Modified radical mastectomy includes an ALND. Neoadjuvant chemotherapy clears the positive axilla (via core biopsy) about 40% of the time. Several studies were designed to determine if an SLNB would be accurate after neoadjuvant chemotherapy and when negative avoid a concomitant ALND. Alliance 1071 and other trials showed that the false-negative rate of an SLNB with a known positive node before neoadjuvant chemotherapy was too high unless at least 3 nodes were obtained as well as the clipped positive node was also obtained. One of the next generation of trials is the NSABP 51. This trial examines in cN1 breast cancer patients who are node negative by SLNB the safety and efficacy of ALND versus XRT. The Alliance 111202 is going even further examining those patients who were node positive before and after neoadjuvant chemotherapy the safety and efficacy of XRT versus axillary radiation.

When performing an RM of MRM for recurrence a second sentinel lymph node biopsy has a high false-negative rate. If the axilla has been disturbed by prior surgery, then alternative drainage is likely to occur. Radioactive injection may or may not be able to locate such drainage especially in a patient that has been previously irradiated. The most likely occurrence would be in the internal mammary chain in the second and third intercostal spaces. If a lymph node in this area cannot be seen by ultrasound, it is unlikely to be significant. These are easy lymph nodes to retrieve and a recurrence in this chain is often difficult to treat.

Haagensen grave signs (p2) are no longer necessarily grave with the advent of neoadjuvant chemotherapy. Skin sparing and nipple skin sparing mastectomies can be performed on those patients with locally advanced disease with complete or partial responses to chemotherapy, previous radiation or expected post op radiation. The reported complication rates are only slightly higher when compared to those patients who did not adjuvant therapy prior to surgery. One must wait 4 to 8 weeks after chemotherapy to perform the mastectomy.

Contralateral mastectomies requested by patients have come under fire in recent years with societies advocating against them as such procedures have not been definitely shown to improved survival. However, survival is not the only parameter by which these procedures should be judged. The fear of recurrence and the actual recurrence itself which is 1% to 2% per year can be devastating for these patients. Symmetry especially for the patient with macromastia or those undergoing reconstruction is important. Informed patient choice should to be given every consideration.

Reconstruction for radical mastectomy requires a tissue reconstruction. By far, the most common type of reconstruction after modified mastectomy is implant under the pectoralis major usually with a dermal matrix to complete a sling-like pattern and natural look. Occasionally, for example, in the athlete the implant can be placed prepectoral within an envelope of dermal matrix.

Infection in this group of patients is serious and may cause the loss of the implant. Therefore I use adhesive drapes in these patients and prep before and after placement of the drapes. I give antibiotics per weight and redoes often. After closure I use skin glue instead of steristrips which has the added advantage of allowing the patient to take a shower. TRAM flaps can be performed and do well in the obese, previously irradiated patient or those at high risk of infection. However, the go to flap in centers where teams are available is the muscle sparing DIEP.

Postoperative pain control seems to receive little attention. In general, most complications can be mitigated if good pain control is obtained from the outset. Patients complain about the pain of drains more than any single area. Simply placing drains where you know the patient's skin is already numb with obviate this source of pain. I do intercostal rib blocks (2 to 6) and have published the value pectoral (major and minor) blocks with bupivacaine. When placing expanders, I also add botulinum toxin injected into the pectoralis major. We showed that attention to postoperative pain and using these techniques reduced the length of stay for reconstructive patients by 1 day. In addition, many of these patients have postoperative scapulothoracic bursitis from lying on the table so long. Pain from scapulothoracic bursitis radiates anteriorly and causes postoperative tightness and pain as well as decreased range of motion of the involved upper extremity. Trigger point injections under the scapula with a mixture of lidocaine, bupivacaine, and corticosteroids give good long-lasting pain relief. Heat and NSAIDs on the scapula are also helpful.

55 Oncoplastic Techniques for Breast Conservation Surgery

Kristine E. Calhoun and Benjamin O. Anderson

ETIOLOGY/PATHOPHYSIOLOGY

Breast conserving therapy was introduced as a surgical option for women with breast cancer beginning in the 1970s. Initially investigated in Europe and then the United States, clinical trials have since demonstrated equivalency in terms of overall survival between lumpectomy with radiation and mastectomy. For the appropriately selected individual, breast conserving therapy can offer adequate treatment, as well as the psychologic benefit of retention of the breast.

In a typical lumpectomy, an incision is made, the tumor removed, and the wound closed without any specific effort made to obliterate the internal cavity. Closing the pericavity fibroglandular tissue may result in cosmetic defects if alignment of the breast tissue is suboptimal. Often times, fibroglandular tissue that is sutured together at middle depth in the breast with the patient supine on the operating table results in a puckered, dimpled appearance with the patient upright. While such a "scoop and run" approach to lumpectomy may work well for smaller tumors, declivity of the skin and/or displacement of the nipple–areolar complex (NAC) may be the end result if the lesion is sizable or the breast small.

For breast conservation to be successful, the cancer must be resected with adequate surgical margins while simultaneously maintaining the breast's shape and appearance. Unfortunately, satisfying these dual goals can be challenging. In 1994, Werner P. Audretsch was one of the first to advocate the use of "oncoplastic surgery" for repair of partial mastectomy defects by combining the techniques of volume reduction with immediate flap reconstruction. Although initially used to describe partial mastectomy combined with large myocutaneous flap reconstruction using the latissimus dorsi or the rectus abdominis muscles (volume replacement), oncoplastic surgical techniques have evolved and the term currently refers to a series of surgical approaches that utilize partial mastectomy with

breast-flap advancement to address tissue defects following wide resection (volume displacement). Once 20% of the breast volume or more has been excised, the risk of significant long-term cosmetic deformity increases. The traditional lumpectomy generally removes 20 to 40 g of tissue, with adverse cosmetic outcomes typically seen when greater than 80 g are removed. In oncoplastic resections, volumes between 200 and 1,000 g can be removed without a significant negative outcome. Such resections allow oncoplastic techniques to broaden the application of breast conserving surgery (BCS) to patients with larger tumors who previously would have been automatically guided toward a mastectomy.

Given that there is considerable variability in oncoplastic techniques and many procedures are self-taught, some have attempted to define these procedures more completely. One such attempt was made by Clough et al. in their Quadrant per Quadrant Atlas for Oncoplastic Surgery, which divides oncoplastic approaches into level 1 (up to 20% breast volume resected, closure achieved primarily) and level 2 (20% to 50% of breast volume resected, closure achieved via the use of mammoplasty) techniques. Level 1 resections are performed without mammoplasty and are easily learned by most surgeons. Level 1 techniques include six basic steps and can be used in any quadrant—skin incision, skin undermining, NAC undermining, full-thickness excision, tissue reapproximation, and NAC repositioning (generally recommended). Level 2 techniques involve mammoplasty repairs and are much more advanced. We will focus on approaches more easily implemented and utilized by breast surgeons, including the parallelogram mammoplasty lumpectomy, batwing mastopexy lumpectomy, donut mastopexy lumpectomy, reduction mastopexy lumpectomy, and the central lumpectomy.

CLINICAL

A thorough understanding of normal breast anatomy is critical to planning an oncoplastic partial mastectomy. One of the fundamental challenges for the oncoplastic breast surgeon is appropriately determining how the target cancer is distributed within the breast and assessing whether the lesion can be resected as a single en bloc fibroglandular resection.

The modern anatomic analysis of ductal anatomy suggests that the number of major ductal systems is probably fewer than ten and that the size of ductal segments can be extremely variable. Not all ducts pass radially from the nipple to the periphery of the breast; instead some travel

directly back from the nipple toward the chest wall. As first described in the 1840s by the surgical anatomist Sir Astley Cooper, single ductal segments may radiate to the sternal (medial) and clavicular (superior) aspects of the breast, with two or three ductal branches layered upon each other, creating a fuller pad of fibroglandular tissue in the axillary (lateral) and abdominal (inferior) aspects of the breast (Fig. 55.1). Although the ductal branches appear to interdigitate with each other within the breast parenchyma, the segments do not communicate with each other via ductal anastomoses.

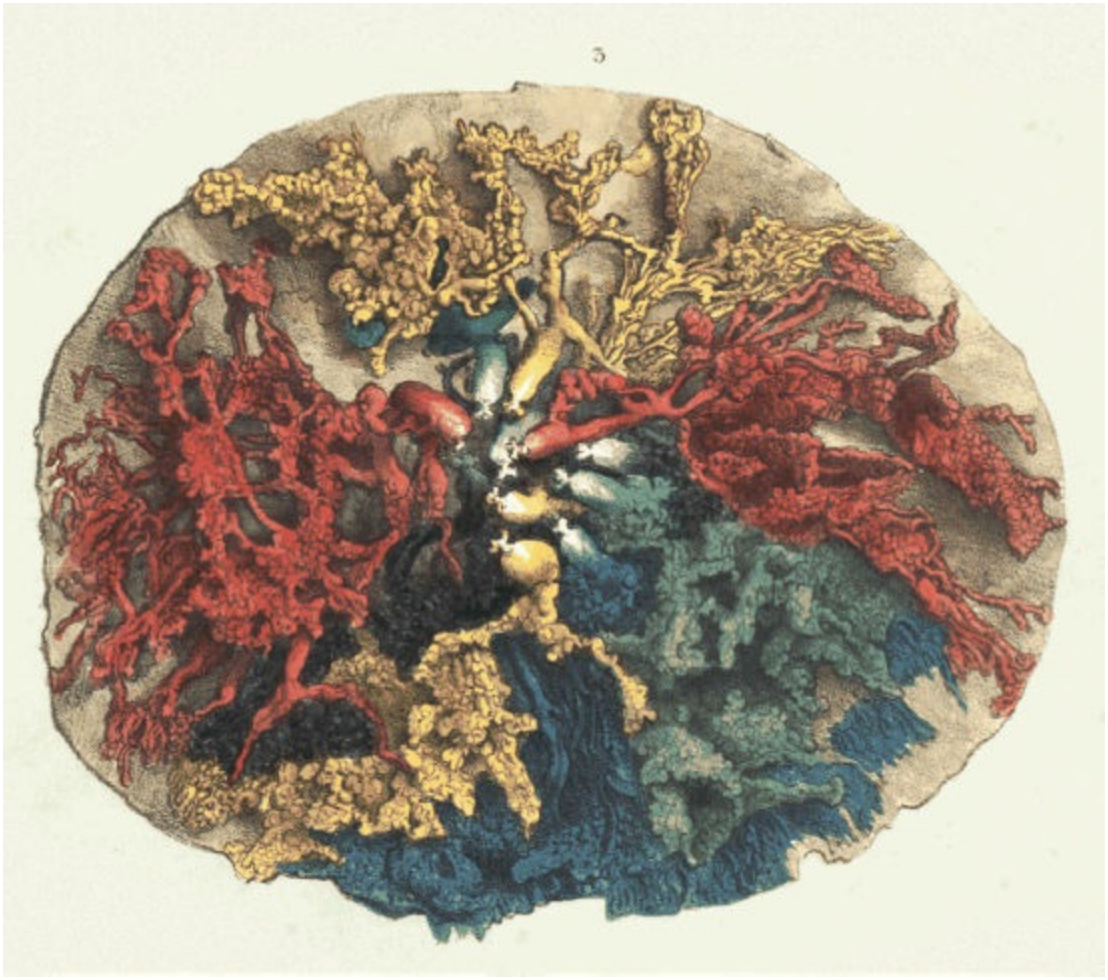

Figure 55.1. Ductal anatomy of the breast illustrating (1) the variability of segmental size and width and (2) how the lower breast has layered ductal segments creating a cushion while the upper breast ductal segments are single layered. (From Cooper AP. On the anatomy of the breast - Plate VI: Ducts and glandules (1840). Paper 16. http://jdc.jefferson.edu/cooper/16. Jefferson Digital Commons 2009. Courtesy of Thomas Jefferson University, Archives & Special Collections.)

In contrast to ductal anatomy, the fibroglandular tissue of the breast has an anastomotic circulatory bed that safely permits oncoplastic resection and mammoplasty fibroglandular advancement with minimal threat to tissue viability. By using volume displacement techniques where the surgeon simply shifts fibroglandular tissues en bloc along the chest wall, the surgeon is able to remodel large amounts of fibroglandular tissue within the skin envelope without major risk of breast ischemia. The axillary and internal mammary arteries are the most common origins of the arterial blood supply of the human. By maintaining communication with one of these two arterial connections, adequate blood supply to the breast parenchyma is maintained during tissue advancement and mastopexy closure.

INDICATIONS/CONTRAINDICATIONS

The use of oncoplastic surgical techniques allows for wider resection that minimizes the degree of subsequent tissue deformity, allowing surgeons to achieve wide surgical margins while preserving breast cosmesis. The indications, as well as the contraindications, for oncoplastic surgery are the same as those of traditional breast conserving surgery. In general, such techniques are offered to those patients otherwise believed to be breast preservation candidates, including patients with single quadrant disease and individuals who are candidates for postsurgical radiation therapy, including partial breast irradiation.

Clough et al. attempted to define selection criteria more by utilizing excision volume, tumor location, and breast density to determine which oncoplastic resection to use. Per their classification system, level 1 techniques are used when less than 20% of the breast volume will be removed, in any quadrant, and for dense breasts. More advanced level 2 resections and repairs are used when 20% to 50% of the breast volume needs to be removed and are preferred for fatty replaced breasts. In our experience, and in that described by Clough and others, tumor quadrant has a major bearing on the selection of technique.

The basic techniques described in this chapter are easily learned and implemented by breast surgeons, even those lacking formal plastic surgery training. In a review of 84 women who underwent partial mastectomy and radiation therapy, Kronowitz and colleagues showed that immediate repair of partial mastectomy defects with local tissues results in fewer complications (23% vs. 67%) and better aesthetic outcomes (57% vs. 33%)

than that with a latissimus dorsi flap, which some surgeons used for delayed reconstructions.

PREOPERATIVE PLANNING

Patients should undergo standard preoperative history and physical examination. Special attention should be given to any prior breast surgical history, including the presence of indwelling breast implants from previous augmentation. Tissue biopsy, preferably using percutaneous core needle sampling, should be performed to provide conclusive proof of malignancy. Excisional biopsy for tissue diagnosis should be avoided, as the resulting skin scar may complicate the placement of the subsequent lumpectomy incision.

Candidates for oncoplastic lumpectomy should undergo a standard preoperative breast imaging workup to establish the full extent of disease (EOD) in the breast. EOD workup typically includes a combination of mammography and ultrasound, with or without the supplemental use of breast MRI. Mammography may underestimate the EOD, especially DCIS, but is still warranted and is often the initial diagnostic study.

While it remains controversial, the use of MRI can contribute to the surgeon's ability to preoperatively determine the EOD present, especially when dealing with mammographically subtle or occult cancers in mammographically dense tissues. Compared with more traditional imaging modalities, the EOD seen on MRI may correlate best with the extent of tumor found at pathologic evaluation and MRI has the lowest false negative rate in detecting invasive lobular carcinoma. Although sensitivity is high, MRI unfortunately has a low specificity of 68% in the diagnosis of breast cancer before biopsy. Up to one third of MRI studies will show some area of enhancement that needs further assessment but ultimately prove to be a histologically benign breast tissue. A consensus statement from the American Society of Breast Surgeons supports the use of MRI for determining ipsilateral tumor extent or the presence of contralateral disease, in patients with a proven breast cancer (especially those with invasive lobular carcinoma), when dense breast tissue precludes an accurate mammographic assessment. For cancers containing both invasive and noninvasive components, a combination of imaging methods may yield the best estimate of overall tumor size.

While planning any lumpectomy, the surgeon needs to accurately identify the targeted area, which is often aided by the use of preoperatively

or perioperatively placed localization wires. Silverstein and colleagues have advocated for the preoperative placement of two to four bracketing wires to delineate the boundaries of a single lesion. In a study by Liberman and colleagues, wire bracketing of 42 lesions allowed for complete removal of suspicious calcifications in 34 (81%). Since single wire localization for larger breast lesions is more likely to result in positive margins, multiple bracketing wires may assist the surgeon in achieving complete excision at the initial resection.

Preoperative marking of skin landmarks with the patient in the upright, sitting position, with identification of the inframammary crease, the anterior axillary fold at the pectoralis major muscle, the posterior axillary fold of the latissimus dorsi muscle, the sternal border of the breast, and the periareolar circle is done. Identifying these structures with the patient in the sitting position is important to the final cosmetic outcome, because these landmarks may be challenging to accurately locate once the patient is asleep on the operating room table.

For all oncoplastic techniques, the patient should be supine on the operating room table with the arms abducted at 90 degrees or in a modified swimmer's position for the sentinel node biopsy portion of the procedure. Having both breasts prepped and draped into the field so that visual comparison with the patient in a beach chair position is possible as the wound is closed can help identify areas in need of immediate revision. Such an approach allows the surgeon to identify areas of unsightly tugging or dimpling inadvertently created during closure, so that they can be addressed at that time rather than at subsequent procedures.

SURGICAL TECHNIQUES

Parallelogram Lumpectomy

This technique, the most basic of the oncoplastic approaches, involves removal of the skin located directly superficial to the cancer, which insures that the two reapproximated skin edges will be equidistant at closure (Figs. 55.2 and 55.3). Parallelogram lumpectomy is most commonly used for superior pole or lateral cancers. Removal of the overlying parallelogram eliminates the existence of excessive, redundant skin after excision and helps prevent future declivity. The surgeon should be cautious when designing the skin ellipse, because removal of too broad of an island can cause substantial shifting of the NAC, thereby creating unintended asymmetry with respect to the contralateral breast. For upper inner

quadrant lesions, the skin island excisions should be small, or even avoided, since medial NAC shifting can create an unnatural appearance.

A rounded parallelogram with two equal length lines is drawn, marking the skin island to be excised in conjunction with the underlying target lesion and surrounding tissues (Fig. 55.2A). For lesions in the upper breast, incisions should be curvilinear, while lesions located within the lower breast, including the 3 o'clock and 9 o'clock positions, should have a radially placed parallelogram (see Lateral Segmentectomy).

After incision of the skin island (Fig. 55.2A), short distance skin flaps are raised along both sides of the wound to a width that encompasses the tumor. The dissection is then carried down through the breast tissue to the chest wall, maintaining a surgical margin around the tumor, and the specimen is then peeled off of the chest wall and removed in a full-thickness en bloc fashion (Fig. 55.2B,D). After the specimen is delivered through the incision and oriented with colored inks or sutures, 4 to 6 marking clips are typically placed at the base of the defect and within the surrounding fibroglandular tissue to mark the areas of tissue that were in closest proximity to the cancerous tumor. Once resection is complete and hemostasis obtained, the fibroglandular tissue at the level of the pectoralis fascia is widely undermined so that breast-tissue can be advanced to cover the exposed muscle without excessive tension. After tissues are mobilized, the margins of the residual cavity are shifted together by the advancement of breast tissue over muscle and sutured at the deepest aspect using 3-0 absorbable suture to close the surgically created defect (Fig. 55.3). The direction of tissue advancement can be adjusted depending upon the location of the fibroglandular defect and the excess tissue that can be shifted for closure. The goal of the mammoplasty (primary full-thickness closure of the fibroglandular tissue) is to perform as complete a closure over the pectoralis muscle as possible to discourage anterior (skin) and posterior (chest wall) tissue communication, thereby avoiding the classic and cosmetically undesirable "skin-pectoral adherence deformity." The superficial tissue layer is closed with interrupted subdermal absorbable sutures (we use 3-0 sutures), while the skin is closed by absorbable subcuticular sutures (we use 4-0 sutures) in routine fashion (Fig. 55.2E).

Lateral Segmentectomy

Essentially a variation of the above described parallelogram lumpectomy, the lateral segmentectomy is especially useful for lesions located within

the lateral breast at the 3 o'clock (left) and 9 o'clock (right) positions (Fig. 55.4A–D). The skin parallelogram is placed radially and positioned such that the closed incision will approach the NAC tangential to the periareolar line (Fig. 55.4A,B). This reduces deviation of the NAC toward the resected segment, gives more forward projection to the nipple, and avoids the downward-displacement that can be caused by a purely horizontal scar. The principles of resection and closure are otherwise the same as those described for the routine parallelogram lumpectomy (Fig. 55.4C,D).

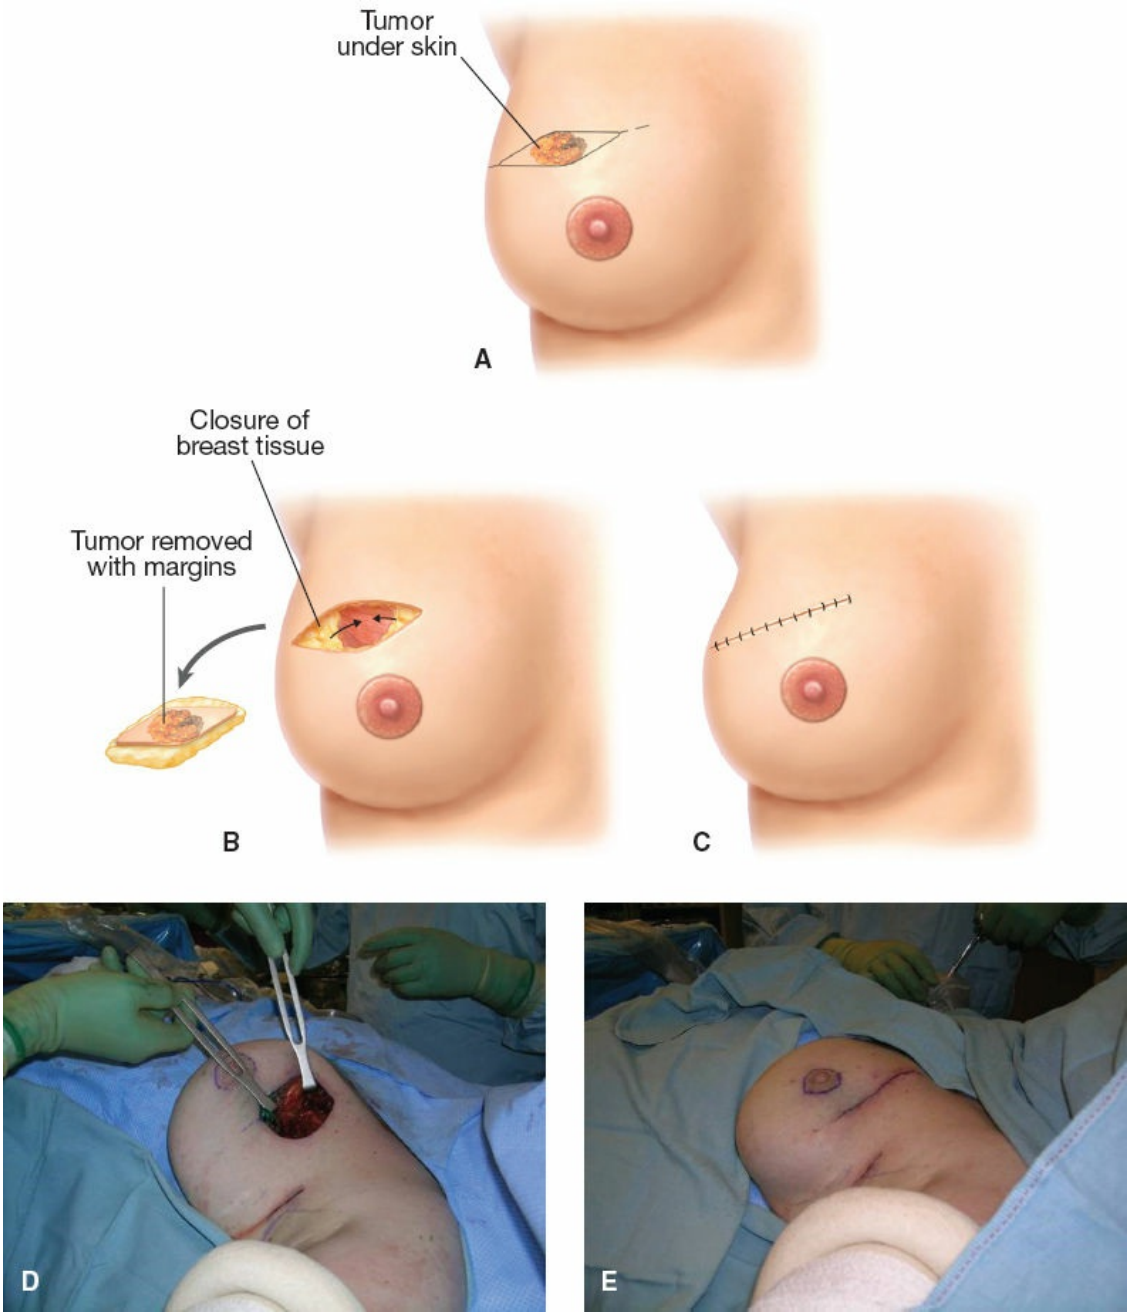

Figure 55.2. Parallelogram mammoplasty: incision design (**A**), full-thickness resection with open cavity prior to tissue

advancement (**B,D**), and final skin closure (**C,E**).

Batwing Lumpectomy

For cancers adjacent or deep to the NAC, but do not directly involve the nipple, lumpectomy can successfully be performed without sacrifice of the nipple itself (Fig. 55.5A–D). The batwing approach simultaneously preserves NAC viability while preserving the breast mound by using a mastopexy closure for the fibroglandular defect of the full-thickness resection. When the batwing incision is oriented laterally, a minor degree of lateral shifting of the NAC may result (Fig. 55.5D). When oriented at 12:00, this procedure may result in upward lifting of the nipple ("mastopexy" or "breast lift"), making a contralateral breast lift to achieve symmetry a distinct possibility.

Two similar semicircle incisions are made with angled "wings" on each side of the areola (Fig. 55.5A,B). The two half-circles are positioned to allow them to be re-approximated to each other at wound closure. Removal of these skin wings allows the semicircles to be shifted together without creating redundant skin folds at closure. Fibroglandular tissue dissection is carried down deep to the known cancer (Fig. 55.5C,D). In most situations, this dissection is carried down to the chest wall, with the breast gland lifted off the pectoralis muscle.

Central Lumpectomy

The cosmetic impact of NAC removal, which unfortunately is required when cancer involves the base of the nipple, likely accounts for the common use of mastectomy among these individuals despite the existence of the alternative option of central lumpectomy (Fig. 55.6A–C). The central lumpectomy is an alternative to total mastectomy that removes the NAC and underlying central tissues, but leaves behind a significant breast mound. The cosmetic outcome with central lumpectomy can range from good to outstanding, depending on the woman's body habitus, and may be better tolerated than mastectomy and subsequent reconstruction. Central lumpectomy can be particularly valuable in women with large breasts where unilateral total mastectomy may create prominent asymmetry. In central lumpectomy, the incision can be made in the pattern of a large parallelogram which encompasses the entire NAC (Fig. 55.6A). Rotating the NAC resection plane so that the incision results in an inverted T-incision may preserve breast shape and prevent flattening that can occur

with the more horizontally placed central lumpectomy incisions. The operative procedures and principles are the same as those of the parallelogram lumpectomy. The mammoplasty closure is performed as described above (Fig. 55.6B,C).

Reduction Mastopexy Lumpectomy

Typically indicted for macromastia and excessive breast ptosis, this procedure can also be adapted for resection of lesions in the lower hemisphere of the breast between the 4 o'clock and 8 o'clock positions (Fig. 55.7). For cancers in the lower pole of the breast, traditional lumpectomy using a circumareolar incision may result in unacceptable down-turning of the nipple due to scar contracture after radiotherapy. This unpleasant cosmetic outcome can be prevented by using the technique of reduction mastopexy lumpectomy. (The distinction between "mammoplasty" and "mastopexy" is that the latter procedure, in addition to closing the fibroglandular tissue to avoid soft tissue deficit and a possible visible divot, also moves the NAC on the skin envelope, thereby creating a breast lift.)

A reduction mastopexy keyhole pattern incision is made and the skin above the areola is de-epithelialized in preparation for skin closure (Fig. 55.7A). A superior pedicle flap is created by inframammary incision and undermining of the breast tissue off the pectoral fascia to mobilize the NAC and underlying tissues. For cancers located in the inferolateral or inferomedial quadrants, the keyhole pattern can be rotated slightly to allow for a more lateral or medial excision, while at the same time the NAC is moved in a direction opposite to that of the surgical defect. Commencing inferiorly and proceeding superiorly beneath the tumor, full-thickness excision of the lesion is accomplished, with at least a 1-cm macroscopic margin of normal tissue, and the skin overlying the lesion being removed (Fig. 55.7B).

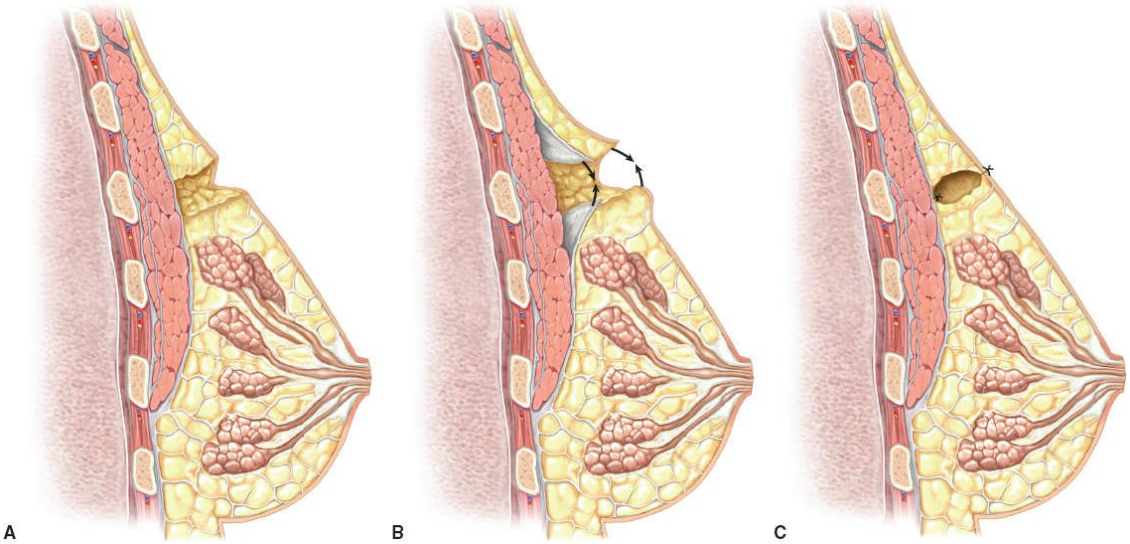

Figure 55.3. Volume displacement (mammoplasty) closure. After resecting the primary breast lesion in a full-thickness resection (**A**), the fibroglandular tissue is separated at the chest wall along the avascular pectoral fascia and advanced on the chest wall to close the fibroglandular defect created by full-thickness resection (**B**) prior to the final skin closure (**C**).

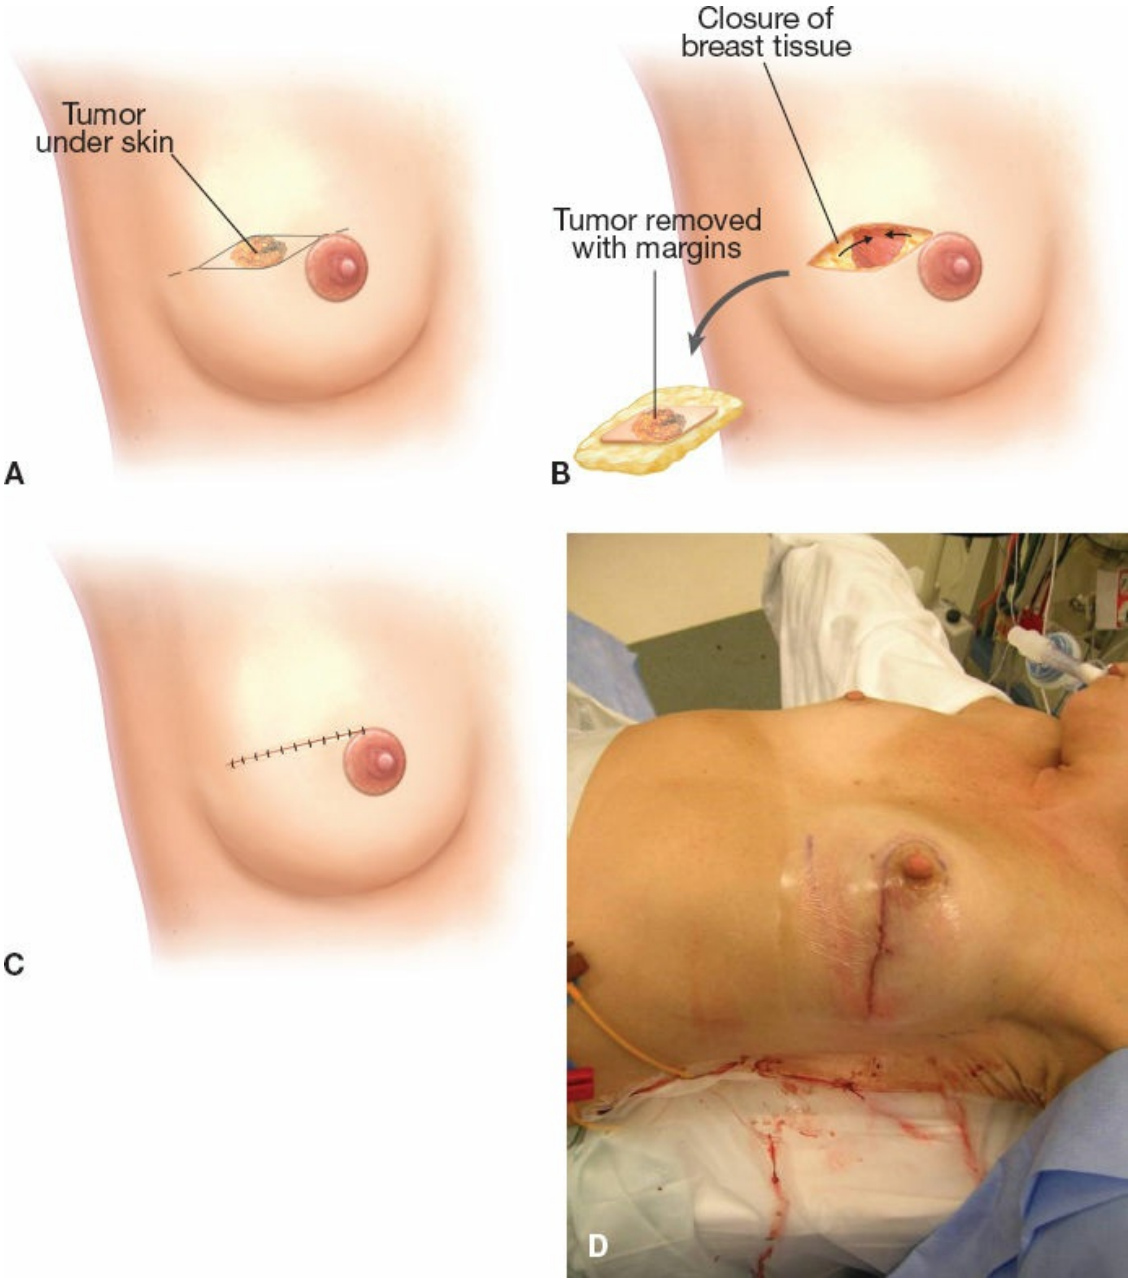

Figure 55.4. Lateral segmentectomy mammoplasty lumpectomy for laterally oriented, segmentally distributed cancers: incision design—noting the tangential approach that the skin incision makes with the nipple–areolar complex (**A**), full-thickness resection with open cavity prior to tissue advancement (**B**), and final skin closure (**C,D**).

Recentralization of the NAC is performed, with the medial and lateral breast flaps undermined and sutured together to fill the excision defect, leaving a typical inverted-T scar (Fig. 55.7C). Uplifting of the NAC by virtue of removal of the superior skin island helps restore a youthful appearance to the breast, but can create asymmetry with the contralateral

breast (Fig. 55.7D). For patients with macromastia, consistent positioning of the breast for radiotherapy may be difficult, resulting in dosing inhomogeneity and suboptimal treatment. These patients can benefit from reduction mastopexy lumpectomy using a unilateral or bilateral approach.

Donut Mastopexy Lumpectomy

The donut mastopexy lumpectomy is best utilized for segmentally distributed cancers located in the upper or lateral breast to achieve resection of long, narrow segments of breast tissue (Fig. 55.8A–E). The donut mastopexy avoids a visible long radial scar placed against Kraissl or Langer lines while allowing for adequate margin resection. In this procedure, two concentric lines are placed around the areola and a periareolar "donut" skin island is excised, with only a periareolar scar visible after this operation (Fig. 55.8A). Separation of this skin island from the underlying tissues is performed, taking care to avoid full devascularization of the areolar skin (Fig. 55.8B). The width of the "donut" skin island should be approximately 1 cm, but is somewhat dependent on the size of areola and expected extent of excision. Removal of this tissue ring is required to allow for both adequate access and exposure to the breast tissue and closure of the skin envelope around the remaining fibroglandular tissue that will reduce tissue volume overall.

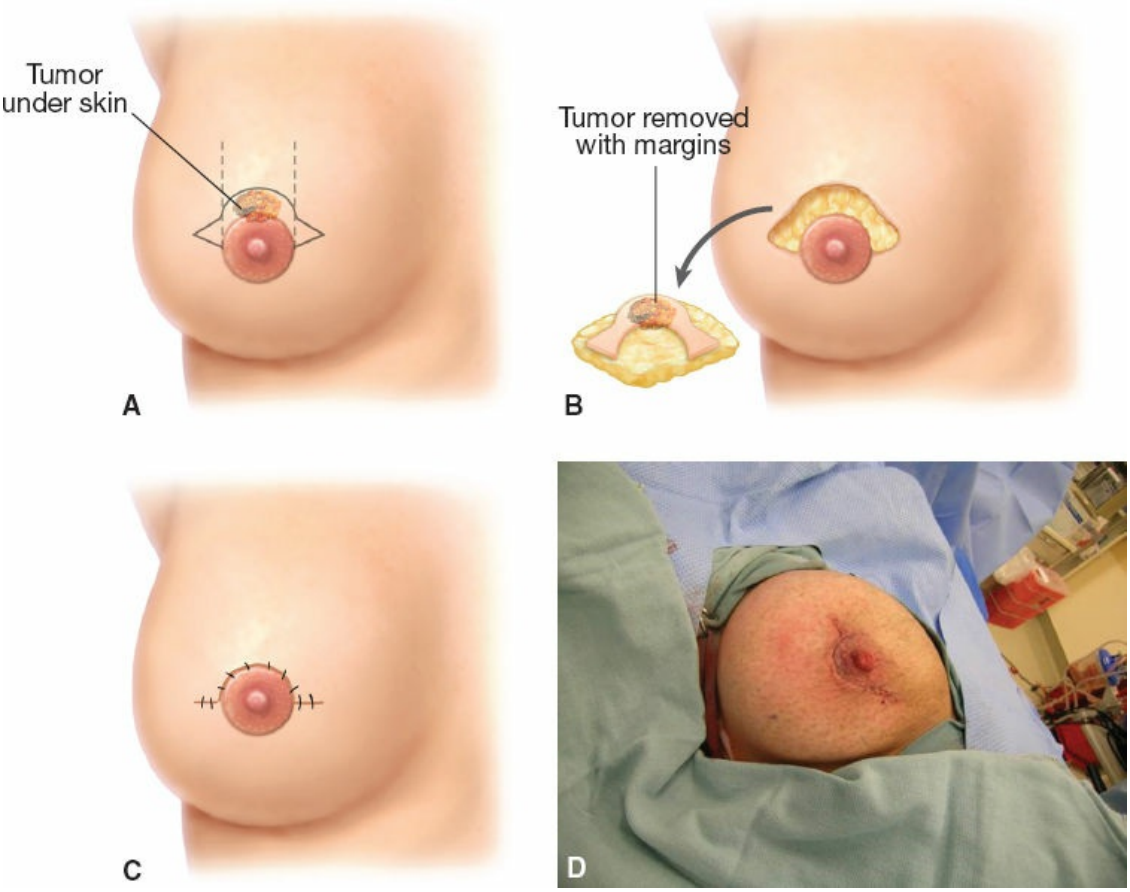

Figure 55.5. Batwing lumpectomy for centrally oriented cancers that do not directly involve the nipple–areolar complex: incision design (**A**) and skin incision (**B**), partial or full-thickness resection including dissection behind the nipple–areolar complex (**C**), final skin closure after mastopexy advancement of fibroglandular tissue behind nipple–areolar complex if needed (**D**).

A skin envelope is created in all directions around the NAC. The quadrant of breast tissue containing the target lesion is fully exposed utilizing the same dissection used for a skin sparing mastectomy. The full thickness breast gland is then separated from the underlying pectoralis muscle and delivered through the circumareolar. The segment of breast tissue with the tumor is resected in a wedge-shaped fashion, with the width of tissue excision balanced against the difficulty that will be created by virtue of an oversized segmental defect. The remaining fibroglandular tissue is returned to the skin envelope; the peripheral apical corners of the fibroglandular tissue are secured to each other and then anchored to chest wall (Fig. 55.8C). This anchoring maintains proper orientation of the mobilized fibroglandular tissue within the skin envelope during the initial phases of healing.

A purse-string using absorbable 3-0 suture is placed around the areola opening at a size that re-approximates the original NAC. Interrupted inverted 3-0 absorbable sutures are placed subdermally around the NAC, at which time the purse-string suture is tied and then 4-0 subcuticular sutures are used to close the wound (Fig. 55.8D). Uplifting of the NAC may create some asymmetry with the untreated breast, so if desired, a contralateral lift can be performed to achieve symmetry (Fig. 55.8E).

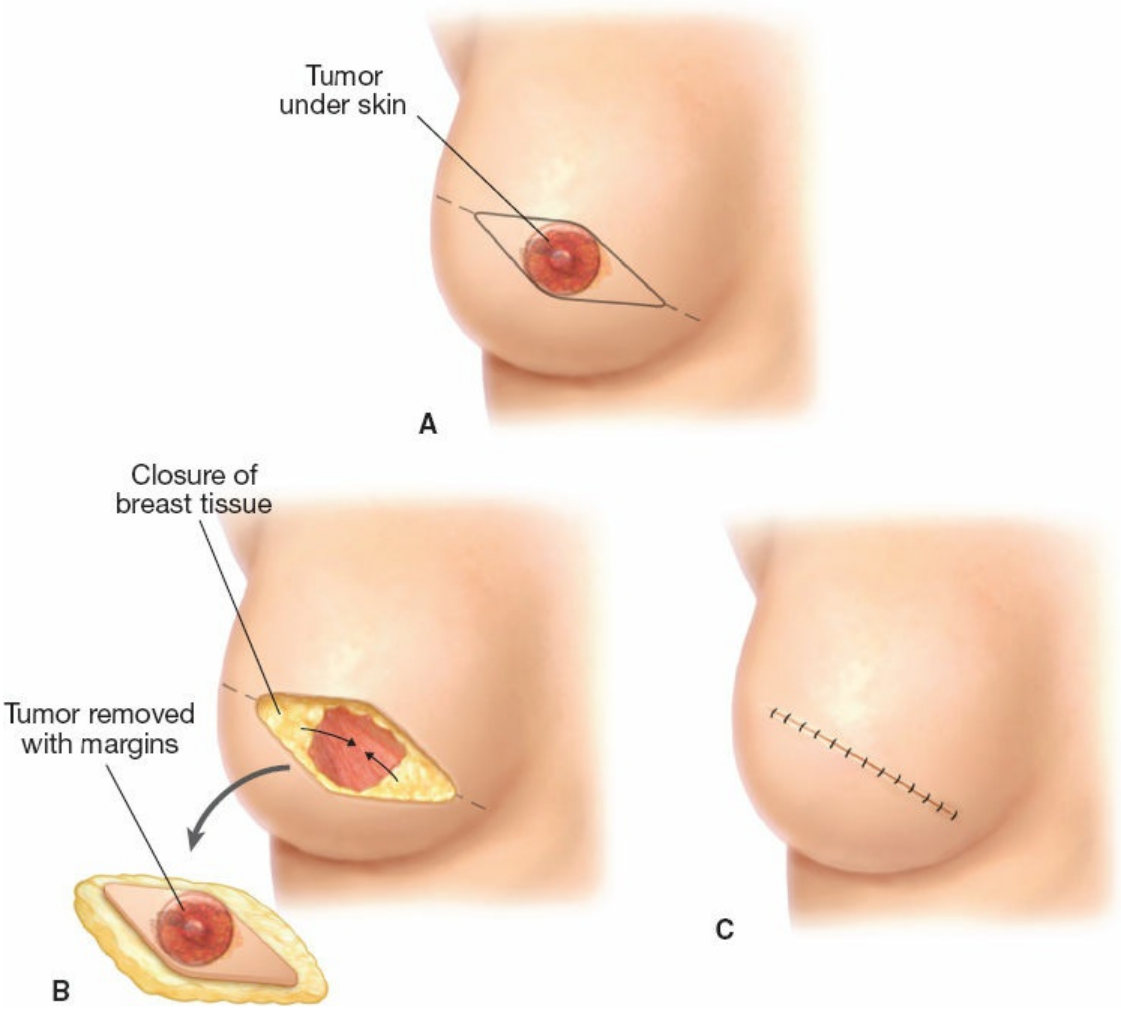

Figure 55.6. Central lumpectomy for centrally oriented cancers that do involve the nipple–areolar complex**:** incision design (**A**), resection (**B**), and final skin closure (**C**).

All oncoplastic procedures can be accompanied by axillary sentinel lymph node (SLN) dissection for staging purposes for those with invasive breast cancers. Consideration should be given to utilization of SLN for exceptionally large volume lumpectomies for ductal carcinoma in situ (DCIS), especially those in the upper outer quadrant, as such resections

may make subsequent lymphatic mapping difficult should surgical pathology reveal upstage to an invasive lesion.

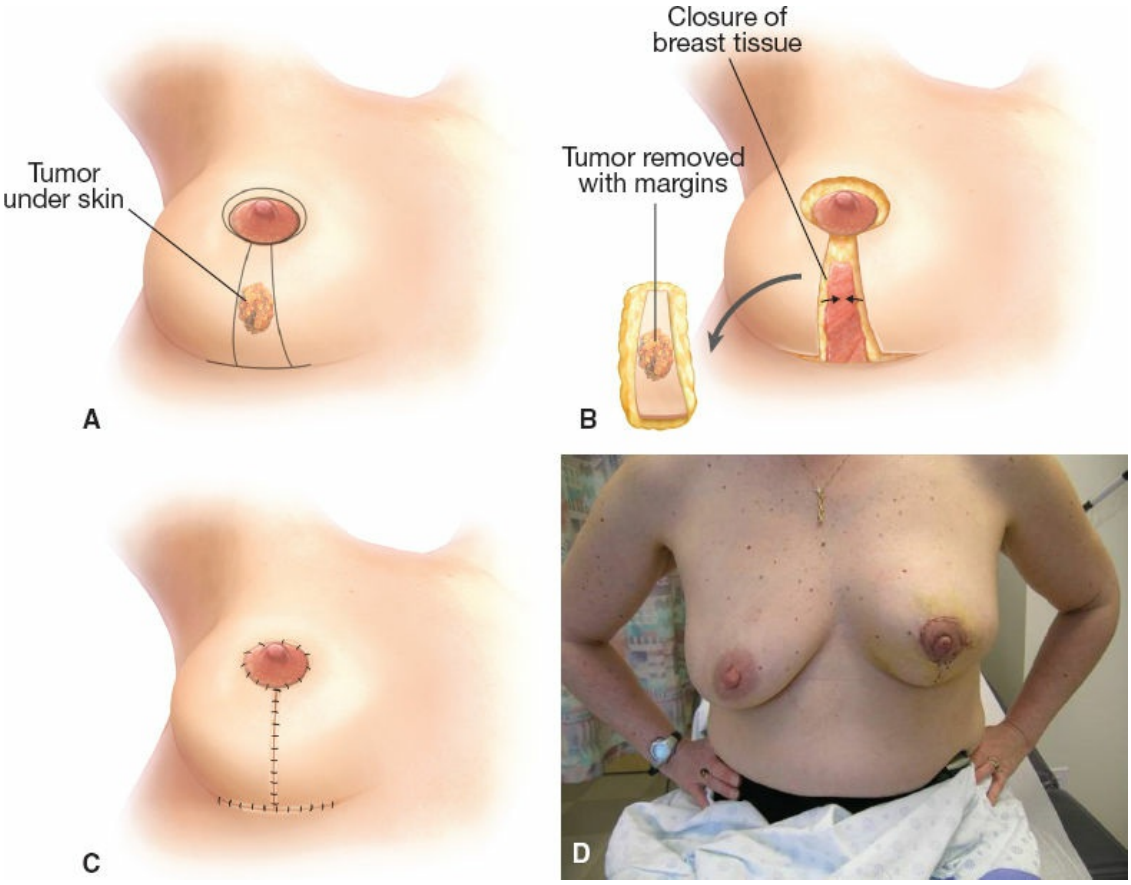

Figure 55.7. Reduction mastopexy lumpectomy for inferiorly 6:00 oriented segmentally distributed cancers: incision design (**A**), full-thickness resection back to chest wall (**B**), final skin closure after mastopexy medial and lateral advancement of fibroglandular tissue along chest wall (**C**). If this resection elevates nipple–areolar complex and creates asymmetry (**D**), a future contralateral breast lift could be considered.

POSTOPERATIVE CARE

Drains are rarely required in standard partial mastectomy cases, as any seroma will generally be reabsorbed. With more extensive dissections, such as the donut mastopexy lumpectomy, fluid accumulation can become more pronounced and may require postoperative aspiration on occasion. In recent years, we have started to occasionally place 15 French round Blake drains overnight to avoid excessive fluid accumulation in the dissected breast that might distort the oncoplastic closure. These drains are typically removed either prior to discharge if kept overnight, or on postoperative

day 1 in the clinic.

Despite more extensive resections and breast remodeling, postoperative care is very similar to that seen with more traditional lumpectomies. Patients are prescribed narcotic pain medication, but often transition to nonprescription medications quickly. We do not give antibiotics beyond the perioperative dose unless there is some pre-existing medical need.

COMPLICATIONS

When using oncoplastic approaches, surgeons without formal training must determine which procedures they are comfortable performing solo. In addition to standard potential postsurgical complications, wound infection, fat necrosis, and delayed healing in the more advanced reduction mastopexy lumpectomy have all been reported with oncoplastic resections. Clough et al. also caution against aggressive undermining of the skin or breast gland from the pectoralis when the native breast is fatty, as this type of breast increases the risk of glandular fat necrosis and subsequent wound complications. The blood supply of the external nipple arises from underlying fibroglandular tissue using major lactiferous sinuses rather than the collateral circulation from surrounding areolar skin, so nipple necrosis may occur if dissection extends high up behind the nipple.

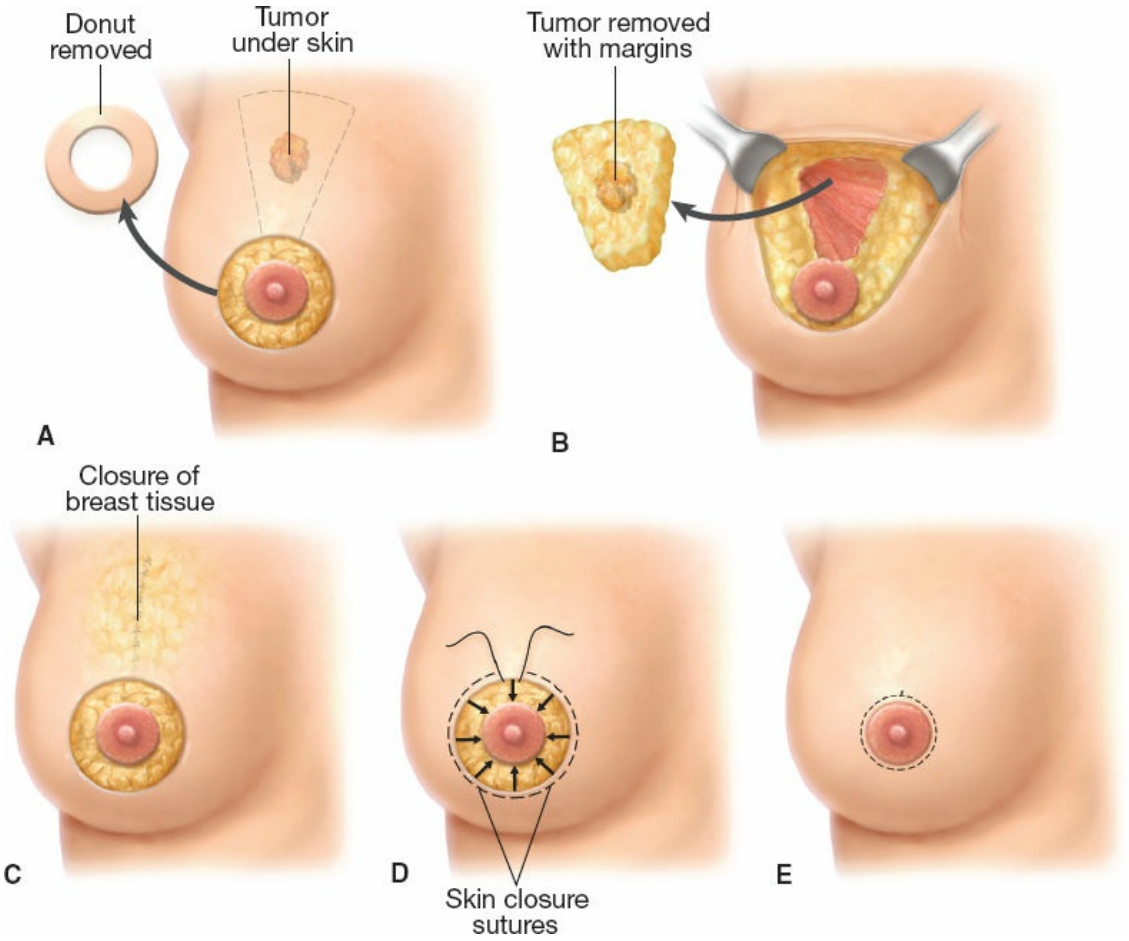

Figure 55.8. Donut mastopexy lumpectomy for upper pole segmentally distributed cancers: incision design and skin incision (**A**), full-thickness resection inside skin envelope (**B**), fibroglandular tissue closure inside skin envelope (**C**), purse-string skin closure to create a "neo-areola" (**D**), and final closure (**E**).

OUTCOMES

As with traditional lumpectomy, the main goal of all the oncoplastic approaches remains negative surgical margin resection. Excision of calcified lesions, masses, and the intended targeted lesion should be confirmed with specimen radiography during surgery. Additional oriented margins can be resected prior to mastopexy closure if specimen radiograph suggests inadequate resection, hopefully eliminating the need for a delayed re-excision.

While some centers utilize intraoperative analysis with frozen section or cytology to aid in decisions regarding the resection of additional segments of tissue, this is not our policy. What constitutes a true "negative margin" has been a topic of considerable debate. A recent consensus statement

from the Society of Surgical Oncology–American Society of Radiation Oncology has endorsed negative margins as being not at ink for invasive cancers and at least 2 mm for in situ lesions, which is now the standard of care at our institution. A recent review article reported a positive margin rate of 11.9%, despite a mean tumor size of 26 mm and a range up to 160 mm when oncoplastic resections are utilized.

If re-excision is needed for inadequate surgical margins, it can be done through the initial incision or possibly an angled “V” incision off of the initial incision to avoid cavitation of the scar. When the positive margin involves a minority of the specimen, only the involved margin(s) of the previous biopsy cavity need to be taken. When all the margins of resection are involved, mastectomy may be needed to attain satisfactory surgical clearance. In this instance, it may be technically challenging to include both the initial oncoplastic incision and the NAC in a subsequent total mastectomy and consultation with the plastic surgeon in the event of immediate postmastectomy reconstruction is mandatory. Cough et al. found that conversion to mastectomy was only necessary in 9% of the patients in the recent review, with 55% of those mastectomy specimens revealing residual disease.

Although there are few large studies of long-term outcomes specifically addressing the use of oncoplastic approaches in breast conservation, the results that are available are promising. One investigation from Europe followed 148 women for a median of 74 months (range 10 to 108 months) and only two were lost to follow-up. Among the 146 individuals available for analysis, there were only 5 (3%) women who suffered an ipsilateral in-breast cancer recurrence after 5 years and all had either T2 or T3 tumors at presentation. These authors argued that their recurrence rates for women with oncoplastic resections and concurrent radiation therapy were comparable, if not better, than the in-breast recurrence rates reported with standard breast conservation techniques. More recently, a meta-analysis comparing BCS alone to oncoplastic approaches found that patients treated with oncoplastic resections had lower rates of positive margins (12.3% vs. 20.6%), lower rates of re-excisions (4% vs. 14.6%), but higher rates of completion mastectomies (6.5% vs. 3.8%) when compared to their traditional BCS counterparts. This was accomplished with lower complication rates (15.5% oncoplastic vs. 25.9% traditional) and achieved lower rates of local recurrence (4.2% vs. 7% in BCS alone) over variable follow-up times, thus demonstrating the safety of these oncoplastic

procedures.

EDITOR'S COMMENT

The 1990 Consensus Conference on Breast Cancer from the National Institutes of Health (NIH) stated that breast conservation therapy (BCT) followed by radiation is the preferred method of treatment for stages I and II breast cancer. The performance of the primary excisional biopsy as well as its pathologic evaluation is a key component in the successful implementation of BCT both cosmetically and medically. Cosmetically, as the best cosmetic results are obtained at the time of the initial operation and with a single excision. The volume of resected breast has been shown to be directly correlated with the ultimate cosmetic outcome. The volume of resected breast tissue is, in general, greater with a re-excision than with a single adequate primary excision of tumor mass. Medically, because several recent well-controlled retrospective studies have shown a significantly elevated local recurrence rate when even focally positive margins were not re-excised. Although all the studies looking at the margin issue are relatively small and by necessity retrospective, the bulk of the presently available evidence favors obtaining negative margins whenever possible. Despite this evidence most centers report a rate of positive margins between 20% and 55% on the initial diagnostic biopsy.

Intraoperative pathologic consultation for breast biopsy is among the most frequent (16% to 62%) as well as the most difficult. The problem is that there is no perfect way to examine margins, especially in the intraoperative setting. Pathologically, there is no standardized sampling method with most noncytologic methods assessing only 10% to 15% of the surface of a relatively rounded breast lesion; nor is there a standardized definition of what constitutes a "negative margin." de Mascarel has calculated that to go from a 90% probability of cancer detection to a 99% probability triples the number of blocks needed to be examined which is doubled again to approach 100%. Carter suggested that it would take 3,000 sections, 6 μm thick, to fully evaluate the margins of a 2 cm breast biopsy, an impossible task intraoperatively and a formidable and impractical task postoperatively. Thus presently available techniques provide only an estimation of margin status. Even when permanent

pathology shows a negative margin, re-excision may show disease in up to 25% of the cases.

Oncoplastic techniques have become more widely used as surgeons are taking bigger specimens and margins as well as submitting shaved margins and certainly have allowed more patients to undergo BCT. These techniques range from the very simple such as using a parallelogram to improve simple standard curvilinear excisions to those that incorporate reduction mammoplasties that leave the patient with more cosmetically pleasing breasts. Most oncoplastic surgeries can be performed by all surgeons without specific plastic surgery training. Cadaver courses are now actively training surgeons on how to incorporate more advanced procedures into their practice. These procedures are needed when excising excess skin and reshaping the breast.

One of my favorite tools after BCT is a scaffolding technique using a lattice of 3-0 prolene just under the skin to not only minimize the cavity but also buttress the skin so it does not sink in after a relatively big excision. There is also a new three-dimensional surgical implant made of a bioabsorbable material that can improve cosmesis as it fills the excision cavity and is absorbed over months. More importantly is its value in more accurately targeting accelerated partial breast irradiation and thus minimizing the dose of radiation with resultant improved cosmesis. The device is absorbed over time but the titanium clips remain permanent marking the cavity site for follow-up screening. The main drawback is the cost of the device.

Upper pole lesions of the breast can be removed with a variety of techniques: round block, crescent mastopexy, batwing resections. The upper inner quadrant is commonly known as no man’s land as it results in an unsightly scar along the cleavage. In my view, a round block technique is ideal for lesions in this area as the incision is made in the areola, a flap is raised over the lesion, and the index lesion removed. Crescent mastopexy requires de-epithelialization around the limbus of the areola and is used for correction in the position of the nipple. Lower pole lesion can be accessed easily from a reduction mastopexy or J or V plasty type of scar. A Benelli or double donut incision can be used to access any location in the breast with good cosmetic results as well as a lift. These advanced types of procedures require additional training and experience.

There is no prospective randomized trial comparing oncoplastic procedures with BCT alone. However, there is a recent meta-analysis that compared BCT (n = 5494) to oncoplastic reduction procedures and those that utilized oncoplastic flaps (n = 3165). All groups had similar percentages of in situ disease and positive nodes. Lumpectomy specimens were three to four times bigger with oncoplastic procedures and positive margins much less (12.2% for flap reconstruction and 12.4% for oncoplastic reduction versus 20% for BCT alone, $p < 0.0001$). Interestingly, complications were actually significantly less ($p < 0.0001$). Not unexpectedly satisfaction was significantly greater by about 10% ($p < 0.0001$). Recurrence was also reported as significantly less in the oncoplastic groups but the mean follow-up time for BCT was significantly

longer so it is unclear that this will remain so.

Pitfalls of oncoplastic surgery included dissection inferior to the inframammary fold which results in lowering the breast and poor cosmesis; dissection to medial resulting in a unibreast; unequal marking of the NAC resulting in asymmetry; incorrect marking of medial and lateral breast borders resulting in poor contour and dog ears and comprise of the nipple blood supply resulting in NAC ischemia and necrosis.

Advantages of oncoplastic surgery are that it allows major resections (20% to 50% of breast volume) without causing deformity, extends the indication for BCT without compromising oncologic goals or aesthetic outcome and avoids the need for secondary reconstruction.

56 Breast Reconstruction Following Mastectomy

James N. Long, John B. McCraw, Jorge I. de la Torre, and Luis O. Vásconez

As reconstructive surgeons, we are tasked with recreating that which has been lost. Indeed our history shows an unending search for the most ideal means by which to accomplish “restoration of form.” In the context of modern breast oncology, we are called on to recreate a breast mound that is aesthetic in its shape and contour while also achieving symmetry with the unoperated side. These goals must be accomplished without handicapping any future treatment for breast cancer while keeping the operation manageable, reproducible, and most importantly safe for the patient. Surgical changes in the modes of treatment for breast cancer have been dramatic since Halsted described his radical mastectomy. We now strive to diagnose disease in its earliest stages, which has made possible modern breast-conserving therapies. Modern breast reconstructive techniques are in a continuous state of evolution, attempting at every turn to improve the cosmetic appearance and function while reducing morbidity. Presently our task is made easier due to the smaller defects produced by newer ablative oncologic techniques. Until the late 1970s to early 1980s, reconstruction of breast was mostly done as a delayed procedure, months or even years after mastectomy. At that time, a number of concerns in performing immediate breast reconstruction existed. First and foremost among these concerns was the question of oncologic safety in immediate reconstruction, especially with the idea of reconstructed tissues hiding local cancer recurrence. In addition, there was concern over possible seeding of breast tumors throughout the chest or donor site. Some surgeons even posited that immediate breast reconstruction could interfere with adjuvant chemotherapy, whereas others feared these lengthy one-stage procedures would increase complication rates.

The advantages of immediate reconstruction are now quite clear and one very important improvement is found in not having to surgically reexpose the mastectomy site to achieve reconstruction. Furthermore, the

patient sustains an emotional benefit from the one-stage procedure, which also serves to diminish the total length of treatment. Many studies have now been completed that have sought to definitively address those concerns surrounding immediate breast reconstruction. From an oncologic safety perspective, most local recurrences are now known to occur either at the subcutaneous tissue margins or along the scar within about 3 years after mastectomy. This has been found to be true even in the patients who have received immediate breast reconstruction. Consequently, recurrences are usually detected with palpation or inspection in both reconstructed and nonreconstructed groups. To address concerns over putative seeding of the donor site, reconstructive surgeons, in cooperation with their oncologic surgery colleagues, have settled on a system, which uses separate surgical teams; this practice includes the use of different instruments, nurses, and surgical staff. To allay concerns over the prospect of immediate reconstruction causing delay in the initiation of adjuvant chemotherapy, a study was performed at the University of Alabama at Birmingham (UAB) comparing a group of 125 patients who underwent immediate reconstruction with a similar group of patients who did not undergo reconstruction. This study demonstrated that the great majority of patients who underwent immediate reconstruction were able to initiate adjuvant chemotherapy within 6 weeks of mastectomy and reconstruction. Counterintuitive to the initial presumption, a significant percentage of patients undergoing mastectomy without reconstruction experienced delayed initiation of adjuvant chemotherapy beyond 6 weeks as a result of the persistence of seromas along the axilla or from mastectomy flap necrosis. The overall complication rates for these two groups of patients were identical (18%).

Breast reconstruction was conceived to address defects of anatomy, and for this reason it is not accurate to consider its implementation as cosmetic surgery but rather as an endeavor to achieve “restoration of form.” Cosmetic surgery implies intent to enhance a patient’s normal appearance rather that to restore it. Of course, it is expected that any reconstructive breast procedure would serve to improve the appearance when referenced against an unreconstructed mastectomy site or radiation injury, but not when weighed against normal anatomy.

When we look to the past, we know that patients with breast cancer were not routinely considered for reconstruction at the time of mastectomy. Although sound rationale for this position existed then, such

as larger tumors and suboptimal methods of reconstruction, these concerns are not usually germane in the current era. We now practice in systems that offer both earlier diagnosis and improved methods of reconstruction that are consistently reproducible and yield satisfactory results. Most mastectomies today are performed for totally curable lesions such as in situ, multi-focal, and minimally invasive breast disease. Out of these advances, we now favor routine breast reconstruction at the time of mastectomy for the patients with stages 0, I, and IIa. Presently, this subset circumscribes the vast majority of patients undergoing mastectomy. Indeed, there presently exists no scientific basis for denying these patients' immediate reconstruction.

When immediate reconstruction is not offered in this current surgical era, it most typically occurs because of a lack of surgical resources at the facility or out of deference to now archaic conventions. Women remain no different from men in their desire to maintain their form; and now, due to the effort of countless patients and surgeons, it is increasingly rare that a woman who chooses to undergo breast reconstruction is denied such opportunity. In the past, many had argued that breast reconstruction was cosmetic and thus nonessential, since reconstructing the breast does not add to the patient's function. These attitudes have been replaced by an understanding that restoring the patients' form does have a significant positive impact on their self-perception, allowing greatly facilitated reintegration into their premorbid life. Since the advent of managed care, breast reconstruction in women has moved from having no financial justification to, in most cases, requiring none. When tumor extirpation causes a physical deformity, treating surgeons should routinely consider reconstruction, understanding that now it is of benefit to their patients and in most cases approved by third-party payers. While breast reconstruction serves as a critical component of the overall process of cancer rehabilitation, it is also vital to restore the patient physically, emotionally, and spiritually. In addition to the psychologic benefits realized from reconstruction, the methods used to achieve these aims have also shown themselves advantageous in the treatment and prevention of radiation injuries of the breast and chest wall. It is clearly recognized that radiation therapy causes a vasculitis that can progressively change skin, muscle, and bone over time. Higher radiation dosages, particularly when concentrated in a localized area, may result in fibrosis of the pectoralis muscle and ischemic necrosis of the costal cartilages and sternum resulting in late

disruption of the overlying skin. Though radiation injuries are less common now than in the past, they still occur in spite of continuous refinements in technique. This is important to consider because in younger women the progressive vasculitis of radiation therapy may cause problems 20 or 30 years after treatment. No matter how carefully performed, radiation therapy will produce a quantity of ulcers, lumpectomy-radiation failures, and other problem wounds that can be best corrected by resection of the irradiated area and coverage of the defect by introducing well-vascularized tissue. When resection of the chest wall is indicated, myocutaneous flaps are known to be indispensable in achieving a safe, durable closure of the wound.

THE IDEAL TOTAL MASTECTOMY

From the perspective of the reconstructive surgeon, the ideal total mastectomy should preserve the pectoralis major muscle and all of the skin that is not essential to tumor resection. When this approach is used, the functional preservation of the shoulder and soft tissue coverage of the ribs is achieved. Extensive skin excision results in a tight closure and is not shown to decrease local recurrence or enhance patient's survival. The removal of this redundant native tissue does however make reconstruction significantly more difficult. Tissue expanders cannot overcome a large skin deficit and the need for more complex autologous flap reconstruction is virtually assured when a mastectomy with radical skin resection is performed. The difference between laxity and tightness is usually a difference of about 2 cm of additional skin with each mastectomy flap. The addition of 4 to 6 cm of skin to the closure is remarkably helpful to any intended reconstruction and is often a determining factor in whether a myocutaneous flap will be required to correct the deformity.

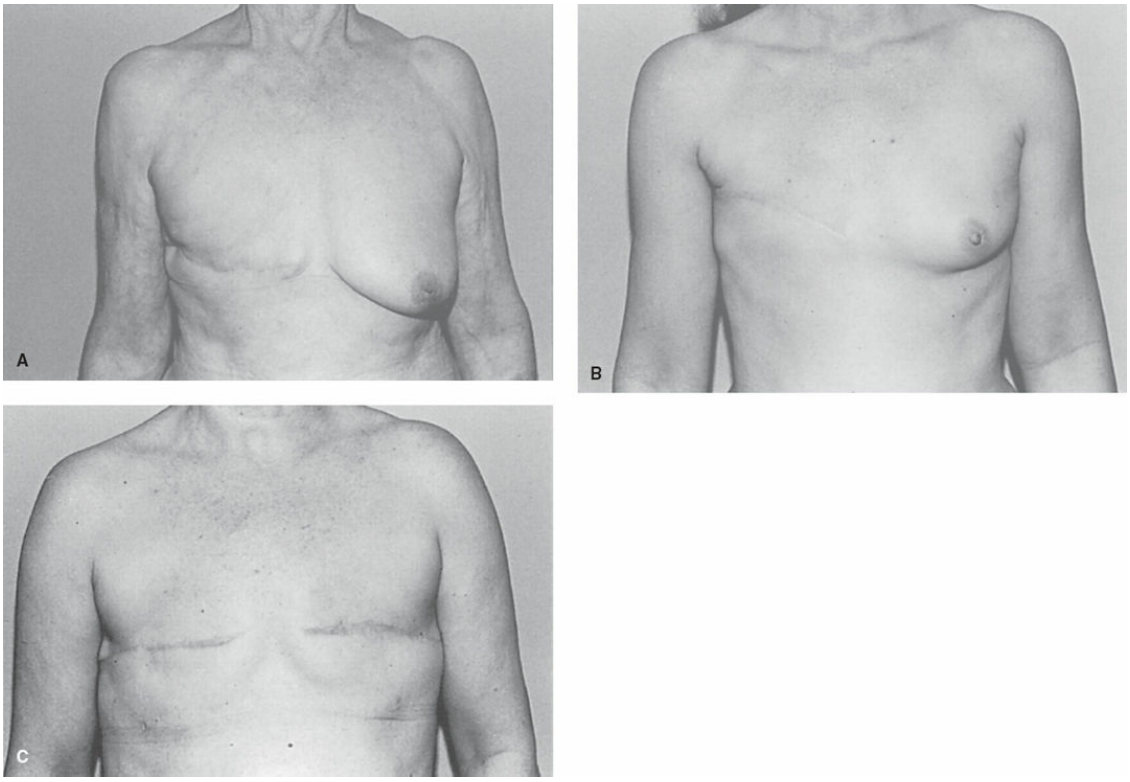

Figure 56.1. A comparison of favorable and unfavorable incisions. **A.** The most favorable low and oblique incision falls in a good line of skin tension and is well hidden. **B.** The high oblique incision, even though higher, is more easily expanded and gives a better scar since it rests in the lines of skin tension. Though inferior to the low oblique, it is still preferred over the common horizontal or Patey incision. **C.** The Patey horizontal incision offers the least favorable scar in terms of unreconstructed function while also limiting reconstructive options.

The placement of incisions is the other key factor that determines if mastectomy scars will be favorable. Here, the leading consideration should be placing incisions along the lines of skin tension. To identify the direction of these lines, pinch the skin, which accentuates the wrinkles native to the resting lines of skin tension. When incisions adhere to these lines precisely, healing occurs with the best chance of avoiding prolonged redness as well as widened or hypertrophic scarring. We favor the complete skin-sparing periareolar incision, with superior-lateral extension when needed and where practicable. When prior biopsy sites preclude the use of skin-sparing option, an elliptical incision is chosen to include the nipple, areola, and prior biopsy site. Either will provide adequate access for any mastectomy. Once complete with resection, we retain all skin redundancy in the closure to assist in any delayed reconstruction. The

worst choice for a closure in a patient who will eventually have a breast reconstruction is the transverse Patey incision. It is inelastic and unexpandable and results in the least attractive scars (Fig. 56.1A–C).

NIPPLE-SPARING MASTECTOMY

In selected patients, particularly those undergoing prophylactic mastectomies for BCRC 1 to 2 nipple-sparing total mastectomies are presently being performed. If this option is chosen, the breast tissue in the undersurface of the preserved nipple should be sent to pathology. In most series of nipple-sparing total mastectomies, the incidence of partial or total nipple necrosis approximates 20%, Although selected series show much less.

PARTIAL MASTECTOMY

Occasionally still unrecognized is that any partial breast deformity is preferable to a complete one. Replacement of up to 50% of the breast volume without the need for skin is a relatively simple reconstructive challenge. This can be accomplished with an autologous latissimus flap in a single stage. The usual skin defect of the non–skin-sparing mastectomy, which approximates 7 cm by 15 cm, can also be readily corrected with the latissimus flap. The favorable nature of the partial defect is a sound reason to choose lumpectomy and radiation when indicated by tumor size and location. When the planned lumpectomy is anticipated to cause breast deformity, even when planning to remove the nipple, breast-conserving therapy is still tenable with good aesthetic outcomes using the latissimus or its perforator variants. Although a partial central mastectomy will deform the breast, the deformity of a complete mastectomy will always be worse than this partial defect. The loss of the central breast and nipple are relatively simple to reconstruct and can be done before or after radiation.

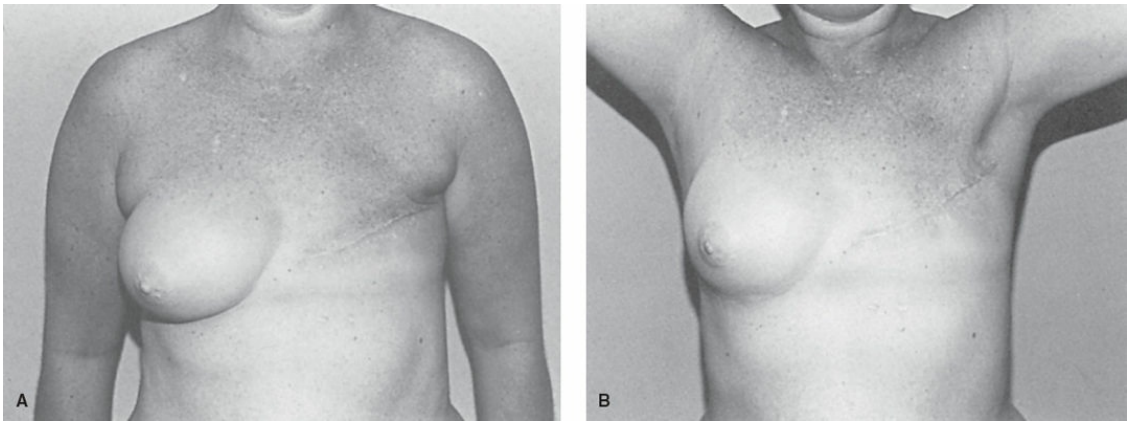

Figure 56.2. A, B. Typical modified radical mastectomy with extensive skin resection. The skin tightness is noticed at 90 degrees and limits shoulder motion beginning at 130 degrees. Because of the scarring, the skin between the incision and the inframammary fold cannot be used in the breast reconstruction and must be replaced by autologous tissue.

The skin-sparing mastectomy limits the skin excision adequate for tumor removal, which includes the nipple, the biopsy site, and any breast skin that is within 1 to 2 cm of the tumor. In most patients with stage I and IIa tumors, this approach is reasonable since tumors are more often deep than they are close to the skin. Even when the tumor lies beneath the nipple, a wide skin ellipse is usually unnecessary. In such cases, the periphery of the ellipse or the margin of tumor excision can be upward 10 to 15 cm, far in excess of that which is required to adhere to any treatment protocol. A circular excision of the nipple/areola complex will typically provide satisfactory margins and exposure with far less impediment to a reasoned reconstructive plan. Axillary sampling (Sentinel Node) is possible through the same circumareolar incision, although an additional axillary incision may be needed. Skin conservation facilitates reconstruction by all methods and greatly improves the aesthetic result that can be achieved by autologous tissue. Even in cases where reconstruction will never be performed, there is no reason to excise the skin widely, except to achieve oncologic clearance. The reconstructive surgeon should not be a solitary voice in encouraging skin conservation. It is in the patient's best interest to avoid radical skin excision when glandular resection and limited skin excision provides the same margin of safety.

MODIFIED RADICAL MASTECTOMY WITH EXTENSIVE SKIN EXCISION

Until the early 1990s when advocates for skin-sparing mastectomy began to be heard, the mastectomy skin excised with the modified radical technique differed little from the standard radical mastectomy. Extensive skin excision became a cornerstone of mastectomy when Handley promoted the permeation theory of centrifugal tumor spread in 1915. Some practicing surgeons today still model their modified radical mastectomy after the description of Patey, employing radical skin excisions with the primary closure—a perceived necessity also promoted by Auchincloss and Madden. Their preferred methodology closely followed the original description given by Moore in 1867. Patey espoused the belief that removal of the pectoralis major muscle contributed little to the cure of breast cancer since the tumor seldom invaded the muscle, except in the case of close margins. Instead, skin permeation with tumor became his primary concern in tumor extirpation and so he attempted primary closure in only about half of his cases. Compared with the radical mastectomy, the Patey mastectomy is less radical with regard to pectoralis major muscle but just as radical in elimination of skin.

In the normal breast, there exists no tightness of either the skin or pectoralis major muscle and 180 degrees of shoulder abduction is the normal full range of motion. By comparison, the skin closure of the standard modified radical mastectomy typically causes skin tension at 90 degrees of shoulder abduction followed by limitation in shoulder motion beginning at 130 degrees of abduction (Fig. 56.2). In practice, the elliptical skin excision usually measures 10 cm by 17 cm, which is easily sufficient to result in skin contracture across the chest. A horizontal skin ellipse has the most deleterious effect on shoulder motion when compared to other incisions because of tethering of normally expansile skin at a site between the inframammary fold and the axilla. The usual transverse skin closure is also the most unfavorable scar for breast reconstruction since it crosses the skin tension lines perpendicularly, usually resulting in scar hypertrophy and mastectomy flap stiffness. The low, oblique scar is much more favorable as the scar tethers at a site normally fixed to the chest wall, the inframammary fold. Though still suboptimal, the vertical closure is less restrictive than the transverse.

Reconstruction of a patient who has had a modified radical mastectomy with extensive skin excision is equal in difficulty to reconstructing the one with a radical mastectomy deformity. Reconstruction in these patients cannot be accomplished by means of an implant or even a tissue expander

alone since all surrounding skin has been “recruited” to achieve closure of the mastectomy defect. Autologous skin flaps are then required to replace lost breast skin as tissue expanders cannot overcome the tightness of the initial skin closure.

RADICAL MASTECTOMY

In the radical mastectomy, skin resection is always extensive and resultantly produces chest wall tightness, visible ribs, and compromise of shoulder mobility. Radical mastectomies are rarely seen today, thanks to earlier diagnosis and an improved understanding of the natural history of breast cancer. Nevertheless, patients still present with these massive deformities created years ago when it was considered the standard of care (Fig. 56.3). Because of the inadequate soft tissue cover, in most cases it is impossible for patients to wear an external prosthesis. Reconstruction of this deformity is clearly not possible by means of implant or tissue expander alone and they require autologous reconstruction. Even under ideal circumstances, it is very difficult to achieve satisfying aesthetic reconstructions from radical mastectomies.

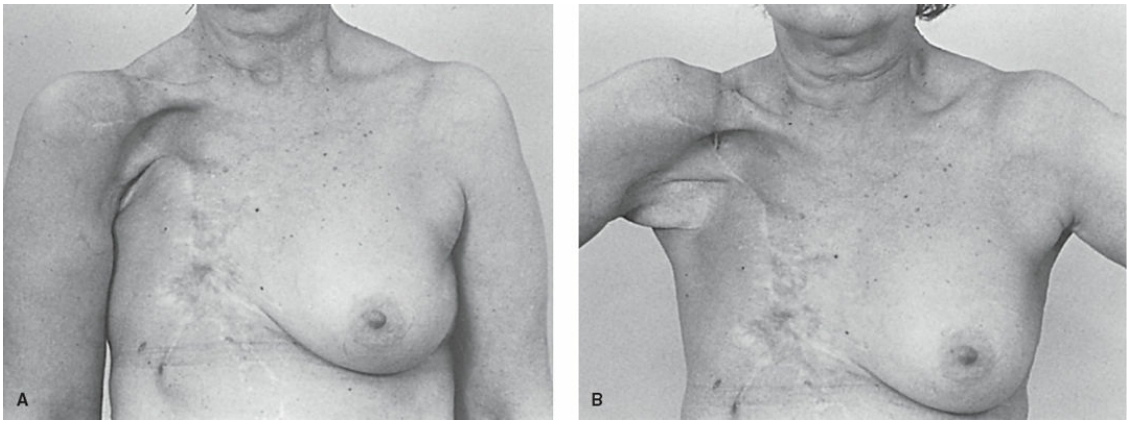

Figure 56.3. A, B. Classic Halsted mastectomy, which includes total resection of the pectoralis major and minor muscles, complete axillary dissection, and skin closure by secondary intention healing. This procedure was used into the 1980s because it was believed to prolong survival in patients with advanced disease.

MASTECTOMY AND RADIATION

When treatment includes postoperative radiation, the functional deformities caused by extensive skin excision are magnified. Radiation

causes scarring between skin and pectoralis major muscle as well as shrinkage of both skin and muscle; it may also have a direct causal effect on producing stiffness of the shoulder joint. Adding radiation to a modified radical mastectomy can extend the functional deficit to that of a radical mastectomy or worse. Because radiation causes persistent perivascular inflammation, it can act to damage the tissue permanently. For this reason, mastectomy flaps subjected to radiotherapy must be presumed to have poor vascularization. Therefore, much of the radiated breast skin must be discarded and replaced with autologous tissue. It is imperative to remove as much of the dyschromatic, visibly irradiated skin as possible. This discoloration provides the surgeon with visible evidence of tissue severely impacted by radiation damage. Though this skin may survive initial reelevation, ischemic necrosis can and often does develop many years later. Radiotherapy precludes an implant reconstruction in almost every instance since irradiated skin lacks pliability and is susceptible to late skin erosion from the underlying implant. Patients who have had augmentation can be considered for conservation therapy, which preserves the implant, but the value of this is unclear as these implants typically become firm because of the radiation, and mammography can also be impeded. Even with implants that are well positioned and intact, these factors combine to produce poor aesthetic results and arguably impaired surveillance.

HISTORICAL DEVELOPMENTS

The history of reconstructive breast surgery has several discrete periods, and the developments of each period have had a dramatic effect on the course of breast cancer surgery. From antiquity until recent times, healing of the mastectomy wound was the primary reconstructive concern in any extensive mastectomy procedure. Until skin grafting became tenable, radical mastectomies were allowed to heal by secondary intention. Small skin grafts were described as early as the 1870s but were not applied to the mastectomy deformity until the turn of the 20th century. Sheet skin grafting was developed in the late 1920s but was available in only a few major medical centers until after World War II. By 1950, only a few hundred surgeons were trained in sheet skin grafting, a technique that was not in general use until the Brown motorized dermatome became available. Elevation of breast skin flaps with primary closure of the mastectomy first appeared in the 1940s but was not accepted as routine until the 1960s. Breast reduction and nipple reconstruction were introduced in the late

1940s but did not gain popularity or safety until the 1970s. The first breast reconstructions were performed by means of tubed skin flaps or silicone implants starting in the early 1960s. In Europe, Tansini reported use of the latissimus dorsi myocutaneous flap for closure of radical mastectomy defects between 1900 and 1925. Alas, myocutaneous flap procedures were all but abandoned until their renaissance in the mid-1970s. Campbell reported his use of the latissimus dorsi muscle flap for chest wall reconstruction in 1950, but his method went unnoticed for another generation. By 1975, myocutaneous flaps were being used for delayed breast and chest wall reconstructions, but myocutaneous flaps were seldom used for immediate reconstructions prior to 1990. In the present, it is difficult to imagine oncologic breast surgery without the modern adjuncts of primary closure, skin grafting, and myocutaneous flaps.

PRIMARY CLOSURE

Extensive skin excision has been a past hallmark of radical, modified, and even simple mastectomies. In each method, breast skin was removed in anticipation this would improve the efficacy of the procedure. This practice was so accepted that it continued for 60 years before being subjected to scientific study. The various types of mastectomy are still differentiated by factors other than skin excision. For example, the modified radical mastectomy is a radical mastectomy in which the pectoralis major muscle is preserved and the simple mastectomy is a modified radical mastectomy without axillary node dissection. Patey's mastectomy is still considered less radical than the Halsted variant since pectoralis major muscle is preserved. However, Patey believed in extremely wide skin excision, in which only half of his mastectomies were primarily closed. Since the reports of Madden and Auchincloss in the early 1960s, primary closure was not considered harmful and thus achieved wide acceptance as the prevailing method. From the mid-1980s to early 1990s, extensive skin excision remained the standard of practice in mastectomy because of lingering suspicions that limited skin excision might be less effective in curing cancer, even though this belief had no scientific basis in fact. It will be interesting to see if our colleagues 50 years from now are as puzzled about our current practices as we are about the total breast skin excisions of the turn of the 20th century.

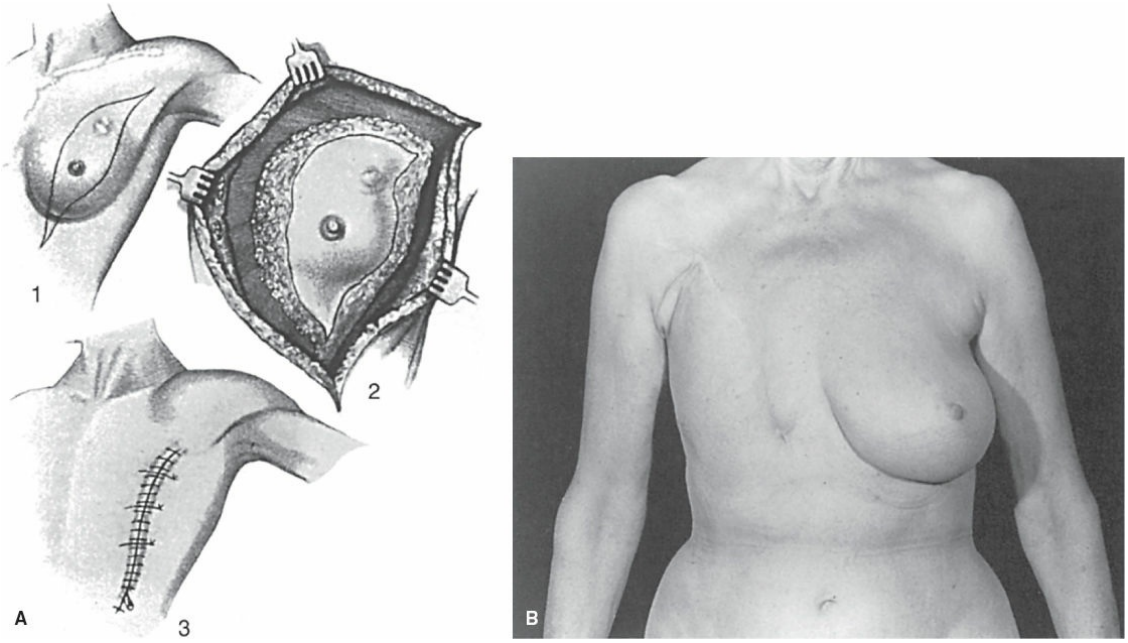

Figure 56.4. A. Illustration from Geschickter's diseases of the breast (1943). Note the extent of the proposed skin excision in this simple mastectomy making primary closure an obvious challenge. **B.** A 1979 clinical example of this mastectomy with a vertical closure demonstrates the same principles of wide skin excision, performed nearly 40 years later.

Primary closure in mastectomy surgery did not develop until the mid-20th century. The Halsted mastectomy, like other radical mastectomies in the early part of the 20th century, was rarely closed primarily. This procedure included resection of skin and breast tissue in a three-dimensional block (Fig. 56.4). This near-total removal of the breast skin was routinely used until the 1940s because elevation of breast skin flaps was believed to interfere with tumor resection by either spreading breast cancer or by leaving it within the tissues of the breast skin. At the time, it was presumed that the breast cancer permeated the entire breast skin, not just the part of the skin that was adjacent to the tumor. When total excision of the breast skin was eventually abandoned, it was replaced with such extreme resections of the skin in the modified radical mastectomy that primary closure remained the exception until the late 1960s.

SKIN GRAFTING

Primary healing of the radical mastectomy was rarely considered until sheet skin grafts became available in the 1920s. Until that time, very small, postage stamp–sized grafts were used. Beginning in 1870, small split-

thickness grafts and full-thickness grafts were used on the face. Most of these grafts were small since dermatomes had not yet been developed which would allow harvesting of larger grafts. In the 1920s, John Staige Davis popularized pinch grafts, which were harvested by shaving a “divot” of skin with a flat knife. This graft was a full-thickness graft in the center and a partial-thickness graft in the periphery to enhance the take of the graft. Even though these small grafts were available at the turn of the century, most mastectomies were nonetheless allowed to heal secondarily by scar epithelium.

Beginning in the late 1920s, Blair and Brown in the United States and Humby and Braithwaite in England popularized sheet skin grafts, which were taken with large handheld knives. These knives were variations on the straight razors of the day and required such dexterity that fewer than a hundred surgeons were trained in these techniques by the start of World War II. Most of these surgeons were those general surgeons who sought additional training in plastic surgery. In the late 1930s, calibrated drum dermatomes, such as the Padgett and Reese, were introduced. The motorized Brown dermatome was not developed until after World War II when it was conceived by Dr. Brown during his wartime imprisonment in Bataan. Even in the 1950s, only a few hundred surgeons in the world attempted skin grafting procedures, and very few of these were on mastectomy patients (Fig. 56.5).

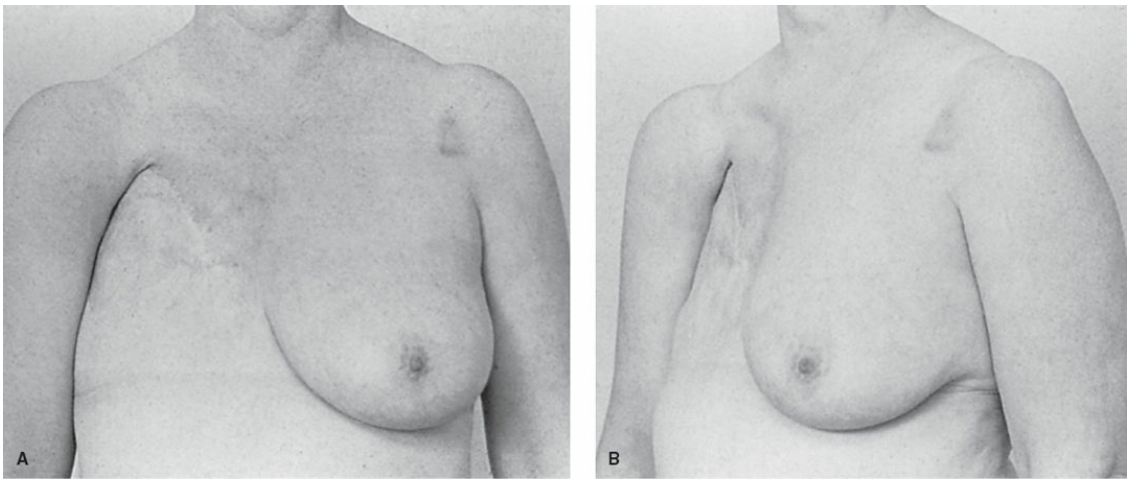

Figure 56.5. A, B. Example of a skin-grafted radical mastectomy done in 1978. The sheet skin graft was a major advance in healing the mastectomy wound.

EARLY FLAPS

In 1896 the latissimus dorsi flap was described by Igninio Tansini, a professor of surgery at the University of Pavia in Italy. In the early part of the 19th century, the breast was removed without elevation of skin flaps, which left a large circular defect taking a number of months to heal. The Tansini method used the same extirpative technique as the Halsted radical mastectomy, but the latissimus dorsi myocutaneous flap was transposed anteriorly to achieve wound closure. The purpose of the latissimus myocutaneous flap was to replace the pectoralis major and to provide skin from the back to close the breast wound primarily. Tansini's early 20th century description of the latissimus dorsi myocutaneous flap is virtually identical to that described independently by Olivari, McCraw, and Muhlbauer around the late 1970s. The Tansini method was the prevailing technique of mastectomy in Europe until about 1920 when Halsted made a grand tour of the European medical centers. Halsted said "Beware of the man with the plastic operation" because he thought that the latissimus flap was both "unnecessary and hazardous." At a time when intravenous fluids, transfusions, and anesthetics were in their early development, Halsted's statement was probably a reasonable one. Nevertheless, it sets back the legitimate use of myocutaneous flaps for breast or chest wall reconstruction for perhaps 50 years. Between 1920 and 1974, Tansini's procedure was abandoned and myocutaneous flaps were not used for immediate reconstruction of the breast until after 1980.

Because of the notable successes of Sir Harold Gillies in repairing World War I maxillofacial injuries, the tubed skin flap reconstructions he advocated became the dominant method of flap reconstruction until myocutaneous flaps were reintroduced in the mid-1970s. Tubed flaps were not applicable to immediate breast reconstruction because the transfer of the tube of skin from the abdomen to the breast consumed a period of at least a year and more than a dozen operations. Tubed flaps were impractical for use in treating radiation injuries since they did not carry an independent blood supply to the damaged area. Until the introduction of myocutaneous flaps, flap resurfacing of radiation wounds was seldom attempted because of high morbidity and frequent recurrence of wounds surrounding the flap. Even as late as the 1970s, tubed flaps were still being used for elective breast reconstruction (Fig. 56.6A–D).

SILICONE BREAST IMPLANTS

The introduction of silicone breast implants by Cronin and Gerow in 1964

was quickly followed by implant popularization led by a number of surgeons over the following 20 years. Their pioneering surgical work was conducted in collaboration with the Dow Chemical Company using polymers constructed from silicone.

Compared with previously available human breast implants, which were made of polyurethane foam, paraffin, or allogenic material, each of which had less than ideal characteristics, the silicone gel implants represented an historic medical breakthrough. This development also initiated the development of a completely new group of medical products derived from silicone, including silicone tubes, lubricants, and linings, which are relatively biologically inert. By the late 1960s, silicone gel implants had begun to find their way into the field of breast reconstruction. Early experience with these implants was not good because of fibrous encapsulation of the implant which occurred beneath the thin mastectomy skin flaps. The better soft tissue coverage of subpectoral placement improved results, just as the even better cover of autologous flaps improved it further. Over time, it became apparent that silicone implants were not as biologically neutral as had been hoped, and many local wound problems such as scarring, low-grade infection, and implant intolerance became causes for concern. Eventually, many of the early implant breast reconstructions failed because distortion produced an appearance known as the half-grapefruit shape, which accurately described the elevated, rounded, and firm implant (Fig. 56.7).

TISSUE EXPANSION

Tissue expanders were introduced in the early 1980s as an alternative to simple silicone implant breast reconstructions. These expandable implants were used to stretch the retained breast skin and create an oversized pocket with the goal of decreasing the encapsulation seen with the permanent silicone implant. Unfortunately, this method was initially applied in unfavorable candidates such as those who had undergone the Patey mastectomy with extensive skin excision; and it was the poor patient selection that gave the technique an initial but unwarranted bad reputation (Fig. 56.8). As experience was gained, the tissue expander became one of the predominant means of breast reconstruction in the patients who had not undergone extensive skin resections. The device is useful at the time of mastectomy to preserve the subcutaneous space, thus preventing primary contraction of mastectomy flaps. Over a period of weeks the device is

gradually inflated, which typically does not cause problems with wound healing. The ideal candidate for placement of an implant or tissue expander is one who is neither thin nor obese and who has a firm rounded and small opposite breast (or previous breast augmentation), a horizontal mastectomy scar with normal surrounding skin, and a well-preserved pectoralis muscle. These prosthetic devices should not be placed under tight, thin, or irradiated skin, even when placed beneath pectoralis muscle.

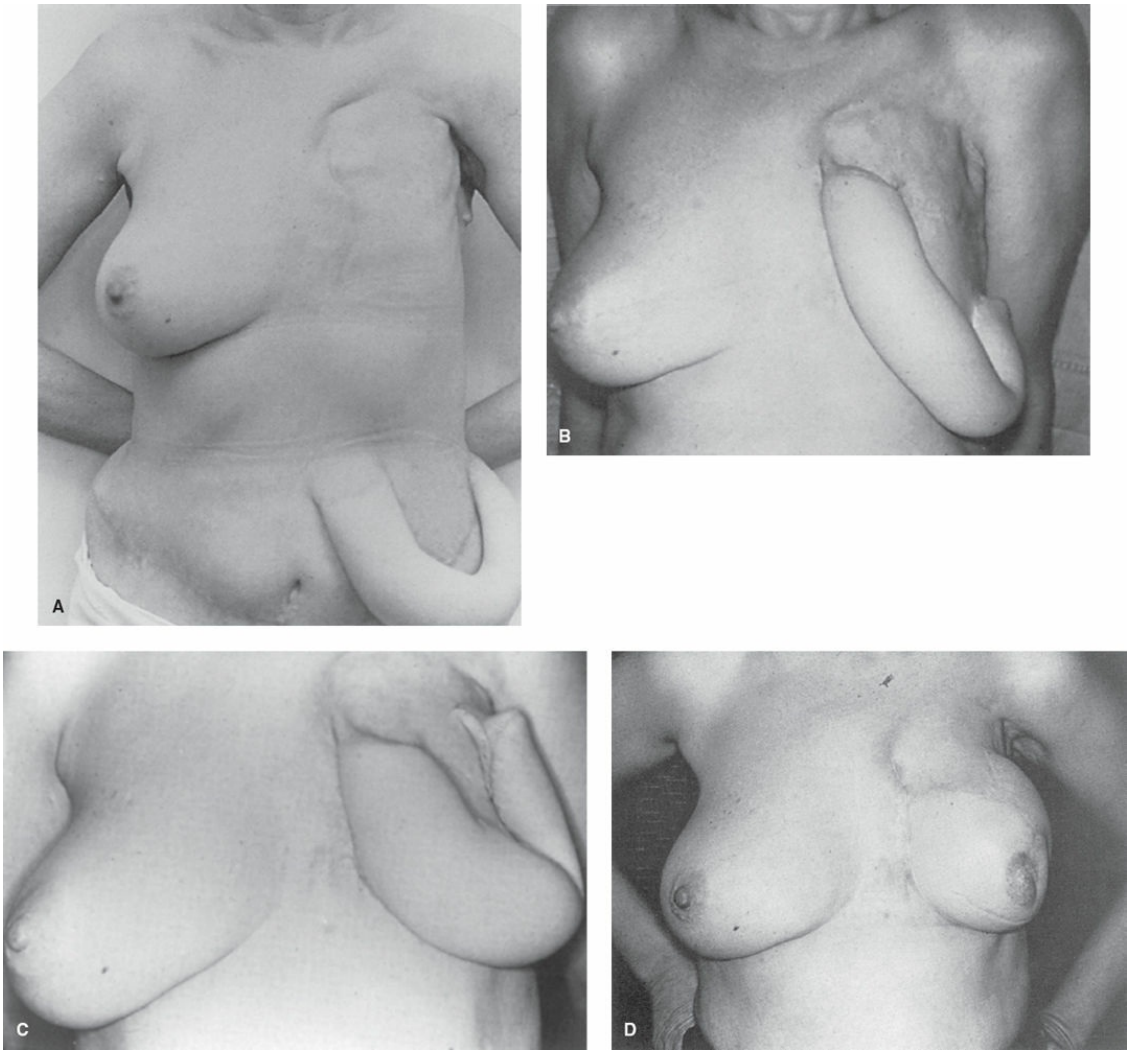

Figure 56.6. A–D. Correction of a radical mastectomy defect with a "waltzing" tubed flap created from abdominal panniculus. The flap, once created, is waltzed up the flank with periods of delay between each step until tissue is in proper position to craft a new breast mound.

Advantages of using implants and tissue expanders for breast reconstruction include simplicity, shortened operative times, and inpatient hospital stays. The disadvantages include the relatively high complication rates up to 30% to 40% that have been seen. Such complications include skin necrosis of the overlying flaps, exposure of the implant, disruption of the mastectomy scar, and, less commonly, infection. Regrettably, these complications in most cases lead to the removal of the implant. Even if successful expansion is achieved, the results can still be unsatisfactory. A fibrous capsule will form around all implants; and if a capsular contracture develops, it can result in both visible and painful deformities. Capsular contractures tend to cephalically displace the implant which produces a

rounded, nonptotic, and unnatural appearance. In addition, contractures lead to thinning of overlying muscle and skin. Despite these failings, tissue expansion continues to enjoy popularity among surgeons and patients throughout the United States. Selected surgeons and institutions have learned to achieve often excellent results using tissue expanders with acceptable complication rates.

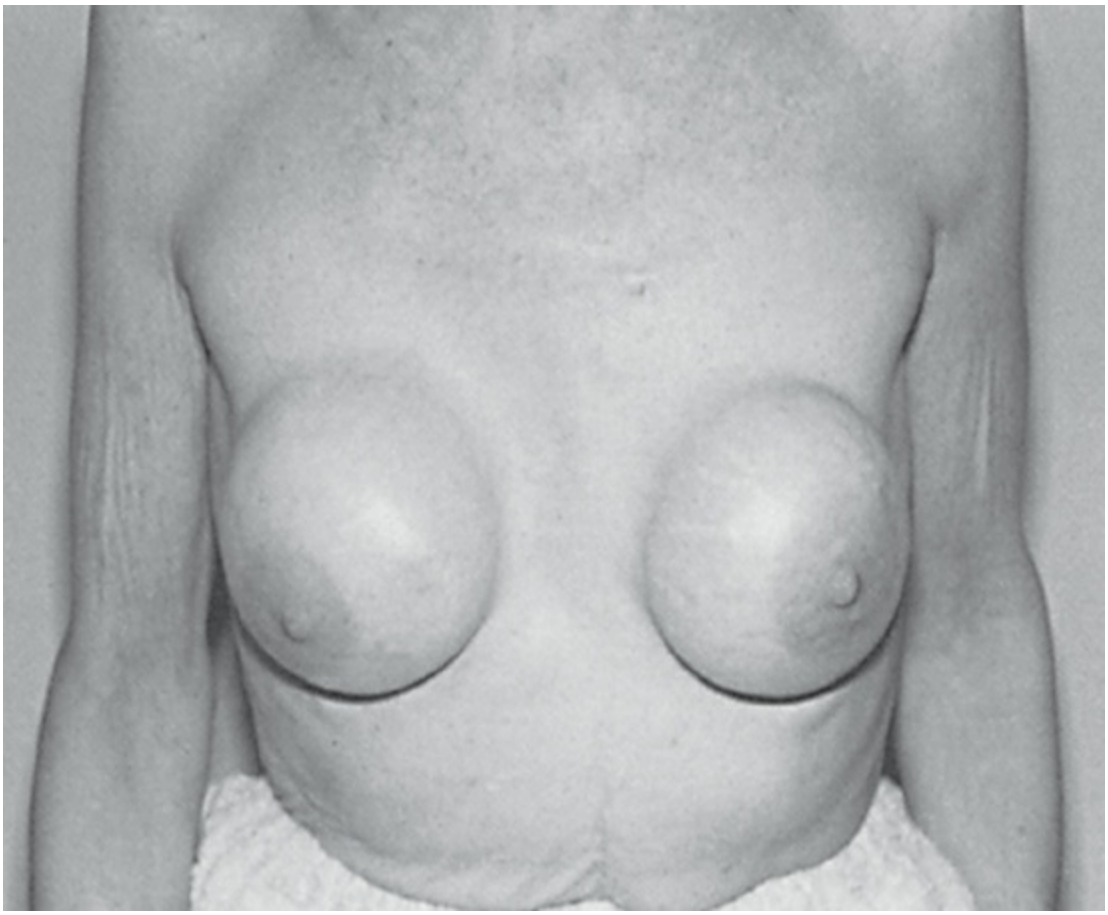

Figure 56.7. Silicone implant reconstruction of a subcutaneous mastectomy, a procedure popularized in the 1970s. The fibrous capsule around the silicone implant eventually constricts causing firmness, unnatural shape, and contour with elevation of the implant.

The most ideal circumstance in which to consider tissue expansion exists when a skin-sparing mastectomy has been performed and neither expansion nor recruitment of skin is required. After the desired dimensions are reached, the expander is removed and a permanent implant placed. Alternately, an autologous myocutaneous flap can be fashioned to reconstitute lost breast volume. As permanent implants are improved and skin-sparing mastectomies gain an even broader based acceptance, tissue

expansion has increased in its popularity. Presently this two-step type of breast reconstruction—expander and replacement with a silicone implant—is the most common method of breast reconstruction performed in approximately 70% of all reconstructions in the United States.

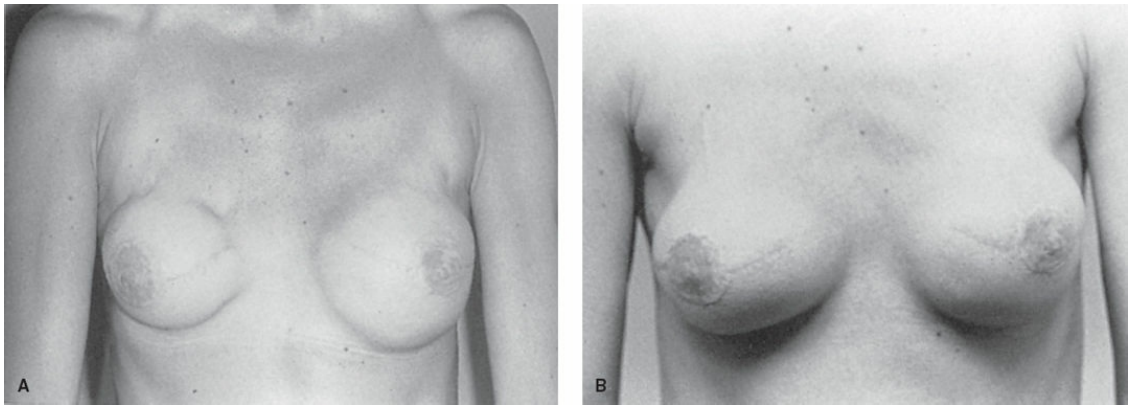

Figure 56.8. A, B. Encapsulated silicone implant reconstruction corrected by tissue expansion. The capsule is first excised then a tissue expander is used to create an oversized pocket for the implant.

MYOCUTANEOUS FLAPS

Subpectoral reconstructions were expected to solve the problem of periprosthetic scarring by placing implants beneath the pectoralis major muscle (as has been observed for cosmetic augmentation mammaplasties). This reduced the incidence of symptomatic capsular contracture from ~100% to <30% during the first 2 years. This marked reduction in contracture was due to a reduction in capsule formation around the implant. In retrospect, this phenomenon provided the first evidence of the protective effect of muscle in preventing periprosthetic scarring and thus capsular contracture (Fig. 56.9). Unfortunately, the skin defect of the modified radical mastectomy was too extensive to correct with an implant, even if capsule formed only beneath the pectoralis muscle.

The latissimus dorsi breast reconstruction was reintroduced in 1977 by Schneider, Hill, and Brown and was popularized by Bostwick, Vásconez, and Jurkiewicz, and others. The latissimus dorsi breast reconstruction offered several breakthroughs with immediate replacement of resected breast skin, replacement of the pectoralis muscle with the latissimus dorsi muscle, and complete muscle coverage of the implant needed for volume restoration. Replacement of the pectoralis major muscle, the anterior axillary fold, and the missing skin revolutionized the reconstruction of the

radical mastectomy defect (Fig. 56.10). The muscular coverage of the implant was anticipated to reduce the rate of capsular contracture to an acceptable level, which it did for 1 to 2 years. However, after 5 years, results were disappointing because of either firmness or contour deformities in at least one third of the patients treated. At the time, the latissimus dorsi myocutaneous flap gave the best aesthetic results with breast reconstruction following radical mastectomy. From the time of its description in 1977 to the height of its popularity in the early 1980s, the latissimus breast reconstruction was recognized as the standard by which all methods of breast reconstruction would be measured. By 1985, the standard latissimus reconstruction was nearly abandoned in favor of either tissue expanders or the transverse rectus abdominis myocutaneous (TRAM) flap reconstruction because of the problems of shape and softness caused by the implant over time. If new implant designs solve the problems with capsular contracture, it is clear that the latissimus myocutaneous flap reconstruction will regain its previous popularity. Presently, the latissimus muscle, with or without skin, is being used with increased frequency to provide cover to the lower half of an expander or an implant. Often it eliminates the previous use of an expander, allowing for a one-stage type of reconstruction.

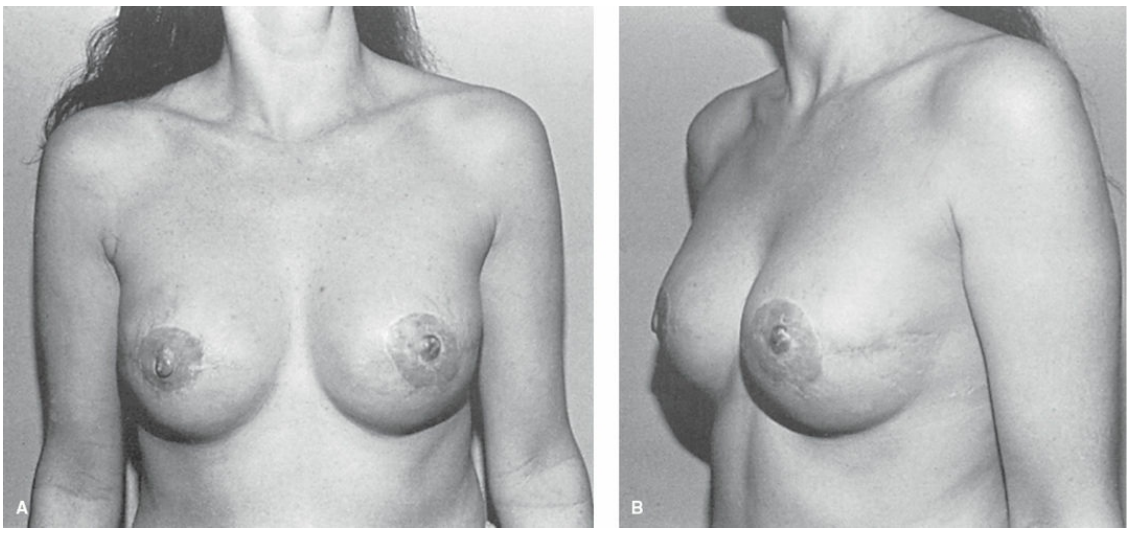

Figure 56.9. A, B. Placement of silicone implants beneath pectoralis major muscle at the time of a skin-sparing mastectomy. Reasonably good results can be seen with subpectoral implant reconstructions when the skin excision is kept minimal.

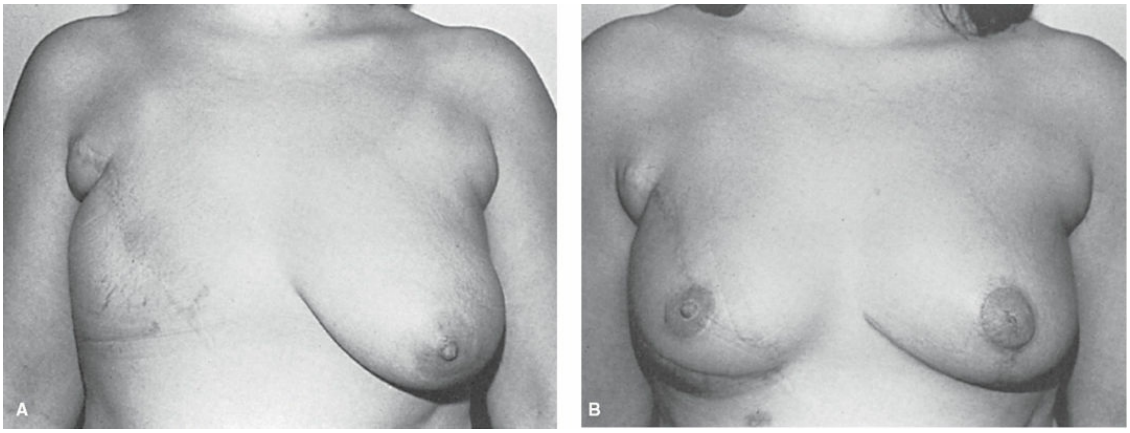

Figure 56.10. A, B. One of the first corrections of a radical mastectomy defect using the latissimus dorsi myocutaneous flap and reduction mammaplasty of the contralateral breast. The latissimus flap provides immediate replacement of lost breast skin and complete coverage of the implant. This allowed creation of a "tear-drop" shape and good symmetry for the first time in radical mastectomy reconstruction.

AUTOGENOUS MYOCUTANEOUS FLAPS

The era of autogenous myocutaneous flaps began in 1982 with the description by Hartrampf of the TRAM flap. This was the first breast reconstruction using only vascularized autologous tissue and it achieved the first uniformly good results with any type of mastectomy. Over a decade, this procedure reached a level of aesthetic excellence that was remarkable. In the late 1980s, the autologous extended latissimus flap was developed as an alternative procedure to the TRAM flap. In the 1990s, microvascular transfer of the TRAM flap including the sophisticated muscle-sparing or DIEP Flap (deep inferior epigastric) expanded indications for breast reconstruction to "high-risk" patients who were considered unacceptable candidates for pedicled TRAM flap reconstructions. High-risk patients included diabetics, smokers, obese, and those with prior radiotherapy. Looking to the future, as the socialization of medicine appears more clearly on the horizon, these complex and expensive procedures may be rationed or even lost for a time as was seen with Tansini's latissimus procedure.

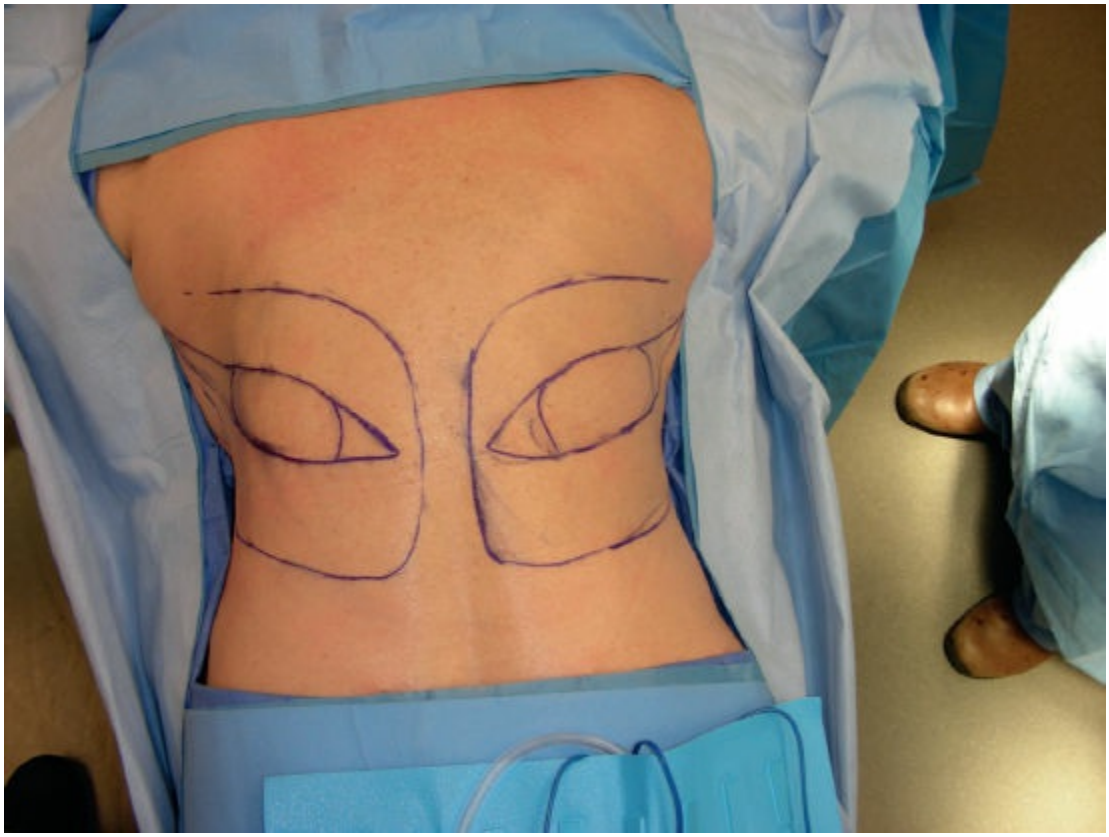

Figure 56.11. These markings, done preoperatively for planned immediate bilateral latissimus dorsi reconstruction with implants, show an outer line, which depicts the planned extent of muscle harvest. The inner ellipse represents the cutaneous portion of the flap harvest. The inner circles (within the ellipse) are the portion of the cutaneous paddle which will not be de-epithelialized in anticipation of this portion being used for reconstruction of the absent nipple–areolar complex and also nipple reconstruction. Note the transverse positioning of the cutaneous harvest which is designed to allow a closure which will fall beneath the back strap of the patient's brassiere.

The autologous extended latissimus breast reconstruction carries fat on the surface of the latissimus muscle to replace breast volume removed during mastectomy. In an average-sized patient, a 2-cm layer of fat on the surface of the latissimus dorsi muscle can provide 500 g of fat, and the skin paddle can carry an additional 300 to 500 g of fat. This total of 800 to 1,000 g is, in most cases, enough to replace the entire volume of breast tissue. If additional volume is needed, a small implant can also be used. The autologous latissimus dorsi flap can be raised at the time of the mastectomy, and an immediate reconstruction can be performed with only a modest increase in operative time (Figs. 56.10 and 56.11). With skin-

sparing mastectomy most reconstructions can be completed in a single stage. Delayed reconstruction, in contrast, requires a second operation producing less satisfactory outcomes than immediate reconstructions. The autologous latissimus dorsi reconstruction is particularly well suited for the modified mastectomy defect (Fig. 56.12). The autologous latissimus dorsi flap is also the procedure of choice for partial mastectomy defects over the more time-consuming and more morbid TRAM flap. If <50% of the breast volume is removed, the autologous latissimus flap can give excellent correction of lumpectomy-irradiation deformities and also in select patients that require mastectomy. Because of the excellent blood supply, the autologous latissimus dorsi flap is particularly useful in high-risk patients who have a history of smoking, diabetes, or marked obesity. Like the posterior-lateral thoracotomy scar, the donor site scar is usually very good. The functional loss of the latissimus muscle is unnoticed except in the most vigorous athletes. It is certainly possible to play golf and tennis and even climb ropes with the absence of latissimus function. It does leave a concave defect in the back. If done unilaterally, the opposite side may need corrective liposuction for symmetry.

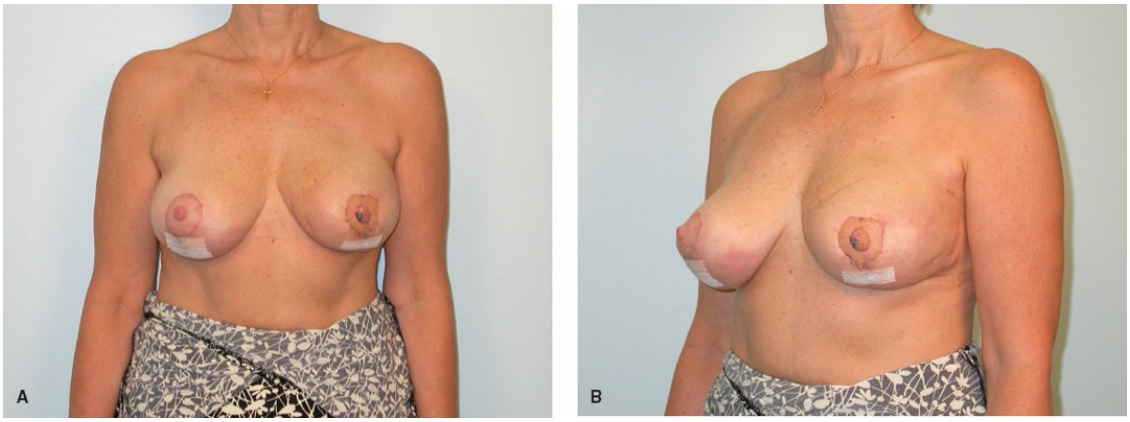

Figure 56.12. Photos (**A**) and (**B**) show a postoperative day #5 patient who underwent immediate reconstruction of the left breast after modified radical mastectomy (MRM) using a latissimus dorsi and implant reconstruction with nipple reconstruction done at the same time. The mastectomy was done through a mastopexy incision (drawn by the plastic surgeon) which gave the oncologic surgeon unparalleled access for MRM. Mirroring incisions were done on the right breast through which a concomitant right mastopexy for symmetry was also done in this patient whose desire was to avoid multiple operations. All that remains to be done on this patient is nipple–areolar complex tattooing on the left, which can be done in an office setting under local

anesthesia. The results seen here are from one operative event seen at POD#5.

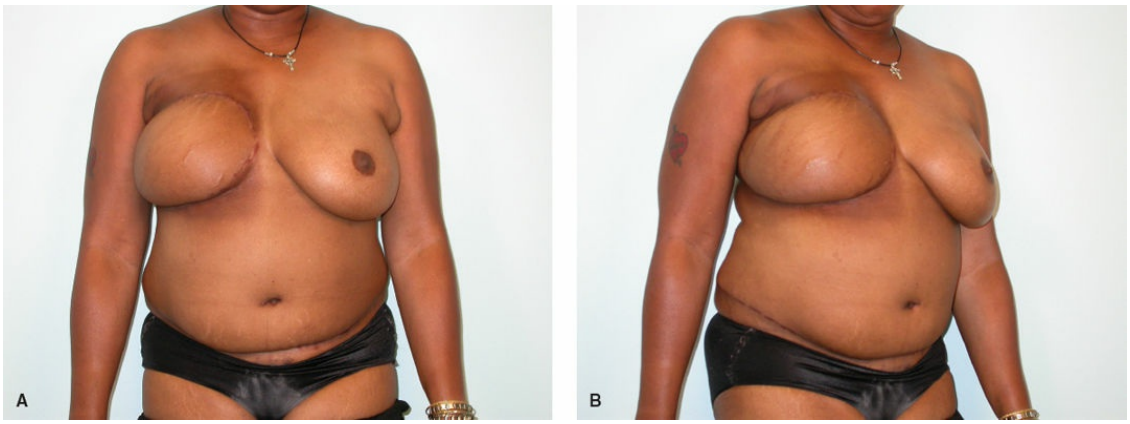

Figure 56.13. This photograph shows a patient who received radiation therapy to the right chest after mastectomy here at postoperative day 21 from a delayed ipsi-pedicled conventional TRAM. This photograph shows that large volume, single-pedicled conventional TRAM flaps are a reasonable option. This patient still needs nipple reconstruction on the right and a mastopexy/reduction on the left for symmetry.

The TRAM flap remains the gold standard of breast reconstruction. Since its description by Hartrampf in 1982, this procedure has gained worldwide acceptance as the procedure of choice for difficult reconstructions, particularly in mastectomies requiring extensive skin removal. In experienced hands, the TRAM flap is extremely reliable and gives predictably good results (Fig. 56.13). Although a long operative procedure, patients recover relatively quickly and can usually be discharged by the fifth postoperative day. Management of the abdominal closure with the TRAM flap is critically important since fascial bulges occur in 4% of the patients. The rectus muscle can usually be raised with only a small vertical strip of anterior rectus abdominis fascia (e.g., 2 to 3 cm in width) leaving a defect which can be easily closed primarily. Bilateral flaps are more difficult to close and synthetic mesh is frequently used as a tensioned onlay to carry the stress that would otherwise exist on the fascial closure. If patients are selected properly, true hernia formation is rare, with an incidence of 0.3% in 400 consecutive patients treated by Hartrampf. Overall, in most series, the incidence of hernia is 4%. The functional loss of a single rectus abdominis muscle is seldom noticed, and 95% of Hartrampf's patients believe their work performance and sporting

activities remained unchanged after surgery. Overall, the TRAM flap reconstruction is exceptionally well accepted by patients. When Hartrampf surveyed his first 300 patients, he asked two questions: “Was the operation worth the time and effort you have invested in it?” and “Would you recommend this method of breast reconstruction to other patients?” Both questions were answered affirmatively by 98% of the patients.

FREE TISSUE TRANSFERS

The modern era of plastic surgery has allowed free tissue transfers for breast reconstruction to gain acceptance in both immediate and delayed procedures treating extensive defects in high-risk patients (Fig. 56.14A–C). If the free TRAM flap is executed with a two-team approach, the operative time is similar to that required for pedicle TRAM flaps, and the free TRAM reconstruction has been shown to have a decreased complication rate and requires fewer revisions. Other free-flap donor sites are suitable and have begun to gain wide popularity over the past several years. These alternative flaps include the Superior Gluteal Artery Perforator (SGAP) flap, the Inferior Gluteal Artery Perforator (IGAP) flap, the Deep Inferior Epigastric Artery Perforator (DIEP) flap, the Superficial Inferior Epigastric Artery (SIEA) flap, and the transverse gracilis flap among others. Presently, the recipient artery for most microvascular breast reconstructions is the internal mammary artery. It provides an easier access, easier molding of the breast, and avoids the axilla, which invariably is subject to axillary sampling. The expense of these microvascular procedures may limit their practicality in a future dominated by cost benefit factors.

A clear description of the patient’s desires regarding breast reconstruction outlines the goals for reconstruction. As breast reconstruction techniques become more sophisticated and refined, so have the expectations of the well-informed patient. They desire a natural and symmetric appearance immediately after mastectomy. This may require ipsilateral or contralateral mastopexy, reduction, or even augmentation during surgery to fulfill these expectations.

Other factors that come into consideration when deciding on the type of breast reconstruction include the type of mastectomy (i.e., skin-sparing technique vs. the standard modified radical mastectomy), body habitus (thin women with scant abdominal donor tissue may not be suitable for TRAM reconstruction; obese women are more difficult to obtain a

satisfactory reconstruction with implants), contralateral breast size and shape, previous abdominal surgery, history of smoking, and of course the overall health of the patient.

Figure 56.14. **A, B.** Preoperative and postoperative views following a bilateral free transverse rectus abdominis myocutaneous flap breast reconstruction. **C.** The nipple reconstructions and tattooing are complete.

CONTRALATERAL PROPHYLACTIC MASTECTOMY

A number of patients elect to have a contralateral prophylactic mastectomy (CPM) at the same time of the mastectomy for cancer, even though it may not be warranted on purely oncologic grounds.

If a patient elects that option, immediate bilateral reconstruction is often performed. Possible reasons for patients to choose bilateral mastectomies include, cancerophobia; the fear of undergoing later a second mastectomy and even worse, chemotherapy for a second time; fear of frequent, involved medical checkups, including painful mammograms; and in a small part, the fact that reconstruction of the breast is a much improved procedure resulting often, in as good or better breasts than before (although without sensibility).

IMPLANTS AND EXPANDERS

Surgical technique for placement of im-plants and tissue expanders is relatively straightforward. The primary concern should be adequate muscular coverage as a tissue expander or implant placed subcutaneously will be fraught with complications. The pectoralis muscle is easily identifiable and provides muscular coverage for only the superomedial aspect of the implant. Dissection must continue inferolaterally beneath the serratus anterior and external oblique musculature. In addition, some of the fascia of the rectus muscle is elevated for coverage inferiorly. Submuscular dissection inferiorly is usually impossible to complete without separating some muscle fibers and fascia. Complete muscle coverage is often difficult or impossible.

Choosing the volume of the implant can be difficult. In such cases, the use of a postoperatively adjustable implant can simplify this task. A suction drain is placed, if felt needed, and the wound is closed in three layers. Perioperative antibiotics are recommended when placing prosthetic devices. Once the desired target volume is reached in the postoperatively adjustable implant, the adjustable prosthesis is replaced by a permanent implant of equal size.

Postoperatively, the surgeon’s main concern is for migration of the implant. During the first week after surgery, the spontaneous upward displacement of the implant may be partially controlled by light compressive dressings applied to the superior pole of the breast. This usually consists of an elastic bandage wrapped under the axillae to apply downward pressure on the implant. After 3 or 4 weeks, these maneuvers are no longer useful since at this time a capsule has formed around the implant and is not easily influenced by externally applied pressure. Because of that, most experienced surgeons place the implant 2 to 3 cm below the desired level, thus allowing for the assured capsular contracture, which will raise the implant.

Capsular contracture is a phenomenon over which surgeons have little control. It provides the advantage of shaping the skin to the implant but also the potential disadvantage of creating distortion. Because of this, it is impossible to predict the precise shape and volume of a breast reconstructed by means of an implant.

Patients who will not accept results that can change over time or who refuse major or multiple operations have been unsatisfied with this method. It should be stressed that implant reconstructions typically require

greater correction of the contralateral breast than do other methods of reconstruction, and this method is notably deficient in creating large and ptotic breasts. Because of this observation, it is often advisable to place a smaller implant in the normal breast to provide the desired roundness and fullness in the superior aspect of the breast, which matches the roundness of the reconstructed breast.

IMPLANTS AND EXPANDERS AND ACELLULAR DERMAL MATRIX

The pectoralis muscle provides coverage of only the upper half of an implant or expander. In an effort to provide coverage to the lower half of the implant, there are a number of maneuvers which can accomplish such coverage. They include a de-epithelializing thoraco-epigastric flap; using autologous dermis (obtained from the suprapubic area), a superficial epigastric flap; or with the use of allogenic dermis (ADM).

ADM is acellular cadaver dermis. It is made acellular and properly treated to decrease its antigenicity. It may come dehydrated or ready for use. An appropriate amount and size is patterned and sutured to the lower edge of the pectoralis major and to the chest wall inferiorly. The implant or expander is placed under the muscle and ADM. Drains are placed, because the ADM is associated with the production of considerable amount of fluid, seromas lasting several weeks in some cases. The ADM remains viable, and eventually attaches to the undersurface of the chest flap and is revascularized.

The technique is quite popular because of its simplicity and ease of availability of ADM. Seromas and infection are problems, as is the development of “redness syndrome” where the overlying skin appears quite red, simulating a superficial skin infection. Its cause is unclear, and it subsides spontaneously after a number of days. Nonetheless, surgeons may well treat with topical antibacterials such as silver sulfadiazine or systemic antibiotics for fear of missing an infectious process.

Recent modifications entail the introduction of a covered implant with ADM and its placement over the pectoralis major muscle in a one stage type of reconstruction. The one stage procedure with a number of modifications is gaining in popularity.

Prospective and comparative studies should be forthcoming to grade the effectiveness of the one- or two-stage procedure.

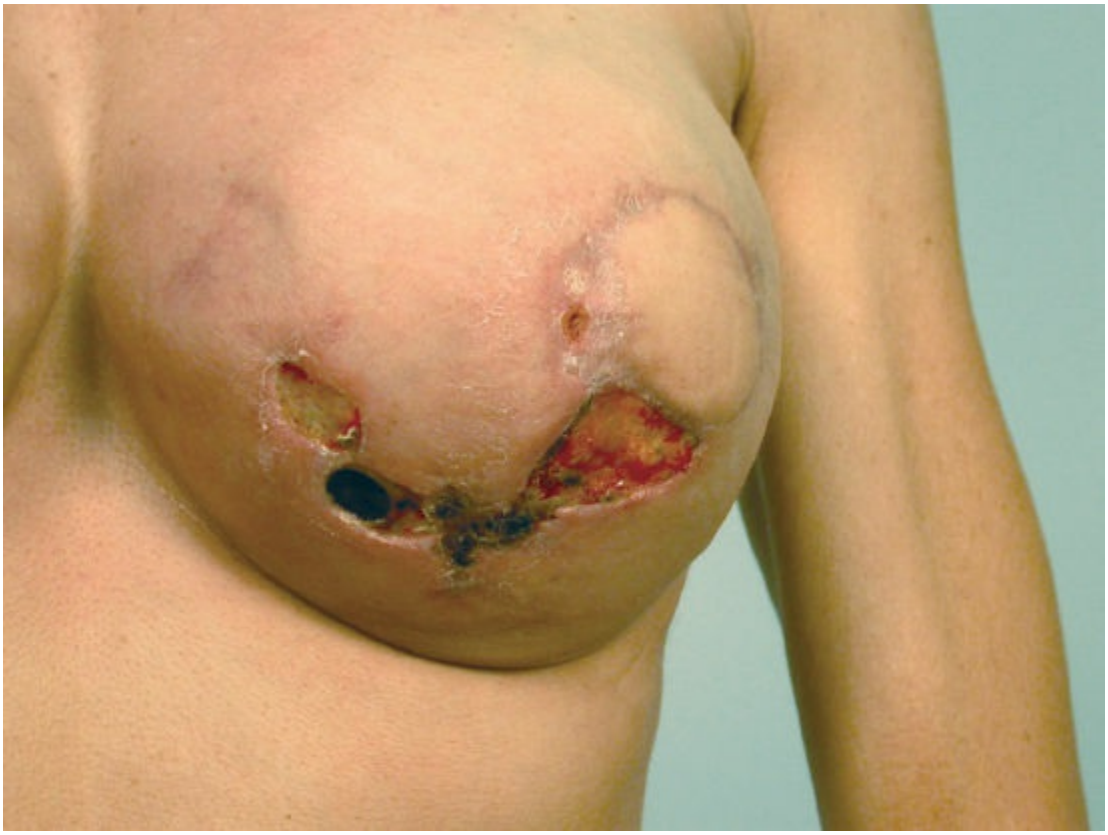

Figure 56.15. Wound healing problems in a patient who has undergone skin-sparing mastectomy, latissimus dorsi, and implant reconstruction with postoperative radiotherapy.

LATISSIMUS DORSI MYOCUTANEOUS FLAP

The patient is marked before mastectomy in the standing position. The skin island, which should be no more than 5 to 6 cm wide, is outlined transversely and in such a fashion so that the donor closure scar will be covered by the brassiere strap. If an immediate reconstruction is to be performed, the patient is placed on a beanbag and the oncologic surgeon performs the mastectomy. After the mastectomy, the patient is repositioned in the lateral decubitus position and maintained there with the use of the beanbag. If properly cleansed and the patient placed on a sterile drape over the bean bag, it is often unnecessary to cleanse and redrape. Alternately, the latissimus dorsi can be harvested first with the patient prone or in lateral decubitus position. The harvest site can be closed and the flap pocketed in the axilla. This minimizes the amount of patient repositioning intraoperatively.

After dividing the paraspinous origins of the muscle while preserving the thoracodorsal neurovascular bundle, the flap, which includes an ellipse of overlying skin, is carefully transposed on its humeral insertion toward

the anterior chest wall beneath a bridge of thoracic skin below the axilla (often, an axillary incision is needed, if not done for the axillary sampling). Once anteriorly, the latissimus dorsi flap can be sutured inferiorly to the anterior chest wall, and superiorly to the undersurface or the anterior aspect of the pectoralis major muscle to create a submuscular pocket within which an implant can be placed. It is imperative that the oncologic surgeon does not damage the thoracodorsal artery or vein during axillary dissection since this is the vascular axis to the latissimus dorsi myocutaneous flap when used as a pedicled flap for breast reconstruction. We suggest the preservation of the thoracodorsal nerve to maintain the volume of the muscle.

Postmastectomy patients who have received preoperative or postoperative radiation to the chest wall and axilla present an increased risk for skin slough and wound-healing problems (Fig. 56.15). The skin and scar of the anterior chest wall should be examined carefully for evidence of telangiectasia, dermal and subcutaneous atrophy, edema, and, in some cases, subcutaneous fibrosis.

Reconstruction is not contraindicated in irradiated patients if the latissimus dorsi flap used is healthy. Using the flap may provide the advantage of bringing a robust blood supply into a deficient region. However, irradiated skin is best excised if damage is considerable. Mastectomy skin flaps in these cases should be minimally elevated and in the submuscular plane. If an implant is used, it must be covered in its entirety with muscle. This method provides a margin of safety where if irradiated skin breaks down, the implant will be protected by the underlying muscle cover (Fig. 56.16A–D). There is a greater chance for severe capsular contracture in postradiated patients, but the latissimus dorsi myocutaneous flap is itself refractory to radiation-induced loss due to its rich blood supply.

TRANSVERSE RECTUS ABDOMINIS MUSCULOCUTANEOUS FLAP

The TRAM flap is the most common method of autologous breast reconstruction. It is an elegant technique that provides the greatest opportunity for symmetry with the contralateral breast while avoiding the use of implants, and when performed with skin-sparing mastectomy, it generally yields the most aesthetically pleasing result. The TRAM flap differs from every other myocutaneous flap in that its vascular supply is

more tenuous requiring much more delicate handling. Complications such as necrosis of the flap and development of a lower abdominal hernia can be troubling for both patient and surgeon. Nevertheless, the inherent characteristics of the flap are such that it provides versatility for the surgeon in restoring myriad defects as well as yielding lasting and gratifying results for patients.

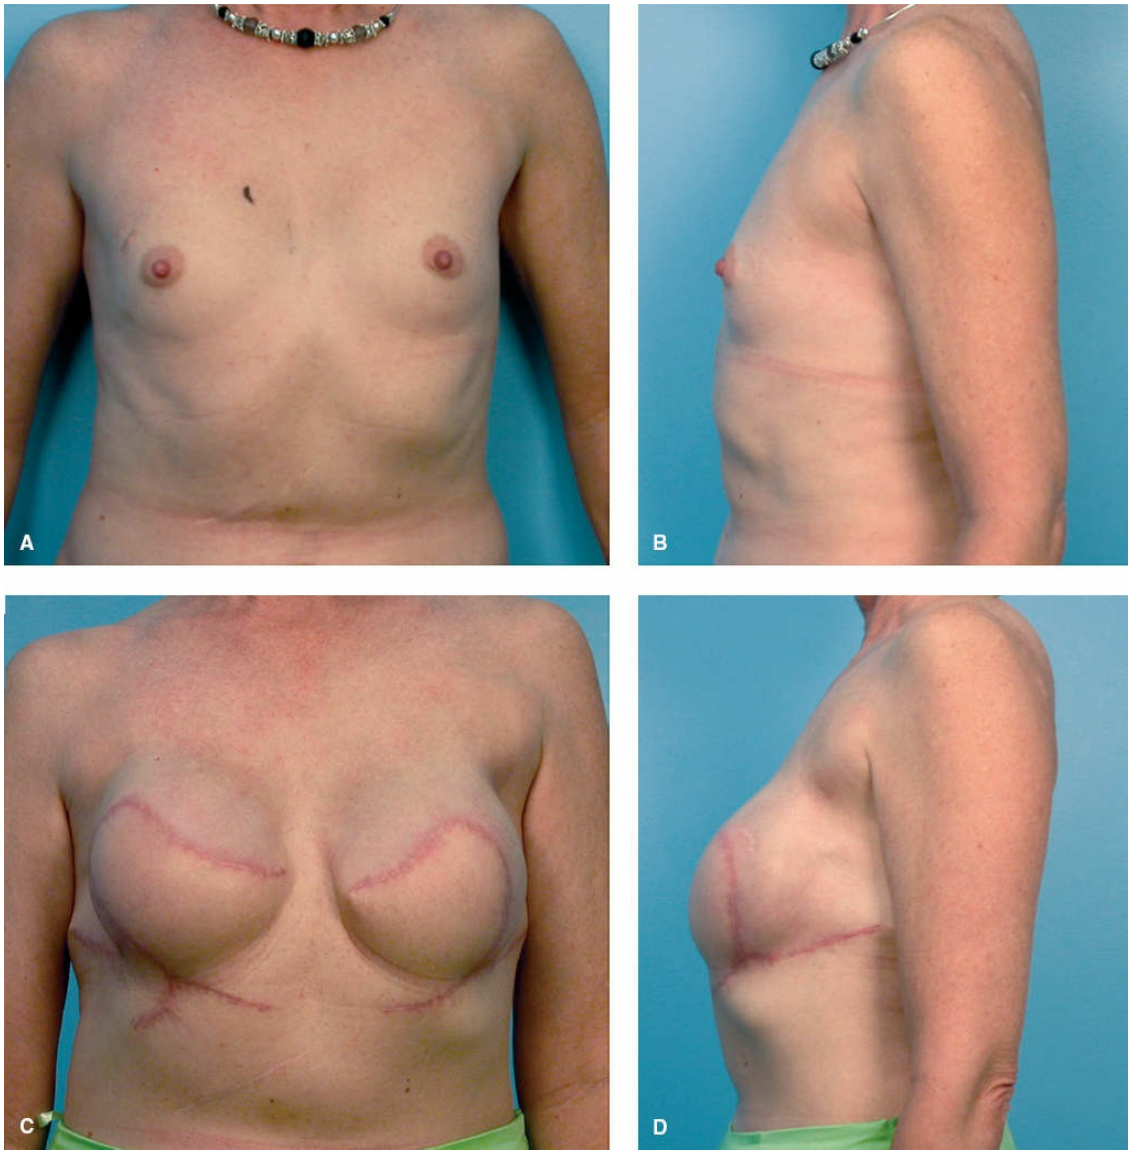

Figure 56.16. **A.** Frontal view of a patient where tissue expansion was attempted within a radiated field producing implant exposure. **B.** Lateral view of same patient, again note the implant exposure. **C.** Frontal view of same patient after latissimus dorsi and implant reconstruction which required partial skin grafting. **D.** Lateral view of the same patient after reconstruction; note the nipple has been reconstructed.

There are many variations of the TRAM flap, one of the reasons why it is considered to be so versatile, and so it is a procedure that can often be tailored to meet the needs of both patient and surgeon. The flaps are categorized by their blood supply. Pedicled TRAM flaps, also known as conventional (vs. free) TRAM flaps, can be based on either one or two pedicles, depending on the size of the flap that is required for reconstruction. These flaps are supplied by musculocutaneous perforating

branches from the deep superior epigastric artery and vein. The pedicled TRAM flaps can also be further categorized as either upper or lower, with the latter being far more common. In addition, the TRAM flap operation is an excellent alternative for reconstruction of the bilateral mastectomy defect. The flap is essentially divided into two, with each half delegated for use unilaterally.

The free TRAM flap utilizes the deep inferior epigastric artery and vein which are used as the axial pedicle for microsurgical transfer and it offers several distinct advantages. First, since the inferior epigastric artery and vein are of large caliber with only a short distance and with fewer choke territories to the tissues of the flap, the blood supply to this flap is considerably more robust than that to its pedicle counterpart. Compared with the pedicle TRAM flap, the free tissue transfer is associated with a lower incidence of fat necrosis, directly attributable to blood supply. Second, only a very small rectangle of rectus muscle which contains the musculocutaneous perforators to the flap needs to be harvested in flap elevation. This significantly decreases donor site morbidity. Further, the free flap does not require tunneling to reach the mastectomy defect. The absence of tunneling eliminates the bleeding than can occur during this portion of the conventional TRAM procedure. Conventional TRAM flaps can also be associated with an epigastric “bulge” as the muscle is turned from the abdomen over the lower costal margins toward the defect. This bulge may have the unwanted effect of obliterating the medial aspect of the inframammary fold.

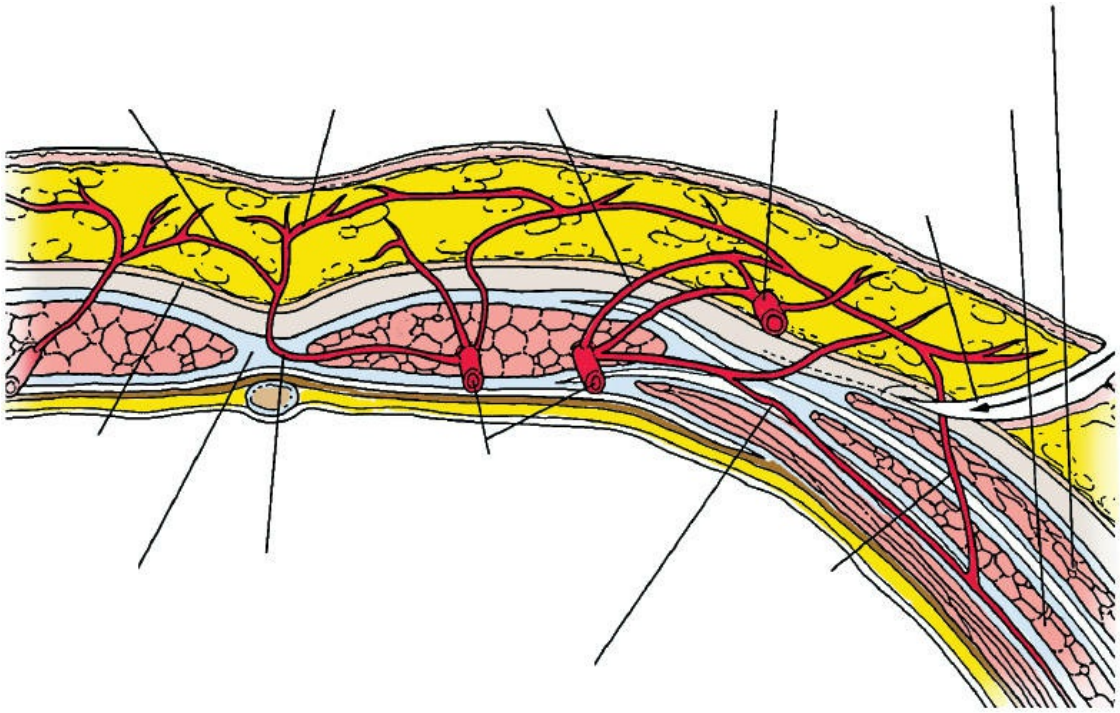

Figure 56.17. Cross-sectional pictorial depicting the musculocutaneous perforators supplying the transverse rectus abdominis myocutaneous flap.

However, the free TRAM flap has its disadvantages. Its proper execution is a greater technical challenge requiring longer operative times. In addition, postoperative monitoring of the flap is very important and must be done by skilled nurses who are trained in the postoperative care of free tissue transfers.

CONVENTIONAL TRAM FLAP

Anatomic Considerations

The TRAM flap is supplied by musculocutaneous perforating branches from the deep epigastric arcade that emerges dominantly in the periumbilical area (Fig. 56.17). There are two rows (medial and lateral) of perforating branches that supply the skin and subcutaneous tissues above. Venous return is essential. The course of the venous blood is through the superficial epigastric veins located above Scarpa fascia. These veins then perforate the fascia and eventually join the venae comitantes of the deep inferior epigastric artery.

Surgical Technique

The flap is outlined, with the upper incision placed at the level of the umbilicus, where it is critical to include the periumbilical perforators. The lower incision is placed suprapubically, as would be done for an aesthetic abdominoplasty, curving gently upward and laterally extending toward the Anterior Superior Iliac Spine (ASIS). The upper incision of the flap is completed and carried down to the anterior rectus sheath where care is used to avoid injury to the sheath. An upper abdominal skin and subcutaneous tissue flap is raised in a plane just superficial to the rectus abdominis sheath to the level of the lower costal margins just lateral to the linea semilunaris and above the xiphoid process in the midline. This fully exposes the anterior sheath of both rectus abdominis muscles above the outlined TRAM flap (Fig. 56.18A,B). A helpful safeguard at this point is to note the two rows of musculocutaneous perforators that are encountered while raising the upper abdominal flap. These provide a guide for the limit of elevation for the TRAM flap both medially and laterally.

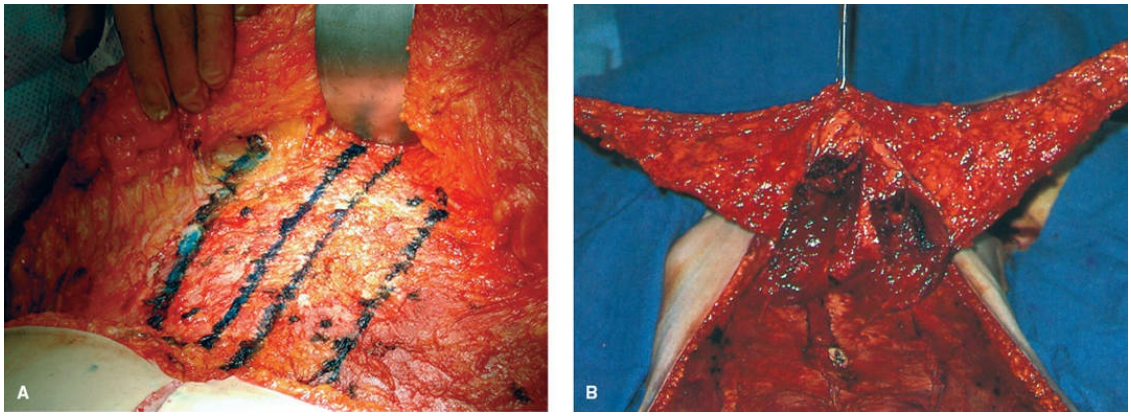

Figure 56.18. A. Photograph of development and elevation of bilateral transverse rectus abdominis myocutaneous flaps, showing marked in methylene blue the planned location of anterior rectus sheath fascial incisions and dots show locations of individual medial and lateral perforators which have been divided. **B.** Intraoperative photo of bilateral flap elevation.

The segment of anterior rectus sheath to be left intact with the muscle is marked. This segment is usually 3 to 4 cm in width, extending from above the costal margin to the upper margin of the TRAM flap. This fascial strip should overlie the medial and lateral rows of perforators. The lower incision on the TRAM flap is then made again down to the anterior rectus sheath. Next the TRAM flap is elevated, lateral to medial, with great care used in keeping the muscular perforators to the flap intact. Next, the

inferior epigastric artery and vein are identified and ligated leaving the muscle and skin paddle totally reliant on perfusion from the deep superior epigastric vascular axis. The rectus muscle is then divided inferiorly and the skin flap with the underlying rectus abdominis muscle is raised superiorly to the level of the costal margin, as the segmental intercostal vessels are divided.

After the TRAM flap is completely elevated, a tunnel must then be made to connect the mastectomy site to the superior-most aspect of the upper abdominal dissection plane which was created by elevation of the upper abdominal flap. The tunnel should be in the midline of the abdomen and then reach the mastectomy site. This allows the rectus muscle to enter the mastectomy defect medially, rather than entering the defect inferiorly, which can ablate the inframammary fold.

Once the TRAM flap is properly positioned, the surgeon shapes and molds the flap to resemble that of the contralateral breast. It is at this point that the poorly perfused and excess portions of the flap are discarded. The goal is to match the opposite breast by using only those portions of the flap with robust blood flow while achieving proper height, projection, and ptosis. The remaining flap skin easily covered by the mastectomy flaps is then de-epithelialized and buried. The flap is supported in position with sutures fixed superiorly and medially. The skin edges are approximated with absorbable deep dermal and running subcuticular sutures. If one is reconstructing immediately following a skin-sparing mastectomy, it is best to mold the pocket of skin and fill the flap to the pocket. To obtain a satisfactory molding of the pocket, one should mark the takeoff to the breast superiorly (from the contralateral breast) which will mark the superior aspect of the breast; close the axillary dissection to the anterior axillary line and place the inferior portion of the flap at the level of the inframammary fold.

FREE TRAM

Most free TRAM flap reconstructions are performed immediately after mastectomy since the recipient vessels (either thoracodorsal axis or the internal mammary axis or it perforators) are exposed by the oncologic surgeon by mastectomy and axillary node dissection. The free TRAM flap is designed on the lower abdominal wall in the same manner as is the conventional flap. The major difference being that the vascular axis for the free TRAM is the inferior epigastric artery and vein rather than the

superior epigastric axis. Since perfusion from the superior epigastric vessels is not required in the free transfer, the entire rectus muscle does not need to be elevated. Instead, only a small cuff of muscle containing the perforators must be included with the flap and its inferior epigastric vascular axis (Fig. 56.19). This confined donor site dissection decreases the donor site morbidity considerably. Once elevated and separated, the free TRAM is transferred to the site of mastectomy on the anterior chest wall where a microvascular anastomosis is performed on the internal mammary artery and vein; rarely to the thoracodorsal vessels which provide the sole blood supply to the flap (Fig. 56.20). Shaping the breast mound and closure are done as with conventional TRAM flaps (Fig. 56.21A,B).

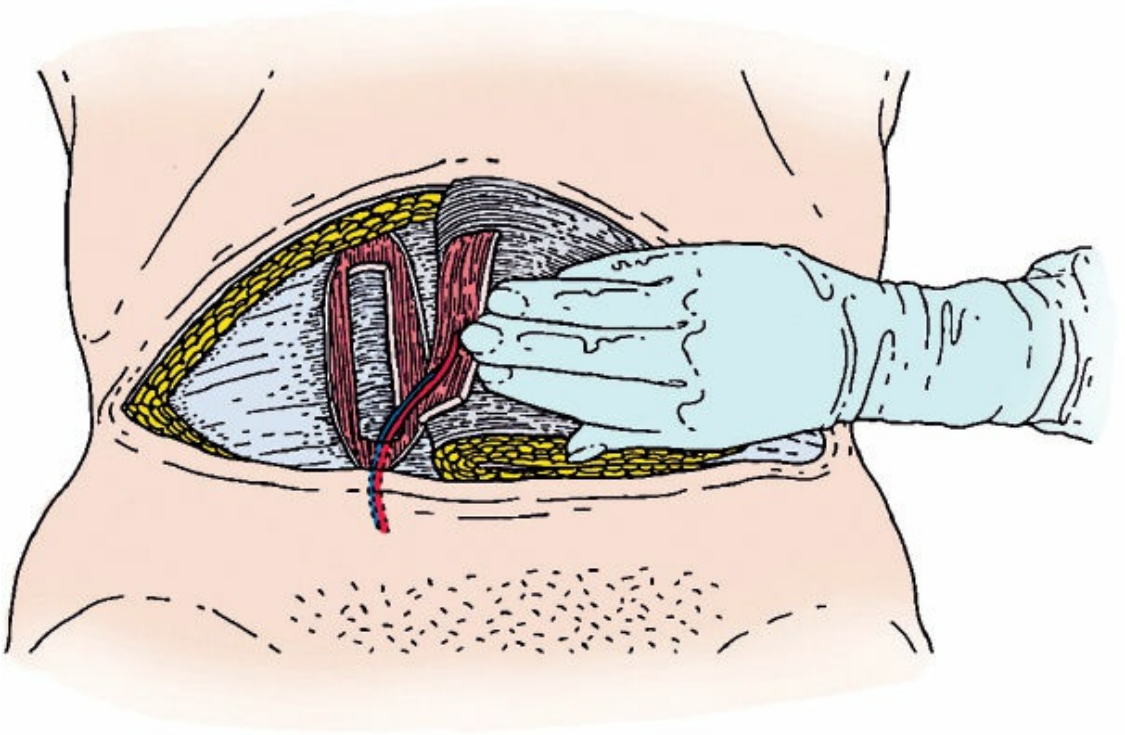

Figure 56.19. Free transverse rectus abdominis myocutaneous flap elevation using the inferior epigastric vascular axis. A small rectangular central portion of the muscle is harvested containing the musculocutaneous perforators. This technique minimizes donor site morbidity.

A sophisticated change in the microvascular type of breast reconstruction is the use of the deep inferior epigastric perforator (DIEP) flap. The dissection of the appropriate perforator and vena comitantes is safely done in experienced hands. The technique usually requires a

preoperative CT angiogram to evaluate the presence of an appropriate perforator.

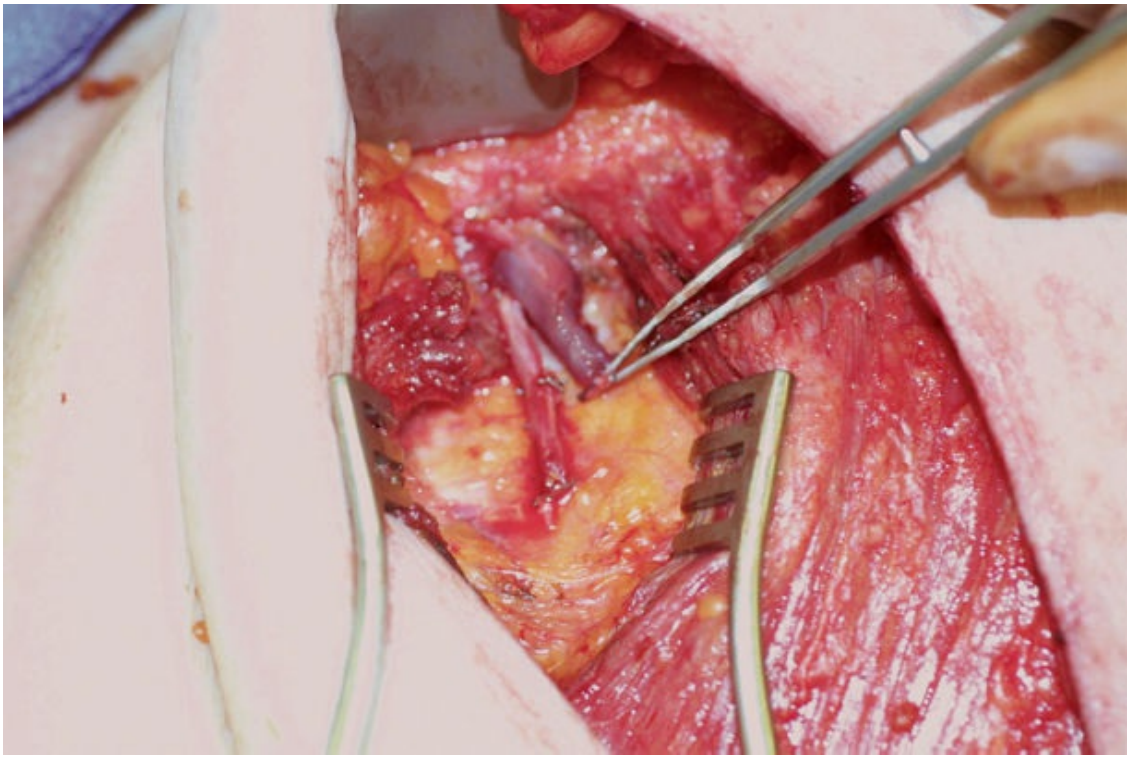

Figure 56.20. Photograph showing exposure and preparation of para-sternal perforators arising from the internal mammary vessels. These will be the recipient axis for free TRAM reconstruction.

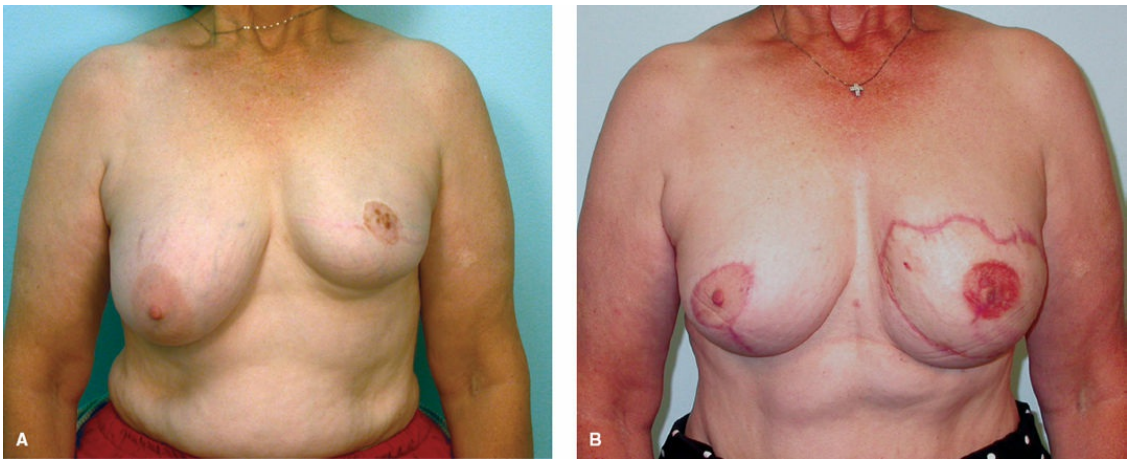

Figure 56.21. **A.** Preoperative view showing previously operated left breast with a ptotic, pendulous right breast. This patient is scheduled for left mastectomy. **B.** Postoperative view showing left TRAM reconstruction with nipple reconstruction complete and tattooing done. Also shown is the right breast reduced in order to achieve symmetry.

RECONSTRUCTION WITH FAT GRAFTING

Several centers are presently offering patients breast reconstruction with the injection of autologous fat.

Fat grating is practiced in almost every reconstructive case to fill a subclavicular hollow or rippling of the skin over an implant. It is particularly useful for the camouflage and filling of defects following lumpectomies. There is also clinical evidence that fat injection ameliorates the leatherly, stiff, inelastic post irradiated skin.

Recently, total breast reconstruction is being performed with autologous fat.

This method requires several injections done at intervals of approximately every 3 months each. Three or four injections are usually needed. Very satisfactory results are shown in selected and well-motivated patients.

Undesirable events include fat necrosis, infection, and inability to match the opposite large breast.

There is not a single, well-accepted method for obtaining the fat or for its injection.

Some plastic surgeons make use of a preinjection suctioning devise (“Brava”) which apparently helps in the creation of a subcutaneous space to allow fat injection as well as encouraging neovascularization of the injected fat.

ONCOPLASTIC RECONSTRUCTIVE SURGERY

For patients who elect lumpectomy and irradiation as the primary treatment of their breast cancer, there is the option of ameliorating the defect or hollowness of the breast by moving the remaining breast tissue around to recreate a rounded projected breast. This has been termed oncoplastic surgery.

It requires considerable knowledge of the blood supply to the breast as well as a thorough knowledge of reduction mammoplasty techniques.

Adequate margins are an imperative concern, since one does not want to move tissue around, until the margins have been cleared. Since most of these patients will also undergo radiotherapy, if the oncoplastic procedure is performed before the radiotherapy, the end result post radiation will be a smaller, thickened breast. If the oncoplastic procedure is done after radiotherapy, there is the increase risk on wound healing by operating on a postradiation tissue.

Of necessity, oncoplasty requires operating on the opposite normal breast in the form of a reduction mammoplasty or mastopexy to obtain symmetry.

OPPOSITE BREAST CONSIDERATIONS

Reduction Mammaplasty

Reduction mammaplasty involves the removal of breast tissue as well as excess skin. It also provides varying degrees of lift. Mastopexy, in contrast, corrects breast ptosis by elevating the breast mound and removing excess skin without removal of substantial breast volume. Each of these procedures can be performed without having an adverse effect on the clinical breast exam or impeding mammographic detection of breast masses. Reduction mammaplasty may be the only procedure indicated in mastectomy patients who do not desire reconstruction. A unilaterally large breast often causes more neck and back pain than bilateral enlargement because of a marked weight imbalance. In patients who undergo breast reconstruction, reduction mammaplasty and mastopexy procedures provide an invaluable tool in achieving symmetry. Both techniques are key in bringing about the restoration of form—the foremost reason for which reconstruction is sought. In the planning of a reduction mammoplasty for symmetry with the reconstructed breast, it is important to recognize the changes which occur with a chosen reduction mammoplasty procedure. For example, the inferior pedicle technique maintains in place the inframammary fold. On the other hand, the superomedial type of reduction mammoplasty raises the inframammary fold and narrows the width of the breast. The inframammary fold as well as the width of the breast should be at approximately the same level to obtain symmetry.

Augmentation Mammaplasty

Augmentation of the normal breast can be considered, but saline and silicone implants are densely radio-opaque and thus can obscure mammographic detection of breast tumors. Some newer implants have similar radiolucency to breast tissue and so even very small calcifications can be visualized through the implant. Subpectoral augmentation is generally preferred over prepectoral augmentation, which has the disadvantages of a higher rate of capsular contracture and greater interference with mammographic detection.

In breast reconstructions where an implant has been placed, the upper portion of the reconstructed breast appears rounded due to the capsule around the implant. In such cases, it is important to consider placing a smaller implant in the reduced or mastopexed normal breast for upper pole symmetry.

Prophylactic Mastectomy

Prophylactic mastectomy is rarely performed in the treatment of breast cancer, except when bilateral prophylactic mastectomies are indicated for those who are at elevated risk (genetic mutations or known familial disease). When a CPM mastectomy is performed, either contemporaneously or at a later date, it can significantly elevate the complexity of reconstruction. For example, thin patients may have adequate tissue for a single breast reconstruction but inadequate soft tissue for a bilateral procedure. To achieve adequate volume, implants must then be used and secondary flaps should be considered. Still, it is important for the reconstructive surgeon to consider that a contralateral mastectomy may be required in the future. If the risk is high that future contralateral mastectomy will be required, then the TRAM flap should be reserved as it is only available once.

NIPPLE RECONSTRUCTION

Nipple reconstruction represents a critically important part of breast reconstruction. Without the nipple, the breast lacks a key defining feature. Its absence alone makes the reconstructed breast look asymmetric—a fact that is unlikely to go unnoticed by reconstructed patients. Successful nipple/areola reconstruction restores the shape and projection of the nipple as well as the shape of the areola and the color to each. The shape of the areola is the foundation for the nipple and is created by a constricted circular closure of the autologous flap. The nipple is formed by local bilobed or trilobed flaps. The arms of these flaps are wrapped around themselves to form a standing cone. The tint of the nipple and areola are provided by imbedding pigments that are color matched to the contralateral side using a tattooing machine. The color of the nipple is usually slightly darker than that of the areola, which serves to provide additional spatial cues to dimensionality. Nipple reconstruction can safely be performed at the time of immediate reconstruction, but most typically it is performed at a later time once the reconstructed breast is has settled.

DELAYED RECONSTRUCTION

Although all patients treated for cancer do not survive, this is not a sound reason to withhold reconstruction from patients, except where reconstruction will interfere with synchronous adjuvant therapies. Existing treatment protocols use severity of the disease as the primary gauge for whether and when reconstruction should be performed. When, patients with ductal carcinoma in situ or minimal breast cancer are considered for immediate reconstruction, only 20% of the patients with invasive breast cancer undergo immediate reconstruction. Many patients are advised to wait until chemotherapy is complete before considering breast reconstruction. After the 6 traumatic months from the time of mastectomy through chemo and radiation therapy, many patients are overwhelmed and exhausted, lacking interest in secondary surgical procedures. The most common reason patients cite for refusing delayed breast reconstruction is a fear of additional procedures.

The commonly expressed goals of the patient seeking delayed reconstruction include the following:

1. Relief from negative feelings: Mastectomy patients come to accept the mastectomy and their diagnosis over time, but at some point they tire of the physical and emotional loss they have sustained. Feelings of “weariness” with the mastectomy deformity and the stigma of being seen as abnormal or different from other women are prevalent. This postmastectomy stigma is reinforced by those with good intentions who ascribe great strength to those who have been “afflicted.” These patients seek to be restored to that time prior to their diagnosis. They want to think, feel, and express themselves in the ways they did before the mastectomy. The problem can be perceived in many ways by these patients. Some see an anatomic deformity, whereas some feel a loss of femininity. No matter their perception, the mirror acts as a constant reminder for them.
2. Symmetry: Symmetry with the opposite breast is the goal of any mastectomy patient, whether stated or not. This goal is seldom obtainable without some form of autologous reconstruction. This decision must be reached by the patient, but we, as reconstructive surgeons, can help them in that process by providing them with the alternatives that can help them meet their goal.
3. Lasting result: The desire for a lasting result is a desire for closure. At some point, the patient wants to feel that the reconstruction is finished

and no more revisions will be required. The reason that implant reconstructions are not acceptable to many patients is that implants are far more likely to require revisions in the future.

4. Forgetting about the mastectomy: Putting the mastectomy in the past is the final goal of any breast reconstruction. In truth, most patients do not have unreasonable expectations. Often, they state that they just want to be able to dress in normal clothes or a similarly mundane activity. Mostly, patients want to return to their life as it was before cancer. They want to forget the trauma of surgery so that they can recover physically and emotionally. To provide for these patients' wishes, the reconstruction must be good enough so that the patients can walk by a mirror without being reminded of the traumatic experiences associated with their breast cancer. To meet this goal, reconstructions must appear natural and give symmetry while providing at least a semblance of natural feel. They should have a good nipple–areolar reconstruction and may require contemporaneous mastopexy or reduction of the contralateral breast. If a large amount of skin was removed with the mastectomy or if the mastectomy was accompanied by radiotherapy, then these goals can be more difficult to achieve. In such cases tissue expansion, implants, and revisions of the autologous tissue may be required.
5. Emotional recovery: The psychologic aspects of the recovery process are not well understood by most doctors since emotional healing has traditionally been left to outside groups such as Reach to Recovery. Though these groups usually function independently of the operating surgeon, they are quite effective because their members are the patients who have first-person experience with both the physical and emotional stresses of cancer treatment. Psychiatrists and psychologists, no matter how well intentioned, come to know these feelings secondhand and are not as effective in counseling mastectomy patients as are the women who have experienced the physical and emotional pain of losing a breast. Generally, breast reconstruction is useful adjunct to the late recovery process, at a time when self-esteem is high and life is viewed as worthwhile. At this point, patients and supporters see delayed reconstruction as healthy investment in a worthwhile life rather than as a way of denying unpleasant truths. It is clearly a mistake to proceed with plans for a breast reconstruction before emotional and psychologic issues have been resolved.

Both physicians and surgeons should be concerned about undertaking

reconstruction in patients who are poor candidates. It is always a disservice to undertake a complex reconstruction when a patient is still emotionally unstable, has unrealistic expectations, or is in poor health. Under such stressors, a truly informed consent cannot be obtained. The surgeon often accepts these patients at the request of their oncologic surgeon who recommends reconstruction as a means to bypass some of the trauma associated with mastectomy. However, it is not inappropriate for the reconstructive surgeon, in concert with the surgical oncologist, to refer such patients for counseling preoperatively. Selective serotonin reuptake inhibitors (SSRI) are among the medications prescribed to the patients in these depressed emotional states. When depressed, patients tolerate complications poorly and lawsuits can ensue since the surgeons are ready outlets for the patient's angst. It is critical to evaluate the emotional state of your patients preoperatively as in these cases it is in the patient's best interest to delay reconstruction until the time when emotional stability can be assured.

Experience from several large breast centers indicate that the complication rate of a delayed reconstruction with implants or expanders is much lower than if one did an immediate reconstruction (30% as compared to 5%). The increase rate in complications is related to: skin flap necrosis, exposure of the implant, infection, or marked asymmetry, if the reconstruction is performed at the same time as the mastectomy.

IMMEDIATE RECONSTRUCTION

Treatment of breast cancer and reconstruction of the mastectomy have been traditionally conceptualized as separate and unrelated issues—one necessary, the other optional. In contrast to other oncologic procedures, treatment is often completed before reconstruction is considered. In virtually all other cancer patients, the reconstruction is completed at the time of the extirpation. Although reconstruction may not be reasonable in a patient with a life span limited to 1 or 2 years, it is a reasonable consideration in any patient who is being treated for cure. Even in patients with advanced disease, immediate autologous reconstruction is reasonable and does not interfere with subsequent treatment or follow-up.

There are understandable historical reasons for the separation of treatment and reconstruction, which are as follows: (a) treatment protocols were developed before reconstructive procedures were available, (b) extensive skin resection has always been a hallmark of both radical and

modified mastectomies, (c) autologous flap reconstructions have become refined over just the past 20 years, and (d) the mastectomy and reconstructive procedures are performed by two different surgical specialties.

If autologous flaps had developed within the specialty of surgery rather than plastic surgery, it follows that they would have become routine at the time of mastectomy over a much shorter time period. Extensive skin resection would have sooner become the exception rather than the rule and reconstruction would likely have been viewed sooner as wholly compatible with adjuvant therapies.

For the foreseeable future, mastectomies will not be replaced by other forms of treatment as there are several conditions that are poorly accommodated by the lumpectomy and radiation paradigm; these include the following:

Familial breast cancer
Multicentric and multifocal breast disease
Central breast cancer that requires sacrifice of the nipple
Cancers that are too large for lumpectomy
Lumpectomy-radiation failures (an increasing number after 20 years of treatment)
Patients who cannot accept radiation.

Routine consideration for breast reconstruction at the time of mastectomy is now scientifically defended for patients with stages 0, I, and IIa. This subset describes the vast majority of patients who are undergoing mastectomy at present. As the safety of breast reconstruction has been demonstrated in careful studies, there is no reason to delay reconstructive measures. There are no data that support the idea that immediate reconstruction interferes with surgical treatment by spreading the cancer, hiding local recurrences, or negatively impacting patient survival. It is recognized that local recurrences are indicators of retained disease and that recurrences exist within retained breast tissue. The only remaining breast tissue following a mastectomy is either in breast skin or in breast tissue that was not removed with mastectomy. After reconstruction, what could have been a chest wall recurrence becomes a skin recurrence, since the skin is physically separated from the chest wall by the reconstruction. Recurrences are never seen within the substance of an autologous flap because the fat and muscle of the flap are poor recipients for the transplantation of breast cancer. Most of the local recurrences occur 2 to 3

years following mastectomy. More importantly, recurrences occur at the subcutaneous tissue level and around the scar. Thus, they are easily palpable during a physical examination.

A number of contemporary reports document the safety of immediate reconstruction. Wang and colleagues reviewed survival data in 172 immediate breast reconstructions performed between 1970 and 1990 and compared them with a control group of similar patients who had had only a mastectomy. In these groups, the flap reconstruction did not interfere with either diagnosis or treatment of the recurrence. There was no difference in 5- and 10-year disease-free survival and there was no difference in reconstructions performed with implants versus autologous flaps or immediate versus delayed reconstructions. Slavin, Love, and Goldwyn reported 161 immediate breast reconstructions, including 41 salvage mastectomies using myocutaneous flaps. Local recurrences that developed were consistent with the stage of the disease, and 76% of these local recurrences represented systemic disease. All local recurrences were found within the native breast skin rather than in relation to the flap. There were no cases of a delay in diagnosis or compromise in the timeliness of treatment. Godfrey, Godfrey, and Romita reviewed patients having immediate reconstruction with advanced disease and confirmed the findings of Slavin and his group that the reconstruction itself had no impact on the outcome of the cancer treatment. Noone and colleagues reported on 306 patients who had implant reconstruction with long-term follow-up. The local and distant recurrences in this group of patients were similar to those expected in patients with like disease. Kroll and colleagues collected 131 patients who had undergone immediate reconstruction, of which 104 had skin-sparing mastectomy. When compared with matched patients, the authors concluded that the skin-sparing mastectomy with immediate reconstruction had no impact on outcomes in this 5-year follow-up.

Although the postulated harmful effects of immediate reconstruction on local recurrence and survival have not materialized, concerns persist over the effect of breast reconstruction on adjuvant therapy. It is biologically important to begin chemotherapy within 28 to 40 days of extirpative treatment, so the reconstruction must be healed enough to tolerate initiation of chemotherapy by the end of the first month. Chemotherapy can be started while there is still a surface wound that has not yet epithelialized, but it cannot be started in the face of frank tissue necrosis,

seroma, or infection. When it is known in advance that the patient will undergo chemotherapy, the choices for reconstruction should include those flaps that are well vascularized and are known to heal with few complications as the first choice. Implants can be used, but if complications arise, it may be necessary to remove the device to facilitate healing and allow chemotherapy to begin. When radiation is planned, tissue expander and implant reconstruction should not be the first option selected because unsatisfactory firmness is the byproduct of implants which are radiated. Only autologous flaps offer a satisfactory solution in these patients and it is preferable to complete reconstruction at the time of mastectomy, again to avoid any delay in treatment. Radiation is usually performed for close margins or because the tumor is large or aggressive. In either case the cause of tumor recurrence or poor patient survival is disease stage, not immediate reconstruction. Should a flap hide a recurrence at a questionable chest wall margin, this could delay the diagnosis of systemic disease but it is so rare as to be a reportable event. Whether immediate reconstruction should be performed at all in stages IIb and III has become more of a social decision than a medical one. The survival in these patients will be poorer that in most patients, but it will not be negatively impacted by autologous reconstruction. If it can be ascertained preoperatively that the patient desires reconstruction, then immediate reconstruction serves the patients interest best. For a few hours added to the procedure, reconstruction can be completed, and the patient does not have to face a second major surgical procedure after chemotherapy. If the flap is placed immediately, radiation may decrease flap volume, but delayed reconstruction in the context of radiation is far more problematic in terms of radiation-induced skin and chest wall injury.

Contemporary oncologic practice guided by phase II/III clinical trials has been significantly refined allowing for multidisciplinary models of treatment that were inconceivable a generation ago. These models employ new combinations of chemotherapy, reconstruction, and radiation that continue their refinement by further study. The introduction of inductive chemotherapy to shrink large breast tumors does not preclude immediate reconstruction. It has been shown that wound healing is not significantly impaired.

Early in the 20th century, the surgeon stood alone in his responsibility for breast cancer treatment, a time when treatment existed only in the form of the radical mastectomy. Today, multidisciplinary support is the rule

rather than the exception and the surgical oncologist now stands as a leader with his colleagues in this coordinated effort. Helping the patient choose among these sophisticated treatment options requires the efforts and mutual cooperation of both surgical oncologist and reconstructive surgeon.

EDITOR'S COMMENT

In this chapter, Vasconez and colleagues have done a nice job of intertwining history and the evolution of breast reconstruction. Much of the story is tied to the evolution of skin preservation—from skin grafting the chest wall to skin sparing and today nipple skin-sparing mastectomy (NSSM) or total skin-sparing mastectomy. This evolution continues with novel reduction techniques, various incisions for improving cosmesis after an NSSM, techniques for reconstruction

of the pendulous breast and coverage of implants with dermal matrix or “autoderm” instead of extensive muscular dissection for coverage. As the ductal lining starts just a few millimeters from the skin, the oncoplastic safety of NSSM has challenged old dogma and demonstrates its safety even when the nipple–areolar complex is spared. Now there is little doubt that leaving the original skin envelope and filling it with tissue or an implant give the best and most immediate of reconstructions. When the nipple is involved as much skin can be spared as is free of cancer. In other words, the nipple is just another margin.

Importantly, the onus is on the cancer surgeon. First, a reconstruction-friendly scar should be made by the primary surgeon. The final result is very much dependent on the condition of the tissue that the cancer surgeon leaves for the reconstructive surgeon. The primary cancer surgeon should avoid the temptation to remove the fat pad superior to the breast mound so that the patient will not have a hollowed inframammary region. The breast tissue proper rarely goes above the first or second rib. Likewise, dissection too medial will result in synmastia. Dissection too inferior on the chest wall results in loss of the inframammary fold. The resulting asymmetry of the position of the breast on the chest wall is difficult to correct. In case the patient decides to have reconstruction later then the scar can be placed just above the inframammary fold saving as much skin superiorly as possible and de-epithelizing the lower flap and folding it under the upper flap (vest over pants) for later use by the plastic surgeon. This not only provides coverage for the implant later with natural tissue but allows the primary surgeon to reduce redundant tissue in laterally in the axilla.

Indications for offering breast reconstruction are broadening. Not offering or delaying reconstruction produces the greatest scar emotionally. I will have to disagree with the authors that reconstruction can only be limited to those with stage 0 to IIa in that recent studies have shown skin-sparing mastectomy to be safe even with locally advanced breast cancer. Systemic presurgical chemotherapy can be offered to the patients with more aggressive disease who will need radiation, or to those patients who need time to stop smoking. Patients with a recurrence after conservative breast surgery and radiation can also have good results using newer flap dissection techniques. Complication rates are higher in the obese, but some are more than willing to accept this for a chance to look and feel normal. Tissue reconstruction in these patients and the use of their own dermis can lower such complications. In addition, there is no doubt that contralateral prophylactic mastectomy (CPM) is on the rise, increasing from 0.4% in 1998 to 4.7% in 2007 to approximately one third in 2016. Why and whether CPM carries a survival benefit is controversial. Patients often elect CPM out of fear of recurrence or to lessen surveillance. The majority of average-risk women will obtain no oncologic benefit from a CPM with the risk of finding occult disease in a CPM of about 1.8%. Certainly sentinel lymph node biopsy of the CPM is not necessary as the risk of lymphedema is 5-fold

higher than the risk of finding an occult cancer. An individualized approach is necessary with thorough discussion of the risks and benefits but ultimately is decided by the patient.

The authors state that there is a 30% to 40% complication rate with implants; in fact, with the "living bra" concept of total implant coverage by chest musculature the explant rate secondary to pain is as high as 25%. Today implants are only partially placed behind the pectoralis major muscle and then a lateral and inferior sling of dermal matrix covers the implant laterally. This along with botulinum toxin to relax the muscle produces less contracture and good cosmetic results with implants and lessens pain. Marcaine can also be used to perform a pectoral block at the time of the open procedure with good results. Pain pumps left in at the time of surgery are not necessary, costly, and increase infection rates. Use of dermal matrix allows the ability to place the implant and finish the reconstruction at the time of the mastectomy with only a few hours added to the procedure and with lower complication rates than those offered by complete tissue reconstruction. Indeed, using such techniques, there is no delay in receiving chemotherapy and much more tolerance of the implant reconstruction to postsurgical radiation therapy with less contracture formation. Once the chest wall is radiated, tissue reconstruction is the only option. The main complication to be reckoned with is flap necrosis. This is a direct result of making the flaps too thin. Flap thickness is one of the most difficult techniques to master. Boneti and colleagues describe a dilation technique to determine the correct thickness of the skin flap and this can significantly decrease flap and nipple necrosis. Indocyanine green fluorescence has also been shown to be helpful.

The American Society of Plastic Surgeons practice surveys showed breast reconstruction is on the decline with a 29% reduction in breast reconstruction cases from 2000 to 2008 at a time when the demand for reconstruction is growing. Only ~6% of the cases submitted for the oral plastic surgery boards and also only ~6% of the cases submitted by plastic surgeons (in practice for 10 years) for Maintenance of Certification examination were breast reconstruction. The process that goes into making a decision to have reconstruction is complex—misperceptions about oncologic safety, difficulty in coordinating surgery schedules, and lack of enough or distribution of plastic surgeons to meet the demand are just a few of the problems. In a recent survey, fewer than one fifth of plastic surgeons perform autologous procedures for more than half of their breast cancer patients even though the results can be superior and more long lasting to implant. Deterrents are expertise, time, and reimbursement. The development of Breast Fellowships with the increasing emphasis on cosmesis has led to what is now termed oncoplastic surgery. However, proper training of such surgeons has lagged as plastic surgery is still only a minimal part of the oncologic breast surgery training. At present a multidisciplinary approach with the patient's best interest in mind seems the best solution coupled with an evolution of techniques and oncoplastic training

programs for the breast surgeon.

57 Chest Wall Resection and Reconstruction for Advanced/Recurrent Carcinoma of the Breast

Kirby I. Bland, Cristiano Boneti, R. Jobe Fix, and Robert J. Cerfolio

INDICATIONS/CONTRAINDICATIONS

With improvements in patient awareness and imaging advancements (e.g., MRI, PET, PET/CT) the diagnosis at an earlier stage of breast cancer will provide enhancement of survival. Nevertheless, the incidence of local–regional recurrence following breast conservation surgery or mastectomy varies between 5% and 40%. The probability of recurrence correlates with the presenting pathobiologic characteristics of the primary neoplasm and/or the American Joint Committee on Cancer (AJCC) clinical tumor stage. Although no international standards for local recurrence have been fully defined, typically the combination of surgery, radiation therapy, chemotherapy, and/or targeted immunotherapy is directed for principal control. Following local–regional recurrence that defines a clinical and radiographically resectable tumor, protocol will typically embrace resection with pathologically negative margins followed by subsequent radiation therapy; many clinics will also utilize hormone-receptor markers (ER, PR, and HER2/neu status) to assist in therapeutic guidance.

For many clinics internationally, despite curability with isolated metastases, chest wall recurrences are left untreated. This rational is based upon previous surgical dogma suggesting that chest wall recurrences are the “harbinger of systemic disease.” However, this principle should not necessarily apply when the patient has been fully staged clinically and radiographically and only the isolated chest wall recurrence is evident.

PREOPERATIVE PLANNING

The authors have previously published guidelines at the University of

Alabama at Birmingham for resection of the chest wall in patients presenting with recurrence/advanced disease related to breast carcinoma. The indications for operation, as discussed, pertain only to an isolated disease that can be surgically managed with curative intent. The chest wall recurrence typically follows cytoreduction resection with neoadjuvant chemotherapy and ER-targeted therapies.

Individuals who have locally confined disease, with requirement of palliation for pain and/or nonhealing/ulcerative lesions related to postirradiation injury with pathologically negative ulcerative sites are included in this group.

It is incumbent upon the oncologic surgeon involved in the care of the patient to establish that there is absence of systemic disease and to exclude multifocally recurrent sites that are being considered for resection.

Relative contraindications include advancing age, short disease-free interval of recurrent disease, diminished pulmonary reserve, biopsy-proven extrathoracic disease, and existing systemic comorbidities (e.g., cardiac, hepatic, renal, and endocrine).

The preoperative evaluation and important preoperative considerations in the management of chest wall recurrence include:

Contemporary radiographic imaging is essential for all patients being considered for full-thickness chest wall resection and reconstruction. To properly evaluate chest wall anatomy and extent of tumor progression, we advocate dedicated chest wall magnetic resonance imaging (MRI) and/or computed tomography (CT) angiography as standard imaging modalities. Standard CT scanning with intravenous contrast also provides invaluable information. Many medical oncologists also consider positron emission tomography (PET) as a definitive test, but coexisting inflammatory sites, especially ulceration sites, with the associated false-positive and false-negative features of PET, do not allow use of this procedure as an exclusive screening modality. However, PET is extremely useful in evaluating systemic disease. Evidence of extensive direct lung invasion and pleural effusion are absolute contraindications for consideration of chest wall resection.

The principal site of focally recurrent disease typically presents between the 3rd and 6th rib interspaces; however, the recurrence location, as well as history of the patient’s operative procedure, is paramount.

Resection that extends beyond four ribs will routinely require rigid chest

wall reconstruction. This maneuver constitutes the creation of mesh with polypropylene that may be used as a singular sheet or with creation of a mesh "sandwiched" together with methyl methacrylate. Recently bioabsorbable materials are increasingly used and have some advantages over nonabsorbable material. The main advantage is that they do not need to be removed if the chest wall graft becomes infected. Myocutaneous flaps should be liberally used to cover the defects of these reconstructions. When defects are small and there is less probability for creation of the flail defect of the chest wall, mesh alone may be sufficient with this smaller area for coverage.

The most versatile and most commonly used flap is the latissimus dorsi pedicle flap. Ideally, flaps from previously irradiated fields should be avoided when possible.

Review of the surgical history is essential, especially if a transverse or vertical rectus abdominis muscle (TRAM) pedicle flap is being considered with prior abdominal operations, as the same will often affect the flap choice for defect coverage.

Lastly, preoperative planning between the surgical oncologist and reconstructive surgeons, following discussion with the medical oncologist, should define the indications, relative merits, and technical approaches essential for full oncologic resection (Table 57.1).

SURGERY POSITIONING AND INCISIONS

Following patient intubation with an appropriately endotracheal tube (a double lumen is not necessary for most operations) the patient is positioned in the supine or lateral decubitus position depending upon the recurrence site, planned resection, and flap choice. The area for harvest of the potential skin flap and graft-donor sites should also be prepped and draped into the operative field.

TABLE 57.1 Preoperative Considerations

- Indications for operation include isolated chest wall recurrence, curative intent, or palliation for painful, nonhealing, ulcerated lesions.
- Preoperative planning between oncologic and reconstructive surgeons should help elucidate flaps that will be available after oncologic resection.
- Absolute contraindications for resections with curative intent include systemic disease or multifocal recurrence.
- Relative contraindications include advanced age, short disease-free interval, poor pulmonary function, and high operative risk.
- Preoperative imaging and staging are essential for evaluation of chest wall anatomy, tumor invasion, metastatic disease, and preoperative planning. Magnetic resonance imaging, positron emission tomography, and computed tomography are standard imaging modalities. Bronchial washings may be appropriate to rule out direct lung invasion if suspicious by imaging.

Resection extending beyond four ribs will usually require rigid chest wall reconstruction with a mesh and methyl methacrylate sandwich. Mesh alone may be sufficient for smaller defects with less risk of flail chest.

Recurrence location, as well as patient's operative history, will affect flap choice for defect coverage. A latissimus pedicle flap is the most versatile and is usually the most readily available. Flaps from previously radiated fields should be avoided if possible.

From Howard JH, Tzeng CWD, Fix RJ, et al. Chest wall resection. In: Klimberg VS, ed. *Atlas of Breast Surgical Techniques.* Philadelphia, PA: Saunders; 2010, with permission.

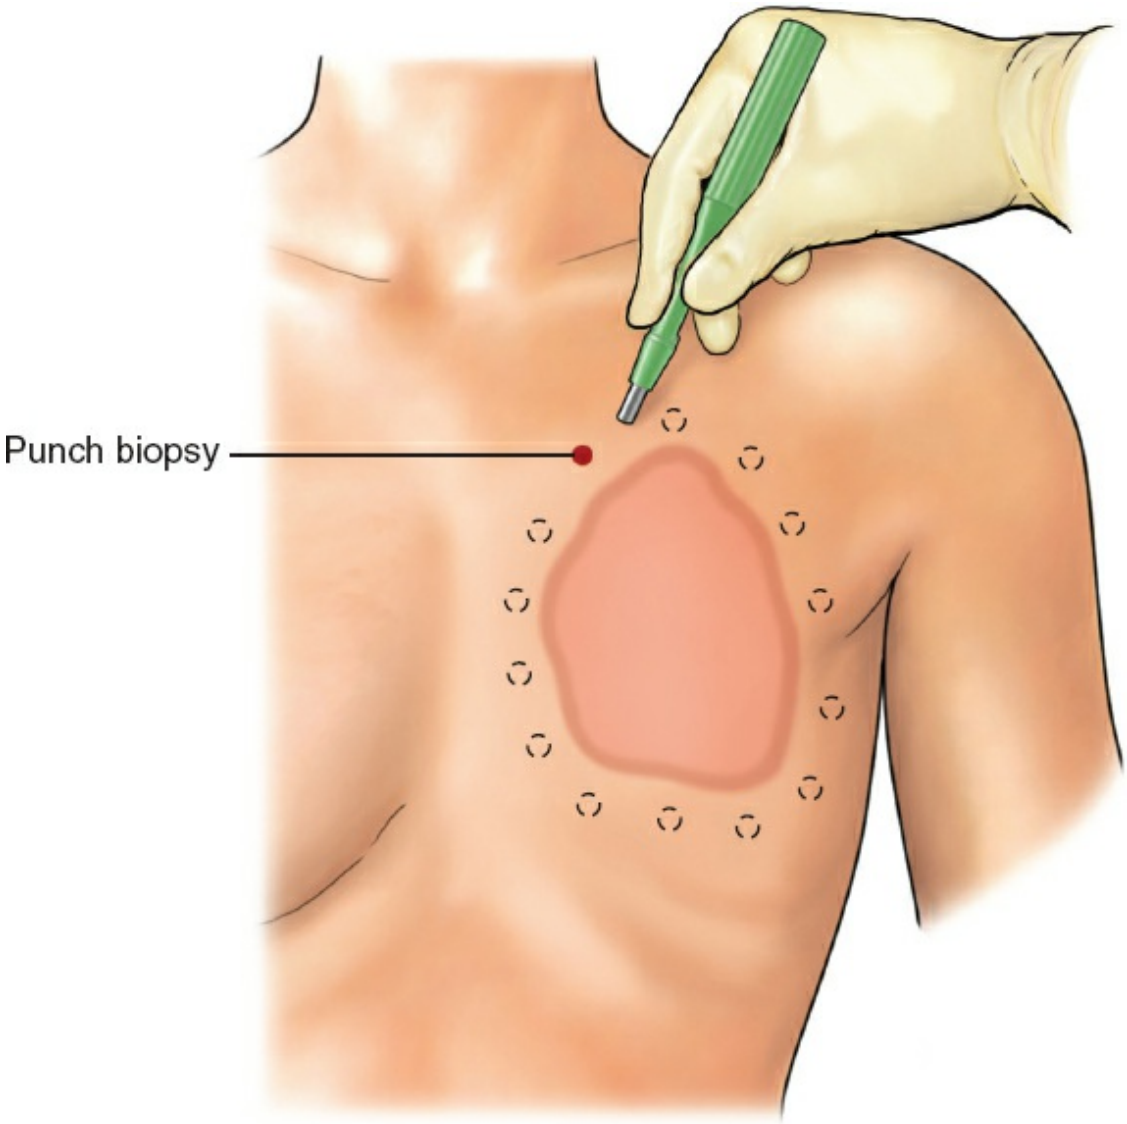

Figure 57.1. Chest wall topographic anatomy with outline of planned marginal clearance. Preferentially a minimal 2-cm margin developed 360 degrees about the periphery of the planned resection area is ideal. A punch biopsy (4 to 6 mm) should be taken approximately every 1 to 2 cm about the tumor margin resection to validate a negative pathologic margin before opening the chest. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

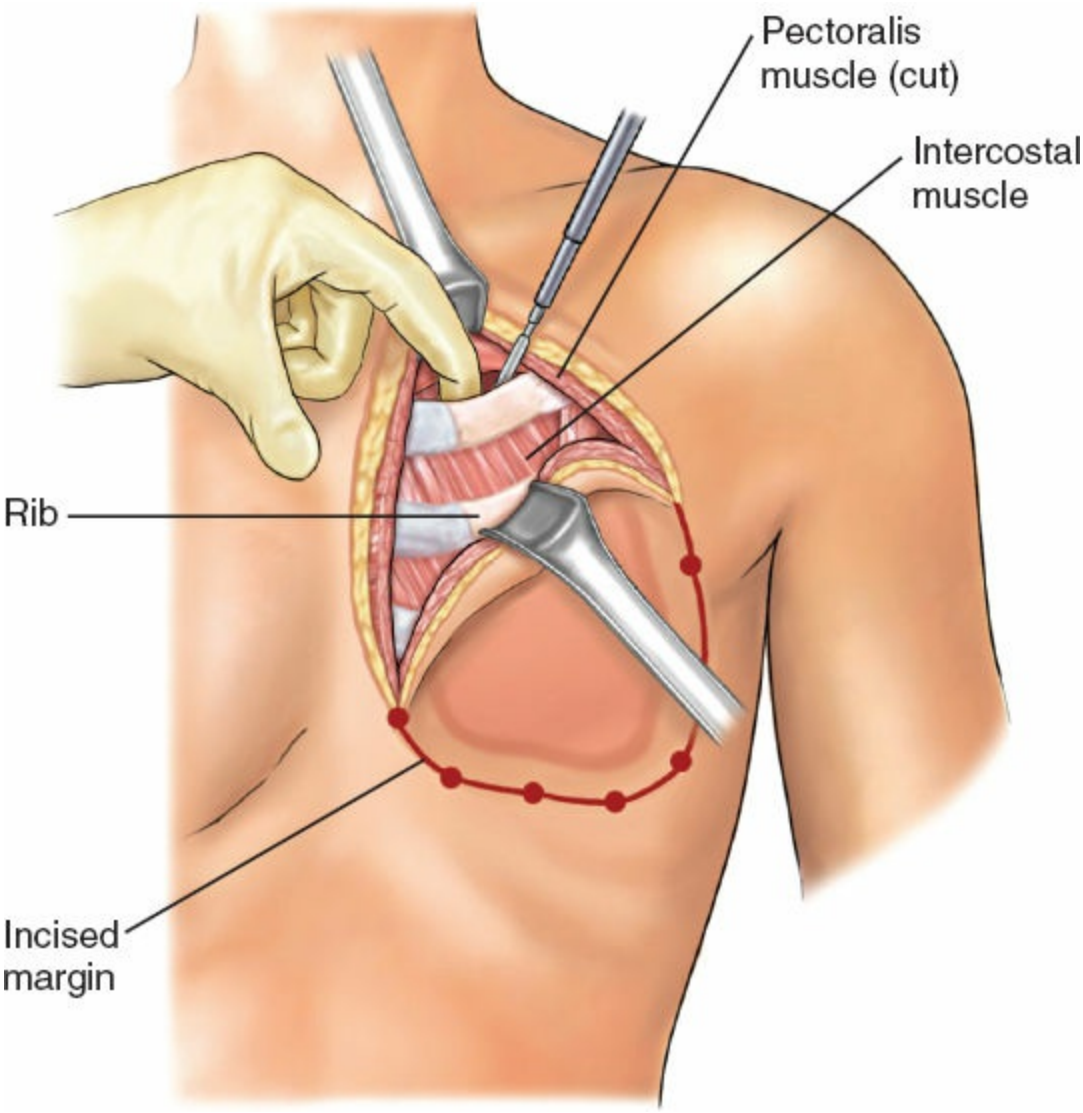

Figure 57.2. In the usual circumstance, incision above the cephalad-most rib with opening on its superior margin is preferable. Upon entering the thorax, prior pleural adhesions created by radiation therapy and/or surgery should be sharply dissected and the lung mobilized. Attention must be focused on the avoidance of injury to the visceral pleura of the lung and inadvertent damage to the pulmonary parenchyma. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

Preferentially, we prefer a minimal 2-cm margin developed 360 degrees around the periphery of the planned resection area (Fig. 57.1). We prefer a 2 cm margin for metastatic lesions and 4 cm for primary chest wall tumors. It is critical that both the oncologic surgeon and the plastic surgeon plan

the operative incision prior to skin incision, estimating the maximum cephalad, caudad, medial, and lateral extent of the tumor, such that the estimate for margins of resection can be discussed with the patient and family prior to the planned resection. Such estimates are simultaneously planned with radiographic imaging, if necessary.

Margins should extend, at minimal, one intercostal space above and below the tumor mass inclusive of the cephalad–caudad aspect of the planned rib resections at a minimum and more if a 2-cm margin is not obtained with just one rib space.

Circumferential full-thickness skin punch biopsies (6 mm) should be sent for frozen section analysis following skin prep and induction. These biopsies will validate a negative pathologic margin prior to incision (Fig. 57.1). Once negative margins are confirmed with pathology, the extent of the incision through the skin overlying the pectoralis major muscle may be completed using cold blade and, thereafter, electrocautery for subcutaneous and muscular tissues.

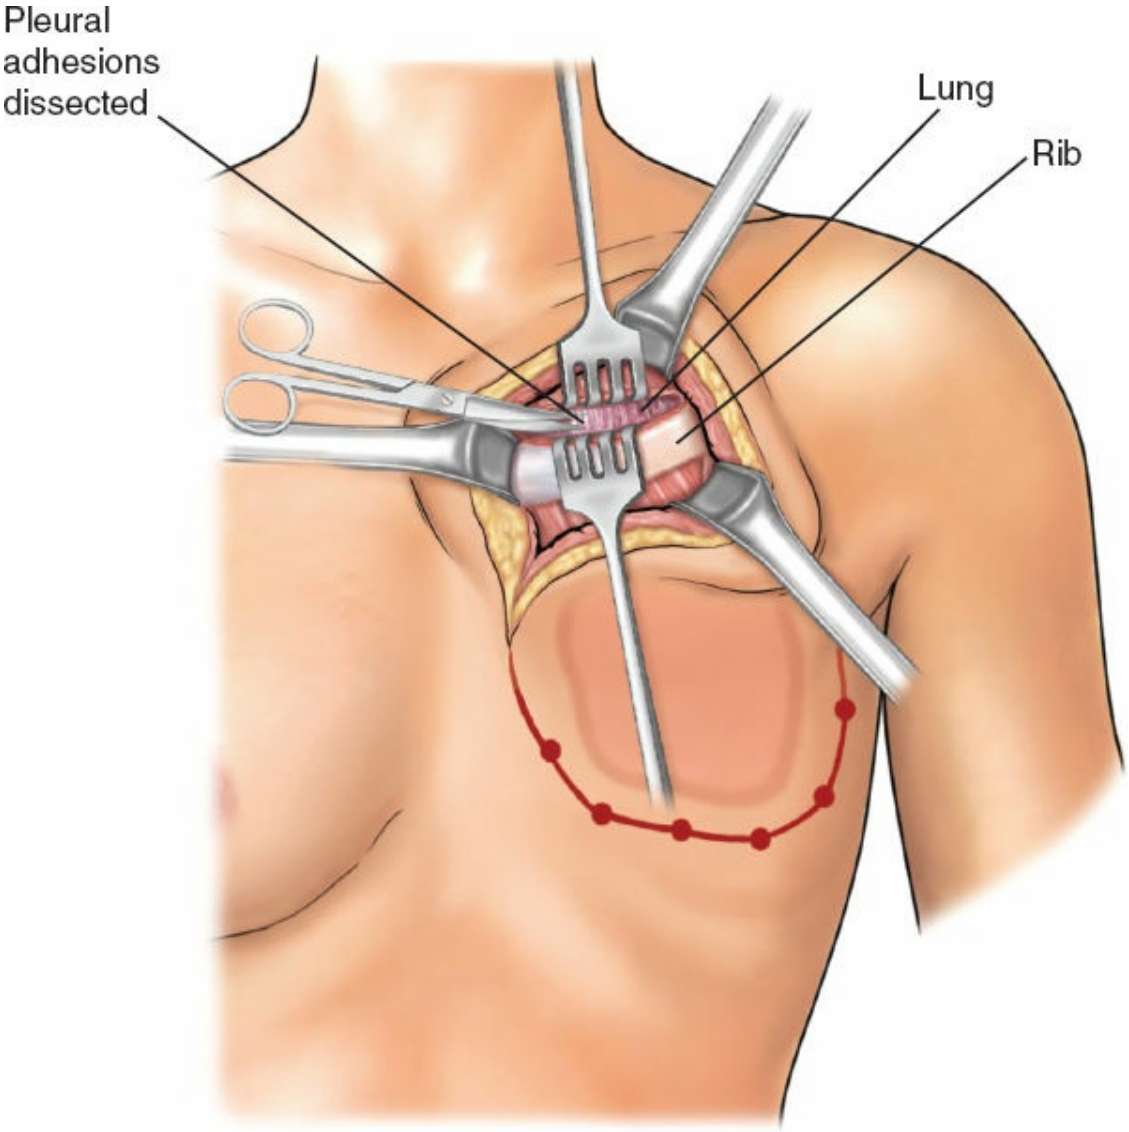

Figure 57.3. Extension of the incision around the periphery of the margins of the tumor mass through the intercostal muscles and via the outline of the punch biopsies that have been confirmed pathologically negative. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

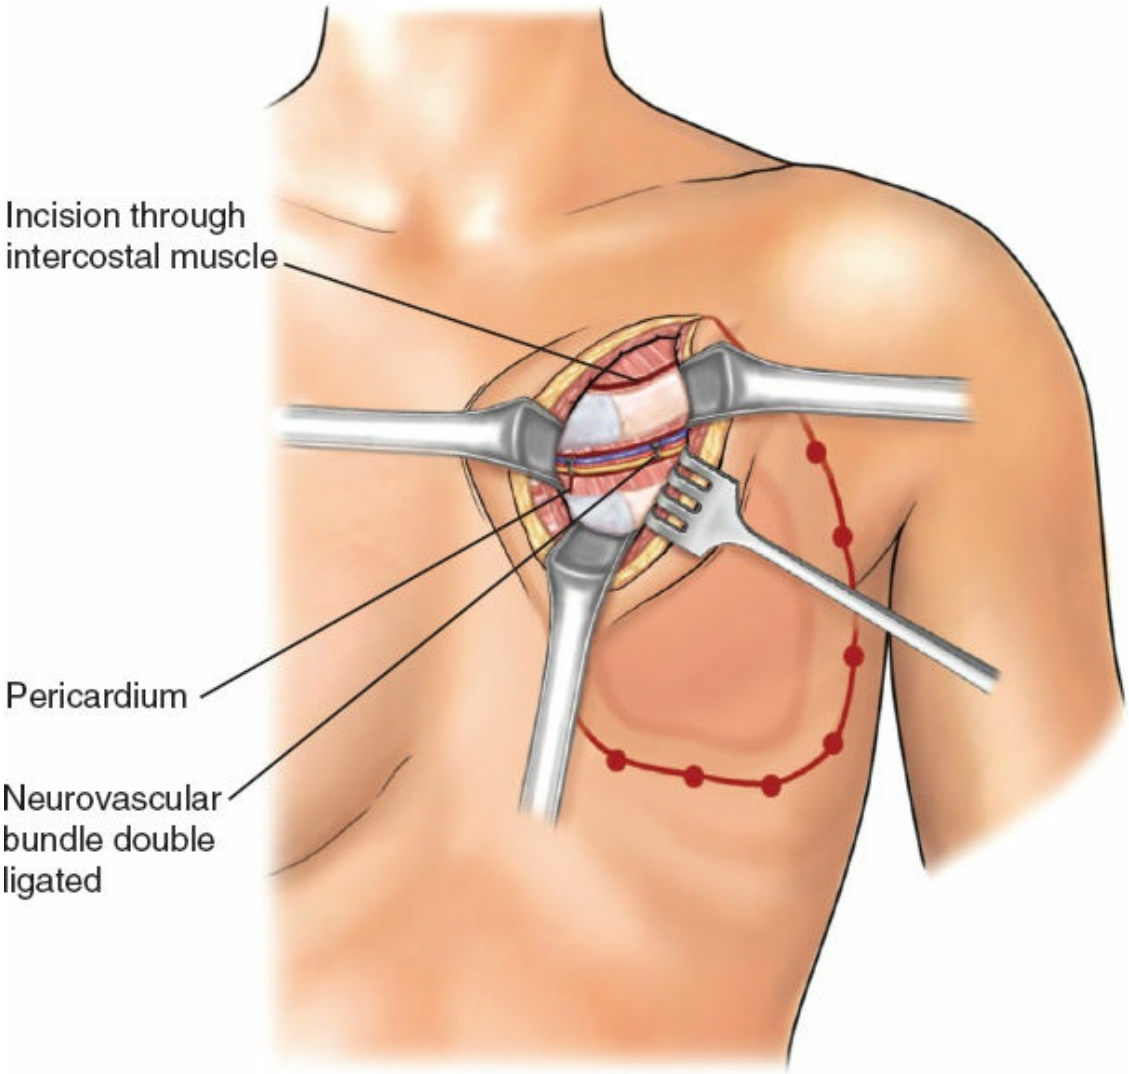

Figure 57.4. Planned line of resection of rib on cephalad-most extension with division on its medial surface following ligation of the neurovascular bundle. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

TECHNIQUE OF RESECTION

The pectoralis major and minor are incised outside the tumor-bearing area to the level of the chest wall; all ribs for planned resection are medially and laterally exposed. The incision will include all previous punch biopsied areas. In the cephalad-most extent of the planned rib resection, the rib is incised on its cephalad surface, and the ipsilateral lung is deflated by the anesthesiologist at the instruction of the surgeon. The thoracotomy should be initiated via the superior margin of the planned resection (Fig.

57.2). Upon entering the thorax, previous pleural adhesions created by prior radiation therapy and/or surgery should be sharply dissected and mobilized. Attention must be directed to avoidance of injury to the parietal pleura and inadvertent damage to the pulmonary parenchyma. When dissection is incomplete or inadequate, lysis of adhesions should be completed and performed with sharp dissection to avoid the formation of an alveolar–pleural fistula. With dense adhesions related to tumor invasion of the parietal pleura of the lung, complete pleurectomy with simultaneous segmental resection of the focally involved lung segment may be necessary. Repair of any parenchymal tears may be completed by stapling or suturing with a 3-0 absorbable polypropylene suture after adequate deflation of the lung without injury. The incision is thereafter extended around the peripheral margins of the tumor mass through the intercostal muscles (Figs. 57.3 to 57.6). The surgeon must be cognizant of ligation of the intercostal neurovascular bundles on the inferior margins of the rib with 2-0 silk suture ligatures (Fig. 57.5).

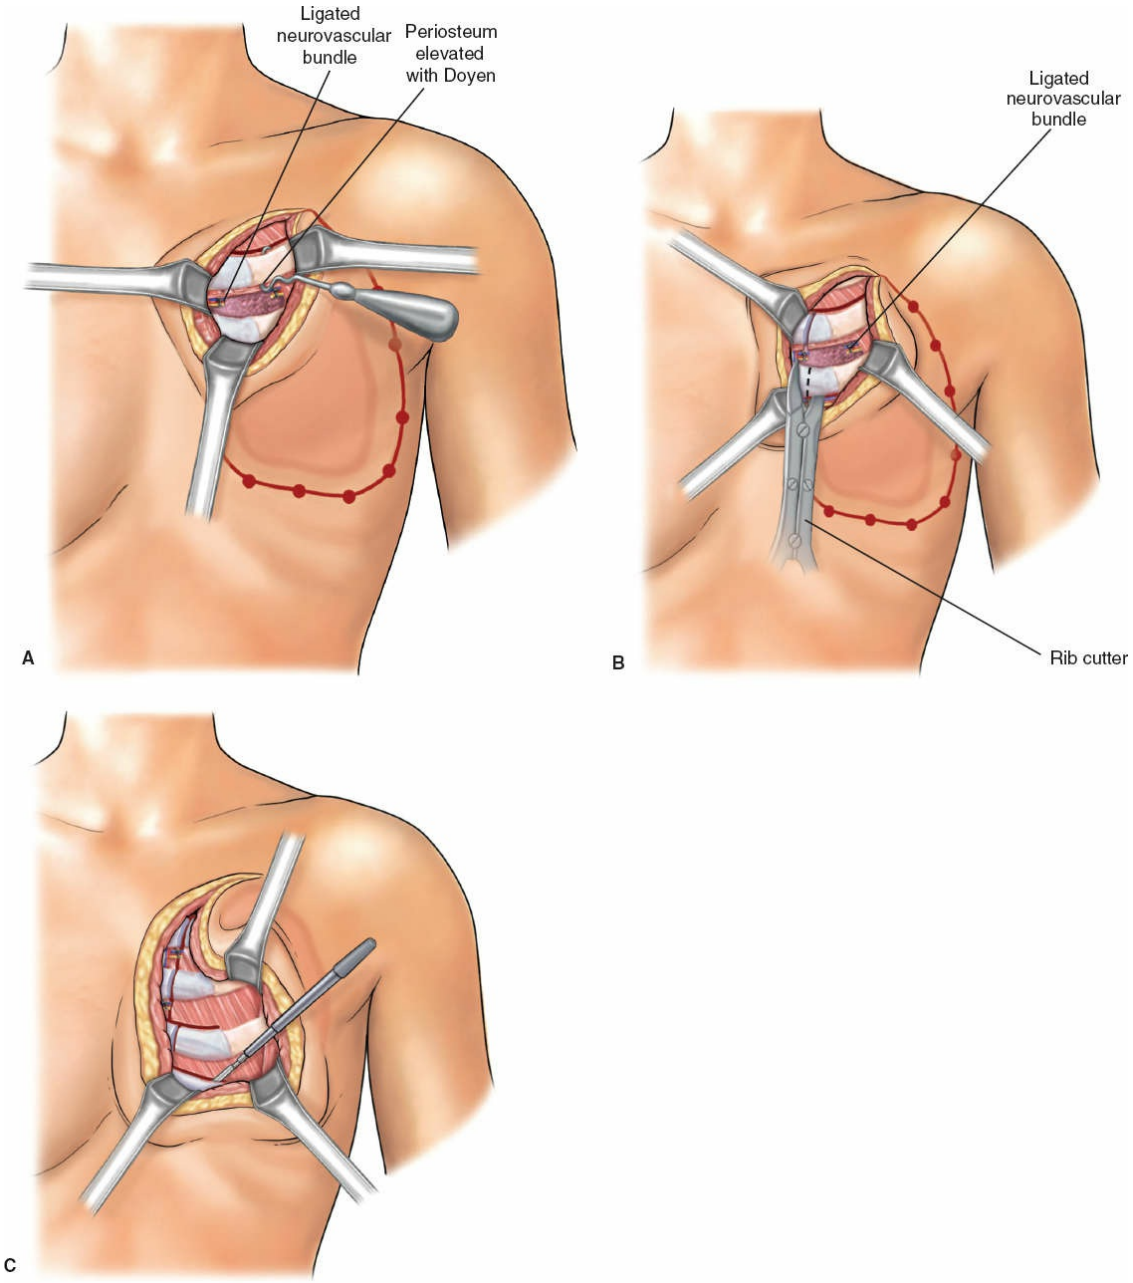

Figure 57.5. A. Isolation and ligation of both medial and lateral neurovascular bundles. **B.** Division of rib on its medial surface with rib cutter. **C.** Further extension of the medial cut with rib cutter to the third rib on its medial surface. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

As the incision is extended around the margins of the resection, the periosteum of the rib should be elevated with a Doyen retractor followed by a periosteal elevator prior to initiating rib division with a rib cutter (Fig.

57.5A). Following completion of the entire incision, the surgeon should be cognizant about including all the punch biopsy sites to ensure negative surgical margin.

When the tumor margin extends medially to the sternum, it may be necessary to utilize a sternal saw or osteotome to create a partial sternotomy up to and inclusive of the biopsied skin that establishes a clear surgical margin. Moreover, the incision should be extended to the sternocostal margin where the internal mammary artery (IMA) can be palpated, ligated, and divided. The sternum thereafter may be partially resected, but diligence must be exercised to protect the pericardium, which may be centrally adherent to the investing parietal pleura of the sternum, secondary to irradiation.

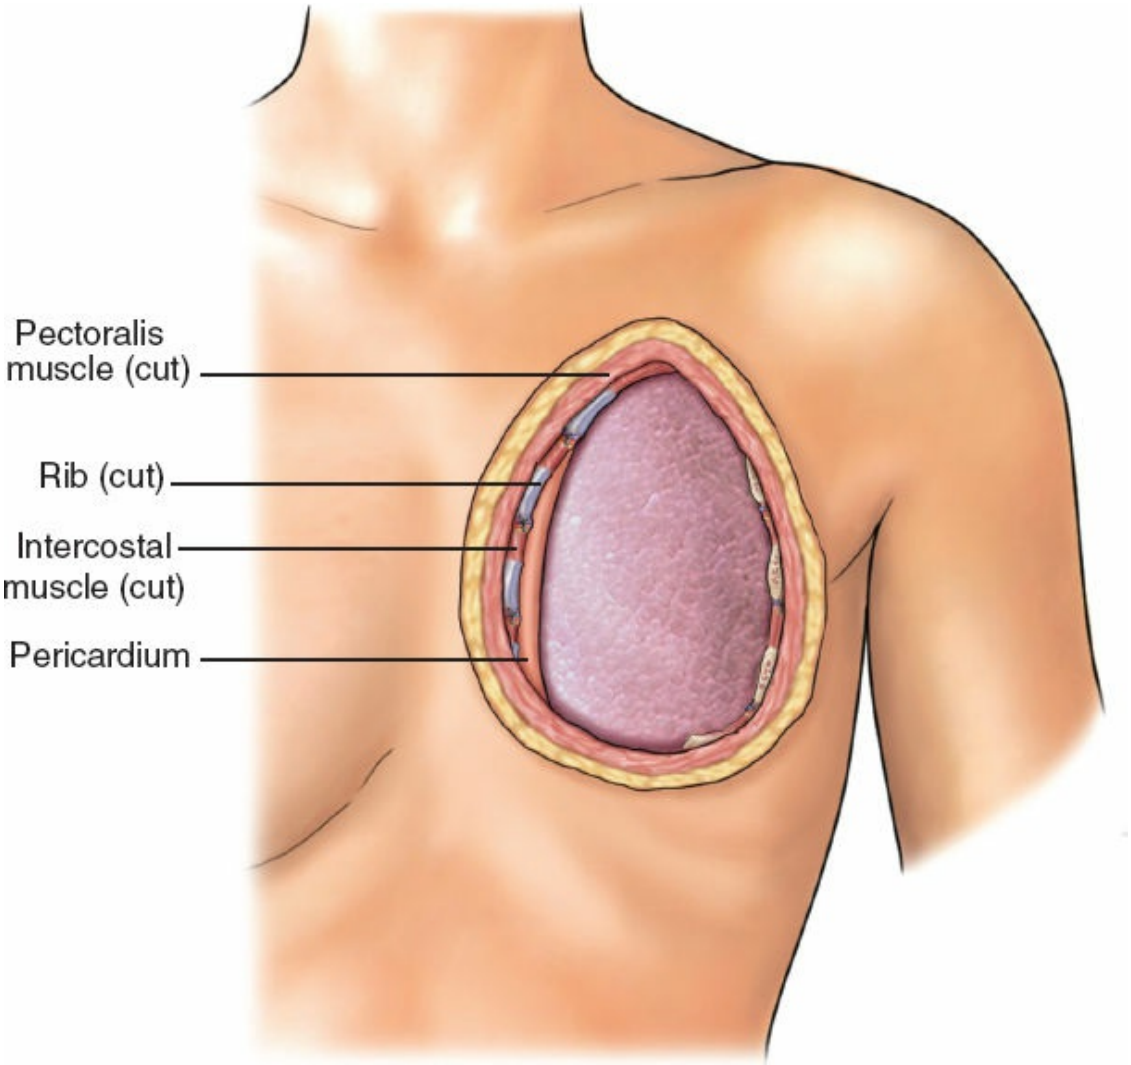

Figure 57.6. The completed resection both medially and laterally, including four ribs in the resection with exposure of the visceral pleural surface of the lung following resection of parietal pleura

with chest wall. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

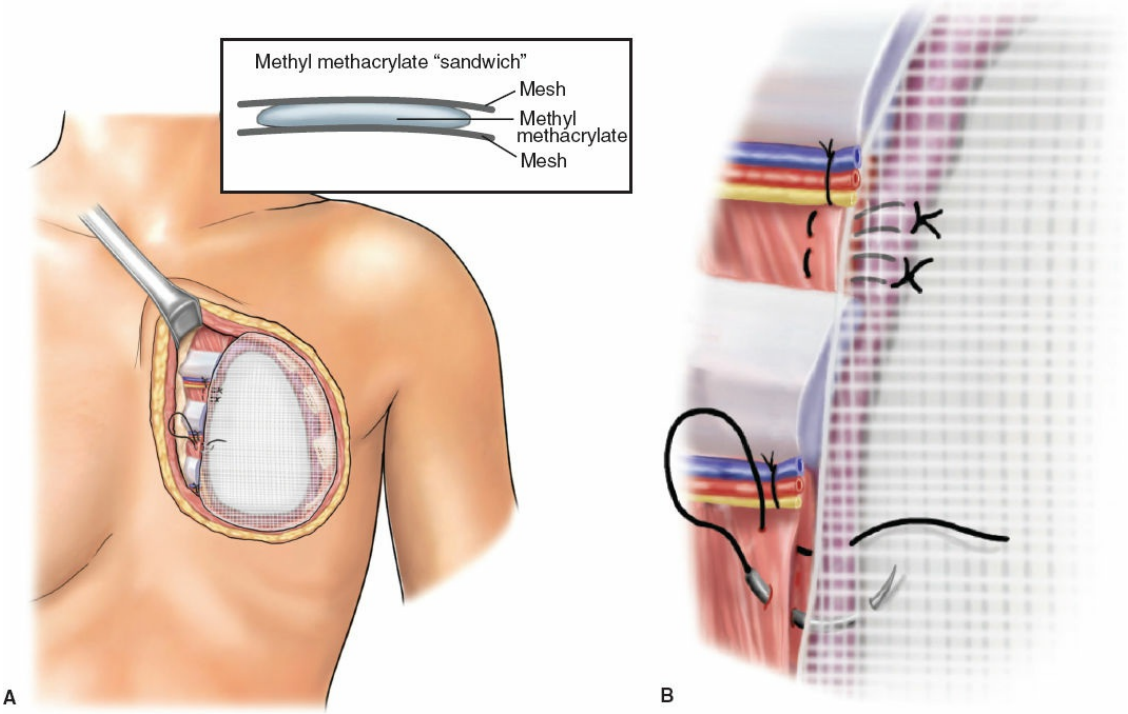

Figure 57.7. A. Inset identifies the optional creation of the methyl methacrylate "sandwich," in which methyl methacrylate interposes between two mesh surfaces of a nonabsorbable polypropylene mesh. The strut of this prosthesis is created with the folding in half of a large piece of polypropylene mesh to ensure coverage of the sandwich over the defect without undue tension. **B.** Suturing of the polypropylene mesh encircling the rib margin on its superior and inferior surface of the resection with creation of the planned suture knots external to the mesh with full-thickness purchase through the musculature of the chest wall. Neurovascular bundle has been separately ligated. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

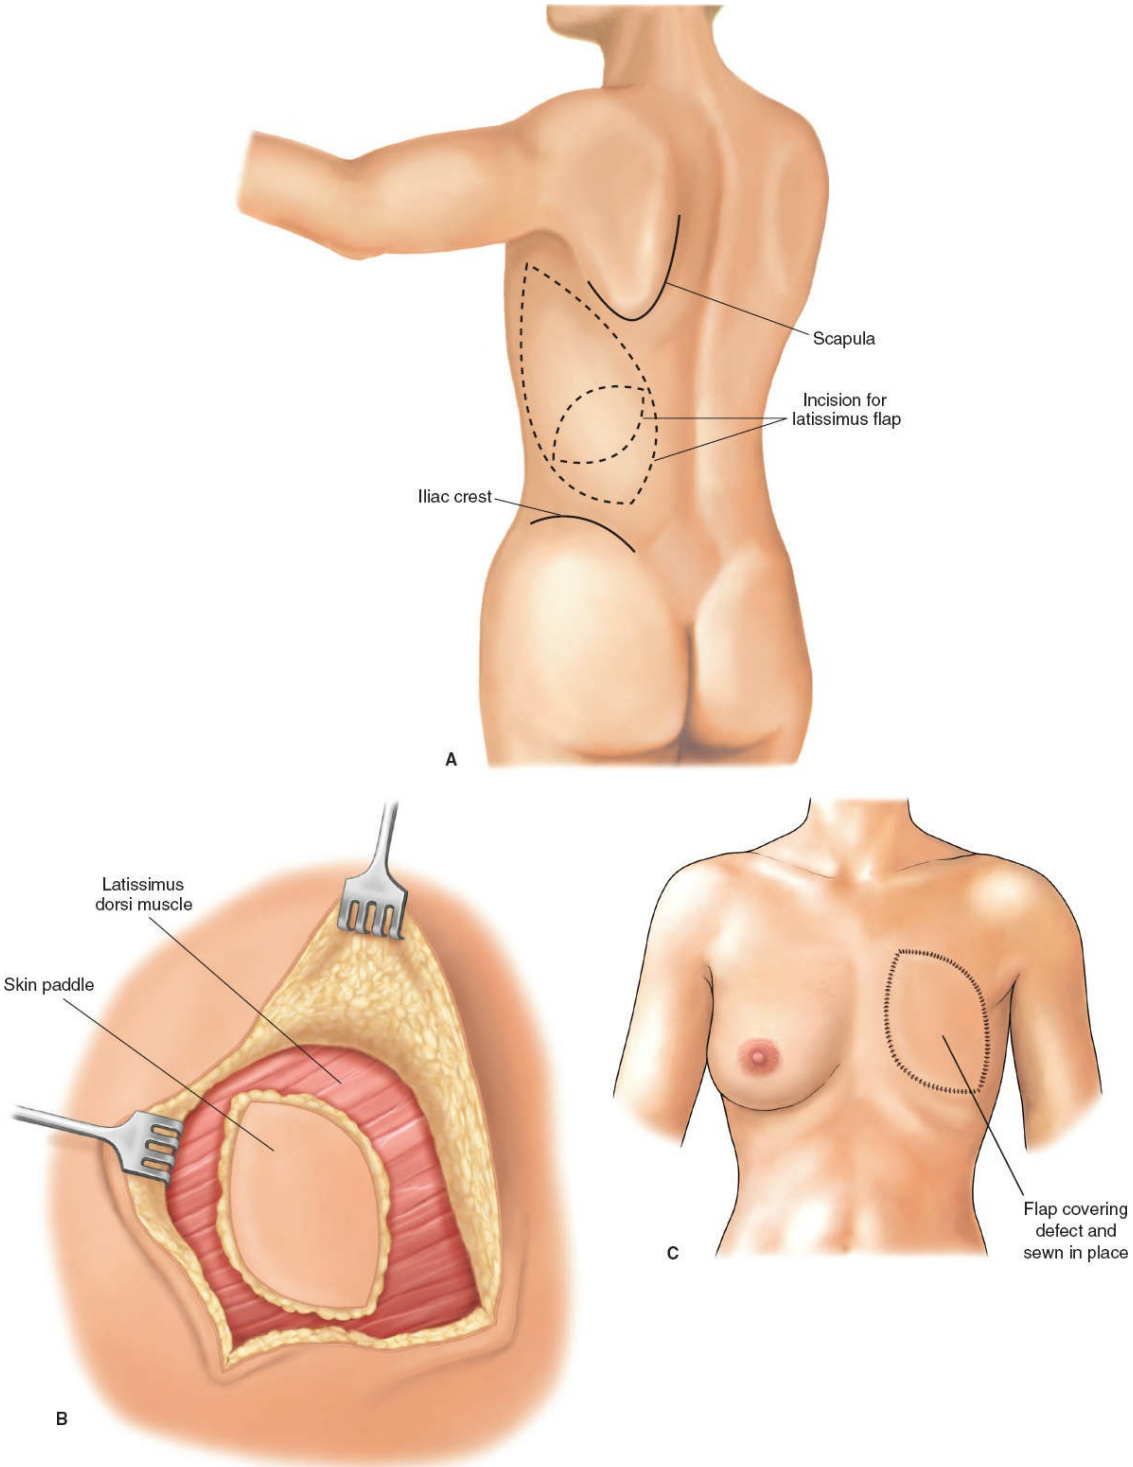

Figure 57.8. **A.** Design of the most commonly utilized and versatile flap reconstruction as a pedicled latissimus dorsi flap. **B.** Note that the flap is inclusive of a vascularized skin panel in the central inner outline, and in which the planned latissimus flap, together with the exposed latissimus muscle and skin panel, has been harvested. **C.** Identification of the completed inset of the vascularized latissimus dorsi pedicled flap following its in situ placement in the created chest wall defect.

In all circumstances, the specimen should be resected en bloc, thus exposing the chest wall defect with the exposed, inflated, protuberant lung. Insufflation of the underlying lung following resection of tumor invasion allows evaluation with visualization of alveolar–parenchymal leak; repair must be instituted for closure of such leaks. If invasive disease is detected grossly or with biopsy, the well-exposed lung can then be managed by a wedge resection of the involved lung with a stapler. Leaking defects should again be oversewn and tested for air leaks prior to tube placement and chest closure (Fig. 57.6). Air leak may increase the risk of infection of the material used to close the chest wall defect and a lung sealant can be applied as well if needed.

Prior to initiating chest wall reconstruction, an apical–posterior chest tube should be placed in the midaxillary line *inferior* to the defect. Only one chest tube is needed.

FLAP RECONSTRUCTION

The inset of Figure 57.7 confirms the methyl methacrylate mesh "sandwich" shaped and contoured for the chest wall defect. This reconstructive sandwich should be layered such that the methyl methacrylate is interposed between two layers of the polypropylene mesh.

The prosthetic strut may be created with the folding in half of a larger piece of polypropylene mesh that ensures coverage of the sandwich over the defect without undue tension. It is important that the methyl methacrylate does not contact the rib so as to avoid the pain of these rubbing against each other postoperatively.

With planning of surface area of the prosthetic strut to cover the defect, the mesh should be contoured beyond all margins of the resection such that it can be sutured to the resected rib edge. We prefer that the first layer of the mesh be sutured to the edges of the wound using nonabsorbable 0 or 1 polypropylene sutures (Fig. 57.7A). Figure 57.7B confirms that suturing should encircle ribs on the superior and inferior edges of the resection and that sutures are created external to the mesh, then full-thickness purchase through the musculature, exiting external to the musculature and incorporating the edges of the prosthetic strut, and are tied external to the mesh (Fig. 57.7A). Care must be taken to avoid entrapping the intercostal neurovascular bundle while securing the mesh. The neurovascular bundle should have previously been ligated in an isolated fashion. All sutures are tied external (anterior) to both folded edges of the mesh.

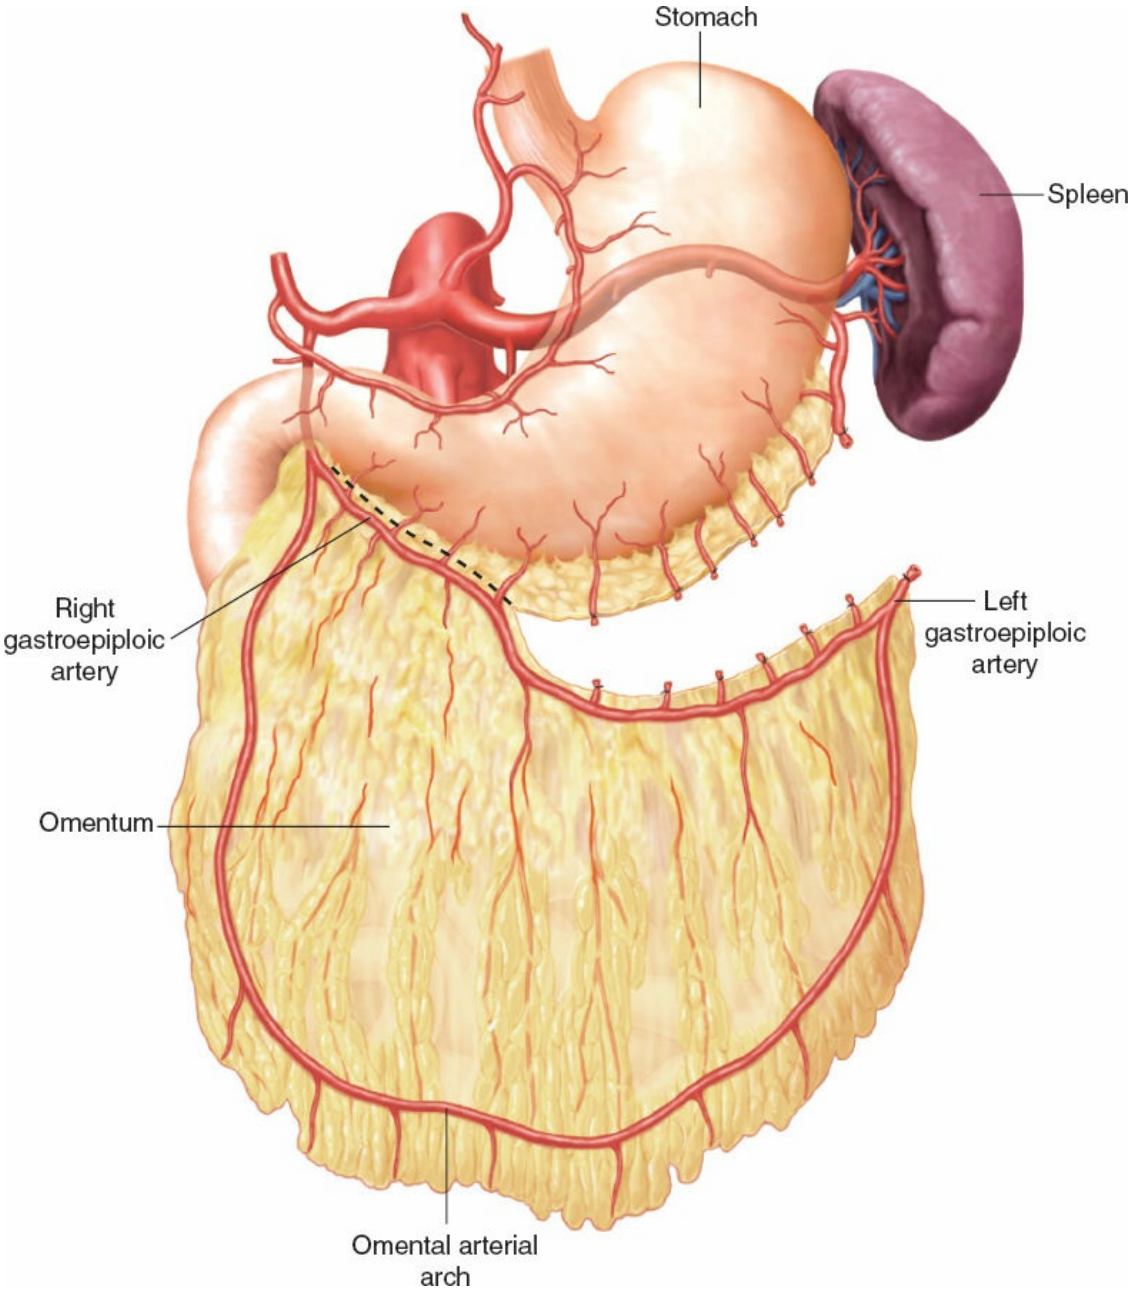

Figure 57.9. The intra-abdominal vasculature of the greater omentum, in which the selection of this approach requires upper midline laparotomy incision for access to the omentum. The omental flap approach by necessity enhances potential morbidity as it adds complexity to the chest wall defect with abdominal entry. Following division of the left gastroepiploic artery, vascular perforators (vasa brevia) to perfuse this arcade are ligated in continuity for revascularization purposes. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

Following placement and completion of suturing of the methyl methacrylate "sandwich," reconstruction of the soft tissue defect is initiated. Again, the most commonly utilized and versatile flap reconstruction of this area is the pedicled latissimus dorsi flap that is inclusive of a vascularized skin paddle. Such design and transfer of tissue is highlighted in Figure 57.8A in which the planned latissimus flap (Fig. 57.8B), together with the exposed latissimus muscle and skin paddle, has been harvested. Figure 57.8C confirms the completed inset of the flap following its in situ placement in the created defect.

Figures 57.9 to 57.11 highlight the omental flap, which designates an increase in potential morbidity as it adds complexity to the chest wall defect with abdominal entry. The omental flap is based upon the right gastroepiploic artery that is utilized for tissue coverage (Fig. 57.9). With selection of this approach, the upper midline laparotomy incision is utilized for access to the omentum. Figure 57.11 indicates that the omentum has been transected together with the splenocolic ligament, and divided from the inferior gastric surface from the splenocolic ligament to the base of the right gastroepiploic artery. Ligation and division of the vasa recta of the anterior and posterior omental leaves is performed using 3-0 nonabsorbable sutures (Fig. 57.11).

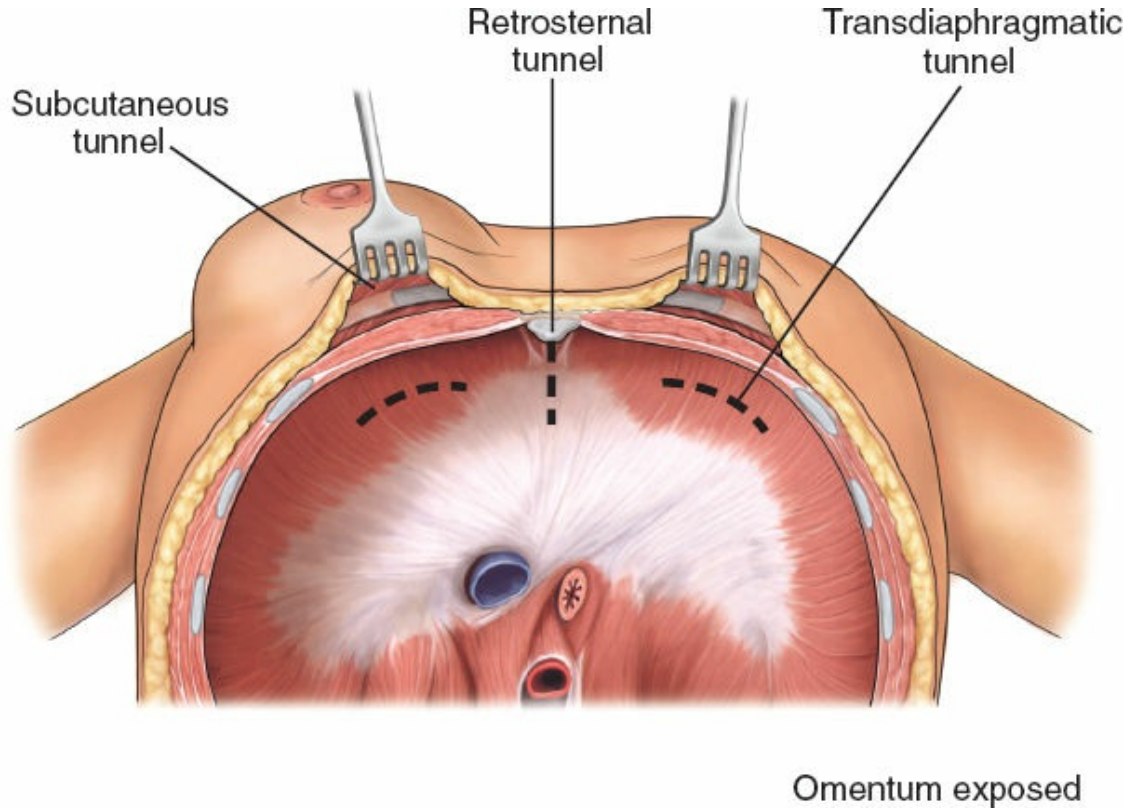

Figure 57.10. The anterior inferior diaphragmatic incisions that

require hepatic mobilization and creation of the transdiaphragmatic tunnel to the created defects of each side and thereafter placement in a subcutaneous tunnel. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

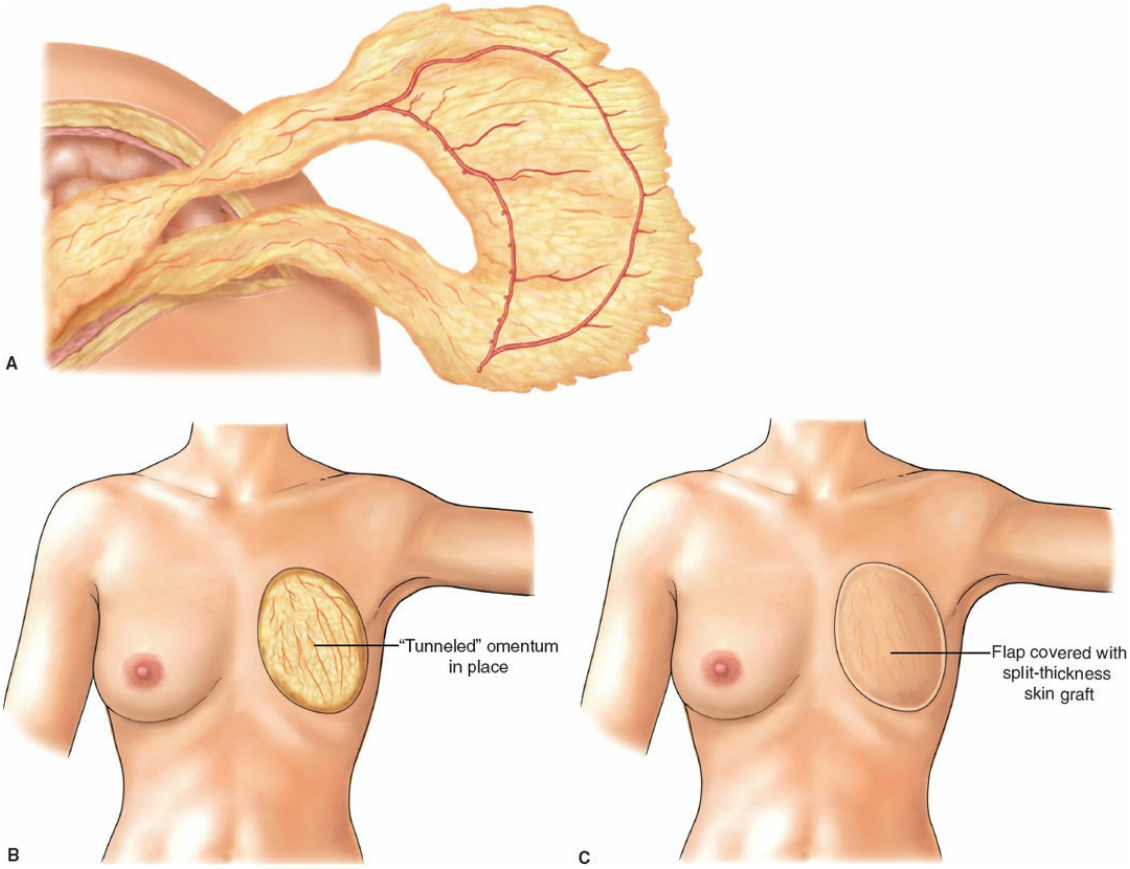

Figure 57.11. A. Mobilization of the omentum, together with the splenocolic ligament, and division from the inferior gastric surface from the gastrocolic ligament to the base of the right gastroepiploic artery. To maintain integrity of the vascular perfusion pedicle, the surgeon must be cognizant of inadvertent rotation of the omental pedicle and avoidance of vascular injury to the peripheral and central components of the pedicle. **B.** The omentum exposed and inserted into the tunneled subcutaneous space created with reconstruction of the defect. **C.** Placement of the optional split-thickness skin-graft coverage of the pedicle, which has been inserted in the patient as visualized at the time of a postoperative visit. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia,

Options exist for transfer of the vascularized omental pedicle flap. After exiting the midline abdominal incision, the omentum may be transferred to the chest wall defect via a retrosternal, transdiaphragmatic, or subcutaneous tunnel as indicated in Figure 57.10. We prefer and almost exclusively use a transdiaphragmatic approach. To maintain the integrity of vascular perfusion, the surgeon must be cognizant of rotation of the omental pedicle to ensure preserved vasculature to its periphery and all the central components of the pedicle. Figure 57.11A confirms the omentum exposed, and Figure 57.11B confirms the adequately planned coverage of the defect prior to tunneling of the omental pedicle. Figure 57.11C confirms the optional skin grafting of the pedicle that has been inset in the patient as visualized at her postoperative visits.

A third option includes a pedicled free flap utilizing the TRAM flaps with skin paddles to bridge alternatives for covering these defects (Fig. 57.12). In addition, for heavily irradiated parasternal and chest wall tissues, most plastic surgeons prefer the free flap harvested as a TRAM reconstruction with anastomosis to the ipsilateral IMA that provides arterial and venous inflow/outflow to the vascularized graft.

A thoracoepigastric flap represents another option, especially for patients with excessive abdominal wall laxity. This versatile flap consists of the mobilization of the upper abdominal wall as a fasciocutaneous flap of variable sizes, according to the defect to be covered, based on the superior epigastric perforator. The donor site is closed primarily resulting in a “reverse abdominoplasty” as it mobilizes the abdominal tissues superiorly (Figs. 57.13 and 57.14).

For very large soft tissue defects, variations of the above-mentioned flaps provide reliable results. One of the described variations is the extended latissimus muscle flap, where a larger area of skin and subcutaneous tissue is rotated with the muscle flap. This results in a donor site defect that can no longer be closed primarily and will require a skin graft.

Another variation described for very large defects is the use of not only one rectus muscle flap, but rotation of *both rectus muscles* en bloc, on a bipedicle technique, providing additional bulk and skin surface to cover the defect.

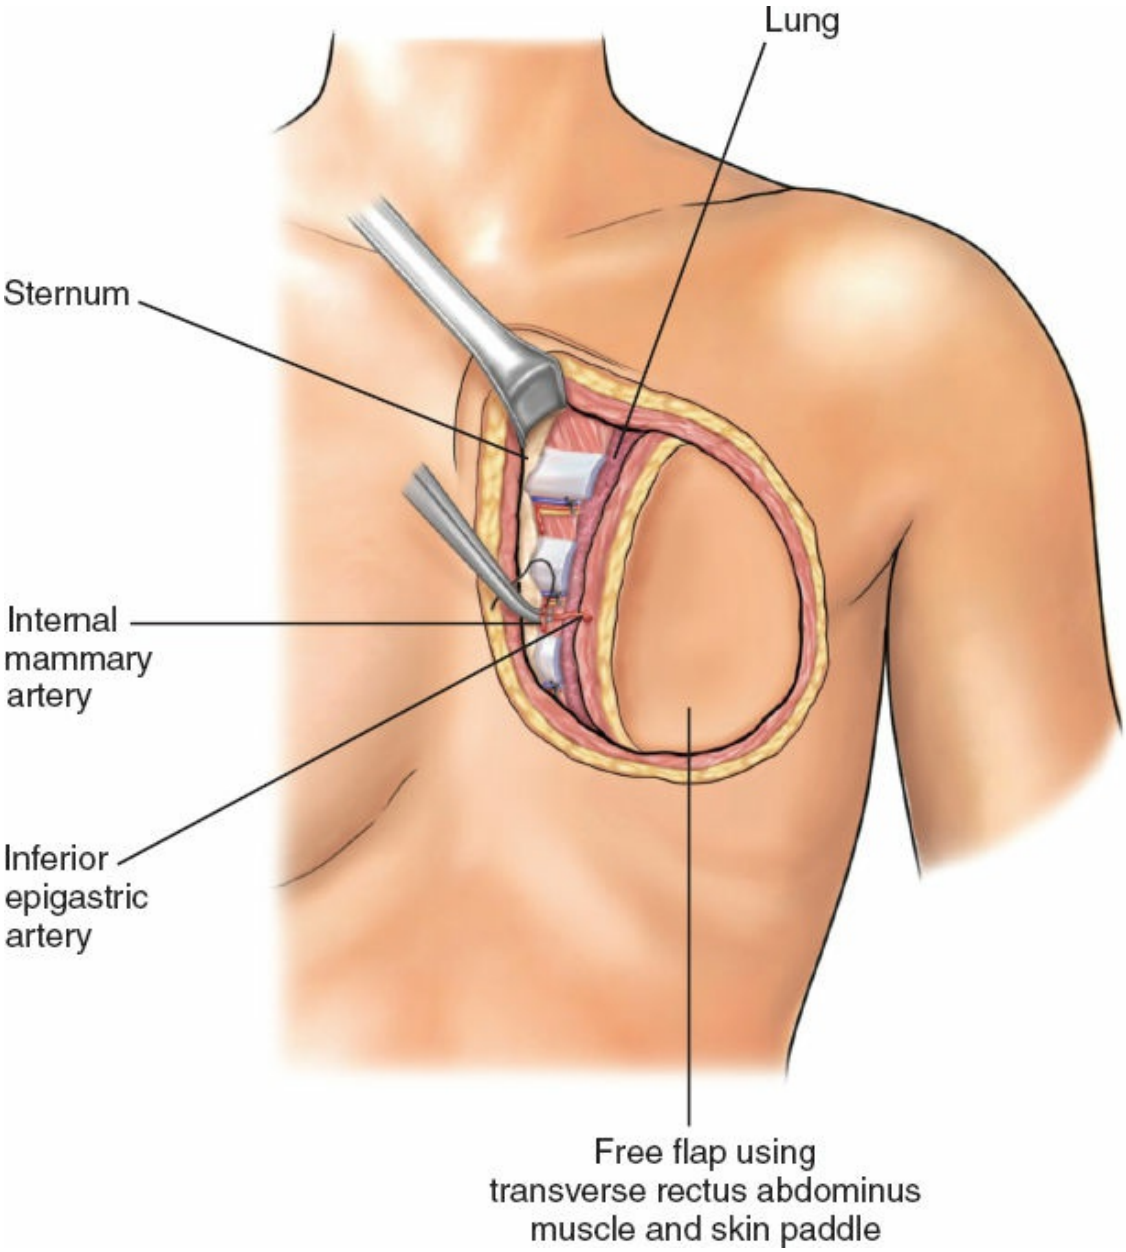

Figure 57.12. An additional option utilizing the pedicled free transverse or vertical rectus abdominis muscle (TRAM) flap as skin panels to bridge as the alternative for covering these defects. In the heavily irradiated parasternal and chest wall tissues, the pedicled free-flap TRAM represents the preferred harvested reconstruction and anastomotic technique. Anastomosis is completed for the vasculature (inferior epigastrics) of the free TRAM to the ipsilateral internal mammary artery (IMA) and provides both arterial inflow and venous outflow to the vascularized graft. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

The inset flap should be closed in two layers inclusive of a deep dermal layer that is sutured with 3-0 absorbable sutures. A running subcuticular closure with an absorbable 4-0 suture is used for the skin.

Chest tube drains are essential to evacuate the pneumothorax created with thoracotomy in these patients. In addition, we prefer large defects having subcutaneous closed-suction drains around the soft tissue reconstruction for avoidance of hematoma and seroma. Internal Doppler probes may be placed for monitoring purposes of the flap's arterial blood supply (Fig. 57.15).

POSTOPERATIVE MANAGEMENT

Immediately following operation, a chest x-ray is obtained to evaluate the potential of an existing and retained pneumothorax that is best drained by functional chest tubes. Proper suction drainage on the catheters is essential for vacuum decompression of the pneumothorax created with the opening of the chest. If the patient has an air leak, water seal is the optimal chest tube setting. Pulmonary management should include preventative care for ventilator-associated pneumonia.

COMPLICATIONS

Aggressive pulmonary toilet following extirpation is an essential part of care to prevent atelectasis and subsequent nosocomial pneumonia. Because of the considerable pain experienced with division of the ribs, postoperative epidural pain control should be considered, together with systemic analgesics and sedation.

Continual wound care and flap management are essential; monitoring for flap ischemia and necrosis are the requisite. Arterial supply can best be evaluated by an internal Doppler that is placed intraoperatively. However, the handheld external Doppler is commonly utilized together with visual inspection of capillary refill. Standard criteria are utilized in the management of chest tubes for the timing of removal of these tubes and subcutaneous drains. Removal is dependent upon complete resolution of the pneumothorax and decreasing subcutaneous serous wound drainage.

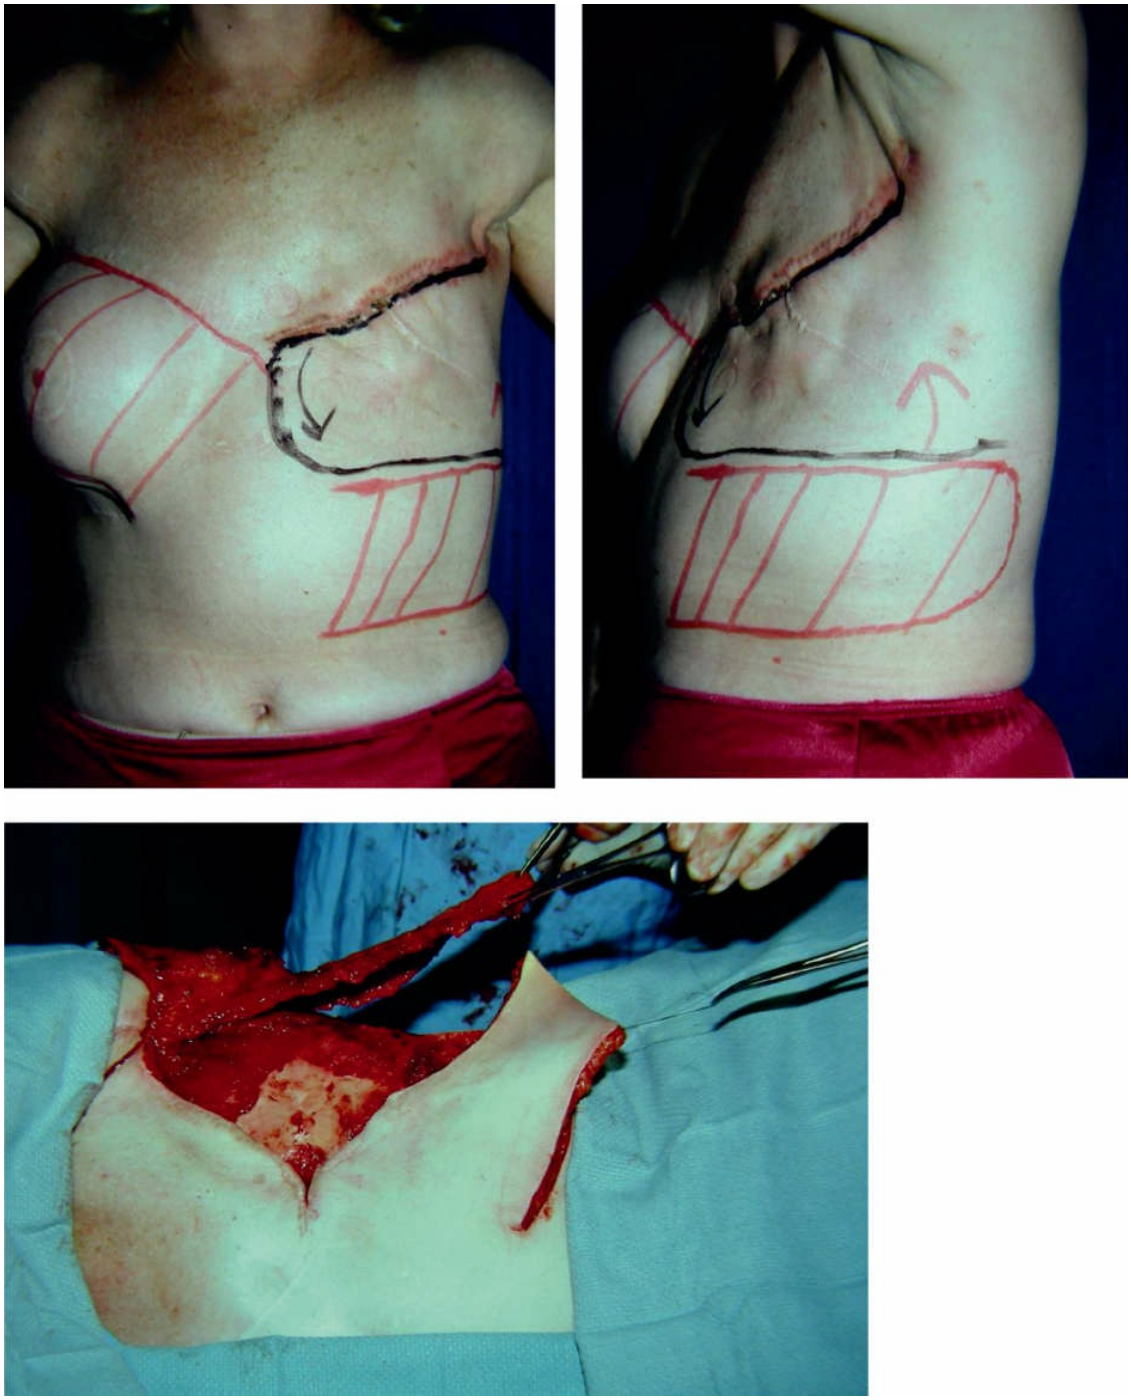

Figure 57.13. Depiction of thoracoepigastric flap where the upper abdominal skin, subcutaneous tissue, and fascia is elevated based on the superior epigastric perforators and rotated superiorly to cover the chest wall defect. The donor site is then approximated primarily.

Morbidity related to these wounds is experienced in virtually all patients. Complications have been reported in as many as 40% of patients and vary from 5% to 40%. The most common complications relate to wound dehiscence, separation and drainage, as well as pneumonia related

to deficient pulmonary toilet. Pulmonary complications also include the risk of reintubation, flail chest, and pleural infection. Wound complications include infection, delayed wound repair, and partial flap or skin-graft necrosis. The serious complications of advanced wound infection often require debridement of portions or all of the methyl methacrylate–polypropylene mesh repair and may include major portions of the reconstruction. Despite the significant morbidity associated with the resection, mortality for the procedure is less than 5%. The surgeon must have a low threshold to evaluate and treat suspected wound and pulmonary infections.

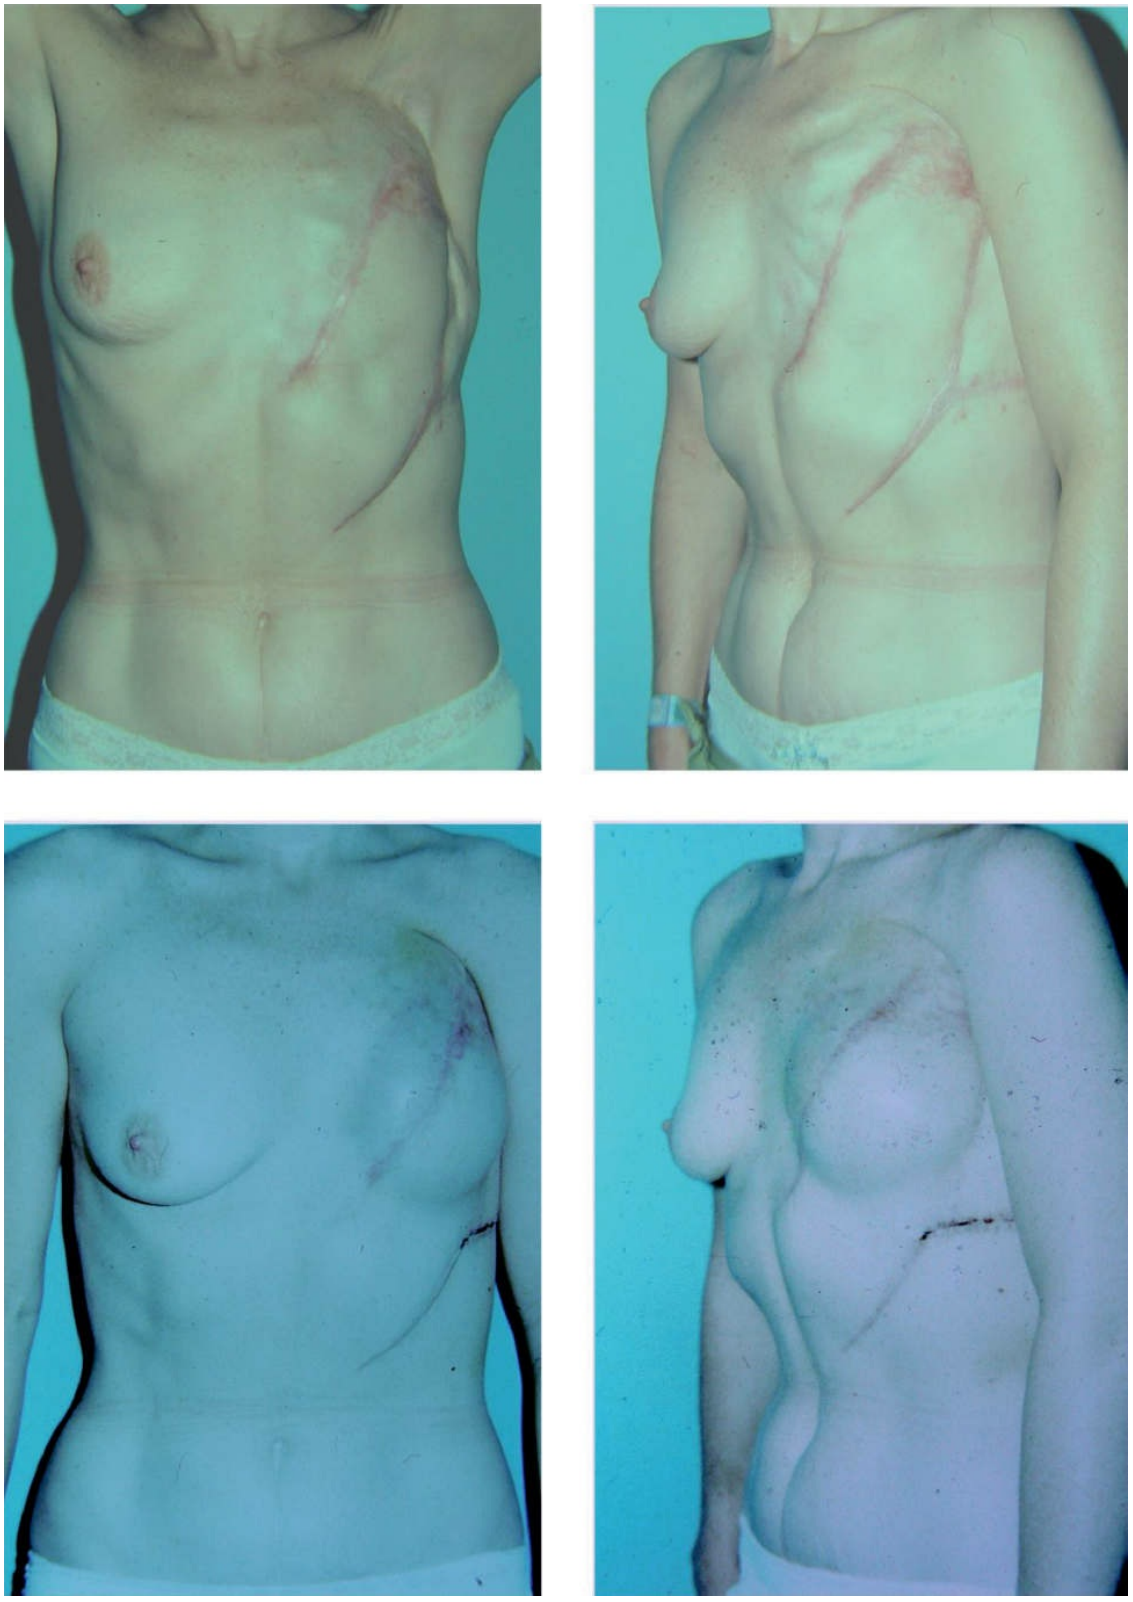

Figure 57.14. Post reconstruction thoracoepigastric flap procedure.

RESULTS

The contemporary surgical literature is devoid of prospective randomized

studies for selective patients undergoing full-thickness chest wall resections that are designed to eradicate locally recurrent/advanced breast carcinoma. Such procedures are regarded as highly mutilating interventions that harbor high morbidity and mortality. Moreover, the utility of plastic reconstruction of the full-thickness chest wall resection for recurrent disease is largely unknown and rarely utilized in surgical clinics. Friedel et al. report the largest series to date for advanced chest wall invasion related to recurrent breast carcinoma utilizing myocutaneous flap coverage. In this series, the cumulative 5-, 10-, and 15-year survival rates were 46%, 29%, and 22%, respectively (median survival, 56 months). When an R0 resection was possible, the 5-year survival was 50.4%. Similarly, outstanding results have been reported by Hanagiri et al., Hameed et al., Veronesi et al., Rivas et al., Cordeiro et al., Suryanarayana Deo et al., Chagpar et al., Kolodziejski et al., Santillan et al., and Pameijer et al.

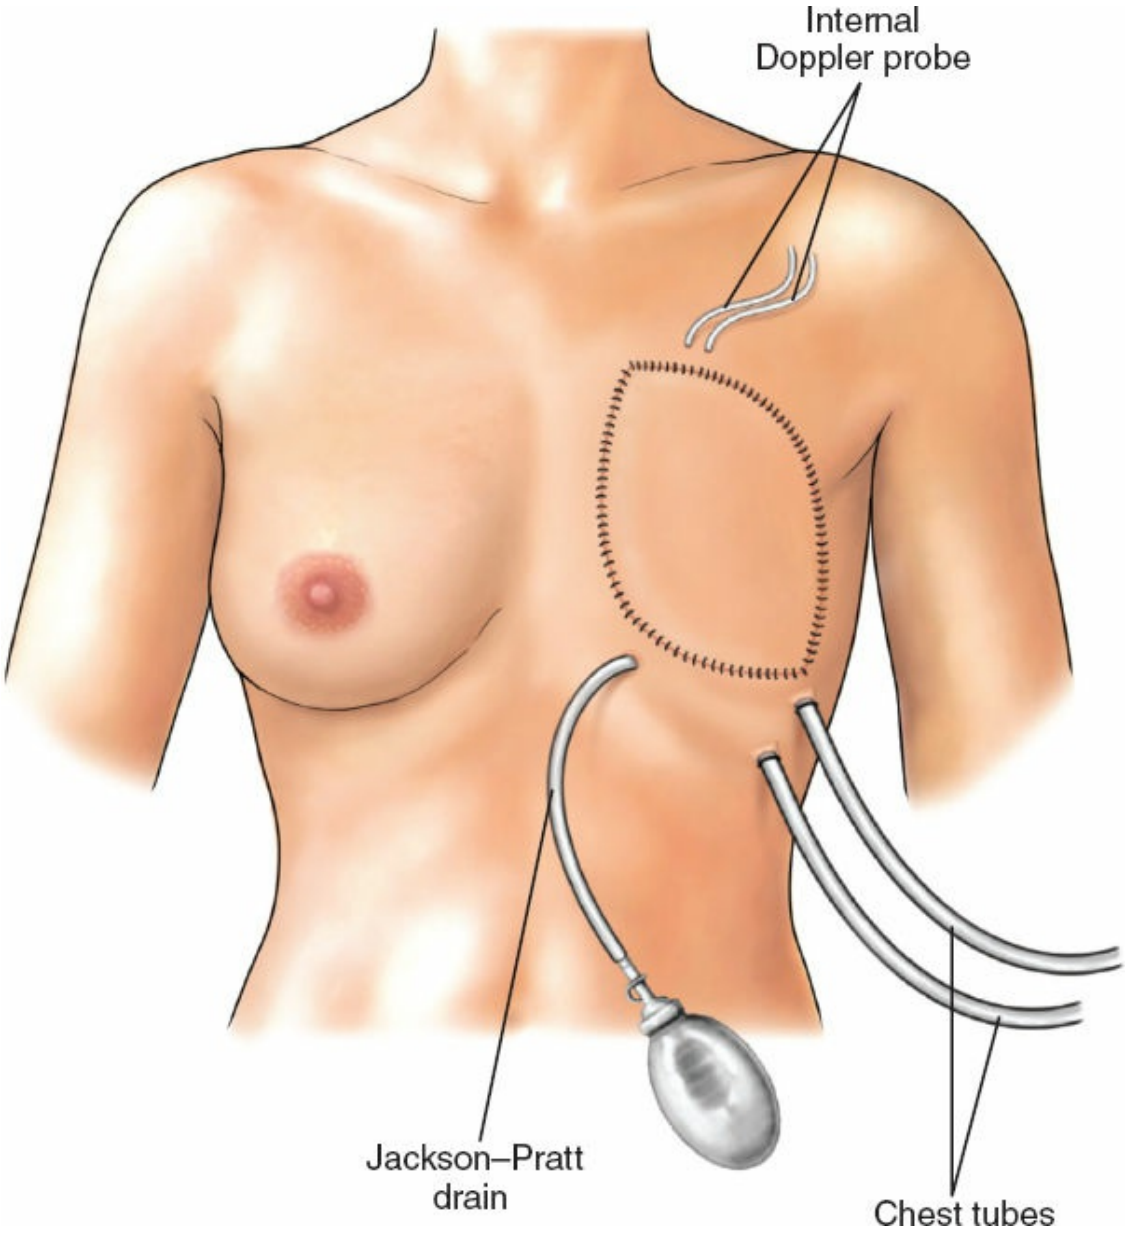

Figure 57.15. Depiction of the inset flap enclosure with completed closure of two layers of the deep dermal layer and a running subcuticular closure with absorbable suture. The opened thorax requires closed-suction chest tubes to evacuate the pneumothorax. In addition, the large defects require subcutaneous closed-suction drainage for evacuation of hematoma and seroma in the reconstruction site. The placement of internal Doppler probes over the vascularized free flap arterial blood flow provides continual monitoring of the patient. (From Bland KI, Fix RJ, Cerfolio RJ. Chest wall resection and reconstruction for advanced/recurrent carcinoma of the breast. In: Bland KI, Klimberg VS, eds. *Master Techniques in General Surgery: Breast Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

In the report by Pameijer et al. from the City of Hope National Medical Center, 71% of patients had an R0 resection; in this cohort, the 5-year disease-free survival was 67%. These reports suggest improvement in long-term palliation and potential cure for this select patient group with chest wall recurrence of breast carcinoma.

CONCLUSIONS

The pathobiologic character of the primary breast neoplasm and prior surgical technique with adjuvant/neoadjuvant approaches determines tumor recurrence.

Sine qua non to eligibility as candidate for chest wall resection is confirmation of the absence of systemic disease following staging.

A team approach with plastic and thoracic surgeons is essential with the oncologic surgeon to allow tissue transfer with reconstruction.

Confirmation of absence of skin/muscle involvement with "punch" biopsy technique enhances local control.

Resections that extend beyond four ribs will routinely require rigid chest wall reconstruction.

Disease-free survival in properly selected patients exceeds 50% at 5 years.

EDITOR'S COMMENT

Chest wall recurrence as well as locally advanced disease of the breast are associated with systemic disease in only about half the cases. Such a disease is associated with sometimes painful open wounds and odorous diseases. Therefore it is incumbent on the surgeon to be able to take care of such diseases. Not all chest wall recurrence is the same and therefore the treatment is not all the same (Moossdorff M, van Roozendaal LM, Strobbe LJ, et al. Maastricht Delphi consensus on event definitions for classification of recurrence in breast cancer research. *J Natl Cancer Inst* 2014;106(12)). Small (<2 cm) and late (>2 years from primary) chest wall recurrences may be handled with simple wide local excision. Depending on the age of the patient (premenopausal vs. postmenopausal) and extent of disease radiation may be added to the younger patient with muscular invasion. Because 50% of patients with recurrence have systemic disease, a metastatic workup is warranted and treat accordingly (Wadasadawala T, Vadgaonkar R, Bajpai J. Management of isolated locoregional recurrences in breast cancer: a review of local and systemic modalities. *Clin Breast Cancer* 2017. pii: S1526–8209(16)30416–5).

The second type of chest wall recurrence presents with multiple nodules of long-standing duration (>3 months) for which the patient has delayed treatment. When left alone these lesions infiltrate the chest wall and ulcerate the overlying

skin. These can also be resected with full thickness resection of the muscle. When infiltrating the deep chest wall they are rarely free of systemic disease. Still, local control is imperative. More often a full thickness involvement requiring rib resection is seen with rarer types of breast cancer such as phylloides or desmoids and do not necessarily have systemic disease. The authors detail in this and other chapters various muscular flaps that can be used to cover the mesh reconstruction. When the chest wall reconstruction is lateral and there is remaining pectoralis major, I have detached the inferior half of the pectoralis major from the ribs, freed it from the underlying pectoralis minor and rotated it to cover the mesh. This works quite well when possible, is easier on the patient and very quickly performed.

The third type of recurrence is inflammatory or carcinoma en cuirasse, that is, diffuse infiltration of the chest wall skin and subcutaneous tissue. Initial local excision in these cases is futile as they will recur almost immediately. In such cases, multimodality therapy is again required but in a different order. Primary systemic therapy is important. We have also reported successful use of subcutaneous injections of interferon in such cases. Photodynamic therapy has been used successfully but requires long procedures, results in ulcers, long healing times and can only be used in relatively superficial disease. When disease on the chest wall fails to respond to such treatment, radiation is a good next step especially when metastatic disease is already present. It can keep the chest wall in check. If there is no systemic disease then an attempt at resection and reconstruction after radiation is warranted. If surgery were to be prior to this radiation, recurrence will occur before the patient can fully heal. It is important prior to any surgical procedure that the surgeon makes every attempt to improve the commensurate poor nutritional status of all these patients. Most assuredly adding radiation prior to surgery will delay the wound healing and prolong drainage but these patients eventually heal with a higher chance of chest wall control. Paying attention to nutrition and prescribing the cofactors for collagen formation, Vitamins A, C and zinc, will aid in successful wound healing.

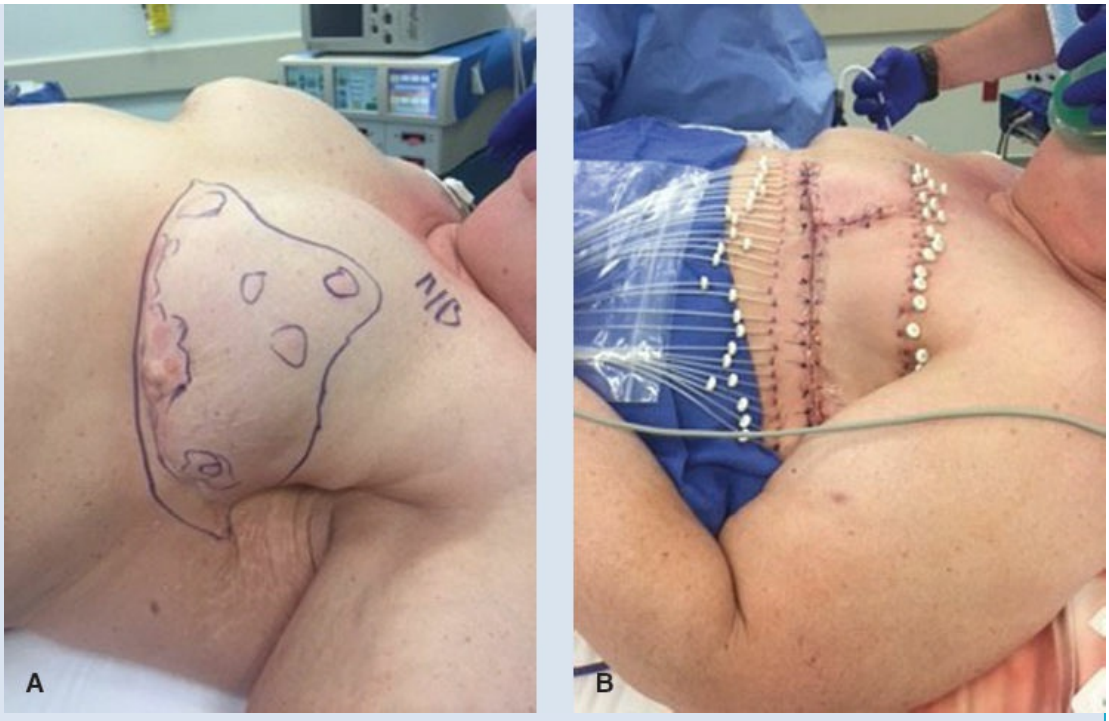

Figure 1. A. Recurrence on chest wall in a patient with reconstruction with implant and radiation. *Purple line* shows area to be resected. **B.** Patient postresection and placement of brachytherapy catheters for reirradiation.

The fourth type of recurrence is in an already irradiated field. Resection often has to be wide requiring flap reconstruction. The authors of this chapter have described extensive chest wall resection and various muscular flaps to cover the chest wall. The method for replacing the rib cage is what I use and is necessary to prevent paradoxical chest wall motion and is radiolucent as to allow radiographic follow-up. Mesh over bone cement has also been used (Rajesh A, Farooq M. Resection and reconstruction following recurrent malignant phyllodes–Case report and review of literature. *Ann Med Surg* 2017;16:14–8). In such cases, especially if the recurrence appears inflammatory or is incompletely resected, reirradiation may be necessary (Marta GN, Hijal T, de Andrade Carvalho H. Reirradiation for locally recurrent breast cancer. *Breast* 2017;33:159–65). These authors reported local control and complete response rates were reported to be 43% to 96% and 41% to 71%, respectively. Reirradiation in combination with hyperthermia suggested improved results (Jones EL, Marks LB, Prosnitz LR: Point: Hyperthermia with radiation for chest wall recurrences. *J Natl Compr Canc Netw* 2007;5:339–44). These cases are rare enough and present with such varied prior treatments, it is difficult to really judge success. At our institution, when chest wall recurrences present in a prior irradiated field, the first obligation is to bolster the patient's nutritional status. Then every attempt is made to resect the chest wall to clean margins. In such patients in order to avoid major flap reconstruction, as the complication rate is high, and if the patient has a remaining contralateral breast, one can perform a

skin-sparing mastectomy of the contralateral breast and fashion that skin into flaps to cover the ipsilateral skin defect. We like to use brachytherapy catheters placed at the time of resection to cover the area of recurrence. As such catheters have a more focused depth of radiation (～1 cm) then reirradiation of vital organs can be avoided. Figure 1A and B demonstrates pre- and postresection with brachytherapy catheters in place. One can except prolonged seroma drainage in such cases (～1 month) so that the surgeon should avoid removing catheters too early. When recurrence is in the sternum or more likely in the case of recurrent breast cancer in a mediastinal node eroding the sternum, major resection is and flap reconstruction is more involved and difficult for the patient (Cranenbroek S, van der Sangen MJ, Kuijt GP, et al. Diagnosis, treatment and prognosis of internal mammary lymph node recurrence in breast cancer patients. *Breast Cancer Res Treat* 2005;89:271–5). Reirradiation with gamma knife can be successful in controlling this disease and should be tried with or without resection. Overall prognosis for these patients is poor. Reconstruction of the sternum involves similar principles. There have been reports of the use of three-dimensional printing based on volumetric scans to provide hardware for reconstructing the sternum (Khalpey Z, Marsh KM, Ferng A, et al. First in man: sternal reconstruction with autologous stem cells. *ASAIO J* 2015;61(5):e31–2).

As one can see, there are as many operations as there are surgeons that can think of them. It is important to note there is not one correct answer except to say that this is a problem that only a multiple modality treatment (chemotherapy, immunotherapy, radiation therapy, surgery, and nutrition) can solve. With enough ingenuity, the passage of time, and technical skill, one can utilize a variety of muscles, skin, and prosthetic material that will give satisfactory coverage where one would not necessarily think it possible. In other words, do not give up if there is a recurrence of the chest wall; utilize your ingenuity and any kind of material, and finally you likely with enough persistence a good clinical result.

58 Clinical Trials and Follow-Up for Breast Cancer

Michael S. Cowher, LaShondria Simpson-Camp, Eleftherios P. Mamounas, and Thomas B. Julian

PRIMARY SURGICAL THERAPY FOR INVASIVE BREAST CANCER

INTRODUCTION

Near the turn of the 20th century, breast cancer was a disease that carried a high mortality and had limited treatment options. Anecdotal reports from small series reported high levels of local recurrences (LR). In the 1895 *Annals of Surgery*, Halsted reported on 50 patients treated with radical mastectomy, with the LR rate of 6%. Although the Halsted radical mastectomy involving en bloc resection of the breast and surrounding chest wall musculature, skin, and axillary contents improved local control, mortality and morbidity remained high. Extensive belief in the value of the Halsted technique lasted into the later part of the 20th century when laboratory and clinical investigations challenged the hypothesis that breast cancer spreads primarily by a local contiguous process from the breast to the regional lymph nodes and eventually to distant sites. Instead, an alternative hypothesis postulated that breast cancer is a systemic disease from early on in its inception because breast cancer cells can reach distant sites through the blood stream without necessarily involving the regional lymph nodes. This paradigm change in the understanding of the biology of breast cancer progression led to the development and conduct of randomized clinical trials that eventually established the new standards for the surgical and adjuvant treatment of the disease.

Randomized clinical trials evaluated the use of less aggressive surgical techniques—with or without radiotherapy (RT)—and the introduction of adjuvant endocrine therapy and adjuvant chemotherapy. The results of these trials set the framework for the multidisciplinary approach to breast cancer and have led to a substantial decrease in breast cancer mortality

while improving the quality of life of breast cancer patients.

This chapter reviews key clinical trials that have led to improvements in breast cancer locoregional and systemic therapies.

National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04

One of the first randomized surgical trials, introduced by the National Surgical Adjuvant Breast and Bowel Project (NSABP), the B-04 study accrued 1,765 patients with breast cancer between 1971 and 1974. Clinically node-negative (cN−) patients were randomly assigned to radical mastectomy, total mastectomy, or total mastectomy plus locoregional axillary RT. Clinically node-positive (cN+) patients were randomly assigned to radical mastectomy or total mastectomy plus axillary RT. With 25 years of follow-up, the B-04 trial continues to show no marked differences in overall survival (OS) between cN− patients who underwent radical mastectomy and those who underwent total mastectomy with or without axillary RT. In addition, for cN+ patients, there were no statistically significant differences in OS between those who had radical mastectomy and those who had total mastectomy with axillary RT. In the cN− patients who had axillary dissection as part of radical mastectomy, 40% had pathologically positive nodes. Despite this, the total mastectomy-only patients (who can be assumed also to have had approximately a 40% N+ rate) had an axillary failure rate of only 19%, suggesting that occult axillary disease may not always progress to clinical relevance and that omission of axillary dissection does not compromise outcome. The NSABP B-04 study began a trend of less extensive (and morbid) surgery for many patients with breast cancer, and was soon followed by studies questioning the need for mastectomy altogether.

Milan I

The Milan I study was an Italian prospective randomized clinical trial that played a critical role in the introduction of breast-conserving therapy (BCT), defined as quadrantectomy followed by RT, as an acceptable treatment option for women with small (<2 cm) operable breast cancers. Between 1973 and 1980, 701 women were randomly assigned to radical mastectomy or BCT. There were no appreciable differences in long-term survival between the groups, despite a higher cumulative incidence of recurrence at 20 years in patients treated with quadrantectomy plus RT. In-

breast tumor recurrence (IBTR) rates after 20 years of follow-up were 8.8% in the BCT group and 2.3% in the radical mastectomy group ($P < 0.001$). In addition, there were no substantial differences between the two groups in the rates of contralateral breast cancer, distant metastases, or secondary primary cancers, and survival.

NSABP B-06

Concurrent with the MILAN I trial, the NSABP B-06 trial compared partial mastectomy (lumpectomy) and axillary node dissection with and without breast RT to modified radical mastectomy (MRM) in patients with breast tumors <4 cm in largest diameter. A total of 2,163 patients were enrolled between 1976 and 1984 and were randomly assigned to one of three arms: MRM, lumpectomy (partial mastectomy) with axillary node dissection, or lumpectomy with axillary node dissection and whole-breast irradiation. With 20 years of follow-up, there continue to be no differences in OS, disease-free survival (DFS), or distant DFS between the mastectomy group and the groups treated with lumpectomy with or without whole-breast RT. BCT was associated with a marginal decrease in breast cancer deaths, but this was partially offset by an increase in deaths from other causes.

Although the lack of differences in OS in B-06 has led to the acceptance of BCT as a local treatment option for patients with operable breast cancer, it is important to note that there were differences in LR among the three arms. IBTR occurred in 39.2% of the lumpectomy-alone arm compared to 14.3% in the lumpectomy-plus-whole breast-RT arm. Chest wall recurrence occurred in 10.2% of the mastectomy group. The majority of ipsilateral recurrences in the lumpectomy-alone group occurred within the first 5 years after surgery; most ipsilateral recurrences in the irradiated and mastectomy arms occurred after 5 years.

The early results and subsequent long-term results of the NSABP B-06 and MILAN I trials have established BCT as the preferred treatment option for women with operable, early-stage invasive breast cancer. Further studies have sought to refine the indications and nuances involved in its appropriate implementation.

Cancer and Leukemia Group B (CALGB) 9343

Questioning the necessity of RT for all patients undergoing lumpectomy for invasive breast cancer, the CALGB 9343 study enrolled women aged

70 and older with clinical stage I (T1N0M0) estrogen-receptor–positive (ER+) breast cancer treated by lumpectomy. Patients were randomly assigned to receive tamoxifen (Tam) plus RT (TamRT) therapy or Tam alone. At 10 years, 98% of the women who received TamRT were free from local and regional recurrences, compared to 90% of those receiving Tam alone. The 10-year estimates of OS were 67% (95% CI, 62% to 72%) in the TamRT group versus 66% (95% CI, 61% to 71%) in the Tam-alone group. The study authors concluded that although RT (in addition to Tam) reduces locoregional recurrence (LRR), the impact of breast cancer in this select group of older women is much less than that of comorbid conditions. They noted that 3% of women in the study have died as a result of breast cancer, whereas 49% have died as a result of other causes. This study has allowed clinicians to consider the omission of RT for women >70 years with ER+ node-negative disease.

European Organisation for Research and Treatment of Cancer (EORTC) 1081

The EORTC 1081 study was a large, multicenter clinical trial designed to demonstrate the safety of BCT compared to MRM in patients with tumors 5 cm or smaller (T I-II) and axillary node-negative or node-positive disease. This study was open for accrual between 1980 and 1986 in the United Kingdom, the Netherlands, Belgium, and South Africa. There were 448 patients randomly assigned to BCT and 420 assigned to MRM. Patients who received BCT were treated with lumpectomy and complete axillary dissection followed by breast RT with tumor bed boost. At the 20-year follow-up, no clinical differences were noted for OS (44.5% in the MRM group vs. 39.1% in the BCT group) or time to distant metastasis. At 10 years, BCT was noted to have a higher LRR rate—20% versus 12% for MRM. In addition, factors associated with increased LRR were found to be dependent on biologic characteristics, including larger tumor size, lymph node metastasis, and receptor type. This study contributed to the earlier body of evidence from the B-06 and Milan I studies, both of which evaluated the safety and effectiveness of BCT for women with relatively small breast tumors. However, one of the main differences between those studies and the EORTC 10801 trial was that the latter generally included patients with larger tumors (80% had T2 tumors), and lymph node metastases (41%). Although tumor size >2 cm and positive lymph node status were found to increase risk for distant metastasis and death, this was

found to be independent from surgical intervention. Thus, the EORTC 10801 trial provided valuable data proving that BCT can safely be performed for patients with larger tumors and positive axillary lymph nodes.

Society of Surgical Oncology (SSO)/American Society for Radiation Oncology (ASTRO) Margin Consensus for Invasive Breast Cancer

Up until 2014, although BCT had become standard practice in the management of early-stage breast cancer, there was no accepted consensus on optimal negative margin width. The Society of Surgical Oncology (SSO) and the American Society for Radiation Oncology (ASTRO) convened a multidisciplinary expert panel to review the available evidence regarding margin width and IBTR and to issue recommendations on the appropriate margin width for patients treated with BCT. The panel used data from a recently published meta-analysis as well as results of randomized trials, reproducibility of margin assessment, and current patterns of multimodality care in order to conclude that (1) positive margins, defined as ink on invasive cancer, are associated with at least a two-fold increase in IBTR, but (2) negative margins (no ink on tumor) optimize IBTR and *the routine practice to obtain negative margins wider than no ink on tumor does not significantly decrease IBTR rates.* Although young age is associated with both increased IBTR after BCT and increased chest wall relapse after mastectomy, there was no evidence that increased margin width nullifies this increased risk in young patients.

PRIMARY SURGICAL THERAPY FOR NONINVASIVE BREAST CANCER

Ductal carcinoma in situ (DCIS) is defined as abnormal cancerous cells confined to the breast ducts. There has recently been considerable debate about the use of the term “carcinoma” in its description, as invasion is a “classic hallmark of cancer.” Regardless, since the advent of screening mammography, the incidence of DCIS has increased markedly, and its propensity to contain an invasive component at excision or to develop into invasive cancer in the future has driven surgical and adjuvant management recommendations. Although there has never been a randomized trial comparing BCT to mastectomy in appropriate patients with DCIS (as was

NSABP B-06 for invasive cancer), there have been several trials addressing the management of DCIS in a less invasive fashion.

NSABP B-17

In 1988, the NSABP began the B-17 trial to investigate BCT in the treatment of DCIS. This trial included 818 patients randomly assigned to receive lumpectomy alone or BCT. The addition of RT resulted in a drop of both the cumulative incidence of noninvasive IBTR from 14.6% to 8.0% ($P = 0.001$) and the incidence of invasive IBTR from 16.8% to 7.7% ($P = 0.00001$). The pathologic finding of moderate or marked comedo-necrosis was an independent risk factor for IBTR in both treatment groups. There was no statistically significant difference in OS between the two groups (86% vs. 87% $P = 0.80$). Updated 12-year follow-up data indicated that RT continues to decrease the rate of both invasive and noninvasive IBTR.

European Organisation for Research and Treatment of Cancer (EORTC) 10853

Similar in design to NSABP B-17, the EORTC 10853 study randomly assigned more than 1,000 women with DCIS to lumpectomy versus lumpectomy followed by whole-breast RT. After 15 years of follow-up, the study continues to show that RT reduced the risk of LR of any kind by 48% ($p < 0.001$). The 15-year invasive cancer LR-free rate was 84% in the lumpectomy group and 90% in the lumpectomy plus breast RT group. No differences were seen for breast-cancer specific survival or OS in either treatment arm.

Independent adverse prognostic factors for LR were age <40 years, symptomatic detection, solid or cribriform growth pattern, and involved margins. This study also found that patients who had an invasive recurrence had decreased survival compared with those without LR and the investigators were unable to identify a subgroup of DCIS patients in whom RT could be withheld.

Eastern Cooperative Oncology Group (ECOG) E5194

The ECOG E5194 trial accrued 670 patients between 1997 and 2002 who had lumpectomy for DCIS without RT. Thirty percent of patients took Tam. Patients were stratified into two groups: (1) low- or intermediate-

grade DCIS with lesions measuring 2.5 cm or less and (2) high-grade DCIS measuring 1 cm or less with margin widths of 3 mm or wider and no residual calcifications on postoperative mammograms. The low/intermediate DCIS group, with 565 eligible patients, demonstrated a 5-year IBTR rate of 6.1%, whereas the high-grade stratum, with 105 eligible patients, showed a 5-year IBTR rate of 15.3%. These results suggested that excision alone is inadequate treatment in patients with high-grade lesions, whereas patients with low/intermediate grade lesions may be treated without RT, given an acceptably low 5-year rate of ipsilateral breast events. However, at 12 years of follow-up, the rates of developing an IBTR continued to rise without a plateau effect: 14.4% for the low/intermediate risk group and 24.6% for the high-risk group with 12-year risks of invasive IBTR of 7.5% and 13.4%, respectively. This suggests that patient life expectancy and impact of RT and recurrence on quality of life should be considered when planning RT for DCIS treated with lumpectomy.

Solin et al. used results from the E5194 study to validate a DCIS recurrence risk score with the use of the Oncotype DX DCIS assay. This 12-gene recurrence score for DCIS is a modification of the 21-gene recurrence score used to predict the risk of recurrence for invasive breast cancer. The assay was evaluated in 327 patients from the E5194 study and was found to be an independent predictor of risk for IBTR (HR = 2.31; P = 0.02). The 10-year risk of any IBTR or invasive IBTR increased continuously as the DCIS Score increased. Patients with a low-risk DCIS Score had a 10-year risk of IBTR or invasive IBTR of 10.6% and 3.7%, respectively. Solin's study provided a new clinical tool using molecular taxonomy for individualized treatment selection for patients with DCIS. The utility of the DCIS recurrence score in predicting IBTR was further validated in another prospectively designed, population-based study that included 571 DCIS patients from Ontario, Canada, who received breast-conserving surgery alone with negative resection margins. In that study, the 10-year risk of IBTR according to DCIS Score risk group was similar to that from ECOG E5194: 12.7% for low-risk, 33.0% for intermediate-risk, and 27.8% for high-risk. DCIS Score was predictive of both invasive and DCIS IBTR (P = 0.03 and P = 0.002, respectively). In the multivariable analysis, the DCIS Score was an independent predictor of LR along with age, tumor size, solid or cribriform DCIS subtype, and multifocality.

NSABP B-24 and B-35

Following the B-17 trial, the NSABP directed attention to Tam as an adjuvant therapy for women treated with BCT for DCIS. The fact that Tam had been shown to markedly reduce IBTR as well as contralateral breast cancer events following BCT for invasive cancer made it an attractive option for patients with DCIS. In the early 1990s, 1,804 women with DCIS treated with BCT were randomly assigned to receive either Tam 20 mg daily for 5 years or placebo for the NSABP B-24 study. In contrast to the B-17 trial, patients were eligible regardless of margin status, and in fact 16% of patients had involved surgical margins. The addition of tamoxifen substantially improved DFS from 77.1% to 83.0% (P = 0.002), and the cumulative incidence of all ipsilateral and contralateral breast cancer events was reduced by 39%, with a reduction of invasive breast cancer events by 45%. Further retrospective analysis of Tam benefit by hormone-receptor status confirmed that the benefit was primarily seen in patients with ER-positive DCIS.

As the use of adjuvant aromatase inhibitors became more widespread for early-stage, invasive, ER-positive breast cancer, the NSABP B-35 study randomly assigned ER-positive, postmenopausal patients having BCT for DCIS to either Tam 20 mg per day or to anastrozole 1 mg per day. Follow-up data with a median of 9 years have recently shown that anastrozole provided a statistically significant improvement in breast cancer–free interval and DFS in the overall study population. Prespecified subset analysis of the treatment effect by age demonstrated that the anastrozole advantage was primarily seen in women younger than 60 years. There was also decreased incidence of thromboembolism in the anastrozole group, compared to the tamoxifen group, making this agent an attractive option for postmenopausal women who undergo BCT for DCIS.

NSABP B-43

DCIS is more likely to overexpress HER2/neu than is invasive cancer, and this overexpression is often associated with more aggressive subtypes of DCIS. Preclinical studies have shown that trastuzumab boosts the effectiveness of RT in xenograft models and in cell lines, without producing a detrimental effect on irradiated HER2-normal cells. Furthermore, several adjuvant trials in patients with invasive breast cancer have shown that trastuzumab added to adjuvant chemotherapy significantly improves DFS and OS. The above rationale led to the conduct

of the NSABP B-43 trial, which randomly assigned patients with DCIS treated with lumpectomy to RT alone or to RT plus two doses of trastuzumab given postoperatively during RT. The aim of this study was to determine if trastuzumab given during RT helps prevent the subsequent occurrence of IBTR or ipsilateral DCIS recurrence. This study has finished accruing patients, and it is currently on follow-up.

NEOADJUVANT CHEMOTHERAPY TRIALS

As BCT became an acceptable treatment for many women with operable breast cancer, the administration of systemic cytotoxic and/or antihormonal therapy was concurrently shown to have benefits for both DFS and OS in patients with positive as well as negative axillary lymph nodes. This benefit encouraged the development of trials demonstrating the use of preoperative systemic therapy for the downstaging of primary tumor size to allow more patients the option of breast conservation. It is important for surgeons treating breast disease to understand current research about optimal neoadjuvant chemotherapy regimens to maximize surgical options and outcomes for breast cancer patients.

NSABP B-18

From 1988 to 1993, NSABP B-18 randomly assigned 1,523 patients with operable breast cancer to surgery and then adjuvant chemotherapy (4 cycles of doxorubicin/cyclophosphamide—ACx4) or the same chemotherapy preoperatively and then surgery. The primary aim was to determine if the administration of neoadjuvant chemotherapy would more effectively prolong DFS and OS than standard adjuvant therapy.

Results on tumor response following neoadjuvant chemotherapy showed that 36% of patients had a complete clinical response (by tumor palpation) and 43% had a partial clinical response, for an overall clinical response rate of 79%. In addition, 13% of patients had no invasive cancer in the breast specimen following neoadjuvant chemotherapy, that is, a pathologic complete response (pCR). The neoadjuvant group with presumed cN+ disease also had a 37% down-staging rate of axillary lymph nodes. Patients who received neoadjuvant chemotherapy were also substantially more likely to have had lumpectomy (67% vs. 60%, P = 0.002).

Initial outcome results from the B-18 trial showed no statistically significant differences in DFS, distant DFS, or OS between the two

groups. However, patients who achieved pCR had statistically significantly better DFS and OS compared to those who had a clinical complete response but residual invasive tumor on pathology specimen, those who had partial clinical response, and those who had no clinical response. Even after adjusting for other known clinical prognostic factors such as nodal status, tumor size, and age, pCR remained an independent predictor for OS.

More recent results with 16 years of follow-up in the B-18 trial continue to show no clinically meaningful differences in DFS and OS between the two treatment groups; however, there are trends in favor of neoadjuvant chemotherapy for both DFS and OS in women younger than 50 years.

NSABP B-27

After the NSABP B-18 trial established the foundation of neoadjuvant chemotherapy in operable breast cancer, the B-27 trial was conducted to evaluate the role of taxanes pre- or postoperatively in addition to neoadjuvant adriamycin-cytoxan x4. From 1995 to 2000, a total of 2,411 patients were randomly assigned to adriamycin-cytoxan x4 followed by surgery versus adriamycin-cytoxan x4 followed by docetaxel x4 and then surgery, versus adriamycin-cytoxan x4, surgery, and then adjuvant docetaxel. All patients began Tam when initiating their cytotoxic therapy.

Although the addition of preoperative docetaxel increased the pCR rate from 13.7% to 26.1% ($P < 0.001$) and decreased the rates of pathologically positive nodes, it did not lead to an increase in the rate of BCT. Furthermore, the addition of neoadjuvant or adjuvant docetaxel to adriamycin-cytoxan x4 did not statistically significantly prolong DFS or OS in the B-27 trial.

NSABP B-40 and B-41

More recently, the NSABP conducted two neoadjuvant trials evaluating novel taxane chemotherapy combinations with or without bevacizumab (for HER2-negative patients) or with trastuzumab, lapatinib, or the combination of the two (for HER2-positive patients). NSABP B-40 randomly assigned patients to one of three chemotherapy regimens (docetaxel followed by adriamycin-cytoxan x4, docetaxel/capecitabine followed by adriamycin-cytoxan x4, or docetaxel/gemcitabine followed by adriamycin-cytoxan x4) with a secondary randomization to receive

bevacizumab or no bevacizumab. The primary aims were to determine if adding capecitabine or gemcitabine to docetaxel followed by adriamycin-cytoxan x4 would increase pCR rates in patients with operable HER2-negative breast cancer and also to determine the effect of bevacizumab on pCR. Although the addition of neoadjuvant bevacizumab was shown to increase the proportion of women having pCR, the addition of capecitabine or gemcitabine to docetaxel followed by adriamycin-cytoxan x4 did not. Further analysis showed that the addition of gemcitabine or capecitabine to neoadjuvant docetaxel followed by adriamycin-cytoxan x4 did not increase DFS or OS, whereas the addition of bevacizumab statistically significantly increased OS (HR 0.65; $P = 0.004$) but did not significantly increase DFS (HR 0.80; $P = 0.06$).

Small molecule tyrosine kinase inhibitors such as lapatinib have shown marked anti-tumor activity in patients with advanced breast cancer. The NSABP B-41 trial compared the addition of trastuzumab, lapatinib, or the combination of both to neoadjuvant paclitaxel given following four cycles of neoadjuvant adriamycin-cytoxan x4 to patients with operable HER2-positive breast cancer. B-41 has shown similar pCR rates for both the trastuzumab (52.5%) and lapatinib (53.2%) groups and a nonsignificant increase in the pCR rate for the combination group (62.0%). Future analysis will attempt to identify predictors of benefit for the combined anti-HER2 therapy.

NSABP B-51/Radiation Therapy Oncology Group (RTOG) 1304

The NSABP B-51/Radiation Therapy Oncology Group (RTOG) 1304 trial is a currently accruing phase III randomized clinical trial designed to evaluate the role of postmastectomy RT and regional nodal RT in patients with documented positive axillary lymph nodes prior to undergoing neoadjuvant chemotherapy, who subsequently convert to pathologically negative axillary nodes after neoadjuvant chemotherapy. The trial's primary endpoint is to examine if postmastectomy and/or regional nodal RT significantly reduces the rate of breast cancer recurrence-free interval. Node positivity has to be documented by either fine needle aspiration or core needle biopsy before the administration of neoadjuvant chemotherapy. Patients then undergo standard neoadjuvant regimens (with the addition of anti-HER2 therapy for patients with HER2-positive tumors) and if they are found at surgery to have negative axillary lymph nodes are eligible for randomization into the trial. Patients can have either

mastectomy or BCT; those undergoing mastectomy are randomly assigned to either no RT or chest wall plus regional-nodal RT, and those undergoing BCT will be randomly assigned to either whole breast RT or whole breast plus regional-nodal RT.

AXILLARY LYMPH NODE STAGING FOR PATIENTS WITH BREAST CANCER

The status of axillary lymph nodes remains the single most important prognostic factor for breast cancer recurrence. However, data as early as the NSABP B-04 trial demonstrated that elective axillary lymph node dissection (ALND) did not impact survival. For this reason, it has become accepted that elective axillary dissection is performed predominantly for staging purposes, to aid in selecting adjuvant systemic therapy, and for local control of axillary disease. Recent randomized trials have demonstrated a survival advantage with the addition of RT in node-positive patients. The appropriate extent of lymph node staging has therefore been the subject of much past and continuing research.

Sentinel Node Versus Axillary Clearance Trial (SNAC)

Originally proposed for penile cancer, the sentinel lymph node (SLN) biopsy principle hypothesizes that malignant cells from the primary tumor follow lymphatic channels to a single lymph node/group of nodes before spreading to further nodes within the basin. Early research applying the SLN biopsy to breast cancer sought to determine whether a negative sentinel node could obviate the need for completion ALND and associated morbidity, namely the development of lymphedema. The SNAC study randomly assigned 1,088 women with cN− early-stage breast cancer to receive either SLN or SLN followed immediately by ALND. The primary endpoint was an increase in arm volume from baseline; secondary endpoints included an increase in arm volume by 15%, early axillary morbidity (defined as arm dysfunction), or disability. Arm volume increased in the SLN group by 2.8%, and by 4.2% in the ALND group ($P = 0.002$). Lower rates of arm swelling ($P < 0.001$), symptoms ($P < 0.001$), and dysfunction ($P = 0.02$) were reported in the SLN group, and disability ($P = 0.5$) was not. The study showed that SLN had a sensitivity of 94.5%, a false-negative rate (FNR) of 5.5%, and a negative predictive value of 98%. The study concluded that SLN follows oncologic principles and

resulted in less morbidity than ALND.

NSABP B-32

The NSABP-32 trial was designed to evaluate SLN biopsy as an alternative to ALND in cN− breast cancer patients. From 1999 to 2004, 5,611 patients from 80 centers were randomly assigned into one of two groups: SLN biopsy followed by ALND or SLN biopsy with ALND only in the event of a positive sentinel node. There were 232 participating surgeons. The primary endpoints of this trial were OS, DFS, and regional control. The trial demonstrated an SLN identification rate of 97%, with 26% of patients having positive SLNs in each group. An FNR of 9.7% was seen in the SLND + ALND group, related to biopsy type and number of SLNs removed. OS, DFS, and LRR were statistically equivalent in both groups. Patients who underwent ALND reported greater morbidity outcomes, including lymphedema, range of motion, sensory defects, and chronic pain. The B-32 trial showed that SLN biopsy is a safe and effective treatment for cN− patients and that the addition of ALND with a negative SLN biopsy does not improve outcomes. On secondary pathologic IHC evaluation of patients diagnosed with negative SLNs by H&E staining, in approximately 16% of cases the SLNs harbored occult metastases. Although differences were demonstrated in OS and DFS between the group with occult metastases and the one without, the absolute difference of OS at 5 years was small, 94.6% (no metastases) versus 95.8% (occult metastases) leading to the conclusion that IHC staining yielded no clinical benefit in evaluating initially negative SLNs.

Axillary Lymphatic Mapping Against Nodal Axillary Clearance (ALMANAC)

The Axillary Lymphatic Mapping Against Nodal Axillary Clearance (ALMANAC) trial, a randomized multicenter trial of SLN biopsy versus standard axillary treatment in operable breast cancer, took the benefits of SLN biopsy in the cN− axilla one step further by demonstrating improved quality of life in patients undergoing SLN biopsy versus ALND. In this study, 1,031 patients were assigned to SLN biopsy or ALND. Those with an SLN-positive axilla were subsequently treated with delayed completion ALND or axillary RT. Such measures as usage of drains, length of hospital stay, and time to resumption of daily activities postoperatively were monitored. All were statistically significant and lower in the SLN group (*p*

< 0.001). Patient-reported quality of life and arm functioning scores were statistically significantly better in the SLN group as well ($p \leq 0.003$). From these results, it was concluded that SLN biopsy should be the treatment of choice for patients with early-stage breast cancer and cN− because it is associated with reduced arm morbidity and better quality of life when compared with ALND.

International Breast Cancer Study Group (IBCSG) 23–01

After SLN biopsy was established as the standard of care for cN− breast cancer by NSABP B-32, research efforts focused on node-positive patients in whom completion ALND could be avoided. The International Breast Cancer Study Group (IBCSG) 23–01 trial was a multicenter randomized trial that attempted to determine whether ALND was superior to SLN biopsy in patients with early-stage (T1–2) breast cancer who were cN− with micrometastatic deposits (<2 mm) in the SLNs. From 2001 to 2010, 934 patients with micrometastasis on SLN biopsy were randomized into two arms: ALND versus no ALND. The study found no meaningful difference in DFS, the study's primary endpoint, or OS. The axillary recurrence rate was 0.2% in the ALND group, versus 0.86% in the SLND-only group. Additional secondary endpoints included lymphedema and sensory and motor neuropathy, which occurred more frequently in the ALND group. These findings reinforced previous results showing a better quality of life for those in the SLN-only group.

American College of Surgeons Oncology Group (ACOSOG) Z0011

The ACOSOG Z0011 trial changed the approach to the axilla in patients with limited SLN involvement. This was a multicenter randomized noninferiority trial conducted from 1999 to 2004 that enrolled 891 patients with T1-T2 cN− invasive breast cancer who underwent lumpectomy and SLN biopsy. Patients with 1 to 2 positive SLNs were randomly assigned to undergo ALND or no further treatment. All patients received whole-breast irradiation, and there was little difference between the two groups in the delivery of adjuvant systemic therapy. The primary endpoint of the study was OS. The study found no clinical difference in 10-year OS, with rates of 86.3% in the SLN biopsy-alone group and 83.6% in the ALND group. Ten-year DFS rates were also similar for both groups. Complications such as wound infections, axillary seromas, and paresthesias were more

common in the ALND group. In addition, subjective but not objective reporting of lymphedema was higher in the ALND group. Z0011 findings highlight the importance of multimodality treatment in achieving locoregional control without the morbidity of an ALND and have altered clinical practice for select early-stage, node-positive breast cancer patients who may omit completion ALND.

EORTC 10981 After Mapping of the Axilla, Radiotherapy or Surgery? (AMAROS) Trial

The AMAROS trial was a phase III study comparing ALND with axillary RT in patients with proven axillary metastasis by SLN biopsy with a detection rate of 97%. The primary endpoint was axillary recurrence. This trial did not compare sentinel lymph node biopsy (SLNB) to ALND in the management of the diseased axilla; rather, it used SLN biopsy as a method for detecting the axilla that needs further treatment with ALND group axillary RT. With a median of 6.1 years of follow-up, 5-year axillary recurrence was 0.43% (95% CI 0.00 to 0.92) in the ALND arm versus 1.19% (0.31 to 2.08) in the axillary RT arm. However, the risk of lymphedema was twice as high (28% vs. 14%) in the ALND arm compared to the axillary RT arm at 5 years of follow-up.

ACOSOG Z1071

As neoadjuvant chemotherapy became increasingly used for women with early- and late-stage breast cancer, questions arose about the acceptability of SLN biopsy in women who were node positive prior to receiving chemotherapy but who converted to cN− after the administration of chemotherapy. The ACOSOG Z1071 trial was conducted to address this issue. The study determined the FNR for SLN biopsy following neoadjuvant chemotherapy in biopsy-proven, node-positive (before chemotherapy) patients. From 2009 to 2011, 649 patients with cN1 disease and 38 patients with cN2 disease underwent chemotherapy followed with both SLN biopsy and ALND. A pCR rate of 41% was achieved on pathologic examination of the SLNs and nodes removed on ALND. Of the remaining patients, 20.6% had residual nodal disease confined to the SLN only, 7.4% confined to the nodes removed on ALND, and 31.1% present in nodes from both SLN and ALND, yielding a false-negative SLN finding rate of 12.6%. The FNR decreased when SLN mapping was performed using both radiolabeled colloid and blue dye (10.8% in combination vs.

20.3% with single agent) and when three or more SLNs were examined (9.1% for ≥3 SLNs vs. 21.1% for 2). Investigators in the Z1071 trial concluded that because the FNR exceeded the prespecified study threshold of 10%, SLN examination should not be performed in patients with clinically node positive disease receiving neoadjuvant chemotherapy. However, dual agent mapping and three or more lymph nodes examined were associated with FNR similar to that found in the B-32 trial, <10%.

SENTinel NeoAdjuvant (SENTINA) Trial

Similar in focus to the Z1071 trial, SENTINA was a four-arm, prospective, multicenter cohort study of 1,737 patients designed to evaluate the role of SLN biopsy in patients who had undergone neoadjuvant chemotherapy for invasive breast cancer. Patients with cN− disease underwent SLN biopsy before the initiation of neoadjuvant chemotherapy. If the SLN was positive, a second SLN procedure and ALND was done after neoadjuvant chemotherapy. Women who were cN+ underwent neoadjuvant chemotherapy, and those who converted to being cN− also had SLN biopsy and ALND. For cN− patients who were pathologically confirmed to be SLN-positive prior to neoadjuvant chemotherapy, the FNR of SLN biopsy after chemotherapy was 51.6%, and for patients who converted from cN+ to cN− with chemotherapy the FNR of SLN after neoadjuvant chemotherapy was 14.2%. However, in the cN+ to cN− group, if both blue dye and radiocolloid was used, the FNR was 8.6% and the FNR decreased as the number of removed SLNs increased.

Alliance A011202

The Alliance A011202 trial is currently recruiting patients with clinically positive axilla (by FNA or core needle biopsy) and who, despite being cN− after neoadjuvant therapy, have a positive SLN at surgery. Patients are randomly assigned to either completion ALND or not. Both groups include RT to the breast/chest wall, un-dissected axilla, supraclavicular nodes, and internal mammary nodes in the first three intercostal spaces. The combined results from this and the NSABP B-51/RTOG 1343 trial should clarify the role of ALND and regional nodal RT for patients who convert from node positive to cN− status after the administration of neoadjuvant chemotherapy.

CONCLUSION

From anecdotal reports to the development and implementation of breast cancer clinical trials, improvements in the treatment and outcomes for breast cancer patients have been the result of a paradigm change in the biologic understanding and management of the disease. Breast cancer mortality has witnessed a steady decline since the mid-1980s. Patients now need not undergo extensive surgical procedures to achieve improved outcomes and as a result enjoy improved quality of life. Treatments based on genetic and genomic assays as well as targeted biologic therapies, along with focused molecular and hormonal treatments, provide a personalized approach in the modern era. Coupled with advanced RT techniques that have resulted in a more precise delivery of treatment with less toxicity, a multidisciplinary approach for each patient can be designed. These advancements are all in large part due to the results of clinical trials. The benefits of such trials have accelerated our understanding of breast cancer biology and have brought improved treatments, a better quality of life, and improved outcomes. Ongoing and new clinical trials will continue to refine this knowledge so that our patients can be better served.

EDITOR'S COMMENT

Cowher and colleagues have shown that the history of breast cancer treatment is inextricably linked to the history of its clinical trials and so, I believe, is its future. Dr. William Thomas Beaver was the clinical pharmacologist at Georgetown University who drafted the initial regulations defining "adequate and controlled" clinical studies. "Clinical trials are systematic experiments performed on human beings for the purpose of assessing the safety and/or efficacy of treatments or care procedures. The function of the controlled clinical trial is not the 'discovery' of a new drug or therapy. Discoveries are made in the animal laboratory, by chance observation, or at the bedside by an astute clinician. The function of the formal controlled clinical trial is to separate the relative handful of discoveries which prove to be true advances in therapy from a legion of false leads and unverifiable clinical impressions, and to delineate in a scientific way the extent of and the limitations which attend the effectiveness of drugs."

Peter Drucker said that the only obstacle to progress is the thought that we already know the answer to the question. Much of the lack of progress or slow implementation of new or better techniques is related to busy clinical practices,

in and of itself and obstacle to clinical trial participation, as well as the surgeon's own bias. One of the trials that illustrate these issues best is the American College of Surgeons Oncology Group (ACOSOG) Z-0011. Proposed by Dr. Armando Guiliano, ACOSOG Z-0011s was a trial ahead of its time (Giuliano AE, Hunt KK, Ballman KV, et al. Axillary dissection vs no axillary dissection in women with invasive breast cancer and sentinel node metastasis: a randomized clinical trial. *JAMA* 2011;305(6):569–75). The hypothesis was, as was already demonstrated by NSABP B-04, that in patients undergoing breast conservation therapy removal of the axillary lymph nodes (ALND) would not negatively impact survival. Regional recurrence was also an endpoint. Unfortunately, the trial closed early due to poor accrual secondary not only to surgeon bias but also to patient bias. Patients often wanted a full ALND or they only wanted a sentinel lymph node (SLN) as they were sure that they were potentially being under- or overtreated depending on their bias, respectively. Unfortunately, the Z-0011 trial was underpowered and had a high percentage of nearly a quarter of patients lost to follow-up. In addition, radiation treatment was given to the undissected axilla that was a protocol deviation. Despite this, the trial did show no difference in survival between the groups at 5- as well 10-year follow-up (Bao J, Giuliano AE. Sentinel lymph node biopsy: from B04 to tumor genomics. *Ann Surg Oncol* 2016; 23(8):2380–82; Giuliano AE, Hunt KK, Ballman KV, et al. Axillary dissection vs no axillary dissection in women with invasive breast cancer and sentinel node metastasis: a randomized clinical trial. *JAMA* 2011;305(6):569–75). Local and regional recurrence likewise did not differ. The authors concluded that SLN biopsy only was adequate to stage the axilla and superior to full ALND. Based on this study, I would conclude either procedure, SLNB+XRT or ALND, would be acceptable as the objective lymphedema was not different between the groups, which is what the study was aimed at proving. This study did give rise to a multitude of other questions and interesting trials. Studies like SOUND (Sentinel node vs Observation after axillary Ultra-souND) have been started to assess whether one could not operate at all but rather follow the clinically node-negative axilla with ultrasound (Gentilini O, Botteri E, Dadda P, et al. Physical function of the upper limb after breast cancer surgery. Results from the SOUND [Sentinel node vs. Observation after axillary Ultra-souND] trial. *Eur J Surg Oncol* 2016;42(5):685–9).

The hypotheses of this trial are that:

- Avoiding axillary surgery and the absence of the pathologic information on the risk of recurrence given by nodal status do not worsen the outcome of patients with small breast cancers.
- Preoperative imaging of the axilla can identify patients with clinically relevant nodal burden.

The investigators at the European Institute of Oncology aim to verify that in the presence of a negative preoperative axillary assessment by physical examination and ultrasound (US), an SLNB can be spared and that the decision

on adjuvant medical treatment can be made based on the biology of the tumor without the prognostic information achieved by an SLNB on the nodal status. Gentilini and colleagues have just reported on the first 180 patients accrued to this trial. The first 180 patients were assessed using the *Quick*DASH (Diability ARM and Shoulder), which ranges from 0 (no disability) to 100 (complete disability). As expected, at 1 week the scores were higher for SLNB, which was 24.0% versus 10.6% for SLNB versus observation. At 6- and 12-month follow-up, these moved more toward baseline and were 4.5% versus 3.3% at 6 months, $p < 0.001$ (Gentilini O, Botteri E, Dadda P, et al. Physical function of the upper limb after breast cancer surgery. Results from the SOUND [Sentinel node vs. Observation after axillary Ultra-souND] trial. *Eur J Surg Oncol* 2016;42(5):685–9). Differences in regional recurrence or survival have not yet been reported.

But what about the clinically positive axilla? Two important trials that depend on the participation by surgeons are that of NSABP B-51 and Alliance 111202. Both enroll node-positive patients proven by US-guided biopsy with clip placement. Patients then undergo primary systemic therapy followed by surgery. If the SLNB is negative (must include the node with the clip), then the patient can be enrolled in the NSABP B-51 and randomized to nothing versus ALND. If the SLNB is still positive, then the patient is randomized on Alliance 111202 to radiation versus ALND. In terms of control of the axilla, my guess is that the recurrence rate in these studies will be equivalent. However, radiation is the gift that keeps on giving and so given a choice I would choose surgery every time. Long-term follow-up will be needed to determine the difference between the complications of radiation of the axilla versus those of definitive surgery.

Another alternative in the axillary treatment question is the addition of Axillary Reverse Mapping or ARM. In this concept, split mapping is used, that is, radioactivity in the breast and blue dye in the arm. This allows identification and separation of the breast lymphatics from those draining the arm and thus their preservation. Our recently published phase II prospective trial in 654 patients demonstrated lymphedema rates less than 1% for SLNB as compared to 5% to 8% in historical controls (Tummel E, Ochoa D, Korourian S, et al. Does axillary reverse mapping prevent lymphedema after lymphadenectomy? *Ann Surg* 2016;265(5):987–992). The lymphedema rate was ~6% for ALND, and if a primary approximation/anastomosis of the lymphatics was performed the rate of lymphedema was nil. A randomized trial to prove this concept is planned.

The authors have done a very nice job of laying out the history of randomized clinical trials. However, I would say one of the most important trials of the last decade that was not mentioned is that of the retrospective genetic analysis of prospectively collected blocks on patients enrolled in NSABP B-14 and B-20 that led to the development of the Oncotype genomic assay. The RT-PCR assay tests 21 genes, 16 of which tests hormone receptors, Her-2-neu genes or genes related to proliferation (Tang G, Cuzick J, Costantino JP, et al. Risk of recurrence and chemotherapy benefit for patients with node-

negative, estrogen receptor-positive breast cancer: recurrence score alone and integrated with pathologic and clinical factors. *J Clin Oncol* 2011;29(33):4365–72). It can be done on excisional biopsy blocks or on core needle biopsy specimens. The test gives a continuous recurrence score that strongly predicts for risk of recurrence as well as benefit or not from chemotherapy. With its use, it has prevented a majority of patients with node-negative hormonally sensitive tumors from having chemotherapy when the Oncotype test indicates a low recurrence score. The test is recommended in the published treatment guidelines of the American Society of Clinical Oncology (ASCO) and National Cancer Centers Network (NCCN). There are several other comparable tests (microarray, IHC, or FISH) that are available but have not been similarly validated. An ongoing trial (TAILORx) is a prospective trial to determine the efficacy of chemotherapy in those patients with a recurrence score via Oncotype in the midrange (18 to 31) where it is not clear as to whether chemotherapy is beneficial or not (Zujewski JA, Kamin L. Trial assessing individualized options for treatment for breast cancer: the TAILORx trial. *Future Oncol* 2008;4(5):603–10). Trial Assessing IndiviuaLized Options for Treatment for breast cancer (TAILORx) randomizes patients in this Oncotype midrange to either chemotherapy or hormonal therapy. The trial has completed accrual and is awaiting maturation to determine a more refined determination of the recurrence score of who really benefits from chemotherapy.

A similar retrospective analysis of blocks was performed on NSABP B-28, which enrolled node-positive patients (Wolmark N, Mamounas EP, Baehner FL, et al. Prognostic impact of the combination of recurrence score and quantitative estrogen receptor expression (ESR1) on predicting late distant recurrence risk in extrogen receptor-positive breast cancer after 5 years of tamoxifen: results from NRG Oncology/National Surgical Adjuvant Breast and Bowel Project B-28 and B-14. *J Clin Oncol* 2016;34(20):2350–58). Again the recurrence score when combined with nodal positivity (1 to 3 vs. ≥4 positive nodes) is predictive of in breast or chest wall recurrence. This may particularly be useful not only in prognosis but predictive in terms of determining the relative lack of benefit of chest wall irradiation in patients with a low recurrence score. This use of the Oncotype in node-positive patients has not gained wide acceptance and is undergoing prospective validation.

Only a properly planned and conducted trial with committed participation by surgeons can solve our tough issues. Surgeons are very important in this process as they are most often the gatekeeper to breast cancer care as well as key to obtaining appropriately preserved tissue for the vast array of markers now available as well as for studies in the future.

V. Suzanne Klimberg

59 The Deep Inferior Epigastric Perforator Flap for Breast Reconstruction

Robert J. Allen and James L. Mayo

INTRODUCTION

In 2013, 232,340 women were diagnosed with invasive breast cancer and 64,640 were diagnosed with in situ cancer. Of women who undergo surgical treatment, two thirds elect to undergo breast-conserving treatment (BCT), while one third elect to undergo mastectomy. With equal survival rates among both treatment modalities in the same tumor populations, the decision to perform mastectomy often is driven by either a desire for improved cosmesis in the setting of a larger tumor/smaller breast or a goal of most significant reduction in the risk of recurrence.

Of the 95,589 women who underwent breast reconstruction in 2013, 80% elected for tissue expander/implant based reconstruction versus 20% autologous reconstruction. Though the vast majority of breast reconstructions are implant-based, the senior author prefers autologous reconstruction for its ability to replace “like with like,” a lower long-term complication profile and more stable long-term patient satisfaction. A 2009 University of Michigan study demonstrated that, over the long term (>9 years), there is a significant decrease in patient satisfaction after implant-based breast reconstruction while patient satisfaction after autologous tissue breast reconstruction remains consistently high.

Autologous breast reconstruction celebrates a storied history centered around the abdomen as the most prolific donor site. Carl Hartrampf popularized the transverse rectus abdominis musculocutaneous (TRAM) flap in the early 1980s paving the way for an alternative to utilizing an implant for breast reconstruction. Unfortunately, this brought with it undesirable complications associated with removing a patient’s entire rectus abdominis muscle such as ventral hernia as well as an unnecessarily high rate of fat necrosis. In the late 80s, the senior author avoided these issues by basing an abdominal flap off of the superficial inferior epigastric

artery (SIEA) converting the flap to a free flap. Utilizing this flap for breast reconstruction was successful but, due to variable vascular anatomy, was not consistently available.

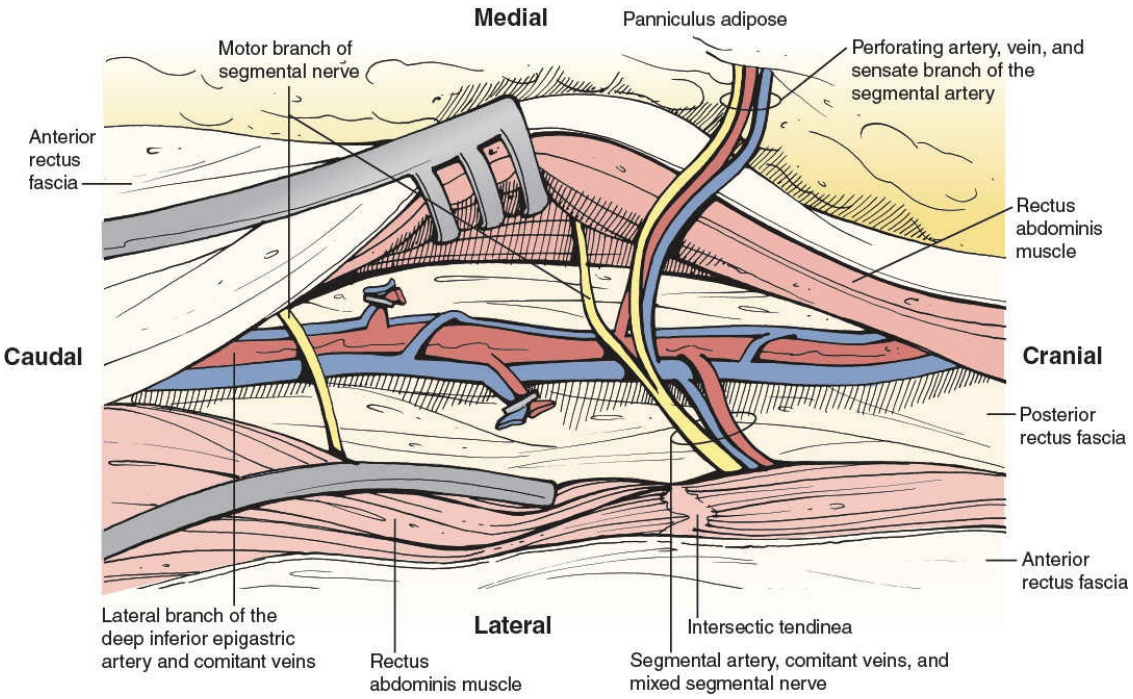

Figure 59.1. The DIEP flap is based on perforating vessels that originate from the deep inferior epigastric system, travel through the rectus abdominis muscle, pierce the anterior rectus sheath, and supply the overlying abdominal skin and fat.

