrast media and anesthetic reactions. Although there has been some success using this regimen, anaphylaxis has occurred despite pretreatment. This approach should not substitute for careful avoidance measures.

» Prognosis

Owing to the ubiquitous nature of natural rubber, the prognosis is guarded for patients with severe latex allergy. Chronic exposure to airborne latex particles may lead to chronic asthma. Chronic dermatitis can lead to functional disability.

3. Vaccines

Mumps-measles-rubella (MMR) vaccine has been shown to be safe in egg-allergic patients (although rare reactions to gelatin or neomycin can occur). Many studies have shown that egg-allergic children can safely receive influenza vaccine injection as a single full dose; skin testing is not necessary. Egg-allergic patients should be observed for 30 minutes after receiving influenza vaccine and if there are concerns about administration, they should be referred to an allergist. Local reactions are not associated with a higher rate of systemic allergic reactions.

4. Radiocontrast Media

Non–IgE-mediated anaphylactoid reactions may occur with radiocontrast media with up to a 30% reaction rate on reexposure. Management involves using a low-molarity agent and premedication with prednisone, diphenhydramine, and possibly an H_2-blocker.

5. Insulin

Approximately 50% of patients receiving insulin have positive skin tests, but IgE-mediated reactions are rare. Insulin resistance is mediated by IgG. If less than 24 hours has elapsed after an allergic reaction to insulin, do not discontinue insulin but rather reduce the dose by one-third, then increase by 2–5 units per injection. Skin testing and desensitization are necessary if the interval between the allergic reaction and subsequent dose is greater than 24 hours.

6. Local Anesthetics

Less than 1% of reactions to local anesthetics are IgE-mediated. Management involves selecting a local anesthetic from another class. Esters of benzoic acid include benzocaine and procaine; amides include lidocaine and mepivacaine. Alternatively, the patient can be skin tested with the suspected agent, followed by a provocative challenge. To rule out paraben sensitivity, skin testing can be done with 1% lidocaine from a multidose vial.

7. Aspirin & Other Nonsteroidal Anti-Inflammatory Drugs

Adverse reactions to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) include urticaria and angioedema; rhinosinusitis, nasal polyps, and asthma (aspirin-exacerbated respiratory disease [AERD]); anaphylactoid reactions; and NSAID-related hypersensitivity pneumonitis. All NSAIDs inhibiting cyclooxygenase (COX) cross-react with aspirin. Cross-reactivity between aspirin and tartrazine (yellow dye No. 5) has not been substantiated in controlled trials. No skin test or in vitro test is available to diagnose aspirin sensitivity. Oral challenge can induce severe bronchospasm in AERD patients. Aspirin desensitization can be performed to ameliorate the symptoms of AERD. Desensitization and cross-desensitization to NSAIDs can be achieved in most patients and maintained for a long term. Leukotriene-receptor antagonists or 5-lipoxygenase inhibitors attenuate the reaction to aspirin challenge and may be beneficial adjunct treatment in aspirin-sensitive asthmatic patients. COX-2 inhibitors are tolerated by patients with AERD.

8. Biological Agents

In recent years, a growing number of biological agents have become available for the treatment of autoimmune, neoplastic, cardiovascular, infectious, and allergic diseases, among others. Their use may be associated with a variety of adverse reactions, including increased risk of infections, neurologic defects, autoimmune syndromes, cardiovascular effects, and hypersensitivity reactions. Desensitization may be possible if there is no other good alternative in those patients who have developed an allergy to these medications.

9. Hypersensitivity to Retroviral Agents

Adverse drug reactions are being reported with increasing frequency to antiretroviral agents, including reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors. Hypersensitivity to abacavir is a well-described, multiorgan, potentially life-threatening reaction that occurs in HIV-infected children. The reaction is independent of dose with onset generally within 9–11 days of initiation of drug therapy. Susceptibility appears to be conferred by the HLA-B*5701 allele with a positive predictive value of > 70% and negative predictive value of 95%–98%. Genetic screening would be cost-effective in Caucasians, but not in African or Asian populations as their HLA-B*5701 allele frequency is < 1%.

10. Adverse Reactions to Chemotherapeutic Agents

A number of chemotherapeutic agents, including monoclonal antibodies, have been implicated in hypersensitivity reactions. Rapid desensitization to unrelated agents, including carboplatin, paclitaxel, and rituximab, has been reported. This 12-step protocol appeared to be successful in both IgE- and non–IgE-mediated reactions.

FOOD ALLERGY

» General Considerations

Food allergy is defined as an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. Food allergy affects approximately 8% of young children and 3%–4% of adults. The most common IgE-associated food allergens in children are milk egg, peanut, soy, wheat, tree nuts, fish, and shellfish. In older patients, fish, shellfish, peanut, and tree nuts are most often involved in allergic reactions, and may be lifelong allergies. The highest prevalence of food allergy is found in children with moderate to severe atopic dermatitis, with approximately 35% affected, whereas chronic conditions such as urticaria and asthma are much less likely due solely to food allergy. Food allergy can be caused by non–IgE-mediated mechanisms, in conditions such as food protein–induced enterocolitis (FPIES) or proctocolitis. It can also be caused by mixed IgE- and non–IgE-mediated mechanisms, as in eosinophilic esophagitis and gastroenteritis (Table 38–9).

Some adverse reactions diagnosed by patients or physicians as food allergy involve non–immune-mediated mechanisms such as pharmacologic and metabolic mechanisms, reactions to food toxins, or intolerances (eg, lactose intolerance). These will not be covered in this chapter.

Table 38–9. Food allergy disorders.

IgE-mediated
Gastrointestinal: Pollen-food allergy syndrome, immediate GI anaphylaxis
Cutaneous: Urticaria, angioedema, morbilliform rashes, and flushing
Respiratory: Acute rhinoconjunctivitis, acute wheezing
Generalized: Anaphylactic shock
Mixed IgE- and non–IgE-mediated
Gastrointestinal: Eosinophilic esophagitis/gastroenteritis/colitis
Cutaneous: Atopic dermatitis
Respiratory: Asthma
Non–IgE-mediated
Gastrointestinal: Food protein–induced enterocolitis, proctocolitis, and enteropathy syndromes; celiac disease
Cutaneous: Contact dermatitis, dermatitis herpetiformis
Respiratory: Food-induced pulmonary hemosiderosis (Heiner syndrome)

» Clinical Findings

A. Symptoms and Signs

A thorough medical history is crucial in identifying symptoms associated with potential food allergy; a history of a temporal relationship between the ingestion of a suspected food and onset of a reaction—as well as the nature and duration of symptoms observed—is important in establishing the diagnosis. For all IgE-mediated reactions, reactions to foods occur within minutes and up to 2 hours after ingestion. For non–IgE-mediated and mixed disorders, reactions can be delayed in onset for more than several hours, such as in FPIES, to possibly days later with onset of vomiting or an eczema flare after food exposure due to eosinophilic esophagitis or atopic dermatitis, respectively. At times, acute symptoms may occur, but the cause may not be obvious because of hidden food allergens. A symptom diary kept for 7–14 days may be helpful in establishing an association between ingestion of foods and symptoms and also provides a baseline observation for the pattern of symptom expression. It is important to record both the form in which the food was ingested and the foods ingested concurrently.

Hives, flushing, facial angioedema, and mouth or throat itching are common. In severe cases, angioedema of the tongue, uvula, pharynx, or upper airway can occur. Gastrointestinal symptoms include abdominal discomfort or pain, nausea, vomiting, and diarrhea. Children with food allergy may occasionally have isolated rhinoconjunctivitis or wheezing. Rarely, anaphylaxis to food may involve only cardiovascular collapse.

B. Laboratory Findings

Typically, fewer than 50% of histories of food allergy will be confirmed by blinded food challenge (although this percentage is much higher in food-induced anaphylaxis). Prick skin testing is useful to rule out a suspected food allergen, because the predictive value is high for a properly performed negative test with an extract of good quality (negative predictive accuracy of > 95%). In contrast, the predictive value for a positive test is approximately 50%. Serum food-specific IgE tests have lower specificity and positive predictive values. However, food-specific IgE levels to milk, egg, peanut, and fish proteins have been established with the ImmunoCAP assay correlating with a greater than 95% chance of a clinical reaction in children, but values have not been established for other foods or populations. A list of nonstandardized and unproven procedures for the diagnosis of food allergy includes the measurement of allergen-specific-IgG, lymphocyte stimulation, cytotoxic assays, applied kinesiology, and provocation neutralization to name a few.

The double-blind, placebo-controlled food challenge is considered the gold standard for diagnosing food allergy, except in severe reactions. If there is high suspicion of possible allergic reactivity to a food with a negative skin test or an undetectable serum IgE level (or both), a food challenge may be necessary to confirm the presence or absence of allergy. Even when multiple food allergies are suspected, most patients will test positive to three or fewer foods on blinded challenge. Therefore, extensive elimination diets are almost never indicated, and an evaluation by an allergist is preferred before multiple foods are eliminated from the diet unnecessarily. Elimination without controlled challenge is a less desirable but at times more practical approach for suspected food allergy. Elimination diets and food challenges may also be the only tools for evaluation of suspected non–IgE-mediated food reactions.

» Differential Diagnosis

Repeated vomiting in infancy may be due to pyloric stenosis or gastroesophageal reflux. With chronic gastrointestinal symptoms, enzyme deficiency (eg, lactase), cystic fibrosis, celiac disease, chronic intestinal infections, gastrointestinal malformations, and irritable bowel syndrome should be considered.

» Treatment

Treatment consists of eliminating and avoiding foods that have been documented to cause allergic reactions. This involves educating the patient, parent, and caregivers regarding hidden food allergens, the necessity for reading labels, and the signs and symptoms of food allergy and its appropriate management (anaphylaxis action plan; a copy of this plan can be obtained from the references). Consultation with a dietitian familiar with food allergy may be helpful, especially when common foods such as milk, egg, peanut, soy, or wheat are involved. All patients with a history of IgE-mediated food allergy should carry self-injectable epinephrine (Auvi-Q or Epipen) and a fast-acting antihistamine, have an anaphylaxis action plan, and consider wearing medical identification jewelry. Clinical trials of oral, sublingual and epicutaneous immunotherapy are currently under investigation as potential future treatments of food allergy. However, diets containing extensively heated (baked) milk and egg are potential alternative approaches to food oral immunotherapy and are changing the previous standard of strict avoidance diets for patients with allergy to these foods.

» Prognosis

The prognosis is good if the offending food can be identified and avoided. Unfortunately, accidental exposure to food allergens in severely allergic patients can result in death. Most children outgrow their food allergies to milk, egg, wheat, and soy but not to peanut or tree nuts (only 20% and 10% of children may outgrow peanut and tree nut allergy, respectively). The natural history of food allergy can be followed by measuring food-specific IgE levels and performing food challenges when indicated. Approximately 3%–4% of children will have food allergy as adults. INSECT ALLERGY

Allergic reactions to insects include symptoms of respiratory allergy as a result of inhalation of particulate matter of insect origin, local cutaneous reactions to insect bites, and anaphylactic reactions to stings. The latter are almost exclusively caused by Hymenoptera includes honeybees, yellow jackets, yellow hornets, white-faced hornets, wasps, and fire ants. Africanized honeybees, also known as killer bees, are a concern because of their aggressive behavior and excessive swarming, not because their venom is more toxic. Rarely, patients sensitized to reduviid bugs (also known as kissing bugs) may have episodes of nocturnal anaphylaxis. Lepidopterism refers to adverse effects secondary to contact with larval or adult butterflies and moths. Salivary gland antigens are responsible for immediate and delayed skin reactions in mosquito-sensitive patients.

» Clinical Findings

A. Symptoms and Signs

Insect bites or stings can cause local or systemic reactions ranging from mild to fatal responses in susceptible persons. The frequency increases in the summer months and with outdoor exposure. Local cutaneous reactions include urticaria as well as papulovesicular eruptions and lesions that resemble delayed hypersensitivity reactions. Papular urticaria is almost always the result of insect bites, especially of mosquitoes, fleas, and bedbugs. Toxic systemic reactions consisting of gastrointestinal symptoms, headache, vertigo, syncope, convulsions, or fever can occur following multiple stings. These reactions result from histamine-like substances

in the venom. In children with hypersensitivity to fire ant venom, sterile pustules occur at sting sites on a nonimmunologic basis due to the inherent toxicity of piperidine alkaloids in the venom. Mild systemic reactions include itching, flushing, and urticaria. Severe systemic reactions may include dyspnea, wheezing, chest tightness, hoarseness, fullness in the throat, hypotension, loss of consciousness, incontinence, nausea, vomiting, and abdominal pain. Delayed systemic reactions occur from 2 hours to 3 weeks following the sting and include serum sickness, peripheral neuritis, allergic vasculitis, and coagulation defects.

B. Laboratory Findings

Skin testing is indicated for children with systemic reactions to insect stings. Venoms of honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp are available for skin testing and treatment. Fire ant venom is not yet commercially available, but an extract made from fire ant bodies appears adequate to establish the presence of IgE antibodies to fire ant venom. Importantly, venom skin tests can be negative in patients with systemic allergic reactions, especially in the first few weeks after a sting, and the tests may need to be repeated. The presence of a positive skin test denotes prior sensitization but does not predict whether a reaction will occur with the patient's next sting, nor does it differentiate between local and systemic reactions. It is common for children who have had an allergic reaction to have positive skin tests for more than one venom. This might reflect sensitization from prior stings that did not result in an allergic reaction or cross-reactivity between closely related venoms. In vitro testing (compared with skin testing) has not substantially improved the ability to predict anaphylaxis. With in vitro testing, there is a 15%–20% incidence of both false-positive and false-negative results. IgE to mosquito saliva antigen can be measured by in vitro assay.

» Complications

Secondary infection can complicate allergic reactions to insect bites or stings. Serum sickness, nephrotic syndrome, vasculitis, neuritis, and encephalopathy may be seen as late sequelae of reactions to stinging insects.

» Treatment

For cutaneous reactions caused by biting insects, symptomatic therapy includes cold compresses, antipruritics (including antihistamines), and occasionally potent topical corticosteroids. Treatment of stings includes careful removal of the stinger, if present, by flicking it away from the wound, not by grasping in order to prevent further envenomation. Topical application of monosodium glutamate, baking soda, or vinegar compresses is of questionable efficacy. Local reactions can be treated with ice, elevation of the affected extremity, oral antihistamines, and NSAIDs as well as potent topical corticosteroids. Large local reactions, in which swelling extends beyond two joints or an extremity, may require a short course of oral corticosteroids. Anaphylactic reactions following Hymenoptera stings should be managed as discussed above (see section on Anaphylaxis). Children who have had severe or anaphylactic reactions to Hymenoptera stings—or their parents and caregivers—should be instructed in the use of autoinjectable epinephrine. Patients at risk for anaphylaxis from an insect sting should also wear a medical alert bracelet indicating their allergy. Children at risk from insect stings should avoid wearing bright-colored clothing and perfumes when outdoors and should wear long pants and shoes when walking in the grass. Patients who experience severe systemic reactions and have a positive skin test should receive venom immunotherapy. Venom immunotherapy is not indicated for children with only urticarial or local reactions.

» Prognosis

Children generally have milder reactions than adults after insect stings, and fatal reactions are extremely rare. Patients aged 3–16 years with reactions limited to the skin, such as urticaria and angioedema, appear to be at low risk for more severe reactions with subsequent stings.

Antimicrobial Therapy

Sarah K. Parker, MD
John W. Ogle, MD

PRINCIPLES OF ANTIMICROBIAL THERAPY

Antimicrobial therapy of infections is arguably the most important scientific development of 20th-century medicine. It contributes significantly to the quality of life of many people and reduces the morbidity and mortality due to infectious disease. The remarkable success of antimicrobial therapy has been achieved with comparatively little toxicity and expense. The relative ease of administration and the widespread availability of these drugs have led many to adopt a philosophy of broad-spectrum empiric antimicrobial therapy for many common infections.

Unfortunately, this era of cheap, safe, and reliable therapy is being limited by the increasing frequency of antimicrobial resistance in previously susceptible microorganisms. The problem of antimicrobial resistance is not new—resistance was recognized for sulfonamides and penicillins shortly after their introduction. What is new is the worldwide dissemination of resistant microorganisms, such as Streptococcus pneumoniae and Staphylococcus aureus, which are more virulent and commonly cause serious infections, not only among hospitalized patients, but also among outpatients.

Until recently the recognition of bacterial resistance was balanced by the promise of newer and more potent antimicrobial agents. Today, because fewer new agents are under development, clinicians are beginning to encounter limitations in their ability to treat some serious bacterial infections. Many factors contribute to the selection of resistant organisms. Our success in treating chronic diseases and immune-compromising conditions, which has resulted in additional years of life for patients, has increased opportunities for selection of resistant strains in inpatient units and chronic care facilities. Overuse of antimicrobial agents also contributes to the selection of resistant strains. Examples include antimicrobial treatment of mildly ill patients with self-limited conditions, such as viral infections, and administration of broad-spectrum antimicrobials to patients whose conditions could be treated with narrow-spectrum agents. Similarly, failure to document infection with cultures obtained prior to starting therapy limits our willingness to stop or narrow the spectrum of antimicrobials. Insufficient research has been conducted to determine the optimal duration of therapy for many infections, with the result that we probably often treat longer than is necessary. Prophylactic strategies, as used for prevention of recurrent otitis media or urinary tract infection (UTI), create a selection pressure for antibiotic resistance.

The decision-making process for choosing an appropriate antimicrobial agent is summarized in Table 39–1. Accurate clinical diagnosis is based on the history, physical examination, and initial laboratory tests. The clinical diagnosis is followed by a consideration of the organisms most commonly associated with the clinical condition, the usual pattern of antimicrobial susceptibility of these organisms, and past experience with successful treatment regimens.

Data regarding US outpatient pediatric prescriptions show that antimicrobials are the most commonly prescribed class of medication, although the number of antimicrobial prescriptions decreased in 2010 compared to 2002. The most frequently prescribed antimicrobials are amoxicillin, azithromycin, amoxicillin-clavulanate, and cefdinir. However, neither azithromycin nor cefdinir is recommended as first-line agent for the most common pediatric conditions, suggesting that these agents may be overprescribed.

Cultures should be obtained in potentially serious infections. Empiric antimicrobial therapy may be initiated and then modified according to the patient's response and the culture results. Often several equally safe and efficacious antimicrobials are available. In this circumstance, the relative cost and ease of administration of these choices should be considered.

Other important considerations include the patient's age, immune status, and exposure history. Neonates and

Table 39–1. Steps in decision making for use of antimicrobial agents.

Step	Action	Example
1	Determine diagnosis	Septic arthritis
2	Consider age and preexisting condition	Previously healthy 2-year-old child
3	Consider common organisms	Staphylococcus aureus, Kingella kingae
4	Consider organism susceptibility	Penicillin- or ampicillin-resistant; frequency MRSA[a] in community
5	Obtain proper cultures[b]	Blood, joint fluid
6	Initiate empiric therapy based on above considerations and past experience (eg, personal, literature)	Cefazolin and cefotaxime, substitute vancomycin for cefazolin if obviously ill or MRSA prevalent
7	Modify therapy based on culture results and patient response	Saureus isolated. Discontinue cefotaxime. Substitute cefazolin for vancomycin if susceptible
8	Follow clinical response	Interval physical examination
9	Stop therapy	Clinically improved or well, minimum 3–4 wk

[a]Methicillin-resistant Saureus.
[b]Indicated for serious or unusual infections or those with unpredictable clinical response to empiric therapy.

young infants may present with nonspecific signs of infection, making the differentiation of serious disease from mild illness difficult. In older children, clinical diagnosis is more precise, which may permit therapy to be avoided or allow use of a narrower-spectrum antibiotic. Immune deficiency may increase the number and types of potential infecting organisms that need to be considered, including organisms that are usually avirulent, but in the altered host may cause serious infections that are difficult to treat. An abnormal immune response may also diminish the severity of the clinical signs and symptoms of infection, leading to underestimation of the severity of illness. The exposure history may suggest the greater likelihood of certain types of infecting organisms. This history includes exposures from family members, classmates, and day care environments and exposure to unusual organisms by virtue of travel, diet, or contact with animals.

Final important considerations are the pace and seriousness of the illness. A rapidly progressive and severe illness should be treated initially with broad-spectrum antimicrobials until a specific etiologic diagnosis is made. A mildly ill outpatient should receive treatment preferentially with narrow-spectrum antimicrobials.

Antimicrobial susceptibility, antimicrobial families, and dosing recommendations are listed in Tables 39–2 to 39–6.

ANTIMICROBIAL STEWARDSHIP

Antimicrobial overuse is problematic worldwide, and its untoward effects are increasingly appreciated. These include resistance on a patient, hospital, and community level, Clostridium difficile colitis, and adverse drug events, all of which lead to excess morbidity and mortality and increased costs. In order to decrease unnecessary and inappropriate use, many hospitals employ antimicrobial stewardship programs (ASPs). ASPs demonstrate not only decreased use of antimicrobials, decreased drug-resistant infections, decreased C difficile colitis, and decreased costs, but also improved clinical outcomes. In pediatrics, ASPs are more recent, but are likely to have similar benefits to those observed in adult hospitals.

Antimicrobial medications are the most commonly prescribed drug class in children. Approximately 40% of outpatient use is in some way inappropriate. Sixty percent of hospitalized children receive antimicrobials. Liberal use in the United States is likely related to high MRSA rates, and increasing occurrence of multidrug resistant gram-negative organisms. There is growing evidence that the antibiotic-altered microbiome may have other long-term deleterious health effects, with evidence for an association with obesity and diabetes. This growing appreciation of harm has led to endorsement of ASP programs by the Infectious Disease Society of America, US News and World Report, Centers for Medicaid and Medicare Services, and some state legislatures.

Stewardship programs are multidisciplinary and collaborative efforts aiming to improve overall antimicrobial use. These programs include infectious disease physicians, infectious diseases pharmacists, data analysts, statisticians, and oversight committees that are crossdisciplinary. They employ various mechanisms to encourage judicious prescribing, including local guideline and policy development, antibiotic use preauthorization programs (where a prescriber must seek permission to prescribe broad-spectrum antimicrobials), postprescriptive review programs (where stewards review use and intervene when there is a question on appropriateness), dose-optimization assessments, prescriber feedback programs (where prescribing habits are compared and contrasted to others on either a unit, practice, or provider level), and educational programs. ASPs are generally financially self-sustaining, if not cost saving.

Antimicrobial stewardship is a responsibility not of just ASPs, rather of all prescribers. The core tennets of stewardship can be applied broadly as outlined here.

1. Understand national guidelines, which encourage both proper diagnosis and responsible antimicrobial choices. Consider the reasons for the guideline

Table 39–2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs.

Organism	Potentially Useful Antibiotics[a]
Bacteria	
Anaerobic bacteria[b]	Cefotetan,[c] cefoxitin,[c] clindamycin, doripenem,[c] ertapenem, imipenem, meropenem, metronidazole, penicillins with or without β-lactamase inhibitor, tigecycline[c]
Bacillus anthracis	Amoxicillin, ciprofloxacin, clindamycin, doxycycline, levofloxacin, rifampin, vancomycin
Bartonella henselae	Azithromycin, ciprofloxacin, clarithromycin, doxycycline, erythromycin, rifampin
Bordetella pertussis	Amoxicillin, azithromycin, clarithromycin, erythromycin, trimethoprim-sulfamethoxazole
Borrelia burgdorferi	Amoxicillin, cefuroxime, cephalosporins (III),[d] clarithromycin, doxycycline
Campylobacter spp	Azithromycin, carbapenems, erythromycin, fluoroquinolones,[c,e] tetracyclines
Clostridium spp	Clindamycin, metronidazole, penicillins, tetracyclines
Clostridium difficile	Fidaxomicin, metronidazole, rifaximin, vancomycin (PO)
Corynebacterium diphtheriae	Clindamycin, erythromycin, penicillins
Enterobacteriaceae[f]	Aminoglycosides,[g] ampicillin, aztreonam, carbapenems, cefepime, cephalosporins, fluoroquinolones,[c,e] tigecycline, trimethoprim-sulfamethoxazole
Enterococcus	Ampicillin (with aminoglycoside), carbapenems (not Efaecium), daptomycin, linezolid, quinupristin-dalfopristin[c] (Efaecium only), tigecycline, vancomycin
Haemophilus influenzae	Amoxicillin-clavulanate, ampicillin (if β-lactamase–negative),[h] cephalosporins (II and III),[d] chloramphenicol, fluoroquinolones,[c,e] rifampin, trimethoprim-sulfamethoxazole
Listeria monocytogenes	Ampicillin with aminoglycoside, trimethoprim-sulfamethoxazole, vancomycin
Moraxella catarrhalis	Amoxicillin-clavulanate, ampicillin (if β-lactamase–negative),[h] cephalosporins (II and III),[d] erythromycin, fluoroquinolones, trimethoprim-sulfamethoxazole
Neisseria gonorrhoeae	Ampicillin (if β-lactamase–negative),[h] cephalosporins (III),[d] penicillins, spectinomycin
Neisseria meningitidis	Ampicillin, cephalosporins (II and III),[d] fluoroquinolones,[c,e] penicillins, rifampin
Nocardia asteroides	Tetracycline, trimethoprim-sulfamethoxazole (+ amikacin for severe infections), linezolid, meropenem or cephalosporins (II and III)[d] for brain abscess
Pasteurella multocida	Amoxicillin-clavulanate, ampicillins, fluoroquinolones, [c,e] penicillins, tetracyclines
Pseudomonas aeruginosa	Aminoglycosides,[g] anti-Pseudomonas penicillins,[c] aztreonam, cefepime, ceftazidime, ciprofloxacin,[c] doripenem, imipenem, meropenem
Salmonella spp	Ampicillin, azithromycin, cephalosporins (III),[d] fluoroquinolones,[c,e] trimethoprim-sulfamethoxazole
Shigella spp	Ampicillin, azithromycin, cephalosporins (III),[d] fluoroquinolones,[c,e] tetracyclines, trimethoprim-sulfamethoxazole
Staphylococcus aureus	Antistaphylococcal penicillins,[i] cefepime, cephalosporins (I and II), ciprofloxacin, clindamycin, erythromycin, rifampin, trimethoprim-sulfamethoxazole, vancomycin
S aureus (methicillin-resistant)	Ceftaroline, clindamycin, daptomycin,[c] linezolid, quinupristin-dalfopristin,[c] tigecycline,[c] trimethoprim-sulfamethoxazole, vancomycin
Staphylococci (coagulase-negative)	Cephalosporins (I and II, if mecA negative),[j] clindamycin, rifampin, vancomycin
Streptococci (most species)	Ampicillin, cephalosporins, clindamycin, enhanced fluoroquinolones,[c,k] erythromycin, meropenem, penicillins, vancomycin
Streptococcus pneumoniae[l]	Ampicillin, cephalosporins, enhanced fluoroquinolones,[c,k] erythromycin, meropenem, penicillin, vancomycin

(Continued)

Table 39–2. Susceptibility of some common pathogenic microorganisms to various antimicrobial drugs. (Continued)

Organism	Potentially Useful Antibiotics[a]
Intermediate organisms	
Chlamydia spp	Azithromycin, clarithromycin, erythromycin, levofloxacin,[c] ofloxacin,[c] tetracyclines
Mycoplasma spp	Azithromycin, clarithromycin, erythromycin, fluoroquinolones,[c,e] tetracyclines
Rickettsia spp	Fluoroquinolones,[c,e] tetracyclines
Fungi	
Candida spp	Amphotericin B, anidulafungin,[c] caspofungin, fluconazole, flucytosine, itraconazole, ketoconazole, micafungin, nystatin, posaconazole[c], voriconazole[c]
Fungi, systemic	Amphotericin B, anidulafungin,[c] caspofungin, fluconazole, itraconazole, ketoconazole, micafungin, posaconazole,[c] voriconazole[c]
Dermatophytes	Butenafine, ciclopirox olamine, clotrimazole, econazole, fluconazole, griseofulvin, haloprogin, itraconazole, ketoconazole, miconazole, naftifine, oxiconazole, seraconazole, sulconazole, terbinafine, tolnaftate
Pneumocystis jiroveci	Atovaquone, clindamycin-primaquine, dapsone, pentamidine, trimethoprim-sulfamethoxazole
Viruses	
Herpes simplex	Acyclovir, cidofovir, penciclovir,[c] famciclovir, foscarnet,[o] idoxuridine,[p] trifluridine,[p] valacyclovir
Human immunodeficiency virus	Six classes: (1) nucleoside reverse transcriptase inhibitors, (2) nonnucleoside reverse transcriptase inhibitors, (3) protease inhibitors, (4) fusion inhibitors, (5) integrase inhibitors, (6) CCR-5 coreceptor antagonists; optimally combinations of ≥ 3 drugs from 2 different classes should be used (see Chapter 41)
Influenza virus	Amantadine,[m] oseltamivir, rimantidine,[m] zanamivir,
Respiratory syncytial virus	Ribavirin[n]
Varicella-zoster virus	Acyclovir, famciclovir, foscarnet,[o] valacyclovir
Cytomegalovirus	Cidofovir (liposomal), fomivirsen (topical or intravitreal), foscarnet, ganciclovir, valganciclovir
Hepatitis B[c]	Adefovir, entecavir, interferon-α, lamivudine, telbivudine, tenofovir
Hepatitis C[c]	Interferon-α, ribavirin, pediatric licensure and dosing for new specific antivirals will become available 2015

[a]In alphabetical order. Selection depends on patient's age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of suspected organism, and drug risk.
[b]Species-dependent.
[c]Not FDA-approved for use in children.
[d]Refer to first (I), second (II)-, or third (III)-generation cephalosporins.
[e]Includes ciprofloxacin, levofloxacin, lomefloxacin, norfloxacin, ofloxacin, moxifloxacin, gatifloxacin, gemifloxacin.
[f]Includes Ecoli, Klebsiella spp, Enterobacter spp, and others; antimicrobial susceptibilities should always be measured.
[g]Amikacin, gentamicin, kanamycin, tobramycin.
[h]Also applies to amoxicillin and related compounds.
[i]Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin.
[j]Only if the coagulase-negative Staphylococcus is also methicillin- or oxacillin-sensitive.
[k]Includes levofloxacin, lomefloxacin, moxifloxacin, gatifloxacin, and gemifloxacin.
[l]Because of increasing frequency of S pneumoniae strains resistant to penicillin and cephalosporins, presumptive therapy for severe infections (eg, meningitis) should include vancomycin until susceptibility studies are available.
[m]Influenza A only. Resistance is common, currently recommended in the United States only for seasonal H1N1 strains.
[n]FDA-approved for therapy of respiratory syncytial virus by aerosol, but clinical studies show variable efficacy.
[o]Used to treat infections with acyclovir-resistant virus.
[p]Ophthalmic preparation.

Table 39–3. Groups of common antibacterial agents.

Group	Examples	Some Common Susceptible Organisms[a]	Common Resistant Organisms	Common or Unique Adverse Reactions
Penicillin group				
Penicillins	Penicillin G, V	Streptococcus, Neisseria	Staphylococcus, Haemophilus, Enterobacteriaceae	Rash, anaphylaxis, drug fever, bone marrow suppression
Ampicillins	Ampicillin, amoxicillin	(Same as penicillins), plus Haemophilus (β-lactamase negative), Escherichia coli, Enterococcus	Staphylococcus, many Enterobacteriaceae	Diarrhea
Antistaphylococcal penicillins	Cloxacillin, dicloxacillin, methicillin, nafcillin, oxacillin	Streptococcus, Staphylococcus aureus	Gram-negative, Staphylococcus (coagulase-negative), Enterococcus, MRSA	Renal (interstitial nephritis), neutropenia
Anti-Pseudomonas penicillins	Azlocillin, piperacillin, ticarcillin most commonly combined with beta-lactamase inhibitor	(Same as ampicillins), plus Pseudomonas	(Same as ampicillins)	Decreased platelet adhesiveness, hypokalemia,
Penicillins with β-lactamase inhibitor combination	Amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate	Broad-spectrum	Some Enterobacteriaceae, Pseudomonas	Diarrhea
Carbapenems	Imipenem-cilastatin meropenem, ertapenem, doripenem	Broad-spectrum, gram-negative rods, anaerobes, Pseudomonas	MRSA,[b] many enterococci	Central nervous system (CNS), seizures
Cephalosporin group				
First-generation (I)	Cefazolin, cephalexin,	Gram-positive	Gram-negative, Enterococcus, some Staphylococcus (coagulase-negative)	Rash; anaphylaxis, drug fever
Second-generation (II)	Cefprozil, cefuroxime, loracarbef	Gram-positive, some Haemophilus, some Enterobacteriaceae	Enterococcus, Pseudomonas, some Staphylococcus (coagulase-negative)	Serum sickness (cefaclor)
	Cefoxitin, cefotetan	Same as second-generation plus anaerobes		
Third-generation (III)	Cefotaxime, ceftriaxone, cefpodoxime, ceftibuten, cefdinir	Streptococcus, Haemophilus, Enterobacteriaceae, Neisseria	Pseudomonas, Staphylococcus	Biliary sludging (ceftriaxone) rash
	Ceftazidime, cefepime	(Same as other third-generation cephalosporins), plus Pseudomonas, some Staphylococcus		
Other drugs				
Clindamycin	Clindamycin	Gram-positive, anaerobes, some MRSA	Gram-negative, Enterococcus	Nausea, vomiting, hepatotoxicity
Vancomycin	Dalbavancin, oritavancin, telavancin, vancomycin	Gram-positive	Gram-negative	"Red man" syndrome, shock, ototoxicity, renal

(Continued)

Table 39–3. Groups of common antibacterial agents. (Continued)

Group	Examples	Some Common Susceptible Organisms[a]	Common Resistant Organisms	Common or Unique Adverse Reactions
Macrolides and azalides	Erythromycin, clarithromycin, azithromycin	Gram-positive Bordetella, Haemophilus, Mycoplasma, Chlamydia, Legionella, Salmonella, Shigella	Some gram-negative	Nausea and vomiting Pyloric stenosis (erythromycin newborns) Arrhythmias (azithromycin)
Monobactams	Aztreonam	Gram-negative aerobes, Pseudomonas	Gram-positive cocci	Rash, diarrhea
Oxazolidinones	Linezolid	Gram-positive aerobes	Gram-negative aerobes	Diarrhea, thrombocytopenia
Streptogramins	Quinupristin-dalfopristin	Gram-positive aerobes	Gram-negative aerobes	Arthralgia, myalgia
Fluoroquinolones[c]	Ciprofloxacin, ofloxacin	Gram-negative, Chlamydia, Mycoplasma, Pseudomonas (ciprofloxacin)	Enterococcus, Streptococcus, Spneumoniae, anaerobes, Staphylococcus	Gastrointestinal (GI), rash, CNS
	Gatifloxacin, levofloxacin, moxifloxacin	Gram-negative, streptococci, Streptococcus pneumoniae, staphylococci	Some Enterococcus	GI, rash, CNS
Tetracyclines	Tetracycline, doxycycline, minocycline	Anaerobes, Mycoplasma, Chlamydia, Rickettsia, Ehrlichia and Anaplasma	Many Enterobacteriaceae, Staphylococcus	Teeth stained,[d] rash, flora overgrowth, hepatotoxicity, pseudotumor cerebri
Sulfonamides	Many	Gram-negative (urine)	Gram-positive	Rash, renal, bone marrow suppression, Stevens-Johnson syndrome
Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole	Saureus, gram-negative, Spneumoniae, Haemophilus influenzae	Streptococcus, Pseudomonas, anaerobes	Rash, renal, bone marrow suppression, Stevens-Johnson syndrome
Rifampin	Rifampin	Neisseria, Haemophilus, Staphylococcus, Streptococcus	Resistance develops rapidly if used as sole agent	Rash, GI, hepatotoxicity, CNS, bone marrow suppression, alters metabolism of other drugs
Aminoglycosides	Amikacin, gentamicin, tobramycin	Gram-negative, including Pseudomonas aeruginosa	Gram-positive, anaerobes, some pseudomonads	Nephrotoxicity, ototoxicity, potentiates neuromuscular blocking agents

[a]Not all strains susceptible; always obtain antimicrobial susceptibility tests on significant isolates.
[b]MRSA = methicillin-resistant Saureus.
[c]Fluoroquinolones are used with caution in children.
[d]Dose-dependent in children younger than age 9 years.

recommendations, and how they are applicable to pathogens in your community and patient population. The antibiotic selections in guidelines are usually the most efficacious choices. For example, in community-acquired pneumonia, a child given high-dose amoxicillin will likely have more time with drug over the mean inhibitory concentration of Streptococcus pneumoniae than they will with any of the oral cephalosporins.

2. Be diagnostically aggressive. This includes clinical diagnostics for signs and symptoms most consistent with bacterial infection, and microbiologic diagnostics when able; it is easier to target antimicrobials to a known microbe, and easier to convince a family to be compliant if you truly believe a child has a bacterial infection.
3. Do not consider antimicrobials as benign. Antibiotics are the largest culprit of unplanned medical visits for

Table 39–4. Guidelines for use of common parenteral antibacterial agents[a] in children aged 1 month or older.

Agent	Route	Dose[b] (mg/kg/d)	Maximum Daily Dose	Interval (h)	Adjustment[c]	Blood Levels[d] (mcg/mL)	
						Peak	Trough
Amikacin[d]	IM, IV	15–22.5	1.5 g	8	R	15–25	< 10
Ampicillin	IM, IV	100–400	12 g	4–6	R		
Ampicilin-sulbactam	IM, IV	100–400	12 g	4–6	R		
Aztreonam	IM, IV	90–120	6 g	6–8	R		
Cefazolin	IM, IV	50–150	6 g	8	R		
Cefepime	IM, IV	100–150	4–6 g	8–12	R		
Cefotaxime	IM, IV	100–200	12 g	6–8	R		
Cefoxitin	IM, IV	80–160	12 g	4–6	R		
Ceftazidime	IM, IV	100–150	6 g	8	R		
Ceftriaxone	IM, IV	50–100	4 g	12–24	R		
Cefuroxime	IM, IV	100–150	6 g	6–8	R		
Clindamycin	IM, IV	25–40	4 g	6–8	R, H		
Gentamicin[d,e]	IM, IV	3–7.5	300 mg	8	R	5–10	< 2
Linezolid	IV, PO	20	1.2 g	12	R		
Meropenem	IV	60–120	2 g	8	R		
Metronidazole	IV	30	4 g	6	H		
Nafcillin	IM, IV	150	12 g	6	H		
Penicillin G	IM, IV	100,000–250,000 U/kg	20 million units	4–6	H, R		
Penicillin G (benzathine)	IM	50,000 U/kg	2.4 million units	Single dose	None		
Penicillin G (procaine)	IM	25,000–50,000 U/kg	4.8 million units	12–24	R		
Tetracycline[f]	IV	20–30	2 g	12	R		
Piperacilin-tazobactam	IV	240–300	16 g	4–6	R		
Tobramycin[d,e]	IM, IV	3–6	300 mg	8	R	5–10	< 2
Vancomycin	IV	40–60	2 g	6	R	20–40[g]	5–10[g]

[a]Not including some newly released drugs, ones not recommended for use in children, or ones not widely used.
[b]Always consult package insert for complete prescribing information. Dosage may differ for alternative routes, newborns (see Table 39–6), or patients with liver or renal failure (see Adjustment column) and may not be recommended for use in pregnant women or newborns. Maximum dosage may be indicated only in severe infections.
[c]Mode of excretion (R = renal, H = hepatic) of antimicrobial agent should be assessed at the onset of therapy and dosage modified or levels determined as indicated in package insert.
[d]Suggested levels to reduce toxicity.
[e]Aminoglycosides are sometimes given as a once-daily dose. See text.
[f]Use with caution in children younger than age 9 years because of tooth staining with repeated doses.
[g]Target peak and trough vancomycin levels are not well correlated with either toxicity or outcome. Measure selectively in meningitis, impaired or changing renal function, or altered volume of distribution. Higher trough levels sometimes indicated for difficult-to-treat infections.

Table 39–5. Guidelines for use of common oral antibacterial agents in children age 1 month or older.

Agent[a]	Dose[b] (mg/kg/d)	Interval (h)	Other Considerations
Amoxicillin	40	8–12	Gastrointestinal (GI) side effects
Amoxicillin[c] (high dose)	80–90	8–12	GI side effects
Amoxicillin-clavulanate[d]	45–90	8–12	GI side effects
Ampicillin	50	6	GI side effects
Azithromycin	10 (first dose) then 5; 12 for pharyngitis	24	GI side effects
Cefdinir	14	12–24	GI side effects
Cefpodoxime	10	12	Taste (suspension)
Cefprozil	30	12	GI side effects
Ceftibuten	9	24	GI side effects
Cefuroxime	30–40	12	GI side effects
Cephalexin	25–50	6	
Ciprofloxacin	20–30	12	
Clarithromycin	15	12	GI side effects
Clindamycin	20–30	6	GI side effects
Dicloxacillin	12–25	6	GI side effects
Doxycycline[d]	2–4	12–24	Teeth stained < 9 y
Erythromycin[e]	20–50	6–12	GI side effects
Levofloxacin			
< 5 y	20	12	
> 5 y	10	24	
Linezolid	20	12	GI side effects
Metronidazole	15–35	8	
Nitrofurantoin	5–7	6	
Oxacillin	50–100	6	
Penicillin V	25–50	6	Taste (suspension)
Rifampin	10–20	12–24	
Sulfisoxazole	120–150	6	
Tetracycline[f]	25–50	6	Teeth stained < 9 y
Trimethoprim-sulfamethoxazole	8–12 (TMP)	12	Stevens-Johnson syndrome

[a]Not including some newly released drugs, ones not recommended for use in children, or ones not widely used.
[b]Always consult package insert for complete prescribing information. Dosage may differ for alternative routes, newborns (see Table 39–6), or patients with liver or renal failure (see Table 39–4, Adjustment column) and may not be recommended for use in pregnant women or newborns. Maximum dosage may be indicated only in severe infections.
[c]Higher-dose amoxicillin indicated for therapy of otitis media in regions where rates of penicillin-resistant S pneumoniae are high.
[d]Several formulations with differing clavulanate concentrations available.
[e]Preparation-dependent.
[f]Use with caution in children younger than age 9 years because of tooth staining with repeated doses.

Table 39–6. Guidelines for use of selected antimicrobial agents in newborns.

	Route	Body Wt (g)	Maximum Dosage (mg/kg/d) [Frequency]				Blood Levels (mcg/mL)	
			< 7 d	Interval (h)	8–30 d	Interval (h)	Peak	Trough
Ampicillin	IV, IM	< 2000	100	12	150	8		
		> 2000	150	8	200	6		
Cefotaxime	IV, IM		100	12	150	8		
Ceftazidime	IV, IM	< 2000	100	12	150	8		
		> 2000	100	8	150	8

		> 2000	15	8	20	6		
Erythromycin	PO	< 2000	20	12	30	8		
		> 2000	20	12	30	8		
Nafcillin	IV	< 2000	50	12	75	8		
		> 2000	75	8	150	6		
Penicillin G[a]	IV	< 2000	100,000	12	150,000	8		
		> 2000	150,000	8	200,000	6		
Piperacillin-tazobactam	IV, IM	< 2000	240	8	240	8		
		> 2000	240	8	320	6		
Vancomycin[b]	IV							

[a]Penicillin dosages are in Units/kg/d. Other preparations (eg, benzathine penicillin) may be given IM. See specific diseases for dosage.
[b]Vancomycin dosing is dependent on gestational age and serum creatinine with monitoring of levels. 10–15 mg/kg/dose every 12–48 h.

adverse drug events, exceeding 150,000 pediatric visits per year. In the United States, there are approximately 478,000 cases of C difficile colitis and two million antimicrobial resistant infections (with at least 23,000 deaths) per year. There are also a multitude of episodes of Stevens-Johnson syndrome, yeast fungemias, central line infections, hospital-acquired infections, and drug-resistant superinfections as a result of antimicrobial use that are all largely untallied.

4. Streamline and deescalate therapy. Narrow therapy to the confirmed or most likely pathogens, avoiding prolonged broad use and double coverage; or, stop altogether if bacterial infection becomes less likely. This will decrease antimicrobial adverse effects, development of resistant and hospital-acquired infections, and C difficile colitis.
5. Use oral therapy when a good oral antimicrobial agent is available, and patient condition allows. Many drugs including metronidazole, clindamycin, fluconazole, levofloxacin, rifampin, linezolid, and trimethoprim/sulfamethoxazole are > 90% bioavailable orally (and ciprofloxacin is 80%) and thus can be used by that route if the gastrointestinal tract is intact. Other drugs are not as bioavailable, but are still appropriate as step-down therapy once the patient is clinically improved.
6. Encourage complete and on-time vaccination. Vaccination, particularly with seasonal influenza and pneumococcus, decreases other infections that are often treated with antimicrobials.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Cultures and other diagnostic material must be obtained prior to initiating antimicrobial therapy—especially when the patient has a serious infection, initial attempts at therapy have failed, a patient has an unusual exposure, or multiagent therapy is anticipated. Whenever cultures identify the causative organism, therapy can be narrowed or optimized according to susceptibility results. Antimicrobial susceptibility testing should be done in a laboratory using carefully defined procedures (as defined by the Clinical and Laboratory Standards Institute).

There are several ways to test antimicrobial susceptibility. Identification of an antibiotic-destroying enzyme (eg, β-lactamase) implies resistance to some β-lactam–containing antimicrobial agents. Tube or microtiter broth dilution techniques can be used to determine the minimum inhibitory concentration (MIC) of an antibiotic, which is the amount of antibiotic (in mcg/mL) necessary to inhibit the organism under specific laboratory conditions. Disk susceptibility testing (also performed under carefully controlled conditions) yields similar results. The E-test is a standardized test for some organisms that correlates well with MICs. Clinical laboratories usually define antimicrobial susceptibility (susceptible, intermediate, and resistant) in relation to levels of the test antibiotic achievable in the blood or another body fluid (cerebrospinal fluid [CSF] or urine).

Organisms are usually considered susceptible to an antibiotic if the MIC of the antibiotic for the organism is significantly lower than levels of that agent achieved in the blood using appropriate parenteral dosages. This assumption of susceptibility should be reconsidered whenever the patient has a focus of infection (eg, meningitis, osteomyelitis, or abscess) in which poor antibiotic penetration might occur, because the levels of antibiotic in such areas might be lower than the MIC. Conversely, although certain organisms may be reported to be resistant to an antibiotic because sufficiently high blood concentrations cannot be achieved, urine concentrations may be much higher. If so, an UTI might respond to an antibiotic that would not be adequate for treatment of septicemia.

Thus, antimicrobial susceptibility testing, although a very important part of therapeutic decision making, reflects assumptions that the clinician must understand, especially for serious infections. Ultimately the true test of the efficacy of therapy is patient response. Patients who do not respond to seemingly appropriate therapy may require reassessment, including reconsidering the diagnosis, reculturing, and repeat susceptibility testing, to determine whether resistant strains have evolved or superinfection with a resistant organism is present. Antimicrobial therapy cannot be expected to cure some infections unless additional supportive treatment (usually surgical) is undertaken.

ALTERATION OF DOSE & MEASUREMENT OF BLOOD LEVELS

Certain antimicrobial agents have not been approved (and often not tested) for use in newborns. For those that have been approved, it is important to recognize that both dose and frequency of administration may need to be altered (see Tables 39–4 and 39–5), especially in young (7 days or younger) or low-birth-weight neonates (≤ 2000 g).

Antimicrobial agents are excreted or metabolized through various physiologic mechanisms (eg, renal, hepatic). It is important to consider these routes of excretion and alter the antimicrobial dosage appropriately in any patient with some degree of organ dysfunction. (See Chapter 24). As indicated in Table 39–4, an assessment of renal or hepatic function may routinely be necessary for patients receiving certain drugs (eg, renal function for aminoglycosides, hepatic function for clindamycin); otherwise, harmful drug levels may accumulate. In some circumstances, a patient may be receiving multiple drugs where the drug interactions are unknown. If significant organ dysfunction is present, drug clearance may be delayed and dosage modification may be necessary (see detailed descriptions in individual drug information packets), and measurement of drug levels may be indicated.

Serum levels of drugs posing a high risk of toxicity (eg, aminoglycosides) are ordinarily measured. Measurement of other drugs (eg, vancomycin) may be useful in selected circumstances (see the following discussion). For certain serious bacterial infections (eg, bacterial endocarditis), measurement of the serum concentration of an antimicrobial may be important to determine optimal therapy.

Certain drug interactions may require modification of drug dosage or other therapeutic alterations. For example, rifampin stimulates the metabolism of warfarin, progesterone, prednisone, and anticonvulsants by stimulating the cytochrome P450 (CYP450) metabolic pathway. Dosage adjustments or alternative medications may be necessary to avoid significant adverse events. Another common example is macrolide and azilide antimicrobials which may cause a prolonged QT interval and may interact with other drugs with the potential to prolong the QT interval. Although many drug interactions are known and well documented, it may be difficult to predict interactions that result from a combination of multiple different medications, and a high level of suspicion regarding adverse clinical events should be maintained.

THE USE OF NEW ANTIMICROBIAL AGENTS

New antibiotics are introduced frequently, often with claims about unique features that distinguish these usually more expensive products from existing compounds. Often these drugs share many properties with existing drugs. The role that any new antimicrobial will play can only be determined over time, during which new or previously unrecognized side effects might be described and the clinical efficacy established. Clinical trials may not be confirmed in the larger number of patients subsequently treated in practice. Because this may take many years, a conservative approach to using new antibiotics seems fitting, especially because their costs are often higher, and appropriate antimicrobial choices for most common infections already exist. It is appropriate to ask if a new antimicrobial has been proved to be as effective as (or more effective than) the current drug of choice, and whether its side effects are comparable (or less common)

and its cost reasonable. The withdrawal of moxalactam and trovafloxacin due to unexpected serious side effects, which were not anticipated despite extensive premarket testing, highlight the caution necessary before using new antimicrobials. The heavy marketing of new cephalosporins and fluoroquinolones, which are very similar to existing drugs, is typical of the difficulty in evaluating antimicrobials.

The development of new antimicrobials is important as a response to the emergence of resistant organisms and for treatment of infections that are clinically difficult to treat (eg, viruses, fungi, and some resistant bacteria). Fortunately, these infections are either rare or (usually) self-limited in immunocompetent hosts.

PROPHYLACTIC ANTIMICROBIAL AGENTS

Antimicrobials can be used to decrease the incidence of postoperative infections (Table 39–7). A dose of an antimicrobial given 30 minutes to one hour prior to surgery can reduce postoperative wound infection. Vancomycin and fluoroquinolones, which require a longer infusion time, may need to be started 2 hours before surgery. The goal is to achieve high levels in the serum at the time of incision and by this means—along with good surgical technique—to minimize viable bacterial contamination of the wound. During a lengthy procedure, a second dose may be given. No evidence exists that multiple subsequent doses of antimicrobials confer additional benefit. The antimicrobial(s) used for prophylaxis are directed toward the flora that most commonly cause postoperative infection at a given anatomic site. Gram-positive cocci, such as S aureus that colonize the skin, are usually targeted, and a first-generation cephalosporin (eg, cefazolin) is a cost-effective choice. Third-generation cephalosporins and other broad-spectrum agents are more expensive and offer less benefit because they are less active than cefazolin against S aureus. Cefoxitin and cefotetan, which have activity against anaerobic bacteria, are useful for procedures, such as colorectal surgery, although cefazolin has been effective for most gynecologic patients. In colorectal surgery, orally administered antimicrobials such as neomycin and erythromycin may be as effective as parenteral antimicrobials.

In hospitals where the predominant S aureus strains are methicillin resistant or in cases where the patient is allergic to penicillin and cephalosporins, vancomycin can be considered. However, prophylactic vancomycin has caused hypotension at the time of induction of general anesthesia. Frequent use of vancomycin as a prophylactic antimicrobial will contribute to the development of vancomycin-resistant strains such as Enterococcus faecalis. For these reasons, vancomycin should generally not be used for prophylaxis, although it might prove useful for individual patients at extremely high risk.

Endocarditis prophylaxis is recommended for certain dental procedures in high-risk cardiac patients. Patients with prosthetic cardiac valves or prosthetic cardiac material during the 6 months following the procedure, unrepaired cyanotic heart disease, children with prior endocarditis, and children with other prosthetic patches, which inhibit endothelialization, should receive prophylaxis. Dental procedures that would trigger prophylaxis are those that involve manipulation of gingival and periapical tissues. Patients with indwelling venous catheters undergoing similar extensive dental procedures should receive prophylaxis. Prophylaxis is not recommended for routine cleanings or orthodontic applications. Prophylaxis is not recommended for gastrointestinal or genitourinary procedures.

Prophylaxis against infection with group A streptococci reduces the recurrence rate for acute rheumatic fever. Postexposure prophylaxis is given after exposure to pertussis, Haemophilus influenzae type b (Hib) infection (depending on age), meningococcus, gonococcus, tuberculosis (household

Table 39–7. Dosing aminoglycosides in newborns.

	Route	Body Wt (g)	Usual Dosage[a] (mg/kg/dose) [Frequency]				Blood Levels (mcg/mL)	
			< 7 d	Interval (h)	8–30 d	Interval (h)	Peak	Trough
Amikacin[a]	IV, IM	< 2000	15	48	15	24–48	15–25	5–10
		> 2000	15	24	15	12–24		
Gentamicin[a]	IV, IM	< 2000	5	48	4–5	24–48	5–10	< 2
		> 2000	4	24	4	12–24		
Tobramycin[a]	IV, IM	< 2000	5	48	4–5	24–48	5–10	< 2
		> 2000	4	24	4	12–24		

[a]Aminoglycoside dosing in neonates requires careful attention to changes in renal function and changes in the volume of distribution. For infants younger than 1200 g, smaller doses may be needed.

exposure), plague, aerosolized tularemia or anthrax, and other high-risk infections. Family or close contacts of patients with severe invasive streptococcal disease may benefit from prophylaxis. Silver nitrate, erythromycin, povidone-iodine, and tetracycline are used in ophthalmic preparations for prevention of gonococcal ophthalmia neonatorum. Children with asplenia or sickle cell disease receive prophylactic penicillin to protect against overwhelming S pneumoniae sepsis, usually started immediately with the onset of fever.

Prophylactic antimicrobials are used for some children at high risk for recurrent UTI, but the number needed to treat to prevent one UTI is high, and decreased renal scarring or other improved renal outcomes have not been shown.

Chemoprophylaxis of children at high risk for influenza, but not immunized against influenza, should be considered, including some immunocompromised children and unimmunized caregivers of at-risk children. Children at high risk, for 2 weeks after immunization and during years when vaccine efficacy is suboptimal, may benefit from prophylaxis. Oseltamivir or zanamivir would be used as each is currently active against influenza A and B.

INITIAL EMPIRIC ANTIMICROBIAL CHOICES FOR SELECTED CONDITIONS

General recommendations for specific conditions are based on the patient's age, diagnosis, site of infection, severity of illness, antimicrobial susceptibility of bacterial isolates, and history of drug allergy. Always consult the package insert for detailed prescribing information. Tables 39–2 to 39–6 include further information.

Neonatal Sepsis & Meningitis

The newborn with sepsis may have signs of focal infection, such as pneumonia or respiratory distress syndrome, or may have subtle nonfocal signs. Group B streptococci, Escherichia coli, and other gram-negative rods are commonly encountered. Listeria monocytogenes is now uncommon in many nurseries, but a recent nationwide outbreak demonstrates the pathogenic potential of this organism. Ampicillin and gentamicin (or another aminoglycoside) are preferred. If meningitis is present, many clinicians substitute a third-generation cephalosporin for the aminoglycoside. S pneumoniae is an uncommon cause of meningitis in neonates. However, if the Gram stain shows gram-positive cocci suggesting S pneumoniae, substitution of vancomycin for ampicillin should be considered. In the newborn with cellulitis, S aureus including methicillin-resistant S aureus (MRSA) and group A streptococci are additional considerations. Nafcillin, oxacillin, or a first-generation cephalosporin is usually added. Vancomycin is added if MRSA is common in the geographic area. Omphalitis is often polymicrobial, and Enterococcus species, gram-negative aerobes, and anaerobes may be causative. Clindamycin, ampicillin, and an aminoglycoside or piperacillin-tazobactam cover the most likely organisms; early surgical intervention is indicated.

Sepsis in an Infant

S pneumoniae and Neisseria meningitidis are most commonly encountered in infants. Haemophilus influenza type B (Hib) infection may occur in unimmunized children. A third-generation cephalosporin is appropriate. Intermediate-level penicillin and cephalosporin resistance in S pneumoniae usually do not cause therapy to fail unless meningitis or another difficult-to-treat infection, such as endocarditis or osteomyelitis, is present.

Occult bacteremia may be encountered in young infants with high fever. Prior to immunization with vaccines effective against Hib, persistent bacteremia and complications including meningitis were seen in approximately 50% of children infected with occult Hib bacteremia. Hib is now a very uncommon cause of occult bacteremia in young children with fever. Similarly, prior to the introduction of the conjugate pneumococcal vaccine, S pneumonia bacteremia was demonstrated in 3%–5% of infants aged 3–36 months with fever of 39°C or greater, no identified source for fever on examination, and white blood cell count (WBC) of equal to or greater than 15,000/mm^3. The risk of bacteremia was 6%–10% in younger children with fever greater than 40°C and WBC of 20,000/mm^3 or higher, and the risk of developing meningitis due to persistent S pneumoniae bacteremia was estimated at 3%. The risk of S pneumoniae bacteremia and its complications is significantly reduced in children immunized with the conjugate pneumococcal vaccines. In clinical trials and subsequent national surveillance for the incidence of disease, the 7-valent pneumococcal vaccine reduced invasive pneumococcal diseases by approximately 90%, which should be lower with the 13-valent pneumococcal vaccine. Observation without antimicrobials, but with appropriate plans for follow-up examinations, is appropriate for most febrile young children who are fully immunized.

Hospital-Acquired Infections

Many bacterial pathogens can cause infection in hospitalized patients. Updated local unit-specific antibiograms are the best guide to etiologic diagnosis and antimicrobial susceptibility. For example, some intensive care units experience frequent infections due to Enterobacter cloacae, whereas in other units Klebsiella pneumoniae is the most common nosocomial isolate. Initial therapy should include antibiotics effective for MRSA and resistant Pseudomonas aeruginosa if these are frequent isolates. E faecalis is a common cause of nosocomial bacteremia in patients with central catheters, particularly in units where cephalosporins are heavily used. Coagulase-negative staphylococci are commonly isolated from patients with indwelling central catheters. In seriously ill patients, when the local experience suggests that

Enterococcus species or coagulase-negative staphylococci are common, the initial regimen should include vancomycin. Because Enterococcus species and coagulase-negative staphylococci commonly cause fever without significant morbidity or mortality, initial regimens without vancomycin are appropriate, with adjustment of treatment after susceptibility is known. If P aeruginosa or other resistant gram-negative rods are common, ceftazidime or cefepime should be included in initial therapy. Candida is a common isolate from blood cultures from immunocompromised or seriously ill patients in the intensive care unit. Empiric antifungal therapy is initiated in some high-risk patients.

Meningitis

Bacterial meningitis in neonates is usually caused by infection with group B streptococci, E coli, other gram-negative rods, or L monocytogenes. A combination of ampicillin and a third-generation cephalosporin is started initially. In an infant or older child, S pneumoniae or N meningitidis are the most common isolates. Hib is uncommon now because of widespread immunization. Increasingly, S pneumoniae with resistance to a third-generation cephalosporin (MIC > 2 mcg/mL) may occur in 3%–5% of isolates.

In bacterial meningitis, peak CSF antimicrobial concentrations four or more times greater than the MIC of the organism are desirable, but this may be difficult to achieve with some drugs if organisms are resistant. The therapeutic problem is complicated if dexamethasone, which reduces the entry of some antimicrobials into the CSF, is also given. Thus, initial therapy of bacterial meningitis in an older child should include vancomycin and a third-generation cephalosporin. Alternatively, meropenem has also been successful. A lumbar puncture should be considered 24–48 hours after the start of therapy to assess the sterility of the CSF. Rifampin should be added if the Gram stain or cultures of CSF are positive on repeated lumbar puncture, if the child fails to improve, or if an isolate has a very high MIC to ceftriaxone. The optimal therapy of highly resistant S pneumoniae meningitis is not well established.

Meningitis in a child with a ventriculoperitoneal shunt is most commonly caused by coagulase-negative staphylococci, many of which are methicillin-resistant. In many of these patients who are not seriously ill, therapy should be postponed while awaiting the appropriate shunt fluid for Gram stain and culture. Seriously ill patients should initially be given vancomycin and a third-generation cephalosporin, because S aureus and gram-negative rods are also common causes of serious infection.

Urinary Tract Infection

E coli is the most common isolate from the urinary tract. Outpatients with symptoms of lower urinary tract disease or with mild illness can be given ampicillin, cephalexin, or trimethoprim-sulfamethoxazole (TMP-SMX). Local experience and resistance rates should guide initial therapy. In selected patients with pyelonephritis, outpatient therapy is effective using parenteral aminoglycosides or ceftriaxone once per day. Oral cefixime and amoxicillin-clavulanate can be used in place of ceftriaxone for outpatient therapy. Ciprofloxacin has been approved by the US Food and Drug Administration for therapy of urinary tract infection (UTI) in children older than 1 year, but it should be reserved for complicated cases. For hospitalized patients with UTI and suspected bacteremia, ampicillin and gentamicin or a third-generation cephalosporin is appropriate. Gram stain should be used to guide the initial choice. For patients with known or suspected resistant organisms, such as P aeruginosa, or for patients with urosepsis, an aminoglycoside and ceftazidime, cefepime, or piperacillin with or without tazobactam may be started. Unit-specific data on typical bacterial species and their patterns of susceptibility, when available, should guide the antimicrobial choice for nosocomial UTIs.

Bacterial Pneumonia

Bacterial pneumonia in newborns generally should be treated with the same antimicrobial choices as sepsis. Infants and older children are frequently infected with S pneumoniae. Amoxicillin is effective in most patients treated as outpatients.

Previously healthy children admitted to the hospital with uncomplicated pneumonia can be treated successfully with amoxicillin orally or ampicillin or penicillin, intravenously.

Children with inadequate immunization, children with high-level pneumococcal resistance (penicillin MIC ≥ 4.0 mg/mL), and children who are seriously ill may benefit from a third-generation cephalosporin given parenterally.

Children with culture-positive paraneumonic effusions should be treated based on the culture and susceptibility report. Children with small or culture-negative parapneumonic effusions should be treated based on the severity of illness.

A rapidly progressive pneumonia, with pneumatoceles or large empyema, may be due to MRSA or group A streptococci, Hib, or another gram-negative rod. Vancomycin should be used in addition to a third-generation cephalosporin in these instances.

Children aged 6 years and older more frequently have infection with Mycoplasma pneumoniae or Chlamydia pneumoniae. Azithromycin is usually preferred for initial empiric therapy.

Skin & Soft Tissue Infections

S aureus and group A streptococcus are the most common causes of skin and soft tissue infections (SSTIs) in children.

Community-acquired MRSA infections are common in many communities and complicate clinical decision making. Culture and susceptibility testing of abscesses, cellulitis, and more serious SSTIs is very important for optimal clinical management. Children with cellulitis more commonly have infection with group A streptococci, and empiric outpatient therapy with cephalexin or dicloxacillin is preferred. Children with small (< 5 cm) abscesses usually are effectively treated with incision and drainage without an antimicrobial. Outpatient therapy of large (> 5 cm) abscesses includes incision and drainage and empiric clindamycin or TMP-SMX, depending on local susceptibility patterns. However, in many communities, 50% or more of MRSA isolates are also resistant to clindamycin, fluoroquinolones, and erythromycin. Knowledge of the local resistance pattern of community-acquired MRSA is helpful in choosing initial antimicrobial therapy. Adequate cultures, the thoroughness of drainage procedures, and careful outpatient follow-up are needed to ensure optimal outcomes. Group A streptococcal infections are not adequately treated with TMP-SMX.

Specific Antimicrobial Agents

PENICILLINS

Penicillins and Aminopenicillins

Penicillin remains the drug of choice for streptococcal infections including acute pharyngitis, acute rheumatic fever prophylaxis, syphilis, oral anaerobic infections, dental infections, N meningitidis infection, leptospirosis, rat-bite fever, actinomycosis, and infections due to Clostridium and Bacillus species (Table 39–8). For oral therapy of minor infections, amoxicillin or ampicillin are usually equivalent, but amoxicillin is better absorbed and tolerated. For systemic therapy, aqueous penicillin G is preferable. For treatment of streptococcal pharyngitis, amoxicillin is recommended. Amoxicillin is preferred therapy for pneumonia and otitis media due to S pneumoniae. Amoxicillin is preferred for oral therapy of Lyme disease in children < 8 years of age. For dog or cat bites, where Pasteurella multocida is commonly encountered, amoxicillin-clavulanate provides good coverage of Pasteurella as well as methicillin-sensitive S aureus (MSSA). An alternative is separate prescriptions for penicillin and an antistaphylococcal drug such as cephalexin, or clindamycin and TMP-SMX in penicillin-allergic patients. For human bites, amoxicillin-clavulanate provides adequate therapy for Eikenella corrodens and other mixed oral aerobes and anaerobes. The β-lactamase inhibitor sulbactam combined with ampicillin is given parenterally for human and animal bites, and some other infections due to organisms from the oral flora in which mixed aerobic and anaerobic bacteria may be resistant to ampicillin due to β-lactamase production.

Penicillinase-Resistant Penicillins

S aureus is usually resistant to penicillin and amoxicillin owing to penicillinase production. Nafcillin, oxacillin, methicillin, and first- and second-generation cephalosporins are stable to penicillinase and are usually equivalent for intravenous therapy. Methicillin is associated with more frequent interstitial nephritis. Oxacillin and methicillin are renally excreted, whereas nafcillin is excreted through the biliary tract. These properties are occasionally considered in children with renal or liver failure. Cost is another important factor for choosing an agent. Often both S aureus and S pyogenes are suspected initially (eg, in cellulitis or postoperative wound infections). The penicillinase-resistant penicillins (PRPs) and first- and second-generation cephalosporins are efficacious for most streptococcal infections, although penicillin remains the drug of choice.

MRSA is an increasingly common and serious community-acquired infection in children and may cause nosocomial infection. MRSA infections are also resistant to all of the PRPs and cephalosporins. Vancomycin is effective against MRSA and coagulase-negative staphylococci. S aureus infections range in severity from minor infections treated on an outpatient basis to life-threatening infections. Since severe infections due to MRSA are a serious concern in many communities, it is important to culture and determine antimicrobial susceptibility of suspected S aureus infections. In communities with frequent MRSA infections, initial therapy of seriously ill children should include vancomycin. MRSA may also be resistant to macrolides and clindamycin by mutations of the bacterial 23s-ribosomal RNA. Many strains reported as clindamycin-susceptible and erythromycin-resistant are actually resistant to clindamycin. This inducible resistance to clindamycin may be detected in erythromycin-resistant MRSA that demonstrate a D-zone in disk susceptibility testing. Community-acquired MRSA is more likely to be susceptible to TMP-SMX, clindamycin, and tetracyclines than hospital-acquired infections.

For outpatient therapy, cloxacillin, dicloxacillin, and first- or second-generation cephalosporins are usually equally effective for infections due to susceptible S aureus. Cost and availability may determine the choice between drugs.

Anti-Pseudomonas Penicillins

Ticarcillin and piperacillin are active intravenously against streptococci, ampicillin-susceptible enterococci, H influenzae, gram-negative rods (including frequently antibiotic-resistant gram-negative rods, such as Enterobacter, Proteus, and P aeruginosa), and gram-negative anaerobes such as Bacteroides fragilis. P aeruginosa is inherently resistant to most antimicrobials, and high levels of these drugs are usually required. The combination of ticarcillin or piperacillin and an aminoglycoside is synergistic against P aeruginosa and many other enteric gram-negative rods. Ticarcillin in a fixed combination with clavulanic acid has activity against β-lactamase–producing strains of Klebsiella, S aureus, and

Table 39–8. Antimicrobial prophylaxis and preferred prophylactic agents: selected conditions and pathogens.[a]

Pathogen (Indication)	Prophylactic Agent
Bacillus anthracis[b]	Amoxicillin (if proved susceptible), ciprofloxacin, doxycycline
Bacterial endocarditis[c]	Ampicillin, ceftriaxone, cefazolin
Bordetella pertussis (exposure to respiratory secretions)	Azithromycin, clarithromycin, erythromycin
Chlamydia trachomatis (genital contact)	Azithromycin, doxycycline
Haemophilus influenzae type b[d] (household exposure)	Rifampin
Mycobacterium tuberculosis (household exposure)	Isoniazid or rifampin
Neisseria meningitidis (household exposure)	Rifampin, ciprofloxacin
Neisseria gonorrhoeae (ophthalmia neonatorum)	Erythromycin, silver nitrate ophthalmic, povidone-iodine
N gonorrhoeae (sexual contact)	Ceftriaxone
Treponema pallidum (sexual contact)	Penicillin
Streptococcus pneumoniae (sickle cell disease, asplenia)	Penicillin
Postoperative wound infection[e]	Cefazolin, vancomycin, and other regimens[e]
Group A streptococci (rheumatic fever)[f]	Benzathine penicillin G, penicillin, sulfadiazine
Group B streptococcal sepsis	Ampicillin (to mother prior to delivery)
Pneumonic Yersinia pestis[g] (exposure)	Tetracycline[h]
Francisella tularensis[g] (aerosolized exposure)	Tetracycline[h]
Vibrio cholera	Tetracycline,[h] trimethoprim-sulfamethoxazole
Recurrent urinary tract infection	Nitrofurantoin, trimethoprim-sulfamethoxazole
Pneumocystis jiroveci—(HIV, some immunocompromised patients)	Atovaquone, clindamycin-primaquine, dapsone, trimethoprim-sulfamethoxazole, pentamidine

[a]Decisions for prophylaxis must take a number of factors into account, including the evidence for efficacy of therapy, the degree of the exposure to an infecting agent, the risk and consequences of infection, the susceptibility of the infecting agent to antimicrobials, and the patient's ability to tolerate and comply with the antimicrobial agent. See individual chapters for discussion.
[b]Decisions for prophylaxis should be made in accordance with the responsible public health department recommendations.
[c]See discussion in Chapter 20.
[d]Prophylaxis provided to family if contacts include unimmunized or partially immunized children younger than age 4 years. Some experts provide prophylaxis in day care settings after one case and some after two cases of Haemophilus influenza type b infection.
[e]Alternative regimens may be used, depending on the site of surgery and the degree of contamination. Vancomycin may be used when the patient is known to be colonized with MRSA or if MRSA is a common postoperative infection.
[f]Oral prophylaxis may be indicated in some patients. Alternative regimens indicated for penicillin-allergic patients. See discussion in text.
[g]Prophylaxis not well established. Carefully assess risk on a case-by-case basis.
[h]Usually not indicated for children younger than 9 years because of tooth staining with repeated doses.

Bacteroides. Piperacillin is more active in vitro against many gram-negative enteric infections and is most commonly used in combination with tazobactam, a β-lactamase inhibitor. Antipseudomonal penicillins cause the same toxicities as penicillin and therefore are usually very safe.

GLYCOPEPTIDE AGENTS

Vancomycin, telavancin, oritavancin, and dalbavancin are glycopeptide antimicrobial agents active against the cell wall of gram-positive organisms. Both dalbavancin and oritavancin have a prolonged half-life that allows once-weekly dosing. Telavancin is dosed once daily. Neither of these three drugs are FDA-approved for use in children. Vancomycin is useful for parenteral therapy of resistant gram-positive cocci such as penicillin- and cephalosporin-resistant S pneumoniae, MRSA, methicillin-resistant coagulase-negative staphylococci, and ampicillin-resistant enterococci. Vancomycin is also used orally for therapy of colitis due to Clostridium difficile, although it should not be used as the drug of first choice. None of the glycopeptides are active against gram-negative infections.

The empiric use of vancomycin has increased tremendously over the last decade. As a result, vancomycin-resistant enterococci (VRE) and coagulase-negative staphylococci have become problems, particularly in inpatient units, intensive care units, and oncology wards. Vancomycin-intermediate and vancomycin-resistant S aureus are now being isolated, which is of concern because of the inherent virulence of many S aureus strains. Vancomycin use should be monitored carefully in hospitals and intensive care units. Vancomycin should not be used empirically when an infection is mild or when other antimicrobial agents are likely to be effective, and should be stopped promptly if infection is caused by organisms susceptible to other antimicrobials.

Rapid infusion of vancomycin is associated with the "red man syndrome," characterized by diffuse red flushing, at times pruritus, and occasionally tachycardia and hypotension. As a result, vancomycin is infused slowly over 1 hour, or even longer if necessary. Diphenhydramine or hydrocortisone (or both) may also be used as premedication.

Measurement of peak-and-trough serum vancomycin concentrations is not necessary in most clinical situations because the levels achieved with standard dosing are usually predictable and nontoxic. Measurement of serum concentrations is helpful in patients with abnormal or unpredictable renal function; in those with altered volume of distribution, as occurs in nephrotic syndrome or shock; and in those receiving higher-dose therapy (eg, for meningitis or other difficult-to-treat infections). For patients receiving antimicrobials for weeks to months, weekly clinical assessment and laboratory assessment of urine, creatinine, and complete blood count should facilitate detection of toxicity.

OXAZOLIDINONES

Linezolid is the first drug in this class of antimicrobials that bind to the 50s-ribosomal RNA subunit and prevent initiation of protein synthesis. Because of this unique mechanism, cross-resistance with other classes of antimicrobials is uncommon.

Linezolid is active against aerobic gram-positive organisms, including streptococci, staphylococci, enterococci, and pneumococci. Because linezolid is active against gram-positive organisms resistant to other antimicrobials (eg, MRSA, methicillin-resistant coagulase-negative staphylococci, VRE, and penicillin-resistant S pneumoniae), it is useful for these difficult to treat infections.

Linezolid is safe and well tolerated in children. Gastrointestinal symptoms are the most commonly encountered side effect. Because neutropenia and thrombocytopenia have been reported with linezolid use, the complete blood count should be monitored in patients at increased risk for these problems and in patients receiving therapy for 2 weeks or longer. Linezolid is an inhibitor of monoamine oxidase (MAO) and should not be used in patients taking MAO inhibitors, or in patients taking phenylpropanolamine or pseudoephedrine.

Linezolid should be used only for infections due to a proven gram-positive pathogen that is known or strongly suspected to be resistant to other available agents.

CEPHALOSPORINS

Cephalosporin agents make up a large and often confusing group of antimicrobials. Many of these drugs are similar in antibacterial spectrum and side effects and may have similar names. Clinicians should learn well the properties of one or two drugs in each class. Cephalosporins are often grouped as "generations" to signify their similar antimicrobial activity. First-generation cephalosporins such as cefazolin intravenously and cephalexin orally are useful mainly for susceptible S aureus infection and UTI due to susceptible E coli. Second-generation cephalosporins, such as cefuroxime intravenously and cefprozil and cefuroxime orally, have somewhat reduced, but acceptable, activity against gram-positive cocci, and greater activity against some gram-negative rods compared with first-generation cephalosporins. They are active against H influenzae and Moraxella catarrhalis, including strains that produce β-lactamase capable of inactivating ampicillin. Third-generation cephalosporins have substantially less activity against gram-positive cocci, such as S aureus, but greatly augmented activity against aerobic gram-negative rods. Cefotaxime and ceftriaxone are examples of intravenous drugs, whereas cefpodoxime and ceftibuten are representative oral drugs. Cefepime is often described as fourth-generation cephalosporins because of its broad activity against gram-positive and gram-negative organisms, including P aeruginosa. Cefepime is less susceptible to β-lactamase degradation and is a poor inducer of β-lactamase, and is thus most useful for organisms resistant to other drugs.

Ceftaroline is a new cephalosporin that has expanded activity against MRSA and some Enterococcus faecalis, while retaining the gram-negative activity of third-generation cephalosporins. Ceftaroline is not sufficiently active against P aeruginosa or Acinetobacter, and is not approved for use in children younger than 18 years old.

No cephalosporin agent, except ceftaroline, has substantial activity against L monocytogenes, enterococci, or MRSA. The only cephems useful for treating anaerobic infections are cefoxitin and cefotetan, which are second generataion cephamycins with activity against B. fragilis. Increasing resistance limits their usefulness. Ceftazidime and cefepime are cephalosporins with activity against P aeruginosa, although resistance of this organism to ceftazidime and cefepime is common in many institutions.

Although allergy to β-lactam antimicrobials is reported commonly by parents, this history is not highly predictive of true allergy. Described serious or anaphylactic-type

reactions warrant caution or avoidance of cephalosporins and penicillins until evaluation by an allergist (see Chapter 38). With nonspecific reactions, these medications can usually be given safely.

Resistance to cephalosporins is common among aerobic gram-negative rods. The presence of inducible cephalosporinases in some gram-negative rod organisms, such as P aeruginosa, Serratia marcescens, Citrobacter, and Enterobacter, has led to clinical failures because of the emergence of resistance during therapy. Extended-spectrum β-lactamases mediate broad resistance to all penicillins, aminopenicillins, cephalosporins, and monobactams. Carbapenems, fluoroquinolones, or combinations including these drugs are used for serious infections due to gram-negative organisms with these enzymes.

AZTREONAM

Aztreonam is the only monobactam antimicrobial agent approved in the United States. Although it is not approved for use in children younger than age 9 months, there is considerable pediatric experience with its use, including in neonates and premature infants. Aztreonam is active against aerobic gram-negative rods, including P aeruginosa. Aztreonam has activity against H influenzae and M catarrhalis, including those that are β-lactamase producers. Most patients with allergy to penicillin or cephalosporins are not sensitized to aztreonam. An exception is the child with a prior reaction to ceftazidime may have reactions to aztreonam because aztreonam and ceftazidime have a common side chain.

Aztreonam delivered by aerosolization by a proprietary nebulization system is approved for therapy of P aeruginosa infection in patients with cystic fibrosis. Safety and efficacy have not been established in children younger than 7 years. Therapy is delivered three times daily for 28 days with a goal to improve respiratory symptoms.

CARBAPENEMS

Meropenem, ertapenem, doripenem, and imipenem are broad-spectrum β-lactam antimicrobials. Imipenem-cilastatin is a combination of an active antibiotic and cilastatin, which inhibits the metabolism of imipenem in the kidneys and thereby results in high serum and urine levels of imipenem. These carbapenems are also active against S pneumoniae, including many penicillin- and cephalosporin-resistant strains. Carbapenems have been used successfully to treat meningitis and may be considered if vancomycin is not tolerated. An increased frequency of seizures is encountered when central nervous system infections are treated with carbapenems. The agents are broadly active against streptococci, MRSA, some enterococci, and gram-negative rods such as P aeruginosa, β-lactamase–producing H influenzae, and gram-negative anaerobes. Ertapenem has less activity against P aeruginosa, Acinetobacter species, and Enterococcus species than meropenem and imipenem. Because carbapenems are active against so many species of bacteria, there is a strong temptation to use them as single-drug empiric therapy. Units that have used carbapenems heavily have encountered resistance in many different species of gram-negative rods.

MACROLIDES & AZALIDES

Erythromycin was once the most commonly used macrolide antimicrobial agent, but now azithromycin and clarithromycin are preferred because of decreased side effects. They are active against many bacteria that are resistant to cell wall–active antimicrobials, and are the drugs of choice for Bordetella pertussis, Legionella pneumophila, C pneumoniae, M pneumoniae, and Chlamydia trachomatis infections (in children in whom tetracycline is not an option). Resistance of common upper respiratory pathogens to the macrolides limits their utility for therapy of pneumonia, otitis media, and sinusitis. Gastrointestinal side effects are common. Interactions with theophylline, carbamazepine, terfenadine, cycloserine, and other drugs may require dosage modifications of erythromycin and clarithromycin. Significant interactions with azithromycin are less common. Erythromycin exposure is associated with pyloric stenosis in newborns, so azithromycin is preferred in most neonates. In adults, macrolides appear to increase cardiac arrhythmogenic risk.

Erythromycin was previously available in many formulations, including the base, estolate, ethyl succinate, and stearate, but is sometimes unavailable or very expensive due to drug shortages and decreased demand. Transient hepatic toxicity occurs in adults, but is much less common in children. Erythromycin base and stearate should be taken with meals for best absorption.

Clarithromycin (macrolide) and azithromycin (azalide) are much less likely than erythromycin to cause nausea, vomiting, and diarrhea, and are usually preferred over erythromycin. Clarithromycin is more active than erythromycin against H influenzae, M catarrhalis, and Neisseria gonorrhoeae and is the drug of choice, usually in combination, for some nontuberculous mycobacterial infections. Azithromycin has a prolonged half-life and antimicrobial effect in tissue. Azithromycin is dosed once daily for 5 days, but must be taken 1 hour before or 2 hours after meals because food interferes with absorption. Although azithromycin is active against H influenzae, some authors report poor eradication of H influenzae from the middle ear. Azithromycin can be used for single-dose therapy of C trachomatis infections. It is beneficial in adolescents when compliance with erythromycin or tetracycline is a concern. Azithromycin is useful for therapy of Shigella and Salmonella infections, including typhoid fever resistant to ampicillin and TMP-SMX, and is

an alternatives to third-generation cephalosporins and fluoroquinolones for these infections. Clarithromycin is effective against Lyme disease, but amoxicillin is the drug of choice in young children. Clarithromycin and azithromycin are alternative drugs for toxoplasmosis in sulfonamide-allergic patients and as alternatives to erythromycin in legionellosis. In vitro and limited clinical experience in treating contacts of pertussis patients suggests efficacy equal to that of erythromycin. Some failures of the newer macrolides have occurred in S pneumoniae sepsis and meningitis, perhaps because of low serum levels despite the high tissue levels achieved. High rates of resistance to macrolides and azalides have been encountered in some communities. Azithromycin is not recommended as first-line therapy for S pneumonia infection, including acute otitis media and community-acquired pneumonia.

CLINDAMYCIN

Clindamycin is active against S aureus, some MRSA, S pyogenes, other streptococcal species except enterococci, and both gram-positive and gram-negative anaerobes. Clindamycin or metronidazole is frequently combined with other antimicrobials for empiric therapy of suspected anaerobic or mixed anaerobic and aerobic infections. Empiric use of clindamycin is justified in suspected anaerobic infections because cultures frequently cannot be obtained and, if obtained, may be slow in confirming anaerobic infection. Examples are pelvic inflammatory disease, necrotizing enterocolitis, other infections in which the integrity of the gastrointestinal or genitourinary tracts is compromised, and sinusitis. Clindamycin does not achieve high levels in CSF, but brain abscesses, toxoplasmosis, and other central nervous system infections, where disruption of the blood-brain barrier occurs, can be successfully treated with clindamycin. Clindamycin should be added to regimens for treatment of serious streptococcal and staphylococcal infections, such as necrotizing fasciitis and toxic shock syndrome, since in vitro and clinical data suggest increased bactericidal killing and improved outcomes. For most oral anaerobes (eg, in a dental abscess), penicillin is more active than clindamycin. Clindamycin has been associated with the occurrence of C difficile–related pseudomembranous colitis. Although diarrhea is a frequent side effect, pseudomembranous colitis is uncommonly due to clindamycin in children.

SULFONAMIDES

Sulfonamides—the oldest class of antimicrobials—remain useful for treatment of UTIs, and for other infections due to E coli and for Nocardia. Although useful for rheumatic fever prophylaxis in penicillin-allergic patients, sulfonamides fail to eradicate group A streptococci and cannot be used for treatment of acute infections.

TMP-SMX is a fixed combination that is more active than either drug alone. Gram-positive cocci including some S pneumoniae, many staphylococci, including MRSA, Haemophilus, and many enteric gram-negative rods are susceptible. Unfortunately, resistance to TMP-SMX has become more common. S pneumoniae resistant to penicillin and cephalosporins is often also resistant to TMP-SMX and erythromycin. In communities, where Shigella and Salmonella enteritidis strains remain susceptible, as do most E coli strains, TMP-SMX is very useful for treatment of both UTIs and bacterial dysentery. TMP-SMX is also the drug of choice for treatment or prophylaxis against Pneumocystis jiroveci infection. Myelosuppressive side effects, may limit the use of TMP-SMX in some immunocompromised children.

Sulfonamide is associated with several cutaneous reactions, including urticaria, photosensitivity, Stevens-Johnson syndrome, purpura, and maculopapular rashes. Hematologic side effects such as leukopenia, thrombocytopenia, and hemolytic anemia are uncommon. Common gastrointestinal side effects are nausea and vomiting. The dermatologic and hematologic side effects are thought to be more common and more severe with TMP-SMX than with sulfonamide alone.

TETRACYCLINES

Tetracyclines, which are effective against a broad range of bacteria, are not commonly used in children because alternative effective drugs are available. Tetracyclines are effective against B pertussis and E coli and many species of Rickettsia, Chlamydia, and Mycoplasma. Doxycycline is a drug of choice for eradication of C trachomatis in pelvic inflammatory disease and nongonococcal urethritis.

Staining of permanent teeth was noted in young children given repeated courses of tetracyclines. As a result, tetracyclines are generally not given to children younger than age 9 years unless alternative drugs are unavailable. A single course of tetracycline does not pose a significant risk of tooth staining. Mucous membrane candidiasis, photosensitivity, nausea, and vomiting are other common side effects. Tetracycline should be taken on an empty stomach, either 1 hour before or 2 hours after a meal. Doxycycline is well absorbed even in the presence of food; administration with food may minimize gastrointestinal side effects. Doxycycline is often preferred because it is better tolerated than tetracycline, and twice-daily administration is convenient.

Tetracycline is used for therapy of Q fever and rickettsial infections such as Rocky Mountain spotted fever, ehrlichiosis, anaplasma, rickettsialpox, and endemic and murine typhus; as an alternative to macrolides for M pneumoniae and C pneumoniae infections; and for treatment of psittacosis, brucellosis, P multocida infection, and relapsing fever.

Tigecycline is a polyketide antimicrobial that is an analogue of tetracycline and a bacteriostatic inhibitor of protein synthesis. Tigecycline is active against gram-negative

aerobes, anaerobes, and many gram-positive cocci including MRSA and VRE. It is approved for intravenous therapy of adults with complicated SSTIs and complicated intra-abdominal infections.

AMINOGLYCOSIDES

The aminoglycosides bind to ribosomal subunits and inhibit protein synthesis. They are active against aerobic gram-negative rods, including P aeruginosa. Streptomycin was the first drug in this class, but today it is used only to treat tuberculosis and the occasional cases of plague and tularemia. Streptomycin is often not available.

Aminoglycosides are used to treat serious gram-negative infections and are given intravenously or intramuscularly. They are also used to treat pyelonephritis, suspected gram-negative sepsis and in other settings where P aeruginosa infections are common, such as cystic fibrosis and burns. Aminoglycosides have activity against gram-positive organisms and, combined with penicillin or ampicillin, may achieve synergistic killing of L monocytogenes and group B streptococci. Penicillin, ampicillin, or vancomycin combined with gentamicin is indicated for therapy of serious enterococcal infections, such as sepsis or endocarditis because of more rapid clinical improvement with combined therapy. Aminoglycosides have activity against S aureus, but are always used in combination with other antistaphylococcal antibiotics.

Aminoglycosides are not active in an acidic environment and may not be effective against abscesses. Aminoglycosides diffuse poorly into the CSF and achieve only about 10% of serum concentrations. As a result, a third-generation cephalosporin is preferred for treatment of meningitis.

Aminoglycosides kill bacteria in a concentration-dependent manner. They also have a prolonged suppressive effect on the regrowth of susceptible organisms (postantibiotic effect). These principles have led some investigators to establish guidelines for once-daily dosing of aminoglycosides, using larger initial doses given every 24 hours. Although aminoglycosides are associated with both renal and eighth nerve toxicity, the entry of the drug into renal and cochlear cells is saturable, and it therefore was predicted that once-daily dosing would result in less toxicity than traditional twice-daily or three-times-daily dosing. Studies in adult patients confirm that once-daily dosing is as efficacious as traditional dosing and is associated with less toxicity. Although there is extensive experience with dosing intervals of 18–36 hours in premature infants, small total daily doses are customarily used (2.0–2.5 mg/kg per dose of gentamicin or tobramycin). A convenient and cost-effective approach in children is based on the experience with adult patients and uses larger daily doses (4–7 mg/kg per dose every 24 hours). Nevertheless, traditional twice-daily or three-times-daily dosing regimens of aminoglycosides, with monitoring of serum levels, are still widely used. Careful monitoring is necessary, particularly in children with abnormal or changing renal function, premature infants, and infants with rapidly changing volumes of distribution. Aminoglycosides are usually infused over 30–45 minutes, and the peak serum concentration is measured 30–45 minutes after the end of the infusion. A trough serum concentration is measured prior to the next dose. The efficacious and nontoxic serum concentrations for gentamicin and tobramycin are trough less than 2 mcg/mL and peak 5–12 mcg/mL; for amikacin, trough less than 10 mcg/mL and peak 20–35 mcg/mL (see Table 39–4). Aminoglycoside levels and creatinine levels should be measured in children expected to receive more than 3 days of therapy, and repeated weekly in children on long-term therapy, even when renal function is normal and stable.

FLUOROQUINOLONES

Fluoroquinolones are well absorbed after oral administration and possess excellent antibacterial, though they vary in their spectrum of activity. Generally, they are active against most of the Enterobacteriaceae, including E coli, Enterobacter, Klebsiella, and many other gram-negative bacteria such as H influenzae, M catarrhalis, N gonorrhoeae, and N meningitidis. Some fluoroquinolones are active against P aeruginosa and other resistant gram-negative pathogens. Ofloxacin and levofloxacin are active against C trachomatis and Mycoplasma. The fluoroquinolones are active against some enterococci, S aureus, MRSA, and coagulase-negative staphylococci. The newer quinolones have good activity against penicillin- and cephalosporin-resistant S pneumonia.

Ciprofloxacin and its otic and ophthalmic preparations are the only fluoroquinolone antimicrobials currently approved for use in children older than 1 year, although fluoroquinolones offer very attractive alternatives to other approved agents. The objection to quinolones is based on the recognition that nalidixic acid and other quinolones cause arthropathy when tested in newborn animals of many species. The fear that children would also be more susceptible than adults to cartilage injury has not been realized in clinical experience. Both retrospective long-term follow-up studies of children given nalidixic acid and prospective studies of children receiving treatment under protocols with fluoroquinolones have shown similar rates of toxicity compared with adult patients. Arthropathy occurs uncommonly, and tendon rupture is a reported rare complication which occurs more commonly in adults. For these reasons, quinolones should be considered for use in children when the benefit clearly outweighs the risk, when no alternative drug is available, and after discussion with the parents.

Ciprofloxacin is useful for oral therapy of resistant gram-negative UTIs, such as those caused by P aeruginosa. Fluoroquinolones are no longer recommended for single-dose therapy of gonorrhea due to frequent resistance, but

ofloxacin and levofloxacin are an alternative therapy for treating Chlamydia infections and pelvic inflammatory disease. Ciprofloxacin, levofloxacin, and ofloxacin are used as therapy of resistant cases of shigellosis. Levofloxacin and ciprofloxacin are usually the drugs of choice for treatment of traveler's diarrhea. Ciprofloxacin is useful for treatment of P aeruginosa infection in patients with cystic fibrosis, and as therapy for chronic suppurative otitis media. Several quinolones are used as therapy for pneumonia due to Legionella, Mycoplasma, or C pneumoniae, although a macrolide is often preferred, and as prophylactic therapy of meningococcal infection. Ofloxacin and levofloxacin are used for treatment of some cases of Mycobacterium tuberculosis and some atypical mycobacterial infections.

METRONIDAZOLE

Metronidazole has excellent activity against most anaerobes, particularly gram-negative anaerobes, such as Bacteroides and Fusobacterium, and against gram-positive anaerobes such as Clostridium, Prevotella, and Porphyromonas. Gram-positive anaerobic cocci such as Peptococcus and Peptostreptococcus are often more susceptible to penicillin or to clindamycin. Because metronidazole lacks activity against aerobic organisms, it is usually given with one or more other antibiotics. Metronidazole is well absorbed after oral administration and has excellent penetration into the central nervous system. Metronidazole is the drug of choice for bacterial vaginosis and for C difficile enterocolitis. It is active against many parasites, including Giardia lamblia and Entamoeba histolytica.

DAPTOMYCIN

Daptomycin has broad bactericidal activity against gram-positive cocci. Daptomycin is a lipopeptide that binds to bacterial cell membranes, resulting in membrane depolarization and cell death. Daptomycin is active against methicillin-sensitive and resistant S aureus, S pyogenes, and Streptococcus agalactiae, as well as E faecium (including vancomycin-resistant strains) and E faecalis (vancomycin-sensitive strains). Daptomycin is given as a once-daily intravenous infusion of 4 mg/kg and is approved for therapy of complicated SSTIs in adults. Daptomycin is dosed 10 mg/kg in children 2–5 years old and 7 mg/kg in children 6–11 years old. Children over 12 years old are dosed with 4 mg/kg. Daptomycin therapy of pneumonia was unsuccessful in a large percentage of cases, and should not be used. Daptomycin is excreted renally, so a modification of dosing is needed in patients with impaired renal function. Nausea, constipation, and headache are the most common side effects of therapy. Daptomycin has well-described but rare side effects on skeletal muscle, so creatinine phosphokinase levels should be evaluated in patients with muscle pain, and some recommend monitoring in high-risk patients.

40 Infections: Viral & Rickettsial

Myron J. Levin, MD
Edwin J. Asturias, MD
Adriana Weinberg, MD

VIRAL INFECTIONS

Viruses cause most pediatric infections. Mixed viral or viral-bacterial infections of the respiratory and intestinal tracts are common, as is prolonged asymptomatic shedding of some viruses in childhood, especially in young children. Thus, the detection of a virus is not always proof that it is the cause of a given illness. Viruses are often a predisposing factor for bacterial respiratory infections (eg, otitis, sinusitis, and pneumonia).

Many respiratory viruses and herpesviruses can now be detected within 24–48 hours by combining culture and monoclonal antibody techniques ("rapid culture technique") or through antigen or nucleic acid detection techniques. Polymerase chain reaction (PCR) amplification of viral genes has led to recognition of previously undetected infections. New diagnostic tests have changed some basic concepts about viral diseases and made diagnosis of viral infections both more certain and more complex. Only laboratories with excellent quality-control procedures should be used. The availability of specific antiviral agents increases the value of early diagnosis for some serious viral infections. Table 40–1 lists diagnostic tests. The viral diagnostic laboratory should be contacted for details regarding specimen collection, handling, and shipping. Table 40–2 lists common causes of red rashes in children that should be considered in the differential diagnosis of certain viral illnesses.

RESPIRATORY INFECTIONS

Many viral infections can cause either upper or lower respiratory tract signs and symptoms, sometimes both in the same patient. Those that produce a predominance of these signs and symptoms are described in the text that follows. Many so-called respiratory viruses can also produce distinct non-respiratory disease (eg, enteritis or cystitis or myocarditis caused by adenoviruses; parotitis caused by parainfluenza viruses). Respiratory viruses can cause disease in any area of the respiratory tree, although certain viruses tend to be closely associated with one anatomic area (eg, parainfluenza with croup, respiratory syncytial virus [RSV] with bronchiolitis) or with discrete epidemics (eg, influenza, RSV, parainfluenza). Thus it is impossible on clinical grounds to be certain of the specific viral cause of an infection in a given child. This information, which is provided by the virology laboratory, is often important for epidemiologic, therapeutic, and preventive reasons. In immunocompromised patients, these annoying, but otherwise benign, viruses can cause severe pneumonia.

VIRUSES CAUSING THE COMMON COLD

The common cold syndrome (also called upper respiratory infection) is characterized by combinations of runny nose, nasal congestion, sore throat, tearing, cough, and sneezing. Low-grade fever may be present. Epidemiologic studies indicate that rhinoviruses, which are the most common cause (30%–40%; more in some series), are present throughout the year, but are more prevalent in the colder months in temperate climates. Adenoviruses also cause colds in all seasons and epidemics are common. RSV, parainfluenza viruses, human metapneumovirus, and influenza viruses cause the cold syndrome during epidemics from late fall through winter. Multiple strains of coronaviruses account for 5%–10% of cold syndromes in winter. The precise role of newly identified respiratory viruses, such as the human bocavirus (a parvovirus) and several polyomaviruses, are under study. Enteroviruses cause the "summer cold." One outcome of the common cold is morbidity continuing for 5–7 days. It is also likely that changes in respiratory epithelium, local mucosal swelling, and altered local immunity are sometimes the precursors of more severe illnesses such as otitis media, pneumonia, and sinusitis. During and following a cold, the bacterial flora changes and bacteria are found in normally sterile areas of the upper airway. Asthma attacks are frequently provoked by any of the viruses that cause the

Table 40–1. Diagnostic tests for viral infections.

Agent	Rapid Antigen Detection (Specimen)	Tissue Culture Mean Days to Positive (Range)	Serology		PCR	Comments
			Acute	Paired		
Adenovirus	+ (respiratory and enteric)	10 (1–21)	–	+	+	"Enteric" strains detected by culture on special cell line, antigen detection, or PCR
Arboviruses	–	–	+	+	+	Acute serum may diagnose many forms
Astrovirus	–	–	–	–	+	Diagnosis by electron microscopy
Calicivirus	– RL	–	–	–	+	Diagnosis by electron microscopy; PCR generally available for norovirus; present in RL for others
Colorado tick virus	On RBC	–	–	RL, CDC	+	
Coronavirus	–	RL	–	+	+	
Cytomegalovirus	+ (tissue biopsy, urine, blood, respiratory secretions)	2 (2–28)	+	+	+	Diagnosis by presence of IgM antibody; rapid culture method generally available; low avidity antibody indicates recent infection
Dengue	+	5 d (RL)	+	+	+	Testing at CDC; 80% seropositive at 6 days
Enterovirus	–	3 (2–8) Coxsackie A difficult to culture	–	++	+	
Epstein-Barr virus	–	–	+	++	++	Single serologic panel defines infection status; heterophil antibodies less sensitive
Hantavirus	–	–	+	ND	RL	Diagnosis by presence of IgM antibody
Hepatitis A virus	–	–	+	ND	RL	Diagnosis by presence of IgM antibody
Hepatitis B virus	+ (blood)	–	+	ND	+	Diagnosis by presence of surface antigen or anticore IgM antibody
Hepatitis C virus	–	–	+	ND	+	Positive serology suggests that hepatitis C could be the causative agent; PCR is confirmatory. PCR may be positive before serology
Herpes simplex virus	+ (mucosa, tissue biopsy, respiratory secretions, skin)	1 (1–7)	+	+	+	Serology rarely used for herpes simplex; IgM antibody used in selected cases
Human herpesvirus 6 and 7	–	2 (RL)	+	+	+	Roseola agent
Human immunodeficiency virus	+ (blood) (acid dissociation of immune complexes); not done in the United States	15 (5–28)	+	ND	+	Antibody proves infection unless passively acquired (maternal antibody gone by age 15 mo); culture not widely available; PCR definitive for early diagnosis in infant (detect RNA or DNA)
Human metapneumovirus	+	2	–	+	+	
Influenza virus	+ (respiratory secretions)	2 (2–14)	–	+	+	Antigen detection 40%–90% sensitive (varies with virus strain)
Lymphocytic choriomeningitis virus	–	–	–	+	RL	Can be isolated in suckling mice

(Continued)

Table 40–1. Diagnostic tests for viral infections. (Continued)

Agent	Rapid Antigen Detection (Specimen)	Tissue Culture Mean Days to Positive (Range)	Serology		PCR	Comments
			Acute	Paired		
Measles virus	+ (respiratory secretions)	–	+	+	+	Difficult to grow; IgM serology diagnostic
Mumps virus	–	> 5	+	+	+	IgM ELISA antibody may allow single-specimen diagnosis
Parvovirus B19	–	–	+	ND	+	Erythema infectiosum agent; IgM serology is often diagnostic, but may be positive for a prolonged period
Parainfluenza virus	+ (respiratory secretions)	2 (2–14)	–	+	+	
Rabies virus	+ (skin, conjunctiva, suspected animal source tissue biopsy)	–	+	+	CDC	Usually diagnosed by antigen detection
Respiratory syncytial virus	+ (respiratory secretions)	2 (2–21)	–	+	+	Rapid antigen detection; 90% sensitive; PCR has excellent sensitivity
Rhinovirus	–	4 (2–7)	–	–	+	Too many strains to type serologically
Rotavirus	+ (feces)	–	–	–	+	Rapid assay methods are usually reliable
Rubella virus	–	> 10	+	+	+	Recommended that paired sera be tested simultaneously
Varicella-zoster virus	+ (skin scraping)	3 (3–21) RL	+	+	+	
West Nile virus	–	RL	+	+	+	IgM antibody usually detected by 1 wk; PCR is useful only on CSF

CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; RBC, red blood cell.
Plus signs signify commercially or widely available; **minus signs** signify not commercially available. **Note:** Results from some commercial laboratories are unreliable. **RL** indicates research laboratory only; **CDC:** Specific antibody titers or PCR available by arrangement with individual research laboratories or the Centers for Disease Control and Prevention. **ND:** Not done.

common cold. These "cold viruses" are a common cause of lower respiratory tract infection in young children. There is no evidence that antibiotics will prevent complications of the common cold.

In 5%–10% of children, symptoms from these virus infections persist for more than 10 days. This overlap with the symptoms of bacterial sinusitis presents a difficult problem for clinicians, especially because colds can produce an abnormal computed tomography (CT) scan of the sinuses. Viruses that cause a minor illness in immunocompetent children, such as rhinoviruses, influenza, RSV, and metapneumovirus, can cause severe lower respiratory disease in immunologically or anatomically compromised children.

There is conflicting evidence that symptomatic relief for children can be achieved with oral antihistamines, decongestants, or cough suppressants. The FDA has recommended that such over-the-counter medications not be used in children less than 2 years old. Topical decongestants provide temporary improvement in nasal symptoms. Vitamin C has not been shown to have a significant preventative or therapeutic role. Zinc therapy for the common cold and prevention with zinc may be effective in adults, but there is great uncertainty about dosing and some adverse effects. Humidified air and garlic do not alter the course of colds.

INFECTIONS DUE TO ADENOVIRUSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Multiple syndromes, depending on the type of adenovirus.
- Upper respiratory infections; most notable is severe pharyngitis with tonsillitis and cervical adenopathy.
- Conjunctivitis.
- Pneumonia.
- Enteric adenoviruses cause mild diarrheal illnesses.
- Definitive diagnosis by antigen detection, PCR, or culture.

There are 57 types of adenoviruses, which account for 5%–15% of all respiratory illnesses in childhood, usually pharyngitis or tracheitis, but including 5% of childhood lower respiratory tract infections. Adenoviral infections, which are common early in life (most prior to age 2 years), occur 3–10 days after exposure to respiratory droplets or fomites. Enteric adenoviruses are an important cause of childhood diarrhea. Epidemic respiratory disease from adenoviruses occurs in winter and spring, especially in closed environments such as day care centers and institutions. Because of latent infection in lymphoid tissue, asymptomatic shedding from the respiratory or intestinal tract is common.

Specific Adenoviral Syndromes

A. Pharyngitis

Pharyngitis is the most common adenoviral disease, and the most common viral cause of severe pharyngitis in children. Fever and adenopathy are common. Tonsillitis may be exudative. Rhinitis and an influenza-like systemic illness may be present. Laryngotracheitis or bronchitis may accompany pharyngitis.

B. Pharyngoconjunctival Fever

Conjunctivitis may occur alone and be prolonged, but most often is associated with preauricular adenopathy, fever, pharyngitis, and cervical adenopathy. Foreign body sensation in the eye and other symptoms last less than a week. Lower respiratory symptoms are uncommon.

C. Epidemic Keratoconjunctivitis

Symptoms are severe conjunctivitis with punctate keratitis and occasionally visual impairment. A foreign body sensation, photophobia, and swelling of conjunctiva and eyelids are characteristic. Preauricular adenopathy and subconjunctival hemorrhage are common.

D. Pneumonia

Severe pneumonia may occur at all ages. It is especially common in young children (age < 3 years). Chest radiographs show bilateral peribronchial and patchy ground-glass interstitial infiltrates in the lower lobes. Symptoms persist for 2–4 weeks. Adenoviral pneumonia can be necrotizing and cause permanent lung damage, such as bronchiectasis and bronchiolitis obliterans. A pertussis-like syndrome with typical cough and lymphocytosis can occur with lower respiratory tract infection. A new variant of adenovirus serotype 14 can cause unusually severe, sometimes fatal pneumonia in children and adults.

E. Rash

A diffuse morbilliform (rarely petechial) rash resembling measles, rubella, or roseola may be present. Koplik spots are absent.

F. Diarrhea

Enteric adenoviruses (types 40 and 41) cause 3%–5% of cases of short-lived diarrhea in afebrile children, especially in those less than 4 years old.

G. Mesenteric Lymphadenitis

Fever and abdominal pain may mimic appendicitis. Pharyngitis is often associated. Adenovirus-induced adenopathy may be a factor in appendicitis and intussusception.

H. Other Syndromes

Immunosuppressed patients, including neonates, may develop severe or fatal pulmonary or gastrointestinal infections or multisystem disease. Hemorrhagic cystitis can be a serious problem in immunocompromised children. Other rare complications that can occur in the immunocompetent child include encephalitis, hepatitis, and myocarditis. Adenoviruses have been implicated in the syndrome of idiopathic myocardiopathy.

» Laboratory & Diagnostic Studies

Diagnosis can be made by conventional culture of conjunctival, respiratory, or stool specimens, but several days to weeks are required. Viral culture using the rapid culture technique with immunodiagnostic reagents detects adenovirus in 48 hours. Adenovirus infection can also be diagnosed using these reagents directly on respiratory

secretions. This is quicker, but less sensitive, than the culture methods. PCR is an important, relatively rapid and sensitive diagnostic method for adenovirus infections. Special cells are needed to isolate enteric adenoviruses. ELISA (enzyme-linked immunosorbent assay) tests rapidly detect enteric adenoviruses in diarrheal specimens. Respiratory adenovirus infections can be detected retrospectively by comparing acute and convalescent sera, but this is not helpful during an acute illness.

» Treatment

There is no specific treatment for adenovirus infections. Intravenous immunoglobulin (IVIG) may be tried in immunocompromised patients with severe pneumonia. Adoptive T-cell transfer has shown promising results in hematopoietic stem cell transplant recipients. There is anecdotal evidence of successful treatment of immunocompromised patients with cidofovir and, more recently, with brincidofovir, a cidofovir derivative with good oral bioavailability and less nephrotoxicity than the parent drug.

Lion T: Adenovirus infections in immune competent and immunocompromised patients. Clin Microbiol Rev 2014;27:441 [PMID: 24982316].

INFLUENZA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Fever, cough, pharyngitis, malaise, congestion.
- » Pneumonia.
- » Encephalitis.
- » Seasonal: late fall through mid-spring.
- » Detection of virus, viral antigens, or nucleic acid in respiratory secretions.

Symptomatic infections are common in children because they lack immunologic experience with influenza viruses. Infection rates in children are greater than in adults and are instrumental in initiating community outbreaks. Epidemics occur in fall and winter. Three main types of influenza viruses (A/H1N1, A/H3N2, B) cause most human epidemics, with antigenic drift ensuring a supply of susceptible hosts of all ages. In recent years, avian influenza A/H5N1 and A/H7N9 caused isolated human outbreaks in Asia that were associated with high rates of hospitalization and death. A swine-origin influenza A/H1N1 caused a human pandemic in 2009 and 2010 and has since circulated with seasonal periodicity. An influenza A/H3N2v of swine origin has also caused clusters of human infections in the last 5 years in the United States, commonly associated with exposure to pigs.