In 1992, Robert Allen, Sr. first reported the use of the deep inferior epigastric artery perforator (DIEP) free flap for breast reconstruction. The DIEP flap is based off of perforators traveling through the rectus abdominis muscle to supply the skin and fat of the lower abdomen (Fig. 59.1). By dissecting these perforators through the rectus muscle to their origin at the deep inferior epigastric vessels, a plastic surgeon is able to spare the rectus muscle morbidity of the TRAM while providing advantageous flap volume and vascularity. The TRAM versus DIEP debate then ensued in the following year as many of the plastic surgeons in the community were still performing TRAM procedures due to lack of familiarity with microsurgical techniques. *The Mastery of Surgery*, 6th edition focused on the benefits of the DIEP versus the TRAM, and at the time of writing this chapter for the 7th edition, the DIEP is accepted as the standard of care first option for autologous breast reconstruction.

Currently, more appropriate debates center around a search for

additional autologous options when the abdomen is not available as a donor site. Numerous flaps have been described from gluteal to thigh-based flaps. The complete microsurgeon has these flaps in his armamentarium and now practices a patient-specific approach utilizing the area of the body that the patient has the most favorable donor site due to body habitus and personal preferences. Still, the clear front-runner for autologous breast reconstruction remains the DIEP flap, and after over 2,000 DIEP flaps with a 99% success rate, we are able to offer this procedure safely, efficiently, and with more aesthetic refinement than ever before.

INDICATIONS

The common indication for autologous (own tissue) breast reconstruction is simply an absent breast after mastectomy for breast cancer. The majority of women are candidates for some form of autologous reconstruction. This can be performed immediately during the same procedure as the mastectomy or in a delayed fashion, often after the patient has received radiation (Fig. 59.2). In the later cases, a tissue expander is often placed at the time of mastectomy to maintain the skin envelope during the interim. Another common indication for autologous breast reconstruction is failed implant-based breast reconstruction. About 25% of our breast reconstruction patients are women who have experienced problems such as infection, capsular contracture, implant displacement, and others after implant-based breast reconstruction. Particularly in women who have had to undergo radiation therapy as an adjunct to their breast cancer treatment, autologous tissue breast reconstruction can create a new breast mound that looks and feels natural while using the woman’s own tissues.

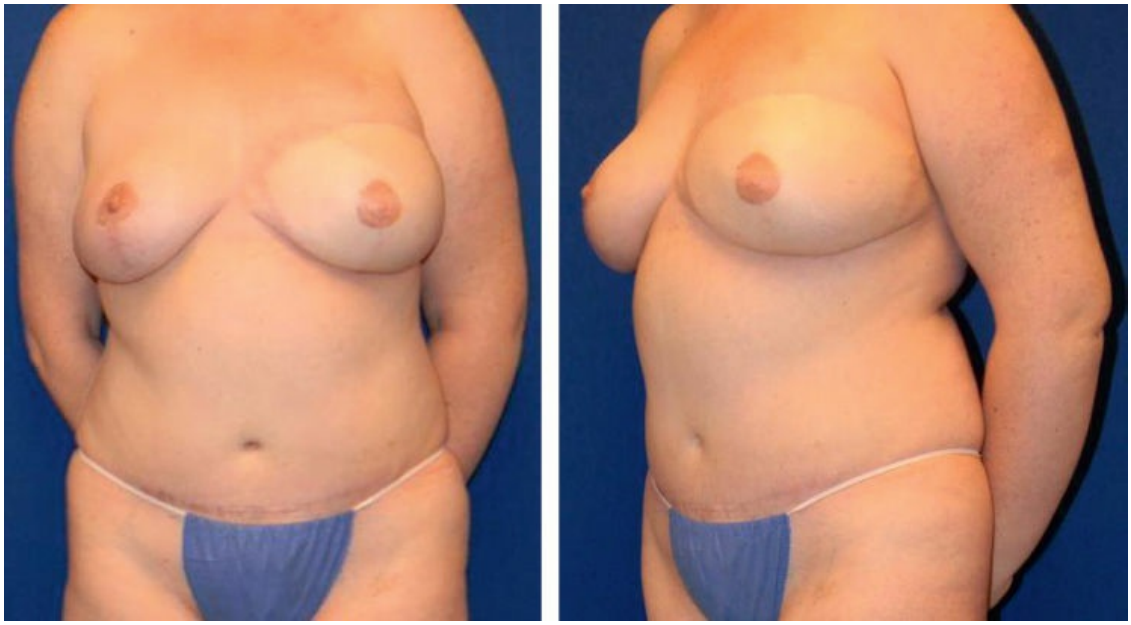

Figure 59.2. Postoperative views of a 45-year-old patient with history of left inflammatory breast cancer 5 years prior treated with left modified radical mastectomy, chemotherapy, radiation. She underwent delayed unilateral left DIEP free flap breast reconstruction followed by nipple reconstruction and areolar tattooing. She subsequently also underwent a right breast reduction mammoplasty for symmetry.

The deep inferior epigastric perforator flap is the first-line modality for autologous breast reconstruction. The best way to describe who is a candidate for DIEP free flap breast reconstruction is to outline who is not a candidate. Outside of medical comorbidities prohibiting surgery, the abdominal donor site characteristics precluding surgery would be insufficient volume of tissue or insufficient blood supply. The blood supply to the lower abdominal flaps can be compromised most commonly by previous surgery such as a previous abdominoplasty during which the perforators to the desired tissue have been transected or by other procedures that risk transecting the deep inferior epigastric vessels such as those requiring a lengthy pfannenstiel incision. Preoperative imaging via either CTA or MRA is standard in our practice as assessment of the abdominal vascularity in the above types of patients is paramount.

Other factors influencing surgical decision making include diabetes, cardiopulmonary disease, autoimmune disease, clotting disorders, obesity, and smoking. Active smokers should be counseled to abstain from tobacco and nicotine use for a minimum of 4 weeks prior to any reconstructive procedure. Liposuction is not an absolute contraindication to DIEP flap

breast reconstruction, but very thin women with no abdominal fat may not have enough subcutaneous tissue to recreate a satisfactory breast mound. If a woman does not have adequate abdominal fat for a DIEP flap breast reconstruction, she may still be able to undergo autologous tissue breast reconstruction, as previously alluded to, using either the thigh or the buttock as donor sites. In addition, our group has combined multiple flaps to achieve desired volume/aesthetics for a given breast reconstruction.

PREOPERATIVE PLANNING

All patients undergo a lengthy preoperative consultation aimed first at developing and understanding a patient's priorities and goals. Then after reviewing her medical/cancer details and performing a detailed physical examination, reconstructive options including short/long-term results and complications are discussed. Setting appropriate expectations and painting a realistic portrait of the perioperative period is very important for morale. On the day of surgery, the patient and surgeon should enter the operative suit confident in the choice of reconstruction as well as each other in performing his/her part. This includes the postoperative period, a vital time for active recovery and healing.

Often the topic of reconstruction begins with the breast surgeon as it is not uncommon for a patient to discuss general reconstructive options at the time of deciding on a mastectomy. Thus, developing a routine line of communication with breast surgeons is imperative to ensuring patient goals are both realistic and achieved through appropriate education and execution. Also, given the fact that some surgeons in the community are still not performing free flap breast reconstruction, offering other modalities such as TRAM flaps or latissimus dorsi/implant reconstructions, the breast surgeons benefit from knowing the reconstructive options as well as their advantages/disadvantages to ensure that each patient has access to the best care available in a given area.

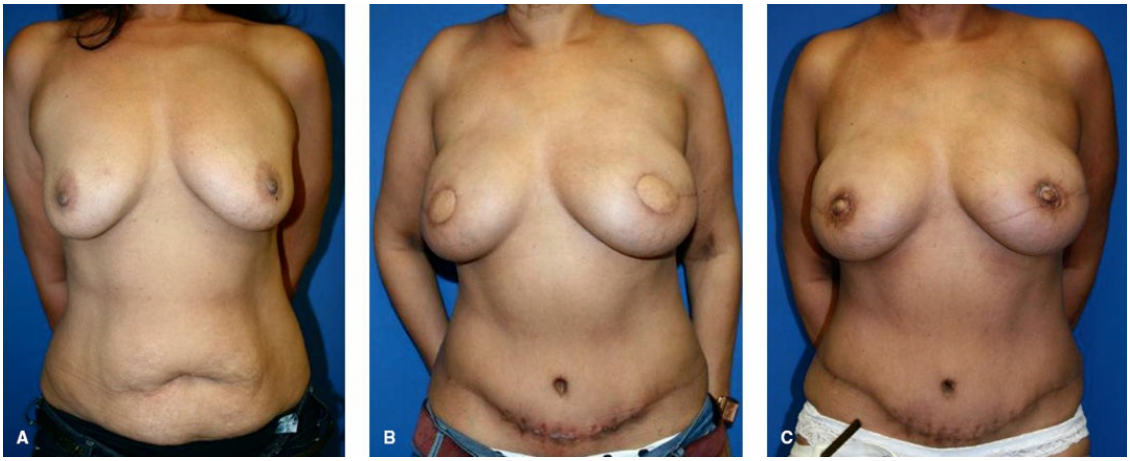

Figure 59.3. Left-preoperative picture of a 57-year-old patient prior to undergoing bilateral mastectomy. Immediately, she had tissue expanders placed which were later removed and bilateral DIEP free flap breast reconstruction performed. Center-postoperative picture after delayed DIEP free flap breast reconstruction. The areola skin is the abdominal flap skin which will be used for nipple reconstruction in the next stage of reconstruction. Right-postoperative picture after delayed bilateral DIEP free flap breast reconstruction followed by next stage nipple reconstruction with skate flaps and revision of the abdominal scar. (Pictures courtesy of Richard Klein, MD, FACS via Orlando Health/UF Health Cancer Center-Orlando.)

Another topic that often arises is the development of a plan for the contralateral breast. First and foremost, a patient should speak to her breast surgeon to discuss the implications of a contralateral prophylactic mastectomy on cancer risk in that breast. This should be weighed against potential complications, though often small, of performing an additional mastectomy. From a reconstructive perspective, a contralateral mastectomy allows for an easier aesthetic symmetry of reconstruction. However, this should not be the driving force. A patient should understand the full spectrum of risk/reward in considering a contralateral prophylactic mastectomy. Then move forward with an educated agreed upon decision.

During the initial reconstructive consultation, potential patients gain an understanding that DIEP flap breast reconstruction involves multiple stages (Fig. 59.3). The first stage centers on performing the actual breast reconstruction creating a new breast with the DIEP flap. This stage is the most extensive and with the longest recovery, though the senior surgeon has been able to get hospital stay to most commonly 3 days with a transition to nonnarcotic pain medicine by discharge. The second stage,

occurring ≥3 months after the initial surgery, involves numerous smaller procedures and is typically an outpatient procedure. At the second stage, nipples are reconstructed, the abdominal donor site is lowered, and the breasts aesthetics are improved. Improving the breast aesthetics can involve fat grafting, removing fat necrosis, and making minor adjustments to increase symmetry between the two breasts. If a unilateral reconstruction was performed, the nonreconstructed breast commonly requires a procedure such as reduction or lift (mastopexy). Second-stage procedures are outpatient with the patient going home the same day. Finally, tattooing of the nipple–areolar complex is performed in an office setting anytime after final healing of earlier stages.

Suitable patients who elect DIEP flap breast reconstruction undergo routine presurgical testing, including appropriate laboratory and diagnostic studies and anesthesia consultation. Blood typing and screening is not necessary. We routinely obtain preoperative imaging—either computed tomography angiography (CTA) or magnetic resonance angiography (MRA)—to delineate the topography of the key deep inferior epigastric perforators (Fig. 59.4). We find that preoperative imaging reduces our operative time by about 1 hour, and it also contributes greatly to patient safety as we are confident about exactly which perforating vessels will be the largest and most robust to use for the DIEP flap. We are able to plan the course of our dissection preoperatively, and we do not waste time guessing which perforating vessels to use while the patient is under general anesthesia.

ANATOMY

A full understanding of the vascular anatomy of the DIEP flap and its variances is crucial to offering consistently successful free flap breast reconstruction. The skin and fat of the DIEP flap are provided blood supply via perforators from the deep inferior epigastric artery. A perforator, simply stated, is a vessel arising from a source vessel and perforating muscle or fascia to supply a given territory (perforasome) of skin and fat. The perforators of the DIEP arise from the deep inferior epigastric vessels and then travel up through the rectus abdominis muscle to pierce the superficial fascia layer on their way to supply surrounding skin and fat of the abdomen. Each perforator bundle will have an artery, two veins, and sometimes a nerve. The deep inferior epigastric artery, after branching from the external iliac artery, travels from lateral to medial in

relation to the rectus abdominis muscle. Often, the vessels will branch into two rows, medial and lateral, each giving off perforators through the rectus abdominis muscle. At least one branch of the deep inferior epigastric artery will continue superiorly to anastomose with the superior epigastric arterial system.

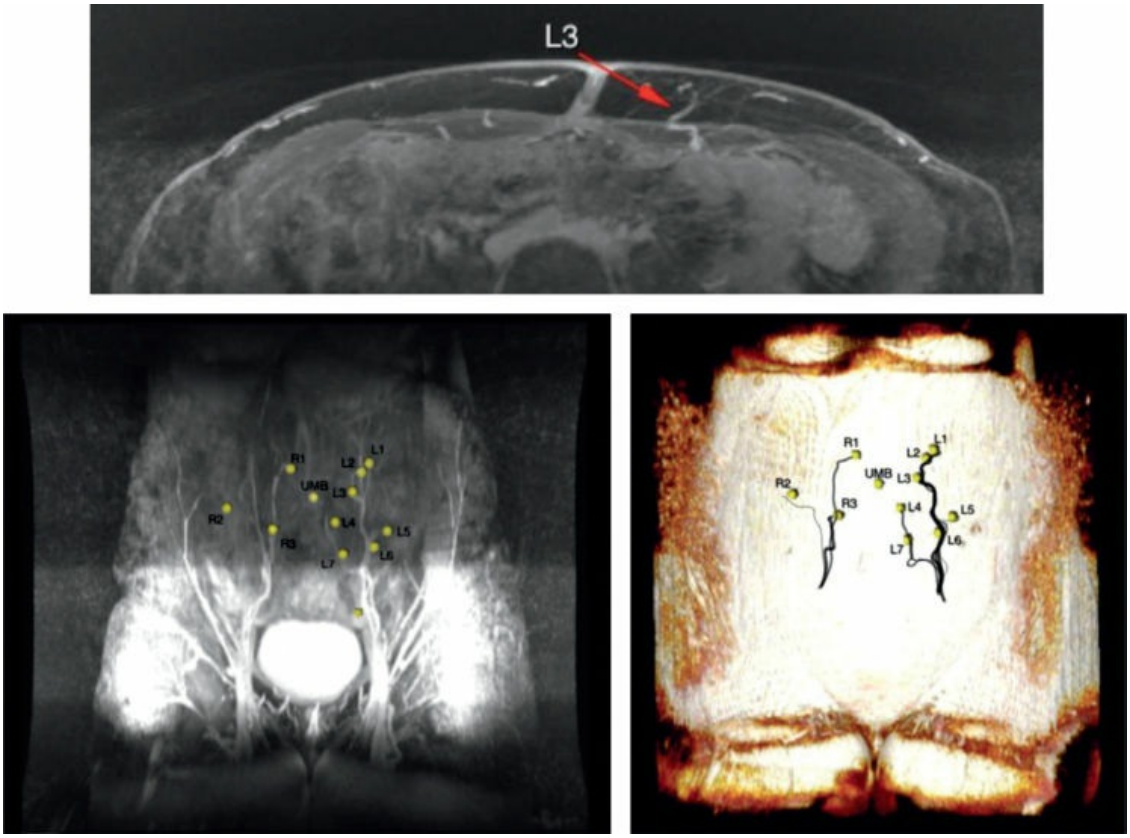

Figure 59.4. Superior MRA of the abdomen: *arrow* marks a perforator in the left hemi-abdomen as it courses deep through the muscle to its origin at the deep inferior epigastric vessels. Inferior left and right MRA images displaying the course of the deep inferior epigastric vessels and their perforators as they leave to perforate the muscle and ultimately supply the skin and fat of the abdominal wall. The preoperative imaging allows selection of the best perforators allowing the surgeon to proceed to the location of those vessels that will ultimately supply the free flap. The perforators are dissected to the origin deep inferior epigastric vessels dissecting inferior until adequate vessel caliber and pedicle length are reached.

The perforators best suited to supply a large area of the lower abdomen are commonly found in a periumbilical area. However, perforators can be located both medially and laterally in relation to the rectus abdominis

muscle, and all supply the surrounding tissue to some degree. The common flap design supplied by these perforators is a transverse, lower abdomen orientation which can be altered superiorly or inferiorly to adequately capture the key perforators. The lower the flap, the more hidden and aesthetically pleasing the resulting scar.

Using either CTA or MRA, the largest perforator(s) may be chosen preoperatively, and then mapped on an *X–Y* axis. The ideal perforator vessel is at least 2 mm in diameter with a short intramuscular course. In 8% of patients, a septocutaneous perforator may be found in which the dominant perforator vessel travels around the medial edge of the rectus abdominis muscle with no intramuscular course at all. This completely eliminates any intramuscular dissection and damage to the musculature, and the best way to identify a septocutaneous perforator is via preoperative imaging. Often, the best perforator vessels are around the umbilicus or slightly above the umbilicus. In these situations, we design our DIEP flap to incorporate the largest and most robust perforator vessels as seen on preoperative imaging.

SURGICAL TECHNIQUE

The day prior to surgery, the patient is seen in the office. After reviewing preoperative imaging and identifying the key perforator(s) supplying each hemi-abdomen, the proposed skin incision markings are placed (Fig. 59.5). First, the perforators are marked based on preoperative imaging coordinates. Some use a handheld Doppler probe to confirm the vessels that they choose preoperatively, and then identify them with direct visualization during flap harvest and perforator isolation. The upper incision is then marked to include the key perforators with the lateral extent of the flaps marked with the patient in a sitting position to avoid leaving excess flank skin after closing the abdomen. Finally, the lower incision is approximated based on lightly pinching the skin to ensure a low-tension closure. The lower skin incision can be adjusted during the operation to ensure a relatively low-tension closure. On the anterior chest wall, inframammary folds are outlined as well as suggested mastectomy skin incisions which vary based on tumor location, breast ptosis and whether or not the nipple areolar complex will be preserved.

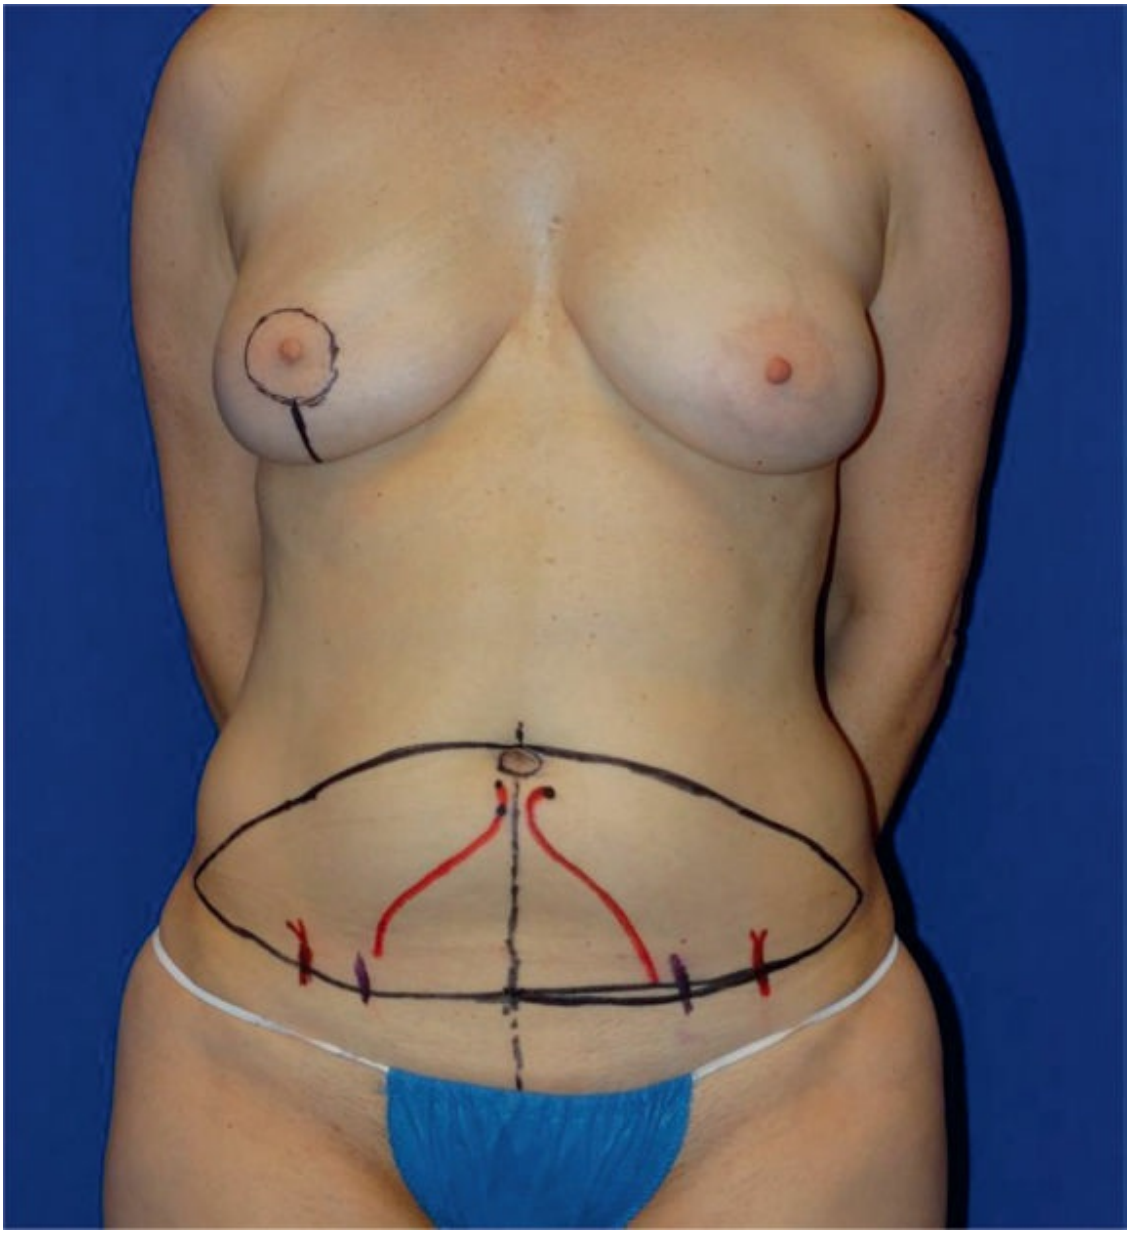

Figure 59.5. Typical preoperative markings showing the proposed incision for the breast surgeon to perform a skin-sparing mastectomy on the right. The abdomen is marked with flap outline as well as the perforators (2 on patient right, 1 on patient left). The lower lines represent the superficial inferior epigastric vein (medial) and artery (lateral).

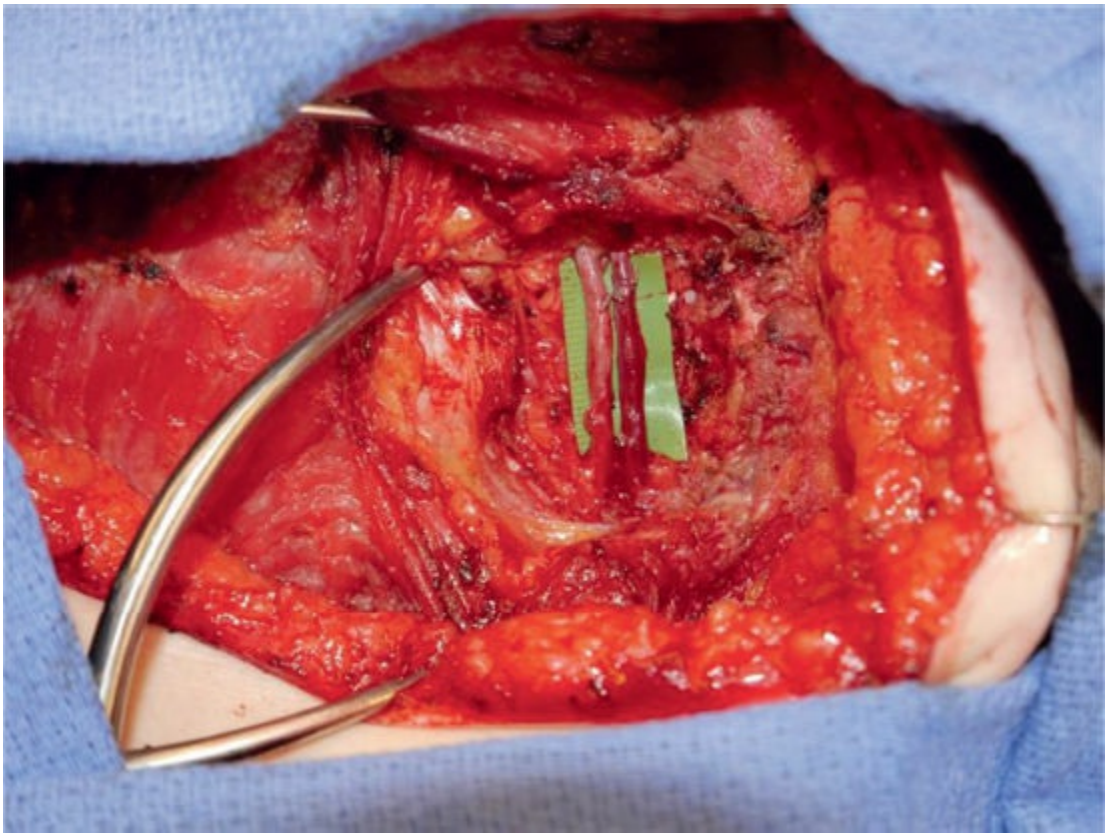

Figure 59.6. The internal mammary vessels (left artery, right vein) have been dissected out after removing the cartilaginous portion of the third rib allowing substantial exposure for vessel anastomosis. Removing a rib is not always necessary if the third or fourth intercostal space is wide enough for adequate exposure.

On the day of surgery, the patient is seen preoperatively to ensure no questions remain. In the operative suite, the patient is positioned supine on the operating table with the arms tucked unless the breast surgeon needs them untucked for the oncologic portion of the case, after which they are both tucked. Simultaneous abdominal flap harvest and preparation of the chest wall vasculature is carried out with a two-team approach. The internal mammary system is typically used as a recipient site (Fig. 59.6). The vessels are approached at the level of the third rib and in the interspace above or below it, depending on which interspace has the greatest width. The diameter of the internal mammary vessels usually increases in size more superiorly. The internal mammary vein often will split into two branches in this area as well, and preoperative MRA can identify the level of branching allowing the surgeon to harvest vessels just above this point. Ultimately, a balance is sought in level of vessel exposure in that one wants sufficient size of vessels but does not want to harvest the

vessels too high as to make exposure for vessel anastomosis cumbersome or to leave no room to expose more of the internal mammary vessels should an injury happen at the initial level of dissection.

First, the pectoralis muscle is split along its fibers over the third rib. It can also be separated from the sternum in a “T” or “L” manner for greater exposure. If necessary for exposure of vessels, the third rib is removed. The periosteum over the cartilaginous (medial) portion of the rib is then incised and stripped from the rib with a periosteal freer/elevator. The third rib is then removed to the sternum and the periosteum carefully excised. Bipolar cautery and sharp dissection are used in this area. Intercostal muscle fibers are excised to exposed a window to the fatty tissue and internal mammary vessels running longitudinally just lateral to the sternum. The vessels are skeletonized preparing them for anastomosis. Alternatively, a portion of the inferior third rib and superior fourth rib are resected to prevent removing a whole rib or, if the interspace is wide enough, no rib is removed, only intercostal muscle. Notably, literature has shown no physical deformity associated with removing the rib. Thus, our group has a very low threshold to remove a rib as a well set up microanastomosis is often key to success. It is important to note that if the vessels are injured during harvest, the recommended recourse is dissecting superiorly to virgin vessels even at the expense of removing another rib. Poor recipient vessels can lead to failure in reconstruction.

Harvesting of the DIEP flap begins with an incision at the upper marked line, dissection through the full thickness of the abdominal wall to the anterior fascia, and elevation of a superior abdominal wall flap. Dissection proceeds to the xiphoid process medially and then costal margin laterally. As much tissue laterally as possible is left undissected in order to preserve lateral perforators supplying the upper abdominal flap. The flap can then be brought down in a window shade fashion to estimate closure tension and adjust the inferior margin as necessary. The umbilicus is then incised. The inferior incision is then made and taken down to fascia. Care is taken to isolate and dissect length on the superficial inferior epigastric vein (SIEV) inferiorly. This vein is a key safeguard when performing DIEP free flap breast reconstruction as an alternative source of venous drainage. Some flaps drain preferentially via a superficial venous system, which can sometimes be recognized as a potential on preoperative imaging. Otherwise this is discovered due to a finding of congestion after the flap has perfused for a time with only the vena comitante providing

venous drainage. Alternatively, one of the perforators to the flap can be injured directly or via traction leaving adequate arterial inflow but insufficient venous outflow. The SIEV is a key bailout in these cases.

If the perforator has already been identified via preoperative imaging, then the dissection can continue directly to the chosen perforator. In a bilateral DIEP flap, the midline incision is made first. If the perforator is a medial row or a septocutaneous perforator, then the chosen perforator is isolated prior to elevating the lateral edges of the abdominal flap. Once the chosen perforator(s) has been identified, the dissection proceeds efficiently with elevation of the skin-fat flap from the underlying rectus fascia. The key perforators are isolated as they enter the anterior rectus fascia. The remainder of the perforators can be either ligated and transected if hindering exposure and dissection of the chosen perforators or left as a bailout should the chosen perforators be injured or inadequate.

Isolation of the DIEP flap proceeds under loupe magnification, and begins by opening the anterior rectus sheath around the selected perforator. Some surgeons incorporate a 1- to 2-mm cuff of the sheath around each perforator, but routinely, no fascia is harvested. Using a microsurgical scissor or bipolar electrocautery, the perforator is followed through the rectus muscle, carefully ligating and diving all small side branches with microsurgical clips. Bipolar electrocautery can be used for smaller branches. If a second or third perforator has been selected, particular attention must be paid to maintaining its continuity in line with the first. Ideally these additional perforators are along the same “row” as the primary, meaning medial or lateral. This will allow preservation of muscle as the perforators will all be along the same line when the muscle is split. If the perforators originate from both medial and lateral rows and are necessary for flap perfusion, a decision must be made to either transect a small portion of muscle or harvest a muscle-sparing type 2 TRAM removing a small portion of muscle between the two rows of perforators. This is rarely necessary.

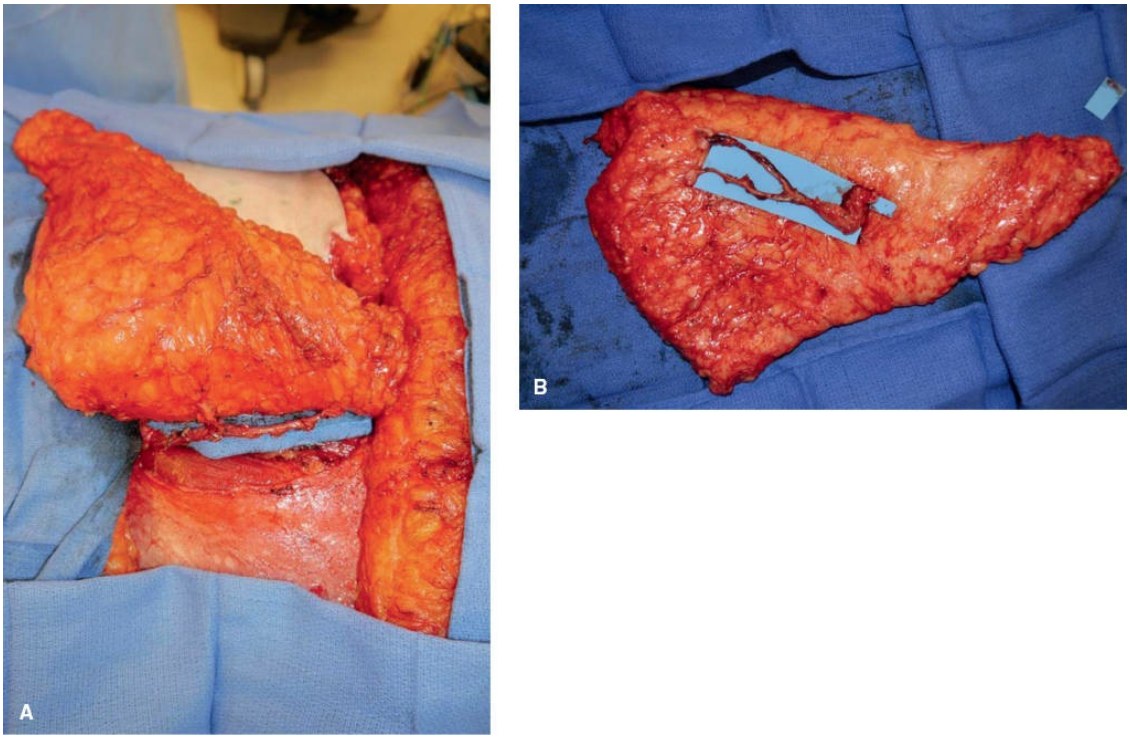

Figure 59.7. A: Deep inferior epigastric perforator artery flap harvested on two perforators. The perforators enter the deep inferior epigastric vessels were then course inferiorly. Below the blue background, the rectus abdominis muscle can be seen spared of any unnecessary trauma. **B:** DIEP free flap harvested. Pedicle seen resting on the blue background.

As dissection proceeds, the muscle is split along the direction of its fibers, preserving all intercostal nerves that do not lie between two perforators. The anterior rectus sheath is also split inferiorly, and the deep inferior epigastric vessels are eventually exposed. These are followed toward their origin from the external iliac artery and vein until adequately sized vessels are reached that match the caliber of the recipient vasculature. At this level, the resulting pedicle length is usually between 9 and 14 cm (Fig. 59.7).

The DIEP flap is then harvested by individually ligating and dividing the deep inferior epigastric artery and its two venae comitantes. It can be helpful to mark the anterior surface of the vessels with methylene blue prior to vessel division to prevent twisting of the pedicle. In addition, the smaller vena comitantes can be clipped, leaving the larger vena comitantes and artery open for anastomosis. The flap is weighed at this time to determine its comparability to the mastectomy specimen or implant. It is then transferred to the anterior chest wall and temporarily secured in

position. This can be done by suturing/stapling the flap to the chest wall or by wrapping the flap in a heparin-soaked lap sponge that is stapled to the chest wall. Routinely, the hemi-abdomen contralateral to the breast being reconstructed is utilized and rotated 90 degrees counterclockwise when transferring left hemi-abdomen to right breast, clockwise when transferring right hemi-abdomen to left breast.

The operating microscope is positioned at the recipient site and the pedicle prepared for microanastomosis, taking care to avoid twisting of the vessels. An end-to-end venous anastomosis is completed with a microvascular coupling device (Fig. 59.8). The end-to-end arterial anastomosis is hand-sewn with 9-0 nylon sutures usually in a running fashion if the vessel match is favorable, otherwise interrupted sutures are used. Once the anastomosis is completed, the vascular clamps are removed and the pedicle assessed for flow. There should be a palpable pulse in the pedicle. Next, the flap can be inspected for bleeding which should be a slow bright red ooze. Venous congestion will usually present slowly as the flap fills with blood and will include brisk dark red blood from the flap, decreased time of capillary refill and, over time, flap swelling.

The DIEP flap is then debulked, contoured, and inset to achieve the desired breast size and shape. At a minimum medial Vicryl sutures are placed to keep the flap from shifting laterally. These are placed to Scarpa fascia of the flap and the most medial chest wall. However, if the breast pocket is at all big, additional sutures can only help to contour an aesthetic breast mound. Areas underlying the native mastectomy flaps are deepithelialized in situ. A closed-suction drain is placed and brought out through the lateral edge of the skin closure or through a separate stab incision. After the flap has been shaped and inset, the skin is closed with 3-0 Monocryl deep dermal and running subcuticular sutures.

Ideally, closure of the abdomen begins as soon as the flap(s) are harvested, and is finished prior to the conclusion of the microvascular anastomosis. The anterior rectus sheath is closed with interrupted 0 V-lock suture. Since no fascia has been harvested, the use of mesh is not necessary. The remainder of the abdominal closure is in layered fashion, using 0 barbed suture to close Scarpa fascia, and 2-0 barbed suture for skin. Two closed-suction drains are placed in the abdomen and brought out through the lateral incision. We have also begun running barbed progressive tension sutures along the abdominal flap tacking the subcutaneous tissue to the anterior fascia of the abdominal wall. This has

allowed placement of only one drain. The umbilicus is brought through the abdominal wall at a predetermined site after removing a full-thickness elliptical core of skin and adipose tissue. It is secured in place using interrupted 3-0 Monocryl in the dermis and 4-0 subcuticular sutures for skin.

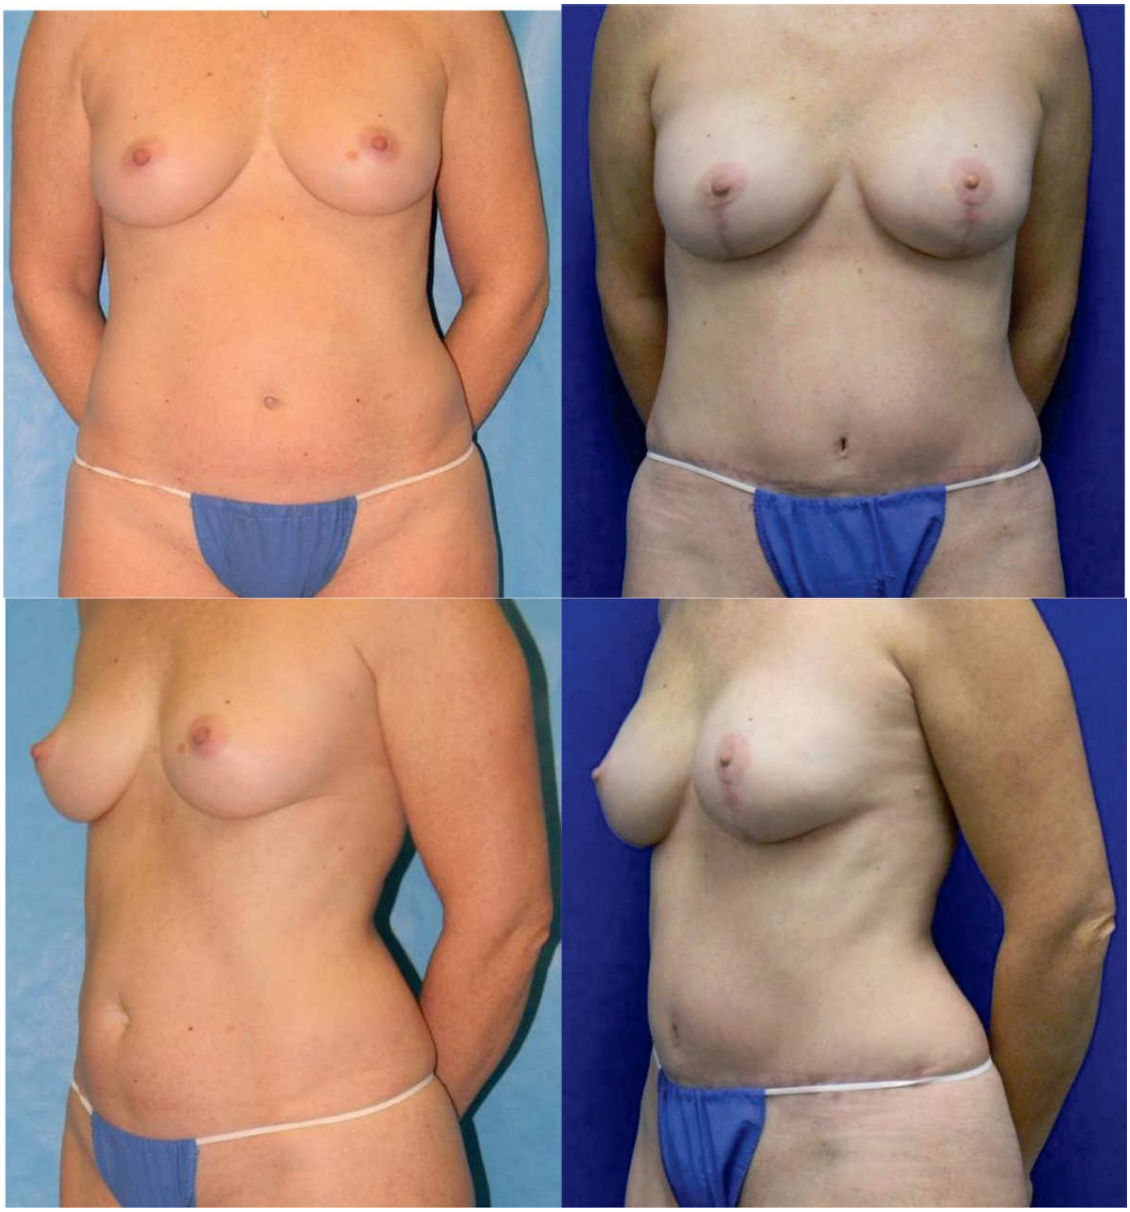

Figure 59.8. A 51-year-old patient who underwent bilateral mastectomy for prophylaxis with immediate DIEP free flap breast reconstruction. Left preop/Right postop.

Once all wounds are closed, the entire anterior body is cleansed and dried. Liquid skin adhesive is placed over the abdominal and breast incisions. A piece of Xeroform is placed within the umbilicus and the flaps are again checked for perfusion. Doppler signals are confirmed and marked with a 5-0 monofilament suture. The patient is usually given some form of IV nonnarcotic pain medicine such as ibuprofen, acetaminophen, or ketorolac then extubated and sent to recovery.

POSTOPERATIVE MANAGEMENT

The patient is monitored in the recovery room for 4 hours postoperatively. Flap checks are performed every 15 minutes during this time, and consist of assessments of skin paddle color, temperature, capillary refill, and Doppler signals. The patient is then moved to a regular private room, where flap checks are performed on an hourly basis overnight. The patient is out of bed to a chair sitting up the day of surgery. In the morning postoperative day 1, the Foley catheter and intravenous lines are removed. The patient is started on a regular diet, and is required to ambulate. Chemical deep vein thrombosis prophylaxis is started as well. Flap checks are continued every 4 hours while the patient is in the hospital. The patient is usually discharged home on postoperative day 3 or 4. After 4 to 6 weeks, patients are encouraged to gradually resume their preoperative levels of activity.

Complications

Much has been written comparing the DIEP with the traditional TRAM flap. It is imperative to meticulously review this literature as many factors confound the outcomes data including surgeon experience, definition of and quality reporting of complications such as fat necrosis, and even poor follow-up as is the case with many NSQIP-based studies. At present time, the DIEP is the gold standard for autologous breast reconstruction and a discussion of comparison to other abdominally based flaps will be brief given the DIEP's known superiority. Unlike the pedicled and free TRAM, the DIEP flap preserves the rectus abdominis muscle to maintain abdominal wall strength and minimize the risk of abdominal bulge or hernia. Preservation of the rectus abdominis muscle decreases abdominal wall morbidity, resulting in improved abdominal wall strength and contour. This translates into less postoperative pain, shorter hospital stays, and quicker recovery. In addition, the longer vascular pedicle allows greater freedom of design that optimizes the aesthetics of breast reconstruction.

DIEP flap breast reconstruction is not without complication maintaining a total complication rate of roughly 25%. Obese patients and smokers tend to suffer more donor site wound healing and mastectomy skin flap necrosis respectively. In our series of over 2,000 DIEP flaps beginning in 1992, the total complication rate compares favorably with other forms of autologous tissue breast reconstructions. Our complication rates include a 10.3% abdominal wound healing complication often associated with an

underlying seroma. We expect these rates to decrease as we have seen favorable results with progressive tension sutures.

Early complications included the need to return to the operating room in 5% of patients: 3.7% because of venous occlusion, 0.5% for arterial occlusion, and the remainder for hematoma. Adoption of a coupling device for venous anastomosis has decreased the take-back rate even further. The rate of total flap loss was 0.5%, with a partial flap loss rate of 2%. The most common complication following autologous breast reconstruction with abdominal tissue is fat necrosis. This is thought to arise in areas of deficient perfusion, often at the flap periphery farthest from the vascular supply. Although early experience with the DIEP flap led to initial reports of fat necrosis rates as high as 60%, improvements in perforator selection and operative technique have led to a significant decrease. It is important to keep this fact in mind when reviewing the available literature on the subject. A retrospective review of our DIEP free flap reconstructions reveal a 10% fat necrosis rate, which is significantly correlated with smoking, obesity, and postreconstruction radiotherapy. These rates are at or below the rates of fat necrosis for other forms of abdominally based free flap breast reconstruction. When performed routinely by an experienced microsurgeon, abdominal hernia is not seen after DIEP free flap breast reconstruction. We have seen a very small percentage of abdominal bulging without true hernia likely due to fascial laxity and this has been associated with the obese population.

CONCLUSION

The DIEP flap technique has expanded the pool of potential reconstructive candidates by allowing for autologous breast reconstruction in previously unsuitable patients, such as obese individuals or those with prior abdominal surgery. With the increasing use of preoperative imaging and a two-microsurgeon team, operative times are minimized and the procedure itself has become safer and more predictable. The DIEP flap represents the gold standard for autologous breast reconstruction using the abdomen and provides the best long-term aesthetic outcome (Fig. 59.8). The increased demand for microsurgical expertise is more than offset by the rewards of minimized donor site morbidity and increased patient satisfaction. DIEP free flap breast reconstruction should be accessible to all potential candidates for autologous breast reconstruction.

EDITOR'S COMMENT

Transverse rectus abdominis muscle (TRAM) flaps revolutionized breast treatment with the promise of reconstruction. The introduction of the deep inferior epigastric perforator (DIEP) flap allowed transfer of skin and soft tissue without the sacrifice of muscle with less morbidity (no sacrifice of rectus or fascia), abdominoplasty, reduced pain and recovery time and long-lasting results. Koshima and colleagues reported the first use of a deep inferior epigastric perforator (DIEP) flap in 1992 using a single periumbilical perforator which was used for mouth and groin reconstruction. At the same time Allen and Treece performed the first DIEP flap for breast reconstruction in order to use the fat and skin of the abdomen for breast reconstruction. The authors of this chapter go so far as to say that DIEP reconstruction should be accessible to all potential candidates for autologous breast reconstruction. This is said though without regard to the lack of availability of qualified surgeons and teams of surgeons or cost and without the discussion of acceptable alternatives. Implants are far and away the most utilized type of reconstruction (70%) in the United States. The patient can have a staged expander reconstruction or a direct to implant reconstruction with immediate results. Granted the cosmesis may not be as superior and deteriorates a bit over time. Implant reconstruction has been driven by, in this "McDonald's Society," immediate results, the low morbidity of implant reconstruction, short hospitalization and recovery and the back-up of tissue reconstruction should the implants fail.

DIEP flaps are indicated in anyone with amastia with or without contralateral reconstruction, lumpectomy-induced breast defect, failed implant reconstruction, or desired augmentation. Factors influencing surgical decision-making include diabetes, cardiopulmonary disease, autoimmune disease, clotting disorders, obesity, and smoking. DIEP flaps do better in such patients but still have a high complication rate, are much more costly (preoperative imaging, two microsurgeon team, long operative times and long recovery times) but with superior and long-lasting results and patient satisfaction.

Contraindications as is in all reconstruction include active smokers, prior abdominoplasty or liposuction. Relative contraindications include patients with prior scars including even an appendectomy scar. One contraindication to DIEP reconstruction that plagues plastic surgeons is the commonality of the presence of a midline scar. Gupta and colleagues have published a small series on the use of two hemi DIEP flaps stacked on each other with two separate anastomoses to the IM to create a breast of sufficient size. Magnetic resonance angiography (MRA) can be invaluable in patients with or without scars to preoperatively to determine perforator anatomy, location, size, and appropriateness which will result in a reduction in intraoperative time. Surgeons are also loathed to use DIEP flaps when a patient will require postoperative radiation therapy. In such situations, a nipple skin-sparing mastectomy can be performed, a short-term

expander placed above the muscle and radiation performed. Then the patient can return to surgery and the expander removed and the skin envelope filled with a DIEP flap thus avoiding the complication of severe fat necrosis created by radiating a flap.

The authors have given a very detailed description of DIEP reconstruction. The DIEP, like the TRAM flap, is based on the deep inferior epigastric artery and vein. The DIEP can also and was previously termed a muscle-sparing TRAM which dissects free the medial or lateral row of DIEP vessel down to the deep inferior epigastric vessels. Although any side can be used an ipsilateral DIEP is shaped/used if the recipient vessels are the thoracodorsal bundle and the contralateral DIEP is used when the internal mammary vessels are to receive the flap which is most of the time. Flap geometry, when there is an absent or an insufficient internal mammary (IM), may also dictate a change in recipient vessel. Use of the thoracodorsal vessel as a recipient vessel obviates the use of a latissimus musculocutaneous flap in case of failure of the DIEP flap. If the IM is used then the IM cannot be used in the future for coronary reconstruction.

Site of recipient vessel has been up to the discretion and preference of the plastic surgeon. Recently, Lhuaire and colleagues did a careful anatomical dissection of 80 cadavers to determine which recipient vessel, IM, circumflex scapular (CS) or thoracodorsal (LD) vessels and how well they matched the deep inferior epigastric vessels in the same cadaver. They found the best match was in the IM vessels, only a little better than CS, and was largest at the third rib. There was a perfect match in only about one third of cases for IM and CSA but one sixth of the time for LDA. Venous congestion is a common reason for flap failure but under studied. Lhuaire and colleagues showed that less than one quarter of the time was there a perfect match for the potential venous anastomoses. Although arteries of these vessels were singular this was not true of the venous vessels. Deep inferior epigastric and CS vessels were duplicative in 10% of cases. IM had two branches in 25% of cases. In this regard, TD vessels appear superior in that there is only one branch 99% of the time.

Advantage of using the IM for the DIEP recipient vessel is that it does have the size vessel matching the donor vessels, ease of inset, found to have a higher internal volume, no impediment to an axillary node dissection if necessary, ease of microscope set-up, and shorter donor pedicle procurement. It does usually require rib removal and as a result possible pulmonary complications. Some believe that respiratory movement puts undue strain on the microvascular anastomosis. If radiation has or is to be given then the quality of the IM can be affected. The CS is the second vessel with the highest vessel diameter match to the DIEP pedicle. The CS vessels are very constant in location, decreased operative time, avoids pulmonary complications and offers the possibility of a second or alternative vein anastomosis in case of insufficient outflow. Particularly important is that an anastomosis to the CS vessels does not affect IM or LD vessels. LD reconstruction then remains a back-up alternative Superficial Inferior Epigastric Perforators (SIEP) can be used when there is an

issue with DIEP. If there is a large SIEP then it portends that the DIEP vessels may be insufficient and then SIEP can be performed, 25% on one DIEP perforator, 50% on two and 25% on three.

Another newer and less established technique not discussed by the authors is preservation of the intercostal nerves to avoid muscle laxity that can mimic a hernia. Sensory nerves can be taken with the DIEP and reanastomosed to recipient nerves in the chest. In a more recent innovation, Yang and colleagues simultaneously combined TRAM/DIEP reconstruction with inguinal node donation to reconstruct patients who had received ALND and radiotherapy to improve postmastectomy lymphedema.

Complication rates with abdominal pedicled myocutaneous flaps to the deep inferior epigastric perforator free flap (DIEP) vary. These flaps vary in difficulty, time to perform, complication rate (roughly 25%), up to and including flap loss, donor site morbidity which is lessened in muscle sparing flaps. Early take back due to problems with arterial or venous occlusion (～5%) have been lessened with the adoption of vascular coupling devices. Tissue reconstruction does have the advantage of less complication in the obese which, in general, have a sevenfold higher risk compared to those who have a normal body mass index. In a systematic review and meta-analysis, Lee and Mun found that muscle sparing flaps like DIEP had less complications, flap loss and fat necrosis than the traditional free TRAM flaps. Zoghbi and colleagues examined the Nationwide Inpatient Sample Database (2010–2011) for all cases of DIEP and free TRAM reconstruction. They identified 15,836 cases. Although the DIEP cohort was much more likely to be obese the TRAM group had more complications including pneumonia, wound infection, and wound dehiscence which resulted in a relative risk of 1.6 in regard to length of stay but not flap loss. Despite this total charges for a DIEP flap were higher. Wade and colleagues showed that complications are much higher with bilateral DIEP reconstruction and total flap loss six times higher when comparing bilateral versus unilateral operations thought mainly due to venous congestion. Donor site morbidity with DIEP is also less when compared to the traditional free flaps. Egeberg and colleagues, in a recent meta-analysis of five studies that compared muscle sparing TRAM with DIEP flaps showed that the relative risk of hernia was halved with DIEP.

V. Suzanne Klimberg

This is an excellent commentary by Dr. Klimberg of various approaches to provide excellent cosmesis of the breast. Cosmesis is essential to make certain women have a satisfactory result to decrease the trauma of mastectomy.

60 Applied Anatomy of the Chest Wall and Mediastinum

Petros Mirilas, Michael E. Halkos, John D. Symbas, Panagiotis N. Symbas, and Lee J. Skandalakis

CHEST WALL

Embryogenesis

The *muscles of the chest* develop from the somites found in the mesoderm. About the 6th week, the somites differentiate into the sclerotomes and the dermatomyotomes. The myotomes elongate and invade the mesoderm of the wall of the embryonic thoracic and abdominal cavities. These myotomes divide into the epimere and the hypomere. The corresponding nerves give a dorsal and a ventral ramus, respectively. The hypomere in turn divides in three layers—outer, intermediate, and inner—that give the three layers of muscles of the chest, that is, the external intercostals, the internal intercostals, and the innermost intercostals; in the abdomen, the hypomere gives off the external oblique, the internal oblique, and the transverse abdominal muscles (Fig. 60.1). This arrangement explains the continuity of the three muscle layers in the thoracic and abdominal wall. The anterior edge of the hypomere gives the rectus abdominis, and, in the thoracic wall, its equivalent: the transverse thoracic muscle.

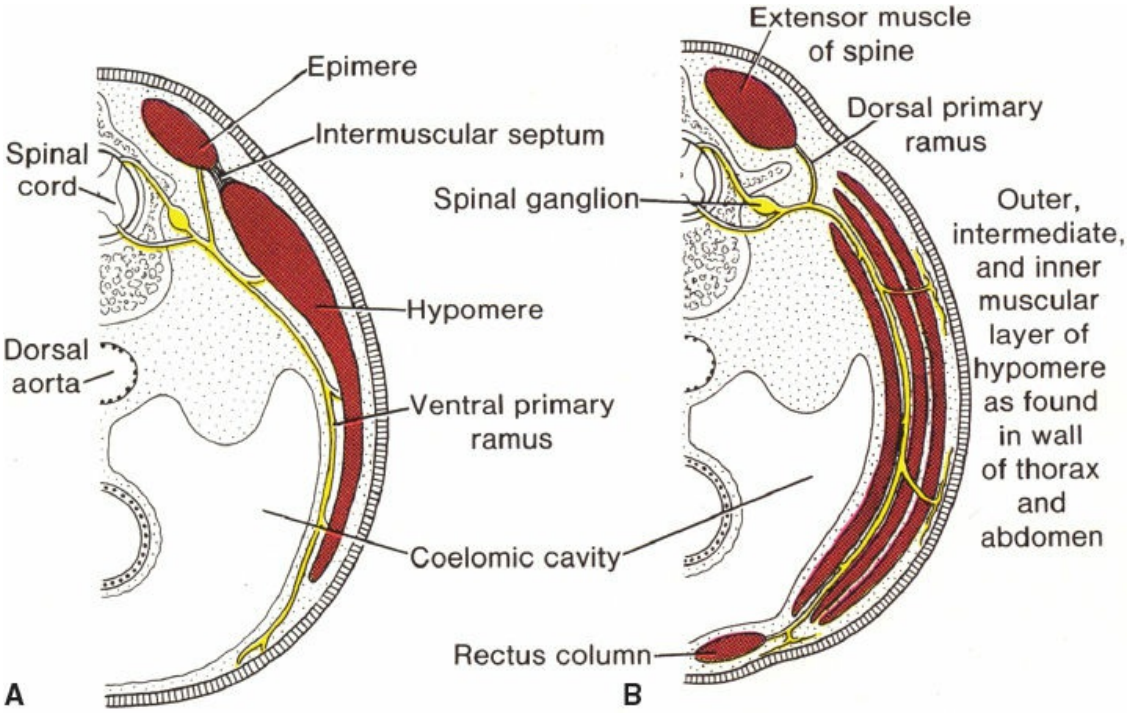

Figure 60.1. A: Transverse section through the thoracic region of a 5-week embryo. The dorsal portion of the body wall musculature (epimere) and the ventral portion (hypomere) are innervated by a dorsal primary ramus and a ventral primary ramus, respectively. **B:** Similar sections as in (**A**), at a later stage of development. The hypomere has formed three separate muscle layers and a ventral longitudinal muscle. (From Sadler TW. *Langman's Medical Embryology*. 10th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2006, with permission.)

The *ribs* develop in the 5th week by the costal processes of the thoracic vertebrae (derivatives of the sclerotomes). They elongate in the same mesodermal layer with the thoracic muscles, and thus the investing fasciae of the intercostal muscles are continuous with the periosteum of the ribs. The embryonic ribs are cartilaginous; ossification takes place about the 9th week.

The *sternum* appears during the 6th week as paired bands of condensed mesenchyme. At the same time, the presternum, a cranial rudiment associated with the development of the shoulder, and two craniolateral pieces, the suprasternal cartilages, will join the two sternal bars, which "zipper" craniocaudally (Fig. 60.2). The manubrium is the result of subsequent ossification in the sternum.

Congenital Anomalies

Sternum deformities (Fig. 60.3): The *pectus excavatum* or funnel chest represents a depression deformity, with the apex at the lower end of the body of the sternum. The *pectus carinatum* or pigeon breast is a protrusion deformity. These deformities are often nonsymmetrical or mixed. *Sternal clefts* (upper, lower, or entire) may be the outcome of an anomaly of fusion of the two sternal bars; this deformity may be associated with ectopia cordis (cardiac ectopia), or, rarely, may be one of the constituents of Cantrell's pentalogy (sternal cleft, diaphragmatic defect, defect of the pericardium and communication with abdomen, cardiac defects).

Rib deformities: The spectrum of these rare anomalies includes unilateral absence, absence of cartilage, separation of cartilage and rib, combined costosternal anomalies, and part of a skeletal disorder combined with the absence of the pectoralis major muscle (Poland's syndrome).

Surface Anatomy

Sternum

Parts of the sternum point to the position of deep structures:

The superior border lies in the same horizontal level as the inferior border of the body of the second thoracic vertebra. McGregor and Du Plessis wrote about this border: A pin pushed back at the middle of the upper border of the sternum would transfix the inner border of the innominate artery just below its division. In the child the top of the aortic arch may reach the upper border of the manubrium, whereas in the adult it is about the level of the center of this bone.

The angle of Ludwig or of Louis, that is, the junction of the manubrium with the body of the sternum, lies on the same horizontal level with the fourth thoracic vertebra, the bifurcation of the aorta (one vertebra higher in the infant), the beginning and the end of the aortic arch, the site where the pleural sacs meet. The angle of Louis is useful for counting the ribs, because the second rib lies opposite to it.

The xiphisternal junction lies at the level of the disk between 9th and 10th thoracic vertebra.

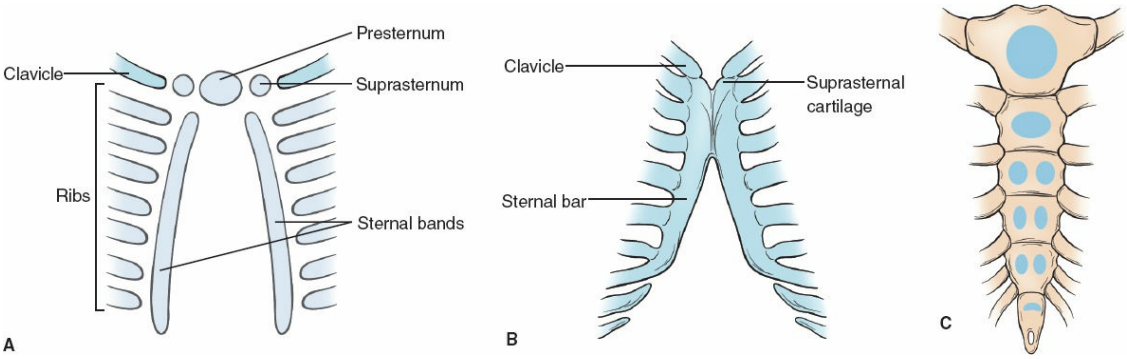

Figure 60.2. Development of the sternum. **A:** Mesenchymal stage (6th week). **B:** Cartilaginous stage (9th week). **C:** Ossification centers appearing after birth.

Lung and Pleura Projection

The classical teaching is that the inferior border of the lungs (defined by percussion) begins at the xiphisternal junction, then is found at the 6th rib in the midclavicular line, the 8th in the midaxillary line, and the 10th vertebra at the spine. The pleura is supposed to be found two spaces below at all these points; an empty *costodiaphragmatic recess* lies in between (Fig. 60.4). However, as O'Rahilly points out, it is not empty but occupied by a very thin part of the lung, which expands further in deep inspiration. Surgically, we must consider that the lung and pleura coexist. It is also important to know the exact levels of the *costomediastinal sinuses* (Fig. 60.4A) to gain transthoracic access to the pericardium, heart, and esophagus without producing pneumothorax; for example, the pericardium can be reached through the fifth and sixth interspaces without opening the pleura. Another must-know tip is the extension of the *cervical pleura* into the neck: the cupola of the pleura lies behind the sternocleidomastoid muscle, 2 to 3 cm or more above the medial third of the clavicle. This space is filled by lung. The subclavian artery, the internal thoracic vessels, the inferior ganglion of the cervical chain, the lower trunk of the cervical plexus all lie on the cervical pleura.

The lung, pleura, liver, stomach, spleen, colon, kidney, and peritoneal cavity extend higher to the periphery of the diaphragm and the inferior border of the lungs. A perforating trauma to the lower intercostals must be considered and treated as thoracoabdominal trauma.

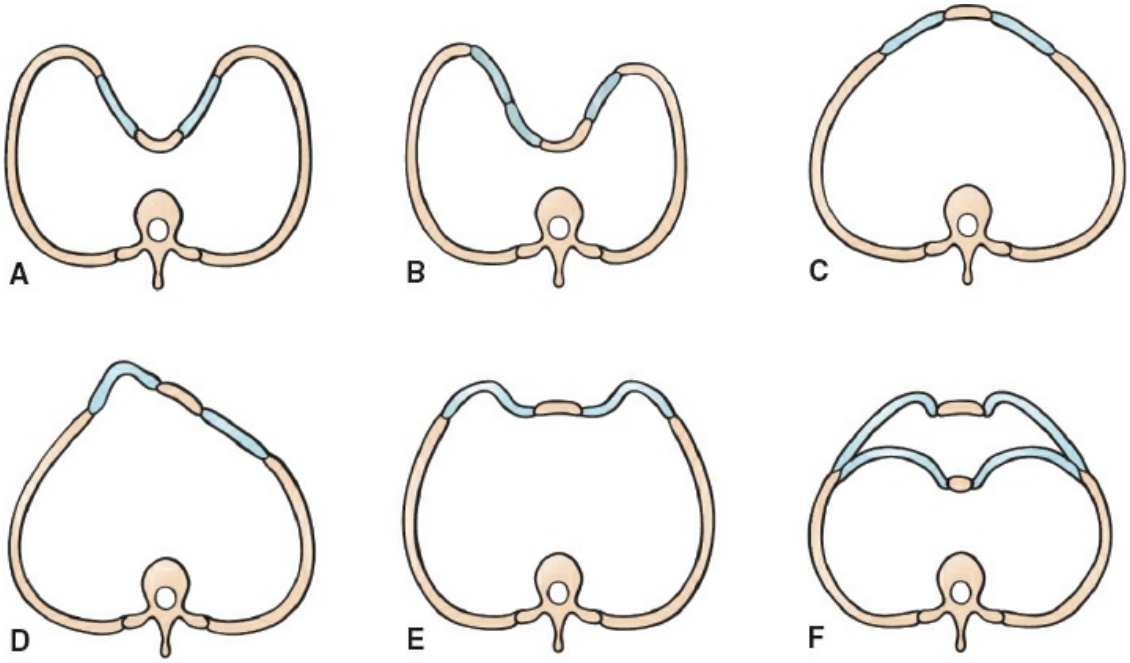

Figure 60.3. Varieties of chest deformities (in cross section). **A, B:** Depression deformities. **C, D:** Protrusion deformities. **E:** Bilateral protrusion. **F:** Chondromanubrial protrusion with gladiolar depression.

Bony Thorax

The thoracic cage includes the sternum, the ribs, and the vertebrae (Fig. 60.5). The sternum consists of the manubrium, the body, and the xiphoid process. The first seven pairs of ribs are the true ribs, and the last five the false ribs; of the last, ribs 8 to 10 articulate with the sternum via supervening costal cartilages, while ribs 11 and 12 do not articulate at all (floating ribs). Occasionally, the 12th rib is missing; a cervical rib is encountered in 1%, producing symptoms only in 10% of these.

A typical rib (Fig. 60.6) has a head, with superior and inferior articulation facets with the superior and inferior vertebra, respectively; a neck; an angle; and the shaft. The costal groove is located in the inferior internal surface of the rib and hosts the neurovascular intercostal bundle. Fracture of the rib due to compression is unusual, and happens at the apex of the curve, sparing the pleura. Otherwise, with direct injury, the fractured rib may traumatize the pleura, the lung, and the intercostal vessels, leading to pneumothorax, hemothorax, or even subcutaneous emphysema.

Muscles

Extrinsic Muscles

The thoracic cage is to a great extent covered by muscles that do not belong to the thorax, but to the shoulder, neck, back, or abdominal wall. The pectoralis muscles, major (lateral and medial pectoral nerve, C5 to C7) and minor, and the serratus anterior (long thoracic nerve) are the extrinsic muscles of the anterior and lateral chest wall (Fig. 60.7). The muscles of the anterior abdominal wall cover the lower ribs: the external oblique from the eight lower ribs (its slips interdigitate with the serratus anterior), the internal oblique (which attaches to the lower three ribs), the internal oblique from the inner surfaces of the eight lower costal cartilages, and the rectus abdominis (which inserts in front of the xiphoid process and into the fifth to seventh costal cartilages).

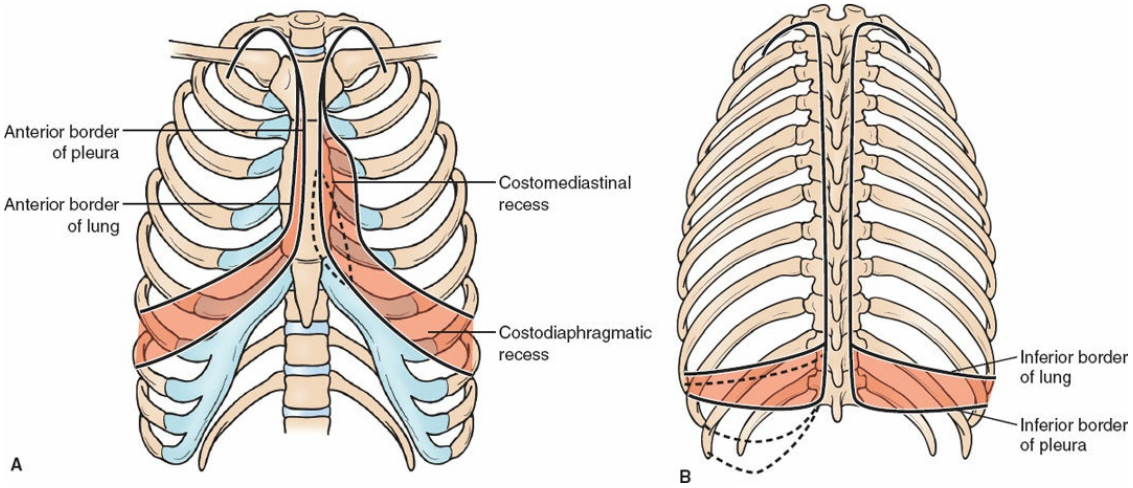

Figure 60.4. A: The pleurae from the front. The interrupted lines represent variants between which the left anterior border of the pleura lies in 70% of instances. The costodiaphragmatic and costomediastinal recesses are indicated in red. **B:** The pleurae from behind. The interrupted lines on the left represent common variations in the position of the inferior border of the pleura. The costodiaphragmatic recesses are shown in red.

The extrinsic muscles of the posterior thoracic wall are the trapezius (spinal accessory nerve, XI), the latissimus dorsi (thoracodorsal nerve), the serratus posterior superior and inferior (segmental rami), the rhomboids, and the levator scapulae (Fig. 60.8).

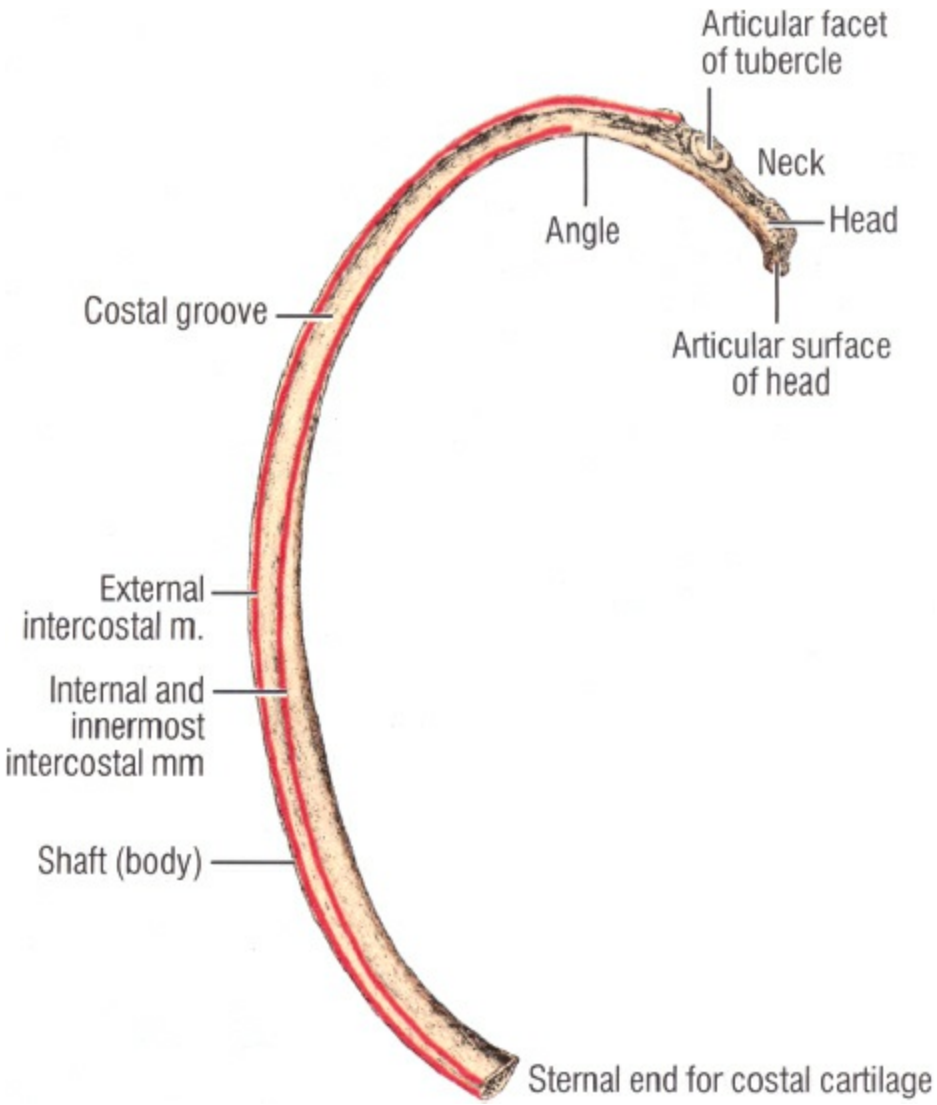

Figure 60.6. "Typical" rib. Surface features of left seventh rib (inferior view). (From Colborn GL, Weidman TA, Mirilas P, et al. Thoracic wall and pleura. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic Basis of Modern Surgery*. Athens GR: Paschalides Medical Publications, 2004, with permission. Modified from Anson BJ, ed. *Morris' Human Anatomy*. 12th ed. New York: McGraw-Hill, 1986.)

Intrinsic Muscles

Similar to the abdominal wall, the thoracic wall includes three muscle layers (Fig. 60.9). The neurovascular bundle lies between the middle and internal layer.

The *superficial layer* consists of the *external intercostal muscles.* Their direction is downward and forward, similar to the external oblique abdominal muscle, with which the lower seven are continuous. They

extend from the tubercle of the rib to the costochondral junction, where they are replaced by the homonymous membrane.

The *middle layer* comprises the *internal intercostal muscles.* They extend from the medial ends of the ribs anteriorly to the angle of the ribs posteriorly, where they are replaced by the homonymous membrane.

The *internal layer* is noncontinuous around the inner surface of the chest wall and comprises the *innermost intercostals,* the *subcostals,* and the *transversus thoracis.*

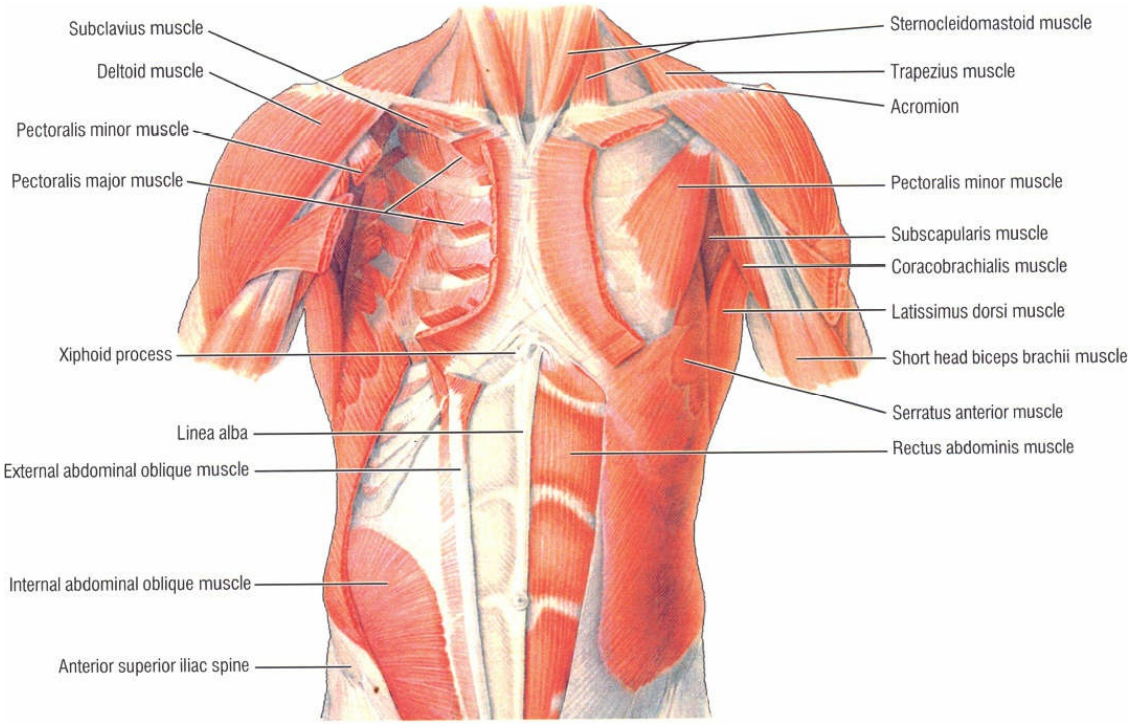

Figure 60.7. Musculature of the anterior body wall. Superficial and deep muscles. (From Colborn GL, Weidman TA, Mirilas P, et al. Thoracic wall and pleura. In: Skandalakis JE, Colborn GL, Weidman TA, et al. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic Basis of Modern Surgery*. Athens GR: Paschalides Medical Publications, 2004, with permission. Modified from Frick H, Kummer B, Putz R. *Wolf-Heidegger's Atlas of Human Anatomy.* 4th ed. New York: Karger, 1990.)

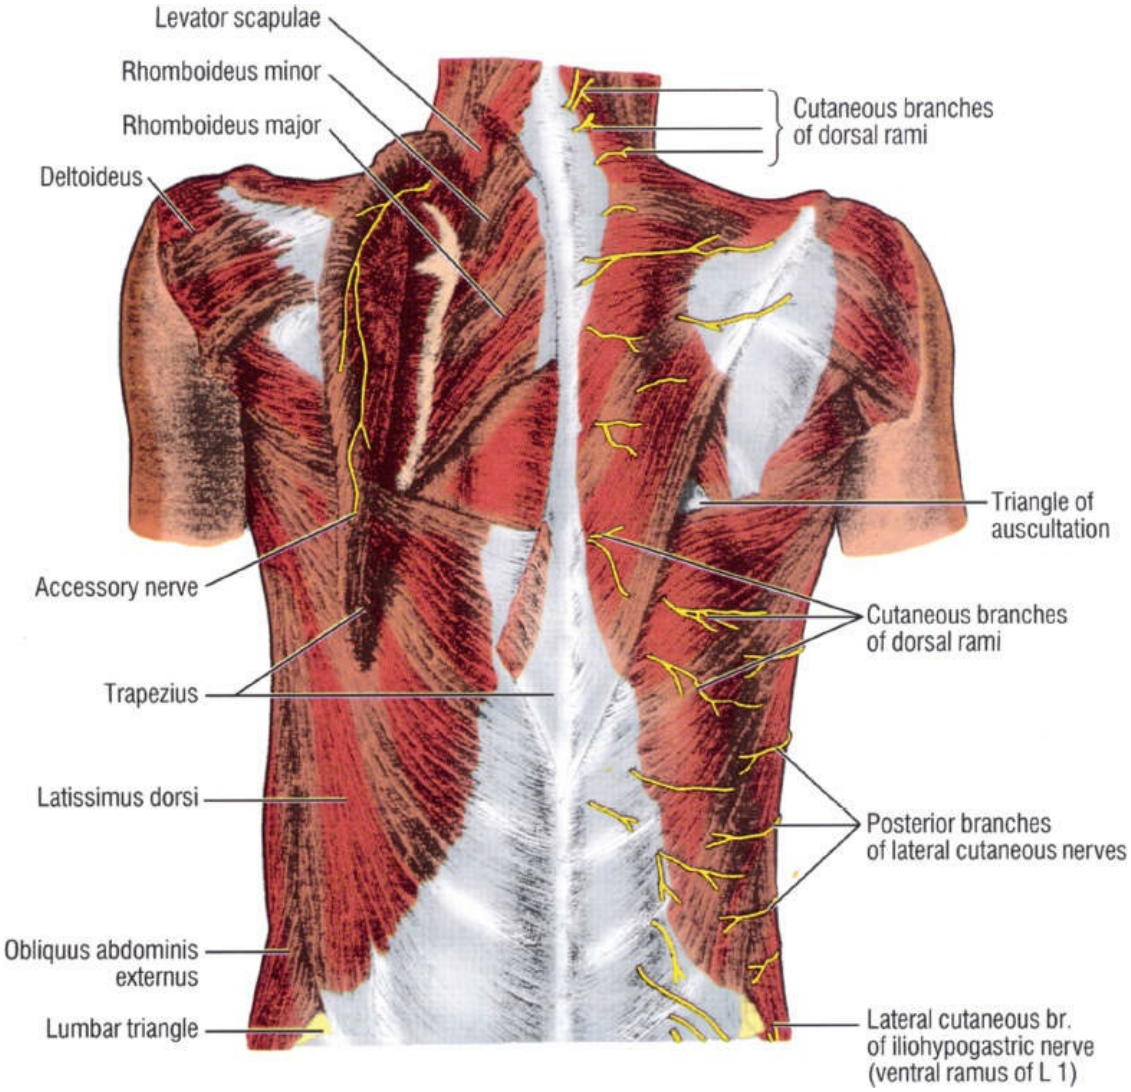

Figure 60.8. Superficial muscles of back and "triangle of auscultation." Trapezius muscle divided and reflected on the left side to show underlying structures. (From Colborn GL, Weidman TA, Mirilas P, et al. Thoracic wall and pleura. In: Skandalakis JE, Colborn GL, Weidman TA, et al. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic Basis of Modern Surgery*. Athens GR: Paschalides Medical Publications, 2004, with permission. Modified from Grant JCB. *An Atlas of Anatomy by Regions*, 4th Edition. Baltimore, MD: Williams & Wilkins, 1956.)

No fat is found between the endothoracic fascia (covering the internal surface of the internal muscle layer) and the pleura. In contrast, in the abdominal wall, preperitoneal fat is found between the endoabdominal fascia and the peritoneum.

Vessels

Arteries

The vascular supply of the chest wall is rich and originates from different sources. The chest wall is supplied by the posterior intercostal arteries arising from the aorta, the internal thoracic and the highest intercostals given off the subclavian artery, and the branches of the axillary artery (Fig. 60.10). Surgical mastery of this two-source arterial network (aorta-subclavian, and axillary arteries) can be reached if the surgeon studies the collateral circulation developing in aortic coarctation (Fig. 60.11).

The principal arteries are the (posterior) intercostals and the internal thoracic arteries. The first two or three pairs of the *intercostal arteries* arise from the highest intercostal artery, a branch of the costovertebral trunk of the subclavian artery. The remaining intercostal arteries are given from the back of the aorta. The right arteries pass in front of the vertebrae, and hence are longer than the left. The intercostal arteries lie behind the azygos and hemiazygos veins, the thoracic duct, and the sympathetic trunk (Fig. 60.10). The arteries course in the costal groove between the vein (above) and the nerve (below). This is true for the dorsal and lateral chest; anteriorly, vessels and nerve are exposed in the spaces. Therefore, in the dorsal and lateral chest, the surgeon must proceed along the superior margin of the lower rib when puncturing in order to aspirate or to perform surgical procedures. This relation with the bone explains the risk for vessel wound in rib fractures.

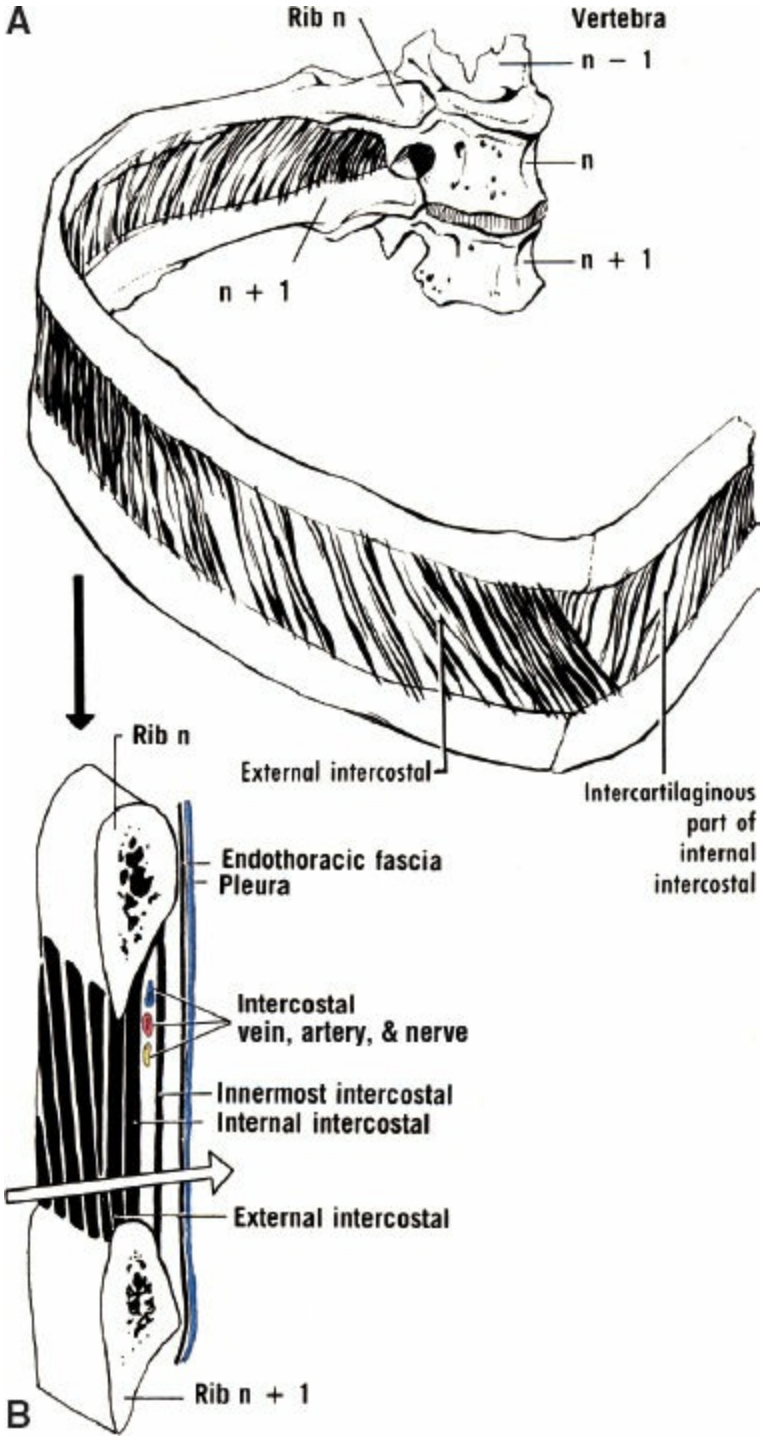

Figure 60.9. The intercostal muscles. **A:** Direction of fibers of the external and internal intercostal muscles. **B:** Vertical section through an intercostal space. White arrow represents path of a needle in pleura aspiration, avoiding the intercostal nerve. (Published in O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy*. Philadelphia, PA: WB Saunders, 1986. Copyright Elsevier.)

The intercostal artery gives off branches. One is the *dorsal* artery, muscular and spinal, which supplies the muscles and skin of the back.

Another branch is the *lateral cutaneous* for the overlying muscles; the third to fifth give small *mammary* branches. In most cases the intercostal artery, at the angle of the rib, gives off a *collateral* artery, which then travels anteriorly immediately above the lower rib. This vessel is much smaller than the main one. It is not unusual to disregard the presence of this vessel during paracentesis through a posterolateral part of an intercostal space; inserting the needle at the upper border of the lower rib to avoid the main intercostal artery and nerve can traumatize the collateral.

The *internal thoracic artery* arises from the first part of the subclavian artery (Fig. 60.12). It courses downward in the thorax just lateral to the sternum, behind the upper six costal cartilages and the internal intercostal muscles, and in front of the transverse thoracic muscle and the pleura. In the sixth space the internal thoracic artery divides into a lateral branch (the *musculophrenic artery*) and a terminal branch, feeding the rectus muscle (the *superior epigastric artery*). The rectus can be used in reconstruction of the breast as a flap reversed upward around the superior epigastric artery. Other branches are the *anterior intercostals arteries* and the *perforating arteries* in the upper six spaces; the latter in the second to fourth spaces supply the breast. The internal thoracic artery can be ligated —for example, in case of trauma resulting in a possibly fatal hemorrhage —in the third intercostal space; lower spaces are much narrower for this procedure.

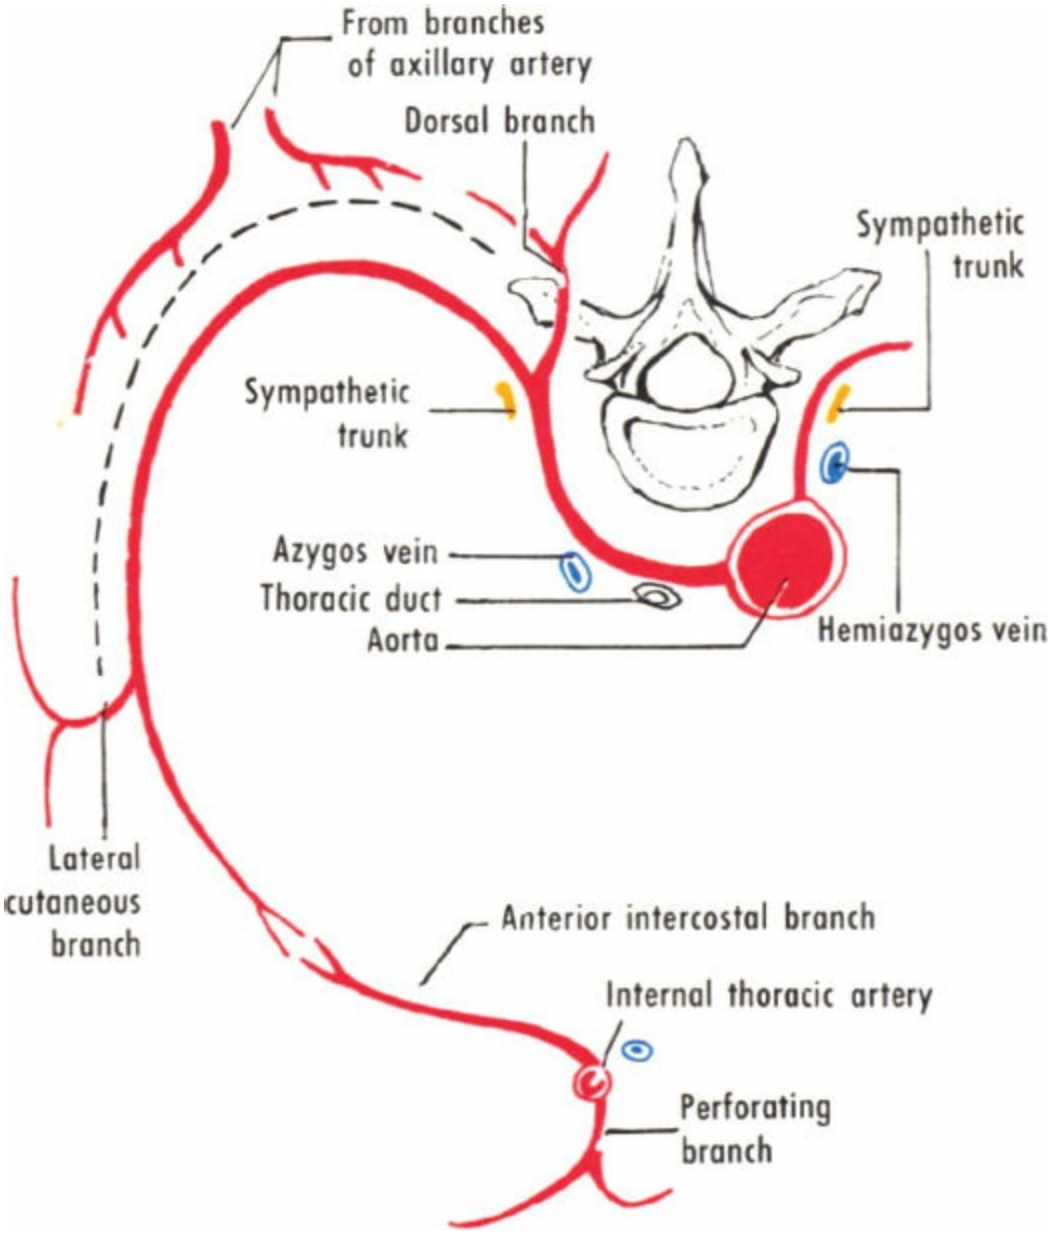

Figure 60.10. Arteries of the thoracic wall. Note that the intercostal vessels pass behind the longitudinally disposed veins and nerves of the posterior mediastinum. (Published in O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy*. Philadelphia, PA: WB Saunders, 1986. Copyright Elsevier.)

The anterior intercostal arteries are sometimes two (inferior and superior) in the respective intercostal space; sometimes the lower, traveling on the upper border of the lower rib, is the bigger. To perform paracentesis through an anterior intercostal space, the surgeon is advised to proceed in the middle of the space to avoid bleeding from the anterior intercostal arteries.

Veins

The *posterior intercostal veins* and the *subcostal veins* follow the posterior intercostal arteries in the costal grooves. The 1st posterior intercostal vein on either side empties into the brachiocephalic vein. The 2nd through 4th veins join the superior intercostal vein, which on the right joins the azygos vein and on the left the left brachiocephalic vein. The left superior intercostal lies next to the aorta and can be mistaken for aortic aneurysm. The rest of the intercostal veins (5th to 12th) empty into the azygos (right side) or into the hemiazygos and accessory hemiazygos on the left side (Fig. 60.13).

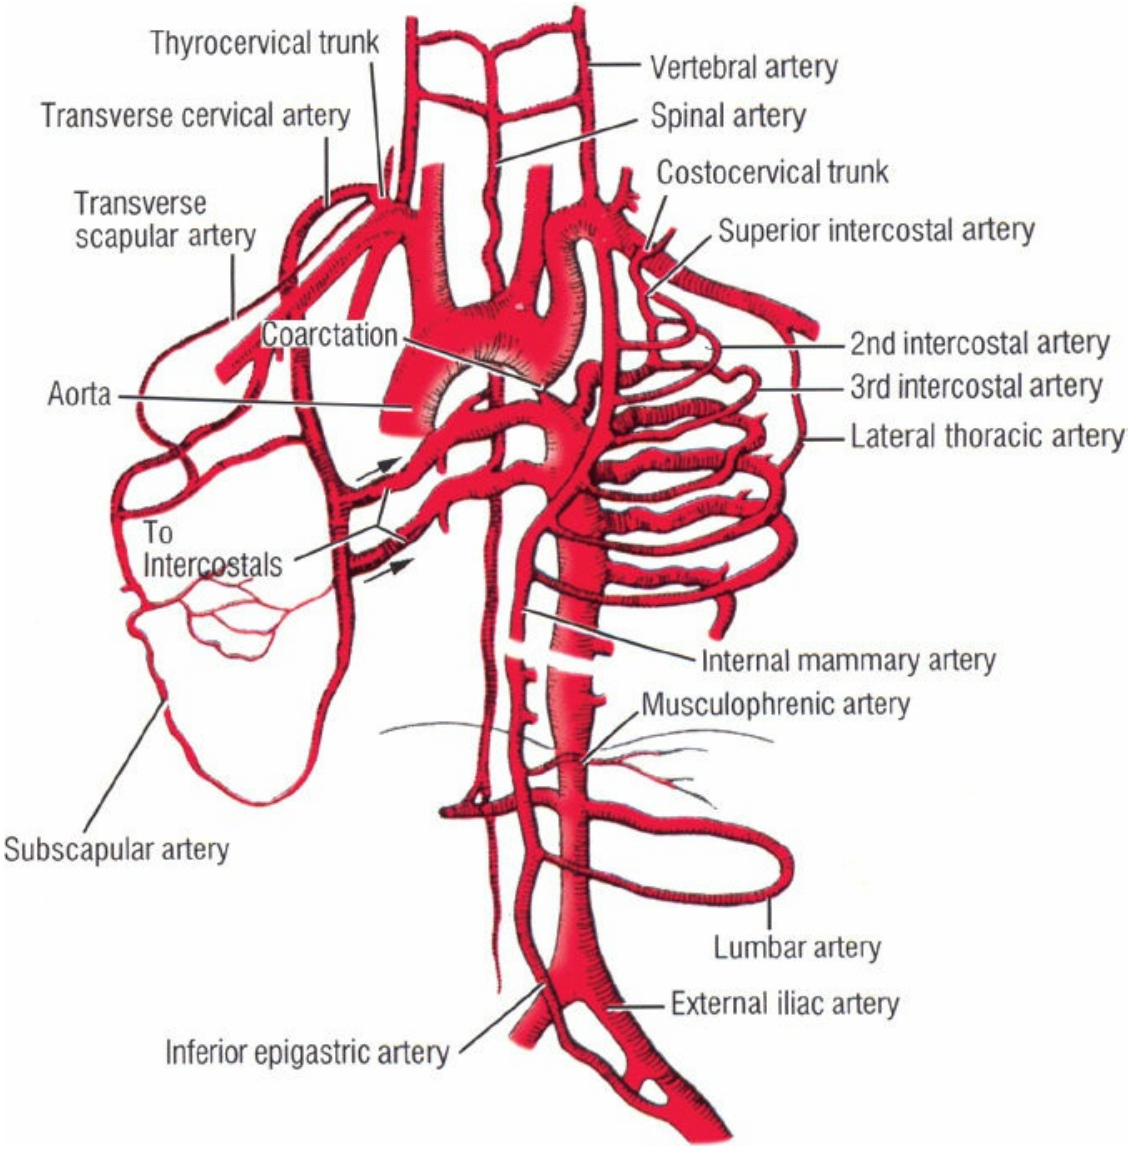

Figure 60.11. Collateral arterial channels in aortic coarctation. (From Edwards EA, Malone PD, Collins JJ Jr. *Operative Anatomy of the Thorax*. Philadelphia, PA: Lea & Febiger, 1972. Copyright Wolters Kluwer.)

The azygos veins are a paravertebral system paralleling the caval system, which not only drains the intercostal veins but also accepts the ascending lumbar veins. It serves most of the venous drainage of the abdominal and thoracic wall and offers an avenue for anastomoses between the superior and inferior vena cava. This system and the vertebral venous system, in effect, bypass the caval system. With increase of intrathoracic or intra-abdominal pressure (expiration, coughing, straining), blood flows in the vertebral system. This offers an avenue for metastases from pelvic, abdominal, and breast tumors. The collateral system is completed by the superficial thoracoepigastric veins, which connect axillary and femoral veins (Fig. 60.13).

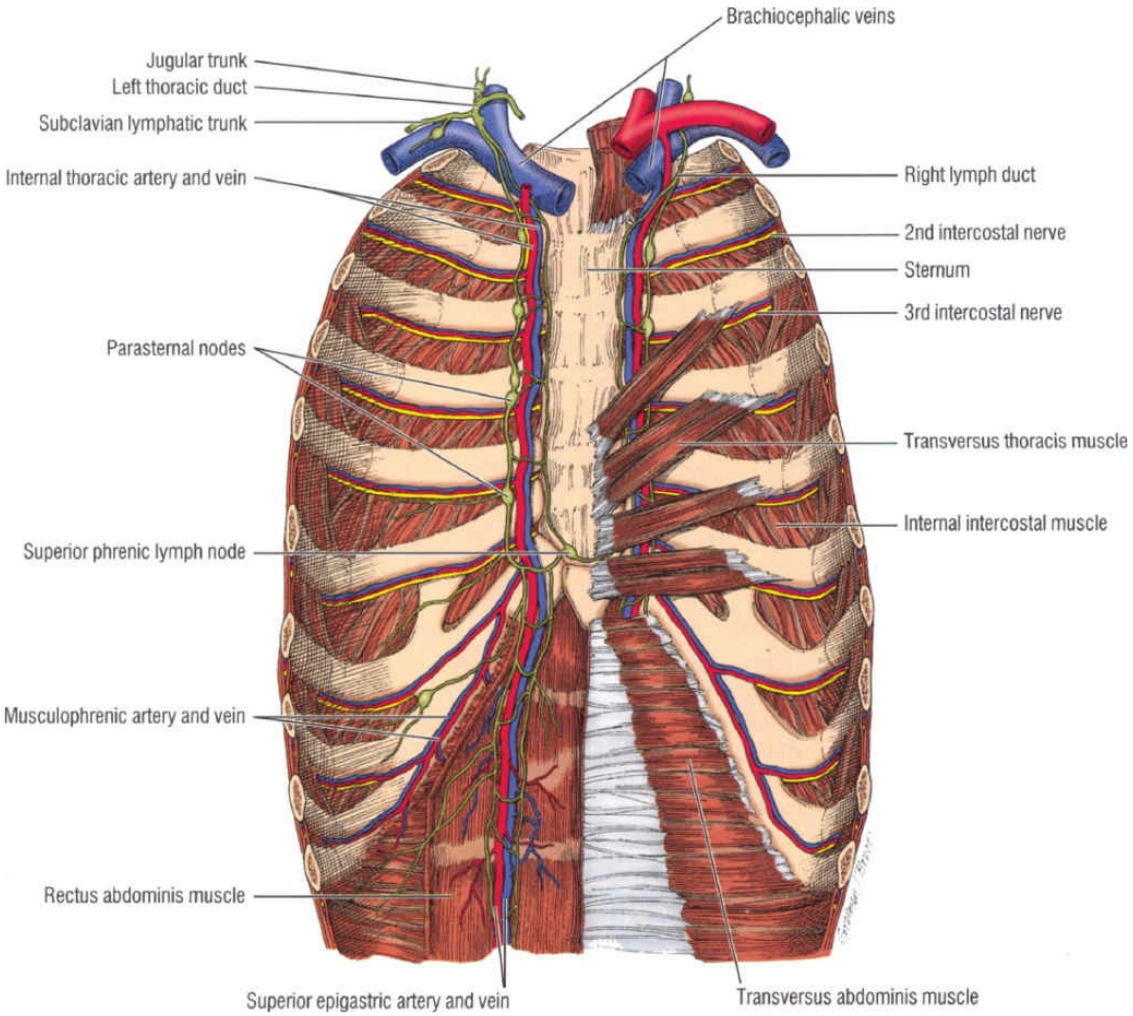

Figure 60.12. Anterior thoracic wall. Relations of vascular and lymphatic structures (dorsal view). Transversus thoracis muscle removed on left side to illustrate vessels more clearly. (From Colborn GL, Weidman TA, Mirilas P, et al. Thoracic wall and pleura. In: Skandalakis JE, Colborn GL, Weidman TA, et al. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic*

Basis of Modern Surgery. Athens GR: Paschalides Medical Publications, 2004, with permission.)

The *internal thoracic veins* accompany the homonymous artery and drain into the counterpart brachiocephalic artery. These veins offer another possibility for collateral circulation; for example, in case of superior vena cava obstruction the flow may follow the internal thoracic and iliac veins and return to the heart by the inferior vena cava and azygos system. The superior epigastric veins communicate with the inferior epigastrics; this is another way of connection between subclavian and femoral veins.

Breast cancer spread may follow a venous route for tumor emboli as follows: Perforating (anterior intercostal) veins empty into the internal thoracic vein and thus in the brachiocephalic vein, which is an avenue for metastases to the lungs. The axillary vein will follow the same pathway. The posterior intercostals will end in the same way via the azygos system. The communication with the vertebral system described above provides an understanding for metastases to the skeleton.

Lymphatics

Superficial

On either side, the anterior quadrant of the trunk above the umbilicus, via a large trunk, drains in the axilla, with the terminus in the pectoral nodes. Efferents of the dorsal upper quadrants terminate in the lateral, central, and subscapular axillary nodes.

Deep

The *internal thoracic (parasternal) nodes* (Fig. 60.12) are along the internal thoracic artery, at the anterior ends of the upper four or five intercostal spaces. They drain the medial part of the breast, the diaphragm, intercostal spaces, and costal pleura, and, partially, the pectoralis major muscle. Their efferents join the bronchomediastinal trunk. Clinically, parasternal nodes give a pathway for metastases from cancer of the breast to disseminate to the lungs, mediastinum, and liver (via connections of superior diaphragmatic nodes).

The *intercostal nodes* (Fig. 60.14)—one or two—are located at the paravertebral portion of each intercostal space. They drain structures along the corresponding intercostal vessels, and the pleura. The efferents of the upper intercostal nodes form the intercostal trunk, which ends in the thoracic duct on the left; on the right, it ascends behind the subclavian

vessels and either empties directly into the subclavian vein or joins the right lymphatic duct. The efferents of the lower nodes form a trunk that descends, passes through the diaphragmatic crura, and enters the cisterna chyli.

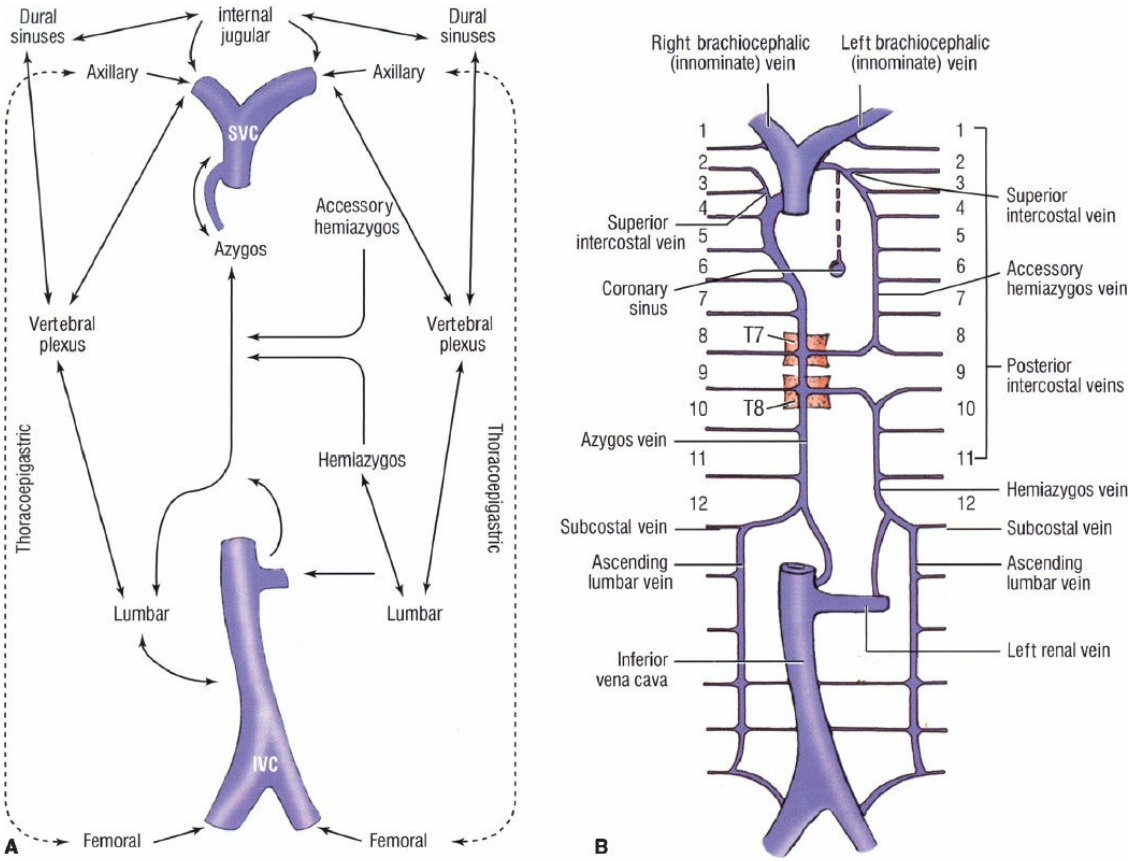

Figure 60.13. A: Main connections of azygos, caval, and vertebral systems of veins. **B:** Main connections of azygos, caval, and vertebral systems of veins. (Modified from O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy*. Philadelphia: WB Saunders, 1986. Copyright Elsevier.)

Nerves

Functionally, the thoracic nerves are motor (to muscles), sensory (from skin and deep tissues), and sympathetic (to vessels, sweat glands, and arrectores pilorum) (Fig. 60.15).

Anatomically, the *first three intercostal nerves* are special in morphology and in the fact that they supply the arm as well as the thorax. The 1st nerve divides into upper and lower parts. The upper part joins the C8 nerve of the brachial plexus. The lower part is a typical intercostal nerve, with the specific feature that its lateral cutaneous branch supplies

the axilla. The 2nd nerve is an otherwise typical intercostal nerve, except for the feature that its lateral cutaneous branch passes into the arm (intercostobrachial nerve). The 3rd nerve also gives a twig to the medial side of the arm from its lateral cutaneous branch.

The *typical intercostal nerve*s are the 4th through the 6th. They supply the thoracic wall and the overlay of extrinsic muscles. Each nerve emerges through an intervertebral foramen and divides into dorsal and ventral rami. The dorsal innervate muscle, bones, and skin of the back. The ventral connect with the sympathetic ganglia via rami communicantes, and innervate serosal membranes (parietal pleura), muscles, and skin of the wall. In fact, the intercostal nerves are the ventral rami, and this applies for all 11 thoracic nerves; the 12th is subcostal. Each intercostal nerve passes below the neck of the numerically corresponding rib and travels together with the intercostal vessels in the costal groove, between the second and third muscle layer. At the angle of the rib it gives a lateral cutaneous branch and a collateral branch that follows the collateral artery (see above for surgical importance). After it crosses the internal thoracic vessels it gives off an anterior cutaneous branch.

The intercostal nerves may be “anesthetized” by nerve block, that is, infiltration with anesthetics of the proper intercostal space, behind the posterior axillary line. This technique is useful in patients with thoracotomy, thoracostomy, or chest trauma who suffer severe pain with respiration and coughing.

The term *thoracoabdominal nerves* is reserved for the nerves 7th through 11th. These nerves surpass the anterior ends of the intercostal spaces behind the costal cartilages. They continue downward again in the same surgical layer between the second and third muscles (internal oblique and transversus abdominis) to reach the posterior wall of the sheath of the rectus abdominis, where they give anterior cutaneous branches. Their lateral cutaneous branches pierce the external oblique and give anterior and posterior branches. The thoracoabdominal nerves innervate the muscles of the abdominal wall, skin, and parietal peritoneum.

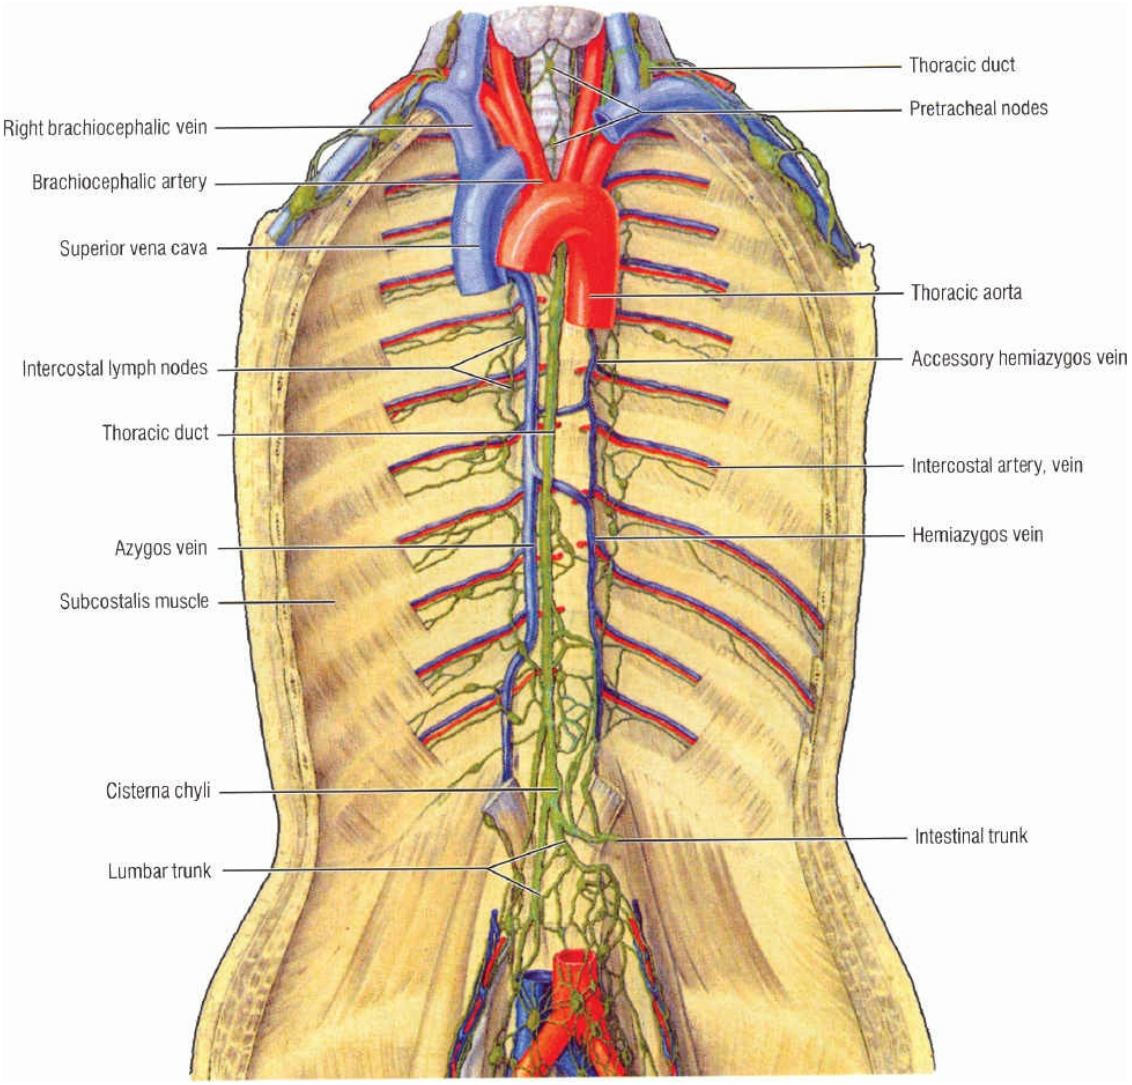

Figure 60.14. Lymphatic relations of the posterior thoracic region. Note the subcostalis muscles. (From Colborn GL, Weidman TA, Mirilas P, et al. Thoracic wall and pleura. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic Basis of Modern Surgery*. Athens GR: Paschalides Medical Publications, 2004, with permission. Modified from Frick H, Kummer B, Putz R. *Wolf-Heidegger's Atlas of Human Anatomy*. 4th ed. New York: Karger, 1990.)

The distribution of the thoracic nerves (intercostal and thoracoabdominal) is segmental. Because there is much overlapping, one has to impair three nerves in order to see an effect of paralysis and anesthesia in the middle one of them. Although extensive thoracic and abdominal incisions are not contraindicated, caution must be exercised by the operating surgeon.

Some hallmarks of the segmental surface distribution are very useful in

practice: The thoracic wall is supplied by T2 to T6. The umbilicus is supplied by T10, and the supraumbilical part of the anterior wall by T7 to T9. The pubic tubercle corresponds approximately to T12 and the infraumbilical to T10 to T11.

Pain from intrathoracic and intra-abdominal splanchna (e.g., esophagus, heart, liver–bile system, etc.) projects on the thoracic or abdominal wall. This is what we like to call “cheating”: pain stimulus transported by the splanchnic thoracic nerves (major, lesser, least) reaches the corresponding sympathetic ganglia. Communication with the respective intercostal or thoracoabdominal nerves results in projection of the pain on the thoracic or abdominal wall.

Abdominal viscera have a characteristic surface distribution of pain. The foregut (esophagus, stomach, duodenum until the entrance of the bile duct) projects pain into the supraumbilical area. The midgut (the rest of the intestine and up to two-thirds of the transverse colon) projects into the umbilical area. The hindgut projects into the supraumbilical area.

MEDIASTINUM

Embryogenesis

The mediastinum arises from the mesentery of the esophagus. This statement may sound bizarre to the surgeon, who is brought up with the knowledge that the esophagus is deprived of serosal layer; that is, it has no mesentery. This misconception has to be changed.

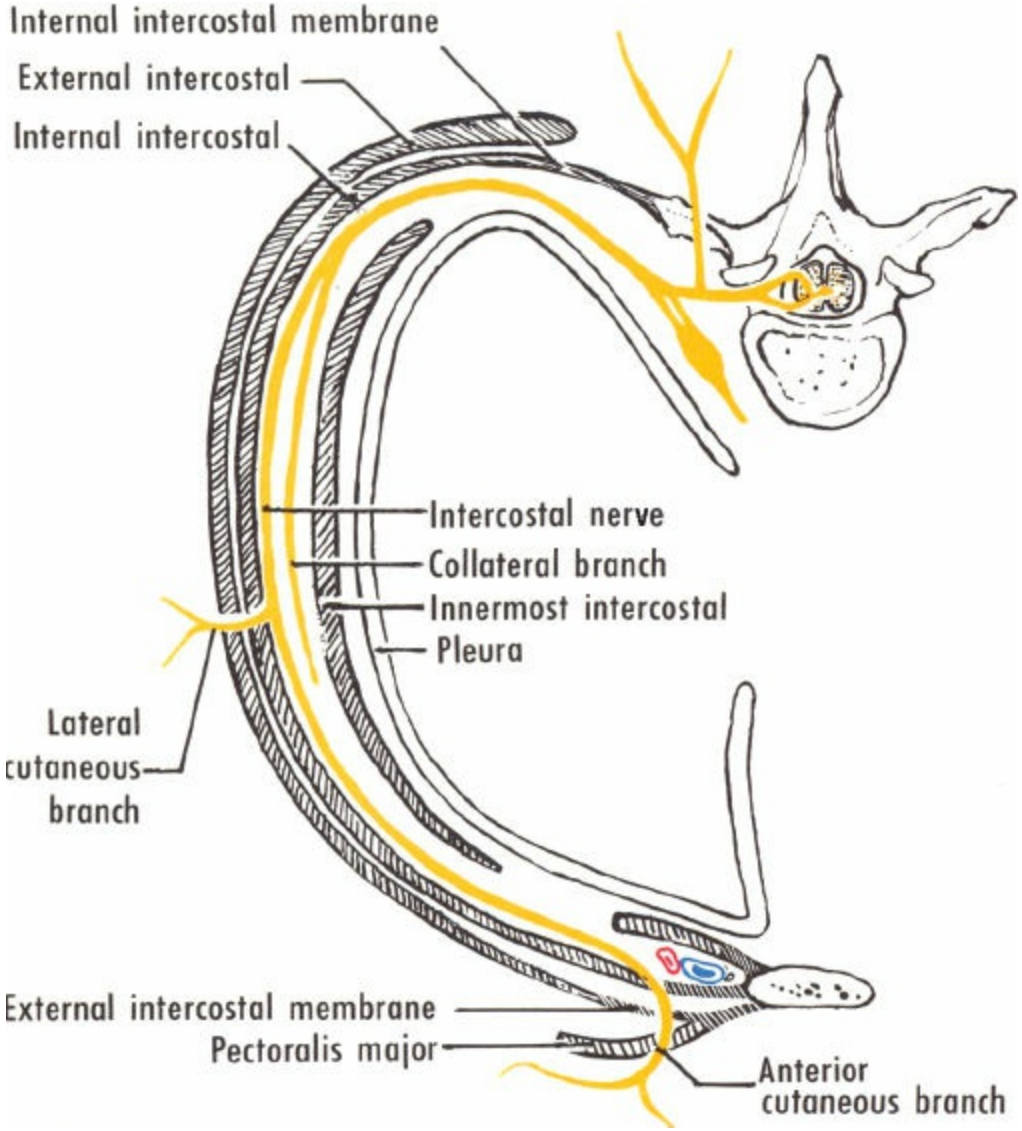

Figure 60.15. A typical intercostal nerve. (From O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy*. Philadelphia, PA: WB Saunders, 1986, with permission.)

In general, the mesentery of the intestine is defined as a double serosal layer that surrounds the viscus and carries the neurovascular bundle to and from it (arteries go in, veins and lymphatics go out, nerves go in and out); any functional tube (e.g., a duct) will also be packed in the mesentery, which also contains a variable amount of fat (Fig. 60.16).

The esophagus develops as part of the embryonic foregut, and initially has a mesentery. The trachea and the lung buds also develop from the foregut, as a diverticulum dividing in front and laterally to the esophagus (Fig. 60.17). The trachea and the lung buds push away the mesentery covering the ventral side of the esophagus. The proliferating lung buds project into the pericardial cavity, covered by serosa (splanchnic pleura)

given by the former mesentery of the esophagus (Fig. 60.18A).

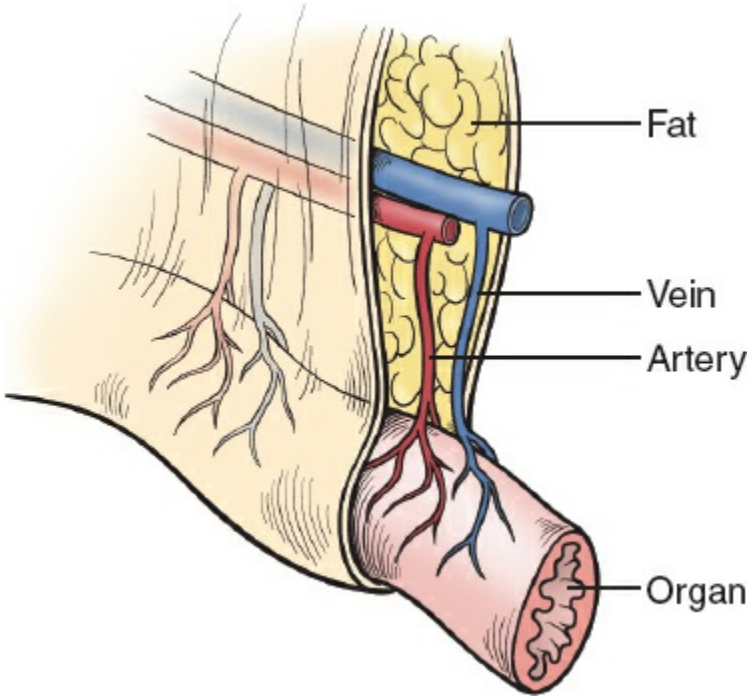

Figure 60.16. Diagrammatic representation of a mesentery.

Two lateral folds, the pleuropericardial folds, appear in the pericardial cavity, each serving as a mesentery for the cardinal vein; the phrenic nerve is also contained in the folds. The two folds unite and fuse with the root of the lungs. After transformations, the two cardinal veins form the superior vena cava. The thoracic cavity separates from the pericardial cavity, and divides into two pleural cavities. The pleuroperitoneal membranes form the fibrous pericardium, and the phrenic nerve finds its position on the pericardium. The developing lungs occupy the pleural cavities (Fig. 60.18B,C).

The communication of the pleural cavities with the abdominal cavity is interrupted by the development of the diaphragm from the septum transversum, the pleuroperitoneal folds, and the muscular components of the wall (Fig. 60.19). As a result of all the above developmental changes, a space is defined above the diaphragm, delineated anteriorly by the pericardium covered by pleura and posteriorly by the remaining mesentery of the esophagus (dorsal mediastinal pleura). The lateral walls of this space are covered by pleura with an opening for the root of the lung. This space is the mediastinum of the mature organism (Fig. 60.20). The mediastinal pleura reflects over the roots of the lungs and continues as visceral pleura. Posterior to the esophagus and aorta, the mediastinal pleura opens up

laterally as parietal pleura.

Compartments of the Mediastinum

To be consistent with most anatomy books and surgical teaching, it is best to divide the mediastinum into four compartments: superior, anterior, middle, and posterior. The latter three, without being explicitly named so, belong to the inferior mediastinum.

Borders

The border between the superior and inferior mediastinum is a plane defined by the angle of Louis (vide supra) anteriorly and the lower end of the fourth thoracic vertebra posteriorly (Fig. 60.21).
The anterior mediastinum lies between the sternum anteriorly and the pericardium posteriorly.
The middle mediastinum is delineated by the pericardium; adjacent structures of the roots of the lungs belong to this compartment.
The posterior mediastinum is located posteriorly to the pericardium.

The superior mediastinum can divided into anterior, middle, and posterior. The great vessels—whose roots are covered by pericardium in the inferior mediastinum—are used for this division, as occupying the middle division.

Contents

As already understood from the embryogenesis, the mediastinum as a whole contains all of thoracic viscera except for the lungs. All organs contained in this mesentery, and as happens with all mesenteries, are packed into loose areolar tissue, which suspends and connects them. A thickening of this tissue is the sternopericardial ligament.

Anterior Mediastinum

Anson and McVay write that the surgical importance of this space is that it is entered during cardiac procedures and during biopsy of the internal thoracic lymph nodes (through the 3rd or 4th space). The anterior mediastinum is the home of lymphomas, Morgagni hernia, or hematoma after sternal fracture. Ectopic goiter or parathyroids as well as thymoma can also be encountered in this compartment.

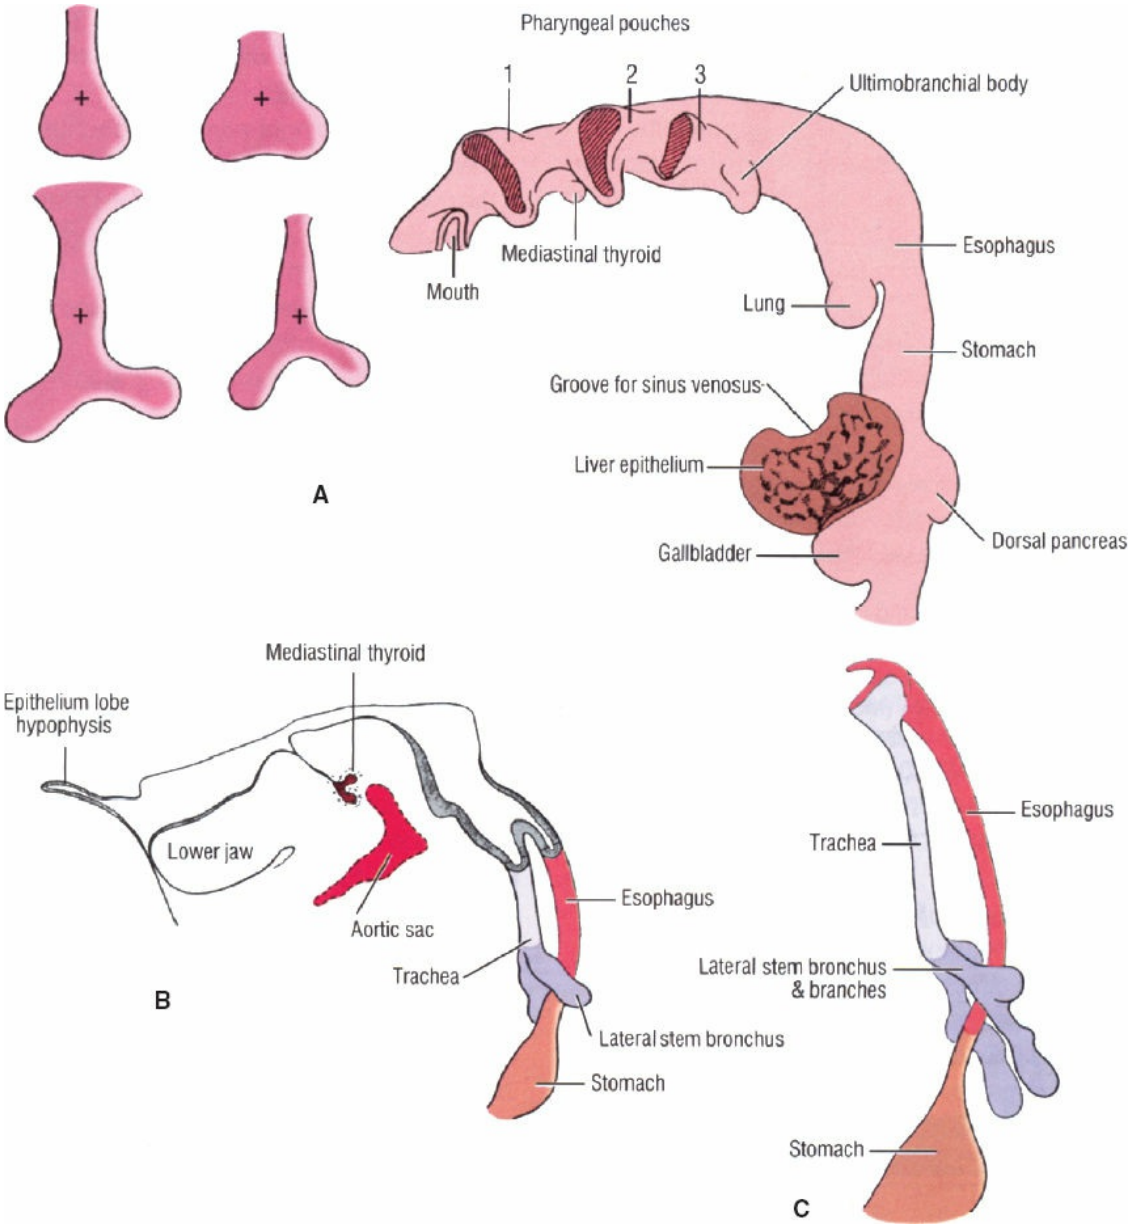

Figure 60.17. Development of trachea and bronchi. **A:** Four anterior and lateral views of lung buds at the end of the 5th week. **B:** Lateral view at the middle of the 6th week. **C:** Lateral view near the end of the 6th week. Developmental horizons in human embryos: description of age groups XV, XVI, XVII, and XVIII. *Contrib Embryol Carnegie Inst Wash* 1948;32:133–204.)

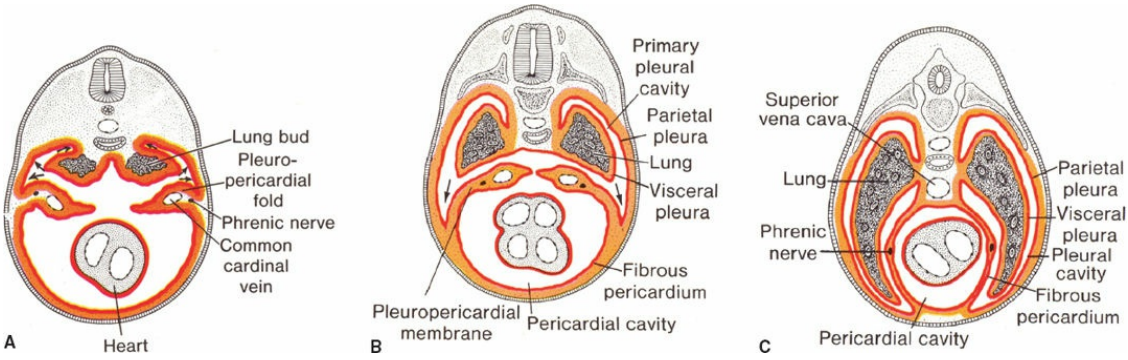

Figure 60.18. **A:** Growth of the lung buds into the pericardioperitoneal canals. Note the pleuropericardial folds. Arrows indicate the direction of expansion of the lung buds. **B:** Transformation of the pericardioperitoneal canals into the pleural cavities and the formation of the pleuropericardial membranes. Note the pleuropericardial folds with the common cardinal vein and phrenic nerve. The mesenchyme of the body wall is split into the pleuropericardial membrane and the definitive body wall. Arrows indicate direction of expansion of the primitive pleural cavity. **C:** Drawing through the thorax after fusion of the pleuropericardial folds with each other and with the root of the lungs. Note the position of the phrenic nerve, which is now in the fibrous pericardium. The right common cardinal vein has developed into the superior vena cava. (From Sadler TW. *Langman's Medical Embryology*. 5th ed. Baltimore, MD: Williams & Wilkins, 1985, with permission.)

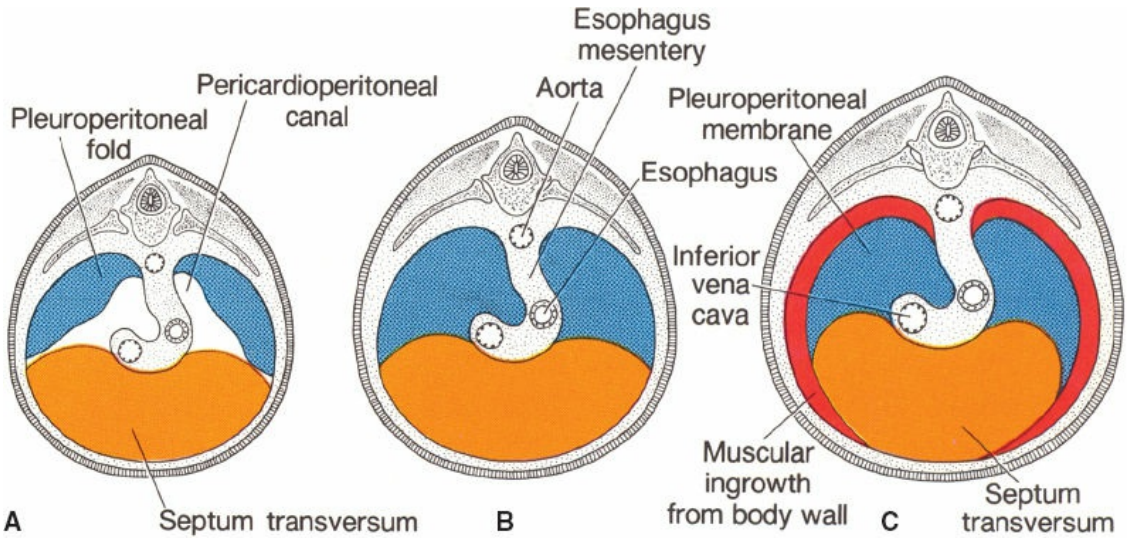

Figure 60.19. Development of the diaphragm. **A:** Pleuroperitoneal folds appear at the beginning of the 5th week. **B:** Pleuroperitoneal folds have fused with the septum transversum and the mesentery of the esophagus in the 7th

week, thus separating the thoracic cavity from the abdominal cavity. **C:** Transverse section at the 4th month of development. An additional rim derived from the body wall forms the most peripheral part of the diaphragm. (From Sadler TW. *Langman's Medical Embryology*. 10th ed. Baltimore, MD: Lippincott Williams & Wilkins, 2006, with permission.)

The chief content is the thymus (Fig. 60.22) (or its remnants), extending from the anterior superior mediastinum to the mediastinum proper. Originating from the 3rd pouch of the embryonic pharyngeal apparatus, the thymus descends together with the inferior parathyroids. Ectopic thymic tissue can be found along the path of descent, from the inferior side of the thyroid to the superior or inferior anterior mediastinum.

The superior part of the thymus lies anterior to the left brachiocephalic vein. A large thymus will cover the superior vena cava, and a large left lobe can reach the pulmonary artery. The inferior part of the thymus lies in front of the pericardium, in close relation with the costomediastinal recess, so that the latter has to be retracted together with the thoracic wall to be exposed during operation.

The vascular supply of the thymus is useful for the surgeon to know. There are small branches from the internal thoracic arteries or their pericardiophrenic branches. Veins from the two lobes unite to form a single vein, which travels on the posterior surface of the thymus and empties into the left brachiocephalic vein. Small venous twigs join the internal thoracic veins.

In the space between the anterior thoracic wall and the pleura run the internal thoracic vessels and accompanying lymphatics and lymph nodes. Here, for surgical reasons they are considered as belonging to the anterior mediastinum, although strictly anatomically they are in front of the pleura.

Middle Mediastinum

The surgical significance of the middle mediastinum centers on congenital anomalies or tumors that can be encountered in this space: congenital vascular anomalies, aneurysms, enteric or bronchogenic cysts, lymphomas, and so on.

Superior

After removing the thymus, one can appreciate the relations of the great vessels (Fig. 60.23). The *right brachiocephalic vein* courses in front and to

the right of the right subclavian artery. The phrenic nerve, after descending on the anterior scalene, passes behind the right brachiocephalic vein on the mediastinal pleura. The nerve then dives medially to find its position on the pericardium. The internal thoracic vessels lie laterally to it and then course anteriorly.

The *left brachiocephalic vein* starts from the left of the left carotid, much above the aortic arch, descends in front of the left subclavian artery and the ascending aortic arch, accepts thyroid veins, joins the right brachiocephalic vein, and forms the superior vena cava. The left phrenic nerve descends behind the left brachiocephalic vein, and then crosses the aortic arch and courses on the pericardium.

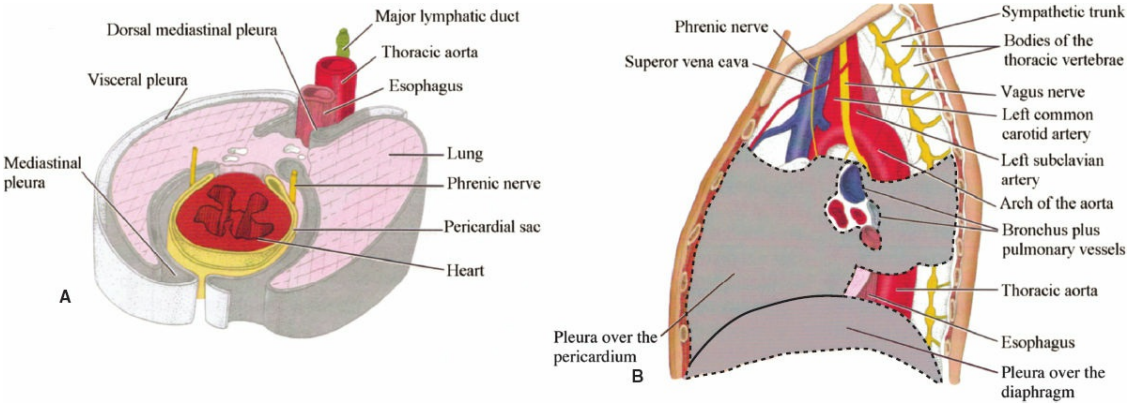

Figure 60.20. **A:** Drawing of a transverse section of the mediastinum of the mature organism. **B:** Schema of the lateral left view mediastinum; lungs are taken away. The dash line shows the border of the cut pleura; a small window is reflected to show the esophagus.

After removing the veins, one can realize relations of vagus nerves, branches of the aorta, and trachea (Fig. 60.24). The *aortic arch* lies in front of the trachea and the left bronchus. As a result, an aneurysm may produce respiratory symptoms. The esophagus (behind the trachea) and the recurrent nerve (in the groove between the trachea and the esophagus) may also be pressed, resulting in difficulty in swallowing and hoarseness; pressure of the sympathetic trunk will produce Horner's syndrome.

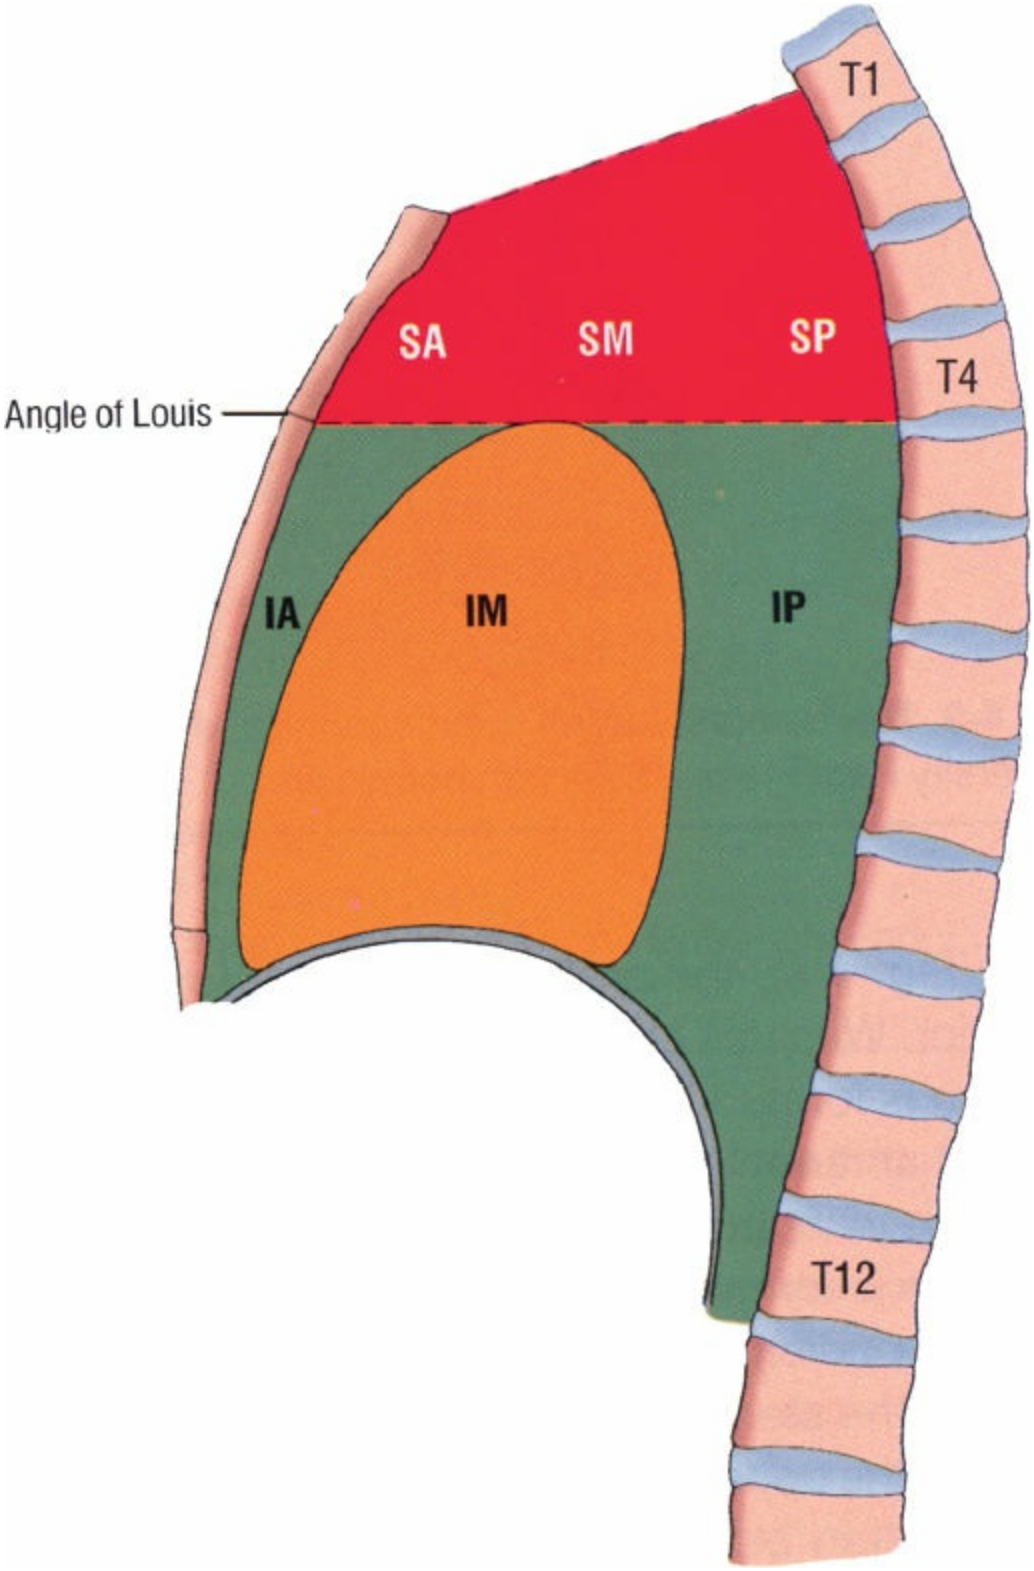

Figure 60.21. Anatomic divisions of the mediastinum. *S,* superior; *I,* inferior; *A,* anterior; *M,* middle; *P,* posterior. (From Colborn GL, Skandalakis JE, Mirilas P, et al. In: Skandalakis JE, Colborn GL, Weidman TA, et al. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic Basis of Modern Surgery*. Athens GR: Paschalides Medical Publications, 2004, with permission.)

The *brachiocephalic artery* is given off by the aortic arch on the right, subdividing into *common carotid* and *subclavian arteries.* On the left these arteries arise from the aortic arch.

The *pulmonary artery* is within the concavity of the aortic arch, but not readily seen because it is enclosed in the pericardium.

The *right vagus nerve,* after giving off the recurrent laryngeal nerve that loops around the right subclavian artery, continues behind the superior vena cava and the ascending aorta to reach the esophagus. The *left vagus* nerve descends between the left common carotid and the left subclavian artery, passes in front of the aortic arch, gives off the recurrent laryngeal nerve, and continues behind the hilum of the lung to reach the esophagus. The course of the phrenic nerves is shown in Figures 60.25 and 60.26.

Inferior

The inferior middle mediastinum contains the structures contained in the pericardium: heart and roots of the great vessels. The phrenic verves and the pericardiophrenic arteries, located on the pericardium and under cover of the mediastinal pleura, are considered contents of this compartment.

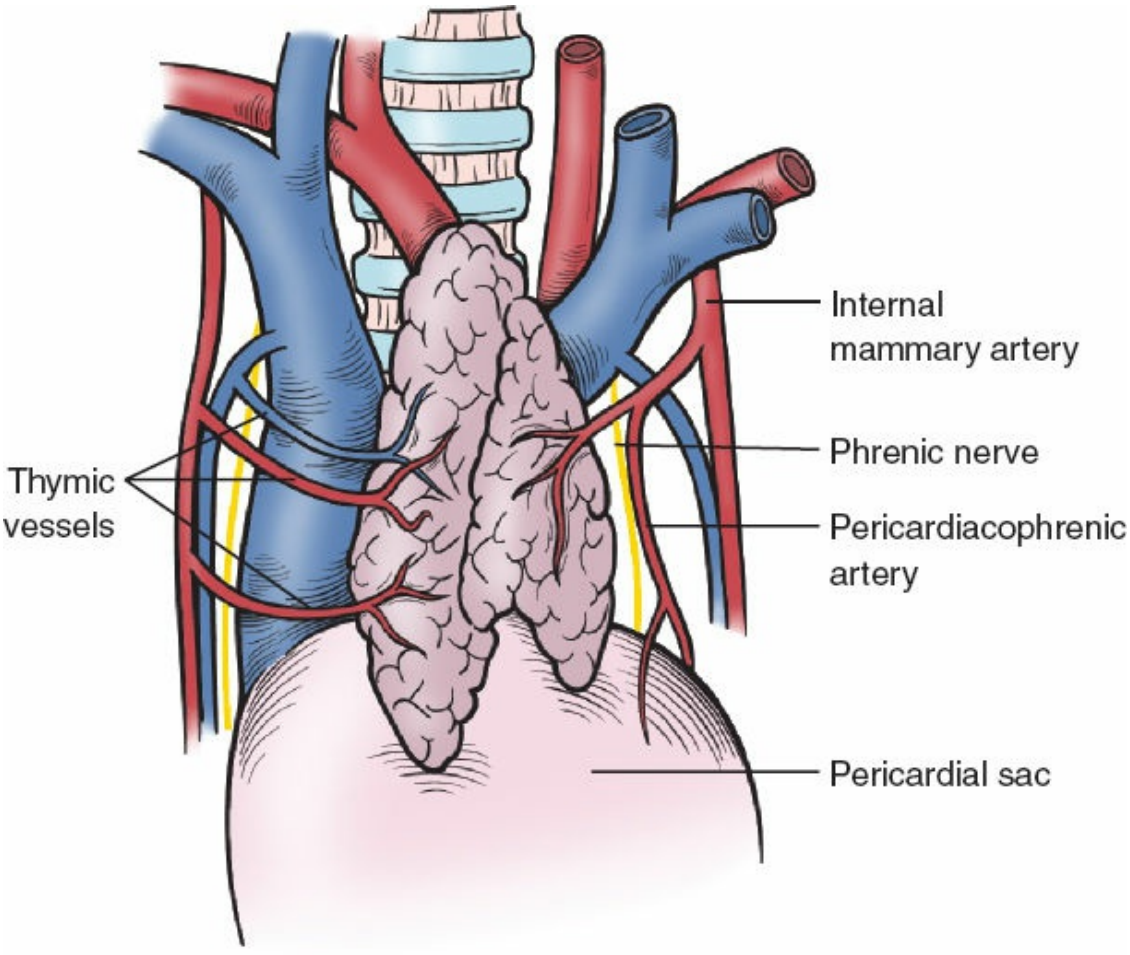

Figure 60.22. The thymus. The lungs and the pleura overlapping the thymus anteriorly are not shown. The chief vein of the thymus is not visible, as it lies behind that organ.

Posterior Mediastinum

The surgical significance of this compartment arises from the pathologic entities located in it: congenital anomalies like esophageal atresia, duplications, bronchogenic or enteric cysts; pathologies of the esophagus and aorta; lymphomas; mesenchymal origin tumors. Characteristic is the location of neurogenic tumors in this compartment.

This compartment of the mediastinum is the most complex and contains viscera traveling from the neck (trachea, esophagus) and continuing to the abdomen (esophagus, descending aorta), nerves (vagus, phrenic, sympathetic, and splanchnic), lymphatics, lymph nodes, etc. In this description, we consider the division into superior and inferior of didactic use only and will not follow it, as the surgeon will treat the compartment as a whole. The course of each entity and its relations can be followed in Figures 60.25 and 60.26. In the right side mostly veins and the esophagus can be seen (venous side) while on the left the aorta covers most other viscera (arterial side).

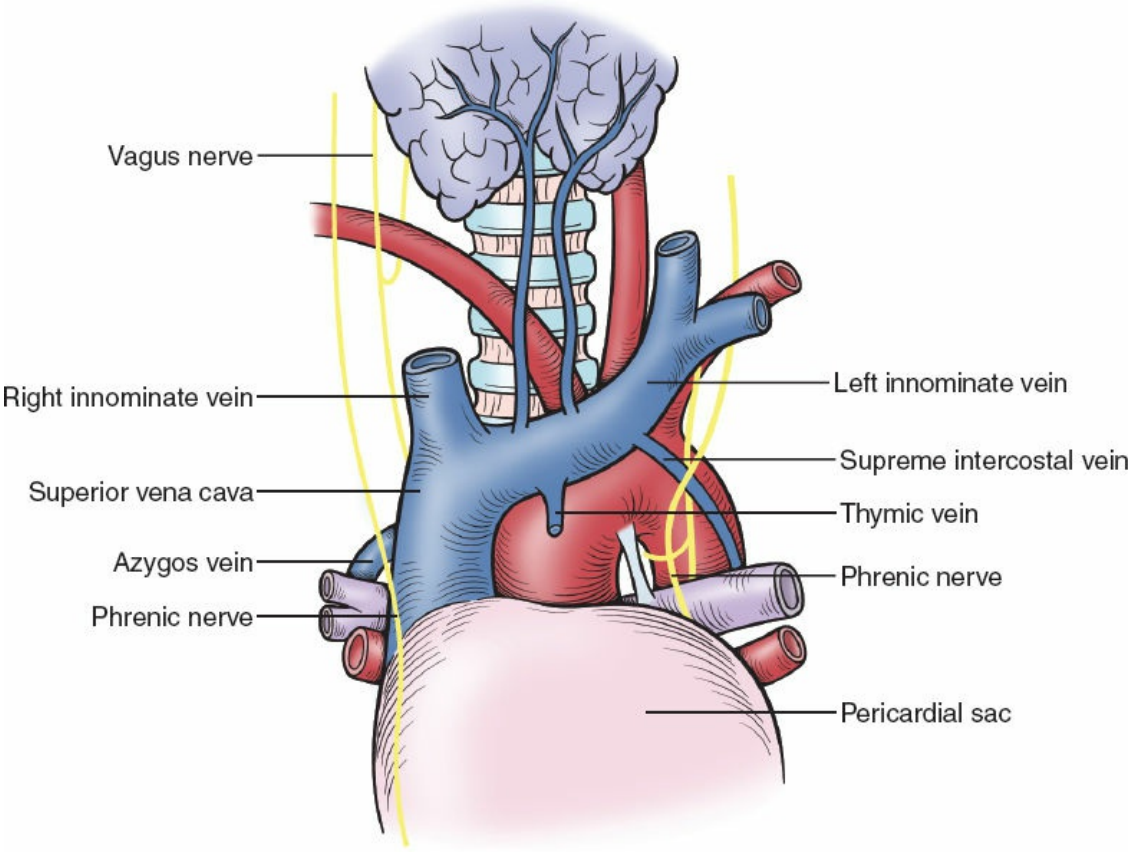

Figure 60.23. The superior mediastinum after removal of the thymus. The lungs and the pleura overlapping the thymus anteriorly are not shown.

The *trachea* is behind the ascending aorta and a bit to the left of it. The aortic arch lies anteriorly and to the left side of the trachea. The trachea is best seen in Figure 60.25. The right vagus nerve is on its right side, and they both descend under the arch of the azygos vein. Behind the trachea is found the *esophagus.* The trachea diverges slightly to the right at its lower end. Thus, the esophagus diverges to the left and passes behind the left bronchus. Then the esophagus turns to the right and descends toward the diaphragm, where it turns again to the left to reach the esophageal hiatus. The esophagus can be followed on the right side of the mediastinum (Fig. 60.25). Therefore, the intrathoracic esophagus is best proceeded from the right side. On the left, most of the esophagus is covered by the aortic arch and the descending aorta (Fig. 60.26). Only a superior part of the esophagus can be seen behind the left subclavian vein. Thus a cervical esophagostomy is performed on the left side of the neck. The *thoracic duct* descends just behind the upper esophagus and can been from the left. The lower intrathoracic esophagus is again seen at the lower end, as a triangular part between the pericardium and the aorta. The esophagus is in contact with the pericardium; this relation has led to development of the transesophageal ultrasound (combined with Doppler).

The *vagus nerves* in the superior mediastinum are well forward, and are best classified as contents of the middle mediastinum (see above). Then they enter the posterior mediastinum, travel on the trachea on the right side (Fig. 60.25), or pass in front of the aortic arch on the left side (Fig. 60.26). Above the hilum of the lung, after giving branches to the pulmonary plexuses, they deviate posteriorly, meet the esophagus, and converge to form a plexus on its wall. On the lower esophagus, the “left trunk” (the term is not strictly appropriate; the trunk is split into the plexus) becomes anterior, and the right, posterior.

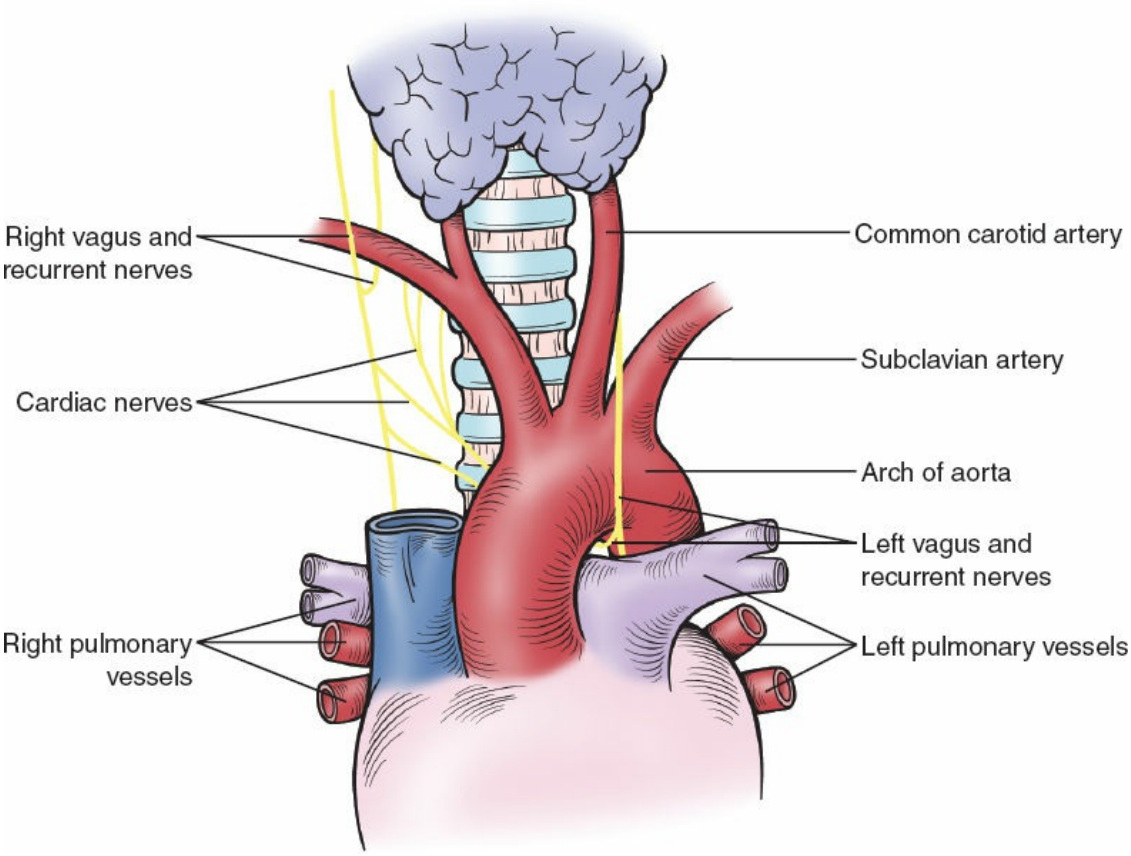

Figure 60.24. The superior mediastinum after removal of the great veins. The phrenic nerve and the pericardial sac have been removed. Portions of pulmonary vessels below the superior mediastinum are shown.

On the right side, *the azygos vein* accepts the *intercostal veins* and the *superior intercostal vein*, and arches over the hilum of the lung to empty into the superior vena cava. Lower on, the azygos vein is found posterior to the esophagus, always keeping a prevertebral location (Fig. 60.25). Ligation of the azygos can be done with impunity, and offers access to the esophagus (e.g., in esophageal atresia). On the left side, the superior intercostal vein crosses over the subclavian artery and the vagus nerve, and then empties into the left *brachiocephalic vein.* The *accessory hemiazygos vein* and the *hemiazygos vein* are located posterior to the aorta and accept intercostal veins (Fig. 60.26).

Figure 60.25. Right side of the mediastinum in an anatomical dissection of a human specimen. The pleura has been removed to display the underlying structures. 1, right subclavian artery; 2, sympathetic trunk and ganglion; 3, right phrenic nerve; 4, superior vena cava; 5, right recurrent laryngeal nerve; 6, right vagus nerve; 7, trachea; 8, esophagus; 9, azygos vein; 10, superior intercostal vein; 11, posterior intercostal vessels; 12, branches of the sympathetic trunk to greater splanchnic nerve; 13, pericardium. (Modified from: Abrahams PH, Hutchings RT, Marks SC. *McMinn's Color Atlas of Human Anatomy*. 4th ed. London: Mosby, 1998, p. 165. Copyright Elsevier.)

The *sympathetic trunks* descend from the neck in front of the posterior intercostal vessels, except for the superior intercostal vein, located anteriorly to the trunk. As described in the thoracic wall part of this chapter, the trunks communicate with the posterior intercostals nerves. Branches from the sympathetic trunks to the greater splanchnic nerve course anteriorly and forward in the paravertebral space (Fig. 60.25).

Mediastinal Lymph Nodes

The mediastinal lymph nodes are of tremendous surgical significance, as site of location of neoplasia or infectious disease. Strictly anatomically, the parasternal and the posterior intercostal nodes lie outside the pleura and belong to the thoracic wall, not the mediastinum. Surgically, however, it is important to have topographicoanatomic knowledge of these nodes:

The *parasternal nodes*: along the interval thoracic vessels. The *brachiocephalic or anterior mediastinal nodes* are found on the brachiocephalic veins. They drain the thymus, walls of the great vessels, the pericardium, and the heart.

The *posterior mediastinal nodes* are along the lower esophagus. They drain the esophagus and pericardium. They are joined by lymphatics to the phrenic nodes and the posterior intercostal nodes.

The *paratracheal nodes* are along each side of the trachea. Their efferents form the paratracheal trunks and join the efferents of the posterior mediastinal nodes to form the *bronchomediastinal* trunks. The right trunk empties into the right thoracic duct and the left into the thoracic duct.

The *nodes of the roots of the lungs* comprise, the pulmonary nodes (in the hilum) and bronchopulmonary nodes (in the root of the lung). They empty into the tracheobronchial nodes (above and below the bifurcation of the trachea). Their efferent trunks join the paratracheal trunks.

The *posterior intercostal nodes* are connected with lymphatics to the posterior mediastinal and phrenic nodes.

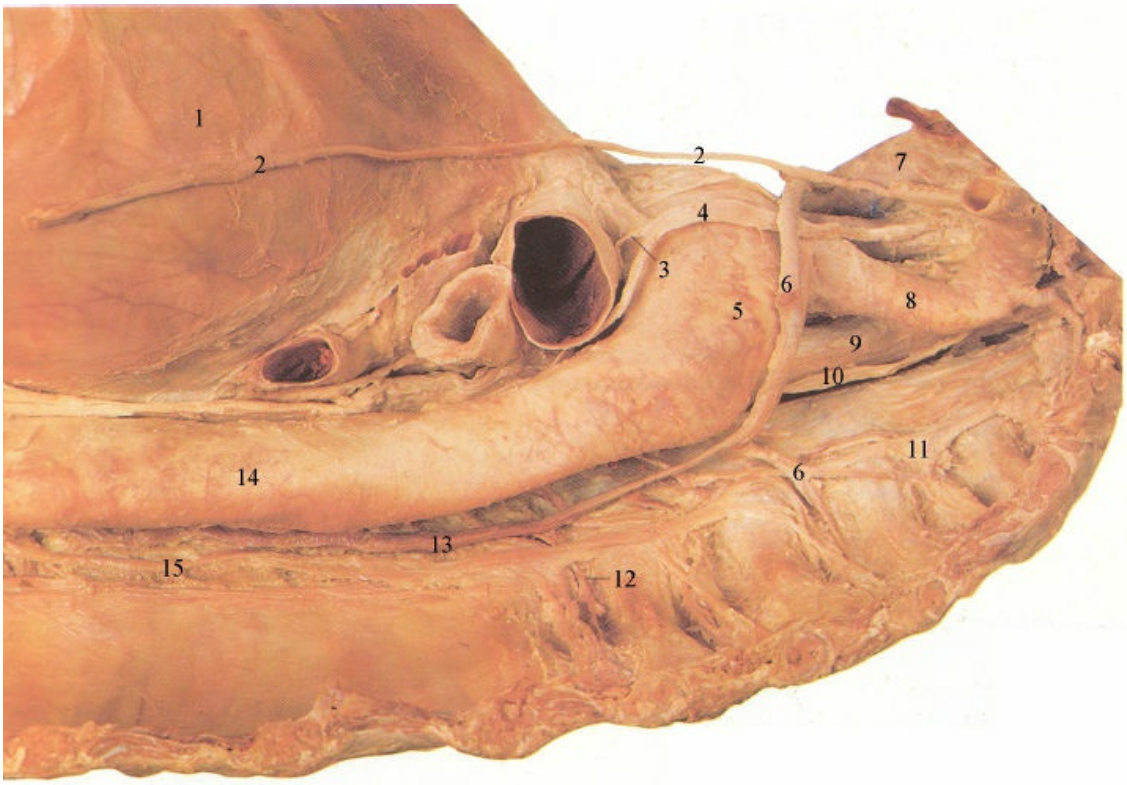

Figure 60.26. Mediastinum left side, anatomical dissection. Similar specimen to that of Figure 60.25. Most of the pleura has been removed to show the underlying structures. 1, pericardium overlying left ventricle; 2, left phrenic nerve; 3, left recurrent laryngeal nerve; 4, left vagus nerve; 5, arch of the aorta; 6, left superior intercostal vein; 7, left brachiocephalic vein; 8, left subclavian artery; 9, esophagus; 10, thoracic duct; 11, sympathetic trunk and ganglion; 12, posterior intercostal vein; 13, accessory hemiazygos vein; 14, thoracic aorta; 15, hemiazygos vein. (Modified from: Abrahams PH, Hutchings RT, Marks SC. *McMinn's Color Atlas of Human Anatomy*. 4th ed. London: Mosby, 1998, p. 167. Copyright Elsevier.)

We can describe the following lymph flow avenues in the mediastinum: (a) Along the internal thoracic vessels (parasternal nodes) toward the brachiocephalic nodes. (b) Along the pericardiomyophrenic artery (phrenic nodes) toward the bronchomediastinal trunks. (c) Along the thoracic duct (posterior mediastinal nodes) toward the bronchomediastinal trunks. (d) In the superior mediastinum, the bronchomediastinal (and the paratracheal) trunks course toward the right and left thoracic ducts. (e) In the inferior middle and posterior mediastinum the flow from intercostal, phrenic, and posterior mediastinal nodes may be downward to the celiac nodes of the abdomen. This is also valid for route (a) [vide supra], with lymph from

abdominal viscera reaching the parasternal nodes. Thus, there is a communication of lymphatics between the abdomen and the mediastinum, of great importance to the surgeon.

EDITOR'S COMMENT

This is another excellent product from the Anatomy School at Emory with the tradition that the Skandalakis family has established, which has been so valuable to surgery in general and to American surgery in particular. Indeed, we have now a lot to consider about the chest, which we have not had to consider previously. This has not happened all at once, but it is an aspect of the development of thoracic surgery, of which the most recent chapter on pulmonary resection involves also the mediastinum. As time has gone on, the ability to treat patients with a number of chemotherapeutic agents, which have heretofore not been known to be effective against carcinoma of the lung, a very

complex—appropriately so—aspect of node numbers and where they are, and what kind of node dissections and node samplings are appropriate for whatever kind of operation is being done segmental, non-anatomical resections, lobectomy, or pneumorectomy. Not much has changed in the past five years—there are some additional dissections. Not as many dissections through the axilla are carried out as in the past, in which the intercostal brachial nerve, which is so nicely described, must be spared because of the numbness of portions of the upper arm and some of the other unfortunate side effects.

It is wise to remember where the arteries and nerves run. The intercostal artery accompanies the vein and the nerve in the costal groove beneath the rib. Thus, when one is doing a thoracentesis, one must insert the needle above the rib and stay close to the rib in order not to injure the intercostal artery and thereby get uncontrolled bleeding. I get very concerned about this, because of the fact that contemporary surgical residents don't have a great deal of experience in doing thoracentesis. They prefer to send these off to the interventional radiologists, and one shudders when one thinks of asking a contemporary young surgical resident like an intern to do a thoracentesis. Nonetheless, it does appear as if in certain programs things are beginning to turn around, and the residents are being asked to do procedures which we could do at a moment's notice. Can the contemporary resident do a thoracentesis without hitting the intercostal artery? I hope so, but I'm not exactly sure. Likewise, can one put in a chest tube? And, if one puts in a chest tube, with what facility can the resident, and specifically the intern, put in the chest tube without again hitting some of the vessels?

In the discussion of the mediastinum, the embryogenesis of the esophagus and the fact that the mediastinum arises from the mesentery of the esophagus are something we are usually unaware of. As the author says, this statement may sound bizarre to the surgeon who is brought up with the knowledge that the esophagus is deprived of the serosal layer, that is, it has no mesentery. This misconception has to be changed. One of the things I learned in this particular edition is that many of the spaces that we take for granted may have occurred embryologically from the spaces developing out of the mesentery that no longer exists. Thus, the statement that the mediastinum develops from the mesentery of the esophagus is something that not only is true but is something that most surgeons are unaware of. True, the esophagus has no mesentery at the present time, or at least it has no serosa, or, if it does have serosa, we are unaware of it; but the fact is that the mediastinum has developed from the mesentery of the esophagus.

For various endocrine surgeons, who have the occasion to go into the mediastinum looking for the wayward parathyroid or occasionally a thyroid remnant that ends up in the mediastinum, the cephalad extension of the anterior and visceral compartments is important. Three quarters of thyroidal goiters that extend to the mediastinum have their extensions limited to the anterior compartment, which is easy to get to, comparatively speaking; but the

remaining one quarter of the thyroidal-goiter extensions is in the visceral compartments. This can actually be forewarned, with a sestamibi scan or other imaging technology. The wayward parathyroid gland, which may end up anywhere between the hyoid bone and the superior level of the heart, has great variability, especially in the visceral compartment, as it develops from the mesentery of the esophagus, which is no longer present. This may require a sternal split or at least an episternal split looking at the horns of the thymus, where one usually finds a parathyroid gland when one is doing a thymectomy for myasthenia gravis. The neck and the anterior mediastinum, thus, must be regarded as components which "work together" and must be viewed as such. As the transhiatal esophagectomy has become more popular, we view esophageal neoplasms as a visceral-compartment organ. We may be aided in our approach to this disease by endoscopic ultrasound to at least define some of the visceral extensions of carcinoma of the esophagus. Despite the fact that it seems that an open thoracotomy, for dissection of the esophagus and its nodes, would give us cleaner dissection, this is not always the case and has been very difficult to prove. The reason for this is perhaps the fact that the adenopathy that occurs with carcinoma of the esophagus is not limited to the section where the carcinoma arises. For example, in carcinoma of the lower esophagus, there may be positive nodes in the upper one-third of the esophagus, that is, in the upper portion of the chest. In addition, there may be positive neck nodes in 20%. This probably is aided and abetted by the fact that there are no valves in lymphatics, and there are no segments to the esophagus or the esophageal nodes as we traditionally consider them. This is somewhat different from the adenopathy of pulmonary resections, in which the adenopathy associated with certain lobes and certain lungs and where to dissect is well known, as detailed very nicely in Chapter 54.

The final point that should be made here is that mediastinal infections are lethal. A perforation of the esophagus, which is not promptly treated, has no barrier, and within 24 hours, the entire mediastinum is filled with pus with an attendant high mortality. Whether it is the anterior compartment or visceral compartment, while theoretically these are separate compartments, in actual fact they do not act as such, there is free spread of pus up and down the mediastinum. Whether or not this is the result of an absent serosa, or whether or not this is because all of the compartments embryologically have fused when the mediastinum is developed is not clear, but this a high-mortality situation.

J.E.F.

61 Thoracic Trauma

J. Wayne Meredith and James Jason Hoth

INTRODUCTION

Trauma continues to be a significant source of patient morbidity and mortality, accounting for 140,000 deaths annually and is the leading cause of death in patients younger than 40 years of age. Although rarely isolated, thoracic injuries are a primary or contributing cause of death in up to 50% of all trauma-related deaths. Fortunately, the majority of thoracic injuries can be treated effectively, and often conclusively, by relatively simple maneuvers at the bedside such as tube thoracostomy. However, 10% to 15% of patients presenting with thoracic trauma have severe, life-threatening injuries that require definitive operative repair. In these patients, the timing of intervention and utilization of the appropriate surgical approach are crucial and should be based on a comprehensive knowledge of the location and nature of the injury. These extremes in injury severity are unique to the chest and require a correspondingly broad range of knowledge and skills on the part of the treating surgeon.

INITIAL EVALUATION

Initial evaluation and treatment of patients with thoracic injuries are guided by the same principles and priorities as initial evaluation and treatment of patients with other injuries. The first priority is to ensure an adequate airway and adequate ventilation. Patients with severe chest trauma commonly require nasotracheal or orotracheal intubation. It is frequently during this stage of evaluation that tube thoracostomy is required for life-threatening pneumothorax. The next priority is control of external hemorrhage and restoration of circulation. External hemorrhage is best controlled by direct pressure. Inadequate perfusion generally results from either hypovolemia or pump (i.e., cardiac) problems. Hypovolemia from hemorrhage, by far the most common cause of inadequate perfusion in the traumatic setting, often must be treated operatively as part of the resuscitative effort. Pump problems are signaled by distended neck veins

and are caused by one of four conditions: (1) tension pneumothorax, (2) pericardial tamponade, (3) coronary air embolism, or (4) cardiac contusion or myocardial infarction (MI). In most blunt trauma patients, urgent treatment of thoracic injury is accomplished during the primary survey because the most common blunt chest injuries can be controlled with endotracheal intubation or tube thoracostomy.

ED THORACOTOMY (EDT)

Emergency department thoracotomy (EDT) is a drastic procedure with limited utility. The therapeutic goals of EDT include control of hemorrhage, effective cardiac compression, cross-clamping the pulmonary hilum in the case of air embolism or massive bronchopleural fistula, relief of cardiac tamponade, and cross-clamping of the descending aorta for lower torso hemorrhage control.

Indications

When making a decision to perform an EDT, three factors must be taken into consideration: mechanism of injury, location of major injury, and signs of life. Better outcomes are seen when performed for penetrating (8% to 10%) injuries rather than blunt injuries (approximately 1%). Patients with isolated penetrating chest injuries have the greatest chance of survival, and the absence of signs of life (palpable pulse, pupillary or gag reflex, demonstrable blood pressure) or asystole on presentation must be considered. In general, the patients most likely to respond favorably to EDT include victims of penetrating trauma, particularly stab wounds, with signs of life either upon presentation to the emergency room or who lose signs of life within 10 minutes of arrival.

Surgical Technique

Once the decision has been made to intervene, the standard incision is a left anterolateral thoracotomy; however, extension across the sternum may be required. After evacuating blood from the chest, attention is directed to the injury. If a great vessel is injured and bleeding, pressure is utilized to staunch hemorrhage. If air embolism is encountered, the pulmonary hilum is clamped or the affected lung may be twisted 180 degrees and air in the aorta evacuated. When hemopericardium is present, the pericardium may be divided longitudinally, and once the hemopericardium is evacuated, the

heart is delivered from the pericardial sac and a temporary repair is then performed using suture or staples. After the cause of arrest has been addressed or in case of resuscitative thoracotomy for intra-abdominal sources of hemorrhage, a cross-clamp may be applied to the descending thoracic aorta once the mediastinal pleura has been carefully opened taking care not to injure the esophagus. Intravascular volume is restored and, if the patient responds, transported to the operating room for definitive repair of injuries.

SECONDARY EVALUATION AND DEFINITIVE DIAGNOSIS

The secondary survey should focus on more subtle evidence of injury that may be detected on physical examination and chest x-ray. Simple rib fractures, flail chest segments, pneumothorax, and hemothorax are often undetected during the primary survey but are common findings after patient workup. Because of continuing improvements in computed tomography (CT) scanning technology, this modality is increasingly being used in the evaluation of the thoracic trauma in stable patients. Indeed, chest CT angiography (CTA) is now routinely employed for definitive diagnosis of aortic and great vessel injuries, rendering standard angiography unnecessary in most cases. In addition, chest CT scanning is increasingly useful in the diagnosis of pulmonary contusion, and tracheobronchial and esophageal injuries. Furthermore, echocardiography can be an important adjunct for assessing proximity wounds to the heart or evaluating a new murmur.

INDICATION FOR URGENT OPERATIVE INTERVENTION

Indications for urgent operative treatment of thoracic injuries fall into five broad categories: (1) hemorrhage, (2) major airway disruption, (3) cardiac and vascular injuries, (4) esophageal disruption, and (5) diaphragmatic disruption. The extent and location of hemorrhage can sometimes be determined from open wounds but are more often established after chest tube insertion. It is important to understand that the pulmonary circulation is a low pressure system and complete re-expansion of the lung will tamponade parenchymal bleeding. In general, if 1,500 mL of blood or more is obtained initially or ongoing bleeding at a rate ≥300 mL/hr for 3

hours is noted, thoracotomy is generally indicated. Caveats to the use of chest tube drainage as an indicator for chest explorations are chest trauma with a delayed presentation and the presence of a coagulopathy. Massive air leakage and the presence of gastric or esophageal contents in the chest tube effluent also necessitate surgical intervention. A continuous air leak seen in conjunction with an inability to expand the lung completely or with inadequate tidal volumes is considered a massive air leak. These findings suggest major tracheobronchial injuries. The presence of cardiac tamponade, demonstrated on physical examination using a combination of findings (Beck's triad: muffled heart tones, distended neck veins, and hypotension) and more recently, by the presence of a pericardial effusion on FAST examination, demands further evaluation with pericardial window or median sternotomy. Lastly, air embolism, a rare entity associated with penetrating injury, occurs when a fistula develops between a bronchus and pulmonary vein and also requires urgent thoracotomy. Typically, the patient is stable until intubated and placed on positive pressure ventilation when sudden cardiovascular collapse and/or the onset of lateralizing neurologic symptoms occur.

CHOICE OF INCISION

Given the indications for chest exploration, selecting the appropriate chest incision is critically important. What makes this decision difficult is that four different compartments must be considered: the right chest, left chest, mediastinum, and in the case of concomitant abdominal injury, the peritoneal cavity. Several factors should be carefully assessed before making a decision. Information regarding missile or injury trajectory, a thorough working knowledge of thoracic/mediastinal anatomy, and the exposures offered by each different incision are vital to choosing the appropriate incision. For example, a left parasternal gunshot wound may injure both the anterior and posterior walls of the left ventricle. Of these two injuries, while the anterior injury is easily exposed and repaired through a median sternotomy or anterior thoracotomy, the posterior injury is more difficult to repair and is best approached with a left posterolateral thoracotomy. A summary of surgical approaches for common traumatic injuries to thoracic viscera is given at Table 61.1.

Median sternotomy (Fig. 61.1) offers adequate exposure for the majority of parasternal stab wounds as these injuries do not typically

penetrate deeply and primarily involve the anterior mediastinum. Likewise, in the instance of right parasternal gunshot wound, a median sternotomy provides good exposure of structures that are likely to be injured, including the right atrium and ventricle, the superior vena cava, atrial appendage, right pulmonary artery, and lung. Furthermore, the incision for a sternotomy may be extended into the neck or supraclavicular fossa to enhance exposure of the great vessels (Fig. 61.1, inset). As previously stated, posterolateral thoracotomy provides superior exposure of the posterior heart and should be used in instances of left parasternal gunshot wound. In addition, for lateral wounds, depending on the side involved, a right or left posterolateral thoracotomy provides the best exposure as these injuries are more likely to be posterior. In cases of massive hemothorax, a posterolateral thoracotomy on the affected side will offer excellent visualization of the great vessels such as the subclavian artery or aorta. A left posterolateral thoracotomy (Fig. 61.2) is the incision of choice in instances of air embolism and massive air leak.

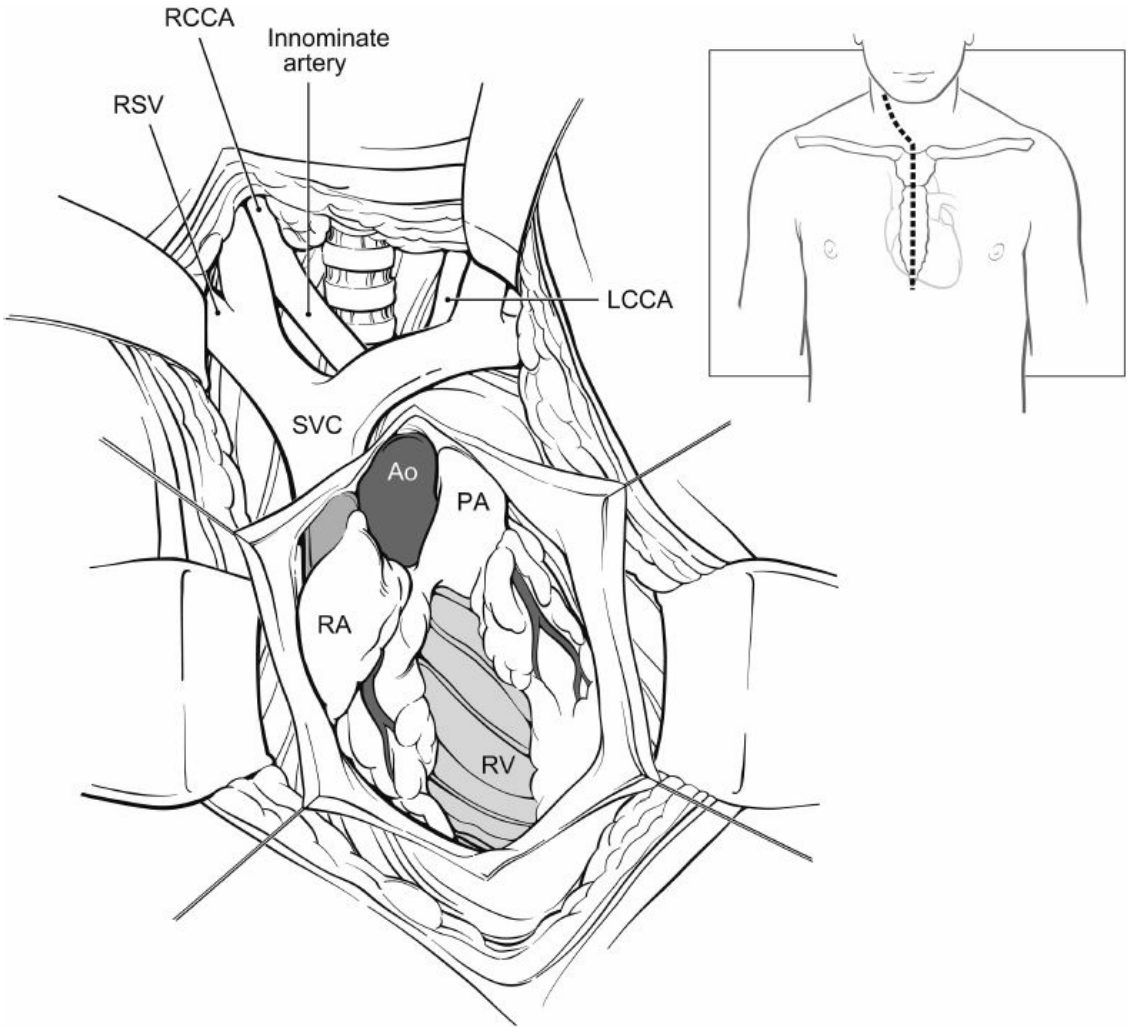

Figure 61.1. Median sternotomy with optional extension. A median sternotomy provides excellent exposure for the right atrium and ventricle, the superior vena cava, atrial appendage, right pulmonary artery, and lung. If necessary, the incision may be extended into the neck or supraclavicular fossa (see *inset*) to enhance exposure of the great vessels. Ao, Aorta; LCCA, left common carotid artery; PA, pulmonary artery; RA, right atrium; RCCA, right common carotid artery; RSA, right subclavian artery; RV, right ventricle; SVC, superior vena cava.

Right thoracotomy is an excellent approach for right lung, tracheal and proximal left mainstem bronchial injuries, a point that is often forgotten. Most upper and mid-esophageal injuries are best approached through a right thoracotomy except in cases of distal esophageal injuries that are best accessed through the left chest. Right heart structures such as the right atrium, right ventricle, atrial appendage, as well as the left atrium are also easily exposed with a right thoracotomy. Left thoracotomy provides adequate exposure of the left lung, left pulmonary hilum, the aorta, the proximal left subclavian artery, left heart chambers, distal esophagus, and distal left mainstem bronchus. A “clam shell” incision, formed by extending a thoracotomy incision transversely across the sternum using either the Lebske knife, a pair of trauma shears or a saw, provides excellent access but suboptimal exposure of every intrathoracic or mediastinal structure except the right ventricle and right atrium. When using this approach, the internal mammary arteries are divided and often do not bleed in the poorly perfused patient. However, once blood pressure is restored, significant hemorrhage from these vessels may result. A more stable closure of the transverse sternotomy may be achieved with sternal plates rather than wires.

CHESTWALL INJURIES

Rib Fractures

Clinical Presentation and Diagnosis

Rib fractures are the most common chest wall injuries resulting from blunt trauma. The main pathophysiologic consequences of rib fractures are pain, splinting, and prevention of adequate cough. The diagnosis should be suspected if pain or splinting occurs on deep inspiration, and it is confirmed by careful physical examination, consisting of anterior–

posterior and lateral–lateral manual compression. If an alert patient feels no pain when these maneuvers are done, clinically significant rib fractures can be excluded. Although rib fractures are often identified on routine chest radiographs, they are more likely to be undetectable on plain radiographs; however, chest CT identifies rib fractures with high sensitivity and specificity.

Treatment

Adequate pain control cannot be emphasized enough especially in those with greater than six rib fractures and over the age of 65. Pain from isolated rib fractures can usually be adequately controlled with oral analgesics, encouraging good pulmonary toilet, and use of thoracic epidural anesthesia in select patients. Increasingly, reports have demonstrated the feasibility of rib fracture repair using a variety of different methods; however, the patients who will benefit the most from these interventions have not been clearly identified. Potential indications for operative repair of rib fractures include flail chest, painful moveable rib fractures that are refractory to conventional management, chest wall deformity/defect, rib fracture nonunion, and during thoracotomy for other indications. Studies have demonstrated excellent outcomes for patients with flail chest of greater than three ribs; however, other indications for repair have not been as clearly defined. A reduction in ventilator days, pneumonia, ICU days, analgesic use, and other morbidities has inconsistently been demonstrated when rib fixation is undertaken. Most trauma surgeons feel there is a role for rib repair, but further clarification of the population of patients who will benefit remains an obstacle.

Sternal Fractures

Clinical Presentation and Diagnosis

The vast majority of sternal fractures result from motor vehicle crashes and may be associated with significant underlying thoracic and abdominal injuries. The diagnosis of sternal fracture is based on the presence of severe pain, often associated with instability, on sternal palpation. Sternal fractures are almost invariably transverse, with the majority occurring near the sternomanubrial joint.

Treatment

Initial management of a sternal fracture is directed toward resuscitation

and identification or exclusion of other life-threatening injuries. In patients with isolated sternal fractures, a normal electrocardiogram (ECG) and a normal chest radiograph suggest that associated serious injuries are unlikely. If the pain is controlled with oral analgesics, these fractures can usually be managed on an outpatient basis. The vast majority of sternal fractures heal with non-operative management. Those that are unstable or are displaced by more than 1 cm of overlap are more likely to exhibit mal-union or non-union and subsequent chronic pain; they may require treatment with open reduction and internal fixation.

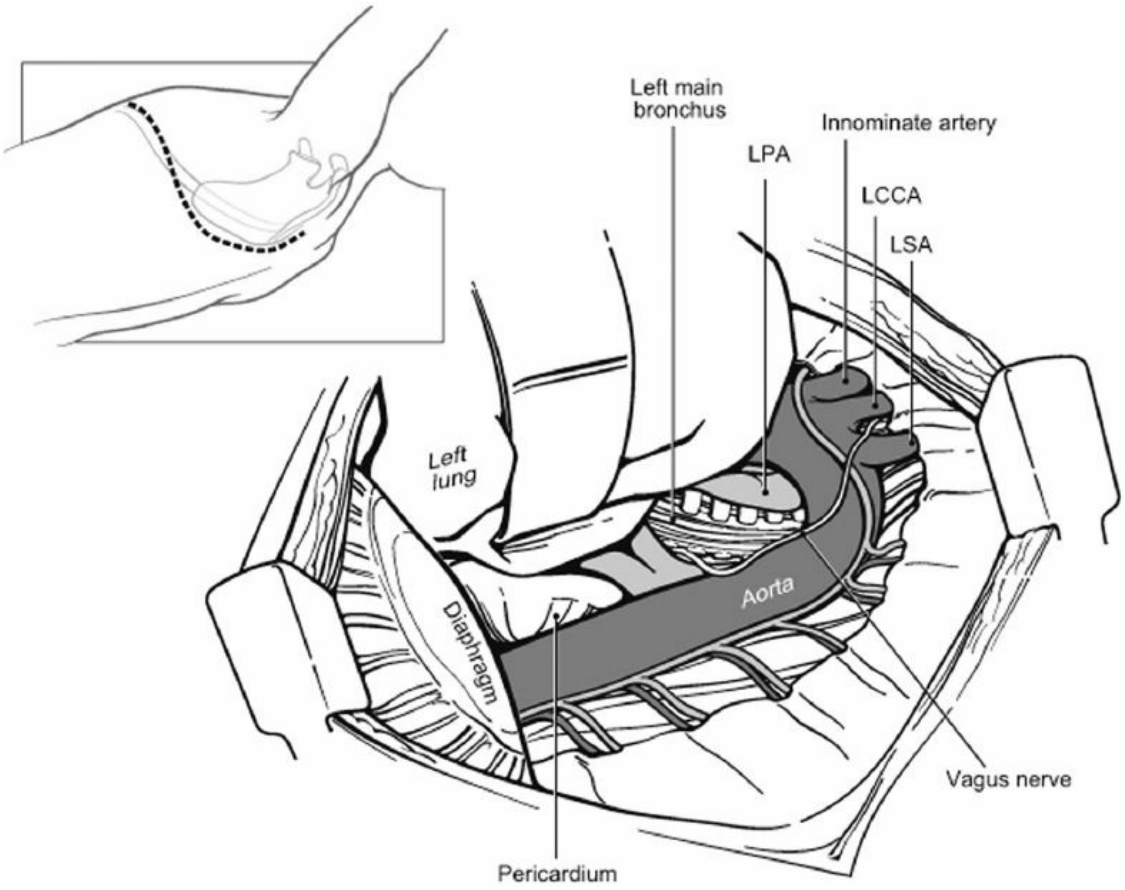

Figure 61.2. Left posterolateral thoracotomy. A left posterolateral thoracotomy (see *inset*) provides excellent exposure of the left pulmonary hilum, left lung, proximal left subclavian artery, descending aorta, distal esophagus, and left diaphragm. LCCA, left common carotid artery; LPA, left pulmonary artery; LSA, left subclavian artery.

Flail Chest

Clinical Presentation and Diagnosis

Flail chest is the most serious of the blunt chest wall injuries. It is common

after any form of blunt thoracic trauma, and though it may occur as an isolated finding, it is usually associated with other significant injuries. It involves fractures of adjacent ribs, each of which is fractured in two or more places so that with spontaneous respiration a panel of chest wall moves independently of, and in the opposite direction to, the remainder of the chest (i.e., paradoxical motion). A flail segment may be overlooked in a patient on positive pressure ventilation because there may be no paradoxical motion without inspiratory effort. The pathophysiology of flail chest consists of three components: alteration of chest wall mechanics impairing adequate ventilation; pulmonary contusion resulting in shunting to produce hypoxemia; and pain with associated splinting and inadequate pulmonary toilet, setting the stage for subsequent infection.

Treatment

Proper management of flail chest hinges on the recognition that the injury is an evolving process not a static condition. Frequent re-evaluation and timely, appropriate intervention are essential. Early and aggressive pain management is essential so to allow an adequate tidal volume and a forceful cough. Oral analgesics rarely suffice. Parenteral narcotics are effective, especially when administered in a patient-controlled analgesia (PCA) device. Intercostal nerve blocks occasionally provide dramatic pain relief, but only for short periods. However, thoracic epidural anesthesia is the mainstay of pain control in patients with flail chest. Epidural anesthesia provides immediate comfort, dramatically improves vital capacity and tidal volume, and most importantly, enables the patient to produce a forceful cough. Ambulation is encouraged, and frequent coughing is required. There is no role for antibiotic prophylaxis or steroid use in the management of patients with flail chest or pulmonary contusion. It is in this group of patients that operative repair of rib fractures has consistently been shown to be the most beneficial (see above) although not required in the majority of instances.

LUNG INJURIES

Lung injury requiring operative intervention is more common following penetrating rather than blunt injury. The majority of cases of pneumothorax or hemothorax can be adequately treated with accurate chest tube placement and full re-expansion of the lung. However, it is estimated that 20% to 40% of patients after penetrating injury and 15% to

20% of patients after blunt injury who require thoracotomy will need some form of lung resection. The vast majority of lung injuries that require thoracotomy can be successfully managed using lung sparing techniques such as non-anatomic stapled resections or tractotomies; however, trauma surgeons should be familiar with anatomic lung resection as well. Operative indications for lung injury tend to fall into one of two categories, hemorrhage or persistent air leak impairing ventilation. The incision of choice for lung injury is a fifth intercostal space posterolateral thoracotomy on the involved side. The most common procedures performed are simple suture repair of superficial lung lacerations or wedge resection of the injured lung using a stapling device.

Lacerations

Operative Indications and Approach

Operative indications for lung injury tend to fall into one of two categories, hemorrhage (>1,500 mL initially or >300 mL/hr for 3 or more hours) or persistent air leak impairing ventilation. The incision of choice is a fifth intercostal space posterolateral thoracotomy on the involved side. The most common procedures performed are simple suture repair of superficial lung lacerations or wedge resection of the injured lung using a stapling device.

Treatment

Bleeding pulmonary lacerations can be oversewn, resected, or explored via stapled pulmonary tractotomy. Bleeding from small or shallow lacerations can be controlled with an over-and-over repair using a continuous absorbable suture. Bleeding from deeper lacerations is controlled with resection or tractotomy. Most pulmonary resections for trauma should be stapled, non-anatomic resections; however, anatomic lung resection is required in rare instances. Mortality is proportional to the amount of lung tissue resected: with suture repair alone, mortality is 9%; with tractotomy, 13%; with wedge resection, 30%; with lobectomy, 43%; and with pneumonectomy, 50%.

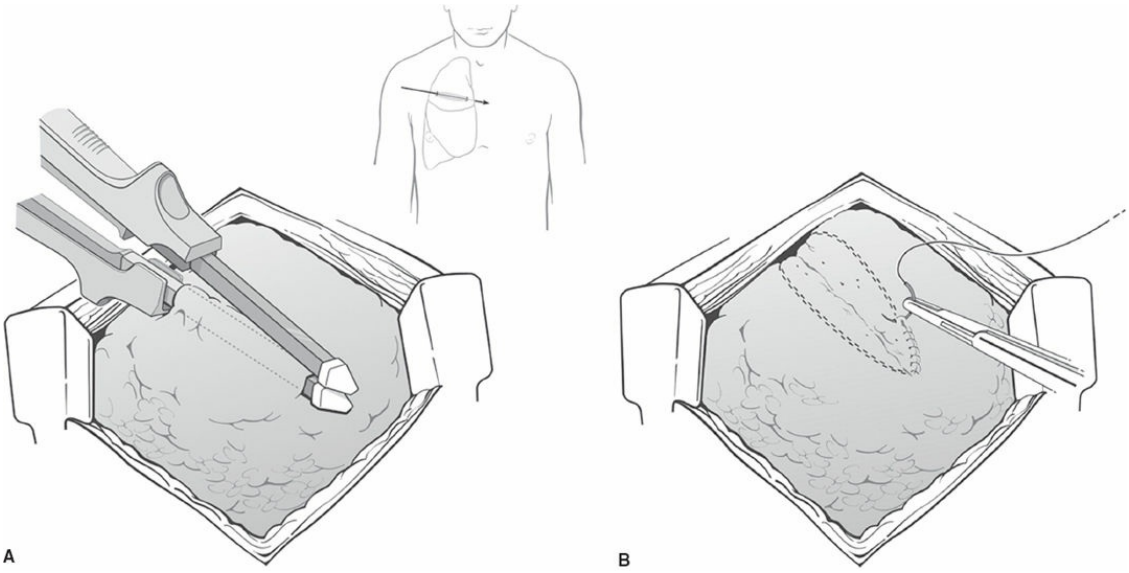

Figure 61.3. Tractotomy for nonhilar injuries. The principle of tractotomy is to open the tract of the bullet or knife wound (**A**, see *inset*) so that larger interior vessels may be identified and ligated individually (**A**). 3-0 polypropylene suture may be used to individually ligate the vessels or may be run along the length of the tractotomy (**B**). Oversewing penetrating lung injury is discouraged.

Tractotomy is especially useful for deep through-and-through injuries that do not involve the hilum. In this technique, the injury tract is opened with a linear stapler or between two aortic clamps (Fig. 61.3). If clamps are used, the cut lung edges are oversewn and the tract left open. Tractotomy exposes bleeding vessels and air leaks inside the tract and permits selective ligation. Occasionally, it exposes an injury to a major vascular or airway structure that must be treated with a formal resection. Because of the risk of exsanguination or excessive devitalization of lung tissue, tractotomy is not indicated when the injury traverses the hilum or when the entire thickness of a lobe will be cut.

The practice of simple oversewing of penetrating lung injuries should be discouraged. Oversewing entrance and exit sites may stop bleeding into the pleural cavity, but it does not stop intraparenchymal bleeding. Blood can then be forced into the tracheobronchial tree resulting in aspiration, pneumonia, acute respiratory distress syndrome (ARDS), and further worsening of the lung injury. Simple maneuvers such as tractotomy, wedge resection, and simple suturing are more commonly performed after penetrating lung injury since more proximal lung injuries are often associated with concurrent fatal mediastinal injuries.

Anatomic resections such as lobectomy and pneumonectomy are more commonly performed if resection is needed after blunt injury. Blunt traumas often result in a more severe and diffuse lung injury that is typically more difficult to treat surgically and has worse outcomes when compared to penetrating trauma. Patients with perihilar injuries are typically in shock or have extensive parenchymal injury (as seen commonly after blunt injury). Hilar control should be the initial maneuver upon entering the chest if profuse lung bleeding is encountered. This can involve placing a large clamp across the pulmonary hilum or dividing the pulmonary ligament to the level of the inferior pulmonary vein and twisting the immobilized lung. Occasionally, intrapericardial control of the pulmonary artery is required in cases of proximal injuries. If both the artery and vein are injured, pneumonectomy is indicated. At this point, lung amputation can be performed using a stapler or alternatively, the hilum may be oversewn. Traumatic pneumonectomy is associated with mortality rates of 50% to 100% and should only be considered if there is no alternative.

Contusions

Clinical Presentation and Diagnosis

Pulmonary contusions are bruises to the lung usually caused by blunt trauma to the chest but sometimes result from penetrating injury by high-velocity weapons. The contused segment of the lung has a profound ventilation-perfusion mismatch, which produces an intrapulmonary right-to-left shunt and hypoxia. The clinical sequelae of lung contusion may vary from simple shortness of breath to respiratory failure requiring mechanical ventilation.

Typically, the bruise is not completely appreciated on chest x-ray, but it is fully evident on chest CT. In fact, the size of the contusion as measured on chest CT is directly proportional to the risk of developing posttraumatic ARDS. Lung contusion is a significant risk factor for pneumonia, and the bruised lung also may serve later as a source of sepsis.

Treatment

Most pulmonary contusions that are not complicated by excessive attempts at resuscitation or by superinfection resolve over 3 to 5 days. Supportive care in the form of cardiovascular, and if necessary, ventilatory support, must be provided. In general, pulmonary contusion is treated in much the

same fashion as flail chest. Steroids are not indicated, because they have no effect on the development or resolution of the contusion and because they set the stage for subsequent infection. Diuretics and prophylactic antibiotics are also unnecessary.

CARDIAC INJURIES

Cardiac injuries may involve the myocardium, coronary arteries, valves, septum, or result in the late presentation of a ventricular aneurysm. Mortality rates range from 10% to 70%, reflecting a variety of presentations and injury mechanisms. Cardiac injuries usually cause either cardiac tamponade or hemorrhagic shock, depending on the nature of the pericardial injury and whether pericardial blood can escape into the pleural space. Pericardial tamponade results from the accumulation of fluid within the pericardial space that compresses the heart and prevents cardiac filling. The sac-like pericardium has poor compliance and as little as 50 mL of blood can effectively cause tamponade. The presence of cardiac tamponade is usually made based on clinical findings of a distinctive dusky, plethoric facial complexion associated with distended neck veins, hypotension, and evidence of pericardial effusion on ultrasound examination. It should be noted, however, that the sensitivity of ultrasound in the detection of hemopericardium is markedly diminished in the presence of a significant hemothorax where blood may be escaping from the injured heart directly into the thoracic cavity leaving only small amounts in the pericardium. Depending upon the hemodynamic status of the patient with tamponade, they should either undergo EDT or be taken to the operating room immediately for a pericardial window or formal chest exploration.

Penetrating

Clinical Presentation and Diagnosis

Patients with penetrating cardiac injuries generally present in one of three ways. In approximately 20% of patients, the injury is clinically silent, at least initially, and is subsequently diagnosed at operation or on diagnostic imaging. In approximately 50%, there is evidence of pericardial tamponade, including one or more of the signs in Beck’s triad (hypotension, distended neck veins, and muffled heart sounds). In the remaining patients, hemorrhagic shock develops after free bleeding from an atrial or ventricular wound into one or both hemithoraces.

Diagnosis of penetrating injuries to the heart often requires a high index of suspicion. Proximity wounds to the heart are defined as those that penetrate the chest wall in the area bounded superiorly by the clavicles, laterally by the midclavicular lines, and inferiorly by the costal margins. Any crossing of the anterior mediastinum by a missile or an instrument is also considered a proximity wound. Because cardiac injuries are present in 15% to 20% of patients who present with proximity wounds, these injuries must be definitively excluded.

As more surgeons become familiar with the use of ultrasonography in the trauma setting, two-dimensional surface echocardiography is gaining acceptance as a means of diagnosing cardiac injuries. When performed by appropriately trained surgeons, this modality detects blood within the pericardial sac with a sensitivity of 96% to 100% and a specificity of 100%, results essentially equivalent to those achieved with a pericardial window. Although cardiac ultrasonography has many advantages, the subxiphoid pericardial window remains the gold standard for diagnosis of cardiac injury. For otherwise stable patients with proximity wounds or suggestive signs and symptoms, a pericardial window should be considered when ultrasonographic findings are equivocal or are unavailable.

Operative Approach

In planning the surgical approach to the repair of cardiac injuries, the location of the entrance and exit wounds, the path of the wounding object, the type of wound created, the associated signs and symptoms, and the level of suspicion for other thoracic visceral injuries are important considerations (Table I). A median sternotomy is a logical extension of a subxiphoid pericardial window and provides access to all four chambers of the heart. It is appropriate for most precordial stab wounds and some low-caliber gunshot wounds. Its main limitations are that it does not allow repair or cross-clamping of the descending aorta or examination or repair of the esophagus and bronchi and that it provides limited exposure of the lower lobes of the lungs and the hemidiaphragms. A left thoracotomy is appropriate for patients who may require cross-clamping of the thoracic aorta and for those with suspected cardiac injuries in conjunction with other complex thoracic visceral injuries. Only occasionally is a right thoracotomy required; this incision generally does not provide optimal exposure of the heart.

Treatment

Atrial wounds are generally amenable to early control by finger pressure or by exclusion with a vascular clamp and simple oversewing. Right or left ventricular free wall injuries away from the coronary arteries may be treated by applying digital pressure over the entrance wound for hemostasis, then placing horizontal mattress sutures under the wound, reinforced with an epicardial continuous suture along the site of injury. Ventricular injuries adjacent to coronary arteries may be repaired in a similar fashion with care being taken not to narrow or occlude the artery. In some instances, especially with injuries near the proximal coronary artery or involving the left anterior descending artery, cardiopulmonary bypass may be required. Simple ligation may be entertained in desperate circumstances. All left ventricular wounds should be repaired with felt-pledgetted or pericardial-pledgetted sutures. Many right ventricular stab wounds can be closed primarily without pledgets if the sutures are tied accurately.

With all penetrating cardiac wounds, it is important to recognize the possibility of associated intracardiac injuries. The surgeon should palpate the heart along the pulmonary outflow tract for a thrill that would indicate a traumatic ventricular septal defect. Digital palpation through atrial wounds should be routinely employed to identify atrioventricularvalvular insufficiency or occasionally, an atrial septal defect. Intraoperative surface echocardiography and transesophageal echocardiography are also excellent at diagnosing intracardiac injuries.

Repair of intracardiac lesions usually can wait until the patient’s condition is stable and cardiac catheterization has been performed, although some patients experience such profound heart failure that immediate operative repair with cardiopulmonary bypass must be performed.

Blunt

Blunt cardiac injuries range from disruption of myocardium, septa, or valvular structures to cardiac contusion. Blunt cardiac injury typically involves a direct blow to the chest, usually sustained in a motor vehicle collision or a fall. Cardiac injuries generally are associated with sternal or rib fractures. The most common location of blunt cardiac injury is the anterior heart, which consists primarily of the right ventricle. A blow that causes the sternum to exert a direct impact on the myocardium may result

in direct injury to myocardial cells, sometimes leading to cell death, mechanical dysfunction, or dysrhythmias. In the rare patient with blunt cardiac rupture who presents to the hospital with signs of life, the most common injury is right atrial perforation. Other lesions seen in patients with vital signs, in order of decreasing incidence, are left atrial perforation, right ventricular perforation, atrial septal perforation, ventricular septal perforation, coronary artery thrombosis, and valvular insufficiency (most commonly involving the tricuspid and mitral valves).

Myocardial Contusion

Clinical Presentation and Diagnosis

The diagnosis of myocardial contusion is elusive. Many tests have been proposed, but none have proved definitive, except for direct visualization of the heart at surgery or autopsy. For practical purposes, the clinically significant sequelae of myocardial contusion are myocardial dysrhythmias and pump failure.

As an initial test, a 12-lead ECG should be obtained whenever blunt cardiac injury is suspected as in the case of a sternal fracture. If the ECG is normal, no further workup is required. If there is an ECG abnormality that does not necessitate treatment (e.g., nonspecific ST-T wave changes), the patient should undergo monitored observation for 12 hours. If there is a more serious ECG abnormality, the patient should undergo observation for at least 24 to 48 hours and may require further testing and treatment, depending on the sequelae of the abnormality. In patients with hemodynamic instability and suspected blunt cardiac injury, echocardiography should be performed promptly. There is no role for cardiac enzyme analysis or cardiac troponin assay in this setting. The latter test may detect myocardial injury, but this information does not complement ECG and echocardiographic findings and has no clinical utility. Similarly, there is no role for nuclear medicine studies.

Treatment

Pump failure associated with cardiac contusion is usually the result of right heart failure, in that most hemodynamically significant cardiac contusions are caused by injury to the anterior right ventricular free wall. Treatment of right heart failure from cardiac contusion consists of inotropic support and reduction of right ventricular afterload. Dysrhythmias secondary to cardiac contusion are treated in the same manner as dysrhythmias of any

other etiology.

TRACHEOBRONCHIAL INJURIES

Injuries to the trachea or main stem bronchi are uncommon in patients who survive to reach the hospital and may occur after blunt or less commonly, after penetrating injury with an estimated incidence of <2%. Regardless of mechanism, most of these injuries occur within 2.5 cm of the carina with main stem bronchial injuries in 86%, distal bronchial injuries in 9%, and complex injuries present in 8%. Associated intrathoracic or mediastinal injuries are common.

Clinical Presentation and Diagnosis

Symptoms depend on the location of the injury and whether the injury communicates with the pleural cavity. Thoracic injuries with pleural communication present with pneumothorax that may or may not be under tension. A pneumothorax that persists after chest tube placement or has a continuous air leak is indicative of tracheobronchial damage. In injuries with extrapleural communication, massive pneumomediastinum is typically encountered, occasionally without pneumothorax. In this case, the diagnosis is more difficult to make and other modalities are required to make the diagnosis. Nonspecific symptoms of tracheobronchial injury can include subcutaneous emphysema and hemoptysis. Most subcutaneous emphysema is due to lung lacerations without major bronchus injury. Subpleural rupture of alveoli is more commonly associated with mediastinal emphysema with or without neck subcutaneous emphysema. Hemoptysis is often a result of aspiration of blood from facial and pharyngeal injuries.

There are an increasing number of reports demonstrating the utility of CT technology in diagnosing tracheobronchial injuries with a sensitivity approaching 100%. Thus, because of its excellent negative predictive value, CT may be employed as a screening tool to look for these injuries in stable patients; however, at present, diagnostic bronchoscopy (rigid or flexible) remains the gold standard to reliably exclude the diagnosis of tracheobronchial injury when suspicion exists. That being said, rarely can one clear the cervical spine sufficiently to attempt rigid bronchoscopy during the initial resuscitation time frame. The injury may be initially missed and present later as tracheal or bronchial stenosis. Thus, the diagnosis of tracheobronchial injury is made based on clinical findings and

radiographic findings (both chest x-ray and CT), and is confirmed with bronchoscopy.

Preoperative Planning

Treatment of tracheobroncial injuries is directed at ensuring or establishing adequate ventilation. When safe, avoidance of positive pressure ventilation is recommended during the initial evaluation, but if necessary, bronchoscopic-guided intubation is suggested. Blind intubation in these patients is extremely hazardous.

Operative Approach

As most intrathoracic injuries occur within 2 cm of the carina, a right thoracotomy can be used to approach virtually all of these injuries except in cases of distal left mainstem bronchial injuries >3 cm from the carina where a left posterolateral thoracotomy is preferable. Primary emphasis should be placed on maintaining an adequate airway. This may require advancing the endotracheal tube under direct vision beyond the level of injury or passing a sterile endotracheal tube through the operative field into one or both lungs and ventilating with a sterile anesthesia circuit.

Treatment

Tracheobronchial injuries should be repaired primarily using interrupted or running absorbable suture with the knots placed on the outside of the lumen to reduce early secretion retention or late granuloma or stricture formation. When limited tracheal resection is required, up to 2 cm of trachea can be easily and safely excised and primary repair performed. Repairs should be buttressed with viable vascularized tissue, usually an intercostal muscle flap, pericardium, omentum, or rarely rhomboid or latissumus muscle flaps. Non-operative management is reserved only for highly selected patients who have lesions that involve less than one third of the bronchial wall with well-opposed edges and minimal tissue loss. In addition, the lung must fully re-expand with chest tube placement, the airleak should stop soon after chest tube insertion, and positive pressure ventilation is not required.

Postoperative Management

Postoperatively, barring other contraindications, a thoracic epidural

catheter should be placed to assist with pain control and ensure adequate pulmonary toilet. Patients on the ventilator should be extubated as soon as possible, ideally immediately after the operation is complete. Routine postoperative use of proton pump inhibitors is recommended as acid and pepsin exposure promotes granuloma formation at the site of repair.

ESOPHAGEAL INJURIES

These injuries are rare and primarily involve the cervical esophagus, typically as the result of gunshot wounds or iatrogenic trauma. Intrathoracic esophageal injuries are present in approximately 1% of gunshot wounds to the chest. Blunt esophageal injuries typically occur in the neck as a result of a direct blow or may occur in the chest just proximal to the esophagogastric junction. Blunt injuries are associated with increased intraluminal pressures against a closed glottis causing a bursting-type injury. Early diagnosis and treatment are of paramount importance as these injuries have significant morbidity and mortality when diagnosis is delayed.

Clinical Presentation and Diagnosis

These wounds are usually diagnosed at the time of exploration for other injuries or on diagnostic studies that are obtained in the stable patient because of the proximity of the wounding agent to the esophagus. Clinical manifestations may be present in 60% to 80% of patients depending on the location, size, amount of contamination, time to diagnosis, and the presence of associated injuries. Symptoms include odynophagia, dysphagia, and hematemesis. A small amount of mediastinal emphysema or small pleural effusion may be seen on chest x-ray. The presence of chest or back pain is also a clue to the presence of esophageal injuries. Tracheal and vascular injuries are often found as associated injuries.

The diagnosis can be definitively made at the time of surgical exploration, on endoscopy, or with esophagoscopy. An esophagram with barium rather than water soluble contrast is recommended for increased sensitivity, superior image quality, and decreased incidence of pneumonitis due to aspiration. Rapid diagnostic evaluation is desirable as the best surgical results are obtained when the duration of time between injury and repair is minimized.

Operative Approach

Upper and middle third thoracic injuries are optimally approached through a right posterolateral thoracotomy in the fourth or fifth interspace, depending upon the level of the injury. However, it is common for exposure of more urgent associated injuries to dictate the interspace selected. Distal third thoracic injuries are best approached through left posterolateral thoracotomy through the 6th intercostal space.

Treatment

Esophageal injuries should be treated early and aggressively. Once the wound is identified, the esophagus is mobilized sparingly to preserve its segmental blood supply but enough so that the injury can be completely defined. Most esophageal injuries when diagnosed and operated on within 24 hours lend themselves to primary repair with a single layer of absorbable monofilament suture.

Depending on the length of time prior to exploration, local inflammation, degree of contamination, and the severity of the injury, primary repair may not be feasible. In these patients, several temporizing techniques to control sepsis have been described in the literature, including esophageal diversion, esophageal exclusion, esophagectomy, and T-tube drainage with later definitive repair. If the patient is in extemis, wide drainage with a chest tube and placement of a nasogastric tube above the injury is a “damage control” option. Regardless, all esophageal repairs should be drained widely with a chest tube(s) and buttressed with viable, vascularized tissue (intercostal muscle flap, pericardial fat pad, gastric wrap or thickened pleura). Prior to initiating diet, a contrast study should be obtained to evaluate the integrity of the anastomosis.

GREAT VESSEL INJURIES

The great vessels of the aorta include the left subclavian, the left common carotid, and the innominate (brachiocephalic) arteries. Great vessel injuries are rarely encountered after penetrating chest trauma with a reported incidence of approximately 4%. The principle reason for this low incidence is that victims typically exsanguinate into the chest or externally prior to arrival at the hospital; however, with improved prehospital care and decreased transit times, these injuries are increasingly encountered at trauma centers.

Clinical Presentation and Diagnosis

The detection of the presence of a great vessel injury can be overt or subtle in presentation, depending on multiple factors including the mechanism and the vessel involved. The presence of a wound at the base of the neck or transmediastinal gunshot wounds should alert the clinician to the possibility of great vessel injury. The patient may be pulseless or moribund at presentation and diagnosis is confirmed at the time of EDT or urgent thoracotomy. Patients with proximal injuries may present with a massive hemothorax, pericardial tamponade, or external bleeding. Pulse deficits in the affected vessel's distribution, brachial plexus injuries, stroke or coma, and the presence of a thrill or bruit in the base of the neck also support the diagnosis of a great vessel injury.

In the stable patient or one who easily stabilizes with resuscitation, the diagnosis can be confirmed with angiography or CTA, if available. Chest x-ray may demonstrate the presence of an apical cap or widened mediastinum.

Operative Approach

After a diagnosis has been made, the patient should be taken to the operating room for exploration. If possible, the placement of a dual lumen endotracheal tube greatly facilitates exposure of these injuries. Many incisions have been described as providing adequate exposure for repair of great vessel injuries. For right subclavian injuries or right parasternal injuries, a median sternotomy with extension into the neck or a supraclavicular extension is recommended. A median sternotomy provides excellent exposure of the ascending aorta, the proximal right subclavian, the innominate, and the common carotid arteries. A left thoracotomy provides optimal exposure of the descending aorta and adequate exposure of the proximal left subclavian and the proximal left common carotid arteries. For distal control when dealing with left subclavian or left common carotid artery injuries, a supraclavicular or neck counter-incision is typically required. Alternatively, a mediansternotomy can be used to connect the incisions ("trapdoor" incision); however, this type of incision provides poor exposure and is associated with significant morbidity. Comprehensive knowledge of chest and neck anatomy is required when exposing these vessels to prevent injury to the phrenic, vagus, and recurrent laryngeal nerves that lie in close proximity to these vessels and to protect the thoracic duct when approaching the left subclavian artery.

Treatment

Once proximal and distal control is obtained, many of these injuries lend themselves to lateral repair or end-to-end primary anastomosis. Interposition grafts composed of polytetrafluoroethylene or knitted Dacron are the conduits of choice. When inflow control may not be achievable, as in cases involving injury at the thoracic outlet or the presence of a large hematoma, endovascular control of the proximal subclavian artery by means of a balloon catheter placed percutaneously through the femoral artery may be necessary.

There is a growing body of literature supporting endovascular management of great vessel injuries. Endovascular repair may be considered in stable patients with ateriovenous fistula or pseudoaneurysm. As with endovascular repair of blunt aortic injuries, concerns with this modality primarily center on the lack of long-term outcomes in a typically young patient population. Associated venous injuries (superior vena cava, internal jugular, innominate) are common, and if possible these should be treated by lateral repair or patch venography. Internal jugular or innominate injuries can be ligated with little ill effect except in patients with closed head injury. Vena cava injuries can be shunted if repair is not feasible and ligated only as a measure of the last resort.

TRAUMATIC AORTIC RUPTURE

Traumatic rupture of the aorta may account for as many as 10% to 15% of all traffic fatalities, and the majority of such injuries are fatal at the scene. Traumatic disruption of the thoracic aorta results from rapid deceleration and is produced by a rotation of the heart creating torsion or a shearing effect caused by differences in the mobility of the aorta above and below the point where the vessel is rotationally fixed. Most thoracic aortic disruptions in survivors occur at the aortic isthmus just distal to the origin of the left subclavian artery, where the aorta is fixed to a significant degree by the ligamentumarteriosum and intercostals.

Clinical Presentation and Diagnosis

Suspicion of an aortic injury is most often triggered by abnormal findings on a chest x-ray in a patient with a high-speed mechanism of injury and multiple other injuries. Most patients show no signs or symptoms on physical examination, but some complain of interscapular pain or

hoarseness, and some exhibit a difference in blood pressure or pulse fullness between the upper and lower extremities or between the right and left upper extremities. Accordingly, the diagnosis is usually made radiographically, often beginning with the recognition of mediastinal hemorrhage on a screening chest x-ray.

Numerous radiographic signs of a torn thoracic aorta have been described. Mediastinal widening is the most frequent indicator of mediastinal hematoma from a torn thoracic aorta. Other important signs are obscuration of the detail of the contour of the aortic knob, opacification of the aortopulmonary window, depression of the left mainstem bronchus, apical cap, deviation of the nasogastric tube, and displacement of the esophagus to the right. These signs may be present in any combination or may be entirely absent in up to 10% of affected patients. Currently, high-speed CT scanning with intravenous (IV) contrast is the diagnostic study of choice in all patients whose injury mechanisms produce a high degree of energy transfer. Using chest CT scanning, aortography may be eliminated in virtually all of these patients before surgical repair; the sensitivity and specificity of CT in this setting approach 100%. Aortography should continue to be used for equivocal cases or cases in which spiral CT is not available.

Indications

Essentially all aortic injuries associated with mediastinal hematomas should be repaired. The timing of repair, however, is less urgent than the timing of certain associated maneuvers that must be done, such as attainment of an adequate airway, control of external or cavitary hemorrhage, and evacuation of intracranial mass lesions. In general, if there is active bleeding from a blunt aortic injury, it will be massive; lesser amounts of bleeding from a chest tube often derive from associated injuries even in the presence of a torn thoracic aorta. If intra-abdominal bleeding is present, laparotomy is indicated before repair of the torn thoracic aorta and before aortography. Similarly, in patients with intracranial hemorrhage that necessitates operative evacuation, craniotomy should take precedence over repair of the torn thoracic aorta.

Preoperative Planning

While one is temporizing, stringent efforts must be made to prevent hypertension and reduce shear forces across the injury, ideally by means of

IV beta blockade. Esmolol, because of its short half-life, is the best agent to use in these patients, who are at risk for sudden hypovolemic episodes of hypotension. The goals of medical therapy are a heart rate <100 beats/min and a systolic blood pressure of approximately 100 to 120 mm Hg. Nitroprusside may have to be given to achieve these goals, but it should not be used until after adequate beta blockade is achieved because it can increase intravascular shear forces when used alone. With careful medical management of aortic injuries, the risk of rupture is low and allows the clinician to address other more life-threatening injuries prior to repair. In fact with certain low-grade or minimal aortic injuries, medical management may be all that is required.

Treatment

Traditional repair techniques include exposure of the aorta and arch through a left thoracotomy and direct repair or interposition graft placement. Although excellent results have been obtained with so-called clamp-and-sew techniques, most guidelines recommend use of some form of distal aortic perfusion (e.g., left atrial–distal aortic bypass or partial cardiopulmonary bypass with femoral cannulation). Systemic heparinization is required for full cardiopulmonary bypass and has been shown to be safe with respect to hemorrhagic complications. After the subclavin and the distal aorta have been controlled, the aortic arch is clamped between the common carotid and left subclavian arteries. It is unnecessary to control the carotid as it is proximal to the proximal clamp. An interposition graft is required for most of these injuries, although 15% to 20% can be treated with suture repair alone. With distal aortic perfusion, the risk of paraplegia is approximately 5% and is independent of clamp time; without distal aortic perfusion, ischemic times longer than 30 minutes are associated with an exponential rise in the incidence of spinal cord injury. Another potential advantage to using cardiopulmonary bypass is the ability to institute deep hypothermic circulatory arrest if needed. This technique may be useful for patients who have previously undergone thoracic aortic surgery or who have complex tears involving the arch.

An alternative modality for the treatment of aortic injury is endovascular stent grafting in which a stent graft is deployed that bridges the injury proximally and distally. Often the orifice of the left subclavian artery is occluded by the graft; however, carotid-subclavian bypass is infrequently required as limb ischemia is rare. The results of multiple

studies indicate endovascular repair to be superior to open repair in terms of mortality, incidence of spinal cord ischemia, renal injury, and graft infection. Thus, in the last decade, there has been a paradigm shift in the management of blunt aortic injuries in which medical management followed by endovascular repair has become the primary therapy rather than open repair. However, studies addressing long-term complications such as the incidence of late stent migration, collapse, erosion, thrombosis, and infection have not been performed. Furthermore, there remain some limitations with the current level of stent graft technology; however, this field is advancing rapidly to overcome these deficiencies, and reports on newer devices are encouraging.

RETAINED HEMOTHORAX AND POSTTRAUMATIC EMPYEMA

Clinical Presentation and Diagnosis

After blunt and penetrating chest trauma, when treating a hemothorax with tube thoracostomy, the goal is complete evacuation of blood from the pleural space and complete expansion of the lung. However, because of improper positioning of the tube, or obstruction of the chest tube, blood may not be completely evacuated from the pleural space and may become contaminated during tube insertion, from a pulmonary air leak or hematogenously.

A retained hemothorax is suggested by the presence of a persistent opacification in the pleural space in a patient with a known previous hemothorax. However, plain chest radiography can be misleading often underestimating the amount of fluid in the chest, and the radiodensity seen can be confused with adjacent pulmonary contusion or atelectasis. Chest CT confirms the diagnosis, providing information about the size and location of the hemothorax that can be used in preoperative planning.

Treatment

Because retained blood serves as a nidus for infection and empyema, aggressive attempts at removal are justified. Placement of additional chest tubes is rarely effective in removing clotted blood from the pleural space and may increase the risk of infection. When used early (<5 days after injury), video-assisted thoracic surgery (VATS) is a cost-effective method for managing clotted hemothoraces and free-flowing blood; however, in

patients who have ongoing bleeding, posterolateral thoracotomy is generally required. A dual-lumen endotracheal tube and single lung ventilation are usually necessary. With the patient in the lateral decubitus position, typically two or three incisions approximately 2 cm in length are used as chest ports and the clotted blood may be evacuated using suction catheters or ringed forceps. Thoracotomy is usually required in cases when the hemothorax has been present for longer periods of time and dense adhesions have formed to the visceral or parietal pleura. Often the hemothorax has become infected. A posterolateral thoracotomy on the affected side through the fifth intercostal space will typically provide adequate exposure. Decortication is necessary if the clotted hemothorax has a fibrous peel. Emphasis should be placed on completely removing the peel from the visceral surface of the pleural so that complete lung expansion may be obtained postoperatively. Ringed forceps or the scalpel may be required to remove the densely adherent peel from the lung, and moderate hemorrhage may be encountered during this part of procedure. Once decortication is complete and the retained hemothorax has been removed, wide drainage with chest tube is required to prevent re-accumulation of blood and facilitate re-expansion of the involved lung.

Postoperative Management

Postoperatively, every effort should be made to mobilize the patient and enhance pulmonary toilet. Toward this end, parental narcotics administered via PCA or thoracic epidural anesthesia will greatly assist with pulmonary toilet. Chest tubes should be discontinued as soon there is no air leak and drainage is <150 mL/day.

CONCLUSION

Thoracic trauma is a contributing factor in a majority of trauma-related deaths. With thorough physical examination and appropriate radiographic evaluation, the majority of these injuries can be identified early and appropriate therapy can be initiated. Most thoracic injuries do not require operative intervention and may be treated with simple life-saving bedside procedures. However, when considering surgical intervention, many variables must be considered in this decision process, and each injury has unique issues to be addressed. Once the need for intervention is apparent, the critical decision for an appropriate surgical approach is based on a complete understanding of the location and nature of the injury.

EDITOR'S COMMENT

Thoracic trauma is a significant cause of trauma-related mortality. It is estimated that 25% of traumatic deaths are related to injuries sustained within the thoracic cage. A recently published study analyzed data from more than 2.5 million injured patients entered in the National Trauma Data Bank Research Data Set from 2012 to 2014. Patients with torso injury were identified utilizing Abbreviated Injury Scale (AIS) for body regions 4 (Thorax) and 5 (Abdomen). A cohort of 42,000 patients with thoracic injury was analyzed. The overall mortality rate of the study population with thoracic trauma was 7.9% (3326/42,135). Torso AIS and pre-hospital time were noted to be strong independent predictors of patient mortality in all population strata of the analysis ($P < 0.05$). The data demonstrated a profound incremental increase in mortality in the early time course after injury associated with torso AIS ≥4. The authors of this particular study conclude, "Our data highlight the critical nature of pre-hospital time in patients with non-compressible torso hemorrhage. However, realizing that evacuation times ≤30 minutes may not be realistic, particularly in rural or austere environments, future efforts should be directed toward the development of therapies to increase the window of survival in the pre-hospital environment." The concept of a "golden hour" following trauma is

widely attributed to R. Adams Cowley, founder of Baltimore's Shock Trauma Institute, who in 1975 stated "the first hour after injury will largely determine a critically injured person's chances for survival." Based on these data, patients with severe hemorrhage from significant thoracic injuries likely have far less than a 60-minute window for definitive therapy before their outcome and survival are compromised.

ED thoracotomy is a dramatic, last-ditch effort to save the life of a patient in extremis due to a chest injury. As mentioned in this chapter, ED thoracotomy is most likely to lead to survival in patients with penetrating thoracic injuries (stab wound > gunshot wound) and signs of life upon presentation to the ED. The American College of Surgeons Committee on Trauma indications for ED thoracotomy include precordial wound in a patient with pre-hospital cardiac arrest, a trauma patient with cardiac arrest after arrival to the ED, or a patient with a truncal wound who is either unconscious or an operating room is unavailable. Relative indications include penetrating thoracic injury with traumatic arrest without previously witnessed cardiac activity, penetrating non-thoracic injury with traumatic arrest with previously witnessed cardiac activity, and blunt thoracic injuries with traumatic arrest with previously witnessed cardiac activity. One recent review of ED thoracotomies performed in a busy urban trauma center identified 180 ED thoracotomies performed over a 6-year period. There were 23 patients who survived ED thoracotomy and hospitalization neurologically intact (12.8%). Over the 6-year study period, several patients survived ED thoracotomy neurologically intact until hospital discharge despite having poor outcome predictors, including multiple GSWs, abdominal exsanguination, asystole or agonal initial cardiac rhythm, unobtainable vital signs, and undetectable signs of life. Because of these issues, many believe that the decision to perform an ED thoracotomy should be made on a case-by-case basis due to exceptions and reported survivors who exceeded the above thresholds. I am not a trauma surgeon and I completed my residency in a medium-sized Midwestern town without a lot of penetrating trauma. I can remember the two ED thoracotomies I performed as a resident with incredible detail despite the fact that these both happened 20 years ago. ED thoracotomy is a dramatic, adrenaline-fueled experience. Surgeons who take care of trauma patients should familiarize themselves with the techniques and approaches to ED thoracotomy described in this chapter given the remote chance that this is necessary, and that a life could be saved as a result. One of the patients I cared for had a penetrating cardiac injury. Staples to the cardiac injury are described in this chapter. My patient had a large hole, and we chose to temporize and stop the exsanguination until a more definitive repair could be performed. We inserted a Foley catheter into the hole, inflated the balloon, and withdrew the catheter until the wound was occluded. If this technique is deployed, it is important to clamp the catheter to prevent exsanguination through the catheter itself. Although my patient with the penetrating cardiac injury did not survive, the Foley catheter did stop the exsanguination and allow us to place a very large

bore IV directly into the right atrium for rapid resuscitation once relative hemostasis from the cardiac wound was attained. A technical note—when incising the pericardium, it is important to avoid injury to the phrenic nerve. The phrenic nerve is a tendonlike structure and can be difficult to visualize in the ED. This is the rationale for the longitudinal pericardiotomy to relieve hemopericardium described in this chapter.

Flail chest results in paradoxical chest wall movement, altered respiratory mechanics, and frequent respiratory failure. Despite advances in ventilator management, flail chest remains associated with significant morbidity and mortality. Operative fixation of the flail segment has been advocated as an adjunct to supportive care. A recently published systematic review and meta-analysis identified nine studies with a total of 538 patients who met inclusion criteria. Compared with control treatment, operative management of flail chest was associated with shorter duration of mechanical ventilation (pooled Effect Size: -4.52 days; 95% confidence interval [CI]: –5.54 to –3.50), intensive care unit length of stay (-3.40 days; 95% CI: –6.01 to –0.79), hospital length of stay (–3.82 days; 95% CI: –7.12 to –0.54), and decreased mortality (pooled Relative Risk: 0.44; 95% CI: 0.28 to 0.69), pneumonia (0.45; 95% CI: 0.30 to 0.69), and tracheostomy (0.25; 95% CI: 0.13 to 0.47). The authors of this study felt that although their findings suggest that operative management of flail chest is associated with significant effects on patient morbidity, mortality, and resource expenditure, that prospective evaluation is still required to determine optimal patient selection, timing, and surgical technique. Time to surgical stabilization in the nine studies included in this analysis varied from <24 hours to >8 days after admission. Multiple techniques were described in the included studies, including metal plates, absorbable plates, and intramedullary fixation. Several studies included patients undergoing fixation with multiple different techniques, and only three reported complications. There may be an optimal technique and fixation device for these injuries, and further study is needed. Current practice varies widely by institution, and opinions regarding the optimal patients and timing of intervention vary. A 2009 survey revealed that one third of surveyed surgeons reported that operative management of flail chest was indicated after failure to wean from mechanical ventilation in 7 days. Another 29% felt that operative management of flail chest was indicated after failure to wean in 14 days. Only 8% felt operative management of flail chest was indicated in patients who did not require mechanical ventilation.

Retained hemothorax is a potentially morbid outcome of traumatic hemothorax requiring tube thoracostomy. The exact incidence of retained hemothorax is difficult to define. Most studies use an estimated volume of 500 mL, the amount of retained blood that can be seen on a plain x-ray, as the threshold for defining and possibly intervening on a retained hemothorax. In one study of 328 patients with retained hemothorax from 20 trauma centers, the rates of empyema and pneumonia in retained hemothorax were 26.8% and 19.5%, respectively. Video-assisted thoracoscopic surgery (VATS) was the

most commonly used initial procedure in 33.5% of these patients, but 26.5% required two and 5.4% required three procedures to clear retained hemothorax or subsequent empyema. Thoracotomy was ultimately required in 20.4%. The strongest independent predictor of successful observation was estimated volume of retained hemothorax ≤300 mL. No relationship between timing of VATS and success rate was identified.

A 2011 guideline published by the Eastern Association for the Surgery of Trauma (EAST) on the management of hemothorax and occult pneumothorax describes current recommendations. With regard to management of hemothorax, attempt of initial drainage of hemothorax should be with a tube thoracostomy. Persistent retained hemothorax, seen on plain films, after placement of a thoracostomy tube should be treated with early VATS, not a second chest tube. A referenced prospective randomized trial demonstrated that patients who had retained hemothorax on plain films 72 hours after initial chest tube output benefited from early VATS instead of a second chest tube. Patients undergoing VATS had significantly shorter duration of chest tube drainage, fewer days in the hospital after the procedure, and lower hospital costs than putting in a second chest tube. In addition, 10 of the 24 patients who underwent a second chest tube required surgical intervention later in their hospital stay. EAST guidelines on retained hemothorax also recommend early VATS, done in the first 3 days to 7 days of hospitalization to decrease the risk of infection and conversion to thoracotomy. Intrapleural thrombolytic may be used to improve drainage of subacute (6- to 13-day duration) loculated or exudative collections, particularly in patients where risks of thoracotomy are significant. A randomized controlled trial designed to compare intrapleural streptokinase instillation to VATS in retained hemothorax enrolled 48 patients. Retained hemothorax resolved equally well in both study groups (72% VATS, 71% streptokinase) with no difference in morbidity.

This is an excellent chapter by Drs. Hoth and Meredith on thoracic trauma. An exceptional level of detail is provided along with a nice description about when to operate and when not to. When there are multiple possible thoracic injuries, the importance of selecting the right approach is appropriately emphasized and outlined. Surgeons who participate in the care of injured patients should be intimately familiar with the information presented in this chapter.

62 Pulmonary Resection

Bryan M. Burt, Shawn S. Groth, and David J. Sugarbaker

HISTORY

The evolution of thoracic surgery parallels the development of endotracheal anesthesia and selective lung ventilation. These techniques permit safe operations to be performed in an open thoracic cavity. Pulmonary surgery has grown in scope and complexity from the simple management of pleural space infections and crude two-stage lobectomies for bronchiectasis via a thoracotomy in the early 1900s to formal anatomical resections for lung cancer via a video-assisted thoracic surgery (VATS) or robot-assisted approach in the present era.

After Dr. Graham successfully performed a pneumonectomy, pneumonectomy became the initial standard of care for all lung cancer patients. Since then, pulmonary resection techniques have gradually evolved. Building on the techniques learned from the treatment of bronchiectasis, Brunn, Blades and Kent, and Churchill developed the techniques for performing lobectomy for lung cancer. In the 1950s, when Churchill and colleagues demonstrated long-term survival after lobectomy for patients with early-stage peripheral lung cancer, lobectomy became widely accepted as the new standard of care. As the surgical techniques and the understanding of pulmonary anatomy improved, anatomic sublobar resection (segmentectomy) emerged. Ever since Jensik and colleagues reported a favorable survival rate in patients with stage I non–small cell lung cancer (NSCLC) undergoing segmentectomy for curative intent, controversy has existed regarding whether lobectomy or segmentectomy is the more appropriate operation for treating early-stage lung cancer, especially in patients who have small peripheral tumors or who are older. Nonetheless, the only published randomized controlled trial that has addressed this topic demonstrated higher local recurrence rates and lower survival rates for patients undergoing sublobar resection (nonanatomic wedge resection or anatomic segmental resection) as compared to lobectomy for stage I NSCLC. Since then, lobectomy and mediastinal lymph node dissection or sampling has remained the standard

of care for early-stage NSCLC. In the 1990s, as experience in minimally invasive techniques evolved, VATS and robot-assisted pulmonary resections for lung cancer emerged.

EPIDEMIOLOGY

Current estimates indicate that by 2017, there will be 222,500 new cases of and 155,870 deaths from lung cancer in the United States. The single most important risk factor for developing lung cancer is smoking, followed by radon and asbestos exposure. The risk for lung cancer is 10-fold higher for smokers than for lifetime nonsmokers (defined as a person who has smoked <100 cigarettes in their lifetime). The risk increases with the quantity of cigarettes, duration of smoking, and starting age. Smoking cessation results in a decrease in precancerous lesions and a reduction in the risk of developing lung cancer.

Lung cancer continues to be the leading cause of cancer-related mortality in this country. The 1- and 5-year relative survival rates for lung cancer are 44% and 17%, respectively. Only 15% of lung cancer patients are diagnosed at an early stage (I or II); 5-year survival rate for such patients is 54%. Greater than half of lung cancer patients (57%) are diagnosed with stage IV disease; the 1-year (26%) and 5-year (4%) survival rates are poor.

Lung cancer is divided into two major histologic groups: small cell lung cancer (SCLC) and NSCLC. NSCLC is more common (85% to 95% of new cases) than SCLC (10% to 15% of new cases) in the United States. There are three major NSCLC subtypes: squamous cell carcinoma (25% to 30% of all lung cancers), adenocarcinoma (40% of all lung cancers), and large cell (undifferentiated) carcinoma (10% to 15% of all lung cancers). In 2011, the International Association for the Study of Lung Cancer (IASLC), American Thoracic Society (ATS), and the European Respiratory Society (ERS), proposed a revised classification system for lung adenocarcinoma. A major contribution of this system is the parsing of lung adenocarcinomas into prognostic categories based upon the extent of pathologic tumor invasion. The term bronchioloalveolar carcinoma (BAC) is no longer used. Tumors previously classified as BAC would likely fall into one of three categories: adenocarcinoma in situ (AIS) which is a ≤3-cm lesion with lepidic growth and no invasive component, minimally invasive adenocarcinoma (MIA), which is a ≤3-cm lesion with lepidic growth and ≤5 mm of invasion, and lepidic predominant adenocarcinoma,

which demonstrates predominantly lepidic growth and >5 mm of invasion. AIS and MIA typically have significantly decreased frequencies of lymphatic spread and significantly improved recurrence-free and overall survival in comparison with other lung adenocarcinomas.

The 5-year survival from SCLC (6%) is significantly lower than from NSCLC (21%). Left untreated, SCLC has a median survival of 2 to 4 months. Although the standard of care for early-stage NSCLC patients is pulmonary resection, the treatment of SCLC is generally nonsurgical (with chemoradiation therapy). Nevertheless, SCLC is responsive to systemic chemotherapy with a median survival approaching 18 to 36 months.

In an effort to detect lung cancers at an earlier stage and improve cancer-specific survival rates, a number of screening trials have emerged. The National Lung Screening Trial (NSLT) reported that annual screening over 3 years with low-dose helical computed tomography (CT) in patients at high risk for lung cancer was associated with a 20% relative reduction in lung cancer mortality. Inclusion criteria for this trial included patients aged 55 to 74 years, 30 or more pack-years of smoking, and former smokers who quit within the previous 15 years.

STAGING OF NSCLC

The seventh edition of the lung cancer stage classification system was adopted in the United States on January 1, 2010. Having an accurate and reproducible staging system is critical for defining prognostic subgroups, planning treatment strategies, and analyzing the results of clinical trials. The Union for International Cancer Control (UICC) and the American Joint Committee on Cancer (AJCC) are the organizations that periodically review, refine, and define the stage classification systems. The TNM Classification of Malignant Tumors (TNM) stage classification system was developed to enable classification of tumor extension (TX to 4), nodal involvement (NX to 3), and distant metastatic spread (M0 to 1a,b).

TABLE 62.1 T, N, M Descriptors for the International Lung Cancer Staging System

T: Primary tumor	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washing but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 3 cm or less without invasion of visceral pleura
T1a	Tumor 2 cm or less in greatest dimension
T1b	Tumor more than 2 cm but not more than 3 cm in greatest dimension
T2	Tumor more than 3 cm but not more than 7 cm; or tumor with any of the following features; involves main bronchus, 2 cm or more distal to the carina; invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor more than 3 cm but not more than 5 cm in greatest dimension
T2b	Tumor more than 5 cm but not more than 7 cm in greatest dimension
T3	Tumor more than 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus less than 2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe as the primary
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe to that of the primary
N: Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M: Distant metastases	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural or pericardial effusion
M1b	Distant metastasis

The most recent seventh edition of the International Lung Cancer Staging system is shown in Table 62.1. The two most common types of stage assessment are *clinical staging* (determined by using all the information available for pretreatment) and *pathologic staging* (determined after resection). Clinical stage is denoted by the prefix "c,"

and pathologic stage by the prefix “p.” Several important points regarding the seventh edition staging system deserve mention. While the *T* descriptor definitions maintain a size threshold of 3 cm as the cut point between a T1 and a T2 tumor, several new cut points have been identified at 2, 5, and 7 cm. Tumors >7 cm in size are classified as T3, since they have a survival rate similar to other T3 tumors characterized by invasion or central location. Another modification of the seventh edition is related to additional tumor nodules. Patients with additional satellite nodules *in the same lobe* as the primary tumor have survival rates similar to T3 and now are classified as $T3_{satell}$, where previously they were classified as T4. Patients with an ipsilateral nodule *in a different lobe* are classified as $T4_{IpisNod}$ or simply T4; they were previously classified as M1. The *N* descriptor categorization (i.e., N0, N1, N2, and N3) has not changed. The number of involved nodal zones does appear to have prognostic impact. Patients with single-zone N1 or N2 involvement have better survival than those with multizone N1 and N2 involvement (5-year survival rate of 48% vs. 35%, $P < 0.09$, and 34% vs. 20%, $P < 0.001$, respectively). Finally, after the above modifications, the cohorts remaining in the M descriptor were separated into two distinct prognostic groups. Patients with pleural dissemination are now classified as M1a, as their prognosis is statistically significantly worse than T4. M1a is reserved for patients with either pleural dissemination or contralateral pulmonary nodules. The M1b subgroup is reserved for distant metastases.

TABLE 62.2 Stage Groups According to TNM Descriptor and Subgroups

T/M	Subgroups	N0	N1	N2	N3
T1	T1a	IA	IIA	IIIA	IIIB
	T1b	IA	IIA	IIIA	IIIB
T2	T2a	IB	IIA	IIIA	IIIB
	T2b	IIA	IIB	IIIA	IIIB
T3	T3>7	IIB	IIIA	IIIA	IIIB
	$T3_{Inv}$	IIB	IIIA	IIIA	IIIB
	$T3_{Satell}$	IIB	IIIA	IIIA	IIIB
T4	$T4_{Inv}$	IIIA	IIIA	IIIB	
	$T4_{IpslNod}$	IIIA	IIIA	IIIB	
				IIIB	
				IIIB	
M1	$M1a_{ContrNod}$	IV	IV	IV	IV
	$M1a_{PlDissem}$	IV	IV	IV	IV

The revised TNM associations with corresponding stage groupings are shown in Table 62.2.

Noninvasive Staging

A standard posteroanterior and lateral chest radiograph can reveal discrete mass lesions as well as atelectasis and postobstructive pneumonia due to the presence of endobronchial tumors. Hilar and mediastinal adenopathy, along with pleural effusion, might also be noted. Chest CT is performed to evaluate surgical anatomy and assess for mediastinal and hilar lymphadenopathy, liver metastasis, and adrenal metastasis. The median sensitivity and specificity of CT scanning for identifying mediastinal lymph node metastasis are 55% and 85%, respectively. A lymph node is considered malignant when its shortest axis is at least 10 mm. The presence of pleural effusion, unresectable T4 tumors, and contralateral nodal involvement can be suggested by chest CT scan.

Positron emission tomography (PET) relies on the uptake and concentration of ^{18}F-2-fluorodeoxyglucose (FDG) in lung cancer cells. It is more sensitive and specific (approximately 90% sensitive and specific) for mediastinal nodal metastases than CT. Most importantly, the negative predictive value of PET CT is 93% to 94% for the detection of mediastinal nodal metastases. The four most common sites of distant NSCLC metastases (stage IV disease) are the brain, bone, liver, and adrenal glands,

and PET CT is also fairly sensitive in detecting metastatic disease (except the brain). PET has an overall sensitivity of 96% (range, 83% to 100%), specificity of 79% (range, 52% to 100%), and accuracy of 91% (range, 86% to 100%). False-negative results can occur in lesions smaller than 1 cm because a critical mass of metabolically active malignant cells is required for PET diagnosis. False negatives may also occur in tumors with a low metabolism, like carcinoid tumors, AIS, and MIA. False-positive FDG uptake is seen in inflammatory conditions, such as bacterial pneumonia, pyogenic abscesses, and aspergillosis; and in granulomatous diseases, such as tuberculosis, sarcoidosis, histoplasmosis, Wegener granulomatosis, and coal miner's lung. In these lesions the FDG uptake has been attributed to granulocyte and/or macrophage activity.

Because of the high rate of glucose metabolism by the brain, PET CT cannot accurately identify brain metastases. For this reason, brain MRI is recommended for patients with stage II, III, and IV diseases to rule out asymptomatic brain metastases if aggressive multimodality therapy is being considered. In the absence of central nervous or bony symptoms in patients presenting with small tumors, the incidence of a true positive finding will be less than 10%. If these sites are excluded, the disease is confined to the chest (stages I to IIIB).

Invasive Staging

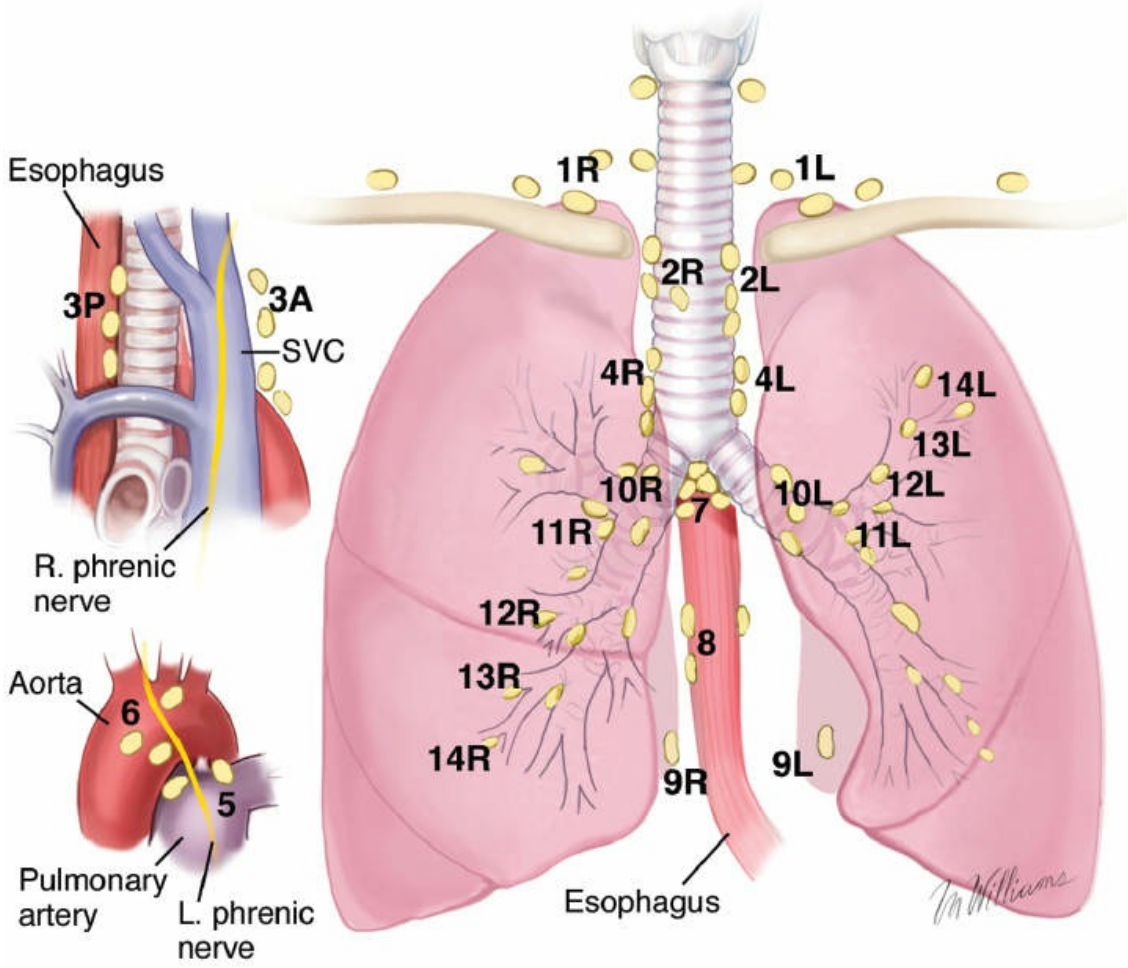
Nearly half of patients with lung cancer have mediastinal disease at diagnosis, and these patients have significantly worse prognosis. Metastases to ipsilateral or subcarinal lymph nodes (N2) are classified as stage IIIA disease. Many centers treat patients with IIIA disease with multimodality therapy including radiation and chemotherapy, reserving surgery for selected patients with single-station N2 disease and for investigational protocols. Metastasis to contralateral mediastinal lymph nodes (N3) is classified as stage IIIB disease. The 5-year survival of patients with IIIB disease is <5%, and these patients are generally offered treatment with chemotherapy alone. Selected patients with T4 disease (direct mediastinal invasion) without mediastinal lymph node metastases are surgical candidates. Thus, accurate pretreatment staging of the mediastinum is critical for treatment and prognostic implications. Given the limitations of CT and PET CT, histologic confirmation of radiographic findings is often required.

Invasive methods of mediastinal nodal staging include cervical

mediastinoscopy, anterior mediastinoscopy (Chamberlain procedure), endobronchial ultrasound (EBUS) with transbronchial nodal aspiration (TBNA), endoscopic ultrasound (EUS) with TBNA and VATS. In the absence of M1 extrathoracic disease, a PET CT showing hypermetabolism in the mediastinum requires pathologic confirmation. At the time of this writing, invasive staging of the mediastinum in patients with early-stage disease (stages I and II) is recommended by the National Comprehensive Cancer Network (NCCN). Based upon a recent prospective trial of early-stage lung cancer patients, we suspect that these recommendations may be altered in the next version of the NCCN guidelines. In this trial, 90 patients with clinical stage T2N0 or T1N0 with standardized uptake value greater than 10 by PET underwent routine cervical mediastinoscopy before lung resection, and only 1 patient (1.1%) had occult metastases detected at mediastinoscopy suggesting that invasive staging of the mediastinum may have limited utility in certain patients with PET negative mediastinums who are being considered for lung cancer resection. The incidence of N2 disease is 18% to 24% in patients with cN1 disease and these patients should undergo invasive mediastinal staging.

Bronchoscopy

Before thoracotomy is performed, the surgeon should perform flexible fiberoptic bronchoscopy to evaluate for anatomic abnormalities, endobronchial tumor extent, and previously undetected lesions. Bronchoscopy is often performed at the time of invasive mediastinal staging.



Supraclavicular Nodes
1 Low cervical, supraclavicular and sternal notch

Superior Mediastinal Nodes
2 Upper paratracheal
3 Prevascular and retrotracheal
4 Lower paratracheal

Aortic Nodes
5 Sub-aortic (AP window)
6 Para-aortic (ascending aorta or phrenic)

Inferior Mediastinal Nodes
7 Subcarinal
8 Paraesophageal (below carina)
9 Pulmonary ligament

N_1 Nodes

Figure 62.1. Lymph node stations in accordance with the IASLC.

Cervical Mediastinoscopy

Intrathoracic lymph nodes are divided into anatomic stations (Fig. 62.1). Mediastinal nodal stations are generally described as single digit nodal

stations, and hilar and parenchymal nodal stations are described using double digits. Cervical mediastinoscopy is a surgical sampling of the mediastinum that can access upper paratracheal nodal stations (2L and 2R), lower paratracheal nodal stations (2L and 4R), and the subcarinal nodal station. An adaptation of this procedure, called extended cervical mediastinoscopy (ECM), can reach the aortopulmonary (AP) window and paraaortic nodal stations on the left side, but this procedure has not been widely accepted into clinical practice.

Cervical mediastinoscopy is performed by positioning the patient supine with the neck fully extended. A small transverse incision is made one fingerbreadth above the sternal notch, and the tissue planes are dissected between the strap muscles down to the pretracheal fascia (Fig. 62.2). This plane is entered, and finger dissection is used to develop a plane along the anterior surface of the trachea posterior to the innominate artery down to the aortic arch (Fig. 62.3). Nodes cranial to the innominate vessels are termed *level 2 nodes.* Nodes caudad to the innominate artery are termed *level 4 nodes.* Subcarinal nodes are level 7. On the left, care is taken to identify and preserve the left recurrent laryngeal nerve as it courses medially to reach the tracheoesophageal groove. Cautery is generally avoided on the left side of the trachea to avoid injury to the nerve. Further dissection along each mainstem bronchus permits the surgeon to sample the tracheobronchial angle (level 4) nodes bilaterally.

Cervical mediastinoscopy is a safe procedure with mortality rates <0.1% and complication rates <1%, including paresis of the left laryngeal recurrent nerve, pneumothorax, pneumonia, injury to the azygos vein, perforation of the esophagus, mediastinitis, and hemorrhage. Bleeding is usually minor and can be controlled with packing. Major bleeding can be controlled with packing only, while one is getting ready to open the chest. Bleeding from major vessels, for example, superior vena cava, azygos vein, brachiocephalic artery, aortic arch, and pulmonary artery, will require expeditious median sternotomy. Small pneumothoraces can occasionally be managed conservatively. A chest x-ray with a new pleural effusion indicates blood draining into the pleural space and one should not hesitate to place a chest tube for drainage. Tracheobronchial injuries can result in a dramatic subcutaneous emphysema or air leak. Most of these injuries are small and will require observation only, but large injuries will require primary repair. Small, contained esophageal leaks can be managed conservatively. Large injuries will require complex repair and

management, which is beyond the scope of this chapter.

Anterior Mediastinoscopy

Anterior mediastinoscopy can be performed to biopsy lesions in the anterior and superior mediastinum that are inaccessible by cervical mediastinoscopy. For NSCLC tumors originating in the left upper lobe, the mediastinal lymph node stations most frequently involved are the paraaortic arch (level 6) and AP window (level 5) nodes. These nodes are generally difficult to access through a standard cervical approach and can be accessed by anterior mediastinoscopy; alternatively, a left VATS may be performed. To perform anterior mediastinoscopy, the patient is placed in the supine position and a 2- to 3-cm incision is made in the second intercostal space on the left side (Fig. 62.4). The pectoral muscle fibers are split to expose the intercostal muscles, the pleura is identified and divided, and the mediastinum is entered. The dissection is carried down gingerly onto the aortic arch and AP window. The internal mammary vessels are identified and swept medially or can be ligated. The mediastinal pleura is swept away laterally and the mediastinoscope is introduced through this incision into the mediastinum. Level 5 and level 6 lymph nodes are sampled, and care is taken to avoid the use of electrocautery near the recurrent laryngeal nerve, which arises from the left vagus nerve and travels under the aortic arch medially to the ligamentum arteriosum.

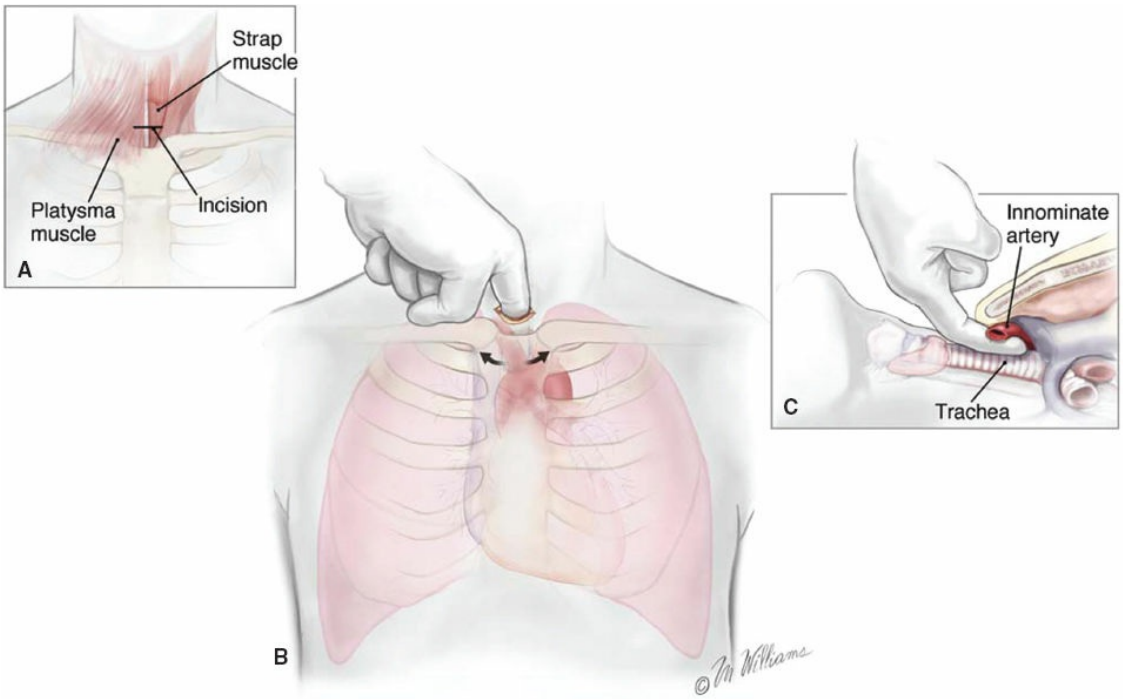

Figure 62.2. A. A 3-cm incision is made in the midline one

fingerbreadth above the sternal notch. **B.** Pretracheal plane fashioned with blunt dissection using the index finger. **C.** Dorsal aspect of the finger remains on the trachea while the volar aspect comes in contact with the innominate artery. Figure 62.3. The mediastinoscope is introduced into the pretracheal tunnel with constant traction anteriorly and a slow rotating motion during the dissection. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 61–2, p. 526.)

Thoracoscopy

Although cervical mediastinoscopy remains the procedure of choice,

especially for the higher mediastinal levels (2 and 4), in some situations cervical mediastinoscopy can be technically challenging (e.g., neoadjuvant chemoradiation and prior mediastinoscopy) or contraindicated (e.g., substernal goiters, previous laryngectomy, previous median sternotomy, aortic arch aneurysm, superior vena cava syndrome, or cervical spine disease that would preclude proper positioning). In such cases, thoracoscopic nodal sampling can be performed. Thoracoscopy can be used to sample stations 2R, 4R, 7, 8, and 9 for right-sided tumors and 5, 6, 7, 8, and 9 for left-sided tumors. In addition to evaluating N2 disease, thoracoscopy is particularly useful in ruling out unresectable T4 invasion in primary lung cancer and T3 invasion in high-risk patients.

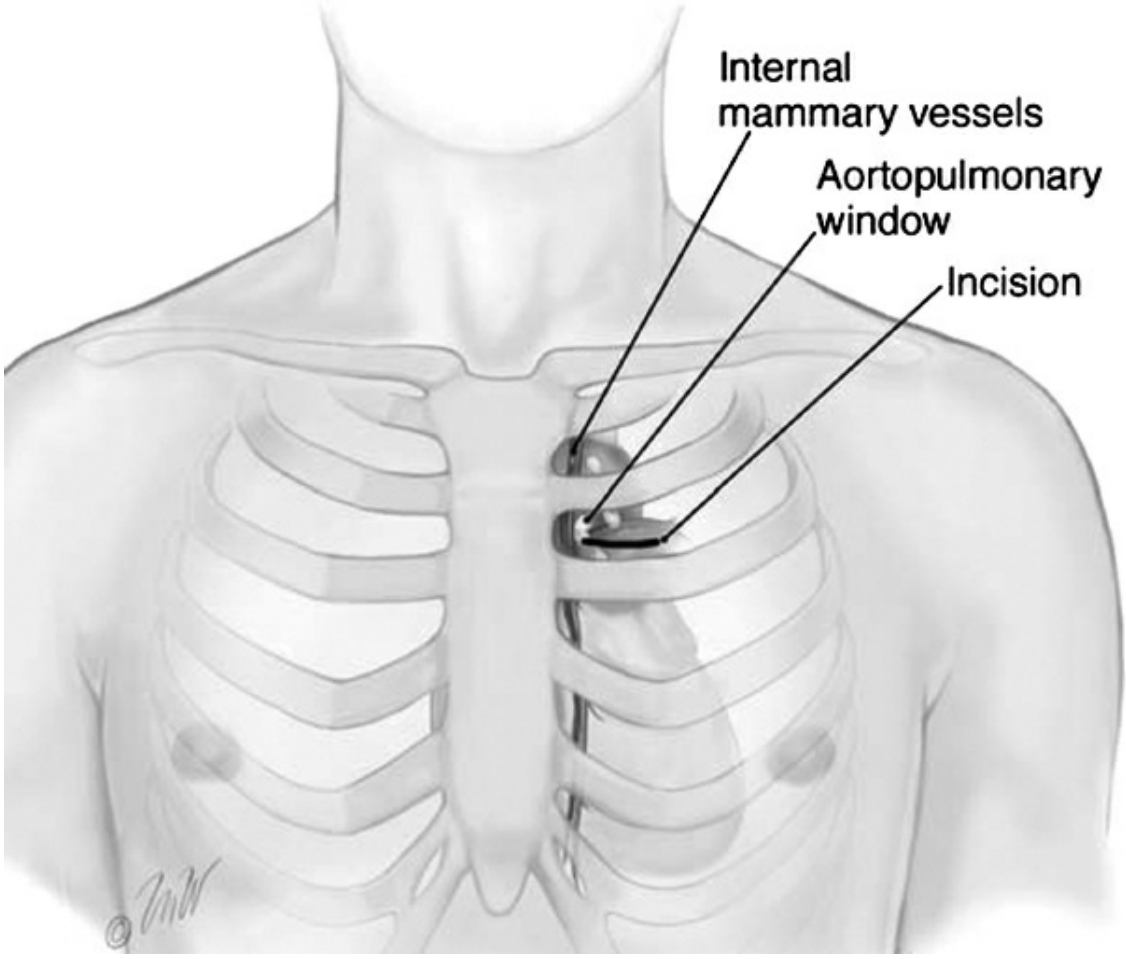

Figure 62.4. A classic 2-cm anterior mediastinotomy incision is made in the second intercostal space on the left side. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 132–6, p. 1105.)

Endobronchial Ultrasound

EBUS is a technique that uses a bronchoscope equipped with either a curvilinear (60 degrees) or radial scanning (360 degrees) ultrasound probe to visualize the airway wall and adjacent structures, including lymph nodes. EBUS-guided transbronchial needle aspiration biopsy (EBUS-TBNA) allows fine-needle aspiration of lymph nodes and other lesions adjacent to the airway under ultrasound guidance (Fig. 62.5), and this technique has been gaining popularity for invasive staging of the mediastinum in patients with NSCLC. EBUS-TBNA can sample nodal stations 2, 4, 7, 10, 11, and 13. It has sensitivity greater than 90% in the staging of NSCLC. The sensitivity of EBUS-TBNA appears similar to mediastinoscopy with enlarged nodes but lower or similar with normal-sized nodes. False-negative rates with EBUS-TBNA are higher than with mediastinoscopy, so nonmalignant EBUS results may be unreliable. False positives have been reported in cases of central squamous cell carcinomas where carcinoma in situ led to contamination of the TBNA needle.

There are scenarios in which EBUS is preferable to mediastinoscopy, including pathologic confirmation of a PET positive mediastinal node. However, for routine staging of the upper mediastinum in NSCLC, the benefits of EBUS over mediastinoscopy remain unproven.

Endoscopic Ultrasound

Transesophageal EUS scanning is an endoscopic technique that provides high-resolution imaging of the mediastinum by using high-frequency ultrasound probes attached to the tip of a flexible endoscope. It offers the additional facility of endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) or tru-cut biopsy (TCB) under real-time ultrasound guidance. This technique allows sampling of mediastinal nodal stations 4L, 7, 8, and 9 as well as some enlarged station 5 nodes.

PREOPERATIVE EVALUATION

Patients considered for pulmonary resection often have existing pulmonary disease, which places them at a higher risk for postoperative morbidity and mortality. The preoperative physiologic assessment of the patient being considered for lung resection should begin with a cardiovascular evaluation and spirometry. Forced expiratory volume in 1 second (FEV_1) and diffusing capacity for carbon monoxide (D_{LCO}) are the most commonly used pulmonary function tests, and their values are inversely correlated with postoperative mortality, respiratory failure, and other

complications following pulmonary resection. Both FEV_1 and D_{LCO} should be measured, and predicted postoperative FEV_1 ($ppoFEV_1$) and D_{LCO} ($ppoD_{LCO}$) should be calculated. These predicted postoperative values have been shown to have stronger correlations of postoperative risk than their parent values. For calculation of $ppoFEV_1$ and $ppoD_{LCO}$ in patients who will undergo lobectomy or sublobar resection (segmentectomy or wedge resection), the anatomic method may be used, in which the percentage of remaining lung is calculated based upon the number of remaining segments, and this percentage is multiplied against the preoperative FEV_1 or D_{LCO} values.

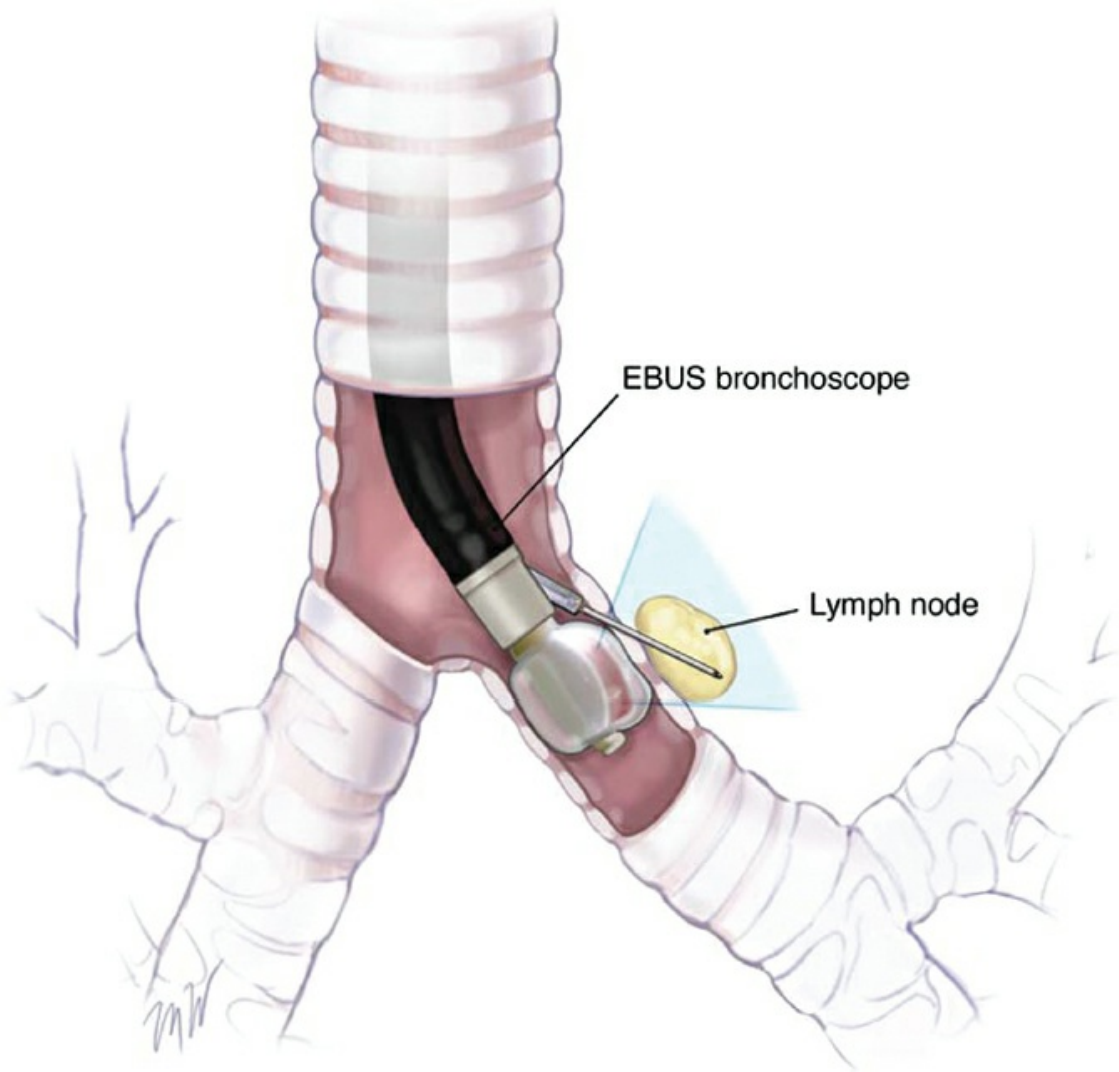

Figure 62.5. EUBS-TBNA. EBUS-guided TBNA procedure for sampling lymph node stations/lesions from the bronchi.

Anatomic Method

% Predicted postoperative FEV_1 = % preoperative FEV_1 − (preoperative FEV_1 × no. of segments to be removed/19), where 19 is the total number of segments in the normal lung.

For the calculation of these ppo values in patients undergoing pneumonectomy, the anatomic method loses accuracy, and a lung perfusion scan is required to calculate the ppo values.

The American College of Chest Physicians (ACCP) recommends that both ppoFEV_1% and ppoD_{LCO}% should be calculated in all patients being considered for lung resection, as it provides a useful preoperative risk stratification algorithm for patients being considered for lung resection. Patients with ppoFEV_1 and ppoD_{LCO} values both greater than 60% are considered at low risk for anatomic lung resection, and no further tests are indicated. Further preoperative risk stratification with a low technology exercise test (e.g., stair climb or shuttle walk test) is recommended for patients whose ppoFEV_1% or ppoD_{LCO}% is <60% predicted (but both above 30% predicted.) A formal cardiopulmonary exercise test is currently recommended for patients with a ppoFEV_1% or ppoD_{LCO}% of <30%.

With regard to ppoFEV_1 and ppoD_{LCO}, several preoperative scenarios deserve mention. An important consideration for risk stratification following pulmonary resection is whether a minimally invasive approach, which is associated with lower morbidity and mortality rate as compared with an open approach, can be offered and successfully accomplished. Moreover, it has been recently demonstrated that the decreased perioperative morbidity advantages of VATS lobectomy are amplified in patients with decreased pulmonary function, and this benefit further translates into decreased postoperative mortality rates for these patients. Patients with obstructed bronchi or nonfunctioning areas of lung can generally tolerate removal of that portion of lung, and these nonfunctioning segments should be accounted for when calculating ppoFEV_1 and ppoD_{LCO}. Patients with upper lobe predominant emphysema and upper lobe lesions may tolerate lung resection better than what would be anticipated based purely on the ppoFEV_1 and ppoD_{LCO} values, owing to the concomitant lung volume reduction benefits. Finally, for patients with small lung cancers and limited pulmonary function, sublobar resection can be performed in specialized centers in patients with very low FEV_1 and D_{LCO} with limited morbidity and mortality.

TREATMENT

The treatment of NSCLC depends upon clinical stage. Anatomic resection, namely lobectomy, is the current gold standard for patients with stage I NSCLC. Anatomic resection entails resection of an anatomic unit of the lung which encompasses all of the draining lymphovascular structures, that is, pneumonectomy, lobectomy, and segmentectomy. A wedge resection is performed to remove a portion of lung containing the lesion of interest and does not conform to an anatomic unit (e.g., a segment). It does not require separate dissection of the arterial supply, venous drainage, airway, and corresponding lymphatic drainage and lymph nodes. The benefit of anatomic resection is decreased local recurrence. For example, in the 1995 randomized trial of lobectomy versus limited resection of T1N0 NSCLC by the Lung Cancer Study Group, patients undergoing lobectomy indeed had decreased rates of local recurrence and a trend toward improved overall survival. To determine whether disease-free survival after sublobar resection (segmentectomy or wedge) is equivalent to that of a lobectomy for patients with small peripheral (≤2 cm) NSCLC, a randomized trial (CALGB 140503) is currently under way. For patients with small lung cancers who have limited pulmonary function, parenchymal-sparing sublobar resections (segmentectomy or wedge resection) can be offered. Similar results have been shown in patients undergoing anatomic sublobar resections (segmentectomy) compared with nonanatomic sublobar resections (wedge resections). For patients who are medically inoperable based upon comorbidities, stereotactic ablative radiotherapy (SABR) is a viable alternative.

Patients with stage II NSCLC are best treated with surgical resection followed by adjuvant chemotherapy, and adjuvant chemotherapy can also be considered in patients with stage IB tumors with high-risk features (size >4 cm, lymphovascular invasion, visceral pleura, invasion). Patients with stage IIIA disease are treated with multimodality therapy including neoadjuvant chemotherapy or chemoradiotherapy followed by surgery or by definitive chemoradiotherapy, depending upon patient and tumor characteristics. For example, patients with single station, nonbulky (<1 cm) N2 disease (IIIA) should be considered for neoadjuvant therapy followed by surgical resection, especially in the context of a clinical trial. Patients with multistation or bulky IIIA disease are probably best treated by definitive chemoradiotherapy. Resection of tumors with contralateral paratracheal nodal disease (IIIB) is generally contraindicated. Patients with

distant metastases (stage IV) are generally treated with systemic chemotherapy. Patients with resectable primary tumors and oligometastatic disease to the brain or adrenal gland may benefit from anatomic resection of the primary site and surgical or radiotherapy to the metastatic site.

ANESTHETIC CONSIDERATIONS

Optimal conditions for lung resection require lung isolation (i.e., deflation of the operative lung). This requires complete ventilatory support of the patient with the contralateral lung and can be achieved by one of two means. A double-lumen tube can be inserted into the trachea with its distal lumen in the long left main bronchus and the tracheal side port directed at the right main bronchus, known as a left-sided double-lumen tube. An inflatable cuff is present above each orifice, allowing for single-lung ventilation. Assurance of proper positioning requires the use of a small-gauge (pediatric) bronchoscope. In operations potentially involving the left main bronchus (left-sided sleeve resections or left pneumonectomy), a right-sided double-lumen tube may be used or a conventional endotracheal tube may be used and the ipsilateral main bronchus blocked with an inflatable “blocker.” Collapse of the lung depends on absorptive atelectasis and is generally longer with a blocker.

Proper perioperative pain control is essential for postoperative pulmonary toilet and to avoid mucous plugging, lobar atelectasis, and perioperative pneumonia. In patients undergoing thoracotomy, major lung resections, or even in patients with poor lung function undergoing lesser resections, effective pain control can mitigate perioperative respiratory complications. In these cases placement of a mid-thoracic-level epidural, tunneled catheter for continuous infusion of local anesthetic, or intercostal nerve blocks with long-acting (liposomal) bupivacaine should be considered. At the time of thoracotomy, dissection of a muscle flap in the interspace of interest and closure of the rib space by placing the sutures through (instead of around) the inferior rib results in improved pain control by avoiding strangulation of the intercostal nerve.

In patients with cardiac dysfunction, pulmonary hypertension, or when pneumonectomy is planned, central venous monitoring and access is often helpful. Arterial access is essential in patients with borderline lung function, and often helpful in any patient undergoing major pulmonary resection. Fluid administration should be judicious. Patients undergoing lobectomy, and especially patients undergoing pneumonectomy, should

receive less than 1,500 mL and, ideally, less than 1,000 mL, of fluid during the operation to minimize the risk of postoperative pulmonary edema.

PRINCIPLES OF PULMONARY RESECTION

Under general anesthesia, all patients undergo a flexible bronchoscopy to evaluate for synchronous endobronchial lesions and anatomic anomalies. For primary endobronchial lesions, a margin of at least 2 cm of grossly uninvolved mainstem bronchus is desired to ensure a curative resection. Second, prior to committing the patient to a thoracotomy, a thoracoscopic examination is performed and the chest cavity inspected for pleural and pericardial metastases, chest wall invasion, adhesions, and location of the lesion in relation to hilar structures as well as to determine the best location for entry into the chest. Once resectability has been established and the appropriate thoracotomy performed, the inferior pulmonary ligament is taken down and the hilum is opened, moving inferiorly to anteriorly and posteriorly, in a “Y”-shaped manner. Next, the major and minor fissures (right) are completed, exposing the pulmonary artery. Dissection in the interlobar fissures is performed carefully as this is the most common site of postoperative air leaks that prolong chest tube removal and hospital stay. Following resection, surgical margins are evaluated by frozen section and a thorough mediastinal lymph node dissection is performed.

Posterolateral Thoracotomy

A posterolateral thoracotomy can be employed for most open lung resections (Fig. 62.6). In this incision the latissimus dorsi muscle is divided, and the serratus anterior muscle is dissected from its underlying attachments and reflected anteriorly. The rib space of interest (typically 5 or 6 depending upon the planned resection) can be identified by counting the ribs by placing the hand beneath the scapula and counting down posteriorly from the first rib. The intercostal muscle is divided along its attachments to the inferior rib. A 2-cm segment of posterior rib can be divided with a rib cutter (“shingling”) to aid exposure and to avoid unintentional rib fracture that can result in chronic postoperative pain.

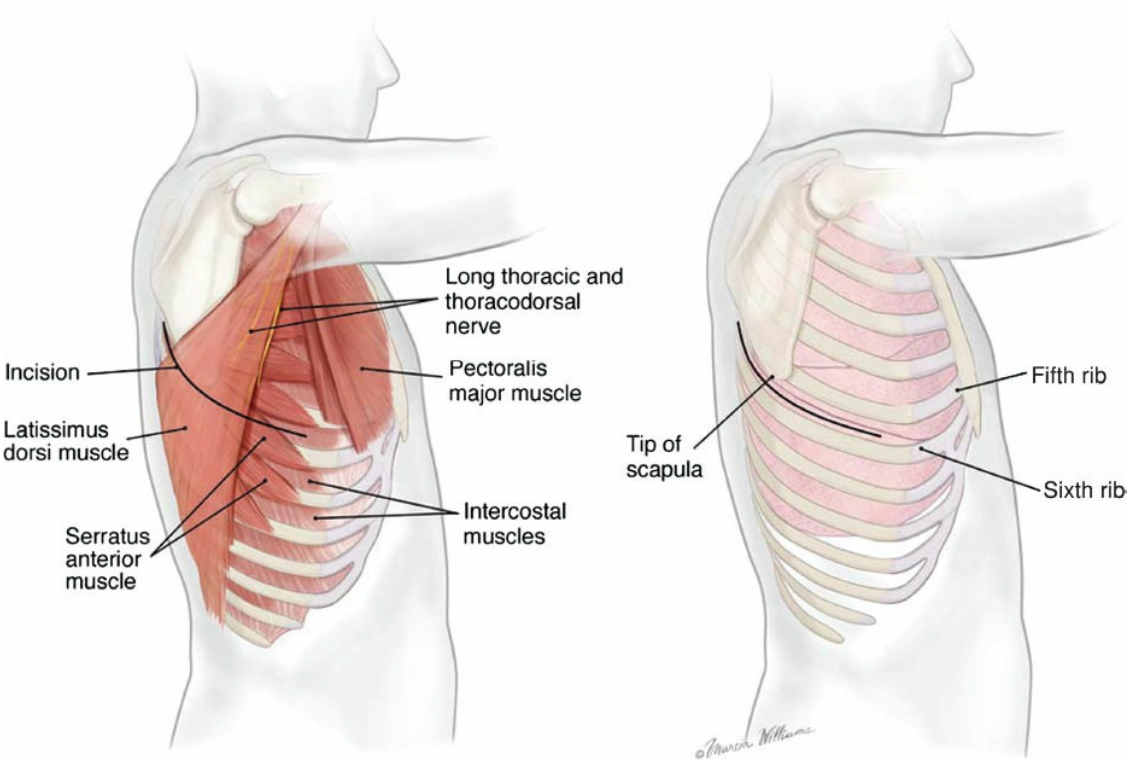

Figure 62.6. Standard posterolateral thoracotomy incision with extrathoracic musculature and surface landmarks. The incision wraps around the tip of the scapula and parallels the course of the sixth rib. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 2–1, p. 6.)

Handling of the Pulmonary Artery

The pulmonary artery is a thin-walled and delicate vessel, much more so than the pulmonary veins. Operative identification and dissection of the pulmonary artery requires meticulous technique to avoid injury, and an intimate understanding of the anatomy of the main pulmonary artery and its branches is necessary for the safe performance of any anatomic resection (Fig. 62.7). Tears in the pulmonary artery can spread in retrograde fashion, at times compromising circulation to the entire lung. The pulmonary artery is encircled by a connective tissue sheath. On entering this sheath, dissection along the vessel can be achieved by gently pushing the sheath away from the pulmonary artery with a blunt instrument such as a metal tip sucker or the curved tips of a Pearson type dissecting scissors. The pulmonary artery itself is never grasped; rather, the connective sheath is grasped and the artery distracted from the sheath. Gentle handling of the lobar branches is important to avoid avulsion of the orifice from the ongoing pulmonary artery. Small tears or dissections of

the artery can often be controlled with simple application of pressure for several minutes as the pulmonary artery circulation is a low pressure system. Otherwise, arteriotomies in the pulmonary artery can be closed with fine (5-0) Prolene. In cases of central tumors with elevated risks for pulmonary artery injury, or for cases suspected to require pulmonary arterioplasty, proximal control of the pulmonary artery at the main pulmonary artery can be obtained early in the case using a vessel loop and tourniquet, and distal control can be achieved in a similar fashion following appropriate dissection.

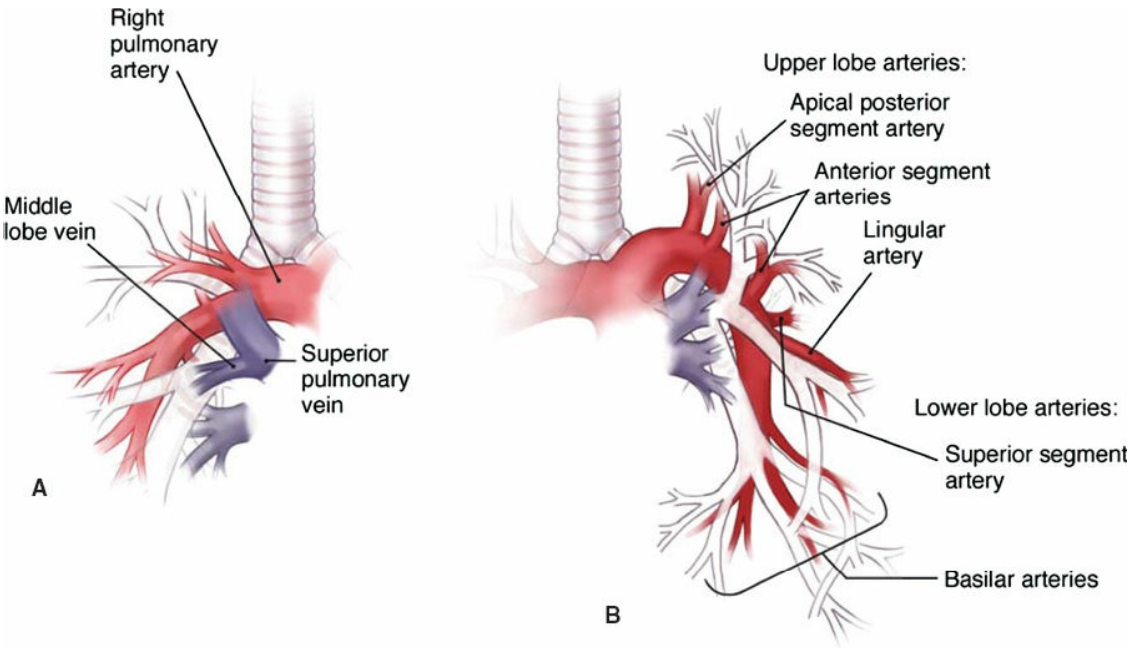

Figure 62.7. A. Right upper lobectomy, hilar exposure. If the superior vein lies anterior to the pulmonary artery, the middle lobe vein must be identified and preserved. **B.** Left upper lobectomy. Pulmonary arterial anatomy pertinent to left upper lobectomy, which can be approached anteriorly, superiorly, posteriorly, or inferiorly. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., A is from Figure 62–2, p. 533. B is from Figure 62–14, p. 538.)

Closure of the Bronchus

Anatomic pulmonary resection requires division of the bronchus which can be done using a surgical stapler or with suture closure, typically with absorbable (e.g., Vicryl) suture placed in a single interrupted fashion. Surgical staplers are often employed for this step of the case as these

devices will facilitate minimally invasive approaches to anatomic resection and are a generally reliable means of bronchus closure. The bronchus should be closed as flush as possible to the airway from which it arises to avoid pooling of secretions, which potentially may lead to stump breakdown. Before staple closure of the bronchus, it is a good practice to re-evaluate airway anatomy. This can be done by either insufflating the operative lung to ensure that there is no impingement on the adjacent airway, or by video bronchoscopy through the double-lumen tube with a pediatric bronchoscope (generally by the anesthesiologist) to assure the remaining airways are open. If the tumor is close to the orifice of the bronchus, then the bronchus is divided with a knife and is closed with interrupted 3-0 Vicryl sutures. After any closure, the bronchial stump should be tested for leaks under water and with 25 cm H_2O of pressure. Pneumonectomy stumps, bronchial sleeve anastomoses, and postirradiation stumps are typically covered with live tissue flaps including intercostal muscle, pleura or pericardium, and vascularized thymic or pericardial fat.

OPEN LOBECTOMY

Lobectomy is currently the gold standard oncologic resection for most cases of NSCLC. Lobectomy involves resection of the involved anatomic lobe of lung parenchyma as well as a thorough nodal dissection. In addition to N1 hilar, interlobar, and segmental draining lymph nodes, a complete mediastinal (N2) lymph node dissection is performed.

Right Upper Lobectomy

After positioning the patient in the left lateral decubitus position, the right chest is typically entered through a serratus-sparing, limited posterolateral thoracotomy through the fifth intercostal space. We routinely shingle the fifth rib posteriorly, removing a 2-cm portion of the rib posteriorly, to allow for atraumatic exposure when spreading the ribs. After inserting the chest retractor, the lung and pleural cavity are inspected for any evidence of pleural disease, and the tumor is identified with palpation. Next, the inferior pulmonary ligament is divided to permit mobility of the remaining lung to fill the apex of the pleural cavity. The oblique and horizontal fissures are examined to assess the need for further dissection. The sequence in dissection and ligation of the pulmonary artery and vein is generally based on the anatomic setting and convenience. The dissection

typically proceeds initially at the anterior hilum. The phrenic nerve is seen coursing over the superior vena cava. The mediastinal pleura is divided posterior to the nerve at its junction with the visceral pleura of the lung anteriorly. This dissection plane is carried superiorly and posteriorly after gently elevating the upper lobe anteriorly. Blunt dissection at the posterior hilum is performed to clarify the right mainstem bronchus and the upper lobe origin with the bronchus intermedius coursing distally. Dissection typically begins at the superior pulmonary vein, which includes the venous drainage of the upper and middle lobe. The veins draining the upper lobe are identified and ligated with a vascular stapler, and care is taken to spare the venous drainage of the middle lobe vein lying inferiorly (Fig. 62.8). Division of the vein from the upper lobe exposes the pulmonary artery, which lays superiorly and behind the vein. A thin layer of fatty and lymphatic tissue can be divided with electrocautery, exposing the main pulmonary artery. The sheath of the artery is gently grasped and divided with blunt scissors. The sheath is retracted and the length of the artery is dissected locating the first branch, the truncus anterior, which supplies the apical and anterior segments of the upper lobe. This branch is isolated and ligated first, using a vascular stapler or suture ligatures (Fig. 62.9).

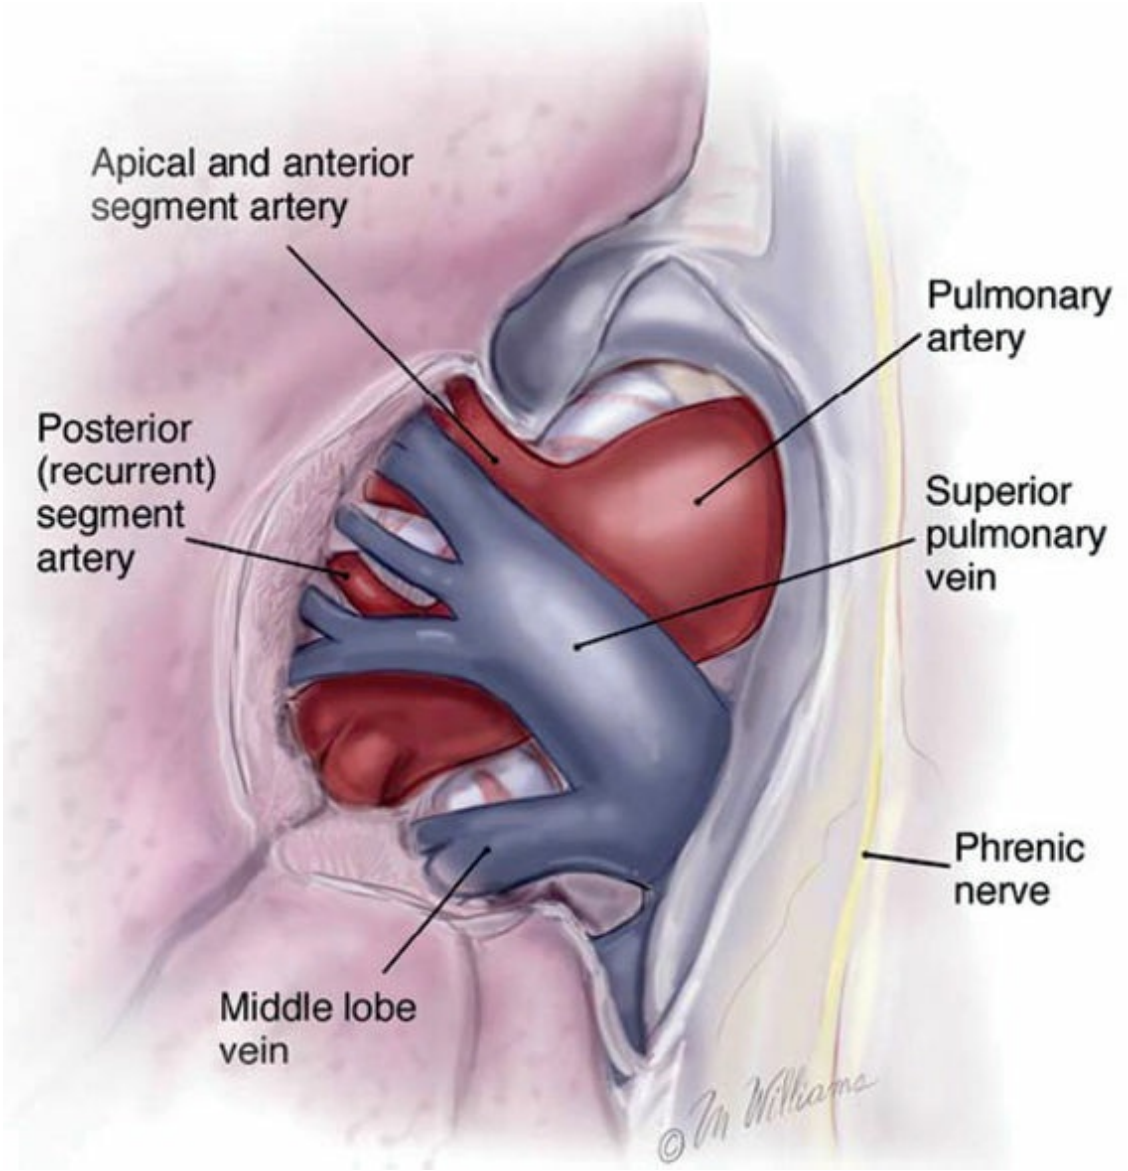

Figure 62.8. Right upper lobectomy, hilar exposure. If the superior vein lies anterior to the pulmonary artery, the middle lobe vein must be identified and preserved. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–3, p. 533.)

Next, division of the right upper lobe bronchus is performed by developing a plane around this lobar bronchus first with scissors and then with a finger. Peribronchial lymph nodes should be harvested both for staging and to allow for stapler placement and closure of the bronchus. The bronchus can be divided either with a heavy tissue (green) load stapler or with scissors or blade and closed with interrupted absorbable sutures (Fig. 62.9). The divided distal bronchus is then grasped with an Allis clamp and retracted inferiorly, exposing the ascending pulmonary artery

branch to the posterior segment of the upper lobe (sometimes termed the *recurrent branch*), which is suture-ligated and divided. This approach is termed the *posterior approach to the ascending branch.* This artery can also be approached anteriorly (with the lung retracted posteriorly) by dissecting distally along the pulmonary artery after division of the truncus anterior. A middle approach to the artery can be performed through dissection of the major fissure which can also further clarify the pulmonary artery anatomy (Fig. 62.10). The specimen is now attached only by its remaining fissures and parenchyma, which are divided with a stapler to provide an airtight resection. After removing the specimen, the bronchial staple line is tested under water for integrity. We do not routinely cover nondependent stumps. In cases where the minor fissure is complete, and the right middle lobe is at risk of torsion, we anchor the right middle lobe to the right lower lobe with a noncutting stapler. A single chest tube is inserted through the anterior inferior incision that was used for thoracoscopic exploration if performed before thoracotomy. The wound is closed after irrigation of the chest and assurance of hemostasis.

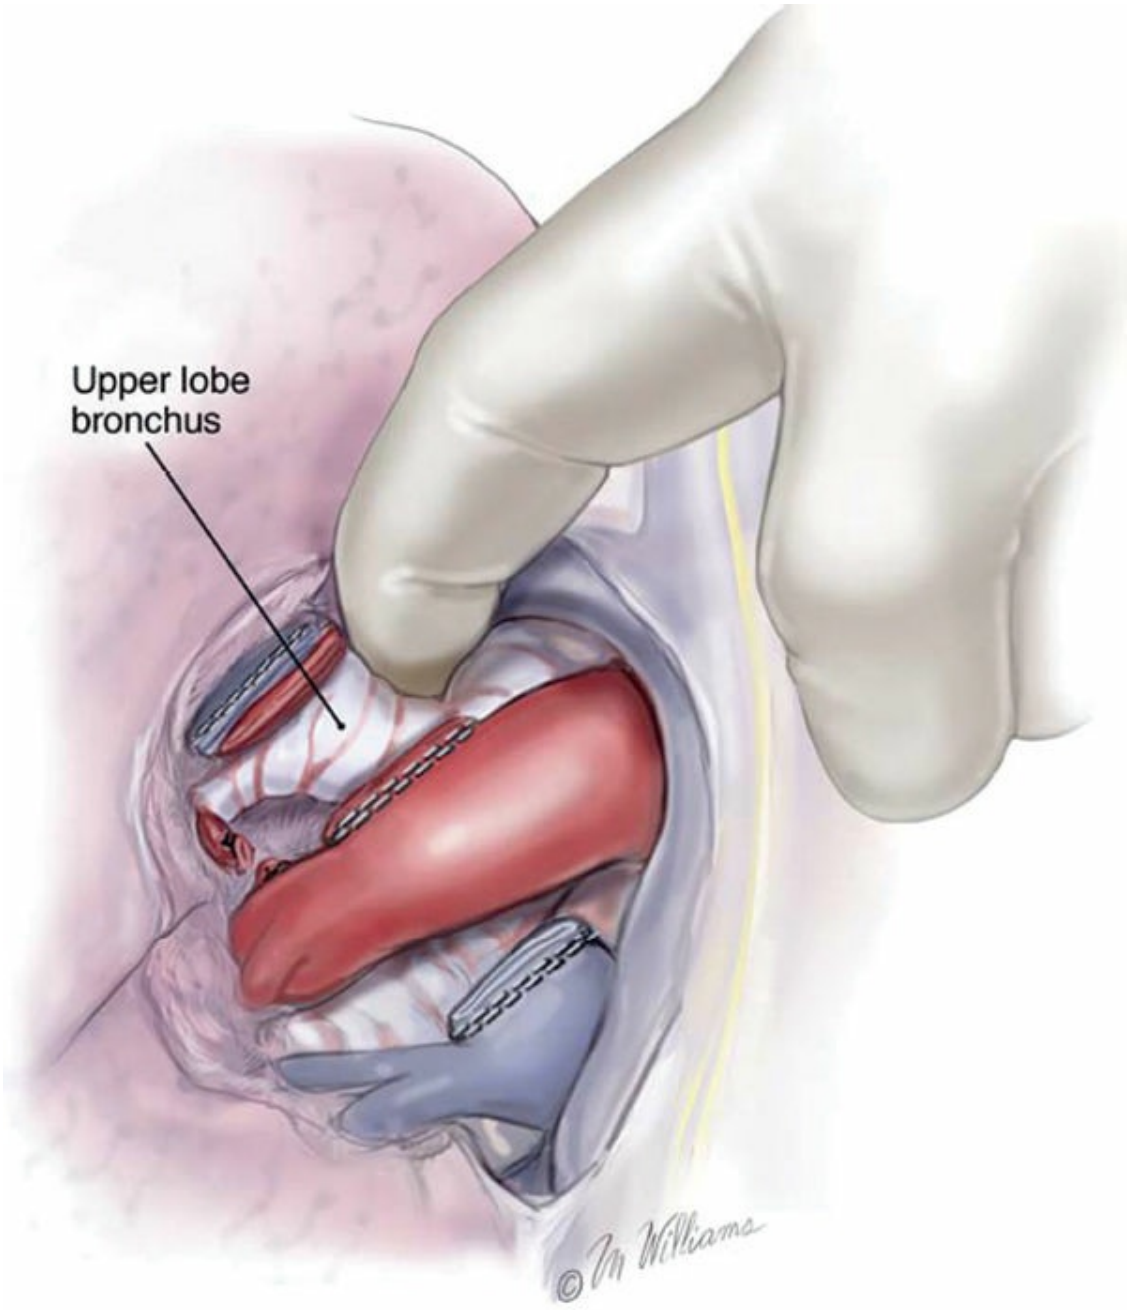

Figure 62.9. Right upper lobectomy. After the vasculature is controlled, the bronchus is resected. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–4, p. 534.)

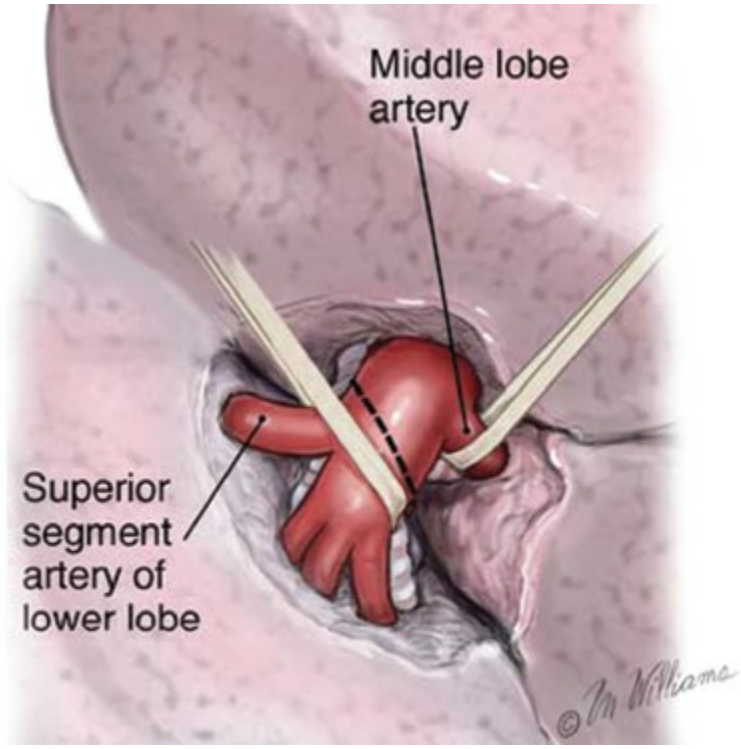

Figure 62.10. Right lower lobectomy. After identifying the middle lobe artery, which is preserved, the basilar segmental artery is encircled and divided. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–9, p. 536.)

Right Middle Lobectomy

To perform a right middle lobectomy, we prefer an anterolateral thoracotomy through the fifth interspace. The dissection begins in the oblique fissure at its intersection with the horizontal fissure. The visceral pleura is opened and the interlobar pulmonary artery is identified in the fissure. With gentle traction anteriorly on the middle lobe, one or two middle lobe arteries are identified and ligated. If necessary, the horizontal fissure is completed with a stapler. The vein from the middle lobe is identified in the anterior hilum most commonly draining into the superior pulmonary vein as described above and ligated. The bronchus to the middle lobe can be identified and divided from the fissure after dividing the middle lobe pulmonary artery or from the anterior hilum after dividing the middle lobe pulmonary vein. Not uncommonly, the right middle lobe is involved by a tumor in the upper or lower lobe, thereby requiring bilobectomy for complete resection.

A standard fifth intercostal space posterolateral thoracotomy is employed for bilobectomy. In the case of the right middle and lower

bilobectomy, the bronchus intermedius can be divided just distal to the upper lobe bronchus takeoff. In the setting of the right upper and middle bilobectomy, the bronchi are divided separately.

Right Lower Lobectomy

A fifth intercostal space posterolateral thoracotomy is performed. The completeness of the fissures determines the ease of exposure of the pulmonary arteries to the right lower lobe. Typically, for a right lower lobectomy, the first step after gaining entry into the chest is to retract the upper and middle lobes anteriorly and the lower lobe posteroinferiorly, spreading open the oblique fissure. Dissection of the visceral pleura reveals the interlobar pulmonary artery. Identification of the middle lobe artery anteromedially aids in the detection of the superior segmental artery posteriorly and opposite the middle lobe artery. The artery to the superior segment of the lower lobe and the arterial trunk to the basilar segments of the lower lobe are isolated and ligated either individually or together, depending upon the vascular anatomy (Fig. 62.10). The inferior pulmonary vein is approached posteriorly. The inferior pulmonary ligament is divided to the level of the lower border of the vein, and level 9 lymph nodes within the ligament are collected. Division of the mediastinal pleura posteriorly allows for clearance of the inferior pulmonary vein away from the lower border of the bronchus and the superior pulmonary vein (Fig. 62.11). After freeing the inferior pulmonary vein anteriorly, a clamp is passed to aid in the stapling of the vein with a vascular stapler. Before division, anomalous middle lobe venous drainage into the inferior pulmonary vein (occurring 5% to 10% of the time) should be ruled out. If the oblique fissure is incomplete, a stapler is applied to separate the middle lobe from the specimen. The lower lobe is now attached by only its bronchi. Care must be taken not to divide the lower lobe bronchus in such a way as to narrow the orifice of the middle lobe bronchus. Not uncommonly, it is safer to divide the superior segmental bronchus separately from the ongoing bronchus to the basal segments. After dividing these bronchi with the 30-mm stapler, we will often cover the dependent stumps of the lower lobe bronchi with vascularized pericardial fat or parietal pleura (Fig 62.11).

Left Upper Lobectomy

The chest is entered through a fifth interspace posterolateral thoracotomy. The hilum is approached anteriorly by gentle lateral and inferior retraction

of the left lung. The mediastinal pleura is incised over the pulmonary artery as it courses beneath the aortic arch. The phrenic nerve is identified anteromedially and the vagus nerve with its recurrent laryngeal branch is identified coursing below the aortic arch from the boundaries of the pleural dissection (Fig. 62.12). Working from the top of the fissure posteriorly with the upper lobe retracted superomedially and lateral reflection of the lower lobe, the interlobar left pulmonary artery is exposed. The most common anatomic variability encountered is the number of segmental pulmonary arterial branches to the upper lobe. Most commonly, four branches (i.e., apicoposterior, anterior, superior lingular, and inferior lingular), one to each of the segments, are present. However, between three and seven pulmonary artery branches may supply the left upper lobe and require identification and ligation (Fig. 62.13). The first branch (truncus branch) to left upper lobe can take off quite proximal on the left main pulmonary artery. Given the relatively shorter length of the left main pulmonary artery (compared with the right main pulmonary artery) to the main pulmonary artery originating from the right ventricle, injury to the truncus branch of the left pulmonary artery can be a treacherous proximal pulmonary artery injury. Great care must be taken in identifying and dividing the truncus branch, and an approach from the anterior hilum can facilitate the approach to this branch. After arterial ligation is complete, attention is shifted to circumferential isolation of the upper lobe bronchus, which is carefully freed from the posterior surface of the superior pulmonary vein. The stapling device is used to divide the bronchus, and the superior vein is then exposed for similar ligation with a vascular stapling device.

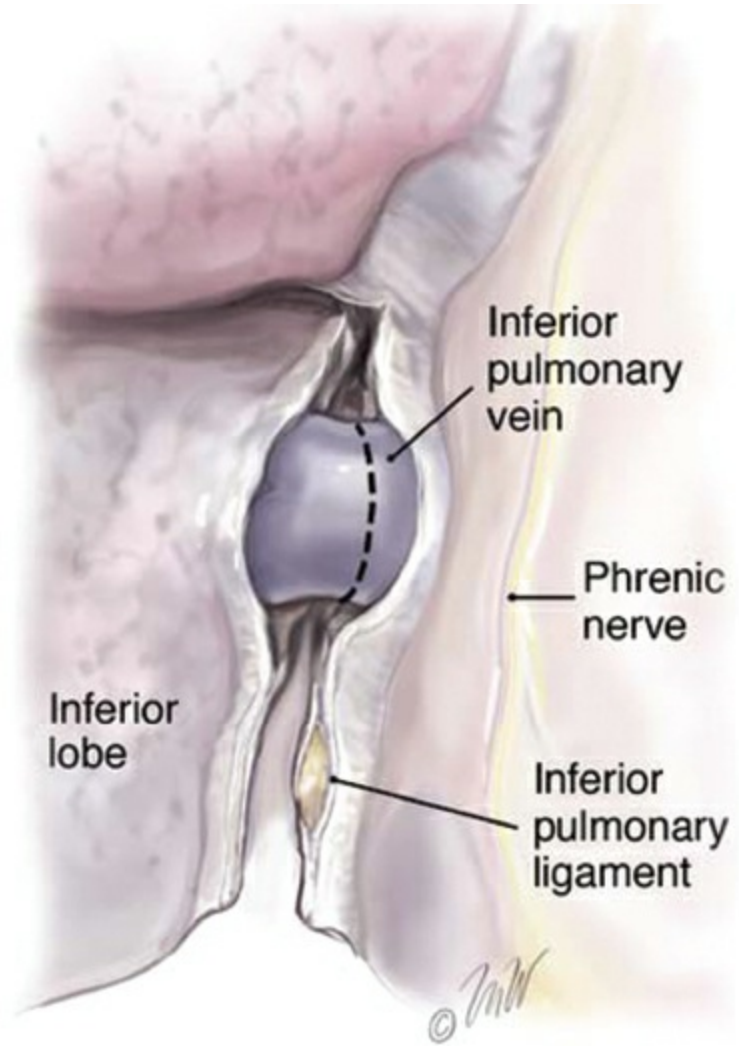

Figure 62.11. Right lower lobectomy. The inferior pulmonary ligament is taken down, with caution to avoid injury to the phrenic nerve, to expose the inferior pulmonary vein. This vein is encircled and divided or clamped and oversewn. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–10, p. 537.)

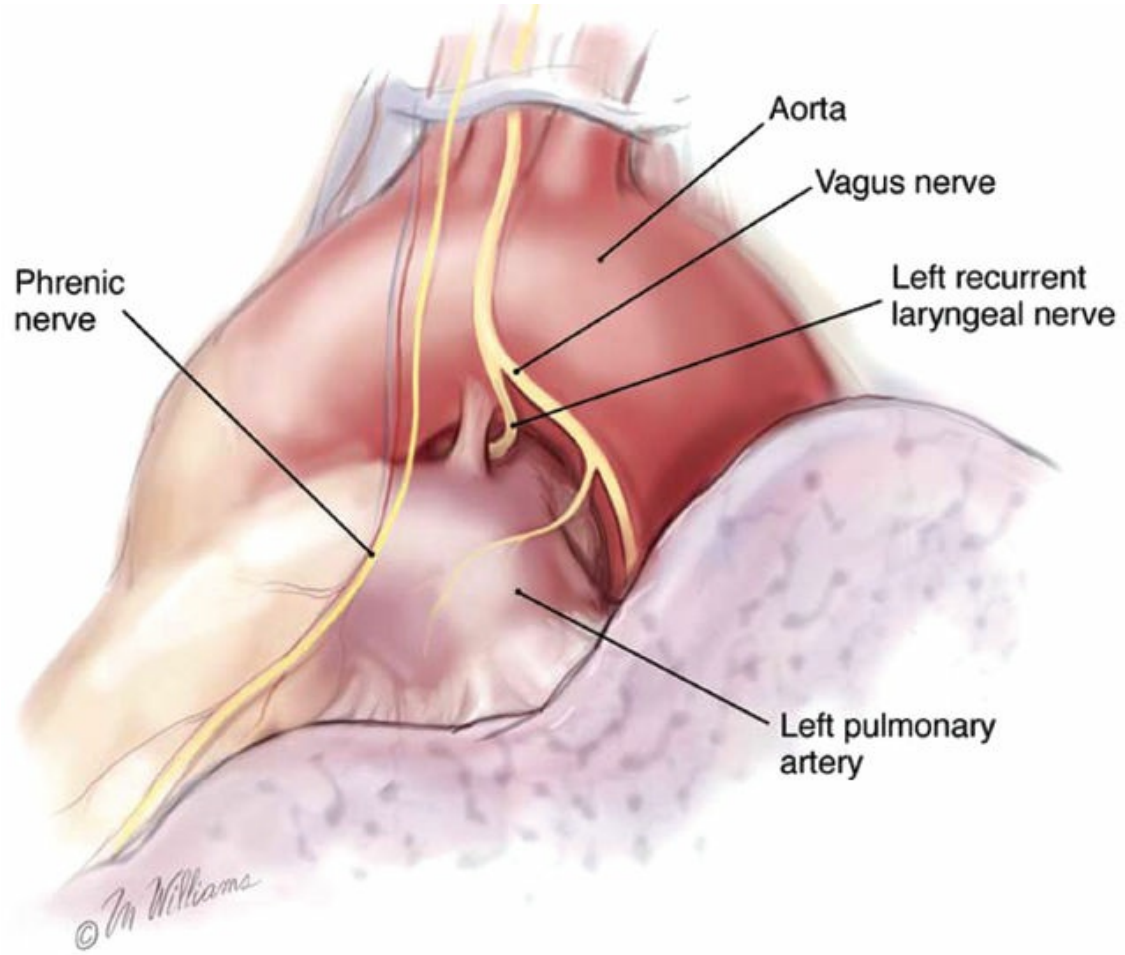

Figure 62.12. Left upper lobectomy. Owing to the proximity of the recurrent laryngeal and phrenic nerves, left upper lobectomy poses many obstacles to easy resection. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–13, p. 538.)

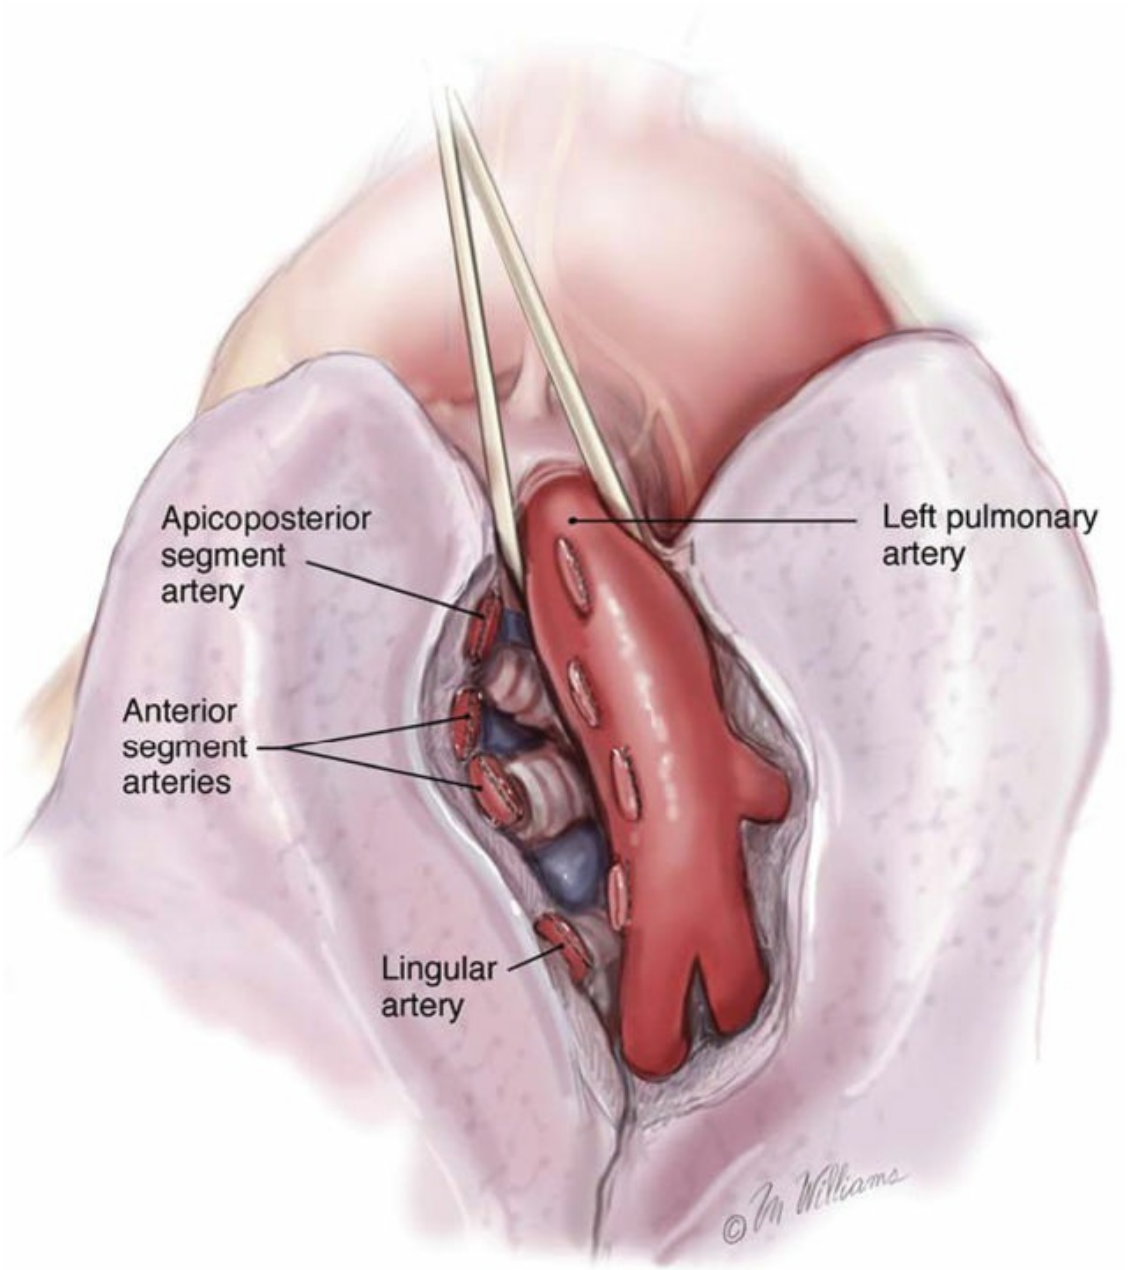

Figure 62.13. Left upper lobectomy. A superior approach to access a peripheral lung mass in the left upper lobe. The main pulmonary artery is encircled with tape to establish control, and the apicoposterior and anterior arterial branches are divided. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 62–15, p. 539.)

Left Lower Lobectomy

The chest is entered through a fifth interspace posterolateral thoracotomy. The dissection for the left lower lobectomy begins posteriorly in the fissure with opening of the pleura and sheath over the main left pulmonary

artery. Reflection of the lower lobe posteriorly allows visualization of the artery to the superior segment of the lower lobe, which is isolated and ligated. Next, the basilar arterial branches are isolated and divided distal to the lingular artery. Similar to a right lower lobectomy, the superior segmental branches and basilar trunk can often be divided as one, if the arterial anatomy allows (Fig. 62.14). The inferior extent of the fissure can then be completed by applying a stapler. The lower lobe is reflected anteriorly and the inferior pulmonary ligament divided to the lower border of the inferior pulmonary vein. The posterior mediastinal pleural attachments to the inferior vein and the plane between the vein and the membranous bronchus are developed. The inferior pulmonary vein is freed circumferentially and then divided with a vascular stapler. The lower lobe is now attached only by its bronchus, which in most cases can be divided with a single stapler fired across the basal bronchi and superior segmental bronchus without compromising the left upper lobe bronchial orifice (Fig. 62.14). We generally will cover this dependent bronchial stump with locally derived vascularized tissue.

Mediastinal Lymph Node Dissection

Lymphadenectomy during pulmonary resection provides improved pathologic cancer staging and should be performed in all patients undergoing pulmonary resection for NSCLC. In addition to removing the hilar, interlobar, and segmental lymph nodes during the course of an anatomic resection, mediastinal nodal dissection should be performed. On the right side, lymph nodes from nodal stations 2R, 4R, 7, 8, 9, and 10R should be removed. A left-sided nodal dissection includes nodal stations 5, 6, 7, 8, 9, and 10L. Mediastinal dissection (removal of all lymph nodes) versus lymph node sampling from these nodal stations has been debated with respect to a survival advantage; however, mediastinal nodal dissection has proven to be safe and to upstage a number of patients with early clinical stage NSCLC.

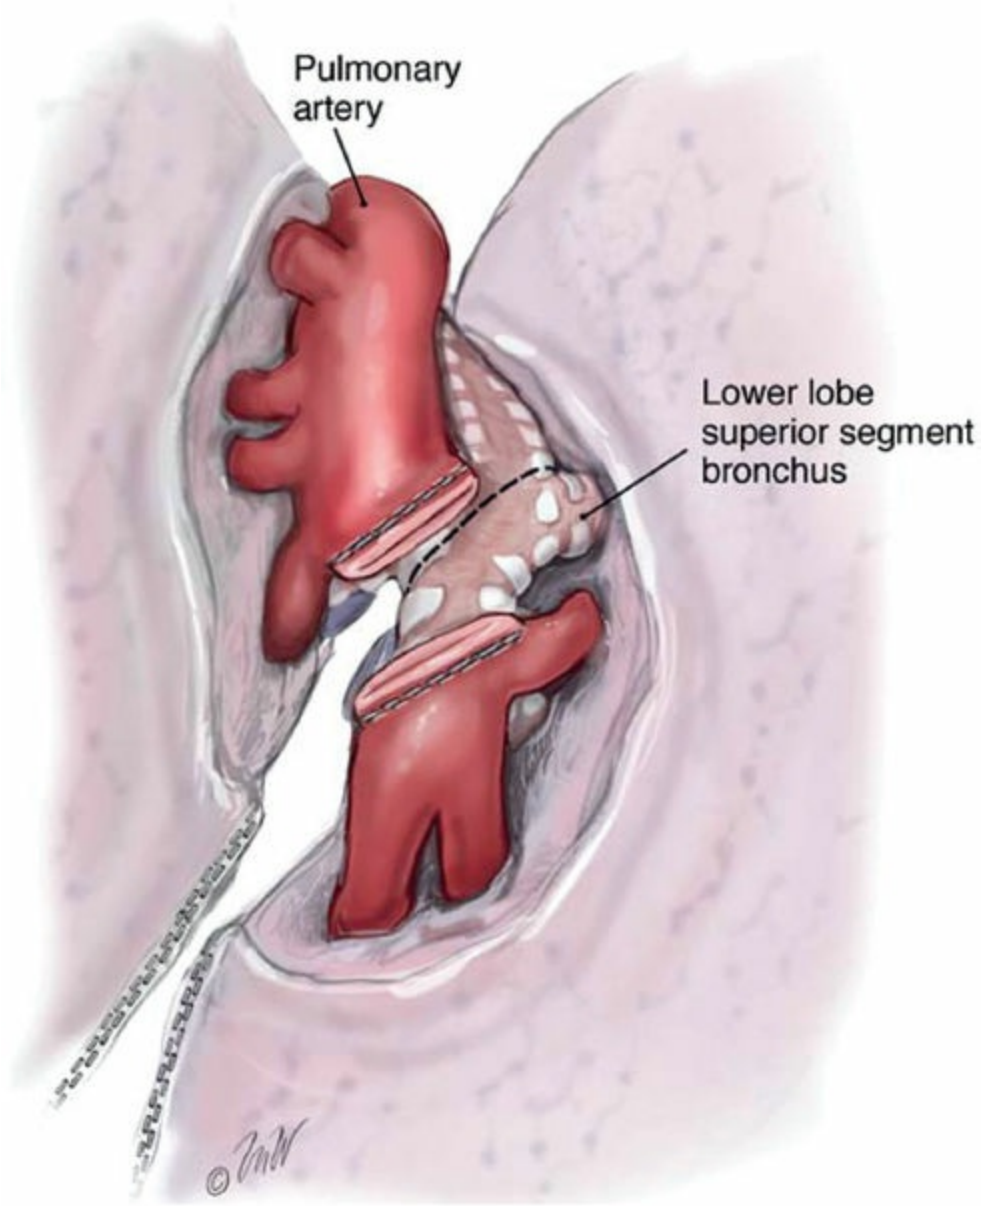

Figure 62.14. Left lower lobectomy. The lower lobe superior segment bronchus is closed with a stapler or interrupted absorbable sutures after the parenchyma between the upper and lower lobes has been divided. VIDEO-ASSISTED THORACOSCOPIC SURGERY

It is becoming increasingly evident that VATS lobectomy holds advantages over thoracotomy with regard to postoperative morbidity. For example, compared to matched patients undergoing thoracotomy and lobectomy, VATS lobectomy has lower incidences of arrhythmia, reintubation, and blood transfusion. Importantly, there are no compromises

in oncologic and long-term survival outcomes by VATS compared with open lobectomy, and patients with compromised pulmonary function should be preferably offered minimally invasive pulmonary resection, when possible.

The principles of anatomic resection by VATS do not differ from traditional open procedures. Hilar elements, such as arteries, veins, and bronchi, must be separately isolated and transected, and a complete lymphadenectomy is performed. To carry out a VATS pulmonary resection, two ports and an access incision are usually required. The access port is an incision 3 to 4 cm in size through which most of the vessel dissection is performed and through which the specimen is extracted at the conclusion of the resection. Rib spreading is avoided to minimize postoperative discomfort. The camera is placed in the seventh or eighth intercostal space in the midaxillary line for right-sided resections and the posterior axillary line for left-sided resections. The posterior port is generally positioned in the fifth to sixth intercostal space behind the tip of the scapula. The access incision is made in the fourth intercostal space in the anterior axillary line for right upper, right middle, and left upper lobectomies and in the fifth intercostal space in the anterior axillary line for lower lobectomies (Fig. 62.15). A standard hilar and mediastinal lymphadenectomy is performed as described above. All resected specimens are placed in a thoracoscopic specimen bag before removal from the thoracic cavity to prevent port-site seeding.