» Clinical Findings

Spread of influenza occurs by way of airborne respiratory secretions. The incubation period is 2–7 days.

A. Symptoms and Signs

Influenza infection in older children and adults produces a characteristic syndrome of sudden onset of high fever, severe myalgia, headache, and chills. These symptoms overshadow the associated coryza, pharyngitis, and cough. Usually absent are rash, marked conjunctivitis, adenopathy, exudative pharyngitis, and dehydrating enteritis. Fever, diarrhea, vomiting, and abdominal pain are common in young children. Infants may develop a sepsis-like illness and apnea. Chest examination is usually unremarkable. Unusual clinical findings include croup (most severe with type A influenza), exacerbation of asthma, myositis (especially calf muscles), myocarditis, parotitis, encephalopathy (distinct from Reye syndrome), nephritis, and a transient maculopapular rash. Acute illness lasts 2–5 days. Cough and fatigue may last several weeks. Viral shedding may persist for several weeks in young children.

B. Laboratory Findings

The leukocyte count is normal to low, with variable shift. Influenza infections may be more difficult to recognize in children than in adults even during epidemics, and therefore a specific laboratory test is highly recommended. The virus can be found in respiratory secretions by direct fluorescent antibody staining of nasopharyngeal epithelial cells, ELISA, optic immunoassay (OIA), and PCR. PCR has the highest sensitivity and specificity, close to 100%, and is rapidly becoming the preferred test. It can also be cultured within 3–7 days from pharyngeal swabs or throat washings. Many laboratories use the rapid culture technique by centrifuging specimens onto cultured cell layers and detecting viral antigen after 48 hours. Other body fluids or tissues (except lung) rarely yield the virus in culture and are more appropriately tested by PCR, which, due to its high sensitivity, can increase influenza detection in respiratory specimens. A late diagnosis may be made with paired serology, using hemagglutination inhibition assays.

C. Imaging

The chest radiograph is nonspecific; it may show hyperaeration, peribronchial thickening, diffuse interstitial infiltrates, or bronchopneumonia in severe cases. Hilar nodes are not enlarged. Pleural effusion is rare in uncomplicated influenza.

» Differential Diagnosis

The following may be considered: all other respiratory viruses, Mycoplasma pneumoniae or Chlamydia pneumoniae (longer incubation period, prolonged illness), streptococcal pharyngitis (pharyngeal exudate or petechiae, adenitis, no cough), bacterial sepsis (petechial or purpuric rash may occur), toxic shock syndrome (rash, hypotension), and rickettsial infections (rash, different season, insect exposure). High fever, the nature of preceding or concurrent illness in family members, and the presence of influenza in the community are distinguishing features from parainfluenza or RSV infections.

» Complications & Sequelae

Lower respiratory tract symptoms are most common in children younger than age 5 years. Hospitalization rates are highest in children younger than 2 years. Influenza can cause croup in these children. Secondary bacterial infections (classically staphylococcal) of the middle ear, sinuses, or lungs (pneumococcal was common in the swine-origin H1N1 pandemic of 2009) are common. Of the viral infections that precede Reye syndrome, varicella and influenza (usually type B) are most notable. During an influenza outbreak, ill children who develop protracted vomiting or irrational behavior should be evaluated for Reye syndrome. Influenza can also cause viral or postviral encephalitis, with cerebral symptoms much more prominent than those of the accompanying respiratory infection. Although the myositis is usually mild and resolves promptly, severe rhabdomyolysis and renal failure have been reported.

Children with underlying cardiopulmonary, metabolic, neuromuscular, or immunosuppressive disease may develop severe viral pneumonia. During the H1N1 pandemic, new high-risk conditions were described: obesity and the first 2 weeks of postpartum.

» Prevention

The trivalent and quadrivalent inactivated influenza vaccines are moderately protective in older children (see Chapter 10). Live attenuated influenza vaccines (LAIV) are usually more efficacious in children and are recommended for immunocompetent children 2 years of age or older. Widespread resistance to adamantanes of seasonal influenza A/H3N2 and H1N1 has made these drugs obsolete for the treatment and prevention of influenza. For prophylaxis oseltamivir is the most widely used agent (children < 15 kg, 30 mg daily; those 15–23 kg, 45 mg daily; those 23–40 kg, 60 mg daily; and those > 40 kg, 75 mg daily). Zanamivir (10 mg daily inhalations) can also be used in children older than age 5 years. Chemoprophylaxis should be considered during an epidemic for high-risk children who cannot be immunized or who have not yet developed immunity (about 6 weeks after primary vaccination or 2 weeks after a booster dose). For outbreak prophylaxis, therapy should be maintained for 2 weeks or more and for 1 week after the last case of influenza is diagnosed.

» Treatment & Prognosis

Treatment consists of general support and management of pulmonary complications, especially bacterial superinfections. Antivirals are of benefit against seasonal influenza in immunocompetent hosts if begun within 48 hours after symptom onset. Treatment duration is 5 days and the doses are twice those used for prophylaxis (see earlier). Studies in immunocompromised patients during the 2009/2010 pandemic showed that oseltamivir was useful in this population even when initiated later than 2 days after the onset of disease. Peramivir, a neuraminidase inhibitor that is available for IV administration, is approved for treatment. New drugs, such as lananimivir, an inhaled neuraminidase inhibitor with a long half-life that allows its single-dose use, and nitazoxanide, a safe and well tolerated oral drug, that was originally introduced for anti-parasitic treatment, but has since shown wide spectrum antiviral activity, are also under consideration for influenza treatment and prophylaxis.

Recovery is usually complete unless severe cardiopulmonary or neurologic damage has occurred. Fatal cases occur in very young infants, immunodeficient and anatomically compromised children, pregnant women, including the first 2 weeks postpartum, and obese individuals.

Effective treatment or prophylaxis of influenza in children markedly reduces the incidence of acute otitis media and antibiotic usage during the flu season.

Grohskopf LA et al; Centers for Disease Control and Prevention: Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP)—United States, 2014–15 Influenza Season. MMWR Morb Mortal Wkly Rep 2014 Aug 15;63(32):691–697 [PMID: 25121712].

PARAINFLUENZA (CROUP)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, nasal congestion, sore throat, cough.
- Croup.
- Detection of live virus, antigens, or nucleic acid in respiratory secretions.

Parainfluenza viruses (types 1–4) are the most important cause of croup. Most infants are infected with type 3 within the first 3 years of life, often in the first year. Similar to type 3, type 4 has year-round circulation alternating years with type 3. Infection with types 1 and 2 is experienced gradually over the first 5 years of life, usually during outbreaks in the fall; most primary infections are symptomatic and frequently involve the lower respiratory tract. The concept that parainfluenza 4 is less pathogenic is currently being reevaluated.

» Clinical Findings

A. Symptoms and Signs

Clinical diseases include febrile upper respiratory infection (especially in older children with reexposure), laryngitis, tracheobronchitis, croup, and bronchiolitis (second most common cause after RSV). The relative incidence of these manifestations is type-specific. Parainfluenza viruses (especially type 1) cause 65% of cases of croup in young children, 25% of tracheobronchitis, and 50% of laryngitis. Croup is characterized by a barking cough, inspiratory stridor (especially when agitated), and hoarseness. Type 2 parainfluenza is more likely to cause bronchiolitis. Parainfluenza virus can cause pneumonia in infants and immunodeficient children, and causes particularly high mortality among stem cell recipients. Onset is acute. Most children are febrile. Symptoms of upper respiratory tract infection often accompany croup.

B. Laboratory Findings

Diagnosis is often based on clinical findings. These viruses can be identified by conventional or rapid culture techniques (48 hours), by direct immunofluorescence on nasopharyngeal epithelial cells in respiratory secretions (< 3 hours), or by PCR (< 24 hours).

» Differential Diagnosis

Parainfluenza-induced respiratory syndromes are difficult to distinguish from those caused by other respiratory viruses. Viral croup must be distinguished from epiglottitis caused by Haemophilus influenzae (abrupt onset, toxicity and high fever, drooling, dyspnea, little cough, left shift of blood smear, and a history of inadequate immunization).

» Treatment

No specific therapy or vaccine is available. Croup management is discussed in Chapter 19. Ribavirin is active in vitro and has been used in immunocompromised children, but its efficacy is unproved.

Frost HM et al: Epidemiology and clinical presentation of parainfluenza type 4 in children: a 3-year comparative study to parainfluenza types 1-3. J Clin Infect Dis 2014;209:695 [PMID: 24133181].

RESPIRATORY SYNCYTIAL VIRUS DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diffuse wheezing and tachypnea following upper respiratory symptoms in an infant (bronchiolitis).
- Epidemics in late fall to early spring (January–February peak).
- Hyperinflation on chest radiograph.
- Detection of RSV antigen or nucleic acid in nasal secretions.

» General Considerations

RSV is the most important cause of lower respiratory tract illness in young children, accounting for more than 70% of cases of bronchiolitis and 40% of cases of pneumonia. RSV is a ubiquitous virus of early childhood. Almost all children develop upper respiratory symptoms; of these 20%–30% will develop lower respiratory infection. Outbreaks occur annually, and attack rates are high; 60% of children are infected in the first year of life, and 90% by age 2 years. During peak season (cold weather in temperate climates), the clinical diagnosis of RSV infection in infants with bronchiolitis is as accurate as most laboratory tests. Despite the presence of serum antibody, reinfection is common. Two distinct genotypes can cocirculate or one may predominate in a community. Yearly shift in prevalence of these genotypes is a partial explanation for reinfection. However, reinfection generally causes only upper respiratory symptoms in anatomically normal children. Immunosuppressed patients may develop progressive severe pneumonia. Children with congenital heart disease with increased pulmonary blood flow, children with chronic lung disease (eg, cystic fibrosis), and premature

infants younger than age 6 months (especially when they have chronic lung disease of prematurity) are also at higher risk for severe illness. No vaccine is available.

» Clinical Findings

A. Symptoms and Signs

Initial symptoms are those of upper respiratory infection. Low-grade fever may be present. The classic disease is bronchiolitis, characterized by diffuse wheezing, variable fever, cough, tachypnea, difficulty feeding, and, in severe cases, cyanosis. Hyperinflation, crackles, prolonged expiration, wheezing, and retractions are present. The liver and spleen may be palpable because of lung hyperinflation, but are not enlarged. The disease usually lasts 3–7 days in previously healthy children. Fever is present for 2–4 days; it does not correlate with pulmonary symptoms and may be absent during the height of lung involvement.

Apnea, poor feeding, and lethargy may be presenting manifestations, especially in premature infants, in the first few months of life. Apnea usually resolves after a few days, often being replaced by obvious signs of bronchiolitis.

RSV infection in older children is more likely to cause tracheobronchitis or upper respiratory tract infection. Exceptions are immunocompromised children and those with severe chronic lung or heart disease, who may have especially severe or prolonged primary infections and are subject to additional attacks of severe pneumonitis.

B. Laboratory Findings

Rapid detection of RSV antigen in nasal or pulmonary secretions by fluorescent antibody staining or ELISA requires only several hours and is more than 90% sensitive and specific. Real-time PCR is more sensitive than antigen testing, but is more expensive. Often the PCR is multiplexed to detect four or more viral respiratory pathogens in the same assay. Rapid tissue culture methods take 48 hours and have comparable sensitivity, but require a carefully collected and handled specimen.

C. Imaging

Diffuse hyperinflation and peribronchiolar thickening are most common; atelectasis and patchy infiltrates also occur in uncomplicated infection, but pleural effusions are rare. Consolidation (usually subsegmental) occurs in 25% of children with lower respiratory tract disease.

» Differential Diagnosis

Although almost all cases of bronchiolitis are due to RSV during an epidemic, other viruses, including parainfluenza, rhinovirus, and especially human metapneumovirus, cannot be excluded. Mixed infections with other viruses, chlamydiae, or bacteria can occur. Wheezing may be due to asthma, a foreign body, or other airway obstruction. RSV infection may closely resemble chlamydial pneumonitis when fine crackles are present and fever and wheezing are not prominent. The two may also coexist. Cystic fibrosis may present with respiratory symptoms resembling RSV infection; a positive family history or failure to thrive associated with GI symptoms, hyponatremia or hypoalbuminemia should prompt a sweat chloride test. Pertussis should also be considered in this age group, especially if cough is prominent and the infant is younger than age 6 months. A markedly elevated leukocyte count should suggest bacterial superinfection (neutrophilia) or pertussis (lymphocytosis).

» Complications

RSV commonly infects the middle ear. Symptomatic otitis media is more likely when secondary bacterial infection is present (usually due to pneumococci or H influenzae). This is the most common complication (10%–20%) of RSV infection. Bacterial pneumonia complicates only 0.5%–1% of hospitalized patients. Sudden exacerbations of fever and leukocytosis should suggest bacterial infection. Respiratory failure or apnea may require mechanical ventilation, but occurs in less than 2% of hospitalized previously healthy full-term infants. Cardiac failure may occur as a complication of pulmonary disease or myocarditis. RSV commonly causes exacerbations of asthma. Nosocomial RSV infection is so common during outbreaks that elective hospitalization or surgery, especially for those with underlying illness, should be postponed. Well-designed hospital programs to prevent nosocomial spread are imperative (see the next section).

» Prevention & Treatment

Children who are very hypoxic or cannot feed because of respiratory distress must be hospitalized and given humidified oxygen as directed by oxygen saturation, and given tube or intravenous feedings. Antibiotics, decongestants, and expectorants are of no value in routine infections. RSV-infected children should be kept in respiratory isolation. Cohorting ill infants in respiratory isolation during peak season (with or without rapid diagnostic attempts) and emphasizing good hand washing may greatly decrease nosocomial transmission.

The utility of bronchodilator therapy alone has not been consistently demonstrated. Often a trial of bronchodilator therapy is given to determine response and is subsequently discontinued if there is no improvement. Racemic epinephrine occasionally works when β-agonists fail. This therapeutic trial should only be undertaken in a hospital setting

and care taken to observe children for an extended period after a positive response. The use of corticosteroids is also controversial in RSV bronchiolitis without complicating features such as asthma and chronic lung disease of prematurity. A meta-analysis of numerous studies of corticosteroid therapy indicated a significant effect on hospital stay, especially in those most ill at the time of treatment, but use of a single dose of corticosteroids in an outpatient setting had no lasting effect on respiratory status and did not prevent hospitalization. The combined use of racemic epinephrine and 5 days of oral dexamethasone significantly reduced hospitalization in one trial, but needs more evaluation before it can be recommended.

Ribavirin is the only licensed antiviral therapy used for RSV infection. It is given by continuous aerosolization. It is rarely used in infants without significant anatomic or immunologic defects. At best, there is a very modest effect on disease severity in immunocompetent infants with no underlying anatomic abnormality. Even in high-risk infants, a favorable clinical response to ribavirin therapy was not demonstrated in several studies, although some data suggest that it might be more efficacious if initiated early in the illness. Nevertheless, ribavirin is sometimes used in severely ill children who are immunologically or anatomically compromised and in those with severe cardiac disease.

Monthly intramuscular administration of humanized RSV monoclonal antibody is now recommended to prevent severe disease in selected high-risk patients during epidemic periods. Monthly administration should be considered during the RSV season for high-risk children (described in Chapter 10). Use of passive immunization for immunocompromised children is logical but not established. RSV antibody is not effective for treatment of established infection.

» Prognosis

Although mild bronchiolitis does not produce long-term problems, 30%–40% of patients hospitalized with this infection will wheeze later in childhood, and RSV infection in infancy may be an important precursor to asthma. Chronic restrictive lung disease and bronchiolitis obliterans are rare sequelae.

HUMAN METAPNEUMOVIRUS INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cough, coryza, sore throat.
- Bronchiolitis.
- Detection of viral antigens or nucleic acid in respiratory secretions.

» General Considerations

Human metapneumovirus (hMPV) is a common agent of respiratory tract infections that is very similar to RSV in epidemiologic and clinical characteristics. Like RSV, parainfluenza, mumps, and measles, hMPV belongs to the paramyxovirus family. Humans are its only known reservoir. Seroepidemiologic surveys indicate that the virus has worldwide distribution. More than 90% of children contract hMPV infection by age 5 years, typically during late autumn through early spring outbreaks. hMPV accounts for 15%–25% of the cases of bronchiolitis and pneumonia in children younger than 2 years. Older children and adults can also develop symptomatic infection.

» Clinical Findings

A. Symptoms and Signs

The most common symptoms are fever, cough, rhinorrhea, and sore throat. Bronchiolitis and pneumonia occur in 40%–70% of the children who acquire hMPV before the age of 2 years. Asymptomatic infection is uncommon. Other manifestations include otitis, conjunctivitis, diarrhea, and myalgia. Acute wheezing has been associated with hMPV in children of all ages, raising the possibility that this virus, like RSV, might trigger reactive airway disease. Dual infection with hMPV and RSV or other respiratory viruses seems to be a common occurrence and may increase morbidity and mortality.

B. Laboratory Findings

The virus has very selective tissue culture tropism, which accounts for its late discovery in spite of its presence in archived specimens from the mid-1950s. The preferred method of diagnosis is PCR performed on respiratory specimens. Rapid shell vial culture is an acceptable, albeit less sensitive, alternative. Antibody tests are available, but are most appropriately used for epidemiologic studies.

C. Imaging

Lower respiratory tract infection frequently shows hyperinflation and patchy pneumonitis on chest radiographs.

» Treatment & Prognosis

No antiviral therapy is available to treat hMPV. Ribavirin has in vitro activity against human metapneumovirus, but there are no data to support its therapeutic value. Children with lower respiratory tract disease may require hospitalization and ventilatory support, but less frequently than with RSV-associated bronchiolitis. Duration of hospitalization in hMPV is typically shorter than in RSV.

° INFECTIONS DUE TO ENTEROVIRUSES AND PARECHOVIRUSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute febrile illness with headache and sore throat.
- Summer–fall epidemics.
- Other common features: rash, nonexudative pharyngitis.
- Common cause of aseptic meningitis.
- Complications: myocarditis, neurologic damage, life-threatening illness in newborns.

Enteroviruses (EV) are a major cause of acute febrile illness in young children. They belong to the family of picornaviruses ("small") and despite having similar nucleic acid and protein components, antigenically have been divided into four groups: polioviruses (PV), coxsackieviruses A and B, and echoviruses. Their common RNA sequences and group antigens have led to diagnostic tests for viral nucleic acid and proteins. A PCR assay is available in many medical centers as a one-step test with results in a few hours. If included in a respiratory panel PCR, cross-reactivity with rhinoviruses can be expected. Viral cultures are more specific but may take 2–5 days. Therefore, for cases of meningoencephalitis and severe unexplained illness in neonates PCR is now the diagnostic method of choice.

Parechoviruses (PeV), also picornaviruses, some formerly considered echoviruses 22 and 23. They are now recognized as responsible for severe infections in young children (sepsis-like, meningitis). Some of the 15 types of parechoviruses infect almost every child before the age of 2 years; others before age 5 years.

Transmission of EV and PeV is fecal-oral or from upper respiratory secretions. Multiple enteroviruses circulate in the community at any one time; summer–fall outbreaks are common in temperate climates, but infections are seen year-round. After poliovirus, coxsackie B virus is most virulent, followed by echovirus. Neurologic, cardiac, and overwhelming neonatal infections are the most severe forms of illness.

ACUTE FEBRILE ILLNESS

Accompanied by nonspecific upper respiratory or enteric symptoms, the sudden onset of fever and irritability in infants or young children is often enteroviral, especially in late summer and fall. More than 90% of enteroviral infections are not distinctive. Occasionally a petechial rash is seen; more often a diffuse maculopapular or morbilliform eruption (often prominent on palms and soles) occurs on the second to fourth day of fever. Rapid recovery is the rule. More than one febrile enteroviral illness can occur in the same patient in one season. The leukocyte count is usually normal. Infants, because of fever and irritability, may undergo an evaluation for sepsis or meningitis and be hospitalized. Approximately half of these infants have aseptic meningitis. In the summer months enterovirus infection is more likely than human herpesvirus 6 (HHV-6) to cause an acute medical visit for fever. Duration of illness is 4–5 days.

Romero JR, Selvarangan R: The human parechoviruses: an overview. Adv Pediatr 2011;58(1):65 [PMID: 21736976].

RESPIRATORY TRACT ILLNESSES

1. Acute Febrile Pharyngitis

Most common in older children, they will often complain of headache, sore throat, myalgia, and abdominal discomfort. The usual duration is 3–4 days. Vesicles or papules may be seen in the pharynx without exudate. Occasionally, enteroviruses are the cause of croup, bronchitis, or pneumonia. They may also exacerbate asthma as seen with the recent outbreaks of EV68.

2. Herpangina

Herpangina is characterized by an acute onset of fever and posterior pharyngeal grayish white vesicles that quickly form ulcers (< 20 in number), linearly along the posterior palate, uvula, and tonsillar pillars. Bilateral faucial ulcers may also be seen. Dysphagia, drooling, vomiting, abdominal pain, and anorexia also occur and, rarely, parotitis or vaginal ulcers. Symptoms disappear in 4–5 days. Coxsackie A viruses cause epidemics; coxsackie B viruses and echoviruses cause sporadic cases.

The differential diagnosis includes primary herpes simplex gingivostomatitis (ulcers are more prominent anteriorly, and gingivitis is present), aphthous stomatitis (fever absent, recurrent episodes, anterior lesions), trauma, hand-foot-and-mouth disease (see discussion in section Rashes [including Hand-Foot-and-Mouth Disease]), and Vincent angina (painful gingivitis spreading from the gum line; older child; underlying dental disease). If the enanthem is missed, tonsillitis might be incorrectly diagnosed.

3. Acute Lymphonodular Pharyngitis

Coxsackievirus A10 has been associated with a febrile pharyngitis characterized by nonulcerative yellow-white posterior pharyngeal papules in the same distribution as herpangina. The duration is 1–2 weeks; therapy is supportive.

4. Pleurodynia (Bornholm Disease, Epidemic Myalgia)

Caused by coxsackie B virus (epidemic form) or many nonpolio enteroviruses (sporadic form), pleurodynia is associated with an abrupt onset of unilateral or bilateral spasmodic pain of variable intensity over the lower ribs or upper abdomen. Associated symptoms include headache, fever, vomiting, myalgias, and abdominal and neck pain. Physical findings include fever, chest muscle tenderness, decreased thoracic excursion, and occasionally a friction rub. The chest radiograph is normal. Hematologic tests are nondiagnostic. The illness generally lasts less than 1 week.

This is a disease of muscles, but the differential diagnosis includes bacterial pneumonia, bacterial and tuberculous effusion, and endemic fungal infections (all excluded radiographically and by auscultation), costochondritis (no fever or other symptoms), and a variety of abdominal problems, especially those causing diaphragmatic irritation.

There is no specific therapy. Potent analgesic agents and chest splinting alleviate the pain.

Tagarakis GI et al: Bornholm disease—a pediatric clinical entity that can alert a thoracic surgeon. J Paed Child Health 2011;47(4):242 [PMID: 21501275].

RASHES (INCLUDING HAND-FOOT-AND-MOUTH DISEASE)

The EV rash can be macular, maculopapular, urticarial, scarlatiniform, petechial, or vesicular. One of the most characteristic is that of hand-foot-and-mouth disease (caused by coxsackieviruses, especially types A5, A10, and A16), in which vesicles or red papules are found on the tongue, oral mucosa, hands, and feet. Often they appear near the nails and on the heels and may last up to 1-2 weeks. Associated fever, sore throat, and malaise are mild. The rash may appear when fever abates, simulating roseola.

Cardiac Involvement

Myocarditis and pericarditis can be caused by a number of nonpolio enteroviruses, particularly type B coxsackieviruses. Most commonly, upper respiratory symptoms are followed by substernal pain, dyspnea, and exercise intolerance. A friction rub or gallop may be detected. Ultrasound will define ventricular dysfunction or pericardial effusion, and electrocardiography may show pericarditis or ventricular irritability. Creatine phosphokinase may be elevated and troponin (hs-TnT) is highly sensitive for acute myocarditis. The disease may be mild or fatal; most children recover completely. In infants, other organs may be involved at the same time; in older patients, cardiac disease is usually the sole manifestation (see Chapter 20 for therapy). Enteroviral RNA is present in cardiac tissue in some cases of dilated cardiomyopathy or myocarditis; the significance of this finding is unknown. Epidemics of EV 71, which occur in Asia, as well as sporadic cases in the United States, are associated with severe left ventricular dysfunction and pulmonary edema following typical mucocutaneous manifestations of enterovirus infection. Enterovirus 71 also can cause isolated severe neurologic disease or neurologic disease in combination with myocardial disease.

Badran SA, Midgley S, Andersen P, Bottiger B: Clinical and virological features of enterovirus 71 infection in Denmark, 2005–2008. Scand J Infect Dis 2011;43(8):642 [PMID: 21526904].

Ooi MH et al: Clinical features, diagnosis, and management of enterovirus 71. Lancet Neurol 2010;9(11):1097 [PMID: 20965438].

Simpson KE, Canter CE: Acute myocarditis in children. Expert Opin Cardiovasc Ther 2011;9(6):771 [PMID: 21714608].

Severe Neonatal Infection

Neonatal EV infection is usually systemic and severe in otherwise normal newborns. Clinical manifestations include fever, rash, pneumonitis, meningo-encephalitis, hepatitis, gastroenteritis, myocarditis, pancreatitis, and myositis. Infected transplacentally or nosocomially, these infants are usually 1 week old, septic, with cyanosis, dyspnea, and seizures. The differential diagnosis includes bacterial and herpes simplex infections, necrotizing enterocolitis, other causes of heart or liver failure, and metabolic diseases. Diagnosis is suggested by the finding of cerebrospinal fluid (CSF) mononuclear pleocytosis and confirmed by detection of EV RNA in CSF, blood, urine, stool, or pharynx. IVIG is often administered, but its value is still uncertain. Some investigational antivirals (eg, pleconaril, pocapavir) have shown potential promise. Passively acquired maternal antibody may protect newborns from severe disease. Parechovirus

infection of neonates is similar to EV but occurs in older neonates, with almost half of infected newborns requiring ICU management. Sepsis-like syndrome and meningitis are the most common presentations with normal inflammatory markers.

Tebruegge M, Curtis N: Enterovirus infections in neonates. Semin Fetal Neonatal Med 2009;14:222 [PMID: 19303380].

CENTRAL NERVOUS SYSTEM ILLNESSES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Partial immunization or underlying immune deficiency.
- Headache, fever, acute muscle weakness.
- Aseptic meningitis.
- Asymmetrical, flaccid paralysis; muscle tenderness and hyperesthesia; intact sensation; late atrophy.

1. Poliomyelitis and Nonpolio Acute Flaccid Paralysis

General Considerations

Poliovirus infection is asymptomatic in 90%–95% of cases; presents as acute febrile illness in about 5% of cases, and aseptic meningitis, with or without paralysis in 1%–3%. Polio has been eliminated with the use of oral polio vaccines (OPV) in > 99% of the population with the only endemic areas now in Nigeria, Pakistan, and Afghanistan. Most older children and adults are now protected due to vaccination or previous silent infection. Occasional cases in the United States have occurred in unprotected travelers to foreign countries or in populations with low polio vaccine coverage who come in contact with visitors from endemic areas. Vaccine-associated paralysis (VAPP) is a rare complication of OPV as a result of reversion of the vaccine virus. The incidence of vaccine-associated paralytic poliomyelitis in the United States was 1:750,000 and 1:2.4 million doses for the first and second dose of OPV, respectively and was most severe in children with hypogammaglobulinemia. Vaccine-derived polio viruses (cVDPV) can also circulate in populations with low immunity and cause outbreaks of acute flaccid paralysis (AFP) similar to wild type polio. Since 2000, inactivated poliovirus vaccine (IPV) has been the only polio vaccine in use in the United States, and is now being integrated in all countries worldwide to prevent VAPP and cVDPV (see Chapter 10).

Other nonpolio EV can present as AFP, including EV71 in Asia, and most recently an outbreak in the United States was linked to EV68.

Clinical Findings

A. Symptoms and Signs

The initial symptoms are fever, myalgia, sore throat, and headache for 2–6 days. In less than 5% of infected children, several symptom-free days are followed by recurrent fever and signs of aseptic meningitis: headache, stiff neck, nuchal rigidity, and nausea. Mild cases resolve completely. In only 1%–2% of those infected, high fever, severe myalgia, and anxiety herald progression to loss of reflexes and subsequent flaccid paralysis. Sensation remains intact, although hyperesthesia of skin overlying paralyzed muscles is common and pathognomonic.

Paralysis is usually asymmetrical. Proximal limb muscles are more often involved than distal, and lower limb involvement is more common than upper. Bulbar involvement affects swallowing, speech, and cardiorespiratory function and accounts for most deaths. Bladder distention and marked constipation characteristically accompany lower limb paralysis. Paralysis is usually complete by the time the temperature normalizes. Atrophy is usually apparent by 4–8 weeks. Most improvement of muscle paralysis occurs within 6 months.

B. Laboratory Findings

In patients with meningeal symptoms, the CSF shows a lymphocytic pleocytosis and a normal glucose with mildly elevated protein concentration. Poliovirus is easy to grow in cell culture and can be readily differentiated from other enteroviruses. It is rarely isolated from spinal fluid but is often present in the throat and stool for several weeks following infection. PCR is now the method of choice for detection. CDC can differentiate wild from attenuated vaccine isolates.

Differential Diagnosis

Aseptic meningitis due to poliovirus is indistinguishable from that due to other viruses. Paralytic disease in the United States is usually due to nonpolio enteroviruses. Polio may resemble Guillain-Barré syndrome (minimal sensory loss, ascending symmetrical loss of function; minimal pleocytosis, high protein concentration in spinal fluid), polyneuritis (sensory loss), pseudoparalysis due to bone or joint problems (eg, trauma, infection), botulism, or tick paralysis. West Nile virus infection can present like AFP in children.

Complications

Complications are the result of permanent destruction of anterior horn cells and paralysis. Respiratory, pharyngeal, bladder, and bowel malfunction are most critical. Death

is usually consequence of respiratory dysfunction. Limbs injured near the time of infection, such as by intramuscular injections, excessive prior use, or trauma, tend to be most severely involved and have the worst prognosis for recovery (provocation paralysis).

» Treatment & Prognosis

Therapy is supportive, although some antivirals are under investigation (eg, pocapavir). Bed rest, fever and pain control (heat therapy is helpful), and careful attention to progression of weakness (particularly of respiratory muscles) are important. No intramuscular injections should be given during the acute phase. Intubation or tracheostomy for secretion control and ventilation, enteral feeding and catheter drainage of the bladder may be needed. Disease is worse in adults and pregnant women. Postpolio muscular atrophy occurs in 30%–40% of paralyzed limbs 20–30 years later, characterized by increasing weakness and fasciculations in previously affected, partially recovered limbs.

2. Nonpolio Viral Meningitis

Nonpolio enteroviruses cause over 80% of cases of aseptic meningitis at all ages, especially in the summer and fall. Nosocomial outbreaks also occur.

» Clinical Findings

The usual EV incubation period is 4–6 days. Most EV infections are subclinical or not associated with central nervous system (CNS) symptoms, therefore a history of sick contact is unusual. Neonates may acquire infection from maternal blood, vaginal secretions, or feces at birth; occasionally the mother has had a febrile illness just prior to delivery.

A. Symptoms and Signs

Incidence is much greater in children younger than age 1 year and CSF pleocytosis is more frequent in very young children undergoing septic work up during the summer and fall. Onset is usually acute with fever, marked irritability, and lethargy in infants. Older children also describe frontal headache, photophobia, and myalgia. Abdominal pain, diarrhea, and projectile vomiting may occur. The incidence of rash varies with the infecting strain. If rash occurs, it is usually seen after several days of illness and is diffuse, macular or maculopapular, occasionally petechial, but not purpuric. Oropharyngeal vesicles and rash on the palms and soles suggest an enterovirus. The anterior fontanel may be full and meningismus present. The illness may be biphasic, with nonspecific symptoms and signs preceding those related to the CNS. In older children, meningeal signs are more frequent, but seizures are unusual, and focal neurologic findings, which are rare, should lead to a search for an alternative cause. Frank encephalitis, which is uncommon at any age, occurs most often in neonates. Because of the overall frequency of enteroviral disease in children, 5%–10% of all cases of encephalitis of proved viral origin are caused by enteroviruses. Enteroviruses tend to cause less severe encephalitis than other viral agents. However, parechoviruses, which have recently been demonstrated to be a significant cause of aseptic meningitis, sometimes cause white matter changes.

Enterovirus 71 infections that begin with typical mucocutaneous manifestations of enteroviruses can be complicated by severe brainstem encephalitis and polio-like flaccid paralysis. Outbreaks of respiratory disease with meningitis and acute paralysis due to EV68 have occurred in California and Colorado. Enterovirus 70 outbreaks are characterized by hemorrhagic conjunctivitis together with paralytic poliomyelitis.

B. Laboratory Findings

Blood leukocyte counts are often normal. The spinal fluid leukocyte count is 100–1000/μL with polymorphonuclear cells predominating early and shifting to mononuclear cells within 8–36 hours. In about 95% of cases, spinal fluid parameters include a total leukocyte count less than 3000/μL, protein less than 80 mg/dL, and glucose more than 60% of serum values. Marked deviation from any of these findings should prompt consideration of another diagnosis (see following section). The syndrome of inappropriate secretion of antidiuretic hormone may occur, but is rarely clinically significant.

Culture of CSF may yield an enterovirus within a few days (< 70%), but EV PCR is the most useful diagnostic method in many centers (sensitivity > 90%) and can give an answer within 24 hours. Parechoviruses will be detected by most PCR methods, but will be identified as "enterovirus." Virus may be detected even with no CSF pleocytosis. Detection of an enterovirus from throat or stool suggests, but does not prove, enteroviral meningitis. Vaccine-derived poliovirus present in feces in infants being evaluated for aseptic meningitis may confuse the diagnosis, but history of travel or exposure to OPV should help.

C. Imaging

Cerebral imaging is not often indicated; if done, it is usually normal. Subdural effusions, infarcts, edema, or focal abnormalities seen in bacterial meningitis are absent except for the rare case of focal encephalitis.

» Differential Diagnosis

Enteroviral infections account for up to 92% of the cases of aseptic meningitis in which an etiologic agent is identified, especially in the summer and fall. Other causative viruses are mosquito-borne (flavivirus, bunyavirus) and are part of

the investigation of encephalitis, but many of them are more likely to cause isolated meningitis. Primary herpes simplex infection can cause aseptic meningitis in adolescents who have a genital herpes infection. In neonates, early herpes simplex meningoencephalitis may mimic enteroviral disease (see section Infections due to Herpesviruses) and if suspected urgent antiviral therapy is recommended. Lymphocytic choriomeningitis virus causes meningitis in children in contact with rodents (pet or environmental exposure). Meningitis occurs in some patients at the time of infection with human immunodeficiency virus (HIV).

Other causes of aseptic meningitis that may resemble enteroviral infection include partially treated bacterial meningitis (recent antibiotic treatment, CSF parameters resembling those seen in bacterial disease and bacterial antigen sometimes present); bacterial parameningeal foci such as brain abscess, subdural empyema, mastoiditis (predisposing factors, lower CSF glucose level, focal neurologic signs, and characteristic imaging); tumors or cysts (malignant cells on cytologic examination, history of neurologic symptoms, higher protein or lower glucose levels in CSF); trauma (presence, without exception, of red blood cells, which may be erroneously assumed to be due to traumatic lumbar puncture, but are crenated and fail to clear); vasculitis (other systemic or neurologic signs, found in older children); tuberculous or fungal meningitis (see Chapters 42 and 43); cysticercosis; para and postinfectious encephalopathies (M pneumoniae, cat-scratch disease, respiratory viruses [especially influenza]); Lyme disease; leptospirosis; rickettsial diseases; and acute demyelinating encephalomyelitis.

» Prevention & Treatment

No specific antiviral therapy exists. Infants are usually hospitalized, isolated, and treated with fluids and antipyretics. Moderately to severely ill infants are given empiric antibiotics for bacterial pathogens until cultures are negative for 48–72 hours. PCR assay for enteroviruses if available may decrease hospital stay and avoid or shorten use of antibiotics. In children and infants at low risk of serious bacterial infection, antibiotics may be withheld and the child observed until PCR results are available. The illness usually lasts less than 1 week. Codeine compounds or other strong analgesics may be needed. With clinical deterioration, repeat lumbar puncture, cerebral imaging, neurologic consultation, and more aggressive diagnostic tests should be considered. Herpesvirus encephalitis is an important consideration in such cases, particularly in infants younger than age 1 month, and often warrants empiric acyclovir until HSV infection can be ruled out.

» Prognosis

In general, enteroviral meningitis has no significant short-term neurologic or developmental sequelae. Developmental delay may follow severe neonatal infections. Unlike mumps, enterovirus infections rarely cause hearing loss.

INFECTIONS DUE TO HERPESVIRUSES

HERPES SIMPLEX INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Grouped vesicles on an erythematous base, typically in or around the mouth or genitals.
- Tender regional adenopathy is common with primary infection.
- Fever and malaise with primary infection.
- Recurrent episodes in many patients.

» General Considerations

There are two types of herpes simplex virus (HSV). Type 1 (HSV-1) causes most cases of oral, skin, and cerebral disease in older children, while both types are now equally common as causes of genital and congenital HSV infections. Latent infection is routinely established in sensory ganglia during primary infection. Recurrences may be spontaneous or induced by external events (eg, fever, menstruation, or sunlight) or immunosuppression. Transmission is by direct contact with infected secretions.

Primary infection with HSV-1 often occurs early in childhood by contact with infected oral secretions of playmates or caretakers, with a second peak of infection later in life as a sexually transmitted disease. Primary infection with HSV-1 is subclinical in 80% of cases and causes gingivostomatitis or genital disease in the remainder. Type 2 (HSV-2), which is transmitted sexually, is also usually (65%) subclinical or produces mild, nonspecific symptoms. Infection with one type of HSV may prevent or attenuate clinically apparent infection with the other type, but individuals can be infected at different times with both HSV-1 and HSV-2. Recurrent episodes are due to reactivation of latent HSV.

The source of primary infection is usually an asymptomatic excreter. Most previously infected individuals shed HSV at irregular intervals. At any one time (point prevalence), more than 5% of seropositive adults excrete HSV-1 in the saliva; the percentage is higher in recently infected children, and detection of viral DNA exceeds 12%. HSV-2 shedding

in genital secretions occurs with a similar or higher point prevalence exceeding 15%, depending on the method of detection (viral isolation vs PCR) and the interval since the initial infection. A history of contact with an active HSV infection is unusual.

» Clinical Findings

A. Symptoms and Signs

1. Gingivostomatitis—High fever, irritability, and drooling occur in infants. Multiple oral ulcers are seen on the tongue and on the buccal and gingival mucosa, occasionally extending to the pharynx. Pharyngeal ulcers may predominate in older children and adolescents. Diffusely swollen red gums that are friable and bleed easily are typical. Cervical nodes are swollen and tender. Duration is 7–14 days. Herpangina, aphthous stomatitis, thrush, and Vincent angina should be excluded.

2. Vulvovaginitis or urethritis (See Chapter 44)—Genital herpes (especially HSV-2) in a prepubertal child should suggest sexual abuse. Vesicles or painful ulcers on the vulva, vagina, or penis and tender adenopathy are typical. Systemic symptoms (fever, flu-like illness, myalgia) are common with the initial episode. Painful urination is frequent, especially in females. Primary infection lasts 10–14 days before healing. Lesions may resemble trauma, syphilis (ulcers are painless), or chancroid (ulcers are painful and nodes are erythematous and fluctuant) in the adolescent, and bullous impetigo or severe chemical irritation in younger children.

3. Cutaneous infections—Direct inoculation onto cuts or abrasions may produce localized vesicles or ulcers. A deep HSV infection on the finger (called herpetic whitlow) may be mistaken for a bacterial felon or paronychia; surgical drainage is of no value and is contraindicated. HSV infection of eczematous skin may result in extensive areas of vesicles and shallow ulcers (eczema herpeticum), which may be mistaken for impetigo or varicella.

4. Recurrent mucocutaneous infection—Recurrent oral shedding is asymptomatic. Perioral recurrences often begin with a prodrome of tingling or burning limited to the vermillion border, followed by vesiculation, scabbing, and crusting around the lips over 3–5 days. Recurrent intraoral lesions are rare. Fever, adenopathy, and other symptoms are absent. Recurrent cutaneous herpes most closely resembles impetigo, but the latter is often outside the perinasal and perioral region, recurs infrequently in the same area of skin, responds to antibiotics, yields a positive result on Gram stain, and Streptococcus pyogenes or Staphylococcus aureus can be isolated. Recurrent genital disease is common after the initial infection with HSV-2. Recurrent infection is shorter (5–7 days) and milder (mean, four lesions) than primary infection and is not associated with systemic symptoms. Recurrent genital disease, which may also recur on the thighs and buttocks, is also preceded by a cutaneous sensory prodrome. Recurrence of HSV-1 in the genital region is much less frequent than are HSV-2 recurrences.

5. Keratoconjunctivitis—Keratoconjunctivitis may be part of a primary infection due to spread from infected saliva. Most cases are caused by reactivation of virus latent in the ciliary ganglion. Keratoconjunctivitis produces photophobia, pain, and conjunctival irritation. Dendritic corneal ulcers may be demonstrable with fluorescein staining. Stromal invasion may occur. Corticosteroids should never be used for unilateral keratitis without ophthalmologic consultation. Other causes of these symptoms include trauma, bacterial infections, and other viral infections (especially adenovirus if pharyngitis is present; bilateral involvement makes HSV unlikely) (see Chapter 16).

6. Encephalitis—Although unusual in infants outside the neonatal period, encephalitis may occur at any age, usually without cutaneous herpes lesions. In older children, HSV encephalitis can follow a primary infection, but usually represents reactivation of latent virus. HSV is the most common identifiable cause of sporadic severe encephalitis. Diagnosis of HSV encephalitis is very important because it can be treated with specific antiviral therapy. Acute onset is associated with fever, headache, behavioral changes, and focal neurologic deficits and/or focal seizures. Mononuclear pleocytosis is typically present along with an elevated protein concentration. In older children, hypodense areas with a medial and inferior temporal lobe predilection are seen on CT scan, especially after 3–5 days, but the findings in infants may be more diffuse. Magnetic resonance imaging (MRI) is more sensitive and is positive sooner. Periodic focal epileptiform discharges are seen on electroencephalograms, but are not diagnostic of HSV infection. Viral cultures of CSF are rarely positive. The PCR assay to detect HSV DNA in CSF is a sensitive and specific rapid test. Without early antiviral therapy, the prognosis is poor. The differential diagnosis includes mosquito-borne and other viral encephalitides, parainfectious and postinfectious encephalopathy, brain abscess, acute demyelinating syndromes, and bacterial meningoencephalitis.

7. Neonatal infections—Infection is occasionally acquired by ascending spread prior to delivery (< 5% of cases), but most often occurs at the time of vaginal delivery from a mother with genital infection. Eight to fifteen percent of HSV-2–seropositive pregnant women at delivery have HSV-2 detected by PCR in the genital tract. However, in most cases this represents reactivation of infection acquired in the distant past. HSV-1 has now become a common cause of neonatal HSV infection. Neonatal infection is rarely acquired from mothers with reactivation disease, whereas

it is frequently acquired during delivery of mothers with current or recent primary infection. This is because transplacentally acquired antibody is usually protective. Occasionally, the infection is acquired in the postpartum period from oral secretions of family members or hospital personnel. A history of genital herpes in the mother may be absent. Within a few days and up to 6 weeks (most often within 4 weeks), skin vesicles appear (especially at sites of trauma, such as where scalp monitors were placed). Some infants (45%) have infection limited to the skin, eye, or mouth. Other infants are acutely ill, presenting with jaundice, shock, bleeding, or respiratory distress (20%). Some infants appear well initially, but dissemination of the infection to the brain or other organs becomes evident during the ensuing week. HSV infection (and empiric therapy) should be strongly considered in newborns with the sepsis syndrome that is unresponsive to antibiotic therapy and has negative bacterial cultures. A mononuclear pleocytosis in the CSF and suggestive skin lesions support this, although skin lesions may be absent at the time of presentation or may never develop. Some infected infants exhibit only neurologic symptoms at 2–3 weeks after delivery: apnea, lethargy, fever, poor feeding, or persistent seizures. The brain infection in these children is often diffuse and is best diagnosed by MRI. The skin lesions may resemble impetigo, bacterial scalp abscesses, or miliaria. Skin lesions may recur over weeks or months after recovery from the acute illness. Progressive culture–negative pneumonitis is another manifestation of neonatal HSV. Most cases of neonatal HSV infection are acquired from mothers with undiagnosed genital herpes, most of whom acquired the infection during the pregnancy—especially near term.

B. Laboratory Findings

Abnormalities in platelets, clotting factors, and liver function tests are often present in patients with multisystem disease. Lymphocytic pleocytosis and elevated CSF protein indicates viral meningitis or encephalitis. Virus may be cultured from infected epithelial sites (vesicles, ulcers, or conjunctival scrapings). Cultures of CSF yield positive results in about 50% of neonatal cases, but are uncommon in older children. HSV will be detected within 2 days by rapid tissue culture methods, but PCR is the preferred diagnostic method for all specimens. A positive test from skin, throat, eye, or stool of a newborn is diagnostic. Vaginal culture of the mother may offer circumstantial evidence for the diagnosis, but may be negative.

Rapid diagnostic tests include immunofluorescent stains or ELISA to detect viral antigen in skin or mucosal scrapings. The PCR assay for HSV DNA is positive (> 95%) in the CSF when there is brain involvement. HSV DNA is often present in the blood of patients with multisystem disease. Typing of genital HSV isolates from adolescents has prognostic value, since HSV-1 genital infection recurs much less frequently than genital HSV-2 infection.

» Complications, Sequelae, & Prognosis

Gingivostomatitis may result in dehydration due to dysphagia; severe chronic oral disease and esophageal involvement may occur in immunosuppressed patients. Primary vulvovaginitis may be associated with aseptic meningitis, paresthesias, autonomic dysfunction due to neuritis (urinary retention, constipation), and secondary candidal infection. HIV transmission is facilitated from individuals who are also seropositive for HSV infection, and HIV acquisition is enhanced in HSV-infected contacts. Extensive cutaneous disease (as in eczema) may be associated with dissemination and bacterial superinfection. Keratitis may result in corneal opacification. Untreated encephalitis is fatal in 70% of patients and causes severe damage in most of the remainder. Even with early acyclovir treatment, 20% of patients die and 40% are neurologically impaired.

Disseminated neonatal infection (25% of cases) is fatal for 30% of neonates in spite of therapy, and 20% of survivors are often impaired. Treated infants with CNS infection (30% of cases) have a 5% mortality and 70% of survivors are impaired; treated neonates with infection limited to skin, eye, and mouth survive without sequelae.

» Treatment

A. Specific Measures

HSV is sensitive to antiviral therapy.

1. Topical antivirals—Antiviral agents are effective for corneal disease and include 1% trifluridine and 3% acyclovir (1–2 drops five times daily). These agents should be used with the guidance of an ophthalmologist and concurrently with oral antiviral therapy.

2. Mucocutaneous HSV infections—These infections respond to administration of oral nucleoside analogues (acyclovir, valacyclovir, or famciclovir). The main indications are severe genital HSV infection in adolescents (see Chapter 44; acyclovir, 400 mg three times daily for 7–10 days) and severe gingivostomatitis in young children. Antiviral therapy is beneficial for primary disease when begun early. Recurrent disease rarely requires therapy. Frequent genital recurrences may be suppressed by oral administration of nucleoside analogues (acyclovir, 400 mg twice daily), but this approach should be used sparingly. Other forms of severe cutaneous disease, such as eczema herpeticum, respond to antivirals. Intravenous acyclovir may be required when disease is extensive in immunocompromised children (10–15 mg/kg or 500 mg/m^2 every 8 hours for 14–21 days).

Oral acyclovir, which is available in suspension, is also used within 72–96 hours for severe primary gingivostomatitis in immunocompetent young children (20 mg/kg per dose [maximum of 400 mg per dose] four times a day for 7 days). Antiviral therapy does not alter the incidence or severity of subsequent recurrences of oral or genital infection. Development of resistance to antivirals, which is very rare after treating immunocompetent patients, occurs in immunocompromised patients who receive frequent and prolonged therapy.

3. Encephalitis—Treatment consists of intravenous acyclovir, 20 mg/kg (500 mg/m^2) every 8 hours for 21 days.

4. Neonatal infection—Newborns receive intravenous acyclovir, 20 mg/kg every 8 hours for 21 days (14 days if infection is limited to skin, eye, or mouth). Therapy should not be discontinued unless a repeat CSF HSV PCR assay is negative near the end of treatment. The outcome at 1 year is improved in infants that receive oral acyclovir (300 mg/m^2/dose three times daily) for 6 months after completion of IV therapy.

B. General Measures

1. Gingivostomatitis—Gingivostomatitis is treated with pain relief and temperature control measures. Maintaining hydration is important because of the long duration of illness (7–14 days). Topical anesthetic agents (eg, viscous lidocaine or an equal mixture of kaolin–attapulgite [Kaopectate], diphenhydramine, and viscous lidocaine) may be used as a mouthwash for older children who will not swallow it; ingested lidocaine may be toxic to infants or may lead to aspiration. Antiviral therapy is indicated in normal hosts with severe disease.

2. Genital infections—Genital infections may require pain relief, assistance with voiding (warm baths, topical anesthetics, rarely catheterization), and psychological support. Lesions should be kept clean; drying may shorten the duration of symptoms. Sexual contact should be avoided during the interval from prodrome to crusting stages. Because of the frequency of asymptomatic shedding, the only effective way to prevent sexual transmission is the use of condoms. Candidal superinfection occurs in 10% of women with primary genital infections.

3. Cutaneous lesions—Skin lesions should be kept clean, dry, and covered if possible to prevent spread. Systemic analgesics may be helpful. Secondary bacterial infection is uncommon in patients with lesions on the mucosa or involving small areas, and with recurrences. Secondary infection should be considered and treated if necessary in patients with more extensive lesions.

4. Recurrent cutaneous disease—Recurrent disease is usually milder than primary infection. Sun block lip balm helps prevent labial recurrences that follow intense sun exposure. There is no evidence that the many popular topical or vitamin therapies are efficacious.

5. Keratoconjunctivitis—An ophthalmologist should be consulted regarding the use of cycloplegics, anti-inflammatory agents, local debridement, and other therapies.

6. Encephalitis—Extensive support will be required for obtunded or comatose patients. Rehabilitation and psychological support are often needed for survivors.

7. Neonatal infection—Infected infants should be isolated and given acyclovir. Cesarean delivery is indicated if the mother has obvious cervical or vaginal lesions, especially if these represent primary infection (35%–50% transmission rate). With infants born vaginally to mothers who have active lesions of recurrent genital herpes, appropriate cultures and PCR should be obtained at 24 hours after birth, and the infant evaluated thoroughly for possible HSV infection. If the results are positive or the infant has suggestive signs or symptoms preemptive therapy should be started. Treatment is given to infants whose culture results are positive or who appear ill. Infants born to mothers with obvious primary genital herpes should also be evaluated, but should then receive therapy before the culture or PCR results are known. For women with a history of genital herpes infection, but no genital lesions, vaginal delivery with peripartum cultures of maternal cervix is the standard. Clinical follow-up of the newborn is recommended when maternal culture results are positive. Repeated cervical cultures during pregnancy are not useful.

A challenging problem is the newborn, especially in the first 3 weeks of life, that presents with fever (or hypothermia) and a sepsis-like picture. This is further confounded in the late summer by the existence of circulating enteroviruses. These infants should be considered for empiric acyclovir therapy, pending results of PCR studies, given the poor outcome of disseminated herpes in the newborn. The index of suspicion is increased when there is a CSF pleocytosis, elevated hepatic transaminase levels, a very ill-appearing infant, rash, or respiratory distress.

VARICELLA & HERPES ZOSTER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Varicella (chickenpox):
- Exposure to varicella or herpes zoster 10–21 days previously; no prior history of varicella.
- Widely scattered red macules and papules concentrated on the face and trunk, rapidly progressing to clear vesicles on an erythematous base, pustules, and then crusts, over 5–6 days.
- Variable fever and nonspecific systemic symptoms.

» Herpes zoster (shingles):
- History of varicella.
- Dermatomal paresthesias and pain prior to eruption (more common in older children).
- Dermatomal distribution of grouped vesicles on an erythematous base.

» General Considerations

Primary infection with varicella-zoster virus results in varicella, which generally confers lifelong immunity, but the virus remains latent lifelong in sensory ganglia. Herpes zoster, which represents reactivation of this latent virus, occurs in 30% of individuals at some time in their life. The incidence of herpes zoster is highest in elderly individuals and in immunosuppressed patients, but herpes zoster occurs in immunocompetent children. Spread of varicella from a close contact is by respiratory secretions or fomites from vesicles or pustules, with an 85% infection rate in susceptible persons. Over 95% of young adults with a history of varicella are immune, as are 90% of native-born Americans who are unaware of having had varicella. Many individuals from tropical or subtropical regions fail to develop varicella in their childhood and remain susceptible through early adulthood. Humans are the only reservoir.

» Clinical Findings

Exposure to varicella or herpes zoster has usually occurred 14–16 days previously (range, 10–21 days). Contact may not be recognized, since the index case of varicella is infectious 1–2 days before rash appears. A 1- to 3-day prodrome of fever, malaise, respiratory symptoms, and headache may occur, especially in older children. The unilateral, dermatomal vesicular rash and pain of herpes zoster is very distinctive. The preeruptive pain of herpes zoster may last several days and be mistaken for other illnesses.

A. Symptoms and Signs

1. Varicella—The usual case consists of mild systemic symptoms followed by crops of red macules that rapidly become small vesicles with surrounding erythema (described as a "dew drop on a rose petal"), form pustules, become crusted, and then scab. Scarring occurs, but it is not common. The rash appears predominantly on the trunk and face. Lesions occur in the scalp, and sometimes in the nose, mouth (where they are nonspecific ulcers), conjunctiva, and vagina. The magnitude of systemic symptoms usually parallels skin involvement. Up to five crops of lesions may be seen. New crops stop forming after 5–7 days. Pruritus is often intense. If varicella occurs in the first few months of life (except for the early postpartum period), it is often mild as a result of transplacentally acquired maternal antibody. Once crusting begins, the patient is no longer contagious. A modified form of varicella occurs in about 15% of vaccinated children exposed to varicella, in spite of receiving a single dose of varicella vaccine. This is usually much milder than typical varicella, with fewer lesions that heal rapidly. Cases of modified varicella are contagious.

2. Herpes zoster (shingles)—This eruption involves a single dermatome (thus unilateral and does not cross the midline), usually truncal or cranial; occasionally a contiguous dermatome is involved. Especially in older children this is preceded by neuropathic pain or itching in the same area (designated the "prodrome"). Ophthalmic zoster may be associated with corneal involvement. The closely grouped vesicles, which resemble a localized version of varicella or herpes simplex, often coalesce. Crusting occurs in 7–10 days. Postherpetic neuralgia is rare in children. Herpes zoster is a common problem in HIV-infected or other immunocompromised children, and is also common in children who had varicella in early infancy (< 1–2 years old) or whose mothers had varicella during pregnancy. Herpes zoster can occur infrequently in children who received the varicella vaccine.

B. Laboratory Findings

Leukocyte counts are normal or low. Leukocytosis suggests secondary bacterial infection. The virus can be identified by fluorescent antibody staining of a lesion smear. When the etiology is critical, as in immune compromised children with atypical disease, PCR is definitive. Serum aminotransferase levels may be modestly elevated during typical varicella.

C. Imaging

Varicella pneumonia classically produces numerous bilateral nodular densities and hyperinflation. This is very rare in immunocompetent children, but is seen more frequently in adults and immunocompromised children.

» Differential Diagnosis

Varicella is usually distinctive. Similar rashes include those of coxsackievirus infection (fewer lesions, lack of crusting), impetigo (fewer lesions, smaller area, no classic vesicles, positive Gram stain, perioral or peripheral lesions), papular urticaria (insect bite history, nonvesicular rash), scabies (burrows, no typical vesicles; failure to resolve), parapsoriasis (rare in children < 10 years, chronic or recurrent, often a history of prior varicella), rickettsialpox (eschar where the mite bites, smaller lesions, no crusting), dermatitis herpetiformis (chronic, urticaria, residual pigmentation), and folliculitis. Herpes zoster is sometimes confused with a linear eruption of herpes simplex or a contact dermatitis (eg, Rhus dermatitis).

» Complications & Sequelae

A. Varicella

Secondary bacterial infection with staphylococci or group A streptococci is most common, presenting as impetigo, cellulitis or fasciitis, abscesses, scarlet fever, or sepsis. Bacterial superinfection occurs in 2%–3% of children with varicella. Before a vaccine became available, hospitalization rates associated with varicella were 1:750–1:1000 cases in children and 10-fold higher in adults.

Protracted vomiting or a change in sensorium suggests Reye syndrome or encephalitis. Because Reye syndrome usually occurs in patients who are also receiving salicylates, these should be avoided in patients with varicella. Encephalitis occurs in less than 0.1% of cases, usually in the first week of illness, and is usually limited to cerebellitis with ataxia, which resolves completely. Diffuse encephalitis can be severe.

Varicella pneumonia usually afflicts immunocompromised children (especially those receiving high doses of corticosteroids or chemotherapy) and adults; pregnant women are at special risk. Cough, dyspnea, tachypnea, rales, and cyanosis occur several days after onset of rash. Varicella may be life-threatening in immunosuppressed patients. In addition to pneumonitis, their disease may be complicated by hepatitis and encephalitis. The acute illness in these children often begins with unexplained severe abdominal pain. Varicella exposure in severely varicella-naïve immunocompromised children must be evaluated immediately for postexposure prophylaxis (see Chapter 10).

Hemorrhagic varicella lesions may be seen without other complications. This is most often caused by autoimmune thrombocytopenia, but hemorrhagic lesions can occasionally represent idiopathic disseminated intravascular coagulation (purpura fulminans).

Neonates born to mothers who develop varicella from 5 days before to 2 days after delivery are at high risk for severe or fatal (5%) disease and must be given varicella-zoster immunoglobulin (VariZIG) and followed closely (see Chapter 10).

Varicella occurring during the first 20 weeks of pregnancy may cause (2% incidence) congenital infection associated with cicatricial skin lesions, associated limb anomalies, and cortical atrophy.

Unusual complications of varicella include optic neuritis, myocarditis, transverse myelitis, orchitis, and arthritis.

B. Herpes Zoster

Complications of herpes zoster include secondary bacterial infection, motor or cranial nerve paralysis, meningitis, encephalitis, keratitis and other ocular complications, and dissemination in immunosuppressed patients. These complications are rare in immunocompetent children. Postherpetic neuralgia occurs in immunocompromised children, but is rare in immunocompetent children.

» Prevention

Varicella-specific hyperimmune globulin is available for postexposure prevention of varicella in high-risk susceptible persons (see Chapter 10). In immunocompetent children, postexposure prophylaxis with acyclovir is effective when it is started at 7–9 days after exposure and is continued for 7 days, as is varicella vaccine when given within 3–5 days of the exposure.

Two doses of the live attenuated varicella vaccine are now part of routine childhood immunization, and "catch-up" immunization is recommended for all other susceptible children and adults.

» Treatment

A. General Measures

Supportive measures include maintenance of hydration, administration of acetaminophen for discomfort, cool soaks or antipruritics for itching (diphenhydramine, 1.25 mg/kg every 6 hours, or hydroxyzine, 0.5 mg/kg every 6 hours), and observance of general hygiene measures (keep nails trimmed and skin clean). Care must be taken to avoid overdosage with antihistaminic agents. Topical or systemic antibiotics may be needed for bacterial superinfection.

B. Specific Measures

Acyclovir is the preferred drug for varicella and herpes zoster infections. Recommended parenteral acyclovir dosage for severe disease is 10 mg/kg (500 mg/m^2) intravenously every 8 hours, each dose infused over 1 hour, for 7–10 days. Parenteral therapy should be started early in immunocompromised patients or high-risk infected

neonates. Hyperimmune globulin is of no value for established disease. The effect of oral acyclovir (80 mg/kg/d, divided in four doses) on varicella in immunocompetent children was modestly beneficial and nontoxic, but only when administered within 24 hours after the onset of varicella. Oral acyclovir should be used selectively in immunocompetent children (eg, when intercurrent illness is present; possibly when the index case is a sibling or when the patient is an adolescent—both of which are associated with more severe disease) and in children with underlying chronic illnesses. Valacyclovir and famciclovir are superior antiviral agents because of better absorption; only acyclovir is available as a pediatric suspension. Herpes zoster in an immunocompromised child should be treated with intravenous acyclovir when it is severe, but oral valacyclovir or famciclovir can be used in immunocompromised children when the nature of the underlying illness and the immune status support this decision.

» Prognosis

Except for secondary bacterial infections, serious complications are rare and recovery complete in immunocompetent hosts.

ROSEOLA INFANTUM (EXANTHEM SUBITUM)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- High fever in a child aged 6–36 months.
- Minimal toxicity.
- Rose-pink maculopapular rash appears when fever subsides.

» General Considerations

Roseola infantum is a benign illness caused by HHV-6 or HHV-7. HHV-6 is a major cause of acute febrile illness in young children. Its significance is that it may be confused with more serious causes of high fever and its role in inciting febrile seizures.

» Clinical Findings

The most prominent historical feature is the abrupt onset of fever, often reaching > 39.5°C, which lasts up to 8 days (mean, 4 days) in an otherwise mildly ill child. The fever then ceases abruptly, and a characteristic rash may appear. Roseola occurs predominantly in children aged 6 months to 3 years, with 90% of cases occurring before the second year. HHV-7 infection tends to occur somewhat later in childhood. These viruses are the most common recognized cause of exanthematous fever in this age group and are responsible for 20% of emergency department visits by children aged 6–12 months.

A. Symptoms and Signs

Mild lethargy and irritability may be present, but generally there is dissociation between other systemic symptoms and the febrile course. The pharynx, tonsils, and tympanic membranes may be injected. Conjunctivitis and pharyngeal exudate are notably absent. Diarrhea and vomiting occur in one-third of patients. Adenopathy of the head and neck often occurs. The anterior fontanelle is bulging in one-quarter of HHV-6–infected infants. If rash appears (20%–30% incidence), it coincides with lysis of fever and begins on the trunk and spreads to the face, neck, and extremities. Rose-pink macules or maculopapules, 2–3 mm in diameter, are nonpruritic, tend to coalesce, and disappear in 1–2 days without pigmentation or desquamation. Rash may occur without fever.

B. Laboratory Findings

Leukopenia and lymphocytopenia are present early. Laboratory evidence of hepatitis occurs in some patients, especially adults.

» Differential Diagnosis

The initial high fever may require exclusion of serious bacterial infection. The relative well-being of most children and the typical course and rash soon clarify the diagnosis. These distinguish roseola from measles, rubella, adenoviruses, enteroviruses, drug reactions, and scarlet fever. The erythrocyte sedimentation rate is normal. If the child has a febrile seizure, it is important to exclude bacterial meningitis. The CSF is normal in children with roseola. In children who receive antibiotics or other medication at the beginning of the fever, the rash may be attributed incorrectly to drug allergy.

» Complications & Sequelae

Febrile seizures occur in up to 10% of patients (even higher percentages in those with HHV-7 infections). There is evidence that HHV-6 can directly infect the CNS, causing

meningoencephalitis. Multiorgan disease (pneumonia, hepatitis, bone marrow suppression, encephalitis) may occur in immunocompromised patients.

» Treatment & Prognosis

Fever is managed readily with acetaminophen and sponge baths. Fever control should be a major consideration in children with a history of febrile seizures. Roseola infantum is otherwise entirely benign. Systemic infection in immune compromised children is treated with antiviral agents.

CYTOMEGALOVIRUS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Primary infection:
- Asymptomatic or minor illness in young children.
- Mononucleosis-like syndrome without pharyngitis in postpubertal individuals.

» Congenital infection:
- Intrauterine growth retardation.
- Microcephaly with intracerebral calcifications and seizures.
- Retinitis and encephalitis.
- Hepatosplenomegaly with thrombocytopenia.
- "Blueberry muffin" rash.
- Sensorineural deafness.

» Immunocompromised hosts:
- Retinitis and encephalitis.
- Pneumonitis.
- Enteritis and hepatitis.
- Bone marrow suppression.

» General Considerations

Cytomegalovirus (CMV) is a ubiquitous herpesvirus transmitted by many routes. It can be acquired in utero following maternal viremia or postpartum from birth canal secretions or maternal milk. Young children are infected by the saliva of playmates; older individuals are infected by sexual partners (eg, from saliva, vaginal secretions, or semen). Transfused blood products and transplanted organs can be a source of CMV infection. Clinical illness is determined largely by the patient's immune competence. Immunocompetent individuals usually develop a mild self-limited illness, whereas immunocompromised children can develop severe, progressive, often multiorgan disease. In utero infection can be teratogenic.

1. In Utero Cytomegalovirus Infection

Approximately 0.5%–1.5% of children are born with CMV infections acquired during maternal viremia. CMV infection is asymptomatic in over 90% of these children, who are usually born to mothers who had experienced reactivation of latent CMV infection during the pregnancy. Symptomatic infection occurs predominantly in infants born to mothers with primary CMV infection, but can also result from recurrent, most likely, reinfection during pregnancy. Even when exposed to a primary maternal infection, less than 50% of fetuses are infected, and in only 10% of those infants is the infection symptomatic at birth. Primary infection in the first half of pregnancy poses the greatest risk for severe fetal damage.

» Clinical Findings

A. Symptoms and Signs

Severely affected infants are born ill; they are often small for gestational age, floppy, and lethargic. They feed poorly and have poor temperature control. Hepatosplenomegaly, jaundice, petechiae, seizures, and microcephaly are common. Characteristic signs are a distinctive chorioretinitis and periventricular calcification. A purpuric (so-called blueberry muffin) rash similar to that seen with congenital rubella may be present. The mortality rate is 10%–20%. Survivors usually have significant sequelae, especially mental retardation, neurologic deficits, retinopathy, and hearing loss. Isolated hepatosplenomegaly or thrombocytopenia may occur. Even mildly affected children may subsequently manifest mental retardation and psychomotor delay. However, most infected infants (90%) are born to mothers with preexisting immunity who experienced a reactivation of latent CMV during pregnancy. These children have no clinical manifestations at birth. Of these, 10%–15% develop sensorineural hearing loss, which is often bilateral and may appear several years after birth.

B. Laboratory Findings

In severely ill infants, anemia, thrombocytopenia, hyperbilirubinemia, and elevated aminotransferase levels are common. Lymphocytosis occurs occasionally. Pleocytosis and an elevated protein concentration are found in CSF. The diagnosis is readily confirmed by isolation of CMV from urine or saliva within 48 hours, using rapid culture methods combined with immunoassay. The presence in the infant of IgM-specific CMV antibodies suggests the diagnosis. Some commercial ELISA kits are 90% sensitive and specific for

these antibodies. Universal screening of asymptomatic children using blood or saliva CMV PCR during the first weeks of life is useful for early detection of children at high risk of developing hearing loss.

C. Imaging

Head radiologic examinations may show microcephaly, periventricular calcifications, and ventricular dilation. These findings strongly correlate with neurologic sequelae and retardation. Long bone radiographs may show the "celery stalk" pattern characteristic of congenital viral infections. Interstitial pneumonia may be present.

» Differential Diagnosis

CMV infection should be considered in any newborn that is seriously ill shortly after birth, especially once bacterial sepsis, metabolic disease, intracranial bleeding, and cardiac disease have been excluded. Other congenital infections to be considered in the differential diagnosis include toxoplasmosis (serology, more diffuse calcification of the CNS, specific type of retinitis, macrocephaly), rubella (serology, specific type of retinitis, cardiac lesions, eye abnormalities), enteroviral infections (time of year, maternal illness, severe hepatitis, PCR), herpes simplex (skin lesions, cultures, severe hepatitis, PCR), and syphilis (serology for both infant and mother, skin lesions, bone involvement).

» Prevention & Treatment

Support is rarely required for anemia and thrombocytopenia. Most children with symptoms at birth have significant neurologic, intellectual, visual, or auditory impairment. Ganciclovir (5 mg/kg every 12 hours, for 6 weeks) has been recommended for children with severe, life- or sight-threatening disease, or if end-organ disease recurs or progresses. A recent randomized placebo-controlled study showed improved efficacy against hearing loss using oral valganciclovir at 16 mg/kg twice daily for 6 months in children symptomatic at birth.

Recent developments in the diagnosis of primary CMV infection during pregnancy using anti-CMV IgM and low-avidity IgG assays followed by quantitative CMV PCR testing of the amniotic fluid at 20–24 weeks gestation have made possible the diagnosis of congenital CMV infection before birth. Many pregnant women elect to terminate gestation under these circumstances. Passive immunoprophylaxis with hyperimmune CMV IgG did not prevent development of congenital disease in a randomized placebo-controlled trial.

2. Perinatal Cytomegalovirus Infection

CMV infection can be acquired from birth canal secretions or shortly after birth from maternal milk. In some socioeconomic groups, 10%–20% of infants are infected at birth and excrete CMV for many months. Infection can also be acquired in the postnatal period from unscreened transfused blood products.

» Clinical Findings

A. Symptoms and Signs

Ninety percent of immunocompetent infants infected by their mothers at birth develop subclinical illness (ie, virus excretion only) or a minor illness within 1–3 months. The remainder develop an illness lasting several weeks characterized by hepatosplenomegaly, lymphadenopathy, and interstitial pneumonitis in various combinations. The severity of the pneumonitis may be increased if there is simultaneous presence of Chlamydia trachomatis. Infants who receive blood products are often premature and immunologically impaired. If they are born to CMV-negative mothers and subsequently receive CMV-containing blood, they frequently develop severe infection and pneumonia after a 2- to 6-week incubation period.

B. Laboratory Findings

Lymphocytosis, atypical lymphocytes, anemia, and thrombocytopenia may be present, especially in premature infants. Liver function is abnormal. CMV is readily isolated from urine and saliva. Secretions obtained at bronchoscopy contain CMV and epithelial cells bearing CMV antigens. Serum levels of CMV antibody rise significantly.

C. Imaging

Chest radiographs show a diffuse interstitial pneumonitis in severely affected infants.

» Differential Diagnosis

CMV infection should be considered as a cause of any prolonged illness in early infancy, especially if hepatosplenomegaly, lymphadenopathy, or atypical lymphocytosis is present. This must be distinguished from granulomatous or malignant diseases and from congenital infections (syphilis, toxoplasmosis, hepatitis B, HIV) not previously diagnosed. Other viruses (Epstein-Barr virus [EBV], HIV, adenovirus) can cause this syndrome. CMV is a recognized cause of viral pneumonia in this age group. Because asymptomatic CMV excretion is common in early infancy, care must be taken to establish the diagnosis and to rule out concomitant pathogens such as Chlamydia and RSV. Severe CMV infection in early infancy may indicate that the child has a congenital or acquired immune deficiency.

» Prevention & Treatment

The self-limited disease of normal infants requires no therapy. Severe pneumonitis in premature infants requires

oxygen administration and often intubation. Very ill infants should receive ganciclovir (6 mg/kg every 12 hours). CMV infection acquired by transfusion can be prevented by excluding CMV-seropositive blood donors. Milk donors should also be screened for prior CMV infection. A common practice of freezing the milk prior to administration was shown to lack preventive effectiveness. It is likely that high-risk infants receiving large doses of IVIG for other reasons will be protected against severe CMV disease.

3. Cytomegalovirus Infection Acquired in Childhood & Adolescence

Young children are readily infected by playmates, especially because CMV continues to be excreted in saliva and urine for many months after infection. The cumulative annual incidence of CMV excretion by children in day care centers exceeds 75%. In fact, young children in a family are often the source of primary CMV infection of their mothers during subsequent pregnancies. An additional peak of CMV infection takes place when adolescents become sexually active. Sporadic acquisition of CMV occurs after blood transfusion and transplantation.

» Clinical Findings

A. Symptoms and Signs

Most young children who acquire CMV are asymptomatic or have a minor febrile illness, occasionally with adenopathy. They provide an important reservoir of virus shedders that facilitates spread of CMV. Occasionally a child may have prolonged fever with hepatosplenomegaly and adenopathy. Older children and adults, many of whom are infected during sexual activity, are more likely to be symptomatic in this fashion and can present with a syndrome that mimics the infectious mononucleosis syndrome that follows EBV infection (1–2 weeks of fever, malaise, anorexia, splenomegaly, mild hepatitis, and some adenopathy; see the next section). This syndrome can also occur 2–4 weeks after transfusion of CMV-infected blood.

B. Laboratory Findings

In the CMV mononucleosis syndrome, lymphocytosis and atypical lymphocytes are common, as is a mild rise in aminotransferase levels. CMV is present in saliva and urine; CMV DNA can be uniformly detected in plasma or blood.

» Differential Diagnosis

In older children, CMV infection should be included as a possible cause of fever of unknown origin, especially when lymphocytosis and atypical lymphocytes are present. CMV infection is distinguished from EBV infection by the absence of pharyngitis, the relatively minor adenopathy, and the absence of serologic evidence of acute EBV infection. Mononucleosis syndromes also are caused by Toxoplasma gondii, rubella virus, adenovirus, hepatitis A virus, and HIV.

» Prevention

Screening of transfused blood or filtering blood (thus removing CMV-containing white blood cells) prevents cases related to this source.

4. Cytomegalovirus Infection in Immunocompromised Children

In addition to symptoms experienced during primary infection, immunocompromised hosts develop symptoms with reinfection or reactivation of latent CMV. This is clearly seen in children with acquired immunodeficiency syndrome (AIDS), after transplantation, or with congenital immunodeficiencies. However, in most immunocompromised patients, primary infection is more likely to cause severe symptoms than is reactivation or reinfection. The severity of the resulting disease is generally proportionate to the degree of immunosuppression.

» Clinical Findings

A. Symptoms and Signs

A mild febrile illness with myalgia, malaise, and arthralgia may occur, especially with reactivation disease. Severe disease often includes subacute onset of dyspnea and cyanosis as manifestations of interstitial pneumonitis. Auscultation reveals only coarse breath sounds and scattered rales. A rapid respiratory rate may precede clinical or radiographic evidence of pneumonia. Hepatitis without jaundice or hepatomegaly is common. Diarrhea, which can be severe, occurs with CMV colitis, and CMV can cause esophagitis with symptoms of odynophagia or dysphagia. These enteropathies are most common in AIDS, as is the presence of a retinitis that often progresses to blindness, encephalitis and polyradiculitis.

B. Laboratory Findings

Neutropenia and thrombocytopenia are common. Atypical lymphocytosis is infrequent. Serum aminotransferase levels are often elevated. The stools may contain occult blood if enteropathy is present. CMV is readily isolated from saliva, urine, buffy coat, and bronchial secretions. Results are available in 48 hours. Interpretation of positive cultures is made difficult by asymptomatic shedding of CMV in saliva and urine in many immunocompromised patients. CMV disease correlates more closely with the presence of CMV in the blood or lung lavage fluid. Monitoring for the appearance

of CMV DNA in plasma or CMV antigen in blood mononuclear cells is used as a guide to early antiviral ("preemptive") therapy.

C. Imaging

Bilateral interstitial pneumonitis is present on chest radiographs.

» Differential Diagnosis

The initial febrile illness must be distinguished from treatable bacterial or fungal infection. Similarly, the pulmonary disease must be distinguished from intrapulmonary hemorrhage; drug-induced or radiation pneumonitis; pulmonary edema; and bacterial, fungal, parasitic, and other virus infections. CMV infection causes bilateral and interstitial abnormalities on chest radiographs, cough is nonproductive, chest pain is absent, and the patient is not usually toxic. Pneumocystis jiroveci infection may have a similar presentation. These patients may have polymicrobial disease. It is suspected that bacterial and fungal infections are enhanced by the neutropenia that can accompany CMV infection. Infection of the gastrointestinal tract is diagnosed by endoscopy. This will exclude candidal, adenoviral, and herpes simplex infections and allows tissue confirmation of CMV-induced mucosal ulcerations.

» Prevention & Treatment

Blood donors should be screened to exclude those with prior CMV infection, or blood should be filtered. Ideally, seronegative transplant recipients should receive organs from seronegative donors. Severe symptoms, most commonly pneumonitis, often respond to early therapy with intravenous ganciclovir (5 mg/kg every 12 hours for 14–21 days). Neutropenia is a frequent side effect of this therapy. Foscarnet and cidofovir are alternative therapeutic agents recommended for patients with ganciclovir-resistant virus. Prophylactic use of oral or intravenous ganciclovir or foscarnet may prevent CMV infections in organ transplant recipients. Preemptive therapy can be used in transplant recipients by monitoring CMV in blood by PCR and instituting therapy when the results reach a certain threshold regardless of clinical signs or symptoms.

INFECTIOUS MONONUCLEOSIS (EPSTEIN-BARR VIRUS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Prolonged fever.
- Exudative pharyngitis.
- Generalized adenopathy.
- Hepatosplenomegaly.
- Atypical lymphocytes.
- Heterophil antibodies.

» General Considerations

Mononucleosis is the most characteristic syndrome produced by EBV infection. Young children infected with EBV have either no symptoms or a mild nonspecific febrile illness. As the age of the host increases, EBV infection is more likely to produce the typical features of the mononucleosis syndrome, including 20%–25% of infected adolescents. EBV is acquired readily from asymptomatic carriers (15%–20% of whom excrete the virus in saliva on any given day) and from recently ill patients, who excrete virus for many months. Young children are infected from the saliva of playmates and family members. Adolescents may be infected through sexual activity. EBV can also be transmitted by blood transfusion and organ transplantation.

» Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–2 months, a 2- to 3-day prodrome of malaise and anorexia yields, abruptly or insidiously, to a febrile illness with temperatures exceeding 39°C. The major complaint is pharyngitis, which is often (50%) exudative. Lymph nodes are enlarged, firm, and mildly tender. Any area may be affected, but posterior and anterior cervical nodes are almost always enlarged. Splenomegaly is present in 50%–75% of patients. Hepatomegaly is common (30%), and the liver is frequently tender. Five percent of patients have a rash, which can be macular, scarlatiniform, or urticarial. Rash is almost universal in patients taking penicillin or ampicillin. Soft palate petechiae and eyelid edema are also observed.

B. Laboratory Findings

1. Peripheral blood—Leukopenia may occur early, but an atypical lymphocytosis (comprising over 10% of the total leukocytes at some time in the illness) is most notable.

Hematologic changes may not be seen until the third week of illness and may be entirely absent in some EBV syndromes (eg, neurologic).

2. Heterophile antibodies—These nonspecific antibodies appear in over 90% of older patients with mononucleosis, but in fewer than 50% of children younger than age 5 years. They may not be detectable until the second week of illness and may persist for up to 12 months after recovery. Rapid screening tests (slide agglutination) are usually positive if the titer is significant; a positive result strongly suggests but does not prove EBV infection.

3. Anti-EBV antibodies—It may be necessary to measure specific antibody titers when heterophile antibodies fail to appear, as in young children. Acute EBV infection is established by detecting IgM antibody to the viral capsid antigen (VCA) or by detecting a fourfold or greater change of IgG anti-VCA titers (in normal hosts, IgG antibody peaks by the time symptoms appear; in immunocompromised hosts, the tempo of antibody production may be delayed). The absence of anti–EBV nuclear antigen (EBNA) antibodies, which are typically first detected at least 4 weeks after the initiation of symptoms, may also be used to diagnose acute infection in immunocompetent hosts. However, immunocompromised hosts may fail to develop anti-EBNA antibodies.

4. EBV PCR—Detection of EBV DNA is the method of choice for the diagnosis of CNS and ocular infections. Quantitative EBV PCR in peripheral blood mononuclear cells has been used to diagnose EBV-related lymphoproliferative disorders in transplant patients.

» Differential Diagnosis

Severe pharyngitis may suggest group A streptococcal infection. Enlargement of only the anterior cervical lymph nodes, a neutrophilic leukocytosis, and the absence of splenomegaly suggest bacterial infection. Although a child with a positive throat culture result for Streptococcus usually requires therapy, up to 10% of children with mononucleosis are asymptomatic streptococcal carriers. In this group, penicillin therapy is unnecessary and often causes a rash. Severe primary herpes simplex pharyngitis, occurring in adolescence, may also mimic infectious mononucleosis. With herpes simplex pharyngitis, some anterior mouth ulcerations should suggest the correct diagnosis. Adenoviruses are another cause of severe, often exudative pharyngitis. EBV infection should be considered in the differential diagnosis of any perplexing prolonged febrile illness. Similar illnesses that produce atypical lymphocytosis include rubella (pharyngitis not prominent, shorter illness, less adenopathy and splenomegaly), adenovirus (upper respiratory symptoms and cough, conjunctivitis, less adenopathy, fewer atypical lymphocytes), hepatitis A or B (more severe liver function abnormalities, no pharyngitis, no lymphadenopathy), and toxoplasmosis (negative heterophil test, less pharyngitis). Serum sickness–like drug reactions and leukemia (smear morphology is important) may be confused with infectious mononucleosis. CMV mononucleosis is a close mimic except for minimal pharyngitis and less adenopathy; it is much less common. Serologic tests for EBV and CMV should clarify the correct diagnosis. The acute initial manifestation of HIV infection can be a mononucleosis-like syndrome.

» Complications

Splenic rupture is a rare complication, which usually follows significant trauma. Hematologic complications, including hemolytic anemia, thrombocytopenia, and neutropenia, are more common. Neurologic involvement can include aseptic meningitis, encephalitis, isolated neuropathy such as Bell palsy, and Guillain-Barré syndrome. Any of these may appear prior to or in the absence of the more typical signs and symptoms of infectious mononucleosis. Rare complications include myocarditis, pericarditis, and atypical pneumonia. Recurrence or persistence of EBV-associated symptoms for 6 months or longer characterizes chronic active EBV. This disease is due to continuous viral replication and warrants specific antiviral therapy. Rarely EBV infection becomes a progressive lymphoproliferative disorder characterized by persistent fever, multiple organ involvement, neutropenia or pancytopenia, and agammaglobulinemia. Hemocytophagia is often present in the bone marrow. An X-linked genetic defect in immune response has been inferred for some patients (Duncan syndrome, X-linked lymphoproliferative disorder). Children with other congenital immunodeficiencies or chemotherapy-induced immunosuppression can also develop progressive EBV infection, EBV-associated lymphoproliferative disorder, lymphoma, and other malignancies.

» Treatment & Prognosis

Bed rest may be necessary in severe cases. Acetaminophen controls high fever. Potential airway obstruction due to swollen pharyngeal lymphoid tissue responds rapidly to systemic corticosteroids. Corticosteroids may also be given for hematologic and neurologic complications, although no controlled trials have proved their efficacy in these conditions. Fever and pharyngitis disappear by 10–14 days. Adenopathy and splenomegaly can persist several weeks longer. Some patients complain of fatigue, malaise, or lack of well-being for several months. Although corticosteroids may shorten the duration of fatigue and malaise, their long-term effects on this potentially oncogenic viral infection are unknown, and indiscriminate use is discouraged. Patients with splenic enlargement should avoid contact sports for

6–8 weeks. Acyclovir, valacyclovir, penciclovir, ganciclovir, and foscarnet are active against EBV and are indicated in the treatment of chronic active EBV.

Management of EBV-related lymphoproliferative disorders relies primarily on decreasing the immunosuppression whenever possible. Adjunctive therapy with acyclovir, ganciclovir, or another antiviral active against EBV as well as γ globulin has been used without scientific evidence of efficacy.

Balfour HH Jr, Dunmire SK, Hogquist KA: Infectious Mononucleosis. Clin Transl Immunology 2015 Feb 27;4(2):e33 [PMID: 25774295].

VIRAL INFECTIONS SPREAD BY INSECT VECTORS

In the United States, mosquitoes are the most common insect vectors that spread viral infections (Table 40–3). As a consequence, these infections—and others that are spread by ticks—tend to occur as summer–fall epidemics that coincide with the seasonal breeding and feeding habits of the vector, and the etiologic agent varies by region. Other insect-borne viral infections are seen in international travelers. Thus, a careful travel and exposure history is critical for correct diagnostic workup.

ENCEPHALITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and headache.
- Change in mental status and/or behavior, with or without focal neurologic deficits.
- Mononuclear cell pleocytosis, elevated protein level, and normal glucose level.

Encephalitis is a common severe manifestation of many infections spread by insects (see Table 40–3). With many viral pathogens, the infection is most often subclinical, or a mild CNS disease such as meningitis is present. These infections have some distinguishing features in terms of subclinical infection rate, unique neurologic syndromes, associated systemic symptoms, and prognosis. The diagnosis is generally made clinically during recognized outbreaks and is confirmed by virus-specific serology. Prevention consists of control of mosquito vectors and precautions with proper clothing and insect repellents to minimize mosquito and tick bites. It is essential before making the diagnosis of arboviral encephalitis, which is not treatable, to exclude herpes encephalitis, which warrants specific antiviral therapy. Delay in administering this therapy may have dire consequences.

West Nile Virus Encephalitis

This flavivirus is the most important arbovirus infection in the United States. In 2003 there were more than 10,000 clinically apparent infections, more than 2900 nervous system infections, and 265 deaths in 47 states. Prevalence had declined significantly, but in 2012 there was a resurgence to more than 5000 reported cases, of which approximately half were neuroinvasive; 240 were fatal. The reservoir of West Nile virus includes more than 160 species of birds whose migration explains the extent of endemic disease. Epidemics occur in summer–fall; most infected individuals are asymptomatic. Approximately 20% develop West Nile Fever characterized by fever, headache, retro-orbital pain, nausea, vomiting, lymphadenopathy, and a maculopapular rash (20%–50%). Less than 1% of infected patients develop meningitis or encephalitis, but 10% of these cases are fatal. The major risk factor for severe disease is age older than 50 years and immune compromise. Children usually manifest with West Nile fever and less than one-third will develop neuroinvasive disease, most likely limited to meningitis. Neurologic manifestations are most often those found with other meningoencephalitides, but some distinguishing features include polio-like acute flaccid paralysis, movement disorders (Parkinsonism, tremor, and myoclonus), brainstem symptoms, polyneuropathy, and optic neuritis. Muscle weakness, facial palsy, and hyporeflexia are common (20%). Recovery is slow and serious sequelae occur in some severely affected patients. Diagnosis is best made by detecting IgM antibody (enzyme immunoassay) to the virus in CSF. This will be present by 5–6 days (95%) after onset. PCR is a specific diagnostic tool, but is less sensitive than antibody detection. Antibody rise in serum can also be used for diagnosis.

Treatment is supportive, although various antivirals and specific immunoglobulins are being studied. The infection is not spread between contacts, but can be spread by donated organs, blood, and breast milk, and transplacentally.

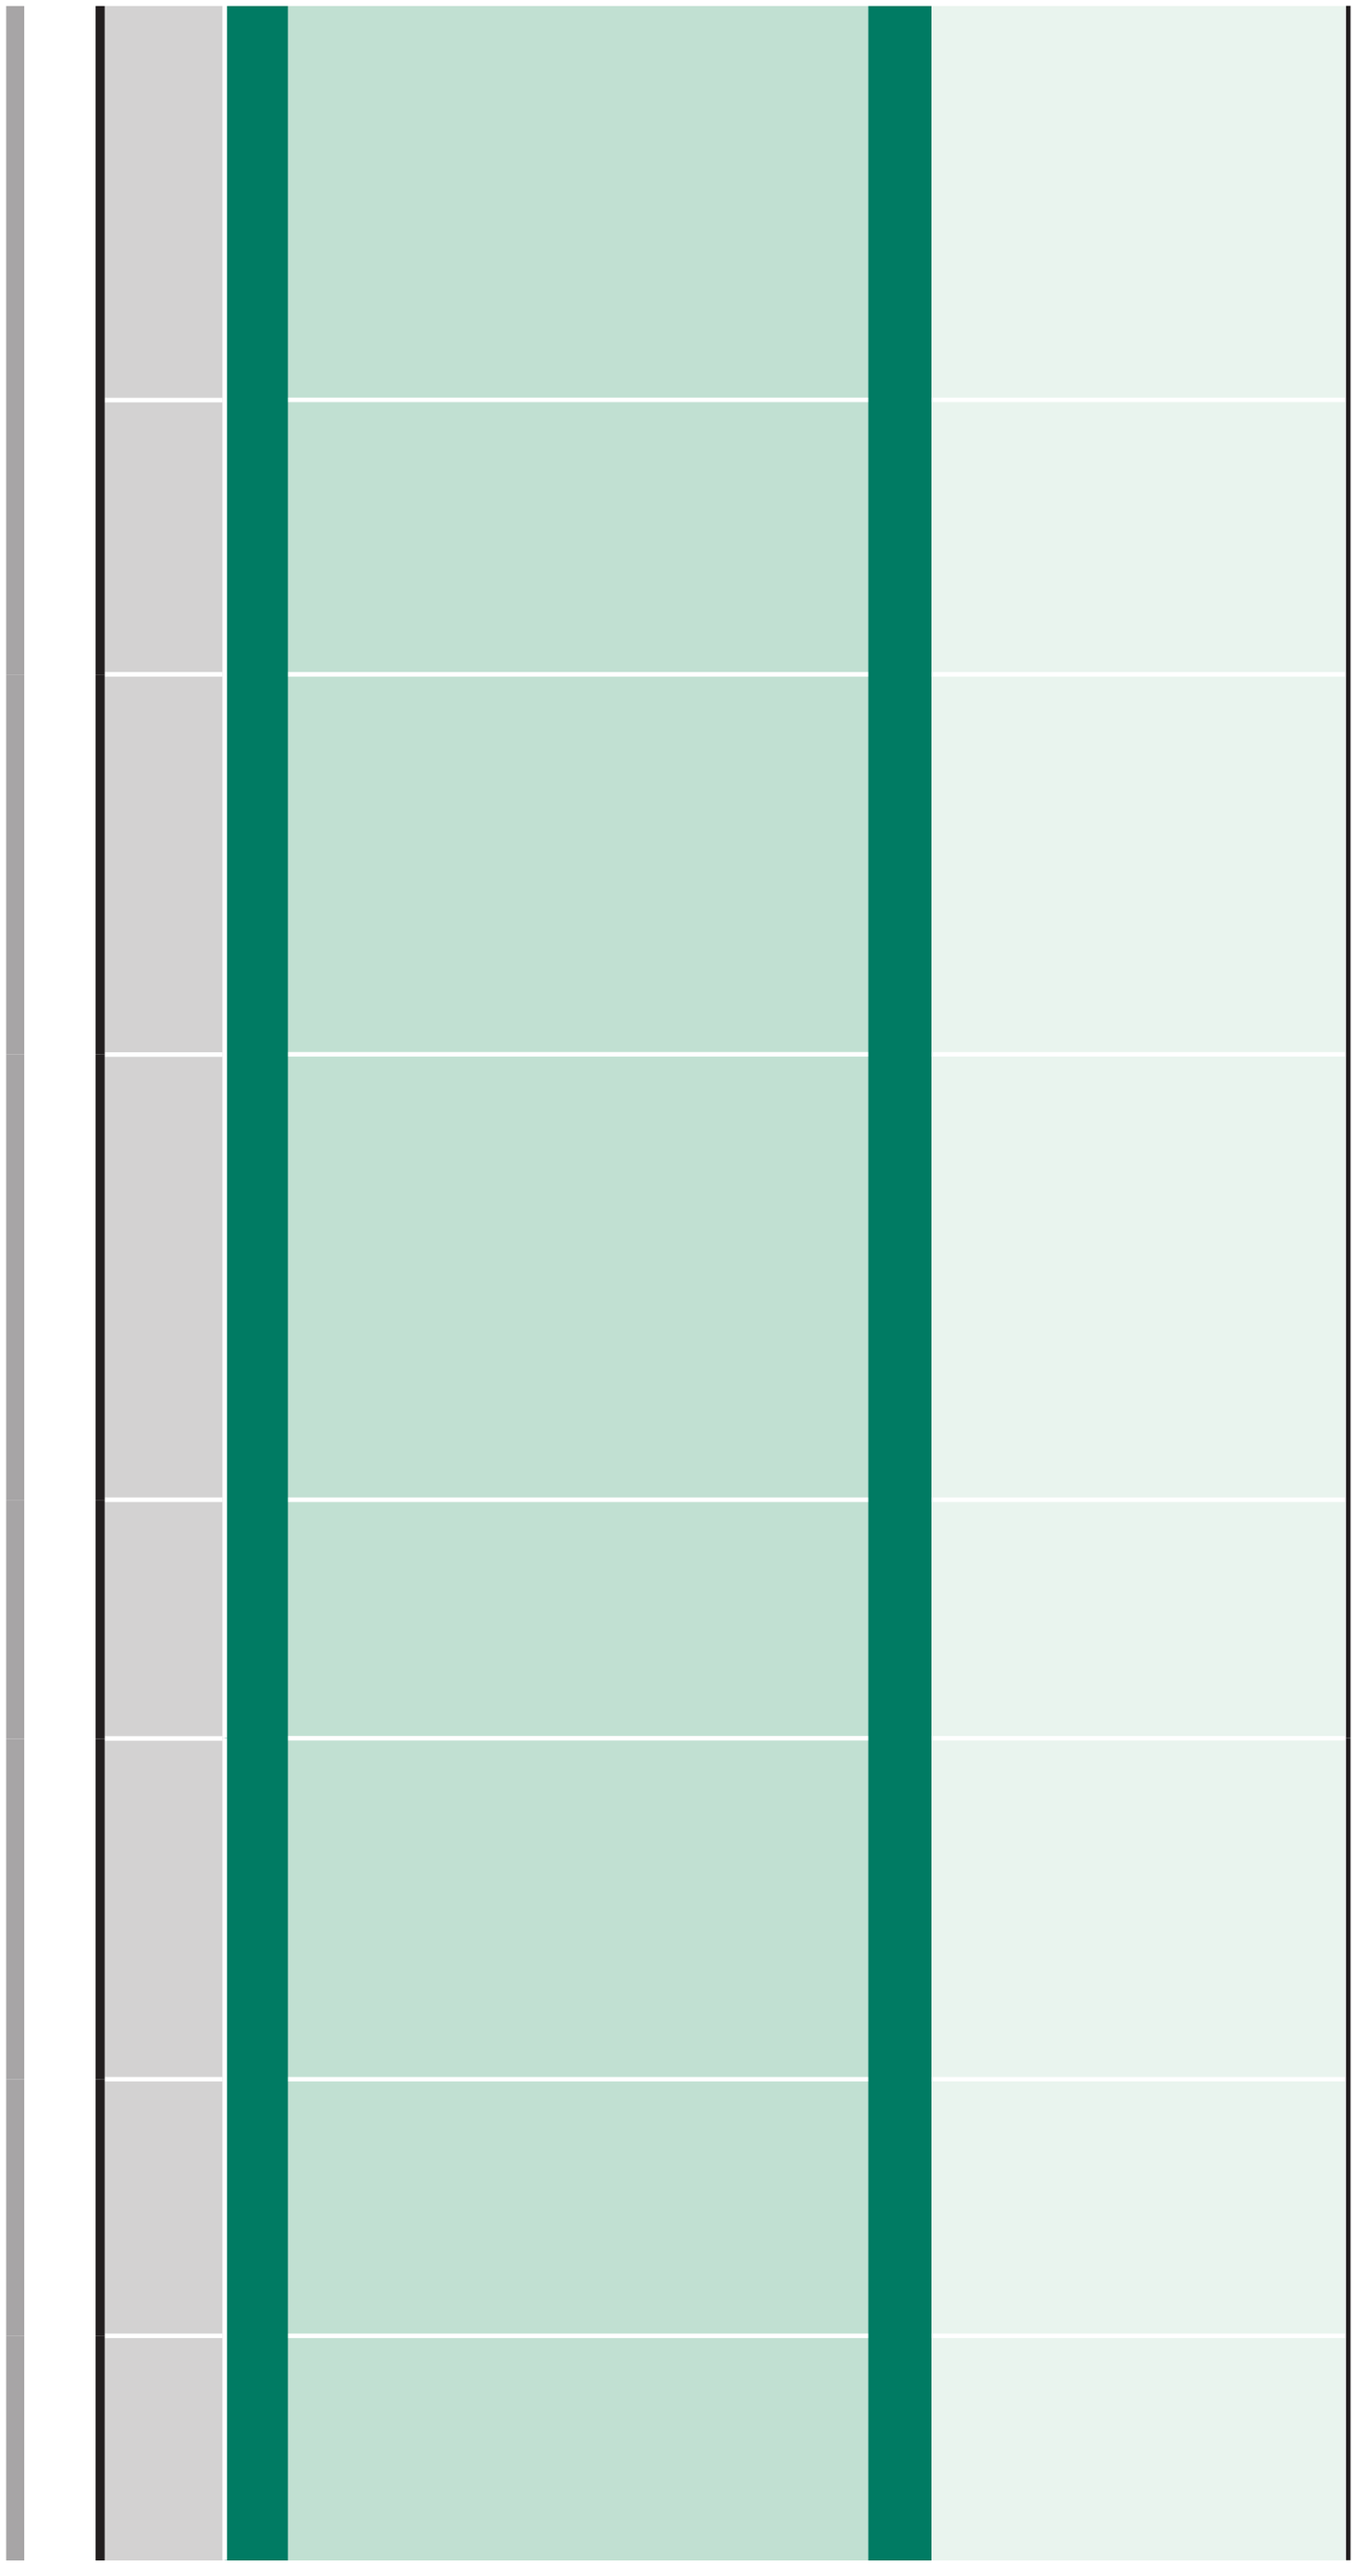
Gaensbauer JT, Lindsey NP, Messacar K, Staples JE, Fischer M: Neuroinvasive arboviral disease in the United States: 2003 to 2012. Pediatrics 2014;134(3):e642–e650 [PMID: 25113294].



DENGUE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Travel or residence in an endemic area.
- First infection (first episode) results in fever and rash; retro-orbital pain, severe myalgia, and arthralgia may occur.
- Second infection with a different serotype of dengue may result in dengue hemorrhagic fever (thrombocytopenia, bleeding, a plasma leak syndrome); this may progress to shock (dengue shock syndrome).

In endemic areas, more than 50 million cases of dengue occur each year, often in severe forms. In the United States, more than 400 cases are diagnosed, most often in travelers from the Caribbean or Asia and less often in those visiting Central and South America, making it the most common arboviral disease in travelers. Dengue is the second most common cause of fever (after malaria) in returning travelers. Dengue occurs in Mexico; Texas and Florida have sporadic indigenous outbreaks and the disease has been epidemic in Puerto Rico. The spread of dengue requires the Aedes mosquito (present in the southern United States), which transmits virus from a reservoir of viremic humans in endemic areas. Most patients have mild disease, especially young children, who may have a nonspecific fever and rash. Severity is a function of age, and prior infection with other serotypes of dengue virus is a prerequisite for severe hemorrhagic complications.

» Clinical Findings

A. Symptoms and Signs

Dengue fever begins abruptly 4–7 days after transmission (range, 3–14 days) with fever, chills, severe retro-orbital pain, severe muscle and joint pain, nausea, and vomiting. Erythema of the face and torso may occur early. After 3–4 days, a centrifugal maculopapular rash appears in half of the patients described as "islands of white in a sea of red". The rash can become petechial, and mild hemorrhagic signs (epistaxis, gingival bleeding, microscopic blood in stool or urine) may be noted. The illness lasts 5–7 days, although rarely fever may reappear for several additional days. Fever may become relatively lower on the third day, only to become higher until defervescence. Since there are four serotypes of dengue virus, multiple sequential infections can occur.

B. Laboratory Findings

In most cases mild leukopenia and thrombocytopenia are common. Liver function tests are usually normal. Diagnosis is made by viral culture of plasma (50% sensitive up to the fifth day), detection of viral antigenemia (90% sensitive during the febrile phase of first infections), dengue PCR during the first 5 days, or detection of IgM-specific ELISA antibodies (70-80% sensitive at the sixth day), or by detecting a rise in type-specific antibody.

» Differential Diagnosis

This diagnosis should be considered for any traveler to an endemic area who has symptoms suggestive of a systemic viral illness, although less than 1 in 1000 travelers to these areas develops dengue. Often the areas visited have other indigenous pathogens circulating (eg, malaria, typhoid fever, leptospirosis, rickettsial diseases, other endemic alphaviruses and flaviviruses, and measles). Especially relevant in travelers from India, Indian Ocean islands, and now Central America and the Caribbean is chikungunya fever, which also presents with fever, and rash, but in 70% of cases is associated with arthralgia/arthritis, rather than myalgia as is seen with dengue. EBV, influenza, enteroviruses, and acute HIV infection may produce a similar illness. Dengue is not associated with sore throat or cough. An illness that starts 2 weeks after the trip ends or that lasts longer than 2 weeks is not dengue or chikungunya fever.

» Complications

More common in endemic areas is the appearance of dengue hemorrhagic fever (DHF), which is defined by significant thrombocytopenia (< 100,000 platelets/μL, bleeding, and a plasma leak syndrome [hemoconcentration = hematocrit > 20% higher than baseline], hypoalbuminemia, and pleural or peritoneal effusions). This occurs most frequently with a second attack of dengue as a consequence antibody enhancement of virus entry into cells and increased cytokine responses; thus, it is rarely seen in typical travelers. DHF can also present in infants after primary dengue infection as a consequence of enhancement from maternal acquired antibodies. Dengue can be transmitted in utero from a pregnant woman infected within 2 weeks prior to delivery. Failure to recognize and treat DHF may lead to dengue shock syndrome, which is defined by signs of circulatory failure and hypotension or shock, and has a high fatality rate (10%). Neurologic complications such as encephalitis, myositis, myelitis, Guillain-Barré syndrome, and mononeuropathies are reported in 5%–10%. In endemic regions, dengue infection should be considered as one of the etiologies of encephalitis.

» Prevention

Prevention of dengue fever involves avoiding high-risk areas and using conventional mosquito avoidance measures. The main vector is a daytime feeder. At least one of the three dengue vaccines in development is now being registered and it has shown to prevent infection by half and reduce the risk of DHF by 90%.

» Treatment

Dengue fever is treated by oral rehydration and antipyretics avoiding nonsteroidal anti-inflammatory agents that affect platelet function. Recovery is complete without sequelae. The hemorrhagic syndrome requires prompt fluid therapy with plasma expanders and isotonic saline and close ICU monitoring.

Simmons CP, Farrar JJ, van Vinh Chau N, Wills B: Dengue. N Engl J Med 2012;366(15):1423 [PMID: 22494122].

COLORADO TICK FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Travel in endemic area; tick bite.
- Fever, chills, headache, retro-orbital pain, myalgia.
- Biphasic fever curve.
- Leukopenia early in the illness.

Colorado tick fever is endemic in the high plains and mountains of the central and northern Rocky Mountains and northern Pacific coast of the United States. The reservoir of the virus consists of squirrels and chipmunks. Many hundreds of cases of Colorado tick fever occur each year in visitors or laborers entering this region, primarily from May through July.

» Clinical Findings

A. Symptoms and Signs

After a 3- to 4-day incubation period (maximum, 14 days), fever begins suddenly together with chills, lethargy, headache, ocular pain, myalgia, abdominal pain, and nausea and vomiting. Conjunctivitis may be present. A nondistinctive maculopapular rash occurs in 5%–10% of patients. The illness lasts 7–10 days, and half of patients have a biphasic fever curve with several afebrile days in the midst of the illness.

B. Laboratory Findings

Leukopenia is characteristic early in the illness. Platelets are modestly decreased. Specific ELISA testing is available, but 2–3 weeks may elapse before seroconversion. Fluorescent antibody staining will detect virus-infected erythrocytes during the illness and for weeks after recovery. Reverse transcription polymerase chain reaction (RT-PCR) is available in some areas that will be positive within the first week of illness.

» Differential Diagnosis

Early findings, especially if rash is present, may suggest enterovirus, measles, or rubella infection. Enteric fever may be an early consideration because of the presence of leukopenia and thrombocytopenia. A history of tick bite, which is often obtained; information about local risk; and the biphasic fever pattern will help with the diagnosis. Because of the wilderness exposure, diseases such as leptospirosis, borreliosis, tularemia, ehrlichiosis, and Rocky Mountain spotted fever will be considerations.

» Complications

Meningoencephalitis occurs in 3%–7% of patients. Cardiac and pulmonary complications are rare.

» Prevention & Treatment

Prevention involves avoiding endemic areas and using conventional means to avoid tick bite. Therapy is supportive. Do not use analgesics that modify platelet function.

Meagher KE, Decker CF: Other tick-borne illnesses: tularemia, Colorado tick fever, tick paralysis. Dis Mon 2012;58(6):370 [PMID: 22608124].

OTHER MAJOR VIRAL CHILDHOOD EXANTHEMS

See section Infections due to Herpesviruses for a discussion of varicella and roseola, the two other major childhood exanthems.

ERYTHEMA INFECTIOSUM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever and rash with "slapped-cheek" appearance, followed by a symmetrical, full-body maculopapular rash.
- Arthritis in older children.
- Profound anemia in patients with impaired erythrocyte production.
- Nonimmune hydrops fetalis following infection of pregnant women.

» General Considerations

This benign exanthematous illness of school-aged children is caused by the human parvovirus B19. Spread is respiratory, occurring in winter–spring epidemics. A nonspecific mild flulike illness may occur during the viremia at 7–10 days; the characteristic rash occurring at 10–17 days represents an immune response. The patient is viremic and contagious prior to—but not after—the onset of rash.

Approximately half of infected individuals have a subclinical illness. Most cases (60%) occur in children between ages 5 and 15 years, with an additional 40% occurring later in life. Forty percent of adults are seronegative. The secondary attack rate in a school or household setting is 50% among susceptible children and 20%–30% among susceptible adults.

» Clinical Findings

Owing to the nonspecific nature of the exanthem and the many subclinical cases, a history of contact with an infected individual is often absent or unreliable. Recognition of the illness is easier during outbreaks.

A. Symptoms and Signs

Typically, the first sign of illness is the rash, which begins as raised, fiery red maculopapular lesions on the cheeks that coalesce to give a "slapped-cheek" appearance. The lesions are warm, nontender, and sometimes pruritic. They may be scattered on the forehead, chin, and postauricular areas, but the circumoral region is spared. Within 1–2 days, similar lesions appear on the proximal extensor surfaces of the extremities and spread distally in a symmetrical fashion. Palms and soles are usually spared. The trunk, neck, and buttocks are also commonly involved. Central clearing of confluent lesions produces a characteristic lacelike pattern. The rash fades in several days to several weeks, but frequently reappears in response to local irritation, heat (bathing), sunlight, and stress. Nearly 50% of infected children have some rash remaining (or recurring) for 10 days. Fine desquamation may be present. Mild low-grade fever, malaise, sore throat, and coryza occur in up to 50% of children. These symptoms appear for 2–3 days followed by a week-long asymptomatic phase before the rashes appear.

Purpuric stocking-glove rashes, neurologic disease, and severe disorders resembling hemolytic-uremic syndrome have also been described in association with parvovirus B19.