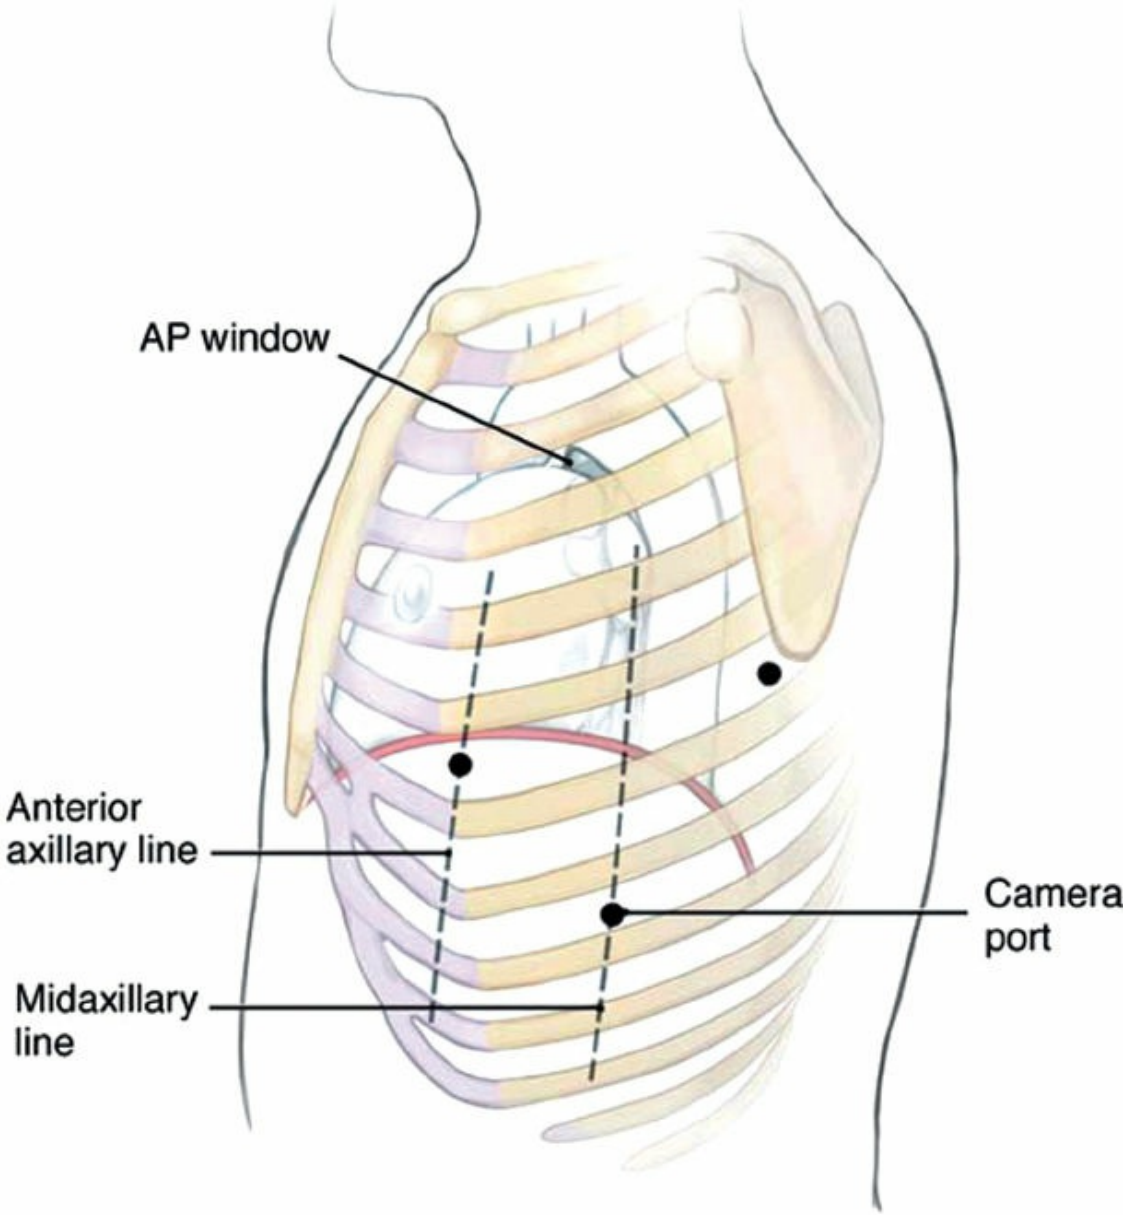

Figure 62.15. Port placement for the three incisions used for right upper lobectomy: inferior camera port, posterior working port, and anterior access/utility incision. Techniques for Specific VATS Resections

Right Upper Lobectomy

Once the ports are placed, the ring forceps is used through the posterior port to gently retract the upper lobe posteriorly. Dissection is performed from anterior to posterior beginning in the anterior hilum. Removal of hilar nodes defines the middle lobe vein and the upper lobe vein. The minor fissure can then be divided using an Endo GIA 30-mm stapler through the

access incision. The superior pulmonary vein is dissected circumferentially, and the upper lobe branches are identified and isolated, taking care to spare the middle lobe vein. To guide the stapler around the vessel, an 8-mm red rubber catheter attached to one anvil of the stapler is helpful; the flared end of the catheter dilates the passage and safely guides the stapler into position (Fig. 62.16). The truncus anterior branch of the right pulmonary artery and the posterior recurrent branch of the pulmonary artery are then identified, isolated, and transected using the endovascular stapler in a similar fashion (Fig. 62.17). The best angle for the articulated vascular stapler is often achieved via insertion through the low posterior port. The posterior hilum is opened and the right mainstem bronchus identified. The fissure between the superior segment of the lower lobe and the posterior segment of the upper lobe is completed and the right upper lobe bronchus is dissected free. The upper lobe is retracted anteriorly using ringed forceps placed through the access incision, and the right upper lobe bronchus is divided using the Endo GIA 30-mm stapler through the posterior port. The lobe is placed into a specimen bag and brought out via the access incision.

Right Middle Lobectomy

VATS middle lobectomy may at times be performed through entirely "thoracoscopic" (i.e., 2 cm or smaller) incisions because the middle lobe is small enough to fit through a 2-cm incision. Middle lobectomy begins with completing the minor fissure between the right upper lobe and the right middle lobe. Dissection of the anterior hilum and mobilization and transection of the middle lobe vein proceed using an endovascular stapler inserted through either the access incision or the posterior port. The middle lobe bronchus is identified lying posterior and slightly inferior to the vein. Through the access incision, the bronchus is dissected free. The middle lobe is then retracted posteriorly, and the bronchus is divided with an Endo GIA 30-mm stapler. This exposes the middle lobe artery that lies posterior and slightly superior to the bronchus. Through the posterior port, the middle lobe is retracted, and the artery is transected with the endovascular stapler passed through the access incision. The final step is completion of the minor fissure between the right middle and lower lobes using an Endo GIA stapler introduced through the access incision.

Right Lower Lobectomy

The first step is dividing the inferior pulmonary ligament with

electrocautery using the extended tip through the posterior port. Level 9 lymph nodes are also harvested at this time. The lower lobe is then retracted posteriorly using a ringed retractor, and the anterior hilum is opened. The inferior pulmonary vein is identified and divided with the endovascular stapler. The lower lobe artery must be isolated within the fissure and dissected free. This is done with blunt and sharp dissection through the access and posterior ports. Once the artery has been isolated, the lower lobe is retracted posteriorly and the artery divided using the endovascular stapler placed through the access incision. Alternatively, if the angle for the stapler via the access incision is not optimal, the stapler can be placed through the posterior incision. Care must be taken to avoid injury to the middle lobe artery. If there is insufficient room between the artery to the right middle and lower lobes, the superior segmental artery and basilar artery can be divided separately. After arterial transection is complete, attention is shifted to opening the posterior hilum and creating the fissure between the superior segment of the right lower lobe and the right upper lobe. This is done with the Endo GIA 30-mm stapler through the posterior port. The lobe can be displaced anteriorly to expose the bronchus, which is isolated with scissors and swab and divided with the Endo GIA 30-mm stapler. In cases in which the middle lobe bronchus is too close to the right lower lobe bronchus, the superior segmental bronchus and the basilar bronchus can be stapled and divided separately.

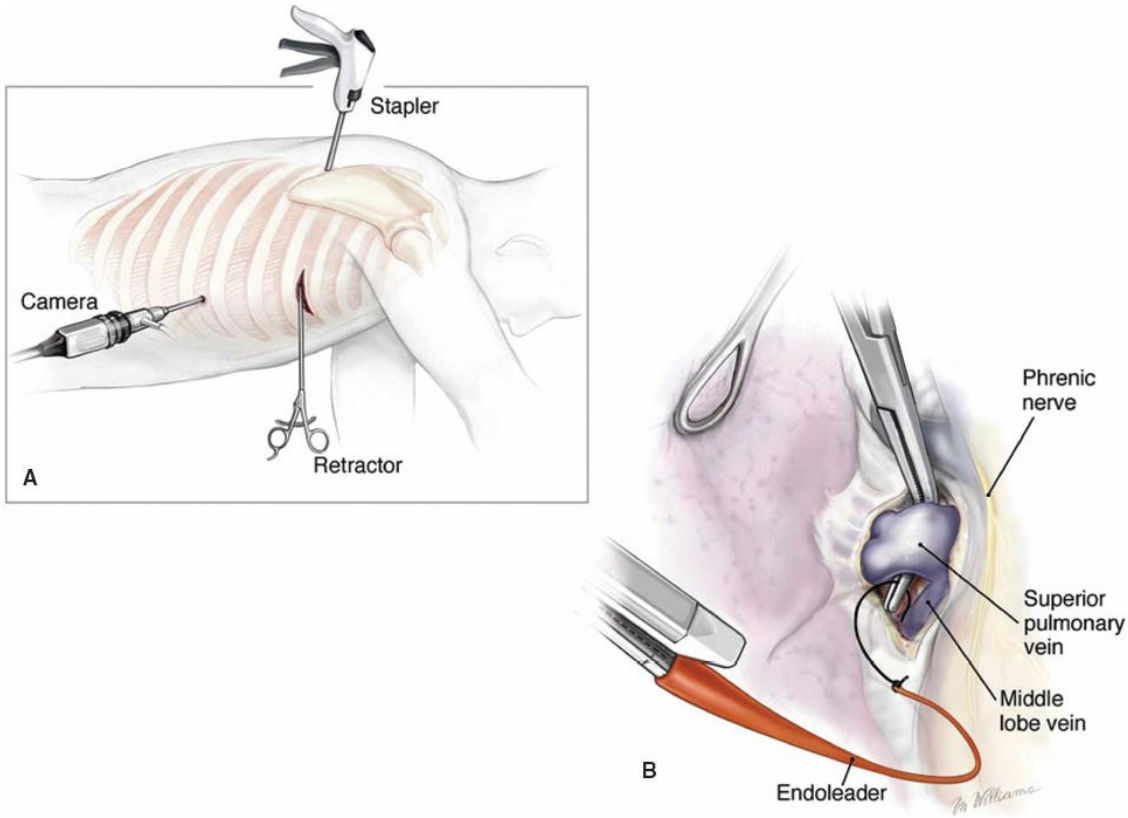

Figure 62.16. An oiled 2-0 silk suture is looped around the superior pulmonary vein, which is divided with an endovascular stapler, usually introduced through the posterior port, which provides the best angle. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 63–2, p. 546.)

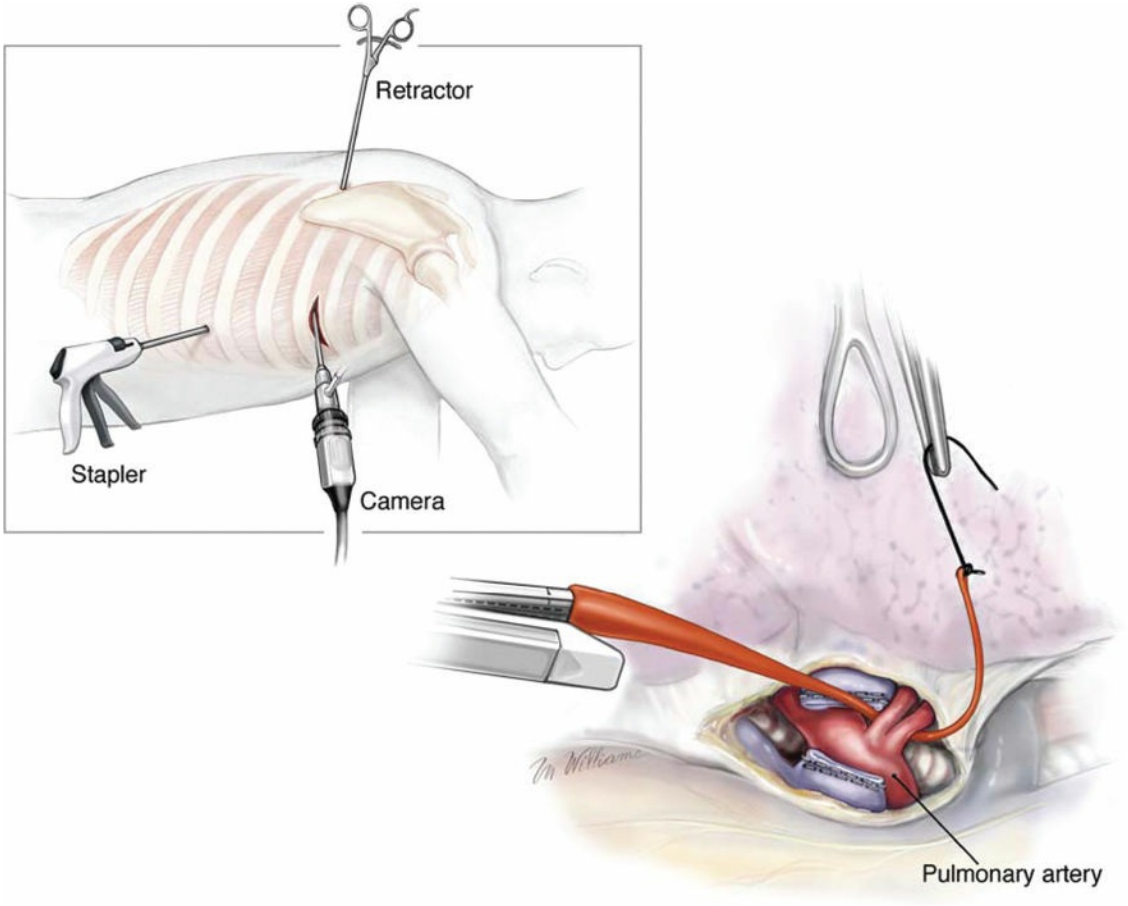

Figure 62.17. The truncus anterior and its variable number of branches are exposed, dissected free, and divided individually or as a trunk depending on configuration and accessibility. Before the arteries are divided, the camera is switched to the anterior access port for better visualization, and the stapler is placed in the inferior port (*inset*). An endovascular stapler fitted with a rubber "endoleader" for guidance is used to divide the vessels. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 63–3, p. 547.)

Left Upper Lobectomy

Left upper lobectomy is technically the most challenging operation that can be carried out using VATS techniques because of the presence of arterial branches that originate from the fissure and those that originate from the proximal pulmonary artery. Furthermore, the pulmonary anatomy to the left upper lobe is variable. The operation is begun by opening the anterior hilum through the anterior access incision, and the superior pulmonary vein is dissected free. Before dividing the superior pulmonary vein, the inferior pulmonary vein must also be identified to assure that it is

spared from injury if an extrapericardial venous confluence is not fully appreciated. The upper lobe is retracted posteriorly and the vein divided with an endovascular stapler, via the access incision or through the posterior incision. Next, the posterior fissure between the superior segment of the lower and the upper lobe is completed with an Endo GIA stapler through the posterior port. The posterior hilum can be opened through the same port. The anterior pulmonary artery, which runs posteriorly between the upper and lower lobe, is carefully dissected free and divided using the endovascular stapler placed through the access incision. The posterior arterial branches and the branches to the lingula are divided through the posterior port with an endovascular stapler. Once arterial transection is completed, dissection continues on the anterior hilum through the access incision and the fissure between the lingula and the lower lobe is completed with the Endo GIA stapler. Finally, the left upper lobe bronchus is dissected free and divided with the Endo GIA stapler through the posterior port. Alternatively, after division of the superior pulmonary vein, the first one or two branches of the pulmonary artery can be divided with a vascular stapler passed through the posterior port. The upper lobe bronchus can then be divided, followed by the remaining branches to the upper lobe originating in the fissure. The fissure is completed last.

Left Lower Lobectomy

The technique for left lower lobectomy is similar to that used to perform a right lower lobectomy. The first step is dissection of the inferior pulmonary ligament and isolation of the inferior pulmonary vein. The lower lobe is grasped with ringed forceps through the access incision and retracted anteriorly. This puts mild tension on the ligament, which is then dissected up to the vein. The anterior fissure between the lingula and the lower lobe is created with an Endo GIA stapler. The lower lobe can then be retracted posteriorly, and the inferior pulmonary vein is divided with the endovascular stapler. Continuing, the posterior fissure is completed between the superior segment of the lower lobe and the upper lobe using an Endo GIA stapler. With sharp and blunt dissection, the pulmonary artery in the fissure is freed using the access incision and the posterior port. Through the posterior port, the superior segmental artery and basilar pulmonary arteries are divided with serial firings of the endovascular stapler. Once arterial ligation is complete, attention is shifted to isolation and dissection of the bronchus. The upper lobe is retracted anteriorly, and the lower lobe bronchus is dissected free from the posterior hilum and

divided using the Endo GIA 30-mm stapler placed through the posterior port.

PNEUMONECTOMY

Indications

In patients with a centrally located tumor, which is invading to hilar structures or involves extensive amounts of both upper and lower lobes, a pneumonectomy is often necessary for a curative resection. Operative mortality rates for pneumonectomy have been reported to be between 5% and 20%; morbidity and mortality rates are highest following neoadjuvant chemoradiation therapy.

Preparation

For left-sided lesions, a bronchial blocker or right-sided double-lumen endotracheal tube is positioned to aid in left lung deflation. For right-sided tumors, the standard left-sided double-lumen endotracheal tube is preferred. The patient is then placed in the lateral decubitus position, and the chest is prepared and draped.

Right Pneumonectomy

A standard fifth intercostal space posterolateral thoracotomy incision is performed as previously described. The sixth rib is marked, and the intercostal muscle flap along the superior border of this rib is harvested for bronchial stump coverage. The sixth rib is shingled posteriorly near the longitudinal ligament. After insertion of the chest retractor, the surgeon systematically evaluates the lung and mediastinum to document the extent of disease. A histologic diagnosis of NSCLC is made by biopsy, if tissue has not been obtained preoperatively. Pleural metastases or adherence to the spine or unresectable mediastinal structures (T4 lesions) should be ruled out. After documenting a localized lung cancer, the tumor is evaluated for resectability. This step requires a circumferential evaluation of the hilar structures with a goal of ligation and division of major vessels and the bronchus with clear margins. The pulmonary artery, veins, and bronchus must be inspected before proceeding with any ligation of these structures and committing the patient to resection. The lung is gently retracted posteroinferiorly to access the hilar structures (main pulmonary artery, right mainstem bronchus, superior pulmonary vein, and azygos

vein) (Fig. 62.18A). The adventitial sheath of the proximal pulmonary artery is dissected superomedially near the origin of the right upper lobe bronchial takeoff. Level 10 (main bronchial or hilar) lymph nodes should be swept up onto the specimen side, revealing the right mainstem bronchus in the space beneath the azygos vein. The vagal afferents to the bronchus are divided, and visible bronchial arteries are cauterized, clipped, or ligated.

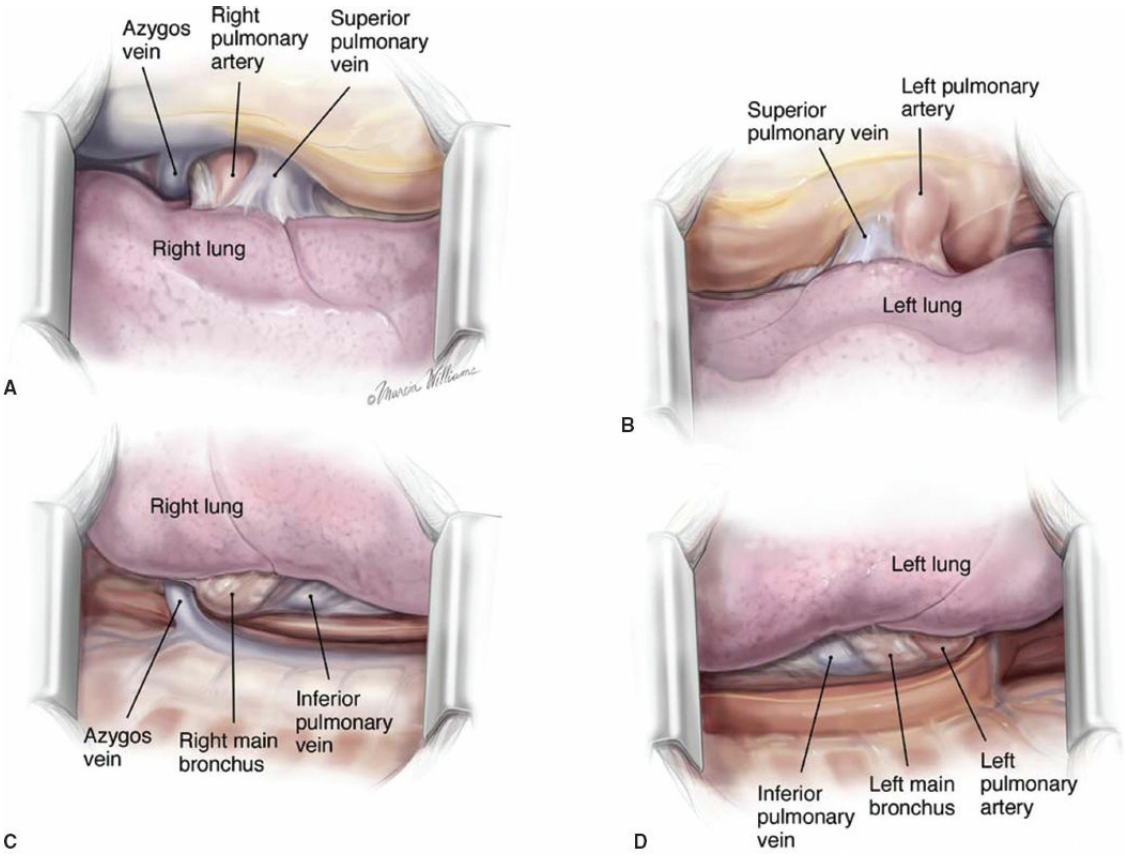

Figure 62.18. Anterior and posterior views of the hilum of the lung from a standard posterolateral thoracotomy. **A.** Anterior view of right lung. **B.** Posterior view of right lung. **C.** Anterior view of left lung. **D.** Posterior view of left lung. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 2–4, p. 8.)

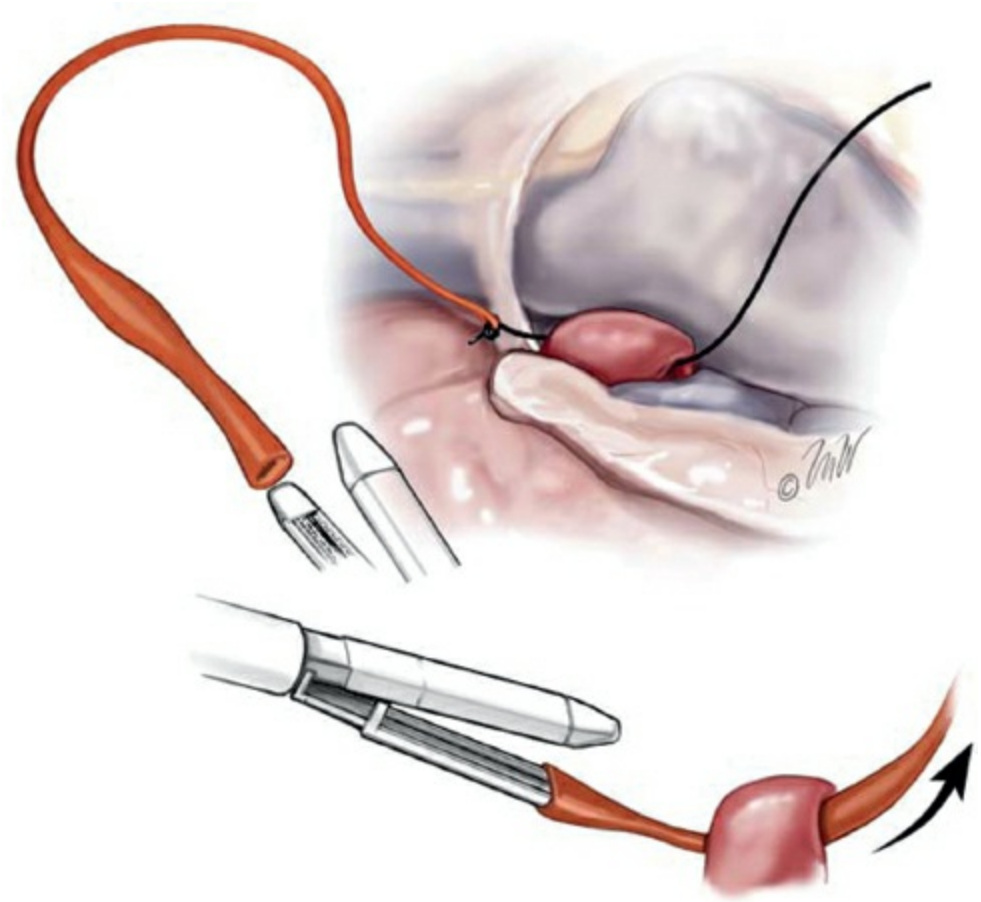

Figure 62.19. The endoleader is passed around the pulmonary artery to guide the safe passage of the endovascular stapler, and the right pulmonary artery is divided. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 103–12, p. 874.)

The lung is then retracted anteriorly, exposing the right mainstem bronchus and subcarinal space (Fig. 62.18B). Level 7 subcarinal lymph nodes are removed, and a finger is passed behind the bronchus to ensure resectability. With the lung retracted superiorly, the inferior pulmonary ligament is divided to the edge of the inferior pulmonary vein and the level 9 lymph nodes are harvested. The lung is then retracted posteroinferiorly and the hilar pleura is opened posterior to the phrenic nerve. The main pulmonary artery and superior and inferior pulmonary veins are evaluated for resectability. The last question to be answered is whether a lesser resection, such as a lobectomy or sleeve lobectomy, can be performed. If not, then attention is directed toward division of the hilar structures. The order of division of the vascular structures or bronchus is not critical and usually proceeds along the lines of the ease of dissection. Our preferred

technique involves division of the right main pulmonary artery first. Other surgeons prefer to divide the inferior and superior pulmonary veins first. Dissection and division of the superior pulmonary vein aids in exposure of the main pulmonary artery, which traverses superior and posterior to the vein.

After sharply dividing the adventitial sheath of the main pulmonary artery, most of the isolation of the vessel can be carried out with gentle, blunt dissection. Occasionally, the truncus anterior branch of the pulmonary artery can be divided separately to provide more room for division of the right main pulmonary artery. If there is sufficient length to accommodate the surgeon's finger, we prefer to use an endovascular stapler to divide the artery (Fig. 62.19). Other surgeons prefer to ligate the artery with nonabsorbable sutures and suture-ligate the proximal end. After division of the artery is complete, the superior pulmonary veins are isolated by dissecting anteriorly in the groove of pericardial reflection between the superior and inferior pulmonary veins. These veins can be similarly divided with separate applications of the stapler. The lung is now tethered only by the bronchus. Reflecting the lung anteriorly affords access to the membranous side of the mainstem bronchus. The bronchus can be divided with suture closure or stapler. We staple the bronchus with a heavy wire 30-mm stapler (Fig. 62.20). The stump should be left as short as possible, flush with the carina, to avoid the dependent pooling of secretions and the higher likelihood of breakdown incumbent with a longer stump. The chest is then irrigated, and the stump is tested for air leakage with 20 to 30 cm H_2O of static positive-pressure ventilation. We routinely cover any pneumonectomy stump with vascularized tissue. A pericardial fat pad based on the superior thymic vessels can easily be mobilized to cover the stump in most instances (Fig. 62.21). The flap is anchored to the airway with absorbable sutures. Other local flap coverage options include an intercostal muscle flap, parietal pleura, pericardium, or omentum. The empty pleural space is examined for hemostasis and the wound is closed without the use of chest tube drainage. A catheter and syringe are used to evacuate 1,000 to 1,200 mL of air from the hemithorax after the patient is placed supine to aid in repositioning the mediastinum to the midline.

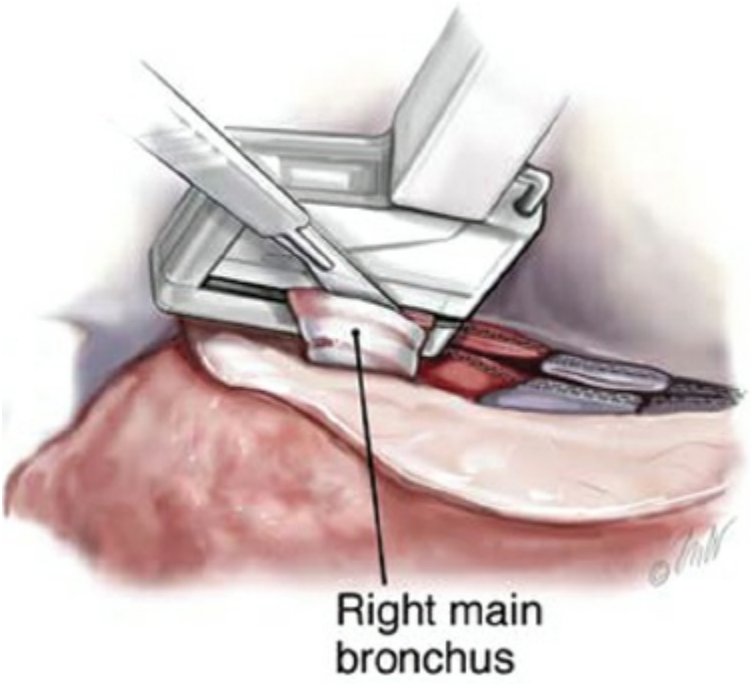

Figure 62.20. The right mainstem bronchus is encircled as close to the carina as possible before division with a heavy gauge wire bronchial stapler. (Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 103–14, p. 875.)

(Reproduced with permission of The McGraw-Hill Companies, *Adult Chest Surgery,* 2009, edited by Sugarbaker et al., Figure 64–1, p. 554.)

Left Pneumonectomy

The left pneumonectomy differs from the right mainly with respect to the anatomy near the aortic arch (Fig. 62.22). Level 5 AP window lymph nodes and the level 6 nodes over the anterior aortic arch are dissected and removed during the initial exploration. This maneuver gives better exposure to the proximal pulmonary artery. The recurrent laryngeal nerve branches off the vagus and courses anteriorly, then inferiorly, to the aortic arch. This structure should be protected except in instances of direct tumor involvement. All hilar structures are inspected and confirmation of tumor resectability is made before ligating or dividing these structures. The vessels are divided in a manner similar to the procedure described for the

right side. Dissection is first carried out in the anterior hilum (Fig 62.18C) then posterior hilum (Fig 62.18D). The left mainstem bronchus is significantly longer than the right, and attaining the desired short stump can be more challenging (Fig. 62.23). Tissue coverage of the stump remains important, and the pedicled pericardial fat pad is used when available.

Occasionally, in an otherwise resectable situation, the tumor involves the proximal hilum, where a safe margin cannot be obtained on the vessels. In this setting, the pericardium can be opened away from the tumor and an intrapericardial plane established for safe ligation of the pulmonary veins or main pulmonary artery of the involved side. In contrast to the right pulmonary artery, which has a long intrapericardial segment and can be easily divided within the pericardium, the left pulmonary artery is short and more difficult to isolate. Small pericardial defects need not be covered or closed, whereas larger defects require patch closure, usually using a surgical membrane, to prevent cardiac herniation into the empty thorax (Fig. 62.24). Such approaches do not increase operative mortality, although the incidence of postoperative supraventricular arrhythmias approaches 30%.

CONCLUSIONS AND GENERAL CONSIDERATIONS

Surgery is a cornerstone in the treatment of patients with NSCLC. Lobectomy is currently the gold standard for patients with early-stage NSCLC. Compared to open lobectomy, thoracoscopic lobectomy results in decreased morbidity and mortality for patients with lung cancer, and these benefits may be exaggerated in patients with decreased pulmonary function. Importantly thoracoscopic lobectomy has similar oncologic outcomes when compared to open lobectomy. In patients with small lung cancers and impaired pulmonary function, sublobar (segmentectomy and wedge resection) can be considered as parenchymal sparing approaches. For patients with tumors involving multiple lobes and central tumors involving hilar structures, pneumonectomy may be required for complete resection. In some cases of central tumors, sleeve resection of an airway and/or pulmonary artery may be possible to avoid pneumonectomy. Complete lymph node dissection is important for all patients undergoing pulmonary resection for NSCLC.

EDITOR'S COMMENT

Since the publication of the last edition, we have expanded our understanding of the staging and treatment of lung cancer. The reasons for this are multiple but can be grouped in at least four overall headings:

1. Most important is a clearer understanding of the types and staging of lung cancer. Key to this is the demonstrated value of positron emission tomography (PET) computed tomography (CT) which as Sugarbaker notes may make unnecessary staging mediastinoscopy and the trend to use EBUS and EUS.
2. In addition, outcomes are improved because of better patient selection and the application of enhanced postoperative recovery protocols including the use of thoracic epidurals for postoperative pain management.
3. Development of new technical expertise with minimally invasive surgery and the development of new instruments.

4. The importance of molecular analysis of tumors for the selection of chemotherapy.

The authors point out the mainstay of treatment for NSCLC is surgery and more explicitly lobectomy unless the indications exist for a pneumonectomy in patients with a centrally located tumor, which is invading to hilar structures or involves extensive amounts of both upper and lower lobes. Key to staging is the assessment of the mediastinal nodes. Furthermore there has been an increasing use of videoscopic lobectomy. PET CT is a standard part of the pretreatment evaluation of NSCLC.

Staging of the mediastinal and hilar lymph nodes plays a crucial role in identifying the best treatment option for patients with confirmed or suspected lung cancer and, in many cases, can simultaneously confirm a diagnosis of cancer. Noninvasive modalities, such as CT, PET and PET CT, are an important first step in this assessment. Ultimately, invasive staging is frequently required to confirm or rule out the presence of metastatic disease within the lymph nodes. The authors describe the various methods of mediastinal nodal staging in the absence of M1 extrathoracic disease, which include cervical mediastinoscopy, anterior mediastinoscopy (Chamberlain procedure), endobronchial ultrasound (EBUS) with transbronchial nodal aspiration (TBNA), endoscopic ultrasound (EUS) with TBNA and VATS.

At this point in time, PET CT showing hypermetabolism in the mediastinum requires pathologic confirmation. Currently invasive staging of the mediastinum in patients with early stage (stages I and II) has been recommended by the National Comprehensive Cancer Network (NCCN). However, as the authors note based upon a recent prospective trial in early-stage lung cancer patients, these recommendations may be altered in the next version of the NCCN guidelines. It is worth emphasizing that in the referenced trial of 90 patients with clinical stage T2N0 or T1N0 with standardized uptake value greater than 10 by PET who underwent routine cervical mediastinoscopy before lung resection, only 1 patient (1.1%) had occult metastases detected at mediastinoscopy if they had a negative PET CT.

Can mediastinoscopy be replaced by less invasive techniques? Several trials have compared endoscopic approaches with cervical mediastinoscopy which is considered the gold standard by many authorities. Yasufuku et al. (A prospective controlled trial of endobronchial ultrasound-guided transbronchial needle aspiration compared with mediastinoscopy for mediastinal lymph node staging of lung cancer. *J Thorac Cardiovasc Surg* 2011;142:1393–400) prospectively enrolled 159 patients with confirmed or suspected lung cancer and performed EBUS immediately followed by cervical mediastinoscopy under general anesthesia in all patients. They reported finding no significant differences in sensitivity (81% vs. 79%), NPV (91% vs. 90%), or accuracy (93% vs. 93%) between the two tests, but higher complications in the mediastinoscopy group. Annema et al. (Mediastinoscopy vs. endosonography

for mediastinal nodal staging of lung cancer: a randomized trial. *JAMA* 2010; 304:2245–52) reported a multicenter study in which 241 patients were randomly assigned to EBUS and EUS followed by mediastinoscopy if no nodal metastasis was identified versus mediastinoscopy alone. They found no difference in sensitivity and NPV between mediastinoscopy and combined EBUS and EUS. It should be noted that the majority of the published experience with EUS staging of lung cancer has included subjects with moderate or higher prevalence of mediastinal disease (>35%). Uncertainty remains with regard to application of this and other staging modalities in cohorts with lower prevalence of disease (e.g., CT- or PET/CT-negative mediastinum).

A study by Wallace et al. (Minimally invasive endoscopic staging of suspected lung cancer. *JAMA* 2008;299:540–6) compared EBUS and EUS and found identical sensitivity between the techniques in 150 patients with known or suspected lung cancer. Kang et al. (EBUS-centred versus EUS-centred mediastinal staging in lung cancer: a randomised controlled trial. *Thorax* 2014;69:261–8) found a significant improvement in sensitivity, accuracy and upstaging when EUS was followed by EBUS, while the converse was not observed. This study suggested that "EUS provides minimal additional diagnostic gain when EBUS is performed first, and that perhaps EBUS alone is sufficient for adequate endoscopic staging of the mediastinum when node stations #5, #8, and #9 are not suspected to be involved with disease on imaging."

Enhanced Recovery After Surgery (ERAS) protocols have been advocated for many operative procedures. The authors outline the details of operative techniques including thoracic surgery. Gimenez-Mila et al. (Design and implementation of an enhanced recovery program in thoracic surgery. *J Thorac Dis* 2016;8(Suppl 1):S37–45) reviewed recent literature on early recovery pathways specific to thoracic surgery. They found that ERAS programs were divided into the preoperative, intraoperative, and postoperative periods. A key part of these programs is promotion of physical activity promotion and educational programs that provide information about the surgery and the surgical pathway. In the perioperative management an optimal pain control strategy, antibiotic prophylaxis and protective ventilation were likewise essential. In addition, they recommended that minimally invasive surgery approaches should be applied if possible and combined with a prospectively designed postoperative care plan that is proactive rather than reactive. They showed that an early recovery program in thoracic surgery can facilitate early discharge from hospital and possibly reduce postoperative complications.

An example of an enhanced recovery (ER) protocol was the report of Scarci et al. (Enhanced recovery pathway for thoracic surgery in the UK. *J Thorac Dis* 2016;8:S78–83). They introduced a multi-disciplinary integrated perioperative pathway. In this study, 154 ER patients were compared with 171 controls from the year before ER was introduced. They found an 80% increase in same-day admissions, with a net gain of more than 300 patient bed-days. Increased use of

video-assisted procedures in the ER group (ER, 32.9% vs. 9.4%, $P = 0.0001$) and a lower rate of admission to the intensive care unit (ER, 5.8% vs. 12.9%, $P = 0.04$), a decreased length of stay (mean ER, 5.2 vs. 11.7 days, $P < 0.0001$), and higher patient satisfaction scores with reduced cost. Use of ER pathways has proven to be a safe perioperative management strategy to improve patient satisfaction and to reduce the length of hospital stay and cost after major thoracic surgery without increasing morbidity or mortality.

Although most lobectomies in the United States are done by an open approach there has been a trend toward application of video-assisted thoracoscopic surgery (VATS) and robotic techniques. Simple thoracoscopy to examine the pleural space and perhaps perform simple wedge resection has existed for years. The application of advanced thoracoscopy to anatomic lung resection began in the early 1990s. Initial reports were greeted with harsh criticism and skepticism. The randomized trial by Kirby et al. (Lobectomy–video-assisted thoracic surgery versus muscle-sparing thoracotomy. A randomized trial. *J Thorac Cardiovasc Surg* 1995;109(5):997–1001) was the beginning of minimally invasive thoracic surgery. In 2008, the number of lobectomies performed by VATS techniques has increased to at a 32% according to the Society of Thoracic Surgeons database (Boffa DJ, Allen MS, Grab JD, et al. Data from The Society of Thoracic Surgeons General Thoracic Surgery database: the surgical management of primary lung tumors *J Thorac Cardiovasc Surg* 2008;135:247–54) and this number has continued to increase as research comparing VATS lobectomy to the open procedure has confirmed the benefits of VATS in early-stage lung cancers with less blood loss, improved operative times, and fewer perioperative complications all favor the minimally invasive approach. The oncologic benefits are similar to open approaches with equivalent 5-year survival.

Robotic surgery was introduced at the end of 1990s in part to overcome the limitations of minimally invasive surgery. Robotic lobectomy has recently had significant focus with increasing numbers of cases. The main advantages of robotic technology over VATS are that natural movements of the surgeon's hands and wrists which are translated by the computer-assisted robotic arms into precise movements. Increasing experience shows the value of the robotic approach. The robotic approach is equivalent to VATS in terms of immediate postoperative results and oncologic results, but may be technically easier to learn. However, most of the studies show an increased cost with this technique. An excellent review by Veronesi is available (Robotic lobectomy and segmentectomy for lung cancer: results and operating technique. *J Thorac Dis* 2015;7(Supp 2):S 122–30).

Recent developments in the molecular analysis of lung cancer have led to developments in targeted and personalized therapy in advanced NSCLC (Coco S, Truini A, Vanni I, et al. Next generation sequencing in non-small cell lung cancer: new avenues toward the personalized medicine. *Curr Drug Targets* 2015;16:47–59). Indeed, as simple as it seems, not all lung cancers are the

same. The advent of next-generation sequencing (NGS) has dramatically revolutionized the molecular knowledge of cancer. The review by Coco et al. reports an overview of different applications of the NGS as novel approach to study NSCLC, and the techniques ability to provide information about the mutational spectrum of this cancer. An additional study (DiBardino DM et al. Next-generation sequencing of non-small cell lung cancer using a customized, targeted sequencing panel: emphasis on small biopsy and cytology. *Cyto J* 2017;14:7) further shows the power of NGS in NSCLC in small biopsy and even cytologic specimens. In this study, the genomic alterations found most commonly were in the *TP53, EGFR, EPHB1, MLL3, APC, SETD2, KRAS, DNMT3A, RB1, CDKN2A, ARID1A, EP300, KDM6B, RAD50, STK11*, and *BRCA2* genes. These can be targeted by novel therapeutic regimens.

SECTION VI

THE DIAPHRAGM

63 Surgical Anatomy of the Diaphragm

Petros Mirilas, Lee J. Skandalakis, Richard R. Ricketts, and Marios Loukas

EMBRYOGENESIS

Embryogenesis of the diaphragm comes from the following sources: transverse septum (ventrally), paired pleuroperitoneal membranes (posteriorly), skeletal muscle derived in situ from the body wall and from migration of cervical myotomes (peripherally) (Fig. 63.1). Some authors of the previous decades believed that the mesentery of the esophagus also contributed to the diaphragm.

Transverse Septum

The septum transversum is a mesenchymal bridge arising from the coelomic wall located between the pericardial cavity and the umbilical vesicle (Fig. 63.2). In early stages this mesenchyme mass separates ventrally the pleural and peritoneal cavities. It extends from the ventral body wall to the ventral border of the foregut.

The cranial part of the septum contributes to the connective tissue of the pericardium and is finally covered by pericardium and pleura. The ventral part of the septum constitutes a sagittal mesentery in which the liver develops. The septum transversum which originates at a cervical level gives genesis to the major part of the diaphragm (central tendon and ventral part). Therefore, the major innervation of the diaphragm is supplied from the phrenic nerve, derived from C3, C4, and C5.

Pleuroperitoneal Membranes

The pleuroperitoneal membranes close the right and left communication between the pleural and peritoneal cavities at approximately the 8th embryonic week. The pleuroperitoneal canals are closed by fusion of their edges. Growth of the adjacent adrenals brings the closing edges from posterolaterally to a more anteromedial final location. The right canal

closes earlier. Originally, the pleuroperitoneal membranes form a large part of the developing diaphragm, but relative growth of other elements reduces their contribution to a small area.

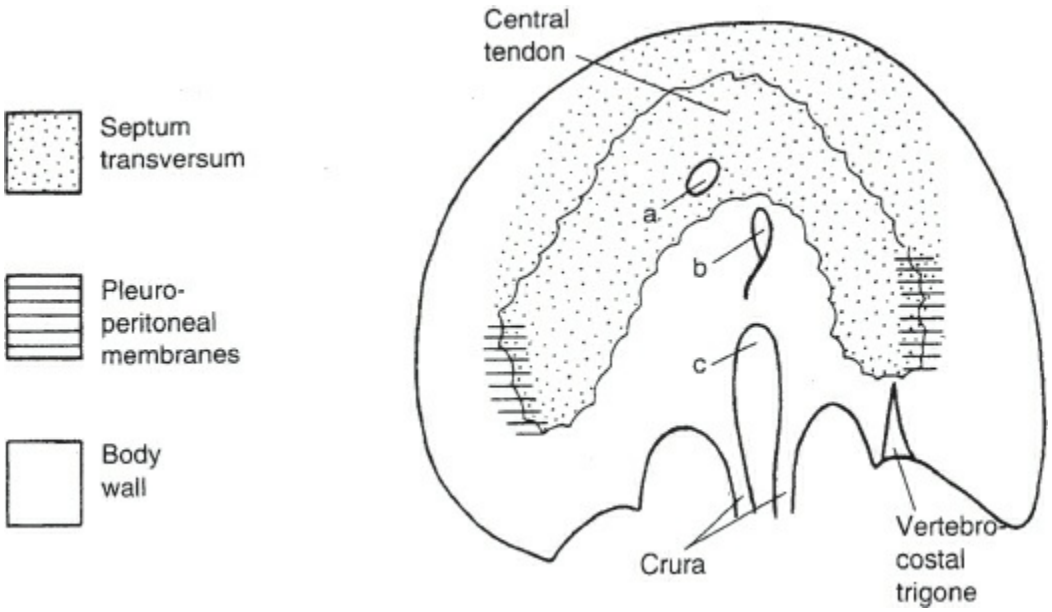

Figure 63.1. Scheme showing the probable origin of the diaphragm. Sharp boundaries are not justified. The vertebrocostal trigone does not mark the closure of the pleuroperitoneal canal. *a,* caval foramen; *b,* esophageal hiatus; *c,* aortic hiatus. Based on findings of Wells. (Republished with permission of John Wiley and Sons, Inc from O'Rahilly R, Müller F. *Human Embryology and Teratology.* 3rd ed. New York: Wiley-Liss, 2001; permission conveyed through Copyright Clearance Center, Inc.)

Muscles of the Body Wall

Myotomes of the 7th to 12th segments contribute the lateral component of the diaphragm by caudal excavation of the thoracic wall to form the costodiaphragmatic recesses. This process produces the final domed shape of the diaphragm, and explains innervation of the peripheral part of the diaphragm by the lower intercostals nerves.

Except from the in situ muscles of the body wall, cervical myotomes accompany the phrenic nerve, migrate, and contribute to the skeletal muscle of the diaphragm. This explains the innervation of the central part of the diaphragm by the phrenic nerve.

Descent of the Diaphragm

In the 3rd week, the transverse septum lies at the level of C3, and the developing diaphragm descends to its final position at the level of L1 by the 8th week (Fig. 63.3). The phrenic nerve, which originates from the third to fifth cervical levels, is carried caudad with the descending diaphragm.

Diaphragmatic Anomalies

A number of areas of the diaphragm can give way under pressure from the abdominal viscera. Most diaphragmatic hernias start in these small areas of weakness and enlarge with age. The specific hernias are described in the following sections and summarized in Table 63.1.

CONGENITAL ANOMALIES

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a displacement of abdominal organs into the thoracic cavity through a weak area or a defect in the diaphragm. It occurs in about 1 per 2,500 live births and accounts for about 8% of all congenital anomalies. CDHs usually occur through the posterolateral foramen of Bochdalek and rarely through the substernal foramen of Morgagni. They are more frequent on the left side (80%) and are very rarely bilateral. The two main pathophysiologic abnormalities in CDH are *pulmonary hypoplasia*, both on ipsilateral and contralateral sides, and *pulmonary hypertension.* Because of the high mortality rate, approximately 30% in live-born infants, the pediatric surgical community has been conducting research into the etiology and pathophysiology of CDH in hopes of affecting better survival rates. This research has been the backbone of the entire field of fetal surgery/fetal intervention.

Many theories have been proposed to explain the appearance of posterolateral diaphragmatic defects:

1. Improper development of the pleuroperitoneal membrane
2. Failure of muscularization of the lumbocostal trigone resulting in an area of weakness
3. Premature return of the intestines into the abdominal cavity when the pleuroperitoneal canal is still “open”
4. Abnormal persistence of lung in the pleuroperitoneal canal
5. Abnormal development of the early lung and posthepatic membrane
6. Abnormal muscle innervation by the phrenic nerve.

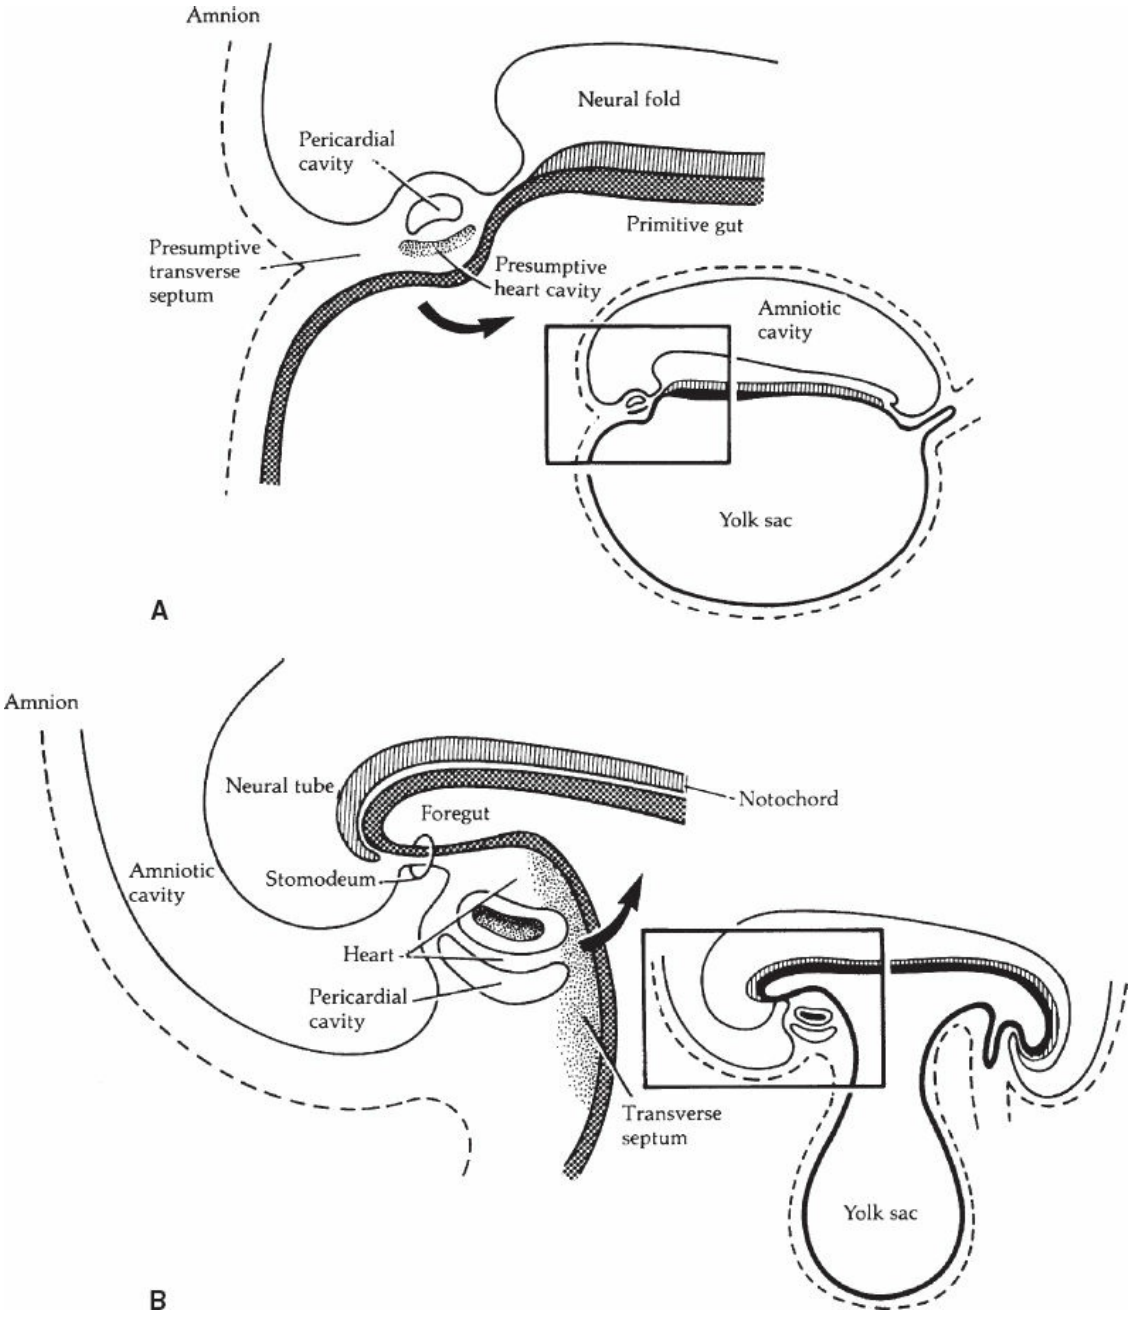

Figure 63.2. Formation of the transverse septum. **A.** The heart and pericardium from anterior to the head of the embryo in the 3rd week. **B.** Rapid growth of the head rotates the heart and the mesoderm, which become the transverse septum, in the direction indicated by the *arrows* in the 4th week.

The most popular theory is that the lung hypoplasia is *secondary* and a direct consequence of a *primary* diaphragmatic defect: inhibited or delayed closure of the pleuroperitoneal canal by 8 weeks of gestation allows the fetal intestine, returning from the extracoelomic cavity at 8 to 10 weeks, to enter the thoracic cavity and impair lung growth and development.

However, Kluth (1995) points out that this series of events has never been observed in embryos or fetuses.

Another popular theory is that the lung is primarily hypoplastic and that the hypoplastic lung in CDH is not the *result* but the *cause* of the diaphragmatic defect (Iritan, 1984).

Two experimental models have been developed to study the embryogenesis and pathophysiology of CDH. In the *murine nitrofen model*, pregnant rats are given 100 mg of nitrofen (a teratogenic agent) orally and then are sacrificed during gestation. The fetuses are examined at various points of development. In the *fetal lamb model*, diaphragmatic hernias are simulated or created in utero in fetal lambs early in gestation. The resultant pathophysiologic abnormalities are then studied at various points in gestation.

Using the experimental murine nitrofen model Kluth has found that the typical features of CDH and pulmonary hypoplasia cannot be explained by inhibited closure of the pleuroperitoneal canals, since these are never large enough to allow for herniation of the gut into the thorax. Also, the maldevelopment of the diaphragm begins early in the embryonic period (corresponding to the 5th week of gestation in humans), and the lungs of the nitrofen-fed rats are already significantly smaller than those of the controls by the end of the embryonic period (8 weeks in humans). He suggests that the murine nitrofen model does not accurately reflect the true pathogenesis of CDH since the manipulations are done in the fetal period of development rather than in the embryonic period. Kluth believes that the hypoplastic lung is secondary to the defect in the diaphragm and is caused by ingrowth of liver (not bowel herniation) into the thorax.

8 weeks

Figure 63.3. The descent of the diaphragm during development. The phrenic nerve arises from the 3rd to the 5th cervical segments and follows the diaphragm down to its final position.

TABLE 63.1 Characteristics of Diaphragmatic Hernias

Hernia	Anatomy	Sac and Herniated Organs	Remarks
Hernia through the foramen of Morgagni (retrosternal hernia, parasternal hernia, anterior diaphragmatic hernia)	Congenital potential hernia through muscular hiatus on either side of the xiphoid process. Usually on the right; bilateral hernias are known. Actual herniation usually the result of postnatal trauma.	Sac present at first. Can rupture later, leaving no trace. Contents: Infants: liver Adults: omentum Can be followed by colon and stomach later.	Rare in infants and children.
Hernia through the foramen of Bochdalek (posterolateral hernia of the diaphragm)	Congenital hernia through the lumbocostal trigone. Can expand to include almost whole hemidiaphragm. More common on left.	Sac present in 10–15%. Contents: small intestine (usual); stomach, colon, spleen (frequent). Pancreas and liver rare. Liver only in right-sided hernia.	Heart and mediastinum shifted to contralateral side. Ipsilateral lung collapsed but usually not hypoplastic. Secondary malrotation is common. Craniorachischisis, tracheoesophageal fistula, and heart defects are common.
Traumatic hernia	Acquired hernia. Tear, usually from esophageal hiatus across dome to left costal attachment of diaphragm.	No sac. Herniated organs: none at first. Spleen, splenic flexure of colon, stomach, left lobe of liver later.	
Peritoneopericardial hernia (defect of the central tendon, defect of the transverse septum)	Congenital hernia through central tendon and pericardium.	Sac rarely present. Contents: stomach, colon.	Has been seen in newborns and adults. Perhaps traumatic in adults. Rare.
Eventration of the diaphragm	Congenital hernia. Diaphragm is thin with sparsely distributed, but normal, muscle fibers. Either or both sides can be affected. Phrenic nerve appears normal. Acquired: paralysis of normal muscle resulting from phrenic nerve injury.	"Sac" is formed by the attenuated diaphragm. Contents: normal abdominal organs under elevated dome of hemidiaphragm. No sac.	Heart and mediastinum shifted to contralateral side. Ipsilateral lung collapsed, but normal. Malrotation and inversion of abdominal viscera are common. As above, without malrotation and inversion.
Hiatal hernia Sliding hiatal hernia Fixed hiatal hernia	Congenital potential hernia. The enlarged esophageal hiatus of the diaphragm permits the cardia of the stomach to enter the mediastinum above the diaphragm. The phrenicoesophageal ligament is attenuated and stretched. The gastroesophageal junction can be freely movable or fixed in the thorax.	Sac lies anterior and lateral to the herniated stomach. Contents: cardiac stomach.	A large hiatus (admitting three fingers) can be a predisposing factor; actual herniation usually occurs in late adult life. Has been seen in newborn infants.
Paraesophageal hernia	Congenital potential hernia. The cardia is in the normal position. The fundus has herniated through the hiatus, into the thorax.	Sac lies anterior to the esophagus and posterior to the pericardium. Contents: fundus of stomach. Body of stomach, transverse colon, omentum, and spleen can enter the sac later.	An esophageal hiatus larger than normal can be the predisposing factor. Actual herniation occurs in late adult life.
Short esophagus	Congenital hernia. The cardia of the stomach is fixed in the mediastinum.	No sac.	This lesion is rare. It appears to be the result of failure of the embryonic esophagus to elongate sufficiently to bring the gastroesophageal junction into the abdomen.

Baglaj and Czernik (2004) point out that caution must be taken in extrapolating data from murine nitrofen studies to humans because of the significant anatomical differences of this model with humans. In murine models CDH occurs on the right side in 50% of embryos and bilaterally in 30%, as opposed to the left-sided predominance in humans. In murine models, the posteromedial diaphragm is affected rather than the posterolateral area as in humans. All murine CDHs contain liver (infrequent in human), and small bowel loops appear late—too late to interfere with lung development. Furthermore, the intrathoracic murine liver appears to be an extra lobe, with the normal liver remaining in the abdominal cavity, rather than a herniation of normal liver into the thorax as is seen in humans.

The fetal lamb model is based on the concept that the pulmonary abnormalities (pulmonary hypoplasia and pulmonary hypertension) are the result of impaired lung growth secondary to the mass effect of the herniated viscera. This led to experimental and then clinical trials to reduce the viscera and close the diaphragmatic defect prenatally, in order to allow space for the lung to grow and develop during the rest of gestation (Harrison, 1991). Following years of experimental prenatal CDH repair (beginning in 1980), the first open prenatal CDH repair in a human was performed at the University of California in San Francisco (UCSF) in 1986. This therapy was only offered to patients who had a nearly 100% predicted mortality with the best available postnatal care. All of the initial infants died. The first successful fetal repair was reported in 1990 (Harrison, 1990). A randomized trial of open fetal repair versus advanced postnatal care showed that prenatal repair was unsuccessful in the most severe cases and did not reduce mortality in the less severe cases.

In the 1990s, it was observed that in congenital high airway obstruction syndrome (CHAOS), lung growth is accelerated and the lung becomes hyperplastic, because of the inability of the fetal lung fluid to exit the lung because of tracheal occlusion. In the fetal lamb CDH model, occlusion of the trachea resulted in reduction of the herniated viscera, increased lung volume, and improvement in gas exchange and compliance. Open fetal tracheal occlusion was first performed in a human in 1996. Technology advanced to the point that endoscopic occlusion through an intact uterus (in an attempt to prevent preterm delivery) became feasible by 1999 (“fetendo”). Initially a clip was applied to the trachea. Because of tracheal damage, current technology involves placing a detachable balloon inside

the trachea endoscopically. An NIH-sponsored randomized trial of Fetendo balloon occlusion versus postnatal care was started in 2003. After 24 patients were randomized, the study was stopped because there was no survival advantage to the fetendo group versus the controls (73% vs. 77%), and the experimental group experienced more premature rupture of membranes and preterm deliveries than the controls.

Hiatal Hernia

Ascent of the stomach into the thorax through the esophageal hiatus of the diaphragm is a common and poorly understood lesion. It has been found in stillborn infants. O'Rahilly pointed out that the anomaly may lie in a delay of the elongation of the esophagus. Thus the stomach is found in an abnormally high position and the hiatus is formed around the stomach instead of the abdominal esophagus. A congenital hiatal hernia predisposes to an adult hiatal hernia, especially with obesity, as fat accumulates in the mesentery of the esophagus.

As in the adult hiatal hernia, congenital hiatal hernia can be of two types: sliding and paraesophageal (Fig. 63.4). In sliding hernia the abdominal esophagus and the stomach move in the thorax. The two requirements for a sliding hiatal hernia appear to be an enlarged hiatus and a weakened phrenicoesophageal ligament. Because both conditions are exacerbated by the hernia, the opening is further dilated and the ligament further stretched.

A congenital paraesophageal hernia permits herniation of the fundus of the stomach into the thorax through the hiatus, usually anterior or sometimes beside the esophagus (Fig. 63.4B). There is a peritoneal sac anterior to the esophagus containing stomach and, in extreme instances, transverse colon and omentum. Obstruction of the distal esophagus or the stomach is the usual result. The two types of hernia can be combined: a paraesophageal hernia may be associated with a sliding hernia.

Congenital Short Esophagus

Congenital short esophagus can simulate hiatal hernia. It is present in children, although it might be asymptomatic. An overall incidence of 1.53% has been documented. The phrenicoesophageal ligament is normal, there is no hernial sac, and the left gastric artery is not displaced upward. The condition is often familial, and it is more common in males. It is sometimes associated with pyloric stenosis, malrotation, and Marfan

syndrome. The authors of this chapter believe that, although it is rare, short esophagus is a true congenital malformation.

There are controversies regarding the existence and incidence of short esophagus. Nyhus (1992) has stated that short esophagus is not congenital, and that the shortening is caused by secondary factors in an esophagus of normal length. He commented that infants who have chalasia develop peptic esophagitis and then shortening of the esophagus.

Barrett esophagus must be distinguished from the congenital short esophagus. Barrett esophagus is associated with reflux, columnar epithelium and to stricture cephalad to the gastroesophageal junction (GEJ). In the congenital esophagus, the distal esophagus is practically a gastric tube, which radiographically cannot be differentiated from hiatal hernia. In this case reflux is significant.

Two conditions must be considered:

1. Irreducible partially supradiaphragmatic true stomach. The stomach has herniated into the thorax through an enlarged diaphragmatic esophageal hiatus and become fixed. This condition is true fixed hiatal hernia. Occasionally, the fixed hernia is not congenital but acquired, with tissue adhesions.
2. Partially supradiaphragmatic true stomach existing from birth and not reducible. This condition is true congenital short esophagus and is very rare.

The congenital short esophagus is not associated with a hernial sac. Branches of the left gastric artery do not pass upward through the hiatus. The authors of the current chapter believe that only a small percentage of hiatal hernias belong to this group.

Horvath et al. (2000) provided an interesting commentary on the term “short esophagus”:

Most esophagi that are short based on preoperative imaging are actually of normal length. It is therefore helpful to think of the short esophagus, as evaluated in the operating room, as falling into three categories: a true, non-reducible short esophagus; a true but reducible short esophagus; and an apparent short esophagus. Perioperative endoscopic or radiologic studies document that all three groups have a GEJ located at or above the hiatus. Both the true reducible and nonreducible short esophagi have sustained enough chronic damage to the esophagus to lead to actual intrinsic shortening, whereas patients with an apparent short esophagus have a normal-length esophagus that is merely accordioned into the distal

mediastinum. The only way to differentiate between these types is surgical mobilization of the mediastinal esophagus. In most patients (i.e., true, reducible short esophagus and apparent short esophagus), it is possible to reduce the GEJ to at least 2.5 cm below the hiatus. However, in a few patients (i.e., true, nonreducible short esophagus), intra-abdominal reduction cannot be accomplished despite extensive transmediastinal or transthoracic esophageal mobilization.

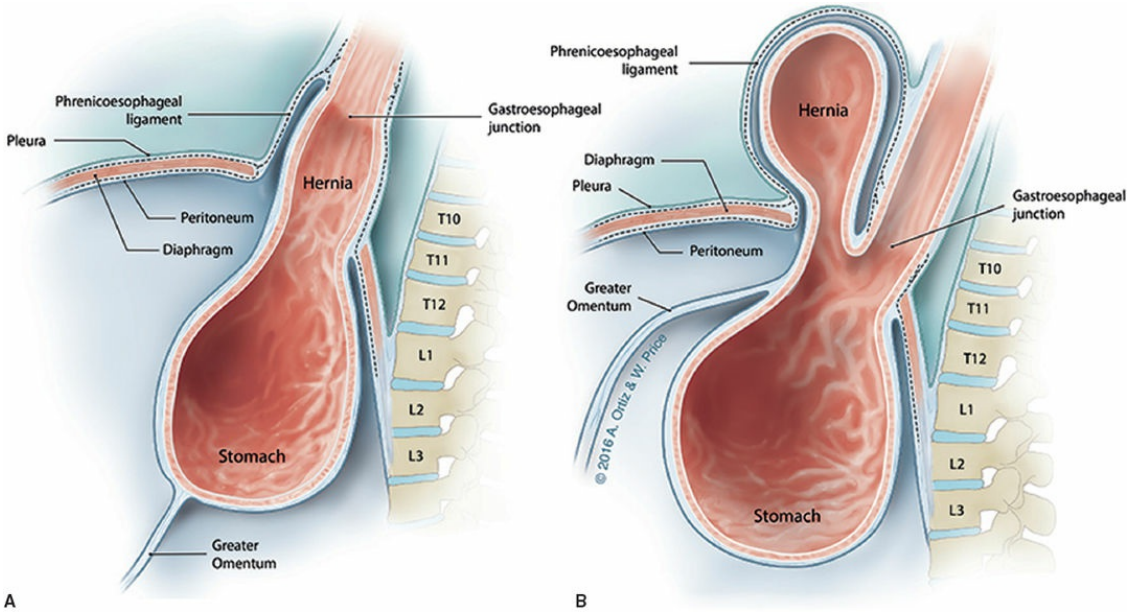

Figure 63.4. Hiatal hernias. **A.** Sliding hiatal hernia seen from the left. The gastroesophageal junction is in the thorax. **B.** Paraesophageal hernia seen from the left. The gastroesophageal junction is in its normal location; the fundus has herniated into the thorax through the hiatus anterior to the esophagus.

Posterolateral (Bochdalek) Defects

The posterolateral (Bochdalek) defect begins at the vertebrocostal trigone, above and lateral to the left lateral arcuate ligament (Fig. 63.5). At the time of intestinal return to the abdomen, this trigone is membranous, with few muscle fibers; even at maturity it is variable in size and degree of muscular development. Spreading of the muscle fibers permits a defect, the foramen of Bochdalek, to form and spread anteriorly on the dome of the diaphragm to include the site of the embryonic pleuroperitoneal canal.

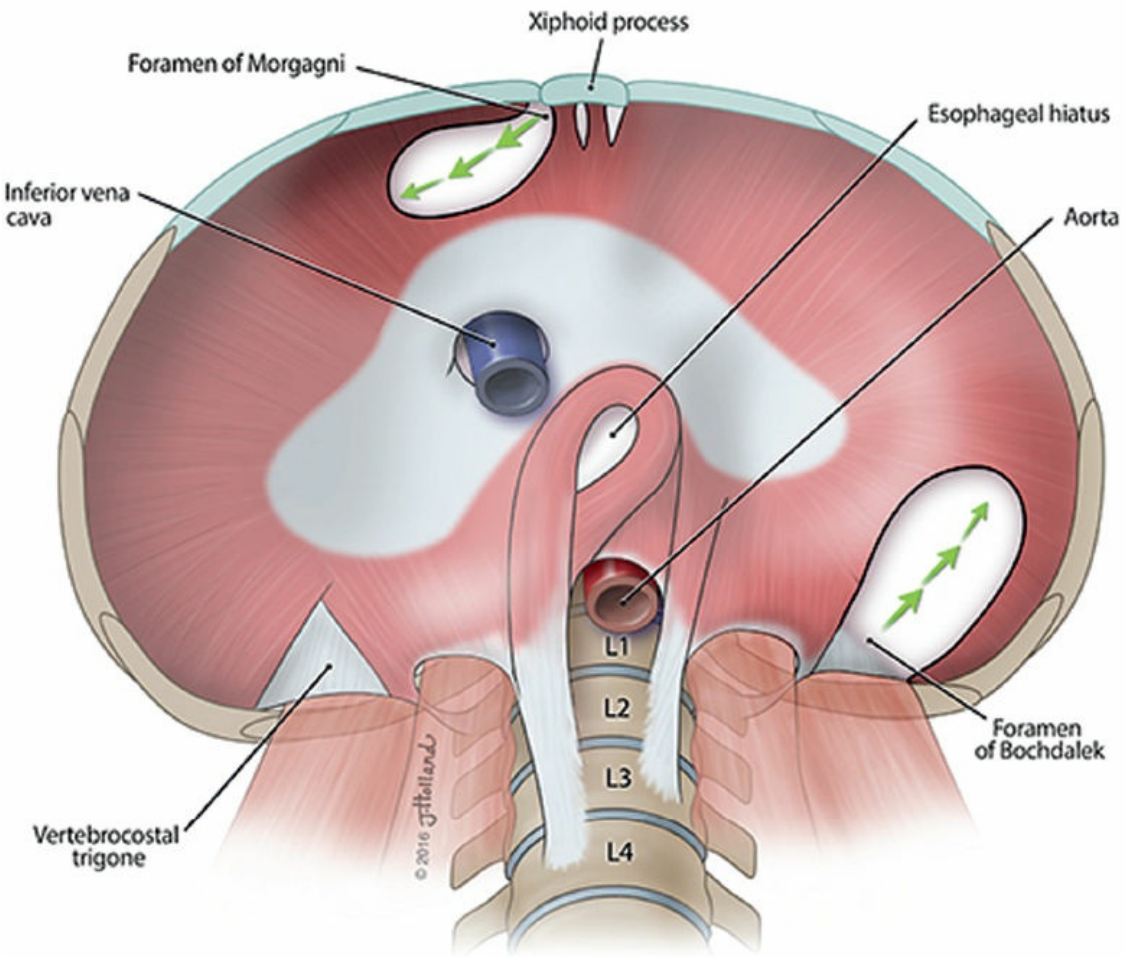

Figure 63.5. The diaphragm from below showing the foramen of Bochdalek and the foramen of Morgagni. Both are weak areas of potential herniation. *Arrows* indicate the direction of enlargement after herniation has begun.

The defect can be as small as 1 cm in diameter, or it might involve almost the entire hemidiaphragm. It is much more common on the left side. During an operation, usually no hernial sac is found. The small intestine, stomach, colon, or spleen can be present in the thorax at birth. The lung on the affected side is usually hypoplastic (Fig. 63.6).

Bilateral congenital posterolateral diaphragmatic hernia is extremely rare and difficult to diagnose.

Parasternal (Morgagni) Defects

Between attachments of the diaphragm to the xiphoid process and the 7th costal cartilage, there is a small gap in the musculature on either side of the xiphoid process (foramina of Morgagni). Herniation at these sites represents only approximately 3% of surgically treated hernias of the

diaphragm. The gaps are filled with fat, and the superior epigastric arteries and veins pass through them (Fig. 63.5).

Herniation through these muscular gaps is almost always the result of postnatal trauma. The hernia occurs more often on the right side, and the herniated organs are usually the omentum, colon, and, eventually, stomach. A sac can be present, or it might have ruptured and disappeared. There might be a predisposition to herniation in persons who have large foramina or more fat between muscle fibers, but this pattern has not been demonstrated. Omental herniation through the foramen of Morgagni has been reported. Laparoscopic procedures have been used to repair this defect.

The Vertebrocostal Trigone

The vertebrocostal trigone (Fig. 63.5) is rather a variation than an anomaly of the diaphragm. The term describes a defective area between the lumbar (vertebral) and costal attachments of the diaphragm. The weak area is usually on the left side. It is usually present but varies in size. The vertebrocostal trigone does not correspond to the site of closure of the pleuroperitoneal membrane (Fig. 63.1). It may be encompassed by a posterolateral defect.

Eventration of the Diaphragm

Congenital eventration describes the abnormal elevation of one leaf (side) of the diaphragm. The entire hemidiaphragm bulges upward, in contrast to the localized defect of a foramen of Bochdalek hernia (Fig. 63.7). The left side is affected more often than the right, and males are affected more often than females. The phrenic nerve appears normal, but the eventrated leaf can consist of a fascial layer with few or no muscle fibers between the pleura and peritoneum. The failure is of muscularization rather than fusion of embryonic components. Intestinal malrotation is often associated. The lung is usually partially collapsed but not hypoplastic; the mediastinum is shifted to the contralateral side, which further reduces ventilation.

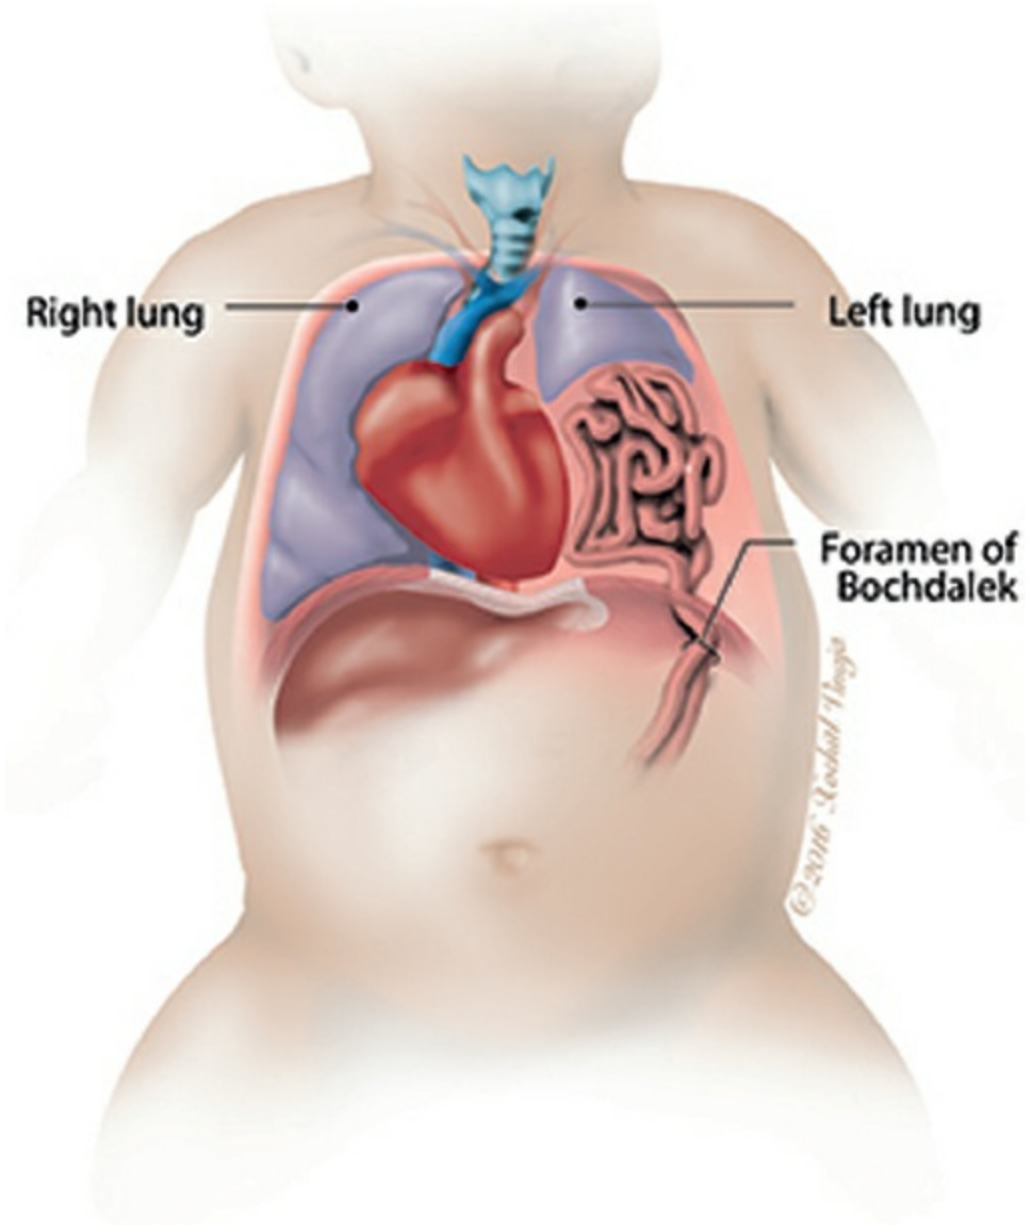

Figure 63.6. Herniation of intestines through the foramen of Bochdalek compressing the left lung. The mediastinum is shifted to the right, also reducing the volume of the right lung.

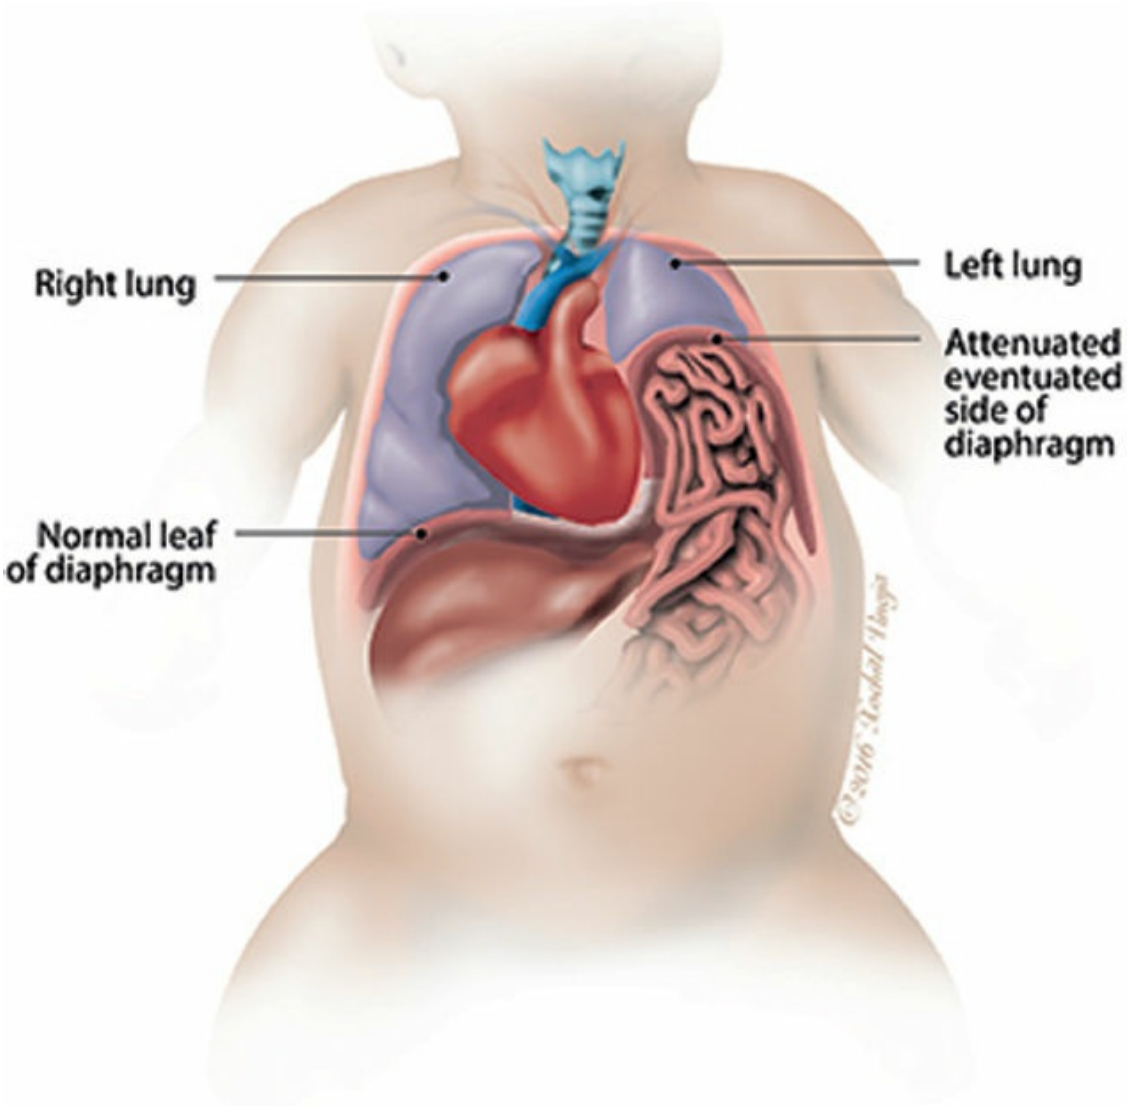

Figure 63.7. Eventration of the left diaphragm. The herniated abdominal organs remain beneath the attenuated but intact side of the diaphragm. Both lungs are compressed, and mediastinum is shifted to the right. Compare with Figure 63.6.

By contrast, *acquired eventration* is the result of phrenic nerve injury with normal musculature. The acquired lesion can be temporary; the congenital lesion is permanent unless repaired.

Eventration can be unilateral or bilateral and can rupture in later life. Eventration and acute gastric volvulus have been seen in pediatric patients.

A common but little-understood lesion that has been reported in stillborn infants is ascent of the stomach into the thorax through the esophageal hiatus of the diaphragm. Its congenital origin is not well established.

Peritoneopericardial Hernia

Peritoneopericardial hernia is a rare hernia that lacks a simple embryologic explanation. The authors of the current chapter believe that this hernia is produced by a residue of the pneumatoenteric recess (this recess give genesis to the lesser sac). Peritoneopericardial hernia has been reported in newborn infants and in adults. A hernial sac, or a trace of one, has been found in a few instances. Because it is in the central tendon and the overlying pericardium, the defect originates in that part of the diaphragm formed by the transverse septum.

Liver herniation into the pericardium through the central tendon has been reported. Investigators have found that symptoms of diaphragmatic hernia might not appear until viscera incarcerate in it years after a causal injury.

Other Anomalies Associated With Diaphragmatic Defects

Diaphragmatic anomalies can be associated with other congenital anomalies, such as Cantrell pentalogy, tracheal agenesis, genetic syndromes with omphalocele, gastroschisis, intestinal atresias and stenoses, and obstructive uropathies.

ANATOMY

Roentgenographic findings support the hypothesis that the cardiac mass is responsible for the caudad displacement of the related hemidiaphragm; this finding is contrary to the classic teaching that it is the liver that lifts the corresponding hemidiaphragm.

The function of the diaphragm, which is composed of skeletal voluntary muscle, is as automatic as the function of the heart, with the difference that the cardiac myocytes function as a syncytium. It has been suggested that the diaphragm is second in importance only to the heart in maintaining life.

Pediatric Diaphragm

The following observations have been made from anatomic and ultrasonographic studies of the diaphragm in newborn infants:

1. The diaphragm inserts only on the anterior costodiaphragmatic rib cage border.
2. From anterolaterally to posteriorly, the diaphragmatic insertion has

increasingly greater distance from the rib cage.

3. The dorsal diaphragm ends its free course at the 11th rib and continues caudally, ending between the 12th rib and the crista iliaca. The diaphragm in the newborn acts as a bellows moving mainly in the posterior part, whereas in the adult it acts as a piston. The diaphragm of the newborn, which has a flat curve because of its large angle of insertion on the rib cage and small area of apposition, has only one physiologic destiny—to suck in the rib cage rather than air. It is this rib cage action that reduces the area of apposition and results in an increase in chest volume.

Origins and Insertions of the Diaphragmatic Musculature

The diaphragm comprises a central tendinous area from which muscle fibers radiate in all directions toward their peripheral attachments (Fig. 63.8).

Sternal Portion

Paired slips of muscle originate from the xiphoid process and the aponeurosis of the transversus abdominis muscle. Small triangular spaces (foramina of Morgagni) separate those slips from the costal fibers and from each other (Figs. 63.5 and 63.8). These small triangular gaps are filled with connective tissue and transmit the superior epigastric vessels (end branches of the internal thoracic [mammary] arteries and veins) and lymphatics that run along them. The sternal portion of the diaphragm arises from xiphoid process and from the aponeurosis of the transversus abdominis.

Costal Portion

Muscle fibers arise from the cartilages of the 7th and 8th ribs, the cartilage and bony portions of the 9th rib, and the distal bony portions of the 10th to 12th ribs.

Lumbar Portion

Posteriorly, the diaphragmatic muscle arises from the crura and the medial and lateral arcuate ligaments (lumbocostal arches). Between the costal and lumbar portion of the diaphragm is the lumbocostal trigone (Fig. 63.5), filled in only with connective tissue.

Surgical Considerations

Hollinshead (1956) has pointed out that the sternocostal part of the diaphragm is in “intimate” relation to the transversus abdominal muscle. They blend and attach together to the lower six costal cartilages. Therefore, they can be separated together from the ribs. The transversal muscle, which is then made continuous with the diaphragm, could be utilized to help in closure of an anterior defect of the diaphragm.

The lumbar part of the diaphragm is in conjunction with the aponeurosis of the transversus muscle, which blends with the deep layer of the thoracodorsal (lumbosacral) fascia. The latter fuses with the anterior layer medially. Therefore, the latissimus dorsi can be of use in the closure of posterior defects of the diaphragm.

Crura

The crura arise from the anterior surface of L1 to L4 on the right, and L1 to L2 or L3 on the left, as well as from the intervertebral discs and the anterior longitudinal ligament. The crural fibers pass superiorly and anteriorly, forming the muscular arms that surround the openings for the aorta and the esophagus; they insert on the central tendon. The crura are tendinous at their origin on the vertebrae, becoming increasingly muscular as they ascend into the diaphragm proper (Fig. 63.9). In our studies of cadavers, we found the crura to be tendinous, posteriorly and medially, from their vertebral origins to the level of the 10th thoracic vertebra in 90% of cadavers. Sutures to approximate the crura should always be placed through the tendinous portions.

The pattern of the crural arms at the esophageal hiatus is variable. Loukas et al. (2008) classified the patterns of the right and left arms of the right and left crus forming the esophageal hiatus (Fig. 63.10). The most common type (Type I, 45%) formed the esophageal hiatus from muscular contributions arising solely from the right crus. In Type II (20%) the esophageal hiatus was formed by muscular contributions from the right and left crura. In Type III (15%), the right and left muscular contributions arose from the right crus with an additional band from the left crus. Type IV (10%) showed that the right and left muscular contributions arose from the right crus, with two additional (anterior and posterior) bands arising from the left crus. Type V (5%) demonstrated the contributions arising solely from the left crus. In Type VI (5%) the right and left contributions originated from the left crus with two additional bands, one from the right crus and one from the left crus.

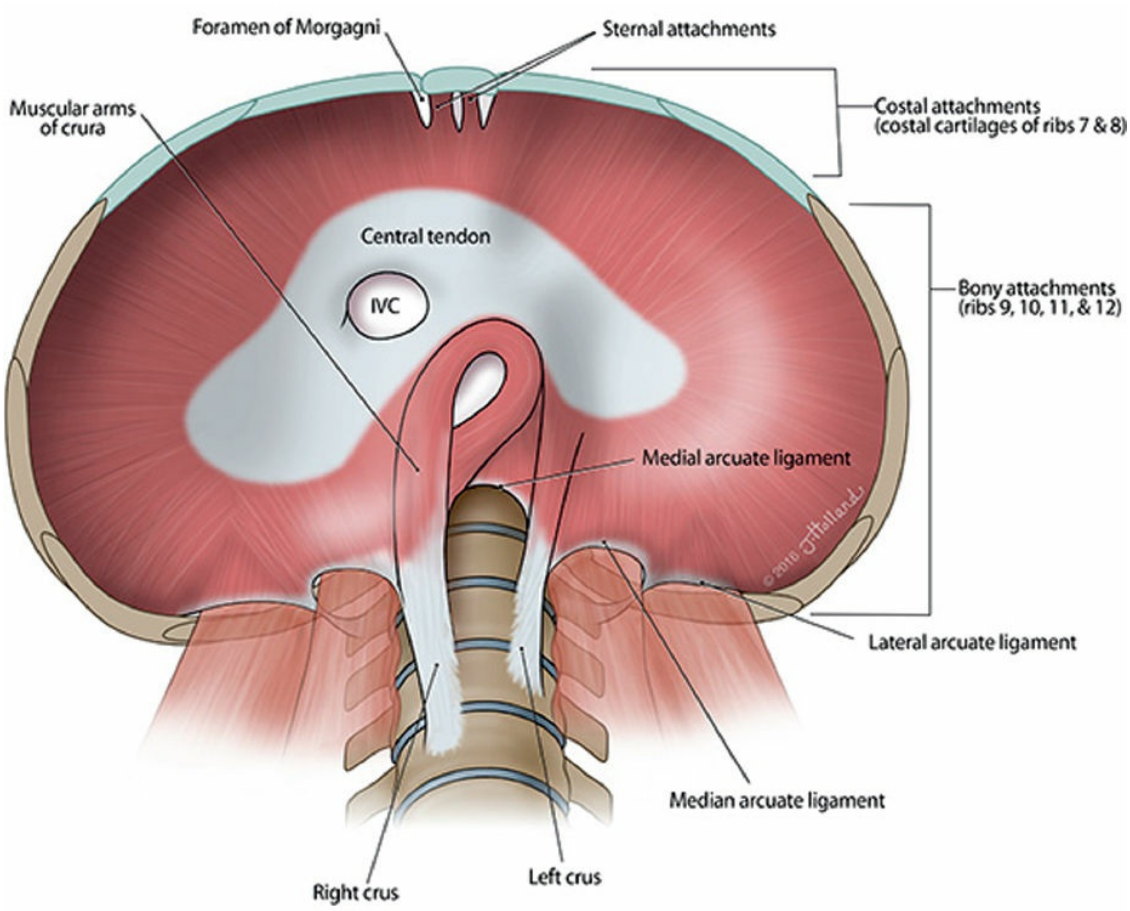

Figure 63.8. The attachment of the muscles of the diaphragm seen from below. IVC, inferior vena cava.

Arcuate Ligaments

The lateral arcuate ligaments (lumbocostal arches) are a thickening of the fascia on the anterior surface of the quadratus lumborum muscles, which attach to the 12th ribs laterally and to the transverse processes of L1 medially. The medial arcuate ligaments (medial arches) compose the similarly thickened fascia on the anterior surface of psoas muscles, which attach to the transverse processes of L1 laterally and to the body of L1 or L2 medially. The medial arcuate ligaments are separated from each other by the crura and the median arcuate ligament, described in the section "Median Arcuate Ligament." From these two pairs of arcuate ligaments on either side arises a portion of the muscle fibers of the posterior portion of the diaphragm (Fig. 63.8). The remaining portion of the diaphragm arises from the crura.

Central Tendon

All the musculature described so far inserts on the fibrous central tendon

of the diaphragm. The thickened portion anterior to the esophageal hiatus and to the left of the caval aperture is sometimes called the cruciform (transverse) ligament. Fibers on the superior surface of the central tendon blend with those of the fibrous pericardium. Patches of muscle are often present among the fibers of the central tendon.

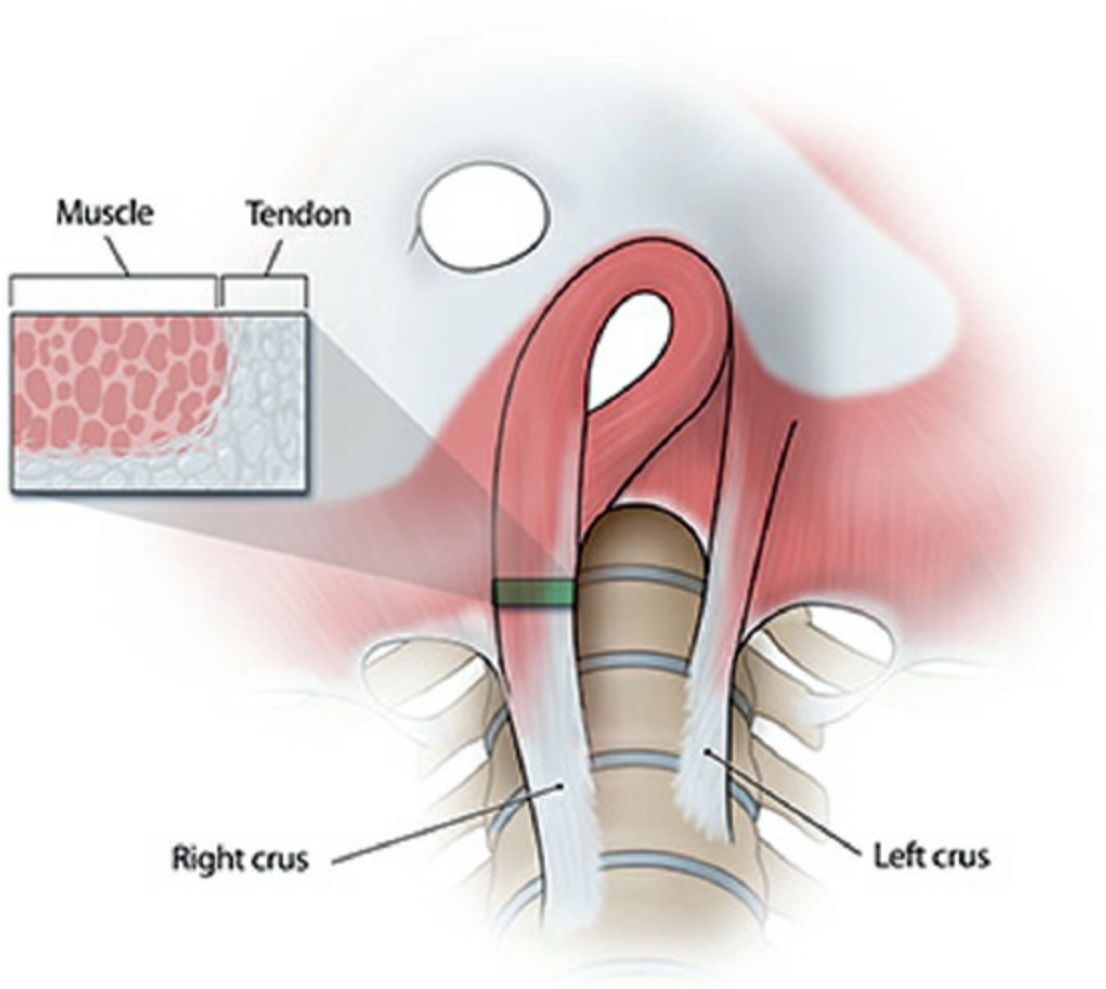

Figure 63.9. The crura consists of both tendinous and muscular tissue; only the tendinous portion holds sutures: 90% the medial edge of the crura is tendinous.

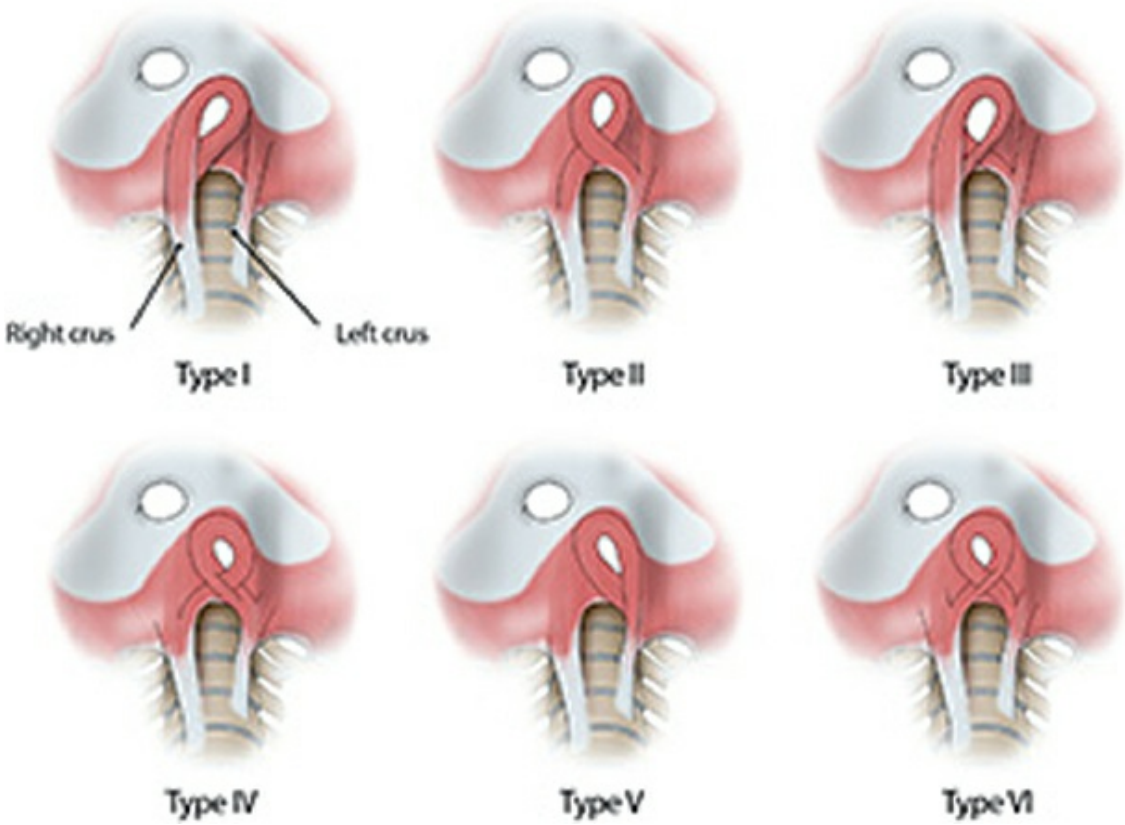

Figure 63.10. Representation of the different types of diaphragmatic crura. (Modified from Loukas M, Wartmann CT, Tubbs RS, et al. Morphologic variation of the diaphragmatic crura: a correlation with pathologic processes of the esophageal hiatus? *Folia Morphol* 2008;67:273–9; with permission.)

Loukas et al. (du Plessis 2015) reported a great variability in the morphology of the muscular and tendinous (central tendon) portions of the diaphragm, contributing unequally to the size of the diaphragm. The central tendon exhibited a V-shaped morphology in the majority of specimens and many displayed a left and right portion (leaflet), in addition to the central anterior leaflet (Fig. 63.11). In the majority of cases (56%), the ratio between tendon and muscle was 10% to 15%; the next often (25%) was tendon/muscle ratio <10%; specimens with high ratios were rarer. These measurements suggest a difference in “availability” of tendon and muscle, suggesting that diaphragmatic procedures would benefit from being tailored to the individual subject based on their specific musculotendinous classification. This information is useful to surgeries such as pericardiectomy following lung cancer resection, as shown in a case by Tamesue et al. (2005), in which the diaphragm is an excellent graft if used as a peddled flap.

OPENINGS OF THE DIAPHRAGM

Hiatus of the Inferior Vena Cava

The hiatus of the IVC lies in the right dome of the central tendon approximately 1 inch to the right of the midline and at the level of T8. The margins of the hiatus are fixed to the vena cava, which is accompanied by branches of the right phrenic nerve (Fig. 63.12).

The collagen fiber bundles forming the right margin of the caval hiatus cross inferiorly to the bundles forming the medial and posterior margins to form a fibrous limb that can be traced to the edge of the central tendon. The tendinous fibers forming the medial margin of the hiatus are attached to the muscle fibers of the right crus. This arrangement is often omitted in textbook illustrations of the caval hiatus. Whether this arrangement of fibers constricts or enlarges the caval hiatus during inspiration has been a source of controversy for many years.

Esophageal Hiatus

The elliptical esophageal hiatus is in the muscular portion of the diaphragm an inch or less to the left of the midline at the level of T10 (Figs. 63.12 and 63.13). The anterior and lateral margins of the hiatus are formed by the muscular arms of the diaphragmatic crura, and the posterior margin is formed by the median arcuate ligament (Fig. 63.8). The anterior and posterior vagal trunks and the esophageal arteries and veins from the left gastric vessels pass through the hiatus with the esophagus. In this region, the portal circulation (left gastric vein) communicates with the systemic circulation (esophageal branches of the azygos veins).

The esophageal hiatus is of great surgical importance and is considered in more detail in the “Median Arcuate Ligament” section.

Hiatal hernia can be defined as the protrusion of a portion of the stomach into the mediastinum through the esophageal hiatus of the diaphragm. A hernial sac is present. Hiatus hernias have been traditionally classified as sliding and paraesophageal. Today, an additional type, combined sliding and paraesophageal is recognized. Congenital short esophagus is also considered as a variant of hiatal hernia. The anatomy of esophageal hiatus in each of these abnormalities is shown in Figure 63.14A.

Sliding Hiatal Hernia

In a sliding hiatal hernia, the esophagus moves freely through the hiatus

with the GEJ being in the thorax or in the normal position at different times. It is usually found in the normal position at autopsy. Sliding hernias (Fig. 63.14B) constitute 90% of all hiatal hernias. Although these hernias do slide back and forth through the hiatus, they are called *sliding hernias* because the stomach composes part of the wall of the hernial sac. Thus, they are analogous with sliding inguinal hernias, which typically involve partially retroperitoneal organs.

A sliding hernia can become secondarily fixed in the mediastinum by adhesion. In such instances, the esophagus appears to be too short to reach the diaphragm because of contraction of the longitudinal muscle coat. This type is uncommon.

Paraesophageal Hiatal Hernia

In the paraesophageal hiatal type of hernia (Fig. 63.14C), the GEJ remains in its normal location. The gastric fundus and greater curvature bulge through the hiatus anterior to the esophagus. Volvulus of the herniated stomach is a major complication.

Combined Sliding and Paraesophageal Hernia

The GEJ is displaced upward as in a sliding hernia in combined sliding and paraesophageal hernia, and the fundus and greater curvature are herniated as in a paraesophageal hernia. Paraesophageal hernias usually are of the combined type (Fig. 63.14D).

Abdominal Esophagus

Anatomically, the last 0.5 to 4.0 cm of the esophagus lies below the diaphragm, forming the abdominal esophagus. With decrease in the length of the abdominal esophagus, the pressure necessary for competence of the sphincter rises exponentially. Normal lower esophageal sphincter pressure values vary from 14.5 to 34.0 mm Hg. Ninety percent of patients who have lower esophageal sphincter pressure below 5 mm Hg experience reflux, regardless of the length of the abdominal esophagus. Similarly, reflux occurs in 90% of patients if the length of their abdominal esophagus is less than 1 cm. Thus, sphincteric incompetence is the result of a low sphincter pressure, a short abdominal esophagus, or both.

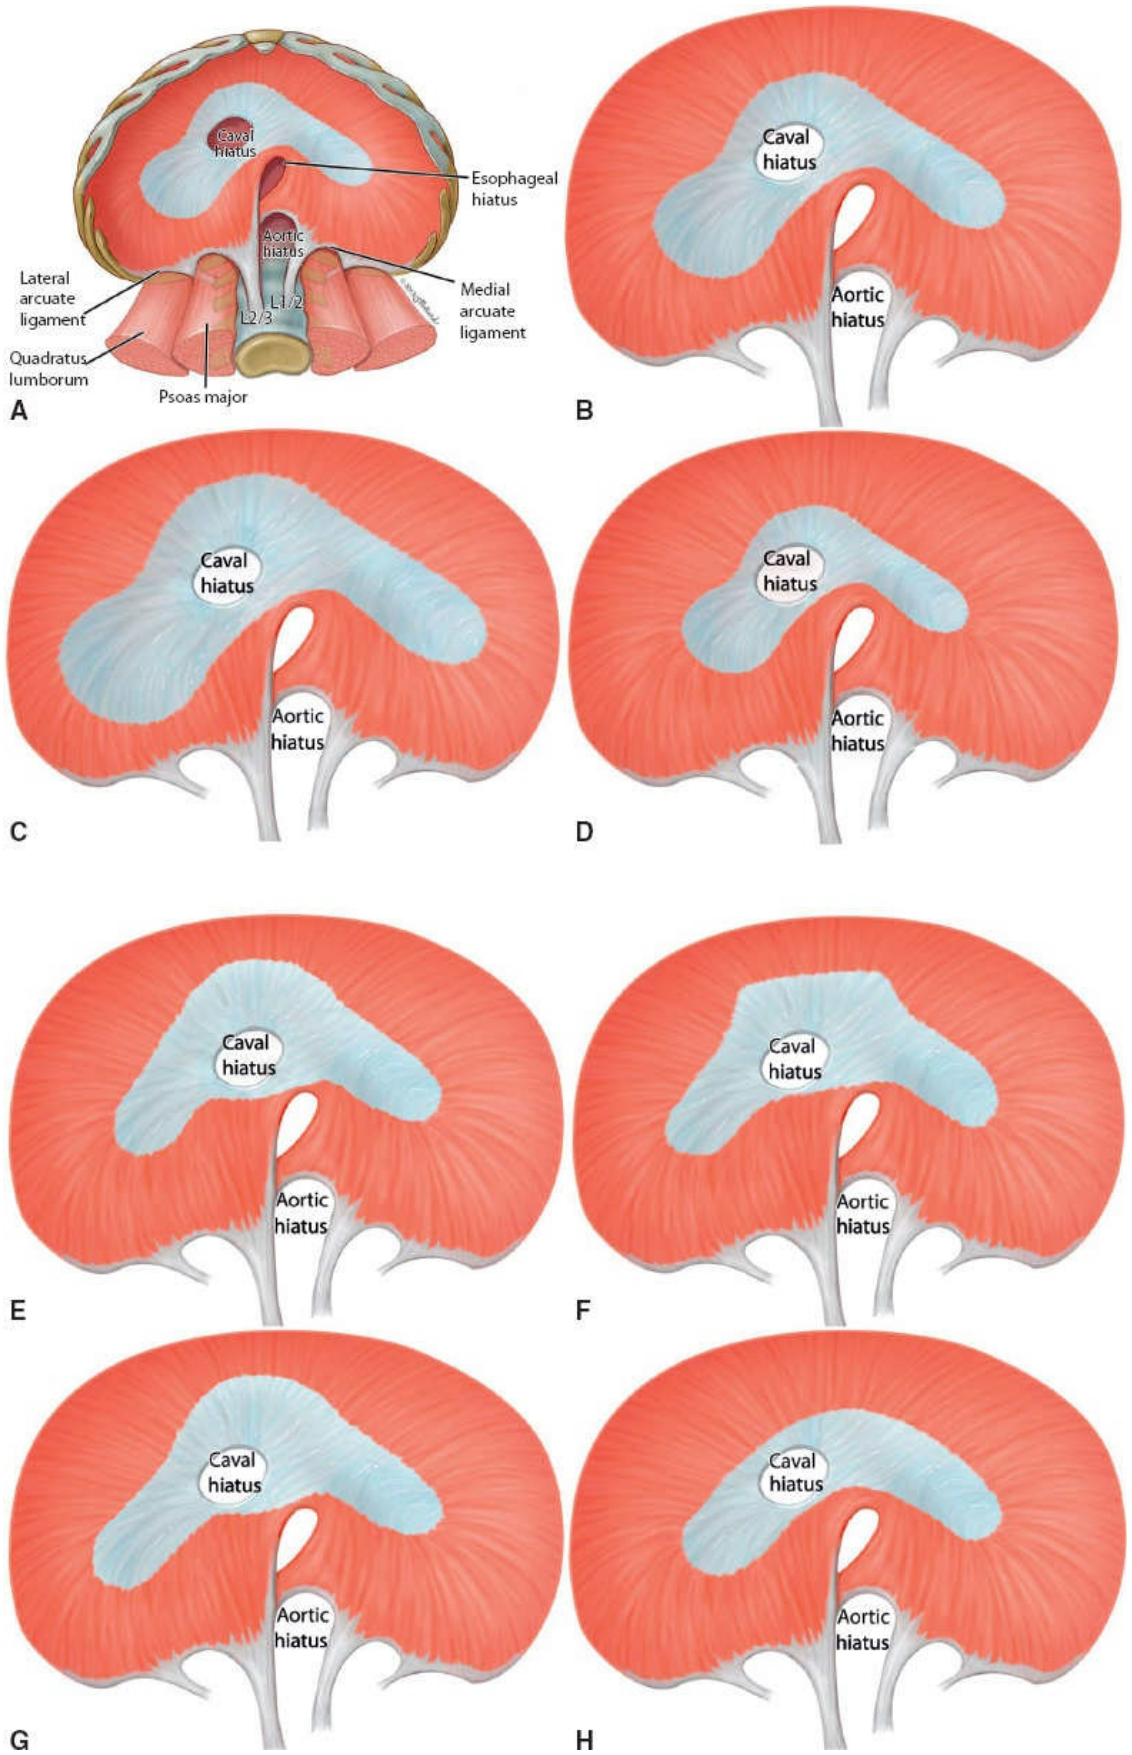

Figure 63.11. Schematic representation of the diaphragm and central tendon with the “normal” in situ anatomy (**A**), the medium

(**B**), large (**C**), and small tendon-to-muscle ratio's (**D**). Schematic representation of the diaphragm and central tendon that shows the morphology of the central portion of the tendon as oval shaped with left and right leaflets different sizes (**E**). The same shape is depicted in (**G**) but with the left and right leaflets of equal or close to equal size (**H**). The central portion has square shape while in h the tendon is elongated with no distinct demarcation between leaflets. (From du Plessis M, Ramai D, Shah S, et al. The clinical anatomy of the musculotendinous part of the diaphragm. *Surg Radiol Anat* 2015;37(9):1013–20; with permission of Springer.)

If the abdominal esophagus were the only factor governing reflux, all patients who have hiatal hernia would have esophagitis. This situation is not the case. If the hernial sac, carried up into the mediastinum, can transmit intra-abdominal pressure to the distal esophagus, it can support the sphincter. It seems clear that the abdominal esophagus plays a role in the prevention of reflux.

Phrenicoesophageal Membrane (Ligament)

A strong, flexible, airtight seal is necessary at the esophageal hiatus of the diaphragm. The seal is provided by the pleura above and the peritoneum below, whereas strength and flexibility are provided by the phrenicoesophageal ligament.

The major component of the ligament is collagenous, elastic fibers that arise as a continuation of the endoabdominal (transversalis) fascia beneath the diaphragm. Some of the elastic fibers penetrate to the submucosa of the esophagus. The transversalis fascia passes upward through the hiatus, forming a truncated cone that inserts in the adventitia and intermuscular connective tissue of the esophagus 1 or 2 cm above the diaphragm. The transversalis fascia also turns downward and inserts into the adventitia of the abdominal esophagus and the stomach. A weaker and less constant component can arise from the endothoracic fascia, passing upward to join the fibers of the endoabdominal fascia. The relations of these components of the phrenicoesophageal ligament are shown in Figure 63.15.

The phrenicoesophageal membrane inserts into the esophagus an average of 3.35 cm above the squamocolumnar epithelial junction. In 227 patients who had esophagitis, as noted by Bombeck et al. (1966), the insertion was only approximately 0.5 cm above the epithelial junction.

Fisher (2012) commented in the previous (6th) edition of Mastery of Surgery that the phrenicoesophageal ligament may have a role in stabilizing the distal esophagus in the esophageal hiatus and thus limiting the superior shift of the esophagus during periods of increased intra-abdominal pressure. In cases of an enlarged esophageal hiatus (e.g., hiatal hernia), the phrenicoesophageal ligament may limit the effect of increased intra-abdominal pressure on the distal esophagus. The phrenicoesophageal ligament was the basis of the Allison repair, which was the earliest repair for hiatus hernia.

The phrenicoesophageal ligament has been often called a “membrane.” Investigators have compared the anatomic and the histologic characteristics of the phrenicoesophageal ligament to the inguinal ligament and reported that the phrenicoesophageal ligament is a fascio-areolar structure, rather than a ligament. In addition, the phrenicoesophageal ligament gives elasticity rather than stability to the esophagus and therefore suggested that the term “lig. phrenicoesophagealis” be removed from the literature. Our histologic findings showed that the phrenicoesophageal ligament is a dense connective tissue formed by collagen and elastic fibers where the nuclei of fibroblasts were elongated in the direction of the collagen fibers and supplied with blood vessels, in all age groups. The collagen fibers were thick and organized in parallel fashion and the elastic fibers surrounded the collagen fibers tightly in the sections taken from younger specimens. Although the collagen alignment in the phrenicoesophageal ligament is not as straight as the alignment in tendons, it has a specific orientation that is regular and parallel. However, this organization is not as irregular as in dense irregular connective tissue. Thus, we suggest that since the phrenicoesophageal ligament also consisted of regularly oriented parallel bundles of collagen fibers, it could be defined as a “visceral ligament.” However, with older age, the number of collagen fibers decreased and became more irregularly arranged. The amount of adipose infiltration was also increased in these specimens.

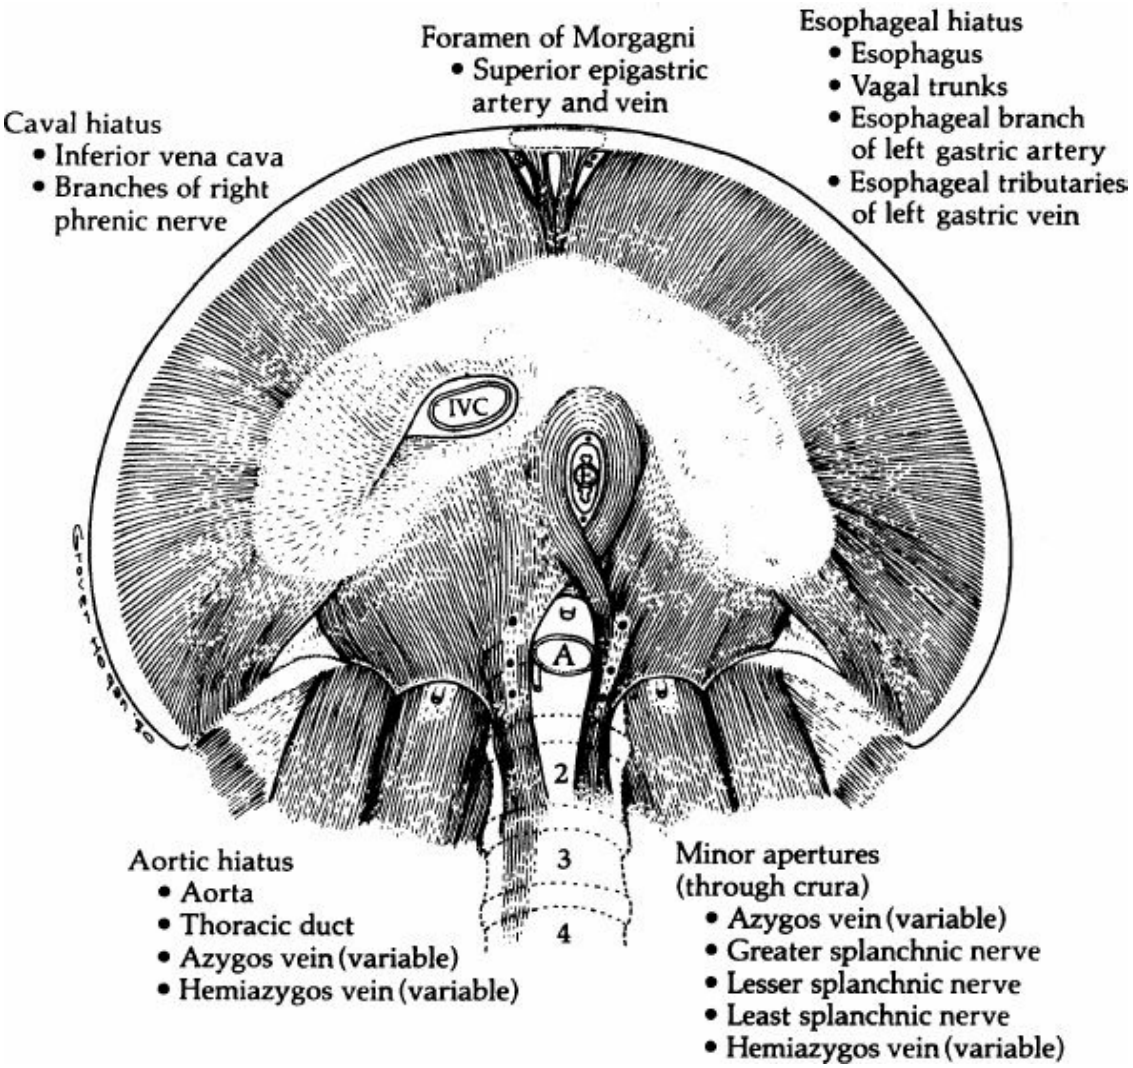

Figure 63.12. The apertures of the diaphragm seen from below and the structures transversing them. A, aorta; E, esophagus; IVC, inferior vena cava.

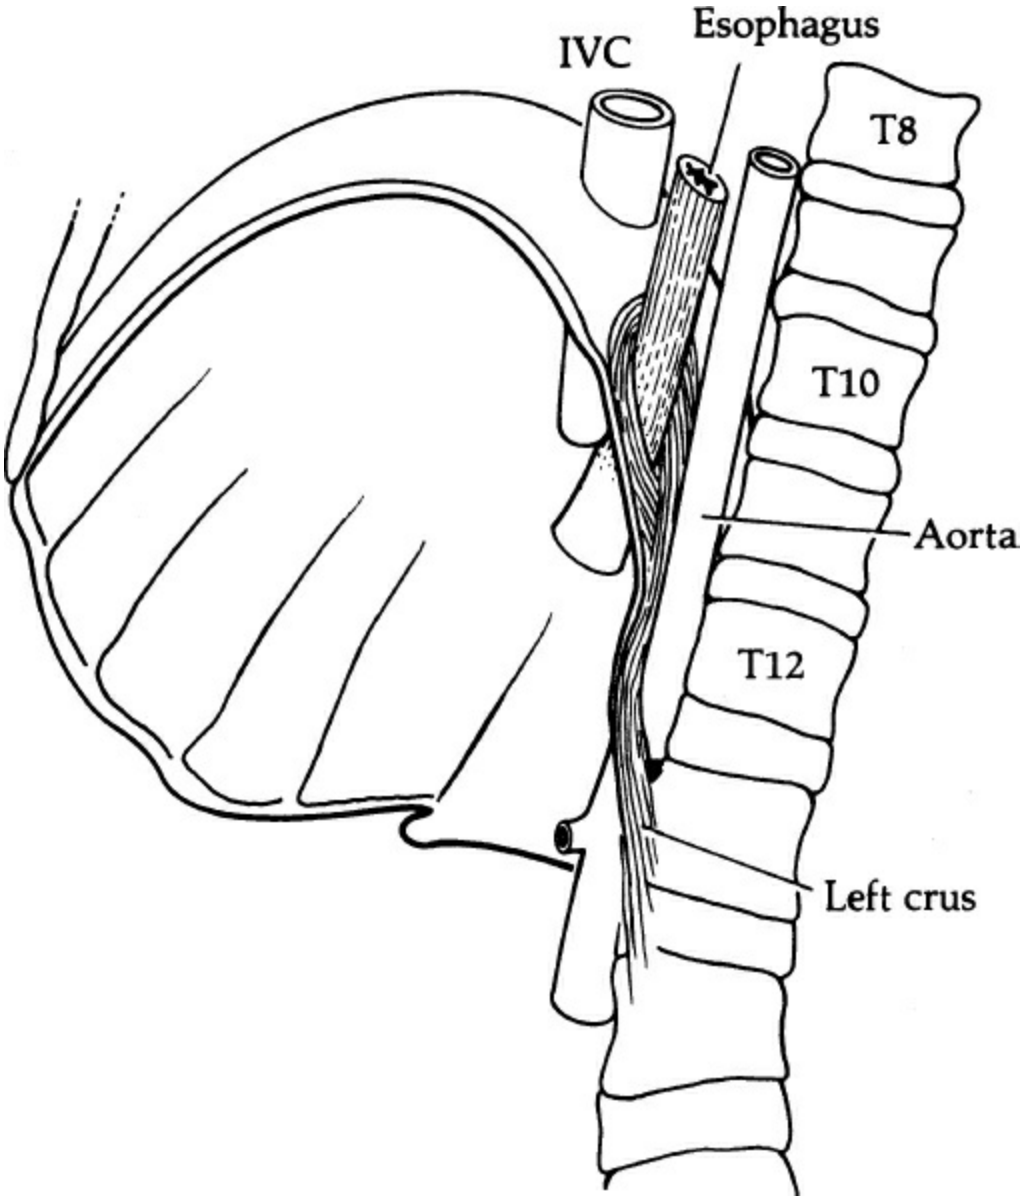

Figure 63.13. The diaphragmatic openings for the inferior vena cava (IVC), the esophagus, and the aorta, as seen from the left.

Descriptions of the phrenicoesophageal ligament vary because the tissue changes with age. In the fetus, the esophagus and diaphragm are tightly joined at the hiatus by connective tissue. With the onset of respiratory movements and swallowing in postnatal life, the two structures become less firmly attached, and the space between them fills with loose connective tissue and fat.

The development of the phrenicoesophageal membrane has been studied by Botros et al. (1983). They agree with Carey and Hollinshead (1955) that loose connective tissue with collagenous and elastic fibers arises from both surfaces of the diaphragm and attaches to the esophagus.

Between these fascial components, a layer of crural striated muscle is found in the 10-week-old fetus. With age, the muscle fibers undergo gradual regression and replacement with collagen fibers. Muscle fibers in the adult phrenicoesophageal membrane should be considered vestigial.

The natural course of the phrenicoesophageal ligament can be summarized as follows (Androulakis et al. 1966):

1. In newborn infants, the phrenicoesophageal ligament is present.
2. In adults, the ligament is attenuated and subperitoneal fat accumulates at the hiatus.
3. In adults who have hiatal hernias, the ligament for all practical purposes does not exist.

Aortic Opening

The oblique course of the aorta takes it behind the diaphragm rather than through it (Fig. 63.13). At the level of T12, the anterior border of the opening is the median arcuate ligament; laterally the diaphragmatic crura form its margins. The thoracic duct and (usually) the azygos vein accompany the aorta.

Other Openings in the Diaphragm

Anteriorly, the superior epigastric vessels pass through the parasternal spaces (foramina of Morgagni). In the dome of the diaphragm, the phrenic nerves pierce the upper surface to become distributed over the lower surface between the muscle and the peritoneum.

The azygos vein can pass behind the diaphragm with the aorta, to the right of the right crus, or it can pierce the right crus. Also passing through the crura are the greater, lesser, and least splanchnic nerves (Fig. 63.12).

Median Arcuate Ligament

The median arcuate ligament is a rim of connective tissue that extends between the crura of the diaphragm and arches over the aorta (Fig. 63.16). In all dissections by Loukas et al. this rim was a constant finding irrespective of the configuration of the crura.

The median arcuate ligament passes in front of the aorta at the level of L1 just above the origin of the celiac trunk (Figs. 63.8 and 63.17). The celiac ganglia lie just below and lateral to the celiac trunk, in intimate juxtaposition. The median arcuate ligament and the origin of the celiac artery become slightly lower with increasing age. In 16% of patients, a low median arcuate ligament covers the celiac artery and can compress it. This clinical condition known as celiac artery compression syndrome (CACS) or Dunbar syndrome has proven controversial in definition and relevance. This condition was first described as chronic abdominal pain because of the mesenteric ischemia caused by extrinsic compression of the celiac artery. Dunbar and others presented surgical approaches to decompress the celiac artery by releasing the median arcuate ligament. Definitive answers have been sought to classify and relieve the clinical symptoms patients experience postprandially. Persistent symptoms following surgical

treatment for CACS have led investigators to question the existence of this disease. Advances in technology such as angiographic MRI and color duplex ultrasonography have refreshed the importance of considering compression of the celiac artery during differential diagnoses. Because of the varying anatomic etiologies of disease, it is not possible to pinpoint a single cause for CACS. Potential etiologies for compression of the celiac artery include a “high take off” origin of the celiac artery compressed by normal diaphragmatic crura and median arcuate ligament, a normal origin of the celiac artery with long diaphragmatic crura and median arcuate ligament, large bilaterally fused celiac ganglia (with or without the involvement of the superior mesenteric ganglia) compressing the celiac trunk, celiacomesenteric trunk compression by diaphragmatic crura and median arcuate ligament, or combinations of the above-mentioned entities.

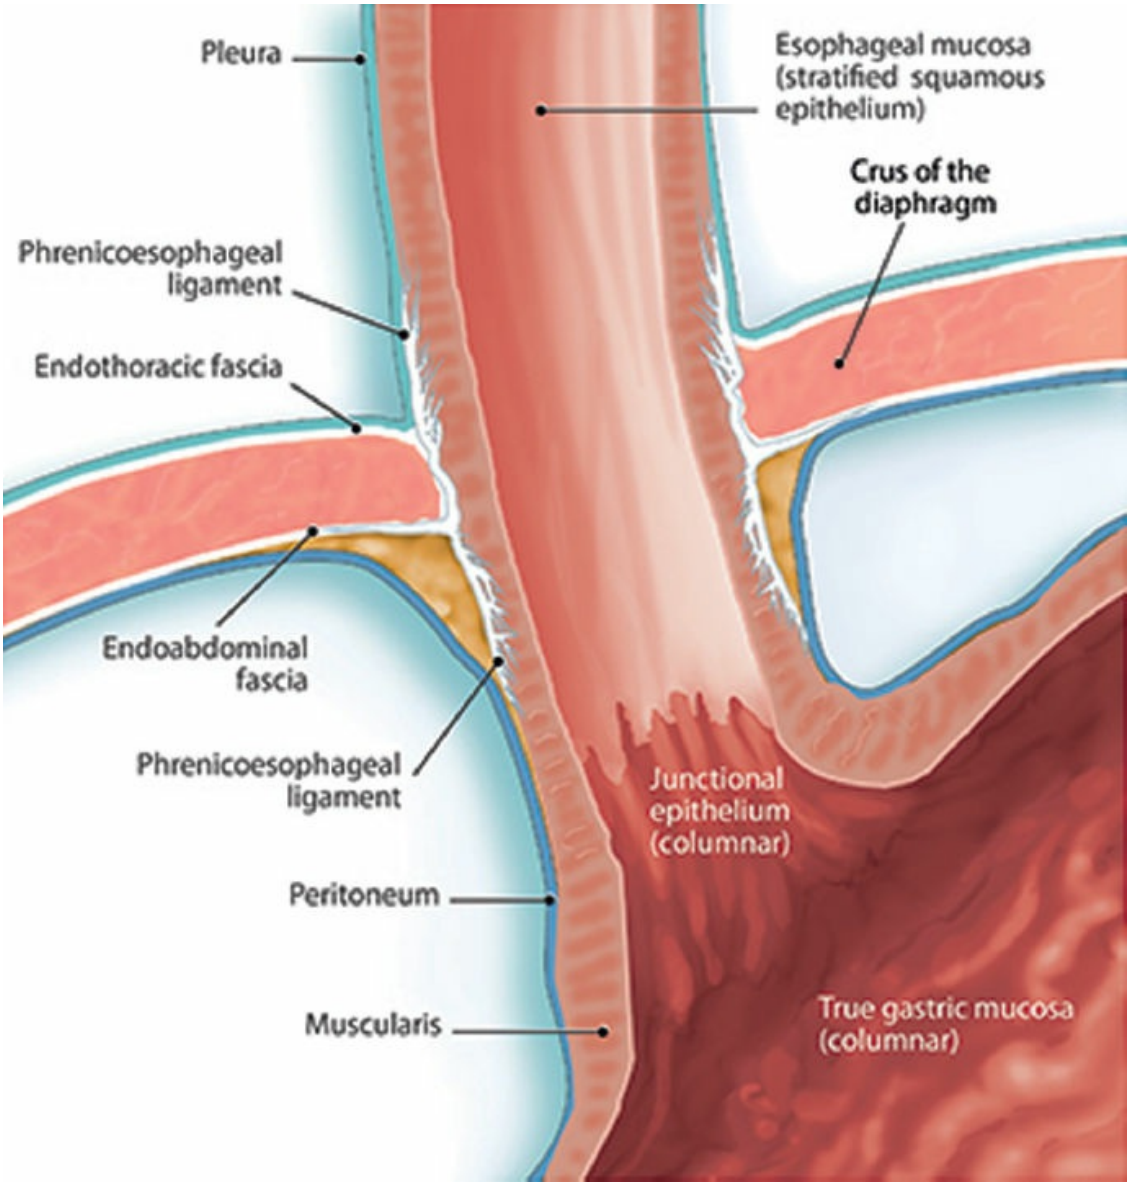

Figure 63.15. Structures at the gastroesophageal junction and the diaphragmatic hiatus.

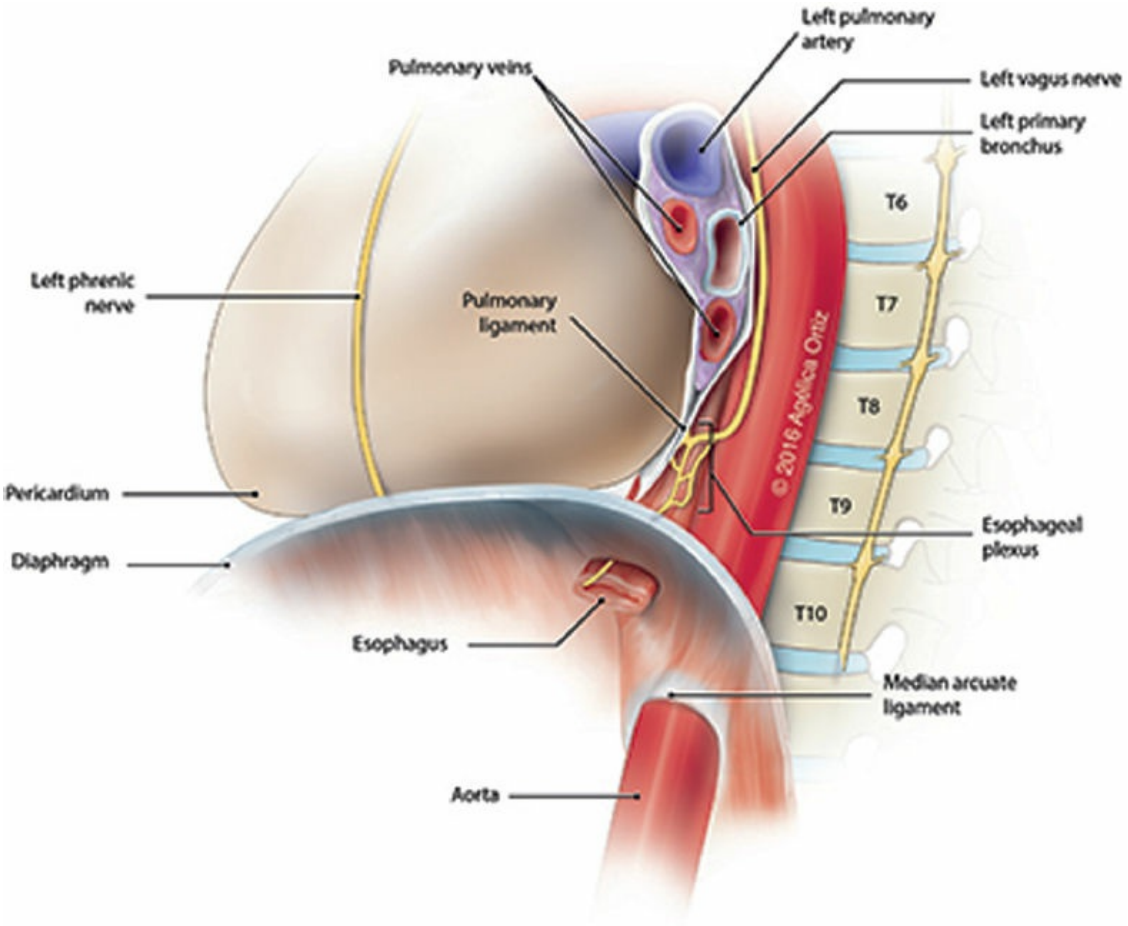

Figure 63.16. Structures in the inferior portion of the left mediastinum.

If there is no true median arcuate ligament, and the muscular arms of the crura are thinned by posterior extension of the esophageal hiatus, the aortic and esophageal openings can become practically confluent, although there is always some connective tissue between them.

In approximately half of the cadavers having hiatal hernia that we examined, the ligament was sufficiently well developed to use in surgical repair of the esophageal hiatus. In the remainder, there was enough preaortic fascia lateral to the celiac trunk to perform a posterior fixation of the GEJ. The celiac ganglion, just below the arcuate ligament, must be avoided.

DIAPHRAGMATIC, PLEURAL, AND MEDIASTINAL RELATIONS

Over much of the anterosuperior surface of the diaphragm, the fibrous tissue of the central tendon is continuous with the fibrous pericardium (Fig. 63.18).

In addition to the pericardium, the mediastinum on the right contains the IVC, the right phrenic nerve and pericardiacophrenic vessels, the right pulmonary ligament, the esophagus with the right vagus nerve and esophageal plexus, the thoracic duct, the azygos vein and azygos arch, the greater and lesser right thoracic splanchnic nerves, the right sympathetic trunk, and the right posterior intercostal arteries (Fig. 63.19).

In the left mediastinum are the pericardium, the left phrenic nerve and pericardiacophrenic vessels, the esophagus, the left vagal trunk, the descending aorta, the hemiazygos vein, the accessory hemiazygos vein, the highest intercostal vein, the greater and lesser left thoracic splanchnic nerves, and the left sympathetic trunk (Fig. 63.16).

The triangle (of Truesdale), formed by the pericardium, the aorta, and the diaphragm, contains the left pulmonary ligament and the distal esophagus. In sliding hiatal hernia, the stomach is in this triangle. The cardiophrenic space is located in the most central portion of the mediastinum and is bordered by the base of the heart, diaphragm, and chest wall. This area of contact between the heart and the diaphragm divides the cardiophrenic space into anterior and posterior. Most pathologic alterations are located in the anterior cardiophrenic space. In normal individuals, the cardiophrenic space is occupied by fat. An increase in the amount of normal pericardial fat is often seen in overweight individuals. The appearance of normal pericardial fat in the cardiophrenic space often simulates tumorous disease on plain chest radiographs. The absence of encapsulation or soft-tissue components is useful to differentiate prominent fat from lipomas or other fat-containing tumors.

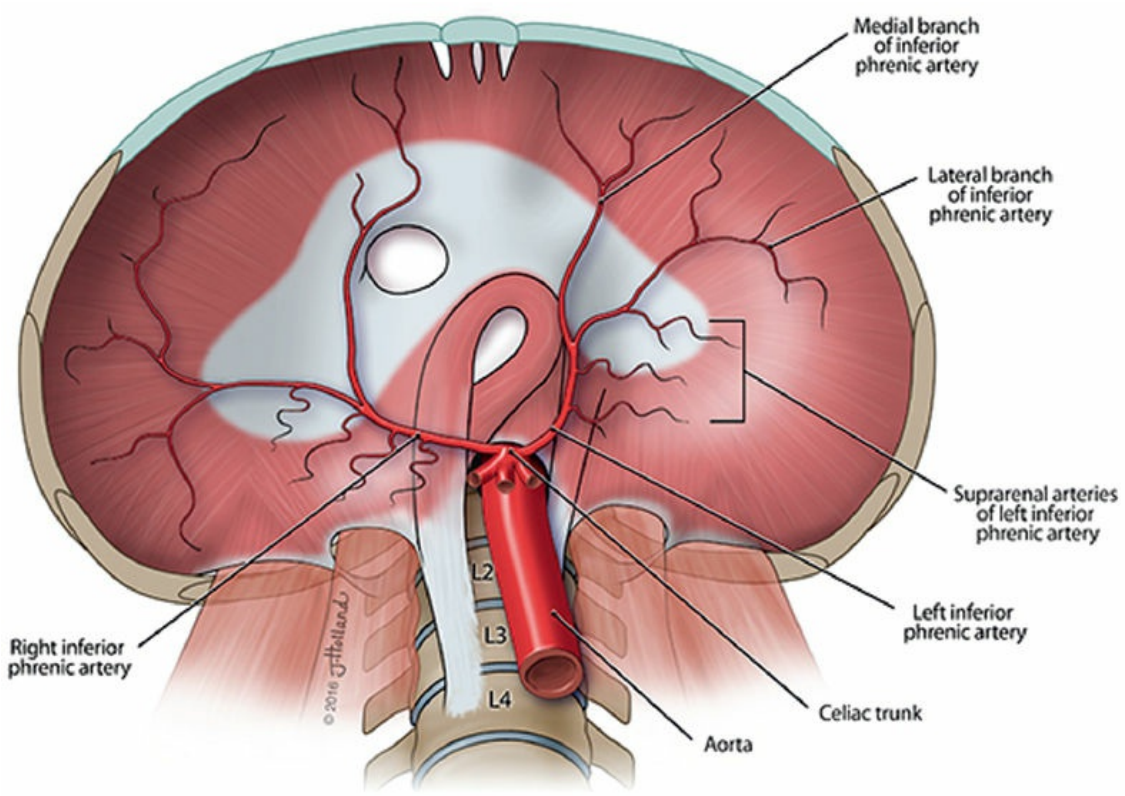

Figure 63.17. Arterial supply of the diaphragm from below. The inferior phrenic arteries can arise from the celiac trunk or directly from the aorta. E, esophagus; IVC, inferior vena cava.

The right pleura is in contact with the lower third of the esophagus almost down to the esophageal hiatus. This situation creates the risk of accidental entrance into the pleural cavity during abdominal operations on the esophageal hiatus. In spite of this proximity of the right pleura, the surgeon, working on the right side of the operation table, is more likely to produce a pneumothorax or hemopneumothorax on the left.

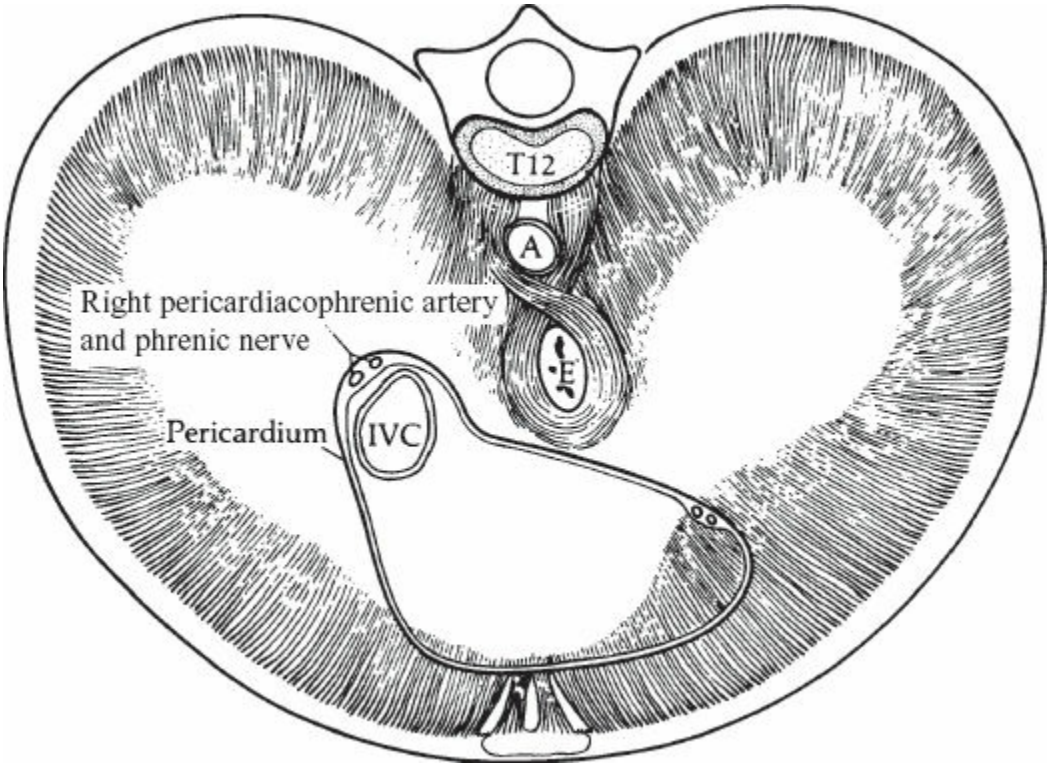

Figure 63.18. The diaphragm viewed from above. The area in contact with the pericardium is indicated. The pericardial fibrous tissue is continuous with that of the diaphragm. A, aorta; E, esophagus; IVC, inferior vena cava.

The diaphragmatic pleura is part of the parietal pleura, and covers all parts of the diaphragm except the part of the central tendon that is in contact with the pericardium. It is heavily fixed to the diaphragm through the phrenicopleural fascia of the endothoracic fascia in such a way that separation from the diaphragm is practically impossible. This situation is in contrast to the costal pleura, which can be stripped away along with the endothoracic fascia.

The costodiaphragmatic recess is located at the reflection of the parietal pleura from the ribs to the diaphragm. The phrenicomediastinal recess (lower part of the costomediastinal recess) is between the mediastinum and the diaphragm.

PERITONEAL ATTACHMENTS ON THE INFERIOR SURFACE OF THE DIAPHRAGM

The primitive dorsal and ventral mesenteries of the abdomen form a number of ligaments related to the diaphragm and the GEJ (Fig. 63.20).

Falciform, Coronary, and Triangular Ligaments

The falciform ligament, a remnant of the primitive ventral mesentery, arises from the anterior abdominal wall and extends to the anterior surface of the liver and the diaphragm. In its free edge encircles the round ligament of the liver, the obliterated left umbilical vein.

The leaves of the falciform ligament separate over the liver to form the anterior and posterior layers of the coronary ligament. Enclosing the bare area on the right, these leaves unite laterally to form the right triangular ligament. On the left, the leaves are in apposition to each other, forming the left triangular ligament. The lower leaf of the right and of the left coronary ligament continue to meet the esophagus. The latter, when entering the abdomen, is covered by peritoneum from infront, lower from infront and laterally, until lower in GEJ, where the esophagus is totally enveloped by the continuation of the lesser omentum. Thus behind the abdominal esophagus there is a bare area on the diaphragm (Fig. 63.20).

One approach to the GEJ is to section the left triangular and left portion of the posterior layer of the coronary ligament. In operating, one must be careful in mobilization of the liver, especially the left lobe, not to injure the left hepatic vein or the IVC.

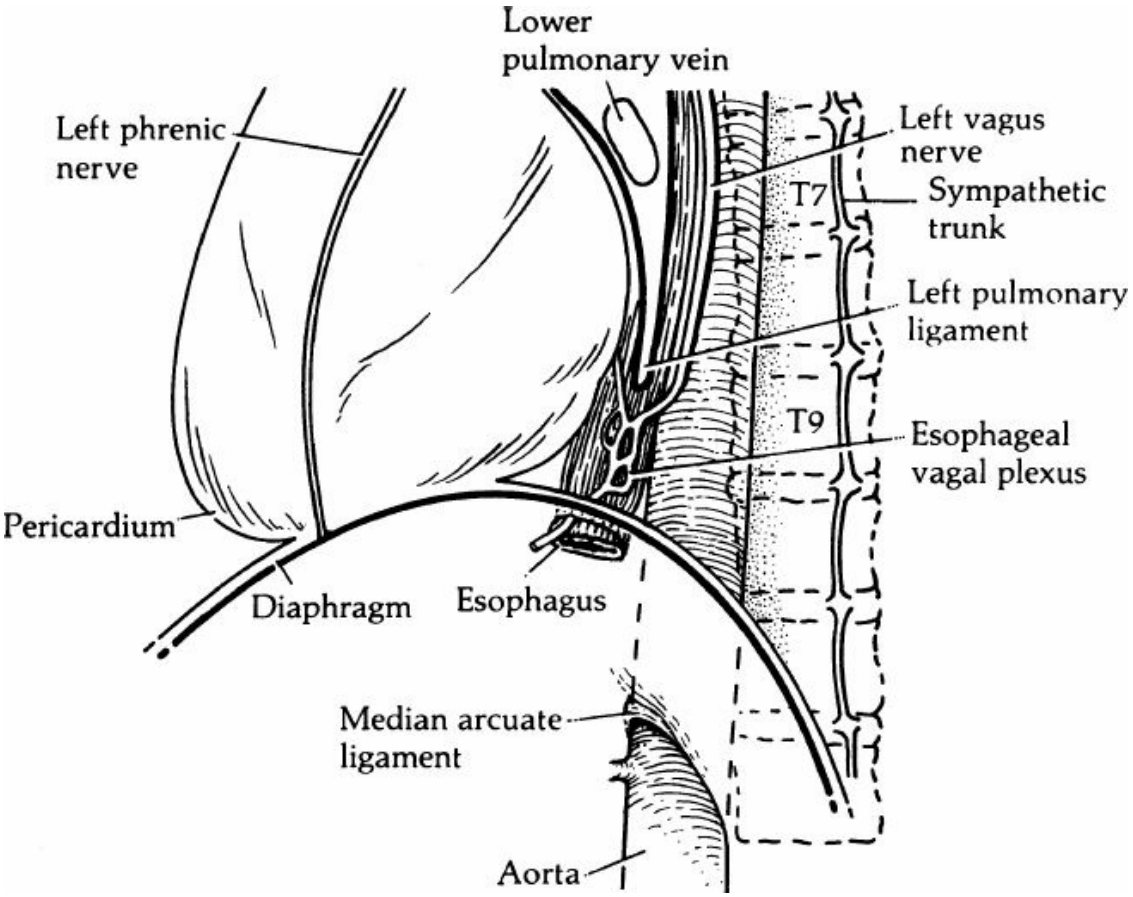

Figure 63.19. Structures in the inferior portion of the right mediastinum. IVC, inferior vena cava.

Gastrophrenic Ligament

The gastrophrenic ligament, the superior portion of the dorsal mesentery, arises from the greater curvature of the fundus and extends upward to the diaphragm (Fig. 63.20). The upper part is transparent and avascular, continuous with the posterior layer of the coronary ligament on the left. The lower part is continuous with the gastrosplenic ligament and contains some short gastric vessels and lymph nodes.

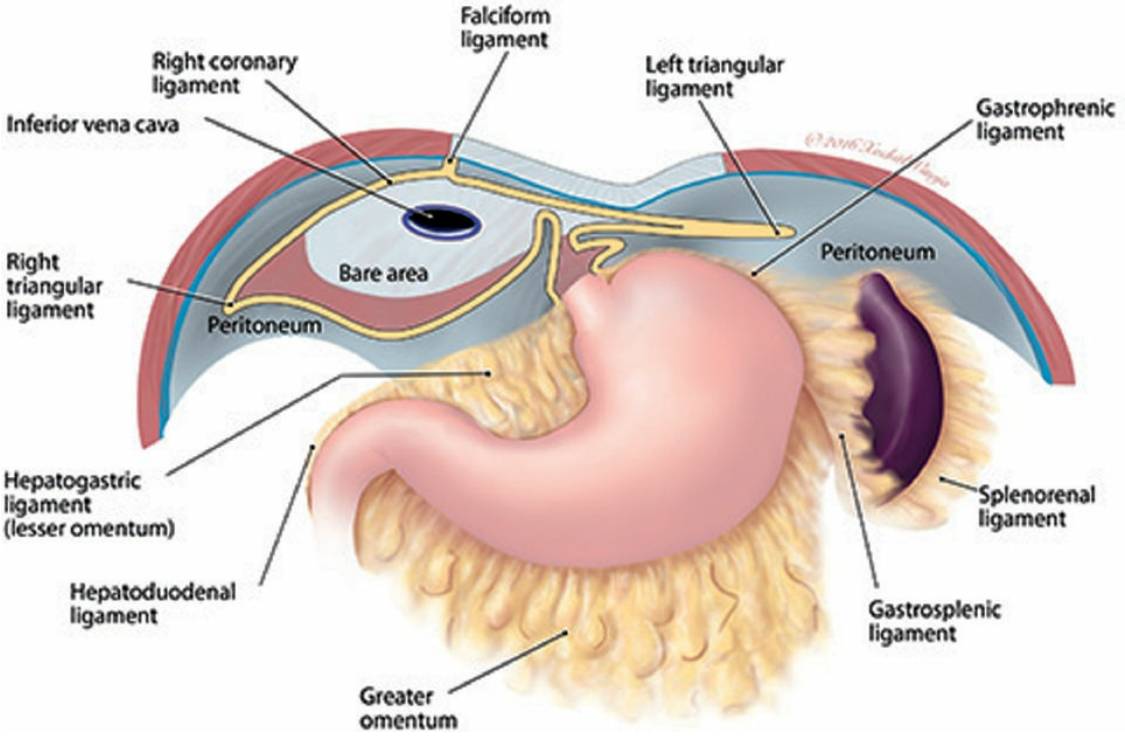

Figure 63.20. Peritoneal reflections of the stomach, gastroesophageal junction, and bare area of the diaphragm. The parietal peritoneum on the diaphragm is shown in *grey color.* The reflections of the parietal peritoneum toward visceral peritoneum are *bright yellow.* The stomach and spleen are covered by the visceral peritoneum. The liver that shares the bare area has been removed. The lower esophagus and lesser omentum have been cut in order to obtain view to the bare area and reflections of the peritoneum.

The upper, avascular area can be perforated by the surgeon's finger in order to insert a Penrose drain around the cardia. The surgeon can thus apply gentle traction on the endoabdominal esophagus and mobilize the GEJ.

VASCULARIZATION OF THE DIAPHRAGM

Arteries

The vascular supply of the diaphragm comes from several sources: (a) The inferior phrenic arteries, which are branches of the abdominal aorta or the celiac axis. (b) The superior phrenic arteries, which are branches of the thoracic aorta. These arteries are distributed to the posterior part of the diaphragm. (c) The pericardiacophrenic arteries, terminal branches of the internal thoracic (mammary) arteries; they follow the phrenic nerves and

supply the central area of the diaphragm. (d) The musculophrenic arteries, also terminal branches of the internal thoracic arteries, running laterally near the attachment of the diaphragm to the lower ribs. (e) The lower intercostal arteries, feeding the posterior periphery of the diaphragm.

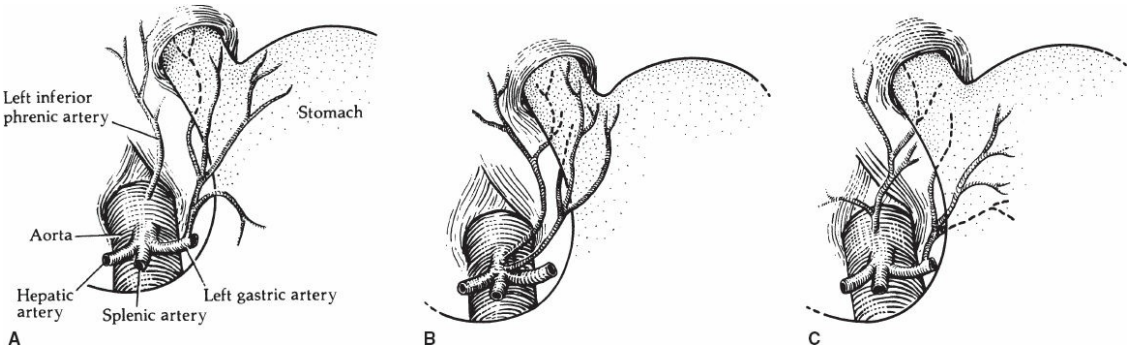

Figure 63.21. Variations in the blood supply to the distal esophagus and the esophageal hiatus. **A:** The inferior phrenic artery supplies the margin of the hiatus. An esophageal branch of the left gastric artery supplies the esophagus and anastomoses with thoracic esophageal arteries. The pattern is the most frequent one. **B:** The esophagus is supplied by esophageal branches of the left gastric and the inferior phrenic arteries without cranial anastomoses. **C:** The esophagus is supplied entirely by a branch of the inferior phrenic artery, which anastomoses with thoracic esophageal arteries. This pattern is rare. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery*. New York: McGraw-Hill, 1983, with permission.)

The major blood supply to the diaphragm comes from the inferior phrenic arteries (Fig. 63.17). Loukas et al. (2005) reported that the right inferior phrenic artery originated from the celiac trunk in 40% of their cadaveric specimens, the aorta in 38%, the right renal artery in 17%, the left gastric artery in 3%, and the hepatic artery proper in 2%. The left inferior phrenic artery originated from the celiac trunk in 47%, the aorta in 45%, the left renal artery in 5%, the left gastric artery in 2%, and the hepatic artery proper in 1%. The inferior phrenic arteries give rise to eight notable branches: ascending, descending, IVC, superior suprarenal, middle suprarenal, esophageal, diaphragmatic hiatal, and accessory splenic. In some persons, the lower esophagus which is supplied by the left gastric artery, receives twigs from the left inferior phrenic artery. In still others, branches of the inferior phrenic artery supply the lower esophagus;

branches of the left gastric artery are confined to the cardia and fundus of the stomach (Fig. 63.21). The margin of the hiatus is always supplied by a branch of the left inferior phrenic artery.

The surgeon must be aware of collateral circulation in several situations. According to Michels, in pathologic situations, such as a hepatocellular carcinoma, there is a possibility of collateral pathways between the arteries mentioned in the first paragraph of this heading. We add the anastomoses between the esophageal branches of the left gastric artery and the left inferior phrenic artery. Sources of collateral circulation for the liver could be branches of the right phrenic artery, and multiple branches in the bare area of the liver (passing from the diaphragm to the liver).

Veins

On the superior surface, small tributaries form the musculophrenic and pericardiacophrenic veins, which run with the corresponding arteries. Respectively, they empty into the internal thoracic and (perhaps) brachiocephalic veins. Posteriorly there is some local drainage into the azygos and hemiazygos veins.

On the inferior surface, the right inferior phrenic vein runs with the artery and empties into the IVC. Loukas et al. (2005) reported that the right inferior phrenic vein drained into the IVC inferior to the diaphragm in 90%, the right hepatic vein in 8%, and the IVC superior to the diaphragm in 2% of specimens. The left inferior phrenic vein drained into the IVC inferior to the diaphragm in 37%, the left suprarenal vein in 25%, the left renal vein in 15%, the left hepatic vein in 14%, and both the IVC and the left adrenal vein in 1% (Fig. 63.22). The branch draining into the vena cava passes in front of the esophagus closely enough to be injured. These findings may have clinical implications for the performance of endoscopic sclerotherapy and mobilization of the supradiaphragmatic segment of the IVC.

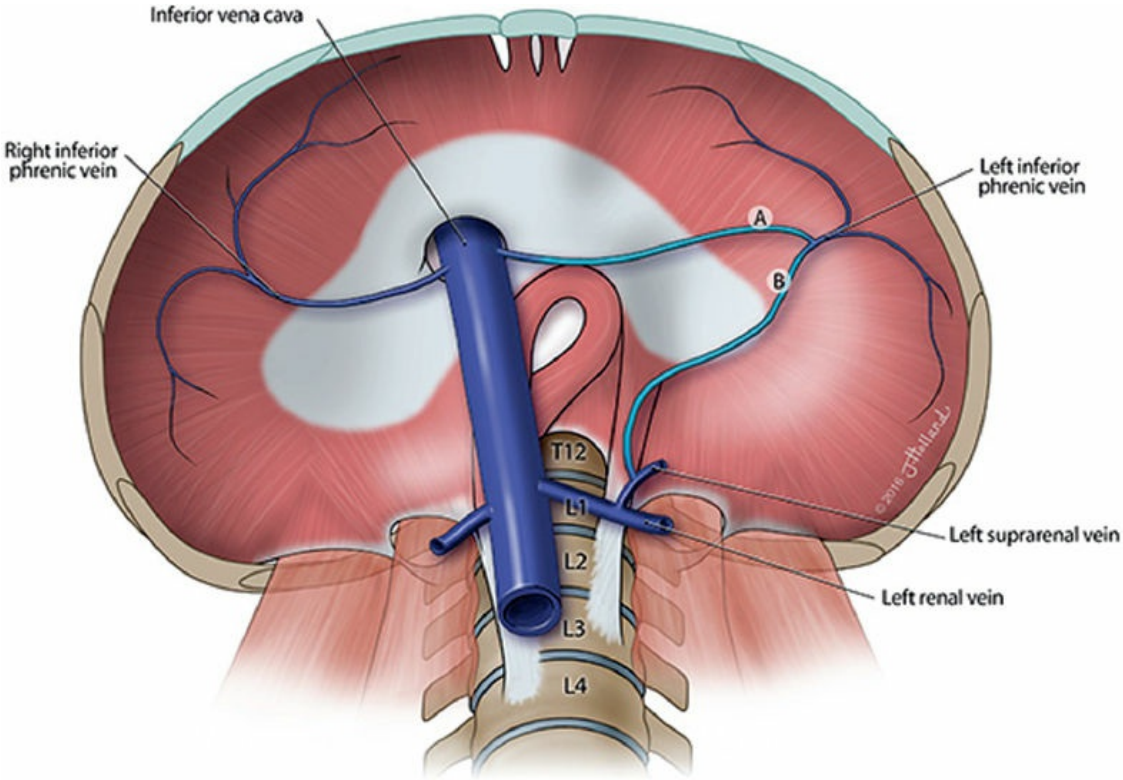

Figure 63.22. Venous drainage of the diaphragm from below. The left inferior phrenic vein may enter the inferior vena cava (IVC) (*A*), the left suprarenal vein (*B*), or both.

LYMPHATIC DRAINAGE OF THE DIAPHRAGM

Almost all the diaphragmatic lymph nodes lie on the superior surface of the diaphragm. These nodes can be divided into anterior, middle, and posterior groups (Fig. 63.23). They receive drainage from the upper surface of the liver, the GEJ, and the abdominal surface of the diaphragm. Efferent lymph vessels from these nodes drain upward to parasternal and mediastinal nodes anteriorly, and to posterior mediastinal and brachiocephalic nodes posteriorly.

The abdominal surface of the diaphragm is drained by lymphatics that direct to the supradiaphragmatic lymph nodes. However, in the abdominal surface there is some drainage via lymphatics that course retroperitoneally and join the renal and cisternal lymph nodes (Fig. 63.24).

The abdominal serosal surfaces of the diaphragm are active in the removal of fluid and cells from the peritoneal cavity. Pores between mesothelial cells from 4 to 12 μm in diameter open directly into the lymphatic vessels of the diaphragm. First seen in 1863 by von Recklinghausen, their existence has been confirmed by electron microscopy. Clinically, they may provide escape for tumor cells,

pathogens, and toxins from the peritoneal cavity. They also provide access for peritoneal dialysis in treating renal failure. All surgeons placing Tenckhoff peritoneal catheters take advantage of this function of the lymphatics in the abdominal surface of the diaphragm.

NERVE SUPPLY TO THE DIAPHRAGM

The right phrenic nerve enters the diaphragm through the central tendon just lateral to the opening for the IVC. Occasionally, it passes through that opening with the vena cava. The left phrenic nerve pierces the superior surface of the muscular portion of the diaphragm just lateral to the left border of the heart.

Both nerves divide or trifurcate at just above the diaphragm, and the branches travel together into the musculature. Small sensory branches are given off to the pleura and to the peritoneum over the central part of the diaphragm. The larger motor branches separate within the diaphragm into three or four major nerve trunks: sternal, anterolateral, posterolateral, and crural; the last two usually have a common trunk. These nerve trunks travel partly within the diaphragmatic musculature and partly on the inferior surface covered only by the peritoneum. The sternal branches of the two sides can anastomose behind the sternum (Fig. 63.25).

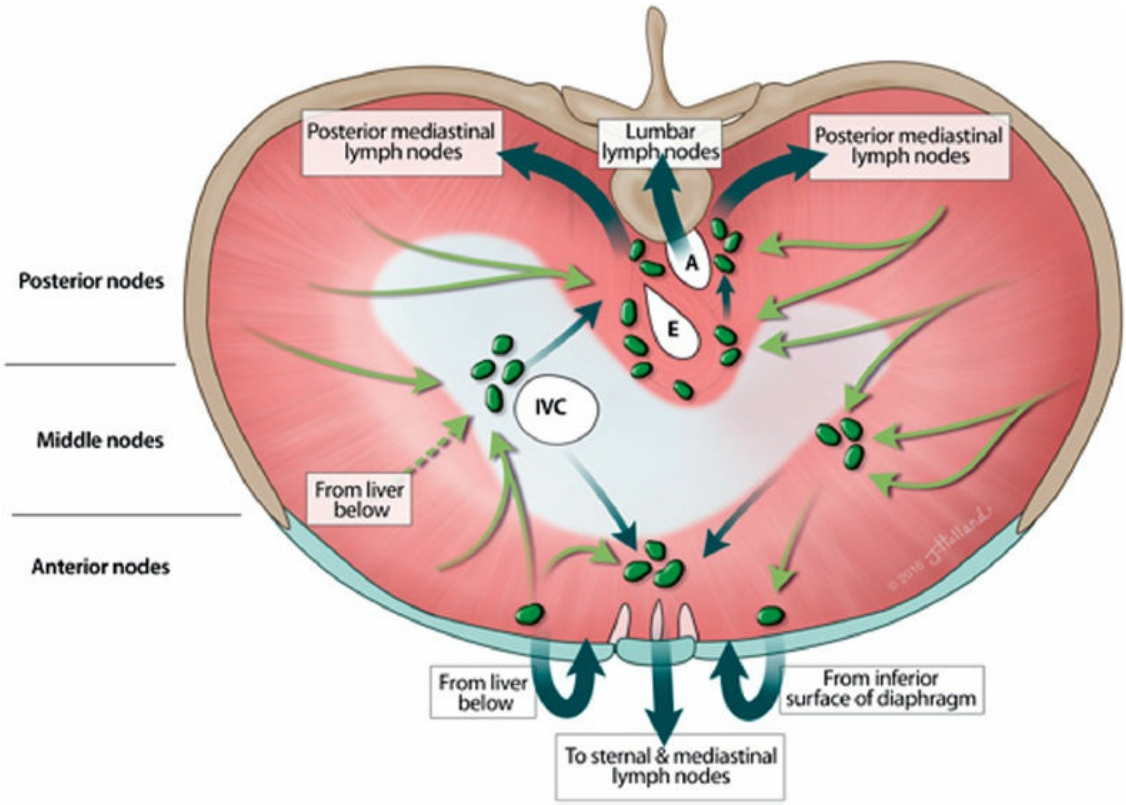

Figure 63.23. Lymphatic drainage of the diaphragm seen from above. The diaphragm receives lymph from the liver below and sends it to ascending sternal, anterior, and posterior mediastinal nodes. *A,* aorta; *E,* esophagus; *IVC,* inferior vena cava.

Recently, Loukas et al. (2016) reported that the right phrenic nerve was found inferior to the diaphragm in 98% of the specimens with 49.1% displaying a right phrenic ganglion. In 22.8% of the specimens there was an additional smaller ganglion (right accessory phrenic ganglion). Most specimens (65.5%) exhibited plexiform communications with the celiac ganglion, aorticorenal ganglion, and suprarenal gland. The left phrenic nerve inferior to the diaphragm was observed in 60% of specimens with 19% containing a left phrenic ganglion. No accessory left phrenic ganglia were observed. The left phrenic ganglion exhibited plexiform communications to several ganglia in 71.4% of specimens. Both phrenic nerves and ganglia were closely related to the diaphragmatic crura. Subdiaphragmatic phrenic nerves, ganglia, and their connections with autonomic ganglia are shown in Figure 63.26.

The presence of a classical phrenic ganglion in approximately 50% of human specimens suggests that this may constitute a potential source of extraphrenic innervation. The communication between the phrenic nerve, phrenic ganglion, and celiac ganglion provides structural evidence to suggest a flow of retrograde impulses via the celiac plexus and phrenic ganglia (peripheral control) for diaphragmatic function. The existence of these communications allows for the possibility of a viscerosomatic communication through which the respiratory function of the diaphragm may in part be controlled peripherally. These “peripheral controls,” if present, may prove particularly active during times when the action of breathing is regulated by variations in autonomic tone, such as sleeping. As reported in the paper by Loukas et al. (2016):

“Additional evidence for viscerosomatic regulation comes from reports describing neurogenic shock and respiratory paralysis following trauma to the epigastrium (Robinson, 1907; Furuya et al., 1979). By extension, if one considers the possibility of this viscerosomatic control, preservation of these fibers could prove particularly important during surgical procedures to the region. Owing to their location anterior to the diaphragmatic crura, the right phrenic ganglion, right accessory phrenic ganglion, and left phrenic ganglion could potentially be injured during operations for repair of diaphragmatic hernia and median arcuate ligament syndrome.

Conversely, if there is indeed sympathetic innervation of the diaphragm and its crura within these fibers, as proposed by Tubbs et al. a highly selective sympathectomy of the phrenic ganglia could be explored as a potential therapeutic alternative in the treatment of median arcuate ligament syndrome (Tubbs et al., 2008).”

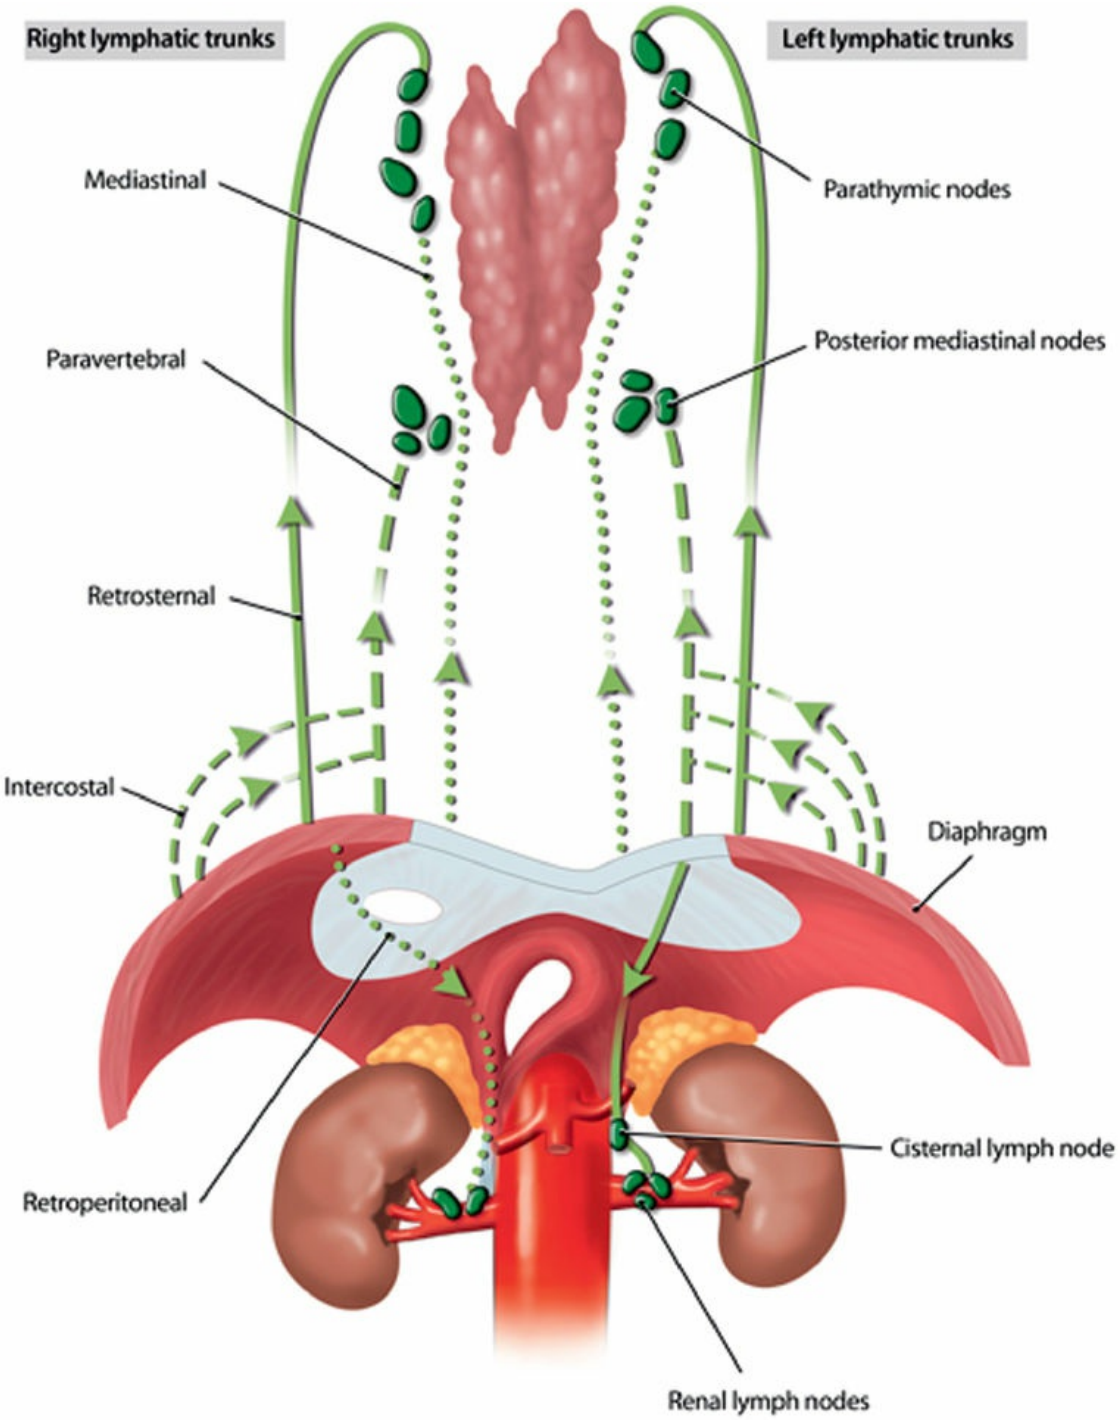

Figure 63.24. Diagram showing an anterior view of the lymphatic drainage routes of the diaphragm and their relative importance. The latter is judged on the basis of size, frequency, and intensity of coloration with ink:…, constant; –, usual; —, occasional. (Redrawn from Abu-Hijleh MF, Habbal 0A, Moqattash ST. The role of the diaphragm in lymphatic absorption from the peritoneal cavity. *J Anat* 1995;186:453–67; with permission from John Wiley and Sons.)

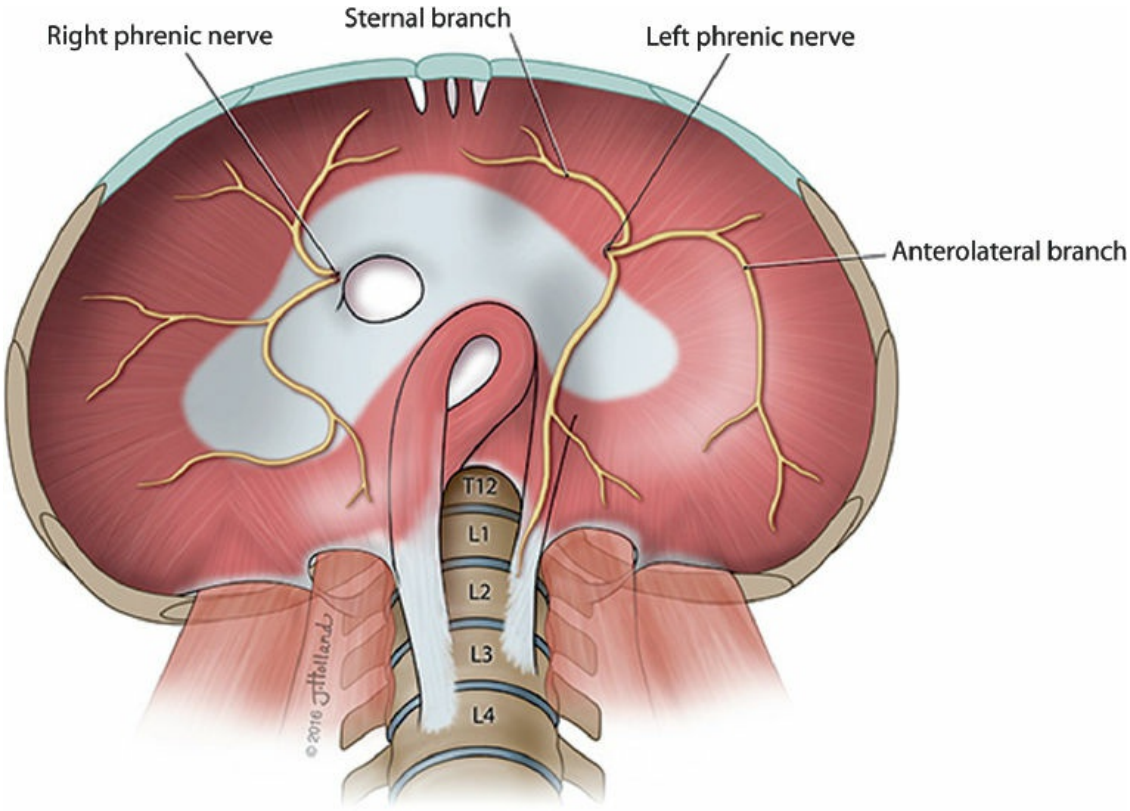

Figure 63.25. The major branches of the phrenic nerves from below. Each phrenic nerve divides just before entering the diaphragm from above.

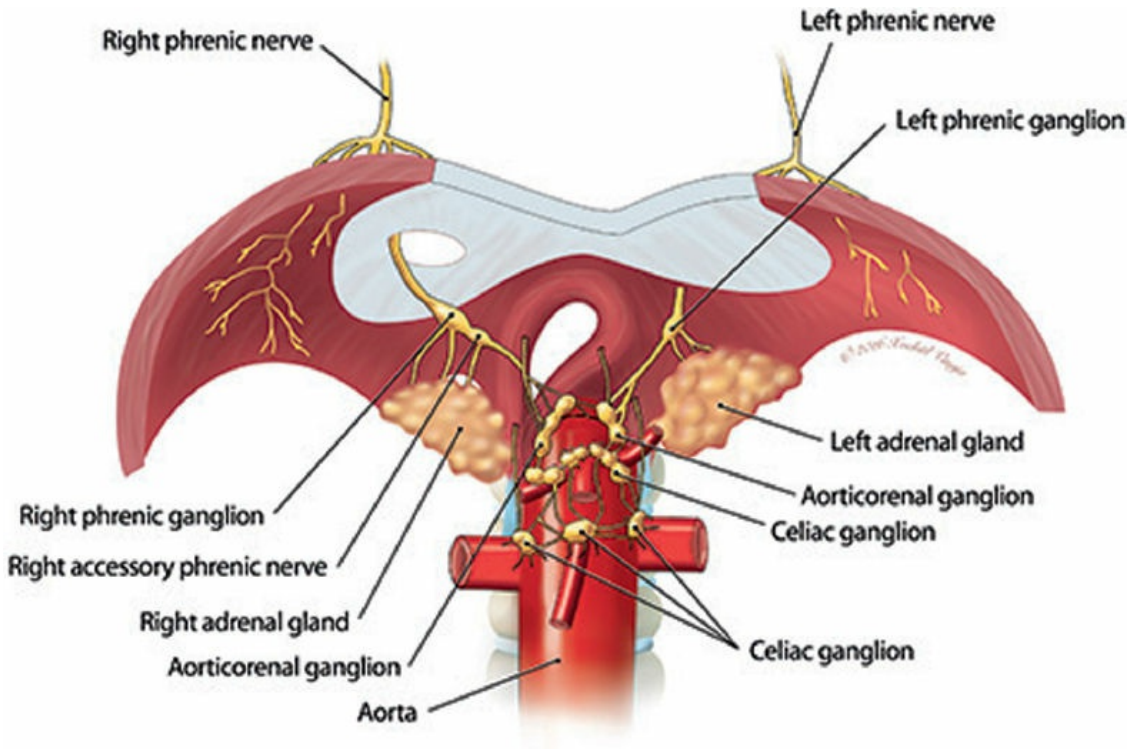

Figure 63.26. Diagrammatic representation of the right and left phrenic ganglia in relation to surrounding structures such as the

celiac, aorticorenal, and superior mesenteric ganglia and the greater and lesser splanchnic nerves. (Modified from Loukas M, Du Plessis M, Louis RG Jr, et al. The subdiaphragmatic part of the phrenic nerve – morphometry and connections to autonomic ganglia. *Clin Anat* 2015;29(1):120–8; with permission from John Wiley and Sons.)

The concept of peripheral autoregulatory functions was first described by Robinson in 1907, who used the term "Abdominal Brain" to describe the celiac plexus, including communications with the phrenic nerve. This idea is further supported through histologic examination of the right phrenic ganglion and right accessory phrenic ganglion by Tubbs (2008). The presence of multipolar autonomic neurons within these ganglia seems to suggest that autonomic innervation may be provided by way of these communications. On the other hand, Hollinshead stated that the diaphragm also receives sympathetic innervation from fibers of the phrenic nerves and of plexuses accompanying inferior phrenic arteries.

CELIAC GANGLIA

The celiac ganglia are closely adherent to the celiac artery at its origin from the aorta, and closely related to the crura of the diaphragm bilaterally. Sutures to approximate the crura must be placed above the ganglia and behind the celiac division of the posterior vagal trunk.

ACKNOWLEDGMENTS

The authors wish to thank the medical illustration team at St. George's University, Grenada, West Indies: Jessica Holland, MS, CMI; Angélica Ortiz, MScBMC; Charles Wesley Price, MS, CMI; and Xochitl Vinaja, MS; for the creation of color illustrations in this chapter, "Surgical Anatomy of the Diaphragm."

EDITOR'S COMMENT

Dr. Mirilas and colleagues have written a detailed and interesting description of the Surgical Anatomy of the Diaphragm. As a surgeon with a lot of experience in operating on and near the diaphragm, I found many of the details informative and quite relevant.

Congenital diaphragm hernia (CDH) is a significant developmental anomaly that is quite interesting when considering the embryologic development of the diaphragm. Because this highly morbid condition can be diagnosed in utero, there is tremendous interest in intervening before birth when CDH is identified. A recent Cochrane review evaluated the antenatal administration of corticosteroids and in utero tracheal occlusion as strategies for addressing CDH in utero. There are relatively few small and retrospective studies available and the authors conclude that there is currently insufficient evidence to recommend in utero intervention for fetuses with CDH as a part of routine clinical practice. CDH is a great model for studying fetal surgery, and I suspect that in time in utero treatment of CDH will become a common procedure when identified at the appropriate stage of development.

Congenital hernias that present in adults are of interest to those of us who do not operate on infants. A Morgagni hernia is more likely to first present in an adult compared to a Bochdalek hernia. While Morgagni hernia represent only 3% of all repaired hernias of the diaphragm, the actual incidence is likely higher. I am a fairly high volume laparoscopic foregut surgeon, and I would estimate that once a year or so I encounter a small Morgagni defect incidentally in a patient in whom I am performing an unrelated procedure. Laparoscopic Morgagni hernia repair is well described and can be performed either primarily or with a mesh interposition.

The concept of a "short esophagus" is controversial. I am from the school of

thought described by Horvath et al. in this chapter who believes that a true short esophagus is an anomaly and highly unusual. Short esophagus is not easily identified prior to surgery and the incidence is directly related to the extent of the mediastinal dissection undertaken at the time of surgery. The reported incidence of short esophagus in the literature varies widely. A recent review article on the topic states "*[Short esophagus] has been reported to be as high as 60% and as low as 0% in older open and more recent laparoscopic series. If the need for a Collis gastroplasty is used as the most restrictive definition, then retrospective review of the literature indicates that between 1% and 5% of patients undergoing GERD-related surgery meet criteria.*" In the current chapter, a true congenital short esophagus is described as a partially supradiaphragmatic stomach existing from birth, not associated with a hernia sac, and not reducible. This is a truly rare condition. When most surgeons describe a short esophagus, they are likely referring to an acquired condition—most often associated with severe GERD or Barrett esophagus that leads to transmural scarring and shortening of the esophagus. In my opinion, in almost all patients in whom the diagnosis of short esophagus is suspected, the GEJ can be mobilized into the abdomen by circumferentially mobilizing the esophagus in the mediastinum, sometimes all the way to the aortic arch. The dilated hiatus often encountered in patients with preoperative concern for a short esophagus facilitates access to the high mediastinum. During high mobilization, surgeons should be aware of the position of the Vagus nerves (left anterior and right posterior, LARP) and the fact that the pleura becomes closely approximated to the esophagus the higher you go. While a pleural tear during high mediastinal dissection is usually of no consequence, in elderly frail patients with decreased cardiopulmonary reserve, there will likely be some compensatory adjustments that need to be made by both the anesthesiologist and the surgeon.

In large and complex paraesophageal hernia repairs, especially in elderly patients with poor tissue integrity and large hiatal defects, it can be exceedingly difficult to close the diaphragm primarily during surgery. Occasionally, a crural relaxing incision is needed to close the hiatus to the appropriate caliber. The description in this chapter on the innervation of the diaphragm is relevant in these cases, especially if a left-sided relaxing incision is considered given the typical location of the phrenic nerve in this area. In certain patients with diaphragm paralysis and the need for mechanical ventilation (especially cervical spine injuries), diaphragm pacing is an option that can lead to ventilator independence. A key part of this procedure is diaphragm mapping to reveal the location of the phrenic nerve, and this work has contributed to our understanding of the anatomy of the diaphragm.

The physiology of the lower esophageal sphincter and the relationship between anatomic abnormalities in this area and gastroesophageal reflux is important to understand. As correctly described in this chapter, reflux is common in patients with hiatal hernia and in patients with a short abdominal component of the lower esophageal sphincter. Fein and colleagues studied 375

consecutive patients with foregut symptoms and no previous foregut surgery. All patients underwent upper endoscopy, esophageal manometry, and 24-hour pH monitoring. The lower esophageal sphincter was considered structurally defective when the resting pressure was less than or equal to 6 mm Hg, the overall length was less than 2 cm, and/or the abdominal length was less than 1 cm. The presence of a hiatal hernia and a defective lower esophageal sphincter were identified as independent predictors of abnormal esophageal acid exposure. The anatomy of the lower esophageal sphincter and the contribution of abnormalities in this anatomy to the presence of pathologic GERD is important. I still struggle to convince gastroenterologists in my community that a patient without a hiatal hernia who suffers from medically refractory GERD symptoms is a candidate for antireflux surgery.

The median arcuate ligament is discussed in this chapter. This is an anatomic structure associated with compression of the celiac axis in some patients. However, the clinical significance and role of this anatomic finding in abdominal symptoms is controversial. A recent review of 20 years of the published literature revealed that median arcuate ligament syndrome involves a vague constellation of symptoms including epigastric pain, postprandial pain, nausea, vomiting, and weight loss. Extrinsic compression of the vasculature and surrounding neural ganglion is thought to be the cause of symptoms. Compression of the vasculature may also be a normal anatomic finding in patients without symptoms complicating the diagnosis. A multi-institutional review of 67 patients with presumed median arcuate ligament syndrome compared the symptomatic outcomes of patients treated surgically (median arcuate ligament release) to patients managed without surgery. After surgical treatment (which was significantly more effective than nonoperative therapy), 37% were asymptomatic and 56% were partially improved. Postexertional pain was predictive of improvement after surgery, while vomiting and unprovoked pain were predictors of poor surgical outcome. My personal results after 15 years as a surgeon and over a dozen patients treated are similar. I prefer to use intraoperative ultrasound and continue to divide median arcuate ligament fibers until the velocities in the celiac artery have normalized. The ligament in patients whose symptoms improve after surgery is often quite thick and can clearly be seen to compress the celiac artery. The use of ultrasound is helpful as this is a nerve-racking procedure and the temptation to quit dividing fibers is huge as the aorta and celiac trunk become more prominent during the release. As someone with a decent experience in these procedures, I wonder if part of the issue with regard to inconsistent symptomatic outcomes relates to my hypothesis than many surgeons do not do a complete release. Using ultrasound, I have routinely observed that when I think I am done dividing muscle fibers (or I want to quit), the ultrasound velocities have not quite normalized. With additional muscle fiber division, normalization of celiac flow velocities is almost always possible, unless there is an intrinsic lesion of the artery itself.

Finally, transitioning from the diaphragm and onto the ventral abdominal

wall, there is some interesting anatomy described in this chapter that is helpful for surgeons who embark on complex abdominal wall reconstructions for hernia. Ventral hernia repair has evolved significantly in the past decade. The trend currently is to use advanced techniques to bring the linea alba together and to reinforce the reconstruction with mesh in the retrorectus position. For larger and more complex hernias, this often requires some form of an abdominal wall component separation and reconstruction. A very popular technique associated with excellent outcomes at the current time is a transversus abdominis release to achieve a posterior components separation. For abdominal wall defects that extend to the sternum and subcostal area, the retromuscular plane is extended cephalad to the costal margin and dorsal to the sternum by sweeping the peritoneum/transversalis fascia off the diaphragm. This allows wide overlap of a large piece of mesh in the sublay position—both laterally and superiorly to the defect. This is an extremely useful technique for repair of complex and large ventral hernias and requires intimate knowledge of the anatomic relationships described so well in this chapter.

Overall, this is an excellent chapter that described anatomic principles and relationships of the diaphragm that are clinically relevant in many different disease states and surgical procedures. Any surgeon who operates on or near the diaphragm would be well served to have a thorough understanding of the concepts described in this chapter.

64 Congenital Diaphragmatic Hernia

Corey W. Iqbal

INTRODUCTION

Congenital diaphragmatic hernia (CDH) occurs in 1 in 2,200 to 5,000 live births. Given the lethality of this lesion and a high rate of in utero fetal demise, still birth, and early neonatal death prior to transfer to a tertiary referral center the true incidence is difficult to capture in epidemiologic studies and the incidence is likely closer to 1 in 2,200 pregnancies—this phenomena is referred to as the hidden mortality of CDH. No congenital anomaly has been more perplexing for pediatric surgeons, as surgical correction of the defect postnatally seems to have very little impact on survival.

Prior to 1940, there were few survivors of CDH. Gross and Ladd reported 9 out of 16 survivors with immediate surgical repair. This became the mainstay of therapy, as experts believed mediastinal compression from the herniated viscera was the inciting factor for mortality. However, survival, at best, was around 50%. In the mid 1980s, Dr. Stolar recognized the impact of pulmonary hypoplasia—a fixed defect that immediate decompression does not reverse—and introduced the idea of “gentilation” and permissive hypercapnia that led to a major paradigm shift. Currently expected survival for CDH may be as high as 70% to 80%.

EMBRYOLOGY

The diaphragm is a predominately fibrous dome that separates the abdominal cavity from the thoracic cavity. The central tendon comprises the majority of the diaphragm with muscular fibers on the periphery anchoring the diaphragm to the rib cage where it functions in ventilation by innervation from the phrenic nerve. The left and right crural fibers split where the esophagus and aorta pass from the thoracic cavity into the abdominal cavity. More than 85% of CDH occur on the left side as a posterolateral defect, classically referred to as the Bochdalek defect after his description in 1848. Right-sided defects and anterior defects

(Morgagni-type defect) occur with less frequency and are discussed in separate sections within this chapter.

In normal development, the fusion of four embryologic components gives rise to the diaphragm: the septum transversum, the pleuroperitoneal folds, the esophageal mesentery, and the body wall mesoderm. The septum transversum fuses dorsally with the body wall mesoderm and gives rise to the central tendon. The pleuroperitoneal folds close from the dorsal and lateral aspects completing separation of the fetal chest and abdomen by 8 weeks. The pleuroperitoneal folds are later replaced by a striated muscle. The esophageal mesentery forms the crural and dorsal fibers. When any of these structures fail to fuse, a diaphragmatic defect results.

The most commonly accepted theory behind the development of CDH is that the pleuroperitoneal folds incompletely fuse; the degree of incomplete fusion can result in a small defect or complete absence of the diaphragm—diaphragmatic agenesis. In 10% to 20% of cases, the pleuroperitoneal folds likely completely fuse, but there is failure of muscularization and a sack results.

Lung development occurs in five phases: embryonic, pseudoglandular, canalicular, saccular, and alveolar. Lung buds give rise to the lobar structures in the embryonic phase. During weeks 7 to 17, the pseudoglandular phase occurs and the bronchial structures develop. Primitive alveoli develop during the canalicular phase along with type I and II pneumocytes—this process occurs up to 24 weeks of gestation. In the setting of a CDH, herniated viscera impair this developmental process resulting in hypoplastic lungs.

It has been widely accepted that the herniated viscera compress the fetal lungs and impairs lung development resulting in pulmonary hypoplasia. However, pulmonary hypoplasia occurs bilaterally, despite a unilateral defect. Therefore, more recently some have proposed a dual hit theory of primary pulmonary hypoplasia affecting diaphragmatic development resulting in a CDH with additional pulmonary injury from compression. Either way, pulmonary hypoplasia results in pulmonary hypertension, inadequate gas exchange, and in many cases, death.

ASSOCIATED ANOMALIES

In 60% of cases, CDH occurs as an isolated event. However, there are often associated anomalies inherent to CDH or that can be a consequence of a CDH such as nonrotation of the intestines and esophageal ectasia. In

40% of cases, CDH occurs as part of a syndrome or in association with another congenital anomaly (nonisolated). Associated anomalies can include congenital heart disease, genitourinary abnormalities, intestinal atresia, bronchopulmonary sequestration, and neurologic defects.

The most common syndrome is Fryns syndrome, but multiple genetic disorders have been described in association with CDH such as trisomy, Beckwith–Wiedemann, and Pierre-Robin. When a genetic association is suspected, families should be tested and counseled accordingly. When CDH is part of a syndrome or nonisolated, the survival rates are less favorable. In fact 95% of stillborns with CDH have a chromosomal abnormality indicating the lethality of nonisolated CDH.

PRENATAL CARE

Diagnosis

As prenatal imaging modalities continue to improve, the detection of congenital anomalies in the prenatal period has become commonplace. The presence of abdominal viscera in the chest is clearly abnormal and readily detected by prenatal ultrasonography (US) in as many as 90% of CDH cases. The ultrasonographer may observe the gastric bubble is not in its normal anatomic position, the liver may be herniated into the chest, and there may not be any appreciable lung on the ipsilateral side. The presence of any abdominal viscera above the inferior tip of the scapula or at the level of the four-chamber view of the heart is abnormal and consistent with a CDH. Polyhydramnios can occur if the stomach is kinked causing amniotic fluid to build up. The finding of polyhydramnios should prompt the ultrasonographer to conduct a careful assessment of the fetal chest to rule out CDH.

Prognostication

The high mortality rate associated with CDH made it a driving force behind the advent of fetal surgery and the concept of in utero intervention for a high-risk congenital anomaly in order to improve the postnatal outcome. Intense investigation in this area has resulted in multiple prognostic measures for CDH in the hopes of identifying those cases at highest risk for death that could potentially benefit from an invasive in utero procedure.

US provides the most studied prognostic factors, although other

modalities such as fetal magnetic resonance imaging (MRI) and fetal echocardiography have also been studied. A detailed US should be obtained in any pregnancy where there is a suspicion for CDH. In addition, fetal echocardiography should be obtained to rule out any structural abnormalities of the heart, which has a significant impact on prognosis and will impact counseling. The routine use of MRI is more controversial. Fetal MRIs can be difficult to obtain if there is significant fetal movement but may offer more objective measures and have less interuser variability than US.

The presence of liver herniation reproducibly predicts a worse outcome for CDH. Therefore, position of the fetal liver should be routinely assessed during fetal US for CDH. The lung-to-head ratio (LHR) is another important prognostic indicator. It is obtained via US by measuring the right lung area at the level of the four-chamber view of the heart and dividing by the fetal head circumference. In multiple studies, an LHR <0.6 was associated with 100% mortality while an LHR >1.35 was associated with 100% survival.

A major criticism of the LHR has been that the fetal lung and head grow at different rates, especially up to 32 weeks of gestation when lung growth begins to level off relative to the head circumference. Consequently, LHR changes with gestational age. This prompted investigators to propose the observed-to-expected ratio for LHR (O/E LHR) based on what the mean expected LHR would be for a specific gestational age in fetuses not affected by CDH. In the original description of the O/E LHR for left-sided defects, O/E LHR of <25% was associated with an 18% survival; O/E LHR of 26% to 45% was associated with a 66% survival; and O/E LHR of >45% was associated with an 89% survival.

Fetal MRI has primarily been used to study lung volumes for antenatal prognostication of CDH. The most studied measurement by MRI is the percent predicted lung volume (PPLV)—also known as the observed-to-expected fetal lung volume (O/E FLV). This calculation is made by subtracting the mediastinal volume from the thoracic volume to determine the expected lung volume. The actual lung volume is then measured and divided by the expected lung volume to create a percentage.

Exactly how the PPLV should be interpreted is not agreed upon. In one study, 15% appeared to be the determinant of survival where those with a PPLV >20% had 100% survival whereas a PPLV of <15% was associated

with only 40% survival. In another study, the cutoff appeared to be 25% where PPLV <25% was associated with a 13% survival and a PPLV >35% was associated with an 83% survival. However, some have reported that PPLV is inferior to LHR in predicting outcomes. Other groups have looked at the raw FLV obtained by fetal MRI as a prognostic indicator. In a series of FLV at 34 to 35 weeks of gestation the investigators reported that survivors had a mean FLV of 35 mL, those requiring ECMO had a mean FLV of 18 mL, and nonsurvivors had a mean FLV of 9 mL. Use of these measures in prenatal counseling should be done judiciously and incorporates one's own institutional experience.

Fetal Interventions

Any fetal intervention carries a risk to both the fetus and a healthy mother. Fetal interventions are associated with fetal demise, preterm labor, the risk of premature rupture of membranes, chorionic membrane separation, chorioamnionitis, and bleeding. Open fetal procedures run the additional risk of uterine dehiscence and rupture with the current pregnancy and any future pregnancies. For these reasons, fetal intervention should be reserved for those situations where a clear benefit exists for the fetus.

In 1990, Dr. Michael Harrison and his team at UCSF published the first successful open fetal CDH repair. This was followed by a prospective trial comparing open fetal repair to postnatal repair that did not show survival benefit with open fetal repair. Open fetal repair has since been abandoned in favor of fetal tracheal occlusion (FeTO). When the fetal trachea is occluded, fluid normally made by the fetal lung parenchyma builds up and leads to pulmonary hyperplasia.

The initial trials investigating FeTO showed dramatic pulmonary hyperplasia but this was not associated with any survival benefit due in large part to the invasiveness of the fetal procedure, which was performed through an open hysterotomy, that resulted in preterm delivery. Consequently, fetoscopy with tracheal clip application was used in a subsequent study which compared fetoscopic FeTO (n = 8) to open FeTO (n = 8) and postnatal CDH repair (n = 13) in pregnancies at <25 weeks of gestation for isolated left-sided CDH with liver-up and LHR <1.4. Survival was greatest in the fetoscopic FeTO group (75%) followed by the postnatal repair group (38%) and the open FeTO group (15%).

Given these promising findings, a prospective randomized trial was initiated at UCSF for pregnancies complicated by isolated left-sided CDH

with liver-up and LHR <1.4. In addition, use of tracheal clips was abandoned in favor of tracheal balloon occlusion. Subjects were randomized to either fetoscopic bronchoscopy through a 5 mm port with tracheal balloon occlusion or postnatal care. The primary outcome was 90-day survival and the study was powered for a 77% survival rate in the FeTO group that required an enrollment of 40 patients. The study was terminated at 24 patients because no survival benefit was found. The nontreatment group had a survival rate much higher than historical controls and what had been expected in the study (77 vs. 73%, $p = 1.0$) that became a major criticism of the study. Yet this improved survival in the postnatal therapy group was likely a reflection of improved perinatal care and "gentilation" techniques introduced at that time. An additional criticism was the inclusion of LHR 1.0 to 1.4 as these defects were likely not as severe as if the study had been limited to an LHR <1.0.

In Europe, the consensus has been to move forward with FeTO and continue to investigate its potential for CDH. Currently the Eurofetus group is sponsoring a multicenter, prospective trial that is studying the optimal timing for FeTO. Investigators in North America have proposed a multicenter, prospective trial on FeTO for CDH as an extension of the Eurofetus trial but are still awaiting FDA approval for the balloon device currently in use throughout Europe.

In the absence of tracheal occlusion, some investigators have proposed that EXIT-to-ECMO may be a viable alternative to improve outcomes for unfavorable CDH. The theory is to provide cardiopulmonary support prior to the fetus becoming hemodynamically compromised. However, the largest experience with EXIT-to-ECMO, out of Boston, found no survival benefit for EXIT-to-ECMO (33% survival) compared to those CDH patients requiring ECMO but not undergoing an EXIT procedure (50% survival). Currently, there does not appear to be a convincing role for EXIT-to-ECMO.

PATHOPHYSIOLOGY

Initial Resuscitation

The underlying factors contributing to the pathophysiologic process of CDH are (1) pulmonary hypoplasia and (2) pulmonary hypertension. These two elements are closely related. Pulmonary hypoplasia results in limited surface area for adequate gas exchange—in some cases the extent of pulmonary hypoplasia is incompatible with life. Pulmonary hypoplasia

results in an underdeveloped pulmonary vasculature that impedes blood flow through the pulmonary circulation, that is, pulmonary hypertension. This further impairs adequate gas exchange by limiting blood flow across the alveolar surface and increases the afterload on the right heart leading to heart failure.

Lung volumes are fixed at birth, however pulmonary hypertension can be potentially managed. Acidosis, hypoxia, and hypercarbia have a significant effect on the reactivity of the pulmonary vasculature causing profound vasoconstriction that exacerbates pulmonary hypertension. Therefore, the initial resuscitation in the newborn with CDH should focus on avoiding hypoxia, hypercarbia, and acidosis. While, it is necessary to optimize ventilation through the existing lung parenchyma, overly aggressive ventilator strategies result in barotrauma that can be detrimental.

Recognizing the need to maintain adequate gas exchange without injuring the fragile lungs of a neonate with CDH, permissive hypercapnia with spontaneous ventilation has been advocated, as it is associated with improved survival. Preductal SaO_2 should be maintained above 85% and $PaCO_2$ up to 45 to 60 mm Hg can be tolerated as long as a pH of >7.3 can be maintained. PO_2 can be used as a guide as well with goals of the preductal PO_2 above 60 mm Hg and a postductal PO_2 above 40 mm Hg. Inhaled nitric oxide (NO) has been administered to facilitate pulmonary arterial vasodilation and treat pulmonary hypertension; however, clinical trials have failed to demonstrate any survival benefit with the use of NO.

If the diagnosis of CDH has been made prenatally, delivery plans should include the presence of a neonatal resuscitation team in a tertiary referral center. Once delivered, decompression of the neonate's intestinal tract with a nasogastric tube is important to prevent further compression of the lungs from air accumulating in the gastrointestinal tract. Intubation should be undertaken, especially for signs of respiratory distress (see Fig. 64.1). Arterial and venous access should be obtained—preferably a right radial arterial line to allow preductal measurements that reflect the cerebral oxygenation. An echo should be obtained early on to assess for pulmonary hypertension.

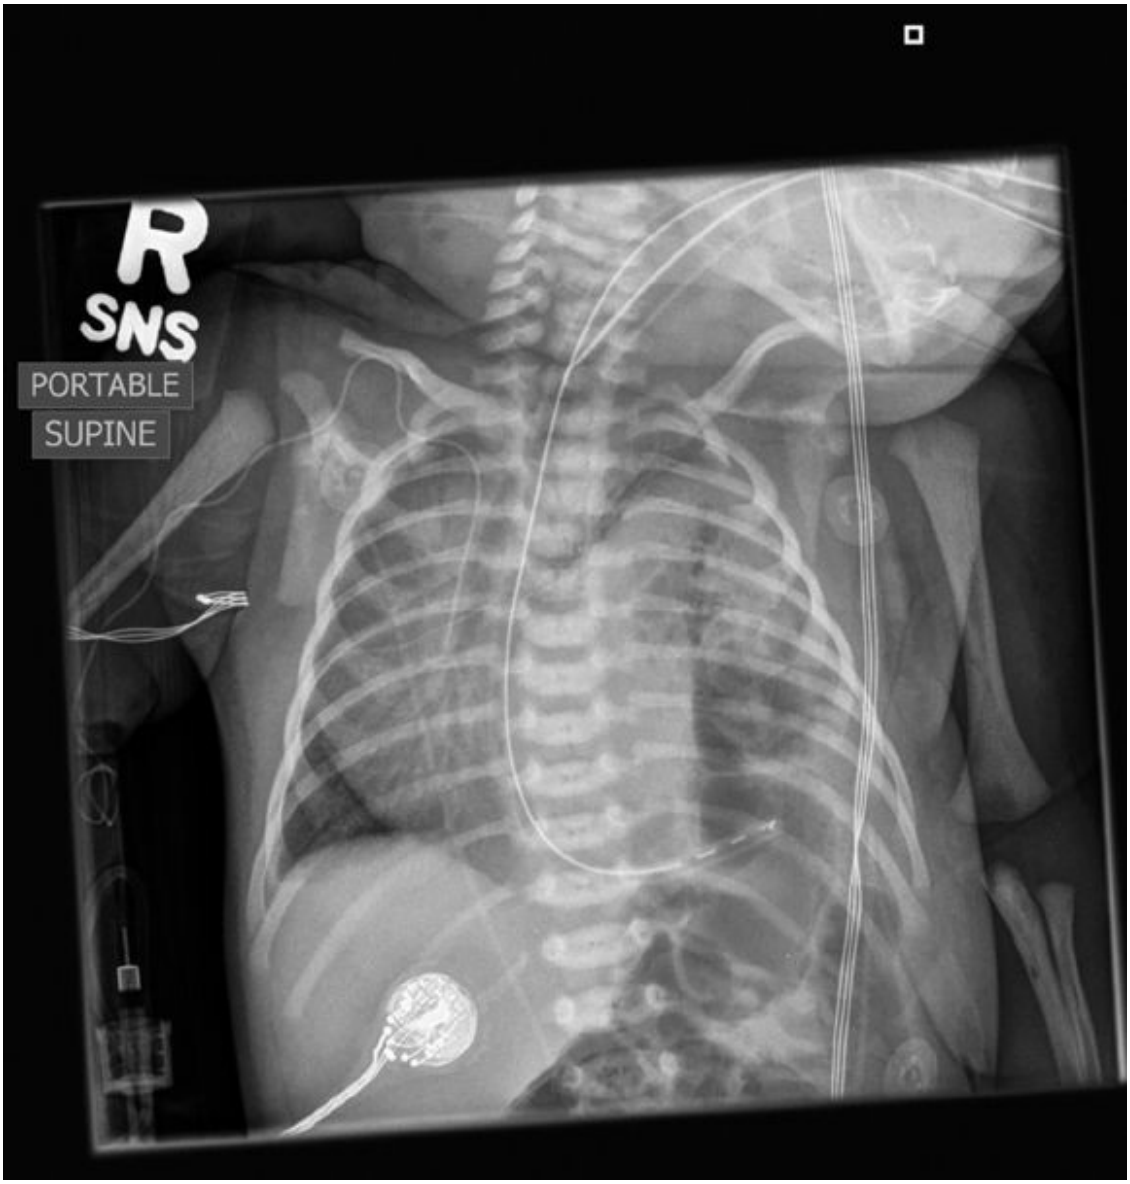

Figure 64.1. Left-sided congenital diaphragmatic hernia on postresuscitative radiograph.

Preoperative Planning

Immediate surgical repair does not correct the fixed lung volumes nor expedite vascular remodeling and subsequent resolution of pulmonary hypertension. Therefore, stabilization of the infant should precede operative repair which should be delayed until the pulmonary hypertension is controlled, which can be followed by echocardiography paying specific attention to right heart function.

In infants unable to maintain adequate gas exchange and with impending heart failure, extracorporeal membranous oxygen (ECMO) has been used as a salvage therapy. Generally speaking, infants ≥34 weeks of

gestational age and ≥2 kg are candidates for ECMO. A specific criterion for ECMO is that the underlying cause is reversible; therefore infants with lethal pulmonary hypoplasia should not be offered ECMO. Neonates who never achieve a preductal SaO_2 ≥90% for at least 60 minutes likely have lethal pulmonary hypoplasia and are poor candidates for ECMO.

For infants on ECMO, the timing of operative repair is controversial. Bleeding is a major complication with any intervention while on ECMO. It has been shown that bleeding complications can be minimized by repair within 24 hours of going on ECMO in conjunction with the administration of aminocaproic acid for 48 hours perioperatively. However, repairing the defect will not reverse the pulmonary hypoplasia and hypertension that necessitated ECMO; therefore, others advocate delaying repair until the infant has come off ECMO.

SURGICAL REPAIR

Multiple methods have been described for the surgical correction of CDH. The most commonly employed method is the open, transabdominal approach, although a minimally invasive thoracoscopic repair has also been described. Which operation is ideal depends on the experience of the surgeon, the clinical condition of the baby, and the suspected size of the defect.

Open Repair

The most common approach for a left-sided CDH is an open technique through a left, sub-costal incision. The incision can either be made transversely, or obliquely, one fingerbreadth below the costal margin. Once the abdominal cavity is entered, a self-retaining retractor is helpful to provide traction cephalad on the anterior chest wall. Using dry sponges, the viscera are gently reduced. Oftentimes a CDH will contain the liver and/or spleen; therefore, care should be taken to minimize trauma to these fragile structures and avoid life-threatening hemorrhage.

Once the hernia has been reduced, malleable retractors can be used to keep the viscera reduced and out of the operative field. In most cases, the defect is posterolateral; therefore, an anterior rim of diaphragm can often be identified and utilized in the repair (see Fig. 64.2). The anterior rim can be traced medially where there is often some diaphragm that will extend posteriorly. There is little need to mobilize the anterior and medial aspects of the diaphragm, however posteriorly the peritoneum can be opened to

help gain some mobility on the posterior leaf (see Fig. 64.3). As this dissection along the posterior rim is carried laterally, the diaphragm is usually lost at the lateral aspect. The surgeon then assesses the size of the defect and determines the most appropriate method of closure based on the defect size and available diaphragm. The CDH study group has created a classification of CDH defect size to help standardize reporting in the literature and this can be useful in describing the defect (see Fig. 64.4).

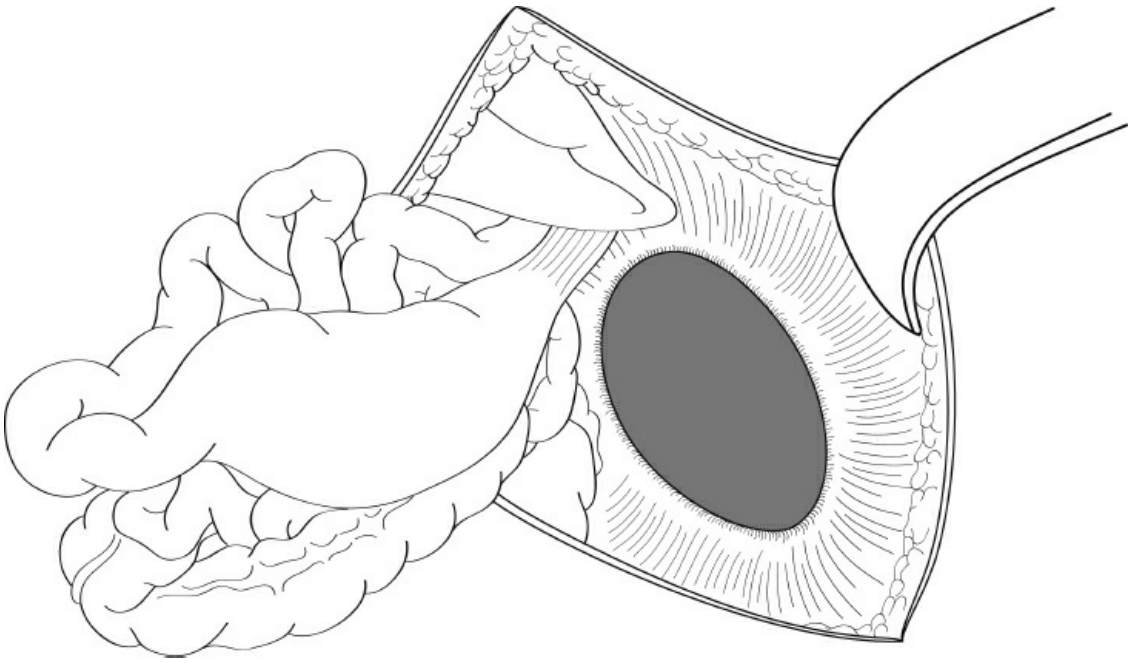

Figure 64.2. After the abdominal viscera are reduced back into the abdomen, the view of the diaphragmatic defect is evident.

If the diaphragm can be closed with minimal tension, then a primary repair can be performed. Most surgeons use nonabsorbable sutures and some advocate the use of pledgets to reduce damage to the tissues and promote scarring; however, there is no convincing data to support their routine use. If the defect is too large for primary closure then a patch must be used. Oftentimes, the medial aspects of the diaphragm can be closed primarily, but the lateral aspect lacks adequate tissue for closure and a patch is still required. There is mixed data on whether a permanent mesh such as stretched polytetrafluoroethylene (PTFE) or a bioprosthetic (of which numerous products are commercially available) is the most suitable patch. The potential advantages to a bioprosthetic are that they resist infection and support in-growth of autologous tissue that will potentially grow with the child reducing chest wall deformities and hernia recurrence. However, much of the patch is not in apposition to vascularized tissue that

most likely limits their efficacy, and current studies have not been convincing that bioprostheses are superior to a nonabsorbable mesh.

When using a patch, the patch is sewn to the diaphragmatic rim using nonabsorbable sutures, with or without pledgets. Securing the patch to the posterolateral chest wall can be challenging when there is little or no rim to sew to. In these cases, the patch is sewn directly to the chest wall by either suturing to the periosteum of the ribs, or passing the suture around the rib. In severe cases, medial diaphragm may be absent as well and the patch may need to be sewn to the adventitia of the aorta and the esophagus.

Recurrence after CDH repair can be as high as 35% and even higher if a patch was necessary. Therefore, more recently surgeons are beginning to go back to the muscle flap repair using the internal oblique muscle flap, which has been shown to reduce recurrence rates to as low as 4% in a single center experience from Utah. The advantage to this approach is that it utilizes autologous tissue that will grow with the child and potentially reduce the risk for recurrence. The disadvantages to a muscle flap are that the incision is made lower on the abdominal wall and can make exposure more difficult during repair; the decision to use the flap must be made prior to incision; and it also leaves the left abdominal wall with some degree of diastasis.

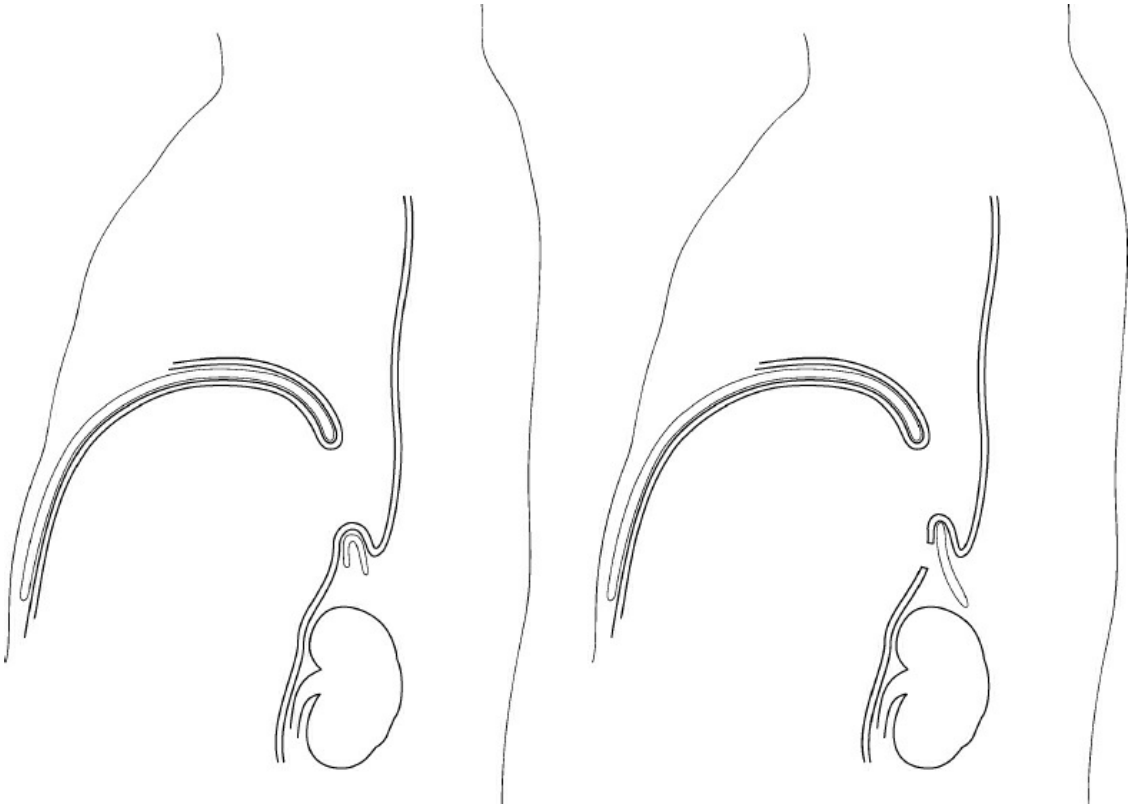

Figure 64.3. The posterior peritoneum can be seen covering the inferior leaf of the diaphragmatic remnant (**left**). Incision of the peritoneum either above or under the posterior rim of the diaphragm enables the diaphragm to be more fully mobilized and the defect can be repaired with less tension.

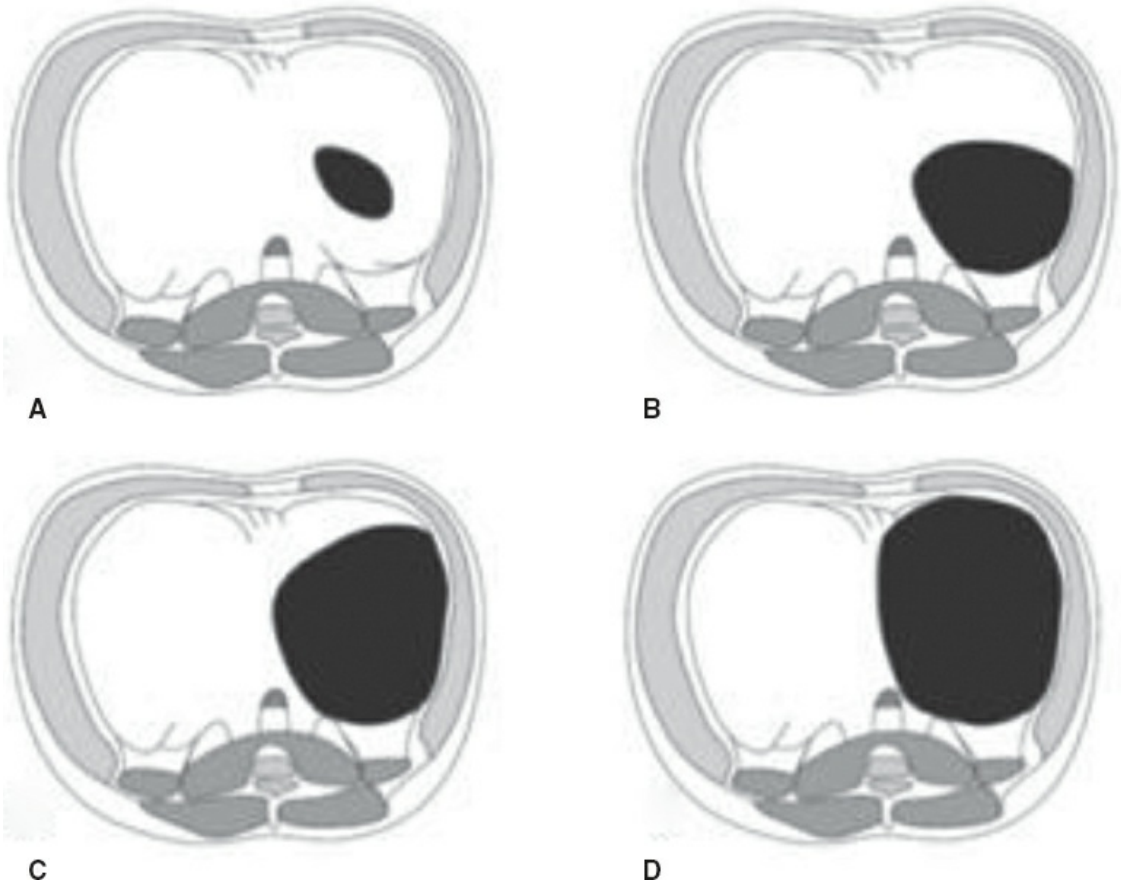

Figure 64.4. Congenital diaphragmatic hernia study group classification of diaphragmatic defect defined as types **A-D**. (Reprinted from Lally KP, Lasky RE, Lally PA, et al. Standardized reporting for congenital diaphragmatic hernia—An international consensus. *J Pediatr Surg* 2013;48(12):2408–15. Copyright © 2013, with permission from Elsevier.)

To perform a muscle flap repair, a bump is placed under the baby's left side to expose the entire lateral chest and abdominal wall. The incision is made at the level of the inferior most portion of the costal margin and extended medially. This lower incision makes it more difficult to retract on the costal margin and expose the defect, and it also leaves less abdominal wall to retract the abdominal viscera once they have been reduced, but it will allow full mobilization of the internal oblique muscle for an excellent muscle flap.

The external oblique muscle is divided carefully to avoid injury to the internal oblique. The plane between the divided external oblique and intact internal oblique muscles is then opened with cautery mobilizing this space up to the costal margin superiorly and down to the iliac crest inferiorly. Once this dissection is complete, the internal oblique muscle is released from its medial attachment to the rectus, from its inferior attachments along the iliac crest, and lastly from the retroperitoneum. Once mobilized, the muscle flap can be packed in warm sponges while the abdominal viscera are reduced and the diaphragm is mobilized. The muscle flap drops in to fill the defect like a garage door and is secured medially, posteriorly, and laterally with nonabsorbable sutures. Care must be taken anteriorly to ensure that there are no defects where the muscle flap folds back on the chest wall as early recurrence can occur in this location.

Once the defect is repaired, the abdominal wall is closed in layers with absorbable sutures. With a muscle flap, there is only one layer of fascia to close. A chest tube is not routinely necessary, and a postoperative pneumothorax is expected given the hypoplastic left lung and reduction of the hernia (see Fig. 64.5).

Thoracoscopic Repair

A minimally invasive approach to CDH repair has been described, although there is a significant amount of controversy associated with this approach with a moratorium on thoracoscopic CDH repair in some regions of the world. When utilizing a minimally invasive approach, the CDH is repaired through the chest with video-assisted thoracoscopic surgery (VATS). With the baby in a right lateral decubitus position, a 5-mm camera port is placed below the tip of the left scapula. The chest is then insufflated to help reduce the abdominal viscera through the defect. Two 3-mm stab incisions are made along the anterior chest wall and blunt graspers are used to fully reduce the hernia. Once reduced, the defect is assessed and either closed primarily or using a patch as discussed above. Even in cases of primary closure, this author prefers to reinforce the repair with a bioprosthetic mesh. A chest tube is not routinely needed after VATS CDH repair unless there is concern for injury to the lung parenchyma that will result in an air leak.

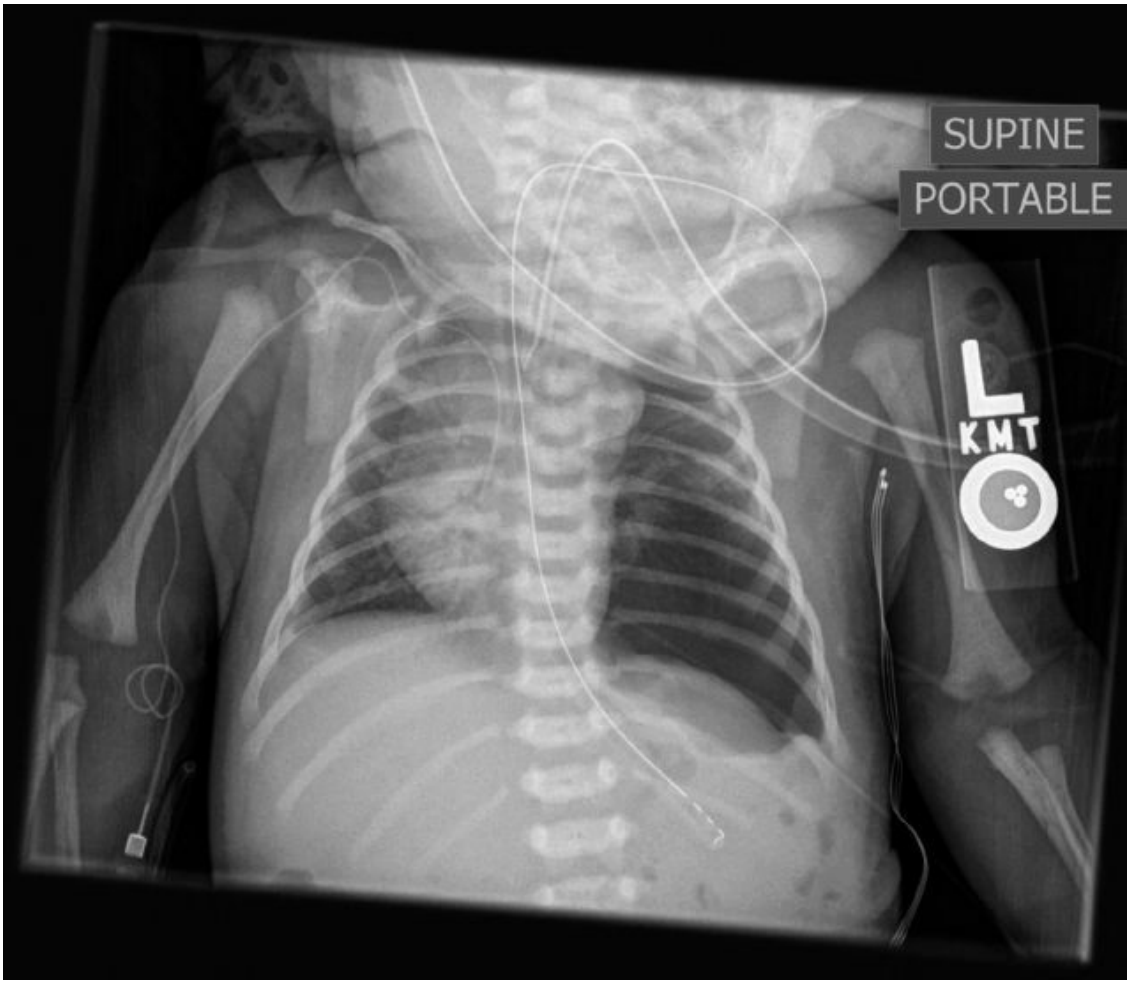

Figure 64.5. Postoperative radiograph after surgical correction of a left-sided congenital diaphragmatic hernia.

Controversy exists regarding this approach because of the potential effects of CO_2 insufflation. CO_2 is readily absorbed by the pleural and peritoneal surfaces—this property makes it ideal for endoscopic procedures. However, the absorption of CO_2 results in a metabolic acidosis that can exacerbate pulmonary hypertension. Hyperventilation to blow off CO_2 can lead to barotrauma and contribute to worse outcomes. It should be recognized, that not all babies with CDH are at the same risk for pulmonary hypertensive crisis, and it has been shown that select cases tolerate the VATS approach. The ideal candidate for a VATS approach, in this author's opinion, is the infant with minimal to no respiratory distress and no evidence of pulmonary hypertension—in most cases this is the CDH diagnosed postnatally.

Postoperative Care

Under ideal circumstances, pulmonary hypertension and gas exchange had stabilized prior to surgical repair. Stress at the time of repair can trigger pulmonary hypertension, and the baby should be closely monitored for this postoperatively. In the absence of any deterioration, ventilator support should be weaned as tolerated. Once there is return of bowel function, feeds can be initiated and advanced to goal.

LONG-TERM OUTCOMES

Overall survival is still quoted around 50%, and if the defect is prenatally diagnosed mortality may be as high as 75%. These reported values reflect a very heterogeneous patient population confounded by the fact that some patients die before they can be transferred to a tertiary referral center or some may have a delayed presentation to a tertiary center, which may explain why there are published survival rates as high as 90%.

Survivors of CDH are still at risk for other long-term problems. Prolonged ventilator dependence can lead to bronchopulmonary dysplasia in 33% and there is a higher rate of reactive airway disease in children with a history of CDH. Pulmonary function tests are normal in 50% to 70% of survivors; however, 25% will have evidence of obstructive airway disease even after 5 years. Abnormal pulmonary function tests can also show restrictive and mixed disorders of pulmonary function.

Sensorineural hearing loss can manifest later in life and requires routine follow-up. Children with CDH can be affected by cerebral palsy, delay in speech and verbal skills, vision loss, and seizure disorders. Neurologic sequelae are more commonplace if ECMO was necessary.

Gastroesophageal reflux can be a problem in up to 60%, of which 10% to 15% will require an antireflux procedure. Nutrition can be a problem for these children who can have respiratory symptoms during feeding contributing to poor growth and failure to thrive with 50% falling in the less than 25th percentile for height and weight. Fortunately, this delay in growth appears to normalize by 2 years, but one third will still require a gastrostomy tube for nutritional support. Growth can also be affected by chest wall deformities in 20% who will develop a pectus excavatum defect and 10% that will develop scoliosis.

Recurrence rates overall are reported to be as high as 35%; however, if a prosthetic patch was required, then recurrence is as high as 50%. The group in Salt Lake City has published favorable rates using an internal oblique muscle flap for large defects with a recurrence rate of 4% at a

median follow-up of 4 years. Recurrence with incarceration as well as adhesions and volvulus can contribute to intestinal obstruction that occurs in 20% of CDH patients.

RIGHT-SIDED CONGENITAL DIAPHRAGMATIC HERNIA

Isolated right-sided CDH accounts for 10% to 15% of CDH. Their lower incidence may be due to the fact that the right hemidiaphragm fuses earlier than the left and has more muscle. These babies are also at risk for pulmonary hypoplasia and require the same resuscitative efforts when prenatally diagnosed. In a single series, survival was reported to be as high as 95% for isolated right CDH. This series included postnatally diagnosed right CDH; however, when looking exclusively at prenatally diagnosed right CDH, overall survival is lower at 59% indicating that right CDH can be as lethal as left CDH.

Data on prognosis for right CDH is limited because it is less frequently encountered. In a single-center experience from UCSF, LHR appeared to have value in prognosticating for right CDH. All children with right CDH and an LHR ≥1.0 survived and none required ECMO. Gestational age did not seem to impact the LHR findings and so an LHR <1.0 for a right CDH can be considered high risk. In fact, tracheal occlusion has been offered to high-risk CDH and appears to have a survival benefit in the UCSF experience: 78% versus 52% survival. However, the numbers from that retrospective review are very small and should be interpreted with caution.

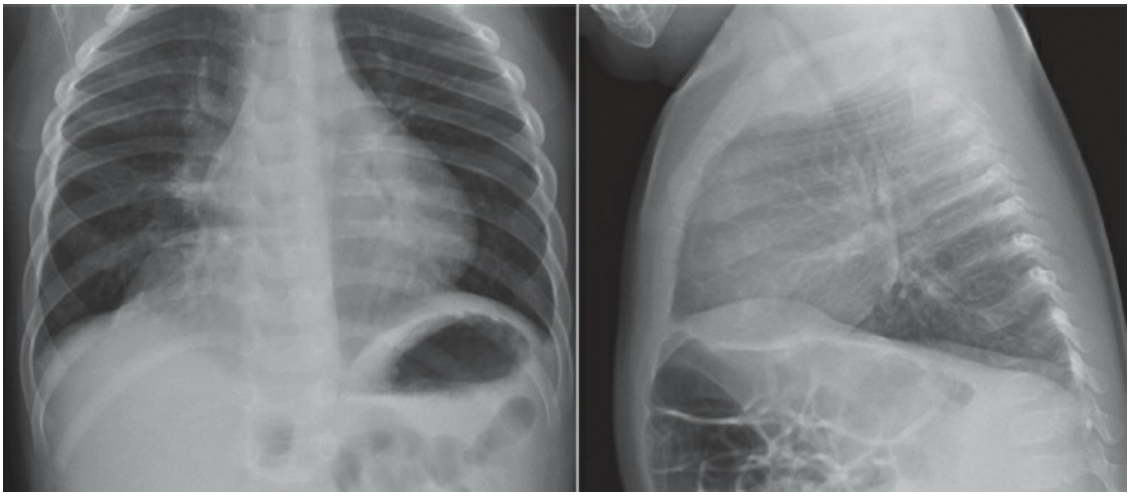

Figure 64.6. Two-view chest radiograph of a Morgagni hernia.

Right CDH are unique due to the involvement of the liver. The

approaches for repair are similar to left CDH except they are performed on the right side. Repair of the defect is similar: primary versus patch repair. Special considerations at the time of repair include caution when reducing the liver as kinking of the hepatic veins can lead to impaired preload and cardiac compromise. In addition, hepatopulmonary fusion can occur where the liver and right lung are fused. For this reason, some surgeons approach right CDH through a low thoracic incision.

MORGAGNI HERNIA

Morgagni hernia, also known as the retrosternal hernia of Morgagni, occurs when the diaphragm fails to fuse with the sternum or anterior chest wall. This type of hernia has not been associated with pulmonary hypoplasia. In fact, this hernia most often presents later in childhood as an incidental finding on a chest radiograph. Obtaining a lateral film in addition to an anteroposterior film helps confirm the diagnosis (see Fig. 64.6). The defect can contain liver if it is central or on the right and may also contain bowel.

This defect tends to be amenable to primary repair. The sack is excised and the diaphragm reapproximated with nonabsorbable sutures. In many cases, there is no diaphragmatic rim on the anterior, central aspect of the defect. In this area, the posterior rim of the defect can be sutured to the abdominal wall. If the defect is too large for primary repair, then a patch should be used.

The Morgagni-type defect is also amenable to laparoscopy. The sack can be excised with a hook cautery, and the defect closed intracorporeally with nonabsorbable sutures. If the anterior rim is lacking, a suture passer can be used through stab incision through the abdominal wall to secure the posterior rim of the diaphragm to the rectus muscles. When performed laparoscopically, the child should be permitted to eat immediately postoperatively with discharge to home the following day.

CONCLUSION

CDH is a frequently encountered congenital anomaly that spans a wide-spectrum of severity. The vast majority are left-sided defects. Improved prenatal diagnosis has led to the detailing of several prognostic parameters that are critical in counseling families and determining candidates for investigational fetal interventions. The pediatric surgeon should be able to provide valuable prognostic information prenatally that will guide families

as they decide what level of care they want for their baby who may ultimately benefit from a delivery plan that ensures the availability of appropriate resources. To date, the greatest impact on survival has been a strategy of gentilation and permissive hypercapnia and delayed surgical repair. Multiple options are available for repair, and are primarily determined by the defect size. Babies who survive CDH are at high risk for long-term problems and require close follow-up beyond the neonatal period.

EDITOR'S COMMENT

Despite significant advances in prenatal, neonatal, and surgical care, congenital diaphragmatic hernia (CDH) remains one of the most challenging congenital anomalies to manage. The mortality rate remains high even in developed countries. The author presents an excellent overview of the different components of this condition and its management. A CDH reflects an embryologic failure in closure of the pleuroperitoneal folds or the *septum transversum* generating a defect that communicates between abdominal and thoracic cavities that allows herniation of the abdominal viscera into the chest resulting in compression of the developing fetal lungs impairing growth. The pathophysiologic basis for impaired lung growth is thought to occur because of a loss of the paracrine effect of intrapulmonary fluid. During the canalicular phase of development, the fetal lung acts as a gland secreting fluid that is rich in growth factors that are essential for lung growth. When the developing lung is compressed, intrapulmonary fluid is extruded into the amniotic space impairing growth. Not only are the bronchiolar branching and the number of alveoli diminished, the development of the pulmonary vasculature is also affected resulting in decreased number of pulmonary distal arterioles that are "shorter, thicker, and narrower." The muscular media thickness augments pulmonary vascular reactivity and pulmonary hypertension.

The size of the diaphragmatic defect directly correlates with the presence of other anomalies and mortality rates. The Congenital Diaphragmatic Hernia Study Group (CDHSG) classified CDH defects into four types in increasing order from A—small defect that can usually be repaired primarily to D—diaphragmatic agenesis (CDHSG, Morini F, Valfrè L, et al. Congenital diaphragmatic hernia: defect size correlates with developmental defect. *J Pediatr Surg* 2013;48(6):1177–82). A large defect guides prenatal counseling and identifies patients most likely to benefit from fetal treatment.

Associated anomalies are found in as high as 40% of CDH patients with more than 50 different genetic abnormalities linked with a CDH. In addition to the syndromes listed by the author, one should be aware of Pallister–Killian syndrome (PKS) caused by an isochromosome 12p duplication (tetrasomy 12p) (Izumi K, Krantz ID. Pallister-Killian syndrome. *Am J Med Genet C Semin Med Genet* 2014;166C(4):406–13). PKS must be distinguished from Fryns syndrome, as the former is not hereditary, while the latter has been attributed to autosomal recessive inheritance. Once confirmed, appropriate counseling can be provided as to the risks of occurrence in future pregnancies.

From a diagnostic standpoint, the currently utilized antenatal testing and imaging tools are amniocentesis, conventional ultrasound and Doppler, tridimensional ultrasound, fetal echocardiography, and fetal MRI. The first indicator on screening ultrasound for the in utero presence of a CDH is malposition/shifted heart and the second more obvious sign is the presence of

the intestines in the fetal chest. The detection of a thoracic position of the gallbladder raises the possibility of a right-sided CDH.

Accurate prenatal prognostic stratification of the severity of a CDH is essential for following reasons: (1) appropriate counseling of parents of the likely outcomes including the consideration of comfort care in severe cases, (2) guidance of prenatal and postnatal care, and (3) consideration for fetal intervention. Most of the prenatal prognostic indicators such as LHR, O/E LHR, PPLV, TLV rely entirely on lung area or volume to predict the degree of pulmonary hypoplasia and do not always correlate with the severity of pulmonary hypertension. In a recent retrospective study, prenatal pulmonary hypertension index (PPHI) and modified McGoon index (MGI) were shown to predict the severity of pulmonary hypertension, the more critical determinant of the postnatal course (Vuletin JF, Lim FY, Cnota J, et al. Prenatal pulmonary hypertension index: novel prenatal predictor of severe postnatal pulmonary artery hypertension in antenatally diagnosed congenital diaphragmatic hernia. *J Pediatr Surg* 2010;45(4):703–8).

The treatment strategy for patients afflicted with congenital diaphragmatic hernias has changed dramatically, evolving from emergent operative repair to physiologic stabilization followed by delayed operative repair. The CDH cohort and its hidden mortality were the genesis of fetal treatment programs. The successful in utero open repair of a CDH in 1990 led to a prospective trial comparing open fetal repair to postnatal repair that did not demonstrate an outcome benefit of in utero repair (Harrison MR, Adzick NS, Bullard KM, et al. Correction of congenital diaphragmatic hernia in utero VII: a prospective trial. *J Pediatr Surg* 1997;32(11):1637–42). A frameshift changing observation that dramatically impacted current fetal intervention paradigms came with the recognition that in the fatal in utero condition of the congenital high airway obstruction syndrome (CHAOS), fetuses on postmortem examination had pulmonary hyperplasia (Silver MM, Thurston WA, Patrick JE, et al. Perinatal pulmonary hyperplasia due to laryngeal atresia. *Hum Pathol* 1988;19:110–3). This physiologic response has undergone intense study leading to the current paradigm of fetal tracheal occlusion (FETO). The goal with FETO is to retain intrapulmonary fluid, inducing lung growth, partially reverting hypoplasia. Although the UCSF-initiated prospective randomized FETO study was terminated early because of a lack of efficacy (due in large part to the improved survival of the postnatally treated cohort) (Harrison MR, Keller RL, Hawgood SB, et al. A randomized trial of fetal endoscopic tracheal occlusion for severe fetal congenital diaphragmatic hernia. *N Engl J Med* 2003;349(20):1916–24), in Europe, it has been demonstrated in a prospective nonrandomized study that included more than 200 cases of severe CDH cases treated, the survival rate of fetuses treated with FETO for left CDH increased from 24.1% to 49.1% and for right CDH from 0% to 35.3% (Jani JC, Nicolaides KH, Gratacós E, et al. Severe diaphragmatic hernia treated by fetal endoscopic tracheal occlusion. *Ultrasound Obstet Gynecol* 2009;34(3):304–10). The Eurofetus consortium is currently

conducting the Tracheal Occlusion to Accelerate Lung Growth Trial (TOTAL) which is comprised of two randomized prospective cohorts to determine if FETO improves survival of fetuses with severe CDH and decreases morbidity in fetuses with moderate CDH. Through the sponsorship of the North American Fetal Therapy Network, an IDE of the detachable balloon used for FETO has been approved by the FDA to allow several fetal therapy centers in North America to perform this intervention. Interestingly, a recent meta-analysis suggests that FETO is beneficial for severe CDH (Al-Maary J, Eastwood MP, Russo FM, et al. Fetal tracheal occlusion for severe pulmonary hypoplasia in isolated congenital diaphragmatic hernia: a systematic review and meta-analysis of survival. *Ann Surg* 2016;264(6):929–33). FETO remains an exciting intervention that could markedly alter the course of CDH patients; however, its role remains experimental and should be offered only at experienced fetal treatment centers.

As the author notes, in some patients with severe CDH, ex utero intrapartum procedure (EXIT) to ECMO is a treatment paradigm offered. The goal of EXIT-to-ECMO is to place the fetus on ECMO prior to severing of the umbilical cord allowing for a smooth transition into the postnatal period, avoiding barotrauma and hemodynamic instability. Although theoretically beneficial, the evidence in support of its efficacy remains uncertain with a recent nonrandomized study of 17 patients (8 EXIT-to-ECMO and 9 non-EXIT) finding it conferred no survival benefit (Shieh HF, Wilson JM, Sheils CA, et al. Does the ex utero intrapartum treatment to extracorporeal membrane oxygenation procedure change morbidity outcomes for high-risk congenital diaphragmatic hernia survivors? *J Pediatr Surg* 2017;52(1):22–5).

Postdelivery, we, as the author recommends, employ the combination of gentle ventilation or “gentilation,” permissive hypercapnia, aggressive management of pulmonary hypertension, and delayed surgical repair. Effective “gentilation” requires committed care with constant bedside attention. We employ a multidisciplinary team of pediatric surgeons and neonatologists who focus on this population. Unfortunately, many infants still require ECMO support. Once on ECMO, when to repair the CDH is of some controversy. In our practice, if a patient can be steadily weaned from ECMO, we proceed with CDH repair just before coming off ECMO. If the patient has severe prenatal prognostic indicators or is not making progress weaning from ECMO, we will repair the CDH earlier in the course with the goal of optimizing cardiopulmonary physiology.

How to repair a CDH varies according to surgeon preference. Whenever feasible, we prefer transversus abdominis muscle flap (TAMF). We have found that in majority of our patients, the TAMF is adequate with less degree of abdominal wall diastasis. It remains to be determined if autologous muscle flap repair will decrease scoliosis and chest wall abnormality when compared to synthetic patches. Abdominal wall repair using a patch may be necessary in patients with inadequate abdominal domain to accommodate the viscera. The

recurrence rate after CDH repair can be as low as 5%.

CDH patients require long-term follow-up. In addition to the issues discussed by the author, close monitoring in the first year for pulmonary hypertension is required with optimization of medical management. Patients with persistent pulmonary hypertension should be transitioned to oral antipulmonary hypertensive agents. Patients with severe pulmonary hypertension may require multiple treatment regimens, including intravenous vasodilators.

Advances in neonatal management and surgical intervention have improved the outcomes of patients who are afflicted with a CDH. Further research expanding our knowledge of the causes of CDH is required along with collaborative efforts developing innovative therapy encompassing all aspects of care such that survival rates and long-term quality of life improves.

65 Eventration of the Diaphragm

Heather R. Nolan, Daniel von Allmen, and Foong-Yen Lim

Diaphragmatic eventration (DE) is a pathologic condition defined by a permanent elevation of an immobile hemidiaphragm that cannot participate actively in respiration. Peripheral muscular attachments are normal, the diaphragmatic apertures are sealed appropriately, and there is no interruption in the pleural or peritoneal layers as is seen with diaphragmatic hernias. Instead, a flap of lax diaphragmatic tissue inhibits appropriate muscular excursion with respiration and intrudes into the thoracic cavity displacing its contents along with the mediastinum. The defect can be unilateral, localized, or bilateral. DE may be a congenital anomaly caused by failure of muscularization of the dome of a hemidiaphragm or it may be acquired as a result of dysfunction of the phrenic nerve in cases such as neuromuscular disease, trauma, or iatrogenic injury. DE is most commonly diagnosed in pediatric patients and occurs in 10 of 100,000 live births, whereas the incidence in adulthood is low, estimated to be between 1 in 10,000 and 1 in 13,000. It is more common in males and affects the left hemidiaphragm more frequently. The effect on the pediatric population is more pronounced as infants and children rely on diaphragmatic excursion for respiration and physiologically their ribs are more horizontally oriented with weaker intercostal muscles. Asymptomatic patients with incidentally discovered eventration do not require any intervention unless the invagination is significant enough to cause compromised future lung growth. In those with recoverable phrenic nerve injury, watchful waiting is reasonable to assess for improvement in nerve function. Conversely, all symptomatic eventration is treated with operative management using a variety of techniques described in detail below.

ANATOMY

Congenital DE is an abnormal elevation of the diaphragm resulting from failure of muscle fibers to develop. Starting at week 4 of gestation, four components coalesce to form the diaphragm—the lateral body walls,

transverse septum, esophageal mesentery, and the pleuro-peritoneal membranes. During the eighth to tenth week of gestation, muscle fibers grow from the lateral body wall to form the membranous and muscular portion of the peripheral diaphragm while the pleuro-peritoneal membranes become a muscular trigone in each hemidiaphragm. Different etiologic factors have been postulated as causes of congenital DE such as failure of migration of myoblasts along normal phrenic nerve branches or from the peripheral chest wall, failure of normal innervation of the primordial diaphragm, congenital infection with *Toxoplasma* or *Cytomegalovirus,* and premature return of the midgut to the peritoneal cavity during development. The sparsely distributed muscle fibers are mechanically nonfunctional, resulting in a lax, thin, elongated membrane.

Normally the diaphragm projects from the 10th rib posteriorly up to the dome at the level of the 5th or 6th rib anteriorly. In the majority of patients, the dome of the left hemidiaphragm is one interspace lower than the right. Elevation of the diaphragm in cases of eventration results from arching of the diaphragm as the lax membrane is unable to withstand the relatively higher intra-abdominal pressures compared to its thoracic counterpart.

Eventrations are frequently unilateral; however, a few cases of bilateral eventration have been reported in the literature. Further categorizations relate to the segment of impaired diaphragm. Eventration is considered complete if the entire hemidiaphragm demonstrates thinning muscle or partial when it involves just a portion. Although a complete eventration of the hemidiaphragm is more common in males, and on the left side, partial eventration is more common on the right side and is of equal sex distribution. The most common site of partial eventration is seen more often in the adult rather than the pediatric population. A weakening in the anteromedial aspect of the right hemidiaphragm occurs commonly in patients over 60 years of age and is usually of no clinical significance.

Disorders that may accompany congenital DE are the same as those that may accompany congenital diaphragmatic hernia (CDH). These include facial (cleft lip and palate), cardiovascular (patent ductus arteriosus, aortic stenosis, ventricular septal defect, and coarctation of the aorta), gastrointestinal (malrotation, gastric volvulus, megacolon), situs inversus, tracheomalacia, genitourinary (horseshoe kidney), musculoskeletal (hemivertebrae, arthrogryposis, Werdnig-Hoffmann disease, and Ehlers-Danlos syndrome), and chromosomal (trisomy 18) abnormalities.

Therefore, when congenital disorders of the diaphragm are suspected, it is essential to evaluate the patient for possible coexistence of other anomalies.

Acquired or secondary DE is often due to pathologic or iatrogenic insult to the phrenic nerve resulting in paralysis of the diaphragm and DE. External trauma, inflammation (pleural, mediastinal, or pulmonary source), or neoplastic invasion of the nerve usually results in complete DE. With diaphragmatic paralysis, the muscle fibers are present but become atrophic with time. Histopathologically, eventration results in the characteristic findings of microscopically few muscle fibers and diffuse fibroelastic changes while paralysis or paresis of the phrenic nerve can lead to thickening of nerve fibers. Birth trauma is by far the most common cause of acquired DE and is usually related to breech presentation or shoulder dystocia resulting in a stretch injury to the C3 through C5 nerve roots. These nerves give rise to the phrenic nerve and brachial plexus and are responsible for motor innervation to the diaphragm. Fractures of the clavicle or humerus are often seen in association. If nerve roots are avulsed, no improvement in the DE is predicted, whereas lesser degrees of injury may potentially recover with time. Acquired DE is also seen after open cardiac procedures, due to surgical dissection, electrocautery, or ice placement. Again, recovery depends on the nature and completeness of the nerve lesion.

CLINICAL PRESENTATION

The anatomic diagnosis of DE is largely based on imaging studies but the clinical presentation is critical to the management algorithm and will vary slightly based on the age of the patient. Dyspnea is the primary presenting symptom and the degree to which it is clinically significant determines the need for surgical intervention. Pulmonary function test (PFT), when can be performed in older children and adults, will demonstrate a restrictive pattern with a decreased forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV1). Lung volumes in the upright and supine position can help delineate the physiologic effect of the DE. PFTs and lung volumes can also be used postoperatively to quantify objective improvement from preoperative values.

Adults

Most adults with congenital DE are asymptomatic and do not require

surgical treatment. DE acquired during adulthood due to phrenic nerve insult results in atrophy and progressive laxity of the diaphragmatic muscle. These patients are likely to present with incidental findings on a chest radiograph obtained for unrelated reasons. When the patient is symptomatic, they typically present with signs and symptoms related to inadequate ventilation (e.g., dyspnea on exertion or with recumbency). In an adult with a previously asymptomatic DE, conditions that cause atelectasis or mild respiratory infection may result in respiratory distress, tachypnea, tachycardia, and even cyanosis. Chest pain, either spontaneous or provoked by flexion, or palpitations caused by cardiac arrhythmias can also be seen. Alternatively, abdominal symptoms including epigastric pain, dysphagia, dyspepsia, belching, and gastroesophageal reflux may be associated with displacement of the viscera into a large DE or secondary to a positional change in the esophagus creating a bend in the esophagus or obstructing the pylorus.

Infants and Children

DE commonly results in respiratory symptoms in infants and children similar in nature to a flail chest. This is due to a more mobile pediatric mediastinum shifting to the contralateral side. This results in compression of contents of both hemithoraces significantly compromising overall cardiopulmonary function. In addition, infants rely much more on diaphragmatic excursion than accessory muscles for respiration, resulting in a greater susceptibility to symptomatic DE. Less commonly, infants and children with DE may present with abdominal symptoms, the most catastrophic of which is acute gastric volvulus, requiring urgent operative intervention.

DIAGNOSIS

The diagnosis of DE is based on a combination of clinical and radiographic characteristics that are necessary to differentiate it from a diaphragmatic hernia or an underlying primary pathologic condition involving the lungs or chest wall. A thorough history is important to provide clues to the presence of other pathology as well as to document the degree of respiratory symptoms, which are the main determinant for surgical intervention. The findings from a physical examination are nonspecific but include dullness to percussion, decreased breath sounds on the affected side, and paradoxic movement of the chest wall with

inspiration.

Prenatal diagnosis of congenital DE is possible with high-resolution prenatal ultrasonography, or magnetic resonance imaging (MRI). DE and CDH may appear similar during fetal imaging, with a hypoplastic ipsilateral lung, and fetal stomach or liver seen in the same axial plane as the heart. With DE, polyhydramnios is relatively infrequent and abdominal circumference is normal or slightly smaller than gestational dates would indicate. Although the paradoxical movement of the diaphragm itself during fetal breathing may not be able to be visualized, paradoxical movement of intra-abdominal viscera can serve as a surrogate. Occasionally, a hypoechoic, thin diaphragmatic membrane can also be seen in cases of DE. One of the additional benefits of prenatal imaging includes an evaluation of the lungs in an effort to predict postnatal outcomes. Various methods and indices exist to categorize the degree of pulmonary hypoplasia including the lung-to-head ratio, observed-to-expected lung-to-head ratio, percent predicted lung volume, and observed-to-expected total fetal lung volume measurements.

Postnatally, the diagnosis is often first suspected based on marked elevation of the hemidiaphragm on a chest radiograph obtained to investigate respiratory distress. The subsequent workup is based on the clinical context. In the absence of a history suggesting phrenic nerve injury, investigations to elucidate the reason for DE should be conducted. In particular, occult neoplastic, infectious, and degenerative diseases of the cervical or mediastinal regions should be considered. Most can be excluded with a cervicothoracic computed tomography (CT) scan. Upper-abdominal CT is useful for excluding subphrenic abnormalities such as abscess or Chilaiditi syndrome that may be the causative factor of the diaphragmatic paralysis. Treatment would then focus on correcting the underlying cause rather than repair of the anatomic abnormality of the diaphragm itself.

While initial imaging often identifies the presence of hemidiaphragmatic elevation, to confirm the diagnosis of DE some form of dynamic imaging must be done to assess the function of the diaphragm. Fluoroscopy, ultrasound, or dynamic MRI can determine whether diaphragmatic movement is absent or decreased, or if the classic “paradoxical” movement of the diaphragm is present during spontaneous ventilation. Normal findings involve the downward motion of both hemidiaphragms on inspiration. Paradoxical motion is observed when

during inspiration paralysis or elevation of the involved hemidiaphragm is identified in conjunction with depression of the contralateral (normal) hemidiaphragm. This finding can be accentuated during fluoroscopic examination using the “sniff” maneuver which entails a fast inspiration through the nose with the mouth closed. Dynamic MRI is also gaining footing as an alternative mode of assessing function with the benefit of excellent anatomic visualization without the associated ionizing radiation. Other imaging modalities include ventilation-perfusion scanning which is less commonly used to demonstrate DE, but can show loss of ventilation on the involved side. Upper-gastrointestinal contrast study has also been described as a useful diagnostic modality to assess GI symptoms and can identify the anatomic location of intra-abdominal structures.

It is important to realize that characteristic physical examination and radiologic findings will not be evident in patients who are undergoing mechanical ventilation. Positive-pressure ventilation eliminates the diaphragmatic asymmetry that is used to secure the diagnosis in spontaneously breathing patients. For patients with history consistent with DE who cannot be extubated, fluoroscopy during brief discontinuation of mechanical ventilation may provide radiologic information to exclude or support the diagnosis of DE. In addition, DE must be considered in infants who have unexplained respiratory distress and require urgent intubation before baseline chest radiography can be obtained.

TREATMENT

Asymptomatic patients do not typically require operative intervention and may be observed. For those with symptoms, supportive therapy for respiratory dysfunction often precedes surgical treatment and includes supplemental oxygen, upright positioning, and treatment of respiratory infections. Rarely, emergency surgery is required due to the severity of respiratory compromise, gastric volvulus, or spontaneous rupture. Otherwise, operative intervention is the primary treatment for symptomatic eventration.

The goals of surgical therapy should be to (a) return the diaphragm to a normal location within the involved hemithorax, (b) reinstate normal capacity to the hemithorax to allow lung growth in infants and children, (c) restore normal visceral location in the abdomen, and (d) stabilize the mediastinum by eliminating paradoxical motion of the diaphragm. These goals have classically been achieved via open thoracotomy. First described

in 1923 by Morrison, the evolution of the open technique has involved either plication of the redundant diaphragm or resection of excess tissue with primary closure of the resulting diaphragmatic defect. More recently, minimally invasive approaches have been described using thoracoscopic or laparoscopic techniques. The obvious advantage of these methods is to reduce the operative morbidity of an open intervention, which may in turn reduce the threshold for pursuing surgical repair.

INDICATIONS

Indications for operative correction of either congenital DE or acquired DE include (a) progressive respiratory distress with atelectasis or pneumonia or (b) failure to wean from mechanical ventilation. In either of these settings, early operative correction, at the time of diagnosis, is warranted because of the limited morbidity of the operative correction and the often dramatic improvement with fixation. Conversely, for asymptomatic DE, surgical correction is generally not indicated.

A relative indication for operative intervention in an infant who has congenital DE is the presence of significant elevation of the hemidiaphragm. This is described as abdominal viscera occupying at least half or more of the volume of the hemithorax. This degree of diaphragmatic elevation results in compromised growth of the ipsilateral lung, and potentially the contralateral lung in cases associated with significant mediastinal shift, similar to that seen in CDH. The capacity for normal lung growth is restored after surgical repair of DE, thus suggesting that early operation in this setting is clinically warranted.

For patients in whom respiratory symptoms are less severe and the etiology is thought to be from recoverable phrenic nerve injury, a delay of several weeks to months to allow for improvement is justified. Lack of improvement or deterioration in respiratory function during observation is an indication for immediate operative repair. In patients with central nervous dysfunction confirmed by extensive neuromuscular testing, phrenic pacing shows promise for improvement of respiratory status through diaphragmatic stimulation.

Surgical correction of DE in older children or adults is less common. Infants have a more compliant chest and mediastinum which results in a reduced capacity to compensate for the physiologic aberrancies of DE compared to their older counterparts. In this population, phrenic nerve injury caused by cardiac or aortic surgery rarely results in clinically

significant respiratory insufficiency to require operative correction of DE. A more compelling indication for correction of acquired DE in older patients is the development of abdominal pain due to displacement of abdominal structures into the chest or cardiac arrhythmias related to cardiac compression. In addition, gastric volvulus or significant gastroesophageal reflux associated with DE should be seen as indications for surgical fixation. Treatment of DE caused by aggressive malignancy or other underlying pathology should be directed at the underlying cause.

SURGICAL TECHNIQUE

Open Operative Repair

The traditional operative approach utilizes a posterolateral thoracotomy. Right-sided DE is best approached through the chest and avoids complications associated with working around the liver. Left-sided DE can be approached via thoracotomy or laparotomy. Thoracotomy offers better anatomic exposure of the phrenic nerve branches. Bilateral eventrations, although rare, are best approached through the abdomen. Patients who present with gastric volvulus and eventration should undergo laparotomy for gastric fixation and diaphragmatic plication.

Historically, both diaphragmatic plication and resection have been described; however, plication is currently preferred over resection for both open and minimally invasive approaches. The open procedure can be performed through a standard posterolateral thoracotomy incision in the 7th to 8th intercostal space (ICS). The initial examination of the diaphragmatic tissue should concentrate on the identification of the phrenic nerve branches (Fig. 65.1). Preservation should be planned even though the potential for recovery is often limited.

The desired outcome of surgical intervention should be the construction of a rigid, flat hemidiaphragm that does not participate in or detract from ventilatory movement. This can be achieved by placing two rows of sutures to imbricate the redundant hemidiaphragm. The initial row is placed along the posterolateral one third of the diaphragm, beginning at the central portion of the diaphragm and proceeding toward the periphery. The sutures are placed parallel to the branches of the phrenic nerve. Each suture placed should incorporate several centimeters of tissue in two to three equally spaced bites. During this imbrication maneuver, the diaphragmatic tissue should be grasped and elevated to separate it from the underlying liver in the case of a right-sided DE, or from the stomach or

spleen in the case of left-sided DE (Fig. 65.2). The entire row of interrupted sutures is placed before they are tied sequentially to imbricate the diaphragm (Fig. 65.3). The suture material selected should be permanent, such as 2-0 braided nylon or monofilament nylon. The second row of sutures is then placed from the center of the diaphragm along the anterior one third of the diaphragm. After plication, the tissue should be taut and thus incapable of flail. If this is not achieved after the placement of both suture lines, the tissue along the suture lines can be plicated again over itself to remove the redundancy in the hemidiaphragm until proper correction is achieved (Fig. 65.4).

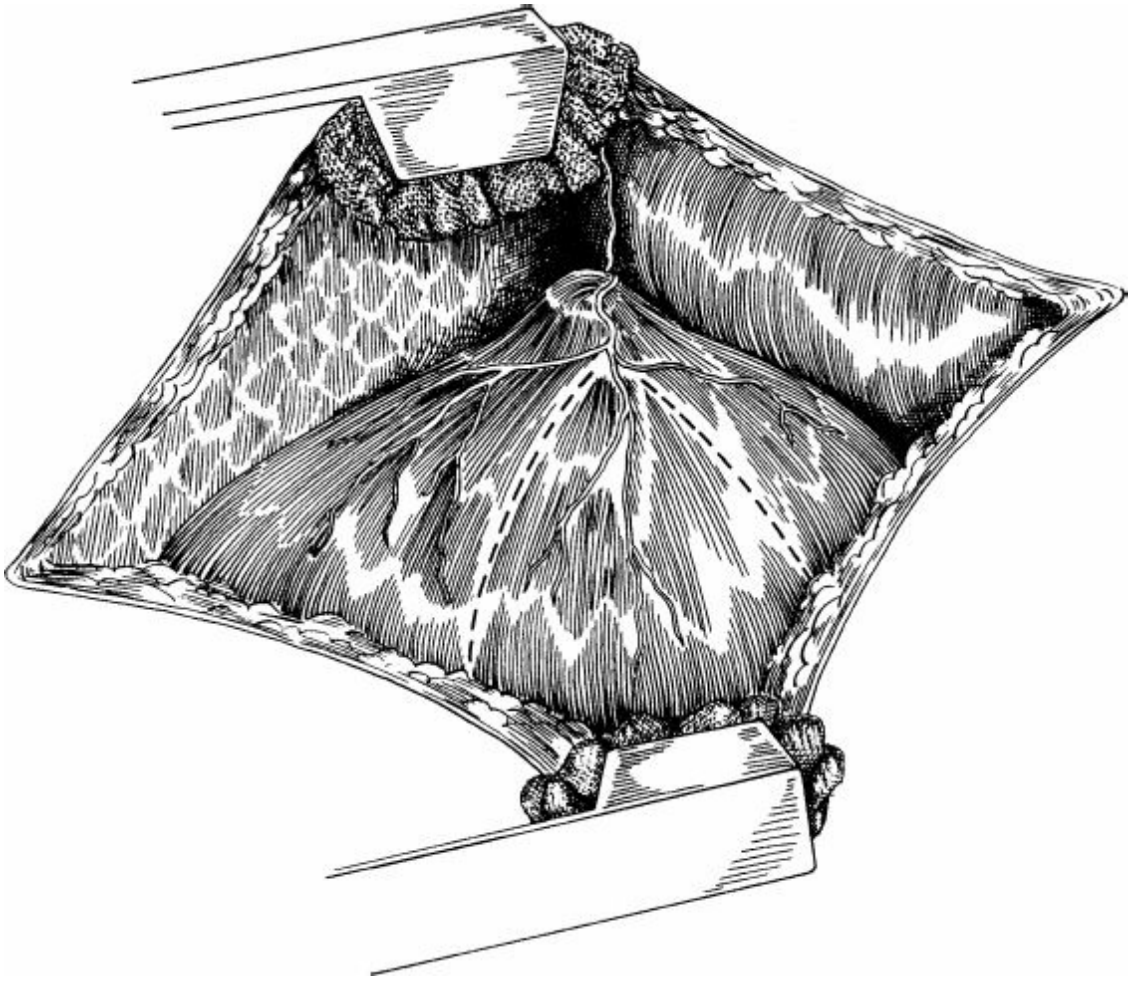

Figure 65.1. Phrenic nerve descending over the central dome of the diaphragm. Right posterolateral thoracotomy. *Dashed line* indicates site of the diaphragmatic plication.

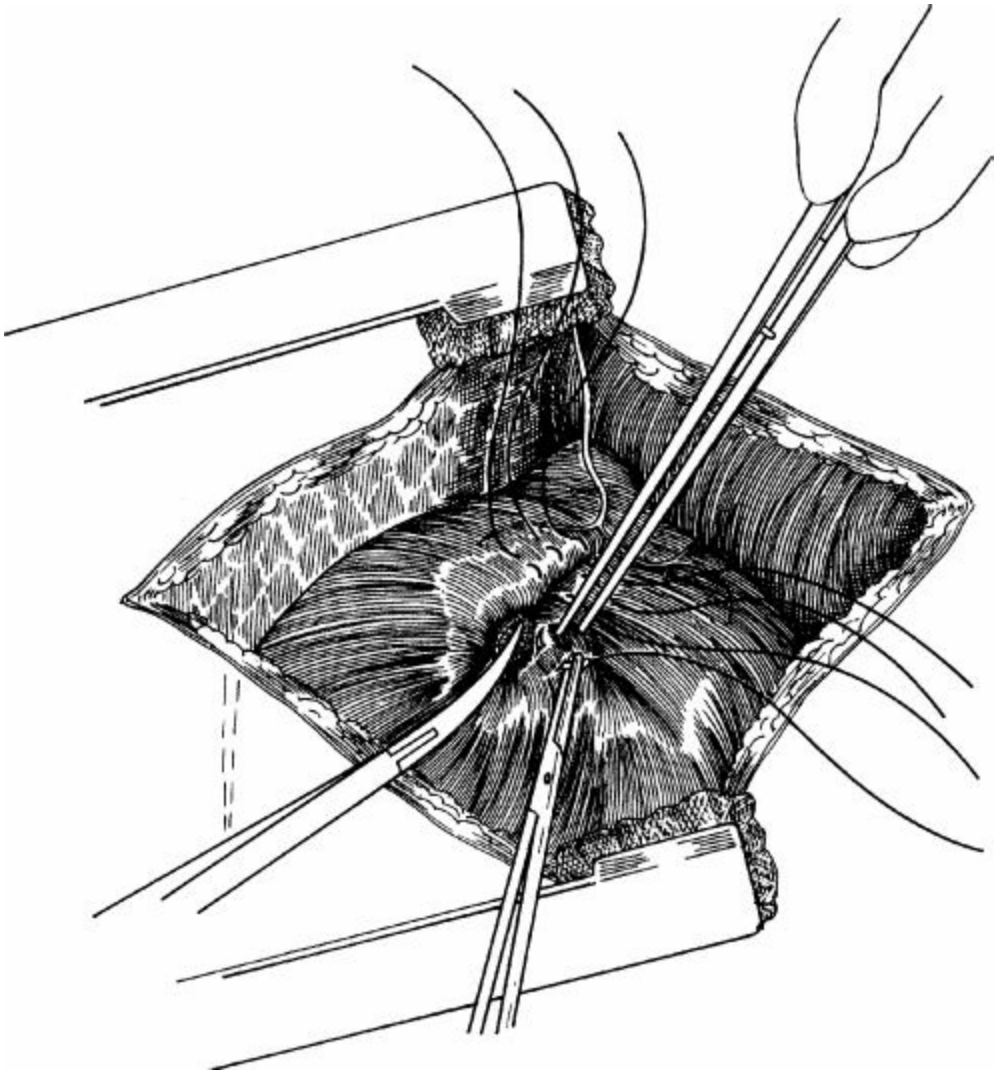

Figure 65.2. Multiple interrupted imbricating sutures are placed between the phrenic nerve branches at the site of the diaphragmatic plication.

Alternatively, one can resect the redundant portion of the diaphragm. A full-thickness ellipse of the central portion of the diaphragm is removed. The resected diaphragm should not include the major branches of the phrenic nerve, and care must be exercised to avoid abdominal visceral injury when the resection margins are established. A two-layer closure is achieved by first placing and then tying the first row of sutures to imbricate the diaphragm margins. To avoid injury to abdominal organs, the second row of sutures that secures the imbrication should not transgress the diaphragm (Fig. 65.5). This procedure also reconstructs a flat, noncompliant diaphragm.

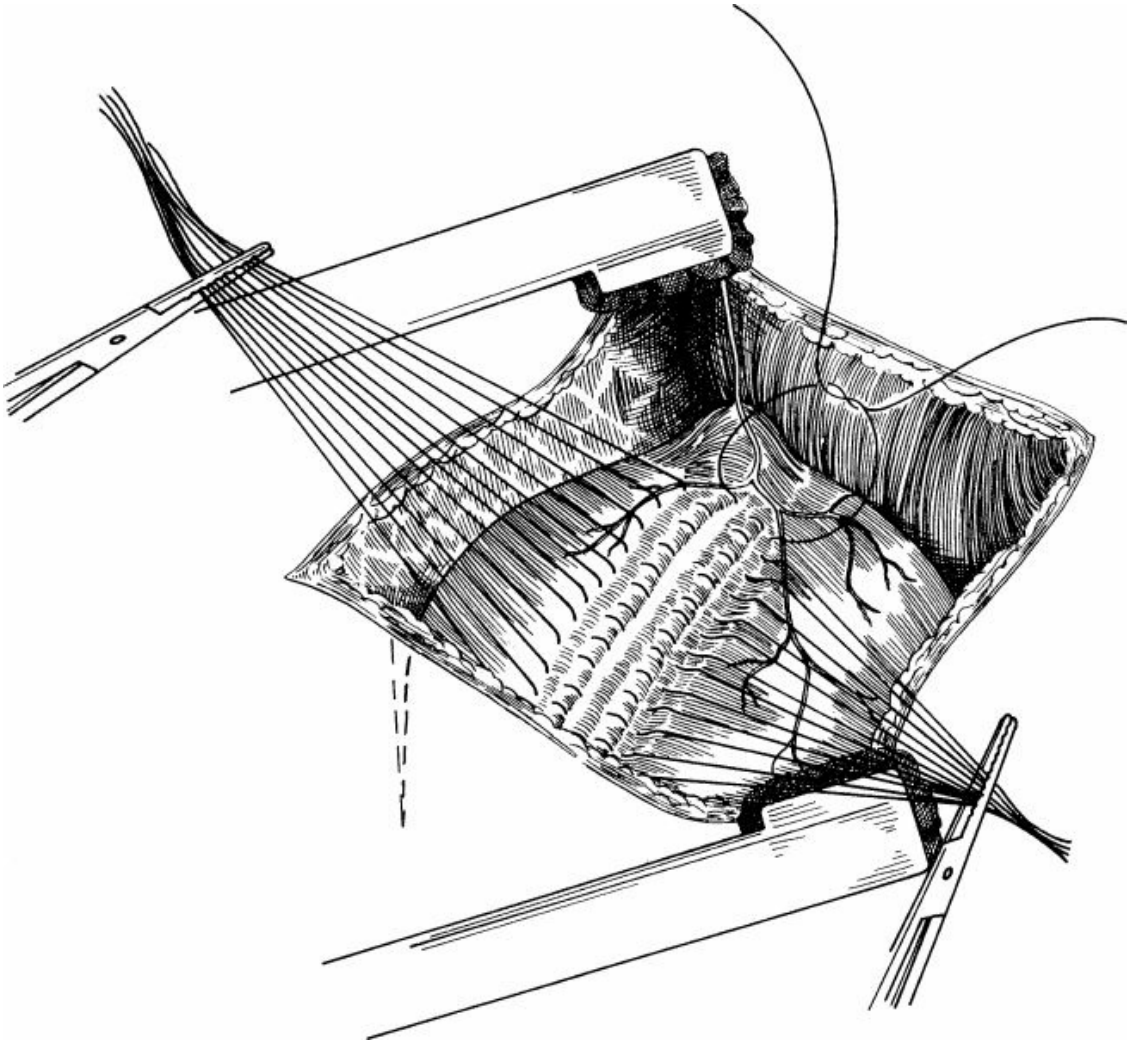

Figure 65.3. Completed suture placement before plication.

A thoracostomy tube is placed for pleural drainage. The patient can often be weaned from mechanical ventilatory support immediately after operation unless there is significant pulmonary hypoplasia. The chest tube is typically removed after 1 to 2 days and the patient is discharged home once they are stable from a respiratory standpoint.

Open abdominal intervention is also described and is typically contemplated for left-sided eventrations. The abdominal approach affords the ability to visualize intra-abdominal structures to prevent plicating bowel or other organs during diaphragmatic repair. The right-sided liver is rarely incorporated in the plication from the thoracic approach and additionally can impede visualization and working space in the abdominal approach.

The open approach, either transthoracic or transabdominal, provides an adequate repair with minimal recurrence. The benefits of minimally

invasive surgery, however, have persuaded many surgeons to employ endoscopic techniques. In the thorax, the video-assisted thoracoscopic surgery (VATS) intervention is associated with a significantly decreased operative time and length of stay, in addition to less postoperative complications and recurrence. Similar improvements in morbidity, mortality, and length of hospital stay in other thoracic and abdominal surgical interventions have prompted further research into endoscopic interventions. As such, the majority of recent literature on eventration revolves around minimally invasive techniques and outcomes.

Minimally Invasive Plication

Thoracoscopic Plication

Minimally invasive surgical techniques, both thoracoscopic and laparoscopic, offer a safe and effective alternative to open diaphragmatic plication. In the thoracoscopic approach, visualization is paramount and can be improved with several methods. In patients of adequate airway size and maturity to accommodate a double-lumen endotracheal tube or bronchial blocker, selective ventilation of the contralateral lung allows improved visibility of the affected diaphragm. In addition, insufflation of the ipsilateral pleural space with carbon dioxide at a pressure of 5 to 6 mm Hg can also optimize exposure. This is especially true in younger, smaller patients with limited space for observation and manipulation of the redundant diaphragm tissue. Recently, there are reports that demonstrate that carbon dioxide insufflation alone is sufficient and single-lung ventilation is not required to achieve adequate visualization.

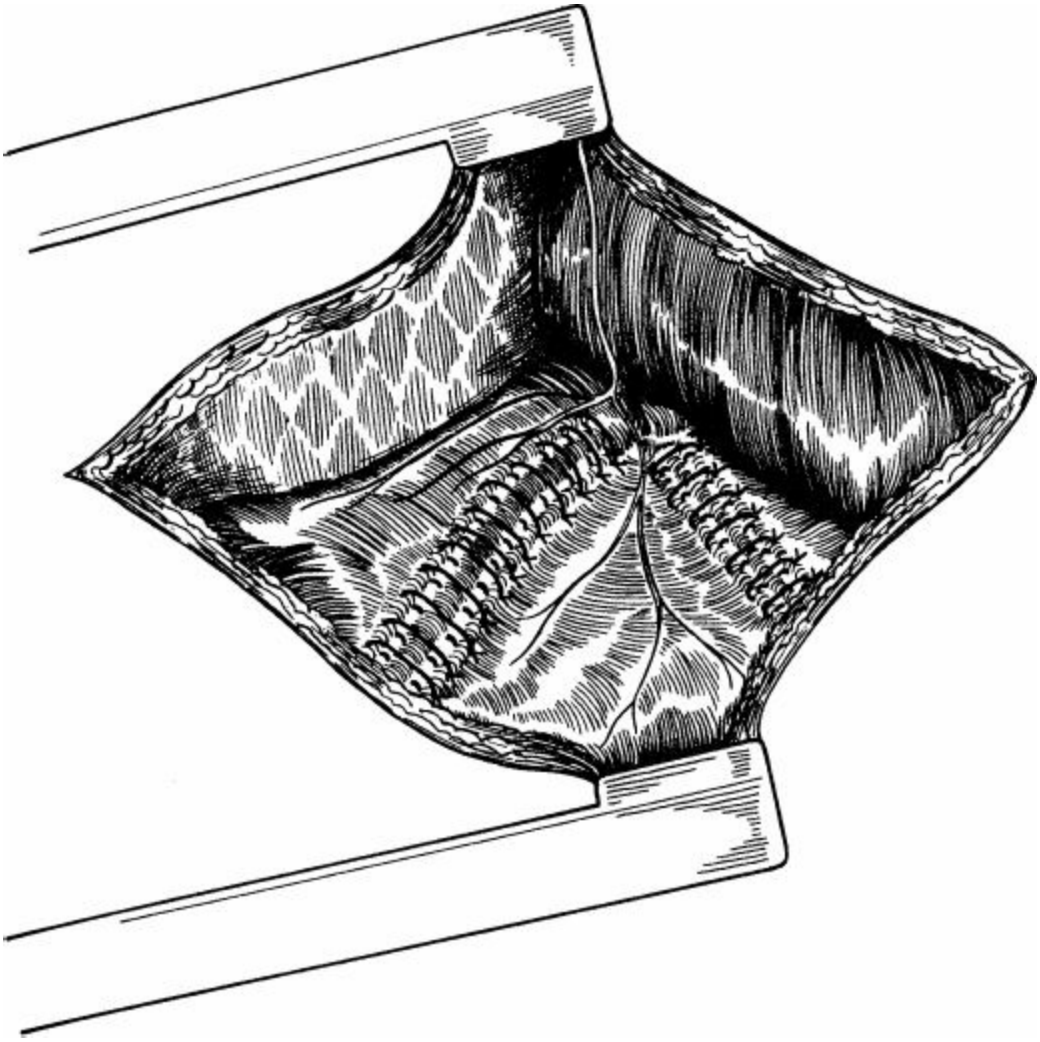

Figure 65.4. Completed diaphragmatic plication, removing the redundancy within the hemidiaphragm.

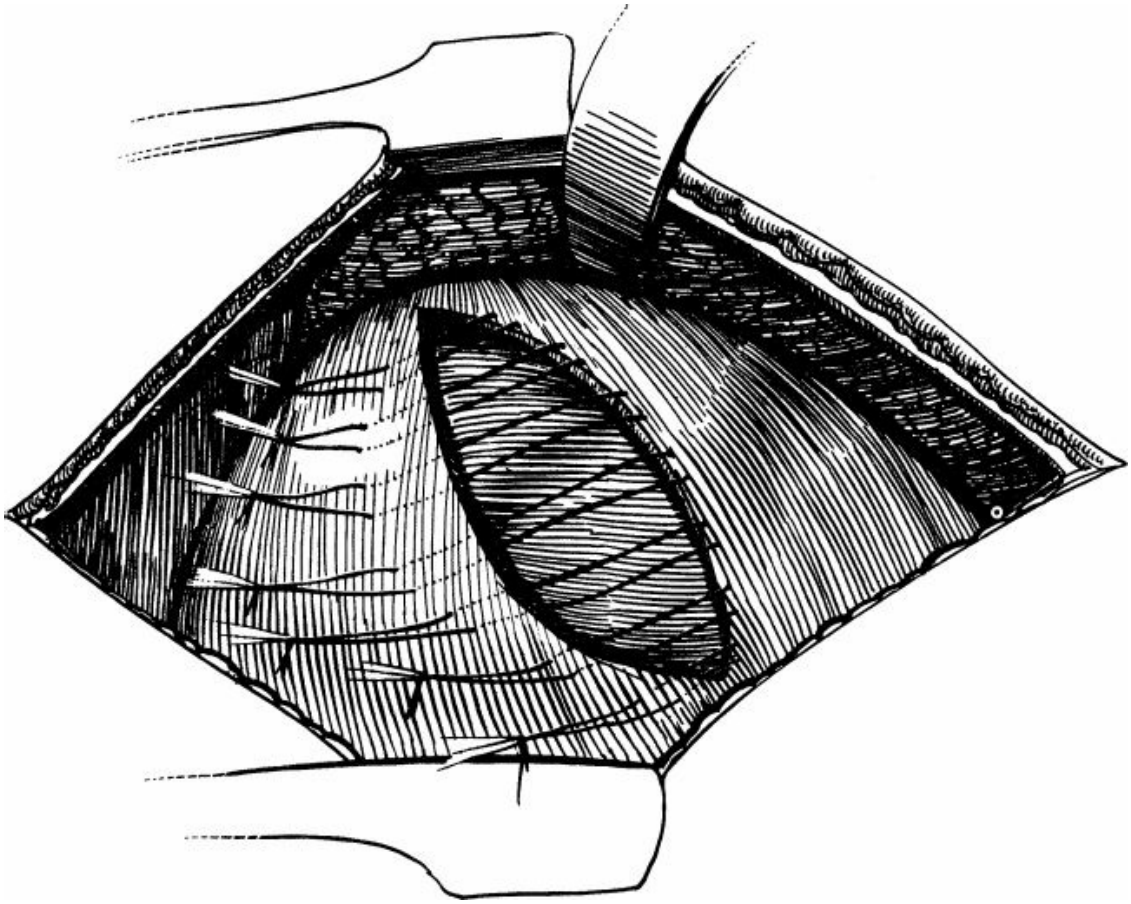

Figure 65.5. Removal of full-thickness ellipse of central portion of the diaphragm in the anteroposterior direction.

Thoracoscopic set-up varies within the literature and is largely based on surgeon preference. A lateral decubitus position or bump is used to help rotate and align the patient. Typically, three to four ports are used and are triangulated toward the target anatomy (Fig. 65.6). Some authors posit that higher trocar placement provides increased working space while others strive for fewer ports and use alternative means of plication. In smaller children and infants, 3-mm instruments can be passed directly through the chest wall without the use of a trocar.

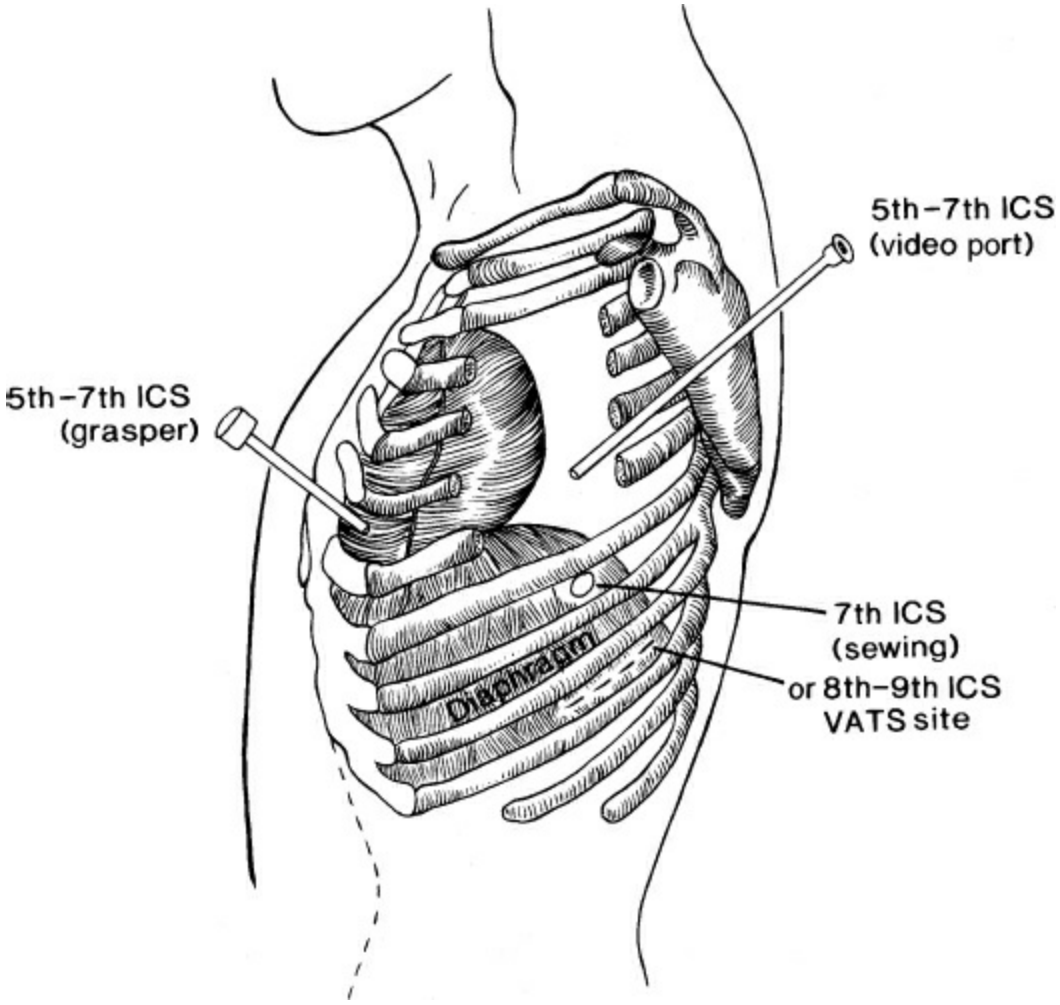

Figure 65.6. Schematic representation of trocar placement for minimally invasive correction of DE. VATS, video-assisted thoracoscopy.

Several techniques for plication have been described. The lax portion of the diaphragm can be folded over onto itself and secured with nonabsorbable suture through all three layers of the diaphragm (Fig. 65.7). Alternatively, the apex of the eventration can be invaginated and sutures passed between the muscular parts of the diaphragm to reapproximate the muscular edges (Fig. 65.8). This technique can be performed with or without a second row of imbrication suture. Similarly, the redundant diaphragm can be grasped with a long vascular clamp and pulled through the jaws of the clamp until laxity is removed. With the clamp applied, the base of the diaphragm is then safely sutured with a running horizontal mattress nonabsorbable suture. This may be repeated several times until the desired effect is achieved. Another method involves an accordion-like maneuver in which sequential bites of diaphragm are taken from one side of the diaphragm to the other producing pleats that recreate the tension of

the hemidiaphragm (Fig. 65.9). This technique has been described with intra- and extracorporeal tension on the suture and has also been demonstrated using a spinal needle to avoid difficult intracorporeal suturing in neonates and small infants. Lastly the use of an endostapler has recently been described and achieves repair through reapproximation along with resection of the redundant diaphragm (Fig. 65.10). The original description of this method required a larger port to accommodate the stapler but with the advent of smaller devices, the trocar size can be significantly diminished.

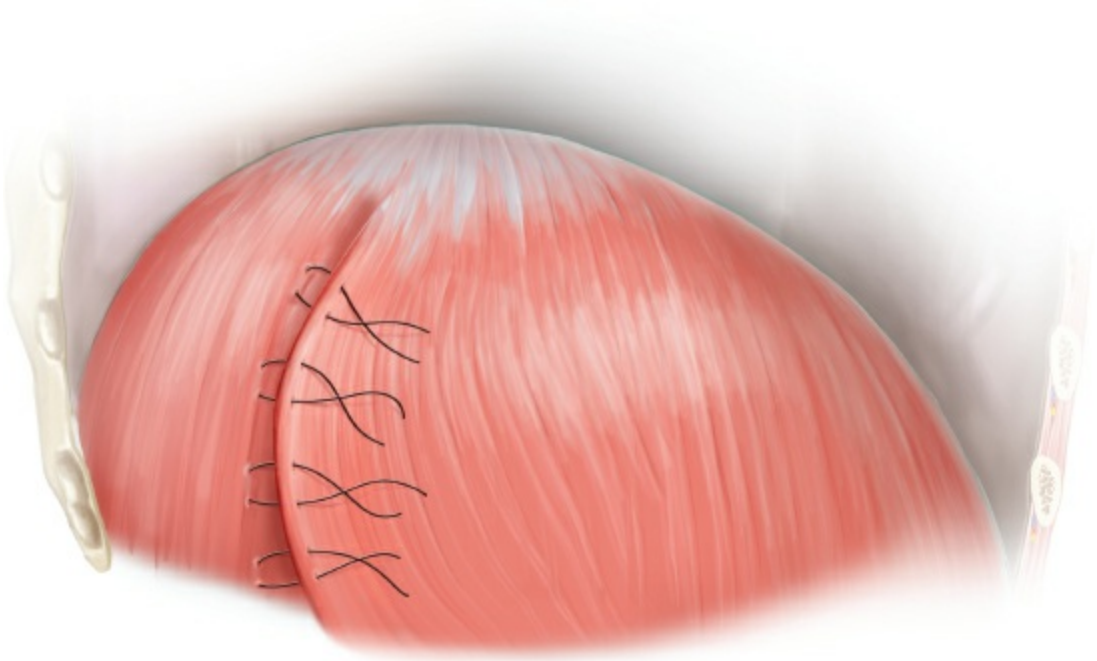

Figure 65.7. Folded plication technique with sutures through three diaphragmatic layers.

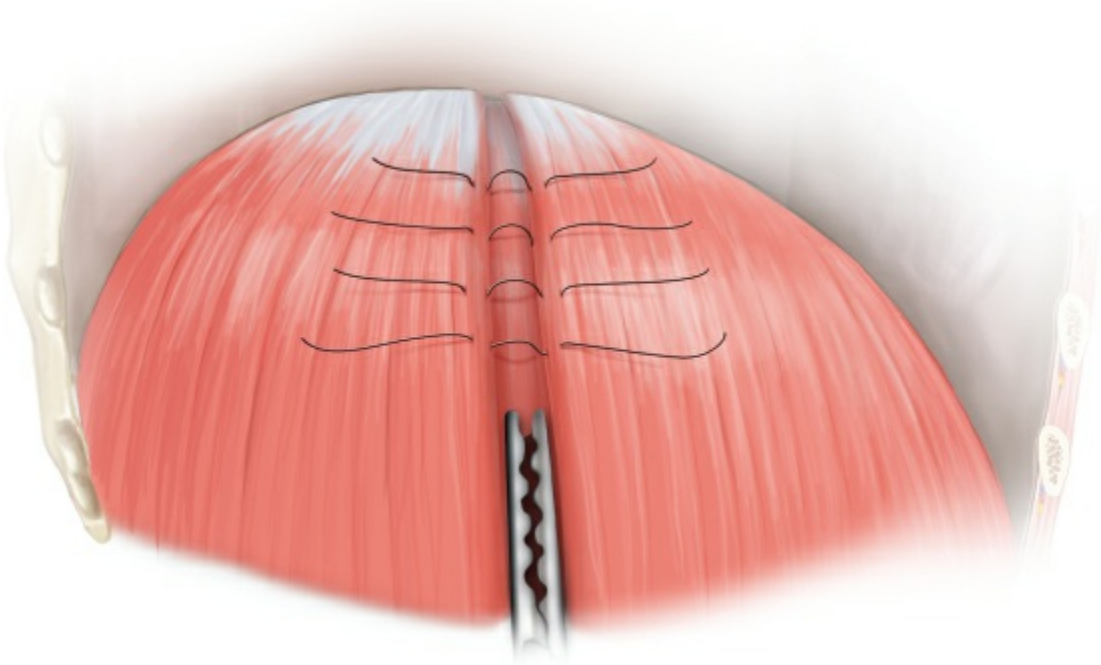

Figure 65.8. Invagination technique with reapproximation of the muscular portions.

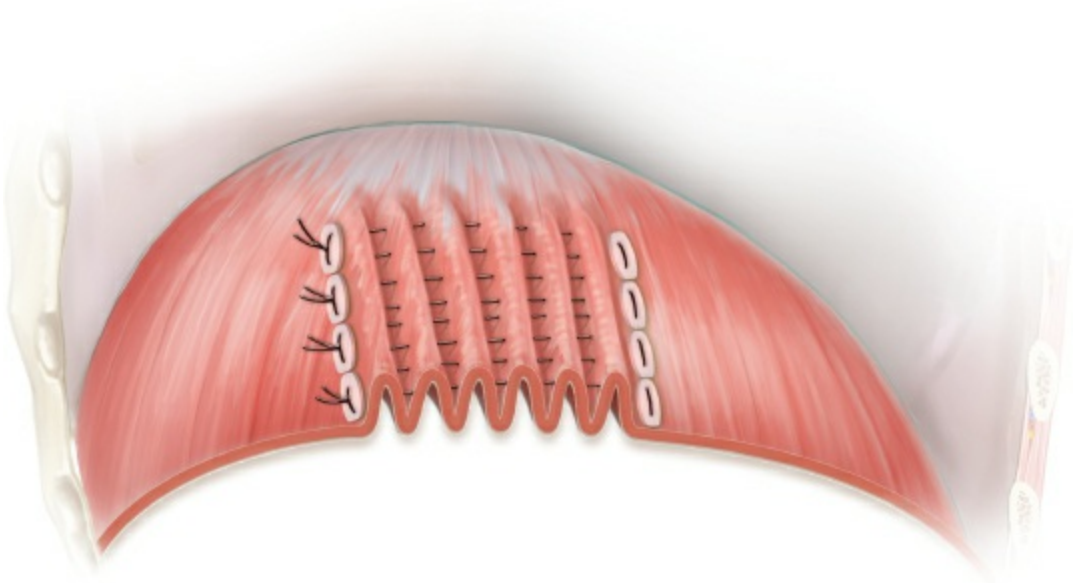

Figure 65.9. Accordion-type plication using a pledgeted u-stitch technique with multiple passes of suture in a linear fashion to create pleats in the lax portion of the diaphragm.

Adjuncts that may facilitate repair include knot-tying devices, fan retractors, and increasingly smaller instruments. In patients with fragile, friable diaphragmatic tissue the use of a stapler has been described to create a reinforced ridge that is used to hold the suture for plication. Visual

inspection confirms flattening of the plicated diaphragm as the induced pneumothorax is released. All carbon dioxide and air is aspirated from the pleural space. Use of a pleural tube varies with some surgeons advocating thoracostomy tubes in all patients, some in select patients, and some with no tube use at all.

In adults, robotic thoracoscopic interventions and single-port surgery have been described; however, the 8-mm robotic ports remain intrusive to the small surface area of the pediatric population and single site interventions require additional small incisions for suturing potentially negating the benefit of an isolated incision.

Laparoscopic Plication

The major advantages of an abdominal approach to plication are (a) the ability to utilize dual-lung ventilation, (b) the avoidance of injury to the lung parenchyma from retraction techniques, (c) a larger operative space in which to work, (d) less risk of injury to intra-abdominal viscera which cannot be directly seen thoracoscopically, and (e) a greater degree of freedom of trocar movement than is permitted with thoracoscopy. The laparoscopic approach also offers the ability to assess the intra-abdominal contents and/or to provide simultaneous additional surgery such as a feeding tube or fundoplication.

Laparoscopic plication of DE can be achieved using a single lumen endotracheal tube with the patient supine in reverse Trendelenburg position. Typically, four trocars (3 mm for infants and toddlers, 5 mm for older children and adults) are deployed, one in the umbilicus (scope) and three others in a half circle. It may be necessary to divide the triangular ligament of the left hepatic lobe to afford exposure to the left hemidiaphragm. Gentle downward retraction on the right hepatic lobe facilitates plication of right-sided DE. In the technique described by Andrade, hook electrocautery is used to make a small hole in the affected diaphragm, inducing an ipsilateral pneumothorax. This equalizes the pressures across the pleural and peritoneal cavities and allows the redundant diaphragm to be grasped and retracted down into the peritoneal cavity. Alternatively, a retraction suture may be placed at the apex of the DE to allow it to be pulled into the operative field and away from the underlying lung parenchyma. After invaginating or retracting the diaphragm, plication is then performed using pledgeted nonabsorbable sutures. Alternatively, the accordion or pleated repair and the stapled repair described previously in the thoracoscopic approach have also been

utilized in the laparoscopic technique. In cases of suture retraction, no further intervention or pleural tube is required. If a hole in the diaphragm is created prior to plication, the plication sutures are positioned in such a way as to incorporate the hole in the repair and a small thoracostomy tube is placed for 24 to 48 hours.

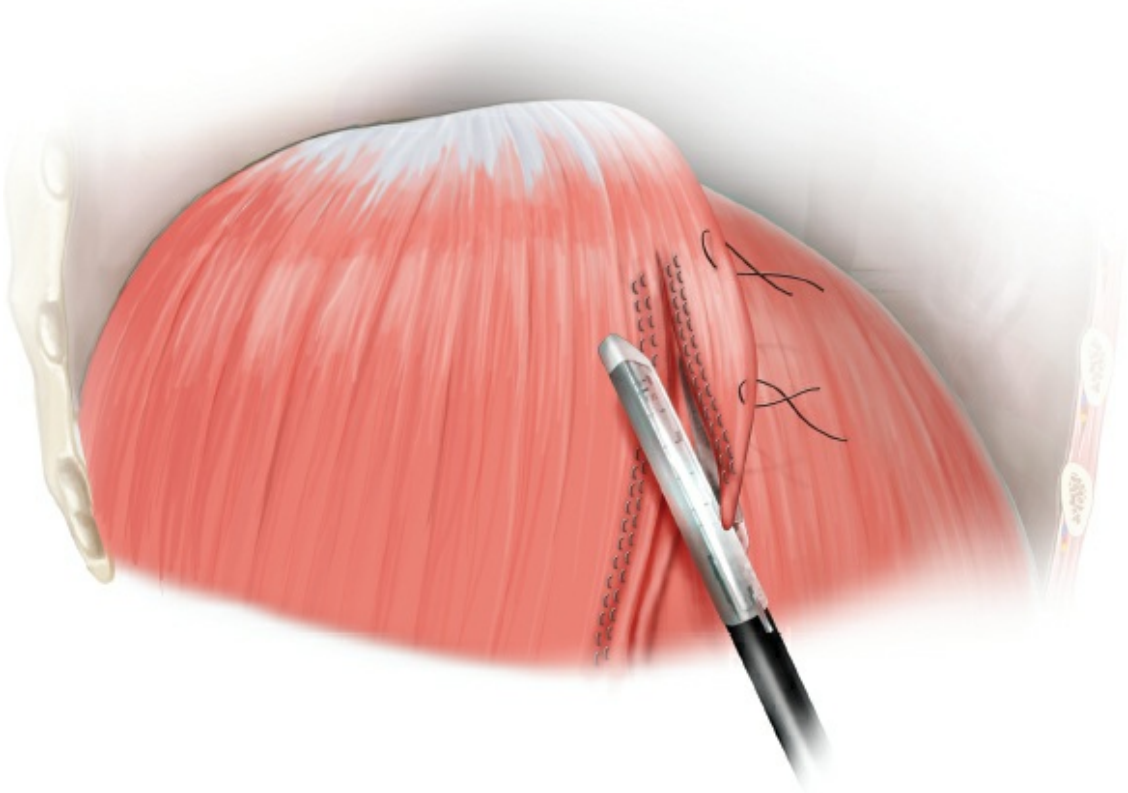

Figure 65.10. Use of an endostapler to simultaneously reapproximate and resect the redundant diaphragm.

Modifications of the laparoscopic technique have included robotic technology in adults and the use of a mesh or patch to augment repair. Tissue engineering to provide special biologic meshes to reinforce the plication repair are also undergoing early investigation.

Comparison of Laparoscopic and Thoracoscopic Plication

Two recent retrospective reviews directly compared laparoscopic and thoracoscopic plication. In a study by Miyano et al., 20 pediatric patients underwent operative repair: 13 in the laparoscopic group and 7 in the thoracoscopic group. Each technique had similar mean operating time, mean duration of postoperative ventilation, and mean time to resume feeding. The thoracoscopic group had one conversion to open procedure

with no major complications reported in either group. Mean intraoperative end-tidal CO_2 was higher in the laparoscopic group. Most notably, there were six cases of recurrence and all of these occurred in the laparoscopic cohort. In a study by Hu et al., 27 pediatric patients underwent plication with all left-sided eventrations repaired laparoscopically, and all right repaired via the thoracoscopic approach. No conversions were required in either group and there was no morbidity or mortality reported.

Two separate studies, Cao et al. and Fujisharo et al., evaluated the laparoscopic and thoracoscopic approach specifically in patients requiring plication after congenital heart surgery. Eighteen patients were reported in the laparoscopic study while only five were reported in the thoracoscopic study. Open conversion was not required in either group and neither study reported any recurrence. With the laparoscopic approach, operative time ranged from 45 to 105 minutes while the thoracoscopic approach was longer ranging from 92 to 169 minutes. Several concerns with the thoracic approach exist including management of adhesions from cardiac interventions and respiratory instability due to the pre-existing congenital heart disease. The patients described in the thoracoscopic study maintained sufficient peripheral tissue oxygenation and although they had adhesions these were able to be dissected thoracoscopically; however, this may account for the longer operative time compared to that reported in the laparoscopic study.

The optimal minimally invasive approach has yet to be conclusively identified. Surgeon preference remains a major determinant but a variety of other factors should also be taken into account including right- or left-sided location, cardiovascular status, and previous or concomitant interventions. Further larger randomized trials are required before definitive superiority is established.

POSTOPERATIVE MANAGEMENT

Postoperatively, there is no contraindication to extubation in the operating room or to immediate initiation of a ventilator weaning protocol. A postoperative plain chest radiograph should be obtained once the patient is breathing spontaneously to document the position of the affected diaphragm. Antibiotics are discontinued within 24 hours and if a chest tube has been placed, it may be removed as soon as the output has decreased appropriately based on the size of the patient. There are no dietary restrictions and the patient discharged as soon as these milestones are met.

COMPLICATIONS

Complications from both open and minimally invasive procedures are uncommon. Care must be taken when placing the plication sutures not to damage structures on the other side of the diaphragm. Pneumonias, deep venous thrombosis, and cardiac events are possible in elderly patients. Pleural effusions can require drainage if the chest tube is removed prematurely and the patient becomes symptomatic. Pneumothorax requiring additional chest tube drainage has also been described.

The recurrence rate for DE is unclear since asymptomatic patients may not be identified. Historically, a recurrence rate of 10% to 15% in adults has been reported; however, recent studies report rates as low as 0%. For the pediatric population, the majority of recent studies report a recurrence rate of 0% with only a handful documenting a low number of recurrences.

CONCLUSION

Plication of DE is a safe and feasible treatment that improves respiratory function. There are a variety of techniques reported in the literature; however, the majority involve small case series or are underpowered. No randomized controlled trials identify a definitively superior method of repair. As the incidence of symptomatic eventration is low, surgeons should rely on the existing evidence to formulate an operative plan. Minimally invasive techniques have shown proven benefits in other arenas and in pediatric eventration retrospective studies. With current advancements in technology it is reasonable to predict that improvements in minimally invasive platforms will assist in the technical feasibility of these procedures. Choice between abdominal and thoracic approaches is not clearly defined and should be left to surgeon preference based on patient presentation and needs.

EDITOR'S COMMENT

Permanent elevation of the diaphragm, an eventration, is a pathologic condition

from which afflicted patients experience some degree of respiratory symptomatology; however, most do not require operative correction. The authors provide excellent overview of the condition. As they note, there are two primary causes of an eventration—congenital and phrenic nerve injury. For those patients who present with the congenital form, the etiology reflects a lack of appropriate diaphragmatic muscularis development resulting in an area of weakness. Although patients are born with the abnormality, they may not be diagnosed until respiratory symptoms are significant enough that an evaluation is begun.

In the infant population, differentiating an eventration from a congenital diaphragmatic hernia (CDH) with a hernia sac can be difficult. For both conditions, an afflicted infant will present with mild respiratory symptoms—often tachypnea—prompting a CXR. The majority of patients with a CDH will have loops of bowel that are visualized in the chest making the diagnosis obvious, but in a patient with a CDH that has a hernia sac, the diaphragm will be elevated and have an abnormal contour which mirrors the findings of an eventration, especially if it occurs on the right. Interestingly, patients with a CDH in which a hernia sac limits the egress of abdominal contents into the chest do not have the same degree of cardiopulmonary vasculature challenges as a patient with a CDH without hernia sac where pulmonary hypoplasia and pulmonary hypertension result in marked physiologic instability requiring diligent intensive care monitoring and often ECMO for stabilization and survival. Patients with a CDH that have a hernia sac, similar to a patient with an eventration, have limited respiratory symptoms and are quite stable. Often they are diagnosed incidentally or later in childhood after a CXR has been obtained for respiratory symptoms. Although we group CDH patients with and without a hernia sac under the same diagnosis, one wonders from a mechanistic process whether, given the marked difference in frequency of pulmonary hypertension, this should be the case. Perhaps, a CDH with a hernia sac and an eventration, even though the muscular defect arises in different parts of the diaphragm, are pathogenically more closely related.

A diaphragmatic eventration induced by traumatic injury to the phrenic nerve is a more readily understandable physiologic process. As the authors note, in infants, the most common cause of a phrenic nerve injury is traction occurring during a difficult delivery (shoulder dystocia with traction injury to C3–C5 nerve roots) resulting in a partial or a permanent phrenic nerve injury. In contrast, injury during congenital heart surgery, typically attributed to ice on the phrenic nerve, is another common cause that in theory should be a transient process that resolves. Pediatric surgeons will be consulted to address both of these etiologies, and if the patient is encountering significant respiratory challenges (failure to extubate, recurrent pneumonias, or persistent tachypnea) surgical intervention is warranted. Eventration diagnosed in an older patient is typically due to a pathologic process encompassing the phrenic nerve and should be investigated as such. Neurodegenerative disorders, infection,

malignancy, and autoimmune disease in the upper mediastinum are potential causes, and due diligence investigation for such possibilities should be completed.

As the authors note, the diagnostic evaluation of a patient with eventration is dependent primarily upon a dynamic study of the diaphragm. A series of options are available, including ultrasound and MRI; however, a simple fluoroscopic sniff test is what we recommend. In an infant and young child, performing a sniff test can be difficult, as their ability to comply with "sniffing" may be limited.

From a clinical standpoint, eventration-induced symptoms are related to pulmonary mechanics. Because the diaphragm does not contract properly, full lung expansion during inspiration may be reduced. In children, symptoms may be more significant as the mechanics of breathing are still in evolution. Additionally, a smaller thoracic cavity in theory could inhibit lung growth—although the mechanistic basis for this inhibition has not been defined. In older patients, the ability to compensate reduces the frequency of respiratory compromise. As the authors note, the indications to address eventration are limited to those patients who encounter significant respiratory challenges. Many patients can be supported with either minimal respiratory support (i.e., nasal CPAP) or postural positioning. Repair is indicated more frequently in the pediatric population, as the respiratory mechanics of a child is more dependent upon full diaphragm excursion.

The authors nicely summarize the treatment options to address diaphragmatic eventration. How to appropriately address an eventration falls into the two alternatives—a resection of the lax diaphragm with primary closure of the resected defect or diaphragmatic plication. Although the evidence in favor of either approach has not been analyzed in a prospective randomized fashion, the ease by which plication can be performed and the minimal morbidity of that approach has resulted in more surgical interest towards that alternative than diaphragmatic resection.

As in all of general surgery, minimally invasive approaches to repair an eventration have been developed and embraced—in the case of eventration this is justified. Both thoracoscopic and laparoscopic approaches have been described with the authors reviewing several recent studies where it has been shown that the thoracoscopic approach is more durable than the laparoscopic approach. This is understandable as with the thoracoscopic approach (which also applies to an open approach should that be considered), there is better visualization of the entire diaphragm and also allows maximal flattening of the diaphragm, which assists in the placement of plication sutures to maximize effect. We use the combination of CO_2 insufflation (pressures of 5 mm Hg) and single lung ventilation, as this has been shown to be helpful (Fujishiro J, Ishimaru T, Sugiyama M, et al. Thoracoscopic plication for diaphragmatic eventration after surgery for congenital heart disease in children. *J Laparoendosc Adv Surg Tech A* 2015;25(4):348–51). A novel, simple

thoracoscopic plication technique was recently reported, in which through a 3-mm camera port, a 3-mm instrument incision without a port, and an 18-gauge spinal needle, the procedure could be achieved (Snyder CW, Walford NE, Danielson PD, et al. A simple thoracoscopic plication technique for diaphragmatic eventration in neonates and infants: technical details and initial results. *Ped Surg Int* 2014;30(10):1013–6). The spinal needle is passed into the chest, and the excess diaphragm is plicated over the needle, after which a nonabsorbable suture is passed through the needle and tied extracorporeally. The needle is passed repeatedly until the desired degree of tension is achieved. Should resection of the diaphragm be chosen, great care must be taken not to further damage what residual phrenic nerve branches are available which would then further alter functional aspects of the diaphragm.

Diaphragmatic eventration is a condition that infrequently will require surgical repair; however, should it be necessary, the morbidity rates following such intervention should be minimal. It seems likely that open approaches will be abandoned as minimally invasive approaches become the primary route used to address this issue.

66 Traumatic Injury to the Diaphragm

H. Leon Pachter, Chad T. Wilson, and Spiros G. Frangos

ANATOMY

The primary muscle responsible for breathing is the diaphragm, a musculoaponeurotic barrier that separates the thoracic and abdominal cavities. Muscle fibers originate higher anteriorly from the sternum's xiphoid process. Their origins laterally and posteriorly are more inferior, arising from the costal cartilages and osseous portions of the lower ribs and the lumbar vertebral bodies and their intervertebral discs (Fig. 66.1). These fibers all insert into the diaphragm's aponeurotic portion known as the central tendon. The right dome is naturally 2 cm higher than the left owing to the mass effect of the underlying liver.

Three major orifices—the caval, esophageal, and aortic—allow for the passage of major structures (Fig. 66.1). Located at the T-8 level, the aponeurotic caval opening allows the inferior vena cava and often the right phrenic nerve to traverse body cavities. The diaphragm's lumbar origin includes left and right crural fibers, which form the boundaries of the esophageal and aortic hiatus. The esophagus and the vagus nerves traverse the esophageal hiatus—a gap between the right crural fibers—at the T-10 level. The aortic hiatus, which is formed by the fibers of the left and the right crura, is located at the T-12 level and allows for passage of the aorta, thoracic duct, and variably the azygos and the hemiazygos veins.

The diaphragm's blood supply comes from inferior and superior phrenic arteries that arise directly from the thoracoabdominal aorta. Superior epigastric and intercostal arteries provide blood to the muscle's costal margins. Venous drainage is through phrenic veins directly into the inferior vena cava. The motor nerve supply of the diaphragm is through left and right phrenic nerves. The left phrenic nerve passes through the muscular diaphragm more anteriorly than the right phrenic nerve, which passes through the aponeurotic central tendon through or in close proximity to the caval opening. The two main trunks typically divide into three main branches: anterior, anterolateral, and posterior.

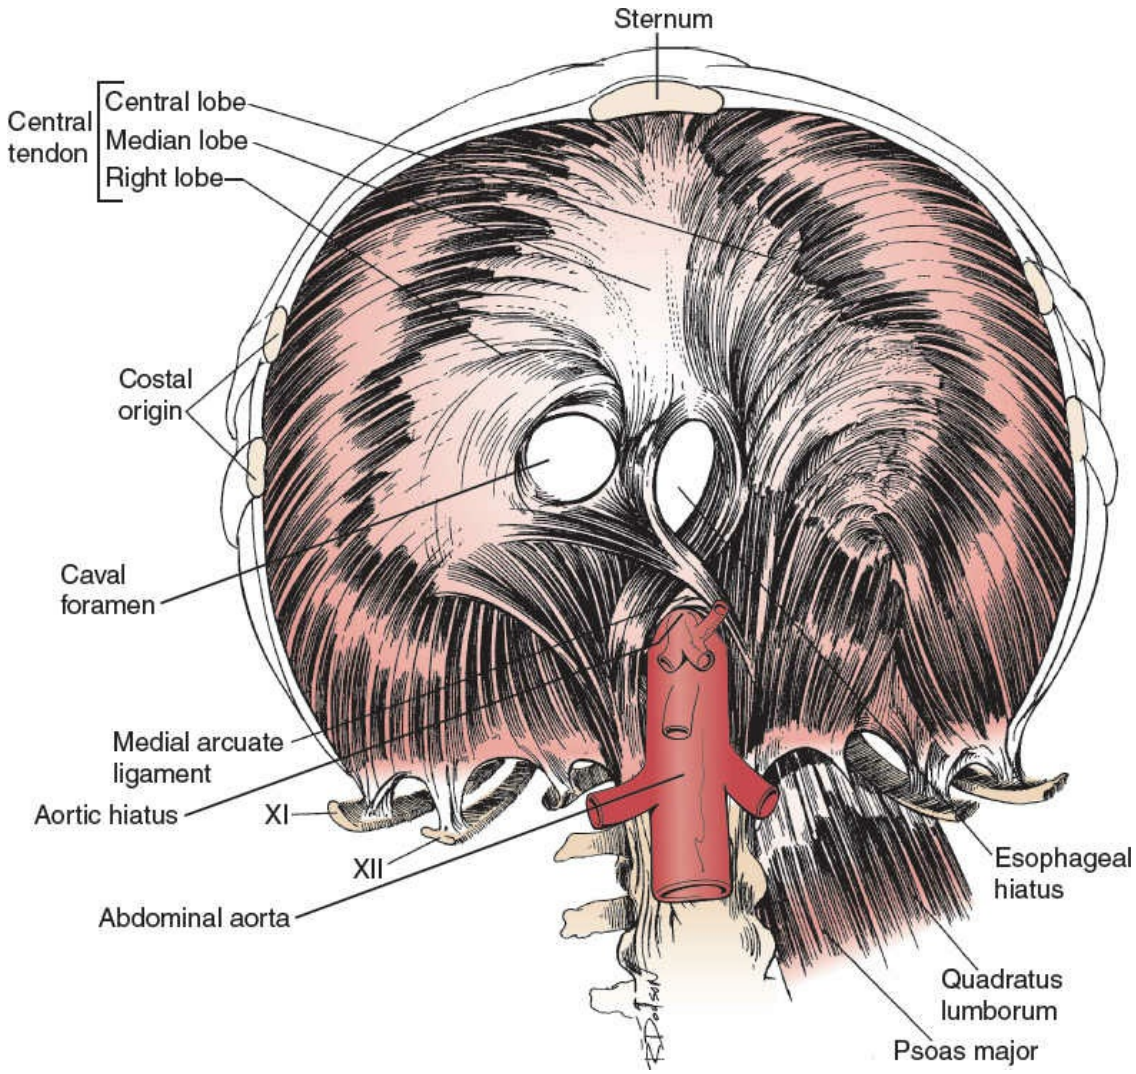

Figure 66.1. Anatomy of the diaphragm; view from below.

An understanding of diaphragmatic anatomy by surgeons who care for trauma patients is important to avoid missed injuries. In addition, the variable topography of the muscle—especially when assessing for trajectory in penetrating trauma—must be recognized. A patient's positioning (e.g., supine vs. erect) and phase and depth of ventilation affect the location of the left and right diaphragmatic domes, which can vary by as much as 10 cm. Each individual's natural build and pulmonary pathophysiology (e.g., chronic obstructive pulmonary disease) play a role in the muscle's topography, as may associated injuries (e.g., a liver hematoma that pushes the diaphragm superiorly). Furthermore, a firm grasp of diaphragmatic anatomy is important in minimizing iatrogenic phrenic nerve injury during operative repair.

ETIOLOGY AND PATHOPHYSIOLOGY

Large studies from the United States suggest that four out of five patients who sustain a diaphragm injury are men, and the mechanism of injury is penetrating two to three times as often as it is blunt. These findings vary among populations as a result of geographic and sociocultural factors.

Left hemidiaphragm injuries are diagnosed more commonly than right in blunt trauma, likely as a result of the force-distribution protection afforded by the extensive solid parenchymal mass of the liver. Penetrating injuries show less left-right bias, although it is plausible that the liver may afford a mild amount of anatomic barrier protection. The fact that right-sided injuries may be less aggressively pursued diagnostically given a lower likelihood of untoward sequelae (e.g., hernia) if missed certainly contributes to a diagnostic bias in comparing injury rates. Bilateral dome injury is uncommon regardless of mechanism as is herniation into the mediastinum. The American Association for the Surgery of Trauma (AAST) organ injury scale for the diaphragm is depicted in Table 66.1.

TABLE 66.1 AAST Organ Injury Scale—Diaphragm[a]

Grade	Injury Description
I	Contusion
II	Laceration ≤2 cm
III	Laceration between 2 and 10 cm
IV	Laceration >10 cm with tissue loss ≤25 cm^2
V	Laceration with tissue loss >25 cm^2

[a]Advance one grade for bilateral injuries up to Grade III.

CLINICAL PRESENTATION

The diaphragm is uncommonly injured in an isolated fashion. Diaphragmatic injury resulting from blunt trauma usually accompanies injury to local structures, including ribs, lung, and abdominal solid viscera, especially the liver and the spleen. Pelvic or long-bone fractures and traumatic brain injury are frequently seen concurrently in these patients, a

predictable association given the significant energy required to rupture a hemidiaphragm. Penetrating injury to the diaphragm is also usually accompanied by injuries to one or more nearby viscera, including the lungs, the liver, the stomach, the spleen, the kidneys, and the colon. Projectiles lead to a greater number of local visceral injuries than do stab wounds. A high index of suspicion for diaphragmatic injury is critical following penetrating thoracoabdominal or high-velocity deceleration mechanisms.

Penetrating Trauma

When evaluating for the possibility of a diaphragmatic injury, the location of the wound is important and can be readily inspected in the emergency department. It is however the trajectory of the foreign body relative to the diaphragm, which is more significant; unfortunately this is much more difficult to ascertain by history and physical examination. Penetrating injuries between the nipples and the lower costal margin place the diaphragm at risk for injury. Anterior and lateral thoracoabdominal penetrating injuries are more likely to lacerate the diaphragm than are those to the back along the same axial plane. Injuries to the diaphragm as a result of penetrating trauma are generally short (1 to 3 cm) lacerations without acute herniation. These patients rarely have any symptoms resulting from the diaphragm injury alone.

The incidence of diaphragmatic injury secondary to penetrating thoracoabdominal trauma is not well-delineated due to variability in the denominator data (i.e., the study population has occult injuries of uncertain clinical significance that may not be detected). Inclusion and exclusion criteria, including anatomical boundaries and indications for imaging studies or operative exploration, are inconsistent between studies.

Although penetrating injury to the diaphragm is more common than blunt, the diagnostic challenges of these smaller injuries are problematic and their natural history is unclear. This leaves clinicians with two vital questions: What is the incidence of occult, and therefore unrepaired, diaphragmatic injuries, *and* what percentage of these untreated patients go on to sustain complications (i.e., abdominal visceral herniation)? Lacking evidence-based answers to these questions, the optimal management of potential injuries is often left to a surgeon’s own experience and judgment.

Blunt Trauma

When considering blunt diaphragmatic injury, a thorough assessment of the severity of the event must be made as the potential for an injury is entirely related to mechanism. Injury frequently occurs as a result of significant deceleration mechanism or truncal impact, contributing to a rapid and abrupt increase in intra-abdominal pressure. For a victim of a motor vehicle collision, the approximate velocity of the incident must be considered because high delta-*v* (i.e., significant change in velocity) decelerations are more likely to lead to rupture of a hemidiaphragm. Occupant compartment intrusion and seat belt use may also play a role. For a victim of a fall, it is important to ascertain the height and the surface of impact to estimate the deceleration forces.

Injuries to the diaphragm as a result of blunt trauma are larger (i.e., usually longer than 5 cm) than penetrating lacerations and are commonly associated with acute herniation. These patients may have symptoms associated with the diaphragm injury, including shortness of breath or respiratory distress, especially with larger defects involving significant herniation. However, in light of the multi-organ system trauma (e.g., brain injury) frequently sustained by these critical patients, which may require therapeutic prioritizing, a delay in diagnosis or treatment of a diaphragm injury may be unpreventable. Because pulmonary symptoms associated with a blunt force diaphragmatic injury are nonspecific, a high index of suspicion is required.

Chronic Diaphragmatic Hernia

Patients with missed or untreated diaphragmatic injuries often present in a delayed fashion with symptoms related to intestinal herniation or strangulation. Over time, small diaphragmatic holes can increase in size as a result of the constant activity of the muscle, and the pressure gradient between pleural and peritoneal cavities can draw intraperitoneal organs into the chest. Presentations vary from mild nausea and vomiting due to intermittent bowel obstructions to pain from incarceration and ischemia to septic shock from strangulated, necrotic, or perforated viscus. Undoubtedly, the consequences of an untreated diaphragm injury can be devastating.

DIAGNOSIS

The diagnosis of diaphragmatic injury in a patient who does not otherwise warrant immediate thoracic or abdominal surgical intervention can be

challenging. Generally, the ability to make an accurate diagnosis outside an operating room (OR) relates to the size of the defect.

Physical Examination

The physical examination is unreliable for diagnosing diaphragmatic injury following blunt or penetrating trauma. There are no highly sensitive signs to detect an underlying injury. Following penetrating injuries, the trajectory of the knife or bullet is more important than the actual location of the skin wound, but trajectory is usually difficult to elicit accurately. Probing a thoracoabdominal wound, especially one overlying the ribcage, is generally discouraged for fear of creating or exacerbating a pneumothorax or intercostal bleeding. The careful insertion of a cotton applicator superficially by an experienced surgeon may however provide some indication of trajectory, and there are instances—e.g., in obese patients, for wounds to the back, for subcutaneous tangential tracts—where this maneuver, when applied cautiously, may be useful information in determining the probability of a deep visceral injury.

The physical examination lacks sensitive or specific signs of a diaphragm injury following blunt trauma as well. However, there are certain signs that are suggestive of injury, including unilateral decreased breath sounds, bowel sounds in the chest, and respiratory distress. Obviously, these are nonspecific findings, but their presence should not be discounted in assessing for diaphragm injury. The multiple associated injuries commonly found in patients with ruptured diaphragms may delay the diagnosis from being made prior to imaging studies.

Imaging

A chest radiograph is commonly performed but rarely diagnostic. This is especially true for penetrating trauma where diaphragm injuries are small and plain films are seldom helpful. A chest x-ray more commonly contributes to the diagnosis following a blunt mechanism and in these circumstances may appear dramatic. Examples of such radiographic evidence include air or an air–fluid level within a hollow viscus overlying the thorax or with the additional “classic” finding of the coiling supradiaphragmatic nasogastric tube. Suggestive findings include abnormality in the contour, shape, or position (e.g., elevation) of the hemidiaphragm, pleural effusion or atelectasis, and mediastinal shift. The chances of seeing these signs may be reduced in patients on positive

pressure ventilation as the contour of the lower lobes of the lungs, when expanded under pressure, mimics that of the intact diaphragm.

Contrast studies that were commonly ordered in the past are now infrequently performed in the acute setting. Most of these techniques rely on gastrointestinal herniation for diagnosis, which is especially rare in the acute period following penetrating trauma. They do still have a role in the evaluation of the patient with a chronic hernia. Diagnostic peritoneal lavage is an inadequate modality for diagnosing diaphragmatic trauma and should not be used for this indication. The detection of red cells, white cells, or bowel contents lacks any specificity and is simply unreliable in the work-up of the diaphragm. A focused assessment with sonography in trauma (FAST) scan is of limited sensitivity in diagnosing diaphragm injury; however, the presence of peritoneal fluid (especially in the concurrent setting of hemothorax or pleural fluid) can suggest diaphragm injury, in particular for penetrating mechanisms However, sonographic features of injury lack specificity and are generally visible with larger lesions.

With its greater sensitivity and specificity, computed tomography (CT) scan has replaced contrast studies. Suggestive findings using this modality include discontinuity of the diaphragm or a wound tract extending up to a hemidiaphragm, while conclusive evidence includes intrapleural abdominal contents. CT has a greater sensitivity for blunt trauma, where injuries tend to be larger, and is less helpful following penetrating mechanisms, where diaphragmatic defects are small and acute herniation rare. Penetrating diaphragm injuries also present a distinct spectrum of radiographic findings from those in blunt trauma with contiguous injury and transdiaphragmatic trajectory acting as best predictors. Diaphragmatic discontinuity, thickening, elevation, or segmental nonrecognition and intrathoracic herniation of abdominal viscera are strong predictors of blunt diaphragmatic rupture. CT scan is far from perfect and certainly may miss a small injury; therefore, a high index of suspicion is required. Advances in imaging technology including 64–slice multidetector CT with reformatted sagittal and coronal images have improved sensitivity further. Older studies suggesting a lower diagnostic accuracy for penetrating injury to the diaphragm are no longer applicable, and CT with multiplanar reformations currently represents the screening imaging modality of choice for diaphragmatic injury. Table 66.2 depicts CT findings associated with diaphragmatic injuries.

Magnetic resonance imaging (MRI) has superior soft tissue resolution compared to CT. However, it currently has a limited role in the acute trauma setting as it is more time-consuming and costly to perform. MRI is absolutely contraindicated in hemodynamically unstable patients.

Surgery

When multidetector CT scan is equivocal for diaphragmatic injury, especially following thoracoabdominal penetrating trauma, further investigation is warranted. Surgery remains the gold standard for diagnosing an injury to the diaphragm, although controversy exists regarding exactly which hemodynamically stable patients who have sustained thoracoabdominal trauma require operative evaluation.

Diagnostic laparoscopy is an excellent modality for evaluating the diaphragm and is the procedure of choice for assessing the diaphragm in patients who lack a clear indication for laparotomy. Although laparoscopy alone is sufficient to rule out a diaphragm injury, it is unclear which patients should undergo the procedure. Available data suggest that almost two thirds of diagnostic laparoscopies in stable patients with penetrating thoracoabdominal trauma will fail to reveal diaphragmatic injury. Exploring all patients would cause a great number to undergo negative explorations with their associated risks and cost. At present, there is no clear consensus as to what an acceptable percentage rate of negative laparoscopy should be in regards to diaphragmatic injury screening. In addition, the clinical significance of small diaphragm injuries is unknown and the diagnosis of a small injury may not have substantial merit. Despite this uncertainty regarding indications, laparoscopy is a reliable way to make the diagnosis when diaphragm injury exists, and for this reason has grown in popularity in the recent years.

TABLE 66.2 CT Findings Associated with Diaphragmatic Injuries

Finding	Sensitivity/Specificity in Blunt Mechanism	Sensitivity/Specificity Penetrating Mechanism
Herniation of abdominal viscera into the chest	75/99%	17/97%
Diaphragm discontinuity	50/95%	40/90%
Segmental nonrecognition of diaphragm	44/91%	–
Thickening of the diaphragm (curled diaphragm sign)	56/95%	48/70%
Elevated intra-abdominal organs	56/99%	–
Thoracic fluid abutting intra-abdominal viscera	31/100%	–
"Collar" sign[a]	62/100%	4/100%
Dependent viscera sign[b]	56/100%	0/100%
Hemothorax *and* hemoperitoneum/contiguous injury[c]	50%/95%	88/82%

[a]A waist-like appearance of herniated organs at the level of the diaphragm.
[b]Absence of interposition of lungs between the upper part of the abdominal organs and the chest wall.
[c]In penetrating, trauma contiguous injury can be blood above and below diaphragm or other findings like pneumoperitoneum below diaphragm and concurrent pneumothorax, or bullet cavitation that crosses diaphragm plane.
Data from Bodanapally UK, Shanmuganathan K, Mirvis SE. et al. MDCT diagnosis of penetrating diaphragm injury. *Eur Radiol* 2009;19:1875–81; and Nchimi A, Szapiro D, Ghaye B. et al. Helical CT of blunt diaphragmatic rupture. *AJR* 2005;184:24–30.

Laparoscopy, however, is not only excellent in its diagnostic accuracy, but it also carries a simultaneous therapeutic advantage in that an injury may be repaired. Laparoscopy provides excellent visual access as well as access for repair in areas that can be hard to see and reach through standard laparotomy. The surgeon must be cautious about introducing air into the pleural cavity during peritoneal insufflation and thereby creating a tension pneumothorax. For this reason, it is imperative to monitor airway pressures, oxygen saturation, end tidal CO_2, and mean arterial pressure as pneumoperitoneum is introduced. Insufflation pressures should not exceed 10–12 mm Hg until the abdominal surface of the diaphragm is evaluated and deemed free of injury. In draping such a patient for laparoscopy, the chest should be prepped in case a thoracostomy tube needs to be inserted if not already present at the time of laparoscopy. With a strategy of low pressure pneumoperitoneum, careful attention to ventilatory parameters, and early diaphragmatic inspection, an iatrogenic tension pneumothorax may be considered a rare event. Laparoscopy should not be used in hemodynamically unstable patients.

Higher level evidence and the development of protocols are necessary

to help delineate which patients would benefit most from screening laparoscopy for suspected diaphragmatic injury. What is clear, however, is that the use of laparoscopy significantly decreases nontherapeutic laparotomy rates and associated costs.

Akin to laparoscopy, thoracoscopy may be used for the diagnosis of diaphragmatic injury and is an exceedingly sensitive modality. Repair of the diaphragm through the chest can be accomplished without concern for creating a tension pneumothorax. However, because the diaphragm rarely gets injured in isolation, an intraperitoneal approach may be preferred in patients who would benefit from operative assessment for intra-abdominal injuries. Whereas the majority of pleural cavity injuries may be safely managed with a thoracostomy tube, a perforated intra-abdominal hollow viscus or hemorrhage emanating from a solid viscus injury requires a timely diagnosis and expeditious surgical intervention.

Prior to scoping techniques, diaphragmatic injuries were most commonly detected at laparotomy. This remains the current mode of diagnosis in patients who require immediate abdominal exploration for hemodynamic instability or peritonitis. In patients who are acutely hemorrhaging from a chest injury with an indication for thoracotomy, an injured diaphragm may be detected and addressed from the chest as well. Concomitant abdominal injuries may be ruled out via an additional abdominal procedure or, in rare selective cases, by a transdiaphragmatic approach to the upper abdomen.

In patients with chronic diaphragmatic hernias related to trauma, a proper history and physical examination may be suggestive. These missed injuries often present with alimentary tract obstruction, incarceration, or strangulation. They are almost always found on the left and the diagnosis can usually be made with plain radiography, although CT scan is frequently used to better delineate size, location, and visceral involvement.

TREATMENT

The treatment for an injured diaphragm is operative whether an injury is acute or chronic.

Regardless of mechanism, acute injuries can usually be repaired primarily. This is especially true for penetrating injuries, which are much smaller. Larger defects secondary to acute blunt mechanisms appear to be more common on the left and are generally amenable to primary suture reapproximation. Complex repairs including use of mesh are uncommonly

required in the acute setting. Rarely, a hemidiaphragm may avulse from the chest wall and may be reattached with nonabsorbable sutures.

Repair may be achieved via laparoscopy/laparotomy or via thoracoscopy/thoracotomy depending on a patient's hemodynamic stability and associated injuries and a surgeon's experience with minimally invasive techniques. Laparoscopic techniques continue to gain traction for definitive exploration and repair, especially for penetrating acute diaphragmatic lesions with fewer associated injuries. Conversion to laparotomy is frequently required when an acute blunt diaphragmatic rupture is diagnosed laparoscopically given the high likelihood of significant additional injuries. Laparotomy remains the most common operative approach for repair of both blunt and penetrating diaphragmatic injuries. Indications for thoracoscopic exploration remain undefined because intra-abdominal organs can rarely be adequately assessed operatively without an additional incision.

Surgery is indicated for chronic diaphragmatic hernias. Thoracotomy has a definite role in these patients since there is no concern for an associated intra-abdominal injury. In addition, reduction through the chest may be easier, as bowel adhered to lung can make for a tedious and difficult dissection trans-abdominally. A mesh repair is practically guaranteed for the treatment of a chronic hernia, where primary reapproximation of the diaphragm would likely involve tension and produce suboptimal results.

INDICATIONS AND CONTRAINDICATIONS

The indications for surgical intervention may be generalized rather simply: Most traumatic diaphragmatic hernias should be repaired. What is less clear and remains controversial is the natural history of the small peripheral diaphragmatic lesion or the right-sided defect abutting the dome of the liver. The actual percentage of these injuries that will go on to become clinically significant is unknown.

PREOPERATIVE PLANNING

Preoperative management in the acute setting involves the principles detailed in the Advanced Trauma Life Support course provided by the American College of Surgeons Committee on Trauma. The level of resuscitation, the adjunctive studies ordered, and the immediate treatments employed for these patients generally relate more to their associated

injuries than to any diaphragmatic lesion they may be harboring.

For chronic diaphragmatic hernias, a routine assessment for cardiac risk and medical clearance should be obtained as for any potentially involved elective surgical procedure.

SURGICAL TECHNIQUE

Laparoscopy

The patient is placed supine on the OR table. For penetrating trauma, if there is no evidence for a previously unrecognized significant hemorrhage, a thorough inspection of the diaphragm should be performed early. This is especially true for patients without a thoracostomy tube, as they may rapidly develop a tension pneumothorax from the CO_2 pneumoperitoneum. The upper abdominal viscera have to be retracted in a way that allows for the entire intraperitoneal diaphragmatic surface to be evaluated, which may be difficult especially posteriorly on the left. Positioning the OR table in reverse Trendelenburg with the right side down is indicated, as is the use of a 30-degree scope for improved inspection. If a nonperipheral injury to the diaphragm is found, a chest tube should be placed not only to prevent a potential tension pneumothorax but also because a lung injury cannot be excluded. The diagnosis may be suspected even prior to scope insertion with insufflation creating a symptomatic pneumothorax or causing a new large air leak in a patient with a previously inserted chest tube. If a lesion is detected, the Ligasure (trademark Covidien) laparoscopic instrument or the Harmonic Scalpel (trademark Ethicon) device may be used for the purposes of ensuring local hemostasis. Nonabsorbable sutures should be placed and tied either intra- or extracorporeally (Fig. 66.2). The specific type of primary repair has not been shown to matter. The Endostitch (trademark Covidien) device may be helpful especially in instances where intracorporeal tying may be a challenge.

An injured hemidiaphragm is usually more obvious following blunt trauma. An experienced laparoscopist may perform the repair and address associated injuries without necessarily converting to an open procedure in a hemodynamically stable patient. If the repair is deemed technically difficult or the exploration deemed suboptimal, converting to laparotomy is indicated. In addition, any instability should prompt consideration for conversion to laparotomy.

Laparotomy

The supine patient is prepped and draped as for any trauma laparotomy. Principles of operative trauma including packing, hemorrhage control, and minimization of contamination are followed. Diaphragmatic evaluation should be thorough, especially for penetrating trauma. On the left, the stomach and the spleen are retracted inferiorly and medially with gentle traction (Fig. 66.3). On the right, the round ligament can be clamped and ligated and the falciform incised so that the liver may be retracted for better visualization. Division of the right triangular and coronary ligaments will allow the surgeon to mobilize the liver inferiorly and medially to expose the undersurface of the right hemidiaphragm (Fig. 66.4). Herniation through an injured diaphragm is usually readily apparent and should be immediately reduced to prevent respiratory insufficiency. Since associated injuries are likely to divert attention from an injured diaphragm intraoperatively, it is important to maintain a high index of suspicion and to thoroughly evaluate the entire undersurface via inspection and/or palpation to prevent a missed lesion.

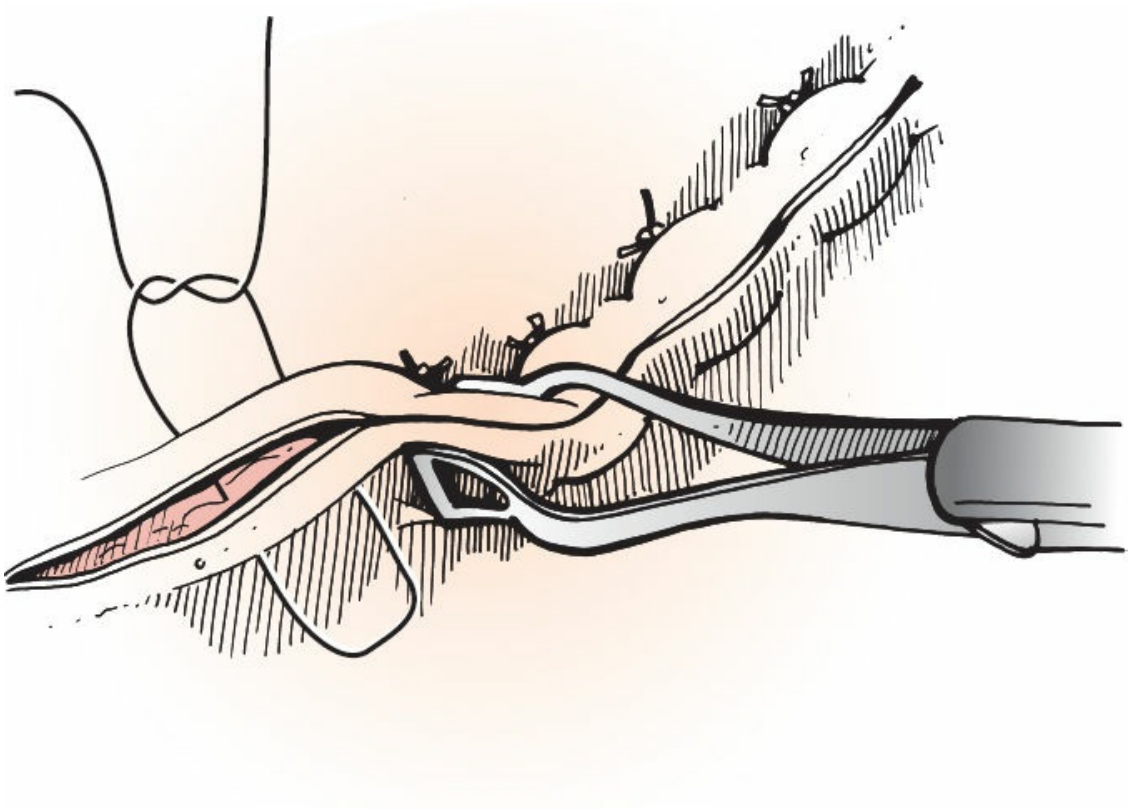

Figure 66.2. Repair of injured diaphragm using interrupted horizontal mattress sutures.

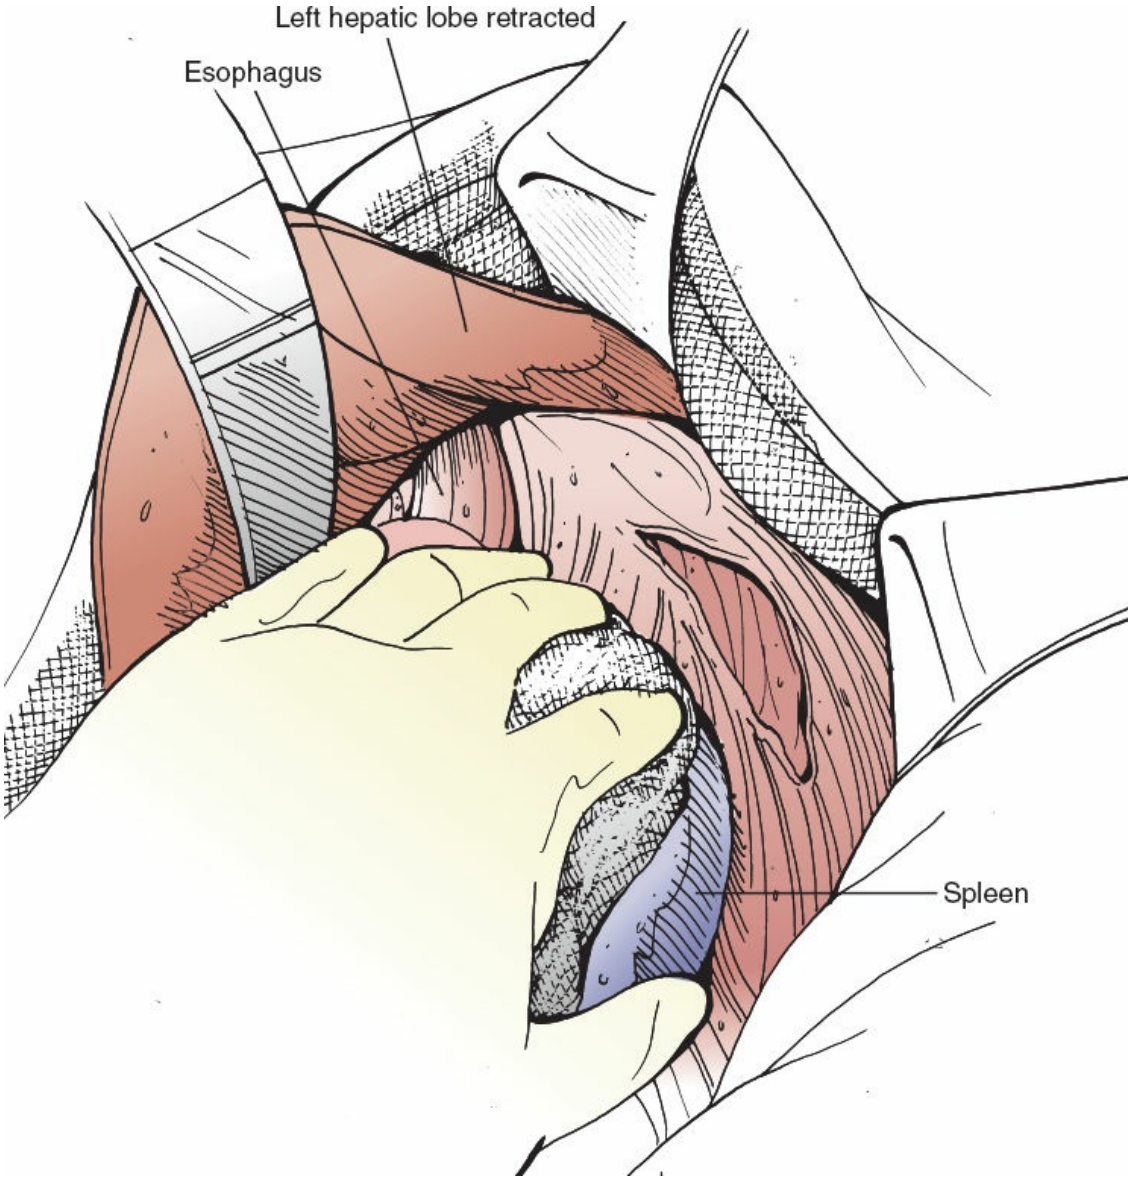

Figure 66.3. To inspect the left hemidiaphragm, the stomach and spleen are retracted inferiorly and medially with gentle traction.

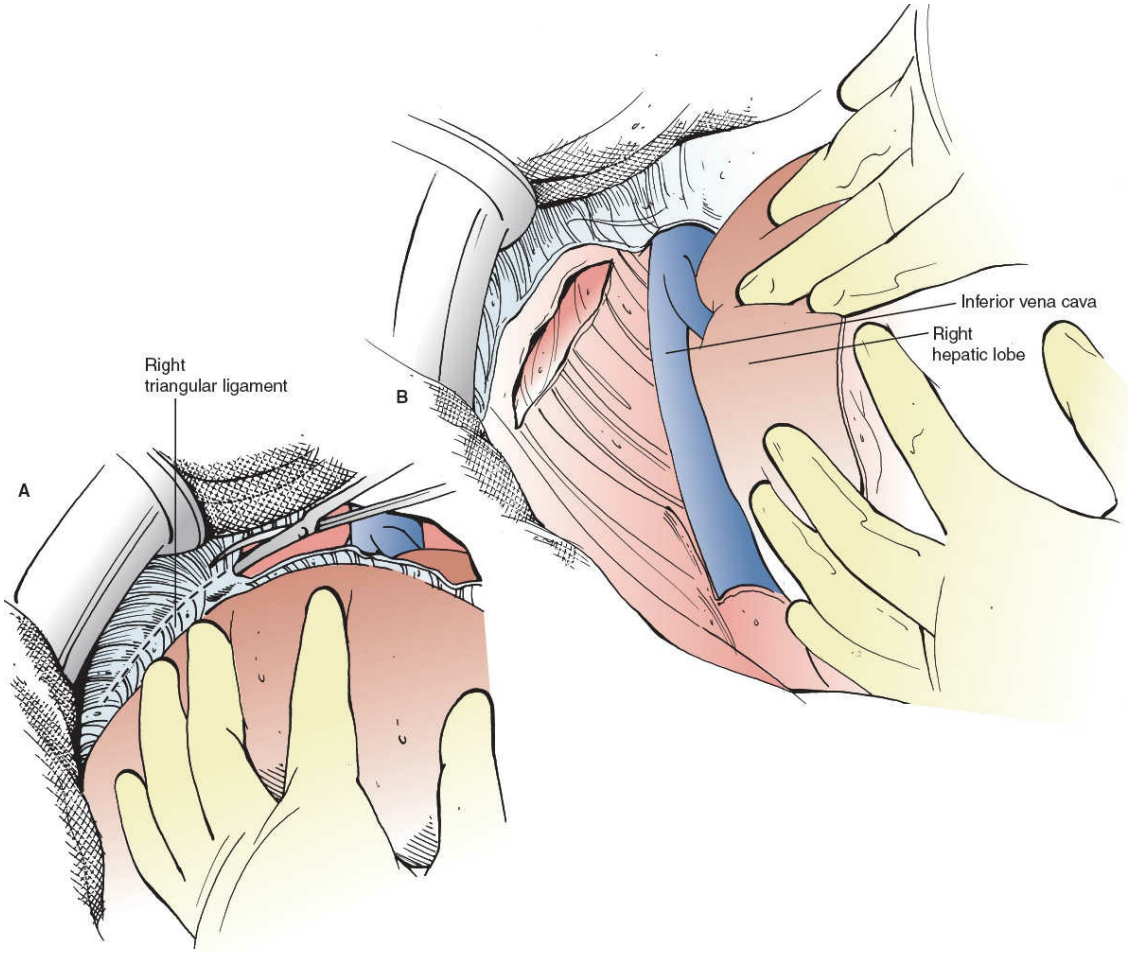

Figure 66.4. To expose the right hemidiaphragm, the right triangular and coronary ligaments are divided and the liver mobilized inferiorly and medially.

In acute trauma to the diaphragm (whether blunt or penetrating) where a lung injury cannot be ruled out, a chest tube should be placed. It may be efficacious to lavage the pleural cavity with saline if there is a concomitant full-thickness bowel injury to reduce the incidence of an empyema. When there is a large diaphragmatic defect, the ipsilateral lower lung lobe may be inspected for injury.

Repair of the injured diaphragm involves debridement of devitalized edges. This is especially important for firearm injuries, where inadequate debridement may play a role in the breakdown of the repair. Hemostasis is assured with bovie electrocautery or suture ligatures. The great majority of acute injuries may be managed with a primary repair. The type of repair—interrupted vs. running, one layer vs. two—has not been shown to matter in terms of recurrence. An interrupted suture repair may include a simple, figure of eight, or horizontal mattress technique (Fig. 66.5). Running

repairs (Fig. 66.6) are often performed in a simple, locked fashion by grasping the lacerated edges with an Allis or Babcock clamp. Zero or no. 1 nonabsorbable suture material (e.g., polypropylene) is preferred. Most surgeons repair the diaphragm in a single layer aiming for an airtight closure.

Prosthetic mesh patches (Goretex, Composix) and biologics (Strattice, Alloderm [registered LifeCell]) are preferred for large defects or for those where primary repair produces too much tension (Fig. 66.7). Interrupted polypropylene sutures should be used to sew in the patch. In the event of an accompanying bowel injury, a nonabsorbable mesh is contraindicated and instead a biologic acellular tissue matrix such as Alloderm or Strattice may be used. In the rare likelihood that the diaphragm has avulsed from the chest wall, it may be reattached in a primary fashion using polypropylene sutures placed circumferentially around the ribs (Fig. 66.8). Alternatively, bone suture anchors appropriately sized for rib thickness can also be used to secure the avulsed diaphragm to the chest wall.

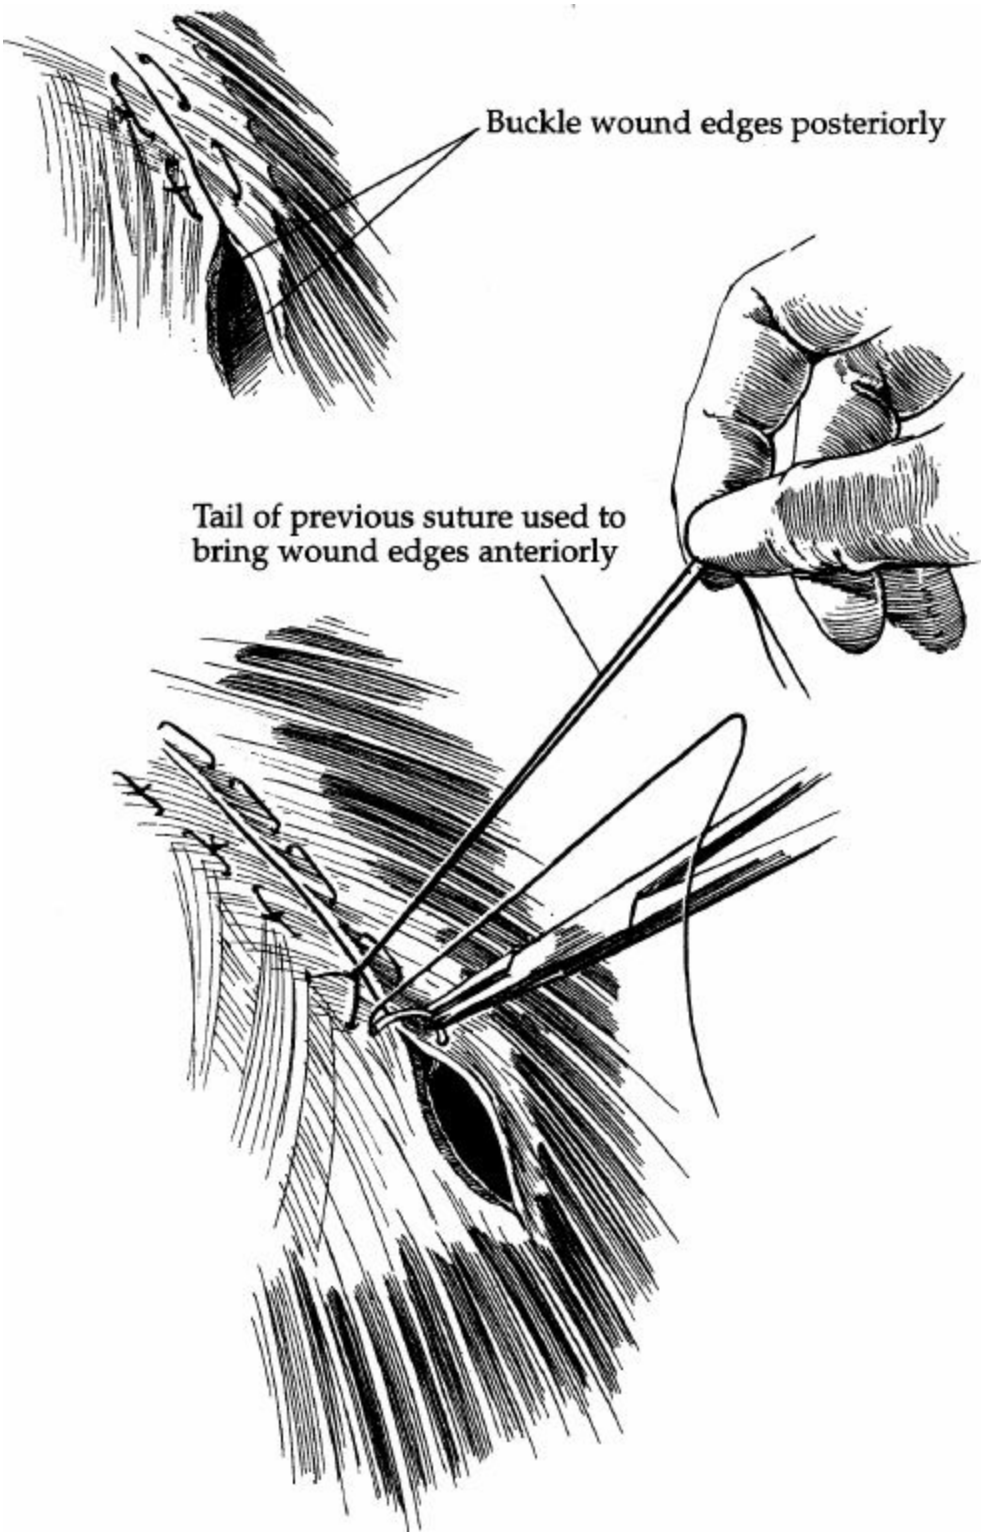

Figure 66.5. Use of the tail of the previously placed suture as a handle to improve exposure for repair of the posterior portion of the defect.

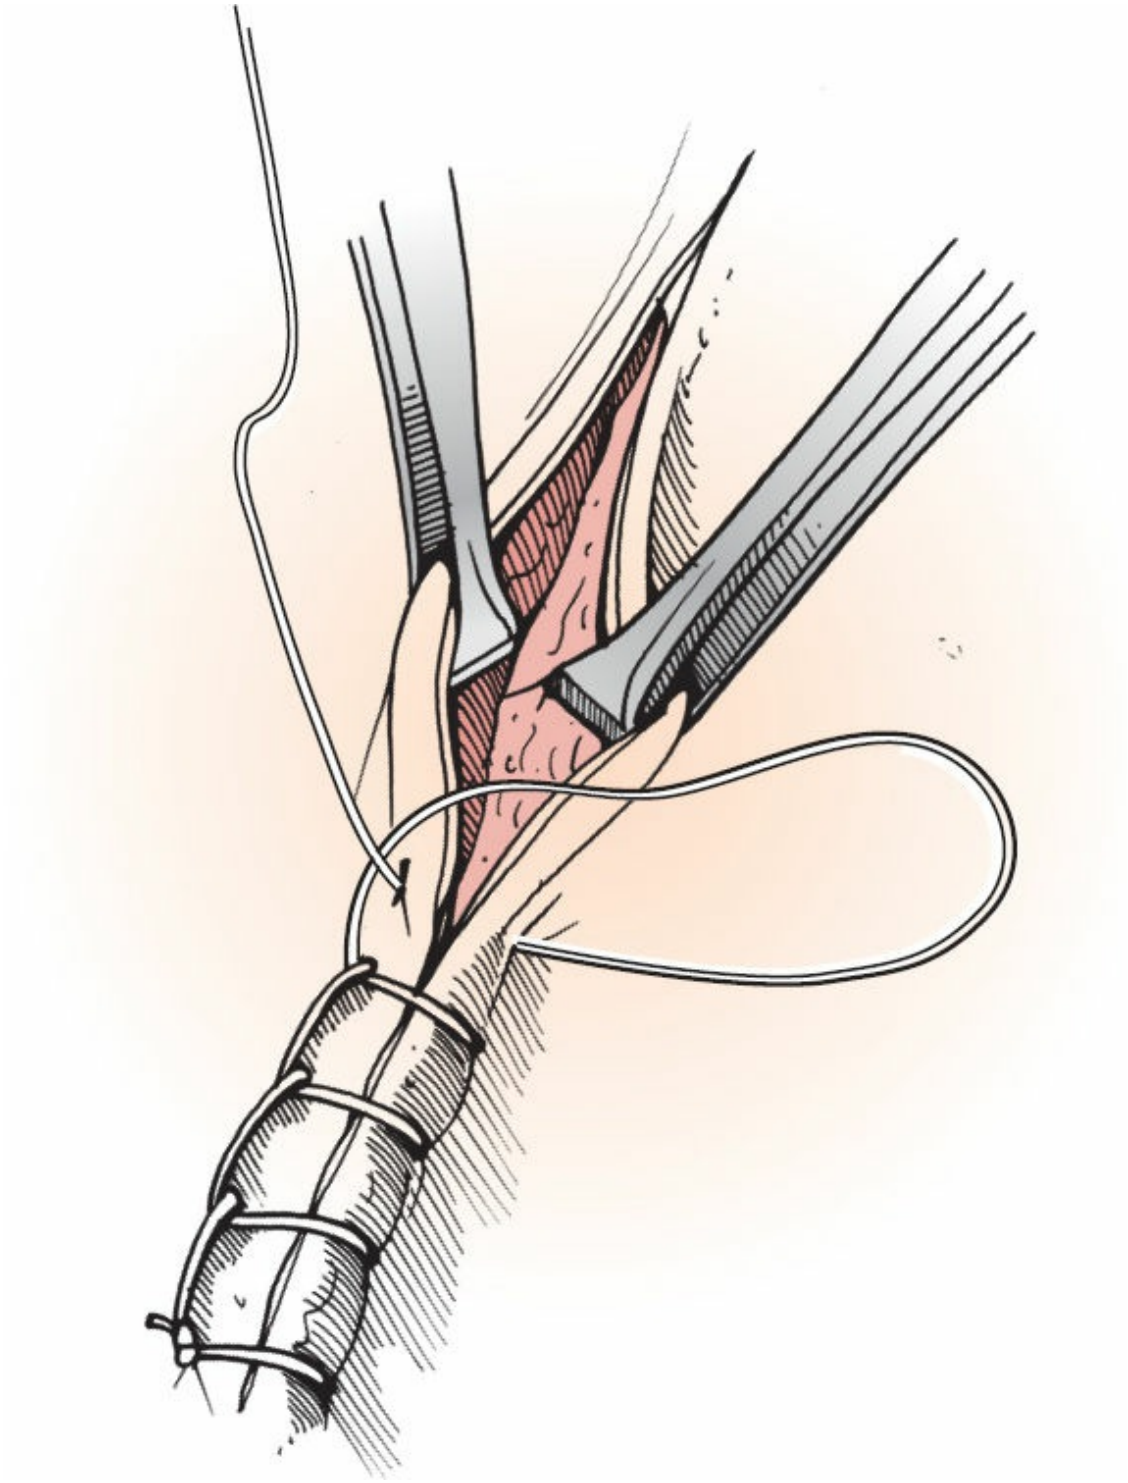

Figure 66.6. Allis clamps may be used to elevate the lacerated edges as a running locked suture is placed. The Allis clamps may be advanced as the edges are brought together.

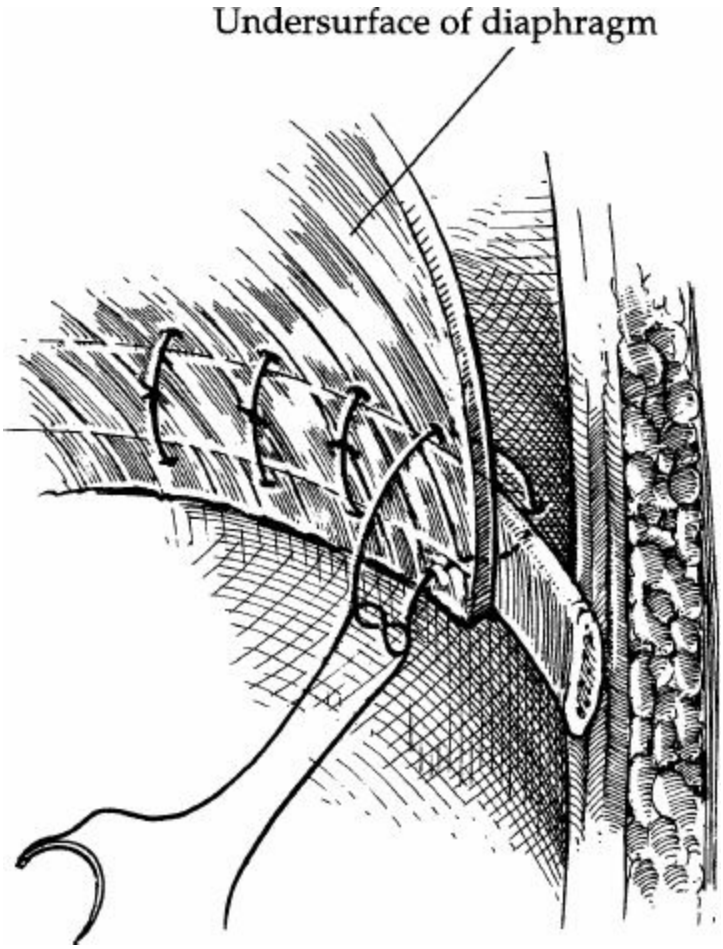

Figure 66.8. Reattachment of diaphragm avulsed from costal origin with interrupted mattress sutures placed around the rib.

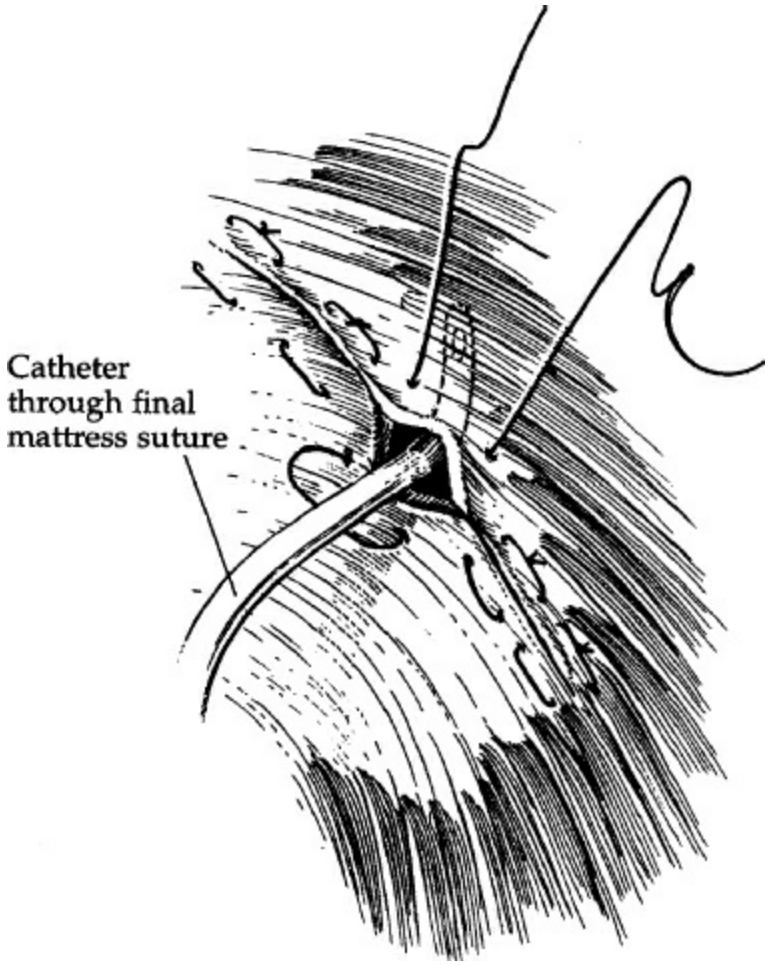

Figure 66.9. Aspiration of residual pneumothorax with a 24-French red rubber catheter. The catheter is extracted as the final suture is tied.

For chronic diaphragmatic herniation, a thoracotomy may provide better visualization for the difficult dissection. The diaphragm repair otherwise follows the same principles as in an acute injury scenario. Practically all of these repairs will require mesh since their long-standing nature has contributed to diaphragmatic scarring, which would make primary reapproximation difficult and create tension. As with any hernia, a tension-free repair is required to minimize recurrence. Following thoracotomy, a chest tube should be employed. If a laparotomy is performed, a red rubber catheter may be used to suction out air from the pleural cavity as the final stitches are tied to negate the need for a thoracostomy tube (Fig. 66.9).

POSTOPERATIVE CARE

Postoperative resuscitation is guided by monitoring vital signs and hourly urine output. Bedside physical examinations and common laboratory tests, including hemoglobin/hematocrit, bicarbonate, pH, base deficit, lactate, and coagulation parameters, can help ensure the adequacy of resuscitation. A postoperative plain radiograph of the chest is relatively routine after any diaphragm repair. The postsurgical management of patients with a diaphragmatic injury is generally influenced more by the accompanying injuries and their related management issues.

COMPLICATIONS AND THEIR MANAGEMENT

The morbidity and mortality of patients with diaphragmatic injuries are directly related to their associated injuries. Patients with diaphragmatic injury from blunt trauma, as opposed to penetrating trauma, have higher mean injury severity scores and an increased mortality rate, primarily as a result of injuries to other organs including the brain and pelvis. In comparison with left-sided injury, right diaphragmatic injury has been shown to be associated with higher rates of death. Overall mortality in patients with diaphragmatic injury approximates one in five.

Complications related to the diaphragm repair include a disruption of the repair, phrenic nerve injury, and peridiaphragmatic infection. Disruption of a repair is more common with large injuries or with those involving avulsion from the chest wall.

Left or right phrenic nerve injuries may be caused by the diaphragmatic rupture at the time of impact or may be iatrogenic as a result of the repair. Peripheral injuries and repairs are much less likely to cause damage to main branches of the phrenic nerves. Diaphragmatic injuries just lateral to the esophageal and caval openings carry a high risk for left and right nerve lesions respectively and must be repaired with the nerve distribution in mind to prevent an iatrogenic injury.

Subdiaphragmatic abscess and empyema are recognized postoperative infections and may be more common with associated hollow visceral injuries. These complications lengthen the duration of intensive care unit and hospital stay and increase morbidity and mortality. Pneumonia is also more common in patients with diaphragmatic rupture.

A missed or incompletely repaired right diaphragm injury when associated with a deep liver injury can lead to a biliopleural fistula. Although papillotomy and biliary stenting are often performed, they are

frequently unsuccessful as negative intrapleural pressures maintain the output of the fistula. These patients often require a thoracotomy for repair of the diaphragm and decortication of the lung.

A missed diaphragm injury with subsequent herniation may lead to severe sequelae. Often in a delayed fashion, these patients may present with symptoms of bowel obstruction, sepsis secondary to strangulation and necrosis, or pulmonary insufficiency. A missed injury may result in septic shock and death.

The repair of a chronic diaphragmatic hernia is more difficult than in the acute setting given the dense intrathoracic adhesions. Since the muscle edges have retracted and fibrosed with time and pressure from the sac contents, these repairs are much more involved, routinely require mesh, and not uncommonly result in complicated hospital courses.

SUMMARY

The diagnosis of traumatic diaphragmatic injury following both penetrating and blunt mechanisms may be difficult. CT with multiplanar reformations represents the screening imaging modality of choice, although diagnostic laparoscopy remains the gold standard for diagnosing an injury. In the hemodynamically stable patient, laparoscopy also allows for peritoneal exploration to assess for associated injuries and for simultaneous therapeutic interventions. Most diaphragm injuries should be repaired, although the aggressiveness with which small injuries, especially on the right, should be sought is controversial. The use of laparoscopy in stable patients is increasing and lowers nontherapeutic laparotomy rates and their associated costs, although laparotomy remains the most common operative approach for repair of diaphragmatic injuries. Acute injuries to the diaphragm should generally be approached through the abdomen, while a thoracic approach offers advantages for chronic injuries with herniation.

EDITOR'S COMMENT

Dr. Pachter and colleagues present a nice review article on an uncommon but serious complication of both blunt and penetrating trauma of the diaphragm. Traumatic diaphragmatic injury (TDI) is a rarely diagnosed injury in trauma. A recently published study utilizing the American College of Surgeons National Trauma Data Bank examined demographics, diagnoses, mechanism of injury, and outcomes for patients with TDI in 2012. There were a total of 833,309 encounters. A total of 3,873 patients had a TDI (0.46%). Of those, 1,240 (33%) patients had a blunt mechanism and 2,543 (67%) had a penetrating mechanism. Patients with blunt TDI were older (44 ± 19 vs. 31 ± 13 years, $P < 0.001$), had a higher injury severity score (33 ± 14 vs. 24 ± 15, $P < 0.001$), and a higher mortality rate (19.8% vs. 8.8%, $P < 0.001$). Compared with patients with penetrating injuries, those with blunt TDI were more likely to have injuries to the thoracic aorta (2.9% vs. 0.5%, $P < 0.001$), lung (48.7% vs. 28.1%, $P < 0.001$), bladder (5.9% vs. 0.7%, $P < 0.001$), and spleen (44.8% vs. 29.1%, $P < 0.001$). Penetrating TDI was associated with liver and hollow viscus injuries. In another study, a trauma registry from a Primary Adult Resource Center for Trauma was queried for patients admitted with a TDI from January 1995 to December 2009, a 15-year period. Most injuries were penetrating (73%) and left-sided (57%). The overall mortality rate in TDI was 21%.

TDI is more commonly diagnosed on the left. As the authors mention, this is likely related to an increased rate of diagnosis of injuries on the left, and potentially related to a protective effect of the liver on the right side. An interesting study of the natural history of right-sided diaphragm injuries in an animal model suggests that the majority of these injuries heal on their own without herniation. The fact that right-sided injuries may be less aggressively pursued diagnostically given a lower likelihood of untoward sequelae (e.g., hernia) if missed certainly contributes to a diagnostic bias in comparing injury rates. As the authors mention several times in this chapter, a high likelihood of suspicion for diaphragm injuries based on the mechanism of injury is warranted, even despite the fact that these injuries are relatively rare.

Having read this chapter, I am left with a few impressions. First of all, I am impressed that TDI is as rare as it is and by the degree of associated injuries observed, especially for blunt injuries. Second, I am surprised that in this day and age, detecting a traumatic diaphragm injury is so difficult without surgery unless organs wind up in body cavities where they don't belong. The rate of initially missed diagnosis on CT scan ranges from 12% to 63%. A missed diagnosis can later present as intrathoracic visceral herniation and strangulation with a mortality rate of 30% to 60%. While multidetector CT (MDCT) is the most sensitive and specific noninvasive test for TDI (MDCT with variable sensitivity and specificity of 61% to 87% and 72% to 100%, respectively, for the diagnosis of diaphragmatic rupture), it is far from 100% accurate. As CT technology and software advance, it is possible the ability of CT to diagnose these injuries reliably will improve, but for now surgery remains the gold standard.

Finally, I would like to make a comment of repairs that require mesh. The authors discuss the different types of mesh that may be used to reconstruct the diaphragm when a primary repair is not possible secondary to tension associated with muscle loss. Reconstruction of the diaphragm and large defects with mesh is much more commonly performed in elective procedures for repair of congenital defects and repair of large hiatal hernias. When a defect can be repaired primarily, especially in an emergent setting, mesh need not be employed. If a defect cannot be closed primarily and mesh is needed, then by definition the mesh is being used to bridge a defect. The goal in such a repair would be to minimize the risk of recurrence while balancing the risk of mesh infection or severe adhesions to the mesh itself—either on the abdominal side or on the thoracic side of the repair. In settings where there is significant contamination of the abdominal cavity—especially in an unstable patient—a permanent prosthetic is associated with an unacceptable risk of chronic infection and a bioabsorbable prosthetic is the best choice. It is highly likely (if not entirely certain) that in these cases a biologic is used to bridge a defect that the patient will experience a recurrence. Data on the abdominal wall and at the esophageal hiatus of the diaphragm suggest that bridging biologic meshes nearly always fails. For these reasons, in the absence of contamination a

biologic mesh such as Strattice or AlloDerm should never be utilized for reconstruction of a diaphragm defect that cannot be closed but with mesh.

Overall, this is an excellent summary describing the diagnosis and management of a rare but significant injury in both blunt and penetrating trauma. Surgeons who take care of trauma patients should be well-acquainted with the information in this chapter. The chronic traumatic diaphragm injury is a different entity, and requires a slightly different approach. This can be a devastating condition if not recognized, and for this reason all general surgeons should be aware of how these injuries may present in a very delayed manner. General surgeons, trauma surgeons, minimally invasive surgeons, and thoracic surgeons should all be familiar with the different options for reconstruction and repair of these chronic diaphragm injuries.

67 Paraesophageal Hernia—Open Repair

W. Scott Melvin and Kyle A. Perry

Paraesophageal hiatal hernia is a relatively rare condition that was first identified on postmortem examination in 1903, and by upper gastrointestinal contrast radiography in 1926. Since that time, the importance of these hernias has been recognized due to their propensity to develop potentially life-threatening complications including gastric volvulus with subsequent strangulation and perforation. Management of paraesophageal hernias (PEHs) has changed considerably during the past 20 years, and several areas of controversy remain as techniques continue to evolve. Although laparoscopic PEH repair has gained increased acceptance, circumstances exist when an open abdominal or thoracic approach is necessary, and surgeons should be familiar with these techniques.

Hiatal hernias occur in approximately 10% of the population, with approximately 10% of these being PEHs. Although congenital PEHs have been reported, the vast majority of these hernias are believed to be acquired. The underlying cause of hiatal enlargement is unknown, but may be related to metabolic defects affecting the extracellular matrix composition with the supporting ligaments of the gastroesophageal junction, increased intra-abdominal pressure, or inherent weakness of the diaphragmatic tissues. PEHs typically present later in life with a two to one female preponderance, and are occasionally seen as a complication of antireflux surgery. There is also a familial occurrence that confers a 20-fold increased risk in younger siblings of children with a hiatal hernia.

Gastric volvulus, first described by Berti in 1896, is defined as the rotation of the stomach greater than 180 degrees around a fixed axis of rotation. Gastric strangulation from acute gastric volvulus is a dreaded complication of PEH and it remains the driving force for recommending elective repair of asymptomatic hernias. Gastric strangulation occurs in up to 28% of cases of acute gastric volvulus, and may progress to gastric necrosis, perforation, and severe sepsis leading to cardiovascular collapse

if it is not diagnosed quickly and aggressively managed. The true incidence of gastric volvulus remains unknown, but it affects males and females equally. Approximately 20% of cases occur in infants and young children, with the remainder occurring in adults older than 50 years of age.

ANATOMY

The esophagus enters the abdomen via the esophageal hiatus of the diaphragm. In most patients the limbs of the right diaphragmatic crus comprise this opening, although varying degrees of contribution from the left crus may be present. Although not anatomically correct, most surgical descriptions of hiatal dissection, including those presented here, refer to these limbs as the right and left diaphragmatic crura. The phrenoesophageal membrane anchors the intra-abdominal esophagus to the diaphragm and tethers the squamocolumnar junction within or just below the diaphragmatic hiatus, preventing displacement of the stomach above the diaphragm. Derangements of this normal esophagogastric anatomy produce herniation of the stomach thorough the esophageal hiatus into the thoracic cavity. Hiatal hernias are classified as types I to IV, with types II to IV representing forms of PEH (Fig. 67.1).

Ninety percent of hiatal hernias are type I (Fig. 67.1A), or sliding, hiatal hernias in which the gastric cardia herniates upward with proximal migration of the lower esophageal sphincter (LES) into the thorax. This produces attenuation of the phrenoesophageal membrane, but it remains intact. The term sliding hiatal hernia applies here because the gastric wall comprises a portion of the hernia sac, analogous to retroperitoneal structures in sliding groin hernias.

Type II, III, and IV hiatal hernias represent forms of paraesophageal herniation. True paraesophageal (type II) hernias are uncommon, constituting about 3% of all hiatal hernias (Fig. 67.1B). In this case, the gastroesophageal junction remains fixed in its normal anatomic location and the gastric fundus herniates through an enlarged hiatus. “Parahiatal” hernias may occur in a position adjacent to, but distinct from, the anatomically intact esophageal hiatus; however, these have been reported to comprise only 0.2% of cases in large series of hiatal hernia repairs. These hernias typically occur on the left side and contain the fundus of the stomach producing a clinical picture and radiographic findings indistinguishable from type II PEHs. Type III hiatal hernias involve elements of both type I and II hernias and represent the majority of PEHs

presenting for surgical repair (Fig. 67.1C). Most often, enlargement of a type I hernia defect allows cephalad migration of the stomach in response to the transdiaphragmatic pressure gradient. A true hernia sac is present with fundic herniation and proximal migration of the gastroesophageal junction into the thorax. This type of hernia is associated with laxity of the elements that retain normal gastric position, and the natural history is to progress to complete gastric herniation with the appearance of an upside-down intrathoracic stomach on contrast radiography (Fig. 67.2). Large hernia defects that contain other viscera or abdominal organs are referred to as type IV hiatal hernias, but these hernias are best thought of as a subgroup of type III.

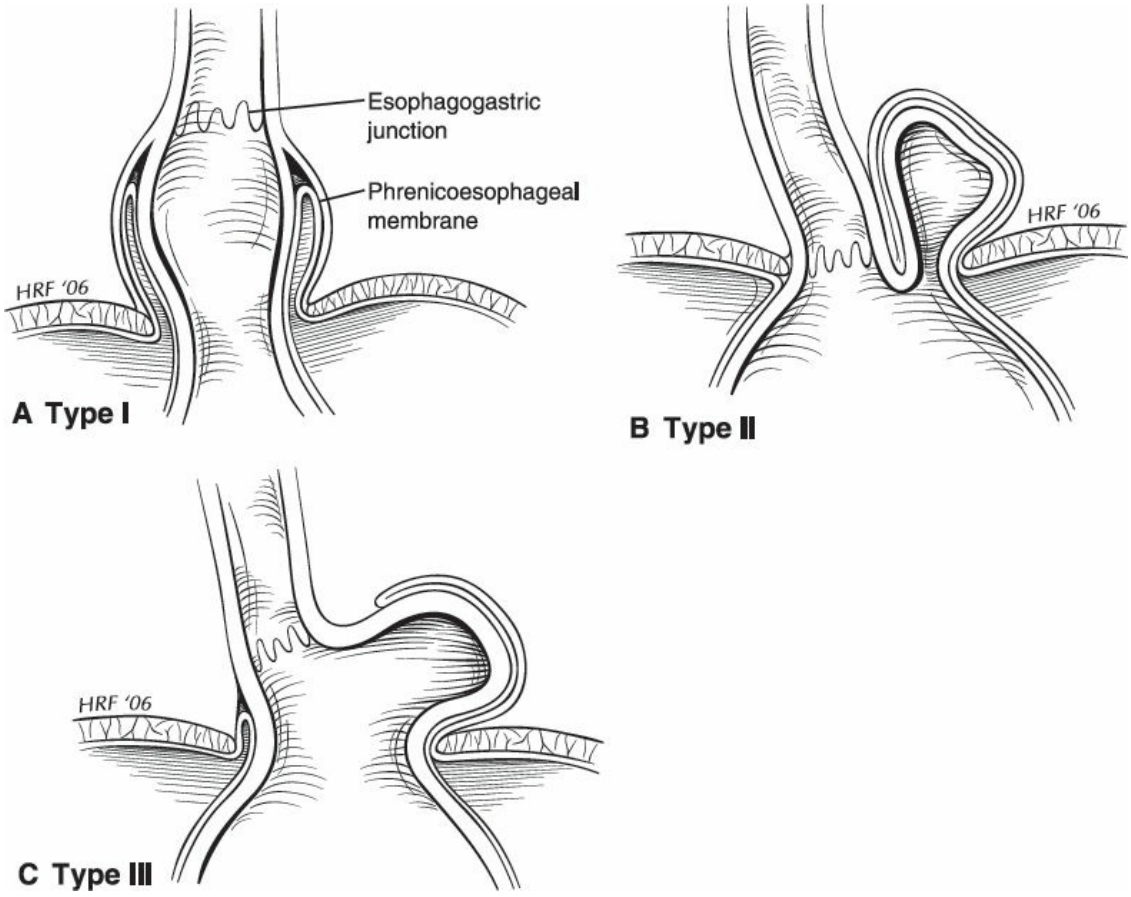

Figure 67.1. Classification of hiatal hernia **A.** Type I, sliding. **B.** Type II, pure paraesophageal. **C.** Type III, mixed hernia.

This classification system can lead to confusion as some hernias may appear to be either a sliding or paraesophageal hiatal hernia depending on patient position. Thus, the term “giant PEH” has been used to describe the large hernias typically classified as type III and IV hiatal hernia. This term refers to hernias in which at least half of the stomach is located within the

thorax on contrast radiography, the hernia measures at least 6 cm in length on preoperative endoscopy, or a distance between the crura of at least 5 cm is noted on intraoperative inspection. Giant hiatal hernias are repaired using the same principles required for all PEHs, but the large hernia sac and propensity for esophageal shortening make these cases especially challenging.

The anatomic classification of gastric volvulus is based on the axis of rotation (Fig. 67.3). Organoaxial volvulus is the most common type, and it accounts for almost all cases of acute gastric volvulus. This involves rotation of the stomach around the anatomic (longitudinal) axis, represented as a line drawn from the cardia to the pylorus, frequently resulting in gastric strangulation. In mesoenteroaxial volvulus, the antrum of the stomach rotates anteriorly and superiorly around a transverse axis that extends from the mid-lesser curvature to the mid-greater curvature. The rotation is typically incomplete and results in intermittent gastric obstruction, rather than acute strangulation.

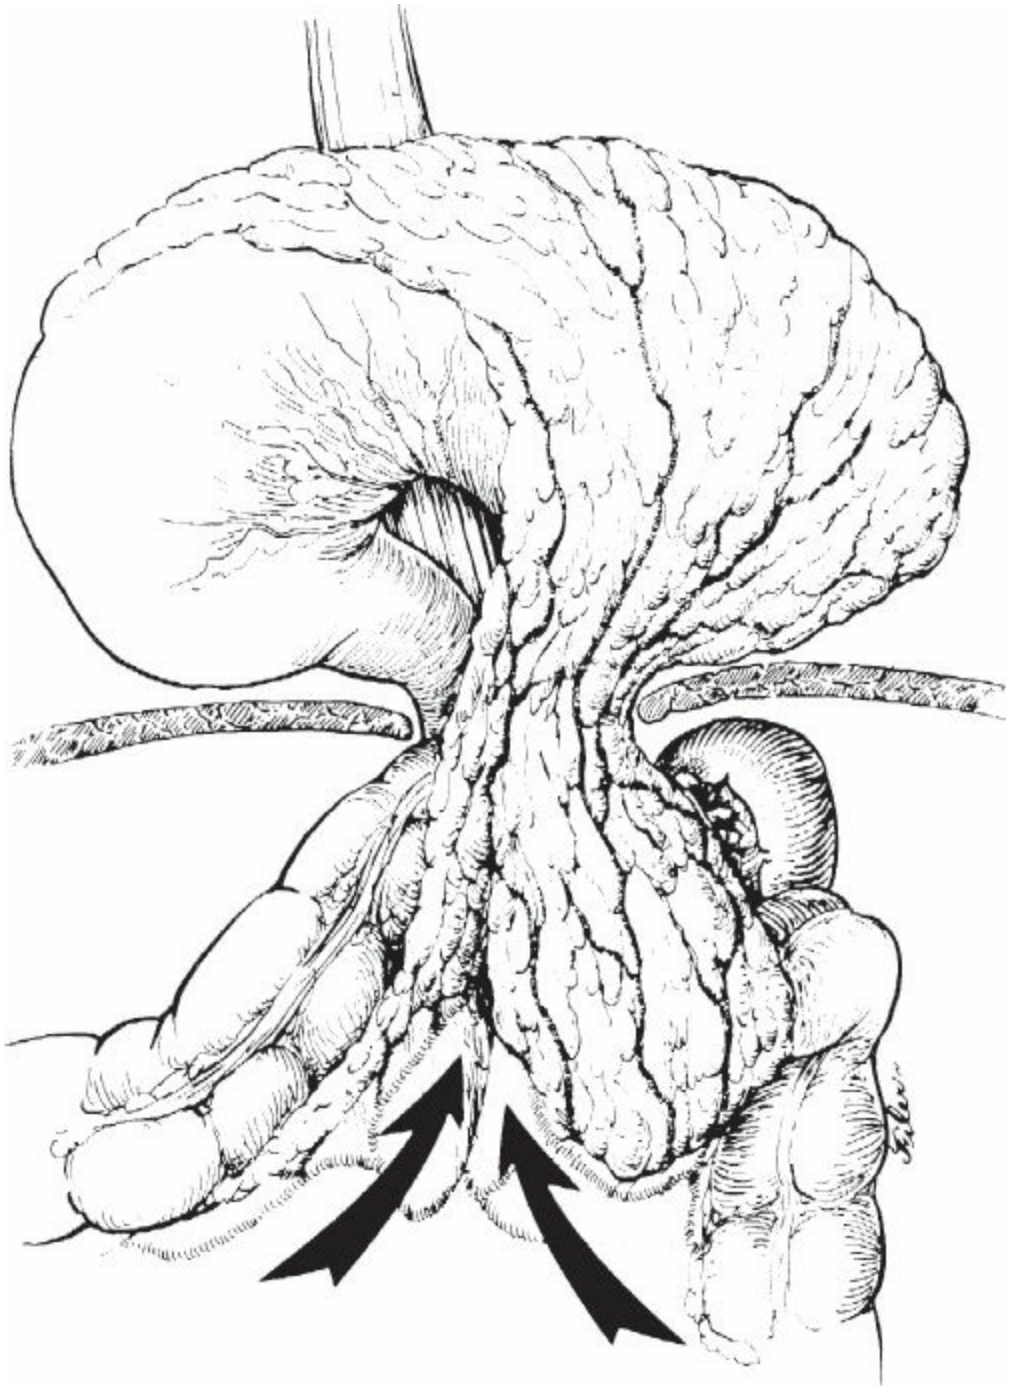

Figure 67.2. Large type III paraesophageal hernia with a large hernia sac and an upside-down intrathoracic stomach.

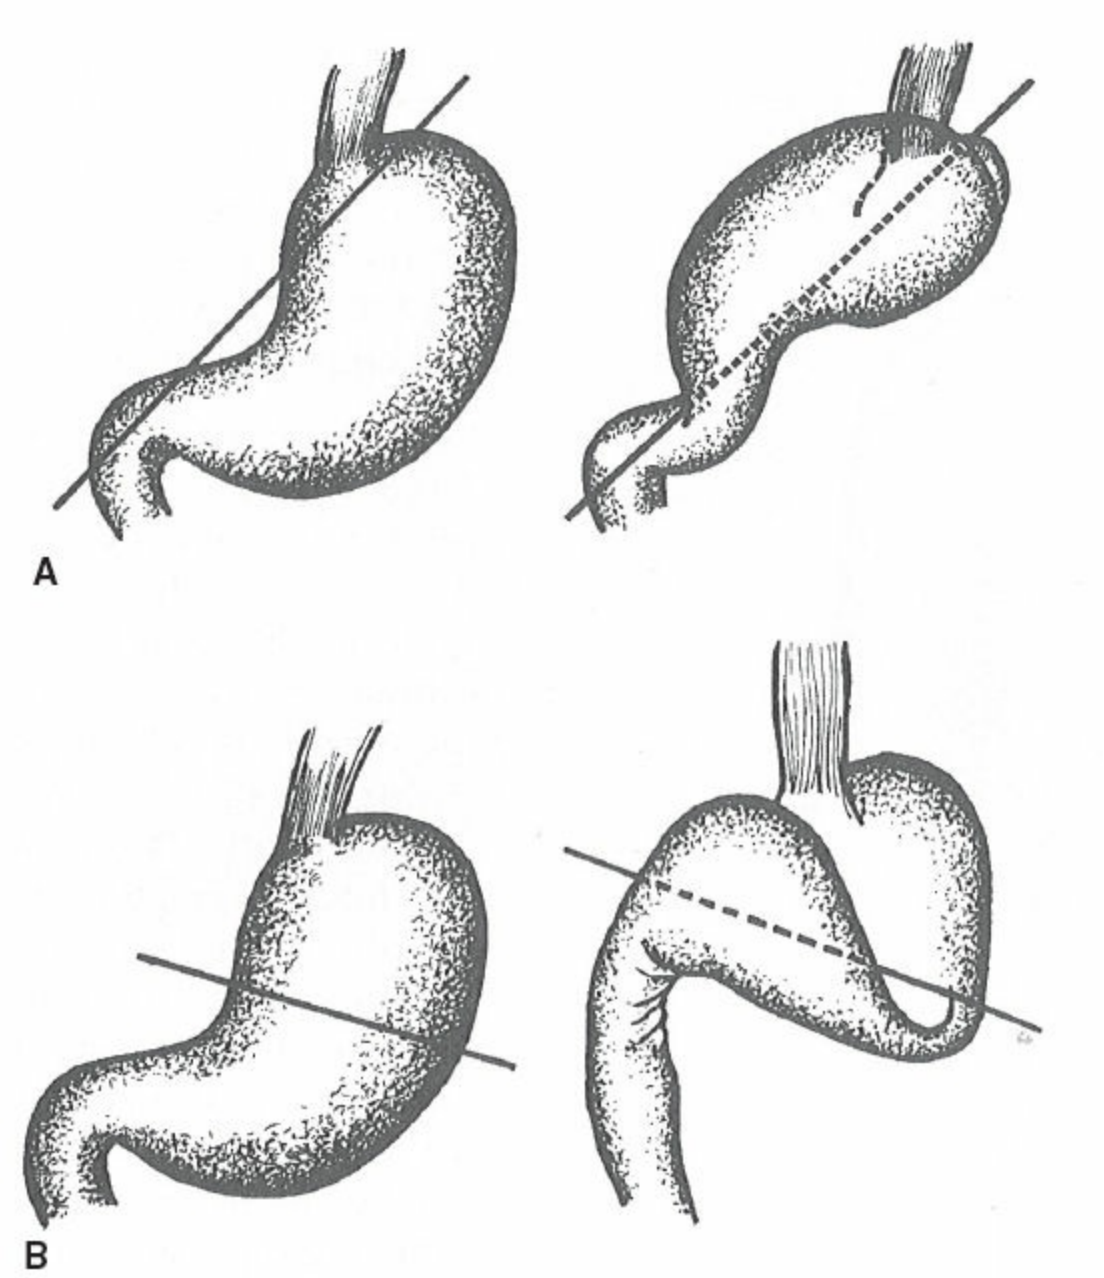

Figure 67.3. Types of gastric volvulus associated with paraesophageal hernia: Organoaxial volvulus (**A**) and Mesentericoaxial volvulus (**B**). *Line* indicates axis of volvulus.

CLINICAL PRESENTATION

Approximately half of all PEHs are clinically silent and become apparent on imaging studies obtained for another reason. Symptoms are caused either by obstruction of the stomach or distal esophagus or by gastroesophageal reflux related to LES incompetence. PEH most commonly present with symptoms of gastric obstruction including epigastric or chest pain, dysphagia, emesis, and postprandial fullness.

Displacement of the LES into the thorax and loss of the angle of His may produce symptoms commonly associated with sliding hiatal hernias such as heartburn, chronic cough, regurgitation, and aspiration. Many of the signs and symptoms of PEH are nonspecific and may mimic those of acute myocardial infarction, gastric ulcer, or pneumonia. One third of patients present with iron deficiency anemia secondary to chronic blood loss from erosions of the gastric mucosa caused by repeated movement across the hiatus, a phenomenon originally described by Collis in 1957, or from an ulcer at the level of the diaphragm described by Cameron.

Acute gastric volvulus typically presents with a history of dysphagia and high gastric obstruction. In 1904, Borchardt described the classic symptom triad of severe epigastric pain, retching and inability to vomit, and inability to pass a nasogastric tube (NGT). Patients may also present with severe chest pain and minimal abdominal findings as the incarcerated segment is often located within the chest. Many patients present with intermittent acute symptoms, and a history of multiple emergency room visits for cardiac events is common. In patients with mesenteroaxial gastric volvulus, diaphragmatic defects are not as common, and ligamentous laxity, aerophagia, or postsurgical changes predominate.

DIAGNOSIS

In the acute setting of foregut obstruction, chest x-ray typically demonstrates a retrocardiac air–fluid level and often a second one below the diaphragm. Pleural effusion, pneumothorax, and pneumoperitoneum are ominous findings that mandate exploration as they are often associated with ischemia and perforation. A barium study will reveal obstruction at the level of the volvulus and can be used as a confirmatory study in this setting if the diagnosis remains uncertain. In the setting of ischemia, the presentation is one of septic shock, with epigastric pain and resultant multiorgan system dysfunction. It should be emphasized that the catastrophic presentations of PEH are quite uncommon.

Several tests may be used to classify the hernia, degree of gastroesophageal reflux, and esophageal motility prior to elective repair. Barium esophagram may suggest the presence of a shortened esophagus and classify the hernia to aid in decision making, especially in frail patients with asymptomatic hernias. In some patients, an upper gastrointestinal series will show complete gastric obstruction due to gastric volvulus, which indicates a need for urgent surgical repair. Upper

endoscopy is required to inspect for gastric ischemia, ulceration, erosion, or cancer. A PEH is identified on retroversion of the scope by noting a separate orifice adjacent to the gastroesophageal junction into which gastric rugal folds ascend. If a gastric ulcer is present, elective surgery should be delayed until after the ulcer is healed, or at least 6 weeks of proton pump inhibitor treatment have been completed. Esophageal manometry can be useful in identifying esophageal motility disorders, which may preclude the use of full fundoplication, but may not be technically possible due to difficulties positioning the catheter beyond the LES. Ambulatory pH testing is rarely useful in evaluation of PEH because the goals of treatment typically involve addressing symptoms related to mechanical obstruction rather than the control of gastroesophageal reflux.

TREATMENT

The repair of PEHs may be approached via thoracotomy, laparotomy, or laparoscopy. The principles of proper surgical repair are the same with each approach:

1. Complete reduction and excision of the hernia sac
2. Reduction of the herniated stomach and 2 to 3 cm of distal esophagus into the abdominal cavity
3. Repair of the diaphragmatic hiatus
4. Fixation of the stomach into the abdomen and/or fundoplication

INDICATIONS

It has been generally accepted that reasonable surgical candidates should undergo repair regardless of symptoms. This recommendation is based on early series that showed an increased mortality after emergency surgery of 30% compared with 1% in elective cases. In 1967, Skinner and Belsey found that 6 of 21 patients with a known diagnosis of PEH died from complications of their hernia when followed conservatively for 5 years.

Other studies have suggested differences in both the natural history of the disease and operative outcomes. Allen et al. followed 23 patients who refused operative repair of PEHs for a median follow-up of 78 months without development of any life-threatening complications. Others have advocated that asymptomatic or minimally symptomatic PEHs may be managed by a strategy of “watchful waiting” with emergency surgery required in only 1.2% of cases with an operative mortality of 5.4% in this

setting. A recent retrospective review of 127 patients undergoing open transabdominal PEH repair in a single institution, however, found emergent surgical repair carried a mortality rate of 22%, compared with 1% for patients undergoing elective repair. In this series, emergent repair was an independent predictor of in-hospital mortality, major complications, readmission to an intensive care unit, and postoperative length of hospital stay.

Our current recommendation is that all type II hernias should be repaired, and consideration should be given to type III hernias regardless of symptoms. However, in the case of an elderly, frail patient with significant comorbidities it may be appropriate to decide on a course of watchful waiting due to increased risks associated with surgical repair in these patients.

Traditionally, transthoracic repair of PEHs has been advocated. Approaching these via thoracotomy provides excellent visualization of the hernia sac from within the mediastinum, allows extensive esophageal mobilization under direct vision, and provides the easiest approach for esophageal lengthening procedures. However, this approach has been associated with longer hospital stay, need for tube thoracostomy, and increased pulmonary complication rates and incisional discomfort. Also, blind reduction of the stomach also leaves the potential for recurrence of organoaxial rotation leading to postoperative intra-abdominal gastric volvulus. Given the high morbidity rates and increased length of hospital stay associated with the transthoracic approach, most PEHs are now repaired using an open or laparoscopic transabdominal approach.

Laparoscopic PEH repair has gained popularity and has been proven feasible, safe, and effective. Laparoscopy provides an attractive option because it combines some of the advantages of both thoracotomy (access to the hiatus, ability to perform extensive mobilization of the esophagus under direct vision) and laparotomy (lower morbidity, no need for single lung ventilation or postoperative chest tube). However, this is a challenging procedure that requires advanced laparoscopic skills and cannot be safely applied in all situations. Current indications for open transabdominal PEH repair include the following:

1. Gastric volvulus with acute peritonitis that cannot be relieved with gastric decompression.
2. Completion of a procedure that has been converted from a laparoscopic approach.

3. Reoperative surgery after a previous laparoscopic or open gastric surgery.
4. Lack of expertise in advanced laparoscopic surgery.

PREOPERATIVE PLANNING

Once the diagnosis of gastric volvulus has been made, intravenous fluid resuscitation should be initiated and an attempt made at gastric decompression with an NGT. If successful, this results in rapid symptom improvement, and allows time for intravenous fluid resuscitation prior to surgical repair. If nasogastric decompression is unsuccessful, the patient must be taken to the operating room immediately for emergent operative repair.

SURGICAL TECHNIQUE

Preparation and Positioning

The patient is placed in the supine position under general anesthesia. A urinary catheter and sequential compression devices are placed, and intravenous antibiotics are administered. Adequate intravenous access is obtained and the arms are carefully padded and tucked at the patient's sides. The surgeon stands to the patient's right with the first assistant on the patient's left.

Incision and Exposure

The abdomen is entered via a midline supraumbilical incision with maximal cephalad extension including dissection of the fascia from the xiphoid process. A table-mounted self-retaining retractor is used to retract the wound edges and costal margin. The triangular ligament of the liver is divided with electrocautery and the left lobe of the liver is retracted to the right with the liver blade of the self-retaining retractor to expose the esophageal hiatus.

Crural Dissection, Reduction of Hernia Sac, and Mobilization of Gastric Fundus

The stomach is gently reduced from the hernia sac and the left diaphragmatic crus is identified. The hernia sac is opened overlying the left crus using electrocautery and the dissection is carried out in the plane between the endothoracic fascia and the hernia sac (Fig. 67.4). After the

anterior phrenoesophageal membrane is divided using electrocautery, the stomach is retracted to the left to expose the right crus. The pars flacida of the lesser omentum is divided and the dissection continues posteriorly along the right crus until the decussation of the crura is visualized. In the case of giant PEHs, care must be taken to identify the left gastric artery and avoid injury to this vessel during dissection. The gastrosplenic omentum is then divided using an ultrasonic dissector, and the short gastric vessels are divided all the way up to the cephalad extent of the stomach as the stomach is completely reduced from the mediastinum. Division of the posterior gastric attachments creates a retroesophageal window through which a Penrose drain is passed around the distal esophagus to facilitate caudad retraction on the esophagus and create exposure for the mediastinal dissection. Dissection proceeds from right to left, and the sac is opened to reveal a plane between the peritoneal sac and the mediastinum. Careful blunt dissection develops this plane, with care taken to identify and preserve the vagal trunks and the scar tissue at the hiatus, which aids in the crural closure. With gentle retraction, the sac can be slowly mobilized out of the mediastinum and reduced into the abdominal cavity. Most individuals excise and remove the hernia sac, but excessive fastidiousness in this exercise risks injury to the vagus nerves as they course in close apposition to the hernia sac in the epiphrenic fat. We usually remove the majority of the sac, including all sac and epiphrenic fat on the left side of the esophagus, well away from the vagal trunks and the end branches of the left gastric artery. In cases of acute gastric volvulus, the viability of the stomach should be assessed at this time, and gastric resection undertaken as necessary. Feeding jejunostomy tube placement should also be considered in these cases.

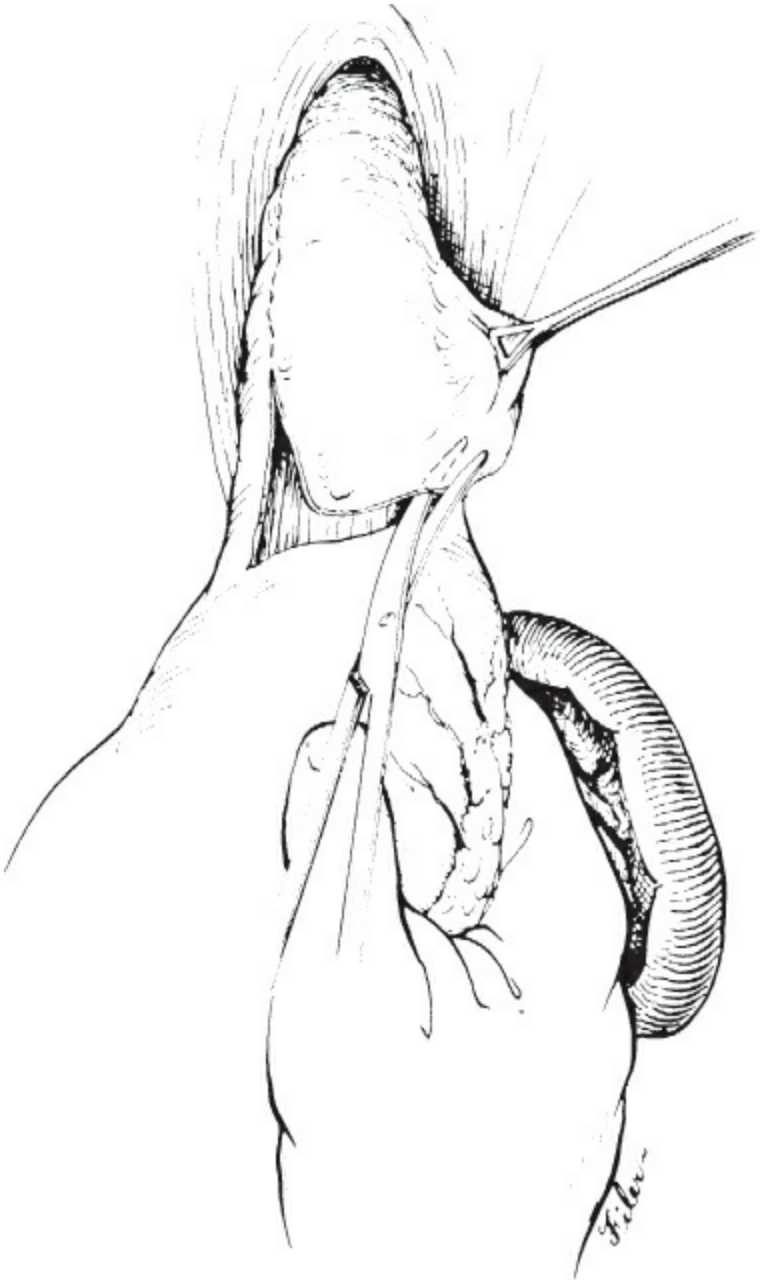

Figure 67.4. Manual reduction of the stomach facilitates identification, dissection, and excision of the anterior hernia sac.

Assessment of Esophageal Length and Esophageal Lengthening

Presbyesophagus has been recognized and studied for several decades, with the Collis gastroplasty described for its treatment in 1957. While some have argued against its existence, most esophageal surgeons today agree that it is a real clinical entity that results from chronic esophageal inflammation in the setting of proximal migration of the gastroesophageal junction. Failure to recognize this condition during PEH repair results in

tension on the hiatal repair, which has been implicated in up to 33% of surgical failures. Although preoperative testing can show the position of the gastroesophageal junction and suggest the presence of shortened esophagus, these tests cannot reliably predict difficulty reducing the stomach to its anatomic position without tension intraoperatively.

When the hernia sac is completely reduced from the mediastinum, it is imperative to have at least 2.5 cm of tension-free intra-abdominal esophageal length. If a shortened esophagus is identified an extensive circumferential mobilization of the intrathoracic esophagus is performed, which usually provides the desired esophageal length. In cases of true shortened esophagus, we perform a wedge gastroplasty over a large bougie. A point is marked 3 cm below the angle of His, and a transverse staple line is created with two or three applications of a linear endo-GIA stapler. When the esophageal dilator is reached, a vertical staple line created along the bougie creates a 3- to 4-cm neoesophagus, and the gastric wedge is removed from the abdomen (Fig. 67.5). Esophageal lengthening procedures should be performed in all cases when adequate tension-free esophageal length cannot be obtained from mediastinal dissection alone.

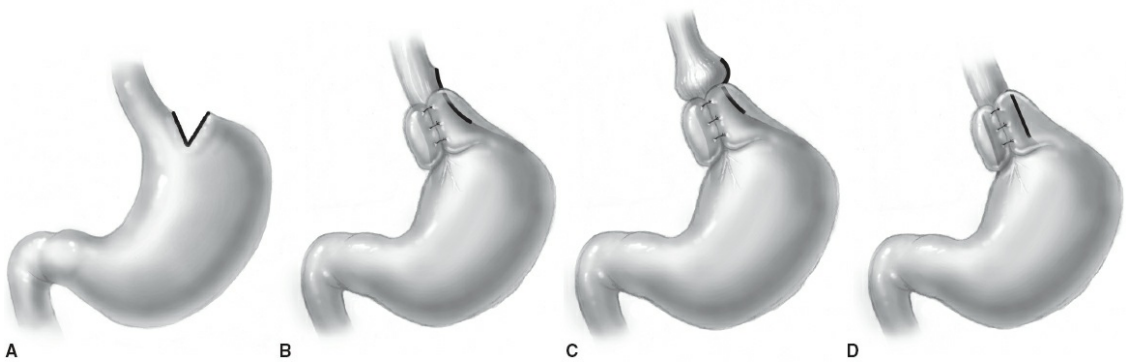

Figure 67.5. Esophageal lengthening via wedge fundectomy. **A.** Appearance of the gastric fundus after creation of transverse and longitudinal staple lines. **B.** Placement of fundoplication too low on the neoesophagus. **C.** Proximal dilation of the neoesophagus creating the appearance of a “slipped” Nissen fundoplication. **D.** Correct position of the fundoplication with complete coverage of the gastric staple lines. (From Van Hove CE, Hunter J, Perry K. Laparoscopic antireflux surgery: esophageal lengthening procedures. In: Soper NJ, Swanström LL, Eubanks WS, eds. Mastery of endoscopic and laparoscopic surgery, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2009.)

Repair of the Crura

After complete reduction of the hernia sac and identification of an adequate length of intra-abdominal esophagus, attention is turned to the crural closure. A posterior cruroplasty is performed using an interrupted, braided nonabsorbable suture such as 0-silk (Fig. 67.6). In cases where the crura are attenuated, pledgeted sutures should be used to distribute tension and minimize tearing of the crural fibers. Once complete, the adequacy of crural closure may be tested by the passage of a 56- to 60-French Maloney dilator, which should completely fill the new hiatal aperture. If the diaphragmatic repair appears to be "pinching" the esophagus with dilator in place, a suture is removed. Conversely, if the closure is loose, the dilator is withdrawn into the upper esophagus and another suture is added.

Uncommonly, we find it necessary to use a mesh reinforcement of the crural repair in situations where the crural muscles are quite attenuated or inadequate for repair. The mesh repair is done with an onlay technique posterior to the esophagus and overlying the edges of the crura away from the esophagus. Mesh should rarely if ever be used as a bridge, and instead should be used to reinforce a primary repair of the hiatus under tension. In certain cases, the hiatal opening is extremely dilated, or the muscle too attenuated in order to accomplish a primary crural closure. In these cases, the use of a crural relaxing incision is recommended. A full thickness incision in the right crus of the diaphragm several millimeters medial to the vena cava and from the base of the crus to the anterior crural vein provides several centimeters of medialization of the muscle. The pleura may be opened during creation of the incision, which is rarely an issue with good communication to the anesthesiologist. Relatively little additional medialization is achieved by opening the pleural membrane, so we avoid entering the right chest during this maneuver if possible. A right-sided relaxing incision is usually all that is needed, although left-sided incisions can be added if needed. Once the hiatus is closed with the medialized muscle following a relaxing incision, mesh is used to close the defect in the diaphragm. If a mesh is needed to reinforce a crural repair, options include a biologic mesh or a permanent prosthesis.

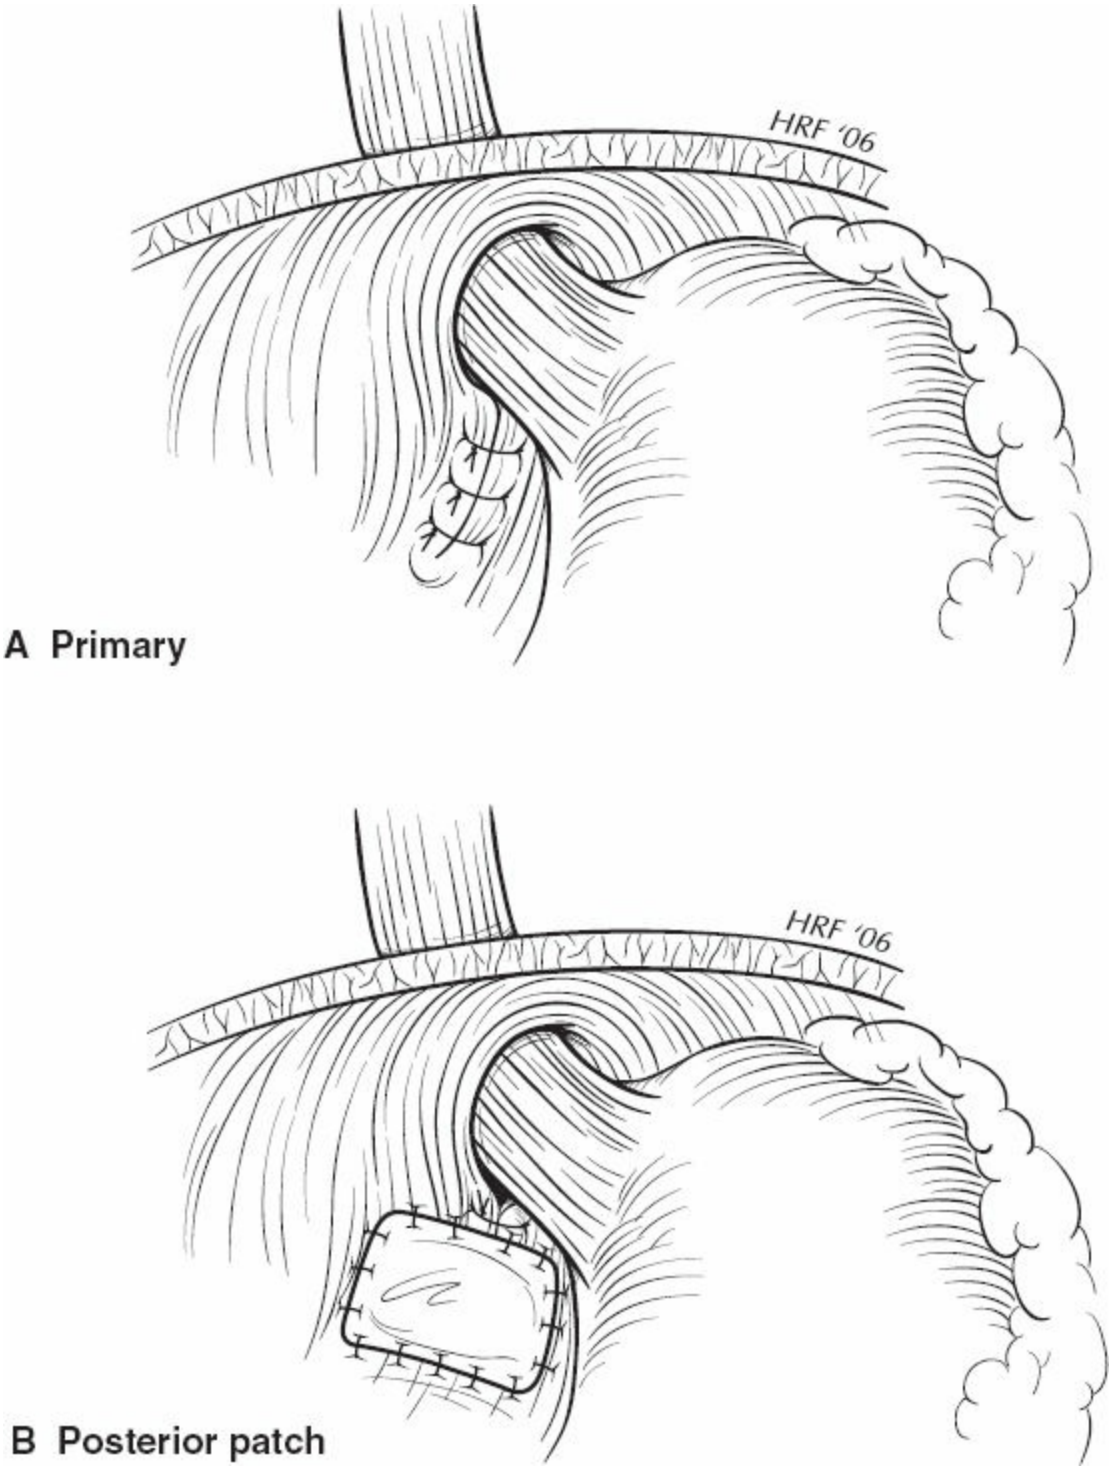

Figure 67.6. Posterior crural closure with and without mesh reinforcement. **A.** Primary. **B.** Posterior patch.

In 2006, a prospective randomized, multicenter trial examined the effect of bioprosthetic mesh on hernia recurrence. This study showed a significant reduction in early recurrences (6-month follow-up) following bioprosthetic mesh repair, without increased dysphagia or impaired quality of life compared with those with primary crural repair. However, 5-year

follow-up was analyzed which demonstrated no significant difference in recurrence rates. This repair appears to have potential, but no direct studies comparing it with synthetic mesh repair have been done, and long-term efficacy and complication rates of each approach need to be determined.

Three prospective studies have shown decreased recurrence rates when prosthetic crural reinforcement is performed compared with primary repair. Two prospective randomized trials have evaluated synthetic mesh reinforcement. One study showed a decreased recurrence rate with polytetrafluoroethylene (PTFE) reinforcement of the crural repair to a median follow-up of 78 months, and another trial showed similar results with Prolene mesh reinforcement of the hiatus. These studies, however, did not carefully assess potential mesh-related complications, and the second series showed an increase in early postoperative dysphagia when mesh was used. Concern also exists about the use of synthetic mesh near the hiatus where movement of the mesh along the esophagus with each respiration can cause complications including mesh erosion, ulceration, stricture, and dysphagia. A decision analysis model of the choice between primary repair and mesh repair of a PEH was constructed in a recent publication. The essential features of the decision were the rate of perioperative complications, PEH recurrence rate, reoperation rate after recurrence, rate of symptomatic recurrence, and type of outcome after reoperation. The literature was reviewed to obtain data for the decision analysis and the average rates used in the baseline analysis. Based on their analysis, the authors of this study concluded that depending on what the decision maker accepts as the recurrence and reoperation rates for PEH repair, either mesh or primary repair may be the treatment of choice; however, the differences between the two are small, and, perhaps, clinically inconsequential.

Fundoplication

After the completion of the crural repair, we routinely perform an antireflux procedure because failure to do so has been associated with a 20% to 40% rate of postoperative reflux and preoperative testing cannot successfully predict postoperative reflux. A Nissen fundoplication is performed unless the patient has a known history of severe esophageal dysmotility, necessitating a partial fundoplication. In this group of patients, a 270-degree posterior (Toupet) fundoplication allows good fixation of the stomach and distal esophagus within the abdomen, and good reflux

control, with a decreased risk of postoperative dysphagia (Fig. 67.7).

A floppy Nissen is performed by passing the fundus of the stomach behind the esophagus (Fig. 67.8). A 56- or 60-French Maloney dilator is advanced into the stomach after the fundus has been successfully passed behind the esophagus in order to reduce the risk of esophageal perforation. When a wedge gastroplasty is performed, the staple line is opposed to the stomach wall, and the most cephalad stitch of the fundoplication is placed on the true esophagus above the neoesophagus, ensuring that no gastric mucosa lies above the fundoplication (Fig. 67.5). The fundoplication is created using three 2-0 silk or braided nylon sutures incorporating the stomach and esophagus with each stitch (Figs. 67.9 and 67.10). An additional suture may be placed from the left posterolateral portion of the wrap to the esophagus.

In select patients, namely, those with severe esophageal dysmotility or gastroparesis, one may consider gastropexy as a preferable means to fix the stomach in its intra-abdominal position. Direct suture fixation of the stomach to the abdominal wall without repair in patients with large hernias was described by Rudolph Nissen. Because of a very high recurrence rate, placement of a gastrostomy tube or full-thickness gastropexy seems more secure in this setting. Percutaneous endoscopic gastrostomy tube placement, usually with several tubes, has been reported with success and may be useful in patients with mesenteroaxial volvulus without a hernia, but should be reserved for use in cases with a hernia in only the most frail of patients.

POSTOPERATIVE MANAGEMENT

Patients are admitted to the hospital, and nausea is aggressively treated with scheduled antiemetics to avoid episodes of retching that can lead to early hernia recurrence or disruption of the fundoplication. An NGT is placed initially and removed after 1 to 2 days. A clear liquid diet is initiated on postoperative day 2, advanced to full liquids on postoperative day 3, and a soft diet on postoperative day 7. The patient is maintained on

a soft food diet for 3 weeks, after which he or she may take a regular diet as tolerated. Patients remain in the hospital until adequate fluid intake and analgesia is obtained, typically 3 to 5 days, and discharged on a full-liquid diet with stool softeners and antiemetic medications as needed.

COMPLICATIONS

Intraoperative complications are rare, but the spleen may be injured during transabdominal fundoplication. Capsular avulsion or small tears causing persistent bleeding occur in approximately 5% of patients, and splenectomy rates of 1% to 3% are reported. Most splenic injuries are minor, and bleeding is easily controlled with tamponade. Another possible complication is injury to the vagus nerves, especially during reoperative cases or in the setting of significant periesophagitis. The sequelae of vagotomy are rarely of long-term clinical relevance, and vagal injury to a single vagal trunk does not necessitate further intervention. Addition of a pyloroplasty should be considered, however, when injury to both vagal trunks is suspected as this may result in gastric atony and severe gastric emptying problems necessitating a late gastric emptying procedure.

The most serious complication, perforation of the esophagus, can cause a great deal of difficulty if it is not recognized. Perforation occurs more frequently in the setting of severe inflammation or revisional surgery. Perforation occurs either during difficult mobilization of the cardia or during the dissection around the back of the esophagus. An unrecognized esophageal perforation is a life-threatening complication, so thorough evaluation of the posterior aspect of the esophagus is mandatory prior to encircling the distal esophagus. If a perforation is identified, it is repaired with interrupted sutures, and the repair is buttressed with the fundoplication. We typically perform an esophagram on postoperative day 1 to ensure that there is no ongoing esophageal leak in this setting.

OUTCOMES

Open transabdominal PEH repair can be performed with low operative mortality of approximately 1% and with lower morbidity than transthoracic PEH repair. A recent population-based study showed a perioperative morbidity rate of 10.6% for open abdominal repair compared with 13.6% for transthoracic repairs. In this report, laparoscopic PEH repair was associated with a perioperative morbidity rate of 7.9%, but concerns remain about the high rate of anatomic hernia recurrence

following laparoscopic PEH repair. In one randomized trial comparing open transabdominal and laparoscopic PEH repair, laparoscopy was associated with a 42% radiographic recurrence rate compared with 15% in the open repair group. These results are comparable with case series reported in the literature; however, most radiographic recurrences in these series are asymptomatic and require no further intervention. Also, in specialized centers, laparoscopic PEH repair has been accomplished with lower rates of radiographic recurrence approaching those associated with open repairs. These results underscore the need for surgeons to assess their own skills and comfort level with these techniques to achieve the best possible outcomes for their patients.

EDITOR'S COMMENT

In this chapter, Drs. Perry and Melvin have done an excellent job describing the techniques and indications for open PEH repair. While open PEH repair is still performed, the use of this approach has declined dramatically in the past 15 years. A review of the Nationwide Inpatient Sample between 2000 and 2013 revealed that the rate of the laparoscopic approach to PEH repair procedures has increased dramatically from 12.1 per 100 procedures to 91.4 per 100 procedures over this interval. Patients undergoing laparoscopic PEH repair were less likely to experience postoperative infection, bleeding, cardiac failure, renal failure, respiratory failure, shock, and inpatient mortality compared to the open abdominal and thoracic approach. In addition, laparoscopic PEH repair was associated with significantly reduced length of hospital stay and overall cost.

Among the four indications listed in this book chapter for open PEH repair, I definitively agree with one of them: "Open PEH is indicated to complete a procedure that has converted to open from laparoscopic." In the hands of a skilled surgeon with experience in laparoscopic PEH repair, the need to convert to open is an unusual event. These procedures in my opinion actually become more difficult when performed by laparotomy. Visualization high into the mediastinum through an abdominal incision is poor. There is a volume–outcome relationship in these procedures—especially for larger hernias (intrathoracic stomach) and in elderly frail patients. A recently published analysis of the relationship between hospital volume and mortality in laparoscopic diaphragm repair utilized the Nationwide Inpatient Sample for the years 2000–2013. A small but significant inverse relationship between hospital case volume and mortality was observed, with a 10% reduction in adjusted odds of in-hospital mortality for every increase in 10 cases per year. Using 10 cases per year as the volume threshold, low-volume hospitals (≤10 cases/year) had almost a twofold higher mortality compared to high-volume hospitals (0.23 vs. 0.12%, respectively, $p = 0.02$). This likely understates the volume–outcome relationship when taking into account outcomes like long-term recurrence and symptomatic or quality-of-life outcomes, as these are difficult to attain from administrative data. In addition, the size and complexity of a particular PEH and the preoperative indications and urgency (short of emergency surgery) are not easily determined from these datasets. In my opinion, extremely large hernias, hernias where "short esophagus" is a preoperative concern, reoperative procedures, and surgery in frail or medically unfit patients should be referred to laparoscopic surgeons with significant experience and expertise in foregut surgery and in dealing with these kinds of hernias. As discussed in this chapter, esophageal lengthening procedures, diaphragm relaxing incisions, and

gastropexy are tricks that every surgeon performing laparoscopic PEH repair needs to have in his/her toolbox “just in case.” In addition, frail and medically unfit patients are less likely to tolerate a prolonged operative time or a complication.

Emergency repair of an incarcerated or a volvulized PEH is also mentioned as an indication for open PEH repair. On the contrary, when a surgeon with experience in laparoscopic PEH repair is available, the laparoscopic approach to repair remains the preferred approach even in an emergency. We recently reviewed the Nationwide Inpatient Sample to compare the outcomes of emergent versus elective PEH repair. Emergent repair was associated with a higher rate of morbidity (33.4 vs. 16.5%, $p < 0.001$) and mortality (3.2 vs. 0.37%, $p < 0.001$) than elective repair. Emergent repair patients were more likely to be male, were older, and more likely to be minority. Logistic modeling revealed that younger age, elective case status, and a laparoscopic approach were independently associated with a lower probability of complications and mortality.

I have a few comments on the procedure technique and potential pitfalls of surgery. In this chapter the authors describe the use of a Maloney dilator for assessing the adequacy of the crural closure. Most surgeons close the hiatal defect posterior to the esophagus. For very large defects, this technique can result in significant anterior displacement and angulation of the esophagus. When passing the esophageal bougie after posterior crural reapproximation, especially if a member of the anesthesia team is passing the bougie, great care and excellent communication is essential. If any degree of resistance passing the bougie is encountered, the attempt should stop. The heavy bougie may be pushing against the back of the hiatal repair and esophageal perforation is possible. There are several methods for dealing with this issue. If the bougie tip is past the hypopharynx and actually in the esophagus (often not the case when it won’t pass), straightening out the distal esophagus at the hiatus can help it pass. If the esophagus is encircled with a Penrose drain or something similar for retraction, make sure the drain is not angulating the distal esophagus. A smaller bougie can be attempted. Another option is not to use a bougie at all. Some surgeons advocate Nissen fundoplication without an esophageal bougie, although this practice is controversial. An esophageal bougie is rarely used in a Toupet partial fundoplication. I actually favor a Toupet in nearly all of these patients given their median age and the difficulty in attaining adequate and accurate esophageal manometry. Presbyesophagus and nonspecific hypomotility disorders are common in patients who develop symptoms other than gastroesophageal reflux disease (GERD) related to a PEH. A Toupet partial fundoplication works just as well for controlling or preventing GERD following PEH repair. A Toupet is less likely to result in severe bloating or dysphagia that a Nissen fundoplication. It is not clear to me that the rates of recurrent hiatal hernia are any higher in PEH repair with a Nissen versus a Toupet. Dysphagia in a frail and deconditioned patient can be a devastating complication to

overcome, especially if repeat surgery is deemed necessary.

The pendulum has swing with regard to surgical repair of PEHs from repairing all of them whether symptomatic or not, to not repairing a hernia if it is associated with no or minimal symptoms, to something in between in the current era. Patients are living longer and many asymptomatic PEHs identified and not repaired in patients in their seventh or eighth decade of life become symptomatic in these same patients in their ninth or tenth decade. It may make sense to fix these hernias when patients are better able to tolerate the operation. Repair of a PEH in an emergent setting or in an elderly and frail patient is a high-risk intervention associated with substantial potential for morbidity and mortality. Any surgeon who takes general surgery call needs to be familiar with the techniques and concepts outlined in this chapter given the possibility that a patient may present needing urgent surgical repair. This chapter is a very nice account of the natural history, indications for surgery, and surgical techniques needed to properly care for these patients.

Jon C. Gould

Professor Gould has a busy practice of various patients which would be the envy of most of us. At the same time he has developed a heightened sense of what causes disasters and the reflexes as to how to avoid them. His experience is enviable and saves lives.

68 Gastroesophageal Reflux Disease in Infants and Children

George W. Holcomb III and Brad W. Warner

Gastroesophageal reflux (GER) is a normal physiologic process that involves relaxation of the lower esophageal sphincter (LES) independent of swallowing, and allows gastric contents to pass into the esophagus. GER often occurs several times per day in healthy infants and children, and is not generally accompanied by symptoms. In contrast, gastroesophageal reflux disease (GERD) is globally defined as troublesome symptoms or complications associated with GER. These symptoms can either be esophageal or extraesophageal, and can be further characterized by esophageal mucosal injury.

ETIOLOGY AND PATHOPHYSIOLOGY

Not all infants with GERD require either medical or surgical management. In fact, the majority of these patients do not require therapy. Twenty years ago, Boix-Ochoa showed that there is a maturation process at the LES. In a group of elegant studies in which he evaluated normal infants and children with manometry, he showed that there is a very small length of intra-abdominal esophagus present at birth. However, over the next several months, the length of intra-abdominal esophagus gradually increases. Similarly, he showed that there is a maturation process to the pressure gradient generated by the LES. This maturation of the pressure gradient at the LES corresponds with elongation of the intra-abdominal esophagus. Therefore, infants with marked reflux who do not exhibit any evidence of failure to thrive, apnea/bradycardia, or aspiration can be observed to see if their symptoms resolve in the first 6 to 12 months of life.

Barriers to reflux include an adequate LES length and intra-abdominal location, an adequate LES pressure, lack of inappropriate LES relaxations, an adequate angle of His, normal esophageal motility, and absence of a hiatal hernia. Maturation of the LES leads to the development of a barrier against reflux. Unfortunately, this barrier's function is not always effective

in preventing GERD. In adults, LES pressures greater than 30 mm Hg have been shown to prevent reflux, whereas pressures between 0 and 5 mm Hg have resulted in abnormal pH studies consistent with reflux in 80% of the patients. These adult studies have also found that GERD is more likely to develop when the LES pressure is less than 6 mm Hg at the respiratory inversion point, and the overall LES length is less than 2 cm, of which less than 1 cm is intra-abdominal.

LES relaxation occurs normally with esophageal peristalsis and allows one to swallow without discomfort. Inappropriate LES relaxations have been shown to occur sporadically in nonaffected infants and children. For a number of years, prolonged transient LES relaxations (TLESRs) have been thought to be the primary mechanism for GER in adult patients. Similarly, prolonged or numerous TLESRs have been documented as the likely cause for GER in up to 50% of infants and children.

Although this barrier function at the LES is highly effective, it is imperfect. A short LES length, TLESRs, location of the LES in the chest, or abnormal smooth muscle function can contribute to the failure of the LES, resulting in GER. Moreover, disruption of the LES secondary to a hiatal hernia, abnormal LES function, or previous esophageal surgery can also result in poor function and subsequent reflux.

A second barrier that has been shown to prevent reflux is the intra-abdominal length (IAL) of the lower esophagus. An IAL of greater than 3 cm in adults with normal abdominal pressure has been shown to provide LES competency 100% of the time, whereas an IAL of less than 1 cm results in significant reflux. The importance of the lower esophageal IAL as a barrier to preventing reflux in adults cannot be overemphasized. Whether or not there is a similar minimum IAL in infants and children remains unclear and is discussed later.

Another impediment to reflux is created by the angle of His. Although the precise functional component of the angle of His is not well known, when this angle becomes more obtuse, reflux is more likely to develop. Conversely, accentuation of the angle of His inhibits reflux. In all fundoplication techniques, the angle of His is made more acute. On the other hand, an obtuse angle can develop following the placement of a gastrostomy because the fundus of the stomach is usually relocated more caudad when the body of the stomach is brought up to the anterior abdominal wall.

The final barrier to reflux is often an important factor when considering

operative therapy in adults, but is rarely significant in children. The ability of the esophagus to clear lumenal contents effectively may be diminished with impaired esophageal motility as a result of abnormal smooth muscle function, impaired vagal stimulation, or obstruction from an esophageal stricture. Although an assessment of esophageal motor function is important in adults, it is rarely necessary in children who have no history of a smooth muscle disorder.

CLINICAL PRESENTATION

In infants and young children, symptoms include persistent vomiting (reflux), refusing to eat that leads to failure to thrive and weight loss, choking, gagging/retching, coughing and sometimes aspiration pneumonia, and apnea/bradycardia events (near-SIDS episodes) from laryngospasm. Sandifer syndrome includes facial asymmetry and spasmodic torticollis associated with GER and occurs when the child twists his or her head in an attempt to straighten the esophagus to promote clearance of the acid. In older children, the symptoms are similar to those seen in adults and include persistent heartburn, esophagitis and stricture, and, occasionally, Barrett's esophagus. Hoarseness or a chronic cough may be manifestations of acid-induced laryngeal edema. Many adolescents have been managed medically for several years prior to referral for operative therapy. Neurologic impairment is a significant comorbidity in infants and children. It is difficult to quantify the degree of neurologic impairment with the need for fundoplication. Many neurologic impaired children need a gastrostomy due to swallowing dysfunction. In this situation, a concomitant fundoplication should be considered. This is especially true in neonates and young infants in whom it is not clear if their clinical reflux will resolve spontaneously. In older children with neurologic impairment and no evidence of GERD, a gastrostomy alone is reasonable.

A recent paper looked at the incidence of the need for fundoplication in patients who initially underwent gastrostomy alone. A total of 684 patients from two different centers underwent gastrostomy alone between 2000 and 2008. Of these, 124 of the gastrostomies were performed using the open technique, 282 were performed laparoscopically, and 278 were performed using the percutaneous endoscopic gastrostomy technique. The mean patient age was 2.9 years. Subsequent fundoplication was performed in 62 of these patients (9.1%). Cerebral palsy and anoxic brain injury had the most significant correlation with the need for subsequent fundoplication

and were independent predictors for fundoplication. Interestingly, the laparoscopic gastrostomy approach had a negative correlation with the subsequent need for fundoplication.

Prior to an operation, nonoperative management is usually trialed. In addition to lifestyle changes such as changing the diet and either reducing the volume of feedings or thickening the feedings, positioning infants in a completely upright position, or even placing them prone, has been found to be helpful in some patients. In addition, several medications can also be trialed including antacids, histamine-2 receptor antagonists (H2RAs), and proton-pump inhibitors (PPIs). PPIs have been shown to have superior efficacy compared to H2RAs and antacids. These medications are able to increase the gastric pH greater than 4 for a longer period of time than the H2RAs. Also, the acid suppression ability of PPIs has not been found to diminish with chronic use. Ideally, the PPIs should be administered about 30 minutes after feedings. Prokinetic agents have also been tried, but these medications have been found to have significant side effects and are not used routinely.

INDICATIONS AND CONTRAINDICATIONS

As has been previously mentioned, most infants with GER do not require operative correction. Indications for fundoplication in infants include an apparent life-threatening event (ALTE) episode, weight loss and growth failure, the neurologically impaired infant who requires a gastrostomy, and the infant who develops aspiration pneumonia. In the patients under 6 months of age, in our experience, the two most common indications for fundoplication are the presence of GERD and growth failure, and the neurologically impaired infant who needs a gastrostomy. Another relatively frequent indication is admission to the hospital for an ALTE episode and the presence of GERD. In a report of 81 infants between 2000 and 2005 undergoing laparoscopic fundoplication for ALTE from Children’s Mercy, all but 3 patients had previously been treated with antireflux medication. Moreover, 71 infants (87.7%) were on antireflux medicines at the time of their ALTE. In this study, the median follow-up was 1,738 days. After fundoplication, only three patients (3.7%) experienced another ALTE. Two required a re-do laparoscopic fundoplication for transmigration of the fundoplication wrap, and one underwent pyloromyotomy for pyloric stenosis. None of these three experienced a recurrent ALTE.

For the patients between 2 and 5 years of age, the most common indication is failure to grow appropriately. For those patients older than 5 years of age, the most common reason for operation is failure of medical management. Included in these two older groups are patients with GER and pulmonary symptoms such as refractory airway disease, and recurrent aspiration with a chronic cough. Throughout all these age ranges, however, the neurologically impaired child who requires gastrostomy is often seen. It is the author's opinion that a neurologically impaired child older than 1 or 2 years of age who requires gastrostomy for poor oral intake but does not exhibit symptoms of GER should undergo gastrostomy alone, realizing that a small percentage will subsequently require fundoplication, but the majority will not. The more difficult question is in the neonate or infant in the intensive care unit with neurologic impairment who requires gastrostomy. As alluded to previously, in this particular patient population, fundoplication is usually recommended because of concern about protecting the airway from aspiration due to the reflux.

There really are no contraindications to a fundoplication. However, at some centers, an open fundoplication is preferred to a laparoscopic operation for the baby with significant heart disease and, especially, babies with single ventricle physiology. This is because of the deleterious physiologic effects of a pneumoperitoneum on venous return to the heart and cardiac output. Other centers feel the laparoscopic approach is beneficial in these patients due to a faster recovery from the operation. Also, some surgeons prefer a partial anterior fundoplication (Thal, Boix-Ochoa) to a Nissen fundoplication, especially in infants with esophageal atresia, as these infants have esophageal dysmotility. Other surgeons feel a loose, floppy Nissen can be constructed in these infants.

Finally, in very complicated patients, usually with significant neurologic impairment and three or four failed fundoplications, some surgeons have utilized a technique called esophago-gastric disconnection to control the reflux. The stomach and esophagus are disconnected, and jejunum is anastomosed to the esophagus in a Roux-en-Y fashion. A gastrostomy is placed in the stomach for feeding and decompression.

PREOPERATIVE PLANNING

Prior to referral to a pediatric surgeon, a pH study often has been performed. This study measures acid reflux and has a sensitivity around 90%. Although it has been assumed that the retrograde flow of acid from

the stomach into the esophagus is present in pathologic reflux disease, newer information indicates that alkaline reflux is quite common as well. This information comes from multichannel intraluminal impedance (MMI), which measures the flow of gastric contents into the esophagus by detecting decreases in impedance from high (the esophagus) to low (the stomach) across electrode pairs that are placed throughout the esophagus and stomach. Recent studies using MII suggest that the pH study may not be the best method of evaluating reflux disease as it only measures acid reflux, and many reflux episodes are actually non-acid reflux with a pH above 4. Therefore, MMI is being increasingly used to evaluate reflux disease in infants and children. Other tests that can be used in children include endoscopy with biopsy and bronchoalveolar lavage with evaluation of the lipid-laden macrophage index and the pepsin content.

An upper gastrointestinal (UGI) contrast study is often used to define the anatomy and ensure that there is no evidence of distal obstruction causing the symptoms. In a report from Children's Mercy, malrotation was found unexpectedly in 4% of the patients scheduled for fundoplication. The UGI study should not be used for diagnostic purposes as it has a sensitivity of only 30% to 50%. A gastric emptying study is usually not performed as a routine part of the preoperative evaluation in children. The reason is that fundoplication has been shown in many studies to enhance gastric emptying. Thus, it is difficult to interpret an abnormal gastric emptying study prior to fundoplication. In the author's experience, the gastric emptying study is only used in the rare patient in whom there is a strong suspicion of gastroparesis. However, it is a routine part of the evaluation for either recurrent symptoms or in the patient who needs a second operation. If there is evidence of delayed gastric emptying prior to a second procedure, then pyloroplasty should be considered. Certainly, for a patient undergoing a third operation, pyloroplasty is recommended. As mentioned previously, esophageal motility disorders are rarely seen in pediatric patients. Thus, esophageal manometry is infrequently used prior to fundoplication.

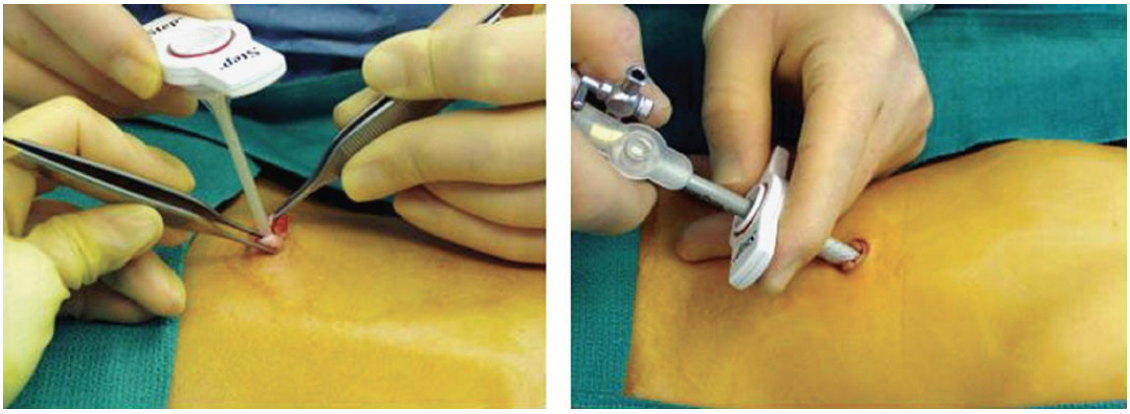

Figure 68.1. A direct cutdown through the center of the umbilical skin and fascia allows the surgeon to introduce an expandable Step sheath (**left**) without using a Veress needle. In this way, injuries from the use of a Veress needle are avoided in infants and small children. Following the introduction of the sheath, a blunt-tipped cannula is introduced through the sheath into the peritoneal cavity (**right**).

A number of operative concerns are peculiar to infants and children. The first concern is safe entry into the abdominal cavity. For this reason, the Veress needle technique is not utilized and the Step system (Covidien, Norwalk, CT) is preferred, especially for infants and young children. When using this system, after incising the center of the umbilical skin and fascia, an expandable sheet without the Veress needle is introduced directly into the peritoneal cavity. A cannula with a blunt tip trocar is then inserted through the sheath (Fig. 68.1).

For many operations, including fundoplication, because of the thin abdominal wall in infants and young children, it is possible to place the working instruments directly through the abdominal wall rather than using accessory cannulas (Fig. 68.2). This is especially advantageous for the instruments that will not be exteriorized and then reintroduced into the abdominal cavity during the operation. In addition to fundoplication, it can also be used for pyloromyotomy, splenectomy, esophagomyotomy, pull-through for Hirschsprung disease, and many other procedures. With this stab incision technique, the number of cannulas needed is reduced, resulting in significant cost savings to the institution and the patient.

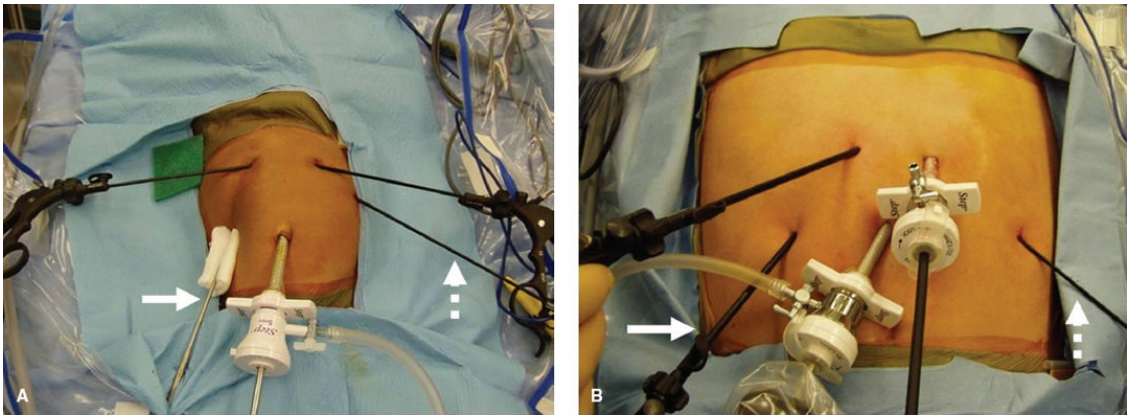

Figure 68.2. There are a number of ways to orient the instruments when performing a laparoscopic fundoplication. With our technique, the 45-degree angled 5-mm telescope is introduced following insertion of the 5-mm umbilical cannula. The liver retractor is introduced in the patient's right subcostal region (*solid arrow*). The two main working ports are in the left and right epigastrium. The main working port for the surgeon is the one in the patient's left epigastric region. It is through this incision that dissecting instruments, needle holder, and suture are introduced. The instrument utilized by the surgical assistant is in the patient's left subcostal region (*dotted arrow*). The stab incision technique can be utilized for both infants (**A**) and adolescents (**B**). (From Holcomb GW III. Laparoscopic Nissen fundoplication. In: Holcomb GW, Georgeson KE, Rothenberg SS, eds. *Atlas of Pediatric Laparoscopy and Thoracoscopy*. Philadelphia, PA: Saunders; 2008, with permission.)

An issue peculiar to children is the type of fundoplication that is performed and the use of a bougie to prevent dysphagia when complete fundoplications are performed. Some surgeons prefer the anterior fundoplication in all patients. The use of an anterior fundoplication has already been mentioned in infants with esophageal atresia. In experienced hands, successful repair can be achieved with an anterior fundoplication that is comparable to that achieved with the Nissen wrap. The main advantage of the anterior fundoplication is thought to be the patient's ability to burp or belch and the lack of symptomatic dysphagia. At the same time, in the author's experience, around 50% of the patients can burp/belch with an appropriately performed Nissen fundoplication, and the incidence of dysphagia is less than 1%. An appropriate sized bougie calibrated for the patient's weight can be used to prevent narrowing the lower esophagus with a Nissen fundoplication and helps prevent symptomatic dysphagia (Table 68.1).

SURGICAL TECHNIQUE

Laparoscopic Nissen Fundoplication

The patient is placed supine on the operating table. Infants and young children are placed at the foot of the table in a frog-leg position. The foot of the table is dropped so that the surgeon can stand at the foot of the table adjacent to the patient. The assistant stands to the surgeon's right and the scrub nurse to his or her left. For older patients in whom this technique is not possible, placement in stirrups is preferred, with the surgeon standing

between the patient's legs. A urinary catheter is not routinely introduced, but an orogastric tube is important to decompress the stomach during the operation. If a gastrostomy is also required, the site of the gastrostomy is marked in the left upper abdomen prior to insufflation. This site for the gastrostomy will be used for one of the stab incisions for the laparoscopic fundoplication.

A 5-mm incision is made in the umbilical skin and carried down through the umbilical fascia and peritoneum. Often an umbilical hernia is present in infants, enabling easy access to the peritoneal cavity in these small patients. Using the Step system, an expandable sheath is introduced through the umbilical incision into the peritoneal cavity (see Fig. 68.1). A 5-mm cannula with a blunt trocar is then introduced through the expandable sheath. CO_2 insufflation is initiated at a flow rate between 2 and 5 L/min, depending on the patient's size. A 5-mm, 45-degree angled telescope is inserted and diagnostic laparoscopy is performed. A 70-degree angled telescope is sometimes helpful for improved visualization, especially in small infants.

Four accessory stab incisions are then created (see Fig. 68.2). The first is in the patient's right subcostal region, through which the liver retractor is introduced and secured to the Thompson Rail Clamp (Thompson Surgical Instruments, Traverse City, MI), which is attached to the operating table. The next is in the patient's right epigastric region, through which the instrument used by the surgeon's left hand is inserted. This is usually an atraumatic grasping forceps. In the patient's left epigastrium (at the site of previously marked gastrostomy, if needed), another stab incision is made. A Maryland dissecting instrument connected to cautery is introduced through this site for use by the surgeon's right hand. In the left subcostal region, another stab incision is made through which an atraumatic grasping forceps is placed. This instrument is used by the assistant standing on the left side of the operating table.

The short gastric vessels are ligated and divided with the Maryland dissecting instrument connected to cautery in all patients to create a tension-free fundoplication (Fig. 68.3). The starting point is along the greater curvature of the stomach cephalad to the incisura. In older children, this dissection is performed with the 5-mm ultrasonic scalpel and a second 5-mm cannula is used in the left epigastric region. This dissection along the greater curvature proceeds to the esophageal hiatus. At the level of the esophageal hiatus, the area is carefully inspected. The results of a recently

completed prospective randomized trial have shown that minimal esophageal mobilization and dissection helps prevent the future problem of transmigration of the fundoplication wrap. Therefore, we now perform very little, if any, esophageal mobilization to prevent the postoperative migration of the wrap (Fig. 68.4). Minimal esophageal mobilization has not led to any deleterious effects regarding the efficacy of the wrap in preventing reflux. The retroesophageal space is now identified and entered from the patient's left side, as it is quite easy to visualize this anatomic region with the 45-degree telescope. A retroesophageal window is then created for passage of the fundus behind the esophagus.

An assessment is now made as to whether there is a significant hiatal hernia that needs to be repaired. In many children, there is a small hiatal hernia, which needs closure. Hiatal hernia repair is performed posteriorly with 2-0 silk suture in infants and young children and 0 silk suture in older children (Fig. 68.5). Usually, one suture is sufficient in younger children, but occasionally, two are required to close the crura around the esophagus. This second suture can be placed either anteriorly or posteriorly to the esophagus. However, it is important not to place these sutures too close to the esophagus, especially posteriorly, as they can narrow the esophagus and cause dysphagia. In order to prevent future transmigration of the fundoplication wrap through the esophageal hiatus after the operation and also to secure the lower esophagus in an intra-abdominal position, four 3-0 silk sutures were previously placed between the wall of the esophagus and the crura. These were placed at the 7, 11, 1, and 5 o'clock positions (Fig. 68.6). All sutures were tied intracorporeally. Now, following the results of a recently completed prospective randomized trial (which compared minimal esophageal dissection and mobilization along with the four esophageal crural sutures to minimal dissection/mobilization alone) that showed there was no advantage to these sutures, we no longer place these four esophagocrural sutures. However, we feel it is very important not to mobilize the intra-abdominal esophagus as this dissection disrupts the phrenoesophageal membrane that can lead to an increased incidence of wrap transmigration. The telescope is now rotated to the patient's right side, and the fundus of the stomach (on the patient's left) is visualized through the retroesophageal space. The fundus is then grasped, but is not brought through the retroesophageal space until the bougie has been introduced by the anesthesiologist. In infants and young children, the appropriate sized bougie is determined according to the patient's weight

(see Table 68.1). Care must be taken to watch as the anesthesiologist guides the bougie into the stomach so that perforation of the intra-abdominal esophagus or stomach does not occur. Once the bougie has been advanced into the stomach, the fundus is brought through the retroesophageal space and sewn to itself in a standard Nissen fundoplication fashion. To create the fundoplication, 2-0 silk sutures are used in younger patients and 0 silk sutures are used in older patients. A portion of the anterior esophageal wall is incorporated in the most cephalad suture. The posterior and anterior vagus nerves are both incorporated within the fundoplication wrap (Fig. 68.7). Usually three sutures are adequate, but occasionally four are needed to ensure a fundoplication length of 2 to 2.5 cm. Following creation of the fundoplication, its length is measured and documented. At this point, the bougie is removed.

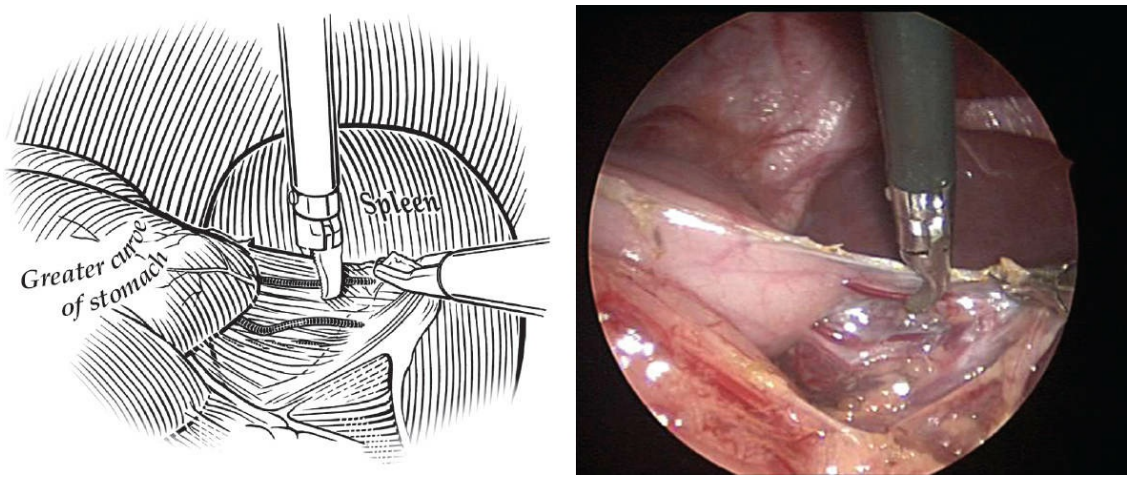

Figure 68.3. The first step in performing a laparoscopic fundoplication in an infant is ligation and division of the short gastric vessels. This is accomplished with cautery connected to a Maryland dissecting instrument. Ligation of these vessels is important in infants in order to create a loose, floppy wrap.

Gastrostomy

If a gastrostomy is also required because of feeding difficulty, the left epigastric incision is enlarged with a hemostat to approximately 5 to 6 mm in diameter. This also allows desufflation of the abdominal cavity so that the stomach can be more easily brought to the anterior abdominal wall. A silicone catheter is placed by the anesthesiologist into the stomach after removal of the bougie, and the stomach is insufflated with 30 to 60 cc of

air. A locking atraumatic grasping forceps is introduced through this left epigastric incision, and a segment of the anterior aspect of the greater curvature of the stomach is grasped and brought to the anterior abdominal wall. Two sutures of 2-0 polydioxanone (PDS, Ethicon Inc., Somerset, NJ) are placed extracorporeally, starting above the epigastric incision, proceeding through the peritoneum and the stomach, and then out through the peritoneum and anterior abdominal wall inferior to the epigastric incision. Each suture is secured with a hemostat. An 18-gauge needle is then introduced through the enlarged epigastric incision into the stomach (Fig. 68.8). Its correct location is confirmed by a rush of air out of the needle. A guidewire is inserted through the needle into the stomach and the needle is removed. A Cook Dilator Set (Cook, Inc., Bloomington, IN) is then used to dilate the tract prior to placing the gastrostomy button. Initially, an 8-French dilator is used to dilate the incision and gastrostomy, followed by 12-, 16-, and then 20-French dilators. Next, the 8-French dilator is introduced through the Mic-Key (Halyard Health, Inc., Alpharetta, GA) gastrostomy button to aid in the placement of the button over the guidewire and into the stomach. Usually, a 12- or 14-French, 0.8-cm button is used in infants, and larger and longer buttons are used in older children. After the gastrostomy button is introduced into the stomach over the guidewire, the balloon is inflated under direct visualization (Fig. 68.9). The dilator and guidewire are then removed from the lumen of the Mic-Key button. Following inflation of the balloon on the button, air is inflated through the button and withdrawn to confirm the button is intragastric. The extracorporeal sutures are then tied over the button to secure the button to the anterior abdominal wall (Fig. 68.10). These sutures are usually cut in 5 days.

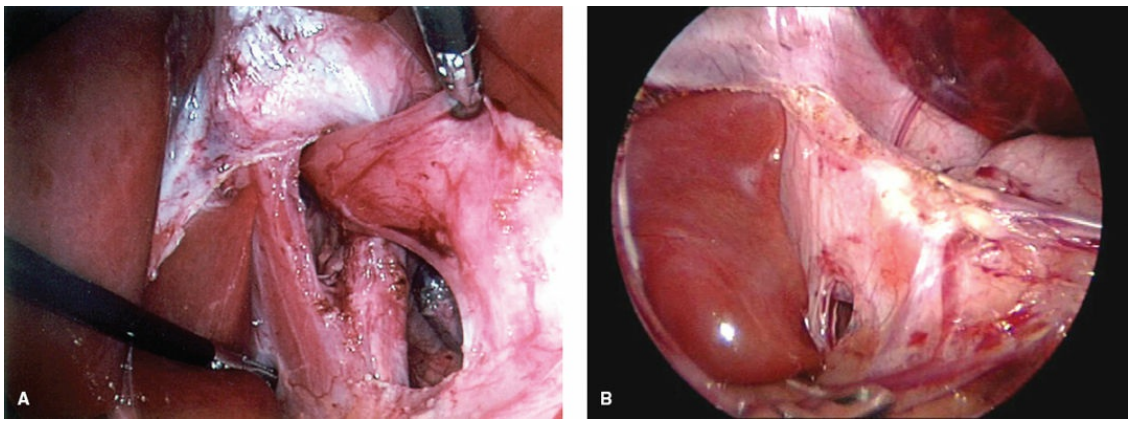

Figure 68.4. There is concern that extensive esophageal dissection and mobilization (**A**) may lead to an increased

incidence of postoperative transmigration of the fundoplication wrap. This concern was initially found in a retrospective review and has been confirmed in a prospective randomized trial. Therefore, our current technique is to perform minimal esophageal dissection and mobilization (**B**) in order to keep the phrenoesophageal membrane intact for the purpose of preventing postoperative wrap transmigration.

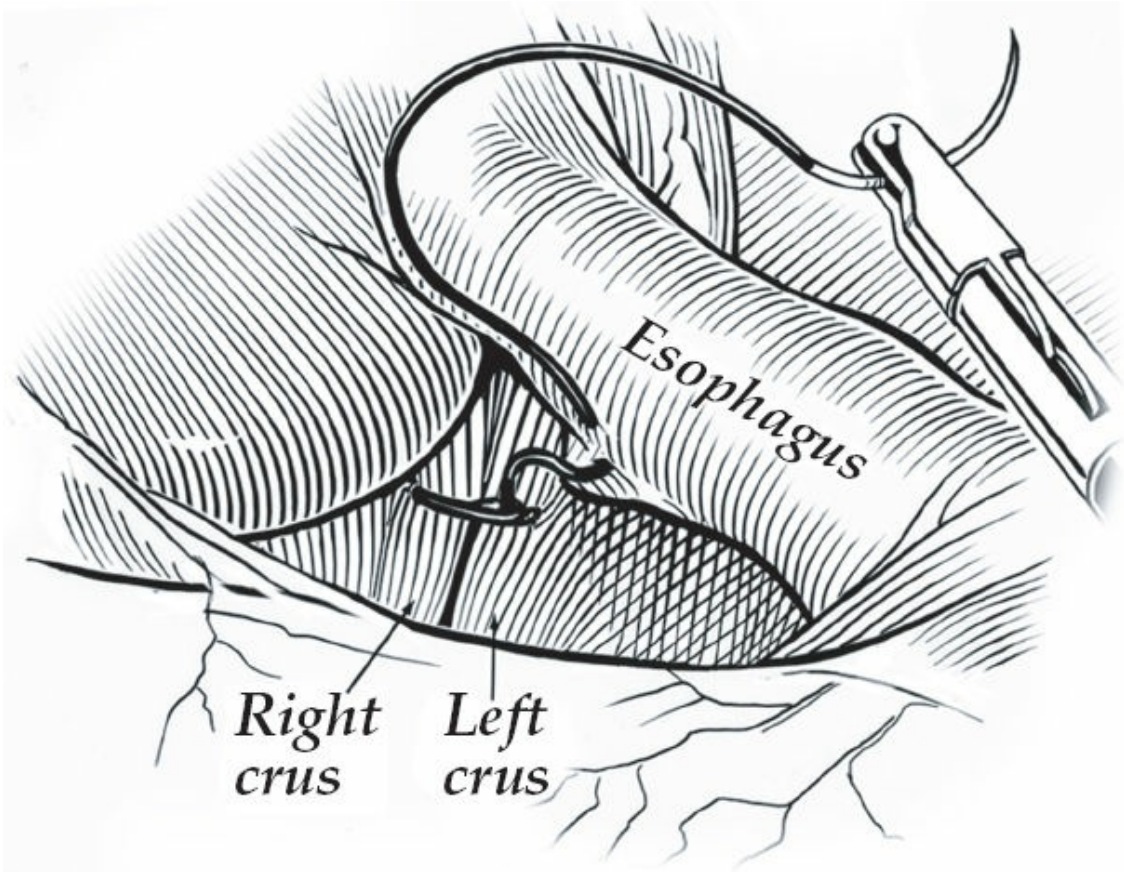

Figure 68.5. Closure of the posterior crura is accomplished with a 2-0 silk suture in infants and 0 silk suture in older children. Also, a portion of the esophagus at ~ 7 o'clock position is often secured with the same stitch in order to help close the hiatal defect posteriorly.

All instruments are then removed and 0.25% bupivacaine is instilled in the incisions for postoperative analgesia. The umbilical fascia is closed with 3-0 absorbable suture in infants and young children, and a larger suture is used in older patients. The umbilical skin is closed with interrupted 5-0 plain catgut sutures in all patients, as these sutures will resorb and will allow drainage if an infection develops. In infants and young children in whom 2.7-mm instruments are used, the skin is

approximated with Steri-strips (3M, St. Paul, MN) as shown in Figure 68.10. If 5-mm instruments were used in older patients, the skin incisions are closed with 5-0 absorbable sutures followed by placement of Steri-strips. A rolled gauze and sterile dressing are placed over the umbilicus. Collodion is used to cover the other incisions.

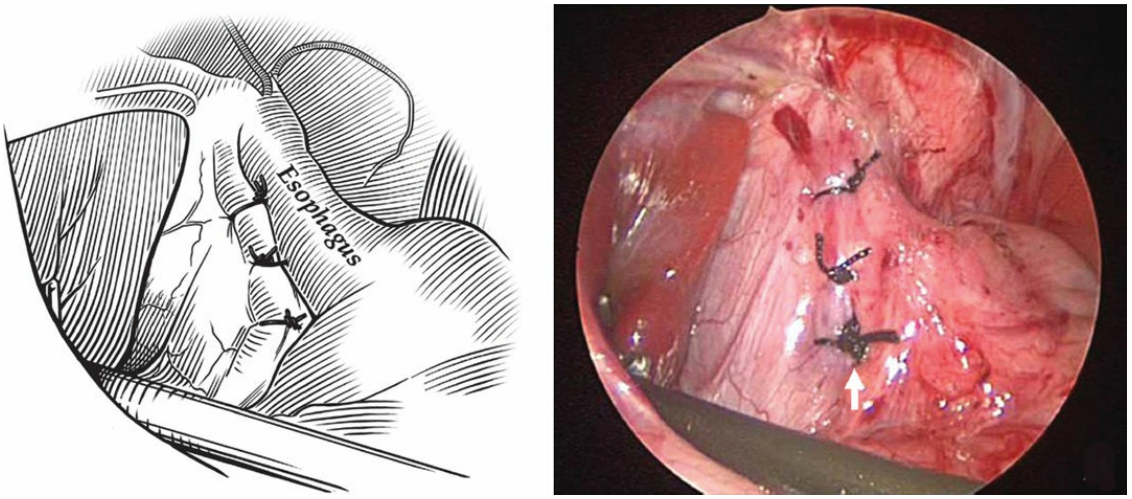

Figure 68.6. The 3-0 silk sutures are used to secure the esophagus to the crura. The photograph depicts these esophagocrural sutures at the 7 and 11 o'clock positions along the right side of the esophagus. Note the suture used to close the crura can also be seen (*arrow*).

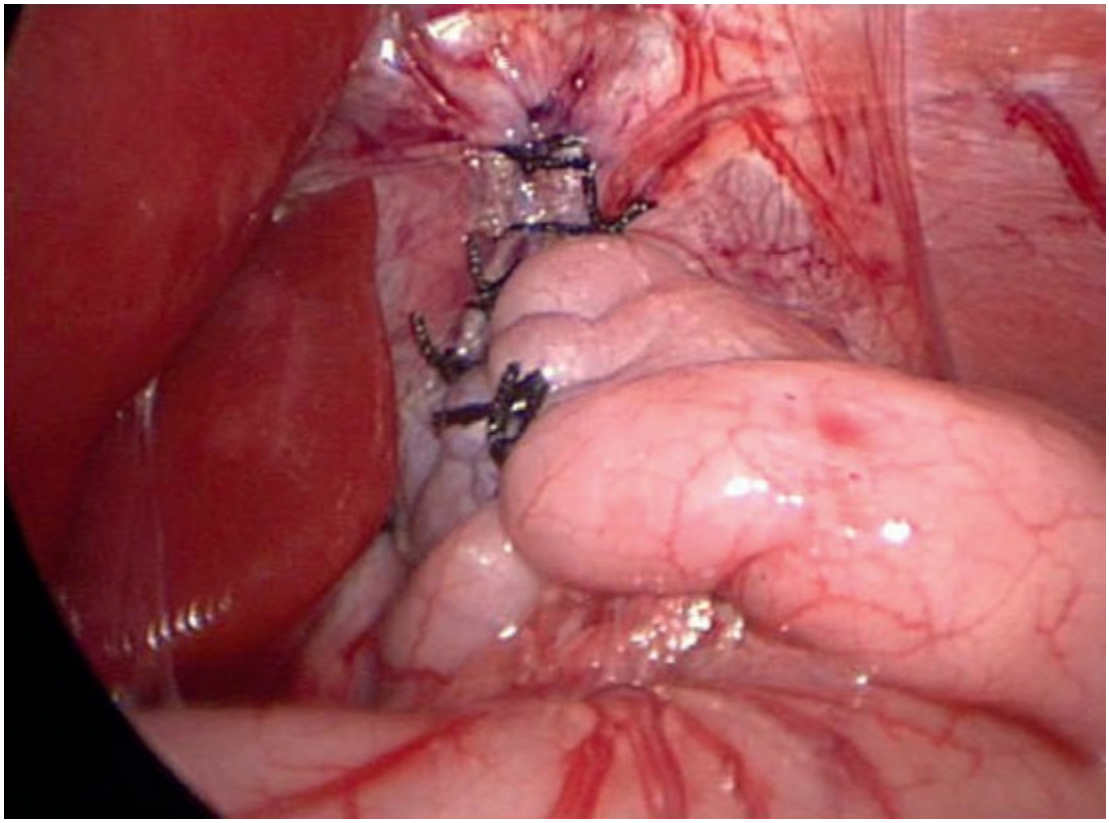

Figure 68.7. Ideally, the suture line for the fundoplication should reside at ~10 or 11 o'clock position as this indicates that the fundoplication is more anteriorly positioned over the esophagus rather than brought through the retroesophageal window posteriorly. The concern with a suture line that is at the 1 or 2 o'clock position is that more of the stomach is brought posteriorly that may cause dysphagia.

Open Fundoplication

The principles of fundoplication performed through the open approach are similar to the laparoscopic operation. Generally, most surgeons prefer an upper midline incision, although some surgeons use a subcostal incision if the child has a broad costal margin. Once the abdominal cavity is entered, the left triangular ligament of the liver is incised that allows the left lobe to be retracted toward the right. A Thompson retractor is helpful for exposure in the open approach. The same operative steps are performed as described for the laparoscopic fundoplication. The short gastrics are divided with cautery or 4-0 silk ties. Minimal dissection of the esophagus is also employed with the open approach as in the laparoscopic operation. The retroesophageal space is opened and sutures are placed in the crura posteriorly if a significant hiatal hernia is present. The bougie is passed

followed by creation of the Nissen fundoplication in a similar manner as described for the laparoscopic operation. The 2-0 and 0 silk sutures are used to create the fundoplication as described previously. The linea alba, subcutaneous tissue, and skin are then closed.

POSTOPERATIVE CARE

Patients are admitted following their operation. If the patient underwent a laparoscopic fundoplication and requires gastrostomy feedings, these are usually initiated 6 to 8 hours following the operation at a low flow and low concentration. The volume and consistency of these feedings can be advanced over a 24-hour period and further advanced when the patient is discharged. If the patient does not require gastrostomy feedings, clear liquids in older patients and formula in infants are initiated the night of the operation. A mechanical soft diet begins the following day in older patients. The mechanical soft diet is usually continued for 3 weeks. In explaining this diet to parents and older children, it is best to describe a soft diet as almost any food but pieces of meat, pizza, or toast. With such a feeding regimen, only one patient among over 900 laparoscopic fundoplications performed by the author has required postoperative dilation for dysphagia.

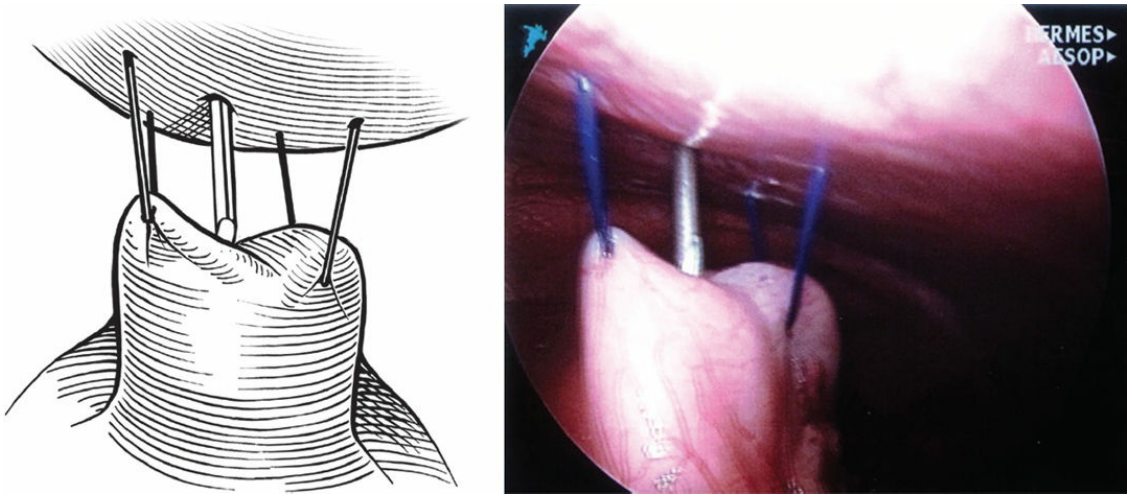

Figure 68.8. Two sutures of 2-0 or 0 PDS (depending on the patient's age) are placed extracorporeally through the abdominal wall, through the stomach, and out through the abdominal wall inferior to the gastrostomy. These sutures are seen on the operative photo and schematic. An 18-gauge needle is then introduced through the left epigastric incision and into the stomach under direct visualization. Following a rush of air

through the needle, a guidewire is placed through the needle and the needle is removed.

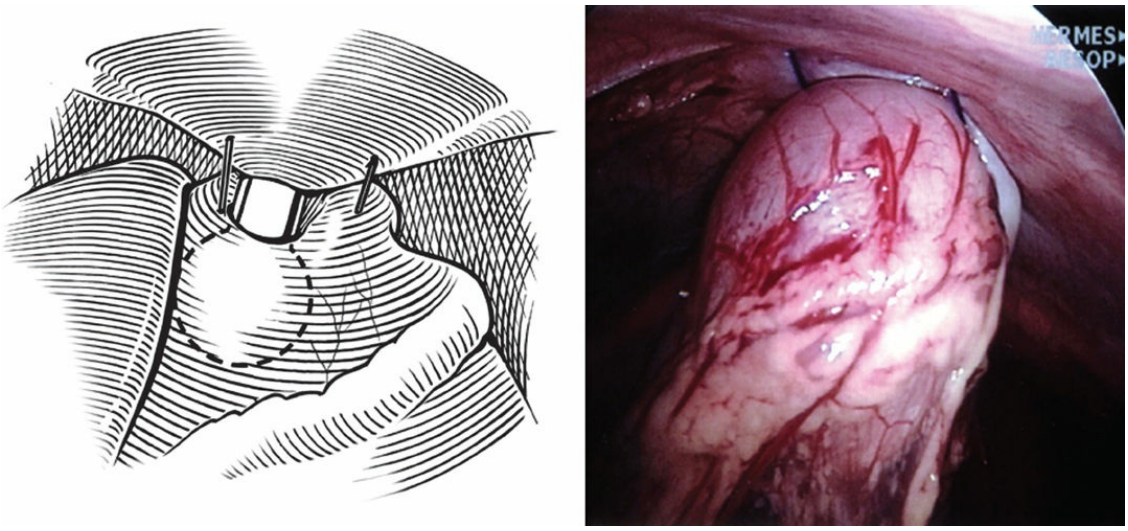

Figure 68.9. After serial dilations of the abdominal wall tract and gastrotomy, the gastrostomy button is introduced over the guidewire and into the stomach. This drawing and operative photograph show the gastrostomy button in the stomach with the balloon inflated.

Figure 68.10. Steri-strips have been used to approximate the remaining three stab incisions. The gastrostomy button has been placed through the left epigastric stab incision. The umbilical fascia has been closed with 3-0 absorbable sutures and the umbilical skin has been closed with 5-0 plain sutures.

With the open operation, an ileus is more likely, so this feeding

schedule is usually started the first postoperative day and similarly advanced. Most patients undergoing the laparoscopic operation are ready for discharge on the first postoperative day. Patients having the open fundoplication are usually more complicated and are in the hospital for 2 to 4 days. All patients are instructed not to allow the incisions to become wet for five days. Older children are asked to restrain their activities for two weeks. At that time, they are seen for a postoperative evaluation, and unrestricted activity is initiated if complications have not developed.

COMPLICATIONS AND THEIR MANAGEMENT

In our experience, as previously discussed, dysphagia is not a common postoperative problem. Wound problems are almost nonexistent with the laparoscopic approach. In several large series of patients undergoing fundoplication (either laparoscopic or open), the need for a second fundoplication varies between 5% and 15%. In many centers with a large experience, the primary reason in infants seems to be transmigration of the fundoplication wrap into the lower chest, thereby limiting the effectiveness of the wrap. As mentioned, one reason may be that the infant's esophagus is short relative to the length of the baby. Therefore, although the fundoplication is intact, it may migrate through the esophageal hiatus due to retraction of the short esophagus.

We performed a recent retrospective review of all patients who underwent laparoscopic Nissen fundoplication at Children's Mercy from 2000 to 2013 and subsequently required a redo operation for recurrence. A total of 796 patients underwent laparoscopic fundoplication during that time. Of these, 82 patients (10.3%) required reoperation during the study period. The mean age at the patient's initial fundoplication was 1.8 ± 3.6 years. Of these 82 patients, 15 (18.3%) required more than one reoperation. Of the 102 reoperations performed, 68 were successfully managed laparoscopically, 31 were performed open from the outset, and 3 started laparoscopically, but required conversion. In those requiring more than one reoperation, there was no difference in age, weight, use of mesh, or time to subsequent reoperation compared with patients who only required one redo procedure.

In analyzing this dataset, 512 patients underwent Nissen fundoplication prior to 2009, of which 70 (13.7%) required reoperation compared with 12 patients of 284 patients (4.2%) who underwent their initial operation after 2009. This was a significant decrease ($p < 0.01$) in the incidence of

reoperation after 2009. Also, there was a significant change in the indication for reoperation after the change in operative technique mentioned previously. Prior to the use of minimal mobilization and the four esophagocrural sutures, wrap transmigration was the primary indication for reoperation (Fig. 68.11). After transitioning to minimal esophageal dissection and mobilization at time of initial operation, wrap disruption became the primary reason for recurrent reflux and the need for reoperation (Table 68.2).

Laparoscopic redo fundoplication following an initial open fundoplication is certainly more difficult, but can be performed. At the time of redo fundoplication, a wide and patulous esophageal hiatus should be anticipated in a patient with transmigration of the wrap. Therefore, an important part of the operation is closure of the enlarged hiatus. Some surgeons close the enlarged hiatus with interrupted silk or other nonabsorbable sutures followed by the fundoplication. Other surgeons believe that reinforcement of this hiatal closure is important to help prevent breakdown of this repair that can occur because of the tension that results from approximating the edges of the hiatus. Therefore, at the time of redo fundoplication for wrap transmigration, whether it is performed open or laparoscopically, a piece of Surgisis can be placed on the abdominal side of the hiatal closure to reinforce the crural closure and help prevent another wrap transmigration (Fig. 68.12).

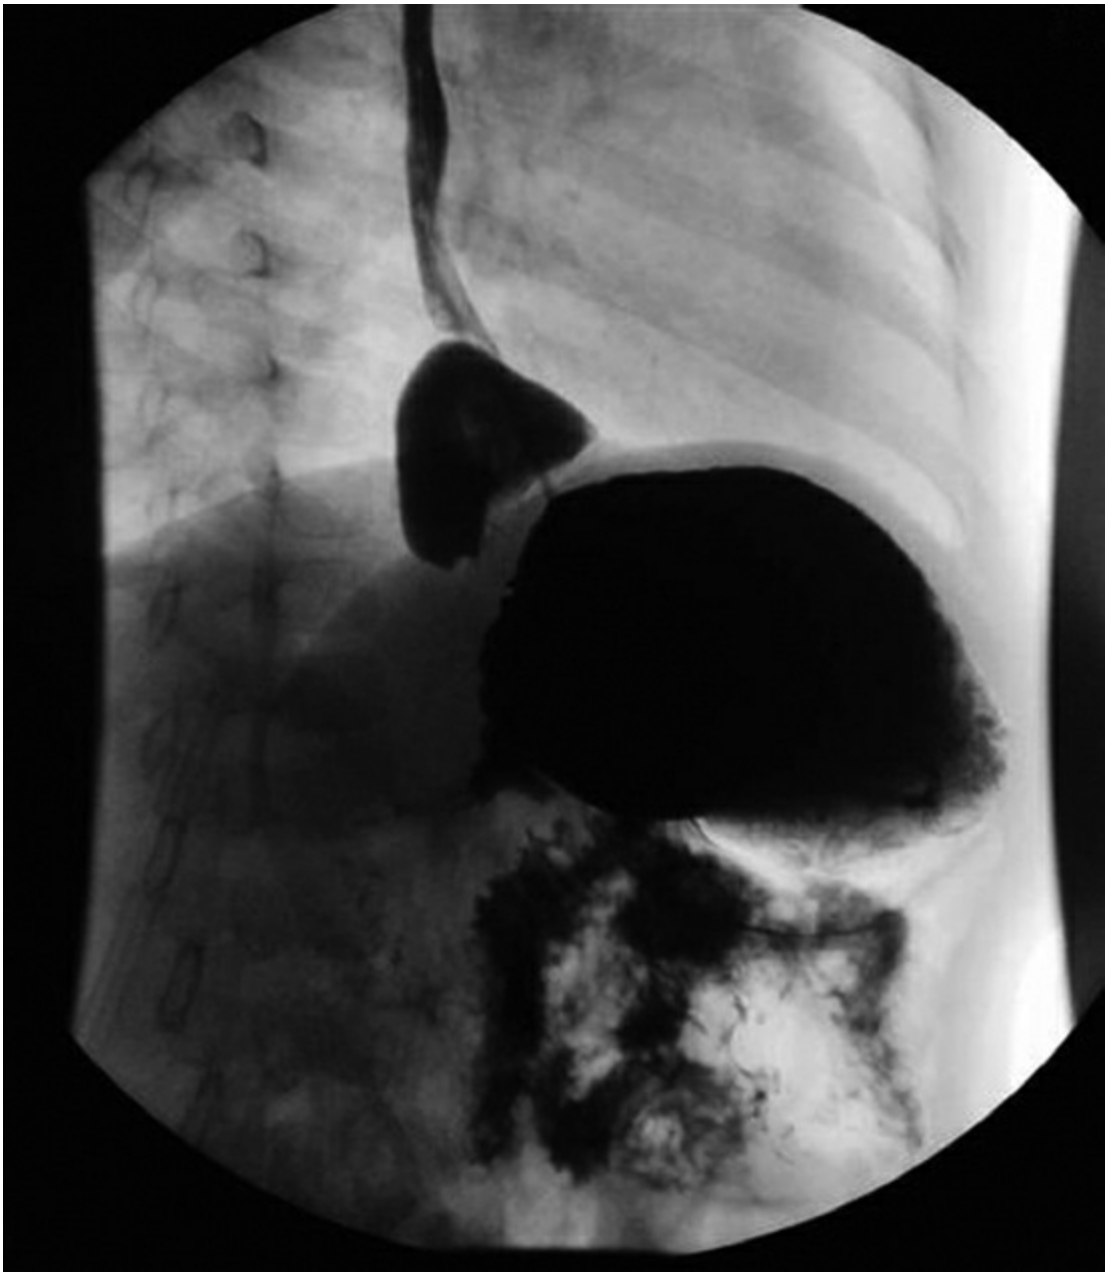

Figure 68.11. At our institution, almost all patients requiring a second fundoplication do so because of transmigration of the fundoplication wrap causing symptomatic gastroesophageal reflux. In our experience, it is unusual for a patient to have breakdown of a wrap that is located intra-abdominally. On this contrast study, the wrap is located in the lower mediastinum.

OUTCOMES

The outcomes following laparoscopic fundoplication are very comparable to the open approach. There are no prospective studies comparing either a partial versus a complete fundoplication or medical management versus surgical therapy for infants and children with GER. Two small prospective

randomized trials have compared open and laparoscopic Nissen fundoplication in children. In one study, 20 children were randomized to open and 19 were randomized to laparoscopic Nissen fundoplication. The mean follow-up in both groups was 4.1 years. Most of the children were neurologically impaired. The incidence of recurrent GER was 12.5% in the open group, and 20% in the laparoscopic group (p = NS). One patient in each group required a redo fundoplication. It was felt that both approaches provided similar control of reflux and a similar quality of life at follow-up. Interestingly, the laparoscopic approach was associated with a reduced incidence of retching at 4-year follow-up. A second study randomized 29 patients between the two approaches. The purpose of this study was to examine inflammatory markers to see if there was a reduction in inflammatory markers in the laparoscopic group. The authors found that there was not a substantially less inflammatory response in the laparoscopic group when compared to the open group in children undergoing Nissen fundoplication. Outside the two prospective trials, most of the known data have been generated from large retrospective studies of both open and, more recently, laparoscopic operations.

TABLE 68.2 Comparison of Patients Prior to and after Change in Surgical Technique

	Initial Surgery		
	Prior to 2009 (n = 512)	After 2009 (n = 284)	P value
Patients requiring reoperation	70 (13.7%)	12 (4.2%)	<.01
Indications for reoperation			
Wrap transmigration	55 (78.5%)	4 (33.3%)	<0.01
Wrap disruption	4 (5.7%)	6 (50%)	<0.01
Recurrent reflux symptoms	1 (1.4%)	2 (16.6%)	0.06
Emergency conditions	4 (5.7%)	0	1.0
Time (years) to first reoperation	2.5 ± 2.6	1.7 ± 1.4	0.3
Patients with >1 reoperation	13	2	1
Mesh at first reoperation	33	4	0.5

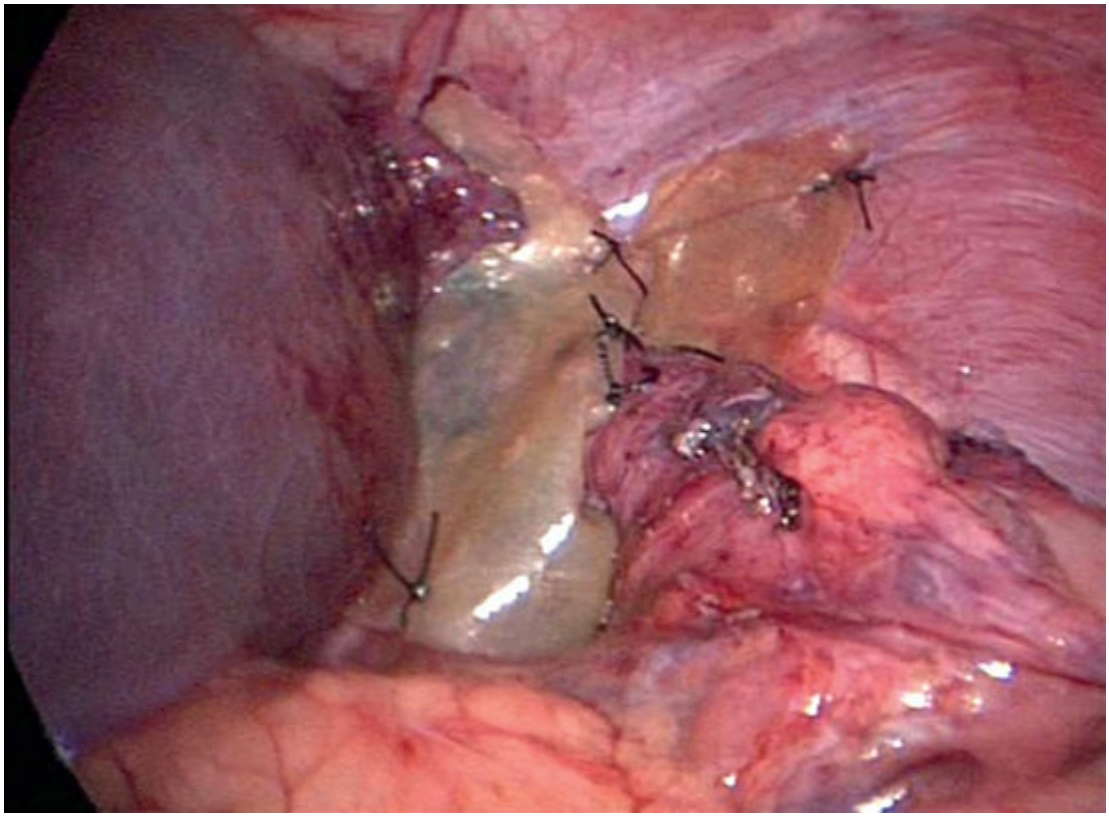

Figure 68.12. This intraoperative photograph shows the Surgisis Gold, which has been wrapped around the esophagus and is sewn to itself anterior to the esophagus. The Surgisis Gold is secured to the esophagus medially and the diaphragm laterally with interrupted 3-0 silk sutures. It is employed to help reinforce the closure of the crura at the time of redo fundoplication. (Reprinted from St. Peter SD, Ostlie DJ, Holcomb, GW III. The use of biosynthetic mesh to enhance hiatal repair at the time of re-do Nissen fundoplication. *J Pediatr Surg* 2007;42(7):1298–301. Copyright © 2007, with permission from Elsevier.)

When looking at the outcomes following fundoplication in infants and children, it is important to understand the patient population. Unfortunately, patients with neurologic impairment are commonly seen by pediatric surgeons for a fundoplication and gastrostomy. The gastrostomy is needed because of the neurologically impaired child's inability to take his or her oral feedings well without oropharyngeal aspiration. The fundoplication is often required because of that child's inability to protect his or her airway from GER and subsequent pulmonary aspiration.

As mentioned, fundoplication seems to be very efficacious in preventing GER based on clinical follow-up. Because of the invasiveness of most tests for reflux, routine pH studies or esophagoscopy and biopsy

are usually not performed in the postoperative period. Therefore, postoperative evaluation is almost entirely clinical. However, because of the nature of this patient population, parents are quite perceptive regarding their child's symptoms and will usually alert their surgeon with any concerns about recurrent reflux. There were several large series in the 1980s describing outcomes for patients undergoing open fundoplication. In general, the need for redo fundoplication was 5% to 15%. Our group at Children's Mercy has been particularly interested in improving outcomes following laparoscopic fundoplication. In a personal series (GWH) between January 2000 and March 2002, 130 patients underwent laparoscopic fundoplication with an incidence of postoperative transmigration of the fundoplication wrap of 12%. At that time, two changes were made in the operative technique. One was to change from fairly extensive esophageal dissection and mobilization to minimal, if any, esophageal dissection and mobilization in order to keep the phrenoesophageal membrane intact and to prevent postoperative wrap transmigration. In addition, the esophagus was secured to the hiatus using 3-0 silk sutures at four sites (8, 11, 1, and 5 o'clock as viewed by the surgeon). This dropped the incidence of transmigration to 5% ($p = 0.072$) in the next 119 patients. In this study, the relative risk of transmigration with extensive esophageal mobilization and without the esophagocrural sutures was 2.29. Based on this retrospective study, our technique changed dramatically to utilizing minimal esophageal dissection and mobilization, and employing the four esophagocrural sutures.

In 2010, our group, along with the pediatric surgical group at the University of Alabama, published a prospective, randomized trial evaluating this concept of minimal esophageal mobilization versus extensive mobilization to validate the previous retrospective findings. In this trial, the primary outcome variable was postoperative wrap transmigration. Based on the previous retrospective review just described, 360 patients were planned to be enrolled in this prospective study with an alpha of 0.05 and a power of 0.8. The large number of patients was needed due to the double randomization sequence (extensive esophageal dissection/mobilization vs. minimal dissection/mobilization and neurologically impaired vs. neurologically normal patients). All patients received four esophagocrural sutures as previously described. Between February 2006 and May 2008, 177 patients were enrolled at the two institutions. There were no differences in demographics or operative time.

One year mortality was 7.8% in the minimal dissection group and 6.9% in the extensive dissection group ($P = 0.99$). There was no mortality related to the operation. In this study, in contrast to previous protocols, a contrast esophagram was performed in all patients at 1-year follow-up to evaluate whether or not transmigration of the wrap had occurred. After approximately half of the patients had been enrolled, an interim analysis was performed. There was a significantly higher transmigration rate of 30% in the patients undergoing extensive esophageal dissection when compared to the transmigration rate in the minimal esophageal mobilization group (7.8%; $P = 0.002$). Also, the need for a redo fundoplication was markedly higher in the patients undergoing the extensive esophageal mobilization (18.4%) when compared with the minimal esophageal dissection group (3.3%; $P = 0.006$). Because the outcomes were significantly different, it was felt unethical to continue the study and the study was closed at the time of the interim analysis when almost half the calculated patients were enrolled. This Level 1 evidence indicates that minimal esophageal mobilization with the use of the four esophagocrural sutures decreases postoperative wrap transmigration and the need for a second fundoplication.

A second prospective randomized trial has recently been completed at Children's Mercy. In this study, 120 patients participated comparing minimal esophageal dissection/mobilization along with the four esophagocrural sutures described previously to minimal esophageal dissection/mobilization without these esophagocrural sutures. Patient demographics were similar between groups. The operative time was significantly longer in the patients with the esophagocrural sutures. No patient in either group developed transmigration of the fundoplication wrap at 2-year follow-up. Thus, it is felt these esophagocrural sutures are not necessary if there is minimal to no esophageal dissection and mobilization.

EDITOR'S COMMENT

Gastroesophageal reflux (GER) is physiologically normal and occurs in all infants; however, when reflux causes troublesome clinical symptoms (i.e., an aspiration pneumonia, an apparent life-threatening event (ALTE), failure to thrive) or complications (endoscopically documented esophagitis, Barrett esophagus, stricture), GER disease (GERD) is present. Because symptoms vary according to age group and coexisting conditions, pediatric GERD is a complex topic with a spectrum of manifestations. The understanding and management of pediatric GERD continue to evolve integrating both medical and surgical options into treatment algorithms. The authors present an excellent overview of pediatric GERD encompassing pathophysiology, indications for surgical intervention, level I data supporting technical details how best to perform an antireflux procedure, and outcomes. The improvement in technical aspects of the surgical procedure, based off prospective randomized surgical studies conducted in large part by the pediatric surgery clinical research team at Mercy Children's Hospital in Kansas City led by the author GWH, is level I data and

although important illuminates an issue of greater importance—the need for properly designed clinical studies to better determine the optimal management of pediatric GERD. Although an antireflux procedure is one of the most common pediatric surgical procedures performed, analysis of the effectiveness of antireflux procedures performed in children is challenging as reported studies vary by the heterogeneity of patient cohorts (e.g., neurologically impaired, after esophageal atresia, broad age range), the indications for surgery, and the lack of a standardized reporting framework for operative technique. A recent systematic review by the American Pediatric Surgical Association's Outcomes Committee (Jancelewicz T, Lopez ME, Downard CD, et al. Surgical management of gastroesophageal reflux disease [GERD] in children: a systematic review. *J Pediatr Surg* 2016 Oct 14. pii: S0022–3468(16):30460–2.) highlights the many aspects of pediatric GERD in which there is a lack of high-quality evidence supporting the current "standard of care" treatment approaches utilized to treat pediatric GERD. The conclusion of the systematic review recommends a paradigm shift in which the focus is placed on better definitions of the disease process, more clearly defined indications for intervention, interventions in more uniform cohorts, and longer-term follow-up, possibly through registries.

From the perspective of better definitions of the disease process, there is a need for the widespread adoption of standardized diagnostic algorithms based on presenting symptoms to aid in categorizing indications for surgery. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition guidelines published in 2009 serves as an excellent template for the standardization (Vandenplas Y, Rudolph CD, Di Lorenzo C, et al. Pediatric gastroesophageal reflux clinical practice guidelines: joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition [NASPGHAN] and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition [ESPGHAN)]. *J Pediatr Gastroenterol Nutr* 2009;49(4):498–547). In the guidelines, treatment algorithms based according to age group (infant vs. older child/adolescent) symptom complex (recurrent emesis, failure to thrive, heartburn, exacerbation of reactive airway disease), complications (esophagitis, Barret's Esophagus), and coexisting conditions (neurologically impaired, esophageal atresia, others) were defined. Within the treatment algorithm were recommendations for when diagnostic interventions such as contrast studies, upper endoscopy and biopsy, pH monitoring, and multiple intraluminal impedance monitoring (MII, which has largely supplanted pH monitoring) should be utilized. By standardizing the diagnostic evaluation, a better understanding of the disease process can be achieved and with it will come more homogeneous cohorts of patients who require treatment for GERD. In so doing, the efficacy of treatment interventions be they medical or surgical can be better assessed. It is uncertain whether those guidelines are being uniformly applied across the pediatric medical community.

In the APSA Outcomes committee systematic review, an analysis on the effectiveness of an antireflux procedure in alleviating symptoms of GERD was

performed and in a consistent fashion, for symptoms ranging from the somewhat subjective—cough, emesis, heartburn to the more clinically significant consequences of an aspiration pneumonia or an ALTE, found a lack of level I or II data supporting efficacy. Nearly all studies were based on institutional experience with varied indications, sample sizes, lack of standardization, and perhaps most concerning, inadequate longitudinal follow-up. When they reviewed the literature for studies focused on efficacy using objective measurements of GERD such as pH monitoring or MMI, there was evidence that antireflux procedures reduced reflux episodes, acid exposure, and impedance values but the studies were underpowered or also had inadequate long-term follow-up. When evaluating efficacy based on age, a population of patients who require particular attention is the neonate/infant group in which an antireflux procedure is performed, the most vulnerable of populations who have longest of long-term consequences. In a review by Pacilli et al. (*Semin Pediatr Surg* 2005;14(1):34–41) focused on this population, multiple studies were combined (with all the attendant limitations of such a combined analysis—single institution retrospective studies subject to selection, attrition, and reporting bias with significant heterogeneity of the indication and patient population) and found that the overall success rate of fundoplication in neonates and infants, defined as a proportion of patients with *subjective* improvement of symptoms, ranged from 67% to 100%, and the incidence of redo fundoplication was 7% to 26%. Clearly, there is a need for better age and efficacy-based studies with more objective assessments in a patient population that has a lifetime ahead of them with such long term consequences.

When one considers the coexisting conditions that may predispose a child to have GERD and how the coexisting condition may impact the efficacy of a fundoplication, more uncertainty is present. As the authors of the chapter mention, the role of an antireflux procedure in the neurologically impaired patient who requires a gastrostomy tube for feeding access has evolved. Abnormal esophageal motility and function of the gastroesophageal sphincter complex with reflux of gastric contents are seen in up to 75% of patients with neurologically impaired. In the past, it was common in a neurologically impaired patient to offer an antireflux procedure while placing a g-tube as the patient “needed” it—resulting in estimates that 40% of the antireflux procedures performed in children were done in this context (Lasser MS, Liao JG, Burd RS. National trends in the use of antireflux procedures for children. *Pediatrics* 2006;118:1828–35). Critical analysis of the literature does not support this approach as an antireflux procedure could engender more complications especially in the neurologically compromised that also have a seizure disorder. The increase abdominal pressure that occurs with seizures can cause the Nissen to “slip” into the chest, which limits the effectiveness of the wrap, may cause dysphagia, and ultimately may require reexploration and revision. A Cochrane review focused in 2013 focused on this population concluded “there remains considerable uncertainty regarding the optimal treatment when faced with the

decision of fundoplication surgery versus antireflux medications for children with GERD and neurologically impaired who are undergoing gastrostomy insertion" (Vernon-Roberts A, Sullivan PB. Fundoplication versus postoperative medication for gastro-oesophageal reflux in children with neurological impairment undergoing gastrostomy. *Cochrane Database Syst Rev* 2013;8:CD006151). As the authors recommend, the routine inclusion of an antireflux procedure when placing a gastrostomy tube can no longer be supported. What is needed is a properly designed prospective trial with adequate longitudinal follow-up in patients with NI comparing fundoplication with gastrostomy versus gastrojejunal tube feeds.

The authors nicely present the details on how they perform an antireflux procedure where they favor a Nissen 360-degree wrap. The level I evidence they generated were important advances and brought to bear clinical research methodology to a surgical procedure; however, as the authors note, there are multiple variants on how best to perform an antireflux procedure including the Nissen 360-degree "complete" wrap, a Thal 180-degree anterior "partial," and the Toupet 180-degree posterior "partial" fundoplication. Interestingly, a group from the United Kingdom has reported level I data comparing outcomes following a complete (Nissen) versus a partial (Thal) in pediatric patients under 21 with a 2.5-year follow-up and found that the complete wrap was more effective but caused more dysphagia and recommended a partial wrap for neurologically intact children with refractory GERD and favor complete fundoplication for NI children (Kubiak R, Andrews J, Grant HW. Long-term outcome of laparoscopic Nissen fundoplication compared with laparoscopic Thal fundoplication in children: a prospective, randomized study. *Ann Surg* 2011;253(1):44–9). More studies like this are needed to document the efficacy of the alternative techniques.

As with many aspects of pediatric general surgery, the utilization of the laparoscopic approach was integrated into antireflux procedures quite quickly and has become the "standard of care." In the APSA outcomes committee review, an analysis of the literature comparing the open versus laparoscopic approach found two underpowered trials, several cohort studies, and multiple retrospective reports. In one of the underpowered trials (poor accrual resulted in the closing of the study prior to reaching an acceptable number of patients) conducted by a team in Norway, 88 children with GERD confirmed by 24-hour pH probe were randomized to undergo laparoscopic or open Nissen fundoplication (Knatten CK, Fyhn TJ, Edwin B. Thirty-day outcome in children randomized to open and laparoscopic Nissen fundoplication. *J Pediatr Surg* 2012;47:1990–6). The primary outcome measure of GERD recurrence was unable to be assessed; however, analysis of secondary outcomes found no difference in early postoperative complications between the two groups indicating laparoscopic Nissen was a viable alternative. Of concern was a follow-up analysis from that study in which the investigators observed a much higher GERD recurrence rate after laparoscopic versus open Nissen (Fyhn TJ,

Knatten CK, Edwin B, et al. Randomized controlled trial of laparoscopic and open Nissen fundoplication in children. *Ann Surg* 2015;261:1061–7). This and other similarly challenged studies led the APSA outcomes committee to reach the conclusion that laparoscopic fundoplication may be comparable to open fundoplication with regard to short-term clinical outcomes; however, long-term effectiveness data remain to be determined.

An important and seemingly obvious consideration is what the long-term complications are after an antireflux procedure performed in a child. Review of the literature indicates that operation to redo or repair the fundoplication after wrap failure is the most often reported adverse event followed by recurrent, new, or persistent symptoms, need for antacid/antireflux medications, abnormal and least commonly mortality. Because of the heterogeneity of the studies, there is no clear consensus as to what defines treatment failure and in that context, difficult to assess long-term complications in a patient population that has a long-term perspective. What is needed is a properly designed longitudinal follow-up study that would allow us to properly inform a family what the long-term challenges are for a patient who undergoes an antireflux procedure in childhood.

Pediatric GERD is a challenging process with long-standing established approaches that are often best practice/institutionally based. The decision when surgical intervention requires multidisciplinary input between the family, surgeon, pediatric gastroenterologist, and the primary pediatric team delivering care. Studies in the future must focus on who best benefits from an antireflux procedure along with longer follow-up to ensure efficacy. As the APSA outcomes committee review concludes, “Until a paradigm shift is realized, management of gastroesophageal reflux in children will remain largely based on anecdotal experience and institutional practice patterns.”

SECTION VII

THE GASTROINTESTINAL TRACT

A THE ESOPHAGUS

69 The Anatomy of the Esophagus

Toni Lerut, Willy Coosemans, Herbert Decaluwe, Georges Decker, Paul De Leyn, Lieven De Pypere, Philippe Nafteux, Dirk Van Raemdonck, and Hans Van Veer

The esophagus is not simply a conduit to allow passage of food and drink from the mouth to the stomach. It is an intensely complex part of the gastrointestinal tract. Cranially the esophagus is a continuation of the hypopharynx, and caudally it continues into the cardia of the stomach. As such, a thorough understanding of the anatomy and physiology of the esophagus should be gained before contemplating surgery of it.

EMBRYOLOGY

Description

The esophagus comes from two sources of the primitive gut. The cranial portion is derived from the pharyngeal gut or pharynx and the caudal part from the pregastric segment of the foregut. With the growth of the embryo, the primitive gut lumen becomes almost filled but later, due to a process of epithelial layer vacuolization, hollows out again. At about 4 weeks of embryonic development, the laryngotracheal groove appears, subsequently forming the tracheobronchial diverticulum on the ventral surface of the foregut, at the level of the fourth pharyngeal pouches (Fig. 69.1A,B). The diverticulum is gradually closed by the tracheoesophageal folds (internal ridges of the lateral esophageal groove), caudally first, forming the tracheoesophageal septum (Fig. 69.1). The endoderm forms the mucosal epithelium and associated ducts and glands. The mesoderm forms the lamina propria, muscularis mucosa, and muscular coat, the branchial arches forming the striated muscle and the visceral splanchnic mesoderm the smooth muscle coat. Arterial and venous supply of the esophagus is segmental. The cranial arteries are derived from the branchial arches and

caudal ones from branches of the aorta. With the unfolding and lengthening of the embryo, the esophagus also lengthens. The original cell lining of the esophagus changes from a two- to three-layer pseudostratified columnar epithelium via a stratified columnar stage to a stratified squamous epithelium by 90- to 130-mm embryo length.

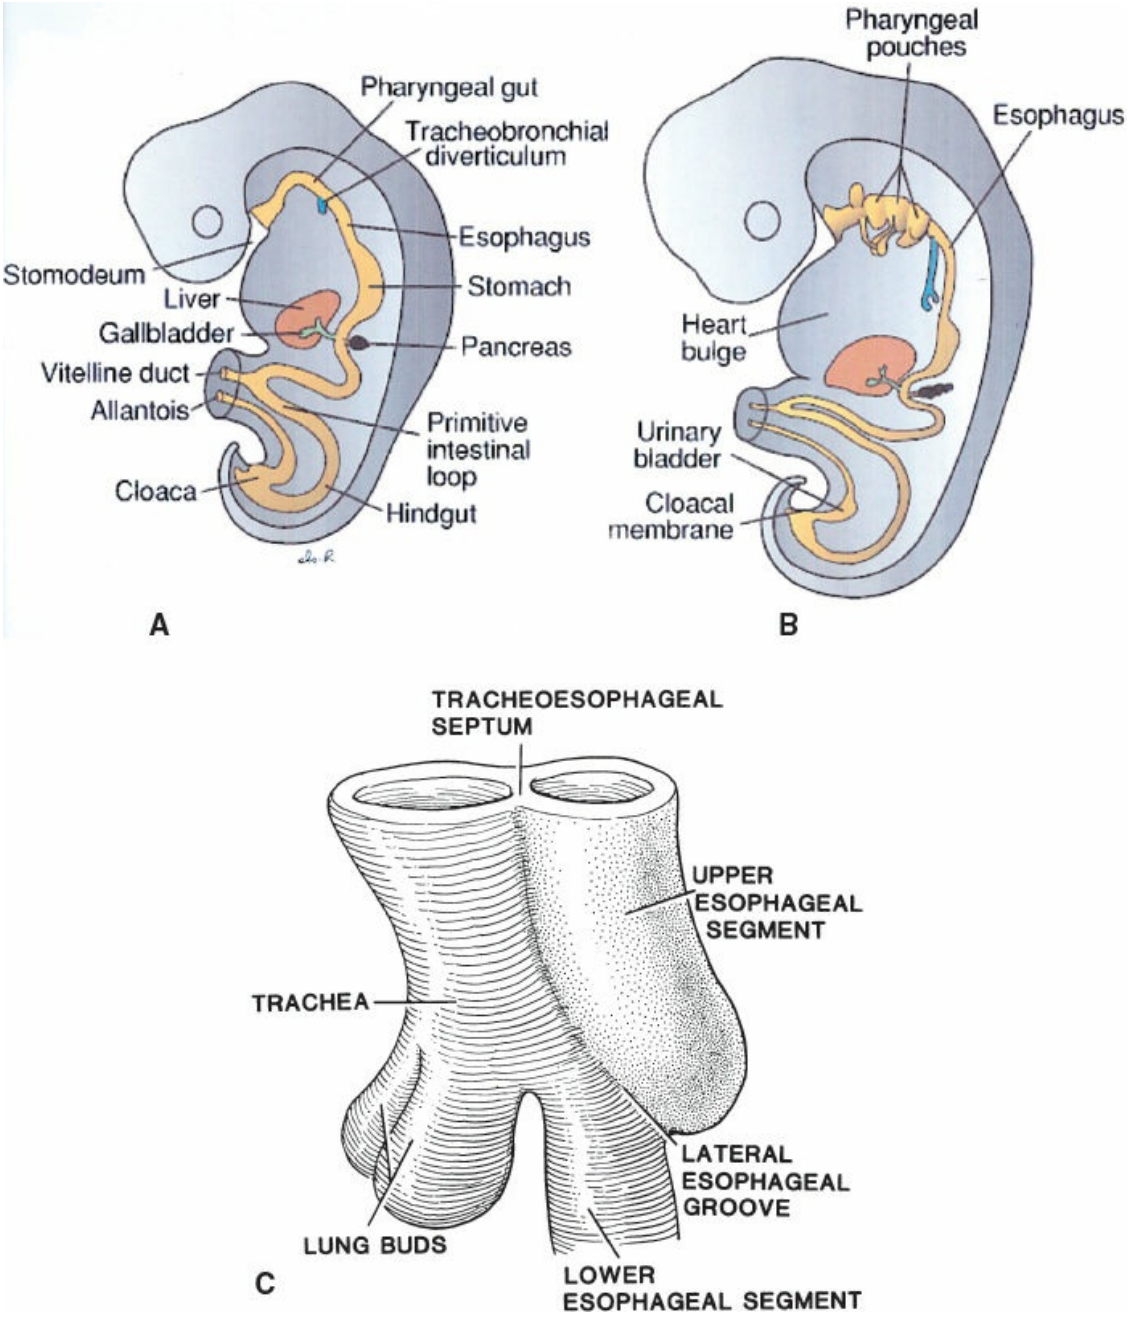

Figure 69.1. **A, B.** Development of tracheobronchial diverticulum from the primitive foregut (4 weeks). (From Sadler TW. *Langman's Medical Embryology.* 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.) **C.** Foregut segment in a 4-week-old embryo, showing division into the upper esophageal segment and the primitive lung buds. (From Blevins CE.

Embryology of the esophagus. In: Shields TW, ed. *General Thoracic Surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:1883.)

Clinical Points of Interest

Overdevelopment of the internal ridges of the tracheoesophageal septum is proposed as the cause of esophageal atresia according to Smith and deviation of the tracheoesophageal septum the cause of tracheoesophageal fistula. Failure of development of the tracheoesophageal septum can cause posterior laryngeal clefts. Defects of vacuolization and/or the persistence of diverticulae during the lengthening of the esophagus may be the cause of embryonic cysts, duplication cysts, webs, rings, and congenital stenosis, the latter including possibly even cartilaginous remnants or rings.

GROSS ANATOMY

Description

The esophagus is about 25 cm long extending from the level of the 6th cervical vertebra down to that of the 11th thoracic vertebra. It is not a fixed structure and moves cranially a few centimeters on swallowing and tilting the head backward. It is anchored superiorly to the cricoid cartilage and pharynx by strips of collagen fibers interspersed with muscle fibers. Similarly, it is tethered along its length to the left and right pleura, the aorta, the left main bronchus, and the fibrous pericardium. These are fine structures macroscopically and consist of a variable amount of collagen, elastic, and muscle fibers. It is normal clinical practice such as in endoscopy to describe the length along the esophagus as being that measured from the incisors teeth, thus including the oropharynx in this measurement. There is a narrowing at 15 to 17 cm (i.e., the upper esophageal sphincter [UES]), another at about 38 to 40 cm (i.e., the lower esophageal sphincter [LES]), and an anterolateral indentation at about 25 cm where the left main bronchus and arch of the aorta cross it anteriorly (Fig. 69.2). The female's esophagus is shorter than the male's by a few centimeters, but in both sexes there is marked variability depending on the height and weight of the individual. The esophagus shows two curves in the anteroposterior plane: although starting in the midline at the junction with the oropharynx, it deviates to the left as it descends to the thoracic inlet then returns to a midline position at about the 5th thoracic vertebra,

before passing once again to the left (Fig. 69.3). The esophagus also follows the contour of the cervical and upper thoracic spine in a lateral plane (Fig. 69.4).

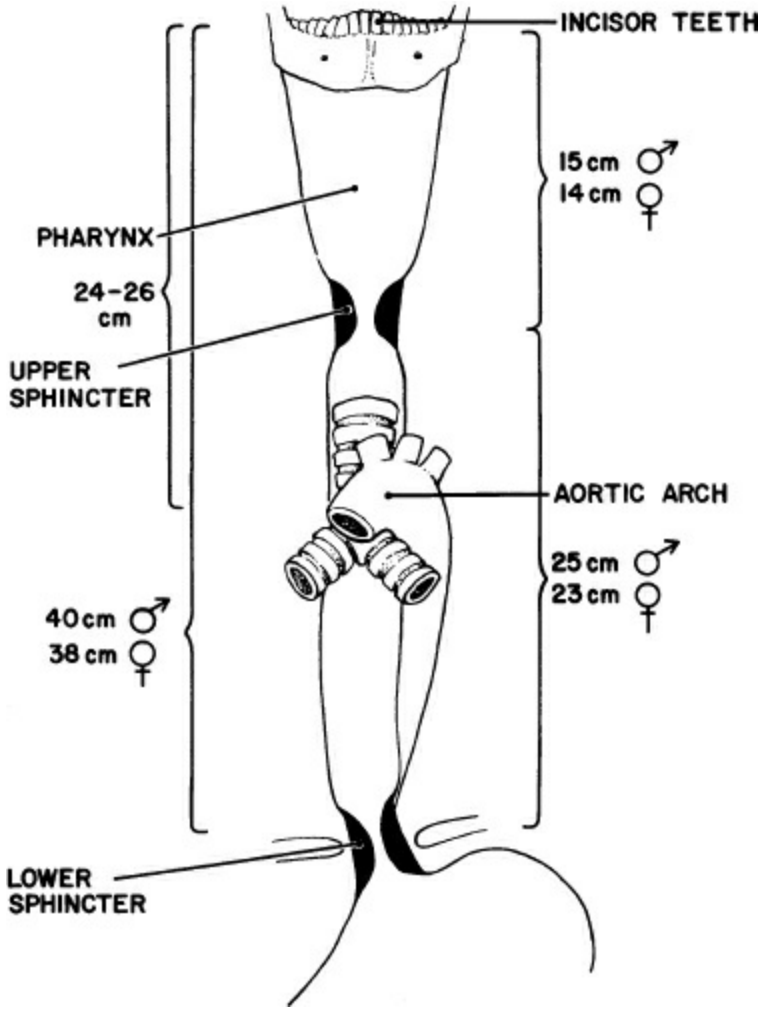

Figure 69.2. Diagram of the indentations of the esophagus with distances from the incisors in males and females. (From Hagen JA, DeMeester TR. Anatomy of the esophagus. In: Shields TW, ed. *General Thoracic Surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:1887.)

The latest edition of the American Joint Committee on Cancer (AJCC) cancer staging manual divides the esophagus into four parts: cervical, upper thoracic, middle thoracic, and lower thoracic esophagus/esophagogastric junction (EGJ) (Fig. 69.5).

Figure 69.3. Anteroposterior view of the esophagus.

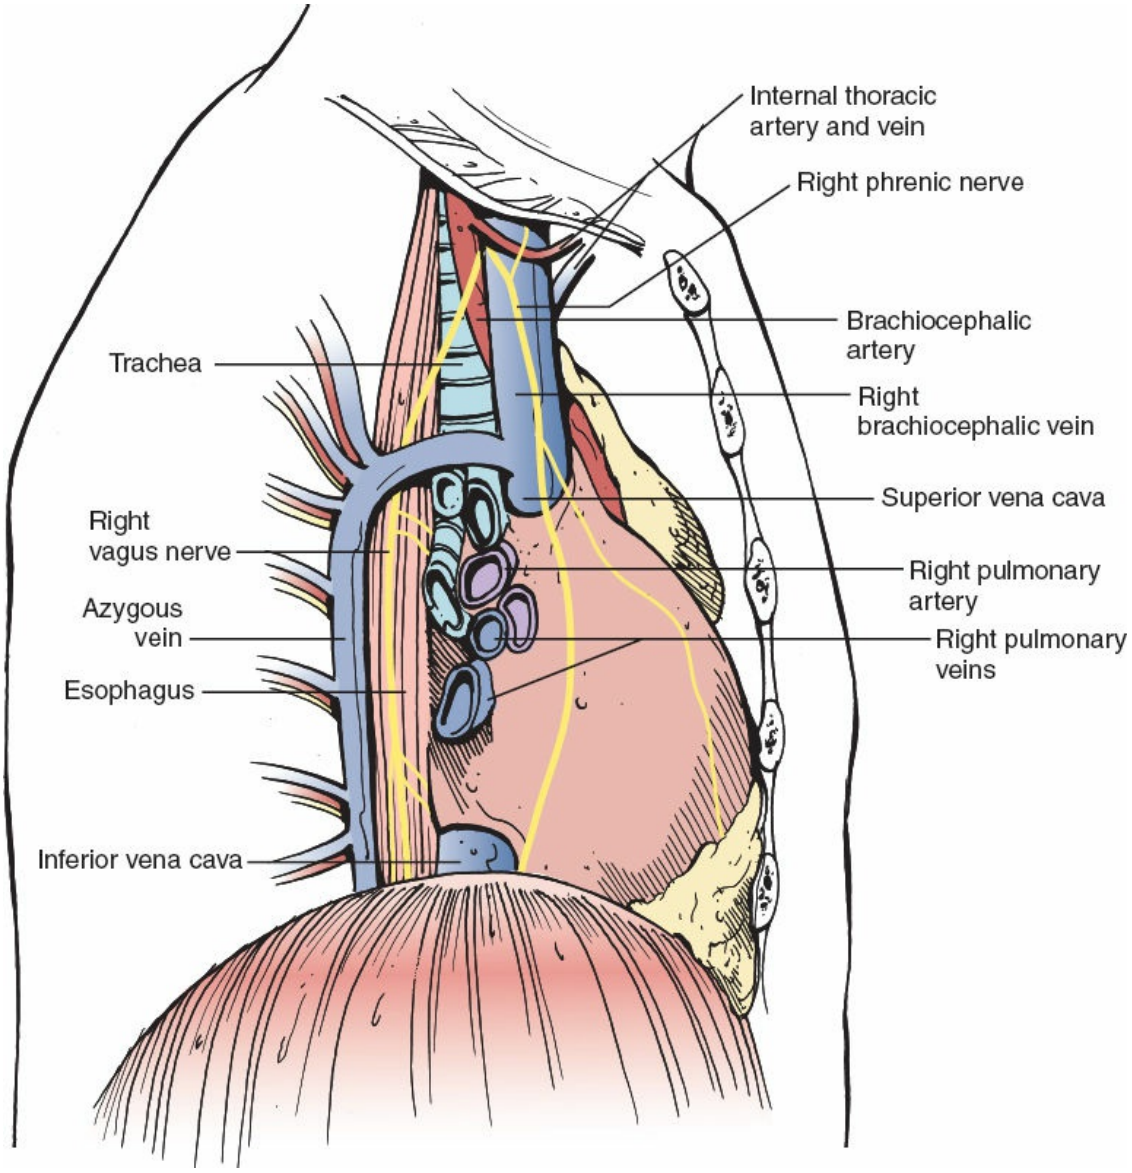

Figure 69.4. Lateral view of the esophagus.

The cervical esophagus lies in the neck, bordered superiorly by the hypopharynx and inferiorly by the thoracic inlet, which lies at the level of the sternal notch. Typical endoscopic measurements for the cervical esophagus measured from the incisors are from 15 to <20 cm.

The upper thoracic esophagus is bordered superiorly by the thoracic inlet and inferiorly by the lower border of the azygos vein. Typical endoscopic measurements from the incisors are from 20 to <25 cm.

The middle thoracic esophagus is bordered superiorly by the lower border of the azygos vein and inferiorly by the inferior pulmonary veins. Typical endoscopic measurements from the incisors are from 25 to <30

cm.

The lower thoracic esophagus is bordered superiorly by the inferior pulmonary veins and inferiorly by the stomach. Because it is the end of the esophagus, it includes the EGJ. Typical endoscopic measurements from the incisors are from 30 to 40 cm.

Clinical and Surgical Points of Interest

Recognition of the different landmark points and the distinct parts of the esophagus is of great help in localizing different lesions and pathologic processes when performing barium swallow contrast radiograms and/or endoscopy. Such reference points are very useful to surgeons to plan access routes to the esophagus, such as a right thoracic approach for supracarinal lesions, and a left thoracic approach for lower third esophageal lesions. The lateral deviation of the esophagus has relevance, for example, in the placement of a cervical esophagostomy, treatment of Zenker diverticula, or fashioning of an esophagogastrostomy, most being performed on the left side of the neck.

The arbitrary 10-cm segment encompassing the distal 5 cm of the esophagus and proximal 5 cm of the stomach, with the EGJ in the middle, is an area of contention. In the eighth edition of the AJCC *Cancer Staging Manual*, cancers whose epicenter is no more than 2 cm into the gastric cardia are stage grouped similar to adenocarcinoma of the esophagus. All other cancers with an epicenter in the stomach >2 cm distal to the EGJ, are stage grouped using the gastric cancer staging system.

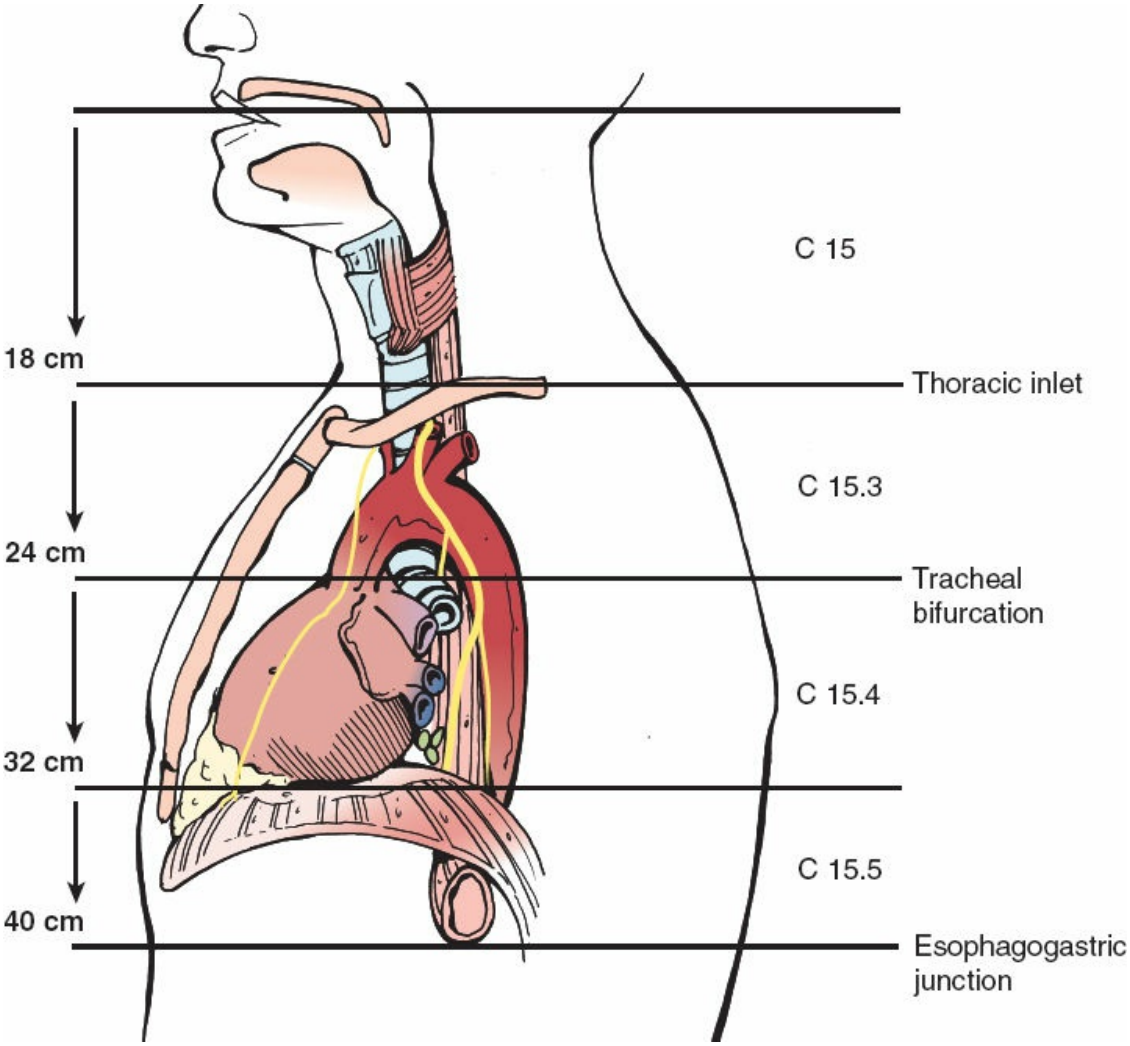

Figure 69.5. The divisions of the esophagus.

THE ESOPHAGEAL SPHINCTERS

Upper Esophageal Sphincter (Fig. 69.6)

The cervical esophagus is ~6 cm long. The UES is a true anatomic sphincter that is composed of the dense cricopharyngeus muscle. When the cricopharyngeus muscle relaxes, the UES opens aided by elevation and forward motion of the larynx. It is attached to the lamina of the cricoid cartilage (Fig. 69.6), and as it passes posteriorly it runs continuously without insertion into the midline raphe of the constrictors, the latter located cranial to it, thereby forming a sling. The cricopharyngeus muscle is considered by Last to be the lower transverse part of the inferior constrictor muscle of the hypopharynx. It blends into the circular fibers of the esophagus below. The longitudinal fibers ascending from the esophagus diverge at this point to form tendons on both sides, the central ones inserting into the posterior lamina of the cricoid cartilage. The

posterior wall of the hypopharynx is relatively weak just above and below the cricopharyngeus. The Killian triangle comprises the area between the thyropharyngeus and cricopharyngeus muscles that comprise the inferior constrictor. Laimer triangle is an area that is formed between the cricopharyngeus muscle above and the divergent longitudinal esophageal muscle fibers below.

Clinical and Surgical Points of Interest

Sometimes and mostly in elderly patients, a pharyngoesophageal pouch develops in Killian triangle, an example of a pulsion diverticulum. However, it is not a true diverticulum as not all layers are involved. The belief is that the pouch forms due to a lack of compliance of the UES and relative weakness of Killian triangle. Although the UES is anatomically short in height, that is, 0.5 cm, manometric measurements show the UES area to be much longer extending into the proximal part of the striated muscle of the cervical esophagus. A myotomy of the UES zone starting distal to the neck of the pouch therefore forms the most significant part of the repair for this condition, rather than excision or diverticulopexy. Importantly, the length of the myotomy should be directed by the manometric not the apparent anatomic, that is, the length of the cricopharyngeal muscle, length. It is important during rigid or flexible esophagoscopy not to enter an esophageal pouch and risk perforation. Indeed, with osteophytes being prevalent at this part of the cervical spine, making esophagoscopy more difficult, this area of weakness is the commonest site of iatrogenic esophageal perforation.

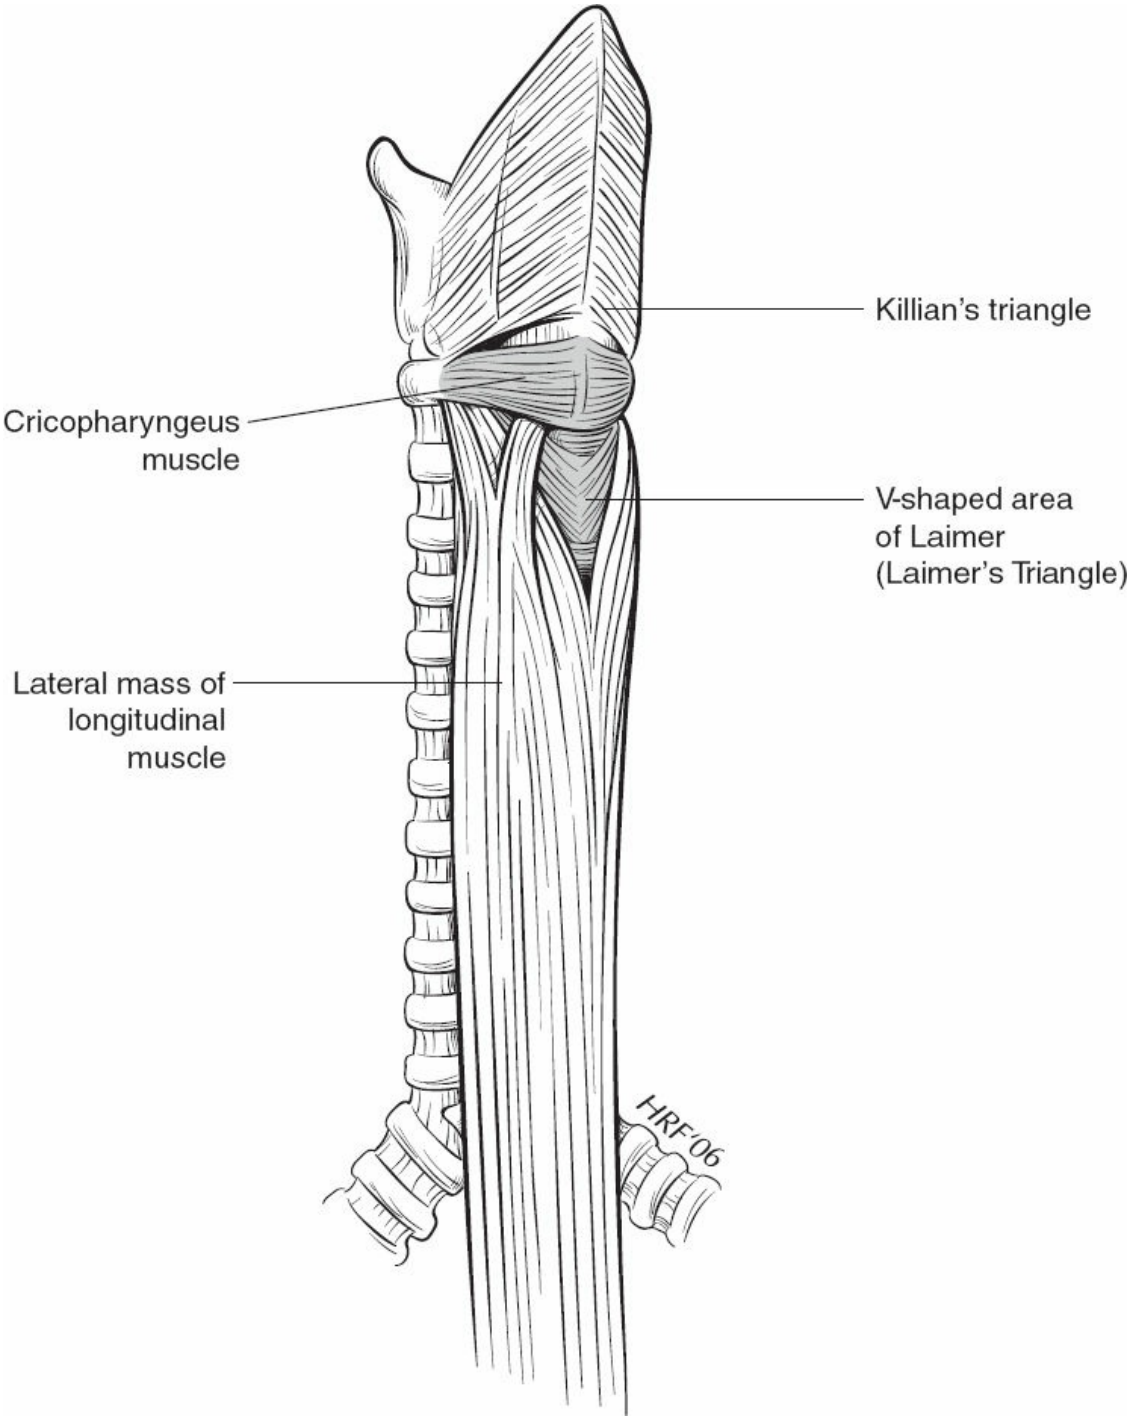

Figure 69.6. Muscle coat arrangement and areas of weakness—Killian and Laimer triangles.

LES and Gastroesophageal Junction (Fig. 69.7)

The LES, however, should be considered more a physiologic sphincter than an anatomic one. It consists of an area of high intraluminal pressure—the high-pressure zone—at the GEJ (gastroesophageal junction), and is influenced by a paracrine hormone effect and the intrinsic nervous system

(see later).

The GEJ has anatomical features that provide a complex antireflux function. The latter includes the length of the intra-abdominal tubular esophagus, the acute angle that the esophagus subtends with the stomach, that is, the angle of His, the gaiter-like effect of the phrenoesophageal ligament, the pinching of the diaphragmatic crura, the sling and clasp fibers of the muscles in the wall (Fig. 69.7), and the rosette of gastric folds of mucosa around the EGJ.

Clinical and Surgical Points of Interest

Endoscopically the LES can be recognized as a relative narrowing just proximal to the GEJ. The GEJ can be endoscopically recognized as the proximal margin of the gastric folds (Fig. 69.8) that in the majority of patients coincides with a pinching at the end of the tubular esophagus and the diaphragmatic indentation. Identifying these endoscopic landmarks allows a precise description of the GEJ, and the confirmation or ruling out of a sliding hiatus hernia. To do so one has to observe the relation between the proximal margin of the gastric folds and the indentation of the diaphragm (Fig. 69.9).

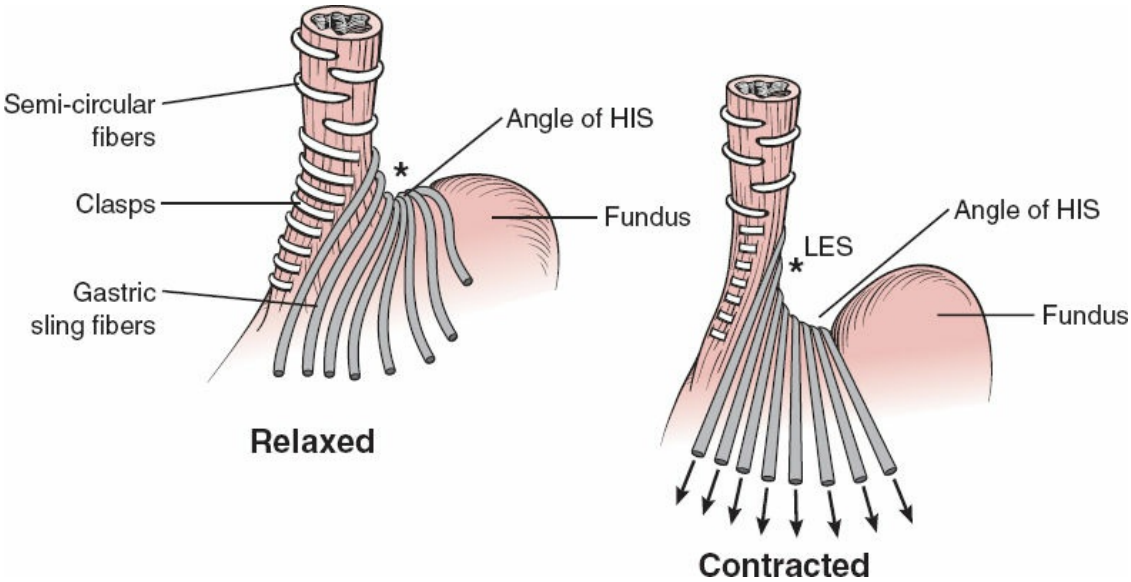

Figure 69.7. Sling and clasp fibers of the LES, in contracted and relaxed states. Sharpening of the angle of His in contracted state. AH, angle of His.

Research has evidenced a key element in preventing reflux is the restoration of 3 to 4 cm of distal esophagus under the diaphragm,

according to Laplace law. This forms the anatomic basis of any type of antireflux surgery. In some patients, the pressure of the LES does not fall to normal resting values on relaxation. This, in conjunction with lack of coordination of the esophageal body, occurs in achalasia (see Nerve Supply Clinical and Surgical Points of Interest). Like the UES, the surgical treatment therefore consists of a myotomy of the last 4 to 6 cm of the esophagus of all layers down to the mucosa, extending 1 to 2 cm onto the stomach. There is discussion as to whether the myotomy should be extended only into the sling fibers or whether it should be performed more to the right and including the clasp fibers. This should be followed by a fundoplication to prevent reflux, classically an anterior (Dor) wrap 4 cm in length.

TISSUE ARCHITECTURE

Description

The esophagus seen in cross-section consists of several layers (Fig. 69.10). The innermost layer is the mucosa, a nonkeratinizing stratified squamous-lined epithelium, except at the GEJ where the mucosa is composed of a columnar epithelium. Cell proliferation takes place in the basal layer lying on a basement membrane; differentiation and maturation occur in the cells progressively, migrating more and more superficially. Next to this is the lamina propria, a layer containing blood vessels, lymphatic capillaries, and nerves. Both the epithelium and the lamina propria contain inflammatory and other cells: melanocytes, neuroendocrine cells, lymphocytes, and Langerhans cells. Adjacent to this layer is the muscularis mucosae that allow crinkling of the mucosa of the esophagus in an undistended state, then the submucosa, loose connective tissue with mucus-secreting glands, and clusters of specialized nerve cells—the Meissner plexus. Outside this is the muscularis propria or muscle coat, composed of two layers—a deep thicker circular and a superficial thinner longitudinal muscle layer with the myenteric or Auerbach plexus found between the two layers. The circular fibers run transversely at the superior and inferior ends of the esophagus but have a helicoidal course between the two. There are more longitudinal fibers laterally in the proximal esophagus, thus making this layer thicker here than the ventral or dorsal sides; however, it becomes more uniform more distally. The longitudinal layer courses in an elongated spiral, turning one quarter around the circumference of the esophagus. There is a loose adventitial covering to the muscular coat, but there is no true serosa and no

mesentery unlike the rest of the distal gastrointestinal tract, except for the rectum. The esophagus can be thought of as consisting of two tubes, one riding almost independently over the other: the inner mucosa and submucosa separated by the muscularis mucosa; the outer muscularis propria.

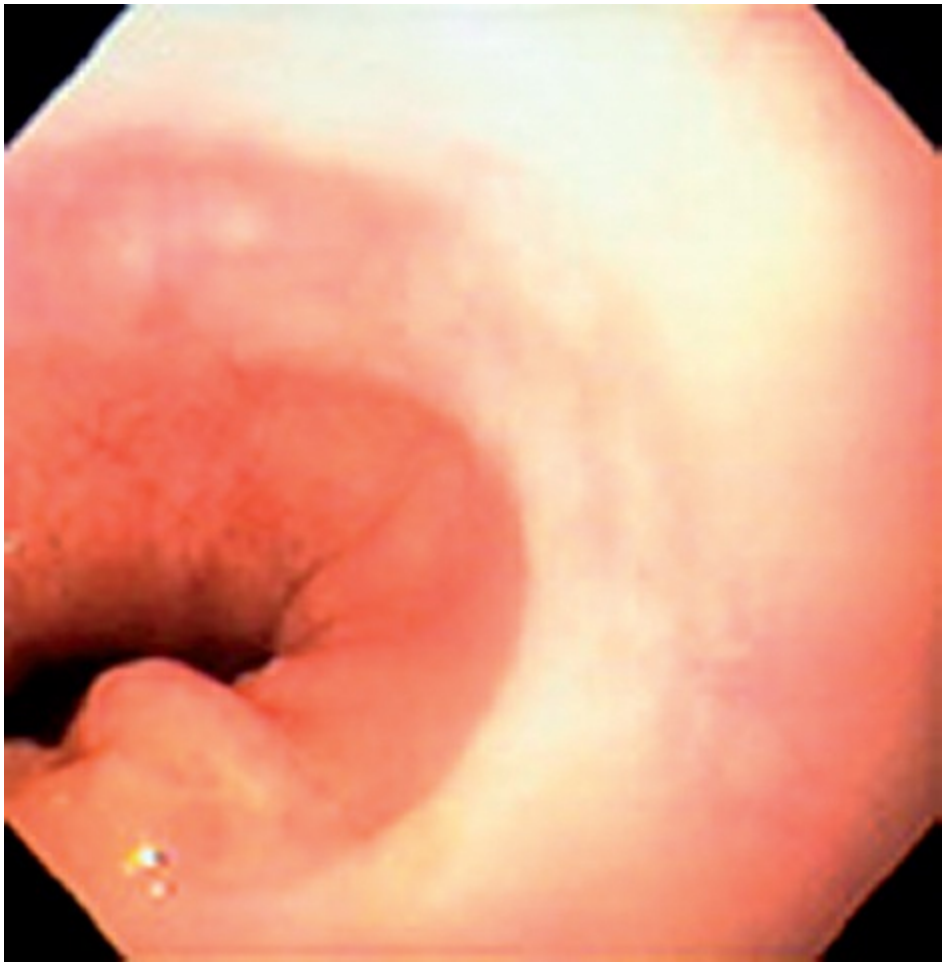

Figure 69.8. Normal endoscopic view of the gastroesophageal junction showing the red velvet appearance of the gastric mucosa and folds and the pale color of the esophagus.

Figure 69.9. Endoscopic view of a hiatus hernia showing the distant pinching of the stomach by the diaphragm and the gastric folds proximal to this.

The esophagus can also be divided into thirds in terms of its muscle type. The proximal third consists purely of striated muscle fibers, the distal third entirely of smooth muscle fibers, and the middle third of a mixture of the two, with a greater proportion of smooth muscle fibers as the esophagus is followed caudally. The circular muscle fibers change from striated to smooth muscle type more proximally than those of the longitudinal muscle layer (Fig. 69.11).

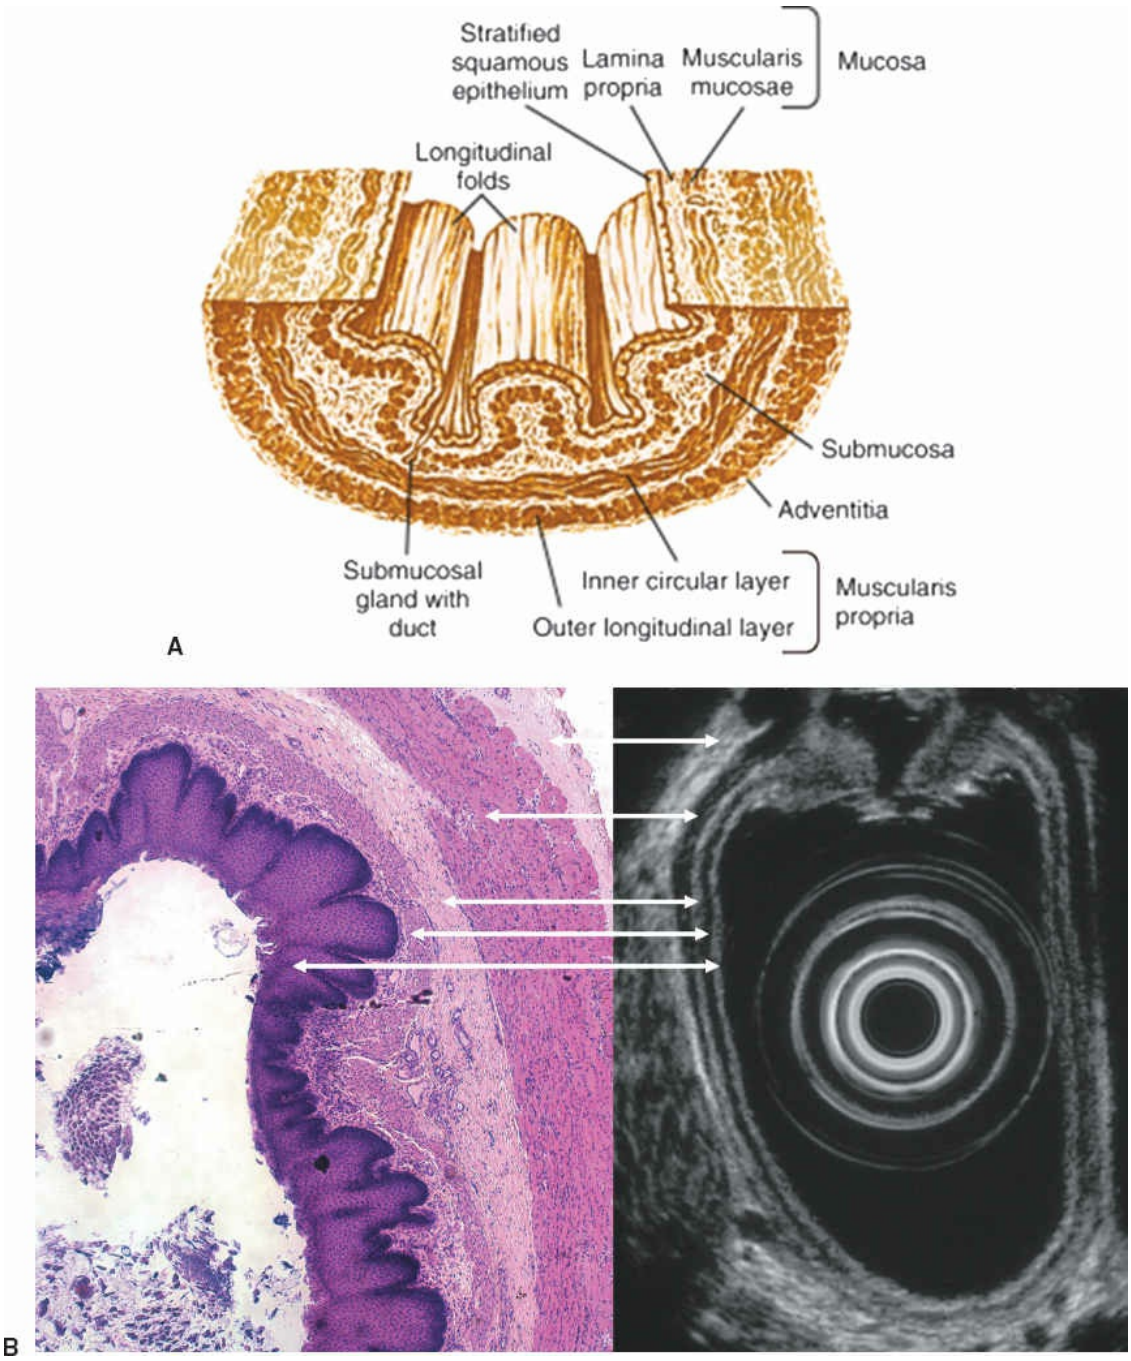

Figure 69.10. A. Histology of the esophagus. (Published in Long J, Orlando R. Anatomy, histology, embryology, and developmental anomalies of the esophagus. Copyright Elsevier 2009.) **B.** Axial endoscopic ultrasound image (right) and histologic specimen (left) from a normal esophagus. The endoscopic ultrasound layers and histologic layers of the esophagus are correlated. (From Kelsey CR, Chino JP, Christensen JD, Marks LB. Oncologic Imaging/Oncologic Anatomy. In: Halperin EC, Wazer DE, Perez CA, Brady LW, eds.

Perez and Brady's Principles and Practice of Radiation Oncology, 6th ed. Philadelphia; 2013, Lippincott Williams & Wilkins.)

Clinical and Surgical Points of Interest

Endoscopic ultrasound shows a characteristic alternation of hyperechoic and hypoechoic bands representing the different layers of the esophageal wall (Fig. 69.10), and aiding especially in the diagnosis of intramural and extramural masses as well as in distinguishing a T1a (intramucosal) from T1b (submucosal) tumors, standard esophagoscopy not being able to contribute this level of detail.

The helicoidal muscle course aids peristalsis and results in significant elastic recoil, thereby making it challenging to measure distances after resection and difficult, if not impossible, to resect an even short segment of esophagus and fashion an esophagoesophageal anastomosis, for example, in the case of trauma, short stricture, or small tumor. In addition, the mucosa can retract several millimeters inside the muscular coat, when the esophagus is transected, making it important to identify and catch both the mucosal and the muscle layer in each suture when performing an esophageal anastomosis.

It may be difficult to discriminate between true (organic) esophageal shortening caused by fibrosis due to chronic reflux esophagitis and that present in cases of—usually large—mixed hiatus hernia due to changes in elastic recoil caused by helicoidal retraction. The amount of shortening of the tubular esophagus in such hernias can be determined by measuring the distance between the distal border of the upper sphincter and proximal border of the LESs, endoscopically or manometrically determined. Contrast X-ray and endoscopic and manometric information are therefore required before embarking on laparoscopic repair of such a hernia to ensure success. Some authors consider a hiatal hernia of >5 cm as well as a large mixed hernia a contraindication for an abdominal—open or laparoscopic—approach.

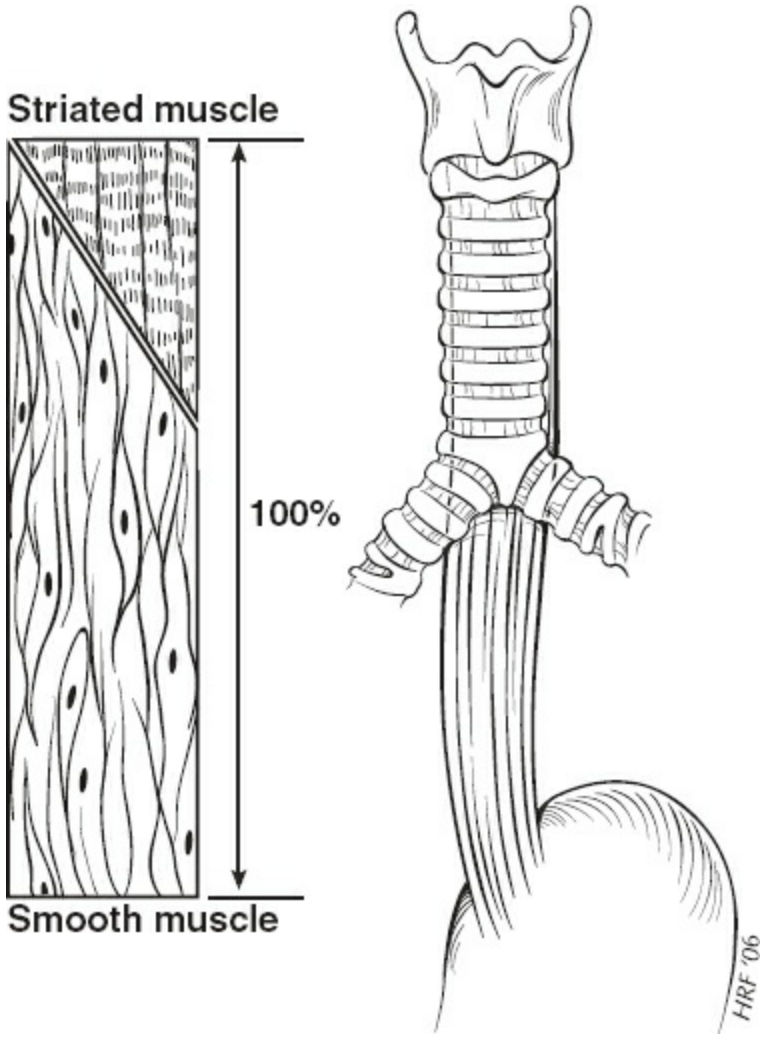

Figure 69.11. Graduation of striated to smooth muscle fibers.

Motility disorders of the esophagus do not involve the proximal esophagus as these are diseases affecting smooth muscle.

Barrett esophagus is a change of the tubular esophageal mucosa from a normal squamous epithelium. Endoscopically it is seen as a velvet red mucosa in the tubular esophagus. Moreover, there is variation in the height of the Z-line—the endoscopically determined transition between the whitish squamous epithelium and the red columnar epithelium, thus making the diagnosis of Barrett esophagus challenging. It is crucial therefore to describe where biopsies are taken from. For this, one must first accurately identify the GEJ (see earlier) and the proximal extent of the squamocolumnar junction, and tongues of Barrett metaplasia if present. According to the American College of Gastroenterology, the contemporary definition of Barrett esophagus requires two major components—a proximally displaced squamocolumnar junction as seen on endoscopy and the identification of acid-mucin–containing goblet cells, that is, specialized

intestinal metaplasia (SIM) in a biopsy from the area of endoscopic abnormality. Based on the length of the columnar segment in the distal esophagus, Barrett esophagus has been arbitrarily divided into short segment (<3 cm) or long segment (≥3 cm). Biopsies in these areas always require the presence of columnar epithelium (columnar epithelium lined lower oesophagus [CELLO]) with presence of intestinal metaplasia. However, biopsies from a macroscopically normal-looking squamocolumnar junction can also contain intestinal metaplasia, considered to be the result of carditis. Studies have shown that progenitor cell populations (stem cells) in the basal layer of the squamous epithelium and in the duct epithelium of the esophageal glands may differentiate into a glandular phenotype, leading to the development of columnar epithelium in the distal esophagus. It is believed that this is the mechanism that results in the development of Barrett esophagus as the result of the healing process in patients suffering from reflux esophagitis, in particular in the presence of mixed acid and biliary reflux.

ARTERIAL SUPPLY

Description

The arterial blood supply to the esophagus tract is segmental (Fig. 69.12). The cervical part of the esophagus is supplied by branches of the inferior thyroid artery from the thyrocervical trunk. Other less consistent arterial blood supply comes from the pharyngeal, subclavian, common carotid, superior thyroid, and vertebral arteries and the costocervical trunk. The upper thoracic esophagus is primarily supplied by branches from the inferior thyroid artery more on the right than the left, and less consistently from an anterior esophagotracheal branch directly from the aorta. The midesophagus, at about the level of the tracheal bifurcation, is supplied by branches of the bronchial arteries or directly from the aorta. The superior bronchial artery originates just below the aortic arch. The vessels are straight and short. The middle and lower thoracic esophagus are supplied by a single short bronchoesophageal branch that arises directly from the ventral surface of the aorta and more variable one or more obliquely coursing unpaired branches arising directly from the aorta. The lowest thoracic and the intra-abdominal segments are supplied by small branches of the left gastric artery and possibly also branches from the left inferior phrenic artery. All branches are small and after supplying the muscularis pass transversely through the outer layers of the esophagus into the

submucosa, where they form rich arterial anastomoses.

Figure 69.12. View of posterior mediastinum with lungs and heart removed, and upper abdomen, showing arterial branches supplying the esophagus. Inset is the anatomic variant of the arterial supply to the distal tubular esophagus and the gastroesophageal junction.

Clinical and Surgical Points of Interest

This arrangement of the arteries accommodates a transhiatal approach to the esophagus for resection, as blunt digital dissection peels these branches off resulting in minimal blood loss and vascular compromise. There is debate about the segmental nature of the arterial supply to the esophagus, with some arguing that this leads readily to devascularization and ischemia. Others feel that the esophagus maintains an excellent blood supply over a long distance and seldom can a failed anastomosis be attributable to its esophageal arterial arrangement. In fact, the rich intramural arterial anastomoses allow an extensive mobilization of the esophagus without compromising its viability. However, extensive devascularization of the tubular esophagus may result occasionally in necrosis, for example, after stenting procedures for very large aneurysms of the aorta starting from the aortic root down to a point below the offspring of the mesenteric artery.

VENOUS DRAINAGE

Description

The venous drainage is also segmental (Fig. 69.13). Subepithelial venous plexi in the lamina propria run longitudinally along the whole length of the esophagus, receiving blood from adjacent capillaries, and drain into the submucous plexus (the intrinsic esophageal venous plexus), then into an extrinsic esophageal venous plexus and thereon into nearby larger veins. The upper esophageal veins drain into the inferior thyroid vein, the brachiocephalic vein, and sometimes directly into the internal jugular vein. The upper thoracic esophageal veins drain into the bronchial, posterior intercostal, azygos, hemiazygos, and accessory azygos veins. Studies of the GEJ have shown perforators from the submucous plexus penetrating the muscle coat to become longitudinal veins that then drain into the inferior phrenic and left gastric veins. Again, venous drainage is variable. The venous plexus on the surface of the abdominal esophagus continuous

with the cardia has many interconnecting pathways to the portal venous system.

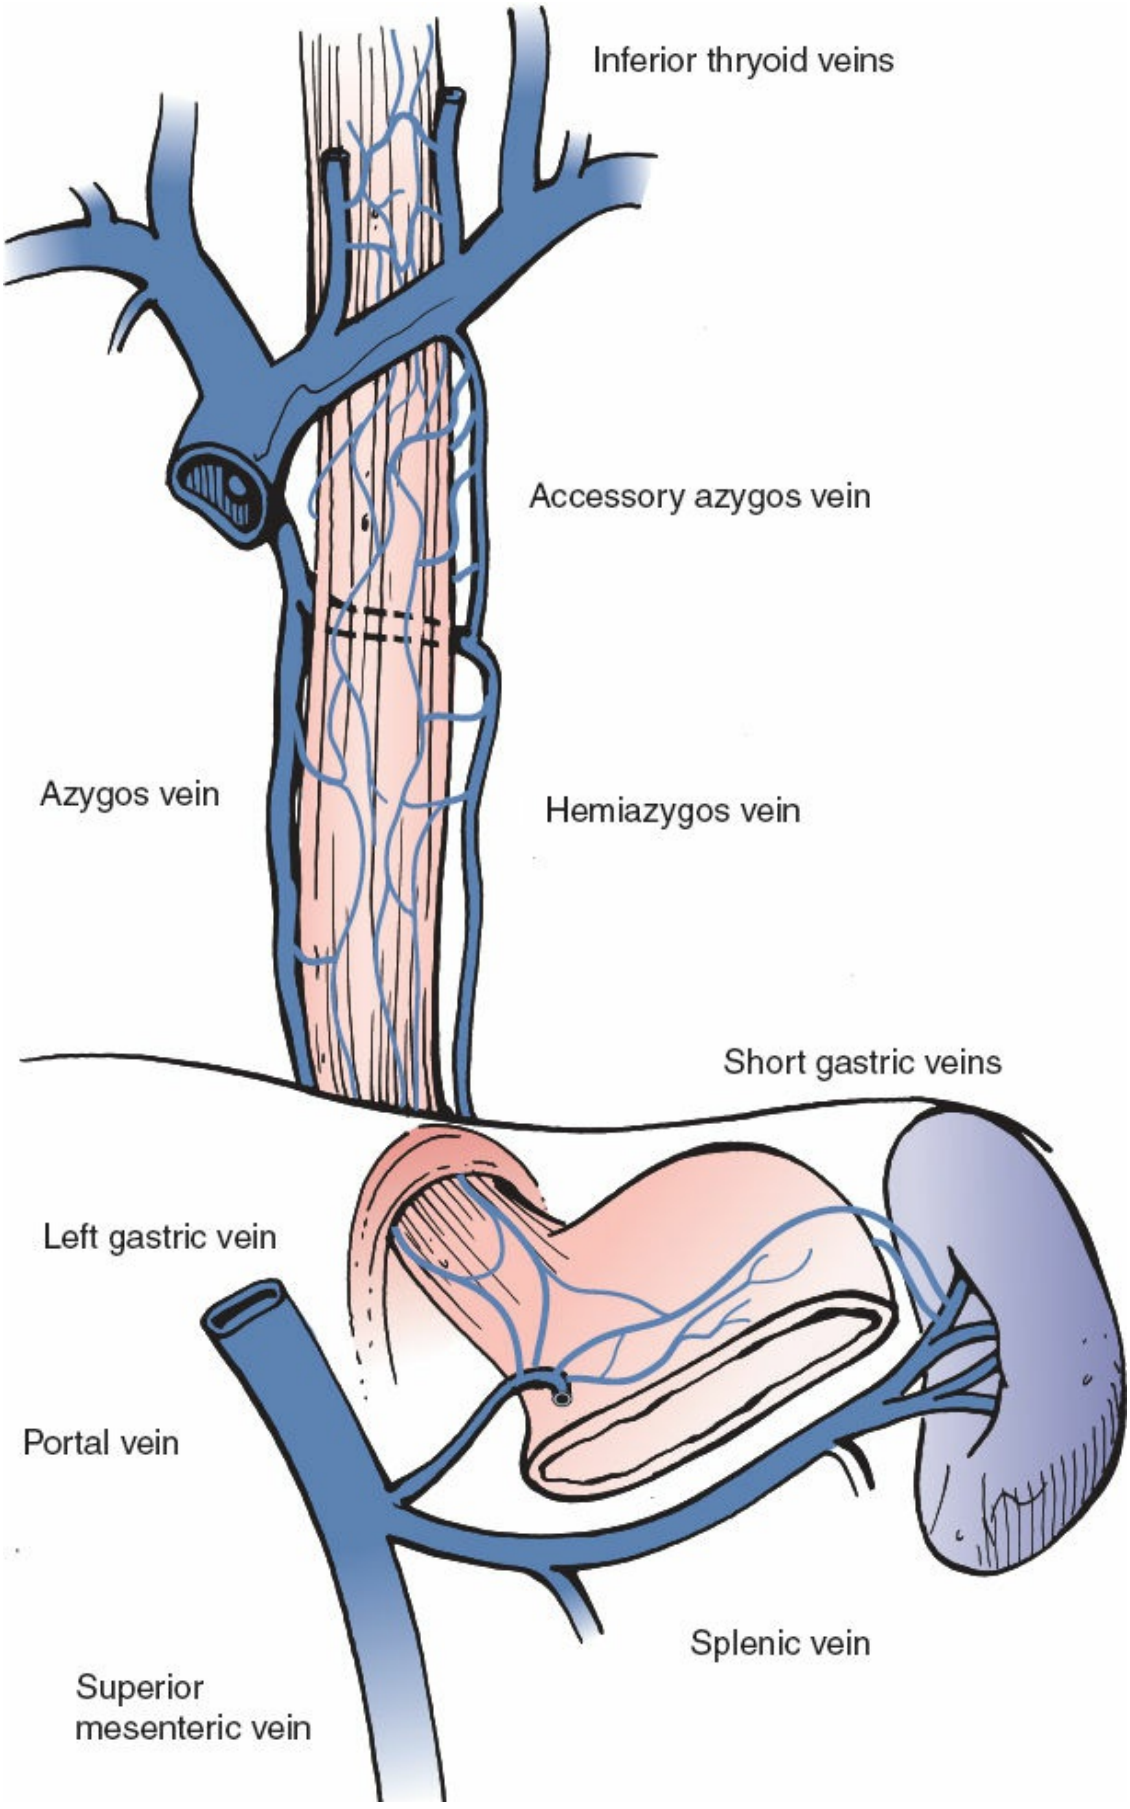

Figure 69.13. View of the posterior mediastinum with lungs and

heart removed, and upper abdomen, showing the venous drainage of the esophagus. Inset is a view of the mucosal veins of the distal esophagus and the gastroesophageal junction.

Clinical and Surgical Points of Interest

The azygos vein can be easily injured in resections of the esophagus particularly in a transhiatal approach, and if tumor is adherent in midthird esophageal cancers. In a right-sided approach to the esophagus for malignancy by thoracotomy or a minimally invasive approach using video-assisted thoracoscopy, the arch of the azygos vein can be divided to allow access to the proximal esophagus and lymph nodes adjacent to the distal trachea, right main bronchus, and recurrent laryngeal nerve.

The rich plexus of interconnecting pathways linking the hepatic portal venous system with the caval veins allows for a diversion of flow in cases of portal venous obstruction leading to dilatation and the formation of varices at the lower end of the esophagus.

LYMPHATIC DRAINAGE

Description

Lymphatic drainage, unlike the arterial blood supply and venous drainage, is not segmental. Moreover, in comparison with other hollow gastrointestinal organs, the esophagus has a unique mucosal lymphatic arrangement. According to electron microscope studies, anastomotic lymphatic capillaries exist in the lower mucosal layers of the esophagus. Mucosal and submucosal lymphatics form a complex interconnecting network that extends the length of the esophagus and exceeds capillaries in number. There are valved lymphatics in the submucosa preferentially coursing longitudinally for large distances, but occasionally perforating the muscle coats interconnecting with subadventitial channels (Fig. 69.14) and then on into outer surface lymphatic trunks. Up to 43% of autopsy studies have shown a direct drainage from the submucosal plexus into the thoracic duct. Studies show that the lymphatics relate to a transverse plane, a divide at the level of the tracheal bifurcation, such that the majority of lymph flow is up to the paratracheal and cervical lymph nodes and down to lower mediastinal and gastric/celiac nodes from this plane (Fig. 69.15). The arrangement of the lymph nodes is in three orders. The most superficial lymph nodes, comprising the first order, are the paraesophageal ones lying

in the periesophageal fatty tissue. The second-order nodes are the mediastinal nodes and those found along the aorta or proximal branches of it; the deep cervical and supraclavicular lymph nodes; and those along the lesser curvature, the left gastric artery, and the coeliac axis. The third-order lymph nodes are more peripheral and consist of the lateral clavicular, pulmonary hilar, splenic hilar/greater curvature, and common hepatic artery lymph nodes. All lymphatics drain into the main thoracic ducts, which have a well-organized system of valves to promote flow against gravity. Classifications (e.g., by the AJCC) have been devised with accompanying lymph node maps to identify regional esophageal and extraregional lymph nodes. Figure 69.16A,B identifies the regional lymph node stations for esophageal cancer including cancer of the EGJ.

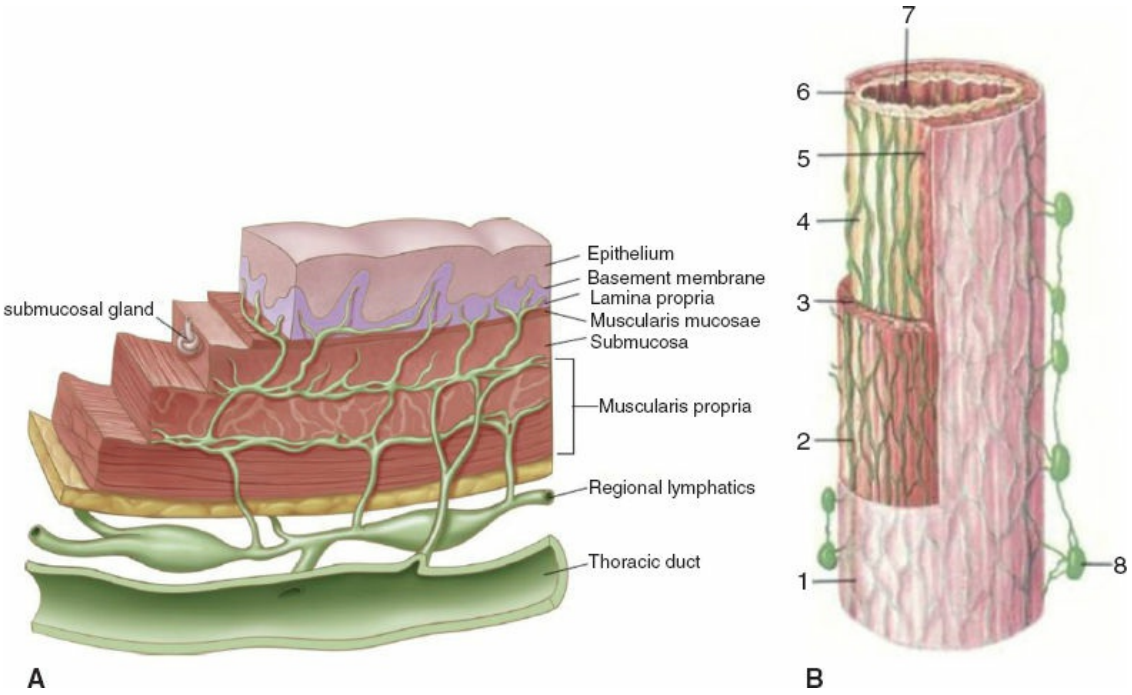

Figure 69.14. A. Schematic showing lymphatics and direction of lymph flow in the mucosa and the submucosa. **B.** Interconnection of mucosal–submucosal network and muscular lymphatic network (with long intramural lymphatics) and paraesophageal lymph nodes. Clinical and Surgical Points of Interest

Cancer cells that invade through the basement membrane of the epithelium may enter the small lymphatics in the lamina propria and then into the submucosal lymphatics that extend the entire length of the esophagus, and the communication of these submucosal lymphatics vessels with the surface lymphatic trunks provides the means for both longitudinal and lateral spread of cancer cells. Because the lymphatic channels are very close to the mucosa, even a stage T1 tumor can have early intramural dissemination and spread some distance along this layer. Because of the preferential longitudinal coursing of lymph, skip lesions can occur. In addition, this lymphatic arrangement explains the high postoperative recurrence rate at the resection margin when a limited resection is performed, and favors a subtotal esophagectomy even in distal third tumors. This also explains why esophageal tumors may extend over a long distance within the esophageal wall before obstructing the esophageal

lumen. Also, a tumor in the upper esophagus could have lymphatic drainage to below the diaphragm, resulting in involvement of the gastric and celiac lymph nodes and even as far as the renal hilum. Similarly, a distal third as well as a gastric cardia tumor may result in positive nodes above the clavicle (Fig. 69.17). Lymph node metastasis in tumors limited to the mucosa (T1a) is a rare event. Therefore in most cases, that is, when the tumor is of limited diameter (<2 cm), endomucosal resection (EMR) eventually combined with radiofrequency ablation in an area of surrounding Barrett metaplasia has become the treatment of choice. In T1b (tumor extending into the submucosa), however, lymph node involvement is frequent with a reported incidence between 30% and 50%. This has been ably demonstrated by various authors. Besides intramural tumoral skip lesions, skip metastases in lymph nodes can occur in such early-stage carcinoma. This early event questions the value of sentinel node detection. The number and level of lymph nodes define the staging and prognosis in the treatment of esophageal carcinoma. Clearance of these nodes determines the residual lymph node disease burden. Approaches that do not allow access to these lymph nodes could be considered inadequate for the purpose of oncologic resection. There is strong evidence that shows that a two- or three-field clearance in appropriate cases gives superior results. In addition, the preferential spread orally of supracarinal tumors and aborally of infracarinal tumors may influence the decision of the route of access. A right thoracic approach may be favored for a supracarinal tumor and a left approach for infracarinal tumors. The thoracic duct is a flimsy structure not easily seen due to its collapsed state, and can be damaged at the time of surgery, resulting in a chylothorax, a potentially life-threatening complication. This can be dealt with by ligating it behind the esophagus in its lowest thoracic level.

The occurrence of lymphatic metastasis in the very early stage of the disease should be kept in mind when using minimally invasive surgery. There is no reason not to perform an adequate lymph node clearance once a tumor penetrates into the submucosa (T1b) given the high incidence of lymph node involvement. Therefore, surgeons using thoracoscopic and laparoscopic approach should familiarize themselves with these lymphadenectomies through the thoracoscope and laparoscope.

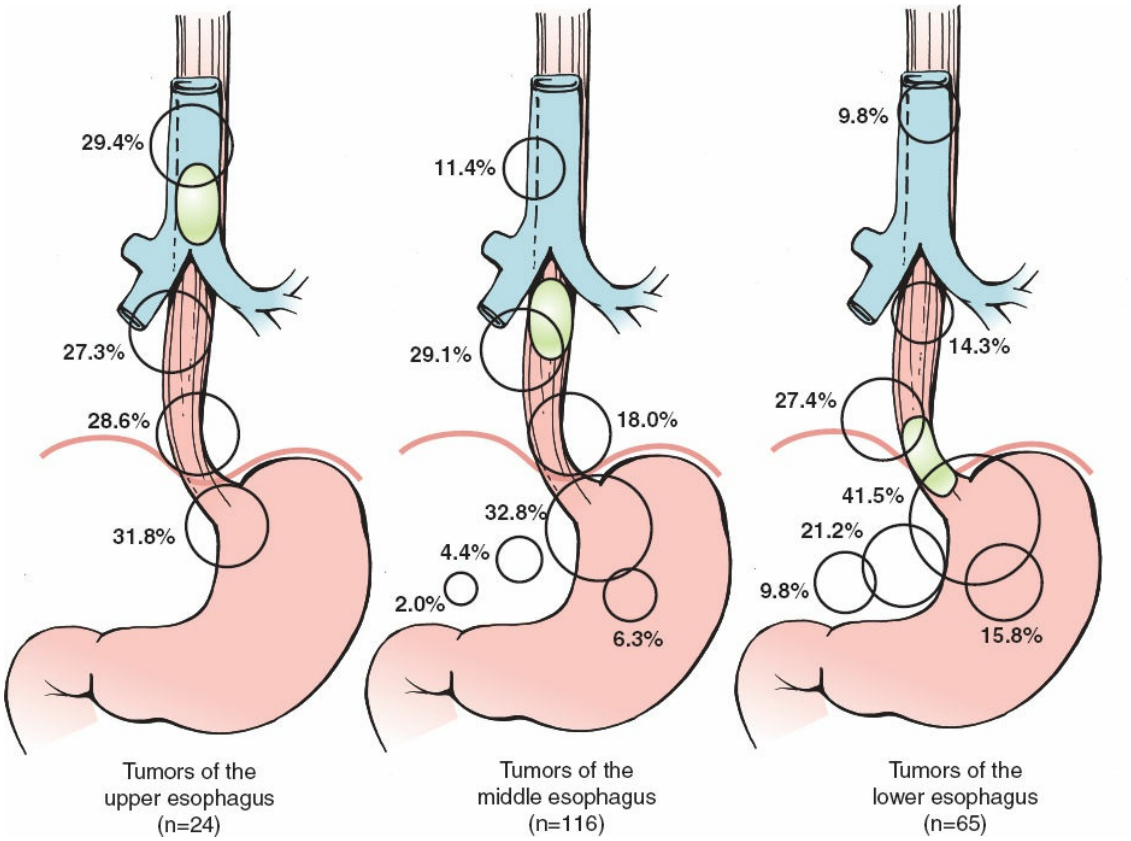

Figure 69.17. Ratio of lymph nodes involved by esophageal tumor to the number of resected cases. (Adapted from Akijama H, Tsurumaru M, Udagawa H, et al. Principles of surgical treatment for carcinoma of the esophagus: analysis of lymph node involvement. *Ann Surg* 1994;220:364.)

Another source of concern when using minimally invasive techniques is the completeness of resection in the more advanced tumor stage (T3). Minimally invasive surgery may require more manipulation as compared with an open approach. Also, the technique of wide peritumoral *en bloc* resection may be more difficult, an incomplete resection with positive lateral margins (R1) being the result, and thus jeopardizing the chance for cure.

NERVE SUPPLY

Description (Fig. 69.18)

The esophagus has a rich nerve supply, both extrinsic and intrinsic (intramural), and controls striated and smooth muscle, glands, and blood vessels. The innervation has parasympathetic and sympathetic components.

The parasympathetic innervation of the esophagus is provided by the vagal nerves. The visceral efferent and efferent cell bodies are located in the dorsal vagal nucleus. The fibers that innervate the striated muscles of the pharynx and the upper segment of the esophagus originate in the nucleus ambiguous. The pharyngoesophageal junction is innervated by the pharyngeal plexus, which is located on the middle constrictor muscle of the pharynx. Smaller branches coming from the 9th and 11th cranial nerve also arrive via the vagal nerves.

By giving off branches to the pharynx, larynx, and trachea, a cervical plexus is formed that also supplies the proximal striated muscles of the esophagus.

The nerve endings of these plexuses make direct synaptic contact through the motor endplates. Both the superior and inferior (recurrent) laryngeal nerves originate from the vagus. The superior laryngeal nerves innervate the intrinsic muscles of the pharynx, hypopharynx, and larynx.

The right recurrent laryngeal nerves originate on the right vagal nerve in front of the subclavian artery, the left one on the left vagal nerve at the lower margin of the aortic arch, lateral to the ligamentum pulmonale. They then swing around these vessels and ascend in the groove between the trachea and the esophagus, giving off a number of branches to both the trachea and proximal intrathoracic and cervical esophagus. Some branches take part in the innervation of the cricopharyngeal muscle. The left recurrent nerve is most pronounced and closest to the esophagus located behind the medial plane of the thyroid entering the larynx just below the cricopharyngeal muscle.

The right recurrent nerve lies somewhat more laterally away from the esophagus when turning around the brachiocephalic trunk. It also divides in several branches before entering into the larynx. The vagal nerves running down pass behind the hilum of the lungs, giving off several small branches to the lungs. The vagal nerves join with fibers of the sympathetic chain to form the esophageal plexus. That is to say that there is intertwining of the left anterior vagus and the right dorsal vagus nerve resulting in a great variation in how both the anterior and posterior vagal nerves split and interconnect. But the result is that both the anterior and posterior vagus trunks contain fibers of the left and right vagus through intertwining when they reorganize at a variable distance from the cardia into two thick trunks running down on the esophageal wall. Together with the esophagus, the vagi pass through the diaphragm to continue their

course along the lesser curvature of the stomach. Finally they divide into several branches on the anterior surface of the stomach—the crow's foot or Latarjet nerve. Branches of the vagus pass laterally to the liver through the gastrohepatic ligament—the hepatic vagal branches—to control gallbladder function. Other branches run along to the hepatic artery, porta hepatis, left gastric artery, and celiac plexus.

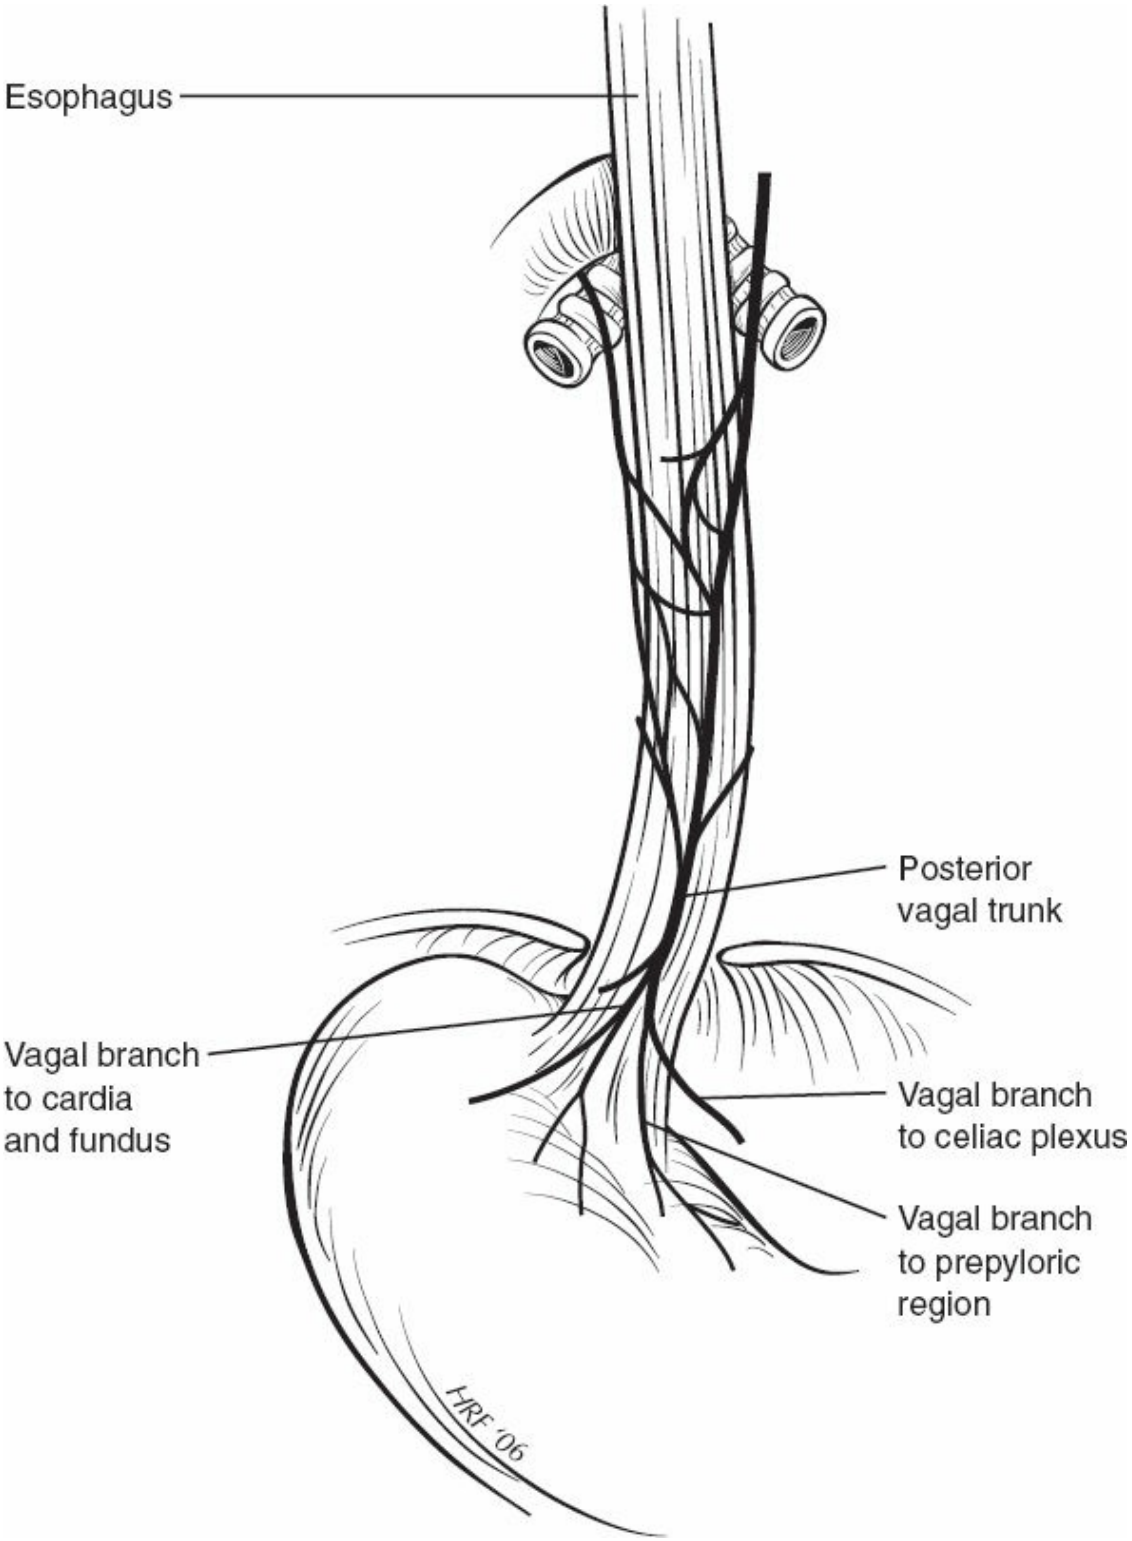

Figure 69.18. Posterior mediastinum with heart and lungs removed; upper abdomen, showing the vagal nerves and nerve plexuses; and sympathetic trunks surrounding and coursing with the esophagus.

The sympathetic nerve supply comes from the cervical and thoracic

sympathetic chain. Sympathetic nerves are involved in motor function of esophageal peristalsis and relaxation, contraction of sphincters, vasoconstriction, and secretory controls of glands. The preganglionary fibers arise from cell bodies in the spinal marrow at the level of T4–T5–T6, leaving the spine via the ventral roots. They make synapse with the corresponding ganglions of the sympathetic chain. The postganglionary fibers reach the esophagus via nerve branches taking off from the sympathetic chain. Some reach the esophageal wall directly, others join the vagal trunk. Thus, the vagal trunks contain postganglionary fibers. The sympathetic fibers form together with the vagal esophageal plexus a dense network between and around the esophagus. The distal esophagus also receives direct sympathetic nerves coming from the celiac ganglion via the periarterial plexus around gastric and phrenic arteries.

The intrinsic nerve supply consists of Meissner plexus in the submucosa and Auerbach (myenteric) plexus in the connective tissue between the longitudinal and circular muscular layers. These contain multipolar ganglion cells and receive afferents from the vagus, sympathetic, and parasympathetic branches via penetrating blood vessels. The fine control of the muscle coat contraction and LES relaxation is by the fibers of the myenteric plexus by nonadrenergic, noncholinergic nitric oxide–mediated inhibition of excitatory neurones, mediated by the interstitial cells of Cajal. Postganglionic fibers of Meissner plexus coordinate peristalsis of the muscularis mucosae and the secretory function of the esophagus. Auerbach plexus regulates the contraction of the muscle coats. All plexuses are interconnected by a network of fibers.

Clinical and Surgical Points of Interest

The recurrent laryngeal nerve is vulnerable in dissections and interventions in the neck, and is not always readily identifiable, in particular on the right side. This is the reason why the left-sided approach is preferred by most surgeons, for example, when performing an anastomosis between the cervical esophagus and gastric tube after esophagectomy. It can also be damaged in the chest at the level of the brachiocephalic trunk on the right, the aortopulmonary window, and more cranially on the left side. Partial and complete paralysis of the vocal cords gives differing symptoms of voice change, difficulties in swallowing, and loss of protection of the airway, leading to aspiration.

It is proposed that the myenteric plexus is involved in diseases of

dysmotility such as achalasia due to decreased numbers of nitric oxide synthetase–producing neurones that cause inhibition of the excitatory intermediate neurones. Recently there has been some evidence produced for viral-induced damage to the myenteric plexus in achalasia. A similar situation exists in Chagas disease where a *Trypanosoma cruzi* infection causes loss of intramuscular ganglion cells. The sharing of visceral afferents allows confusion of symptoms. Thus, esophageal pathology may give symptoms misinterpreted as cardiac pain. Also, in addition to gastroesophageal reflux causing nocturnal aspiration and asthma, there is evidence of acid-mediated reflex bronchoconstriction caused by a vagally mediated reflex, local axonal reflexes, heightened bronchial reactivity, and microaspiration, all resulting in neurogenic inflammation. Damage to the vagal nerves in antireflux surgery will cause dumping, decreased gastric emptying, failure of relaxation of the pyloric outlet, and diarrhea. In particular, the anterior vagal nerve is at risk when performing laparoscopic antireflux surgery as it is barely visible and distinguishable under the phrenoesophageal membrane.

ANATOMICAL RELATIONS

Description

Knowledge of the anatomical topography of the esophagus is imperative before embarking on esophageal surgery. Above the clavicle, the esophagus lies posterior to the trachea, separated by loose areolar tissue from its membranous part (Fig. 69.19). The pretracheal fascia covers the trachea and esophagus and diverges to wrap round the thyroid gland. The buccopharyngeal fascia acts as a sheath that extends caudally from posterior to the pharyngeal muscles to the posterior wall of the esophagus, and laterally to the carotid sheath. Posterior to this is first the alar fascia and then the prevertebral fascia. Thus, a paraesophageal (anterior to the buccopharyngeal fascia) and a retroesophageal space (posterior to the fascia) exist. The recurrent laryngeal nerve lies in the tracheoesophageal groove, the left more closely applied than the right due to the right recurrent nerve wrapping round the brachiocephalic trunk. The inferior lobe of the thyroid gland extends to reach a position anterolateral to the esophagus and the middle thyroid vein and inferior thyroid artery anterolateral to that (Fig. 69.20A). Lateral to the thyroid structures is the carotid sheath with the common carotid artery the most medial. The thoracic duct lies to the left of the esophagus, its highest point being about

4 cm above the clavicle as it drains into the venous confluence.

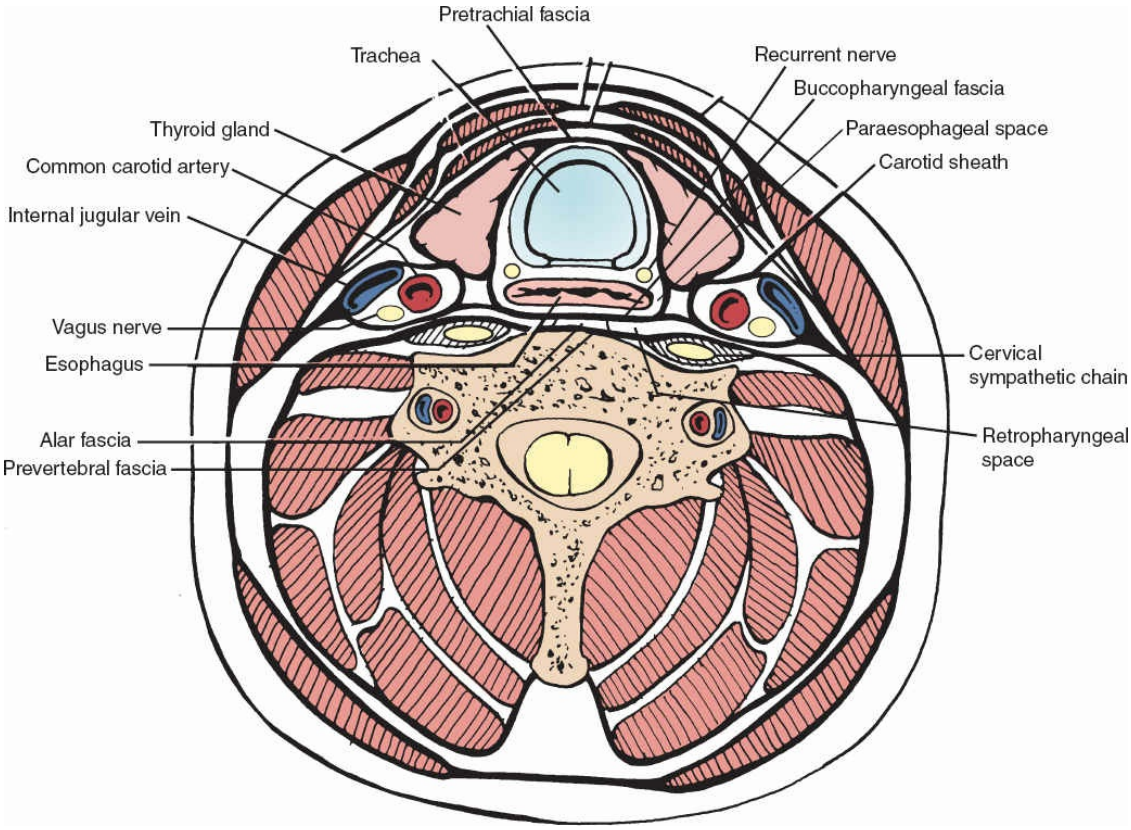

Figure 69.19. Schematic of cross-section of cervical esophagus with anatomically related structures and the paraesophageal and retroesophageal spaces. VII denotes the seventh cervical vertebra. Cross-section of the neck at the level of the thyroid isthmus.

After passing into the thorax, the esophagus gradually inclines to the left, as can be seen on computer tomography reconstruction (Fig. 69.20) and runs posterior and medial to the aortic and azygos arches and the left main bronchus. Its course continues to the right of the descending thoracic aorta. The left and right mediastinal pleura abut it laterally, and the left recurrent laryngeal nerve lies lateral to it (Fig. 69.20). The thoracic duct is in a posterolateral position. At the level of the tracheal bifurcation, the esophagus is in a midline position behind the subcarinal lymph nodes, with the thoracic duct crossing immediately posterior to it.

Below the tracheal bifurcation (Fig. 69.20), the esophagus runs to the right of the descending aorta, posterior to the fibrous pericardium and in between the left and right mediastinal pleura (Fig. 69.20). The anterior and posterior vagal trunks run longitudinally on the esophageal surface, and

the esophagus passes through the diaphragm to the left of the midline into the abdomen (Fig. 69.20). As it does so, there is a fat pad that marks the position of the superior margin of the phrenoesophageal ligament or membrane (Fig. 69.21), a condensation of pleura, endothoracic fascia, transversalis fascia, and the peritoneum, that consists of two sheaths. The upper one is inserted into the lower 1 to 3 cm of the thoracic esophagus. Although the fibers of this sheath are mainly inserted into the outer muscular layer of the esophagus, some penetrate the wall as far as the submucosa. The lower sheath is inserted into the cardia but is separated from the GEJ by a fat pad and loose areolar connective tissue. At the level of the gastric fundus below the cardia, the fibers of this lower sheath disappear into the serosa and the gastrohepatic and gastrosplenic ligament. As a result, the phrenoesophageal membrane is well developed anteriorly but weak posteriorly. Elastic and collagenic fibers are its main elements at histologic examination. They are arranged in bundles forming a meshwork resulting in the necessary strength and plasticity to cope with the continuous respiratory movements of the diaphragm. The phrenoesophageal segment acts as a barrier between the negative intrathoracic pressure and the positive abdominal pressure. It provides at the same time an airtight seal between the thoracic and abdominal cavities. Studies of patients of different ages have suggested that the inferior leaf of the phrenoesophageal ligament is weaker than the superior and with advancing age the ligament ascends into the thorax. The esophagus parts company with the aorta as it descends into the abdomen, moving anteriorly to reach the esophageal hiatus, the aorta passing posteriorly to the median arcuate ligament.

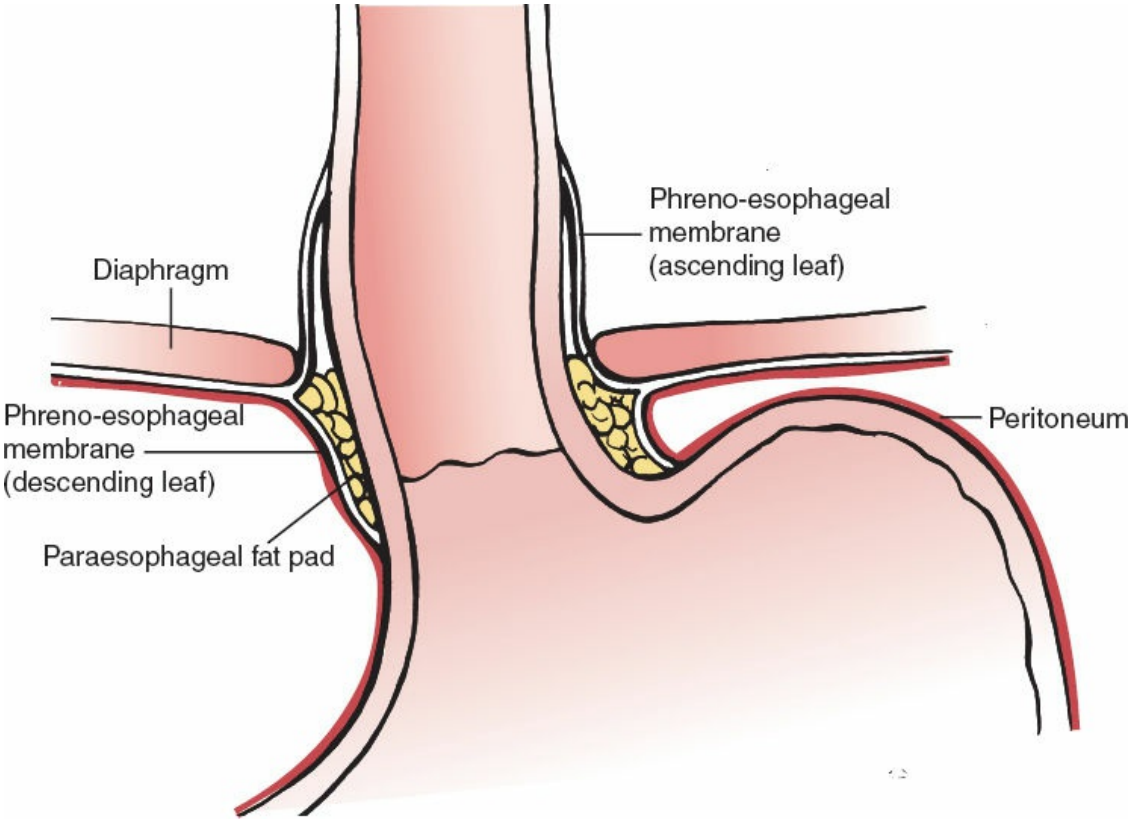

Figure 69.21. Diagram showing the distal esophagus, gastroesophageal junction, and formation of the phrenoesophageal ligament. Attachment and structure of the phrenoesophageal membrane.

The crural arrangement is complex (Fig. 69.22) and variable. The crura have an origin from the first four lumbar vertebrae. The left crus does not divide but the right crus has superficial and deep components, the latter forming a sling around the esophagus. In the most common arrangement, the superficial fibers of the right crus pass anterosuperiorly in a lazy curve to insert into the central tendon of the diaphragm, forming the right pillar; the deeper fibers twist acutely to wrap around the left side of the esophagus, forming the left pillar. The left crus lies to the left of this passing to the left of the aorta and therefore is not an immediate relation to the esophagus. However, in 40% patients the sling does include components of the left crus. Where the right and left crura cross, the median arcuate ligament forms. Posterior to the median arcuate ligament is the descending thoracic aorta as it passes through the diaphragm at the level of the 12th thoracic vertebra. As the esophagus passes the hiatus, a concentric narrowing of the lumen occurs (which, however, is not synonymous with the high-pressure zone although the high-pressure zone

extends into this area). The length of the intra-abdominal segment is said to be from 0.5 to 2.5 cm.

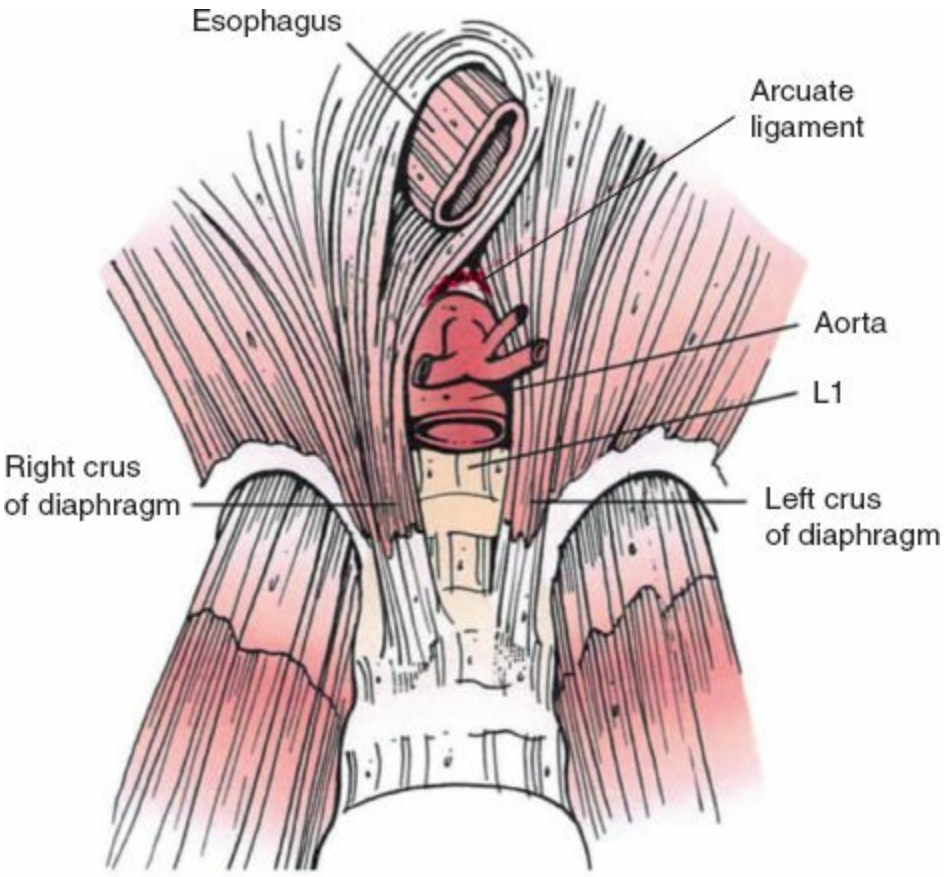

Figure 69.22. Diagram showing the most common variant of anatomic arrangement of the diaphragmatic crura. L1 denotes the first lumbar vertebra.

The angle formed between the left margin of the intra-abdominal segment and the gastric fundus is referred to as the angle of His, based on who first described it in 1903 (see Fig. 69.7).

The intra-abdominal esophagus passes into the cardia of the stomach. At this point, the density of the circular muscle fibers of the esophagus is the greatest (Fig. 69.23A), particularly on the lesser curve side, which combined with the similarly dense oblique muscle fibers of the stomach (Fig. 69.23B) contributes to the antireflux mechanism of the LES, together with the anatomic relation between the esophagus and the area of the hiatus.

The abdominal esophagus is invested in a peritoneal covering consisting of the two layers of the hepatogastric ligament. The hepatogastric ligament extends from the porta hepatis to the lesser

curvature of the stomach and abdominal esophagus. The hepatogastric ligament encloses the abdominal esophagus on the right, and it leaves and comes together on the left side to form the gastrosplenic ligament. The lesser sac lies behind these two ligaments so that there is a bare area in the posterior wall of the stomach.

Clinical and Surgical Points of Interest

The cervical prevertebral fascia is strong enough to take fixing sutures in diverticulopexy operations for a Zenker diverticulum. The retroesophageal space continues inferiorly to the posterior mediastinum, thus permitting the spread of infection from the neck to the mediastinum and causing potentially fatal mediastinitis. Necrotizing mediastinitis resulting from pharyngeal perforation and peritonsillar or dental abscesses may result in rapid and disastrous dissemination of sepsis.

The separation from the aorta in the lower thorax makes the esophagus vulnerable to perforations at this point, especially Boerhaave syndrome. The tear is typically found posterolaterally, thus making a left thoracotomy the ideal approach. Because of the close relation between the cervical esophagus and the pars membranacea of the trachea, great care must be taken at the time of dissection not to cause a tear in the pars membranacea. This is the case in particular when performing blunt transhiatal dissection.

Equally important is to avoid damaging the recurrent laryngeal nerve. These nerves are especially vulnerable just below the point where they pass under the inferior constrictor muscle to become intralaryngeal. When correcting a Zenker diverticulum or when performing a high cervical anastomosis, the surgeon must be aware of these anatomic particularities. Over its course in the mediastinum, the esophagus is surrounded by loose fatty tissue creating a fat plane between the esophagus and descending aorta. Disappearance of this fat plane in a patient presenting with a cancer of the esophagus may indicate irresectability.

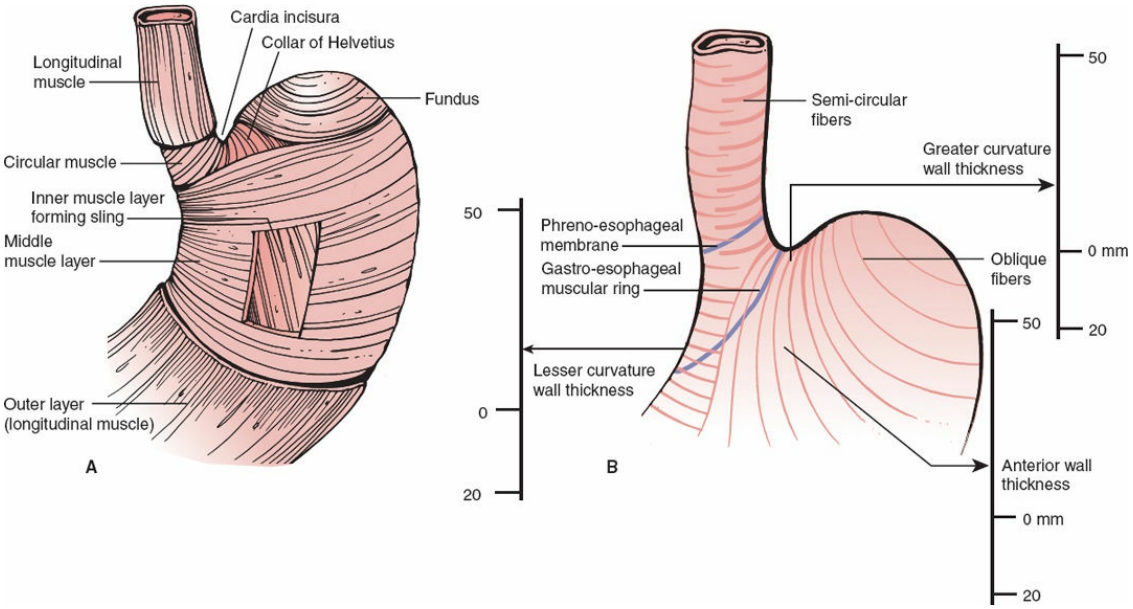

Figure 69.23. **A.** Drawing showing the density of circular muscle fibers at the cardia. **B.** Diagram showing the density of the circular fibers at the gastroesophageal junction and the absolute thickness of the anterior wall and lesser curvature and greater curvature of the stomach.

The upward movement of the phrenoesophageal ligament with age has been proposed as the reason for the increased incidence of hiatus hernia in the elderly. Although most patients with gastroesophageal reflux have a hiatal hernia, many individuals have no reflux. One potential explanation is that the point of attachment of the phrenoesophageal ligament may influence the likelihood of development of reflux. High insertion of the phrenoesophageal ligament onto the thoracic esophagus allows for a still adequate length of the lower esophagus exposed to intra-abdominal pressure transmitted through the hiatal sac.

From an anatomical–surgical point, the antireflux mechanism is based on the following elements:

1. Thickening of the gastric oblique sling fibers and the clasp fibers, which form the lower esophageal sphincter.
2. Intra-abdominal pressure
3. Rosette-like configuration of the top end of the gastric mucosal folds
4. The sharp angle of the fundus (angle of His)
5. The phrenoesophageal membrane and its insertion into the esophagus
6. The pinching of the diaphragmatic crura

Together with the restoration of the 3 to 4 cm of the distal esophagus

under the diaphragm, reconstruction of the angle of His by creating a fundoplication adds to the creation of an antireflux barrier.

Crural sutures to close the hiatus, such as in antireflux surgery, have to be placed with care as the inferior vena cava lies just lateral to the right pillar. Likewise, crural sutures placed too deep and posterior may injure the aorta, causing a false aneurysm.

Since the report of the first laparoscopic antireflux operation by Dallemagne in 1991, further developments and refinements in videoscopic surgery related to esophageal surgery have been spectacular.

Laparoscopic antireflux surgery has become the standard, and gradually more complex operations are becoming manageable using laparoscopic and thoracoscopic approaches. The mediastinal esophagus can be mobilized from the abdomen through the hiatus up to the level of the carina. Lengthening gastroplasty to deal with a shortened esophagus is increasingly used. Giant paraesophageal hernias and motor disorders, for example, achalasia, are successfully treated by laparoscopy, with excellent early results. Reoperations, for example, after failed antireflux surgery, are now mostly performed via a laparoscopic approach as well. Thoracoscopic–laparoscopic esophagectomy for cancer of the esophagus has become the routine in some centers of excellence.

It must be clear, however, that on preoperative evaluation, indications for surgery of esophageal problems are the same as for open surgery. In this respect, familiarity with the anatomic details is equally, if not more, important.

Well-designed prospective studies or trials and long-term follow-up are required to confirm the advantages of videoscopic esophageal surgery over open surgery, in particular when dealing with more complex pathology.

EDITOR'S COMMENT

This is an excellent chapter written by a prominent group of esophageal surgeons. I have really enjoyed writing these commentaries on the anatomy chapters as these represent the perfect opportunity to discuss some of the finer technical points of the surgical procedures commonly performed in these anatomic areas.

The discussion on the LES illustrates well the complexity of the anatomy and physiology of the anatomic reflux barrier. The LES is not an actual sphincter muscle as is found in other areas of the gastrointestinal tract such as the pylorus and the anus. There are three very important characteristics of a competent LES —the failure of any one of which can lead to gastroesophageal reflux disease. These are the overall length, the intra-abdominal length, and the LES pressure. Antireflux surgery with a fundoplication restores the mechanical antireflux barrier by addressing abnormalities of the LES in several ways. It has been demonstrated that a laparoscopic Nissen fundoplication restores the gastroesophageal junction into the abdominal cavity in patients with a hiatal hernia. The crural closure and the fundoplication both contribute to the overall

sphincter length increase that is observed following a fundoplication. The crural closure may contribute more to the increased LES pressure than the fundoplication, but they both play a role.

On the opposite end of the spectrum from GERD is achalasia. In achalasia, the LES does not relax appropriately with swallowing. This is combined with a loss of esophageal peristalsis that usually results in impaired esophageal emptying. In some patients who defer treatment or are inadequately treated, this can lead to significant esophageal dilation. The anatomic defect appears to be a decrease or loss of inhibitory ganglion cells in the esophageal myenteric plexus. Histologic analysis of specimens in patients who ultimately undergo esophageal resection for end-stage achalasia demonstrates myenteric inflammation and progressive depletion of ganglion cells and neural fibrosis. Macroscopically, there may often be thickening of the circular muscular layer of the distal esophagus. Surgical myotomy can be curative. One of the most essential aspects of an adequate myotomy is the distal extent that this travels onto the stomach. These outcomes demonstrate the complex anatomy and associated physiology of the LES, both in health and in disease.

The UES is an important anatomic and functional area that receives less attention than it deserves. In achalasia, it has been demonstrated that in many patients the UES may act as a barrier to prevent supraglottic reflux and aspiration. In patients with GERD and extraesophageal symptoms, the UES is shorter and more hypotonic than in patients without GERD and/or those with GERD without extraesophageal symptoms. Normal UES function and physiology, especially when it comes to the function of the UES in GERD, is poorly characterized.

Knowledge of the vagus nerves and their anatomic locations at the GE junction as well as in the mediastinum is important for surgeons performing foregut surgical procedures. During a primary Nissen fundoplication, the posterior vagus just above the GE junction is fairly easy to identify. The anterior vagus, as mentioned, is more difficult to identify. One trick to finding this nerve is to lift the GE junction fat pad anteriorly. The anterior vagus is usually traveling from the left lateral side of the esophagus and rotating anteriorly to ultimately wind up on the anterior lesser curve of the stomach by traveling just under this fat pad. When suturing a fundoplication to the esophagus, it is important to avoid passing a stitch through this vagus. When performing a Heller myotomy for achalasia, it is helpful to first identify the anterior vagus nerve, so this can be mobilized and protected during the myotomy. As one moves proximally on the esophagus and into the mediastinum for esophageal mobilization in the case of a hiatal or paraesophageal hernia repair, it is imperative to be aware that the anterior vagus will come in lateral to the esophagus on the left and the posterior will come in to the right of the esophagus before moving posteriorly. The true incidence of clinically significant postsurgical gastroparesis following inadvertent (or even intentional) bilateral vagotomy is unknown. In my personal series of more than 100

reoperative fundoplications (data not yet published), 5% of patients with 1 prior attempt, 29% of patients with 2 prior attempts, and 44% of patients with 3 prior attempts at fundoplication suffered from postsurgical gastroparesis. The presumed etiology in these patients is vagal nerve injury. In the reoperative setting, it can be especially difficult to identify the vagus nerves and to differentiate these from scar tissue.

When reading about the surgical repair of large hiatal/paraesophageal hernias, the topic of a "short esophagus" often comes up. A recent review article on the topic states "*If the need for a Collis gastroplasty is used as the most restrictive definition [for short esophagus], then retrospective review of the literature indicates that between 1% and 5% of patients undergoing GERD-related surgery meet criteria.*" In my opinion, true short esophagus is a rare and congenital anomaly present in about 1% of patients in whom this condition is considered prior to surgery. Short esophagus is a diagnosis made intraoperatively and after extensive mediastinal dissection has failed to bring the gastroesophageal junction into the abdominal cavity. Reference is made in the current chapter to the opinion held by some surgeons that hiatal hernias greater than 5 cm should not be repaired by an abdominal approach. This is a minority opinion and the current practice across the country suggests the same. In an analysis of the 2006–2008 Nationwide Inpatient Sample, we determined that paraesophageal hernia repair was performed via a transabdominal laparoscopic approach in 42%, via a thoracic approach in 7%, and via an open abdominal approach in 50%.

Barrett esophagus (BE) is discussed in this chapter. As mentioned, there is variation in the height of the Z-line, which can make the diagnosis of BE challenging. The Prague classification system is a grading system for BE developed by the International Working Group for the Classification of Esophagitis that helps endoscopists to adequately describe the severity of BE using a standard nomenclature. The Prague classification system emphasizes the use of esophageal landmarks to assess the circumference (C) and maximal (M) extent of the endoscopically visualized BE segment. The proximal notch of gastric cardia tissue under moderate insufflation forms the lower measurement boundary. The two upper measurement boundaries are marked by the proximal limit of the circumferential Barrett segment (C) and the longest tongue of Barrett's (M). Accurate documentation in a reliable and reproducible manner that allows endoscopists to communicate to each other about where a specific biopsy is taken as well as the extent of BE observed on endoscopy is important.

Jon C. Gould

This is an erudite commentary which tells us that there is still room for discussion as to what happens to the esophagus in reflux and pain in the upper esophagus. We still have a lot to learn. Dr. Gould as usual writes an erudite commentary which is a pleasure to read.

70 Transthoracic Antireflux Procedures

Tom R. DeMeester

In 1853 Henry Ingersoll Bowditch published a monograph titled *A Treatise on Diaphragmatic Hernia* in which he commented on the then-current state of knowledge regarding hiatal hernia: “Owing to the ignorance of most of the observers in regard to the true nature of the affection (hiatal hernia), their modes of treatment have been entirely empirical and generally very absurd, and not a few times absolutely harmful to the patient.” Initially, the therapy of hiatal hernia focused only on the surgical correction of the anatomical diaphragmatic defect. The symptoms of hiatal hernia were poorly understood and given no consideration. The possibility that hiatal hernia could encourage the reflux of gastric contents into the esophagus was foreign to the prevailing thought. A typical example of the thinking at the time was one of the publications of Stuart Harrington. He reported on 51 patients with a diaphragmatic hiatal hernia and focused only on describing the anatomical defect and the closure of the hiatus as the surgical treatment. There was no mention of the symptomatology.

It was not until Philip Allison’s publication in 1951 that the symptoms associated with hiatal hernia were linked to the reflux of gastric juice or its contents into the esophagus with the possible development of esophagitis. Allison introduced the term “reflux esophagitis” and emphasized that it was due to a defect in the cardia that allowed acidic gastric juice to reflux into the esophagus. He stated that “it will be noted that it is during inspiration, when the suction pressure in the chest would tend to draw the gastric contents into the esophagus, that the crus of the diaphragm contracts and obstructs this.” Allison theorized, along with others, that “although no internal sphincter can be demonstrated, there is an intrinsic mechanism which contributes to continence.” Allison hypothesized that the latter was due to the anatomical geometry of the gastroesophageal junction since he noted that when the esophagus and stomach were removed from the body, a greater pressure was necessary to drive fluid from the stomach into the esophagus than in the opposite direction. Allison

went on to describe the first rational hiatal hernia repair. The focus was on restoring the normal anatomy of the gastroesophageal junction by reducing the hernia and repositioning the gastroesophageal junction into its normal intra-abdominal location. By doing so he hoped to improve the closing of the gastroesophageal junction by the contracting crus, but added that “if the intrinsic mechanism is ineffective, the diaphragm alone may not be enough to ensure complete continence.” Recognition of a high incidence of symptomatic and anatomic recurrence after the repair led Allison to retract the operation in 1973.

Allison’s contribution altered the surgical approach to hiatal hernia disease. Surgeons started to develop procedures designed to place the gastroesophageal junction in an intra-abdominal position in a more effective manner. A posterior gastropexy was devised by Lucious Hill in 1967, which anchored the gastroesophageal junction and its associated phrenoesophageal membrane to the median arcuate ligament of the aortic hiatus. The Nissen full fundoplication, introduced in 1956, and the Belsey Mark IV partial fundoplication introduced by David Skinner 1967 were designed to establish an intra-abdominal segment of esophagus surrounded by a cuff of stomach in the hope of forming a functional flap valve. The Belsey Mark IV repair was performed through a thoracic incision, the Hill repair through an abdominal incision, and the Nissen repair through an abdominal or thoracic incision.

In 1957 Lee Collis added an important contribution to the repair of hiatal hernia. He introduced a method to manage the shortening of the esophagus that occurred with advanced disease due to reflux-induced intramural fibrosis. He described a technique that adds 3 to 4 cm to the esophageal length by creation of a short proximal gastric tube along the lesser curvature of the stomach. This ingenious technique relieved the tension on a hiatal hernia repair caused by a shortened esophagus and reduced the incidence of reherniation. Later, surgeons added the placement of a partial or full fundoplication around the short gastric tube to improve the competency of the repair.

In 1956 esophageal manometry was introduced by F. Earl Fyke and Charles Cole. This technology led to the discovery of a nonanatomical sphincter at the gastroesophageal junction (Fig. 70.1). This became known as the lower esophageal sphincter and was subsequently shown to be the major barrier against the reflux of gastric contents into the esophagus. In 1979 Dorothy Liebermann-Meffert showed with tedious dissection an

asymmetrical muscle thickening in the wall of the esophagus located below the diaphragm and above the angle of His. A manometrically defined high-pressure zone was located in the area and the length of the high-pressure zone was similar to the length of the thickening. The highest pressure was found in the area of greatest muscle thickening. The ability to measure the height and length of the lower esophageal high-pressure zone allowed assessment of various antireflux procedures in their ability to improve the function of the newly discovered barrier. Of the three procedures, the Nissen full fundoplication was most effective in restoring the competency of the lower esophageal sphincter, followed by the Belsey partial fundoplication and the Hill posterior esophagogastropexy.

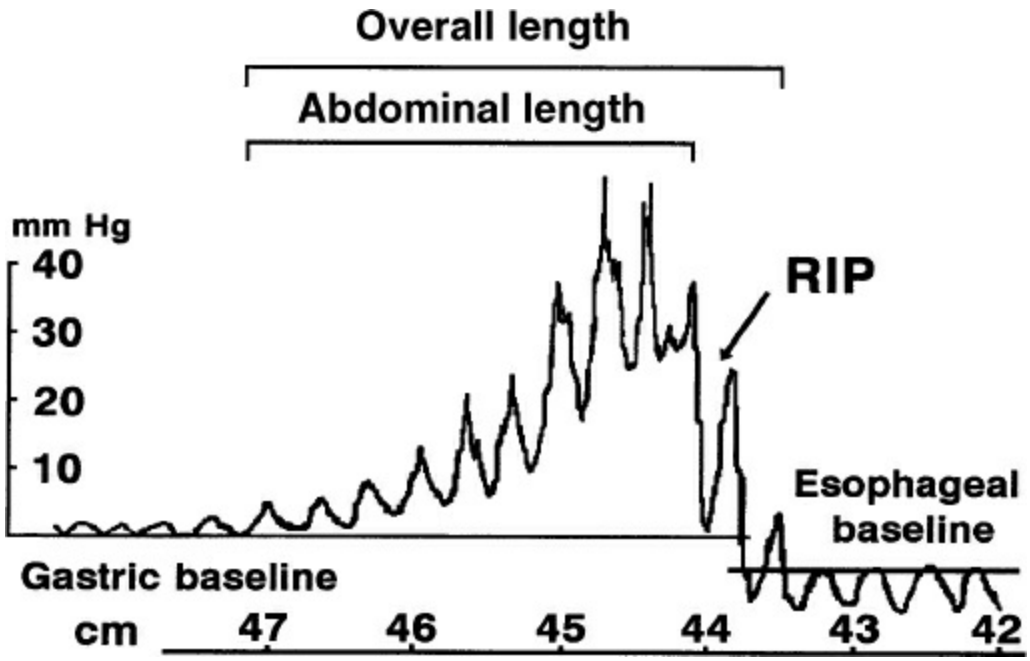

Figure 70.1. Normal manometric tracing of the lower esophageal sphincter obtained by pulling the transducer from the stomach through the gastroesophageal junction and into the esophagus. Note the resting baseline gastric pressure is greater than the resting baseline esophageal pressure. There are positive deflections with inspiration in the gastric or intra-abdominal portion of the record and the negative deflections with inspiration in the intrathoracic or esophageal portion of the record. RIP, respiratory inversion point.

In 1991 Bernard Dallemagne performed the first laparoscopic Nissen fundoplication in a human. He successfully performed laparoscopic ligation of the short gastric vessels, safe posterior dissection of the abdominal portion of the esophagus, and plication of the lower esophagus

between a fold of anterior and posterior fundus. These were significant accomplishments at that time. Today, laparoscopic Nissen fundoplication has become commonplace, and its safe, effective, and patient-friendly reputation has encouraged its use for advanced reflux disease. The major drawbacks of the procedure are the side effects of postprandial bloating, inability to belch or vomit, and a small but significant incidence of persistent dysphagia.

Today, surgeons are comfortable performing laparoscopically a high mediastinal dissection to mobilize the esophagus and a Collis gastroplasty if at least 2 to 3 cm of distal esophagus does not lie comfortably and free of tension in the abdomen after the mobilization. Currently, only the most complex multiple re-do operation requires an open operation, usually done through a transabdominal incision. Rarely is an open transthoracic Nissen performed. I have not performed one in the past 10 years. The only time a thoracic approach is likely to be considered is when a thoracotomy is required for another reason and an antireflux operation also needs to be done. This being said, it is probably wise to describe the technique just in case the need to perform the procedure arises. Indeed, the well-trained esophageal surgeon should have complete mastery of both a partial and full fundoplication whether performed laparoscopically, transabdominally, or transthoracically.

PRINCIPLES OF AN ANTIREFLUX REPAIR

Antireflux surgery is based on the principle that altering the anatomy of an organ can, in some situations, improve the organs function. For a surgeon to do so requires a thorough knowledge of the organs function and an acceptance that the results, because of the various situations encountered, are likely not to be as good as extirpation surgery. The surgeon’s attention to detail and his ability to adapt the procedure to various situations encountered are essential to achieving the best results. In that regard, there are four principles important in restoring the gastroesophageal barrier that should be understood by all surgeons who perform antireflux procedures.

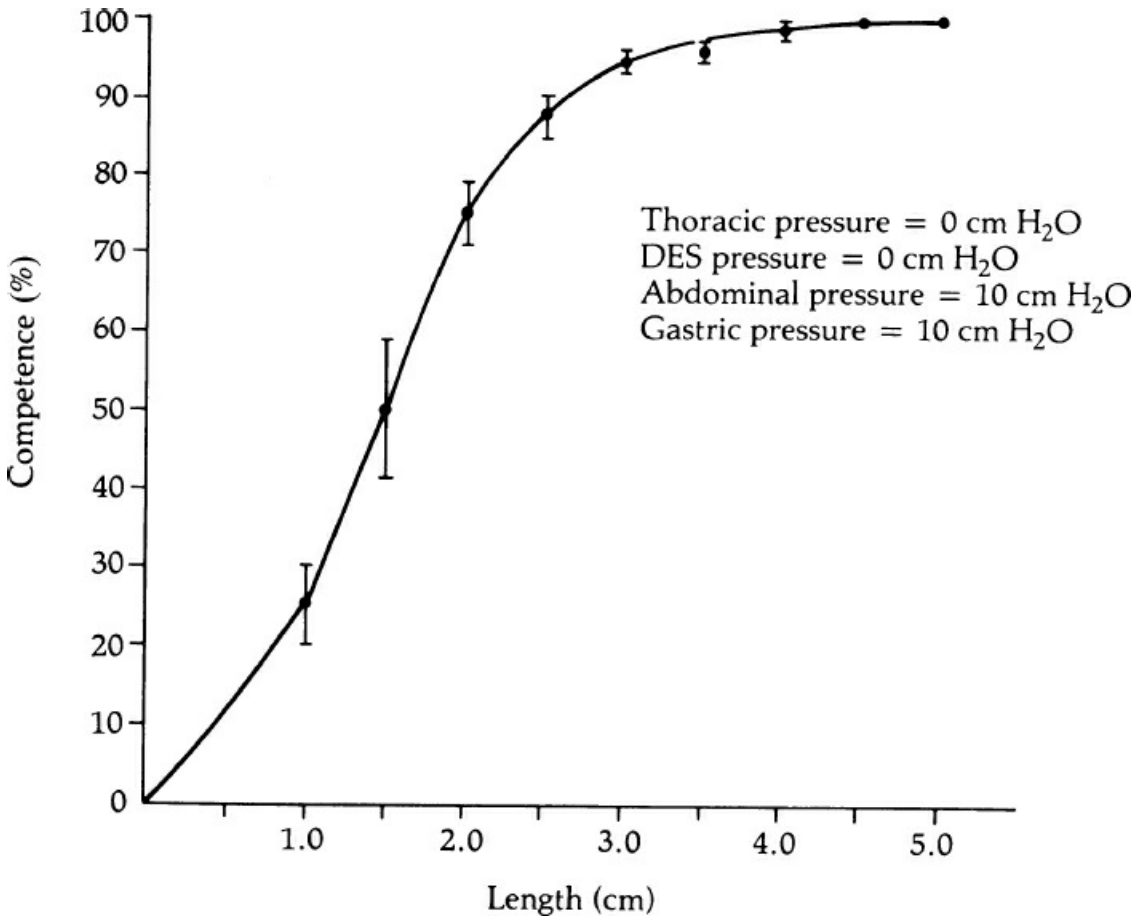

Figure 70.2. The length of abdominal sphincter required for competency in the absence of intrinsic sphincter tone. An abdominal length of 4 cm is required for 100% competence. DES, distal or lower esophageal sphincter.

First, the operation should permanently restore at least 2 cm of abdominal esophagus so that the lower esophageal sphincter can respond to the challenges in intra-abdominal pressure. We showed that the degree of competence provided by the lower esophageal sphincter against resting intra-abdominal pressure is a direct function of its abdominal length independent of its intrinsic muscle tone (Fig. 70.2). This relationship is very efficient in that as intra-abdominal pressure increases, the abdominal length of the lower esophageal sphincter necessary for competence decreases (Fig. 70.3). The intrinsic muscle tone in the lower esophageal sphincter augments this efficiency further. The relationship breaks down when the abdominal length of the sphincter is ≤1 cm (Fig. 70.4). At this length, even high levels of intrinsic muscle tone are unable to restore competency. Consequently, the permanent restoration of 2 cm of the abdominal sphincter length in a patient with normal sphincter tone

maintains the competency of the sphincter over a wide range of intra-abdominal pressures challenges. These observations encourage sufficient mobilization of the distal esophagus so that a ≥2-cm segment rests below the diaphragm without tension. Furthermore, the construction of a conduit to ensure transmission of intra-abdominal pressure challenges around the abdominal esophagus is also an important aspect of restoring competency. A complete or partial fundoplication serves this purpose. In the absence of a conduit, the development of postoperative periesophageal adhesions can prevent the transmission of intra-abdominal pressure challenges to the abdominal portion of the lower esophageal sphincter. This allows the pressure challenges to act unequally on the stomach and the sphincter's abdominal length, resulting in sphincter incompetency and reflux.

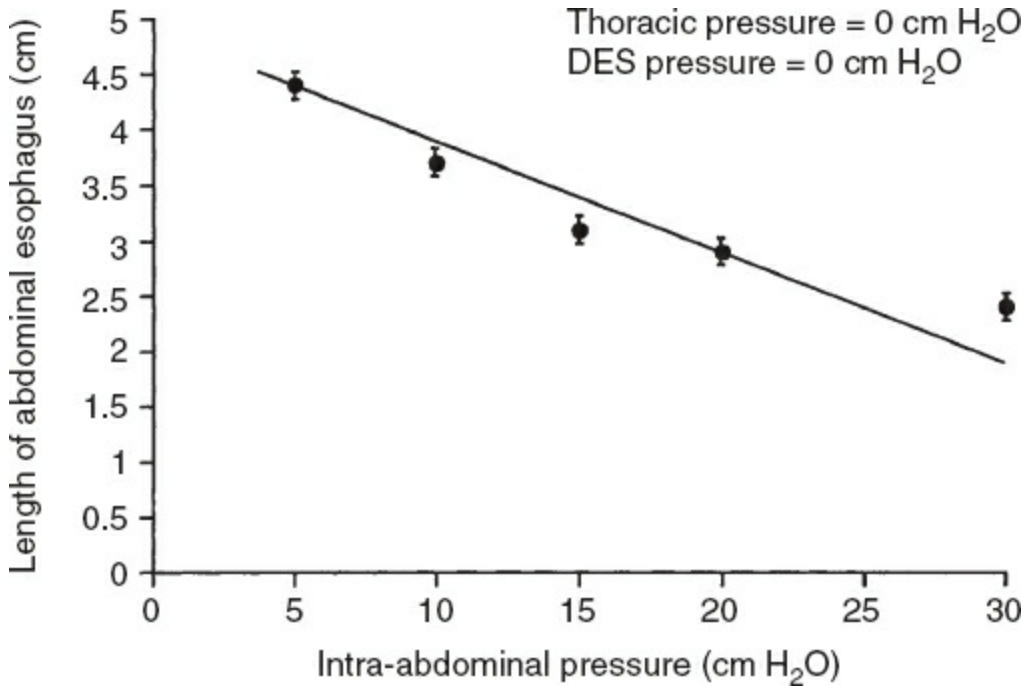

Figure 70.3. The mechanical efficiency of abdominal sphincter length to maintain competency in the absence of intrinsic sphincter tone to challenges of increased intra-abdominal pressure. Increases in intra-abdominal pressure require shorter abdominal sphincter length to maintain competency. DES, distal or lower esophageal sphincter.

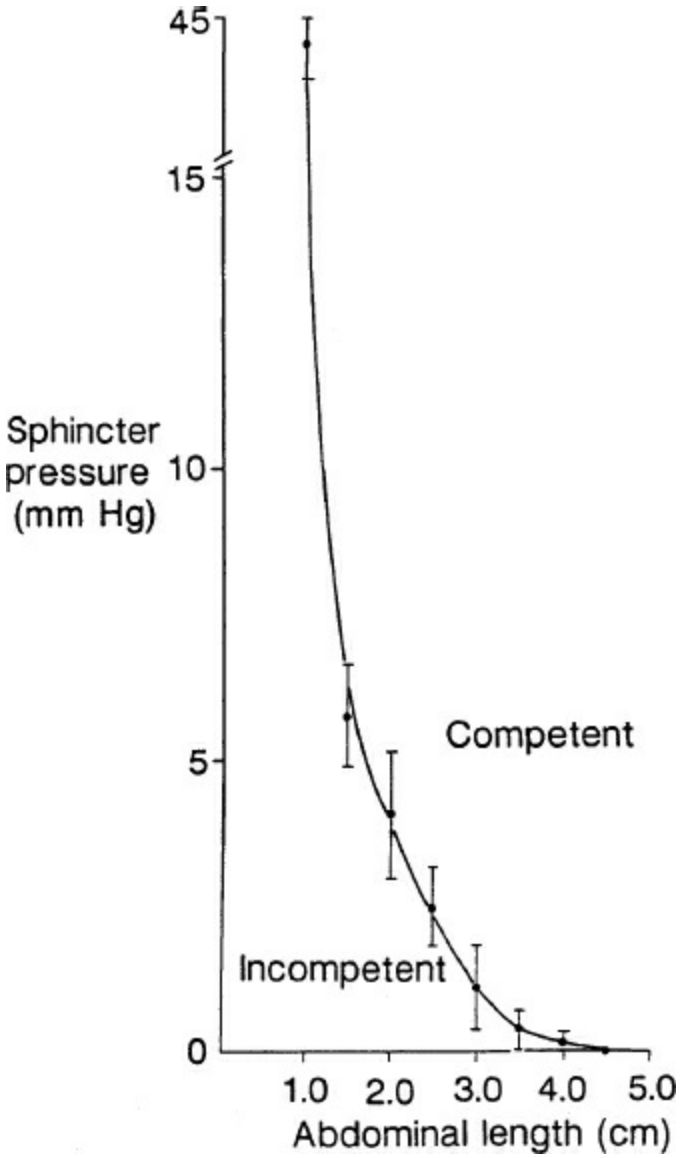

Figure 70.4. The effect of intrinsic sphincter tone on the length of abdominal esophagus required to maintain competency against intra-abdominal pressure challenges. More intrinsic sphincter pressure is required for shorter abdominal sphincter lengths. Physiologic intrinsic sphincter pressure is unable to compensate for abdominal sphincter length ≤1 cm.

The second principle is to use a technique that prevents reflux from episodes of gastric distention and independent increase in gastric pressure over intra-abdominal pressure. This requires augmenting the resting distal esophageal sphincter pressure to a level equal to or greater than three times the resting gastric pressure (~15 mm Hg), and maintaining an overall sphincter length of at least 2 cm. A gastric fundoplication reliably augments the resting lower esophageal sphincter pressures. The level of increase is related to the degree of fundoplication and is likely due to the

addition of gastric muscle tone to the intrinsic muscle tone of the sphincter (Fig. 70.5).

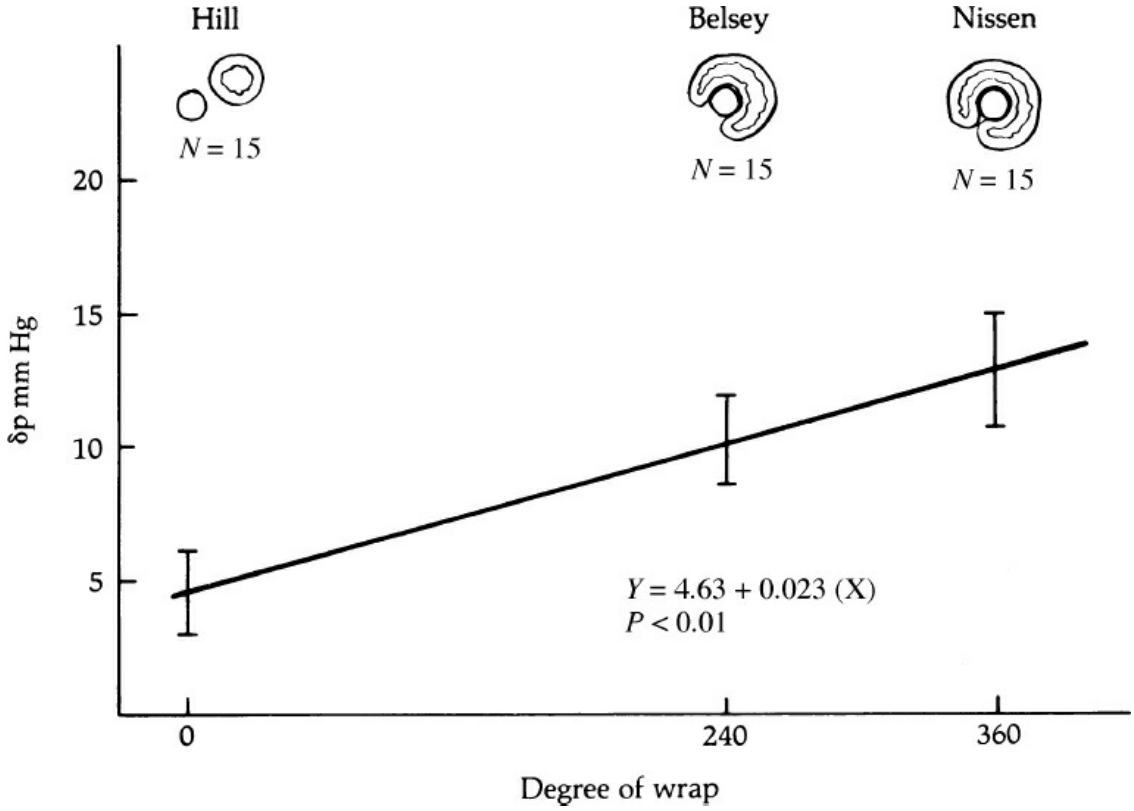

Figure 70.5. The increase in postoperative sphincter pressure over preoperative pressure obtained with various degree of fundoplication.

The transient loss of sphincter length is a recognized cause of reflux in a person with normal sphincter resting pressure and length. Dr. Ayazi has shown that transient losses in abdominal sphincter length are caused by gastric distention. The abdominal sphincter length shortens by effacement into the distended fundus like the neck of a balloon shortens into the distended portion of the balloon with inflation. The shorter the sphincter length becomes, the greater is the intrinsic sphincter pressure required to maintain competence (Fig. 70.6). A fundoplication acts like a collar around the sphincter that effectively prevents the loss of sphincter length in response to gastric distention.

The third principle is to restrict the portion of stomach used to construct the fundoplication to the gastric fundus. To facilitate normal swallowing, the distal esophageal sphincter must relax. On deglutition, a vagal-mediated relaxation of the distal esophageal sphincter and fundus of the stomach occurs. This relaxation lasts for ~10 seconds and is followed by

rapid recovery to its former resting tone. To ensure relaxation of the reconstructed sphincter, only the fundus of the stomach should be used to construct the fundoplication since it is known to relax when the distal esophageal sphincter relaxes.

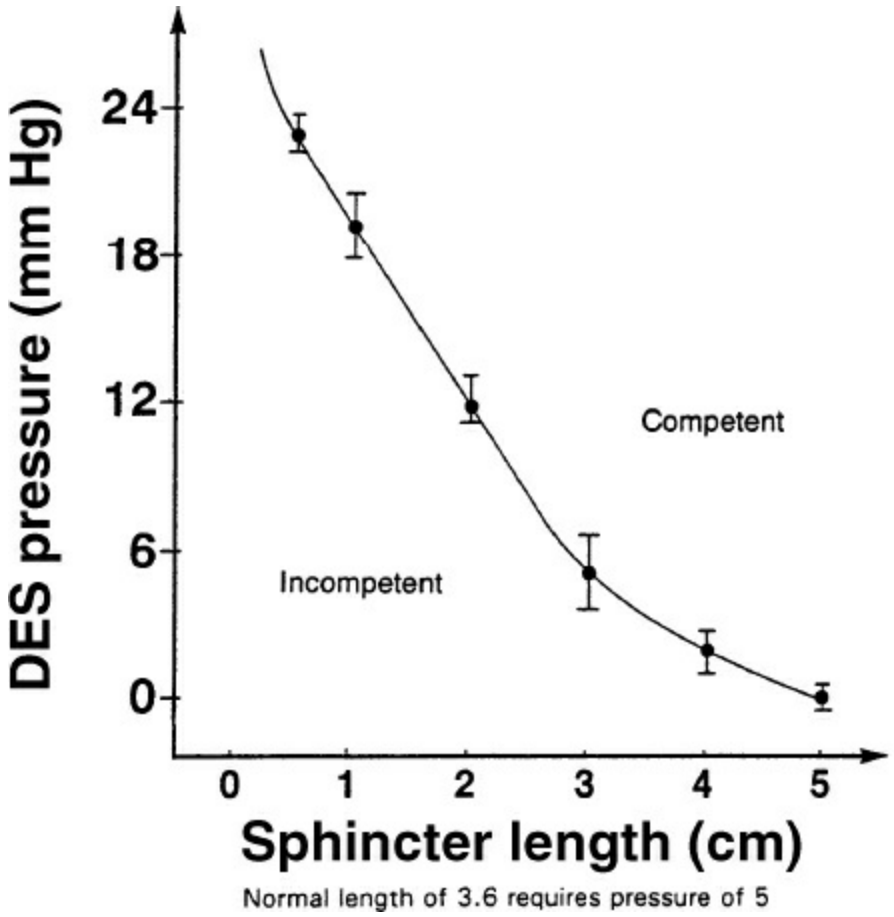

Figure 70.6. The relationship of overall lower esophageal sphincter length and pressure to maintain competency against intragastric pressure challenges. DES, distal or lower esophageal sphincter.

The fourth principle is to use a technique that matches the resistance to flow through the reconstructed sphincter to the propulsive power of the esophageal body. The choice between a 360-degree or partial 240-degree fundoplication is influenced by the strength of the peristaltic contractions. Normal wave progression and strong contractions do well with a complete 360-degree fundoplication. When the prevalence of peristaltic wave progression is reduced to <50%, or esophageal contraction amplitudes in the distal half of the esophagus are ≤20 mm Hg, a partial 270-degree fundoplication is recommended as this degree of fundoplication has no measurable resistance to esophageal emptying (Fig. 70.7). Inappropriate

matching of the body of the esophagus to the resistance of the reconstructed sphincter causes a delay in the passage of food through the sphincter and symptoms of dysphagia. A complete 360-degree fundoplication provides excellent control of reflux but adds considerable resistance to the passage of a bolus through a relaxed sphincter. This resistance is related to the postoperative level of sphincter pressure and the length of the fundoplication. The postoperative sphincter pressure should not be in the hypertensive range and the length of the sphincter should not exceed 1.5 to 2.0 cm (Fig. 70.7).

INDICATIONS FOR THE THORACIC APPROACH

Although the indications for an antireflux repair and the biomechanics of an antireflux repair done by laparoscopic and open approaches are similar, there are specific situations in which an open thoracic approach provides an advantage. These include the following:

1. A patient who has an intrathoracic stomach and a history of multiple previously failed antireflux repairs. A repeat open operation in this situation can be technically easier through the chest.
2. A patient who has extensive shortening of the esophagus. The thoracic approach in this situation allows for maximum mobilization of the esophagus in order to place the repair, without tension, in the abdomen with or without a gastroplasty to lengthen the esophagus.
3. A patient with reflux disease who requires a thoracotomy for another reason. If the pulmonary disease is on the left side, an open transthoracic approach allows both problems to be addressed through one incision.

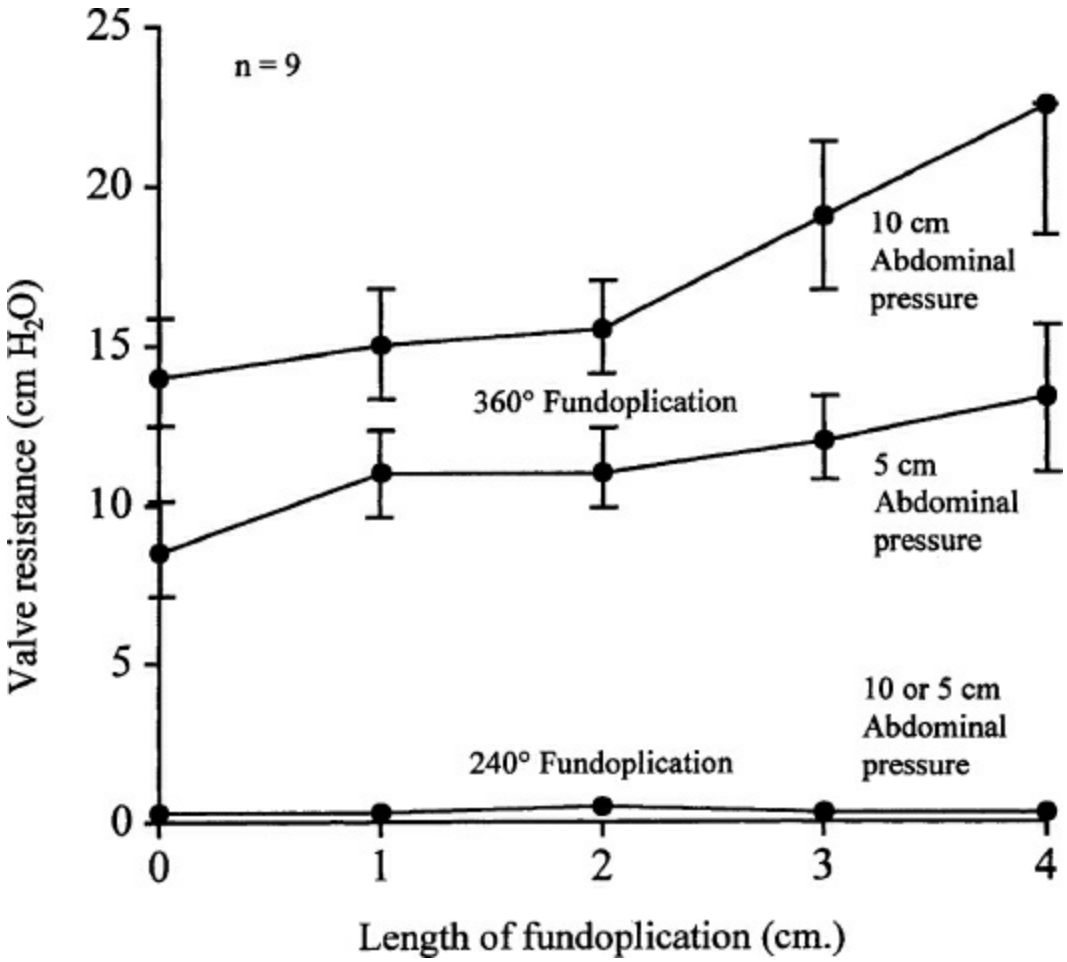

Figure 70.7. The amount of pressure the esophageal body must generate to overcome the resistance of a 360-degree or 240-degree fundoplication of various lengths, in the absence of intrinsic tone, and at different levels of abdominal pressure.

SURGICAL TECHNIQUE

Belsey Mark IV Partial Fundoplication

Professor Ronald Belsey of Great Britain introduced the Belsey partial fundoplication in 1967. The technical details of the Belsey and the transthoracic Nissen operation are similar, differing only in the completeness of the gastric fundoplication and the length of tension-free intra-abdominal esophagus necessary to perform the repair. The former requires a minimum of 4 cm and the latter 2 cm. Consequently, the clinical success of a Belsey repair decreases progressively from 90% in the patients who have no esophageal shortening to 50% in those who have significant shortening.

The diaphragmatic hiatus is approached through a left posterolateral thoracotomy in the sixth intercostal space (i.e., along the upper border of

the seventh rib). For the patients who had a previous failed antireflux repair, we prefer to use the seventh intercostal space. This allows better exposure of the abdomen through a peripheral diaphragmatic incision. The incision is made circumferentially in the anterolateral portion of the diaphragm, 2 to 3 cm from the chest wall, for a distance of 10 to 15 cm. A sufficient fringe of diaphragm must be left along the chest wall to allow for easy closure of the incision. If further abdominal exposure is necessary, the thoracic incision can be extended across the costal margin and diagonally down to the abdominal midline, dividing the fibers of the left rectus muscle. The operation is made easier if a double-lumen endobronchial tube is used for anesthesia and the left lung is selectively deflated.

The esophagus is mobilized from the diaphragm to underneath the aortic arch. Care is taken not to injure the vagal nerves. Branches of the vagal plexus going to the left and right lung must be divided to obtain maximal esophageal length. This allows construction, without tension, of a partial fundoplication over a 4-cm segment of abdominal esophagus. Two vessels arise from the proximal descending thoracic aorta just distal to the arch and pass over the esophagus to the left main stem bronchus. They are the left superior and inferior bronchial arteries. Ligation of these arteries is also necessary to fully mobilize the esophagus. In addition to these arteries, two to three direct esophageal branches come off the distal descending thoracic aorta and pass directly to the esophagus. These are also ligated and divided without concern about ischemic necrosis of the esophagus. There is sufficient blood supply to maintain the integrity of the esophagus through its intrinsic arterial plexus, fed by the inferior thyroid artery in the neck and by the branches from the right bronchial artery in the thorax. This degree of mobilization is necessary to place the repair into the abdomen without undue tension. Failure of adequate mobilization is one of the major causes for subsequent breakdown of a repair and the return of symptoms.

Freeing the gastroesophageal junction and gastric cardia from the diaphragmatic hiatus is the most difficult portion of the procedure, but can usually be completed through the esophageal hiatus. It is unnecessary to make a counterincision through the central tendon of the diaphragm or to enlarge the hiatus by an incision through the crura. The dissection is started by gaining access to the abdominal cavity through the phrenoesophageal membrane. It can be difficult at times to find the correct

tissue plane once the membrane has been divided due to the protrusion of the properitoneal fat. Persistence and dissection underneath the retracted left crus, away from the gastric vessels, eventually yield entry into the free peritoneal space. Entering the abdominal cavity is easier when a hiatal hernia is present.

The proper stance of the surgeon at the operating table aids in freeing the hiatus. With the patient in the left posterior thoracotomy position, the surgeon should stand adjacent to the patient's back, facing the head of the table. The left index and middle fingers are placed through the diaphragmatic hiatus into the abdominal cavity, with the palm facing the patient's feet. The surgeon's line of vision is down and backward under his or her left axilla. With judicious use of the left thumb, index, and middle fingers, the surgeon is able to spread the hiatal tissues and divide them with a scissors controlled by the right hand. In this position, the left hand is also used to retract the esophagus and protect the vagal trunks. Although it sounds somewhat awkward, this stance greatly facilitates the most difficult part of the operation.

All the attachments between the gastric cardia and diaphragmatic hiatus are divided. The short gastric vessels are divided and ligated one by one to allow good mobilization of the fundus. When free, the fundus and part of the body of the stomach are drawn up through the hiatus into the chest (Fig. 70.8). The vascular fat pad, which lies on the anterior and lesser curvature surface of the cardia, is excised. Care must be taken during this dissection to avoid injury to the vagal nerves. The fundus of the stomach must adhere firmly to the lower esophagus, and the fat pad, if not removed, interferes with synechia formation between these two structures.

The completely mobilized esophagus is encircled with a Penrose drain and retracted toward the anterior border of the hiatus to give exposure for the closure of the posterior hiatus. The right and left crura of the diaphragmatic hiatus are identified and approximated with interrupted figure-eight nonabsorbable 0 sutures (Ethibond), taking generous bites of muscle. Usually, there is a decussation of muscle fibers from the right crus that passes anteriorly over the aorta to join muscle fibers from the left crus, but occasionally the aorta lies free within the enlarged hiatus. In either situation, the first crural suture is placed close to the aorta. Traction on this first posterior crural stitch elevates the right crus toward the surgeon and facilitates the placement of subsequent crural sutures. Occasionally, it is necessary to mobilize the pericardium off the diaphragm to give better

exposure of the fascia and muscle making up the right crus. The subsequent crural sutures should incorporate the fascia from the periphery of the central tendon that blends in with the muscle fibers making up the right crus.

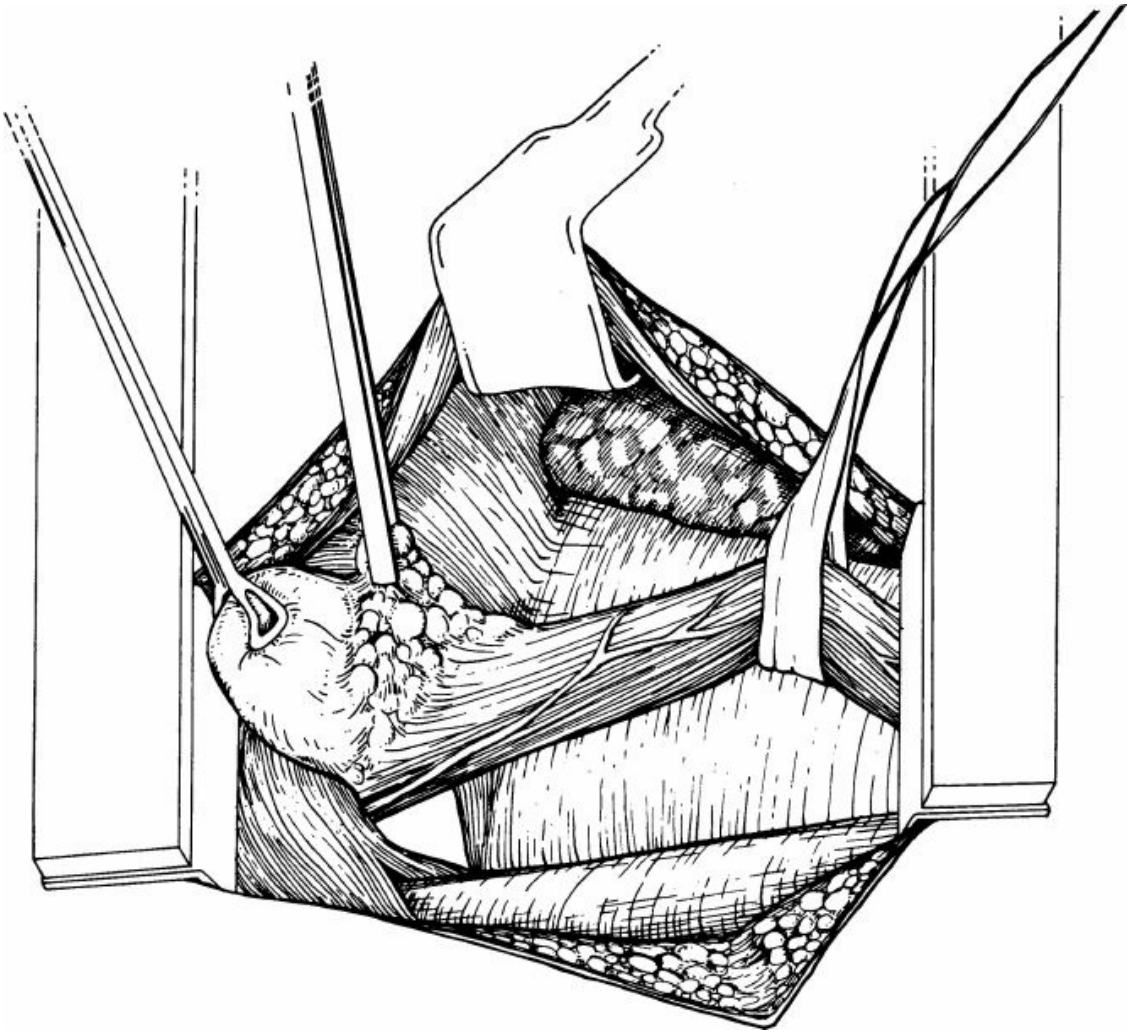

Figure 70.8. Mobilization of the esophagus and stomach through a left posterolateral thoracotomy. The esophagus, gastroesophageal fat pad, stomach, diaphragmatic hiatus, aorta, pericardium, and lung are depicted. The fundus of the stomach is drawn through the hiatus into the chest with a Babcock clamp. The forceps is on the vascular fat pad at the gastroesophageal junction.

On the left side, the sutures are passed through the muscle fibers of the left crus and the firmly adherent overlying pleura. Approximately three to four figure-eight sutures, placed 1 cm apart, are necessary to approximate the crura and to adequately reduce the size of the hiatus. All sutures are

initially placed prior to tying because it is easier to remove those not needed than to add additional sutures after the hiatus has been closed. Tying the crural sutures is the last step in the repair (Fig. 70.9).

The construction of the gastric fundoplication is the keystone of the antireflux repair in that its proper function is responsible for fulfilling the four principles necessary to reestablish the competence of the cardia. In the Belsey Mark IV operation, the fundus of the stomach is plicated around the anterior two thirds of the lower 4 cm of esophagus. The partial fundoplication is held in place by two rows of three horizontal mattress sutures placed equidistantly and in the seromuscular layers of the stomach and the muscular layers of the esophagus. Number 000 silk sutures are used, and each suture obtains a firm grip of the esophageal muscle fibers by passing down to, but not through, the muscularis mucosae. The first row of sutures is placed 1.5 cm above the cardia and is tied only tight enough to obtain tissue apposition without disrupting the muscle fibers of the esophagus. It is important to remember that the hiatus is approached surgically from the left lateral position. To construct the fundoplication over the anterolateral two thirds of the esophagus, it is necessary that the far right suture be placed in the right lateral wall of the esophagus. This is out of the surgeon's view and requires rotation of the esophagus before placement of the suture. A common mistake is placing this suture too far anteriorly, resulting in an anterolateral fundoplication displaced to the left (Fig. 70.10).

A second row of 000 sutures is placed 2 cm above the first row, using the position of the previously placed first row of sutures as a guide (Fig. 70.11). The second row of sutures is tied carefully so as to give tissue apposition without strangulation. The tails of these sutures are not cut, but are separately rethreaded on a large thin Ferguson needle and are passed 0.5 cm apart from each other through the diaphragm from the abdominal to the thoracic surface 1.0 to 1.5 cm from the edge of the hiatus. The diaphragmatic sutures are placed at the 4, 8, and 12 o'clock positions on a clock face, oriented with the 6 o'clock position at the posterior hiatus between the right and left crura just anterior to the aorta (Fig. 70.12). It is important to properly place the right lateral, or 4 o'clock, suture to avoid the common error of putting this suture too far anteriorly, in the 1 or 2 o'clock positions, and constructing an anterolateral fundoplication displaced to the left. These sutures must be carefully placed to avoid injury to the abdominal structures. A spoon retractor has become a popular

instrument to aid in placing these sutures without snagging abdominal mesentery or omentum. The needle is guided along the inner surface of the spoon held firmly against the undersurface of the diaphragm before it is passed through the diaphragm.

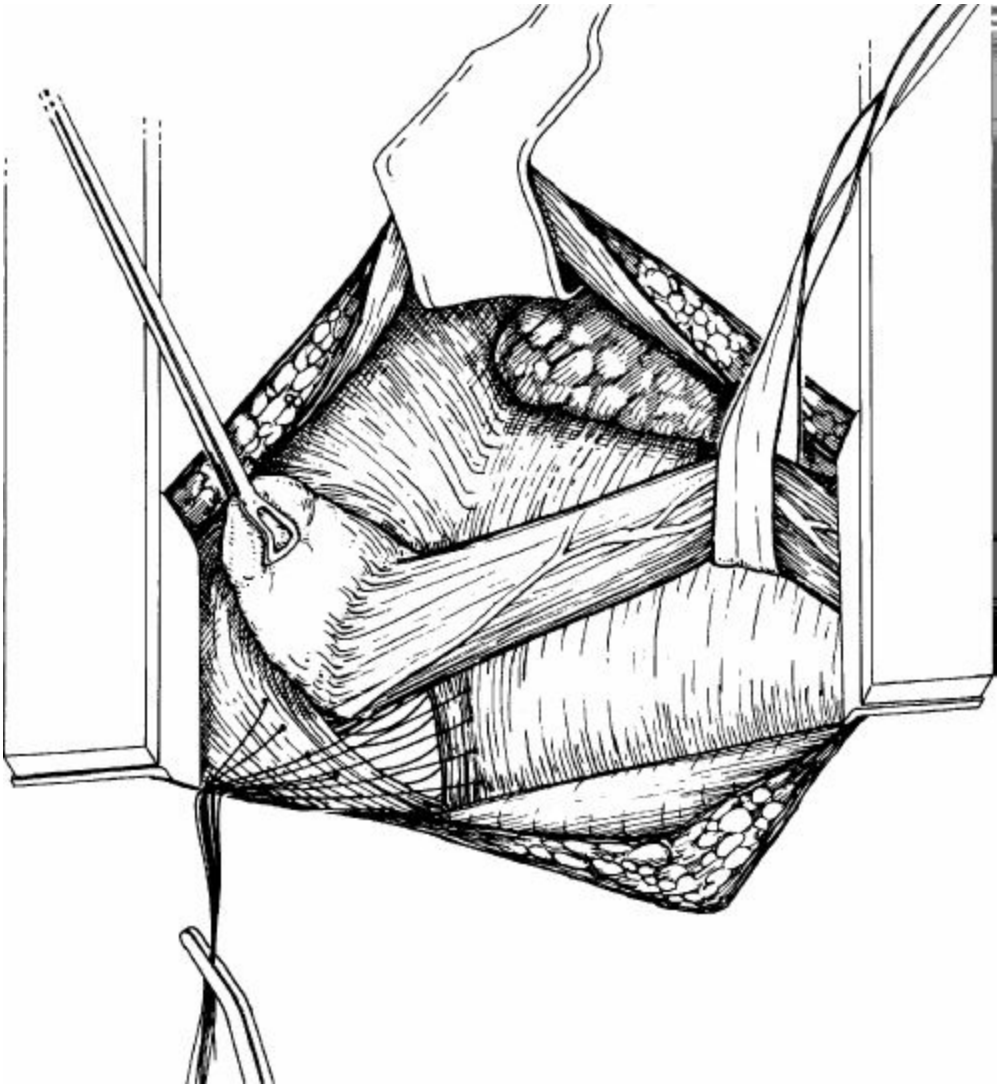

Figure 70.9. A transthoracic exposure showing the vascular fat pad removed and anterior retraction of the esophagus with placement of the crural sutures for closure of the posterior hiatus.