B. Laboratory Findings

A mild leukopenia occurs early in some patients, followed by leukocytosis and lymphocytosis. Specific IgM and IgG serum antibody tests are available, but care must be used in choosing a reliable laboratory for this test. IgM antibody is present in 90% of patients at the time of the rash. Nucleic acid detection tests are often definitive, but parvovirus DNA may be detectable in blood for prolonged periods. The disease is not diagnosed by routine viral culture.

» Differential Diagnosis

In children immunized against measles and rubella, parvovirus B19 is the most frequent agent of morbilliform and rubelliform rashes. The characteristic rash and the mild nature of the illness distinguish erythema infectiosum from other childhood exanthems. It lacks the prodromal symptoms of measles and the lymphadenopathy of rubella. Systemic symptoms and pharyngitis are more prominent with enteroviral infections and scarlet fever.

» Complications & Sequelae

A. Arthritis

Arthritis is more common in older patients, beginning with late adolescence. Approximately 10% of older children have severe joint symptoms. Girls are affected more commonly than boys. Pain and stiffness occur symmetrically in the peripheral joints. Arthritis usually follows the rash and may persist for 2–6 weeks, but resolves without permanent damage.

B. Aplastic Crisis and Other Hematologic Abnormalities

Parvovirus B19 replicates primarily in erythroid progenitor cells. Consequently, reticulocytopenia occurs for approximately 1 week during the illness. This goes unnoticed in individuals with a normal erythrocyte half-life, but results in severe anemia in patients with chronic hemolytic anemia.

Pure red cell aplasia, leukopenia, pancytopenia, idiopathic thrombocytopenic purpura, and a hemophagocytic syndrome have been described. Patients with HIV infection and other immunosuppressive illnesses may develop prolonged anemia or pancytopenia. Patients with hemolytic anemia and aplastic crisis, or with immunosuppression, may be contagious and should be isolated while in the hospital.

C. Other End-Organ Infections

Parvovirus is under study as a potential cause of a variety of collagen-vascular diseases. Parvovirus has been associated with neurologic syndromes, hepatitis, and suppression of bone marrow lineages. It is implicated as a cause of myocarditis.

D. In Utero Infections

Infection of susceptible pregnant women may produce fetal infection with hydrops fetalis. Fetal death occurs in about 6% of cases, most often in the first 20 weeks. This rate of fetal loss is higher than expected in typical pregnancies. Congenital anomalies have not been associated with parvovirus B19 infection during pregnancy.

» Treatment & Prognosis

Erythema infectiosum is a benign illness for immunocompetent individuals. Patients with aplastic crisis may require blood transfusions. It is unlikely that this complication can be prevented by quarantine measures, because acute parvovirus infection in contacts is often unrecognized and is most contagious prior to the rash. Pregnant women who are exposed to erythema infectiosum or who work in a setting in which an epidemic occurs should be tested for evidence of prior infection. Susceptible pregnant women should then be followed up for evidence of parvovirus infection. Approximately 1.5% of women of childbearing age are infected during pregnancy. If maternal infection occurs, the fetus should be followed by ultrasonography for evidence of hydrops and distress. In utero transfusion or early delivery may salvage some fetuses. Pregnancies should not be terminated because of parvovirus infection. The risk of fetal death among exposed pregnant women of unknown serologic status is less than 2.5% for homemakers and less than 1.5% for school teachers.

Intramuscular immunoglobulin is not protective. High-dose IVIG has stopped viremia and led to marrow recovery in some cases of prolonged aplasia. Its role in immunocompetent patients and pregnant women is unknown.

Terhas G et al: Neurologic consequences of a parvovirus infection. J Clin Virol 2013;56(2):156 [PMID: 23182456].

MEASLES (RUBEOLA)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Exposure to measles 9–14 days previously.
- Prodrome (2–3 days) of fever, cough, conjunctivitis, and coryza.
- Koplik spots (few to many small white papules on a diffusely red base on the buccal mucosa) 1–2 days prior to and after onset of rash.
- Maculopapular rash spreading from the face and hairline to the trunk over 3 days and later becoming confluent.
- Leukopenia.

» General Considerations

Measles in one of the most contagious infectious diseases of childhood that presents as a febrile exanthema. The attack rate in susceptible individuals is extremely high; spread is via respiratory droplets. Considered eliminated from the United States in 2000, frequent outbreaks have occurred recently (644 cases in 2014, and 176 cases in the first 2 months of 2015), mainly due to lower vaccine coverage, increasing vaccine hesitancy, and importation. It is recommended that all children receive two doses prior to primary or secondary school entry (see Chapter 10). Morbidity and mortality rates in the developing world are substantial because of underlying malnutrition and secondary infections. Because humans are the sole reservoir of measles, there is the potential to eliminate this disease worldwide.

» Clinical Findings

A history of contact with a suspected case may be absent because airborne spread is efficient and patients are contagious during the prodrome. Contact with an imported case may not be recognized. In temperate climates, epidemic measles is a winter–spring disease. Because measles was uncommon in the United States, a high index of suspicion is required during outbreaks.

A. Symptoms and Signs

After 2–3 days of a prodrome of sneezing, eyelid edema, tearing, copious coryza, photophobia, and harsh cough, high fever and lethargy become prominent. Koplik spots are white macular lesions on the buccal mucosa, typically opposite the lower molars. These are almost pathognomonic for rubeola, although they may be absent. A discrete maculopapular rash begins when the respiratory symptoms and fever are maximal and spreads quickly from the face to the trunk, coalescing to a bright red. As it spreads to the extremities, the rash fades turning coppery from the face and is completely gone within 6 days; fine desquamation may occur. Diarrhea can occur in young children and lead to hospitalization; persistent fever and cough may signal pneumonia.

B. Laboratory Findings

Lymphopenia is characteristic. Total leukocyte count may fall to 1500/μL. The diagnosis is usually made by detection of measles IgM antibody in serum drawn at least 3 days after the onset of rash, and may be made later by detection of a significant rise in IgG antibody. Direct detection of measles antigen by fluorescent antibody staining of nasopharyngeal cells is a useful rapid method. PCR testing of oropharyngeal secretions or urine is extremely sensitive and specific and can detect infection up to 5 days before symptoms.

C. Imaging

Chest radiographs often show hyperinflation, perihilar infiltrates, or parenchymal patchy, fluffy densities. Secondary consolidation or effusion may be visible.

» Differential Diagnosis

Table 40–3 lists other illnesses that may resemble measles.

» Complications and Sequelae

A. Respiratory Complications

These occur in up to 15% of patients. Bacterial superinfection of the lungs, middle ear, sinus, and cervical nodes are most common. Fever that persists after the third or fourth day of rash and/or leukocytosis suggests such a complication. Bronchospasm, severe croup, and progressive viral pneumonia or bronchiolitis (in infants) also occur. Immunosuppressed patients are at much greater risk for fatal pneumonia than are immunocompetent patients.

B. Cerebral Complications

Encephalitis occurs in 1 in 2000 cases. Onset is usually within a week after appearance of rash. Symptoms include combativeness, ataxia, vomiting, seizures, and coma. Lymphocytic pleocytosis and a mildly elevated protein concentration are usual CSF findings, but the fluid may be normal. Forty percent of patients so affected die or have severe neurologic sequelae.

Subacute sclerosing panencephalitis (SSPE) is a slow measles virus infection of the brain that becomes symptomatic years later in about 1 in 100,000 previously infected children. This progressive cerebral deterioration is associated with myoclonic jerks and a typical electroencephalographic pattern. It is fatal in 6–12 months. High titers of measles antibody are present in serum and CSF.

C. Other Complications

These include hemorrhagic measles (severe disease with multiorgan bleeding, fever, and cerebral symptoms), thrombocytopenia, appendicitis, keratitis, myocarditis, and premature delivery or stillbirth. Mild liver function test elevation is detected in up to 50% of cases in young adults; jaundice may also occur. Measles causes transient immunosuppression; thus, reactivation or progression of tuberculosis (including transient cutaneous anergy) can occur in children.

» Prevention

The current two-dose active vaccination strategy provides > 97% protection. Vaccine should not be withheld for concurrent mild acute illness, tuberculosis or positive tuberculin skin test, breast feeding, or exposure to an immunodeficient contact. The vaccine is recommended for HIV-infected children without severe HIV complications, with CD4 cells ≥ 15%, and preferably receiving antiretroviral therapy.

» Treatment and Prognosis

Vaccination prevents the disease in susceptible exposed individuals if given within 72 hours (see Chapter 10). Immunoglobulin (0.25 mL/kg intramuscularly; 0.5 mL/kg if immunocompromised) will prevent or modify measles if given within 6 days. Suspected cases should be diagnosed promptly and reported to the local health department.

Recovery generally occurs 7–10 days after onset of symptoms. Therapy is supportive: eye care, cough relief (avoid opioid suppressants in infants), and fever reduction (acetaminophen, lukewarm baths; avoid salicylates). Secondary bacterial infections should be treated promptly; antimicrobial prophylaxis is not indicated. Ribavirin is active in vitro and may be useful in infected immunocompromised children. In malnourished children, vitamin A supplementation should be given to avoid blindness and decrease mortality.

Mayo-Wilson E et al: Vitamin A supplementation for preventing mortality, illness, and blindness in children aged under 5: systematic review and meta-analysis. Brit Med J 2011;343:d5094 [PMID: 21868478].

RUBELLA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of rubella vaccination usually absent.
- Fever with postauricular and occipital adenopathy.
- Maculopapular rash beginning on face, rapidly spreading to the entire body, and disappearing by fourth day.
- Congenital infection.
  - Retarded growth and development.
  - Cataracts, retinopathy.
  - Purpuric "blueberry muffin" rash at birth.
  - Jaundice, thrombocytopenia.
  - Deafness.
  - Congenital heart defect.

» General Considerations

Rubella is a togavirus that causes a mild, self-limited exanthema (over 80% of infections are subclinical), but infection during pregnancy leads to teratogenicity and miscarriage. Rubella is transmitted by aerosolized respiratory secretions. Patients are infectious 5 days before until 5 days after the rash. Endemic rubella is absent in the United States and the Americas, and congenital rubella in infants born to unimmunized women and the occasional woman who is reinfected in pregnancy, is now very rare. Sporadic cases occur in migrants to the United States from Asia and Africa.

» Clinical Findings

The incubation period is 14–21 days. The nondistinctive signs may make exposure history unreliable. A history of immunization makes rubella unlikely but still possible. Congenital rubella usually follows maternal infection in the first trimester.

A. Symptoms and Signs

1. Infection in children—Young children may only have rash. Older patients often have a nonspecific prodrome of low-grade fever, ocular pain, sore throat, and myalgia. Postauricular and suboccipital adenopathy (sometimes generalized) is characteristic. This often precedes the rash by one week or may occur without rash. The rash consists of erythematous discrete maculopapules beginning on the face and spreading to the trunk and extremities within 24 hours. Scarlatiniform, morbilliform and erythema infectiosum-like rash variants may occur. The rash fades from the face to extremities by the third day. Enanthema is usually absent.

2. Congenital infection—More than 80% of women infected in the first 4 months of pregnancy (25% near the end of the second trimester) deliver an affected infant; congenital disease occurs in less than 5% of women infected later in pregnancy. Later infections can result in isolated defects, such as deafness. The main manifestations are as follows:

a. Growth retardation—Between 50% and 85% of infants are small at birth and remain so.

b. Cardiac anomalies—Pulmonary artery stenosis, patent ductus arteriosus, ventricular septal defect.

c. Ocular anomalies—Cataracts, microphthalmia, glaucoma, retinitis.

d. Deafness—Sensorineural (> 50% of cases).

e. Cerebral disorders—Chronic encephalitis; retardation.

f. Hematologic disorders—Thrombocytopenia, dermal nests of extramedullary hematopoiesis or purpura ("blueberry muffin" rash), lymphopenia.

g. Others—Hepatitis, osteomyelitis, immune disorders, malabsorption, diabetes.

B. Laboratory Findings

Leukopenia is common, and platelet counts may be low. Congenital infection is associated with low platelet counts, abnormal liver function tests, hemolytic anemia, and CSF pleocytosis in the newborn period. Virus may be isolated from oral secretions or urine from 1 week before to 2 weeks after onset of rash. Children with congenital infection are infectious for months. Direct RNA amplification (PCR) is now common and very sensitive. Serologic immunoassay diagnosis is best made by demonstrating a fourfold rise in antibody titer between specimens drawn 1–2 weeks apart. The first should be drawn promptly, because titers increase rapidly after onset of rash; both specimens must be tested simultaneously by a single laboratory. Rubella IgM is present in 50% of patients at the onset of the rash, but in almost all by 5 days later. Because the decision to terminate a pregnancy is usually based on serologic results, testing must be done carefully.

C. Imaging

Pneumonitis and bone metaphyseal longitudinal lucencies may be present in radiographs of children with congenital infection.

» Differential Diagnosis

Rubella may resemble infections due to measles, enterovirus, adenovirus, EBV, roseola, parvovirus, and T gondii. Drug reactions may also mimic rubella. Because public health implications are great, sporadic suspected cases should be confirmed serologically or virologically.

Congenital rubella must be differentiated from congenital CMV infection, toxoplasmosis, and syphilis.

» Complications & Sequelae

A. Arthralgia and Arthritis

Both occur more often in adult women. Polyarticular involvement (fingers, knees, wrists) lasting a few days to weeks is typical. Frank arthritis occurs in a small percentage of patients. It may resemble acute rheumatoid arthritis.

B. Encephalitis

With an incidence of about 1:6000, this is a parainfectious encephalitis associated with a low mortality rate. A syndrome resembling SSPE (see section on Measles) has also been described in congenital rubella.

C. Rubella in Pregnancy

Infection in the mother as in older children is self-limited and not severe.

» Prevention

Rubella is one of the infections that could be eradicated (see Chapter 10 for the indication and efficacy of rubella vaccine). Standard prenatal care should include rubella antibody testing. Seropositive mothers are at no risk; seronegative mothers are vaccinated after delivery.

A pregnant woman possibly exposed to rubella should be tested immediately; if seropositive, she is considered protected and without risk to the fetus. If she is seronegative, a second specimen should be drawn in 4 weeks, and both specimens should be tested simultaneously. Seroconversion in the first trimester is associated with high fetal risk; such women require counseling regarding therapeutic abortion.

When pregnancy termination is not an option, some experts recommend intramuscular administration of immunoglobulin (up to 0.55 mL/Kg IM) within 72 hours after exposure in an attempt to prevent infection. Only very small fractions of IgG are transferred to the fetus in early pregnancy and the efficacy of this practice is unknown.

» Treatment & Prognosis

Symptomatic therapy is sufficient. Arthritis may improve with administration of anti-inflammatory agents. The prognosis is poor in congenitally infected infants, in whom most defects are irreversible or progressive. The severe cognitive defects in these infants seem to correlate closely with the degree of growth failure.

° INFECTIONS DUE TO OTHER VIRUSES

HANTAVIRUS CARDIOPULMONARY SYNDROME

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Influenza-like prodrome (fever, myalgia, headache, cough).
- » Rapid onset of unexplained pulmonary edema and myocardiopathy.
- » Residence or travel in endemic area; exposure to aerosols from deer mouse droppings or secretions.

» General Considerations

Hantavirus cardiopulmonary syndrome is the first native bunyavirus infection endemic in the United States. This syndrome is distinctly different in mode of spread (no arthropod vector) and clinical picture from other bunyavirus diseases.

» Clinical Findings

Hantavirus cardiopulmonary syndrome has been confirmed in more than 34 states and Canada that have the appropriate rodent reservoirs. Epidemics occur when environmental conditions favor large increases in the rodent population and increased prevalence of virus.

A. Symptoms and Signs

After an incubation period of 1–3 weeks, onset is sudden, with a nonspecific virus-like prodrome: fever; back, hip, and leg pain; chills; headache; and nausea and vomiting. Abdominal pain may be present. Sore throat, conjunctivitis, rash, and adenopathy are absent, and respiratory symptoms are absent or limited to a dry cough. After 1–10 days (usually 3–7), dyspnea, tachypnea, and evidence of a pulmonary capillary leak syndrome appear. This often progresses rapidly over hours. Hypotension is common, not only from hypoxemia but also from myocardial dysfunction. Copious, amber-colored, nonpurulent secretions are common. Decreased cardiac output due to myocardiopathy and elevated systemic vascular resistance distinguish this disease from early bacterial sepsis.

B. Laboratory Findings

The hemogram shows leukocytosis with a prominent left shift and immunoblasts, thrombocytopenia, and hemoconcentration. Lactate dehydrogenase (LDH) is elevated, as are liver function tests; serum albumin is low. Creatinine is elevated in some patients, and proteinuria is common. Lactic acidosis and low venous bicarbonate are poor prognostic signs. A serum IgM ELISA test is positive early in the illness. Otherwise, the diagnosis is made by specific staining of tissue or PCR, usually at autopsy.

C. Imaging

Initial chest radiographs are normal. Subsequent radiographs show bilateral interstitial infiltrates with the typical butterfly pattern of acute pulmonary edema, bibasilar airspace disease, or both. Significant pleural effusions are often present. These findings contrast with those of other causes of acute respiratory distress syndrome.

» Differential Diagnosis

In some geographic areas, plague and tularemia may be possibilities. Infections with viral respiratory pathogens

and Mycoplasma have a slower tempo, do not elevate the LDH, and do not cause the hematologic changes seen in this syndrome. Q fever, psittacosis, toxin exposure, legionellosis, and fungal infections are possibilities, but the history, tempo of the illness, and blood findings, as well as the exposure history, should be distinguishing features. Hantavirus cardiopulmonary syndrome is a consideration in previously healthy persons with a febrile illness associated with unexplained pulmonary edema.

» Treatment & Prognosis

There is no established antiviral therapy. Management should concentrate on oxygen therapy and mechanical ventilation as required. Because of capillary leakage, Swan-Ganz catheterization to monitor cardiac output and inotropic support—rather than fluid therapy—should be used to maintain perfusion. Venoarterial extracorporeal membrane oxygenation can provide short-term support for selected patients. The strains of virus present in North America are not spread by person-to-person contact. No isolation is required. The case fatality rate is 30%–40%. Guidelines are available for reduction of exposure to the infectious agent.

MUMPS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- No prior mumps immunization or waning vaccine immunity
- Parotid gland swelling.
- Aseptic meningitis with or without parotitis.

» General Considerations

Mumps is one of the classic childhood infections. Mumps virus, a paramyxovirus, is spread by the respiratory route and attacks almost all nonprotected children (asymptomatically in 30%–40% of cases). As a result of prior clinical or subclinical infection, or childhood immunization, 95% of adults are immune, although immunity can wane in late adolescence. When the susceptibles accumulate occasional epidemics (~400 cases in 2012) can occur, which are aborted by reimmunization of the at-risk population. Infected patients are infectious from 2 days prior to 5 days after the onset of parotitis. The incubation period is 14–21 days. In an adequately immunized individual, parotitis is usually due to another cause. Currently in the United States, less than one case is reported per 100,000 population. The vaccine is so efficacious that clinical disease is rare in immunized children. However, an outbreak in Guam occurred even when most children had two doses of vaccine, likely spread by crowding.

» Clinical Findings

A. Symptoms and Signs

1. Salivary gland disease—After a prodrome of fever, severe headache, aches and anorexia, tender swelling of parotid glands occurs (70%–80% bilateral). The ear is displaced upward and outward; the mandibular angle is obliterated. Parotid stimulation with sour foods may be quite painful. The orifice of the Stensen duct may be red and swollen; yellow secretions may be expressed, but pus is absent. Parotid swelling dissipates after 1 week.

2. Meningoencephalitis—Once the most common cause of aseptic meningitis, mumps meningitis was manifested by severe headache, vomiting, and/or asymptomatic mononuclear pleocytosis. Fewer than 10% of patients had clinical meningitis or encephalitis. Parotitis is present in only half of the cases of mumps meningoencephalitis. Although neck stiffness, nausea, and vomiting can occur, encephalitic symptoms are rare (1:4000 cases of mumps); recovery in 3–10 days is the rule.

3. Pancreatitis—Epigastric abdominal pain may represent transient pancreatitis. Because salivary gland disease may elevate serum amylase, specific markers of pancreatic function (lipase, amylase isoenzymes) are required for assessing pancreatic involvement.

4. Orchitis, oophoritis—Involvement of the gonads is associated with fever, local tenderness, and swelling and is second to parotitis as presentation of mumps in adolescents. Epididymitis is usually present. Most often unilateral it resolves in 1–2 weeks. Although one-third of infected testes atrophy, bilateral involvement and sterility are rare.

5. Other—Thyroiditis, mastitis (especially in adolescent females), arthritis, and presternal edema (occasionally with dysphagia or hoarseness) may be seen.

B. Laboratory Findings

Peripheral blood leukocyte count is usually normal. CSF may contain a modest number of cells (eg, 250 cells/μL,

predominantly lymphocytes), with mildly elevated protein and normal to slightly decreased glucose. Viral culture or PCR tests of saliva, throat, urine, or spinal fluid may be positive for at least 1 week after onset. Paired sera assayed by ELISA or a single positive IgM antibody test are currently used for diagnosis.

» Differential Diagnosis

A history of contact with a child with parotitis is not proof of mumps exposure. Mumps parotitis may resemble cervical adenitis (the jaw angle may be obliterated, but the ear does not usually protrude; the Stensen duct orifice is normal; leukocytosis and neutrophilia are observed), bacterial parotitis (pus in the Stensen duct, toxicity, exquisite tenderness), recurrent parotitis (idiopathic or associated with calculi), tumors or leukemia, and tooth infections. Many viruses, including parainfluenza, enteroviruses, EBV, CMV, and influenza, can cause parotitis. Parotid swelling in HIV infection is less painful and tends to be bilateral and chronic, but bacterial parotitis occurs in some children with HIV infection.

Unless parotitis is present, mumps meningitis resembles that caused by enteroviruses or early bacterial infection. An elevated amylase level is a useful clue in this situation. Isolated pancreatitis is not distinguishable from many other causes of epigastric pain and vomiting. Mumps is a classic cause of orchitis, but torsion, bacterial or chlamydial epididymitis, Mycoplasma infection, other viral infections, hematomas, hernias, and tumors must also be considered.

» Complications

The major neurologic complication is nerve deafness (usually unilateral) which can result in inability to hear high tones. Although rare, occurring in less than 0.1% of cases of mumps, it may occur without meningitis. Aqueductal stenosis and hydrocephalus (especially following congenital infection), myocarditis, transverse myelitis, and facial paralysis are other rare complications.

» Treatment & Prognosis

Treatment is supportive and includes provision of fluids, analgesics, and scrotal support for orchitis. Systemic corticosteroids have been used for orchitis, but their value is anecdotal.

White SJ et al: Measles, mumps, and rubella. Clin Obstet Gynecol 2012;55(2):550 [PMID: 22510638].

RABIES

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of animal bite 10 days to 1 year (usually < 90 days) previously.
- Paresthesias or hyperesthesia in bite area.
- Progressive limb and facial weakness in some patients (dumb rabies; 30%).
- Irritability followed by fever, confusion, combativeness, muscle spasms (especially pharyngeal with swallowing) in all patients (furious rabies).
- Rabies antigen detected in corneal scrapings or tissue obtained by brain or skin biopsy; Negri bodies seen in brain tissue.

» General Considerations

Rabies is an acute progressive CNS viral zoonotic infection. It remains a serious public health problem wherever animal immunization is not widely practiced or when humans play or work in areas with sylvan rabies. Infection is almost invariably fatal and will occur in 40% after rabid animal bites. Any warm-blooded animal may be infected, but susceptibility and transmissibility vary with different species. Bats often carry and excrete the virus in saliva or feces for prolonged periods; they are the major cause of rabies in the United States. Dogs and cats, responsible for most rabies in the world, are usually clinically ill within 10 days after becoming contagious (the standard quarantine period for suspect animals). Valid quarantine periods or signs of illness are not fully known for many species. Rodents rarely transmit infection. Animal vaccines are very effective when properly administered, but a single inoculation may fail to produce immunity in up to 20% of dogs.

The risk is assessed according to the type of animal (high-risk animals include bats, raccoons, skunks, and foxes), wound extent and location (infection more common after head or hand bites, or if wounds have extensive salivary contamination and are not quickly and thoroughly cleaned), geographic area (urban rabies is rare to nonexistent in the US cities; rural rabies is possible, especially outside the United States), and animal vaccination history (risk low if

documented). Most rabies in the United States is caused by bat genotypes, yet a history of bat bite is often not obtained especially in young children. Aerosolized virus in caves inhabited by bats has caused infection.

» Clinical Findings

A. Symptoms and Signs

Most cases occur within 3–12 weeks of exposure and may present with vague symptoms. Paresthesia at the bite site is usually the first symptom. Nonspecific anxiety, excitability, or depression follows, then muscle spasms, drooling, hydrophobia, delirium, and lethargy. Swallowing or even the sensation of air blown on the face may cause pharyngeal spasms. Seizures, fever, cranial nerve palsies, coma, and death follow within 7–14 days after onset. In a minority of patients, the spastic components are initially absent and the symptoms are primarily flaccid paralysis and cranial nerve defects. The furious components appear subsequently.

B. Laboratory Findings

Leukocytosis is common. CSF is usually normal, but may show elevation of protein and mononuclear cell pleocytosis. Cerebral imaging and electroencephalography are not diagnostic. Infection in an animal may be determined by use of the fluorescent antibody test to examine brain tissue for antigen. Rabies virus is excreted in the saliva of infected humans, but the diagnosis is usually made by antigen detection in scrapings or tissue samples of richly innervated epithelium, such as the cornea or the hairline of the neck. Classic Negri cytoplasmic inclusion bodies in brain tissue are not always present. Seroconversion measured by neutralizing antibody occurs after 7–10 days and clinical recovery has been associated with detection of neutralizing antibody and clearance of infectious rabies virus in the CNS.

» Differential Diagnosis

Failure to elicit the bite history in areas where rabies is rare may delay diagnosis. Other disorders to be considered include parainfectious encephalopathy; encephalitis due to herpes simplex, mosquito-borne viruses, or other causes of viral encephalitis or acute paralysis. However, classic furious rabies is not readily confused with these alternative diagnoses.

» Prevention

See Chapter 10 for information regarding vaccination and postexposure prophylaxis. Rabies immunoglobulin and diploid cell vaccine have made prophylaxis more effective and minimally toxic. Because rabies is almost always fatal, presumed exposures must be managed carefully.

» Treatment & Prognosis

Survival is very rare, but it has been reported in a very small number of patients receiving meticulous intensive care and the Milwaukee protocol that focuses on the altered CNS metabolic state. Early diagnosis is important for the protection and postexposure prophylaxis of patient contacts.

Yousaf MZ et al: Rabies molecular virology, diagnosis, prevention and treatment. Virol J 2012;9:50 [PMID: 22348291].

RICkETTSIAL INFECTIONS

Rickettsiae are pleomorphic, gram-negative coccobacilli that are obligate intracellular parasites. Rickettsial diseases are often included in the differential diagnosis of febrile rashes. Severe headache, myalgia, and pulmonary symptoms are prominent manifestations of rickettsial disease. The endothelium is the primary target tissue, and the ensuing vasculitis is responsible for severe illness.

All rickettsioses are transmitted by arthropod contact (ticks, fleas, lice—depending on the disease), either by bite or by contamination of skin breaks with vector feces. Except Rocky Mountain spotted fever and murine typhus, all other rickettsial diseases have a characteristic eschar at the bite site, called the tache noire. Evidence of arthropod contact by history or physical examination may be lacking, especially in young children. The geographic distribution of the vector is often the primary determinant for suspicion of these infections. Therapy often must be empiric. Many new broad-spectrum antimicrobials are inactive against these cell wall–deficient organisms; tetracycline is usually effective.

Q fever, which is not a rickettsiae, is included here because it was long classified as such and, like rickettsiae, is an obligate intracellular bacterium. It is not transmitted by an insect vector and is not characterized by rash.

HUMAN EHRLICHIOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residing or travel in endemic area when ticks are active.
- Tick bite noted (~75%).
- Fever, headache, rash (~67%), gastrointestinal symptoms.
- Leukopenia, thrombocytopenia, elevated serum transaminases, hypoalbuminemia.
- Definitive diagnosis by specific serology.

In children, the major agent of North American human ehrlichiosis is Ehrlichia chaffeensis. The reservoir hosts are

probably wild rodents, deer, and sheep; ticks are the vectors. Most cases caused by this agent are reported in the south-central, southeastern, and middle Atlantic states (Arkansas, Missouri, Oklahoma, Kentucky, Tennessee, and North Carolina are high-prevalence areas). Almost all cases occur between March and October, when ticks are active.

A second ehrlichiosis syndrome, seen in the upper Midwest and Northeast (Connecticut, Wisconsin, Minnesota, and New York are high-prevalence areas), is caused by Anaplasma phagocytophilum and Ehrlichia ewingii. Anaplasmosis also occurs in the western United States. Several new pathogenic Ehrlichia species have been discovered recently.

E chaffeensis has a predilection for mononuclear cells, whereas A phagocytophilum and E ewingii infect and produce intracytoplasmic inclusions in granulocytes. Hence, diseases caused by these agents are referred to as human monocytic ehrlichiosis or human granulocytic ehrlichiosis, respectively. Ehrlichiosis, Lyme disease, and babesiosis share some tick vectors; thus, dual infections can occur and should be considered in patients who fail to respond to therapy.

» Clinical Findings

In approximately 75% of patients, a history of tick bite can be elicited. The majority of the remaining patients report having been in a tick-infested area. The usual incubation period is 5–21 days.

A. Symptoms and Signs

Fever is universally present and headache is common (less so in children). Gastrointestinal symptoms (abdominal pain, anorexia, nausea, and vomiting) are reported in most pediatric patients. Distal limb edema may occur. Chills, photophobia, conjunctivitis, and myalgia occur in more than half of patients. Rash occurs in ~50% of children with monocytic ehrlichiosis and is less common in granulocytic ehrlichiosis. Rash may be erythematous, macular, papular, petechial, scarlatiniform, or vasculitic. Meningitis occurs. Interstitial pneumonitis, acute respiratory distress syndrome, and renal failure occur in severe cases. Physical examination reveals rash (not usually palms and soles), mild adenopathy, and hepatomegaly. In children without a rash, infection may present as a fever of unknown origin.

B. Laboratory Findings

Laboratory abnormalities include leukopenia with left shift, lymphopenia, thrombocytopenia, and elevated aminotransferase levels. Hypoalbuminemia and hyponatremia are common. Disseminated intravascular coagulation can occur in severe cases. Anemia occurs in one-third of patients. CSF pleocytosis (mononuclear cells; increased protein) is common. The definitive diagnosis is made serologically, either by a single high titer or a fourfold rise in titer. The Centers for Disease Control and Prevention uses an immunofluorescent antibody test to distinguish between the etiologic agents. Intracytoplasmic inclusions (morulae) may occasionally be observed in mononuclear cells in monocytic ehrlichiosis, and are usually observed in polymorphonuclear cells from the peripheral blood or bone marrow in granulocytic ehrlichiosis. Specific PCR testing can provide an early diagnosis where this is available.

» Differential Diagnosis

In regions where these infections exist, ehrlichiosis should be included in the differential diagnosis of children who present during tick season with fever, leukopenia or thrombocytopenia (or both), increased serum transaminase levels, and rash. The differential diagnosis includes septic or toxic shock, other rickettsial infections (especially Rocky Mountain spotted fever), Colorado tick fever, leptospirosis, Lyme borreliosis, relapsing fever, EBV, CMV, viral hepatitis and other viral infections, Kawasaki disease, systemic lupus erythematosus, and leukemia.

» Treatment & Prognosis

Asymptomatic or clinically mild and undiagnosed infections are common in some endemic areas. The disease may last several weeks if untreated. One-quarter of hospitalized children require intensive care. Meningoencephalitis and persisting neurologic deficits occur in 5%–10% of patients. Doxycycline, 2 mg/kg every 12 hours (IV or PO; maximum 100 mg per dose) for 7–10 days, is the treatment of choice. Patients with suspected disease must be treated preemptively concurrently with attempts to establish the diagnosis. Response to therapy should be evident in 24–48 hours. Deaths are uncommon in children. Immune compromise and asplenia are risk factors for severe disease.

St. Clair K, Decker CF: Ehrlichioses: anaplasmosis and human ehrlichiosis. Disease-A-Month 2012;58(6):346 [PMID: 22608121].

ROCKY MOUNTAIN SPOTTED FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residing or travel in endemic area when ticks are active.
- Fever, rash (palms and soles), gastrointestinal symptoms, headache.
- Tick bite reported (50%).
- Thrombocytopenia, hyponatremia.
- Definitive diagnosis by specific serology.

Rickettsia rickettsii causes one of many similar tick-borne illnesses characterized by fever and rash that occur worldwide. Most are named after their geographic area. Dogs and rodents, as well as large mammals, are reservoirs of R rickettsii.

Rocky Mountain spotted fever is the most severe rickettsial infection and the most important (~2000 cases per year) in the United States. It occurs predominantly along the eastern seaboard; in the southeastern states; and in Arkansas, Missouri, and Oklahoma. It is much less common in the west. Most cases occur in children exposed in rural areas from April to September. Infection can be acquired from dog ticks.

» Clinical Findings

A. Symptoms and Signs

After the incubation period of 3–12 days (mean, 7 days), there is high fever (> 40°C, often hectic), usually of abrupt onset, myalgia, severe and persistent headache (retro-orbital), toxicity, photophobia, vomiting, abdominal pain, and diarrhea. A rash occurs in more than 95% of patients and appears 2–6 days after fever onset as macules and papules; most characteristic (65%) is involvement of the palms, soles, and extremities; the face is spared. The rash becomes petechial and spreads centrally from the extremities. The rash reflects infection of endothelial cells, which also causes vascular leak and resulting edema, hypovolemia, and hypotension. Conjunctivitis, splenomegaly, pneumonitis, meningismus, and confusion may occur.

B. Laboratory Findings

Laboratory findings reflect diffuse vasculitis: thrombocytopenia, hyponatremia, early mild leukopenia, proteinuria, mildly abnormal liver function tests, hypoalbuminemia, and hematuria. CSF pleocytosis is common. Serologic diagnosis is achieved with indirect fluorescent or latex agglutination antibody methods, but generally is informative only 7–10 days after onset of the illness. Skin biopsy with specific fluorescent staining is a specific and moderately sensitive diagnostic method available during the first week of the illness.

» Differential Diagnosis

The differential diagnosis includes meningococcemia, measles, meningococcal meningitis, staphylococcal sepsis, EBV infection, enteroviral infection, leptospirosis, Colorado tick fever, scarlet fever, murine typhus, Kawasaki disease, and ehrlichiosis.

» Treatment & Prognosis

To be effective, therapy for Rocky Mountain spotted fever must be started early, most often on the basis of a high clinical suspicion prior to rash onset in endemic areas. It is important to remember that atypical presentations, such as the absence of pathognomonic rash, can lead to delay in appropriate therapy. Rash is rarely present during the first day of diagnosis and in 50% within 3 days of onset of fever. Doxycycline is the treatment of choice for children, regardless of age. Dosing is 2 mg/kg every 12 hours (IV or PO; maximum 100 mg per dose) for 2 or 3 days after the temperature has returned to normal for a full day. A minimum of 10 days of therapy is recommended. Because tick attachment lasting 6 hours or longer is needed, frequent tick removal is a preventive measure.

Complications and death result from severe vasculitis, especially in the brain, heart, and lungs. The mortality rate is 5%–7%. Persistent neurologic deficits occur in 10%–15% of children who recover. Delay in therapy is an important determinant of sequelae and mortality.

Woods CR: Rocky mountain spotted fever in children. Pediatr Clin N Am 2013;60:455 [PMID: 23481111].

ENDEMIC TYPHUS (MURINE TYPHUS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Residing in endemic area.
- » Fever for 10–14 days.
- » Headache, chills, myalgia.
- » Maculopapular rash spreading from trunk to extremities (not on palms and soles) 3–7 days after fever onset.
- » Definitive diagnosis by serology.

Endemic typhus is present in the southern United States, mainly in southern Texas, and in Southern California, and in Hawaii. The disease is transmitted by fleas from infected rodents or inhalation of rodent feces. Domestic cats, dogs, and opossums may play a role in the transmission of suburban cases. No eschar appears at the inoculation site. The incubation period is 6–14 days. Headache, myalgia and arthralgia, and chills slowly worsen. Fever may last 10–14 days. After 3–7 days, a rash appears. Truncal macules and papules spread to the extremities; the rash is rarely petechial and resolves in less than 5 days. The location of the rash in typhus, with sparing of the palms and soles, helps distinguish the disease from Rocky Mountain spotted fever. Rash may be absent in 20%–40% of patients. Hepatomegaly

may be present. Intestinal and respiratory symptoms may occur. Mild thrombocytopenia and elevated liver enzymes may be present. Prolonged neurologic symptoms can occur. Clinicians in endemic areas should consider early treatment when presented with a child with protracted fever, rash, and headache. Doxycycline is the drug of choice, which should be continued for 3 days after evidence of clinical improvement. Fluorescent antibody and ELISA tests are available.

Liddel PW, Sparks MJ: Murine typhus: endemic Rickettsia in southwest Texas. Clin Lab Sci 2012;25(2):81 [PMID: 20120614].

Q FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Exposure to farm animals (sheep, goats, cattle) and pets.
- Flu-like illness (fever, severe headache, myalgia).
- Cough; atypical pneumonia.
- Hepatomegaly and hepatitis.
- Diagnosis by serology.

Coxiella burnetii is transmitted by inhalation rather than by an arthropod bite. Q fever is also distinguished from rickettsial diseases by the infrequent occurrence of cutaneous manifestations and by the prominence of pulmonary disease. The birth tissues and excreta of domestic animals and of some rodents are major infectious sources. The organisms may be carried long distances in fine particle aerosols. Unpasteurized milk from infected animals may also transmit disease.

Clinical Findings

A. Symptoms and Signs

Most patients have a self-limited flu-like syndrome of chills, fever, severe headache, and myalgia of abrupt onset occurring 10–25 days after exposure. Abdominal pain, vomiting, chest pain, and dry cough are prominent in children. Examination of the chest may yield few findings, as in other atypical pneumonias. Hepatosplenomegaly is common. The illness lasts 1–4 weeks and frequently is associated with weight loss. Only about 50% of infected patients develop significant symptoms.

B. Laboratory Findings

Leukopenia with left shift is characteristic. Thrombocytopenia is unusual, which is another distinction from rickettsial diseases. Aminotransferase and γ-glutamyl transferase levels are elevated, but significant bilirubin elevation is unusual. Diagnosis is made by finding an antibody response (fourfold rise or single high titer in ELISA; IFA, or CF antibody assay) to the phase II organism. Chronic infection is indicated by antibody against the phase I organism. IgM ELISA and specific PCR tests are available.

C. Imaging

Pneumonitis occurs in 50% of patients. Multiple segmental infiltrates are common, but the radiographic appearance is not pathognomonic. Consolidation and pleural effusion are rare.

Differential Diagnosis

In the appropriate epidemiologic setting, Q fever should be considered in evaluating causes of atypical pneumonias, such as M pneumoniae, viruses, Legionella, and C pneumoniae. It should also be included among the causes of mild to moderate hepatitis without rash or adenopathy in children with exposure to farm animals.

Treatment & Prognosis

Typically the illness lasts 1–2 weeks without therapy. The course of the uncomplicated illness is shortened with doxycycline. Therapy is continued for several days after the patient becomes afebrile (usually 10–14 days). Quinolones are also effective.

One complication is chronic disease, which often implies myocarditis or granulomatous hepatitis. Meningoencephalitis is a rare complication. C burnetii is also one of the causes of "culture-negative" endocarditis. Coxiella endocarditis often occurs in the setting of valve abnormalities and is difficult to treat; mortality approaches 50%.

41 Human Immunodeficiency Virus Infection

Elizabeth J. McFarland, MD

» General Considerations

Human immunodeficiency virus (HIV) is a retrovirus that primarily infects cells of the immune system, including helper T lymphocytes (CD4 T lymphocytes), monocytes, and macrophages. The function and number of CD4 T lymphocytes and other affected cells are diminished by HIV infection, resulting in profound effects on both humoral and cell-mediated immunity. In the absence of treatment, HIV infection causes generalized immune incompetence, with progression from mild to severe symptoms/diagnoses, the latter of which are conditions that meet the definition of acquired immunodeficiency syndrome (AIDS) and, eventually, death. The clinical diagnosis of AIDS is made when an HIV-infected individual develops any of the Stage 3 opportunistic illnesses or other conditions listed in Table 41–1. In adults and children older than 6 years, the criteria for a diagnosis of AIDS also include an absolute CD4 T-lymphocyte count of 200 cells/μL or less.

» Epidemiology

The World Health Organization (WHO) estimated in 2014 that there were 36.9 million adults and 2.6 million children living with HIV (http://www.who.int/hiv/data/epi_core_july2015.png?ua=1). Over 90% live in low- and middle-income countries, primarily sub-Saharan Africa and South and Southeast Asia. Although the number of new infections is estimated to have peaked globally in 1997, infection and mortality rates remain high. Among children younger than 15 years, there were 220,000 new infections and 150,000 deaths in 2014. High rates of new pediatric infections are the result of ongoing mother-to-child transmission (MTCT) in resource-limited settings where access to preventative measures is often not accessible; fewer than 67% of pregnant women received recommend treatment in 2013 (http://www.who.int/hiv/data/arvpmtct2014.png?ua=1).

MTCT rates would be 20%–40% overall, if there is no intervention. Transmission occurs in utero, at the time of labor and delivery (peripartum), or during breast-feeding (postnatal transmission). However, MTCT can be reduced to less than 1%–2% with prenatal, perinatal, and postnatal interventions (see section Prevention). The successful implementation of these interventions in the United States has made new vertically acquired HIV cases rare (< 200 cases annually). In the United States, the number of children younger than 13 years living with HIV was estimated at 2579 in 2012 (http://www.cdc.gov/hiv/library/reports/surveillance/2013/surveillance_Report_vol_25.html#3). As a result of effective combination antiretroviral treatment (cART), perinatally infected children who receive treatment are surviving into adolescence and young adulthood. In the United States, perinatally infected individuals comprised 22% of those living with HIV in the 13- to 24-year-old age group.

After puberty, infections result primarily from sexual contact (men having sex with men [MSM] and heterosexual), with a smaller proportion resulting from injecting drug use. In recent years, there have been approximately 50,000 new HIV-1 infections annually in the United States among which youth are overrepresented, since the proportion of new infections among young people aged 13–29 years exceeds this age group's proportion in the total population (39% of new HIV infections vs 21% in the total population). Most at risk are young black MSM, who accounted for 45% of new HIV infections overall, and 55% of new HIV infections among young MSM (http://www.cdc.gov/hiv/statistics/basics/ataglance.html).

Occupational exposure resulting from accidental needle sticks or, rarely, mucosal exposure to blood may occur. As a result of careful donor screening and testing of donated blood, HIV transmission resulting from blood products is now extremely rare in the United States (1:2,000,000 transfusions). Casual, classroom, or household contact with an HIV-infected person poses no risk of transmission.

Table 41–1. HIV-related symptoms in children.

Mild symptoms

Having two or more of the following conditions:
Lymphadenopathy
Hepatomegaly
Splenomegaly
Dermatitis
Parotitis
Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Moderate symptoms

Anemia, neutropenia, thrombocytopenia
Bacterial meningitis, pneumonia, sepsis (single episode)
Candidiasis, oropharyngeal, persisting > 2 mo, in a child > 6 mo of age
Cardiomyopathy
Cytomegalovirus infection with onset < age 1 mo
Diarrhea, recurrent or chronic
Hepatitis
Herpes simplex virus stomatitis (> 2 episodes in 1 y), bronchitis, pneumonitis, esophagitis at < 1 mo of age
Herpes zoster, two or more episodes or more than one dermatome
Leiomyosarcoma
Lymphoid interstitial pneumonia
Nephropathy
Nocardiosis
Persistent fever (lasting > 1 mo)
Toxoplasmosis with onset < age 1 mo
Varicella, complicated

Severe (Stage 3-defining) opportunistic illnesses and other conditions

Bacterial infections, multiple or recurrent[a]
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive[b]
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal, (> 1 mo duration)
Cytomegalovirus disease (other than liver, spleen, or nodes) with onset > age 1 mo
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV
Herpes simplex virus: chronic oral lesions (> 1 mo), or bronchitis, pneumonitis, or esophagitis (onset at > age 1 mo)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (> 1 mo duration)
Kaposi sarcoma
Lymphoma: Burkitt, immunoblastic, or primary lesion in brain
Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary[b], disseminated, extrapulmonary
Mycobacterium, other species or unidentified, disseminated or extrapulmonary
Pneumocystis jiroveci pneumonia
Pneumonia, recurrent[b]
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of the brain with onset > age 1 mo
Wasting syndrome

[a]Only among children age < 6 years.
[b]Only among adults, adolescents, and children ≥ 6 years.

» Pathogenesis and Disease Course

In most cases, HIV infection occurs via mucosal exposure. At the time of exposure, virus breaches the mucosal barrier, is transported to regional lymph nodes, replicates, and spreads throughout all lymphoid tissues. Based on nonhuman primate models, replicating virus is found throughout the lymphoid tissue by 48 hours postinfection. During the first days after infection, there is a massive loss of mature CD4 T-helper lymphocytes, especially in the gut mucosa. Approximately 2 weeks after exposure, high levels of HIV are detected in the bloodstream. In adults without therapy, the level of viremia declines concurrent with the appearance of an HIV-specific host immune response, and plasma viremia usually reaches a steady-state level about 6 months after primary infection. The amount of virus present in the plasma at that point, known as the "set point," and thereafter is predictive of the rate of disease progression for the individual. A period of clinical latency usually occurs, lasting

from 1 year to more than 12 years, during which the infected person is asymptomatic. However, ongoing viremia and immune activation causes subclinical injury to the immune system. The virus and anti-HIV immune responses are in a steady state such that CD4 T-lymphocyte parameters may be stable. Eventually, the balance favors the virus, and the viral burden increases as the CD4 T-lymphocyte count declines, at which time the individual becomes susceptible to opportunistic illnesses.

Infants with in utero HIV infection have virus detectable in the blood at birth. Those infected peripartum test negative for virus at birth but have virus detected by 2–4 weeks of age. Infant viremia rises steeply, reaching a peak at age 1–2 months. In contrast with adults, infants have a gradual decline in plasma viremia that extends to age 4–5 years. Up to 50% of infants will have rapid disease progression to AIDS or death by age 2 years. Although this rapid progression is associated with high-level viremia, measurement of plasma virus and/or CD4 T-lymphocyte parameters do not identify all infants at risk for rapid progression.

Combination antiretroviral treatment (cART) can forestall disease progression for many years (≥ 20 years). However, cells with latent HIV infection persist and viral replication recurs if cART is interrupted. Therefore, with current regimens, treatment must be lifelong. Even with effective viral suppression, ongoing immune activation results in cardiovascular and central nervous system damage consistent with premature aging. Nevertheless, HIV infection can be considered a chronic disease for people with access to treatment, rather than an acutely terminal disease.

PERINATALLY HIV-EXPOSED INFANT

» Clinical Findings

Newborns with perinatal HIV infection rarely have symptoms or physical examination findings at birth, and there is no recognized primary infection syndrome in infants. However, 30%–80% of infected infants develop symptoms within the first year of life. Hepatomegaly, splenomegaly, lymphadenopathy, parotitis, and recurrent respiratory tract infections are signs associated with slow progression. Severe bacterial infections, progressive neurologic disease, anemia, and fever are associated with rapid progression. Initiation of cART in early infancy can prevent disease progression and is associated with fewer CD4 T cells with persistent HIV infection. Hence, early diagnosis is critical and can be accomplished using laboratory testing during the first weeks of life.

» Laboratory Diagnosis

Infants born to HIV-infected mothers will have transplacental maternal HIV antibody regardless of their infection status. The median time to seroreversion is 13.9 months and most uninfected infants become antibody negative by 18 months; in a minority of infants, however, maternal antibody is detected until age 24 months. Therefore, early diagnosis must be made by direct detection of virus. Age-specific laboratory criteria defining infection status are outlined in Table 41–2. The preferred test for infant diagnosis is detection of HIV nucleic acid (DNA or RNA) in blood. Positive HIV nucleic acid testing (NAT) at any age requires a subsequent sample for confirmation to rule out a false positive, particularly for a test with low RNA copy number (< 5000 copies/mL), and lab error. Interestingly, some HIV-infected infants treated very early in infancy do not develop a serologic response to HIV and are HIV antibody-negative after clearance of maternal antibody, despite documentation of infection by direct viral detection.

HIV NAT is positive in blood at birth for the fraction of infants infected in utero but negative for infants who acquire infection at birth. Almost all infected infants with either in utero or peripartum acquisition will have detectable HIV NAT by 2 weeks of life, over 95% will have detectable virus by 4 weeks, and virtually all by 4 months. Thus, infection can be "presumptively" excluded by negative HIV NAT at age 2 and 4 weeks, in the absence of breast-feeding. Definitive evidence of absence of infection is defined by negative HIV NAT at greater than 1 and 4 months. At 12–24 months of age, for infants with negative HIV NAT, many clinicians will obtain HIV antibody testing to demonstrate reversion to seronegative status.

Breast-fed infants may acquire HIV at any time until they are fully weaned, and virus may not be detected until several weeks or months after exposure. Therefore, breast milk–exposed infants should be tested at 6 weeks, 3 months, and 6 months after their last exposure.

» Management and Outcome of the Perinatally HIV-Exposed Infant

Antiretroviral (ARV) prophylaxis for 6 weeks is recommended for infants born to HIV-infected mothers, with or without breast milk exposure. During the period of ARV prophylaxis, some infants have reversible anemia or neutropenia that is usually not clinically significant. Subsequently, children who have been exposed to HIV and to ARV prophylaxis (but who remain uninfected) are generally healthy, but some studies in resource-limited setting find higher morbidity and mortality among exposed, uninfected

Table 41–2. Age-specific laboratory criteria defining infection status.

Age < 18 mo:

Infected:

- Positive results on two separate determinations on blood or tissue (excluding cord blood) for one or more of the following HIV detection tests: HIV nucleic acid detection (DNA or RNA), HIV antigen (p24), HIV nucleotide sequence (genotype), HIV culture.

Definitively uninfected—lacking prior positive nucleic acid tests or clinical evidence of HIV infection (see Table 41–1) and one of the following:

- Two negative HIV nucleic acid (DNA or RNA) detection tests from separate specimens, one obtained at age ≥ 1 mo and another at age ≥ 4 mo.

Or

- Two negative HIV antibody tests from separate specimens obtained at age ≥ 6 mo.

Presumptively uninfected—lacking prior positive nucleic acid tests or clinical evidence of HIV infection (see Table 41–1) and one of the following:

- Two negative HIV nucleic acid detection (DNA or RNA) tests from separate specimens, one obtained at age ≥ 2 wk and another at age ≥ 4 wk.

Or

- One negative HIV nucleic acid detection test obtained at age ≥ 8 wk.

Age ≥ 18 mo[a]:

Infected: Any combination of the following tests demonstrated on at least two separate occasions:

- A multitest algorithm including a positive HIV antibody or antigen/antibody test with a positive confirmatory test using a different test principle. Tests methods may include conventional or rapid immunoassays, an HIV-1/2 differentiating test, HIV Western blot, immune fluorescent test.
- Positive HIV nucleic acid amplification test (HIV DNA or RNA), HIV antigen (p24), HIV nucleotide sequence (genotype), HIV culture.

[a]Although the majority of exposed infants are antibody negative by 18 mo of age, in some studies, up to 14% of exposed children have detectable HIV antibodies until age 24 months. If needed, positive HIV NAT testing differentiates infection from persistent maternal antibodies.

Adapted with permission from Centers for Disease Control and Prevention (CDC): Revised surveillance case definition for HIV infection--United States, 2014, MMWR Recomm Rep. 2014 Apr 11;63(RR-03):1-10.

infants. Alterations in growth, neurocognitive development, immune, and organ function parameters are also reported in this population, but their clinical significance is not yet known. Some studies have found symptoms consistent with mitochondrial toxicity associated with ARV exposure; other studies have failed to confirm these findings. There is biological plausibility for this toxicity because the nucleoside analogue drugs used for prevention of mother to child transmission (PMTCT) may cause mitochondrial toxicity. The issue remains controversial, but at present it is clear that the benefit of prenatal and postnatal treatment to prevent HIV transmission outweighs the potential risk. Ongoing studies are important to elucidate the effects of in utero and perinatal HIV and ARV exposure.

HIV-infected infants have a high risk of Pneumocystis jiroveci pneumonia (PCP), with the peak incidence at age 2–6 months. Thus, prophylaxis for P jiroveci pneumonia is given to infants born to HIV-infected mothers beginning at age 4–6 weeks. PCP prophylaxis may be deferred for infants who are demonstrated to be presumptively HIV-uninfected by age 6 weeks. Infants with ongoing HIV exposure via breast-feeding are recommended to continue PCP prophylaxis, at least until HIV infection has been excluded after cessation of breast-feeding.

ACUTE RETROVIRAL SYNDROME

Among adolescents and adults with primary acute HIV infection, nonspecific symptoms (eg, flu- or mild mononucleosis-like illness) beginning 2–4 weeks after exposure occur in 30%–90%, but they are frequently not severe enough to be brought to medical attention. This acute retroviral syndrome, with symptoms of fever, malaise, and pharyngitis, is often indistinguishable from other similar viral illnesses. Less common but more distinguishing features are rash, oral and genital ulcerations, aseptic meningitis, and thrush. In the early weeks after acute, behaviorally acquired infection, HIV antibody may be absent. However, HIV nucleic acid tests will be positive and should be obtained when acute retroviral syndrome is in the differential diagnosis. Many laboratories have implemented tests which detect both HIV antibody and HIV p24 antigen as their standard HIV screening test. These tests are more sensitive for acute infection since antigen

Table 41–3. HIV infection stage based on age-specific CD4 T-lymphocyte counts and percentages of total lymphocytes.

Stage	Age of Child					
	< 1 y		1–5 y		≥ 6 y	
	Cells/μL	%	Cells/μL	%	Cells/μL	%
1.	≥ 1500	≥ 34	≥ 1000	≥ 30	≥ 500	≥ 26
2.	750–1499	26–33	500–999	22–29	200–499	14–25
3.	< 750	< 26	< 500	< 22	< 200	< 14

may be detected in advance of antibodies. Most patients will seroconvert by 6 weeks after exposure, but occasionally seroconversion does not occur for 3–6 months. Additional information on behaviorally acquired HIV is found in Chapter 44.

PROGRESSIVE HIV DISEASE

A. Clinical Findings

1. Disease staging—The Centers for Disease Control and Prevention (CDC) published revised disease staging for HIV-infected adults, adolescents, and children in 2014 (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm). (Tables 41–1 and 41–3). Stage 1, 2, and 3 are determined by categories of age-adjusted absolute CD4 T-lymphocyte counts and percentages that indicate progressively severe immune suppression; Stage 3 is defined as AIDS (Table 41–3). Acquired immunodeficiency syndrome is also diagnosed in individuals having one or more of the severe opportunistic illnesses or other serious conditions listed in Table 41–1. Stage 0 is applied to adults or adolescents who had a negative HIV diagnostic test in the 180 days preceding their positive HIV test, indicating recent acquisition of infection, irrespective of their CD4 count and/or clinical conditions. An individual's staging may vary with time, improving or worsening depending on the outcome of the patient's treatment course. The WHO has established a clinical staging system that is used widely outside the United States (Table 41–4). Disease stage as well as level of plasma viremia and clinical symptoms are used in determining the urgency with which to initiate ARV therapy in children.

2. Infections related to immunodeficiency—Progressive immune dysfunction of both humoral and cell-mediated responses results in susceptibility to infections. Bacteremia, especially due to Streptococcus pneumoniae, occurs at rates of 3 per 100 child-years without cART and decreases to 0.36 per 100 child-years with cART, but this remains at least three times higher than in HIV-uninfected children. Infections with Mycobacterium tuberculosis are a major cause of morbidity in countries with high rates of endemic tuberculosis (TB). Given the frequency of coinfection, diagnosis of M tuberculosis in a child is an indication for HIV testing. Likewise, children with HIV infection and their family members should have regular evaluation for M tuberculosis exposure and testing if appropriate. Herpes zoster (shingles) occurs 10 times more frequently among untreated HIV-infected children compared with age-matched healthy children.

Late-stage immunodeficiency is accompanied by susceptibility to a variety of opportunistic pathogens. Pneumonia caused by P jiroveci is a common AIDS-defining diagnosis in children with unrecognized HIV infection who, therefore, are not receiving PCP prophylaxis. The incidence is highest between ages 2 and 6 months and is often fatal during this period. Symptoms are difficult to distinguish from those of viral or atypical pneumonia (see Chapter 43). Persistent candidal mucocutaneous infections (oral, cutaneous, and vaginal) are common. Candidal esophagitis occurs with more advanced disease. Cytomegalovirus (CMV) infections may result in disseminated disease, hepatitis, gastroenteritis, retinitis, and encephalitis. Disseminated infection with Mycobacterium avium complex (MAC), presenting with fever, night sweats, weight loss, diarrhea, fatigue, lymphadenopathy, hepatomegaly, anemia, and granulocytopenia, may occur in those who have CD4 T-lymphocyte counts below 50–100/μL. A variety of diarrheal pathogens that cause mild, self-limited symptoms in healthy persons may result in severe, chronic diarrhea in HIV-infected persons. These include Cryptosporidium parvum, Microsporidia, Cyclospora, Isospora belli, Giardia lamblia, and bacterial

Table 41–4. World Health Organization clinical staging of HIV for infants and children with established HIV infection.

Clinical stage 1: Asymptomatic
- Asymptomatic
- Persistent generalized lymphadenopathy

Clinical stage 2: Mild symptoms
- Unexplained persistent hepatosplenomegaly
- Papular pruritic eruptions
- Fungal nail infection
- Angular cheilitis
- Lineal gingival erythema
- Extensive wart virus infection
- Extensive molluscum contagiosum
- Recurrent oral ulcerations
- Unexplained persistent parotid enlargement
- Herpes zoster
- Recurrent or chronic upper respiratory tract infections (otitis media, otorrhea, sinusitis, or tonsillitis)

Clinical stage 3: Advanced symptoms
- Unexplained moderate malnutrition or wasting not adequately responding to standard therapy
- Unexplained persistent diarrhea
- Unexplained persistent fever
- Persistent oral candidiasis (after first 6–8 wk of life)
- Oral hairy leukoplakia
- Acute necrotizing ulcerative gingivitis or periodontitis
- Lymph node tuberculosis
- Pulmonary tuberculosis
- Severe recurrent bacterial pneumonia
- Symptomatic lymphoid interstitial pneumonitis
- Chronic HIV-associated lung disease including bronchiectasis
- Unexplained anemia, neutropenia, thrombocytopenia

Clinical stage 4: Severe symptoms
- Unexplained severe wasting, stunting, or severe malnutrition not responding to standard therapy
- Pneumocystis pneumonia
- Recurrent severe bacterial infections (such as empyema, pyomyositis, bone or joint infection, or meningitis but excluding pneumonia)
- Chronic herpes simplex infection
- Esophageal candidiasis (or candidiasis of trachea, bronchi, or lungs)
- Extrapulmonary tuberculosis
- Kaposi sarcoma
- Cytomegalovirus infection: retinitis or cytomegalovirus infection affecting another organ, with onset at age older than 1 mo
- Central nervous system toxoplasmosis (after 1 mo of life)
- Extrapulmonary cryptococcosis
- HIV encephalopathy
- Disseminated endemic mycosis (coccidiomycosis or histoplasmosis)
- Disseminated nontuberculous mycobacterial infection
- Chronic cryptosporidiosis (with diarrhea)
- Chronic isosporiasis
- Cerebral or B-cell non-Hodgkin lymphoma
- Progressive multifocal leukoencephalopathy
- Symptomatic HIV-associated nephropathy or HIV-associated -cardiomyopathy

pathogens. Chronic parvovirus infection manifested by anemia can occur.

3. Organ system disease—HIV infection may directly affect a variety of organ systems and produce disease manifestations that include encephalopathy, pneumonitis, hepatitis, diarrhea, hematologic suppression, nephropathy, and cardiomyopathy. On average, HIV-infected children have lower than normal neuropsychological functioning. In many children, neuropsychological deficits do not normalize when ARV therapy is started, despite suppression of viremia. Without cART, findings include acquired microcephaly, progressive motor deficit, ataxia, pseudobulbar palsy, and failure to attain (or loss of) developmental milestones.

Lymphoid interstitial pneumonitis, which is common in untreated children with HIV infection, is characterized by a diffuse peribronchial and interstitial infiltrate composed of lymphocytes and plasma cells. It may be asymptomatic or associated with dry cough, hypoxemia, dyspnea or wheezing on exertion, and clubbing of the digits. Children with this disorder frequently have enlargement of the parotid glands and generalized lymphadenopathy.

4. Malignancy—Children with HIV are at increased risk of malignancy. The most commonly occurring tumors are non-Hodgkin lymphomas, which may occur at unusual extranodal sites (central nervous system, bone, gastrointestinal tract, liver, or lungs). Human papillomavirus infection of the cervix is more likely to progress to neoplasia, and the rate of progression is not altered by cART. Carcinoma due to anal human papillomavirus is also a concern. Kaposi sarcoma, a skin and mucous membrane malignancy, common in HIV-infected MSM with advanced disease, is also observed among HIV-infected African children, but it is rare in children in the United States.

B. Laboratory Findings

Established HIV infection in perinatally-exposed children older than 18–24 months, in children whose mothers were not HIV–infected, and in adolescents may be diagnosed by detecting HIV antibody using a multi-test algorithm typically including an HIV antibody/antigen immunoassay. A confirmatory test on the same sample using an assay that detects antibody using different antigen or test principle

(indicated by a different manufacturer) is performed because rare individuals have cross-reacting antibodies which result in a false-positive antibody tests. If the initial test used detects both HIV antigen and anti-HIV antibody and the confirmatory test that detects only antibody is non-reactive, follow-up HIV NAT is indicated if acute HIV infection is a possibility since antigen detection may precede antibody formation. Definitive diagnosis of HIV infection requires a positive result on a second sample obtained on a different occasion.

The hallmark of HIV disease progression is decline in the absolute number and percentage of CD4 T lymphocytes and an increasing percentage of CD8 T lymphocytes. The CD4 T-lymphocyte values are predictive of the child's risk of opportunistic infections. Healthy infants and children have CD4 T-lymphocyte numbers that are much higher than in adults; these gradually decline to adult levels by age 5–6 years. Hence, age-adjusted values must be used when assessing a child's absolute CD4 T-lymphocyte count (see Table 41–3). CD4 T-lymphocyte percentage is used when CD4 T cell count is not available.

Hypergammaglobulinemia of IgG, IgA, and IgM is characteristic in untreated HIV. Late in the disease, some individuals may become hypogammaglobulinemic. Hematologic abnormalities (anemia, neutropenia, and thrombocytopenia) may occur due to effects of HIV disease or cART. Cerebrospinal fluid (CSF) may either be normal or may be associated with elevated protein and a mononuclear pleocytosis; HIV nucleic acid testing may be positive in CSF.

C. Differential Diagnosis

HIV infection should be in the differential diagnosis for children being evaluated for immunodeficiency. Depending on the degree of immunosuppression, the presentation in HIV infection may be similar to that of B-cell (eg, hypogammaglobinemia), T-cell, or combined immunodeficiencies (eg, severe combined immunodeficiency) (see Chapter 33). HIV infection should also be considered in the evaluation of children with failure to thrive, developmental delay, chronic lung disease, and M tuberculosis infection. Chronic HIV infection presenting with generalized lymphadenopathy or hepatosplenomegaly may resemble infections with viruses such as EBV or CMV in children or adolescents. Because blood tests are definitive for the diagnosis of HIV infection, the diagnosis can be readily established or excluded. In rare cases, HIV-infected children with hypogammaglobulinemia have falsely negative antibody tests but may be diagnosed with a nucleic acid–based test. Absence of maternal risk factors or history of negative test results during pregnancy should not dissuade from testing for HIV if the patient has signs consistent with HIV-associated disease since maternal acquisition of HIV late in pregnancy can result in transmission to the infant and may be missed by maternal prenatal HIV testing.

» Treatment

HIV infection calls for specific cART to prevent progressive deterioration of the immune system as well as prophylactic measures at late stages of HIV infection to prevent opportunistic infections. Guidelines for the treatment of HIV and prevention of opportunistic infections developed by US national working groups of pediatric HIV specialists are published by the U.S. Public Health System at: http://www.aidsinfo.nih.gov. The treatment paradigm changes frequently; therefore, prior to initiating treatment, expert consultation should be obtained.

A. Specific Measures

1. Principles of HIV treatment—Combination ART reduces HIV replication and thereby results in an increase in CD4 T-lymphocyte count and reconstitution of immune function. HIV has a high spontaneous mutation rate that leads to emergence of drug resistance if viral suppression is incomplete. Prevention of resistance mutations requires that virus is not replicating and thus has no opportunity to generate new mutations. Regimens that fully suppress viral replication (plasma HIV RNA < 75 copies/mL) are key to long-term treatment success.

The current standard regimens are combinations of three drugs, including two drugs with different mechanisms of action. Optimally, children on cART will have laboratory monitoring every 3–4 months to confirm viral suppression. If plasma virus becomes consistently detectable (> 200 copies/mL), the underlying cause must be determined (eg, poor adherence or viral resistance), and, if necessary, a change in the medication combination is made.

Within 3–6 months of successful cART, circulating HIV declines to below the limit of detection and CD4 T-lymphocyte counts improve and may normalize. However, HIV persists in long-lived resting cells, and cessation of ARV treatment results in resumption of viremia and decline in CD4 T lymphocytes. Therefore, treatment for HIV with currently available modalities must be lifelong.

Strict adherence to the prescribed treatment is critical. A wide range of issues may impact adherence, including pill burden, dosing frequency, and tolerability as well as psychosocial factors such as developmental stage, mental health of child and caregiver, HIV knowledge, and beliefs about treatment. Programs and services that enhance adherence are essential adjuncts of any HIV treatment regimen.

2. Criteria for initiation of antiretroviral medications— Even without treatment, many individuals with HIV will have slow disease progression and are asymptomatic for several years. This has led to debate about the optimal timing for initiation of cART. The current paradigm has shifted toward earlier initiation. Early treatment has advantages of more complete immune reconstitution and reduced risk of disease complications but presents potential risks of increased medication toxicity and development of viral resistance. Country-specific treatment guidelines are published and updated when new evidence is available. The criteria for initiation may differ among countries, particularly for resource-rich versus resource-limited settings. WHO recommendations are found at: http://www.who.int/hiv/pub/guidelines/en/.

The United States guidelines recommend clinicians consider treatment for all HIV-infected children and adolescents even at early stages of the disease. Infants with perinatally acquired HIV have a 30%–50% risk of progression to AIDS or death by age 12–24 months, and there are no tests that reliably identify these rapid progressors. A randomized trial that compared early versus deferred treatment for infants demonstrated a survival benefit with early treatment. Therefore, infants younger than 12 months per US guidelines, and younger than 2 years per WHO guidelines, irrespective of clinical or immunologic progression, or those at Stage 3 should begin treatment as soon as possible after diagnosis. For children who have survived longer prior to diagnosis, the risk of rapid progression is less. However, those with evidence of clinical progression (moderate symptoms and WHO Stages 3 and 4) or with low CD4 T-lymphocyte counts (stage 2) are recommended to start treatment. High plasma viral load (> 100,000 copies/mL) is independently associated with near-term disease progression and is another indicator for initiating treatment. For children lacking evidence of disease progression and with low viral loads, deferred treatment may be considered, but most clinicians recommend treatment to reduce the effects of HIV on growth, development, and organ systems.

3. Antiretroviral medications—There are 24 ARV medications approved by the U.S. Food and Drug Administration (FDA) categorized into five different drug classes for the treatment of HIV. An additional category, pharmacokinetic enhancers, includes two drugs with drug-drug interactions which increase the area under the curve and minimum concentrations of other ARV agents, particularly the protease inhibitor class. Many of the drugs have pediatric indications for older children, but pharmacokinetic data and administration forms appropriate for infants and toddlers are not available for many. Specific drugs in each class and the mechanism of action of each class are described briefly in Table 41–5.

Table 41–5. U.S. Food and Drug Administration–approved antiretroviral drug class (mechanism of action) and specific drugs in class.

Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs)	Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)	Protease Inhibitors (PIs)
(Chain termination of HIVDNA)	(Synthesis of HIVDNA inhibited)	(Production of noninfectious virions)
Abacavir (ABC; Ziagen)[a]	Efavirenz (EFV, Sustiva)[a]	Atazanavir (ATV, Reyataz)[a]
Didanosine (ddI; Videx)[a]	Etravirine (ETR, Intelence)	Darunavir (DRV, Prezista)[a]

4. Complications of antiretroviral medications—ART may result in a range of adverse effects. Each medication has specific toxicities which are described in detail at http://aidsinfo.nih.gov/guidelines/html/2/pediatric-arv-guidelines/113/appendix-a–pediatric-antiretroviral-drug-information. Common adverse events are gastrointestinal distress, hematologic toxicity (anemia, neutropenia), elevated liver enzymes, dyslipidemia (elevated LDL-cholesterol and triglycerides), glucose intolerance, and abnormal fat distribution (lipodystrophy). Reduced bone mineral content and renal dysfunction may result from drug effects as well as from direct effects of HIV. Several drugs (eg, nevirapine, abacavir) have been associated with severe hepatitis, sometimes associated with a systemic hypersensitivity reaction which may be life-threatening if not identified early or upon rechallenge with the same medication. The nucleoside and nucleotide analogues have low-level affinity for the human mitochondrial DNA polymerase. Therefore, these analogues may be incorporated into mitochondrial DNA, which is one mechanism that may lead to adverse effects. Mitochondrial toxicity can result in lactic acidosis, a rare, but potentially fatal, complication. During the initial weeks of treatment, immune restoration may lead to worsening or unmasking of symptoms due to underlying infection with other organisms such as M tuberculosis, an event termed immune reconstitution inflammatory syndrome (IRIS).

B. General Measures

1. Immunizations—Although vaccines are immunogenic in HIV-infected children, the magnitude and durability of the antibody responses to vaccines are often diminished even when administered to a child on effective cART. Additional doses to boost responses are recommended for some vaccines. More vigorous vaccine responses are found in children with suppressed plasma virus and restored CD4 T-lymphocyte counts. Therefore, for children who were immunized prior to establishment of effective cART, reimmunization should be considered and is recommended for some vaccines (eg, measles-mumps-rubella vaccine).

All inactivated vaccines are safe to administer to HIV-infected children. Annual immunization with inactive influenza vaccine after age 6 months is recommended for HIV-infected children and their close contacts. For live attenuated viral vaccines, the immune status of the child must be considered. Varicella and mumps-measles-rubella vaccines (but not the combined measles-mumps-rubella-varicella vaccine) are recommended for HIV-infected children, provided they are Stage 1 or 2 (see Table 41–3) and only mildly symptomatic (see Table 41–1). Current studies are investigating rotavirus vaccine in HIV-exposed and HIV-infected infants. The majority of infants born to HIV-infected women in the United States will be HIV-uninfected, so rotavirus vaccine is recommended even though it will be initiated before HIV infection is definitively excluded by early testing. Live attenuated influenza vaccine (LAIV) is not recommended for HIV-infected individuals, although initial studies have not identified safety concerns; close contacts may receive LAIV. Yellow fever vaccine is contraindicated in symptomatic HIV infection or with Stage 3 CD4 T-lymphocyte count, but has been well tolerated in asymptomatic, Stage 1 individuals and may also be considered for children in Stage 2. Bacille Calmette-Guérin (BCG), oral polio, smallpox, and live typhoid vaccines should not be given to HIV-infected people.

For some vaccines, additional doses or changes to the routine schedule are recommended. Children who have not received Haemophilus influenzae type b (Hib) vaccine and pneumococcal conjugate vaccine (PCV13) series as infants (eg, immigrants) may benefit from Hib vaccine (two doses between 12 and 59 months of age; one dose after 59 months of age) and two doses of PCV13 (separated by 8 weeks) which may be given after the usual cutoff age of 60 months. The 23-valent pneumococcal polysaccharide vaccine (PPSV) should also be given after age 2 years (and after a PCV13 series), with a second dose given 5 years later. Meningococcal conjugate vaccine (MCV) may be given

at the routine ages, but because antibody responses to the vaccine may be suboptimal, HIV-infected children should receive a two-dose primary series. The response to hepatitis B vaccine is particularly unreliable in people with HIV infection. Therefore, a test for hepatitis B surface antibody should be obtained after the three-dose series. If the titer is less than 10 mIU/mL, a second series of three vaccinations is recommended.

2. Prophylaxis for infections—Children with suppressed CD4 T-lymphocyte numbers benefit from primary and secondary prophylactic treatment to prevent opportunistic infections. Children who have had their CD4 T-lymphocyte counts restored with ARV therapy to category 1 or 2 for over 3 months can be taken off prophylactic treatments.

Antibiotic prophylaxis for P jiroveci pneumonia has been extremely effective. HIV-infected infants should receive Pneumocystis prophylaxis until age 12 months, after which prophylaxis is based on assessment of symptoms and age-adjusted CD4 T-lymphocyte counts every 3 months. Children with low CD4 T-lymphocyte parameters (Stage 3; see Table 41–3) should continue/begin PCP prophylaxis. Published guidelines from the CDC for P jiroveci pneumonia prophylaxis are summarized in Table 41–6.

3. Psychosocial support and mental health—Evaluation and support for psychosocial needs of HIV-affected families is imperative. As with other chronic illnesses, HIV infection affects all family members and also carries additional social stigma. Emotional concerns and financial needs, which are more prominent than medical needs at many stages of the disease process, influence the family's ability to comply with a medical treatment regimen. HIV-infected children often have comorbid mental health conditions. Rates of attention-deficit/hyperactivity disorder range from 20% to 50% in various studies. Hospital admissions for mental health disorders are more frequent among HIV-infected children. In one study, dual diagnosis of HIV and a mental health disorder occurred in 85% of adolescents who acquired HIV infection through high-risk behaviors. Ideally, care should be coordinated by a team of caregivers that is familiar with HIV disease and its comorbidities, newest therapies, and community resources.

Table 41–6. Drug regimens for Pneumocystis jiroveci prophylaxis for children older than 4 wk.

Recommended regimen
Trimethoprim-sulfamethoxazole, 150 mg TMP/m^2/d plus 750 mg SMX/m^2/d, administered orally, divided into two doses per d/3 d a week on consecutive days
Alternative (same total daily dosages):
Single-daily dose 3 d a week on consecutive days
Divided twice-daily doses 7 d a week
Divided twice-daily doses 3 d a week on alternate days
Alternative if trimethoprim-sulfamethoxazole is not tolerated
Dapsone, 2 mg/kg/d (not to exceed 100 mg) orally once daily or 4 mg/kg (not to exceed 200 mg) orally once weekly
Atovaquone, age 1–3 mo and > 24 mo, 30 mg/kg orally once daily; age 4–24 mo, 45 mg/kg orally once daily
Aerosolized pentamidine (children > age 5 y), 300 mg via inhaler monthly

PREVENTION

» Prevention of Mother-to-Child Transmission (PMTCT)

A number of ARV regimens given to the mother antenatally and post-partum and to the infant post-partum and, if applicable, during breastfeeding reduce MTCT rates to 1%–2% without breast-feeding and 2%–5% with breast-feeding. The United States Public Health Services publishes detailed guidelines that are updated frequently (http://aidsinfo.nih.gov/contentfiles/PerinatalGL.pdf). In the United States, all identified HIV-infected pregnant women are prescribed cART during pregnancy and labor, infant zidovudine for 6 weeks, and avoidance of breast-feeding. Mothers receive intravenous zidovudine during labor and infants receive combination ARV medications if there is a higher risk of transmission (eg, no or late maternal cART and/or lacking viral suppression). Elective C-section prior to labor will also reduce transmission risk for women who have plasma viral load ≥ 1000 copies/mL. The same interventions are effective in resource-limited settings, but in these countries, breast-feeding has a demonstrated survival value and is therefore recommended. Studies demonstrate that maternal cART begun in pregnancy plus infant ARV prophylaxis for the first 6 weeks of life is more effective in preventing transmission than more limited maternal regimens. Continuation of maternal cART for the duration of breast-feeding or extended nevirapine prophylaxis given to the infant are both interventions that reduce

transmission resulting from breast milk; a study directly comparing the two approaches is ongoing.

Key to prevention of mother-to-child transmission (PMTCT) is identification of pregnant women with HIV infection. The CDC and the American College of Obstetrics and Gynecology recommend routine HIV testing, with an option to refuse, early in gestation for all pregnant women. Women with ongoing risk factors for HIV acquisition (multiple partners, sexually transmitted diseases [STDs], substance use) should be tested again in late gestation. A woman presenting in labor without previously documented HIV testing should have HIV testing using assays that yield results within 60 minutes or less. ARV medications, even if implemented as late as 48 hours postpartum, may reduce transmission by as much as 50%. The current regimen recommended when maternal HIV infection is diagnosed during labor is maternal intravenous zidovudine during labor and delivery plus infant treatment with two or three ARV medications and avoidance of breastfeeding. A CDC-funded consult line is available 24/7 for questions about prevention of perinatal HIV transmission (http://nccc.ucsf.edu/clinician-consultation/perinatal-hiv-aids/, 888-448-8765).

» Prevention of Sexual Transmission

Latex condoms used consistently and correctly are highly effective in preventing sexual transmission. Behavioral interventions to increase use of condoms and other safer sex practices have been a cornerstone of prevention efforts. However, the success rate with behavioral interventions has been inadequate in most populations. Several biomedical prevention interventions, added to condom use, have demonstrated efficacy in randomized clinical trials. These include (1) male circumcision—approximately 50% reduction in female-to-male transmission; (2) pre-exposure prophylaxis (PrEP) for HIV-uninfected partners using daily tenofovir-emtricitabine—44%–70% reduction for MSM and 60%–70% reduction for discordant heterosexual couples (summaries at http://www.cdc.gov/hiv/prep/); and (3) cART of HIV-infected individuals—96% reduction in the risk of transmission to HIV-uninfected partners. Finally, postexposure prophylaxis (PEP) using combination ARV drugs initiated within 72 hours after a known HIV exposure was associated with reduced transmission in case-cohort studies. The CDC supports a consult service for questions regarding postexposure prophylaxis (PEP line, 888-488-4911, http://nccc.ucsf.edu/clinical-resources/pep-resources/pep-quick-guide/).

Since treatment reduces the risk of transmission to others, there is a public health benefit to early diagnosis. Therefore the Centers for Disease Control and Prevention (CDC) recommends that HIV screening tests be conducted in routine health care settings with patient knowledge and right to refuse for patients aged 13–64 years and that all adults should be tested at least once for HIV during their lives. In 2011, the American Academy of Pediatrics recommended at least one-time testing for 16- to 18-year-old adolescents, irrespective of risk factors, living in areas of high (≥ 0.1%) or unknown seroprevalence. In areas of lower seroprevalence, testing is encouraged for all sexually active adolescents and those with other risk factors for HIV infection.

» Prevention Through Universal Precautions

Horizontal transmission (in the absence of sexual contact or injecting drug use) of HIV is exceedingly rare and is associated with exposure of broken skin or mucous membranes to HIV-infected blood or bloody secretions. Several cases have resulted from HIV-infected caregivers feeding children premasticated food; hence, families should be advised against this practice. Saliva, tears, urine, and stool are not contagious if they do not contain gross blood. A barrier protection (eg, latex or rubber gloves or thick pads of fabric or paper) should be used when possible contact with blood or bloody body fluids may occur. Objects that might be contaminated with blood, such as razors or toothbrushes, should not be shared. No special care is required for dishes, towels, toys, or bedclothes. Blood-soiled clothing may be washed routinely with hot water and detergent. Contaminated surfaces may be disinfected easily with a variety of agents, including household bleach (1:10 dilution), some commercial disinfectants (eg, Lysol), or 70% isopropyl alcohol.

The infant or child who is well enough to attend day care or school should not be treated differently from other children. The exception may be a toddler with uncontrollable biting behavior or bleeding lesions that cannot be covered adequately; in these situations, the child may be withheld from group day care. Families may choose to make the school health care provider and/or teacher aware of the diagnosis, but there is no legal requirement that any individual at the school or day care center be informed. The parents and child may prefer to keep the diagnosis confidential, because the stigma associated with HIV infection remains difficult to overcome. Because undiagnosed HIV-infected infants and children might be enrolled, all schools and day care centers should have policies with simple guidelines for using universal precautions to prevent transmission of HIV infection in these settings.

QUALITY ASSURANCE AND OUTCOME METRICS

The care of HIV-infected children and adults has been informed by numerous clinical trials, many completed through multi-center networks. Although the field continues to evolve, evidence-based care guidelines have been published by the Unites States Public Health Service and are updated regularly, sometimes multiple times within a year (http://aidsinfo.nih.gov/). The guidelines establish best practices for prevention of transmission, timing of initiation of treatment, choice of ARV, monitoring frequency, and prophylaxis for opportunistic infections for which the Human Resources and Services Administration HIV/AIDS Bureau has established quality performance measures (http://hab.hrsa.gov/deliverhivaidscare/habperformmeasures.html). In addition to treatment guidelines, an emphasis for successful HIV care is the continuum of HIV care necessary for a patient to achieve and maintain suppressed viremia. These include rapid initial linkage to care after diagnosis, engagement and retention in care measured by health care visit frequency, prescription of cART, and successful adherence to treatment. Success with each of these steps in care is a necessary underpinning of successful long-term health for the individual and also has public health benefits since transmission risk is markedly reduced when viremia is suppressed with cART. Several national quality groups collect and publish data across groups of clinics on these continuum of care outcomes, thereby setting national metrics and providing technical assistance to HIV programs (in+care Campaign at http://www.incarecampaign.org/; National Quality Center at http://nationalqualitycenter.org/index.cfm; The HIV Research Network at https://cds.johnshopkins.edu/hivrn/).

BACTERIAL INFECTIONS

GROUP A STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Streptococcal pharyngitis:
- Clinical diagnosis based entirely on symptoms; signs and physical examination unreliable.
- Throat culture or rapid antigen detection test positive for group A streptococci.

» Impetigo:
- Rapidly spreading, highly infectious skin rash.
- Erythematous denuded areas and honey-colored crusts.
- Group A streptococci are grown in culture from most (not all) cases.

» General Considerations

Group A streptococci (GAS) are common gram-positive bacteria producing a wide variety of clinical illnesses, including acute pharyngitis, impetigo, cellulitis, and scarlet fever. GAS can also cause pneumonia, septic arthritis, osteomyelitis, meningitis, and other less common infections. GAS infections may also produce postinfectious sequelae (rheumatic fever and acute glomerulonephritis).

Almost all GAS are β-hemolytic. These organisms may be carried without symptoms on the skin and in the pharynx, rectum, and vagina. All GAS are sensitive to penicillin. Resistance to erythromycin is common in some countries and has increased in the United States.

» Prevention

GAS pharyngitis usually occurs after contact with respiratory secretions of a person infected with GAS. Crowding facilitates spread of GAS and outbreaks of pharyngitis and impetigo occur. Prompt recognition and institution of antibiotics may decrease spread. Treatment with antibiotics prevents acute rheumatic fever.

» Clinical Findings

A. Symptoms and Signs

1. Respiratory infections

a. Infancy and early childhood (age < 3 years)—The onset is insidious, with mild symptoms (low-grade fever, serous nasal discharge, and pallor). Otitis media is common. Exudative pharyngitis and cervical adenitis are uncommon in this age group.

b. Childhood type—Classic GAS pharyngitis presents with the sudden onset of fever, sore throat, malaise, and often vomiting. On examination, tonsillar exudate and tender anterior cervical adenopathy are usually noted. Petechiae are frequently seen on the soft palate. In **scarlet fever**, the skin is diffusely erythematous and appears sunburned and roughened (sandpaper rash); most intense in the axillae, groin, and on the abdomen and trunk. It blanches except in the skin folds, which do not blanch and are pigmented (Pastia sign). The rash usually appears 24 hours after the onset of fever and rapidly spreads over the next 1–2 days. Desquamation begins on the face at the end of the first week and becomes generalized by the third week. Early in the infection, there is circumoral pallor and the surface of the tongue is coated white, with the papillae enlarged and bright red (white strawberry tongue). Subsequently desquamation occurs, and the tongue appears beefy red (strawberry tongue). Petechiae may be seen on any mucosal surfaces.

2. Impetigo—Streptococcal impetigo begins as a papule that vesiculates and then breaks, leaving a denuded area covered by a honey-colored crust. Both Staphylococcus aureus and GAS are isolated in some cases. The lesions spread readily and diffusely. Local lymph nodes may become swollen and inflamed. Although the child often lacks systemic symptoms, a high fever and toxicity may be present. If flaccid bullae are noted, the disease is called bullous impetigo and is caused by an epidermolytic toxin-producing strain of S aureus.

3. Cellulitis—The portal of entry is often an insect bite or superficial abrasion. A diffuse, rapidly spreading cellulitis occurs that involves the subcutaneous tissues and extends along the lymphatic pathways with only minimal local suppuration. Local acute lymphadenitis occurs. The child is usually acutely ill, with fever and malaise. In classic erysipelas, the involved area is bright red, swollen, warm, and very tender. The infection may extend rapidly from the lymphatics to the bloodstream.

Streptococcal perianal cellulitis is an entity peculiar to young children. Pain with defecation often leads to constipation, which may be the presenting complaint. The child is afebrile and otherwise well. Perianal erythema, tenderness, and painful rectal examination are the only abnormal physical findings. Scant rectal bleeding with defecation may occur. A perianal swab culture usually yields heavy growth of GAS. A variant of this syndrome is streptococcal vaginitis in prepubertal girls. Symptoms are dysuria and pain; marked erythema and tenderness of the introitus and blood-tinged discharge are seen.

4. Necrotizing fasciitis—This dangerous disease is reported sporadically and may occur as a complication of varicella infection. About 20%–40% of cases are due to GAS; 30%–40% are due to S aureus; and the rest are a result of mixed bacterial infections. The disease is characterized by extensive necrosis of superficial fasciae, undermining of surrounding tissue, and usually systemic toxicity. Initially the skin overlying the infection is tender and pale red without distinct borders, resembling cellulitis. Blisters or bullae may appear. The color deepens to a distinct purple or in some cases becomes pale. Tenderness out of proportion to the clinical appearance, skin anesthesia (due to infarction of superficial nerves), or "woody" induration suggest necrotizing fasciitis. Involved areas may develop mild to massive edema. Early recognition and aggressive debridement of necrotic tissue are essential.

5. Group A streptococcal infections in newborn nurseries—GAS epidemics occur occasionally in nurseries. The organism may be introduced into the nursery from the vaginal tract of a mother or from the throat or nose of a mother or a staff member. The organism then spreads from infant to infant. The umbilical stump is colonized while the infant is in the nursery. Most often, a colonized infant develops a chronic oozing omphalitis days later. The organism may spread from the infant to other family members. Serious and even fatal infections may develop, including sepsis, meningitis, empyema, septic arthritis, and peritonitis.

6. Streptococcal sepsis—Serious illness from GAS sepsis is now more common both in children and in adults. Rash and scarlet fever may or may not be present. Prostration and shock result in high mortality rates. Pharyngitis is uncommon as an antecedent illness. Underlying disease is a predisposing factor.

7. Streptococcal toxic shock syndrome (STSS)—Toxic shock syndrome can be caused by GAS. Like S aureus–associated toxic shock, multiorgan system involvement is a prominent part of the illness. The diagnostic criteria include (1) isolation of GAS from a normally sterile site, (2) hypotension or shock, and (3) at least two of the following: renal impairment (creatinine > two times the upper limit of normal for age), thrombocytopenia (< 100,000/mm^3) or coagulopathy, liver involvement (transaminases or bilirubin ≥ two times normal), acute respiratory distress syndrome, erythematous macular rash, or soft tissue necrosis (myositis, necrotizing fasciitis, gangrene). In cases that otherwise meet clinical criteria, isolation of GAS from a nonsterile site (throat, wound, or vagina) is indicative of a "probable case."

B. Laboratory Findings

Leukocytosis with a marked shift to the left is seen early. Eosinophilia regularly appears during convalescence. β-Hemolytic streptococci are cultured from the throat or site of infection. For suspected GAS pharyngitis, the throat should be swabbed and the specimen sent for GAS testing (rapid antigen detection tests and/or culture for GAS) because the clinical features of some viral infections may overlap with the clinical features of GAS. In children and adolescents, negative rapid antigen tests should be backed up by a culture. Patients with positive rapid strep antigen tests do not need a confirmation by throat culture, since the specificities of antigen tests are high. The organism may be cultured from the skin and by needle aspiration from subcutaneous tissues and other involved sites such as infected nodes. Occasionally blood cultures are positive.

Antistreptolysin O (ASO) titers rise about 150 units within 2 weeks after acute infection. Elevated ASO and anti-DNase B titers may be useful in documenting prior throat infections in cases of acute rheumatic fever. The streptozyme test detects antibodies to streptolysin O, hyaluronidase, streptokinase, DNase B, and NADase. It is somewhat more sensitive than the measurement of ASO titers.

Proteinuria, cylindruria, and minimal hematuria may be seen early in children with streptococcal infection.

True poststreptococcal glomerulonephritis is seen 1–4 weeks after the respiratory or skin infection.

» Differential Diagnosis

Streptococcal infection in early childhood must be differentiated from adenovirus and other respiratory virus infections. The pharyngitis in herpangina (coxsackievirus A) is vesicular or ulcerative. Herpes simplex also causes ulcerative lesions, which most commonly involve the anterior pharynx, tongue, and gums. In infectious mononucleosis, the pharyngitis is also exudative, but splenomegaly and generalized adenopathy are typical, and laboratory findings are often diagnostic (atypical lymphocytes, a positive heterophile, or other serologic test for mononucleosis). Uncomplicated streptococcal pharyngitis improves within 24–48 hours if penicillin is given and by 72–96 hours without antimicrobials.

Arcanobacterium hemolyticum may cause pharyngitis with scarlatina-like or maculopapular truncal rash. In diphtheria, systemic symptoms, vomiting, and fever are less marked; pharyngeal pseudomembrane is confluent and adherent; the throat is less red; and cervical adenopathy is prominent. Pharyngeal tularemia causes white rather than yellow exudate; there is little erythema; and cultures for β-hemolytic streptococci are negative. A history of exposure to rabbits and a failure to respond to antimicrobials may suggest the diagnosis. Oral gonococcal infection may also cause pharyngitis with tonsillar exudate. Leukemia and agranulocytosis may present with pharyngitis and are diagnosed by bone marrow examination.

Scarlet fever must be differentiated from other exanthematous diseases, erythema due to sunburn, drug reactions, Kawasaki disease, toxic shock syndrome, and staphylococcal scalded skin syndrome (see also Table 40–3).

» Complications

Suppurative complications of GAS infections include sinusitis, otitis, mastoiditis, cervical lymphadenitis, pneumonia, empyema, septic arthritis, sepsis, and meningitis. Spread of streptococcal infection from the throat to other sites—principally the skin (impetigo) and vagina—is common and should be considered in every instance of chronic vaginal discharge or chronic skin infection, such as that complicating childhood eczema. Both acute rheumatic fever and AGN are nonsuppurative complications of GAS infections.

A. Acute Rheumatic Fever (See Chapter 20)

B. Acute Glomerulonephritis

AGN can follow streptococcal infections of either the pharynx or the skin—in contrast to rheumatic fever, which follows pharyngeal infection only. AGN may occur at any age, even infancy. In most reports of AGN, males predominate by a ratio of 2:1. Rheumatic fever occurs with equal frequency in both sexes. Certain GAS strains are associated with poststreptococcal glomerulonephritis (nephritogenic types).

The median period between infection and the development of glomerulonephritis is 10 days. In contrast, acute rheumatic fever occurs after a median of 18 days.

C. Poststreptococcal Reactive Arthritis

Following an episode of group A streptococcal pharyngitis, reactive arthritis develops in some patients. This reactive arthritis is believed to be due to immune complex deposition and is seen about 1–2 weeks following the acute infection. Patients with poststreptococcal reactive arthritis do not have the full constellation of clinical and laboratory criteria needed to fulfill the Jones criteria for a diagnosis of acute rheumatic fever.

» Treatment

A. Specific Measures

Treatment is directed toward both eradication of acute infection and prevention of rheumatic fever. In patients with pharyngitis, antibiotics should be started early to relieve symptoms and should be continued for 10 days to prevent rheumatic fever. Although early therapy has not been shown to prevent AGN, it seems advisable to treat impetigo promptly in sibling contacts of patients with poststreptococcal nephritis. Neither sulfonamides nor trimethoprim-sulfamethoxazole (TMP-SMX) is effective in the treatment of streptococcal infections. Although topical therapy for impetigo with antimicrobial ointments (especially mupirocin) is as effective as systemic therapy, it does not eradicate pharyngeal carriage and is less practical for extensive disease.

1. Penicillin—For GAS pharyngitis, the following regimens can be used. Except for penicillin-allergic patients, penicillin V (phenoxymethyl penicillin) is the drug of choice. Penicillin resistance has never been documented. For children weighing < 27 kg, the regimen is 250 mg, given orally two or three times a day for 10 days. For children or adults weighting > 27 kg, 500 mg two or three times a day is recommended. Giving penicillin V twice daily is as effective as more frequent oral administration. Alternatively, amoxicillin 50 mg/kg/d given orally in two or three divided doses can be used. Another alternative for treatment of pharyngitis and impetigo is a single dose of penicillin G benzathine given intramuscularly (600,000 units for children weighing ≤ 27 kg [60 lb] and 1.2 million units for children weighing > 27 kg). Intramuscular delivery ensures compliance, but is painful. Parenteral therapy is indicated if vomiting is present. Mild cellulitis due to GAS may be treated orally or

intramuscularly. For severe or invasive GAS infections intravenous antibiotics are indicated.

GAS cellulitis requiring hospitalization can be treated with aqueous penicillin G (150,000 U/kg/d, given intravenously in four divided doses) or cefazolin (100 mg/kg/d, given intravenously in three divided doses) until there is marked improvement. Penicillin V (50 mg/kg/d in four divided doses) or cephalexin (50–75 mg/kg/d in four divided doses may then be given orally to complete a 10-day course. Acute cervical lymphadenitis may require incision and drainage. Treatment of necrotizing fasciitis requires emergency surgical debridement followed by high-dose parenteral antibiotics appropriate to the organisms cultured.

2. Other antibiotics—Cephalexin and azithromycin l are other effective oral antimicrobials. Clindamycin is also effective, but resistance is occasionally present (labs can check for susceptibility to clindamycin). For penicillin-allergic patients with pharyngitis or impetigo the following alternative regimens have been used: azithromycin (12 mg/kg/d; maximum 500 mg per dose) once daily for 5 days, or clindamycin (20–30 mg/kg/d in three divided doses; maximum 600 mg per dose) for 10 days. Patients with immediate, anaphylactic hypersensitivity to penicillin should not receive cephalosporins, because up to 15% will also be allergic to cephalosporins. Macrolide resistance rates vary and may be high in some areas of the world. In general, macrolide resistance rates in most areas of the United States are between 5% and 8%. In most studies, bacteriologic failures after cephalosporin therapy are less frequent than failures following penicillin. However, there are few conclusive data on the ability of these agents to prevent rheumatic fever. Therefore, penicillin remains the agent of choice for nonallergic patients. Many strains are resistant to tetracycline.

For serious infections requiring intravenous therapy, aqueous penicillin G (250,000 U/kg in six divided doses) given intravenously is usually the drug of choice. Cefazolin (100 mg/kg/d intravenously or intramuscularly in three divided doses); clindamycin (30–40 mg/kg/d intravenously in four divided doses); and vancomycin (40 mg/kg/d intravenously in four divided doses) are alternatives in penicillin-allergic pediatric patients. Clindamycin should not be used alone empirically for severe, suspected GAS infections because a small percentage of isolates in the United States are resistant to it.

3. Serious GAS disease—Serious GAS infections, such as pneumonia, osteomyelitis, septic arthritis, sepsis, endocarditis, meningitis, and STSS, require parenteral antimicrobial therapy. Penicillin G is the drug of choice for these invasive infections. Clindamycin, as a second agent along with penicillin G, is advocated by many experts for STSS or necrotizing fasciitis. Necrotizing fasciitis requires prompt surgical debridement. In STSS, volume status and blood pressure should be monitored and patients evaluated for a focus of infection, if not readily apparent. Intravenous immunoglobulin (in addition to antibiotics) has been used in severe cases.

4. Treatment failure—Even when compliance is perfect, organisms will be found in cultures in 5%–35% of children after cessation of therapy. Reculture is indicated only in patients with relapse or recrudescence of pharyngitis or those with a personal or family history of rheumatic fever. Repeat treatment at least once with an oral cephalosporin or clindamycin is indicated in patients with recurrent culture-positive pharyngitis.

5. Prevention of recurrences in rheumatic individuals—The preferred prophylaxis for rheumatic individuals is benzathine penicillin G, 1.2 million units (600,000 units for patients < 27 kg) intramuscularly every 4 weeks. If the risk of streptococcal exposure is high, every-3-week dosing is preferred. One of the following alternative oral prophylactic regimens may be used: penicillin V, 250 mg twice daily; or sulfadiazine, 0.5 g once a day (if < 27 kg) or 1 g once a day (if > 27 kg). In patients allergic to both penicillin and sulfonamide drugs, erythromycin 250 mg twice daily orally can be used. If carditis is absent, continued prophylaxis is recommended for at least 5 years after the last episode of acute rheumatic fever or until 21 years of age (whichever is longer). Prophylaxis should be continued longer if the risk of contact with persons with GAS is high (eg, parents of school-aged children, pediatric nurses, and teachers). In the presence of carditis without residual heart or valvular disease, a minimum of 10 years after the last episode of acute rheumatic fever or until 21 years of age (whichever is longer) is the minimum duration. If the patient has residual valvular heart disease, many recommend lifelong prophylaxis. These patients should be at least 10 years from their last episode of rheumatic disease and at least 40 years of age before considering discontinuation of prophylaxis. Those with severe valvular heart disease or with risk of ongoing exposure to GAS may benefit from lifelong prophylaxis.

6. Poststreptococcal reactive arthritis—In contrast to rheumatic fever, nonsteroidal agents may not dramatically improve joint symptoms. However, like patients with rheumatic fever, some patients with poststreptococcal reactive arthritis have developed carditis several weeks to months after their arthritis symptoms began. Patients should be monitored for development of carditis for the next 1–2 years. Some experts recommend antibiotic prophylaxis of these patients (same prophylaxis regimens as in prevention of recurrences of acute rheumatic fever) for 1–2 years and monitoring for signs of carditis (see recommendations for prevention of recurrences of rheumatic fever, above). If carditis does not develop, prophylaxis could then be discontinued. If carditis develops, the patient should be considered

to have acute rheumatic fever and prophylaxis continued as described above.

B. General Measures

Acetaminophen is useful for pain or fever. Local treatment of impetigo may promote earlier healing. Crusts should first be soaked off. Areas beneath the crusts should then be washed with soap daily.

C. Treatment of Complications

Rheumatic fever is best prevented by early and adequate penicillin treatment of the streptococcal infection.

D. Treatment of Carriers

Identification and treatment of GAS carriers is difficult. There are no established clinical or serologic criteria for differentiating carriers from the truly infected. Between 10% and 15% of school-aged children in some studies are asymptomatic pharyngeal carriers of GAS. Streptococcal carriers are individuals who do not mount an immune response to the organism and are therefore believed to be at low risk for nonsuppurative sequelae.

Some children receive multiple courses of antimicrobials, with persistence of GAS in the throat, leading to a "streptococcal neurosis" on the part of families.

In certain circumstances, eradication of carriage may be desirable: (1) when a family member has a history of rheumatic fever; (2) when an episode of STSS or necrotizing fasciitis has occurred in a household contact; (3) multiple, recurring, documented episodes of GAS in family members despite adequate therapy; and (4) during an outbreak of rheumatic fever or GAS-associated glomerulonephritis. Clindamycin (20–30 mg/kg/d, given orally in three divided doses; maximum dose 300 mg) or a combination of rifampin (20 mg/kg/d, given orally for 4 days) and penicillin in standard dosage given orally has been used to attempt eradication of carriage.

» Prognosis

Death is rare except in infants or young children with sepsis or pneumonia. The febrile course is shortened and complications eliminated by early and adequate treatment with penicillin.

Clin Infect Dis 2012;55(10):e86–e102 [PMID: 22965026]. Available at: http://cid.oxfordjournals.org/content/early/2012/09/06/cid.cis629.full.

GROUP B STREPTOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Early-onset neonatal infection:

- Newborn younger than age 7 days, with rapidly progressing overwhelming sepsis, with or without meningitis.
- Pneumonia with respiratory failure is frequent; chest radiograph resembles that seen in hyaline membrane disease.
- Blood or cerebrospinal fluid (CSF) cultures growing group B streptococci (GBS).

» Late-onset Infection:

- Meningitis, sepsis, or other focal infection in a child aged 1–16 weeks with blood or CSF cultures growing GBS.

» Prevention

Many women of childbearing age possess type-specific circulating antibody to the polysaccharide antigens for group B Streptococcus (GBS). These antibodies are transferred to the newborn via the placental circulation. GBS carriers delivering healthy infants have significant serum levels of IgG antibody to this antigen. In contrast, women delivering infants who develop either early- or late-onset GBS disease rarely have detectable antibody in their sera.

Currently, there is no licensed vaccine for group B Streptococcus disease prevention. Vaccines have been studied in pregnant women and research is ongoing.

» CDC Recommendations for Prevention of Perinatal GBS Disease

1. Caregivers for pregnant women are referred to the CDC guidelines for screening of pregnant women for GBS and use of intrapartum antibiotic prophylaxis (IAP), —see Centers for Disease Control and Prevention Guidelines http://www.cdc.gov/mmwr/pdf/rr/rr5910.pdf and http://www.cdc.gov/groupbstrep/clinicians/obstetric-providers.html.
2. Indications and nonindications for IAP to prevent early-onset group B streptococcal (GBS) disease are given in Table 42–1.
3. Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns (management of a newborn whose mother received IAP for prevention of GBS or suspected chorioamnionitis)—Figure 42–1.

Table 42–1. Indications and nonindications for intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal (GBS) disease.

Intrapartum GBS Prophylaxis Indicated	Intrapartum GBS Prophylaxis Not Indicated
• Previous infant with invasive GBS disease	• Colonization with GBS during a previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• GBS bacteriuria during any trimester of the current pregnancy[a]	• GBS bacteriuria during previous pregnancy (unless an indication for GBS prophylaxis is present for current pregnancy)
• Positive GBS vaginal-rectal screening culture in late gestation[b] during current pregnancy[a]	• Negative vaginal and rectal GBS screening culture in late gestation[b] during the current pregnancy, regardless of intrapartum risk factors
• Unknown GBS status at the onset of labor (culture not done, incomplete, or results unknown) and any of the following: • Delivery at < 37 wk' gestation[c] • Amniotic membrane rupture ≥ 18 h • Intrapartum temperature ≥ 100.4°F (≥ 38.0°C)[d] • Intrapartum NAAT[e] positive for GBS	• Cesarean delivery performed before onset of labor on a woman with intact amniotic membranes, regardless of GBS colonization status or gestational age

NAAT, nucleic acid amplification tests.
[a]Intrapartum antibiotic prophylaxis is not indicated in this circumstance if a cesarean delivery is performed before onset of labor on a woman with intact amniotic membranes.
[b]Optimal timing for prenatal GBS screening is at 35–37 weeks' gestation.
[c]Recommendations for the use of intrapartum antibiotics for prevention of early-onset GBS disease in the setting of threatened preterm delivery are presented in Figure 42–1.
[d]If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.
[e]NAAT testing for GBS is optional and might not be available in all settings. If intrapartum NAAT is negative for GBS but any other intrapartum risk factor (delivery at < 37 weeks' gestation, amniotic membrane rupture at ≥ 18 hours, or temperature ≥ 100.4°F [≥ 38.0°C]) is present, then intrapartum antibiotic prophylaxis is indicated.

» Clinical Findings

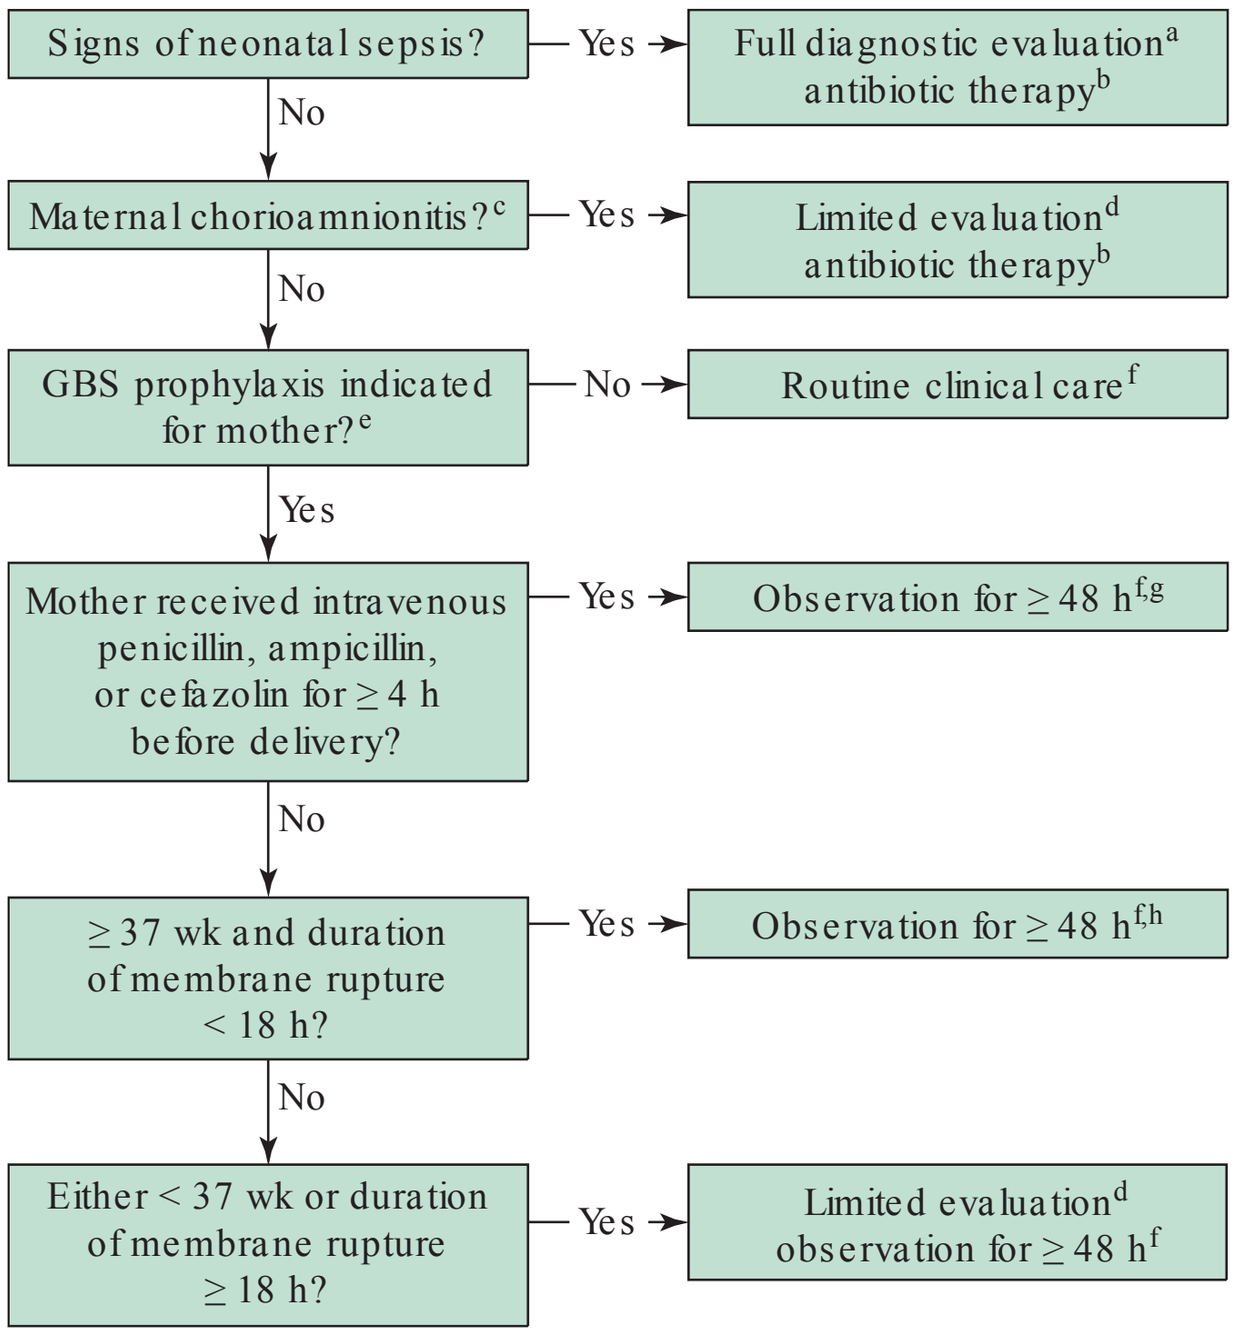
The incidence of perinatal GBS disease has declined dramatically since screening of pregnant mothers and provision of IAP began. Although most patients with GBS disease are infants younger than age 3 months, cases are seen in infants aged 4–5 months. Serious infection also occurs in women with puerperal sepsis, immunocompromised patients, patients with cirrhosis and spontaneous peritonitis, and diabetic patients with cellulitis. Two distinct clinical syndromes distinguished by differing perinatal event and, age at onset occur in infants.