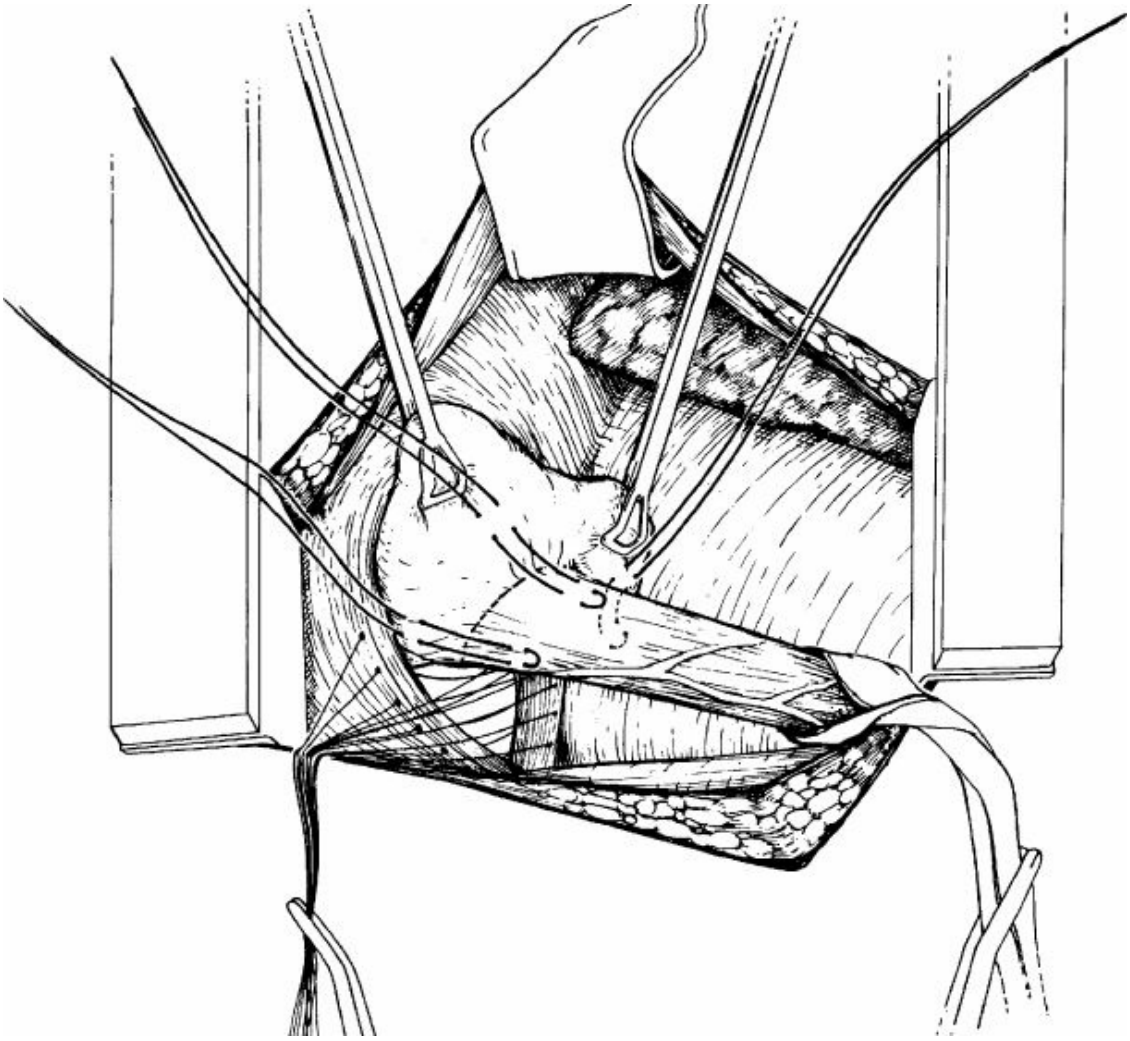

Figure 70.10. Construction of a Belsey 240-degree partial fundoplication showing placement of the first row of sutures 1.5 to 2.0 cm above the gastroesophageal junction. Particular attention must be given to placement of the right lateral suture (see text).

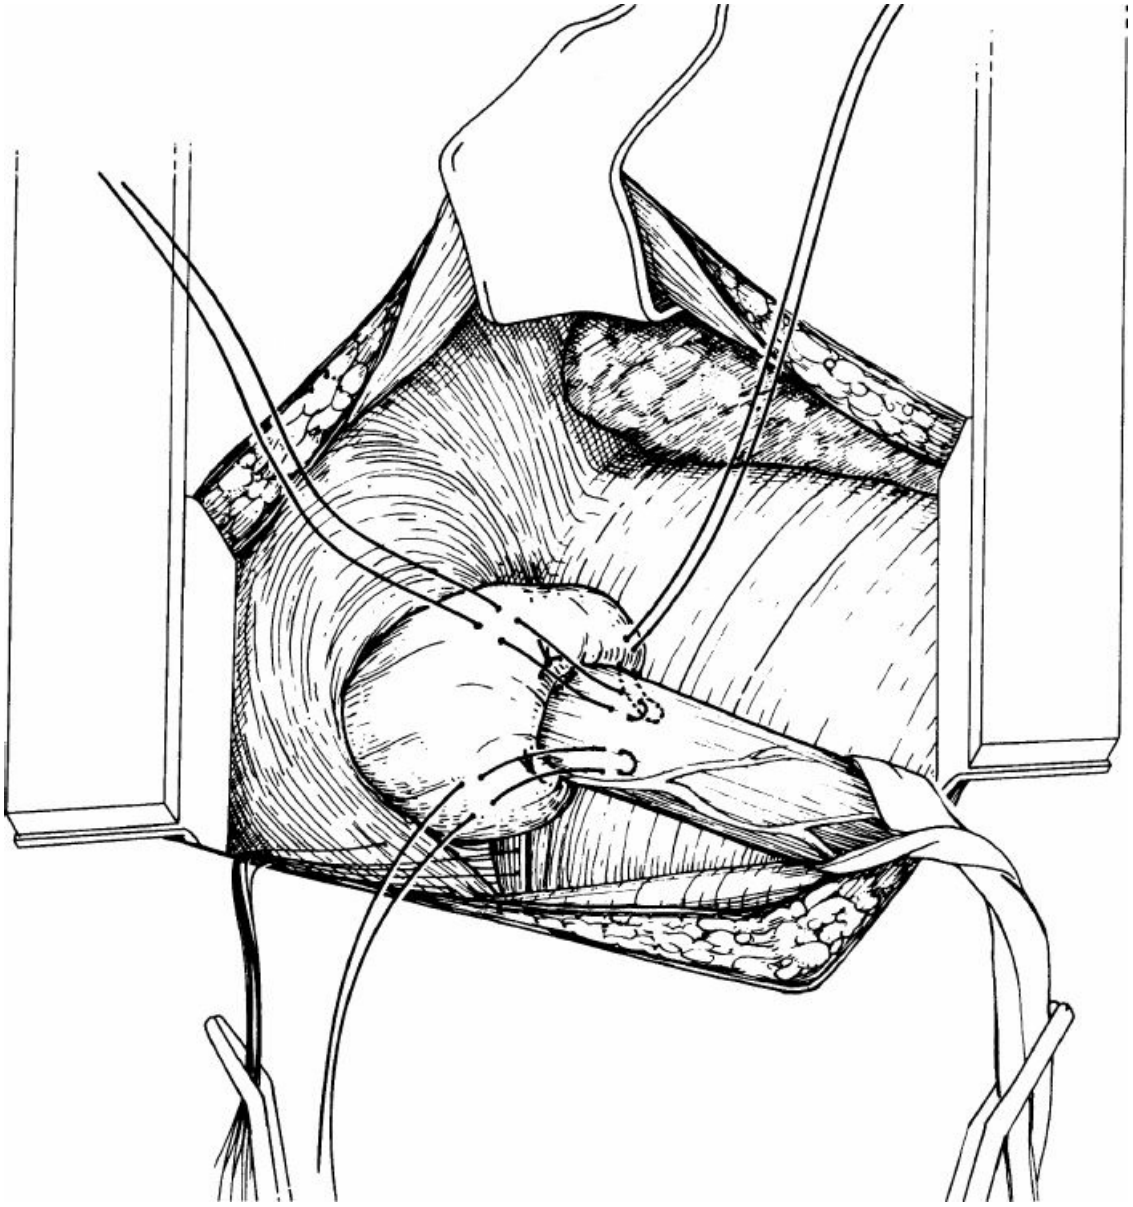

Figure 70.11. Continued construction of the Belsey 240-degree partial fundoplication showing placement of the second row of sutures 2 cm above the row of previously tied sutures.

The partial fundoplication is massaged through the hiatus and into the abdomen. It is not dragged down into the abdomen by pulling on the diaphragmatic sutures, but rather is placed into the abdomen by compressing the fundic ball with the hand and manually maneuvering it through the hiatus. Resistance to placing the repair into the abdomen can result from the shoelace obstruction of the previously placed crural sutures. Opening the crural sutures, as loosening the laces of a shoe, relieves the obstruction and helps in placing the partial fundoplication into the abdomen. Once in the abdomen, the fundoplication should remain

there without tension on the holding sutures. A gentle up-and-down hand motion on the diaphragm should not encourage the fundoplication to pop back through the esophageal hiatus. If the repair remains in the abdomen unaided, the previously placed crural sutures are tied. The holding sutures are then tied, approximating the knot against the previously tied knot so as to avoid any redundancy in the suture between the repair and the diaphragm (Fig. 70.13). An additional safety factor of the double-knot technique is that if one of the tails of the holding sutures breaks while it is being tied, it is not necessary to take the repair down, pull the stomach back up into the chest, and inserting a new suture. Simple anchoring of the single remaining tail to the diaphragm is sufficient to hold the cardia in position. The technique also prevents tying the sutures too tight and causing necrosis of the incorporated esophageal and gastric tissue.

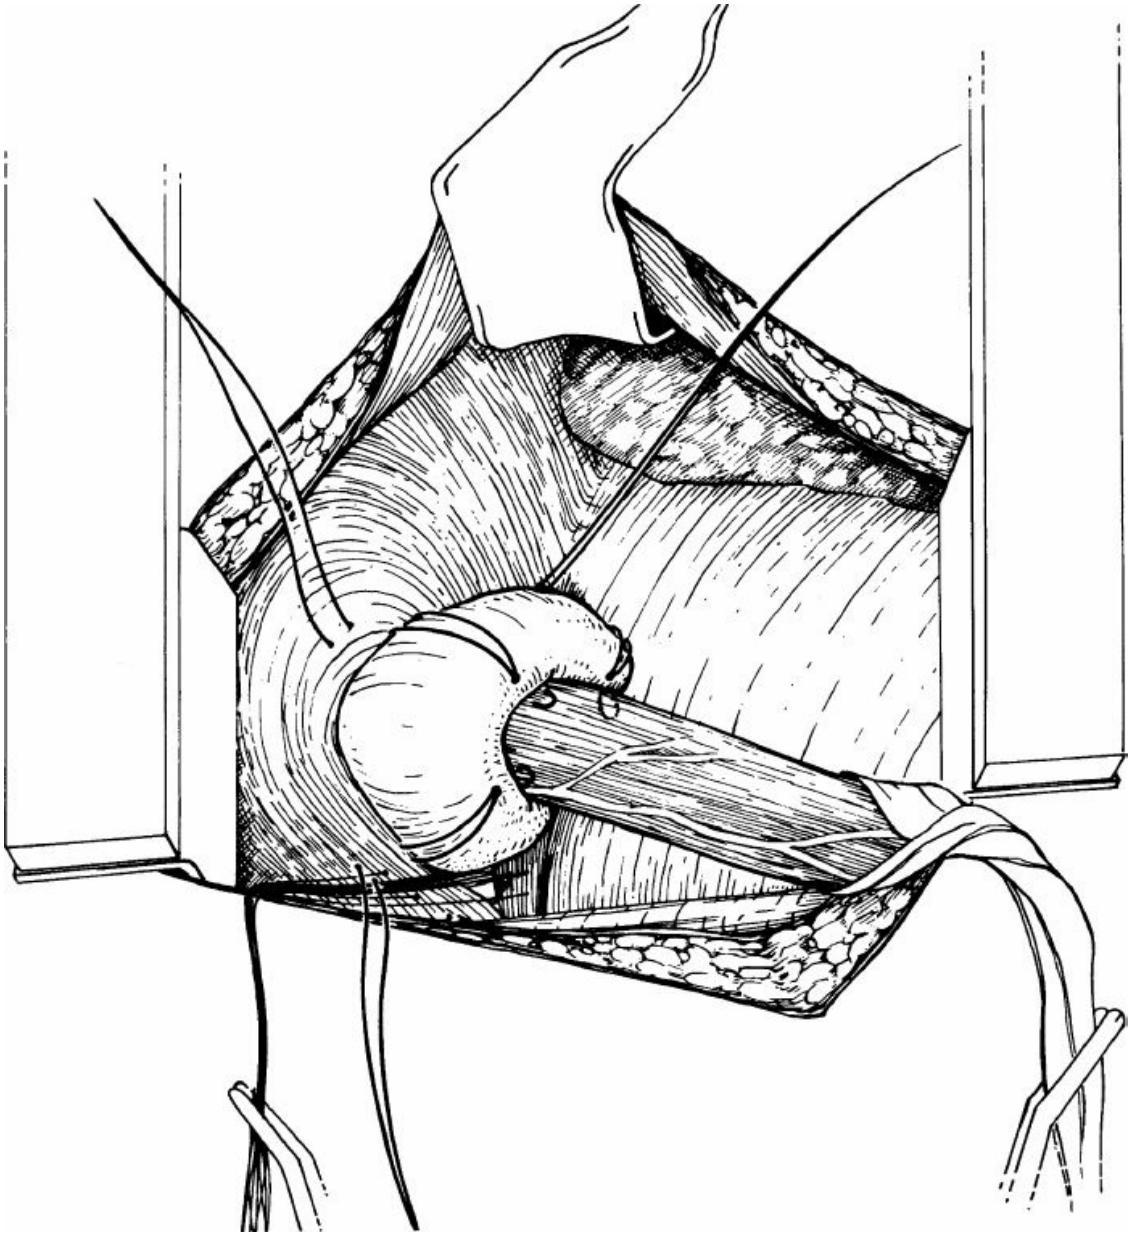

Figure 70.12. Continued construction of a Belsey 240-degree partial fundoplication showing the tails of the previously tied second-row sutures are placed through the diaphragm, 0.5 cm apart and 1.0 to 1.5 cm from the edge of the hiatus. Note the placement of the sutures at the 4, 8, and 12 o'clock positions on an imaginary clock face oriented with the 6 o'clock position posterior in the hiatus between the right and left crura just anterior to the aorta.

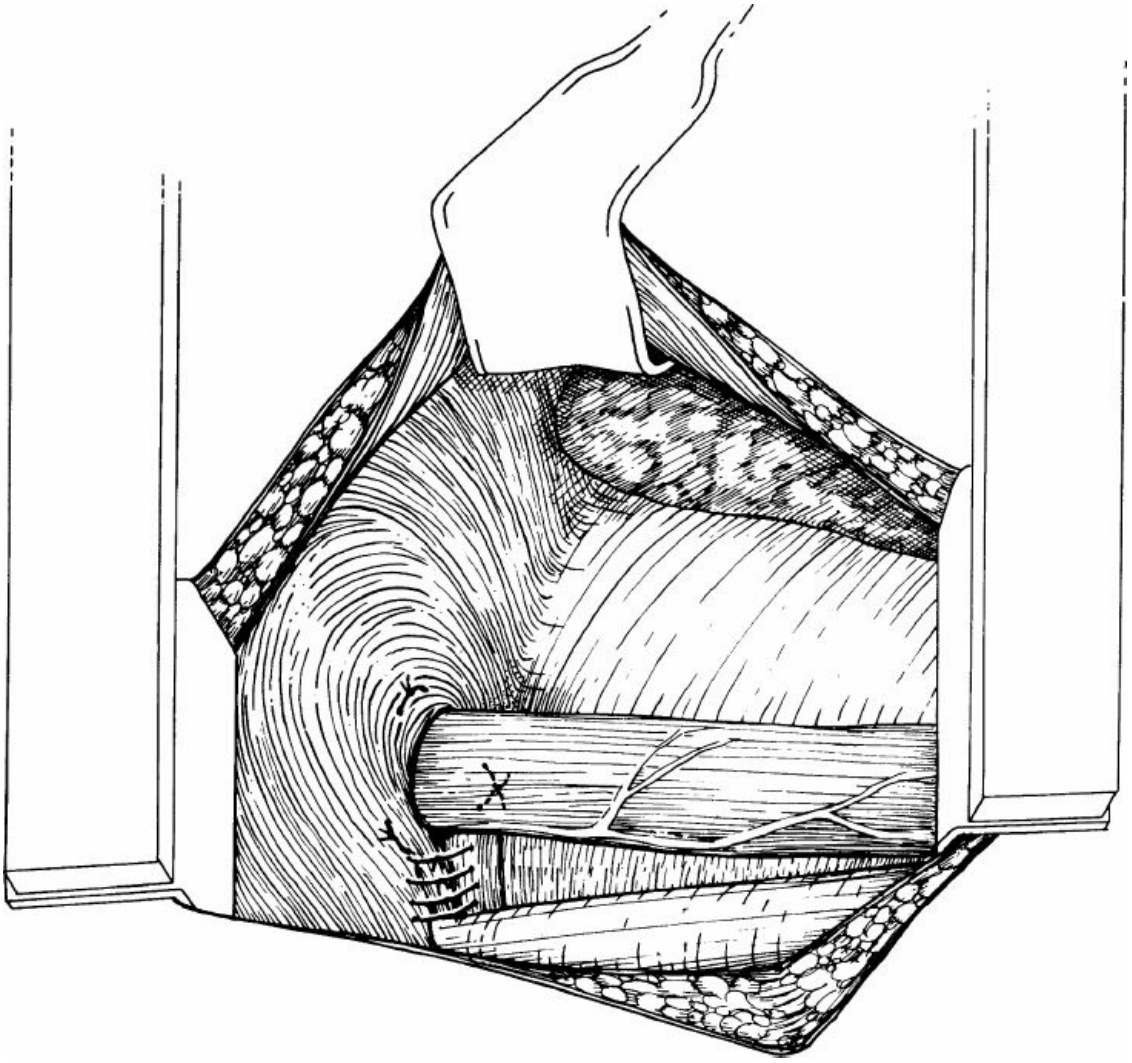

Figure 70.13. A completed Belsey 240-degree partial fundoplication showing the right and left crura approximated after tying the previously placed crural sutures. The positions of the tied holding sutures are also shown.

If the fundoplication tends to ride up through the hiatus, tension on the repair is too great. It is usually caused by inadequate mobilization of the esophagus. If after further attempts at mobilization the tendency remains, a Collis gastroplasty may be necessary.

Transthoracic Collis Gastroplasty

Dr. John Leigh Collis of Great Britain initially introduced the concept of a gastroplasty in 1957 as an antireflux procedure. It was modified in 1987 by Dr. Griffith Pearson to include a Belsey-type partial fundoplication over the gastroplasty tube. The Collis–Belsey procedure, as it was called, is performed in the patients who have gastroesophageal reflux disease

(GERD) complicated by esophageal fibrosis and shortening. As a result of the severe alterations in esophageal body structure and function, many of these patients present with dysphagia in addition to heartburn and regurgitation.

The gastroplasty procedure lengthens the esophagus by constructing a tube along the lesser curve of the stomach to create a "neoesophagus." This allows construction of a tension-free partial Belsey Mark IV or a full Nissen fundoplication over the gastric tube and reduces the risk of subsequent retraction of the fundoplication into the chest. We prefer to combine the full Nissen fundoplication with a gastroplasty because it provides better reflux control. The gastroplasty component of the procedure, in addition to adding esophageal length, provides relatively noninflamed tissue to which the stomach can be sewn in performing the fundoplication. The operation improves the competency of the lower esophageal sphincter sufficiently to heal the reflux-induced esophagitis and ulceration, and soften the fibrotic strictures. With settling of the inflammation, there is some restoration of esophageal compliance and a little improvement in esophageal body contraction amplitude, but commonly the loss is not reversible.

Surgical staplers have made the construction of the gastroplasty tube simple and reliable and prevent spillage of gastric contents into the chest or abdomen. The relative ease with which a gastroplasty and partial fundoplication can be performed has made the procedure particularly suited for the patients who have the sequelae of advanced disease and has reduced the need for esophageal resection and replacement.

To perform the Collis gastroplasty procedure, the esophageal and gastric mobilizations are performed as described for the Belsey Mark IV partial fundoplication. The Collis gastroplasty tube is created along the lesser curvature of the stomach, in continuity with the distal esophagus and for a length of 4 to 5 cm, over a 48-Fr Maloney bougie (Fig. 70.14). The tube can be readily constructed using a single fire of the GIA stapler. To achieve a uniform tube diameter along the lesser curvature, traction is exerted on the greater curvature before the jaws of the stapler are closed (Fig. 70.15). The resultant staple line creates a wedge of fundus that is resected by stapling across the fundus, in a line perpendicular to the staple line on the gastric tube, from the greater curvature to the end of the staple line on the gastric tube (Fig. 70.16). The whole length of the staple line is oversewn with a running absorbable suture (Fig. 70.17). This sutured

reinforcement is essential to prevent subsequent leakage or fistulization from the staple lines. A Belsey partial fundoplication (Figs. 70.18 and 70.19) or preferably a full Nissen fundoplication (Figs. 70.20 and 70.21) is performed over and around the gastroplasty tube. The gastroplasty tube continues to produce acid from its oxyntic mucosa, but rarely is it in sufficient quantities to produce esophagitis or cause heartburn. This is likely due to compression of the gastroplasty tube by the fundoplication. Caution must be exercised in constructing Collis gastroplasty tubes in the patients who have had previous antireflux or gastric surgery. These previous procedures may have interrupted the blood supply to the lesser curvature, resulting in devascularization of the gastroplasty tube and subsequent ischemic necrosis.

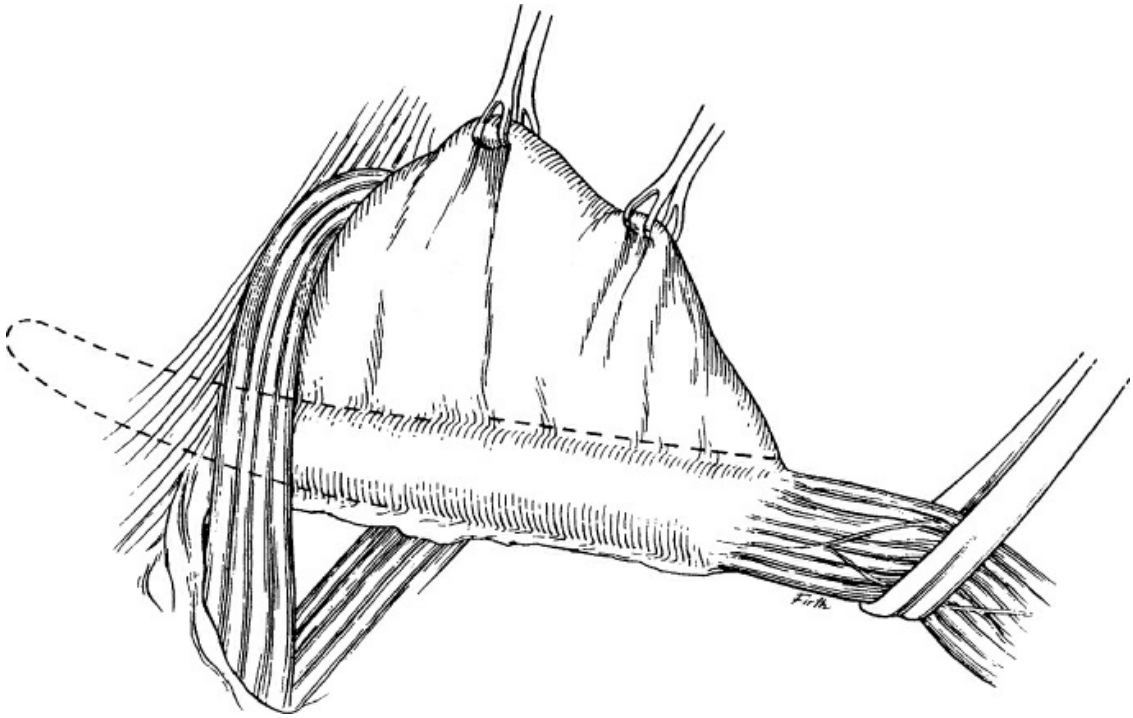

Figure 70.14. Position of the stomach for performing a Collis gastroplasty. A 48-Fr bougie is passed into the stomach. The *dashed line* indicates the proposed site for stapling and cutting the gastric wall to form a gastric tube in continuity with the esophagus.

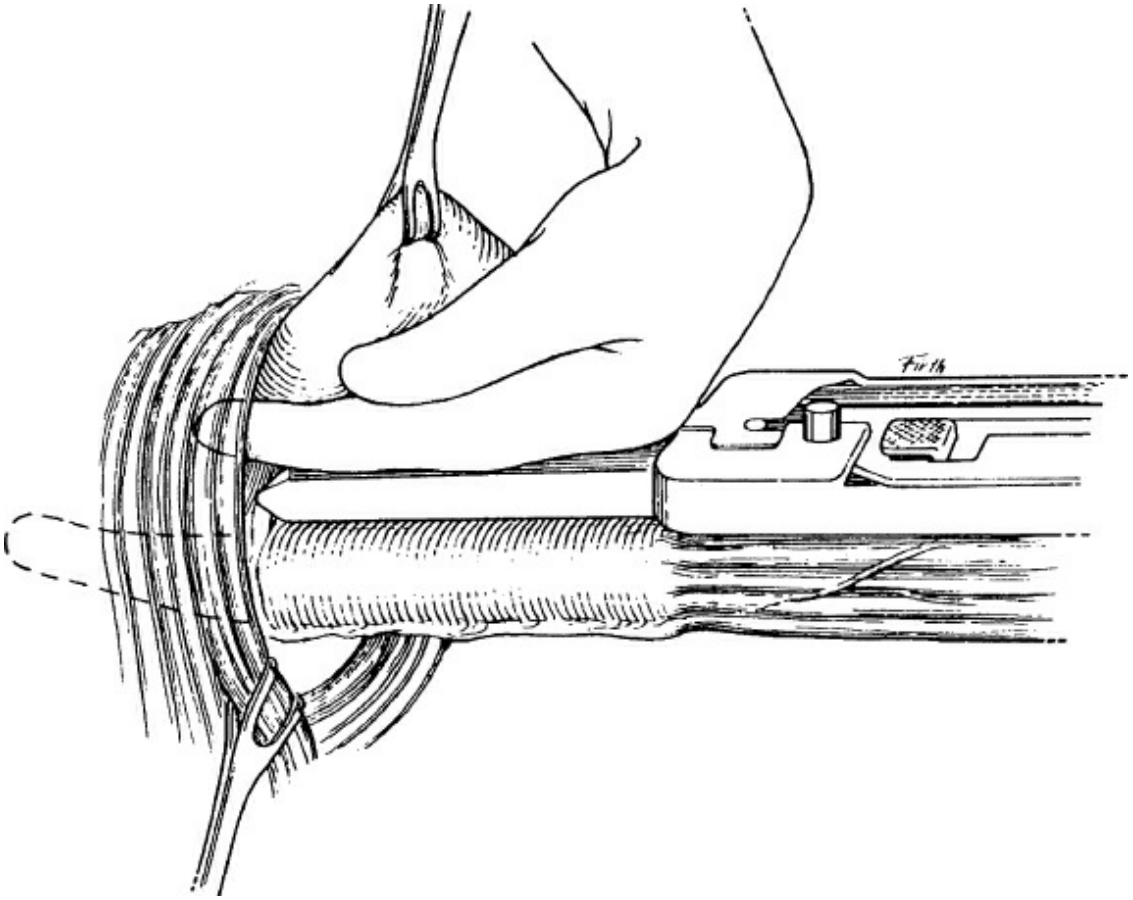

Figure 70.15. Prior to dividing the fundus of the stomach with a GIA stapler, traction is exerted on the greater curvature side of the fundus before closing the jaws of the stapler. This ensures that the gastric tube closely approximates the diameter of the indwelling 48-Fr bougie throughout its length.

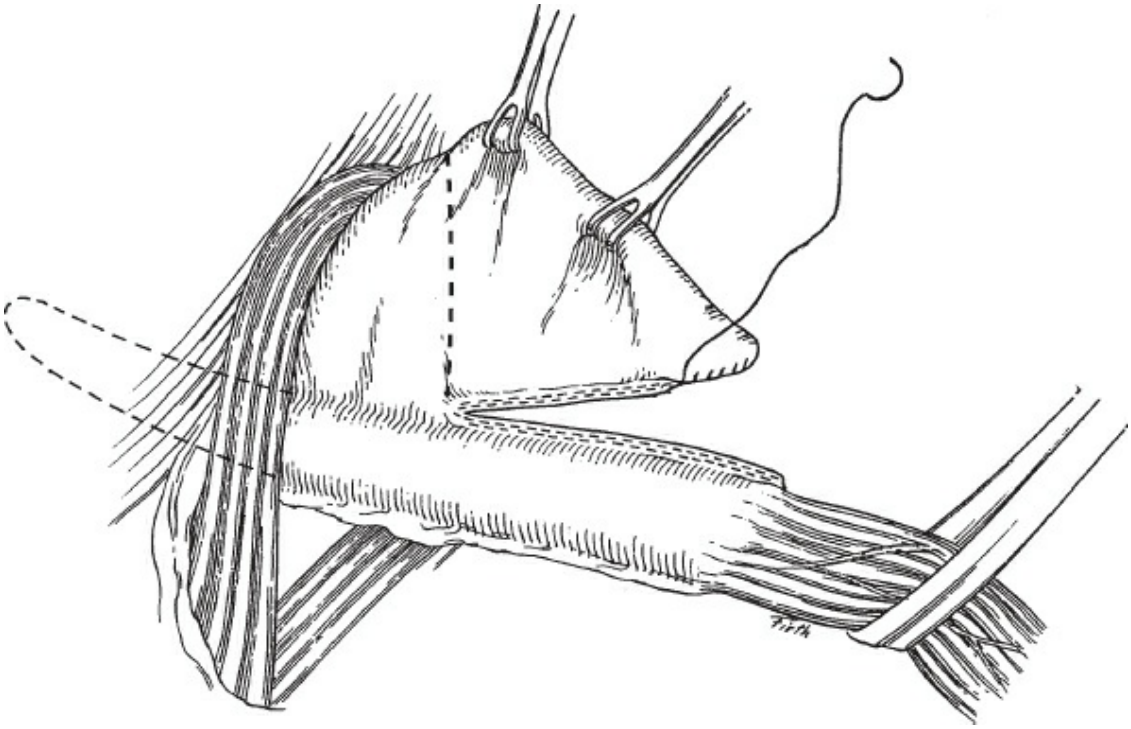

Figure 70.16. The fundus of the stomach is stapled and cut to form a 5-cm gastric tube along the proximal portion of the lesser curvature. This effectively lengthens the esophagus by approximately 4 to 5 cm. The wedge of stomach is removed by stapling vertically from the greater curvature down to the horizontal staple line along the *dotted line*.

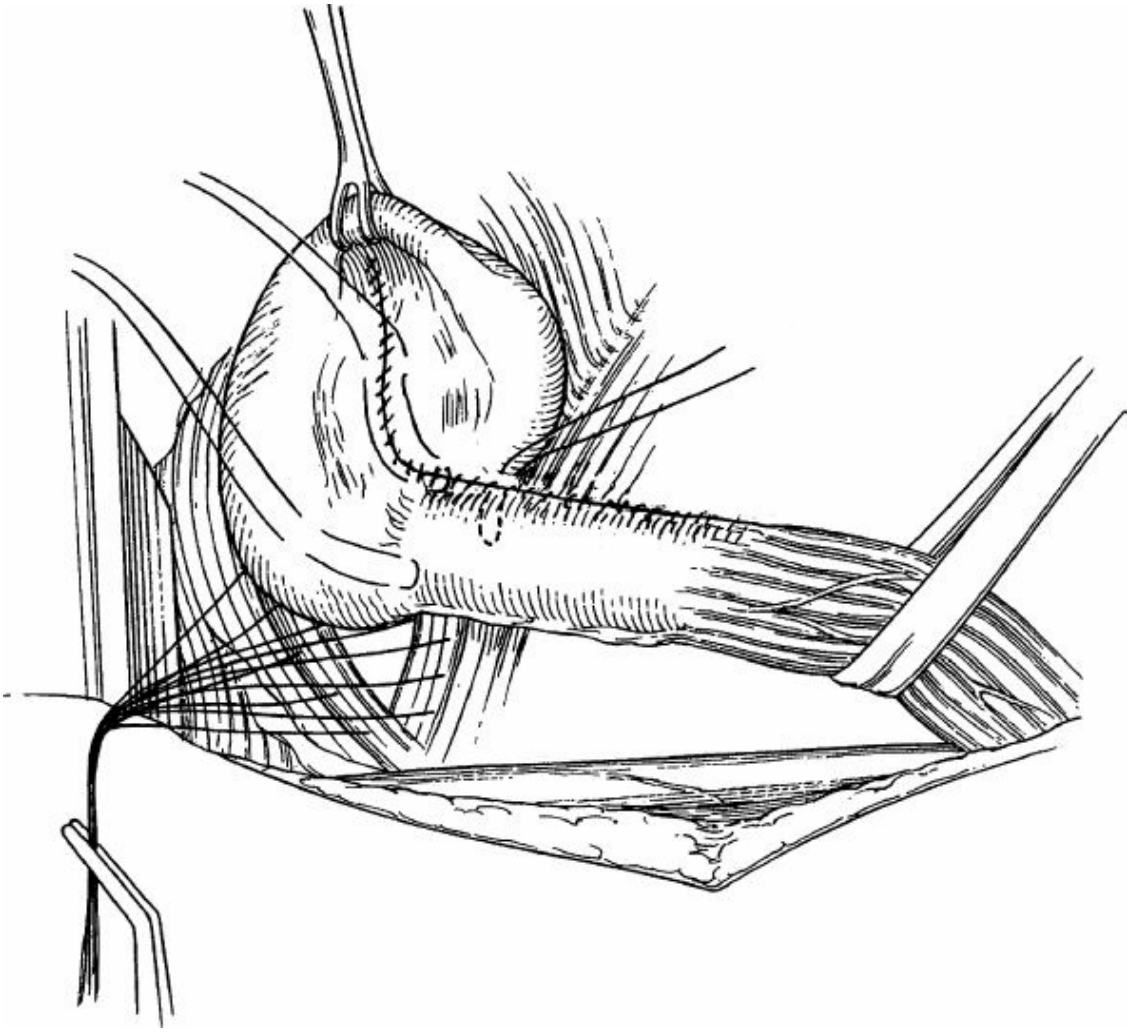

Figure 70.17. The staple line is inverted by a running suture and a Belsey 240-degree partial fundoplication is constructed around the gastroplasty tube. The first row of sutures is placed 1.5 cm above the end of the gastroplasty tube. Particular attention must be given to place the right lateral suture far to the right to avoid constructing a partial fundoplication that covers only the left anterior-lateral portion of the gastroplasty tube.

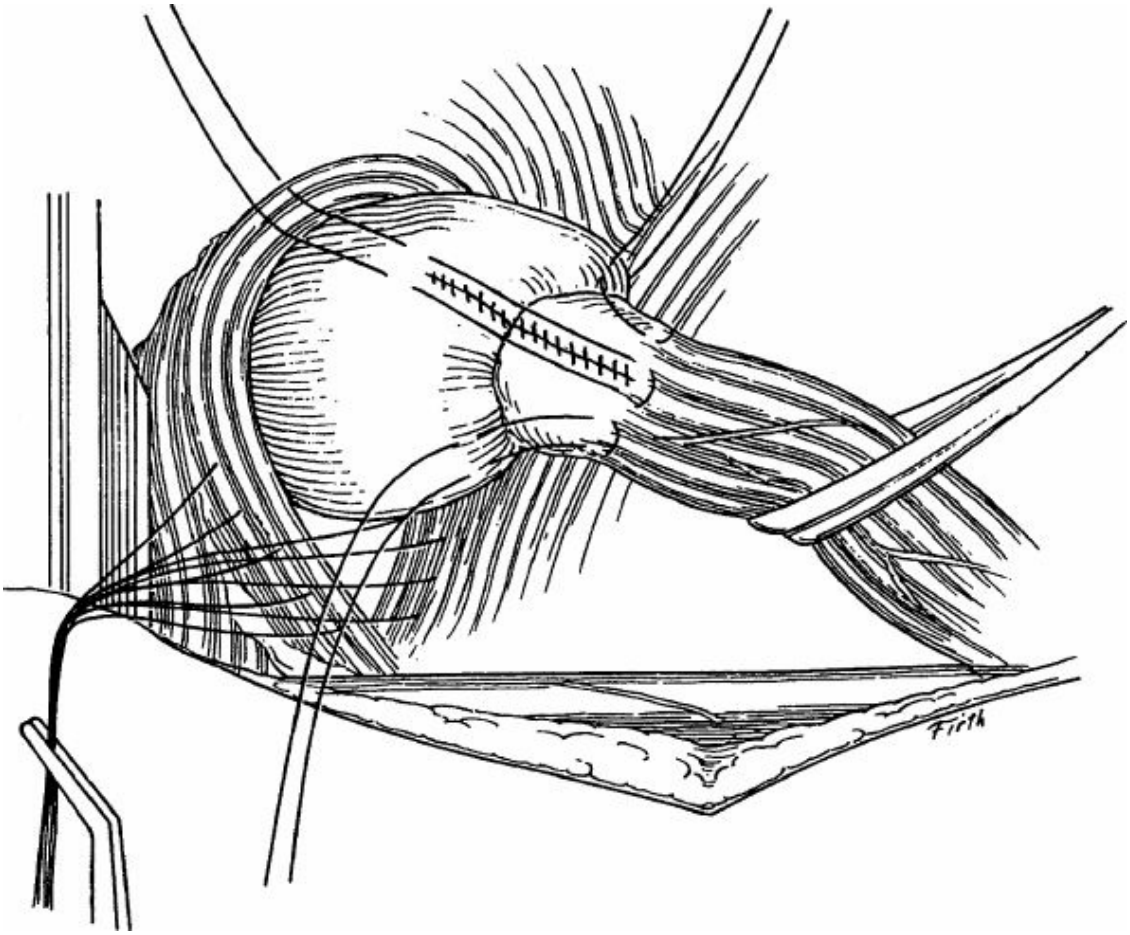

Figure 70.18. Continued construction of the Belsey 240-degree partial fundoplication over the gastroplasty tube by placing a second row of sutures 1.5 cm above the first row of sutures and a third row of sutures 1.0 to 1.5 cm above the previously tied sutures of the second row.

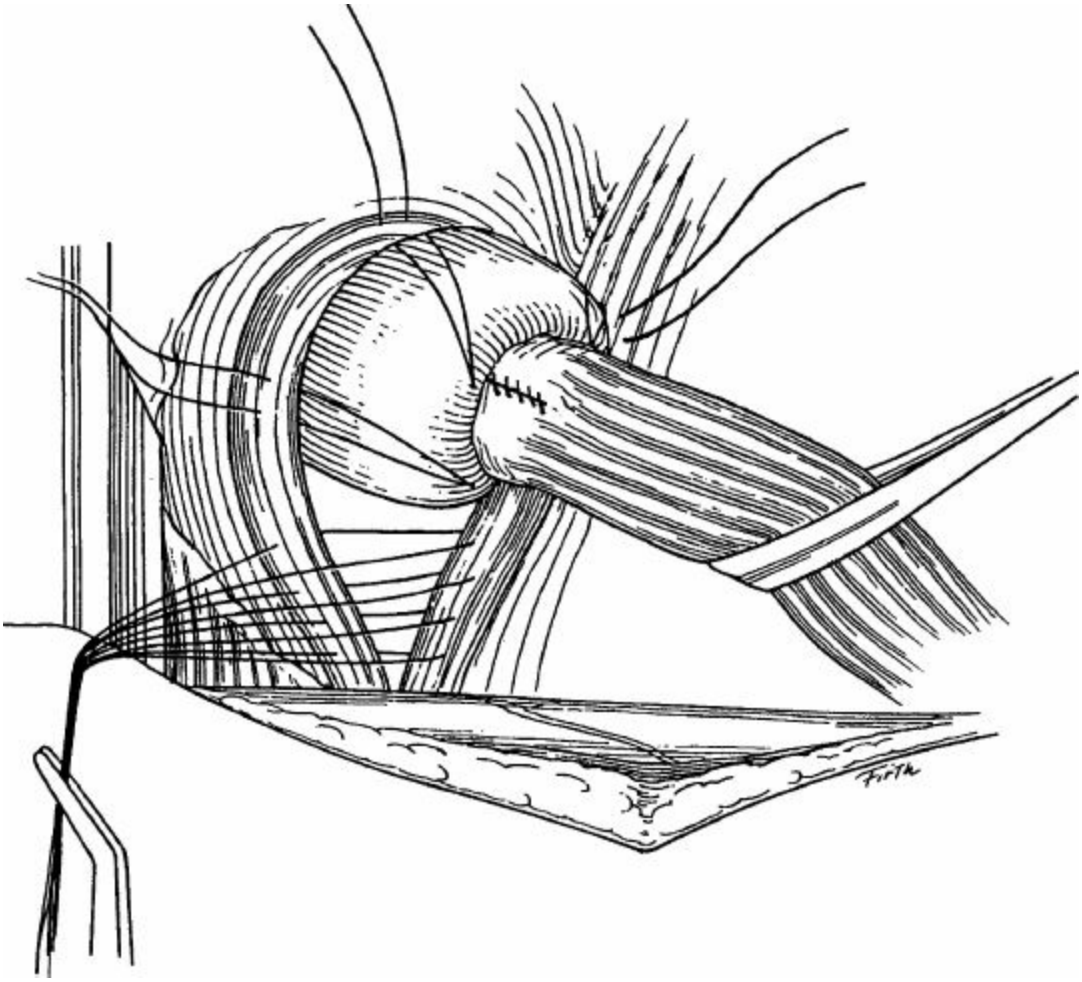

Figure 70.19. Continued construction of the Belsey 240-degree partial fundoplication showing placement of the tails of a third row of sutures through the diaphragm, 0.5 cm apart and 1.0 cm from the edge of the hiatus. Note the placement of the sutures at the 4, 8, and 12 o'clock positions on an imaginary clock face oriented with the 6 o'clock position posterior in the hiatus between the right and left crura just anterior to the aorta.

Transthoracic Nissen Fundoplication

Rudolf Nissen initially described the Nissen fundoplication in German literature in 1956 and subsequently in English literature in 1961. The original procedure was subsequently modified in 1986 to reduce the incidence of side effects. It was found that at reoperation in the patients who complained of recurrent heartburn and regurgitation, traces of a previous fundoplication were completely absent due to disruption of the fundic sutures. This suggested the need for stronger sutures placed in a more durable manner. Other patients complained of dysphagia and inability to belch, even though an endoscope could be passed easily

through the fundoplication and into the stomach. In these patients, the fundoplication was too tight or too long. Observations made from a biomechanic model of the cardia indicated that the fundoplication should be at least 60 Fr in diameter, only 1.5 to 2.0 cm long, and held in place with permanent reinforced sutures. The technique that emerged used one permanent 00 polypropylene suture placed in a U-shaped pattern with two 1.5 × 0.5 cm polytetrafluoroethylene (PTFE) pledgets for reinforcement. The PTFE pledgets are cut to exact size to keep the fundoplication a standard length and give reproducible results. The diameter of the fundoplication was standardized by loosely constructing it over a 60-Fr bougie. When completed, the approximated lips of the fundoplication lie over the anterior right lateral surface of the lower esophagus or gastroplasty tube.

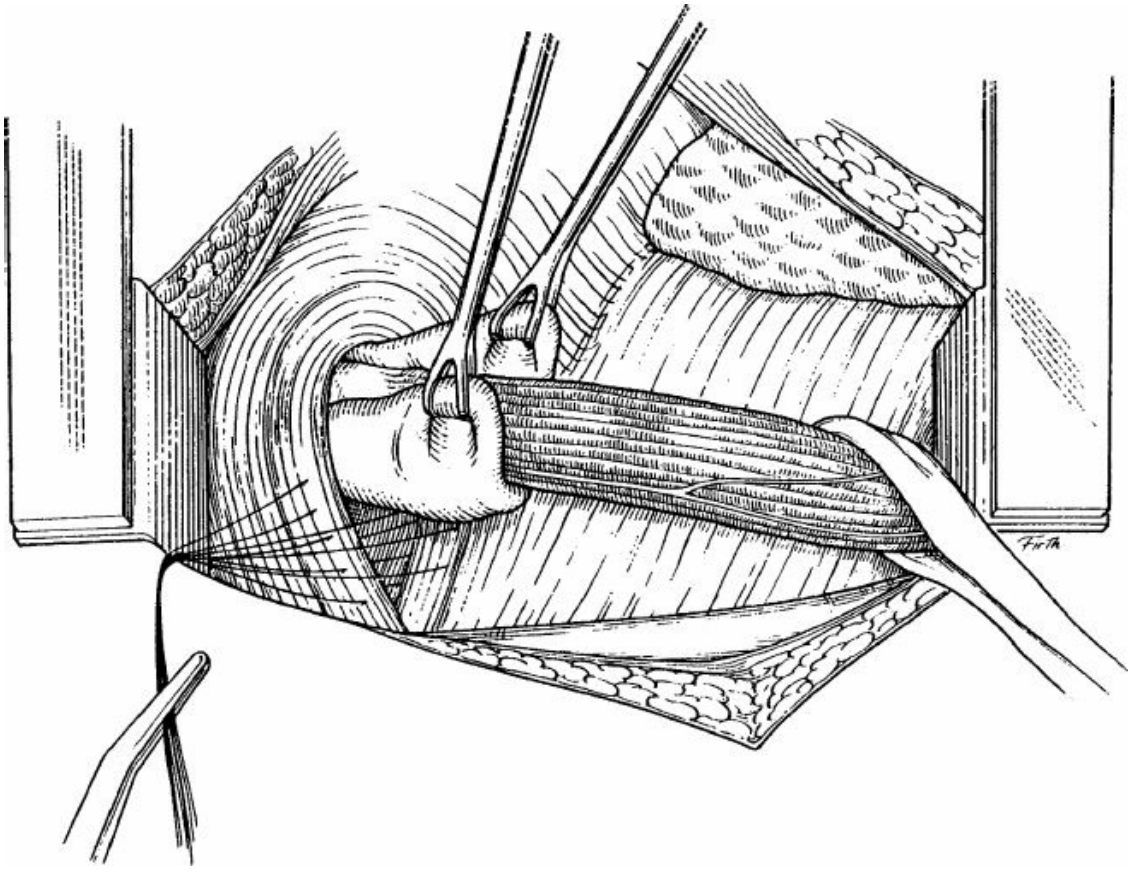

Figure 70.20. Construction of a Nissen 360-degree full fundoplication showing the posterior and anterior fundic wall brought up through the hiatus and plicated around the lower esophagus.

To perform a transthoracic Nissen fundoplication, the esophagus and

cardia are mobilized, and the fundus of the stomach brought up through the hiatus as described for the Belsey operation. When completely mobilized, the fundus of the stomach is placed in its normal left lateral relationship to the esophagus and then plicated around the distal esophagus with the posterior fundic wall posterior and the anterior fundic wall anterior to the esophagus (Fig. 70.20). A 60-Fr bougie is passed by the anesthesiologist into the stomach for accurate sizing of the fundoplication. The lips of the fundoplication are secured in an anterior-right lateral position with a U-stitch, consisting of a double-arm 00 polypropylene suture and a 1.5 × 0.5 cm PTFE pledget on the outside of each fundic lip. A portion of the anterior-right lateral esophageal wall down to, but not through, the muscularis mucosa is incorporated into the stitch. The two limbs of the U-suture are placed through the posterior fundic lip, parallel to each other and separated by 1 cm, and through the esophagus 1 cm above the gastroesophageal junction identified by the site of insertion of the phrenoesophageal membrane. This sandwiches the esophageal wall between the anterior and posterior fundic lips and the two PTFE pledgets (Fig. 70.21).

The polypropylene suture slides through the tissue without sawing and allows a test sizing of the fundoplication without producing damage to the tissue. When the edges of the fundoplication are drawn together, the diameter of the wrap should be large enough to allow the insertion of the surgeon's index fingertip between the stomach and the esophagus containing the 60-Fr dilator (Fig. 70.22). If the surgeon's fingertip cannot fit, the fundoplication is too tight and the U-stitch must be placed more laterally and inferior in the stomach, enlarging the internal diameter of the fundoplication. If the surgeon's fingertip inserts too easily, the fundoplication is too floppy and the U-stitch must be placed more medially and superior on the stomach, reducing the internal diameter of the fundoplication. When the fundoplication is of proper size, the bougie is removed and the limbs of the U-stitch are tied securely. Since only one suture is used to secure the fundoplication, it is important that it is made of permanent material and that PTFE pledgets are used to reinforce its purchase on the tissues.

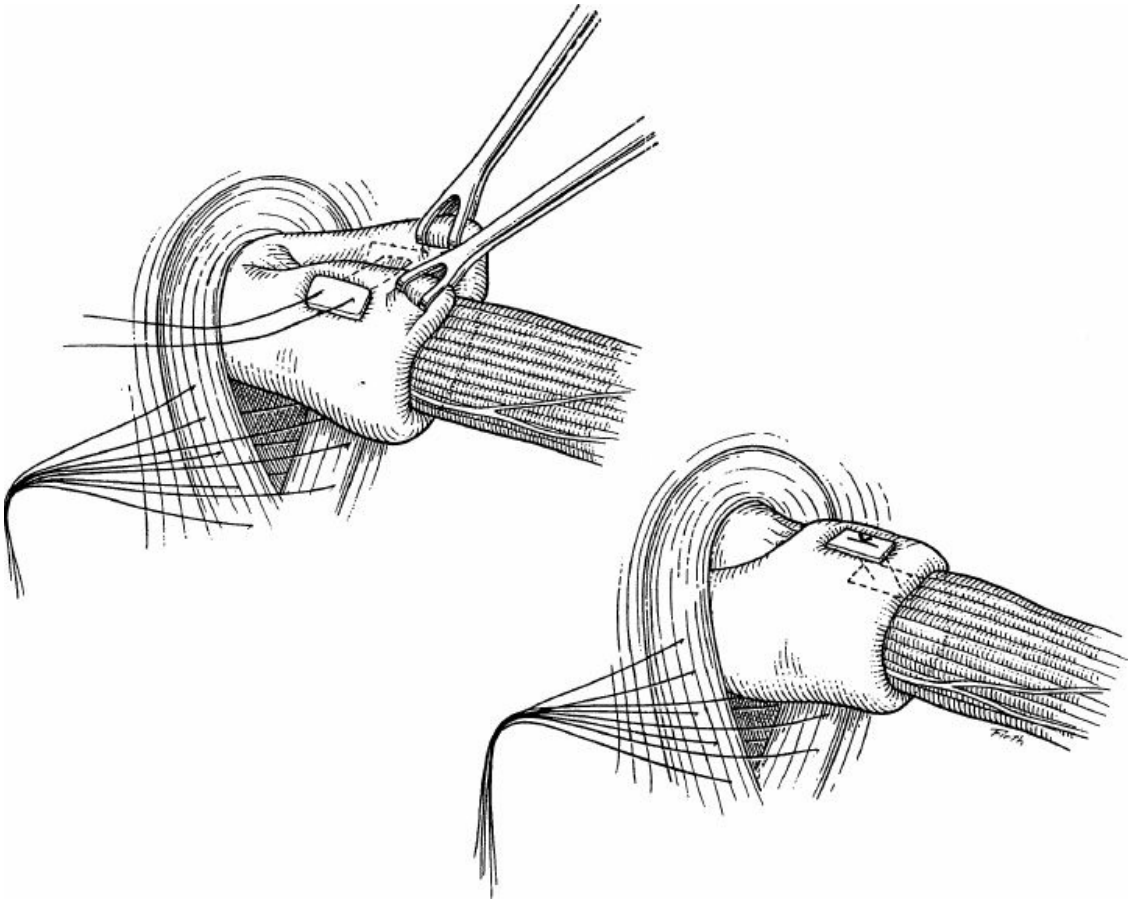

Figure 70.21. Continued construction of a Nissen 360-degree full fundoplication showing the placement of the U-stitch with pledgets. A 60-Fr bougie is passed into the stomach to allow accurate sizing of the fundoplication. The fundoplication is placed 1 cm above the gastroesophageal junction with the anterior and posterior fundic lips approximating on the right anterior-lateral wall of the esophagus.

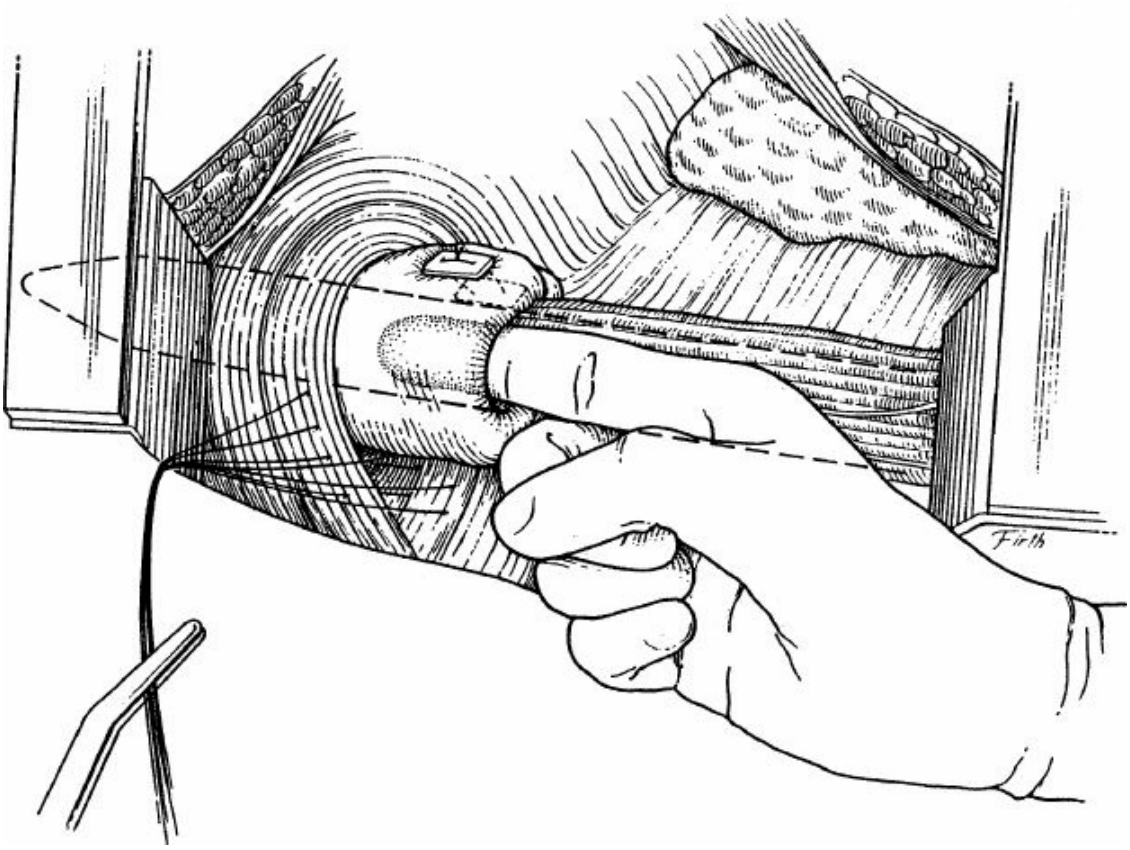

Figure 70.22. Continued construction of a Nissen 360-degree full fundoplication showing the testing of the size of the diameter of the fundoplication by the insertion of the surgeon's index finger between the fundoplication and the esophagus containing the 60-Fr dilator. The stomach and esophagus are in their normal position with the U-stitch located on the right anterior-lateral wall of the esophagus.

When complete, the fundoplication is massaged into the abdomen in a manner similar to that described for the Belsey Mark IV operation. No sutures are used in the Nissen procedure to hold the repair in the abdomen; the fundoplication serves as the anchoring device. Again, as with the Belsey Mark IV operation, the fundoplication should not protrude out of the hiatus when placed in the abdomen. If it does, the repair is under too much tension, and a Collis gastroplasty should be performed. The fundoplication should not be left in the chest as this encourages intrathoracic gastric distension, which cannot be relieved by a belch and can result in gastric ischemia and perforation.

Once the repair is in the abdominal position, the previously placed crural sutures are tied, starting posteriorly at the aortic hiatus and progressing anteriorly until the size of the hiatal opening just allows

insertion of the surgeon’s index finger adjacent to the empty esophagus. Any unused sutures are removed (Fig. 70.23). Leaving the hiatal opening too large encourages reherniation. In the Belsey repair, the closure of the crura provides a posterior buttress against which the intra-abdominal segment of the esophagus is compressed, whereas in the Nissen procedure, the crural closure helps hold the repair in the abdomen. At the completion of the procedure, a nasogastric tube is passed by the anesthesiologist without guidance from the surgeon into the stomach to ensure that there has been no angulation of the fundoplication in relationship to the distal esophagus. A chest tube for drainage of the pleural cavity is placed and the chest incision is closed.

Nasogastric suction is used to avoid overdistention of the stomach in the immediate postoperative period. Gastric distention rarely causes a breakdown of a full Nissen fundoplication if performed as described, but can be detrimental to a Belsey partial fundoplication. A barium swallow is performed on the 6th postoperative day to check the repair and demonstrate free passage of barium into the stomach. Patients often experience slight dysphagia when oral intake is begun, but this usually disappears quickly as the postsurgical edema subsides. Occasionally, dysphagia persists for a longer period. This can be caused by an intramural gastric hematoma at the site of the fundoplication. When present, it will generally absorb within 4 to 6 weeks, and the dysphagia subsides. When the patient recovers from anesthesia, they usually note relief from their heartburn and regurgitation. Before discharge, the patient should be counseled that until the habit of air swallowing is broken, he or she may experience increased abdominal distention and flatus. Early satiety is common until the patient gains confidence in his swallowing ability and takes fewer swallows to ingest their meal, and, as a consequence, ingests in less air with their food.

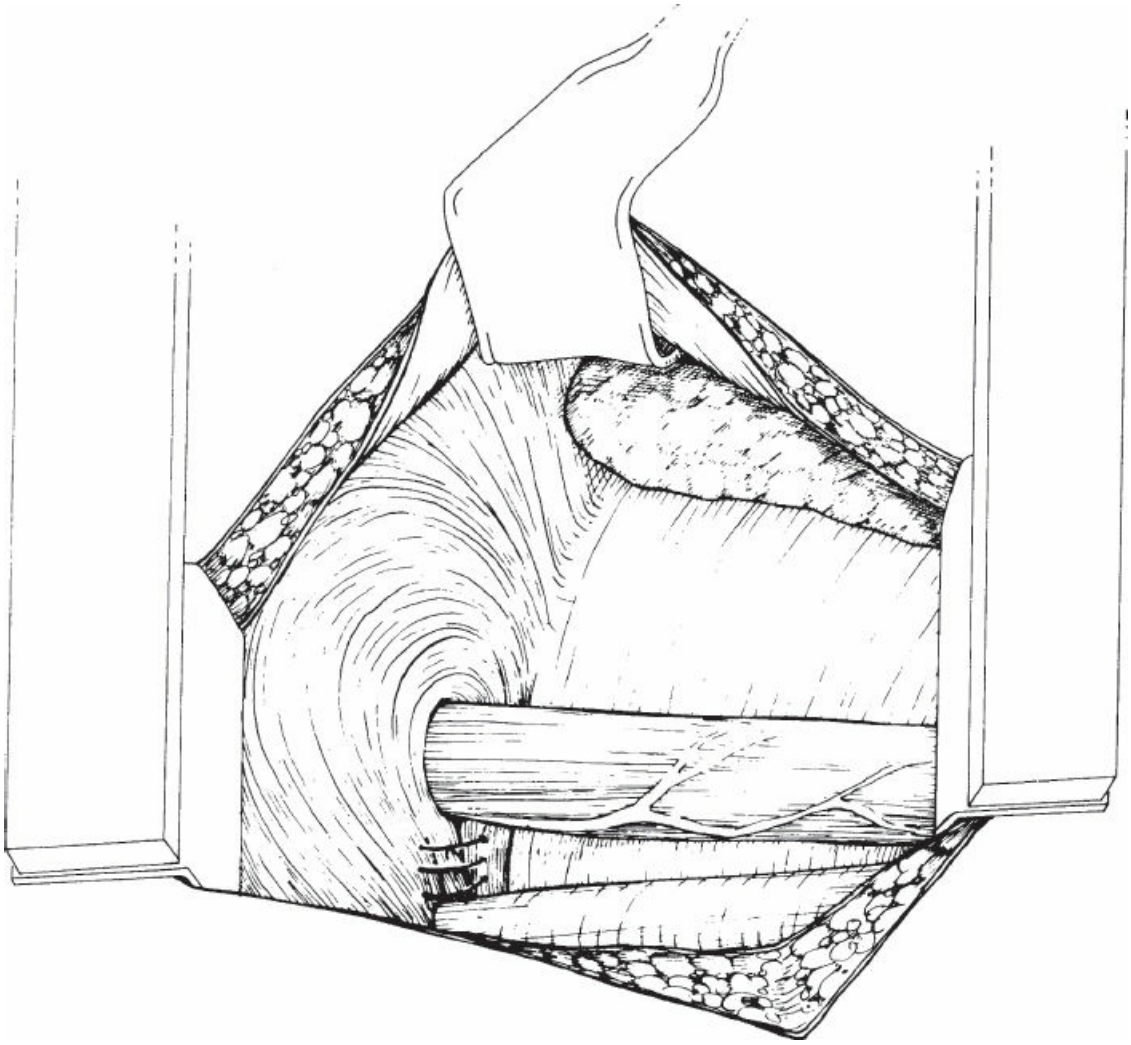

Figure 70.23. A completed Nissen 360-degree full fundoplication with the fundoplication in the abdomen, and the right and left crura approximated by tying the previously placed crural sutures.

We have evaluated our patients after surgery with esophageal manometry, 24-hour esophageal pH monitoring, and a questionnaire about their esophageal symptoms and eating habits. Comparison of the results of these studies with the results of similar studies obtained from healthy volunteers has helped to objectively evaluate what has been accomplished by the surgical repair. Consequently, the described technique represents a refinement of the method initially published by the originators of the operation. The surgeon must keep in mind that the operation is designed to improve the function of the gastroesophageal barrier and offhanded alterations in technique can have a profound effect on postoperative function. No change in technique should be made unless its effects on function are known.

EDITOR'S COMMENT

Dr. DeMeester is part of the chain of superb surgeons who have brought transthoracic procedures to the United States. A little bit of history outlined in this chapter is worthwhile. I am old enough to remember the repair that Allison proposed in 1951. Allison proposed to cinch up the crura and to use the phrenico-esophageal "ligament" in to reinforce it and to allow the repair to hold, as holding the stomach in the abdomen did not work. First of all, only 50% of the patients have a phrenico-esophageal membrane, as I call it, because it is too flimsy, in my humble opinion, to be called "a ligament." Thus, what one does, if it is absent, is reef up and shut the crura and try and restore the normal anatomic relationships in the abdomen of the stomach and the intra-abdominal esophagus. Second, it did not take long for the repair to tear loose. It was estimated by Allison himself that 80% of the repairs had recurred anatomically. Interestingly enough, only 50% of the patients whose repairs recurred because of splitting of the phrenico-esophageal membrane redeveloped symptoms, suggesting that it was not at all a question of whether or not one could restore the high-pressure zone (as we now know what the mechanism of repair was, and that some patients still had relief). And then, we went into the modern era of basically knowing what we were trying to do, and that is restore a length of intra-abdominal esophagus and thus the high-pressure zone and finding ways of holding it there.

At the Mass General Hospital, there was a rotation in which residents went to the Frenchay Hospital in Bristol, where Mr. Belsey held forth, and I use that term advisedly, to learn about antireflux procedures and the thoracic repair that bears Mr. Belsey's name as the Mark IV. Unfortunately, by the time I reached the level of the residency in which I would have been eligible to go, Mr. Belsey was no longer the chief, and the rotation policy was abolished, which is too bad. David Skinner, who was my predecessor as chief resident on the East Surgical Service in 1963, was among those who were most taken by the aspect of the Belsey repair and also for esophagectomy, and afterward become an acolyte of Mr. Belsey. While Mr. Belsey was an interesting character, there are many

worse people to whom one could be an acolyte. Dr. Skinner was a lifelong student of the esophagus and brought back the discipline of the single-layer running-wire anastomosis of Mr. Belsey and the Belsey Mark IV repair in esophagectomy and esophageal anastomosis. As residents of the Mass General Hospital, we got to do many Belsey Mark IV antireflux procedures, and in my opinion it was an excellent repair. Probably, the best part of it was that one mobilized the "short esophagus" in the chest, and was able to bring it down below the diaphragm by the series of sutures that have been described in this chapter and in previous chapters on the Belsey Mark IV repair, and thus solidify the high-pressure zone within the abdomen and to prevent the repair from slippage. I did quite a number of these, and I thought it was an excellent operation, particularly for patients who were somewhat larger than the standard individual on whom you would do a Nissen fundoplication. One of the advantages of the Belsey Mark IV repair done transthoracically is that you do not have to do a Collis gastroplasty with its attendant requirement of the patient taking proton-pump inhibitors for the rest of his or her life, and also that you could see what you had actually done. It remains a great favorite of mine, and I was disappointed to hear from Dr. DeMeester, when he agreed to do the chapter, that he had not done a Belsey procedure for 10 years. That is unfortunate, because it is, in addition to being a very good procedure, "fun to do." I do believe that, in patients in whom one must do a Collis gastroplasty, given the propensity of patients to stop taking their medication, that one is probably better off mobilizing the stomach through the chest and bringing it down and gaining the length of the esophagus that one needs to avoid a Collis gastroplasty. It seems I am in the minority, but I do not know what happens when patients stop taking their proton-pump inhibitors when they have a Collis gastroplasty—Do they develop an ulcer? Do they get a perforation? Do they get a stricture once again?

Having bid our adieus to the Belsey repair, let me quote a number of papers in which the Belsey repair and the partial posterior fundoplication is followed up by Mardani Jalal et al. (Mardani J, Lundell L, Engström C. Total or posterior partial fundoplication in the treatment of GERD: results of a randomized trial after 2 decades of follow-up. *Ann Surg* 2011;253(5):875–8), in which they followed a group of 137 patients, who had participated in more than 18 years of follow-up at the most, for a randomized trial, which randomized the Toupet posterior partial fundoplication and the Belsey antireflux procedure carried out between 1983 and 1991. Of these 137 patients with gastroesophageal reflux, 26% had died, and 16% could not be traced. The symptom outcomes were assessed by the use of validated self-reporting questionnaires. The authors point out that there are not very many studies in which the symptomatology improvement is actually researched and known.

As far as the outcomes, long-term control of heartburn and acid regurgitation, which the authors interpreted as mild to no symptoms, was present in 80% and 82% after 10 years, and after a total fundoplication in the

80% outcome and 90% after the partial posterior fundoplication. Likewise, dysphagia scores were at 4.6% in group I and 3.3% in group II, and presence of rectal flatulence and gas distension were of similar magnitude in the two groups. Of the patients, 23% with total fundoplication noted some ability to vomit, compared with 31% of the Toupet. In my opinion, I agree with the authors that this is a remarkable record after so many years, and that one can say that the Belsey transthoracic procedure is an excellent procedure with a long-term beneficial outcome.

In another similar follow-up by Ayazi S. and the team headed by the author at the University of Southern California (Ayazi S, Tamhankar A, DeMeester SR, et al. The impact of gastric distension on the lower esophageal sphincter and its exposure to acid gastric juice. *Ann Surg* 2010;252(1):57–62), they attempted to determine what happens to the sphincter when gastric distension of 750 mL occurs and does it really shorten the sphincter and allow increased exposure to the esophagus and acid gastric juice. They studied this mechanism by filling the progressive gastric distension with air and demonstrating progressive shortening of the lower esophageal sphincter ($P < 0.0001$). After infusion of 750 cc of air, there was significant reduction in the median lower-esophageal-sphincter length but not in the thoracic length. As this got to be larger, gastric acid started to slosh back into the esophagus, reducing the pH. At rest, the pH step-up point was 0.5 cm above the lower border of the lower esophageal sphincter, and the distension moved a median of 1.0 cm cephalad within the lower esophageal sphincter. Simultaneously, with the loss of length there was a reduction in lower-esophageal-sphincter pressures of 27.4 mm Hg. They conclude that gastric distension is a real entity, and that the acid does enter into the esophagus when the sphincter is shortened.

Another outcome of 5 years' follow-up is the intra-thoracic stomach and the attempt to follow it objectively in Mittal SK et al. (Mittal SK, Bikhchandani J, Gurney O, et al. Outcomes after repair of the intrathoracic stomach: objective follow-up of up to 5 years. *Surg Endosc* 2011;25(2):556–66). They started with the proposal that they would like to follow the intra-thoracic stomach for 5 years and then they had begun to use mesh for some time to prevent herniation of the stomach, which had been present in 75% of the volume of the stomach on barium swallow. They studied 73 patients with intrathoracic stomach with a mean age of 71 years, and interestingly two thirds were female. There were 7 transthoracic and 66 transabdominal repairs, and there was one intra-operative death due to bleeding. Of the reviewed patients, antireflux procedures were done in 43, of which 20 were Nissens, 18 were Toupet, 4 were Roux-en-Y gastric bypasses, and 1 Dor. Ten patients had Collis gastroplasty for short esophagus. Mesh was used in only 13.7% of the patients and used for crus reinforcement. Follow-up was available for 88% at 1 year, 78% at 3 years, and 92% at 5 years. The authors state that there is no difference in the use of proton-pump inhibitors and that of other antacid medications. Most important, the mean satisfaction scores were 9.1, 9.0, and 9.0 at 1, 3, and 5 years, respectively.

The authors further state that there is a high level of patient satisfaction, and my observation is that if you can do that in this group of patients, that is very good.

Finally, there is a group of really difficult patients, in whom surgical reintervention is necessary for gastroesophageal reflux disease. This is present only in about 3% of the patients, and this kind of treatment has been reported before in several studies. However, there are a minimum of long-term data on patients who underwent subsequent operation because of recurrent reflux symptoms with troublesome dysphagia after primary antireflux surgery.

The symptomatic outcome was determined by questionnaires. Esophageal manometry and 24-hour pH monitoring were performed to assess the objective outcome. There were 144 reinterventions in 130 patients, 94 of whom had recurrent reflux and troublesome dysphagia in 50. Belsey Mark IV fundoplication through a left-sided thoracotomy was performed in 78 and a subsequent Nissen or partial fundoplication during 66 reinterventions. During a follow-up period of 5 years, symptoms were absent but significantly improved in 70%. Of those patients who were tested, esophageal acid exposure was normalized in 70% of the patients after surgery and postoperative complications occurred after 14 subsequent operations. This chapter by Furnée EJB et al. (Furnée EJ, Draaisma WA, Broeders IA, et al. Surgical reintervention after antireflux surgery for gastroesophageal reflux disease: a prospective cohort study in 130 patients. *Arch Surg* 2008;143(3):267–74) indicates that this particular type of reoperation does very well for patients who require this type of reoperation because it is not simple and there can be many pitfalls in which patients' outcomes are not very good, but can be corrected by reoperation.

71 Laparoscopic Esophagectomy

James D. Luketich and Lara W. Schaheen

INTRODUCTION

Although a complex and technically challenging operation, esophagectomy is often a life-saving and life-enhancing option for patients with early-stage esophageal cancer, perforation or caustic injury, failed antireflux operations, and end-stage functional disorders of the esophagus.

Open approaches to esophageal resection have historically been associated with significant morbidity and mortality and in some cases excluding patients from surgical intervention. A 10-year review of the open esophagectomy experience within the Veterans Affairs system revealed a morbidity of 50% and a mortality of 10%. In an analysis of a national Medicare database, Birkmeyer and associates revealed that the mortality rates from esophagectomy in the United States ranged from 8% in high-volume centers to a staggering 23% in low-volume centers. Although a reduction in complication rates and improved outcomes have been reported by experienced surgeons in high-volume centers, morbidity remains considerable.

In the 1990s, the growing confidence in laparoscopic surgical techniques and instrumentation led to the introduction of various minimally invasive approaches to esophageal resection. Early minimally invasive resection techniques often hybridized more traditional open techniques with newer less invasive approaches. Collard was the first to describe a thoracoscopic technique for esophageal dissection. The first entirely laparoscopic esophagectomy was performed through a transhiatal approach in 1995 by DePaula. In 1996 Luketich and associates at the University of Pittsburgh began performing totally minimally invasive esophagectomy (MIE) via a Mckeown approach and published one of the first large series with a zero percent mortality in their first 77 patients.

Over the past decade, our experience with MIE has evolved considerably. In some of our very first few cases, we utilized the totally laparoscopic transhiatal approach; however, we soon recognized its limited visualization of vital intra-thoracic structures and difficulty performing a

complete mediastinal lymphadenectomy. We quickly transitioned to a minimally invasive modified McKeown approach with thoracoscopic mobilization of the intrathoracic esophagus, laparoscopic gastric tube creation, and creation of a cervical anastomosis. This approach became our procedure of choice for approximately 500 cases and offered reduced perioperative morbidity and mortality in comparison to many open series.

In our experience, we noted as others did that esophageal cancer had transitioned from squamous cell pathology to a lower third adenocarcinoma. Thus, some of the limitations of the McKeown approach, including the need to bring the conduit to the neck, requiring extra length, the need for a cervical dissection, and possibility of associated recurrent laryngeal nerve dysfunction, led us to adopt the Ivor Lewis minimally invasive approach. As described in open series, we noted that the use of a cervical anastomosis led to a significant number of anastomotic leaks and subsequent strictures. We also noted that many of our surgical residents were completing their training with little independent operative experience in the neck area and faced a significant learning curve associated with the cervical dissection that led us to a preference for the minimally invasive Ivor Lewis esophagectomy. This completely laparoscopic-thoracoscopic approach avoids a neck dissection essentially eliminating recurrent laryngeal nerve injury, and allows a more aggressive gastric resection margin, amputation of the most proximal tip of the newly created gastric conduit that is the most susceptible to ischemia and potential leak, and clear visualization during creation of the intrathoracic anastomosis.

Minimally invasive techniques for esophageal resection have evolved significantly from the initial hybrid approaches of laparotomy combined with thoracoscopy to the current definition of MIE, which is performed entirely using laparoscopic and thoracoscopic techniques. Although technically demanding and associated with a significant operator learning curve, when performed at high-volume centers it has been shown to carry similar morbidity, mortality, and oncologic outcomes as open esophagectomy while offering shorter operative times, less blood loss, and shorter hospital stay with no increase in morbidity.

The safety and feasibility of MIE have been demonstrated in several single-institution studies and meta-analyses, yet the results from a large, prospective, multicenter trial investigating MIE have only recently emerged. The eastern oncology cooperative group study (E2202) examined the outcomes of 17 credentialed sites in the United States that

performed MIE on patients with biopsy-proven high-grade dysplasia or esophageal cancer of the mid-esophagus or distal esophagus. Esophagectomy was performed using either a modified McKeown MIE or an Ivor Lewis MIE technique. Protocol surgery was completed in 95 of 104 patients (91.3%). Median ICU stay and hospital stay were 2 and 9 days, respectively. The 30-day mortality for patients who underwent MIE was 2.1%. Adverse events included anastomotic leak (8.6%), acute respiratory distress syndrome (ARDS) (5.7%), and atrial fibrillation (2.9%). At a median follow-up of 35.8 months, the estimated 3-year overall survival was 58.4% (95% CI: 47.7% to 67.6%). Locoregional recurrence occurred in only 7 patients (6.7%). This trial demonstrated that MIE is safe, feasible, with low perioperative morbidity and mortality and good oncologic results, and suggests that MIE can be adopted by other centers with appropriate expertise in open esophagectomy and minimally invasive surgery.

INDICATIONS

Indications for the minimally invasive approach for esophagectomy include Barrett's esophagus with high-grade dysplasia who are not candidates for endoscopic resection techniques, resectable esophageal cancer, end-stage achalasia, intractable esophageal strictures, and reconstructive surgery for patients with a history of failed antireflux operations.

While patients with advanced T4 esophageal cancers are generally not candidates for surgical resection, those with esophageal cancers of all other T stages may be amenable to MIE in experienced hands. As with open operations, a history of prior surgical interventions or preoperative chemo-radiation can add an additional level of complexity. Patients who have a history of previous thoracic or abdominal operations or those who have received neoadjuvant chemo-radiation remain candidates for a minimally invasive esophageal resection in experienced hands. Although no standardized contraindications regarding the use of a minimally invasive approach in esophageal resection exist, patient characteristics and surgeon's experience should be considered carefully when determining the appropriate operative approach.

As there are several minimally invasive techniques available for esophagectomy, the choice between MIE approaches is, to a large degree, based on surgeon preference. However, the operative approach chosen

may be dictated by the anatomic location of tumor and the margins required to achieve an R0 resection. The minimally invasive Ivor Lewis approach can be utilized for distal esophageal cancers, short-to-moderate length Barrett's with high-grade dysplasia, and gastroesophageal junction tumors extending onto the gastric cardia. Total laparoscopic and thoracoscopic Ivor Lewis resections should not be performed for esophageal cancers of the upper third of the esophagus with significant proximal extension due to concern for adequate margins of resection, but rather would benefit from a McKeown approach with the creation of a cervical anastomosis. Some mid-esophageal tumors can be approached with the Ivor Lewis technique, but a very high intrathoracic anastomosis may be needed to gain a negative margin.

SURGICAL TECHNIQUE

Laparoscopy

Before proceeding with the placement of the laparoscopic ports, esophagogastroscopy is performed in all patients to confirm tumor location, evaluate response to neoadjuvant therapy, and access the suitability of the stomach for tubularization and use as an esophageal conduit. Endoscopic insufflation should be minimized in an effort to limit small bowel dilation, which can significantly reduce intra-abdominal visualization. For proximal, mid-esophageal, and squamous tumors, a single lumen endotracheal tube is initially placed to allow for complete bronchoscopic evaluation prior to transitioning to a double lumen endotracheal tube.

The patient is placed supine with arms extended and a padded footboard attached to allow for maximal reverse Trendelenburg positioning. Invasive arterial monitoring and a double-lumen endotracheal tube is placed initially in anticipation of the thoracoscopic phase. The xiphoid process, costal margins, and midline are outlined. The distance between the xiphoid process and umbilicus is measured and divided into thirds. Five ports are utilized for gastric mobilization, conduit creation, and pyloroplasty. Using an open Hassan cut down technique, a 10-mm blunt port is placed two thirds of the distance from the xiphoid process to the umbilicus and 2 cm to the right of midline in the right paramedian area.

Pneumoperitoneum is set to 15 mm Hg, and the patient is placed in steep reverse Trendelenburg position. Under direct laparoscopic

visualization a 10-mm port is placed 2 cm to the left of midline slightly below the level of the original port. The 10-mm 30-degree laparoscopic camera and insufflation are then moved to this left paramedian port. Prior to the placement of additional ports, an intraperitoneal survey should be performed to assess for findings that may preclude successful surgical resection and reconstruction. Additional 5-mm ports are placed at the left subcostal margin and the right subcostal margin with a minimum of a hand's breadth apart from other ports to avoid unwanted contact between ports (Fig. 71.1). A 5-mm port is placed in the right lateral flank location just below the 12th rib to support a liver retractor. A self-retaining retractor is used to elevate the left lobe of the liver and expose the hiatus. The gastrohepatic ligament is divided to expose the right crus. The gastroesophageal junction is freed from the hiatus by dissection up the right crus. The dissection is carried anteriorly and the phrenoesophageal ligament is taken down, to expose the anterior hiatus and left crus. The medial border of the right and left crus is dissected exposing the retroesophageal window and completes the circumferential mobilization of the esophagus.

Once circumferential dissection of the distal esophagus is completed, the stomach is retracted superiorly to expose the celiac vessels and allow for lymph node dissection. A complete lymphadenectomy is performed sweeping all nodal and fatty tissue with the specimen. After complete dissection of the left gastric and celiac nodes, dissection is continued along the superior border to the pancreas and cephalad toward the base of the right and left crus; this dissection plane is then made continuous with the preaortic dissection plane into the distal thoracic cavity. The left gastric artery and vein are then isolated and divided at their base using an Endo-GIA vascular stapler.

The right gastroepiploic arcade is clearly identified, the gastro-colic omentum is divided lateral to this arcade, and a window is created in the greater omentum allowing for entry into the lesser sac. The dissection is then continued along the greater curve of the stomach being certain to leave 2 to 3 cm of omental fat and avoid injury to the stomach while dividing the short gastrics (Fig. 71.2). In patients who have received neoadjuvant chemo-radiation, a pedicled omental flap is created to buttress the intrathoracic esophagogastric anastomosis. As dissection nears the anticipated level of the esophagogastric anastomosis, a segment of healthy omentum supplied by two to three perforating vessels at the level of the

distal gastroepiploic arcade is identified. Omental mobilization is carried laterally such that a 3- to 4-cm wide pedicled omental flap is created near the prospective line of the future esophagogastric anastomosis. As the left gastroepiploic and gastrosplenic vessels are divided during mobilization, the omental flap is supplied by distal branches of the right gastroepiploic artery alone and thus should not be larger than 8 to 10 cm long as to prevent vascular steal from the tubularized conduit. Manipulation of the stomach should be avoided and a “no touch” technique utilized to minimize traumatic injuries to the tissue or vascular supply.

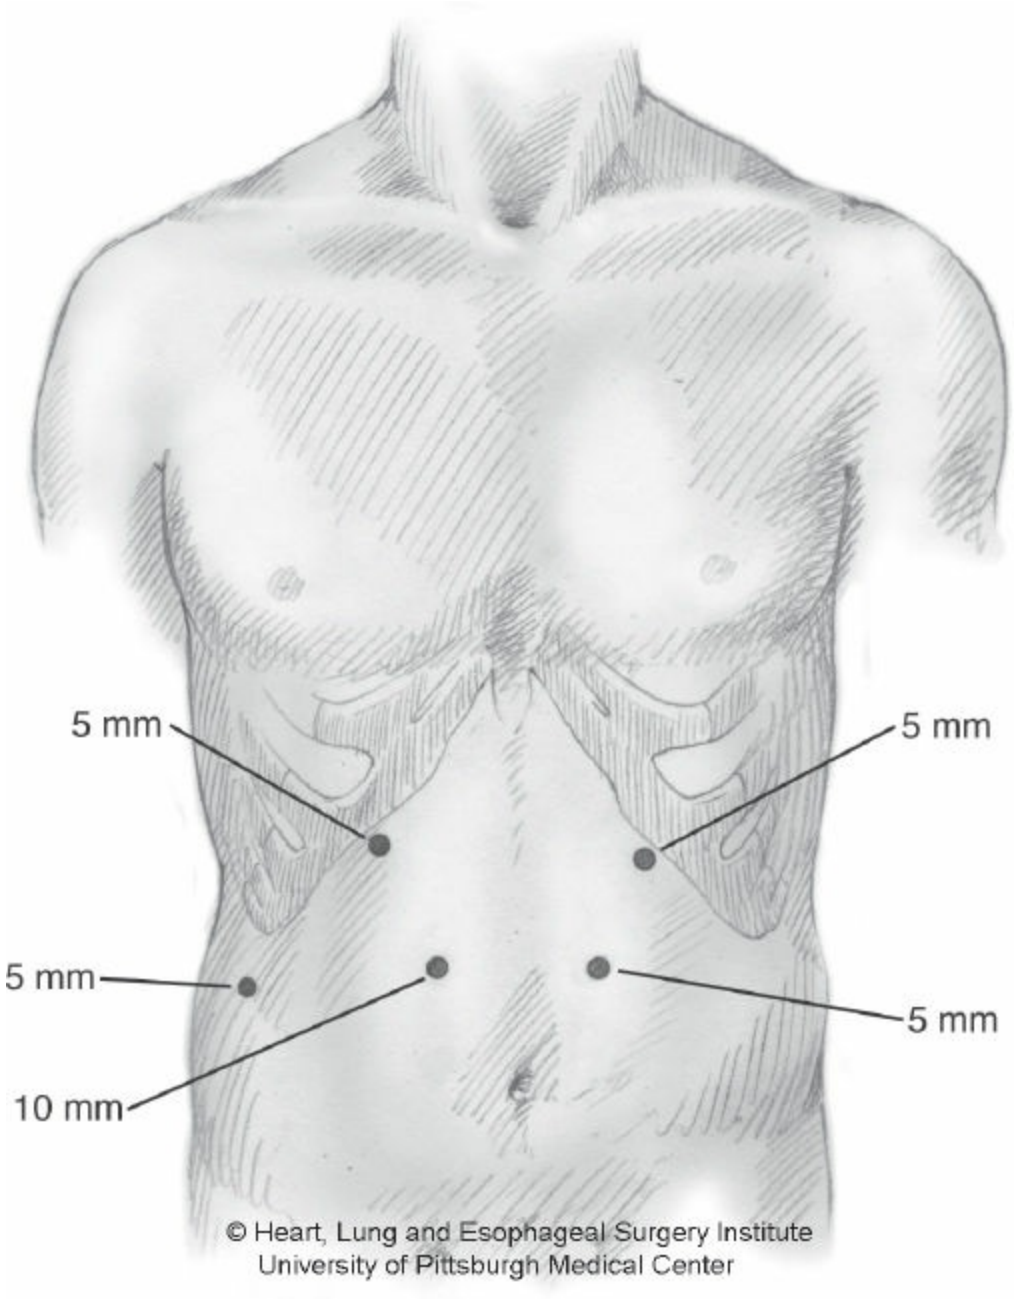

Figure 71.1. Laparoscopic port placement. (Image © Heart,

Lung, and Esophageal Surgery Institute University of Pittsburgh Medical Center.)

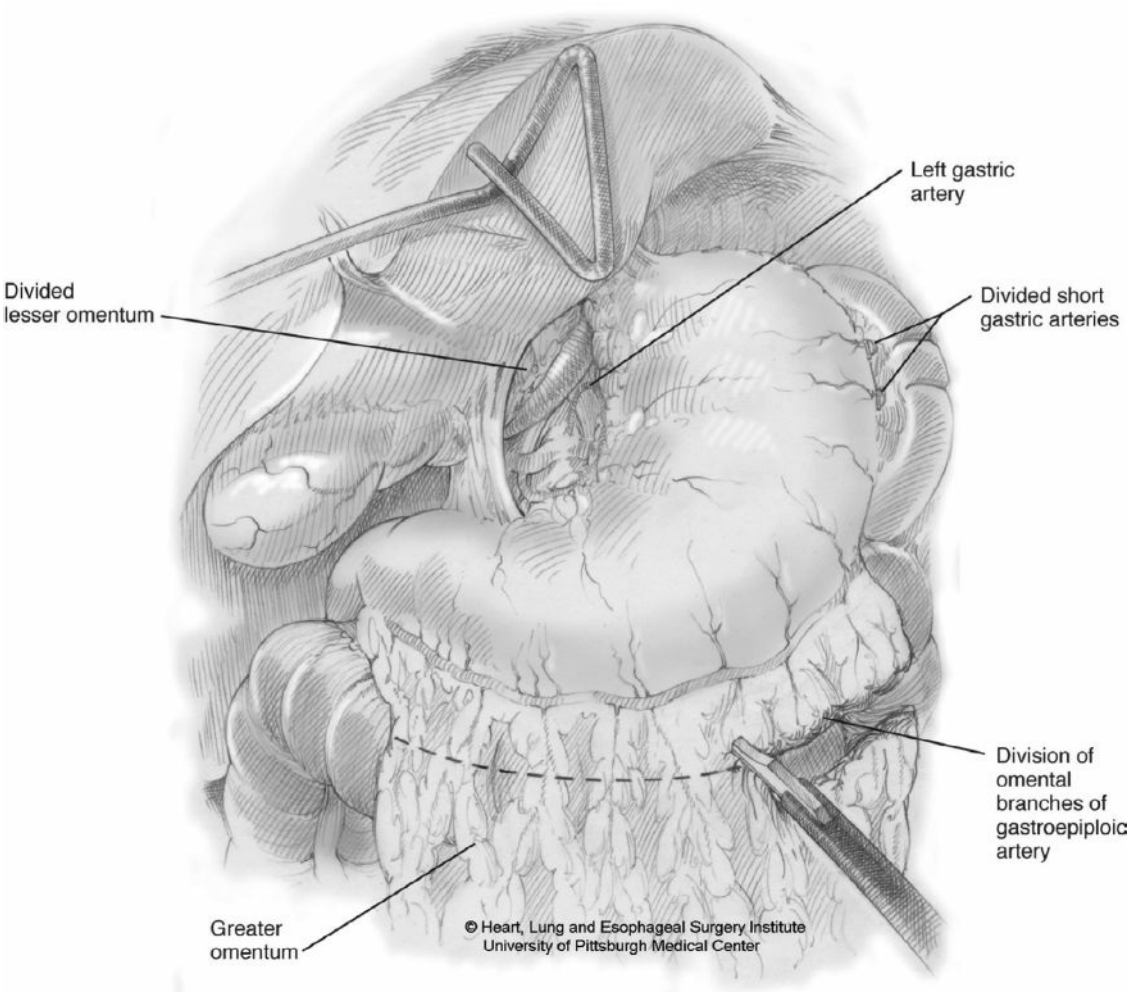

Figure 71.2. Abdominal dissection. (Image © Heart, Lung, and Esophageal Surgery Institute University of Pittsburgh Medical Center.)

Mobilization of the stomach is then carried back toward the pyloroantral region, a Kocher maneuver is performed, and the retrogastric and duodenal attachments are carefully dissected in order to achieve adequate mobilization. The ability of the pylorus to reach the level of the right crus demonstrates adequate mobilization and should be assessed at several time points to determine the degree of dissection required. If there is any difficulty with this maneuver, further pyloroantral mobilization is generally required.

Creation of the gastric conduit can be performed either before or after the completion of the pyloroplasty. Early conduit creation is often performed in patients with significant underlying vascular disease and

often provides additional time to assess the viability of the gastric tube as a conduit. An additional 12-mm port is placed in the distal right paraumbilical area to assist with the creation of the gastric tube and placement of the jejunostomy tube.

The gastric tube is then constructed by first using a vascular load of the Endo-GIA stapler to divide the lesser-curve vessels and fat at an angle toward the incisura while also preserving the right gastric vessels. The first stapler load used is a vascular load, with a staple height of 2.5 mm, to minimize small-vessel oozing along the lesser curve (Fig. 71.3). It is important that no stomach is divided in this initial staple fire. The angle of the first few staple firings will be determined by the desired gastric tube diameter and should be placed accordingly. We prefer to create a gastric tube that is 3 to 4 cm wide. During this stapling, we grasp the tip of the fundus at the line of the short gastrics and apply slight traction toward the spleen. A second grasper is applied through the right paraumbilical port to the antral area with slight downward retraction. This simultaneous traction functions to keep the gastric tube on slight stretch affording a more consistent stapler application. The thick gastric antrum may require the black stapling cartridge with a staple height of 4.5 mm. As the stapling continues toward the fundus, the gastric wall thickness generally diminishes and subsequent stapler loads are transitioned to purple loads with a staple height of 3.5 mm (Endo-GIA Reloads with Tri-staple Technology, Covidien). Subsequent firings of the stapler should be maintained in a line parallel to the greater-curvature arcade and line of the divided short gastrics. It is important to stay parallel to the line of the short gastrics in order to create a consistent tube width and avoid spiraling of the tubularized gastric conduit. The staple line is inspected for hemostasis, and sites of active bleeding are clipped. A single endostitch is placed approximately 4 cm from the pylorus at the transition between the gastric reservoir and the newly tubularized conduit. The stitch is cut long and functions to identify the transition between intra-abdominal and intrathoracic conduit and prevent the common mistake of pulling redundant conduit into the chest. The superior aspect of the gastric tube is then stitched to the specimen (Fig. 71.4). These sutures should be placed from the tip of the fundic portion of the tube to the lesser-curve region of the resected specimen being sure to maintain the appropriate orientation. This also tends to minimize the bulk as the specimen and gastric tube as they are passed through the hiatus. If an omental flap was created, the

distal end of the omental flap should be secured to the tip of the conduit. The specimen and distal aspect of the gastric conduit should be tucked into the hiatus to ensure easy intrathoracic passage.

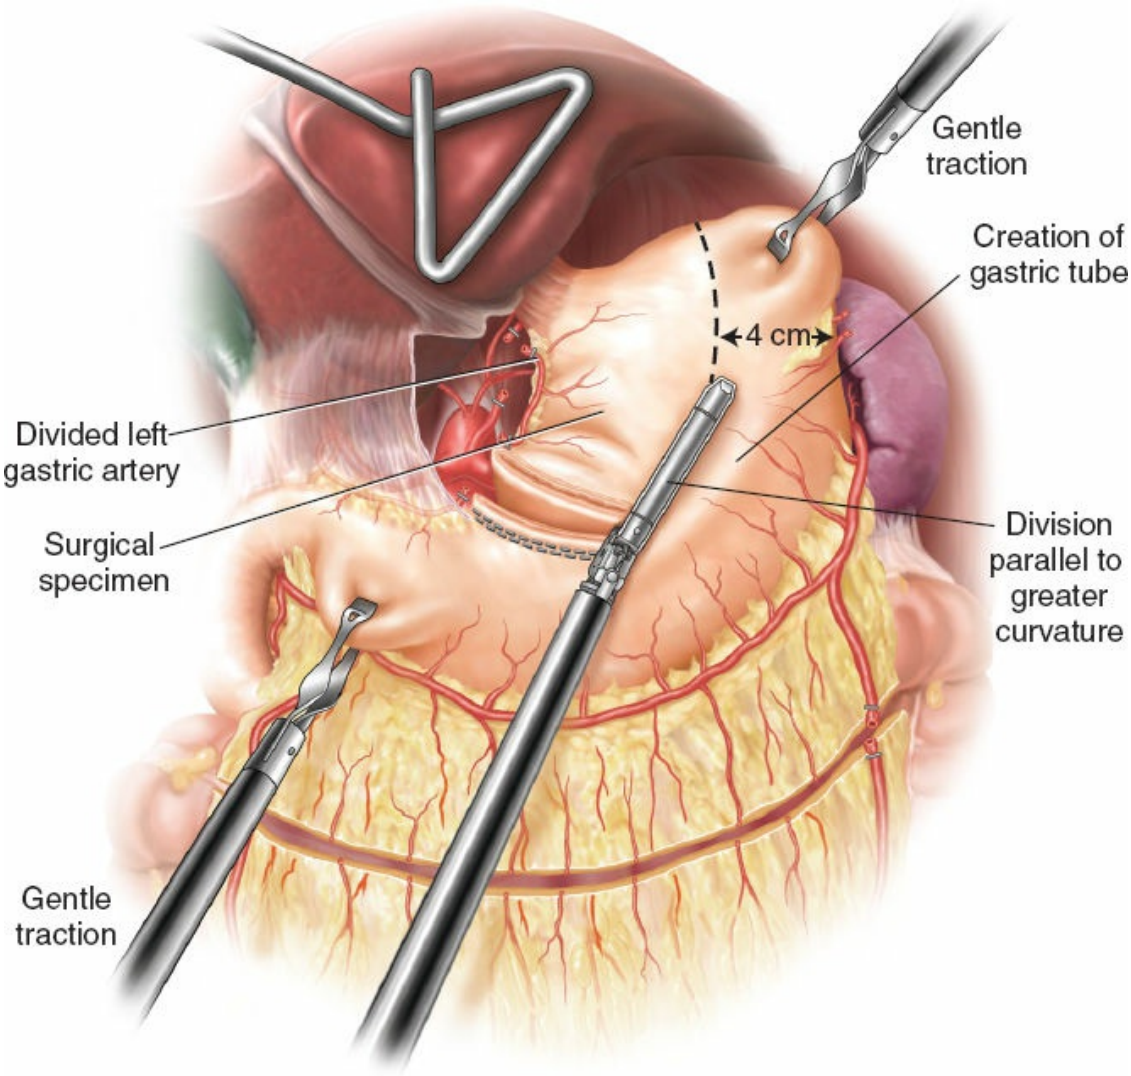

Figure 71.3. Creation of the gastric conduit.

Pyloroplasty

Having previously completely mobilized the stomach, retrogastric, and duodenal attachments, a pyloroplasty is then performed in a Heineke-Mikulicz fashion (Fig. 71.5). Two 2-0 endostitches are placed in the most superior and inferior aspect of the pylorus to provide retraction. These sutures are then used to retract the pylorus anteriorly and away from the posterior wall of the stomach while ultrasonic shears are used to incise the anterior wall of the pylorus. The pyloroplasty is then closed transversely using simple interrupted 2-0 endosutures being sure to include mucosa in

each stitch. After completion of the pyloroplasty, a freely mobile portion of omentum is identified and tacked over the pyloroplasty.

Feeding Jejunostomy

A grasper is applied to the adjacent fatty epiploicae of the transverse colon, and the colon is retracted cephalad identifying the ligament of Treitz. A small needle is placed percutaneously into the peritoneal cavity in the left lower quadrant under direct laparoscopic visualization in order to mark the intended site of jejunostomy creation. A loop of jejunum approximately 40 cm distal to the ligament of Treitz is then attached to the anterior abdominal wall using a single 2-0 endostitch at the site previously marked by the needle. A 12-Fr needle catheter feeding jejunostomy tube is inserted into the jejunum percutaneously using a Seldinger technique (B-Braun, Bethlehem, PA). The percutaneous jejunostomy kit employs a guidewire Seldinger technique, and this guidewire is threaded into the small bowel followed by the dilator, and then the feeding catheter cut to a distance of approximately 25 cm (Fig. 71.6). The feeding tube is then secured with placement of 2 witzel stitches, and further tacked to the anterior abdominal wall using an additional 2-0 endostitch in a purse-string fashion. A single suture is placed approximately 3 cm distal to the entrance site of the feeding tube, to prevent torsion of the distal jejunal limb. The feeding catheter is secured on the skin. If any doubt exists as to true luminal placement, on-the-table intestinal contrast imaging of the J-tube should be performed (such as with diatrizoate meglumine and diatrizoate sodium [gastrograffin]).

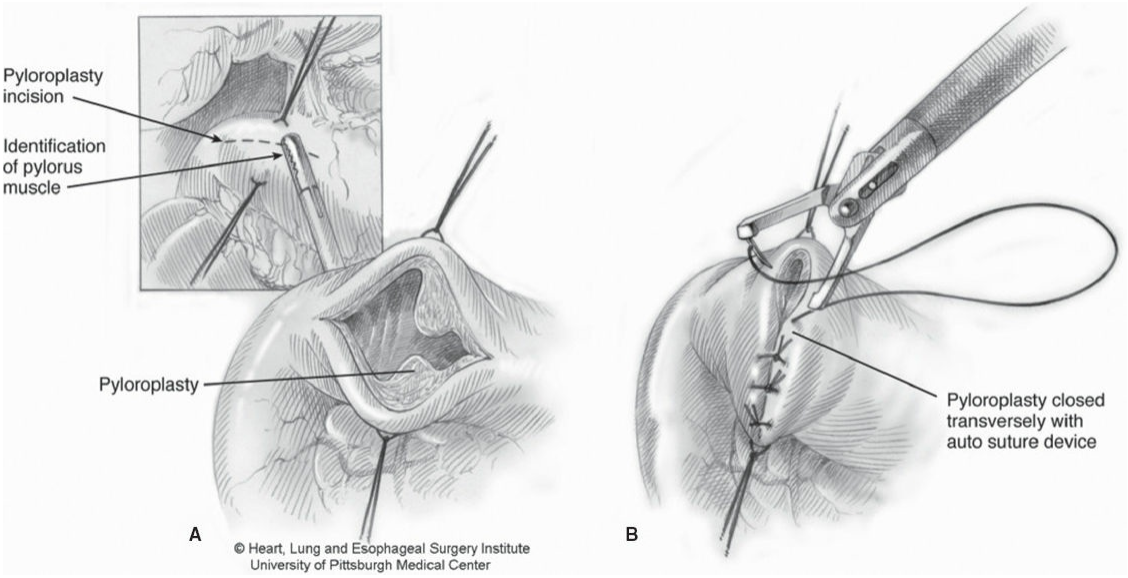

Figure 71.5. Laparoscopic pyloroplasty. (Image © Heart, Lung, and Esophageal Surgery Institute University of Pittsburgh Medical Center.)

Thoracoscopy

The patient is placed in the left lateral decubitus position. Once correct positioning of the double-lumen tube is confirmed, the right lung should be isolated immediately, to provide adequate time for decompression. The operating table is flexed to move the iliac crest away from the costal margin and expand the intercostal spaces and the position of the right scapula is marked.

Five ports are used to complete the intrathoracic dissection. A 10-mm camera port is inserted in the eighth intercostal space just anterior to the mid-axillary line. We prefer this port to be low on the chest and in a more anterior position, so as to enter the chest just above the costophrenic recess. This position affords a nice panoramic view of the chest and also limits any run down of blood onto the thoracoscope. An additional 10-mm port is placed approximately 2 cm posterior to the posterior axillary line in the eighth or ninth interspace. This is the main dissection port for the harmonic ultrasonic scalpel (Ethicon, Cincinnati, OH). A 10-mm port is placed in the fourth interspace along the anterior axillary line in order to allow utilization of a fan retractor to provide retraction of the lung. A 5-mm port is placed inferior to the scapular tip. A final 5-mm port is placed at the sixth intercostal space at the anterior axillary line. A 48-in 0 Endostitch is then placed in the central tendon of the right diaphragm and brought out percutaneously through the low anterior chest wall near the

costophrenic recess using an Endo-Close device (U.S. Surgical). Downward traction on this stitch pulls the diaphragm inferiorly allowing for better visualization of the distal esophagus and hiatus.

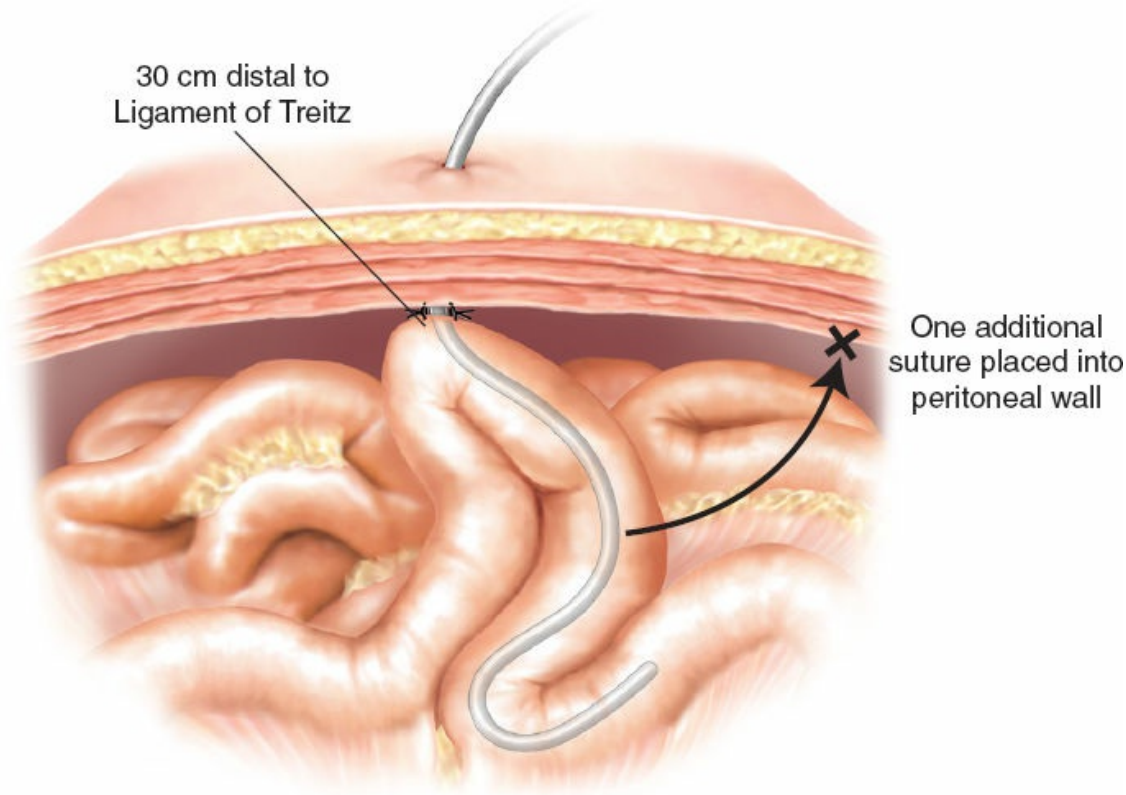

Figure 71.6. Laparoscopic jejunostomy tube.

Dissection begins by taking down the inferior pulmonary ligament up to the level of the inferior pulmonary vein. With the lung retracted anteriorly, the mediastinal pleura is excised along the plane between the edge of the lung and the esophagus and is resected with the specimen up to the azygos vein. The subcarinal lymph nodes are excised en bloc with the esophagus. Care must be taken to avoid injury to the posterior membrane of the right mainstem bronchus, carina, and trachea. The active blade of the dissection device should be oriented away from the posterior membranous airway in order to minimize potential injury. The anesthesiologist can be asked to remove the suction catheter from the endotracheal tube in order to allow for better visualization of the posterior membranous airway. Dissection is carried up to the azygos vein, which is isolated from the mediastinal pleura and divided with an Endo-GIA vascular stapler. Once at the level of the divided azygos vein, the vagus nerve is divided. Above the level of the azygos vein, the dissection plane is transitioned onto the wall of the

esophagus to avoid recurrent laryngeal nerve injury and the surrounding tissue is dissected away from the esophagus.

The mediastinal pleura is then divided superficially near the hiatus and along the posterior groove to the esophagus. Care must be taken in this plane to avoid injury to the thoracic duct and underlying aorta. In cases of difficult dissection, a Penrose drain can be placed around the esophagus and used to provide retraction away from the posterior esophageal attachments and assist with circumferential dissection. Tributaries from the thoracic duct to the esophagus are at risk for subsequent leak, and liberal use of Endo-clips should be used to minimize postoperative chylous leaks. Aortoesophageal vessels are identified, isolated, clipped, and divided to minimize bleeding. All surrounding periesophageal soft tissue and lymph node tissue are taken with the esophagus. The deep margin of the dissection is the contralateral pleura.

Once the esophagus is mobilized fully, the specimen and proximal portion of the gastric conduit are delivered into the chest. The suture attaching the specimen and the conduit is divided. Care must be taken to maintain the proper orientation of the gastric conduit and prevent torsion. Proper orientation requires that the staple line face the lateral right chest wall, and in the left lateral decubitus position the staple line should be facing up toward the operators. The proximal esophagus is divided with thoracoscopic scissors at or above the level of the azygos vein, thus separating the entire specimen. Next, a non–rib-spreading 4- to 5-cm access incision is made between the surgeon’s working port and the tip of the scapula. A wound protector (Applied Medical, Rancho Santa Margarita, CA) is placed to protect the skin and chest wall from trocar implants. The specimen is removed through the access incision and sharply excised and examined on the back table to ensure adequate gastric and esophageal margins prior to being sent for pathologic analysis.

The proximal cut edge of the esophagus is assessed, and the surgeon must make a determination of the appropriate-sized EEA (end-to-end anastomosis) anvil to use. We most commonly use a 28-mm EEA stapler in an effort to minimize the risk of anastomotic stricture. The proximal esophagus can be gently dilated with a large Foley balloon, if needed. The anvil of an EEA stapler is then placed (Fig. 71.7). A total of two purse string sutures are placed using 2-0 endostitch to secure the anvil in the proximal esophagus. Care must be taken to include all layers of the esophagus in the purse-string sutures to ensure creation of a complete

anastomosis with use of the EEA.

The gastric conduit is then delivered entirely into the chest until the distal marking stitch placed during the laparoscopic portion is seen at the hiatus. The proximal end of the gastric conduit is then opened, irrigated, and cleaned of debris. The EEA stapler is delivered into the chest through the access incision (Fig. 71.8). It is gently placed into the open gastric conduit like “a foot in a sock” being certain to maintain appropriate staple line orientation. The spike is then brought out along the line of the greater curve distal to the opening at a point that will allow removal of any potential gastric tip ischemia. This spike is then attached to the anvil, the stapler fired, and the anastomosis is created (Fig. 71.9). The open end of the gastric conduit through which the EEA stapler was introduced is now resected using sequential loads of the Endo-GIA articulating stapler (Fig. 71.10). This partial gastrectomy specimen is then sent to pathology as the final gastric margin. A nasogastric tube is placed and observed to pass through the anastomosis. The surrounding omentum or omental flap is then placed circumferentially around the anastomosis and sutured in place. A 2-0 Endostitch is used to attach the gastric conduit to the right crus and minimize thoracic migration of the gastric conduit. The chest and port sites are irrigated aggressively with antibiotic solution. A 10-mm Jackson-Pratt drain is placed posteriorly with the distal aspect beyond the newly formed esophagogastric anastomosis. Intercostal bupivacaine is injected to provide temporary regional anesthesia. A single 28-Fr straight chest tube is placed through the camera port and directed posteriorly toward the apex (Fig. 71.11). The lung is inflated to check for any injury to the posterior membranes of the trachea or bronchus. The access incision is closed in multiple layers being certain to approximate muscular edges. Once the patient is returned to the supine position, the oropharynx and nasopharynx are suctioned of all secretions and the nasogastric tube secured at a midconduit position of 35 to 40 cm. The double-lumen endotracheal tube is exchanged for a single-lumen tube to allow for complete toilet bronchoscopy and inspection for airway trauma or injury.

RESULTS

Our experience with minimally invasive laparoscopic and thoracoscopic esophagectomy, the largest reported experience to date, highlights some of the potential advantages and pitfalls of this approach. Our initial experience with 222 patients has now grown to more than 2,000 MIEs at the University of Pittsburgh Medical Center. A review of our experience with more than 1,000 patients demonstrated excellent morbidity, mortality, and oncologic outcomes. The modified McKeown MIE was performed electively in 481 patients and the Ivor Lewis MIE in 530. By 2006, the Ivor Lewis had become the preferred approach and thus the majority of patients in the last 5 years of the study period received an Ivor Lewis MIE. The median length of stay (8 days) and ICU stay (2 days) were similar between the two approaches. The median number of lymph nodes resected was 21. The overall operative mortality of both groups was 1.68%. Overall morbidity, mortality, lymph node harvest, and cancer outcomes for the

entire cohort were similar or better than most published series of open esophagectomies. The Ivor Lewis MIE subgroup had a significantly lower incidence of recurrent nerve injury of 1% and significantly lower operative mortality of 0.9% at 30 days.

Nagpal and colleagues performed a meta-analysis of 12 studies with a total of 672 patients who underwent esophagectomy via an open, hybrid or minimally invasive approach. The investigators concluded that MIE was associated with better operative and postoperative outcomes. MIE patients had less blood loss and shorter ICU and hospital stays. In addition, the MIE group had a 50% decrease in morbidity with a significantly lower incidence of respiratory complications in comparison with the open esophagectomy group. No significant differences in anastomotic leak, stricture, gastric conduit ischemia, chylothorax, vocal cord palsy, or 30-day mortality were found. In the subgroup analysis, the investigators found that patients who underwent even one stage of their esophagectomy minimally invasively (e.g., laparotomy with thoracoscopy or laparoscopy with thoracotomy) had significantly less blood loss and fewer respiratory complications compared with patients who underwent open esophagectomy. Oncologic outcomes were comparable in all three groups.

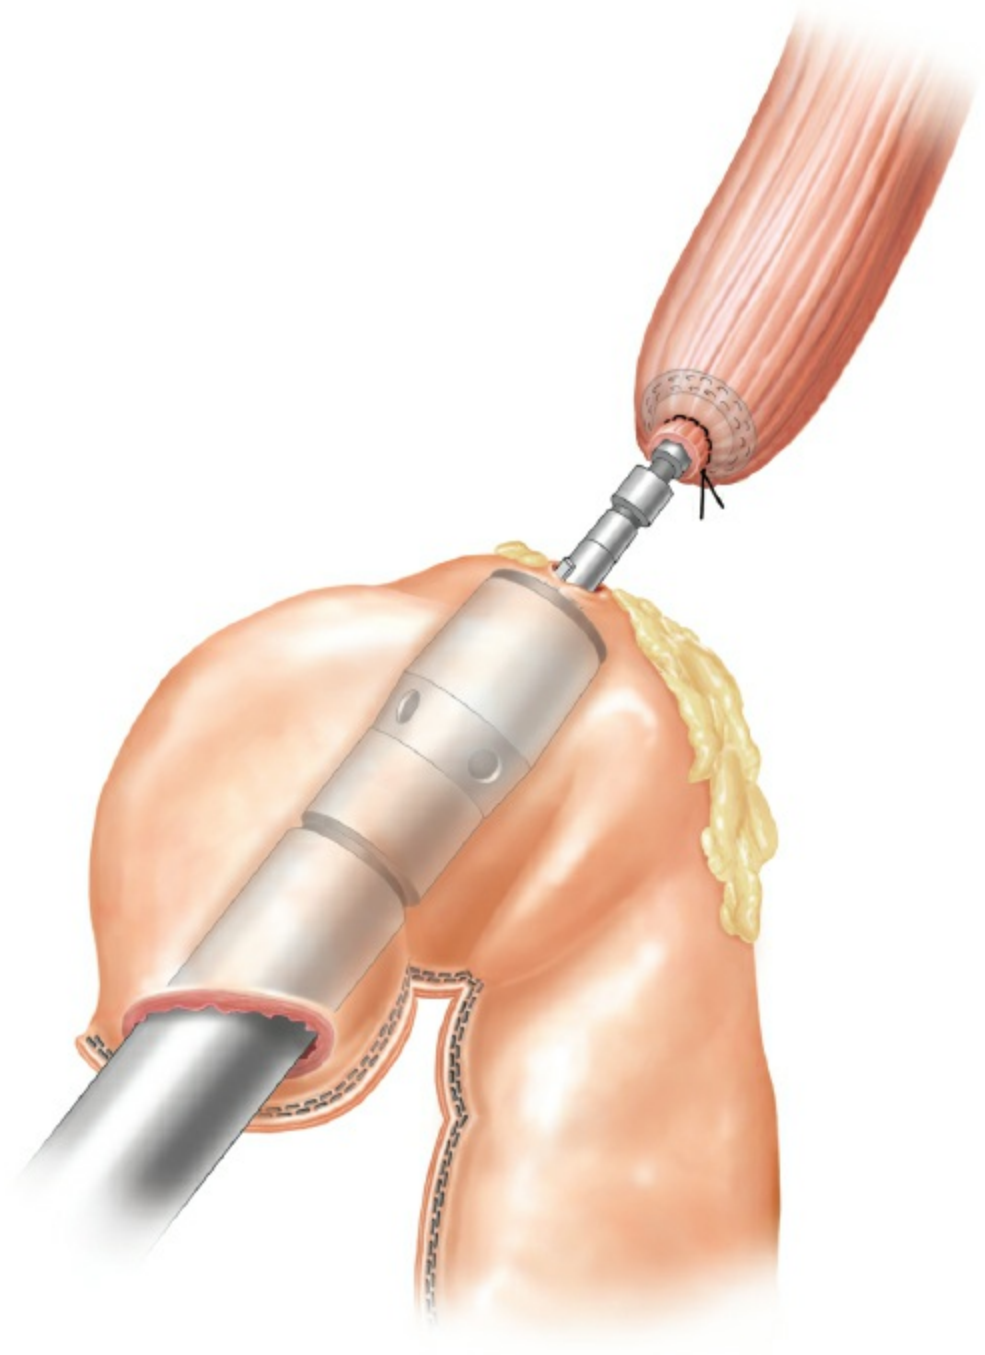

Figure 71.9. Alignment of the EEA stapler.

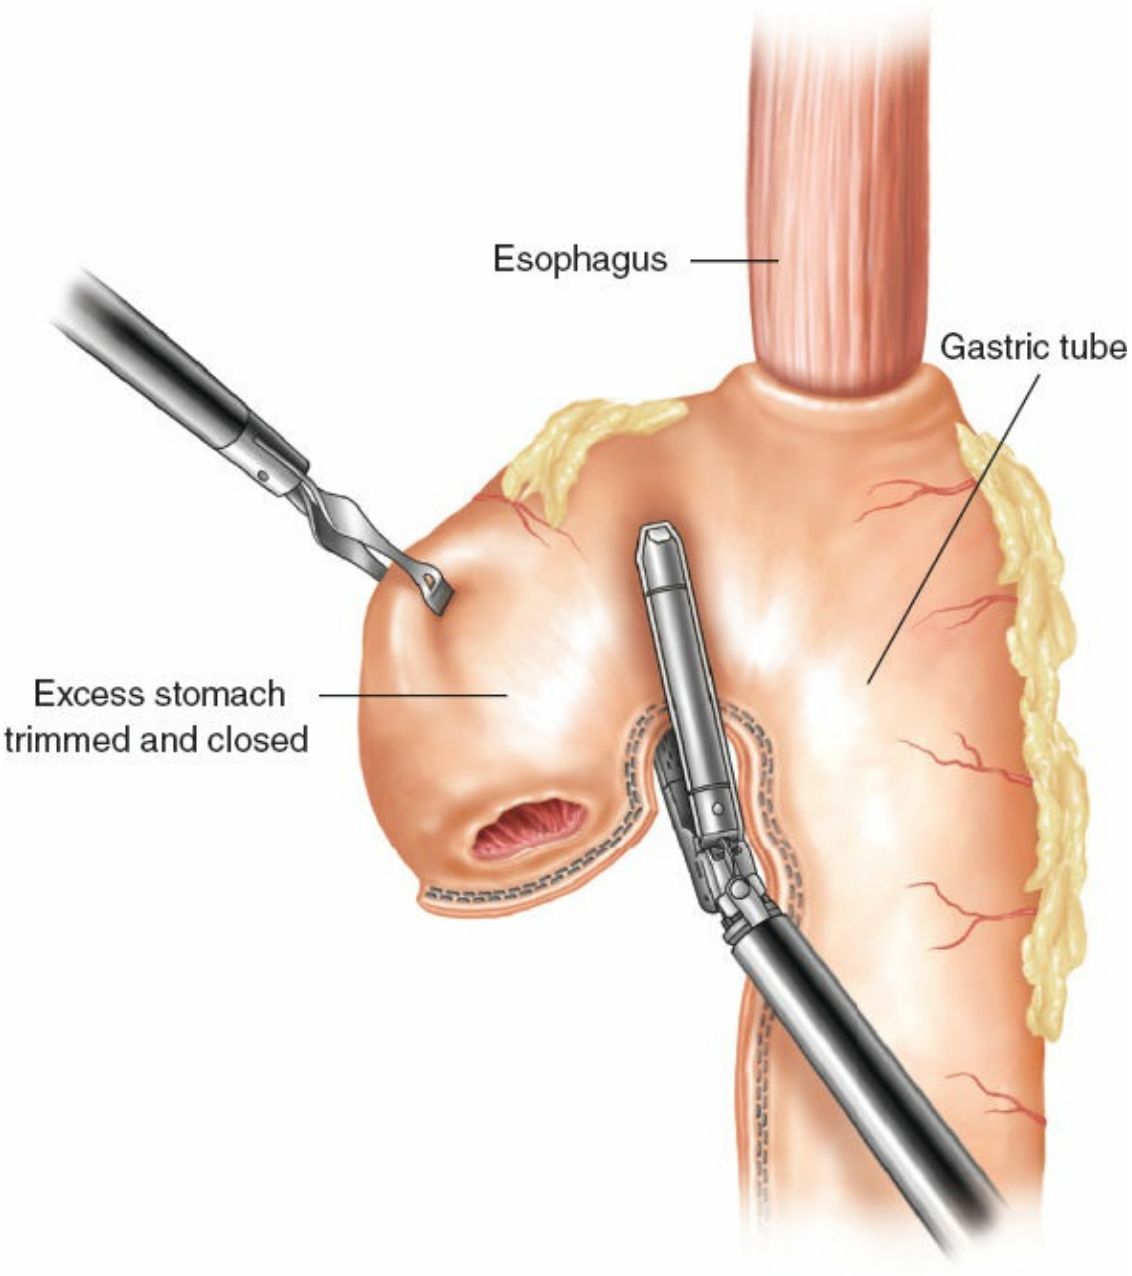

Figure 71.10. Closure of the conduit.

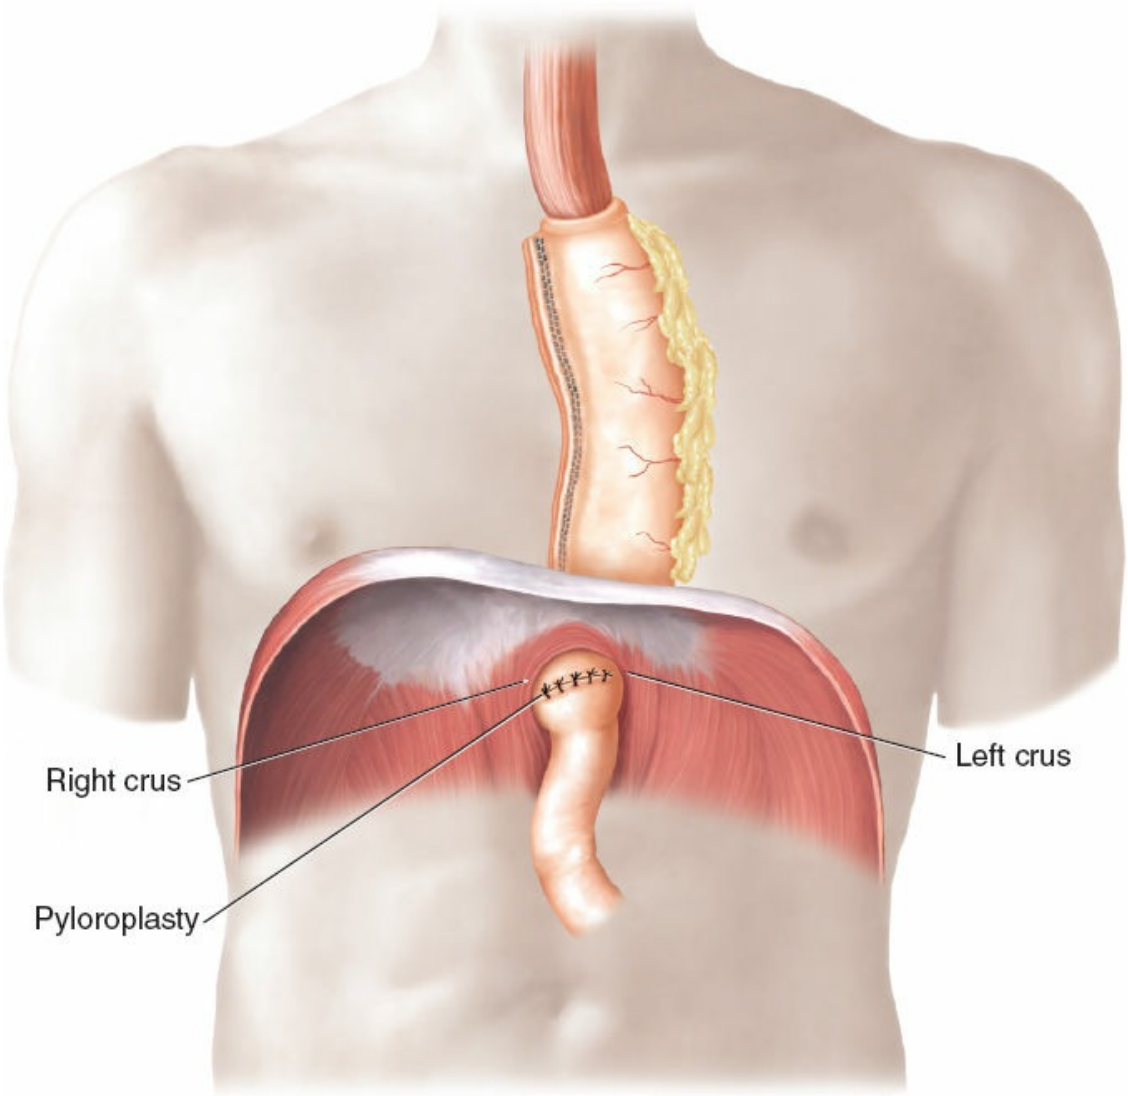

Figure 71.11. Finished reconstruction.

A meta-analysis performed by Dantoc and colleagues examined the oncologic outcomes and 5-year mortality in patients undergoing open esophagectomy versus MIE. This review included 17 case-controlled studies with a total of 1,586 patients. Lymph node yield was significantly higher in the MIE group, median 16 nodes (range 5.7 to 33.9), as compared with the open group, median 10 nodes (range 3.0 to 32.8). The 5-year survival rates were similar in the MIE group (12.5% to 67%) and the open group (16% to 57%). The investigators concluded that MIE provides oncologic outcomes equivalent to those of open esophagectomy.

Biere and colleagues performed the first multicenter randomized controlled trial that compared open transthoracic esophagectomy with minimally invasive transthoracic esophagectomy. They examined outcomes from five centers in three countries from June 2009 until March

2011. They demonstrated a significantly higher rate of pulmonary complications in the open esophagectomy group in comparison to the minimally invasive group. In the open esophagectomy group, 29% of patients had a pulmonary infection within the first 2 weeks and 34% while in hospital. This compared to only 9% and 12% in the minimally invasive group. This trial demonstrated that patients who receive MIE have an improved short-term outcome for pulmonary infections, hospital stay, and quality of life in comparison to those undergoing an open esophagectomy, with no compromise in oncologic principles.

Puntambekar and colleagues demonstrated that thoracolaparoscopic esophagectomy can be accomplished safely in patients over the age of 70 with low morbidity and mortality. In an analysis of 68 elderly patients who received MIE, they reported a mean ICU stay of 3.84 days, mean hospital stay 12.7 days, cardiac complications rate of 10.3%, and a 30-day perioperative mortality of 4.4%. Kilic et al. demonstrated a low mortality of 1.8% in obese patients with a body mass index (BMI) greater than 30. These reports suggest that MIE can be performed in high-risk patients who might not otherwise be considered for surgical resection.

COMPLICATIONS

Morbidity associated with open esophagectomies can be significant, ranging from 35% to 50%. A review of some of the largest series of MIE, transhiatal esophagectomy, and transthoracic esophagectomy compared with a 10-year review of all esophagectomies performed at the Veterans Affairs Medical Centers illustrated favorable outcomes in mortality, length of stay, and several major complication criteria (Table 71.1).

Hulscher published a randomized trial comparing transhiatal and transthoracic open esophagectomies. When compared side by side, the MIE approach seems to impart a lower incidence of anastomotic leaks and vocal cord paralysis (Table 71.2). Sgourakis et al. performed a meta-analysis of more than a 1,000 patients comparing open thoracotomy esophagectomy with both video-assisted thoracoscopic surgery (VATS)/laparoscopic esophagectomy and VATS/laparotomy hybrid esophagectomy. This study demonstrated lower morbidity in patients who had a complete MIE with a VATS/laparoscopic approach.

Thoracic Complications

Bleeding and transfusion requirements were less with the minimally

invasive approach, but it is important to note that even small amounts of bleeding can obscure the operative field, making progress difficult and requiring conversion to an open procedure. Hence, the aortoesophageal vessels must be identified and clipped and bleeding from the azygos vein and peribronchial arteries avoided. Injury to the posterior membranes of the bronchus and trachea must be carefully avoided, especially during mediastinal lymph node dissection. Cautery, auto-sonic, or harmonic scalpel use in close proximity to the posterior membranous airway can lead to tissue damage resulting in an air leak, local ischemia, and subsequent development of a tracheogastric conduit fistula.

Outcomes after esophagectomy: a ten-year prospective cohort. *Ann Thorac Surg* 2003;75(1):217; discussion 222.

The thoracic duct is at risk for subtle injuries leading to the development of a chylothorax. Early in our experience, in our initial 77 patients undergoing MIE, we noted 3 patients with delayed chylothorax, leading us to become more cautious in this area and transition to the liberal use of metal clips on thoracic duct branches. Vocal cord paralysis from

injury to the recurrent laryngeal nerve is minimized by dividing the vagus nerve just above the azygos vein and dissecting this away from the esophagus. We generally do not perform a lymph node dissection above this level in an effort to avoid injury to the recurrent laryngeal nerves and due to the lack of definitive evidence that lymph node clearance in the upper chest is essential for gastroesophageal junction tumors.

Abdominal Complications

Disruption of the main gastroepiploic arcade can be devastating to the viability of the gastric conduit. Likewise, one must be certain that there is adequate room at the hiatus for the conduit to lie without strangulation. In our series, there was an incidence of gastric tip necrosis of 3.2%. Delayed hiatal herniation of abdominal viscera is also a possibility if the gastric conduit is not properly tacked to the hiatus. Kent et al. reported approximately a 2% incidence of diaphragmatic hernias and a 2% risk of redundant gastric conduit, leading to delayed gastric emptying, reflux, and obstruction. Eighty-five percent of patients with such anatomical complications benefited from reoperative revisional surgery. Orringer's series identified a 2% rate of splenectomy in 2007 open transhiatal esophagectomies.

A decade of experience with transthoracic and transhiatal esophagectomy. *Am J Surg* 2002;183(2):162.

Orringer's open series also noted a 3% incidence of wound infections and dehiscence. The national Veteran's Affairs study revealed a 10.9% rate of wound infections with a 3.7% rate of wound dehiscence. When open transhiatal and transthoracic procedures were prospectively evaluated, the transhiatal approach was associated with a 5% incidence of wound dehiscence and a 2% incidence was associated with the transthoracic approach. Delayed incisional hernias are seldom reported but are estimated to occur in 5% to 10% of long-term survivors. In our initial minimally invasive series of 222 patients, a 0.9% incidence of minor wound infection was seen with only one early incisional port site hernia and no wound dehiscence was observed.

Postoperative Complications

Cardiopulmonary complications, including atrial fibrillation (2.9%), ARDS (5.7%), and pneumonitis (3.8%), were the most frequently encountered complications following MIE in the multi-institution E2202 trial. Our overall anastomotic leak rate requiring surgery with the McKeown approach was 5% and decreased to 4% with the Ivor Lewis approach. The reported leak rate for open procedure is approximately 9.1%. Other MIE series demonstrate similar leak rates. Moderate strictures at the gastroesophageal cervical anastomosis are common and generally can be managed with one or two outpatient dilations. Using the Ivor Lewis approach and a 28-mm EEA stapler, strictures still occur, but generally are less clinically significant and respond favorably to dilations.

ALTERNATIVE APPROACHES

MIE encompasses an array of thoracoscopic and laparoscopic techniques that all seek to reduce the morbidity of an open procedure. Several groups have reported variations in technique that may provide insight in this emerging field. Bonavina described the use of a video mediastinoscope from the cervical incision to assist his mediastinal dissection during a laparoscopic transhiatal esophagectomy. He reported that 10 of 12 operations were successful with a mean operative time of 270 minutes. Mean hospital stay was 10 days with no ICU stays. Palanivelu described a prone approach to thoracic mobilization in an effort to facilitate operative exposure. Low rates of anastomotic leak (3%), low mortality (1.5%), and equivalent stage-specific survival compared with open series have been shown with this thoracoscopic prone approach.

The robotic-assisted esophagectomy is emerging as a potential minimally invasive approach to esophagectomy. Park and colleagues reported their experience with 114 patients who underwent robot-assisted thoracoscopic esophagectomy with extensive mediastinal lymphadenectomy followed by cervical esophagogastrostomy. Their series reported a total operative time of 419 minutes with a mean of 43.5 lymph nodes resected. The most common complication was recurrent laryngeal nerve palsy (26.3%), followed by anastomotic leak (14.9%) and pulmonary complications (9.6%). They reported a median hospital stay of 16 days, and 90-day mortality was observed in 2.5% of patients.

CONCLUSION

MIE is a technically challenging operation with a steep learning curve. However, in a high-volume academic setting, technical proficiency can be achieved over time. Recent reports clearly demonstrate comparable, and possibly improved, mortality and morbidity following MIE in centers with significant experience in open and minimally invasive techniques. When MIE is performed by the most experienced surgeons in our center, the mortality is less than 1%, with a hospital stay of 6 days and, in our experience, patients enjoy a more rapid return to their premorbid lifestyle and quality of life.

EDITOR'S COMMENT

Since the initial reports of a minimally invasive approach to esophagectomy were published by Cuschieri et al. (Endoscopic oesophagectomy through a right thoracoscopic approach. *J R Coll Surg* 1992;37:7–11) and DePaula et al. (*Surg Laparosc Endosc Percut Tech* 1995;5:1–5), minimally invasive esophagectomy (MIE) has gained substantial popularity as the technique of choice for the surgical treatment of esophageal cancer. Much of this growth in popularity of MIE is due to the outstanding published results (Luketich JD, Pennathur A, Awais O, et al. Outcomes after minimally invasive esophagectomy: review of over 1000 patients. *Ann Surg* 2012;256:95–103) and the leadership of Dr. Luketich and his team at the University of Pittsburgh.

The safety and feasibility of this technically demanding procedure have now been demonstrated not only in single institution studies but also in prospective, multi-institutional studies (Luketich, Pennathur A, Franchetti Y, et al. Minimally invasive esophagectomy: results of a prospective phase II multicenter trial—the eastern cooperative oncology group (E2202) study. *Ann Surg* 2015;261:702–7; Biere, van Berge Henegouwen MI, Maas KW, et al. Minimally invasive versus open oesophagectomy for patients with oesophageal cancer: a multicentre, open-label, randomised controlled trial. *Lancet* 2012;379:1887–92). On balance, when compared to the traditional open, transthoracic esophagectomy, MIE is associated with less postoperative morbidity (primarily fewer pulmonary complications) and shorter lengths of stay in the ICU and in the hospital (Biere, van Berge Henegouwen MI, Maas KW, et al. Minimally invasive versus open oesophagectomy for patients with oesophageal cancer: a multicentre, open-label, randomised controlled trial. *Lancet* 2012;379:1887–92 and Sihag et al. *Eur J Cardiothor Surg* 2012;42:430–7). However, despite the authors' assertions that MIE is also associated with lower mortality rates than the open procedure, the comparison they choose is a published study from the Veterans Affairs, which is hardly representative of the results achieved by the finest, high-volume centers in the United States. Indeed,

Sihag et al. recently published a study (Minimally invasive versus open esophagectomy for esophageal cancer: a comparison of early surgical outcomes from the society of thoracic surgeons national database. *Ann Thor Surg* 2016;101(4):1281–8) comparing the short-term outcomes of open esophagectomy (OE) versus MIE for esophageal cancer in the United States between 2008 and 2011 by querying the Society of Thoracic Surgeons National Database, which includes primarily centers of excellence throughout the United States. These authors found that the overall postoperative morbidity and mortality rates were essentially the same for OE (62.4% and 3.9%, respectively) and MIE (61.5% and 3.3%). Nonetheless, there is widespread agreement that MIE is associated with lower rates of wound infection, ileus, postoperative transfusion, and pulmonary complications than OE; is associated with a better short-term quality of life than OE; and has a shorter median length of hospital stay than OE. In fact, with the use of fast-track protocols in patients undergoing MIE, the length of stay can be safely reduced to 7 days as opposed to 12 days in the conventionally treated group (Pan, Hu X, Yu Z, et al. Use of a fast-track surgery protocol on patients undergoing minimally invasive oesophagectomy: preliminary results. *Interact Cardiovasc Thor Surg* 2014;19:441–7). The fast-track protocol includes a semi-liquid meal administered up to 6 hours prior to surgery as well as 200 mL of a 10% glucose solution 3 hours prior to surgery, no nasogastric tube or abdominal drains, early removal of the chest tube and foley catheter, prevention of hypothermia, early physical therapy, and early enteral nutrition (including oral feeding 48 hours after surgery).

In addition to its proven safety and feasibility as a standard approach to the surgical treatment of esophageal cancer, MIE has also been demonstrated to have equal oncologic efficacy as OE. Tapias et al. (Outcomes with open and minimally invasive ivor Lewis esophagectomy after neoadjuvant therapy. *Ann Thor Surg* 2016;101(3):1097–103) reviewed the outcomes of 130 consecutive patients undergoing MIE (n = 56) or OE (n = 74) for esophageal cancer after neoadjuvant therapy and showed similar nodal yields (median of 20 lymph nodes) and 5-year overall survival rates (OE, 61% vs. MIE, 50%) between the two groups. Moreover, since patients undergoing MIE typically recover more quickly than those undergoing OE, they are more likely to receive any recommended adjuvant therapy in a timely fashion. In fact, Zahoor et al. (A propensity-matched analysis comparing survival after primary minimally invasive esophagectomy followed by adjuvant therapy to neoadjuvant therapy for esophagogastric adenocarcinoma. *J Thor Cardiovasc Surg* 2015;149:538–47) performed a propensity-matched analysis comparing survival after primary MIE followed by adjuvant therapy to neoadjuvant therapy followed by MIE for esophageal cancer and found no difference in survival rates, although only 65% of stage IIb or higher patients undergoing upfront MIE received adjuvant therapy. The authors of this study argued that this approach permits more accurate pathologic stage assignment and could minimize the risk of overtreatment in patients with early-stage disease.

Although the authors do not explicitly state that they routinely perform a D2 lymphadenectomy together with MIE for adenocarcinomas of the gastroesophageal junction (GEJ), they do briefly describe the dissection of the D2 nodes along the left gastric (station 7), celiac (station 9), and proximal splenic (station 11) arteries. However, I think that it is worth emphasizing that for Siewert type II (true cardia) and type III (subcardial) GEJ adenocarcinomas in particular, in which the predominant pattern of lymphatic spread is to the upper abdomen, a D2 lymphadenectomy should be performed together with the esophagogastrectomy (Kakeji Y, Yamamoto M, Ito S, et al. Lymph node metastasis from cancer of the esophagogastric junction, and determination of the appropriate nodal dissection. *Surg Today* 2012;42:351–8). Indeed, whereas Siewert type I tumors frequently metastasize to both mediastinal (~50%) and upper abdominal (~50%) lymph nodes, the lymphatic drainage of type II tumors is primarily directed toward the abdominal nodal basins (~70%), especially the paracardial, lesser curvature, and left gastric nodes, as opposed to the mediastinal nodes (~30%). Type III tumors are similar to type II tumors in almost exclusively metastasizing to intra-abdominal lymph nodes (~90%) and only rarely metastasizing to nodes within the chest (~10%) (Pedrazzani, de Manzoni G, Marrelli D, et al. Lymph node involvement in advanced gastroesophageal junction adenocarcinoma. *J Thorac Cardiovasc Surg* 2007;134:378–85).

In addition to its short-term benefits, MIE is associated with longer term benefits as well, including an improved quality of life (QOL) compared to OE. Maas et al. (Quality of life and late complications after minimally invasive compared to open esophagectomy: results of a randomized trial. *World J Surg* 2015;39:1986–93) conducted a 1-year follow-up analysis of the QOL of patients participating in the first, multicenter, randomized controlled clinical trial comparing OE with MIE (Biere, van Berge Henegouwen MI, Maas KW, et al. Minimally invasive versus open oesophagectomy for patients with oesophageal cancer: a multicentre, open-label, randomised controlled trial. *Lancet* 2012;379:1887–92). They found that patients undergoing MIE had better physical activity, global health, and pain scores than those patients undergoing OE. Interestingly, almost 40% of patients in both groups developed anastomotic strictures, requiring a median of five dilations per patient, although most patients underwent a three-field McKeown-type esophagectomy with a cervical anastomosis.

Of course, in order to achieve expert results similar to those of Dr. Luketich, one must master this technically challenging surgical procedure, and a few groups have examined the learning curve for MIE. Tapias and Morse (Minimally invasive Ivor Lewis esophagectomy: description of a learning curve. *J Am Coll Surg* 2014;218:1130–40) studied the first 80 MIEs performed by a single surgeon with experience in minimally invasive esophageal surgery at a high-volume center and estimated that the learning curve for MIE is approximately 35 to 40 cases. Dhamija et al. (Learning curve to lymph node

resection in minimally invasive esophagectomy for cancer. *Innovations* 2014;9:286–91) estimated that the ability to perform an adequate lymphadenectomy during MIE improves over time and plateaus after the first 25 cases. Lastly, Hernandez et al. (Defining the learning curve for robotic-assisted esophagogastrectomy. *J Gastrointest Surg* 2013;17:1346–51) established that for surgeons proficient in performing MIE, the learning curve for a robotic-assisted procedure appears to begin near proficiency after 20 cases.

Although Dr. Luketich and his team herein describe the laparoscopic approach to MIE, given the advantages of the robotic platform in accelerating the learning curve of MIE with the help of magnified three-dimensional view, improved articulation of instruments, and improved dexterity and ergonomics, it only stands to reason that robotic transthoracic esophagectomy will soon become a standard of care for esophageal cancer. Puntambekar et al. (Robotic transthoracic esophagectomy. *BMC Surgery* 2015;15:47) published the largest series of robotic esophagectomy for esophageal cancer (n = 83) and found that it was not only feasible but allowed precise en bloc dissection with lymphadenectomy in the mediastinum while minimizing operative time, blood loss, and complications. The first randomized, controlled trial (ROBOT trial) comparing robot-assisted esophagectomy with open transthoracic esophagectomy for esophageal cancer was launched in 2012 and is currently accruing patients. Of note, surgeons in this trial will perform the thoracic portion of the Ivor Lewis esophagectomy robotically while performing the abdominal portion laparoscopically (van der Sluis, Ruurda JP, van der Horst S, et al. Robot-assisted minimally invasive thoraco-laparoscopic esophagectomy versus open transthoracic esophagectomy for resectable esophageal cancer, a randomized controlled trial (ROBOT trial). *Trials* 2012;13:230).

In terms of the risk of anastomotic stricture, the authors assert that they try to use a 28-mm EEA stapler to minimize this risk, which in published series is on the order of 30% for the circular stapled technique. Price et al. (A comprehensive review of anastomotic technique in 432 esophagectomies. *Ann Thor Surg* 2013;95:1154–61) at the Mayo Clinic published a comprehensive review of the outcomes with various anastomotic techniques in 432 esophagectomies over a 4-year period. As expected, stricture rates were higher for anastomoses in the neck compared to the chest (26% vs. 15%). For Ivor Lewis esophagectomies, in particular, the 1-year probability of stricture formation was 32% for the circular stapled technique, 27% for the hand-sewn technique, and only 8.6% for the linear-stapled technique. A recent meta-analysis (Zhou et al. Comparison of two different mechanical esophagogastric anastomosis in esophageal cancer patients: a meta-analysis. *J Cardiothor Surg* 2015;10:67) also confirmed the significantly reduced risk of stricture formation with the linear-stapled technique compared to the circular-stapled technique (Risk Ratio 0.26, 95% CI: 0.11–0.60, P = 0.002).

There has been much written about the necessity of performing a pyloroplasty to minimize the risk of gastric outlet obstruction and aspiration

pneumonia. Although the authors describe routinely performing one as part of their MIE, other authors have shown that a pyloroplasty may not be necessary. Lanuti et al. at the Massachusetts General Hospital studied 242 patients (n = 159 had a pyloromyotomy and n = 83 had no pyloric drainage) who underwent OE and found that performance of a pyloromyotomy does not reduce the incidence of symptomatic delayed gastric emptying nor aspiration pneumonia.

The authors also describe placement of a closed suction drain posterior to the esophagogastric anastomosis, presumably to facilitate the detection and (potentially) the drainage of a possible anastomotic leak. Interestingly, there is a recently published study (Perry et al. Serial drain amylase can accurately detect anastomotic leak after esophagectomy and may facilitate early discharge. *Ann Thor Surg* 2015;100:2041–7), which reported that measuring the amylase levels from such drains on a daily basis after esophagectomy may prove more accurate in the detection of an anastomotic leak than a barium esophagram. Specifically, a drain amylase level of 38 IU/L on postoperative day 4 yielded a sensitivity of 100% and a specificity of 52% in detecting a clinically significant leak. Given the relatively low sensitivity of a barium esophagram for the detection of a leak, which in most studies is only on the order of 50%, combined with its potential risks, including aspiration pneumonitis and mediastinitis, perhaps consideration should be given to this simple, low-risk test.

John T. Mullen

72 Nissen–Rossetti Antireflux Fundoplication (Open Procedure)

David I. Watson

The modern era of antireflux surgery began in the 1950s with the description of fundoplication by Nissen. Nissen's original procedure entailed a 360-degree wrap of the fundus of the stomach around the distal esophagus. This was constructed using the anterior and posterior walls of the fundus, without dividing the short gastric blood vessels. Subsequently, a number of modifications have been described, with the aim of either simplifying the performance of the procedure, reducing perioperative morbidity, or preventing side effects. In the mid-1960s, Nissen and Rossetti modified Nissen's original technique so that the anterior wall of the fundus alone was used to construct the 360-degree wrap. Subsequently, DeMeester and Donohue advocated division of the short gastric blood vessels to enable the construction of a "floppy" Nissen fundoplication.

More recently, however, the results from six prospective randomized trials of Nissen fundoplication with and without division of the short gastric vessels have demonstrated that division of the short gastric blood vessels is not necessary. Equivalent reflux control and a similar prevalence of dysphagia at follow-up of up to 10 years are achieved without routinely dividing these vessels. Furthermore, the randomized trials have shown that dividing the vessels actually increases the complexity of the procedure, and produced a poorer outcome in three of the six trials due to an increase in the incidence of bloating symptoms following vessel division.

Until the early 1990s, the Nissen–Rossetti fundoplication was performed using an open abdominal approach, and, less commonly, thoracic access. Following the development of laparoscopic approaches, the vast majority of primary antireflux procedures are now performed laparoscopically, and excellent outcomes have been reported for this approach. This means that the open approach is now used only in a minority of patients undergoing antireflux surgery. Indications for an open surgical approach currently include the following:

1. Lack of expertise in advanced laparoscopic surgery.
2. Patient preference.
3. Completion of a fundoplication that has been converted from a laparoscopic to an open approach (e.g., because of intraoperative difficulties).
4. Concurrent open surgical procedure.
5. Reoperative surgery following a previous laparoscopic or open approach.

The first three indications are now quite rare, as laparoscopic approaches are the standard of care for primary antireflux surgery these days. The main indication for open surgery is now a reoperative procedure. Some reoperative surgeries can be completed using a laparoscopic approach. However, a proportion can be performed only via open surgery, and this is most likely following a previous open operation, or more than two previous laparoscopic antireflux procedures. The transthoracic approach to antireflux surgery has significant morbidity and is now rarely used. It is perhaps best reserved for complex reoperative surgery when at least two previous abdominal operations have been performed—this is rarely undertaken. For this reason, this chapter focuses on the open abdominal approach.

INDICATIONS

1. Symptomatic gastroesophageal reflux in patients in whom medical treatment with acid suppression has not adequately relieved symptoms.
2. Patients with gastroesophageal reflux in whom symptoms are well controlled by medical therapy, but who do not wish to take medication lifelong.
3. Giant mixed or paraesophageal hiatus hernia where some or all of the symptoms are mechanical (e.g., chest pain, intermittent dysphagia)—that is, not due to reflux alone.

The majority of patients fall into the first category.

PREOPERATIVE PLANNING

It is important to take a complete history and to confirm that the symptoms are actually due to gastroesophageal reflux. Typical reflux symptoms include heartburn, water brash (volume regurgitation of acid-tasting liquid), and epigastric pain. Other symptoms that can be caused by reflux

include dysphagia, odynophagia, postprandial fullness, early satiety, upper abdominal bloating, anorexia, nausea, chronic cough, voice change, throat irritation, and wheezing. In general, surgery is very effective for controlling typical symptoms, whereas the response of atypical symptoms to fundoplication is variable.

Preoperative Investigations

Preoperative work entails the following investigations:

1. Endoscopy
2. Barium meal radiology
3. pH monitoring
4. Impedance monitoring
5. Esophageal manometry

Which investigations are included as part of preoperative work-up is tailored to the clinical presentation. Endoscopy should be performed in all patients to determine the presence or absence of ulcerative esophagitis, Barrett esophagus, or hiatal hernia. Up to 50% of patients presenting for surgery have no evidence of esophagitis at endoscopy, often because they are using proton pump inhibitor medication. In these patients 24-hour pH monitoring is required to confirm the diagnosis of reflux. Although many surgeons use pH monitoring routinely, the author's preference is a selective approach in which pH monitoring is used primarily to investigate patients who do not have typical reflux symptoms and evidence of reflux at endoscopy. Impedance monitoring is sometimes added if other tests are negative for reflux, or to clarify the significance of atypical symptoms. However, for the majority of patients impedance monitoring does not change actual clinical decision making.

Esophageal manometry should be performed routinely in all patients undergoing Nissen–Rossetti fundoplication. It identifies the occasional patient with achalasia, and these patients require different treatment. It also identifies a subgroup of patients who have disordered esophageal body motility, and in these patients a partial fundoplication may be better surgical approach.

Barium-meal radiography is not performed routinely in individuals undergoing a primary antireflux operation, but should be considered if a large hiatal hernia is suspected to evaluate and document the anatomy. Barium-meal radiography is also useful to clarify anatomy when

considering revisional surgery. For revisional surgery, the author's preference is to undertake full workup with endoscopy, manometry, pH monitoring (and sometimes impedance monitoring), and barium-meal radiography in all patients, so that any diagnosis of recurrent reflux is confirmed with certainty, and anatomy is well understood before progressing to surgery.

SURGICAL TECHNIQUE

Positioning and Instrumentation

For the open transabdominal approach, the patient is placed on the operating table in the supine position. Good exposure is essential, and this is achieved by using a sternal retractor that lifts the sternum and the costal arch forward. An abdominal wall retractor is also used to separate the abdominal wound edges laterally. The author's preference is to use a sternal retractor that attaches by a chain to a crossbar positioned above the patient's face. An alternative is the Rochard retractor, which uses two blades to lift and retract the costal margin. Exposure can be improved further by bending the operating table forward 20 to 30 degrees to flex the patient at the waist, and then bend the headpiece backward by a similar amount (see Fig. 72.1). This shifts the abdominal wound in a cranial direction, and flattens the diaphragm to improve access to the hiatal region. If this is done, the sternal retractor must be attached to the headpiece of the operating table. A fixed retraction system (e.g., Iron Intern or Omnitract) is used to retract the left lobe of the liver. Extra-long surgical instruments are usually needed for the operative procedure, especially when operating on men and obese patients. A renal vein retractor or 1-inch wide Deaver retractor is also useful for displacing the esophagus when undertaking hiatal repair.

An upper midline abdominal incision is used for access. Proximally, this should extend between the xiphisternum and the left costal margin, and distally it finishes just above or just below the umbilicus. The aim of the procedure is to form an effective antireflux valve by constructing a 360-degree wrap around the distal esophagus, using the anterior gastric wall.

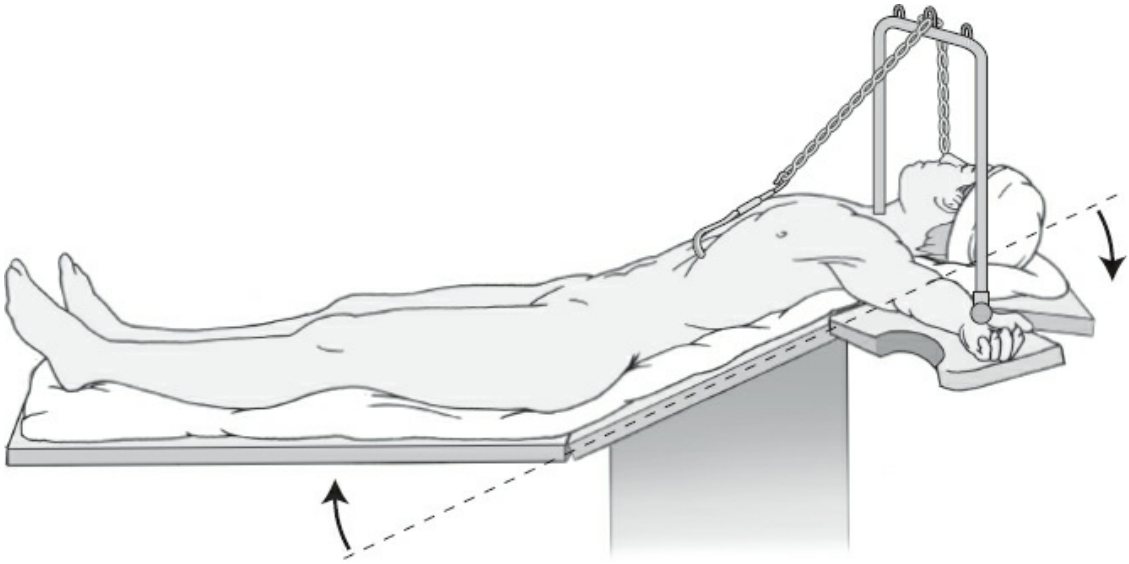

Figure 72.1. Positioning for open Nissen–Rossetti fundoplication: overall head-up tilt, hips flexed, sternal retractor, and neck extended.

Hiatal Dissection

The left lobe of the liver is displaced forward and to the right to expose the upper stomach and the region of the esophageal diaphragmatic hiatus. It is not necessary to divide the triangular ligament of the left lobe of the liver to displace the lobe medially, except on the rare occasion when the liver is excessively enlarged.

The stomach is retracted downward, and the lesser omentum is opened above and below the hepatic branch of the vagus nerve (which is preserved), to display the caudate lobe of the liver and the right hiatal pillar. The phrenoesophageal ligament is divided next (Fig. 72.2). This comprises two layers, a superficial layer of peritoneum and a deeper fibrous tissue layer. Both layers are divided carefully, so that the layer of tissue that covers both sides of the muscle of the right and left hiatal pillars is preserved. The aim of this initial dissection is to display the edges of both hiatal pillars, as far posteriorly as possible, stopping short of the uppermost short gastric blood vessel on the left side. The anterior and lateral aspects of the lower 4 to 6 cm of the esophagus are displayed during this dissection.

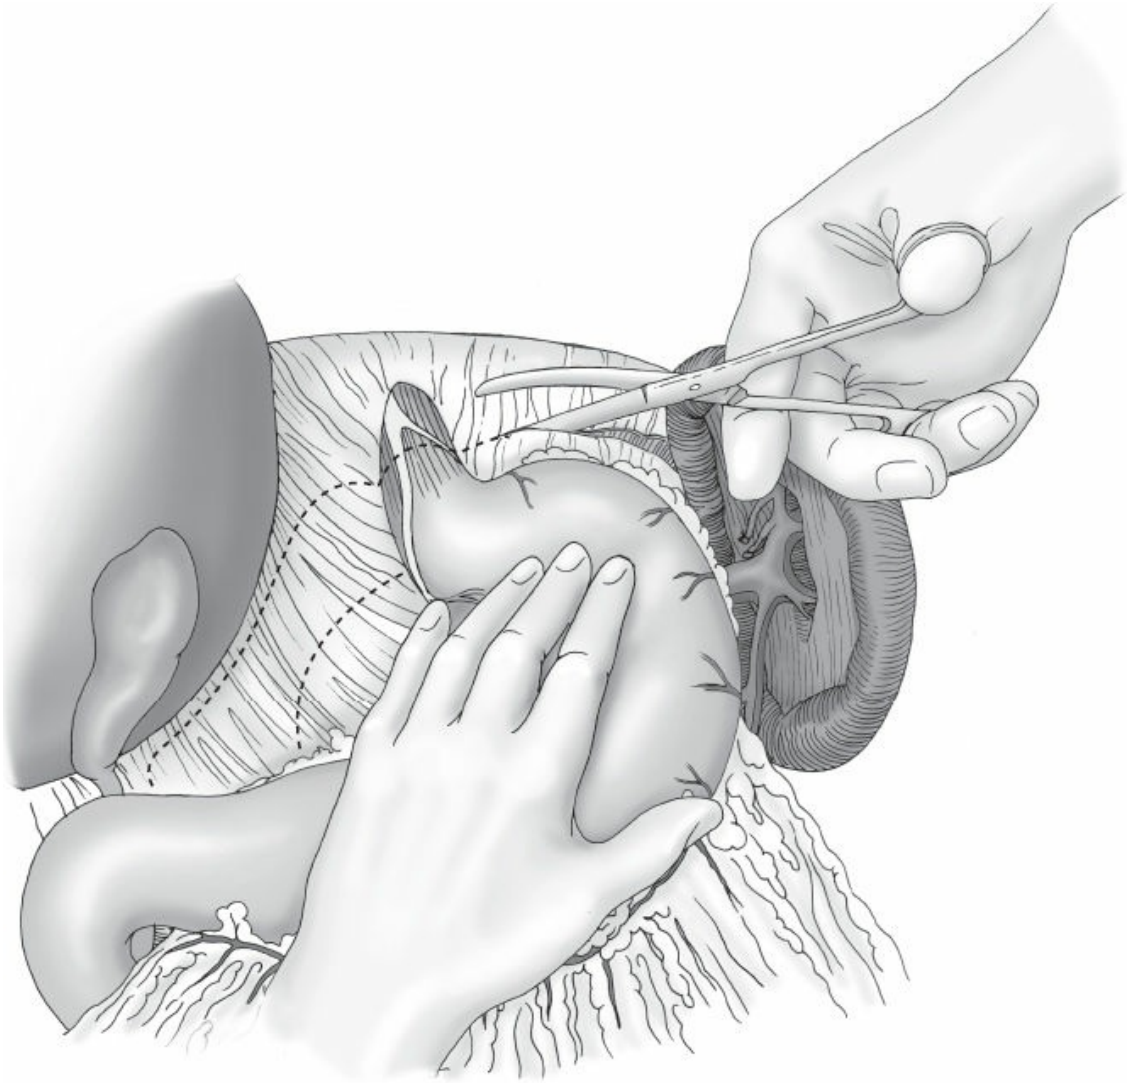

Figure 72.2. Division of the phrenoesophageal ligament and opening the lesser omentum above and below the hepatic branch of the vagus nerve.

Care is taken to preserve both vagus nerves. The anterior vagal branches run along the anterior wall of the esophagus. They are not formally dissected from the esophageal wall, and hence they are routinely included in the fundoplication. The hepatic branch of the anterior vagus nerve is preserved, and the fundoplication is constructed so that it sits above this. The posterior vagus nerve usually sits separately behind the esophagus. It can be readily identified, and it is usually displaced further posteriorly and excluded from the fundoplication. However, if it is attached to the esophagus by a thick layer of connective tissue, it can be included in the fundoplication.

The longitudinal muscle of the distal esophagus is gradually freed from its surroundings by blunt finger dissection, and a space is dissected behind

the esophagus, from left to right, using the index and middle fingers. Once a posterior “window” has been created, a nylon tape or a plastic tube is passed around the distal esophagus. Traction is applied to the tape to lift the esophagus anteriorly, and this exposes the posterior hiatus (Fig. 72.3). The posterior aspect of the distal 6 cm of the esophagus is then fully mobilized. The posterior aspect of the upper part of the stomach can also be separated from the diaphragm at this stage if necessary.

Mobilization of the esophagus is the most dangerous part of the operation, and there is a small risk of esophageal perforation during this step. This risk is greatest if the esophageal wall is inflamed, edematous, or friable, or if previous hiatal surgery has been performed. The consequences of perforation may be greater if it occurs through the posterior wall, as a transmural lesion in the back wall of the esophagus can be overlooked. As long as dissection is in the correct layer, there is little risk of hemorrhage, as the divided structures contain only minute vessels. For this reason, if dissection is performed correctly, it will be relatively bloodless. The surgeon must, however, watch for an accessory left gastric artery running with the hepatic branch of the vagus nerve. If this nerve is preserved, injury to the vessel is unlikely.

Care should also be taken with the left inferior phrenic artery. This runs dorsally to the cardia and fundus, with one or more branches arising directly from the aorta or celiac trunk. It can be, but is not often, damaged during mobilization of the anterior surface of the fundus. In approximately 5% of patients, it arises from the left gastric artery and runs along the edge of the right hiatal pillar. In this situation, it should be ligated and divided to facilitate hiatal dissection. If necessary, the upper short gastric vessels can also be divided, although this is required in less than 5% of Nissen fundoplications.

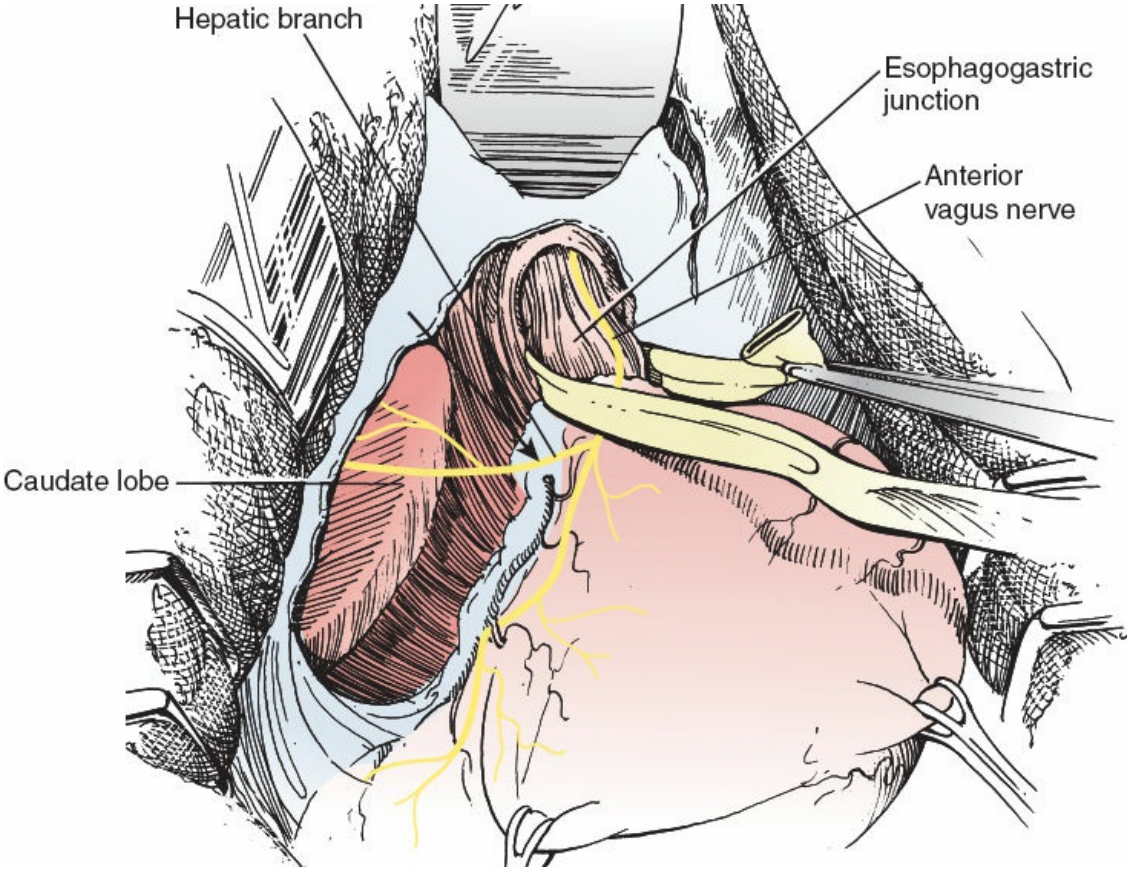

Figure 72.3. Tape passed around the esophagus, lifting the esophagogastric junction forward to display the posterior hiatus.

Hiatal Repair

The hiatus is routinely repaired using posteriorly placed sutures. These should narrow the hiatus to approximately 2.5 cm in diameter (Fig. 72.4). To do this, the reconstructed hiatal rim should sit loosely (not tightly) around the esophagus with a 52-Fr bougie sited across the gastroesophageal junction. In patients without a hernia or with a small hiatal hernia, one or two interrupted 2-0 nonabsorbable sutures should be placed. If a larger hernia is present, more sutures should be placed. When repairing the hiatus, the right and left hiatal pillars are exposed posteriorly by retracting the abdominal esophagus to the left with a renal vein retractor or similar narrow-bladed retractor. The first suture is placed through the pillars from left to right, immediately in front of the posterior junction of the two pillars. Subsequent sutures are placed progressively anteriorly to each previous suture, until the hiatal opening is reduced to the appropriate size. If the hernia defect is very large, the posterior sutures can be supplemented if necessary with anterior hiatal sutures, or a piece of prosthetic material can be used to reinforce the repair. If a bougie is used

to calibrate the hiatal repair, the repair is performed first without the bougie, and the bougie is passed subsequently to assess the hiatal size.

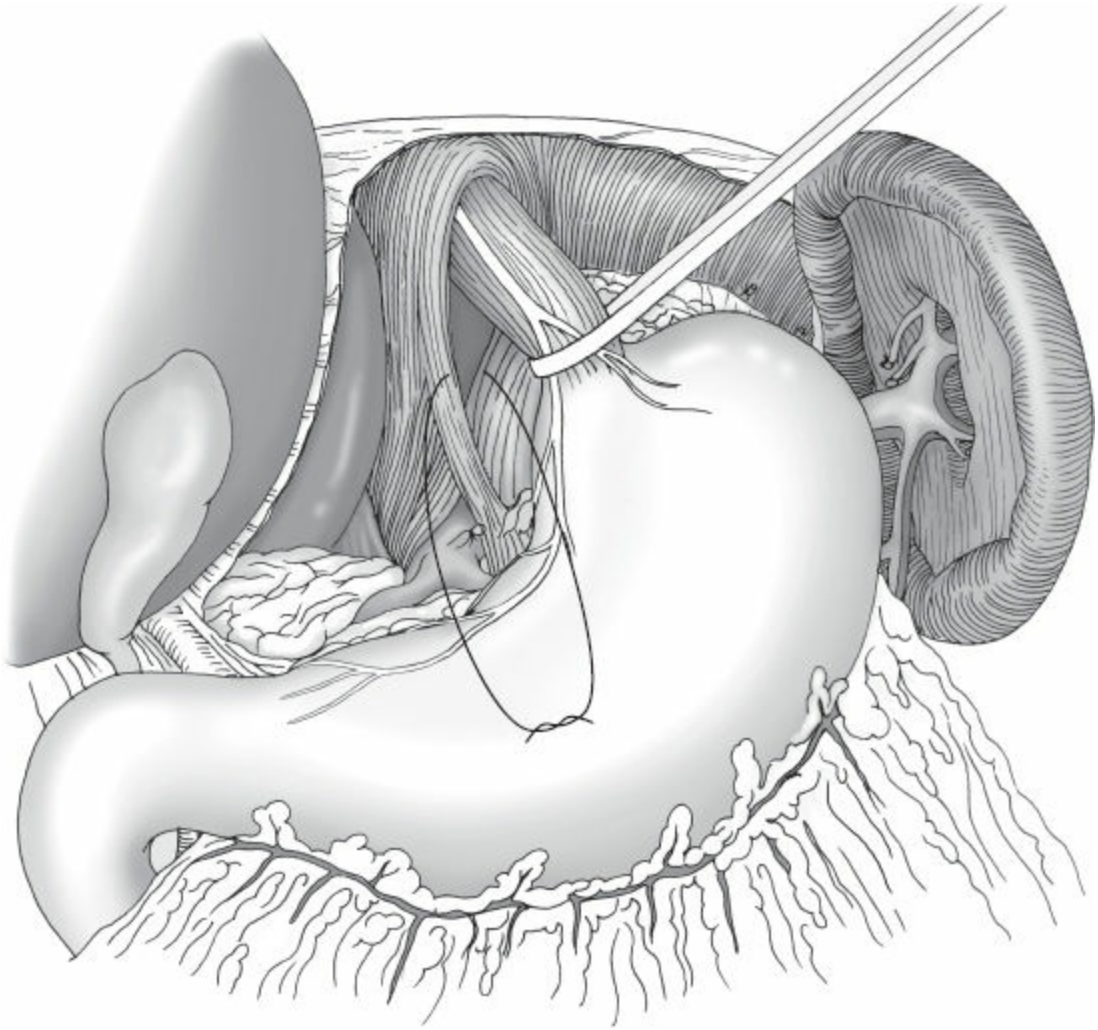

Figure 72.4. Repair of the hiatus by suturing the hiatal pillars behind the esophagus.

Fundoplication

The anterior wall of the fundus, midway between the greater and lesser curvatures of the stomach, at the level of the cardia or just above, is pushed behind the esophagus with the fingers of the right hand until it appears between the left side of the esophagus and the liver. The stomach is then grasped with two pairs of long atraumatic Babcock forceps, and manipulated to ensure that it comes around the back of the esophagus loosely (Fig. 72.5). If the stomach is tight, and does not sit comfortably without undue tension, the Babcock forceps should be progressively adjusted and a looser piece of stomach grasped. This is continued until a

satisfactorily loose piece of stomach is identified. An anterior fold of stomach is then formed from the more distal part of the anterior fundic wall and held with a Babcock forceps so that the two pieces of stomach can be wrapped around the esophagus without pulling or stretching the distal section of the esophagus. This should be done so that there is not excessive tension on the stomach, and the fundus sits comfortably around the lower part of the esophagus. If it is not possible to create a loose enough fundoplication, then it is occasionally necessary to divide the short gastric vessels, or, alternatively, a partial fundoplication can be performed. This scenario is unusual.

Three interrupted 2-0 nonabsorbable monofilament sutures are placed to form the fundoplication. The sutures are not tied at this stage (Fig. 72.6). The sutures are passed deeply through the serosa and muscle of the stomach wall on both sides, and also more superficially through the muscle of the esophageal wall. Some surgeons choose not to include the esophageal wall in these sutures. A Maloney-style mercury-weighted 52-Fr esophageal bougie (or similar) is then passed into the stomach to calibrate the fundoplication. The sutures are tied down after placing the bougie, and the fundoplication should be checked to ensure that it is not too tight. With the bougie still in place, it should be possible for the surgeon to pass a finger between the fundoplication and the left side of the esophagus to ensure that the fundoplication is loose (Fig. 72.7). The completed fundoplication should be between 1 and 2 cm in length (Fig. 72.8). Some surgeons place additional sutures between the fundoplication and the hiatal rim in an attempt to stabilize the fundoplication. However, this step does not prevent the cardia from telescoping within the wrap, and for this reason, the author does not advise this. A wound drain is also unnecessary.

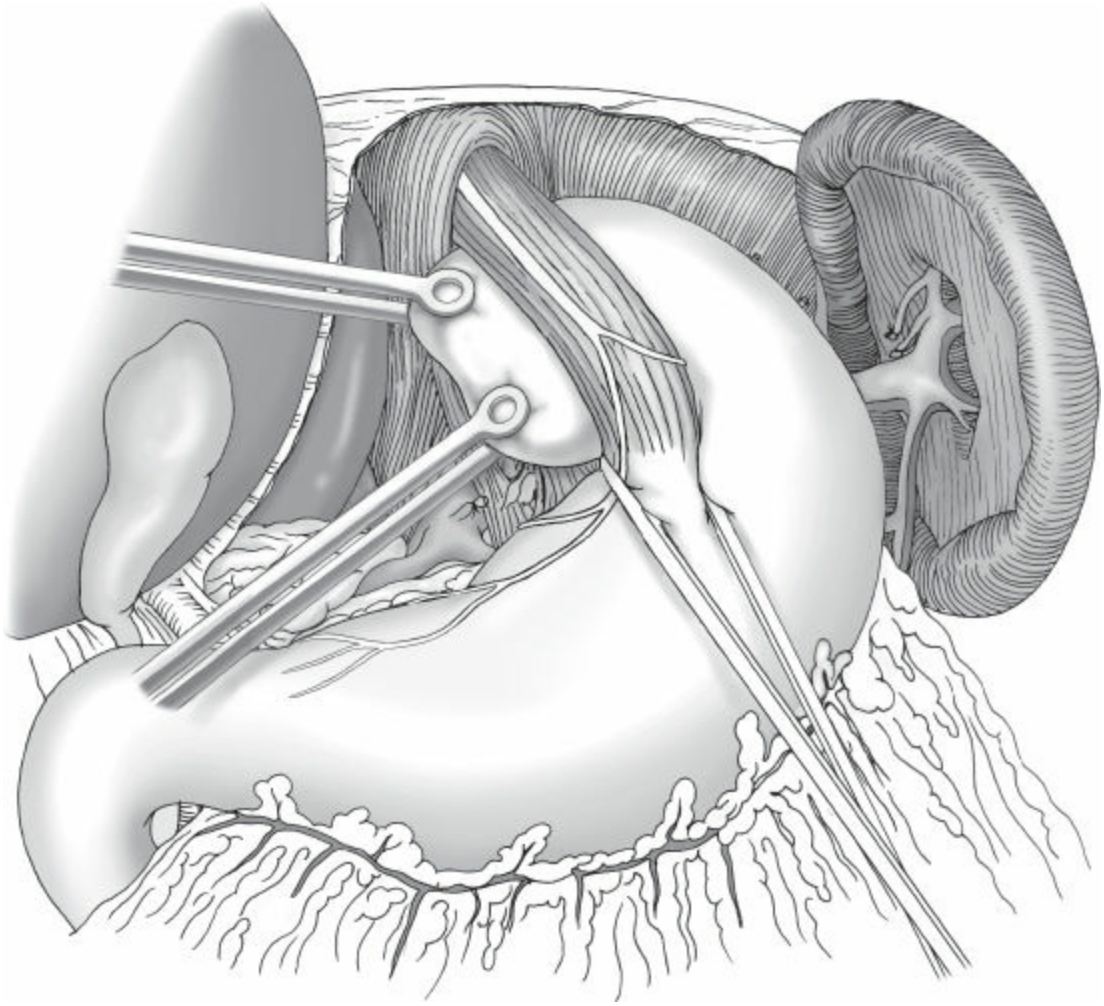

Figure 72.5. The anterior fundus is passed behind the esophagus, and manipulated with Babcock forceps.

POSTOPERATIVE CARE

A nasogastric tube is rarely needed following fundoplication, and its presence can precipitate retching. For this reason, it is best omitted. Intravenous fluids are required for the first 1 to 2 days. Oral fluids are introduced on the first postoperative day, and a vitamised diet is introduced on the second day. The author routinely arranges for a barium-swallow radiograph on the first or second postoperative day to ensure that a satisfactory procedure has been performed. Most patients can leave the hospital between 3 and 5 days after surgery. Diet is restricted to vitamised food for 3 to 4 weeks, and then gradually increased to a normal diet over the next 4 to 8 weeks. At 3 months after surgery, 20% of the patients will still have some dietary restrictions, although after 12 months 95% will be able to eat a full range of food. For the first 3 months, patients should also eat carefully, and chew their food well. Fizzy drinks should be avoided for

at least 3 months.

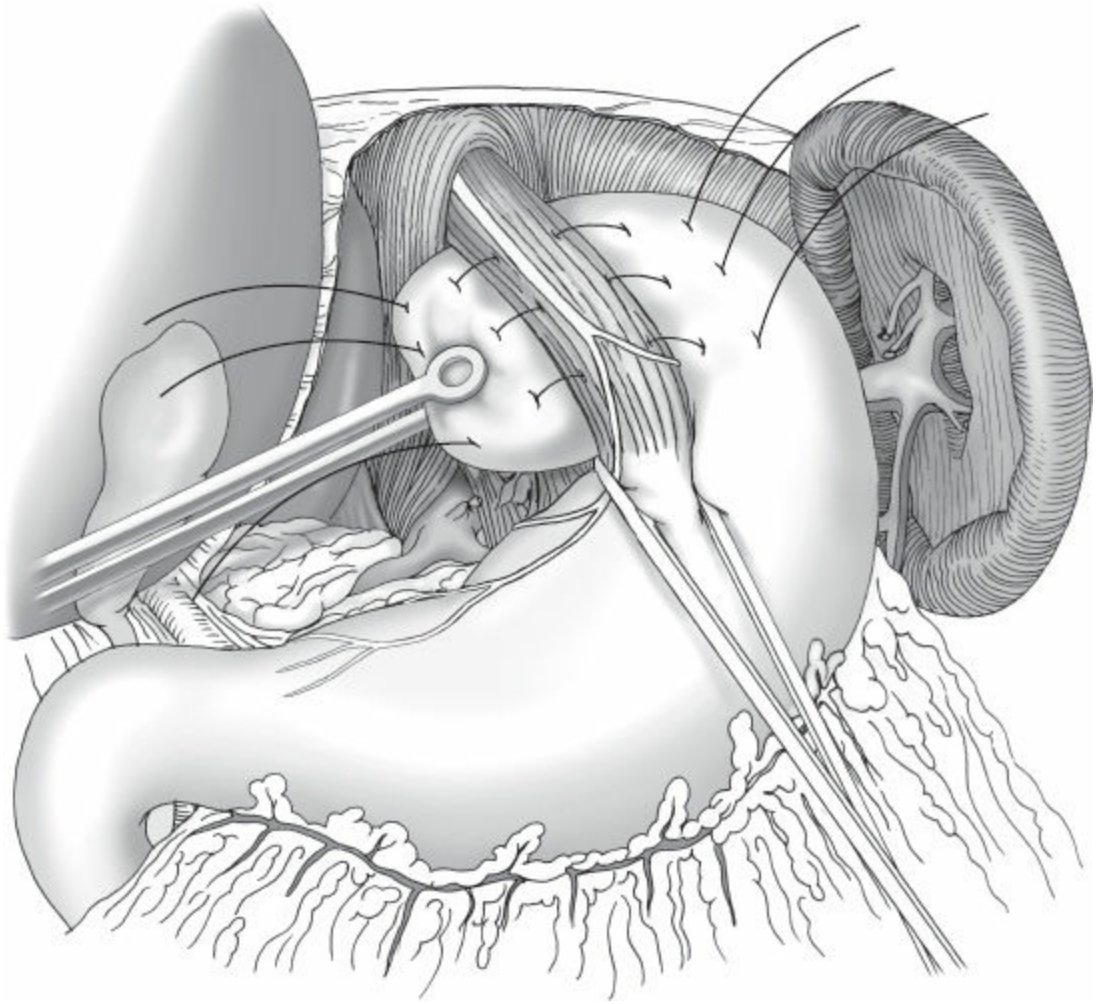

Figure 72.6. Placement of sutures for the fundoplication.

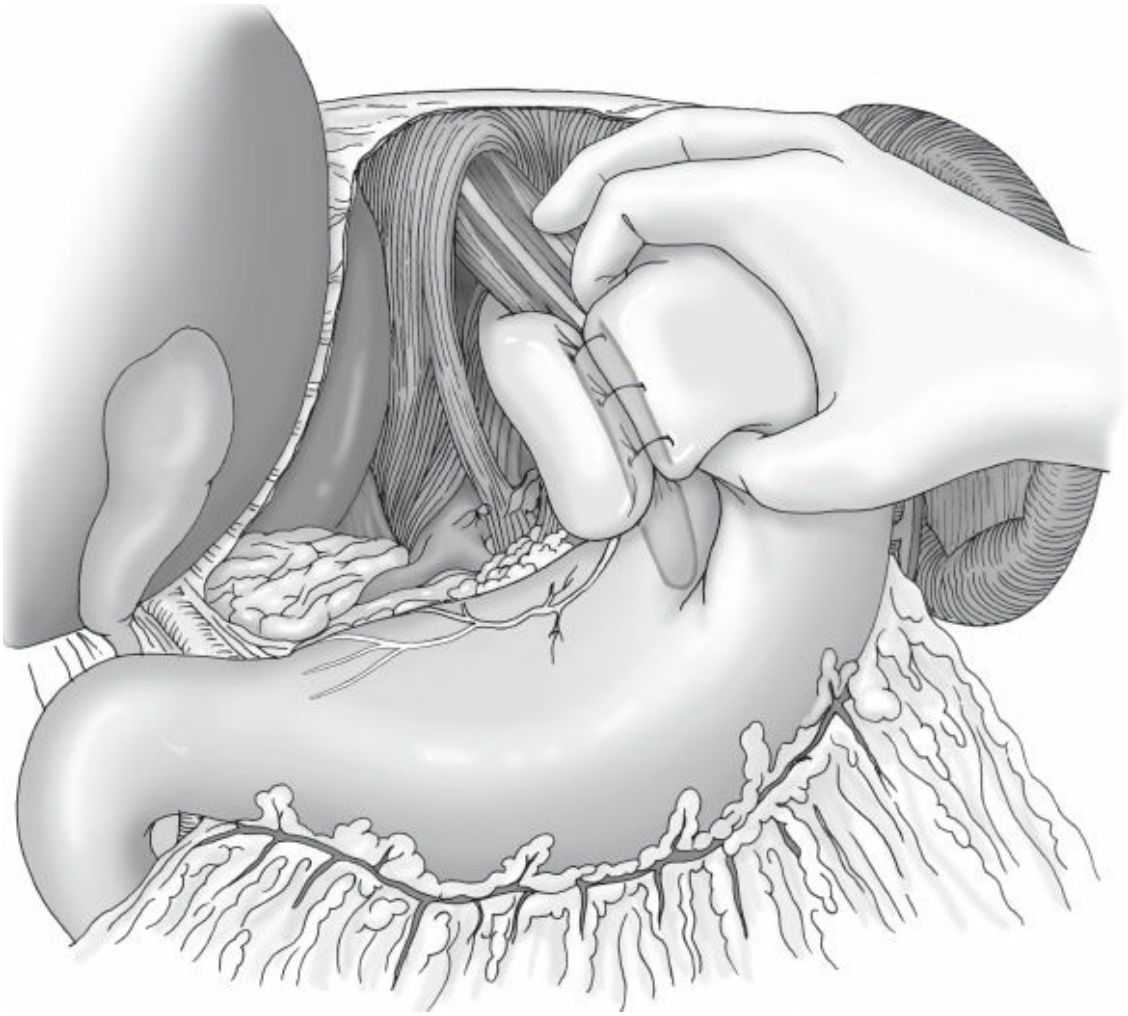

Figure 72.7. The fundoplication is checked by passing a finger between the fundoplication and the esophagus while a bougie is positioned in the lumen of the esophagus.

TECHNIQUE FOR LARGE HIATAL HERNIA

Although most large hiatus hernias can be repaired using laparoscopic techniques, an open technique is occasionally required for the patients who present acutely with an incarcerated stomach, or to complete a procedure that cannot be completed laparoscopically, or to repair a recurrent hernia. The surgical strategy for the open repair of large paraesophageal and mixed hiatal hernias entails the following:

1. Upper midline abdominal incision.
2. Initial decompression of the herniated stomach using a nasogastric tube if the stomach is not empty.
3. Dissection of the hernia sac from the hiatal pillars while preserving the fascial covering over the muscle at the hiatal rim.
4. Complete removal of the sac from the mediastinum. (The stomach

reduces into the abdomen as the sac is progressively dissected from the chest, and the distal esophagus is exposed by this dissection.)

5. Narrowing of the widened hiatus with posteriorly placed nonabsorbable sutures, and reinforcement with mesh if desired.
6. Additional anterior hiatal sutures if necessary to achieve adequate hiatal narrowing.
7. Fundoplication constructed using three nonabsorbable sutures, and calibrated using a 52-Fr bougie.

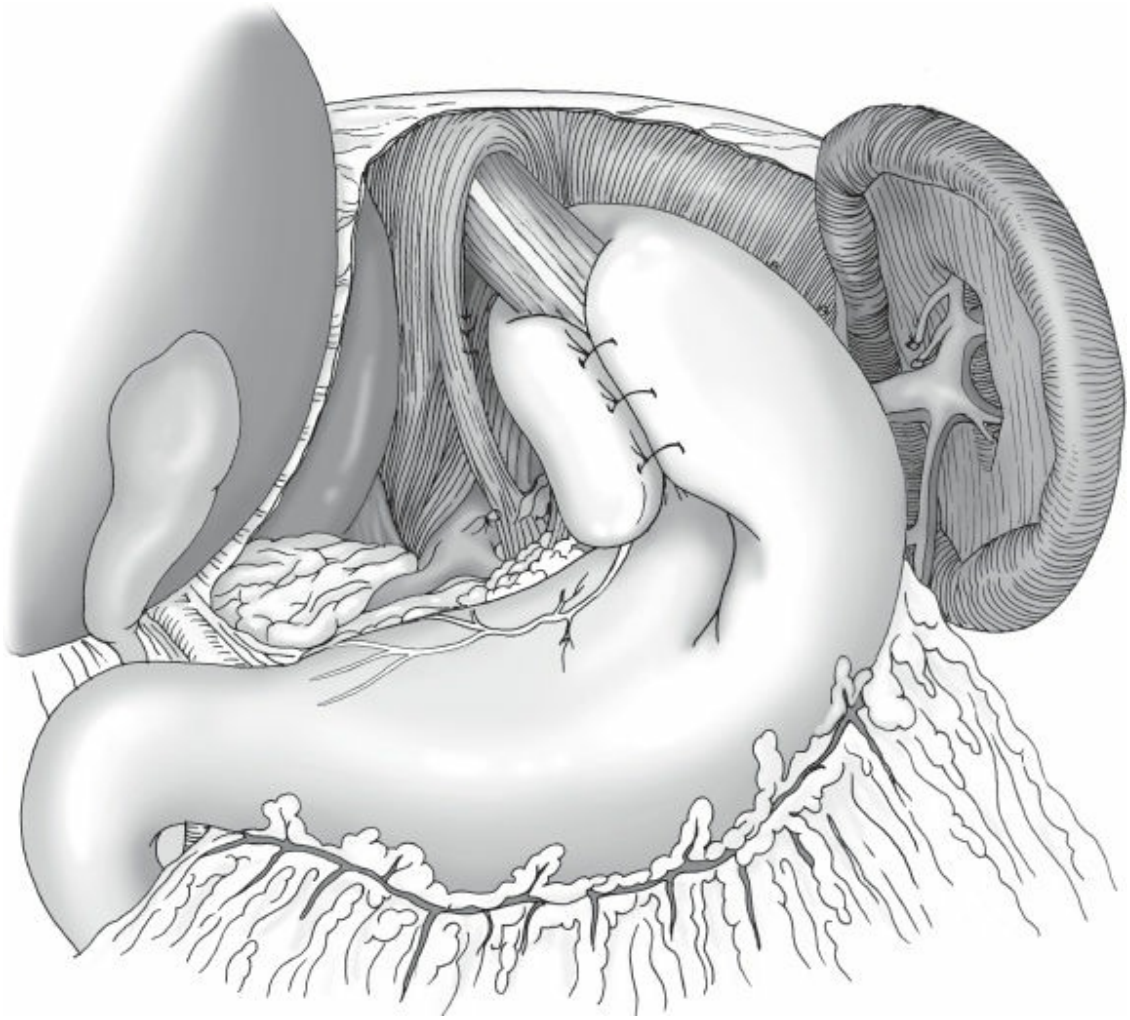

Figure 72.8. The completed Nissen–Rossetti fundoplication.

The fundus of the stomach is quite mobile when a large hiatal hernia is present, and a loose fundoplication can almost always be constructed without dividing the short gastric vessels. The author prefers not to place sutures between the fundoplication and the diaphragm, as this minimizes the risk of the cardia telescoping within the wrap. If the hernia sac has been completely removed from the chest, and the esophagus is well

mobilized, the gastroesophageal junction usually sits below the level of the diaphragm without tension. However, in a small number of patients with a true short esophagus (<2%), an alternative approach, such as a Collis gastroplasty, will need to be undertaken to allow an intra-abdominal fundoplication to be performed. In an attempt to minimize the risk of hernia recurrence, some surgeons reinforce the hiatal repair with a mesh prosthesis. There is evidence from some randomized trials that this reduces the risk of early radiologic recurrence of hiatus hernia, although other trials have shown no advantage for mesh, or no longer-term outcome benefit. Hence, evidence that mesh reinforcement translates to a significant improvement in the clinical outcome is still controversial, and there is a small risk of mesh eroding into the esophageal lumen. The author's preference is to now avoid mesh repair of the hiatus.

ADDITIONAL PROCEDURES

Before the 1990s, some surgeons added a vagotomy and drainage procedure, or a highly selective vagotomy, to an open Nissen fundoplication. The rationale for these additional procedures was gastric acid reduction and a drainage procedure to improve gastric emptying. Delayed gastric emptying is common in patients with reflux, and it will often be found if a gastric emptying study is performed before surgery. Unfortunately, truncal vagotomy can be followed by diarrhea and other postvagotomy problems, and pyloroplasty can add additional morbidity. Both of these can lead to digestive disturbances and should be avoided. Highly selective vagotomy also adds no additional benefit and is unnecessary.

REOPERATIVE SURGERY

Revision antireflux surgery is more difficult than primary surgery for reflux, particularly if the previous procedure was performed using an open technique. Upper abdominal adhesions must be divided to expose the operative field. The left lobe of the liver is usually adherent to the anterior wall of the upper stomach and the previous fundoplication. This must first be separated from the stomach to expose the hiatal region. The tissue planes in the hiatal region are often difficult to find, and the hiatal rim and esophagus must be dissected with caution to avoid perforation of the esophagus or stomach. The vagal nerve trunks are difficult to identify during revision surgery and are often divided. The principles of revision

surgery entail the following:

1. Division of adhesions.
2. Dissection of the hiatal rim and esophagus.
3. Identification of the previous fundoplication.
4. Restoration of normal anatomy by fully reversing the previous fundoplication.
5. Hiatal repair.
6. Formation of a new fundoplication.

COMPLICATIONS

Intraoperative complications are rare. The spleen, however, may be injured during transabdominal fundoplication. Capsular avulsion or small tears causing persistent hilar bleeding occur in approximately 5% of the patients, and splenectomy rates of 1% to 3% have been reported. Splenectomy is less likely during Nissen–Rossetti fundoplication because the short gastric blood vessels are not ligated. Most splenic injuries are minor, and bleeding can easily be controlled with tamponade. Any temptation to use diathermy or to suture the spleen should be resisted, as these maneuvers can make bleeding worse and precipitate splenectomy.

Another possible complication is injury to the vagal trunks, which can occur in the reoperative situation, or occasionally in the presence of marked inflammation of the cardioesophageal junction. The sequelae of vagotomy are rarely of long-term clinical relevance.

The most serious complication, accidental perforation of the esophagus, can cause a great deal of difficulty. Perforation is more likely if the esophagus is severely inflamed (periesophagitis), or if the operation is for revision of a previous fundoplication. Perforation occurs either during difficult mobilization of the cardia or during the attempt to either pass an instrument or dissect around the back of the esophagus. An unrecognized perforation of the esophagus is a life-threatening complication. Thorough evaluation of the situation, particularly of the posterior aspect of the esophagus, before encircling the distal esophagus with any instrument is therefore mandatory. If a perforation is identified, this should be repaired with sutures, and the suture line should then be covered with the fundoplication. This will usually be followed by a successful outcome. However, if the perforation is missed, and repair is delayed, leakage from the suture line is more likely. For this reason, drains should be placed around the hiatal area, and a gastrostomy and feeding jejunostomy

performed if reoperation is required. They are invaluable if an esophageal fistula ensues.

Postfundoplication Side Effects

Following a successful fundoplication, vomiting is not possible, and belching can be more difficult due to the presence of an overcompetent fundoplication valve. In addition, flatulence is common. Belching is always more difficult in the first few months after a total fundoplication, and because many patients become accustomed to swallowing air during the course of their reflux disease, aerophagia is also common in the early postoperative period. Aerophagic patients tend to have more problems postoperatively. However, as follow-up progresses, belching becomes easier in the majority of the patients, and the problem of aerophagia tends to diminish by the end of the first postoperative year in most patients. Upper abdominal bloating symptoms following fundoplication are often blamed on the surgery. However, this symptom is also common in patients who have not undergone surgery. Its overall incidence decreases following fundoplication, although some patients will develop this as a new problem.

Dysphagia occurs in most patients during the first 2 to 3 postoperative weeks, and this is usually due to postoperative edema in the fundoplication or the perihiatal region, as well as transient disturbances of esophageal motor function. It is usually worst in the second and third weeks. It can also occur if the wrap is made too tight. This will manifest as total or near-total esophageal obstruction, which requires early operative reintervention and reconstruction of a looser fundoplication. Less commonly, dysphagia can occur due to excessive scar formation around the distal esophagus at the hiatal rim. Symptoms of this problem usually commence around 7 to 10 days after surgery. Late dysphagia can also follow intrathoracic migration of the collar-like wrap that constricts the fundus and gastroesophageal junction.

Failure

Late failure following fundoplication presents either as recurrent gastroesophageal reflux or hiatus hernia, or both. There are two reasons for the development of recurrent reflux: loosening of the original fundoplication or wrap slippage. The majority of patients with recurrent reflux still have a fundoplication present. However, the fundoplication does not provide an effective barrier to reflux if it comes to lie around the

cardia or upper stomach, rather than around the distal esophagus. Apposition of the fundus to the distal esophagus is critical for the maintenance of an antireflux barrier. Telescoping of the gastroesophageal junction through the 360-degree fundoplication (“slipped Nissen”) during follow-up accounts for most instances of recurrent reflux. Recurrent reflux becomes more common as follow-up progresses, the incidence being approximately 10% at 10 years. The other problem of hiatus herniation can cause mechanical symptoms such as dysphagia and chest pain. This problem usually occurs quite early following the surgery, and the symptoms progress as the hernia progressively enlarges. Both problems can be corrected by revision surgery.

OUTCOMES

A good outcome following Nissen–Rossetti fundoplication is expected in approximately 90% of the patients at 10 years follow-up. The causes of failure are evenly divided between recurrent reflux and persistent troublesome side effects. Six randomized trials of Nissen–Rossetti fundoplication versus Nissen fundoplication with division of the short gastric vessels have shown equivalent outcomes for both reflux control and postfundoplication dysphagia. In three of the trials, the incidence of “wind-related” side effects at late follow-up was less following Nissen–Rossetti fundoplication.

CONCLUSIONS

Open Nissen–Rossetti fundoplication achieves an excellent outcome in the majority of patients who undergo surgery for gastroesophageal reflux, and it is relatively simple to perform. The open approach for primary surgery, however, has now been largely replaced by laparoscopic techniques, and the open approach is now performed only in a subgroup of patients who undergo surgery for reflux. The main role of the open approach is now in the treatment of patients who are undergoing revision surgery, as well as in the small group of patients who require conversion of an attempted laparoscopic approach to an open procedure, or those who are undergoing a concurrent open abdominal procedure. Nevertheless, to successfully deal with the more complex scenarios that can arise during antireflux surgery, surgeons should be able to undertake open antireflux surgery.

EDITOR'S COMMENT

Open procedures for reflux are rarely performed today. However, Prof. Watson has provided a lovely chapter on the open repair which he probably uses for a number of the redos or corrections, which he and I discussed by e-mail. The chapter begins with a history of the Nissen type of repair and its evolution over the past 60 years. The thrust of the chapter and the manuscripts which will be quoted is that the Nissen–Rossetti-type of repair is the standard repair for reflux. It is also clear that an adequate securing of the hiatus is essential in order for there not to be recurrence, as I will point out in what follows. Not mentioned in the chapter is a new indication in addition to troublesome reflux, esophageal ulceration, and progress toward a stricture, and that is nonseasonal asthma which may in time lead to pulmonary fibrosis. Dr. Thomas DeMeester seems to be convinced that this repair is best in conversations that I have had with him about the chapter I have asked him to write in these volumes. This chapter does not deal with laparoscopic repair. Prof. Watson, however, has been quoted in the literature for his comparative studies between open and laparoscopic

approaches and is obviously comfortable with either.

Over the past 60 years, there has been a great deal of work in the evolution of this technique in which it appears that a number of controversies have been resolved, including disordered motility and its treatment including whether the hiatus is closed or not, division of the short gastrics, and reasons for recurrence. Martin Fein and Florian Seyfried (*J Gastrointest Surg* 2010;14(suppl 1):S67–S74) in an excellent paper given at the DeMeester Festschrift, "Is there a role for anything other than a Nissen's operation?," review the available comparative trials including Nissen versus Toupet (four trials) and Toupet or Nissen versus anterior fundoplication (five trials). A number of comparisons in nonrandomized and, presumably, nonconcurrent studies were also included. First, should antireflux procedures be done at all? The answer appears to be yes, as Lundell et al. (Seven-year follow-up of a randomized clinical trial comparing proton-pump inhibition with surgical therapy for reflux oesophagitis. *Br J Surg* 2007;94:198–203) and Lundell (Comparing laparoscopic antireflux surgery with esomeprazole in the management of patients with chronic gastro-oesophageal reflux disease: a 3-year interim analysis of the LOTUS trial. *Gut* 2008;57:1207–13.) conclude after 3- and 7-year follow-ups that surgical repair is at least as good as prolonged PPI inhibition. Similar results were reached by Catarci et al. (Evidence-based appraisal of antireflux fundoplication. *Ann Surg* 2004;239:325–37) and Lundell again (Therapy of gastroesophageal reflux: evidence-based approach to antireflux surgery. *Dig Dis* 2007;25:188–96). The details of the studies that are properly randomized appear in Table 1 of Fein's paper, but one can see that the numbers are quite small in each group. In comparing partial to anterior wraps, the short gastrics are divided, giving less tension to the repair and enabling a floppier Nissen with bougies as large as 60 Fr.

Booth et al. (Randomized clinical trial of laparoscopic total (Nissen) versus posterior partial (Toupet) fundoplication for gastro-oesophageal reflux disease based on preoperative oesophageal manometry. *Brit J Surg* 2008;95:57–63), Fibbe et al. (Esophageal motility in reflux disease before and after fundoplication: a prospective, randomized, clinical, and manometric study. *Gastroenterology* 2001;121:5–14), Strate et al. (Laparoscopic fundoplication: Nissen versus Toupet two-year outcome of a prospective randomized study of 200 patients regarding preoperative esophageal motility. *Surg Endosc* 2008;22:21–30), and Zornig et al. (Nissen vs Toupet laparoscopic fundoplication. *Surg Endosc* 2002;16:758–66) all compared Nissen repair versus posterior Toupet repairs. The short gastrics were divided. Watson (Prospective randomized double-blind trial between laparoscopic Nissen fundoplication and anterior partial fundoplication. *Brit J Surg* 1999;86:123–30; Multicenter, prospective, double-blind, randomized trial of laparoscopic Nissen vs anterior 90 degrees partial fundoplication. *Arch Surg* 2004;139:1160–7; Five-year follow-up of a randomized clinical trial of laparoscopic total versus anterior 180 degrees fundoplication. *Brit J Surg* 2005;92:240–3) showed that

dysphagia persists in the Nissen repairs, but recurrence is present in the anterior repairs. Similar results were reported by Lundell (Hagedorn C, Jonson C, Lonroth H, et al. Efficacy of an anterior as compared with a posterior laparoscopic partial fundoplication: results of a randomized, controlled clinical trial. *Ann Surg* 2003;238:189–96; Engstrom C, Lonroth H, Mardani J, et al. An anterior or posterior approach to partial fundoplication? Long-term results of a randomized trial. *World J Surg* 2007;31:1221–5). The same pattern of recurrence of symptoms and dysphagia in the Nissen repair and recurrence in the anterior repairs is discussed in Baigrie et al. (Randomized double-blind trial of laparoscopic Nissen fundoplication versus anterior partial fundoplication. *Brit J of Surg* 2005;92:819–23) and Spence et al. (Single center prospective randomized trial of laparoscopic Nissen versus anterior 90 degrees fundoplication. *J Gastroint Surg* 2006;10:698–705). Hagedorn et al. (*op. cit.*), after a 5-year follow-up, report that reflux is higher after anterior fundoplication (60%) versus after Nissen (24%), as measured by pH telemetry. Only a small number of patients required reoperation.

In nonrandomized trials (Table 4: Fein's review), there were higher recurrence rates for the Toupet repair than after a Nissen. But what are we actually talking about? The Nissen repair is not a Nissen repair. It may not be standardized. The hiatal opening may be repaired or it may not, and if it is repaired, how many sutures and how tight is the hiatal repair? Is a bougie used, and if so how large is it and what is the extent of the wrap?

The next controversy is the "tailored approach" which is controversial and in the opinion of many is a failure. Dysphagia, in the opinion of Strate (*op. cit.*), is the result of transhiatal migration. Herniation of the wrap appears to be the reason for a high dysphagia rate in a number of papers. In addition, a number of authors stated that trying to tailor the procedure as to whether or not there is a peristaltic disorder does not work (Fein and Seyfried, *op. cit.*), as a peristaltic disorder is not the reason not to perform a Nissen repair. According to Fibbe et al. (*op. cit.*), the principal cause of reoperation is the failure of hiatal repair.

Tatum et al. (High-resolution manometry in evaluation of factors responsible for fundoplication failure. *J Am Coll Surg* 2010;210:611–19) utilized high-resolution manometry in an effort to determine the etiology of symptoms that between 10% and 25% of patients undergoing antireflux procedures eventually redevelop. This technique allows for sensitive and reliable information about the status of the lower esophageal sphincter. Recurrent hiatal hernia or failure of the hiatal closure results in a dual high-pressure zone (HPZ). Twenty-three patients with recurrent symptoms or abnormal 24-hour pH monitoring and 11 asymptomatic post-Nissen patients were tested with this technique. In the 11 successful patients, only one (9%) had a dual HPZ, while 13 of the 23 unsuccessful patients had a dual HPZ suggesting breakdown of the hiatal repair (56%). The mean LES pressure tended to be higher in the successful group but because of small numbers, just missed the significance. If a dual HPZ equals a breakdown of the hiatal repair, this would suggest what other investigators have

stated, that recurrence of symptoms especially seem to indicate that the hiatal repair has broken down.

There has been some discussion as to whether the long-term outcomes in fundoplication are better in nonerosive esophageal disease. Broeders (Long-term outcome of Nissen fundoplication in non-erosive and erosive gastro-oesophageal reflux disease. *Brit J Surg* 2010;97:845–52) showed a similar fall in PPI use (82% dropping to 21% in the nonerosive group and 81% decreasing to 15% in the erosive group, both $P < 0.0001$). Total 87% of patients with erosive gastrointestinal reflux disease healed their erosions.

Finally, Tsuboi et al. (*Surg Endosc*, published online 2010) attempted to show that good training results in better outcomes even after a short period of experience. However, the follow-up was only for 1 year, thereby invalidating their conclusions as most good papers in this area have evaluated their patients after 5 or, perhaps, as long as 7 years but at least a minimum of 3 years. The conclusions of this paper have not been proved because of the short follow-up.

73 Modified Hill Repair for Gastroesophageal Reflux

Donald E. Low and Mustapha El-Lakis

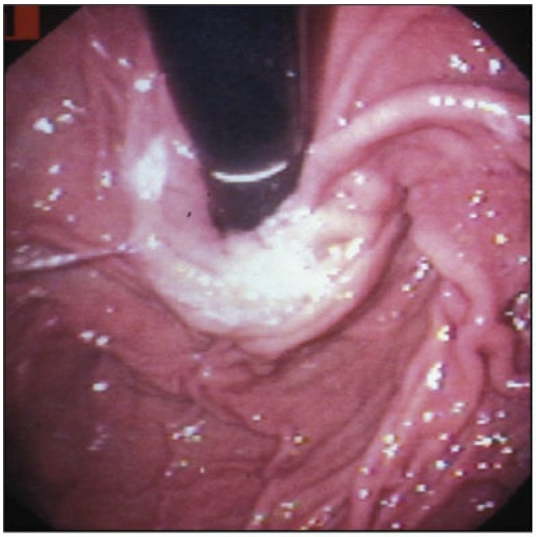
Gastroesophageal reflux disease (GERD) is the most common gastrointestinal problem in humans. Currently, 20% of the US population experience heartburn at least once per week. In addition, more money is spent on heartburn medication than any other drug class other than the cholesterol-lowering agents. The goal of antireflux surgery is to control the symptoms and the secondary complications of reflux. Of the four most popular antireflux operations (Nissen fundoplication, Belsey Mark IV, Toupet, and Hill procedures), the Hill procedure is the only operation that originated in the United States. Unlike the more common Nissen fundoplication, the Hill repair has undergone very little modification since its inception at the Virginia Mason Medical Center in Seattle by Dr. Lucius Hill in 1959. The unique feature of the Hill repair is the fact that the operation is based on reestablishing normal anatomy and the normal barriers to gastroesophageal (GE) reflux. These normal anatomic barriers include the presence of a segment of intra-abdominal esophagus, the GE flap valve apparatus, and a competent lower esophageal sphincter.

The least understood of these natural antireflux mechanisms and the one most amenable to surgical restoration is the GE flap valve (Fig. 73.1). All three of the standard operations restore this anatomic structure; however, the Hill operation does so by restoring the normal posterior attachments and tightening the collar-sling musculature, thereby reestablishing the acute angle of His between the esophagus and stomach. Alternatively, the Nissen and Belsey operations restore the valve by horizontal or vertical fundoplications, which rely on more tenuous sutures between the fundus and the esophagus to stabilize the repair (Fig. 73.2).

In our institution, healthy volunteers and those with documented GERD were examined with retroflexed inspection of the GE junction at the time of upper endoscopy. A grading system for the GE valve was established from these findings (see Fig. 73.3). This grading system has been shown to be highly accurate when used in preoperative assessment of the patients

with GERD. It has also led to a greater understanding of esophageal anatomy as reflected by a cited alteration to the description of the GE junction in *Gray's Anatomy* (see Fig. 73.1).

The Hill repair is a transabdominal repair and is the only repair that firmly anchors the GE junction in the abdomen to the strong crural musculature and underlying preaortic fascia. Originally, Dr. Hill recommended the placement of anchoring sutures through the median arcuate ligament. This aspect of the repair, which involves dissection and suture placement to the median arcuate ligament fascia, with its close proximity to the celiac axis, has intimidated surgeons who are not familiar with this anatomy and may explain why this operation has not been as widely accepted as the Nissen fundoplication. The median arcuate ligament is formed by the condensation of the preaortic fascia and is located on the anterior surface of the aorta just superior to the celiac axis. We have advocated an approach using the more easily accessible crural musculature with retrocrural preaortic fascia as the anchor for the repair. This is an important adaptation to the original description of the Hill repair as it simplifies the repair sutures, as many surgeons were not willing to consider the increased difficulty and risk involved with dissecting out the celiac axis and median arcuate ligament.



Endoscopic view of the cardiac orifice from below, showing the valve-like fold illustrated.

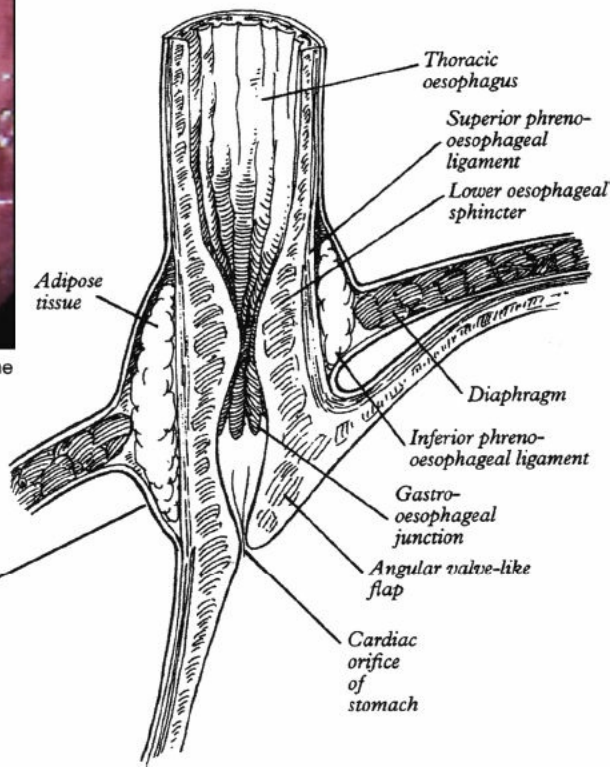


Diagram showing the valve-like structure formed by the cardiac angle wall at the cardiac orifice.

Figure 73.1. The gastroesophageal flap valve is a musculomucosal valve created by the angle of His. The valve is an important adjunct to the sphincter in preventing reflux. The valve closes against the lesser curve with increased intragastric pressure, which produces a functional barrier against reflux. (Published in Bannister LH. Stomach. In: Bannister LH, Berry MM, Collins P, et al., eds. *Gray's Anatomy*, 38th ed. New York: Churchill Livingstone; 1995:1757. Copyright Elsevier.)

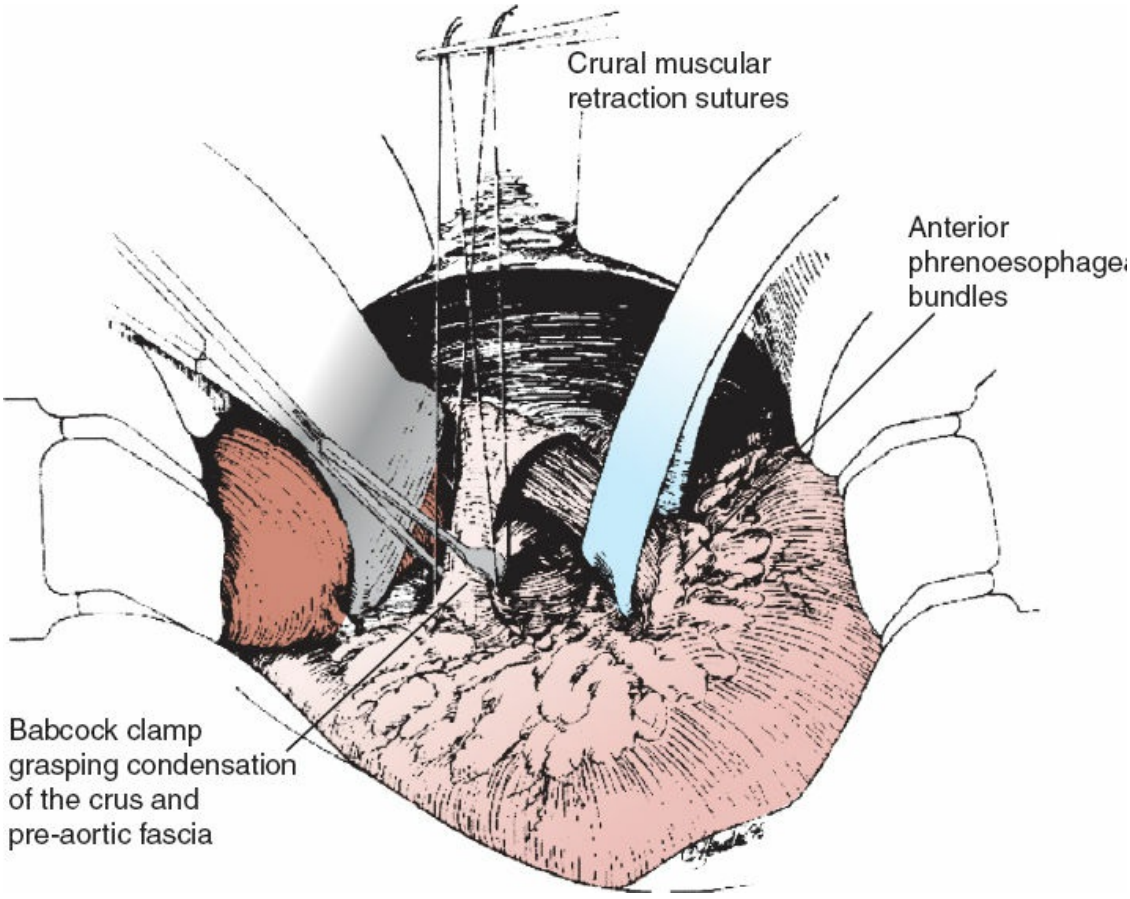

Figure 73.2. BABCOCK clamp shown grasping the right and left crural muscles and the preaortic fascia. Two heavy sutures have been placed above and below the clamp through the crural fibers and preaortic fascia to facilitate retraction away from the aorta to allow the placement of the anchoring sutures.

The Nissen fundoplication was the first antireflux procedure described in 1956. It was then modified by Toupet, Dor, Gaurner, and Rossetti with the premise of reducing various complications such as dysphagia, gas bloat. Previous reports have suggested a higher incidence of dysphagia (26%), gas bloat (25% to 38%), and recurrent GERD after the Nissen repair. These concerns have often been associated with slipped repairs or recurrent hiatal hernia resulting from the lack of a strong posterior fixation of the GE junction. With the Hill procedure, any tendency of the repair to be pulled up into the chest is significantly reduced because of the dependable fixation of the GE junction within the abdominal cavity. This posterior fixation is particularly important in patients with Barrett esophagus, chronic esophagitis, esophageal stricture, and paraesophageal hernia, which has been associated with shortening of the esophagus. Many surgeons advocate the Collis modifications of the standard Belsey and

Nissen operations to avoid recurrent hiatal hernia when esophageal shortening is suspected preoperatively or discovered intraoperatively.

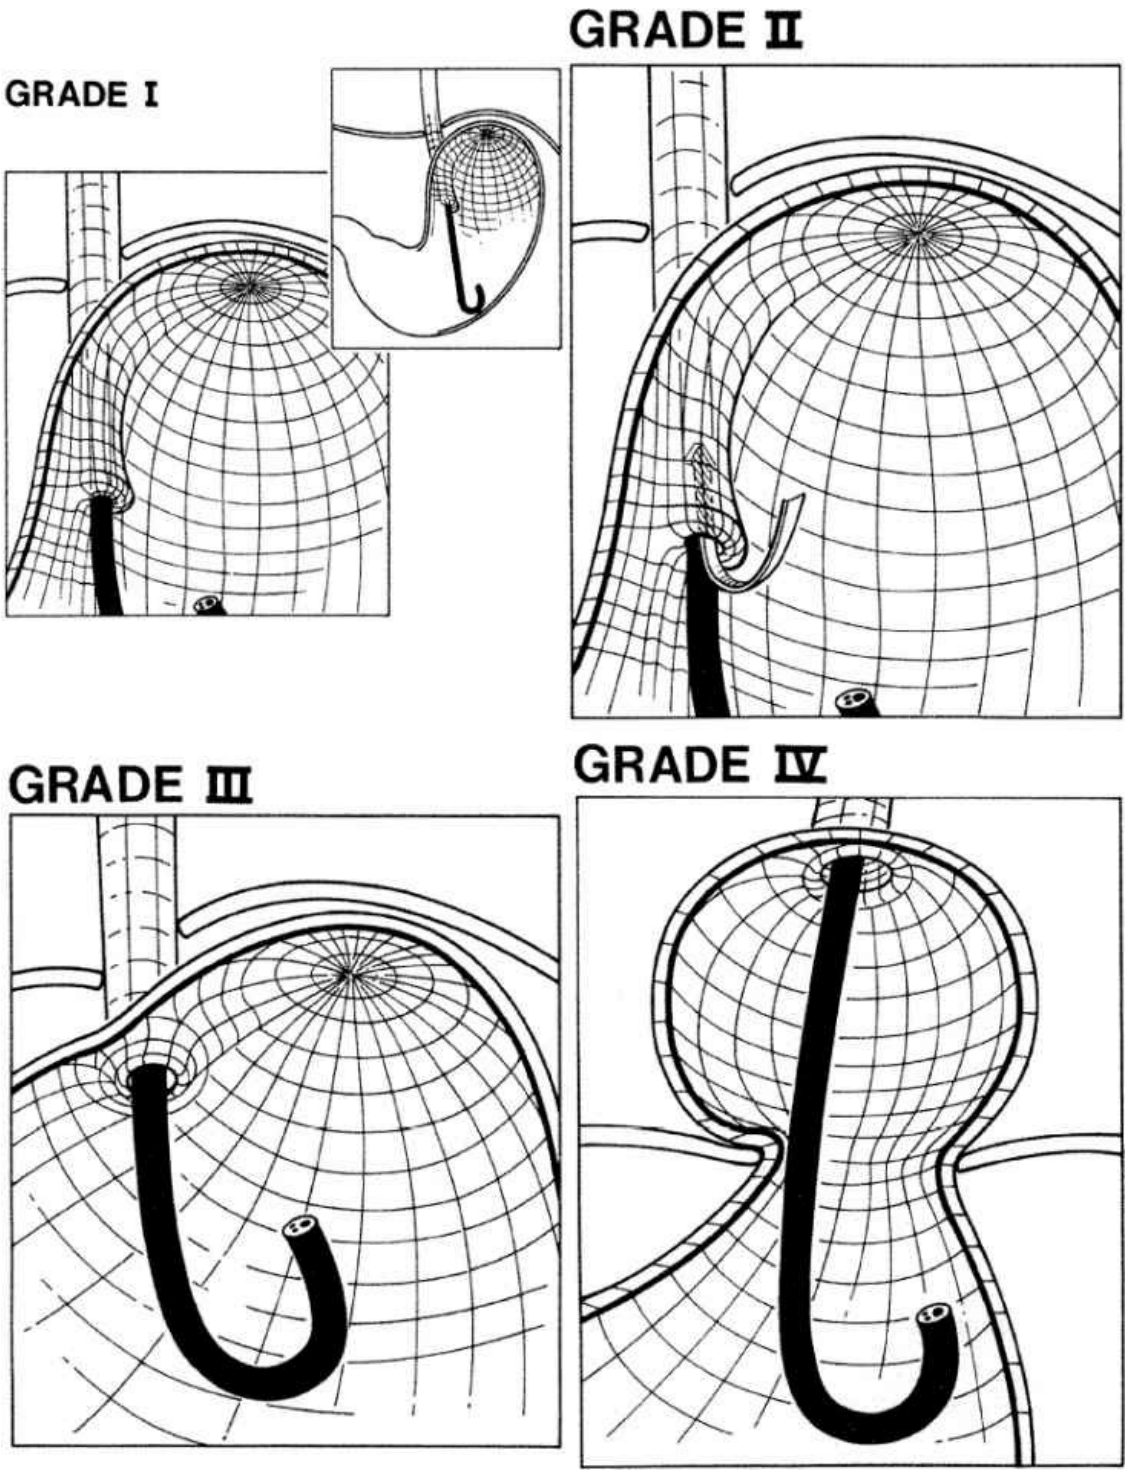

Figure 73.3. The four grades of the gastroesophageal valve. A Grade I valve is a normal musculomucosal valve that stays adherent to the endoscope through all phases of respiration, opens only for swallowing and belching, and closes promptly after opening. A Grade II valve is slightly less defined and shorter than the Grade I, opens with swallowing and belching, closes promptly, and does not allow reflux. The Grade III valve is poorly defined, opens frequently without the stimulus of swallowing or belching, stays open, allows reflux, and is often associated with a

hiatal hernia. The Grade IV valve shows no definition to the musculomucosal fold, stays open constantly, and is associated with a hiatal hernia.

In our experience, adequate length of intra-abdominal esophagus can virtually always be obtained and maintained without the need for any esophageal lengthening techniques by appropriate extensive mobilization of the esophagus from the abdomen (see Fig. 73.5) and use of the firmly anchored Hill operation. This issue strongly suggests that the Hill repair has significant advantages over the other repairs, particularly when dealing with short esophagus and paraesophageal hernias.

We continue to advocate the routine use of intraoperative manometry to control the degree of plication at the level of the GE junction to minimize the incidence of postoperative dysphagia and to eliminate the need for inserting a bougie when constructing the repair. The routine application of intraoperative manometry allows modification of the repair (see Surgical Technique) to obtain lower esophageal sphincter pressures between 25 and 55 mm Hg. These intraoperative pressures have been shown to translate postoperatively to pressures in the normal range, between 15 and 30 mm Hg.

INDICATIONS AND PREOPERATIVE PLANNING

Appropriate patient selection is essential to help ensure good outcomes, including improvement in quality of life. The majority of operative candidates should have typical symptoms that are chronic and refractory to standard medical therapy. With the increasing application of the laparoscopic approach to the treatment of GERD, an ever-increasing temptation is to offer surgical treatment to the patients who are asymptomatic but require regular or high-dose medications. This can be acceptable, especially in young patients who wish to avoid lifetime dependence on medications. If a good outcome is to be achieved in these asymptomatic patients, however, attention to patient selection and operative approach must be particularly meticulous.

All patients being considered for antireflux surgery should undergo preoperative endoscopy and manometry to document the presence of Barrett esophagus, esophageal cancer, or significant motility disorder. Manometry occasionally provides alternative diagnosis, such as scleroderma or achalasia, for which antireflux surgery may be

contraindicated or it may lead to modification of the surgical approach. High-resolution manometry allows the evaluation of esophageal motility by drawing esophageal pressure topography (EPT) to categorize patients according to the Chicago Classification. Impedance combined with manometry or to pH testing can identify whether motility defects and reflux are contributing to patient's symptoms. Abnormal levels of acid reflux documented by standard pH devices especially when correlated with patient symptoms are considered important for predicting operative success. False negative results in standard pH tests can occur in 30% of the cases. Impedance testing can differentiate between acidic and nonacidic reflux that can provide additional data when standard pH studies are normal. Our practice includes routine endoscopy, high-resolution manometry, and 24-hour pH studies in the majority (>90%) of patients to confirm the diagnosis by verifying an abnormal level of GE reflux and, more important, to demonstrate a high level of correlation between symptoms and reflux episodes.

OPEN HILL OPERATION: SURGICAL TECHNIQUE

The operation is performed with the use of both general and epidural anesthesia whenever possible. The epidural is continued postoperatively in a patient-controlled mode, which has greatly facilitated early patient mobilization and discharge. The patient is positioned supine with the right arm tucked and left arm abducted at 90 degrees. A limited upper abdominal midline incision is made from the xiphisternum to 4 to 6 cm above the umbilicus, with the xiphoid process excised if necessary. The "upper hand" retractor system (V. Mueller, Allegiance, and Deerfield, IL) is used throughout the procedure and utilizes two right-angled retractor blades suspended from a transverse bar positioned 3 to 4 cm above the patient's chest. The blades of the retractor are placed under the right and left costal margins, which are retracted superiorly and laterally. This retraction results in a verticalization of the diaphragm, which allows the operating team to work straight down on the GE junction rather than struggling under the diaphragm. The lower aspect of the incision is held open with a Balfour retractor (Fig. 73.4). The left lateral segment of the liver is then mobilized from the diaphragm, with the triangular ligament taken down and the inferior phrenic vein carefully avoided. The gastrohepatic ligament including the hepatic branches of the vagus nerves is incised. This allows retraction of the caudate lobe and the lateral

segment of the left lobe of the liver to the right using a deep Harrington retractor (see Fig. 73.4). The dissection then proceeds over the anterior aspect of the esophageal hiatus. Any hiatal hernia is reduced and the peritoneal reflection is incised to identify the anterior surface of the esophagus. Gentle finger dissection along the right and left crux of the diaphragm facilitates delineation of the esophagus, which is manually encircled; the posterior vagus nerve is kept closely applied to the esophagus. This dissection should be easy to perform in a virtually bloodless plane when done correctly. A 1-in. Penrose drain is then passed around the esophagus and both vagus nerves to facilitate retraction through the remainder of the mobilization of the esophagogastric (EG) junction. Dissection proceeds inferiorly along the medial aspect of the right crus to the point where it converges with the left crus. The esophagus is gently retracted anteriorly and to the patient's left, and the lower aspect of the left crus is mobilized. The peritoneal coverings of the left and right crus should be preserved. The fundus is completely mobilized from the EG junction to the level of the first short gastric vessel. A significant advantage of the Hill operation over the classic Nissen fundoplication is that there is no need to take down the short gastric vessels. If any indication is identified of esophageal shortening at this point, the distal esophagus can be mobilized for a variable distance to facilitate complete reduction of the EG junction into the abdomen. The mobilization can involve up to 10 to 12 cm of distal esophagus and is best accomplished while retracting the crus with BABCOCK clamps to improve visualization (Fig. 73.5).

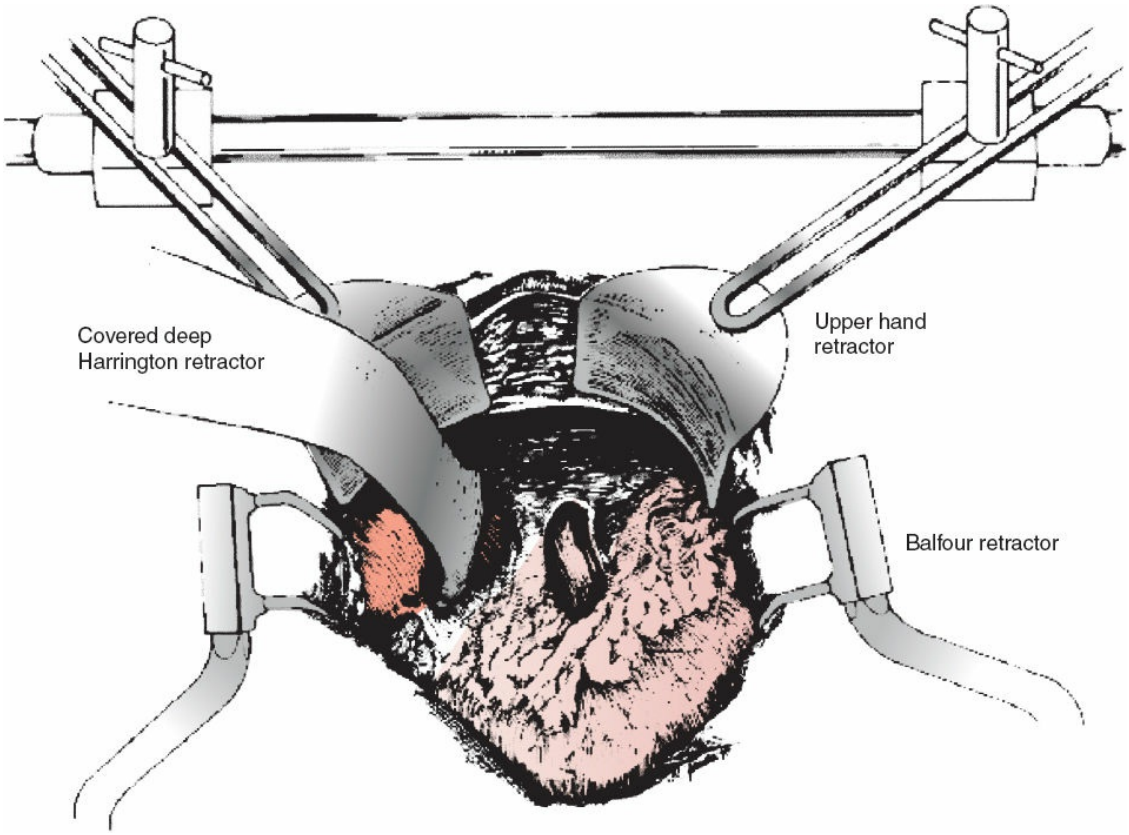

Figure 73.4. The retraction apparatus used to provide exposure of the esophageal hiatus. The setup facilitates the "verticalization" of the diaphragm, so the surgical team can look straight down to the operative field.

If the esophagus is mobilized as described along its normal anatomic planes, both the anterior and posterior phrenoesophageal bundles will be intact and easily visible at the level of the EG junction. The Hill repair uses these strong tissue bundles to recreate the angle of His and reestablish the esophageal flap valve apparatus while anchoring the repair in the abdomen. The phrenoesophageal bundles are composed of fibrofatty tissue and vary significantly in size and bulk according to the patient's body habitus. They form the natural attachments of the EG junction to the diaphragm (see Fig. 73.2).

The upper edge of the preaortic fascia is identified by passing a finger between the right and left crus down to the surface of the aorta. Usually a layer of areolar tissue is present anterior to the aortic fascia; generally, this can be entered bluntly and the surgeon's finger passed underneath the fascia. The preaortic fascia can then be lifted anteriorly along with the junction of the right and left crus of the diaphragm and grasped with a BABCOCK clamp (see Fig. 73.2). In some older individuals or patients

with very large hiatal hernias, the preaortic fascia is not obvious; in these instances, or when the crural musculature is strong and will provide an adequate anchoring point, only the confluence of the right and left crus should be grasped with the BABCOCK. Two No. 1 silk sutures are then placed through the grasped tissue ~1 cm apart at the level of the confluence of the crura to act as stay sutures. These sutures are used to elevate the crural musculature away from the aorta when placing the repair sutures and are used only for retraction purposes (see Fig. 73.2). The esophageal hiatus is then closed, which usually requires one to three figure-of-eight 0 silk sutures with Teflon felt pledgets (Deknatel Division, Fall River, MA). This closure is continued to a point where the tip of a finger can still be easily inserted along the esophagus and through the hiatus. Too tight a closure leads to postoperative dysphagia, which does not respond to dilation (Fig. 73.6). Large hiatal hernias can lead to the esophageal hiatus becoming largely dilated. In these circumstances, utilizing only posterior hiatal closure sutures can distort the path of the esophagus too far anteriorly. Alternatively hiatal closure sutures can also be placed at 10:00 and 2:00 o'clock to decrease the potential for distortion and postoperative dysphagia (Fig. 73.7).

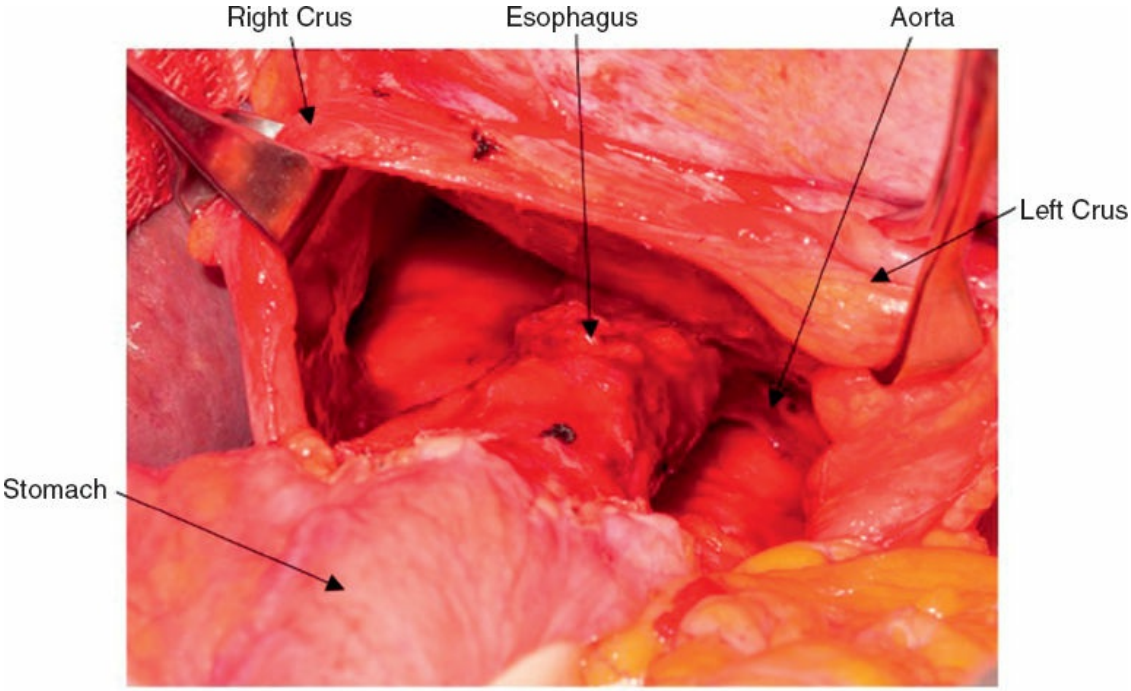

Figure 73.5. The esophagus completely mobilized and dissected circumferentially. The right and left crus are grasped with BABCOCK clamps and retracted, which allows esophageal mobilization high into the mediastinum.

The repair is initiated by grasping the anterior and posterior phrenoesophageal bundles with BABCOCK clamps. The anterior bundle is grasped lateral to the anterior vagus nerve at the base of the angle of His just distal to the esophagofundic junction (Fig. 73.8). The posterior bundle is identified by rotating the posterior fundus to the patient's right behind the EG junction where it can be grasped with a BABCOCK clamp just beside the posterior vagus nerve. The repair is done with five 0 silk sutures. The first is placed laterally on the anterior phrenoesophageal bundle, including a component of the underlying gastric serosa. The same suture is then passed through the superior aspect of the posterior bundle and then down through the crus and preaortic fascia, which is retracted anteriorly using the previously placed stay sutures. The next four sutures are placed in a similar fashion, with each stitch taken more medial on the anterior bundle and more inferior on the posterior bundle and also passed through the crural fibers and preaortic fascia (Fig. 73.9). The position of the anterior and posterior vagus nerves should be noted during the placement of each repair stitch. The first three sutures are placed with Teflon pledgets.

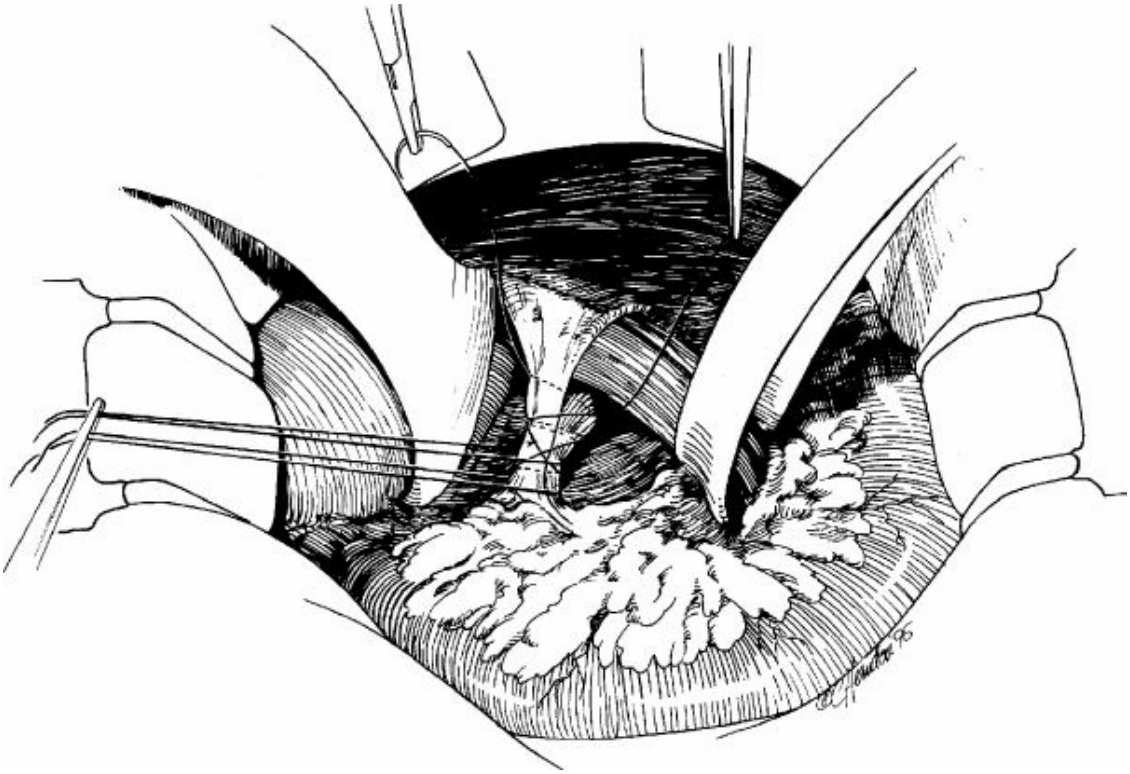

Figure 73.6. Left and right crura are closed with interrupted figure-of-eight silk sutures.

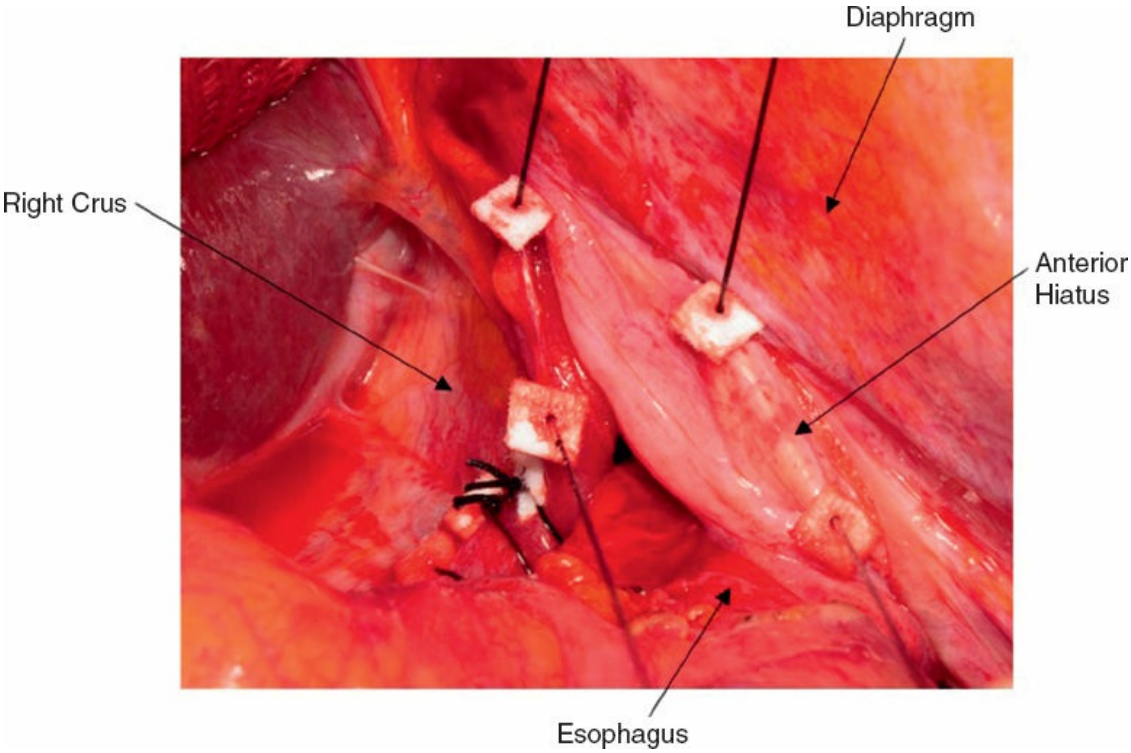

Figure 73.7. 10 o'clock sutures placed in addition to posterior hiatal closure sutures to accomplish hiatal closure around the esophagus and to minimize its anterior displacement.

Once these repair sutures are placed, the first two are tied down to the crural musculature with a single knot and clamped. These two initial sutures are the key aspect of the repair. This deepens the angle of His and produces an easily palpable GE flap valve (Fig. 73.10). The valve is best appreciated by palpation at the level of the EG junction. The valve can be easily assessed at the point where it encircles the nasogastric tube (Fig. 73.11). With the first two sutures tied down and clamped, intraoperative manometric testing is carried out to allow a preliminary assessment of the repair. We use a standard four-channel manometric tube (Medtronic, Skovlunde, Denmark) with manometric side ports located 5 cm apart from the tip of the catheter; this tube can be hooked up to a standard manometric machine or an arterial line transducer. Several sequential manometric pull-throughs of the GE junction are done. Intraoperative pressures ranging between 25 and 55 mm Hg translate into normal postoperative lower esophageal sphincter pressures and reduce the incidence of postoperative dysphagia. The lower esophageal sphincter pressure can be assessed precisely and tension adjusted intraoperatively by tightening or loosening the first two sutures. After the measurements are completed, the first two sutures are tied down permanently and the remaining three sutures are tied.

The two crural retraction sutures are removed. Final manometric pull-through measurements are then obtained. The repair is completed by the placement of the two interrupted 3-0 silk sutures placed on the left lateral and anterior aspects of the EG junction from the fundus to the esophageal muscle and then to the rim of the esophageal hiatus. These sutures help to further close the hiatus and accentuate the GE flap valve apparatus (Figs. 73.10 and 73.12). The nasogastric tube is positioned in the stomach and the abdomen is closed. The EG junction is now fixed posteriorly and can resume normal motility and clearance.

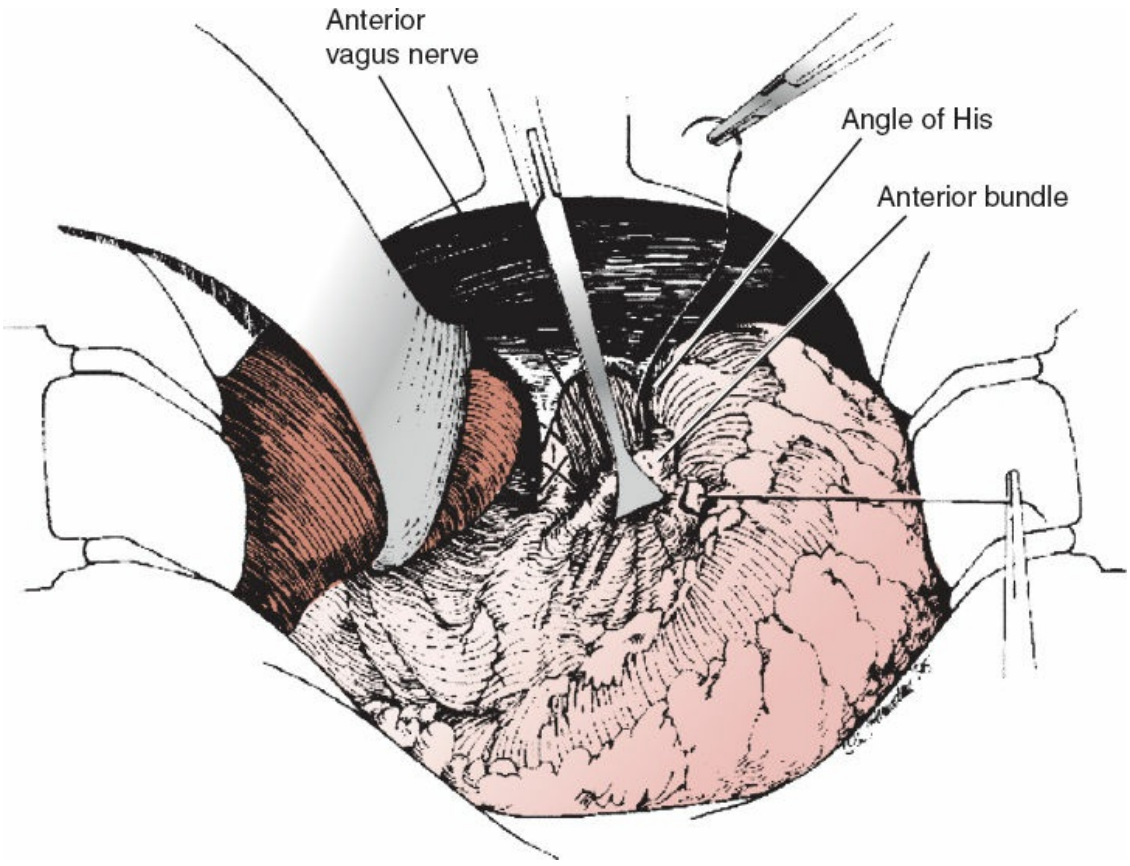

Figure 73.8. BABCOCK clamp shown grasping the anterior phrenoesophageal bundle. The first of five sutures is shown passing through the bundle and its underlying serosa. Notice that this stitch is placed lateral to the anterior vagus nerve, which is visualized as each suture is inserted.

RESULTS

Multiple published reports document the efficacy of the Hill repair for controlling primary reflux, as well as its effectiveness in the patients with reflux-associated esophageal stricture and recurrent reflux and failed

previous repairs and paraesophageal hernias.

The longest follow-up study examining the outcome of antireflux surgery was for the patients undergoing the Hill repair and was published in 1988. This review reported on the long-term results (15 to 29 years) in 167 patients after the Hill repair. The review found that 88% of the patients were still completely satisfied with their results at a mean follow-up of 17.8 years.

More recently, there has been a comprehensive review of the subjective and objective outcomes of the open Hill operation in the patients with giant paraesophageal hernias. This paper involved 72 consecutive patients with a mean age of 69 years, and all of whom presented with paraesophageal hernias involving at least 50% of the stomach. The operative approach was standardized to include sac excision and primary closure of the esophageal hiatus in 97% of the patients. The standard Hill procedure was used in 96%, and no patients underwent a Collis gastroplasty. In spite of being an open operation in elderly patients, the median postoperative hospital stay was 4.5 days and there was no mortality in the series. Follow-up included subjective and objective assessment, which demonstrated statistically significant improvement in both heartburn and dysphagia scores and overall improvement in quality of life. Objective follow-up carried out at a mean of 30 months demonstrated recurrent hernias in 18%, most of which were small, sliding hiatal hernias and none of which required revision on the basis of hernia recurrence or new or recurrent symptoms. This study highlights the efficacy and safety of the Hill repair in a complex operative population and also provides what is often missing from other postoperative assessments, specifically objective assessment of technical as well as symptomatic results.

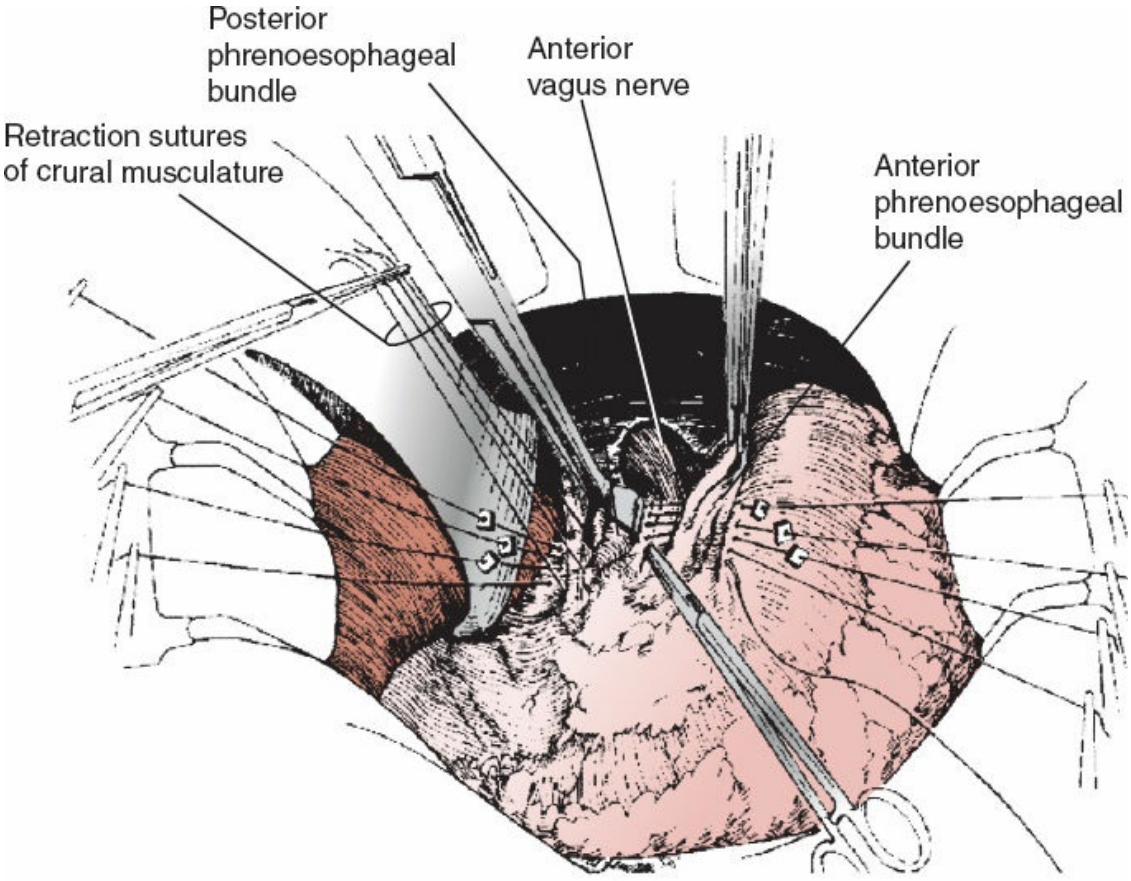

Figure 73.9. The nearly completed repair. All five sutures are demonstrated through the anterior bundle, which is held by the forceps. The posterior bundle is being rotated and held by the BABCOCK. The stitches in the posterior bundle are inserted just posterior to the directly visualized posterior vagus nerve. The sutures are also passed through the crural muscles and preaortic fascia (instead of the median arcuate ligament), which is retracted away from the aorta with the stay sutures (held in the hemostat).

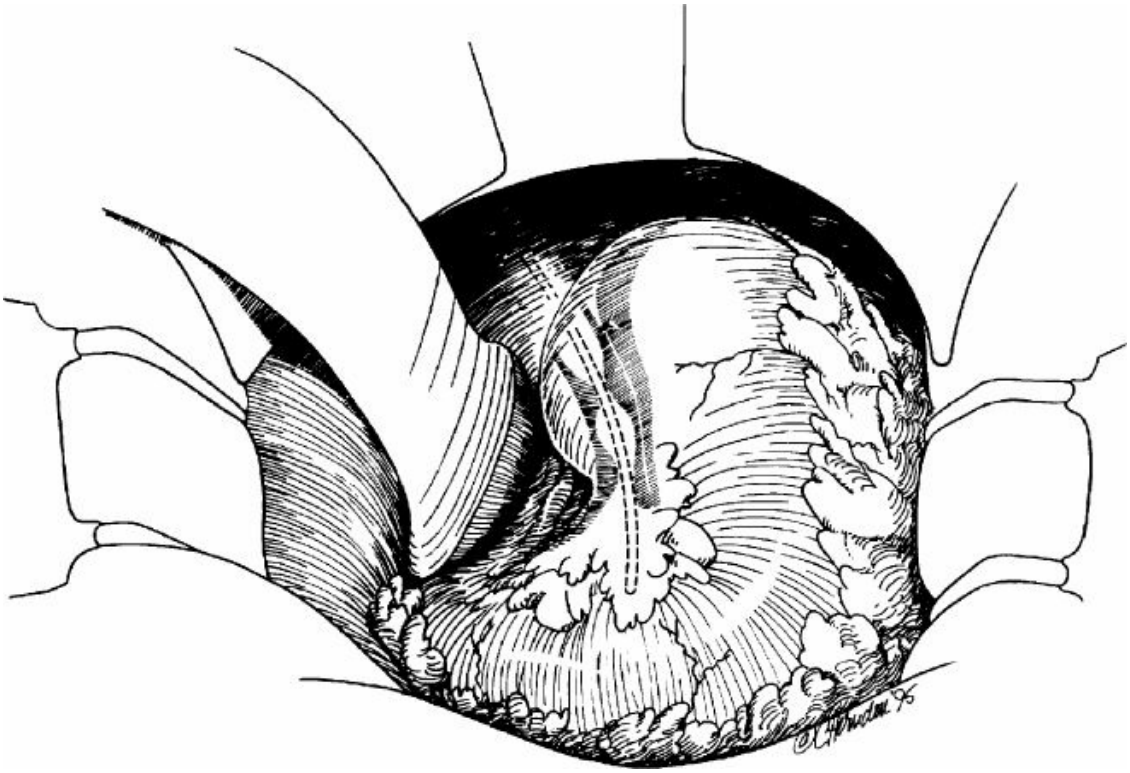

Figure 73.10. Relationship of the completed repair and how it deepens the angle of His and produces a very pronounced flap valve (shown highlighted through the anterior gastric wall), which is the major mechanism for controlling reflux postoperatively.

LAPAROSCOPIC HILL OPERATION: SURGICAL TECHNIQUE

The Hill operation has also seen successful application using the laparoscopic approach. Initially, it was felt that morbid obesity, failed previous antireflux operations, and previous extensive upper abdominal surgery were contraindications; however, additional experience has shown that even these patients can selectively undergo a successful laparoscopic Hill operation.

The tenets of the workup and patient preparation remain the same as the open operation. The repair remains based on secure posterior fixation of the GE junction, tightening of the collar sling musculature, and accentuation of the GE valve. This achieves the combined goals of deepening the angle of His, thereby recreating the GE valve and augmenting the lower esophageal sphincter.

Technical differences include the fact that three tacking sutures are placed between the posterior wall of the gastric fundus and the left side of the crural musculature to align the posterior phrenoesophageal bundle and

facilitate the placement of the actual repair sutures (Fig. 73.13). In addition, the anterior and posterior phrenoesophageal bundles are not grasped with instruments as in the open repair but sewn freehand under direct vision (see Fig. 73.13). Four, rather than five, sutures are utilized and the sutures are inserted bottom to top in the crura and posterior bundle, and right to left in the anterior bundle, which is also different than the open repair. The anchoring sutures are placed in the condensation of the crural musculature and the preaortic fascia, but, without the benefit of the retraction sutures utilized in the open repair, a laparoscopic BABCOCK is often valuable to intermittently grasp the anchoring tissue to avoid injuring the underlying aorta.

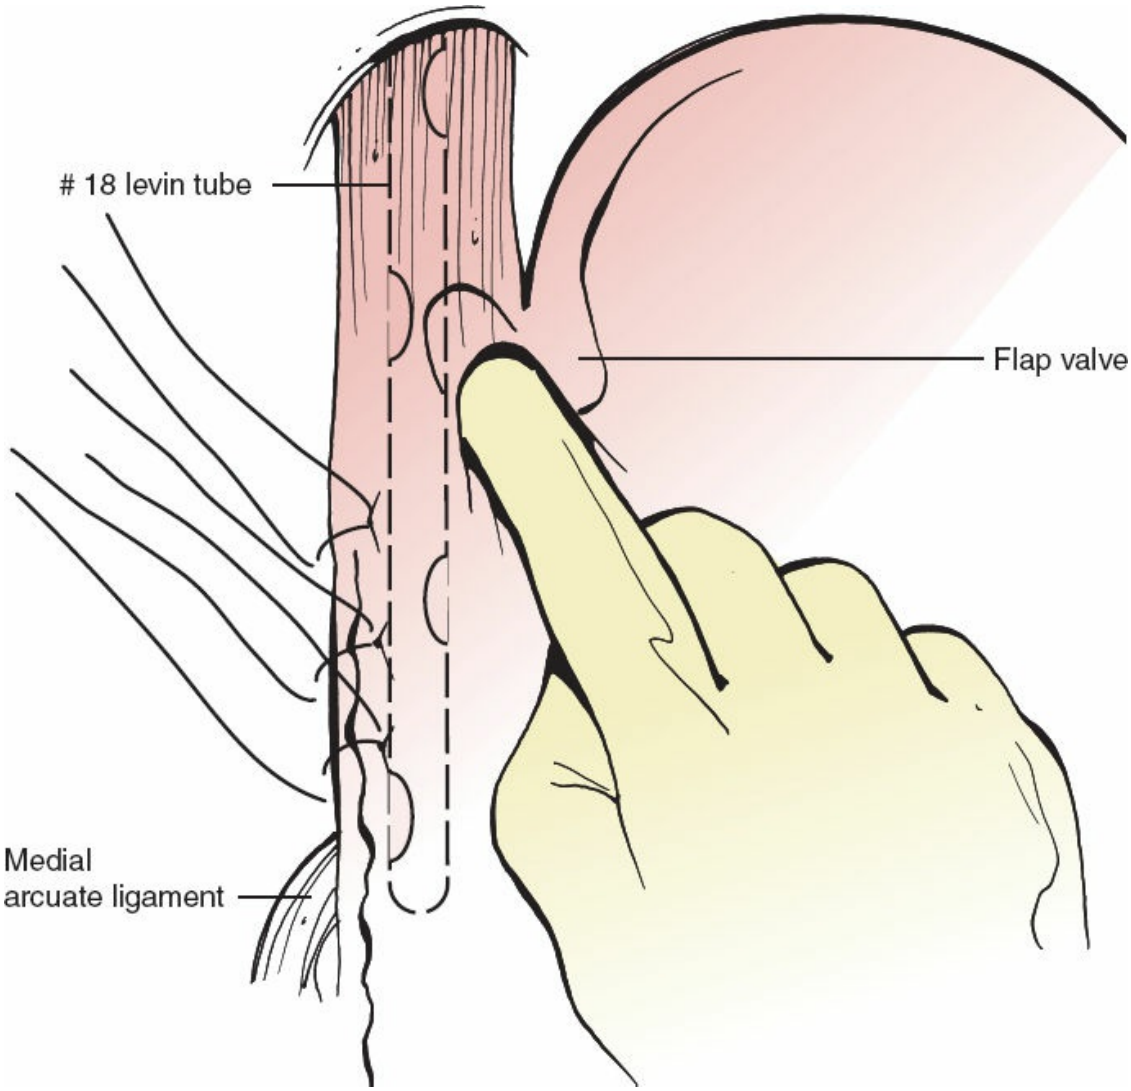

Figure. 73.11. Intraoperative assessment of the flap valve by palpating through the anterior wall of the stomach along the indwelling nasogastric tube.

Because of the fact that the construction of the GE flap valve cannot be manually assessed during its construction as in the open repair (see Fig. 73.11), the laparoscopic operation is typically done under endoscopic guidance that can visually assess the flap valve and facilitate the placement of a wire for the intraoperative insertion of a 42-Fr bougie over which the repair is classically done. Alternatively, a lighted bougie can be used.

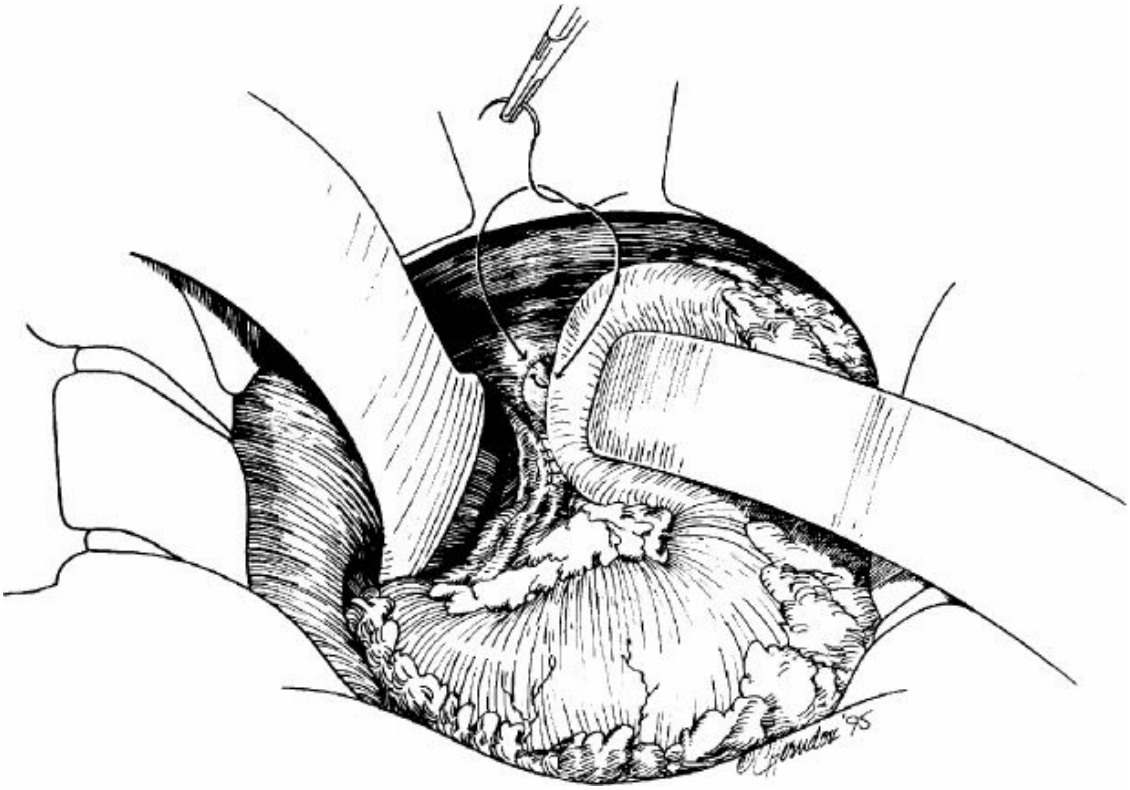

Figure 73.12. View of one of the two sutures that is inserted to seal off the anterior hiatus and maximally accentuate the depth of the angle of His and the flap valve. The suture passes from the anterior aspect of the fundus down to the wall of the esophagus and out through the anterior rim of the hiatus.

The last two sutures are temporarily tied and clamped, standard manometric pressures are taken. The pressures targeted in the laparoscopic repair are different than in the open operation with readings of 20 to 45 mm Hg being preferred. With appropriate measurements being obtained with the initial two sutures, all four repair sutures are permanently tied with final assessments of the valve being done endoscopically and final manometric pressures being obtained.

DISCUSSION

We have found the Hill repair to be a highly efficacious and safe operation. It is an excellent option for operable primary reflux, but it is particularly effective and is likely the best approach to recurrent and complicated reflux problems, especially those involving giant paraesophageal hernias, short esophagus, and in the patients with previous gastric resections. The Hill repair is predicated on restoring the normal anatomy of the GE junction. This is a firmly anchored repair that results in the fixation of the GE junction in its normal intra-abdominal location. By reestablishing the acute angle of His between the esophagus and the stomach, the Hill repair secures the intra-abdominal esophagus and accentuates the flap valve. The grading system for this flap valve has been shown to be highly accurate in assessment of patients with GERD (see Fig. 73.3). The flap valve produced by the Hill repair is the major mechanism of controlling reflux postoperatively and is becoming increasingly well documented and understood, as shown by its current recognition in *Gray's Anatomy*.

We have made minor technical changes from the original description of the Hill repair. The anchoring of the repair to the confluence of the diaphragmatic crus and the preaortic fascia rather than the median arcuate ligament should make the procedure easier to learn and apply in a variety of clinical situations. The results obtained with the Hill repair are durable, with effective long-term symptom control being documented extending over 15 to 20 years following surgery.

A randomized multi-institution comparison of the laparoscopic Nissen fundoplication (LNF) versus laparoscopic Hill repairs (LHR) has been conducted comparing 56 and 46 patients respectively with a 12-month follow-up. Quality-of-life scores improved significantly for both repairs. Dysphagia scores were equivalent postoperatively. Although the mechanism of repair was different, there was no difference in subjective and objective outcomes.

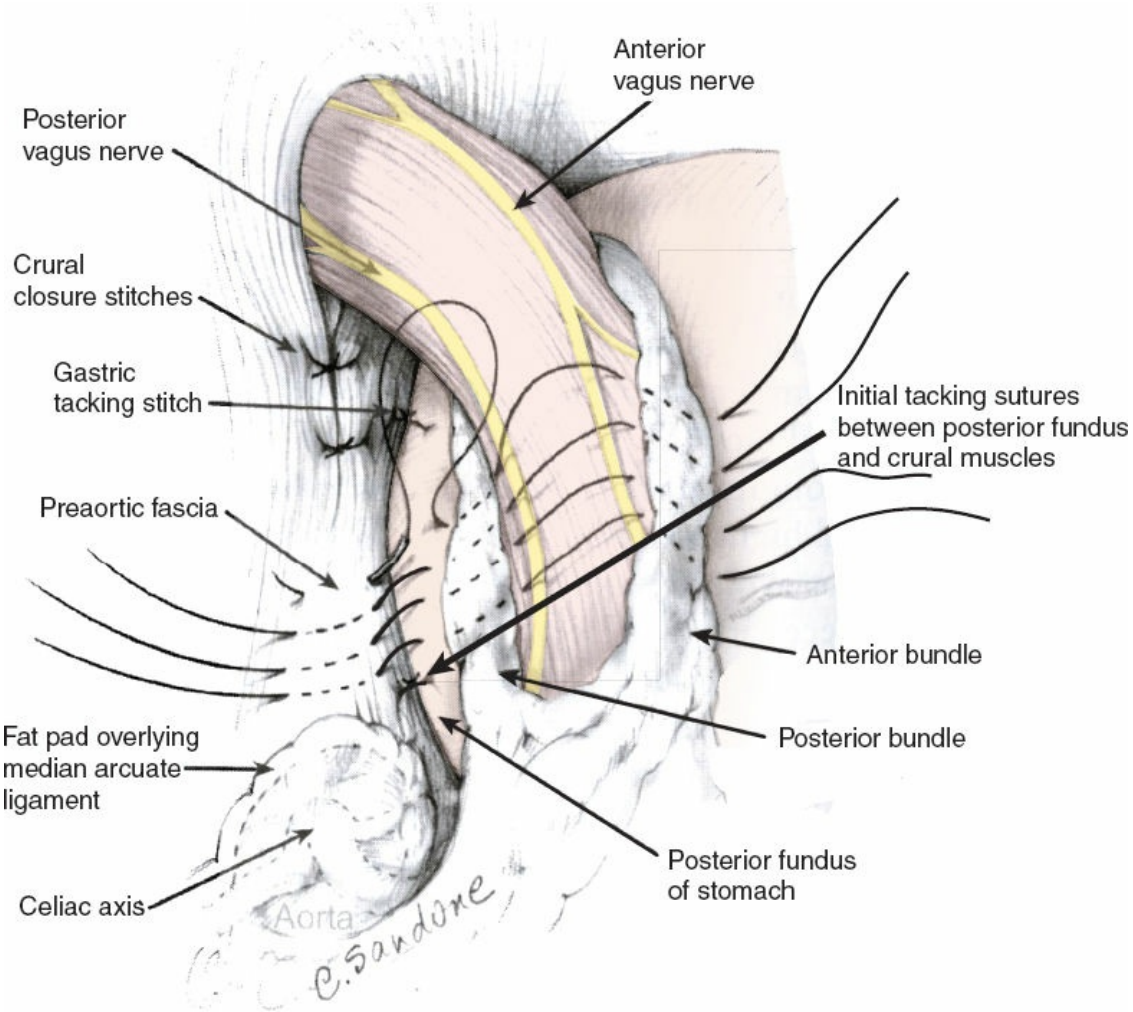

Figure 73.13. Overview of the laparoscopic Hill repair sutures. The critical component of the Hill repair is the recreation of the gastroesophageal valve by fixing the anterior and posterior phrenoesophageal bundles to the preaortic fascia. Crural closure sutures in this illustration have been placed. A tacking suture has also been placed to bring the posterior aspect of the fundus to the left portion of the preaortic fascia, thus aligning the tissues to facilitate the repair. (Adapted from Yang SC, Cameron DE. *Current Therapy in Thoracic and Cardiovascular Surgery*. 1st ed. St. Louis, MO: Mosby; 2004. Copyright © 2004 Elsevier, with permission.)

Based on the fact that LNF and LHR have different mechanisms and in an attempt to mitigate the individual weakness of LNF and LHR, a pilot study was published in 2013 describing a hybrid technique of laparoscopic Nissen-Hill antireflux procedure for patients with paraesophageal hernia and Barrett esophagus. They reestablished the angle of His by two Hill sutures and then constructed the routine Nissen procedure. A total of 24

patients with symptomatic giant paraesophageal hernias and/or GERD with nondysplastic Barrett metaplasia were included with a median follow-up of 13 months. The results showed improvement in DeMeester scores, quality-of-life metrics, and in mean long-term dysphagia severity score index. There was also an increase in the mean lower esophageal sphincter pressures. This study illustrated the feasibility and safety of combining the best qualities of two technically different antireflux procedures.

A prospective trial conducted in 2015 evaluated the safety and clinical efficacy of the hybrid procedure. Fifty patients with symptomatic paraesophageal hernia and/or nondysplastic BE underwent the laparoscopic Nissen-Hill procedure with a follow-up period of 13 months. Mean DeMeester scores improved. Preoperative symptoms were controlled in 90% with only 6% needing resumption of antisecretory medication. All quality-of-life metrics improved significantly. This study established the safety and technical feasibility of the hybrid procedure in groups at higher risk of recurrence.

EDITOR'S COMMENT

I must confess prior to launching this commentary that I like the Hill repair and it is my preferred repair. Realistically, it can only be carried out open, although there are those who perform it laparoscopically; it is not easy, but it does solve the problem which is basic to reflux, in accomplishing the following four goals in antireflux surgery:

1. It mobilizes and secures a length of intra-abdominal esophagus, thereby restoring the high-pressure zone.
2. It results in a satisfactory way of holding the esophagus and the high-pressure zone within the abdomen.
3. It restores the angle of His.
4. As a secondary benefit, because of the fact that the wrap is not total, or 360 degrees, but advertises being 270 degrees and more likely is about 180 degrees in most people's hands, burping or failure to be able to burp is not a problem, and thus patients do not have a problem with inability to burp which some patients undergoing the Nissen procedure do have a significant problem with.

In addition, the Hill repair can be carried out in patients who have a prior gastrectomy. The Nissen fundoplication is very difficult to do in patients who have a significant gastric resection, and while I admit that the number of patients undergoing gastrectomy nowadays have decreased remarkably, if a vagotomy was carried out as part of the gastrectomy despite the attempt to close the hiatus on the part of some surgeons, it does set up a patient for reflux because the closure of the hiatus alone following vagotomy is usually not sufficient to prevent reflux. Thus, in patients with diminished gastric mass, the antireflux procedure can only be carried out simply by Hill repair which must be open. I realize that there are other alternatives, but to me it seems that the Hill repair serves the purpose very nicely.

How good is the Hill repair and how durable? Aye et al. including Dr. Lucius

Hill (The Hill antireflux repair at 5 institutions over 25 years. *Am J Surg* 2011;201:597–602) reviewed five institutions and their Hill repairs over 25 years. In two of the institutions, Lucius Hill–trained surgeons or centers (HTCs) performed the procedures, and three other institutions were either self-taught or developed the skill themselves. Surgeons from the Swedish Medical Center and the Virginia Mason Center in Seattle and a surgeon from Queen's University in Kingston made up the HTCs, while the Massachusetts General Hospital, where I learned how to do the Hill repair; the Norfolk Surgical Group in Norfolk, Virginia; and University Medical Center in Kansas City were the independent performers of the Hill repair. There were a large number of patients—1,381—who were reviewed at the five sites. Follow-up was <2 years in 153 and these were excluded, and 47 were either with incomplete data or deceased, and thus, 1,181 patients were included in the study. Further, HTCs included 843 patients, of which 779 from the Swedish Medical Center and the Virginia Mason Center in Seattle, 64 from Queen's University. Of the independent centers, 57 from Kansas University Medical Center, 247 from the Norfolk Surgical Group, and only 34 at the Massachusetts General Hospital. The preoperative symptoms were relatively common: heartburn, dysphagia, regurgitation, chest pain, cough, and hoarseness. These symptoms were largely present for more than 2 years. All patients underwent flexible upper endoscopy, and the diagnosis of esophagitis was present in most. There were 37 patients who had Barrett metaplasia and esophagitis was present in only 443. Further, 96% of the patients noted improvement in their symptoms, and there was no difference between the independent hospitals, 81.1%, and 79% of the HTCs. It is difficult to understand how 96% noted improvement in their symptoms, although the 79% and 81% were patients with no/mild symptoms. There were no differences between the HTCs and the independent centers, and in most situations, the independent centers did slightly better but it was not statistically significant. The complications to the procedures were 11%, including splenic injury in 9% of the patients, and the usual wound infections, pneumothorax, pleural effusion, pulmonary embolism, and fistula formation, all in <1% of the patients. The resumption of antisecretory medications was low, with only 22% reporting any use at all. Anatomic recurrence was 6.9% and reoperation rate was only 1.9%.

This is in remarkable contrast to Spechler et al. (Long-term outcome of medical and surgical therapies for gastroesophageal reflux disease: follow-up of a randomized controlled trial. *J Am Med Assoc* 2001;285:2331–8) who reported that 62% of the surgical patients were back on regular medication and 16% required reoperation at the 10-year follow-up. In short, the Hill repair produces excellent results that are durable and are not a surprise to me from my own personal experience, although in view of them one wonders who the Nissen is so commonly performed around the country, other than fixing the gastroesophageal junction to either the median arcuate ligament which is present in <50% of the patients and which is close to the celiac axis which frightens many surgeons or the crura alongside the esophagus.

Patients with gastroesophageal reflux disease in severe cases suffer voice loss, chronic cough, globus, and sore throat. While some of these patients will respond to proton pump inhibitor therapy, the results after the Hill repair have not heretofore been reported. Wright and Rhodes (Improvement of laryngopharyngeal reflux symptoms after laparoscopic Hill repair. *Am J Surg* 2003;185:455–61) analyzed symptomatic improvement in 145 patients who underwent laparoscopic Hill hiatal hernia repair. Gastroesophageal reflux was generally improved compared with preoperative symptoms. While the improvement in symptoms such as bloating, dysphagia, regurgitation, etc., were in the 81% to 96%, improvement in the symptoms of laryngopharyngeal reflux were in the 89% to 92% and, of course, the *P* value was <0.001. This is an excellent result, again with the Hill repair in a very troublesome symptom. Unfortunately, asthma which some investigators have associated with gastroesophageal reflux and in which an association probably exists improved only in 25%.

An endoluminal approach to the Hill procedure was reported by Fritscher-Ravens A and Swain P from St. Mary's Hospital in London (Endoluminal fundoplication–the Hill procedure. *Minim Invasive Ther Allied Technol* 2006;15:366–72), in which the antireflux procedure was carried out endoscopically. The purpose of this paper was the feasibility of the crural repair under endoscopic ultrasound to identify the structure in pigs. These were survival experiments in 14 pigs utilizing the linear array of echoendoscopes. Parts of the right crus were identified, and an endoscopic sewing device was used allowing sutures to be placed through a 2.8-mm accessory channel. Knot tying and thread cutting through the 2.8-mm channel required new techniques. Preoperative manometry showed a median lower esophageal pressure of 11 mm Hg; this increased to 22 mm Hg after stitch placement. I agree with the authors that it did appear possible to safely place the sutures into the right crus and thus increase the lower esophageal sphincter pressure. At postmortem examination in a survival experiment, the length of LES increased from 2.8- to 3.5-cm postprocedure which is probably neither statistically significant nor is it physiologically significant. At postmortem, the force to pull the tags out of the median arcuate ligament or what resembled the median arcuate ligament was 2.8 kg. This paper shows that this is possible, but with most endoscopic approaches to antireflux procedures whether they be bulking or some other type of procedure, this unfortunately has not withstood the test of time, but it is good that people are trying to do it.

74 Laparoscopic Antireflux Surgery

Nathaniel J. Soper and Eric S. Hungness

INTRODUCTION

Laparoscopic antireflux surgery continues to play a major role in the treatment of gastroesophageal reflux disease (GERD). Most operations for GERD involve plicating the gastric fundus 90 to 360 degrees around the distal esophagus. The most commonly performed fundoplication is the Nissen 360-degree fundoplication, which results in >90% long-term control of reflux symptoms. Other fundoplications (e.g., Hill, Belsey, Toupet, Dor, Guarner, Lind) have been developed, applied, and reported, but modifications of the Nissen fundoplication currently are the most widely used operations for GERD.

A randomized trial comparing transabdominal open Nissen fundoplication with medical therapy in patients with complicated GERD proved surgical therapy to be more effective. Despite these findings, many patients and physicians opted instead for lifelong medication and significant lifestyle limitations until 1991, when Dallemagne and Geagea reported the first laparoscopic Nissen fundoplications (LNF). Although LNF follows the same surgical principles as the open operation, randomized trials showed that the laparoscopic approach reduces postoperative pain and shortens both hospitalization and recuperation with outcomes (symptomatic and functional) similar to that of the open operation. Hence, there was a rapid increase in surgical treatment of GERD, with LNF gaining acceptance as an efficacious therapy for GERD.

Over the past decade, however, the number of antireflux operations being performed has diminished. This decrease is likely related to both increased awareness of complications of LNF and “better” medications being developed, resulting in increased resistance from the medical community to refer patients for surgical evaluation. Recent reports and FDA warnings of potential complications with long-term proton pump inhibitor (PPI) use, however, have caused increased discussion in the medical community of the role of surgery in the treatment of GERD.

GASTROESOPHAGEAL REFLUX DISEASE

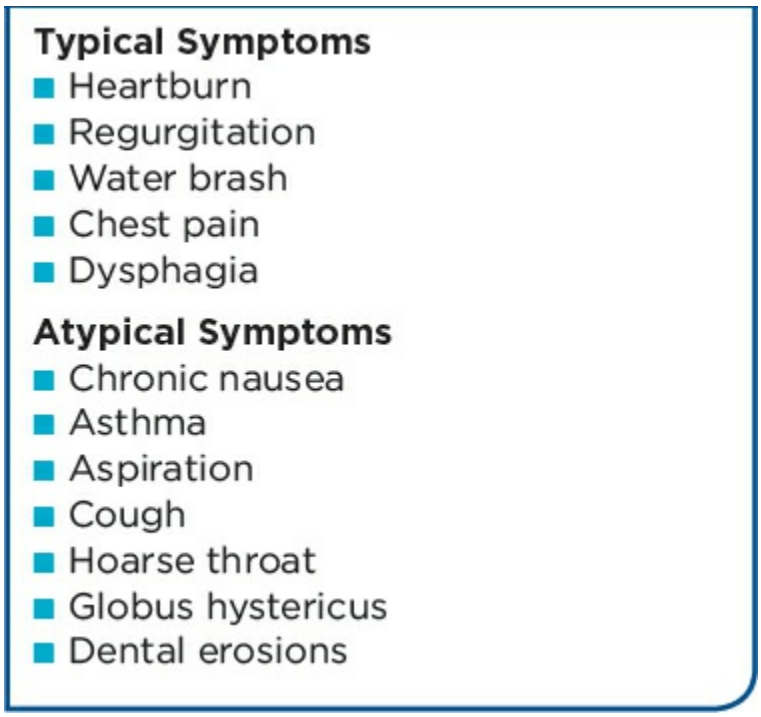
Demographics and Clinical Presentation

Over 60 million Americans complain of heartburn and indigestion, with approximately 40% of the total US population experiencing reflux on a monthly basis, 20% on a weekly basis, and 7% on a daily basis. Patients with GERD may exhibit typical or atypical symptoms (Table 74.1). GERD often presents as heartburn and regurgitation and can progress to dysphagia, odynophagia, and chest pain. Although typical of GERD, these symptoms may also be caused by other entities that must be included in the differential diagnosis, including cardiopulmonary disease, other foregut problems, gallbladder disease, and functional disturbances.

Anatomy

Barriers to gastroesophageal reflux (GER) include the lower esophageal sphincter (LES), the presence of an intra-abdominal segment of esophagus, the diaphragmatic crura, the phrenoesophageal membrane, the angle of His, and esophageal clearance of acid. The LES and hiatal crura appear to be the major barriers (Fig. 74.1A,B). The LES separates two adjacent lower-pressure zones and normally remains tonically contracted except during swallowing, when it relaxes in advance of the peristaltic wave. LES contraction receives important amplification during inspiration and conditions in which the abdominal pressure is increased by contraction of the crural diaphragm. GER events in healthy individuals normally result from the phenomenon known as *transient relaxation* of the LES complex, in which spontaneous (nonswallow initiated) events permit GER by obliterating the high-pressure zone through a vagally mediated mechanism that is usually stimulated by gastric or pharyngeal stimulation.

TABLE 74.1 Symptoms of Gastroesophageal Reflux Disease



Pathophysiology

GER occurs physiologically in all healthy individuals to a limited degree. Patients with GERD experience reflux more frequently and for longer periods of time than healthy persons. Reflux events may occur by three primary mechanisms: (i) spontaneously, accompanying transient LES relaxations; (ii) stress reflux associated with a weakened LES, the pressure of which does not exceed that of the elevated intra-abdominal pressure; and (iii) in individuals with severe reflux, essentially a nonexistent LES that cannot maintain competency at any point, resulting in spontaneous GER. Many patients with GERD exhibit a hiatal hernia with the proximal stomach residing in the negative pressure environment of the chest, which contributes to GER. Patients with long-standing and/or severe GERD may ultimately develop Barrett esophagus, columns of metaplastic esophageal mucosa associated with an increased risk of adenocarcinoma.

Some authors have proposed that transient LES relaxations initially cause damage to the esophageal mucosa. This is exacerbated by stress reflux usually caused by gastric distention, most commonly from overeating. The progressive mucosal inflammation leads to LES dysfunction, which leads to further reflux. This vicious cycle eventually leads to an incompetent LES. These events may also lead to esophageal dysmotility that may prevent normal esophageal clearance of acid.

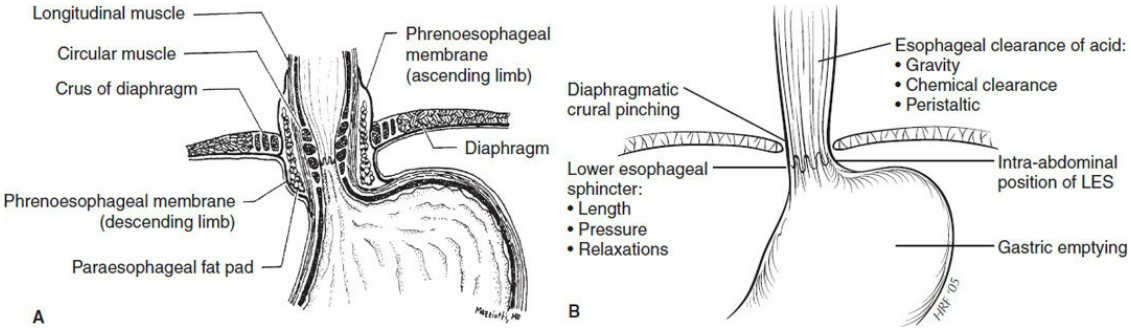


Figure 74.1. A. Anatomy of the gastroesophageal junction (GEJ). Anatomic components of the antireflux barrier include the lower esophageal sphincter (LES), the presence of an intra-abdominal segment of esophagus, the diaphragmatic crura, the phrenoesophageal membrane, and the angle of His. The LES and hiatal crura appear to be the major antireflux barrier components with the LES separating two adjacent lower-pressure zones and normally remaining tonically contracted except during swallowing, when it relaxes in advance of the peristaltic wave. **B.** The physiologic features controlling gastroesophageal reflux disease are multifactorial and include esophageal peristaltic and chemical clearance of acid, mechanical barriers such as the LES and diaphragmatic crura, and gastric emptying.

Savary et al. established a grading system for the endoscopic appearance of reflux-induced damage to the esophageal mucosa as follows: grade I (mild erythema), grade II (isolated ulcerations), grade III (confluent severe ulcerations), and grade IV (secondary complications including Barrett esophagus and stricture). The Los Angeles Classification System, the most commonly used system by gastroenterologists, grades esophagitis according to breaks in the esophageal mucosa: grade A (≤5 mm in length), grade B (>5 mm in length), grade C (continuous between two mucosal folds), and grade D (≥75% of esophageal circumference). However, up to 60% of patients with clinical GERD will have normal-appearing esophageal mucosa at endoscopy. Barrett esophagus is estimated to occur in approximately 10% of patients with GERD. Studies demonstrate that patients with GERD and Barrett esophagus have an estimated 0.4% per patient-year risk of developing adenocarcinoma, compared with a 0.07% per patient-year risk for patients with GERD but without Barrett esophagus.

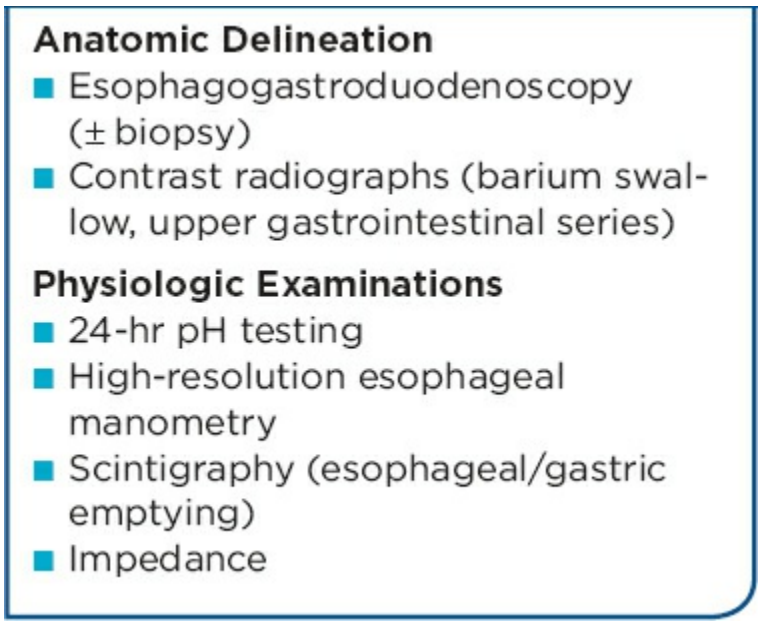
Diagnosis

Factors other than mechanical barrier deficits at the LES may lead to GERD, and GERD-like symptoms can be reported in the absence of GERD. The esophageal body plays an important role in clearing acid present within its lumen, a function that is aided by the presence of gravity and saliva. Esophageal peristaltic dysfunction is directly related to the degree of mucosal disease, and most patients with Barrett esophagus exhibit abnormalities of esophageal motor function. Abnormalities of the gastric reservoir, including gastric dilatation and delayed gastric emptying, may also predispose to GER. Antireflux operations are designed solely to correct a functionally defective reflux barrier; therefore, tests that measure the function not only of the LES itself but also of the esophagus and stomach may be appropriate in patients with GERD-related symptoms.

Preoperative Testing

Many diagnostic modalities are available for studying patients suspected of having GERD (Table 74.2). A history of recurrent heartburn alone is usually adequate to establish the clinical diagnosis of GERD and initiate empiric medical therapy. However, diagnostic tests should be performed in patients with persistent symptoms, symptoms and signs indicating significant tissue injury (e.g., dysphagia, anemia, or guaiac positive stools), and any patient in whom the diagnosis is uncertain. Individuals who are being considered for antireflux surgery require additional tests of the anatomic and physiologic features of the stomach and esophagus.

TABLE 74.2 Diagnostic Tests for Gastroesophageal Reflux Disease



In patients with typical symptoms of GERD, the minimal diagnostic evaluation is esophagogastroduodenoscopy (EGD). High-resolution esophageal manometry should be performed preoperatively to assess the adequacy of esophageal peristalsis. pH testing (24-hour transnasal or 48-hour Bravo) may be helpful, but is not mandatory in patients with typical symptoms if esophagitis is present. However, patients without esophagitis and those who have atypical symptoms of GERD or other functional gut disorders, such as irritable bowel syndrome, and those patients with an atypical response to medical therapy require more detailed preoperative investigation, generally including a pH test to prove the presence of GERD. Some transnasal pH probes also have impedance measurement capability, which is helpful to delineate symptomatic non-acid reflux events.

Anatomic Delineation

EGD is an essential part of the evaluation of patients being considered for antireflux surgery. Barrett esophagus usually appears as salmon-colored mucosal extensions up into the distal esophagus and is confirmed by biopsy that shows intestinal metaplasia. Given the increasing incidence of esophageal adenocarcinoma and the association between long-standing heartburn and adenocarcinoma, the gastroesophageal mucosa should probably be assessed endoscopically at least once in all patients with persistent or severe symptoms of GERD. If Barrett esophagus with dysplasia is discovered on biopsy, the patient should be considered for radiofrequency ablation prior to antireflux surgery.

Contrast radiographs of the upper gastrointestinal tract may be helpful to assess the size of any associated hiatal hernia, to localize precisely the gastroesophageal junction in relation to the esophageal hiatus, and to qualitatively assess the adequacy of esophageal peristalsis and gastric emptying.

Physiologic Examinations

The "gold standard" to confirm the presence of GER is a 24-hour esophageal pH assessment, quantifying the number and duration of episodes of acid reflux into the esophagus. Furthermore, this test correlates subjective symptoms with reflux events and differentiates between upright and supine GER. The sensitivity of prolonged pH monitoring in identifying pathologic GER ranges from 50% to 100% (mean, 85%), and the specificity is somewhat higher. This test requires cessation of H_2-blockers for 3 days and PPIs for 7 days prior to testing. The indwelling wireless esophageal probe has made this outpatient test more tolerable than when nasoesophageal probes were used; and although it is still relatively expensive, it also allows for capture of data up to 72 hours. False-negative tests may result from patients refraining from normal dietary and physical activities during the time the pH probe is in place.

Recently, intraluminal impedance monitoring has been added to the arsenal of diagnostic tests for GERD. Diagnosing GERD by pH monitoring alone depends on acid reflux, and may not detect low-acid or non-acid reflux. The precise role of impedance monitoring in the workup of patients with GERD still needs to be defined, but should be considered especially in patients with atypical and refractory symptoms.

High-resolution esophageal manometry should be performed in all patients before antireflux surgery is considered. With this test, the length, location, and pressure of the LES are assessed along with the ability of the LES to relax during swallowing. In addition, and more importantly, both the amplitude and efficacy of swallowing-induced peristalsis of the esophageal body are measured. Esophageal manometry identifies the rare individual with a primary motility abnormality (such as achalasia or scleroderma) with symptoms of GER. The degree of peristaltic failure caused by the GERD can also be assessed. The surgeon may, thereby, gauge whether a full 360-degree fundoplication will likely result in significant dysphagia, which may result in a tailoring of the antireflux operation. Furthermore, if dysphagia develops postoperatively, a baseline

study is of value in determining subsequent treatment.

In patients whose symptoms include significant nausea and vomiting, and in those patients with severe insulin-dependent diabetes, a scintigraphic gastric emptying test should probably be performed to exclude a significant gastric-emptying abnormality. If a marked delay in gastric emptying is diagnosed, a pyloroplasty or pyloromyotomy should be considered at the time of antireflux surgery. Recent studies have demonstrated significant improvement in both symptoms and gastric emptying scintigraphy for reflux patients with severe gastroparesis ($T_{1/2}$ >150 minutes) undergoing combined LNF and pyloroplasty.

Treatment

Medical

Virtually all patients should receive a short-term (2-month) trial of intensive medical therapy before considering an antireflux operation. Modern medical treatment of reflux disease is aimed at decreasing gastric acidity and reducing esophageal exposure to gastric contents with the goal of healing the injured esophageal mucosa, eliminating symptoms, and preventing or treating the complications of GERD. Most patients with GERD have relatively mild symptoms and may be managed empirically without further testing unless accompanied by signs indicative of significant tissue injury (e.g., dysphagia or gastrointestinal blood loss). The primary tenets of GERD management include lifestyle modifications (Table 74.3) and medical therapy. Unfortunately, recommendations for significant lifestyle modifications are usually ignored. Although most patients with GERD can be managed adequately with PPIs, many eventually require escalating doses over time, relapse quickly when medication is stopped, or desire to be free of medications and their significant expense and potential complications. It is this group of patients who may benefit greatly from LARS.

TABLE 74.3 Lifestyle Modifications for Gastroesophageal Reflux Disease

- Weight loss
- Alteration of diet
  - Avoid chocolate, peppermint, fat, onions, garlic, alcohol, caffeine, and nicotine
  - Nothing by mouth for 2–3 hrs before bedtime
- Elevation of head of bed 6–10 in
- Limit potentially precipitating activities, such as bending over or strenuous exercise

Surgical

Indications for Surgical Therapy

Conditions that require a surgical approach to GERD remain controversial. Foremost, the diagnosis of GERD must be clearly established. For a patient with typical symptoms (heartburn or regurgitation), at least one piece of objective evidence of reflux must be present. For patients with atypical symptoms, two pieces of corroborative evidence of GERD should be demonstrated. In addition to objective evidence of GERD, the most common indications for performing antireflux surgery can be summarized as follows: (a) complications of GERD not responding to medical therapy (e.g., esophagitis, stricture, recurrent aspiration or pneumonia, Barrett esophagus); (b) GERD symptoms interfering with lifestyle, despite medical therapy; (c) GERD associated with paraesophageal hernia; (d) chronic GERD requiring continuous drug therapy in a patient desiring discontinuation of medical therapy (e.g., financial burden, noncompliance, lifestyle choice, young age); and (e) intolerance to PPI therapy (Table 74.4).

Some features of preoperative physiologic testing predict a poor response to long-term acid suppression therapy and should be considered as rationale for referral to surgical therapy earlier in the course. These features include diminished contractility of the esophageal body, large hiatal hernia, markedly hypotensive LES, severe erosive esophagitis that is poorly responsive to antacid therapy, and Barrett esophagus.

TABLE 74.4 Indications for Laparoscopic Antireflux Surgery

- Complications of GERD unresponsive to medical therapy
- Esophagitis
- Stricture
- Recurrent aspiration or pneumonia
- Barrett esophagus
- Continued symptoms despite maximal medical treatment
- Symptomatic paraesophageal hernia
- Patient desire to discontinue PPI therapy
- Financial burden
- Lifestyle choice
- Young age
- Intolerance to PPI therapy

Whether the mere presence of Barrett esophagus should be an indication for antireflux surgery remains controversial. The development of Barrett esophagus generally occurs after long-term, severe GERD, and is therefore a marker for patients unlikely to respond to medical therapy. In addition, recent studies suggest that antireflux surgery results in regression of short-segment intestinal metaplasia in up to 35% of patients and regression of low-grade dysplasia to nondysplastic Barrett esophagus in up to 75%. Likewise, surgery has been shown to reduce progression of intestinal metaplasia to dysplasia compared to medical therapy. However, no prospective randomized trial has answered the question whether medical or surgical therapy prevents the progression of Barrett esophagus to adenocarcinoma. Two recent meta-analyses gave conflicting results on this question. Based on these studies, we believe that patients with Barrett esophagus and severe symptoms of GERD should be offered surgical therapy. More data will be required before definitive recommendations can be made regarding the need for operative therapy in patients who have Barrett esophagus but fewer symptoms.

Radiofrequency ablation has emerged as an effective therapy for the eradication of Barrett esophagus. Short-term results have been promising with up to 100% endoscopic and histologic removal of Barrett esophagus and low-grade dysplasia. The use of this modality in conjunction with Nissen fundoplication (to help prevent recurrence of Barrett esophagus) is

now accepted.

Contraindications to Surgical Therapy

Most, if not all, patients with GERD can be managed effectively for short periods of time with intensive medical therapy. A poor response to aggressive medical therapy may therefore portend a poor prognosis after antireflux surgery. There are fewer absolute contraindications to LARS. These include the inability to tolerate a general anesthetic or laparoscopy and an uncorrectable coagulopathy. Numerous conditions, however, render LARS more difficult and should be considered relative contraindications (Table 74.5). These factors include previous upper abdominal surgery, particularly operations around the diaphragm or esophageal hiatus, and severe obesity. In obese patients, access to the abdominal cavity is not generally a problem, but the omentum and gastrosplenic ligament may be bulky and difficult to retract adequately, and fatty infiltration of the left lateral segment of the liver may make exposure of the esophageal hiatus problematic. These patients should be considered for bariatric surgery, as this usually eliminates GERD in addition to addressing obesity-related comorbidities. Chronic reflux can cause stricture and shortening of the esophagus and prevent the creation of a tension-free intra-abdominal gastric wrap, causing wrap disruption or intra-thoracic displacement. The propulsive force of the esophagus must also be sufficient to propel food across a reconstructed valve. If peristalsis is significantly diminished, a partial wrap may be preferable. Patients having the factors listed in Table 74.5 should probably not be managed by surgeons during their initial learning curve of LARS.

TABLE 74.5 Relative Contraindications for Laparoscopic Antireflux Surgery

- Previous upper abdominal (especially subdiaphragmatic) surgery
- Morbid obesity
- Severe esophagitis ± stricture
- Short esophagus
- Large paraesophageal hiatal hernia

Basic Tenets of Antireflux Surgery

The basic tenets of LARS include restoration of an effective LES and creation of a gastroesophageal valve. These concepts are based on a variety of considerations that have been touted in the literature, such as the role of an intra-abdominal segment of esophagus, the function of the gastric muscularis used to wrap around the esophagus, and the physiologic implications of the law of Laplace. Almost all antireflux operations involve plicating the lower esophagus with gastric smooth muscle, usually the gastric fundus. The notable exception to performing fundoplication is the Hill esophagogastropexy, as described elsewhere in this text.

Fundoplication requires wrapping the *fundus* itself, not the body of the stomach, around the *esophagus*, rather than around the proximal body of the stomach. The fundus, unlike the remainder of the stomach, exhibits a physiologic phenomenon known as receptive relaxation that causes decreased tone of the gastric fundic smooth muscle in association with swallowing-induced relaxation of the LES. If the fundoplication is performed around the stomach rather than the esophagus, periodic contractions of the gastric smooth muscle within the wrap are insufficient to allow free passage of intraluminal contents, and therefore result in dysphagia.

The fundoplication should reside within the abdomen without tension, and the crura should be closed adequately to prevent migration of the stomach or the fundoplication into the chest. If this occurs, an iatrogenic paraesophageal hernia has been created.

In general, complete (360-degree) fundoplications such as the Nissen fundoplication create more resistance to flow (both prograde, which may result in an increased incidence of dysphagia, and retrograde, as desired to lessen the risk of postoperative reflux) and may be more durable over the long term than partial fundoplications. In contrast, partial fundoplications have less resistance to flow, both prograde and retrograde, and are associated with less postoperative dysphagia and postoperative abdominal bloating, but have a greater risk of recurrent reflux or disruption of the wrap.

Choice of Approach

The precise mechanism whereby antireflux surgery exerts its effects remains incompletely understood, and each operation works in a slightly different fashion. Currently, most patients are thought to be best suited to an LNF (Table 74.6). Atypical patients, however, may warrant an

alternative approach. Those patients with a short esophagus will require an esophageal-lengthening procedure, in the form of either a laparoscopic Collis gastroplasty or a transthoracic Collis operation. Effort should be made to avoid a lengthening procedure by maximizing the intra-mediastinal esophageal dissection; however, if obtaining 3 cm of intra-abdominal esophagus is not possible, a Collis procedure is necessary. Because of potential acid secretion in the neo-esophagus and the risk of peptic stricture/esophagitis, these patients should be given postoperative PPI therapy. Patients who have undergone previous subdiaphragmatic foregut surgery or have a hostile abdomen from multiple prior operations may also be best served by a transthoracic approach. Individuals who have previously undergone partial gastrectomy may not have adequate fundus to perform a true fundoplication and may require an alternative operation, such as the Hill esophagogastropexy.

TABLE 74.6 Choice of Operation for Antireflux Surgery

Typical Patient
■ Transabdominal (laparoscopic) fundoplication
Atypical Patient
■ Esophageal-lengthening procedure (Collis)
■ Transthoracic operation (Belsey)
■ Esophagogastropexy (Hill)
■ Esophageal resection

Transthoracic

The primary transthoracic operation used for the control of GER has been the Belsey Mark IV (Chapter 68). In this operation, the distal esophagus is mobilized, and the proximal stomach is delivered through the esophageal hiatus. An anterior 270-degree plication of the fundus is performed up onto the esophagus, buttressed by the diaphragmatic crura. The usual mode of access for the Belsey repair has been a left thoracotomy. McKernan and Champion reported early follow-up on a small series of thoracoscopic-modified Belsey fundoplications with excellent results; however, a recent 5-year follow-up demonstrated high morbidity and recurrence.

Transabdominal

In the total or complete fundoplications, the fundus of the stomach is wrapped circumferentially around the lower esophagus. First described in 1956, the Nissen fundoplication, with various modifications from the original description, has long been the preferred surgical alternative to medical therapy for the treatment of refractory GERD. The fundoplication is accomplished by circumferentially dissecting the distal esophagus, mobilizing the gastric fundus, and plicating the fundus around the lower esophagus, creating a high-pressure zone. This increases the resting tone of the sphincter mechanism, diminishes transient lower esophageal sphincter relaxations, and improves its response to elevated intragastric pressure. Nissen's original description of the operation involved mobilizing the abdominal esophagus and lesser curvature of the proximal stomach and wrapping the posterior wall of the fundus around to join the anterior aspect of the fundus. The newly created fundoplication varied from 3 to 6 cm in length and included the esophageal wall in the fundoplication. Nissen did not describe division of the short gastric vessels using his technique. Two surgeons working with Nissen modified the technique, again without division of the short gastric vessels, to wrap the anterior portion of the fundus around the esophagus such that even less mobilization of the upper stomach was required. This is the Rossetti or Rossetti-Hill modification of the Nissen fundoplication as described elsewhere in the text (Fig. 74.2).

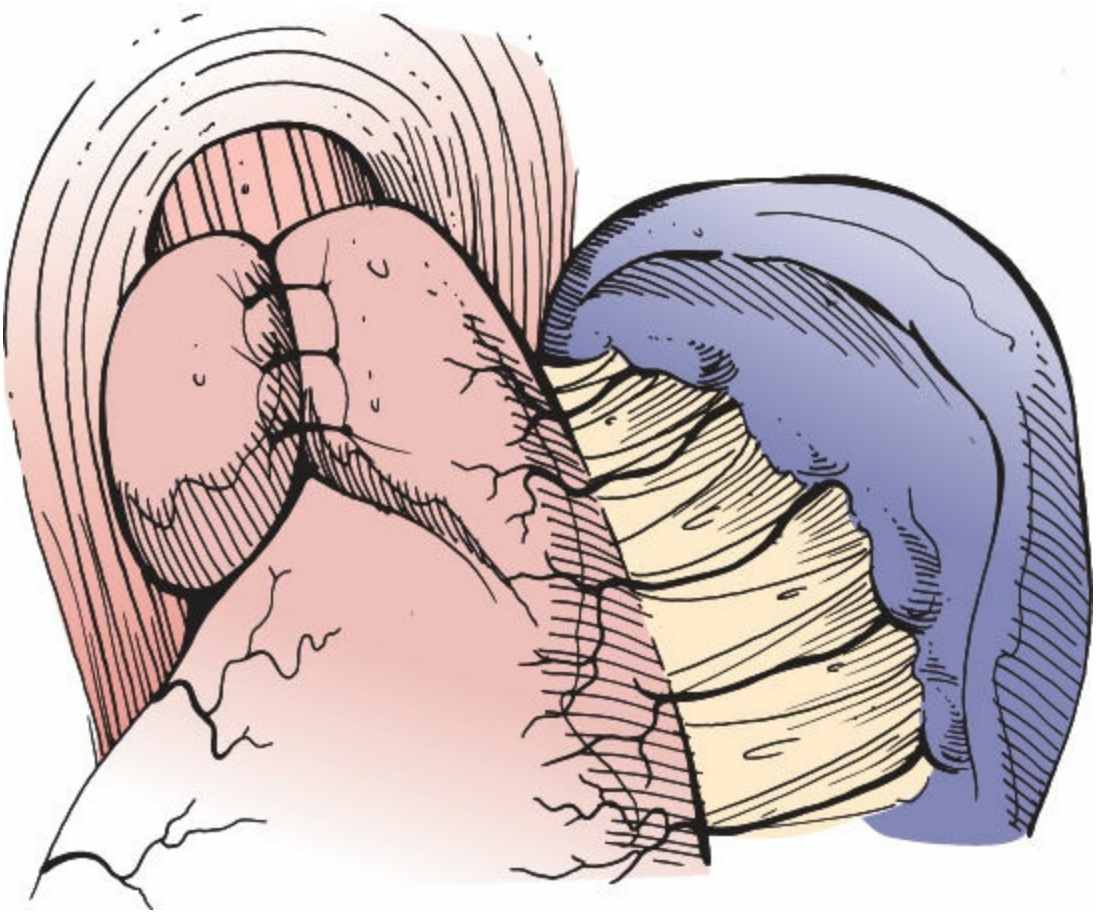


Figure 74.2. Rossetti–Hell modification of the Nissen fundoplication. The Rossetti or Rossetti–Hell modification of the Nissen fundoplication includes wrapping the anterior portion of the fundus around the esophagus without division of the short gastric vessels and with minimal mobilization of the upper stomach, creating a 3- to 6-cm 360-degree fundoplication.

However, most surgeons in the United States today perform a *short, floppy Nissen fundoplication.* In this modification of the Nissen fundoplication, the short gastric vessels are divided with full fundic mobilization. The lateral border of the fundus is wrapped around the esophagus and sutured to the anterior edge of the medial fundus, creating a short (<2.5 cm) fundoplication that is usually fashioned over a No. 50 to 60 French esophageal dilator (Fig. 74.3).

Partial Fundoplications

Partial fundoplications have been used because of concerns that the complete fundoplication may be hypercontinent, leading to some of the well-described postoperative sequelae of the Nissen fundoplication, such as dysphagia, inability to belch, and the gas-bloat syndrome. Partial

fundoplications attempt to provide effective reflux prevention with minimal esophageal outflow resistance. In general terms, partial fundoplications are more difficult to conceptualize and perform for the novice surgeon, limiting their widespread application. There are also concerns that the long-term durability of such repairs will not be as good as that for the Nissen fundoplication. Some surgeons use partial fundoplications for all patients who are undergoing antireflux surgery, whereas other surgeons use partial fundoplications in specific situations. Possible indications for selective use of partial fundoplications are listed in Table 74.7. These include diminished esophageal motility, either primary or secondary, severe aerophagia, reoperative situations, or anatomic conditions that preclude a tension-free complete fundoplication.

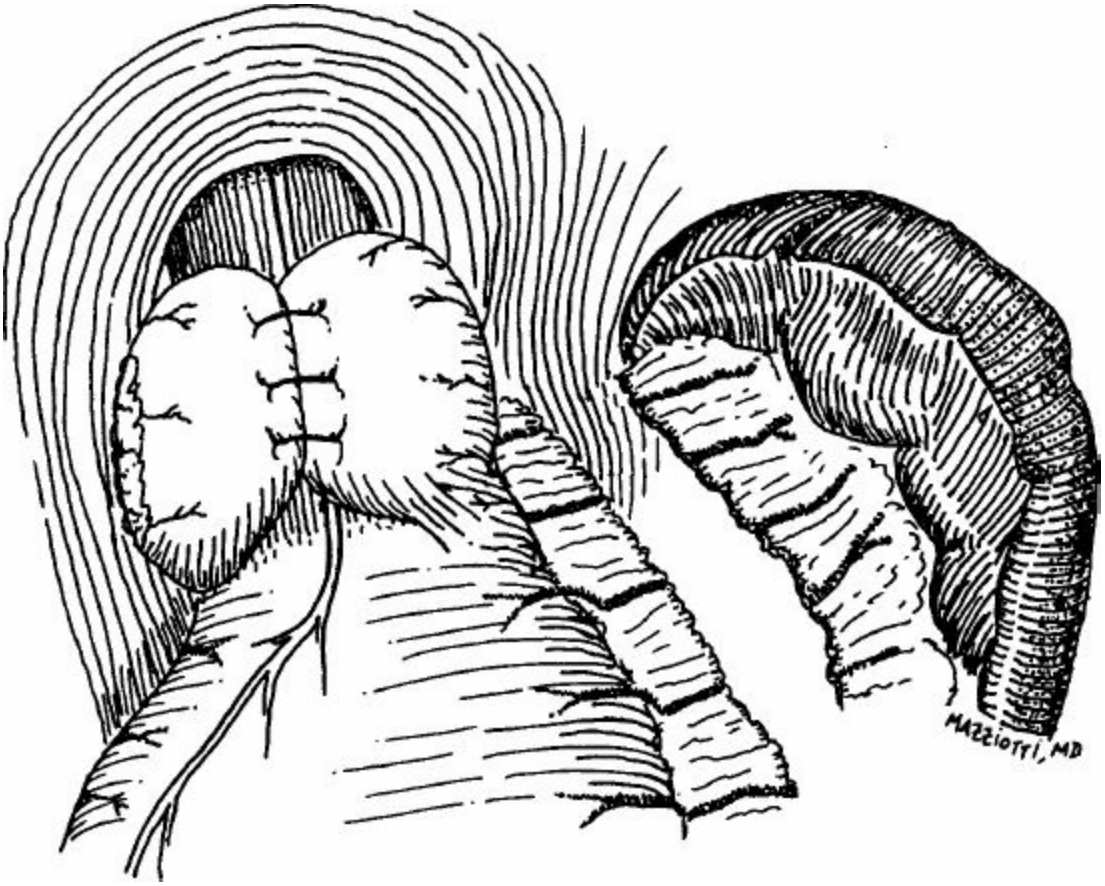

Figure 74.3. "Short and floppy" Nissen fundoplication. *The short, floppy Nissen fundoplication* is a modification of the complete fundoplication in which the short gastric vessels are divided with full fundic mobilization, and the lateral border of the fundus is wrapped around the esophagus and sutured to the anterior edge of the medial fundus. The fundoplication is short (<2.5 cm), is created with three interrupted sutures 5 to 8 mm apart, and is fashioned over a large esophageal dilator. (Reprinted with

permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

TABLE 74.7 Indications for Partial Fundoplication

- Poor esophageal clearance because of esophageal motility abnormality
- Severe aerophagia, particularly in patients with daytime reflux associated with belching
- Insufficient gastric fundus to allow a loose total fundoplication (i.e., tubular stomach, previous gastrectomy)
- Psychological inability to tolerate the side effects of fundoplication
- In association with Heller myotomy for achalasia

A partial listing of the types of partial fundoplications in use is outlined in Table 74.8. These include anterior fundoplications, posterior fundoplications, and the Hill esophagogastropexy. All of these operations have been performed laparoscopically. The Dor fundoplication (Fig. 74.4) is a 180- to 200-degree anterior fundoplication that has been used primarily in association with laparoscopic Heller esophagomyotomy for achalasia. The Watson fundoplication involves fixation of the esophagus in an intra-abdominal location with plication of the fundus along the left anterolateral border of the esophagus and has been championed as a more "physiologic" antireflux procedure. The Hill repair (Fig. 74.5) involves plication of the lesser gastric curvature around the right side of the esophagus with an esophagogastropexy to the median arcuate ligament. Because this operation requires intraoperative manometry for optimal performance, it has not been applied widely.

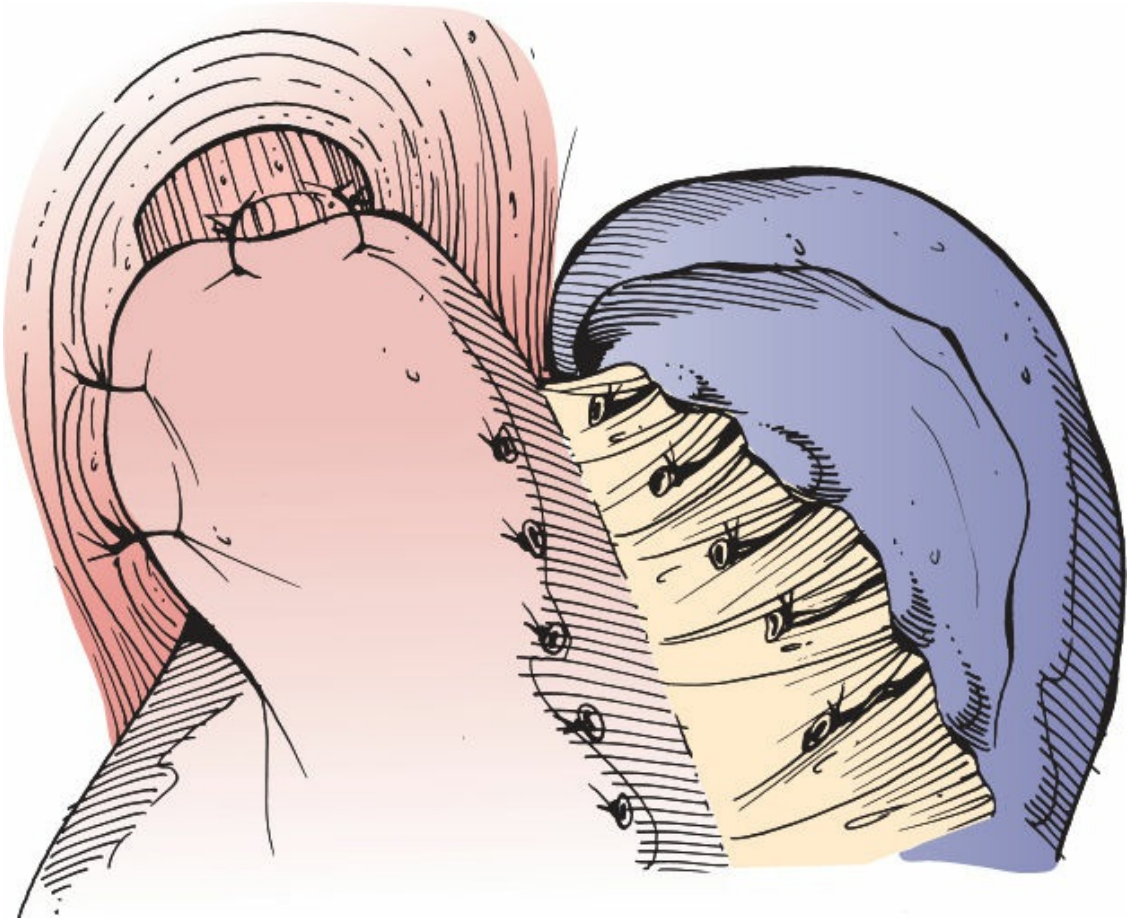

Figure 74.4. Dor fundoplication. The Dor 180- to 200-degree anterior fundoplication is used primarily in association with laparoscopic Heller esophagomyotomy for achalasia.

The Toupet fundoplication and its variations (e.g., Guarner, Lind) have been the most commonly used partial fundoplication since the introduction of laparoscopic fundoplications (Fig. 74.6). With this procedure, the fundus is pulled posterior to the esophagus with suture of the leading edge of the wrapped fundus to the right anterior aspect of the esophagus while the left (medial) side of the fundus is sutured to the left anterolateral aspect of the esophagus. Varying numbers of sutures may be placed between the fundus and the crura for further stabilization.

TABLE 74.8 Alternative Procedures and Their Variations

Procedure	Type of Fundoplication
Partial fundoplications	Belsey Mark IV 270-degree anterior (transthoracic) Dor 180- to 200-degree anterior Thal 90-degree anterior Toupet 270-degree posterior Watson 120-degree anterolateral
Esophagogastropexy	Hill repair 90-degree lesser-curve plication

LAPAROSCOPIC ANTIREFLUX SURGERY

Technical Principles

Laparoscopic antireflux operations are advanced laparoscopic procedures requiring skills that are best developed and practiced in a nonclinical setting to facilitate efficiency and superior technical performance in the human operating room. Technical principles common to all fundoplications include the following:

Dissection should be done away from the esophagus, and the esophagus should never be directly grasped or manipulated with traumatic instruments to avoid esophageal wall injury.
All dissection must be performed under direct vision.
The fundus, rather than any other part of the stomach, must be plicated around the esophagus, rather than around the proximal stomach.
There must not be tension present at the conclusion of the fundoplication, either axially (tending to pull the repair up through the hiatus into the mediastinum) or rotational (pulling the fundus counterclockwise back to the left, creating a twist of the lower esophagus).

Preoperative Planning

During the preoperative office visit, the expectations and risks of LARS are discussed with the patient. Patients are counseled that if at any point a laparoscopic approach cannot be continued safely, the operation will be converted to an open procedure. Gastric or esophageal perforation, injury to the vagus nerves, spleen, or other abdominal viscera, dysphagia, and bloating are all delineated as potential complications and that disruption of the crural repair or wrap as well as migration of the wrap into the mediastinum may require reoperation. Healthy patients are admitted the day of surgery after an overnight fast.

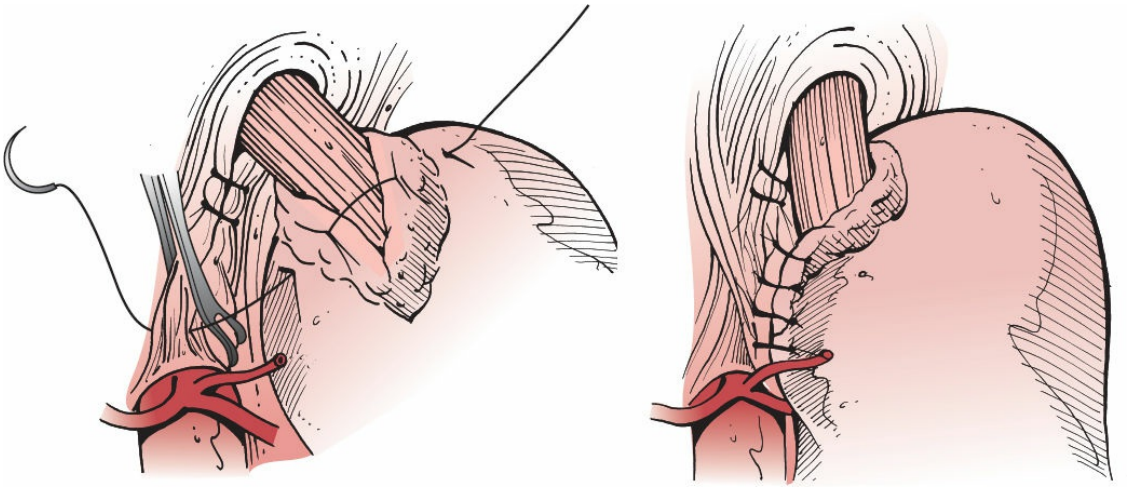

Figure 74.5. Hill esophagogastropexy. The Hill repair involves plication of the lesser gastric curvature around the right side of the esophagus with an esophagogastropexy to the median arcuate ligament, and requires intraoperative manometry for optimal performance.

Patient Positioning and Equipment

The patient must be carefully positioned to protect both the patient and the surgeon from injury and muscular fatigue. Wires, tubes, and other connections to the laparoscopic equipment must be organized to minimize inconvenience and entanglement while maximizing the ergonomics of the operating space. The surgeon stands between the patient's abducted legs facing directly forward during the operation. The legs may be abducted with low lithotomy stirrups or flat, padded boards that allow the knees to be extended and minimize the potential for lower extremity neurovascular traction injury. Video monitors are positioned at the head of the table to allow ergonomically neutral visualization by the surgeon and the assistants. The patient must be firmly affixed to the operating table and padded in the appropriate locations because the table is generally maintained in steep head-up position to allow gravity to displace the abdominal viscera from the subdiaphragmatic region and bring the patient's upper abdomen toward the surgeon. Our practice is to use a vacuum beanbag mattress that supports gently around the patient's sides and perineum to prevent intraoperative movement. The table must be positioned at an appropriate height and angle to permit the surgeon to operate with the hands in a neutral position to prevent shoulder and elbow fatigue.

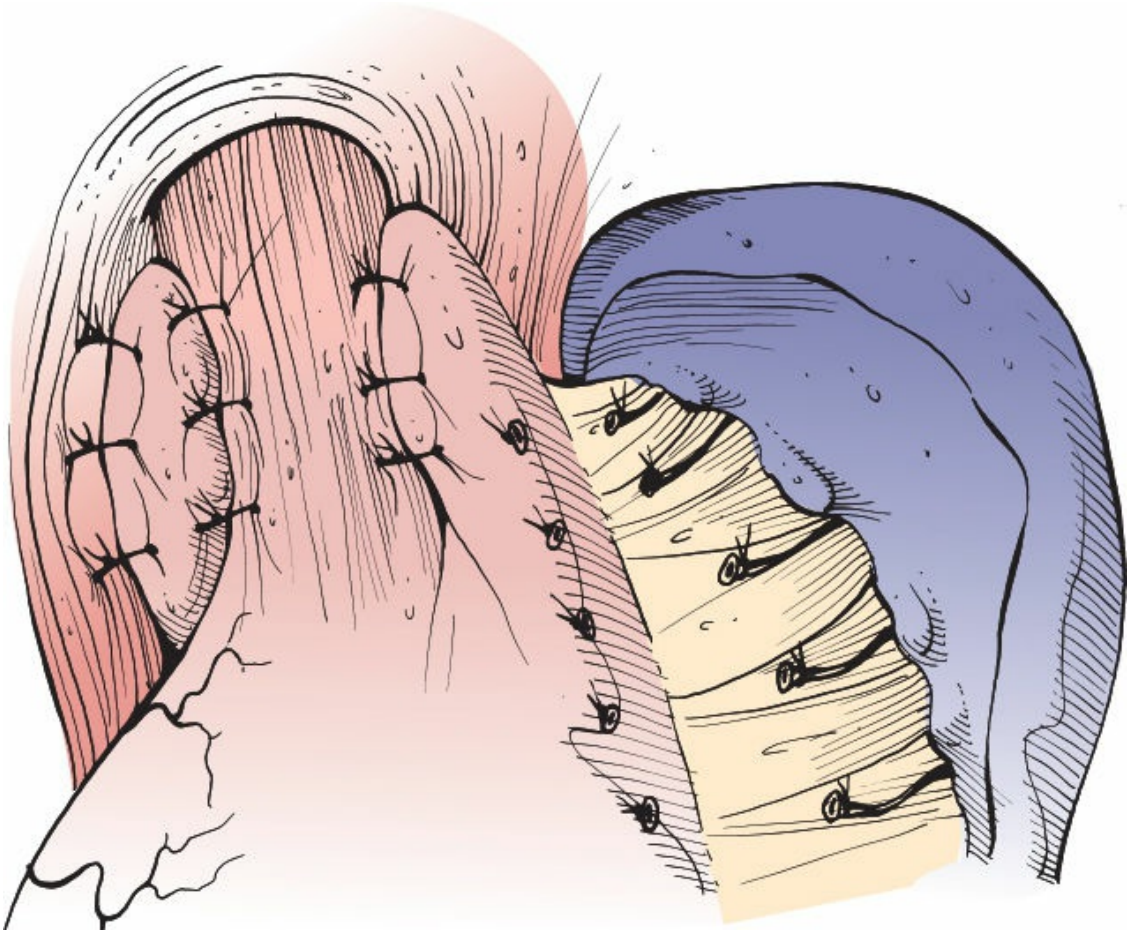

Figure 74.6. Toupet fundoplication. The Toupet fundoplication and its variations have been the most commonly used partial fundoplication since the introduction of laparoscopic fundoplications. The fundus is pulled posterior to the esophagus with suture of the leading edge of the wrapped fundus to the right anterior aspect of the esophagus while the left (medial) side of the fundus is sutured to the left anterolateral aspect of the esophagus. Varying numbers of sutures may be placed between the fundus and the crura for further stabilization.

Several basic varieties of instrumentation are recommended to facilitate the performance of LARS. These include angled laparoscopes (either 30 or 45 degrees), which allow alternative views of the operative field and adequate visualization of the retrofundic and retroesophageal regions. An adequate, atraumatic liver retractor is imperative to allow the left lateral segment of the liver to be elevated for prolonged periods without capsular injury. We use a self-retaining device to hold the liver retractor in an immobile position throughout the operation. This prevents boredom and fatigue by the assistant and decreases the frequency with which the liver retractor is repositioned, and thus the chance of capsular injury.

Atraumatic grasping instruments should be available, including Babcock and DeBakey-type forceps. Appropriate instrumentation for achieving hemostasis and dividing tissues bloodlessly should also be available. These instruments include bipolar and/or monopolar electrosurgical devices, and ultrasonic coagulation and cutting devices. The equipment must be maintained on a regular basis, and back-up instruments should be available in the case of intraoperative failure of any of the devices. Also, a flexible endoscope should be available to allow intraluminal evaluation of the esophagus and stomach, should the need arise.

Abdominal Access and Port Placement

The esophageal hiatus is usually located directly posterior to the xiphoid process. Laparoscopic instruments are generally 30 to 40 cm in length. Ideally, the instrument midpoint should be located at the level of the abdominal wall (fulcrum) during critical portions of advanced laparoscopic procedures to maximize its range of motion during tissue manipulation and establish a 1:1 ratio between external hand movements and internal instrument tip translations. The ports are thus positioned in an arc between 10 and 15 cm inferior to the xiphoid process and costal margin, which are marked prior to pneumoperitoneum.

An open or closed technique may be used to access the peritoneal cavity. With the open technique, a cutdown is performed through a small incision; the fascia is incised under direct vision; sutures are placed at the fascial level; and the peritoneal cavity is entered under direct vision. A Hasson-type trocar and sheath is then placed into the peritoneal cavity, and the abdomen is insufflated with carbon dioxide gas. Alternatively, a Veress needle may be passed directly into the peritoneal cavity. Appropriate maneuvers are performed to document a safe intraperitoneal location of the needle tip, and the peritoneal cavity is insufflated to a pressure of 12 to 15 mm Hg.

Because the esophagus generally enters the abdomen from a slightly right-to-left orientation, and because the falciform ligament and liver limit the right lateral placement of the port for the surgeon’s left hand, we generally place the laparoscope to the left of the midline in a supraumbilical location approximately 12 cm caudal to the midline costal margin (Fig. 74.7). This positioning also prevents the initial port being place within the ligamentum teres. An infraumbilical port site is generally too far inferior on the abdominal wall for operations at or around the

esophageal hiatus.

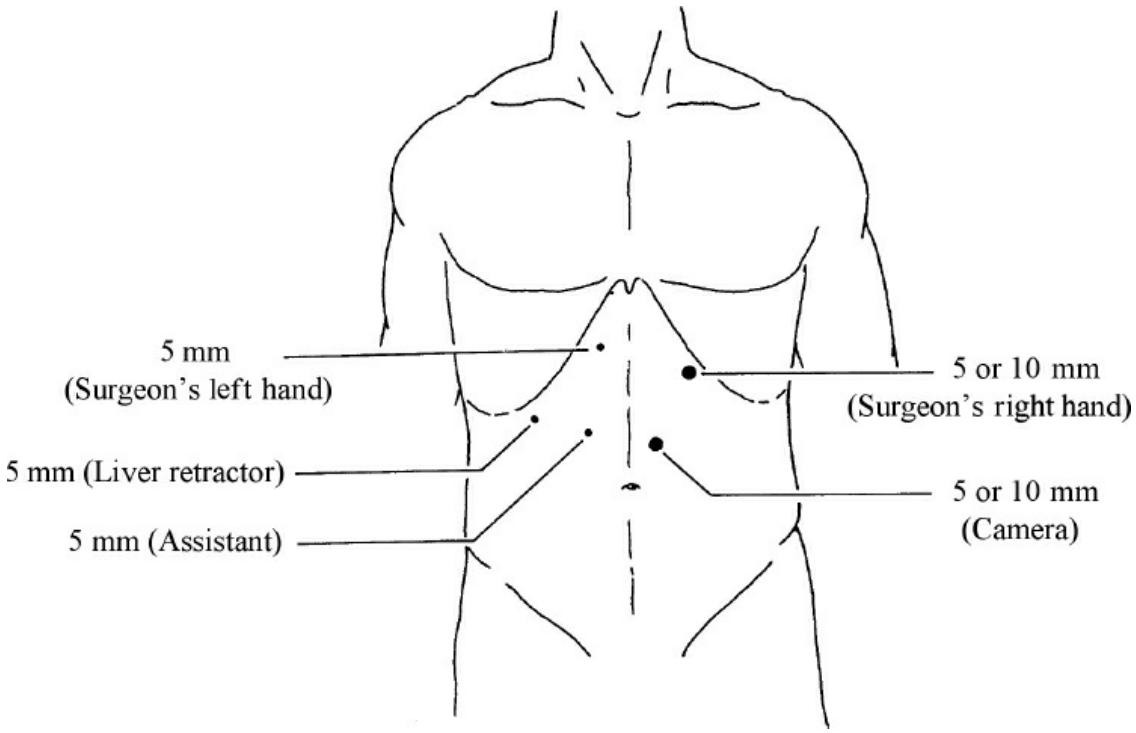

Figure 74.7. Port placement. The costal margin and xiphoid process are marked prior to pneumoperitoneum. The laparoscope is placed to the left of the midline in a supraumbilical location approximately 12 cm caudal to the xiphoid process. With the camera port to the left of midline, the surgeon's right-hand 10-mm port is generally 10 cm from the xiphoid and two fingerbreadths below the left costal margin. A 5-mm right lateral port for the liver retractor is placed at least 15 cm from the xiphoid process two fingerbreadths below the right costal margin. The 5-mm assistant's port is located halfway between the camera and liver retractor. The surgeon's left-hand 5-mm port is inserted after the liver retractor is placed and is generally 5 to 10 cm from the xiphoid process in a right paramedian location.

The skin incision is made in the appropriate location, and a radial dilating sheath and trocar are inserted while the abdominal wall is manually elevated for countertraction. The laparoscope is inserted and a visual exploration is performed of the abdominal cavity, with particular attention paid to the area immediately posterior to the initial trocar insertion site. Currently, we believe that the 10-mm diameter high-definition laparoscopes provide a better video image for advanced procedures because they allow a wider field of view and more brilliant

illumination, even though the use of 2- and 5-mm scopes has been described by other surgeons.

The patient is then rotated into a severe reverse Trendelenburg position, and the accessory ports are placed under direct vision. For optimal visual orientation, the working instruments should be entering the operative field from a 30- to 60-degree angle on either side of the laparoscope. The surgeon's right-hand port is generally placed 10 cm from the xiphoid and two fingerbreadths below the left costal margin. Surgeon preference and instrument use pattern dictate the size of this trocar. We continue to use a 10-mm port because an SH-size needle can be inserted through the valve, whereas if a 5-mm port is used, straight or "ski" needles must be used for suturing. Other "automatic" suturing devices also require a 10-mm port. The 5-mm liver retractor port is then placed at least 15 cm from the xiphoid process two fingerbreadths below the right costal margin. The assistant's 5-mm port is placed halfway between the camera and liver retractor ports. The left lateral segment of the liver is elevated with a self-retaining liver retractor before the surgeon's left-hand 5-mm port is placed. Its precise location depends to an extent on the size and location of the retracted liver and the shape of the liver retractor itself. A Veress needle can be used to "sound out" potential sites on the abdominal wall for this port placement before the incision is made and the final trocar and sheath are inserted.

Other surgeons have described alternative techniques in which the assistant stands to the left of the patient and manipulates tissue through a port placed in the left subcostal region. Others prefer the laparoscopic camera port to be placed in a midline position. Each of these alternatives for port positioning is valid, and surgeons must decide the optimal positioning for the operating team.

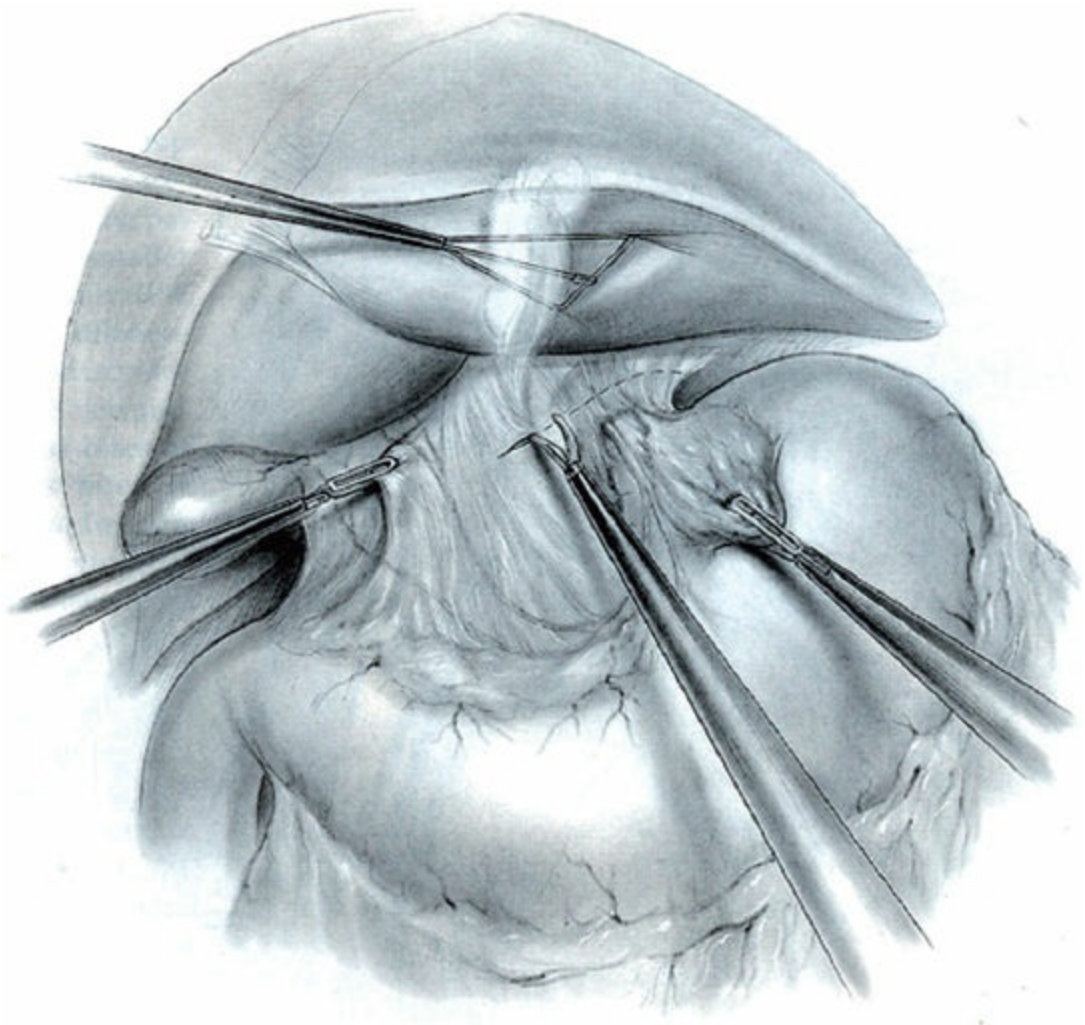

Figure 74.8. Initial dissection: division of gastrohepatic ligament superior to the hepatic branch of the vagus nerve. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

Initial Dissection

The anterior gastric wall or the gastroesophageal fat pad is then grasped by the assistant and pulled caudally and to the patient's left, placing traction on the gastrohepatic omentum. The gastrohepatic omentum is divided, beginning just superior to the hepatic branch of the vagus nerve (Fig. 74.8). The surgeon must be wary of the aberrant left hepatic artery of Hyrtl running beside the hepatic branch of the vagus nerve. Although they are encountered in fewer than 5% of patients, they may comprise the majority of arterial inflow to the left lateral segment of the liver. The hepatic branch of the vagus nerve generally does not need to be divided to gain adequate

visualization as long as there is not a large hiatal hernia and one is using an angled laparoscope. The gastrohepatic omentum is divided up to the level of the right crus of the diaphragm and the phrenoesophageal membrane is divided in a transverse direction, with care taken to divide only the most anterior portion to prevent injury to the underlying esophagus and anterior vagus nerve. The gastric fundus is then pulled inferiorly and to the right. The gastrophrenic ligament is divided to mobilize the gastric cardia.

A meticulous dissection is then undertaken around the esophageal hiatus (Fig. 74.9). During the hiatal dissection, the assistant retracts the fat pad inferiorly to place tension on the distal esophagus. Having already divided the phrenoesophageal membrane, it is generally easy to insinuate a blunt-tipped instrument just medial to the right crus of the diaphragm and to establish a plane between the esophagus and the right crus. The surgeon's left-hand instrument grasps or pushes the crus to the patient's right, while the right-hand instrument gradually and gently sweeps the esophagus and paraesophageal tissue to the left to bluntly mobilize the distal esophagus. The posterior vagus nerve is generally clearly seen and is swept along with the esophagus to the left. This mobilization continues in an orad direction as far as possible and then distally to the level of the crus. The tissue attached to the medial border of the base of the right crus is divided until the origin of the right crus from the left crus is visualized from the right side of the esophagus.

Once the right side of the esophagus has been mobilized, the surgeon's right-hand instrument sweeps anterior to the esophagus and elevates the anterior crural arch while gently pushing the esophagus posterior with the blunt side of the left-hand instrument. The posterior-medial aspect of the left crus is visualized, and all of the paraesophageal tissues are swept posteriorly to develop the plane to the left of the esophagus. Generally, the anterior vagus nerve and left pleura are visualized at this time. The initial dissection of the mediastinum is therefore completed, freeing the esophagus from the pleura, the aorta, and the lateral crural attachments. The anterior and posterior vagus nerves are clearly identified to avoid injury. If the pleura are inadvertently lacerated during the dissection, the surgeon must communicate with the anesthetist that this event has occurred. Assuming that the lung parenchyma is not injured, the capnothorax (carbon dioxide) generally poses no serious complications to the patient. The anesthetist can increase the airway pressure while the surgeon slightly decreases the insufflator's pressure limit, and adequate

ventilation and perfusion can usually be maintained. It is almost never necessary to place a chest tube for these pleural tears.

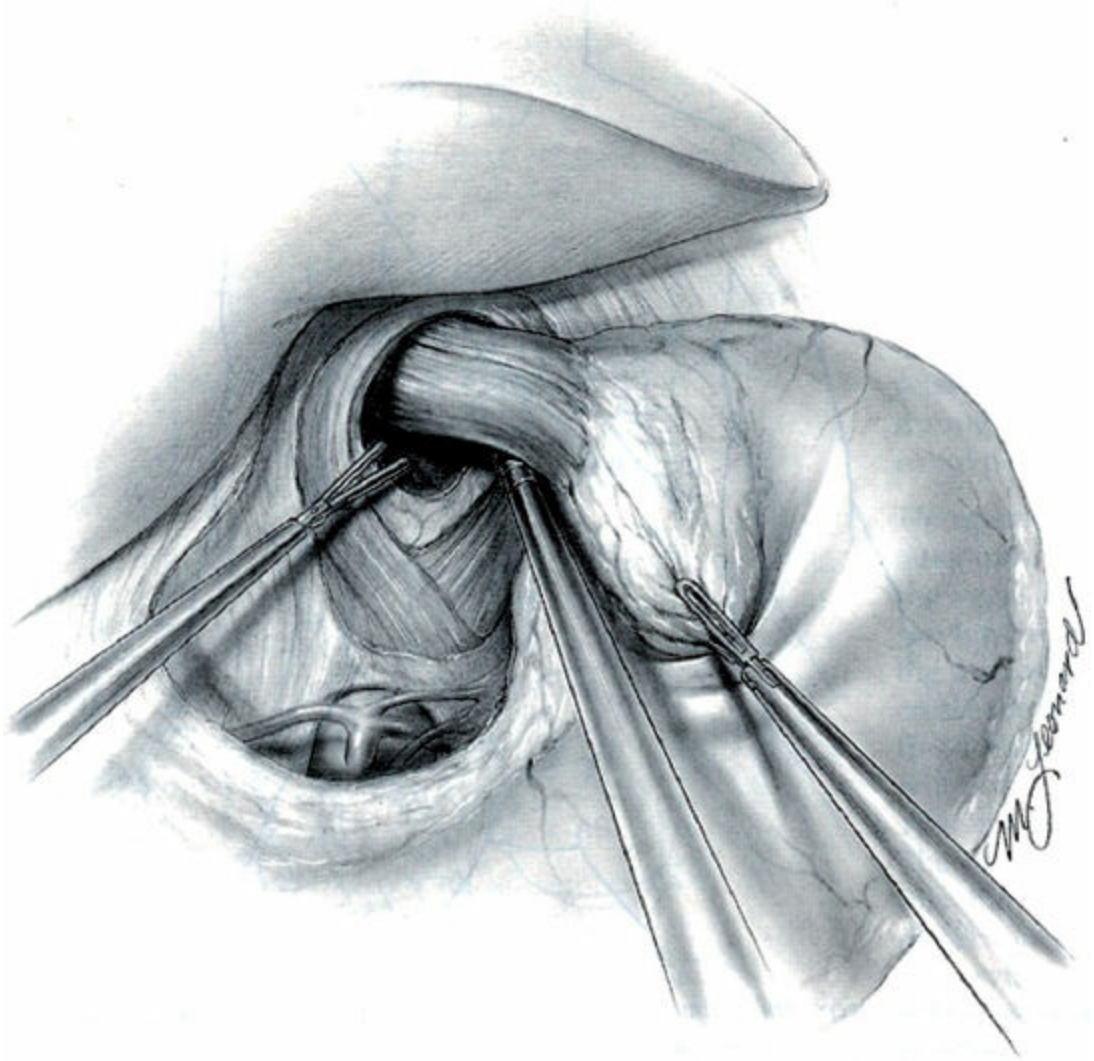

Figure 74.9. Retraction of the fat pad, crural dissection, and identification of vagus nerves. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

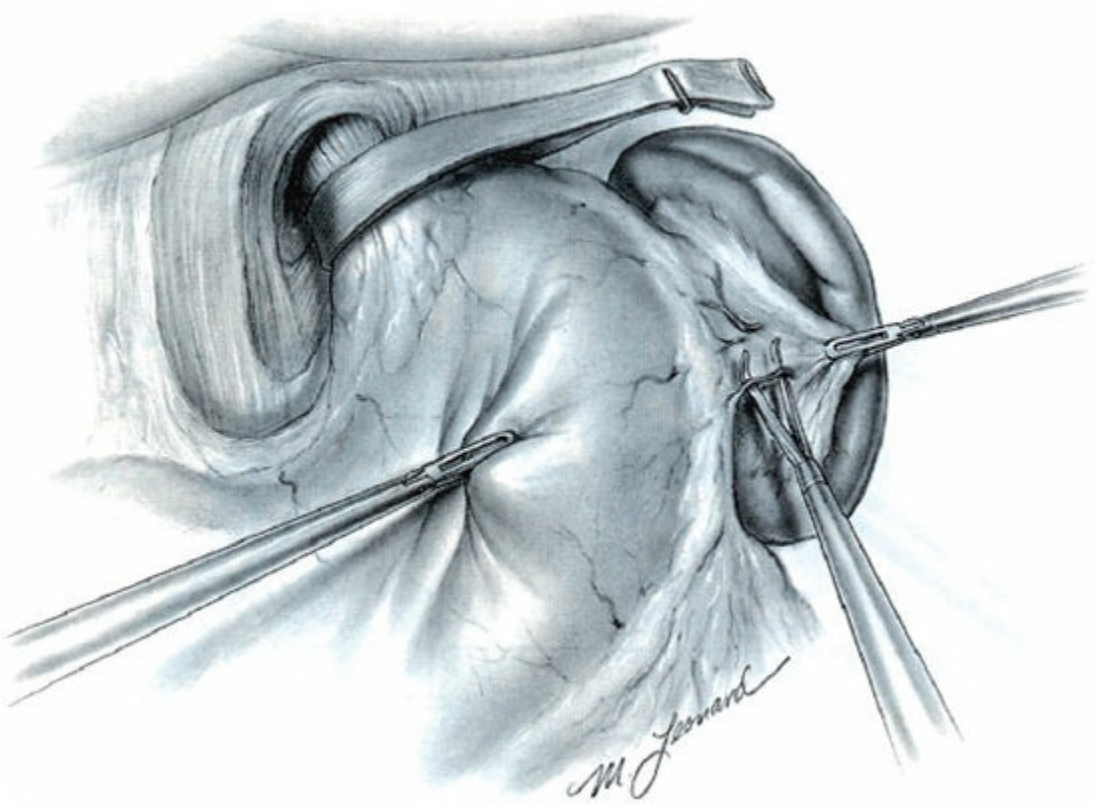

Figure 74.10. Division of the short gastric vessels to the base of the left crus to allow complete fundic mobilization. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery*. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

The gastric fundus is then mobilized (Fig. 74.10). The left lateral border of the fundus is grasped, elevated, and retracted to the right while the gastrosplenic ligament is grasped, elevated, and retracted to the left. Division of the short gastric vessels is started at a point 10 to 15 cm inferior to the angle of His. The precise location is different with each patient, and it probably makes no difference if excessive fundus is mobilized, but there may be difficulty in creating a tension-free wrap if an inadequate length of fundus is mobilized. We select a point orad to the most proximal gastroepiploic vessels, which are identified by their caudally directed orientation. At this site, a short gastric vessel is identified visually, and a “window” is made between the short gastric vessel and the gastric wall. With the use of a small amount of blunt dissection, entry can usually be made into the free lesser sac, identified by visualizing the space bounded medially by the posterior gastric wall. Once entry into the lesser sac has been gained, traction on the stomach and countertraction on the

gastrosplenic ligament are maintained to align the greater curvature of the stomach with the visual axis of the laparoscope. The short gastric vessels and all other attachments to the fundus are then divided sequentially, proceeding from distal to proximal until the entire fundus has been mobilized.

Division of this tissue may be performed with individually placed clips and sharp division, ultrasonic shears, or bipolar electrosurgery. Prospective randomized trials have shown the ultrasonic shears to perform this task more rapidly and more cheaply than clipping and sharp division. Although we and others have shown an improved outcome with regard to dysphagia and wrap disruption when the fundus is fully mobilized, a prospective randomized trial showed no benefit to short gastric vessel division, although the degree of fundic mobilization in this study was not clear. Division of the short gastric vessels, however, is clearly necessary in certain anatomic situations to allow a tension-free fundoplication. Performing this maneuver routinely develops increased skill and confidence. Dividing the short gastric vessels enhances visualization of the high retrogastric space, which facilitates division of the gastropancreatic ligaments and the posterior gastric vessels. The sites of insertion of the short gastric vessels also clearly identify the lateral border of the fundus, which will later be used for the fundoplication. For all of these reasons, we advocate division of the short gastric vessels and full mobilization of the fundus during all fundoplications.

After complete fundic mobilization, the retroesophageal space is visualized from the left side. The medial border of the left crus of the diaphragm is dissected back to its junction with the right crus, joining the plane previously begun from the right side. A large window is thereby created posterior to the esophagus and the proximal stomach, and anterior to both crura. Once the window is created, many surgeons place a Penrose drain for inferior traction on the gastroesophageal junction (Fig. 74.11). This is a useful maneuver and should be encouraged if traction is difficult to achieve by other means. We generally use the fundus as a retractor, reaching from right to left behind the esophagus to grasp the fundus and retract it back to the right side behind the esophagus. Placing caudal traction on the wrapped fundus, the gastroesophageal junction and distal esophagus can be brought further into the abdominal cavity.

Once the fundus has been pulled to the right behind the esophagus, it is checked for rotational tension and torsion. To assess rotational tension, the

wrapped fundus is released and observed. If it retracts back around the esophagus to the left, there is tension that must be eliminated by dividing more fundal attachments. To check for a twist or entrapment of the wrapped fundus in the posterior window, the “shoeshine” maneuver is performed (Fig. 74.12). The leading edge of the fundus that has been passed behind and to the right of the esophagus is grasped, along with the fundus to the left of the esophagus. The fundus is then retracted back and forth to make sure that it slides easily, the tissues on both sides are in continuity, and the fundus is not twisted.

The distal esophagus is checked to make sure that it has been adequately mobilized to allow at least 3 cm to reside within the abdomen when the traction is released. If this is not possible, further esophageal mobilization must be performed within the mediastinum. If it is not possible to mobilize the esophagus to allow an adequate length of intra-abdominal esophagus, an esophageal lengthening procedure should be performed.

After adequate esophageal mobilization, the crura are re-approximated posterior to the esophagus. Inferior and left lateral traction is maintained on the proximal stomach either by atraumatic graspers placed on the wrapped fundus or with the sling of Penrose drain (Fig. 74.13). One or more sutures are always used to close the crura because even in the absence of a hiatal hernia preoperatively, an iatrogenic one has been created by the paraesophageal dissection. The crura are initially closed posterior to the esophagus, but we usually add one anterior suture to stimulate scarification in this location. We generally use 0 or 2-0 nonabsorbable braided polyester sutures on an SH needle for this purpose. The intra-abdominal crural fascia is incorporated in the sutures rather than the muscle body alone. The crura are closed until they lightly touch the empty esophagus, but it should be possible to pass an instrument between the esophagus and the crura. Esophageal dilators stiffen the esophagus and make it difficult to retract the esophagus anterior for adequate visualization of the posterior crural closure and are, therefore, not used during crural closure.

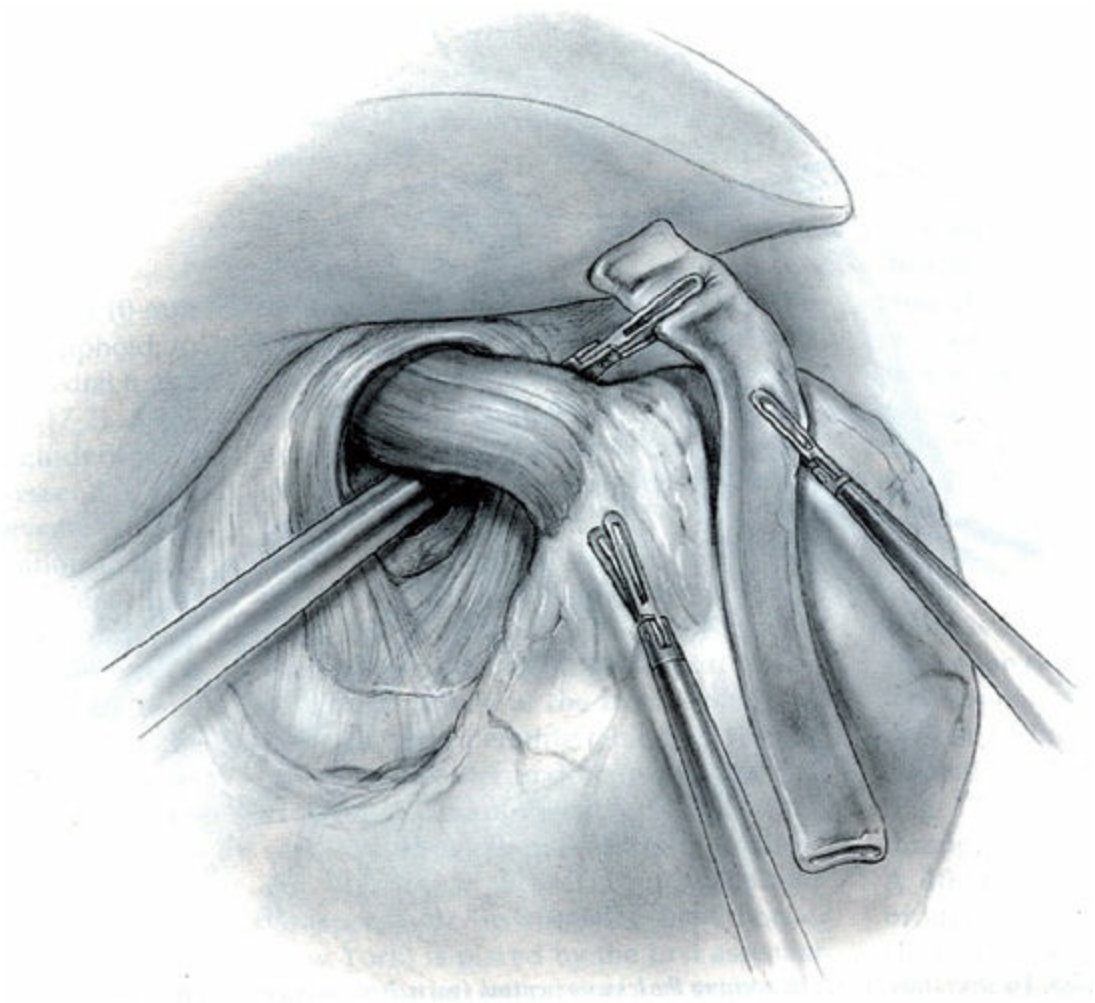

Figure 74.11. A Penrose drain is placed around the esophagus or the gastric fundus is pulled posterior and to the right of the esophagus to provide inferior retraction (optional). (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

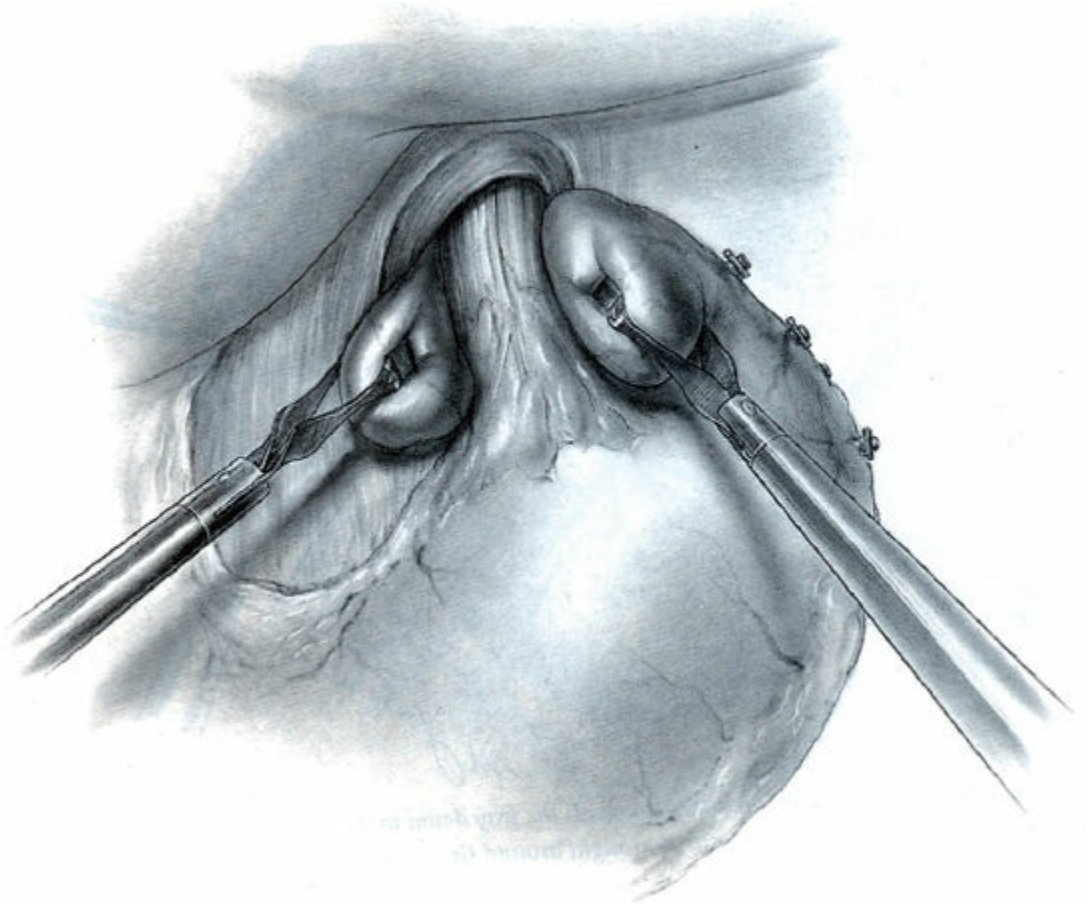

Figure 74.12. The gastric fundus is first pulled posterior and to the right of the esophagus and the “shoeshine” maneuver is performed to ensure that it slides easily and is not twisted. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

If closure of the crura appears to be under tension, we now consider performing a right side crural relaxing incision. In the past, we routinely reinforced the crural sutures with bioprosthetic mesh when repairing large hiatal hernias, as promising studies showed reduced rates of reherniation up to 1 year post-op. However, a 5-year follow-up study showed equal rates of re-herniation with or without mesh. We discourage the use of prosthetic material immediately adjacent to the esophagus; it should not be placed circumferentially, and every type of prosthesis has been reported to have the capacity to erode into the esophagus or proximal stomach.

Fundoplication

Most authors advocate the placement of an indwelling bougie dilator during creation of the wrap. We serially pass No. 50 and 60 French Maloney dilators and suture the fundoplication with a dilator in place. Great care must be taken during the passage of the dilators to prevent inadvertent perforation of the esophagus or stomach. The gastroesophageal junction should be maintained in a nonangulated position by the surgeon and the assistant. The dilators are placed under direct vision with clear and constant communication maintained between the individual inserting the dilator and the surgical team. The two sides of fundus are then abutted around the distal esophagus to ascertain whether a tension-free wrap may be achieved.

The medial fundus to the left of the esophagus is then sutured to the leading edge of the wrapped fundus to the right of the esophagus. This may be accomplished with the use of a single-pledgeted horizontal mattress suture of 0 or 00 polypropylene suture or with several interrupted braided polyester sutures. We have used the latter approach. Three heavy-gauge nonabsorbable sutures on SH needles are used, taking deep seromuscular, but non-fullthickness, suture bites in the fundus to the left and right of the esophagus spaced approximately 5 to 8 mm apart (Fig. 74.3). One or two of the three sutures catch the anterior muscularis of the esophagus to the right of the anterior vagus nerve. Great care must be taken during knotting of the sutures to prevent anterior traction, which could cause a tear of the esophageal wall. The dilator is then removed, and the wrap is checked for degree of looseness by passing a 5-mm diameter instrument between the left side of the wrap and the esophagus. The length of the fundoplication should be <2.5 cm, and it must be situated around the esophagus rather than inferiorly on the proximal stomach. The gastroesophageal fat pad is not excised in most patients unless it is so large that it interferes with the ability to perform an adequate fundoplication. The fat pad functions as a handle and is a visual marker of the angle of His. The suggested orientation of the wrap (the point on the esophagus at which the two sides of fundus are joined) varies in different centers. Some surgeons advocate that this junction be placed at the right lateral position of the esophagus, presumably to prevent rotational traction. We tend to place the sutures to the right of the anterior midline of the esophageal wall, with the esophageal sutures placed just to the right of the anterior vagus nerve.

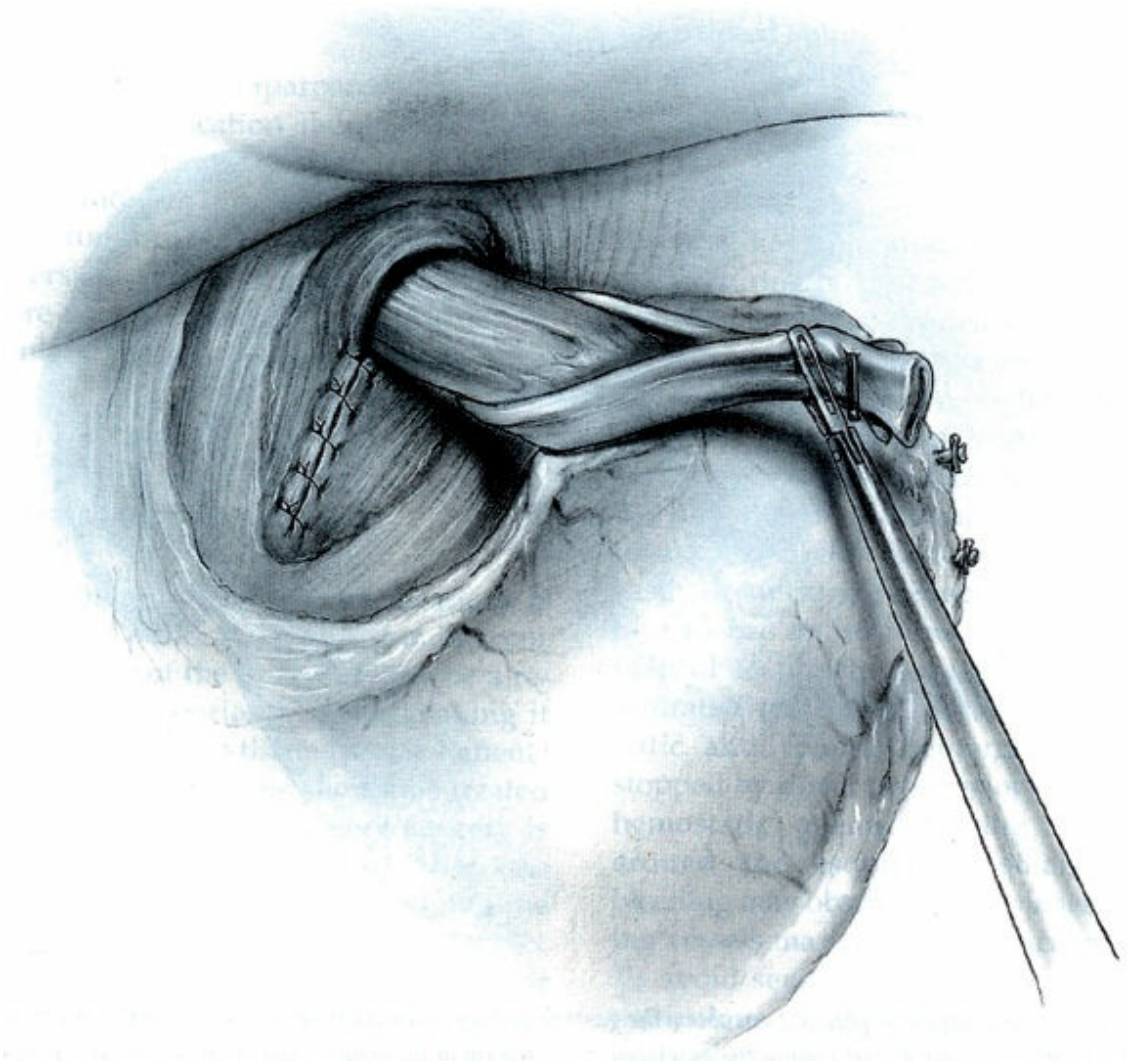

Figure 74.13. Closure of the crural opening posterior to the esophagus with interrupted, nonabsorbable suture. If a Penrose drain is not used, the gastric fundus is used for retraction to expose the crura. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

Port Removal and Closure

With the fundoplication completed, the liver retractor is removed, and the undersurface of the liver is examined for capsular tears or bleeding. The upper abdomen is aspirated and checked for hemostasis. The ports are then removed under direct vision. Any port larger than 5 mm in diameter and located below the costal margins on exsufflation of the abdomen should have its fascia closed with heavy-gauge suture, unless radial dilating

trocars are used. If the abdominal wall is thick, we perform this approximation using a fascial closure device under direct vision rather than attempting to suture the deep fascia through the small skin incision after removing the laparoscopic instruments. The abdomen is exsufflated, the ports are removed, and each incision is infiltrated with bupivacaine.

Postoperative Management

Before leaving the operating room, the patient is administered intravenous ketorolac and ondansetron. A nasogastric tube is rarely placed. The patient is given ice chips overnight and allowed clear liquids the morning after the operation. If tolerated, a soft diet is ordered for lunch. We admit patients to the hospital after the operation, but some groups have performed true outpatient LARS. The patient receives scheduled ketorolac and ondansetron intravenously through the first 12 to 18 hours after the operation to minimize the need for narcotics and to diminish the chance of postoperative vomiting and associated disruption of the crural closure and migration of the wrap into the chest. Because of edema narrowing the esophagus in the early postoperative interval, the patient is placed on a soft diet for the first 2 to 4 weeks. Should the patient experience pain out of proportion to what is expected, or if the patient vomits in the early postoperative period, a water-soluble contrast swallow radiograph is obtained to evaluate for disruption or displacement of the wrap or unrecognized perforation. The patients are seen in the outpatient office at 2 to 4 weeks after the operation. Although rapid resumption of full activity is encouraged, activities requiring the Valsalva maneuver are discouraged for at least 6 weeks after the operation.

LAPAROSCOPIC PARTIAL FUNDOPLICATIONS

The general approach and initial dissection for laparoscopic partial fundoplications are identical to those for the Nissen fundoplication. Partial fundoplications are generally reserved for patients with poor esophageal motility associated with GERD, either because of the reflux itself or because of a primary motility disorder associated with reflux. Recent studies, however, suggest that most patients with decreased esophageal motility have better control of reflux after complete fundoplication with equivalent rates of dysphagia. When partial fundoplication is used, the Toupet fundoplication has been the main alternative.

Although it may be possible to construct a partial fundoplication

without fundic mobilization or division of the short gastric vessels, our preference has been to perform complete fundic mobilization routinely, regardless of the type of fundoplication. The precise technical details of the Toupet fundoplication vary considerably among different surgeons. Some authorities describe fixation of the fundoplication to the crura, whereas others have omitted this step. Most individuals use multiple interrupted sutures of heavy-gauge nonabsorbable sutures to fix the fundoplication between 200 and 270 degrees around the posterior circumference of the esophagus.

If the fundus is sutured to the crura, this is performed before a dilator is passed into the esophagus. The wrapped fundus is pulled well to the patient's left to expose the posterior aspect of the wrapped fundus and the crura. Several sutures are placed between both the posterior left aspect of the fundus and the left crus, and between the posterior right aspect of the fundus and the right crus of the diaphragm to stabilize the wrap. A No. 50 French dilator is then inserted, and several interrupted sutures are placed between the anterior esophageal wall and the left and right sides of the gastric fundus. Although the dilator is not absolutely necessary, we feel that it helps by making the esophagus assume a more tubular shape for precise suture placement. The sutures can then be placed with the use of clock-face references. We generally place three sutures between the right anterolateral aspect of the esophagus (at the 11 o'clock position) and the leading edge of the wrapped portion of fundus. Usually, the most cephalad suture is also placed through the crus. The sutures in the esophageal wall should be relatively deep but not full thickness to prevent entry into the lumen with the potential for fistula formation. Several interrupted sutures are placed to create a wrap that is 2 to 3 cm in length along the right lateral aspect of the esophagus. The medial fundus to the left of the esophagus is then grasped with an atraumatic grasping forceps, elevated, and pulled toward the left anterolateral border of the esophagus. Three interrupted sutures of heavy nonabsorbable material are then placed between the fundus to the left of the esophagus and the left anterior lateral wall of the esophagus (at the 1 o'clock position). Care is taken to avoid the anterior vagus nerve while these sutures are being placed. The dilator is then removed, and the area is examined for hemostasis.

It is unclear whether sutures should be placed between the fundoplication and the diaphragm during LARS. Although these sutures may help to buttress the wrap, they may also fix the fundoplication in an

unnatural position in relation to the diaphragm. The axial motion of the esophagus during swallowing and the bellows action of the diaphragm during breathing may pull on these sutures, placing tension on the fundoplication with the potential for its disruption. We recently have begun omitting the sutures between the fundus and the crura of the diaphragm. Instead, multiple interrupted sutures are placed between the fundus and the esophagus in an attempt to fix the wrap permanently in position without the diaphragmatic sutures. Given the impossible task of determining the precise depth of suture "bites" in the esophagus and the understandable anxiety of the surgeon about entering the esophageal lumen or perforating the esophagus, these fundoplication-anchoring sutures may be less deep than ideal, possibly leading to the observed greater incidence of wrap disruption with laparoscopic Toupet fundoplication than with LNF.

Postoperative care of patients who have undergone laparoscopic partial fundoplications is identical to that of patients who have undergone Nissen fundoplication. If the surgeon is concerned about the possibility of esophageal perforation or if the patient retches or vomits in the early postoperative interval, a water-soluble contrast radiograph should be obtained to evaluate for perforation or wrap disruption before any oral intake. If the surgeon suspects an esophageal perforation during the operation, an oral gastric tube should be used to instill methylene blue to assess for perforation while the patient is on the operating table. Alternatively, an endoscope can be passed with performance of a bubble test. Most esophageal and gastric perforations discovered during the operation may be closed laparoscopically with multiple fine sutures, and the adequacy of the repair can be checked by insufflating air or carbon dioxide into the esophagus after flooding the area with saline solution. If possible, the repaired perforation should be buttressed by the fundoplication.

RESULTS OF LAPAROSCOPIC ANTIREFLUX SURGERY

More than 10,000 cases of LARS have been reported in the literature since LNF was first reported in 1991. The results compiled from several large series are summarized in Table 74.9. To keep the outcomes of LARS in perspective, they should be compared with those of open antireflux operations. Splenic injury occurs in up to 8% of open cases, and the mortality rate ranges up to 1.4%. Pulmonary complications occur between

1% and 6.5% of open operations. The length of hospital stay after open fundoplication varies with the institution and the type of health care system. Prospective randomized trials and a recent meta-analysis comparing laparoscopic with open Nissen fundoplication have revealed similar outcomes (symptomatic and physiologic) with reduced hospital stays. Long-term follow-up for the open procedures (>10-year follow-up) demonstrates a success rate >90% for the control of GERD symptoms.

TABLE 74.9 Compiled Results of Laparoscopic Antireflux Surgery

Complication	Incidence
Mortality	0.0–0.5%
Major morbidity	2–10%
Splenectomy	Rare
Converted	1–12%
Early reoperation	0–3%
Early dysphagia	10–90%
Late dysphagia	5–10%
Anatomic failure	5–10%

Early Results

Early postoperative results of LARS demonstrate perioperative rates of mortality and splenic injury both nearly zero. Conversion from a laparoscopic to an open procedure is higher early in a surgeon's experience with the operation, but in most series the conversion rate is <5%. The operative time averages 1 to 3 hours, with a clear learning curve. In series from the United States, the duration of postoperative hospitalization averages <2 days with anecdotal reports of performing outpatient LARS. Respiratory and wound complications are uncommon because of the minimally invasive nature of the access approach with diminished perioperative pain. Perioperative complications requiring reoperation occur in <1% of patients and include perforation of the stomach or esophagus and migration of the fundoplication into the chest as a result of perioperative retching. Early results of Nissen fundoplications, Rossetti-Nissen fundoplications, and partial fundoplications all appear similar, although several reports suggest a higher incidence of dysphagia after the Rossetti-Nissen technique.

Intermediate and Late Results

Postoperative foregut symptoms are relatively common after antireflux surgery, whether performed with open or laparoscopic techniques. Dysphagia is a common problem early after operation, but diminishes over time such that only 5% to 10% of all patients will experience occasional mild dysphagia, and only 1% to 2% of patients will require esophageal dilatation. The so-called gas-bloat syndrome is a relatively uncommon finding, and most patients with postoperative bloating also had significant bloating before the operation. Many patients with GERD develop the habit of swallowing frequently to promote esophageal clearance of acid, leading to aerophagia. With a tight fundoplication, an inability to belch with bloating may occur but often resolves over time. Recurrent reflux symptoms are present in up to 5% of patients, and wrap disruption or migration either into the chest or down onto the stomach occurs in up to 10% of patients over the long term. Most patients are satisfied with the operation, with overall satisfaction rates ranging from 87% to 100%. The quality of life is improved after LARS. Atypical symptoms of GERD, particularly chest pain and pulmonary symptoms, are less reliably resolved after LARS than typical symptoms.

Partial Fundoplications

The long-term outcome after laparoscopic posterior partial fundoplications does not appear to be as good as after complete fundoplications. In their early experience, Patti and colleagues selectively used partial fundoplications for patients with “dysfunction of esophageal peristalsis,” and showed improvement in esophageal peristalsis and postoperative esophageal pH testing. However, they reported their long-term results and concluded that the laparoscopic partial fundoplication was less effective than total fundoplication in resolving GERD with an equivalent incidence of postoperative dysphagia. Other groups have shown similar results, prompting many centers to abandon partial fundoplications except in the setting of severe esophageal motility disorders (i.e., scleroderma, achalasia). Cai et al. however, reported equivalency between laparoscopic Nissen versus Dor partial fundoplication in a recent 10-year follow-up of a prospective randomized clinical trial. We still believe that partial fundoplication is valuable in certain situations and should be part of the surgical armamentarium in treating GERD.

COMPLICATIONS/AVOIDING PITFALLS

The learning curve for LARS requires 30 to 50 operations and is reflected by decreasing operative time and diminishing rates of complications and failed fundoplications. Complications fall into two main categories: anatomic and functional. Anatomic complications usually result in postoperative dysphagia and may be the result of excessively tight closure of the esophageal hiatus, a tight wrap, or tension on the wrap causing twisting of the lower esophagus. Failed fundoplications can take several forms (Fig. 74.14). The most common fundoplication-associated complication after LARS is migration of the wrap through the hiatus into the mediastinum. This is often heralded by new-onset substernal or epigastric pain rather than reflux symptoms. The wrap itself may disrupt or migrate down onto the stomach (the so-called slipped Nissen), but this complication is more frequent after open Nissen fundoplication than after laparoscopic fundoplication. We previously reviewed our experience with anatomic fundoplication failure. Fundoplication disruption and/or migration is associated with surgical inexperience, shortcomings of surgical technique, the presence of a large hiatal hernia, and the occurrence of diaphragmatic stressors, including perioperative vomiting. To prevent fundoplication failure, therefore, the surgeon must carefully select patients, perform the operation with specific attention to full mobilization of the fundus and esophagus, and close the crura around the esophagus adequately.

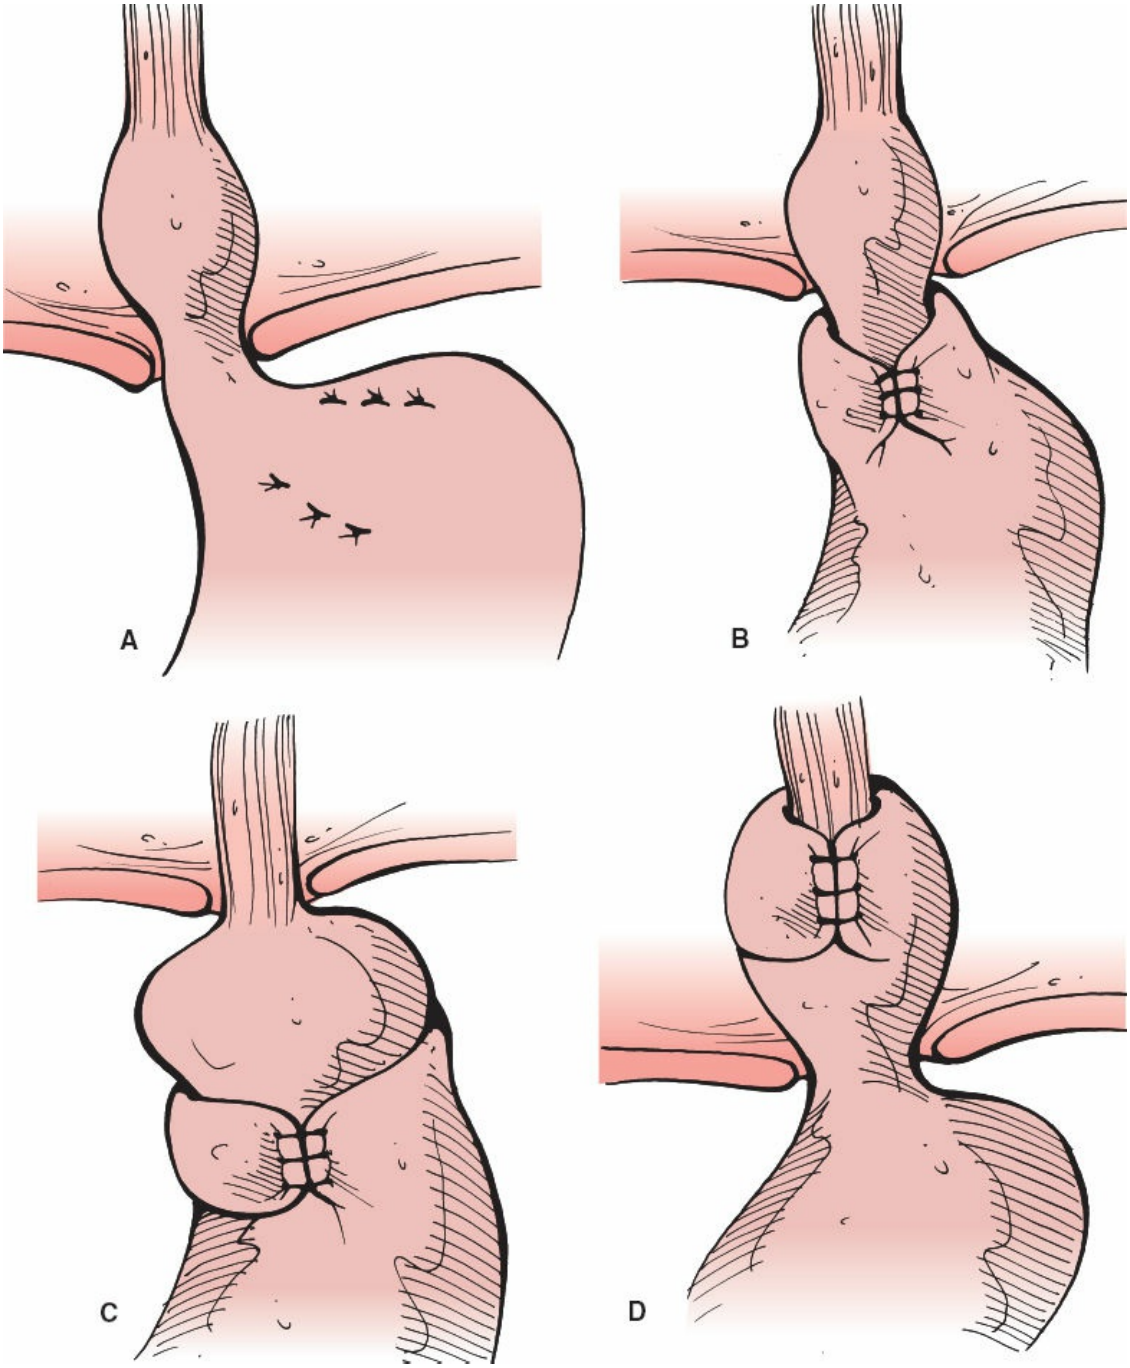

Figure 74.14. Types of fundoplication failures. **A.** Disrupted wrap. **B.** Sliding hiatal hernia with wrap in abdomen. **C.** "Slipped" fundoplication onto proximal stomach. **D:** Intrathoracic migration of the fundoplication. (Reprinted with permission from Desai KM, Soper NJ. Laparoscopic Nissen fundoplication. In: Soper NJ, Swanström LL, Eubanks WS, eds. *Mastery of Endoscopic and Laparoscopic Surgery.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005:193.)

The management of fundoplication failures after LARS is complex. A barium swallow usually confirms the presence of fundoplication failure,

and this study will also allow an assessment of the location of the gastroesophageal junction in relation to the esophageal hiatus. Before considering reoperative treatment for fundoplication failure, esophageal motility must be assessed to determine the type of fundoplication that can be supported by the amplitude and progression of esophageal peristalsis. If the gastroesophageal junction is located within the abdomen, attempted laparoscopic repair is appropriate. If the gastroesophageal junction is well above the diaphragm, our approach is to perform a thoracotomy with Collis gastroplasty and fundoplication. The patient must be aware that the rates of complication and conversion to open surgery are likely to be much higher in these reoperative situations. After multiple operations or in the presence of severe paraesophageal mediastinal fibrosis, subtotal gastrectomy or esophagectomy may be the best alternative for a patient with failed fundoplication. Finally, some patients have postoperative symptoms and are unhappy with the outcome despite an anatomically and functionally intact fundoplication. These symptoms are usually not related to recurrent GER.

Functional complications usually manifest as bloating, but may also rarely result from dumping syndrome due to the increased gastric emptying seen after fundoplication. Severe bloating symptoms, not attributable to anatomic complication, are usually the result of gastroparesis, either initially undiagnosed or the result of vagus nerve injury. This is one of the reasons why patients who have more atypical symptoms preoperatively should have a gastric emptying scan. Patients with documented severe delayed gastric emptying preoperatively should be offered a concomitant pyloroplasty as several recent reports have demonstrated improvement in bloating symptoms for these patients. This also suggests that patients diagnosed with severe delayed gastric emptying after LARS may also benefit from pyloroplasty if severe bloating systems persist, are not the result of an anatomic failure, and do not respond to pro-kinetic agents. Injury to the vagus nerves at initial operation may result in the bloating described above; however, conflicting data exist as some authors advocate cutting the vagus nerves to avoid a Collis procedure when esophageal shortening is present, and have not demonstrated an increase in postoperative gastroparesis. In addition to pyloroplasty, conversion to Roux-en-Y gastric bypass with resection of the gastric remnant has been described with mixed results.

REOPERATIVE SURGERY

Patients with ongoing, recurrent or new symptoms following transabdominal antireflux surgery may require reoperation. With over 1,000 reoperative cases published in the literature, the most common presenting symptom in this group of complex patients is recurrent GERD, followed by dysphagia, gas bloat, and hiatal hernia. These patients require careful workup before considering an operative approach, as reoperation is technically challenging, and should only be approached by surgeons with extensive LARS experience. Patients in whom several previous antireflux operations have failed and/or who have high-grade dysplasia in the presence of Barrett esophagus may be best managed by esophagectomy.

Patient Selection/Preoperative Workup

Patients being considered for reoperative LARS must undergo a thorough workup beginning with a detailed history of the original and existing symptoms. Whether the patient has recurrent symptoms versus a new symptom can help guide the surgeon in the choice of operation. Additional workup with pH-testing, EGD, UGI, and manometry is essential for the majority of patients, while gastric scintigraphy may help delineate patients with delayed gastric emptying. If available, it is also helpful in reviewing the prior operative note to assist with the operative planning. Table 74.10 details a sample clinical decision algorithm. For example, a patient with recurrent GERD symptoms found to have a disrupted Nissen fundoplication and a positive pH study may best be served with a redo Nissen fundoplication. Alternatively, a patient with new dysphagia and an intact Nissen fundoplication may require conversion to a partial fundoplication. Discussion of these complex patients in a multidisciplinary conference of surgeons and gastroenterologists can aid in the decision making for medical or operative management (see Table 74.10). A recent paper commented that up to one third of patients referred for reoperation were deemed to be better served with medical management.

Laparoscopic Versus Thoracotomy Approach

The majority of reoperative antireflux operations can be successfully approached laparoscopically; however, some debate exists as to the optimal surgical approach for some patients. The primary decision usually rests in the number of prior operations and the presence of esophageal

shortening or a paraesophageal hernia. Again, it is often helpful to have complex cases discussed in a multidisciplinary fashion to determine if a laparoscopic or thoracoscopic approach should be taken. This also allows a thoracic surgeon to know about the patient and be on standby should the laparoscopic surgeon need to convert and not feel comfortable in proceeding with a thoracotomy.

TABLE 74.10 Sample Clinical Decision Algorithm for Reoperative Laparoscopic Antireflux Surgery

Initial Symptom	Initial Operation	Symptom	Findings	Potential Treatment
GERD	Nissen	GERD	+pH	Redo Nissen
GERD	Nissen	Any	Intrathoracic herniation	Redo Nissen or transthoracic Collis/Belsey
GERD	Nissen	Dysphagia	Esophageal dysmotility	Convert to partial
GERD	Nissen	Dysphagia	Twisted or tight fundoplication	Redo Nissen
GERD	Partial	GERD	+pH	Convert to Nissen
GERD	Nissen	Gas bloat	Negative	Convert to partial or medical management
Any	Partial	Dysphagia	Any	Undo fundoplication
Any	Any	GERD, dysphagia, or chest pain	Negative	Medical management
Any	Any	Dysphagia	Slipped fundoplication	Redo fundoplication
Any	Nissen	Dysphagia	Achalasia	Heller, Toupet, or Dor
Any	Any	Gas bloat	Delayed gastric emptying	Pyloromyotomy
Any	Any	GERD	High-grade dysplasia	Esophagectomy or EMR
Any	Multiple prior	Any	Any	Esophagectomy or gastrectomy

EMR, electronic medical record; GERD, gastroesophageal reflux disease.

Dissection Technique

The steps for reoperative LARS are generally the same as that of an initial operation. Consideration of intra-abdominal adhesions, particularly if the initial operation was open, may alter the initial trocar placement position (right upper quadrant vs. midline) and technique (open Hasson vs. Veress needle). Dense adhesions should be expected, especially from the fundoplication to the undersurface of the left lobe of the liver, and are then carefully dissected. Adhesiolysis near the prior fundoplication and esophagus should be performed sharply to avoid thermal damage. The initial fundoplication then needs to be completely undone. During this portion of the dissection, identification and preservation of the vagus nerves can be challenging. Reviewing the previous operative report may be helpful in avoiding injury to these nerves, particularly if the initial surgeon did not incorporate them within the fundoplication. Gastric or esophageal perforation has been reported in approximately 10% to 15% of reoperative cases. These are usually recognized intraoperatively, primarily

repaired, and buttressed with the fundoplication. Hiatal hernia is a contributing factor in up to 50% of recurrent disease. In order to reduce the risk of an additional recurrence, some centers, including ours, routinely use absorbable or biologic mesh to reinforce the crural closure or consider a right-sided crural relaxing incision during these reoperative cases.

Results/Complications

Over the past decade, there have been numerous reports with favorable results for reoperative laparoscopic antireflux operations. A recent meta-analysis demonstrated an 81% success rate, although the definition of "success" varied among the 13 studies that measured this endpoint. An encouraging 73% of patients would have the surgery again, although only 5 studies asked this question. Not surprisingly, operative times and intraoperative complication rates were higher, while conversion rates and hospital length of stay were similar.

LAPAROSCOPIC MAGNETIC SPHINCTER AUGMENTATION

Magnetic sphincter augmentation is emerging as another laparoscopic procedure to help treat patients with GERD. With this procedure, the LINX device (string of magnetic beads) is placed laparoscopically around the gastroesophageal junction. The magnetic force of the beads is strong enough to overcome the intragastric pressure decreasing reflux events. As long as adequate peristalsis exists (preoperative manometry mandatory), a food bolus will overcome the magnetic force of the beads to allow for passage. A minimal dissection technique is used to create a retroesophageal tunnel between the posterior vagus and the esophagus. A sizing device is passed through the window to help choose the appropriate one of five available sized LINX inplants. The beads are passed through the window and closed with a self-containing mechanism. Patients are expected to have transient dysphagia for the first several weeks and are encouraged to "work it out" by maintaining a regular diet. This regimen allows the beads to continue to be able to separate as the body forms a capsule around the device. Multiple recent studies have demonstrated good reflux control with a low complication profile in selected carefully patients with pH study documented GERD with <2 cm hiatal hernia.

CONCLUSIONS

LARS is the gold standard for patients requiring surgical therapy of GERD, due to the minimally invasive nature and the excellent long-term outcomes of these procedures. For optimal results, good patient selection is the key and LARS must be performed by experienced surgeons with technical skill and acumen. Significant postoperative symptoms require full anatomic and functional diagnostic testing prior to considering revisional surgery. “Re-do” esophageal surgery has much higher rates of complications and failure than primary operations, and should be performed only by those with extensive experience in esophageal surgery.

EDITOR'S COMMENT

The worldwide experience with laparoscopic antireflux surgery has grown exponentially. Various surgical societies have developed and published practice guidelines for the performance of antireflux surgery. As the Society of American Intestinal and Endoscopic Surgeons (SAGES) indicates: "the laparoscopic Nissen fundoplication is a unique operation in the realm of General Surgery, in that the indication for operation is based on the patient's subjective assessment of symptoms, the fundamental aspect of the operation includes an element of surgeon artistry, and the results are largely subjective. Outcomes are therefore highly dependent on patient expectations, and it is difficult to extrapolate the results of a given surgeon's technique to a population served by many surgeons using the same technique." In other words, this is an operation where patient selection and surgeon experience matter as the art of the surgery remains important. Fortunately, with time, the science behind the approaches selected continues to improve with further publication of randomized trials comparing surgery versus medical therapy for gastroesophageal reflux disease (GERD) or comparing different surgical approaches for this condition. As obesity continues to increase in the United States, the epidemic of reflux disease and development of esophageal adenocarcinoma are alarming and a major health concern.

As the authors indicate, laparoscopic antireflux surgery remains an important treatment option for GERD. Dr. Soper and colleagues have done an outstanding job describing in great detail the various steps and pitfalls associated with the workup of possible GERD and performance of partial and complete fundoplications. To complement their previous contributions to *Mastery of Surgery* in this area, per-oral endoscopic myotomy (POEM) for achalasia and endoluminal approaches for GERD have been added in the present edition.

The authors describe the standard workup for patients with GERD, which includes 24-hour pH monitoring, upper endoscopy, upper gastrointestinal barium swallow study, manometry and possibly an evaluation of gastric emptying. There has been little change in the performance of these tests over the last several years except for the continued evolution of high-resolution manometry (HRM). HRM has become increasingly important and is now the new worldwide standard for the clinical evaluation of esophageal motility disorders. The implementation of HRM is a major improvement compared to conventional manometry. As a result, esophageal HRM has replaced conventional manometry in the clinical evaluation of patients with esophageal symptoms, especially dysphagia. HRM is useful to identify the patient with achalasia or scleroderma who has symptoms of GERD. It is also useful in

tailoring the type of antireflux operation (Savarino E, de Bortoli N, Bellini M, et al. Practice guidelines on the use of esophageal manometry—a GISMAD-SIGE-AIGO medical position statement. *Dig Liver Dis* 2016;48(10):1124–35). Postoperative manometry combined with upper endoscopy or barium esophagogram is of value for the assessment of postoperative dysphagia, particularly when it persists for 4 weeks after surgery (Pandolfino JE, Kahrilas PJ. AGA technical review on the clinical use of esophageal manometry. *Gastroenterology* 2005;128(1):209–24). Indeed, they may reveal a migration or disruption of the wrap or abnormalities in terms of peristaltic function, LES pressure, and LES relaxation (i.e., wrap too tight).

The technical steps and maneuvers during laparoscopic antireflux surgery, in the presence and absence of a hiatal hernia, should be carefully understood and committed to memory. This chapter details them very nicely and is based on the author's many years of experience. For instance, tacking the fundus of the stomach to the diaphragm (particularly on the left side) should be done in the absence of a dilator being present in the esophagus. Just try it with a 56 French dilator present and you will understand how difficult this is! In addition, esophageal dilators stiffen the esophagus and inhibit anterior retraction of the esophagus to allow posterior crural closure. Therefore, they are best left out of the esophagus until after crural closure. I have also found that the use of the Enseal to be particularly effective in working around the esophagus as the outer blades do not become that hot and minimize transmission of heat to adjacent critical structures. In addition, use of the Endo Stitch can greatly facilitate suturing.

Controversy continues regarding the effectiveness of Nissen fundoplication versus partial fundoplication in their ability to control symptoms of GER. A recently reported randomized trial compared 5-year results of a Nissen or Toupet utilizing a 1.5- or 3-cm wrap. Nissen or Toupet fundoplication achieved sufficient control of reflux with success rates of 85% at 5-year follow-up. There were no significant differences in the postoperative dysphagia, esophagitis, and bloating rates. However, a significant difference in failure rates was found between 1.5- and 3-cm Toupet groups ($p < 0.05$). A 1.5 cm Toupet fundoplication wrap length was associated with a 32.4% incidence of esophagitis and was concluded to be insufficient (Mickevicius A, Endzinas Z, Kiudelis M, et al. Influence of wrap length on the effectiveness of Nissen and Toupet fundoplications: 5-year results of prospective, randomized study. *Surg Endosc* 2013;27(3):986–91). On the other hand, 12-year follow-up of a randomized trial comparing laparoscopic Nissen versus 180-degree anterior fundoplication was recently reported and had demonstrated subtle improvement in those patients undergoing a Nissen fundoplication. Of the initial 163 patients randomized, only 55% completed 12-year follow-up. There were no differences in heartburn, dysphagia, gas-related symptoms, patient satisfaction, or surgical reintervention rate between the two groups. However, the use of acid suppressing drugs was less common after Nissen than after 180-degree anterior

fundoplication. In addition, the proportion of patients with absent or only mild symptoms was slightly higher after Nissen fundoplication: 45 or 50 (90%) versus 28 of 38 (74%, $p = 0.04$) (Roks DJ, Broeders JA, Baigrie RJ. Long-term symptom control of gastro-oesophageal reflux disease 12 years after laparoscopic Nissen or 180° anterior partial fundoplication in a randomized clinical trial. *Br J Surg* 2017. doi:10.1002/bjs.10473. [Epub ahead of print]).

Perhaps the most exciting new development in the management of achalasia continues to be the evolving technique of per-oral endoscopic myotomy (POEM) for achalasia. Although long-term data are limited with the use of POEM, a recent report combining the experience with 10 tertiary care centers had a minimum of 2 years of follow-up in 205 patients. Clinical success of POEM was achieved in 91% of patients at 2 years. Procedure-related adverse events occurred in 8.2% of patients and 1 patient required surgical intervention. Abnormal esophageal acid exposure and reflux esophagitis were documented in 37% and 18% of patients, respectively (Ngamruengphong S, Inoue H, Chiu PW, et al. Long-term outcomes of per-oral endoscopic myotomy in patients with achalasia with a minimum follow-up of 2 years: an international multicenter study. *Gastrointest Endosc* 2016. pii: S0016–5107(16)30586–7).

Recently, Dr. Madhu Sanaka from the Cleveland Clinic presented 31 POEM patients and 88 laparoscopic Heller myotomy (LHM) patients, testing their levels of pH 2 months post-treatment. While POEM patients showed no statistically significant increase in reflux symptoms, they *did* have higher abnormal pH study findings; 48% of POEM patients had abnormal levels of esophageal acid exposure compared with 14% of LHM patients. Most POEM patients are managed with an anti-reflux medication. This is often unnecessary for LHM patients, because LHM includes a fundoplication.

Many clinicians continue to perform a partial-thickness myotomy—dissecting only the circular muscle layer and preserving the outer longitudinal esophageal muscles. But some centers now perform a modified POEM that duplicates surgical full-thickness myotomy with Dor fundoplication. In this hybrid procedure, the endoscopist extends the procedure as far into the stomach as possible. There is currently debate about how much of the gastric side should be cut. Following the endoscopic portion, the surgeon performs the anti-reflux procedure. Patients benefit from a significant reduction in the risk of reflux—a frequent complication of myotomy resulting from disruption of the LES and phrenoesophageal attachments. This avoids the need to be dependent on proton pump inhibitors long term following POEM. The next several years will further clarify the appropriate use of POEM in the management of achalasia.

Steven N. Hochwald

75 Peroral Endoscopic Myotomy for Achalasia and Endoluminal Approaches for GERD

Edward D. Auyang and Eric S. Hungness

INTRODUCTION

Achalasia is an esophageal motility disorder affecting approximately 1 in 100,000 people per year in which there is primary aperistalsis of the esophagus with nonrelaxation of the lower esophageal sphincter (LES). These anatomy abnormalities result in dysphagia and regurgitation. Ernest Heller performed the first surgical transthoracic esophagomyotomy in 1913. Until the 1990s, open myotomy, either via thoracic or abdominal approach, had been the only surgical treatment option. In 1991, minimally invasive esophagomyotomy was introduced. The first reported laparoscopic myotomy was by Cuschieri in 1991 and the first thoracoscopic myotomy by Pellegrini in 1992. These provided for greater durability of treatment with less postoperative morbidity compared to open myotomy.

Historic treatment of achalasia involved using a sponge-tipped whale bone to push food beyond the LES after each meal. Initial nonsurgical treatment was in the form of pneumatic balloon dilation in the 1970s and 1980s. In the 1990s, botulinum toxin (BTX) injection of the LES was introduced as an additional endoscopic treatment option for achalasia. The long-term durability of dilation and BTX injection has been mixed.

In 2008, Inoue reported the first case series of peroral endoscopic myotomy (POEM) for achalasia. This is an endoscopic approach that allows for dividing the circular fibers of the LES without the need for abdominal or thoracic incisions. Since then, approximately 4,000 POEM cases have been performed worldwide.

Gastroesophageal reflux disease (GERD) is a common problem among the global population in which the LES is incompetent and allows for reflux of gastric contents into the esophagus. This causes symptoms including heartburn, regurgitation, and nocturnal aspiration. Esophagitis is

a result of chronic abnormal reflux and can progress to Barrett metaplasia, dysplasia, and potentially esophageal cancer.

GERD has been treated primarily with medications, ranging from antacids, to H2-blockers, to most recently proton-pump inhibitors (PPI). For most patients, medical treatment is adequate to suppress symptoms. For patients who are refractory, surgical fundoplication has been the treatment of choice. The first gastric fundoplication was performed by Rudolf Nissen in 1955. With the advent of minimally invasive surgery in the 1990s, Dallemagne and Geagea performed the first laparoscopic Nissen fundoplication in 1991. This has been the gold standard for surgical treatment of GERD.

Like for achalasia, endoluminal treatments have been developed as alternative treatments for GERD. These include endoluminal plication and ablative remodeling. The goal of these treatments is to either recreate the gastroesophageal flap valve or remodel the tissue of the LES.

Etiology, pathophysiology, and clinical presentation of achalasia and GERD along with their surgical treatments are covered in other chapters. We will be examining the endoluminal treatments of both of these disease processes.

PERORAL ENDOSCOPIC MYOTOMY

Indications and Contraindications

POEM is performed under general anesthesia (GA) and therefore, contraindication to GA is a contraindication for performing POEM. Relative contraindications include previous achalasia interventions such as BTX, pneumatic dilation, and Heller myotomy or advanced achalasia with sigmoid deformity, particularly early in the surgeon's learning curve. There are reports that previous interventions may result in scarring of the LES making creation of a submucosal plane difficult. Sigmoid deformity of the esophagus poses significant difficulty in creating the submucosal tunnel during POEM. Conversely, there have also been multiple reports of performing POEM after these interventions and even after previous laparoscopic Heller myotomy. Having performed over 175 clinical cases to date, the Northwestern Esophageal center approaches each patient individually but will offer POEM to most, if not all, patients with achalasia.

Preoperative Planning

Patients undergoing POEM should have a complete achalasia workup, including esophagogastroduodenoscopy (EGD), barium swallow esophagram (UGI), and high-resolution esophageal manometry. These tests will confirm the diagnosis of achalasia and rule out the presence of other diseases that may cause pseudoachalasia, such as esophageal cancer.

Patients are instructed to be on a liquid diet for 48 hours prior to the procedure to allow for complete emptying of the esophagus. Patients who have a high risk of retained food in the esophagus undergo EGD 2 days prior to the procedure for clearance. Candida esophagitis has also been reported in patients with achalasia. We recommend nystatin oral suspension (100,000 units/mL) swish and swallow for 7 days or fluconazole (100 mg) PO for 5 days for prophylactic treatment and to reduce the high candida burden known to exist in achalasia patients. The patient is *nil per os* (NPO) at midnight prior to the procedure. Preoperative antibiotics and deep venous thromboembolism (DVT) prophylaxis are administered per guidelines for laparoscopic myotomy. Good intraoperative blood pressure control (SBP <120 mm Hg) helps reduce the risk of submucosal bleeding. The endotracheal tube is taped off the right side of the patient's mouth.

Technique

POEM is performed in the operating room under rapid sequence GA with endotracheal intubation, due to the significant risk of aspiration for achalasia patients. Positive-pressure ventilation also helps any possible untoward effects of CO_2 insufflation within the submucosal tunnel and mediastinum. There is a small risk of esophageal perforation with POEM and therefore, appropriate operating room instruments are on stand-by for laparoscopic or open surgical intervention if needed. Pneumoperitoneum occurs in up to 40% of patients and is easily controlled with the placement of a Veress needle.

The patient is positioned in supine position with the left arm tucked. EGD is performed initially to confirm clearance of the esophagus and absence of candida. Once confirmed, a high-definition (HD) endoscope with CO_2 insufflation and an obliquely cut endoscopic dissecting cap (long bevel positioned posterior) is used for this procedure.

The distance of the gastroesophageal junction (GEJ) from the incisors is first measured to determine the length of myotomy to be created and the start point for the submucosal tunnel. The myotomy is typically made for a

length of 6 cm above the GEJ and 3 cm onto the stomach. The submucosal tunnel is started 4 cm proximal to the proximal portion of the myotomy, thus 12 cm above the GEJ.

The mucosa is lifted with the injection of saline with indigo carmine (or methylene blue) on the anterior esophagus (12 o'clock position) (Fig. 75.1A,B). With the mucosa raised, a triangle tip endoscopic cautery knife is used to create a 2 cm longitudinal incision in the mucosa to allow for entry of the endoscope into the submucosal space (Figs. 75.1C and 75.2A). Coagulating the submucosal tissue and exposing the circular muscle within this initial 2 cm opening greatly facilitates scope entry into the submucosal space. The anterior submucosal tunnel is lengthened using precise endoscopic cautery dissection of the submucosal fibers connecting the circular muscle and mucosa. Additional saline injection can be used to assist in tunnel creation with "hydrodissection." Submucosal vessels are coagulated as they are encountered. In addition, epinephrine can be added to the saline to assist with hemostasis, but is usually reserved for the initial and final injection. The submucosal tunnel is carried at least 3 cm onto the cardia of the stomach (Fig. 75.2B). There are several methods of helping to determine adequate tunnel length: (1) measurement from incisiors; (2) tunnel narrowing at the GEJ that widens onto the cardia; (3) observation of "palisading" blood vessels in cardia; (4) disorganization of circular fibers on cardia; and (5) visualization of blue dye/blanching cardiac mucosa on retroflexion within stomach (Fig. 75.1D). Gastric distention makes distal tunnel creation more difficult, so decompression of the stomach is important when dissecting near the GEJ.

After the tunnel has been created, the endoscope is drawn back to 6 cm above the GEJ as the starting location for the myotomy. This usually leaves 3 to 4 cm of overlap from where the tunnel and the myotomy starts, which theoretically reduces the chance for esophageal leak should the clips become dislodged. The triangle tip cautery knife is then used to divide the circular muscle, proceeding distally onto the gastric cardia (Figs. 75.1E and 75.2C). Care is taken not to divide the longitudinal fibers of the esophagus and perforate into the mediastinum. While this is preferred, splaying of the longitudinal muscle is quite common since it is very thin but is of little consequence as long as mucosal closure is secure (Fig. 75.1F). Of note, the muscle layers of the stomach have obliquely running fibers that will help identify extension of the myotomy onto the gastric cardia. In addition, new techniques using real-time esophageal

distensibility have been utilized to assess for adequate myotomy length during POEM, though application is still in its infancy.

Once the myotomy is completed, the scope is withdrawn from the tunnel. Careful inspection is performed to confirm hemostasis and visualize any potential mucosal perforations. If a mucosal injury is found or suspected, clip closure/reinforcement is used. Small bleeding from the cut edge of myotomy are easily controlled with cautery. Bleeding from the mucosa usually stops on its own, but manual pressure from within the true esophageal lumen is sometimes required. Cautery should not be used to control hemostasis on the mucosal side of the tunnel. In addition, good blood pressure control (SBP <120 mm Hg) is key to reduce the risk of submucosal bleeding. The endoscope is removed from the submucosal tunnel and introduced into the stomach. The GEJ should be much more widely open and retroflexion confirms no perforation of the stomach.

The mucosal incision is then closed using endoscopic clips. Clips are placed from distal to proximal to completely reapproximate the mucosa (Figs. 75.1G and 75.2D).

Postoperative Care

The patient is kept strictly NPO overnight. On postoperative day 1, an UGI is should be considered to confirm absence of esophageal perforation/leak prior to starting the patient on a clear liquid diet. We routinely did a POD1 UGI for the first 80 cases, but did not find any clinical utility except when there were worrisome clinical signs such as increased pain, dysphagia, or tachycardia. The patient is discharged on full liquids for 1 week followed by soft foods for 3 additional weeks. After that, the diet is liberalized but patients are advised to chew well, eat smaller more frequent meals. In addition, it is recommended not to consume certain foods such as breads, chunks of meat, and large quantities of raw fiber for this same duration.

Complications and Their Management

Intraoperative complications are associated with two main phases of the procedure, tunnel creation, and myotomy. During tunnel creation, bleeding and perforation can occur. Bleeding is managed with cautery coagulation either with the dissecting knife or endoscopic graspers/biopsy forceps. In

addition, epinephrine in the saline solution will help with hemostasis of smaller vessels. Perforation can occur with the use of cautery during creation of the tunnel or during the myotomy. These can be prevented with more frequent injection to lift the mucosa from the muscle fibers during tunneling. Full perforations are typically small. They may be clipped from using endoclips. In the event of a large perforation, laparoscopic or open surgical closure of the perforation may be necessary.

The most concerning postoperative complication is a perforation and leak. UGI is performed on postoperative day 1 to confirm abscess of a leak. If a leak is found, endoscopic or laparoscopic closure of the perforation is performed immediately. There have been reports of delayed leaks and perforations that have been treated with percutaneous drainage or operative repair.

Mediastinal emphysema may be identified on postoperative imaging, though this is typically without clinical consequence if no leak is identified.

Outcomes

In the largest case series of POEM to date, Inoue reported a significant reduction in symptom score and LES pressure at 2 months and at 3 years. GERD was seen in 16.8% of patients at 2 months and 21.3% of patients at 3 years. The adverse event rate was 3.2% with no mortalities.

Treatment of GERD after POEM is being actively studied. Patients may be placed on PPI's for symptomatic treatment. In addition, there are studies being undertaken to determine if there are technique changes that can be made to decrease post-POEM GERD such as location of myotomy. Patients who have GERD symptoms should be followed with EGD as there have been reports of post-POEM Barrett esophagus and reflux-related strictures.

Conclusion

POEM is a significant minimally invasive advancement with promising results with regard to treatment of achalasia. Long-term outcomes will be determined with additional experience.

ENDOLUMINAL TREATMENTS FOR GERD

Indications and Contraindications

The indications for endoluminal treatments for GERD are similar for surgical treatments—refractory symptoms despite maximized medical management or contraindications to medication therapy. The potential advantage of endoluminal treatments is that some procedures may be performed under conscious sedation without GA, thus allowing a larger population to be treated compared to surgical fundoplication. There are anatomic contraindications for endoluminal fundoplication and radiofrequency ablation (RF) including presence of hiatal hernias longer than 2 cm and wider than 3 cm.

Preoperative Planning

Patients undergoing endoluminal treatments for GERD should have a complete esophageal workup, including EGD, UGI, and esophageal manometry. These tests will evaluate for other disorders of the esophagus that may present as GERD-like symptoms. In addition, the extent of esophagitis and presence of Barrett's must be assessed as other treatments may take priority over simply treating the reflux mechanism. These studies are also necessary to identify anatomic abnormalities that may be contraindications.

There are two primary endoluminal treatments for GERD on the market. EsophyX (Endogastric Solutions, Redwood City, WA) is a device to create incisionless fundoplication that was approved in 2007 by the U. S. Food and Drug Administration (FDA). The Stretta procedure (Mederi Therapeutics Inc, Greenwich, CT) utilizes RF to remodel the LES by contracting collagen and creating a barrier to gastric pressure. In addition, Medigus ultrasonic surgical endostapler (MUSE; Medigus, Omer, Israel), a new endoscopic stapling procedure that creates an anterior partial wrap, has recently entered the market. Each will be discussed individually.

ESOPHYX TRANSORAL INCISIONLESS FUNDOPLICATION

Technique

The EsophyX device is an instrument that is deployed in the stomach with an endoscope that creates a full-thickness plication of the GEJ using H-shaped polypropylene fasteners (Fig. 75.3). The device has gone through several revisions. Transoral incisionless fundoplication (TIF) 1 produced a gastro-gastric wrap at the level of the GEJ. TIF 2 placed the fasteners

above the GEJ to create a gastroesophageal flap valve that replicates a laparoscopic fundoplication. TIF 2.0 is the current technique.

Figure 75.3. EsophyX device.

General endotracheal anesthesia is induced. Endoscopy is performed to confirm no hiatal hernia longer than 2 cm and wider than 3 cm. The device is introduced transorally with CO_2 insufflation. The device is retroflexed and the lesser curve and greater curve landmarks are identified and a helical screw is deployed at the GEJ to retract the tissue. A paddle-shaped tissue mold is then used to deploy polypropylene fasteners to create a "crimp." This technique is performed circumferentially with sequential deploying of fasteners to create a 270-degree fundoplication. After completion, the device is removed and final endoscopy is performed to assess the plication and assess for bleeding or perforation (Fig. 75.4).

Postoperative Care

Patients are kept in the hospital and discharged the following day. They are kept on omeprazole 40 mg for 14 days to promote mucosal healing around fasteners. They are kept on a liquid diet for 2 weeks, then given soft food from weeks 3 to 7. They resume a regular diet after 2 months.

Complications and Their Management

The most commonly reported direct complications of TIF, though few, are bleeding and perforation. Bleeding has been self-limited though patients have required blood transfusion. Perforation is rare and has been treated with laparoscopic transabdominal drainage and partial fundoplication over the damaged esophagus.

Outcomes

Outcomes have varied by study and overall data with regard to randomized controlled studies has been lacking. There are several series that have reported no benefit after TIF. One study reported a 68.4% treatment failure rate. Causes have included technique, missed hernia, or postoperative retching that has disrupted the TIF fundoplication. Patients who have had failure after TIF, however, can be considered for reoperation and surgical fundoplication.

A recent multicenter randomized controlled trial reported the efficacy of TIF versus omeprazole for treatment of symptomatic regurgitation. TIF eliminated symptomatic regurgitation in 67% of patients compared to 45% for PPI. There is little data comparing TIF to laparoscopic fundoplication. The Society for American Gastrointestinal and Endoscopic Surgeons (SAGES) recently reviewed studies related to TIF and confirmed the lack of strong long-term data.

STRETTA

Technique

The Stretta device is an inflatable balloon catheter system with four electrode needle sheaths (Fig. 75.5). Radiofrequency energy is delivered to the electrodes causing the heating of adjacent cells. Power is delivered to achieve a target temperature of 65° to 85°C for 1-minute cycles. The RF induced fibrosis of the LES, thus reducing tissue compliance and transient LES relaxation. These are thought to recreate barrier functions of the LES to reflux.

Patients are placed under deep sedation and initial endoscopy is performed. Patients with hiatal hernias >2 cm in length or having severe esophagitis are excluded. Using a guidewire exchange technique, the Stretta catheter is introduced into the esophagus and placed 2 cm proximal to the Z-line. The balloon is inflated and the electrode needles are

deployed into the esophageal wall. Energy is delivered for a duration of 1 minute. The needles are retracted, the balloon is deflated, and the catheter is rotated 45 degrees. Energy is delivered for another 1-minute cycle. This technique is repeated to cover a length 2 cm above and 1.5 cm below the Z-line. The mucosa is then cooled with water irrigation (Fig. 75.6).

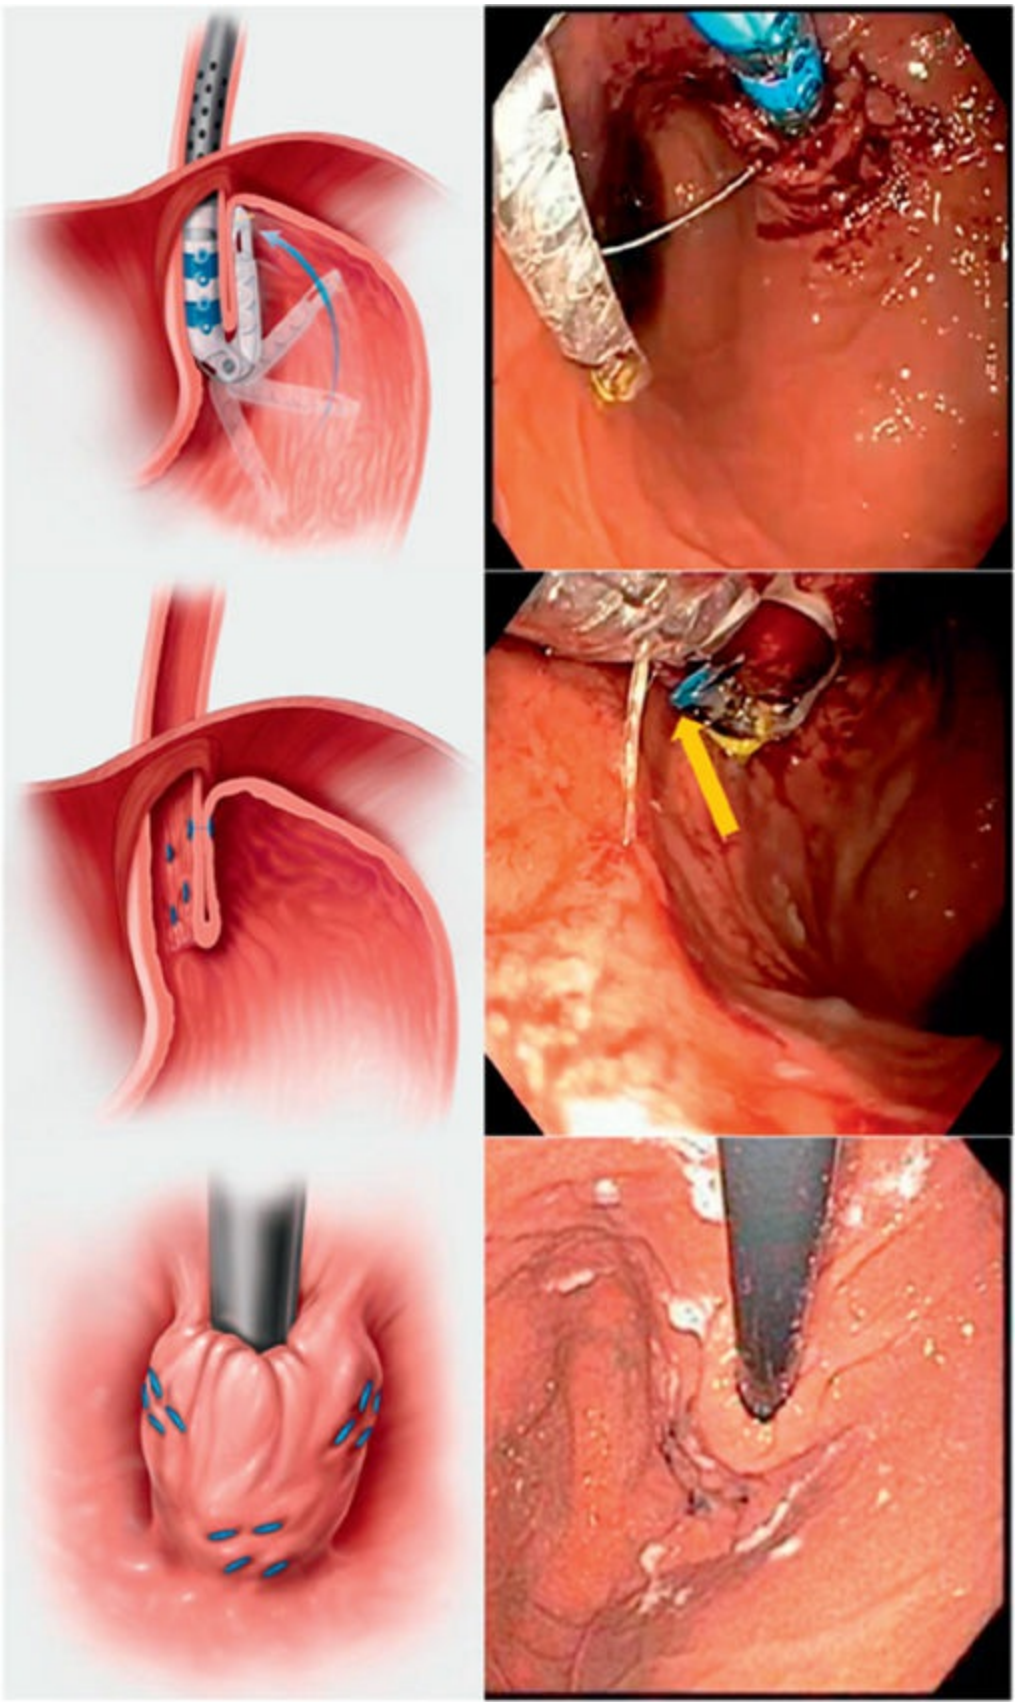

Figure 75.4. TIF Procedure with endoscopic images. (Hunter JG, Kahrilas PJ, Bell Rc, et al. Efficacy of transoral fundoplication vs omeprazole for treatment of regurgitation in a randomized

controlled trial. *Gastroenterology* 2015;148:324–333.e5. doi: 10.1053/j.gastro.2014.10.009. Open Access—No permissions required.)

Figure 75.5. Stretta device. Courtesy of Ray Bengermino and Paul Spier, Mederi Inc. (Images provided by Mederi Therapeutics Inc.)

Postoperative Care

Patients are discharged home on the same day as the procedure. They are instructed to monitor for symptoms of bleeding.

Complications and Their Management

Only mild symptoms have been reported. These include minor bleeding and pain. No perforations have been reported and there have been no reported deaths in the literature.

Outcomes

In a recent meta-analysis, Stretta was shown to significantly improve heartburn scores and improve quality of life. While acid exposure decreased, postprocedural DeMeester score did not normalize. A SAGES review of studies involving Stretta found durable symptomatic treatment and reduction in medication use for symptomatic GERD for 48 months in patients meeting selection criteria.

MEDIGUS ULTRASONIC SURGICAL ENDOSTAPLER

Technique

The device is a stand-alone unit designed to be operated by a single user. It is designed in the shape of an endoscope with a video camera, light source, ultrasonic transducer, and stapling mechanism at the tip (Fig. 75.7). The device is inserted transorally and advanced down the esophagus through an endoscopic overtube with 17 mm internal diameter. It is retroflexed to identify the location for placing staples to create a partial anterior fundoplication. The fundic tissue is compressed against the esophagus and the ultrasonic transducer measures tissue thickness. Once it reaches 1.4 to 1.6 mm, the stapler is fired. This process is repeated several times to mimic a partial anterior fundoplication with a Hill Grade I valve with no visible esophageal mucosa visible on retroflexion. If a small sliding hernia is identified, it is reduced by increasing intrathoracic pressure by increasing ventilator positive end-expiratory pressure (PEEP) to reduce the stomach into the abdomen.

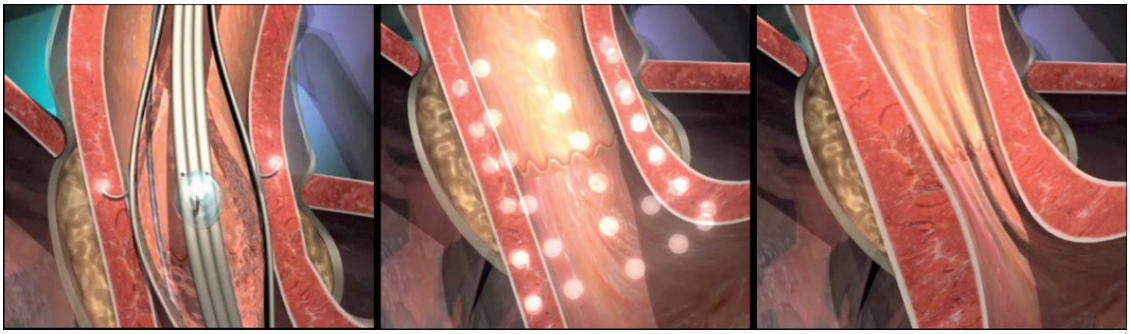

Figure 75.6. Stretta procedure. Courtesy of Ray Bengermino and Paul Spier, Mederi Inc. (Image provided by Mederi Therapeutics Inc.)

Postoperative Care

Patients were observed up to 72 hours postprocedure. UGI was performed

on POD 1 to evaluate for leaks.

Complications and Their Management

So far, less than 100 procedures have been reported worldwide; so complication rates and outcome data are limited. In the initial multi-institutional trial of 64 subjects followed to 6 months, there were two major adverse events. One was an upper GI bleed requiring hospitalization and transfusion. The second was an esophageal perforation resulting in leak and empyema which required drainage. Additional complications have included pneumomediastinum and pneumothorax. Other common complications included chest pain in 16 patients and sore throat in 15 patients.

Outcomes

Improvement in GERD quality of life scores and pH testing have shown improvement in initial studies at 6 months and 4 years. GERD-HRQL scores reduced at 6 months and 4 years, though 12 of 37 patients (32%) were still on PPIs at 6 months. Patients followed to 6 months showed an improvement in DeMeester score from 49.4 ± 47.2 to 29.1 ± 22.0. Normalization of DeMeester score (<14.72) was seen at 6 months in 13 of 35 patients (37.1%).

CONCLUSION

Surgery has been a mainstay for treatment of diseases of the esophagus and GEJ. The advent of minimally invasive surgical options in the early 1990s provided additional benefits of decreased hospitalization time and less postoperative morbidity compared to open operations.

In an effort to decrease morbidity associated with abdominal or thoracic incisions, endoluminal techniques have been developed for treatment of these disease processes. POEM has emerged as potential incisionless treatment for achalasia and early results have shown promise. Stretta and EsophyX have also gained momentum as incisionless endoluminal treatments for GERD with new techniques such as MUSE being currently investigated.

Long-term results of these treatment options are still to be determined, but may offer an even less invasive approach to both common and uncommon disorders of the stomach and esophagus.

EDITOR'S COMMENT

Perhaps the most exciting new development in the management of achalasia continues to be the evolving technique of POEM for achalasia. Although long-term data is limited with the use of POEM, a recent report combining the experience with 10 tertiary care centers had a minimum of 2 years of follow-up in 205 patients. Clinical success of POEM was achieved in 91% of patients at 2 years. Procedure-related adverse events occurred in 8.2% of patients and 1 patient required surgical intervention. Abnormal esophageal acid exposure and reflux esophagitis were documented in 37% and 18% of patients, respectively (Ngamruengphong S, Inoue H, Chiu PW, et al. Long-term outcomes of per-oral endoscopic myotomy in patients with achalasia with a minimum follow-up of 2 years: an international multicenter study. *Gastrointest Endosc* 2016. pii: S0016–5107(16)30586–7).

Recently, Dr. Madhu Sanaka from the Cleveland Clinic presented 31 POEM patients and 88 laparoscopic Heller myotomy (LHM) patients, testing their levels of pH 2 months posttreatment. While POEM patients showed no statistically significant increase in reflux symptoms, they *did* have higher abnormal PH study findings. Forty-eight percent of POEM patients had abnormal levels of esophageal acid exposure, compared to 14% of LHM patients. Most POEM patients are managed with an antireflux medication. This is often unnecessary for LHM patients, because LHM includes a fundoplication.

Many clinicians continue to perform a partial-thickness myotomy—dissecting only the circular muscle layer and preserving the outer longitudinal esophageal muscles. But some centers now perform a modified POEM that duplicates surgical full-thickness myotomy with Dor fundoplication. This hybrid procedure—the endoscopist extends the procedure as far into the stomach as possible and if it looks satisfactory—there is currently debate about how much of the gastric side should be cut—then the surgeon performs the antireflux procedure. Patients benefit from a significant reduction in the risk of reflux—a frequent complication of myotomy resulting from disruption of the LES and phrenoesophageal attachments. This avoids the need to be dependent

on proton pump inhibitors long term following POEM.

Many experts feel that the absence of an antireflux wrap following POEM leads to an increased risk of reflux with consequent esophagitis in about one third of patients. Therefore, surgical myotomy with an antireflux wrap could be the preferred choice when long-standing gastroesophageal reflux could potentially lead to damage (de Pascale S, Repici A, Puccetti F, et al. Peroral endoscopic myotomy versus surgical myotomy for primary achalasia: single-center, retrospective analysis of 74 patients. *Dis Esophagus* 2017;30(8):1–7). However, others argue that laparoscopic antireflux surgery could be reserved for this subset of patients with esophagitis or symptoms or GERD rather than utilizing a surgical Heller myotomy and DOR or toupet fundoplication on all patients. The increased utilization of transoral incisionless fundoplication may also lead to complete endoscopic management of patients with achalasia by reserving it for symptomatic patients with GERD following POEM. Although randomized trials comparing transoral incisionless fundoplication to surgical fundoplication do not exist, transoral incisionless fundoplication has been shown to improve symptoms of GERD in the short term compared to medical management (Huang X, Chen S, Zhao H, et al. Efficacy of transoral incisionless fundoplication (TIF) for the treatment of GERD: a systematic review with meta-analysis. *Surg Endosc* 2017;31(3):1032–44). The next several years will further clarify the appropriate use of POEM and other advanced endoscopic treatments in the management of achalasia.

76 Minimally Invasive Treatment of Achalasia and Other Esophageal Dysmotility

Michael S. Nussbaum, Bestoun H. Ahmed, and Jeffrey L. Ponsky

Most disorders of esophageal motility affect both the esophageal body and the lower esophageal sphincter (LES). The best known and most common of these disorders is achalasia, a primary disorder of the LES with secondary absence of peristalsis in the esophageal body. Achalasia is characterized principally by dysphagia. Diffuse esophageal spasm (DES) and nutcracker esophagus (NE), on the other hand, are primary disorders of esophageal body motility, which are characterized predominantly by substernal chest pain and, to a lesser degree, by dysphagia. Hypertensive LES is the least common of the disorders, characterized by symptoms of dysphagia, chest pain, and, at times, associated gastroesophageal reflux disease (GERD). The distinguishing manometric features of hypertensive LES include elevated LES basal pressure, with normal swallow-induced relaxation and normal esophageal body peristalsis.

ACHALASIA

ANATOMY/PHYSIOLOGY

The LES is a high-pressure segment separating the gastric cavity from the esophageal lumen. The main function of this sphincter is to prevent the reflux of gastric contents into the esophagus, which has a lower intraluminal pressure than the stomach. The LES must relax with swallowing to allow the passage of ingested material from the esophagus into the stomach. Abnormalities of either one of these functions are major causes of esophageal symptoms. Defects in the antireflux barrier function result in GERD and its complications. Defective relaxation of this sphincter results in dysphagia.

The LES is not a static barrier, but responds to a variety of stimuli with changes in the force of its closure. Multiple factors are responsible for the

maintenance of the resting tone of the LES. Neural, humoral, and myogenic factors all contribute to basal sphincter pressure. The specific mechanism responsible for relaxation of LES pressure with swallowing remains to be elucidated. The response appears to be mediated through the vagus nerves. The neurotransmitter for sphincter relaxation is not adrenergic or cholinergic mediated, since adrenergic and cholinergic blockade fails to inhibit relaxation. The general nerve poison tetrodotoxin will abolish neurally mediated responses with little or no effect on smooth muscle. Tetrodotoxin will inhibit vagus-stimulated relaxation of the LES, indicating that this is a neurogenic mechanism. The neurotransmitter responsible for vagus-stimulated LES relaxation by definition is a nonadrenergic, noncholinergic inhibitor. Vasoactive intestinal polypeptide (VIP) is found in rich supply in the nerves in the region of the LES and is the most likely candidate for the specific LES inhibitory stimulus.

Esophageal achalasia is a complex motor abnormality of the esophageal body and LES, characterized by incomplete relaxation of the LES and aperistalsis. The prevalence of achalasia is ~10 cases per 100,000 population, with an estimated incidence of ~1 case per 100,000 people per year and, after GERD, is the second most common functional disorder of the esophagus requiring operation. The etiology is unknown, with data suggesting the possibility of several inciting mechanisms for achalasia, including infection, genetic inheritance, autoimmune disease, and neuronal degeneration as possible causes. Various studies have been performed investigating the possibility of several inciting mechanisms for achalasia. However, the sequence of events leading to this mechanism continues to be poorly understood. Currently, achalasia remains an idiopathic condition that is associated with a patchy inflammatory response consisting of cytotoxic T-lymphocyte, eosinophil, and mast cell infiltration in the esophageal myenteric (Auerbach) plexus with myenteric neural fibrosis, loss of ganglion cells, hypertrophy of the two muscle layers, and hypertrophy of nerve fibers. Preganglionic vagal neurons originating in the dorsal motor nucleus innervate two types of postganglionic nerves in the myenteric plexus of the lower esophagus smooth muscles: (1) the excitatory acetylcholine-secreting neurons and (2) the inhibitory VIP- and nitric oxide (NO)-secreting neurons. It is hypothesized that the aperistalsis of achalasia is secondary to interruption of normal vagal cholinergic motor function, whereas the failure of LES relaxation is due to derangement of the vagal inhibitory (VIP and NO) nerves. Multiple histopathologic studies

have confirmed the loss of inhibitory neurons in the esophageal myenteric plexus as the pathologic hallmark of achalasia. There is a selective loss of postganglionic inhibitory neurons, which contain both NO and VIP, whereas, there is sparing of the postganglionic stimulatory (cholinergic) neurons. This produces a loss of inhibitory input, resulting in a nonrelaxing, hypertensive LES. This is demonstrated by an exaggerated motor response (spasm) to injection of cholinergic agonists, demonstrating a classic supersensitive response of the denervated tissue. Similarly, the LES is also supersensitive to both methacholine and pentagastrin in achalasia. The elevated LES tone may be the consequence of disproportionate loss of inhibitory influence. In addition, NO synthetase levels in the LES muscle are considerably lower in achalasia compared with normals. Depletion of interstitial cells of Cajal (ICC) networks and potential changes in the electrical activity of smooth muscle cells may also play a crucial role. The reduction in CD117-positive ICC and the associated reduced NO synthetase release might underlie the profound ICC impairment and could possibly be responsible for the lack of LES relaxation, because of missing inhibitory neurotransmission. It is unclear, however, whether the ICC loss is largely caused by the accelerated attrition of mature cells or their impaired regeneration. It is further unclear whether the diminished availability of the potent smooth-muscle relaxant, NO, is a primary or a secondary phenomenon. The aperistalsis of the esophageal body is attributed to the loss of the latency gradient along the esophageal body that permits sequential contractions along the esophageal body, a process also thought to be mediated by NO. While several theories have been proposed based on known pathologic disease processes, contemporary thought has suggested that several biologic processes may lead to a common mechanism of neuron loss, which subsequently manifests as achalasia. As more studies have come out, the complexity of possible pathogenic mechanisms has increased.

While the underlying pathogenesis of achalasia is far from being completely defined or understood, the various clinical and histopathologic data have led to a working model for the mechanism of the disease. Specifically, it is a neurodegenerative process that involves genetic susceptibility and an immune-mediated mechanism, involving a combination of genetic factors, including genetic characteristics of the immune system, which establish some potential to develop the disease. Among susceptible individuals, this process may be precipitated by

exposure to infectious agents that stimulate the immune system and provoke a deleterious immune response on the inhibitory myenteric neurons. Achalasia can also be one manifestation of the widespread myenteric plexus destruction in Chagas disease, a consequence of infection with the parasite *Trypanosoma cruzi*. Patients with Chagas disease often have other features of autonomic neural destruction including megacolon, cardiac disease, and neurologic abnormalities. Some data suggest that age- and gender-based differences may exist. However, further study is needed into the genetic, immune, and infectious disease components of the process to provide further insight to and understanding of the mechanism of achalasia.

CLINICAL PRESENTATION

Whatever the etiology, esophageal motor disorders such as achalasia lead to a combination of three esophageal symptom complexes. First and foremost is the insidious development of dysphagia caused by failure of propulsive force, obstruction to flow, and incoordination of contraction and relaxation. The diagnosis of achalasia should be suspected in patients complaining of dysphagia for solids and liquids with regurgitation of bland food and saliva. Frequent associated symptoms may include regurgitation, cough, and aspiration. In addition to dysphagia, some individuals with achalasia describe esophageal pain as well as gastroesophageal reflux symptoms. The cause of these symptoms is speculative, but may be due to an inability to adequately clear the refluxed acid. Conversely, these symptoms may also be related to retention of acid beverages, such as carbonated or fruit drinks and, in some cases, the production of lactic acid from retained food in a markedly dilated esophagus. Respiratory symptoms are also common in patients with achalasia (20% to 40%), like cough, sore throat, and chronic aspiration. Most achalasia patients have some degree of mild to moderate weight loss of 5 to 20 lb at presentation.

DIAGNOSIS

Many patients with achalasia are initially misdiagnosed with GERD. Nearly 40% of achalasia patients will complain of some degree of heartburn due to either poor clearance of refluxed acid or from exogenous ingested acid. Upon further questioning, the most common complaint in achalasia is dysphagia of both solids and liquids with regurgitation of saliva and food. Most will have some degree of weight loss, although not

usually excessive. About 40% of patients with achalasia will complain of substernal chest pain. Other frequent symptoms are respiratory complications (nocturnal cough [30%] and aspiration), mostly observed in patients with significant esophageal stasis.

When achalasia is suspected, the best initial screening study is a barium esophagram, which will show some degree of dilation of the esophagus, loss of primary peristalsis, and a smooth tapering of the lower esophagus. An epiphrenic diverticulum may also be present in this setting. Richter has popularized a modification of the barium esophagram known as the "timed barium swallow," which assesses esophageal emptying of barium in the upright position over 5 minutes. The test can be repeated serially after therapy to evaluate the patient's response to various treatment modalities. Findings at endoscopy include retained saliva, liquid, and food in the esophagus without mechanical obstruction. Esophagogastroduodenoscopy (EGD) should also be carried out to rule out pseudoachalasia due to extrinsic compression or infiltration by a tumor, especially adenocarcinoma of the proximal stomach, at the level of the gastroesophageal (GE) junction. Approximately 2% to 4% of patients suspected of achalasia suffer from pseudoachalasia. Pseudoachalasia should be suspected in elderly patients, when there is a short duration of symptoms, and in the setting of marked weight loss. Endoscopic ultrasound may be a useful adjunct in such patients where there is a high suspicion for pseudoachalasia. Patients with a previous fundoplication or bariatric procedure (lap-band, gastric bypass) may also present with signs and symptoms that mimic achalasia, and it is extremely difficult to make the diagnosis of achalasia in the context of these operations. In these cases, it is important to look for mechanical causes of obstruction, such as anastomotic stricture, tight lap-band, or an obstructed fundoplication.

While EGD and barium esophagram are important screening studies, neither is sensitive enough to make a definitive diagnosis of achalasia. The gold standard test for confirming the diagnosis of achalasia is esophageal manometry, demonstrating esophageal body aperistalsis and incomplete LES relaxation. There are four classic manometric characteristics, which usually include: hypertensive LES, present in ~50% of patients; nonrelaxing LES; esophageal aperistalsis; and elevated lower esophageal baseline pressure. A subset of achalasia patients can have simultaneous contraction waves of variable amplitudes, consistent with preserved muscle function; this is termed *vigorous achalasia.* Esophageal

manometry is required to establish the diagnosis of achalasia and must be done in any patient where invasive treatments, such as pneumatic dilation (PD), endoscopic or surgical myotomy, are planned. Esophageal manometry is typically performed with a water-perfused catheter with five pressure transducers placed 5 cm apart. A typical catheter is 4 to 5 mm in diameter and contains eight channels oriented around the circumference. Water-perfused systems are relatively inexpensive, require little maintenance, and rarely malfunction. However, they are subject to many limitations and inaccuracies. They are uncomfortable for the patient and can induce uncontrollable swallowing. The studies are time-consuming due to the need for evaluating multiple swallows and the use of a pull-through technique to assess the function of the LES. Since the entire esophageal body is usually sampled at only five or fewer points along its length, localized or segmental abnormalities may be missed and the side holes may not be consistently parallel to the bank of pressure transducers, especially in curved locations such as the pharynx or the GE junction. These difficulties are even greater in analysis of the LES because of its short length and its frequent movement with swallowing and respiration. Finally, interpretation of motility tracings is prone to subjectivity and inter-observer variability.

High-resolution manometry (HRM) is faster to perform, more comfortable and acceptable to patients, and appears to provide more accurate and precise evaluation of a wide range of esophageal motility problems. The combination of solid-state miniaturized transducers spaced at very close intervals coupled with the analytical capacity of modern sophisticated software systems has allowed the evolution of this manometric technology. By greatly increasing the number of sensors and reducing the distance between them, it provides a comprehensive representation of the entire pressure profile along the esophagus. The visual display or topographic contour plot makes interpretation more intuitive. In addition to the advantage of the user-friendly visual representation, the software permits the easy calculation of many new parameters. The baseline may be easily adjusted to either gastric pressure or atmospheric pressure depending on the area of interest. In addition, the closely spaced transducers extending from the pharynx to the stomach and straddling the LES allow for simultaneous recording with fewer artifacts than required with the time-consuming traditional water-perfused manometry with pull-through technique. Once it is located in the stomach,

the entire topography of the esophagus and the upper and lower sphincters is identifiable at a glance.

The HRM catheter is heavier and more rigid, making it easier to pass into position without endoscopic guidance. This is particularly important in patients with a dilated esophagus or a large hiatal hernia. This new technology has provided the opportunity to develop novel parameters for classifying functional abnormalities, which is particularly important in achalasia. New studies of achalasia using HRM have revealed three distinct subtypes of this condition (Figs. 76.1 and 76.2): subtype I, classic achalasia with minimal pressurization and impaired LES (esophagogastric junction [EGJ]) relaxation; subtype II, achalasia with impaired EGJ relaxation, absent peristalsis, and pan-esophageal pressurization; and subtype III, achalasia with spasm. These groups have different responses to medical or surgical therapies, with group 2 having the best response and group 3, the worst. Thus, HRM may offer advantages over conventional methods, including improved identification of motility disorders, hiatal hernia, outflow obstruction, and ease of interpretation. HRM studies are shorter than those using conventional methods, interpretation is image based, and correlates with objective endoscopic and physiologic findings. The introduction of HRM in the evaluation of motility disorders appears to provide a significant advance in the outpatient evaluation of esophageal function.

TREATMENT/INDICATIONS

It is important to acknowledge that achalasia is an incurable disease and treatment should be directed toward the relief of symptoms. The goal of any treatment for achalasia is directed toward reducing the pressure gradient across the LES, in order to eliminate the outflow obstruction and to relieve a patient's symptoms of dysphagia and regurgitation, improve esophageal emptying, and prevent the development of mega esophagus while maintaining a barrier against GERD. Historically, the most popular treatment for achalasia has been by forceful PD. The first case of achalasia was reported over 300 years ago by Thomas Willis and the patient was successfully treated by dilation with a whale bone. PD has become much easier and more standardized with the development of the Rigiflex balloon system (Boston Scientific Corp., MA). The success rate of PD is 55% to 70% with a single dilation but can be increased to nearly 90% with multiple dilations. However, the risk of perforation with each dilation is at least 2% and has been reported as high as 16% in some series. Age (older than 60 years old) is the most important risk factor for esophageal perforation (hazard ratio 3.4 compared with <60). Furthermore, when stratified by age, balloon dilation is <50% effective in patients younger than 40 years; male gender; single dilation with a 3.0 cm balloon; posttreatment LES pressure above 10 mm Hg; and poor esophageal emptying. The only absolute contraindication to PD is poor cardiopulmonary status or other comorbid illnesses preventing surgery should an esophageal perforation occur. In the only prospective, randomized trial performed comparing surgery with balloon dilation using an older single balloon system, surgical myotomy outperformed balloon dilation 95% to 65%. Other more recent studies have failed to show a

difference in outcome between the two procedures, both for short- and long-term follow-up. In a recent large series of 209 patients with achalasia who were treated with PD between 1992 and 2002, initial dilation and then operation for short-term failures yielded good long-term results in >70% and treatment satisfaction in >80% of patients. The postdilation resting LES pressure is a major determinant of long-term success and the postdilation LES pressure can be used as a therapeutic target to determine the number of dilations needed. High long-term success rates can be obtained with repeat dilations for late recurrences and operation for early recurrences. Thus, management with initial dilation followed by a rigorous dilation protocol can provide good or excellent long-term results and high patient satisfaction rates. However, while PD has been found to have a more lasting effect on dysphagia than other nonsurgical treatments, outside of a rigorous dilation protocol, most studies have not demonstrated the long-term outcomes seen after surgical myotomy. Self-expanding stents have been used to treat achalasia. Li et al. reported a 10 years clinical success rate of 83% for the 30-mm stent, while for 20-mm stent and PD was 0%.

Botulinum toxin (BOTOX) is a potent presynaptic inhibitor of acetylcholine release from nerve endings that has proven to be a useful treatment in achalasia. BOTOX causes a short-term paralysis of the muscle by blocking the unopposed cholinergic stimulation of the LES, which is devoid of inhibitory influence in achalasia. The treatment is limited and most treatment effects are associated with approximately a 50% reduction in the basal LES pressure. This reduction may be sufficient to allow esophageal emptying when esophageal pressure rises to a level where it can overwhelm the partially paralyzed LES. BOTOX is easy to perform and has low complication rates. BOTOX injection is less effective than balloon dilation and requires retreatment to maintain an efficacy rate of 65%. The use of BOTOX injection for early recurrences after initial failed dilations is even less successful. Of greater concern is the fact that BOTOX injection leads to scar formation in the submucosal plane, which results in a more difficult myotomy and higher mucosal perforation rate (up to 30%) during dissection. Thus, BOTOX should be reserved for the treatment of patients who are poor candidates for operation and balloon dilation (dilated sigmoid esophagus) or as a bridge to surgery. An additional utility for BOTOX is in aiding in the diagnosis of patients who have equivocal findings on initial evaluation. A good response to BOTOX

is usually an indication that the patient will have long-term relief following successful dilation or surgical myotomy. BOTOX can also be considered as an adjunct treatment in patients with residual spastic contractions above the myotomy site or LES; however, outcome-related data are lacking.

Pharmacologic treatment of achalasia with either long-acting oral nitrates or calcium channel blockers attempts to recreate a balance between the stimulatory and inhibitory influences by inhibiting intramural neurons, and thus decreasing the resting and residual pressure of the LES by smooth muscle relaxation. The phosphodiesterase-5-inhibitor, sildenafil, has also been shown to lower the LES tone and residual pressure in patients with achalasia. Other less commonly used medications include anticholinergics (atropine, dicyclomine, cimetropium bromide), β-adrenergic agonists (terbutaline), and theophylline. The most commonly employed calcium channel blocker is nifedipine, showing time to maximum effect after ingestion of 20 to 45 minutes with duration of effect ranging from 30 to 120 minutes. Thus, it should be used (10 to 30 mg) sublingually 30 to 45 minutes before meals for best response. The clinical response with pharmacologic agents is short acting and the side effects, such as headache, hypotension, and pedal edema, are common limiting factors in their use. Furthermore, they do not provide complete relief of symptoms. The success of such treatment is sporadic at best, is unreliable, and is not recommended for long-term management. These agents are commonly reserved for patients with achalasia who cannot or refuse to undergo more definitive therapies with PD or surgical myotomy and those who have failed BOTOX injections.

Esophagocardiomyotomy was introduced by Ernest Heller in 1914, and remains the most effective long-term treatment for achalasia. When properly performed, a Heller myotomy can be expected to result in permanent relief of dysphagia in 85% to 100% of patients. The operation, as described by Heller, was performed through the abdomen and has remained a popular approach in much of Europe and South America. In 1958, Ellis et al. described the transthoracic approach, which remained the most common approach for performing this procedure in North America, until recently. Despite excellent results with operation and an esophageal perforation incidence of <1%, most patients (75%) opted for balloon dilation as primary therapy because of the significant morbidity associated with a thoracotomy or laparotomy. With advances in videoscopic technology in the early 1990s, this operation was readily transitioned to a

minimally invasive approach. By reducing the pain, the incision size, and the postoperative disability, the surgical therapy has become more attractive to patients.

Initially, minimally invasive videoscopic esophagomyotomy was performed with a thoracoscope. Although effective, the thoracoscopic approach is associated with several difficulties. First, the perpendicular approach to the esophagus is less favorable for attaining and maintaining the submucosal plane than is the horizontal approach afforded by laparoscopic access. It is difficult to judge the appropriate distal end of the myotomy, allowing complete division of the LES without inducing postoperative reflux. Outcomes of thoracoscopic myotomy, as measured by both dysphagia relief and development of postoperative reflux, have been shown to be inferior to the laparoscopic approach in numerous studies. Finally, postoperative pain and length of hospital stay are generally greater following the thoracoscopic approach as compared to the laparoscopic. Today, esophageal myotomy is performed almost invariably through a laparoscopic approach.

Following the rapid acceptance of laparoscopic antireflux procedures, the laparoscopic Heller myotomy (LHM) became a natural extension of this experience and has proven to be more effective than the thoracoscopic procedure with less overall morbidity. The procedure is simpler to learn and to perform, and it allows routine hemifundoplication to prevent postoperative reflux. In selected patients such as a hostile, multiply operated abdomen, following a failed abdominal myotomy, or in diffuse esophageal dysmotility, the thoracic approach may still be preferred. LHM is associated with an 80% long-term success rate. A recent meta-analysis reported success rates of 89% after a mean follow-up of 35 months. Successful LHM may be predicted by high lower esophageal sphincter pressure (LESP), no prior therapy, short symptom duration, or absence of sigmoidal esophagus.

Failure of esophagocardiomyotomy to relieve the dysphagia may be attributable to either incompletely relieving the obstructive achalasia or an obstructing antireflux mechanism distal to the aperistaltic esophagus. In an evaluation of the effect of preoperative PD or BOTOX injection on outcomes after LHM for achalasia in 134 patients, multiple endoscopic treatments were associated with poorer outcomes, and these authors suggest that dilation or BOTOX should be limited to achalasia patients who fail surgical therapy.

Recent data show that both the proximal and distal extents of the myotomy are important. It has been recently recognized that an epiphrenic diverticulum may develop, which is believed to be caused by absence of coverage by the fundoplication over the proximal extent of the myotomy. This increased recognition of the potential for diverticulum formation has led many to limit the proximal extent of the myotomy to that, which can be covered by an anterior fundoplication. It has long been the belief that overzealous extension of the myotomy onto the stomach, in an attempt to avoid incomplete myotomy, is associated with a high incidence of reflux and associated esophagitis. However, recent studies have demonstrated that relief of dysphagia is improved with lengthening of the distal extent of myotomy from 2 to 3 cm onto the cardia of the stomach with disruption of the gastric sling fibers, further decreasing LES pressure. Since an effective myotomy should lower esophageal outflow resistance and improve esophageal emptying, it also increases the propensity for development of GE reflux. There is often a poor correlation between symptoms of reflux and pathologic reflux as demonstrated by pH study. The importance of the addition of a fundoplication to the myotomy has, until recently, been debated.

A prospective, randomized study by the group at Vanderbilt University demonstrated that Heller myotomy plus a Dor anterior fundoplication is superior to Heller myotomy alone in regard to the incidence of postoperative reflux as measured by 24-hour pH testing. Furthermore, there was no increase in dysphagia in the fundoplication group. In this study, abnormal acid exposure on pH monitoring was found in 47% of patients without an antireflux procedure and 9% in patients who had a posterior Dor fundoplication. A subsequent cost–utility analysis based upon the results of this randomized double-blind trial found that myotomy plus Dor fundoplication was more cost-effective than myotomy alone because of the costs of treating GERD. Following successful esophageal myotomy, patients may continue to have minor symptoms of dysphagia, which is attributable to esophageal aperistalsis. The type of fundoplication is important in order to avoid significant obstruction. In general, a 360-degree fundoplication should not be used in patients undergoing a myotomy for achalasia because it will be too obstructive in this setting. The most recent achalasia guidelines from the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) recommended that patients who undergo myotomy should have a fundoplication to prevent

reflux. Although it has been fairly well established that adding a fundoplication is beneficial for reducing the rate of GERD after myotomy, there is less certainty on the best approach (anterior Dor or posterior Toupet). Both the posterior Toupet and the anterior Dor partial fundoplications have been used effectively, and a recent multicenter trial has suggested no difference between the posterior and anterior fundoplications. Proponents of the Toupet claim the advantage that it holds the edges of the myotomy apart and provides a better antireflux mechanism when the patient is in the supine position. However, in the patient with a markedly dilated esophagus before myotomy, the Toupet may be too obstructing and either an anterior fundoplication or no fundoplication at all is recommended. Proponents of the Dor partial fundoplication prefer the added security of covering the exposed mucosa with the fundus and the avoidance of complete mobilization of the abdominal esophagus, which is required when constructing a Toupet wrap. Dor fundoplication does not require extensive mobilization of the fundus, the short gastric vessels are left intact, and posterior dissection is unnecessary, thus eliminating the disruption of the posterior aspect of the phrenoesophageal ligament. Because of the preservation of these natural posterior attachments and its easier technical construction, most surgeons have migrated toward routine Dor fundoplication. Given the significant chance of reflux after myotomy even with an added partial fundoplication, all patients who complain of heartburn or who have an abnormal postoperative pH study should be treated with long-term proton pump inhibitor (PPI) therapy.

The best surgical treatment (myotomy vs. esophagectomy) for patients with achalasia and a markedly dilated esophagus has been debated; however, several recent studies have reported successful treatment of achalasia with LHM in the setting of a markedly dilated esophagus (>6 cm diameter) and even in patients with extreme mega-esophagus (>10 cm). Occasionally, the degree of esophageal aperistalsis is so advanced that myotomy alone does not relieve the dysphagia and the patient is better served with esophagectomy. Esophagectomy should be considered in a patient with a dilated sigmoid esophagus who remains symptomatic and has had a previous myotomy, with a resting LES pressure of <10 mm Hg.

The utility of intraoperative manometry in laparoscopic myotomy is clear. The technique is safely performed, adds little time to the case, and clearly identifies persistent areas of residual high pressure at the

esophagogastric junction, especially when enhanced with real-time three-dimensional pressure imaging. Intraoperative esophageal manometry can be used during achalasia surgery to verify the myotomy, to provide an objective means of determining the correct length of myotomy, and to better calibrate the reconstructed LES pressure during antireflux procedures. With the recent advent of laparoscopic myotomy, intraoperative manometry has enjoyed a resurgence of popularity as an adjunct to the minimally invasive procedure. If the combination of intraoperative manometry and endoscopy can better guide the extent of the myotomy, then perhaps, one no longer has to choose (or guess) between either incomplete relief of achalasia or incompetence of the cardia. Clearly, intraoperative manometry can improve the adequacy of myotomy. In addition, it may prove a useful tool in decreasing the incidence of significant dysphagia after the antireflux procedure.

Recent developments in gastrointestinal endoscopic methodology, originating from work done in the study of natural orifice surgery (NOTES), have led to the conceptualization and practice of per-oral Endoscopic Myotomy (POEM) an intramural endoscopic approach to the division of the distal esophageal and proximal gastric muscular layer with resultant relaxation of the LES. This procedure was conceptualized and studied in the laboratory by a team led by Pasricha. It was then first performed in humans by a thoracic surgeon, Inoue, in Japan. The method, carried out under general anesthesia, involves creation of an esophageal submucosal tunnel, which is carried onto the proximal stomach (Fig. 76.3). The loose areolar tissue holding the mucosa to the underlying muscle is divided. The muscles of the esophageal and gastric wall are then divided under direct vision. At the conclusion of the procedure, the small entrance to the submucosal tunnel is closed with endoscopic clips. There is no surgical incision on the exterior of the patient's body.

Candidates for POEM include patients with a diagnosis types I, II, or III achalasia, and some patients with NE. Patients who have failed PD and previous Heller myotomy may also be candidates. However, massive esophageal dilatation, severely tortuous esophagus, and large epiphrenic diverticula may be contraindications.

PREOPERATIVE PREPARATION

Prior to operation, the patient should be placed on clear liquids for 48 hours to allow the retained food in the dilated esophagus to pass. The

patient is instructed to shower with chlorhexidine soap the night before the operation and should be NPO after midnight. Bilateral pneumatic compression boots should be placed on the lower extremities prior to induction. A single dose of preoperative antibiotic is given, and a rapid sequence induction anesthesia should be performed in order to minimize the risk of aspiration. Blind placement of a nasogastric tube or esophageal stethoscope should be discouraged in these patients because of the risk of perforation of the esophagus.

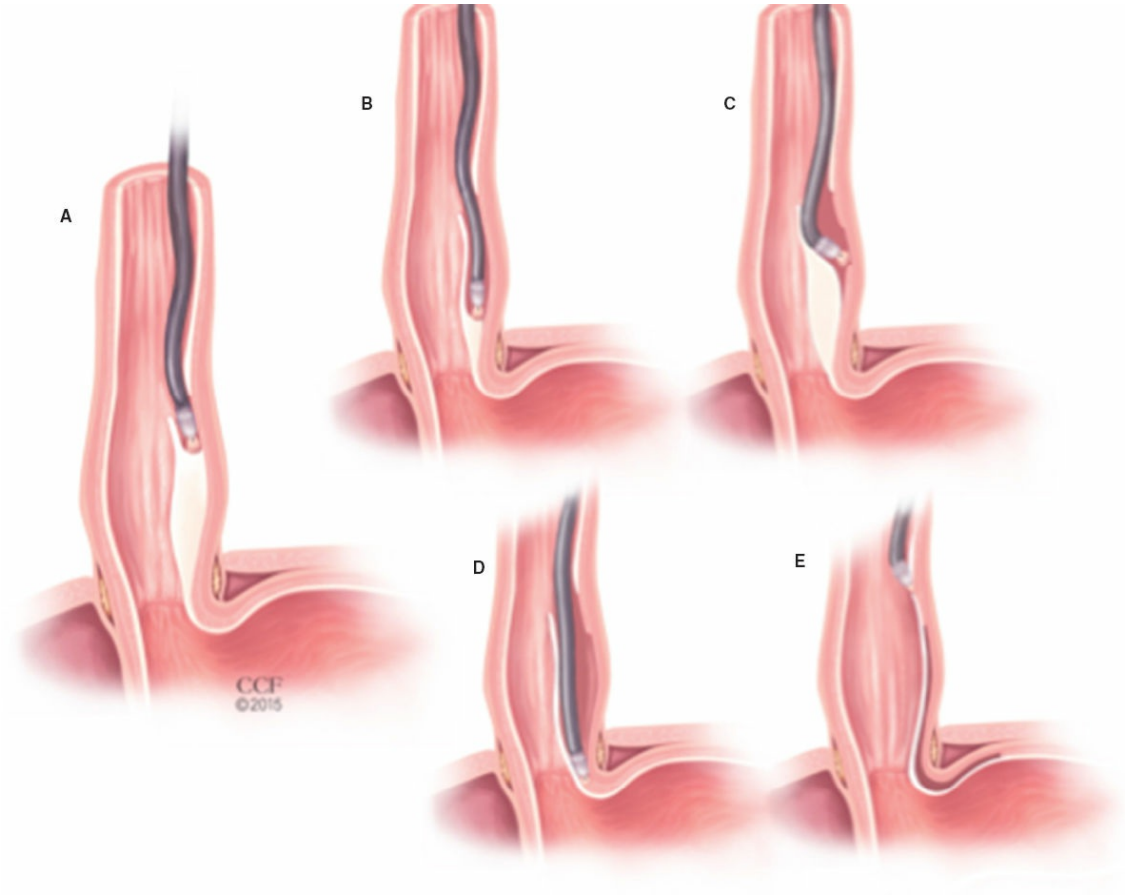

Figure 76.3. Steps in the per-oral endoscopic myotomy.

LAPAROSCOPIC ESOPHAGOCARDIOMYOTOMY

The patient is positioned supine on the operating table with the sequential compression devices placed on the lower extremities. A general endotracheal anesthetic is administered and the patient is positioned with the arms tucked by their sides. The patient's legs are placed in adjustable leg holders in a low lithotomy position or in a split leg position, and a urinary catheter is placed (Fig. 76.4). An endoscope is placed through the patient's mouth, down the esophagus, and into the stomach and left in position for the intraoperative manometry and directed myotomy. The skin of the lower chest and abdomen is cleansed with an antibacterial surgical prep solution. A carbon dioxide pneumoperitoneum is established with a Veress needle puncture via the umbilicus to an intra-abdominal pressure of 15 mm Hg.

All port sites are injected prior to incision with 0.5% bupivacaine. The initial laparoscopic port (either 5 mm or 10 mm depending upon the size of the angled laparoscope) is placed 15 cm below the xiphoid and just to the left of midline. A 30-degree angled laparoscope is placed through this port,

and four additional ports are placed under direct vision. Two 5-mm ports are placed just below both costal margins 15 cm lateral to the xiphoid, and two ports (5 mm on the patient's right and a 10-mm port on the left) are placed 10 cm from the xiphoid and 3 to 4 cm on either side of the midline (Fig. 76.5). The patient is positioned in a reverse Trendelenburg position and a flexible 5-mm liver retractor is placed via the right costal margin port and positioned under the lateral segment of the left lobe of the liver, and elevated to expose the hiatus and the GE junction. At this point, the endoscope is advanced through the pylorus, a guidewire is passed into the duodenum via the endoscope and a manometry catheter is placed over the wire into the body of the stomach, and baseline pressures are measured using a pull-back technique across the LES.

The cardia of the stomach is grasped with an atraumatic grasper from the left lateral port, and the stomach and GE junction are retracted in a leftward and caudad direction. Hiatal exposure is performed using a grasper in the left hand and an ultrasonic shears in the right hand. If a patient is undergoing a myotomy alone or an anterior (Dor) fundoplication, care is taken to only dissect the anterior aspect of the esophagus and to leave as much of the phrenoesophageal ligament intact as possible.

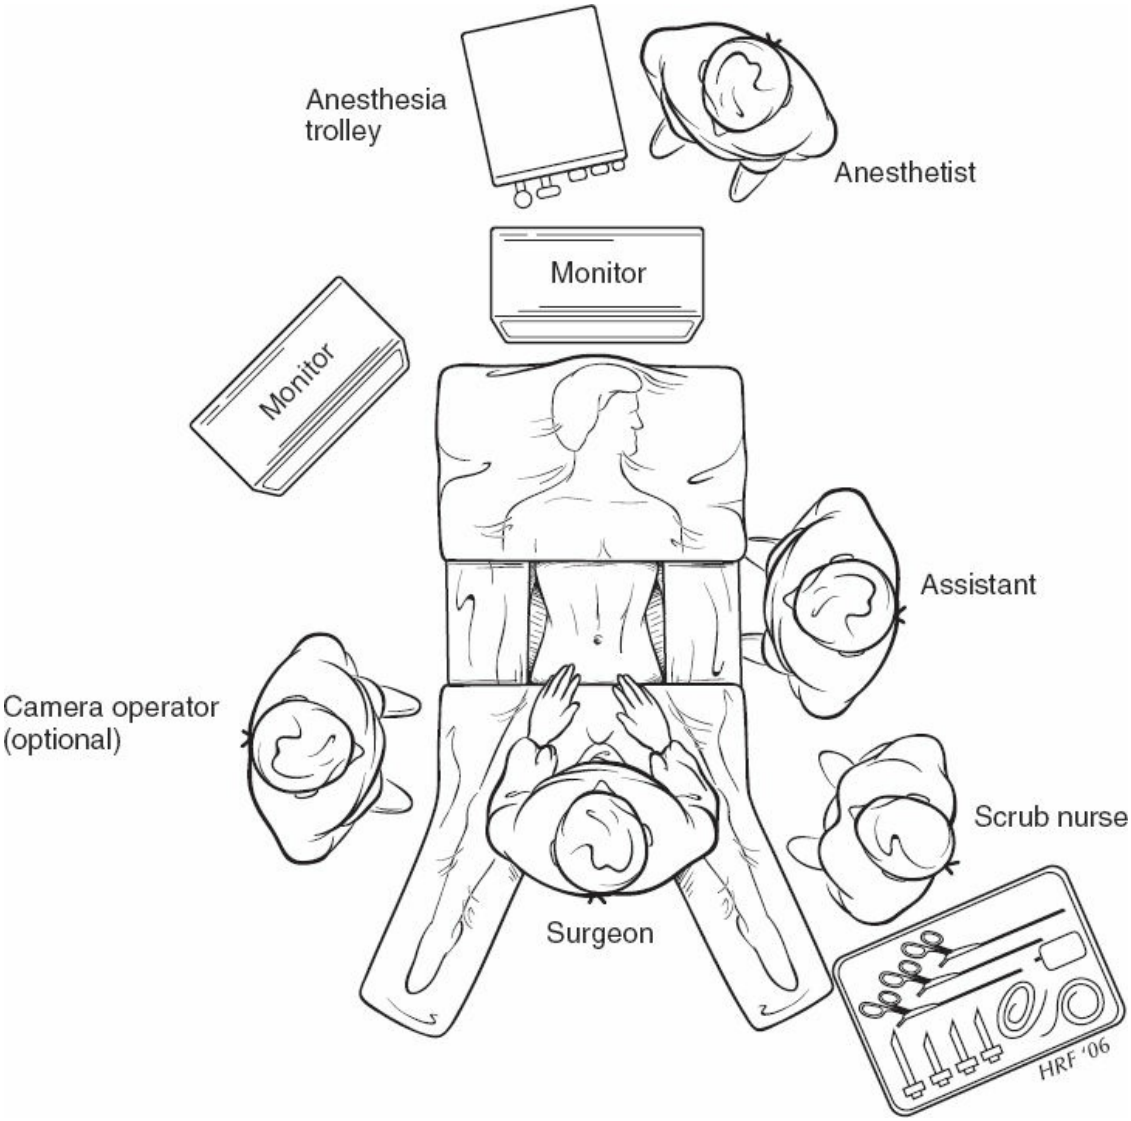

Figure 76.4. Patient position on the operating table for a laparoscopic myotomy. The low lithotomy position with arms tucked allows the surgeon to operate from a midline, coaxial orientation.

If a posterior (Toupet) fundoplication is planned, the esophagus is circumferentially mobilized by clearing the retroesophageal window. The posterior vagus is identified and retracted along with the esophagus, using a Penrose drain placed around the esophagus. The short gastric vessels are divided (only when performing a Toupet fundoplication) using the ultrasonic shears, and the pancreatic and diaphragmatic attachments to the gastric fundus are released (Fig. 76.6).

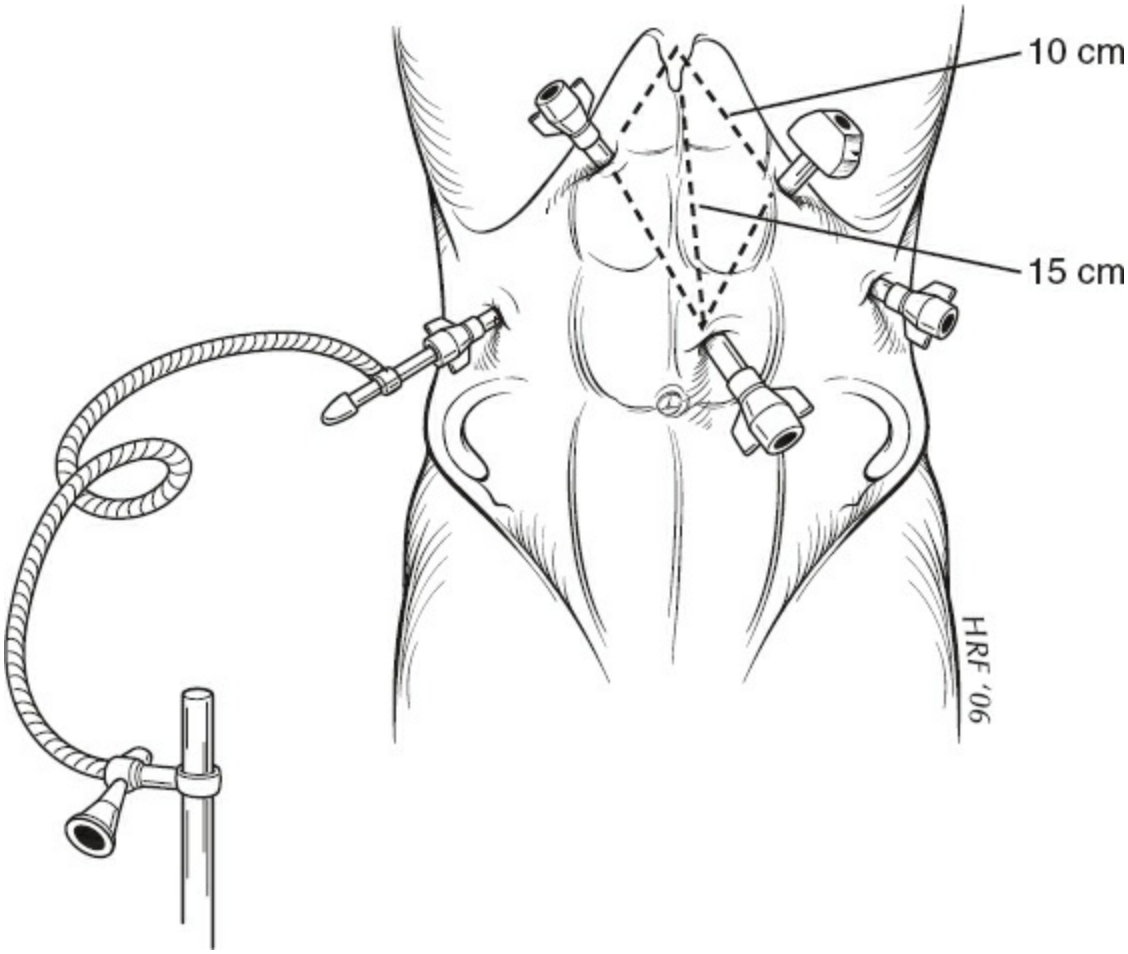

Figure 76.5. Port placement for a laparoscopic myotomy. The surgeon's right hand and left hand form an equilateral triangle with the hiatus and the laparoscope port. The liver retractor and assistant's right hand complete two other equilateral triangles.

After the lower esophagus, anterior vagus nerve, and cardia of the stomach are exposed, the GE fat pad is excised and the anterior esophagus is treated with a concentrated solution of 1:1,000 epinephrine applied by a kittner gauze dissector to aid with hemostasis. The myotomy is then carried out utilizing blunt dissectors, a scissors or hook without electrocautery, and/or an ultrasonic shears (Fig. 76.7). The myotomy is begun on the esophagus and carried proximally a distance of 5 to 6 cm from the GE junction and distally 1.5 to 2 cm onto the cardia. The myotomy is guided by intraoperative endoscopy to ascertain that it is carried at least 1.5 to 2 cm beyond the squamocolumnar junction (Fig. 76.8). Electrocautery and ultrasonic dissection are used sparingly to avoid inadvertent mucosal perforation. Hemostasis is obtained with the use of the epinephrine (1:1,000) soaked kittner and 2 × 2 in gauze sponges. The myotomy should be tested with underwater air insufflation to ensure that

there are no inadvertent mucosal injuries. Mucosal holes are sutured with 4-0 absorbable sutures, and the repair is always tested again with endoscopic insufflation. When the myotomy is felt to be complete, repeat manometry is performed to confirm successful ablation of the pathologic high-pressure zone. If the myotomy is incomplete, then it should be extended until a satisfactory pressure reduction is obtained.

The esophageal hiatus is reapproximated, if necessary, with one to two 0-braided polyester sutures. If an anterior (Dor) fundoplication (Fig. 76.9) is performed, four 2-0 polyester intracorporeal sutures are placed. On the left side, a suture is placed between the fundus, the apex of the left crus, and the superior (cephalad) cut edge of the muscularis to the left of the esophagus. A second suture is placed 2 cm inferior (caudad) to the first suture approximating the left side of the fundus and the left side of the myotomy. The third suture is placed between the fundus and the superior (cephalad) cut edge of the muscularis to the right of the esophagus and the apex of the right crus. Finally, the fourth suture is placed between the right side of the fundus and the inferior (caudad) right side of the myotomy to complete an anterior partial fundoplication. In this way, the entire exposed aspect of the mucosa is covered by fundus to prevent the late development of a distal esophageal diverticulum.

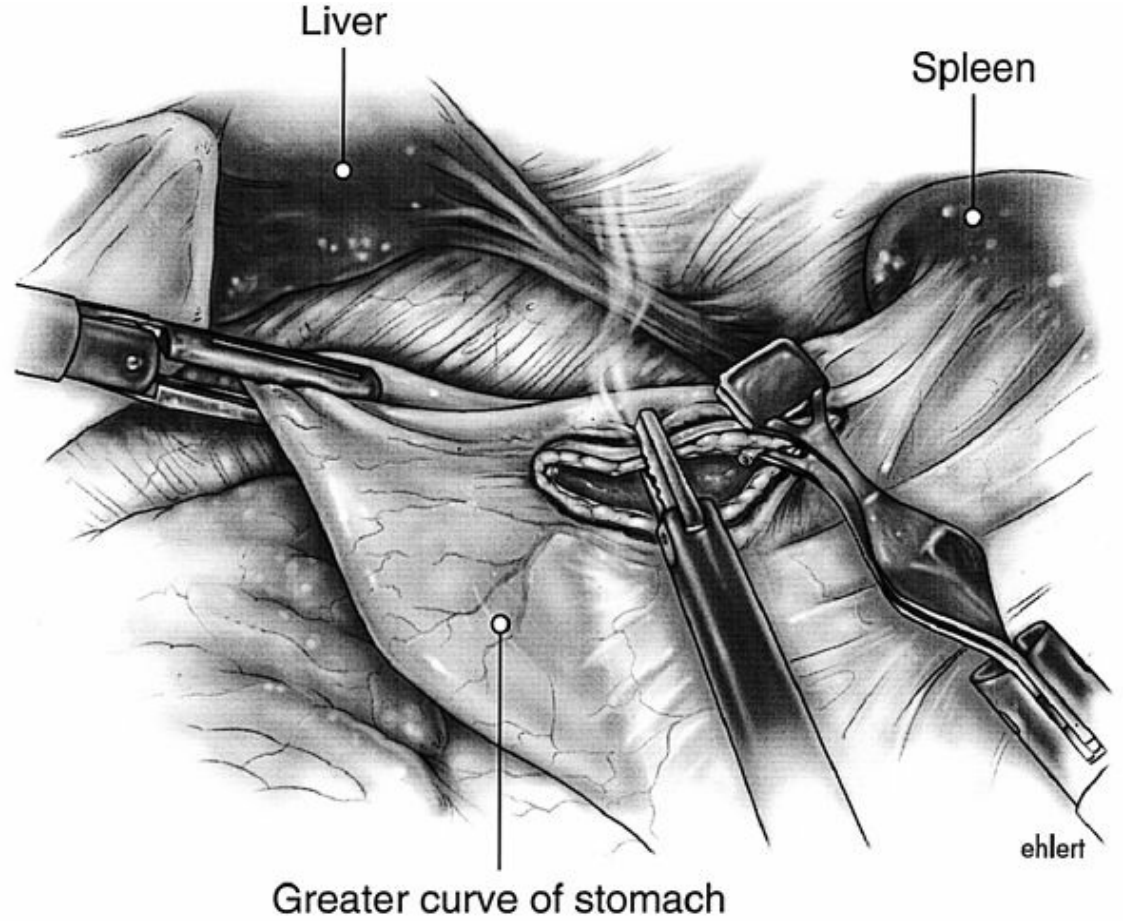

Figure 76.6. Dissection of the short gastric vessels. The assistant retracts the gastrocolic and gastrosplenic ligament anterolaterally toward the spleen, while the surgeon's left hand provides counter traction on the fundus. Ultrasonic shears are used to divide the short gastric vessels.

When a posterior (Toupet) fundoplication is chosen, the fundus is grasped from the right and brought around behind the esophagus through the retroesophageal window, and the posterior fundoplication is fashioned utilizing eight 2-0 braided polyester intracorporeal sutures (Fig. 76.10). On the right side, a suture is placed between the superior (cephalad) extent of the myotomy and the fundus. The outside of the fundus is sutured to the apex of the right crus with a second suture. Finally, two additional sutures are placed further caudad from the first suture, between the cut edge of the muscularis to the right of the esophagus and the fundus, placing each of the three sutures 1 cm apart to create a 2-cm long fundoplication. An identical series of four sutures are placed on the left side of the myotomy and left crus to complete the fundoplication (Fig. 76.11).

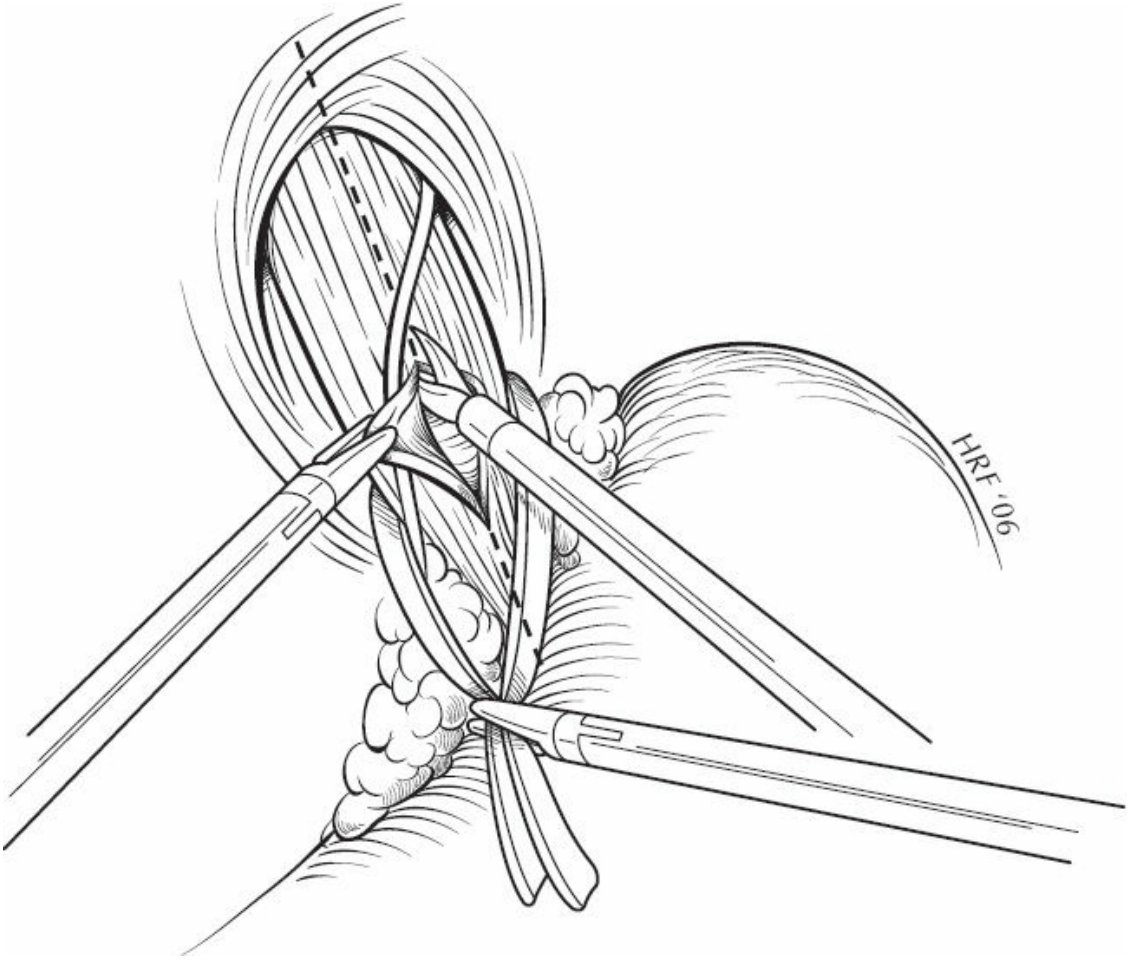

Figure 76.7. Division of the longitudinal muscle fibers of the esophagus is begun 2 to 3 cm above the gastroesophageal junction. Care must be taken to avoid full-thickness injury.

Manometry is repeated at the conclusion of the fundoplication in order to obtain a new baseline and to be certain that the fundoplication does not cause an excessive amount of pressure (the pressure should be no >20 mm Hg). The Penrose drain is removed from around the esophagus, the operative field is irrigated and inspected, the secondary ports are removed under direct vision, and the primary port is used to desufflate the abdomen and then it is removed. The incisions are closed, the urinary catheter is removed, and the patient is transported to the postanesthetic care unit.

ROBOTIC-ASSISTED LAPAROSCOPIC ESOPHAGOMYOTOMY

Recent experience using both the three-arm and four-arm computer-enhanced telesurgery device (*da Vinci* Surgical System, Intuitive Surgical, Sunnyvale, CA, USA) has demonstrated that this is a safe and effective

treatment method for this particular foregut disorder. Computer assistance allows scaling of hand motions, successful dissection of esophageal musculature in a three-dimensional field, and improved ease of suturing. The benefits of magnification and three-dimensional imaging can help prevent esophageal perforation and identify residual circular muscle fibers. Several large studies comparing the robotic with the laparoscopic method have demonstrated equivalent efficacy in relieving the symptoms of achalasia, while the robotic method is safer because it decreases the incidence of esophageal perforation to nearly 0%, even in patients who had previous dilation and BOTOX treatment. Furthermore, patients demonstrated a high level of satisfaction with their health-related quality of life following robotic-assisted LHM and fundoplication, when compared with laparoscopic patients.

The operative technique for the robotic-assisted procedure is essentially the same as described above for the laparoscopic approach. Because of the circumference and increased length of the robotic telescope, the initial access port must be either a 10/12-mm or 8-mm port and should be placed ~2 cm further caudad (17 cm) from the xiphoid. The secondary ports must also be further apart, with a minimum four finger-breadth distance between each port to allow for full range of motion of the robotic arms. The right lateral subcostal port is still used for the static placement of a 5-mm liver retractor; the other three ports are for robotic instruments and can be either 8 mm or 5 mm in size, depending upon the size of the robotic hand instruments available. The myotomy is carried out utilizing a hook dissector, which has a full 7-degree range of articulation and monopolar cautery.

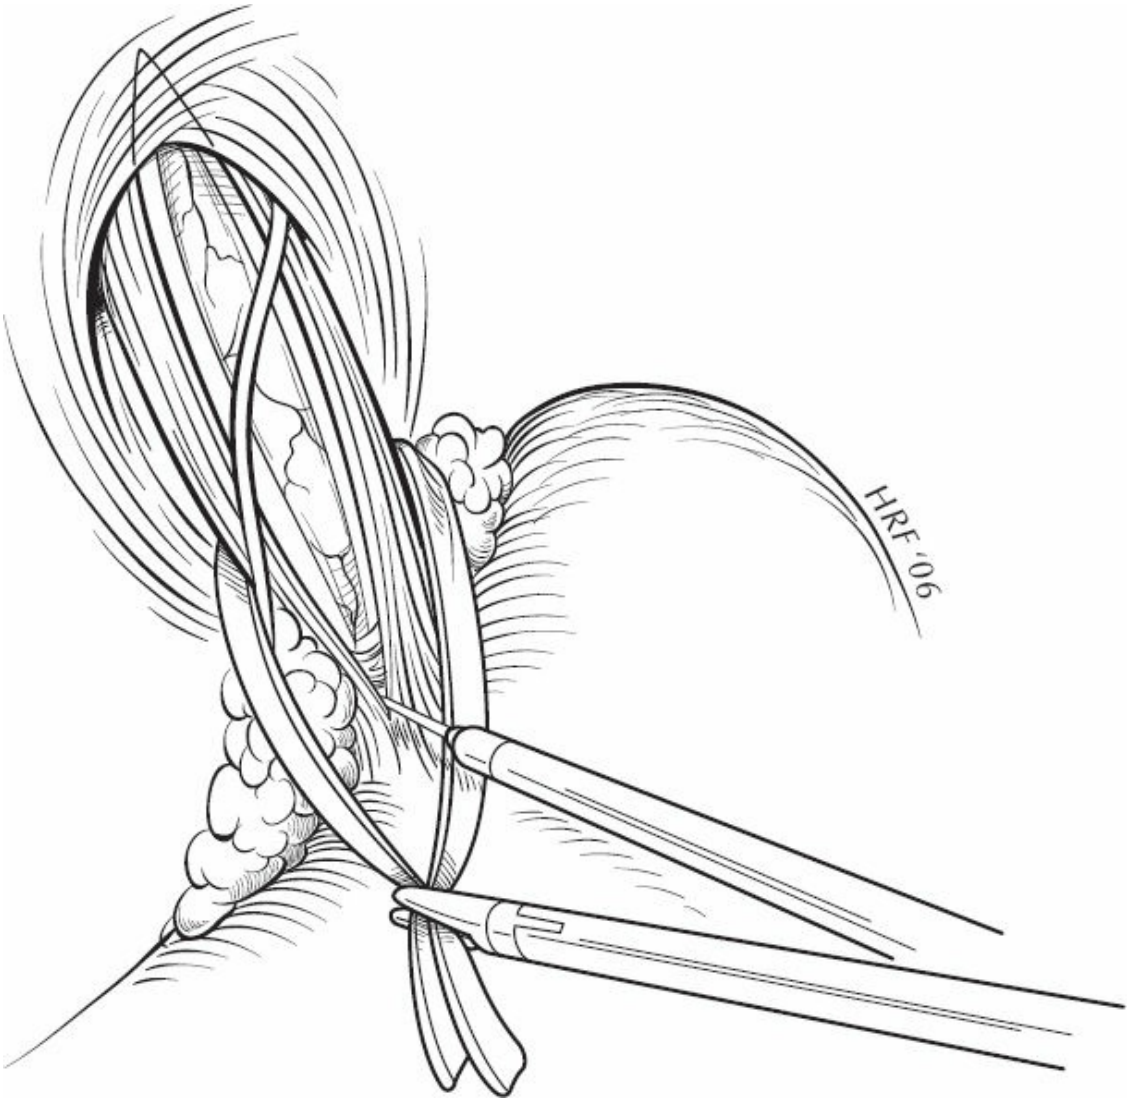

Figure 76.8. The completed myotomy extends onto the cardia of the stomach for 2 cm beyond the squamocolumnar junction as measured using intraluminal endoscopy. The cut edges of the myotomy are separated for at least one third of the circumference of the esophagus.

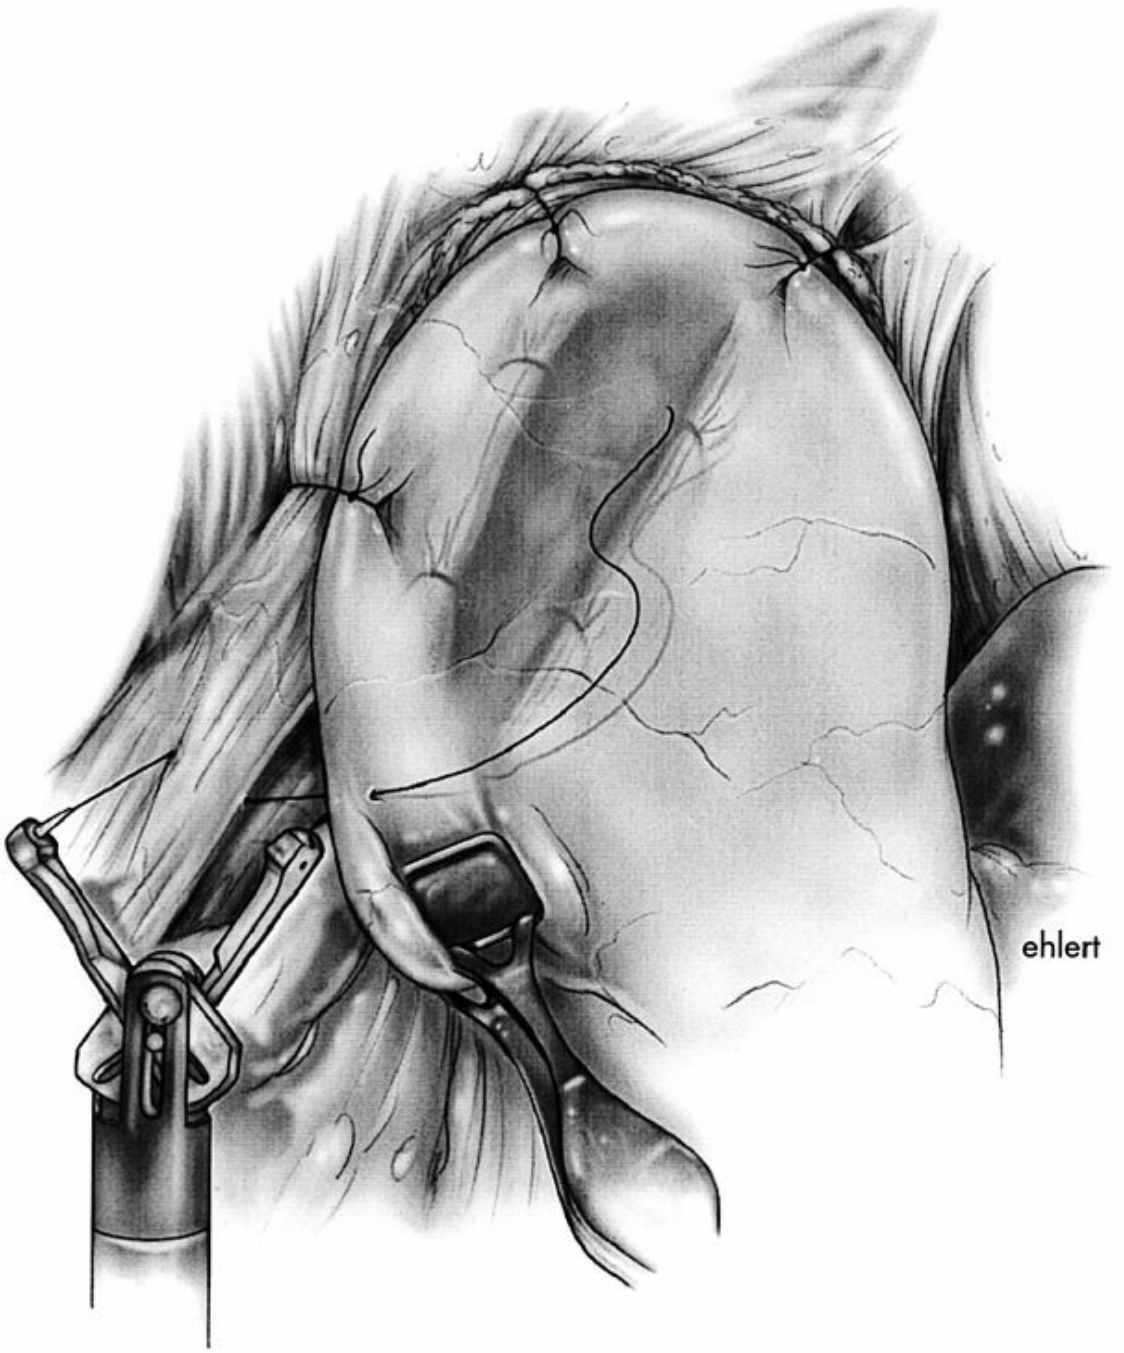

Figure 76.9. Completed anterior partial fundoplication. Several sutures are used to anchor the fundus to the cut edge of the myotomy. The fundus is also anchored to the hiatus. The anterior fundoplication allows the esophageal mucosa to be buttressed by the gastric serosa, and is especially useful if the mucosa was injured during the myotomy.

THORACOSCOPIC ESOPHAGOMYOTOMY

As mentioned earlier, in selected patients such as a hostile, multiply operated abdomen or following a failed abdominal myotomy, the thoracic

approach may still be considered. The thoracic approach is also appropriate in managing patients with proximal esophageal motility abnormalities. Thoracoscopic esophagomyotomy can be performed via either thoracic cavity with the patient in a lateral decubitus position. A double-lumen endotracheal tube is used to allow selective ventilation of the contralateral lung. The surgeon and the assistant stand behind the patient, while the instrument nurse stands facing the patient. The primary videoscope port is placed in the fourth or fifth intercostal space, just inferior and posterior to the tip of the scapula. Two working ports are placed in the second/third and the sixth/seventh intercostal spaces in the mid-axillary line to create an equilateral triangle with the videoscope port. A fourth port or small incision is placed anteriorly to provide retraction of the lung (Fig. 76.12).

The lung is deflated and the esophagus and esophageal hiatus are visualized. As described above, endoscopic and manometric guidance can be used to aid in the identification and dissection of the esophagus, as well as confirming completion of the myotomy. The mediastinal pleura overlying the esophagus is incised and the inferior pulmonary ligament is divided. Dissection is kept to a minimum in order to preserve the normal hiatal structures. Dissection is extended caudad as far as the right hemidiaphragm. If a long myotomy is being performed, dissection is carried proximally beyond the azygous vein on the right and up to the arch of the aorta on the left. The azygous vein can be ligated, clipped, or stapled once it is mobilized off of the esophagus. Myotomy is carried out in a similar fashion to that described in the laparoscopic approach (Fig. 76.13). Because of the perpendicular approach, an L-hook is most useful with careful use of monopolar electrocautery, once the longitudinal and circular fibers are elevated away from the esophagus (Fig. 76.14). The endoscope can facilitate this by applying suction to deflate the mucosa. The myotomy is begun 2 to 3 cm above the GE junction and carried distally beyond the endoscopically identified squamocolumnar junction. The proximal extent of the myotomy depends upon the underlying diagnosis and the intraoperative manometric findings. The integrity of the esophageal mucosa is tested with endoscopic insufflation. Addition of an antireflux procedure is difficult to perform and is usually not employed when using a thoracoscopic approach. A small caliber chest tube is placed, the lung is reexpanded, and the port sites are closed.

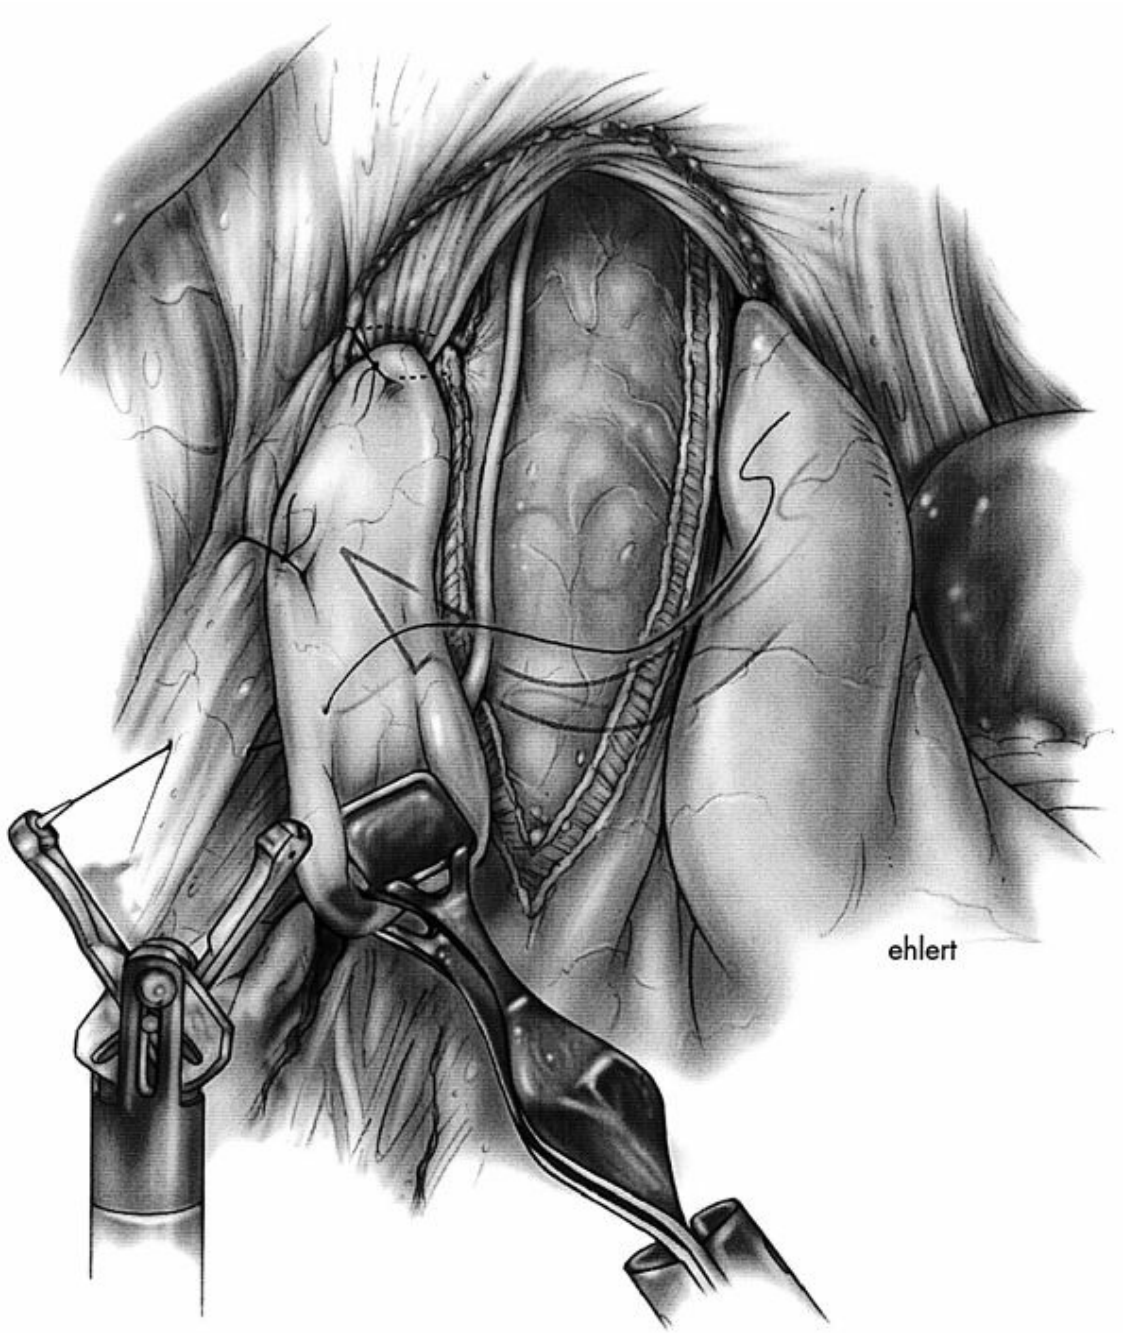

Figure 76.10. The first sutures of a partial posterior fundoplication are used to anchor the fundus to the right crus. This type of antireflux procedure has the advantage of keeping the cut edges of the myotomy separated.

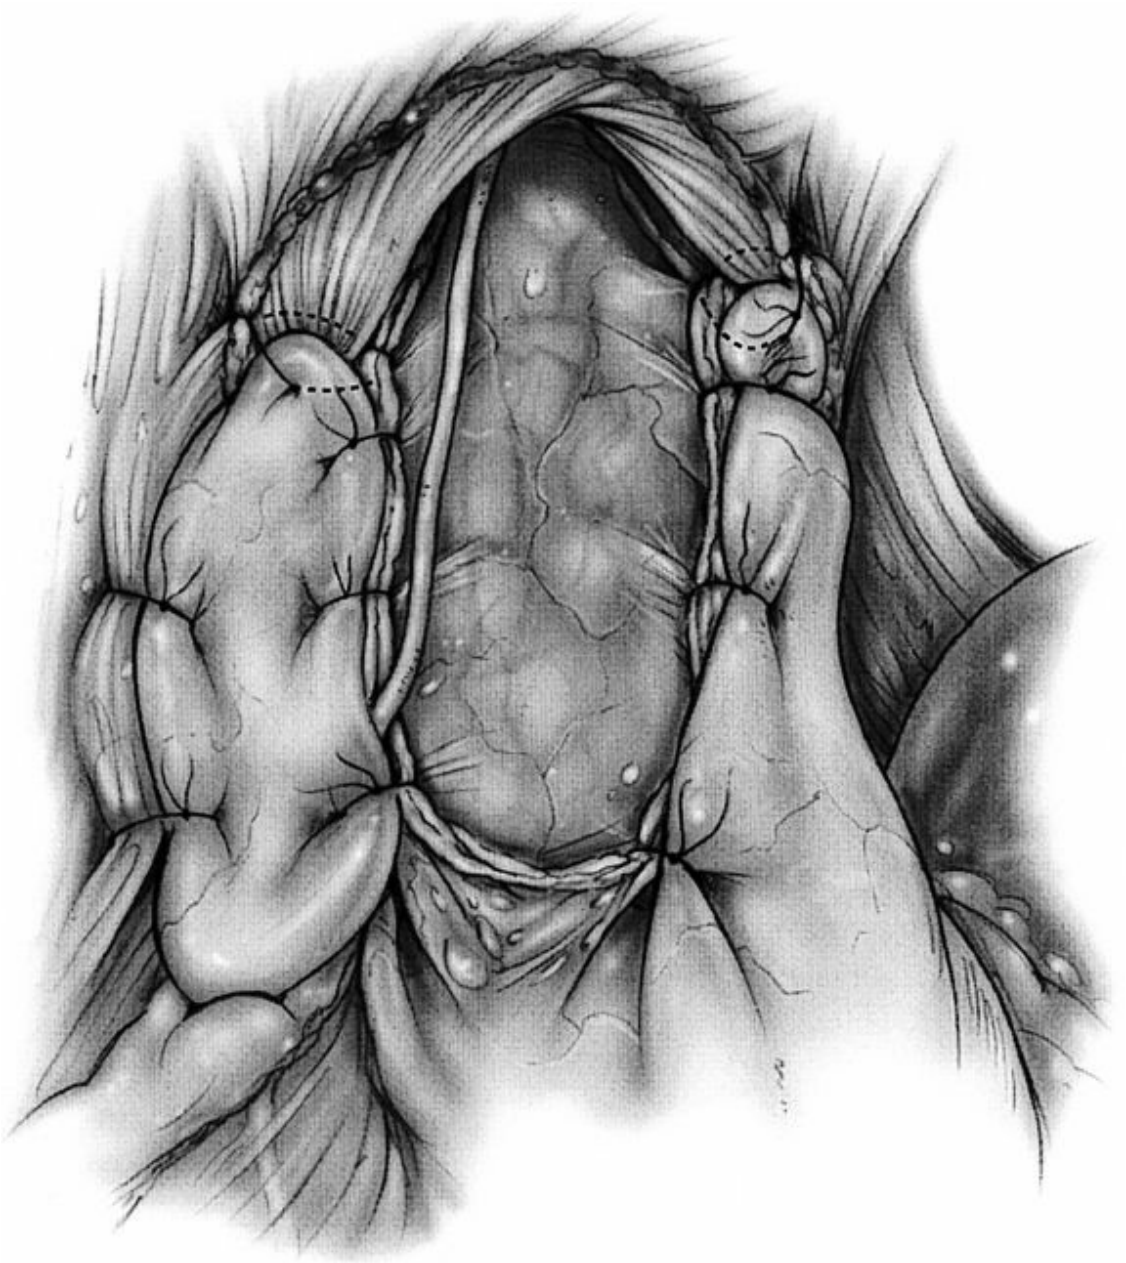

Figure 76.11. Completed posterior partial fundoplication. The fundus is anchored to the crura and the cut edge of the myotomy. The anterior vagus usually passes between the two most distal sutures on the right as it courses toward the lesser omentum.

PER-ORAL ENDOSCOPIC MYOTOMY (POEM)

Patients are evaluated and prepared for POEM in the same way as they would be for a Heller myotomy. Most of these procedures have been performed in the operating theater, although some have been reported to occur in specialized endoscopic suites. All have occurred under general anesthesia with endotracheal intubation. After a careful inspection of the esophagus and stomach, the location of the esophagogastric junction is

noted. In some cases, an endoscopic clip or injection of blue dye may be placed just below the junction for later use in assessing the extent of dissection.

The endoscope is affixed with a plastic cap to assist in dissection and often an overtube is used to facilitate frequent scope removal and reinsertion. An injection of a mixture of saline and indigo carmine or methylene blue is injected into the submucosal space at a point 10 to 15 cm proximal to the esophagogastric junction and a bleb raised. This bleb is then incised with a monopolar cutting current applied with a specialized endoscopic electrode. The injection and incision are most often performed on the anterior esophageal wall, although some have performed the injection and the myotomy posteriorly. After incision of the esophageal mucosa, a submucosal tunnel is created using cautery current to selectively divide the loose areolar tissue that joins the mucosal to the underlying muscle (Fig. 76.15). During this process, the circular muscle fibers of the esophageal wall are clearly visible. Once the tunnel is believed to extend beyond the esophagogastric junction and on to the proximal stomach, the extent of dissection may be verified by returning the scope to the native esophagus and advancing it into the stomach where a retroflex view of the cardia will show blue discoloration if the tunnel is of sufficient extent. If blue dye has been injected into the proximal stomach prior to the tunnel creation, it may be noted during the tunnel dissection when the proximal stomach is reached. If the surgeon has chosen to place an endoscopic clip in the stomach at the beginning of the procedure, fluoroscopic visualization of the scope in the stomach, under the diaphragm, and near the clip may be another useful way to assure that the dissection has gone sufficient distance.

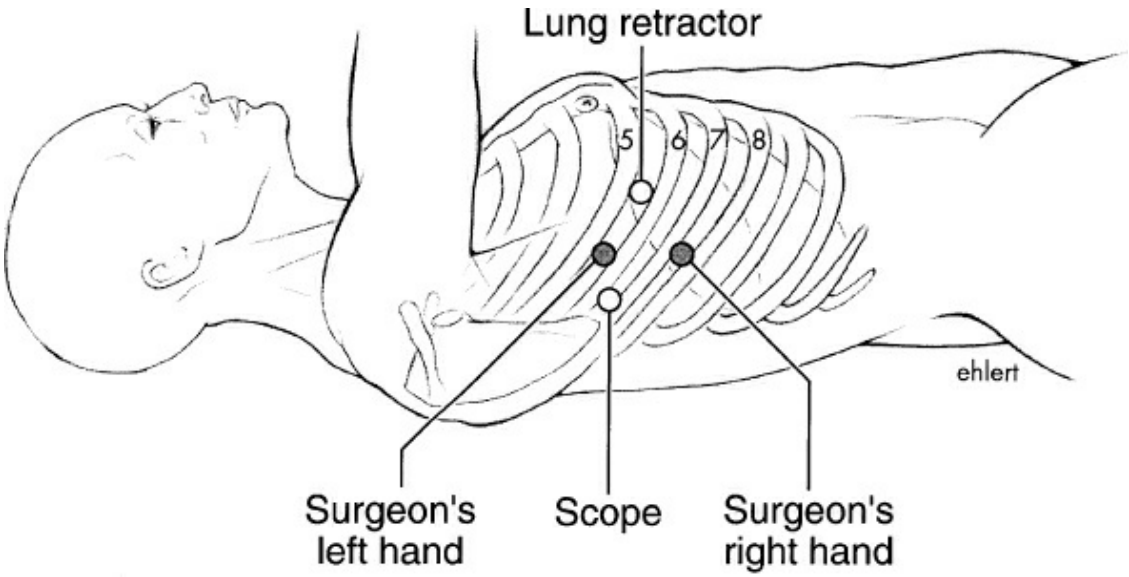

Figure 76.12. Port placement for a right thoracic myotomy. The videoscope is placed in the sixth intercostal space near the tip of the scapula. The surgeon's right hand and left hand are placed in the midaxillary line to create equilateral triangles with the videoscope and the mid-thoracic esophagus. A fourth port is placed more anterior to facilitate retraction of the lung.

After determination that the tunnel is of adequate length, the endoscope is withdrawn to several centimeter beyond the mucosal incision and cautery current is used to divide the esophageal muscle (Fig. 76.16). Most surgeons have chosen to divide only the circular (inner) muscular layer, leaving the longitudinal layer as a barrier between the mucosa and the mediastinum. Others have divided both layers. Comparative studies have shown no clinical difference in outcome between the two methods. In most cases, in spite of sparing the longitudinal fibers, most are torn or splayed out after division of the circular fibers. Following the myotomy, the scope is advanced through the native esophagus and esophagogastric junction to assure that relaxation is sufficient. Following this, the tunnel is sealed by endoscopic clipping of the original mucosotomy (Fig. 76.17).

POSTOPERATIVE CARE

The patient is kept NPO overnight, on intravenous fluids and parenteral analgesics. A gastrografin followed by barium swallow is often performed on the first postoperative day to confirm that there is no extravasation (gastrografin) or obstruction (barium) to flow. If the esophagram is normal, the patient is started on a clear liquid diet and advanced to a post-

fundoplication diet as tolerated. A recent review of 260 patients demonstrated a poor positive predictive value of routine esophagram after LHM, and the authors concluded that esophagography should be used selectively in the immediate postoperative period after an uncomplicated procedure. The patient is discharged once tolerating the post-fundoplication diet, usually on the evening of the first postoperative day. They can be transitioned to a regular diet within 2 weeks following discharge. Postoperative care after POEM is similar to care after LHM. Patients are generally discharged in a day or two following the procedure.

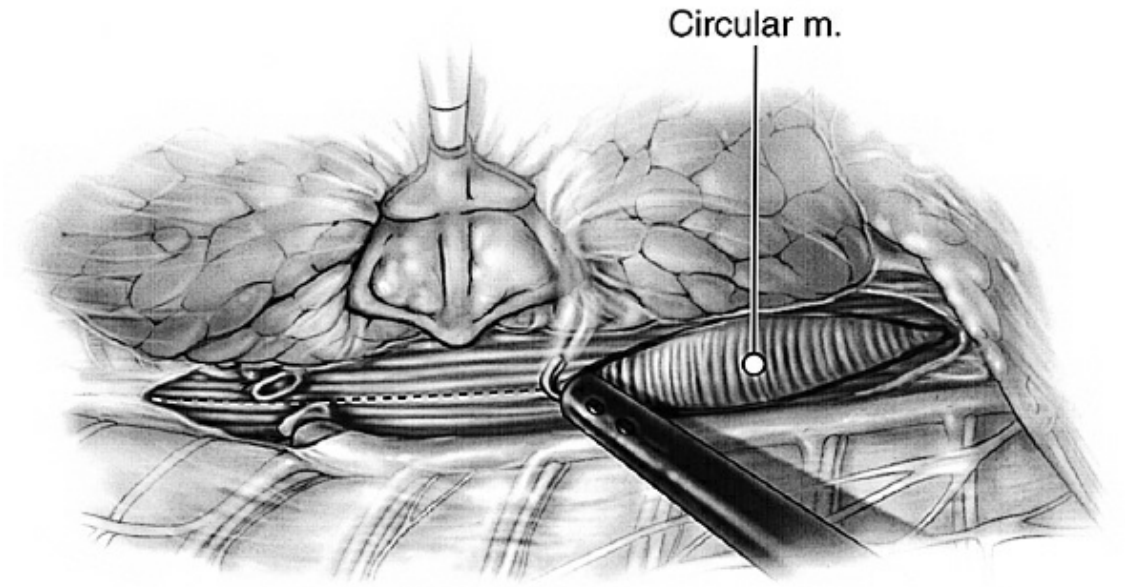

Figure 76.13. Longitudinal muscle fiber division is more difficult with the thoracoscopic approach, as the instruments have a perpendicular orientation to the esophagus.

The longer-term postoperative concerns are directed toward the management of postoperative complications, such as persistence/recurrence of dysphagia, GERD, and the development of esophageal carcinoma. Failures requiring postoperative treatment occur with an incidence of up to 14% in most recent series. The most frequently reported reason for “early” reoperation in achalasia following Heller myotomy is inadequate myotomy. Laparoscopic revision for failed Heller myotomy is feasible with low morbidity and encouraging results. However, the best treatment for failed LHM is the prevention of failures through the routine use of intraoperative endoscopy and intraoperative manometry to ensure that all muscle fibers have been separated properly and by assuring that an adequate length of the myotomy extends at least 2

cm on the gastric cardia. When symptoms—especially dysphagia—do persist or recur after a short interval following Heller myotomy, intensive examinations with barium esophagram, upper gastrointestinal endoscopy, functional testing with esophageal manometry, and—in cases with suspected development of GE reflux—pH monitoring are mandatory to determine the exact cause of failure. Additional findings such as epiphrenic diverticulum or hiatal hernia should be corrected simultaneously. DES associated with achalasia requires extended myotomy, best performed via a transthoracic route.

The risk of postoperative GERD can be minimized by the routine construction of a partial fundoplication in the majority of patients. In that setting ~9% of patients will develop pathologic GERD as defined by an abnormal DeMeester score on pH testing. Since the development of GERD symptoms is not a reliable predictor in this patient population with abnormal innervation of the distal esophagus, all patients should undergo pH testing at 3 to 6 months after LHM. If they have pH study proven GERD, most patients can be successfully treated with lifetime PPI medication. However, close follow-up and long-term routine endoscopic surveillance is required because of the increased incidence of peptic stricture, Barrett esophagus, and esophageal carcinoma in all of these patients. The development of peptic stricture in this setting can present a major therapeutic challenge, and surgical intervention is frequently required. Distal esophageal or GE strictureplasty with antrectomy and Roux-en-Y diversion for peptic stricture and severe postoperative GERD should be considered in extreme cases.

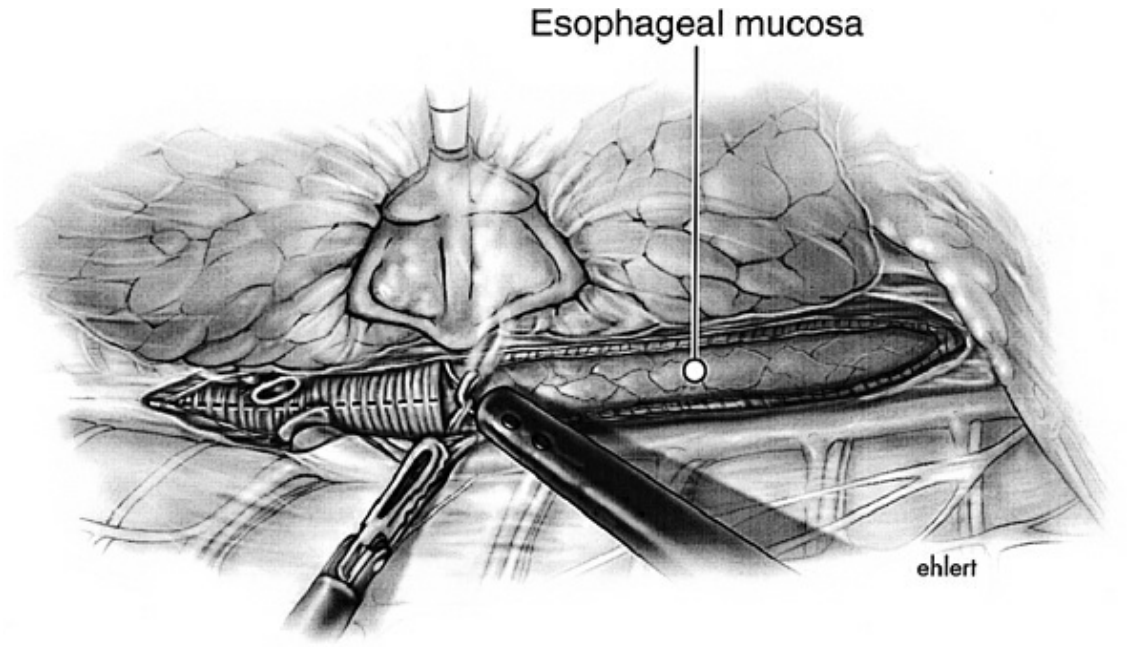

Figure 76.14. The circular muscle fibers are divided by separating and elevating them from the submucosal plane as in the laparoscopic approach.

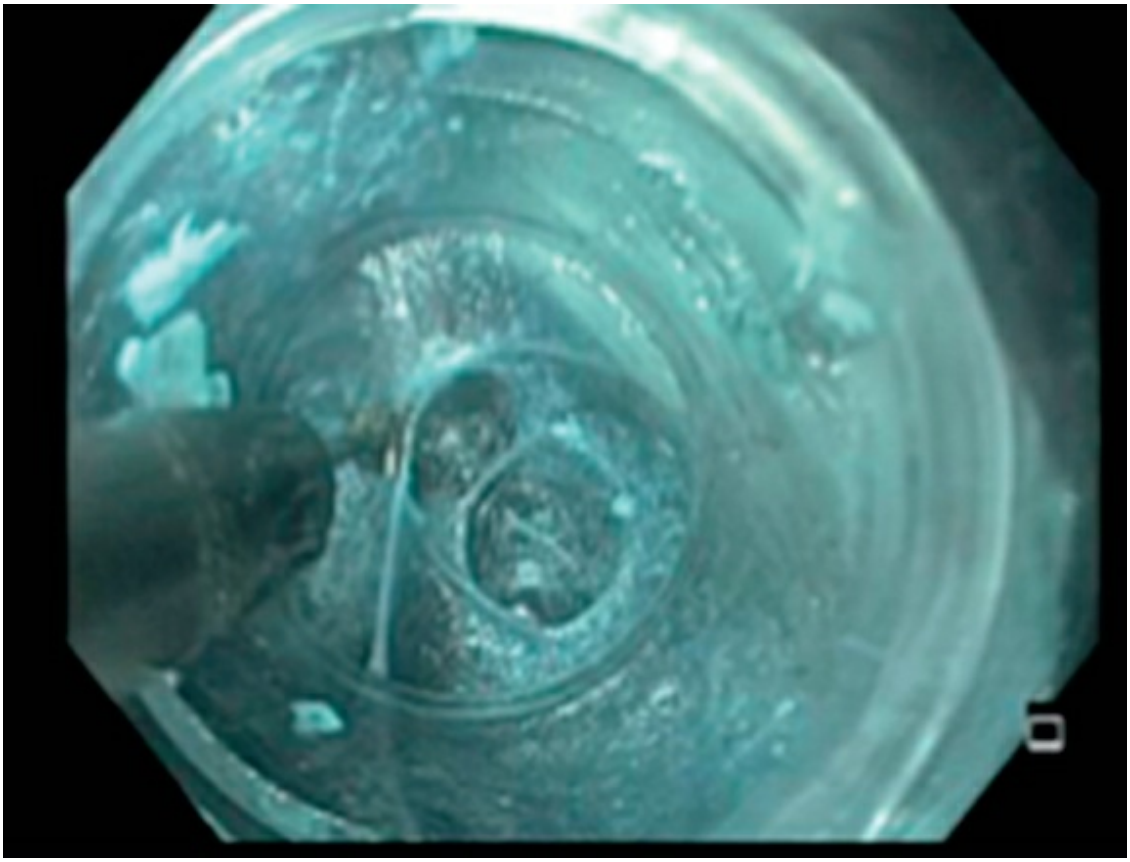

Figure 76.15. The loose areolar tissue between the mucosa and the esophageal muscle is divided to create a submucosal tunnel.

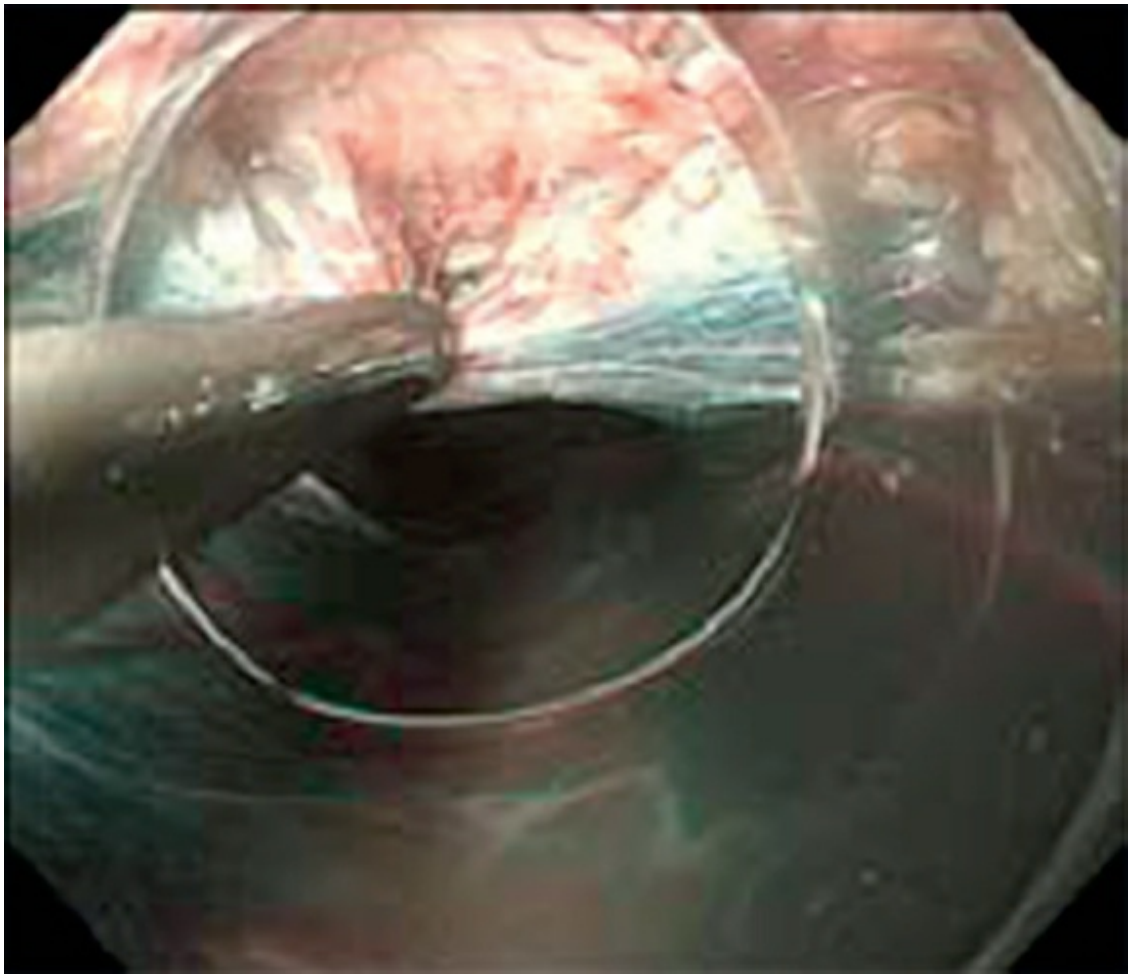

Figure 76.16. The inner circular muscle layer of the esophagus and proximal stomach is divided with cautery.

There have been several thousand POEM procedures performed throughout the world, and objective data collection suggests that results and outcomes are equivalent to those of Heller myotomy. There is, however, a significant incidence of abnormal gastroesophageal reflux following POEM of around 40%. This has been noted in numerous studies. Although most patients are asymptomatic, use of prophylactic acid suppression with long-term PPI therapy has been suggested to protect the distal esophagus from acid injury.

The incidence of developing both esophageal squamous cell carcinoma and adenocarcinoma is significantly higher in achalasia patients than in age- and sex-adjusted controls. The risk of developing esophageal squamous cell carcinoma in patients with long-standing achalasia has been estimated to occur from 1% up to 33% of patients, which is nearly 15 times greater than the general population. Development of adenocarcinoma after myotomy as a complication of Barrett esophagus

might be caused by extending the myotomy too far onto the gastric cardia, failure of the antireflux procedure, or failure of endoscopic surveillance and follow-up in this high-risk population.

Individualized remedial surgery is required to correct many of these problems. Further investigations should focus on comparing the length of the myotomy, the type of added antireflux procedure, and the histopathologic/immunohistochemical findings with regard to scarring in untreated and repeatedly myotomized patients. Reoperation for achalasia may require esophagectomy to relieve symptoms if other measures fail.

OTHER ESOPHAGEAL MOTILITY DISORDERS

PRIMARY ESOPHAGEAL MOTILITY DISORDER (PEMD)

Many esophageal motility abnormalities detected during manometry lack a classification or are categorized as nonspecific motility disorders. With the exception of achalasia, other esophageal motility disorders are poorly understood and studied. Named motility disorders include DES and NE, which are considered primary esophageal motility disorders (PEMD). DES is characterized by simultaneous contractions in >20% and <100% of wet swallows, intermittent peristalsis, and amplitudes >30 mm Hg. In DES, these manometric abnormalities may be found over the total length of the esophagus, but are usually confined to the distal two thirds. NE is a variant of DES, which is characterized by a rapid progression of the esophageal pump with mean distal amplitude waves measuring >180 mm Hg in the presence of normal peristalsis. The LES in patients with PEMD may show normal resting pressure with complete relaxation following deglutition, but may also present with intermittent episodes of incomplete relaxation. The etiology of DES and NE is unknown, and conflicting definitions of the diseases increase the controversies around the topic.

Figure 76.17. The esophageal mucosotomy is closed with clips.

Chest pain is believed to be the most common symptom associated with NE, and NE is the most common manometric finding in patients with noncardiac chest pain. Dysphagia is described as an uncommon finding in NE, while chest pain with dysphagia is the most common presenting symptom of DES. Heartburn symptoms are present in a large number of patients with PEMD. GERD is also commonly associated with secondary esophageal dysmotility, and symptoms such as dysphagia and chest pain may accompany heartburn in these patients. Both DES and NE can only be considered a PEMD in the absence of GERD. If GERD is present, the motility abnormality should be considered secondary and treatment should be directed toward reflux. Symptoms alone are not very useful in the setting of most foregut diseases and correlate poorly with the diagnosis of GERD and PEMD. Thus, pH monitoring is an essential tool in the evaluation of patients with manometric findings suggestive of either DES or NE. Abnormal acid exposure is detected in the majority of patients with manometric findings suggestive of PEMD.

A variety of medications such as nitrates and calcium channel blockers have been used in the treatment of PEMD; however, no single drug has proven to be predictably effective. Most of these drugs act by decreasing

the strength of the peristaltic contractions. In patients with GERD-induced motility disorders, a side effect of these medications may be the relaxation of the LES and consequent worsening of GERD. An acid-reducing medication in patients with GERD and manometric PEMD improves symptoms in >75% of the patients.

The initial treatment of patients with primary PEMD should include medical therapy and life-style adjustments. Indications for operative treatment are not as clear as in achalasia and should only be carried out by surgeons with considerable experience with the technique of long esophagomyotomy. The presence of chest pain alone is not an indication for operative intervention. Long esophageal myotomy is indicated for dysphagia in a patient with documented DES, and whose symptoms are not relieved by medical therapy. The technique of long myotomy is carried out via a thoracoscopic approach as described above, carrying the myotomy over the entire distance of the manometric abnormality. Patients with segmental or DES are at risk for developing an epiphrenic or mid-esophageal diverticulum. The presence of such diverticula complicates the procedure, requiring dissection of the neck of the diverticulum and division via an endoscopic linear stapler. The overlying muscle is reapproximated with permanent sutures, and then the myotomy is performed on the opposite esophageal wall.

HYPERTENSIVE LOWER ESOPHAGEAL SPHINCTER

Hypertensive LES is a primary disorder of esophageal motility characterized by a resting pressure in the LES that exceeds the upper limit of normal, while esophageal body peristalsis is normal. The most common symptoms are dysphagia and chest pain. However, in a certain subset of patients, acid reflux may accompany the hypertensive LES. Thus, as with PEMD the symptoms may be secondary to reflux or alteration of the configuration of the cardia when hypertensive LES is associated with GERD and a type III hiatal hernia. The combination of manometry and pH testing is again essential in defining primary versus secondary hypertensive LES. A laparoscopic myotomy with partial fundoplication is indicated for primary hypertensive LES, while a laparoscopic Nissen fundoplication should be performed in patients with secondary hypertensive LES with associated GERD.

CONCLUSION

After GERD, achalasia is the most common functional disorder of the esophagus, requiring surgical intervention. The most effective long-term treatment for achalasia is surgical esophagocardiomyotomy. The goal of myotomy is the destruction of the nonrelaxing LES. This was achieved in the past via either a laparotomy or thoracotomy. However, with the development of minimal access videoscopic techniques, the laparoscopic (and robotic, where available) approach has become the procedure of choice because of its equal effectiveness and more rapid recovery as compared to the open procedures. When the LES is surgically disrupted, there is an unacceptably high incidence of pathologic GERD. The combination of an incompetent LES and diminished ability to clear the esophageal acid leads to an increased exposure of the esophagus to acid. Thus, it is generally recommended that an antireflux procedure (partial fundoplication) be performed in addition to the myotomy in the majority of patients. The use of intraoperative manometry and intraoperative endoscopy provides useful information in the accurate destruction of the LES and creation of an antireflux mechanism. Thoracoscopic esophagomyotomy is reserved for reoperative cases and patients with disease involving the more proximal esophagus. Esophagectomy is recommended in patients with prior myotomy, low LES pressure, and a dilated sigmoid esophagus. Per-oral endoscopic myotomy has recently been shown to be an effective method for therapy of achalasia and should be used in appropriate candidates to achieve the most optimum outcomes.

EDITOR'S COMMENT

Achalasia is a complex motor abnormality of the esophagus that is considered a neurodegenerative process. As the authors point out achalasia is an idiopathic condition that is associated with a patchy inflammatory response consisting of cytotoxic T-lymphocyte, eosinophil, and mast cell infiltration in the esophageal myenteric (Auerbach) plexus with myenteric neural fibrosis, loss of ganglion cells, hypertrophy of the two muscle layers, and hypertrophy of nerve fibers. The disease itself leads to the failure of peristalsis of the body of the esophagus as well as the inability of the lower esophageal sphincter to relax. Nussbaum and Ponsky point out that the aperistalsis of achalasia is secondary to

interruption of normal vagal cholinergic motor function, whereas the failure of LES relaxation is due to derangement of the vagal inhibitory (VIP and NO) nerves. Multiple histopathologic studies have confirmed the loss of inhibitory neurons in the esophageal myenteric plexus as the pathologic hallmark of achalasia. The incidence is between one and three per 100,000 per year and is most common in the third to fourth decades of life. It is being recognized more frequently in the elderly. Indeed there is a secondary peak in incidence after 60 years of age. Studies have shown that healthy older people, when compared to the young, have: (a) a lower number of ganglion cells in the intramural myenteric plexus; (b) a reduced normal relaxation of the lower esophageal sphincter; and (c) a reduced esophageal peristalsis (Schechter RB, Lemme EM, Novais P, et al. Achalasia in the elderly patient: a comparative study. *Arq Gastroenterol* 2011;48(1):19–23). Thus, as both age and achalasia can produce comparable degenerative changes in the intramural myenteric plexus.

The diagnosis is established by manometry after an esophagram and esophagoscopy to exclude other causes of dysphagia including an esophageal stricture or cancer. High-resolution manometry has replaced conventional manometry. High-resolution manometry offers several advantages: (1) a visual display simplifies placement, (2) the pressure pattern is measured simultaneously avoiding the need to repetitive pull-throughs and catheter repositioning, and (3) a standard display with computer algorithms allow easier more objective interpretation. Using the high-resolution technique has led to a reclassification of the disease into three subtypes as the authors' note.

There are several types of therapies for this disease. Pharmacologic treatment with oral nitrates or calcium channel blockers has sporadic success and is generally unreliable and should be reserved for those who cannot or decline definitive therapies or have failed Botox injections.

Botox injections are effective in about 65% of patients but require repeated treatments. The LES pressure has been reported to decrease as much as 50% a week after treatment. Patients older than 50 years of age have been reported to have nearly double the response rate, compared with younger patients (82% vs. 43%) (Shim CS. Endoscopic botulinum toxin injection: Benefit and limitation. *Gastrointest Interv* 2014:3;19–23). A positive response is predictive of a good response to myotomy. Botox causes scarring the esophageal wall. Due to the initial widespread use of Botox, many patients underwent injection as the first approach in the treatment of achalasia, but some of these patients were later referred for surgery because of the recurrence of symptoms. It has been shown that a previous application of Botox made the myotomy much more difficult, increasing the operative time, and increased the risk of mucosal perforation. In Horgan and Pelligrini's report on their initial experience with 57 patients undergoing surgery, 15 had previous Botox injections; 2 (13.3%) of these patients experienced a mucosal perforation during the myotomy due to the difficulty of separating the mucosa from the muscularis (Horgan S, Hudda K, Eubanks T, et al. Does botulinum toxin injection make esophagomyotomy a

more difficult operation? *Surg Endosc* 1999;13(6):576–9). They reported that none of the patients without Botox had a mucosal perforation. This experience has been repeated over and over again. As such many believe that the application of Botox may not be appropriate as a first line of treatment, due to the short interval of symptom relief, the high relapse rates, the requirement of several applications, and the potential associated risks, especially in those patients who will subsequently undergo surgery. Perhaps the use of Botox should be reserved for elderly patients who tend to have better results or patients with multiple medical problems who are poor candidates for more invasive procedures and for those patients unwilling to undergo either surgery or pneumatic dilatation.

The dilation of the LES is considered the most effective nonsurgical treatment of achalasia. It creates a controlled (or not so controlled) disruption of the LES muscle, resulting in relief of the distal esophageal obstruction with secondary symptomatic improvement. It has been commonly used since the late 1970s as the initial treatment of achalasia. The success rate for pneumatic dilation is between 55% and 70% with symptom improvement in 50% to 89% of patients. Some patients will require a second or third dilatation to achieve up to 90% relief of symptoms. The reported rate esophageal after dilatation is between 2% and 12% of patients with a mortality rate of 1% to 2%. The perforation usually occurs above the cardia on the left side of the esophagus. Postdilation water-soluble contract studies are frequently used to diagnose perforation. In select patients a nontransmural tear may be treated initially with conservative therapy but one must have a high index of suspicion and a low threshold to go to surgery. Pneumomediastinum at initial presentation predicts failure of medical therapy. If there is a transmural perforation, then treatment usually consists of a left thoracotomy, perforation closure, a contralateral myotomy, anterior fundoplication, and pleural drainage.

Heller myotomy is the surgical treatment of choice. It may be performed as an open procedure or with videoscopic techniques transthoracic or transabdominal. Cuschieri first described the laparoscopic approach. Robotic techniques have been developed. According to the SAGES guidelines after laparoscopic esophagomyotomy, symptomatic improvement has been reported in 89% of patients (range 77–100) but that clinical deterioration occurs over long follow-up periods. Csendes et al. demonstrated in a randomized controlled trial that while response rates were 95% at 5 year follow-up, the success rate was reduced to 75% after a mean follow-up of 15.8 years (Csendes A, Braghetto I, Burdiles P, et al. Very late results of esophagomyotomy for patients with achalasia: clinical, endoscopic, histologic, manometric, and acid reflux studies in 67 patients for a mean follow-up of 190 months. *Ann Surg* 2006;243:196–203). SAGES notes that transabdominal is superior to transthoracic esophageal myotomy due to improved postoperative reflux control by the addition of an antireflux procedure, performed only when the myotomy is done transabdominally. Laparoscopic myotomy offers decreased

postoperative pain, length of stay, and morbidity compared to open myotomy. There is no advantage to robotic myotomy except perhaps a reduction in esophageal mucosal perforation. The laparoscopic approach also allows routine incorporation of an antireflux procedure after myotomy. Laparoscopic myotomy is the procedure of choice for the surgical treatment of achalasia in most patients.

There is clear consensus that a partial fundoplication should be performed routinely to reduce the incidence of gastroesophageal reflux. There seems to be equivalent results with an anterior myotomy (180 degrees) (Dor) compared to a posterior (270 degrees) (Toupet).

The per-oral esophageal myotomy (POEM) was described since the sixth edition. A recent meta-analysis involved 7 studies compared POEM with Laparoscopic Heller Myotomy (LHM) in a nonrandomized manner with 486 included patients (196 in POEM group and 290 in LHM group) ranging from 8 to 180 patients per study (Marano L, Pallabazzer G, Solito B, et al. Surgery or Peroral Esophageal Myotomy for Achalasia: A Systematic Review and Meta-Analysis. *Medicine* 2016;95(10):e3001). In this study the efficacy in reduction of Eckardt score was the primary outcome measure of this study. The study showed that POEM resulted in a success rate of 90%, similar to initial treatment success of LHM. In addition there was no significant difference between POEM and LHM as regard the time of interventions, postoperative pain score, and analgesic requirement. Length of hospital stay was significantly less in POEM compared to LHM. Complications of POEM include esophageal perforation in 3% to 16% of cases. Many of these were inherent to the procedure and could be managed conservatively with no perioperative mortality or conversion to another procedure. It is clear that the procedure should be performed at centers and by physicians with significant operative experience. The learning curve is estimated to be 20 cases. Symptomatic gastroesophageal reflux is a common problem after POEM occurring in 16% to 20% of patients. Nearly 65% of patients are reported to have endoscopic findings of reflux after POEM. The incidence of GERD may be the limiting factor in POEM. Time will tell if POEM will make it to the eighth edition.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology factor for the development of esophageal cancer varies between the two major histologic subtypes of squamous cell and adenocarcinoma. Smoking and drinking as independent contributing factors are shown by prospective studies of patients who drink but do not smoke and, conversely, of patients who smoke but do not drink.

Genetic predisposition contributes to the pathogenesis of squamous cell cancer. Genetic polymorphism is important in individuals with chronic alcohol consumption. Approximately 36% of East Asians show a physiologic response to drinking that includes facial flushing, nausea, and tachycardia. This facial flushing response is predominantly related to an inherited deficiency in the enzyme aldehyde dehydrogenase 2 (ALDH2). Alcohol is metabolized to acetaldehyde by alcohol dehydrogenase, and the acetaldehyde is in turn metabolized by ALDH2 to acetate. Two main variants for ALDH2 exist, resulting from the replacement of glutamate with lysine at position 487. Only individuals homozygous with the glutamate allele have normal catalytic activity. Homozygotes with the lysine alleles have no detectable activity, while heterozygotes with Glu/Lys alleles have much reduced ALDH2 activity. The inability to fully metabolize acetaldehyde results in its accumulation in the body leading to the facial flushing and unpleasant side effects. Lys/Lys homozygotes could not tolerate much alcohol because of the intensity of the side effects, and so paradoxically they do not have increased risk because they would refrain from consuming significant amount of alcohol. Individuals who are Glu/Lys heterozygotes may drink, yet have suboptimal catalytic activity and thus the acetaldehyde accumulates. These are the individuals most susceptible to the carcinogenic effects, which is related to acetaldehyde causing DNA damage and other cancer-promoting effects.

Other dietary and environmental factors are important, such as

nitrosamines and their precursors (nitrate, nitrite, and secondary amines). Nutritional depletion of vitamins A, C, E, niacin, riboflavin, molybdenum, manganese, zinc, magnesium selenium, as well as fresh fruits and vegetables, together with an inadequate protein intake, predisposes the esophageal epithelium to neoplastic transformation. Other dietary risk factors include consumption of hot beverages, opium smoking, chewing betel nuts, and mate drinking in South American countries.

The human papillomaviruses and certain fungi belonging to the genera *Fusarium, Alternaria, Geotrichum, Aspergillus, Cladosporium,* and *Penicillium* are infective agents variably found to be associated with esophageal cancer.

Patients with other aerodigestive malignancies have a particularly high risk of developing squamous cell carcinoma of the esophagus, presumably because of exposure to similar environmental carcinogens and "field cancerization." Using esophageal cancer as the index tumor, multiple primary cancers were found in 9.5% of patients, of whom 70% were in the aerodigestive tract. The overall incidence of synchronous or metachronous esophageal cancer in patients with primary head and neck cancer is estimated to be 3%.

Diseases that are known to predispose to esophageal cancer are few. The risk from achalasia is estimated to be 7- to 33-fold, but symptoms of achalasia are present for an average of 15 to 20 years before the emergence of cancer. Other diseases include lye corrosive strictures, Plummer-Vinson syndrome, tylosis, and celiac disease.

For adenocarcinoma, ample evidences have demonstrated that the significant rising incidence can be attributed to the epidemic obesity, gastroesophageal reflux disease, and Barrett esophagus, which are less common in Asian populations. Gastroesophageal reflux disease affects up to 44% of the general population in the United States, and ~5% to 8% will develop Barrett esophagus, with an estimated annual rate of neoplastic transformation of 0.5%. Epidemiologic data suggest a protective role of *Helicobacter pylori* against reflux. The high prevalence of *H. pylori* infection in Eastern populations may guard against reflux and Barrett esophagus, and may account for the difference in cancer cell type. However, this association remains controversial.

CLINICAL PRESENTATION

Most patients present with symptomatic, advanced cancers. The main

symptom is progressive dysphagia or sometimes bleeding, more commonly encountered with adenocarcinoma. Other symptoms include regurgitation, odynophagia, weight loss, and hemoptysis when airway involvement is present. A frank tracheobronchial fistula leads to coughing and choking on drinking and is characteristic. Hoarseness of voice indicates recurrent laryngeal nerve involvement. Bleeding from aortoesophageal fistula is uncommon. Physical examination is usually unremarkable. The most likely site of a positive physical sign is the supraclavicular fossa, where metastatic nodes should be searched for. When diagnosis is made in asymptomatic patients, either incidentally or in screening or surveillance program, the prognosis is generally better.

INDICATIONS AND CONTRAINDICATIONS FOR RESECTION

The primary indication for surgical resection is for potential cure, which can be achieved in patients whose tumors are confined to its wall and only limited local-regional disease is found. One should aim to maximize the chance of an R0 resection (macroscopic and microscopic clearance of proximal, distal, and lateral margins), a parameter that has consistently been shown to result in the best long-term survival. Surgical resection with intentionally palliative intent is rarely performed, although sometimes this is indicated in certain circumstances, such as a bleeding esophageal/gastroesophageal junction tumor requiring frequent blood transfusion (more commonly encountered with adenocarcinoma since squamous cell cancers rarely have significant bleeding), or a cervical esophageal cancer, which has been treated by chemotherapy or radiotherapy, but residual tumor still precludes satisfactory oral alimentation. Situations such as these are difficult to palliate without surgical resection.

Increasingly, neoadjuvant treatments including chemotherapy or chemoradiotherapy are used to treat esophageal cancer. Consistently, these strategies have been shown to result in a higher rate of R0 resection, and a pathologic complete response (in resected surgical specimen) can be achieved in ~10% for chemotherapy alone, and up to 30% for chemoradiotherapy. Practice does vary around the globe. In Japan, two courses of cisplatin and 5-fluorouracil before surgical resection is a standard of care based on a Japan Clinical Oncology Group Trial (JCOG 9907). The Dutch Chemoradiotherapy for Oesophageal Cancer followed

by Surgery Study (CROSS) trial has demonstrated significant survival benefits using neoadjuvant chemoradiotherapy (using Carboplatin and Paclitaxel with 41.1 Gy of external radiotherapy) for both squamous cell and adenocarcinoma and is widely adopted. Yet for gastroesophageal junction adenocarcinomas, many regard them more like gastric cancers and pre- and postoperative chemotherapy (using regimen from that such as the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) Trial) is also utilized. Postoperative chemoradiotherapy also has its advocate. Regardless of regimens, some form of preoperative therapy is very commonly used and this has impact on consideration of surgical resection. When a nonsurgical strategy is planned, often with chemoradiotherapy with a higher radiation dose, surgery for salvage (for incomplete response or recurrence) has significant morbidity and even mortality rates, worse than that in the neoadjuvant setting. Possibility of cure, however, still exists provided only local-regional disease is present. How surgical resection should be integrated into programs of multimodality treatment remains controversial.

PREOPERATIVE PLANNING

Disease Staging

Adequate staging is of paramount importance to ensure a high chance of R0 resection and for planning the surgical approach. Endoscopy and endoscopic ultrasound should be performed, and a positron emission tomography-computed tomography (PET-CT) scan is important to look for nodal and distant spread. A bronchoscopy is also mandatory of tumors that are located near the tracheobronchial tree. Involvement of the airway precludes surgical resection. A percutaneous ultrasound of the neck +/– FNA of cervical nodes is also performed. As alluded to in the section above, preoperative chemo(radiotherapy) is commonly performed, disease staging after such treatments has limited accuracy, and this has to be taken into account when surgery is anticipated.

Patient Selection and Preparation

Other considerations mainly focus on patients' physiologic risks. Factors often cited as being predictive of morbidity and mortality after esophagectomy include advanced age, poor performance status, nutritional depletion and weight loss, more proximally located tumor, poor pulmonary

function, cirrhosis, and abnormal cardiac evaluation. Patients suffering from adenocarcinoma and squamous cell cancers also have different risk profiles. Patients with squamous cell cancers are more likely to be malnourished, have high alcohol intake, are smokers, and have more impairment of pulmonary and hepatic functions. Patients with adenocarcinomas, on the other hand, are more likely to be overweight, and are more at risk from cardiovascular diseases.

Preoperative assessments include a detailed history and clinical physical examination, simple blood profiles, chest radiograph, electrocardiogram, and pulmonary spirometry. More detailed cardiac work-up including echocardiography, myocardial perfusion scans, or angiograms is selectively applied when specific indications exist. Cirrhosis is not a contraindication to esophagectomy, although increased complications may be expected. The presence of esophageal varices usually contraindicates surgery.

In general, limited improvement can be made to a patient's physiologic status, perhaps with the exception of coronary revascularization with angioplasty and coronary stenting in the presence of significant coronary ischemia. Antithrombotic medications such as aspirin and Clopidogrel are often indicated post coronary intervention for a period of time. In such patients, it is prudent to treat them with neoadjuvant therapy, so that time is not lost in waiting for an optimal time for surgery post coronary stenting.

Patients must stop smoking and alcohol intake. Chest physiotherapy is instituted, and incentive spirometry is a good preoperative exercise. Those with chronic obstructive airway disease should have their bronchodilator therapy optimized. Patients with high-grade esophageal tumor stenosis may have lost substantial amount of weight. A fine-bore nasogastric tube can be placed for nutritional support while work-up is performed, and is preferable over parenteral nutrition or gastrostomy or jejunostomy feeding. Diabetic control should be optimized with medication or insulin therapy.

Immediate preoperative preparations include prophylactic antibiotics to be given at anesthesia induction, deep vein thrombosis prophylaxis. Bowel preparation is not necessary, unless a colonic interposition is intended. Further perioperative management is to be discussed in a later section.

SURGICAL TECHNIQUE

Choice of Surgical Approach

The choice of the appropriate technique for esophagogastrectomy depends mainly on (a) the location of the tumor, (b) the intended extent of lymphadenectomy, and (c) reconstructive technique. The surgeon should be versatile and well versed with the many different methods to adapt to different clinical situations.

Tumor Location

Cervical Esophageal Cancer

In 1960, Ong and Lee first described the procedure of pharyngo-laryngo-esophagectomy (PLE) as a one-stage, three-phase operation that involved cervical and abdominal incisions and a thoracotomy. A thoracotomy is first performed for esophageal mobilization; this is followed by cervical incision for pharyngolaryngectomy and cervical esophageal extirpation. A permanent terminal tracheostomy is constructed. A laparotomy is used for delivering the gastric conduit to the neck for pharyngogastric anastomosis. Modern surgical technique has replaced the thoracotomy with transhiatal esophageal mobilization. Thoracoscopic (or laparoscopic) esophageal mobilization is also an alternative and has become our preferred method.

In patients with cervical esophageal cancer that is truly limited to the neck, or that has limited extension below the sternal notch and an adequate distal margin can be obtained, a cervical esophagectomy can be performed without the need for total esophagectomy. A manubrial resection can be added to improve exposure. Surgical field can be reached up to the top of the aortic arch. For reconstruction of the resultant defect, deltopectoral or pectoralis major myocutaneous flaps are options for reconstruction after resection, but perhaps more suitable is the use of free grafts, such as jejunal interposition, anterolateral thigh flap, or posterior tibial flap. Comparing with gastric pull-up, these free grafts are advantageous because the techniques avoid mediastinal dissection, although expertise in performing microvascular anastomosis is essential. The use of free jejunal graft has become the favored method at the author’s institution. The leakage rate is 4% and failure rate 2%. Swallowing problem does exist in some patients, related to the disordered motility of the jejunum.

The need to sacrifice the larynx does make surgical resection an unattractive option, and definitive chemoradiation is often the first choice of treatment, with surgery reserved for salvage only. In case of salvage, surgery is expectedly more difficult especially after heavy irradiation.

Intrathoracic Esophageal Cancer

For tumors in the upper thoracic esophagus, obtaining a sufficient proximal resection margin dictates an anastomosis placed in the neck. For this reason, resection is best carried out by a three-phase esophagectomy or the McKeown approach. In this procedure, a right thoracotomy is first carried out to mobilize the thoracic esophagus together with lymphadenectomy. This is followed by abdominal and neck incisions for the mobilization of the esophageal substitute placing the anastomosis in the neck.

The majority of intrathoracic cancers are squamous esophageal cancers located in the middle and lower esophagus, and Barrett adenocarcinomas in the lower esophagus. A common approach was that described independently by Lewis (1946) and Tanner (1947). The operation begins with an abdominal phase, in which the stomach is prepared; a right thoracotomy and resection of the tumor together with lymphadenectomy follow this. The stomach is then brought up into the chest for anastomosis with the proximal esophagus at the apex of the pleural cavity.

An alternate approach involves a single left thoracotomy incision. Through a left thoracotomy and incision in the diaphragm, both the esophagus and the stomach could be mobilized and resection carried out, and stomach delivered into the chest for anastomosis, either below or above the aortic arch. Proximally, the aortic arch hinders surgical access, making mobilization of the proximal esophagus and subsequent anastomosis difficult. The approach is therefore more suitable for cancer of the cardia or the distal esophagus where an adequate resection margin is obtained below the aortic arch. Distally, however, exposure for the celiac trifurcation lymph node dissection and the pylorus for a drainage procedure are also hampered. Extending the incision across the costal margin to the upper abdomen as a single thoracoabdominal incision gives excellent exposure of the left upper quadrant as well as the mediastinum. But this is a much larger wound.

A transhiatal approach, whereby the thoracic part of the esophagus is mobilized by blunt and often blind dissection through the enlarged esophageal hiatus, and the mobilized stomach is then delivered to the neck and anastomosed to the cervical esophagus. This approach precludes thorough extended mediastinal lymphadenectomy, especially of the mid- and superior mediastinum. Randomized trials have shown lower cardiopulmonary complication rates compared to open thoracotomy; mortality rates are similar. With modern surgical technique and

perioperative care, the benefits of reducing potential morbidity by the transhiatal approach are offset by the inability to perform adequate lymphadenectomy. From a purely safety point of view, transhiatal resection is not suitable for patients with advanced middle- or upper-third tumors, especially patients with tumors closely related to the tracheobronchial tree and after neoadjuvant radiation therapy; tumor infiltration or fibrosis may obliterate tissue planes and make blind dissection unsafe. As such, its application is more suitable for distal esophageal tumors, for which much of the mobilization can be performed under visual control.

Minimally invasive esophagectomy (MIE) has a variety of different techniques; combinations of thoracoscopy, laparoscopy, mediastinoscopy, and open laparotomy and thoracotomy have been advocated. Thoracoscopic esophagectomy enables lesser surgical trauma, and at the same time, mediastinal lymphadenectomy equivalent (if not even better) to that of an open approach. Laparoscopic esophagectomy (without thoracoscopy) can reproduce a transhiatal esophagectomy, and indications are similar. A European multicenter randomized trial (TIME trial) showed that pulmonary complications are significantly less when MIE was compared with open transthoracic approach. Equivalent oncologic clearance (by number of nodes retrieved) is accomplished.

Gastroesophageal Junction Cancer

For cancers that are limited to the abdominal esophagus or gastric cardia, an abdominal-right thoracic approach as in a Lewis–Tanner esophagectomy is one option, with the proximal stomach also resected in order to gain an adequate distal resection margin. A left thoracoabdominal incision through the seventh or eighth rib space also gives excellent exposure of the low mediastinum and upper abdomen. When a thoracotomy is not desired, opening the hiatus widely by splitting the crura laterally and the diaphragm anteriorly can gain access to the low posterior mediastinum, and distal esophagectomy can be performed with the anastomosis performed from the abdomen without the need for a thoracic incision. The anastomosis is made easier with a mechanical stapler. When the proximal stomach is involved by tumor, many prefer a total gastrectomy with Roux-en-Y reconstruction. A Japanese randomized trial comparing a transabdominal versus a left thoracoabdominal approach for adenocarcinomas that have infiltrated 3 cm or less into the esophagus demonstrated no difference in long-term survival between the two and

extended total gastrectomy via the abdominal approach is advocated. A thoracotomy can be avoided, provided frozen sections are carried out to ensure a negative proximal margin. This is sometimes difficult to achieve and ascertain preoperatively. Many would prefer a esophagogastrectomy, preserving the distal stomach for esophagogastrostomy in the chest as in a Lewis–Tanner esophagectomy.

Intended Lymphadenectomy

Knowledge of nodal spread is essential in esophagectomy. Esophageal cancer spreads early, and the lymph nodes can extend from the neck to the celiac axis. The nomenclature and the definition of extent of lymphadenectomy are shown in Figure 77.1. For squamous cell cancers, it is customary to perform a total mediastinal lymphadenectomy. The most difficult areas are those around the right and left recurrent laryngeal nerves, as the nerves are prone to injury. Data from Japan have shown a high incidence of cervical nodal metastases as well, so addition of a neck phase with bilateral cervical nodal dissection is advocated. This constitutes a three-field lymphadenectomy (upper abdomen, mediastinal and neck). For nodes in the neck, the majority of metastases are located below the omohyoid muscle, especially around the paratracheal/paraeophageal area as a continuum of the recurrent laryngeal nerve nodal package from the superior mediastinum. The whole chain of nodes can be regarded as one unit. Performing such extensive nodal dissection imposes more complications (especially those related to nerve injury), so patient selection is important. It should only be performed in patients with sufficient physiologic reserve, with curative intent. When a thorough mediastinal dissection is performed, often most of the paratracheal/paraesophaegal recurrent laryngeal nerve nodes in the neck have been removed from below. Increasingly the indication of a formal neck dissection is being debated and more selectively applied. In patients with lower third tumors for instance, neck dissection may not be necessary. In adenocarcinomas of the lower esophagus or gastroesophageal junction, most surgeons do not perform thorough superior mediastinal or cervical lymphadenectomy as data have suggested nodal spread is predominantly distal in direction, and if metastases are found in the upper mediastinum or neck, prognosis is poor that additional lymphadenectomy may not be beneficial. This remains controversial.

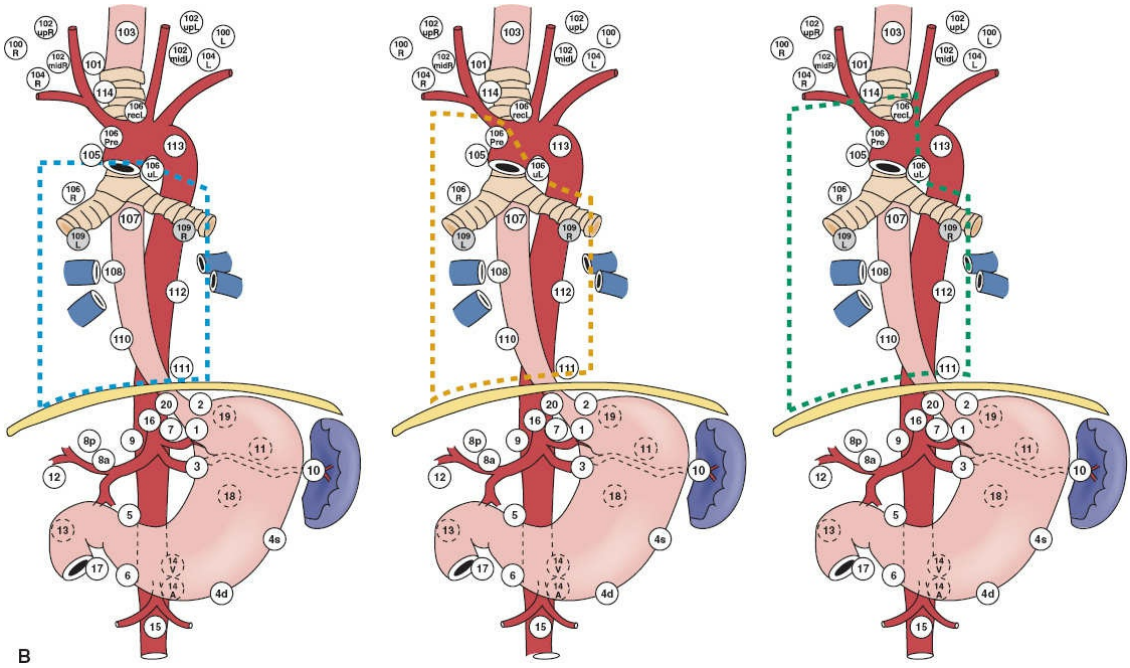

Figure 77.1. Nodal stations according to the American Joint Committee on Cancer (AJCC) manual (**A**) and the Japan Society for Esophageal Diseases (**B**). Regional nodes extend from the cervical region to around the celiac trifurcation. Infracarinal lymphadenectomy is defined as standard mediastinal lymphadenectomy (BI: dotted area defines the area of lymphadenectomy). When superior mediastinal dissection is performed but only including the right recurrent laryngeal nerve and right paratracheal area, it is termed extended mediastinal lymphadenectomy (BII). When the left recurrent laryngeal nerve chain including the subaortic area and left paratracheal area is dissected, it is called complete mediastinal lymphadenectomy (BIII). Upper abdominal lymphadenectomy around the celiac trifurcation with complete mediastinal and bilateral cervical lymphadenectomy is called three-field lymphadenectomy.

The choice of surgical access and intended extent of lymphadenectomy are therefore related; when an extended lymph node dissection is intended in the mediastinum (especially above the tracheal bifurcation), an open transthoracic or thoracoscopic approach is mandatory. When bilateral cervical nodal dissection is planned, a cervical anastomosis makes sense.

Reconstructive Technique

If radiation therapy to the posterior mediastinum after surgical resection is planned, it may be prudent to place the substitute organ in the retrosternal route to avoid radiation injury so a three-phase esophagectomy is

indicated. When a colonic loop is planned for esophageal replacement, sometimes it is advantageous to prepare the colonic conduit before esophageal resection to ensure its viability, especially when the vasculature of the colon has been demonstrated to be suboptimal on preoperative arteriogram. In such cases, the abdominal phase of the operation precedes the thoracic phase, dictating a retrosternal route of conduit placement, unless a second change of body position is undertaken.

Detailed Surgical Techniques

The following sections describe the three phases of an esophagogastrectomy: the abdominal, thoracic, and cervical phases. These three phases can be combined in different surgical approaches, depending on considerations detailed above. For example a Lewis–Tanner esophagectomy will involve the abdominal followed by a right thoracic phase, while a three-phase McKeown esophagectomy will involve the thoracic, followed by an abdominal and cervical phase.

Abdominal Phase

Surgical access can be gained through either an upper midline or an upper rooftop incision. The latter gives improved exposure to the upper abdomen, especially in an obese patient. The stomach used for esophageal replacement is prepared by first taking the gastrocolic omentum off the greater curvature of the stomach but preserving the right gastroepiploic vessels and arcades (Fig. 77.2). Detachment is begun near the pyloric region and continued toward the spleen. Complete omentum resection is not necessary. Division of the gastrocolic omentum can be carried out just outside the right gastroepiploic vessels. It is of paramount importance to preserve these vessels because they form the most important blood supply to the stomach after mobilization. As one approaches the spleen, the division of the short gastric vessels can stay close to the stomach wall. The left crus is exposed when the short gastric vessels are divided and the fundus mobilized medially. The phrenoesophageal membrane is detached and the abdominal esophagus and cardia can be freed on the left side.

The gastrohepatic ligament is then detached from the liver and from the portal structures. In some cases, an aberrant left hepatic artery is seen arising from the left gastric artery. Although its ligation can usually be done with impunity, postoperative deranged liver function and even partial liver necrosis have been reported. When found to be sizable, the artery

should be preserved. This can be accomplished by dissecting upward along the left gastric artery from the celiac axis and ligating vessels going into the lesser curvature of the stomach while preserving this vessel. Dissection from the right side toward the esophageal hiatus frees the right crus, and dissection anterior to the esophagus will meet the already dissected plane from the left. The anterior vagus nerve can be divided at this point. The esophagus is thus freed on both sides as well as anteriorly. A sling placed around the lower esophagus may help later dissection by providing retraction.

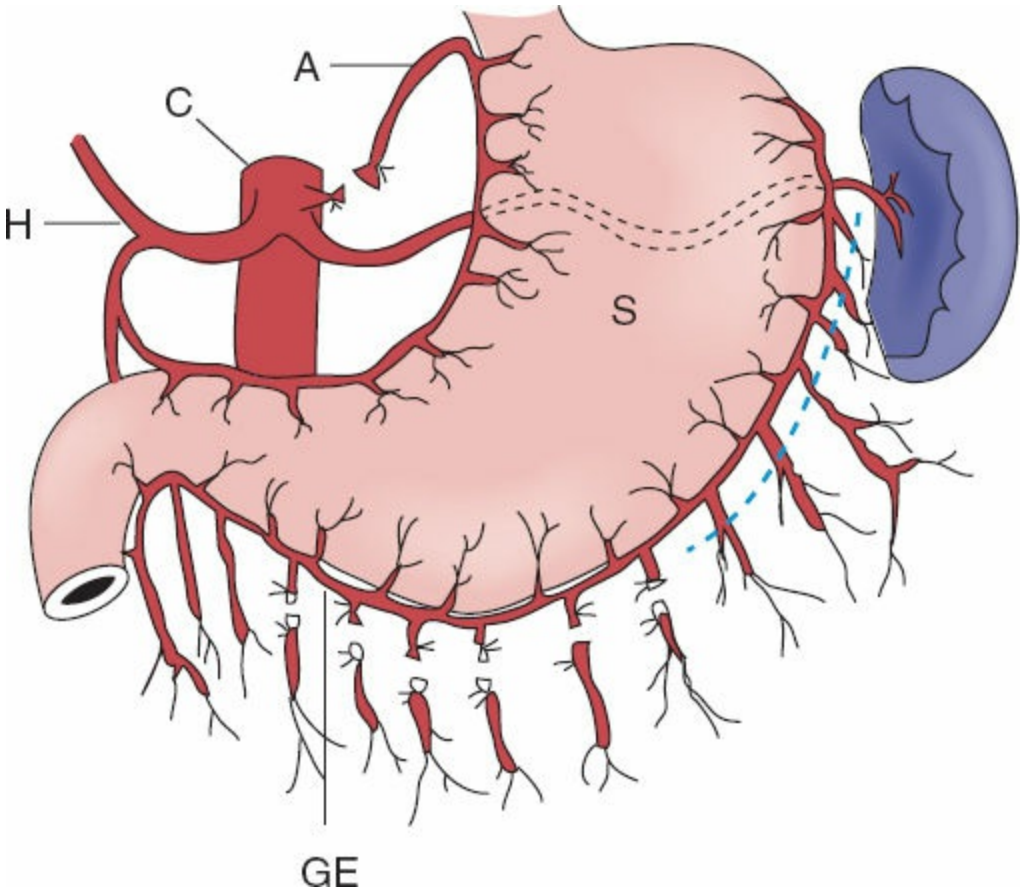

Figure 77.2. The stomach is mobilized by first taking the gastrocolic omentum off the greater curvature of the stomach but preserving the right gastroepiploic arcade. This can be carried out just outside the right gastroepiploic vessels. Short gastric vessel division can be done close to the stomach wall. Dissection of the celiac trifurcation starts on the surface of the hepatic artery toward the left side. Usually, the coronary vein lies anterior to the left gastric artery, and its division precedes the arterial isolation, ligation, and division between ligatures. C, celiac axis; S, splenic artery; H, hepatic artery; A, left gastric artery ligated at its origin; GE, gastroepiploeic artery.

For a tumor of the distal esophagus located at the hiatal opening, especially for a transmural T3/T4 tumor, a cuff of diaphragmatic crura can be removed together with the tumor. Division of the hiatal musculature is begun on the left side. Bleeding from the lateral edge is controlled with suturing or electrocautery. Division is continued along the front and then to the right side until a cuff of muscle is freed. When a cuff of muscle from the esophageal hiatus is removed, both pleural cavities are likely to be entered, but this is of no serious consequence.

The stomach is then reflected upward and dissection is begun at the celiac trifurcation. Using fine electrocautery, dissection is performed along the anterior aspect of the common hepatic artery. This is usually easily performed. Lymphadenectomy can then proceed laterally toward the hepatoduodenal ligament. For a tumor of the intrathoracic esophagus, formal dissection of lymph nodes along the hepatoduodenal ligament (common bile duct and hepatic artery alongside) is not necessary. Medially toward the origin of the left gastric artery at the celiac axis, the left gastric or coronary vein requires ligation. The origin of the left gastric artery is identified separately as it comes off the celiac axis, and it is doubly ligated and cut between ligatures. Further dissection toward the left will clear the lymphatic tissues on the splenic artery. The areolar tissue thus superior to the common hepatic artery and proximal splenic artery is cleared en bloc with the abdominal esophagus toward the hiatus. Continued dissection upward can be carried out through the esophageal hiatus along the front of the aorta. Areolar tissues are freed from the aorta and remain attached to the resected specimen. The cardia and abdominal esophagus are thus freed totally. With fine electrocautery and selective use of metal clips for small vessels, often the celiac trifurcation lymph node dissection can be a bloodless exercise.

On the lesser curvature, the right gastric vessels are divided at a convenient point (Fig. 77.3). This point, however, should be located distal to at least the third branch of the left gastric artery counting from its origin and this ensures adequate lymph node clearance. The preparation of the lesser curvature makes subsequent transection of the stomach easier during the thoracic phase of a Lewis–Tanner operation. When a three-phase esophagectomy is carried out, the stomach can be transected with linear staplers at this stage. The stomach is straightened and the highest point marked. The stomach is transected from the lesser curvature toward this point.

Many factors determine gastric emptying after esophagectomy, including the necessary vagotomy, the size of the gastric tube, and the route of placement of the conduit. Vagotomy in theory will inhibit gastric emptying, a smaller size gastric tube drains better than a whole-stomach conduit, and a stomach brought up to the neck via the posterior mediastinum empties better compared to one in the right thoracic cavity because angulation at the hiatus is avoided. Delayed gastric emptying also rarely occurs with retrosternal route of reconstruction. A Heineke–Mikulicz pyloroplasty or a pyloromyotomy is performed. Some surgeons opine that a pyloric drainage procedure will enhance enterogastric bile reflux. In the author's experience, clinically significant symptomatic biliary gastritis is uncommon. A Kocher maneuver is not mandatory, provided the stomach is of sufficient length. However, this maneuver is easily performed, and does have the advantage of straightening the "axis" of the pyloroduodenal region when the stomach is brought up to the right thoracic cavity.

Right Transthoracic Phase

The patient is placed in a left lateral decubitus position (Fig. 77.4). A double-lumen endotracheal tube provides isolation of the right lung. A single-lumen endotracheal tube with a bronchial blocker is preferred by the author. This is less traumatic, and the tube being less stiff allows better retraction of the trachea and bronchi. This is especially important when nodal dissection above the tracheal bifurcation is intended, and for thoracoscopic resection. A posterolateral thoracotomy through the fifth intercostal space is usually performed. Alternatively, an anterolateral thoracotomy can also be done. The author prefers the latter. When superior mediastinal nodal dissection is planned, a fourth space access provides easier exposure for this part of the dissection. However, exposure for dissection of the lower mediastinum then becomes slightly more difficult. A controlled fracture of the fifth or sixth rib posteriorly eases distraction of the rib space. Patients who have had previous inflammatory pulmonary disease, especially tuberculosis, may have dense pleural adhesions; these can be time consuming to divide. Two rib spreaders placed at right angles to each other are used to open up the rib space.

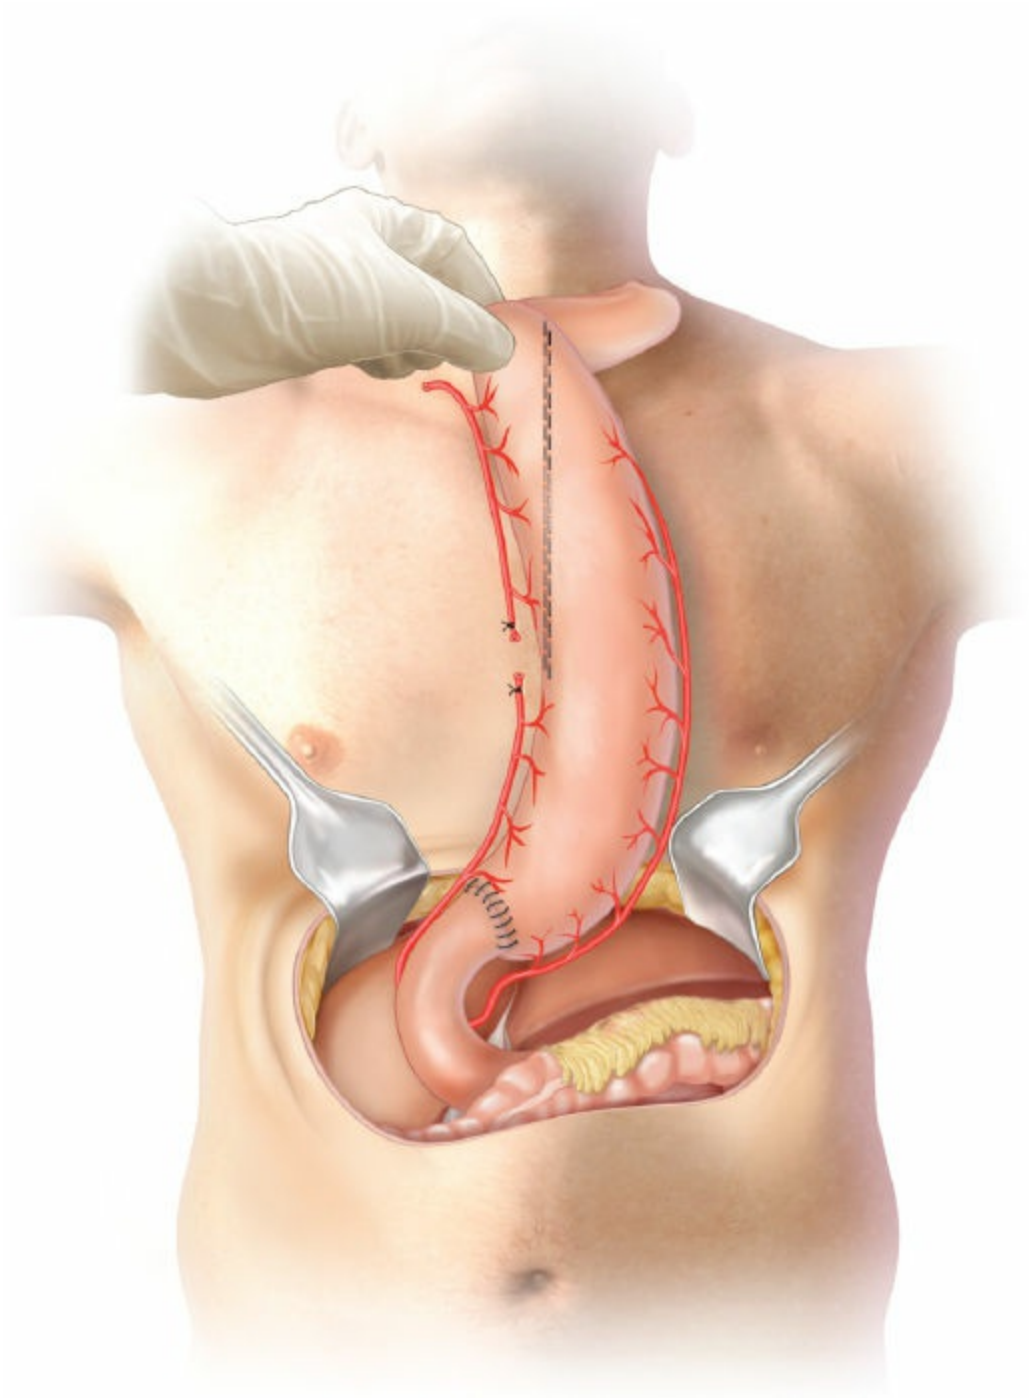

Figure 77.3. The lesser curvature is prepared at a point of transaction at least distal to the third branch from the origin of the left gastric artery. This removes the potential cancer bearing area. The stomach is straightened and its highest point selected. Transection of the stomach can start from the already prepared point at the lesser curvature toward this highest point with linear staplers. The stomach should be stapled just within the branches coming from the lesser curvature so that the conduit is not too narrow. When the width of the gastric tube is narrow more length will be gained but risk impairing the blood supply to the conduit.

When a Lewis–Tanner esophagectomy is planned, the transection line need not be completed, and this will ease delivery of the conduit to the chest. When a three-phase esophagectomy is performed, the transection line can be completed while in the abdomen. A pyloroplasty is performed for drainage.

The arch of the azygos vein as it crosses the esophagus is divided and transfixed; usually, two branches of the vein posteriorly on the spine are divided and resected as well. The right bronchial artery, which can be quite sizable, runs just beneath the vein. It can be preserved if desired.

The superior mediastinal segment of the esophagus can be mobilized first. When a standard mediastinal dissection is performed without a formal superior mediastinal lymphadenectomy, it is sufficient to perform periesophageal dissection of the esophagus at this level. The mediastinal pleura is opened on the back of the trachea. The esophagus is freed from the back of the trachea anteriorly and posteriorly from the spine; it can be slung with a tape to ease later dissection. One should avoid cautery in front of the esophagus, to avoid tracheal injury. Dissection is carried out to the apex. Often, a large branch from the inferior thyroid artery running on the esophagus needs division. The whole length of the upper esophagus is thus freed to the apex.

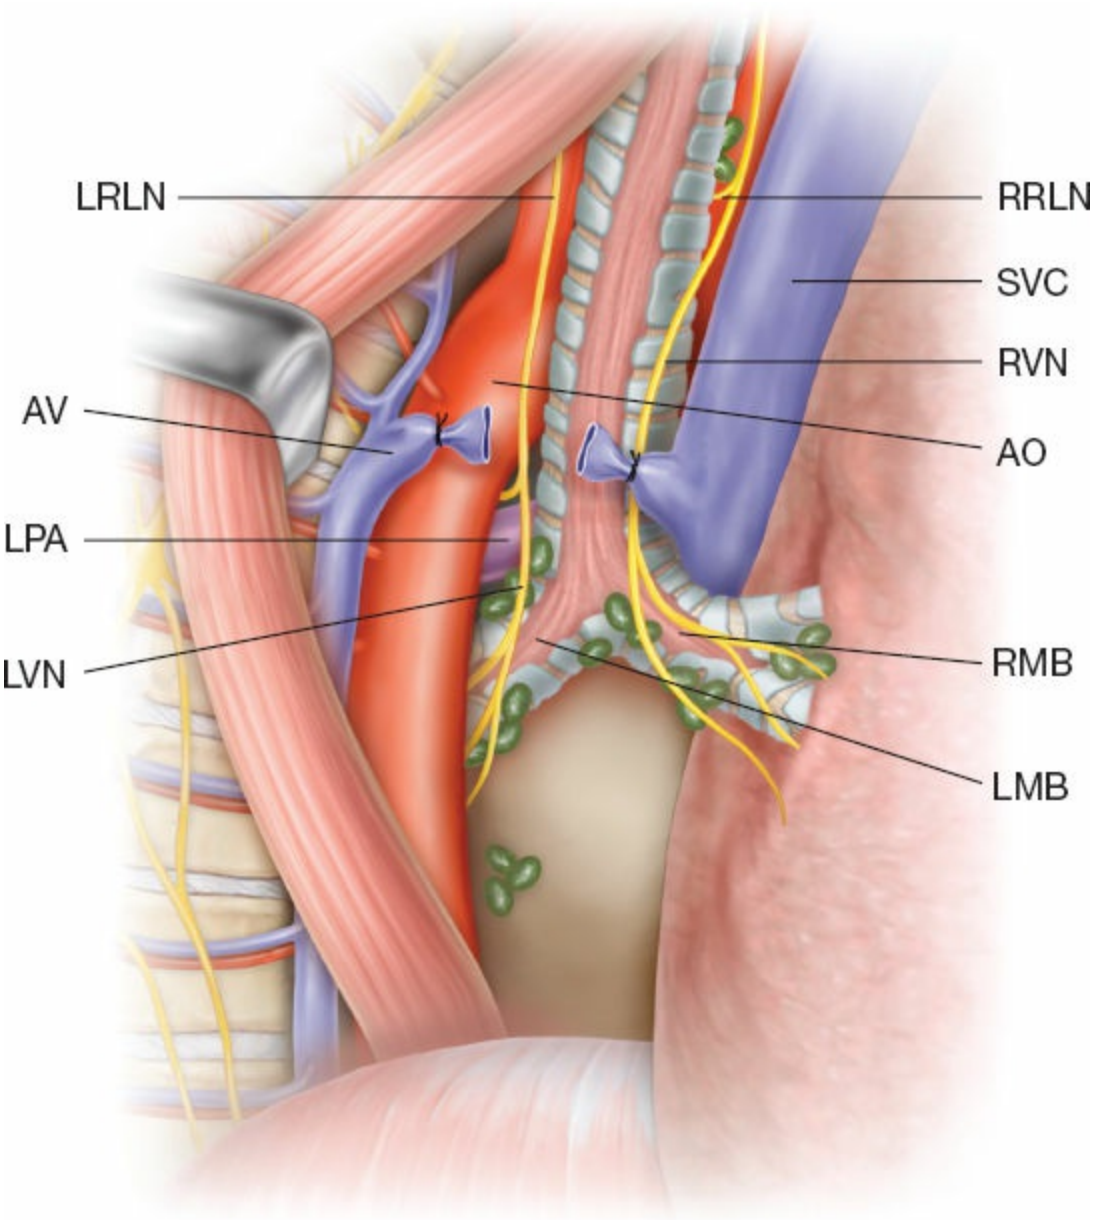

Figure 77.4. Dissection of the mediastinum: The esophagus has been mobilized and retracted to one side. The dissection plane anteriorly is on the pericardium; the right main bronchus, tracheal bifurcation, and left main bronchus have been exposed; and the carinal lymph node cast can be taken en bloc with the esophagus or separately. The mediastinal pleura is opened longitudinally just along the anterior aspect of the azygos vein. The thoracic duct has been ligated and divided near the diaphragmatic hiatus, and resected en bloc with the periaortic connective tissue on the esophagus itself. In the superior mediastinal, the right paratracheal area between the right vagus nerve and the superior vena cava harbors the paratracheal nodal stations. The right recurrent laryngeal nerve nodes surround the area where the nerve hooks around the subclavian artery. The left paratracheal

area contains the left recurrent laryngeal nerve nodes. Retraction of the trachea is necessary to resect nodes along this nerve. The subaortic arch nodes are also taken, preserving the left recurrent laryngeal nerve medially as it runs on the arch. RRLN, right recurrent laryngeal nerve; SVC, superior vena cava; RVN, right vagus nerve; AO, aortic arch; LMB, left main bronchus; P, pericardium; LVN, left vagus nerve; LPA, left pulmonary artery; AV, azygos vein; LRLN, left recurrent laryngeal nerve.

At this point, attention is drawn to the lower mediastinal dissection. The inferior pulmonary ligament is divided with electrocautery to the root of the inferior pulmonary vein. Dissection is then carried on the posterior surface of the pericardium. The right main bronchus is identified, and lymph nodes and connective tissue inferior to it are taken en bloc with the esophagus. Further dissection will lead to the infracarinal lymph node package. This is usually a vascular area. When the lymph nodes are retrieved, small vessels may retract into the precarinal area. Packing with gauze followed by careful hemostasis will control the oozing. The infracarinal dissection is followed toward the left to expose the left main bronchus and the lymph nodes and fatty tissues inferior to its edge. Sharp dissection with careful hemostasis is essential to avoid thermal injury to the membranous parts of the bronchi.

Attention is next turned to the posterior dissection. The mediastinal pleura is incised along the anterior aspect of the length of the azygos vein from above downward. When the point just above the hiatus is reached, the dissection plane deepens onto the surface of the aorta. Anteriorly within the areolar tissue between the azygos vein and the surface of the aorta is the thoracic duct, which is identified, isolated, and ligated. A metal clip marking the site is useful, in case postoperative chylothorax occurs. Routine ligation of the duct lessens the chance of this complication. When the dissection reaches the esophagus anteriorly, the thoracic duct, the areolar, and connective tissue on the aorta are removed en bloc with the esophagus. This resection continues from below upward, until the previous dissection plane from anteriorly on the left main bronchus is met. Vessels that run from the aorta directly to the esophagus should be carefully ligated or cauterized. In cases where a bulky or infiltrative cancer of the mid-esophagus is encountered, the esophagus can be divided first with a stapler near the diaphragmatic hiatus. The stump can then be pulled upward, improving exposure for tumor mobilization. The limits of the lymph node

dissection extend inferiorly to the crura of the diaphragm, anterior on the pericardium, right main bronchus, apically at the tracheal bifurcation, and posteriorly from the left main bronchus along the length of the descending aorta. Further dissection upward should meet the previously slung upper esophagus so that the whole intrathoracic esophagus is freed. The pleura on the left side can be resected en bloc with the esophagus; a cuff of pericardium attached to the primary tumor can also be removed, to improve lateral tumor clearance.

If a three-phase esophagectomy is intended, the chest can now be closed. A 24-Fr chest drainage tube is placed toward the apex. The patient is then turned supine for the abdominal and cervical phases of the operation.

In a Lewis–Tanner esophagectomy, after esophageal mobilization, the gastric tube is delivered up through the diaphragmatic hiatus into the right chest. The division of the stomach is best performed using linear staplers. Gastric transection can be begun at a point located on the greater curvature of the stomach toward the site at the lesser curvature previously prepared during the abdominal phase of the operation. Usually, two to three linear staplers are necessary. A redundant fundus should be resected to avoid postoperative stasis. Inversion of the stapled line ensures hemostasis and would protect against the occasional leak, though this is rare. A Satinsky clamp is then applied across the supra-aortic segment of the esophagus near the apex of the thoracic cavity. A proximal margin of 10 cm from the tumor edge should be aimed at, as this margin almost eliminates the chance of subsequent anastomotic recurrence. The esophagus is divided distal to the clamp. The esophagus with the tumor is thus removed, and the gastric tube is placed in the mediastinum ready for anastomosis.

Superior Mediastinal Lymph Node Dissection

The previous section describes the right transthoracic esophagectomy with a standard infracarinal mediastinal lymphadenectomy. The following describes the procedure of superior mediastinal dissection.

After the arch of the azygos vein is divided, attention is turned to the right paratracheal area. The right vagus nerve is easily identified. The mediastinal pleura over it is opened, and the nerve traced upward to the base of the subclavian artery. The right recurrent laryngeal nerve is found when the fatty tissue inferior to the subclavian artery and posterior to the vagus is dissected. The vagus from the neck and the recurrent nerve together form the two prongs of a “fork” straddling the subclavian artery.

Lymph nodes are removed with the fatty tissue. These nodes connect with the cervical paratracheal and paraesophageal nodes superior to the subclavian artery, which can be removed later in the cervical phase of the operation. This whole chain of lymph node is known as the right recurrent laryngeal nerve lymphatic chain, and it has a high incidence of metastases. One should be cautious in the use of electrocautery to avoid thermal injury to the recurrent nerve. The use of a nerve stimulator as in thyroid surgery can aid identification of the nerve and its preservation.

The right paratracheal area situated between the superior vena cava and the trachea anterior to the vagus nerve contains the right paratracheal nodal basin. These nodes can be removed after the right recurrent laryngeal nerve is identified and protected. Dissection can be carried out from above downward to the tracheobronchial area superior to the right main bronchus. Compared to the right recurrent laryngeal nerve nodes, this right paratracheal area is less frequently involved by lymph node metastases.

The dissection of the left paratracheal area (left recurrent laryngeal nerve chain) is better commenced with the esophagus slung with a tape retracting it posteriorly, but retaining the fibroareolar tissue attachment to the trachea (the mesentery). In this manner, the left recurrent laryngeal nerve is more easily located within this “mesentery.” If the esophagus has been isolated first, then the left recurrent laryngeal nerve tends to remain deeper in the left paratracheal area and therefore more difficult to dissect, especially the nodal tissues anterior to the nerve. A combination of blunt and sharp dissection longitudinally helps locate the left recurrent laryngeal nerve. Once the nerve is identified, lymph node tissue anterior to it in the paratracheal area is removed. This continues toward the apex of the thoracic cavity, reaching an area that can be dissected later from the neck. The thoracic duct that has been isolated from below—its distal portion can be identified running upward—can be resected.

The recurrent nerve is also traced downward on the aortic arch. The infra-aortic arch nodes can be removed by dissecting posteriorly toward the spine. In this area, the left bronchial artery arising from the arch of the aorta can be preserved. It is also very important not to injure the left pulmonary artery in the subaortic area.

Cervical Phase

In a transhiatal or three-phase esophagectomy without cervical lymphadenectomy, a left transverse supraclavicular incision is made extending from just beyond the sternocleidomastoid muscle to the right of

the midline suffices. An incision parallel to the anterior border of the sternocleidomastoid is a satisfactory alternative, the horizontal incision is cosmetically more pleasing, and gives equally good exposure. The left side is chosen because at this level the esophagus is more inclined to the left. Dissection is limited to medial to the carotid sheath. Once the middle thyroid vein is divided and the thyroid retracted to the right, the trachea and esophagus will come into view, especially when this follows the thoracic phase. Dissection of the esophagus should be easy if sufficient dissection has been performed from below. If this cervical phase precedes the thoracic phase or this is part of a transhiatal resection, dissection is first made close to the carotid sheath, and then the posterior wall of the esophagus is separated from the prevertebral fascia behind. Next, attention is turned to isolating the esophagus from the trachea. Dissection should be made as close as possible to the esophageal wall. Traction and compression to the tracheoesophageal groove should be avoided to preserve the recurrent laryngeal nerve (Fig. 77.5). A sling around the esophagus with a tape helps with retraction. If the thoracic phase precedes the cervical phase, a tape around the esophagus in the superior medistinum, with the tails pushed up in the left paraesophageal area, will aid retrieval of the esophagus in the neck as the tape is readily located once the space medial to the carotid sheath is opened.

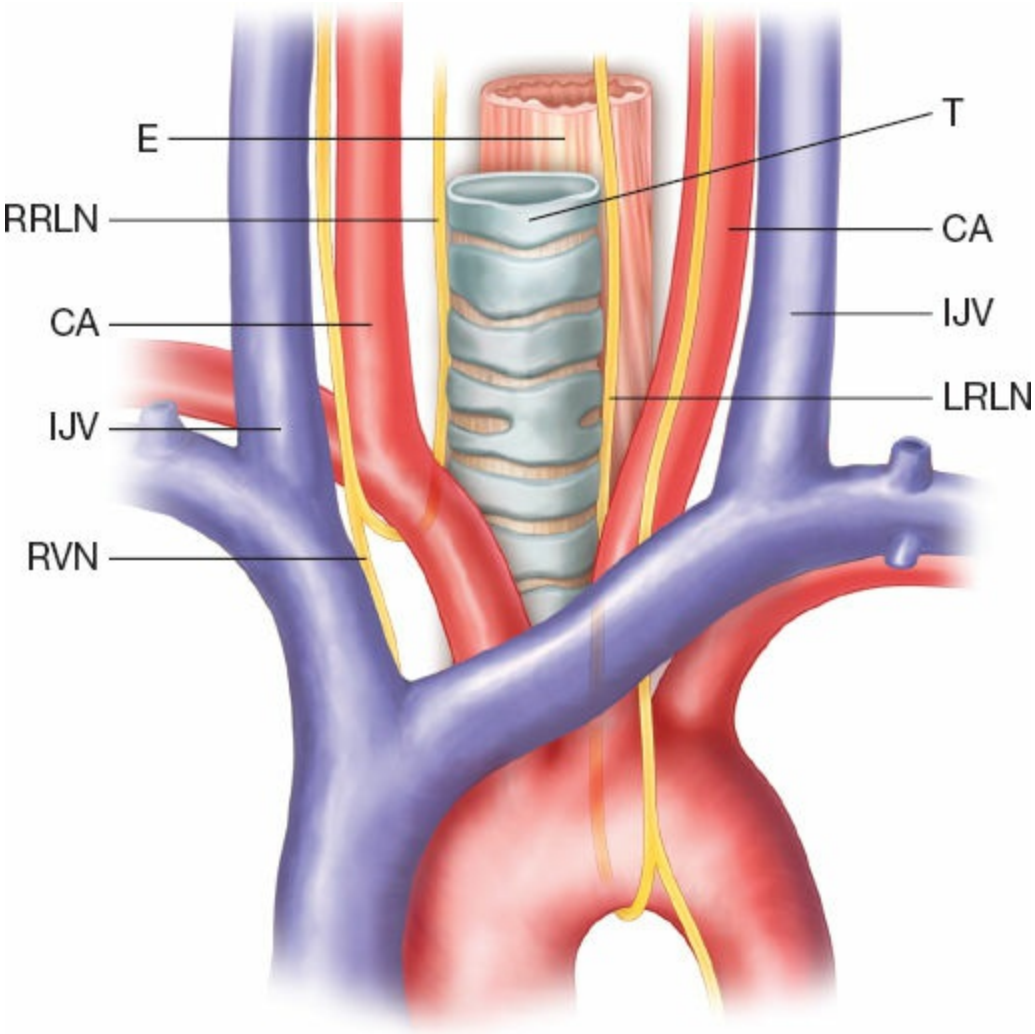

Figure 77.5. Cervical anatomy related to the recurrent laryngeal nerves. On the right side, the right recurrent laryngeal nerve is often situated more laterally as it emerges from the chest. On the left side, the nerve is usually more closely applied in the tracheoesophageal grove. The most important nodes are those along the recurrent nerves extending into the superior mediastinum. E, esophagus; RRLN, right recurrent laryngeal nerve; CA, carotid artery; IJV, internal jugular vein; RVN, right vagus nerve; T, trachea; LRLN, left recurrent laryngeal nerve.

In a transhiatal resection, the residual attachment to the pleura beyond the finger introduced through the neck has to be stripped by the hand inserted through the hiatus from the abdomen. Identifying the correct plane established after cervical mobilization facilitates this step. The whole length of the thoracic esophagus can thus be freed.

Cervical Lymphadenectomy

When three-field lymphadenectomy is performed, a collar incision is made one finger breadth above the clavicle (Fig. 77.6A,B). The anterior jugular vein may require ligation and division. It is not necessary to divide the sternocleidomastoid muscle. The sternohyoid and sternothyroid muscles can be divided to ease exposure. The main focus of nodal dissection is the area below the omohyoid muscles and medially as lymphatic spread above them is uncommon. A dissection plane is easily found above the deep cervical fascia so that the transverse cervical artery and phrenic nerve should stay below the plane of dissection and are preserved. Fatty tissue and lymph nodes are removed toward the carotid sheath, bounded inferiorly by the clavicle. The tissues around the carotid artery and internal jugular vein are removed en bloc. The middle thyroid vein is divided. Dissection medial to the carotid artery leads to the paratracheal nodes anterior to the recurrent laryngeal nerves and the paraesophageal nodes. These are the most critical nodes, as they are the upper limits of the recurrent laryngeal nerve chains from the mediastinum. Involved nodes are most likely found along their paths. Identification of the nerves early is essential to avoid inadvertent injury. On the right side, the recurrent laryngeal nerve lower down toward the clavicle is often at a distance from the tracheoesophageal groove, while on the left side the nerve is much more closely situated in the tracheoesophageal groove. Again a nerve stimulator may be useful. After a thorough mediastinal dissection, the recurrent laryngeal nerves are usually easily found, because dissection from below has partially exposed the nerve. On the left side, the thoracic duct can sometimes be seen. Chylous leak is prevented by ligation of the duct in the thoracic phase of the operation.

Minimally Invasive Esophagectomy

Thoracoscopy

A double-lumen endobronchial tube is introduced for single-lung ventilation, but a single-lumen endotracheal tube with a right bronchial blocker is preferred. The patient is placed in a left lateral decubitus position as for a posterolateral thoracotomy (Fig. 77.7). The right arm is raised to expose the armpit. This will allow more unimpeded use of thoracoscopic instruments. The surgeon stands at the back of the patient, and the first assistant stands on the opposite site. The second assistant using the videoscope stands next to the surgeon on his left side. His position will need to change to his right during the latter part of the

operation when the videoscope changes direction. Two monitors are used: one opposite to the surgeon near the head end of the table and the other opposite to the first assistant.

With the right lung collapsed, a mini-thoracotomy of 5 cm is made in the fourth intercostal space (or fifth space if only an infracarinal dissection is intended) with its posterior limit at the mid-axillary line (MAL). This mini-thoracotomy is useful and permits easier tracheal and lung retraction with a retractor placed through this small wound. A silicone wound retractor (Applied Medical) placed in this wound is sufficient and no forceful retraction with a metal wound distracter is necessary. A 5-mm port is placed in the fifth space at the posterior axillary line (PAL), one 10-mm port is inserted in the seventh space in the mid axillary line, and another 10-mm port placed in the seventh space just posterior to the PAL. The port placements need to be adjusted according to the build of the particular patient. When superior mediastinal nodal dissection is carried out, an additional port at the third space PAL is often added.

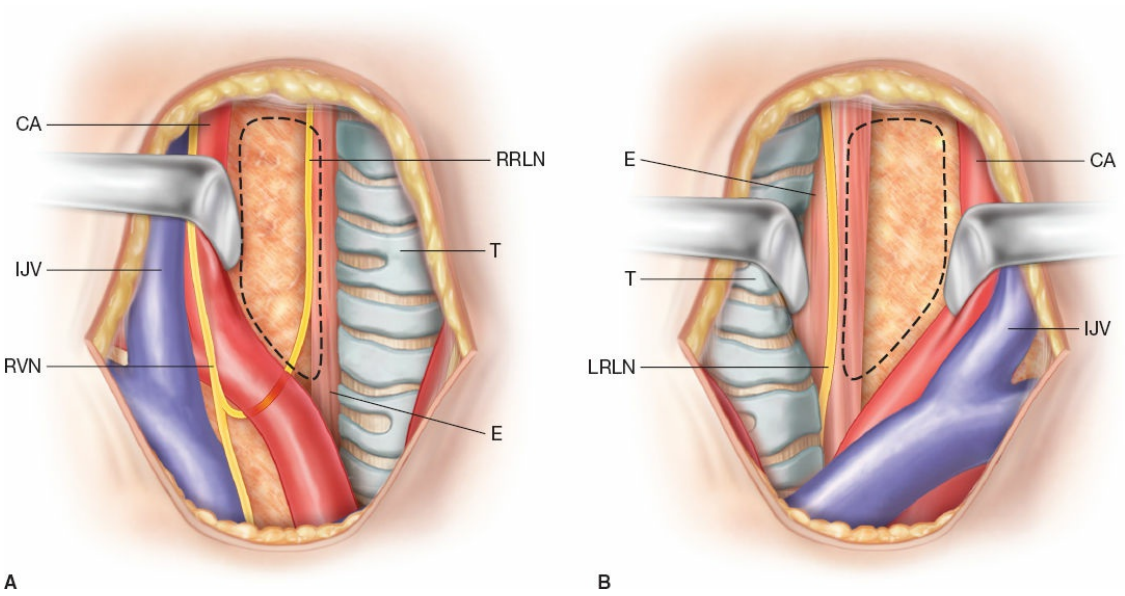

Figure 77.6. **A** and **B:** The area marked by the dotted line indicated the most likely area to harbor metastatic nodes. The chain of recurrent laryngeal nerve nodes extends into the mediastium as a cervicothoracic chain. E, esophagus; T, trachea; LRLN, left recurrent laryngeal nerve; RRLN, right recurrent laryngeal nerve; IJV, internal jugular vein; CA, carotid artery; RVN, right vagus nerve.

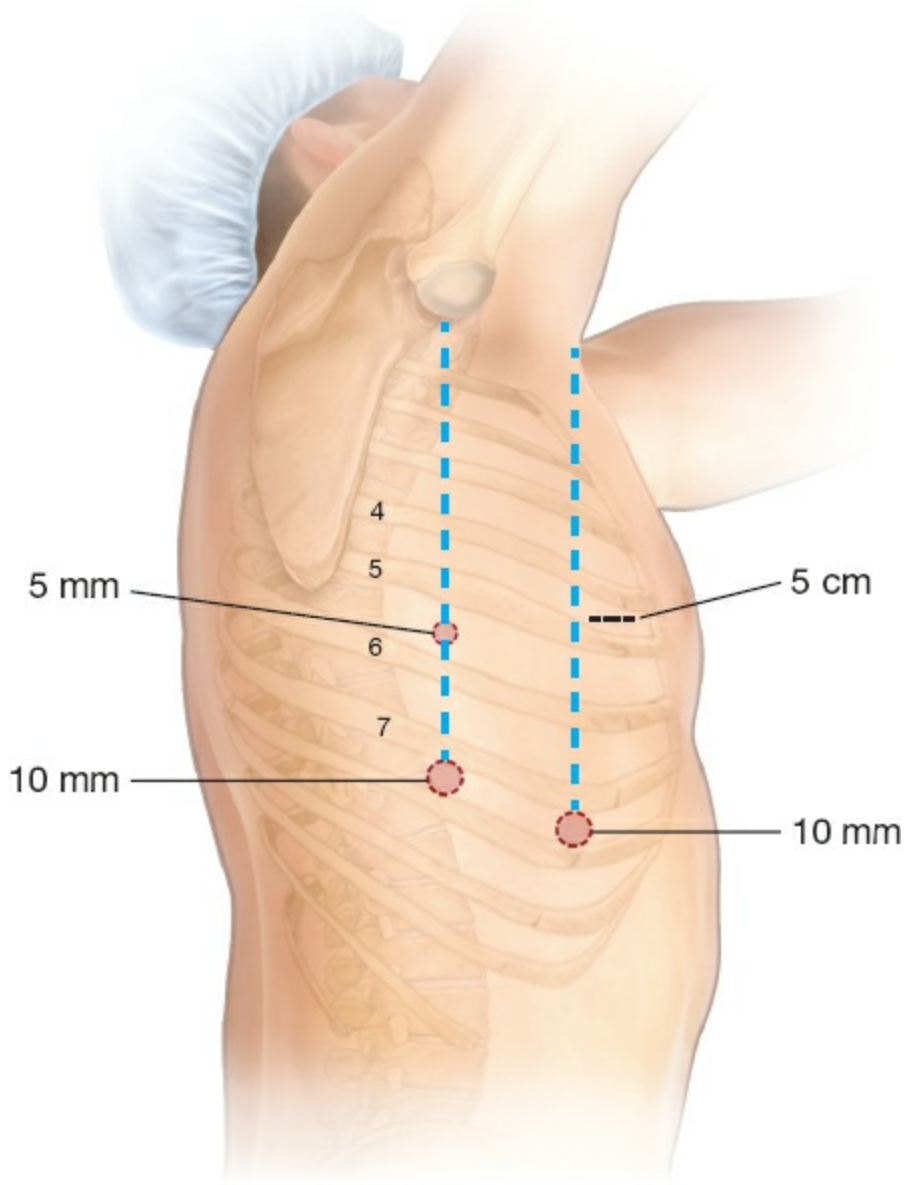

Figure 77.7. Thoracoscopic port sites and positioning: patient in full left lateral position. The surgeon stands at the back of the patient; 5-cm minithoracotomy in the fourth intercostal space with the posterior limit of the incision at the mid-axillary line (MAL). Another 5-mm port placed in the fifth space at the posterior axillary line (PAL). One 10-mm port placed in the seventh space in the PAL, and one 10-mm port in the seventh space MAL. When superior mediastinal lymphadenectomy is carried out, it often helps to add a 5-mm port site at the third intercostal space PAL. During the first phase of the procedure, the videoscope is introduced via the port at the seventh space PAL. When anterior dissection on the pericardium, carina, and left main bronchus is performed, the videoscope is changed to the seventh spaceport at MAL. Similarly, this port is used for superior mediastinal dissection.

The videoscope is introduced in the seventh space posterior port. For this part of the mobilization, the monitor opposite the first assistant can be turned upside down so that his view will be the same as one would see during an open operation. Mobilization of the esophagus is begun by first incising the mediastinal pleura overlying the esophagus below the level of the inferior pulmonary vein. Once a short segment of esophagus is mobilized, a sling (a PDS 1 suture) is placed around the esophagus to ease retraction. Dissection essentially follows the same routine as in open surgery. The division of the azygos vein arch is eased by the use of endovascular stapler. Once the posterior aspect of the esophageal dissection and periaortic tissue including the thoracic duct is dissected, the videoscope can switch to the seventh space port at the MAL. Anterior dissection along the right bronchus, carina, and left bronchus can proceed. During this part of the dissection, the monitor opposite the first assistant can be turned back to its normal position since the direction of view is the same for the surgeon as well as for the assistant. Once infracarinal dissection is finished, the superior mediastinal lymphadenectomy can be performed just as that described in the section on open surgery. Dissection around the recurrent laryngeal nerve has to be particularly meticulous; judicious use of energy source will lessen the chance of nerve injury. After the thoracoscopic phase is completed, the wounds can be closed with a small chest tube placed via the seventh spaceport pointing at the apex. Current practice of the author includes placement of a 19 Fr silicone drain with 4 channels along the sides with a solid core center (Blake drain). It is a closed suction drain connected to a vacuum reservoir, without the need for an underwater seal. Only in cases with extensive pulmonary adhesiolysis or air-leak a conventional chest tube will be placed. This is much more comfortable for the patients. The laparoscopic and cervical phase of the operation can then proceed.

Some surgeons prefer using the prone position for the thoracoscopic phase. The surgeon and the assistant both would stand at the front of the patient. In this position, the lungs, blood, and fluid tend to fall by gravity below the plane of dissection, thus improving exposure of the posterior mediastinum. Reliance on the assistant for retraction is also less. There is some preliminary data showing that oxygenation may be better using the prone compared with the left lateral approach. The potential drawback of the prone position is that dissection of the recurrent laryngeal nerve chains (especially the left) may be more difficult, since the dissection instruments

are coming anteriorly, and thus have to climb over the trachea before the left paratracheal space can be reached. More forceful retraction of the trachea may be required. Other disadvantages include the more difficulty in positioning, and should emergent conversion to open thoracotomy is required, this is more cumbersome.

Laparoscopy and Cervical Phase

The patient is turned to the supine position with the legs apart (Fig. 77.8). The surgeon stands on the right side, the first assistant on the left side, and the second assistant in between the legs holding the videoscope. The first port is placed with a subumbilical cut-down technique. Pneumoperitoneum is established. A 5-mm epigastric port is placed just below the xiphoid and this is converted immediately into a Nathanson liver retractor. One 5-mm port is placed just below the right costal margin slightly medial to the anterior axillary line; another 5-mm port is placed in between this port and the umbilical port about one fist-length away. Two similar ports are placed in the left side. The gastric mobilization and lymphadenectomy are just like the open procedure as described.

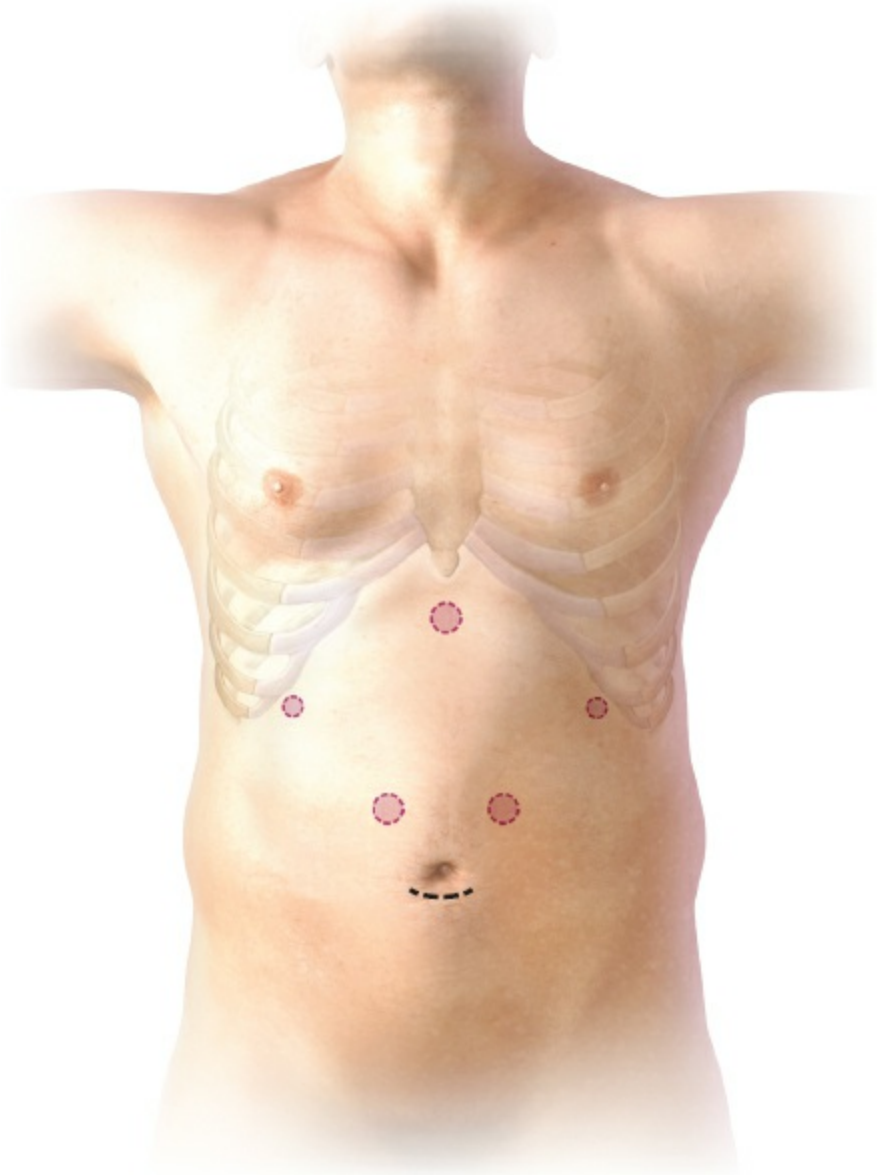

Figure 77.8. Port sites for laparoscopic gastric mobilization. The subumbilical port admits the videoscope, the surgeon stands on the patient's right side, and the assistant surgeon on the left. A Nathanson liver retractor replaces the epigastric port.

The neck is then explored. The esophagus is divided in the neck; the distal stump is closed and tagged to a chest tube or latex drain. Pneumoperitoneum is reestablished. The esophagus with the attached chest tube is grasped and pulled down into the abdomen. The Nathanson retractor is then removed, and this epigastric port is converted to a 5-cm midline mini-laparotomy. A silicone wound retractor is placed. The chest tube with the esophagus and mobilized stomach is pulled outside the abdomen. The lesser curvature of the stomach is prepared just like in open surgery and linear staplers are used to transect the stomach to make it into

a gastric tube. The specimen can then be removed. The apex of the gastric tube is tagged to the chest tube from the neck and replaced back into the abdominal cavity. Through the mini-laparotomy, a pyloroplasty can be performed.

The gastric conduit can be placed inside a plastic bag (such as that used to sheath an intraoperative ultrasound probe), tagged to the chest tube or latex drain, and then delivered to the neck for esophagogastrostomy. The bag protects the stomach (especially the vascular arcades) inside the posterior mediastinum, and also helps slide the conduit upward. The wounds can be closed after the esophagogastrostomy.

Routes of Reconstruction

In a Lewis–Tanner esophagectomy, the conduit is delivered up to the thoracic cavity for anastomosis. When a three-phase or transhiatal procedure is performed, the conduit can be brought up to the neck via the orthotopic (posterior mediastinum), retrosternal, or subcutaneous route.

To make a retrosternal tunnel, the space at the back of the xiphoid is entered. A tunnel is opened up behind the sternum. A flat malleable retractor is introduced to further open the space behind the upper part of the sternum. Little bleeding occurs if dissection is kept in a plane close to the back of the sternum near the midline. The upper part of the tunnel is made from the neck; the right plane can be correctly identified by following the sternal attachments of the strap muscles. Using the index finger, a space is opened by blunt dissection, again keeping close behind the sternum to avoid injury to underlying vascular structures. The narrowest part of the tunnel is usually at the thoracic inlet, and a space of three fingers is generally created to allow for adequate room for the passage of the conduit. Minor bleeding from the tunnel is self-limited and is usually controlled by gauze packing. It is not necessary to resect the manubrium sterni and the clavicular head to provide sufficient space.

The subcutaneous route is rarely used. To make the subcutaneous tunnel, the skin at the upper end of the abdominal incision is lifted up, and, with the use of scissors and electrocautery, the subcutaneous plane is opened up. The tunnel is prepared in a similar manner proximally from the cervical incision. The subcutaneous space in the intervening presternal segment is freed by using a pair of long scissors.

It is important to close the diaphragmatic hiatus after extirpation of the esophagus when the retrosternal or subcutaneous routes are used. Herniation of intestine into the thoracic cavity may occur otherwise.

The Esophageal Anastomosis

The esophageal anastomosis can be performed by a hand-sewn technique, circular stapler, or linear staplers. Whichever technique is used, equally low leakage rate can be achieved. Circular stapler is easier to use in an intrathoracic anastomosis and is less operator dependent, but stricture rate tends to be higher especially when the esophagus is small and a small-sized stapler is used. The hand-sewn anastomosis can be used in any position, and is certainly more economical. When thoracoscopic esophagectomy is performed, it is more difficult to perform the anastomosis in the thoracic cavity and most would prefer a cervical anastomosis.

For the hand-sewn anastomosis, the author uses a single-layer continuous monofilament, absorbable suture of 4/0 Maxon. To ensure success, there must not be tension, and careful apposition of the esophagus and conduit is needed. Tight suturing resulting in strangulation of tissue must be avoided. Other methods using double-layer and/or interrupted suturing, nonabsorbable sutures have their advocates. The method of anastomosis is less important than its proper application.

In the author's institution, all anastomoses in the neck are hand-sewn; similar method is used when open intrathoracic anastomosis is performed. In thoracoscopic intrathoracic anastomosis, a circular stapler is used, and placement of the anvil is eased by using the ORVIL (Medtronic). First the esophagus in the chest is transected with a linear stapler, then the anvil is placed trans-orally (ORVIL). The stapling gun is then introduced by opening up slightly the mini-thoracotomy to put inside the gastric tube to engage the anvil before firing. Another indication of the circular stapler is during trans-abdominal resection of a cancer of the gastroesophageal junction. To ensure a sufficient proximal margin in the lower posterior mediastinum, a hand-sewn anastomosis has poor exposure, and so this double-stapling technique just like the intrathroacic anastomosis can be done.

Preparation of a Colon Conduit for Interposition

The right and transverse colons are based on the middle colic vessels, and the left colon is based on the ascending branch of the left colic vessels (Figs. 77.9 to 77.11). Whichever part of the colon is used, the same meticulous method of preparation is required. When possible, we prepare the conduit in an isoperistaltic manner. A preoperative angiogram can help

in selecting the most appropriate segment, particularly in patients with previous abdominal operations, and preempts anomalous vascular anatomy. In countries where colonic diseases are prevalent, a preoperative colonoscopy may also be useful.

The steps in the mobilization of either right or left colon are similar. On the right side, mobilization of the terminal ileum across the iliac vessels and the ureter enables the terminal ileum, cecum, appendix, and ascending colon to be lifted out of the abdomen. As mobilization proceeds proximally, the duodenum and the head of the pancreas are safe-guarded; in this region, the main right colic vessel may be encountered as it courses over the uncinate process of the pancreas.

Mobilization of the left colon proceeds in a similar manner as before, and the sigmoid colon is freed from the retroperitoneum toward the midline and can also be brought out of the abdominal wound. The splenic flexure is similarly mobilized.

The transverse colon is prepared by detaching the greater omentum from its antimesenteric border. The omentum is first detached left of the midline to enter the lesser sac; further separation can then proceed more readily. Little bleeding should be encountered, and only occasionally does a blood vessel need ligation.

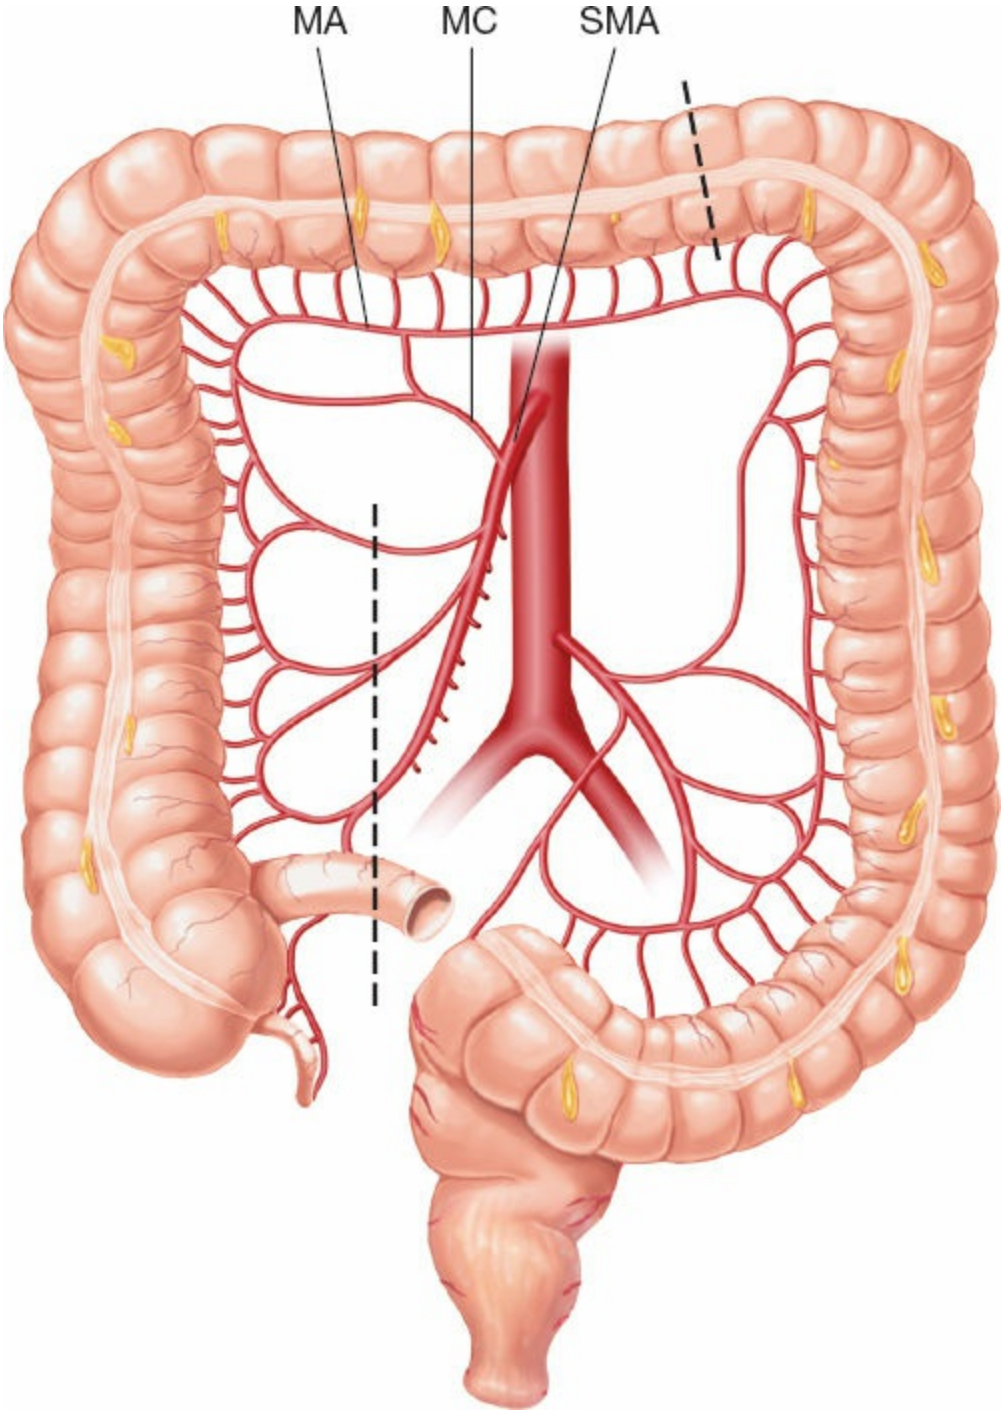

Figure 77.9. The vascular supply of the colonic conduits: right ileocolon loop used. The supply is based on the middle colic vessels with or without preservation of the right colic vessels, most often only the main ileocolic truck needs division for adequate length of the terminal ileum to reach the neck. Careful preservation of the marginal arcade is essential to ensure good vascularization of the colonic loop. *Dashed line* indicates the line of transection of the colon. MC, middle colic vessels; SMA, superior mesenteric artery; MA, marginal arcade.

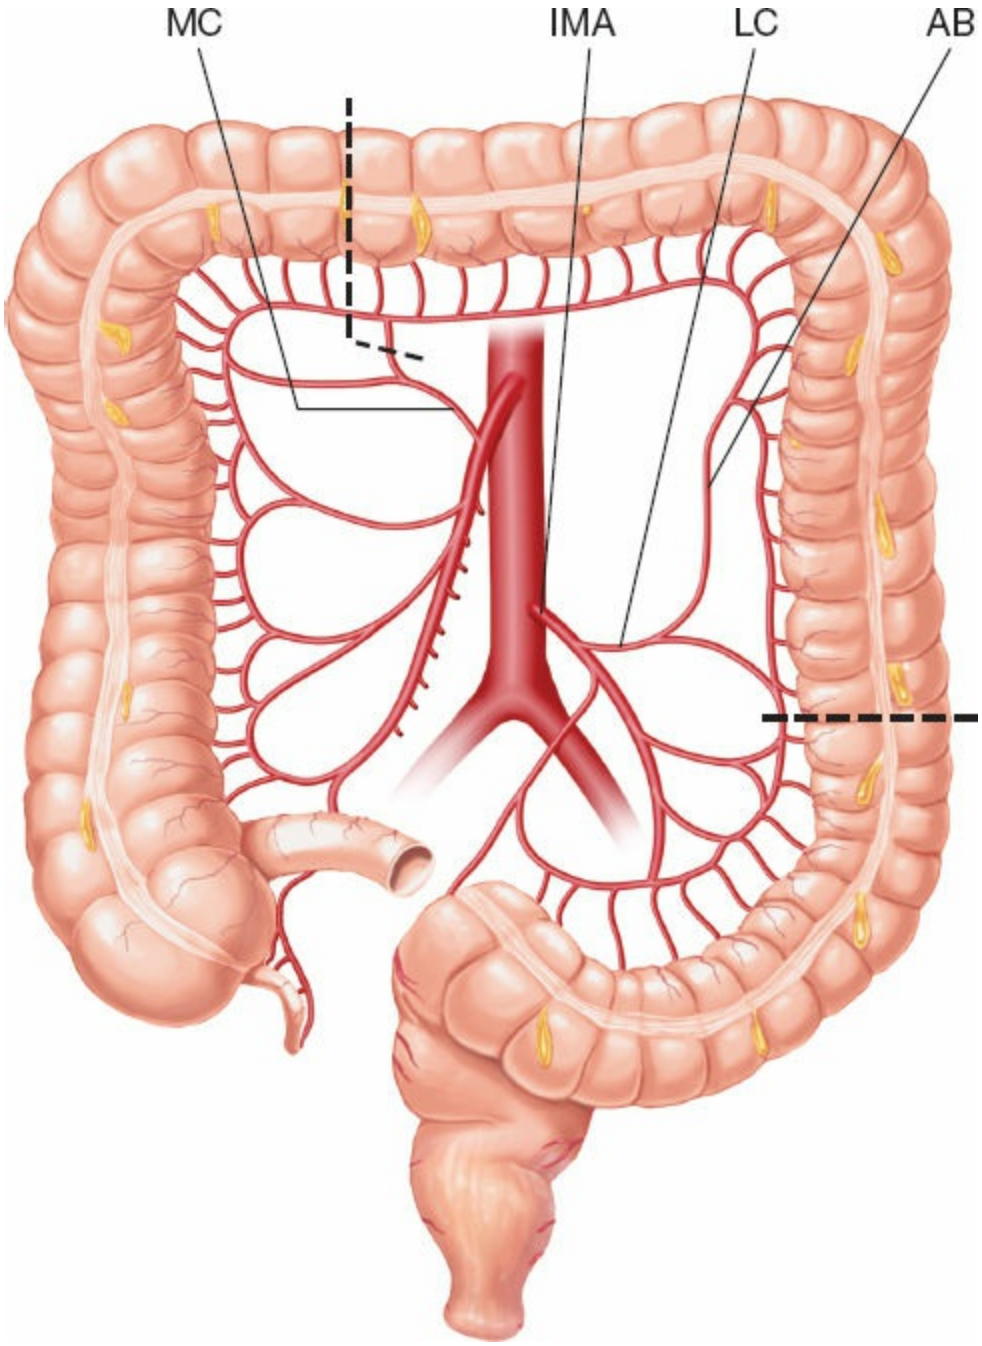

Figure 77.10. Left colon conduit. The vascular supply is based on the ascending branch of the left colic artery. *Dashed line* indicates the lines of transection. IMA, inferior mesenteric artery; MC, middle colic vessel; LC, left colic artery; AB, ascending branch.

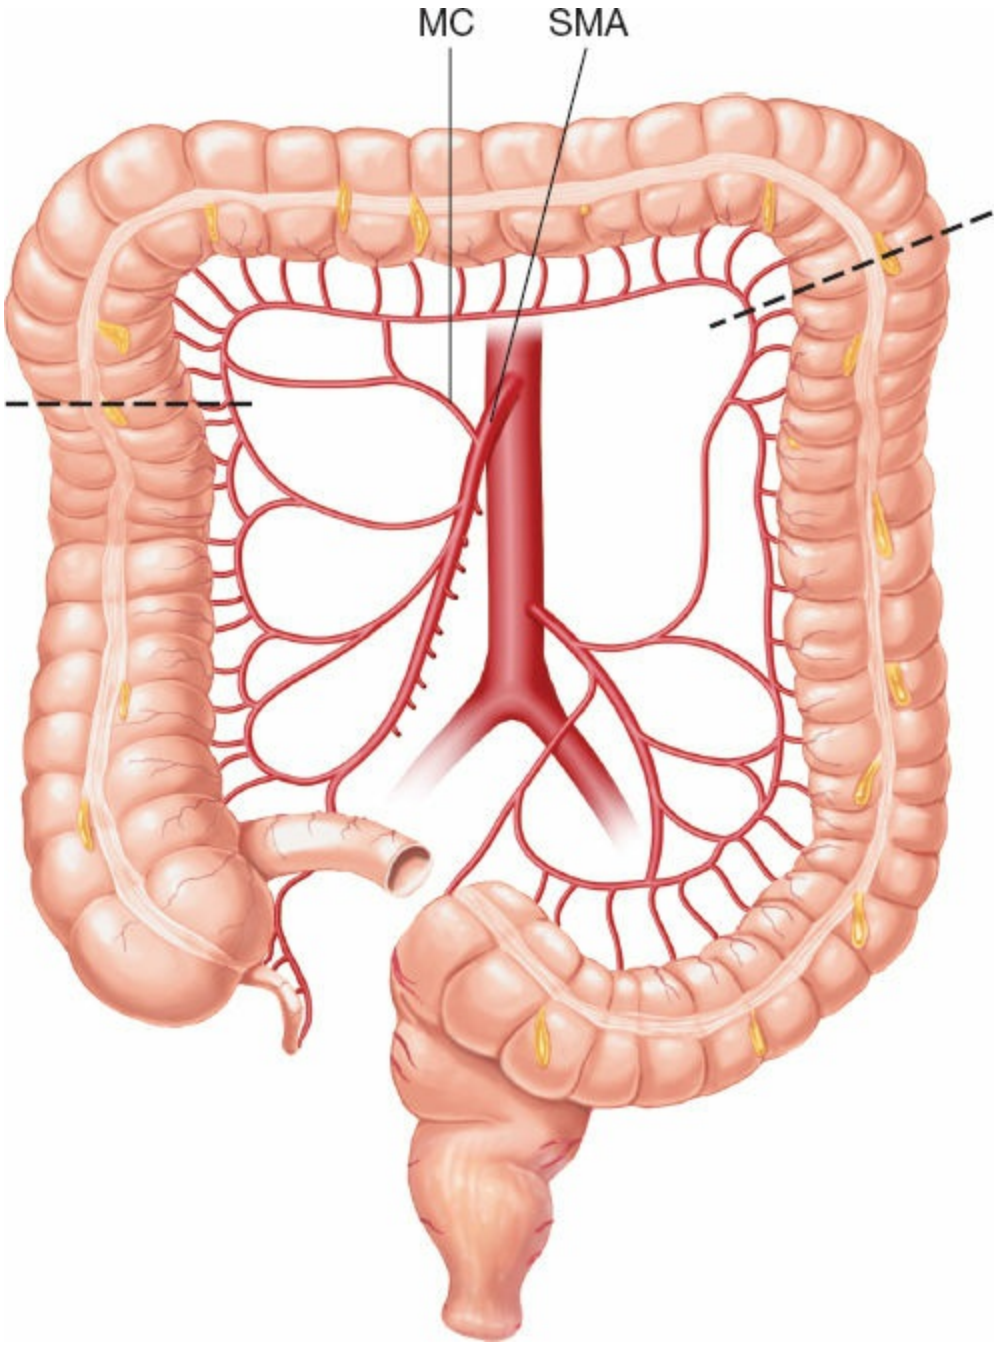

Figure 77.11. Transverse colon conduit. The vascular supply is based on the middle colic vessels. *Dashed line* indicates the lines of transection. SMA, superior mesenteric artery; MC, middle colic artery.

The author prefers using the right ileocolon, using the terminal ileum to anastomose with the esophagus. In the right colonic mesentery, there is usually a large area between the ileocolic and the right colic branches that is devoid of blood vessels. We divide the ileocolic vessels near the origin and then follow this down to the ileum about 15 to 30 cm from the cecum, where the ileum is divided. Usually only the main trunk of the ileocolic

vessels needs division. The marginal arcade connection from the left colic vessels should be preserved. A point on the transverse colon is chosen left of the middle colic vessels. Dissection should be done meticulously between the bowel wall and the marginal arcade (so preserving its connection to the right side) for a short distance to prepare the bowel for transection. Once this part of the transverse colon is divided, the proximal end of the transected bowel is used for the cologastric (if part of the stomach is still preserved) or colojejunal anastomosis. The distal end of the divided colon is anastomosed to the divided ileum to restore intestinal continuity. Often side-to-side anastomses are easier for both. The appendix is removed before bringing the ileocolonic loop up for anastomosis with the esophagus. The loop is usually brought up to the neck via the retrosternal route.

For the left colon, the sustaining arterial supply is the ascending branch of the left colic artery, which originates from the inferior mesenteric artery. When this branch is small and when only the left colon is available, we have used this segment in an antiperistaltic manner, with the blood supply based on the middle colic vessels. Usually, the ascending branch of the left colic artery is robust and the middle colic vessels can be divided. The venous drainage through the inferior mesenteric vein to the splenic vein has to be safeguarded during the preparation of the left colon.

Preparation of the Jejunal Conduit

The duodenojejunal junction is identified, and the proximal jejunum is then examined for completeness of arterial and venous arcades (Fig. 77.12). In patients with a thick mesentery, transillumination by a strong light from behind is helpful.

Dissection is begun in the upper jejunum, at a point approximately halfway between the edge of the intestine and the root of the mesentery, proximal to the branching of the main jejunal arteries. Sometimes the superior mesenteric artery divides into a few main branches with good marginal arcades joining the various main trunks. It is more problematic if the branches are small, and the marginal arcade on the intestine is small or is incomplete. Depending on the vascular supply, a point is first chosen based on a large artery. Usually, three to four sets of jejunal arteries and veins have to be divided for a sufficient length of mesentery and intestine to reach the neck. When a shorter length of jejunum is required, such as for intrathoracic anastomosis, less dissection of the mesentery is required. The proximal end of the intended jejunal conduit is usually 10 to 15 cm from

the duodenojejunal junction. Dissection is started at a safe distance from the marginal arcade. The four sets of jejunal vessels are isolated and then clamped with bulldog clamps to test the adequacy of the marginal arcades. To further ensure that the blood supply is sufficient to support the circulation to the conduit, a soft clamp is applied across the intestine at the upper jejunum to abolish any contribution from the proximal arcade. Often, the conduit of jejunum thus isolated undergoes active peristalsis. After a few minutes, if the color remains pink and the jejunum does not appear congested, and if arterial pulsation can be seen in the arcades, the viability of the jejunal conduit is assured.

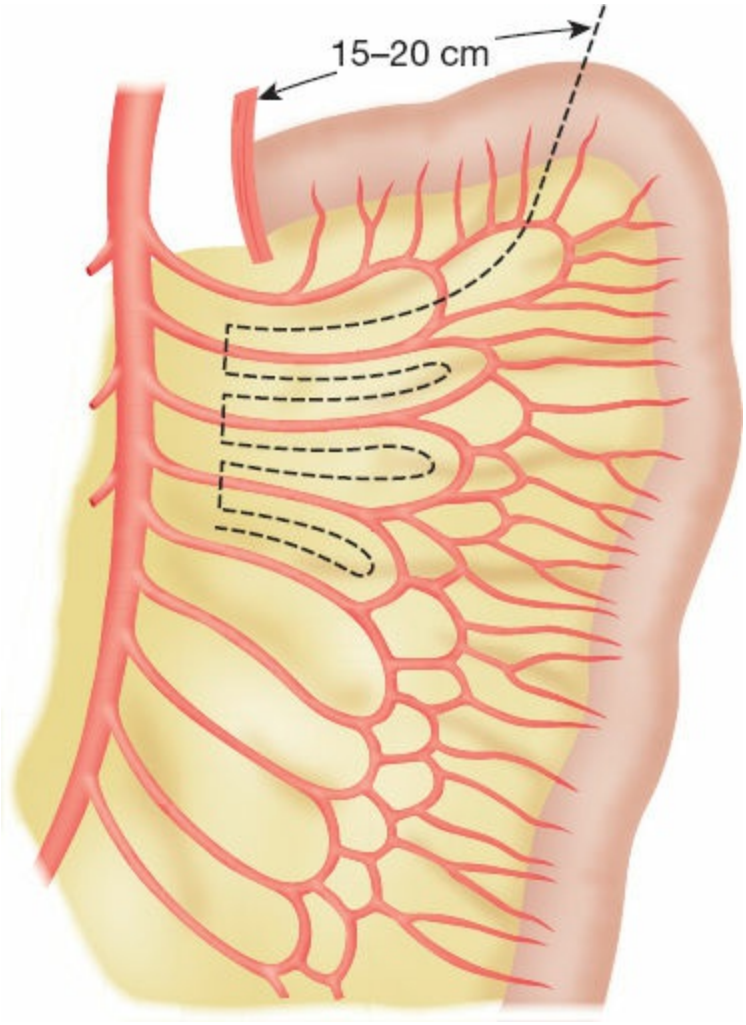

Figure 77.12. The jejunum prepared for esophageal replacement. The upper jejunum is used with division of three to four sets of jejunal arteries. Roux-en-y reconstruction is used.

When there is doubt about the vascular supply of the conduit, evidenced by flaccidity and congestion of the bowel wall and absence of arterial

pulsation, the most proximal bulldog clamp on the jejunal vessel can be released and the viability reassessed. However, if only three branches are divided, the mesentery may reach the neck only with some tension, which should be avoided. Under these circumstances, mobilization of the entire mesentery by dividing the peritoneum at the root as it crosses over the aorta allows the conduit, together with the entire mesentery, to move 4 to 5 cm higher and thus relieve any tension on the anastomosis. It is not the length of the bowel, but that of the mesentery, that limits the length attained.

After the adequacy of the blood supply of the jejunal conduit has been tested, the bulldog clamps and the soft intestinal clamp are removed. The arterial and venous branches are mobilized separately, then divided and ligated with fine ties. The jejunum is then divided proximally. The conduit is then placed in the retrocolic, retrogastric position (when appropriate) before being delivered to the right chest or neck for anastomosis. When a long jejunal loop has to reach the neck however, often the blood supply may not be reliable and augmentation with mirovascular anastomosis may be necessary.

PERIOPERATIVE CARE

Enhanced Recovery After Surgery Program (ERAS) has a definite place in the perioperative management of patients undergoing esophagectomy. However, practice varies and many components of ERAS are not proven. The routine program practiced at the author's institution is shown in Table 77.1.

Pain relief is a major component to postoperative care for esophagectomy, although with the introduction of minimally invasive surgery this may have become less crucial. Epidural analgesia has been our routine method. Overhydration results in more pulmonary morbidities and should be avoided. In general tubes and drains that are used should be of small caliber, as few as possible, and early removal enhances comfort and early mobilization. A nasogastric tube is rarely needed. When a pyloric drainage procedure has been done, especially when a cervical esophagogastrotomy is made, delayed gastric emptying problem is uncommon. Liquid diet can be introduced early, and when tolerated, a soft diet can be started. There is no need for routine contrast study to check the integrity of the anastomosis. Early introduction of diet also would not increase leak rates. The decision to advance oral diet is based on clinical

parameters, and not radiologic appearance. In centers that are experiencing a high leak rate however, this policy may not be appropriate. Other adjuncts like chest physiotherapy, incentive spirometry, mobilization exercise, and preoperative counseling are all contributory to early recovery.

COMPLICATIONS AND THEIR MANAGEMENT

Cardiopulmonary complications are most common; patients are elderly with pre-existing morbidities, surgery is carried out in three body cavities, and extensive mediastinal dissection predisposes to complications. Many patients also have had preoperative radiotherapy to the lungs and heart.

Atelectasis and pneumonia are managed by chest physiotherapy, incentive spirometry, adequate pain relief, avoidance of fluid overload, appropriate antibiotics, and if needed, sputum suction by bronchoscopy.

Atrial fibrillation occurs in around 20% of patients; it is benign in most and is treated by antiarrhythmic medication. In some patients, it is a reflection of underlying serious complication, such as bronchopneumonia or more importantly surgical morbidities such as anastomotic leak or ischemia of the conduit. Its occurrence should prompt appropriate investigations, such as an endoscopy.

Recurrent laryngeal nerve injury is not uncommon when superior mediastinal lymphadenectomy is carried out. Intraoperative nerve monitoring helps lessen this complication. Postoperatively patient will experience hoarseness of voice, coughing becomes less effective, and aspiration may be a problem when diet is introduced. In some patients, hoarseness may not be apparent because of excellent compensation from the contralateral vocal cords. Routine laryngoscopy will document clearly the incidence of nerve paralysis. When nerve palsy is present, more active pulmonary treatment is necessary, and introduction of oral diet should be more cautious. Early injection thyroplasty (within the first 3 to 4 days of diagnosis) is a simple procedure and may expedite recovery.

TABLE 77.1 Routine Perioperative Management at the University of Hong Kong

Preoperative period	Stop smoking and alcohol intake Counseling and education Chest physiotherapy and incentive spirometry
Day of operation	Carbohydrate loading 6 h before surgery Allow fluids 2 h before surgery Prophylactic antibiotics Deep vein thrombosis prophylaxis Epidural analgesia/Patient-controlled analgesia Intraoperative care Fluid management: Goal-directed therapy 19 Fr small vacuum suction drain (Blake drain) No feeding jejunostomy Routine endotracheal tube extubation
Day 1	Bronchoscopy to document state of vocal cords when bilateral recurrent laryngeal nerves dissection has been performed and/or cervical anastomosis Fluid restriction: IV fluid 1–1.5 L/day with additional challenge if necessary Chest physiotherapy Mobilization Sips of water by mouth
Day 2	IV fluid 1–1.5 L/day Chest physiotherapy Remove nasogastric tube Mobilization
Days 3–4	IV fluid 1–1.5 L/day Chest physiotherapy Liquid diet by mouth Remove chest drain if the output is <300 mL in the last 24 h Mobilization Urinary catheter taken off
Days 5–6	IV fluid 1–1.5 L/day (taken off if taking sufficient liquid by mouth) Remove epidural catheter and changing to patient-controlled analgesia or oral analgesics Chest physiotherapy Mobilization Soft diet
Day 7	Discharge if stable and tolerating diet well

Gross ischemia of the conduit usually presents early, within the first 2 to 3 days after operation. Sepsis is obvious. It is important to be proactive and treat this complication expeditiously so that further deterioration does not occur. A high index of suspicion is required. It is the author's practice to have a very low threshold for endoscopy to examine the state of the conduit and anastomosis whenever there are signs of deterioration. Signs leading to endoscopic examination can be unexplained tachycardia, atrial

fibrillation, or poor arterial oxygenation. A normal endoscopy at 3 days after surgery will assure the absence of gross ischemia, and other sources of sepsis (usually pulmonary or urinary) should be looked for. Gross ischemia dictates taking down of the conduit, adequate drainage, and staged reconstruction later once sepsis is under control. In selected cases with ischemia limited to a small portion of the gastric conduit, when the patient is hemodynamically stable with minimal sepsis (importance of early diagnosis before deterioration) and when an adequate length of stomach remains after resection of the ischemic portion, immediate reanastomosis is an option.

Clinically apparent thoracic anastomotic leaks usually occur within the first week. Signs of sepsis, excessive output from the chest drain, which may be turbid in color, may lead to diagnosis. The location and magnitude of the leak can be visualized by a water-soluble contrast study. A carefully performed flexible endoscopic examination is also helpful and will not worsen the leak. For small contained leaks, CT-guided drainage of pockets of collection may suffice. In septic patients with a sizable leak, exploration is warranted. Direct repair is seldom possible or effective, drainage is the key.

For a cervical anastomosis, leakage is suspected when there is inflammation and pain of the neck wound. Turbid infected discharge is found when the skin stitches are removed. Leaks that are truly confined to the neck are simply treated by laying the wound open with daily washing and frequent changes of dressing. The patient is usually not septic. Leaks that communicate with the mediastinum may require formal exploration and placement of mediastinal drains.

In all leaks, treatment with broad-spectrum antibiotics is required and is guided by culture and sensitivity results. Nutritional support is essential. With an intrathoracic stomach, careful endoscopic placement of a fine-bore feeding tube distal to the leak into the duodenum for enteral feeding is useful. A second tube, a nasogastric tube placed in the intrathoracic stomach, will help decompress the stomach and avoid reflux of gastric contents through the anastomosis. Total parenteral nutrition is required if placement of a feeding tube is not successful. Injection of fibrin glue, placement of intraluminal stents, and clip closure of the defect are increasingly used to treat leaks; sealing of the leak allows early control of sepsis and resumption of oral alimentation. The stent can be removed afterward, depending on the severity of the leak in the first place. Usually

4 to 6 weeks will suffice for adequate healing.

Chylous leak is suspected when there is excessive chest drainage. A milk challenge, looking at the color of the effluent before and after taking milk by mouth or via the nasogastric tube, will usually be obvious. This can be aided by biochemical testing of the drain fluid, measuring triglyceride level. In low output fistula of usually <500 mL to 1 liter per day, conservative management for a brief period of time with TPN or a mid-chain triglyceride diet may suffice. Sandostatin has not been shown to be useful. In case of persistence or if output is >1 liter per day, prolonged conservative treatment is not recommended and early reexploration is warranted. A lymphangiogram preoperatively will help locate the site of leakage, and intraoperative milk feed will also serve the same purpose. However, increasingly interventional radiologic method of percutaneous embolization has gained success, and has reduced the need for surgical reexploration.

OUTCOME

The outcome of esophagectomy has improved dramatically over the past three decades. In dedicated centers, mortality from this once feared operation is in the region of 2% to 3%. Morbidities however do remain substantial, especially pulmonary complications. Anastomotic leak rates vary widely, from 1% to 2% to even >20%, and this must be technique dependent. Despite high leak rates in some centers, mortality remains low since supportive treatment has also improved.

Improvement in surgery is evident both in reducing immediate postoperative mortality rates, and also in the extent of lymphadenectomy, which has been shown to be related to long-term prognosis. Multimodality treatment strategies with chemotherapy +/– radiotherapy have also contributed a great deal to survival. Response to neoadjuvant therapy is closely related to prognosis; the best is in patients who have shown substantial or even complete pathologic response to therapy. Overall after treatment in a mutimodality treatment program, a 5-year survival of 40% to 50% is expected. Disease stage remains the most powerful predictor of outcome. Early diagnosis is the best way to treat this deadly disease.

EDITOR'S COMMENT

Although squamous cell carcinoma remains the dominant histologic subtype of esophageal carcinoma throughout the world, there has been a dramatic shift in the epidemiology of esophageal carcinoma in the West, where there has been a marked increase in the incidence of adenocarcinoma (Arnold M, Pandeya N, Byrnes G, et al. Global burden of cancer attributable to high body-mass index in 2012: a population-based study. *Lancet Oncol* 2015;16:36–46). Many studies have implicated obesity, gastroesophageal reflux disease (GERD), and cigarette smoking as the major risk factors for this rising incidence of adenocarcinoma in the West (Thrift AP. The epidemic of oesophageal carcinoma: Where are we now? *Cancer Epidemiol* 2016;41:88–95). Barrett esophagus, a condition in which the normal squamous epithelium is replaced by intestinal-type columnar epithelium due to chronic acid reflux, confers an at least 10-fold increased risk of esophageal adenocarcinoma (Hvid-Jensen F, Pedersen L, Drewes AM, et al.

Incidence of adenocarcinoma among patients with Barrett's esophagus. *N Engl J Med* 2011;365:1375–83), and so these patients are entered into a program of routine endoscopic surveillance. However, it remains unclear whether such surveillance results in a decrease in overall mortality from esophageal adenocarcinoma.

The management of locally advanced esophageal carcinoma has evolved from surgery or radiotherapy as a single modality to trimodal therapy, including neoadjuvant chemoradiotherapy (nCRT) followed by surgery, which has been shown to confer a significant survival advantage over surgery alone (van Hagen P, Hulshof MC, van Lanschot JJ, et al. Preoperative chemoradiotherapy for esophageal or junctional cancer. *N Engl J Med* 2012;366:2074–84). The optimal timing of surgery after nCRT for esophageal carcinoma has not been established in prospective clinical trials. Lin et al. (Increasing the interval between neoadjuvant chemoradiotherapy and surgery in esophageal cancer: a meta-analysis of published studies. *Dis Esophagus* 2016;29(8):1107–14) performed a systematic literature search and meta-analysis of published studies on this topic and found that a longer interval (more than the standard 7 to 8 weeks) from the end of nCRT to surgery did not increase the pathologic complete response rate or have any effect on the anastomotic leak rate or overall postoperative morbidity or mortality rates. In contrast, performing surgery within 7 to 8 weeks after nCRT resulted in better R0 resection and 2-year overall survival rates, leading these authors to conclude that surgery is best performed within 8 weeks after the completion of nCRT.

Definitive chemoradiation therapy (CRT) is a reasonable treatment option for patients with squamous cell carcinoma of the esophagus who are high-risk operative candidates, as even patients with locoregionally advanced tumors enjoy high rates of pathologic complete response (CR). Yet despite the high CR rates, locoregional failure occurs in up to 60% of patients, and salvage esophagectomy is the only real option to achieve long-term survival in this setting. However, salvage esophagectomy after definitive CRT is associated with high rates of postoperative morbidity (~65%) and mortality (~8%) and 5-year survival rates of <30%, and so patient selection is key. Watanabe et al. (Salvage Esophagectomy After Definitive Chemoradiotherapy for Patients with Esophageal Squamous Cell Carcinoma: Who Really Benefits from this High-Risk Surgery? *Ann Surg Oncol* 2015;22:4438–44) examined the outcomes of 63 patients who underwent salvage esophagectomy after definitive CRT for esophageal squamous cell carcinoma at the Cancer Institute Hospital in Tokyo and concluded that the patients who benefit most from this high-risk surgery are those with pretreatment T1 or T2 tumors who relapse after a CR. For patients with relatively shallow, locally recurrent lesions in the esophagus without regional nodal metastasis after definitive CRT, salvage endoscopic therapies such as endoscopic mucosal resection (EMR) and photodynamic therapy (PDT) are highly effective, less invasive treatment options than salvage esophagectomy (Hatogai K, Yano T, Kojima T, et al. Local efficacy and

survival outcome of salvage endoscopic therapy for local recurrent lesions after definitive chemoradiotherapy for esophageal cancer. *Radiation Oncol* 2016;11:31).

Although definitive CRT is an option for patients with adenocarcinoma of the esophagus who are deemed to be poor operative candidates, trimodal therapy (including esophagectomy after CRT) is considered the standard of care, as it is associated with improved survival in retrospective studies (McKenzie S, Mailey B, Artinyan A, et al. Improved outcomes in the management of esophageal cancer with the addition of surgical resection to chemoradiation therapy. *Ann Surg Oncol* 2011;18:551–8; Shridhar R, Freilich J, Hoffe SE, et al. Single-institution retrospective comparison of preoperative versus definitive chemoradiotherapy for adenocarcinoma of the esophagus. *Ann Surg Oncol* 2014;21:3744–50).

Dr. Law asserts that one should aim for a proximal margin of 10 cm from the tumor in order to minimize the risk of a subsequent anastomotic recurrence. Indeed, there has been much written about the optimal gross proximal esophageal margin in patients undergoing esophagogastrectomy or transhiatal total gastrectomy for adenocarcinoma of the GE junction in particular. Minimum gross proximal margins of anywhere from 5 cm to 12 cm have been proposed by many different authors, on the basis that intramural skip lesions should be resected even though they are >5 cm away from the main tumor. However, such tumors with distant intramural skip lesions typically also exhibit extensive lymphovascular invasion and multiple regional nodal metastases and thus have a poor prognosis even if resected completely. Barbour et al. (Adenocarcinoma of the gastroesophageal junction: influence of esophageal resection margin and operative approach on outcome. *Ann Surg* 2007;246:1–8) demonstrated that an in vivo gross proximal esophageal margin length of 5 cm (corresponding to a length of 3.8 cm in the resected specimen due to shrinkage) was an independent prognostic factor for survival in patients with Siewert I, II, or III adenocarcinoma of the GEJ who underwent complete gross resection without neoadjuvant therapy. Mine et al. (Proximal margin length with transhiatal gastrectomy for Siewert type II and III adenocarcinomas of the oesophagogastric junction. *Br J Surg* 2013;100:1050–4), however, found that an in vivo gross proximal margin length of only 28 mm (corresponding to 20 mm in the resected specimen) was adequate for the vast majority of patients with Siewert type II and III GEJ tumors. This study is extraordinarily important, as the choice of operative approach to adenocarcinomas of the GEJ is highly dependent on the location of the tumor and the desired proximal margin. In many cases of adenocarcinoma of the GEJ, a 3-cm proximal margin is achievable via a transhiatal approach, thus sparing the patient the potential morbidity of a thoracotomy.

Another area of controversy in the surgical treatment of esophageal carcinoma is in the need for upper/middle thoracic lymphadenectomy in patients with either adenocarcinoma of the GEJ or squamous cell carcinoma of the lower

esophagus. In a very simple but elegant study, Mine et al. (Thoracic lymph node involvement in adenocarcinoma of the esophagogastric junction and lower esophageal squamous cell carcinoma relative to the location of the proximal end of the tumor. *Ann Surg Oncol* 2014;21:1596–1601) at the Cancer Institute Hospital in Tokyo investigated whether stratification based on the proximal end of the esophageal tumor as assessed by preoperative CT scan images would be useful in predicting upper/middle thoracic lymph node (LN) involvement. These authors used the vena cava foramen (VCF), defined as the level at which the IVC could be clearly separated from the liver parenchyma, as the landmark on the CT scan. For tumors with proximal ends *below* the VCF, the incidence of upper/middle thoracic LN involvement was 0% for adenocarcinomas of the GEJ and 5.9% for squamous cell carcinomas of the lower esophagus, whereas these percentages were over 35% for tumors with their proximal ends *above* the VCF. Thus, this stratification system based on preoperative CT scan images could be used to determine the extent of thoracic lymphadenectomy required for a given patient with a distal esophageal carcinoma.

Minimally invasive esophagectomy (MIE) has gained substantial popularity as the technique of choice for the surgical treatment of esophageal cancer. On balance, when compared to the traditional open, transthoracic esophagectomy (OE), MIE is associated with less postoperative morbidity (primarily fewer pulmonary complications) and shorter lengths of stay in the ICU and in the hospital (Biere SS, van Berge Henegouwen MI, Maas KW, et al. Minimally invasive versus open oesophagectomy for patients with oesophageal cancer: a multicentre, open-label, randomised controlled trial. *Lancet* 2012;379:1887–92; Sihag S, Wright CD, Wain JC, et al. Comparison of perioperative outcomes following open versus minimally invasive Ivor Lewis oesophagectomy at a single, high-volume centre. *Eur J Cardiothor Surg* 2012;42:430–7). In addition to its proven safety and feasibility as a standard approach to the surgical treatment of esophageal cancer, MIE has also been demonstrated to have equal oncologic efficacy and longer-term improvements in quality of life (QOL) compared to OE. Given the advantages of the robotic platform in accelerating the learning curve of MIE with the help of a magnified three-dimensional view, improved articulation of instruments, and improved dexterity and ergonomics, it only stands to reason that robotic transthoracic esophagectomy will soon become a standard of care for esophageal cancer. The first randomized, controlled trial (ROBOT trial) comparing robot-assisted esophagectomy with open transthoracic esophagectomy for esophageal cancer was launched in 2012 and is currently accruing patients.

Dr. Law and his group perform all of their cervical anastomoses in hand-sewn fashion with a single layer of continuous, absorbable suture, and this same method is used for open, intrathoracic anastomoses. For thoracoscopic procedures, Dr. Law prefers the circular stapled technique with the ORVIL. Price et al. (A comprehensive review of anastomotic technique in 432 esophagectomies. *Ann Thor Surg* 2013;95:1154–61) at the Mayo Clinic

published a comprehensive review of the outcomes with various anastomotic techniques in 432 esophagectomies over a 4-year period. As expected, stricture rates were higher for anastomoses in the neck compared to the chest (26% vs. 15%). For Ivor–Lewis esophagectomies in particular, the 1-year probability of stricture formation was 32% for the circular stapled technique, 27% for the hand-sewn technique, and only 8.6% for the linear-stapled technique. A recent meta-analysis by Deng et al. (Hand-sewn vs linearly stapled esophagogastric anastomosis for esophageal cancer: a meta-analysis. *World J Gastroenterol* 2015;21:4757–64) confirmed the significantly reduced risk of both stricture formation (Risk Ratio [RR] 0.56, 95% CI: 0.49–0.64; $P < 0.00001$) and anastomotic leak (RR 0.51, 95% CI: 0.41–0.65; $P < 0.00001$) with the linear-stapled technique compared to the hand-sewn technique.

Although the cause of anastomotic leakage after an esophagogastric anastomosis is thought to be multifactorial, ischemia of the gastric conduit no doubt plays a major role. Ischemic conditioning of the stomach is a method that has been employed to reduce the risk of anastomotic leak by increasing the perfusion of the gastric conduit. This technique consists of partial gastric devascularization through either embolization or laparoscopic ligation of several arteries to the stomach (with the exception of the right gastroepiploic artery) days or weeks before the completion of the esophagogastric anastomosis, with the aim to provide time for the stomach to adapt to the ischemic conditions created by the abrupt disruption of its normal vascular supply. In several studies, this procedure is performed at the same time as a staging laparoscopy with or without feeding jejunostomy tube placement. A thorough review of this technique by Kechagias et al. (*Ann Thor Surg* 2016;Feb 5, Epub ahead of print) shows that the widespread use of ischemic conditioning of the stomach is not justified at this time and that further clinical research with more rigorous methodology is needed in order to identify which patients may truly benefit from this technique.

Dr. Law advocates *not* obtaining a routine contrast study to evaluate for an anastomotic leak, as leaks in the neck or chest are usually quite easily recognized by clinical examination. Indeed, contrast esophagograms are beset by a number of potential problems, including low sensitivity and positive predictive values for detecting a leak as well as the risk of aspiration (and resultant pneumonia) in up to 45% of patients (Jones CM, Heah R, Clarke B, et al. Should routine radiological assessment of anastomotic integrity be performed after oesophagectomy with cervical anastomosis? Best evidence topic (BET). *Int J Surg* 2015;15:90–4). Nonetheless, a contrast esophagogram can be useful in confirming the clinical suspicion of a leak and in documenting its size and location, as this study has specificity rates in the detection of a leak in excess of 90%.

In terms of the treatment of an esophageal anastomotic leak, esophageal stent placement offers the advantages of earlier oral nutrition, reduced hospital stay, reduced morbidity, reduced anastomotic stricture rates, and equal efficacy as

compared to traditional operative repair with primary closure. In order to limit stent-related complications, it is recommended that esophageal stents be removed at 2 weeks when placed for an anastomotic leak and at 4 weeks when placed for an esophageal perforation (Freeman RK, Ascioti AJ, Dake M, Mahidhara RS. An assessment of the optimal time for removal of esophageal stents used in the treatment of an esophageal anastomotic leak or perforation. *Ann Thor Surg* 2015;100:422–8).

John T. Mullen

78 Transhiatal Esophagectomy Without Thoracotomy

Mark B. Orringer

INTRODUCTION

In the mid-1970s, the technique of transhiatal esophagectomy (THE) without thoracotomy and cervical esophagogastric anastomosis (CEGA) was rediscovered, refined, and popularized. Until that time, a transthoracic esophagectomy with an intrathoracic esophagogastric anastomosis was the standard approach to esophageal resection and reconstruction. THE and a CEGA challenged two prevailing surgical tenets: (1) The maximum upward reach of the mobilized North American Caucasian stomach was to the apex of the right chest, and (2) preservation of an intra-abdominal gastric reservoir was important in patients with benign esophageal disease. The purported advantages of the THE were (a) avoidance of a thoracotomy (and therefore less postoperative respiratory distress) and (b) a CEGA (in which an anastomotic leak resulted in a salivary fistula, which was well managed by open drainage and was seldom associated with mediastinitis and its 50% mortality). THE was initially criticized because of concern about inadequate hemostasis in mobilizing the esophagus from the mediastinum "blindly" and failure to permit an en bloc lymph node dissection felt important in other oncologic operations.

Over the past 40 years, the technique of THE has been progressively refined, and the author now regards this approach as the procedure of choice in the majority of patients requiring esophageal resection and reconstruction for both benign and malignant esophageal disease. The technical refinements in mobilizing and handling the stomach, dissecting the esophagus transhiatally, preparing the gastric conduit, positioning the stomach within the posterior mediastinum, and constructing the CEGA are reviewed in this chapter along with management of the most serious complications and results of the operation.