A. Early-Onset Infection

"Early-onset" illness is observed in newborns younger than 7 days old. Risk factors for early-onset group GBS disease include maternal GBS colonization, gestational age less than 37 weeks, rupture of membranes > 18 hours prior to presentation, young maternal age, history of a previous infant with invasive GBS disease, African-American or Hispanic ethnicity, and low or absent maternal GBS anticapsular antibodies. The onset of symptoms in the majority of these infants is in the first 48 hours of life, and most are ill within 6 hours. Apnea is often the first sign. Sepsis, shock, meningitis, apnea, and pneumonia are the most common clinical presentations. When early-onset infection is complicated by meningitis, more than 80% of the bacterial isolates are serotype III. Newborns with early-onset disease are severely ill at the time of diagnosis, and more than 50% die. Although premature infants are at increased risk for the disease, most infants with early-onset infections are full-term. Newborns with early-onset infection acquire GBS in utero as an ascending infection or during passage through the birth canal.

B. Late-Onset Infection

"Late-onset" infection occurs in infants between ages 7 days and 4 months (median age at onset is about 4 weeks). Maternal obstetric complications are not usually associated with late-onset infection. These infants are usually not as ill at the time of diagnosis as those with early-onset disease, and the mortality rate is lower. In recent series, about 37% of patients



[a]Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (if respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).
[b]Antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including Escherichia coli and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.
[c]Consultation with obstetric providers is important to determine the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.
[d]Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).
[e]See Table 42–1 for indications for intrapartum GBS prophylaxis.
[f]If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.
[g]If ≥ 37 weeks' gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.
[h]Some experts recommend a CBC with differential and platelets at age 6–12 hours.

▲**Figure 42–1.** Algorithm for secondary prevention of early-onset group B streptococcal (GBS) disease among newborns. (Reproduced with permission from Verani JR, McGee L, Schrag SL: Prevention of perinatal group B streptococcal disease. Revised guidelines from CDC, 2010. MMWR Recomm Rep 2010;59(RR-10):1–32).

have meningitis and 46% have sepsis. Septic arthritis and osteomyelitis, meningitis, occult bacteremia, otitis media, ethmoiditis, conjunctivitis, cellulitis (particularly of the face or submandibular area), lymphadenitis, breast abscess, empyema, and impetigo have been described. The exact mode of transmission of the organisms is not well defined.

C. Laboratory Findings

Culture of GBS from a normally sterile site such as blood, pleural fluid, or CSF provides proof of diagnosis. Frequent false-positive results limit the usefulness of testing for GBS antigen in urine and CSF.

» Treatment

Intravenous ampicillin and an aminoglycoside is the initial regimen of choice for newborns with presumptive invasive GBS disease. For neonates 7 days of age or younger with meningitis, the recommended ampicillin dosage is 200–300 mg/kg/d, given intravenously in three divided doses. For infants older than 7 days of age, the recommended ampicillin dosage is 300 mg/kg/d, given intravenously in four divided doses.

Penicillin G can be used alone once GBS is identified and clinical and microbiologic responses have occurred. GBS is less susceptible than other streptococci to penicillin, and high doses are recommended, especially for meningitis. In infants with meningitis, the recommended dosage of penicillin G varies with age: for infants age 7 days or younger, 250,000–450,000 U/kg/d, given intravenously in three divided doses; for infants older than age 7 days, 450,000–500,000 U/kg/d, given intravenously in four divided doses.

A second lumbar puncture after 24–48 hours of therapy is recommended by some experts to assess efficacy. Duration of therapy is 2 weeks for uncomplicated meningitis; at least 4 weeks for osteomyelitis, cerebritis, ventriculitis, or endocarditis; and 10 days for bacteremia. Therapy does not eradicate carriage of the organism.

Although streptococci have been universally susceptible to penicillins, increased minimum inhibitory concentrations (MICs) have been observed in some isolates. Resistance of isolates to clindamycin and erythromycin has increased significantly worldwide.

In infants diagnosed with GBS infection and who are part of a multiple birth (twins, triplets, etc) define a risk for acquisition of invasive GBS disease in their siblings. Those siblings should be closely monitored and if signs of illness occur, promptly evaluated and antibiotics instituted for possible systemic infection.

Centers for disease control and prevention (CDC): prevention of perinatal group b streptococcal disease revised guidelines from CDC, 2010. MMWR 2010;59(RR-10):1–32. Available at: http://www.cdc.gov/mmwr/pdf/rr/rr5910.pdf.

STREPTOCOCCAL INFECTIONS WITH ORGANISMS OTHER THAN GROUP A OR B

» General Considerations

Streptococci of groups other than A and B are part of the normal flora of humans and can occasionally cause disease. Group C or group G organisms occasionally produce pharyngitis, but without risk of subsequent rheumatic fever. AGN may occasionally occur. Group D streptococci and Enterococcus species are normal inhabitants of the gastrointestinal tract and may produce urinary tract infections, meningitis, and sepsis in the newborn, as well as endocarditis. Nosocomial infections caused by Enterococcus are frequent in neonatal and oncology units and in patients with central venous catheters. Nonhemolytic aerobic streptococci and β-hemolytic streptococci are normal flora of the mouth. They are involved in the production of dental plaque and probably dental caries, and are the most common cause of subacute infective endocarditis. Finally, there are numerous anaerobic and microaerophilic streptococci, normal flora of the mouth, skin, and gastrointestinal tract, which alone or in combination with other bacteria may cause sinusitis, dental abscesses, brain abscesses, and intra-abdominal or lung abscesses.

» Prevention

Streptococci (other than group A or B) are common normal flora in humans. Some disease caused by these organisms can be prevented by maintaining good oral hygiene. Spread of vancomycin-resistant enterococcal strains can be limited by good infection control practices in healthcare environments. Development of resistant strains can also be limited by antimicrobial stewardship. There are no vaccines that prevent infections with these organisms.

» Treatment

A. Enterococcal Infections

Enterococcus faecalis and Enterococcus faecium are the two most common and most important strains causing human infections. In general, E faecalis is more susceptible to antibiotics than E faecium, but antibiotic resistance is commonly seen with both species. Invasive enterococcal infections should be treated with ampicillin if the isolate is susceptible or vancomycin in combination with gentamicin. Gentamicin should be discontinued if susceptibility testing demonstrates high-level resistance to gentamicin. Isolates that are resistant to both ampicillin and vancomycin necessitate other therapeutic options.

1. Infections with ampicillin-susceptible enterococci— Lower tract urinary infections can be treated with oral amoxicillin. Pyelonephritis should be treated intravenously with ampicillin and gentamicin (gentamicin dosing may need to be adjusted for altered renal function). Sepsis or meningitis in the newborn should be treated intravenously with a combination of ampicillin and gentamicin. Peak serum gentamicin levels of 3–5 mcg/mL are adequate as gentamicin is functioning as a synergistic agent. Endocarditis requires 6 weeks of intravenous treatment. Ampicillin or penicillin in combination with gentamicin is used in susceptible strains. Consult the American Heart Association guidelines for infective endocarditis for treatment recommendations for endocarditis.

2. Infections with ampicillin-resistant- or vancomycin-resistant enterococci—Ampicillin-resistant enterococci

are often susceptible to vancomycin. Vancomycin-resistant enterococci are usually also resistant to ampicillin. Linezolid is approved for use in children only for vancomycin-resistant E faecium infections. Two other agents are approved in adults against certain vancomycin-resistant enterococci. Daptomycin is approved for adults with vancomycin-resistant E faecalis infections, Quinupristin-dalfopristin is approved for adults with vancomycin-resistant E faecium (not effective against E faecalis) infections. Isolates resistant to linezolid, daptomycin, and quinupristin-dalfopristin have been reported. Infectious disease consultation is recommended when use of these drugs is entertained or when vancomycin-resistant enterococcal infections are identified.

B. Viridans Streptococci Infections (Subacute Infective Endocarditis)

It is important to determine the penicillin sensitivity of the infecting strain as early as possible in the treatment of viridans streptococcal endocarditis. Resistant organisms are most commonly seen in patients receiving penicillin prophylaxis for rheumatic heart disease. Treatment of endocarditis varies depending on whether the patient has native valves or prosthetic valves/material and whether the organism is penicillin susceptible. Refer to the American Heart Guidelines on Infective Endocarditis for a complete discussion and recommendations.

C. Other Viridans Streptococci–Related Infections

Viridans streptococci are normal flora of the gastrointestinal tract, respiratory tract, and the mouth. In many cases, isolation of viridans streptococci from a blood culture is considered to be a "contaminant" in the absence of signs or symptoms of endocarditis or other invasive disease. However, in children who are immunocompromised, have congenital or acquired valvular heart disease, or who have indwelling lines, viridans streptococci may be a cause of serious morbidity. About one-third of bacteremias in patients with malignancies may be due to bacteria from the Streptococcus viridans group. Mucositis and gastrointestinal toxicity from chemotherapy are risk factors for developing disease. Even in children with normal immune systems, viridans streptococci sometimes cause serious infections. For example, viridans streptococci isolated from an abdominal abscess after rupture of the appendix represents a true pathogen. Streptococcus anginosus, a member of the Streptococcus viridans group, can cause intracranial abscess (often as a complication of sinusitis) and abdominal abscesses. In patients with risk factors or signs/symptoms for subacute endocarditis, isolation of one of the members of the Streptococcus viridans group should prompt consideration and evaluation for possible endocarditis (see previous section).

Increasing prevalence of antibiotic resistance has been seen over the last 10 years in isolates of the streptococci viridans group. Penicillin resistance varies with geographic region, institution, and the populations tested, but ranges from 30% to 70% in oncology patients. Cephalosporin resistance is also relatively common. Therefore, it is important to obtain antibiotic susceptibilities to the organism to select effective therapy. Vancomycin, linezolid, and quinupristin-dalfopristin remain effective against most isolates.

PNEUMOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Bacteremia:
  - High fever (> 39.4°C).
  - Leukocytosis (> 15,000/μL).
- Pneumonia:
  - Fever, leukocytosis, and tachypnea.
  - Localized chest pain.
  - Localized or diffuse rales. Chest radiograph may show lobar infiltrate (with effusion).
- Meningitis:
  - Fever, leukocytosis.
  - Bulging fontanelle, neck stiffness.
  - Irritability and lethargy.
- All types:
  - Diagnosis confirmed by cultures of blood, CSF, pleural fluid, or other body fluid.

General Considerations

Sepsis, sinusitis, otitis media, pneumonitis, meningitis, osteomyelitis, cellulitis, arthritis, vaginitis, and peritonitis are part of the spectrum of pneumococcal infection. Clinical findings that correlate with occult bacteremia in ambulatory patients include age (6–24 months), degree of temperature elevation (> 39.4°C), and leukocytosis (> 15,000/μL). Although each of these findings is in itself nonspecific, a combination of them should arouse suspicion. This constellation of findings in a child who has no focus of infection may be an indication for blood cultures and antibiotic therapy.

Streptococcus pneumoniae is a common cause of acute purulent otitis media and is the organism responsible for most cases of acute bacterial pneumonia in children. Effusions are common, although frank empyema is less common. Abscesses also occasionally occur.

The incidence rate of pneumococcal meningitis has decreased since incorporation of the pneumococcal conjugate vaccine into the infant vaccine schedule. However, pneumococcal meningitis is still more common than Haemophilus influenzae type b meningitis. Pneumococcal meningitis, sometimes recurrent, may complicate serious head trauma, particularly if there is persistent leakage of CSF. This has led some physicians to recommend the prophylactic administration of penicillin or other antimicrobials in such cases.

Children with sickle cell disease, other hemoglobinopathies, congenital or acquired asplenia, and some immunoglobulin and complement deficiencies are unusually susceptible to pneumococcal sepsis and meningitis. They often have a catastrophic illness with shock and disseminated intravascular coagulation (DIC). The spleen is important in the control of pneumococcal infection. Autosplenectomy may explain why children with sickle cell disease are at increased risk of developing serious pneumococcal infections. Children with cochlear implants are at higher risk for pneumococcal meningitis.

S pneumoniae rarely causes serious disease in the neonate. However, occasionally pneumonia, sepsis, or meningitis may occur and clinically is similar to GBS infection.

Historically, penicillin was the agent of choice for pneumococcal infections, and some strains are still highly susceptible to penicillin. However, pneumococci with moderately increased resistance to penicillin are found in most communities. The prevalence of these relatively penicillin-resistant strains in North America varies geographically. Pneumococci with high-level resistance to penicillin and multiple other drugs are increasingly encountered throughout the United States. Pneumococci from normally sterile body fluids should be routinely tested for susceptibility to penicillin as well as other drugs.

» Prevention

Two pneumococcal vaccines are licensed for use in children in the United States: 13-valent pneumococcal conjugate vaccine (PCV13) and 23-valent pneumococcal polysaccharide vaccine (PPSV23). PCV13 was licensed in 2010 (replacing the 7-valent pneumococcal vaccine). It contains antigens from 13 pneumococcal serotypes and is currently recommended for routine use in the infant and childhood immunization schedule. These vaccines and indications for use (including use of pneumococcal vaccines in children at high risk for invasive pneumococcal disease) are discussed in detail in Chapter 10.

» Clinical Findings

A. Symptoms and Signs

In pneumococcal sepsis, fever usually appears abruptly, often accompanied by chills. There may be no respiratory symptoms. In infants and young children with pneumonia, fever, and tachypnea without auscultatory changes are the usual presenting signs. Respiratory distress is manifested by nasal flaring, chest retractions, and tachypnea. Abdominal pain is common. In older children, the adult form of pneumococcal pneumonia with signs of lobar consolidation may occur, but sputum is rarely bloody. Inspiratory pain (from pleural involvement) is sometimes present, but is less common in children. With involvement of the right hemidiaphragm, pain may be referred to the right lower quadrant, suggesting appendicitis. Vomiting is common at onset but seldom persists. Convulsions are relatively common at onset in infants.

Meningitis is characterized by fever, irritability, convulsions, and neck stiffness. The most important sign in very young infants is a tense, bulging anterior fontanelle. In older children, fever, chills, headache, and vomiting are common. Classic signs are nuchal rigidity associated with positive Brudzinski and Kernig signs. With progression of untreated disease, the child may develop opisthotonos, stupor, and coma.

B. Laboratory Findings

Leukocytosis is often pronounced (20,000–45,000/μL), with 80%–90% polymorphonuclear neutrophils. Neutropenia may be seen early in very serious infections. The presence of pneumococci in the nasopharynx is not a helpful finding, because up to 40% of normal children carry pneumococci in the upper respiratory tract. Large numbers of organisms are seen on Gram-stained smears of endotracheal aspirates from patients with pneumonia. In meningitis, CSF usually shows an elevated white blood cell (WBC) count of several thousand, chiefly polymorphonuclear neutrophils, with decreased glucose and elevated protein levels. Gram-positive diplococci may be seen on some (but not all) stained smears of CSF sediment. Antigen detection tests are not useful. Isolation of S pneumoniae from a normally sterile site (eg, blood, cerebrospinal fluid, joint fluid, middle ear fluid) or from a suppurative focus confirms the diagnosis.

» Differential Diagnosis

There are many causes of high fever and leukocytosis in young infants; besides invasive pneumococcal disease. The differential diagnosis includes viral infection, urinary tract infection, unrecognized focal infection elsewhere in the body, salmonellosis, or early acute shigellosis.

Staphylococcal pneumonia may be indistinguishable early in its course from pneumococcal pneumonia.

In primary pulmonary tuberculosis, children do not have a toxic appearance, and radiographs show a primary focus associated with hilar adenopathy and often with pleural involvement. Miliary tuberculosis presents a classic radiographic appearance.

Pneumonia caused by Mycoplasma pneumoniae is most common in children aged 5 years and older. Onset is insidious, with infrequent chills, low-grade fever, prominent headache and malaise, cough, and, often, striking radiographic changes. Marked leukocytosis (> 18,000/μL) is unusual.

Pneumococcal meningitis is diagnosed by lumbar puncture. Without a Gram-stained smear and culture of CSF pneumoccal meningitis is not distinguishable from other types of acute bacterial meningitis.

» Complications

Complications of sepsis include meningitis and osteomyelitis; complications of pneumonia include empyema, parapneumonic effusion, and, rarely, lung abscess. Mastoiditis, subdural empyema, and brain abscess may follow untreated pneumococcal otitis media. Both pneumococcal meningitis and peritonitis are more likely to occur independently without coexisting pneumonia. Shock, DIC, and Waterhouse-Friderichsen syndrome resembling meningococcemia are occasionally seen in pneumococcal sepsis, particularly in asplenic patients. Hemolytic-uremic syndrome may occur as a complication of pneumococcal pneumonia or sepsis.

» Treatment

A. Specific Measures

All S pneumoniae isolated from normally sterile sites should be tested for antimicrobial susceptibility. The term "nonsusceptible" is used to describe both intermediate and resistant isolates. Strains that are nonsusceptible to penicillin, ceftriaxone (or cefotaxime), and other antimicrobials are increasingly common globally. Antimicrobial susceptibility breakpoints for S pneumoniae to penicillin and ceftriaxone/cefotaxime are based on whether the patient has meningitis and the drug route (oral vs intravenous), Table 42–2. Therapy of meningitis, empyema, osteomyelitis, and endocarditis due to nonsusceptible S pneumoniae is challenging because penetration of antimicrobials to these sites is limited. Infectious disease consultation is recommended for advice regarding these problems. For empiric therapy of serious or life-threatening infections pending susceptibility test results, vancomycin and ceftriaxone (or vancomycin and cefotaxime) are recommended.

1. Bacteremia—Prior to routine childhood immunization with conjugated pneumococcal vaccine, 3%–5% of blood cultures in patients < 2 years of age yielded S pneumonia, but these percentages decreased with the current vaccine schedule. Many experts treat suspected bacteremia in children that are not seriously ill with ceftriaxone (50 mg/kg, given intramuscularly or intravenously). However, meningitis occurs with the same frequency despite presumptive therapy. All children with blood cultures that grow pneumococci should be reexamined as soon as possible. The child who has a focal infection, such as meningitis, or who appears septic should be admitted to the hospital to receive parenteral antimicrobials. If the child is afebrile and appears well or mildly ill, outpatient management is appropriate. Severely ill or immunocompromised children, in whom invasive infection with S pneumoniae is suspected, should be empirically treated with vancomycin (in addition to other appropriate antibiotics to cover other suspected pathogens). If meningitis is also suspected, use ceftriaxone or cefotaxime in addition to vancomycin until the susceptibilities of the organism are known.

2. Pneumonia—For infants (≥ 1 month of age) with susceptible organisms appropriate regimens include ampicillin (150–200 mg/kg/d intravenously in four divided doses) aqueous penicillin G (250,000–400,000 U/kg/d, given intravenously in four to six divided doses), cefotaxime (50 mg/kg intravenously every 8 hours), or ceftriaxone (50 mg/kg intravenously every 12–24 hours). If susceptibilities are not known and the patient is severely ill or immunocompromised, vancomycin should be used as part of the regimen to

Table 42–2. Penicillin breakpoints (minimum inhibitory concentrations [MIC]) for Streptococcus pneumoniae by susceptibility category—Clinical and Laboratory Standards Institute, 2008.

Drug	Clinical Syndrome and Drug Route	Susceptibility Category MIC (mcg/mL)		
		Susceptible	Intermediate	Resistant
Penicillin	Meningitis, intravenous penicillin	≤ 0.06	None[a]	≥ 0.12
	Nonmeningitis, intravenous penicillin	≤ 2	4	≥ 8
	Nonmeningitis, oral penicillin	≤ 0.06	0.12–1	≥ 2
Cefotaxime or ceftriaxone	Meningitis, intravenous cefotaxime or ceftriaxone	≤ 0.5	1	≥ 2
	Nonmeningitis, intravenous cefotaxime or ceftriaxone	≤ 1	2	≥ 4

[a]There is no intermediate category for meningitis.
Reproduced with permission from Centers for Disease Control and Prevention (CDC): Effects of new penicillin susceptibility breakpoints for Streptococcus pneumoniae–United States, 2006–2007, MMWR Morb Mortal Wkly Rep. 2008 Dec 19;57(50):1353–1355.

provide coverage for penicillin- or cephalosporin-resistant pneumococcus. Once results of susceptibility testing are available, the regimen can be tailored. Mild pneumonia may be treated with amoxicillin (80–90 mg/kg/d) for 7–10 days. Alternative regimens include oral macrolides (resistance may be high) and cephalosporins.

3. Otitis media—Most experts recommend oral amoxicillin (80–90 mg/kg/d, divided in two doses) as first-line therapy. The standard course of therapy is 10 days; however, many physicians treat uncomplicated, mild cases in children 6 years of age or older for 5–7 days. Treatment failures may be treated with amoxicillin-clavulanate (80–90 mg/kg/d of the amoxicillin component in the 14:1 formulation), intramuscular ceftriaxone, cefuroxime axetil, or cefdinir. Azithromycin can also be used in patients with type I hypersensitivity reactions to penicillin or cephalosporin, but resistance to macrolides may be high.

4. Meningitis—Until bacteriologic confirmation and susceptibility testing are completed, patients should receive vancomycin (60 mg/kg/d, given intravenously in four divided doses) and cefotaxime (225–300 mg/kg/d intravenously in four divided doses), OR vancomycin (see previous dosage) and ceftriaxone (100 mg/kg/d, given intravenously in two divided doses). Patients with serious hypersensitivity to beta-lactam antibiotics (eg, penicillins, cephalosporins) can be treated with a combination of vancomycin (see previous dosage) and rifampin (20 mg/kg/d in two divided doses). Note, this regimen does not include gram negative coverage so additional antimicrobial agents may be needed if an organism has not been definitively identified. Use of vancomycin alone or use of rifampin alone is not recommended. Vancomycin combined with meropenem is an alternative for penicillin or cephalosporin allergic patients and this regimen provides additional gram-negative coverage until culture and susceptibility results are obtained. Corticosteroids (dexamethasone, 0.6 mg/kg/d, in four divided doses for 4 days) are controversial but are recommended by many experts as adjunctive therapy for pneumococcal meningitis. A repeat lumbar puncture at 24–48 hours should be considered to ensure sterility of the CSF if dexamethasone is given, if resistant pneumococci were initially isolated, or if the patient is not demonstrating expected improvement after 24–48 hours on therapy.

If the isolate is penicillin-susceptible, aqueous penicillin G can be administered (300,000–400,000 U/kg/d, given intravenously in four to six divided doses for 10–14 days). Alternatively, use of ceftriaxone or cefotaxime is an acceptable alternative therapy for penicillin- and cephalosporin-susceptible isolates. Consult an infectious disease specialist or the Red Book (American Academy of Pediatrics, 2012) for a complete discussion of pneumococcal meningitis and for therapeutic options for isolates that are nonsusceptible to penicillin or cephalosporins.

» Prognosis

In children, case fatality rates of less than 1% should be achieved except for meningitis, where rates of 5%–20% still prevail. The presence of large numbers of organisms without a prominent CSF inflammatory response or meningitis due to a penicillin-resistant strain indicates a poor prognosis. Serious neurologic sequelae, particularly hearing loss, are frequent following pneumococcal meningitis.

STAPHYLOCOCCAL INFECTIONS

» General Considerations

Staphylococcal infections are common in childhood and range from local mild infections to overwhelming systemic infections. Diseases caused by staphylococci include, but are not limited to, furuncles, carbuncles, scalded skin syndrome, osteomyelitis, pyomyositis, septic arthritis, pneumonia, bacteremia, endocarditis, meningitis, and toxic shock syndrome (TSS). Staphylococci are the major cause of osteomyelitis and septic arthritis and are an uncommon but important cause of bacterial pneumonia. They are found in infections at all ages and in multiple sites, particularly when infection is introduced from the skin or upper respiratory tract or when closed compartments become infected (pericarditis, sinusitis, cervical adenitis, surgical wounds, abscesses in the liver or brain, and abscesses elsewhere in the body).

Staphylococci that do not produce the enzyme coagulase are termed coagulase-negative and are seldom speciated in the clinical microbiology laboratory. Most S aureus strains produce coagulase. S aureus and coagulase-negative staphylococci are normal flora of the skin and respiratory tract. The latter rarely cause disease except in compromised hosts, the newborn, or patients with indwelling lines.

Most strains of S aureus elaborate β-lactamase that confers penicillin resistance. This can be overcome in clinical practice by the use of a cephalosporin or a penicillinase-resistant penicillin, such as oxacillin, nafcillin, cloxacillin, or dicloxacillin. Methicillin-resistant S aureus (MRSA) are

resistant in vivo to all of these penicillinase-resistant penicillins and cephalosporins. MRSA has dramatically increased in prevalence globally as both a healthcare-associated and a community-associated pathogen. Healthcare-associated infections are likely to be multidrug resistant. Community-associated MRSA may be susceptible to clindamycin and/or TMP-SMX, but resistance rates to these agents vary widely geographically. MRSA strains with intermediate susceptibility to vancomycin are occurring more frequently and occasionally vancomycin-resistant strains are isolated. The existence of such strains is of concern because of the inherent virulence of most strains of S aureus and because of the limited choices for therapy.

S aureus produces a variety of exotoxins. Two toxins are recognized as playing a central role in specific diseases: exfoliatin and staphylococcal enterotoxin. The former is largely responsible for the various clinical presentations of scalded skin syndrome. Enterotoxin causes staphylococcal food poisoning. The exoprotein toxin most commonly associated with TSS has been termed TSST-1. Panton-Valentine leukocidin (PVL) is an exotoxin produced by some clinical isolates of methicillin-susceptible S aureus (MSSA) and MRSA strains. PVL is a virulence factor that causes leukocyte destruction and tissue necrosis. PVL-producing S aureus strains are often community-acquired, and have most commonly produced boils and abscesses. However, they also have been associated with severe cellulitis, osteomyelitis, and deaths from necrotizing pneumonia in otherwise healthy children and young adults.

» Prevention

No licensed vaccines are available. Patients with recurrent skin infections with S aureus should practice good skin hygiene to try to prevent recurrences. Keeping fingernails short, good skin hygiene, not sharing towels or other personal items, and use of a clean towel daily may help prevent recurrences.

» Clinical Findings

A. Symptoms and Signs

1. Staphylococcal skin diseases—Dermal infection with S aureus causes pustules, furuncles, carbuncles, or cellulitis. Community-associated MRSA and MSSA frequently cause skin and soft tissue infections. MRSA furuncles and abscesses are extraordinarily common in clinical practice. Parents initially may think the child has a spider bite. Skin lesions can be seen anywhere on the body but are commonly seen on the buttocks in infants and young children. Factors that facilitate transmission of MRSA or MSSA include crowding, compromised skin (eg, eczema), participation on contact sports teams, day care attendance, bare skin contact with surfaces used by others (exercise mats, sauna benches), and sharing towels or other personal items.

S aureus are often found along with streptococci in impetigo. If the strains produce exfoliatin, localized lesions become bullous (bullous impetigo).

Scalded skin syndrome is a toxin-mediated illness caused by exfoliative toxins A and B produced by certain strains of S aureus. The initial infection may begin at any site but is in the respiratory tract in most cases. Skin erythema, often beginning around the mouth, is accompanied by fever and irritability. The involved skin becomes tender to touch. A day or so later, exfoliation begins, usually around the mouth. The inside of the mouth is red, and a peeling rash is present around the lips, often in a radial pattern. Generalized, painful peeling may follow, involving the limbs and trunk but often sparing the feet. More commonly, peeling is confined to areas around body orifices. If erythematous but unpeeled skin is rubbed, superficial epidermal layers separate from deeper ones and slough (Nikolsky sign). Generally, if secondary infection does not occur, there is healing without scarring. In the newborn, the disease is termed Ritter disease and may be fulminant.

2. Osteomyelitis and septic arthritis—(See Chapter 26.) MRSA invasive disease including osteomyelitis and septic arthritis is being seen increasingly.

3. Staphylococcal pneumonia—Staphylococcal pneumonia in infancy is characterized by abdominal distention, high fever, respiratory distress, and toxemia. It may occur without predisposing factors or after minor skin infections. The organism is necrotizing, producing bronchoalveolar destruction. Pneumatoceles, pyopneumothorax, and empyema are frequently encountered. Rapid progression of disease is characteristic. Frequent chest radiographs to monitor the progress of disease are indicated. Presenting symptoms may be typical of paralytic ileus, suggestive of an abdominal catastrophe.

Invasive MRSA infections are increasing and have been reported in all age groups. Many cases are in patients who develop MRSA pneumonia as a complication of influenza. MRSA or MSSA pneumonias are rapidly progressive, severe, and often devastating. Complications are frequent including necrotizing pneumonia, pneumatoceles, and/or empyemas. Purulent pericarditis occurs by direct extension in about 10% of cases, with or without empyema.

4. Staphylococcal food poisoning—Staphylococcal food poisoning is a result of ingestion of enterotoxin produced by staphylococci growing in uncooked and poorly refrigerated food. The disease is characterized by vomiting, prostration, and diarrhea occurring 2–6 hours after ingestion of contaminated foods.

5. Staphylococcal endocarditis—S aureus may produce infection of normal heart valves, of valves or endocardium in children with congenital or rheumatic heart disease, or of artificial valves. About 25% of all cases of endocarditis are

due to S aureus. The great majority of artificial heart valve infections involve either S aureus or coagulase-negative staphylococci. Infection usually begins in an extracardiac focus, often the skin. Involvement of the endocardium should be considered when blood cultures grow S aureus, particularly when cultures are persistently positive. Suspicion must be highest in the presence of congenital heart disease, particularly ventricular septal defects with aortic insufficiency but also simple ventricular septal defect, patent ductus arteriosus, and tetralogy of Fallot.

The presenting symptoms in staphylococcal endocarditis are fever, weight loss, weakness, muscle pain or diffuse skeletal pain, poor feeding, pallor, and cardiac decompensation. Signs include splenomegaly, cardiomegaly, petechiae, hematuria, and a new or changing murmur. The course of S aureus endocarditis is rapid, although subacute disease occurs occasionally. Peripheral septic embolization and uncontrollable cardiac failure are common, even when optimal antibiotic therapy is administered, and may be indications for surgical intervention (see section "Staphylococcal Endocarditis").

6. Toxic shock syndrome—TSS is characterized by fever, blanching erythroderma, diarrhea, vomiting, myalgia, prostration, hypotension, and multiorgan dysfunction. It is due to S aureus focal infection, usually without bacteremia. Large numbers of cases have been described in menstruating adolescents and young women using vaginal tampons. TSS has also been reported in boys and girls with focal staphylococcal infections and in individuals with wound infections due to S aureus. Additional clinical features include sudden onset; conjunctival suffusion; mucosal hyperemia; desquamation of skin on the palms, soles, fingers, and toes during convalescence; DIC in severe cases; renal and hepatic functional abnormalities; and myolysis. The mortality rate with early treatment is now about 2%. Recurrences are seen during subsequent menstrual periods in as many as 60% of untreated women who continue to use tampons. Recurrences occur in up to 15% of women given antistaphylococcal antibiotics who stop using tampons.

7. Coagulase-negative staphylococcal infections—Localized and systemic coagulase-negative staphylococcal infections occur primarily in immunocompromised patients, high-risk newborns, and patients with plastic prostheses or catheters. Coagulase-negative staphylococci are the most common nosocomial pathogen in hospitalized low-birth-weight neonates in the United States. Intravenous administration of lipid emulsions and indwelling central venous catheters are risk factors contributing to coagulase-negative staphylococcal bacteremia in newborn infants. In patients with an artificial heart valve, a Dacron patch, a ventriculoperitoneal shunt, or a central venous catheter, coagulase-negative staphylococci are a common cause of sepsis or catheter infection, often necessitating removal of the foreign material and protracted antibiotic therapy. Because blood cultures are frequently contaminated by this organism, diagnosis of genuine localized or systemic infection is often difficult.

B. Laboratory Findings

Moderate leukocytosis (15,000–20,000/μL) with a shift to the left is occasionally found, although normal counts are common, particularly in infants. The sedimentation rate is elevated. Blood cultures are frequently positive in systemic staphylococcal disease and should always be obtained when it is suspected. Similarly, pus from sites of infection should always be aspirated or obtained surgically, examined with Gram stain, and cultured both aerobically and anaerobically. There are no useful serologic tests for staphylococcal disease.

» Differential Diagnosis

Staphylococcal skin disease takes many forms; therefore, the differential list is long. Bullous impetigo must be differentiated from chemical or thermal burns, from drug reactions, and, in the very young, from the various congenital epidermolytic syndromes or even herpes simplex infections. Staphylococcal scalded skin syndrome may resemble scarlet fever, Kawasaki disease, Stevens-Johnson syndrome, erythema multiforme, and other drug reactions. A skin biopsy may be critical in establishing the diagnosis. Varicella lesions may become superinfected with exfoliatin-producing staphylococci and produce a combination of the two diseases (bullous varicella).

Severe, rapidly progressing pneumonia with formation of abscesses, pneumatoceles, and empyemas is typical of S aureus infection and GAS but may occasionally be produced by pneumococci and H influenzae.

Staphylococcal food poisoning is often epidemic. It is differentiated from other common-source gastroenteritis syndromes (Salmonella, Clostridium perfringens, and Vibrio parahaemolyticus) by the short incubation period (2–6 hours), the prominence of vomiting (as opposed to diarrhea), and the absence of fever.

Endocarditis is suspected with S aureus bacteremia, particularly when a significant heart murmur or preexisting cardiac disease is present (see Chapter 20).

Newborn infections with S aureus can resemble infections with streptococci and a variety of gram-negative organisms. Umbilical and respiratory tract colonization occurs with many pathogenic organisms (GBS, Escherichia coli, and Klebsiella), and both skin and systemic infections occur with virtually all of these organisms.

TSS must be differentiated from Rocky Mountain spotted fever, leptospirosis, Kawasaki disease, drug reactions, adenovirus, and measles (Table 42–3).

Table 42–3. Interpretation of tuberculin skin test reactions.[a]

Degree of Risk	Risk Factors	Positive Reaction
High	Recent close contact with a case of active tuberculosis Chest radiograph compatible with tuberculosis Immune compromise; HIV infection	≥ 5 mm induration
Medium	Current or previous residence in high-prevalence area (Asia, Africa, Latin America) Skin test converters within past 2 y Intravenous drug use Homeless or residence in a correctional institution Recent weight loss or malnutrition Leukemia, Hodgkin disease, or diabetes mellitus Age < 4 y	≥ 10 mm induration
Low	Children ≥ 4 y without any risk factor	≥ 15 mm induration

[a]Standard intradermal Mantoux test, 5 test units. Measure perpendicular to the long axis of the arm. Induration only, not erythema, is measured.

» Treatment

A. Specific Measures

The incidence of community-acquired MRSA isolates varies greatly geographically, but in many communities in the United States MRSA is the most common pathogen isolated from skin and soft tissue infections. For empiric coverage of potentially life-threatening infections with suspected S aureus (in which susceptibilities are not known) initial therapy should include vancomycin in combination with either nafcillin or oxacillin (in addition to appropriate antibiotic therapy for other suspected pathogens). Antibiotic therapy can then be adjusted based on identification of the organism and susceptibility results.

Currently, manycommunity-acquired MRSA strains are susceptible to TMP-SMX and some are susceptible to clindamycin; however, this varies greatly geographically. Knowledge of local MRSA susceptibility patterns is useful in guiding empiric therapy. Less serious infections in nontoxic patients may be initially treated using TMP-SMX or clindamycin, while awaiting cultures and susceptibility data, if community MRSA resistance to these agents is low.

For MSSA strains, a β-lactamase–resistant penicillin is the drug of choice (oxacillin or nafcillin). In serious systemic disease, in osteomyelitis, and in the treatment of large abscesses, intravenous therapy is indicated initially (oxacillin or nafcillin, 100–150 mg/kg/d in four divided doses). In serious or life-threatening illness, consultation with an infectious disease physician is recommended.

Cephalosporins may be considered for MSSA infections in patients with a history of penicillin sensitivity, unless there is a history of type 1 hypersensitivity reaction (anaphylaxis, wheezing, edema, or hives). Cefazolin, 100–150 mg/kg/d, given intravenously in three divided doses, or cephalexin, 50–100 mg/kg/d, given orally in four divided doses, can be used once a child is able to take oral antibiotics. The third-generation cephalosporins should not generally be used for staphylococcal infections.

For serious S aureus infections, initial therapy with vancomycin (15 mg/kg/dose intravenously every 6 hours) plus nafcillin or oxacillin is recommended until susceptibilities are available. For nosocomially acquired MRSA infections, vancomycin should be used until results of susceptibility testing are available to guide therapy (isolates are frequently clindamycin and TMP-SMX–resistant). Infections due to MRSA do not respond to cephalosporins despite in vitro testing that suggests susceptibility. For treatment of meningitis, vancomycin must be given in higher doses (60 mg/kg/d divided into four doses). The addition of rifampin is advocated by some (rifampin should not be used alone to treat this condition).

1. Skin infections—Treatment of skin and soft tissue infections depends, in part, on the extent of the lesion, immunocompetence of the host, and the toxicity of the patient. Afebrile, well-appearing patients with small abscesses may do well with incision and drainage (with or without the addition of oral antimicrobials). More serious infections or infections in immunocompromised patients should be treated more aggressively. Hospitalization and intravenous antibiotics may be required. Culture and susceptibility testing will help guide therapy.

For patients who are not sick enough to require hospitalization or intravenous therapy, selection of the best empiric antimicrobial depends on local rates of MRSA and local susceptibilities. β-Lactam antibiotics, such as penicillins and cephalosporins, can no longer be depended on as single agents for the majority of cases in communities with high MRSA rates. TMP-SMX or clindamycin (depending on local susceptibility patterns) may be used for empiric staphylococcal coverage. However, Group A streptococci are generally resistant to TMP-SMX and in a small number of cases may also be resistant to clindamycin. Many clinicians empirically use a combination of TMP-SMX and cefazolin for initial treatment until susceptibilities are known. Linezolid is another option, although the cost of this drug is high.

2. Osteomyelitis and septic arthritis—Treatment should be begun intravenously, with antibiotics selected to cover the most likely organisms (staphylococci in hematogenous osteomyelitis; meningococci, pneumococci, staphylococci in children younger than age 3 years with septic arthritis; staphylococci and gonococci in older children with septic arthritis). Knowledge of local MRSA rates will help guide empiric therapy. Antibiotic levels should be kept high at all times.

Clinical studies support the use of intravenous treatment for osteomyelitis until fever and local symptoms and signs have subsided—usually at least 3–5 days—followed by oral therapy. For both osteomyelitis and joint infections, good compliance with oral therapy is important for successful cure.

Nafcillin, oxacillin, or cefazolin can be used for intravenous therapy of MSSA strains. Clindamycin is an alternative agent if the organism is susceptible and the patient does not have a severe or life-threatening infection or ongoing bacteremia. Dicloxacillin, 100–150 mg/kg/d in four divided doses or cephalexin, 100–150 mg/kg/d in four divided doses) can be used when the patient is ready for oral therapy.

Vancomycin can be used initially for MRSA osteomyelitis, while awaiting final susceptibilities. Antibiotic regimens for MRSA osteomyelitis should be based on susceptibility results; isolates may be susceptible to clindamycin or linezolid, but susceptibility patterns vary geographically.

The C-reactive protein (in the first or second week after therapy is started) and the erythrocyte sedimentation rate (usually measured weekly) are good indicators of response to therapy. Surgical drainage of osteomyelitis or septic arthritis is often required (see Chapter 26).

3. Staphylococcal pneumonia—In areas of the country where MRSA is not prevalent, or if the isolate is known to be MSSA, nafcillin and oxacillin are the usual drugs of choice. Vancomycin can be used empirically until results of cultures and susceptibility tests are obtained if MRSA rates are high. In sicker patients, vancomycin plus nafcillin or vancomycin plus oxacillin can be used (in addition to coverage of other pathogens) until the etiologic agent and susceptibilities are established. Linezolid has been reported to be as efficacious as vancomycin for the treatment of resistant gram-positive pneumonia and soft tissue infections.

Empyema and pyopneumothorax require drainage. The choice of chest tube versus thoracoscopic drainage depends on the practitioner's experience and skill. If staphylococcal pneumonia is treated promptly and empyema drained, resolution in children often is complete.

4. Staphylococcal food poisoning—Therapy is supportive and usually not required except in severe cases or for small infants with marked dehydration.

5. Staphylococcal endocarditis—The treatment of staphylococcal endocarditis depends on whether the patient has a prosthetic valve or material in the heart and on the susceptibilities of the organism. Please see the American Heart Association's Guidelines on Infective Endocarditis: Diagnosis and Management and consult an infectious disease physician for this serious and sometimes complicated problem. High-dose, prolonged parenteral treatment is indicated. Therapy lasts in all instances for at least 6 weeks.

Occasionally, medical treatment fails. Signs of treatment failure are (1) recurrent fever without apparent treatable other cause (eg, thrombophlebitis, respiratory or urinary tract infection, drug fever), (2) persistently positive blood cultures, (3) intractable and progressive congestive heart failure, and (4) recurrent (septic) embolization. In such circumstances—particularly (2), (3), and (4)—evaluation for valve replacement becomes necessary. Antibiotics are continued for at least another 4 weeks after blood cultures are proven negative. Persistent or recurrent infection may require a second surgical procedure.

6. Toxic shock syndrome—Treatment is aimed at expanding blood volume, maintaining perfusion pressure with inotropic agents, ensuring prompt drainage of a focus of infection (or removal of tampons or foreign bodies), and giving intravenous antibiotics.

Vancomycin, in addition to a β-lactam antibiotic (oxacillin or nafcillin), can be used for empiric therapy. Many experts also add clindamycin, since clindamycin is a protein synthesis inhibitor and may turn off toxin production. Clindamycin should not be used empirically as a single agent until susceptibilities are known.

Intravenous immunoglobulin has been used as adjunctive therapy. Some experts believe that corticosteroid therapy may be effective if given to patients with severe illness early in the course of their disease.

7. Vancomycin-resistant *S aureus* infections (VRSA)—Reports of VRSA isolates are rare but are likely to increase in frequency. Such isolates are sometimes susceptible to clindamycin or TMP-SMX. If not, therapeutic options are limited and include use of quinupristin-dalfopristin, linezolid, or daptomycin, assuming the strain is susceptible to these agents. Quinupristin-dalfopristin is not FDA-approved for children less than 16 years of age; daptomycin is not FDA-approved for children less than 18 years of age. Consultation with an infectious disease specialist is recommended.

8. Coagulase-negative staphylococcal infections—Bacteremia and other serious coagulase-negative staphylococcal infections are treated initially with vancomycin, with susceptibility results guiding subsequent therapy. Coagulase-negative staphylococci are uncommonly resistant to vancomycin (see Chapter 39 for dosing).

MENINGOCOCCAL INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Fever, headache, vomiting, convulsions, shock (meningitis).

» Fever, shock, petechial or purpuric skin rash (meningococcemia).

» Diagnosis confirmed by culture of normally sterile body fluids.

» General Considerations

Meningococci (Neisseria meningitidis) may be carried asymptomatically for months in the upper respiratory tract. Less than 1% of carriers develop disease. Meningitis and sepsis are the two most common forms of illness, but septic arthritis, pericarditis, pneumonia, chronic meningococcemia, otitis media, conjunctivitis, and vaginitis also occur. Meningococcal cases in the United States have declined recently; currently there are about 800–1000 cases annually. The highest attack rate for meningococcal meningitis is in the first year of life, with a secondary peak during the teen years. The development of irreversible shock with multiorgan failure is a significant factor in the fatal outcome of acute meningococcal infections.

Meningococci are gram-negative organisms containing endotoxin in their cell walls. Endotoxins cause capillary vascular injury and leak as well as DIC. Meningococci are classified serologically into groups: A, B, C, Y, and W-135 are the groups most commonly implicated in systemic disease. Currently in the United States, serogroups B, C, and Y each account for about 30% of cases; however, this distribution varies significantly with age. In infants about half the cases are caused by Serogroup B. In US adolescents, Serogroups B, C, and W-135 cause most cases. Over the last few years, several outbreaks on college campus have been caused by Serogroup B. Serogroup A causes epidemics in sub-Saharan Africa, but only occasionally is associated with cases of meningococcal disease in the United States. Sulfonamide resistance is common in non–serotype-A strains. N meningitidis with increased MICs to penicillin G are reported from South Africa and Spain. A small number of these isolates are reported in the United States. Resistant isolates are susceptible to third-generation cephalosporins. Few isolates are resistant to rifampin.

Patients deficient in one of the late components of complement (C6, C7, C8, or C9) are uniquely susceptible to meningococcal infection, particularly group A meningococci. Deficiencies of early and alternate pathway complement components also are associated with increased susceptibility.

» Prevention

A. Chemoprophylaxis

Household contacts, day care center contacts, and hospital personnel directly exposed to the respiratory secretions of patients are at increased risk for developing meningococcal infection and should be given chemoprophylaxis. The secondary attack rate among household members is about 1000 times the attack rate in the general population. Children between the ages of 3 months and 2 years are at greatest risk, presumably because they lack protective antibodies. Secondary cases may occur in day care centers and in classrooms. Hospital personnel are not at increased risk unless they have had contact with a patient's oral secretions, for example, during mouth-to-mouth resuscitation, intubation, or suctioning procedures. Approximately 50% of secondary cases in households have their onset within 24 hours of identification of the index case. Exposed contacts should be notified promptly. If they are febrile, they should be fully evaluated and given high doses of penicillin or another effective antimicrobial pending the results of blood cultures.

All high-risk contacts should receive chemoprophylaxis for meningococcal disease as soon as an index case is identified. High-risk contacts are defined as:

- All household contacts (especially children < 2 years of age)
- Persons with child care or preschool contact with the index patient at any time in the 7 days prior to illness onset
- Persons with direct exposure to index patients secretions (sharing of drinks, straws, cigarettes, toothbrushes, eating utensils, kissing) during the 7 days prior to illness onset
- Persons who have performed mouth-to-mouth resuscitation or performed unprotected endotracheal intubation of the index patient during the 7 days prior to illness onset
- Persons who have slept in the same dwelling as the index patient within 7 days of illness onset
- Passengers who were seated directly next to the index patient on a flight of more than 8 hours duration

The most commonly used agent for meningococcal chemoprophylaxis is oral rifampin given twice daily for

2 days (600 mg for adults; 10 mg/kg for children older than 1 month (maximum dosage 600 mg); and 5 mg/kg for infants younger than 1 month). Rifampin may stain a patient's tears (and contact lenses), sweat, and urine orange; it may also affect the reliability of oral contraceptives, and alternative contraceptive measures should therefore be employed when rifampin is administered. Rifampin should not be given to pregnant women. Instead, intramuscular ceftriaxone is the preferred agent: 125 mg given as a single dose if the patient is < 15 years old; 250 mg given as a single dose if ≥ 15 years old. Penicillin and most other antibiotics (even with parenteral administration) are not effective chemoprophylactic agents, because they do not eradicate upper respiratory tract carriage of meningococci. Ciprofloxacin (20 mg/kg as a single dose, maximum dose 500 mg) effectively eradicates nasopharyngeal carriage in adults and children but is not approved for use in children or in pregnant women. Throat cultures to identify carriers are not useful.

B. Vaccine

Several types of vaccines are currently licensed in the United States for meningococcal disease prevention. A quadrivalent polysaccharide vaccine (MSPV-4) prepared from purified meningococcal polysaccharides (A, C, Y, and W-135) is available for children and adults older than 2 years of age. Quadrivalent meningococcal conjugate vaccines and one bivalent conjugate meningococcal-HIB vaccine (see Chapter 10) are used in children and adults between the ages of 6 weeks and 55 years. Meningococcal conjugate vaccine is preferred over the polysaccharide vaccine. In general, conjugate vaccines provide longer-lasting immunity and a more robust immune response than polysaccharide vaccines. A Serogroup B vaccine was recently licensed for ages 10–25 years. (See Chapter 10 for a discussion on meningococcal vaccines.)

» Clinical Findings

A. Symptoms and Signs

Many children with clinical meningococcemia also have meningitis, and some have other foci of infection. All children with suspected meningococcemia should have a lumbar puncture.

1. Meningococcemia—A prodrome of upper respiratory infection is followed by high fever, headache, nausea, marked toxicity, and hypotension. Purpura, petechiae, and occasionally bright pink, tender macules or papules over the extremities and trunk are seen. The rash usually progresses rapidly. Occasional cases lack rash. Fulminant meningococcemia is characterized by DIC, massive skin and mucosal hemorrhages, and shock. This syndrome also may be caused by H influenzae, S pneumoniae, or other bacteria. Chronic meningococcemia is characterized by periodic bouts of fever, arthralgia or arthritis, and recurrent petechiae. Splenomegaly often is present. Patients may be free of symptoms between bouts. Chronic meningococcemia occurs primarily in adults and mimics Henoch-Schönlein purpura.

2. Meningitis—In many children, meningococcemia is followed within a few hours to several days by symptoms and signs of acute purulent meningitis, with severe headache, stiff neck, nausea, vomiting, and stupor. Children with meningitis generally fare better than children with meningococcemia alone, probably because they have survived long enough to develop clinical signs of meningitis.

B. Laboratory Findings

The peripheral WBC count may be either low or elevated. Thrombocytopenia may be present with or without DIC (see Chapter 30). If petechial or hemorrhagic lesions are present, meningococci can sometimes be seen microscopically in tissue fluid expressed from a punctured lesion. CSF is generally cloudy and contains more than 1000 WBCs/μL, with many polymorphonuclear neutrophils and gram-negative intracellular diplococci. A total hemolytic complement assay may reveal absence of late components as an underlying cause.

» Differential Diagnosis

The skin lesions of H influenzae or pneumococci, enterovirus infection, endocarditis, leptospirosis, Rocky Mountain spotted fever, other rickettsial diseases, Henoch-Schönlein purpura, and blood dyscrasias may be similar to meningococcemia. Severe S aureus sepsis has been reported in some patients to present with purpura. Other causes of sepsis and meningitis are distinguished by appropriate Gram stain and cultures.

» Complications

Meningitis may lead to permanent central nervous system (CNS) damage, with deafness, convulsions, paralysis, or impaired intellectual function. Hydrocephalus may develop and requires ventriculoperitoneal shunt. Subdural collections of fluid are common but usually resolve spontaneously. Extensive skin necrosis, loss of digits or extremities, intestinal hemorrhage, and late adrenal insufficiency may complicate fulminant meningococcemia.

» Treatment

Blood cultures should be obtained for all children with fever and purpura or other signs of meningococcemia, and antibiotics should be administered immediately as an emergency procedure.

Children with meningococcemia or meningococcal meningitis should be treated as though shock were imminent even if their vital signs are stable when they are first seen.

If hypotension is present, supportive measures should be aggressive, because the prognosis is grave in such situations. Treatment should be started emergently in an intensive care setting, but should not be delayed while transporting the patient. Shock may worsen following antimicrobial therapy due to endotoxin release. To minimize the risk of nosocomial transmission, patients should be placed in respiratory isolation for the first 24 hours of antibiotic treatment.

A. Specific Measures

Antibiotics should be initiated promptly. Because other bacteria, such as S pneumoniae, S aureus, or other gram-negative organisms, can cause identical syndromes, initial therapy should be broad. Vancomycin and cefotaxime (or ceftriaxone) are preferred initial coverage. Once N meningitidis has been isolated, penicillin G, cefotaxime, or ceftriaxone intravenously for 7 days are the drugs of choice. Relative penicillin resistance is uncommon but has been reported in the United States.

B. General Measures

Most cases of invasive meningococcal disease are treated with intravenous antibiotics for 7 days.

1. Cardiovascular—(See Chapter 14 for management of septic shock.) Corticosteroids are not beneficial. Sympathetic blockade and topically applied nitroglycerin have been used locally to improve perfusion.

2. Hematologic—Adjunctive therapy with heparin is controversial. Because hypercoagulability is frequently present in patients with meningococcemia, some experts believe heparin should be considered when DIC is present. Recombinant tissue plasminogen activator, concentrated antithrombin III, and recombinant protein-C infusions have been tried experimentally to reverse coagulopathy (see Chapter 30 for the management of DIC).

» Prognosis

Unfavorable prognostic features include shock, DIC, and extensive skin lesions. The case fatality rate in fulminant meningococcemia is over 30%. In uncomplicated meningococcal meningitis, the fatality rate is much lower (10%–20%).

Centers for Disease Control and Prevention (CDC): Meningococcal disease. Available at: http://www.cdc.gov/meningococcal/clinical-info.html.

Cohn AC et al: Centers for Disease Control and Prevention (CDC): Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR Recomm Rep 2013;62(RR-2):1 [PMID: 231515099]. Available at: http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm.

GONOCOCCAL INFECTIONS (SEE CHAPTER 44)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purulent urethral discharge with intracellular gram negative diplococci on smear in male patients (usually adolescents).
- Purulent, edematous, sometimes hemorrhagic conjunctivitis with intracellular gram-negative diplococci in 2- to 4-day-old infants.
- Fever, arthritis (often polyarticular) or tenosynovitis, and maculopapular peripheral rash that may be vesiculopustular or hemorrhagic.
- Positive culture of blood, pharyngeal, or genital secretions.
  - Nucleic acid amplification test on urine on genital secretions.

» General Considerations

Neisseria gonorrhoeae is a gram-negative diplococcus. Although morphologically similar to other neisseriae, it differs in its ability to grow on selective media and to ferment carbohydrates. The cell wall of N gonorrhoeae contains endotoxin, which is liberated when the organism dies and is responsible for the production of a cellular exudate. The incubation period is short, usually 2–5 days.

Reported cases of gonorrhea exceeded 333,000 in the United States in 2013. Gonococcal disease in children may be transmitted sexually or nonsexually. Prepubertal gonococcal infection outside the neonatal period should be considered presumptive evidence of sexual contact or child abuse. Prepubertal girls usually manifest gonococcal vulvovaginitis without cervicitis because of the neutral to alkaline pH of the vagina and thin vaginal mucosa.

In the adolescent or adult, the workup of every case of gonorrhea should include a careful and accurate inquiry into the patient's sexual practices, because pharyngeal infection resulting from oral sex must be detected if present and may be difficult to eradicate. Efforts should be made to identify and provide treatment to all sexual contacts. Programs of expedited partner treatment where prescriptions are provided without first examining the sexual contact increase successful treatment. Young women are at risk for serious health consequences including infertility due to gonococcal and chlamydia infection. When prepubertal children are infected, epidemiologic investigation should be thorough.

» Clinical Findings

A. Symptoms and Signs

1. Asymptomatic gonorrhea—The ratio of asymptomatic to symptomatic gonorrheal infections in adolescents and adults is probably 3–4:1 in women and 0.5–1:1 in men. Asymptomatic infections are as infectious as symptomatic ones.

2. Uncomplicated genital gonorrhea

a. Male with urethritis—Urethral discharge is sometimes painful and bloody and may be white, yellow, or green. There may be associated dysuria. The patient usually is afebrile.

b. Prepubertal female with vaginitis—The only clinical findings initially may be dysuria and polymorphonuclear neutrophils in the urine. Vulvitis characterized by erythema, edema, and excoriation accompanied by a purulent discharge may follow.

c. Postpubertal female with cervicitis—Symptomatic disease is characterized by a purulent, foul-smelling vaginal discharge, dysuria, and occasionally dyspareunia. Fever and abdominal pain are absent. The cervix is frequently hyperemic and tender when touched. This tenderness is not worsened by moving the cervix, nor are the adnexa tender to palpation.

d. Rectal gonorrhea—Rectal gonorrhea often is asymptomatic. There may be purulent discharge, edema, and pain during evacuation.

3. Pharyngeal gonorrhea—Pharyngeal infection usually is asymptomatic. There may be some sore throat and, rarely, acute exudative tonsillitis with bilateral cervical lymphadenopathy and fever.

4. Conjunctivitis and iridocyclitis—Copious, usually purulent exudate is characteristic of gonococcal conjunctivitis. Newborns are symptomatic on days 2–4 of life. In the adolescent or adult, infection probably is spread from infected genital secretions by the fingers.

5. Pelvic inflammatory disease (salpingitis)—The interval between initiation of genital infection and its ascent to the uterine tubes is variable and may range from days to months. Menses frequently are the initiating factor. With the onset of a menstrual period, gonococci invade the endometrium, causing transient endometritis. Subsequently salpingitis may occur, resulting in pyosalpinx or hydrosalpinx. Rarely infection progresses to peritonitis or perihepatitis. Gonococcal salpingitis occurs in an acute, a subacute, or a chronic form. All three forms have in common tenderness on gentle movement of the cervix and bilateral tubal tenderness during pelvic examination.

Gonococci or Chlamydia trachomatis are the cause of about 50% of cases of pelvic inflammatory disease. A mixed infection caused by enteric bacilli, Bacteroides fragilis, or other anaerobes occur in the other 50%.

6. Gonococcal perihepatitis (fitz-hugh and curtis syndrome)—Typically the patient presents with right upper quadrant tenderness in association with signs of acute or subacute salpingitis. Pain may be pleuritic and referred to the shoulder. Hepatic friction rub is a valuable but inconstant sign.

7. Disseminated gonorrhea—Dissemination follows asymptomatic more often than symptomatic genital infection, often from gonococcal pharyngitis or anorectal gonorrhea. The most common form of disseminated gonorrhea is polyarthritis or polytenosynovitis, with or without dermatitis. Monoarticular arthritis is less common, and gonococcal endocarditis and meningitis are rare.

a. Polyarthritis—Disease usually begins with the simultaneous onset of low-grade fever, polyarthralgia, and malaise. After a day or so, joint symptoms become acute. Swelling, redness, and tenderness occur, frequently over the wrists, ankles, and knees but also in the fingers, feet, and other peripheral joints. Skin lesions may be noted at the same time. Discrete, tender, maculopapular lesions 5–8 mm in diameter appear that may become vesicular, pustular, and then hemorrhagic. They are few in number and noted on the fingers, palms, feet, and other distal surfaces. In patients with this form of the disease, blood cultures are often positive, but joint fluid rarely yields organisms. Skin lesions often are positive by Gram stain but rarely by culture. Genital, rectal, and pharyngeal cultures must be performed.

b. Monoarticular arthritis—In this somewhat less common form of disseminated gonorrhea, fever is often absent. Arthritis evolves in a single joint. Dermatitis usually does not occur. Systemic symptoms are minimal. Blood cultures are negative, but joint aspirates may yield gonococci on smear and culture. Genital, rectal, and pharyngeal cultures must be performed.

B. Laboratory Findings

Demonstration of gram-negative, kidney-shaped diplococci in smears of urethral exudate in males is presumptive evidence of gonorrhea. Positive culture confirms the diagnosis. Negative smears do not rule out gonorrhea. Gram-stained smears of cervical or vaginal discharge in girls are more difficult to interpret because of normal gram-negative flora, but they may be useful when technical personnel are experienced. Gonococcal pharyngitis requires culture for diagnosis. Nucleic acid amplification tests (NAAT) on urine or genital specimens now enable detection of N gonorrhoeae

and C trachomatis. These tests have excellent sensitivity and are replacing culture in many laboratories. All children or adolescents with a suspected or established diagnosis of gonorrhea should have serologic tests for syphilis and HIV.

If cultures are obtained use of a selective chocolate agar containing antibiotics (eg, Thayer-Martin agar) is needed to suppress normal flora. If bacteriologic diagnosis is critical, suspected material should be cultured on chocolate agar as well. Because gonococci are labile, agar plates should be inoculated immediately and placed without delay in an atmosphere containing CO_2 When transport of specimens is necessary, material should be inoculated directly into an appropriate transport medium prior to shipment to the laboratory. In cases of possible sexual molestation, notify the laboratory that definite speciation is needed, because nongonococcal Neisseria species can grow on the selective media.

» Differential Diagnosis

Urethritis in the male may be gonococcal or nongonococcal (NGU). NGU is a syndrome characterized by discharge (rarely painful), mild dysuria, and a subacute course. The discharge is usually scant or moderate and non-purulent. C trachomatis is the only proven cause of NGU. Doxycycline (100 mg orally twice a day for 7 days) is efficacious. Single-dose azithromycin, 1 g orally, may achieve better compliance. C trachomatis has been shown to cause epididymitis in males and salpingitis in females.

Vulvovaginitis in a prepubertal female may be due to infection caused by miscellaneous bacteria, including Shigella and GAS, Candida, and herpes simplex. Discharges may be caused by trichomonads, Enterobius vermicularis (pin-worm), candidiasis or foreign bodies. Symptom-free discharge (leukorrhea) normally accompanies rising estrogen levels.

Cervicitis in a postpubertal female, alone or in association with urethritis and involvement of Skene and Bartholin glands, may be due to infection caused by Candida, herpes simplex, Trichomonas, or discharge resulting from inflammation caused by foreign bodies (usually some form of contraceptive device). Leukorrhea may be associated with birth control pills.

Salpingitis may be due to infection with other organisms. The symptoms must be differentiated from those of appendicitis, urinary tract infection, ectopic pregnancy, endometriosis, or ovarian cysts or torsion.

Disseminated gonorrhea presents a differential diagnosis that includes meningococcemia, acute rheumatic fever, Henoch-Schönlein purpura, juvenile rheumatoid arthritis, lupus erythematosus, leptospirosis, secondary syphilis, certain viral infections (particularly rubella, but also enteroviruses and parvovirus), serum sickness, type B hepatitis (in the prodromal phase), infective endocarditis, and even acute leukemia and other types of cancer. The fully evolved skin lesions of disseminated gonorrhea are remarkably specific, and genital, rectal, or pharyngeal cultures, plus cultures of blood and joint fluid, usually yield gonococci from at least one source.

» Prevention

Prevention of gonorrhea is principally a matter of sex education, condom use, and identification and treatment of contacts.

» Treatment

Antimicrobial-resistant gonococci are a serious problem. N gonorrhoeae infections resistant to tetracyclines, penicillins, and fluoroquinolones are common. Fluoroquinolone and oral cephalosporins are no longer recommended for therapy in the United States. In some cases, clinicians will have very limited choices for therapy. Many clinical laboratories do not routinely perform antimicrobial susceptibility tests on N gonorrhoeae, and many infections are documented by nonculture methods.

A. Uncomplicated Urogenital, Pharyngeal, or Rectal Gonococcal Infections in Adolescents

Ceftriaxone (250 mg intramuscularly in a single dose), and azithromycin (1 g orally in a single dose) is recommended. Ceftizoxime, cefotaxime, and cefotetan parenterally are alternative single-dose therapies. Fluoroquinolones are no longer recommended for therapy due to increasing rates of resistance. If ceftriaxone cannot be used, cefixime (400 mg orally in a single dose) and doxycycline (100 mg orally twice daily for 7 days) is recommended. Azithromycin (2 g orally once) can be used in the case of severe cephalosporin allergy.

Tetracyclines should be avoided in pregnancy, and repeated doses may stain the teeth of young children. Erythromycin or amoxicillin is recommended for therapy of C trachomatis in pregnant women; azithromycin is an alternative regimen. Repeat testing 3 weeks after completion of therapy is recommended in pregnant women.

A repeat culture 7 days after therapy is not necessary in asymptomatic adolescents after the ceftriaxone–doxycycline regimen, should be done if either oral regimen has been used.

B. Disseminated Gonorrhea

Recommended regimens include ceftriaxone (1 g intramuscularly or intravenously once daily) or cefotaxime (1 g intravenously every 8 hours or ceftizoxime (1 g intravenously every 8 hours). Oral therapy may follow parenteral therapy 24–48 hours after improvement. Recommended regimens include cefixime (400 mg) twice daily to complete 7 days of therapy. Fluoroquinolones are not recommended. If concurrent infection with Chlamydia is present or has not

been excluded, a course of doxycycline, azithromycin, or erythromycin should also be prescribed.

C. Pelvic Inflammatory Disease

Doxycycline (100 mg twice a day orally) and either cefoxitin (2 g intramuscularly or intravenously every 6 hours) or cefotetan (2 g intramuscularly or intravenously every 12 hours) are given until the patient is clinically improved, then doxycycline is administered by mouth to complete 14 days of therapy. Clindamycin and gentamicin given intravenously until the patient improves clinically may be used rather than cefoxitin. Many other regimens have been used for therapy of pelvic inflammatory disease, although comparative efficacy data are limited.

D. Prepubertal Gonococcal Infections

1. Uncomplicated genitourinary, rectal, or pharyngeal infections—These infections may be treated with ceftriaxone (50 mg/kg/d to a maximum of 125 mg intramuscularly in a single dose). Children older than age 8 years should also receive doxycycline (100 mg orally twice daily for 7 days). The physician should evaluate all children for evidence of sexual abuse and coinfection with syphilis, Chlamydia, and HIV.

2. Disseminated gonorrhea—This should be treated with ceftriaxone (50 mg/kg once daily parenterally for 7 days).

Centers for Disease Control and Prevention (CDC): Update to CDC's sexually transmitted diseases treatment guidelines, 2012: oral cephalosporins no longer recommended treatment for gonococcal infections. MMWR 2012;61(31):6590 [PMID: 22874837].

Workowski KA, Berman S; Centers for Disease Control and Prevention (CDC): Sexually transmitted diseases treatment guidelines, 2010. MMWR 2010;59(RR-12):1 [PMID: 21160459].

BOTULISM

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Dry mucous membranes.
- Diplopia; dilated, unreactive pupils.
- Descending paralysis.
- Difficulty in swallowing and speaking within 12–36 hours after ingestion of toxin-contaminated food.
- Multiple cases in a family or group.
- Hypotonia and constipation in infants.
- Diagnosis by clinical findings and identification of toxin in blood, stool, or implicated food.

» General Considerations

Botulism is a paralytic disease caused by Clostridium botulinum, an anaerobic, gram-positive, spore-forming bacillus normally found in soil. The organism produces an extremely potent neurotoxin. Of the seven types of toxin (A–G), types A, B, and E cause most human diseases. The toxin, a polypeptide, is so potent that 0.1 mg is lethal for humans.

Food-borne botulism usually results from ingestion of toxin-containing food. Preformed toxin is absorbed from the gut and produces paralysis by preventing acetylcholine release from cholinergic fibers at myoneural junctions. Virtually any food will support the growth of C botulinum spores into vegetative toxin-producing bacilli if an anaerobic, nonacid environment is provided. The food may not appear or taste spoiled. The toxin is heat-labile, but the spores are heat-resistant. Inadequate heating during processing (temperature < 115°C) allows the spores to survive and later resume toxin production.

Infant botulism occurs in infants less than 12 months of age. The toxin is produced by ingested C botulinum spores which germinate and produce toxin in the gastrointestinal tract.

Annually, 10–15 cases of wound botulism are reported. Most cases occur in drug abusers with infection in intravenous or intramuscular injection sites.

» Prevention

Infant botulism is acquired by ingestion of botulism spores which then sporulate into C botulinum organisms that can form botulinum toxin. Honey can contain botulism spores so it is recommended that honey not be consumed by infants less than 12 months of age. Corn syrups that have not been pasteurized may pose a theoretical risk and some organizations (American Academy of Pediatrics) recommend that infants less than 12 months should not consume unpasteurized corn syrup.

Food-borne botulism is acquired by ingesting preformed botulism toxin in food. In the United States, food-borne botulism is most commonly seen with ingestion of home-canned foods of low acidity (ie, corn, asparagus, green beans). However, other foods have also been associated with botulism. Persons who eat home-canned foods should consider boiling foods for at least 10 minutes or heating to 80°F for 30 minutes (can destroy potential toxin). Safe food handling practices include keeping foods either refrigerated (< 45°F) or hot (> 185°F), and disposing of any cracked jars or bulging/dented cans.

» Clinical Findings

A. Symptoms and Signs

The incubation period for food-borne botulism is 8–36 hours. The initial symptoms are lethargy and headache. These are

followed by double vision, dilated pupils, ptosis, and, within a few hours, difficulty with swallowing and speech. The mucous membranes often are very dry. Descending skeletal muscle paralysis may be seen. Death usually results from respiratory failure.

Botulism patients present with a "classic triad": (1) afebrile; (2) symmetrical, flaccid, descending paralysis with prominent bulbar palsies; and (3) clear sensorium. Recognition of this triad is important in making the clinical diagnosis. Botulism is caused by a toxin, thus there is no fever unless secondary infection (eg, aspiration pneumonia) occurs. Common bulbar palsies seen include dysphonia, dysphagia, dysarthria, and diplopia (four "Ds").

Infant botulism is seen in infants younger than age 12 months (peak onset 2–8 months). Infants younger than age 2 weeks rarely develop botulism. The initial symptoms are usually constipation and progressive, often severe, hypotonia. Clinical findings include loss of facial expression, constipation, weak suck and cry, pooled oral secretions, cranial nerve deficits, generalized weakness, and, on occasion, apnea. The characteristic electromyographic pattern of brief, small, abundant motor-unit action potentials (BSAPs) may help confirm the diagnosis.

B. Laboratory Findings

The diagnosis is made by demonstration of C botulinum toxin in stool, gastric aspirate or vomitus, or serum. Serum and stool samples can be sent for toxin confirmation (done by toxin neutralization mouse bioassay at CDC or state health departments). In infant botulism, serum assays for C botulinum toxin are usually negative. The tests take time and therapy should not be withheld awaiting testing results. Foods that are suspected to be contaminated should be kept refrigerated and given to public health personnel for testing. Laboratory findings, including CSF examination, are usually normal. Electromyography suggests the diagnosis if the characteristic brief, small abundant motor-unit action potentials (BSAP) abnormalities are seen. A nondiagnostic electromyogram does not exclude the diagnosis.

» Differential Diagnosis

Guillain-Barré syndrome is characterized by ascending paralysis, sensory deficits, and elevated CSF protein without pleocytosis.

Other illnesses that should be considered include poliomyelitis, post diphtheritic polyneuritis, certain chemical intoxications, tick paralysis, and myasthenia gravis. The history and elevated CSF protein characterize postdiphtheritic polyneuritis. Tick paralysis presents with a flaccid ascending motor paralysis. An attached tick should be sought. Myasthenia gravis usually occurs in adolescent girls. It is characterized by ocular and bulbar symptoms, normal pupils, fluctuating weakness, absence of other neurologic signs, and clinical response to cholinesterase inhibitors.

» Complications

Difficulty in swallowing leads to aspiration pneumonia. Serious respiratory paralysis may be fatal despite assisted ventilation and intensive supportive measures.

» Treatment

A. Specific Measures

Patients with suspected botulism should be hospitalized and monitored closely for signs of impending respiratory failure and inability to manage secretions. Early treatment of botulism with antitoxin is beneficial. The type of antitoxin treatment recommended differs depending on the type of botulism. Treatment should begin as soon as the clinical diagnosis is suspected (prior to microbiologic or toxin confirmation). Contact your State Health Department's emergency 24-hour telephone number immediately when a case of botulism is suspected to assist in therapeutic decisions and to help obtain treatment product.

For treatment of suspected infant botulism, intravenous human botulism immunoglobulin (BabyBIG) is approved by the U.S. Food and Drug Administration (FDA). BabyBIG contains neutralizing antibodies against type A and B toxin. A placebo-controlled clinical trial of BabyBIG use in infant botulism showed substantial reductions in the mean hospital stay, mechanical ventilation days, and intensive care days in the BabyBIG–treated group. Baby-BIG is not indicated for use in any form of botulism (wound, food-borne) other than infant botulism. To obtain BabyBIG (in any state), contact the California Department of Public Health (24-hour telephone number: 510-231-7600; www.infantbotulism.org/). Antimicrobial agents are not recommended to treat infant botulism, except when bacterial complications occur (ie, pneumonia, line infection, etc).

For other types of botulism (noninfant botulism), patients should be treated with heptavalent botulinum antitoxin (HBAT), which is only available from the CDC under an investigational new drug protocol. HBAT is an equine-derived antitoxin that contains antibodies to all seven botulinum toxin types (A through G). The treatment protocol (available from the CDC) includes detailed instructions for intravenous administration of antitoxin. State Health Departments can assist practitioners in obtaining the antitoxin; if State Health Department officials are unavailable, the CDC ([770] 488-7100) can be contacted for help in obtaining the product and for consultation. In addition, epidemic assistance, and laboratory testing services are available from the CDC through state health departments. For wound botulism, penicillin or

metronidazole is recommended, once HBAT has been given. Surgical debridement of involved tissue is recommended.

B. General Measures

General and supportive therapy consists of bed rest, ventilatory support (if necessary), fluid therapy, and enteral or parenteral nutrition. Aminoglycoside antimicrobials and clindamycin may exacerbate neuromuscular blockage and should be avoided.

» Prognosis

The mortality rate has declined substantially in recent years and currently is at 6%.

TETANUS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nonimmunized or partially immunized patient.
- History of skin wound.
- Spasms of jaw muscles (trismus).
- Stiffness of neck, back, and abdominal muscles, with hyperirritability and hyperreflexia.
- Episodic, generalized muscle contractions.
- Diagnosis is based on clinical findings and the immunization history.

» General Considerations

Tetanus is caused by Clostridium tetani, an anaerobic, gram-positive bacillus that produces a potent neurotoxin. In unimmunized or incompletely immunized individuals, infection follows contamination of a wound by soil containing Clostridial spores from animal manure. The toxin reaches the CNS by retrograde axon transport, is bound to cerebral gangliosides, and increases reflex excitability in neurons of the spinal cord by blocking function of inhibitory synapses. Intense muscle spasms result. Two-thirds of cases in the United States follow minor puncture wounds of the hands or feet. In many cases, no history of a wound can be obtained. Injecting substances and drug abuse may be risk factors (in individuals who are not tetanus-immune). In the newborn, usually in underdeveloped countries, infection generally results from contamination of the umbilical cord. The incubation period typically is 4–14 days but may be longer. In the United States, cases in young children are due to failure to immunize. Eighty-five percent of cases occur in adults older than 25 years.

» Prevention

A. Tetanus Toxoid

Active immunization with tetanus toxoid prevents tetanus. Immunity is almost always achieved after the third dose of vaccine. Tetanus immunoglobulin (TIG) is an additional agent used to prevent tetanus in persons who have received less than three doses of tetanus toxoid or in immunocompromised patients who do not make sufficient antibody (ie, HIV infection; see Chapter 10). A tetanus toxoid booster at the time of injury is needed if none has been given in the past 10 years—or within 5 years for heavily contaminated wounds. Nearly all cases of tetanus (99%) in the United States are in nonimmunized or incompletely immunized individuals. Many adolescents and adults lack protective antibody.

B. Wound Care and Prophylaxis for Tetanus-Prone Wounds

Wounds that are contaminated with soil, debris, feces, or saliva are at increased risk for tetanus. Puncture wounds, crush injuries, avulsions, frostbite, burns, or other wounds that contain devitalized tissue are also at increased risk of infection with C tetani. All wounds should be adequately cleaned, foreign material removed, and debrided if necrotic or devitalized tissue or residual foreign matter is present. The decision to use tetanus toxoid–containing vaccine, human TIG, or both depends on the type of injury and the tetanus immunization status of the patient (see Chapter 10; Table 10–5). TIG should be used in children with fewer than three previous tetanus toxoid immunizations (DPT, DPaT, DT, Td, Tdap) who have tetanus-prone wounds and should be administered to HIV-infected children with tetanus-prone wounds, regardless of their immunization history. When TIG is indicated for wound prophylaxis 250 units are given intramuscularly regardless of age. If tetanus immunization is incomplete, a dose of age-appropriate vaccine

should be given. When both are indicated, tetanus toxoid and TIG should be administered concurrently at different sites using different syringes (see Chapter 10).

Prophylactic antimicrobials are useful if the child is unimmunized and TIG is not available.

» Clinical Findings

A. Symptoms and Signs

The first symptom often is mild pain at the site of the wound, followed by hypertonicity and spasm of the regional muscles. Characteristically, difficulty in opening the mouth (trismus) is evident within 48 hours. In newborns, the first signs are irritability and inability to nurse. The infant may then develop stiffness of the jaw and neck, increasing dysphagia, and generalized hyperreflexia with rigidity and spasms of all muscles of the abdomen and back (opisthotonos). The facial distortion resembles a grimace (risus sardonicus). Difficulty in swallowing and convulsions triggered by minimal stimuli such as sound, light, or movement may occur. Individual spasms may last seconds or minutes. Recurrent spasms are seen several times each hour, or they may be almost continuous. In most cases, the temperature is normal or only mildly elevated. A high or subnormal temperature is a bad prognostic sign. Patients are fully conscious and lucid. A profound circulatory disturbance associated with sympathetic overactivity (elevated blood pressure, tachycardia, arrhythmia) may occur on the second to fourth day, which may contribute to the mortality rate.

B. Laboratory Findings

The diagnosis is made on clinical grounds. There may be a mild polymorphonuclear leukocytosis. The CSF is normal with the exception of mild elevation of opening pressure. Serum muscle enzymes may be elevated. Anaerobic culture and microscopic examination of pus from the wound can be helpful, but C tetani is difficult to grow, and the drumstick-shaped gram-positive bacilli often cannot be found.

» Differential Diagnosis

Poliomyelitis is characterized by asymmetrical flaccid paralysis in an incompletely immunized child. The history of an animal bite and the absence of trismus may suggest rabies. Local infections of the throat and jaw should be easily recognized. Bacterial meningitis, phenothiazine reactions, decerebrate posturing, narcotic withdrawal, spondylitis, and hypocalcemic tetany may be confused with tetanus.

» Complications

Complications include sepsis, malnutrition, pneumonia, atelectasis, asphyxial spasms, decubitus ulcers, and fractures of the spine due to intense contractions. They can be prevented in part by skilled supportive care.

» Treatment of Tetanus

A. Specific Measures

Human TIG in a single dose of 3000–6000 units, intramuscularly, is given to children and adults. Some experts suggest that a dose of 500 units is just as effective. Infiltration of part of the TIG dose around the wound is recommended. If TIG is indicated, but not available, intravenous immunoglobulin in a dose of 200–400 mg/kg intravenously can be infused over several hours (although it is not licensed for this indication; see package insert for infusion instructions). In countries where TIG or immunoglobulin are not available, equine tetanus antitoxin may be available. Surgical debridement of wounds is indicated, but more extensive surgery or amputation to eliminate the site of infection is not necessary. Antibiotics are given in an attempt to decrease the bacterial load to decrease toxin production: oral or intravenous metronidazole (30 mg/kg/d in four divided doses; maximum 4 g/d) for 10–14 days is the preferred agent. An age-appropriate tetanus toxid containing vaccine should be administered in a different limb from the TIG administration site.

B. General Measures

Treatment of tetanus is usually best accomplished in an intensive care unit. The patient is kept in a quiet room with minimal stimulation. Control of spasms and prevention of hypoxic episodes are crucial. Benzodiazepines can be used to help control spasms and provide some sedation. Mechanical ventilation and muscle paralysis are necessary in severe cases. Nasogastric or intravenous feedings should be used to limit stimulation of feedings and prevent aspiration.

» Prognosis

The fatality rate in newborns and heroin-addicted individuals is high. The overall mortality rate in the United States is 11%. The fatality rate depends on the quality of supportive care, the patient's age, and the patient's vaccination history. Many deaths are due to pneumonia or respiratory failure. If the patient survives 1 week, recovery is likely.

Centers for Disease Control and Prevention (CDC): Clinical Information. http://www.cdc.gov/tetanus/clinicians.html.

Centers for Disease Control and Prevention (CDC): Tetanus. Available at: http://www.cdc.gov/vaccines/pubs/pinkbook/downloads/tetanus.pdf.

GAS GANGRENE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Contamination of a wound with soil or feces.
- Massive edema, skin discoloration, bleb formation, and pain in an area of trauma.
- Serosanguineous exudate from wound.
- Crepitation of subcutaneous tissue.
- Rapid progression of signs and symptoms.
- Clostridia cultured or seen on stained smears.

» General Considerations

Gas gangrene (Clostridial myonecrosis) is a necrotizing infection that follows trauma or surgery and is caused by several anaerobic, gram-positive, spore-forming bacilli of the genus Clostridium. Occasionally the source is the gastrointestinal tract and muscles are hematogenously seeded. The spores are found in soil, feces, and vaginal secretions. In devitalized tissue, the spores germinate into vegetative bacilli that proliferate and produce toxins, causing thrombosis, hemolysis, and tissue necrosis. C perfringens, the species causing approximately 80% of cases of gas gangrene, produces at least eight toxins. The areas involved most often are the extremities, abdomen, and uterus. Clostridium septicum may also cause myonecrosis and causes septicemia in patients with neutropenia. Nonclostridial infections with gas formation can mimic clostridial infections and are more common. Neutropenia is a risk factor for this severe infection.

» Prevention

Gas gangrene can be prevented by the adequate cleansing and debridement of all wounds. It is essential that foreign bodies and dead tissue be removed. A clean wound does not provide a suitable anaerobic environment for the growth of Clostridial species.

» Clinical Findings

A. Symptoms and Signs

The onset of gas gangrene usually is sudden, often 1 day after trauma or surgery (mean, 3–4 days), but can be delayed up to 20 days. Pain and swelling usually are intense. The skin around the wound becomes discolored (pale, red, or purple), with hemorrhagic bullae, serosanguineous exudate, and crepitus may be observed the subcutaneous tissues. The absence of crepitus does not rule out the diagnosis. Systemic illness appears early and progresses rapidly to intravascular hemolysis, jaundice, shock, toxic delirium, and renal failure.

B. Laboratory Findings

Isolation of the organism requires anaerobic cultures. The wound exudate, soft tissue, muscle and blood can be cultured. Gram-stained smears may demonstrate many gram-positive rods and few inflammatory cells.

C. Imaging

Radiographs may demonstrate gas in tissues, but this is a late finding and is also seen in infections with other gas-forming organisms or may be due to air introduced into tissues during trauma or surgery.

D. Operative Findings

Direct visualization of the muscle at surgery may be necessary to diagnose gas gangrene. Early, the muscle is pale and edematous and does not contract normally; later, the muscle may be frankly gangrenous.

» Differential Diagnosis

Gangrene and cellulitis caused by other organisms and Clostridial cellulitis (not myonecrosis) must be distinguished. Necrotizing fasciitis may resemble gas gangrene.

» Treatment

A. Specific Measures

Penicillin G (300,000–400,000 U/kg/d intravenously in six divided doses) should be given. Clindamycin, metronidazole, meropenem, and ertapenem are alternatives for penicillin-allergic patients. Some experts recommend a combination of penicillin and clindamycin; clindamycin may inhibit toxin production.

B. Surgical Measures

Surgery should be prompt and extensive, with removal of all necrotic tissue. Compartment syndromes can occur even if there are few cutaneous findings. Checking compartment pressures in patients with severe pain and any signs of compartment syndrome is prudent.

C. Hyperbaric Oxygen

Hyperbaric oxygen therapy is controversial but good outcomes have been reported in nonrandomized studies using hyperbaric oxygen in combination with surgery and antibiotics.

» Prognosis

Clostridial myonecrosis is fatal if untreated. With early diagnosis, antibiotics, and surgery, the mortality rate is

20%–60%. Involvement of the abdominal wall, leukopenia, intravascular hemolysis, renal failure, and shock are ominous prognostic signs.

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Gray, adherent pseudomembrane, most often in the pharynx but also in the nasopharynx or trachea.
- Sore throat, serosanguinous nasal discharge, hoarseness, and fever in a nonimmunized child.
- Peripheral neuritis or myocarditis.
- Positive culture.
- Treatment should not be withheld pending culture results.

General Considerations

Diphtheria is an acute infection of the upper respiratory tract or skin caused by toxin-producing Corynebacterium diphtheriae. Diphtheria in the United States is rare; five cases have been reported since 2000; none since 2003. However, significant numbers of elderly adults and unimmunized children are susceptible to infection. Diphtheria still occurs in epidemics in countries where immunization is not universal. Unimmunized travelers to these areas may acquire the disease.

Corynebacteria are gram-positive, club-shaped rods with a beaded appearance on Gram stain. The capacity to produce exotoxin is conferred by a lysogenic bacteriophage and is not present in all strains of C diphtheriae. In immunized communities, infection probably occurs through spread of the phage among carriers of susceptible C diphtheriae rather than through spread of phage-containing bacteria themselves. Diphtheria toxin kills susceptible cells by irreversible inhibition of protein synthesis.

The toxin is absorbed into the mucous membranes and causes destruction of epithelium and a superficial inflammatory response. The necrotic epithelium becomes embedded in exuded fibrin with WBCs and RBCs (red blood cells), forming a grayish pseudomembrane over the tonsils, pharynx, or larynx. Any attempt to remove the membrane exposes and tears the capillaries, resulting in bleeding. The diphtheria bacilli within the membrane continue to produce toxin, which is absorbed and may result in toxic injury to heart muscle, liver, kidneys, and adrenals, and is sometimes accompanied by hemorrhage. The toxin also produces neuritis, resulting in paralysis of the soft palate, eye muscles, or extremities. Death may occur as a result of respiratory obstruction or toxemia and circulatory collapse. The patient may succumb after a somewhat longer time as a result of cardiac damage. The incubation period is 2–7 days.

Clinical Findings

A. Symptoms and Signs

1. Pharyngeal diphtheria—Early manifestations of diphtheritic pharyngitis are mild sore throat, moderate fever, and malaise, followed fairly rapidly by prostration and circulatory collapse. The pulse is more rapid than the fever would seem to justify. A pharyngeal membrane forms and may spread into the nasopharynx or the trachea, producing respiratory obstruction. The membrane is tenacious and gray and is surrounded by a narrow zone of erythema and a broader zone of edema. The cervical lymph nodes become swollen, which is associated with brawny edema of the neck (so-called bull neck). Laryngeal diphtheria presents with stridor, which can progress to airway obstruction.

2. Other forms—Cutaneous, vaginal, and wound diphtheria account for up to one-third of cases and are characterized by ulcerative lesions with membrane formation.

B. Laboratory Findings

Diagnosis is clinical. Direct smears are unreliable. Material is obtained from the nose, throat, or skin lesions, if present, for culture, but specialized culture media are required. Between 16 and 48 hours is required before identification of the organism. A toxigenicity test is then performed. Cultures may be negative in individuals who have received antibiotics. The WBC count usually is normal, but hemolytic anemia and thrombocytopenia are frequent.

Differential Diagnosis

Pharyngeal diphtheria resembles pharyngitis secondary to β-hemolytic streptococcus, Epstein-Barr virus, or other viral respiratory pathogens. A nasal foreign body or purulent sinusitis may mimic nasal diphtheria. Other causes of laryngeal obstruction include epiglottitis and viral croup. Guillain-Barré syndrome, poliomyelitis, or acute poisoning may mimic the neuropathy of diphtheria.

» Complications

A. Myocarditis

Diphtheritic myocarditis is characterized by a rapid, thready pulse; indistinct heart sounds, ST-T wave changes, conduction abnormalities, dysrhythmias, or cardiac failure; hepatomegaly; and fluid retention. Myocardial dysfunction may occur from 2 to 40 days after the onset of pharyngitis.

B. Polyneuritis

Neuritis of the palatal and pharyngeal nerves occurs during the first or second week. Nasal speech and regurgitation of food through the nose are seen. Diplopia and strabismus occur during the third week or later. Neuritis may also involve peripheral nerves supplying the intercostal muscles, diaphragm, and other muscle groups. Generalized paresis usually occurs after the fourth week.

C. Bronchopneumonia

Secondary pneumonia is common in fatal cases.

» Prevention

A. Immunization

Immunization with diphtheria toxoid combined with pertussis and tetanus toxoids (DTaP) should be used routinely for infants and children (see Chapter 10).

B. Care of Exposed Susceptibles

Children exposed to diphtheria should be examined, and nose and throat cultures obtained. If signs and symptoms of early diphtheria are found, antibiotic treatment should be instituted. Immunized asymptomatic individuals should receive diphtheria toxoid if a booster has not been received within 5 years. Unimmunized close contacts should receive either erythromycin orally (40 mg/kg/d in four divided doses) for 10 days or benzathine penicillin G intramuscularly (25,000 U/kg), active immunization with diphtheria toxoid, and close observation.

» Treatment

A. Specific Measures

1. Antitoxin—Suspected diphtheria should be reported promptly to the Centers for Disease Control Emergency Center (770-448-7100) so diphtheria antitoxin can be obtained. Diphtheria antitoxin is no longer commercially available. To be effective, diphtheria antitoxin should be administered within 48 hours (see Chapter 9).

2. Antibiotics—Penicillin G (150,000 U/kg/d intravenously or intramuscularly) should be given for 14 days. For penicillin-allergic patients, erythromycin (40 mg/kg/d) is given orally for 14 days.

B. General Measures

Obervation of patients t in the hospital for 10–14 days is usually required. All patients must be strictly isolated for 1–7 days until respiratory secretions are noncontagious. Isolation may be discontinued when two successive nose and throat cultures at 24-hour intervals are negative. These cultures should not be taken until at least 24 hours have elapsed since the cessation of antibiotic treatment.

C. Treatment of Carriers

All carriers should receive eithererythromycin (40 mg/kg/d orally in three or four divided doses) or, penicillin V potassium (50 mg/kg/d) for 10 days, or benzathine penicillin G (600,000–1,200,000 units intramuscularly), and they must be quarantined. Before they can be released, carriers must have two negative cultures of both the nose and the throat taken 24 hours apart and obtained at least 24 hours after the cessation of antibiotic therapy.

» Prognosis

Mortality varies from 3% to 25% and is particularly high in the presence of early myocarditis. Neuritis is reversible; it is fatal only if an intact airway and adequate respiration cannot be maintained. Permanent heart damage from myocarditis occurs rarely.

INFECTIONS DUE TO ENTEROBACTERIACEAE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Diarrhea by several different mechanisms due to Ecoli.
- Hemorrhagic colitis and hemolytic-uremic syndrome.
- Neonatal sepsis or meningitis.
- Urinary tract infection.
- Opportunistic infections.
- Diagnosis confirmed by culture.

General Considerations

Enterobacteriaceae are a family of gram-negative bacilli that are normal flora in the gastrointestinal tract and are also found in water and soil. They cause gastroenteritis, urinary tract infections, neonatal sepsis and meningitis, and opportunistic infections. E coli is the organism in this family that most commonly causes infection in children, but Klebsiella, Morganella, Enterobacter, Serratia, Proteus, and other genera are also important, particularly in the immune compromised host. Shigella and Salmonella are discussed in separate sections.

E coli strains capable of causing diarrhea were originally termed enteropathogenic E coli (EPEC) and were recognized by serotype. It is now known that E coli may cause diarrhea by several distinct mechanisms. Classic EPEC strains cause a characteristic histologic injury in the small bowel termed adherence and effacement. Enterotoxigenic E coli (ETEC) causes a secretory, watery diarrhea. ETEC adheres to enterocytes and secretes one or more plasmid-encoded enterotoxins. One of these, heat-labile toxin, resembles cholera toxin in structure, function, and mechanism of action. Enteroinvasive E coli (EIEC) are very similar to Shigella in their pathogenetic mechanisms. Shigella-toxin producing E coli (STEC) cause hemorrhagic colitis and the hemolytic-uremic syndrome. The most common STEC serotype is O157:H7, although several other serotypes cause the same syndrome. These strains elaborate one of several cytotoxins, closely related to Shiga toxin produced by Shigella dysenteriae. Outbreaks of hemolytic-uremic syndrome associated with STEC have followed consumption of inadequately cooked ground beef. Thorough heating to 68–71°C is necessary. Unpasteurized fruit juice, various uncooked vegetables, and contaminated water also have caused infections and epidemics. The common source for STEC in all of these foods and water is the feces of cattle or several other animals. Person-to-person spread including spread in day care centers by the fecal-oral route has been reported. Over 6400 cases of STEC were reported in the United States in 2012.

E coli that aggregate on the surface of hep cells in tissue culture are termed enteroaggregative E coli (EAggEC). EAggEC causes diarrhea by a distinct but unknown mechanism.

Eighty percent of E coli strains causing neonatal meningitis possess a specific capsular polysaccharide (K1 antigen), which, alone or in association with specific somatic antigens, confers virulence. Klebsiella, Enterobacter, Serratia, and Morganella are normally found in the gastrointestinal tract and in soil and water. Klebsiella may cause a bronchopneumonia with cavity formation. Klebsiella, Enterobacter, and Serratia are often hospital-acquired opportunists associated with antibiotic usage, debilitated states, and chronic respiratory conditions. They frequently cause urinary tract infection or sepsis. Many of these infections are difficult to treat because of antibiotic resistance. Antibiotic susceptibility tests are necessary. Parenteral third-generation cephalosporins are usually more active than ampicillin, but resistance due to high-level production of chromosomal cephalosporinase may occur. Aminoglycoside antibiotics are usually effective but require monitoring of serum levels to ensure therapeutic and nontoxic levels. Carbapenem-resistant Enterobacteriaceae are a serious concern due to limited options for therapy.

Clinical Findings

A. Symptoms and Signs

1. E coli gastroenteritis—E coli may cause diarrhea of varying types and severity. ETEC usually produce mild, self-limiting illness without significant fever or systemic toxicity, often known as traveler's diarrhea. However, diarrhea may be severe in newborns and infants, and occasionally an older child or adult will have a cholera-like syndrome. EIEC strains cause a shigellosis-like illness, characterized by fever, systemic symptoms, blood and mucus in the stool, and leukocytosis, but currently are uncommon in the United States. STEC strains cause hemorrhagic colitis. Diarrhea initially is watery and fever usually is absent. Abdominal pain and cramping occur; diarrhea progresses to blood streaking or grossly bloody stools. Hemolytic-uremic syndrome occurs within a few days of diarrhea in 2%–5% of children with STEC diarrhea and is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (see Chapter 24).

2. Neonatal sepsis—Findings include jaundice, hepatosplenomegaly, fever, temperature lability, apneic spells, irritability, and poor feeding. Respiratory distress develops when pneumonia occurs; it may appear indistinguishable from respiratory distress syndrome in preterm infants. Meningitis is associated with sepsis in 25%–40% of cases. Other metastatic foci of infection may be present, including pneumonia and pyelonephritis. Sepsis may lead to severe metabolic acidosis, shock, DIC, and death.

3. Neonatal meningitis—Findings include high fever, full fontanelles, vomiting, coma, convulsions, pareses or paralyses, poor or absent Moro reflex, opisthotonos, and occasionally hypertonia or hypotonia. Sepsis coexists or precedes meningitis in most cases. Thus, signs of sepsis often accompany those of meningitis. CSF usually shows a cell count of over 1000 WBC/μL, mostly polymorphonuclear neutrophils, and bacteria on Gram stain. CSF glucose concentration is low (usually less than half that of blood), and the protein is elevated above the levels normally seen in newborns and premature infants (> 150 mg/dL).

4. Acute urinary tract infection—Symptoms include dysuria, increased urinary frequency, and fever in the older child. Nonspecific symptoms such as anorexia, vomiting,

irritability, failure to thrive, and unexplained fever are seen in children younger than age 2 years. Young infants may present with jaundice. As many as 1% of school-aged girls and 0.05% of boys have asymptomatic bacteriuria. Screening for and treatment of asymptomatic bacteriuria is not recommended.

B. Laboratory Findings

Because E coli are normal flora in the stool, a positive stool culture alone does not prove that the E coli in the stool are causing disease. Serotyping, biochemical and nucleic acid tests for enterotoxin production or invasiveness, and tests for P-fimbriae are performed in research laboratories. MacConkey agar with sorbitol substituted for lactose (SMAC agar) is useful to screen stool for STEC. Serotyping and testing for STEC enterotoxin are available at many state health departments and increasingly from commercial and hospital laboratories. Blood cultures are positive in neonatal sepsis. Cultures of CSF and urine should also be obtained. The diagnosis of urinary tract infections is discussed in Chapter 24.

» Differential Diagnosis

The clinical picture of EPEC infection may resemble that of salmonellosis, shigellosis, or viral gastroenteritis. Neonatal sepsis and meningitis caused by E coli can be differentiated from other causes of neonatal infection only by blood and CSF culture.

» Treatment

A. Specific Measures

1. E coli **gastroenteritis—**Gastroenteritis due to EPEC seldom requires antimicrobial treatment. Fluid and electrolyte therapy, preferably given orally, may be required to avoid dehydration. Bismuth subsalicylate reduces stool volume by about one-third in infants with watery diarrhea, including ETEC. In nursery outbreaks, E coli gastroenteritis has been treated with neomycin (100 mg/kg/d orally in three divided doses for 5 days). Clinical efficacy is not established. Traveler's diarrhea may be treated with azithromycin in children and with fluoroquinolones in adults, although resistance to these drugs is increasing. The risk of hemolytic-uremic syndrome is not proven to be increased by antimicrobial therapy of enterohemorrhagic Escherichia coli (EHEC) cases, but most experts recommend no treatment of suspected cases.

2. E coli **sepsis and pneumonia—**The drugs of choice are ampicillin (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 4–6 hours), cefotaxime (150–200 mg/kg/d, given intravenously or intramuscularly in divided doses every 6–8 hours), ceftriaxone (50–100 mg/kg/d, given intramuscularly as single dose or in two divided doses), and gentamicin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in divided doses every 8 hours). Initial therapy often includes at least two drugs until microbial etiology is established and susceptibility testing is completed. Treatment is continued for 10–14 days. Amikacin or tobramycin may be used instead of gentamicin if the strain is susceptible. Third-generation cephalosporins are often an attractive alternative as single-drug therapy and do not require monitoring for toxicity.

3. E coli **meningitis—**Third-generation cephalosporins such as cefotaxime (200 mg/kg/d intravenously in four divided doses) are given for a minimum of 3 weeks. Ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) and gentamicin (5.0–7.5 mg/kg/d intramuscularly or intravenously in three divided doses) also are effective for susceptible strains. Serum levels need to be monitored. Treatment with intrathecal and intraventricular aminoglycosides does not improve outcome.

4. Acute urinary tract infection—(See Chapter 24.)

» Prognosis

Death due to gastroenteritis leading to dehydration can be prevented by early fluid and electrolyte therapy. Neonatal sepsis with meningitis is still associated with a mortality rate of over 50%. Most children with recurrent urinary tract infections do well if they have no underlying anatomic defects. The mortality rate in opportunistic infections usually depends on the severity of infection and the underlying immune compromising condition.

PSEUDOMONAS INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Opportunistic infection.
- Confirmed by cultures.

General Considerations

Pseudomonas aeruginosa is an aerobic gram-negative rod with versatile metabolic requirements. The organism may grow in distilled water and in commonly used disinfectants, complicating infection control in medical facilities. P aeruginosa is both invasive and destructive to tissue as well as toxigenic due to secreted exotoxins, all factors that contribute to virulence. Other genera previously classified as Pseudomonas frequently cause nosocomial infections and infections in immunocompromised children. Stenotrophomonas maltophilia (previously Pseudomonas maltophilia) and Burkholderia cepacia (previously Pseudomonas cepacia) are the most frequent.

P aeruginosa is an important cause of infection in children with cystic fibrosis, neoplastic disease, neutropenia, or extensive burns and in those receiving antibiotic therapy. Infections of the urinary and respiratory tracts, ears, mastoids, paranasal sinuses, eyes, skin, meninges, and bones are seen. Pseudomonas pneumonia is a common nosocomial infection in patients receiving assisted ventilation.

P aeruginosa sepsis may be accompanied by characteristic peripheral lesions called ecthyma gangrenosum. Ecthyma gangrenosum also may occur by direct invasion through intact skin in the groin, axilla, or other skinfolds. P aeruginosa is an infrequent cause of sepsis in previously healthy infants and may be the initial sign of underlying medical problems. Osteomyelitis of the calcaneus or other foot bones occurs after punctures such as stepping on a nail and is commonly due to P aeruginosa.

P aeruginosa is a frequent cause of malignant external otitis media and of chronic suppurative otitis media. Outbreaks of vesiculopustular skin rash have been associated with exposure to contaminated water in whirlpool baths and hot tubs.

P aeruginosa infects the tracheobronchial tree of nearly all patients with cystic fibrosis. Mucoid exopolysaccharide, an exuberant capsule, is characteristically overproduced by isolates from patients with cystic fibrosis. Although bacteremia seldom occurs, patients with cystic fibrosis ultimately succumb to chronic lung infection with P aeruginosa. Infection due to B cepacia has caused a rapidly progressive pulmonary disease in some colonized patients and may be spread by close contact.

Clinical Findings

The clinical findings depend on the site of infection and the patient's underlying disease. Sepsis with these organisms resembles gram-negative sepsis with other organisms, although the presence of ecthyma gangrenosum suggests the etiologic diagnosis. The diagnosis is made by culture. Pseudomonas infection should be suspected in neonates and neutropenic patients with clinical sepsis. A severe necrotizing pneumonia occurs in patients on ventilators.

Patients with cystic fibrosis have a persistent bronchitis that progresses to bronchiectasis and ultimately to respiratory failure. During exacerbations of illness, cough and sputum production increases with low-grade fever, malaise, and diminished energy.

The purulent aural drainage without fever in patients with chronic suppurative otitis media is not distinguishable from that due to other causes.

Prevention

A. Infections in Debilitated Patients

Colonization of extensive second- and third-degree burns by P aeruginosa can lead to fatal septicemia. Aggressive debridement and topical treatment with 0.5% silver nitrate solution, 10% mafenide cream, or silver sulfadiazine will greatly inhibit P aeruginosa contamination of burns. (See Chapter 12 for a discussion of burn wound infections and prevention.)

B. Nosocomial Infections

Faucet aerators, communal soap dispensers, disinfectants, improperly cleaned inhalation therapy equipment, infant incubators, and many other sources that usually are associated with wet or humid conditions all have been associated with Pseudomonas epidemics. Patient-to patient transmission by hospital staff carrying Pseudomonas on the hands occurs in some units where hand hygiene is inadequate. Careful maintenance of equipment and enforcement of infection control procedures are essential to minimize nosocomial transmission.

C. Patients with Cystic Fibrosis

Chronic infection of the lower respiratory tract occurs in nearly all patients with cystic fibrosis. The infecting organism is seldom cleared from the respiratory tract, even with intensive antimicrobial therapy, and the resultant injury to the lung eventually leads to pulmonary insufficiency. Treatment is aimed at controlling signs and symptoms of the infection.

Treatment

P aeruginosa is inherently resistant to many antimicrobials and may develop resistance during therapy. Mortality

rates in hospitalized patients exceed 50%, owing both to the severity of underlying illnesses in patients predisposed to Pseudomonas infection and to the limitations of therapy. Antibiotics effective against Pseudomonas include the aminoglycosides, ureidopenicillins (piperacillin), β-lactamase inhibitor with a ureidopenicillin (piperacillin-tazobactam), expanded-spectrum cephalosporins (ceftazidime and cefepime), imipenem, meropenem, and ciprofloxacin. Colistin has been used in some children with multidrug resistance. Antimicrobial susceptibility patterns vary from area to area, and sometimes by unit within a hospital. Resistance tends to appear as new drugs become popular. Treatment of infections is best guided by clinical response and susceptibility tests.

Gentamicin or tobramycin (5.0–7.5 mg/kg/d, given intramuscularly or intravenously in three divided doses) or amikacin (15–22 mg/kg/d, given in two or three divided doses) in combination with piperacillin (240–300 mg/kg/d, given intravenously in four to six divided doses) or with another antipseudomonal β-lactam antibiotic is recommended for treatment of serious Pseudomonas infections. Ceftazidime (150–200 mg/kg/d, given in four divided doses) or cefepime (150 mg/kg/d, given in three divided doses) has activity against susceptible strains. Treatment should be continued for 10–14 days. Treatment with two active drugs is recommended for all serious infections. Aerosolized antipseudomonal antibiotrics, tobramycin, and aztreonam have been very usefukl adjunctive therapy for patients with cystic fibrosis.

Pseudomonas osteomyelitis due to punctures requires thorough surgical debridement and antimicrobial therapy for 2 weeks. Pseudomonas folliculitis does not require antibiotic therapy.

Oral or intravenous ciprofloxacin is also effective against susceptible P aeruginosa, but is not approved by the FDA for use in children except in the case of urinary tract infection. Nonetheless, in some circumstances of antimicrobial resistance, or when the benefits clearly outweigh the small risks, ciprofloxacin may be used.

Chronic suppurative otitis media responds to intravenous ceftazidime (150–200 mg/kg/d in three or four divided doses) given until the drainage has ceased for 3 days. Twice-daily ceftazidime with aural debridement and cleaning given on an outpatient basis has also been successful. Swimmer's ear may be caused by P aeruginosa and responds well to topical drying agents (alcohol–vinegar mix) and cleansing.

» Prognosis

Because debilitated patients are most frequently affected, the mortality rate is high. These infections may have a protracted course, and eradication of the organisms may be difficult.

SALMONELLA GASTROENTERITIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Nausea, vomiting, headache, meningismus.
- Fever, diarrhea, abdominal pain.
- Culture of organism from stool, blood, or other specimens.

» General Considerations

Salmonellae are gram-negative rods that frequently cause food-borne gastroenteritis and occasionally bacteremic infection of bone, meninges, and other foci. Approximately 2400 serotypes of Salmonella enterica are recognized. Salmonella typhimurium is the most frequently isolated serotype in most parts of the world. Although 53,800 cases were reported in 2012, it is estimated that only 1% are reported, suggesting that more than 5 million cases occur yearly in the United States.