PATHOPHYSIOLOGY

Most often, patients requiring esophageal resection and reconstruction suffer from esophageal obstruction, which not only has nutritional consequences from *impaired caloric intake* but is also associated with *pulmonary sepsis* associated with impaired swallowing. Hypovolemia and *dehydration* are common. Humans produce 1 to 1.5 L of saliva each day, and the patient who is unable to swallow saliva comfortably and is constantly regurgitating and expectorating it may become severely *hypokalemic.*

INDICATIONS AND CONTRAINDICATIONS

THE is indicated in most conditions for which esophageal resection and reconstruction are required. In 2007, the author and his associates reported a series of 2,007 transhiatal esophagectomies, 1,525 of which (76%) had been performed for carcinoma of the intrathoracic esophagus and 482 (24%) for a wide variety of benign conditions (Table 78.1). Although an esophagomyotomy is a highly effective procedure for the treatment of achalasia, this neuromotor esophageal abnormality is not curable, and patients seen after a failed esophagomyotomy, a reflux stricture that has developed after an esophagomyotomy without an antireflux procedure, or those with a megaesophagus of advanced achalasia are candidates for esophagectomy. With the advent of histamine-2 blockers and proton pump inhibitors, the number of esophageal reflux strictures requiring resection has dramatically fallen. On the other hand, the dramatic increase in the number of laparoscopic fundoplications performed for control of gastroesophageal reflux and repair of hiatal hernias and recurrent hiatal hernias has generated an increasing number of failed fundoplications that are becoming a more common indication for esophagectomy. In patients with severe dysphagia or refractory esophagitis after two failed hiatal hernia repairs, the likelihood of achieving lasting reflux control and relief of dysphagia with a third antireflux operation is so low that the author advises an esophagectomy *if* another operation is the only alternative. Clinically significant gastroesophageal reflux following a properly performed CEGA is uncommon, and with no esophagus, the patient is no longer symptomatic from esophagitis. The decision to perform an esophagectomy for recurrent reflux or hiatal hernia, however, is a difficult one, and patients must understand that the outcome may include cervical dysphagia, reflux from the intrathoracic stomach, and dumping symptoms as problematic as their presenting symptoms.

In the author's experience with more than 2,000 transhiatal esophagectomies, this approach has been applicable in 98% of all patients requiring esophageal resection. However, clear contraindications to THE or utilizing the stomach as an esophageal replacement exist. Patients with upper or middle third esophageal carcinoma, who have tracheobronchial invasion documented by bronchoscopy and biopsy, magnetic resonance imaging, computed tomography, or esophageal endoscopic ultrasonography, are not candidates for a THE. Similarly, the author will not proceed with a THE in any patient with documented distant (M1) metastatic esophageal cancer. If the patient has undergone a prior esophageal operation (fundoplication, esophagomyotomy, perforation repair), safe transhiatal mobilization of the esophagus may prove to be impossible, and the surgeon must be prepared to convert to an open thoracotomy and transthoracic esophagectomy. Carcinoma of the esophagogastric junction and cardia with gastric invasion may necessitate resection of a major portion of the stomach to achieve an adequate margin and preclude esophageal replacement with stomach. In patients with such tumors, the suitability of the colon as an esophageal substitute should be determined with a preoperative barium enema examination and a colon bowel prep carried out in the event that a colonic interposition is required to reestablish alimentary continuity after resection of the esophagus and stomach. Without question, the most important contraindication to proceeding with a THE is the surgeon's assessment at the time of transhiatal mediastinal exploration that the esophagus is so adherent to adjacent vital structures that a transthoracic mobilization of the esophagus under direct vision is safer.

TABLE 78.1 Indications for Transhiatal Esophagectomy (2,007 Patients)

	Number (%)		
	Group I—1,063 PTS 1976–1998	Group II—944 PTS 1998–2006	Total—2,007 PTS 1976–2006
Benign conditions	**278 (26%)**	**204 (22%)**	**482 (24%)**
Neuromotor dysfunction	92 (33%)	47 (23%)	139 (29%)
Achalasia	69	44	113
Spasm/dysmotility	21	3	24
Scleroderma	2	0	2
Stricture	74 (27%)	21 (10%)	95 (20%)
Gastroesophageal reflux	40	7	47
Caustic ingestion	18	6	24
Radiation	4	2	6
Other	12	6	18
Barrett mucosa with high grade dysplasia	53 (19%)	90 (44%)	143 (30%)
Recurrent gastro-esophageal reflux	21 (8%)	6 (3%)	27 (6%)
Recurrent hiatus hernia	14 (5%)	14 (7%)	28 (6%)
Acute perforation	15 (5%)	9 (5%)	24 (5%)
Acute caustic injury	5 (2%)	1 (1%)	6 (1%)
Other	4 (1%)	16 (8%)	20 (4%)
Carcinoma of the intrathoracic esophagus	785 (74%)	740 (78%)	1,525 (76%)
Site			
Upper third	35 (4%)	16 (2%)	51 (3%)
Middle third	164 (21%)	63 (9%)	227 (15%)

PATIENT SELECTION AND PREOPERATIVE PREPARATION

The importance of careful nutritional assessment, medical evaluation, and documentation of adequate pulmonary function and cardiac reserve in insuring a successful outcome after THE cannot be overstated. In contrast

to how major operations were undertaken several decades ago, aggressive preoperative preparation of the patient for THE is now the rule and is consistently rewarded by decreased morbidity and mortality. The author is adamant, even in those with carcinoma, that patients completely abstain from cigarette smoking for a minimum of 3 weeks before operation. An incentive inspirometer is issued to the patient at the time of the first consultation, and regular daily pulmonary physiotherapy is instituted before the patient is admitted for esophagectomy. Patients are instructed to walk 3 miles daily when physically able prior to their scheduled operation, and the importance of early postoperative ambulation is emphasized. If esophageal obstruction is severe, a nasogastric feeding tube is inserted, and administration of supplemental tube feedings at home is initiated. A percutaneous gastrostomy is avoided as it creates the later need to close a hole in the stomach and increases the incidence of postoperative wound infection in the nearby THE upper abdominal incision. Patients are typically admitted for their esophagectomy on the day of the scheduled operation. Preoperative intravenous hyperalimentation is virtually never used, as is the case with hospitalization immediately prior to surgery.

SURGICAL TECHNIQUE

THE is performed in four phases: abdominal, cervical, mediastinal, and the anastomosis. Typically, after induction of general endotracheal anesthesia, flexible esophagoscopy is performed to verify the distance of the esophageal pathology from the upper incisor teeth and to verify that there is a sufficient length of normal proximal esophagus to allow construction of a CEGA. After the esophagoscopy, a nasogastric tube is inserted to decompress the stomach and aid in identifying the esophagus during its mobilization in the neck. The head is turned to the right and supported on a soft head ring, and the neck is extended by placing a small rolled sheet beneath the scapulae. The skin of the anterior neck, chest, and abdomen is prepped and draped from the mandibles to the pubis and anterior to both midaxillary lines. Two large bore peripheral intravenous lines and a radial artery catheter for intraoperative monitoring of blood pressure are placed and carefully padded as the arms are placed at the patient’s sides. The author prefers to avoid “bumping up one side” to allow performance of an anterolateral thoracotomy if needed. If it is necessary to convert to a transthoracic esophagectomy, this is best performed through a true posterolateral thoracotomy, and the author prefers to temporarily close the

abdominal wound, cover it with a plastic surgical drape, and turn the patient to his or her side for performance of the transthoracic mobilization. The chest is then closed, and the patient rolled supine once again for completion of the esophageal reconstruction. A table-mounted self-retaining (upper-hand) retractor optimizes exposure of the upper abdomen for a THE.

Abdominal Phase

The peritoneal cavity is entered through an upper midline supraumbilical incision (Fig. 78.1, inset). The triangular ligament of the liver is divided with electrocautery, and the left lobe of the liver is folded downward and retracted to the right with the liver blade of the upper hand retractor. The left abdominal wall is retracted laterally with the standard abdominal wall retractor blade. A planned esophagectomy for cancer is aborted with the findings of peritoneal implants, hepatic metastases, or bulky unresectable celiac adenopathy. On initial exploration of the abdomen, the stomach is assessed immediately for its suitability as an esophageal substitute. If a prior gastrostomy has been performed, this is taken down from the abdominal wall and the gastrostomy site temporarily closed with a figure-eight chromic suture. The greater omentum along the high greater curvature of the stomach is retracted to the left, and a “clear space” between the stomach wall and the omentum is developed. Once the lesser omental space has been entered behind the greater omentum, fingers inserted into this opening and behind the omentum can be used to define the high short gastric and left gastroepiploic vessels entering the stomach in this region. Several of these vessels are progressively defined, clamped with 13-in long right-angled clamps, divided, and secured with 2-0 silk ties. Care should be taken to divide these vessels well away from the gastric wall to avoid ischemic injury, and traction on the stomach should be minimized to avoid gastric trauma.

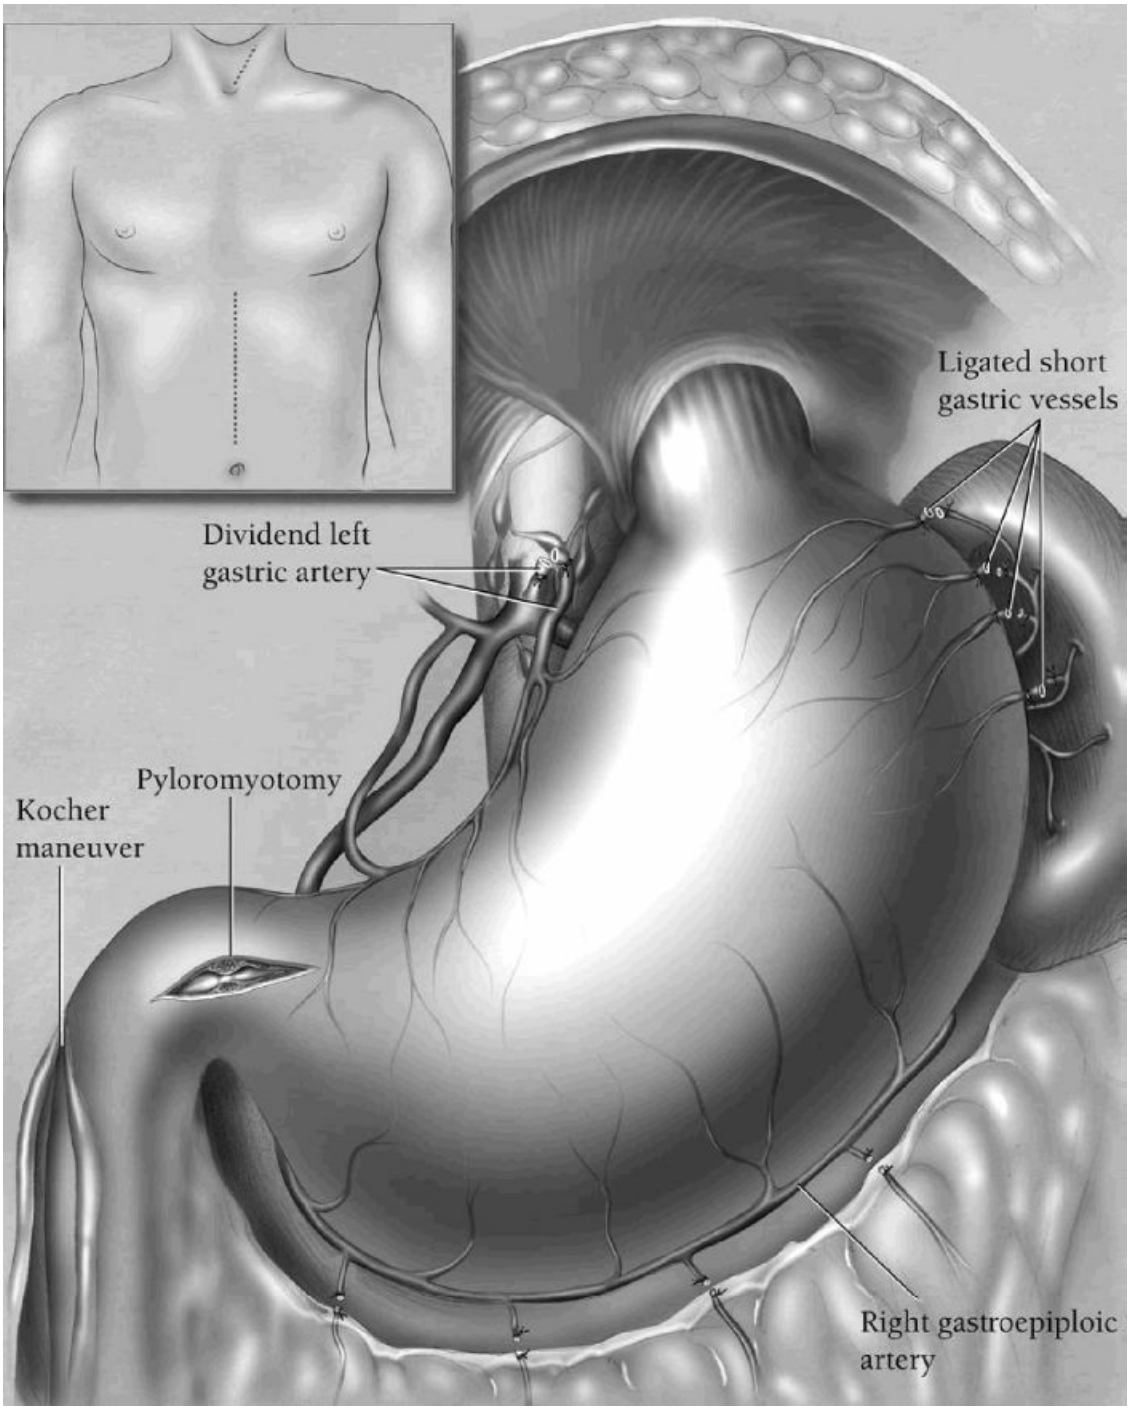

Figure 78.1. Diagram depicting the abdominal and cervical incisions (*inset*) and operative anatomy for the abdominal phase of the procedure. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

Rather than dividing more of the high short gastric vessels at this point, the dissection is carried inferiorly along the greater curvature of the stomach toward the pylorus, dividing each remaining major left

gastroepiploic branch approximately 1.5 to 2 cm away from the greater curvature of the stomach to minimize trauma to the gastric wall. The termination of the right gastroepiploic artery at its communication with the left gastroepiploic artery is identified. From this point inferiorly along the stomach, care is taken to divide the greater omentum 1.5 to 2 cm inferiorly to the right gastroepiploic artery to preserve patency of this vessel, which is the main blood supply of the mobilized stomach when it is used as an esophageal replacement. Once the greater omentum has been separated from the stomach to the level of the pylorus, the remaining attached omentum along the high greater curvature of the stomach is retracted to the left, and the highest short gastric vessels are mobilized, clamped, divided, and ligated. Care is taken to avoid injury to the spleen; gastric necrosis, which results from ligating the gastroepiploic vessels too near the stomach wall; and contusion of the high greater curvature from excessive traction and retraction of the stomach. When the entire greater curvature of the stomach is freed from its adjacent omentum, adhesions between the stomach and the retroperitoneum are carefully divided with electrocautery to ensure complete gastric mobility.

The peritoneum overlying the esophageal hiatus is incised, and the esophagogastric junction is encircled with a 1-in rubber drain. Attention is then turned to the lesser curvature of the stomach. One hand is placed behind the stomach from the greater curvature side until the fingers can be seen through the filmy gastrohepatic omentum along the lesser curvature of the stomach. The gastrohepatic omentum is incised and divided superiorly to the level of the diaphragmatic hiatus with electrocautery. As the gastrohepatic omentum is being divided, it is carefully palpated for an aberrant left hepatic artery arising from the left gastric artery. If the vessel is present, it is preserved. Retraction of the midstomach to the left tenses the soft tissues along the high lesser curvature. The left gastric vein is identified, mobilized, clamped between long right-angled clamps, divided, and ligated with 2-0 silk ties. The adjacent left gastric artery is identified at its origin from the celiac axis. The vessel is doubly ligated toward the celiac artery, clamped, and divided reflecting adjacent lymph nodes to the left with the stomach. The remaining soft tissue adjacent to the lesser curvature of the stomach is progressively divided with electrocautery moving toward the diaphragmatic hiatus so that the soft tissue margin is maximized. With mobilization of the high lesser curvature and entire greater curvature of the stomach now completed, attention is redirected to

the diaphragmatic hiatus.

The phrenoesophageal attachments and adjacent soft tissue are mobilized away from the diaphragmatic hiatus and toward the distal esophagus and esophagogastric junction with electrocautery, and the lower mediastinum is entered. It may be necessary to resect an adjacent rim of the diaphragmatic hiatus if tumor is adherent to the muscle at this point. Insertion of a narrow “heart” Deaver retractor into the hiatus anteriorly and upward traction on it exposes the distal esophagus within the posterior mediastinum and allows mobilization of the soft tissue on either side toward the esophagus. This dissection is typically carried out well into the lower mediastinum using a combination of alternating lateral retraction of the esophagus to tense the contralateral soft tissue, elevation of the tissue with a long right-angled clamp, and division with a long needle-tipped electrocautery. As the esophagus is being progressively mobilized from the low mediastinum, attention should be paid to the pleura on either side, as entry into either pleural cavity warrants later placement of a chest tube. During its mobilization, the esophagus is grasped and “rocked” from side to side to verify that it is not excessively fixed to the adjacent spine, prevertebral fascia, or aorta. In this fashion, mobilization of the distal esophagus and its adjacent periesophageal soft tissue is achieved to the level of the carina. As the dissection is performed, the radial artery blood pressure should be watched carefully to avoid prolonged hypotension resulting from cardiac displacement. Once the distal 10 cm of esophagus has been completely freed from the mediastinum, an abdominal pack is inserted through the diaphragmatic hiatus into the low mediastinum to facilitate hemostasis.

A generous Kocher maneuver is performed until there is sufficient mobilization to allow the pylorus to be elevated from its usual location in the right upper quadrant of the abdomen to a point aligned with the xiphoid process. Two pyloric traction sutures of 3-0 silk are then placed, one on the superior and one on the inferior aspect of the pylorus, and are used to elevate the pylorus into the field in preparation for a pyloromyotomy. Beginning 1.5 to 2 cm on the gastric side of the pylorus, the gastric muscle is elevated from the underlying submucosa with a fine-tipped right-angled clamp and divided with a needle-tipped electrocautery. The muscle incision is carried directly across the pylorus and 0.5 to 1 cm onto the duodenum, exposing the characteristic fine venous plexus that characterizes duodenal submucosa. Inadvertent entry into the

pyloroduodenal mucosa is managed by closing the hole with several interrupted 5-0 polypropylene sutures; the pyloromyotomy is not converted to a pyloroplasty. A pyloromyotomy is preferred over a pyloroplasty because it avoids a suture line at right angles to the vertical axis of the stomach, which will be pulled upward toward the neck. Hemostatic metallic clips are placed on both traction sutures near the pylorus prior to cutting them to allow future identification of the level of the pylorus at subsequent radiographic follow-up.

A 14 French rubber jejunostomy feeding tube is inserted 15 to 20 cm distal to the ligament of Treitz and secured in place with a Weitzel maneuver. The jejunostomy tube is not yet brought through the abdominal wall but rather emerges from the inferior end of the abdominal incision and is clamped with a hemostat and covered with a towel, which is clamped on either side to the drapes to minimize the chance of dislodging the feeding tube during the subsequent dissection. With gastric mobilization, dissection of the distal esophagus from the inferior mediastinum, the Kocher maneuver, pyloromyotomy, and feeding jejunostomy completed (Fig. 78.1), the abdominal phase of the operation ends, and attention is turned to the neck.

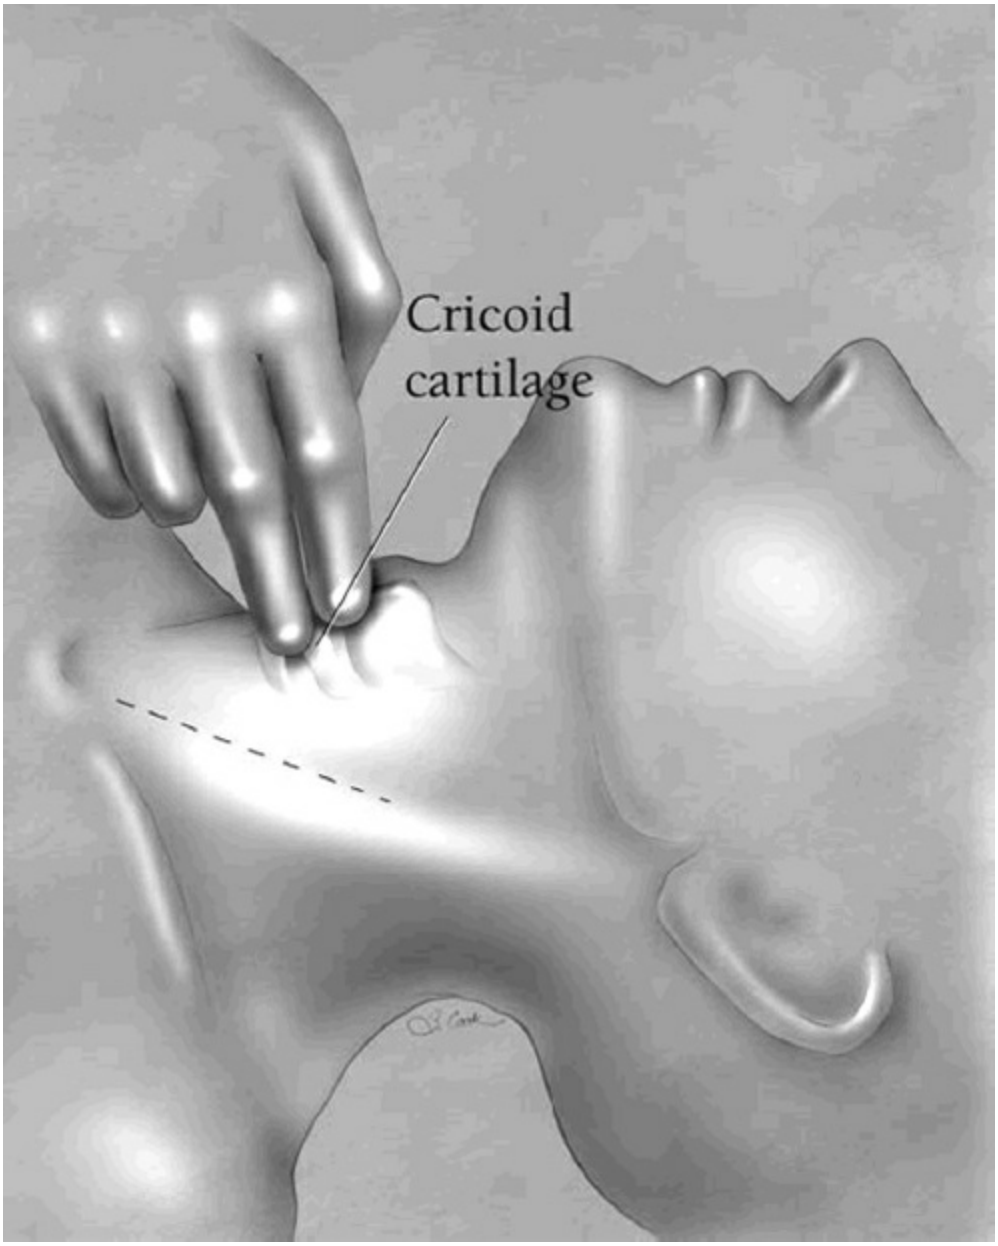

Figure 78.2. A 5- to 7-cm oblique incision paralleling the anterior border of the left sternocleidomastoid muscle is made and extended no >2 to 3 cm superior to the cricoid cartilage. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

Cervical Phase

During the cervical phase of the operation, it is preferable that the surgeon stand on the left side of the operating table. The cricoid cartilage is palpated to identify the level of the cricopharyngeus sphincter. A 5- to 7-cm oblique incision paralleling the anterior border of the left sternocleidomastoid muscle is made and extended no more than 2 to 3 cm

superior to the cricoid cartilage (Fig. 78.2). The incision is carried through the underlying platysma muscle, and the fascia along the anterior edge of the sternocleidomastoid muscle is incised in the direction of the wound. Blunt finger retraction is used to separate the sternocleidomastoid muscle from the underlying cervical fascia medial to it. Retraction of the sternocleidomastoid muscle laterally allows identification of the underlying omohyoid muscle, the central tendon of which is elevated with a right-angled clamp and divided (Fig. 78.3). Elevation of the medial belly of the divided omohyoid muscle tenses the contiguous omohyoid fascia layer, which is incised in the direction of the wound superiorly and inferiorly. The omohyoid fascia layer leads to the carotid sheath and its contents, which are gently retracted laterally. The larynx and the trachea are simultaneously retracted medially by the assistant's index finger (Fig. 78.4). No metal retractor is placed against the tracheoesophageal groove during any portion of the operation to minimize the risk of recurrent laryngeal nerve (RLN) injury. As the interior jugular vein is retracted laterally, the middle thyroid vein is often identified and should be mobilized, clamped at either end with fine right-angled clamps, divided, and ligated. Using the cricoid cartilage as a landmark, the inferior thyroid artery is identified at the same level at the depths of the cervical wound. The artery is clamped with fine right-angled clamps, divided, and ligated. The deep cervical fascia overlying the prevertebral fascia is now incised over the length of the cervical incision. The prevertebral fascia is palpated at the depths of the wound, and the superior mediastinum is entered by blunt finger dissection along the prevertebral fascia. As the trachea is retracted medially, the left anterior cervical strap muscles are tensed, elevated with a right-angled clamp near the left clavicle, and divided with electrocautery, thereby facilitating exposure of the esophagus at the thoracic inlet.

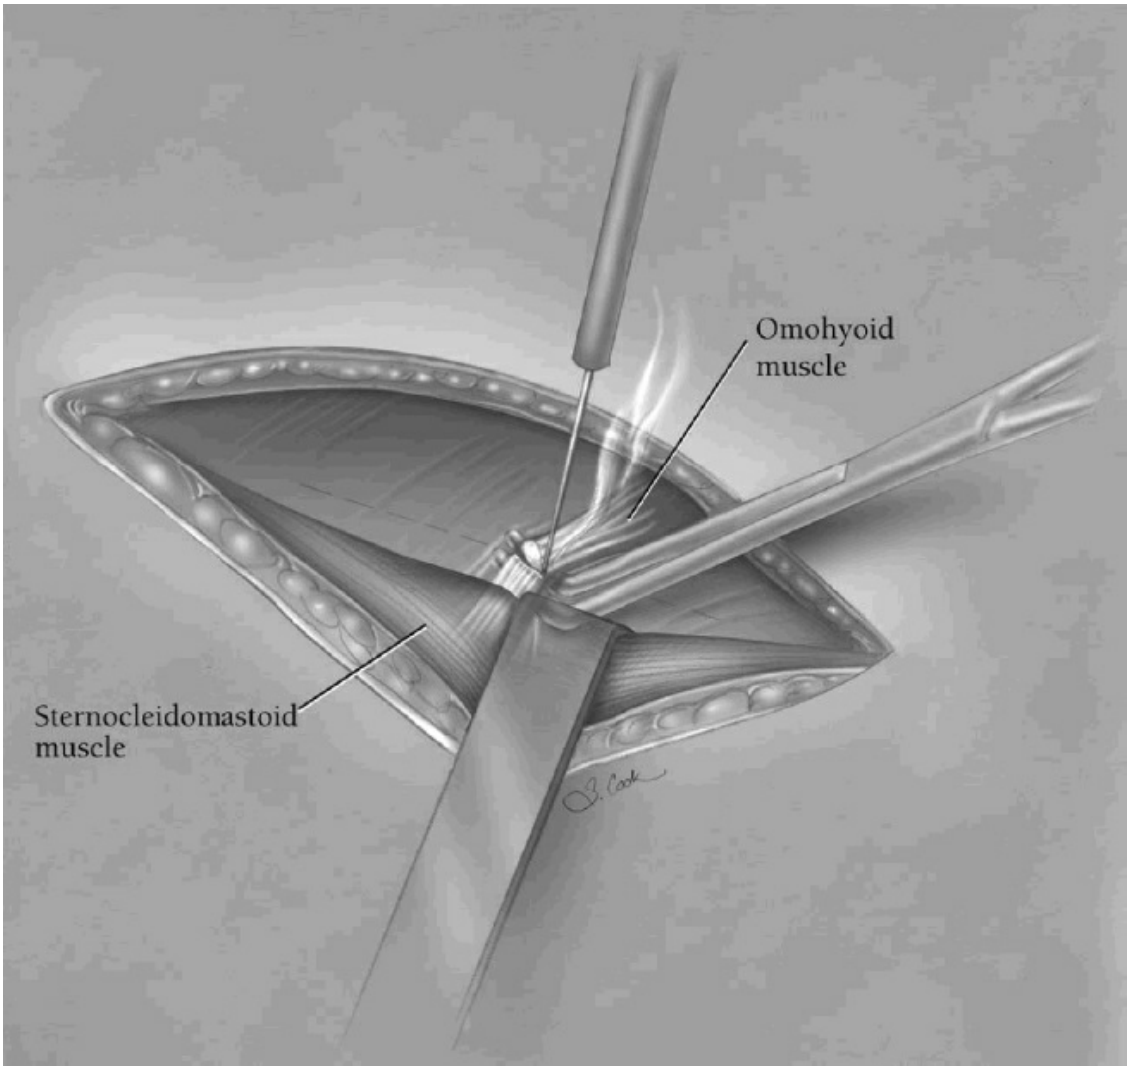

Figure 78.3. Retraction of the sternocleidomastoid muscle laterally allows identification of the underlying omohyoid muscle, the central tendon of which is elevated with a right-angled clamp and divided. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

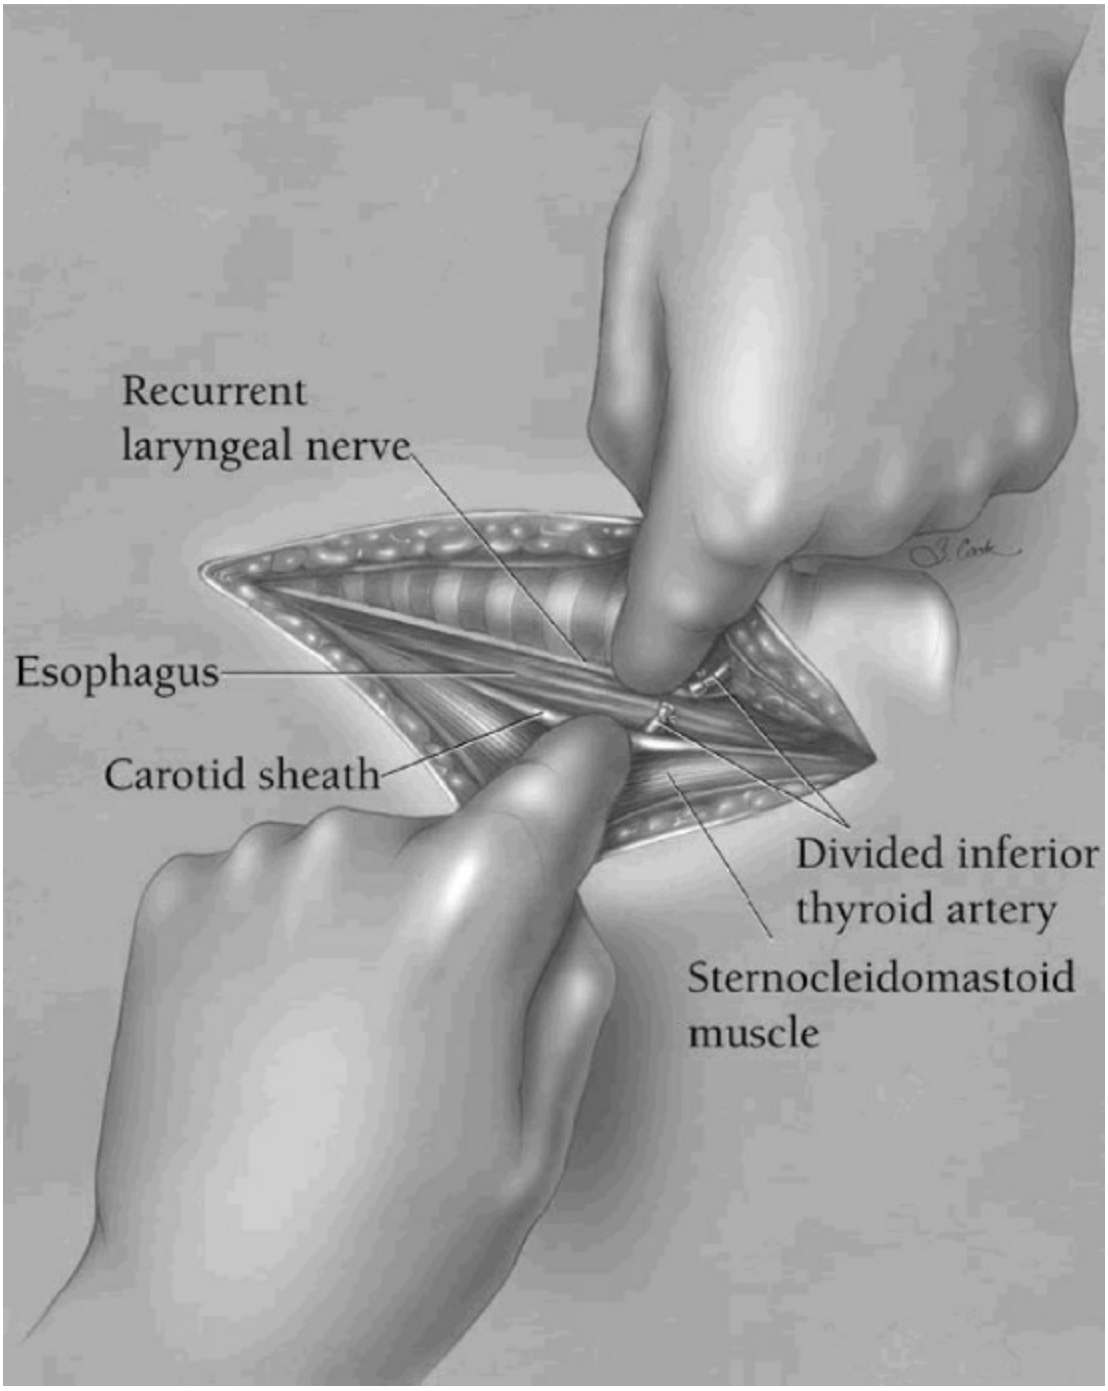

Figure 78.4. The larynx and the trachea are simultaneously retracted medially by the assistant's index finger, and the sternocleidomastoid muscle and carotid sheath laterally. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

The first assistant elevates the esophagus out of the superior mediastinum by applying gentle upward traction on the tracheoesophageal groove at the level of the cricoid cartilage (Fig. 78.5). This maneuver

provides a greater length of cervical esophagus in the wound for subsequent mobilization. The tracheoesophageal groove is developed by sharp dissection posterolateral to the RLN, but no active attempt is made to visualize the nerve. The anterior wall of the esophagus is gently mobilized along the length of the incision. By careful blunt dissection, the surgeon's index finger proceeds medially anterior to the esophagus, which is retracted laterally until the index finger can palpate the medial edge of the esophagus and the prevertebral fascia behind it.

While maintaining upward traction on the tracheoesophageal groove and keeping the left index finger medial to the esophagus and against the prevertebral fascia immediately behind it, a long right-angled clamp is passed posteriorly along the lateral aspect of the esophagus until its tip can be felt by the index finger medially. Once this circumferential mobilization of the esophagus is completed, the esophagus is encircled with a 1-in rubber drain (Fig. 78.6). By retracting the rubber drain superiorly, the cervicothoracic esophagus is elevated to the surface of the wound. As the esophagus is elevated, blunt dissection of the esophagus from the superior mediastinum is carried out while keeping the volar aspects of the fingers closely applied to the esophagus (Fig. 78.7). With the cervical esophagus encircled and several centimeters of the upper thoracic esophagus bluntly mobilized within the superior mediastinum, the cervical dissection is completed.

Mediastinal (Transhiatal) Dissection

With gentle downward traction on the 1-in rubber drain encircling the esophagogastric junction and avoiding trauma to the upper stomach, the opposite hand is passed into the posterior mediastinum along the prevertebral fascia posterior to the esophagus (Fig. 78.7). Resectability of the esophagus and its contained tumor, if present, is continually assessed by "rocking" the esophagus to be certain that it is not fixed to adjacent tissues.

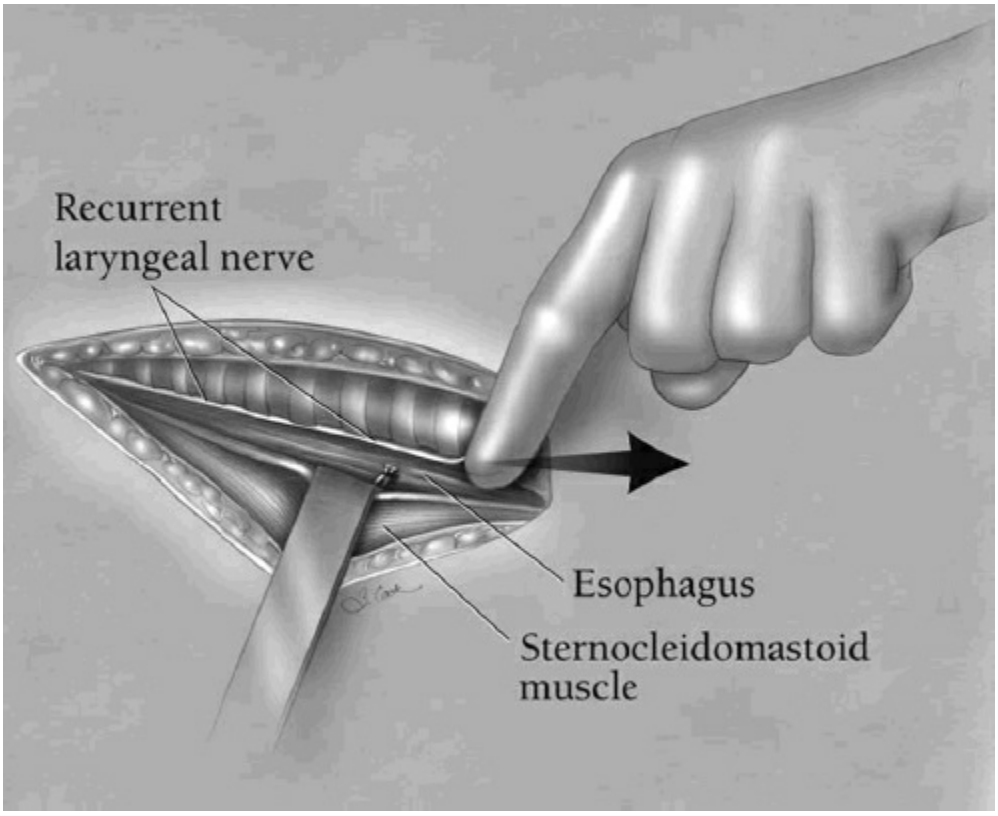

Figure 78.5. Elevation of the esophagus out of the superior mediastinum by applying gentle upward traction on the tracheoesophageal groove at the level of the cricoid cartilage. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

With the rubber drain encircling the cervical esophagus retracted anteriorly and toward the patient's right, a "half-sponge on a stick" is inserted through the cervical incision behind the esophagus and is advanced downward through the superior mediastinum along the prevertebral fascia (Fig. 78.8). Eventually, the sponge can be felt by the fingers inserted through the diaphragmatic hiatus from below. Any remaining posterior esophageal prevertebral soft tissue is disrupted by the sponge-on-a-stick pushed against the fingers inserted from below through the diaphragmatic hiatus. During this portion of the operation and all subsequent phases of the mediastinal dissection, the hand inserted through the diaphragmatic hiatus and into the mediastinum must be constantly kept posteriorly against the prevertebral fascia to avoid creating pressure against the heart anteriorly and resulting hypotension from the cardiac displacement. The radial artery blood pressure is continually monitored during this transhiatal mobilization of the esophagus so that prolonged

hypotension is avoided. Once this posterior mobilization of the esophagus has been completed, a 28 French Argyll Saratoga sump catheter is inserted through the cervical incision and advanced downward into the mediastinum to assist in clearing blood from the posterior mediastinum.

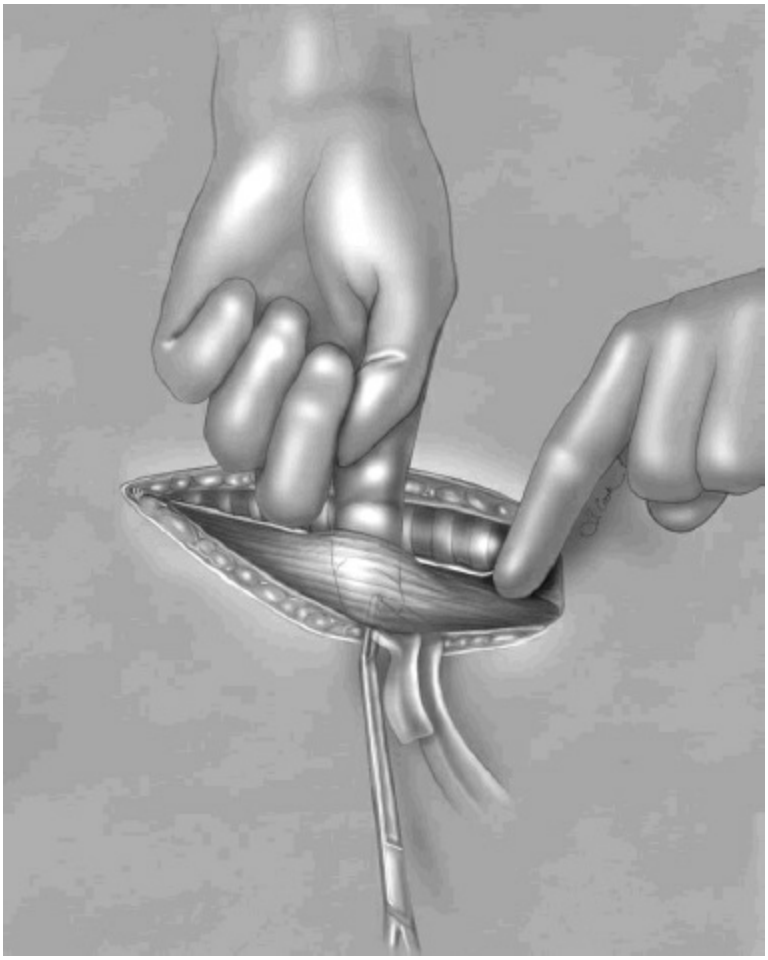

Figure 78.6. A long right-angled clamp is passed posteriorly along the lateral aspect of the esophagus until its tip can be felt by the index finger medially. There is no contact between the clamp and the tracheoesophageal groove to prevent recurrent laryngeal nerve injury. When the circumferential mobilization of the esophagus is complete, the esophagus is encircled with a 1-in rubber drain. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

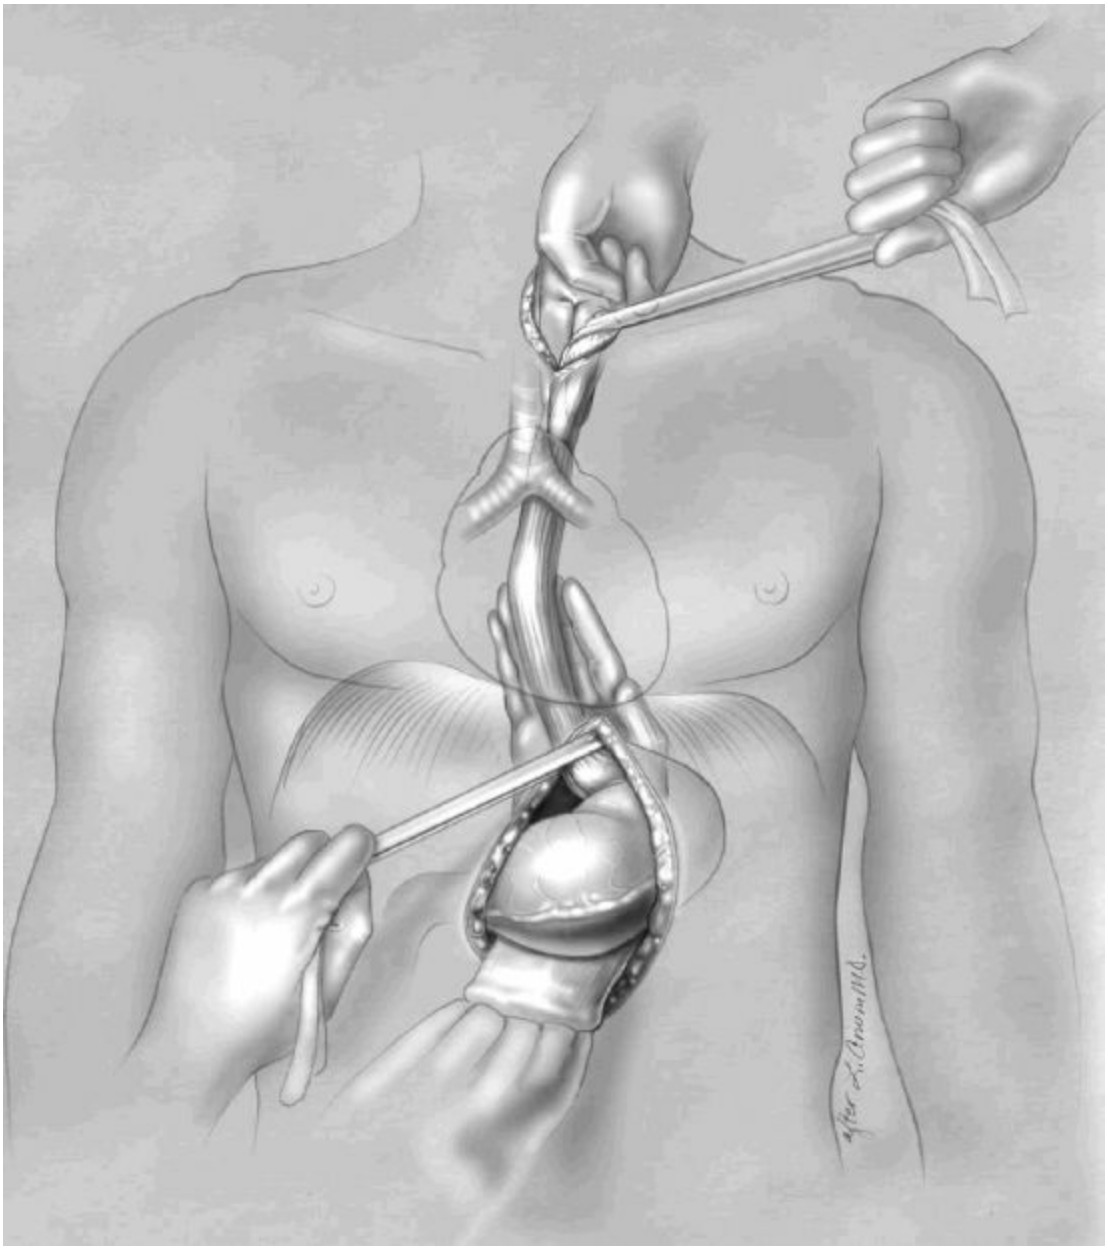

Figure 78.7. As the esophagus is elevated, blunt dissection from the superior mediastinum is carried out while keeping the volar aspects of the fingers closely applied to the esophagus. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

After completion of the posterior dissection of the esophagus, the anterior dissection is begun. As the rubber drain encircling the esophagogastric junction is retracted inferiorly, the surgeon's hand is inserted palm downward against the anterior surface of the esophagus and is slowly advanced upward into the mediastinum (Fig. 78.9). Similarly, the rubber drain encircling the cervical esophagus is retracted superiorly and

toward the patient's left shoulder as two fingers are inserted along the anterior wall of the esophagus and advanced downward into the superior mediastinum toward the fingers being advanced upward from below. Care is needed to avoid injury to the pericardium as the fingers inserted through the hiatus are advanced upward into the posterior mediastinum, or a tear of the posterior membranous trachea as the fingers inserted through the cervical incision sweep the esophagus away from the trachea anterior to it (Fig. 78.10).

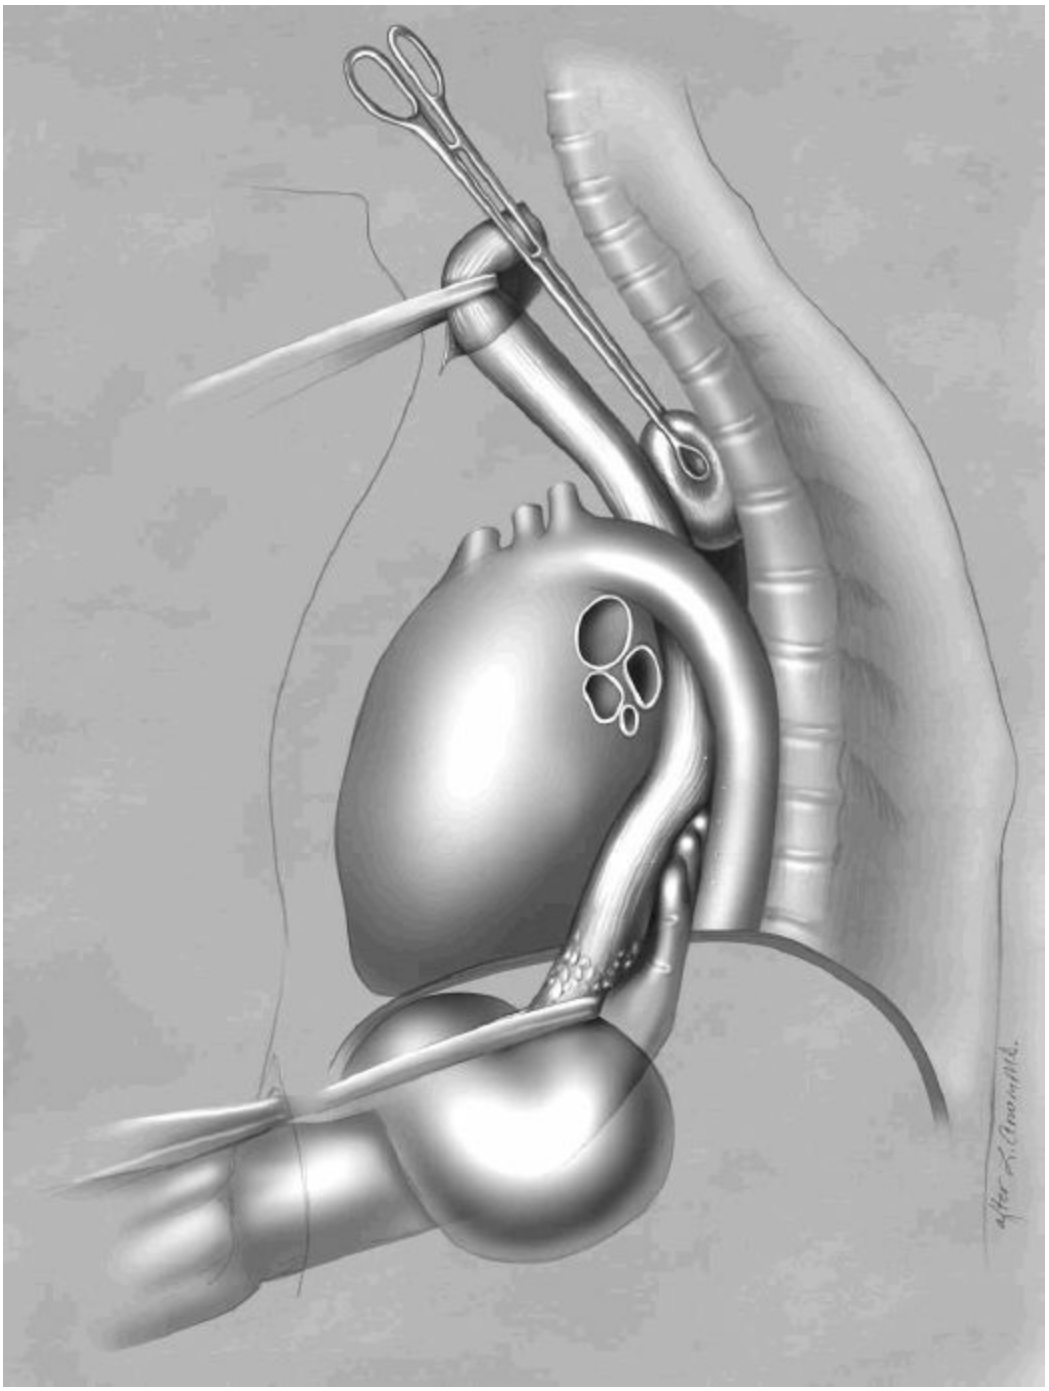

Figure 78.8. A “half-sponge on a stick” is inserted through the cervical incision behind the esophagus and is advanced downward through the superior mediastinum along the prevertebral fascia. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

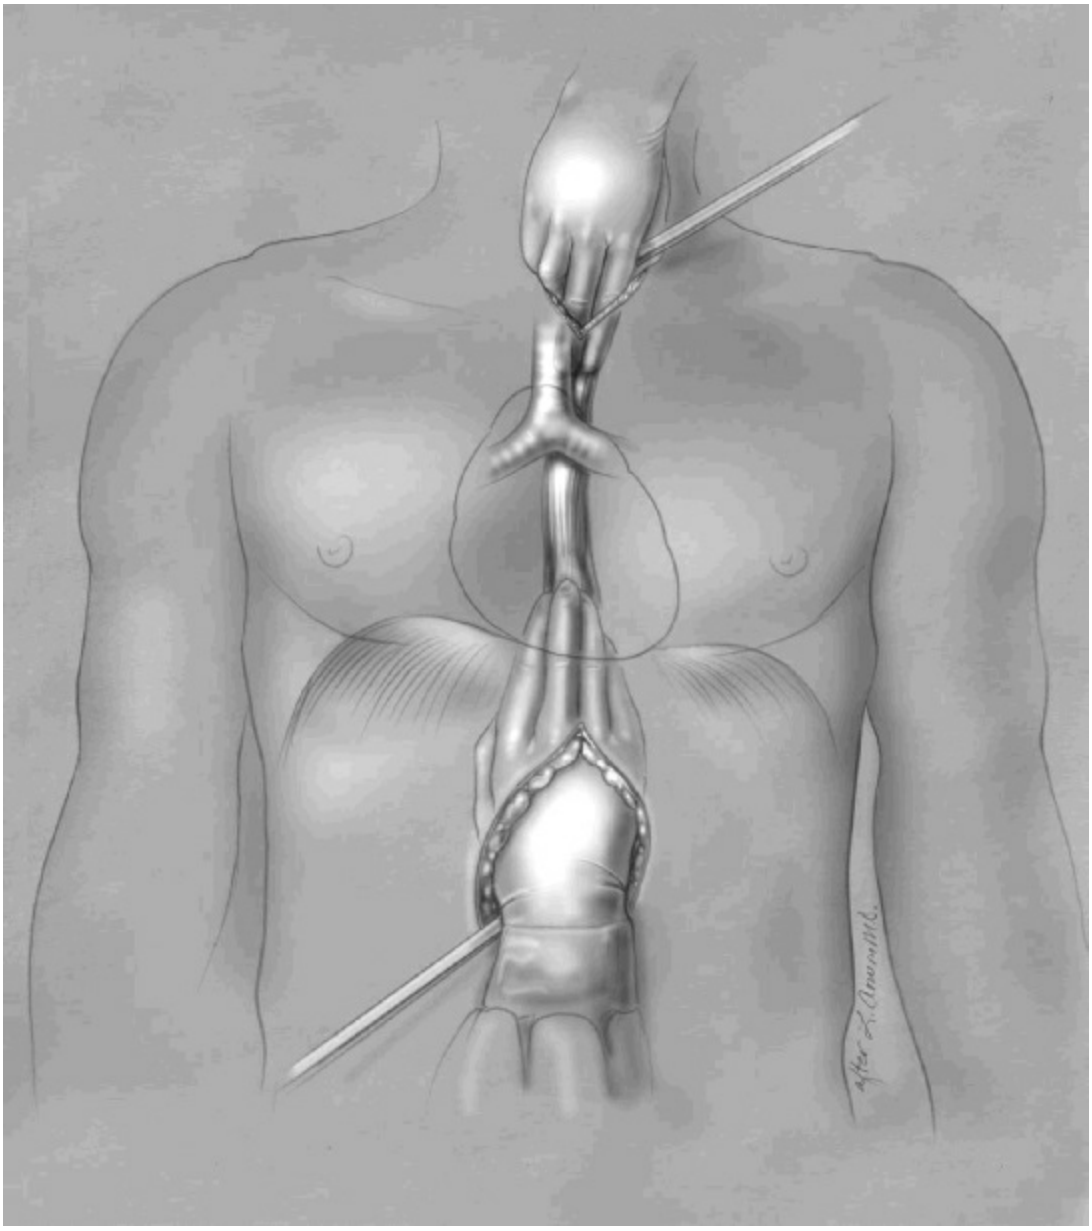

Figure 78.9. As the rubber drain encircling the esophagogastric junction is retracted inferiorly, the surgeon’s hand is inserted palm downward against the anterior surface of the esophagus and is slowly advanced upward into the mediastinum. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

After completion of both the anterior and posterior esophageal dissections, the cervical esophagus is elevated farther out of the superior mediastinum by the surgeon's left index finger "hooked" around it, as lateral esophageal attachments are progressively swept away from the esophagus by the index finger of the right hand, which is progressively advanced downward into the superior mediastinum. This results in complete circumferential mobilization of a 5- to 8-cm length of the upper thoracic esophagus (Fig. 78.11).

One hand is now inserted through the diaphragmatic hiatus and is advanced along the anterior esophageal wall toward the mobilized upper thoracic esophagus (Fig. 78.12). The upper thoracic esophagus is "trapped" against the prevertebral fascia between the index and middle fingers, and with a downward raking motion of the hand, filmy periesophageal attachments and fine vagal branches are avulsed (Fig. 78.13). Larger and more firm vagal nerve branches are encountered below the level of the pulmonary hila, and these are either fractured by firm compression between the thumb and the index finger or delivered downward toward the diaphragmatic hiatus where they can be visualized, elevated with long right-angled clamps, and divided (Fig. 78.13, inset).

After mobilization of the entire intrathoracic esophagus has been completed, 2 to 3 in of the esophagus is elevated out of the mediastinum and into the cervical wound. The previously placed nasogastric tube is pulled back until it is above the level of the upper esophageal sphincter, and using a GIA surgical stapler, the esophagus is divided obliquely from front to back (not transversely), leaving the anterior tip slightly longer than the posterior (Fig. 78.14). Unless the existing esophageal pathology precludes it (e.g., long segment Barrett mucosa with the squamocolumnar junction in the midesophagus, midesophageal carcinoma, etc.), the cervical esophagus divided intentionally 3 to 4 cm longer than is estimated will be required for construction of the anastomosis. If for any reason there is difficulty getting the gastric fundus to reach to the neck, the "extra" esophageal length may prove to be extremely valuable in performing the anastomosis without tension. If the esophagectomy is being performed for benign disease of the distal esophagus, the upper esophagus is divided in the neck at approximately the junction of the upper and middle thirds. If the cephalad reach of the gastric fundus into the neck wound is not adequate, a partial upper sternotomy can be carried out, and the additional length of upper esophagus used for construction of the anastomosis within

the thoracic inlet.

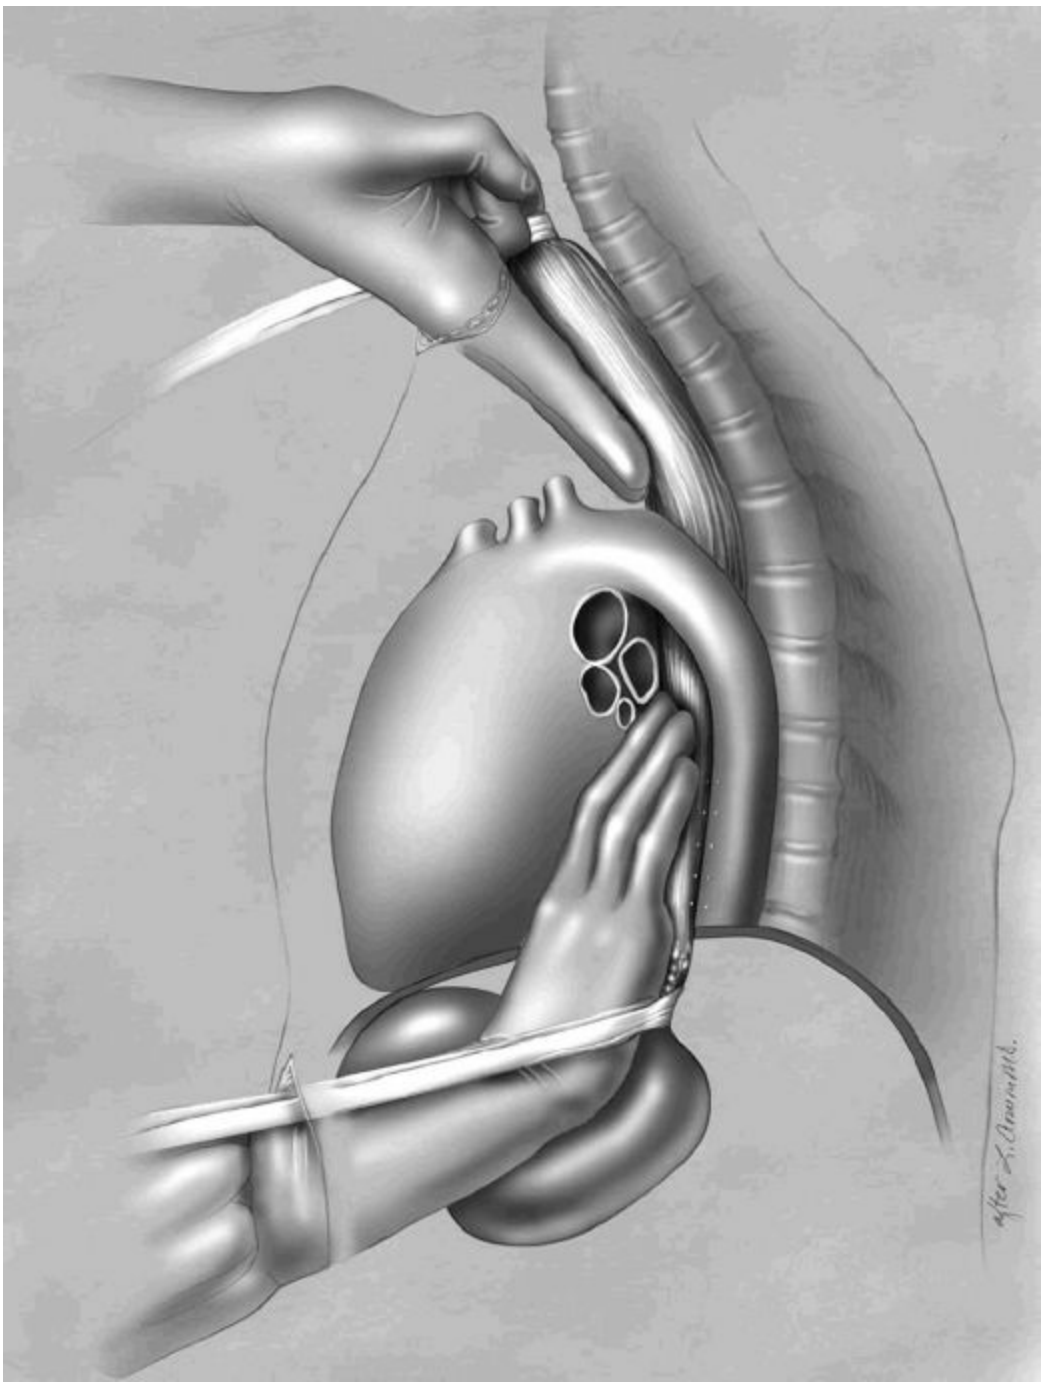

Figure 78.10. The fingers inserted through the hiatus are advanced upward into the posterior mediastinum, and the fingers inserted through the cervical incision sweep the esophagus away from the trachea anterior to it. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

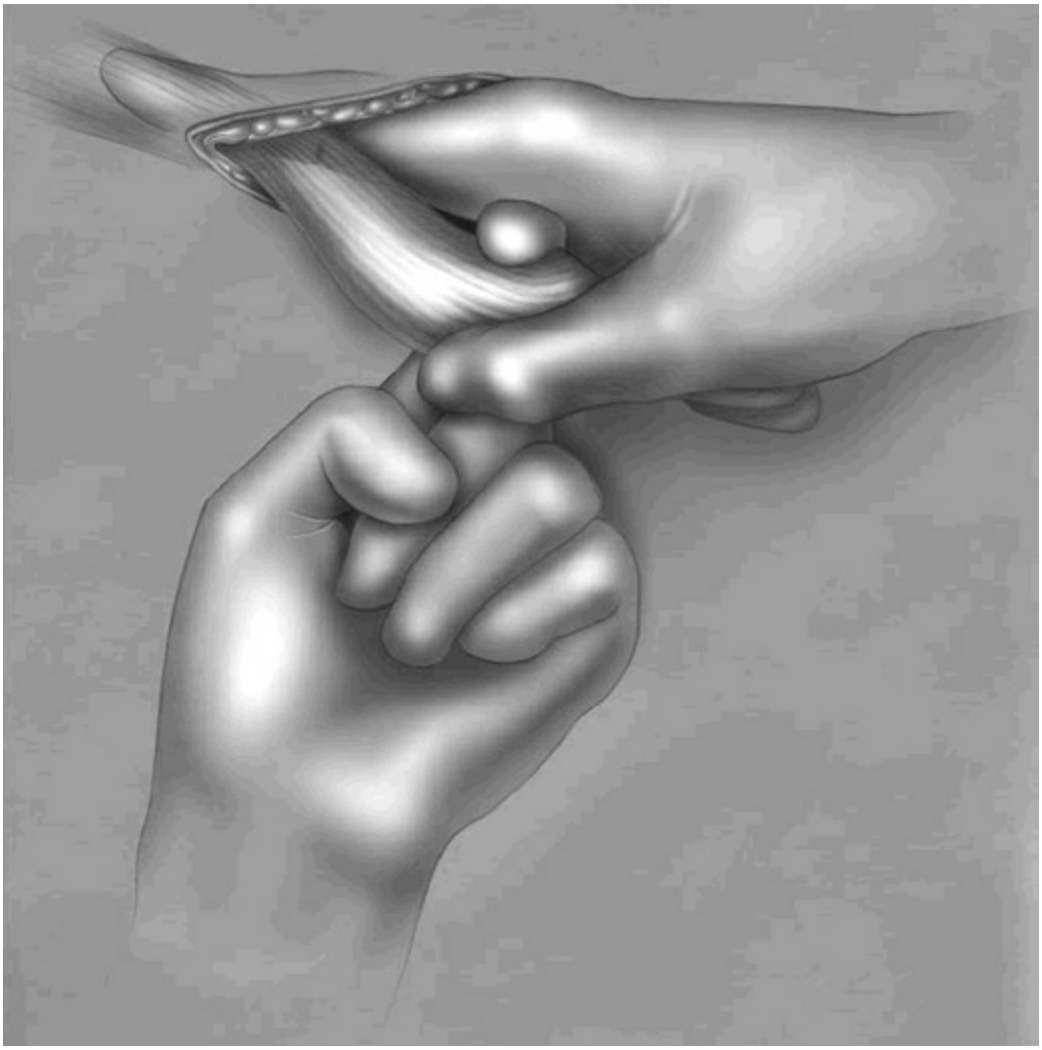

Figure 78.11. The cervical esophagus is elevated farther out of the superior mediastinum by the surgeon's left index finger "hooked" around it, as lateral esophageal attachments are progressively swept away from the esophagus by the index finger of the right hand, which is gradually advanced downward into the superior mediastinum. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

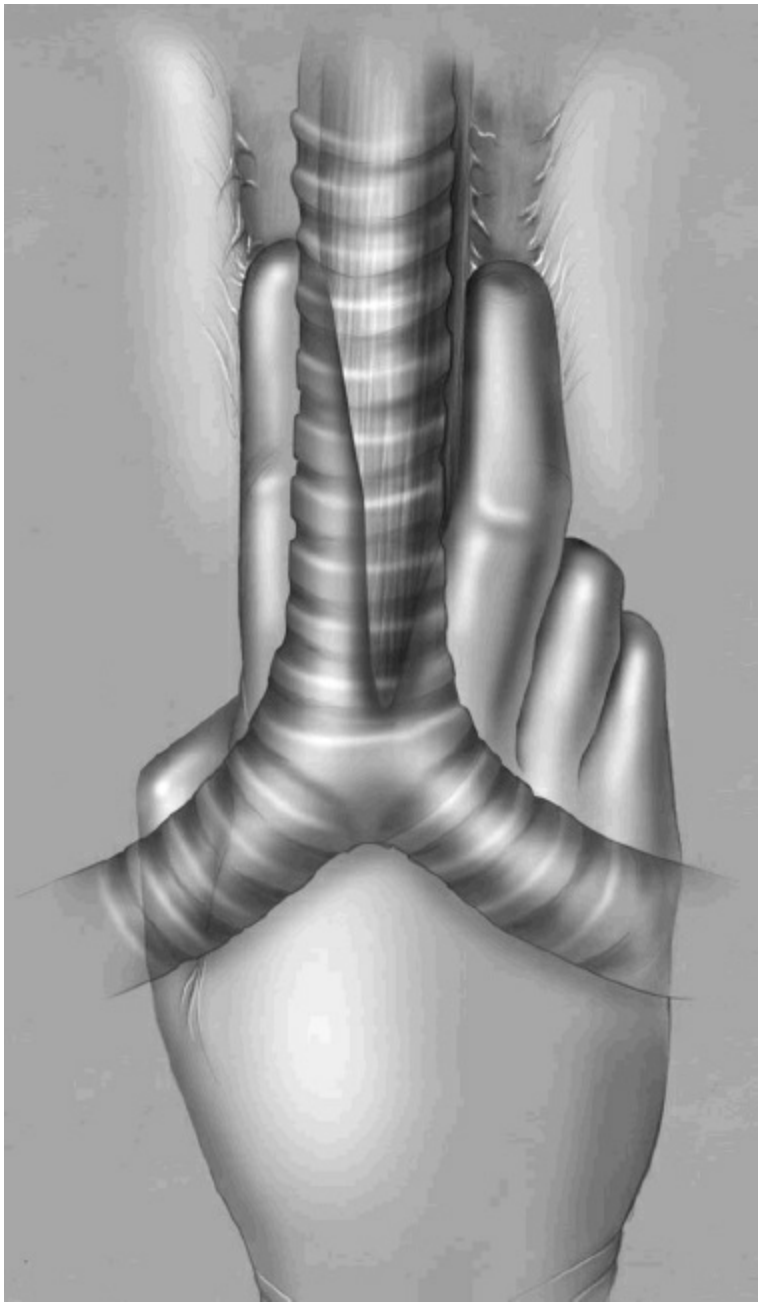

Figure 78.12. One hand is now inserted palm downward through the diaphragmatic hiatus and is advanced along the anterior esophageal wall toward the mobilized upper thoracic esophagus. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

After division of the esophagus in the cervical wound, the stomach is grasped within the abdomen and delivered out of the abdominal wound as the attached thoracic esophagus is brought downward from the posterior mediastinum. With the entire thoracic esophagus now freely in the field, time should not be spent examining the esophageal pathology. Rather, a 28

French Argyll Saratoga sump catheter should be inserted through the cervical incision and into the posterior mediastinum to evacuate blood, as a long narrow Deaver retractor placed into the diaphragmatic hiatus facilitates inspection of the posterior mediastinum for (1) untoward bleeding and (2) entry into either chest as indicated by violation of the mediastinal pleura and visibility of the lung. If either pleural cavity has been entered, a 28 French chest tube is placed below the inframammary crease in the appropriate anterior axillary line, advanced to the apex of the chest, secured to the skin, and connected to underwater seal drainage. When a chest tube is needed, the blades of the upper hand retractor should be temporarily removed during chest tube insertion, as the entry site of the chest tube is distorted by the retraction.

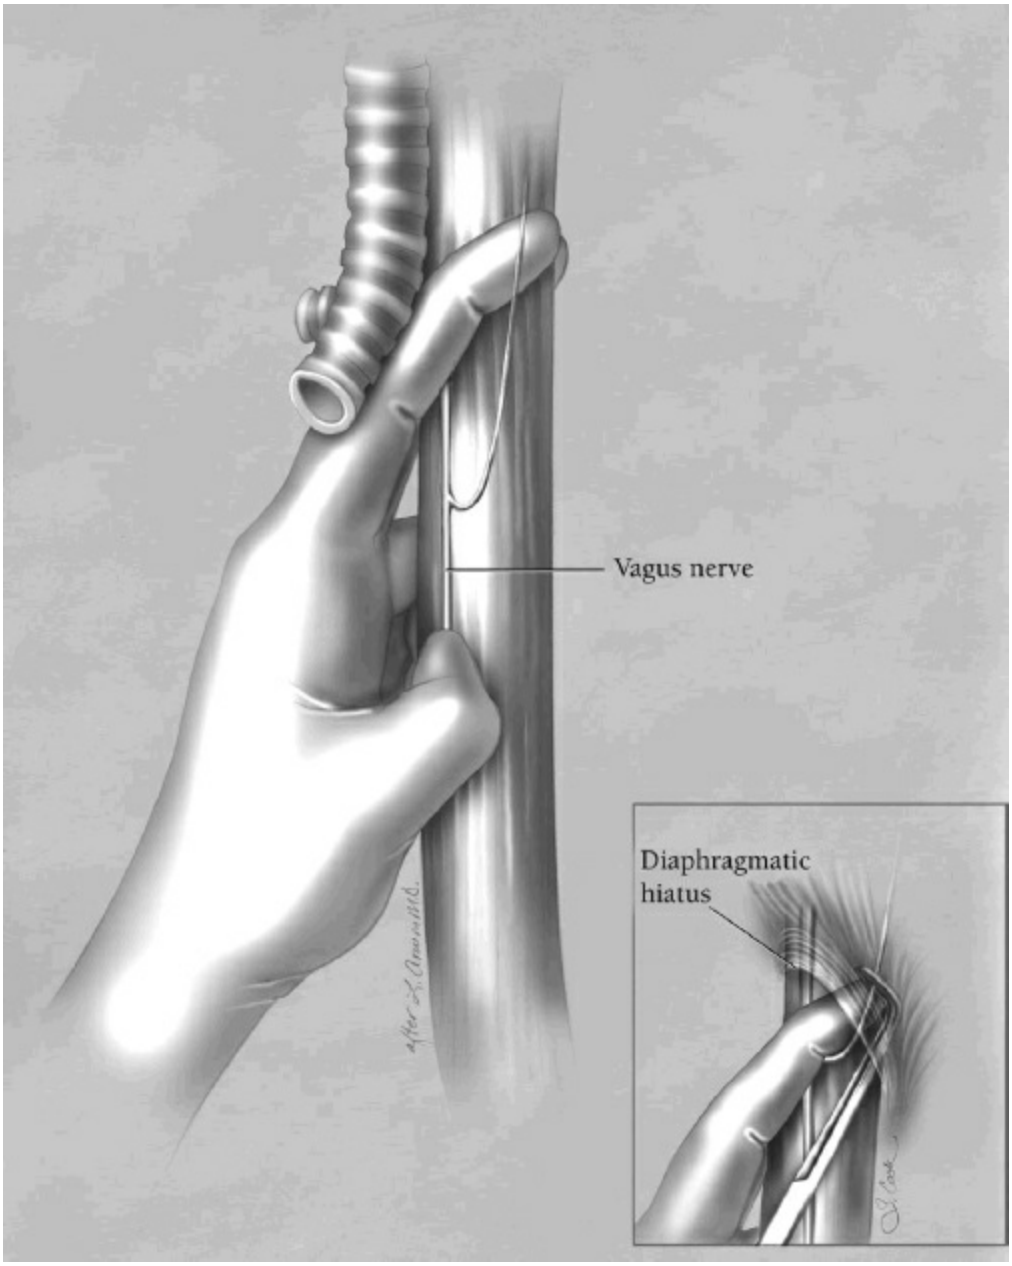

Figure 78.13. The upper thoracic esophagus is “trapped” against the prevertebral fascia between the index and middle fingers, and with a downward raking motion of the hand, filmy periesophageal attachments and fine vagal branches are avulsed. Larger and more firm vagal nerve branches are encountered below the level of the pulmonary hila, and these are either fractured by firm compression between the thumb and the index finger or delivered downward toward the diaphragmatic hiatus where they can be visualized, clamped with long right-angled clamps, and divided (*inset*). (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

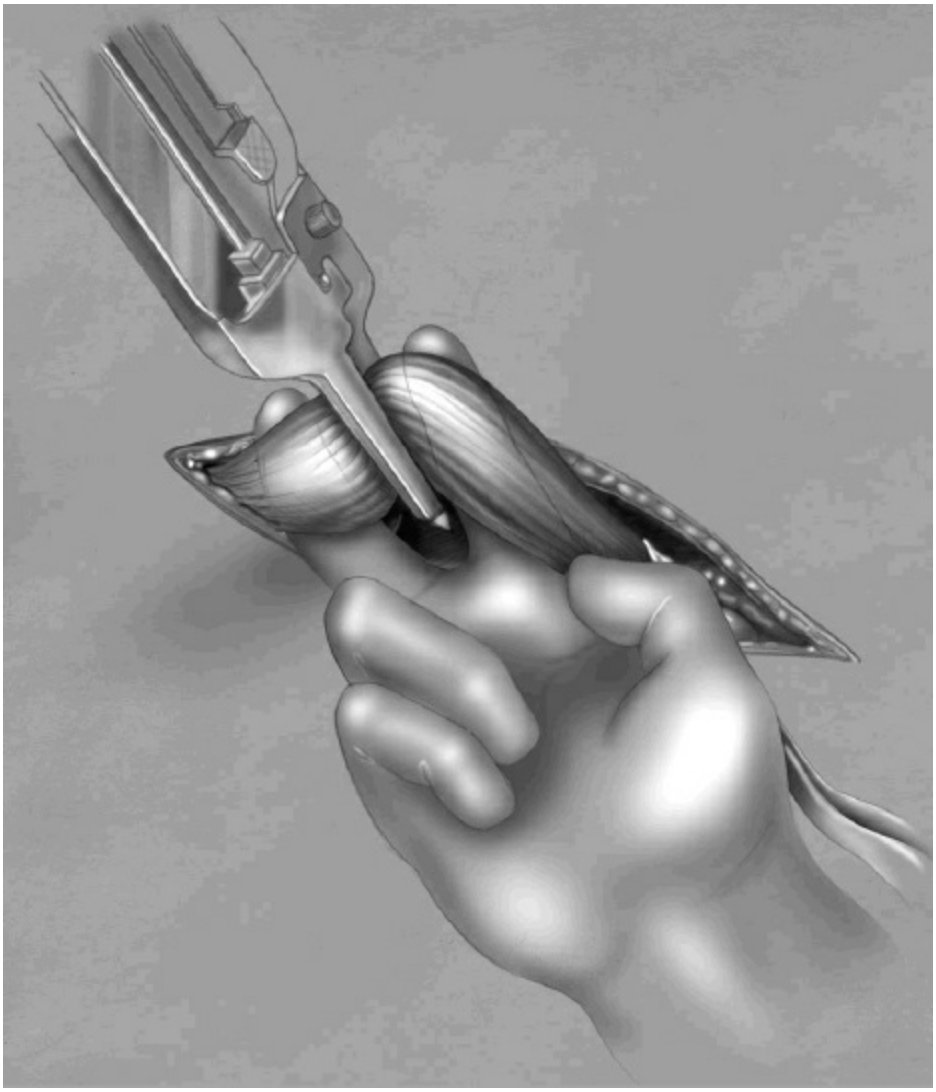

Figure 78.14. The previously placed nasogastric tube is pulled back until it is above the level of the upper esophageal sphincter, and using a GIA surgical stapler, the esophagus is divided obliquely from front to back (not transversely), leaving the anterior tip slightly longer than the posterior. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

After delivering the esophagus out of the posterior mediastinum, the liver blade of the upper hand retractor is removed and replaced with a standard body wall blade, since the liver blade pulls the lesser curvature of the stomach toward the liver and right upper quadrant and impedes maximum upward reach of the stomach through the posterior mediastinum and into the neck. Once it is confirmed that there is no significant mediastinal bleeding and assessing the need for a chest tube(s), the posterior mediastinum is packed with a large abdominal pack inserted

through the diaphragmatic hiatus, and two narrow “thoracic packs” inserted downward into the superior mediastinum through the neck wound. As the superior mediastinum is being packed, one finger is placed against the tracheoesophageal groove to ensure that there is no contact between the packing forceps and the recurrent laryngeal nerve.

After packing the posterior mediastinum to encourage hemostasis, attention is redirected to the stomach and attached esophagus, which are now placed on the anterior chest wall. The highest point along the greater curvature of the stomach that will reach toward the neck is gently grasped with a moist gauze pack by the thumb and index finger and drawn upward toward the neck. A site along the lesser curvature of the stomach at approximately the level of the second vascular arcade (“crow’s foot”) is identified and cleaned of overlying fat and blood vessels between right-angled clamps and ties. The upper stomach is then progressively divided approximately 4 to 6 cm distal to the esophagogastric junction with approximately three applications of the GIA 60–3.5 stapler, starting at the area of the “cleaned” lesser curvature and proceeding toward the greater curvature (Fig. 78.15). With each successive application and firing of the stapler, the stomach is progressively straightened. “Tubularization” of the stomach is minimized as much as possible to ensure preservation of the maximum amount of gastric submucosal collateral circulation. The esophagus and attached portion of proximal stomach are removed from the field and inspected on the back table to ensure adequate proximal and distal margins beyond tumor, Barrett mucosa, or other esophageal pathology.

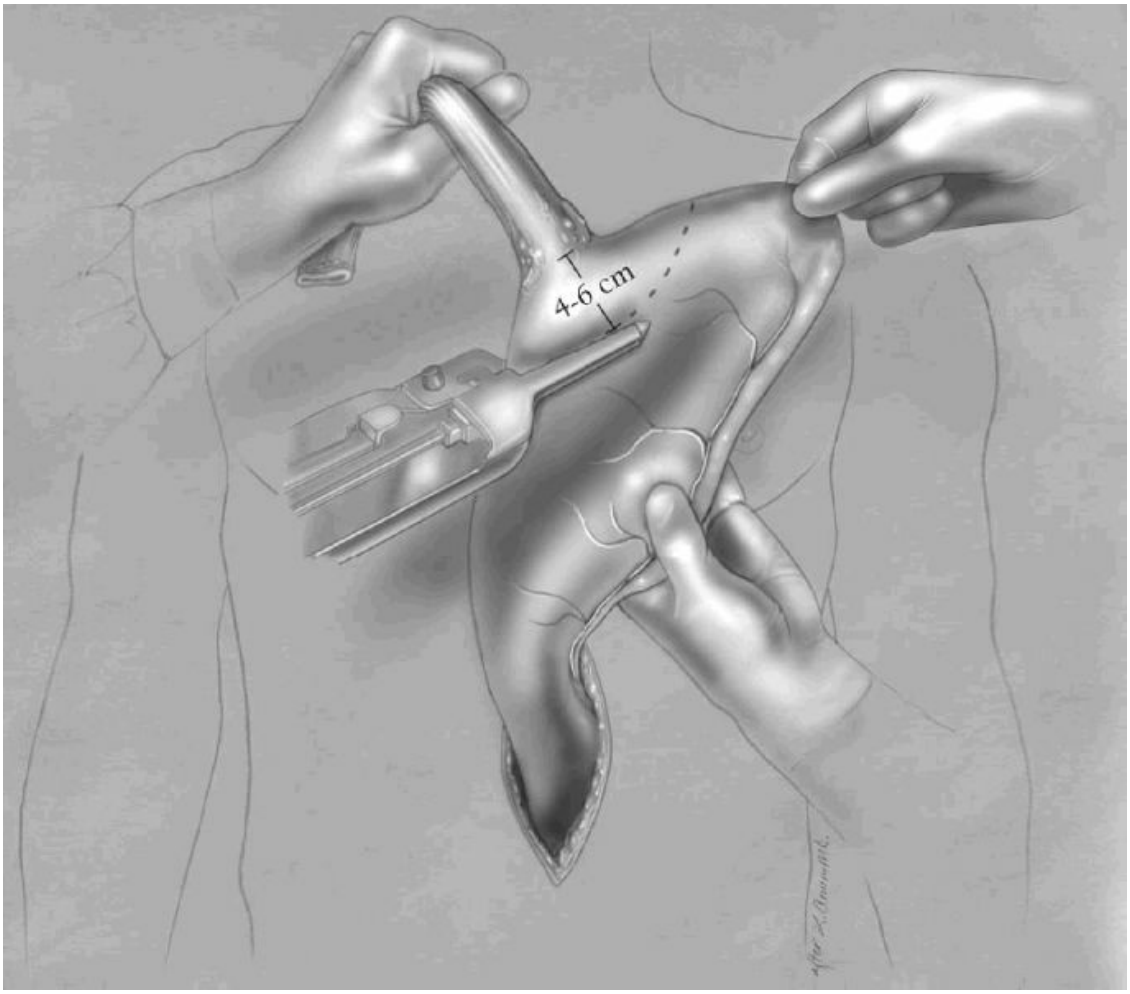

Figure 78.15. The upper stomach is progressively divided approximately 4 to 6 cm distal to the esophagogastric junction with three or four applications of the GIA 60–3.5 stapler applied from the lesser curvature toward the fundus. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

The gastric staple suture line is oversewn with a running 4-0 absorbable polyglycolic acid stitch, which is interrupted at its midpoint to minimize the chance that the stitch will break as the stomach is drawn into the neck. The mobilized stomach placed upon the anterior chest typically reaches above the level of the supersternal notch. The gastric staple line is toward the patient's right side, and the preserved right gastroepiploic vascular arcade is toward the patient's left (Fig. 78.16).

The previously placed abdominal and thoracic gauze packs are removed from the posterior mediastinum, which is again inspected for bleeding. Transposition of the stomach through the posterior mediastinum is now carried out. Over the years, the importance of minimizing trauma to the

stomach prior to transposing it through the posterior mediastinum and into the neck wound has become one of the most important principles of the operation. No traction sutures are placed into the stomach nor suction devices used to pull it upward. With a narrow Deaver retractor placed into the hiatus and elevated, the left upper quadrant abdominal contents are retracted to the left, and the left lobe of the liver retracted to the right. The hand and forearm are inserted upward through the diaphragmatic hiatus along the prevertebral fascia until two or three fingers emerge from the neck incision, thereby ensuring that there is an adequate posterior mediastinal tunnel unimpeded by residual undivided fibrous or vagal bands. The stomach is then gently pushed through the diaphragmatic hiatus along the prevertebral fascia and advanced upward beneath the aortic arch until the tip of the gastric fundus can be palpated through the neck incision. A Babcock clamp inserted downward into the superior mediastinum through the cervical incision is used to gently grasp the stomach (Fig. 78.17). The clamp is not ratcheted closed in order to minimize trauma to the stomach. The hand alongside the stomach within the posterior mediastinum is gradually withdrawn and the stomach gently pushed upward from below as the Babcock clamp is used to guide the gastric tip into the cervical wound. Approximately 4 to 5 cm of gastric length above the level of the clavicles is achieved by pushing the stomach upward through the posterior mediastinum than by pulling it upward through the neck incision (Fig. 78.17, inset).

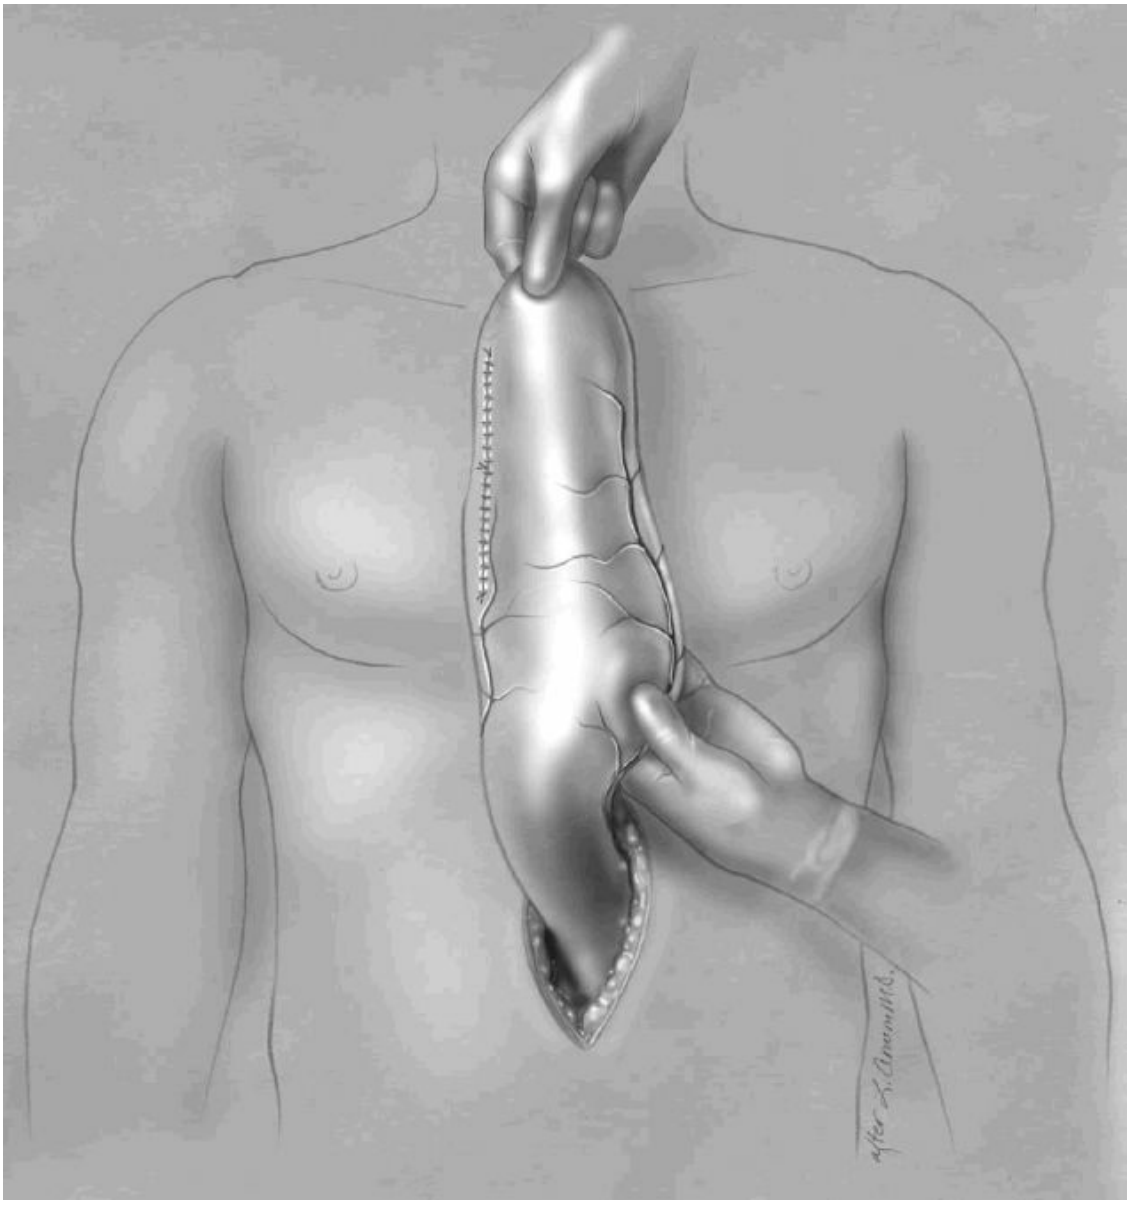

Figure 78.16. The mobilized stomach placed upon the anterior chest typically reaches above the level of the suprasternal notch. The gastric staple suture line is toward the patient's right side. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

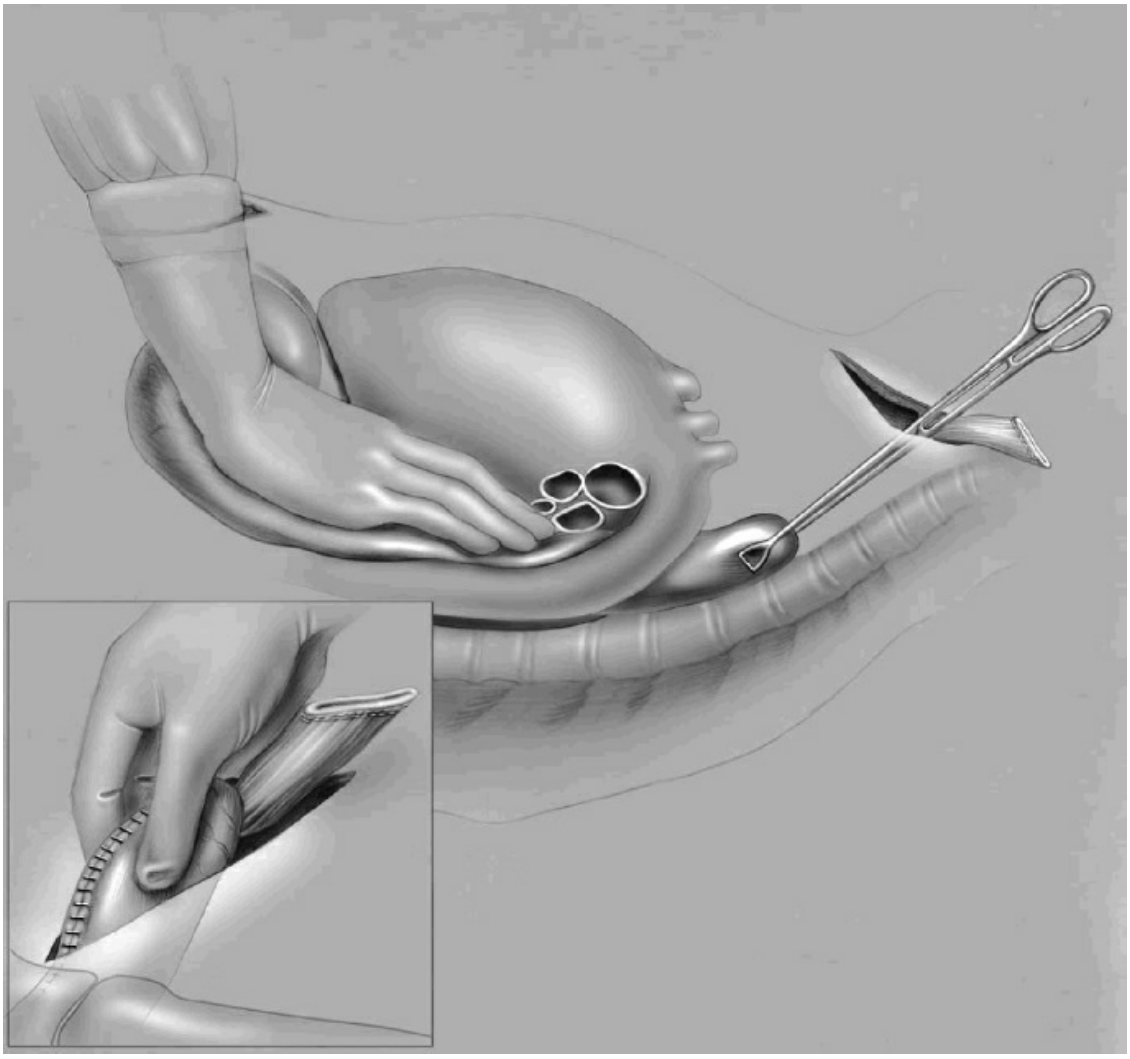

Figure 78.17. A Babcock clamp inserted downward into the superior mediastinum through the cervical incision is used to gently grasp the stomach. An approximately 4 to 5 cm length of stomach above the level of the clavicles is achieved by pushing the stomach upward through the posterior mediastinum rather than by pulling it upward through the neck incision (*inset*). (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

Once sufficient stomach has been delivered into the neck incision, it is important to verify that an inadvertent twist of the stomach has not occurred while it was positioned in the chest. While gently holding the tip of the gastric fundus in the cervical wound, the anterior surface of the stomach is simultaneously palpated through the diaphragmatic hiatus and the neck incision to be certain that it is smooth and untwisted and that the gastric staple line is toward the patient's right side. "Suspension sutures"

between the gastric fundus and the prevertebral fascia in the neck are avoided to prevent unnecessary trauma to the vulnerable gastric tip. In addition, suturing the stomach to the prevertebral fascia may at times inoculate the intervertebral disc space, resulting in an epidural abscess. When the stomach has been properly mobilized and positioned in the posterior mediastinum and neck, the tip of the stomach visible in the cervical wound will be pink, healthy, and viable. Retraction of the stomach back downward into the posterior mediastinum seldom occurs unless undue traction is placed on it through the abdominal wound. A hemostat placed on the stump of a ligated high short gastric vessel allows easy assessment during completion of the abdominal portion of the procedure that the tip of the stomach is still situated in the cervical wound, which is covered with a saline-moistened guaze.

It has been the author's practice to isolate the abdominal incision from the cervical wound before opening the esophagus for the anastomosis in order to avoid contamination of the abdominal wound by intraoral contents. Therefore, the abdominal phase of the operation is completed entirely before beginning construction of the anastomosis. Prior to abdominal wound closure, the diaphragmatic hiatus is inspected. Typically, after the hand and forearm have been inserted into the posterior mediastinum during the esophageal mobilization, the hiatus has been stretched and occasionally the left crus partially torn, requiring hemostasis with electrocautery. To prevent subsequent herniation of intestine into the posterior mediastinum alongside the intrathoracic stomach, the hiatus is narrowed with one or two no. 1 silk sutures until it loosely accommodates three fingers placed alongside the stomach. To further discourage late migration of intestine through the hiatus, the edge of the diaphragmatic hiatus is sutured to the anterior gastric wall with one or two interrupted 3-0 silk sutures, the left lobe of the liver is returned to its normal position, and the previously divided triangular ligament of the liver is sutured back to the edge of diaphragmatic hiatus with an interrupted 3-0 silk suture. Typically, after a gastric "pull-up," the pyloromyotomy comes to rest 3 to 4 cm below the level of the diaphragmatic hiatus and beneath the left lobe of the liver. The feeding jejunostomy tube is brought out through a small left upper quadrant abdominal wall stab wound. The jejunostomy tube site is sutured against the anterior abdominal wall with four interrupted 3-0 silk sutures. Each suture is marked with Hemoclip before cutting. The small "diamond" on abdominal imaging formed by the Hemoclips facilitates a

future percutaneous jejunostomy should a feeding tube ultimately be required again. The jejunostomy tube is then sutured to the skin to secure it in place. The color of the gastric tip visible in the cervical wound is periodically inspected to be certain that venous congestion has not occurred as a result of overzealous narrowing of the diaphragmatic hiatus. If necessary, a hiatal suture can be removed before beginning the abdominal wound closure. Once the incision is closed, it is covered with a sterile towel and then with a separate drape to completely isolate it from the cervical field and potential contamination by oral bacteria during subsequent construction of the CEGA.

Cervical Esophagogastric Anastomosis

As indicated previously, the properly mobilized stomach reaches 4 to 5 cm above the level of the clavicles. The lesser curvature gastric staple line is oriented toward the patient's right side (Fig. 78.18A). The anterior surface of the stomach at the level of the suprasternal notch is gently grasped with a Babcock clamp, rotated even more to the right to further displace the gastric staple line away from the subsequent anastomotic site, and elevated superiorly even further into the wound, and a 3-0 silk seromuscular traction suture is placed distal to the clamp (Fig. 78.18B). This suture is used to draw the anterior surface of the stomach to the level of the skin and is then secured to the drapes with a hemostat. During placement of this suture, the stapled divided end of the cervical esophagus is grasped with an Allis clamp, elevated, and retracted to the patient's right to facilitate exposure (Fig. 78.18B).

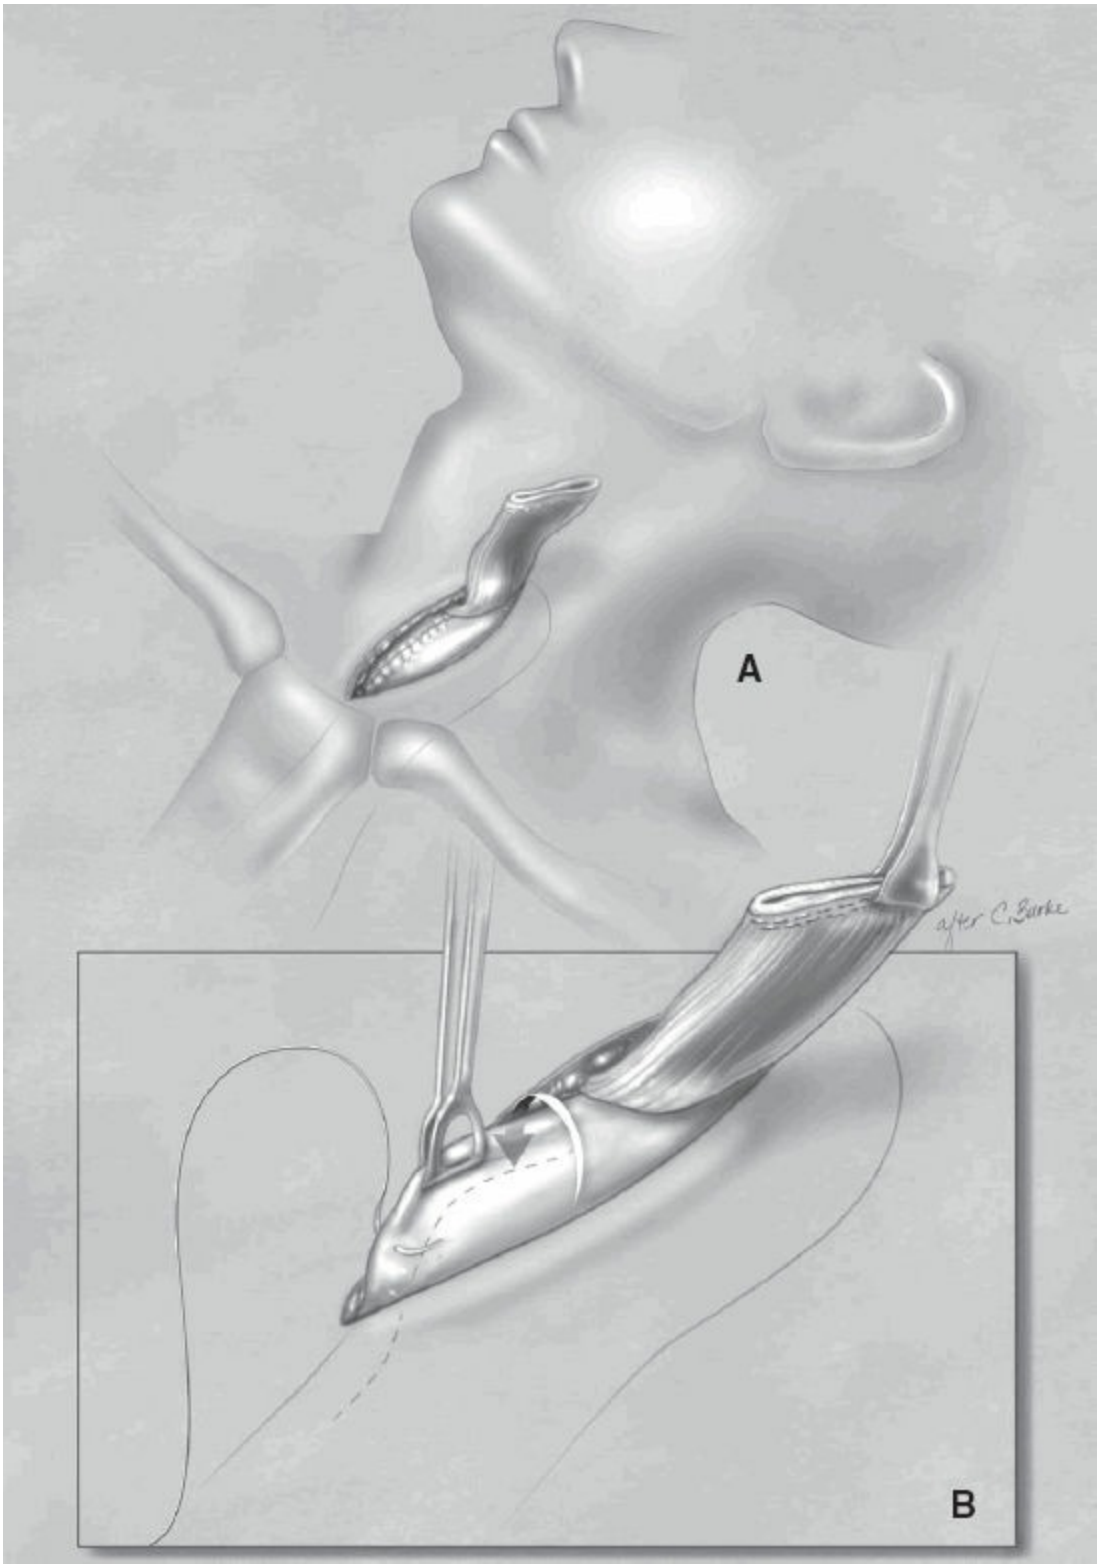

Figure 78.18. **A.** The lesser curvature gastric staple line is oriented toward the patient's right side. **B.** The anterior surface of the stomach at the level of the suprasternal notch is gently grasped with a Babcock clamp, rotated even more to the right to further displace the gastric staple line away from the subsequent anastomotic site, and elevated superiorly even farther into the

wound, and a 3-0 silk seromuscular traction suture is placed distal to the clamp. The anterior gastric wall is elevated by tension on the traction stitch, which is secured to the drapes with a hemostat. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

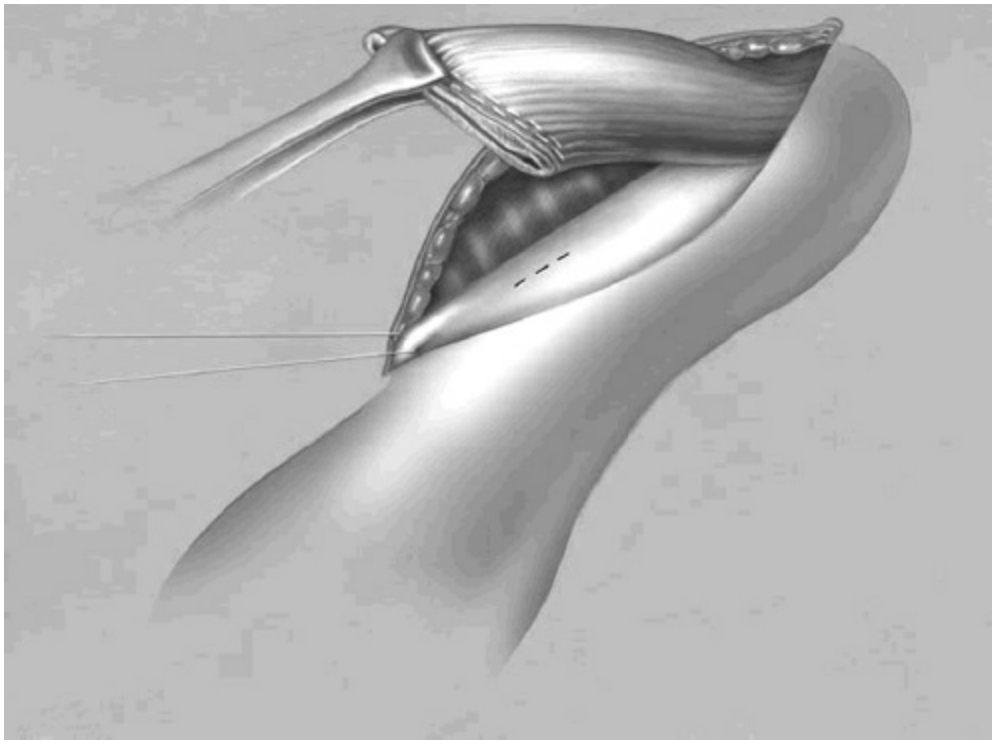

Figure 78.19. The divided end of the esophagus is approximated against the anterior gastric wall, a site for the anastomosis is selected (*dotted line*), and a 1.5- to 2-cm vertical gastrotomy is performed using the cutting current of electrocautery.

The divided end of the esophagus is approximated against the anterior gastric wall, a site for the anastomosis is selected, and a 1.5- to 2-cm vertical gastrotomy is performed using the cutting current of electrocautery (Fig. 78.19). The vertical gastrotomy must be placed low enough from the most superior aspect of the gastric tip to allow subsequent insertion of a 3-cm-long staple cartridge. In addition, there must be sufficient remaining cervical esophageal length so that once the anterior gastric wall traction suture is removed and the stomach drops somewhat downward into the thoracic inlet, there will not be undue tension on the anastomosis. The stapled esophageal suture line is grasped with two Allis clamps, the cervical esophagus held obliquely with a DeBakey forceps, and the staple suture line amputated sharply distal to the forceps, which serves as a guide

for the transection (Fig. 78.20). In patients with carcinoma, the amputated tip of the esophagus is submitted to the pathology department as the "proximal esophageal margin of resection."

Two key stay sutures are now placed to align the esophagus and the stomach. The first suture is a full-thickness 4-0 stitch through the anterior tip of the divided esophagus. The second is a 4-0 stitch that passes into the stomach and emerges approximately 6 to 7 mm from the upper corner of the vertical gastrotomy, then through the posterior corner of the divided cervical esophagus, entering the wall 6 to 7 mm from the end and emerging through the mucosa 2 to 3 mm from its end (Fig. 78.21). Downward traction on these two sutures aligns the back wall of the cervical esophagus with the front wall of the stomach while an Endo-GIA universal articulating 30-3.5 staple cartridge (Covidien) is inserted simultaneously into the esophagus and the stomach. The thinner anvil portion of the cartridge goes into the stomach and the thicker staple-bearing portion of the cartridge goes into the esophagus (Fig. 78.22). The cartridge is gently rotated until its tip is pointed toward the patient's right ear, continually aligning the esophagus with the anterior wall of the stomach (Fig. 78.22A,B), maintaining downward traction on the stay sutures as the staple cartridge is advanced inward, and ensuring that the lesser curvature gastric staple suture line remains well rotated toward the patient's right side so that it does not intersect with the anastomotic staple line.

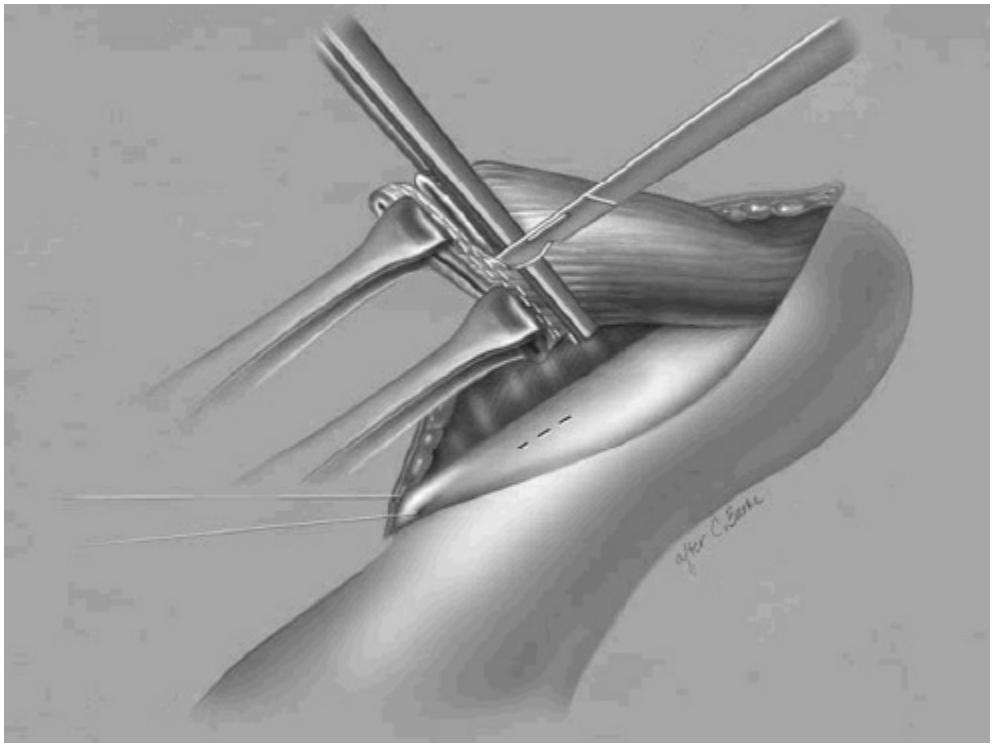

Figure 78.20. The stapled esophageal suture line is grasped with two Allis clamps, the cervical esophagus held obliquely with a DeBakey forceps, and the staple suture line amputated sharply distal to the forceps, which serves as a guide for the transection. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

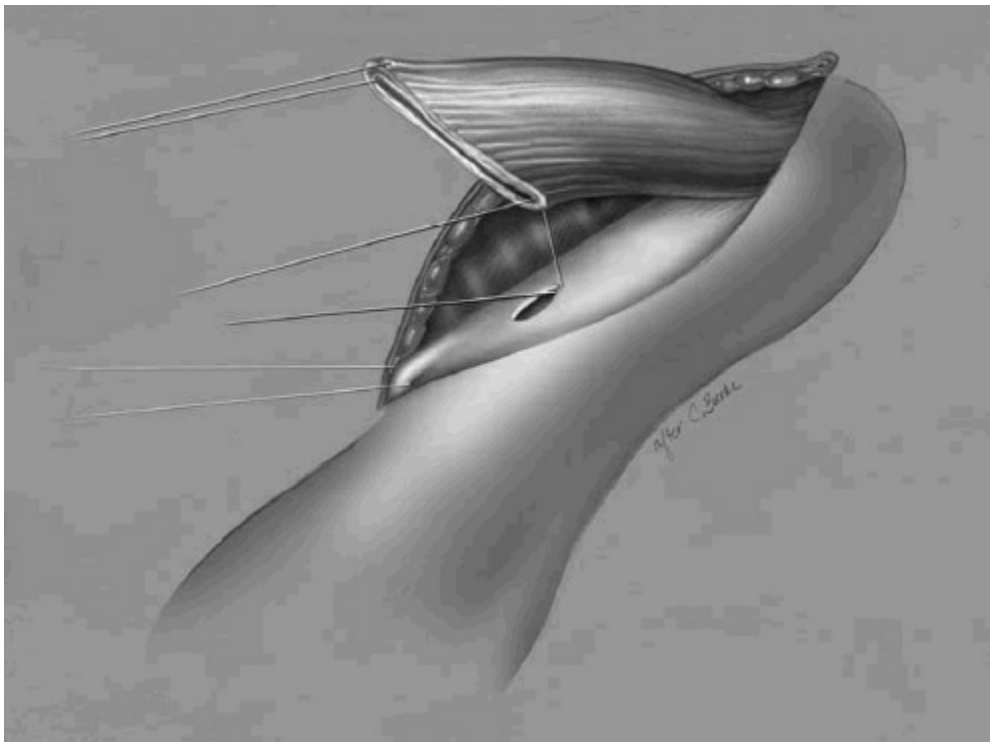

Figure 78.21. Two key stay sutures (4-0 polyglatin-Vicryl-Ethicon) are now placed to align the esophagus and the stomach. The first suture is a full-thickness stitch through the anterior corner of the divided esophagus. The second is a stitch that passes into the stomach and emerges approximately 6 to 7 mm from the upper corner of the vertical gastrotomy, then through the posterior corner of the divided cervical esophagus, entering the muscle 6 to 7 mm from the end and emerging through the mucosa 2 to 3 mm from its end. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

The staple cartridge is closed but not fired at this time. Two interrupted 4-0 absorbable polyglactin (Vicryl) sutures between the anterior gastric wall and adjacent esophagus are placed on either side of the stapler to serve as "suspension" sutures, which take tension off the anastomosis (Fig. 78.23). After placement of the suspension sutures, the stapler is fired, thereby approximating the posterior esophageal wall and the anterior gastric wall and dividing the now common wall between them. The staple cartridge is removed. A 4-0 absorbable polyglactin (Vicryl-Ethicon) traction suture is placed at either corner of the gastrotomy and opened esophagus (Fig. 78.24). A 16 French nasogastric tube is inserted by the anesthesiologist and advanced across the anastomosis and down into the intrathoracic stomach. Anterior closure of the esophagotomy and gastrotomy is achieved with a running, full-thickness 4-0 absorbable monofilament (PDS-Ethicon) suture on the inner layer (Fig. 78.25) followed by a layer of interrupted 4-0 absorbable monofilament (PDS-Ethicon) sutures on the outer layer (Fig. 78.26). A metallic Hemoclip is placed on either of the corner sutures before they are cut to assist with future radiographic localization of the anastomosis. The wound is irrigated with iodine solution. The anterior gastric wall traction suture is removed, and the stomach is gently pushed downward into the thoracic inlet. A ¼-in rubber drain is placed at the depths of the wound near the anastomosis and is secured to the inferior edge of the skin incision with a suture. The cervical wound is then closed with no more than five to six interrupted absorbable sutures in muscle fascia, and the skin edges are approximated with running 4-0 nylon. After dressing all incisions and tube sites and being certain that the nasogastric tube irrigates freely and is functioning properly, a portable chest radiograph is obtained in the operating room to verify that there is no unexpected hemo- or pneumothorax and that all

tubes are properly positioned.

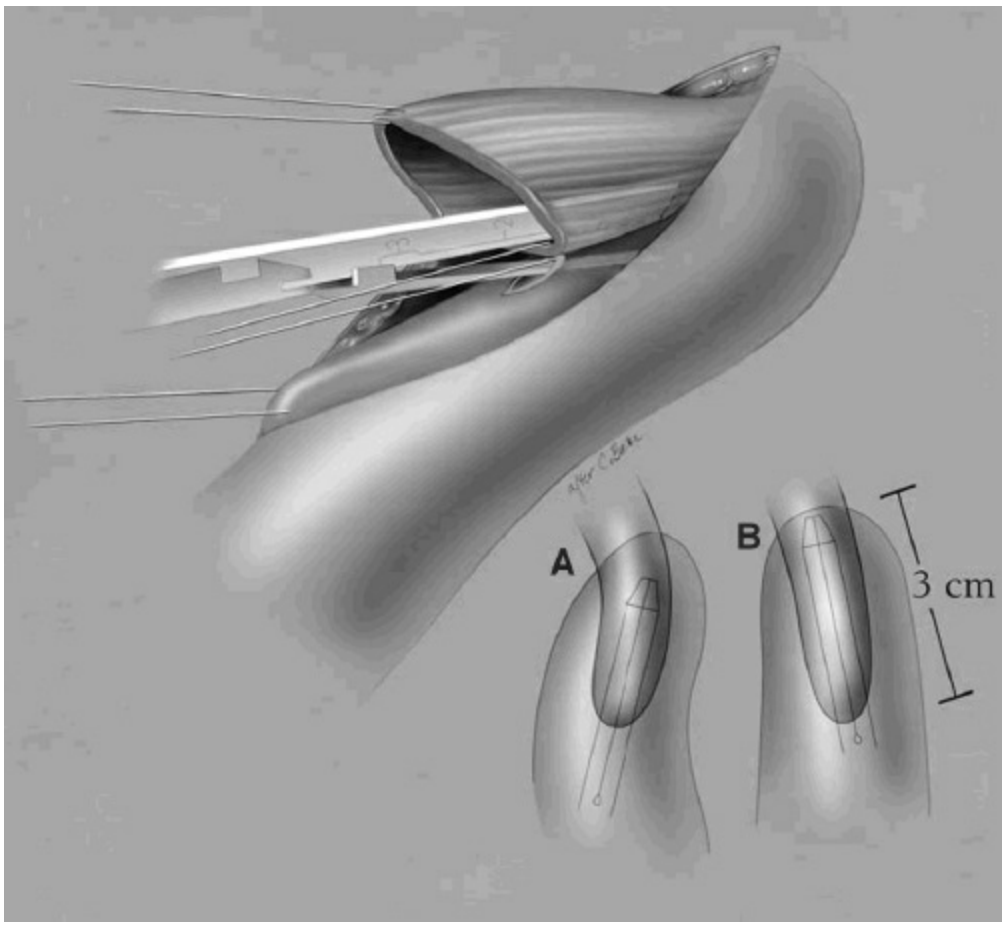

Figure 78.22. While maintaining downward traction on the two stay sutures, an Endo-GIA universal articulating 30-3.5 staple cartridge (Covidien) is inserted simultaneously into the esophagus and the stomach (**A,B**). The cartridge is gently rotated until its tip is pointed toward the patient's right ear, continually aligning the esophagus with the anterior wall of the stomach. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

POSTOPERATIVE CARE

Preoperative conditioning of the patient for a THE with mandatory smoking cessation for a minimum of 3 weeks, walking 3 miles a day, and using an incentive inspirometer issued at the time of the initial consultation is consistently rewarded by a smoother postoperative course. The patient is extubated in the operating room, recovered from anesthesia, and is then moved to a monitored hospital bed and not the intensive care unit. Initial upright posturing with the head elevated at 45 degrees to prevent

gastroesophageal reflux is standard, but fewer patients actually sustain this because postoperative nocturnal regurgitation after a side-to-side stapled CEGA is uncommon. Epidural anesthesia or intravenous patient-controlled anesthesia (PCA) for the first 4 to 5 postoperative days typically provides sufficient analgesia so that the incentive inspirometer can be used the afternoon and evening of the operation, and ambulation (walking in the hallways) can be started the morning of the 1st postoperative day. Hourly use of the incentive inspirometer (five deep breaths at the start of each hour) and walking at least four times a day continue throughout the hospitalization. Chest tubes are discontinued when there is no air leak and drainage is less than 60 cc per 2 consecutive 8-hour nursing shifts. The cervical wound drain is removed on the 3rd postoperative day. Ice chips (<30 cc per hour) for throat comfort are permitted the night of the operation. Suction is applied to the nasogastric tube for 24 hours, then dependent drainage for 24 hours, and if the drainage has been below 200 cc per shift for 2 shifts, the tube is removed. If having no nasogastric tube is well tolerated, a clear liquid diet is begun the next day along with low volume jejunostomy tube feedings. Diet is advanced to full liquids the next day and to a “mechanical soft” (“mushy”) diet the next. The latter is continued for the first several postoperative weeks, after which diet is then gradually liberalized. A postoperative barium swallow is obtained on day 7 prior to discharge to document: (1) no anastomotic leak, (2) satisfactory emptying of the intrathoracic stomach, and (3) unobstructed flow past the jejunostomy tube site. When dumping symptoms (postprandial cramping and diarrhea) occur, they are treated with smaller more frequent feedings and withholding liquids until after meals to minimize gastric distention, avoiding glucose loads, and avoiding milk and dairy products. At times, diphenoxylate may be needed. Patients are typically discharged taking only oral nourishment, and the jejunostomy tube is not routinely used. The tube is removed in follow-up clinic 3 to 4 weeks after discharge unless there is severe dysphagia requiring dilatations and enteral nourishment, or pending adjuvant chemoradiation that may warrant support with jejunostomy tube feedings.

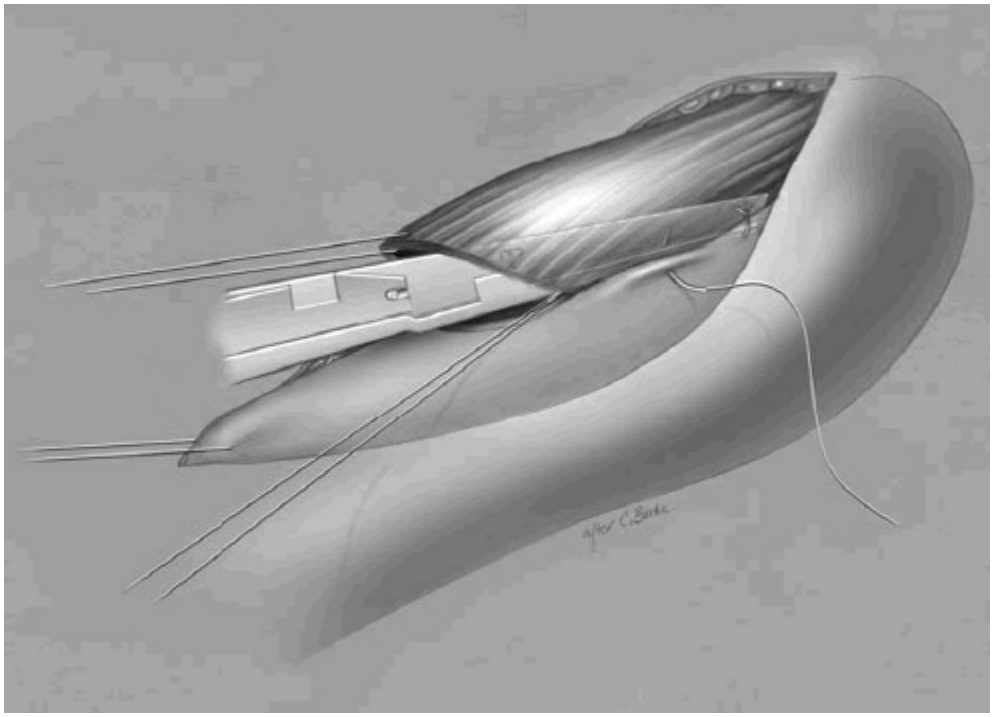

Figure 78.23. Two interrupted 4-0 absorbable polyglactin (Vicryl-Ethicon) sutures between the anterior gastric wall and adjacent esophagus are placed on either side of the stapler to serve as “suspension” sutures, which take tension off the anastomosis. traction suture is placed at either corner of the gastrotomy and opened esophagus. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

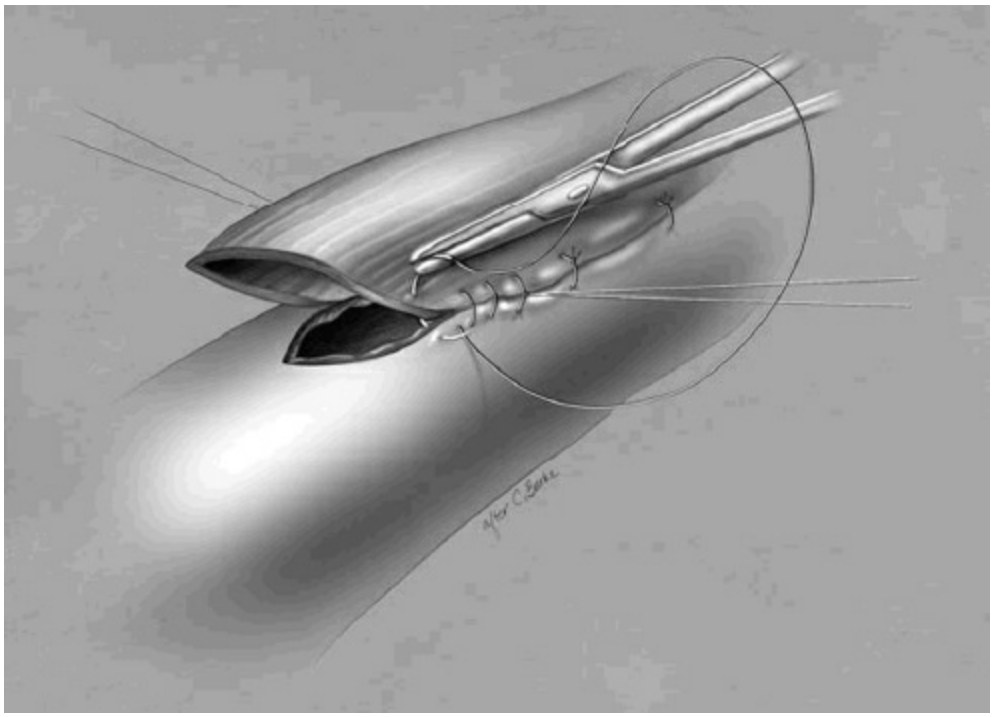

Figure 78.25. After a 16 French nasogastric tube inserted by the anesthesiologist is advanced down into the intrathoracic stomach, anterior closure of the esophagotomy and gastrotomy is achieved with a running, full-thickness 4-0 monofilament absorbable (PDS-Ethicon) suture on the inner layer. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

COMPLICATIONS AND THEIR MANAGEMENT

The complications of THE may be intraoperative, postoperative, or those occurring in long-term follow-up. *Intraoperatively*, entry into one or both pleural cavities in the process of mobilizing the esophagus occurs in nearly 75% of patients, is detected by inspection of both sides of the mediastinal pleura through the diaphragmatic hiatus after removal of the esophagus, and is treated by insertion of chest tubes. Splenic injury can occur in the process of dividing the highest short gastric vessels, usually responds to application of topical thromboplastin, and does not require a splenectomy. Entry into the pyloric or duodenal mucosa while performing the

pyloromyotomy is managed by closing the defect with interrupted 5-0 polypropylene and reinforcing the site with an adjacent omental fat pad flap. Two particular intraoperative disasters associated with THE bear emphasis: massive bleeding and a tracheal tear. Occurring in <1% of THEs, they are rarely discussed in review articles. Consequently, "walking through" the steps of controlling mediastinal hemorrhage or a tracheal tear during a THE—the indications for a thoracotomy and selecting the appropriate side—may be life-saving.

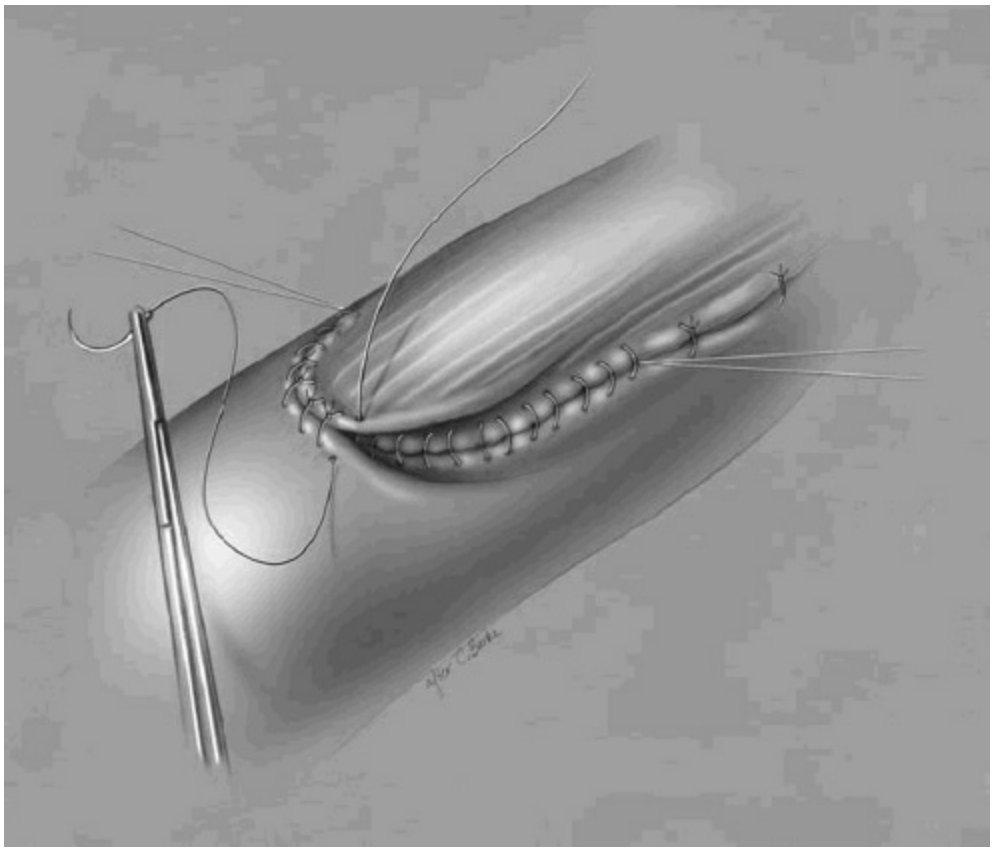

Figure 78.26. Interrupted inverting 4-0 monofilament absorbable (PDS-Ethicon) sutures are used on the outer layer to complete the anastomosis. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

Mediastinal Bleeding

The surgeon should be alerted to the potential for a bleeding complication in a patient a history of bleeding tendencies, a family history of clotting disorders, or the use of anticoagulants or platelet inhibitors. Prior esophageal surgery results in increased periesophageal mediastinal fibrosis, and this is particularly the case after an esophagomyotomy in

which the exposed submucosa has a tendency to adhere to the anterior wall of the adjacent aorta. Mediastinal calcifications due to granulomatous disease seen on preoperative chest radiographs or CT scans often indicate a more difficult subcarinal esophageal dissection.

With unexplained, prolonged severe hypotension during the transhiatal esophageal mobilization, even after the surgeon's hand is removed from the posterior mediastinum, major bleeding should be suspected. If the patient is adequately hydrated and the hypotension has been induced by cardiac displacement, the blood pressure should quickly return to baseline once the hand has been withdrawn from the hiatus. This is not the time for administering pressor agents. If there is no excessive bleeding from either the cervical incision or the hiatus, bilateral 28 French chest tubes should be inserted quickly through low inframammary incisions in the anterior axillary lines, advanced to the apices, secured to the skin, and connected to suction thereby allowing assessment for inapparent intrathoracic bleeding. The two large bore intravenous lines, standard in this operation, allow for volume replacement. Retraction of the hiatus with a narrow Deaver retractors permits direct inspection of the mediastinum. The 28 French Argyle Saratoga sump catheter inserted through the cervical incision helps to evacuate blood from the mediastinal field. If the mediastinal bleeding appears to be "high," draining into the chest through an opening in the pleura, particular from the right side of the high mediastinum, it is likely that the azygos vein has been torn. The posterior mediastinum should be packed quickly through the hiatus with two large laparotomy packs from "below" and two narrow thoracic packs placed behind the esophagus through the cervical wound (Fig. 78.27), protecting the RLN in the tracheoesophageal groove with fingers as the packing is being performed (Fig. 78.27, inset). The abdomen is quickly closed with 4–5 through and through No. 2 monofilament sutures, and the incision covered with an adhesive surgical drape (Fig. 78.28, inset). The cervical wound is similarly closed quickly with running monofilament suture and the incision covered with an adhesive surgical drape. The patient is turned to the left lateral decubitus position and padded for a right posterolateral thoracotomy. A fifth interspace thoracotomy is performed, and the bleeding site (usually a torn azygos vein) identified and controlled. If single lung ventilation is needed for better exposure, the carina is identified and the right mainstem bronchus pinched between the thumb and index finder to occlude it as the anesthesiologist advances the deflated endotracheal tube in the left

mainstem bronchus. If the esophagus has not yet been removed, the esophageal mobilization is completed. The patient is again turned supine, positioned as before, the cervical and abdominal incisions reopened, and the esophageal replacement with the stomach in the posterior mediastinum and a CEGA carried out as originally planned.

In another scenario, at times, once the esophagus has been removed after the transhiatal mobilization, untoward dark venous bleeding from either the cervical incision or the hiatus is managed as above with bilateral chest tubes and mediastinal packing. After waiting 5 minutes, natural hemostatic mechanisms may come into play. If no blood wells up out of the wounds after careful removal of the packs, the posterior mediastinum is inspected through the hiatus. The thrombosed end of the torn azygos vein may be seen and further occluded with a Hemoclip on a long applier or clamped with 14-in extra-long right-angled clamps and ligated. On the other hand, if bleeding resumes after the packs are removed, the mediastinum is repacked, the cervical and abdominal incisions temporarily closed as above, and the patient turned and positioned for a right posterolateral thoracotomy.

Bright red arterial bleeding from the hiatus during the transhiatal esophageal mobilization is quickly assessed by inserting the Argyle Saratoga sump catheter through the cervical wound and “spot sucking” through the hiatus with a Yankauer suction from the lower end of the table. An aortic esophageal arterial bleeder may be identified through the hiatus, clamped with a long right angle clamp, and ligated. Mediastinal packing as described above is again performed and the esophageal bed assessed after 5 minutes. If an ill-advised attempt at blunt dissection of the esophagus from the adherent descending thoracic aorta is undertaken, the resulting hemorrhage from an aortic esophageal wall tear may not be controllable before fatal exsanguination has occurred.

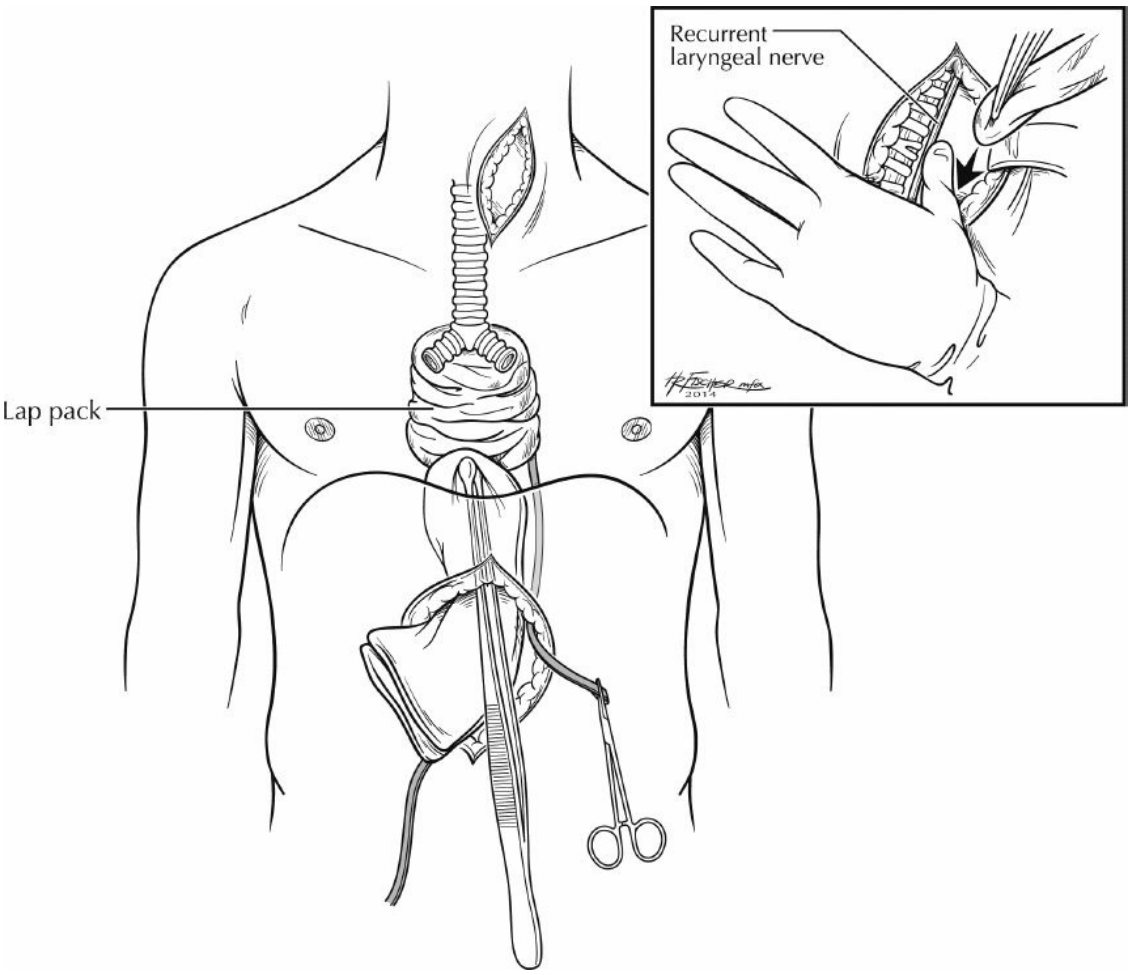

Figure 78.27. To tamponade posterior mediastinal bleeding, two large laparotomy packs are quickly advanced upward into the mediastinum through the retracted hiatus using long Russian forceps, and two narrow “thoracic” packs are advanced into the mediastinum through the cervical incision. The recurrent laryngeal nerve is protected against direct contact with the forceps by a finger held across it (*inset*). (Republished with permission of Springer, from Orringer MB. Transhiatal esophagectomy-intraoperative disasters. In: Pawlik TM, Maithel SK, Merchant NB, eds. *Gastrointestinal Surgery: Management of Complex Perioperative Complications*. New York: Springer; 2015:35–51, permission conveyed through Copyright Clearance Center, Inc.)

Tracheal Tear

As noted above, when mobilizing the esophagus away from the carina during the THE, the fingers must be kept posteriorly as possible to avoid an airway injury. A sudden rush of cool air over the fingers in the posterior mediastinum during the transhiatal dissection, particularly with the

anesthesiologist becoming aware of “losing air” from the anesthetic circuit, is indicative of a posterior membranous tracheal tear. This is not the time for intraoperative bronchoscopy. The anesthesiologist must untape the endotracheal tube so that it is completely mobile. The surgeon’s hand is inserted through the hiatus anterior to the esophagus with the palm and volar aspects of the fingers facing forward. The hand is advanced behind the trachea and the posterior membranous trachea palpated to define the site and extent of the tear and control it with gentle pressure (Fig. 78.29A). The injury is typically distal to the endotracheal tube balloon. The anesthesiologist must deflate the balloon and advance the tube forward (often adding a tube extension) as the surgeon guides the tube into the left mainstem bronchus (Fig. 78.29B). Several passes may be required, but if the right mainstem bronchus is occluded by pinching it as the tube is advanced, a successful left-sided intubation is facilitated. The cuff is inflated after several centimeters of the tube have been advanced into the left mainstem bronchus and single lung ventilation of the left lung instituted. The tube is secured in place by the anesthesiologist and adequate oxygenation is confirmed. While it has been reported that membranous tracheal tears occurring during a THE may seal off against the intrathoracic stomach after extubation of the patient and not require repair, in the absence of reliable indicators of which tears can be managed expectantly in this fashion, the author is not comfortable with this approach. A right posterolateral thoracotomy allows direct reliable suture repair of membranous tears of the lower trachea and carina. Therefore, once adequate oxygenation has been achieved with single left lung ventilation, the abdominal and cervical incisions are temporarily closed as described above for the management of mediastinal bleeding, the patient turned, the thoracotomy and tracheal repair with interrupted 4-0 Vicryl performed, the esophageal mobilization completed, and the patient repositioned supine for the gastric mobilization through the mediastinum and construction of the CEGA. Single left lung ventilation is maintained until the end of the case when the patient is awakened and the tube withdrawn to prevent disruption of the tracheal repair by positive airway pressure. Another alternative approach to repair of the trachea is extension of the cervical incision downward over the upper sternum across the sternomanubrial junction and performance of a partial upper sternal splint (Fig. 78.30). Once the esophagus has been extracted, exposure of the posterior membranous trachea for a direct suture repair is usually feasible.

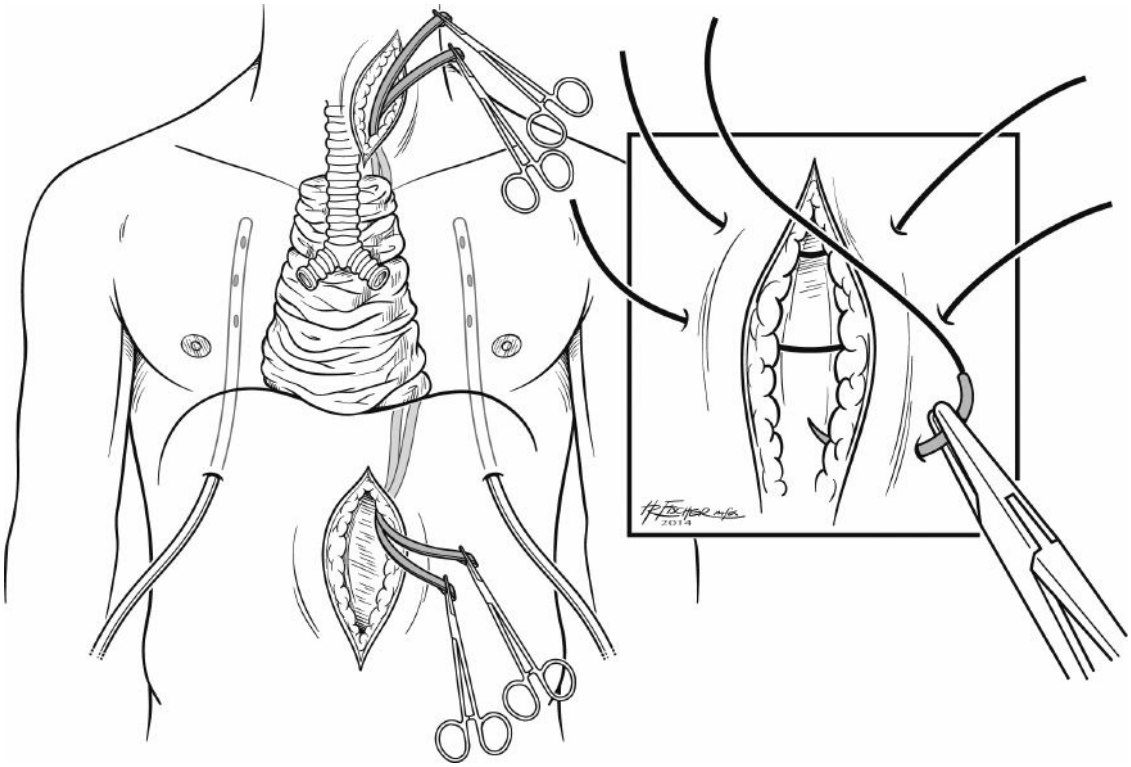

Figure 78.28. With unexplained hypotension and concern for possible intrathoracic bleeding, bilateral chest tubes are quickly placed to allow assessment of blood loss into the chest. Posterior mediastinal bleeding is tamponaded by two large laparotomy packs pushed high into the posterior mediastinum from “below,” and two narrow thoracic packs pushed into the superior mediastinum from “above” through the cervical incision. All packs are “tagged” with hemostats so they are not lost. After 5 to 10 minutes of observation while intravascular volume is replaced and blood pressure restored to a more normal level, if a “second look” into the mediastinum after removing all packs documents persistent bleeding, the mediastinum is repacked. The abdomen is quickly closed with three or four through-and through heavy sutures (*inset*), the cervical wound quickly closed, both incisions covered with adherent plastic surgical drapes, and the patient turned and positioned for a posterolateral thoracotomy. (Republished with permission of Springer, from Orringer MB. Transhiatal esophagectomy-intraoperative disasters. In: Pawlik TM, Maithel SK, Merchant NB, eds. *Gastrointestinal Surgery: Management of Complex Perioperative Complications*.New York: Springer; 2015:35–51, permission conveyed through Copyright Clearance Center, Inc.)

Complications that become manifest *postoperatively* after a THE are RLN injury, CEGA leak, chylothorax, and wound infections. RLN injury

is not simply the “nuisance” of a hoarse voice, as the accompanying cervical dysphagia and aspiration may be life-threatening. Although most patients tolerate the hoarseness and are able to progress their diet as tolerated, a subgroup experience intractable aspiration that is not adequately managed with jejunostomy tube feedings. While the otolaryngologists will typically advise 6 months of waiting to determine if the RLN injury is reversible, or if the patient will learn to adapt to it, in patients with recurrent aspiration aspiration, an early vocal cord medialization procedure with an absorbable material (e.g., Gelfoam) may provide gratifying relief and be life-saving. Chylothorax complicating an esophagectomy is accompanied by loss of protein (albumin) and lymphocytes and is associated with a 50% mortality. Aggressive early surgical intervention (within 1 week of the diagnosis) is advocated if despite a no fat diet, and octreotide injections, the chest tube output persists with a volume of 400 to 600 cc per 8-hour shift or more. A thoracotomy and direct thoracic duct ligation after “priming” the duct with cream administered through the jejunostomy tube for 4 to 6 hours before the operation have been our practice for years. Recently, however, percutaneous thoracic duct embolization of the thoracic duct by the interventional radiologists has been shown to be a very effective means of dealing with this problem and has become the first-line approach. Abdominal wound infections after a THE are very unusual. A cervical wound infection is virtually always indicative of an anastomotic leak. A CEGA leak is managed by opening the cervical wound completely at the bedside, initiating saline gauze wound packing, and maintaining nutrition through the jejunostomy feeding tube placed at the operation. While a CEGA results in a transient salivary fistula rather than mediastinitis associated with an intrathoracic esophageal anastomotic leak, this is far from a benign complication. A CEGA stricture follows 50% of leaks as healing occurs, and dysphagia resulting from an operation intended to restore comfortable swallowing is hardly a successful outcome. Because of the high rate of anastomotic stricture after a leak, we routinely incorporate bedside esophageal dilatations with Maloney bougies (36, 40, and 46 French) within 1 week of opening and packing the cervical wound. Small CEGA leaks do not require that the patient refrain from swallowing any nourishment. With practice, gentle cervical pressure over the wound usually provides sufficient occlusion of the leak that liquids and soft foods can be swallowed while the fistula closes.

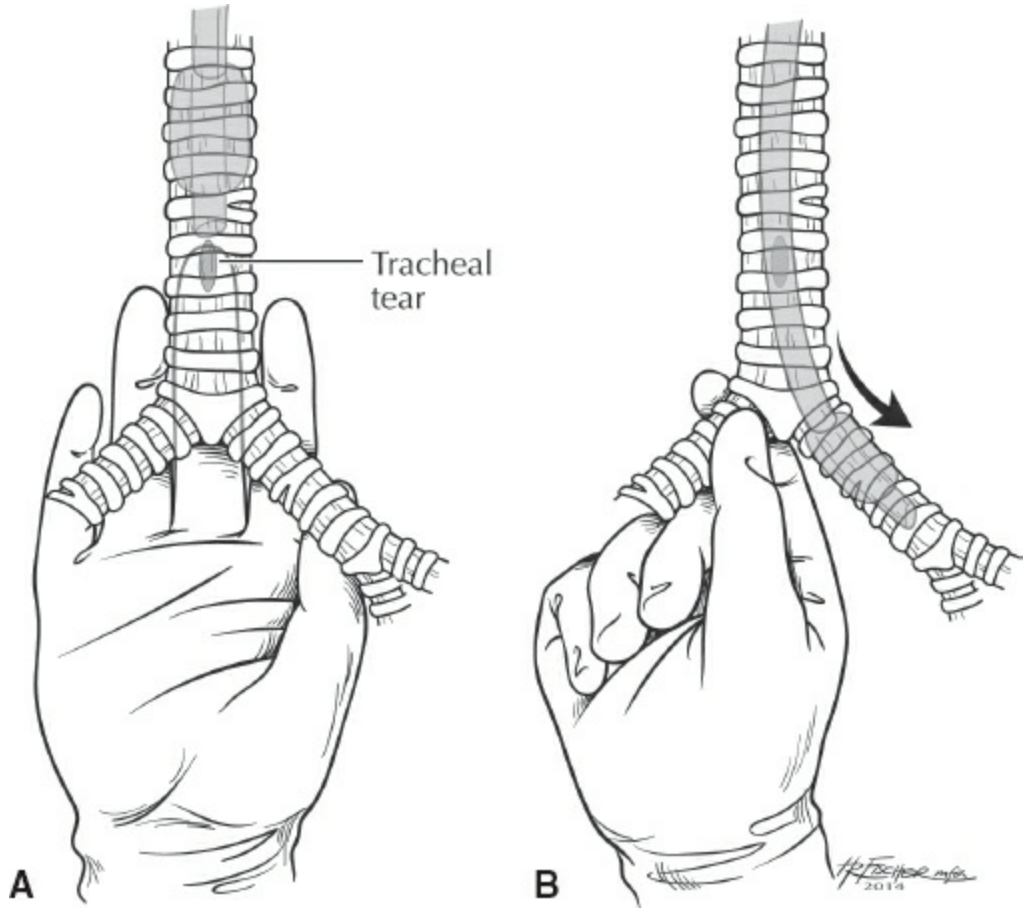

Figure 78.29. A. With a sudden air leak during THE, a posterior membranous tracheal tear is located and gently temporarily controlled with the volar aspect of the middle finger inserted through the diaphragmatic hiatus. **B.** Single lung ventilation of the left lung is achieved by occluding the right mainstem bronchus between the index finger and thumb and having the anesthesiologist advance the tube with the balloon deflated into the left mainstem bronchus beyond the site of the tear. Satisfactory oxygenation with single lung ventilation can be maintained until after the airway is repaired. (From Orringer MB. Transhiatal esophagectomy-intraoperative disasters. In: Pawlik TM, Maithel SK, Merchant NB, eds. *Gastrointestinal Surgery: Management of Complex Perioperative Complications*. New York: Springer; 2015:35–51. Copyright © 2015 Springer, with permission of Springer.)

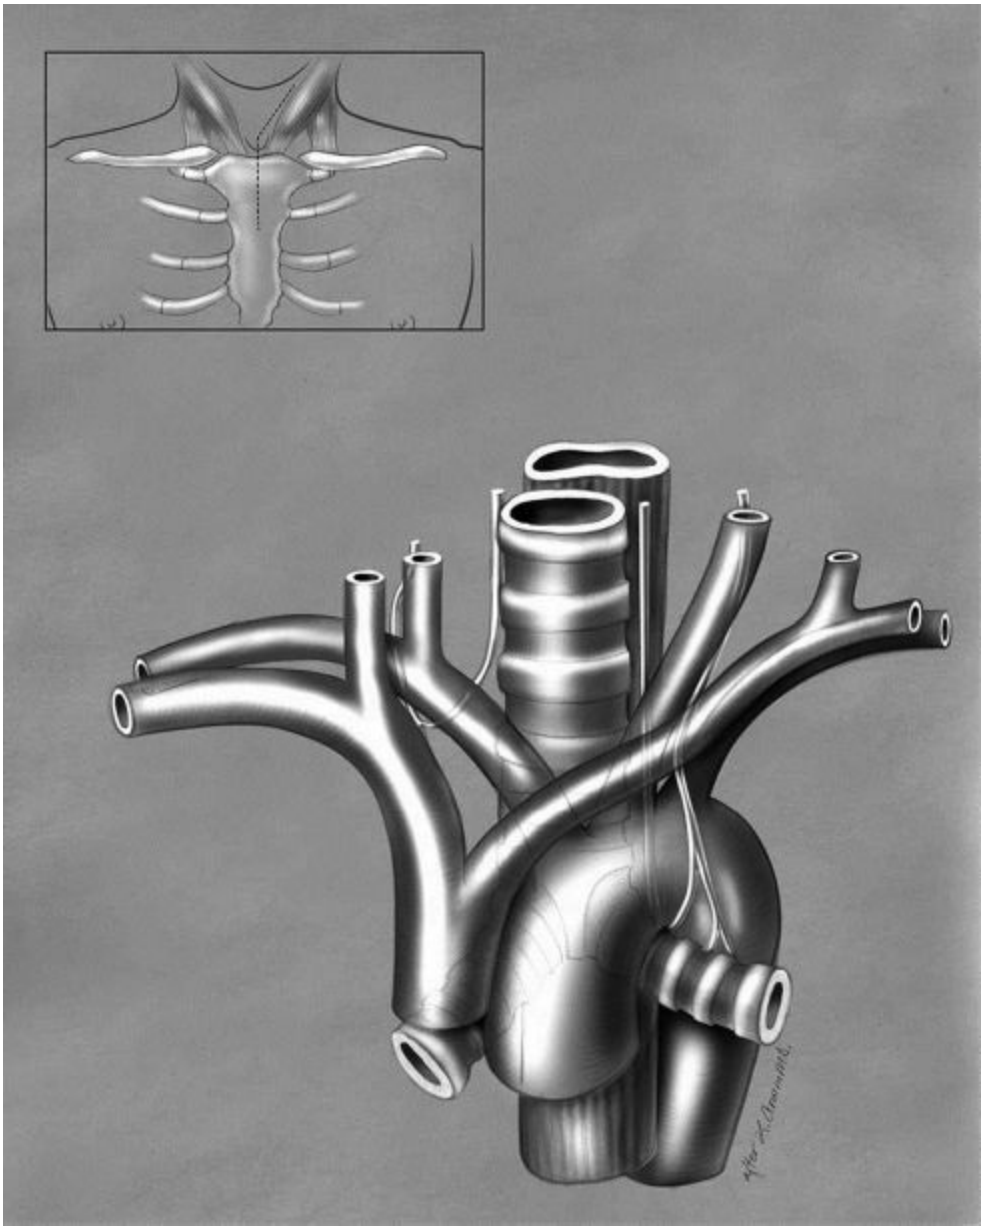

Figure 78.30. If a tear of the posterior membranous trachea is detected after transhiatal mobilization and removal of the esophagus, a partial upper sternal split may provide adequate exposure for direct tracheal repair. The oblique left cervical incision is extended downward in the midline over the manubrium and just across the sternomanubrial junction (*inset*). With a partial sternotomy and a small sternal retractor, access to the superior mediastinum and posterior membranous trachea to the level of the carina as shown is achieved, and suturing of the tracheal tear may be possible without the need for a thoracotomy. (From Orringer MB. Transhiatal esophagectomy without thoracotomy. *Oper Tech Thorac Cardiovasc Surg* 2005;10:63, with permission.)

Long-term complications of THE may include intractable dumping syndrome and a refractory CEGA structure. Dumping symptoms after eating (most often cramping and diarrhea but at times nausea, tachycardia, diaphoresis, and prostration) occur in nearly 25% of patients who undergo a vagotomy. Most often, these symptoms respond to an “anti-dumping” regimen: avoiding over distention of the stomach by eating smaller, more frequent meals, and withholding liquids until after the meal has been eaten; avoiding milk, dairy products, and high carbohydrate loads; addition of fiber to the diet to slow gastrointestinal transit time; and diphenoxylate. Dumping symptoms generally resolve or become manageable after 6 to 9 months. Those with refractory and persistent dumping may require institution of Asian diets—predominately rice, stir-fried vegetables, and fruit. Patients with end-stage achalasia and megaesophagus undergoing a THE appear to have a “parasympathetic dystrophy” that renders them more prone to long-term distressing dumping.

Most patients who experience dysphagia after a THE and CEGA respond to an occasional outpatient passage of tapered Maloney esophageal dilators (36, 40, and 46 French sizes). A 46 French is usually required to ensure comfortable swallowing. For those who develop a recalcitrant CEGA stricture, a standardized therapeutic protocol has been developed and includes instruction in an implementation of self-dilatation with a Maloney dilator. Home use of a Maloney dilator is the simplest, most cost-effective, and efficient means of dealing with this problem. Transferring the care of these patients to a gastroenterologist who typically addresses the problem with multiple time-consuming endoscopic dilatations is expedient but not optimal. Esophageal surgeons should have ready access to a full range of sizes of Maloney esophageal dilators and an established process for issuing them for home use.

OUTCOMES

Since 1976, THE without thoracotomy has been performed by the Thoracic Surgery Service at the University of Michigan Medical Center in more than 3,000 patients. Our experience with the initial 2,000 was reported in 2007. Seventy-six percent of these operations were for carcinoma and 24% for benign disease. Twenty-four percent of the patients were 71 years of age or older and 5% were 80 years of age or older, an increasing number of octogenarians and nonagenarians undergoing THE on our service. Despite initial concerns expressed three

decades ago about the ability of the stomach to reach to the neck in most patients, there is now little question that the properly mobilized otherwise normal stomach will always reach to the neck for construction of a CEGA. Stomach was used as the esophageal substitute in 97% of these operations, only those with a prior gastric resection or those requiring a gastric resection at the time of esophagectomy undergoing a colonic interposition.

Four intraoperative deaths (<1%) occurred as a result of uncontrollable mediastinal bleeding during the THE. Among 3,200 THEs performed at the University of Michigan since 1976, 8 (0.25%) tracheobronchial tears have occurred, 4 repaired through a right posterolateral thoracotomy and 4 through a partial sternal split. All healed without additional postoperative morbidity. Approximately 75% of patients required a chest tube into one or both pleural cavities as a result of violation of the mediastinal pleura during the esophagectomy. Other infrequent intraoperative complications included splenic injury necessitating a splenectomy (3%) and violation of gastric or duodenal mucosa during performance of a pyloromyotomy (<2%), in each case managed successfully by the placement of several 5-0 polypropylene sutures to close the defect and buttressing the closure with adjacent omentum. Postoperative complications included the need to return the patient to the operating room for control of mediastinal bleeding within the first 24 hours in seven patients (<1%) and RLN injury in <5%. If care is taken to avoid placement of any metallic retractors against the tracheoesophageal groove during the cervical portions of the operation, injury to the RLN is rare, in our latest 1,000 patients between 1% and 2%. Less than 2% of our THE patients have experienced pulmonary complications (pneumonia and/or atelectasis) of sufficient severity to prolong their hospital stay. This reflects both the decreased physiologic impact of this type of esophagectomy, which avoids a thoracotomy, and better preoperative preparation by having the patients stop cigarette smoking well in advance of surgery and use an incentive inspirometer. Chylothorax occurred in <1% of our patients and was managed successfully in each case by an aggressive policy of early thoracic duct ligation. More recently, percutaneous thoracic duct embolization by our interventional radiologists has become our initial approach to a post-esophagectomy chylothorax.

Worldwide, the CEGA leak rate averages approximately 14%. It was 13% in our first 1,000 patients to undergo THE and CEGA. However, since adopting the side-to-side stapled CEGA as described in this chapter,

our overall CEGA leak rate is now <3%. Our hospital mortality for THE was 4% in our first 1,000 patients and 1% in our next 1,000 patients. Seventy-one percent of our patients had no postoperative complications. The hospital stay after a THE now averages 7 to 8 days. While an admirable achievement, there is a growing general awareness of the disparity between 30-day and 90-day mortality after esophagectomy, and more data are needed to better define this and improve short-term results.

It must be realized that the functional results of esophageal substitution with stomach are not measured with a satisfactory postoperative barium swallow examination that shows no anastomotic leak and satisfactory emptying of the intrathoracic stomach. Postoperative dysphagia due to anastomotic stricture, posturally related regurgitation, and postvagotomy "dumping" symptoms are all important parameters to be considered. Fortunately, 80% of these patients typically have either an excellent or good result (either no symptoms or occasional cervical dysphagia, regurgitation, or postvagotomy diarrhea requiring no treatment); 17% have a "fair" result (dysphagia requiring an occasional dilation, regurgitation requiring that the patient sleep upright at night, or abdominal cramping or diarrhea after eating requiring medication for control of symptoms); and 3% have a "poor" result (the need for ongoing dilation therapy for a CEGA stricture or aggressive treatment of reflux and intractable dumping symptoms).

The survival of patients undergoing THE for carcinoma has been comparable to that reported for patients undergoing more "radical" esophagectomy and lymph node dissection. The overall actuarial survival rate has been 51% at 2 years and 29% at 5 years, the stage of the resected tumor, as with every patient undergoing an esophagectomy for cancer, being an important determinant of survival after THE. Particularly with the use of neoadjuvant chemoradiation therapy and its potential to eradicate micrometastatic disease, proponents of a direct mediastinal lymph node dissection in patients undergoing esophagectomy have a much weaker argument for a transthoracic approach. Among 583 of our patients who received chemotherapy and radiation therapy before their THE, 125 (21%) were "complete responders" (T0N0 tumor), and their 2-year survival rate was 80% and 5-year survival rate was 58%.

Just as THE generated controversy years ago as a less invasive operation, recent advocates of minimally invasive esophagectomy (MIE) must respond to concerns about this approach. Important operative

principles for a successful THE have clearly been established: preparation of as wide a gastric conduit as possible to preserve submucosal collateral circulation, maximization of the length of the gastric conduit by progressive straightening and cephalad traction with each stapling along the lesser curvatures, a generous Kocher maneuver to facilitate the cephalad reach of the mobilized stomach, a gastric drainage procedure, absolute avoidance of trauma to the tip of the stomach being used for the subsequent esophagogastric anastomosis (no suturing to drains, plastic bags, etc.), direct evaluation and enlargement of the posterior mediastinum by the hand and forearm inserted through the hiatus after extraction of the esophagus to ensure an unimpeded passageway for the gastric conduit, and a CEGA to avoid the risk of mediastinitis associated with an anastomotic leak. With MIE, the stomach is "tubularized" to facilitate mobilization through the hiatus and into the posterior mediastinum that has not been enlarged directly by the hand and forearm and to minimize possible torsion of the intrathoracic stomach that can occur when the right mediastinal pleura has been opened widely; a generous Kocher maneuver is not readily achieved and is often omitted; for the same reason, a gastric drainage procedure may not be done, with predictable increased postoperative problems with gastric emptying; the stomach cannot be "straightened" to the same extent as in the open procedure when it is stapled in situ within the abdominal cavity, thereby increasing tension on the esophagogastric anastomosis and increasing the risk of a leak; and the tip of the mobilized stomach is sutured endoscopically to the divided proximal stomach, traumatizing the area to be used for the anastomosis. As an acknowledgment of the increased anastomotic leak rate due to the above technical issues, proponents of the MIE have gone "full circle" and are advocating an intrathoracic esophagogastric anastomosis, accepting the consequences of mediastinitis from an anastomotic leak in the name of "improved minimally invasive technology." With endoscopic cutting and coagulation for hemostasis, at times too near the trachea or gastric wall, late fistulas between the airway and intrathoracic stomach, seldom seen after a THE, are being reported after MIE. Time will tell whether the added cost and complications associated with MIE warrant general adoption of this technique of esophageal resection.

THE and CEGA are now an established efficient means of treating patients requiring esophagectomy and esophageal reconstruction for both benign and malignant disease. With aggressive preoperative preparation of

the patients and use of epidural anesthesia for postoperative analgesia, our patients are typically extubated in the operating room, are not admitted to the intensive care unit, and are ambulatory the following day. Frequent ambulation and use of the incentive inspirometer are continued postoperatively. The nasogastric tube is removed on the third postoperative day; diet is progressively advanced; and on the seventh postoperative day, a barium swallow examination is obtained to verify that (a) there is no anastomotic leak, (b) the stomach empties adequately through the pyloromyotomy site, and (c) there is no significant obstruction at the site of the feeding jejunostomy tube. Patients are typically discharged after the barium swallow examination on the seventh or eighth postoperative day.

EDITOR'S COMMENT

Dr. Orringer has written a beautiful and detailed chapter on transhiatal esophagectomy (THE)—an operation that I imagine he has performed literally more often than any other surgeon. This chapter is ripe with very specific technical descriptions and valuable discussions regarding the subtle signs of intraoperative trouble and how to safely and efficiently manage these potential life-threatening complications.

In the current era, the majority of esophagectomies are performed in an open manner and with a thoracotomy and intra-thoracic anastomosis (Ivor Lewis). A recently published review of the Society of Thoracic Surgeons Database reveals that of 3,780 esophageal resections, 62% were either an open transhiatal or Ivor Lewis resection and 22% were performed with a minimally invasive approach (minimally invasive esophagectomy or MIE). Of the open cases, the Ivor Lewis esophagectomy was the most common with 1,291 procedures in the study interval. Open THE was a close second in terms of frequency with 1,065 procedures during the study. From this same manuscript, the morbidity and mortality rates of open and MIE were similar, although MIE was associated with a longer operative time and rate of reoperation. A third type of esophageal resection is known as the McKeown procedure and involves three incisions—an abdominal incision, a right thoracotomy, and a left cervical incision for a cervical anastomosis.

The rationale for a thoracic incision (and accepting the potential morbidity of an intrathoracic anastomotic complication in the case of the Ivor Lewis procedure) is a belief that better visualization of the tumor and a more extensive resection afforded by the thoracic approach including en bloc resection of periesophageal tissue and mediastinal lymph nodes lead to better oncologic outcomes. The transhiatal approach described in this chapter avoids the morbidity associated with a chest incision. This is associated with less pain and fewer pulmonary complications. The cervical anastomosis converts an anastomotic leak from a potentially life-threatening complication with mediastinal sepsis to a non–life-threatening wound complication (and a fistula with increased rate of anastomotic stenosis as also described in this chapter). The fact that there is a roughly equal distribution of transthoracic and transhiatal esophagectomies performed more than 80 years after Turner first described the transhiatal approach is a sign that both techniques are acceptable and there is no current consensus as to the best approach. Decisions regarding surgical technique are frequently based on personal bias, surgeon experience, and comfort with a procedure.

There are a few large meta-analysis published comparing transhiatal to transthoracic esophagectomy in an attempt to determine the most advantageous

approach. Unfortunately, most of the studies included in both meta-analysis are retrospective in nature and were not consistent with regards to technique and therapy in addition to surgery (chemotherapy and radiation before or after surgery). A meta-analysis by Rindani included almost 5,500 patients from 44 series published between 1986 and 1996. Postoperative respiratory and cardiovascular complications were similar with each surgical approach. The transhiatal approach was associated with a higher rate of anastomotic leak and recurrent laryngeal nerve injuries. Thirty-day mortality was 6.3% after transhiatal and 9.5% after transthoracic resection, but survival at 5 years was equivalent. A more recent meta-analysis by Boshier included 5,900 patients in publications up to January 2010. Transthoracic operations took longer and were associated with a significantly longer length of stay. There was no difference in blood loss. The transthoracic group had significantly more respiratory complications, wound infections, and early postoperative mortality, whereas anastomotic leak, anastomotic stricture, and recurrent laryngeal nerve palsy rate was significantly higher in the transhiatal group. Analysis of 5-year survival showed no significant difference between the groups and was subject to significant heterogeneity. A large population-based study has been published, which has evaluated the results of both approaches through the Surveillance, Epidemiology and End Results (SEER)-Medicare linked database from 1992 to 2002. A lower operative mortality was found after THE (6.7% vs. 13.1%). Although observed 5-year survival was higher after THE, after adjusting for stage, patient, and provider factors, no significant 5-year survival difference was found.

The above are important comparisons to bring forward. Dr. Orringer has a massive experience with THE, and the technique he described is developed based on a 40-year experience with the procedure. Even in the past decade since he published the results of 2,000 procedures, he has realized an improvement in morbidity and mortality. Most other surgeons performing esophagectomy will not have the benefit of the experience described here, and no matter how carefully they read Dr. Orringer's chapter would have a hard time replicating his results. There is clearly a volume–outcomes relationship in esophagectomy—a high-risk and complex procedure with a not insignificant rate of morbidity and mortality. I suspect that in esophagectomy, the experience is similar to what we have seen in inguinal hernia surgery—a much more common operation worldwide. While laparoscopic and open mesh-based as well as open tissue-based inguinal hernia repairs are well described with excellent results in terms of morbidity and recurrence rates, no one technique is superior. High-volume, thoughtful, and expert hernia surgeons have excellent results regardless of preferred technique. Like many other things in surgery, do a lot of an operation over a long period and you can get really good results.

I have a few comments on specific topics mentioned in this chapter. First, with regards to smoking cessation prior to surgery, Dr. Orringer describes his strict policy of no cigarette smoking for 3 weeks prior to surgery. There is an

increasing body of literature on this topic when it comes to many different kinds of surgical procedures, and evidence supports this as a sound policy. A recently published collective review revealed that smoking substantially increases the risk of cardiac, respiratory, and septic complications after surgery. Smoking is also linked to inferior long-term surgical outcomes, decreased patient satisfaction, and increased overall costs to the health care system. Importantly, smoking abstinence can avert these negative consequences. This is an important point to which all surgeons should pay attention. Studies show that although up to 75% of smokers who undergo surgery would like to quit, only about half of all surgeons routinely counsel their patients to stop smoking.

As a bariatric and foregut surgeon with a practice full of patients who have failed numerous previous hiatal hernia and antireflux operations, I would suggest that a Roux-en-Y gastric bypass (RYGB) is a better alternative to a THE in patients with two or more failed hiatal hernia repairs. While there is no level-1 evidence to support this suggestion, there is a reasonable body of literature describing RYGB as a salvage operation in failed fundoplication. I agree that these are difficult patients to manage, and surgery of any type should be a last resort.

Overall this is an excellent and very detailed chapter that includes insight and data not available in the published, peer-reviewed literature. Surgeons who perform THE in their practice would be well served to carefully read this chapter, especially the sections where Dr. Orringer describes the intraoperative disasters of massive bleeding and tracheal tear, and his approach to recognizing and managing these issues.

79 Esophageal Perforation

Eric M. Pauli and Jeffrey M. Marks

INTRODUCTION

Esophageal perforation is a process with numerous etiologies and presentations that carries significant morbidity and mortality if not managed appropriately and aggressively. Novel, less invasive techniques and tools have helped to replace prior more debilitating treatments such as esophageal diversion and/or major thoracic or abdominal surgery. An understanding of the pathophysiology, clinical presentation, available management tools/algorithms, and techniques for treatment are all vital to safely managing these complex patients.

ETIOLOGY

Spontaneous Perforation

Spontaneous esophageal perforations have been well described since the Dutch physician Hermann Boerhaave reported the case of the Grand Admiral of Holland who died as a result of a “spontaneous” rupture of the esophagus in 1724. Spontaneous perforation refers to cases where there is no preceding trauma, intervention, or caustic exposure. Any activity that acutely increases the intraesophageal pressure can lead to perforation. Although the majority of cases are thought to be related to aggressive vomiting, other processes leading to this acute intraesophageal pressure may lead to full-thickness disruption of the esophageal wall. Reported cases have occurred after excessive lifting, laughing, gagging, or seizure activity.

Spontaneous perforations predominantly occur in the distal esophagus, with mid-esophageal and cervical esophageal perforations being quite rare. The anatomy of the esophagus must be understood in that the distal 3 to 4 cm of the esophagus is intra-abdominal and therefore perforations may lead to mediastinal and thoracic soilage but also intra-abdominal contamination based on the site of the perforation (Fig. 79.1).

Unlike iatrogenic perforations, which usually result in tears comparable

to the associated tool/intervention, spontaneous perforations routinely lead to very long, longitudinal defects with irregular edges. This may complicate surgical or endoscopic repair leading to a more challenging and less effective intervention.

Traumatic Perforation

Penetrating trauma and less commonly blunt trauma can result in esophageal perforation, with the site of perforation related to surrounding anatomical structures. Stab and gunshot wounds to the neck, mediastinum, and upper abdomen may all lead esophageal perforation. Due to the unprotected nature of the cervical esophagus, this is the most commonly injured area following penetrating trauma. The intrathoracic esophagus is well protected by the chest wall and other mediastinal structures and is therefore less commonly involved following penetrating trauma. Isolated esophageal injuries are rare, and associated organ injuries to vascular, pulmonary, and mediastinal structures should be anticipated and addressed. Blunt trauma as a source for esophageal perforation is less common and may be difficult to diagnose in patients with multiorgan blunt injury.

Figure 79.1. The cervical esophagus lies in the neck, bordered superiorly by the hypopharynx and inferiorly by the thoracic inlet, which lies at the level of the sternal notch. Typical endoscopic measurements for the cervical esophagus measured from the incisors are from 15 to <20 cm. The upper thoracic esophagus is bordered superiorly by the thoracic inlet and inferiorly by the lower border of the azygos vein. Typical endoscopic measurements from the incisors are from 20 to <25 cm.

Iatrogenic Perforation

Iatrogenic perforations represent the most common etiology for esophageal perforation and may occur at the time of an esophageal intervention such as nasogastric tube placement or endoscopic procedures, or doing a nonesophageal procedure such as endotracheal intubation with inadvertent tube placement into the esophagus.

Diagnostic flexible esophagogastroduodenoscopy (EGD) is rarely associated with esophageal perforations, but predominantly will occur in the cervical esophagus and are related to both technical issues and underlying anatomical issues. Forceful advancement of the endoscope may lead to cervical esophageal perforation and is more commonly seen in placement of endoscopic ultrasound scopes, side-viewing duodenoscopes, or transesophageal echocardiogram probes, due to the lack of luminal view with advancement of the scope. Anatomical considerations such as cervical ribs, vertebral osteophytes, Zenker diverticulum, prior radiation, neoplasms, and esophageal strictures may be associated with an increased risk of perforation of the cervical esophagus with endoscopic evaluations. Rigid esophagoscopy, which is not commonly performed, was associated with higher rates of perforation as compared to flexible endoscopy.

Therapeutic endoscopic procedures are more commonly associated with perforations than diagnostic procedures and again are related to both technical and anatomical considerations. Esophageal dilation with both balloons and rigid dilator systems can lead to perforation. Dilation with pneumatic balloons (30 to 40 mm diameter) for achalasia is associated with a rate of perforation of 1% to 5%. Prior dilations and larger balloon size lead to higher risk of perforation. Rigid dilation using wire guided systems (Savory or Maloney dilators) may lead to perforation at the cervical esophagus as well as at the more distal site of stricture being addressed by the dilation. Fluoroscopy will help guide wire placement and position, but does not eliminate the risk of perforation. Anatomical

considerations that increase the risk of perforation are the same as those associated with perforation from diagnostic endoscopic procedures. In addition, dilation of esophageal malignancies, radiation induced strictures, complex strictures, long segment strictures, and those following prior dilation have a greater risk of perforation.

Esophageal stent placement rarely leads to perforation, but predominantly occurs at the site of the stenosis or stricture, and is related to either inappropriate transluminal wire position or forceful advancement of the rigid deployment system without fluoroscopic guidance. Delayed perforations resulting in aortoesophageal fistula, pulmonary fistulae (tracheobronchial), or mediastinitis may occur as a result of radial forces of the esophageal stent at the site of the stenosis/stricture, or at the proximal or distal end of the stent where the metal prongs may erode through the esophageal wall. Lengthy stent placement beyond 8 weeks may increase this complication, as well as placement of too wide of a stent in a very tight malignant or benign stricture.

Endoscopic mucosal ablation or resection may also lead to perforation. Prior ablative therapies such as photodynamic therapy (PDT) were associated with risks of stricture and very low risks of perforation. Radio frequency ablative therapies which have now replaced PDT rarely result in perforation and are mostly related to technical errors in passage of the ablative balloons.

Endoscopic resection of esophageal lesions is divided into mucosal resection (endoscopic mucosal resection—EMR) and submucosal dissection (endoscopic submucosal dissection—ESD). EMR entails removal of smaller lesions either in piece meal fashion or following engagement of the tissue with either placement of a rubber band, or suctioning of tissue into a cap. The captured tissue is then removed via thermal snare resection. Perforation can occur if deeper tissues are captured, leading to a full-thickness resection. Perforation rates are related to clinician experience as well as prior endoscopic therapy at the same site. ESD or en bloc resection similarly is associated with perforation based on the same factors.

Esophageal perforation at the time of surgery can occur during any neck dissection resulting in cervical esophageal injury (e.g., thyroidectomy, cervical spine treatment, carotid endarterectomy, and tracheostomy). Intrathoracic esophageal injury is most commonly related to thoracic aortic surgery and less commonly spinal surgery. Intra-abdominal esophageal

injury is the most common and related to foregut or hiatus surgery (e.g., paraesophageal hernia repair, Nissen fundoplication, Heller myotomy, gastric bypass, and gastrectomy). Intraoperative endoscopy at the time of any foregut surgery will help to quickly identify any breach in esophageal integrity and allow for immediate repair rather than having a delayed presentation with associated increased morbidity.

Iatrogenic drug–induced perforations are not common and are related to both the medication and the presence of any esophageal dysmotility disorders or anatomical abnormalities (e.g., scleroderma, achalasia, Schatzki ring, peptic stricture, and esophageal diverticulum), allowing for increased mucosal exposure to the offending agents. The most likely medications associated with perforation include potassium chloride, NSAIDs, quinidine, and any sustained release formulas in the presence of delayed passage into the gastric lumen.

OTHER NONIATROGENIC PERFORATIONS

Caustic Injury

Caustic injuries to the esophagus leading to perforation are related to both the offending agent and the performance of endoscopic evaluation or nasogastric tube placement, if not done carefully. Therefore, perforations can occur as either an early or delayed process. Liquefactive necrosis of the esophagus following lye ingestion may lead to full-thickness necrosis and resultant perforation, occurring as late as 5 days post insult.

Infectious Injury

Infectious sources for esophageal perforation are quite rare. Esophageal candidiasis, herpetic esophagitis, and cytomegalovirus esophagitis have all been published in case reports as source for esophageal perforation. Immunocompromised patients and those with esophageal dysmotility disorders are at increased risk of these infectious processes.

Foreign Body Injury

Esophageal perforation related to foreign body ingestion can occur immediately or as a delayed presentation. The site of the injury is related to underlying anatomical site of impedance to bolus transit such as the upper esophageal sphincter, lower esophageal sphincter, or strictures/webs. Perforation of sharp foreign bodies may present immediately or within 1 to

2 days, and pressure necrosis and resultant perforation from impacted food or other object can lead to a delayed presentation.

PATHOPHYSIOLOGY

The anatomical position of the esophagus as it traverses through the neck, mediastinum, and peritoneal cavity results in different inflammatory responses to perforation. In addition, the structure of the esophagus (with a lack of serosal surface) allows for unabated periesophageal infection following disruption of the mucosal and muscular tissues. Perforation of the cervical esophagus leads to a localized periesophageal abscess in the neck, most commonly on the left side. As the esophagus enters into the thoracic cavity, it courses along the right side of the mediastinum and mid-esophageal perforation therefore in addition to mediastinitis can result in empyema of the right chest. Finally, as the esophagus traverses the diaphragmatic hiatus, it is on the left side, although it must be understood that proximal to the gastroesophageal junction, there is a component of intraperitoneal esophagus. Distal esophageal perforations therefore may lead to either a left-sided empyema or subdiaphragmatic infection, that is, peritonitis.

The ensuing infectious and inflammatory response is secondary to the vast polymicrobial aerobic and anaerobic pathologic flora that exists in the oropharynx. Contamination of the affected site is related to swallowed saliva and food, as well as from reflux of gastroduodenal contents (i.e., gastric acid, bile, pancreatic secretions). Patients who are immunosuppressed may have bacterial and fungal flora in the mouth and foregut, and those patients on acid suppressive therapy will have greater bacterial counts in the gastric lumen, allowing for more intense infectious processes.

CLINICAL PRESENTATION

Patients with esophageal perforation will have presenting symptoms and signs based on the timing of the injury, the site of the perforation, and underlying comorbid diseases. As stated above, the course of the esophagus from the left cervical region to the right mediastinum and finally back to the left chest prior to entry into the abdomen will help define the diagnosis and site of perforation. As with all patients, a thorough history and physical is required including timing and type of intervention or suspected injury, any anatomical or surgical abnormalities,

and all underlying comorbid diseases and medications.

Cervical Esophageal Perforation

A cervical perforation from either iatrogenic or noniatrogenic causes will lead to a periesophageal inflammatory process in the neck. Pain, chills, drooling, dysphagia, and odynophagia may be common complaints. On physical examination, fever or tachycardia may be present. Subcutaneous cervical emphysema or skin changes, tenderness, fullness, or tracheoesophageal deviation may be signs of cervical esophageal perforation and resultant abscess. Earlier presentation following injury may result in less severe physical findings and more vague clinical complaints.

Mid-Esophageal Perforation

Mid-esophageal perforation and resultant mediastinitis will result in systemic inflammatory response but less succinct physical findings. Patients may complain of centralized chest or back pain, malaise, chills, shortness of breath, pleuritic chest pain, as well as dysphagia and odynophagia. Physical findings of fever, tachycardia, hypotension, auscultatory rales, and muffled heart tones may be present, although complete lack of physical findings may occur. Hamman sign, a crunching sound synchronized with the heartbeat, may be auscultated if there is significant pneumomediastinum associated with the perforation.

Distal Esophageal Perforation

Similar to mid-esophageal perforations, patients may present with complaints of pleuritic chest pain, although now on the left side, chills, malaise, shortness of breath, as well as abdominal pain. Physical findings also may be similar with the addition of signs of peritonitis including guarding and diffuse abdominal tenderness.

DIAGNOSIS

Diagnosis of esophageal perforation requires a high index of suspicion based on history and patients physical presentation. A thorough review of interventions performed or suspected source for injury is helpful in identifying the presence and site of perforation. Although history and physical exam may help predict the presence of a perforation, confirmation

of the diagnosis is routinely based on radiographic imaging or endoscopic findings. Chest x-ray may reveal subcutaneous emphysema in the neck, pneumomediastinum, left or right pleural effusions or pneumothoraces, and pneumoperitoneum. These radiographic findings will help guide the diagnosis of the site of injury based on descriptions above. Plain radiographic studies may confirm suspicion of a perforation but most likely will not lead to a definitive diagnosis. CT scan of the neck, chest, and abdomen may show more succinctly the hallmark signs of esophageal perforation including extraluminal air or fluid in the periesophageal tissues. Extravasation of contrast as well as any identified inflammatory processes with resultant abscess or fluid collections will help guide treatment.

Oral contrast radiographic images, however, are the true definitive diagnostic study. In patients with an aspiration risk (i.e., suspected impacted foreign body), Gastrografin should be avoided due to the resultant severe pulmonary inflammatory and edematous process which can follow aspiration. In these scenarios, dilute barium is preferred. False-negative contrast studies do occur, and if suspicion remains high for perforation in the face of a normal contrast study, patients should continue to be treated as if a perforation is present. Positive studies may reveal free extravasation of contrast into the chest or peritoneal cavity or merely a contained leak (Fig. 79.2). Clinical presentation in conjunction with radiographic findings will guide appropriate therapeutic interventions.

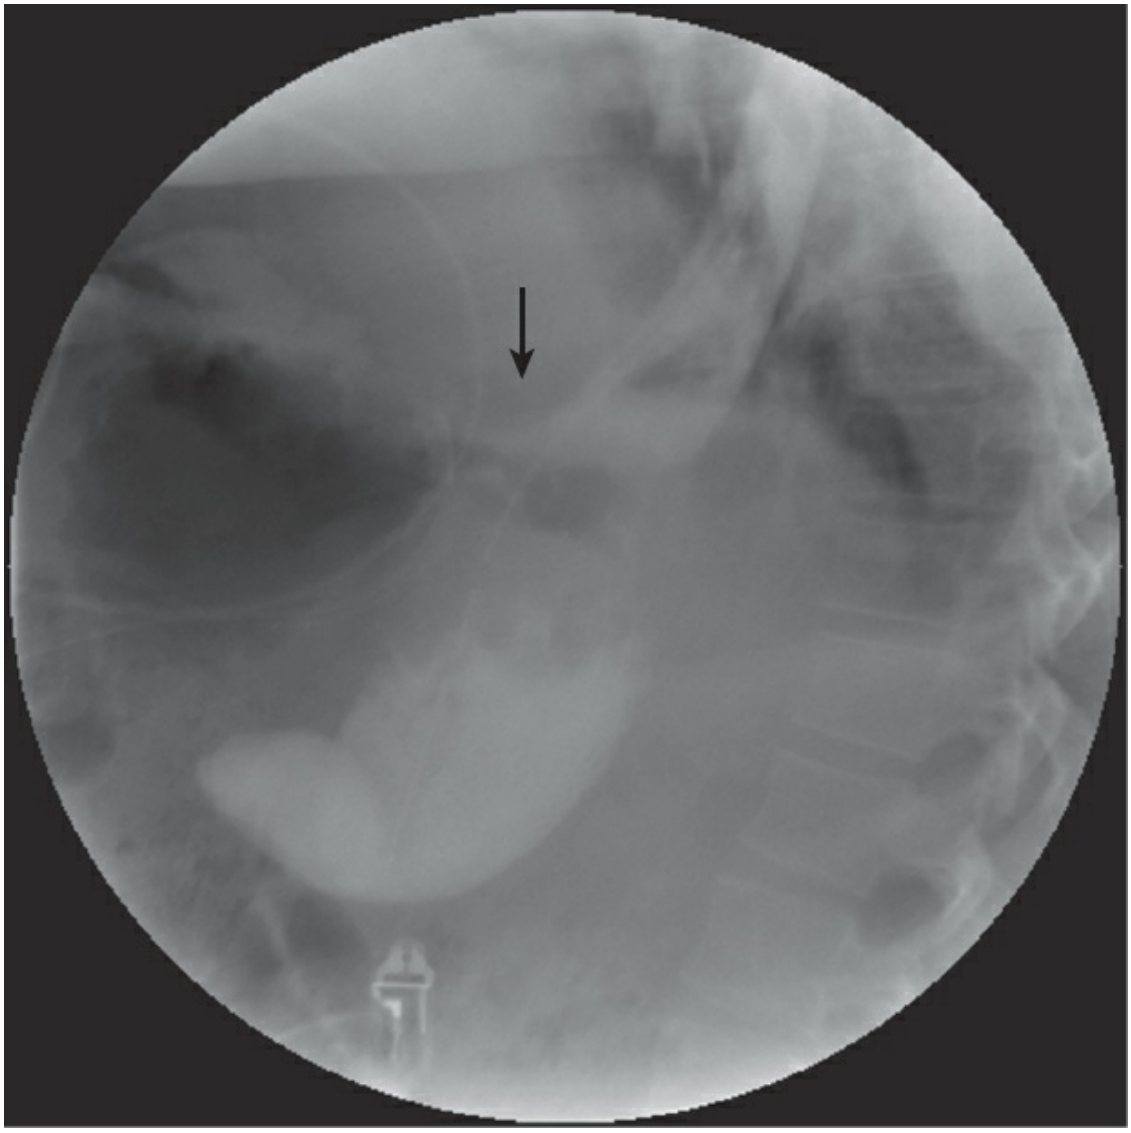

Figure 79.2. Lateral fluoroscope image demonstrating an anterior perforation of the abdominal esophagus with uncontained contrast leak in a patient who had uncontrolled retching while mechanically ventilated following a hernia repair.

Esophageal perforation was previously considered a contraindication to flexible endoscopy. However, with increased clinical experience, as well as development of endoscopic therapies to treat esophageal perforation, endoscopic evaluation is now a vital component of the workup in suspected esophageal perforation. In the presence of equivocal radiographic findings, endoscopy may help confirm or exclude actual presence of this process. In addition, the extent of associated mucosal damage/ischemia can be determined. Injection of contrast via the endoscope at a suspected site of perforation can also increase the potential for confirmation of diagnosis.

Care must be taken of course when performing flexible endoscopy in the face of suspected perforation with careful advancement of the endoscope and utilization of carbon dioxide insufflation rather than room air.

PREOPERATIVE PLANNING

Patients with suspicion for esophageal perforation require expedient confirmation of diagnosis followed by directed therapy to treat systemic responses to the severe inflammatory process, as well precautions to minimize further extraluminal contamination. The degree of systemic response is related to the site of injury, timing of presentation, and underlying pathology and comorbid diseases. For those patients unable to manage their own oral secretions due to associated esophageal obstruction or periesophageal abscess, immediate airway control with endotracheal intubation is imperative.

Localized source control with directed drainage (i.e., thoracentesis, thoracostomy tube, incision, and drainage of neck abscess) may be necessary to confirm diagnosis and alleviate pulmonary and septic consequences. Broad-spectrum antibiotics with coverage of gram-negative and gram-positive aerobes, anaerobes, and fungal organisms are recommended. Those patients who are immunosuppressed may require antiviral medications as well.

Despite the potential devastating complications of esophageal perforations, nonsurgical management of carefully selected patients has been described in multiple reports. Medical therapy with intravenous antibiotics, nasogastric decompression, and parenteral nutrition was first described by Cameron et al. in 1979 and has been studied and modified since that time. Guidelines for such conservative therapy include (1) patients who are clinically stable with minimal signs of sepsis on presentation (and do not develop them during therapy), (2) instrumentation type (generally iatrogenic) perforations in which the patient had been on a regime of nothing-by-mouth (NPO) in the period surrounding the perforation, (3) perforation is detected early (or the patient presents late but has developed “tolerance” to the perforation, and (4) perforation is contained within the neck, mediastinum, or abdomen with no free extravasation of contrast (perforation drains back into the esophagus) and no signs of crepitus, pneumothorax, or pneumoperitoneum.

For patients not meeting these criteria, or who fail conservative

management, surgery is indicated. Regardless of the location of the perforation, the goals of therapeutic intervention are the same; to prevent further contamination through the luminal defect; to restore gastrointestinal (GI) tract continuity (if possible); to manage the sequelae of neck, mediastinal, pleural or peritoneal infection (including the debridement of all necrotic or infected tissues); and to provide a route for enteral (or parenteral) nutrition.

SURGICAL TECHNIQUES

Surgical Approach

The surgical approach to an esophageal perforation depends on the location of the perforation, the patient's clinical condition, the age of the perforation, and the tools/skill set available to the surgeon. Flexible GI endoscopy, minimally invasive (thoracoscopy or laparoscopy), and open surgery (via the neck, chest and/or abdomen) all have a role in the surgical management of esophageal perforation.

Perforation of the cervical esophagus can usually be exposed through an oblique incision in the left neck. The sternocleidomastoid muscle is retracted laterally and the omohyoid muscle and middle thyroid vein divided. By retracting the trachea medially, blunt dissection can be used to free the esophagus into the mediastinum (Fig. 79.3).

Perforation in the upper two thirds of the thoracic esophagus can be approached through a right posterolateral thoracotomy in the fourth, fifth, sixth, or seventh intercostal space (depending on the level of the perforation). The perforation of the lower third of the thoracic esophagus can be approached through a left posterolateral thoracotomy in the sixth, seventh, or eighth intercostal space. Following thoracotomy, the lung is retracted anteriorly and the esophagus identified and encircled with a Penrose drain for retraction.

If the perforation is in the abdominal esophagus, the esophagus can be approached through an upper midline laparotomy. Mobilization and rightward retraction of the left lateral segment of the liver facilitates access to the esophageal hiatus. Division of the short gastric vessels not only facilitates exposure but provides mobilized fundus to utilize as a buttress later in the repair.

Minimally invasive approaches for the management of the esophageal perforation (thoracoscopy or laparoscopy) rely on port placement similar to other minimally invasive esophageal surgeries (such as esophagostomy

or Heller myotomy). Port placement (right chest, left chest or abdominal) depends on knowledge of the location of the perforation as outlined above.

While initially applicable only to early, uncontaminated perforations, advances in minimally invasive technology and techniques now enable surgeons to perform more complex esophageal perforation repairs via thoracoscopy and laparoscopy. Similarly, advances in therapeutic flexible endoscopy over the last decade have permitted endoscopic tools to be applied to an ever widening array of esophageal perforation types.

ENDOSCOPIC MANAGEMENT

At centers with a high level of expertise in therapeutic flexible endoscopy, endoscopic interventions can be used to eliminate, replace, or augment many of the traditional surgical methods. Endoscopic management of esophageal perforation requires coordination with a multidisciplinary team, as the endoscopist may not possess the necessary skill or knowledge to address the surgical aspects of the disease process. All endoscopy performed in the setting of a perforation should be conducted utilizing low pressure carbon dioxide insufflation with the standard high pressure room air endoscope pump maintained off throughout the procedure. Failure to use carbon dioxide can quickly result in high pressure room air entering the mediastinum, pleural cavity, or peritoneum, resulting in rapid cardiopulmonary decline. Such pressure can also disrupt a contained perforation and result in air that can linger clinically and on imaging studies for weeks after the procedure, potentially creating a diagnostic dilemma (i.e., concern for an ongoing leak).

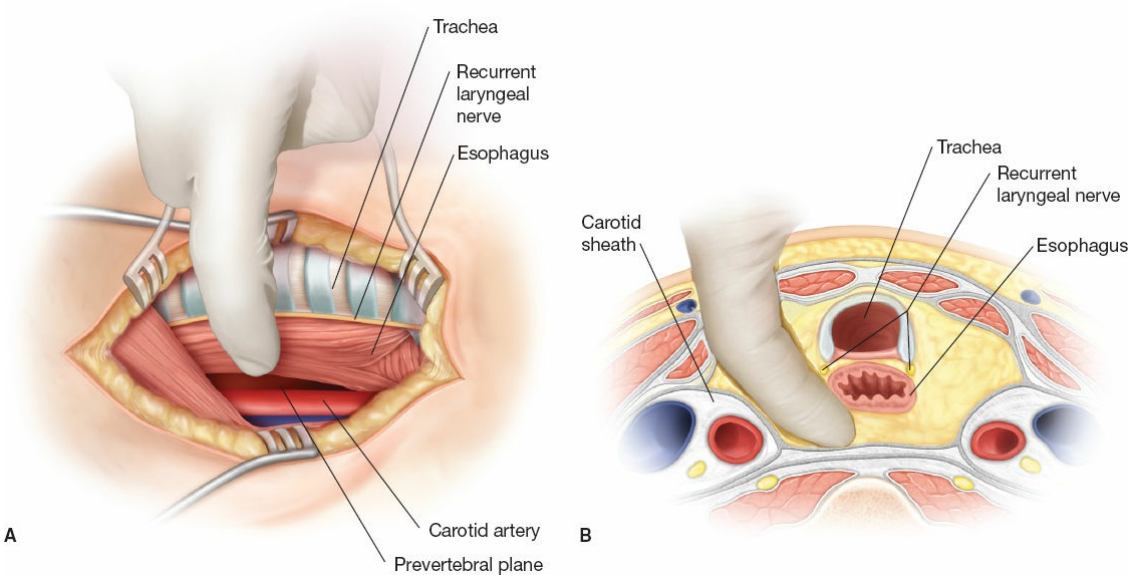

Figure 79.3. A. Transverse section showing the prevertebral space. Dissection is carried out medial to the carotid sheath. The recurrent laryngeal nerve is protected within the tracheoesophageal groove. **B.** Lateral view of the dissected prevertebral space with trachea, esophagus, and recurrent laryngeal nerve retracted anteriorly.

ENDOSCOPIC STENTING

Managing an esophageal perforation with a fully or partially covered endoscopic stent is a commonly employed method for a patient who cannot tolerate a thoracotomy. Stents are deployed under endoscopic and/or fluoroscopic guidance across the area of perforation. The use of stents for this purpose is an off label indication which should be disclosed to the patient. Stents do not result in complete exclusion of the area of perforation; leak around the stent (from both above and below), or through the stent (through imperfections in the polymer coating) are a near universal finding on contrast imaging studies. Patients undergoing stent management of their perforation will still require drainage of any pleural or peritoneal fluid collections and will still need enteral feeding access. Stents placed in the absence of a stricture or tumor have a high rate of migration. Such migration can result in the perforation no longer being covered. Stents cannot be placed across the cervical esophagus (due to pain, sensation of globus, and high migration rates). Stents placed across the gastroesophageal junction result in a high rate of gastric reflux. Patients with distal esophageal perforations being managed with a stent should be fed postpyloric to reduce the risk of tube feed-related reflux and aspiration.

ENDOSCOPIC DEFECT CLOSURE

Endoscopic clips that are passed through the endoscopic working channel and are deployed within the lumen of the GI tract were initially designed for hemostasis and endoluminal marking. They are also referred to as through the scope clips (TTSCs), hemoclips, and endoclips. TTSCs have been shown to be successful in closing iatrogenic defects in the GI tract. Limitations to their success are their small size, small closing force, and mucosa-only tissue apposition; although in the right setting such as small defects that are not gaping, they can be quite effective. Larger defects are more likely to be unsuccessfully managed with TTS clips and therefore

surgeons receive a biased view of the true success rate of the most commonly applied endoscopic therapy.

Over the scope clips (OTSCs, Ovesco Endoscopy, Tubingen, Germany and Padlock, Aponos Medical, Kingston, NH) have gained popularity for the closure of GI tract defects. Their ease of use, large capacity caps, and short learning curve are the factors responsible for their surge in use. Ovesco OTSC are made of elastic, biocompatible nitinol and are capable of full-thickness closure of defects measuring 2 cm in diameter (Fig. 79.4). Because of the larger size of OTSC compared to TTSC, they are able to close larger defects and take full-thickness bites of the tissue. They also provide a larger closure force due to their design. The downside to these OTSC devices is that they have a large outer diameter profile and passage of these may lead to the perforation of the esophagus. Airway protection with endotracheal intubation is routinely required during their placement.

The endoscopic suturing platform (Overstitch, Apollo Endosurgery, Austin, TX) is a disposable device that is attached to the end of a therapeutic double channel endoscope. It allows for the placement of full-thickness absorbable or nonabsorbable sutures. The device can be used multiple times without the need to remove the scope from the patient. The sutures can also be applied in a running or interrupted fashion (including simple and figure-of-eight sutures). Since its introduction, it has been successfully used in the closure of esophageal fistulae, acute perforations, and at sites of full-thickness endoscopic resection.

ENDOSCOPIC ENTERAL ACCESS

Enteral feeding access can be obtained in the majority of situations. Percutaneous endoscopic gastrostomy (PEG) tube placement (via Ponsky pull method) can be safely performed in the setting of many esophageal perforations. If concern exists about passing gastrostomy per os, then an introducer method of gastrostomy insertion utilizing GI T-anchors may be employed. A jejunal extension to the gastrostomy (PEG-J) or a direct percutaneous endoscopic jejunostomy (PEJ) should be considered for postpyloric feeding in patients with known gastroesophageal reflux disease (GERD), hiatal hernia, gastroparesis, or if an endoscopic stent will be placed across the gastroesophageal junction. For patients with a hostile abdomen, who are not suitable candidates for PEG or PEJ, an endoscopically placed nasojejunal feeding tube can be considered.

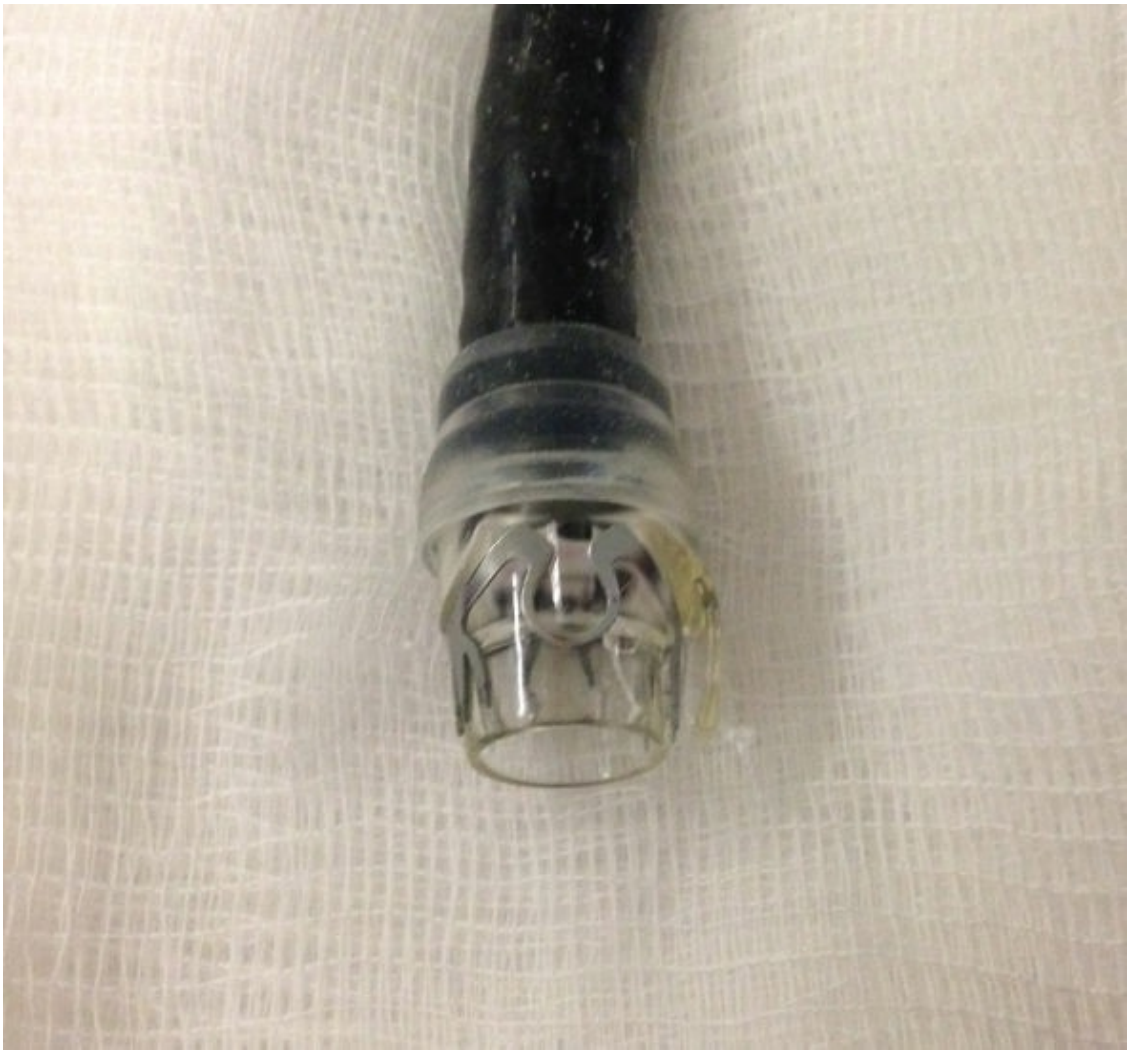

Figure 79.4. Ovesco OTSC mounted on the distal tip of a therapeutic endoscope and ready for deployment at a defect 2 cm or less in size.

Figure 79.5. Vacuum-assisted closure device composed of a porous sponge sutured to a nasogastric decompression tube.

ENDOSCOPIC VACUUM-ASSISTED DEVICES

Vacuum-assisted sponge closure has been used in the setting of chronic esophageal perforations in stable patients. Porous sponge foam is cut to be just smaller than the defect and sutured to the end of a nasogastric decompression tube (Fig. 79.5). This is then grasped with endoscopic graspers and introduced into the defect. The nasogastric tube is then maintained on continuous external suction which minimizes secretions escaping through the defect while increasing blood flow to the area. Furthermore, the sponge induces granulation of the surrounding tissue and promotes healing. Sponges need to be changed every 2 to 3 days. Small defects with adjacent nonseptated fluid collections are more amenable to this therapy.

SURGICAL MANAGEMENT

Primary Closure

Primary closure of the perforation is the most frequently used and most preferable method of surgical treatment. The most important goals of a primary closure are debridement of all nonviable tissue and closure of the

esophageal mucosa and muscle in separate layers. Because the mucosal rent may extend beyond the muscular tear, the muscle layer should be incised to delineate the full length of the mucosal defect to allow complete closure (Fig. 79.6). The mucosal layer is repaired with interrupted absorbable sutures and the muscular layer with interrupted permanent sutures taking care not to narrow the esophageal lumen (Fig. 79.7). A nasogastric tube or endoscope is inserted above the suture line to permit a bubble leak test to be performed with the suture line submerged in saline. Absence of air bubbles indicates an intact suture line. The nasogastric tube is advanced across the repair site and positioned within the stomach.

Depending on the ease of closure and the quality of the esophageal tissue, reinforcement of the closure with healthy tissue flap may be added. If indicated, the lung is decorticated to ensure full reexpansion. A large caliber thoracostomy tube is positioned posterior in the chest cavity near the lateral boarder of the vertebral column to evacuate the pneumothorax, permit full lung expansion, reduce the risk of empyema, and manage any recurrent esophageal leak. For cervical or abdominal perforations, a Jackson-Pratt or Blake drain is positioned near the repair.

Reinforcement of Primary Closure

Reinforcement of the primary closure with well-vascularized tissue is recommended to reduce the risk of postoperative leakage in the cases of late presentation or delayed diagnosis (>24 hours). In cases where the muscle layer cannot be identified or cannot be closed, the mucosa should be securely closed and the reinforcement becomes mandatory.

Native tissues for reinforcement include a pleural flap in the cases with thickened pleura (Fig. 79.8), a pericardial fat pad flap, a diaphragmatic flap (Fig. 79.9), or an omental flap. The gastric fundus can be mobilized and used to cover the distal thoracic and abdominal esophagus (Fig. 79.10). The pectoralis major muscle or the sternocleidomastoid muscle can be used as a cover for the cervical esophagus (Fig. 79.11). Flaps constructed from the serratus, pectoralis major, and latissimus dorsi muscles have been used to close upper thoracic esophageal perforations. By and large, however, an intercostal musculopleural flap is the most commonly used tissue for reinforcement.

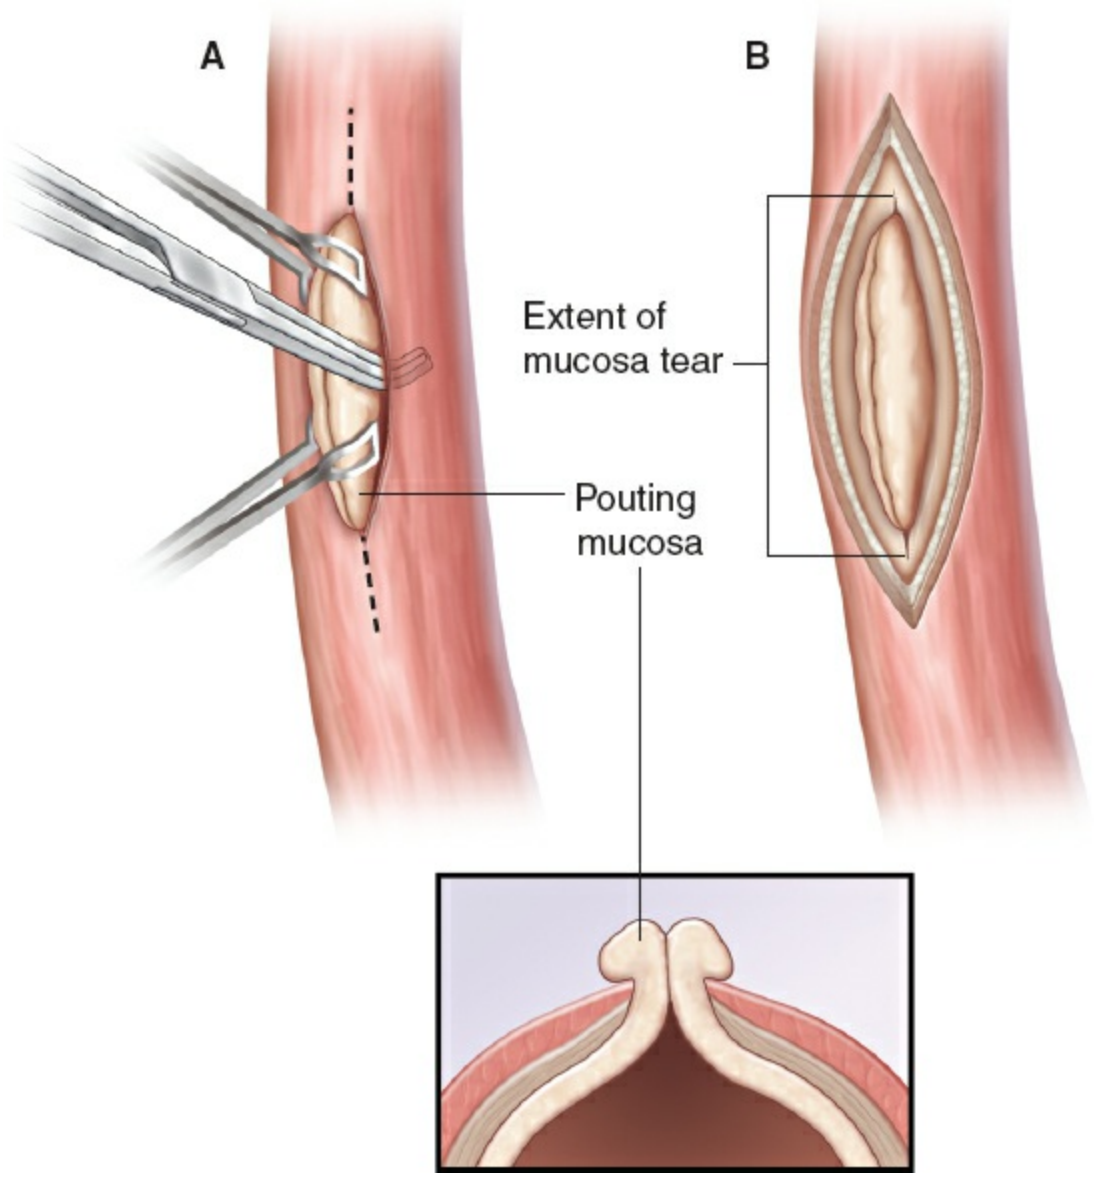

Figure 79.6. **A.** Mucosa pouting through the muscular defects is grasped with clamps. The proximal and distal esophageal myotomy is extended to visualize the full extent of the mucosal perforation. **B.** The entirety of the mucosal and submucosal perforation is visualized in preparation for debridement and closure.

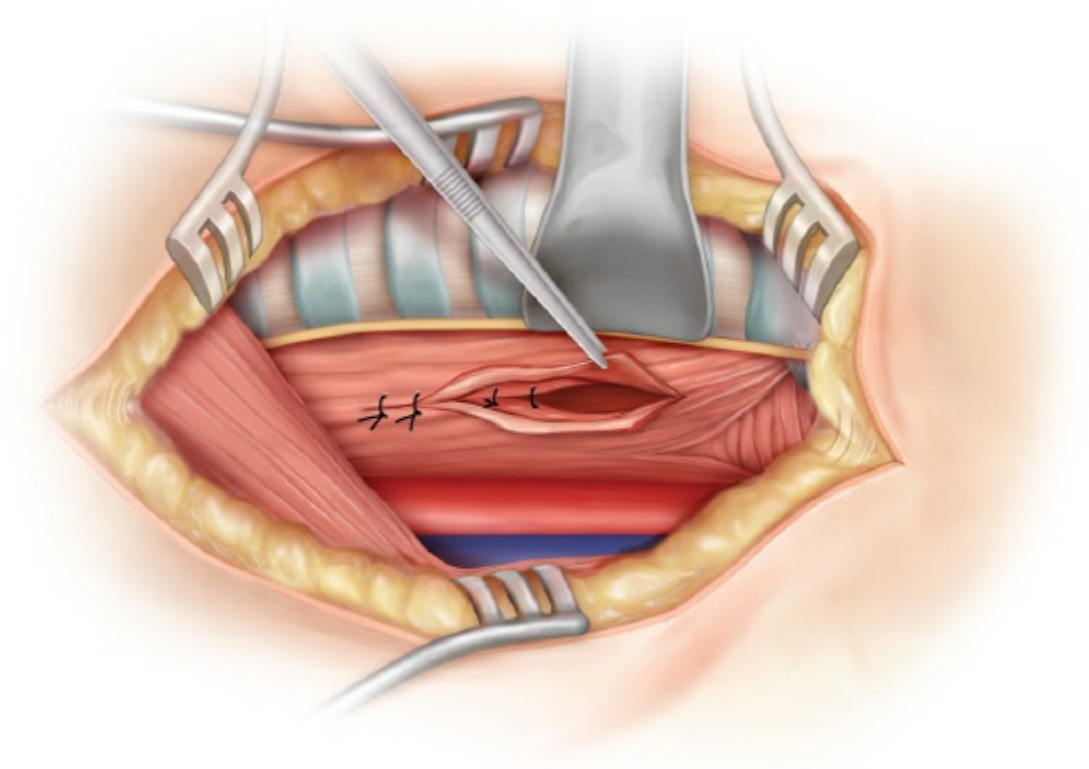

Figure 79.7. Primary repair of esophageal perforation in two layers of simple interrupted sutures. An inner layer of absorbable suture on the mucosa and an outer layer of permanent suture on the muscular layer.

If the procedure is being conducted as an open thoracotomy, the periosteum of the rib below the incision is incised and stripped from its upper border, and the periosteum, pleura, and the intervening intercostal muscle bundle with associated neurovascular bundle are then mobilized for the full extent of the thoracotomy incision (Fig. 79.12). To ensure the flap is of adequate length to reach the esophagus, an umbilical tape can be used to mark the distance needed for adequate length. To create a flap that terminates in a spatulated fashion, a generous width of pleura is resected anteriorly. The spatulated end ensures sufficient tissue coverage of a longer length of repair. The flap is transected anteriorly, is rotated posterior in the thorax, applied to the site of the esophageal repair, and carefully sutured to the muscle closure or muscle remnants (Fig. 79.13). The excess pleura is fixed to whatever mediastinal tissue is available to maintain the flap in position and prevent rotation.

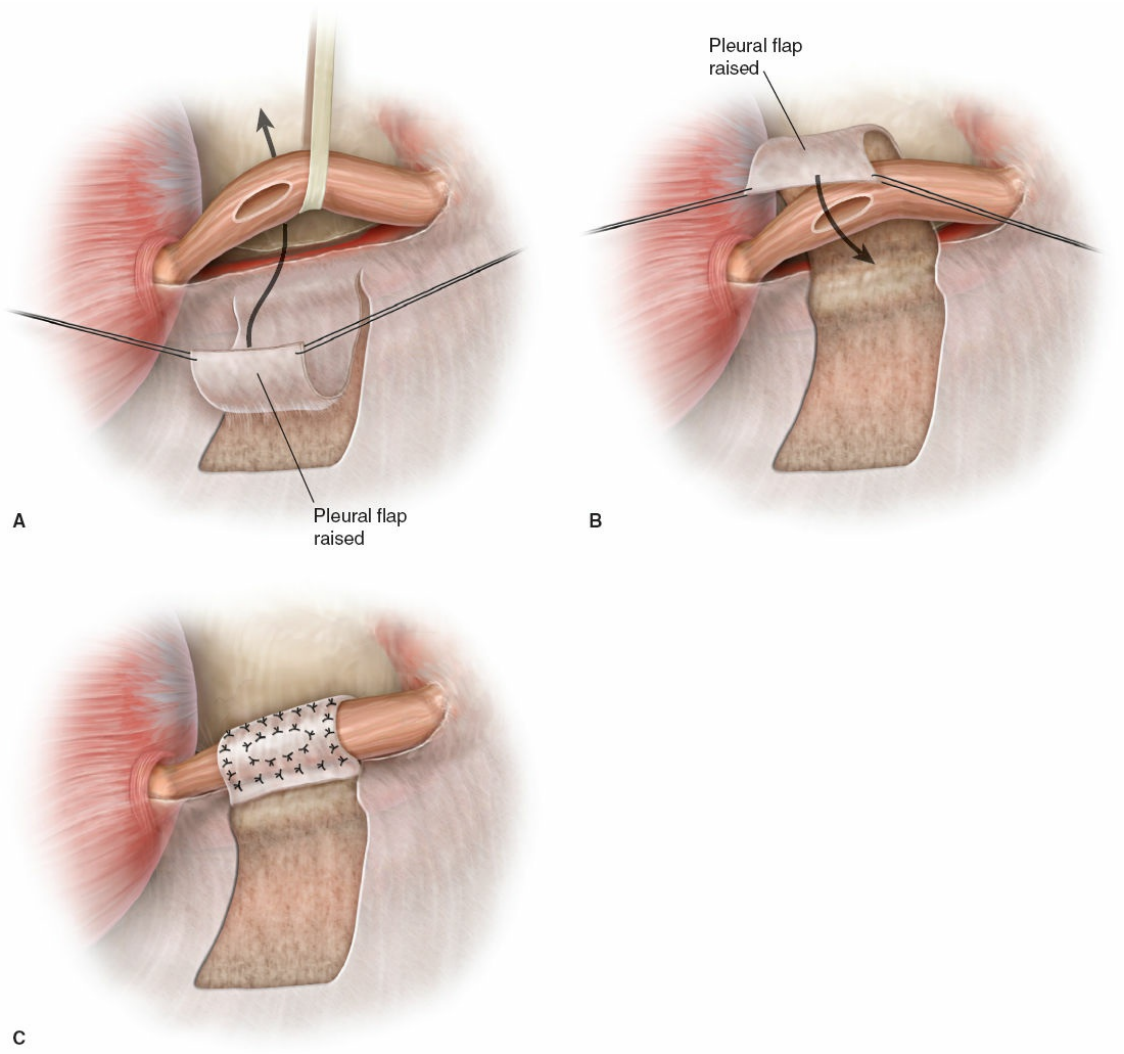

Figure 79.8. **A.** Mobilization of a parietal pleural flap for buttressing of a distal esophageal perforation. **B.** The pleural flap is wrapped around the perforated esophagus **C.** Numerous fine sutures are used to tack the pleural flap to the healthy esophageal muscle, isolating the perforation.

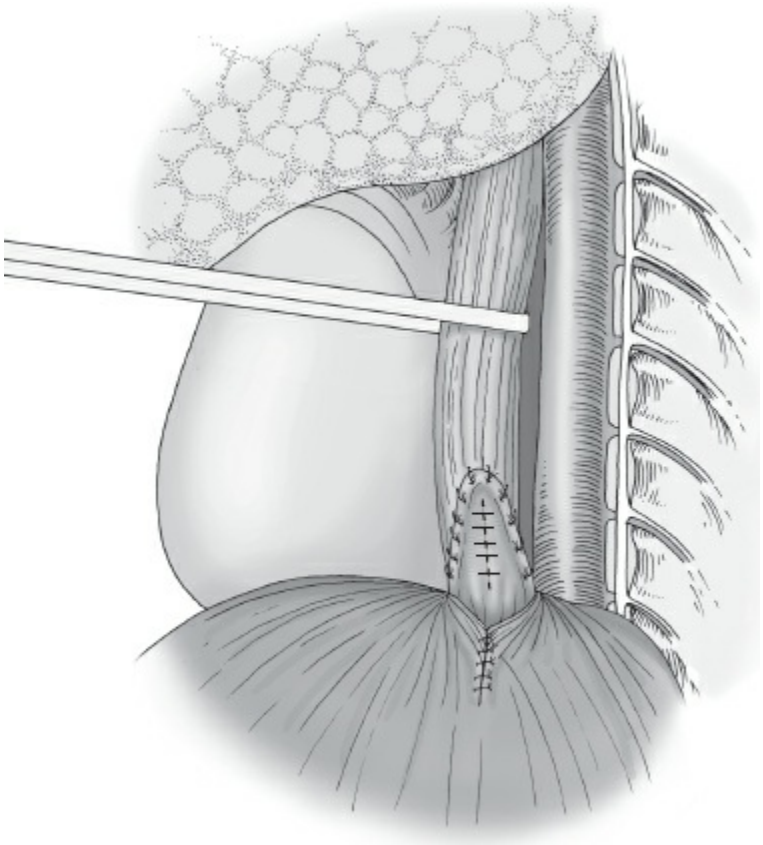

Figure 79.9. A diaphragmatic flap is prepared by cutting the diaphragm in a U-shaped fashion and then rotating the muscular flap to cover the repair site. The diaphragm is then closed linearly.

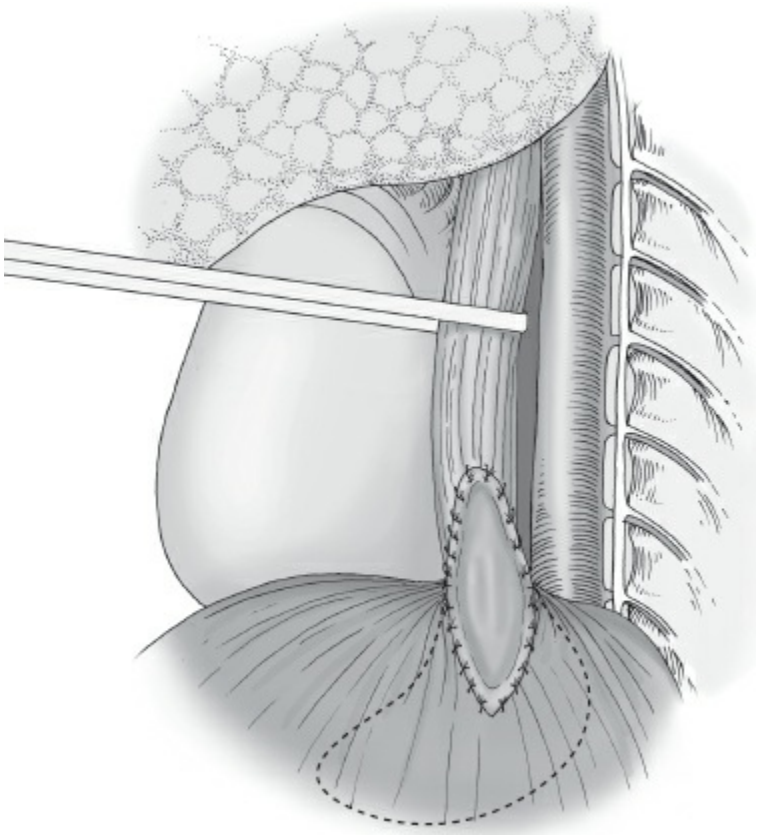

Figure 79.10. A gastric flap is created by ligation of the short gastric vessels and pulling the mobilized fundus through a diaphragm incision. The flap is then sewn to the esophageal repair site as well as the diaphragm itself.

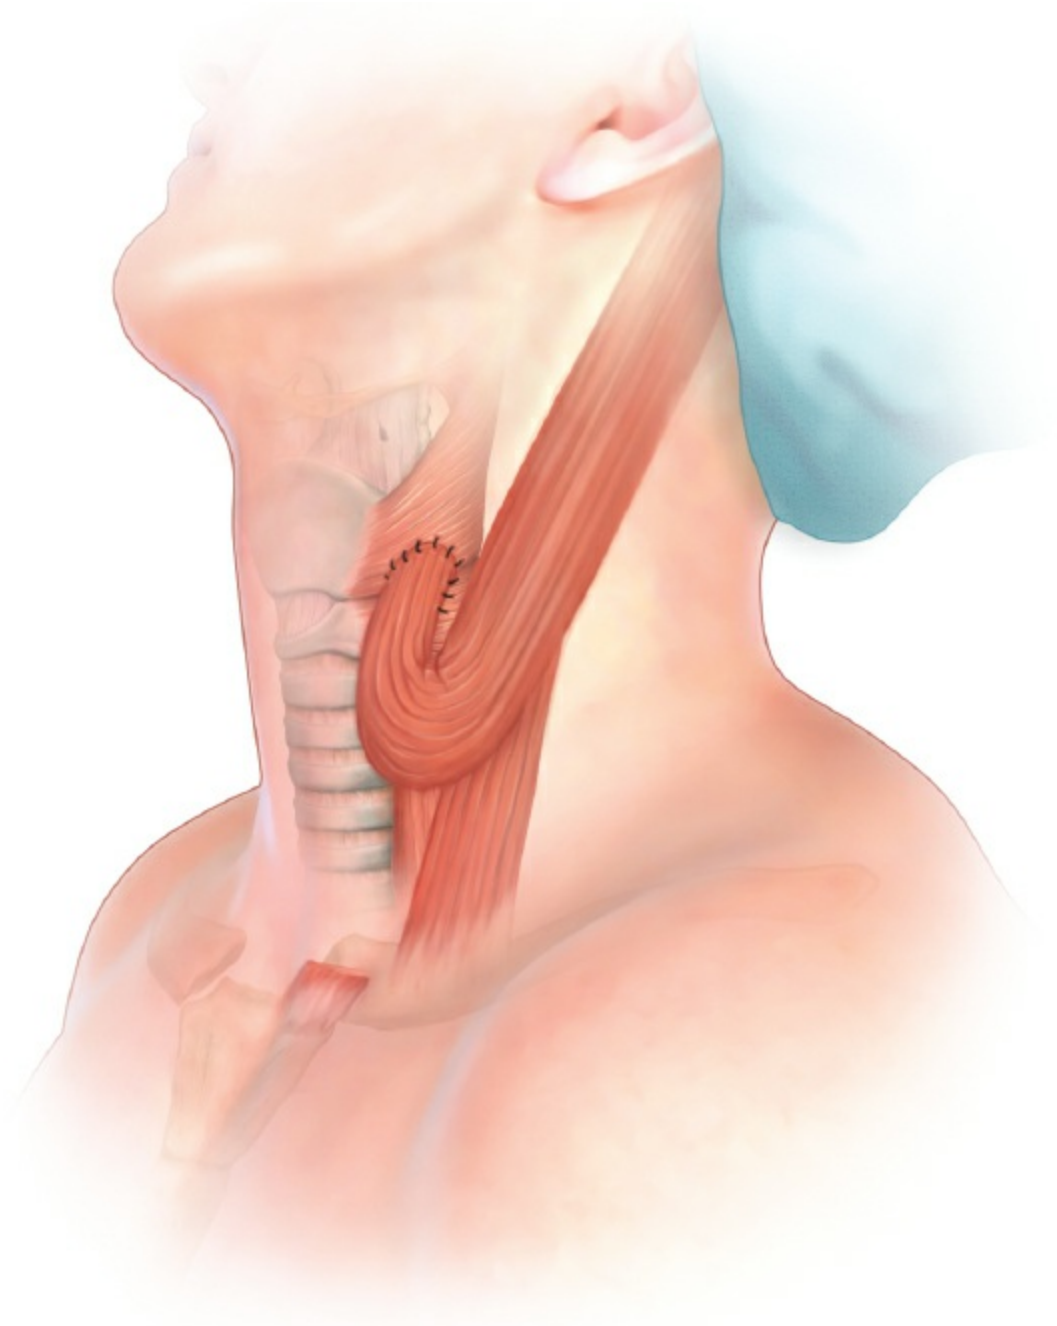

Figure 79.11. A sternocleidomastoid flap is created by detaching the medial head of the muscle from the manubrium, dividing the lower portion of the muscle and securing it to the repair site with suture.

Exceptions to Primary Closure

While primary repair of the perforation is the preferred management strategy, exceptions arise in which such a repair is not technically feasible and an alternative strategy must be employed. Such exceptions include (a) perforations able to be managed with drains alone (such as cervical

esophageal perforations that cannot be accessed surgically), (b) perforations too large to be primarily repaired but amenable to tube based repairs, and (c) perforations warranting an esophageal resection (such as perforated esophageal cancers, perforations in the setting of diffuse esophageal necrosis and/or mediastinal necrosis from alkali ingestion, or perforated end-stage achalasia).

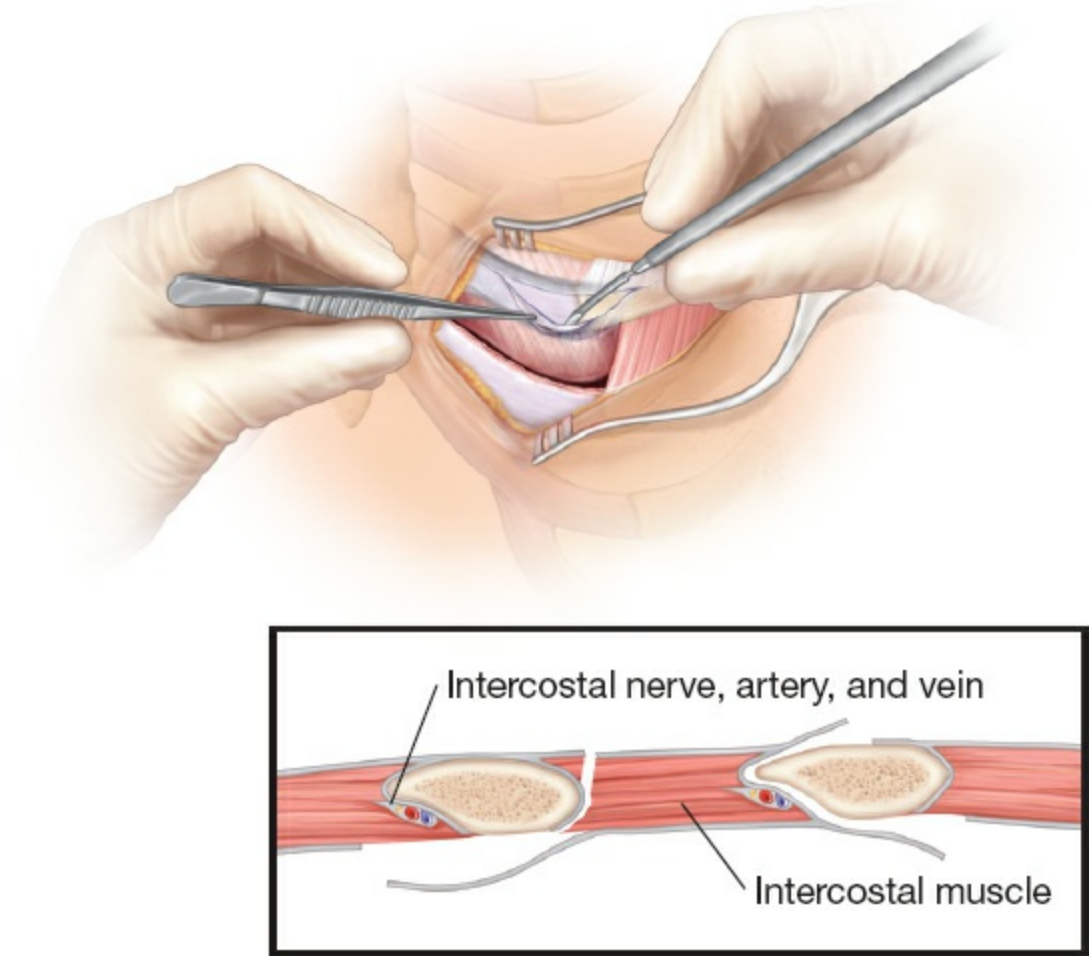

Figure 79.12. Dissection of intercostal flap. The intercostal muscles are dissected form the superior rib by removing the periosteum and following the lower border of the superior rib. Care is taken to preserve the neurovascular bundle with the flap as this is essential to flap viability. The dissection plan is depicted in the inset.

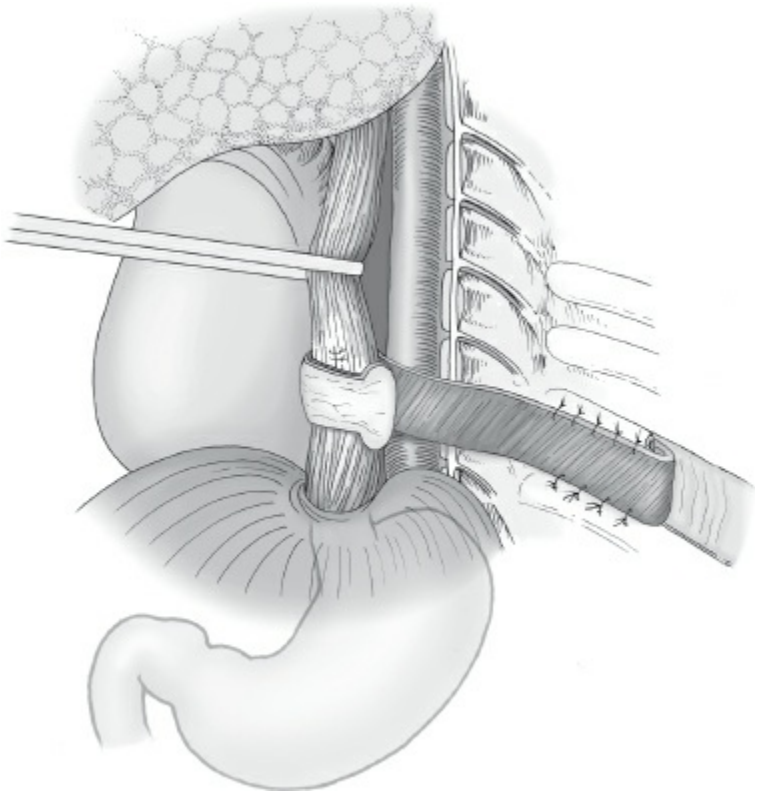

Figure 79.13. Once the intercostal muscle flap has been created, the neurovascular bundle is divided anteriorly and the muscle rotated to the posterior thorax. It is wrapped around the esophagus and secured with sutures to the repair site as well as the posterior pleura to prevent torsion or tension of the flap.

Drainage Alone

For cervical esophageal perforations not able to be completely accessed or visualized, drain placement alone may be sufficient because they can effectively evacuate the neck in a fashion not possible with thoracic or abdominal esophageal perforations (where the mediastinum, pleura or peritoneum are not able to be effectively drained). It is important to evaluate and treat any distal obstruction in such a circumstance.

T-Tube Drainage

In the event that mucosal closure cannot be accomplished in the thoracic esophagus, or if adequate tissue for reinforcement is not available, the perforation can be managed with a T-tube to convert the perforation into a controlled fistula. A large bore silastic tube is inserted into the perforation with short limbs positioned proximal and distal in the esophagus and the long limb traversing the pleural cavity and exiting the chest laterally (Fig.

79.14). A nasogastric tube can be passed through the luminal portion of the tube to aid in gastric decompression and prevent tube migration. The tube should be secured to the diaphragm in a position that keeps it from eroding into the aorta. Mediastinal and pleural drains should also be placed.

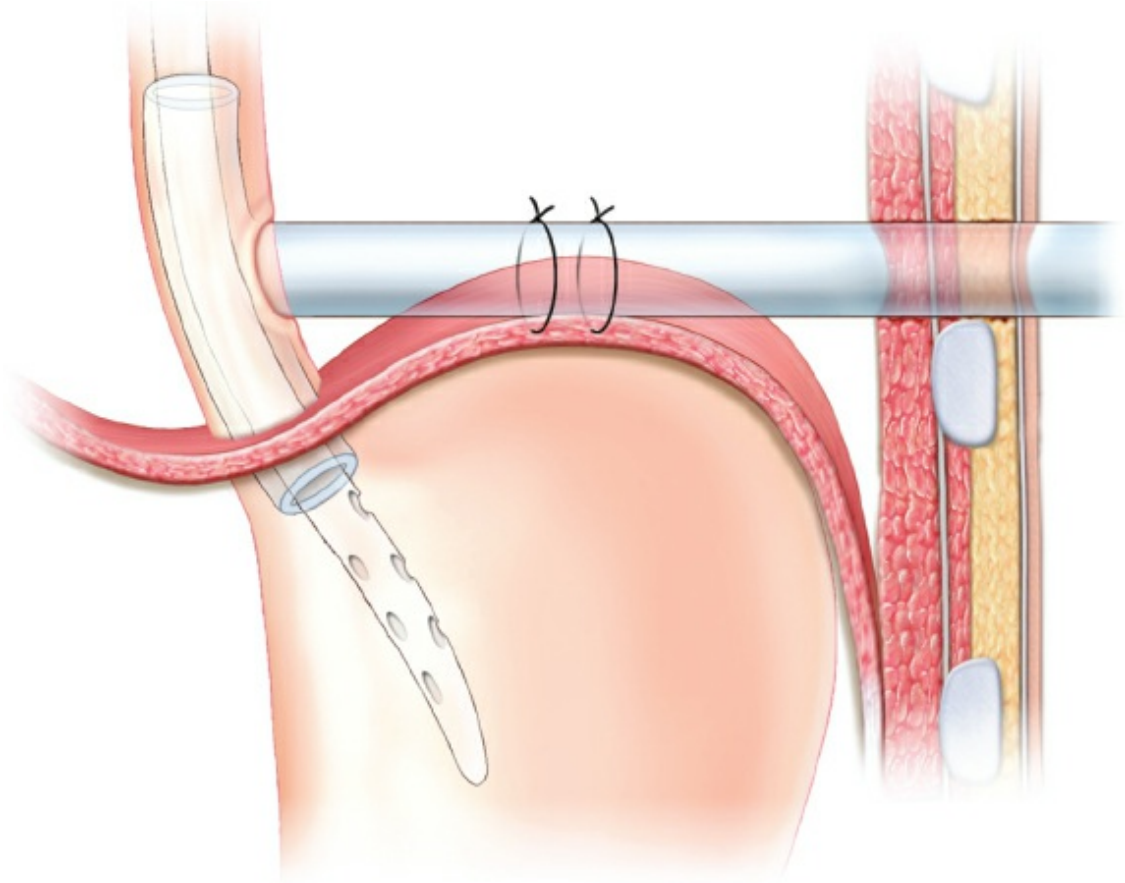

Figure 79.14. T-tube management of a large esophageal perforation. A silastic T-tube is introduced into the perforation with limbs running proximal and distal. The long end of the tube is lateralized through the thorax and secured to the diaphragm to prevent dislodgement and erosion. A nasogastric tube can be passed through the luminal portion of the tube to permit further gastroesophageal decompression.

Exclusion and Diversion

The exclusion and diversion method permits the management of complicated esophageal perforations without the need for esophageal resection. The method includes (1) primary suture of the perforation, (2) wide drainage of contaminated tissue, (3) creation of a loop or end-cervical esophagostomy (and drainage of the distal esophageal remnant), (4) closure of the gastroesophageal junction with temporary suture or staples

(without transection), and (5) creation of a gastrostomy and jejunostomy (Fig. 79.15). The disadvantage of this procedure is that it requires an end-to-end anastomosis of the esophagus in the neck 1 to 2 months after the diversion procedure, putting the patient at risk of a second major surgery. This method is therefore only indicated for the cases in which no other effective method is available and esophageal resection is not desirable. It should be an option of last resort.

Esophageal Resection

Esophageal resection is indicated for perforations associated with carcinoma or extensive necrosis of the esophagus that preclude any other method of management outlined above. A transhiatal or transthoracic approach can be used provided that adequate mediastinal and pleural debridement can be performed through the chosen approach. Reconstruction is performed immediately or, more typically, as a second stage procedure, depending on the patient's condition. The patient is generally left with an end cervical esophagostomy and gastrostomy. Reconstruction with a colon gastric conduit via the substernal or subcutaneous route is often best deferred for several months until mediastinitis has resolved and the patient is in stable, satisfactory condition.

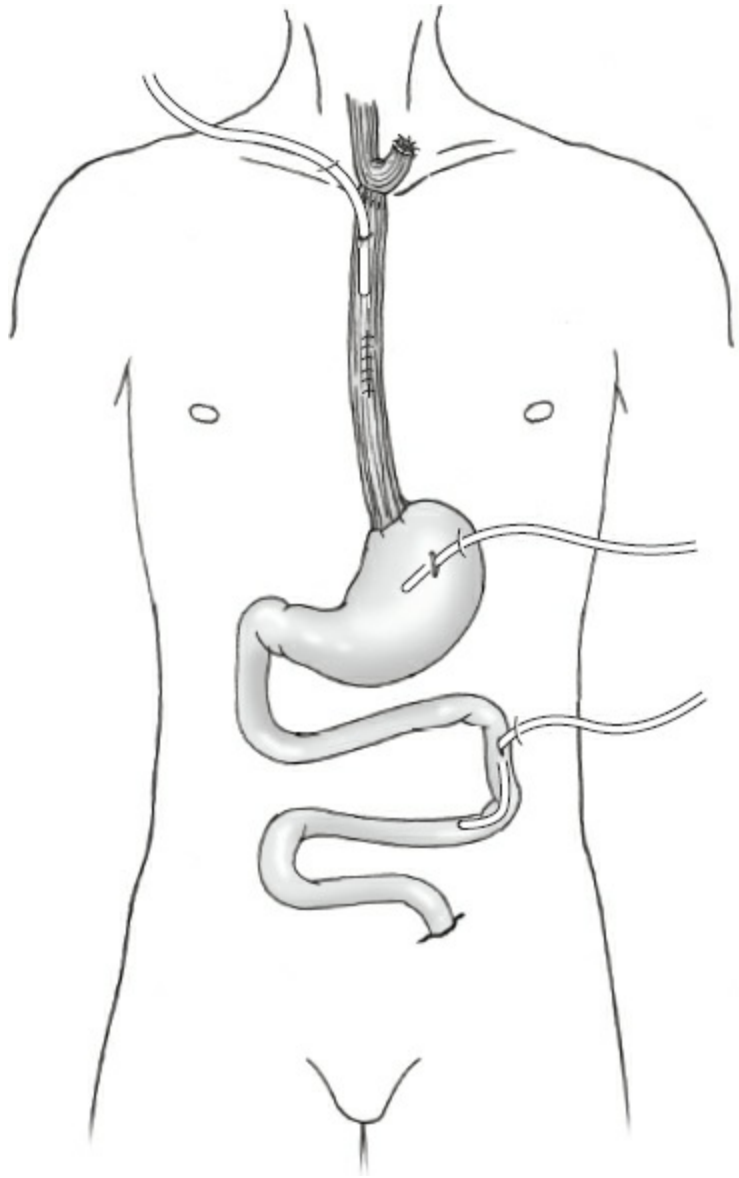

Figure 79.15. Esophageal diversion and exclusion includes (1) primary suture of the perforation, (2) wide drainage of contaminated tissue, (3) creation of a loop or end-cervical esophagostomy (and drainage of the distal esophageal remnant), (4) closure of the gastroesophageal junction with temporary suture or staples (without transection), and (5) creation of a gastrostomy and jejunostomy.

Enteral Feeding Access

After closing the chest or neck, the patient is placed in a supine position, and draining gastrostomy and feeding jejunostomy are performed via an open or laparoscopic approach. Gastrostomy prevents gastroesophageal reflux, and the jejunostomy is essential to maintain nutrition and facilitate healing. A gastrojejunal tube (for both decompression and distal feeding)

is an acceptable alternative.

POSTOPERATIVE CARE

Mechanical Ventilation

Postoperative mechanical ventilation is mandatory for the patients with sepsis who have compromised pulmonary function. Mechanical ventilation ensures that the lung remains fully expanded and adheres to the site of esophageal repair, and it may provide additional support. Elective use of mechanical ventilation and positive end expiratory pressure (PEEP) may be helpful in maintaining lung expansion.

Nutritional Support

Patients are generally kept NPO for a minimum of 5 to 7 days postoperative, and during this time their gastrostomy, jejunostomy, or nasojejunal tube should be used to provide enteral nutrition. If enteral access was obtained, the decision to obtain central IV access and begin parenteral nutrition depends on the surgeons concerns for a postoperative leak (i.e., the difficulty of the repair and the degree of contamination) as well as the patient's baseline level of nutrition before the perforation. In clinically stable patients, oral intake may begin following contrast imaging of the esophagus (typically a Gastrografin swallow study followed by thin barium) that fails to demonstrate leak.

Antibiotic Management

Broad-spectrum IV antibiotics should continue for 7 to 10 days postoperatively, but may continue longer based on the patient's clinical status.

Drain Management

Nasogastric tubes are typically removed following a negative upper GI swallow study. Drains placed around the primary repair site are maintained until the patient is tolerating an oral diet without evidence of leak. Tube thoracostomy is removed when there is no evidence of esophageal leak, empyema, or pneumothorax.

COMPLICATIONS AND THEIR MANAGEMENT

There are no large case series dealing with the overall type and frequency of postoperative complications. Smaller series report the following common complications.

Ongoing Leak

Ongoing (or recurrent) leak from the esophageal repair site is diagnosed clinically as higher than anticipated drain output. Fluid analysis will demonstrate salivary amylase within the drains. Controlled leak (without overt signs of systemic illness) can be managed conservatively with continued distal feeding, NPO status, and drain maintenance. While many leaks will close spontaneously with this regimen, an esophagocutaneous fistula can develop that requires delayed surgical intervention. As a result of this, stable patients with a persistent, controlled leak may undergo an attempt at endoscopic closure, stenting, or vacuum therapy as outlined above. Uncontrolled leak generally presents with signs of systemic infection and warrants ongoing antibiotics and potential urgent reoperative intervention for improved drainage or esophageal diversion/resection.

Stricture

Stricture formation following esophageal repair typically presents later (generally following recovery) with symptoms of dysphagia and can be managed with endoscopic dilation. The endoscopist should be aware of the location and length of the prior repair.

Mortality

The most common cause of death following esophageal perforation (and repair) is multisystem organ failure as a result of ongoing sepsis. Mortality rates are higher for spontaneous perforations than iatrogenic and traumatic (40% vs. 9% to 19%), higher for thoracic and abdominal perforations when compared to cervical perforations (30% vs. 6%), and higher for delayed diagnosis (>24 hours) when compared to early diagnosis (27% vs. 14%).

OUTCOMES

Nonoperative Management

Sarr et al. and Michel et al. used Cameron's criteria to nonoperatively manage perforations and reported mortality rates of 13% and 12.5%,

respectively. Using more highly selective patient criteria and close patient evaluation, some authors have reported a 100% success rate with nonoperative management. Nonsurgical treatment may therefore be indicated in specific situations.

Endoscopic Therapy

Haito-Chavez et al. examined a multicenter experience with OTSCs for full-thickness GI tract defects. Of the 48 patients with acute perforations they examined, 10 were in the esophagus. There were no technical device failures within this group, and they reported a 91.4% success rate of the primary OTSC therapy for all acute perforations (including esophagus, gastric, and colon).

Vacuum-assisted sponge devices have been used successfully in small esophageal defects. In one series of five patients with fluid collections related to a leak at an esophageal anastomosis, all five patients resolved their leak with vacuum-assisted sponge therapy. The median length of therapy was 28 days with nine sponge changes. Two of the patients developed stenosis at the anastomosis and one suffered from a fatal hemorrhage after a dilation procedure revealed an aortoanastomotic fistula.

Surgical Therapy

The largest reported cases series of esophageal perforation from Brinster et al. retrospectively evaluated 726 patients at the University of Pennsylvania from 1990 to 2003. The overall mortality rate of 18% was heavily influenced by the time to diagnosis, the location of the perforation, and the type of repair performed. Primary repair (without or with flap reinforcement) performed within the first 24 hours conferred a 96% survival rate.

EDITOR'S COMMENT

Pauli and Marks have written a very nice chapter on the modern management of esophageal perforation. One of the most interesting aspects of the current version of this chapter is how much has evolved compared to the previous version of the same chapter. Stents and endoscopic treatments of esophageal perforation have evolved as a viable treatment of many patients. Endoscopic closure of defects and even endoscopic vacuum therapy (EVT) is now described. With the evolution of Natural Orifice Transluminal Endoscopic Surgery (NOTES) techniques and technologies, it is likely that the options for nonsurgical management of upper GI perforations will continue to expand.

Per Oral Endoscopic Myotomy (POEM) for achalasia is an interesting and relatively new procedure where the mucosa of the proximal esophagus is opened, a submucosal tunnel is created, and a circular myotomy is performed. In some cases, either unintentionally or intentionally, a full-thickness transluminal myotomy is created. In these cases, the endoscopist surgeon finds him/herself in the mediastinum. These cases rarely result in significant postoperative morbidity despite the fact that this is essentially an iatrogenic esophageal perforation. It has been shown in previous studies that the interval between the occurrence of perforation and the diagnosis is predictive of morbidity and mortality. As endoscopic and endoluminal surgery becomes more commonplace (endoscopic full-thickness resection of early cancers, endoscopic bariatric and GERD procedures, etc.), we are likely to become more comfortable and experienced managing esophageal perforations without laparotomy or thoracotomy—especially in the iatrogenic cohort.

Attempts have been made to enhance decision making with regard to the optimal management of esophageal perforation by utilizing a perforation severity score (PSS). Schweigert et al. studied the PSS in a review of cases of esophageal perforation from 1990 to 2014. Low-, intermediate-, and high-score groups were identified. Out of 288 patients with esophageal perforation

presenting during the study interval, perforation-related morbidity, length of stay, frequency of operative treatment, and mortality increased with increasing PSS strata. Patients with high PSS were 3.37 times more likely to have operative management compared with low PSS.

A recent analysis of all the published case series reporting the use of metallic and plastic stents in the management of postoperative anastomotic leaks, spontaneous esophageal perforations, and iatrogenic esophageal perforations was conducted by Dasari et al. Primary outcomes assessed were technical success rates and complete healing rates. Secondary outcomes assessed were stent migration rates, stent perforation rates, duration of hospital stay, time to stent removal, and mortality rates. A total of 27 case series with 340 patients were included. Technical and clinical success rates of stenting were 91% and 81%, respectively. Stent migration rates were significantly higher with plastic stents than with metallic stents. Based on their analysis, the authors concluded that endoscopic management of esophageal anastomotic leaks and perforations with the use of esophageal stents is technically feasible, safe, and effective when performed along with mediastinal or pleural drainage.

Lazar et al. reviewed the use of endoscopic clips—through the scope and over the scope in the management of esophageal perforations. Thirty-eight articles including 127 patients were included. Based on their review, the authors felt that clips can be used in the treatment of early (<24 hours), iatrogenic, spontaneous esophageal perforations in the case of limited injury or contamination. “TTS (through the scope) clips are efficacious in the treatment of 10 mm lesions, while bigger (<20 mm) lesions can be treated successfully with OTSC (over the scope clips) clips, whose effectiveness is similar to that of surgical treatment.”

Vacuum sponge therapy is increasingly being recognized as a new promising method for repairing upper GI defects of different etiology. Vacuum-assisted closure (VAC) therapy relies on continuous or intermittent suction and drainage to decrease bacterial contamination, secretions, and local edema. At the same time, perfusion and granulation are promoted. Kuehn et al. reported their single center experience with EVT for substantial wall defects in the upper GI tract. Between 2011 and 2015, 126 polyurethane sponges were placed in the upper GI defects of 21 patients. The most frequent indication for EVT was anastomotic leakage after esophageal or gastric resection (n = 11) and iatrogenic esophageal perforation (n = 8). The median number of sponge insertions was five (range, 1 to 14) with a mean changing interval of 3 days (range, 2 to 4). Median time of therapy was 15 days (range, 3 to 46). EVT in combination with surgery took place in 9 of 21 patients (43%). A successful vacuum therapy for upper intestinal defects with local control of the septic focus was achieved in 19 of 21 patients (90.5%). Based on this experience, the authors concluded that EVT is a promising approach for postoperative, iatrogenic, or spontaneous lesions of the upper GI tract.

Iatrogenic perforations represent the most common etiology for esophageal

perforation and may occur at the time of an esophageal intervention such as nasogastric tube placement or endoscopic procedures. In patients with surgically altered anatomy (Roux-en-Y gastric bypass for example), the risk of esophageal perforation may be especially high. As the authors of this chapter comment, intra-abdominal esophageal injury related to foregut or hiatus surgery such as paraesophageal hernia repair, fundoplication, or Heller myotomy is likely the most common cause of esophageal perforation. Prevention of these injuries requires knowledge of the steps of each procedure most likely to result in an esophageal injury. During fundoplication, the risk of esophageal perforation is highest during passage of the esophageal bougie to calibrate the fundoplication. Careful passage of the bougie, visualization of the distal esophagus, and excellent communication between anesthesia and the surgeon are key factors to minimizing the possibility of esophageal perforation during bougie passage. Some authors even advocate abstaining from the use of a bougie to avoid this possibility entirely, although this practice is somewhat controversial. In a retrospective review of 1,200 foregut surgical procedures from a high volume center, 4.2% of patients experienced either a gastric or an esophageal perforation. The highest rate of perforation was in laparoscopic reoperative hiatal hernia repair (compared to Heller myotomy, primary fundoplication, and paraesophageal hernia repair). The most common mechanisms of perforations were suture placement for primary antireflux surgery, traction for paraesophageal hernia repair, and for Heller myotomy perforations were most likely to occur during the myotomy. Reoperative hiatal hernia repair perforations were most likely to result from dissection/wrap takedown (73%) and traction (14%). Perforations were recognized and repaired intraoperatively in most cases (84%). Perforations discovered postoperatively were more likely to require reoperation, to require more GI and radiologic interventions, and to have higher morbidity than perforations recognized intraoperatively. The authors of this study conclude that if perforations are recognized and repaired intraoperatively, they require minimal postoperative intervention. Unrecognized perforations usually require reoperation and result in significantly greater morbidity. Intraoperative endoscopy and a high index of suspicion for a possible perforation are necessary, especially in reoperative cases.

Esophageal perforation still remains a deadly complication, especially when recognized in a delayed manner. As endoluminal and transluminal foregut surgical technology and capabilities advance, it is likely that the options for managing esophageal perforation in a minimally invasive and effective manner will continue to evolve.

80 Repair of Esophageal Atresia and Tracheoesophageal Fistula

George W. Holcomb III

The earliest description of a baby with esophageal atresia (EA) has been attributed to William Durston in 1670. However, it was not until 1939 that a baby survived following operative intervention. On successive days in November 1939, two different babies in two different cities underwent an initial gastrostomy followed, at a later date, by esophageal substitution. The first successful primary repair was performed by Dr. Cameron Haight in Ann Arbor in 1941 through a left thoracotomy. The baby developed an anastomotic leak and stricture, but required only one esophageal dilatation. She stayed in the hospital for many months, but recovered uneventfully and led a normal life. Interestingly, she had a son who was born with EA and a distal fistula.

EA is really a spectrum of anomalies. A number of classification systems (Gross, Vogt, etc.) have been described. However, it seems best to describe the anomaly rather than classify it (Fig. 80.1). EA with an associated tracheoesophageal fistula (TEF) is the most common variant of the EA spectrum of diseases and occurs in about 85% to 88% of all EA cases. Isolated EA (without an associated TEF) occurs in about 7% to 8% of the cases. EA with a proximal fistula is found in 1% to 2% of the cases. The fistula is similar to the H-type TEF and starts proximally on the trachea and ends distally in the dilated proximal esophagus. EA with both a proximal and distal TEF is found in 1% or less of the cases. Although not technically part of the EA classification, an H-type TEF is considered part of the spectrum because these patients also have one or more associated anomalies related to the VACTERL syndrome (**V**ertebral, **A**tresias [GI tract], **C**ardiac, Tracheoesophageal [**TE**], **R**enal, **L**imb). This isolated TEF is usually located in the lower cervical region or upper thoracic cavity, and is almost always amenable to repair through a right cervical approach. The H-type TEF is actually the third most common of these anomalies.

ETIOLOGY

It remains controversial as to the exact etiology for the development of EA/TEF. Around the fourth week of gestation, the foregut begins to differentiate into a dorsal esophageal part and a ventral respiratory segment. Originally, it was felt that the ventral respiratory segment separates from the esophagus by the formation of lateral tracheoesophageal folds which fuse in the midline to create the tracheoesophageal septum. This separation of the trachea and esophagus is usually complete by 6 to 7 weeks of gestation. According to this theory, if there is incomplete fusion of these tracheoesophageal folds, a defective tracheoesophageal septum could develop with an abnormal connection between the trachea and esophagus. However, chick embryo studies have not demonstrated these lateral tracheoesophageal folds. Instead, cranial and caudal folds have been found in the region of the tracheoesophageal separation. According to a second theory, EA/TEF could develop due to an imbalance in the growth of these cranial and caudal folds. A third theory is based on a defect in intracellular signaling due to a deficiency in the sonic hedgehog (Shh) genes. In culture experiments, the fistula tract has been induced to branch by exogenous administration of the Shh signaling molecule and its receptor. These studies support the fistula as arising from the respiratory tract because the normal lung, but not normal esophagus, branches in response to the Shh signaling. Finally, from rat studies, a fourth theory postulates that EA/TEF might result from disturbances in either apoptosis or epithelial proliferation.

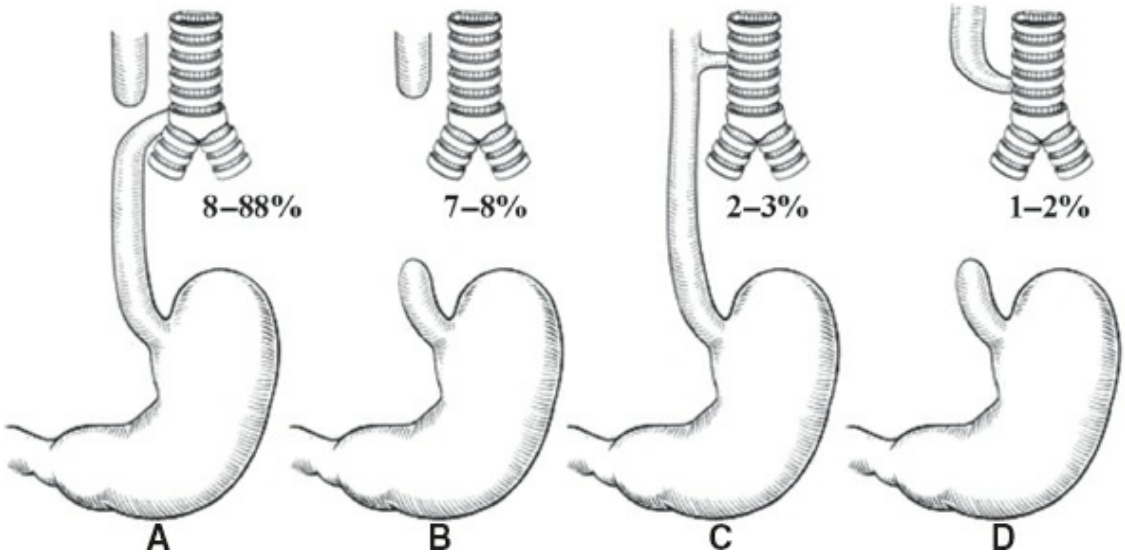

Figure 80.1. This schematic depicts the spectrum of anomalies seen in patients with esophageal atresia (EA) and

tracheoesophageal fistula (TEF). The incidence of each anomaly is also noted. The most common anomaly is EA with a distal TEF (**A**). Next in incidence is EA without a TEF (**B**). Third is an H-type TEF (**C**). EA with a proximal (but not distal) TEF occurs in about 1% of the cases (**D**).

EA is usually a sporadic occurrence. The incidence of EA/TEF is about 1 per 3,500 births. There appears to be a slight male predominance of 1.3. Among parents who have one affected child, the risk of another affected child is between 0.5% and 2%. In addition, the risk of a child with EA/TEF born to a mother or father with EA/TEF is 3% to 5%. A number of etiologic agents have been identified including medications such as progesterone and estrogen, maternal diabetes, thalidomide exposure, the use of methimazole in early pregnancy, and the prolonged use of contraceptive pills, among others. Also, chromosomal anomalies including Trisomy 18 and 21 have been identified in 5% to 10% of the cases. Finally, defects in three different genes have been found to be associated with EA/TEF.

CLINICAL PRESENTATION

On occasion, the diagnosis of EA with or without a fistula can be suspected antenatally. The two findings that can be attributed to EA on prenatal ultrasound (US) are the development of maternal polyhydramnios and an absent or small gastric bubble. However, as polyhydramnios and a small stomach bubble can be found in a number of other fetal anomalies, these findings are not specific for EA. Regardless, their association together does raise the possibility of EA in the fetus. Magnetic resonance imaging (MRI) is a relatively new modality for looking at fetal thoracic conditions. In one study looking at 10 fetuses that were thought to be at risk for EA on the basis of prenatal US findings, the MRI was 100% sensitive for the identification of the five EA/TEF babies.

Postnatally, the diagnosis is usually first suspected when the baby has feeding difficulties and a nasogastric tube cannot be passed into the stomach. In babies with known polyhydramnios or other stigmata of the VACTERL syndrome, a nasogastric tube should be inserted before feeding, thereby excluding the diagnosis of EA. If the nasogastric tube cannot be passed into the stomach, a plain radiograph is obtained. With EA, the tip of the catheter is usually visualized in the superior

mediastinum at the T2 to T4 level (Fig. 80.2). It is important to identify whether air is seen in the gastrointestinal tract, thereby indicating the presence of a distal TEF. A gasless abdomen would be seen in a baby with isolated EA (Fig. 80.3). Interestingly, there have been scattered reports describing a baby with EA and distal TEF with mucous occluding the distal fistula. In such a baby, the abdomen may be gasless on the initial plain radiograph.

As mentioned, the VACTERL syndrome is the strongest syndromic association with the entire EA spectrum of conditions. The frequencies of these associated conditions are as follows: vertebral (6% to 20%), atresias of the intestinal tract (10% to 15%), cardiac (15% to 35%), renal (5% to 15%), and limb (5% to 20%). EA has also been seen occasionally in patients with the CHARGE syndrome (**C**oloboma, **H**eart anomalies, **A**tresia of the choanae, **R**etardation, **G**enital hypoplasia, and **E**ar deformities).

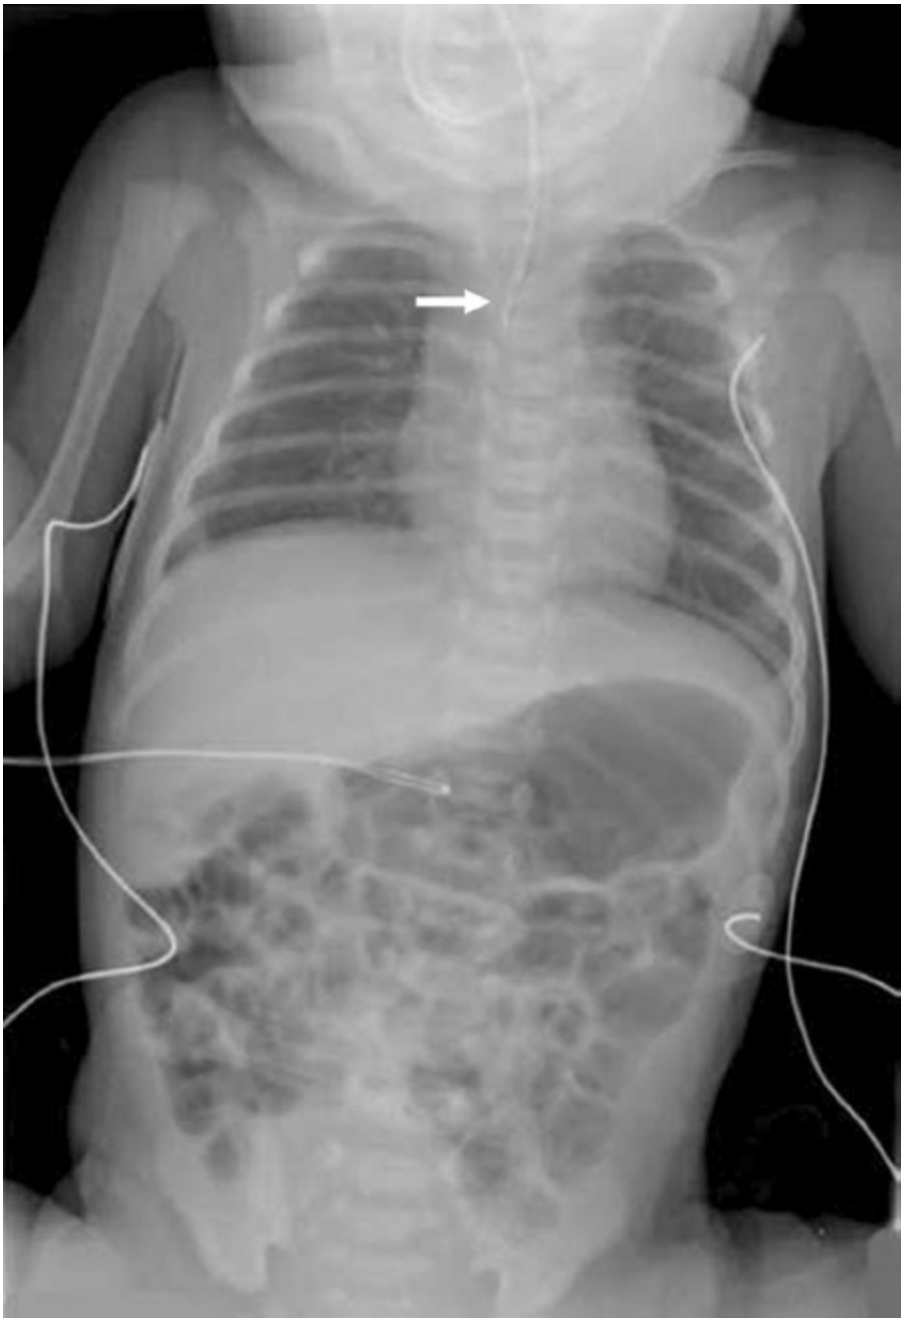

Figure 80.2. This baby developed coughing and feeding intolerance shortly after birth. A nasogastric tube was introduced, but could not be advanced past the upper thoracic esophagus (*arrow*). Air is noted in the stomach, small intestine, and colon. This is a classic radiograph for a baby with EA and a distal TEF.

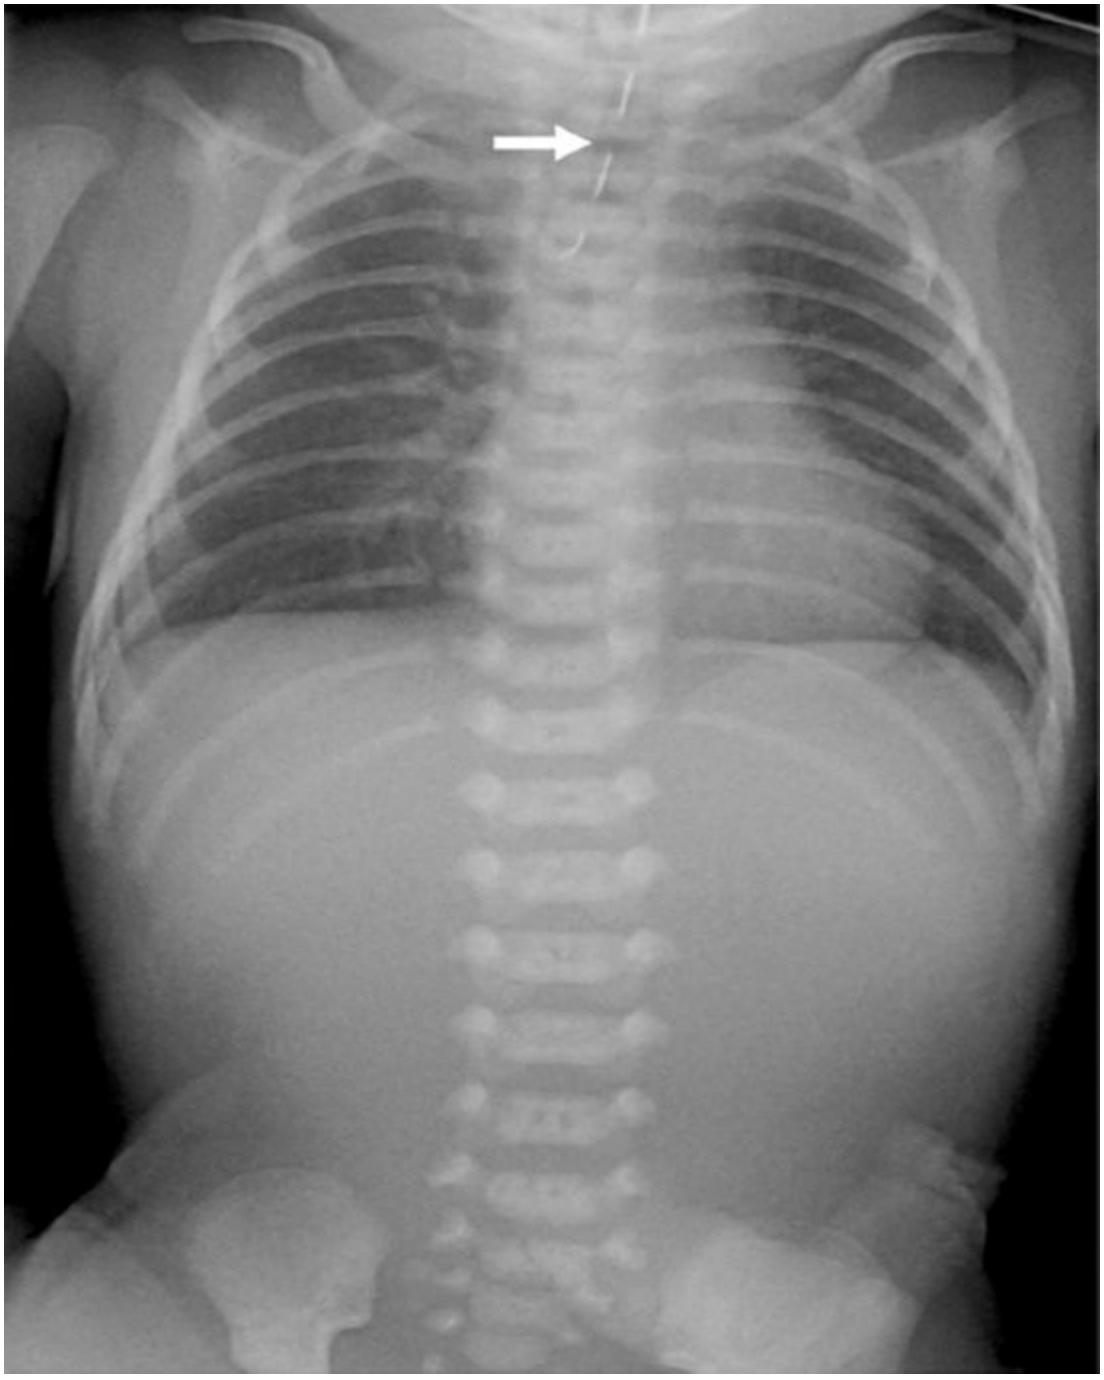

Figure 80.3. This baby has esophageal atresia without a distal fistula. Note the *arrow* is identifying the nasoesophageal tube in the proximal esophageal pouch. There is no air in the stomach or intestinal tract.

In a 2007 paper from our institution, we reviewed the incidence of the VACTERL association in 112 patients with EA anomalies seen between 1985 and 2005. There were 62 males and 50 females. In this review, 24.1% of the babies had vertebral anomalies, 14.3% had intestinal atresias, and 32.1% had cardiac anomalies, which was defined as an intrinsic heart

lesion other than a patent foramen ovale or patent ductus arteriosus. The most common cardiac condition was a ventriculoseptal defect (VSD) found in 22.3% cases. However, a VSD was found as an insolated condition in only 7.1% of the patients. Cyanotic heart disease was found in only 4.5% of the babies and all were tetralogy of Fallot. Of these 112 babies, renal anomalies occurred in 17% and skeletal in 16.1%. A distal TEF was found in 95.5% of these babies.

TABLE 80.1 Waterston Classification

Group	Criteria
A.	Birth weight over 2,500 g and well
B.	Birth weight 1,800–2,500 g and well, or any weight with moderate pneumonia or anomalies
C.	Birth weight <1,800 g, or any weight with severe pneumonia or anomalies

Several clinical classification systems have been developed over the past 65 years. In 1962, David Waterston proposed a classification system based primarily on the baby's birth weight and health status (Table 80.1). This classification is not currently utilized very much, but it was an important classification system during the time that the operative repair of babies with EA was being refined. The Montreal classification system improves upon the Waterston system and accounts for the severity of associated congenital anomalies and any respiratory disease. In this system, birth weight is not a significant factor for mortality, but the need for preoperative ventilation is a factor (Table 80.2). In 1994, Spitz proposed that birth weight and significant congenital heart disease are the major factors associated with mortality (Table 80.3). This classification system may be the most reliable for predicting prognosis for babies with EA and distal fistula. Recently, an updated prognostic classification system from surgeons at Great Ormond Street Hospital for Children makes a prognostic distinction between babies with cardiac disease and low birth weight.

TABLE 80.2 Montreal Classification

Group	Criteria
I.	No ventilator dependence, with minor or major anomalies; or ventilator dependence and minor anomalies
II.	Ventilator dependence, with major anomalies; or life-threatening anomalies regardless of pulmonary status

TABLE 80.3 Spitz Classification

Group	Criteria
I.	Birth weight >1,500 g without major cardiac disease
II.	Birth weight <1,500 g, or major cardiac disease
III.	Birth weight <1,500 g and major cardiac disease

PREOPERATIVE PLANNING

Once the diagnosis is made, further workup for VACTERL associations is important. In addition to the physical examination that may identify anorectal or limb anomalies, renal and spinal US are necessary. Also, a cardiac echo or thoracic US should be performed to try to identify the location of the aortic arch, as the operative approach ideally should be on the side opposite the aortic arch. In approximately 5% of the babies, the aortic arch will descend on the right side, making a right thoracic approach much more difficult. In such a patient, a left thoracic approach should be considered.

In a term baby, EA or EA/TEF is rarely an emergency and there is usually adequate time to complete the preoperative workup and plan the operative approach. However, in the preterm infant with EA and distal TEF and with respiratory distress syndrome requiring mechanical ventilation, the sudden inability to ventilate the baby can be encountered due to the preferential flow of the ventilated gas through the endotracheal tube (ETT), down the trachea, and out through the TEF. This flow pattern

results in poor pulmonary inflation and abdominal distention, both of which inhibit adequate ventilation. Gastric and duodenal perforations have been described. In such cases, a variety of maneuvers have been successful, including immediate gastrostomy with placement of the tube to underwater drainage, immediate thoracotomy with ligation of the fistula, and attempted placement of a Fogarty balloon past the ETT and into the fistula, thereby occluding it. Isolated case reports on the management of babies with this complication can be found in the literature.

While the infant is awaiting operation, it is important to prevent complications resulting from aspiration. The baby should be placed in a head-up position and tilted to one side. Also, it is important that the nasoesophageal catheter is on constant suction. Finally, the baby's mouth and pharynx should be suctioned as necessary, as not all the oral and esophageal secretions will be removed via the nasoesophageal catheter. If the baby requires intubation and ventilation, gentle low pressure ventilation is essential. If the fistula has to be ligated emergently (but is not divided), a delayed primary anastomosis should be performed within 10 to 14 days, as recanalization of the distal fistula is likely to occur.

Preoperative discussion with the anesthesiologist is very important, especially if a thoracoscopic approach is planned. The most important aspect for thoracoscopic repair of EA/TEF is adequate visualization. Impaired visualization often occurs due to the lung being overinflated with traditional ventilation. Also, the anesthesiologist (or anesthesia resident in a teaching hospital) may have limited experience with these cases and fail to understand the importance of low pressure, low volume ventilation to reduce the lung inflation. Moreover, hypercarbia can easily develop. To counteract the problem of lung inflation, CO_2 insufflation has been utilized as a positive pressure maneuver to decompress the lung to allow an optimal view. However, this is not always successful in keeping the lung deflated. Over the past several years, our group has utilized the high-frequency ventilator (HFV) in the operating room for ventilation in the babies undergoing the thoracoscopic approach. With the use of the HFV and proper positioning of the ETT, the lung remains deflated and an adequate operating space is created. Also, the duration of the operation is not as important because the oscillating ventilator is able to remove the CO_2 very efficiently and hypercarbia is not common. Assuming a healthy 3- to 3.5-kg infant, the initial settings are a mean airway pressure of 13 to 15 cm H_2O, a ΔP of 30 to 35, and FiO_2 of 70%. This can usually be

weaned to 40% or so after 10 to 15 minutes. The major problem with using the HFV is with the movement (shaking) of the baby during the ventilation, but this is something that the surgeon becomes accustomed after the first few cases. The Hertz is usually set initially at 11 to 13 but can be decreased to 8 to 9 if the baby is shaking too much (1 Hz is defined as 60 breaths/s). With this background, we rarely perform these operations on the weekend or at night, as our respiratory therapists are routinely involved with management of the HFV in the operating room.

The open operation for EA/TEF was utilized exclusively until 1999 when Lobe and Rothenberg reported their experience in Berlin with thoracoscopic repair in a 3-month-old infant at the time of the annual IPEG meeting. This infant had EA without TEF. At the following year's IPEG meeting, Rothenberg described the thoracoscopic repair of EA/TEF in a newborn. Soon thereafter, other experienced pediatric surgeons began to utilize this approach and retrospective reports followed.

The major advantage of the thoracoscopic approach is the avoidance of musculoskeletal sequelae such as winged scapula, breast deformities in females, spine deformities, and limitation in arm/shoulder abduction. However, this approach can be difficult. It is quite applicable in straightforward cases with a short distance between the two esophageal ends. In my experience, it can safely be utilized in about 75% of newborns with EA/TEF.

SURGICAL TECHNIQUE—THORACOSCOPIC APPROACH FOR EA/TEF

The baby is positioned supine on the operating table and the oropharynx is suctioned. It is my preference to perform a preoperative bronchoscopy for the purpose of identifying the site of the distal fistula. Others may perform a bronchoscopy to exclude a proximal fistula. However, only a very small percentage (1% to 2%) of these babies has a proximal fistula. By knowing the location of the distal TEF, the surgeon has a better understanding of the gap length between the two esophageal segments and where the distal fistula inserts into the trachea. For instance, if the fistula is identified entering the carina (Fig. 80.4), the gap length between the distal and proximal segments could be relatively large (up to 3 to 4 cm). On the other hand, if the fistula is seen to enter the mid-trachea, the gap length will likely be much shorter. The distance between the two esophageal segments will also depend on how caudal the proximal esophageal pouch extends.

This bronchoscopy takes less than 5 minutes and can provide important information to the surgeon performing the repair.

Following bronchoscopy, the baby is intubated and placed in the left lateral decubitus position (assuming the aortic arch is on the left side). The position of the ETT is not as important if HFV is being utilized, although, optimally, the ETT is not in the fistula or right mainstem bronchus. However, if conventional mechanical ventilation is employed, it is best to position the ETT distal to the origin of the fistula (if possible). This is more easily accomplished when the TEF originates in the mid-trachea. However, with the TEF originating at the carina or close to it, the slightest movement of the ETT may cause its tip to enter the distal fistula or one of the mainstem bronchi.

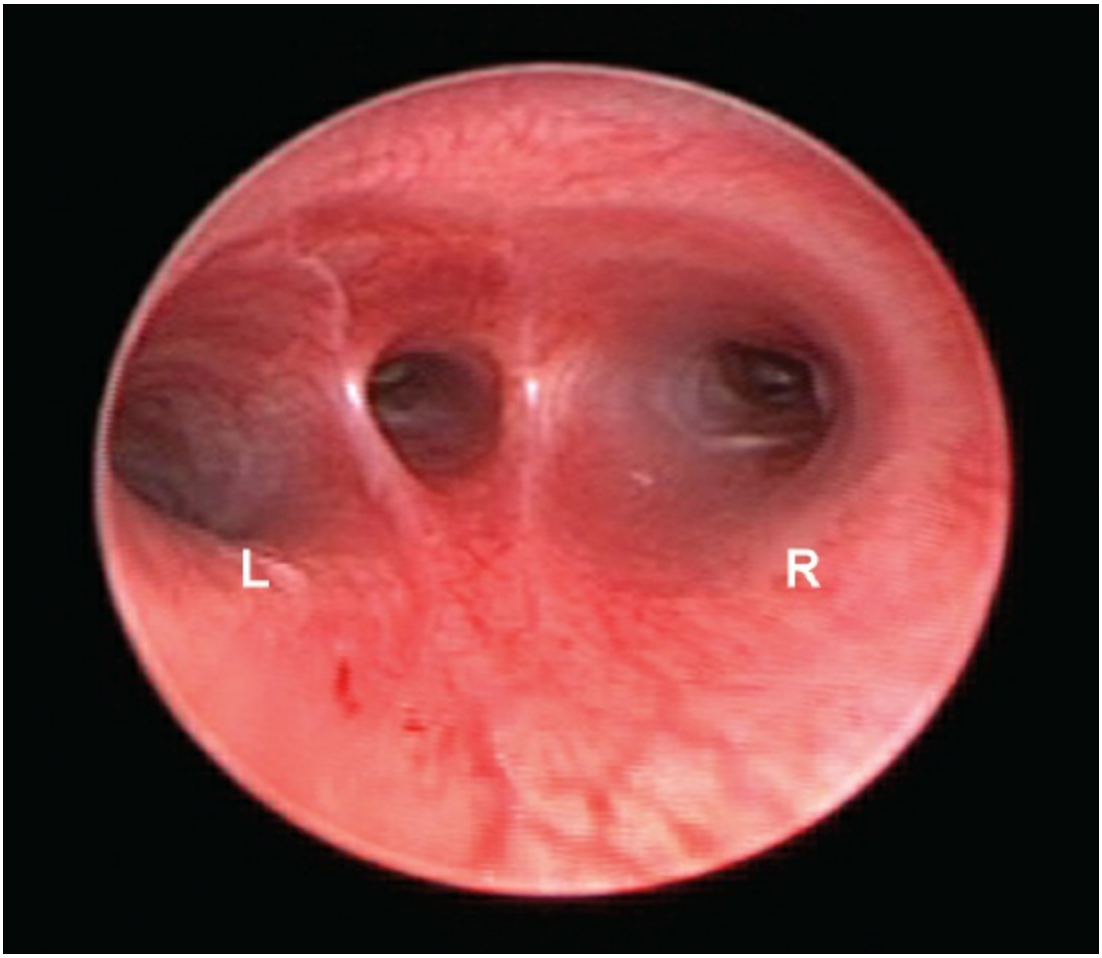

Figure 80.4. Bronchoscopy is often helpful for identifying the location of the distal fistula which allows the surgeon a better understanding of the expected gap length between the two esophageal segments. In this baby, the fistula is seen entering the carina which indicates that there could be a relatively large gap length between the proximal and distal esophageal

segments. R, right mainstem bronchus; L, left mainstem bronchus.

After positioning the baby in the left lateral decubitus and slightly prone position (assuming a left aortic arch) close to the left edge of the operating table, a small roll is placed under the shoulders and left flank to enhance the right intercostal spaces. A 12- to 14-Fr silicone catheter is introduced through the baby's mouth and into the upper esophageal pouch. The table is tilted slightly to the left and in reverse Trendelenburg. The surgeon will stand on the left side of the table with the camera operator to his/her left. The scrub nurse is usually opposite the surgeon at the level of the camera operator. The monitor is situated opposite the surgeon for optimal viewing (Fig. 80.5A). The first cannula is usually introduced at approximately the eighth intercostal space in the posterior axillary line. This 5-mm port is inserted using a cutdown technique, and the cannula with a blunt trocar is gently advanced into the thoracic cavity. This cannula will be used for insertion of the telescope attached to the camera. With the high-frequency oscillator, only a small amount of CO_2 insufflation (1 to 2 L/min at a pressure of 3 to 5 mm Hg) is needed to decompress the lung. A 45-degree or 70-degree, 4-mm telescope is then introduced through this cannula and the thoracic cavity visualized. At this point, the surgeon can decide the optimal location of the two working instruments which he/she will utilize for the operation. Through stab incisions, these 2.7-mm instruments generally are introduced at the fourth and fifth or fourth and sixth intercostal spaces in the mid- to posterior axillary line. If needed, a fourth stab incision is made posteriorly and inferiorly at the 10th or 11th intercostal space through which another instrument can be introduced for additional lung retraction (Fig. 80.5B).

Generally, the azygos vein is well seen as is the proximal esophageal pouch with the silicone catheter in it (Fig. 80.6). If it is difficult to see the pouch, the anesthesiologist is asked to gently manipulate the silicone catheter. This maneuver will usually identify the proximal pouch. Distally, the TEF has been identified preoperatively by bronchoscopy, so the surgeon has a good idea of its site of communication with the trachea. Also, if conventional ventilation is being used, the fistula can often be seen to distend with each ventilating breath. This is not as apparent with the oscillating ventilator. If needed, the azygos vein is ligated and divided with cautery, which aids in identifying the fistula. If ligation/division of the

vein is not needed, it is left intact as it will often lie between the fistula ligation site on the trachea and the subsequent esophageal anastomosis. The pleura overlying the fistula is opened and the fistula is gently identified and mobilized (Fig. 80.7). Care should be taken to protect the vagal nerve fibers which are usually seen coursing along the trachea and fistula.

After definitive identification of the TEF, it is helpful to better identify the proximal esophageal pouch to gain a further understanding of the amount of proximal pouch mobilization that will be required in preparation for the esophageal anastomosis. If the two esophageal segments are in close proximity to each other, very little dissection of the proximal or distal esophageal segment is needed. However, often the two segments are widely separated and the proximal pouch needs to be dissected to the thoracic inlet in order to gain esophageal length. This can be performed in a variety of ways. We prefer the use of cautery to gently mobilize the proximal pouch, taking great care as the proximal esophagus is intimately adherent to the membranous trachea. In one case, dense adherence between the proximal esophageal pouch and trachea was encountered. The reason for this dense connection was unclear at the time. Postoperatively, it was realized that this was the site of a proximal TEF. Therefore, if the dissection between the proximal pouch and trachea is unusually difficult, a proximal fistula may be present and should be evaluated in the postoperative period if respiratory problems develop.

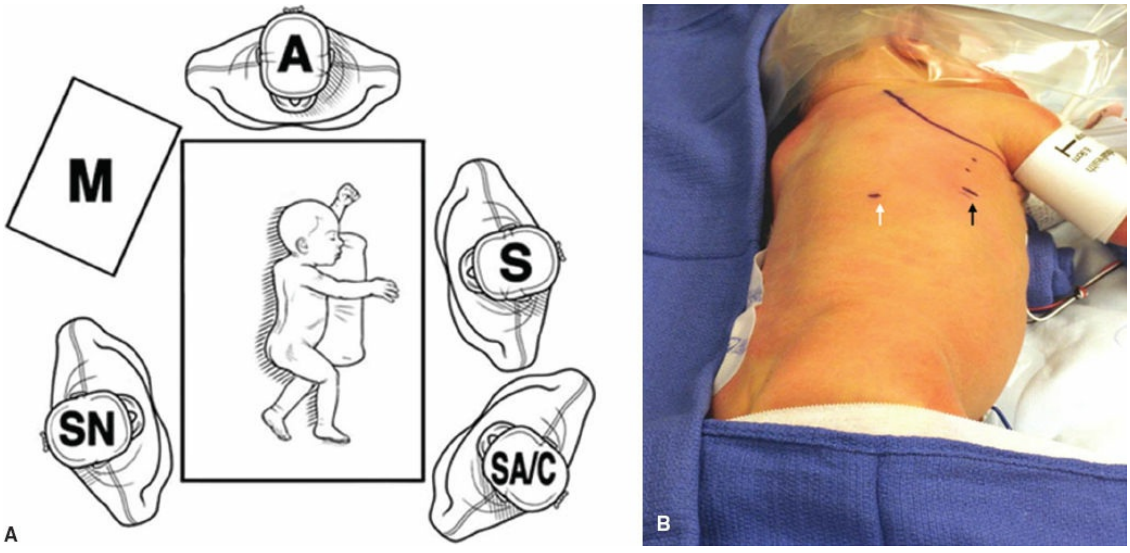

Figure 80.5. A. The location of the operating personnel and monitor is depicted at the left. The surgeon (*S*) stands on the left side of the table with the surgical assistant/camera operator

(*SA*/*C*) to his/her left. The scrub nurse (*SN*) is usually opposite to the surgeon at the level of the camera operator. The monitor (*M*) is situated opposite the surgeon for optimal viewing. *A* is the anesthesiologist. **B.** On the right, the baby has been positioned in a left lateral decubitus and slightly prone position. The location of the ports/instruments is depicted. Also, the inferior border of the scapula has been marked. The initial port (*black arrow*) is introduced using a cutdown technique and a 5-mm cannula with blunt trocar will be gently advanced into the thoracic cavity. This will be the site for insertion of the angled telescope. Above this site are two small marks which represent the stab incisions for the two working instruments for the surgeon. If needed, a retracting instrument can be introduced through a posteriorly and inferiorly created stab incision (*white arrow*).

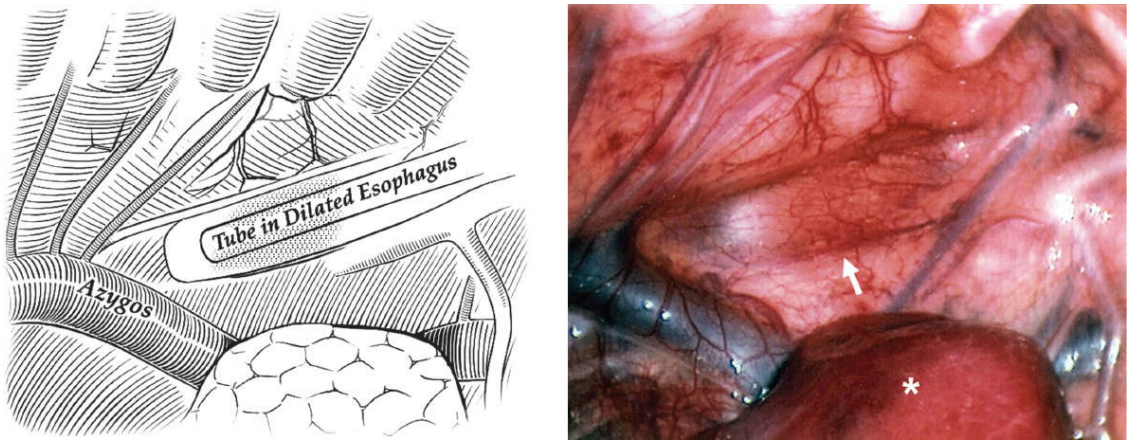

Figure 80.6. The schematic (**left**) and intraoperative photograph depict the creation of adequate intrathoracic working space with lung deflation (*asterisk*), achieving a nice view of the thoracic cavity. A red rubber catheter has been inserted in the proximal pouch (*arrow*) which aids in its identification. Note the azygos vein coursing to the superior vena cava. Just beneath this vein is the typical location for the distal esophagus entering the trachea.

Once the proximal esophagus has been mobilized and is ready for the anastomosis, the distal fistula is ligated and divided. It is not ligated and divided earlier because the distal esophageal segment will often retract into the retropleural tissues during the dissection of the proximal pouch and can, on occasion, be difficult to find. Therefore, we prefer to mobilize the proximal esophageal pouch prior to ligating and dividing the distal fistula in a baby who is stable.

The fistula can be divided in a number of ways. A nonlocking metal

clip (Fig. 80.8) or a locking polymer clip (Hem-O-Lok, Teleflex Medical, Research Triangle Park, NC) can be utilized to ligate the fistula. Also, the fistula can be divided and the trachea closed with one or two silk or Vicryl (Ethicon Inc, Somerville, NJ) sutures. We have utilized all of these techniques. Transmigration of the metal clip may have led to a recurrent fistula in one case, so we prefer either the locking plastic clip or suture closure of the tracheal side of the fistula. Others have used the metal clip without problems.

Once the fistula is divided, the esophagoesophagostomy is performed in a similar fashion to the open operation. Ideally, the posterior row of sutures are placed and tied after all the posterior sutures have been introduced. At times, however, it is easier to tie the sutures individually. We prefer to tie the sutures intracorporeally, whereas others utilize an extracorporeal technique. Also, our preference is to use silk for the anastomosis, but others prefer polydioxanone (PDS; Ethicon Inc, Somerville, NJ) or Vicryl. In another 2007 report from our institution, we found that the suture material does not have an impact on either the development of an anastomotic leak or the need for subsequent esophageal dilation. Once the posterior row of sutures are tied, a 6-Fr tube (Fig. 80.9) is inserted through the infant's nares, across the esophageal anastomosis, and into the stomach. We find this stent useful for a variety of reasons including the ability to feed the baby through it if desired. The anterior portion of the anastomosis is then completed in an interrupted fashion (Fig. 80.10).

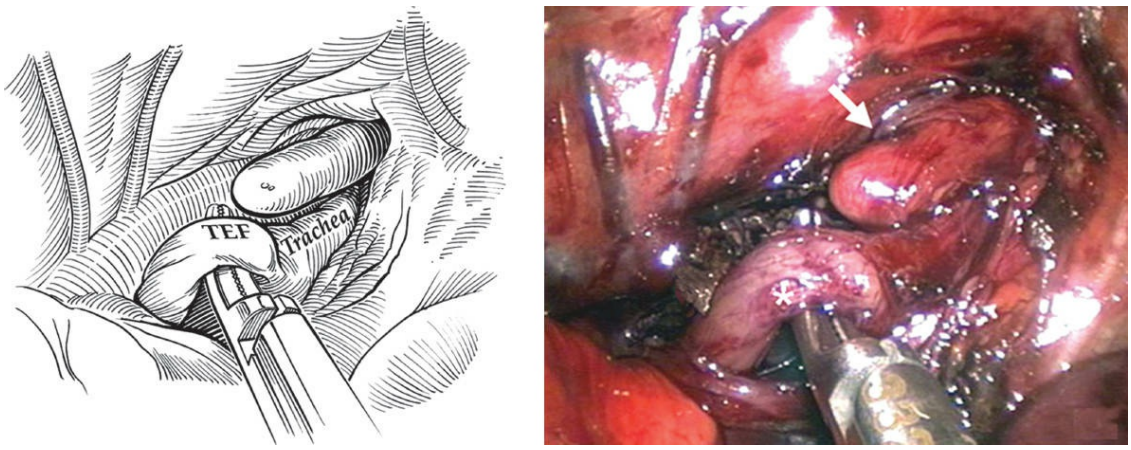

Figure 80.7. In this drawing (**left**) and operative photograph, the distal esophagus (*asterisk*) has been identified and is being encircled just distal to its insertion on the trachea. The *arrow* indicates the proximal esophagus in the photograph. The azygos vein has been divided. (Reprinted with permission from Holcomb

GW III, Georgeson KE, Rothenberg SS, eds. *Atlas of Pediatric Laparoscopy and Thoracoscopy*, 1st ed. Philadelphia, PA: Copyright Elsevier; 2008.)

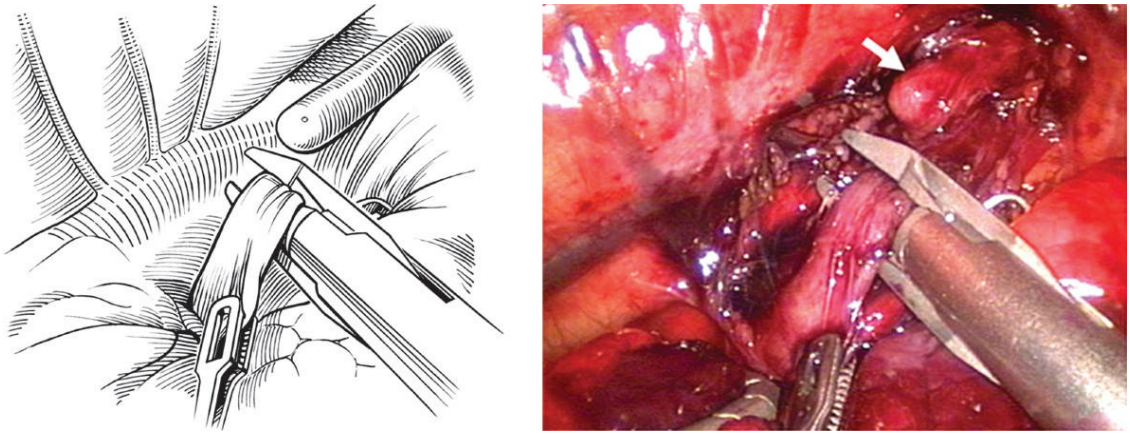

Figure 80.8. In the drawing (**left**) and photograph, an endoscopic clip applier is being positioned across the distal fistula to ligate it. An *arrow* indicates the proximal esophagus in the photograph. (Reprinted with permission from Holcomb GW III, Georgeson KE, Rothenberg SS, eds. *Atlas of Pediatric Laparoscopy and Thoracoscopy*. 1st ed. Philadelphia, PA: Copyright Elsevier; 2008.)

After completing the anastomosis, attention is turned toward trying to separate the esophageal suture line from the fistula closure on the trachea. Usually, these two sites will abut each other. An intact azygos vein often serves this purpose. Also, surgeons have tried interposing pleura or retropleural tissue to separate the two suture lines to prevent a recurrent TEF. However, this is not always easy. On occasion we have interposed a piece of small intestine submucosa (Surgisis, Cook Inc., Bloomington, IN) between the esophageal suture line and fistula to separate them (Fig. 80.11). A small silastic drain is then introduced through one of the stab incisions and positioned near the anastomosis. The 5 mm cannula site is closed with 4-0 and 5-0 absorbable sutures. Steri-Strips (3M Co., St. Paul, MN) are used to close the stab incision(s). Anesthesia is terminated and the baby is transported back to the Neonatal Intensive Care Unit where the baby is gradually weaned from the ventilator over a period of hours to days, depending on the baby's preoperative respiratory status.

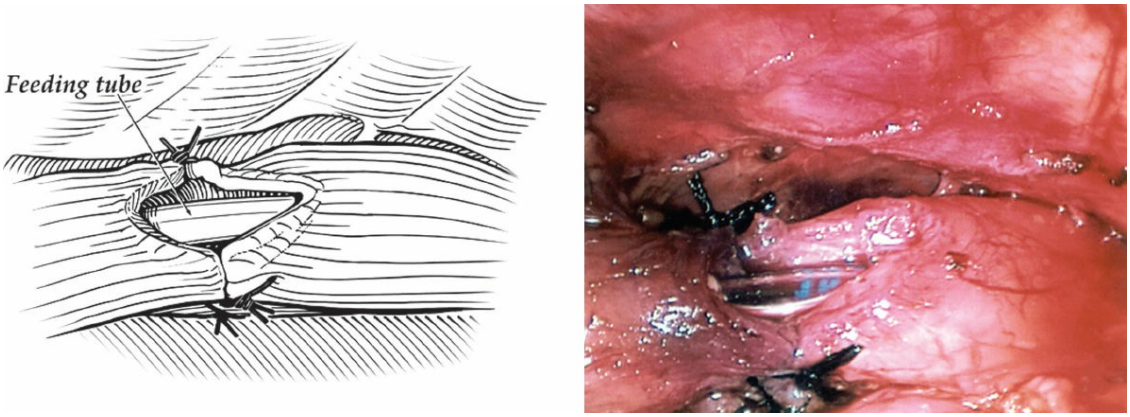

Figure 80.9. In this schematic and operative photograph, after completing the posterior part of the anastomosis, a soft 6-Fr tube has been introduced through the infant's nares, through the esophageal anastomosis, and into the stomach. This is often helpful in the postoperative period for feeding.

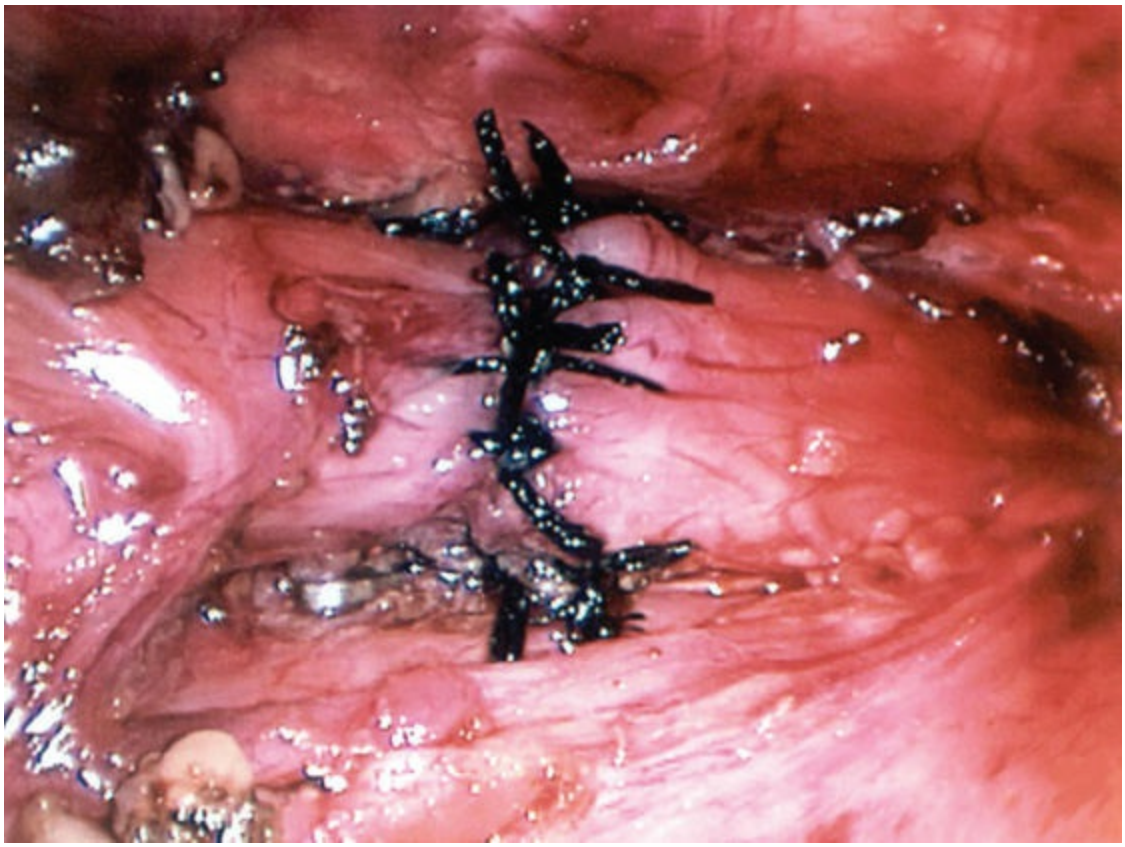

Figure 80.10. The anterior portion of the esophageal anastomosis has been completed with interrupted silk sutures which were tied intracorporeally. (Reprinted with permission from Holcomb GW III, Georgeson KE, Rothenberg SS, eds. *Atlas of Pediatric Laparoscopy and Thoracoscopy*, 1st ed. Philadelphia, PA: Copyright Elsevier; 2008.)

SURGICAL TECHNIQUE—OPEN APPROACH FOR EA/TEF

The principles between the open and thoracoscopic operation for EA/TEF are similar. With the open approach, a short posterolateral incision is made below the level of the tip of the scapula (Fig. 80.12). The latissimus dorsi muscle is retracted posteriorly, the scapula is retracted superiorly, and the serratus anterior muscle is retracted medially. Often, it is not necessary to divide the serratus muscle which avoids the risk of wing scapula. The fourth intercostal space is usually entered, although the third intercostal space can be used if the fistula and/or upper pouch are high in the mediastinum. If possible, an extrapleural dissection is utilized, and an infant rib spreader is inserted for additional exposure. The azygos vein can be left intact, or can be divided, depending on whether or not the operation can be performed without dividing it. At this point, the TEF is identified and encircled with a vessel loop. The upper esophageal pouch is then identified with the oroesophageal tube in it. A traction suture can be placed through both the tip of the pouch and the tube which helps facilitate dissection of the proximal pouch. The pouch is then dissected cephalad as far as needed for mobilization.

Once the proximal pouch has been mobilized sufficiently, the fistula is divided with fine tenotomy scissors and the tracheal side oversewn with 5-0 interrupted or continuous suture (Fig. 80.13). The distal esophageal opening is then gently dilated with a right angle clamp. 4-0 or 5-0 sutures of either absorbable or nonabsorbable material are used to secure the back wall of the esophageal anastomosis. It is important to take a full-thickness bite of both the proximal and distal esophagus with these sutures. Once the back wall of the anastomosis has been completed, a silastic tube is then placed by the anesthesiologist through the nose and into the esophagus, and through the anastomosis and down into the stomach as described previously for the thoracoscopic operation. Closure of the anterior part of the anastomosis is then performed in a similar fashion as the posterior wall, except that the knots are on the outside of the anastomosis on the anterior wall (Fig. 80.14). If the two ends of the esophagus are too far apart for a safe primary anastomosis, a circular myotomy as initially described by Livaditis can be performed to lengthen the proximal pouch. A beaver blade is used to perform the myotomy (Fig. 80.15). Each myotomy generally increases the length of the proximal esophagus by approximately 1 cm. Rarely, a second myotomy may be necessary to relieve tension at the

anastomosis.

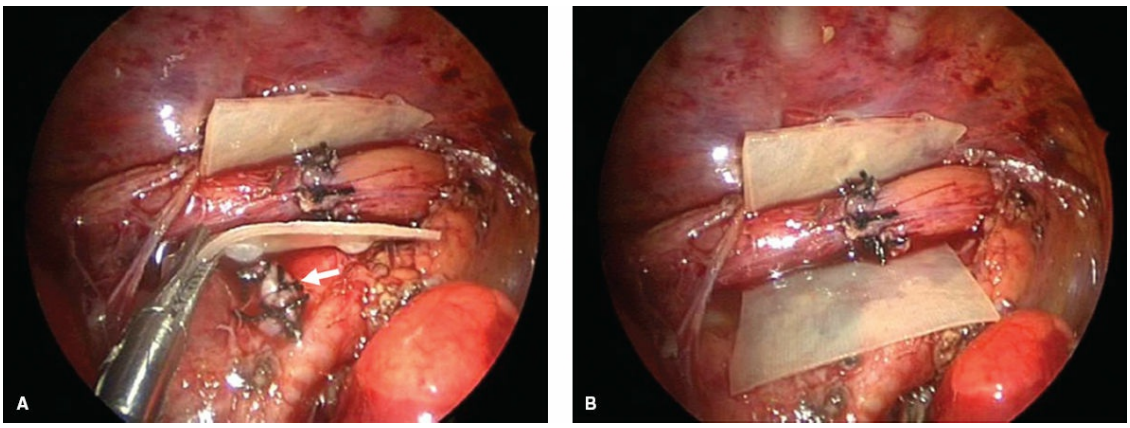

Figure 80.11. After completing the esophageal anastomosis, it is important to try to separate the esophageal suture line from the fistula closure on the trachea, if possible. Often, these two sites will lie next to each other. We now interpose a piece of Surgisis between the two suture lines to separate them (**A** and **B**). On the left (**A**), the *arrow* indicates the fistula closure on the trachea. We have not had a recurrent fistula developed after instituting this maneuver several years ago. (Reprinted with permission from St. Peter SD, Calkins CM, Holcomb GW III, et al. The use of biosynthetic mesh to separate the anastomoses during the thoracoscopic repair of esophageal atresia and tracheoesophageal fistula. *J Laparoendosc Adv Surg Tech* 2007;17:380–2.)

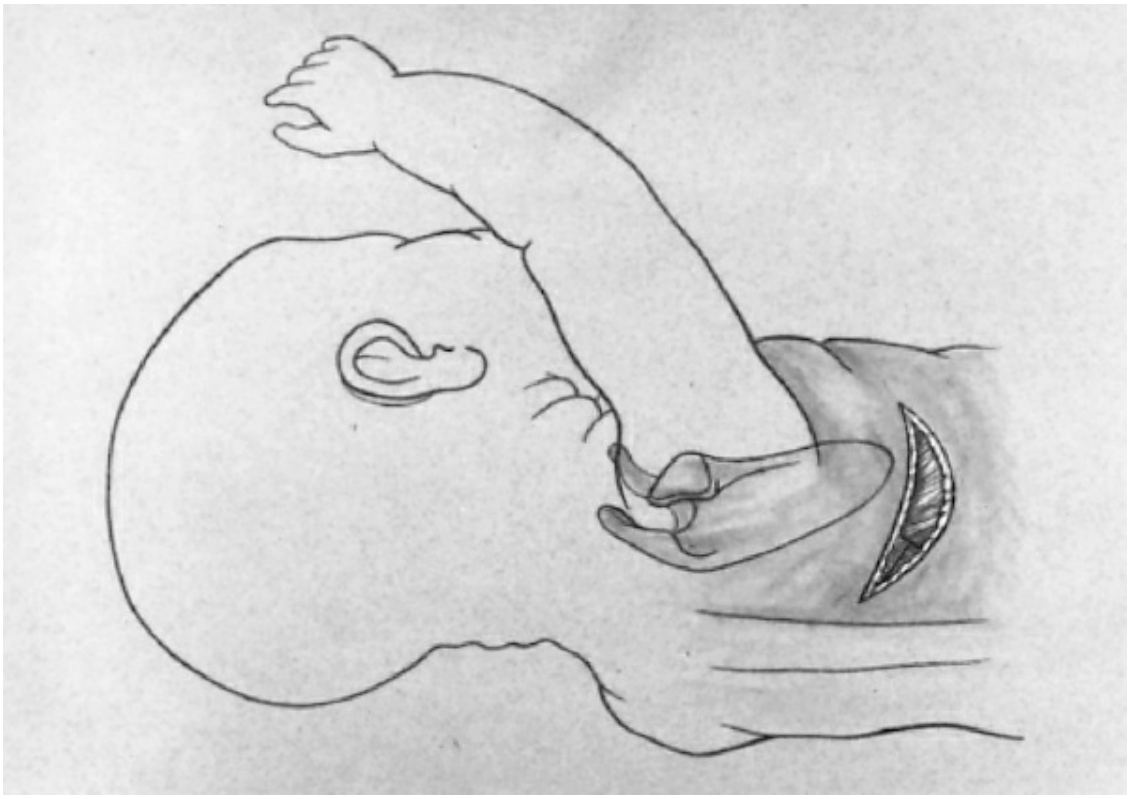

Figure 80.12. A posterolateral incision is made just below the tip of the scapula. The latissimus dorsi muscle is divided while the serratus anterior muscle is retracted anteriorly and medially.

Following completion of the anastomosis, mediastinal pleura, pericardium, or other mediastinal tissue should be interposed between the tracheal closure and the esophageal anastomosis. As mentioned, often the intact azygos vein sits nicely between these two structures and serves the same purpose. A soft silastic chest drain is then placed near the anastomosis and connected to bulb suction. The incision is then closed with absorbable suture.

POSTOPERATIVE CARE

Postoperatively, as mentioned, the ventilator is gradually weaned. We do not routinely utilize a standard number of days of neuromuscular paralysis. However, in general, the babies remain on the ventilator for at least 2 or 3 days and are sedated during that time. The infants are weaned from the ventilator when ready, and are extubated as soon as possible. Between postoperative days 5 and 7, a water-soluble contrast study is performed to evaluate for the presence of an anastomotic leak. If there is no evidence of a leak, oral feeding is initiated as tolerated and the small chest drain is

removed. If the babies do not tolerate oral feedings well, they are supplemented through the nasogastric stent that was placed at the time of the anastomosis. When the oral feedings improve, the stent is removed and the baby is transitioned to full oral feedings. The infants are then discharged when ready for home care.

COMPLICATIONS AND THEIR MANAGEMENT

Anastomotic Leak

A leak rate of between 10% and 21% has been reported in several studies following EA/TEF repair via thoracotomy (Fig. 80.16). However, these studies often include patients with isolated EA as well (in which the leak rate is higher), so the true incidence of leaks following open repair of EA/TEF is unclear. However, most leaks are small and will close spontaneously given enough time. In the largest study (104 patients) describing thoracoscopic repair of EA/TEF, the anastomotic leak rate was 7.6%.

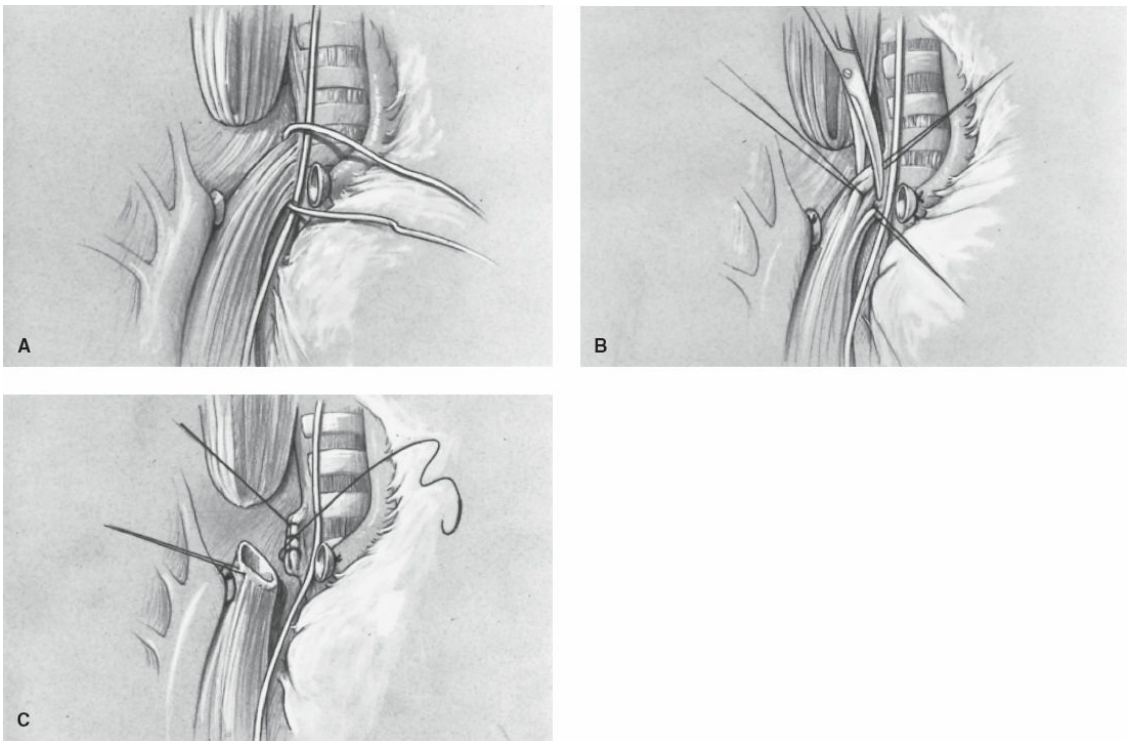

Figure 80.13. A. The tracheoesophageal fistula site is mobilized circumferentially distal to the fistula, and the area is encircled with a vessel loop. **B.** Traction sutures are placed, with great care taken not to encroach on the lumen of the trachea, which can result in narrowing with closure. Division of the fistula is then performed using tenotomy scissors. **C.** The tracheal end is closed

with a 5-0 continuous or interrupted suture. The closure is tested with positive-pressure ventilation to rule out a leak. The tracheal suture line is covered with mediastinal pleura to reduce the risk of recurrent tracheoesophageal fistula should an anastomotic leak occur.

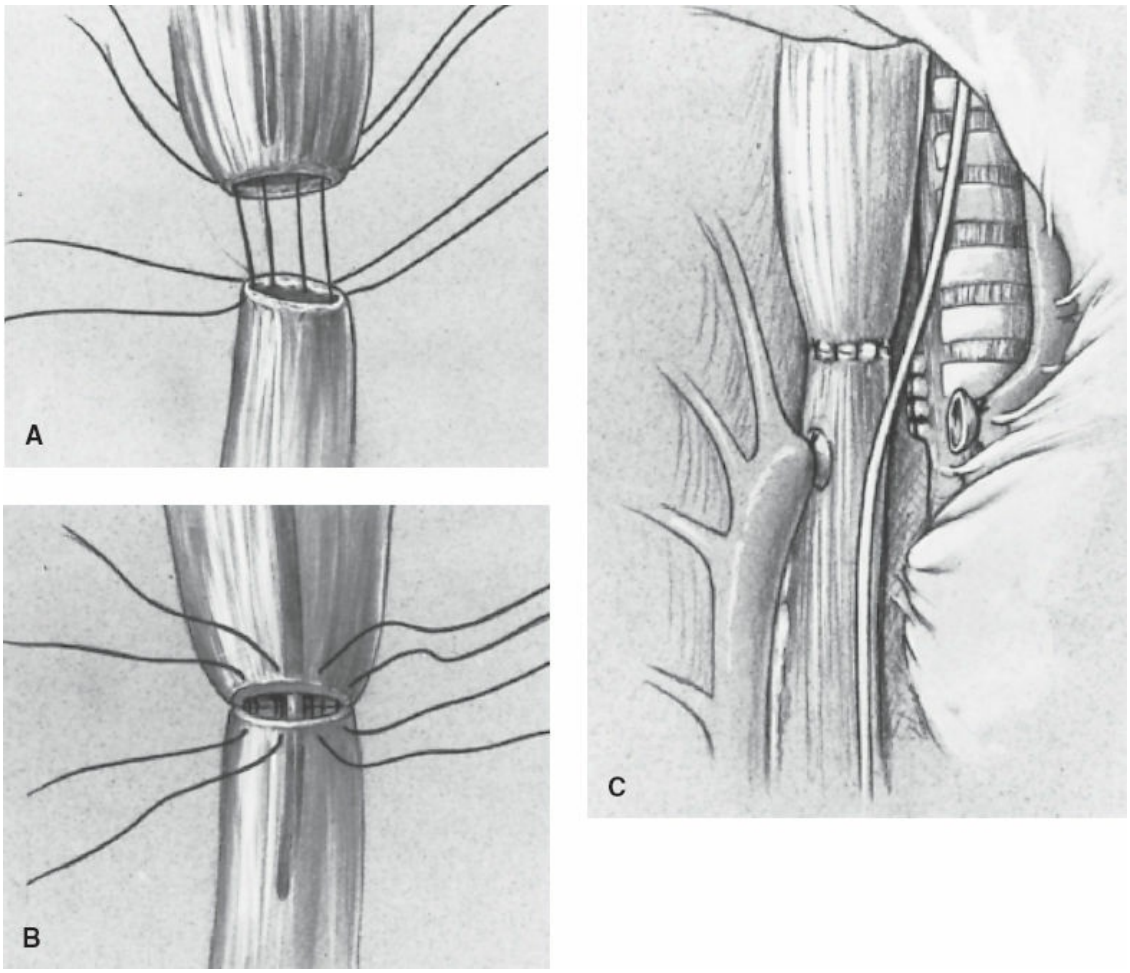

Figure 80.14. **A.** A single-layer anastomosis is performed with full-thickness, interrupted 4-0 sutures, involving mucosa and muscularis. The posterior sutures are placed with the suture knots on the inside. **B.** After the posterior suture line is completed, a feeding tube is advanced into the distal esophagus and stomach. The anterior sutures are inserted to complete the single-layer anastomosis. **C.** The completed anastomosis, sutured tracheal fistula repair, and ligated azygos vein are demonstrated.

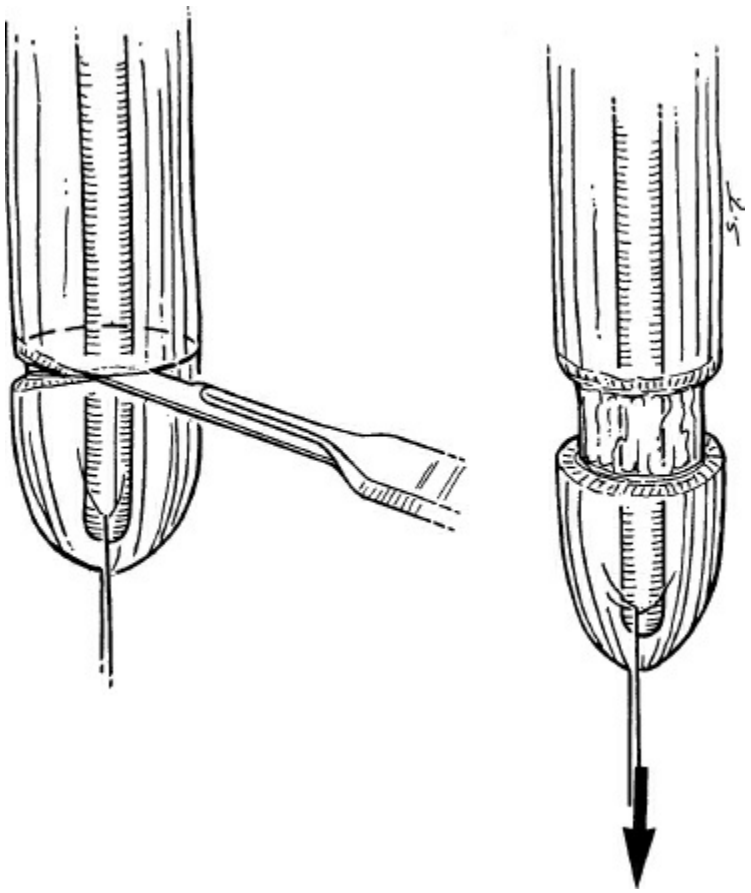

Figure 80.15. Circular myotomy of the proximal esophageal pouch is useful to gain 1 cm of esophageal length for a tension-free anastomosis.

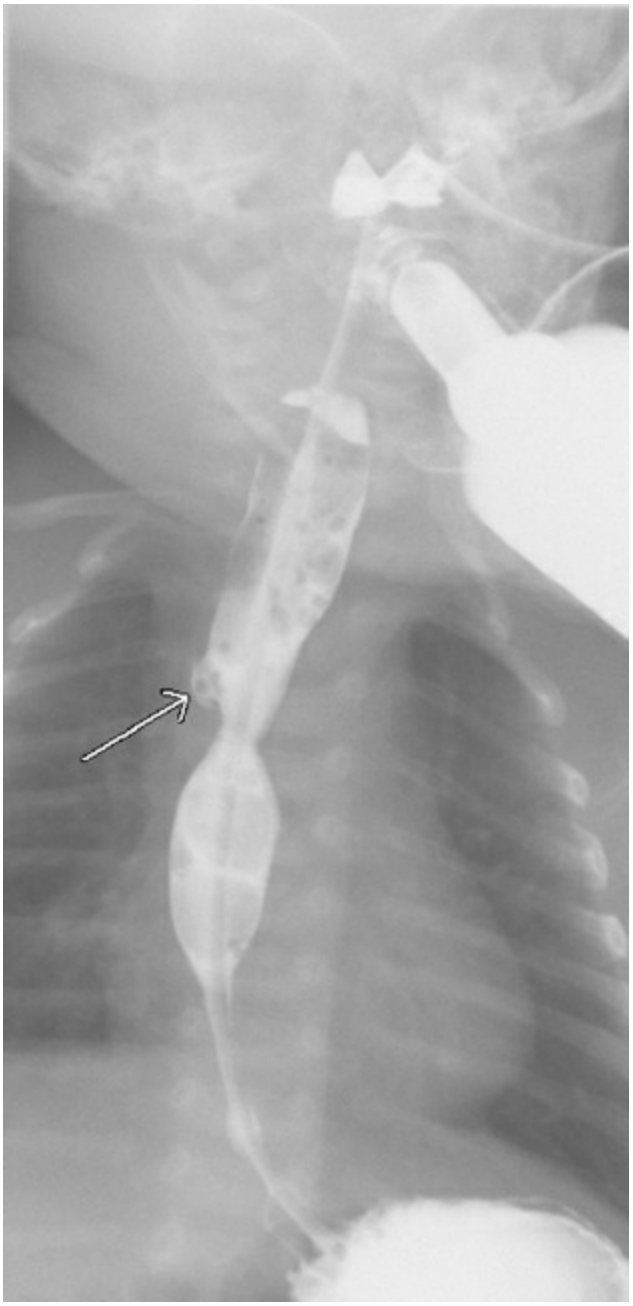

Figure 80.16. Esophogram showing an anastomotic leak at *arrow.*

Anastomotic Stricture

There is no uniform definition for an anastomotic stricture. Some authors define a stricture based on the anastomotic appearance on the initial contrast study, some describe it as a baby needing one esophageal dilation, and others define it as a baby who needs more than one dilation. Therefore, there is a wide range in the reported incidence of an anastomotic stricture following open repair, varying from 4% to 33%. In the study describing 104 patients undergoing thoracoscopic repair, an

anastomotic stricture was defined as a significant narrowing on the initial esophagram. In this series, four babies (3.8%) were found to have a stricture. Also, in this series, 32 babies (31.7%) required one dilation, 12 babies required two dilations (11.5%), and 9 babies (8.6%) required three or more dilations. Strictures usually respond nicely to dilation and anastomotic resection is not usually necessary. Failure of an anastomotic stricture to respond to dilation may be due to gastroesophageal reflux (GER).