Salmonella are able to penetrate the mucin layer of the small bowel and attach to epithelial cells. Organisms penetrate the epithelial cells and multiply in the submucosa. Infection results in fever, vomiting, and watery diarrhea; the diarrhea occasionally includes mucus and polymorphonuclear neutrophils in the stool. Salmonella infections in childhood occur in two major forms: (1) gastroenteritis (including food poisoning), which may be complicated by sepsis and focal suppurative complications; and (2) enteric fever (typhoid fever and paratyphoid fever) (see section Typhoid Fever and Paratyphoid Fever). Although the incidence of typhoid fever has decreased in the United States, the incidence of Salmonella gastroenteritis has greatly increased in the past 15–20 years. The highest attack rates occur in children younger than age 6 years, with a peak in the age group from 6 months to 2 years.

Salmonellae are widespread in nature, infecting domestic and wild animals. Fowl and reptiles have a particularly high carriage rate. Transmission occurs by the fecal-oral

route via contaminated food, water, fomites, and sometimes person-to-person. Numerous foods, especially milk and egg products are associated with outbreaks. Animal contact also can be a source for Salmonella.

Because salmonellae are susceptible to gastric acidity, the elderly, infants, and patients taking antacids or H_2-blocking drugs are at increased risk for infection. Most cases of Salmonella meningitis (80%) and bacteremia occur in infancy. Newborns may acquire the infection from their mothers during delivery and may precipitate outbreaks in nurseries. Newborns are at special risk for developing meningitis.

» Clinical Findings

A. Symptoms and Signs

There is a very wide range of severity of infection. Infants usually develop fever, vomiting, and diarrhea. The older child also may complain of headache, nausea, and abdominal pain. Stools are often watery or may contain mucus and, in some instances, blood, suggesting shigellosis. Drowsiness and disorientation may be associated with meningismus. Convulsions occur less frequently than with shigellosis. Splenomegaly occasionally occurs. In the usual case, diarrhea is moderate and subsides after 4–5 days, but it may be protracted.

B. Laboratory Findings

Diagnosis is made by isolation of the organism from stool, blood, or, in some cases, from urine, CSF, or pus from a suppurative lesion. The WBC count usually shows a polymorphonuclear leukocytosis but may show leukopenia. Salmonella isolates should be reported to public health authorities for epidemiologic purposes.

» Differential Diagnosis

In staphylococcal food poisoning, the incubation period is shorter (2–4 hours) than in Salmonella food poisoning (12–24 hours), fever is absent, and vomiting rather than diarrhea is the main symptom. In shigellosis, many polymorphonuclear leukocytes usually are seen on a stained smear of stool, and the peripheral WBC count is more likely to slow a marked left shift, although some cases of salmonellosis are indistinguishable from shigellosis. Campylobacter gastroenteritis commonly resembles salmonellosis. Culture of the stools is necessary to distinguish the causes of bacterial gastroenteritis.

» Complications

Unlike most types of infectious diarrhea, salmonellosis is frequently accompanied by bacteremia, especially in newborns and infants. Septicemia with extraintestinal infection is seen, most commonly with Salmonella choleraesuis but also with Salmonella enterica, typhimurium, and paratyphi serotypes. The organism may spread to any tissue and may cause arthritis, osteomyelitis, cholecystitis, endocarditis, meningitis, pericarditis, pneumonia, or pyelonephritis. Patients with sickle cell anemia or other hemoglobinopathies have a predilection for the development of osteomyelitis. Severe dehydration and shock are more likely to occur with shigellosis but may occur with Salmonella gastroenteritis.

» Prevention

Measures for the prevention of Salmonella infections include thorough cooking of foodstuffs derived from contaminated sources, adequate refrigeration, control of infection among domestic animals, and meticulous meat and poultry inspections. Raw and undercooked fresh eggs should be avoided. Food handlers and child care workers with salmonellosis should have three negative stool cultures before resuming work. Asymptomatic children, who have recovered from Salmonella infection, do not need exclusion.

» Treatment

A. Specific Measures

In uncomplicated Salmonella gastroenteritis, antibiotic treatment does not shorten the course of the clinical illness and may prolong convalescent carriage of the organism. Colitis or secretory diarrhea due to Salmonella may improve with antibiotic therapy.

Because of the higher risk of sepsis and focal disease, antibiotic treatment is recommended in infants younger than age 3 months, in severely ill children, and in children with sickle cell disease, liver disease, recent gastrointestinal surgery, cancer, depressed immunity, or chronic renal or cardiac disease. Infants younger than age 3 months with positive stool cultures or suspected salmonellosis sepsis should be admitted to the hospital, evaluated for focal infection including cultures of blood and CSF, and given treatment intravenously. A third-generation cephalosporin is usually recommended due to frequent resistance to ampicillin and TMP-SMX. Older patients developing bacteremia during the course of gastroenteritis should receive parenteral treatment initially, and a careful search should be made for additional foci of infection. After signs and symptoms subside, these patients should receive oral medication. Parenteral and oral treatment should last a total of 7–10 days. Longer treatment is indicated for specific complications. If susceptibility tests indicate resistance to ampicillin, third-generation cephalosporins or TMP-SMX should be given. Fluoroquinolones also are efficacious but are not approved for administration to children. Fluoroquinolones or azithromycin are used for strains resistant to multiple other drugs.

Empiric therapy of gram-negative meningitis is with meropenem (120 mg/kg/d) intravenously in three divided

doses or cefepime (150 mg/kg/d) in three divided doses with adjustment based on culture and susceptibility testing.

Often ampicillin (200–300 mg/kg/d intravenously in four to six divided doses) or a third-generation cephalosporin (cefotaxime, ceftriaxone) is used for 4–6 weeks to complete therapy.

Outbreaks on pediatric wards are difficult to control. Strict hand washing, cohorting of patients and personnel, and ultimately closure of the unit may be necessary.

B. Treatment of the Carrier State

About half of patients may have positive stool cultures after 4 weeks. Infants tend to remain convalescent carriers for up to a year. Antibiotic treatment of carriers is not effective.

C. General Measures

Careful attention must be given to maintaining fluid and electrolyte balance, especially in infants.

» Prognosis

In gastroenteritis, the prognosis is good. In sepsis with focal suppurative complications, the prognosis is more guarded. The case fatality rate of Salmonella meningitis is high in infants. There is a strong tendency to relapse if treatment is not continued for at least 4 weeks.

TYPHOID FEVER & PARATYPHOID FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Insidious or acute onset of headache, anorexia, vomiting, constipation or diarrhea, ileus, and high fever.
- Meningismus, splenomegaly, and rose spots.
- Leukopenia; positive blood, stool, bone marrow, and urine cultures.
- Fever in the returning traveller.

» General Considerations

Typhoid fever is caused by the gram-negative bacillus Salmonella enterica serotype Typhi and Parathyphi. Children have a shorter incubation period than do adults (usually 5–8 days instead of 8–14 days). The organism enters the body through the walls of the intestinal tract and, following a transient bacteremia, multiplies in the reticuloendothelial cells of the liver and spleen. Persistent bacteremia and symptoms then follow. Reinfection of the intestine occurs as organisms are excreted in the bile. Bacterial emboli produce the characteristic skin lesions (rose spots). Typhoid fever is transmitted by the fecal-oral route and by contamination of food or water. Unlike other Salmonella species, there are no animal reservoirs of typhoid; each case is the result of direct or indirect contact with the organism or with an individual who is actively infected or a chronic carrier.

About 350 cases per year were reported in the United States in 2012, 80% of which are acquired during foreign travel.

» Clinical Findings

A. Symptoms and Signs

In children, the onset of typhoid fever usually is sudden rather than insidious, with malaise, headache, cough, crampy abdominal pains and distention, and sometimes constipation followed within 48 hours by diarrhea, high fever, and toxemia. An encephalopathy may be seen with irritability, confusion, delirium, and stupor. Vomiting and meningismus may be prominent in infants and young children. The classic lengthy three-stage disease seen in adult patients often is shortened in children. The prodrome may last only 2–4 days, the toxic stage only 2–3 days, and the defervescence stage 1–2 weeks.

During the prodromal stage, physical findings may be absent, but abdominal distention and tenderness, meningismus, mild hepatomegaly and splenomegaly may be present. The typical typhoidal rash (rose spots) is present in 10%–15% of children. It appears during the second week of the disease and may erupt in crops for the succeeding 10–14 days. Rose spots are erythematous maculopapular lesions 2–3 mm in diameter that blanch on pressure. They are found principally on the trunk and chest and they generally disappear within 3–4 days. The lesions usually number fewer than 20.

B. Laboratory Findings

Typhoid bacilli can be isolated from many sites, including blood, stool, urine, and bone marrow. Blood cultures are positive in 50%–80% of cases during the first week and less often later in the illness. Stool cultures are positive in about 50% of cases after the first week. Urine and bone marrow cultures also are valuable. Most patients will have negative

cultures (including stool) by the end of a 6-week period. Serologic tests (Widal reaction) are not as useful as cultures because both false-positive and false-negative results occur. Leukopenia is common in the second week of the disease, but in the first week, leukocytosis may be seen. Proteinuria, mild elevation of liver enzymes, thrombocytopenia, and DIC are common.

» Differential Diagnosis

Typhoid and paratyphoid fevers must be distinguished from other serious prolonged fevers. These include typhus, brucellosis, malaria, tularemia, tuberculosis, psittacosis, vasculitis, lymphoma, mononucleosis, and Kawasaki disease. Prolonged fever is a common presentation of typhoid in a returning traveler. The diagnosis of typhoid fever often is made clinically in developing countries, but the accuracy of clinical diagnosis is variable. In developed countries, where typhoid fever is uncommon and physicians are unfamiliar with the clinical picture, the diagnosis often is not suspected until late in the course. Positive cultures confirm the diagnosis.

» Complications

The most serious complications of typhoid fever are gastrointestinal hemorrhage (2%–10%) and perforation (1%–3%). They occur toward the end of the second week or during the third week of the disease.

Intestinal perforation is one of the principal causes of death. The site of perforation generally is the terminal ileum or cecum. The clinical manifestations are indistinguishable from those of acute appendicitis, with pain, tenderness, and rigidity in the right lower quadrant.

Bacterial pneumonia, meningitis, septic arthritis, abscesses, and osteomyelitis are uncommon complications, particularly if specific treatment is given promptly. Shock and electrolyte disturbances may lead to death.

About 1%–3% of patients become chronic typhoid carriers. Chronic carriage is defined as excretion of typhoid bacilli for more than a year, but carriage is often lifelong. Adults with underlying biliary or urinary tract disease are much more likely than children to become chronic carriers.

» Prevention

Routine typhoid vaccine is not recommended in the United States but should be considered for foreign travel to endemic areas. An attenuated oral typhoid vaccine produced from strain Ty21a has better efficacy and causes minimal side effects but is not approved for children younger than age 6 years. The vaccine is repeated after 5 years. A capsular polysaccharide vaccine (ViCPS) requires one intramuscular injection and may be given to children age 2 years and older. (See Chapter 10.)

» Treatment

A. Specific Measures

Third-generation cephalosporins such as cefotaxime (150 mg/kg divided in three doses), azithromycin (10 mg/kg on day 1, followed by 5 mg/kg for 7 days), or a fluoroquinolone are used for presumptive therapy. Antimicrobial susceptibility testing and local experience are used to direct subsequent therapy. Equally effective regimens for susceptible strains include the following: TMP-SMX (10 mg/kg trimethoprim and 50 mg/kg sulfamethoxazole per day orally in two or three divided doses), amoxicillin (100 mg/kg/d orally in four divided doses), and ampicillin (100–200 mg/kg/d intravenously in four divided doses). Aminoglycosides and first- and second-generation cephalosporins are clinically ineffective regardless of in vitro susceptibility results. Ciprofloxacin or other fluoroquinolones are efficacious but not approved in children, but may be used for multiply resistant strains. Treatment duration is 14–21 days. Patients may remain febrile for 3–5 days even with appropriate therapy.

B. General Measures

General support of the patient is exceedingly important and includes rest, good nutrition and hydration, and careful observation, with particular regard to evidence of intestinal bleeding or perforation. Blood transfusions may be needed even in the absence of frank hemorrhage.

» Prognosis

A prolonged convalescent carrier stage may occur in children. Three negative cultures after all antibiotics have been stopped are required before contact precautions are stopped. With early antibiotic therapy, the prognosis is excellent, and the mortality rate is less than 1%. Relapse occurs 1–3 weeks later in 10%–20% of patients despite appropriate antibiotic treatment.

SHIGELLOSIS (BACILLARY DYSENTERY)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cramps and bloody diarrhea.
- High fever, malaise, convulsions.
- Pus and blood in diarrheal stools examined microscopically.
- Diagnosis confirmed by stool culture.

General Considerations

Shigellae are nonmotile gram-negative rods of the family Enterobacteriaceae that are closely related to E coli. The genus Shigella is divided into four species: S dysenteriae, Shigella flexneri, Shigella boydii, and Shigella sonnei. Approximately 15,000–20,000 cases of shigellosis are reported each year in the United States. S sonnei followed by S flexneri are the most common isolates. S dysenteriae, which causes the most severe diarrhea of all species and the greatest number of extraintestinal complications, accounts for less than 1% of all Shigella infections in the United States.

Shigellosis may be a serious disease, particularly in young children, and without supportive treatment an appreciable mortality rate results. In older children and adults, the disease tends to be self-limited and milder. Shigella is usually transmitted by the fecal-oral route. Food- and water-borne outbreaks are increasing in occurrence, but are less important overall than person-to-person transmission. The disease is very communicable—as few as 200 bacteria can produce illness in an adult. The secondary attack rate in families is high, and shigellosis is a serious problem in day care centers and custodial institutions. Shigella organisms produce disease by invading the colonic mucosa, causing mucosal ulcerations and microabscesses. A plasmid-encoded gene is required for Shiga toxin production; chromosomal genes are required for invasiveness; and smooth lipopolysaccharides are required for virulence. An experimental vaccine is under development and is safe and immunogenic in young children.

Clinical Findings

A. Symptoms and Signs

The incubation period of shigellosis is usually 1–3 days. Onset is abrupt, with abdominal cramps, urgency, tenesmus, chills, fever, malaise, and diarrhea. Hallucinations and seizures sometimes accompany high fever. In severe forms, blood and mucus are seen in small stools (dysentery), and meningismus and convulsions may occur. In older children, the disease may be mild and characterized by watery diarrhea without blood. In young children, a fever of 39.4°C–40°C is common. Rarely there is rectal prolapse. Symptoms generally last 3–7 days.

B. Laboratory Findings

The total WBC count varies, but often there is a marked shift to the left. The stool may contain gross blood and mucus, and many neutrophils are seen if mucus from the stool is examined microscopically. Stool cultures are usually positive; however, they may be negative because the organism is somewhat fragile and present in small numbers late in the disease, and because laboratory techniques are suboptimal for the recovery of shigellae.

Differential Diagnosis

Diarrhea due to rotavirus infection is a winter rather than a summer disease. Usually children with viral gastroenteritis are not as febrile or toxic as those with shigellosis, and the stool does not contain gross blood or neutrophils. Intestinal infections caused by Salmonella or Campylobacter are differentiated by culture. Grossly bloody stools in a patient without fever or stool leukocytes suggest E coli O157:H7 infection. Amebic dysentery is diagnosed by microscopic examination of fresh stools or sigmoidoscopy specimens. Intussusception is characterized by an abdominal mass (so-called currant jelly stools) without leukocytes, and by absence of initial fever. Mild shigellosis is not distinguishable clinically from other forms of infectious diarrhea.

Complications

Dehydration, acidosis, shock, and renal failure are the major complications. In some cases, a chronic form of dysentery occurs, characterized by mucoid stools and poor nutrition. Bacteremia and metastatic infections are rare but serious complications. Febrile seizures are common. Fulminating fatal dysentery and hemolytic-uremic syndrome occur rarely. Reiter syndrome may follow Shigella infection in patients with HLA-B27genotype.

Treatment

A. Specific Measures

Resistance to TMP-SMX (10 mg/kg/d trimethoprim and 50 mg/kg/d sulfamethoxazole, given in two divided doses orally for 5 days) and ampicillin (100 mg/kg/d divided in four doses) is common and limits the use of these drugs to cases where results of susceptibility testing are known. Amoxicillin is not effective. Parenteral ceftriaxone is effective. Azithromycin (12 mg/kg/d on day 1, then 6 mg/kg/d for 2 days) is effective, but laboratories do not routinely perform

susceptibility testing for azithromycin. Ciprofloxacin (500 mg, given twice daily for 5 days) is efficacious in adults but is not approved for use in children. However, it may be used in children who remain symptomatic and in need of therapy, and when multiply resistant strains limit other preferred choices. Successful treatment reduces the duration of fever, cramping, and diarrhea and terminates fecal excretion of Shigella. Presumptive therapy should be limited to children with classic shigellosis or known outbreaks. Afebrile children with bloody diarrhea are more commonly infected with EHEC. Antimicrobial therapy of EHEC may increase the likelihood of hemolytic-uremic syndrome, and is not recommended.

B. General Measures

In severe cases, immediate rehydration is critical. A mild form of chronic malabsorption syndrome may supervene and require prolonged dietary control.

» Prognosis

The prognosis is excellent if vascular collapse is prevented or treated promptly by adequate fluid therapy. The mortality rate is high in very young, malnourished infants who do not receive fluid and electrolyte therapy. Convalescent fecal excretion of Shigella lasts 1–4 weeks in patients not receiving antimicrobial therapy. Long-term carriers are rare.

CHOLERA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of severe watery diarrhea.
- Persistent vomiting without nausea or fever.
- Extreme and rapid dehydration and electrolyte loss, with rapid development of vascular collapse.
- Contact with a case of cholera or with shellfish, or the presence of cholera in the community.
- Diagnosis confirmed by stool culture.

» General Considerations

Cholera is an acute diarrheal disease caused by the gram-negative organism Vibrio cholerae. It is transmitted by contaminated water or food, especially contaminated shellfish. Epidemics are common in impoverished areas where hygiene and safe water supply are limited. Typical disease is generally so dramatic that in endemic areas the diagnosis is obvious. Individuals with mild illness and young children may play an important role in transmission of the infection.

Asymptomatic infection is far more common than clinical disease. In endemic areas, rising titers of vibriocidal antibody are seen with increasing age. Infection occurs in individuals with low titers. The age-specific attack rate is highest in children younger than age 5 years and declines with age. Cholera is unusual in infancy.

Cholera toxin is a protein enterotoxin that is responsible for symptoms. Cholera toxin binds to a regulatory subunit of adenylyl cyclase in enterocytes, causing increased cyclic adenosine monophosphate and an outpouring of NaCl and water into the lumen of the small bowel.

Nutritional status is an important factor determining the severity of the diarrhea. Duration of diarrhea is prolonged in adults and children with severe malnutrition.

Cholera is endemic in India and southern and Southeast Asia and in parts of Africa. The most recent pandemic, caused by the El Tor biotype of V cholerae 01, began in 1961 in Indonesia. Epidemic cholera spread in Central and South America, with a total of 1 million cases and 9500 deaths reported through 1994. A severe cholera outbreak in Haiti began in October 2010. More than 500,000 cases and 6000 deaths are estimated. Cholera in the United States occurs after foreign travel or as a result of consumption of contaminated imported food. There is an endemic focus off the US gulf coast with cases due to consumption or raw or undercooked shellfish. Interstate shipment of oysters has resulted in cholera in several inland states. Cholera is now rare in the United States with 10–20 cases per year reported.

V cholerae is a natural inhabitant of shellfish and copepods in estuarine environments. Seasonal multiplication of V cholerae may provide a source of outbreaks in endemic areas. Chronic cholera carriers are rare. The incubation period is short, usually 1–3 days.

» Clinical Findings

A. Symptoms and Signs

Many patients infected with V cholerae have mild disease, with 1%–2% developing severe diarrhea. During severe cholera, there is a sudden onset of massive, frequent, watery stools, generally light gray in color (so-called rice-water stools) and containing some mucus but no pus. Vomiting may be projectile and is not accompanied by nausea. Within

2–3 hours, the tremendous loss of fluids results in life-threatening dehydration, hypochloremia, and hypokalemia, with marked weakness and collapse. Renal failure and irreversible peripheral vascular collapse will occur if fluid therapy is not administered. The illness lasts 1–7 days and is shortened by appropriate antibiotic therapy.

B. Laboratory Findings

Markedly elevated hemoglobin (20 g/dL) and marked acidosis, hypochloremia, and hyponatremia are seen. Stool sodium concentration may range from 80 to 120 mEq/L. Culture confirmation requires specific media and takes 16–18 hours for a presumptive diagnosis and 36–48 hours for a definitive bacteriologic diagnosis.

» Prevention

Cholera vaccine is available outside of the United States and provides 50%–75% efficacy. Protection lasts 3–6 months. Cholera vaccine is not required nor generally recommended for travelers. Tourists visiting endemic areas are at little risk if they exercise caution in what they eat and drink and maintain good personal hygiene. In endemic areas, all water and milk must be boiled, food protected from flies, and sanitary precautions observed. Simple filtration of water is highly effective in reducing cases. Thorough cooking of shellfish prevents transmission. All patients with cholera should be isolated.

Chemoprophylaxis is indicated for household and other close contacts of cholera patients. It should be initiated as soon as possible after the onset of the disease in the index patient. Tetracycline (500 mg/d for 5 days) is effective in preventing infection. TMP-SMX may be substituted in children.

» Treatment

Physiologic saline or lactated Ringer solution should be administered intravenously in large amounts to restore blood volume and urine output and to prevent irreversible shock. Potassium supplements are required. Sodium bicarbonate, given intravenously, also may be needed initially to overcome profound metabolic acidosis from bicarbonate loss in the stool. Moderate dehydration and acidosis can be corrected in 3–6 hours by oral therapy alone, because the active glucose transport system of the small bowel is normally functional. The optimal composition of the oral solution (in milliequivalents per liter [mEq/L]) is as follows: Na^+, 90; Cl^-, 80; and K^+, 20 (with glucose, 110 mmol/L).

Treatment with tetracycline (50 mg/kg/d orally in four divided doses for 2–5 days) or azithromycin (10 mg/kg/d in one dose for 1–5 days) shortens the duration of the disease in children and prevents clinical relapse but is not as important as fluid and electrolyte therapy. Tetracycline resistance occurs in some regions, and ciprofloxacin may be used depending on local resistance patterns. TMP-SMX or azithromycin should be used in children younger than age 9 years.

» Prognosis

With early and rapid replacement of fluids and electrolytes, the case fatality rate is 1%–2% in children. If significant symptoms appear and no treatment is given, the mortality rate is over 50%.

CAMPYLOBACTER INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Fever, vomiting, abdominal pain, diarrhea.
- Definitive diagnosis by stool culture.

» General Considerations

Campylobacter species are small gram-negative, curved or spiral bacilli that are commensals or pathogens in many animals. Campylobacter jejuni frequently causes acute enteritis in humans. In North America and Europe, enteritis due to C jejuni is more common than that due to Salmonella or Shigella. Campylobacter fetus causes bacteremia and meningitis in immunocompromised patients. C fetus may cause maternal fever, abortion, stillbirth, and severe neonatal infection. Helicobacter pylori (previously called Campylobacter pylori) causes gastritis and peptic ulcer disease in both adults and children (see Chapter 21).

Campylobacter colonizes domestic and wild animals, especially poultry. Numerous cases have been associated with sick puppies or other animal contacts. Contaminated food and water, improperly cooked poultry, and person-to-person spread by the fecal-oral route are common routes of transmission. Outbreaks associated with day care centers, contaminated water supplies, and raw milk have been reported. Newborns may acquire the organism from their mothers at delivery.

Clinical Findings

A. Symptoms and Signs

C jejuni enteritis can be mild or severe. In tropical countries, asymptomatic stool carriage is common. The incubation period is usually 1–7 days. The disease usually begins with sudden onset of high fever, malaise, headache, abdominal cramps, nausea, and vomiting. Diarrhea follows and may be watery or bile-stained, mucoid, and bloody. The illness is self-limiting, lasting 2–7 days, but relapses may occur. Without antimicrobial treatment, the organism remains in the stool for 1–6 weeks. Immune compromised patients may suffer prolonged or relapsing disease or complications due to bacteremia.

B. Laboratory Findings

The peripheral WBC count generally is elevated, with many band forms. Microscopic examination of stool reveals erythrocytes and pus cells.

Isolation of C jejuni from stool is not difficult but requires selective agar, incubation at 42°C rather than 35°C, and incubation in an atmosphere of about 5% oxygen and 5% CO_2 (candle jar is satisfactory).

Differential Diagnosis

Campylobacter enteritis may resemble viral gastroenteritis, salmonellosis, shigellosis, amebiasis, or other infectious diarrheas. Because it also mimics ulcerative colitis, Crohn disease, intussusception, and appendicitis, mistaken diagnosis can lead to unnecessary diagnostic testing or surgery.

Complications

The most common complication is dehydration. Other uncommon complications include erythema nodosum, convulsions, reactive arthritis, bacteremia, urinary tract infection, and cholecystitis. Guillain-Barré syndrome may follow C jejuni infection by 1–3 weeks.

Prevention

No vaccine is available. Hand washing and adherence to basic food sanitation practices help prevent disease. Hand washing and cleaning of kitchen utensils after contact with raw poultry are important.

Treatment

Treatment of fluid and electrolyte disturbances is important. Antimicrobial treatment with erythromycin in children (30–50 mg/kg/d orally in four divided doses for 5 days), azithromycin (10 mg/kg/d orally once daily) for 3 days, or ciprofloxacin terminates fecal excretion. Fluoroquinolone-resistant C jejuni are now common worldwide. Therapy given early in the course of the illness will shorten the duration of symptoms. Antimicrobials used for shigellosis, such as TMP-SMX and ampicillin, are inactive against Campylobacter. Supportive therapy is sufficient in most cases.

Prognosis

The outlook is excellent if dehydration is corrected and misdiagnosis does not lead to inappropriate diagnostic or surgical procedures.

TULAREMIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- A cutaneous or mucous membrane lesion at the site of inoculation and regional lymph node enlargement.
- Sudden onset of fever, chills, and prostration.
- History of contact with infected animals, principally wild rabbits, or history of tick exposure.
- Positive culture or immunofluorest staining of samples from mucocutaneous ulcer or regional lymph nodes.
- High serum antibody titer.

General Considerations

Tularemia is caused by Francisella tularensis, a gram-negative organism usually acquired directly from infected animals (principally wild rabbits) or by the bite of an infected tick. Occasionally infection is acquired from infected domestic dogs or cats; by contamination of the skin or mucous membranes with infected blood or tissues; by inhalation of infected material; by bites of fleas or deer flies that have been in contact with infected animals; or by ingestion of contaminated meat or water. The incubation period is short, usually 3–7 days, but may vary from 2 to 25 days.

Ticks are the most important vector of tularemia and rabbits are the classic vector. It is important to seek a history

of rabbit hunting, skinning, or food preparation in any patient who has a febrile illness with tender lymphadenopathy, often in the region of a draining skin ulcer.

» Prevention

Children should be protected from insect bites, especially those of ticks, fleas, and deer flies, by the use of proper clothing and repellents. Because rabbits are the source of most human infections, the dressing and handling of such game should be performed with great care. Rubber gloves should be worn by hunters or food handlers when handling carcasses of wild rabbits. If contact occurs, thorough washing with soap and water is indicated. For postexposure prophylaxis from an intentional release of F tularensis, a 14-day course of doxycycline or ciprofloxacin is recommended (children less than 8 years should not receive doxycycline unless benefits outweigh risks; in children less than 18 years ciprofloxacin is not approved for this indication—weigh benefits and risk).

» Clinical Findings

A. Symptoms and Signs

Several clinical types of tularemia occur in children. Sixty percent of infections are of the ulceroglandular form that starts as a relatively nonpainful, reddened papule that may be pruritic and quickly ulcerates. Soon, the regional lymph nodes become large and tender. Fluctuance quickly follows. There may be marked systemic symptoms, including high fever, chills, weakness, and vomiting. Pneumonitis occasionally accompanies the ulceroglandular form or may be seen as the sole manifestation of infection (pneumonic form). A detectable skin lesion may be absent, and localized lymphoid enlargement may exist alone (glandular form). Oculoglandular and oropharyngeal forms also occur. The latter is characterized by tonsillitis, often with membrane formation, cervical adenopathy, and high fever. In the absence of a primary ulcer or localized lymphadenitis, a prolonged febrile disease reminiscent of typhoid fever can occur (typhoidal form). Splenomegaly is common in all forms.

B. Laboratory Findings

F tularensis can be recovered from ulcers, regional lymph nodes, blood, and sputum of patients with the pneumonic form. However, the organism grows only on an enriched medium (blood-cystine-glucose agar), and laboratory handling is dangerous owing to the risk of airborne transmission to laboratory personnel. Immunofluorescent staining of biopsy material or aspirates of involved lymph nodes is diagnostic, although it is not widely available.

The WBC count is not remarkable. The diagnosis is typically confirmed with serologic testing. Antibodies are usually present during the second week of illness. In the absence of a positive culture, a tube agglutination antibody titer of ≥ 1:160 or a microagglutination titer of ≥ 1:128 is considered presumptively positive for the diagnosis of tularemia. Confirmation of disease is established by demonstration of a fourfold antibody titer rise between acute and convalescent serum samples. PCR of blood, lymph node aspirate, or tissue may be available through State Health Departments.

» Differential Diagnosis

The typhoidal form of tularemia may mimic typhoid, brucellosis, miliary tuberculosis, Rocky Mountain spotted fever, and mononucleosis. Pneumonic tularemia resembles atypical or mycotic pneumonitis. The ulceroglandular type of tularemia resembles pyoderma caused by staphylococci or streptococci, plague, anthrax, and cat-scratch fever. The oropharyngeal type must be distinguished from streptococcal or diphtheritic pharyngitis, mononucleosis, herpangina, or other viral pharyngitides.

» Treatment

A. Specific Measures

Historically, streptomycin was the drug of choice. However, gentamicin is efficacious, more available, and familiar to clinicians. A 10-day course is usually sufficient, although more severe infections may need longer therapy. Doxycycline is effective, but relapse rates are higher. Doxycycline is not usually recommended for children younger than 8 years of age unless benefits of use outweigh the risk of dental staining. Doxycycline is a static (as opposed to cidal) agent and should be given for at least 14 days. Ciprofloxacin also can be used in patients with less severe disease. Ciprofloxacin is not approved for this indication in children younger than 18 years, and is not usually recommended in children unless benefits outweigh risks.

B. General Measures

Antipyretics and analgesics may be given as necessary. Skin lesions are best left open. Glandular lesions occasionally require incision and drainage.

» Prognosis

The prognosis is excellent in most cases of tularemia that are recognized early and treated appropriately.

Center for Disease Control (CDC) and Prevention: Tularemia. Available at: http://www.cdc.gov/tularemia/clinicians/index.html.

Harik NS: Tularemia: epidemiology, diagnosis and treatment. Pediatr Annals 2013;42(7):288–292 [PMID: 23805970].

PLAGUE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Sudden onset of fever, chills, and prostration.
- Regional lymphadenitis with suppuration of nodes (bubonic form).
- Hemorrhage into skin and mucous membranes and shock (septicemia).
- Cough, dyspnea, cyanosis, and hemoptysis (pneumonia).
- History of exposure to infected animals.

General Considerations

Plague is an extremely serious acute infection caused by a gram-negative bacillus, Yersinia pestis. It is a disease of rodents that is transmitted to humans by flea bites. Plague bacilli have been isolated from ground squirrels, prairie dogs, and other wild rodents in many of the western and southwestern states in the United States. Most cases have come from New Mexico, Arizona, Colorado, and California. Direct contact with rodents, rabbits, or domestic cats provides exposure to fleas infected with plague bacilli. Most cases occur from June through September. Human plague in the United States appears to occur in cycles that reflect cycles in wild animal reservoirs.

Prevention

Proper disposal of household and commercial wastes and chemical control of rats are basic elements of plague prevention. Flea control is also important. Children vacationing in remote areas should be warned not to handle dead or dying animals. Domestic cats that roam freely in suburban areas may contact infected wild animals and acquire infected fleas. There is no commercially available vaccine for plague.

All persons exposed to plague in the previous 6 days (via personal contact with an infected person, contact with plague infected fleas, or exposure to infected tissues) should be given antimicrobial prophylaxis or be instructed to report fever or other symptoms to their physician. Persons who have close personal contact (< 2 m) with a person with pneumonic plague should receive antimicrobial prophylaxis for 7 days from the last exposure. Doxycycline or ciprofloxacin are the recommended agents for prophylaxis. For children younger than 8 years, TMP-SMX is an alternative agent but the efficacy is unknown. Patients on prophylaxis should still seek prompt medical care for onset of fever or other illness.

Clinical Findings

A. Symptoms and Signs

Plague assumes several clinical forms; the two most common are bubonic and septicemic. Pneumonic plague is uncommon.

1. Bubonic plague—After an incubation period of 2–8 days there is the sudden onset of high fever, chills, headache, vomiting, and marked delirium or clouding of consciousness. A less severe form also exists, with a less precipitous onset, but with progression over several days to severe symptoms. Although the flea bite is rarely seen, the regional lymph node, usually inguinal and unilateral, is/are painful and tender, 1–5 cm in diameter. The node usually suppurates and drains spontaneously after 1 week. Plague bacilli produce endotoxin that causes vascular necrosis. Bacilli may overwhelm regional lymph nodes and enter the circulation to produce septicemia. Severe vascular necrosis results in widely disseminated hemorrhage in skin, mucous membranes, liver, and spleen. Myocarditis and circulatory collapse may result from damage by the endotoxin. Plague meningitis or pneumonia may occur following bacteremic spread from an infected lymph node.

2. Septicemic plague—Plague may initially present as septicemia without evidence of lymphadenopathy. In some series, 25% of cases are initially septicemic. Septicemic plague carries a worse prognosis than bubonic plague, largely because it is not recognized and treated early. Patients may present with a nonspecific febrile illness characterized by fever, myalgia, chills, and anorexia. Septicemic plague may be complicated by secondary seeding of the lung causing plague pneumonia. Necrosis of distal body parts such as fingers, toes, and the nose tip may occur.

3. Primary pneumonic plague—Inhalation of Y pestis bacilli causes primary plague pneumonia. This form of plague is transmitted from human-to-human and to humans from cats with pneumonic plague and would be the form of plague most likely seen after aerosolized release of Y pestis in a bioterrorist incident. After an incubation of 1–6 days, the patient develops fever, cough, shortness of breath, and bloody, watery, or purulent sputum. Gastrointestinal symptoms are sometimes prominent. Because the initial focus of infection is the lung, buboes are usually absent; occasionally cervical buboes may be seen.

B. Laboratory Findings

Aspirate from a bubo contains bipolar-staining gram-negative bacilli. Pus, sputum, and blood all yield the organism. Rapid diagnosis can be made with fluorescent antibody detection or polymerase chain reaction (PCR) on clinical specimens (available through State Health Departments).

Confirmation is made by culture or serologic testing. Laboratory infections are common enough to make bacterial isolation dangerous. Cultures are usually positive within 48 hours. Paired acute and convalescent sera may be tested for a fourfold antibody rise.

» Differential Diagnosis

The septic phase of the disease may be confused with illnesses such as meningococcemia, sepsis caused by other bacteria, and rickettsioses. The bubonic form resembles tularemia, anthrax, cat-scratch fever, streptococcal adenitis, and cellulitis. Primary gastroenteritis and appendicitis may have to be distinguished.

» Treatment

A. Specific Measures

Streptomycin or gentamicin for 7–10 days (or until several days after defervescence) is effective. For patients not requiring parenteral therapy, doxycycline, ciprofloxacin or chloramphenicol may be given. Doxycycline is not usually recommended for children younger than 8 years of age and ciprofloxacin is not usually recommended for children less than 18 years of age unless benefits of use outweigh the risk. However, plague is a potentially life-threatening condition and benefits of these agents outweigh potential risks. Plague bacilli that are multiply resistant to antimicrobials are uncommon but of serious concern.

Mortality is extremely high in septicemic and pneumonic plague if specific antibiotic treatment is not started in the first 24 hours of the disease.

Every effort should be made to effect resolution of buboes without surgery. Pus from draining lymph nodes is infectious.

B. General Measures

State health officials should be notified immediately about suspected cases of plague. Pneumonic plague is highly infectious, and droplet isolation is required until the patient has been on effective antimicrobial therapy for 48 hours. All contacts of patients with pneumonic plague should receive antibiotic prophylaxis for 7 days after the last exposure. Contacts should see a physician immediately for any illness or fever.

» Prognosis

The mortality rate in untreated bubonic plague is about 50%. The mortality rate for treated pneumonic plague is 50%–60%. Recent mortality rates in New Mexico were 3% for bubonic plague and 71% for the septicemic form.

Centers for Disease Control and Prevention (CDC): Plague. Available at: http://www.cdc.gov/plague/healthcare/clinicians.html.

HAEMOPHILUS INFLUENZAE TYPE B INFECTIONS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Purulent meningitis in children younger than age 4 years with direct smears of CSF showing gram-negative pleomorphic rods.
- Acute epiglottitis: high fever, drooling, dysphagia, aphonia, and stridor.
- Septic arthritis: fever, local redness, swelling, heat, and pain with active or passive motion of the involved joint in a child 4 months to 4 years of age.
- Cellulitis: sudden onset of fever and distinctive cellulitis in an infant, often involving the cheek or periorbital area.
- In all cases, a positive culture from the blood, CSF, or aspirated pus confirms the diagnosis.

» General Considerations

H influenzae type b (Hib) has become uncommon because of widespread immunization in early infancy. The 99% reduction in incidence seen in many parts of the United States is due to high rates of vaccine coverage and reduced nasopharyngeal carriage after vaccination. Forty percent of cases occur in children younger than 6 months who are too young to have completed a primary immunization series. Hib may cause meningitis, bacteremia, epiglottitis (supraglottic croup), septic arthritis, periorbital and facial cellulitis, pneumonia, and pericarditis. Non-type b encapsulated strains may cause meningitis, bacteremia and other disease similar to Hib. Recently, an increase in H influenzae types a and f invasive disease has been observed. Third-generation cephalosporins are preferred for initial therapy of invasive Haemophilus infections. Ampicillin is adequate for culture-proved susceptible strains.

Unencapsulated, nontypeable H influenzae frequently colonize the mucous membranes and cause otitis media, sinusitis, bronchitis, and pneumonia in children and adults. Unencapsulated, nontypeable H influenza also cause invasive disease. Neonatal sepsis similar to early-onset GBS is recognized. Obstetric complications of chorioamnionitis and bacteremia are usually the source of neonatal cases.

Ampicillin resistance occurs in 25%–40% of nontypeable H influenzae. Beta-lactamase-negative, ampicillin-resistant (BLNAR) H influenzae has emerged as a clinically important pathogen in Europe, Japan, and Canada. In the United States, the prevalence of BLNAR strains currently remains at around 3%.

» Prevention

Several carbohydrate protein conjugate Hib vaccines are currently available (see Chapter 10).

The risk of invasive Hib disease is highest in unimmunized, or partially immunized, household contacts of a Hib patient when the contact is younger than 4 years of age. The following situations require rifampin chemoprophylaxis of all household contacts (except pregnant women) to eradicate potential nasopharyngeal colonization with Hib and limit risk of invasive disease: (1) families where at least one household contact is younger than age 4 years and either unimmunized or incompletely immunized against Hib; (2) an immunocompromised child (of any age or immunization status) resides in the household; or (3) a child younger than age 12 months resides in the home and has not received the primary series of the Hib vaccine. Preschool and day care center contacts may need prophylaxis if more than one case has occurred in the center in the previous 60 days (discuss with state health officials). The index case also needs chemoprophylaxis if less than 2 years of age or if the patient resides in a household with a household contact at risk of disease (as described above) and if treated with an antibiotic regimen other than ceftriaxone or cefotaxime (both are effective in eradication of Hib from the nasopharynx). Household contacts and index cases older than 1 month of age who need chemoprophylaxis should be given rifampin, 20 mg/kg per dose (maximum adult dose, 600 mg) orally, once daily for 4 successive days. Infants who are younger than 1 month should be given oral rifampin (10 mg/kg per dose once daily for 4 days). Rifampin should not be used in pregnant females. Chemoprophylaxis is not recommended for household contacts of children with invasive disease caused by H. influenzae strains other than type B.

» Clinical Findings

A. Symptoms and Signs HIB and Non-Type B Invasive Disease

1. Meningitis—Infants usually present with fever, irritability, lethargy, poor feeding with or without vomiting, and a high-pitched cry.

2. Acute tpiglottitis—The most useful clinical finding in the early diagnosis of Haemophilus epiglottitis is evidence of dysphagia, characterized by a refusal to eat or swallow saliva and by drooling. This finding, plus the presence of a high fever in a toxic child—even in the absence of a cherry-red epiglottis on direct examination—should strongly suggest the diagnosis and lead to prompt intubation. Stridor is a late sign (see Chapter 19).

3. Septic arthritis—In the prevaccine era, Hib was a common cause of septic arthritis in unimmunized children younger than age 4 years in the United States. The child is febrile and refuses to move the involved joint and limb because of pain. Examination reveals swelling, warmth, redness, tenderness on palpation, and severe pain on attempted movement of the joint.

4. Cellulitis—Cellulitis due to Hib occurs almost exclusively in children between the ages of 3 months and 4 years but is now uncommon as a result of immunization. The cheek or periorbital (preseptal) area is often involved.

B. Laboratory Findings

The WBC count in Hib infections may be high or normal with a shift to the left. A positive culture of blood, CSF, aspirated pus or fluid from the involved site proves the diagnosis. In untreated meningitis, CSF smear may show the characteristic pleomorphic gram-negative rods.

C. Imaging

A lateral view of the neck may suggest the diagnosis in suspected acute epiglottitis, but misinterpretation is common. Intubation should not be delayed to obtain radiographs.

» Differential Diagnosis

A. Meningitis

Meningitis must be differentiated from head injury, brain abscess, tumor, lead encephalopathy, and other forms of meningoencephalitis, including mycobacterial, viral, fungal, and bacterial agents.

B. Acute Epiglottitis

In croup caused by viral agents (parainfluenza 1, 2, and 3, respiratory syncytial virus, influenza A, adenovirus), the child has more definite upper respiratory symptoms, cough, hoarseness, slower progression of obstructive signs, and lower fever. Spasmodic croup usually occurs at night in a child with a history of previous attacks. Sudden onset of choking and paroxysmal coughing suggests foreign body aspiration. Retropharyngeal abscess may have to be differentiated from epiglottitis.

C. Septic Arthritis

Differential diagnosis includes acute osteomyelitis, prepatellar bursitis, cellulitis, rheumatic fever, and fractures and sprains.

D. Cellulitis

Erysipelas, streptococcal cellulitis, insect bites, and trauma (including popsicle panniculitis or other types of freezing injury) may mimic Hib cellulitis. Periorbital cellulitis must be differentiated from paranasal sinus disease without cellulitis, allergic inflammatory disease of the lids, conjunctivitis, and herpes zoster infection.

» Complications

A. Meningitis (See Chapter 25)

B. Acute Epiglottitis

The disease may rapidly progress to complete airway obstruction with complications owing to hypoxia. Mediastinal emphysema and pneumothorax may occur.

C. Septic Arthritis

Septic arthritis may result in rapid destruction of cartilage and ankylosis if diagnosis and treatment are delayed. Even with early treatment, the incidence of residual damage and disability after septic arthritis in weight-bearing joints may be as high as 25%.

D. Cellulitis

Bacteremia may lead to meningitis or pyarthrosis.

» Treatment

All patients with bacteremic or potentially bacteremic H influenzae diseases require hospitalization for treatment. The drugs of choice in hospitalized patients are a third-generation cephalosporin (cefotaxime or ceftriaxone) until the sensitivity of the organism is known. Meropenem is an alternative choice. Persons with invasive Hib disease should be in droplet isolation for 24 hours after initiation of parenteral antibiotic therapy.

A. Meningitis

Therapy is begun as soon as bacterial meningitis is suspected. Empiric intravenous therapy recommended for meningitis (until organism identified) is vancomycin in combination with either cefotaxime or ceftriaxone. Once the organism has been identified as Haemophilus influenza and the susceptibilities are known, the antibiotic regimen can be tailored accordingly. Most isolates will be susceptible to ceftriaxone or cefotaxime, and some to ampicillin. Meropenem is an alternative agent. Therapy should preferably be given intravenously for the entire course. Ceftriaxone may be given intramuscularly if venous access becomes difficult.

Duration of therapy is 10 days for uncomplicated meningitis. Longer treatment is reserved for children who respond slowly or have complications.

Dexamethasone given immediately after diagnosis and continued for 4 days may reduce the incidence of hearing loss in children with Hib meningitis. The use of dexamethasone is controversial, but when it is used the dosage is 0.6 mg/kg/d in four divided doses for 4 days. Starting dexamethasone more than 6 hours after antibiotics have been initiated is unlikely to provide benefits.

Repeated lumbar punctures are usually not necessary in Hib meningitis. They should be obtained in the following circumstances: unsatisfactory or questionable clinical response, seizure occurring after several days of therapy, if the neurologic examination is abnormal or difficult to evaluate, or prolonged (7 days) or recurrent fever.

B. Acute Epiglottitis (See Chapter 19)

C. Septic Arthritis

Initial therapy should include an effective antistaphylococcal antibiotic and cefotaxime or ceftriaxone until identification of the organism is made and continued, once the isolate is known to be Haemophilus and susceptibilities are known. Occasionally isolates are resistant to third generation cephalosporins. Meropenem, if the isolate is susceptible, can be used as an alternative. If a child is improved following initial intravenous therapy, the patient can be transitioned to oral therapy based on susceptibilities. Possible oral agents should be chosen based on susceptibilities but might include amoxicillin/clavulanate (90–100 mg/kg/d of amoxicillin component in four divided doses every 6 hours). Alternative agents include second- or third-generation cephalosporins. Antibiotics should be administered under supervision to complete a 4-week course (longer if complications or signs and symptoms are unresolved). Drainage of infected joint fluid is an essential part of treatment. In joints other than the hip, this can often be accomplished by one or more needle aspirations. In hip infections—and in arthritis of other joints when treatment is delayed or clinical response is slow—surgical drainage is advised.

D. Cellulitis, Including Orbital Cellulitis

Initial therapy for orbital cellulitis should be broad spectrum antibiotics. Once the organism is known to be H influenzae and susceptibilities are known, cefotaxime, ceftriaxone, or meropenem can be used depending on susceptibilities for H influenzae coverage. Mixed infections are common and may require additional agents. Therapy is given parenterally for at least 3–7 days (some clinicians treat up to 2 weeks intravenously) followed by oral treatment. There is usually marked improvement after 72 hours of treatment. The total antibiotic course will vary with the severity of the infection, response to therapy, whether or not an abscess was present, and whether or not drainage was performed. A minimum course of 21 days is reasonable

in uncomplicated cases without abscess and good therapeutic response, assuming all signs of orbital cellulitis have completely resolved. In cases with severe ethmoid sinusitis and evidence of boney destruction at least a 4-week treatment course is advisable. Complicated cases may require longer treatment courses.

» Prognosis

The case fatality rate for Hib meningitis is less than 5%. Young infants have the highest mortality rate. One of the most common neurologic sequelae, developing in 5%–10% of patients with Hib meningitis, is sensorineural hearing loss. Patients with H influenzae meningitis should have their hearing checked during the course of the illness or shortly after recovery. Children in whom invasive Hib infection develops despite appropriate immunization should have tests to investigate immune function and to rule out HIV. The case fatality rate in acute epiglottitis is 2%–5%. Deaths are associated with bacteremia and the rapid development of airway obstruction. The prognosis for the other diseases requiring hospitalization is good with the early institution of adequate antibiotic therapy.

PERTUSSIS (WHOOPING COUGH)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Prodromal catarrhal stage (1–3 weeks) characterized by mild cough and coryza, but without fever.
- Persistent staccato, paroxysmal cough ending with a high-pitched inspiratory "whoop."
- Leukocytosis with absolute lymphocytosis.
- Diagnosis confirmed by PCR or culture of nasopharyngeal secretions.

» General Considerations

Pertussis is an acute, highly communicable infection of the respiratory tract caused by Bordetella pertussis and characterized by severe bronchitis. Children usually acquire the disease from symptomatic family contacts. Adults and adolescents who have mild respiratory illness, not recognized as pertussis, frequently are the source of infection. Asymptomatic carriage of B pertussis is not recognized. Infectivity is greatest during the catarrhal and early paroxysmal cough stage (for about 4 weeks after onset).

Pertussis cases have increased in the United States since 2000. In 2007, about 10,000 cases were reported; increased to more than 16,000 cases in 2009, and 48,277 cases in 2012. The morbidity and mortality of pertussis is greatest in young children. Fifty percent of children younger than age 1 year with a diagnosis of pertussis are hospitalized. Deaths occur primarily in children less than one year and are increasing in frequency.

The duration of immunity following natural pertussis is not known but is not lifelong. Reinfections are usually milder. Immunity following vaccination wanes in 5–10 years. The majority of young adults in the United States are susceptible to pertussis infection, and disease is probably common but unrecognized. Decreased efficacy of acellular vaccines compared to whole cell vaccines and low rates of immunization in some communities has led to increasing numbers of cases. Vaccine hesitancy has resulted in low rates of immunization and contributes significantly to epidemics of pertussis in the United States.

Bordetella parapertussis and Bordetella holmesii cause a similar but milder syndrome.

B pertussis organisms attach to the ciliated respiratory epithelium and multiply there; deeper invasion does not occur. Disease is due to several bacterial toxins, the most potent of which is pertussis toxin, which is responsible for the typical lymphocytosis.

» Clinical Findings

A. Symptoms and Signs

The onset of pertussis is insidious, with catarrhal upper respiratory tract symptoms (rhinitis, sneezing, and an irritating cough). Slight fever may be present; temperature greater than 38.3°C suggests bacterial superinfection or another cause of respiratory tract infection. After about 2 weeks, cough becomes paroxysmal, characterized by 10–30 forceful coughs ending with a loud inspiration (the whoop). Infants and adults with otherwise typical severe pertussis often lack characteristic whooping. Vomiting commonly follows a paroxysm. Coughing is accompanied by cyanosis, sweating, prostration, and exhaustion. This stage lasts for 2–4 weeks, with gradual improvement. Paroxysmal coughing may continue for some months and may worsen with intercurrent viral respiratory infection. In adults, older children, and partially immunized individuals, symptoms may consist only of irritating cough lasting 1–2 weeks. Clinical pertussis is milder in immunized children.

B. Laboratory Findings

WBC counts of 20,000–30,000/μL with 70%–80% lymphocytes typically appear near the end of the catarrhal stage; and the degree of lymphocytosis correlates with the severity of disease. Severe pulmonary hypertension and hyperleukocytosis (> 70,000/μL) are associated with severe disease and death in young children with pertussis. Many older children and adults with mild infections never demonstrate lymphocytosis. The blood picture may resemble lymphocytic leukemia or leukemoid reactions. Identification of B pertussis by culture or PCR from nasopharyngeal swabs or nasal wash specimens proves the diagnosis. The organism may be found in the respiratory tract in diminishing numbers beginning in the catarrhal stage and ending about 2 weeks after the beginning of the paroxysmal stage. After 4–5 weeks of symptoms, cultures are almost always negative. Culture requires specialized media and careful attention to specimen collection and transport. PCR detection has replaced culture in most pediatric centers because of improved sensitivity, decreased time to diagnosis, and cost. Enzyme-linked immunosorbent assays (ELISAs) for detection of antibody to pertussis toxin or filamentous hemagglutinin may be useful for diagnosis but interpretation of antibody titers may be difficult in previously immunized patients. The chest radiograph reveals thickened bronchi and sometimes shows a "shaggy" heart border.

» Differential Diagnosis

The differential diagnosis of pertussis includes bacterial, tuberculous, chlamydial, and viral pneumonia. The absence of fever in pertussis differentiates this disease from most bacterial infections. Cystic fibrosis and foreign body aspiration may be considerations. Adenoviruses and respiratory syncytial virus may cause paroxysmal coughing with an associated elevation of lymphocytes in the peripheral blood, mimicking pertussis.

» Complications

Bronchopneumonia due to superinfection is the most common serious complication. It is characterized by abrupt clinical deterioration during the paroxysmal stage, accompanied by high fever and sometimes a striking leukemoid reaction with a shift to predominantly polymorphonuclear neutrophils. Atelectasis is a second common pulmonary complication. Atelectasis may be patchy or extensive and may shift rapidly to involve different areas of lung. Intercurrent viral respiratory infection is also a common complication and may provoke worsening or recurrence of paroxysmal coughing. Otitis media is common. Residual chronic bronchiectasis is an infrequent but serious complication. Apnea and sudden death may occur during a particularly severe paroxysm. Seizures complicate 1.5% of cases, and encephalopathy occurs in 0.1%. The encephalopathy frequently is fatal. Anoxic brain damage, cerebral hemorrhage, or pertussis neurotoxins are hypothesized, but anoxia is most likely the cause. Epistaxis and subconjunctival hemorrhages are common.

» Prevention

Active immunization (see Chapter 10) with DTaP vaccine should be given in early infancy. The occurrence and increased recognition of disease in adolescents and adults contributes to the increasing number of cases. A booster dose of vaccine in adolescents between the ages of 11 and 18 years is recommended. Subsequent booster doses of Tdap are recommended for adults aged 18–60 years to replace Td boosters. Immunization of pregnant women in the last trimester, new mothers, care givers of infants less than 6 months, and healthcare workers of young children is also recommended.

Chemoprophylaxis with azithromycin should be given to exposed family, household and hospital contacts, particularly those younger than age 2 years, although data to support the efficacy of such preventive therapy are not strong. Hospitalized children with pertussis should be isolated because of the great risk of transmission to patients and staff. Several large hospital outbreaks have been reported.

» Treatment

A. Specific Measures

Antibiotics may ameliorate early infections but have no effect on clinical symptoms in the paroxysmal stage. Azithromycin is the drug of choice because it promptly terminates respiratory tract carriage of B pertussis. Azithromycin is often preferred due to ease of compliance and decreased gastrointestinal side effects. Resistance to macrolides has been rarely reported. Clarithromycin may also be used. Erythromycin given 4 times daily for 14 days is acceptable but not preferred. Ampicillin (100 mg/kg/d in four divided doses) may also be used for erythromycin-intolerant patients. Erythromycin has been associated with pyloric stenosis in infants less than 1 month of age. Azithromycin is recommended for therapy or prophylaxis in infants less than 1 month.

Corticosteroids reduce the severity of disease but may mask signs of bacterial superinfection. Albuterol (0.3–0.5 mg/kg/d in four doses) has reduced the severity of illness, but tachycardia is common when the drug is given orally, and aerosol administration may precipitate paroxysms.

B. General Measures

Nutritional support during the paroxysmal phase is important. Frequent small feedings, tube feeding, or parenteral fluid supplementation may be needed. Minimizing stimuli that trigger paroxysms is probably the best way of controlling cough. In general, cough suppressants are of little benefit.

C. Treatment of Complications

Respiratory insufficiency due to pneumonia or other pulmonary complications should be treated with oxygen and assisted ventilation if necessary. Convulsions are treated with oxygen and anticonvulsants. Bacterial pneumonia or otitis media requires additional antibiotics. Infants with an extremely high white blood cell count (> 70,000/uL) are at high risk of death and may benefit from extra-corporeal membrane oxygenation (ECMO).

» Prognosis

The prognosis for patients with pertussis has improved in recent years because of excellent nursing care, treatment of complications, attention to nutrition, and modern intensive care. However, the disease is still very serious in infants younger than age 1 year; most deaths occur in this age group. Children with encephalopathy have a poor prognosis.

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Early-onset neonatal disease:
  - Signs of sepsis a few hours after birth in an infant born with fetal distress and hepatosplenomegaly; maternal fever.
- Late-onset neonatal disease:
  - Meningitis, sometimes with monocytosis in the CSF and peripheral blood.
  - Onset at age 9–30 days.
  - Immune-suppressed patients:
  - Fever and meningitis.

» General Considerations

Listeria monocytogenes is a gram-positive, non–spore-forming aerobic rod distributed widely in the animal kingdom and in food, dust, and soil. It causes systemic infections in newborn infants and immunosuppressed older children. In pregnant women, infection is relatively mild, with fever, aches, and chills, but is accompanied by bacteremia and sometimes results in intrauterine or perinatal infection with grave consequences for the fetus or newborn. One-fourth of cases occur in pregnant women, and 20% of their pregnancies end in stillbirth or neonatal death. Listeria is present in the stool of approximately 10% of the healthy population. Persons in contact with animals are at greater risk. Outbreaks of listeriosis have been traced to contaminated cabbage in coleslaw, soft cheese, hot dogs, luncheon meats, and milk. Listeria infections have decreased since the adoption of strict regulations for ready-to-eat foods; 821 cases were reported in 2010. A large multistate outbreak due to contaminated cantaloupe caused more than 20 deaths in elderly and immunocompromised patients in 2011, and demonstrates the potential of this organism to cause serious illness.

Like GBS infections, Listeria infections in the newborn can be divided into early and late forms. Early infections are more common, leading to a severe congenital form of infection. Later infections are often characterized by meningitis, especially in immune compromised children.

» Clinical Findings

A. Symptoms and Signs

In the early neonatal form, symptoms of listeriosis usually appear on the first day of life and always by the third day. Fetal distress is common, and infants frequently have signs of severe disease at birth. Respiratory distress, diarrhea, and fever occur. On examination, hepatosplenomegaly and a papular rash are found. A history of maternal fever is common. Meningitis may accompany the septic course. The late neonatal form usually occurs after age 9 days and can occur as late as 5 weeks. Meningitis is common, characterized by irritability, fever, and poor feeding.

Listeria infections are rare in older children and usually are associated with immunodeficiency. Several recent cases were associated with tumor necrosis factor-alpha inhibitors. Signs and symptoms are those of meningitis, usually with insidious onset.

B. Laboratory Findings

In all patients except those receiving white cell depressant drugs, the WBC count is elevated, with 10%–20% monocytes. When meningitis is found, the characteristic CSF cell count is high (> 500/μL) with a predominance of polymorphonuclear neutrophils in 70% of cases. Monocytes may

predominate in up to 30% of cases. Gram-stained smears of CSF are usually negative, but short gram-positive rods may be seen. The chief pathologic feature in severe neonatal sepsis is miliary granulomatosis with microabscesses in liver, spleen, CNS, lung, and bowel.

Culture results are frequently positive from multiple sites, including blood from the infant and the mother.

» Differential Diagnosis

Early-onset neonatal disease resembles hemolytic disease of the newborn, GBS sepsis or severe cytomegalovirus infection, rubella, or toxoplasmosis. Late-onset disease must be differentiated from meningitis due to echovirus and coxsackievirus, GBS, and gram-negative enteric bacteria.

» Prevention

Immunosuppressed, pregnant, and elderly patients can decrease the risk of Listeria infection by avoiding soft unpasteurized cheeses, by thoroughly reheating or avoiding delicatessen and ready-to-eat foods, by avoiding raw meat and milk, and by thoroughly washing fresh vegetables.

» Treatment

Ampicillin (150–300 mg/kg/d every 6 hours intravenously) is the drug of choice in most cases of listeriosis. Gentamicin (2.5 mg/kg every 8 hours intravenously) has a synergistic effect with ampicillin and should be given in serious infections and to patients with immune deficits. Vancomycin may be substituted for ampicillin when empirically treating meningitis. If ampicillin cannot be used, TMP-SMX is effective. Cephalosporins are not effective. Treatment of severe disease should continue for at least 2 weeks; meningitis is treated 2–3 weeks.

» Prognosis

In a recent outbreak of early-onset neonatal disease, the mortality rate was 27% despite aggressive and appropriate management. Meningitis in older infants has a good prognosis. In immunosuppressed children, prognosis depends to a great extent on that of the underlying illness.

TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- All types: positive tuberculin test in patient or members of household, suggestive chest radiograph, history of contact, and demonstration of organism by stain and culture.
- Pulmonary: fatigue, irritability, and undernutrition, with or without fever and cough.
- Glandular: chronic cervical adenitis.
- Miliary: classic snowstorm appearance of chest radiograph.
- Meningitis: fever and manifestations of meningeal irritation and increased intracranial pressure, with characteristic CSF.

» General Considerations

Tuberculosis is a granulomatous disease caused by Mycobacterium tuberculosis. It is a leading cause of death throughout the world. Children younger than age 3 years are most susceptible. Lymphohematogenous dissemination through the lungs to extrapulmonary sites, including the brain and meninges, eyes, bones and joints, lymph nodes, kidneys, intestines, larynx, and skin, is more likely to occur in infants. Increased susceptibility occurs again in adolescence, particularly in girls within 2 years of menarche. Tuberculosis cases have declined from a high of 26,673 new cases in 1992 to 9,582 new cases reported in 2013. Only 485 of these new cases were in children less than 14 years old. High-risk groups include ethnic minorities, foreign-born persons, prisoners, residents of nursing homes, indigents, migrant workers, and healthcare providers, 65% of cases occurred in foreign born persons. Rates of tuberculosis in American Indians, Asian, Hawaiian and pacific islanders and Hispanic people are substantially greater than rates in Caucasians. Nationally about 1% if the tuberculosis cases are multiple drug resistant (MDR). HIV infection is an important risk factor for both development and spread of disease. Pediatric tuberculosis incidence mirrors the trends seen in adults.

Exposure to an infected adult is the most common risk factor in children. The primary complex in infancy and childhood consists of a small parenchymal lesion in any area of the lung with caseation of regional nodes and calcification. Postprimary tuberculosis in adolescents and adults commonly occurs in the apices of the lungs and is likely to cause chronic progressive cavitary pulmonary disease with less tendency for hematogenous dissemination. Mycobacterium bovis infection is clinically identical to M tuberculosis. M bovis may be acquired from unpasteurized dairy products obtained outside the United States.

Clinical Findings

A. Symptoms and Signs

1. Pulmonary—(See Chapter 19.)

2. Miliary—Diagnosis is suggested by the classic "snowstorm" or "millet seed" appearance of lung fields on radiograph, although early in the course of disseminated tuberculosis the chest radiograph may show no or only subtle abnormalities. Choroidal tubercles are sometimes seen on funduscopic examination. Other lesions may be present and produce osteomyelitis, arthritis, meningitis, tuberculomas of the brain, enteritis, or infection of the kidneys and liver.

3. Meningitis—Symptoms include fever, vomiting, headache, lethargy, and irritability, with signs of meningeal irritation and increased intracranial pressure, cranial nerve palsies, convulsions, and coma.

4. Lymphatic—Enlarged cervical lymph nodes usually present in a subacute manner. Involved nodes may become fixed to the overlying skin, suppurate, and drain.

B. Laboratory Findings

The tuberculin skin test (TST; 0.1 mL of intermediate-strength purified protein derivative inoculated intradermally) is positive at 48–72 hours if there is significant induration (see Table 42–3). Parental reporting of skin test results is often inaccurate. All tests should be read by professionals trained to interpret TST. False-negative results occur in malnourished patients, in those with overwhelming disease, and in 10% of children with isolated pulmonary disease. Temporary suppression of tuberculin reactivity may be seen with viral infections (eg, measles, influenza, varicella, and mumps), after live virus immunization, and during corticosteroid or other immunosuppressive drug therapy. For these reasons, a negative TST test does not exclude the diagnosis of tuberculosis. When tuberculosis is suspected in a child, household members and close adult contacts (eg, teachers and caregivers) also should be tested. Multiple puncture tests (tine tests) should not be used because they are associated with false-negative and false-positive reactions, and because standards for interpretation of positive results do not exist. Interferon gamma release assays (IGRAs) are approved to replace TST tests in adults and children older than 4 years. These assays, which have much higher specificity due to less common false-positive results from nontuberculosis mycobacteria and BCG, are increasingly used in programs of screening for tuberculosis. They are done on blood obtained by venipuncture and are further advantageous in requiring only a single visit. These tests are preferred in BCG-immunized children older than 4 years. IGRA are reported as positive, negative or indeterminate.

The ESR and CRP is usually elevated in symptomatic children. Children have pauci-bacillary disease and it may be difficult to prove the diagnosis. Cultures of pooled early morning gastric aspirates from three successive days will yield M tuberculosis in about 40% of cases, but smears on gastric specimens are usually negative. Biopsy may be necessary to establish the diagnosis, but it may be difficult to justify invasive tests in mildly ill or asymptomatic children. Therapy should not be delayed in suspected cases. The CSF in tuberculous meningitis shows slight to moderate pleocytosis (50–300 WBCs/μL, predominantly lymphocytes), decreased glucose, and increased protein.

The direct detection of mycobacteria in body fluids or discharges is best done by staining specimens with auramine-rhodamine and examining them with fluorescence microscopy; this method is superior to the Ziehl-Neelsen method.

C. Imaging

Chest radiograph should be obtained in all children with suspicion of tuberculosis at any site or with a positive skin test. Segmental consolidation with some volume loss and hilar adenopathy are common findings in children. Paratracheal adenopathy is a classic presentation. Pleural effusion also occurs with primary infection. Cavities and apical disease are unusual in children but are common in adolescents and adults.

Differential Diagnosis

Pulmonary tuberculosis must be differentiated from fungal, parasitic, mycoplasmal, and bacterial pneumonias; lung abscess; foreign body aspiration; lipoid pneumonia; sarcoidosis; and mediastinal cancer. Cervical lymphadenitis is most likely due to streptococcal or staphylococcal infections. Cat-scratch fever and infection with atypical mycobacteria may need to be distinguished from tuberculous lymphadenitis. Viral meningoencephalitis, head trauma (child abuse), lead poisoning, brain abscess, acute bacterial meningitis, brain tumor, and disseminated fungal infections must be excluded in tuberculous meningitis. A positive TST or IGRA in the patient or family contacts is frequently valuable in suggesting the diagnosis of tuberculosis. A negative TST or IGRA does not exclude tuberculosis.

Prevention

A. BCG Vaccine

Bacille Calmette–Guérin (BCG) vaccines are live-attenuated strains of M bovis. Although neonatal and childhood administration of BCG is carried out in countries with a high prevalence of tuberculosis, protective efficacy varies greatly with vaccine potency and method of delivery. BCG given to infants decreases disseminated tuberculosis but does not protect against pulmonary tuberculosis later in childhood or adolescence. In the United States, BCG vaccination is not

recommended. Because the great majority of children who have received BCG still have negative TST tests, the past history of BCG vaccination should be ignored in interpreting the skin test. IGRA is recommended rather than TSTs for screening BCG-immunized children older than 4 years.

B. Isoniazid Chemoprophylaxis

Daily administration of isoniazid (10 mg/kg/d orally; maximum 300 mg) is advised for children who are exposed by prolonged close or household contact with adolescents or adults with active disease. Isoniazid is given until 8–10 weeks after last contact. At the end of this time, a TST or IGRA test should be repeated, and therapy should be continued for an additional 7 months if the test is positive.

C. Other Measures

Tuberculosis in infants and young children is evidence of recent exposure to active infection in an adult, usually a family member or household contact. The source contact (index case) should be identified, isolated, and given treatment to prevent other secondary cases. Reporting cases to local health departments is essential for contact tracing. Exposed tuberculin-negative children should usually receive isoniazid chemoprophylaxis. If a repeated skin test is negative 8–10 weeks following the last exposure, isoniazid may be stopped. Routine tuberculin skin testing is not recommended for children without risk factors who reside in communities with a low incidence of tuberculosis. Children with no personal risk for tuberculosis but who reside in communities with a high incidence of tuberculosis should be given a skin test at school entry and then again at age 11–16 years. Children with a risk factor for acquiring tuberculosis should be tested every 2–3 years. Incarcerated adolescents and children living in a household with HIV-infected persons should have annual skin tests.

Children who immigrate into the United States from a country with a high incidence of infection should receive TST or IGRA on entry to the United States or upon presentation to healthcare providers. A past history of BCG vaccine should not delay testing.

» Treatment

A. Specific Measures

Most children with suspected active tuberculosis in the United States are hospitalized initially. However, if the source case is known and the child is not seriously ill, hospitalization is often not needed. If the infecting organism has not been isolated from the presumed source, reasonable attempts should be made to obtain it from the child using morning gastric aspirates, sputum, bronchoscopy, thoracentesis, or biopsy when appropriate. Unfortunately, cultures are frequently negative in children, and the risk of these procedures must be weighed against the yield.

Therapy is given daily for 14 days and then reduced to two to three times per week for the duration of the course. Directly observed administration of all doses of antituberculosis therapy by a trained healthcare professional is essential to ensure compliance with therapy.

Children with positive skin tests (see Table 42–3) without symptoms and a normal chest radiograph have latent tuberculosis and should receive 9 months of isoniazid (10 mg/kg/d orally; maximum 300 mg) therapy. Rifampin (10–15 mg/kg/d orally; maximum 600 mg) for 4 months is efficacious and compliance is greatly improved with the shorter duration of therapy. A combination of isoniazid and rifapentine given once per week for 12 weeks is effective in adolescents older than 12 years and adults. In children with active pulmonary disease, therapy for 6 months using isoniazid (10 mg/kg/d), rifampin (15 mg/kg/d), pyrazinamide (25–30 mg/kg/d), and ethambutol (25 mg/kg/d) in a single daily oral dose for 2 months, followed by isoniazid plus rifampin (either in a daily or twice-weekly regimen) for 4 months appears effective for eliminating isoniazid-susceptible organisms. For more severe disease, such as miliary or CNS infection, duration is increased to 12 months or more. In communities with resistance rates greater than 4%, initial therapy should usually include four drugs. The duration of therapy is prolonged in immune compromised children and if drug resistance necessitates alternative regimens.

1. Isoniazid—The hepatotoxicity from isoniazid seen in adults and some adolescents is rare in children. Transient elevation of aminotransferases (up to three times normal) is common early in treatment, but therapy is continued unless clinical illness occurs. Routine monitoring of liver function tests is unnecessary unless prior hepatic disease is known, other hepatotoxic drugs are administered, or the child is severely ill. Peripheral neuropathy associated with pyridoxine deficiency is rare in children, and it is not necessary to add pyridoxine unless significant malnutrition coexists or if the child is strictly breast-fed.

2. Rifampin—Although it is an excellent bactericidal agent, rifampin is never used alone to treat active disease, owing to rapid development of resistance. Hepatotoxicity occurs but rarely with recommended doses. Rifampin causes an orange color of urine and secretions which is benign but may stain contact lenses or clothes. Rifampin interacts with many medications including anticonvulsants, some seizure medications, birth control pills, and Coumadin.

3. Pyrazinamide—This excellent sterilizing agent is most effective during the first 2 months of therapy. With the recommended duration and dosing, it is well tolerated. Although pyrazinamide elevates the uric acid level, it rarely causes symptoms of hyperuricemia in children. Use of this

drug is now common for tuberculous disease in children, and resistance is uncommon. Oral acceptance and CNS penetration are good although gastro-intestinal side effects are common.

4. Ethambutol—Because optic neuritis is the major side effect in adults, ethambutol has usually been given only to children whose vision can be reliably tested for loss of color differentiation. Optic neuritis is rare and usually occurs in adults receiving more than the recommended dosage of 25 mg/kg/d. Documentation of optic toxicity in children is lacking despite considerable worldwide experience. Therefore, many four-drug regimens for children now include ethambutol.

5. Streptomycin—Streptomycin (20–30 mg/kg/d, given intramuscularly in one or two doses) should be given for 1 or 2 months in severe disease. The child's hearing should be tested periodically during use as ototoxicity is common.

B. Chemotherapy for Drug-Resistant Tuberculosis

The incidence of drug resistance is increasing and reaches 10%–20% in some areas of the United States. Transmission of multiple drug-resistant and extensively drug-resistant strains to contacts has occurred in some epidemics. Therapy should continue for 18 months or longer. Often, four to six first- and second-line medications are needed. Consultation with a local expert in treating tuberculosis is recommended.

C. General Measures

Corticosteroids may be used for suppressing inflammatory reactions in meningeal, pleural, and pericardial tuberculosis and for the relief of bronchial obstruction due to hilar adenopathy. Prednisone is given orally, 1 mg/kg/d for 2 weeks, with gradual withdrawal over the next 4–6 weeks. The use of corticosteroids may mask progression of disease. Accordingly, the clinician needs to be sure that an effective regimen is being used.

» Prognosis

If bacteria are sensitive and treatment is completed, most children are cured with minimal sequelae. Repeat treatment is more difficult and less successful. With antituberculosis chemotherapy (especially isoniazid), there should now be nearly 100% recovery in miliary tuberculosis. Without treatment, the mortality rate in both miliary tuberculosis and tuberculous meningitis is almost 100%. In the latter form, about two-thirds of patients receiving treatment survive. There may be a high incidence of neurologic abnormalities among survivors if treatment is started late.

INFECTIONS WITH NONTUBERCULOUS MYCOBACTERIA

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic unilateral cervical lymphadenitis.
- Granulomas of the skin.
- Chronic bone lesion with draining sinus (chronic osteomyelitis).
- Tuberculin skin test (TST) of 5–8 mm, negative chest radiograph, and negative history of contact with tuberculosis.
- Diagnosis by positive culture.
- Disseminated infection in patients with AIDS.

» General Considerations

More than 130 species of acid-fast mycobacteria other than M tuberculosis may cause subclinical infections and occasionally clinical disease resembling tuberculosis. Strains of nontuberculous mycobacteria (NTM) are common in soil, food, and water. Organisms enter the host by small abrasions in skin, oral mucosa, or gastrointestinal mucosa.

Mycobacterium avium complex (MAC), Mycobacterium kansasii, Mycobacterium fortuitum, Mycobacterium abscessus, Mycobacterium marinum, and Mycobacterium chelonae are most commonly encountered. M fortuitum, M abscessus, and M chelonae are "rapid growers" requiring 3–7 days for recovery, whereas other mycobacteria require several weeks. After inoculation they form colonies closely resembling M tuberculosis morphologically.

» Clinical Findings

A. Symptoms and Signs

1. Lymphadenitis—In children, the most common form of infection due to mycobacteria other than M tuberculosis is cervical lymphadenitis. MAC is the most common organism.

A submandibular or cervical node swells slowly and is firm and initially somewhat tender. Low-grade fever may occur. Over time, the node may suppurate and drain chronically. Nodes in other areas of the head and neck and elsewhere are sometimes involved. Chronic intermittent drainage is common, but in many cases healing occurs after 4–12 months.

2. Pulmonary disease—In the western United States, pulmonary disease is usually due to M kansasii or MAC, In the eastern United States and in other countries, disease is usually caused by MAC. In adults, there is usually underlying chronic pulmonary disease. Immune deficiency, particularly deficiency of cellular immunity, is commonly present. Presentation is clinically indistinguishable from that of tuberculosis. Adolescents with cystic fibrosis may be infected with nontuberculous mycobacteria with resulting fever and declining pulmonary function.

3. Swimming pool granuloma—This is commonly due to M marinum. A solitary chronic granulomatous lesion with satellite lesions develops after minor trauma in infected swimming pools or other aquatic sources. Minor trauma during exposure to home aquariums or other aquatic environments may also lead to infection.

4. Chronic osteomyelitis—Osteomyelitis is caused by MAC, M kansasii, M fortuitum, or other rapid growers. Findings include swelling and pain over a distal extremity, radiolucent defects in bone, fever, and clinical and radiographic evidence of bronchopneumonia. Such cases are rare.

5. Meningitis—Disease is due to M kansasii and may be indistinguishable from tuberculous meningitis.

6. Disseminated infection—Rarely, apparently immunologically normal children develop disseminated infection due to nontuberculous mycobacteria. Children are ill, with fever and hepatosplenomegaly, and organisms are demonstrated in bone lesions, lymph nodes, or liver. Chest radiographs are usually normal. Between 60% and 80% of patients with AIDS acquired MAC infection in the past, characterized by fever, night sweats, weight loss, and diarrhea. Infection usually indicates severe immune dysfunction and is associated with CD4 lymphocyte counts less than 50/μL. Infection is now very rare to more effective HIV therapy.

B. Laboratory Findings

In most cases, there is a negative or small reaction (< 10 mm) when Mantoux testing is done. Larger reactions may be seen particularly with M marinum infection. IGRA tests are commonly negative although M marinum, M kansasii, and M szulgai may cause cross-reactions. The chest radiograph is negative, and there is no history of contact with a case of tuberculosis. Needle aspiration of the node excludes bacterial infection and may yield acid-fast bacilli on stain or culture. Fistulization should not be a problem because total excision is usually recommended for infection due to atypical mycobacteria. Cultures of any normally sterile body site may yield MAC in immunocompromised patients with disseminated disease. Blood cultures are positive, with a large density of bacteria.

» Differential Diagnosis

See section on differential diagnosis in the previous discussion of tuberculosis and in Chapter 19.

» Treatment

A. Specific Measures

The usual treatment of lymphadenitis is complete surgical excision. Occasionally excision is impossible because of proximity to branches of the facial or other nerves or the salivary glands. Response of extensive adenopathy or other forms of infection to chemotherapy varies according to the infecting species and susceptibility but is often disappointingly slow. Usually, combinations of two to four medications administered for months are required. Isoniazid, rifampin, and ethambutol (depending on sensitivity to isoniazid) will result in a favorable response in almost all patients with M kansasii infection. Chemotherapeutic treatment of MAC is much less satisfactory because resistance to isoniazid, rifampin, and pyrazinamide is common. Susceptibility testing is useful to optimize therapy. Most clinicians favor surgical excision of involved tissue if possible and treatment with at least three drugs to which the organism has been shown to be sensitive. Disseminated disease in patients with AIDS requires a combination of three or more active drugs. Clarithromycin or azithromycin and ethambutol are started, in addition to one or more of the following drugs: ethionamide, capreomycin, amikacin, rifabutin, rifampin or ciprofloxacin. M fortuitum and M chelonei are usually susceptible to amikacin plus cefoxitin or meropenem followed by clarithromycin, azithromycin, or doxycycline, and may be successfully treated with such combinations. Swimming pool granuloma due to M marinum is usually treated with doxycycline (in children older than 9 years) or rifampin, plus ethambutol, clarithromycin, or TMP-SMX for a minimum of 3 months. Surgery may also be beneficial.

B. Chemoprophylaxis

Unsuccessfully treated children with HIV are given chemoprophylaxis with azithromycin or clarithromycin to prevent disseminated MAC infection when $CD4^+$ T-lympocyte counts fall below age specific levels.

C. General Measures

Isolation of the patient is usually not necessary. General supportive care is indicated for the child with disseminated disease.

» Prognosis

The prognosis is good for patients with localized disease, although fatalities occur in immunocompromised patients with disseminated disease.

Centers for Disease Control and Prevention (CDC): Mycobacterium avium complex. Available at: www.cdc.gov/ncidod/dbmd/diseaseinfo/mycobacteriumavium_t.htm.

Lopez-Varela E at el: Non-tuberculous mycobacteria in children: muddying the waters of tuberculosis diagnosis. Lancet Respir Med 2015;3(3):244 [PMID: 25773213].

LEGIONELLA INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Severe progressive pneumonia in a child with compromised immunity.
- Diarrhea and neurologic signs are common.
- Direct fluorescent antibody staining of respiratory secretions and urinary antigen tests are highly specific but do not identify all infections.

» General Considerations

Legionella pneumophila is a ubiquitous gram-negative bacillus that causes two distinct clinical syndromes: Legionnaires disease and Pontiac fever. Over 40 species of Legionella have been discovered, but not all cause disease in humans. L pneumophila causes most infections. Legionella is present in many natural water sources as well as domestic water supplies (faucets and showers), and fountains. Contaminated cooling towers and heat exchangers have been implicated in several large institutional outbreaks. Person-to-person transmission has not been documented.

Few cases of Legionnaires disease have been reported in children. Most were in children with compromised cellular immunity. In adults, risk factors include smoking, underlying cardiopulmonary or renal disease, alcoholism, and diabetes.

L pneumophila is thought to be acquired by inhalation of a contaminated aerosol. The bacteria are phagocytosed but proliferate within macrophages. Cell-mediated immunity is necessary to activate macrophages to kill intracellular bacteria.

» Prevention

No vaccine is available. Legionella is naturally found in water, so ensuring proper disinfectant and water temperature maintenance of water supplies will help prevent cases. Good cleaning, attention to pH, and proper disinfectants in hot tubs is important. Chlorine or monochloramine treatment of municipal water supplies has been shown to reduce the number of organisms and the risk of infection.

» Clinical Findings

A. Symptoms and Signs

In Legionnaires disease there is an abrupt onset of fever, chills, anorexia, and headache. Pulmonary symptoms appear within 2–3 days and progress rapidly. The cough is nonproductive early. Purulent sputum occurs late. Hemoptysis, diarrhea, and neurologic signs (including lethargy, irritability, tremors, and delirium) are seen. Pontiac fever is a milder, self-limited illness without evidence of pneumonia.

B. Laboratory Findings

The WBC count is usually elevated in Legionnaires disease. Chest radiographs show rapidly progressive patchy consolidation. Cavitation and large pleural effusions are uncommon. Cultures from sputum, tracheal aspirates, or bronchoscopic specimens, when grown on specialized media are positive in 70%–80% of patients at 3–5 days of culture. Direct fluorescent antibody staining of sputum or other respiratory specimens is only 50%–70% sensitive but 95% specific. A false-positive test can be seen in patients with tularemia. A negative result on culture or direct fluorescent antibody staining of sputum or tracheal secretions does not rule out disease due to Legionella. PCR detection of respiratory secretions for Legionella is available at some centers. Urine antigen tests for Legionella antigen are highly specific, but only detect L pneumophila serotype 1, which is the most community-acquired L pneumophila infection. Performance of both culture and urine antigen testing should facilitate diagnosis. Serologic tests are available, but a maximum rise in titer may require 4–6 weeks.

» Differential Diagnosis

Legionnaires disease is usually a rapidly progressive pneumonia in a patient who appears very ill with unremitting fevers. Other bacterial pneumonias, viral pneumonias, Mycoplasma pneumonia, and fungal disease are all possibilities and may be difficult to differentiate clinically in an immunocompromised patient.

» Complications

In sporadic untreated cases, mortality rates are 5%–25%. The mortality rate is < 5% in normal hosts with early, appropriate therapy. In immunocompromised patients with untreated disease, mortality approaches 80%. Hematogenous dissemination may result in extrapulmonary foci of infection,

including pericardium, myocardium, and kidneys. Legionella may be the cause of culture-negative endocarditis.

» Treatment

Intravenous azithromycin, 10 mg/kg/d given as a once-daily dose (maximum dose 500 mg), is the drug of choice in most children. In immunocompromised patients, levofloxacin is recommended (not approved for this indication in children < 18 years of age) because fluoroquinolones are bactericidal agents. Doxycycline (not recommended for children < 8 years of age unless benefit exceeds risk) and TMP-SMX are alternative agents. Duration of therapy is 5–10 days if azithromycin is used; for other antibiotics a 14- to 21-day course. Oral therapy may be substituted for intravenous therapy as the patient's condition improves.

» Prognosis

Mortality rate is high if treatment is delayed. Malaise, problems with memory, and fatigue are common after recovery.

CHLAMYDOPHILA INFECTIONS (PSITTACOSIS [ORNITHOSIS], C PNEUMONIAE, & C TRACHOMATIS)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Psittacosis:

- Fever, cough, malaise, chills, headache.
- Diffuse rales; no consolidation.
- Long-lasting radiographic findings of bronchopneumonia.
- Isolation of the organism or rising titer of complement fixing antibodies.
- Exposure to infected birds (ornithosis).

» Neonatal Chlamydophila (Chlamydia) conjunctivitis:

- Watery, mucopurulent, to blood tinged discharge and conjunctival injection presenting from a few days of life until 16 weeks of age.
- May be associated with neonatal Chlamydophila pneumonia.
- Identification of Chlamydophila conjunctivitis or pneumonia in a neonate should prompt evaluation and treatment of the mother and her sexual partner.

» General Considerations

Psittacosis is caused by Chlamydophila psittaci. When the agent is transmitted to humans from psittacine birds (parrots, parakeets, cockatoos, and budgerigars), the disease is called psittacosis. However, other avian genera (eg, pigeons and turkeys) are common sources of infection in the United States, and the general term ornithosis often is used. Human-to-human spread rarely occurs. The incubation period is 5–14 days. The bird from which the disease was transmitted may not be clinically ill.

Chlamydophila pneumoniae (formerly Chlamydia pneumoniae) may cause atypical pneumonia similar to that due to M pneumoniae. Transmission is by respiratory spread. Infection is most prevalent during the second decade. Lower respiratory tract infection due to C pneumoniae is uncommon in infants and young children. C pneumoniae has been associated with acute chest syndrome in children with sickle cell disease.

Chlamydophila trachomatis causes urogenital infections in adults including asymptomatic infections, lymphogranuloma venereum, nongonococcal urethritis, epididymitis, cervicitis, and pelvic inflammatory disease. Serovars D–K (and L1, L2, L3 in lymphogranuloma venereum) are responsible for most of these infections. Sexually transmitted urogenital infections caused by Chlamydophila are discussed in Chapter 44. In infants born to infected mothers, C trachomatis infection can be acquired through exposure in the birth canal, causing neonatal conjunctivitis and/or pneumonia. The risk of acquisition for a baby born vaginally to an infected mother is about 50%.

The disease called "trachoma" is rare in the United States. Trachoma is caused by certain C trachomatis serovars (A–C). This chronic keratoconjunctivitis can cause inflammation and neovascularization of the cornea, leading to corneal scarring and blindness.

» Prevention

Persons cleaning bird cages of sick birds should use caution (wear N95 mask, eye protection, gloves) when cleaning cages or disposing of bird droppings to avoid aerosolization of C psittaci. C psittaci is susceptible to 1% Lysol or a 1:100 dilution of household bleach; either can be used to disinfect cages. Sick birds should be evaluated by a veterinarian and treated with antimicrobials. C pneumoniae is transmitted person to person by infected respiratory tract secretions. Prevention involves avoidance of known infected persons, using good hand hygiene, and encouraging good respiratory hygiene (covering mouth with coughing, disposing of tissues contaminated with respiratory secretions).

The diagnosis and treatment of genital Chlamydophila (chlamydial) infections in pregnant women and their sexual partners is the most effective way to prevent neonatal conjunctivitis and pneumonia (see Chapter 44).

Clinical Findings

A. Symptoms and Signs

1. C psittaci pneumonia—The disease is extremely variable but tends to be mild in children. The onset is rapid or insidious, with fever, chills, headache, backache, malaise, myalgia, and dry cough. Signs include pneumonitis, altered percussion notes and breathe sounds, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Splenomegaly, epistaxis, prostration, and meningismus are occasionally seen. Delirium, constipation or diarrhea, and abdominal distress may occur.

2. C pneumoniae pneumonia—Clinically, C pneumoniae infection is similar to M pneumoniae infection. Most patients have mild upper respiratory infections. Lower respiratory tract infection is characterized by fever, sore throat (perhaps more severe with C pneumoniae), cough, and bilateral pulmonary findings and infiltrates.

3. C trachomatis neonatal conjunctivitis and pneumonia—Neonatal conjunctivitis caused by C trachomatis can occur from a few days until 12–16 weeks after birth. There may be mild to moderate swelling of the lids and watery or mucopurulent discharge. The conjunctivae may be friable and there may be some bloody discharge. Pneumonia may occur in babies with or without neonatal conjunctivitis. Pneumonia is most commonly seen between 2 and 12 weeks of age. Most babies are afebrile and have tachypnea and a staccato cough.

4. C Trachomatis trachoma—Trachoma is seen in developing countries in Africa, Asia, Latin America, the Middle East, and some Pacific and East Pacific islands. It is the most common cause of acquired blindness worldwide. The peak incidence is seen at 4–6 years of age, with scarring and blindness occurring in adulthood. Infections occur from direct contact with infected secretions (eye, nose, throat) or by direct contact with contaminated objects (secretions on towels, washcloths, handkerchiefs).

B. Laboratory Findings

1. C Psittaci—In psittacosis, the WBC count is normal or decreased, often with a left shift. Proteinuria is common. C psittaci is present in the blood and sputum during the first 2 weeks of illness, but can represent a hazard to laboratory workers. A diagnosis can be made if a culture (blood or respiratory tract specimen) is positive for the organism, or there is a fourfold rise in complement fixation titers in specimens obtained at least 2 weeks apart. Evidence of a probable case includes a respiratory sample that is PCR positive for C psittaci or a serum C psittaci IgM antibody titer above 1:32 (microimmunofluorescent or complement fixation assay). The titer rise may be blunted or delayed by therapy. Infection with C pneumoniae may lead to diagnostic confusion because cross-reactive antibody may cause false-positive C psittaci titers.

2. C Pneumoniae—Eosinophilia is sometimes present. A fourfold rise in C pneumoniae IgG titer (microimmunofluorescence antibody test) is the preferred test. IgG antibody peaks 6–8 weeks after infection. C pneumoniae can be isolated from nasal wash or throat swab specimens after inoculation into cell culture. A PCR is urgently not commercially available.

3. C Trachomatis—In infants with suspected Chlamydial pneumonia or conjunctivitis, nucleic acid amplification tests (such as PCR) have not been FDA approved for testing conjunctival samples or respiratory samples (nasopharyngeal, tracheal aspirate) in infants. Culture or nonamplified direct detection methods are usually utilized. In countries where the disease trachoma occurs, the diagnosis is made clinically.

C. Imaging

The radiographic findings in psittacosis are those of central pneumonia that later becomes widespread or migratory. Psittacosis is indistinguishable from viral pneumonias by radiograph. Signs of pneumonitis may appear on radiograph in the absence of clinical suspicion of pulmonary involvement. Pneumonia from C pneumoniae produces variable radiographic findings including bilateral interstitial infiltrates or a unilateral subsegmental infiltrate. In neonatal pneumonia due to C trachomatis, infiltrates, and often hyperinflation, are seen.

Differential Diagnosis

Psittacosis can be differentiated from viral or mycoplasmal pneumonias only by the history of contact with potentially infected birds. In severe or prolonged cases with extrapulmonary involvement the differential diagnosis is broad, including typhoid fever, brucellosis, and rheumatic fever.

C pneumoniae pneumonia is not distinguishable clinically from Mycoplasma or viral pneumonia.

C trachomatis conjunctivitis must be differentiated from gonococcal conjunctivitis, chemical conjunctivitis, or viral conjunctivitis. Gonococcal conjunctivitis is often severe, with purulent drainage. A culture of the conjunctival discharge (plated on Thayer-Martin media) can aid in the diagnosis of gonococcal conjunctivitis.

Complications

Complications of psittacosis include myocarditis, endocarditis, hepatitis, pancreatitis, and secondary bacterial pneumonia. C pneumoniae infection may be prolonged or may recur.

Treatment

Psittacosis—Doxycycline should be given for 10–14 days after defervescence to patients older than 8 years with psittacosis. Alternatively, erythromycin or azithromycin may be used in younger children. Supportive oxygen may be needed.

Chlamydophila pneumonia—Most suspected infections are treated empirically. C pneumoniae responds to macrolides (azithromycin, erythromycin). Doxycycline is an alternative in those patients 8 years and older. A 10- to 14-day course is recommended for erythromycin or doxycycline; when using azithromycin the treatment length is 5 days.

Neonatal conjunctivitis or pneumonia—The consensus recommendation is a 10-day course of erythromycin base or ethylsuccinate (50 mg/kg/d given in four divided doses). Some infants have recrudescence of symptoms after the antibiotic course finishes or failure of symptoms to fully resolve. These infants can be retreated with a second course of erythromycin. An association with receipt of erythromycin and development of pyloric stenosis in infants less than 6 weeks of age has been reported. Parents should be informed of this potential risk and the symptoms of pyloric stenosis. Data on the use of azithromycin for these conditions in neonates is very limited, but azithromycin 20 mg/kg, given as an oral single dose once daily for 3 days, may be efficacious. The diagnosis of an infant with chlamydial conjunctivitis and/or pneumonia should prompt evaluation and treatment of the mother and her sexual partner for Chlamydia and other sexually transmitted diseases (see Chapter 44).

CAT-SCRATCH DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- History of a cat scratch or cat contact.
- Primary lesion (papule, pustule, or conjunctivitis) at site of inoculation.
- Acute or subacute regional lymphadenopathy.
- Laboratory studies excluding other causes.
- Biopsy of node or papule showing histopathologic findings consistent with cat-scratch disease and occasionally characteristic bacilli on Warthin-Starry stain.
- Positive cat-scratch serology (antibody to Bartonella henselae).

» General Considerations

The causative agent of cat-scratch disease is B henselae, a gram-negative bacillus that also causes bacillary angiomatosis. Cat-scratch disease is usually a benign, self-limited form of lymphadenitis. Patients often report a cat scratch (67%), bite (less common), or contact with a cat or kitten (90%). The cat almost invariably is healthy. Cats become infected via an infected flea; the flea becomes infected when feeding on a cat that is bacteremic with B henselae. Occasionally dogs can be infected and transmit disease. The clinical picture is that of a regional lymphadenitis associated with an erythematous papular skin lesion without intervening lymphangitis. The disease occurs worldwide and is more common in the fall and winter. It is estimated that more than 20,000 cases per year occur in the United States. The most common systemic complication is encephalitis.

» Prevention

Cat-scratch disease can be largely prevented by avoiding contact with cats, especially kittens. Flea control of animals will reduce cat-to-cat transmission.

» Clinical Findings

A. Symptoms and Signs

About 50% of patients with cat-scratch disease develop a primary lesion at the site of the wound. The lesion usually is a papule or pustule that appears 7–10 days after injury and is located most often on the arm or hand (50%), head or leg (30%), or trunk or neck (10%). The lesion may be conjunctival (10%). Regional lymphadenopathy appears 10–50 days later and may be accompanied by mild malaise, lassitude, headache, and fever. Multiple sites are seen in about 10% of cases. Involved nodes may be hard or soft and 1–6 cm in diameter. They are usually tender, warm, and erythematous and 10%–20% suppurate. Lymphadenopathy usually resolves in about 2 months but may persist for up to 8 months.

Unusual manifestations include erythema nodosum, thrombocytopenic purpura, conjunctivitis (Parinaud oculoglandular fever), parotid swelling, pneumonia, osteolytic lesions, mesenteric and mediastinal adenitis, neuroretinitis, peripheral neuritis, hepatitis, granulomata of the liver and spleen, and encephalopathy.

Immunocompetent patients may develop an atypical systemic form of cat-scratch disease. These patients have prolonged fever, fatigue, and malaise. Lymphadenopathy may be present. Hepatosplenomegaly or low-density hepatic or splenic lesions visualized by ultrasound or computed tomography scan are seen in some patients.

Infection in immunocompromised individuals may take the form of bacillary angiomatosis, presenting as vascular tumors of the skin and subcutaneous tissues.

Immunocompromised patients may also have bacteremia or infection of the liver (peliosis hepatis).

B. Laboratory Findings

Serologic evidence of Bartonella infection by indirect immunofluorescent antibody with IgG titer of > 1:256 is strongly suggestive of recent infection. A positive IgM antibody is sometimes positive. PCR assays are available. Cat-scratch skin test antigens are not recommended.

Histopathologic examination of involved tissue may show pyogenic granulomas or bacillary forms demonstrated by Warthin-Starry silver stain (bacillary forms on stain are not specific for cat scratch disease). Later in the course necrotizing granulomas may be seen. There usually is some elevation in the ESR. In patients with CNS involvement, the CSF is usually normal but may show a slight pleocytosis and modest elevation of protein.

» Differential Diagnosis

Cat-scratch disease must be distinguished from pyogenic adenitis, tuberculosis (typical and atypical), tularemia, plague, brucellosis, lymphoma, primary toxoplasmosis, infectious mononucleosis, lymphogranuloma venereum, and fungal infections.

» Treatment

Treatment of cat-scratch disease adenopathy is controversial because the disease usually resolves without therapy and the patient is typically not exceedingly ill. Treatment of typical cat-scratch disease with a 5-day course of azithromycin has been shown to speed resolution of lymphadenopathy in some patients. In some reports, ciprofloxacin, rifampin, or TMP-SMX have been useful. Azithromycin is used by many experts if treatment of adenopathy is desired because it is given once a day and is reasonably priced. In one randomized placebo-controlled trial, lymph node volume decreased faster than placebo by 1 month, but there was no difference in long-term resolution in the azithromycin and placebo groups. The best therapy is reassurance that the adenopathy is benign and will subside spontaneously with time (mean duration of illness is 14 weeks). In cases of nodal suppuration, needle aspiration under local anesthesia relieves the pain. Excision of the involved node is indicated in cases of chronic adenitis.

Immunocompromised patients with evidence of infection should be treated with antibiotics: long-term therapy (months) in these patients with azithromycin or doxycycline often is needed to prevent relapses. Immunocompetent patients with more severe disease or evidence of systemic infection (eg, hepatic or splenic lesions) should also be treated with antibiotics.

» Prognosis

The prognosis is good if complications do not occur.

Centers for Disease Control and Prevention: Bartonella. Available at: http://www.cdc.gov/bartonella/clinicians/index.html.

Klotz SA, Elliott IV: Cat-scratch disease. Am Fam Physician 2011;83(2):152–155 [PMID: 21243990].

SPIROCHETAL INFECTIONS

SYPHILIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Congenital:

- All types: history of untreated maternal syphilis, a positive serologic test or a positive darkfield examination.
- Newborn: hepatosplenomegaly, characteristic radiographic bone changes, anemia, increased nucleated red cells, thrombocytopenia, abnormal spinal fluid, jaundice, edema.
- Young infant (3–12 weeks): snuffles, maculopapular skin rash, mucocutaneous lesions, pseudoparalysis (in addition to radiographic bone changes).
- Children: stigmata of early congenital syphilis, interstitial keratitis, saber shins, gummas of nose and palate.

» Acquired:

- Chancre of genitals, lip, or anus in child or adolescent.
- History of sexual contact and a positive serologic test.

» General Considerations

Syphilis is a chronic, generalized infectious disease caused by a spirochete, Treponema pallidum. In the acquired form, the disease is transmitted by sexual contact. Primary syphilis is characterized by the presence of an indurated painless chancre, which heals in 7–10 days. A secondary eruption involving the skin and mucous membranes appears in 4–6 weeks. After a long latency period, late lesions of tertiary syphilis involve the eyes, skin, bones, viscera, CNS, and cardiovascular system.

Congenital syphilis results from transplacental infection. Infection may result in stillbirth or produce illness in the newborn, in early infancy, or later in childhood. Syphilis occurring in the newborn and young infant is comparable to secondary disease in the adult but is more severe and maybe life-threatening. Late congenital syphilis (developing in childhood) is comparable to tertiary disease.

The incidence of primary and secondary syphilis is increasing in the United States particularly among gay men. 15,667 new cases of primary and secondary syphilis, 322 cases of congenital syphilis (< 1 year) and nearly 50,000 total cases were reported in 2012.

» Prevention

A serologic test for syphilis should be performed at the initiation of prenatal care and repeated at delivery in women at increased risk for syphilis. Serologic tests may be negative on both the mother and infant at the time of birth if the mother acquires syphilis near term. Adequate treatment of mothers with secondary syphilis before the last month of pregnancy reduces the incidence of congenital syphilis from 90% to less than 2%. Examination and serologic testing of sexual partners and siblings should also be done.

» Clinical Findings

A. Symptoms and Signs

1. Congenital syphilis

a. Newborns—Most newborns with congenital syphilis are asymptomatic. If infection is not detected and treated, symptoms develop within weeks to months. When clinical signs are present, they usually consist of jaundice, anemia with or without thrombocytopenia, increase in nucleated red blood cells, hepatosplenomegaly, and edema. Overt signs of meningitis (bulging fontanelle or opisthotonos) may be present, but subclinical infection with CSF abnormalities is more common.

b. Young infants (3–12 weeks)—The infant may appear normal for the first few weeks of life only to develop mucocutaneous lesions and pseudoparalysis of the arms or legs. Shotty lymphadenopathy may be felt. Hepatomegaly is universal, with splenomegaly in 50% of patients. Other signs of disease similar to those seen in the newborn may be present. Anemia has been reported as the only presenting manifestation of congenital syphilis in this age group. "Snuffles" (syphilitic rhinitis), characterized by a profuse mucopurulent discharge, are present in 15–25% of patients. A syphilitic rash is common on the palms and soles but may occur anywhere on the body. The rash consists of bright red, raised maculopapular lesions that gradually fade, occasionally the rash is vesicular or bullous. Moist lesions occur at the mucocutaneous junctions (nose, mouth, anus, and genitals) and lead to fissuring and bleeding.

Syphilis in the young infant may lead to stigmata recognizable in later childhood, such as rhagades (scars) around the mouth or nose, a depressed bridge of the nose (saddle nose), and a high forehead (secondary to mild hydrocephalus associated with low-grade meningitis and frontal periostitis). The permanent upper central incisors may be peg-shaped with a central notch (Hutchinson teeth), and the cusps of the sixth-year molars may have a lobulated mulberry appearance.

c. Children—Bilateral interstitial keratitis (at age 6–12 years) is characterized by photophobia, increased lacrimation, and vascularization of the cornea associated with exudation. Chorioretinitis and optic atrophy may also be seen. Meningovascular syphilis (at age 2–10 years) is usually slowly progressive, with mental retardation, spasticity, abnormal pupillary response, speech defects, and abnormal CSF. Deafness sometimes occurs. Thickening of the periosteum of the anterior tibias produces saber shins. A bilateral effusion in the knee joints may occur but is not associated with sequelae. Soft inflammatory growths called gummas may develop in the nasal septum, palate, long bones, and subcutaneous tissues.

2. Acquired syphilis—The primary chancre of the genitals, mouth, or anus may occur from genital, anal, or oral sexual contact. If the chancre is missed, signs of secondary syphilis, such as rash, fever, headache, and malaise, may be the first manifestations.

B. Laboratory Findings

1. Darkfield microscopy—Treponemes can be seen in scrapings from a chancre and from moist lesions, but darkfield examinations are not often available.

2. Serologic tests for syphilis—There are two general types of serologic tests for syphilis: treponemal and nontreponemal. There are two types of nontreponemal tests: Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR), which are useful for screening and may be quantitated to follow disease activity and adequacy of therapy. False-positive nontreponemal tests can occur in patient with measles, hepatitis, mononucleosis, lymphoma, tuberculosis, endocarditis, pregnancy, autoimmune diseases, and intravenous drug abuse. When evaluating a newborn infant for potential syphilis, umbilical cord blood specimens should not be used for nontreponemal tests: a false-positive test may result from Wharton jelly contamination of the sample. Conversely, a false-negative test may be seen in the setting where maternal infection occurred late in pregnancy.

Positive nontreponemal tests should be confirmed with a more specific treponemal test such as the fluorescent treponemal antibody absorbed (FTA-ABS) test or the T pallidum particle agglutination (TP-PA) test. False-positive FTA-ABS tests are uncommon except with other spirochetal diseases such as leptospirosis, rat bite fever, and Lyme disease.

One or two weeks after the onset of primary syphilis (chancre), the FTA-ABS test becomes positive. The nontreponemal tests usually turns positive a few days later. By the time the secondary stage has been reached, virtually all patients show both positive FTA-ABS and positive

nontreponemal tests. During latent and tertiary syphilis, the VDRL may become negative, but the FTA-ABS test usually remains positive. The quantitative VDRL or a similar nontreponemal test should be used to follow-up treated cases (see following discussion).

EIA tests specific for T pallidum are available in many laboratories and are replacing FTA-ABS and TP-PA tests. As these are rapid, inexpensive tests with greater specificity, a different screening strategy is now often used. The initial screen is done with EIA test followed by the RPR or VDRL, if positive.

In newborns and infants, positive serologic tests in cord sera may represent passively transferred antibody rather than congenital infection and therefore must be interpreted in light of clinical and laboratory data. Serial measurement of quantitative RPR or VDRL is also very useful, because passively transferred antibody in the absence of active infection should decays with a normal half-life of about 18 days (see discussion of evaluation of infants for congenital syphilis section on Initial Evaluation and Treatment). Elevated total cord IgM is a helpful but nonspecific finding. Demonstration of characteristic treponemes by darkfield examination of material from a moist lesion (skin; nasal or other mucous membranes) is definitive but this test is not often available. Mouth lesions would be best examined by direct fluorescent antibody to distinguish T pallidum from nonpathogenic treponemes commonly found in the mouth.

For evaluation of possible neurosyphilis, the CSF should be examined for cell count, glucose, protein, and a CSF VDRL. A negative CSF VDRL does not rule out neurosyphilis.

C. Imaging

Radiographic abnormalities are present in 90% of infants with symptoms of congenital syphilis and in 20% of asymptomatic infants. Metaphyseal lucent bands, periostitis, and a widened zone of provisional calcification may be present. Bilateral symmetrical osteomyelitis with pathologic fractures of the medial tibial metaphyses (Wimberger sign) is almost pathognomonic.

» Differential Diagnosis

A. Congenital Syphilis

1. Newborns—Sepsis, congestive heart failure, congenital rubella, toxoplasmosis, disseminated herpes simplex, cytomegalovirus infection, and hemolytic disease of the newborn have to be differentiated. A positive Coombs test and blood group incompatibility distinguish hemolytic disease.

2. Young infants—Injury to the brachial plexus, poliomyelitis, acute osteomyelitis, and septic arthritis must be differentiated from pseudoparalysis. Coryza due to viral infection often responds to symptomatic treatment. Rash (ammoniacal diaper rash) and scabies may be confused with a syphilitic eruption.

3. Children—Interstitial keratitis and bone lesions of tuberculosis are distinguished by positive tuberculin reaction and chest radiograph. Arthritis associated with syphilis is unaccompanied by systemic signs, and joints are nontender. Mental retardation, spasticity, and hyperactivity are shown to be of syphilitic origin by strongly positive serologic tests.

B. Acquired Syphilis

Herpes genitalis, traumatic lesions, and other venereal diseases must be differentiated from primary chancers.

» Treatment

A. Specific Measures

Penicillin is the drug of choice for T pallidum infection. If the patient is allergic to penicillin, azithromycin, ceftriaxone or one of the tetracyclines may be used, but are of unknown efficacy.

1. Congenital syphilis

a. Initial evaluation and treatment—Newborns should not be discharged from the hospital until the mother's serologic status for syphilis has been determined. Infants born to seropositive mothers require careful examination and quantitative nontreponemal syphilis testing. The same quantitative antitreponemal test used in evaluating the mother should be used in the infant so the titers can be compared. Maternal records regarding any prior diagnosis of syphilis, treatment, and follow-up titers should be reviewed. Infants should be further evaluated for congenital syphilis in any of the following circumstances:

- The maternal titer has increased fourfold.
- The infant's titer is at least fourfold greater than the maternal titer.
- Signs of syphilis are found on examination.
- Maternal syphilis was not treated or was inadequately treated during pregnancy.
- Maternal syphilis was treated with a nonpenicillin regimen, or the regimen or dose of medication is undocumented.
- Maternal syphilis was treated during pregnancy, but therapy was completed less than 4 weeks prior to delivery.
- Maternal syphilis was treated appropriately during pregnancy, but without the appropriate decrease in maternal nontreponemal titers after treatment.

The complete evaluation of an infant for possible congenital syphilis includes complete blood count, liver function tests, long bone radiographs, CSF examination (cell counts, glucose, and protein), CSF VDRL, and quantitative

serologic tests. In addition, the placenta and umbilical cord should be examined pathologically using fluorescent antitreponemal antibody, if available. An ophthalmologic examination may also be done.

Treatment for congenital syphilis is indicated for infants with consistent physical signs; umbilical cord or placenta positive for DFA-TP staining or darkfield examination; abnormal radiographs; elevated CSF protein or cell counts; reactive CSF VDRL; or serum quantitative nontreponemal titer that is more than fourfold higher than the maternal titer (using same test). Newborns with proved or suspected congenital syphilis should receive either (1) aqueous crystalline penicillin G, 50,000 U/kg per dose intravenously every 12 hours (if < 1 week old) or (2) every 8 hours (if 1–4 weeks old) for 10 days. Procaine penicillin G, 50,000 U/kg in a single daily dose for 10 days is an alternative if compliance is assured. All infants diagnosed after age 4 weeks should receive 50,000 U/kg per dose aqueous crystalline penicillin intravenously every 4–6 hours for 10 days.

Additionally, treatment should be given to infants whose mothers have inadequately treated syphilis, to those whose mothers received treatment less than 1 month before delivery, to those whose mothers have undocumented or inadequate serologic response to therapy, and to those whose mothers were given nonpenicillin drugs to treat syphilis. In these instances, if the infant is asymptomatic, has a normal physical examination, normal CSF parameters, nonreactive CSF VDRL, normal bone films, quantitative nontreponemal titer less than fourfold of the mother's titer, and good follow-up is certain, some experts would give a single dose of penicillin G benzathine, 50,000 U/kg intramuscularly. If there is any abnormality in the preceding evaluation or if the CSF testing is not interpretable, the full 10 days of intravenous penicillin should be given. Close clinical and serologic monthly follow-up is necessary.

Asymptomatic, seropositive infants with normal physical examinations born to mothers who received adequate syphilis treatment (completed > 4 weeks prior to delivery) and whose mothers have an appropriate serologic response (fourfold or greater decrease in titer) to treatment may be at lower risk for congenital syphilis. Some experts believe complete laboratory and radiographic evaluation in these infants (CSF and long bone films) is not necessary. Infants who meet the preceding criteria, who have nontreponemal titers less than fourfold higher than maternal titers, and for whom follow-ups are certain can be given benzathine penicillin G, 50,000 U/kg, administered intramuscularly in a single dose. Infants should be followed with quantitative serologic tests and physical examinations until the nontreponemal serologic test is negative (see discussion of follow-up, next). Rising titers or clinical signs usually occur within 4 months in infected infants, requiring a full evaluation (including CSF studies and long bone radiographs) and institution of intravenous penicillin therapy.

b. Follow-up for congenital syphilis—Children treated for congenital syphilis need physical examinations every 2–3 months after completion of therapy, and both physical examinations and quantitative VDRL or RPR tests should be performed until the tests become nonreactive. Repeat CSF examination, including a CSF VDRL test, every 6 months until normal is indicated for infants with a positive CSF VDRL reaction or with abnormal cell counts or protein in the CSF. A reactive CSF VDRL test at the 6-month interval is an indication for retreatment. Titers decline with treatment and are usually negative by 6 months. Repeat treatment is indicated for children with rising titers or stable titers that do not decline.

2. Acquired syphilis of less than 1 year's duration— Benzathine penicillin G (50,000 U/kg, given intramuscularly, to a maximum of 2.4 million units) is given to adolescents with primary, secondary, or latent disease of less than 1 year's duration. All children should have a CSF examination (with CSF VDRL) prior to commencing therapy, to exclude neurosyphilis. Adolescents and adults need a CSF examination if clinical signs or symptoms suggest neurologic involvement or if they are HIV-infected.

3. Syphilis of more than 1 year's duration (late latent disease)—Syphilis of more than 1 year's duration (without evidence of neurosyphilis) requires weekly intramuscular benzathine penicillin G therapy for 3 weeks. CSF examination and VDRL test should be done on all children and patients with coexisting HIV infection or neurologic symptoms. In addition, patients who have failed treatment or who were previously treated with an agent other than penicillin need a CSF examination and CSF VDRL.

4. Neurosyphilis—Aqueous crystalline penicillin G is recommended, 200,000–300,000 U/kg/d in four to six divided doses, given intravenously for 10–14 days. The maximum adult dose is 4 million units per dose. Some experts recommend following this regimen with an intramuscular course of benzathine G penicillin, 50,000 U/kg given once a week for 3 consecutive weeks, to a maximum dose of 2.4 million units.

B. General Measures

Penicillin treatment of early congenital or secondary syphilis may result in a dramatic systemic febrile illness termed the Jarisch-Herxheimer reaction. Treatment is symptomatic, with careful follow-up. Transfusion may be necessary in infants with severe hemolytic anemia.

» Prognosis

Severe disease, if undiagnosed, may be fatal in the newborn. Complete cure can be expected if the young infant is given penicillin. Serologic reversal usually occurs within 1 year.

Treatment of primary syphilis with penicillin is curative. Permanent neurologic sequelae may occur in meningovascular syphilis.

RELAPSING FEVER

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Episodes of relapses fever, chills, malaise.
- Occasional rash, arthritis, cough, hepatosplenomegaly, conjunctivitis.
- Diagnosis suggested by direct microscopic identification of spirochetes in smears of peripheral blood. Diagnosis confirmed with serologic testing.

» Prevention

Measures that decrease exposures to soft ticks and body lice will prevent most cases. Soft-bodied ticks often are found in rodent burrows or nests, so decreasing rodent access to homes and eliminating rodents in the home is helpful. Body-louse infestation can be treated with hygiene and pediculicides.

» General Considerations

Relapsing fever is a vector-borne disease caused by spirochetes of the genus Borrelia. There are two forms: epidemic relapsing fever is transmitted to humans by body lice (Pediculus humanus) and endemic relapsing fever by soft-bodied ticks (genus Ornithodoros). Tick-borne relapsing fever is endemic in the western United States. Transmission usually takes place during the warm months, when ticks are active and recreation or work brings people into contact with ticks. B hermsii causes most tick-borne infection in the United States. Infection is often acquired in mountain camping areas and cabins. The ticks are nocturnal feeders and remain attached for only 5–20 minutes. Consequently, the patient seldom remembers a tick bite. Rarely, neonatal relapsing fever results from transplacental transmission of Borrelia. Both louse-borne and tick-borne relapsing fever may be acquired during foreign travel.

» Clinical Findings

A. Symptoms and Signs

The incubation period is 2–18 days. The attack is sudden, with high fever, chills, sweats, tachycardia, nausea and vomiting, headache, myalgia, and arthralgia. After 3–7 days, the fever falls. Relapses occur at intervals of several days to weeks. The relapses duplicate the initial attack but become progressively less severe. In louse-borne relapsing fever, there is usually a single relapse. In tick-borne infection, 2–10 relapses occur.

Hepatomegaly, splenomegaly, pneumonitis, meningitis, and myocarditis may appear later in the course of the disease. An erythematous rash may be seen over the trunk and extremities, and petechiae may be present. Jaundice, iritis, conjunctivitis, cranial nerve palsies, and hemorrhage occur more commonly during relapses.

B. Laboratory Findings

During febrile episodes, the patient's urine contains protein, casts, and occasionally erythrocytes; a marked polymorphonuclear leukocytosis is present; about 25% of patients have a false-positive serologic test for syphilis. Spirochetes can be found in the peripheral blood by direct microscopy in approximately 70% of cases by darkfield examination or by Wright, Giemsa, or acridine orange staining of thick and thin smears. Spirochetes are not found during afebrile periods. Immunofluorescent antibody (or ELISA confirmed by Western blot) can help establish the diagnosis serologically. However, high titers of Borrelia hermsii can cross-react with Borrelia burgdorferi (the agent in Lyme disease) or Leptospira in immunofluorescent antibody assay, ELISA, and Western blots. Serologic specimens can be sent to the Division of Vector-Borne Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO 80522.

» Differential Diagnosis

Relapsing fever may be confused with malaria, leptospirosis, dengue, typhus, rat-bite fever, Colorado tick fever, Rocky Mountain spotted fever, collagen-vascular disease, or any fever of unknown origin.

» Complications

Complications include facial paralysis, iridocyclitis, optic atrophy, hypochromic anemia, pneumonia, nephritis, myocarditis, endocarditis, and seizures. CNS involvement occurs in 10%–30% of patients.

» Treatment

For children younger than age 8 years who have tick-borne relapsing fever, penicillin or erythromycin should be given for 10 days. Older children may be given doxycycline.

Severely ill patients should be hospitalized. Patients may experience a Jarisch-Herxheimer reaction (usually noted in the first few hours after commencing antibiotics). Isolation precautions are not necessary for relapsing fever. Contact precautions are recommended for patients with louse infestations.

» Prognosis

The mortality rate in treated cases of relapsing fever is very low, except in debilitated or very young children. With treatment, the initial attack is shortened and relapses prevented. The response to antimicrobial therapy is dramatic.

Centers for Disease Control: Relapsing fever. Available at: http://www.cdc.gov/relapsing-fever/.

LEPTOSPIROSIS

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Biphasic course lasting 2–3 weeks.
- Initial phase: high fever, headache, myalgia, and conjunctivitis.
- Apparent recovery for 2–3 days.
- Return of fever associated with meningitis.
- Jaundice, hemorrhages, and renal insufficiency (severe cases).
- Positive leptospiral agglutination test.

» General Considerations

Leptospirosis is a zoonosis caused by many antigenically distinct but morphologically similar spirochetes. The organism enters through the skin or respiratory tract. Classically the severe form (Weil disease), with jaundice and a high mortality rate, was associated with infection with Leptospira icterohaemorrhagiae after immersion in water contaminated with rat urine. It is now known that a variety of animals (eg, dogs, rats, and cattle) may serve as reservoirs for pathogenic Leptospira and that severe disease may be caused by many different serogroups.

In the United States, leptospirosis usually occurs after contact with dogs. Cattle, swine, or rodents may transmit the organism. Sewer workers, farmers, slaughterhouse workers, animal handlers, and soldiers are at risk for occupational exposure. Outbreaks have resulted from swimming in contaminated streams and harvesting field crops. In the United States, about 100 cases are reported yearly, about one-third of them in children.

» Prevention

Preventive measures include avoidance of contaminated water and soil, rodent control, immunization of dogs and other domestic animals, and good sanitation. Gloves, boots, and other protective clothing can be worn when contact is unavoidable. Antimicrobial prophylaxis with doxycycline may be of value to certain high-risk occupational groups with short-term exposures. Doxycycline is not approved for use in children less than 8 years of age unless benefits exceed risk.

» Clinical Findings

A. Symptoms and Signs

1. Initial phase—The incubation period is 4–19 days (mean, 10 days). Chills, fever, headache, myalgia (especially lumbar area and calves), conjunctivitis without exudate, photophobia, cervical lymphadenopathy, and pharyngitis commonly occur. The initial leptospiremic phase lasts for 3–7 days.

2. Phase of apparent recovery—Symptoms typically (but not always) subside for 2–3 days.

3. Systemic phase—Fever reappears and is associated with headache, muscular pain, and tenderness in the abdomen and back, and nausea and vomiting. Conjunctivitis and uveitis are common. Lung, heart, and joint involvement occasionally occur. These manifestations are due to extensive vasculitis.

a. CNS involvement—The CNS is involved in 50%–90% of cases. Severe headache and mild nuchal rigidity are usual, but delirium, coma, and focal neurologic signs may be seen.

b. Renal and hepatic involvement—In about 50% of cases, the kidney or liver is affected. Gross hematuria and oliguria or anuria is sometimes seen. Jaundice may be associated with an enlarged and tender liver.

c. Gallbladder involvement—Leptospirosis may cause acalculous cholecystitis in children, demonstrable by abdominal ultrasound as a dilated, nonfunctioning gallbladder. Pancreatitis is unusual.

d. Hemorrhage—Petechiae, ecchymoses, and gastrointestinal bleeding may be severe.

e. Rash—A rash is seen in 10%–30% of cases. It may be maculopapular and generalized or may be petechial or purpuric. Occasionally erythema nodosum is seen. Peripheral desquamation of the rash may occur. Gangrenous areas are sometimes noted over the distal extremities. In such cases,

skin biopsy demonstrates the presence of severe vasculitis involving both the arterial and the venous circulations.

B. Laboratory Findings

Leptospires are present in the blood and CSF only during the first 10 days of illness. They appear in the urine during the second week, where they may persist for 30 days or longer. Culture is difficult and requires specialized media and conditions. The WBC count often is elevated, especially when there is liver involvement. Serum bilirubin levels usually remain below 20 mg/dL. Other liver function tests may be abnormal; the aspartate transaminase usually is elevated only slightly. An elevated serum creatine kinase is frequently found. CSF shows moderate pleocytosis (< 500/μL), predominantly mononuclear cells, increased protein (50–100 mg/dL), and normal glucose. Urine often shows microscopic pyuria, hematuria, and, less often, moderate proteinuria (or greater). The ESR is elevated markedly. Chest radiograph may show pneumonitis.

Serum antibodies measured by enzyme immunoassay may be demonstrated during or after the second week of illness. The confirmatory test is a microscopic agglutination test performed at the CDC. Leptospiral agglutinins generally reach peak levels by the third to fourth week. Fourfold or greater titer rise in acute and convalescent specimens is diagnostic. A PCR assay may be available at specialized research centers or through the CDC.

» Differential Diagnosis

During the prodrome, malaria, typhoid fever, typhus, rheumatoid arthritis, brucellosis, and influenza may be suspected. Later, depending on the organ systems involved, a variety of other diseases need to be distinguished, including encephalitis, viral or tuberculous meningitis, viral hepatitis, glomerulonephritis, viral or bacterial pneumonia, rheumatic fever, subacute infective endocarditis, acute surgical abdomen, and Kawasaki disease (see Table 40–3).

» Treatment

A. Specific Measures

Aqueous penicillin G (150,000 U/kg/d, given in four to six divided doses intravenously for 7–10 days) should be given when the diagnosis is suspected. Alternative agents include parenteral cefotaxime, ceftriaxone, or doxycycline. A Jarisch-Herxheimer reaction may occur. Oral doxycycline may be used for mildly ill patients. Doxycycline should not be used in children less than 8 years or pregnant women.

B. General Measures

Symptomatic and supportive care, in addition to antibiotics, is indicated. Contact isolation is recommended, due to potential transmission from contact with urine.

» Prognosis

Leptospirosis is usually self-limiting and not characterized by jaundice. The disease usually lasts 1–3 weeks but may be more prolonged. Relapse may occur. There are usually no permanent sequelae associated with CNS infection, although headache may persist. The mortality rate in the United States is 5%, usually from renal failure. The mortality rate may reach 20% or more in elderly patients who have severe kidney and hepatic involvement.

LYME DISEASE

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Characteristic skin lesion (erythema migrans) 3–30 days after tick bite.
- Arthritis, usually pauciarticular, occurring about 4 weeks after appearance of skin lesion. Headache, chills, and fever.
- Residence or travel in an endemic area during the late spring to early fall.

» General Considerations

Lyme disease is a subacute or chronic spirochetal infection caused by B burgdorferi that is transmitted by an infected deer tick (Ixodes species). The disease was known in Europe for many years as tick-borne encephalomyelitis, often associated with a characteristic rash (erythema migrans). Discovery of the agent and vector followed investigation of an outbreak of pauciarticular arthritis in Lyme, Connecticut, in 1977.

The most prominent endemic areas in the United States include the Northeast, upper Midwest, and West Coast. The northern European countries also have high rates of infection. Over 30,000 confirmed or probable cases were reported in the United States in 2012. Although both under-reporting and overreporting occur, it is estimates that more than 300,000 cases per year occur in the United States. Knowledge of the local epidemiology is important as Lyme disease is common in many areas of the United States, but rare in

the mountain states. The disease is spreading as a result of increased infection in and distribution of the tick vector. Most cases with rash are recognized in spring and summer, when most tick bites occur; however, because the incubation period for joint and neurologic disease may be months, cases may present at any time. Ixodes ticks are very small, and their bite is often unrecognized.

» Clinical Findings

A. Symptoms and Signs

Erythema chronicum migrans, the most characteristic feature of Lyme disease, is recognized in 60%–80% of patients. Between 3 and 30 days after the bite, a ring of erythema develops at the site and spreads over days. It may attain a diameter of 20 cm. The center of the lesion may clear (resembling tinea corporis), remain red, or become raised (suggesting a chemical or infectious cellulitis). Mild tenderness may occur. Most patients are otherwise asymptomatic. Some have fever (usually low-grade), headache, and myalgias. Multiple satellite skin lesions, urticaria, or diffuse erythema may occur. Untreated, the rash lasts days to 3 weeks.

In up to 50% of patients, arthritis develops several weeks to months after the bite. Recurrent attacks of migratory, monoarticular, or pauciarticular arthritis involving the knees and other large joints occur. Each attack lasts for days to a few weeks. Fever is common and may be high. Complete resolution between attacks is typical. Chronic arthritis develops in less than 10% of patients, more often in those with the DR4 haplotype.

Neurologic manifestations, which develop in up to 20% of untreated patients, usually consist of Bell palsy, aseptic meningitis (which may be indistinguishable from viral meningitis), or polyradiculitis. Peripheral neuritis, Guillain-Barré syndrome, encephalitis, ataxia, chorea, and other cranial neuropathies are less common. Seizures suggest another diagnosis. Untreated, the neurologic symptoms are usually self-limited but may be chronic or permanent. Self-limited heart block or myocardial dysfunction occurs in about 5% of patients.

Although fatigue and nonspecific neurologic symptoms may be prolonged in a few patients, Lyme disease is not a cause of chronic fatigue syndrome. Persistence of symptoms of fatigue, myalgia, and arthralgia for greater than 6 months are termed post-Lyme disease syndrome, but there is no evidence that chronic Lyme infection exists.

B. Laboratory Findings

Most patients with only rash have normal laboratory tests. Children with arthritis may have moderately elevated ESRs and WBC counts; the antinuclear antibodies and rheumatoid factor tests are negative or nonspecific; streptococcal antibodies are not elevated. Circulating IgM cryoglobulins may be present. Joint fluid may show up to 100,000 cells with a polymorphonuclear predominance, normal glucose, and elevated protein and immune complexes; Gram stain and culture are negative. In patients with CNS involvement, the CSF may show lymphocytic pleocytosis and elevated protein; the glucose and all cultures and stains are normal or negative. Abnormal nerve conduction may be present with peripheral neuropathy.

C. Diagnosis

Lyme disease is a clinical diagnosis. Local epidemiology, history of travel to endemic areas, physical examination, and laboratory features are important to consider. Serologic testing may support the clinical diagnosis. Antibody testing should only be performed in experienced laboratories. Serologic diagnosis of Lyme disease is based on a two-test approach: an ELISA and an immunoblot to confirm a positive or indeterminate ELISA. Antibodies may not be detectable until several weeks after infection has occurred; therefore, serologic testing in children with a typical rash is not recommended. Therapy early in disease may blunt antibody titers. Many studies have shown considerable intralaboratory and interlaboratory variability in titers reported. Serologic testing of patients with nonspecific complaints from low prevalence areas results in falsely positive tests. Overdiagnosis of Lyme disease based on atypical symptoms and positive serology appears to be common. Sera from patients with syphilis, HIV, and leptospirosis may give false-positive results. Patients who receive appropriate treatment for Lyme disease may remain seropositive for years. Diagnosis of CNS disease requires objective abnormalities of the neurologic examination, laboratory or radiographic studies, and consistent positive serology.

» Differential Diagnosis

Aside from the disorders already mentioned, the rash may resemble pityriasis, erythema multiforme, a drug eruption, or erythema nodosum. Erythema chronicum migrans is nonscaly, minimally tender or nontender, and persists longer in the same place than many of the more common childhood erythematous rashes. The arthritis may resemble juvenile rheumatoid arthritis, reactive arthritis, septic arthritis, reactive effusion from a contiguous osteomyelitis, rheumatic fever, leukemic arthritis, systemic lupus erythematosus, and Henoch-Schönlein purpura. Spontaneous resolution in a few days to weeks helps differentiate Lyme disease from juvenile rheumatoid arthritis, in which arthritis lasting a minimum of 6 weeks is required for diagnosis. The neurologic signs may suggest idiopathic Bell palsy, viral or parainfectious meningitis or meningoencephalitis, lead poisoning, psychosomatic illness, and many other conditions.

» Prevention

Prevention consists of avoidance of endemic areas, wearing long sleeves and pants, frequent checks for ticks, and application of tick repellents. Ticks are attached for a minimum of 36–48 hours before transmission of Lyme disease occurs. Ticks should be removed with a tweezer by pulling gently without twisting or excessive squeezing of the tick. Permethrin sprayed on clothing decreases tick attachment. Repellents containing high concentrations of N, N-Diethyl-meta-toluamide (DEET) may be neurotoxic and should be used cautiously in young children and infants and washed off when tick exposure ends. Prophylactic antibiotics for tick bites in asymptomatic individuals are not usually recommended.

» Treatment

Antimicrobial therapy is beneficial in most cases of Lyme disease. It is most effective if started early. Prolonged treatment is important for all forms. Relapses occur in some patients on all regimens.

A. Rash, Early Infections

Amoxicillin, 50 mg/kg/d orally in two divided doses (to a maximum of 2 g/d) for 14–21 days can be used for children of all ages. Doxycycline (100 mg orally twice a day) for 14–21 days may be used for children older than age 8 years. Erythromycin (30 mg/kg/d) or cefuroxime (30 mg/kg/d) orally in two divided doses (maximum 1g/d) is used in penicillin-allergic children.

B. Arthritis

The amoxicillin or doxycycline regimen (same dosage as for the rash) should be used, but treatment should continue for 4 weeks. Parenteral ceftriaxone (50–75 mg/kg/d) or penicillin G (300,000 U/kg/d, given intravenously in four divided doses for 2–4 weeks) is used for persistent arthritis.

C. Bell Palsy

The same oral drug regimens may be used for 3–4 weeks.

D. Other Neurologic Disease or Cardiac Disease

Parenteral therapy for 2–4 weeks is recommended with either ceftriaxone (50–75 kg/d in one daily dose), penicillin G (300,000 U/kg/d intravenously in four divided doses), or cefotaxime (150-200 mg/kg/d) divided in three doses.

43 Infections: Parasitic & Mycotic

Kevin Messacar, MD
Samuel R. Dominguez, MD, PhD
Myron J. Levin, MD

PARASITIC INFECTIONS

Parasitic diseases are common and may present clinically in a variety of ways (Table 43–1). Although travel to endemic areas suggests particular infections, many parasites are transmitted through fomites or acquired from contact with human carriers and can occur anywhere.

Selection of Patients for Evaluation

The incidence of parasitic infections varies greatly with geographic area. Children who have traveled or lived in areas where parasitic infections are endemic are at risk for infection with a variety of intestinal and tissue parasites. Children who have resided only in developed countries are usually free of tissue parasites (except Toxoplasma). Searching for intestinal parasites is expensive for the patient and time-consuming for the laboratory. More than 90% of ova and parasite examinations performed in the United States are negative; many have been ordered inappropriately on patients without exposure to endemic areas. An approach to determining which children with diarrhea need such examinations is presented in Figure 43–1. It can be more cost-effective to empirically treat symptomatic US immigrants with albendazole for common intestinal parasites and to investigate only those whose symptoms persist.

Immunodeficient children are very susceptible to protozoal intestinal infections. Multiple opportunists are frequently identified, and the threshold for evaluation should be low for these children.

Swanson SJ et al: Albendazole therapy and enteric parasites in United States-bound refugees. N Engl J Med 2012;366(16): 1498–1507 [PMID: 22512482].

Specimen Processing

Contact the laboratory for proper collection procedures for tissue parasites. For intestinal parasites, diarrheal stools may contain trophozoites that die rapidly during transport. The specimen should be examined immediately or placed in a stool fixative such as polyvinyl alcohol. Fixative vials for home collection of stool are commercially available and maintain specimens stable at room temperature. Formed stools usually contain cysts that are more stable. It is also best to fix these after collection, although they may be reliably examined after transport at room temperature. The US Centers for Disease Control and Prevention (CDC) provide a website (http://dpd.cdc.gov/dpdx) to assist in the laboratory diagnosis of common parasitic diseases, including specimen collection and processing.

Eosinophilia & Parasitic Infections

Although certain parasites commonly cause eosinophilia, in developed countries other causes are much more common. These include allergies, drugs, and other infections. Heavy intestinal nematode infection causing eosinophilia is easily detected on a single ova and parasite examination. Light nematode infections and common protozoal infections—giardiasis, cryptosporidiosis, and amebiasis—rarely cause eosinophilia. Eosinophilia is also unusual or minimal in more serious infections such as amebic liver abscess and malaria.

The most common parasitic infection in the United States that causes significant eosinophilia with negative stool examination is toxocariasis. In a young child with unexplained eosinophilia and a negative stool examination for parasites, a serologic test for Toxocara is the next appropriate test. Trichinosis, which is a rare parasitic infection in the United States, causes marked eosinophilia. Strongyloidiasis

Table 43–1. Signs and symptoms of parasitic infection.

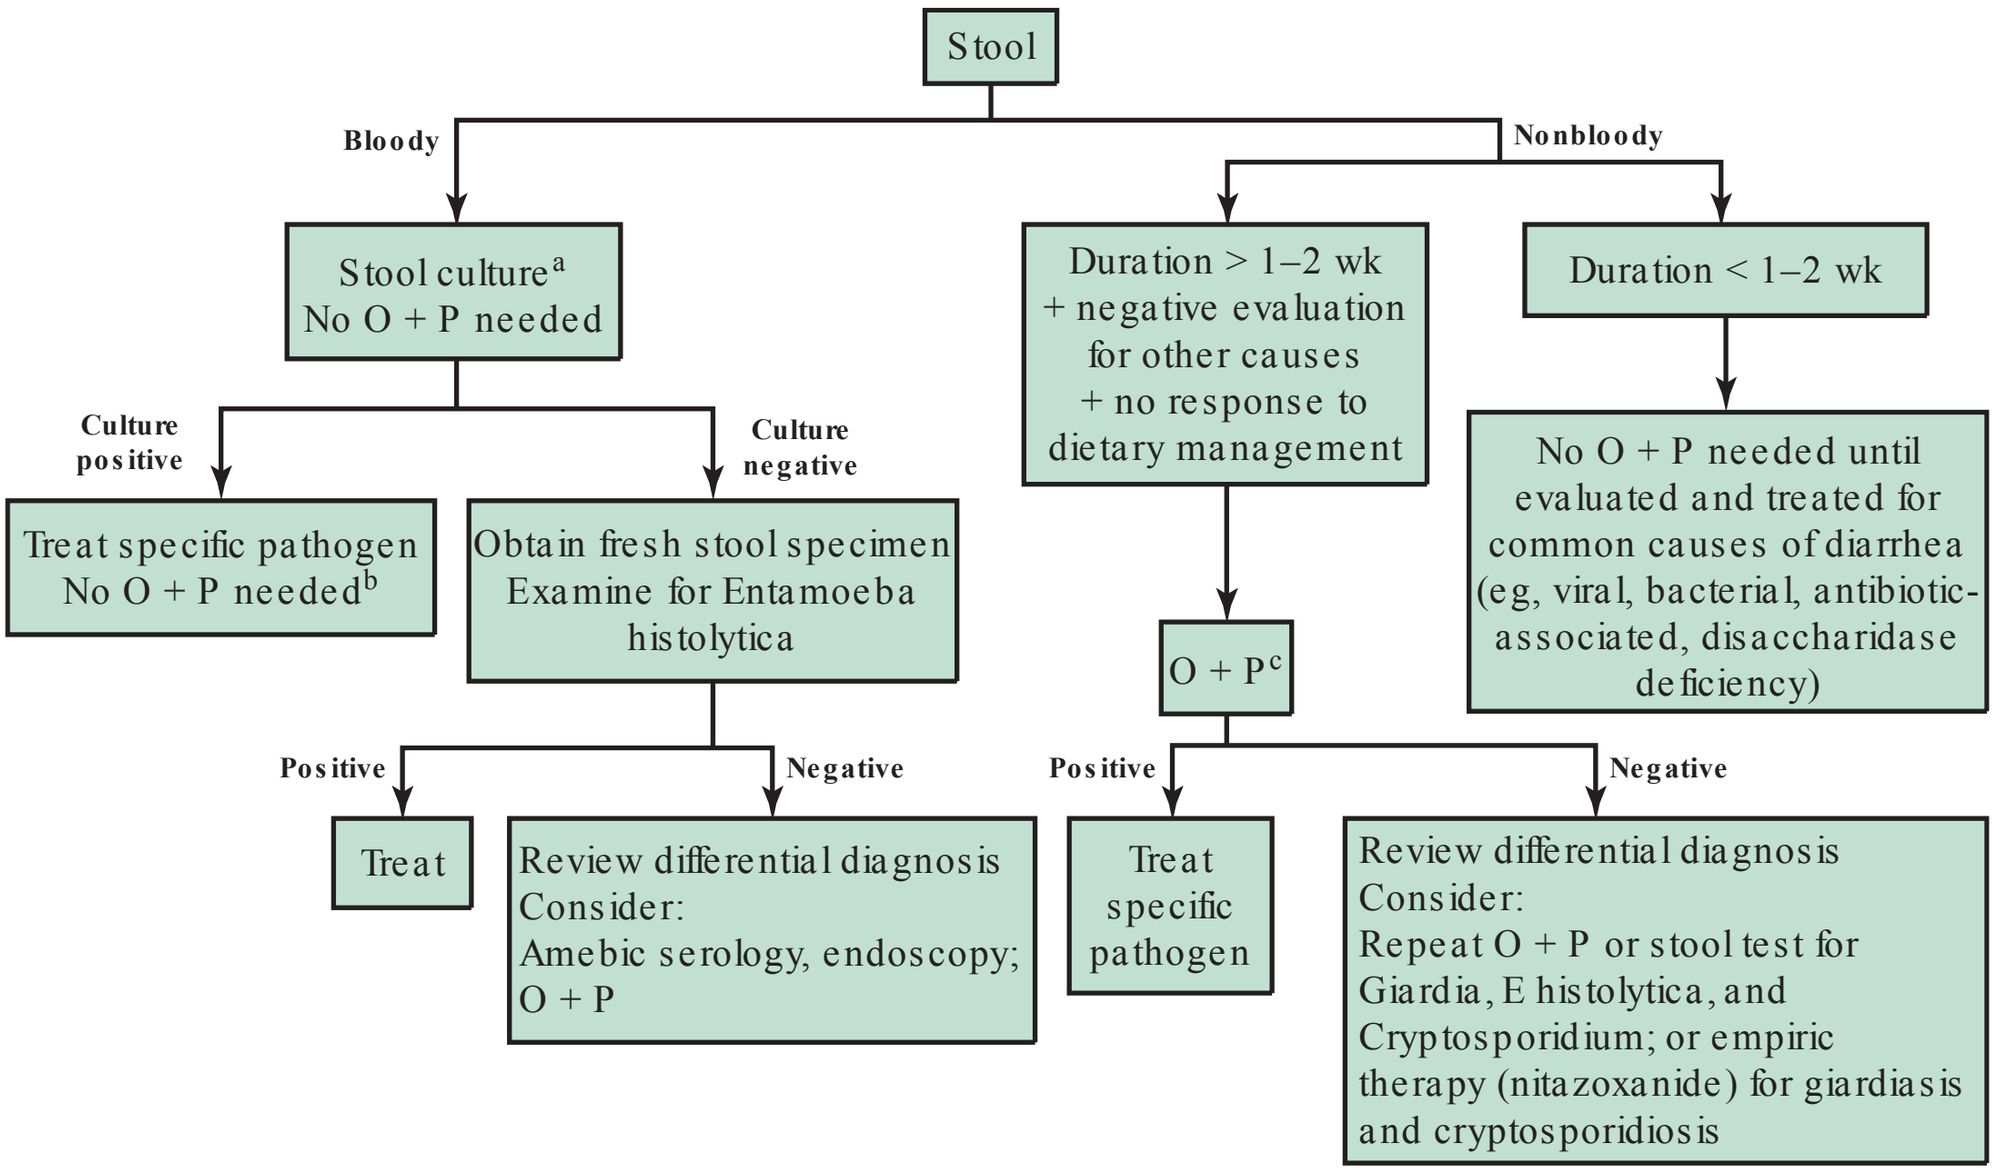
Sign/Symptom	Agent	Comments[a]
Abdominal pain	Anisakis	Shortly after raw fish ingestion.
	Ascaris	Heavy infection may obstruct bowel, biliary tract.
	Clonorchis	Heavy, early infection. Hepatomegaly later.
	Entamoeba histolytica	Hematochezia, variable fever, diarrhea.
	Fasciola hepatica	Diarrhea, vomiting.
	Hookworm	Iron deficiency anemia with heavy infection.
	Strongyloides	Eosinophilia, pruritus. May resemble peptic disease.
	Trichinella	Myalgia, periorbital edema, eosinophilia.
	Trichuris	Diarrhea, dysentery with heavy infection.
Cough	Ascaris	Wheezing, eosinophilia during migration phase.
	Paragonimus westermani	Hemoptysis; chronic. May mimic tuberculosis.
	Strongyloides	Wheezing, pruritus, eosinophilia during migration or dissemination.
	Toxocara	Affects ages 1–5 y; hepatosplenomegaly; eosinophilia.
	Tropical eosinophilia	Pulmonary infiltrates, eosinophilia.
Diarrhea	Blastocystis	Possibly with heavy infection in immunosuppressed or immunocompetent individuals.
	Cyclospora	Watery; severe in immunosuppressed individuals.
	Cryptosporidium	Watery; chronic in immunosuppressed individuals.
	Dientamoeba fragilis	Only with heavy infection.
	E histolytica	Hematochezia, variable fever; no eosinophilia.
	Giardia	Afebrile, chronic; anorexia.
	Schistosoma	Chronic; hepatosplenomegaly (some types).
	Strongyloides	Abdominal pain; eosinophilia.
	Trichinella	Myalgia, periorbital edema, eosinophilia.
	Trichuris	With heavy infection.
Dysentery	Balantidium coli	Swine contact.
	E histolytica	Few to no leukocytes in stool; fever; hematochezia.
	Schistosoma	During acute infection.
	Trichuris	With heavy infection.
Dysuria	Enterobius	Usually girls with worms in urethra, bladder; nocturnal, perianal pruritus.
	Schistosoma (S haematobium)	Hematuria. Exclude bacteriuria, stones (some types).
Headache (and other cerebral symptoms)	Angiostrongylus	Eosinophilic meningitis.
	Baylisascaris procyonis	Eosinophilic meningitis.
	Gnathostoma	Eosinophilic meningitis.
	Naegleria	Freshwater swimming; rapidly progressive meningoencephalitis.
	Plasmodium	Fever, chills, jaundice, splenomegaly. Cerebral ischemia (with P falciparum).
	Taenia solium	Cysticercosis. Focal seizures, deficits; hydrocephalus, aseptic meningitis.
	Toxoplasma	Meningoencephalitis (especially in infants and the immunosuppressed); focal lesions in immunosuppressed; hydrocephalus in infants.
	Trypanosoma	African forms. Chronic lethargy (sleeping sickness).
Pruritus	Ancylostoma braziliense	Creeping eruption; dermal serpiginous burrow.
	Enterobius	Perianal, nocturnal.
	Filaria	Variable; seen in many filarial diseases; eosinophilia.
	Hookworm	Local at penetration site in heavy exposure.
	Strongyloides	Diffuse with migration; may be recurrent.
	Trypanosoma	African forms; one of many nonspecific symptoms.

(Continued)

Table 43–1. Signs and symptoms of parasitic infection. (Continued)

Sign/Symptom	Agent	Comments[a]
Rash	Hookworm	Pruritic, papulovesicular rash at site of penetration.
	Schistosoma	Maculopapular rash at site of penetration.
	Strongyloides	Pruritic rash at site of penetration.
	Toxoplasma	Maculopapular rash seen with congenital and sometimes acquired infection.
Anemia	Diphyllobothrium	Megaloblastic due to vitamin B_{12} deficiency; rare.
	Hookworm	Iron deficiency.
	L donovani	Fever, hepatosplenomegaly, leukopenia (kala-azar).
	Plasmodium	Hemolysis.
	Trichuris	Heavy infection; due to iron loss.
Eosinophilia	Angiostrongylus	Eosinophilic meningitis.
	Baylisascaris procyonis	Eosinophilic meningitis.
	Fasciola	Abdominal pain.
	Gnathostoma	Eosinophilic meningitis.
	Filaria	Microfilariae in blood; lymphadenopathy.
	Onchocerca	Skin nodules, keratitis.
	Schistosoma	Chronic; intestinal or genitourinary symptoms.
	Strongyloides	Abdominal pain, diarrhea.
	Toxocara	Hepatosplenomegaly, cough; affects ages 1–5 y.
	Trichinella	Myalgia, periorbital edema.
	Tropical pulmonary eosinophilia	Cough; pulmonary infiltrates.
	T solium (cysticercosis)	Eosinophils in CSF.
Hematuria	Schistosoma	S haematobium. Bladder, urethral granulomas. Exclude stones.
Hemoptysis	P westermani	Lung fluke. Variable chest pain; chronic.
Hepatomegaly	Clonorchis	Heavy infection. Tenderness early; cirrhosis late.
	Echinococcus	Chronic; cysts.
	E histolytica	Toxic hepatitis or abscess. No eosinophilia.
	L donovani	Splenomegaly, fever, pancytopenia.
	Schistosoma (not haematobium)	Chronic; hepatic fibrosis, splenomegaly (some types).
	Toxocara	Splenomegaly, eosinophilia, cough; no adenopathy.
Splenomegaly	L donovani	Hepatomegaly, fever, anemia.
	Plasmodium	Fever, chills, jaundice, headache.
	Schistosoma (not haematobium)	Hepatomegaly.
	Toxocara	Eosinophilia, hepatomegaly.
	Toxoplasma	Lymphadenopathy, other symptoms.
Lymphadenopathy	Filaria	Inguinal typical; chronic.
	L donovani	Hepatosplenomegaly, pancytopenia, fever.
	Schistosoma	Acute infection; fever, rash, arthralgia, hepatosplenomegaly.
	Toxoplasma	Cervical common; may involve single group of nodes; splenomegaly.
	Trypanosoma	Localized near bite or generalized; hepatosplenomegaly (Chagas disease); generalized (especially posterior cervical) in African forms.

[a]Symptoms usually related to degree of infestation. Infestation with small numbers of organisms is often asymptomatic.



O + P = Ova and parasite examination.
[a]Shigella, Salmonella, Campylobacter, Escherichia coli O 157, Yersinia: assay for Clostridium difficile toxin if recent antimicrobial use.
[b]Unless critically ill, from endemic area for amebiasis, or unresponsive to standard therapy.
[c]Include examination for Cryptosporidium and Cyclospora; immediate stool fixation needed if stool is diarrheal.

▲**Figure 43–1.** Parasitologic evaluation of acute diarrhea.

is a cause of eosinophilia that may be difficult to diagnose with stool examinations. The differential diagnosis of eosinophilia is broad for patients who have been in developing countries (see Table 43–1).

» Splenomegaly, anemia.
» Can progress to coma, seizures.
» Malaria parasites in peripheral blood smear.

PROTOZOAL INFECTIONS

SYSTEMIC INFECTIONS

1. Malaria

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Residence in or travel to an endemic area (fever in the returning traveler).
» Cyclic paroxysms of fever, chills, and intense sweating.
» Headache, backache, cough, abdominal pain, nausea, vomiting, diarrhea.

» General Considerations

Malaria causes approximately 1 million deaths each year, over 80% of which occur in children younger than 5 years of age in sub-Saharan Africa. Global efforts toward malaria prevention and treatment have led to declining mortality and morbidity. Approximately 1500 imported cases are diagnosed in the United States each year; local transmission may occasionally take place from imported cases. Human malaria is caused by five Plasmodium species—Plasmodium vivax (most common), Plasmodium falciparum (most virulent), Plasmodium ovale (similar to P vivax), Plasmodium malariae, and Plasmodium knowlesi (a primate parasite recognized as a cause of malaria in humans).

The female Anopheles mosquito transmits the parasites. Infected mosquitoes inoculate sporozoites into the

bloodstream of a susceptible host, resulting in infection of hepatocytes. In the hepatic phase, the parasites mature into schizonts, which rupture and release merozoites into the circulation. The parasites infect and rupture red blood cells in the erythrocytic phase, as they mature from trophozoites to schizonts and release additional merozoites. In early stages of infection, asynchronous erythrocytic cycles of hemolysis commonly cause daily fevers. Eventually, synchronous erythrocytic cycles begin as parasites rupture the infected cells at more regular 48- or 72-hour intervals. Survival is associated with a progressive decrease in intensity of cycles. Relapses years later may occur from persistent hepatic infection, which occurs in P vivax and P ovale infections.

Susceptibility varies genetically; certain red cell phenotypes are partially resistant to P falciparum infection (hemoglobin S, hemoglobin F, thalassemia, and possibly glucose-6-phosphate dehydrogenase [G6PD] deficiency). The worldwide distribution of malaria species is determined to some extent by host genetic factors that have evolved in response to selective pressure from malaria. The absence of P vivax from Africa reflects the lack of specific Duffy blood group substances among most native Africans. Recurrent infections result in acquired species-specific immunity, which does not prevent infection, but decreases parasitemia and symptoms. Normal splenic function is an important factor because of the immunologic and filtration functions of the spleen. Asplenic persons develop rapidly progressive malaria with many circulating infected erythrocytes (including mature forms of P falciparum). Maternal immunity protects the neonate.

» Clinical Findings

A. Symptoms and Signs

Clinical manifestations vary according to species, strain, and host immunity. Fever and vomiting are the most common presenting symptoms in children. Infants commonly present with recurrent fever, irritability, poor feeding, vomiting, jaundice, and splenomegaly. Rash is usually absent, which helps distinguish malaria from some viral infections in patients presenting with similar symptoms. In older children, the classic symptoms of fever with chills, rigors, headache, backache, myalgia, and fatigue are more easily elicited. Fever may be cyclic (every 48 hours for all but P malariae infection, in which it occurs every 72 hours) or irregular (most commonly observed with P falciparum). Between attacks, patients may look quite well. If the disease is untreated, relapses cease within a year in P falciparum and within several years in P vivax infections, but may recur decades later with P malariae infection. Infection during pregnancy often causes intrauterine growth restriction or premature delivery but rarely true fetal infection.

Physical examination in patients with uncomplicated cases may show only mild splenomegaly and anemia.

B. Laboratory Findings

The diagnosis of malaria relies on detection of one or more of the five human plasmodia in thick and thin blood smears. Three separate sets of thick and thin smears separated by 12–24 hours in a 72-hour period are recommended to rule out malaria infection. Thick smears are most sensitive for detection of small numbers of malaria parasites; thin smears allow identification of species and semiquantitative determination of percentage of parasitemia.

Most acute infections are caused by P vivax, P ovale, or P falciparum, although 5%–7% are due to multiple species. Identification of the Plasmodium species relies on morphologic criteria and requires an experienced observer. Bench aids to assist in the identification of Plasmodium species can be found at http://www.dpd.cdc.gov/dpdx/HTML/Malaria.htm. A U.S. Food and Drug Administration (FDA)-approved antigen detection test is available and approved for rapid diagnostic testing of malaria. This test should be used in conjunction with microscopic examination to confirm diagnosis, look for mixed infection, and quantitate degree of parasitemia. The rapid antigen test has poor sensitivity for low levels of parasitemia. Up-to-date information on rapid diagnostic testing for malaria can be found at www.cdc.gov/malaria/diagnosis_treatment/index.html. Alternative techniques of similar or higher diagnostic accuracy for P falciparum include DNA hybridization and polymerase chain reaction (PCR), which are only available in research and reference laboratories and at CDC and some health departments.

The degree of parasitemia determined from thin smears is particularly useful in the management of infections caused by P falciparum and P knowlesi, in which high parasitemia (> 5% infected erythrocytes) is associated with high morbidity and mortality and requires hospitalization. Treatment response of P falciparum and chloroquine-resistant P vivax infections is best monitored by daily parasitemia assays. Constant or increased number of infected erythrocytes after 48 hours of treatment or after the second hemolytic crisis suggests an inadequate therapeutic response.

Hemolytic anemia and thrombocytopenia are common; the incidence of leukocytosis is variable.

» Differential Diagnosis

Clinical features may not reliably distinguish malaria from other infections in children, so a high index of suspicion in patients with exposure in endemic areas is necessary. The differential diagnosis of fever in a returning traveler should be based on diseases endemic to the region of travel and may include typhoid fever, tuberculosis, rickettsial disease, brucellosis, leptospirosis, yellow fever, dengue fever, chikungunya, and borreliosis. However, other common causes of fever, such as influenza, Mycoplasma pneumoniae or enteroviral infection, and serious bacterial causes such as occult sinusitis,

meningitis, pneumonia, or bacteremia should be considered. Malaria may also coexist with other diseases.

» Complications & Sequelae

Severe complications, which are limited to P falciparum and P knowlesi infection, result from hemolysis, microvascular obstruction, and tissue ischemia. The most common complications of malaria in children are cerebral malaria, respiratory distress, severe anemia, and/or hypoglycemia. Cerebral malaria, which is the most serious and life-threatening complication of malaria in children, may progress to seizures, coma, and death. Approximately 20% of children with cerebral malaria die and 10% have long-term neurologic sequelae. Signs of severe malaria in children include altered mental status, seizures, respiratory distress, hypoglycemia, acidosis, and parasitemia greater than 5%.

» Prevention

Malaria chemoprophylaxis regimens (see Chapter 45) should be instituted 2 weeks (weekly regimens) to 2 days (daily regimens) before traveling to an area of endemic infection. Because the antimalarial drugs recommended for prophylaxis do not kill sporozoites, therapy should be continued for 1 week (atovaquone-proguanil) or 4 weeks (all other regimens) after returning from an endemic area to cover infection acquired at departure.

No drug regimen guarantees protection against malaria. If fever develops within 1 year (particularly within 2 months) after travel to an endemic area, the possibility of malaria should be considered. Insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis.

» Treatment

Treatment for malaria includes a variety of supportive strategies in addition to the antimalarial drugs. It is advisable to hospitalize nonimmune patients infected with P falciparum and P knowlesi until a decrease in parasitemia is demonstrated, indicating that treatment is effective and severe complications are unlikely to occur. Patients with signs of severe malaria (parasitemia > 5%, cerebral malaria, acidosis, hypoglycemia, shock) require intensive care and parenteral treatment. Malaria due to P knowlesi should be treated like P falciparum malaria as it might progress rapidly into severe disease.

Partially immune patients with uncomplicated P falciparum and P knowlesi infection and nonimmune persons infected with P vivax, P ovale, or P malariae can receive outpatient treatment if follow-up is reliable. For children, hydration and treatment of hypoglycemia are of utmost importance. Anemia, seizures, pulmonary edema, and renal failure require conventional management. Corticosteroids are contraindicated for cerebral malaria because of increased mortality. As of 2013, exchange transfusion is no longer recommended by the CDC for the treatment of severe malaria.

Choice of antimalarial treatment depends on the immune status of the person, plasmodium species, degree of parasitemia, and resistance patterns in the geographical region of acquisition. An algorithm for the treatment of malaria is shown in Figure 43–2 and a description of the recommended antimalarial drugs available in the United States with updated treatment guidelines is available at the CDC website (http://www.cdc.gov/malaria/diagnosis_treatment/treatment.html). Artemisinin derivatives clear parasites very rapidly and are widely used as key components, often as first-line therapy, in malaria treatment worldwide. These are available in the United States for the treatment of severe malaria only by contacting the CDC (http://www.cdc.gov/malaria/diagnosis_treatment/artesunate.html) or the Malaria Hotline at 770-488-7788.

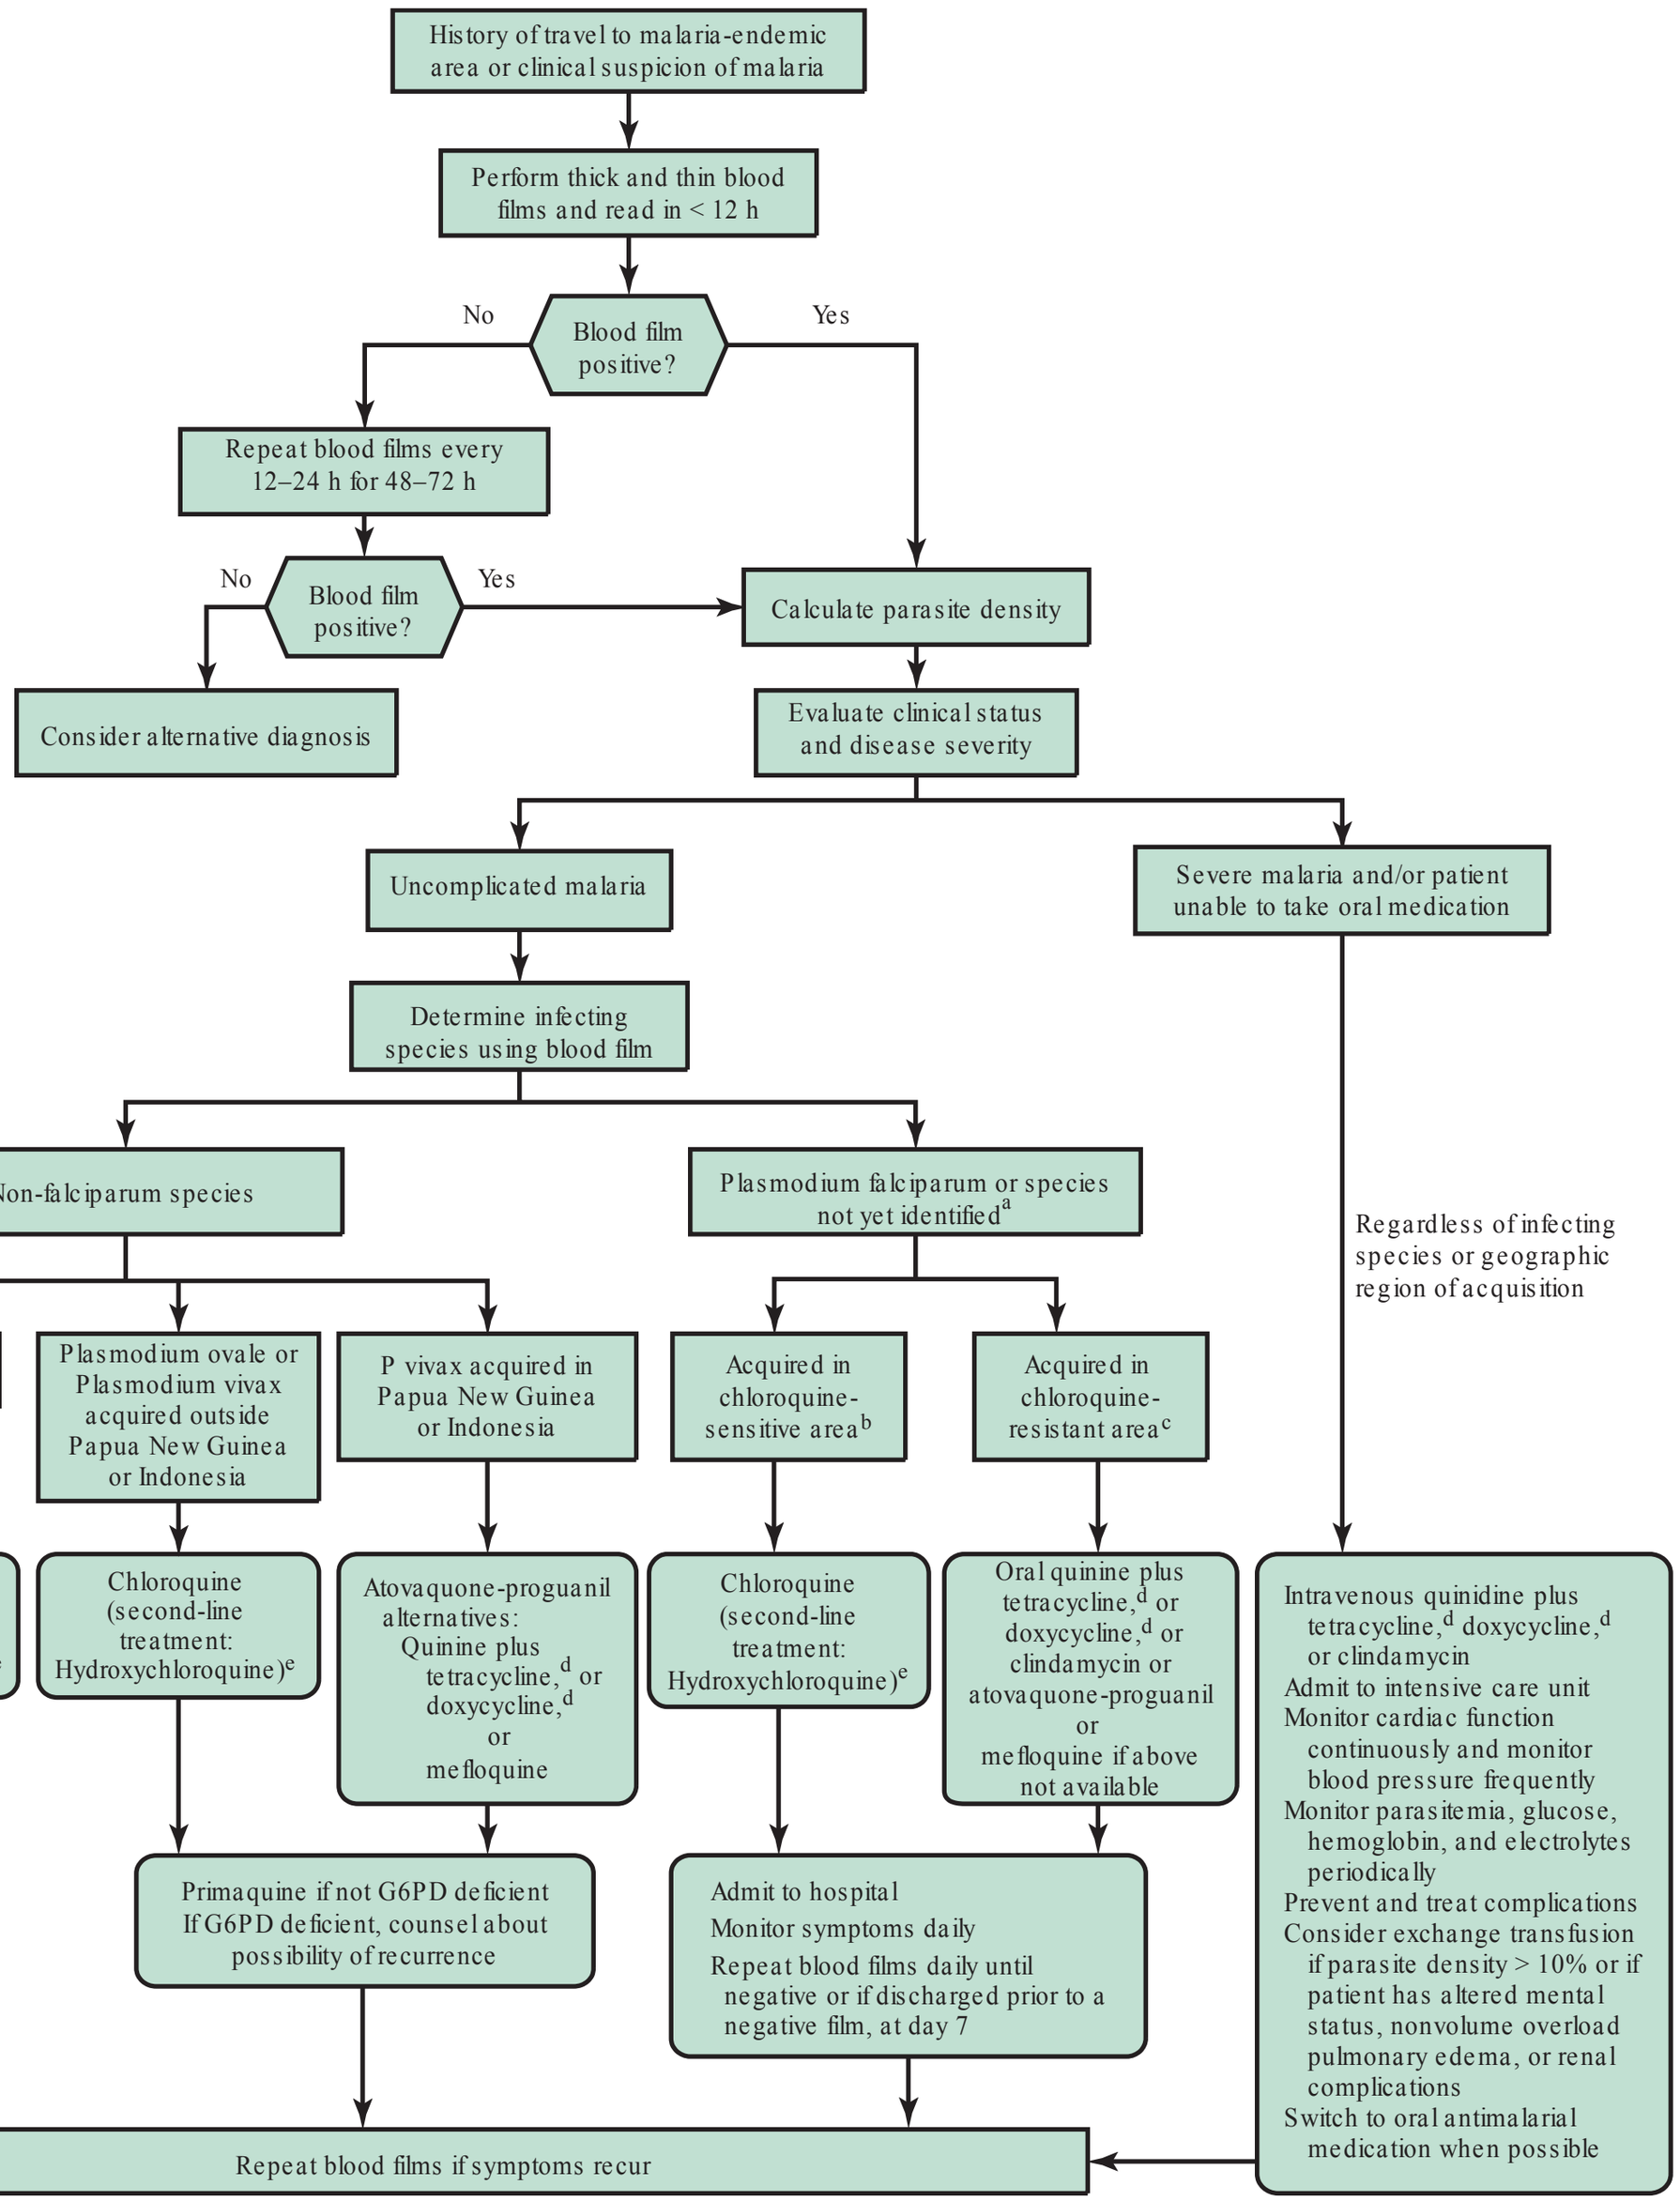
2. Babesiosis

Babesia microti is a malaria-like protozoan that infects humans bitten by infected Ixodes scapularis (deer tick), one of its intermediate hosts and vectors. After inoculation, the protozoan penetrates erythrocytes and starts an asynchronous cycle that causes hemolysis. In the United States, the majority of cases occur in the Northeast and upper Midwest from May to October. Babesia infection is also a transfusion-transmissible disease.

» Clinical Findings

A. Symptoms and Signs

The incubation period is 1–4 weeks after tick bite, or 1–9 weeks after blood transfusion. Many times the tick bite is unnoticed. Approximately half of infected children are asymptomatic. Symptoms are nonspecific and most commonly include sustained or cyclic fever up to 40.9°C, shaking chills, and sweats. Other associated nonspecific symptoms include malaise,



[a]If species not yet identified is subsequently diagnosed as a non-falciparum infection, then complete treatment as per the identified species recommendations. G6PD indicates glucose-6-phosphate dehydrogenase.
[b]Central America west of the Panama Canal, Mexico, Hispaniola, parts of China, and the Middle East.
[c]All malaria-endemic countries except those listed in second footnote.
[d]Contraindicated in pregnant women and children younger than 8 years of age.
[e]Drug options for chloroquine-resistant P falciparum may also be used if chloroquine or hydroxychloroquine cannot be used.

▲**Figure 43–2.** Malaria treatment algorithm. (Adapted with permission from Centers for Disease Control and Prevention. Malaria.)

fatigue, anorexia, arthralgias, myalgias, and headache. Physical examination findings are usually minimal, but may include hepatosplenomegaly, jaundice, or dark urine. The disease is usually self-limited, causing symptoms for 1–2 weeks with fatigue that may persist for months. Severe cases have been described in asplenic patients and immunocompromised hosts. Because Babesia, Borrelia burgdorferi, and Anaplasma phagocytophilum share a common vector, physicians should consider the possibility of coinfection in patients diagnosed with any of these pathogens.

B. Laboratory Findings

The diagnosis is made by identifying babesial parasites in blood by microscopic evaluation of thin or thick blood smears or by PCR amplification of babesial DNA. Babesia parasites are intraerythrocytic organisms that resemble P falciparum ring forms. The tetrad form (Maltese cross), if visualized, is pathognomonic. Specific serologic tests are also available through the CDC. Hemolytic anemia, as well as thrombocytopenia, is common.

» Treatment

Azithromycin (10 mg/kg up to 500 mg on the first day, followed by 5 mg/kg up to 250 mg/day) in combination with atovaquone (20 mg/kg, up to 750 mg, twice a day) for 7–10 days is the treatment of choice for mild to moderate disease. This is efficacious and causes fewer adverse side effects than other regimens. For severely ill patients, clindamycin (10 mg/kg, up to 600 mg, every 8 hours) in combination with quinine (8 mg/kg, up to 650 mg, every 8 hours) is standard of care. Longer courses of treatment may be needed in immunocompromised patients. Partial or complete RBC exchange transfusion is indicated for persons with severe babesiosis, as indicated by high-grade parasitemia (≥ 10%); significant hemolysis; or renal, hepatic, or pulmonary compromise.

3. Toxoplasmosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Congenital toxoplasmosis: chorioretinitis, microphthalmia, strabismus, microcephaly, hydrocephaly, convulsions, psychomotor retardation, intracranial calcifications, jaundice, hepatosplenomegaly, abnormal blood cell counts.
- Acquired toxoplasmosis in an immunocompetent host: lymphadenopathy, hepatosplenomegaly, rash.
- Acquired or reactivated toxoplasmosis in an immunocompromised host: encephalitis, chorioretinitis, myocarditis, and pneumonitis.
- Ocular toxoplasmosis: chorioretinitis.
- Serologic evidence of infection with Toxoplasma gondii or demonstration of the agent in tissue or body fluids.

» General Considerations

Toxoplasma gondii is a worldwide parasite of animals and birds. Felines, the definitive hosts, excrete oocysts in their feces. Ingested mature oocysts or tissue cysts lead to tachyzoite invasion of intestinal cells. Intracellular replication of the tachyzoites causes cell lysis and spread of the infection to adjacent cells or to other tissues via the bloodstream. In chronic infection, T gondii appears as bradyzoite-containing tissue cysts that do not trigger an inflammatory reaction. In immunocompromised hosts, tachyzoites are released from cysts and begin a new cycle of infection.

The two major routes of Toxoplasma transmission to humans are oral and congenital. Oral infection occurs after ingestion of cysts from food, water, or soil contaminated with cat feces or from ingestion of undercooked meat or other food products that contain cysts. Oocysts survive up to 18 months in moist soil but is limited in dry, very cold, or very hot conditions and at high altitude, which probably accounts for the lower incidence of toxoplasmosis in these climatic regions. In the United States, less than 1% of cattle and 25% of sheep and pigs are infected with toxoplasmosis. In humans, depending on geographic area, seropositivity increases with age from 0 to 10% in children younger than 10 years to 3%–70% in adults.

Congenital transmission occurs during acute infection of pregnant women. Rarely, fetal infection has been documented in immunocompromised mothers who have chronic toxoplasmosis. Treatment during pregnancy decreases transmission by 60%.

» Clinical Findings

Clinical toxoplasmosis can be divided into four groups: (1) congenital infection, (2) infection acquired in the immunocompetent host, (3) infection acquired or reactivated in the immunocompromised host, and (4) ocular disease.

A. Congenital Toxoplasmosis

Congenital toxoplasmosis, which is the result of acute infection during pregnancy, occurs in 1 in 3000 to 10,000 live births in the United States. The rate of transmission and disease severity in the baby vary according to when in pregnancy the infection is acquired. First-trimester infections lead to

congenital infections about 10%–20% of the time, but the clinical disease is severe with microcephaly or hydrocephaly, severe chorioretinitis, hearing loss, convulsions, abnormal cerebrospinal fluid (CSF) (xanthochromia and mononuclear pleocytosis), cerebral calcifications, and mental retardation. Other findings include strabismus, eye palsy, maculopapular rash, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, thrombocytopenia, lymphocytosis and monocytosis, and an erythroblastosis-like syndrome. Infection of a mother in the third trimester results in a 70%–90% rate of congenital infection, but the majority of these children are asymptomatic at birth, although many will develop ocular disease later and some will have subtle neurologic deficits.

B. Acquired Toxoplasma Infection in the Immunocompetent Host

Typically, acquired infection in the immunocompetent host is asymptomatic. About 10%–20% of patients develop an infectious mononucleosis-like syndrome with lymphadenopathy and/or a flu-like illness. The nodes are discrete, variably tender, and do not suppurate. Cervical lymph nodes are most frequently involved, but any nodes may be enlarged. Less common findings include fever, malaise, myalgias, fatigue, hepatosplenomegaly, lymphopenia (usually < 10%), and liver enzyme elevations. Unilateral chorioretinitis may occur. Recovery typically occurs without any specific antiparasitic treatment, although lymph node enlargement may persist or may wax and wane for a few months to 1 or more years.

C. Acute Toxoplasmosis in the Immunodeficient Host

Patients infected with human immunodeficiency virus (HIV), and those with lymphoma, leukemia, or transplantation, are at high risk for developing severe disease (most commonly central nervous system [CNS] disease, but also chorioretinitis, myocarditis, or pneumonitis) following acute infection or reactivation. Toxoplasmic encephalitis is a common cause of mass lesions in the brains of persons with HIV/AIDS.

D. Ocular Toxoplasmosis

Ocular toxoplasmosis is an important cause of chorioretinitis in the United States. It results from reactivation of congenital infection or acquired infection. Congenitally infected individuals are usually asymptomatic until the second or third decade of life when symptomatic eye disease occurs due to the rupture of tissue cysts and the release of bradyzoites and tachyzoites into the retina. Typically, ocular toxoplasmosis presents as a focal necrotizing retinochoroiditis often associated with a preexistent chorioretinal scar, and variable involvement of the vitreous, retinal blood vessels, optic nerve, and anterior segment of the eye. The appearance of the ocular lesion is not specific and mimics other granulomatous ocular diseases.

E. Diagnostic Findings

Serologic tests are the primary means of diagnosis, but results must be interpreted carefully. Reference laboratories with special expertise in toxoplasma serologic assays and their interpretation are preferred for establishing a diagnosis. Active infection can also be diagnosed by PCR of blood or body fluids; by visualization of tachyzoites in histologic sections or cytology preparations, cysts in placenta or fetal tissues; or by characteristic lymph node histology. IgG antibodies become detectable 1–2 weeks after infection, peak at 1–2 months, and thereafter persist for life. IgM antibodies, measured by ELISA (enzyme-linked immunosorbent assay) or particle agglutination, appear earlier and decline faster than IgG antibodies, but can last for 12–18 months after acute infection. Absence of both serum IgG and IgM virtually rules out the diagnosis of toxoplasmosis. Acute toxoplasmosis in an immunocompetent host is best documented by analyzing IgG and IgM in paired blood samples drawn 3 weeks apart. Because high antibody titers (IgM or IgG) can persist for several months after acute infection, a single high-titer determination is nondiagnostic; seroconversion or a fourfold increase in titer confirms the diagnosis. In the immunocompromised host, serologic tests are not sensitive, and active infection is documented by PCR or finding tachyzoites by histologic examination.

The diagnosis of toxoplasmosis in the older child with visual complaints is usually made by finding T gondii IgG or IgM antibodies in the serum combined with the presence of a typical eye lesion. The diagnosis can be confirmed by detecting T gondii DNA by PCR in the aqueous humor.

Diagnosis of congenital infection can be difficult and is made by a combination of serologic testing, parasite isolation, and clinical findings. Prenatally, diagnosis can be made by PCR of amniotic fluid. Postnatally, evaluation of the baby should include Toxoplasma-specific IgG, IgM, IgA, and IgE of the newborn and mother. A congenital infection is confirmed serologically by detecting persistent or increasing IgG antibody levels compared to the mother, persistently positive IgG antibodies beyond the first year of life, and/or a positive T gondii–specific IgM or IgA antibody test. Persistence of the other antibodies also indicates infection of the infant. Blood, CSF, and amniotic fluid specimens should be assayed by PCR for the presence of T gondii in a reference laboratory. In addition, the child should have thorough ophthalmologic, auditory, and neurologic evaluation; a lumbar puncture; and computed tomographic (CT) scan of the head (to detect CNS calcifications).

» Differential Diagnosis

Congenital toxoplasmosis must be differentiated from infection with cytomegalovirus, rubella, herpes simplex, syphilis, listeriosis, erythroblastosis, and the encephalopathies that accompany degenerative diseases. Acquired infection can

mimic viral, bacterial, or lymphoproliferative disorders. Ocular toxoplasmosis can mimic other infectious, noninfectious, and neoplastic ocular conditions.

» Prevention

Primary prevention of toxoplasmosis in pregnant women (and immunocompromised patients) is an essential public health goal and guidelines have been published by the CDC. These include (1) cook meat until well-done 145–165°F (no longer pink in center); (2) peel and/or wash fruits and vegetables thoroughly before eating; (3) wash hands, cutting boards, kitchen surfaces, and utensils after contact with raw meat; (4) avoid drinking untreated water from unsanitary sources; (5) wear gloves when gardening or coming in contact with soil or sand, as cat feces may contaminate them; and (6) pregnant women should avoid changing cat litter. If they cannot avoid changing cat litter, they should change it daily as oocysts require 48–72 hours to sporulate and become infectious. Serologic screening of pregnant women remains a controversial tool in the prevention of congenital toxoplasmosis.

» Treatment

Treatment of acute toxoplasmosis in the immunocompetent host does not require specific therapy, unless the infection occurs during pregnancy. Toxoplasmic chorioretinitis presenting beyond infancy is treated the same way regardless of whether it is due to reactivation or primary infection. Treatment consists of oral pyrimethamine (2 mg/kg maximum, 200 mg loading dose followed by 1 mg/kg daily [maximum 75 mg]) plus sulfadiazine (100 mg/kg daily, maximum 1500 mg), given with leucovorin (10–20 mg three times a week). In addition, corticosteroids (prednisone 1 mg/kg daily) are given when lesions threaten vision. Treatment is given for 1–2 weeks after the resolution of symptoms. The duration of additional therapy should be guided by frequent ophthalmologic examinations. Pyrimethamine can cause gastrointestinal upset, leukopenia, thrombocytopenia, and rarely, agranulocytosis; weekly complete blood counts should be checked while on therapy.

A year of treatment is recommended for all congenitally infected infants. Children treated with pyrimethamine (loading dose 2 mg/kg daily for 2 days followed by 1 mg/kg daily for 6 months followed by 1 mg/kg every Monday, Wednesday, and Friday for 6 months) plus sulfadiazine (100 mg/kg divided twice daily for 12 months) plus leucovorin (10 mg 3 times a week) have better neurodevelopmental and visual outcomes than historical controls. While on therapy, infants should be monitored for bone marrow toxicity.

In primary maternal infection during the first 18 weeks of pregnancy, spiramycin is recommended to attempt to prevent fetal infection. Spiramycin does not cross the placenta, so does not treat fetal infection. If fetal infection has been documented or if primary maternal infection occurs after the first 18 weeks of pregnancy, pyrimethamine, sulfadiazine, and leucovorin are recommended. Pyrimethamine is teratogenic and should not be used before 18 weeks of gestation.

GASTROINTESTINAL INFECTIONS

1. Amebiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Acute dysentery: diarrhea with blood and mucus, abdominal pain, tenesmus.

Or

» Chronic nondysenteric diarrhea.

Or

» Hepatic abscess.

» Amoebas or cysts in stool or abscesses; amebic antigen in stool.

» Serologic evidence of amebic infection.

» General Considerations

Amebiasis is defined as an infection with Entamoeba histolytica regardless of symptoms. This parasite is found worldwide, but has a particularly high prevalence in areas with poor sanitation and socioeconomic conditions. In the United States, infections are seen in travelers to and emigrants from endemic areas. The majority of infections are asymptomatic (> 90%), but tissue invasion can result in amebic colitis, hepatic abscess, and hematogenous spread to other organs. Transmission is usually fecal-oral. Infections with two other Entamoeba species, E dispar and E moshkovskii, are morphologically indistinguishable from

E histolytica. Infections with these species are approximately 10 times more common than infection with E histolytica, but are not thought to cause human disease.

» Clinical Findings

A. Symptoms and Signs

Patients with intestinal amebiasis can have asymptomatic cyst passage, or be symptomatic with acute amebic proctocolitis, chronic nondysenteric colitis, or ameboma. Because all E dispar and E moshkovskii infections and up to 90% of E histolytica infections are asymptomatic, carriage is the most common manifestation of amebiasis. Patients with acute amebic colitis typically have a 1- to 2-week history of loose stools containing blood and mucus, abdominal pain, and tenesmus. A minority of patients are febrile or dehydrated. Abdominal examination may reveal pain over the lower abdomen.

Fulminant colitis is an unusual complication of amebic dysentery that is associated with a grave prognosis (> 50% mortality), and is characterized by severe bloody diarrhea, fever, and diffuse abdominal pain. Children younger than age 2 years are at increased risk for this condition. Chronic amebic colitis causes recurrent episodes of bloody diarrhea over a period of years and is clinically indistinguishable from idiopathic inflammatory bowel disease. An ameboma is a localized amebic infection, usually in the cecum or ascending colon, which presents as a painful abdominal mass.

The most common complications of intestinal amebiasis are intestinal perforation, toxic megacolon, and peritonitis. Perianal ulcers, a less common complication, are painful, punched-out lesions that usually respond to medical therapy. Infrequently, colonic strictures may develop following colitis.

Patients with amebic liver abscess, the most common form of extraintestinal amebiasis, typically present with acute fever and right upper quadrant tenderness. The pain may be dull, pleuritic, or referred to the right shoulder. Physical examination reveals liver enlargement in less than 50% of affected patients. Some patients have a subacute presentation lasting 2 weeks to 6 months. In these patients, hepatomegaly, anemia, and weight loss are common findings, and fever is less common. Jaundice and diarrhea are rarely associated with an amebic liver abscess. In children with fever of unknown origin who live in, or travel to, endemic areas, amebic liver abscess should be considered in the differential diagnosis.

The most common complication of amebic liver abscess is pleuropulmonary amebiasis due to rupture of a right liver lobe abscess. Lung abscesses may occur from hematogenous spread. Cough, dyspnea, and pleuritic pain can be caused by the serous pleural effusions and atelectasis that frequently accompany amebic liver abscesses. Rupture of hepatic abscesses can lead to peritonitis and more rarely to pericarditis. Amebic brain abscess is an infrequent manifestation.

B. Diagnostic Findings

The differential diagnosis of acute amebic colitis includes bacterial (eg, Salmonella spp, Shigella spp, E coli spp, Campylobacter spp), parastitic (eg, Schistosoma mansoni, Balantidium coli), and noninfectious (eg, inflammatory bowel disease, diverticulitis, ischemic colitis) causes of dysentery. Chronic amebic colitis has to be distinguished from inflammatory bowel disease and Cyclospora. Liver abscess must be distinguished from echinococcal hydatid cyst. Occult blood is present in virtually all cases of amebic colitis and can be used as an inexpensive screening test. Fecal leukocytes are uncommon.

Intestinal amebiasis can be presumptively diagnosed by detecting the parasite on stool examination or mucosal biopsy. However, E histolytica is morphologically identical to nonpathogenic E dispar and E moshkovskii and cannot be easily differentiated by microscopy. The presence of trophozoites with ingested red blood cells in feces is more suggestive of pathogenic E histolytica infection. Ideally, a wet mount preparation of the stool should be examined within 20 minutes after collection to detect motile trophozoites. Otherwise, specimens should be fixed with polyvinyl alcohol or refrigerated to avoid disintegration of the trophozoites. The antigen detection test for stool is very sensitive and more specific, because it detects E histolytica–specific antigens that do not cross-react with E dispar. Colonoscopy and biopsy are most helpful in diagnosing amebic colitis when stool samples lack ova or parasites. Barium studies are contraindicated for patients with suspected acute amebic colitis due to risk of perforation.

The presence of antibodies against E histolytica can differentiate E histolytica from E dispar infections. Specific antibody is induced by both intestinal and extraintestinal invasive amebiasis. ELISA assays are positive in approximately 95% of patients with extraintestinal amebiasis, 70% with intestinal E histolytica disease, and 10% of asymptomatic patients shedding E histolytica cysts. However, these antibodies persist for years, and a positive result does not distinguish between acute and past infection. Antibody testing can be useful in a traveler from a nonendemic area who is returning from a trip to an endemic area. Ultrasonographic examination and CT are sensitive techniques to detect hepatic abscesses and can be used to guide fine-needle aspiration to obtain specimens for definitive diagnosis. Because an amebic abscess may take up to 2 years to completely resolve on CT scans, imaging techniques are not recommended for therapeutic evaluation. PCR-based testing has the highest sensitivity and specificity for the diagnosis of E histolytica, but is only available in certain research and reference laboratories.

Table 43–2. Treatment of amebiasis.

Type of Infection	Drug of Choice	Dosage
Asymptomatic	Paromomycin	25–35 mg/kg/d in three doses for 7 d
	or	
	Iodoquinol	30–40 mg/kg/d (maximum, 2 g) in three doses for 20 d
	or	
	Diloxanide furoate[a]	20 mg/kg/d up to 1.5 g/d in three doses for 10 d
Intestinal disease and hepatic abscess[b]	Metronidazole	35–50 mg/kg/d up to 2.25 g/d in three doses for 10 d
	or	
	Tinidazole[c]	50 or 60 mg/kg up to 2 g/d for 3 d

[a]Diloxanide furoate is available from the CDC Drug Service: (404) 639–3670.
[b]Treatment should be followed by iodoquinol or paromomycin.
[c]Not marketed in the United States; higher dosage.

» Prevention & Treatment

Travelers to endemic areas should drink bottled or boiled water and eat cooked or peeled vegetables and fruits to prevent enteric infection.

Treatment of amebic infection is complex because different agents are required for eradicating the parasite from the bowel or tissue (Table 43–2). Whether treatment of asymptomatic cyst passers is indicated is controversial. The prevalent opinion is that asymptomatic infection with E histolytica, as evidenced by amebic cysts in the stool and a positive serologic test, should be treated in nonendemic areas. If serologic tests are negative, the cysts are more likely to represent infection with the nonpathogenic E dispar, which does not require treatment.

Asymptomatic E histolytica cyst excreters may be treated with paromomycin, a nonabsorbable intraluminal amebicide. Diloxanide and iodoquinol are alternative intraluminal agents. Metronidazole is not effective against cysts.

Patients with symptomatic intestinal amebiasis or extraintestinal disease require treatment with an absorbable agent, such as metronidazole or tinidazole, followed by an intraluminal agent. Metronidazole has a disulfiram-like effect and should be avoided in patients receiving ethanol-containing medications. Tinidazole, a more potent nitroimidazole against amebic infection, can be used for shorter treatment courses and is well tolerated in children. Treatment of invasive amebiasis should always be followed with an intraluminal cysticidal agent, even if the stool examination is negative. Metronidazole and paromomycin should not be given concurrently, because the diarrhea that is a common side effect of paromomycin may make it difficult to assess response to therapy. In most patients with amebic liver abscess, aspiration is unnecessary and does not speed recovery. Patients with large, thin-walled hepatic abscesses may need therapeutic aspiration to avoid abscess rupture. Drainage may also be considered when response to medical therapy is inadequate.

2. Giardiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Chronic relapsing diarrhea, flatulence, bloating, anorexia, poor weight gain.
- No fever or hematochezia.
- Detection of trophozoites, cysts, or Giardia antigens in stool.

» General Considerations

Giardiasis, caused by Giardia intestinalis (formerly Giardia lamblia), is the most common intestinal protozoal infection in children in the United States and in most of the world. The infection is classically associated with drinking contaminated water, either in rural areas or in areas with faulty purification systems. Even ostensibly clean urban water supplies can be contaminated intermittently, and infection has been acquired in swimming pools. Fecal-oral contamination allows person-to-person spread. Day care centers are a major source of infection. No symptoms occur in 25% of infected persons, facilitating spread to household contacts. Food-borne outbreaks also occur. Giardiasis may occur at any age, although infection is rare in neonates.

» Clinical Findings

A. Symptoms and Signs

Giardia infection is followed by either asymptomatic cyst passage, acute self-limited diarrhea, or a chronic syndrome of diarrhea, malabsorption, and weight loss. Acute diarrhea

occurs 1–2 weeks after infection and is characterized by abrupt onset of diarrhea with greasy, malodorous stools; malaise; flatulence; bloating; and nausea. Fever and vomiting are unusual. The disease has a protracted course (> 1 week) and frequently leads to weight loss. Giardiasis can be a self-limited infection in some patients, and in others cause chronic symptoms. Patients who develop chronic diarrhea complain of profound malaise, lassitude, headache, and diffuse abdominal pain in association with bouts of diarrhea—most typically foul-smelling, greasy stools—intercalated with periods of constipation or normal bowel habits. This syndrome can persist for months until specific therapy is administered or until it subsides spontaneously. Chronic diarrhea frequently leads to malabsorption, steatorrhea, vitamins A and B_{12} deficiencies, and disaccharidase depletion. Lactose intolerance, which develops in 20%–40% of patients can persist for several weeks after treatment, and needs to be differentiated from relapsing giardiasis or reinfection.

B. Laboratory Findings

Giardia antigen detection by means of ELISAs, nonenzymatic immunoassays, and direct fluorescence antibody tests are the standard diagnostic tests in the United States. They have a more rapid return of results, and are more sensitive and specific than stool ova and parasite examination. In resource-poor areas without access to antigen tests, the diagnosis of giardiasis can be made by finding the parasite in stool. For ova and parasite examination, a fresh stool provides the best results. Liquid stools have the highest yield of trophozoites, which are more readily found on wet mounts. With semiformed stools, the examiner should look for cysts in fresh or fixed specimens, preferably using a concentration technique. When these techniques are applied carefully, one examination has a sensitivity of 50%–70%; three examinations increase the sensitivity to 90%. With a careful stool ova and parasite examination or with the use of a new antigen test, direct sampling of duodenal aspirates or biopsy is restricted to particularly difficult cases.

» Prevention

The prevention of giardiasis requires proper treatment of water supplies and interruption of person-to-person transmission. Where water might be contaminated, travelers, campers, and hikers should use methods to make water safe for drinking. Boiling is the most reliable method; the necessary time of boiling (1 minute at sea level) will depend on the altitude. Chemical disinfection with iodine or chlorine and filtration are alternative methods of water treatment.

Interrupting fecal-oral transmission requires strict hand washing. However, outbreaks of diarrhea in day care centers might be particularly difficult to eradicate. Reinforcing hand washing and treating the disease in both symptomatic and asymptomatic carriers may be necessary.

» Treatment

Metronidazole, tinidazole, and nitazoxanide are the drugs of choice for treatment of giardiasis. When given at 5 mg/kg (up to 250 mg) three times a day for 5–7 days, metronidazole has 80%–95% efficacy. The drug is well tolerated in children. Tinidazole has an efficacy approaching 90% when given as a single dose of 50 mg/kg (up to 2 g). Nitazoxanide is available in liquid formulation and requires only 3 days of treatment. Recommended doses are 100 mg (5 mL) every 12 hours for children 12–47 months of age, 200 mg every 12 hours for 4- to 11-year-olds, and 500 mg every 12 hours for children 12 years or older. For patients who do not respond to therapy, or are reinfected, a second course with the same drug or switching to another drug is equally effective. In cases of repeated treatment failure, albendazole (400 mg/d for 5–10 days), although not specifically recommended in the United States for the treatment of giardiasis, is an effective option.

http://www.cdc.gov/parasites/giardia/.

Huang DB et al: An updated review on Cryptosporidium and Giardia. Gastroenterol Clin North Am 2006;35:291 [PMID: 16880067].

3. Cryptosporidiosis

Cryptosporidia are intracellular protozoa that gained importance because they cause severe and devastating diarrhea in patients with acquired immunodeficiency syndrome (AIDS) and in other immunodeficient persons. This ubiquitous parasite infects and reproduces in the epithelial cell lining of the digestive and respiratory tracts of humans and most other vertebrate animals. Humans acquire the infection from contaminated drinking water, recreation water sources (including swimming pools, fountains, and lake water), or from close contact with infected humans or animals. Cryptosporidia are the leading cause of recreational water-associated outbreaks in the United States. Petting zoos and day care centers have been other sources of Cryptosporidia outbreaks. Most human infections are caused by C parvum or C hominis, although other species have been reported to cause human disease.

» Clinical Findings

A. Symptoms and Signs

Immunocompetent persons infected with Cryptosporidium spp usually develop self-limited diarrhea (2–26 days) with

or without abdominal cramps. Diarrhea can be mild and intermittent or continuous, watery, and voluminous. Low-grade fever, nausea, vomiting, loss of appetite, and malaise may accompany the diarrhea. Children younger than age 2 years are more susceptible to infection than older children. Immunocompromised patients (either cellular or humoral deficiency) tend to develop a severe, prolonged, chronic diarrhea which can result in severe malnutrition, and subsides only after the immunodeficiency is corrected. Other clinical manifestations associated with cryptosporidiosis in immunocompromised hosts include cholecystitis, pancreatitis, hepatitis, biliary tree involvement, and respiratory symptoms.

B. Laboratory Findings

Visualization of Cryptosporodia oocysts in the stool is diagnostic. Direct immunofluorescent antibody (DFA) of stool is the test of choice for visualizing oocysts. Oocysts can also be visualized with a modified Kinyoun acid-fast stain on concentrated stool. ELISA and point-of-care rapid tests are commercially available and superior to conventional microscopy.

» Prevention & Treatment

Prevention of Cryptosporidium infection is limited by oocyst resistance to some of the standard water purification procedures and to common disinfectants. Enteric precautions are recommended for infected persons. Boiled or bottled drinking water may be considered for those at high risk for developing chronic infection (eg, inadequately treated patients with AIDS).

Immunocompetent patients and those with temporary immunodeficiencies respond to treatment with nitazoxanide, antidiarrheal agents, and hydration. Immunocompromised patients usually require more intense supportive care with parenteral nutrition in addition to hydration and nonspecific antidiarrheal agents. Nitazoxanide for 3 days is the treatment of choice; recommended doses are 100 mg (5 mL) every 12 hours for children 12–47 months of age, 200 mg every 12 hours for 4- to 11-year-olds, and 500 mg every 12 hours for children 12 years or older. For patients with advanced AIDS, antiparasitic therapy alone has not proven efficacious. Institution of effective antiretroviral therapy results in elimination of symptomatic cryptosporidiosis.

http://www.cdc.gov/parasites/crypto/.

Huang DB et al: An updated review on Cryptosporidium and Giardia. Gastroenterol Clin North Am 2006;35:291 [PMID: 16880067].

4. Cyclosporiasis

Cyclospora spp are ubiquitous coccidian parasites that infect both humans and a variety of animals worldwide. Cyclospora cayetanensis is the only species known to infect humans. Cyclosporiasis is seen in three main epidemiologic settings: sporadic cases in endemic areas (particularly Haiti, Guatemala, Peru, and Nepal), travelers to endemic areas, and in food- or water-borne outbreaks in nonendemic areas, particularly in relation to importation of fresh produce. The incubation period is approximately 7 days (range 2–14 days). Infection may be asymptomatic, cause mild to moderate self-limited diarrhea, or cause protracted or severe diarrhea. In the immunocompetent host, diarrhea usually lasts 10–25 days but may be followed by a relapsing pattern that can last several months. Diarrhea (5–15 movements per day) is usually watery, sometimes explosive, and often accompanied by nausea, vomiting, abdominal cramping, and bloating. Profound fatigue, anorexia, and myalgias have been reported. The infection can be unusually severe in immunocompromised patients, especially those with HIV/AIDS. Although the illness is self-limited, it may last for several weeks. Diagnosis is based on finding oocysts 8–10 mm in diameter on examination of stool specimens stained with acid-fast stain. PCR of stool is available at the CDC and some reference laboratories. The treatment of choice is trimethoprim-sulfamethoxazole for 7 days.

Ortega YR et al: Update on Cyclospora cayetanensis, a food-borne and waterborne parasite. Clin Micro Rev 2011;23:218–234 [PMID: 20065331].

5. Free-Living Amoebas

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute meningoencephalitis: fever, headache, meningism, acute mental deterioration.
- Swimming in warm, freshwater in an endemic area.
- Chronic granulomatous encephalitis: insidious onset of focal neurologic deficits.
- Keratitis: pain, photophobia, conjunctivitis, blurred vision.

» General Considerations

Infections with free-living amoebas are uncommon. Naegleria species, Acanthamoeba species, and Balamuthia amoebas have been associated with human disease, primarily infections of the central nervous system.

Acute meningoencephalitis, caused by Naegleria fowleri, occurs mostly in children and young adults. Patients present with abrupt fever, headache, nausea and vomiting, disturbances in smell and taste, meningismus, and decreased mental status a few days to 2 weeks after exposure. N fowleri is found in warm fresh water and moist soil. Infection is often associated with swimming in warm freshwater lakes and using contaminated tap water for nasal irrigation. CNS invasion occurs after nasal inoculation of N fowleri which travel along the olfactory nerves via the cribiform plate to the brain. The disease is rapidly progressive and nearly universally fatal within a week of symptom onset.

Chronic granulomatous encephalitis, caused by Acanthamoeba or Balamuthia, can occur in immunocompetent patients, but occurs more commonly in immunocompromised patients. There is no association with freshwater swimming. This disease has an insidious onset of focal neurologic deficits, and approximately 50% of patients present with headache. Skin, sinus, or lung infections with Acanthamoeba precede many of the CNS infections and may still be present at the onset of neurologic disease. The granulomatous encephalitis progresses to fatal outcome over a period of weeks to months (average 6 weeks).

Acanthamoeba keratitis is a corneal infection associated with minor trauma or use of soft contact lenses in otherwise healthy persons. Clinical findings of Acanthamoeba keratitis include radial keratoneuritis and stromal ring infiltrate. Amebic keratitis usually follows an indolent course and initially may resemble herpes simplex or bacterial keratitis; delay in diagnosis is associated with worse outcomes.

» Clinical Findings & Differential Diagnosis

Amebic encephalitis should be included in the differential diagnosis of acute meningoencephalitis in children with a history of recent freshwater swimming. The CSF is usually hemorrhagic, with leukocyte counts that may be normal early in the disease but later range from 400 to 2600/mL with neutrophil predominance, low to normal glucose, and elevated protein. The etiologic diagnosis relies on finding trophozoites on a wet mount of the CSF. Immunofluorescent and PCR-based diagnostic assays are available through the CDC.

Granulomatous encephalitis is diagnosed by brain biopsy of CT-identified nonenhancing lucent areas. The CSF of these patients is usually nondiagnostic with a lymphocytic pleocytosis, mild to severe elevation of protein (> 1000 mg/dL), and normal or low glucose. Acanthamoeba and Balamuthia amoebas have only rarely been found in the CSF; however, they can be visualized in brain biopsies or grown from brain or other infected tissues. Immunofluorescent and PCR-based diagnostic assays are available through the CDC.

Acanthamoeba keratitis is diagnosed by finding the trophozoites in corneal scrapings or by isolating the parasite from corneal specimens or contact lens cultures.

» Prevention

Because primary amebic meningitis occurs infrequently, active surveillance of lakes for N fowleri is not warranted. However, in the presence of a documented case, it is advisable to close the implicated lake to swimming. Sterile or boiled water should be used for nasal irrigation. Acanthamoeba keratitis can be prevented by heat disinfection of contact lenses, by storage of lenses in sterile solutions, and by not wearing lenses when swimming in freshwater or showering.

» Treatment

Treatment of acute amebic meningoencephalitis caused by N fowleri should be attempted with high-dose intravenous amphotericin B with the possible addition of miconazole and rifampin. Azithromycin has in vitro and in vivo activity against Naeglaria and may be tried as an adjuvant. Successful treatment of Balamuthia encephalitis has been reported using a combination of flucytosine, pentamidine, fluconazole, sulfadiazine, and a macrolide. Acanthamoeba encephalitis should be treated with a combination of pentamidine, an azole, flucytosine, and sulfadiazine.

Miltefosine is an investigational new drug with in vitro activity against free-living ameba which has become available for treatment through the CDC (contact the CDC Emergency Operation Center at 770-488-7100). Though treatment numbers are small, miltefosine-containing treatment regimens conveyed a survival advantage in B mandrillaris and Acanthamoeba infection. Efficacy in Naeglaria infection is unknown.

Acanthamoeba keratitis responds well to surgical debridement followed by 3–4 weeks of topical 1% miconazole; 0.1% propamidine isethionate; and polymyxin B sulfate, neomycin, and bacitracin (Neosporin).

TRICHOMONIASIS

Trichomonas vaginalis infection is discussed in Chapter 44.

METAZOAL INFECTIONS

NEMATODE INFECTIONS

1. Enterobiasis (Pinworms)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Anal pruritus.
- Worms in the stool or eggs on perianal skin.

General Considerations

This worldwide infection is caused by Enterobius vermicularis. The adult worms are about 5–10 mm long and live in the colon; females deposit eggs on the perianal area, primarily at night, which cause intense pruritus. Scratching contaminates the fingers and allows transmission back to the host (autoinfection) or to contacts through fecal-oral spread.

Clinical Findings

A. Symptoms and Signs

Pinworms are associated with intense localized pruritis of the anus and vulva. Adult worms may migrate within the colon or up the urethra or vagina in girls. They can be found within the bowel wall, in the lumen of the appendix (usually an incidental finding by the pathologist), in the bladder, and even in the peritoneal cavity of girls.

B. Laboratory Findings

The usual diagnostic test consists of pressing a piece of transparent tape on the child's anus in the morning prior to bathing, then placing it on a drop of xylene on a slide. Microscopic examination under low power usually demonstrates the ova. Occasionally, eggs or adult worms are seen in fecal specimens. Parents may also visualize adult worms in the perianal region, often at nighttime while the child is asleep.

Differential Diagnosis

Nonspecific irritation or vaginitis, streptococcal perianal cellulitis (usually painful with marked erythema), and vaginal or urinary bacterial infections may at times resemble pinworm infection, although the symptoms of pinworms are often so suggestive that a therapeutic trial is justified without a confirmed diagnosis.

Treatment

A. Specific Measures

Treat all household members at the same time to prevent reinfections. Because the drugs are not active against the eggs, therapy should be repeated after 2 weeks to kill the recently hatched adults.

Pyrantel pamoate, available without a prescription, is given as a single dose (11 mg/kg; maximum 1 g); it is safe and very effective. Albendazole (400 mg or 200 mg in children 1–2 years of age) in a single dose is also highly effective for all ages (though not approved by the US FDA).

B. General Measures

Personal hygiene must be emphasized. Nails should be kept short and clean. Children should wear undergarments in bed to diminish contamination of fingers; bedclothes should be laundered frequently; infected persons should bathe in the morning, thereby removing a large proportion of eggs. Although eggs may be widely dispersed in the house and multiple family members infected, the disease is mild and treatable.

Brown MD: Enterobius vermicularis. N Engl J Med 2006;354:e12 [PMID: 16571876].
http://www.cdc.gov/parasites/pinworm/.

2. Ascariasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal cramps and discomfort.
- Large, white or reddish, round worms, or ova in the feces.

General Considerations

The whipworm, hookworms (see below), and Ascaris comprise the "soil-transmitted helminths." These parasites cause human infection through contact with eggs or larvae that thrive in the moist soil of the tropics and subtropics. Worldwide, more than a billion people are infected with at least one of these parasites, and, especially in less developed countries, it is not uncommon for children to be chronically infected with multiple worms. These parasites are strongly associated with poverty and lack of clean water and sanitation. Children infected with these worms are at increased

risk for malnutrition, stunted growth, intellectual disability, and cognitive and education deficits. Together, the soil-transmitted helminths are one of the world's most important causes of physical and intellectual impairment.

Ascaris lumbricoides is a worldwide human parasite. Ova passed by carriers may remain viable for months under the proper soil conditions. The ova contaminate food or fingers and are subsequently ingested by a new host. The larvae hatch, penetrate the intestinal wall, enter the venous system, reach the alveoli, are coughed up the trachea and swallowed, returning to the small intestine, where they mature. The female lays thousands of eggs daily.

» Clinical Findings

A. Symptoms and Signs

The majority of infections with A lumbricoides are asymptomatic, although moderate to heavy infections are associated with abdominal pain, weight loss, anorexia, diarrhea, and vomiting, and may lead to malnutrition. During the larval migratory phase, an acute transient eosinophilic pneumonitis (Löffler syndrome) may occur. Acute intestinal obstruction has been associated with heavy infections, which is more common in children due to their smaller intestinal diameter and their higher worm burden. Worm migration can cause appendicitis, common bile duct obstruction (resulting in biliary colic, cholangitis, or pancreatitis), or peritonitis.

B. Laboratory Findings

The diagnosis is made by observing the large roundworms (1.5–4 cm) in the stool or by microscopic detection of the ova on stool examination.

» Treatment

Albendazole (400 mg in a single dose, or 200 mg in children 1–2 years of age), mebendazole (100 mg twice a day for 3 days or 500 mg once), and pyrantel pamoate (a single dose of 11 mg/kg; maximum 1 g) are all highly effective for treatment. In cases of intestinal or biliary obstruction, piperazine (150 mg/kg initially, followed by six doses of 65 mg/kg every 12 hours by nasogastric tube) can be used to paralyze the worms and help relieve obstruction. However, surgical removal is occasionally required.

Bethony J et al: Soil-transmitted helminth infections: ascariasis, trichuriasis, and hookworm. Lancet 2006;367:1521 [PMID: 16679166].
http://www.who.int/intestinal_worms/.
http://www.cdc.gov/parasites/sth/.
Keiser J et al: Efficacy of current drugs against soil-transmitted helminth infections. JAMA 2008;299:1937–1948 [PMID: 18430913].

3. Trichuriasis (Whipworm)

Trichuris trichiura is a widespread human and animal parasite common in children living in warm, humid areas conducive to survival of the ova. Ingested infective eggs hatch in the upper small intestine. The adult worms live in the cecum and colon; the ova are passed and become infectious after several weeks in the soil. Unlike Ascaris, Trichuris does not have a migratory tissue phase. Symptoms are not present unless the infection is severe, in which case pain, diarrhea, iron deficient anemia, and mild abdominal distention are present. Massive infections may also cause rectal prolapse and dysentery. Detection of the characteristic barrel-shaped ova in the feces confirms the diagnosis. Adult worms may be seen in the prolapsed rectum or at proctoscopy; their thin heads are buried in the mucosa, and the thicker posterior portions protrude. Mild to moderate eosinophilia may be present.

Treatment with mebendazole (100 mg orally twice a day for 3 days) or albendazole (400 mg in a single dose for 3 days, or 200 mg in children 1–2 years of age) tends to improve gastrointestinal symptoms.

Bethony J et al: Soil-transmitted helminth infections: Ascariasis, trichuriasis, and hookworm. Lancet 2006;367:1521 [PMID: 16679166].
http://www.who.int/intestinal_worms/.
http://www.cdc.gov/parasites/sth/.
Keiser J et al. Efficacy of current drugs against soil-transmitted helminth infections. JAMA 2008;299:1937–1948 [PMID: 18430913].

4. Hookworm

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Iron-deficiency anemia.
- » Abdominal discomfort, weight loss.
- » Ova in the feces.

» General Considerations

The common human hookworms are Ancylostoma duodenale and Necator americanus. Both are widespread in the tropics and subtropics, with an estimated 600–700 million people infected worldwide. The larger A duodenale is more pathogenic because it consumes more blood, up to 0.5 mL per worm per day.

The adults live in the jejunum. Eggs are passed in the feces and develop and hatch into infective larvae in warm, damp soil within 2 weeks. The larvae penetrate human skin on contact, enter the blood, reach the alveoli, are coughed

up and swallowed, and develop into adults in the intestine. The adult worms attach to intestinal mucosa, from which they suck blood. Blood loss is the major sequela of infection. Infection rates reach 90% in areas without sanitation.

Ancylostoma braziliense and Ancylostoma caninum (the dog and cat hookworm) cause cutaneous larva migrans, a creeping skin eruption in children and others who come in contact with soil contaminated with cat and dog feces. Larvae produce pruritic, reddish papules at the site of skin entry and intensely pruritic, serpiginous tracks or bullae are advanced as they migrate through the skin, which is pathognomonic for this disease. Larvae can move up to a few centimeters a day and activity can continue for several weeks, but eventually the rash is self-limiting. In the United States, the disease is most prevalent in the Southeast. Most cases in the United States are imported by travelers returning from tropical and subtropical areas.

» Clinical Findings

A. Symptoms and Signs

Patients with hookworm infection usually are asymptomatic or have complaints of diarrhea. Chronic hookworm infection leads to blood loss and iron deficiency anemia. Heavy infection can cause hypoproteinemia with edema. Chronic hookworm infection in children may lead to growth delay, deficits in cognition, and developmental delay. The larvae usually penetrate the skin of the feet and cause a stinging or burning sensation, followed by an intense local itching (ground itch) and a papulovesicular rash that may persist for 1–2 weeks. Pneumonitis associated with migrating larvae is uncommon and usually mild, except during heavy infections. Colicky abdominal pain, nausea, and/or diarrhea and marked eosinophilia may be observed.

B. Laboratory Findings

The large ova of both species of hookworm are found in feces and are indistinguishable. Microcytic anemia, hypoalbuminemia, eosinophilia, and hematochezia occur in severe cases.

» Prevention

Avoiding fecal contamination of soil and avoiding barefoot skin contact with potentially contaminated soil is recommended.

» Treatment

A. Specific Measures

Albendazole (400 mg orally in a single dose, or 200 mg in children 1–2 years of age) is significantly more efficacious than mebendazole or pyrantel pamoate and is considered the drug of choice for treatment of hookworm infections. Mebendazole (100 mg orally twice a day for 3 days) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g, daily for 3 days) are second-line options.

B. General Measures

Iron therapy may be as important as worm eradication.

» Prognosis

The outcome after therapy is excellent, but reinfection is common in endemic areas.

http://www.cdc.gov/parasites/sth/.

Keiser J et al: Efficacy of current drugs against soil-transmitted helminth infections. JAMA 2008;299:1937–1948 [PMID: 18430913].

5. Strongyloidiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Abdominal pain, diarrhea.
- Eosinophilia.
- Larvae in stools and duodenal aspirates.
- Serum antibodies.

» General Considerations

Strongyloides stercoralis is unique in having both parasitic and free-living forms; the latter can survive in the soil for several generations. The parasite is found in most tropical and subtropical regions of the world. The adults live in the submucosal tissue of the duodenum and occasionally elsewhere in the intestines. Eggs deposited in the mucosa hatch rapidly; the first-stage (rhabditiform) larvae, therefore, are the predominant form found in duodenal aspirates and feces. The larvae mature rapidly to the tissue-penetrating filariform stage and initiate internal autoinfection. The filariform larvae also persist in soil and can penetrate the skin of another host, subsequently migrating into veins and pulmonary alveoli, reaching the intestine when coughed up and swallowed.

Older children and adults are infected more often than are young children. Even low worm burden can result in significant clinical symptoms. Immunosuppressed patients may develop fatal disseminated strongyloidiasis, known as the hyperinfection syndrome. Autoinfection can result in persistent infection for decades.

» Clinical Findings

A. Symptoms and Signs

Chronic S stercoralis infections can be asymptomatic or cause cutaneous, gastrointestinal, and/or pulmonary symptoms. At the site of skin penetration, a pruritic rash may occur. Large numbers of migrating larvae can cause wheezing, cough, shortness of breath, and hemoptysis. Although one-third of intestinal infections are asymptomatic, the most prominent features of strongyloidiasis include abdominal pain, distention, diarrhea, vomiting, and occasionally malabsorption.

Patients with cellular immunodeficiencies and those on corticosteroids or chemotherapy may develop disseminated infection, involving the intestine, the lungs, and the meninges. Gram-negative sepsis may complicate disseminated strongyloidiasis.

B. Laboratory Findings

There is no gold standard for diagnosis, which can be difficult because of low parasite load and irregular larval output. Finding larvae in the feces, duodenal aspirates, or sputum is diagnostic. IgG antibodies measured by ELISA or immunoblot are relatively sensitive (83%–93%). The presence of specific antibody does not distinguish between past and present infection, and Strongyloides antibody assays can cross-react with other helminth infections. Marked eosinophilia is common. Because the rate of detection of Strongyloides larvae in a single fecal sample is low (~25%), all patients who have visited an endemic area and present with GI symptoms should be evaluated with three serial stool samples (for ova and parasites), and serology (ELISA) for S stercoralis should be performed. Patients with pulmonary symptoms with suspected strongyloides infection should have sputum samples evaluated for the detection of S stercoralis.

» Differential Diagnosis

Strongyloidiasis should be differentiated from peptic disease, celiac disease, regional or tuberculous enteritis, and hookworm infections. The pulmonary phase may mimic asthma or bronchopneumonia. Patients with severe infection can present with an acute abdomen.

» Prevention & Treatment

Ivermectin (two doses of 0.2 mg/kg given 1–14 days apart) is the drug of choice. Tiabendazole at a dose of 25 mg/kg orally twice orally twice a day for three days is an alternative therapy. Albendazole has a much lower efficacy. Relapses are common. In the hyperinfection syndrome, 1–3 weeks of therapy with ivermectin may be necessary and multiple follow-up stool studies for 2 weeks after therapy are indicated to ensure clearance of larvae. Patients from endemic areas should be tested for specific antibodies and receive treatment before undergoing immunosuppression.

6. Visceral Larva Migrans (Toxocariasis)

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- » Visceral involvement, including hepatomegaly, marked eosinophilia, and anemia.
- » Posterior or peripheral ocular inflammatory mass.
- » Elevated antibody titers in serum or aqueous fluid; demonstration of Toxocara larvae in biopsy specimen.

» General Considerations

Visceral larva migrans is a worldwide disease. The agent is the cosmopolitan intestinal ascarid of dogs and cats, Toxocara canis or Toxocara cati. The eggs passed by infected animals contaminate parks and other areas that young children frequent. Children with pica are at increased risk. In the United States, seropositivity ranges from 2.8% in unselected populations to 23% in southern states to 54% in rural areas. Ingested eggs hatch and penetrate the intestinal wall, then migrate to the liver. Most of the larvae are retained in the liver, but some may pass through the organ reaching the lungs, eyes, muscles, and/or the CNS, where they die and incite a granulomatous inflammatory reaction.

» Clinical Findings

A. Visceral Larva Migrans

Toxocariasis is usually asymptomatic, but young children (aged 1–5 years) sometimes present with anorexia, fever, fatigue, pallor, abdominal pain and distention, nausea, vomiting, and cough. Hepatomegaly is common, splenomegaly is unusual, and adenopathy is absent. Lung involvement, usually asymptomatic, can be demonstrated readily by radiologic examination. Seizures are common, but more severe neurologic abnormalities are infrequent. Eosinophilia with leukocytosis, anemia, and elevated liver function tests are

typical. ELISA is sensitive, specific, and useful in confirming the clinical diagnosis. Most patients recover spontaneously, but disease may last up to 6 months.

B. Ocular Larva Migrans

This condition occurs in older children and adults who present with a unilateral posterior or peripheral inflammatory eye mass. History of visceral larva migrans and eosinophilia are typically absent. Anti-Toxocara antibody titers are low in the serum and high in vitreous and aqueous fluids.

C. Diagnostic Findings

Hypergammaglobulinemia may be present and elevated isohemagglutinins sometimes result from cross-reactivity between Toxocara antigens and human group A and B blood antigens. The diagnosis is confirmed by finding larvae in granulomatous lesions. High ELISA serology and the exclusion of other causes of hypereosinophilia provide a presumptive diagnosis in typical cases.

» Differential Diagnosis

Diseases associated with hypereosinophilia must be considered. These include trichinosis (enlarged liver not common; muscle tenderness common), eosinophilic leukemia (rare in children; eosinophils are abnormal in appearance), collagen-vascular disease (those associated with eosinophilia are rare in young children), strongyloidiasis (no organomegaly; enteric symptoms are common), early ascariasis, tropical eosinophilia (occurring mainly in India), allergies, and hypersensitivity syndromes.

» Prevention & Treatment

A. Specific Measures

The clinical benefit of specific anthelmintic therapy is not defined. Treatment with albendazole (400 mg twice a day for 5 days) or mebendazole (100–200 mg twice a day for 5 days) is indicated for severe complications involving the brain, lung, or heart.

B. General Measures

Treating any cause of pica, such as iron deficiency, is important. Corticosteroids are used to treat marked inflammation of lungs, eyes, or other organs. Pets should be dewormed routinely. Other children in the household may be infected. Mild eosinophilia and positive serologic tests may be the only clue to their infection. Therapy is not necessary for these individuals.

Rubingsy-Elefant G et al: Human toxocariasis: diagnosis, worldwide seroprevalences and clinical expression of the systemic and ocular forms. Ann Trop Med Parasitol 2010;104:3–23 [PMID: 20149289].

7. Trichinosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Vomiting, diarrhea, and abdominal pain within 1 week of eating infected meat.
- Fever, periorbital edema, myalgia, and marked eosinophilia.

» General Considerations

Trichinella are small roundworms that infest hogs and several other meat-eating animals. Currently, there are eight recognized Trichinella species, with Trichinella spiralis being the most commonly recognized and most adapted to domestic and wild swine. The most important source of human infection worldwide is the domestic pig, but in Europe meat from wild boars and horses caused several prominent outbreaks. The human cycle begins with ingestion of viable larvae in undercooked meat. In the intestine, the larvae develop into adult worms that mate and produce hundreds of larvae. The larvae enter the bloodstream and migrate to the striated muscle where they continue to grow and eventually encyst. Symptoms are caused by the inflammatory response in the intestines or muscle.

» Clinical Findings

A. Symptoms and Signs

Most infections are asymptomatic. The severity of clinical disease is strongly correlated with the number of ingested larvae. Infection can be divided into two phases: an intestinal phase and a muscular (or systemic) phase. The initial bowel penetration may cause fever, headache, chills, and gastrointestinal complaints within 1 week after ingestion of contaminated meat. This may progress to the classic myopathic form, which consists of fever, eyelid or facial edema, myalgia, and weakness. Complications, including myocarditis, thromboembolic disease, and encephalitis, occasionally occur. The leading pathologic process of trichinellosis is vasculitis, which can manifest as a maculopapular exanthem, subungual bleeding, conjunctivitis and subconjunctival hemorrhages, headaches, dry cough, and painful movement of the eye muscles. Severe cerebral involvement

or myocarditis can be fatal. Symptoms usually peak after 2–3 weeks but may last for months. Children typically have milder clinical and laboratory findings than adults.

B. Diagnosis

The diagnosis of trichinosis should be based on three main criteria: (1) clinical findings (fever; myalgias; eyelid and/or facial edema; gastrointestinal symptoms; and subconjunctival, subungual, and retinal hemorrhages); (2) laboratory findings (nonspecific eosinophilia and increased levels of muscle enzymes, antibody detection, and/or detection of larvae in a muscle biopsy); and (3) epidemiologic investigation.

» Differential Diagnosis

The classic symptoms are pathognomonic if one is aware of this disease. It has to be distinguished from gastrointestinal pathogens, serum sickness, dermatomyositis, typhoid fever, sinusitis (facial swelling is unilateral), influenza with myopathy, toxocariasis, and invasive schistosomiasis.

» Prevention

Because a microscopic examination must be performed, meat in the United States is not inspected for trichinosis. Although all states require the cooking of hog swill, hog-to-hog or hog-to-rat cycles may continue. All pork and sylvatic meat (eg, bear or walrus) should be cooked at least > 160°F. Freezing meat to at least 5°F for 3 weeks may also prevent transmission. Animals used for food should not be fed or allowed access to raw meat.

» Treatment

Albendazole (400 mg twice daily for 8–14 days) is the drug of choice for trichinosis. Mebendazole is an acceptable alternative and can be given at a dose of 200–400 mg three times a day for 3 days followed by 400–500 mg three times a day for 10 days. Concurrent corticosteroids (prednisone 30–60 mg/d for 10–15 days) are used for treatment of severe symptoms. Administration of analgesics is sometimes required.

» Prognosis

Prognosis for severe cases with cardiac and cerebral complications is poor, with a mortality rate around 5%. In milder cases, prognosis is good, and most patients' symptoms disappear within 2–6 months.

Gottstein B et al: Epidemiology, diagnosis, treatment, and control of trichinellosis. Clin Micro Rev 2009;22:127–145 [PMID: 19136437].

http://www.cdc.gov/parasites/trichinellosis/.

Ozdemir D et al: Acute trichinellosis in children compared with adults. Pediatr Infect Dis J 2005:24:897 [PMID: 16220088].

8. Raccoon Roundworm Infections

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Eosinophilic meningoencephalitis or encephalopathy.
- Ocular larva migrans.
- Contact with raccoons or raccoon feces.

» General Considerations

Human infections with Baylisascaris procyonis, the raccoon roundworm, are increasingly recognized, particularly in children. The definitive host of this ascarid is the raccoon. Humans who ingest the eggs excreted in raccoon feces become intermediate hosts when the larvae penetrate the gut and disseminate via the bloodstream to the brain, eyes, viscera, and muscles. Young age, pica, and exposure to raccoon feces represent the main risk factors for this infection. Most of the infections are asymptomatic, but cases of severe encephalitis (neural larva migrans) and endophthalmitis (ocular larva migrans) occur. Symptoms typically begin 2–4 weeks after inoculation. CNS infections characteristically present as acute, rapidly progressive encephalitis with eosinophilic pleocytosis of the CSF (varies from 4% to 68% eosinophils in mild pleocytosis). Both CNS and ocular infections resemble other larva migrans infections such as toxocariasis; therefore B procyonis should be considered in the differential diagnosis of these infections when Toxocara serology is negative. The diagnosis of B procyonis is established by observing the larvae on examination of tissue biopsies or by serology (of serum or CSF), and should be considered in the differential diagnosis in anyone with CSF eosinophilia. Antihelmintic drugs have not been shown to have any beneficial effect for the treatment of baylisascariasis, since they lack larvicidal effects in human tissues. Nevertheless, albendazole (20–40 mg/kg/d for 1–4 weeks) has been used to treat most cases, together with anti-inflammatory drugs. Complete resolution of symptoms has not been achieved thus far. Immediate prophylactic treatment with albendazole (25 mg/kg daily for 20 days) should be considered for those with known ingestion of raccoon feces.

CESTODE INFECTIONS (FLUKES)

1. Taeniasis & Cysticercosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Mild abdominal pain; passage of worm segments (taeniasis).
- Focal seizures, headaches (neurocysticercosis).
- Cysticerci present in biopsy specimens, on plain films (as calcified masses), or on CT scan or magnetic resonance imaging (MRI).
- Proglottids and eggs in feces; specific antibodies in serum or CSF.

» General Considerations

Pigs are the usual intermediate host of the tapeworm Taenia solium. Human cysticercosis occurs when the eggs, which are excreted in the feces of a person infected with the parasite, are ingested. Importantly, cysticercosis cannot be acquired by eating pork. Ingestion of infected pork results in adult tapeworm infection (taeniasis) because infected pork contains the larval cysts that develop into the adult tapeworm but does not contain the eggs which cause cysticercosis.

Larvae released from ingested eggs enter the circulation to encyst in a variety of tissues, especially muscle and brain. Full larval maturation occurs in 2 months, but the cysts cause little inflammation until the larvae die months to years later. Inflammatory edema ensues with calcification or disappearance of the cyst. A slowly expanding mass of sterile cysts at the base of the brain may cause obstructive hydrocephalus (racemose cysticercosis).

T solium and the beef tapeworm (Taenia saginata), which can causes taeniasis but not cysticercosis, are distributed worldwide. Contamination of foods by eggs in human feces allows person-to-person spread without exposure to meat or travel to endemic areas. Asymptomatic cases are common, but T solium is the most common helminth infection of the CNS and a leading cause of acquired epilepsy in the world.

» Clinical Findings

A. Symptoms and Signs

1. Taeniasis—In most tapeworm infections, the only clinical manifestation is the passage of fecal proglottids, which are white, motile segments of tapeworm 1–2 cm in size. Children may harbor the adult worm for years and complain of abdominal pain, anorexia, and diarrhea.

2. Cysticercosis—In the parenchymatous form, the parasite lodges in tissue as a single or multiple cysts. Granuloma formation results with eventual pericystic inflammation, which is the cause of seizures in most patients. The initial stage of the cyst is viable, where the scolex exists within the cyst and there is minimal or no enhancement due to a limited host immune response. As the scolex dies, either due to the host immune response or cysticidal treatment there is a strong immune response, characterized by enhancement on CT or MRI. As the cyst further degenerates, it calcifies, leading to punctuate calcifications on CT scan. Brain cysts may remain silent or cause seizures, headache, hydrocephalus, and basilar meningitis. Rarely, the spinal cord is involved. Neurocysticercosis manifests an average of 5 years after exposure, but may cause symptoms in the first year of life. In the eyes, cysts cause bleeding, retinal detachment, and uveitis. Definitive diagnosis requires histologic demonstration of larvae or cyst membrane. Presumptive diagnosis is often made by the characteristics of the cysts seen on CT scan or MRI. The presence of T solium eggs in feces is uncommon with cysticercosis (see above) but can support the diagnosis.

B. Laboratory Findings

Neuroimaging is the mainstay of diagnosis of neurocysticercosis. The diagnosis should be suspected in any patient who has lived in an endemic area and presents with a compatible clinical picture and suggestive lesions on neuroimaging.

Eggs or proglottids may be found in feces or on the perianal skin (using the tape method employed for pinworms). Eggs of both Taenia species are identical. The species are identified by examination of proglottids.

Peripheral eosinophilia is minimal or absent. CSF eosinophilia is seen in 10%–75% of cases of neurocysticercosis; its presence supports an otherwise presumptive diagnosis.

ELISA antibody titers are eventually positive in up to 98% of serum specimens and over 75% of CSF specimens from patients with neurocysticercosis. Solitary cysts are associated with seropositivity less often than are multiple cysts. High titers tend to correlate with more severe disease. CSF titers are higher if cysts are near the meninges.

The differential diagnosis of neurocysticercosis includes tuberculous granuloma, microabscesses, arachnoid cyst, neoplasms, and vascular lesions.

» Treatment

A. Taeniasis

Oral praziquantel (5–10 mg/kg once) or niclosamide (50 mg/kg once, maximum 2 g) can be used for treatment of tapeworm carriers.

B. Cysticercosis

The treatment modalities for neurocysticercosis include cysticidal agents (to kill larvae), corticosteroids (to decrease or

prevent the inflammatory reaction), antiepileptic drugs (to control seizures if present), and surgery (to remove cysts or for placement of a shunt for hydrocephalus). Most experts would recommend treatment with a cysticidal agent in most cases of neurocysticercosis, except in patients with inactive, calcified lesions. In patients with viable parenchymal cysts, cysticidal therapy decreases the burden of parasites and the number of seizures. Similarly, cysticidal therapy is associated with more complete and faster resolution on imaging and fewer seizures in patients with a single, small enhancing lesion. Ophthalmic examination should be conducted prior to cysticidal therapy to rule out intraocular cysts.

Albendazole, 15 mg/kg/d (maximum, 800 mg) divided in two doses daily for 8–15 days, is the treatment of choice. Larval death may result in clinical worsening because of inflammatory edema. A concurrent course of dexamethasone (0.1 mg/kg/d to a max of 6 mg/d) is recommended to decrease these symptoms. Corticosteroids are mandatory treatment for large intraventricular cysts and encephalitis (dexamethasone 0.1 mg/kg/d or prednisolone 1 mg/kg/d for as long as needed). Giant subarachnoidal cysts may require more than one cycle of therapy or surgery (or both). Minimally invasive neurosurgery (neuroendoscopic extraction) is the currently recommended management of intraventricular cysts. Follow-up scans every several months help assess the response to therapy.

» Prevention

Prevention requires proper cooking of meat, careful washing of raw vegetables and fruits, treating intestinal carriers, avoiding the use of human excrement for fertilizer, and providing proper sanitary facilities.

» Prognosis

The prognosis is good in intestinal taeniasis. Symptoms associated with a few cerebral cysts may disappear in a few months; heavy brain infections may cause death or chronic neurologic impairment. Seizures may persist even in those patients with only calcified lesions and anticonvulsants may be needed indefinitely.

Del Brutto OH: Neurocysticercosis: new thoughts on controversial issues. Curr Opin Neurol 2013 Jun;26(3):289–294 [PMID: 23493161].

Garcia HH et al: Cysticercosis of the central nervous system: how should it be managed? Curr Opin Infect Dis 2011;24:423–427 [PMID: 21788891].

http://www.cdc.gov/parasites/cysticercosis/.

2. Hymenolepiasis

Hymenolepis nana, the cosmopolitan human tapeworm, is a common parasite of children; Hymenolepis diminuta, the rat tapeworm, is rare. The former is capable of causing autoinfection. Larvae hatched from ingested eggs penetrate the intestinal wall and then reenter the lumen to mature into adults. Their eggs are immediately infectious for the same or a new host. The adult is only a few centimeters long. Finding the characteristic eggs in feces is diagnostic.

H diminuta has an intermediate stage in rat fleas and other insects; children are infected when they ingest these insects.

Light infections with either tapeworm are usually asymptomatic; heavy infection can cause diarrhea and abdominal pain. Therapy is with praziquantel (25 mg/kg once).

http://www.cdc.gov/parasites/hymenolepis/.

3. Echinococcosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Cystic tumors of liver, lungs, kidneys, bones, brain, and other organs.
- Eosinophilia.
- Urticaria and pruritus if cysts rupture.
- Protoscoleces or daughter cysts in the primary cyst.
- Positive serology.
- Epidemiologic evidence of exposure.

» General Considerations

Dogs, cats, and other carnivores are the hosts for Echinococcus granulosus. Cystic and alveolar echinococcosis (hydatid disease) cause significant morbidity and mortality worldwide. Endemic areas include Australia, New Zealand, and the southwestern United States, including Native American reservations where shepherding is practiced. The adult tapeworm lives in sheep intestines, and eggs are passed in the feces. When ingested by humans, the eggs hatch, and the larvae penetrate the intestinal mucosa and disseminate via the bloodstream to produce cysts; the primary sites of involvement are the liver (60%–70%) and the lungs (20%–25%). A unilocular cyst is most common. Over time, the cyst may reach 25 cm in diameter, although most are much smaller. The cysts of Echinococcus multilocularis are multilocular and demonstrate more rapid growth.

» Clinical Findings

A. Symptoms and Signs

The clinical manifestations of echinococcosis are variable and depend primarily on the site, size, and condition of the cysts. The rates of growth of cysts are variable, and range between

1 and 5 cm in diameter per year. A slowly growing cyst often goes unnoticed until it causes dysfunction due to its size. Liver cysts can cause hepatomegaly, right upper quadrant pain, nausea, and vomiting. If a cyst ruptures, the sudden release of its contents can result in a severe allergic reaction. Cysts may cause biliary obstruction. Most hepatic cysts are in the right lobe.

Rupture of a pulmonary cyst causes coughing, dyspnea, wheezing, urticaria, chest pain, and hemoptysis; cyst and worm remnants are found in sputum. Brain cysts may cause focal neurologic signs and convulsions; renal cysts cause pain and hematuria; bone cysts cause pain.

B. Laboratory Findings

Antibody assays are useful to confirm a presumptive diagnosis, but some patients with echinococcosis do not have a detectable immune response (related to the integrity of the cyst and sequestration of echinococcal antigens inside the cyst).

Confirmation may be obtained by ultrasonography-guided fine-needle aspiration coupled with parasitologic examination for protoscoleces, rostellar hooks, antigens, or DNA. Eosinophilia is present in only about 25% of patients. Serologic tests are useful for diagnosis and follow-up of therapy.

C. Imaging

The presence of a cyst-like mass in a person with appropriate epidemiologic exposure supports the diagnosis. Visualization of daughter cysts is highly suggestive of echinococcosis. CT, MRI, and ultrasonography are useful for the diagnosis of deep-seated lesions. Abdominal ultrasonography is the most widely used diagnostic tool. Pulmonary or bone cysts may be visible on plain films.

» Differential Diagnosis

Tumors, bacterial or amebic abscess, cavitary tuberculosis (pulmonary), mycoses, and benign cysts must be considered.

» Complications

Sudden cyst rupture with anaphylaxis and death is the worst complication. If the patient survives, secondary infections from seeding of daughter cysts may occur. Segmental lung collapse, secondary bacterial infections, effects of increased intracranial pressure, and severe renal damage due to renal cysts are other potential complications.

» Treatment

There is no "best" treatment option for cystic echinococcus and no clinical trial has compared all the different treatment modalities. Treatment indications are complex and based on cyst characteristics, available medical/surgical expertise and equipment, and adherence of patients to long-term monitoring. Because treatment involves a variety of options and expertise, patients should be referred to recognized reference and national/regional treatment centers, whenever available. Definitive therapy of E multilocularis requires meticulous surgical removal of the cysts. A surgeon familiar with this disease should be consulted. Albendazole chemotherapy should be initiated for several days prior to surgery. Chemotherapy alone has been shown to cure about one-third of patients. Albendazole (15 mg/kg/d divided in two doses for 3 months, max 400 mg twice daily), sometimes with the addition of praziquantel, is the regimen of choice. A third treatment option is a four-step procedure (PAIR: puncture, aspiration, injection, and reaspiration). This procedure consists of (1) percutaneous puncture using ultrasound guidance, (2) aspiration of liquid contents, (3) injection of a protoscolicidal agents (95% ethanol or hypertonic saline for at least 15 minutes), and (4) reaspiration. PAIR is indicated for uncomplicated cases. If the cyst leaks or ruptures, the allergic symptoms must be managed immediately. For alveolar echinococcus, radical surgery for complete resection of the cyst is the goal. In some patients (particularly in those in whom complete resection is not possible), lifetime chemotherapy may be required.

» Prognosis

Patients with large liver cysts may be asymptomatic for years. Surgery is often curative for lung and liver cysts, but not always for cysts in other locations.

TREMATODE INFECTIONS

Schistosomiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Transient pruritic rash after exposure to freshwater.
- Fever, urticaria, arthralgias, cough, lymphadenitis, and eosinophilia.
- Weight loss, anorexia, hepatosplenomegaly, or hematuria.
- Eggs in stool, urine, or rectal biopsy specimens.

General Considerations

One of the most common serious parasitic diseases, schistosomiasis, is caused by several species of Schistosoma flukes. Schistosoma japonicum, Schistosoma mekongi, and S mansoni involve the intestines and Schistosoma haematobium, the urinary tract. The first two species are found in eastern and southeastern Asia; S mansoni in tropical Africa, the Caribbean, and parts of South America; and S haematobium in Africa. Important transmission sites include Lake Malawi and Lake Victoria in Africa, Poyang and Dongting Lakes in China, and along the Mekong River in Laos.

Infection is caused by free-swimming larvae (cercariae), which emerge from the intermediate hosts, certain species of freshwater snails. The cercariae penetrate human skin, migrate to the liver, and mature into adults, which then migrate through the portal vein to lodge in the bladder veins (S haematobium), superior mesenteric veins (S mekongi and S japonicum), or inferior mesenteric veins (S mansoni). Clinical disease results primarily from inflammation caused by the many eggs that are laid in the perivascular tissues or that embolize to the liver. Escape of ova into bowel or bladder lumen allows microscopic visualization and diagnosis from stool or urine specimens, as well as contamination of freshwater and infection of the snail hosts that ingest them.

Clinical Findings

Much of the population in endemic areas is infected but asymptomatic. Only heavy infections produce symptoms.

A. Symptoms and Signs

Schistosomiasis progresses in three distinct phases: acute, chronic, and advanced disease. The cercarial penetration may cause a maculopapular, pruritic rash, comprising discrete, erythematous, raised lesions that vary in size from 1 to 3 cm. The symptoms of acute schistosomiasis (Katayama syndrome) can last from days to weeks, and can include fever, malaise, cough, diarrhea, hematuria, and right upper quadrant pain. The chronic stages of gastrointestinal disease are characterized by hepatic fibrosis, portal hypertension, splenomegaly, ascites, and bleeding from esophageal varices. The chronic stages of genitourinary tract disease may result in obstructive uropathy, stones, infection, bladder cancer, fistulas, and anemia due to chronic hematuria. Terminal hematuria in children from an endemic region is a red flag for urinary schistosomiasis. Spinal cord granulomas and paraplegia due to egg embolization into the Batson plexus have been reported.

B. Laboratory Findings

The diagnosis is made by finding the species-specific eggs in feces (S japonicum, S mekongi, S mansoni, and occasionally S haematobium) or urine (S haematobium and occasionally S mansoni). If no eggs are found, concentration methods should be used. Because the shedding of eggs can vary, three specimens should be obtained. Urine specimens should be collected between 10 am and 2 pm to coincide with the timing of maximal egg secretion. Testing should wait until 2 months after the last known freshwater contact as this is the time required for worms to start producing eggs following infection. A rectal biopsy may reveal S mansoni and should be done if other specimens are negative. Serological tests are also available and may be helpful in making the diagnosis in patients who are not excreting eggs. Peripheral eosinophilia is common, and eosinophils may be seen in urine.

Prevention

The best prevention is to avoid contact with contaminated freshwater in endemic areas. Efforts to destroy the snail hosts have been successful in areas of accelerated economic development.

Treatment

A. Specific Measures

Praziquantel is the treatment of choice for schistosomiasis. A dosage of 40 mg/kg/d in two divided doses (S mansoni or S haematobium) over 1 day or 20 mg/kg three times a day (S japonicum or S mekongi) over 1 day is very effective and nontoxic. Praziquantel has no effect on eggs and immature worms and therefore a repeat dose 4–6 weeks later is sometimes needed.

B. General Measures

The patient's urinary tract should be evaluated carefully in S haematobium infection; reconstructive surgery may be needed. Hepatic fibrosis requires careful evaluation of the portal venous system and surgical management of portal hypertension when appropriate.

Prognosis

Therapy decreases the worm burden and liver size, despite continued exposure in endemic areas. Early disease responds well to therapy, but once significant scarring or severe inflammation has occurred, eradication of the parasites is of little benefit.

Mycotic Infections

Fungi can be classified as yeasts, which are unicellular and reproduce by budding; as molds, which are multicellular and consist of tubular structures (hyphae) and grow by elongation and branching; or as dimorphic fungi, which can exist either as yeasts or molds depending on environmental conditions. Categorization according to anatomic and epidemiologic features is shown in Table 43–3. Fungal cells are taxonomically distinct from plant and animal cells. These differences, especially cell wall and cell membrane components, are utilized for diagnosis and are the basis of specific therapy.

In the United States, systemic disease in normal hosts is commonly caused by three endemic organisms—Coccidioides, Histoplasma, and Blastomyces—which are restricted to certain geographic areas. Prior residence in or travel to these areas, even for a brief time, is a prerequisite for inclusion in a differential diagnosis. Of these three, Histoplasma most often relapses years later in patients who are immunosuppressed.

Immunosuppression (especially depressed T-cell–mediated immunity), foreign bodies (eg, urinary and central catheters), ulceration of gastrointestinal and respiratory mucosa, severe burns, broad-spectrum antimicrobial therapy, malnutrition, HIV infection, and neutropenia or neutrophil defects are major risk factors for fungal infections (termed "opportunistic fungal infections").

Laboratory diagnosis may be difficult because of the small number of fungi present in some lesions, slow growth of some organisms, and difficulty in distinguishing normal colonization of mucosal surfaces from infection. A tissue biopsy with fungal stains and culture is the best method for diagnosing some systemic fungal disease. Repeat blood cultures may be negative even in the presence of intravascular infections. Serologic tests are useful for diagnosing coccidioidomycosis and histoplasmosis, and antigen detection in urine and blood is useful for diagnosing blastomycosis, histoplasmosis, cryptococcosis, and aspergillosis.

The common superficial fungal infections of the hair and skin are discussed in Chapter 15.

Table 43–3. Pediatric fungal infections.

Type	Agents	Incidence	Diagnosis	Diagnostic Tests	Therapy	Prognosis
Superficial	Candida[a] Dermatophytes Malassezia	Very common	Simple	KOH prep	Topical	Good
Subcutaneous	Sporothrix[a]	Uncommon	Simple[b]	Culture	Oral	Good
Systemic: normal host (endemic)	Coccidioides Histoplasma Blastomyces	Common: regional	Often presumptive	Chest radiograph; serology, antigen detection; histology; culture of body fluids or tissue	None[c] or systemic	Good
Systemic: opportunistic infection	Candida[a] Pneumocystis[d] Aspergillus Mucorales Malassezia Pseudallescheria Cryptococcus	Uncommon	Difficult[e]	Tissue biopsy, culture, antigen/fungal product detection (cryptococcosis, candida, filamentous fungi, pneumocystis)	Systemic, prolonged	Poor if therapy is delayed and in severely immune compromised hosts

KOH, potassium hydroxide.
[a]Candida and Sporothrix in immunocompromised patients may cause severe, rapidly progressive disease and require systemic therapy.
[b]Sporotrichosis may require biopsy for diagnosis.
[c]Can be self-limited in normal host.
[d]Asymptomatically infects many normal hosts.
[e]Except Cryptococcus, which is often diagnosed by antigen detection.

Blastomycosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in, or travel to, an endemic area.
- In immunocompetent patients, most often a self-limited flu-like illness; acute pneumonia occurs in a minority of cases.
- Complications include progressive pneumonia and disseminated disease (CNS, skin, bone and joints, genitourinary tract).
- Diagnosis by culture of specimens from bronchoscopy, skin, or other tissue, or antigen detection.

» General Considerations

The causative fungus, Blastomyces dermatitidis, is found in soil primarily in the Mississippi and Ohio River valleys, additional southeastern and south central states, and the states bordering the Great Lakes. Transmission is by inhalation of spores. Subclinical disease is common. Severe disease is much more common in adults and males. In children, infection rates are similar in both sexes.

» Clinical Findings

A. Symptoms and Signs

Primary infection is often unrecognized or associated with cough with purulent sputum, chest pain, headache, weight loss, night sweats, and fever. These occur several weeks to months after inoculation. Infection is most often self-limited in immunocompetent patients, but in some patients an indolent progressive pulmonary disease occurs after an incubation period of 20–100 (median 45) days. Cutaneous lesions usually represent disseminated disease. Skin lesions are slowly progressive and ulcerative with a sharp, heaped-up border or verrucous appearance. Bone disease resembles other forms of chronic osteomyelitis. Lytic skull lesions in children are typical, but long bones, vertebrae, and the pelvis may be involved. Extrapulmonary disease occurs in 25%–40% of patients with progressive disease. A total body radiographic examination is advisable when blastomycosis is diagnosed in the skin or other extrapulmonary site. The genitourinary tract involvement characteristic of dissemination in adults is rare in prepubertal children.

B. Laboratory Findings

An initial suppurative response is followed by an increase in mononuclear cells and subsequent formation of noncaseating granulomas. Diagnosis requires isolation or visualization of the fungus. Pulmonary specimens (sputum, tracheal aspirates, or lung biopsy) may be positive using conventional or fungal cell wall stains. The budding yeasts have refractile thick walls and are very large and distinctive (figure-of-eight appearance). The fungus can be readily isolated in most laboratories, but a week is often required. Sputum specimens are positive in more than 80% of cases and in almost all bronchial washings, and skin lesions are positive in 80%–100%. Antibody tests are generally not helpful for diagnosis, but an ELISA antigen detection method, similar to that used for histoplasmosis, readily detects Blastomyces antigen in serum, urine, and lung lavage fluids. In this assay, there is cross-reactivity with histoplamosis.

C. Imaging

Radiographic lobar consolidation and fibronodular interstitial and alveolar infiltrates are typical in cases with progressive pneumonia; effusions, hilar nodes, and cavities are less common. The paucity of cavitation distinguishes acute blastomycosis from histoplasmosis and tuberculosis. Miliary patterns also occur with acute infection. Chronic disease can develop in the upper lobes, with cavities and fibronodular infiltrations similar to those seen in tuberculosis. However, unlike tuberculosis or histoplasmosis, these lesions rarely caseate or calcify.

» Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections and is generally confused with atypical community-acquired pneumonia. Blastomycosis should be considered when a significant pulmonary infection in an endemic area fails to respond to antibiotic therapy. Subacute infection mimics tuberculosis, histoplasmosis, and coccidioidomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

» Treatment

If the patient is symptomatic at the time of diagnosis with moderately severe or life-threatening blastomycosis (especially if immunocompromised), or has CNS infection, therapy should be initiated with the lipid formulation of amphotericin B (3–5 mg/kg intravenously) for 1–2 weeks or until improved. This is followed by oral itraconazole (5–10 mg/kg/d; divided into two doses) for 6 months. Mild to moderate blastomycosis is often treated with oral itraconazole alone for 6–12 months. Bone disease may require a full year of itraconazole therapy. Surgical debridement is required for devitalized bone, drainage of large abscesses, and pulmonary lesions not responding to medical therapy.

Candidiasis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- In normal or immunosuppressed individuals: superficial infections (oral thrush or ulcerations, vulvovaginitis, erythematous intertriginous rash with satellite lesions); fungemia related to intravascular devices.
- In immunosuppressed individuals: systemic infections (candidemia with renal, hepatic, splenic, pulmonary, or cerebral abscesses); chorioretinitis; cutaneous nodules.
- In either patient population: budding yeast and pseudohyphae are seen in biopsy specimens, body fluids, or scrapings of lesions; positive culture.

General Considerations

Disease due to Candida is caused by Candida albicans in > 50% of cases in children; severe systemic infection may also be caused by Candida tropicalis and Candida parapsilosis and a few other Candida species. Speciation is important because of differences in pathogenicity and response to antifungal therapy.

C albicans is ubiquitous, usually in small numbers, on skin, mucous membranes, or in the intestinal tract. Normal bacterial flora, intact epithelial barriers, neutrophils, and macrophages, in conjunction with antibody and complement and normal lymphocyte function, are factors in preventing invasion. Disseminated infection is almost always preceded by prolonged broad-spectrum antibiotic therapy, instrumentation (including intravascular catheters), and/or immunosuppression. Patients with diabetes mellitus are prone to superficial Candida infection; thrush and vaginitis are most common. Candida is the fourth most common blood isolate in hospitals in the United States and is a common cause of catheter-related urinary tract infection.

Clinical Findings

A. Symptoms and Signs

1. Oral candidiasis (Thrush)—Adherent creamy white plaques on the buccal, gingival, or lingual mucosa are seen. These may be painful. Lesions may be few and asymptomatic, or they may be extensive, extending into the esophagus. Thrush is very common in otherwise normal infants in the first weeks of life and may last weeks despite topical therapy. Spontaneous thrush in older children is unusual unless they have recently received antimicrobials. Corticosteroid inhalation for asthma predisposes patients to thrush. HIV infection should be considered if there is no other reason for oral thrush, especially when it is persistent or recurrent. Angular cheilitis is the name given to painful erythematous fissures caused by Candida at the corners of the mouth, often in association with a vitamin or iron deficiencies.

2. Vaginal infection—Vulvovaginitis occurs in sexually active girls, in diabetic patients, and in girls receiving antibiotics. Thick, odorless, cheesy discharge with intense pruritus is typical. The vagina and labia are usually erythematous and swollen. Outbreaks are more frequent before menses.

3. Skin infection

a. Dermatitis—Diaper dermatitis is often due entirely or partly to Candida. Pronounced erythema with a sharply defined margin and satellite lesions is typical. Pustules, vesicles, papules, or scales may be seen. Weeping, eroded lesions with a scalloped border are common. Any moist area, such as axillae, under breasts, and inguinal or neck folds, may be involved.

b. Scattered red papules or nodules—Such findings in immunocompromised patients may represent cutaneous dissemination.

c. Paronychia and onychomycosis—These conditions occur in immunocompetent children but are also associated with immunosuppression, hypoparathyroidism, or adrenal insufficiency (Candida endocrinopathy syndrome). The selective absence of specific innate and T-cell responses to Candida can lead to marked, chronic skin and nail infections called chronic mucocutaneous candidiasis.

d. Chronic draining otitis media—This may occur in patients who have received multiple courses of antibiotics and are superinfected with Candida.

4. Enteric infection—Esophageal involvement in immunocompromised patients is the most common enteric manifestation, resulting in substernal pain, dysphagia, and painful swallowing. Nausea and vomiting are common in young children. Most patients do not have thrush. Stomach or intestinal ulcers also occur.

5. Pulmonary infection—Because the organism frequently colonizes the upper respiratory tract, it is commonly isolated from respiratory secretions. Thus, demonstration of tissue invasion is needed to diagnose Candida pneumonia or tracheitis. It is rare, seen mainly in immunosuppressed patients and patients intubated for long periods, usually while taking

antibiotics. The infection may cause abscesses, nodular infiltrates, and effusion.

6. Renal infection—Candiduria may be the only manifestation of disseminated disease. More often, candiduria is associated with instrumentation, an indwelling catheter, or anatomic abnormality of the urinary tract. Symptoms of cystitis may be present. Masses of Candida may obstruct ureters and cause obstructive nephropathy. Candida casts in the urine suggest renal tissue infection.

7. Other infections—Myocarditis, meningitis, and osteomyelitis usually occur only in immunocompromised patients or neonates, generally in those with high-grade candidemia. Endocarditis may occur on an artificial or abnormal heart valve, especially when an intravascular line is present.

8. Disseminated candidiasis—Skin and mucosal colonization precedes but does not predict dissemination. Too often, dissemination is confused with bacterial sepsis. This occurs in neonates—especially premature infants—in an intensive care unit setting and is recognized when a sick infant fails to respond to antibiotics or when candidemia is documented. Invasive disease can occur in > 50% of very low-birth-weight infants. These infants often have unexplained feeding intolerance, cardiovascular instability, apnea, new or worsening respiratory failure, glucose intolerance, thrombocytopenia, or hyperbilirubinemia. A careful search in immunocompromised patients should be carried out for lesions suggestive of disseminated Candida (retinal cotton-wool spots or chorioretinitis; nodular dermal abscesses). If these findings are absent, diagnosis is often based presumptively on the presence of a compatible illness in an immunocompromised patient; a burn patient; or a patient with prolonged postsurgical or intensive care unit course who has no other cause for symptoms and who fails to respond to antimicrobials. Such patients usually have Candida colonization of mucosal surfaces. Treatment for presumptive infection is often undertaken because candidemia is not identified antemortem in many such patients.

Hepatosplenic and renal candidiasis occurs in immunosuppressed patients. The typical case is a severely neutropenic patient who develops chronic fever, variable abdominal pain, and abnormal liver function tests. No causative bacterial pathogen is isolated, and there is no response to antimicrobials. Ultrasound or CT scan of the liver, spleen, and kidney demonstrates multiple round lesions. Biopsy is needed to confirm the diagnosis.

B. Laboratory Findings

Budding yeast cells are easily seen in scrapings or other samples. A wet mount preparation of vaginal secretions is 40%–50% sensitive; this is increased to 50%–70% with the addition of 10% potassium hydroxide to the sample. The use of a Gram-stained smear is 70%–100% sensitive. The presence of pseudohyphae suggests tissue invasion. Positive cultures from nonsterile sites may reflect colonization and need to be carefully evaluated, but Candida should never be considered a contaminant in cultures from normally sterile sites. Candida grows on routine media more slowly than many bacteria; growth is usually evident on agar after 2–3 days and in blood culture within 3, but cultures may remain negative (10%–40%) even with disseminated disease or endocarditis. Newly available spectrophotometric methods greatly shorten the delay in diagnosis and speciation. Candida in any number in appropriately collected urine suggests true infection. The ability of yeast to form germ tubes when incubated in human serum gives a presumptive speciation for C albicans.

» Differential Diagnosis

Thrush may resemble milk or formula (which can be easily wiped away with a tongue blade or swab, revealing normal mucosa without underlying erythema or erosion), other types of ulcers (including herpes), or oral changes induced by chemotherapy. Skin lesions may resemble contact, allergic, chemical, or bacterial dermatitis; miliaria; folliculitis; or eczema. Vulvovaginitis needs to be distinguished from other causes of vaginal discharge and discomfort. Candidemia and systemic infection should be considered in any seriously ill patient with the risk factors previously mentioned.

» Complications

Arthritis and meningitis occur more often in neonates than in older children, and abscesses can occur in any organ. The greater the length or extent of immunosuppression and the longer the delay before therapy, the more likely that complications will occur.

» Treatment

A. Oral Candidiasis

In infants, oral nystatin suspension (100,000 units four to six times a day in the buccal fold after feeding until resolution) usually suffices. Nystatin must come in contact with the lesions because it is not absorbed systemically. Older children may use it as a mouthwash (200,000–500,000 units five times a day), although it is poorly tolerated because of its taste. Clotrimazole troches (10 mg) four times a day are an alternative in older children. Prolonged therapy with either agent or more frequent dosing may be needed. Painting the lesions with a cotton swab dipped in gentian violet (0.5%–1%) is visually dramatic and messy but may help refractory cases. Eradication of Candida from pacifiers, bottle nipples, toys, or the mother's breasts (if the infant is breast-feeding and there is candidal infection of the nipples) may be helpful.

Oral azoles, such as fluconazole (6 mg/kg/d), are effective in older children with candidal infection refractory to nystatin. Discontinuation of antibiotics or corticosteroids is advised when possible.

B. Skin Infection

Cutaneous infection usually responds to a cream or lotion containing nystatin, amphotericin B, or an imidazole (miconazole, clotrimazole, and others). Associated inflammation such as severe diaper dermatitis is helped by concurrent use of a topical low concentration corticosteroid cream, such as 1% hydrocortisone. It may help to keep the involved area dry; a heat lamp and nystatin powder may be used. Suppression of intestinal Candida with nystatin and eradicating thrush may speed recovery and prevent recurrence of diaper dermatitis.

C. Vaginal Infections

Vulvovaginal candidiasis (see Chapter 44) is treated with clotrimazole, miconazole, triazoles, or nystatin (cheapest if generic is used) suppositories or creams, usually applied once nightly for 3–7 days. A high-dose topical clotrimazole formulation need to be given for only a single night. Oral azole therapy is equally effective. A single 150-mg oral dose of fluconazole is effective for vaginitis. It is more expensive but very convenient. Candida balanitis in sexual partners should be treated, but no controlled study has shown that treating colonization of male sexual partners prevents recurrence in females. Frequent recurrent infections may require elimination of risk factors, the use of oral therapy, or some prophylactic antifungal therapy, such as a single dose of fluconazole weekly for 6 months.

D. Renal Infection

Candiduria in an immunocompetent host with a urinary catheter may respond to catheter removal. Candiduria is treated in all high-risk patients, usually with a 7- to 14-day course of fluconazole (3–6 mg/kg/d), which is concentrated in the urine. Amphotericin B is warranted for patients with fluconazole-resistant organisms. Renal abscesses or ureteral fungus balls require intravenous antifungal therapy. Removal of an indwelling catheter is imperative.

E. Systemic infection

1. Disseminated Candida infection—Systemic infection is dangerous and resistant to therapy. Surgical drainage of abscesses and removal of all infected tissue (eg, a heart valve) are required for cure. Hepatosplenic candidiasis should be treated until all lesions have disappeared or are calcified on imaging studies. Treatment with lipid forms of amphotericin B retain the antifungal potency of the free drug and are much better tolerated. Although they are much more expensive than amphotericin B, they are indicated for patients who are intolerant of conventional therapy and for those whose infection is refractory to treatment or who have a high likelihood of developing renal toxicity from amphotericin B therapy.

Flucytosine (50–75 mg/kg/d orally in four doses; keep serum levels < 75 mcg/mL) may be additive or synergistic to amphotericin B. Unlike amphotericin B, flucytosine penetrates tissues well. It should not be used as a single agent in serious infections because resistance develops rapidly.

Fluconazole and itraconazole (best absorbed from the liquid solution) and newer azole drugs, such as voriconazole and posaconazole, or echinocandins, are used interchangeably or in conjunction with amphotericin. They are often preferred because they are less likely to be toxic. They are acceptable alternatives for serious C albicans infections in nonneutropenic patients and are often effective as first-line therapy in immunocompromised patients. Fluconazole is well absorbed (oral and intravenous therapy are equivalent), reasonably nontoxic, and effective for a variety of Candida infections. Fluconazole dosage is 8–12 mg/kg/d in a single daily dose for initial therapy of severely ill children. Selected patients with prolonged immunosuppression (eg, after hematopoietic stem cell transplantation) should receive prophylactic azole, echinocandin, or intermittent amphotericin B prophylaxis. The decision to use systemic azole therapy should include consideration of the local experience with azole-resistant Candida and if the patient had recent prophylaxis or treatment with azoles. Susceptibility testing for Candida species is available to guide this decision. Candida glabrata and C krusei are common isolates that may be resistant to fluconazole; these are often susceptible to the newer azoles and echinocandins. Candida lusitaniae is usually resistant to amphotericin.

Correction of predisposing factors is important (eg, discontinuing antibiotics and immunosuppressives, improving control of diabetes, and removing infected devices and lines).

2. Candidemia—Infected central venous lines should be removed immediately; this alone often is curative. If the infection is considered limited to the line and environs, a 14-day course (after the last positive culture) of a systemic antifungal agent following line removal is recommended for nonneutropenic patients. This is because of the late occurrence of focal Candida infection, especially retinal infection, in some cases. Persistent fever and candidemia suggest infected thrombus, endocarditis, or tissue infection.

» Prognosis

Superficial disease in normal hosts has a good prognosis; in abnormal hosts, it may be refractory to therapy.

Early therapy of systemic disease is often curative if the underlying immune response is adequate. The outcome is poor when therapy is delayed or when host response is inadequate. Candidemia in the severely premature neonate increases the chance of death and poor neurodevelopmental outcome.

Coccidioidomycosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in, or travel to, an endemic area.
- Primary pulmonary form: fever, chest pain, cough, anorexia, weight loss, and often a macular rash, erythema nodosum, or erythema multiforme.
- Primary cutaneous form: skin trauma followed in 1–3 weeks by an ulcer and regional adenopathy.
- Spherules seen in pus, sputum, CSF, joint fluid; positive culture.
- Appearance of precipitating (early) and complement-fixing antibodies (late).

» General Considerations

Coccidioidomycosis is caused by the dimorphic fungus Coccidioides (immitis or posadasii), which are endemic in the Sonoran Desert areas of western Texas, southern New Mexico and Arizona, southern California, northern Mexico, and South America. Infection results from inhalation or inoculation of arthrospores (highly contagious and readily airborne in the dry climate). Even brief travel in or through an endemic area, especially during windy seasons, may result in infection. Human-to-human transmission does not occur. More than half of all infections are asymptomatic, and less than 5% are associated with significant pulmonary disease. Chronic pulmonary disease or dissemination occurs in less than 1% of cases.

» Clinical Findings

A. Symptoms and Signs

1. Primary disease—The incubation period is 10–16 days (range, 7–28 days). Symptoms vary from those of a mild fever and arthralgia to severe influenza-like illness with high fever, nonproductive cough, pleuritic chest pains, arthralgias, headache, and night sweats. Upper respiratory tract signs are uncommon. Signs vary from none to rash, rales, pleural rubs, and signs of pulmonary consolidation. Weight loss may occur.

2. Skin disease—Up to 10% of children develop erythema nodosum or erythema multiforme. These manifestations imply a favorable host response to the organism. Less specific maculopapular eruptions occur in a larger number of children. Skin lesions can occur following fungemia. Primary skin inoculation sites develop indurated ulcers with local adenopathy. Contiguous involvement of skin from deep infection in nodes or bone also occurs. The presence of chronic skin lesions should lead to a search for internal infection.

3. Chronic pulmonary disease—This is uncommon in children. Chronic disease is manifested by chronic cough (occasionally with hemoptysis), weight loss, pulmonary consolidation, effusion, cavitation, or pneumothorax.

4. Disseminated disease—This is less common in children than adults, and is more common in infants, neonates, pregnant women (especially during the third trimester), black people, Filipinos, American Indians, and patients with HIV or other types of immunosuppression. More than one organ may be involved. The most common extra-pulmonary sites involved are bone or joint (usually a single bone or joint; subacute or chronic swelling, pain, redness), nodes, meninges (slowly progressive meningeal signs, ataxia, vomiting, headache, and cranial neuropathies), and kidneys (dysuria and urinary frequency). As with most fungal diseases, the evolution of the illness is usually slow.

B. Laboratory Findings

Direct examination of respiratory secretions, pus, CSF, or tissue may reveal large spherules (30–60 μm) containing endospores germinating in tissue. The organism is detected by using periodic acid–Schiff reagent, methenamine silver, and calcofluor stains. Characteristic colonies grow within 2–5 days on routine fungal and many other media. CSF cultures are often falsely negative.

The sedimentation rate is usually elevated. Eosinophilia may occur, particularly prior to dissemination, and is more common in coccidioidomycosis than in many other conditions with similar symptoms. Meningitis causes a

mononuclear pleocytosis (70% contain eosinophils) with elevated protein and mild hypoglycorrhachia.

Antibodies consist of precipitins (usually measurable by 2–3 weeks in 90% of cases and gone by 12 weeks) and complement-fixing antibodies (delayed for several weeks; appear as the precipitins are falling and should disappear by 8 months). Thus, serum precipitins usually indicate acute infection. The extent of the complement-fixing antibody response reflects the severity of infection. Persistent high levels suggest dissemination. ELISA assays, which detect IgM and IgG antibodies against coccidioidal antigens, become positive in some patients as early as 1–3 weeks after onset of symptoms. The presence of antibody in CSF indicates CNS infection; CSF and serum antibody titers correlate with disease progression and response to therapy.

Galactomannan antigen from Coccidioides is detected in urine and serum of patients. This occurs more frequently in severe disease compared to moderate disease. Testing both types of specimens should provide a diagnosis overall in more than 75% of patients.

C. Imaging

Approximately half of symptomatic infections are associated with abnormal chest radiographs—usually infiltrates with hilar adenopathy. Pulmonary consolidation, effusion, and thin-walled cavities may be seen. About 5% of infected patients have asymptomatic nodules or cysts after recovery. Unlike tuberculosis reactivation, apical disease is not prominent. Bone infection causes osteolysis that enhances with technetium. Cerebral imaging may show hydrocephalus and meningitis; intracranial abscesses and calcifications are unusual. Radiographic evolution of all lesions is slow.

» Differential Diagnosis

Primary pulmonary infection resembles acute viral, bacterial, or mycoplasmal infections; subacute presentation mimics tuberculosis, histoplasmosis, and blastomycosis. Chronic pulmonary or disseminated disease must be differentiated from cancer, tuberculosis, or other fungal infections.

» Complications

Dissemination of primary pulmonary disease is associated with permissive ethnic background, prolonged fever (> 1 month), a negative skin test, high complement-fixation antibody titer, and marked hilar adenopathy. Local pulmonary complications include effusion, empyema, and pneumothorax. Cerebral infection can cause noncommunicating hydrocephalus due to basilar meningitis.

» Treatment

A. Specific Measures

Mild pulmonary infections in most normal patients require no therapy. These patients should be assessed for 1–2 years to document resolution and to identify any complications. Antifungal therapy is used for prolonged fever, weight loss (> 10%), prolonged duration of night sweats, severe pneumonitis (especially if persisting for 4–6 weeks), or any form of disseminated disease. Neonates, pregnant women, high-risk racial background, and patients with high antibody titers also receive treatment.

Lipid formulation of amphotericin B is used to treat extensive pulmonary or disseminated disease or disease in immunosuppressed patients (2–5 mg/kg/d). In general, the more rapidly progressive the infection, the more compelling the case for amphotericin B therapy. For less severe disease and for meningeal disease, fluconazole or itraconazole are preferred (duration of therapy is 3–6 months or is lifelong for meningeal disease). Measurement of serum levels is suggested to monitor therapy. Chronic fibrocavitary pneumonia is treated for at least 12 months. Itraconazole may be superior to fluconazole. Refractory infection often responds to voriconazle together with caspofungin, and refractory meningitis may require prolonged intrathecal or intraventricular amphotericin B therapy.

B. General Measures

Most pulmonary infections require only symptomatic therapy, self-limited activity, and good nutrition. Patients are not contagious.

C. Surgical Measures

Excision of chronic pulmonary cavities or abscesses may be needed. Infected nodes, sinus tracts, and bone are other operable lesions. Azole therapy should be given prior to surgery to prevent dissemination and should be continued for 4 weeks arbitrarily or until other criteria for cure are met.

» Prognosis

Most patients recover. Even with amphotericin B, however, disseminated disease may be fatal, especially in those racially predisposed to severe disease. Reversion of the skin test to negative or a rising complement-fixing antibody titer is an ominous sign. Individuals who later in life undergo immunosuppressive therapy or develop HIV may experience reactivation of dormant disease. Thus, some transplant, rheumatology, and oncology programs determine prior infection by serology and either provide prophylaxis or observe patients closely during periods of intense immune suppression.

McCarty JM et al: Pediatric coccidioidomycosis in central California: a retrospective case series. Clin Infect Dis 2013;56(11):1579 [PMID: 23463637].

Cryptococcosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Acute pneumonitis in immunocompetent individuals.
- Immunosuppressed patients especially vulnerable to CNS infection (headache, vomiting, cranial nerve palsies, meningeal signs; mononuclear cell pleocytosis).
- Cryptococcal antigen detected in CSF; also in serum and urine in some patients.
- Cryptococcus is readily isolated on routine media.

General Considerations

Cryptococcus neoformans is a ubiquitous soil yeast. It survives best in soil contaminated with bird excrement, especially that of pigeons. However, most infections in humans are not associated with a history of significant contact with birds. Inhalation is the presumed route of inoculation. Infections in children are rare, even in heavily immunocompromised patients such as those with HIV infection. Immunocompetent individuals can also be infected, especially by Cryptococcus gattii, which is an emerging pathogen in Canada and the Pacific Northwest. Asymptomatic carriage does not occur.

Clinical Findings

A. Symptoms and Signs

1. Pulmonary disease—Pulmonary infection precedes dissemination to other organs. It is frequently asymptomatic (ie, many older children and adults have serologic evidence of prior infection) and less often clinically apparent than cryptococcal meningitis. Pneumonia is the primary manifestation in one-third of patients; CNS disease is the primary manifestation in 50% of patients. Cryptococcal pneumonia may coexist with CNS involvement. Symptoms are nonspecific and subacute—cough, weight loss, and fatigue.

2. Meningitis—The most common clinical disease is meningitis, which follows hematogenous spread from a pulmonary focus. This is much more likely to occur in an immunosuppressed patient (especially HIV). Symptoms of headache, vomiting, and fever occur over days to months. Meningeal signs and papilledema are common. Cranial nerve dysfunction and seizures may occur.

3. Other forms—Cutaneous forms are usually secondary to dissemination. Papules, pustules, and ulcerating nodules are typical. Bones (rarely joints) may be infected; osteolytic areas are seen, and the process may resemble osteosarcoma. Many other organs, especially the eyes, can be involved with dissemination.

B. Laboratory Findings

The CSF usually has a lymphocytic pleocytosis; it may be completely normal in immunosuppressed patients with meningeal infection. Direct microscopy may reveal organisms in sputum, CSF, or other specimens. The capsular antigen can be detected by latex agglutination or ELISA, which are both sensitive (> 90%) and specific. False-negative CSF tests occur rarely. Serum, CSF, and urine should be tested when this infection is suspected. The serum may be negative if the only organ infected is the lung. The organism grows well after several days on many routine media; for optimal culture, collecting and concentrating a large volume of CSF (10 mL) is recommended because the number of organisms may be low.

C. Imaging

Radiographic findings are usually lower lobe infiltrates or nodular densities; less often effusions; and rarely cavitation, hilar adenopathy, or calcification. Single or multiple focal mass lesions (cryptococcoma) may be detected in the CNS on CT or MRI scan.

Differential Diagnosis

Cryptococcal meningitis may mimic tuberculosis, viral meningoencephalitis, meningitis due to other fungi, or a space-occupying CNS lesion. Lung infection is difficult to differentiate from many causes of pneumonia.

Complications

Hydrocephalus may be caused by chronic basilar meningitis. Symptomatic and recalcitrant intracranial hypertension is common. Significant pulmonary or osseous disease may accompany the primary infection or dissemination.

Treatment

Patients with symptomatic pulmonary disease should receive fluconazole for 3–6 months. All immunocompromised patients with cryptococcal pulmonary disease should have a lumbar puncture to rule out CNS infection; this should also be done for immunocompetent patients with cryptococcal antigen in the serum. Severely ill patients should receive amphotericin B (0.7 mg/kg/d). Meningitis is treated with amphotericin B (increase dose to 1 mg/kg/d) and flucytosine (100 mg/kg/d). This combination is synergistic and allows lower doses of amphotericin B to be used. Induction therapy is usually

2 weeks for CNS infections. Fluconazole can be substituted for flucytosine. After this, fluconazole alone (10 mg/kg/d) is maintained for 8 weeks and then continued at a reduced dose (determined by moderate serum levels) for an additional 6–12 months. Some evidence suggests that voriconazole or posaconazole may have greater anticryptococcal activity. Fluconazole remains the preferred maintenance therapy to prevent relapses in high-risk (eg, HIV) patients. CSF antigen levels should be checked after 2 weeks of therapy. Intracranial hypertension is treated by frequent spinal taps or a lumbar drain.

» Prognosis

Treatment failure, including death, is common in immunosuppressed patients, especially those with AIDS. Lifelong maintenance therapy may be required in these patients. Poor prognostic signs are the presence of extrameningeal disease, fewer than 20 cells/μL of initial CSF, and initial CSF antigen titer greater than 1:32.

La Hoz RM, Pappas PG: Cryptococcal infections: changing epidemiology and implications for therapy. Drugs 2013;73:495–504 [PMID: 23575940].

Histoplasmosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Residence in or travel to an endemic area.
- Pneumonia with flulike illness.
- If disseminated, hepatosplenomegaly, anemia, leukopenia.
- Histoplasmal antigen in urine, blood, bronchoalveolar lavage fluid or CSF.
- Detection by staining the organism in smears or tissue, or by culture.

» General Considerations

The dimorphic fungus Histoplasma capsulatum is found in the central and eastern United States (Ohio and Mississippi River valleys), Mexico, and most of South America. Soil contamination is enhanced by the presence of bat or bird feces. Infection is acquired by inhaling spores that transform into the pathogenic yeast form seen in infected tissues, especially within macrophages. Infections in endemic areas are very common at all ages and are usually asymptomatic. Over two-thirds of children are infected in these areas. Reactivation is rare in children, but occurs after treatment with immune suppressive agents, such as biological response modifiers and chemotherapy. Reactivation may occur years after primary infection. Reinfection also occurs. The extent of symptoms with primary infection or reinfection is influenced by the size of the infecting inoculum.

» Clinical Findings

Because human-to-human transmission does not occur, infection requires exposure in the endemic area—usually within prior weeks or months. Congenital infection does not occur.

A. Symptoms and Signs

1. Asymptomatic infection (90% of infections)—Asymptomatic histoplasmosis is usually diagnosed by the presence of scattered calcifications in lungs or spleen and a positive skin test or serology. The calcification may resemble that caused by tuberculosis, but may be more extensive than the usual Ghon complex.

2. Pneumonia—Approximately 5% of patients have mild to moderate disease. The cause of this illness is usually not recognized as being histoplasma. Acute pulmonary disease may resemble influenza with fever, malaise, myalgia, arthralgia, and cough occurring 1–3 weeks after a heavy exposure (may be longer with less intense exposure). The subacute form resembles infections such as tuberculosis with cough, weight loss, night sweats, and pleurisy. Chronic disease is unusual in children. Physical examination may be normal, or rales may be heard. A small number of patients may have immune-mediated signs such as arthritis, pericarditis, and erythema nodosum. The usual duration of the disease is less than 2 weeks, followed by complete resolution, but symptoms may last several months before resolving without antifungal therapy.

3. Disseminated infection (5% of infections)—Fungemia during primary infection probably occurs in the first 2 weeks of all infections, including those with minimal symptoms. Transient hepatosplenomegaly may occur, but resolution is the rule in immunocompetent individuals. Heavy exposure, severe underlying pulmonary disease, and immunocompromise are risk factors for progressive infection characterized by anemia, fever, weight loss, organomegaly, bone marrow involvement, and death. Dissemination may occur in otherwise immunocompetent children; usually they are younger than age 2 years.

4. Other forms—Ocular involvement consists of multifocal choroiditis. This usually occurs in immunocompetent adults who exhibit other evidence of disseminated disease. Brain, pericardium, intestine, and skin (oral ulcers and nodules) are other sites that can be involved. Adrenal gland involvement is common with systemic disease.

B. Laboratory Findings

Routine tests are normal or nonspecific in the benign forms. Pancytopenia is present in many patients with disseminated

disease. The diagnosis can be made by demonstrating the organism by histology or culture. Tissue yeast forms are small and may be mistaken for artifact. They are usually found in macrophages, occasionally in peripheral blood leukocytes in severe disease, but infrequently in sputum, urine, or CSF. Cultures of infected fluids or tissues may yield the organism after 1–4 weeks of incubation on fungal media, but even cultures of bronchoalveolar lavage or transbronchial biopsy specimens in immunocompromised patients are often negative (15%). Thus, bone marrow and tissue specimens are needed. Detection of histoplasmal antigen in blood, urine, CSF, and bronchoalveolar lavage fluid is the most sensitive diagnostic test (90% positive in the urine with disseminated disease, 75% positive with acute pneumonia), but false-negative results may occur. Both urine and serum should be tested for optimal results. The level of antigen correlates with the extent of the infection, and antigen levels can be used to follow the response to therapy and to indicate low-grade infection persisting after completion of therapy (eg, in a child with HIV infection).

Antibodies may be detected by immunodiffusion and complement fixation; the latter rises in the first 2–6 weeks of illness and falls thereafter unless dissemination occurs. Cross-reactions occur with some other endemic fungi. A single high titer or rising titer indicates a high likelihood of disease, but antigen detection has replaced serology as a rapid diagnostic test.

C. Imaging

Scattered pulmonary calcifications in a well child are typical of past infection. Bronchopneumonia (focal mid-lung infiltrates) occurs with acute disease, often with hilar and mediastinal adenopathy, occasionally with nodules, but seldom with effusion. Localized or patchy infiltrates occur in subacute disease. Apical cavitation occurs with chronic infection, often on the background of preexisting pulmonary infection.

» Differential Diagnosis

Pulmonary disease resembles viral infection, other causes of community acquired pneumonia, tuberculosis, coccidioidomycosis, and blastomycosis. Systemic disease resembles disseminated fungal or mycobacterial infection, leukemia, histiocytosis, or cancer.

» Treatment

Most patients with acute pulmonary disease will benefit from oral itraconazole. Those with subacute disease are generally better when the diagnosis is established, but if still symptomatic should receive oral therapy. Treatment with lipid formulation of amphotericin B (2–5 mg/kg/d) is indicated for severe pulmonary disease (diffuse radiographic involvement); disseminated disease; or when endovascular, CNS, or chronic pulmonary disease is present; and for children younger than age 1 year. Disseminated disease in infants may respond to as few as 10 days of amphotericin B, although 4–6 weeks is usually recommended. Patients with severe disease (especially pulmonary) may benefit from a short course of corticosteroid therapy. Surgical excision of chronic pulmonary lesions is rarely required. Itraconazole (3–5 mg/kg/d for 6–12 weeks; achieve peak serum level of > 1.0 mcg/mL) appears to be equivalent to amphotericin B therapy for mild disease and can be substituted in severe disease after a favorable initial (2 weeks) response to amphotericin B. With chronic pulmonary, CNS, or disseminated disease, prolonged therapy for at least a year should be considered.

Quantitation of fungal antigen is useful for directing therapy, and should be monitored for 1 year after successful treatment of severe disease. Relapse may occur in up to 15% of patients with treated chronic disease. Histoplasmosis can reactivate in previously infected individuals who subsequently become immunosuppressed. Chronically immunosuppressed patients may require lifelong maintenance therapy with itraconazole.

» Prognosis

Patients with mild and moderately severe infections have a good prognosis. With early diagnosis and treatment, infants with disseminated disease usually recover; the prognosis worsens if the immune response is poor.

Sporotrichosis

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

- Subacute cutaneous ulcers.
- New lesions appearing proximal to existing lesions along a draining lymphatic.
- Absence of systemic symptoms.
- Isolation of Sporothrix schenckii from wound drainage or biopsy.

» General Considerations

Sporotrichosis is caused by Sporothrix schenckii, a dimorphic fungus present as a mold in soil, plants, and plant products from most areas of North and South America. Spores of the fungus can cause infection when they breach the skin at

areas of minor trauma. Sporotrichosis has been transmitted from cutaneous lesions of pets.

» Clinical Findings

Cutaneous disease is by far the most common manifestation. Typically at the site of inapparent skin injury, an initial papular lesion will slowly become nodular and ulcerate. Subsequent new lesions develop in a similar fashion proximally along lymphatics draining the primary lesion. This sequence of developing painless, chronic ulcers in a linear pattern is strongly suggestive of the diagnosis. Solitary lesions may exist and some lesions may develop a verrucous character. Systemic symptoms are absent and laboratory evaluations are normal, except for acute-phase reactants. The fungus rarely disseminates in immunocompetent hosts. Cavitary pneumonia is an uncommon manifestation when patients inhale the spores. Immunocompromised patients, especially those with HIV infection, may develop disseminated skin lesions and multiorgan disease with extensive pneumonia.

» Differential Diagnosis

The differential diagnosis of nodular lymphangitis (sporotrichoid infection) includes other endemic fungi and some bacteria, especially atypical mycobacteria, pyoderma gangrenosum, nocardiosis, and syphilis. Diagnosis is made by culture. Biopsy of skin lesions will demonstrate a suppurative response with granulomas and provides the best source for laboratory isolation. Occasionally, the characteristic yeast will be seen in the biopsy.

» Treatment & Prognosis

Treatment is with itraconazole (200 mg/d or 5 mg/kg/d) for 2–4 weeks after lesions heal, usually 3–6 months. Prognosis is excellent with lymphocutaneous disease in immunocompetent children. Pulmonary or osteoarticular disease, especially in immunocompromised individuals, requires longer therapy. Amphotericin B may be required for disseminated disease, CNS disease, and severe pulmonary disease. Surgical debridement may be required.

PNEUMOCYSTIS AND OTHER OPPORTUNISTIC FUNGAL INFECTIONS

The name of this category indicates that fungi that are normally not pathogenic, or do not cause severe disease, may do so when given the opportunity by changes in host defenses. They occur most commonly when patients are treated with corticosteroids, antineoplastic drugs, or radiation, thereby reducing the number or function of neutrophils and T cells. Inborn errors in immune function (combined immunodeficiency or chronic granulomatous disease) may also be complicated by these fungal infections. Opportunistic infections are facilitated by altering the normal flora with antibiotics and by disruption of mucous membranes or skin with antineoplastic therapy or indwelling lines and tubes.

Table 43–4 indicates that filamentous fungi are prominent causes of severe systemic fungal disease in immunocompromised patients. Aspergillus species (usually fumigatus) and Zygomycetes (usually Mucorales) cause subacute pneumonia and sinusitis and should be considered when these conditions do not respond to antibiotics in immunocompromised patients. Aspergillus species also commonly cause invasive disease in patients with chronic granulomatous disease. Mucormycosis is especially likely to produce severe sinusitis in patients with chronic acidosis when the diabetes is poorly controlled. This fungus may invade the orbit and cause brain infection. Mucormycosis also occurs in patients receiving iron chelation therapy. These fungal infections may disseminate widely. Imaging procedures may suggest the etiology, but they are best diagnosed by aspiration or biopsy of infected tissues. A characteristic CT finding is the "halo sign," which is a ground-glass opacity surrounding a pulmonary nodule or mass. The "reversed halo sign" is a focal rounded ground-glass opacity surrounded by a crescent or complete ring of consolidation. Detection of galactomannose and β-D-glucan in blood and alveolar fluid is useful for the diagnosis of presumptive of aspergillosis and other opportunistic fungal pathogens.

Although Cryptococcus can cause disease in the immune competent hosts, it is more likely to be clinically apparent and severe in immunocompromised patients. This yeast causes pneumonia and is a prominent cause of fungal meningitis. Candida species in these patients cause fungemia and multiorgan disease, with lungs, esophagus, liver, and spleen frequently affected (see the earlier section on Disseminated Candida Infection).

Opportunistic fungal infections should always be included in the differential diagnosis of unexplained fever or pulmonary infiltrates in immunocompromised patients. These pathogens should be aggressively pursued with imaging studies and with tissue sampling when clues are available. Cryptococcus and Aspergillus may be demonstrated with specific antigen tests. Opportunistic infections are difficult to treat because of the deficiencies in host immune response. Treatment should be undertaken with consultants who are expert in managing these infections. Voriconazole is the drug of choice for many mold infections,

Table 43–4. Unusual fungal infections in children.

Organism	Predisposing Factors	Route of Infection	Clinical Disease	Diagnostic Tests	Therapy and Comments
Aspergillus species	None	Inhalation of spores	Allergic bronchopulmonary aspergillosis; wheezing, cough, migratory infiltrates, eosinophilia.	Organisms in sputum; positive skin test; specific IgE antibody; elevated IgE levels.	Hypersensitivity to fungal antigens. Use steroids. Antifungals may not be needed.
	Immunosuppression	Inhalation of spores	Progressive pulmonary disease: consolidation, nodules, abscesses. Sinusitis Disseminated disease: usually lung, brain; occasionally intestine, kidney, heart, bone. Invades blood vessels.	Demonstrate fungus in tissues by stain or culture; septate hyphae branching at 45-degree angle; antigen/fungal component detection may be useful.	Amphotericin B, voriconazole, and oral caspofungin are equally effective; these can be used in combination.
Malassezia furfur, M pachydermatis	Central venous catheter, usually lipid infusion (can occur in the absence of lipid)	Line infection from skin colonization	Sepsis; pneumonitis, thrombocytopenia.	Culture of catheter or blood on lipid-enriched media (for M furfur; M pachydermatis does not need lipid). Fungus may be seen in buffy coat.	Discontinuation of lipid may be sufficient. Remove catheter. Short-term amphotericin B may be added. Organism ubiquitous on normal skin; requires long-chain fatty acids for growth.
Mucorales (Mucor, Rhizopus, Absidia)	Immunosuppression, diabetic acidosis, iron overload	Inhalation, mucosal colonization	Rhinocerebral: sinus, nose, necrotizing vasculitis; central nervous system spread. Pulmonary. Disseminated: any organ.	Demonstrate broad aseptate hyphae branching at 90-degree angles in tissues by stain Culture: rapidly growing, fluffy fungus.	Amphotericin B, surgical debridement; voriconazole and posaconazole also often effective or can be used as a second agent for combined therapy. Poor prognosis.
Scedosporium spp	Immunosuppression	Inhalation	Disseminated abscesses (lung, brain, liver, spleen, other).	Culture of pus or tissue.	Surgical drainage; voriconazole or caspofungin.
	Minor trauma	Cutaneous	Mycetoma (most common).	Yellow-white granules in pus. Culture.	Aggressive surgery. Amputation may be needed.

but both echinocandins and amphotericin B formulations are good alternatives. Serum levels of voriconazole should be determined to guide therapy. Combinations of current antifungal drugs are being tested to improve the outcome. Many children who will have depressed phagocytic and T-cell–mediated immune function for long periods (eg, after hematopoietic stem cell transplants) should receive antifungal prophylaxis during the period of severe immune suppression, most often with fluconazole or itraconazole. Very-low-birth-weight infants, who are at high risk for systemic Candida infection, often receive similar prophylaxis for prolonged periods.

Malassezia furfur is a yeast that normally causes the superficial skin infection known as tinea versicolor (see Chapter 15). This organism is considered an opportunist when fungemia is associated with prolonged intravenous therapy, especially with central lines used for hyperalimentation. The yeast, which requires skin lipids for its growth, can infect lines when lipids are present in the infusate. Some species will grow in the absence of lipids. Unexplained fever and thrombocytopenia are common. Pulmonary infiltrates may be present. The diagnosis is facilitated by alerting the bacteriology laboratory to add olive oil to culture media. The infection will respond to removal of the line or the lipid supplement. Amphotericin B may hasten resolution.

PNEUMOCYSTIS JIROVECI INFECTION

ESSENTIALS OF DIAGNOSIS & TYPICAL FEATURES

» Significant immunosuppression.

» Fever, tachypnea, cough, dyspnea.

» Hypoxemia; diffuse interstitial infiltrates.

» Detection of the organism in specimens of pulmonary origin.

» General Considerations

Although classified as a fungus on the basis of structural and nucleic acid characteristics, Pneumocystis responds readily to antiprotozoal drugs and antifols. It is a ubiquitous pathogen. Initial infection is presumed to occur asymptomatically via inhalation, usually in early childhood, and to become a clinical problem upon reactivation during immune suppression. There is evidence that person-to-person transmission may contribute to symptomatic disease in immune compromised individuals. In the normal host clinical disease rarely occurs. A syndrome of afebrile pneumonia similar to that caused by Chlamydia trachomatis in normal infants has been described, but its etiology is rarely appreciated. Whether by reactivation or new exposure, severe signs and symptoms occur chiefly in patients with abnormal T-cell function, such as hematologic malignancies and organ transplantation. Pneumocystis also causes severe pneumonia in patients with γ-globulin deficiency and is an AIDS-defining illness for children with advanced HIV infection. Prophylaxis usually prevents this infection (see Chapter 41).

Prolonged, high-dose corticosteroid therapy for any condition is a risk factor; onset of illness as steroids are tapered is a typical presentation. Severely malnourished infants with no underlying illness may also develop this infection, as can those with congenital immunodeficiency. The incubation period is usually at least 1 month after onset of immunosuppressive therapy.

» Clinical Findings

A. Symptoms and Signs

In most patients, a gradual onset of fever, tachypnea, dyspnea, and mild, nonproductive cough occurs over 1–4 weeks. Initially the chest is clear, although retractions and nasal flaring are present. At this stage the illness is nonspecific. Hypoxemia out of proportion to the clinical and radiographic signs is an early finding; however, even minimally decreased arterial oxygen pressure values should suggest this diagnosis in immunosuppressed children. Tachypnea, nonproductive cough, and dyspnea progress. Respiratory failure and death occur without treatment. In some children with AIDS or severe immunosuppression from chemotherapy or organ transplantation, the onset may be abrupt and progression more rapid. Acute dyspnea with pleuritic pain may indicate the complication of pneumothorax.

The general examination is unremarkable except for tachypnea and tachycardia; rales may be absent. There are no upper respiratory signs, conjunctivitis, organomegaly, enanthem, or rash.

B. Laboratory Findings

Laboratory findings reflect the individual child's underlying illness and are not specific. Serum lactate dehydrogenase levels may be elevated markedly as a result of pulmonary damage. In moderately severe cases, the arterial oxygen pressure is less than 70 mm Hg or the alveolar-arterial gradient is less than 35 mm Hg.

C. Imaging

Early chest radiographs are normal. The classic pattern in later films is bilateral, interstitial, lower lobe alveolar disease starting in the perihilar regions, without effusion,

consolidation, or hilar adenopathy. High-resolution CT scanning may reveal extensive ground-glass attenuation or cystic lesions. Older HIV-infected patients present with other patterns, including nodular infiltrates, lobar pneumonia, cavities, and upper lobe infiltrates.

D. Diagnostic Findings

Diagnosis requires finding characteristic round (6–8 mm) cysts in a lung biopsy specimen, bronchial brushings, alveolar washings, induced sputum, or tracheal aspirates. Tracheal aspirates are less sensitive, but are more rapidly and easily obtained. They are more often negative in children with leukemia compared with those with HIV infection; presumably, greater immunosuppression permits replication of a larger numbers of organisms. Because pneumonia in immunosuppressed patients may have many causes, negative results from tracheal secretions should prompt more aggressive diagnostic attempts. Bronchial washing using fiberoptic bronchoscopy is usually well tolerated and rapidly performed.

Several rapid stains—as well as the standard methenamine silver stain—are useful. The indirect fluorescent antibody method is most sensitive. These methods require competent laboratory evaluation, because few organisms may be present and many artifacts may be found.

» Differential Diagnosis

In immunocompetent infants, C trachomatis pneumonia is the most common cause of the afebrile pneumonia syndrome described for Pneumocystis. In older immunocompromised children, the differential diagnosis includes influenza, respiratory syncytial virus, cytomegalovirus, adenovirus, and other viral infections; bacterial and fungal pneumonia; pulmonary emboli or hemorrhage; congestive heart failure; and Chlamydia pneumoniae and M pneumoniae infections. Lymphoid interstitial pneumonitis, which occurs in older infants with untreated HIV infection, is more indolent and the patient's lactate dehydrogenase level is normal (see Chapter 41). Pneumocystis pneumonia is rare in children who are complying with prophylactic regimens.

» Prevention

Children at high risk for developing Pneumocystis infection should receive prophylactic therapy. Children at risk include those with hematologic malignancies, children who for other reasons are receiving intensive chemotherapy or high-dose corticosteroids, and children with organ transplants or advanced HIV infection. All children born to HIV-infected mothers should receive prophylaxis against Pneumocystis starting at age 6 weeks unless HIV infection has been ruled out by tests for HIV in serum. If the infant is infected treatment is often continued for the first year of life, or until the patient's immunologic status is defined sufficiently to direct additional prophylaxis (see Chapter 41). The prophylaxis of choice is trimethoprim-sulfamethoxazole (150 mg/m^2/d of trimethoprim and 750 mg/m^2/d of sulfamethoxazole) for 3 consecutive days of each week. Alternatives to this prophylaxis regimen are described in Chapter 41.

» Treatment

A. General Measures

Supplemental oxygen and nutritional support may be needed. The patient should be in respiratory isolation.

B. Specific Measures

Trimethoprim-sulfamethoxazole (20 mg/kg/d of trimethoprim and 100 mg/kg/d of sulfamethoxazole in four divided doses intravenously or orally if well tolerated) is the treatment of choice. Improvement may not be seen for 3–5 days. Duration of treatment is 3 weeks in HIV-infected children. Methylprednisolone (2–4 mg/kg/d in four divided doses intravenously) should also be given to HIV-infected patients with moderate to severe infection (partial oxygen pressure < 70 mm Hg or alveolar-arterial gradient > 35) for the first 5 days of treatment. The dosage is reduced by 50% for the next 5 days and further by 50% until antibiotic treatment is completed. If trimethoprim-sulfamethoxazole is not tolerated or there is no clinical response in 5 days, pentamidine isethionate (4 mg/kg once daily by slow intravenous infusion) should be given. Clinical efficacy is similar with pentamidine, but adverse reactions are more common. These reactions include dysglycemia, pancreatitis, nephrotoxicity, and leukopenia. Other effective alternatives utilized in adults include atovaquone, trimethoprim plus dapsone, and primaquine plus clindamycin.

» Prognosis

The mortality rate is high in immunosuppressed patients who receive treatment late in the illness.

Sexually Transmitted Infections

Daniel H. Reirden, MD
Ann-Christine Nyquist, MD, MSPH

The rate of sexually transmitted infections (STIs) acquired during adolescence remains high despite widespread educational programs and increased access to health care. By senior year in high school, nearly half of youth will have had sexual intercourse. The highest age-specific rates for gonorrhea, chlamydia, and human papillomavirus (HPV) infection occur in adolescents and young adults (15–24 years of age). While this age group accounts for only 25% of the sexually active population, it accounts for almost half of the incident STI infections. Adolescents contract STIs at a higher rate than adults because of sexual risk taking, age-related biologic factors, and barriers to health care access. In every state and the District of Columbia, adolescents can provide consent for the diagnosis and treatment of STIs without parental consent. Only one state requires the notification of a parent in the event of a positive test; 18 others allow for the disclosure to a parent. In many states, adolescents can also provide consent for human immunodeficiency virus (HIV) counseling and testing. Since individual state laws vary, health care providers should be knowledgeable about the legal definitions regarding age of consent and confidentiality requirements in their state.

Providers should screen sexually experienced adolescents for STIs and use this opportunity to discuss risk reduction. Since not all adolescents receive regular preventive care, providers should use acute care visits to offer screening and education. Health education counseling should be nonjudgmental and appropriate for the developmental level, yet sufficiently thorough to identify risk behaviors because many adolescents may not readily acknowledge engaging in these behaviors.

ADOLESCENT SEXUALITY

The spectrum of sexual behavior includes holding hands and kissing, touching, mutual masturbation, oral-genital contact, and vaginal and anal intercourse. Each has its associated risks. A small, but statistically significant, trend has occurred in the epidemiology of sexual risk taking toward less sexual involvement and later onset of vaginal intercourse. The most recent Youth Risk Behavior Survey (2013) reports that 47% of high school students have had vaginal intercourse; 6% percent of teenagers initiated sex by age 13. Racial and gender differences exist; non-Hispanic black adolescents report a higher prevalence of sexual activity and an earlier age of initiation. Thirty-four percent of students had sex in the 3 months prior to the survey—49% of twelfth-graders and 20% of ninth-graders. Over 15% of students reported having had four or more lifetime sexual intercourse partners. Among those youth currently sexually active, 59% reported that either they or their partner had used a condom during their last sexual intercourse. Paradoxically, condom use decreases with age—63% of ninth-graders reported condom use at their last intercourse compared with 53% of twelfth-graders. Substance use contributes to an increase in risky sexual activity and 22% of sexually active youth report that they used alcohol or drugs prior to their last intercourse.

Although there may be variations among groups of teens, oral sex is relatively common in adolescents with approximately two-thirds of 15–24 year-olds reporting oral sexual activity. Anal intercourse occurs in both hetero- and homosexual populations. Adolescent development is a time of exploration, including one's sexual orientation. Frequently, teenagers may not identify themselves as gay, lesbian, or bisexual; thus, sensitive, nonjudgmental history taking is necessary to elicit a history of same-sex partners. Adolescents struggling with their emerging sexual orientation and associated stigma may engage in sexual activity with partners of both sexes or use substances to cope, thereby impairing their decision-making abilities.

Alexander SC et al. Sexuality talk during adolescent health maintenance visits. JAMA Pediatr 2014;168:163–169 [PMID: 24378686]. Doi:10.1001/jamapediatrics.2013.4338.

Centers for Disease Control and Prevention: Youth risk behavior surveillance—United States, 2013. MMWR Surveill Summ 2014;63(SS–4) [PMID: 24918634].
Shafii T, Burstein G: The adolescent sexual health visit. Obstet Gynecol Clin N Am 2009;36:99 [PMID: 19344850]. http://www.guttmacher.org/statecenter/adolescents.html. Accessed February 2, 2016.

RISK FACTORS

Certain behaviors and experiences put the adolescent at higher risk for developing STIs. These include early age at sexual debut, lack of condom use, multiple partners, prior STI, history of STI in a partner, and sex with a partner who is three or more years older. The type of sex affects risk as well, with intercourse being riskier than oral sex. Other risk-taking behaviors associated with STIs in adolescents are smoking, alcohol use, drug use, dropping out of school, pregnancy, and depression.

The adolescent female is especially predisposed to chlamydia, gonorrhea, and HPV infection because the cervix during adolescence has an exposed squamocolumnar junction. The rapidly dividing cells in this area are especially susceptible to microorganism attachment and infection. During early to midpuberty, this junction slowly invaginates as the uterus and cervix mature, and by the late teens to early 20s the squamocolumnar junction is inside the cervix.

Centers for Disease Control and Prevention: Youth risk behavior surveillance—United States 2013. MMWR Surveill Summ 2014;63(SS–4) [PMID: 24918634].

PREVENTION OF SEXUALLY TRANSMITTED INFECTIONS

Efforts to reduce STI risk behavior should begin before the onset of sexual experimentation: first by helping youth personalize their risk for STIs and encouraging positive behaviors that minimize these risks, and then by enhancing communication skills with sexual partners about STI prevention, abstinence, and condom use.

Primary prevention focuses largely on education and risk-reduction techniques. It is essential to recognize that a key task of adolescence is developing a sexual identity. Teenagers are sexual beings that will decide if, when, and how they are going to initiate sexual involvement. Health care providers should routinely address sexuality as part of well-adolescent checkups. Being open and frank about the risks and benefits of each specific type of sexual activity will help youth think about their decision and the consequences. Although more than 90% of students have been taught about HIV infection and other STIs in school, adolescents still have a difficult time personalizing risk. Discussing prevalence, symptoms, and sequelae of STIs can raise awareness and help teenagers make informed decisions about initiating sexual activity and the use of safer sex techniques. Abstinence is theoretically an effective method of preventing sexually transmitted infections. However, many studies have failed to show sustainable protection. Making condoms available reiterates the message that safer sex is vital to health. Discussing condoms, dental dams, and the proper use of lubrication also facilitates safer sex practices. Condoms prevent infections with HIV, HPV, gonorrhea, Chlamydia, and herpes simplex virus (HSV). They are probably effective in preventing other STIs as well.

Secondary prevention requires identifying and treating STIs (see the next section Screening for Sexually Transmitted Infections) before infected individuals transmit infection to others. Access to confidential medical care is critical to this objective. Identifying and treating STIs in partners is essential in limiting the spread of these infections. Cooperation with the state or county health department is valuable, because these agencies assume the responsibility for locating the contacts of infected persons and ensuring appropriate treatment.

Tertiary prevention is directed toward complications of a specific illness. Examples of tertiary prevention would be treating pelvic inflammatory disease (PID) before infertility develops, following the serologic response to syphilis to prevent late-stage syphilis, treating cervicitis to prevent PID, or treating a chlamydial infection before epididymitis ensues.

Finally, preexposure vaccination against hepatitis B, hepatitis A, and HPV reduces the risk of acquiring these preventable STIs. All adolescents should have prior or current immunization against hepatitis B (see Chapter 10). However, because hepatitis B infection is frequently sexually transmitted, this vaccine is especially critical for all unvaccinated patients being evaluated for an STI. Hepatitis A vaccination is recommended for all individuals. Preexposure vaccination for HPV will decrease the risk for cervical dysplasia and cervical cancer in females, and decreases the risk for genital warts and both anal and oropharyngeal cancer in males and females, which can occur decades later (see Chapter 10).

SCREENING FOR SEXUALLY TRANSMITTED INFECTIONS

The ability of the health care provider to obtain an accurate sexual history is crucial in prevention and control efforts. Teenagers should be asked open-ended questions about their sexual experiences to assess their risk for STIs. Questions must be clear to the youth, so choose language that the adolescent will understand. If the adolescent has ever

engaged in sexual activity, the provider needs to determine what kind of sexual activity (mutual masturbation or oral, anal, or vaginal sex); whether it has been opposite-sex, same-sex, or both; whether birth control and condoms were used; and whether it has been consensual or forced. During the interview, the clinician should take the opportunity to discuss risk-reduction techniques regardless of the history obtained from the youth.

A routine laboratory screening process is warranted if the patient has engaged in intercourse, presents with STI symptoms, or reports a partner with an STI. The availability of nucleic acid amplification tests (NAATs), primarily for Chlamydia and Neisseria gonorrhoeae, has changed the nature of STI screening and intervention. These amplification tests are more than 95% sensitive and more than 99% specific, using either urine or cervical/urethral or vaginal swabs. Annual screening of all sexually active females aged 25 years or younger is recommended for Chlamydia trachomatis and Neisseria gonorrhoeae. Routine chlamydial testing should be considered for all adolescent males, especially for males who have sex with men, have new or multiple sex partners, or are in correctional facilities. For men who have sex with men, consideration should be given to testing oropharyngeal and rectal sites, as asymptomatic infections are common. Use of NAAT is recommended for samples from these sites, but such tests are not currently FDA-approved and providers must locate a laboratory that has performed the necessary validation studies.

Initial screening for urethritis in males begins with a physical examination. A first-catch urine sample (the first 10–20 mL of voided urine collected after not voiding for 2 hours) should be sent for Chlamydia and N gonorrhoeae testing if there are no signs (urethral discharge or lesions) or symptoms. With signs or symptoms of urethritis, a urethral swab should be sent to test for both N gonorrhoeae and Chlamydia. A wet mount preparation should then be done on a spun urine sample or from urethral discharge, evaluating for the presence of Trichomonas vaginalis. Newer technologies, such as enzyme-linked immunoassays (EIA) and NAAT testing, have become available that allow greater sensitivity and specificity in making the diagnosis of T vaginalis in males and females.

Screening asymptomatic females is more complicated because a variety of approaches are available. Generally, either a first-void urine specimen, a cervical swab, or a vaginal swab is used to screen for Chlamydia and N gonorrhoeae by NAAT. Any vaginal discharge symptoms should include evaluation of wet mount of vaginal secretions to check for bacterial vaginosis and trichomoniasis, and a potassium hydroxide (KOH) preparation to screen for yeast infections. The Papanicolaou (Pap) smear serves to evaluate the cervix for the presence of dysplasia. The first Pap smear should be performed at age 21 years and then every 3 years. HPV typing is not recommended.

In urban areas with a relatively high rate of syphilis and in males who have sex with men, a screening test should be drawn yearly or more frequently if higher risk encounters are more frequent. Rapid plasma regain (RPR) antibody tests should be done in all individuals in whom a concomitant STI is present. HIV antibody testing is recommended at least once for all patients and repeat testing undertaken when an STI is present or the history suggests multiple partners and high-risk behaviors.

Henry-Reid LM et al: Current pediatrician practices in identifying high-risk behaviors of adolescents. Pediatrics 2010;125:e741 [PMID: 20308220].

SIGNS & SYMPTOMS

The most common symptoms in males are dysuria and penile discharge resulting from urethral inflammation. However, providers should be aware that many urethral infections are asymptomatic. Less common symptoms are scrotal pain, hematuria, proctitis, and pruritus in the pubic region. Signs include epididymitis, orchitis, and urethral discharge. Rarely do males develop systemic symptoms. However, especially for MSM, but for any sexually active adolescent at risk for HIV infection who presents with nonspecific viral symptoms, acute HIV seroconversion illness should be considered in the differential diagnoses. For females, the most common symptoms are vaginal discharge and dysuria. Again, infection may be asymptomatic. Vaginal itching and irregular menses or spotting are also common. Abdominal pain, fever, and vomiting, although less common and specific, are signs of PID. Pain in the genital region and dyspareunia may be present.

Signs that can be found in both males and females with an STI include genital ulcerations, adenopathy, and genital warts.

° THe moST common anTiBioTic-reSPonSiVe Sexually TranSmiTTed infecTionS

C trachomatis and N gonorrhoeae are STIs that are epidemic in the United States and are readily treated when appropriate antibiotics are administered in a timely fashion.

CHLAMYDIA TRACHOMATIS INFECTION

» General Considerations

C trachomatis is the most common bacterial cause of STIs in the United States. In 2013, over 1.4 million cases in adolescents and young adults were reported to the CDC. C trachomatis is an obligate intracellular bacterium that

replicates within the cytoplasm of host cells. Destruction of Chlamydia-infected cells is mediated by host immune responses.

» Clinical Findings

A. Symptoms and Signs

Clinical infection in females manifests as dysuria, urethritis, vaginal discharge, cervicitis, irregular vaginal bleeding, or PID. The presence of mucopus at the cervical os (mucopurulent cervicitis) is a sign of chlamydial infection or gonorrhea. Chlamydial infection is asymptomatic in 75% of females.

Chlamydial infection may be asymptomatic in 70% of males or manifest as dysuria, urethritis, or epididymitis. Some patients complain of urethral discharge. On clinical examination, a clear white discharge may be found after milking the penis. Proctitis or proctocolitis from Chlamydia may occur in adolescents practicing receptive anal intercourse.

B. Laboratory Findings

NAAT is the most sensitive (92%–99%) way to detect Chlamydia. Enzyme-linked immunosorbent assay (ELISA) or direct fluorescent antibody (DFA) tests are less sensitive, but may be the only testing option in some centers.

A cervical or vaginal swab, using the manufacturer's swab provided with the specific test, or first-void urine specimen, should be obtained. For urine screening, yields of testing are maximized when collecting between 10 and 20 mL of urine and ensuring that patient has not voided for 2 hours. Often a single swab can be used to collect both the Chlamydia and N gonorrhoeae specimen. To optimize detection of Chlamydia from the cervix, columnar cells need to be collected by inserting the swab in the os and rotating it 360 degrees. NAAT is not licensed for rectal samples but some laboratories have validated testing on rectal specimens for C trachomatis. Thus, when a rectal specimen is obtained, this must often be evaluated by less sensitive culture methods unless there is access to a laboratory that has validated Chlamydia NAAT for nongenital sites.

In general, a first-void urine sample, or urethral swab for NAAT, should be obtained at least annually. Some studies suggest that more frequent screenings—every 6 months—in higher-prevalence populations can decrease the rate of chlamydial infection. For both males and females, testing urine allows for more frequent screening and simplifies screening in large group settings, such as schools and correctional facilities.

» Complications

Epididymitis is a complication in males. Reiter syndrome occurs in association with chlamydial urethritis. This should be suspected in male patients who are sexually active and present with low back pain (sacroiliitis), arthritis (polyarticular), characteristic mucocutaneous lesions, and conjunctivitis. PID is an important complication in females.

» Treatment

Infected patients and their contacts, regardless of the extent of signs or symptoms, need to receive treatment (Table 44–1). Reinfection caused by failure of contacts to receive treatment or the initiation of sexual activity with a new infected partner puts the adolescent at high risk of acquiring a repeat chlamydial infection within several months of the first infection. Because of this increased risk, all infected females and males should be retested approximately 3 months after treatment.

NEISSERIA GONORRHOEAE INFECTION

» General Considerations

Gonorrhea is the second most prevalent bacterial STI in the United States, where 333,000 new N gonorrhoeae infections were reported in 2013. While overall rates have decreased, gonorrhea rates continue to be highest among adolescents and young adults, and the rate of gonorrhea among men compared to women is higher. Among females in 2013, 20- to 24-year-olds and 15- to 19-year-olds had the highest rates of gonorrhea; among males, 20- to 24-year-olds had the highest rate.

Sites of infection include the cervix, urethra, rectum, and pharynx. In addition, gonorrhea is a cause of PID. Humans are the natural reservoir. Gonococci are present in the exudate and secretions of infected mucous membranes.

» Clinical Findings

A. Symptoms and Signs

In uncomplicated gonococcal cervicitis, females are symptomatic 23%–57% of the time, presenting with vaginal discharge and dysuria. Urethritis and pyuria may also be present. Mucopurulent cervicitis with a yellowish discharge may be found, and the cervix may be edematous and friable. Other symptoms include abnormal menstrual periods and dyspareunia. Approximately 15% of females with endocervical gonorrhea have signs of involvement of the upper genital tract. Compared with chlamydial infection, pelvic inflammation with gonorrhea has a shorter duration, but an increased intensity of symptoms, and is more often associated with fever. Symptomatic males usually have a yellowish-green urethral discharge and burning on urination, but most males (55%–67%) with N gonorrhoeae are asymptomatic. Both males and females can develop gonococcal proctitis and pharyngitis after appropriate exposure.

Table 44–1. Treatment regimens for sexually transmitted infections.

	Recommended Regimens	Pregnancy[a] [Category]
Pelvic inflammatory disease (PID)		
Parenteral therapy regimen A Note: Therapy should be continued for 24–48 h after patient has improved; therapy can then be switched to either oral regimen to complete a 14-d course	Cefotetan, 2 g IV every 12 h or Cefoxitin, 2 g IV every 6 h plus Doxycycline, 100 mg IV or orally every 12 h	Safe [B] Safe [B] Contraindicated [D]
Parenteral therapy regimen B Note: Once clinically improved for 48 h, patients can continue clindamycin, 100 mg PO bid for 14 d total[c]	Clindamycin, 900 mg IV every 8 h plus Gentamicin, 2 mg/kg IV/IM loading dose, then 1.5 mg/kg IV every 8 h[b]	Safe [B] Safe [B]
Alternative parenteral regimens	Ampicillin/sulbactam, 3 g IV every 6 h plus Doxycycline, 100 mg IV or orally every 12 h	Safe [A] Contraindicated [D]
Recommended outpatient regimen Note: Pregnant patients with PID and women with tubo-ovarian abscesses should be hospitalized and given parenteral antibiotics[c]	Ceftriaxone, 250 mg IM once plus Doxycycline, 100 mg orally twice a day for 14 d with or without Metronidazole, 500 mg orally twice a day for 14 d or Cefoxitin, 2 g IM once plus probenecid, 1 g orally as a single dose plus Doxycycline, 100 mg orally twice a day for 14 d with or without Metronidazole, 500 mg orally twice a day for 14 d or Other parenteral third-generation cephalosporin (eg, ceftizoxime or cefotaxime) plus Doxycycline, 100 mg orally twice a day for 14 d with or without Metronidazole, 500 mg orally twice a day for 14 d	Safe [B] Contraindicated [D] Safe [B] Safe [B] Contraindicated [D] Safe [B] Safe [B] Contraindicated [D] Safe [B]
Cervicitis		
Chlamydia	Azithromycin, 1 g orally as single dose or Doxycycline, 100 mg orally twice a day for 7 d	Safe [B] Contraindicated [D]
Gonorrhea, uncomplicated		
Cervicitis, urethritis, rectal, pharyngitis Note: Empiric combination treatment with azithromycin is recommended due improving treatment efficacy and potentially delaying the emergence and spread of resistance to cephalosporins	Ceftriaxone, 250 mg IM as single dose plus Azithromycin, 1 g orally as single dose	Safe [B] Safe [B]
Alternative Oral regimen (if ceftriaxone is not available)	Cefixime, 400 mg orally twice a day or Cefixime suspension, 400 mg by suspension (200 mg/5 mL) orally twice a day plus Azithromycin, 1 g orally as single dose	Safe [B] Safe [B] Safe [B]
Gonorrhea, disseminated		
Note: Treat IV until clinically improved (usually 48 h; then switch to PO); complete at least a 7-d course	Ceftriaxone, 1 g IV or IM every 24 h plus Azithromycin, 1 g orally as single dose	Safe [B] Safe [B]

(Continued)

Table 44–1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy[a] [Category]
Alternative regimens	Cefotaxime, 1 g IV every 8 h	Safe [B]
	or	
	Ceftizoxime, 1 g IV every 8 h	Safe [B]
	plus	
	Azithromycin, 1 g orally as single dose	Safe [B]
Nongonococcal, nonchlamydial urethritis		
	Azithromycin, 1 g orally as single dose	Safe [B]
	or	
	Doxycycline, 100 mg orally twice a day for 7 d	Contraindicated [D]
Alternative regimens	Erythromycin base, 500 mg orally four times a day for 7 d	Safe [B]
	or	
	Erythromycin ethylsuccinate, 800 mg orally four times a day for 7 d	Safe [B]
	or	
	Levofloxacin, 500 mg orally once daily for 7 d	Contraindicated [C]
	or	
	Ofloxacin, 300 mg orally twice a day for 7 d	Contraindicated [C]
Recurrent or persistent urethritis	Metronidazole, 2 g orally as single dose	Safe [B]
	or	
	Tinidazole, 2 g orally as single dose	Contraindicated [C]
	plus	
	Azithromycin, 1 g orally as single dose (if not used for initial episode)	Safe [B]
Proctitis, proctocolitis, and enteritis		
	Ceftriaxone, 250 mg IM	Safe [B]
	plus	
	Doxycycline, 100 mg orally twice a day for 7 d	Contraindicated [D]
Trichomonas vaginalis vaginitis or urethritis		
	Metronidazole, 2 g orally as single dose	Safe [B]
	or	
	Tinidazole, 2 g orally as single dose	Contraindicated [C]
Alternative regimen	Metronidazole, 500 mg orally twice a day for 7 d	Safe [B]
Bacterial vaginosis		
	Metronidazole, 500 mg orally twice a day for 7 d	Safe [B]
	or	
	Metronidazole, 0.75% gel, 5 g intravaginally once daily for 5 d	Safe [B]
	or	
	Clindamycin cream, 2%, one applicator intravaginally at bedtime for 7 d	Safe [B]
Alternative regimen	Clindamycin, 300 mg orally twice a day for 7 d	Safe [B]
	or	
	Clindamycin ovule, 100 mg intravaginally once at bedtime for 3 d	Safe [B]
	or	
	Tinidazole, 2 g orally once daily for 2 d	Contraindicated [C]
	or	
	Tinidazole, 1 g orally once daily for 5 d	Contraindicated [C]
Vulvovaginal candidiasis		
	Butoconazole, clotrimazole, miconazole, terconazole or tioconazole, intravaginally for 1, 3, or 7 d	Safe [B]
	or	
	Butoconazole sustained-release, 5 g once intravaginally	Safe [B]
	or	
	Fluconazole, 150 mg oral tablet, in single dose	Contraindicated [C]

(Continued)

Table 44–1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy[a] [Category]
Syphilis		
Early (primary, secondary, or latent < 1 y)	Benzathine penicillin G, 2.4 million units IM (for patients > 40 kg) or Benzathine penicillin G, 50,000 U/kg IM (for patients < 40 kg); up to 2.4 million units in one dose	Safe [B] Safe [B]
Late (> 1-y duration or of unknown duration)	Benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units IM each at 1-wk intervals or Benzathine penicillin G, 50,000 U/kg IM (for patients < 40 kg) once a week for 3 consecutive wk; up to 2.4 million units in one dose	Safe [B] Safe [B]
Tertiary (with normal CSF examination)	Benzathine penicillin G, 7.2 million units total, administered as three doses of 2.4 million units IM each at 1-wk intervals or Benzathine penicillin G, 50,000 U/kg IM (for patients < 40 kg) once a week for 3 consecutive wk; up to 2.4 million units in one dose	Safe [B] Safe [B]
Neurosyphilis		
	Aqueous crystalline penicillin G, 18–24 million U/d, administered as 3–4 million units IV every 4 h or continuous infusion for 10–14 d or	Safe [B]
Alternative regimen (if compliance can be assured)	Procaine penicillin, 2.4 million units IM once daily plus Probenecid 500 mg orally four times a day for 10–14 d	Safe [B] Safe [B]
Epididymitis		
Most likely caused by gonococcal or chlamydial infection	Ceftriaxone, 250 mg IM as single dose plus Doxycycline, 100 mg orally twice a day for 10 d	
Most likely caused by enteric organisms	Ceftriaxone, 250 mg IM as single dose plus Levofloxacin, 500 mg orally once daily for 10 d or Ofloxacin, 300 mg orally twice a day for 10 d	
C trachomatis infection		
Cervicitis or urethritis	Azithromycin, 1 g orally as single dose or Doxycycline, 100 mg orally twice a day for 7 d	Safe [B] Contraindicated [D]
Alternative regimen[b]	Erythromycin, 500 mg orally four times a day for 7 d or Erythromycin ethylsuccinate, 800 mg orally four times a day for 7 d or Levofloxacin 500 mg orally once daily for 7 d or Ofloxacin, 300 mg orally twice a day for 7 d	Safe [B] Safe [B] Contraindicated [C] Contraindicated [C]
Granuloma inguinale		
	Azithromycin, 1 g orally once a week or 500 mg daily for at least 3 wk and until all lesions have completely healed	Safe [B]

(Continued)

Table 44–1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy[a] [Category]
Alternative regimen	Ciprofloxacin, 750 mg orally twice a day for at least 3 wk and until all lesions have completely healed	Contraindicated [C]
	or	
	Erythromycin base, 500 mg orally four times a day for at least 3 wk and until all lesions have completely healed	Safe [B]
	Or	
	Doxycycline, 100 mg orally twice a day for 3 wk or and until all lesions have completely healed	Contraindicated [D]
	or	
	Trimethoprim–sulfamethoxazole, one double-strength tablet orally twice a day for at least 3 wk and until all lesions have completely healed	Contraindicated [C]
Lymphogranuloma venereum		
	Doxycycline, 100 mg orally twice a day for 21 d	Contraindicated [C]
Alternative regimen	Erythromycin, 500 mg orally four times a day for 21 d	Safe [B]
Herpes simplex infection		
First episode, genital	Acyclovir, 400 mg orally three times a day for 7–10 d	Safe [B]
	or	
	Acyclovir, 200 mg orally five times a day for 7–10 d	Safe [B]
	or	
	Famciclovir, 250 mg orally three times a day for 7–10 d	Safe [B]
	or	
	Valacyclovir, 1 g orally twice a day for 7–10 d	Safe [B]
Episodic therapy for recurrent genital herpes	Acyclovir, 400 mg orally three times a day for 5 d	Safe [B]
	or	
	Acyclovir, 800 mg orally twice a day for 5 d	Safe [B]
	or	
	Acyclovir, 800 mg orally three times a day for 2 d	Safe [B]
	or	
	Famciclovir, 125 mg orally twice a day for 5 d	Safe [B]
	or	
	Famciclovir, 1000 mg orally twice a day for 1 d	Safe [B]
	or	
	Famciclovir, 500 mg once orally, followed by 250 mg orally twice a day for 2 d	Safe [B]
	or	
	Valacyclovir, 500 mg orally twice a day for 3 d	Safe [B]
	or	
	Valacyclovir, 1 g orally once daily for 5 d	Safe [B]
Suppressive therapy for recurrent genital herpes	Acyclovir, 400 mg orally twice a day	Safe [B]
	or	
	Famciclovir, 250 mg orally twice a day	Safe [B]
	or	
	Valacyclovir, 500 mg orally daily (if < 10 recurrences per year; if ≥ 10 recurrences, use 1 g daily)	Safe [B]
Chancroid		
	Azithromycin, 1 g orally as single dose	Safe [B]
	or	
	Ceftriaxone, 250 mg IM once	Safe [B]
	or	
	Ciprofloxacin, 500 mg orally twice a day for 3 d	Contraindicated [D]
	or	
	Erythromycin base, 500 mg orally three times a day for 7 d	Safe [B]

(Continued)

Table 44–1. Treatment regimens for sexually transmitted infections. (Continued)

	Recommended Regimens	Pregnancy[a] [Category]
Human papillomavirus infection		
External lesions (patient-applied) Note: Topical therapies usually require weekly treatments for 4 consecutive weeks	Podofilox, 0.5% solution or gel; apply twice a day for 3 d; used by patient at home; practitioner needs to demonstrate how compound is applied (to be used only on external lesions)	Contraindicated [C]
	or	
	Imiquimod 5% cream, applied 3 times a week overnight (maximum of 16 wk)	Contraindicated [C]
	or	
	Imiquimod 3.75% cream, applied daily at bedtime (maximum of 16 wk)	Contraindicated [C]
	or	
	Sinecatechins 15% ointment, applied 3 times daily (maximum of 16 wk)	Unknown safety
	Podophyllin, 25% in benzoin tincture applied directly to warts; wash off in 1–4 h; weekly [contraindicated for urethral or intravaginal lesions]	Contraindicated [X]
	or	
External lesions (provider-applied)	Trichloroacetic acid (85%) or bichloracetic acid; apply directly to warts; wash off in 6–8 h; weekly	Safe
	or	
	Cryotherapy: liquid nitrogen, cryoprobe safe laser surgery	Safe
Ectoparasitic infections		
Pubic lice[d]	Permethrin 1% creme rinse: wash off after 10 min	Safe [B]
	or	
	Pyrethrins with piperonyl butoxide: apply, wash off after 10 min	Safe [B]
Alternative regimen	Malathion 0.5% lotion: wash off after 8–12 h	Safe [B]
	or	
	Ivermectin, 250 mcg/kg repeated in 2 wk	Contraindicated [C]
Scabies[d]	Permethrin cream 5%: apply to entire body from the neck down, wash off after 8–14 h	Safe [B]
	or	
	Ivermectin, 200 mcg/kg orally, repeat in 2 wk	Contraindicated [C]
Alternative regimen	Lindane (1%): apply to entire body from neck down, wash off after 8 h	Contraindicated [C]

IM, intramuscular; IV, intravenous; NAAT, nucleic acid amplification test.

[a]FDA use in pregnancy ratings: [A] Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy. [B] No evidence of risk in humans. Adequate, well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility. [C] Risk cannot be ruled out. Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy; but the potential benefits outweigh the potential risk. [D] Positive evidence of risk. Studies in humans, or investigational or postmarketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective. [X] Contraindicated in pregnancy. Studies in animals or humans, or despite adverse findings in animals, or investigational or postmarketing reports have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.

[b]Single daily dose (3–5 mg/kg) IV can be substituted.

[c]Doxycycline is contraindicated in pregnancy. Alternative therapies during pregnancy which include erythromycin, azithromycin, and amoxicillin are not as effective, but are clinically useful if the recommended regimens cannot be used due to allergy or pregnancy.

[d]Bedding and clothing need to be decontaminated by washing in hot water or by dry cleaning. Regimen may be repeated in 1 week if complete response is not achieved.

B. Laboratory Findings

A first void urine sample or cervical or vaginal swab from females should be sent for NAAT. Culture or NAAT for N gonorrhoeae in males can be achieved with a swab of the urethra or first-void urine. Urethral culture is less sensitive (85%) compared with the 95%–99% sensitivity using NAAT methods on either urethral or urine specimens. Gram stain of urethral discharge showing gram-negative intracellular diplococci indicates gonorrhea in a male.

If proctitis is present, appropriate cultures should be obtained and treatment for both gonorrhea and chlamydial infection given. If oral exposure to gonorrhea is suspected, cultures should be taken and the patient given empiric treatment. If there is access to a laboratory that has validated NAAT for oropharyngeal or rectal specimens, this will substantially increase detection over culture methods.

» Differential Diagnosis

Gonococcal pharyngitis needs to be differentiated from pharyngitis caused by streptococcal infection, herpes simplex, adenovirus, and infectious mononucleosis. Chlamydial infection needs to be differentiated from gonococcal infection.

» Complications

Disseminated gonococcal infection occurs in a minority (0.5%–3%) of patients with untreated gonorrhea. Hematogenous spread most commonly causes arthritis and dermatitis. The joints most frequently involved are the wrist, metacarpophalangeal joints, knee, and ankle. Skin lesions are typically tender, with hemorrhagic or necrotic pustules or bullae on an erythematous base occurring on the distal extremities. Disseminated disease occurs more frequently in females than in males. Risk factors include pregnancy and gonococcal pharyngitis. Gonorrhea is complicated occasionally by perihepatitis.

» Treatment (see Table 44–1)

In 2010, the CDC made two significant changes to gonorrhea treatment recommendations: dual treatment with azithromycin and ceftriaxone regardless of anatomic site involved. Oral cefixime treatment of gonorrhea was removed from CDC's recommended treatment in 2012. These changes reflect increasing resistance to cephalosporins; the frequency of coinfection with Chlamydia; and the need to increase consistency of treatment regimens.

CDC guidelines also state that N gonorrhoeae and C trachomatis do not require tests of cure when they are treated with first-line medications, unless the patient remains symptomatic. If retesting is indicated, it should be delayed for 1 month after completion of therapy if NAATs are used. Retesting might also be considered for sexually active adolescents likely to be reinfected. Due to increasing resistance of N gonorrhoeae to cephalosporins, providers considering treatment failure should also obtain a gonorrhea culture to assess for antibiotic resistance. Patients should be advised to abstain from sexual intercourse until both they and their partners have completed a course of treatment. Treatment for disseminated disease may require hospitalization. Quinolones should no longer be used to treat gonorrhea due to high levels of quinolone resistance in all populations in the United States. Failure of initial treatment should prompt reevaluation of the patient and consideration of retreatment with ceftriaxone.

Kirkcaldy RD, Bolan GA, Wasserheit JN: Cephalosporin-resistant gonorrhea in North America. JAMA 2013;309:185 [PMID: 23299612].

° The Spectrum of Signs & Symptoms of Sexually Transmitted infections

The patient presenting with an STI usually has one or more of the signs or symptoms described in this section. Management considerations for STIs include assessing the patient's adherence to therapy and ensuring follow-up, treating STIs in partners, and determining pregnancy risk. Treatment of each STI is detailed in Table 44–1.

CERVICITIS

» General Considerations

In most cases of cervicitis no organism is isolated. The most common causes include C trachomatis or N gonorrhoeae. HSV, T vaginalis, and Mycoplasma genitalium are less common causes. Bacterial vaginosis is now recognized as a cause of cervicitis. Cervicitis can also be present without an STI.

» Clinical Findings

A. Symptoms and Signs

Two major diagnostic signs characterize cervicitis: (1) purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab and (2) easily induced bleeding with the passage of a cotton swab through the cervical os. Cervicitis is often asymptomatic, but many patients with cervicitis have an abnormal vaginal discharge or postcoital bleeding.

B. Laboratory Findings

Although endocervical Gram stain may show an increased number of polymorphonuclear leukocytes, this finding has a low positive predictive value and is not recommended for diagnosis. Patients with cervicitis should be tested for C

trachomatis, N gonorrhoeae, and trichomoniasis by using the most sensitive and specific tests available at the site.

Complications

Persistent cervicitis is difficult to manage and requires reassessment of the initial diagnosis and reevaluation for possible re-exposure to an STI. Cervicitis can persist despite repeated courses of antimicrobial therapy. Presence of a large ectropion can contribute to persistent cervicitis.

Treatment

Empiric treatment for both gonorrhea and chlamydial infection is recommended because coinfection is common. If the patient is asymptomatic except for cervicitis, then treatment may wait until diagnostic test results are available (see Table 44–1). Follow-up is recommended if symptoms persist. Patients should be instructed to abstain from sexual intercourse until they and their sex partners are cured and treatment is completed.

Hobbs MM, Sena AC: Modern diagnosis of trichomonas vaginalis infection. Sex Transm Infect 2013;89(6):424–428 [PMID: 23633669].

PELVIC INFLAMMATORY DISEASE

General Considerations

Pelvic inflammatory disease (PID) is defined as inflammation of the upper female genital tract and may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. It is the most common gynecologic disorder necessitating hospitalization for female patients of reproductive age in the United States. The incidence is highest in teenage girls. Those who are sexually active have a high risk (1 in 8) of developing PID, whereas women in their 20s have one-tenth the risk. Predisposing risk factors include multiple sexual partners, younger age of initiating sexual intercourse, prior history of PID, and lack of condom use. Lack of protective antibody from previous exposure to sexually transmitted organisms and cervical ectopy contribute to the development of PID. Many adolescents with subacute or asymptomatic PID are never identified.

PID is a polymicrobial infection. Causative agents include N gonorrhoeae, Chlamydia, anaerobic bacteria that reside in the vagina, and genital mycoplasmas. Vaginal douching and other mechanical factors such as older intrauterine devices or prior gynecologic surgery increase the risk of PID by providing access of lower genital tract organisms to pelvic organs. Recent menses and bacterial vaginosis have been associated with the development of PID.

Clinical Findings

A. Symptoms and Signs

PID may be challenging to diagnose because of the wide variation in the symptoms and signs. No single historical, clinical, or laboratory finding has both high sensitivity and specificity for the diagnosis. Diagnosis of PID is usually made clinically (Table 44–2). Typical patients have lower abdominal pain, pelvic pain, or dysuria. Systemic symptoms such fever, nausea or vomiting may be present. Vaginal discharge is variable. Cervical motion tenderness, uterine or adnexal tenderness, or signs of peritonitis are often present. Mucopurulent cervicitis is present in 50% of patients. Tubo-ovarian abscesses can often be detected by careful physical examination (feeling a mass or fullness in the adnexa).

B. Laboratory Findings

Laboratory findings may include elevated WBCs with a left shift and elevated acute phase reactants (erythrocyte sedimentation rate or C-reactive protein). A positive test for N gonorrhoeae or C trachomatis is supportive, although 25% of the time neither of these bacteria is detected. Pregnancy needs to be ruled out, because patients with an ectopic pregnancy can present with abdominal pain and concomitant pregnancy will affect management.

Table 44–2. Diagnostic criteria for pelvic inflammatory disease.

Minimum criteria
Empiric treatment of PID should be initiated in sexually active young women and others at risk for sexually transmitted infections if one or more of the following minimum criteria are present:
• They are experiencing pelvic or lower abdominal pain and no other cause(s) for the illness can be identified
• Cervical motion tenderness or uterine tenderness or adnexal tenderness
Additional supportive criteria
Oral temperature > 38.3°C (101°F)
Abnormal cervical or vaginal mucopurulent discharge or cervical friability
Presence of abundant white blood cells on microscopic evaluation of vaginal secretions diluted in saline
Elevated erythrocyte sedimentation rate or elevated C-reactive protein
Laboratory documentation of infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*
Definitive criteria (selected cases)
Histopathologic evidence of endometritis on endometrial biopsy
Tubo-ovarian abscess on sonography or other radiologic tests
Laparoscopic abnormalities consistent with PID

Adapted, with permission, from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2014 draft.

C. Diagnostic Studies

Laparoscopy is the gold standard for detecting salpingitis. It is used if the diagnosis is in question or to help differentiate PID from an ectopic pregnancy, ovarian cysts, or adnexal torsion. Endometrial biopsy should be performed in women undergoing laparoscopy who do not have visual evidence of salpingitis as some women may only have endometritis. The clinical diagnosis of PID has a positive predictive value for salpingitis of 65%–90% in comparison with laparoscopy. Pelvic ultrasonography also is helpful in detecting tubo-ovarian abscesses, which are found in almost 20% of teens with PID. Transvaginal ultrasound is more sensitive than abdominal ultrasound. All women who have acute PID should be tested for N gonorrhoeae and C trachomatis and should be screened for HIV infection.

» Differential Diagnosis

Differential diagnosis includes other gynecologic illnesses (ectopic pregnancy, threatened or septic abortion, adnexal torsion, ruptured and hemorrhagic ovarian cysts, dysmenorrhea, endometriosis, or mittelschmerz), gastrointestinal illnesses (appendicitis, cholecystitis, hepatitis, gastroenteritis, or inflammatory bowel disease), and urinary tract illnesses (cystitis, pyelonephritis, or urinary calculi).

» Complications

Scarring of the fallopian tubes is one of the major sequelae of PID. After one episode of PID, 17% of patients become infertile, 17% develop chronic pelvic pain, and 10% will have an ectopic pregnancy. Infertility rates increase with each episode of PID; three episodes of PID result in a 73% infertility rate. Duration of symptoms appears to be the largest determinant of infertility. Hematogenous or lymphatic spread of organisms from the fallopian tubes rarely causes inflammation of the liver capsule (perihepatitis) resulting in symptoms of pleuritic right upper quadrant pain and elevation of liver function tests.

» Treatment

The objectives of treatment are both to achieve a clinical cure and to prevent long-term sequelae. There are no differences in short- and long-term clinical and microbiologic response rates resulting from parenteral or oral therapy. PID is frequently managed at the outpatient level, although some clinicians argue that all adolescents with PID should be hospitalized because of the rate of complications. Severe systemic symptoms and toxicity, signs of peritonitis, inability to take fluids, pregnancy, nonresponse or intolerance of oral antimicrobial therapy, and tubo-ovarian abscess favor hospitalization. In addition, if the health care provider believes that the patient will not adhere to treatment, hospitalization is warranted. Pregnant women with PID should be admitted to hospital and treated with parental antibiotics to reduce the increased risk of morbidity. Surgical drainage may be required for adequate treatment of tubo-ovarian abscesses.

The broad spectrum antibiotic regimens described in Table 44–1 cover the numerous microorganisms associated with PID. All treatment regimens should be effective against N gonorrhoeae and C trachomatis because negative endocervical screening tests do not rule out upper reproductive tract infection with these organisms. Outpatient treatment should be reserved for compliant patients who have classic signs of PID without systemic symptoms. Patients with PID who receive outpatient treatment should be reexamined within 24–48 hours, with phone contact in the interim, to detect persistent disease or treatment failure. Patients should have substantial improvement within 48–72 hours. An adolescent should be reexamined 7–10 days after the completion of therapy to ensure the resolution of symptoms.

Trent M: Status of adolescent pelvic inflammatory disease management in the United States. Curr Opin Obstet Gynecol 2013;25(5):350–356 [PMID: 24018871].

URETHRITIS

» General Considerations

The most common bacterial causes of urethritis in males are N gonorrhoeae and C trachomatis. Additionally, T vaginalis, HSV, Ureaplasma urealyticum, and M genitalium cause urethritis. Approximately 15%–25% of nongonococcal, nonchlamydial urethritis can be attributed to either M genitalium or U urealyticum. Coliforms may cause urethritis in males practicing insertive anal intercourse. Mechanical manipulation or contact with irritants can also cause transient urethritis. It is important to recognize that urethritis in both males and females is frequently asymptomatic.

Females often present with symptoms of a urinary tract infection and "sterile pyuria" (no enteric bacterial pathogens isolated), which reflects urethritis caused by the organisms described above.

» Clinical Findings

A. Symptoms and Signs

If symptomatic, males present most commonly with a clear or purulent discharge from the urethra, dysuria, or urethral pruritus. Hematuria and inguinal adenopathy can occur. Most infections caused by C trachomatis and T vaginalis are asymptomatic, while 70% of males with M genitalium and 23%–90% with gonococcal urethritis are symptomatic.

B. Laboratory Findings

In a symptomatic male a positive leukocyte esterase test on first-void urine, or microscopic examination of first-void urine demonstrating more than 10 WBCs per high-power field, is suggestive of urethritis. Gram stain of urethral secretions demonstrating more than 5 WBCs per high-power field is also suggestive. Gonococcal urethritis is established by documenting the presence of WBCs containing intracellular gram-negative diplococci. Urethral swab or first-void urine for NAAT should be sent to the laboratory to detect N gonorrhoeae and C trachomatis. Evaluation for T vaginalis should be considered as newer technologies increase the sensitivity and specificity of detecting T vaginalis over wet mount. Microscopic examination of urethral discharge is not a sensitive test. Specific NAAT testing of urine is available for Mycoplasma and Ureaplasma, though it is not often clinically utilized.

» Complications

Complications include recurrent or persistent urethritis, epididymitis, prostatitis, or Reiter syndrome.

» Treatment (See Table 44–1)

Patients with objective evidence of urethritis should receive empiric treatment for gonorrhea and chlamydial infection, ideally directly observed in the office. Some data suggest better outcomes for treatment of Mycoplasma genitalium with azithromycin. If the infection is unresponsive to initial treatment and the infection is NAAT-negative, trichomoniasis should be ruled out and nongonococcal, nonchlamydial urethritis should be suspected and treated appropriately. Patients should be instructed to return for evaluation if symptoms persist or recur after completion of initial empiric therapy. Symptoms alone, without documentation of signs or laboratory evidence of urethral inflammation, are not a sufficient basis for retreatment. Sexual partners should either be evaluated or treated for gonorrhea and chlamydial infection.

EPIDIDYMITIS

» General Considerations

Epididymitis in a male who is sexually active is most often caused by C trachomatis or N gonorrhoeae. Epididymitis caused by Escherichia coli occurs among males who are the insertive partners during anal intercourse and in males who have urinary tract abnormalities.

» Clinical Findings

A. Symptoms and Signs

Epididymitis presents as a constellation of pain, swelling, and inflammation of the epididymis. In many cases, the testis is also involved.

B. Laboratory and Diagnostic Studies

Diagnosis is generally made clinically. Color Doppler ultrasound can help make the diagnosis. Although often not available, radionuclide scanning of the scrotum is the most accurate method of diagnosis. Laboratory evaluation is identical to evaluation for suspected urethritis.

» Differential Diagnosis

Acute epididymitis must be distinguished from orchitis due to infarct, testicular torsion, viral infection, testicular cancer, tuberculosis, or fungal infection.

» Complications

Infertility is rare, and chronic local pain is uncommon.

» Treatment

Empiric therapy (see Table 44–1) is indicated before culture results are available. As an adjunct to therapy, bed rest, scrotal elevation, and analgesics are recommended until fever and local inflammation subside. Lack of improvement of swelling and tenderness within 3 days requires reevaluation of both the diagnosis and therapy. Sex partners should be evaluated and treated for gonorrhea and chlamydial infections.

PROCTITIS, PROCTOCOLITIS, & ENTERITIS

» General Considerations

Proctitis occurs predominantly among persons who participate in anal intercourse. Enteritis occurs among those whose sexual practices include oral-fecal contact. Proctocolitis can be acquired by either route depending on the pathogen. Common sexually transmitted pathogens causing proctitis or proctocolitis include C trachomatis (including lymphogranuloma venereum [LGV] serovars), Treponema pallidum, HSV, N gonorrhoeae, Giardia lamblia, and enteric organisms. As many as 85% of rectal infections with N gonorrhoeae and C trachomatis are asymptomatic. The presence of symptomatic or asymptomatic proctitis may facilitate the transmission of HIV infection.

» Clinical Findings

A. Symptoms and Signs

Proctitis, defined as inflammation limited to the distal 10–12 cm of the rectum, is associated with anorectal pain, tenesmus, and rectal discharge. Acute proctitis among persons who have recently practiced receptive anal intercourse is most often sexually transmitted. The symptoms of proctocolitis combine those of proctitis, plus diarrhea or abdominal cramps (or both), because of inflamed colonic mucosa more than 12 cm from the anus. Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis.

B. Laboratory and Diagnostic Studies

Evaluation may include anoscopy or sigmoidoscopy, stool examination, culture or NAAT for appropriate organisms, and serology for syphilis.

» Treatment

Management will be determined by the etiologic agent (see Table 44–1 and Chapter 42). Reinfection may be difficult to distinguish from treatment failure.

VAGINAL DISCHARGE

Adolescent girls may have a normal physiologic leukorrhea, secondary to turnover of vaginal epithelium. Infectious causes of discharge include T vaginalis, C trachomatis, N gonorrhoeae, and bacterial vaginosis pathogens. Candidiasis is a yeast infection that produces vaginal discharge, but is not usually sexually transmitted. Vaginitis is characterized by vaginal discharge, vulvar itching, and irritation, and sometimes with vaginal odor. Discharge may be white, gray, or yellow. Physiologic leukorrhea is usually white, homogeneous, and not associated with itching, irritation, or foul odor. Mechanical, chemical, allergic, or other noninfectious irritants of the vagina may cause vaginal discharge.

1. Bacterial Vaginosis

» General Considerations

Bacterial vaginosis is a polymicrobial infection of the vagina caused by an imbalance of the normal bacterial vaginal flora. The altered flora has a paucity of hydrogen peroxide–producing lactobacilli and increased concentrations of anaerobic bacteria (Prevotella sp and Mobiluncus sp), Gardnerella vaginalis, Ureaplasma, and Mycoplasma. It is unclear whether bacterial vaginosis is sexually transmitted, but it is associated with having multiple sex partners and women with bacterial vaginosis are at increased risk for other STIs.

» Clinical Findings

A. Symptoms and signs

The most common symptom is a copious, malodorous, homogeneous thin gray-white vaginal discharge. Patients may report vaginal itching or dysuria. A fishy odor may be most noticeable after intercourse or during menses, when the high pH of blood or semen volatilizes the amines.

B. Laboratory Findings

Bacterial vaginosis is most often diagnosed by the use of clinical criteria, which include (1) presence of thin, white discharge that smoothly coats the vaginal walls, (2) fishy (amine) odor before or after the addition of 10% KOH (whiff test), (3) pH of vaginal fluid greater than 4.5 determined with narrow-range pH paper, and (4) presence of "clue cells" on microscopic examination. Clue cells are squamous epithelial cells that have multiple bacteria adhering to them, making their borders irregular and giving them a speckled appearance. Diagnosis requires three out of four criteria, although many female patients who fulfill these criteria have no discharge or other symptoms.

» Complications

Bacterial vaginosis during pregnancy is associated with adverse outcomes such as premature labor, preterm delivery, intraamniotic infection, and postpartum endometritis. In the nonpregnant individual, it may be associated with PID and urinary tract infections.

» Treatment

All female patients who have symptomatic disease should receive treatment to relieve vaginal symptoms and signs of infection (see Table 44–1). Pregnant patients should receive treatment to prevent adverse outcomes of pregnancy. Treatment for patients who do not complain of vaginal discharge or itching, but who demonstrate bacterial vaginosis on routine pelvic examination, is unclear. Because some studies associate bacterial vaginosis and PID, the recommendation is to have a low threshold for treating asymptomatic bacterial vaginosis. Follow-up visits are unnecessary if symptoms resolve. Recurrence of bacterial vaginosis is not unusual. Follow-up examination 1 month after treatment for high-risk pregnant patients is recommended.

Males do not develop infection equivalent to bacterial vaginosis and are often asymptomatic. Treatment of male partners has no effect on the course of infection in females although treatment is recommended for female partners.

Donders G: Diagnosis and management of bacterial vaginosis and other types of abnormal vaginal bacterial flora: a review. Obstet Gynecol Surv 2010;65:462 [PMID: 20723268].

2. Trichomoniasis

» General Considerations

Trichomoniasis is caused by T vaginalis, a flagellated protozoan that infects 3.7 million people annually in the United States.

» Clinical Findings

A. Symptoms and Signs

Fifty percent of females with trichomoniasis develop a symptomatic vaginitis with vaginal itching, a green-gray malodorous frothy discharge, and dysuria. Occasionally postcoital

bleeding and dyspareunia may be present. The vulva may be erythematous and the cervix friable.

B. Laboratory Findings

Mixing the discharge with normal saline facilitates detection of the flagellated protozoan on microscopic examination (wet preparation). This has a sensitivity of only 60%–70% even with immediate evaluation of the slide to achieve optimal results. Culture and NAAT testing are available when the diagnosis is unclear. NAAT tests are sensitive, but expensive, and not readily available. Two FDA-approved, point-of-care antigen-based detection assays for T vaginalis are available, but false positive results are problematic in low disease prevalence populations. Both antigen assays are performed on vaginal secretions and have a sensitivity greater than 83% and a specificity greater than 97%. Trichomonal urethritis frequently causes a positive urine leukocyte esterase test and WBCs on urethral smear.

» Complications

Trichomonas infection in females has been associated with adverse pregnancy outcomes. Male partners of females diagnosed with trichomoniasis have a 22% chance of having trichomoniasis. Half of males with trichomoniasis will have urethritis. Male partners should receive empiric therapy for trichomoniasis. Rescreening for T vaginalis at 3 months following initial infection is recommended for women due to the high rate of reinfection.

» Treatment

See Table 44–1 for treatment recommendations.

Coleman JS et al: Trichomonas vaginalis vaginitis in obstetrics and gynecology practice: new concepts and controversies. Obstet Gynecol Surv 2013;68:43 [PMID: 23322080].

3. Vulvovaginal Candidiasis

» General Considerations

Vulvovaginal candidiasis is caused by Candida albicans in 85%–90% of cases. Most females will have at least one episode of vulvovaginal candidiasis in their lifetime, and almost half will have two or more episodes. The highest incidence is between ages 16 and 30 years. Predisposing factors include recent use of antibiotics, diabetes, pregnancy, and HIV. Risk factors include vaginal intercourse, especially with a new sexual partner, use of oral contraceptives, and use of spermicide. This disease is usually caused by unrestrained growth of Candida that normally colonizes the vagina asymptomatically or is infected secondarily from Candida present in the GI tract. Recurrences reflect reactivation of colonization.

» Clinical Findings

A. Symptoms and Signs

Typical symptoms include pruritus and a white, cottage cheese-like vaginal discharge without odor. The itching is more common midcycle and shortly after menses. Other symptoms include vaginal soreness, vulvar burning, vulvar edema and redness, dyspareunia, and dysuria (especially after intercourse).

B. Laboratory Findings

The diagnosis is usually made by visualizing yeast or pseudohyphae with 10% KOH (90% sensitive) or Gram stain (77% sensitive) in the vaginal discharge. Fungal culture can be used if symptoms and microscopy are not definitive or if disease is unresponsive or recurrent. However, culture is not very specific as colonization is common in asymptomatic females. Vaginal pH is normal with yeast infections.

» Complications

The only complication of vulvovaginal candidiasis is recurrent infections. Most females with recurrent infection have no apparent predisposing or underlying conditions.

» Treatment

Short-course topical formulations effectively treat uncomplicated vaginal yeast infections (see Table 44–1). The topically applied azole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80%–90% of patients who complete therapy. Oral fluconazole as a one-time dose is an effective oral treatment. Patients should be instructed to return for follow-up visits only if symptoms persist or recur. Six-month prophylaxis regimens have been effective in many female patients with persistent or recurrent yeast infection. Recurrent disease is usually due to C albicans that remains susceptible to azoles, and should be treated for 14 days with oral azoles. Some nonalbicans Candida will respond to itraconazole or boric acid gelatin capsules (600 mg daily for 14 days) intravaginally. Treatment of sex partners is not recommended, but may be considered for females who have recurrent infection.

GENITAL ULCERATIONS

In the United States, young, sexually active patients who have genital ulcers have genital herpes or syphilis. The relative frequency of each disease differs by geographic area and patient population; however, in most areas, genital herpes is the most prevalent of these diseases. More than one of these diseases could be present in a patient with genital ulcers. All ulcerative diseases are associated with an increased risk for HIV infection. Oral and genital lesions may be presenting symptoms during primary HIV infection (acute

retroviral syndrome). Less common causes of genital ulceration include chancroid and donovanosis.

Location of the ulcers is dependent on the specific type of sexual behavior. Ulcers may be vaginal, vulvar, cervical, penile, or rectal. Oral lesions may occur concomitantly with genital ulcerations or as stand-alone lesions in HSV infection and syphilis. Each etiologic agent has specific characteristics that are described in the following sections. Lesion pain, inguinal lymphadenopathy, and urethritis may be found in association with the ulcers.

1. Herpes Simplex Virus Infection (See Also Chapter 40)

» General Considerations

HSV is the most common cause of visible genital ulcers. HSV-1 and HSV-2 are viruses that infect primarily humans. HSV-1 is commonly associated with infections of the face, including the eyes, pharynx, and mouth. HSV-2 is most commonly associated with anogenital infections. However, each serotype is capable of infecting either region. HSV-1 infections are frequently established in children by age 5 through oral acquisition; lower socioeconomic groups have higher infection rates. Both HSV-1 and HSV-2 cause STIs. The prevalence of both infections in the United States increases during teen years. In this age group and young adults, HSV-1 has become the predominant cause of genital infection. Rates of HSV-2 seroprevalence reach 20%–40% in 40-year-olds. HSV infections are lifelong as a result of latent infection of sensory ganglia, although many individuals infected with either type of HSV infection have not been diagnosed because of mild or unrecognized symptoms. Nevertheless, these individuals can still asymptomatically shed virus and thereby unknowingly transmit the infection, and they can reactivate the virus to cause clinical infection in themselves.

» Clinical Findings

A. Symptoms and Signs

Symptomatic initial genital HSV infection causes vesicles of the vulva, vagina, cervix, penis, rectum, or urethra, which are quickly followed by shallow, painful ulcerations. Atypical presentation of HSV infection includes vulvar erythema and fissures. Urethritis may occur. Initial infection can be severe, lasting up to 3 weeks, and be associated with fever and malaise, as well as localized tender adenopathy. The pain and dysuria can be extremely uncomfortable, requiring sitz baths, topical anesthetics, and occasionally catheterization for urinary retention.

Symptoms tend to be more severe in females. Recurrence in the genital area with HSV-2 is likely (65%–90%). Approximately 40% of individuals infected with HSV-2 will experience more than or equal to six recurrences per year in the early years after initial infection. Prodromal pain in the genital, buttock, or pelvic region is common prior to recurrences. Recurrent genital herpes is of shorter duration (5–7 days), with fewer lesions and usually no systemic symptoms. Commonly, there is decreased frequency and severity of recurrences over time, although approximately one-third of individuals fail to demonstrate this time-dependent improvement. First-episode genital herpes infection caused by HSV-1 is usually the consequence of oral-genital sex. Primary HSV-1 infection is as severe as HSV-2 infection, and treatment is the same. Recurrence of HSV-1 happens in less than 50% of patients, and the frequency of recurrences is much less than in those patients with prior HSV-2 infection.

B. Laboratory Findings

Diagnosis of genital HSV infection is often made presumptively, but in one large series this diagnosis was incorrect for 20% of cases. Several laboratory tests can aid in confirmation of the diagnosis. Viral culture has been the gold standard and can provide results in as few as 48 hours. Culture must be obtained by unroofing an active vesicle and swabbing the base of the lesion. DFA testing can provide results within hours. DFA can also determine serotype, which is important for prognosis. NAAT of viral DNA is becoming a more common diagnostic method.

» Differential Diagnosis

Genital HSV infections must be distinguished from other ulcerative STI lesions, including syphilis, chancroid, and lymphogranuloma venereum. Non-STIs might include herpes zoster, Behçet syndrome, or lichen sclerosis. (See next two sections Syphilis and Chancroid.)

» Complications

Complications, almost always soon only with the first episode of genital HSV infection, include viral meningitis, urinary retention, transmission to newborns at birth, and pharyngitis. Infection with genital HSV, whether active or not, greatly increases the likelihood of transmitting or acquiring HIV infection within couples discordant for HIV.

» Prevention

All patients with active lesions should be counseled to abstain from sexual contact. Almost all patients have very frequent periodic asymptomatic shedding of HSV, and most cases of genital HSV infection are transmitted by persons who are unaware that they have the infection or are asymptomatic when transmission occurs. Reactivation with asymptomatic shedding occurs even in individuals who were asymptomatically infected. Individuals with prior

HSV infection should be encouraged to use condoms to protect susceptible partners. Antiviral prophylaxis of infected individuals reduces shedding and significantly reduces the chance of transmission to their sexual partners.

» Treatment

Antiviral drugs administered within the first 5 days of primary infection decrease the duration and severity of HSV infection (see Table 44–1). The effect of antivirals on the severity or duration of recurrent disease is limited. For best results, therapy should be started with the prodrome or during the first day of the attack. Patients should have a prescription at home to initiate treatment. If recurrences are frequent and cause significant physical or emotional discomfort, patients may elect to take antiviral prophylaxis on a daily basis to reduce the frequency (70%–80% decrease) and duration of recurrences. Treatment of first or subsequent attacks will not prevent future attacks, but recurrence frequency and severity decrease in many individuals over time.

Hollier LM, Straub H: Genital herpes. Clin Evid (Online) 2011;1603 [PMID: 21496359].

2. Syphilis

» General Considerations

Syphilis is an acute and chronic STI caused by infection with Treponema pallidum. The national rate of syphilis has increased annually since reaching an all time low in 2000. Increases have been observed in both genders, but predominantly in males who have sex with men, who now account for 75% of primary and secondary cases reported to the CDC. In 2013, the CDC reported an increase of 10.9% (17,375) in new cases of primary and secondary syphilis. In 2013, the rate among men aged 15–19 years was the highest reported since 1995. Men between the ages of 20 and 24 years have the highest rates of syphilis; 4 out of 10 people with syphilis are also infected with HIV.

» Clinical Findings

A. Symptoms and Signs

Skin and mucous membrane lesions characterize the acute phase of primary and secondary syphilis. Lesions of the bone, viscera, aorta, and central nervous system predominate in the chronic phase (tertiary syphilis) (see Chapter 42). Prevention of syphilis is also important because syphilitic mucosal lesions facilitate transmission of HIV.

Primary syphilis usually presents as a solitary chancre at the point of inoculation. Characteristically, the chancre presents as a painless, indurated, nonpurulent ulcer with a clean base and associated nontender, firm adenopathy. The chancre appears on average 21 days (range: 3–90 days) after exposure and resolves spontaneously 4–8 weeks later. Because it is painless, it may go undetected, especially if the lesion is within the vagina, oropharynx, urethra, or rectum. Chancres may occur on the genitalia, anus, or oropharynx. Secondary syphilis occurs 4–10 weeks after the chancre appears, with generalized malaise, adenopathy, and a nonpruritic maculopapular rash that often includes the palms and soles. Secondary syphilis resolves in 1–3 months, but can recur. Verrucous lesions known as condylomata lata may develop on the genitalia. These must be distinguished from genital warts.

B. Laboratory Findings

If the patient has a suspect primary lesion, is at high risk, is a contact, or may have secondary syphilis, a nontreponemal serum screen—either RPR or VDRL—should be performed. If the nontreponemal test is positive, then a specific treponemal test—a fluorescent treponemal antibody-absorbed (FTA-ABS) or microhemagglutination–T pallidum (MHA-TP) test—is done to confirm the diagnosis. An additional diagnostic tool is darkfield microscopy, which can be used to detect spirochetes in scrapings of the chancre base. Darkfield examinations and DFA tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis.

If a patient is engaging in high-risk sexual behavior or is living in an area in which syphilis is endemic, RPRs should be drawn yearly to screen for asymptomatic infection. Annual RPR testing among high-risk groups is essential to distinguish between early latent syphilis (1 year or less postinfection), late latent syphilis (> 1 year postinfection), or syphilis of unknown duration, as treatment recommendations vary. Syphilis is reportable to state health departments, and all sexual contacts need to be evaluated. Patients also need to be evaluated for other STIs, especially HIV. HIV-infected patients have increased rates of failure with some treatment regimens and treatment of the HIV infection should occur as soon as indicated after diagnosis.

» Complications

Untreated syphilis can lead to tertiary complications with serious multiorgan involvement, including aortitis and neurosyphilis. Transmission to the fetus can occur from an untreated pregnant individual (see Chapters 2 and 42).

» Treatment

See Table 44–1 for treatment recommendations. Patients should be reexamined and serologically evaluated with nontreponemal tests at 6 and 12 months after treatment. If signs or symptoms persist or recur, or patients do not have a fourfold decrease in their nontreponemal test titer, they should

be considered to have failed treatment or be reinfected and need retreatment.

3. Chancroid

» General Considerations

Chancroid is caused by Haemophilus ducreyi. It is relatively rare outside of the tropics and subtropics, but is endemic in some urban areas in the United States, and has been associated with HIV infection, drug use, and prostitution. A detailed history, including travel, may prove to be important in identifying this infection.

» Clinical Findings

A. Symptoms and Signs

The typical lesion begins as a papule that erodes after 24–48 hours into an ulcer. The ulcer is painful and has ragged, sharply demarcated edges and a purulent base (unlike syphilis). The ulcer is typically solitary and somewhat deeper than HSV infection. The lesions may occur anywhere on the genitals and are more common in men than in women. Tender, fluctuant (unlike syphilis and HSV) inguinal adenopathy is present in 50% of patients. A painful ulcer in combination with suppurative inguinal adenopathy is very often chancroid.

B. Laboratory Findings

Gram stain shows gram-positive cocci arranged in a boxcar formation. Culture, which has a sensitivity of less than 80%, can be performed on a special medium that is available in academic centers. NAAT testing may improve laboratory diagnosis in areas where such testing is available.

» Differential Diagnosis

Chancroid is distinguished from syphilis by the painful nature of the ulcer and the associated tender suppurative adenopathy. HSV vesicles often produce painful ulcers, but these are multiple, smaller, and shallower than chancroid ulcers. Adenopathy associated with initial HSV infection does not suppurate. A presumptive diagnosis of chancroid should be considered in a patient with typical painful genital ulcers and regional adenopathy when the test results for syphilis and HSV are negative.

» Treatment

Symptoms improve within 3 days after therapy (see Table 44–1). Most ulcers resolve in 7 days, although large ulcers may take 2 weeks to heal. All sexual contacts need to be examined and given treatment, even if asymptomatic. Individuals with HIV coinfection may have slower rates of healing or treatment failures.

4. Lymphogranuloma Venereum

» General Considerations

Lymphogranuloma venereum (LGV), caused by C trachomatis serovars L1, L2, or L3, is generally rare in the United States. The disease is endemic in Southeast Asia, the Caribbean, Latin America, and areas of Africa. Since 2003, an increased number of cases in the United States, Western Europe, and Canada have occurred primarily among men who have sex with men and have been associated with HIV coinfection.

» Clinical Findings

A. Symptoms and Signs

Patients with LGV present with a painless vesicle or ulcer that heals spontaneously, followed by development of tender adenopathy that is typically unilateral. A classic finding is the groove sign—an inguinal crease created by concomitant involvement of inguinal and femoral nodes. These nodes become matted and fluctuant and may rupture. LGV can cause proctocolitis with rectal ulceration, purulent anal discharge, fever, tenesmus, and lower abdominal pain, primarily in men who have sex with men.

B. Laboratory Findings

Diagnosis of LGV can be difficult. It generally requires a clinical suspicion based on physical examination findings. Lesion swabs and lymph node aspirates can be tested for Chlamydia by culture, DFA, or NAAT. NAAT is not FDA cleared for rectal specimens. Additional genotyping is necessary to differentiate LGV from non-LGV serovars of Chlamydia. In the absence of laboratory testing to confirm the diagnosis, one should treat for LGV if clinical suspicion is high.

» Differential Diagnosis

Differential diagnosis during the adenopathy phase includes bacterial adenitis, lymphoma, and cat-scratch disease. Differential diagnosis during the ulcerative phase encompasses all causes of genital ulcers.

» Treatment

See Table 44–1 for treatment recommendations. Despite effectiveness of azithromycin for non-LGV chlamydial infections, there have been no controlled treatment trials to recommend its use in LGV. HIV-infected individuals are treated the same as non-HIV infected individuals, but should be monitored closely to assess response to treatment.

White JA: Manifestations and management of lymphogranuloma venereum. Curr Opin Infect Dis 2009;22:57 [PMID: 19532081].

5. Other Ulcerations

Granuloma inguinale, or donovanosis, is caused by Klebsiella granulomatis, a gram-negative bacillus that is rare in the United States, but is endemic in India, the Caribbean, and southern Africa. An indurated subcutaneous nodule erodes to form a painless, friable ulcer with granulation tissue. Diagnosis is based on clinical suspicion and supported by a Wright or Giemsa stain of the granulation tissue that reveals intracytoplasmic rods (Donovan bodies) in mononuclear cells. See Table 44–1 for treatment recommendations. Relapse may occur 6–18 months after apparently effective treatment with a 3-week course of doxycycline.

GENITAL WARTS & HUMAN PAPILLOMAVIRUS

» General Considerations

Condylomata acuminata, or genital warts, are caused by HPV, which can also cause cervical dysplasia and cervical cancer. HPV is transmitted sexually. An estimated 20 million people in the United States are infected annually with HPV, including approximately more than 9 million sexually active adolescents and young adults 15–24 years of age. The majority (74%) of new HPV infections occurs among those 15–24 years of age; in females younger than age 25 years, the prevalence ranges between 28% and 46%. It is estimated that 32%–50% of adolescent females having sexual intercourse in the United States have HPV infections, though only 1% may have visible lesions. Thirty to 60% of males whose partners have HPV have evidence of condylomata on examination. An estimated 1 million new cases of genital warts occur every year in the United States.

Although there are almost 100 serotypes of HPV, types 6 and 11 cause approximately 90% of genital warts, and HPV types 16 and 18 cause more than 70% of cervical dysplasia and cervical cancer. The infection is more common in persons with multiple partners and in those who initiate sexual intercourse at an early age.

Pap smears should be obtained starting at age 21 and then every 3 years. More frequent and earlier evaluations are recommended if there are additional risk factors such as coinfection with HIV.

» Clinical Findings

A. Symptoms and Signs

For males, verrucous lesions are found on the shaft or corona of the penis. Lesions also may develop in the urethra or rectum. Lesions do not produce discomfort. They may be single or found in clusters. Females develop verrucous lesions on any genital mucosal surface, either internally or externally, and often develop perianal lesions.

B. Laboratory Findings

External, visible lesions have unique characteristics that make the diagnosis straightforward. Condylomata acuminata can be distinguished from condylomata lata (syphilis), skin tags, and molluscum contagiosum by application of 5% acetic acid solution. Acetowhitening is used to indicate the extent of cervical infection.

Pap smears detect cervical abnormalities. HPV infection is the most frequent cause of an abnormal smear. Pap smear findings are graded by the atypical nature of the cervical cells. These changes range from atypical squamous cells of undetermined significance (ASCUS) to low-grade squamous intraepithelial lesions (LSIL) and high-grade squamous intraepithelial lesions (HSIL). LSIL encompasses cellular changes associated with HPV and mild dysplasia. HSIL includes moderate dysplasia, severe dysplasia, and carcinoma in situ.

Follow-up for ASCUS is controversial, as only 25% progress to dysplasia, and the remainder are stable or regress. Updated recommendations prefer repeat cytology in 12 months with no HPV DNA testing. If a test for HPV DNA is performed and is positive, then repeat cytology in 12 months is recommended. If the grade of the atypical squamous cells remains uncertain or if there is HSIL, colposcopy is recommended. If LSIL is detected, colposcopy is not needed, but a repeat Pap smear should be done in 1 year, and if LSIL or HSIL are subsequently detected, the patient should be referred for colposcopy for direct visualization or biopsy of the cervix (or both). If a Pap smear shows signs of inflammation only, and concomitant infection such as vaginitis or cervicitis is present, the smear should be repeated after the inflammation has cleared.

» Differential Diagnosis

The differential diagnosis includes normal anatomic structures (pearly penile papules, vestibular papillae, and sebaceous glands), molluscum contagiosum, seborrheic keratosis, and syphilis.

» Complications

Because genital warts can proliferate and become friable during pregnancy, many experts advocate their removal during pregnancy. HPV types 6 and 11 can cause laryngeal papillomatosis in infants and children. Complications of appropriate treatment include scarring with changes in skin pigmentation or pain at the treatment site. Pap smears with persistent or high-grade dysplasia require biopsy and/or resection, which may result in cervical abnormalities that complicate pregnancy. Cervical cancer is the most common and important sequelae of HPV.

» Prevention

The use of condoms significantly reduces, but does not eliminate, the risk for transmission to uninfected partners.

The quadrivalent HPV vaccine is 96%–100% effective in preventing HPV-6 and 11–related genital warts and HPV-16 and 18–related cervical dysplasia. It is recommended for females aged 9–26 years and males aged 9–21 years. Males are protected against genital warts and anal cancer, which has a significantly increased incidence in males who practice anal sex. The bivalent HPV vaccine is greater than 93% effective in preventing HPV-16– and 18–related cervical dysplasia, but has no effect on genital warts. It is recommended only for girls aged 10–25 years (see Chapter 10).

» Treatment

Penile and external vaginal or vulvar lesions can be treated topically. Treatment may need to occur weekly for 4–6 weeks. An experienced practitioner should treat internal and cervical lesions (see Table 44–1). Treatment may clear the visible lesions, but not reduce the presence of virus, nor is it clear whether transmission of HPV is reduced by treatment.

Warts may resolve or remain unchanged if left untreated or they may increase in size or number. Treatment can induce wart-free periods in most patients. Most recurrences occur within the 3 months following completion of a treatment regimen. Appropriate follow-up of abnormal Pap smears is essential to detect any progression to malignancy.

OTHER VIRAL INFECTIONS

1. Hepatitis (See Also Chapter 22)

» General Considerations

In the United States, viral hepatitis is linked primarily to three viruses: hepatitis A (HAV), hepatitis B (HBV), and hepatitis C (HCV). Each virus has the potential to be spread through sexual activity. HAV is spread via fecal-oral transmission and oral-anal contact. Both HBV and HCV are spread through contact with blood or body fluids. Sexual transmission of HBV is believed to be much more efficient than that of HCV although recent data has suggested increased transmission of HCV in MSM.

Universal immunization recommendations for HAV and HBV have contributed to the decline in prevalence of these diseases. However, individuals born before implementation of routine vaccination, especially those in high-risk groups (multiple sexual partners or men who have sex with men), should receive vaccination.

2. Human Immunodeficiency Virus (See Also Chapter 41)

» General Considerations

In 2009, 39% of new HIV infections in the United States occurred in youth and young adults aged 13–29 years. Data suggest that adolescents and young adults are less likely to be aware of their HIV infection than older individuals with HIV. Because of the long latency period between infection with HIV and progression to AIDS, it is felt that many HIV-positive young adults contracted HIV during adolescence. CDC incidence data indicate that young men who have sex with men continue to be the highest-risk group, particularly young men of color. Young women account for approximately one-third of the infections in this age group with black and Hispanic women bearing a disproportionate burden of the disease. Risk factors for contracting HIV include a prior STI, infrequent condom use, practicing insertive or receptive anal sex (both males and females), prior genital HSV infection, practicing survival sex (ie, trading sex for money or drugs), intravenous drug or crack cocaine or crystal methamphetamine use, homelessness, and being the victim of sexual abuse (males).

HIV infection should be considered in all sexually active youth, whether they have sex with males, females, or both. The CDC and the United States Preventative Services Task Force recommend adolescents be offered HIV testing at least once. Individual risk factors should then be used to determine the frequency of repeat testing. Opportunities for HIV screening in adolescents should include STI screening or treatment, pregnancy testing, or routine health evaluations. Most states allow adolescents to consent to HIV testing and treatment, but providers should be aware of their particular State's laws.

» Clinical Findings

A. Symptoms and Signs

Adolescents may be asymptomatic with recent HIV infection or may present with the acute retroviral syndrome, which is evident 2–6 weeks after exposure. The acute clinical syndrome, which occurs in about 50% of patients, is generally indistinguishable from other viral illnesses with respect to fever, malaise, and upper respiratory symptoms. Distinguishing features include generalized lymphadenopathy, rash, oral and genital ulcerations, aseptic meningitis, and

thrush. After the acute illness, signs and symptoms may be absent for many years.

B. Laboratory Findings

If acute HIV infection is suspected, HIV testing should be done by HIV RNA PCR testing or HIV DNA PCR testing. Routine serological testing may not be positive for 6 weeks or longer. Viral load values of less than 10,000 copies/mL by RNA PCR may indicate a false positive in this setting and repeat testing would be indicated.

In 2014, the CDC updated its recommendations for HIV screening. The new recommendations are based on the availability of technologies that allow for earlier detection of HIV infection than offered by ELISA followed by Western Blot confirmation. The new testing algorithm for serum or plasma recommends the use of a HIV 1/2 antigen/antibody combination immunoassay for initial testing. This test detects antibodies to both HIV-1 and HIV-2 and the HIV-1 p24 antigen. This detects both established infections and more recent infections.

» Treatment

The most important aspect of identifying adolescents and young adults with HIV infection is linking them to care. Data support the treatment of youth with HIV infection in care settings that provide comprehensive, multidisciplinary care. These settings will be best equipped to provide emotional support, preventative care, risk reduction for contacts, access to research, and guidance on the appropriate timing of antiretroviral therapies.

Moyer VA: Screening for HIV: U.S. Preventative Services Task Force Recommendation Statement. Ann Intern Med 2013;159(3):161–168 [PMID: 23698354].

3. HIV Postsexual Exposure Prophylaxis

Adolescents may present to health care providers seeking nonoccupational HIV postexposure prophylaxis (nPEP) following an assault or a high-risk sexual encounter. The risk of acquiring HIV infection through sexual assault or abuse is low but present. The risk for HIV transmission from a positive contact per episode of receptive penile-anal sexual exposure is estimated at 0.5%–3%; the risk per episode of receptive vaginal exposure is estimated at less than 0.1%–0.2%. HIV transmission also occurs from receptive oral exposure, but the risk is unknown. The risk of HIV transmission may be increased in certain conditions: trauma, including bleeding, with vaginal, anal, or oral penetration; site of exposure to ejaculate; HIV viral load in ejaculate; duration of HIV infection in the assailant or partner; and presence of an STI, prior genital HSV infection, or genital lesions in either partner. The risk is greatly reduced if the contact is successfully receiving antiretroviral therapy.

Health care providers that consider offering PEP should take into account the likelihood that exposure to HIV occurred, the potential benefits and risks of such therapy, and the interval between the exposure and initiation of therapy. It will be helpful to know the HIV status of the sexual contact. The CDC provides an algorithm for consideration of PEP. In general, PEP is not recommended when more than 72 hours have passed since exposure. If the patient decides to take PEP, clinical management should be implemented according to published CDC guidelines. Providers should be aware that structural barriers exist to obtaining PEP, and that adolescent assault victims have a high discontinuation rate due to adverse effects from the medication.

Jain S, Mayer KH: Practical guidance for nonoccupational postexposure prophylaxis to prevent HIV infection: an editorial review. AIDS 2014;28(11):1545–1554 [PMID: 24785956].

4. HIV Preexposure Prophylaxis (PrEP)

In July 2012, the CDC issued interim guidance on the use of PrEP in adult heterosexual couples; interim guidance on its use in adult MSM was released in 2011. The guidance followed the Food and Drug Administration's approval of a coformulated HIV antiretroviral (tenofovir and emtricitabine) for use as preexposure prophylaxis based on data from two large international trials. The approval for use does not include individuals under age 18 years. Further research is being conducted to determine safety and acceptability in younger individuals at high risk for HIV acquisition. Providers considering the use of PrEP in a minor at risk of infection would be advised to consult with an experienced prescriber and know the laws of their particular state with respect to providing preventive HIV medication without parental consent.

Centers for Disease Control and Prevention (CDC): Interim guidance for clinicians considering the use of preexposure prophylaxis for the prevention of HIV infection in heterosexually active adults. MMWR Morb Mortal Wkly Rep 2012 Aug 10;61(31):586–589 [PMID: 22874836].

ECTOPARASITIC INFECTIONS

1. Pubic Lice

Pthirus pubis, the pubic louse, lives in pubic hair. The louse or the nits can be transmitted by close contact from person to person. Patients complain of itching and may report having seen the insect. Examination of the pubic hair may reveal the louse crawling around or attached to the hair. Closer inspection may reveal the nit or sac of eggs, which is a gelatinous material (1–2 mm) stuck to the hair shaft. See Table 44–1 for treatment recommendations.

2. Scabies

Sarcoptes scabiei, the causative organism in scabies, is smaller than the louse. It can be identified by the classic burrow, which is created by the organism laying eggs and traveling just below the skin surface. Scabies can be sexually transmitted by close skin-to-skin contact and can be found in the pubic region, groin, lower abdomen, or upper thighs. The rash is intensely pruritic, especially at night, erythematous, and scaly. See Table 44–1 for treatment options. Ivermectin is an oral therapeutic option for scabies that may hold particular promise in the treatment of severe infestations or in epidemic situations. When treating with lotion or shampoo, the entire area needs to be covered for the time specified by the manufacturer. One treatment usually clears the infestation, although a second treatment may be necessary. Bed sheets and clothes must be washed in hot water. Both sexual and close personal or household contacts within the preceding month should be examined and treated.

45 Travel Medicine

Suchitra Rao, MBBS
Sarah K. Parker, MD

INTRODUCTION

Twenty-seven million people from the United States travel internationally per year; one-third of them travel to developing nations. Fifty to seventy percent of travelers become ill during their travel overseas. The number of children traveling with families continues to increase. Children are especially susceptible to infectious diseases, trauma, and other health problems, which vary with the destination. Preparation for travel with children and infants includes consideration of the destination-specific risks, underlying medical problems, and administration of both routine and travel-related vaccines. The physician involved in pretravel counseling should focus on the issues listed in Table 45–1.

PREPARING CHILDREN AND INFANTS FOR TRAVEL

Travel Plans

Parents and care providers should be advised that travel with children and infants is much more enjoyable when the number of journeys in a single trip is limited; travel time is kept relatively short; and travel delays are anticipated. Planning for delays and other problems should include bringing new or favorite toys or games for distraction, and carrying extra food and drink, changes of clothing, and fever medications.

Medical Care During Travel

It is useful to obtain names and addresses of local health care providers at the family's destination. This is available from travel medicine practitioners or from the membership directory of the International Society of Travel Medicine. The International Association for Medical Assistance to Travelers website (www.iamat.org) is another useful resource with a worldwide directory of providers proficient in English. Travel insurance, which is highly encouraged, should not only cover medical care at the destination, but also provide 24-hour help lines with information regarding English-speaking physicians and hospitals, and arrange and pay for evacuation to a medical facility that provides necessary treatment if not available locally. In emergencies, parents and caretakers should take their children to the largest medical facility in the area, which is more likely to have a pediatric unit and trauma services.

Trauma

Trauma is a common cause of morbidity and mortality in traveling children. Parents should rent larger, safer vehicles, and use car seats whenever possible. However, in many developing countries, car seats are not available, so caretakers may need to travel with their own. Taxis often do not have seatbelts, so it may be necessary to request taxis with seatbelts by calling in advance.

Air Travel

Healthy term infants can travel by commercial pressurized airplane. Children at higher risk during air travel may include premature infants and those with chronic cardiac or pulmonary disease, so appropriate counseling with their specialist is indicated. Many parents request advice regarding sedation of their child during travel. While this is not recommended, the most widely used agent is diphenhydramine. It is advisable to try a test dose prior to travel as idiosyncratic reactions and overdosing can lead to an anticholinergic syndrome or a paradoxical stimulating effect.

Ear Pain

Children and infants often have pain during ascent and descent of commercial airplanes due to changes in middle ear pressure causing retraction or protrusion of the tympanic membrane. Methods said to alleviate or minimize ear

Table 45–1. Preparing for travel—issues specific to travel as indicated.

Vaccinations (indications, safety, and tolerability)
Insect precautions (use of protective clothing, repellants, bed nets, insecticides)
Malaria chemoprophylaxis (benefits of a particular regimen vs potential adverse reactions)
Food and water precautions and environmental risks from water-borne disease
Traveler's diarrhea and self-treatment
Health insurance/evacuation insurance
Trauma prevention and car seats
Access to medical care during travel
Altitude sickness
Disease outbreaks in destination
Climate
Jetlag
Animal exposure, trauma from animals
General health and routine illness
Clothing and footwear
Copies of prescriptions, vaccination documentation, physician's letter, list of medications
Travel-specific medications
Safe sex counseling
First-aid kits
Crime and safety

pain during these times include chewing, swallowing, nursing, and bottle feeding.

Motion Sickness

Almost 60% of children will experience motion sickness during travel. While older children have symptoms similar to those in adults (such as nausea, epigastric discomfort, headache, general discomfort), children younger than 5 years may have gait abnormalities as the predominant symptom. Nonpharmacologic strategies include eating a light meal at least 3 hours before travel; avoiding dairy products and foods high in calories, protein, and sodium before travel; sitting in the middle of the back seat or in the front seat if age-appropriate; focusing on a stable object or the horizon; avoiding reading or other visual stimuli; eye closure; fresh air; and limiting excessive head movement. Pharmacologic intervention has not been well studied in children, but if necessary, antihistamines such as diphenhydramine is recommended for children younger than 12 and scopolamine is acceptable for children older than 12 years. These measures, however, are not evidence-based.

High Altitude

Acute mountain sickness is as common in children as in adults, but it may go unrecognized due to its subtle presentation, such as unexplained fussiness or change in appetite and sleep patterns. High-altitude pulmonary edema (HAPE) is seen in children traveling to high altitudes; it also occurs in children who live at high altitude, descend for an extended period, and return to altitude. Mild symptoms of altitude sickness can be treated with rest and hydration, or analgesics such as ibuprofen or acetaminophen. High-altitude sickness is milder and resolves much more quickly in children compared to adults, so prophylaxis is usually not required. Acetazolamide has not been studied in children for acute mountain sickness, but it is safe in this age group and has been used for both prophylaxis and treatment. The pediatric dose is 5 mg/kg/d (125 mg maximum) divided twice daily, starting 1 day before ascent, and continued for 2 days at high altitude.

Medications/First-Aid Kit

A small medical kit is useful when traveling. Included in this kit should be medications for illnesses that the child experiences at home, trip-specific items, and the usual first-aid kit items (Table 45–2). Medications should be purchased prior to travel, as those obtained at some destinations may be of poor quality or contain toxic substances.

Table 45–2. First-aid kit for international travel.

Medications
Malaria prophylaxis
Acetaminophen and ibuprofen
Antibiotics
Antihistamines
Topical formulations
Hydrocortisone ointment
Antibiotic and antifungal ointment
Insect repellants
Sunscreen
Antibacterial soap/alcohol-based hand sanitizer
Antiseptic wipes
Other
Bed nets
Thermometer
Medicine spoon and cup
Oral rehydration salts in powder form
Sterile cotton balls, cotton tip applicators
Tweezers, scissors, safety pins
Water purification tablets
Gauze bandages
Tape—hypoallergenic, waterproof
Triangular bandage/sling/splint
Tongue depressor
Adhesive bandages
Flashlight
First-aid book
Copies of prescriptions, list of medications, copy of insurance coverage

VACCINATIONS—ROUTINE CHILDHOOD VACCINES MODIFIED FOR TRAVEL

Many vaccine-preventable diseases remain prevalent in developing countries, and outbreaks still occur in areas where these diseases are considered rare. The schedule for some vaccines may be accelerated for travel, and some vaccines can be given earlier than the recommended age. Vaccination pertaining to children traveling follows the routine vaccination schedule as outlined in Chapter 10. The recommended intervals balance the high-risk age for disease with infant immunologic responses. The recommended minimum interval between doses is listed in Table 45–3. Barriers to some early immunizations are antibody from the mother interfering with an infant's ability to mount an antibody response, particularly to live vaccines, and the lack of a T-cell–dependent immune response to certain immunogens in those younger than 2 years. Minor febrile illnesses are not a contraindication to routine or travel vaccines and should not lead to their postponement. Live vaccines should be given together or separated by 30 days or more.

Diphtheria-Tetanus-Acellular Pertussis Vaccine

Immunization is recommended prior to travel to developing countries because of the greater risk of disease from diphtheria, tetanus, and pertussis. Tetanus risk is high in several areas of the developing world where fecal contamination of soil is extensive. Infants should receive their first diphtheria-tetanus-acellular pertussis (DTaP) at 6 weeks of age for an adequate immune response, with a 4-week interval between the subsequent two doses. Adequate protection is achieved after the third dose. The fourth dose may be given 6–12 months after the third dose provided that the child is 12 months of age or older. Tdap is licensed for children at least 11 years of age. Adolescents and adult caretakers, who are prominent vectors in the spread of pertussis to young children, should receive a single Tdap booster. If more than 5 years has elapsed since the last dose, a booster should be considered for children and adolescents to minimize tetanus risk. Tdap is preferred to Td in children older than 11 years if they have not received Tdap previously.

Table 45–3. Accelerated vaccinations.

Vaccine	Minimum Age for First Dose	Minimum Time to Second Dose (wk)	Minimum Time to Third Dose (wk)	Minimum Time for Fourth Dose (wk)
MMR	12 mo[a]	4	–	–
Hepatitis B	Birth	4	8[b]	–
DTaP	6 wk	4	4	6 mo
Hib	6 wk	4	4	8[c]
IPV	6 wk	4	4	6 mo[d]
MCV	6 wk[e]	8	[e]	[e]
MPS4	2 y[e]	5 y	[e]	[e]
PCV	4 wk	4	4	8
Varicella	12 mo	4	–	–
Rotavirus	4 wk[f]	4	4	–
Hepatitis A	1 y	6 mo	–	–

DTaP, diphtheria-tetanus-acellular pertussis; DTP, diphtheria-tetanus-pertussis; Hib, Haemophilus influenzae type b; IPV, inactivated polio vaccine; MCV, meningococcal conjugate vaccine; MMR, measles-mumps-rubella; MPS4, meningococcal polysaccharide; PCV, pneumococcal conjugate vaccine.
[a]Children traveling abroad may be vaccinated as early as 6 months of age. Before departure, children aged 6–11 months should receive the first dose of MMR vaccine. This will not count toward their series, and they will still require two doses after 12 months of age.
[b]The third dose should be given at least 4 months after the first dose and at a minimum of 6 months of age.
[c]If third dose is given after 4 years, the fourth dose is not required.
[d]Recommended at 6–18 months of age, minimum age 4 years for final dose.
[e]Minimum 6 weeks for Hib-MenCY, 9 months for Menactra (MCV4-D), 2 years for Menveo (MCV4-CRM). Repeat vaccination depends on host status and ongoing risk factors.
[f]This differs from the package insert but is validated by data held by the manufacturer.

Haemophilus influenzae Type b Vaccine

The indications for vaccination of Haemophilus influenzae type b (Hib) in children traveling are the same as for the US residents. If previously unvaccinated, infants younger than 15 months should receive at least two doses prior to travel. An accelerated schedule can start at a minimum of 6 weeks of age, with a 4-week interval between the first, second, and third doses, and at least 8 weeks between third and fourth doses.

Hepatitis A Vaccine

Hepatitis A is one of the most common vaccine-preventable illnesses globally, and vaccination should be provided prior to travel to developing countries. The disease is much less common in children from the developed world, so they are likely to be susceptible when traveling to high-risk areas. Although two doses of the vaccine are recommended 6–12 months apart, a single dose will provide protection during the trip if given at least 2 weeks prior to departure. The earliest age of administration is 1 year in the United States. Immune globulin for hepatitis A (0.02 mL/kg IM) can be given for protection of children younger than 1 year, or if travel will occur within 2 weeks of travel consultation. This interferes with MMR and varicella vaccination, so these vaccines should be given 2 weeks prior to immunoglobulin.

Hepatitis B Vaccine

Areas of high endemicity for hepatitis B include most of Asia, the Middle East, Africa, and the Amazon Basin. Unimmunized children are at risk if they receive blood transfusions that have not been screened for HBV surface antigen (HBsAg) or are exposed to unsterilized medical or dental equipment. Children traveling to developing countries should be vaccinated before departure. An accelerated schedule is possible, with the second dose given with a minimum 4-week interval, and the third dose given at least 8 weeks after the second dose. The third dose should not be given before 24 weeks of age.

Influenza Vaccine

Children are at high risk of respiratory infection during travel. The influenza vaccine is recommended for travel during the influenza season, which is between September and March in the Northern Hemisphere, and between April and August in the Southern Hemisphere, and year round in the tropics. The vaccine available in the United States may not protect against new strains circulating in the Southern Hemisphere. Influenza vaccine is recommended for children at least 6 months of age; those younger than 9 years will need two doses of vaccine administered at least 4 weeks apart if they have never previously received the vaccine containing the 2009 H1N1 antigen contained in all influenza vaccines since 2010–2011. The current vaccines available are: the trivalent or quadrivalent inactivated vaccine (IIV) given intramuscularly, and the quadrivalent live attenuated vaccine (LAIV) given intranasally. It is preferable to be vaccinated at least 2 weeks prior to departure. The annual seasonal influenza vaccine may not be routinely available in the United States from the late spring to early fall, when it may be needed for travelers but may be available at some travel clinics. Revaccination is not recommended for those who will be traveling during April through September and were vaccinated the preceding fall.

Measles-Mumps-Rubella (MMR) Vaccine

While measles is no longer endemic in the United States, it is still prevalent in many parts of the world, including Europe, Africa, and Asia. Children as young as 6 months of age traveling outside the United States are recommended to receive the vaccine, but any doses given prior to 12 months do not count toward an adequate two-dose series, as maternal antibodies may interfere with the immune response. These infants will still require one dose of measles-mumps-rubella (MMR) at 12–15 months of age and a second dose at 4–6 years of age. The second dose aims to protect those individuals (~5%) who did not respond the first time. If an accelerated schedule is required, two doses must be separated by minimum of 4 weeks.

Meningococcal Vaccine

The highest risk for meningococcal disease is for travelers to the meningitis belt of Africa, (sub-Saharan region) especially during the dry season, and travelers on the Hajj or Umrah pilgrimage to Mecca. Notably, meningococcal disease is decreasing in this region due to vaccination against type A. There are two meningococcal vaccines available. The conjugated quadrivalent (MCV4) vaccine is approved for use in persons aged 9–23 months (two doses 8 weeks apart) and 2–55 years (one dose). This vaccine is recommended for those who live or travel to areas with high rates of meningitis. It must be given at least 10 days before international travel. The quadrivalent meningococcal polysaccharide vaccine (MPSV4) is licensed for persons 2 years or older. Both types of vaccines protect against serotypes A, C, Y, and W-135. The duration of protection is 3 years in children and 5 years in adults, and boosters are indicated for ongoing exposure and at risk hosts. Hib-MenCY-TT is the approved vaccination for the age group 6 weeks to 9 months, and a more recent combined Hib and N meningitidis serogroup C conjugate vaccine has been licensed for those younger than 6 weeks of age. These should not be used for children travelling to the meningitis belt or the Hajj, as serogroup A is the predominant organism in these regions; a previously vaccinated infant reaching the age of 9 months and travelling to endemic areas should be revaccinated with MCV4. MPSV4 should be used for persons older than 56 years. Vaccination can be considered in children younger than 9 months with risk factors and/or traveling to an endemic area. Meningococcal vaccination is required by the Saudi Arabian government for pilgrims undertaking the Hajj or Umra pilgrimage to Mecca and Medina, because of the international outbreak of Neisseria meningitidis A in 1987 and W-135 in 2000 and 2001. Further information concerning geographic areas recommended for meningococcal vaccination can be obtained from http://www.cdc.gov/travel.

Pneumococcal Vaccine

The indications for vaccination against Streptococcus pneumoniae in children traveling are the same as for the US residents. The 13-valent pneumococcal conjugate vaccine (PCV 13) is recommended for routine use in children aged 5 years or younger. For children aged 5 years or younger who have completed the PCV 7 series, a single additional dose of PCV 13 is recommended. The minimal interval is 4 weeks between the first three doses and 8 weeks between the third and fourth dose. In addition, the pneumococcal polysaccharide (PPSV23) is recommended for children and adults aged 2 years or older who have certain underlying medical conditions, and for all adults aged 65 years or older.

Polio Vaccine

Transmission of wild-type polio still occurs in regions of Asia and Africa, and vaccine-derived polio is transmitted in other regions. Adequate immunization with inactivated polio vaccine (IPV) should be administered prior to travel to developing countries. The minimum age of administration is 6 weeks of age for IPV. The recommended interval between each dose is 4 weeks. One additional lifetime dose (a fifth dose) of the IPV should be given to caretakers who are traveling to areas with recent circulating polio.

Rotavirus Vaccine

Rotavirus is the most common cause of severe gastroenteritis in infants and young children worldwide, and vaccination with the complete series is recommended prior to travel if age-appropriate. The minimum and maximum age for the first dose is 4 weeks and 14 weeks, 6 days respectively. There is insufficient data on the safety in older infants. The minimum interval between doses is 4 weeks.

VACCINATIONS—TRAVEL-SPECIFIC

Japanese Encephalitis Vaccine

Japanese encephalitis (JE) is caused by a flavivirus transmitted by the night-biting Culex mosquito. The risk of contracting severe JE is low, especially for travelers who will have a brief stay in an endemic area, as the infection rate in Culex mosquitoes is 3% or lower, and only 1 in 200 infections with JE leads to neuroinvasive disease. The symptoms of JE include seizures, paralysis, coma, and mental status changes; residual neurological damage occurs in 50% of those with clinical disease. The case fatality rate is 30% in those with severe disease. Most symptomatic cases occur in children younger than 10 years and in the elderly. The areas at risk include most of Asia, Eastern Russia, some areas of the Western Pacific, and the Torres Strait Islands of Australia. The peak season is between April and October, during and just after the rainy season. The JE vaccine licensed and available for use in the United States is Ixiaro, an inactivated Vero cell culture-derived vaccine. It was approved in May 2013 for use in children aged 2 months of age and older. The primary series is two doses administered 28 days apart. For adults and children aged 3 years and older, each dose is 0.5 mL. For children aged 2 months to 2 years, each dose is 0.25 mL.

Rabies Vaccine

Rabies is found worldwide and contracted through the bite or saliva-contaminated scratch of infected animals. Canine rabies is highly endemic in parts of Africa, Asia, and Central and South America (Rabnet—www.who.int/rabies/rabnet/en/—provides country-specific animal and human data), where 40% of rabies occurs in children younger than 14 years. This increased risk is because children are attracted to animals, are more likely to be bitten, and may not report minor encounters with animals. Most cases of rabies in travelers occur through the bite of an infected dog, cat, or monkey (particularly those that live near temples in parts of Asia). Bats, mongooses, and foxes are other animals that can transmit disease.

Rabies vaccine is currently available for pre-exposure and postexposure prophylaxis. It is recommended for travelers to areas in which rabies is endemic and for those who will have occupational or recreational exposure (such as cavers), especially if access to medical care will be limited when traveling. The risk of a bite from a potentially rabid animal is up to 2% for travelers to the developing world. There are three types of inactivated virus vaccine available, which are administered prior to exposure in three doses at days 0, 7, and 21 or 28. Vaccination prior to exposure may not be completely protective; further doses

are required if a high-risk bite occurs. The minimum age of administration is 1 year, and duration of protection is 2 years. Malaria chemoprophylaxis with mefloquine or chloroquine should begin 1 month after completing the rabies vaccine series to avoid interference with the immune response.

It is important to counsel travelers about animal avoidance, thorough cleansing of a bite wound with irrigation for at least 5 minutes, and the need for previously vaccinated individuals to seek additional vaccination on days 0 and 3 if an exposure occurs. In the event of a bite in a nonvaccinated individual, rabies immunoglobulin and four doses of vaccine at days 0, 3, 7, and 14 are required, ideally within 24–48 hours after contact.

Yellow Fever Vaccine

Yellow fever is a flavivirus transmitted by mosquitoes, found in urban and rural areas in sub-Saharan Africa and equatorial South America. Of those infected with the virus, 15% have moderate to severe infection. The licensed 17D strain live attenuated vaccine is highly effective. It must be administered 10 days before travel to an endemic region to allow for the development of protective antibodies. It is required by many countries for reentry after travel to an endemic area, and receipt of the vaccine should be documented in the International Certificate of Vaccination that became available in December 2007 (wwwnc.cdc.gov/travel/yellowbook provides an updated list of countries in which yellow fever vaccination is recommended). For this reason, it is only administered at certified clinics. The vaccine is given subcutaneously, and a booster is required every 10 years for certain groups of individuals (but immunity is probably lifelong after a single dose). The recommended minimum age of administration is 9 months, and vaccine should not be administered to at-risk infants younger than 6 months, because of the increased risk of encephalitis (0.5–4 per 1000 vaccinees). The risk of severe vaccine-related disease is also higher in adult caretakers older than 60 years. The decision to immunize infants who are 6–8 months of age must balance the infant's risk for exposure with the risk for vaccine-associated encephalitis. The vaccine is contraindicated in individuals with egg allergy or immunosuppression (including HIV with CD4 T-lymphocyte counts less than 200 cells/mm^3 a history of thymus disorder or thymectomy). A letter of medical exemption may be required for these travelers. In addition to age limitations, precautions to vaccination include asymptomatic HIV infection and CD4 T-lymphocyte count of 200–499 cells/mm^3, pregnancy, and breast-feeding. Adverse effects include encephalitis (15 per million doses for those aged > 60 years) and multisystem disease (5 per million doses in older people).

Cholera Vaccine

The cholera vaccine is no longer produced in the United States and is no longer recommended for international travel, as the disease is rare in travelers.

Typhoid Vaccine

The risk of typhoid fever in travelers is 1–10:100,000, depending on the destination. Areas at risk include South Asia, West and North Africa, South America, and Latin America. Travelers to the Indian subcontinent are at greatest risk.

The vaccine is recommended for long-term travelers traveling to an endemic area, those traveling off standard tourist routes, immunocompromised travelers, those of south Indian ancestry, and patients with cholelithiasis. There are two vaccines available: a capsular polysaccharide (ViCPS) and a live attenuated (Ty21a) vaccine. The ViCPS is given intramuscularly 2 weeks prior to travel. The minimum age of administration for this vaccine is 2 years; efficacy is 75% over 2 years. The Ty21a is an oral vaccine given as four doses every second day, which needs to be completed more than 1 week prior to travel to be effective. It is licensed for children older than 6 years; efficacy is 80% over 5 years. It is contraindicated in immunodeficient populations. Antibiotics interfere with growth of the vaccine strain bacteria. Mefloquine, chloroquine, and prophylactic doses of atovaquone-proguanil can be given concurrently with the typhoid vaccine. Fever, headache, and severe local pain and swelling are reported with the ViCPS more frequently than with other vaccines.

Tuberculosis

Tuberculosis risk is increased for travelers, especially when visiting Africa, Asia, Latin America, and the former Soviet Union. The risk is higher in long-term travelers to countries with a high incidence of tuberculosis and is highest among health care workers. Bacillus Calmette-Guérin (BCG) vaccination is given soon after birth in many countries, but not in the United States. It protects against miliary and meningeal tuberculosis, but not against pulmonary disease, with efficacy only established in children younger than 1 year. It may be considered in children younger than 5 years who will be in a high-risk area for a prolonged period and have a negative test for tuberculosis (tuberculin skin test [TST] or interferon gamma release assay [IGRA]). It should not be given to immunosuppressed individuals. BCG is not widely available in the United States and may be administered in the destination country. A preferred alternative is that travelers to high-prevalence areas have a test for tuberculosis prior to travel and 3 months after return. It should be noted that live virus vaccines can create an anergic state, in which

tuberculosis testing can be falsely negative. Therefore, testing should be performed on the same day as any live vaccine administration, or 28 or more days later.

TRAVELER'S DIARRHEA

Diarrhea is one of the most common illnesses in travelers to the developing world. Children are at highest risk, usually having more severe and prolonged illness than adults. Traveler's diarrhea is defined in adults as three or more loose stools in a 24-hour period, plus either fever, nausea, vomiting, or abdominal cramping. There is no strict definition in child travelers, as the pattern, consistency, and frequency of stools vary during the course of childhood. A useful definition for traveling children is a change in normal stool pattern, with an increase in frequency (at least three stools per 24 hours) and a decrease in consistency to an unformed state. Most illnesses resolve over a 3- to 5-day period and occur in the first 2 weeks of travel. Enterotoxigenic Escherichia coli (ETEC) is the most common cause, accounting for up to one-third of cases. Other pathogens implicated are listed in Table 45–4. Counseling prior to travel includes education and caution with food handling and food and water consumption, and provision for self-treatment in the event of illness.

Table 45–4. Pathogens causing traveler's diarrhea.

Bacterial	
	Enterotoxigenic Escherichia coli (ETEC)
	Enteroaggregative Ecoli
	Salmonella spp
	Shigella spp
	Campylobacter jejuni

Parasitic	
	Giardia lamblia
	Cyclospora cayetanensis
	Cryptosporidium hominis
	Entamoeba histolytica

» Prevention

Travelers should seek restaurants with a good safety reputation; eat hot, thoroughly cooked food; eat fruits and vegetables that can be peeled; and avoid tap water. They should also avoid ice cubes, fruit juices, fresh salads, unpasteurized dairy products, cold sauces and toppings, open buffets, undercooked foods, and food or beverages from street vendors. They should check the integrity of caps before buying bottled water to avoid bottles filled with tap water. It is also useful to remind the travelers about hand washing after using the toilet and before eating. Families can consider using alcohol-containing hand sanitizers as an alternative to soap and water when access is limited during travel. Pasteurized or boiled milk is considered safe provided that it is stored at the appropriate temperature. It may be necessary to bring powdered milk to mix it with safe drinking water if the quality of milk is questionable. While these measures seem logical and should be recommended, there is little evidence that they prevent traveler's diarrhea, either in adults or in children.

Chemoprophylaxis & Treatment

The principles of treatment include adequate hydration and a short course of antibiotics when warranted; medical attention should be sought for severe or prolonged disease.

For mild disease, hydration may be all that is necessary, without any diet restriction. This can be achieved with oral rehydration therapy to supplement a regular diet. Packets of dry rehydration powder to be mixed with water are available from pharmacies, either prior to travel or at the destination. If this is not available, parents can be instructed on how to make oral rehydration solution (Table 45–5) or to use a sports drink such as Gatorade as a suitable alternative in older children and toddlers. The breast-fed infant should continue to breast-feed, in addition to receiving oral rehydration therapy.

The vomiting child is at greater risk of dehydration, so aggressive rehydration is crucial. Parents should be

Table 45–5. Recipe for oral rehydration solution.

• ¼ teaspoon (1.25 cc) salt
• ¼ teaspoon (1.25 cc) bicarbonate of soda[a]
• 2 tablespoons (30 cc) sugar
• 1 L of water

[a]If bicarbonate of soda is not available, substitute an additional ¼ teaspoon (1.25 cc) of salt.

reassured that some fluid will be absorbed even if vomiting is ongoing. This is best achieved with small amounts of fluid, given often to prevent further vomiting.

The antimotility agent loperamide, which is often used in adults to minimize symptom duration, is not advised for children because of the risk of adverse events such as toxic megacolon, ileus, extrapyramidal signs, hallucinations, and coma. Bismuth subsalicylate decreases the number of unformed stools in adults. Its routine use is not recommended in pediatrics, as aspirin is contraindicated in children younger than 18 years because of the risk of Reye syndrome, and dosing of bismuth has not been established for children.

For children with signs and symptoms of bacterial gastroenteritis, such as fever or blood in the stool, empiric antibiotic therapy should be considered. The drug of choice in children is azithromycin (10 mg/kg orally once a day for 3 days). It is available in a powdered form that can be reconstituted and stored without refrigeration. It is a good choice because of the growing resistance of many gastroenteritis-causing bacteria to ciprofloxacin. There are no pediatric trials of empiric azithromycin, so the dosing recommendations are based on pharmacokinetic data and studies involving the treatment of diarrhea in Africa and Thailand. Ciprofloxacin is currently not recommended for treatment of traveler's diarrhea in children, though it is used for treatment in adults.

Trimethoprim-sulfamethoxazole (TMP-SMX) has been used to treat traveler's diarrhea in children but is no longer recommended because of increasing antibiotic resistance. Rifaximin, a nonabsorbable derivative of rifamycin, is effective in treating ETEC and other noninvasive enteropathogens. Since it is not absorbed, high concentrations are achieved in the intestinal lumen and it has a good safety profile. It is licensed for patients 12 years of age and older at a treatment dose of 200 mg three times a day for 3 days.

The use of prophylactic antibiotics is not recommended because of the risk of adverse events to prevent a disease of limited morbidity, as well as the effect of potential for emergence of antibiotic resistance. Rifaximin, however, is showing promise in adult studies as a chemoprophylactic agent, but it is expensive and requires further study in pediatrics.

Probiotics are of unproven benefit for the prevention of traveler's diarrhea, with contradictory reports of efficacy in adult studies.

MALARIA PROPHYLAXIS & PREVENTION (SEE ALSO CHAPTER 43)

Malaria is the most common preventable infectious cause of death among travelers, and a common cause of fever in the returned traveler. Children comprise 20% of imported cases of malaria. It is largely a preventable disease in travelers through personal protective measures and chemoprophylaxis. However, no method is 100% protective. The risk of acquiring malaria varies with the season, climate, altitude, number of mosquito bites, and destination, with the highest risk in Oceania, Africa, the Indian subcontinent, and the Amazon.

» Prevention of Mosquito Bites

Malaria is transmitted via the night-biting Anopheles mosquitoes. Mosquito bites are avoided by staying in well-screened and air-conditioned rooms from dusk until dawn, wearing clothing covering arms and legs, and avoiding scented soaps, shampoos, and perfumes. Mosquito nets are highly effective and can be used over beds, cribs, playpens, car seats, and strollers. Repellants containing 25%–50% DEET are also recommended, as this concentration confers 5–8 hours of protection. When used appropriately, DEET is safe for infants and children older than 2 months. It should not be applied to children's hands, mouth, or near the eyes, and is best washed off upon returning indoors. There have been case reports of seizures and toxic encephalopathy with use of DEET, but these cases occurred with misapplication. Icaridin (also known as picaridin) is an alternative to DEET available in many countries. A concentration of 20% icaridin is as effective as DEET-containing products. It lacks the corrosiveness and greasy texture of DEET, and has been advised as safe for use in children by the American Academy of Pediatrics. However, because it is relatively new, it lacks the safety profile of DEET, especially for children. PMD is a plant-based repellant derived from lemon eucalyptus, and at a 30% concentration is of equal efficacy to DEET. It may be used on children older than 6 months. It is considered safe if directions are followed and has been advocated for use by the Centers for Disease Control. Clothing and bed nets may be sprayed with insecticides such as permethrin, which confers protection for 2–6 weeks, even with regular washing.

Further studies are needed to establish its safety profile in children. The combination of DEET every 8–12 hours and permethrin on clothing is over 99% effective in prevention of mosquito bites.

» Chemoprophylaxis

Prophylactic medications suppress malaria by killing asexual blood stages of the parasite before they cause disease, so protective levels of medication must be present in the blood before developing parasites are released from the liver. Therefore, it is necessary to start prophylaxis before the first possible exposure and to continue it for a sufficient period after return to a safe area.

The choice of antimalarial depends on the age of the child, resistance patterns, restrictions on the agent of choice, the child's ability to swallow tablets, the frequency of dosing, cost, availability of medication, and access to a compounding pharmacy for adequate dispensing of medication. For most children, once-weekly mefloquine is preferable and is approved for use in children of any age. Atovaquone/proguanil is available in pediatric dosing, although only in tablet formulation. It is currently approved in most countries for children weighing greater than 5 kg. Doxycycline is another alternative but should be used only in children 8 years or older because of the risk of teeth staining. Chloroquine is the drug of choice in areas of chloroquine sensitivity (Mexico, Hispaniola, Central America, west and north of the Panama Canal, and parts of North Africa, the Middle East, and China). Pediatric and adult dosing, side effects, and other information about malaria chemoprophylaxis are in Table 45–6.

Antimalarial medications (with the exception of atovaquone/proguanil) are bitter, so it may be necessary to grind the medication into a very sweet food, such as chocolate syrup or sweetened condensed milk. Infants may need to have their medication prepared by a compounding pharmacy, where the appropriate dose can be placed in a gelatin capsule, which can then be opened by the caregiver and mixed into food or liquid.

Lüthi B1, Schlagenhauf P2. Risk factors associated with malaria deaths in travellers: A literature review. Travel Med Infect Dis. 2015 January - February;13(1):48–60 [PMID: 25022610].

VISITS TO FRIENDS & RELATIVES (VFR) IN HIGH-RISK AREAS

Individuals who return to their home country are at the highest risk of travel-related infectious diseases. Sixty percent of malaria cases and over 75% of typhoid cases occur in these travelers, and VFR children are at highest risk of hepatitis A. The reasons for this include the following:

- Longer stays and increased likelihood of pregnancy or young age in the traveler
- Travel to remote rural areas
- Intimate contact with the local population
- Decreased likelihood of seeking (or following) pretravel advice because of familiarity with their home country
- Assumed immunity to infections
- Sociocultural barriers—for example, language barriers, prohibitive cost of vaccines, and medications if lower socioeconomic status, belief systems of illness
- Eating and sleeping in local households, where hygiene may be suboptimal
- Use of high-risk forms of transportation

Thus, certain issues need to be emphasized when discussing travel for VFRs. Given the risk of waterborne infections, visiting families should boil water and milk if other safe drinking water is expensive; consume only piping hot foods and beverages; and follow proper hand-washing techniques at all times. Vaccination recommendations and malaria prophylaxis are of greater importance in VFRs. Similarly, VFRs provide greater opportunity for contracting vaccine-preventable diseases, such as typhoid, rabies, yellow fever, and meningococcal infection. They are associated with a higher risk of exposure to people with tuberculosis, so for this reason tuberculosis testing is recommended approximately 3 months after return from travel.

Leder K et al: Illness in travelers visiting friends and relatives: a review of the GeoSentinel Surveillance Network. Clin Infect Dis 2006;43(9):1185–1193 [PMID: 17029140].

HIV & SEXUALLY TRANSMITTED DISEASES (SEE ALSO CHAPTER 41)

Adolescent travelers may partake in high-risk activities while traveling, putting them at risk of human immunodeficiency virus (HIV) and other sexually transmitted diseases (STDs). The adolescent traveler should be counseled about the risks of STDs and abstinence or safe sexual practices. Bringing a supply of latex condoms may be appropriate along with instruction on their proper use. They should be advised that HIV and STDs can also be contracted via oral sex and

in nonsexual activities such as intravenous drug use. They should avoid tattoos, pedicures, and dental care while traveling. There may be a risk of HIV and other virus transmission through injections and blood transfusion, as many developing countries do not have adequate blood banking and transfusion protocols. In fact, 10%–20% of countries have inadequate screening.

Antiretroviral therapy is recommended if there is exposure to a known HIV-positive contact, and may be considered if the source is unknown. The usual recommended regimens are outlined in Chapter 41.

Further information on HIV can be found in Chapter 41.

MMWR: http://aidsinfo.nih.gov/contentfiles/NonOccupationalExposureGL.pdf.

FEVER IN THE RETURNED TRAVELER

More than half of travelers to the developing world experience a health-related travel problem during their trip; 8% require medical attention on return. The majority will develop common medical problems, such as upper respiratory tract infections, pneumonia, urinary tract infections, and otitis media, with the remainder developing travel-related infections. The most common of these diseases are malaria (21%), acute traveler's diarrhea (15%), dengue fever (6%), and typhoid/enteric fever (2%). Children who travel with caretakers visiting friends and relatives are at greatest risk. New pathogens and the changing epidemiology of some infectious diseases pose new risks to travelers—such as Ebola, avian influenza, multidrug-resistant TB, chikungunya virus, and leishmaniasis.

Symptomatic returning travelers should be urgently and thoroughly evaluated for travel-related illness to prevent serious life-threatening disease and transmission to close contacts. The initial evaluation should include questions directed toward the travel itinerary, with dates of arrival and departure, specific activities, rural versus urban location, and accommodations. Specific information should be obtained regarding fresh water contact (eg, schistosomiasis, leptospirosis in some areas), sexual contacts, animal exposures, activities or hobbies, ill person contacts, and sources of food and water. A complete medication and vaccination history should be sought. It should be noted that despite malaria chemoprophylaxis and protection against mosquitoes, no regimen is 100% protective. A thorough physical examination should include dermatologic examination, eye examination for scleral icterus, conjunctival injection or petechiae, and evaluation for hepatosplenomegaly or lymphadenopathy. Routine laboratory evaluation includes a complete blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), serum chemistry, liver enzyme profile, and urinalysis. The laboratory evaluation should also focus on diseases that are life-threatening, with thick and thin smears for malaria (ideally three that are 12 hours apart), and blood cultures for typhoid fever. Specific testing should be done as directed by findings on history, physical examination, and preliminary laboratory test findings (Table 45–7). It may be necessary to seek the opinion of individuals with experience in international travel medicine, if available.

Fever is the most common complaint in a child who becomes ill after international travel. The most common travel-related infectious causes of fever are summarized in Table 45–8. A more detailed description of the symptoms,

Table 45–7. Laboratory evaluations to consider for fever in the returned traveler.

Routine
Hematologic
Complete blood count and differential
Thick and thin blood smear (ideally collect three at 12-h intervals)
Sedimentation rate
C-reactive protein
Electrolytes
Liver function tests
Blood culture
Urine
Urinalysis
Culture
Specific to presentation
Hematologic
Serologies for specific pathogens
Stool
Bacterial culture
Fecal leucocytes
Giardia and Cryptosporidium antigen test
Clostridium difficile toxin (if antibiotic exposure)
Ova and parasite examination
Special studies (eg, stool for Entamoeba histolytica antigen, special stains)
Cerebrospinal fluid
Cell count with differential, protein, glucose, culture, freeze extra sample
Antibody and polymerase chain reaction tests as appropriate
Imaging studies
Chest radiography and abdominal ultrasound imaging as appropriate
Other specialized tests
Placement of PPD (purified protein derivative)
Morning gastric aspirates or sputum for AFB (acid-fast bacilli) stain
Bronchoscopy
Sigmoidoscopy, colonoscopy
Skin biopsy
Bone marrow aspirate
Skin snips (eg, for Onchocerciasis)

signs, diagnosis, and treatment of these diseases that can occur in the returning traveler are presented in Chapters 40, 42, and 43.

46 Chemistry & Hematology Reference Intervals

Frank J. Accurso, MD
Georgette Siparsky, PhD

Laboratory tests provide valuable information necessary to evaluate a patient's condition and to monitor recommended treatment. Chemistry and hematology test results are compared with those of healthy individuals or those undergoing similar therapeutic treatment to determine clinical status and progress. In the past, the term normal ranges relayed some ambiguity because statistically, the term normal also implied a specific (Gaussian or normal) distribution and epidemiologically it implied the state of the majority, which is not necessarily the desirable or targeted population. This is most apparent in cholesterol levels, where values greater than 200 mg/dL are common, but not desirable. Use of the term reference range or reference interval is therefore recommended by the International Federation of Clinical Chemistry (IFCC) and the Clinical and Laboratory Standards Institute (CLSI) to indicate that the values relate to a reference population and clinical condition.

Reference ranges are established for a specific age, sex, and sexual maturity; they are also defined for a specific pharmacologic status, dietary restrictions, and stimulation protocol. Similarly, diurnal variation is a factor as is degree of obesity. Some reference ranges are particularly meaningful when combined with other results (eg, parathyroid hormone and calcium), or when an entire set of analytes is evaluated.

Laboratory tests are becoming more specific and measure much lower concentrations than ever before. Therefore, reference ranges should reflect the analytical procedure as well as reagents and instrumentation used for a specific analysis. As test methodology continues to evolve, reference ranges are modified and updated.

CHALLENGES IN DETERMINING & INTERPRETING PEDIATRIC REFERENCE INTERVALS

The pediatric environment is particularly challenging for the determination of reference intervals since growth and developmental stages do not have a distinct and finite boundary by which test results can be tabulated. Reference ranges may overlap and, in many cases, complicate diagnosis and treatment. Collection and allocation of test results by age for the purpose of establishing a reference range is a convenient and manageable way to report them, but caution is needed in their interpretation and clinical correlation.

A particular difficulty lies in establishing reference ranges for analytes whose levels are changed under scheduled stimulation conditions. The common glucose tolerance test is such an example, but more complex endocrinology tests require skill and extensive experience to interpret. Reference ranges for these serial tests are established over a long period of time and are not easily transferable between test methodologies.

GUIDELINES FOR USE OF DATA IN A REFERENCE RANGE STUDY

The College of American Pathologists provides guidelines for the adoption of reference ranges used in hospitals and commercial clinical laboratories. It recognizes the enormous task of establishing a laboratory's own reference ranges, and recommends alternatives to the process. A laboratory may acquire reference ranges by:

1. Conducting its own study to evaluate a statistically significant number of "healthy" volunteers. It is a monumental task for a laboratory to develop its own pediatric reference ranges, because parental consent

and procedural approval by review boards need to be addressed. The numerous age categories to be evaluated also add to the complexity and size of the study.

2. Adopting ranges established by the manufacturer of a particular analytical instrument. The laboratory must validate the data by analyzing a sample of 20 "reference" subjects (patients representing that specific population) to confirm that the adopted range is truly representative of that group.
3. Using reference data in the general medical literature and conferring with physicians to make sure the data agree with their clinical experience. A validation study is also recommended.
4. Analyzing hospital patient data. Laboratory test results from hospital patients have been used to compute reference ranges provided they fulfill stated clinical criteria. Patient records need to indicate that the patient's specific medical condition does not influence the analyte whose reference range is being determined. For example, a child undergoing surgery for bone fracture repair is expected to have normal electrolytes and thyroid function, whereas a child examined for precocious puberty should not be included in a reference range study for luteinizing hormone.

Statistically, the sample size of a hospital patient study should be considerably larger than that of a healthy group. A study from a healthy population may require 20 subjects to be statistically significant, whereas a hospital population should evaluate a minimum of 120 patients.

STATISTICAL COMPUTATION OF REFERENCE INTERVALS

The establishment of reference intervals is based on a statistical distribution of test results obtained from a representative population. The CLSI recommendation for data collection and statistical analysis provides guidelines for managing the data. For clinicians, it is not important that they can reproduce the calculation. It is far more critical to understand the benefits and restrictions provided by the described statistical approaches and to evaluate patient results with these limitations in mind.

In reviewing the statistics, 95% of all results will be inherently included in the reference range. Note that 5% of that population will have "abnormal" results, when in fact they are "healthy" and an integral part of the reference group study. Similarly, an equivalent 5% of the "ill" population will have laboratory results within the reference range. These are inherent features of the statistical computation. Taking that analysis one step further, the probability of a healthy patient having a test result within a calculated reference range is

$$P = .95$$

When multiple tests or panels of tests are used, the combined probability of all the test results falling in their respective reference ranges drops dramatically. For example, the probability of all results from 10 tests in the complete metabolic panel being in the reference range is

$$P = (.95)^{10} = .60$$

Therefore, about one-third of healthy patients will have one test result in the panel that is outside the reference range.

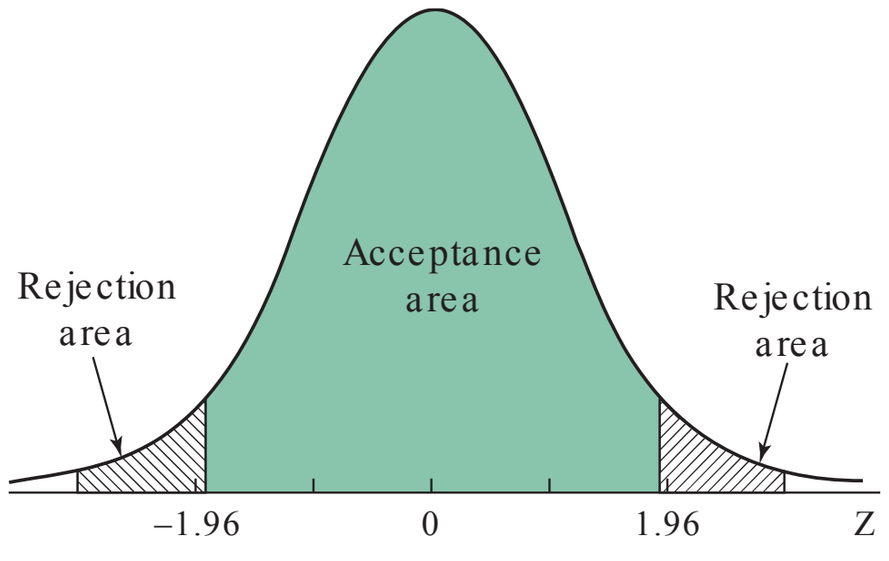
A. Parametric Method of Computation

The parametric method of establishing reference intervals is simple, though not always representative, since it is based on the assumption that the data have a Gaussian distribution. A mean (x) and standard deviation (s) are calculated; test results of 95% of that specific population will fall within the mean ±1.96s, as shown in Figure 46–1.

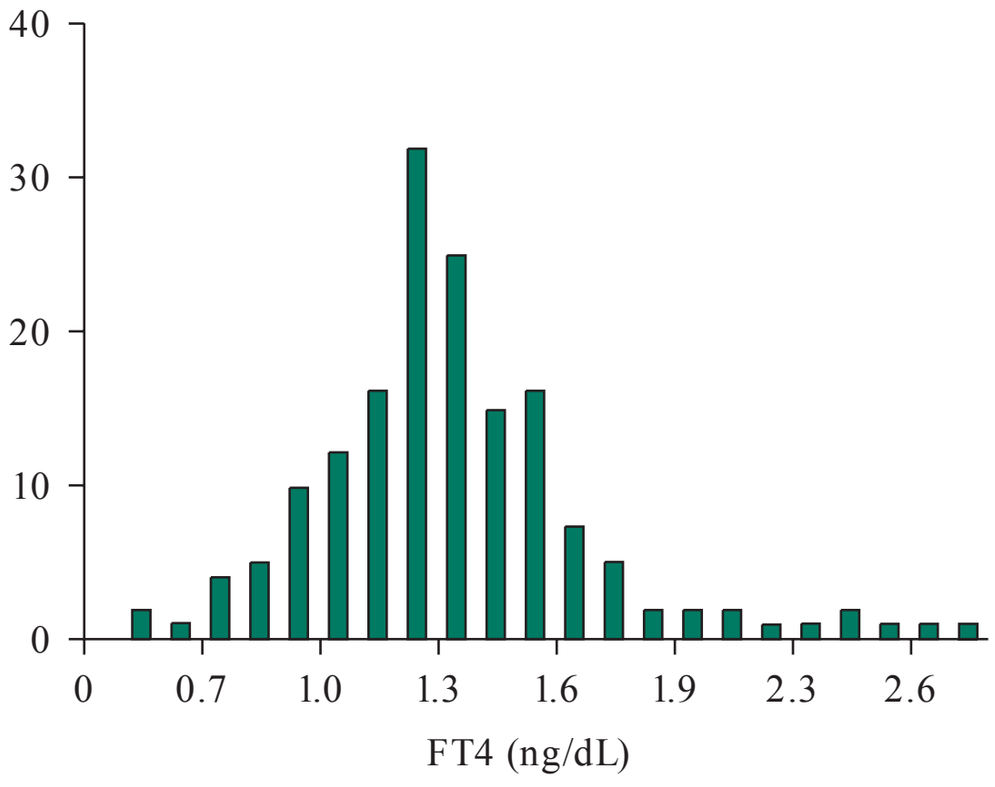
Where the distribution is not Gaussian, a mathematical manipulation of the values (eg, plotting the log of the value, instead of the value itself) may give a Gaussian distribution. The mean and standard deviation are then converted back to give a usable reference range.

B. Nonparametric Method of Computation

The nonparametric method of establishing reference ranges is currently recommended by CLSI, since it defines outliers



▲**Figure 46–1.** Gaussian distribution and parametric calculation using x ± 1.96s to define the range.



▲**Figure 46–2.** Histogram of free thyroxine (FT4) using clinic and hospital patients at Children's Hospital in Denver.

as those in the extreme 2.5 percentile of the upper and lower limits of data, respectively. The number of data points excluded at the limits depends on the skew of the curve, and so the computation accommodates a non-Gaussian distribution. A histogram depicting the non-Gaussian distribution of data from a free thyroxine reference range study conducted at Children's Hospital in Denver is shown in Figure 46–2.

Ichihara K, Boyd JC; IFCC Committee on Reference Intervals and Decision Limits (C-RIDL): An appraisal of statistical procedures used in derivation of reference intervals. Clin Chem Lab Med 2010 Nov;48(11):1537–1551 [PMID: 21062226].

WHY REFERENCE INTERVALS VARY

Recent modifications to reference ranges are due to the introduction of new and improved analytical procedures, advanced automated instrumentation, and standardization of reagents and reference materials. Reference ranges are also affected by preanalytical variations that can occur during sample collection, processing, and storage.

Preanalytical variations of biological origin can occur when specimens are drawn in the morning versus in the evening, or from hospitalized recumbent patients versus ambulatory outpatients. Variations also may be caused by metabolic and hemodynamic factors. Preanalytical factors may be a product of the socioeconomic environment or ethnic background (eg, genetic or dietary).

Analytical variations are caused by differences in analytical measurements and depend on the analytical tools as well as an inherent variability in obtaining a quantitative value. Furthermore, new reagents, instruments, and improved testing procedures added to the clinical laboratory results in an element of variability between tests.

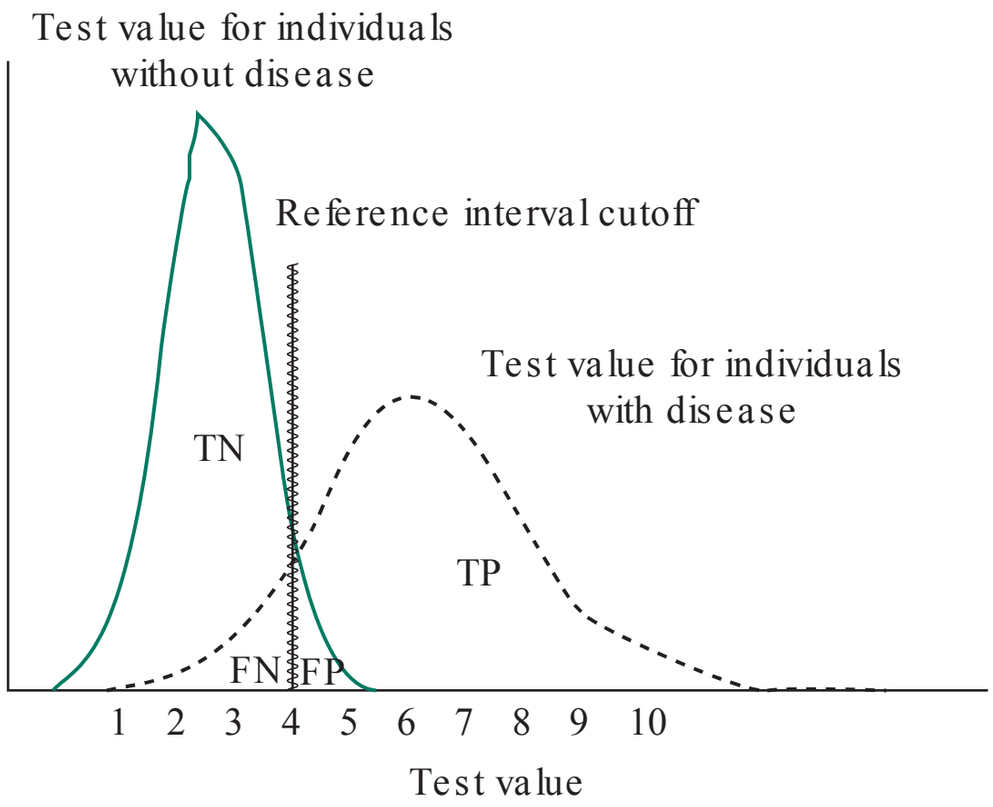
1. **Antigen-antibody reactions** have revolutionized clinical chemistry, but have also added a degree of variability because biologically derived reagents have different specificity and sensitivity. In addition to the targeted analyte, some of its metabolites are also measured, and these may or may not be biologically active.
2. **Reference materials** continue to be reviewed and evaluated by organizations such as the World Health Organization and the National Institute for Standards and Technology.
3. **Analytical instrumentation** with advanced electronics and robotics has improved accuracy of results and increased throughput. However, they have added an element of variability between instruments from different manufacturers.
4. **Analytical detection methods** have also made big strides as they have expanded from simple ultraviolet-visible spectrophotometry to fluorescence, nephelometry, radioimmunoassay, and chemiluminescence.

Jung B, Adeli K: Clinical laboratory reference intervals in pediatrics: The CALIPER initiative. Clin Biochem 2009 Nov;42 (16–17):1589–1595 [Epub 2009 Jul 7] [PMID: 19591815].

SENSITIVITY & SPECIFICITY

Despite its statistical derivation, a reference interval does not necessarily provide a finite and clear-cut guideline as to whether a patient has a condition. There will always be a segment of the population with test values that fall within the reference interval, but clinical manifestations that indicate disease is present. Similarly, a segment of the population will have test values outside the reference interval, but no clinical signs of disease. The ability of a test and corresponding reference interval to detect individuals with disease is defined by the diagnostic sensitivity of the test. Similarly, the ability of a test to detect individuals without disease is described by the diagnostic specificity. These characteristics are governed by the analytical quality of the test as well as the numerical parameters (reference interval) that define the presence of disease. The tolerance level for the desired sensitivity and specificity of a test requires significant input from clinicians.

Generally, specificity increases as sensitivity decreases. A typical reference range frequency distribution, shown in Figure 46–3 (solid line), provides information on the test results of a number of healthy subjects, or individuals without the disease. A second curve (dashed line) shows test results for individuals with the disease. As with most tests, there is an overlap area. A patient with a test result of 1 is likely healthy,



▲**Figure 46–3.** Frequency distribution of test results for patients with and without disease. FN, false negative; FP, false positive; TN, true negative; TP, true positive.

and the result indicates a true negative (TN) for the presence of disease. A patient with a test result of 9 is likely to have the disease and the test result is a true positive (TP). There is a small, but significant, population with a test result of 2–5 in whom the test is not 100% conclusive. A statistical analysis may determine the most likely cutoff for healthy individuals, but the clinically acceptable cutoff depends on the test as well as clinical correlation. Where the treatment is aggressive and has serious side effects, a clinician may choose to err on the side of caution and hold treatment for anyone with a test value of less than 6.

If cutoff values for the reference interval are such that a test result indicates that a healthy patient has the disease, the result is a false positive (FP). Conversely if a test result indicates that a patient is well when in fact he or she has the disease, the result is a false negative (FN). To define the ability of the test and reference interval to identify a disease state, the diagnostic sensitivity and specificity are measured.

$$\text{Diagnostic sensitivity} = TP/(TP + FN)$$

$$\text{Diagnostic specificity} = TN/(TN + FP)$$

In the example shown in Figure 46–3, a reference interval of 0.5–3 will provide more TN results and minimize FP results. Alternatively, a reference interval of 0.5–4 will increase the rate of FN. Thus, an increase in sensitivity leads to a decrease in specificity. A medical condition that requires aggressive treatment may necessitate a test and corresponding reference interval with a high sensitivity, which is a measure of the TP rate. This is accomplished at the expense of lowering specificity.

A reference interval is a statistical representation of test results from a finite population, but it is by no means inclusive of every member of the group. It is merely one component in the measure of a patient's status to be viewed in relation to the sensitivity and specificity of the test.

PEDIATRIC REFERENCE INTERVALS

The establishment of reference ranges is a complex process. Assumptions are made in the management of data processes, regardless of whether "healthy" individuals or hospital patients are used for the accumulation of test results. Analytical instrument manufacturers conduct large studies to identify reference intervals for each specific analyte, and pediatric values have always been the most challenging. Some of the manufacturers' recommended reference intervals are listed in Table 46–1 for general chemistry, Table 46–2 for endocrinology, and Table 46–3 for hematology. The interpretation of chemistry and hematology laboratory results is equally complex and forms a continuous challenge for physicians and the medical community at large.

general considerations, 1257–1258
laboratory findings, 1258
prevention, 1258
prognosis, 1259
symptoms and signs, 1258
treatment, 1258–1259
Gastroesophageal reflux (GER) and GERD
clinical findings, 611–612
diagnostic studies, 612
extraesophageal manifestations of reflux disease, 611–612
infants with gastroesophageal reflux, 611
older children with reflux, 611
esophagitis associated with, 612f
in newborn, 55–56
treatment and prognosis, 612–613
Gastrointestinal bleeding, 639–642, 640t
differential diagnosis of, 641t
history, 639–640
identification of sites of, 640t
imaging studies, 640
laboratory findings, 640
in newborn
lower, 55
upper, 55
physical examination, 640
treatment, 641–642
Gastrointestinal infections, protozoal, 1300–1305
amebiasis, 1300–1302
cryptosporidiosis, 1303–1304
cyclosporiasis, 1304
free-living amoebas, 1304–1305
giardiasis, 1302–1303
Gastrointestinal polyposis syndromes, 635t
Gastrointestinal symptoms and signs, 636–652
abdominal pain, 643–645
clinical findings, 644
differential diagnosis, 644
prognosis, 644–645
treatment, 644–645
acute abdomen, 645
acute diarrhea, 636–637
other viral infections causing, 637
rotavirus infection, 636–637
chronic diarrhea, 637–639
causes of, 638–639
allergic diarrhea, 638
antibiotic therapy, 638
chronic nonspecific diarrhea, 638–639
diet and medications, 638
extraintestinal infections, 638
malnutrition, 638
immunologic causes of, 639
other causes of, 639
gastrointestinal bleeding, 639–642, 640t
history, 639–640
imaging studies, 640
laboratory findings, 640
physical examination, 640
treatment, 641–642
inflammatory bowel disease, 649–652
clinical findings, 649
complications, 650
differential diagnosis, 649–650
general considerations, 649
quality improvement, 652
treatment, 650–652
malabsorption syndromes, 645–649
abetalipoproteinemia, 649
acrodermatitis enteropathica, 649
celiac disease (gluten enteropathy), 646–647
clinical findings, 645–646
cow's milk protein intolerance, 648
dietary fructose intolerance, 648
disaccharidase deficiency, 647
glucose-galactose malabsorption, 648
intestinal lymphangiectasia, 648
other genetic disorders causing, 649
pancreatic insufficiency, 649
protein-losing enteropathy, 646
treatment, 646
vomiting, 642–643
clinical findings, 643
cyclic vomiting syndrome, 643
clinical findings, 643
differential diagnosis, 643
treatment, 643
differential diagnosis, 643
treatment, 643
Gastrointestinal tract, 611–652
disorders of the colon, 628–633
anal fissure, 630–631
Clostridium difficile infection in children, 631–633
congenital aganglionic megacolon (Hirschsprung disease), 628–629
congenital anorectal anomalies, 631
constipation, 629–630
disorders of the esophagus, 611–617
caustic burns of the esophagus, 615–616
eosinophilic esophagitis, 613–615
foreign bodies in the alimentary tract, 616–617
gastroesophageal reflux and GERD, 611–613
disorders of the peritoneal cavity, 633–634
chylous ascites, 633–634
peritonitis, 633
disorders of the stomach and duodenum, 617–622
congenital diaphragmatic hernia, 620–621

congenital duodenal obstruction, 621–622
gastric and duodenal ulcer, 619–620
hiatal hernias, 617–618
pyloric stenosis, 618–619
duplications of, 627–628
gastrointestinal tumors and malignancies, 634–636
cancers of the esophagus, small bowel, and colon, 635–636
intestinal hemangiomas and vascular malformations, 636
juvenile polyps, 634–635
mesenteric and omental cysts, 636
major gastrointestinal symptoms and signs, 636–652
abdominal pain, 643–645
acute abdomen, 645
acute diarrhea, 636–637
chronic diarrhea, 637–639
gastrointestinal bleeding, 639–642
inflammatory bowel disease, 649–652
malabsorption syndromes, 645–649
vomiting, 642–643
small intestine, 622–628
acute appendicitis, 627
duplications of the gastrointestinal tract, 627–628
inguinal hernias, 625–626
intestinal atresia and stenosis, 622
intestinal malrotation, 622–623
intussusception, 624–625
Meckel diverticulum, 626
patent omphalomesenteric duct, 626
short bowel syndrome, 623–624
umbilical hernias, 626
surgical conditions in newborn, 52–56
Gastrointestinal tumors and malignancies, 634–636
cancers of the esophagus, small bowel, and colon, 635–636
intestinal hemangiomas and vascular malformations, 636
clinical presentation, 636
treatment, 636
juvenile polyps, 634–635
mesenteric and omental cysts, 636
Gastroschisis, in newborn, 54
Gaucher disease
clinical and laboratory features, 1073t