Recurrent TEF

The development of a recurrent TEF varies between 2% and 15% depending on the literature report and the decade in which the study was published. Recurrence of the TEF is more likely if an anastomotic leak developed or there was excess tension on the anastomosis. Generally, the higher incidences were reported 30 years ago and the lower incidences are in the most recent time period. In the 104 patients undergoing thoracoscopic repair, two (1.9%) developed a recurrent TEF.

Management of a recurrent fistula can be difficult. Occasionally, a recurrent fistula can be found on a contrast swallowing study. Usually, however, bronchoscopy is needed to either make or confirm the diagnosis. Traditionally, management has required a thoracic approach. However, recently, a number of tracheoscopic treatment techniques have been described, including chemocauterization with 50% trichloroacetic acid, plugging the fistula with Surgisis (Fig. 80.17), or injecting it with Tisseal (Baxter, Deerfield, IL) (or both). Using a laser to abrade the fistula has also been described. Because repair of a recurrent TEF can be difficult, we have tried to prevent it by interposing either native tissue or Surgisis between the trachea and the esophagus at the time of the primary repair.

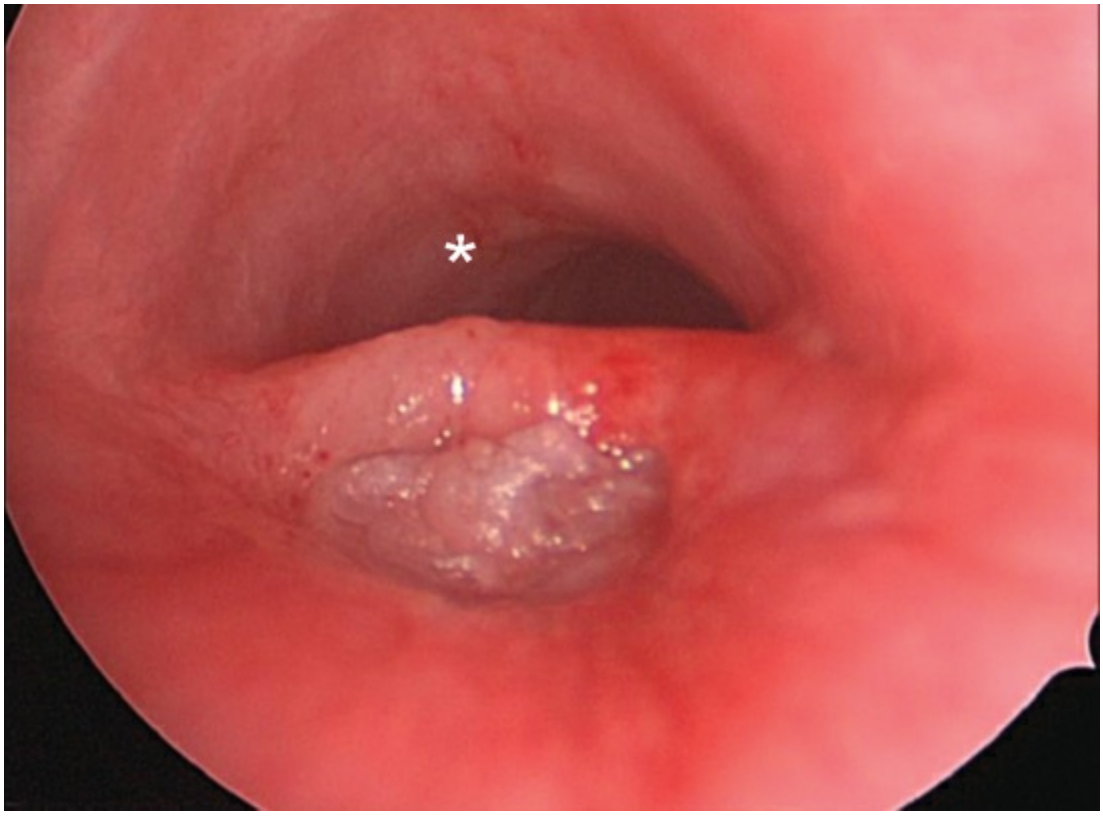

Figure 80.17. Management of a recurrent fistula can be difficult. Recently, we have been asked to treat several patients with recurrent TEF. In a stable patient, our initial approach has been a tracheoscopic approach with plugging the fistula with Surgisis. In this endoscopic view, Surgisis has been introduced into the recurrent tracheoesophageal fistula to occlude it. The tracheal lumen is identified with the *asterisk.*

Tracheomalacia

Tracheomalacia is a well-known problem that is found in almost every baby with EA and TEF. The softening of the tracheal cartilage is thought due to the distension of the adjacent esophagus during gestation. The symptoms are usually mild, but can occasionally be life-threatening. In a severely symptomatic baby, an aortopexy is occasionally required to suspend the aorta and aortic arch against the posterior surface of the sternum. As the anterior wall of the trachea is attached to the aorta, it is suspended as well and the tracheal lumen is thereby enlarged. This operation can be performed through a thoracotomy, mediasternotomy, or thoracoscopically. In the multi-institutional report of 104 babies undergoing thoracoscopic repair of EA/TEF, 7 babies (6.7%) required a thoracoscopic aortopexy.

Gastroesophageal Reflux and Esophageal Dysmotility

Almost all infants with EA with/without TEF will have some degree of GER, and all have esophageal dysmotility. Up to 50% of the babies will have significant GER and many will require a fundoplication. In the 104 babies undergoing thoracoscopic repair, 26 (25%) also required a laparoscopic fundoplication. A recent review on GER and EA described the need for fundoplication in 46% of babies with EA/TEF. Whether or not a complete (Nissen) or partial (Thal) fundoplication should be performed is often argued. Some authors believe that a loose floppy Nissen can be performed in a baby with esophageal dysmotility without causing dysphagia. Others, however, feel that an anterior partial fundoplication is superior to a Nissen as it is less likely to create an obstruction in the presence of disordered esophageal peristalsis.

ESOPHAGEAL ATRESIA WITHOUT A FISTULA

This anomaly is the second most common in the spectrum of EA. Usually, there is a significant gap between the two esophageal ends as the distal esophagus is not connected to the trachea. The gap is usually at least 2 cm and often longer. Gaps of 2 cm or less can usually be repaired primarily, but when the gap is longer, a number of other maneuvers are usually necessary. Ultimately, if the gap cannot be bridged, esophageal replacement with stomach, colon, or small intestine is required. Esophageal replacements are not considered optimal as they are prone to long-term complications as the patient grows. For this reason, most surgeons try to preserve the native esophagus and perform a delayed esophageal repair. Measures utilized to help bridge a significant gap between the two esophageal ends include staged stretching of the proximal esophagus by initially performing an esophagostomy and then periodically advancing it inferiorly onto the chest wall as described by Kimura and Soper. Also, Folker developed a technique that induces tension on the proximal and distal esophagus in an accelerated fashion with the intent to induce esophageal growth. Sutures are placed on each end of the esophagus with pledgets. The sutures are crossed in the thoracic cavity and brought out onto the chest wall above and below the incision and tied over silastic buttons. Tension is placed on the sutures each day in order to induce growth on the two esophageal ends. This technique can be performed thoracoscopically as well (Fig. 80.18). Results have been very good in his series of patients, but not all pediatric surgeons have been able

to achieve similar good results with this technique.

H-TYPE TEF

Isolated TEF (without an associated EA) is the third most common condition found in the spectrum of patients with EA. The diagnosis is often delayed, but persistent coughing or choking during feeding, especially with liquids, is usually found in these babies. Recurrent pneumonia is common as well.

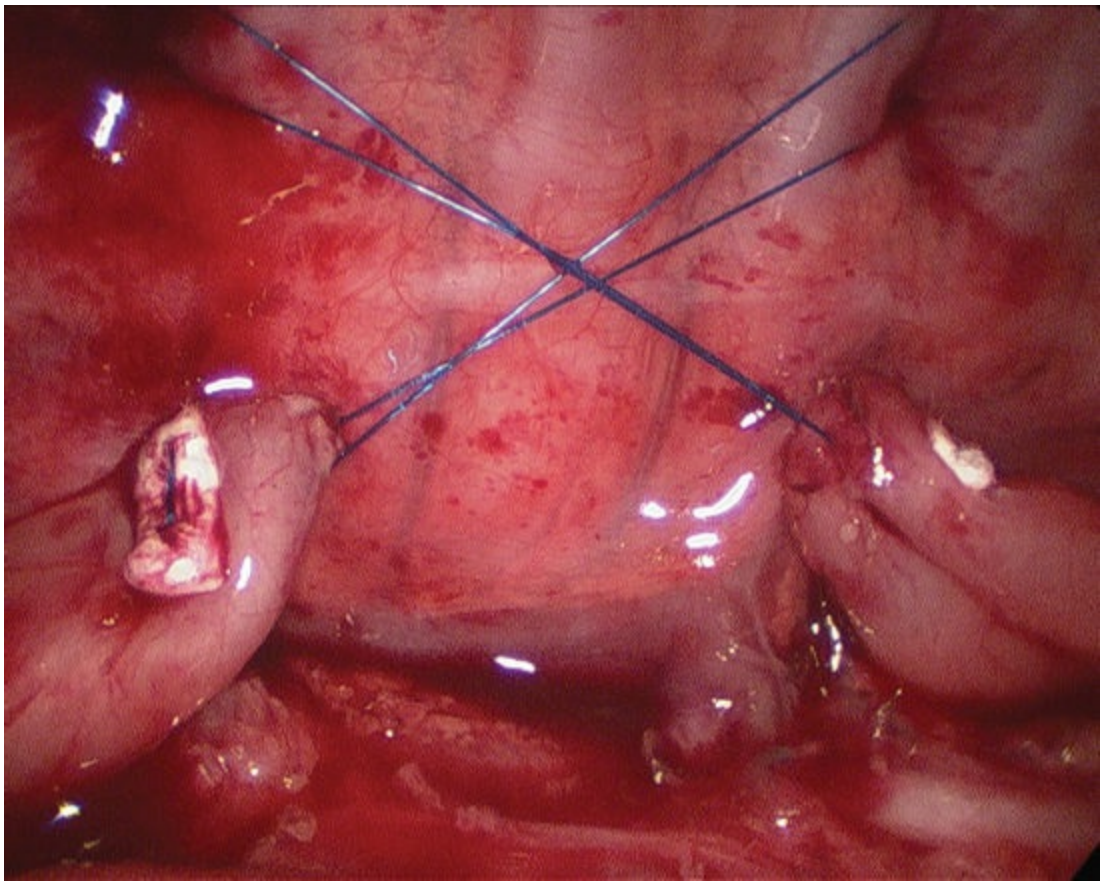

Figure 80.18. Foker technique, thoracoscopic illustration of pledgeted traction sutures.

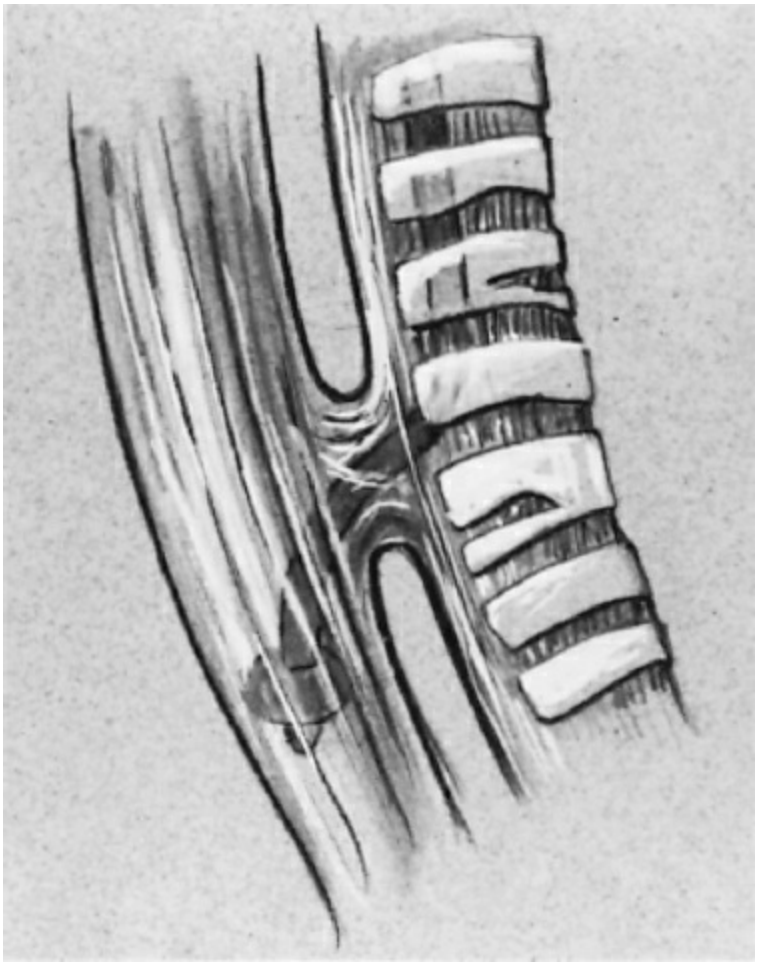

Figure 80.19. Identification of an H-type fistula is aided by placing a Fogarty catheter through the fistula at bronchoscopy.

Most of these isolated TEFs can be approached through a low right cervical incision. Bronchoscopy can be especially helpful to confirm the diagnosis as they are not always evident on esophageal contrast studies. Also, at the time of repair, placement of a fine Fogarty or ureteral catheter through the bronchoscope, through the fistula, and into the esophagus is helpful for identification of the fistula at exploration (Fig. 80.19). At exploration, the esophagus is identified by palpating the nasogastric tube and the fistula is found by palpating the Fogarty catheter. When the fistula is identified, it is divided on the esophageal side to avoid narrowing of the trachea. It is important to identify the vagus nerve and the recurrent laryngeal nerve as they can be injured during the dissection. Both the trachea and esophageal sides are closed with interrupted fine absorbable sutures. A small drain is often placed postoperatively until an esophagram is performed between days 4 and 7.

OUTCOMES

Short-term outcomes following EA/TEF repair have improved significantly over the past 70 years since the first successful repair. A poor outcome is usually associated with other severe congenital anomalies, primarily cardiac in nature, or with a large gap between the esophageal segments. In a recent review looking at outcomes in newborn babies with EA/TEF in the United States, the Kids' Inpatient Database was queried. A total of 4,168 cases were identified with an overall in-hospital mortality of 9%. Multivariate logistic regression analysis identified a birth weight less than 1,500 g, operation within 24 hours, gestational age less than 28 weeks, and the presence of a VSD as independent predictors of in-hospital mortality. A recent review from Great Ormond Street Hospital for Children showed an overall survival rate from 2001 to 2011 of 93% versus 92.6% from 1993 to 2004. However, in the more recent time period, there was significant improved survival in Spitz's group 2 (birth weight less than 1,500 g or major cardiac anomaly) of 82.4%. Also, of the patients in Group 2 who died, 90% had major cardiac anomalies.

Over the long term, dysphagia and food impaction at the site of the esophageal anastomosis are sometimes found in adolescents or young adults who were born with EA/TEF. It is not unusual to perform an esophagoscopy for removal of food impaction in a teenager who has undergone repair of EA/TEF.

A recent report from Helsinki described 588 patients who underwent repair of EA from 1947 to 1985. A total of 235 of these patients were alive with their native esophagus and 169 responded to contact. The information provided by the first 101 patients who replied and agreed to participate made up the clinical study group. Symptomatic GER was found in 34% and dysphagia in 85% of these patients. Vertebral anomalies were found in 45% of the patients with the most common site being in the cervical spine. The risk of significant scoliosis was 13-fold when compared with the healthy control population and thoracotomy-induced rib fusion and other associated anomalies were the strongest predictors for scoliosis. However, in most patients, the clinical course of their scoliosis was mild and did not require bracing or repair. There were no instances of esophageal cancer found in these patients. Interestingly, the authors found that there was no difference in the overall health-related quality of life between patients and controls, indicating that these patients learn to live well with their esophageal dysmotility and scoliosis.

EDITOR'S COMMENT

In the field of pediatric surgery, repair of an EA/TEF is one of the most satisfying operative procedures performed converting a life-threatening

congenital anomaly into a surgically reconstructed conduit with life-long benefit. In this chapter, the author presents an excellent overview of the condition. Patients with EA/TEF often have associated congenital anomalies. The VACTERL combination is most well recognized and when the attendant anomalies are present, proper sequencing of the interventions required is critical. If congenital heart disease is present, stabilization of cardiac function takes priority with the type of congenital heart disease dictating the cardiac intervention required. If an additional GI tract anomaly is present, duodenal atresia and imperforate anus being the most common, intervention in the abdomen may be required first. Especially in a patient with duodenal atresia, duodenal reconstruction should occur first as correcting the esophageal atresia with a proximal obstruction could stress the integrity of the esophageal anastomosis. In patients with imperforate anus, there is more latitude to the sequencing of the procedures.

Although EA patients uncommonly require emergent treatment, the premature infant with a TEF can be challenging. Premature infants have immature lungs and often require mechanical ventilatory support and if a large TEF is present, can result in preferential shunting of air into the GI tract resulting in progressive abdominal distention (Templeton JM, Templeton JJ, Schnaufer L, et al., *J Ped Surg* 1985;20(4):394–87). The distention inhibits respiratory mechanics creating a vicious cycle as increased ventilatory support is required. Unimpeded, progressive luminal distention may result in GI perforation exacerbating a tenuous situation. In addition to the strategies described by the author, occluding the distal esophagus at the GE junction with a vessel loop passed twice around the esophagus (similar to a POTTS maneuver around a blood vessel) can be an effective route to temporarily impede air egress through the esophagus allowing stabilization of the neonate's ventilatory requirements. Once stable, division of the TEF through the chest can be performed and the vessel loop removed.

Low–birth-weight infants (<1,500 g) deserve careful consideration. Some of these may be premature and face the challenges described above but others may be small for gestational age and if the TEF is not causing respiratory symptoms are stable. In these patients, the timing of repair is of some debate. Primary repair can be performed safely but studies report increased rates of anastomotic leak and stricture (Petrosyan M, Estrada J, Hunter C, et al. Esophageal atresia/tracheoesophageal fistula in very low-birth-weight neonates: improved outcomes with staged repair. *J Pediatr Surg* 2009;44:2278–81). A staged approach in which the TEF is divided and a G-tube is placed allowing for maturation and growth followed by delayed reconstruction is favored by some and although two procedures are required, may have lower overall morbidity. For the practicing surgeon, primary and staged repair are complimentary alternatives and depending on the specific clinical scenario encountered utilized appropriately.

An ECHO is obtained in all patients with esophageal atresia. It is important

for the surgeon to review the ECHO result establishing on which side of the chest the aortic arch is found. Repairing a TEF with the arch in the field, although successfully performed, can make the procedure more challenging (Parolini F, Armellini A, Boroni G, et al. The management of newborns with esophageal atresia and right aortic arch: a systematic review or still unsolved problem. *J Pediatr Surg* 2016;51(2):304–9). If a right-sided aortic arch is present, one should consider an approach through the left chest to repair the EA. When there is an aberrant arch, a vascular ring is likely present therefore care must be taken to ensure the ring does not cause a distal esophageal obstruction.

As the author notes, the first thoracoscopic repair of an EA/TEF was reported in 1997. Since that time, the thoracoscopic approach has received widespread attention and the author describes in excellent detail, important aspects of the thoracoscopic approach, especially the suggestion to use high-frequency jet ventilation. The benefit of thoracoscopic procedures in pediatric patients remains to be defined. A recent systematic review of pediatric studies evaluating the advantages of video-assisted thoracoscopy revealed that there is no high level of evidence supporting minimally invasive techniques (Dingemann C, Ure B, Dingemann J. Thoracoscopic procedures in pediatric surgery: what is the evidence? *Eur J Pediatr Surg* 2014;24(01):14–9). The evidence in favor of thoracoscopic TEF repair is based on institutional and multi-institutional retrospective case series reviews (Holcomb GW, Rothenberg SS, Bax KM, et al. Thoracoscopic repair of esophageal atresia and tracheoesophageal fistula: a multi-institutional analysis. *Ann Surg* 2005;242(3):422–8). The pediatric surgery community must address whether the benefits of the thoracoscopic approach are greater than the potential risks given the long-term goal of a life time of the esophagus as a conduit. The purported potential benefits of the procedure, decreased rates of a winged scapula and scoliosis are at best poorly documented late complications of the open approach and may not mitigate the risks of a thoracoscopic approach.

Placement of a foreign material between the esophagus and trachea (Surgisis) and the placement of a trans-anastomotic feeding tube as the author recommends has some attendant risks as a recent retrospective multi-institutional study found that they were associated with an increased incidence of either an anastomotic leak or stenosis (Lal et al. *J Ped Surg* 2016;16:305–9). The Midwest Pediatric Surgical Consortium is conducting a prospective observational trial to determine the impact of a bundle of measures including the elimination of the placement of both foreign material and trans-anastomotic tubes assessing its impact on complication rates.

Patients with long-gap EA patients remain the most vexing with a diverse array of alternative strategies utilized to restore GI tract continuity. Consensus has been reached in so far as preservation of the native esophagus is preferred over any other replacement conduit; however, depending on the gap between the two ends of the esophagus can be extremely difficult to achieve. Lengthening of the native esophagus using various techniques in which

continuous application of tension to the two ends of the esophagus have been shown to be effective but comes at the expense of multiple operative explorations (Foker JE, Linden BC, Boyle EM Jr, et al. Development of a true primary repair for the full spectrum of esophageal atresia. *Ann Surg* 1997;226(4):533–41). If the native esophagus cannot be saved, the choice of replacement conduit includes the stomach, colon, and jejunal interposition with a meta-analysis suggesting the gastric pullup associated with a higher respiratory morbidity but fewer gastrointestinal complications (Gallo G, Zwaveling S, Groen H, et al. Long-gap esophageal atresia: a meta-analysis of jejunal interposition, colon interposition, and gastric pull-up. *Eur J Pediatr Surg* 2012;22(6):420–5). Several major children's hospitals have established centers with specialized focus on complex esophageal reconstruction combining multidisciplinary input to optimize treatment strategies and outcome (Lobeck I, Dupree P, Stoops M, et al. Interdisciplinary approach to esophageal replacement and major airway reconstruction. *J Pediatr Surg* 2016;51(7):1106–9; Smithers CJ, Hamilton TE, Manfredi MA, et al. Categorization and repair of recurrent and acquired tracheoesophageal fistulae occurring after esophageal atresia repair. *J Pediatr Surg* 2017;52(3):424–30). The impact of these centers of excellence will become apparent in the coming years.

As the author notes, the challenges following TEF repair can be separated into technical versus physiologic. Technical challenges include anastomotic leak, stenosis and recurrent fistula. The physiologic challenges are tracheomalacia, gastroesophageal reflux, and esophageal dysmotility. An esophageal leak is the most frequent complication following TEF repair. A controlled leak will heal but likely at the expense of a stenosis. Esophageal stenosis will also occur de novo. The pathogenesis of the stenosis may be GER but can be due to other anatomic abnormalities. Pyloric stenosis can occur in any infant and should it arise in a patient with a TEF, will trigger a stenosis. An intrinsic distal esophageal stenosis due to an aberrant cartilaginous ring can also occur albeit with much less frequency (Newman B, Bender TM. Esophageal atresia/tracheoesophageal fistula and associated congenital esophageal stenosis. *Pediatr Radiol* 1997;27(6):530–4). These rings are best addressed with resection as dilatation is associated with higher complications rates.

A recurrent fistula is problematic (Smithers CJ, Hamilton TE, Manfredi MA, et al. Categorization and repair of recurrent and acquired tracheoesophageal fistulae occurring after esophageal atresia repair. *J Pediatr Surg* 2017;52(3):424–30). In the past, the recurrence of a fistula mandated re-exploration but with advances in endoscopic techniques, a recurrent fistula, especially if small may be amenable chemocauterization and fibrin glue–induced closure. If endoscopic approaches fail, exploration is warranted and in these circumstances, placement of an autologous graft between the esophagus and trachea is warranted (Bruch SW, Hirschl RB, Coran AG. The diagnosis and management of recurrent tracheoesophageal fistulas. *J Pediatr* Surg 2010;45(2):337–40). In cases of re-recurrence, slide tracheoplasty has also been

shown to be effective (Provenzano MJ, Rutter MJ, von Allmen D, et al. Slide tracheoplasty for the treatment of tracheoesophogeal fistulas. *J Pediatr Surg* 2014;49(6):910–4).

The physiologic challenges that patients with an EA/TEF encounter are life-long. Tracheomalacia if severely symptomatic can be improved with an aortopexy (Kay-Rivest E, Baird R, Laberge JM, et al. Evaluation of aortopexy in the management of severe tracheomalacia after esophageal atresia repair. *Dis Esophagus* 2015;28(3):234–9). Gastroesophageal reflux disease (GERD) is frequent. Should reflux be severe, an antireflux procedure is warranted. Because of intrinsic dysmotility in the reconstructed esophagus, partial or very "loose" complete wraps are indicated. Long-term follow-up is critical as late effects like the development of Barrett metaplasia is worrisome (Schneider A, Gottrand F, Bellaiche M, et al. Prevalence of Barrett esophagus in adolescents and young adults with esophageal atresia. *Ann Surg* 2016;264(6):1004–8).

Gregory M. Tiao

81 Pathology and Treatment of Zenker Diverticulum

Christopher R. Morse

Zenker diverticula (ZD) are a form of pulsion diverticulum occurring in an area of muscular weakness (Killian triangle) located between the inferior constrictor and cricopharyngeus muscles. The condition was first described by Ludlow in 1764 and subsequently, Zenker published a series of 23 cases in 1877. Symptoms include dysphagia, regurgitation of undigested food, globus sensation, halitosis, and aspiration pneumonia. Surgical intervention has been recognized as the only effective treatment and shown to result in the improvement of symptoms and quality of life with little morbidity.

Initial attempts at repair often failed secondary to leaks and the development of mediastinitis. Early modification of technique involved a diverticulopexy (Schmid). Further evolution of the technique involved pexy of the diverticulum with an interval resection of the diverticulum approximately a week later. It was not until the late 1950s when the concept of a two-stage surgery was challenged with a one-stage approach and a cricopharyngeal myotomy was added.

Repair continued to focus on open resection/pexy and cricopharyngeal myotomy, but recently, the endoscopic repair of ZD has been described and is gaining popularity. This has been an evolution of endoscopic techniques ranging from a sharp division of the diverticular spur with a knife (Mosher) to a needle knife division to bipolar cautery division to laser division, all with varying degrees of success. The most common approach to an endoscopic approach at present is a transoral stapling of the diverticulum with a modified tip to the stapler. As many Zenker patients are elderly with significant comorbid disease, an endoscopic approach avoiding the need for a neck incision may provide several potential advantages.

ETIOLOGY AND PATHOPHYSIOLOGY

The prevailing hypothesis for the development of a ZD is a pulsion diverticulum secondary to a “hypertensive” cricopharyngeal muscle. The decrease in compliance of the cricopharyngeus leads to a “blowout” of the mucosa in a transition zone between and hypopharynx and the esophagus (Killian triangle). The proximal and lateral borders of the triangle are the horizontal cricopharyngeal muscle and the oblique fibers of the constrictor pharyngeus inferior muscle and the area of weakness extends posteriorly. As the pouch dilates and distends, it tends to progress inferiorly, capturing the cricopharyngeus muscle between the diverticulum and the esophagus.

CLINICAL PRESENTATION

Typically a disease of the elderly, symptoms associated with a ZD are variable and correlate with the size of the diverticulum. Early on, with poor compliance of the cricopharyngeus and prior to the development of the diverticular pouch, the primary complaint is primarily choking and dysphagia. With the development of the diverticulum, patients often report dysphagia with the regurgitation of undigested food, halitosis, and aspiration events. Approximately one third of patients with a ZD report losing weight. In the elderly, aspiration can lead to a life-threatening pneumonia (Table 81.1 Previous chapter). There are few findings on physical examination, although can include in rare cases cervical borborygmi and crepitus. The differential diagnosis in these patients includes esophageal cancer with obstructive symptoms, esophageal webs and strictures, Killian–Jamieson diverticuli below the cricopharyngeus, tracheoesophageal fistula, and esophageal foreign body.

TABLE 81.1 Zenker Diverticulum: Clinical Presentation and Symptoms

Clinical Presentation	
Mean age	68 yrs
Symptoms	
Dysphagia	80%
Regurgitation	58%
Choking	20%
Coughing	18%
Globus sensation	21%
Weight loss	23%
Other	14%
Associated Pathology	
Pulmonary infection	37%
Upper GI pathology	60%
Documented reflux	44%
Other	52%

EVALUATION AND PREOPERATIVE PLANNING

A barium swallow and upper gastrointestinal esophagoscopy should be performed in all patients. A barium swallow typically reveals a cervical midline protrusion at the level of the posterior hypopharyngeal wall (Fig. 81.1). Esophageal motility, based on the work of Cook et al., will demonstrate a hypertensive and restrictive pattern of the upper esophageal sphincter. However, motility studies are not necessary in the evaluation of a ZD and it is often difficult to pass the motility catheter. An EGD, performed at the time of the procedure, allows for the evaluation of the diverticulum, removal of any debris from the diverticulum, and an opportunity to examine the esophagus for other pathology. For open, transcervical procedures, there are no size criteria for repair and diverticulum can be repaired at almost any size with symptoms. However, for a transoral stapled approach, the diverticulum should be at least 3 cm in size to allow for entrance of the stapler and a complete cricopharyngeal myotomy. In addition, for a transoral stapled approach, patients should be evaluated for limited mouth opening and inability to adequately extend the neck that can make placement of the Weerda scope laryngoscope difficult.

Figure 81.1. Barium Swallow demonstrating a Zenker diverticulum with the classic posterior midline protrusion.

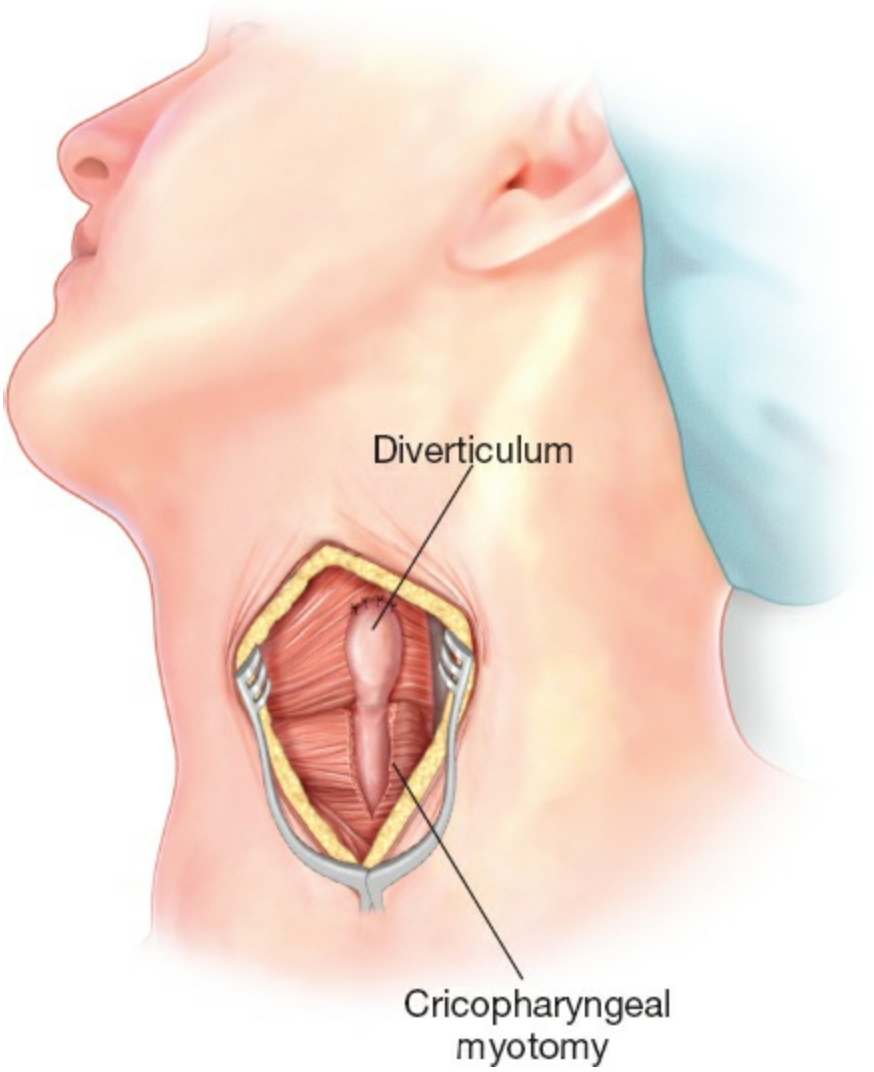

Figure 81.2. Repair of Zenker diverticulum with suspension diverticulopexy and cricopharyngeal myotomy.

SURGERY

There are several open approaches to the repair of a ZD. First is a cricopharyngeal myotomy for small, early diverticulum. Occasionally, in the setting of a small diverticulum, performing an extensive cricopharyngeal myotomy will cause the smallest of pouches (typically <1 cm) to disappear as the mucosa “pouts” with the myotomy. The second approach is a cricopharyngeal myotomy with suspension of the diverticulum (Fig. 81.2). In this situation, the diverticulum is suspended behind the pharynx by suturing it to either the pharyngeal musculature or the prevertebral fascia. An advantage to this approach is the avoidance of opening the diverticulum and preventing the complications of infection and fistula. The third and most commonly described approach is a

diverticulectomy and cricopharyngeal myotomy where the diverticulum is resected and the esophagus closed with a stapler or a hand-sewn technique and an extensive cricopharyngeal myotomy performed (Fig. 81.3). More recently, an endoscopic transoral approach now commonly using a laryngoscope and modified stapler allows for division of the common wall between the esophagus and diverticular pouch. This technique avoids a cervical incision (Fig. 81.4).

There is no special equipment needed for an open transcervical diverticulectomy/diverticulopexy and cricopharyngeal myotomy. With a diverticulectomy, a Maloney bougie is placed prior to stapling and a TA stapler is typically used for the resection of the diverticulum.

Performing a transoral stapled Zenker diverticulectomy requires a Weerda scope laryngoscope (Karl Storz, Tuttlingen, Germany) (Fig. 81.5), a modified stapler with the anvil shortened to allow stapling and cutting to the end of the stapler and 5-mm 30-degree laparoscope to allow for additional visualization.

Positioning

For a transcervical diverticulectomy or diverticulopexy, the patient is placed supine on the operating room table and, after general anesthesia is induced, the head is turned to the right to expose the left neck. Padding is placed beneath the shoulders to extend the neck. For a transoral diverticulectomy, the patient is placed supine on the operating table with the head positioned at the top of the operating table. General anesthesia is established using a small diameter endotracheal tube. Arms are typically tucked at the sides in both procedures.

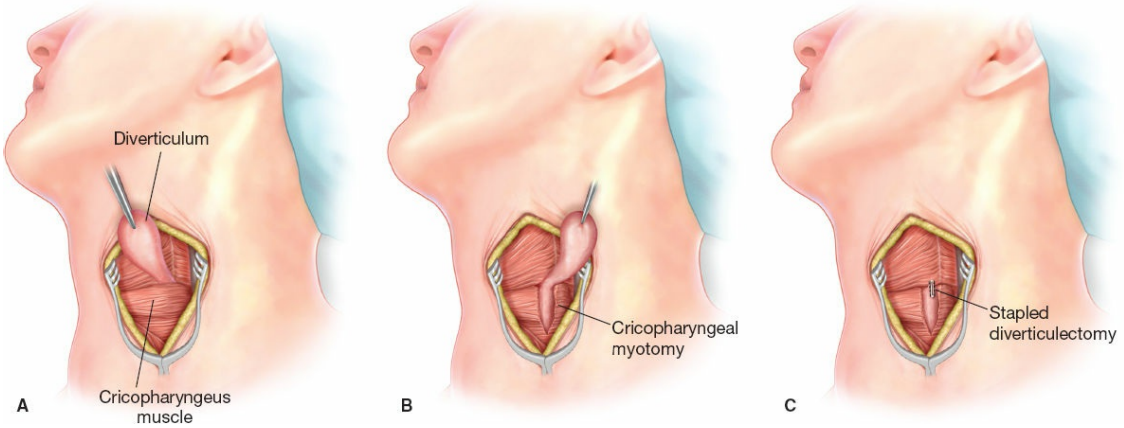

Figure 81.3. Repair of Zenker diverticulum (**A**) with cricopharyngeal myotomy (**B**) and stapled diverticulectomy (**C**).

Figure 81.4. Transoral stapling of Zenker diverticulum using a modified stapler and laryngoscope.

Technique

An open approach for either a diverticulopexy or diverticulectomy both with cricopharyngeal myotomy, an incision is made along the anterior border of the sternocleidomastoid muscle reflecting the carotid sheath laterally. The omohyoid muscle can be divided if necessary for visualization. The prevertebral fascia is identified and moving medially; the esophagus was dissected out with the diverticulum extending posteriorly and inferiorly. After elevation and dissection to the base of the diverticulum, a myotomy is created starting with the division of the cricopharyngeus and extending to the base of the diverticulum. The myotomy should extend 5 to 6 cm distally and completely through the cricopharyngeus. It is then extended 1 to 2 cm onto the hypopharynx proximally. With the myotomy complete, for a diverticulopexy, the dissected diverticulum can be suspended with 4 or 5 silk stitches to the posterior aspect of the pharyngeal esophageal junction. Conversely, the diverticulum can be suspended from the prevertebral fascia in this region.

For a diverticulectomy with the myotomy complete and the diverticulum completely dissected out to its base, a 48 French Maloney bougie is placed within the esophagus and a TA stapler is used to come across the base of the diverticulum. If the diverticulum is to be resected sharply and the suture line closed by hand, this is performed with a two-layer technique with absorbable suture for the inner layer. Some surgeons

advocate for closing muscle over the hand-sewn repair, or buttressing with muscle around the esophagus. If needed, the myotomy can be shifted to be made lateral to the diverticulum, rather than extending from the base of the pouch.

For the transoral stapled approach, the patient is placed in the “sniffing” position and flexible esophagoscopy performed to assess the size of the diverticulum and remove any retained material from the diverticulum. Rigid esophagoscopy is performed using the Weerda laryngoscope (Karl Storz, Tuttlingen, Germany). This scope has two jaws. One jaw is placed in the esophagus and the second is placed in the diverticulum. The jaws are then expanded which allows clear visualization of the diverticulum and the common septum formed by the cricopharyngeus muscle and the esophagus. The addition of a 5-mm 30-degree laparoscope alongside the Weerda laryngoscope can further enable visualization of the diverticulum. A traction suture (US Surgical Endostitch-Norwalk, Connecticut) is placed in the common septum. The traction suture helps to expose the septum and facilitates a complete cricopharyngeal myotomy. Using the suture to provide traction on the common septum, the modified stapler is placed across the septum and fired. The modified anvil is placed within the diverticulum and the disposable cartridge within the esophageal lumen. Further firings of the stapler as needed are performed to ensure the common septum is divided to the base of the diverticulum. Occasionally, the stitch is replaced after a firing of the stapler to further expose the septum. Other options for division of the common septum via a rigid endoscopic approach include the use of a harmonic scalpel and CO_2 laser in combination with the Weerda laryngoscope.

Figure 81.5. Weerda laryngoscope. (From Luketich: With kind permission from: Morse CR, Fernando HC, Ferson PF, et al. Preliminary experience by a thoracic service with endoscopic transoral stapling of cervical (Zenker's) diverticulum, (Figure 1). *J Gastrointest Surg* 2007;11:1901–4. Springer Science+Business Media.)

Finally, there are a number of flexible endoscopic options first reported in 1995. As the procedures are endoscopic, they can be performed with monitored anesthesia and without the need for neck flexion. Techniques used to divide the common septum include electrocautery including needle knife and argon beam coagulation. A transparent hood is attached to the scope to improve visualization and stabilize the instrumentation/scope. Starting at the top of the septum, an incision is made with either the needle knife or argon beam probe and extended inferior. Some operators place clips on either side of the septum to facilitate dissection and advocate for the placement of an nasogastric tube to further facilitate visualization. Without a diverticuloscope, the nasogastric tube has the benefit of serving as an incisional guide when dividing the septum.

POSTOPERATIVE MANAGEMENT

No nasogastric tube is left. With an open approach, a small drain is often

left in place adjacent to the repair. A barium swallow is obtained on the first postoperative day and a liquid diet initiated if satisfactory. The drain is removed after the swallow study and the patient discharged to home on the same day with specific dietary advancement instructions over several weeks. With a transoral/endoscopic approach, a small residual spur is often noted at the inferior aspect of the divided cricopharyngeus on the barium swallow that is thought to be of minimal clinical significance and postoperative manage is similar, except there is no drain placed.

Complications

A leak from the staple line is extremely uncommon and can typically be handled conservatively with antibiotic therapy and nothing by mouth. With an open, left neck approach, a traction injury to the recurrent laryngeal nerve can occur and often resolves with time. Also the formation of a hematoma or wound infection is possible with an open approach. The most commonly reported injury with a transoral stapled approach is a dental injury from the placement of the laryngoscope. Much less frequent, but with significant morbidity, is descending mediastinitis.

RESULTS

There are several large series of open approaches, with most reporting very low complication rates, almost no mortality and excellent symptomatic outcomes (Table 81.2). Lerut report a series of 289 patients with a complication rate of 8.5%, no mortalities and a recurrence rate of 0.03%. Clinical outcomes were outstanding with 94.2% of patients reporting excellent symptom improvement.

The endoscopic options in the treatment of ZD began with Mosher in 1917 with the diverticular spur was divided sharply with a knife/punch biopsy. This was abandoned after seven patients secondary to a patient death. In 1960, Dohlman and Mattson furthered the endoscopic technique using a fixed laryngoscope and a diathermy knife. In their initial 100 cases, they reported no significant complications and 7% of patients with a recurrence of symptoms. In 1982, Van Overbeek reported the endoscopic division of the common diverticular wall with a CO_2 laser. This was done in conjunction with an operating microscope and large diverticuli required several sessions. Collard revolutionized the endoscopic treatment of ZD by the introduction of the endoscopic stapler. They described modifying the tip of the stapler and used video assistance with the procedure. Chang

followed up in this work with a study reporting 150 patients where they reported a 12.5% recurrence rate and 73% of patients with resolution of symptoms. A recent study from Gutschow et al. compared open surgical intervention to endoscopic repair by either endoscopic stapling or endoscopic laser division. In examining 84 patients approached with an open approach and 79 with an endoscopic approach (25 stapled and 54 laser), they note that in larger diverticulum (3 cm or larger), there was difference between the endoscopic and open procedures when examining patients who were either asymptomatic who had mild occasional symptoms at 86% versus 56% with excellent relief of symptoms. However, at less than 3 cm the results dropped off significantly at 85% versus 25% patients reporting results. Further confirming the size criteria of 3 cm for a endoscopic approach is Vinosky, who noted an almost 23% recurrence rate for patients with diverticula less than 3 cm in size.

Finally for a flexible endoscopic approach to ZD, there are a number of studies totally upward for 650 patients. The largest series to date is from Huberty (2013) with 134 patients. The technique employed a needle knife and soft diverticuloscope. Patients on average require 1.2 interventions with a complication rate reported at 2%. There was a 23% recurrence rate. The dysphagia scores were noted to improve from 1.88 to 0.34 (p <0.05).

Today, ZD can be treated safely with low mortality irrespective of the approach. Almost all patients treated for ZD, again irrespective of approach, can be started on oral intake 1 to 2 days following the procedure and can discharged expeditiously. Certainly a transoral stapled endoscopic approach is not appropriate for diverticula less than 3 cm and a review and there are now an increase in reports of endoscopic treatments for ZD. Complicating any interpretation of these results is the lack of any consistent definitions for outcome measures and the unpredictable reporting of complications. However, it does appear that an endoscopic approach results in more frequent reinterventions and a higher incidence of recurrence and/or insufficient control of symptoms. A randomized trial with consistent definitions and end points would certainly help to clarify the landscape, but is unlikely to be performed.

EDITOR'S COMMENT

The key elements to managing a Zenker diverticulum (ZD) are correction of the hypertensive upper esophageal sphincter (UES), the cricopharyngeal muscle, and reducing the ability of the diverticulum to serve as reservoir for food and other swallowed materials. There are several important points that should be considered: the necessity of a myotomy, the length of the myotomy, and then how to determine what is the best treatment approach for a given patient: an open cervical approach, a transoral stapled technique, or an endoscopic

approach.

Is it necessary to do myotomy to treat ZD? The consensus today is yes. This is based on the rationale of that UES dysfunction could be a cause of the formation of the diverticulum. The literature supports the concept myotomy is crucial to successful treatment. Skinner et al. (Recurrent Zenker's diverticulum: treatment with crycopharyngeal myotomy. *Am Surg* 1998;64:192–5) reported their experience in dealing with recurrent ZD and identified that most patients with an early recurrence had an inadequate cricopharyngeal myotomy. Those who underwent reoperation with a completed myotomy had symptom relief during a 53-month follow-up. Gutschow et al. (Management of pharyngoesophageal (Zenker's) diverticulum: which technique? *Ann Thorac Surg* 2002;74:1677–82) compared open diverticulectomy alone (n = 34) with open cervical approaches along with myotomy (n = 67). The results showed no difference in terms of "good" or "excellent" symptomatic outcomes. However, they noted that diverticulectomy without myotomy predisposed to the development of postoperative fistula and recurrence. Yong Yuan et al. reported a meta-analysis on the treatment of ZD (Yuan Y, Zhao YF, Hu Y, et al. Surgical treatment of Zenker's diverticulum. *Dig Surg* 2013;30:207–18). In 41 studies of open surgeries, only 2 studies did not perform myotomy. They also noted that 2,526 patients out of 2,826 treated with open surgery for ZD received either myotomy alone or along with other approaches, which reflects that most surgeons consider the dysfunction of UES as an etiologic factor for ZD.

How long should the myotomy be? Morse et al. in this chapter state "the myotomy should extend 5 to 6 cm distally and completely through the cricopharyngeus…and…then extended 1 to 2 cm onto the hypopharynx proximally." In order to achieve a complete myotomy, the following muscles should be divided: cricopharyngeus muscle, the inferior pharyngeal constrictor, and the cervical esophageal striated muscle. Yong Yuan et al. note that "there is no general agreement on the exact length of the myotomy, ranging from 2 to 6 cm." Comparing ZD patients with healthy controls, Lerut et al. (Zenker's diverticulum: is a myotomy of the cricopharyngeus useful? How long should it be? *Hepatogastroenterology* 1992;39:127–31) demonstrated that pathologic changes occur in cricopharyngeal muscle as well as the cervical esophageal striated muscle and recommend a long (4 to 5 cm) myotomy for better outcomes. Most employ a linear myotomy as described in this chapter but Duranceau et al. (Physiologic response to cricopharyngeal myotomy and diverticulum suspension. *Surgery* 1983;94:655–62) propose a flap-resected myotomy arguing that this could prevent subsequent healing of the muscle fibers that could lead to a recurrence. It seems that in most cases a long longitudinal myotomy (4 to 6 cm) should be performed but individual variation in cervical muscular anatomy could require a myotomy of lesser extent or perhaps even more.

As described in the current chapter, ZD may be managed by an open cervical technique, a transoral procedure, or endoscopic procedures. The open cervical

approach had been the gold standard until the evolution of transoral and endoscopic techniques. The open cervical approach may consist of cricopharyngeal myotomy with diverticulectomy, myotomy alone for diverticula less than 1 cm, myotomy and inversion of the diverticulum and myotomy and suspension of the diverticulum: diverticulopexy. At our center, we rarely employ the later technique as use of stapling devices to facilitate diverticulectomy has reduced complications. However, there are reports demonstrating the efficacy of diverticulopexy and there may be some merit particularly in the severely debilitated patient. Brigand et al. (Suspension diverticulopexy for Zenker's diverticulum. *J Chir (Paris)* 2008;145:341–5) report diverticulopexy with cricopharyngeal myotomy is an effective, reliable, and reproducible technique for the correction of ZD smaller than 5 cm. In this author's opinion, diverticulectomy should be reserved for larger diverticula. Not many surgeons consider inversion of the diverticulum, but it may be a valuable technique. Mantsopoulos et al. (Evaluation of the different transcervical approaches for Zenker diverticulum. *Otolayngol Head Neck Surg* 2012;146:725–9) reported 54 patients with ZD were treated using a transcervical approach. Three with a small diverticulum underwent a simple myotomy of the cricopharyngeal muscle. Myotomy was combined with a diverticulum inversion in 14 patients and myotomy with diverticulectomy was performed in 37 patients. The surgical procedures were compared with regard to mean anesthesia time, duration of hospitalization, overall complication rate and rate of serious complications, recurrence rate, and follow-up results. They found that hospitalization times were significantly shorter in the inversion group (p = 0.024). No statistically significant differences were observed between the transcervical modalities for any of the other variables investigated. They concluded that inversion is an effective modality and is by definition less traumatic than traditional diverticulectomy. Although the size of the diverticulum appeared to be a helpful criterion, careful intraoperative evaluation is the key element in deciding which transcervical procedure should be used. It is this authors' view that inversion should always "be considered if the individual anatomy of the diverticulum sac (in terms of pharyngeal pouch size and intactness of the mucosa) allows it."

Given that the typical patient is frail and elderly with significant comorbidities, there has been a trend to use transoral or endoscopic techniques more frequently. There is debate about which of the procedures is best and there is no consensus about which approach is superior. To date, there is no strong evidence to conclude whether a procedure is superior over another, and the results vary significantly in different studies because of varied inclusion criteria, sample size, length of follow-up period, and the percentage lost to follow-up. A summary of the comparative studies between 1990 and 2011 by Yong Yuan et al. demonstrated the following:

1. The overall morbidity and mortality rate for the endoscopic approach was

8.7% and 0.2%, respectively, whereas it was 10.5% and 0.6% for open surgery.
2. Application of the endoscopic technique also has reduced the fistula rate from 3.3% in open surgery to 0.6% and eliminated injury to the recurrent laryngeal nerve.
3. The endoscopic approach has increased the risk of esophageal mucosal damage, intraoperative bleeding, and dental injuries, accounting for a higher risk of conversion during the rigid endoscopic procedure.
4. As for the convalescent period, some studies reported that endoscopic approaches needed less anesthetic and operative time, allowed earlier resumption of oral intake, and required a shorter hospital stay.
5. The open cervical approach and transoral endoscopic approach usually require one treatment. The flexible endoscopic procedure is usually performed in stages to reduce the incidence of complications.
6. The recurrence rate for transoral or endoscopic treatment varies from 7% to 40% and that for an open cervical approach varies from 7% to 15%. As many of the studies are uncontrolled and retrospective, it is difficult to arrive at definitive conclusions regarding the overall comparative success rate.

While I believe most authorities would agree that an open surgical approach has a lower recurrence rate than a rigid or flexible endoscopic approach, it may be helpful to look at two recent reports. A study by Shahawy et al. (A comparative study of outcomes for endoscopic diverticulotomy versus external diverticulectomy. *Otolaryngol Head Neck Surg* 2014;151(4):646–51) reported an experience with both endoscopic diverticulectomy and external diverticulectomy using the linear cutting stapler. They conducted a retrospective analysis comparing these two procedures in terms of in-hospital parameters, complications, return to normal diet, and rates of symptom recurrence. The analysis consisted of 67 patients seen at Brigham and Women's Hospital between 1990 and 2012. Although the cervical stapler-assisted procedure for ZD carried a longer intraoperative time and a slightly longer hospital stay than the endoscopic approach, it provided similar days until initiation of an oral diet and a similar incidence of postoperative complications. It was superior to the endoscopic approach when one considers its much lower rate of symptomatic recurrence and need for revision procedures. The rate of recurrent symptoms was significantly higher in the endoscopic group at 39% (13 patients) compared with 0 recurrences in the open cervical group (p = 0.00011). Another recent study by Bonavina et al. is informative as well (Long-term outcome and quality of life after transoral stapling for Zenker diverticulum. *World J Gastroenterol* 2015;21(4):1167–72). They report a prospective experience in 100 patients treated with transoral stapling between 2001 and 2013. The overall success rate was 76% and was improved with a modification of the techniques using a traction suture on the septum. This has been noted by others as well. In this

study, the median age was 75 years. Transoral stapling was performed using a Weerda diverticuloscope under general anesthesia. The technique was modified over time by applying traction sutures to facilitate engagement of the common septum inside the stapler. They reported complications in 4% of the patients but no mortalities. There was improvement in dysphagia and regurgitation scores (p <0.001) during a median follow-up of 63 months. In addition, there was a significant decrease in the median number of pneumonia episodes per year. The overall long-term success rate of the procedure was 76% being greater in patients of 70 years of age or older compared to younger individuals. The application of traction sutures on the septum was associated with an improved success rate compared with the standard procedure. They further noted that all items of the health-related quality of life questionnaire were significantly higher compared to baseline.

From the literature, there is agreement for several considerations. First a transoral or endoscopic approach should be limited to diverticula between 3 cm and 7 cm. The results are superior with open diverticulectomy compared to endoscopic procedures for diverticula less than 3 cm. In addition, transoral or endoscopic treatment of large diverticula >7 cm could lead to a long dynamic segment of the cervical esophagus (Bonavina L, Bona D, Abraham M, et al. Long-term results of endosurgical and open surgical approach for Zenker diverticulum. *World J Gastroenterol* 2007;13:2586–89; Gutschow CA, Hamoir M, Rombaux P, et al. Management of pharyngoesophageal (Zenker's) diverticulum: which technique? *Ann Thorac Surg* 2002;74:1677–82). In addition, there is agreement that the transoral approach and perhaps the endoscopic approach may be more difficult in the following situations: a patient whose diverticular septum cannot be well exposed, such as small pouch, a stiff neck, poor ability to open the mouth widely, prominent maxillary teeth, a short neck, a retrognathic mandible, a large tongue, a rigid cervical kyphosis, and obesity. The flexible endoscopic treatment is promising and may be performed without the need of general anesthesia and hyperextension of the neck and may be preferred in some situations.

Summary

Surgical treatment of ZD has evolved over the previous two decades to a predominantly endoscopic approach but an open cervical approach is still required in a substantial number of cases. It is likely that endoscopic techniques will evolve further with advances in technology. The open cervical approach will serve as a mainstay for small and large diverticula and in those who cannot undergo an endoscopic approach.

B THE STOMACH AND DUODENUM

82 Anatomic Considerations in Gastroduodenal Surgery

Petros Mirilas, Marios Loukas, and Lee J. Skandalakis

INTRODUCTION

The purpose of this chapter is to describe the embryology and anatomy of the stomach and duodenum—not in fine detail, but as it is approached in gastroduodenal surgery. An understanding of the anatomy flows from an understanding of the embryology.

The vast majority of gastroduodenal surgeries are still open and traditional. Laparoscopic surgery of the stomach and duodenum continues to evolve. Understanding the anatomic entities will allow the student and the experienced surgeon to transition easily from traditional surgery to a more minimally invasive approach when appropriate, and as supported by advances in device technology.

EMBRYOLOGY OF THE STOMACH, DUODENUM, OMENTA, AND OTHER GASTRIC PERITONEAL LIGAMENTS

Below the tracheal diverticulum, the foregut of the embryo forms the esophagus, which extends until the dilation marking the developing stomach (Fig. 82.1). The gastric dilation is initially (5th week) positioned at the level of C3 to C5 vertebrae (Fig. 82.1A). With the growth of the embryo, the foregut elongates; thus, the length of the esophagus increases and the stomach descends. At the end of 7th week, the stomach is found between T11 and L4 (Fig. 82.1B).

The stomach and duodenum develop between the two folds of the

mesentery. With reference to the intestine, the mesentery is divided into dorsal mesentery, which connects these splanchna to the posterior abdominal wall, and ventral mesentery, connecting them to the anterior abdominal wall (Figs. 82.2 and 82.3).

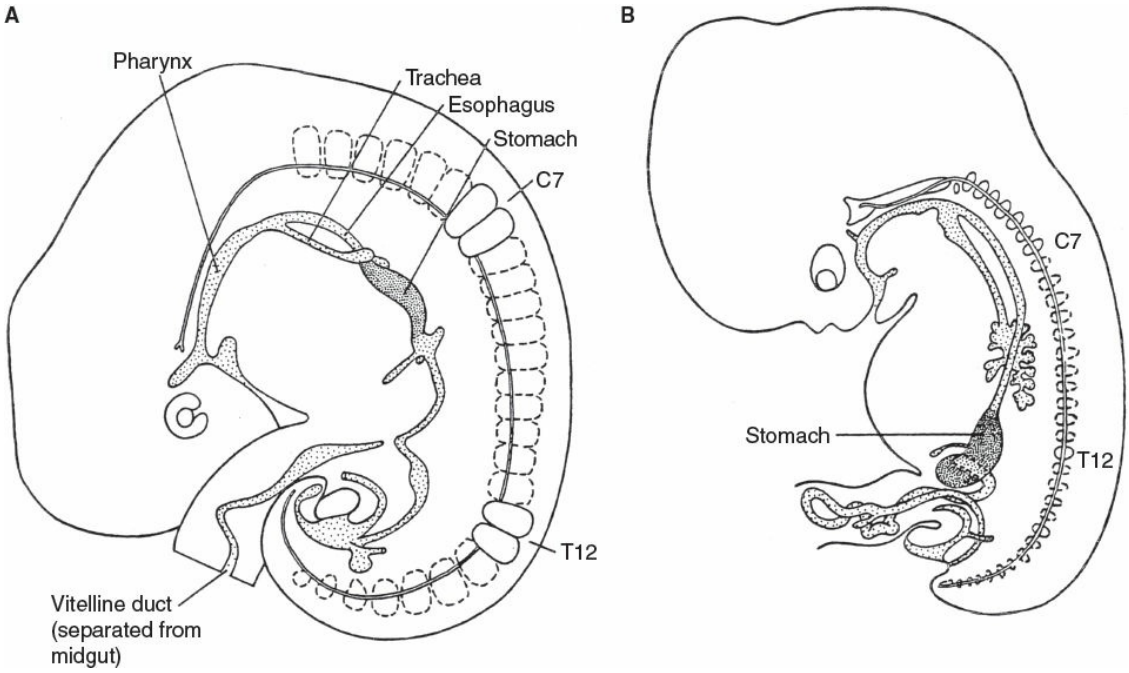

Figure 82.1. The embryonic gut, showing the changes in position of the stomach. **A.** Shape of the stomach at 6.3 mm (6th week). **B.** Rotation and descent of stomach essentially completed at 17.5 mm (end of 2nd month). (From Skandalakis JE, Gray SW, Ricketts R. The stomach. In: Skandalakis JE, Gray SW. *Embryology for Surgeons*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994:151.)

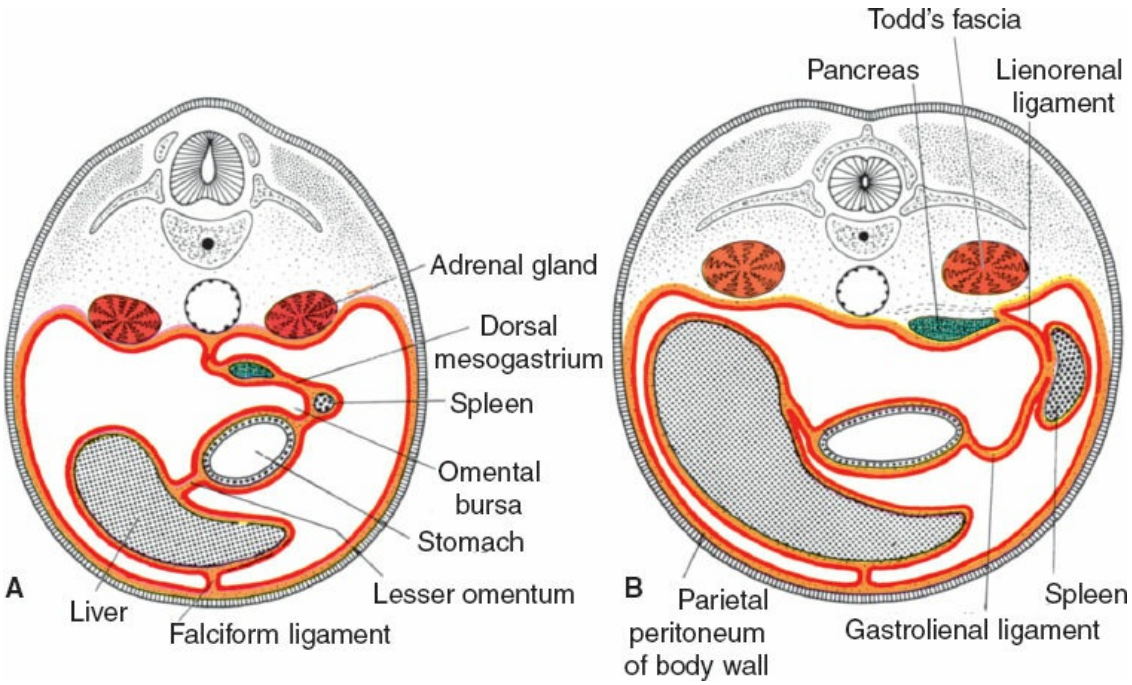

Figure 82.2. A. Transverse sections through the region of the stomach, liver, and spleen, showing formation of the lesser peritoneal sac, rotation of the stomach, and position of the spleen and tail of the pancreas between the two leaves of the dorsal mesogastrium. **B.** With further development, the pancreas assumes a retroperitoneal position. (From Sadler TW. *Langman's Medical Embryology*. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:210.)

Other organs also develop in this configuration: the liver develops in the ventral mesentery and is connected to the anterior abdominal wall by the falciform ligament and to the stomach by the lesser omentum. In the dorsal mesentery, the spleen and pancreas are found; the pancreas is behind the spleen. The peritoneal ligament between stomach and spleen is the gastrosplenic ligament, and then follows the ligament between spleen and pancreas and finally the ligament connecting the pancreas to the posterior wall.

The initial development of these organs in a row (liver-stomach-spleen-pancreas) changes dramatically with the formation of the omental bursa, that is, the cavity behind the stomach. O'Rahilly and Muller point out that the omental bursa develops by the coalescence of small spaces and initially forms the right pneumatoenteric recess, between the lung and stomach. The liver develops below this recess; the recess is associated with the liver and is named the hepatoenteric recess. Finally, the lesser sac develops behind the stomach, extends with a superior recess behind the liver, and

with an inferior recess between the two leaves of the great omentum. From the beginning, the bursa has a communication with the rest of the abdomen, the omental foramen (Winslow's) (Fig. 82.4). Fischer commented that "*the omental bursa, which is the cavity behind the stomach, has a great deal of influence over the anatomical arrangement of the liver—stomach—spleen—pancreas.*"

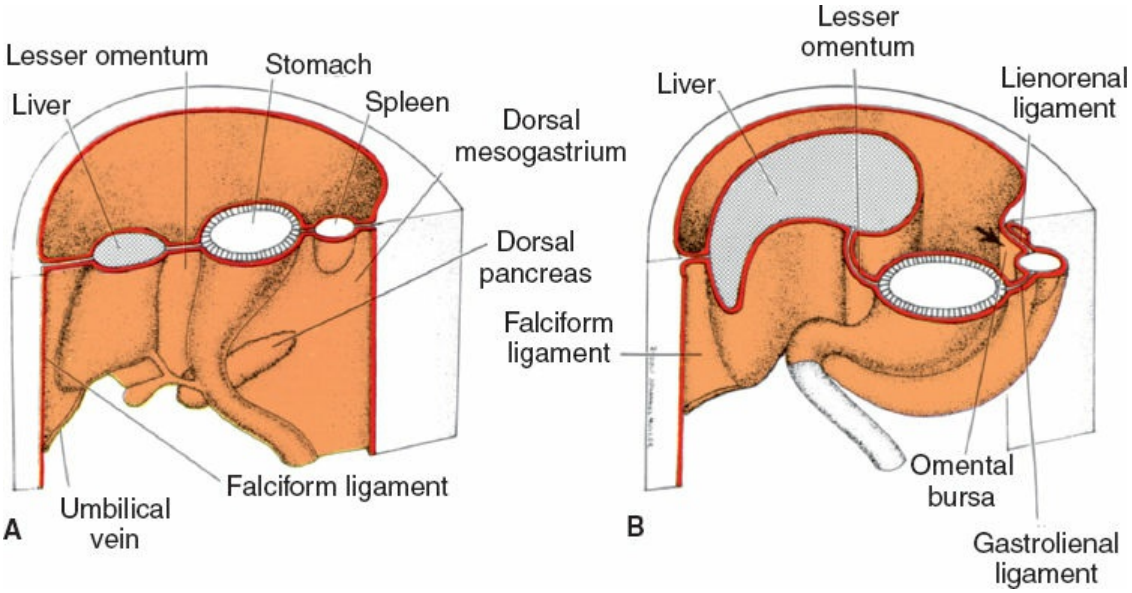

Figure 82.3. A. The position of the spleen, stomach, and pancreas at the end of the 5th week. Note the position of the spleen and pancreas in the dorsal mesogastrium. **B.** Position of spleen and stomach at the 11th week. Note formation of the omental bursa or lesser peritoneal sac. (From Sadler TW. *Langman's Medical Embryology*. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:209.)

The initial theories of embryologists were that a left turn of the stomach takes place and forms the omental bursa. These ideas were useful to understand the alteration of positioning of the vagus nerves: the left vagus on the anterior gastric wall, the right vagus on the posterior abdominal wall. However, such conjectures cannot explain the upper extension of the bursa around the caudate lobe of the liver or the opening of this cavity, the omental foramen (Winslow's).

The truth about the "left turn" of the stomach relies on differential growth of the left wall of the stomach. This results in the formation of a lesser and greater curvature of the stomach, and the repositioning of the ventral and dorsal mesogastria. Thus, the lesser omentum and the gastrosplenic ligament become horizontal (Figs. 82.2 and 82.3). Other

major morphogenetic events are the growth and right-posterior location of the liver and the posterior positioning of the pancreas, which attaches to the posterior abdominal wall and becomes a secondarily retroperitoneal organ. The ligament attaching the pancreas to the posterior abdominal wall disappears, and an avascular plane (Todd's fascia) develops behind the pancreas (Fig. 82.2B). The remaining ligament connecting the spleen to the pancreas now becomes the splenorenal (lienorenal) ligament. The increased growth of the left side of the stomach also affects the respective dorsal mesogastrium, namely the gastrosplenic ligament, which bulges downward and forms the omentum. The posterior double-layered leaf of the omentum attaches on the mesentery or the transverse colon; then, the two leaves of the omentum hanging down from the colon fuse between themselves (Fig. 82.5).

As a general rule, mesenteries connect organs to the abdominal wall and each other and carry all the vascular, neural, and lymph supply for the organs developing within them. Fulfilling this description of a mesentery, the lesser omentum will supply the pathway for the neurovascular supply of the liver, and will be the courier of the hepatic artery, portal vein, ducts, nerves, and lymphatics. The falciform ligament is the mesentery for the umbilical vessels reaching the hilum of the liver. The gastrosplenic ligament contains the short gastric arteries; the splenorenal ligament carries the splenic vessels. The vessels deriving all from the aorta all lie in the retroperitoneum, where they course for a distance and then enter the respective mesenteries to reach the splanchna they supply. For instance, in the adult configuration, the hepatic artery courses retroperitoneally and then enters the lesser omentum, as does the portal vein. The right gastric artery also enters the lesser omentum to reach the lesser curvature.

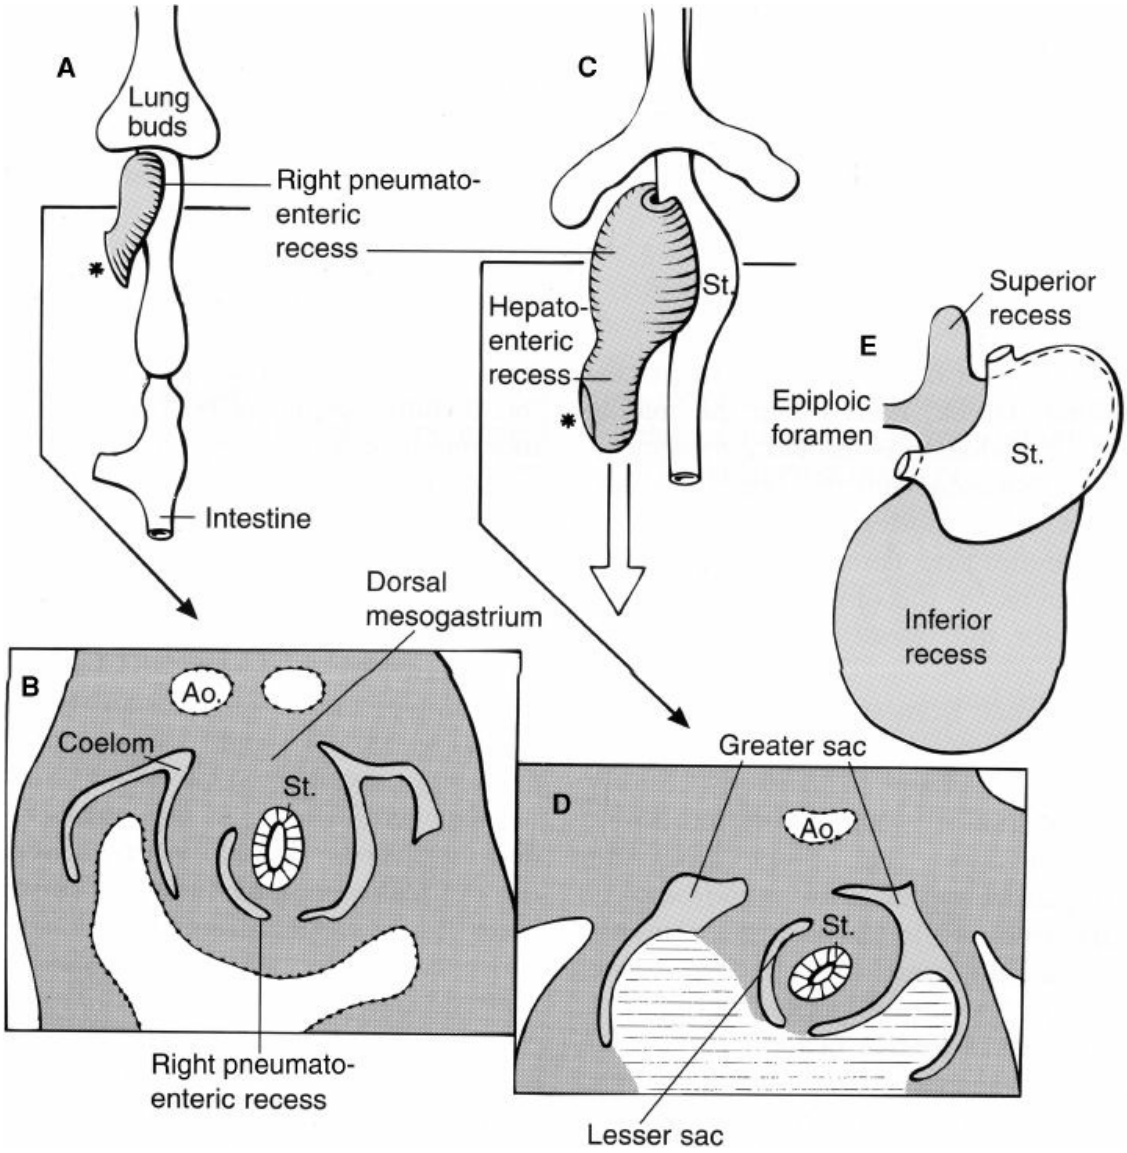

Figure 82.4. Development of the lesser sac of the peritoneal cavity. **A.** Ventral view of the gut at 4½ weeks showing appearance of the right pneumatoenteric recess. The recess communicates with the coelom, and the opening (*asterisk*) may represent the future epiploic foramen. **B.** A day or so later, the recess is becoming wrapped around the right aspect of the stomach (St). **C.** Scheme of the form of the lesser sac in the adult as seen from in front. Superior and inferior recesses are evident, and the lesser and greater sacs communicate by the epiploic foramen. (Modified with permission of John Wiley & Sons, Inc. from O'Rahilly R, Müller F. *Human Embryology and Teratology*. 3rd ed. New York: Wiley-Liss; 2001, permission conveyed through Copyright Clearance Center, Inc.)

The lower esophagus also has a mesentery, the mesoesophagus. After it passes the diaphragm, the lower esophagus lies retroperitoneally; further

caudad it regains its mesentery, which is broad. The result is that the abdominal esophagus is covered by peritoneum anteriorly and on both sides laterally, while its posterior surface toward the diaphragm is still retroperitoneal, giving way to the entrance of the left gastric artery for the lower esophagus and the upper lesser curvature of the stomach.

The adult duodenum corresponds to an area of the embryonic foregut and midgut distal to the stomach. The embryonic midgut undergoes a normal herniation into the umbilical cord during the 5th week of gestation (Fig. 82.6A). This part of the intestine is fed by the superior mesenteric artery (SMA). The herniated intestine undergoes a rotation of 90 degrees around the axis of this artery, bringing the colon over the small intestine. In the 10th week, intestines return in the abdomen. The duodenum comes back first and takes its position under the SMA, while the cecum is still in the umbilical cord (Fig. 82.6B). The distal ileum and the colon are positioned in front of the SMA, and during their return they undergo another 180-degree rotation. Knowledge of these relations is essential for the surgeon in order to understand the normal anatomy, and the cases of anomalies of rotation affecting the duodenum as well as the possible compression of the duodenum under the SMA.

As pointed out previously, abdominal splanchna develop in the mesentery. So does the duodenum, which initially has a mesentery (mesoduodenum). The ventral pancreas also develops dorsally in the mesoduodenum and is met by the ventral pancreas, by way of the “left turn” of the stomach, also affecting this lower area (Fig. 82.7). The duodenum and the pancreas finally locate retroperitoneally (secondarily retroperitoneal organs). The right leaf of the mesentery becomes posterior, meets the parietal peritoneum of the dorsal abdominal wall, and fuses with it, forming an avascular plane. The surgeon who knows this can approach from the left (where no mesentery is found and consequently no vessels exist), dissect and detach the duodenum together with the head of the pancreas, and recreate the original mesentery with all vessels in hand, without risk of bleeding (Kocher’s maneuver).

Another aspect of embryology necessary to understand the anomaly of a preduodenal portal vein is that the vitelline (omphaloenteric) veins, which follow the intestine of the embryo, undergo a major reconstruction of communications between them to form the portal vein (Fig. 82.8). Normally, the anterior communication disappears and the posterior stays; a portal vein thus formed would locate behind the duodenum. In the opposite

case (the anterior, lower communication is kept and the posterior, upper disappears), a preduodenal portal vein is formed.

Another point of embryologic consideration for the surgeon is that the embryogenesis of the lymphatics follows the arteries. This is extremely important to remember and applies everywhere. All lymph nodes are encountered along arteries; nodes and the end of the lymph flow lie at the stem of the arteries. Since the mother artery of the upper abdomen is the celiac trunk, the final destination of lymph flow will be the celiac nodes. The nerves also follow the arteries to reach the respective splanchna. The formation of arteries is a strong morphogenetic event; veins are not the guide for lymphatics and nerves.

Finally, of great importance for the surgeon is to understand that the duodenum is a product of the foregut and midgud. This has tremendous consequences on the blood supply, innervation, and lymphatic drainage:

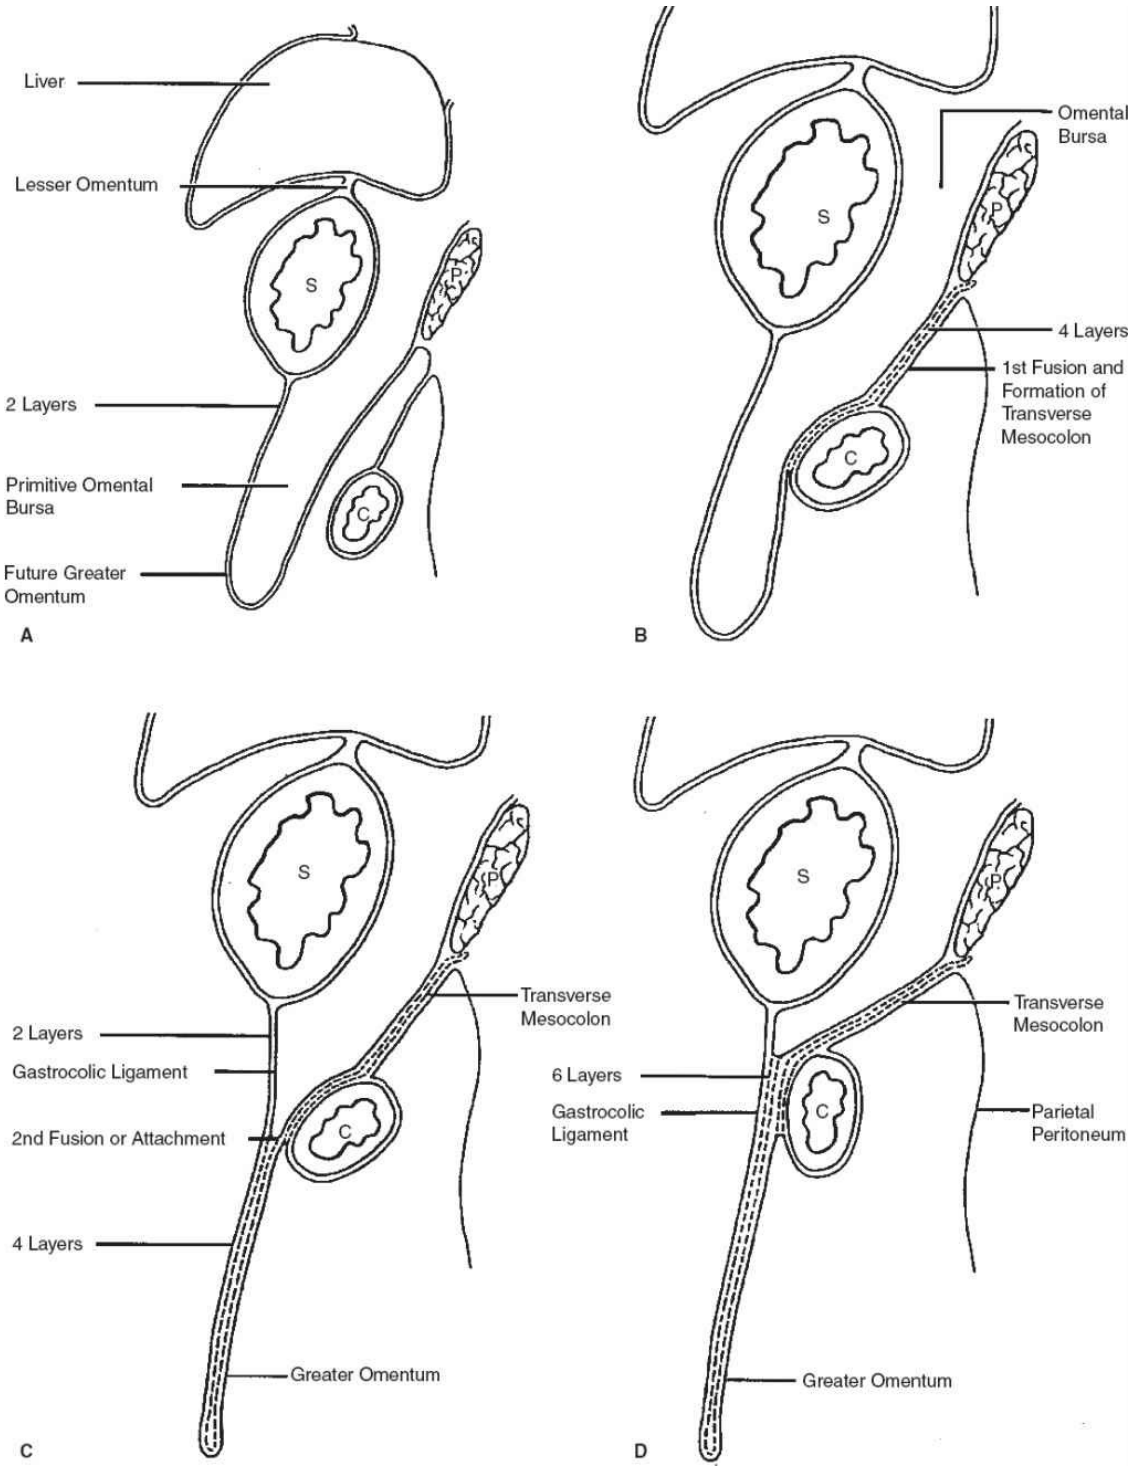

Figure 82.5. Formation of greater omentum. **A.** After rotation of stomach and formation of omental bursa. **B.** First fusion of posterior wall of omental bursa to transverse colon and mesocolon. **C, D.** Second fusion or attachment of anterior and posterior walls of omental bursa to form adult omentum. C, colon; P, pancreas; S, stomach.

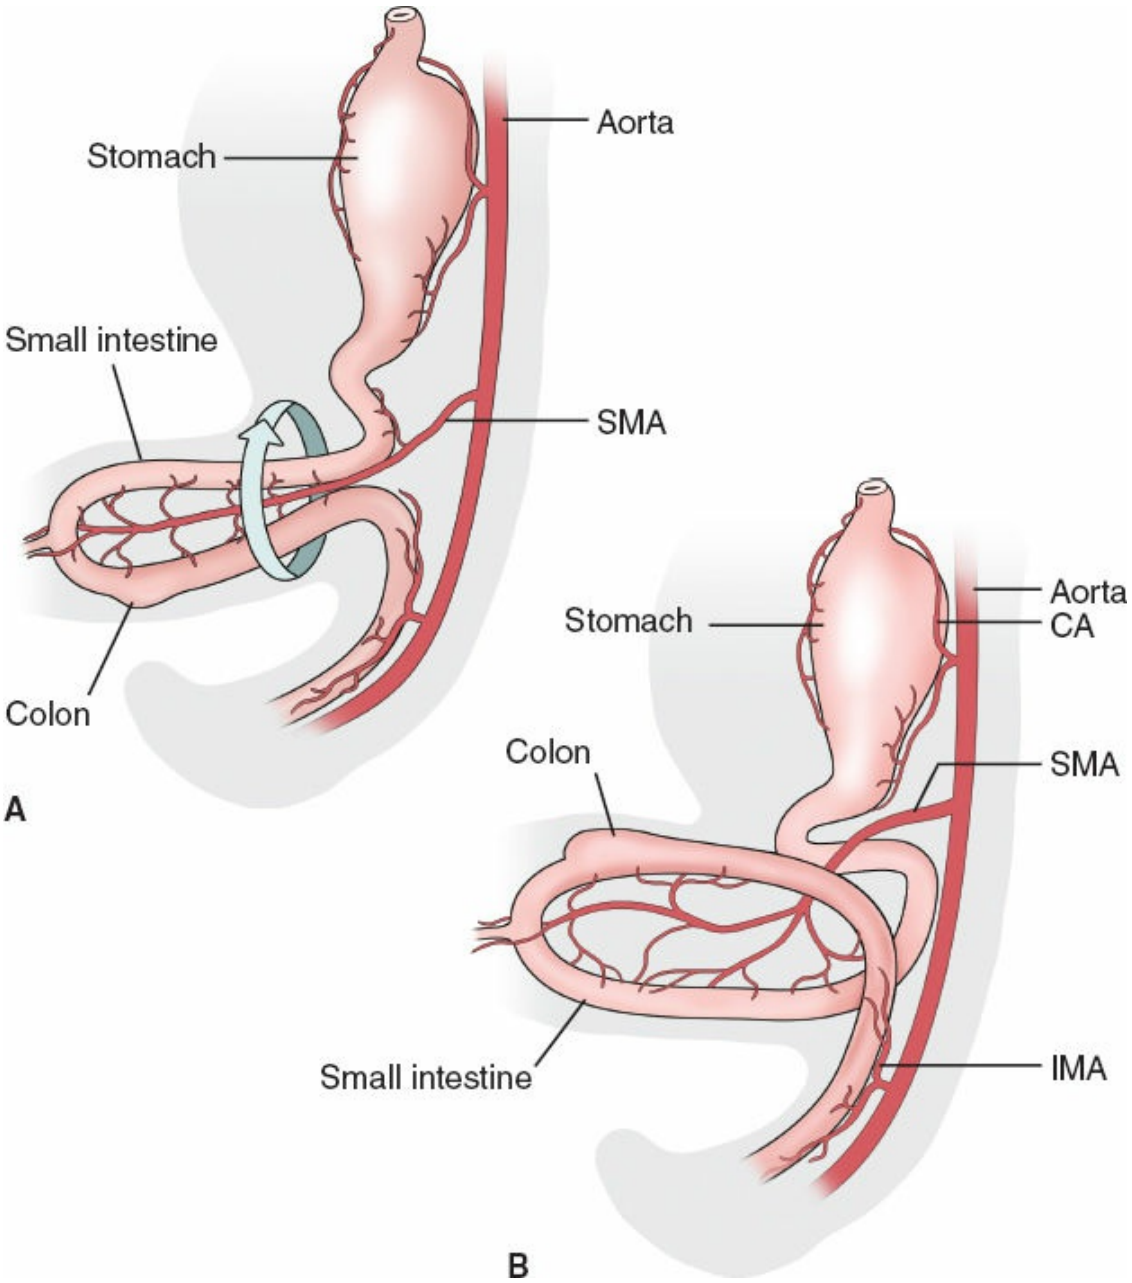

Figure 82.6. **A.** Primary rotation of the herniated embryonic midgut through 90 degrees. The superior mesenteric artery (SMA) lies in the axis of rotation. This artery, the celiac axis (CA), and the interior mesenteric artery (IMA) are the persisting elements of the primitive vitelline arterial system. **B.** The return of the intestines to the abdomen in the 10th week begins with the cranial loop. The future duodenum passes under the SMA. The cecum is still in the umbilical cord. (From Gray SW, Akin JT Jr, Milsap JH Jr, et al. Vascular compression of the duodenum. *Contemp Surg* 1976;9:38–9.)

The first part of the duodenum and the second part up to the entrance of the bile duct are given from the foregut and thus are supplied by branches

of the celiac artery.
The second part of the duodenum beyond the entrance of the bile duct is supplied by branches of the superior mesenteric artery.

CONGENITAL ANOMALIES OF THE STOMACH AND DUODENUM

Stomach

Congenital anomalies of the stomach are presented in Table 82.1.

Duodenum

1. *Malrotation and nonrotation:* The duodenum is not located under the superior mesenteric artery; the duodenojejunal flexure is absent. In incomplete (mixed) rotation, the prearterial segment has failed to rotate; the congenitally high cecum lies in front of the duodenum, where it is fixed to the posterior abdominal wall and may compress the duodenum (Fig. 82.9A). In nonrotation, the postarterial part (distal ileum or colon) of the midgut returns first; the colon is found on the left and the small intestine on the right (Fig 82.9B).

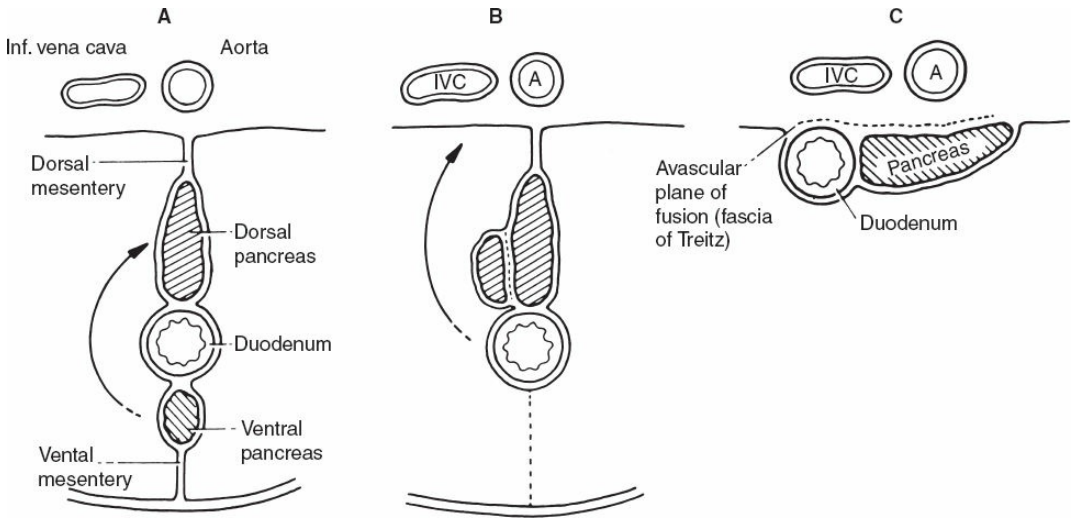

Figure 82.7. Rotation of the pancreas and duodenum. **A.** Primitive relations of dorsal and ventral pancreatic primordia. **B.** Disappearance of ventral mesentery and rotation of ventral pancreas. **C.** Final retroperitoneal position of duodenum and pancreas. The plane of fusion of the mesoduodenum is the avascular fascia of Treitz. (From Skandalakis JE, Gray SW, Rowe JS, et al. Anatomic complications of pancreatic surgery. *Contemp Surg* 1979;15:17–40.)

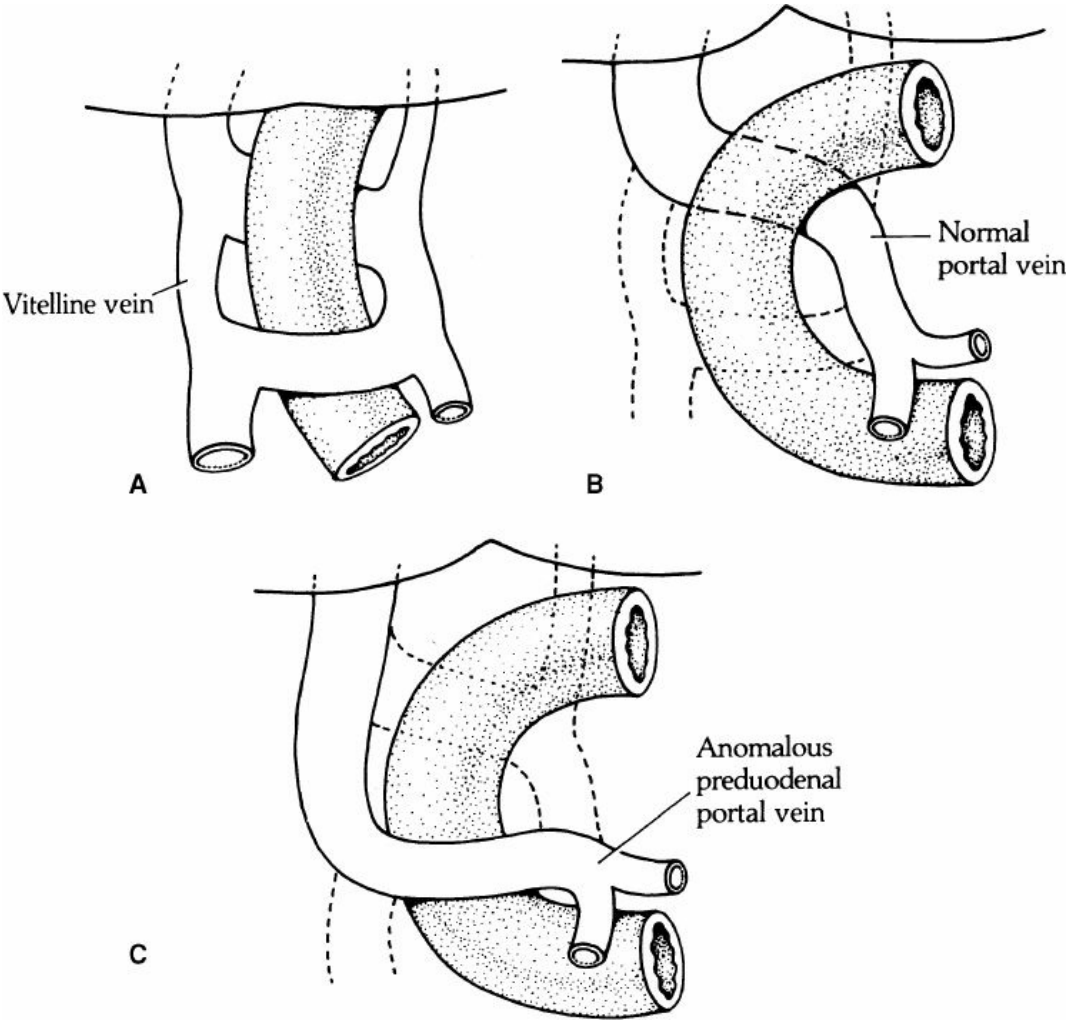

Figure 82.8. Embryonic origin of a preduodenal portal vein. **A.** Embryonic, extrahepatic communications between the vitelline veins. **B.** Normal development. The persisting superior communicating vein forms part of the normal, retroduodenal portal vein. **C.** Anomalous persisting inferior communicating vein forms part of an abnormal preduodenal portal vein. (From Skandalakis JE, Gray SW, Rowe JS Jr, et al. Anatomical complications of pancreatic surgery. *Contemp Surg* 1979;15:17–40.)

2. *Duodenal stenosis and atresia:* anomalies caused by failure of recanalization of the lumen of the duodenum, which is normally occluded between 4th and 7th week by proliferation of the epithelium, followed by recanalization. Stenosis of the duodenum may be associated with annular pancreas or with aberrant pancreatic tissue in the duodenal wall.
3. *Duodenal diverticula:* usually on the concave (i.e., pancreatic) wall of the second and third part of the duodenum. They are usually solitary

and asymptomatic. O'Rahilly suggests that they may be caused by persistence of normally occurring transitory diverticula that are present in the embryo.

4. *Preduodenal portal vein:* caused by abnormal formation of the portal vein as described above (Fig. 82.8). The vein may compress the duodenum to the point of obstruction.
5. *Superior mesenteric artery syndrome:* the result of the compression of the third part of the duodenum between the superior mesenteric artery and the aorta (Fig. 82.10). The condition may be caused by a short mesentery of a congenitally narrow angle between the artery and the aorta.
6. A similar condition is the *nutcracker syndrome*, which refers to compression of the left renal vein between the superior mesenteric artery and the aorta (Fig. 82.10). The result is renal venous hypertension that leads to hematuria due to rupture of thin-walled veins into the collecting system.

Gross Anatomic Parts of the Stomach and Duodenum

The gross anatomic parts of the stomach are: the cardia, the fundus, the body, the antrum (which is the proximal part of the pylorus), and the pyloric canal (Fig. 82.11). There is no external demarcation between the cardia and the fundus of the stomach. The fundus is considered as the part of the stomach located above the entrance of the esophagus. The body of the stomach is the part between the fundus and the pylorus. Again, there is no external demarcation between the body and the fundus. A fairly consistent landmark is an angular notch found two thirds of the way down the lower curvature, which delimits the body from the pyloric portion; a slight constriction at the end of the pyloric portion marks its junction with the duodenum (Fig. 82.12). The junction of the body of the stomach with the antrum can be estimated as in Figure 82.13. While an external examination provides no clue to the line of junction between the stomach and duodenum, some surgeons use the so-called pyloric vein to be as their guide (Fig. 82.12).

The duodenum has an upper, a descending, a horizontal, and an ascending part. The first, or free, part is not attached to the posterior abdominal wall. This part is attached to the hilum of the liver by the hepatoduodenal ligament. It is covered by peritoneum from in front and behind, unlike the rest parts of the duodenum that are retroperitoneal.

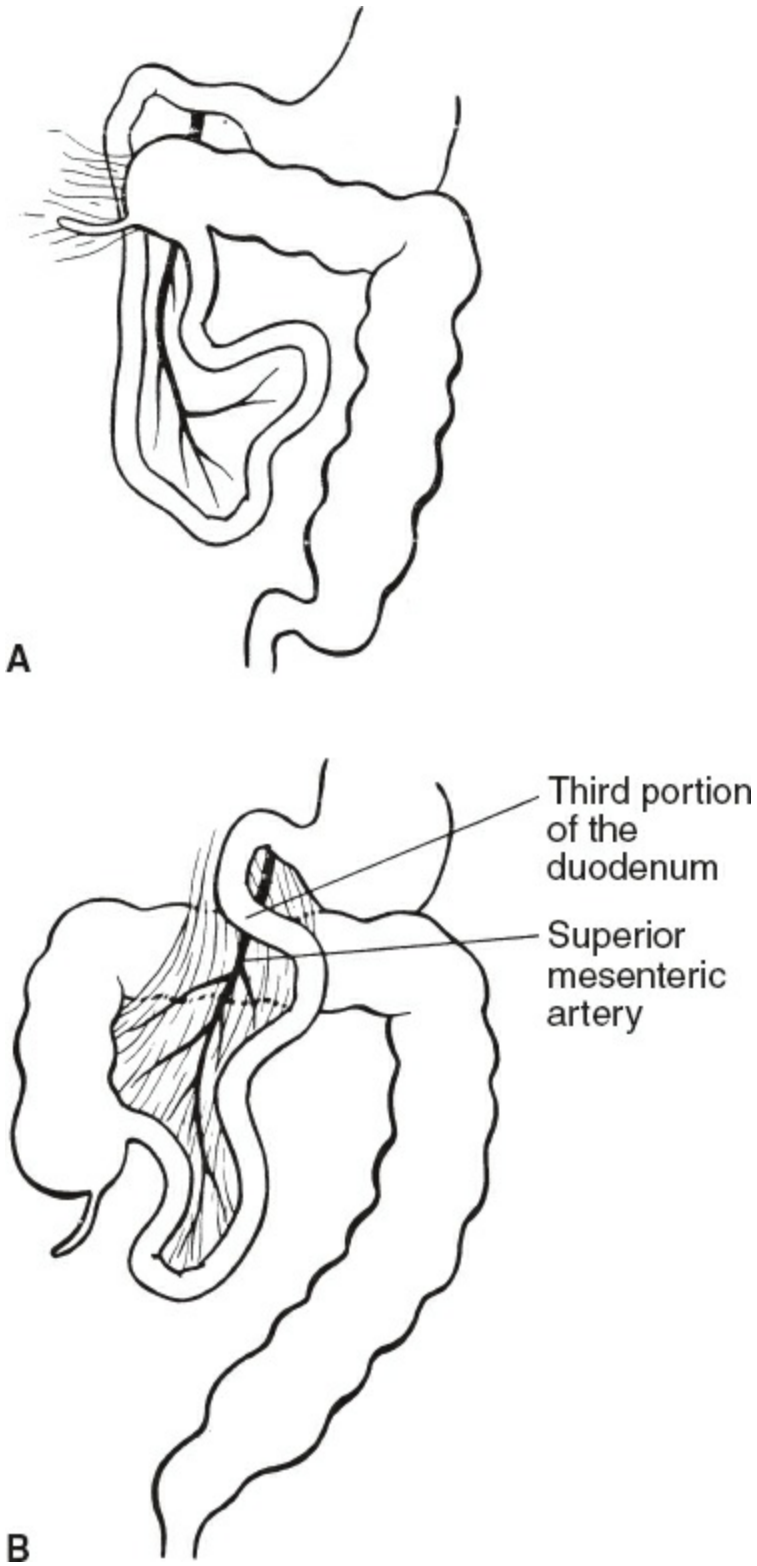

Figure 82.9. **A.** Mixed rotation. **B.** Nonrotation. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomic Complications in General Surgery*. New York: McGraw-Hill; 1983.)

TABLE 82.1 Anomalies of the Stomach

Anomaly	Prenatal Age at Onset	First Appearance	Sex Chiefly Affected	Relative Frequency	Remarks
Agastria and microgastria	Week 4	Infancy	?	Very rare	Many associated gastrointestinal tract and splenic anomalies
Malposition	Week 10	Any age	M	Rare	May be associated with diaphragmatic eventration and hernia
Atresia and stenosis	?	Infancy to adulthood	?	Rare	Maternal hydramnios familial occurrence (?) autosomal recessive associated with epidermolysis bullosa
Membranous partial		Infancy to adulthood			
Membranous entire	?	Infancy to adulthood			
Complete (solid)	Weeks 6–7				
Gastroduodenal discontinuity	?				
Luminal with microscopic canal	?				
Typical stenosis with perforated membrane(s)					
Hourglass stomach	?	Any age	?	Rare	Usually not congenital
Congenital pyloric stenosis	Postnatal week 2	2–4 weeks	M	Very common	Not a true anomaly
Infantile					
Adult					
Congenital muscular defect	Weeks 8–10	Infancy	?	Rare	May not be congenital
Diverticula	?	40–70 years	Equal	Rare	May not be congenital
Duplication, double pylorus	Week 3	Any age	F	Rare	Faulty separation of endoderm and notochordal plate
Mucosal heterotopia	Weeks 4–5				Adhesion or metaplasia
From other organs to stomach					
Pancreas					
Small bowel					
Others					
From stomach to other organs					
Congenital arteriovenous malformations	?	Adult	M	Rare	May not be congenital
Teratoma		Infancy to adulthood	M	Rare	Benign (usually)
Gastroduodenal adhesions	?	?	?	?	?

From Skandalakis JE, Gray SW. *Embryology for Surgeons*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994, with permission.

From a surgical standpoint, the stomach can be divided into two almost separate organ systems or “gastric units,” each with its own special anatomy, pathology, and surgical significance. The proximal gastric unit consists of the gastroesophageal junction and the proximal stomach (Fig. 82.14). The distal gastric unit includes the gastric antrum, pylorus, and the first part of the duodenum (Fig. 82.15). The border between the proximal and distal stomach is an arbitrary line from the lesser curvature to the greater curvature (Fig. 82.16). This may be thought of as (a) a line starting on the lesser curvature at the third vein down from the gastroesophageal junction to the greater curvature at the point where the left gastro-omental vessels come closest to the gastric wall, or (b) a line starting on the lesser curvature at the first descending branch of the left gastric artery to the greater curvature at the midpoint of the left gastro-omental artery.

Gastric Wall

The wall of the stomach consists of serosa, muscularis, submucosa, and mucosa. The serosa is visceral peritoneum. The muscular layer consists of

three sub-layers: outer longitudinal, middle circular, and inner oblique. From a surgical standpoint, surgeons consider the three sub-layers to be one. One U-shaped band of the inner oblique runs longitudinally and parallel to the lesser curvature on both the anterior and posterior surfaces of the stomach (Fig. 82.17). Contraction of this band is presumably responsible for the "gastric canal." In general, the musculature of the fundus is thin, that of the body is considerably heavier, while in the pylorus the circular ones and certain oblique ones are particularly well developed.

The submucosal layer is the vascular layer of the gastric wall. It is the home of arterial and venous plexuses, characterized by rich anastomoses and excellent collateral circulation. There are distinct differences in the gastric mucosa of the cardia, fundus, body, antrum, and pylorus of the stomach. The distal esophageal mucosa and proximal duodenal mucosa should be added to complete the landscape of "gastric" mucosa from a surgical standpoint.

Surgicoanatomic Units of the Gastroduodenum

Surgically, the gastroesophageal and gastroduodenal junctions are perhaps the most difficult anatomic units in the operating room. The term "junction" attributed to these areas better applies to histology rather than in anatomy, and describes the abrupt changes in mucosal lining.

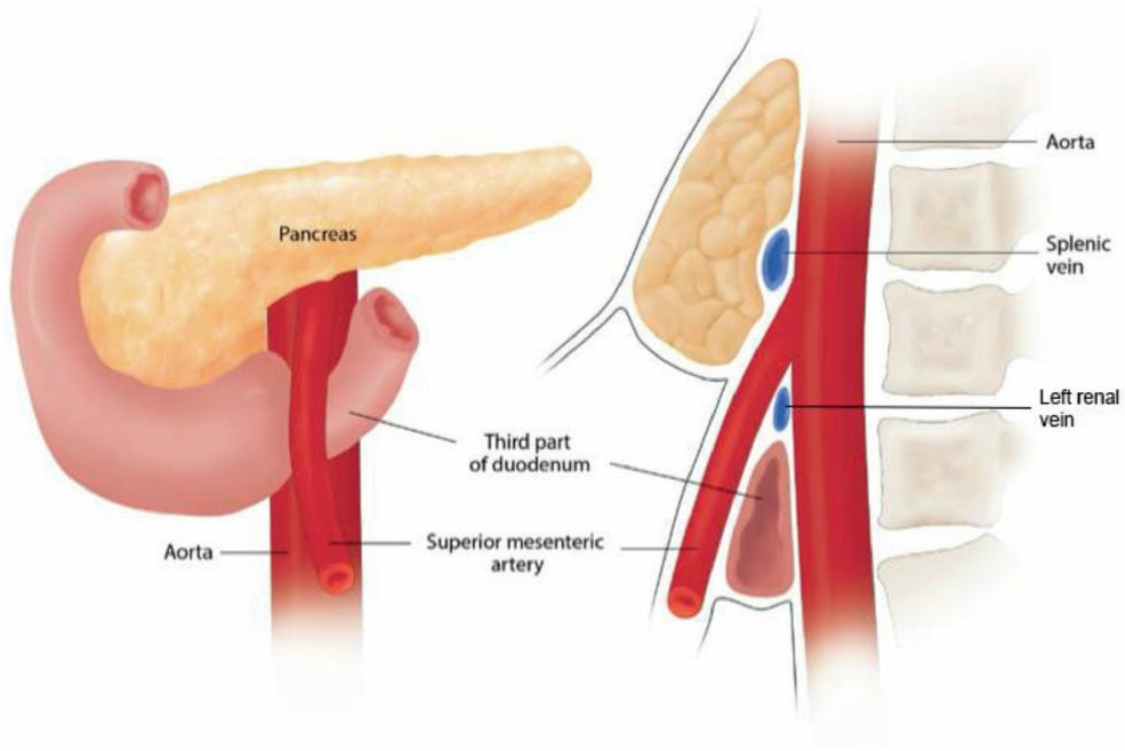

Figure 82.10. Superior mesenteric artery syndrome. The third portion of the duodenum can be compressed between the superior mesenteric artery and the aorta. Similarly, in the nutcracker syndrome, the left renal vein can be compressed in the angle between the two arteries. (Modified from Skandalakis JE, Gray SW, Ricketts R, et al. The small intestines. In: Skandalakis JE, Gray SW. *Embryology for Surgeons*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994:233.)

Gastroesophageal Junction

The esophagus joins the stomach in the abdomen, just below the diaphragm. The gastroesophageal junction can be anatomically defined as the point where the distal esophagus joins the proximal stomach (cardia).

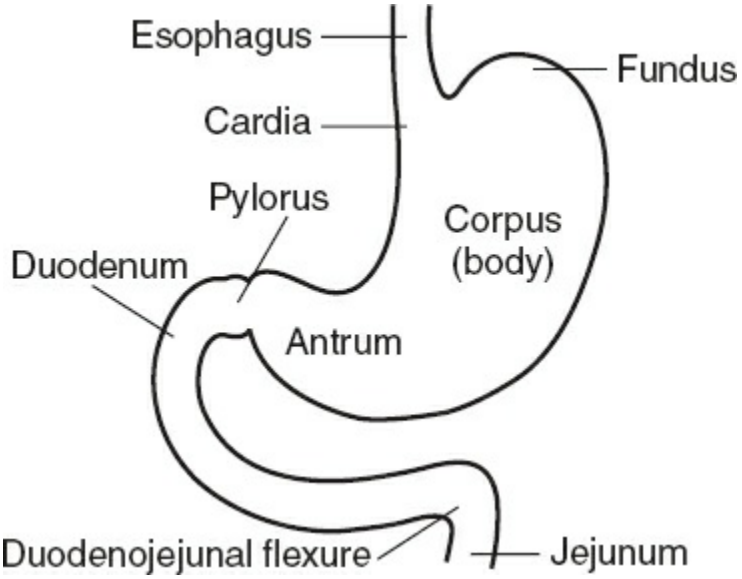

Figure 82.11. Gross anatomic areas of the stomach. (Modified from Griffith CA. Anatomy of the stomach and duodenum. In: Wastell C, Nyhus LM, Donahue PE, eds. *Surgery of the Esophagus, Stomach, and Small Intestine*. 5th ed. Boston, MA: Little, Brown; 1995, permission conveyed through Copyright Clearance Center, Inc.)

The abdominal esophagus lies at the level of the 11th or 12th thoracic vertebrae. It is found lower in tall asthenic individuals and higher in short subjects. In its passage through the esophageal hiatus, the esophagus is bounded by the two diaphragmatic crura and the phrenoesophageal membrane (Fig. 82.18). The length of the abdominal esophagus is from 0.5 to 2.5 cm, but the surgeon has access to an appreciable length of esophagus below the diaphragm.

The abdominal esophagus is related to surrounding structures:

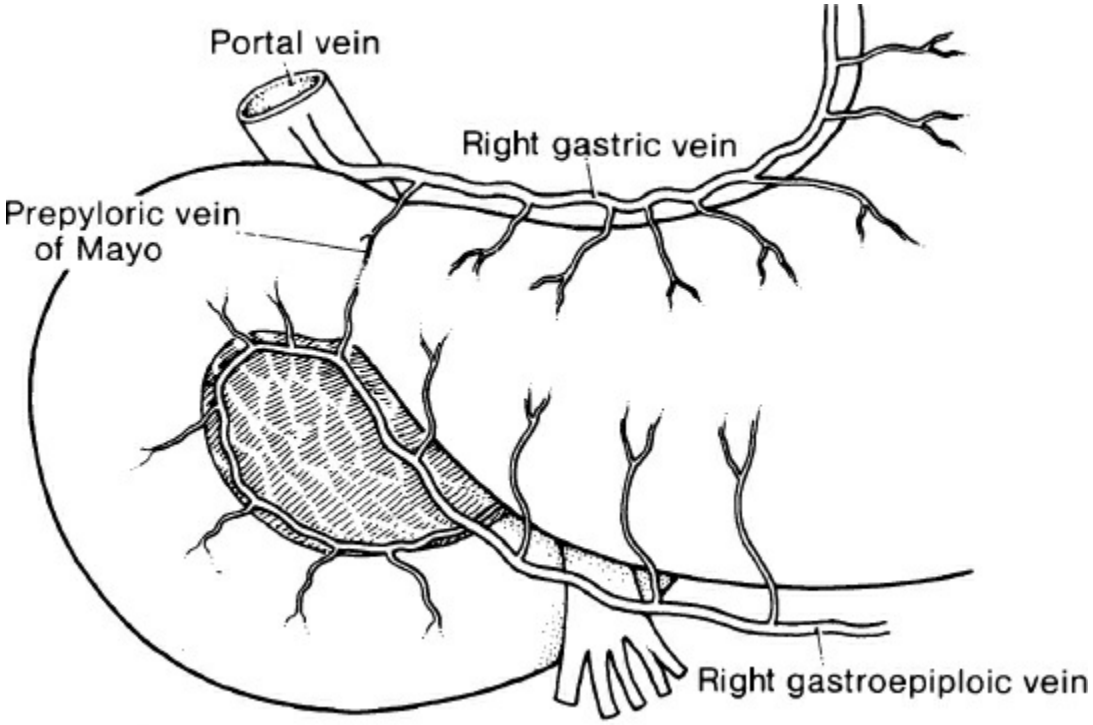

Figure 82.12. The prepyloric vein of Mayo. If present, this indicates the location of the pylorus. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery.* New York: McGraw-Hill; 1983.)

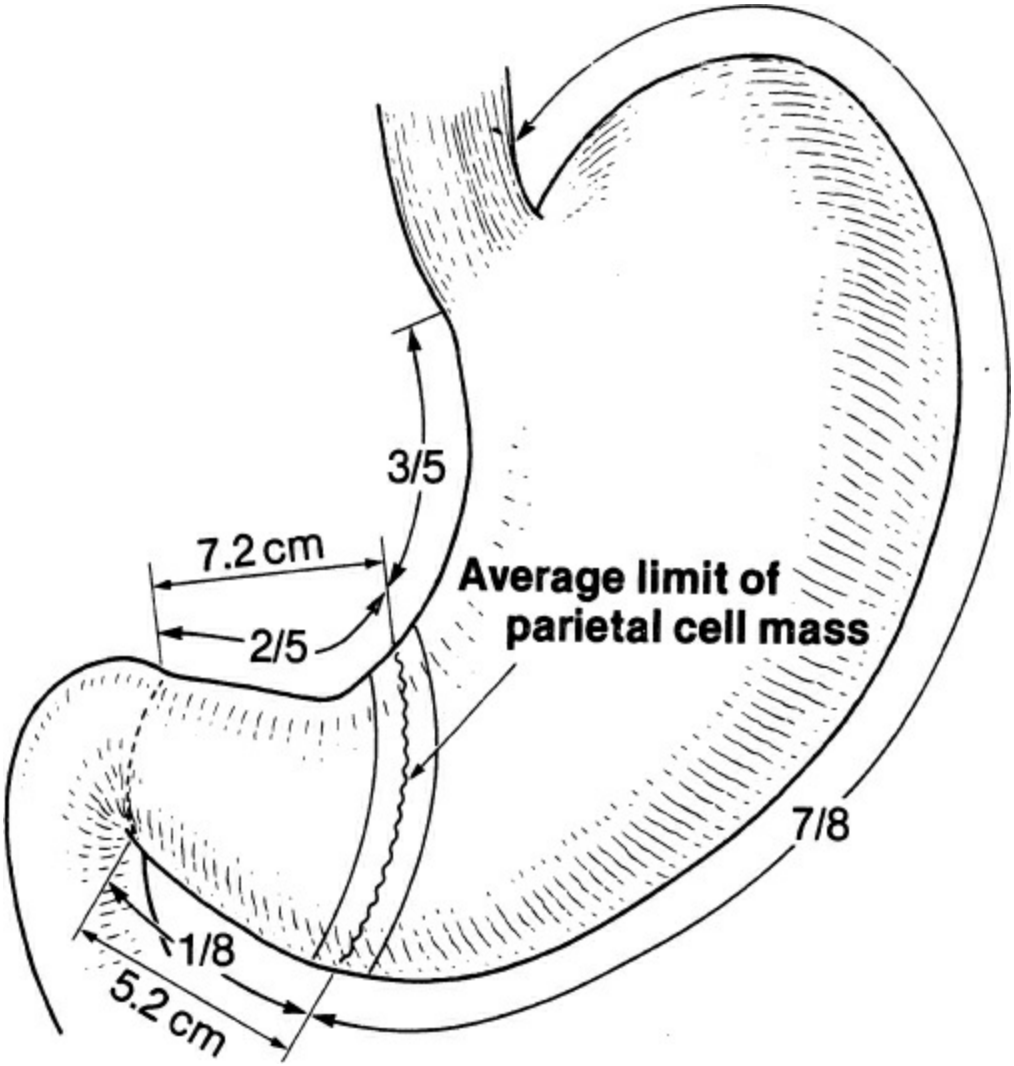

Figure 82.13. The antrum–body junction in the "average stomach" is found at two fifths of the distance from the pylorus to the cardia along the lesser curvature and one eighth of the same distance along the greater curvature. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery*. New York: McGraw-Hill; 1983.)

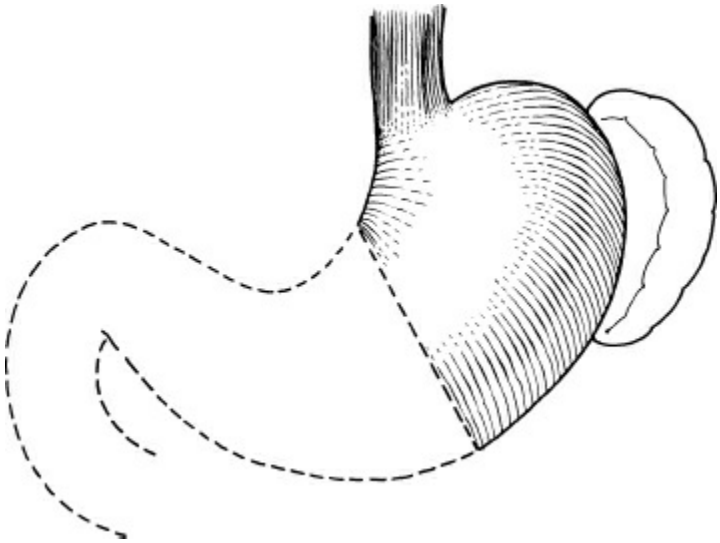

Figure 82.14. The proximal gastric surgical unit. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery.* New York: McGraw-Hill; 1983.)

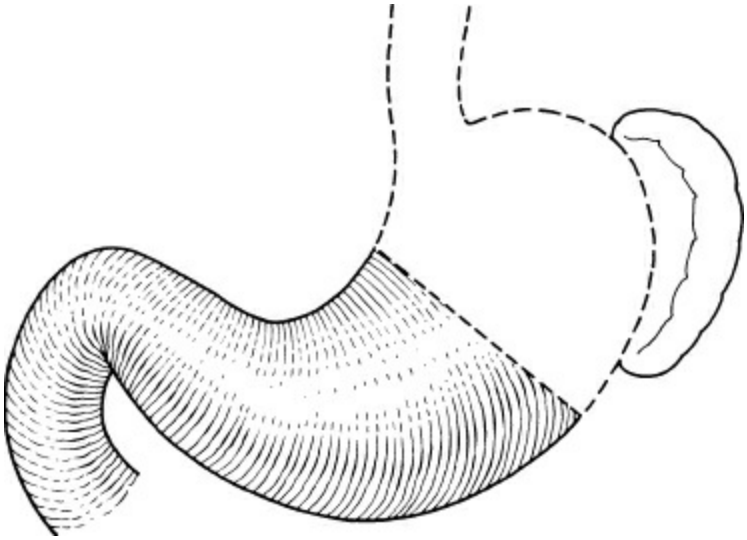

Figure 82.15. The distal gastric surgical unit. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery.* New York: McGraw-Hill; 1983.)

Anterior: Posterior surface of left lobe of liver
Posterior: Right crus of diaphragm, aorta
Right: Caudate (spigelian) lobe of liver
Left: Fundus of stomach

As noted above, the endoabdominal esophagus is covered anteriorly and laterally by peritoneum at its upper part, and is fully enveloped by peritoneum at its lower part. Under the peritoneum are found the

esophagus, the vagus nerves, anterior and posterior and their branches, and the left gastric vessels (Fig. 82.19). The gastric vessels find their entrance to the lower esophagus at the area where its posterior surface, just below the diaphragm, is still retroperitoneal.

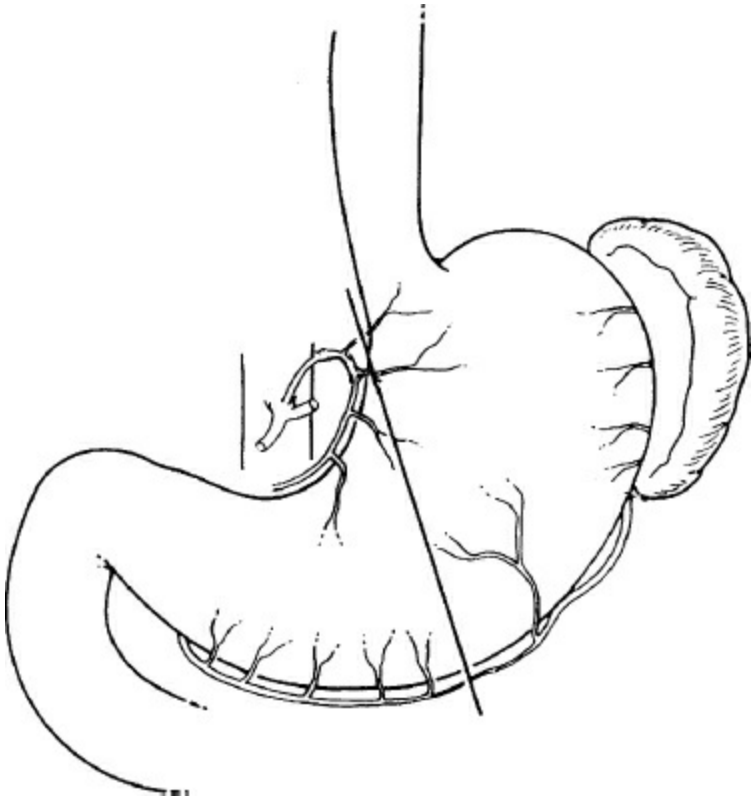

Figure 82.16. Arbitrary landmarks of proximal and distal gastric units.

Because the histologic junction between the esophagus and stomach is not coincident with the external junction, the “gastroesophageal junction” differs with each specialist (e.g., anatomist, surgeon, radiologist, and endoscopist) who speaks of it (Fig. 82.20). For example, a surgeon would point out that, by taking the lowest connective tissue fibers attaching the esophagus to the diaphragm as the inferior limit, there is no “abdominal” esophagus.

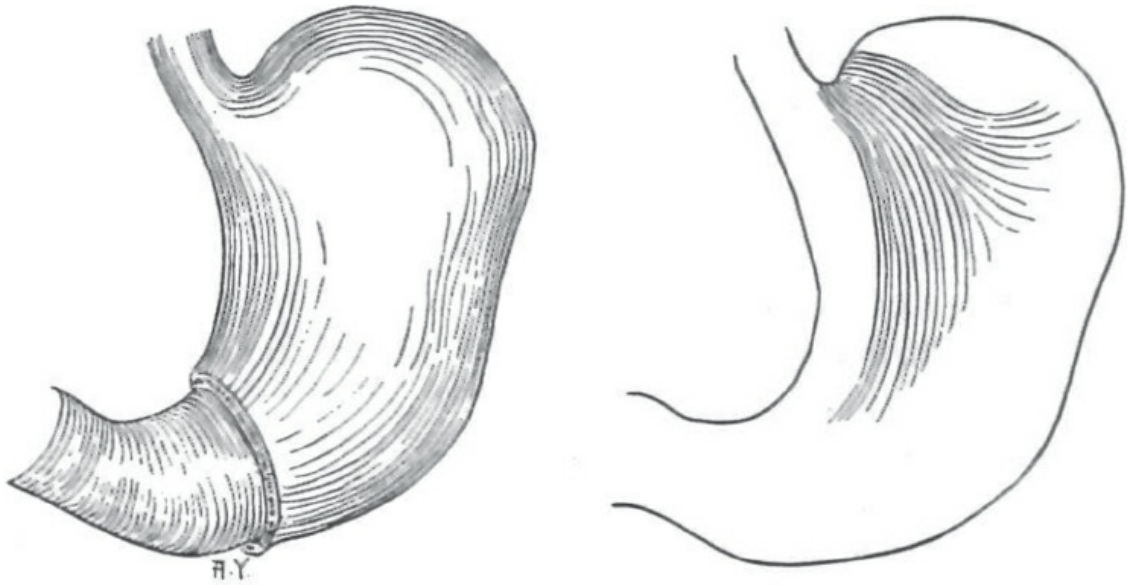

Figure 82.17. Diagrams of the general disposition of the three layers of gastric musculature. In (**A**), the longitudinal fibers have been cut away at the pyloric end of the stomach to show the circular ones; the longitudinal musculature is heavier at the curvatures, and thinner over the anterior and posterior surfaces of the body of the stomach. (**B**) shows the innermost or oblique layer of muscle. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956:387, Fig. 275.)

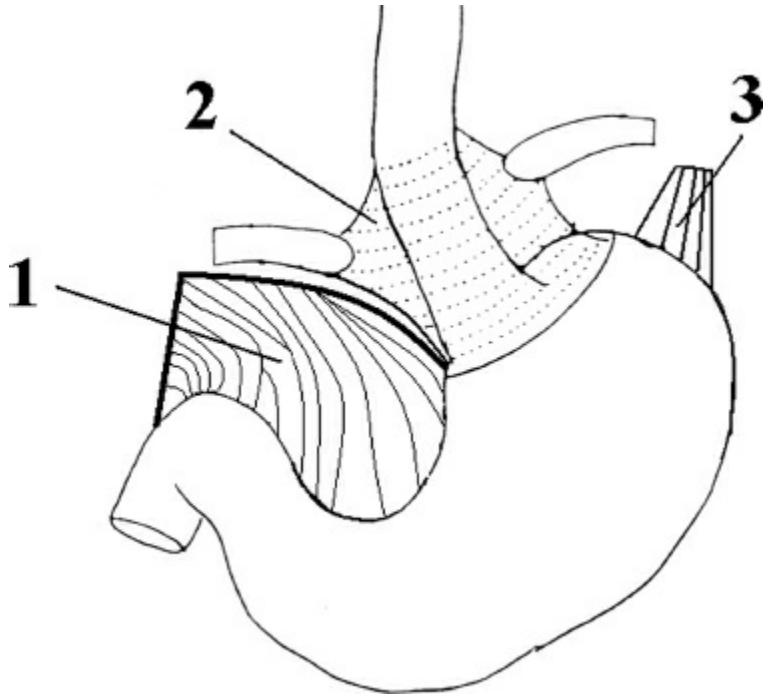

Figure 82.18. Anchoring structures of the endoabdominal esophagus. The diaphragmatic crura are not shown. 1. lesser

omenum (cut), 2. phrenoesophageal membrane, 3. gastrophrenic ligament.

The histologic junction is marked by an irregular boundary between stratified squamous epithelium and columnar epithelium. The loose submucosal connective tissue allows the mucosa to move freely over the muscularis, bulging in folds into the stomach at deglutition. The junctional level may change even at rest, being lower in the full stomach than in the empty one.

The columnar epithelium forms a mucosa unlike that of the body of the stomach. Its glands, lacking chief and parietal cells, secrete mucus. Histologists refer to these as cardiac glands. "Junctional epithelium" has been proposed as a name for this area between typical esophageal and typical gastric mucosae (Fig. 82.21). According to Odze, "*The true gastric cardia is an extremely short segment (less than 0.4 mm) of mucosa that is typically composed of pure mucous glands, or mixed mucous/oxyntic glands that are histologically indistinguishable from metaplastic mucinous columnar epithelium of the distal esophagus. In patients with gastroesophageal reflux disease, whether physiologic or pathologic, the length of cardia-type epithelium increases and extends proximally above the level of the anatomic gastroesophageal junction into the distal esophagus.*"

Most anatomists and surgeons share the idea that there is no true anatomical sphincter to guard the cardiac orifice of the stomach. However, a slight thickening of the circular musculature of the distal esophagus has been described, grossly visible in 64% of specimens. To answer the question whether an anatomical sphincter does exist in the lower esophagus, one of the authors of this chapter (ML) undertook a study in cadavers and found a distinct thickening of the circular muscle layer of the gastro-esophageal region in all specimens. The mean length of this muscular thickening was measured to be 3.1 cm. The thickest part of this segment was at its midsection. This mid-part had a mean thickness of 5.4 mm. The thickness of the esophagus immediately superior to the sphincter had a mean of 2.7 mm. These findings strongly suggest the presence of an internal esophageal sphincter in the distal esophagus.

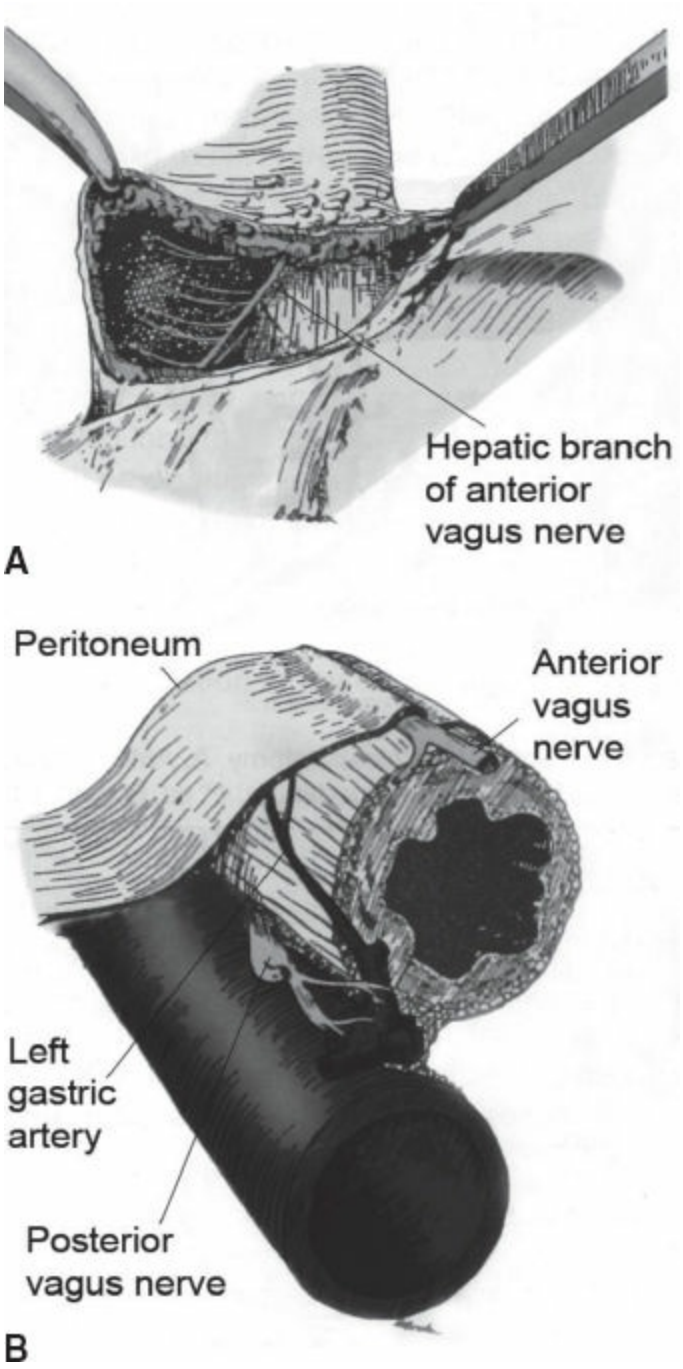

Figure 82.19. Abdominal esophagus and peritoneal reflections. **A.** The two forceps hold the opened peritoneum on the anterior surface of the esophagus. The hepatic branch of the anterior vagus (superficially) and the celiac branch of the posterior vagus can be seen. **B.** The peritoneum covers the esophagus antreriorly and laterally. In this area, the left gastric artery finds its way to the lower esophagus and stomach. The anterior and posterior vagus nerves can also be seen. (Modified from Skandalakis LJ, Colborn GL, Weidman TA, et al. Stomach. In: Skandalakis JE, Colborn GL, Foster RS Jr, et al., eds. *Skandalakis' Surgical Anatomy: The Embryologic and Anatomic*

Basis of Modern Surgery. Athens: Paschalidis Medical Pablications; 2004: Fig. 15-61B and C.)

Various other structures have been held responsible for closing the cardia and preventing reflux from the stomach into the esophagus:

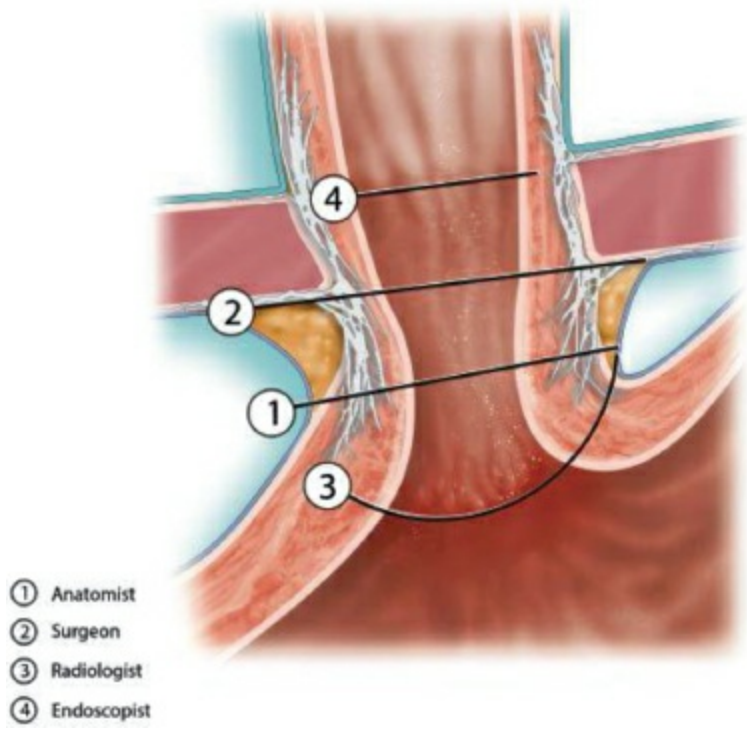

Figure 82.20. Views of the gastroesophageal junction from the point of view of four specialties. Each is "correct." (Modified from Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery.* New York: McGraw-Hill; 1983.)

The angle of His at which the esophagus enters the stomach
The pinchcock action of the diaphragm
The mucosal rosette, a plug of loose esophageal mucosa
The sling of oblique fibers of the gastric musculature. This component has gained great support for its role in cardiac closure. The arrangement of muscles at the gastresophageal junction led to the term "spiral constrictor" for these muscles.
The phrenoesophageal ligament: the esophagus is attached to the diaphragm at the hiatus with a strong, flexible, airtight seal ligament or (better) membrane. On top of this membrane are the pleura and peritoneum, while connective tissue fibers originating from the endoabdominal fascia (investing fascia of the inferior surface of the

diaphragm, continuation of the transversalis fascia) and from the endothoracic fascia above the diaphragm, insert into the intermuscular connective tissue of the lower esophagus (Fig. 82.21). These fibers allow for a 2-cm vertical movement of the esophagus.

The gastroesophageal junction has been found to be a highly competent barrier to reflux of gastric content into the esophagus. While the lower esophageal sphincter may be the most important component of the barrier, a fold of muscle and mucosa created by the angle of entry of the esophagus into the stomach (the so-called gastroesophageal flap valve) also contributes to the closing mechanism.

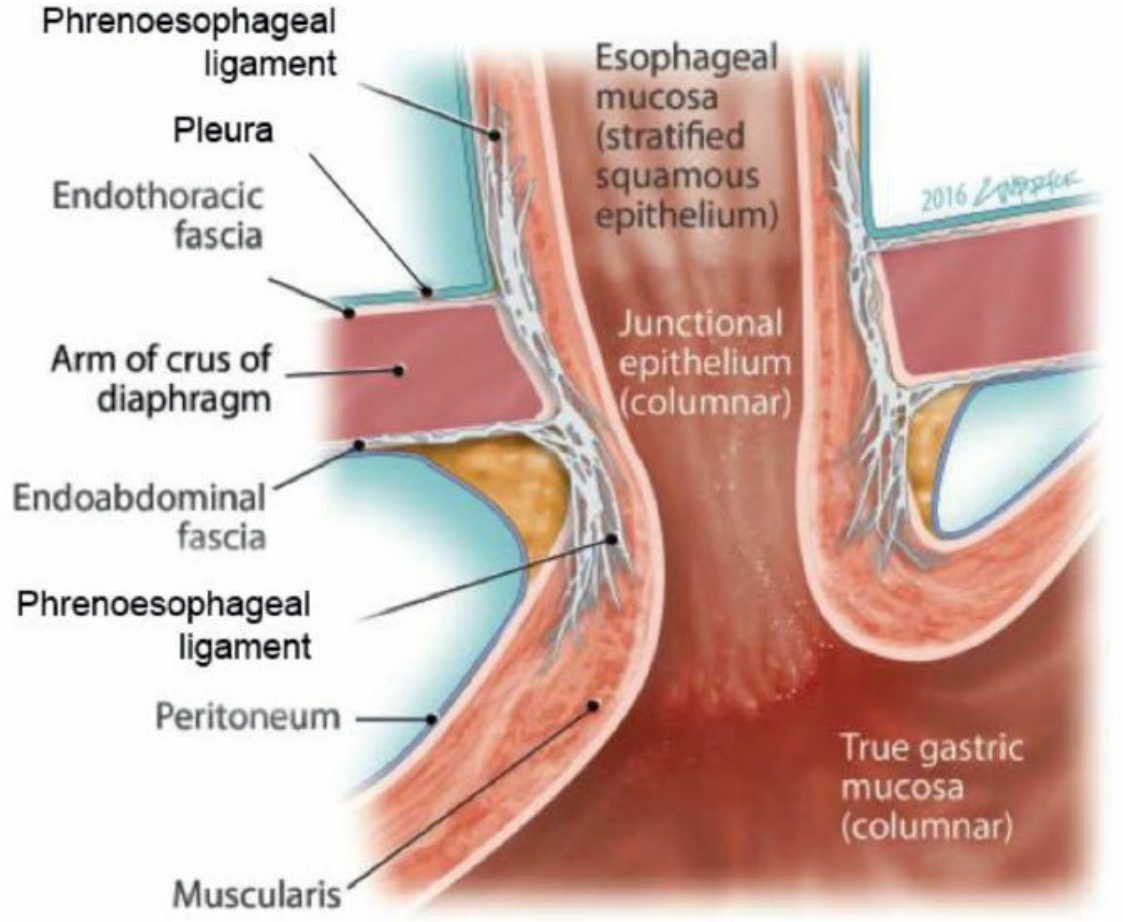

Figure 82.21. Coronal section through gastroesophageal junction and esophageal hiatus of the diaphragm. (Based on Figure 19, in Skandalakis LJ, McClusly AD, Loukas M, et al. Anatomic considerations in gastroduodenal surgery. In: Fisher JE, *Mastery of Surgery*. 6th ed. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2012:957–80.)

A major pathophysiologic effect of hiatus hernia is gastroesophageal

reflux, which contributes to esophageal mucosal injury, most notably in patients with severe gastroesophageal reflux disease. Together with the crural diaphragm, the lower esophageal sphincter functions as antireflux barrier, protecting the esophagus from caustic gastric content. Achalasia and gastroesophageal reflux disease are two typical examples of dysfunction of the lower esophageal sphincter. In the presence of normal anatomy of the gastroesophageal junction (i.e., absence of hiatus hernia), the pressure of the gastroesophageal junction is the most important determinant of the strength of the antireflux barrier. The normal pressure of the lower esophageal sphincter ranges from 14.5 mm Hg to 34 mm Hg.

GASTRODUODENAL JUNCTION

The gastroduodenal junction is the boundary between the pylorus of the stomach and the first part of the duodenum. Histologically, there is an abrupt transition in mucosal morphology, and this is the exact site of the "junction". However, surgically, the gastroduodenal junction is conceived as much broader, including the pyloric sphincter and the proximal first part of the duodenum.

In the past, the distal end of the pylorus that extends in the duodenum has been called "pyloric canal" or "pyloric antrum" or even "pyloric ring." This polyphony was to describe the pyloric sphincter, which is the area of the stomach more heavily supplied with circular muscle that is the remainder of the organ. The pylorus is a region rather than a sharply defined structure. Its valve action is to control the flow of partially digested food from the stomach. At its narrowest point, the luminal size never exceeds 19 mm. The size is important in estimating the optimal size of artificial openings, such as in gastrojejunostomies or pyloroplasties.

The pylorus is indistinguishable from the antrum of the stomach. In contrast, there is a sudden transition from the thick wall of the pylorus to the thin wall of the duodenum. The propyloric vein of Mayo can be seen at the area of transition, but the change from a thick to a thin wall can be usually palpated as well.

At the pyloroduodenal junction, the continuity of the circular muscle is interrupted by an annular septum that arises from the connective tissue of submucosa. Proximal to this ring, the circular muscle layer is thickened to form the pyloric sphincter (Fig. 82.22). Distal to the ring, the circular muscle coat of the duodenum is thinner. The sudden decrease of the wall thickness as one passes from the pylorus to the duodenum results in an "os

pylorous” surrounded by a duodenal “fornix.” The existence of this fornix must be kept in mind when performing a pyloromyotomy.

In the initial investigations of the pyloric sphincter, Torgensen (1942) described the septum separating the pyloric sphincter from the duodenum, and stated that this happens only on the side of the greater curvature; on the lesser curvature, the circular fibers are continuous with those of the first part of the duodenum. Moreover, he described that the pyloric sphincter has two portions, a pyloric portion and a duodenal portion, being separated by the septum.

The longitudinal muscle layer of the stomach is also interrupted at the end of the pylorus, except on the side of the lesser curvature, where the most peripheral fibers of the pylorus maintain continuity with those of the duodenum. Most longitudinal fibers turn toward the lumen and terminate in the thick circular muscle (Fig. 82.22). Thus, they form a ring that makes a dilator mechanism within the pylorus. In contradiction to most gut sphincters, the human pylorus maintains a patent lumen most of the time, only intermittently becoming a tightly closed barrier arresting transit to and from the stomach. Contraction of its proximal and distal muscle loops and occlusion of its lumen by mucosal folds mediates pyloric closure.

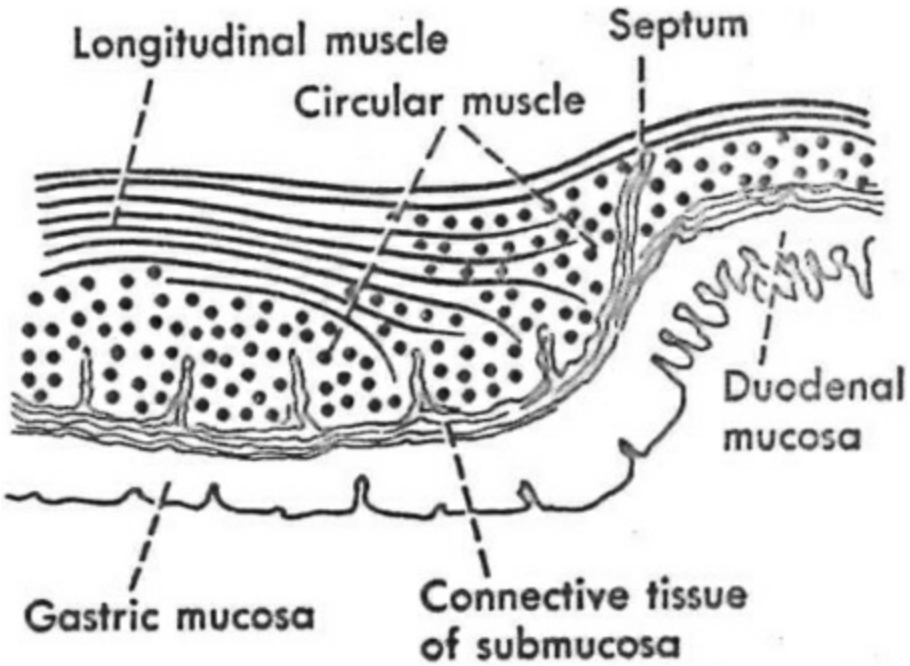

Figure 82.22. Diagram of the arrangement of the muscle fibers in the gastroduodenal junction at longitudinal section through the pyloric sphincter and first part of the duodenum. Note the longitudinal muscle fibers of the stomach that disappear in the thickened circular muscle, and also a few that continue to the

duodenum. Note also that the submucosa sends connective tissue septa into the circular muscle, and that an especially thick one of those separates the circular muscle of the stomach from that of the duodenum. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper; 1956:389, Fig. 276.)

The pyloric sphincteric cylinder and the pyloric mucosal zone are two anatomic and functional units of the pyloric part of the stomach. The cylinder, 3 to 5 cm in length when fully contracted, contains a thickened aboral section, the pyloric ring. The entire cylinder functions as a unit: when the cylinder contracts, the pyloric ring narrows in diameter, as does the pyloric aperture. Keet commented: "On the aboral side, both the cylinder and the mucosal zone end at the ring. The entire cylinder is lined by pyloric mucosa, but the mucosal zone extends orally beyond the confines of the cylinder. In gastric ulcer, it may extend much further up into the stomach. In contrast to the cylinder, the greatest length of the mucosal zone is on the lesser curvature."

From the above descriptions, it is evident that the gastroduodenal junction is the home of the pyloric sphincter and is much wider toward the antrum and duodenum. On this basis, as noted above, it is more important for the surgeon to regard the "distal gastric unit," which includes the antrum, the pylorus, and 1 inch (2.5 cm) of the first part of the duodenum. The latter retains the primitive mesentery and thus is attached to the hepatogastroduodenal ligament (distal part of the lesser omentum) and the distal part of the gastrocolic ligament (greater omenum) (see below). This segment can be mobilized together with the pylorus and antrum of the stomach.

PERITONEAL RELATIONS OF THE STOMACH AND DUODENUM

The stomach is covered anteriorly and posteriorly by peritoneum. This peritoneum is provided by the two leaves of the lesser omentum. The omentum (which has two leaves) extends from the hilum of the liver to the stomach and duodenum, by way of the hepatogastric and the hepatoduodenal ligament respectively (Fig. 82.23). After enveloping the stomach, the two leaves continue as gastrophrenic ligament, from the upper part of the great curvature of the stomach to the diaphragm, and as

gastrosplenic ligament from the upper part of the great curvature of the stomach to the spleen (Fig. 82.23).

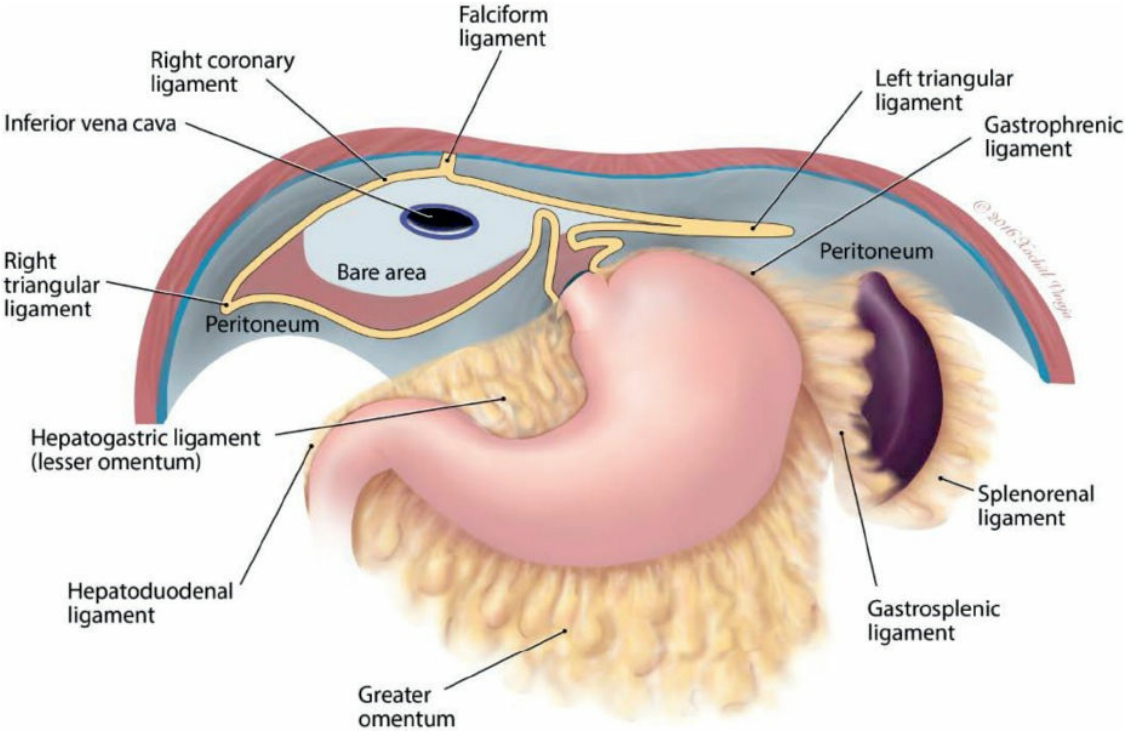

Figure 82.23. Mesenteries of stomach. The yellow line depicts the cut peritoneal reflections around the liver, and esophagus. In the bare area of the liver, the grey color signifies the tendon of the diaphragm and the brownish color shows the muscular part of the diaphragm. (Based on Figure 82.21, in Skandalakis LJ, McClusly AD, Loukas M, et al. Anatomic considerations in gastroduodenal surgery. In: Fisher JE, *Mastery of Surgery*. 6th ed. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2012: 957–80.)

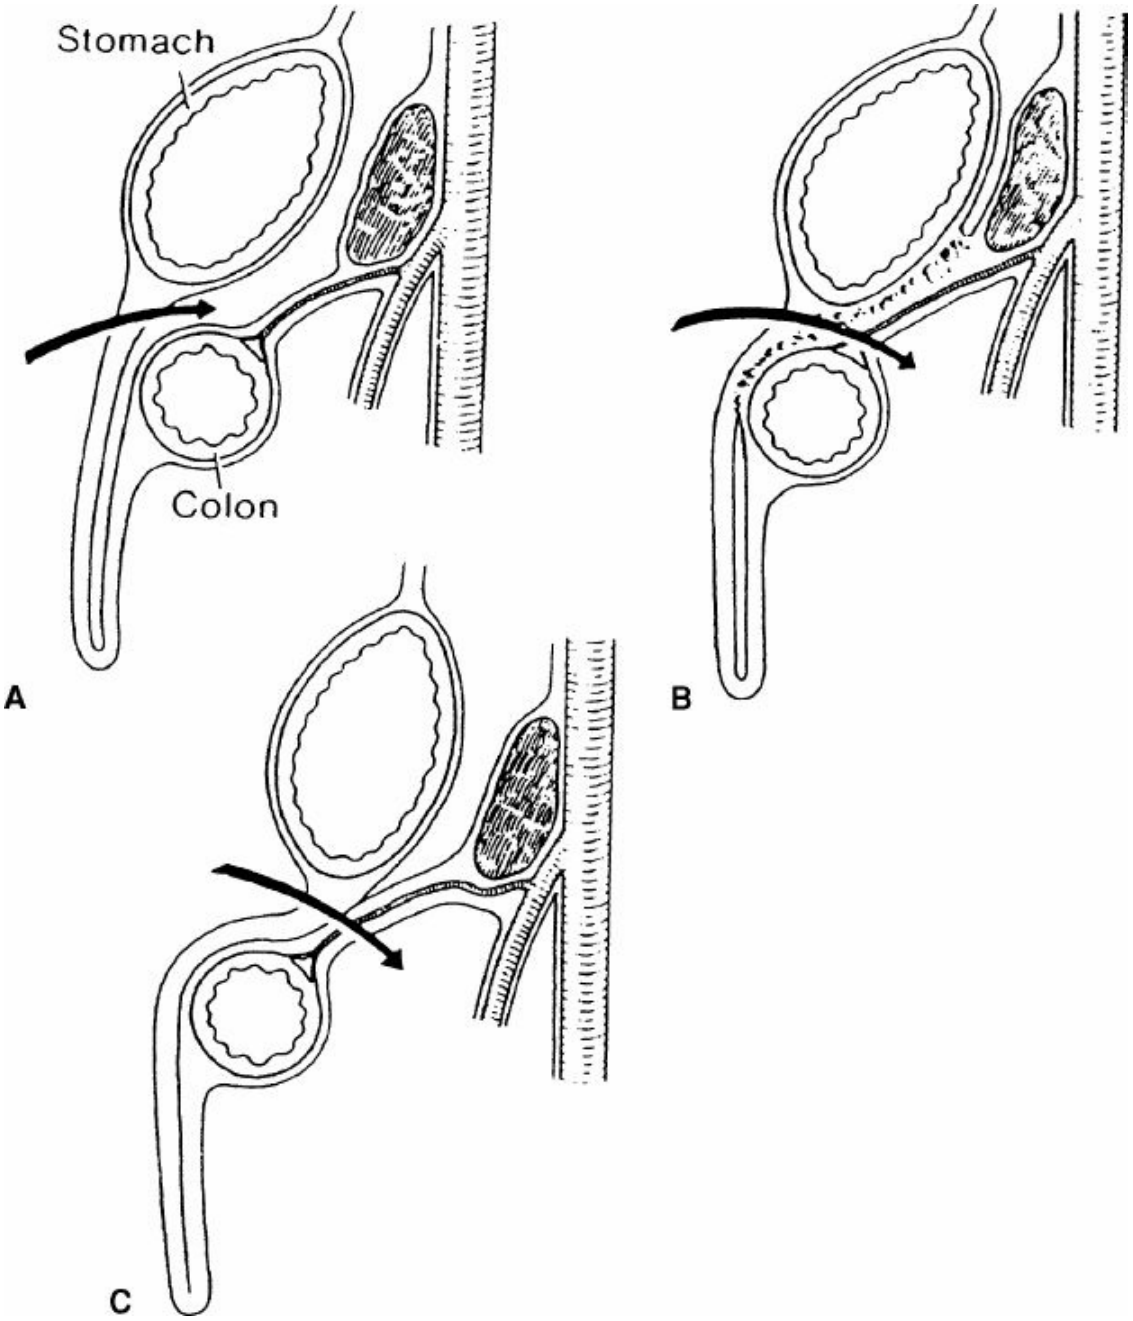

Figure 82.24. Entrance to the lesser sac. **A.** Normal anatomy. *Arrow* indicates entrance through the greater omentum. Middle colic artery in transverse mesocolon in no danger. **B.** Pathologic fixation of the omentum and posterior wall of the stomach with transverse mesocolon. **C.** Normal anatomy, but entrance so far inferior may injure middle colic artery. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery*. New York: McGraw-Hill; 1983.)

The peritoneum of the anterior surface of the stomach continues upward and covers the anterior and lateral surfaces of the distal abdominal esophagus. The proximal abdominal esophagus, whose posterior surface is

in contact with the diaphragm, is covered only anteriorly by peritoneum.

From the lower part of the great curvature of the stomach, the two leaves of the peritoneum continue as the two leaves of the greater omentum, descending down and then ascending again. They attach to the transverse colon and its mesentery, and continue as such until the pancreas. The fusion of peritoneal layers during this course is shown in Figure 82.5. From there, the two leaves diverge toward the parietal peritoneum of the posterior abdominal wall (lower) or the posterior wall of the omental bursa.

The first part of the duodenum is not attached to the posterior abdominal wall, and therefore free to follow the movements of the pyloric part of the stomach. It is connected with the porta hepatis with the hepatoduodenal ligament, which is the lower part of the lesser omentum. In this ligament are found the portal vein, hepatic artery, and bile duct. The second, third, and fourth part of the duodenum are retroperitoneal.

SURGICAL CONSIDERATIONS OF PERITONEAL REFLECTIONS AROUND THE STOMACH AND DUODENUM

The abdominal esophagus is partially covered by peritoneum. This does not prohibit the existence of the “mesoesophagus,” which contains vessels, nerves, and lymphatics, and must be dissected with attention.

Every ligament or omentum of the stomach is part of the mesentery, and contains vessels, nerves, and lymphatics (except perhaps for the gastrophrenic ligament), and has to be carefully handled and dissected.

Within the lesser omentum, the hepatic triad (hepatic artery, portal vein, bile duct), the right and left gastric arteries, the hepatic branch of the anterior vagus nerve, and lymphatics are contained. A fluid collection within only the lesser sac should be considered postoperative fluid after gastric or hepatobiliary surgery or an inflammatory exudate from pancreatitis, cholecystitis, or gastric perforation. Inflammatory infiltrates in the lesser sac are commonly secondary to acute pancreatitis.

The hepatoduodenal ligament contains the hepatic triad and the left gastric artery.

The hepatogastric ligament carries the anterior branch of the vagus nerve and the left gastric artery.

The whole vascular supply of the duodenum comes from the left side, which permits mobilization from the right side.

Entrance to the lesser sac (Fig. 82.24) normally requires ligation of branches of the gastroepiploic vessels. However, pay extreme attention to the middle colic artery that may be pathologically fixed to the anterior wall and be at risk.

VASCULAR SUPPLY OF THE STOMACH AND OMENTUM

The stomach is among the best vascularized of organs (Fig. 82.25). Not only is it supplied by many arteries, but its wall also contains a rich anastomosing network of vessels extrinsically and intrinsically. General surgeons know that the stomach can survive after ligation of all but one of its primary arteries, and that extragastric ligation does not control bleeding from a gastric ulcer.

ARTERIES

The following is a listing, or summation, of all the arteries that supply the stomach. Each of the principal arteries of supply originates from the celiac trunk. The arteries are:

- left gastric
  - ascending branch: esophageal
  - descending branch: gastric
- hepatic
  - right gastric
  - gastroduodenal
  - anterior superior pancreaticoduodenal
  - retroduodenal
  - posterior superior pancreaticoduodenal
  - supraduodenal
  - right gastroepiploic (major branches)
- splenic
  - posterior gastric
  - short gastrics
  - left gastro-omental (major branches)
  - dorsal pancreatic
  - great pancreatic

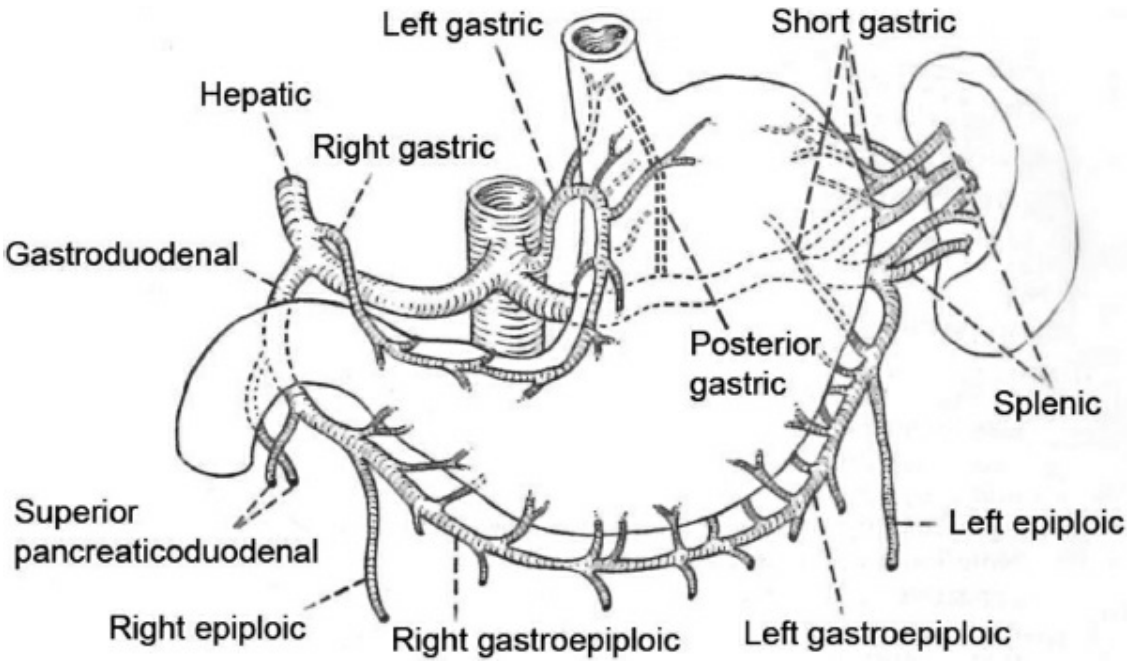

Figure 82.25. Arteries of the stomach. (Modified from Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956:390, Fig. 277.)

Left Gastric Artery

In approximately 90% of individuals, the left gastric (or coronary) artery is a branch of the celiac axis. However, it may arise from the common hepatic artery, splenic artery, aorta, or SMA (Fig. 82.26). In 4% of individuals, it arises from a gastrosplenic trunk; in 3%, it has a direct aortic origin; and in 2%, the left gastric is a branch of a hepatogastric trunk. A case of left gastric artery originating directly from the aorta has been reported.

The artery travels upward behind the posterior wall of the omental bursa, frequently in a fold of peritoneum (the so-called gastropancreatic fold). It passes across the posteromedial surface of the stomach at about the gastroduodenal junction to reach the lesser curvature of the stomach; here, in approximately 95% of cases, it provides 1 to 3 esophageal branches, which anastomose with the esophageal arteries from the aorta. The esophageal branches have anterior and posterior distributions, and are not associated with the locations of the vagal nerves. The rich anastomoses between thoracic esophageal branches, left inferior phrenic, and left gastric branches can result in troublesome retrograde bleeding from these branches on the posterior side of the stomach. The main part of the artery

continues onto the lesser curvature of the stomach.

The left gastric artery may give origin (in 24% of cases) to an aberrant left hepatic branch. This latter vessel should be sought when the left gastric artery appears uncommonly large.

The left gastric artery commonly divides into an anterior and a posterior branch before attaining the lesser curvature, and, in such cases, the esophageal and cardioesophageal arteries may arise from either of those vessels; more commonly, however, the cardioesophageal artery arises from the anterior gastric branch. The anterior branch runs obliquely across the body of the stomach toward the great curvature. It ends in numerous small ramifications and forms a “crow’s foot” (of Prayne) similar to the anterior nerve of Latarjet. The anterior branch terminates about 4 to 6 cm proximal to the pylorus. The posterior branch follows the lesser curvature until its anastomosis with the right gastric artery.

After its cardioesophageal branch, the left gastric artery usually curves down to the right and thereafter descends along the lesser curvature. As it descends, it bifurcates into an anterior branch that sends branches to the anterior gastric wall and a posterior branch to the posterior gastric wall. The left gastric artery ends by anastomosing with the right gastric artery. Nevertheless, there may be no external anastomoses, but only internal ones.

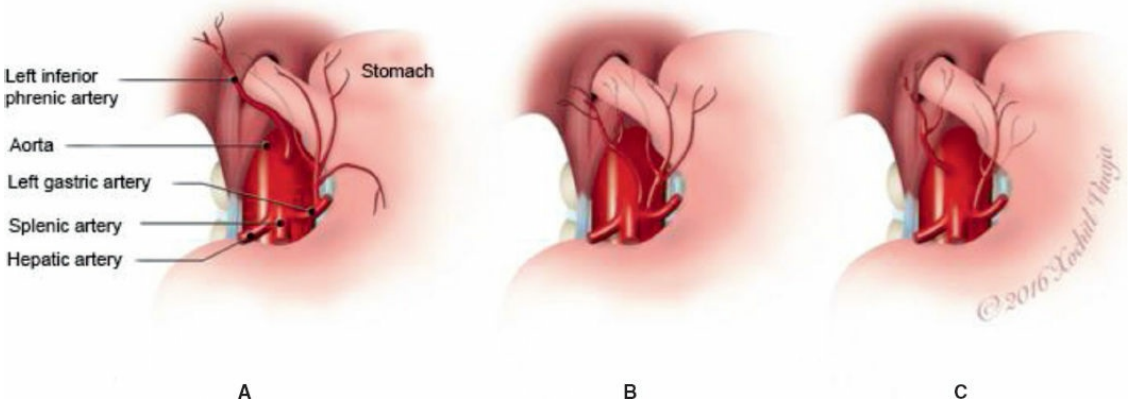

Figure 82.26. Arteries of distal esophagus and proximal stomach. **A.** Inferior phrenic artery supplies margin of hiatus. Esophageal branch of left gastric artery supplies distal esophagus and passes through hiatus to anastomose with thoracic esophageal arteries. **B.** Branches of inferior phrenic and left gastric arteries supply distal esophagus with no thoracic anastomoses. **C.** Branches of inferior phrenic artery supply distal esophagus with thoracic anastomoses (rare). (Based on Figure

24, in Skandalakis LJ, McClusly AD, Loukas M, et al. Anatomic considerations in gastroduodenal surgery. In: Fisher JE, *Mastery of Surgery*. 6th ed. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2012: 957–80.)

Hollinshead underlines that because of its direct course to the gastroesophageal junction, the left gastric artery allows little mobility to the upper portion of the stomach. It follows that when this has to be mobilized and raised through the diaphragm, as in excision of the lower part of the esophagus, the left gastric artery has to be sacrificed.

Right Gastric Artery

The right gastric artery is a small branch that arises most commonly from the proper hepatic artery (50% to 68%), left hepatic artery (28.8% to 40.5%), common hepatic (3.2%), or other, less frequent, sources. If it arises from the hepatic artery, this may happen before or after the origin of the gastroduodenal artery.

The right gastric artery normally descends toward the lesser curvature of the stomach and continues along the lesser curvature between the leaves of the lesser omentun to anastomose with the terminal branches of the left gastric artery. The right gastric artery gives origin to one or more suprapyloric branches. Anterior and posterior branches from these anastomose with infrapyloric vessels, and, with the supraduodenal artery, supply the distal gastric unit (e.g., the antrum, pyloric canal, and the first inch of the first part of the duodenum). The right gastric artery passes along the lesser curvature for approximately 4 to 6 cm, approximately 0.5 cm from the lesser curvature, before anastomosing with the left gastric artery. The right gastric artery is the origin of the supraduodenal artery in 13% of studied instances.

Right Gastro-Omental Artery

The right gastro-omental or gastroepiploic artery is a branch of the gastroduodenal artery (or its continuation) in most cases. It occasionally arises from the SMA or from the anterior superior pancreaticoduodenal artery. After giving origin to an infrapyloric branch, the artery passes along the greater curvature of the distal stomach within the great omentum. Sometimes it is very close to the curvature, and sometimes a centimeter or more away from it. It gives 8 to 18 singular or paired anterior and posterior

branches to the gastric wall.

The right gastroepiploic artery also gives descending branches into the great omentum, (anterior epiploic or omental) and finally anastomoses with the left gastroepiploic artery given from the splenic artery. At the right border of the omentum, the right gastroepiploic artery gives its major branch, the right epiploic artery, which is a branch for the posterior layer of the omentum. This anastomoses with a corresponding (posterior) left epiploic artery from the left gastroepiploic artery.

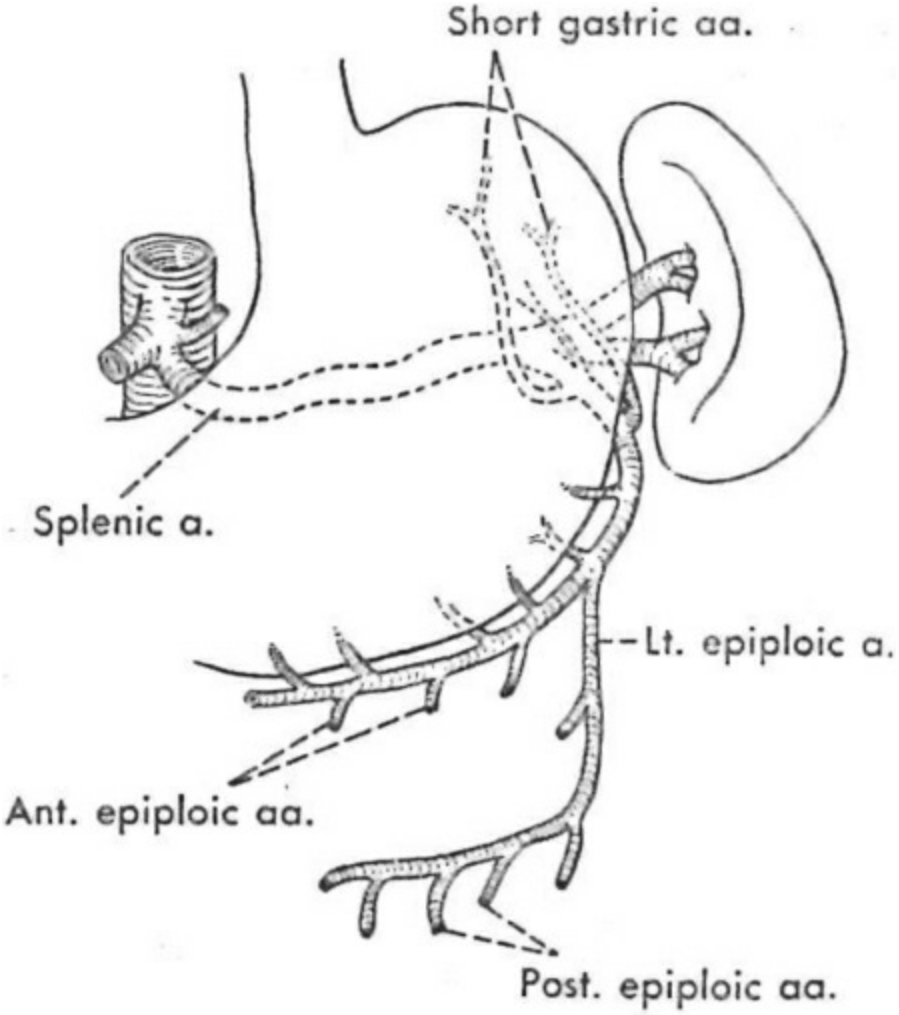

Figure 82.27. Origin, course, and branches of the left gastro-epiploic artery. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956:393, Fig. 281.)

For omental viability during distal gastrectomy, the right gastro-omental artery should be preserved by one of the following methods: ligating its gastric branches close to the stomach wall, ligating the anterior

omental, or ligating the right gastro-omental distal and close to the origin of the right omental. We prefer to ligate the gastric branches and to imbricate the greater curvature with continuous suture at its “nude,” not resected, part. Some surgeons have not found a need for routine imbrication of the stomach after ligation of the short gastric arteries. Although this is a true and valid opinion, we continue to advise that if there are doubts about the ligation of these vessels, especially the occasional short vessels, the gastric wall should be imbricated.

Left Gastro-Omental Artery

According to Michels, the left gastro-omental artery is a highly variable artery. It arises in most cases (72%) from the distal splenic, inferior splenic terminal, middle part of the splenic trunk, or superior splenic terminal. The observations of Van Damme and Bonte differ rather widely from those of Michels. They state that the left gastro-omental artery arises from the splenic directly in only 26% of individuals. In 66%, it takes origin from the splenic artery by a common stem with the inferior polar splenic branch.

The left gastro-omental artery is the largest branch of the splenic artery (Fig. 82.27). It runs toward the gastrosplenic ligament, to the right and parallel to the great curvature of the stomach. Its course is either along the curvature, or 2 cm or more below it. It may give an inferior polar artery to the spleen and two to four gastric arteries to the stomach. In its course along the great curvature, the left gastro-omental artery gives many ascending anterior and posterior branches to the stomach, branches to the tail of the pancreas, a left epiploic artery, and descending omental arteries (anterior omental). The left epiploic artery runs in the posterior layer of the great omentum below the level of the transverse colon. The left epiploic artery usually anastomoses with the corresponding contralateral branch of the right gastro-omental artery, and also gives some twigs to the transverse colon (posterior epiploic).

In splenectomy, ligation of the splenic artery and vein should be located distal to the origin of the left gastroepiploic vessels. Better still, the surgeon should ligate the splenic vessels very close to their entrance into the spleen. This avoids the postoperative bleeding, which follows ligation proximal to the origin of the left gastroepiploic artery.

Short Gastric Arteries

Approximately five to seven short gastric arteries arise from the terminal

branches of the splenic artery or from the left gastro-omental artery. They may appear to emerge from the substance of the spleen at its hilum, having arisen from terminal splenic branches within the organ. The short gastric vessels provide arterial blood supply of the fundus and upper part of the body of the stomach. Although their branches are distributed to the anterior and posterior surfaces, they appear to supply somewhat more of the posterior surface than the anterior. Outside the gastric wall, the short gastric arteries do not anastomose with each other or with other arteries of the stomach. Therefore, the short gatric arteries alone are inadequate to supply the distal part of the proximal gastric unit.

The first short gastric arteries reach the greater curvature about 2 to 6 cm to the left of the gastroesophahgeal junction. The length of the short gastric arteries varies; some are short, some are long. During splenectomy, specific attention must be paid to the shorter of gastric arteries; these need careful ligation. Imbrication of the greater omentum is a safety measure, not only to avoid bleeding, but also to avoid possible necrosis with perforation.

Posterior Gastric Artery

In approximately 80% of the population, an additional artery may arise variably from the proximal, middle, or distal segment of the splenic artery. It travels up, posterior to the stomach, to vascularize the distal esophagus, cardia, and fundus (Fig. 82.25). This is the posterior (or dorsal) gastric artery. This artery has received great attention, particularly because of its potential clinical significance. Inadvertent ligation or division of the artery can cause focal necroses or postoperative hemorrhage.

The posterior gastric artery is identified as that artery that provides the predominant arterial supply to the posterior wall of the superior portion of the gastric body near the cardiac region and fundus. In a study by Loukas et al. in 120 cadavers, a posterior gastric artery was identified in 81.6% of specimens. The most common origin of the posterior gastric artery was from the left gastric artery (type I), occurring in 41.8% of specimens. In decreasing order of prevalence, were origins from the splenic artery (Type II), occurring in 25.5%; from both the left gastric and splenic arteries as double posterior gastric arteries (Type III) in 22.4%; and from the celiac trunk (Type IV) occurring in 10.2%. The importance of accurate delineation of the posterior gastric artery is crucial for pancreatic transplantation and gastric tumor removal. In addition, knowledge of

variations in this vessel's origin could prove useful in transcatheter arterial embolization for the treatment of chronic bleeding from gastric ulcers. Furthermore, ligation of this vessel during partial gastrectomy, pancreaticoduodenectomy, and parietal cell vagotomy may result in gastric wall necrosis and gastric stump leak.

From our observations, we found that the farther distally along the splenic artery one finds an artery arising that passes vertically toward the fundic region, the more likely it is to provide a superior splenic polar branch. Most distally, at the terminal branching of the splenic artery, a small fundic branch to the stomach may arise from the superior polar branch.

Arterial Circulation of the Gastric Walls

The stomach can survive ischemia after ligation of all but one of its major branches. It is known that the stomach should have adequate circulation after ligation of three major branches (e.g., left gastric, hepatic, and splenic) with preservation of the right gastric or right gastro-omental artery and leaving in situ the other ligated branches. As each of the smaller branches of these arteries penetrates the muscularis of the stomach, it supplies the submucosal plexus. It is this submucosal plexus that interconnects with the extragastric arteries and allows the stomach to tolerate extensive ligation of its extrinsic blood supply. It should be noted that the mucosa of the lesser curvature is supplied by small extrinsic branches of the left and right gastric arteries, rather than by vessels from the submucosal plexus. Despite the richness of the vascular supply of the stomach, necrosis and perforation of the lesser curvature can occur with proximal selective vagotomy in an occasional case. Similarly, necrosis and perforation of the greater curvature after ligation of the short gastric arteries during splenectomy can rarely be encountered, perhaps caused by failure of collateral circulation, as Griffith suggested.

Ischemic necrosis of the gastric remnant after gastrectomy has been reported. The submucosal plexus, which contains many arteriovenous shunts, is the collecting arterial blood reservoir. There is no question that this plexus is the central point of collateral circulation. In fact, dye can reach all intramural branches of all four major arteries after ligating all extramural vessels and injecting any one of the four major arteries.

Because of these findings, Griffith stated the following:

Ligation of most or all extrinsic arteries does not control bleeding from

gastric ulcer.
The stomach remains viable after ligation of all arteries except the right gastro-omental artery and perhaps the right gastric artery.
With subtotal gastrectomy, the gastric remnant remains viable with circulation from the left gastro-omental artery and the short gastric arteries after the left gastric artery is ligated. If present, the posterior gastric artery participates in survival of the remnant.
With 90% to 95% gastrectomy, the remnant stays alive and well because of the descending esophageal arteries. As Griffith stated, however, necrosis rarely can occur.

The blood supply of the proximal gastric pouch depends on three sources: (a) the ascending branch of the left gastric artery, (b) the short gastric arteries, and (c) the posterior gastric artery (if present).

If the spleen is removed, the short gastric arteries must be sacrificed. Every effort should be made to avoid injuring the ascending branches of the left gastric arteries. Adhesions of the posterior gastric wall must not be cut; such adhesions may contain the posterior gastric artery.

The more sparse circulation of gastric vessels is in the pyloric portion of the stomach. The vessels in this region are somehow compressed by the hypertrophic muscle. Compared with the cardia, the pylorus seems to have a less adequate blood supply.

Arterial Supply of the Greater Omentum

The omentum is richly supplied by the right and left gastroepiploic (gastro-omental) arteries (Figs. 82.28 and 82.29). The right gastroepiloic artery is given off from the gastroduodenal artery and the left from the splenic artery. Both gastroepiploic arteries pass tortuously along the greater gastric curvature and decrease in diameter by giving off gastric and epiploic branches at a ratio of 3:1. Finally, having become minute, both gastroepiploics anastomose to the left of the midline of the greater gastric curvature on the exterior or interior of the gastric wall by forming an arcade. The distance of the arcade from the stomach wall varies from 0 to 4 cm.

There are different descriptions of the omental arteries. The classic description, as given by Griffith (Fig. 82.28), defines as anterior omental the branches of the arcade of right and left gastroepiploic arteries that descend in the anterior layer of the omentum. These are said to descend until the edge of the omentum and then ascend in the posterior layer. There

they anastomose between themselves and with the right and left omental arteries; the later are given from the corresponding gastroepiploics and course in the posterior layer of the omentum. The connections of the ascending anterior omental with the right and left form the “arc of Barkow,” located 2 to 4 cm below the transverse colon. A few of the posterior omental arteries from the transverse, dorsal, or great pancreatic arteries enter the arc. Other posterior omental arteries enter the transverse colon directly or anastomose with the vasa recta of the middle colic circulation.

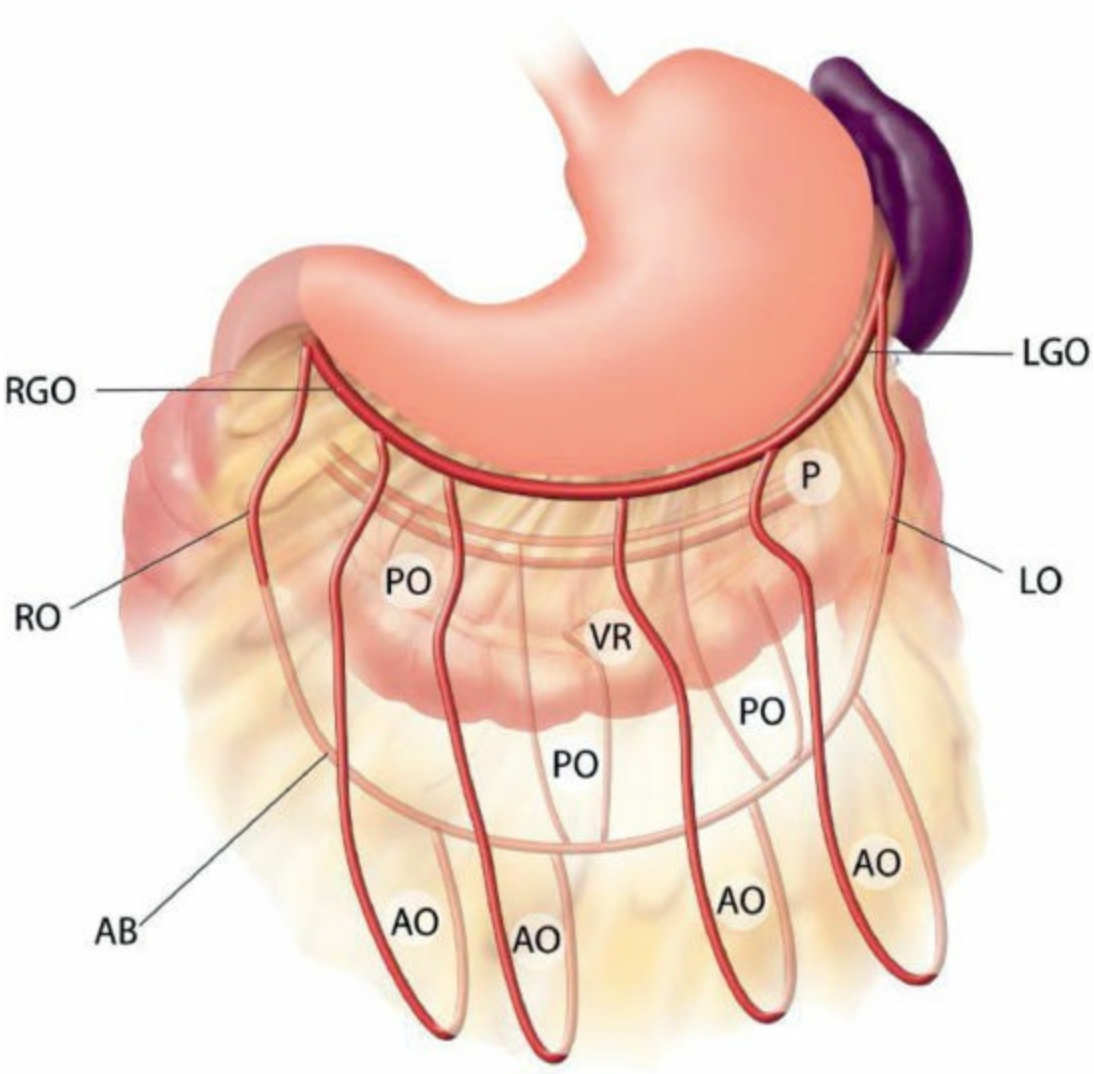

Figure 82.28. Arterial supply to the greater omentum. For description, see text. AB: arc of Barkow, AO: anterior omental, LGO: left gastro-omental, LO: left omental, P: pancreatic, RGO: right gastro-omental, PO: posterior omental, RO: right omental, VR: vasa recta of the middle colic circulation. (Based on Griffith CA. Anatomy. In: Nyhus LM, Wastell C, eds. *Surgery of the Stomach and Duodenum.* 4th ed. Boston, MA: Little, Brown;

1986.)

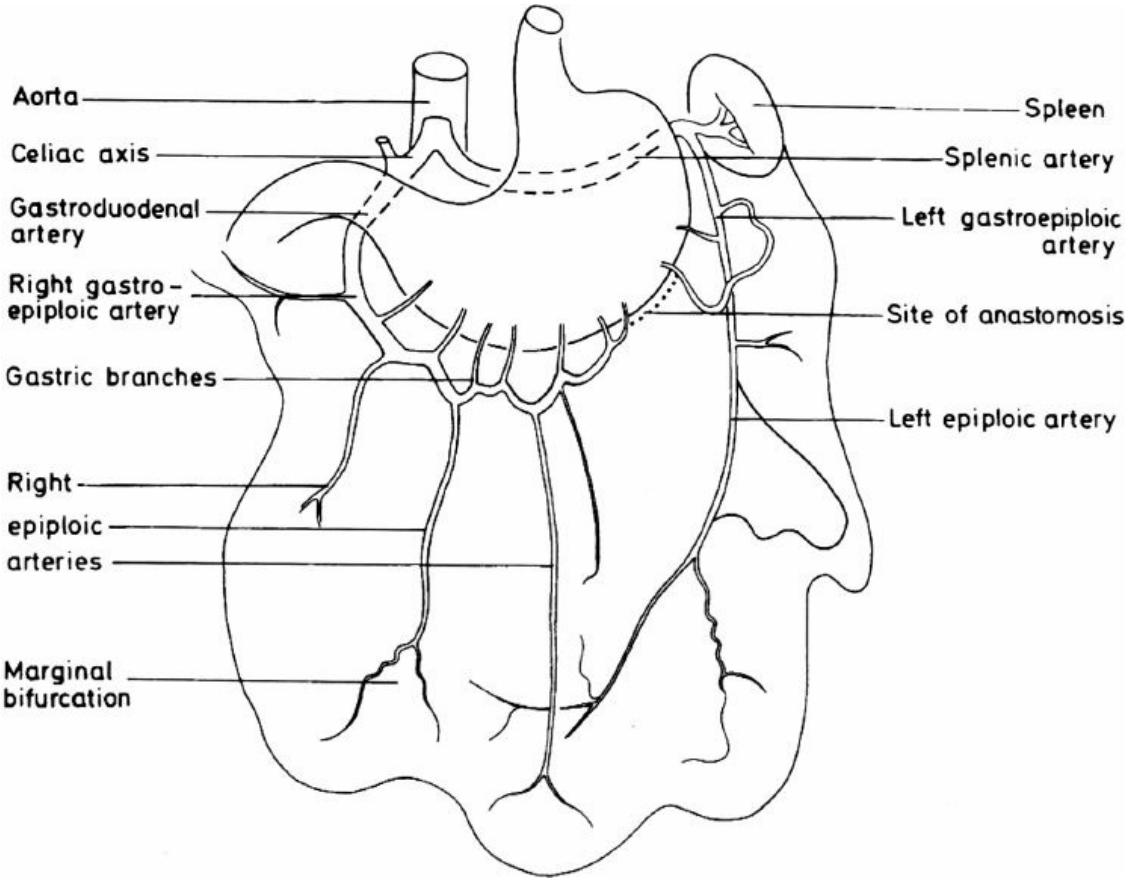

Figure 82.29. Nomenclature, origin, and individual distribution of omental arteries. (Republished with permission of Springer, from Liebermann-Meffert D, White H, eds. *The Greater Omentum: Anatomy, Physiology, Pathology, Surgery, with an Historical Survey.* New York: Springer-Verlag; 1983:37, permission conveyed through Copyright Clearance Center, Inc.)

Dorothea Liebermann-Meffert, a very respected researcher and surgeon of the omentum, claims that in 50% of cases there are no complete gastroepiploic and epiploic arterial arcades (Fig. 82.29). Instead, there is actually no standard pattern. In her investigations, she found 5 to 13 epiploic arteries originating from the right epiploic artery and only one main vessel from the left epiploic artery. They descend in the trabecula mostly at right angles to the greater curvature and bifurcate close to the omental margin, where they eventually anastomose with small branches with adjacent epiploic vessels. In 50% of specimens, the left epiploic coursed downward posteriorly close to the omental margin below the spleen-giving many branches to this area of omentum, thus making it the

best vascularized area; in the rest, it had an oblique course while giving posterior epiploic arteries. The traditional arc was found in just 1 out of 16 specimens, and there was no connection with pancreatic, mesocolon, or transverse colon arteries. Knowledge and preservation of the main vessels are essential to successful lengthening of the omentum in reconstructive surgery.

Ligation of the anterior omental branches or ligation of the right gastroepiploic artery distal to the origin of the right epiploic artery has been advised. It is an open question whether this approach is better than the ligation of the gastric branches that arise from the right and left gastroepiploic arteries to the greater curvature of the stomach. Although the latter may be tedious, it is the opinion of the authors that it is a better choice and is safer.

Remember: The preservation of the blood supply of the omentum in benign gastric disease may be accomplished by careful ligation of the gastroepiploic vessels along the greater curvature of the stomach.

VASCULAR SUPPLY OF THE DUODENUM

In this chapter, we focus on the gastroduodenal anatomy and do not explicitly describe the duodenum beyond the first part, which is supplied mostly by branches of the gastroduodenal artery (see below). The second, third, and fourth part of the duodenum that are bound to the head of the pancreas are supplied by branches of the two pancreaticoduodenal arcades, the anterior and posterior, with superior branches coming from the celiac artery and inferior ones from the SMA (Fig. 82.30). The latter is dictated from the embryologic origin of the pancreas from the foregut (celiac artery) and the midgut (superior mesentery artery). The branches of the pancreaticodudenal arcades are described in detail elsewhere in this book.

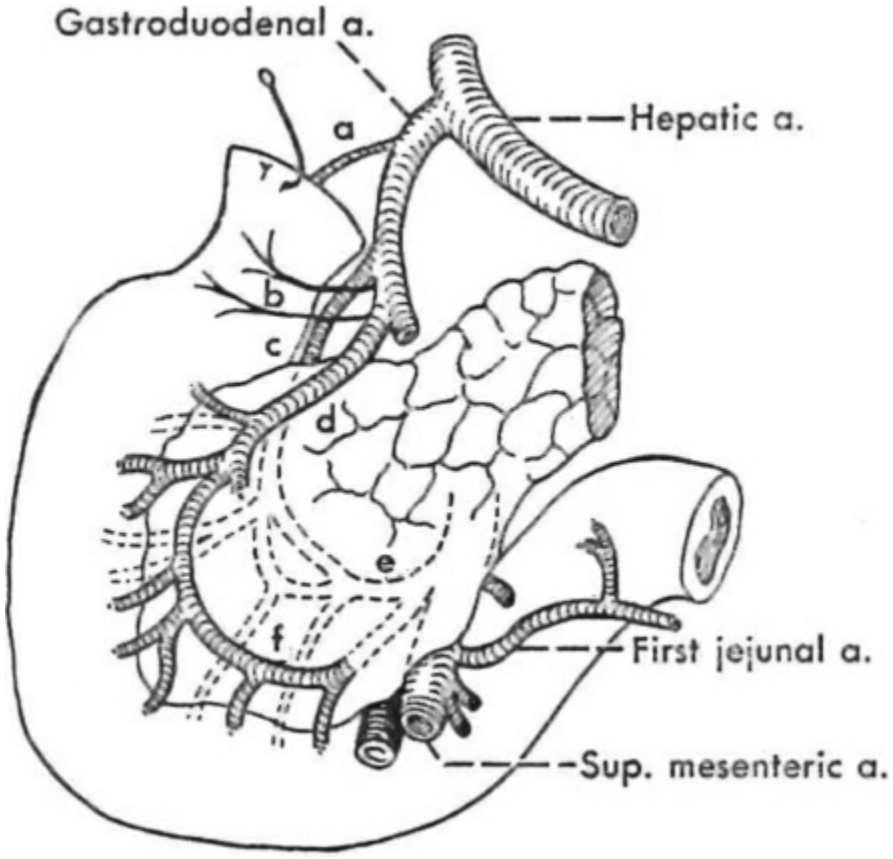

Figure 82.30. Arteries of the duodenum. Those embedded in or running behind the pancreas are shown by *broken lines*. *a,* supradudodenal artery; *b,* retroduodenal and recurrent branches to the first part of the duodenum; *c,* posterior superior pancreaticoduodenal artery; *d,* anterior superior pancreaticoduodenal artery; *e,* posterior inferior pancreaticoduodenal artery; *f,* anterior inferior pancreaticoduodenal artery. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper; 1956:391, Fig. 278.)

Vascular Supply of the First Part of the Duodenum

In contrast to the rich blood supply of the stomach, the arterial supply to the first part of the duodenum is sparse. The arteries of the first part of the duodenum are small: the supraduodenal artery, retroduodenal arteries, and tiny branches from the right gastric or the right gastroepiploic artery (Fig. 82.31).

The gastroduodenal artery is usually the first branch of the (common) hepatic artery. It arises behind, at the upper border or above the first part of the duodenum and then descends behind it. Typically, the gastrodudenal gives off the supradudenal artery; however, there are cases where the latter

arises from the hepatic artery, or the gartoduodenal artery is absent and the right gastric artery takes over to supply the first part of the dudodenum. The supraduodenal artery supplies the upper two thirds of the anterior surface of the first part of the duodenum, and about one third of the posterior surface. The remaining part of the posterior surface is supplied by the retroduodenal artery, which can be single or multiple, in the latter case arising from arteries of the neighborhood such as the anterior superior pancreaticodudenal or the right gastroepiploic arteries (Fig. 82.31).

Regarding the anastomoses between the pylorus and first part of the duodenum, we learn from Hollishead:

"In contrast to the cardiac end of the stomach, where anastomoses between the vessels of the stomach and those of the esophagus are apparently constant and of clinical and surgical importance, it seems to be generally agreed that anastomotic channels between the vessels of the pyloric end of the stomach and the first part of the duodenum are either nonexistent or minimal, and have no practical importance when they do occur."

VEINS

The veins of the stomach correspond to the arteries (Fig. 82.32). They course in parallel to the arteries along the curvatures, and each ends separately in the portal vein. These veins do not have valves, and circulation may shift from one direction to the other when pressure dictates so. For this reason, when portal hypertension is present, the anastomosis of the left gastric vein (portal circulation) with the lower esophageal veins (azygos circulation) leads to esophageal varices.

It is also well known that occlusion of the splenic vein produces obvious extrinsic varicosities of the veins of the proximal gastric unit (short gastrics, left gastro-omental) (Fig. 82.33). Occasional involvement of the right gastro-omental vein and intrinsic gastric and even duodenal varices are also possible. The endoscopist can mistake these varices for hemorrhagic gastritis.

Remember: A great venous arch can develop between the left and right gastro-omental veins during portal hypertension, forming a congested vascular bridge between the splenic and portal veins.

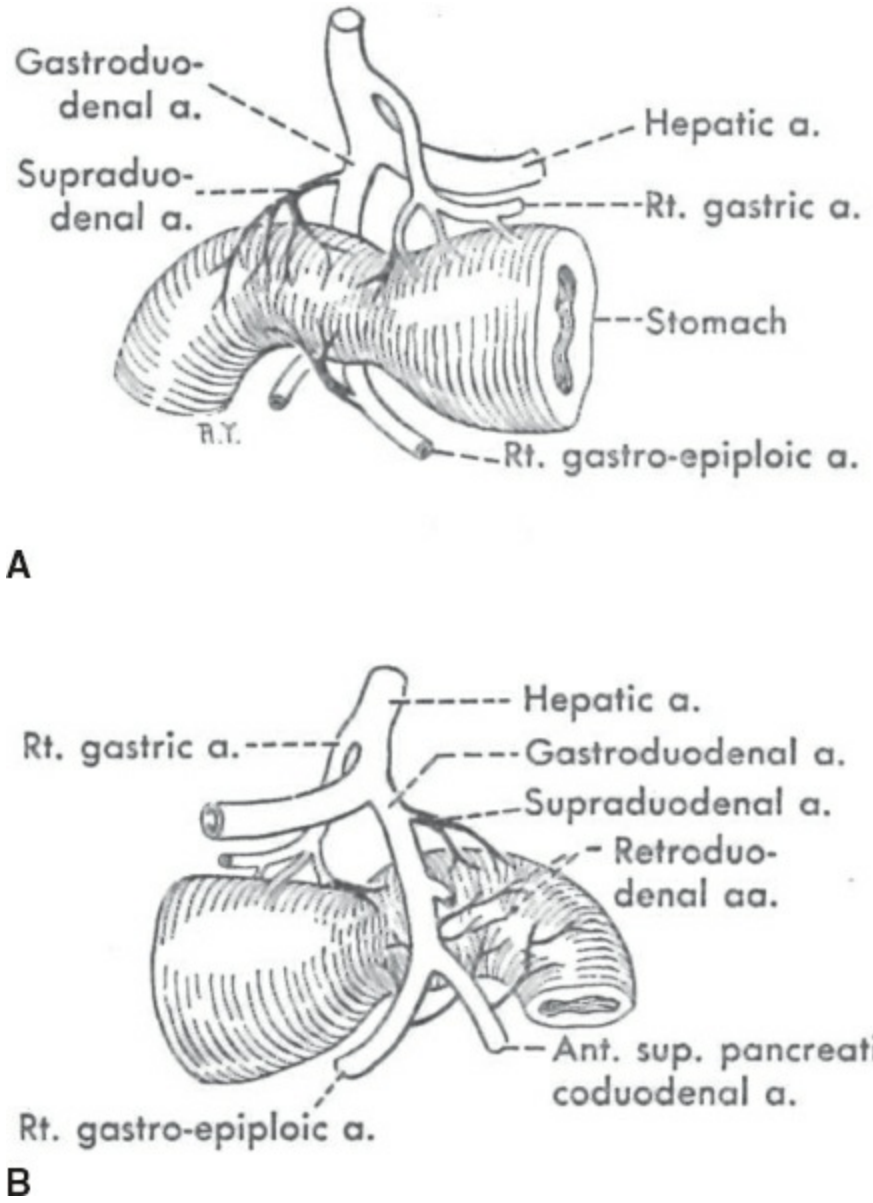

Figure 82.31. Anterior (**A**) and posterior (**B**) views of the blood supply of the first part of the duodenum. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper; 1956:391, Fig. 279.)

Left Gastric (Coronary) Vein

The left gastric vein is often referred to as the *coronary vein.* One can find the beginning of the left gastric vein at the middle of the lesser curvature, running close to the curvature to a point 2 to 3 cm from the inferior border of the esophageal hiatus where it receives one to three esophageal tributaries. From this point, the left gastric vein turns downward and obliquely to the right to join the portal vein. It accompanies the corresponding artery behind the posterior wall of the omental bursa. The coronary vein may also turn backward to enter the splenic vein. Douglas et al. reported that more commonly it ended in the portal vein just above the level of formation of this (59%), or higher in the portal vein (25%) or in the splenic vein (17%) (Fig. 82.34). An intrahepatic termination of the left gastric vein has been reported.

Right Gastric Vein

The small right gastric vein partially drains the distal gastric unit. It follows the right gastric artery at the distal lesser curvature, passing from left to right and draining into the portal system. The prepyloric vein of Mayo is a tributary of the right gastric vein and is the external landmark of the gastroduodenal junction.

Statistics for the drainage of venous vessels in the area are not in total agreement, but to facilitate memorization, we rounded the relevant percentages (22% to 38%) to the number 30%. Note that this is a memorization aid only, and not completely accurate.

Both right and left gastric veins enter the upper portal in 30%.
Both right and left gastric veins enter the lower portal in 30%.
Both right and left gastric veins enter the junction in 30%.

Right Gastro-Omental Vein

The right gastro-omental vein drains the distal stomach and accompanies the right gastro-omental artery in the great omentum. The right gastro-omental empties into the superior mesenteric vein, usually about 5 cm below the junction of the latter with the splenic vein. In rare cases, it may enter the portal vein itself or the splenic vein (Fig. 82.35).

Frequently, the right gastro-omental vein, near its ending, is joined by a

vein from the mesocolon to form the so-called gastrocolic vein, which is short and located beneath the root of the transverse mesocolon, traveling along the anterior surface of the head of the pancreas.

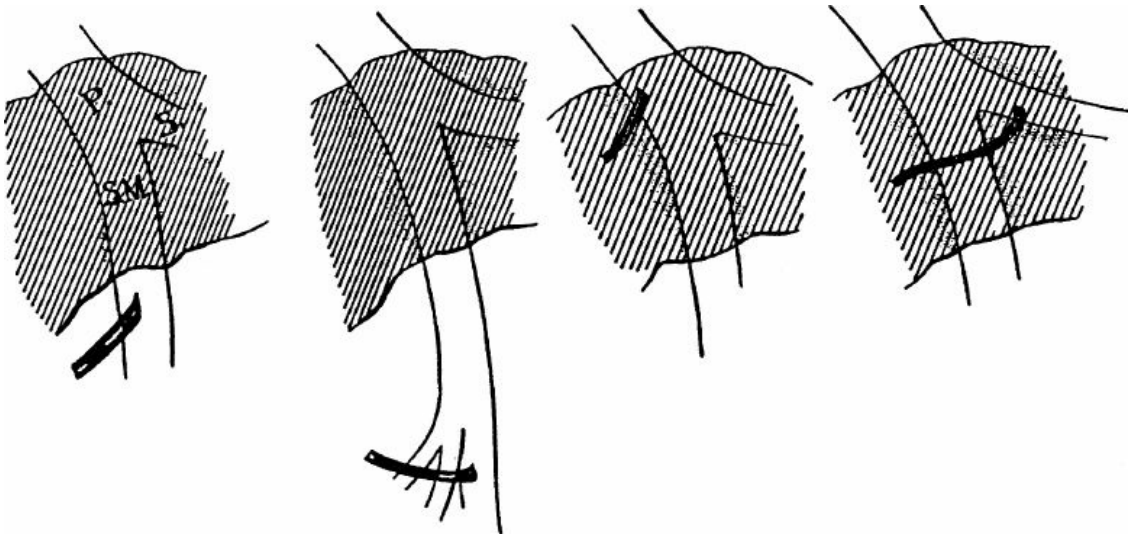

Figure 82.35. Major variations in place of ending of right gastro-omental (gastroepiploic) vein (*shaded*). Diagonally shaded area represents neck of pancreas. Frequency, from view's left to right, is 84%, 12%, 2%, and 2%. P, portal vein; S, splenic vein; SM, superior mesenteric vein. (From Douglass BE, Baggenstoss AH, Hollinshead WH. The anatomy of the portal vein and its tributaries. *Surg Gynecol Obstet* 1950;91:562. Major variations in location of ending of short gastric veins: a, terminate in upper portion or hilus of spleen; b, terminate in lower anterior portion; c, short gastric veins empty directly into spleen. The common ending of one of several short gastrics in a splenic vein (approximately 50% of specimens), and occasional (approximately 2%) ending of one in left gastro-omental not shown. (From Douglass BE, Baggenstoss AH, Hollinshead WH. The anatomy of the portal vein and its tributaries. *Surg Gynecol Obstet* 1950;91:562. Reprinted with permission from *the Journal of the American College of Surgeons*, formerly *Surgery Gynecology & Obstetrics*.)

Left Gastro-Omental Vein

The left gastro-omental vein drains into the splenic vein or into one of the terminal branches of the splenic vein, usually the lower terminal branches (Fig. 82.36). Because the ending of this vein is variable, ligation should be placed as close as possible to the hilum.

Short Gastric Veins

The short gastric veins partially drain the proximal gastric unit. They accompany the corresponding arteries in the gastrosplenic ligament. The great majority of these vessels drain into the splenic vein or one of its contributing veins. According to Douglass et al., in the majority of cases, the short gastric veins enter the upper part of the splenic hilum (Fig. 82.37).

LYMPHATICS

Gastric Lymphatics

The classical view of the gastric lymphatic drainage is shown in Table 82.2 and Figure 82.38. These nodes follow the arteries of the stomach. Some groups, such as the gastroepiploic and the pancreaticosplenic, have been considered of secondary importance since their efferent vessels drain in the celiac nodes, referred by Visalli as "the vortex of the metastatic whorl."

Despite the order of numbering in this classical classification, the largest area of drainage is into the lymphatics of the lesser curvature along the left gastric artery toward the superior gastric nodes (III in Fig. 82.38). These nodes drain almost all the lesser curvature and a large part of the body of the stomach. The next largest area of drainage is the one that drains the pylorus and follows the right gastroepiploic artery toward the inferior gastric nodes (I in Fig. 82.38). These nodes may be found at 3 to 4 cm from the great curvature. The nodes found at the right end of this chain are the subpyloric lymph nodes. The third important area of drainage is from the great curvature, fundus and body along the left gastroepiploic artery and short gastric vessels, which drains into the left gastroepiploic and pancreaticosplenic lymph nodes (III in Fig. 82.38). And the fourth area (IV in Fig. 82.38) is rather small, the distal upper portion of the pylorus. Drainage here is associated with the upper border of the head of the pancreas (right suprapancreatic and lower hepatic nodes).

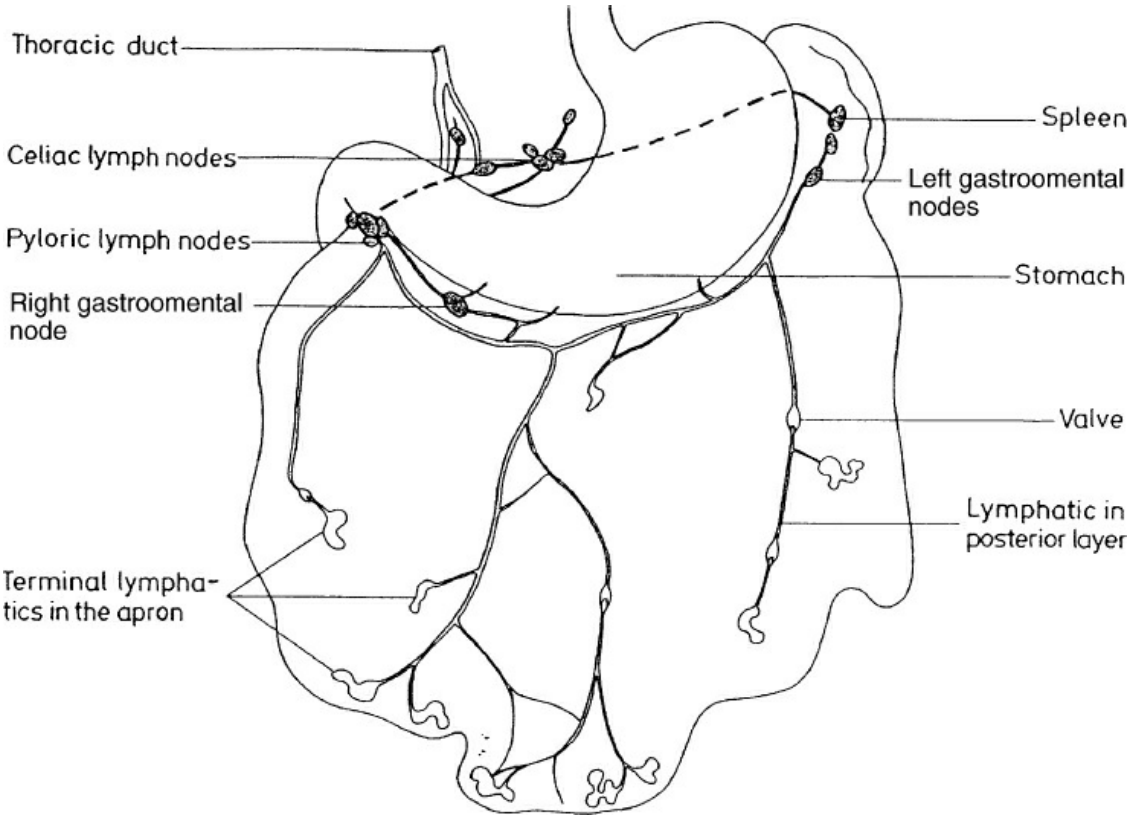

Figure 82.39. Lymphatic drainage of the great omentum. (Modified from Liebermann-Meffert D. Omentum in the adult. In: Liebermann-Meffert D, White H, eds. *The Greater Omentum: Anatomy, Physiology, Pathology, Surgery With a Historical Survey.* New York: Springer-Verlag; 1983, permission conveyed

through Copyright Clearance Center, Inc.)

Gastric lymphatics are continuous with esophageal lymphatics at the cardiac orifice. Lymph from the abdominal esophagus drains in the superior left gastric, paracardial and inferior diaphragmatic nodes.

Lymphatics of the stomach together with veins have a key role in metastasis of gastric cancer. O'Rahilly expresses this colorfully:

"The blood and the lymphatic drainage of the stomach are such that cancer can easily spread: (1) to the liver, by the portal vein or by reversal of flow in lymphatic vessels from the liver; (2) to the pelvis, by retroperitoneal lymphatic vessels; (3) to any other part of the body, both directly by veins and indirectly by way of the thoracic duct. The thoracic duct may be composed of several trunks in the neck, and one or more of these trunks may enter a cervical node."

Lymphatics of the Greater Omentum

The lymphatics of the great omentum are closely associated with the large vessels of the omentum. Thereof the collecting system follows two drainage pathways for the lymphatics of the omentum (Fig. 82.39): one travels to the right toward the subpyloric nodes and the other travels to the left toward the splenic nodes. In the proximal apron of the omentum, there is communication with lymphatics that drain the stomach and pass into the greater gastric curvature.

> Lymph drainage of the peritoneal cavity may largely bypass the lymphatic system of the omentum. The peritoneal cavity is mainly drained through the celiac lymph nodes to the thoracic duct.

Strikingly, we learn from Liebermann et al. that omental lymph nodes seem to be absent or at least very infrequent in the omental apron, in the gastrocolic ligament, and along the great curvature. They found none in the 16 omenta investigated.

When the omentum adheres to a part of the intestine, lymphatic connections rapidly (within a week) develop between the two. The lymph drainage of the omentum is important in metastasis, direct involvement of the omentum by malignant disease, infraction, and torsion.

Lymphatics of the Duodenum

Lymphatics of the duodenum run on its anterior and posterior surface. The

major lymph flow of the duodenum is directed toward the anterior and posterior pancreaticoduodenal nodes, which drain toward the hepatic nodes cranially and to the central superior mesenteric nodes caudally, respectively. In addition, the superior part of the duodenum drains into the pyloric nodes, whose afferents drain up to the hepatic nodes. Respectively, the third part of the duodenum and the gastroduodenal flexure have connections with the inferior pancreatic and central superior mesenteric nodes.

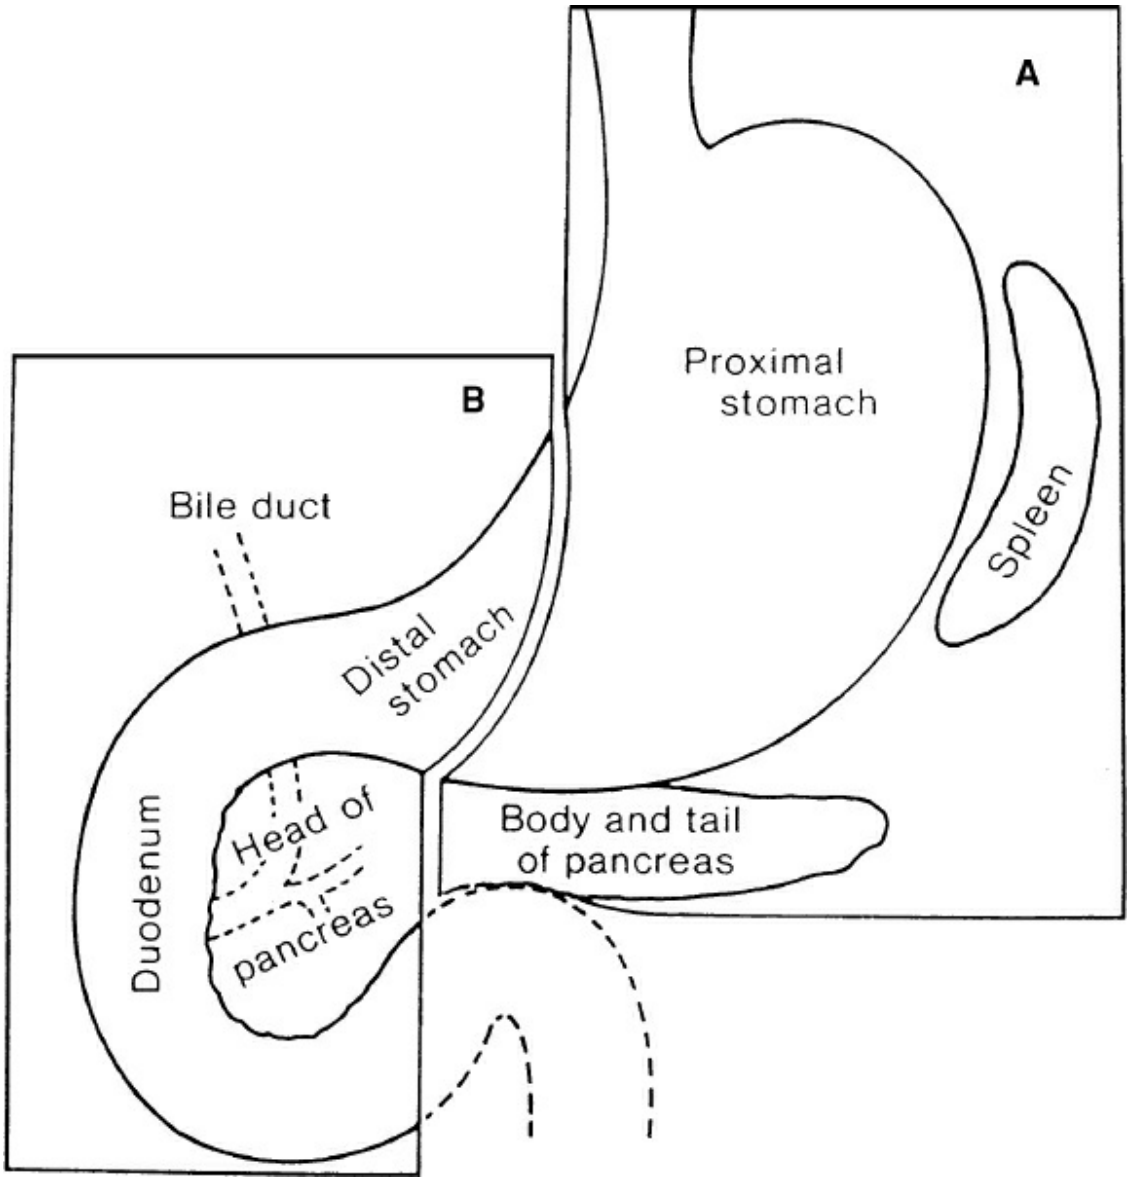

Figure 82.40. Plans for en bloc resections. **A.** Proximal stomach and related organs sharing a common blood supply and lymphatic drainage. **B.** Distal stomach and related organs. (From Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery.* New York: McGraw-Hill;

1983.)

There is no agreement whether lymphatics of the stomach anastomose with those of the duodenum. However, gastric cancer may involve the duodenum in a percentage (26% to 38%).

Proximal and Distal Gastric Units

After presentation of blood supply and lymphatic drainage of the gastroduodedum, the concept of "proximal and distal gastric unit," introduced earlier in this chapter, is now more clear: the embryology of the stomach and related organs is such that the body and tail of the pancreas (derived from the dorsal pancreatic anlagen) and the spleen lie in the dorsal mesogastrium. They share a common blood supply (splenic artery) and a common lymphatic drainage with the proximal portion of the stomach. The head of the pancreas (derived from the ventral pancreatic anlagen) lies in the mesoduodenum. The pancreatic head shares its blood supply (pancreaticoduodenal and gastroduodenal arteries) and lymphatic drainage with the duodenum, the distal common bile duct, and the distal stomach.

Theoretically, cancer of the proximal stomach can be effectively treated by en bloc resection of the organs supplied by the left gastric and splenic arteries (Fig. 82.40A): distal esophagus, proximal two thirds of the stomach and greater omentum, spleen, and body and tail of the pancreas. Similarly, cancer of the distal stomach can be treated by en bloc resection of the organs supplied by the common hepatic artery, sparing, of course, the artery itself (Fig. 82.40B): head of the pancreas, distal stomach and greater omentum, duodenum, and distal bile duct.

INNERVATION OF THE STOMACH AND DUODENUM

Innervation of the Stomach

The functional components of the innervation of the stomach is shown in Figure 82.41. The stomach is innervated by sympathetic and parasympathetic fibers. The sympathetic innervation is effectuated through branches of the thoracic splanchic nerves that reach the celiac ganglia; from there branches of the celiac plexus travel on a network on the arteries. The sympathetic pathway also conducts afferent impulses that mediate sensations, including pain. The sympathetic nerves are

vasoconstrictor to the gastric vasculature and inhibitory to gastric musculature; to the pylorus, they are motor, and result in constriction.

The parasympathetic innervation to the stomach is given by the branches of the vagus verves; these also transfer afferent sensory fibers. The parasympathetic innervation to the stomach either courses through the celiac ganglia and then on the arteries' plexus together with the sympathetic fibers, or goes directly to the stomach with branches of the vagus verves. Sensory fibers also exit in this parasympathetic network, mostly to mediate reflexes, such as the reflex of activation of gastric secretion.

Parasympathetic Innervation (Vagus Nerves)

The left and right vagus nerves descend parallel to the esophagus and form the esophageal vagal plexus between the level of the tracheal bifurcation and the level of the diaphragm. From this plexus, two vagal trunks, anterior and posterior, form and pass through the esophageal hiatus of the diaphragm. Each trunk subsequently separates into two divisions. The anterior trunk gives a hepatic division and an anterior gastric division; the posterior trunk gives the celiac division and the posterior gastric division (Fig. 82.42).

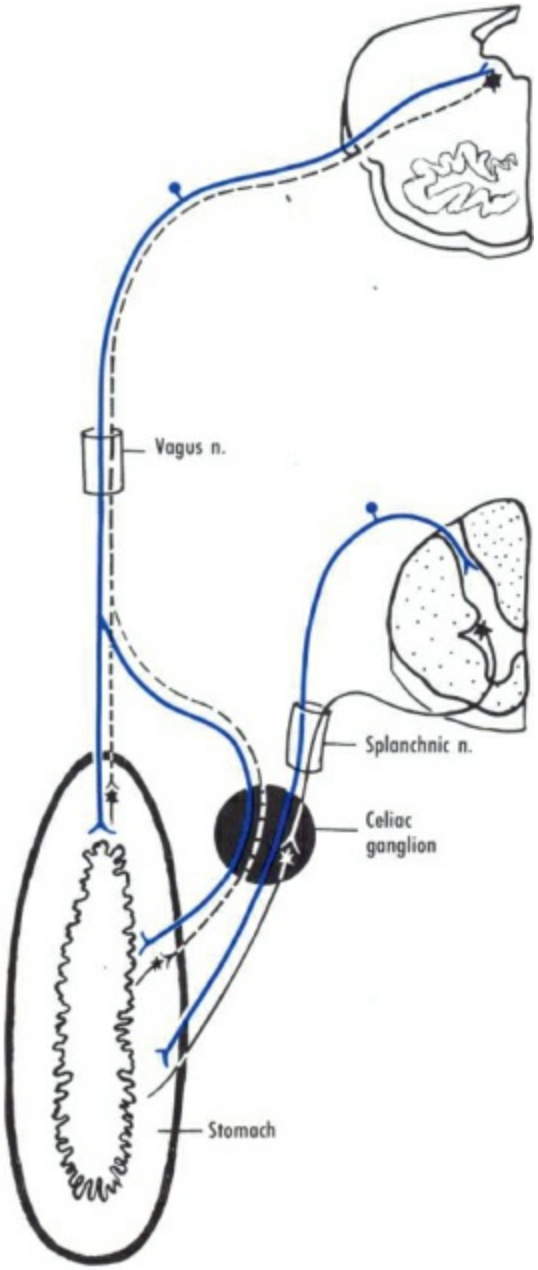

Figure 82.41. Functional components of the innervation of the stomach. Sympathetic fibers are shown as continuous lines, parasympathetic fibers as interrupted lines, and sensory fibers in blue. (Published in O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy: A Regional Study of the Human Structure.* 5th ed. Philadelphia, PA: W. B. Sunders Co; 1986:390, Fig. 35–7. Copyright Elsevier.)

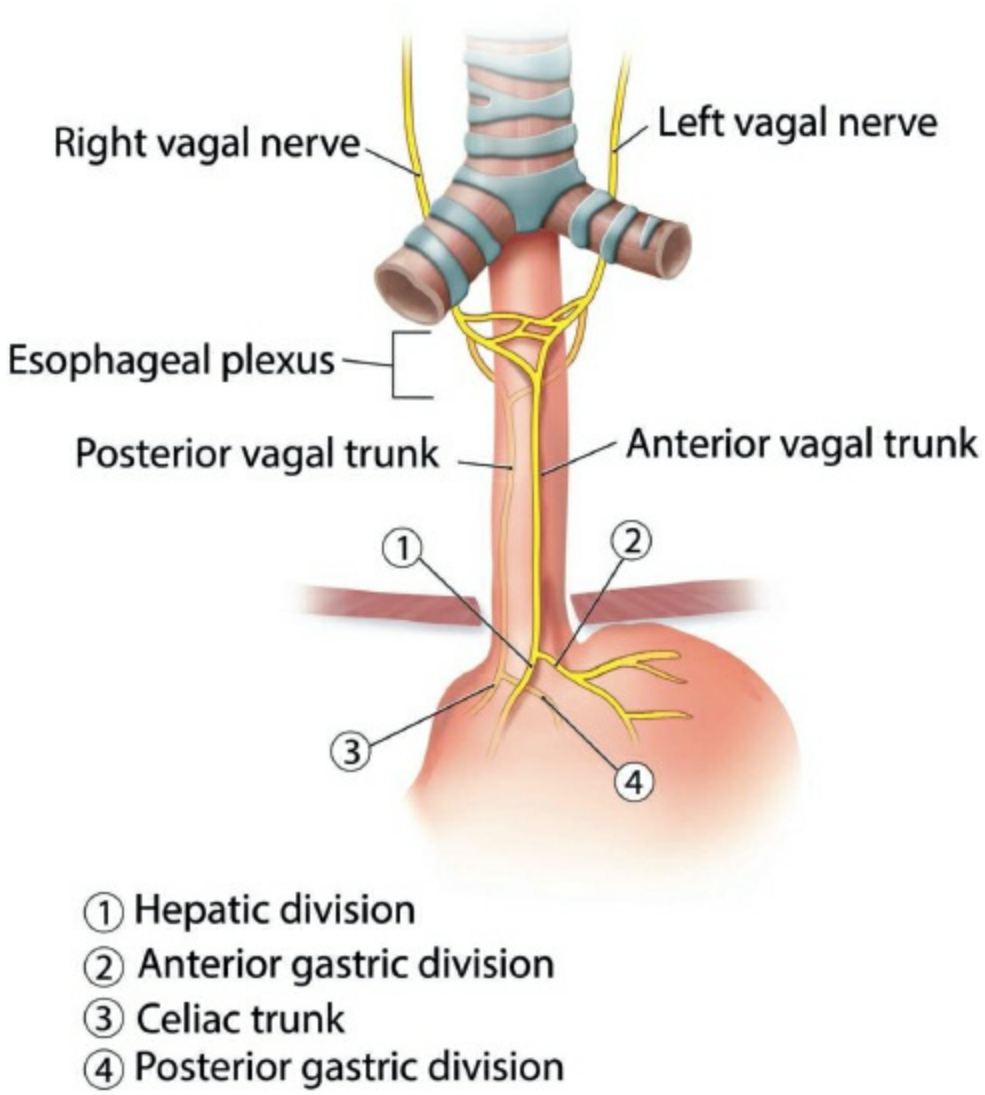

Figure 82.42. Terminology of vagal structures of thorax and abdomen. In this example, two vagal trunks pass through hiatus to enter abdomen. 1, hepatic division; 2, anterior gastric division; 3, celiac division; 4, posterior gastric division. (Modified from Skandalakis JE, Rowe JS Jr, Gray SW, et al. Identification of vagal structures at the esophageal hiatus. *Surgery* 1974;75:233. Copyright Elsevier.)

For the surgeon planning a truncal vagotomy, the pattern of the vagus nerves at the esophageal hiatus is important. The basic configuration and variations are well known. The thoracic pattern, however, is not visible to the abdominal surgeon, who must proceed on the basis of the structures that can be seen.

In our study of vagal structures in 100 cadavers, we found the following:

Two vagal structures only in 88% (Fig. 82.42). These are the anterior and

posterior vagal trunks, which have not yet split to form the four typical divisions. Both trunks are usually to the right of the midline of the esophagus.

Four vagal structures in 7%. These are the four divisions of the vagal trunks. Division has occurred above the diaphragm (Fig. 82.43A).

More than four vagal structures in 5%. These may be divisions and branches of divisions (Fig. 82.43B) (the anterior and posterior trunks lie entirely within the thorax), and elements of the esophageal vagal plexus (Fig. 82.43C) (the anterior and posterior trunks lie entirely within the abdomen).

Anterior Vagal Trunk

The anterior vagal trunk (Fig. 82.44) sends the hepatic division to the liver and pylorus and continues to the lesser curvature of the stomach as anterior division.

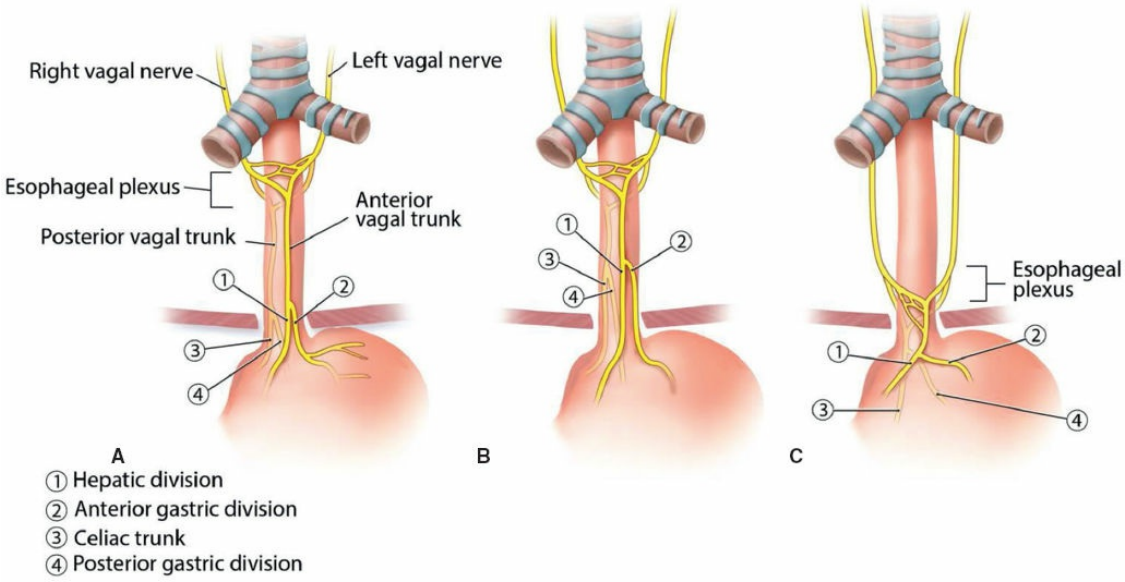

Figure 82.43. Possible configurations of four or more vagal structures emerging through hiatus. **A.** Divisions have separated just above diaphragm. **B.** Divisions and branches arise above diaphragm. **C.** Elements of esophageal plexus extend below diaphragm; vagal trunks entirely within abdomen. 1, hepatic division; 2, anterior gastric division; 3, celiac division; 4, posterior gastric division. (Modified from Skandalakis JE, Rowe JS Jr, Gray SW, et al. Identification of vagal structures at the esophageal hiatus. *Surgery* 1974;75:233. Copyright Elsevier.)

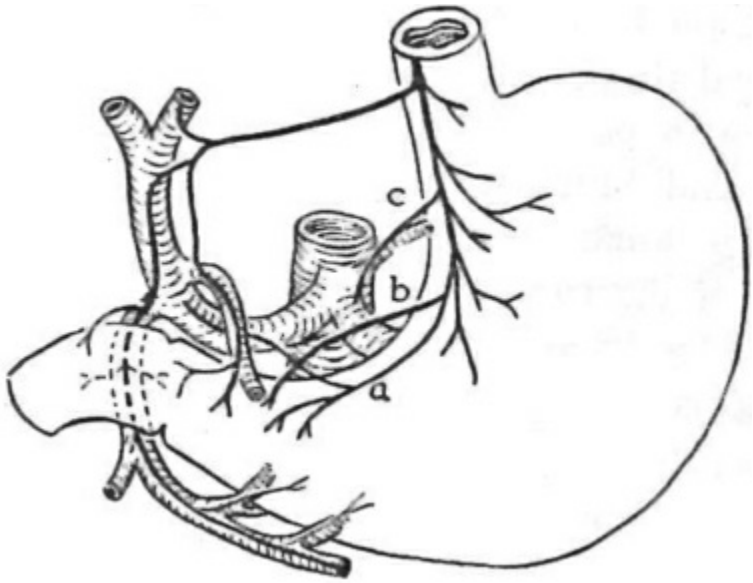

Figure 82.44. Drawing of the distribution of the anterior vagal trunk to the stomach. The hepatic division is unlabeled; it is the first upper branch. *a*, great anterior gastric nerve; *b,* pyloric branch; *c,* branches to the celiac plexus along the left gastric artery. Here fibers are shown to reach the great curvature by way of the right gastroepiploic artery. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper;1956;403, Fig. 291.)

Hepatic Division

The hepatic division of the anterior vagal trunk usually separates from the anterior gastric division at the level of the abdominal esophagus (Fig. 82.44). It courses through the upper, avascular portion of the hepatogastric ligament to reach the porta hepatis. It typically accompanies an aberrant left hepatic branch of the left gastric artery.

At the porta hepatis, some fibers continue into the liver as part of the hepatic plexus on the hepatic arteries. Others descend along the proper hepatic artery and are also part of the hepatic plexus. In dissection, nerve fibers can be traced to the pyloric end of the stomach, including the sphincter, pancreas, and first part of the duodenum. The hepatic division was frequently found in multiple and usually closely parallel branches in our dissections (Fig. 82.45).

Anterior Gastric Division

After giving off the hepatic division, the anterior trunk continues on the lesser curvature of the stomach and gives gastric branches (4 to 10) to the cardia and a major “great anterior gastric nerve” that can be traced until

the pyloric sphincter (but never to the sphincter itself). This nerve parallels the left gastric artery and communicates with a corresponding branch of the posterior vagal trunk. The terminal portion of the pylorus is supplied by the anterior trunk, not by the gastric nerves but through the hepatic branch or other branches of the anterior trunk. The reader is invited to study Figure 82.44.

Congress from Skandalakis JE, Gray SW, Soria RE, et al. Distribution of the vagus nerve to the stomach. *Am Surg* 1980;46:130, permission conveyed through Copyright Clearance Center, Inc.)

Hereafter we present our own experience. Among 100 specimens we dissected, the separation of the anterior gastric and hepatic divisions occasionally occurred above the diaphragm, but usually laid on the abdominal esophagus or the cardia. In 96 of our 100 specimens, a major branch of the anterior gastric division formed the principal anterior nerve of the lesser curvature (anterior nerve of Latarjet). It usually laid from 0.5 to 1.0 cm from the lesser curvature. In one of the specimens, it laid beneath the serosa of the gastric wall. This nerve can be traced distally to approximately the level of the incisura in most subjects, but in many it reaches the pylorus, and in a few it is visible as far as the first part of the duodenum (Fig. 82.45). Vagal branches that are subserosal at the surface may penetrate the muscularis and continue down to the antrum in the submucosal (Meissner) plexus.

From 2 to 12 branches pass from the principal nerve to the stomach wall. The average number in our subjects was six. In two of our subjects, the anterior nerve of Latarjet was duplicated; each nerve supplied its own branches to the stomach wall (Fig. 82.45B). The longer of these nerves is called the *antral nerve.* In some subjects, there is no true nerve of Latarjet; a fan of gastric branches arises from the anterior vagal trunk above the origin of the hepatic division, and one or more long branches below this origin descend to supply the antrum (Fig. 82.45). Even where a definite nerve of Latarjet is present, there are usually some, and often many, branches to the gastric cardia and fundus that arise from the anterior trunk proximal to the origin of the hepatic division. Although we have often seen the nerve of Latarjet branch in the “crow’s foot” formation, this pattern is far from constant, being equivocal in some cases and absent in many.

Celiac Branches

Celiac branches are given off the anterior trunk near the cardia and reach the celiac plexus retrogradely, by following the left gastric artery (see Fig. 82.44C). A few others arise from the hepatic division and follow the hepatic artery retrogradely toward the celiac plexus.

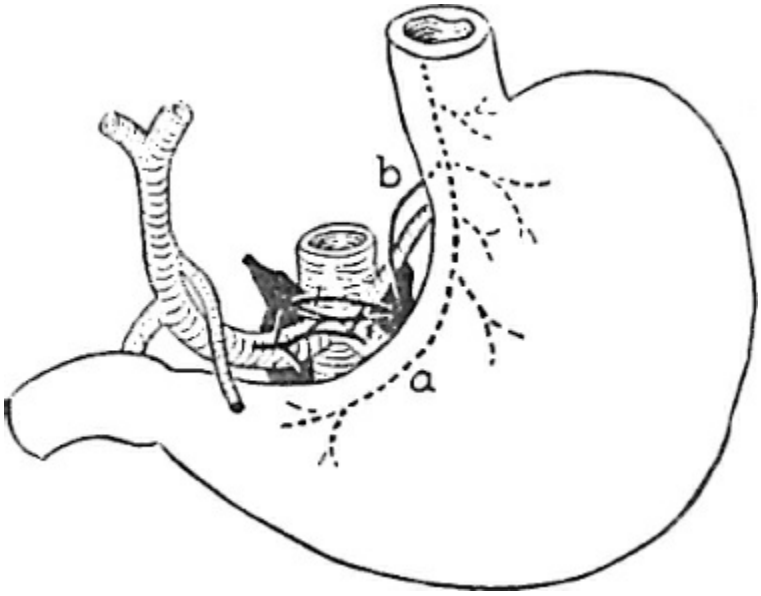

Figure 82.46. Schema of the distribution of the posterior vagal trunk to the stomach. *a,* great posterior gastric nerve, on the lesser curvature; *b,* celiac division. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper; 1956:404, Fig. 292.)

Posterior Vagal Trunk

The pattern of the posterior vagal trunk is quite similar to the anterior trunk, except for the hepatic (and pyloric) branch. The posterior trunk has a posterior gastric division and a celiac division (Fig. 82.46).

Posterior Gastric Division

In most subjects, the posterior gastric division forms the principal posterior nerve of the lesser curvature (posterior nerve of Latarjet). As a rule, the posterior nerve appears to terminate slightly higher on the lesser curvature and possesses fewer gastric branches than does the anterior nerve. In no case has a posterior nerve been observed to reach the duodenum.

The gastric branches arise from the posterior vagal trunk in a variable fashion (Fig. 82.47). In a number of specimens, the gastric branches of the posterior nerve of Latarjet fell into superior and inferior groups. The superior branches arose from the posterior vagal trunk just below, or even above, the diaphragm (Fig. 82.47B). The inferior branches arose from the descending posterior nerve of Latarjet and supplied only the lower body and the antrum. Between these two groups of branches, the lesser curvature had no grossly visible nerve supply. In many of our specimens, the most superior gastric branch, the “criminal nerve” of Grassi, arose at or above the origin of the celiac division. Usually, no single branch seemed

worthy of this dramatic term. In 18 of our 100 specimens, a true posterior nerve of Latarjet was absent; branches arising from the celiac division turned back toward the lesser curvature, and one or more long branches descended to innervate the antrum (Fig. 82.47E).

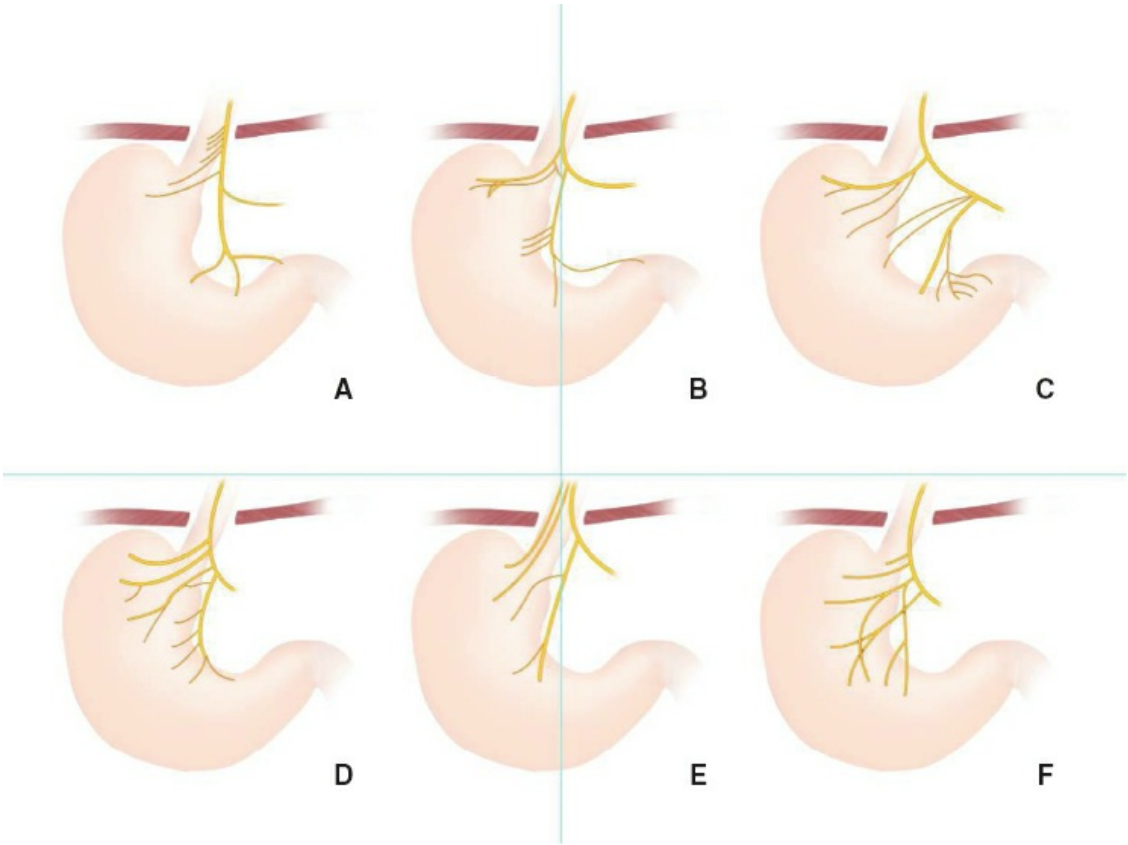

Figure 82.47. Patterns of posterior gastric and celiac divisions of posterior vagal trunks. **A.** Most frequent pattern. **B.** Superior branches arise below the diaphragm. **C.** Posterior nerve reaches pylorus; anterior nerve ends at antrum. **D.** Posterior gastric division forms principal posterior nerve of lesser curvature (posterior nerve of Latarjet). **E.** Superior branches arise above the diaphragm. **F.** True posterior nerves absent; branches to the lesser curvature (and one or more from the antrum) arise from the celiac division. (Modified with permission of Southeastern Surgical Congress from Skandalakis JE, Gray SW, Soria RE, et al. Distribution of the vagus nerve to the stomach. *Am Surg* 1980;46:130, permission conveyed through Copyright Clearance Center, Inc.)

Celiac Division

The celiac division is a large proportion of the posterior trunk and the largest of the four vagal divisions. It leaves the posterior trunk at the point

where the left gastric artery reaches the lesser curvature. It lies in the gastropancreatic peritoneal fold created by the elevation of the peritoneum by the left gastric artery as the nerve follows this artery. In all our cases, it was single and led directly to the celiac plexus. This division may follow the left gastric artery or the right crus of the diaphragm, or it may take an intermediate position in the triangle bounded by the artery, the crus, and the right margin of the stomach. Vagal fibers connect the stomach with the brainstem as they terminate in the gastric mesenteric plexus.

Sympathetic Innervation

The sympathetic chains, the thoracic splanchnic nerves containing afferent and efferent fibers, and the celiac ganglia form the basic elements of the sympathetic innervation of the stomach and duodenum. Branches of the celiac plexus accompany the arteries (Fig. 82.48). In addition, fibers from the hepatic plexus pass to the upper body and fundus of the stomach via the upper limit of the lesser omentum.

Efferent

The thoracic splanchnic nerves are formed mostly by preganglionic fibers from the intermediolateral cell column of the spinal cord at levels T5 to T10. The greater and lesser splanchnic nerves terminate within the celiac ganglia, where preganglionic fibers synapse upon the collateral ganglion cells. Postganglionic fibers from the celiac ganglia reach the stomach and duodenum via their blood supply.

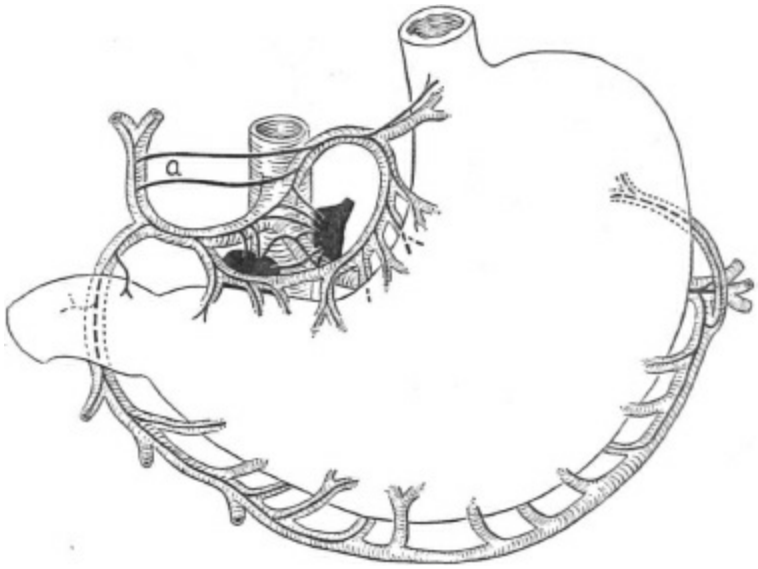

Figure 82.48. Drawing of the sympathetic innervation to the stomach. a. branches from the hepatic plexus that course

through the lesser omentum to reach the stomach through the plexus on the left gastric artery. (From Hollinshead WH. *Anatomy for Surgeons. Volume 2. The Thorax, Abdomen, and Pelvis.* New York: Hoeber-Harper;1956:405, Fig. 294.)

Afferent

Afferent fibers for the sense of pain from the organs supplied by the celiac artery (including the stomach) pass through the celiac plexus and thoracic splanchnic nerves to the sympathetic chains. They reach spinal nerves at thoracic levels T5 to T10. The cell bodies of these fibers are found in dorsal root ganglia at those levels.

Referred Pain

Most sensation of pain from the stomach is poorly localized and is referred to the central epigastium, together with the other structures of the foregut that share blood supply from the celiac axis. Pain from the gastroesophageal junction is referred to the lower retrosternal area. The stimulus of pain ascends with the sensory fibers of the sympathetic innervation. The sympatheric chains communicate with the thoracoabdominal intercostal nerves, and thus the pain is roughly projected on the body wall.

INNERVATION OF THE GREAT OMENTUM

In the omentum, there are nerve fibers for the omental vessels, but not for the omental tissue. This explains the apparent lack of sensory perception.

INNERVATION OF THE DUODENUM

The duodenum apparently shares the pattern of sympathetic and parasympathetic innervation of the stomach in its proximal part, as far as supplied by branches of the celiac artery. The distal part of the duodenum, beyond the entrance of the bile duct, is supplied by branches of the SMA. Thereof, the superior mesenteric ganglia are responsible for giving plexuses on the inferior arteries of the pancreaticoduodenal arcades. Referred pain is the same as in all foregut, and projects in the epigastrium.

EDITOR'S COMMENT

Dr. Mirilas and colleagues have written a very nice and detailed chapter on anatomic considerations in gastroduodenal surgery. There are many anatomic considerations and details that have relevance for those of us that perform upper gastrointestinal surgery. The description of the anatomic and functional basis of the lower esophageal sphincter (LES) is very informative. A very interesting description of the evolution of the understanding of the LES and gastroesophageal reflux was published in the *Annals of Surgery* in 2015. The mere existence of a LES was a matter of great debate at first. In 1956, the existence of a manometric high-pressure zone at the distal end of the esophagus was first described. In 1979, investigators at the University of Chicago used 24-hour pH monitoring and manometric measurements of the LES in the same patients to determine which manometric parameters were related to competency of the LES. The analysis of 266 consecutive patients indicated that the competency of the LES depended not only on its overall pressure but also on its abdominal length. Current thinking is that a competent LES is dependent on the triad of adequate pressure, overall length, and intra-abdominal length. If one of more of these characteristics of the LES is deficient, the risk of a patient developing pathologic GERD increases.

As mentioned throughout this chapter, the arterial supply of the stomach is robust and the collateral network is extensive. A 90% to 95% gastrectomy as described is much like the pouch in a gastric bypass. In a gastric bypass, the descending esophageal arteries and the ascending branch of the left gastric artery perfuse the pouch. A gastric bypass can be used as a salvage procedure in the case of multiple failed fundoplication procedures and to control recurrent GERD, to avoid a fundoplication in the setting of severe postsurgical gastroparesis following a failed fundoplication, to treat concurrent obesity in the setting of a prior fundoplication (failed or not), and for other reasons. When the distal esophagus has previously been extensively mobilized, the blood supply from the descending esophageal arteries may be compromised. In these cases, it is important to ensure that the gastric pouch is created distal to the left gastric artery and to take great care in preserving the ascending branches of this artery on the lesser curve. Ischemia and necrosis of the pouch can result in these multiple revision cases if one is not cognizant and careful. An interesting demonstration of the arterial supply of the stomach as described is seen in those rare cases of incarcerated paraesophageal hernia with ischemia/necrosis. While the proximal stomach may be ischemic or necrotic, there is typically a 1 cm or so cuff of cardia and stomach immediately adjacent to the esophagus that

survives. This may allow for a gastrojejunostomy rather than an esophagojejunostomy in cases where resection and anastomosis is appropriate.

The discussion of the arterial supply of the omentum is informative. Omentum has been used in diverse clinical settings to stimulate angiogenesis in ischemic tissues and to promote wound healing. The harvesting of omental tissue has been used for reconstruction and revascularization of extraperitoneal wounds and defects including mediastinitis, perforated viscus, and fistulas. We have even performed laparoscopic mobilization of an omental flap with subcutaneous tunneling to the brain as an indirect bypass in Moyamoya disease (a disease characterized by idiopathic, progressive, and chronic occlusion of major intracranial arteries). The omental pedicle can remain viable and can reach just about anywhere if the pedicle is based on an intact right gastroepiploic artery and vein.

SMA syndrome is discussed in this chapter. This is a rare and somewhat controversial condition caused by compression of the third portion of the duodenum between the aorta and the SMA. This results in chronic, intermittent, or acute complete or partial duodenal obstruction. The symptoms are nonspecific and include bloating, nausea and vomiting, early and prolonged satiety, and weight loss.

Any factor that sharply narrows the angle between the abdominal aorta and the SMA can cause entrapment and compression of the third part of the duodenum. Precipitating conditions include severe and rapid weight loss, prolonged bed rest, and even body casts. The difficult part of making the diagnosis is that many patients with a low BMI have a narrow angle of the SMA and aorta with no symptoms. CT angiogram, MR angiogram, and upper GI series are useful in making the diagnosis. In some patients, supplemental feedings and weight gain can lead to an improvement or resolution of symptoms. Surgical treatment is typically duodenojejunostomy to bypass the compressed portion of the duodenum. Investigators at the Cleveland Clinic recently reported outcomes on a series of 18 patients diagnosed with SMA syndrome to undergo surgery over a 10-year period. Although 14 of 18 patients reported initial symptom improvement, at latest follow-up, only 6 patients reported symptomatic improvement or resolution.

Intestinal malrotation and nonrotation is an interesting phenomenon that illustrates the embryologic development of the midgut. There are a large range of clinical presentations and aberrations in anatomy that can result. Most cases are diagnosed in infancy and childhood and typically before 2 years of age. The classic presentation in an infant is bilious emesis. Upper GI is diagnostic in these children and demonstrates an abnormal duodenal–jejunal junction (usually the duodenum does not cross the midline), and in the case of volvulus an abrupt cutoff of contrast in the proximal small bowel. Less common is a congenital malrotation or nonrotation that presents in an adult. These patients can present with a variety of symptoms including abdominal bloating, pain, nausea, vomiting, weight loss, or other nonspecific complaints. Treatment of a

malrotation at any age is performed surgically and with a Ladd procedure. The steps to a Ladd procedure include reduction of the volvulus if present, complete lysis of adhesive coloduodenal adhesions (so-called Ladd bands), widening of the base of the mesentery, and prophylactic appendectomy. This can be performed laparoscopically, although it requires a lot of skill. I perform about one to two Ladd procedures a year in adults, and I always scrub with a pediatric surgeon who can help keep me oriented.

Paraduodenal hernias are not discussed in this chapter, although these are rare internal hernias related to congenital openings in the mesenteries. Left-sided paraduodenal hernias are more common than right. In a left-sided hernia, the small bowel herniates through the fossa of Landzert, a congenital failure of fusion of the descending colon mesentery to the peritoneum in the left upper quadrant. In a right-sided hernia, the small bowel herniates through the fossa of Waldeyer, a congenital failure of fusion of the ascending colon mesentery to the peritoneum in the right lower quadrant. Right-sided hernias are associated with small bowel malrotation. Patients with paraduodenal hernias can present acutely with a closed loop small bowel obstruction or more commonly with chronic symptoms such as abdominal pain, nausea, or vomiting. In a left paraduodenal hernia, clusters of small bowel loops can be identified in the left anterior pararenal space, behind the inferior mesenteric vein, and behind the left colic artery. In a right paraduodenal hernia, clusters of small bowel loops can be seen inferior to the third portion of the duodenum, behind the superior mesenteric vein and artery, and behind the right colic vein.

A thorough understanding of the embryology and anatomy of the gastroduodenal anatomy is important for surgeons who operate in and around this part of the GI tract. A number of rare congenital conditions can present emergently and in previously undiagnosed patients. The content described in this chapter is important for surgeons to master.

83 Percutaneous Endoscopic Gastrostomy

Jeffrey L. Ponsky and Benjamin K. Poulose

INTRODUCTION

The endoscopic technique of gastrostomy placement, percutaneous endoscopic gastrostomy (PEG), has permitted long-term gastric access for feeding or decompression without the need for general anesthesia or laparotomy. Reports of comparisons with traditional gastrostomy suggest that the method offers equivalent results with less patient discomfort and at a lower cost. Complications, although consistent with those noted with the open procedure, can be minimized by appropriate patient selection and attention to technical details. Although a number of modifications of the originally described technique have been suggested, the original “pull” method and the closely related “push” approach are the most well-accepted and widely practiced methods.

INDICATIONS AND CONTRAINDICATIONS

The most common and appropriate indication for PEG is the need for long-term alimentation in patients unable to eat but with functional gastrointestinal tracts. Such individuals include those with progressive neurologic diseases, stroke victims, individuals with severe psychomotor handicap, patients with head or facial trauma, and patients with oropharyngeal tumors. The method has also been useful in administering unpalatable medications to children, in the administration of nighttime supplemental feedings to patients with inflammatory bowel disease, as a route for returning external biliary drainage to the gastrointestinal tract, and in providing gastric decompression in those patients with carcinomatosis or radiation enteritis.

Contraindications to PEG are few, but important to consider in minimizing morbidity and mortality of this procedure. The procedure should be avoided in patients with massive ascites, bleeding diatheses, or severe malnutrition as tract formation is impaired and leakage may result.

Multiple system organ failure or systemic sepsis should be corrected prior to the placement of a PEG, as infectious complications are more likely to occur. Feedings may be provided by the nasoenteric route until these problems are resolved. Also, the performance of PEG in patients with very limited life expectancy (i.e., <30 days) is meddlesome and costly, contributing to the high in-hospital mortality reported following the procedure. The underlying disease process gives some estimation of the risk of mortality not related to the placement of the PEG itself. In general, patients undergoing PEG placement for head and neck malignancies, or patients with trauma injuries, nonstroke neurologic disorders, or gastroparesis are considered low risk. Patients with stroke or malignancies other than head and neck cancer have the highest risk. PEG has not proven particularly useful in patients with aspiration secondary to severe gastroesophageal reflux, and in some cases it may exacerbate the problem.

TECHNIQUE

The patient is prepared by fasting overnight or by withholding enteral feedings for 6 to 8 hours prior to the procedure. Preprocedural imaging, if available, is reviewed for anatomic alterations such as a large hiatal hernia. Intravenous access is established for the administration of sedation and wound infection prophylaxis. A preoperative intravenous antibiotic, usually a cephalosporin, is administered to reduce the incidence of wound infection in the abdominal wall surrounding the tube. Swabbing of the oropharynx with an antiseptic solution can help reduce bacterial counts in the mouth and thus may help protect against wound infection. Moderate sedation using an intravenous opioid analgesic and benzodiazepine is usually sufficient for PEG insertion. Alternatively, deep sedation with intravenous propofol can be used in concert with the anesthesia team. Respiration, blood pressure, pulse rate, and oxygen saturation are monitored.

The patient is placed on the endoscopy table in the supine position. Although this position is most appropriate for the performance of PEG, it predisposes to the accumulation of secretions in the patient's oropharynx and may lead to aspiration. Therefore, frequent evacuation of this material by suctioning is imperative. Abdominal hair in the upper abdomen is clipped and the skin cleaned with a preparatory solution, and draped in a sterile manner. The procedure is commenced with the introduction of the gastroscope into the patient's esophagus. This can be somewhat difficult

with the patient in the supine position and may be facilitated by slightly turning the patient to the left for the passage of the instrument. The scope is then advanced into the stomach and the room lights are dimmed. A rapid but thorough inspection of the stomach and duodenum should be performed to rule out pathology or pyloric obstruction. The instrument is then pulled back into the gastric body and turned anteriorly as the assistant inspects the external aspect of the abdominal wall, looking for transillumination. Transillumination of the abdominal wall by the light from the endoscope can help localize the optimal area for gastric lumenal access. Finger palpation of the abdominal wall may reveal a point of light when gentle pressure is applied. Once the point of brightest transillumination is identified, continued finger pressure is applied to this site by the assistant, and this should create a clear and prominent indentation of the gastric wall that is visible to the endoscopist. Multiple sites may be palpated until the best transillumination and gastric indentation are achieved. Alternate palpation of two separate fingers adjacent to each other with visible confirmation of two separate indentations on endoscopic examination can also help identify an area for safe gastric access. Extra time spent at this stage of the procedure is well worth the effort and will help reduce inadvertent puncture of adjacent organs (Fig. 83.1).

The “safe tract” technique, described by Foutch et al., has been developed to help minimize the risk of visceral injury during PEG placement. This approach is especially useful in obese patients where other methods of gastric lumenal access localization are inadequate. In this method, the best site for puncture is initially localized by transillumination and finger pressure, as previously described. Then, using a syringe half-filled with local anesthetic in its barrel, a small-caliber needle is inserted into the skin at the proposed spot and suction is applied to the plunger. The syringe is slowly advanced into the stomach until the needle is seen to enter the gastric lumen endoscopically and air is seen to bubble into the syringe barrel externally. Should air appear in the barrel prior to the appearance of the needle in the gastric lumen, one may assume that there is a loop of bowel interposed between the stomach and the abdominal wall. The needle is removed and an alternative site is selected and tested in the same manner. In this way, the possibility of a fistulous communication is minimized (Fig. 83.2). A few milliliters of local anesthetic are infiltrated into the skin at the selected site, and a 5-mm incision is made through the

skin and into the subcutaneous tissue.

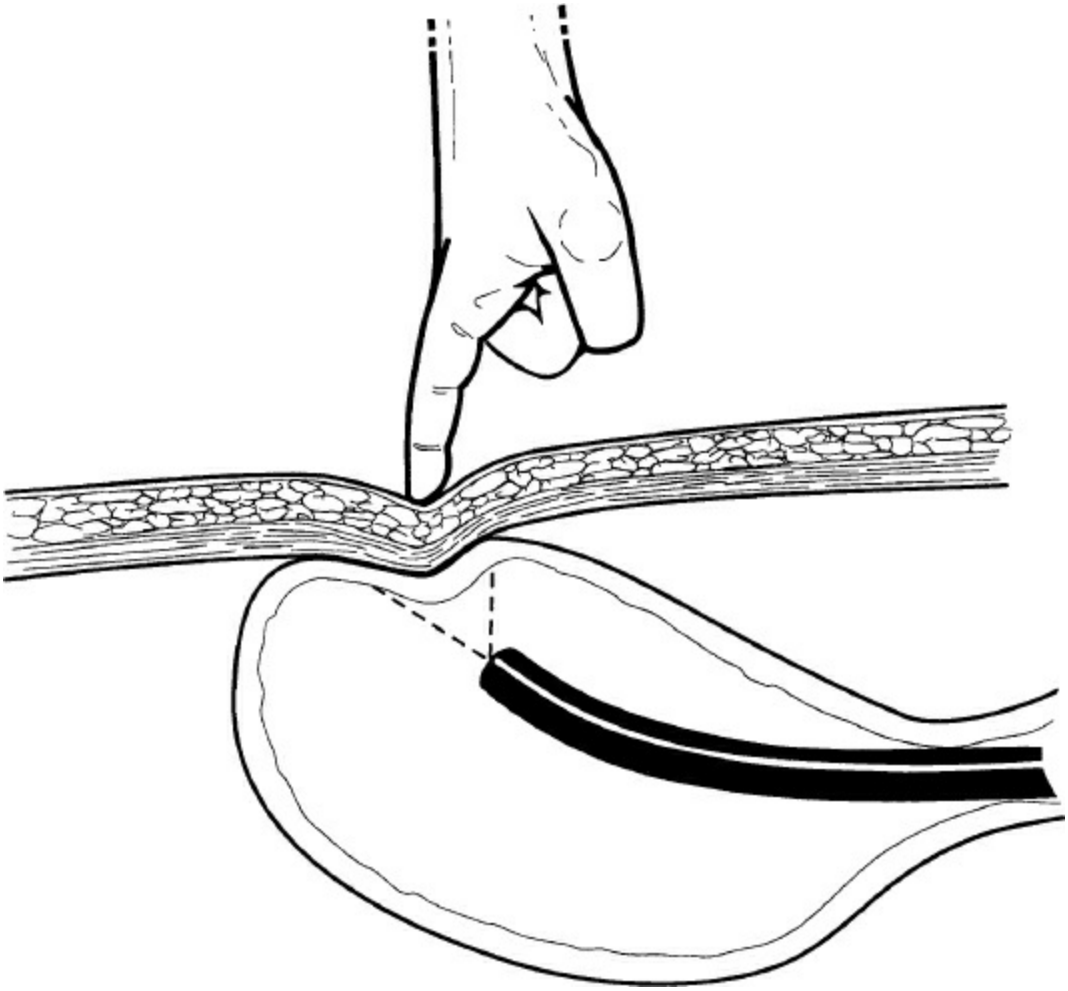

Figure 83.1. The site for gastric lumenal access should be carefully selected, using transillumination of the abdominal wall and gastric indentation with finger pressure as a guide.

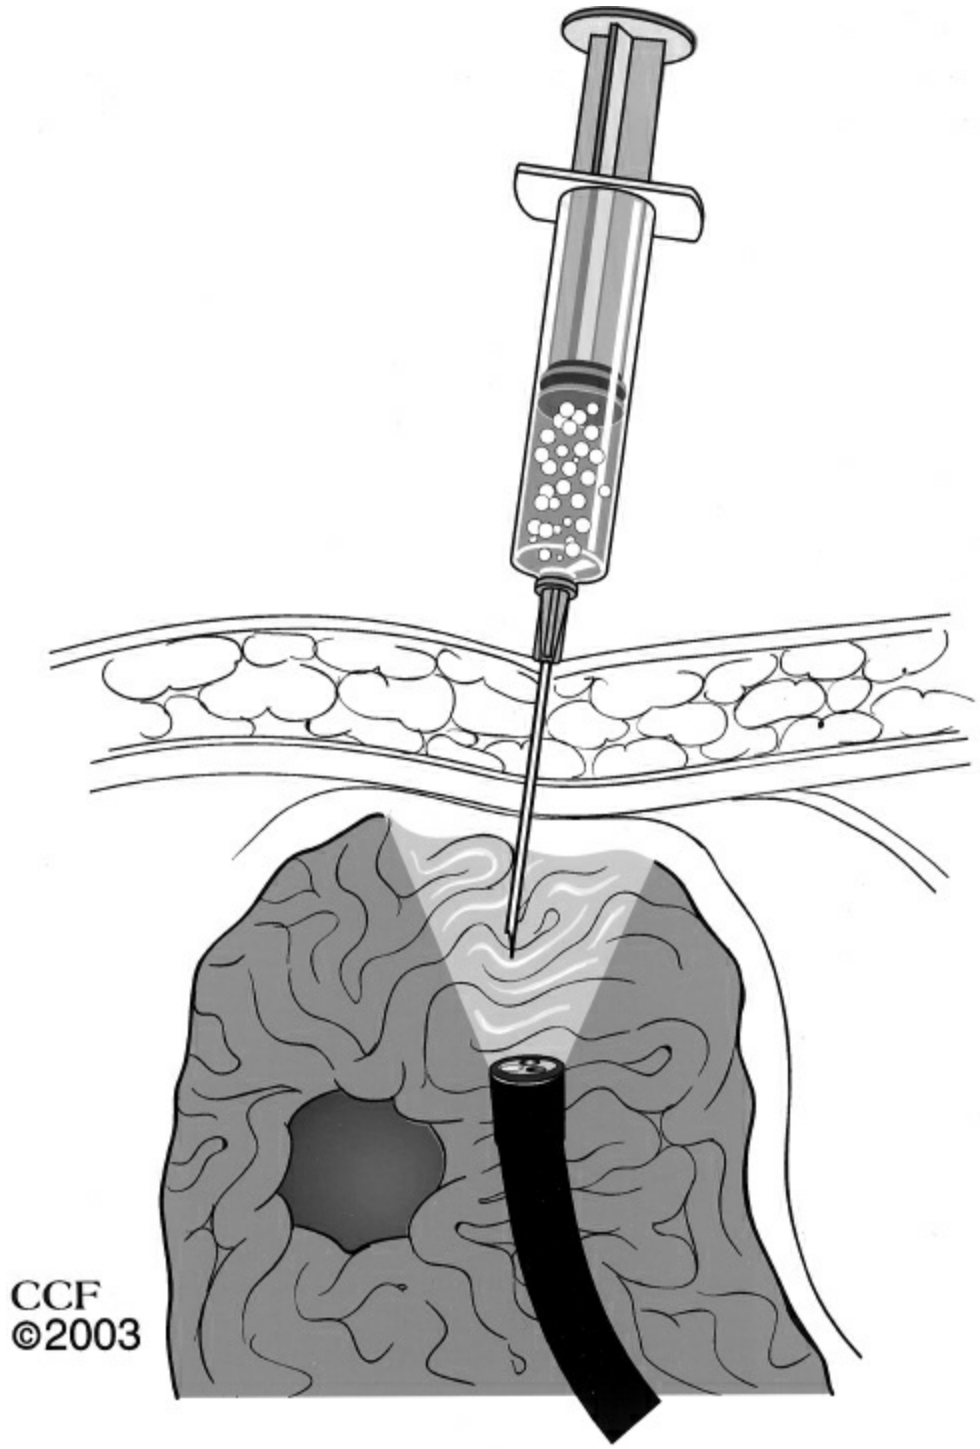

Figure 83.2. The “safe tract” method will help to protect against inadvertent puncture of an adjacent viscus. The syringe is slowly advanced into the stomach until the needle is seen to enter the gastric lumen and air is seen to bubble into the syringe barrel. Should air appear in the barrel prior to the appearance of the needle in the gastric lumen, one may assume that there is a loop of bowel interposed between the stomach and the abdominal wall. (Image © CCF 2003.)

While the assistant anesthetizes the abdominal wall skin, the endoscopist uses a polypectomy snare, passed through the biopsy channel of the endoscope, to surround the area of gastric indentation. When the endoscopist is ready, the assistant passes a needle cannula with an outer plastic sheath through the skin incision and into the stomach. This maneuver is done swiftly to minimize displacement of the gastric wall away from the abdominal wall. The open polypectomy snare in the gastric lumen will surround the cannula and is tightened around it. The inner needle is then removed and a long suture or wire is threaded through the cannula into the stomach. After several centimeters of the suture have entered the stomach, the snare is slightly loosened, the cannula pulled back a bit, and the snare retightened around the suture itself (Fig. 83.3). The gastroscope is then withdrawn from the patient's mouth, pulling the suture along with it.

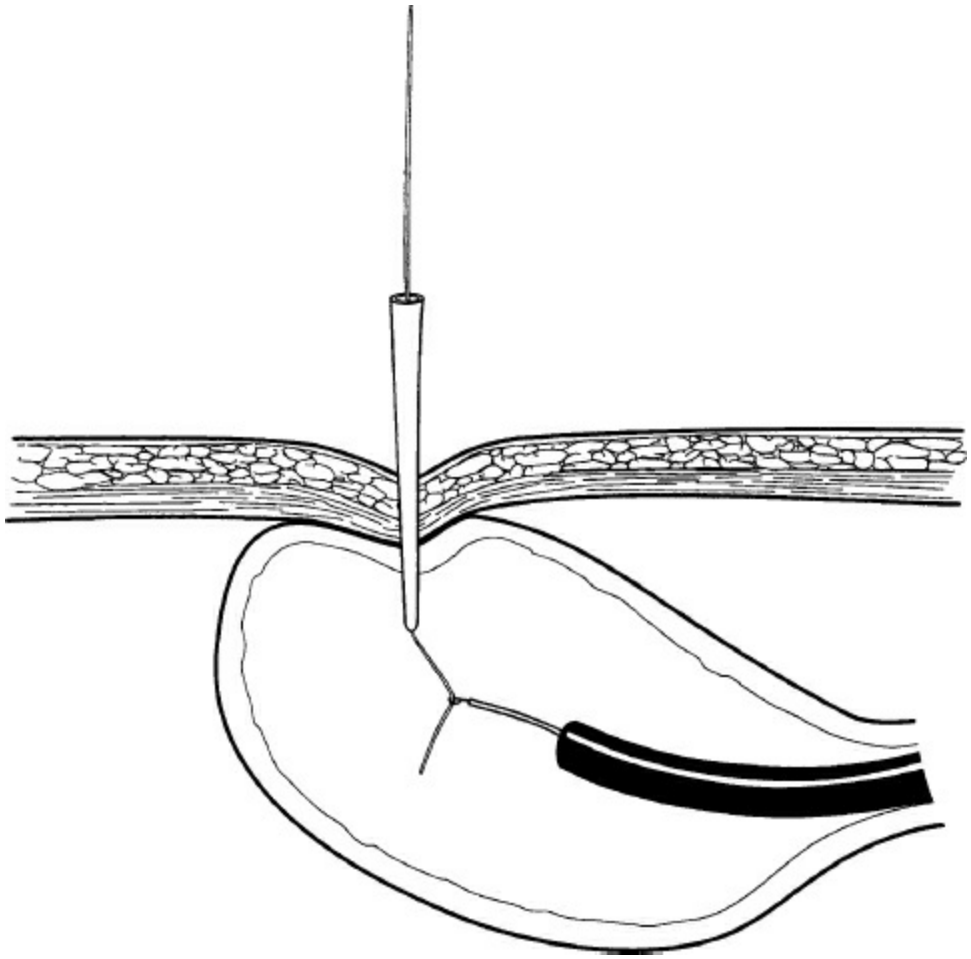

Figure 83.3. Once several centimeters of suture have entered the gastric lumen, the snare is loosened from around the cannula, repositioned on the suture, and once again tightened.

The two most frequently used techniques for PEG are the pull and the push methods. Typically, 20 French PEG tubes are inserted. In the pull method, the gastrostomy tube is affixed to the suture exiting the patient's mouth and pulled down through the esophagus and into the stomach, its end emerging from the abdominal wall (Fig. 83.4). In the push method, a guidewire instead of a suture is used and the tube is threaded over the wire and pushed down the esophagus and into the stomach as tension is applied to both ends of the guidewire (Fig. 83.5). In each method, when the tube emerges from the abdominal wall it is grasped and pulled upward. The gastroscope is reintroduced to monitor the position of the head of the catheter (i.e., the intralumenal bumper) and to ensure that it comes to lie in contact with the gastric mucosa.

The second passage of the instrument can be facilitated by snaring half the head of the gastrostomy catheter and following this down with the endoscope into the esophagus (Fig. 83.6). The head of the catheter should come to lie in loose contact with the gastric mucosa (Fig. 83.7). When the head of the catheter is determined to be in the correct position, pull is discontinued on the tube. An outer bolster is applied to the tube and moved close to the skin (Fig. 83.8). The bolster should not apply pressure to the skin; a distance of 2 or 3 mm from the skin is advisable. Tension is not necessary to hold the stomach in contact with the abdominal wall and, in fact, has been associated with ischemic necrosis of the intervening tissue with subsequent abdominal wall infection, tube extrusion, and, occasionally, separation of the stomach from the abdominal wall. The bolster may be sutured to the abdominal wall, but this is usually not necessary with most traction-removal–type PEG tubes. An occlusive dressing is discouraged because it encourages skin maceration and fungal infection. Preferably, the site should be left open and cleansed with saline or peroxide twice daily. With uncomplicated insertion, feedings, flushes, and medications may be commenced without delay following the procedure.

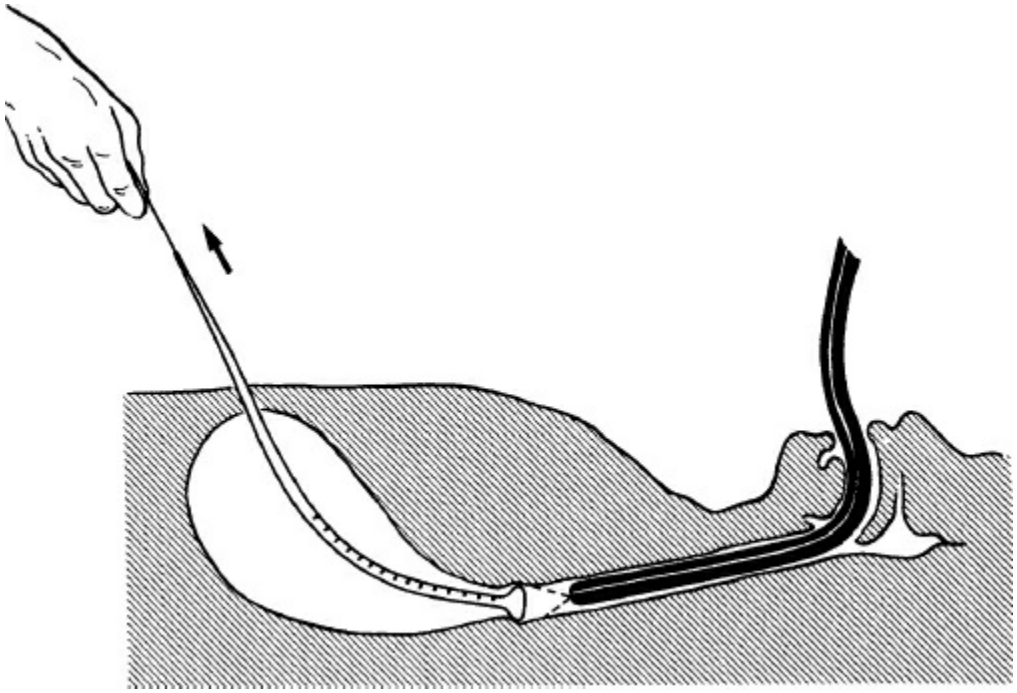

Figure 83.4. The suture is affixed to the end of the gastrostomy catheter, and the catheter is pulled down the esophagus, into the stomach, and out of the abdominal wall. The scope is reintroduced to follow the progress of the tube, and care is taken to avoid undue tension.

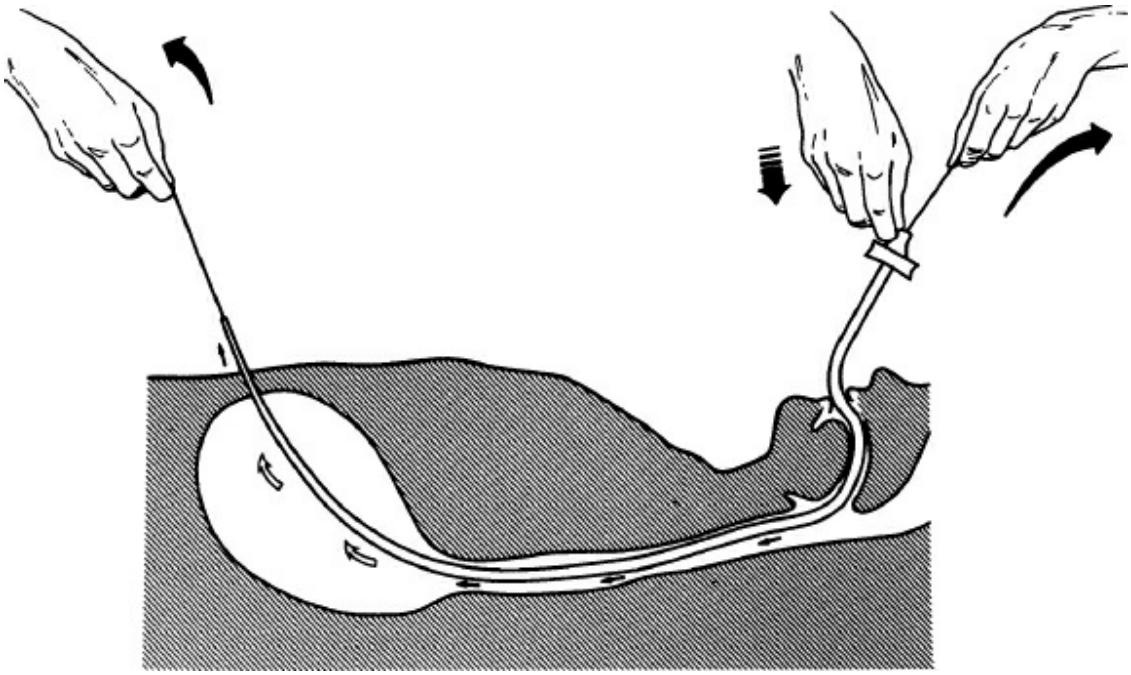

Figure 83.5. In the “push” method, both ends of the guidewire are held taut as the tube is pushed over the wire and out of the abdominal wall.

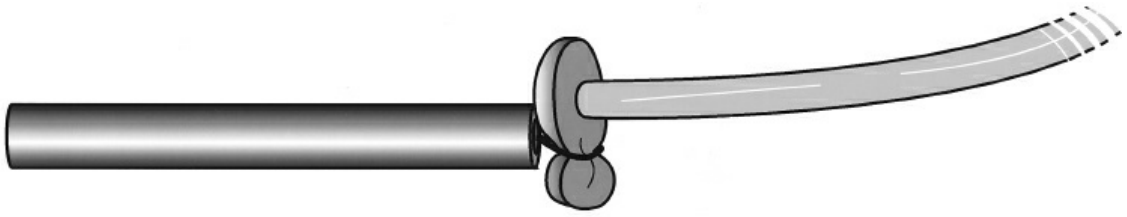

Figure 83.6. The second passage of the instrument can be facilitated by snaring half the head of the gastrostomy catheter and following down with the endoscope into the esophagus. (Image © CCF 2003.)

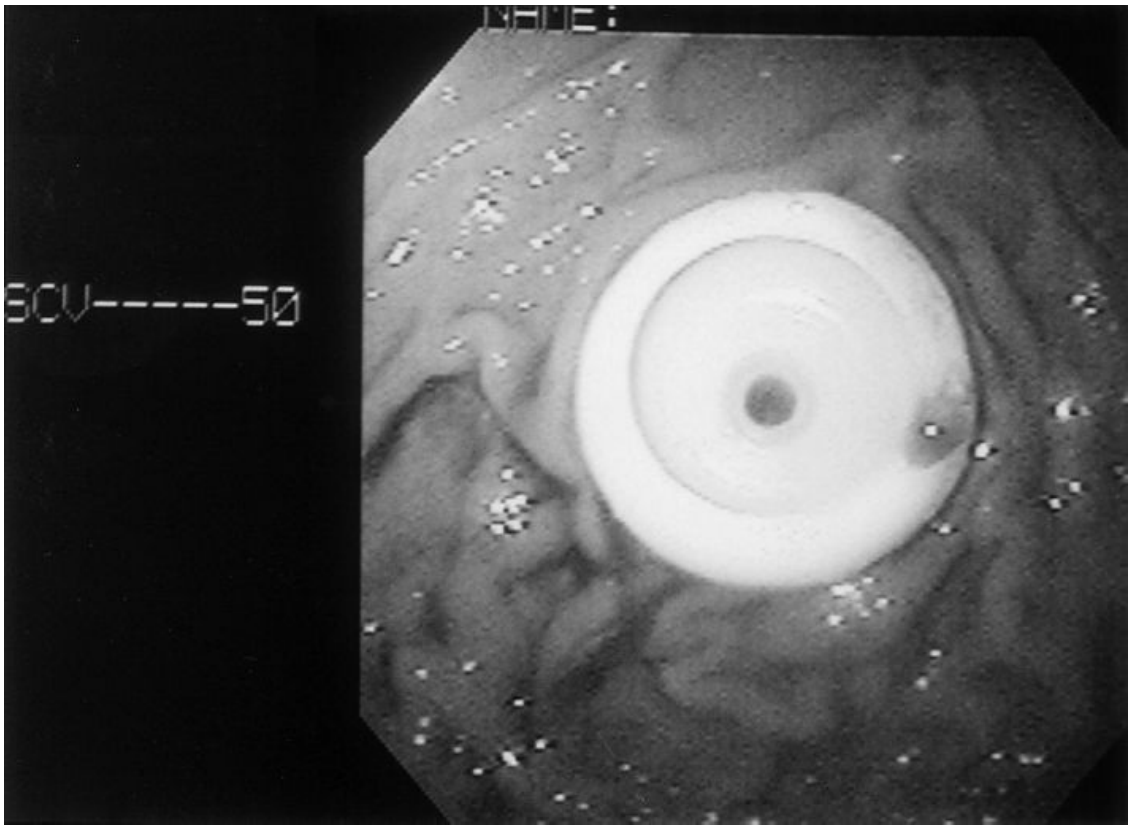

Figure 83.7. The head of the gastrostomy tube should be noted to lie in loose contact with the gastric mucosa.

Alternative methods of PEG placement have been developed for situations where traversal of the oropharyngeal tract by the PEG tube may be inadvisable or impossible. These situations typically include patients with esophageal strictures or oropharyngeal tumors. In general, smaller-caliber (i.e., pediatric) endoscopes are used to traverse the area of difficult

anatomy and the gastric lumen is insufflated and visualized. In the modified Russell technique, T-fasteners are used to appose the gastric wall to the abdominal wall and a peel-away introducer used to introduce the feeding catheter into the stomach. The SLiC method uses a similar principle with a 7- to 8-mm dilating trocar placed directly into the gastric lumen under endoscopic visualization. An obturator is used to place a 20 French Malecot catheter through the sheath of the trocar into the stomach; the sheath is then removed over the catheter.

POTENTIAL COMPLICATIONS

Most of the complications associated with PEG are usually minor, but some may be life-threatening. Immediate postprocedural bleeding can usually be controlled with temporary tube traction placed on the mucosal surface of the stomach. Care must be taken to ensure no undue compression of the gastric and abdominal wall once hemostasis has been achieved. Minor irritation around the tube, wound exudate, and skin irritation can be handled by close attention to cleansing and use of appropriate skin preparations. When fungal infection seems likely, antifungal powders or creams are beneficial. Redness, swelling, tenderness, or fluctuance around the tube should initiate concern regarding the presence of an abdominal wall infection. When this suspicion exists, the area may be aspirated or incised to look for pus. Antibiotics should be administered, and any tension between the outer bolster and the skin should be relieved. When the infection seems to be spreading or the patient deteriorating, one may suspect a necrotizing abdominal wall infection and surgical debridement should be initiated.

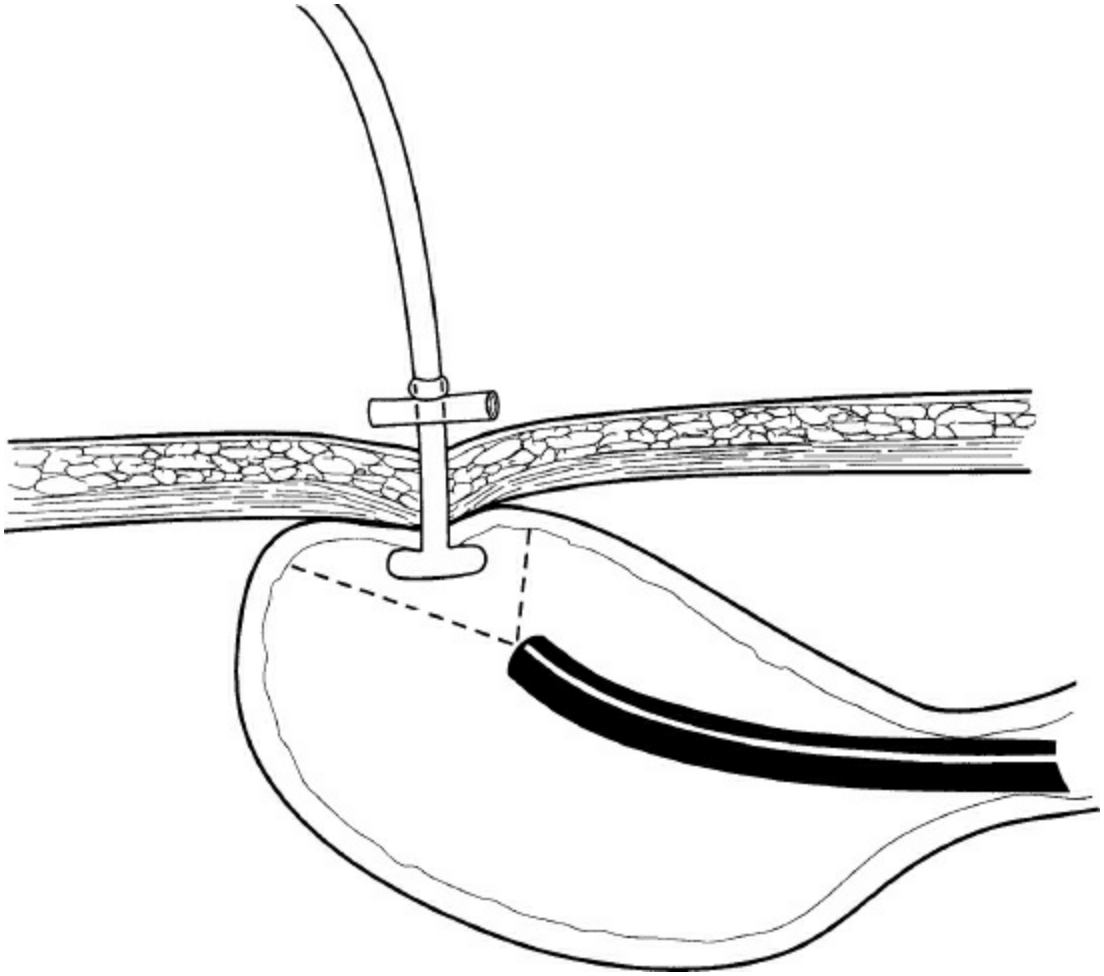

Figure 83.8. An outer bolster is applied to prevent the tube from migrating inward. This should be placed several millimeters from the skin.

Migration of the gastrostomy tube through the abdominal wall has been reported and is almost always secondary to excessive traction with necrosis of the intervening abdominal wall tissue. Again, this can be prevented by avoidance of compression of the abdominal wall and stomach. The type of external bolster is less important than correct placement at the skin level. Our preference is to use a simple linear crossbar-type bolster that affords easy assessment of its position along the tube and distance from the skin. In addition to avoiding unnecessary compression at the time of original insertion, vigilance must be maintained by caregivers in reassessing bolster position on a regular basis to prevent tissue ischemia and resulting necrosis. Conversely, if the outer bolster is placed too far from the skin (i.e., more than several centimeters), the tube may migrate inward, obstructing the pylorus. Should this occur, it is a simple matter to pull the catheter back and place the bolster closer to the

skin.

Gastrocolic fistula has been known to occur following PEG. This can be the result of puncture of the colon at the time of the performance of the procedure or a result of pinching the colon between the stomach and abdominal wall. This problem may appear long after placement of the gastrostomy or at the time of tube replacement. Frequently, the patient will have diarrhea. This should prompt an upper or lower gastrointestinal study using barium. When identified, these fistulae are usually easily managed by simply removing the gastrostomy catheter, with the fistulous tract closing within several days.

Separation of the stomach from the abdominal wall may occur soon after the performance of the PEG. Early after the performance of the procedure, the tube may be inadvertently pulled out by patient or staff. If this is recognized, treatment with nasogastric suction and intravenous antibiotics may be all that is required, with the procedure being repeated in 5 to 7 days. Should the patient show signs of deterioration or sepsis, an immediate laparotomy is indicated. The use of an abdominal binder can help prevent inadvertent early PEG dislodgement. Separation may also be the result of tissue necrosis resulting from excessive tension on the tube. When a patient develops signs of abdominal sepsis following a PEG, it is wise to stop feedings and confirm the intragastric position of the tube with a contrast study. Contrast agent is introduced through the tube and its position in the stomach ensured (Fig. 83.9).

Figure 83.9. Injection of water-soluble contrast following a percutaneous endoscopic gastrostomy tube change demonstrates disruption of the tract and intraperitoneal extravasation.

Figure 83.10. Fluoroscopic observation notes the position of the "enteroscope" deep within the small bowel and helps to localize the site of lumenal access for direct percutaneous endoscopic jejunostomy.

EXPANDED APPLICATIONS OF PEG TECHNIQUE

Since the introduction of PEG two decades ago, it has become apparent that the method provides additional opportunities for gastrointestinal access. These have included establishment of portals for intragastric surgery, creation of a percutaneous cecostomy for colonic decompression, and direct jejunostomy for enteral access in patients who are unable to tolerate gastric feedings. The latter is accomplished by the same method as followed for percutaneous gastrostomy but employs the use of longer "enteroscopes" or small-caliber colonoscopes to permit deep intubation of the small bowel. Smaller-size tubes, 15 or 16 French, are commercially available and are used for this procedure. The "safe tract" technique and

fluoroscopic guidance may facilitate site selection for safe lumenal access (Figs. 83.10 and 83.11).

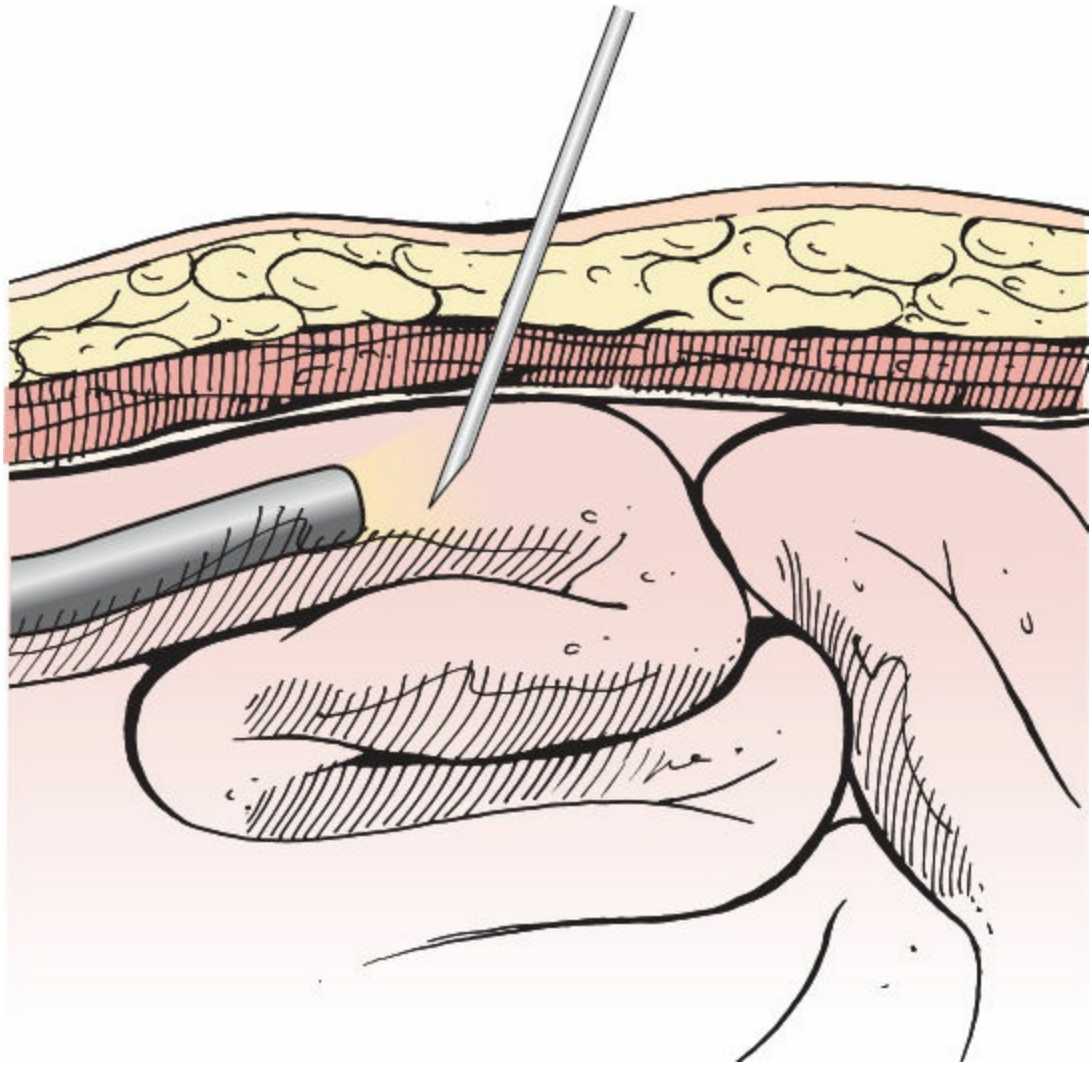

Figure 83.11. The “safe tract” method is also used to help localize the appropriate loop of small intestine for jejunal access.

CONCLUSION

PEG has become the method of choice for the establishment of gastrostomy in appropriately selected patients. Improvements in details of technique, familiarity with the prevention and management of complications, and new developments in tube design have helped improve the safety and expand the applications of the method. Attention to details of the technique and careful patient selection will ensure that the best results are achieved.

EDITOR'S COMMENT

Enteral feeding is the preferred method of delivering nutrition to patients with a functioning gastrointestinal tract. For those patients unable to safely feed themselves, the PEG tube has long been considered an optimal technique for restoring enteral nutrition. Dr. Jeffrey Ponsky developed the technique in 1980 and now shares his pearls of wisdom related to this procedure and technique in

this edition of *Mastery of Surgery*. This is an excellent chapter describing different techniques and considerations in the placement of gastrostomy tubes endoscopically.

Since the introduction of the PEG technique in 1980, the utilization of endoscopically placed gastrostomy tubes for enteral feeding has increased dramatically. A recent review of the Nationwide Inpatient Sample (NIS) examining patients in the United States >65 years of age revealed that from 1993 to 2003, placement of PEG tube increased by 38% in elderly patients. In 1993, the rate was 2.71 procedures during hospitalization per 1,000 people. This rate increased to 3.75 procedures during hospitalization per 1,000 people by 2003. Placement of PEG tube in patients with Alzheimer dementia doubled (5% to 10%) over the study period. In Taiwan, 99% of the entire population in covered by the National Health Insurance (NHI) Program. A review of the NHI database revealed that from 1997 to 2010, the incidence of PEG increased from 0.1 to 3.8/105 population and incidence of PEG among aged patients increased from 0.9 to 19.0/105 population. Cerebrovascular events and esophageal cancer were increasingly common indication for PEG placement. Medical costs, Charlson Comorbidity Index (CCI) scores, and post-PEG mortality rates were higher in the 2005 to 2010 period than in the 1997 to 2004 period. It appears from these data that PEG is being utilized at an increasing rate and in sicker and older patients as well.

A recently published systematic review revealed that in more than 1,000 patients to receive a percutaneous gastrostomy tube, that the 30-day mortality following PEG was 5.5%. This likely relates in part to the health status of patients to receive a PEG, but also speaks to potential morbidity and complications that can be observed in this procedure. Almost every year at a surgical morbidity and mortality conference in my home institution, a significant complication from PEG placement is presented. Ponsky and Poulose emphasize that for any patient with sepsis after PEG, feedings should be stopped immediately and contrast study performed to confirm proper tube placement. When position is in doubt and a patient is ill, diagnostic laparoscopy or laparotomy is usually warranted.

In addition to endoscopic guided placement of a gastrostomy tube, fluoroscopic imaging can be used to guide percutaneous access. The benefit of radiographic guidance includes the ability to avoid the sedation required to perform an endoscopy to place the tube. Aspiration is potential risk of PEG. Radiographic guidance is helpful in patients with head and neck cancers for whom upper endoscopy is difficult or contraindicated. Percutaneous image-guided gastrostomy is most commonly performed transabdominally under fluoroscopic guidance. First, a nasogastric tube is placed to insufflate the stomach, followed by gastropexy under fluoroscopic or ultrasound guidance using one to four “T-fasteners” arranged around the planned gastrostomy site to bring the stomach to the abdominal wall (gastropexy). Using the Seldinger technique, a needle is passed into the stomach followed by a guidewire over

which the tract can be dilated and eventually a gastrostomy tube can be passed. The colon can be opacified with contrast to ensure a radiologic window by administering oral contrast the night before the procedure or a contrast enema. A systematic review and meta-analysis of PEG versus radiographically guided gastrostomy revealed that 30-day mortality was significantly lower in PEG (OR, 0.60; 95% CI, 0.38−0.94; P = 0.026). This is partly related to differences in patient populations offered each technique. Another advantage of transoral PEG compared to transabdominal percutaneous image-guided gastrostomy is the more robust and larger tube that is usually placed. In a transabdominal approach, the catheter must be pushed through the gastric wall. Therefore, despite the use of dilators or peel-away sheaths that help facilitate catheter insertion into the stomach, the diameter of the catheters is generally smaller than PEG tubes. The smaller size, combined with the use of a balloon as an internal bumper instead of the mushroom bumper of pull-type transoral tubes, contributes to the relatively higher occlusion rates, more frequent tube displacements, and less reliable internal fixation of the image guided percutaneous tubes. For these reasons, while percutaneous image-guided gastrostomy holds some advantages over PEG, it is generally not employed as a routine first-line alternative to PEG.

When a PEG or percutaneous image-guided gastrostomy is impossible, difficult, or inadvisable for various reasons (obesity, previous gastric bypass, failed attempts to place due to interposed intra-abdominal organs between stomach and abdominal wall), a surgeon is well advised to have a variety of additional options at his/her disposal. For many of these challenging situations, laparoscopic-assisted PEG is an alternative. Laparoscopic-assisted PEG combines the advantages of PEG with direct intraperitoneal visualization, helping ensure a safe tube placement tract free of intervening organs or structures. In uncomplicated cases, laparoscopic-assisted PEG can be performed with two or even one 5-mm trocar and does not require an advanced laparoscopic skill set. In patients undergoing laparoscopic surgery for another indication (laparoscopic paraesophageal hernia repair for example), laparoscopic-assisted PEG is a simple way to achieve enteral access. Some surgeons advocate for the placement of a laparoscopic-assisted PEG at the time of paraesophageal hernia repair in the case of large and complex hernias and in elderly frail patients as a mechanism for reducing the stomach and any associated gastric volvulus or obstruction. Laparoscopic and open gastrostomy tube placement are useful techniques in cases where endoscopic gastrostomy tube placement is impossible or contraindicated (as in the case of a postgastric bypass patient who requires enteral access in the remnant stomach). The laparoscopic gastrostomy tube placement technique does require a more advanced skill set than laparoscopic-assisted PEG as gastropexy is typically needed to fix the stomach to the posterior abdominal wall.

In patients who cannot tolerate gastric feedings or in whom gastric feedings are contraindicated, percutaneous endoscopic gastrostomy with jejunal

extension (PEG-J) is an endoscopic technique that may prove useful. Patients with severe GERD and aspiration, gastroparesis necessitating a venting gastrostomy and access to the jejunum for enteral nutrition and some patients with refractory symptoms due to chronic pancreatitis may benefit from PEG-J. The technique of PEG-J involves an initial placement of a PEG tube using the same techniques described in this chapter. If feasible in PEG-J, a location on the distal gastric body is ideal in PEG-J to minimize the opportunity for the jejunal extension to coil in the stomach. Once the PEG is in place, a guidewire is placed through the gastric tube and grasped endoscopically. The guidewire is then advanced to the jejunum (15 to 20 cm distal to the ligament of Treitz) under endoscopic and fluoroscopic guidance. The guidewire is released and a 12Fr, 60- or 90-cm jejunal tube is then threaded over the guidewire into the jejunum under fluoroscopic guidance. A recently published series of 102 PEG-J tubes demonstrated an overall technical success rate of 97%. During a median follow-up period of 22 months (1 to 46 months, $n = 90$), at least one tube malfunction occurred in 52/90 (58%; 177 episodes) after a median of 53 days (3 to 350 days), requiring a median of two tube replacements. Short-term (<30 days) tube malfunction occurred in 28/90 (31%) and delayed in 24/90 (27%); these included dislodgement (29%), clogging (26%), and kinking (14%). The PEG-J is a useful technique for dual enteral access to the stomach and jejunum, but requires an advanced endoscopic skill set and can be somewhat labor intensive to maintain as described.

General surgeons are often called upon to establish enteral access in patients requiring both temporary and long-term access. Given the aging population and complex postsurgical anatomy that these patients can present with, familiarity with a variety of techniques including and related to the PEG can be extremely useful.

Jon C. Gould

Dr. Gould has discussed an entrance to the GI tract which is somewhat different that the feeding tube that I am accustomed to. A tube may be utilized as the author states but most of the time I use tube feedings rather than TPN when I can. I find myself using percutaneous latex tubes often. I am accustomed to open gastrostomy or jejunostomy. There are many approaches but the key for all is a careful and safe "permanent" access. Secure sutures so tube does not slip or leak.

84 Distal Gastrectomy With Billroth I or Billroth II Reconstruction

Rudolf Bumm and J. Rüdiger Siewert

Partial gastrectomies consist of the removal of the distal portion of the stomach. According to the type of disease (ulcer or carcinoma) and the location of the basic disease (duodenal ulcer, gastric ulcer, high-gastric ulcer), they are performed as antral, two-thirds, four-fifths, or high subtotal gastrectomy. *Distal partial gastrectomy* is named according to the type of anastomosis between the small intestine and the gastric remnant, regardless of the extent of the gastrectomy.

The Billroth I (BI) operation is a gastroduodenostomy that can be performed end-to-end or end-to-side. In the Billroth II (BII) reconstruction the gastrojejunostomy is performed end-to-side. As an alternative, Roux-Y (RY) reconstructions can be done (see Chapter 82). A decisive difference between the BI and BII procedure is that in BI reconstruction the duodenal passage remains intact. Because of anastomotic requirements, the BI operation is, as a rule, performed as an antrectomy. Gastroduodenostomy is difficult or impossible after more extended gastrectomies, because direct anastomoses between gastric fundus and duodenum may not be free of tension and followed by postoperative complications. Therefore, for the more extended partial gastrectomy, a BII or RY reconstruction should be favored. Furthermore, it is an interesting but unexplained clinical impression that mobility of the duodenum seems to be better in women and one can do a BI with greater resections than with males.

HISTORICAL NOTE

Pean and Rydigier attempted partial gastrectomies in 1879 and 1880, respectively, with neither of their patients surviving. Theodor Billroth performed the first successful partial gastrectomy on a patient who had antral carcinoma in 1881. He reconstructed the gastrointestinal passage by a superior end-to-end gastroduodenostomy with the duodenum anastomosed to the lesser curvature side of the stomach (Fig. 84.1A).

Billroth later changed his surgical technique by effecting the anastomosis to the greater curvature (Fig. 84.1B). The reconstruction of the gastroduodenal passage in the BI operation has undergone numerous modifications. The end-to-end anastomosis (EEA) was performed as a posterior or anterior gastroduodenostomy, or the duodenal end was connected to the entire circumference of the cut edge of the stomach (Fig. 84.1C–E). End-to-side gastroduodenostomy was performed by anastomosing the stomach to the side of the duodenum opposite the major duodenal papilla or entirely below the level of the papilla (Fig. 84.1F,G). Further modifications are the tube-shaped resection for ulcers high on the stomach and subsequent reanastomosis of the duodenum to the greater curvature side of the stomach (Fig. 84.1H), and antrectomy performed in combination with gastric vagotomy and followed by an EEA (Fig. 84.2).

The technique most frequently used today is the Schoemaker modification of the BI operation, with partial closure of the stomach remnant along the lesser curvature and an inferior gastroduodenostomy.

ARGUMENTS IN FAVOR OF BI GASTRECTOMY

A leading argument in favor of BI anastomosis as compared with other forms of gastrectomy (e.g., BII) is the preservation of the duodenal passage. The question arises as to whether the important functions of the duodenum are dependent on the presence (or absence) of the food passage.

Acids are neutralized in the duodenum by pancreatic and duodenal bicarbonate through neural and hormonal regulation. After distal stomach resection, this regulation is disturbed regardless of the type of anastomosis. Proportioned, regulated stomach emptying is no longer possible because the antrum and pylorus are gone, and the value of providing a duodenal passage cannot be properly assessed because rapid and uncoordinated emptying of the stomach precludes the function of the digestive process that normally takes place in the duodenum. However, the benefit of the duodenal passage is clearer with regard to the function of the pancreas, the changes in the stomach remnant, and the function of the cardia.

The duodenal brake, a mechanism for shutting off acid, does not operate even if food passes the duodenum because of the denervation of transection. However, release of hormones in the duodenum does not necessarily require innervation. Better absorption of calcium and iron in the duodenum are proven advantages of the BI hookup.

Figure 84.1. A–I: Modifications of the BI resection from a historical point of view.

Experimental and clinical investigations indicate undisturbed pancreatic function, even after gastrectomy, but altered pancreatic function is apparent after gastrojejunostomy (BII). Fat loss in the feces is considerably greater after BII resection than after gastroduodenostomy. This loss may indicate insufficient digestion of food by pancreatic enzymes.

In a recent randomized comparison between patients after BI and RY reconstructions, endoscopic examination revealed that the frequency of bile reflux and degree of inflammation in the remnant stomach were less in the RY group than in the BI group, which is most likely due to the absence of pylorus in the RY group. However, RY reconstructions did not prevent esophagitis and were associated with more initial stasis complications.

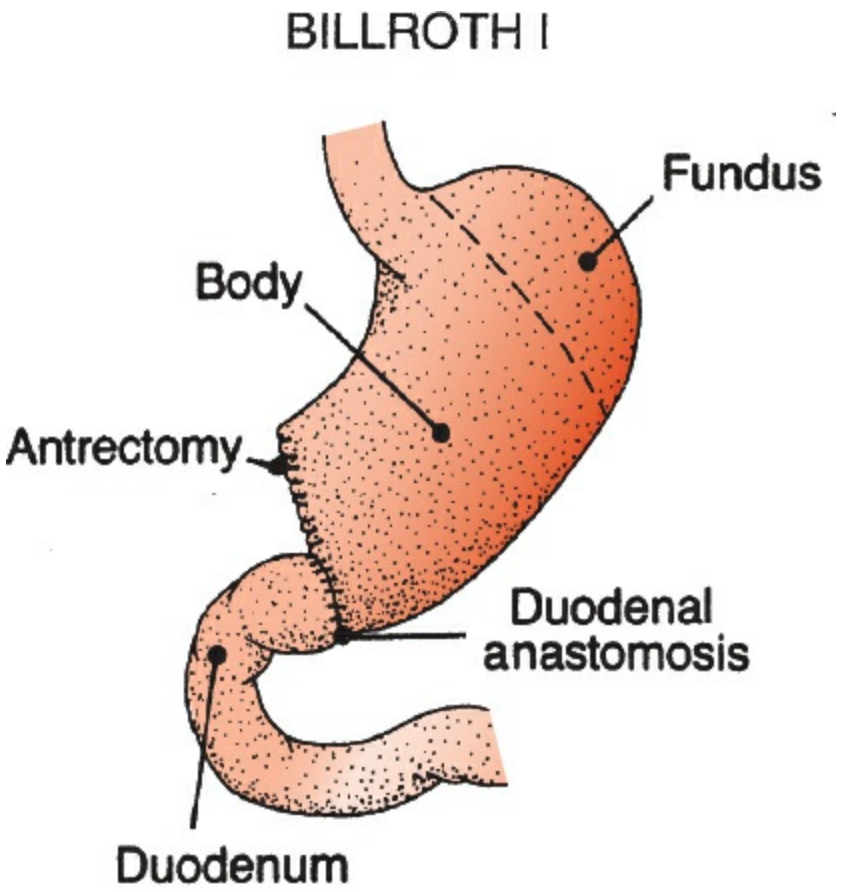

Figure 84.2. Billroth I gastrectomy. (From Diepenbrock NH. Quick Reference to Critical Care, 4th Edition (2012); Wolters Kluwer Health | Lippincott Williams & Wilkins.

Even histologic changes of the stomach mucosa characteristic of chronic atrophic gastritis seem to be present to a lesser degree after a BI resection than after BII. The same is true for the frequency of carcinoma of the stomach remnant.

Cardiac function tests demonstrate similar lower esophageal sphincter pressures in reaction to a test meal before and after gastroduodenostomy. After BII resection, the tonicity of the lower esophageal sphincter decreases, but this functional disturbance of the cardia is rarely of clinical relevance.

ARGUMENTS IN FAVOR OF BII GASTRECTOMY OR RY RECONSTRUCTION

The main argument in favor of BII reconstructions is that a larger portion of the stomach can be resected and lymphadenectomy is easier. In all cases in which a BI reconstruction could only be accomplished with tension, one should choose BII. In some cases a BII reconstruction results in early dumping symptoms (see following discussion). Those patients should undergo, if conservative treatment fails, relaparotomy and reconstruction according to RY. The RY offers a better control to avoid enterogastric reflux into the gastric remnant and is the method of choice when early dumping or reflux problems occur.

INDICATIONS OF PARTIAL GASTRECTOMY

Gastric Ulcer

The main indication for partial gastric resections is gastric ulcer, and this is usually a recurrent ulcer after adequate antisecretory treatment and eradication of *Helicobacter pylori.* Partial gastrectomy is the method of choice because

1. the gastric ulcer is removed in toto during distal resection and can be examined histologically,
2. the point of least resistance on the antrum–corpus border of the lesser curvature is eliminated,
3. the number of chief cells is reduced by removal of a part of the fundus,
4. the antrum as the point for the formation of gastrin is eliminated,
5. the remainder of the stomach is partly vagotomized by dissection of the lesser curvature above the resection border and the standard reconstruction for partial gastrectomy in gastric ulcer patients is BI.

Prepyloric Ulcer

Prepyloric ulcers represent a good indication for partial gastric resections. Because of its secretory behavior, this ulcer type was, as far as the surgical and therapeutic consequences were concerned, previously included with duodenal ulcers and historically represented an indication for vagotomy only. However, results after 5 years of using this procedure showed relatively high recurrence rates; therefore, it can be concluded that prepyloric ulcers would be better regarded as gastric ulcers as far as surgical treatment is concerned. Partial gastric resections for prepyloric ulcers should, in our view, be combined with selective gastric vagotomy.

Complicated Ulcers

Although elective ulcer surgery has strongly decreased in the decade of potent antisecretory drugs, the frequency of operations for complicated ulcers has remained relatively stable.

The classic indications for partial gastric resections in ulcer surgery are perforation, bleeding, obstruction, and intractability. In addition, gastric "ulcers" may mask or be at risk for the development of gastric adenocarcinoma. Therefore, all gastric ulcers must be biopsied and followed until healing. Giant gastric ulcers (>3 cm) have a 30% incidence of harboring a cancer.

Early Carcinoma and Carcinoma of the Antrum

Partial gastric resections cannot be recommended as a standard treatment of locally advanced gastric cancer because a total gastrectomy with adequate lymphadenectomy is the method of choice. As an exception, in our institution patients with well-differentiated and early (T1/T2 N0) gastric adenocarcinomas undergo *subtotal gastric resection*, in which four-fifths of the stomach is resected with a standard D2 lymphadenectomy, and a BII or RY reconstruction is done. In the Far East, mucosal cancers of the antrum are common and more frequently resected by partial gastrectomy and BI reconstruction. Sentinel lymph node dissection after distal gastrectomy for early gastric cancer has been evaluated with conflicting short-term and open long-term results. Therefore, the general use of this technique for discriminating between partial or total gastrectomy for early gastric cancer cannot yet be recommended.

SURGICAL TECHNIQUE: BI GASTRECTOMY

Gastroduodenostomy with Anastomosis to the Side of the Greater Curvature of the Stomach

As a rule, midline epigastric incision is the best approach (Fig. 84.2). Alternatively, a transverse epigastric rectus muscle-cutting incision or an upper vertical muscle-splitting incision to the right can be made.

The dissection of the stomach begins at the middle of the greater curvature by incision of the gastrocolic ligament. Thus, the omental bursa is opened. The dissection for gastric ulcers can be done between the gastroepiploic vessels and the gastric wall. In carcinoma, the greater omentum corresponding to the extent of the resection of the greater curvature must be removed at the same time. When the omental bursa has been opened, the flimsy part of the gastrohepatic omentum may be pierced by the finger, and a soft rubber Penrose drain can be placed around the stomach. The dissection is then continued step-by-step along the greater curvature toward the duodenum. Near the pylorus, the greater curvature of the omentum becomes thick and divides into a front and back layer. The dissection should be continued bluntly in the loose intermediate tissue in the direction of the duodenum; the layers of tissue carrying the vessels should then be ligated individually.

The preparation of the duodenum begins above or just below the second portion of the duodenum from a lateral direction, the so-called Kocher maneuver. The peritoneal reflection is sharply cut along the lateral duodenal wall between the second portion of the duodenum and the beginning of the hepatoduodenal ligament. By putting traction on the second portion of the duodenum medially, the retroperitoneal tissue is loosened (part bluntly, part sharply) until the duodenum is mobilized. In this way, a good general exposure can be achieved; this important maneuver facilitates the subsequent gastroduodenostomy. The preparation of the free first part of the duodenum is then continued.

By stretching the stomach, the dissection proceeds along the greater curvature toward the left medial duodenal wall, then toward the back wall, and finally toward the lateral duodenal wall as far as the beginning of the hepatoduodenal ligament. In this way, 3 to 5 cm of the back wall of the duodenum can be exposed, usually without technical difficulty. The transition from the free first part of the duodenum to the part fixed dorsally on the pancreas can be recognized from the course of the gastroduodenal

artery (Fig. 84.3). At this point, the serosa reaches from the duodenum to the head of the pancreas. The surgeon must be especially careful here because the artery is important for the blood supply to the duodenum and the pancreas.

After mobilization of the duodenum, the dissection is continued along the lesser curvature of the stomach. The right gastric artery is divided between clamps and ligated (Fig. 84.4). Difficulties may arise as a result of penetration of a gastric ulcer. Frequently, a penetrating gastric ulcer can be pinched free of underlying tissue by finger pressure.

We recommend addition of a selective vagotomy of the gastric remnant only for benign ulcer surgery in which gastric hypersecretion is assumed as one of the main pathogenetic factors, that is, in cases with multiple ulcers or prepyloric ulcers. In these rare cases we carefully divide the vagal branches of the anterior and posterior vagus that lead to the gastric remnant and leave the hepatic vagal branches intact.

In every case, the dissection must leave an adequate portion of intact stomach wall for subsequent anastomosis with the duodenum. According to the localization of the ulcer, the dissection of the stomach along the lesser curvature can be continued to the proximal resection line. The layers of the gastrohepatic omentum rest at varying intervals on the front or back wall of the stomach. These layers encompass a tissue rich in fat within which the branches of the left gastric artery and vagal branches are found. The dissection proceeds by bluntly forcing the intermediate tissue apart and individually severing the front and back layer of the gastrohepatic omentum. As long as the ascending trunk of the left gastric artery is not directly involved, it should remain intact during the resection.

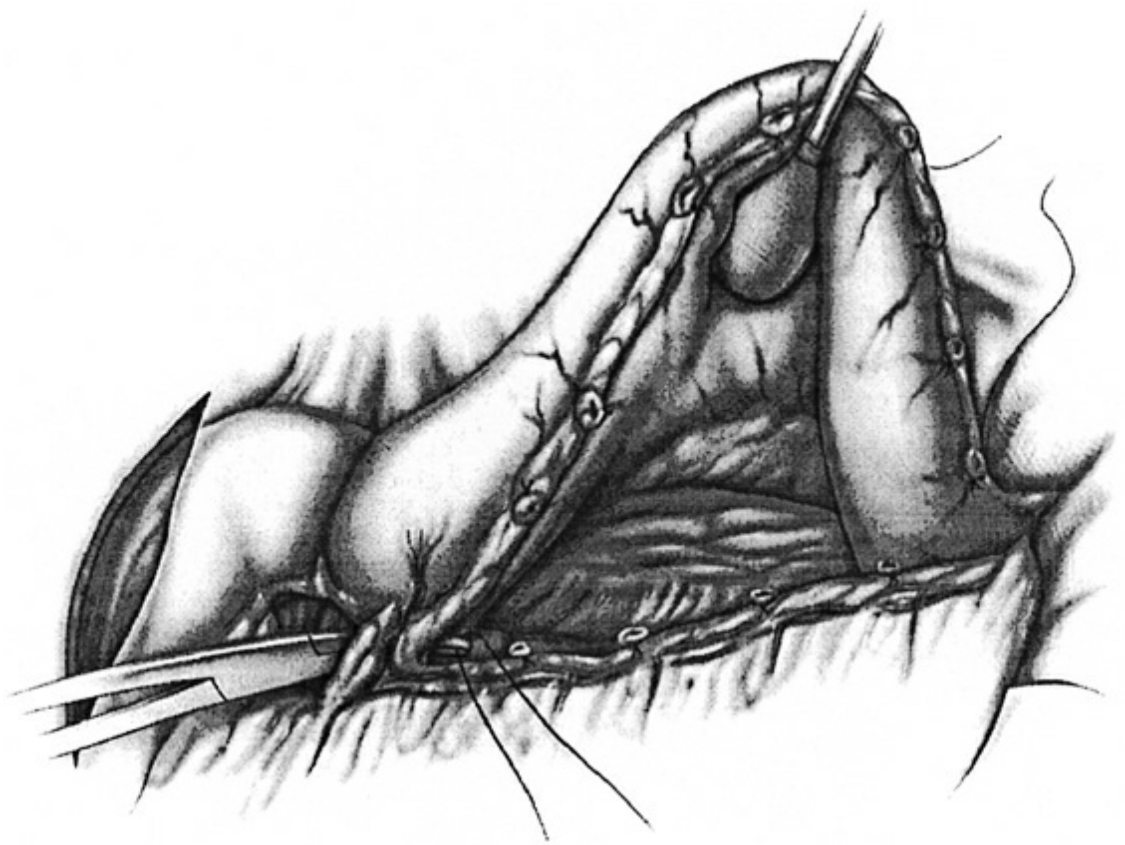

Figure 84.3. Dissection of the greater curvature and ligation of the gastroepiploic artery. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

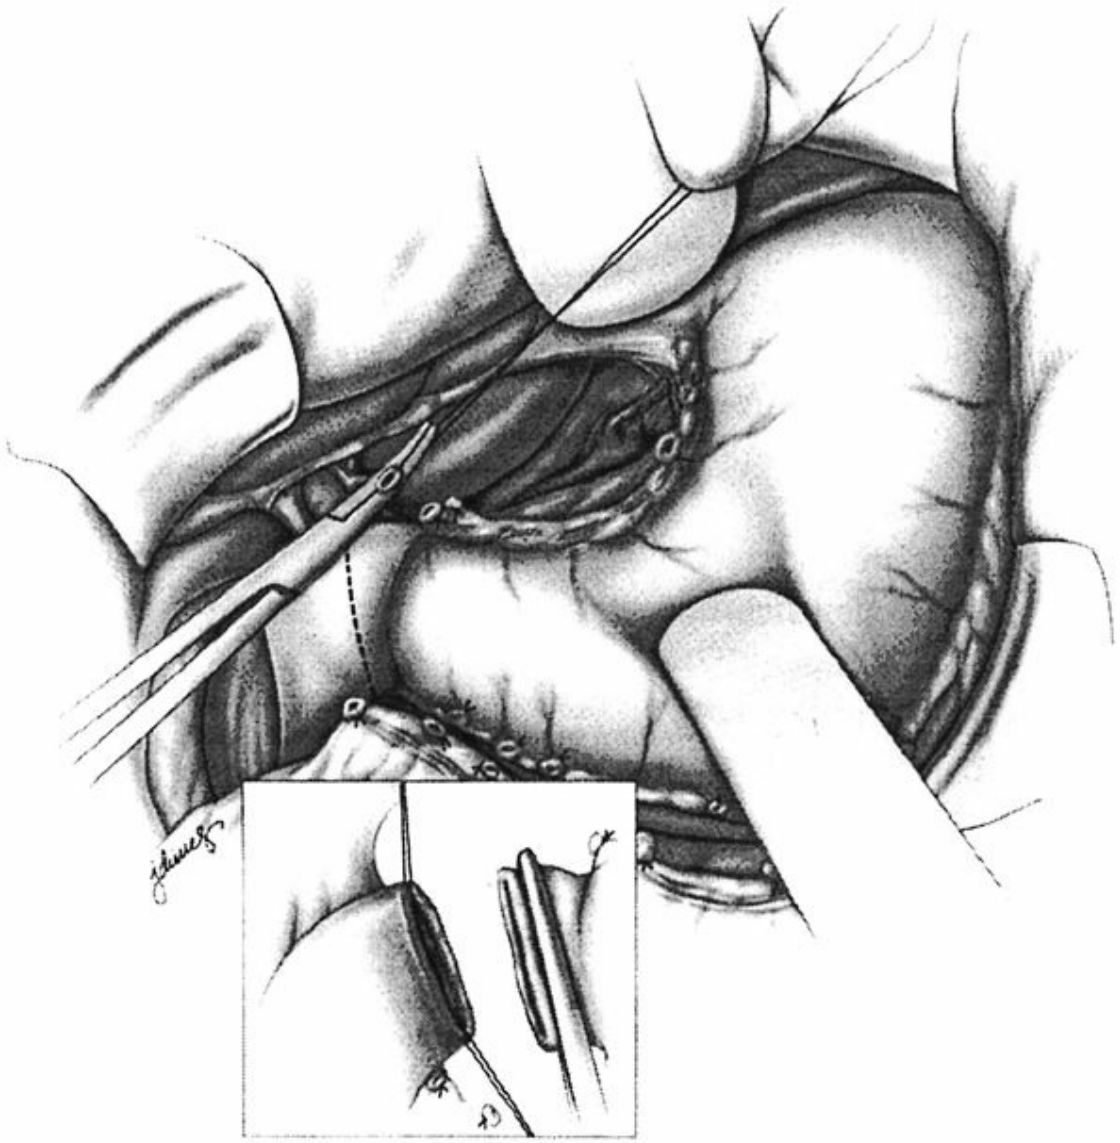

Figure 84.4. Dissection of the lesser curvature and ligation of the right gastric artery. The duodenum is transected below the proximal clamp (*inset*). (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

The actual resection starts with the cutting of the duodenum between holding or guy sutures. The duodenum is temporarily closed with a sponge; the resection borders of the stomach are then determined.

A sewing instrument (e.g., stapler, TA-90 (Covidien) or TL90 (Ethicon)) facilitates the final step of stomach removal. The incision follows at an angle of 45 degrees to the lesser curvature (Fig. 84.2). The staple line can, but need not, be oversewn (Fig. 84.5). After removal of the

distal portion of the stomach, a clamp is fitted at right angles to the greater curvature. The clamp is thus pushed far enough orally for the removal level to correspond in size to the duodenal lumen. The remaining aboral end is cut off after stay sutures are placed at each cut edge (Fig. 84.5). It is recommended that the so-called von Haberer submucosal sutures (4-0 polyglycolic acid) be used in the front and back walls to achieve hemostasis. The anastomosis should be performed without clamps.

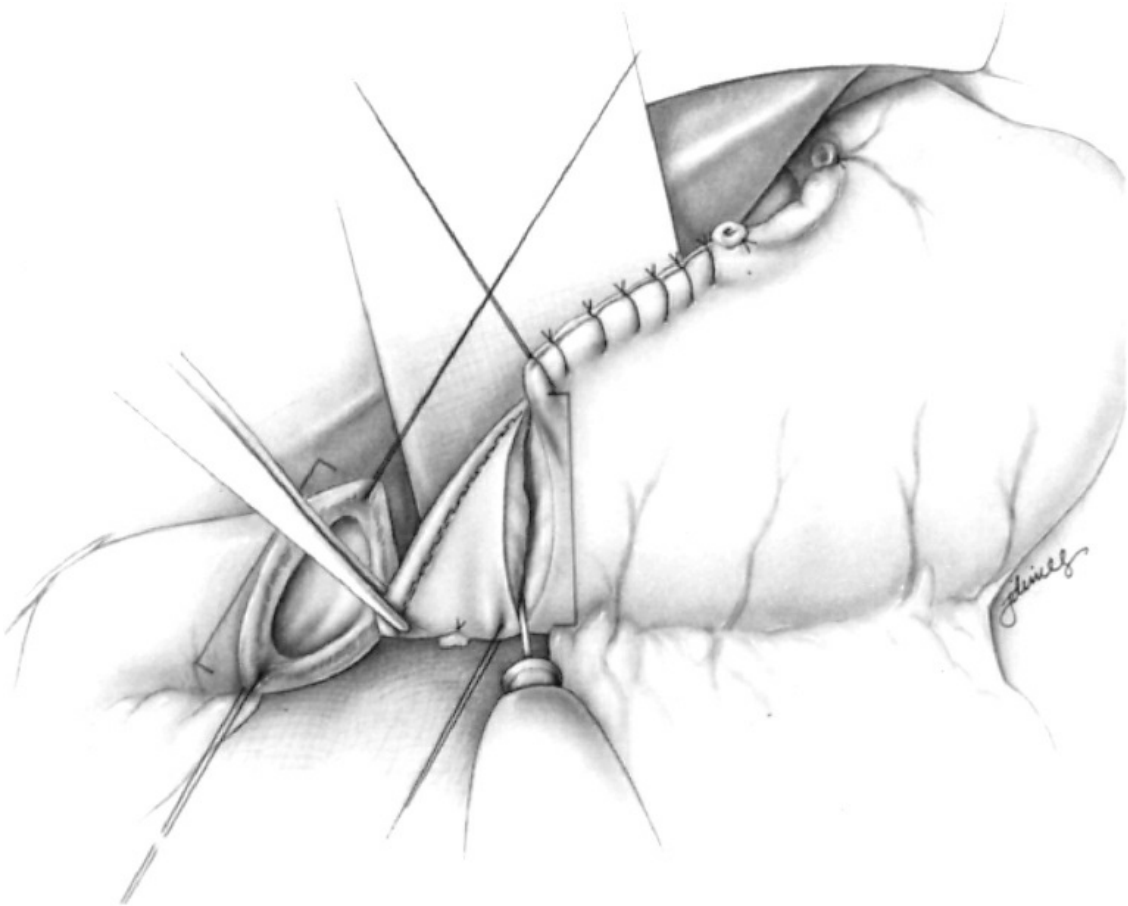

Figure 84.5. Distal gastric resection. After removal of the distal stomach and the distal end of the greater curvature, the two cut surfaces are placed adjacent to each other. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

The end-to-end gastroduodenostomy is accomplished by anastomosing the duodenum to the end of the greater curvature. For this purpose, the two cut surfaces are placed adjacent to each other and two corner stitches are placed, starting at the stomach through the seromuscular layers with

tangential grasping of the mucosa. At the duodenum, this stitch is done from inside to outside. The corner suture at the lesser curvature is tied, whereas the suture on the opposite side is left open (Fig. 84.6). The back wall is reconstructed by interrupted back stitches (3-0 polyglycolic acid). These stitches start through all layers of the back wall at the cut edge of the lesser curvature from inside to outside and go through all layers of the posterior wall of the duodenum from outside to inside. The suture is led back grasping only the mucosa, first of the duodenum and then of the stomach (Fig. 84.7). Knotting these sutures leads to an exact coaptation, especially at the level of the mucosa (Fig. 84.7, inset). The front wall is best closed with one row of interrupted sutures through all layers with tangential stitches of the mucosa with the same technique as the corner stitches (Fig. 84.8). Special attention must be paid to the so-called Jammerecke (angle of sorrow) on the lesser curvature (Fig. 84.9). It is advisable to use the triple seromuscular structure, which includes the duodenal walls as well as the front and back wall of the stomach. Another alternative is shown in Figure 84.10.

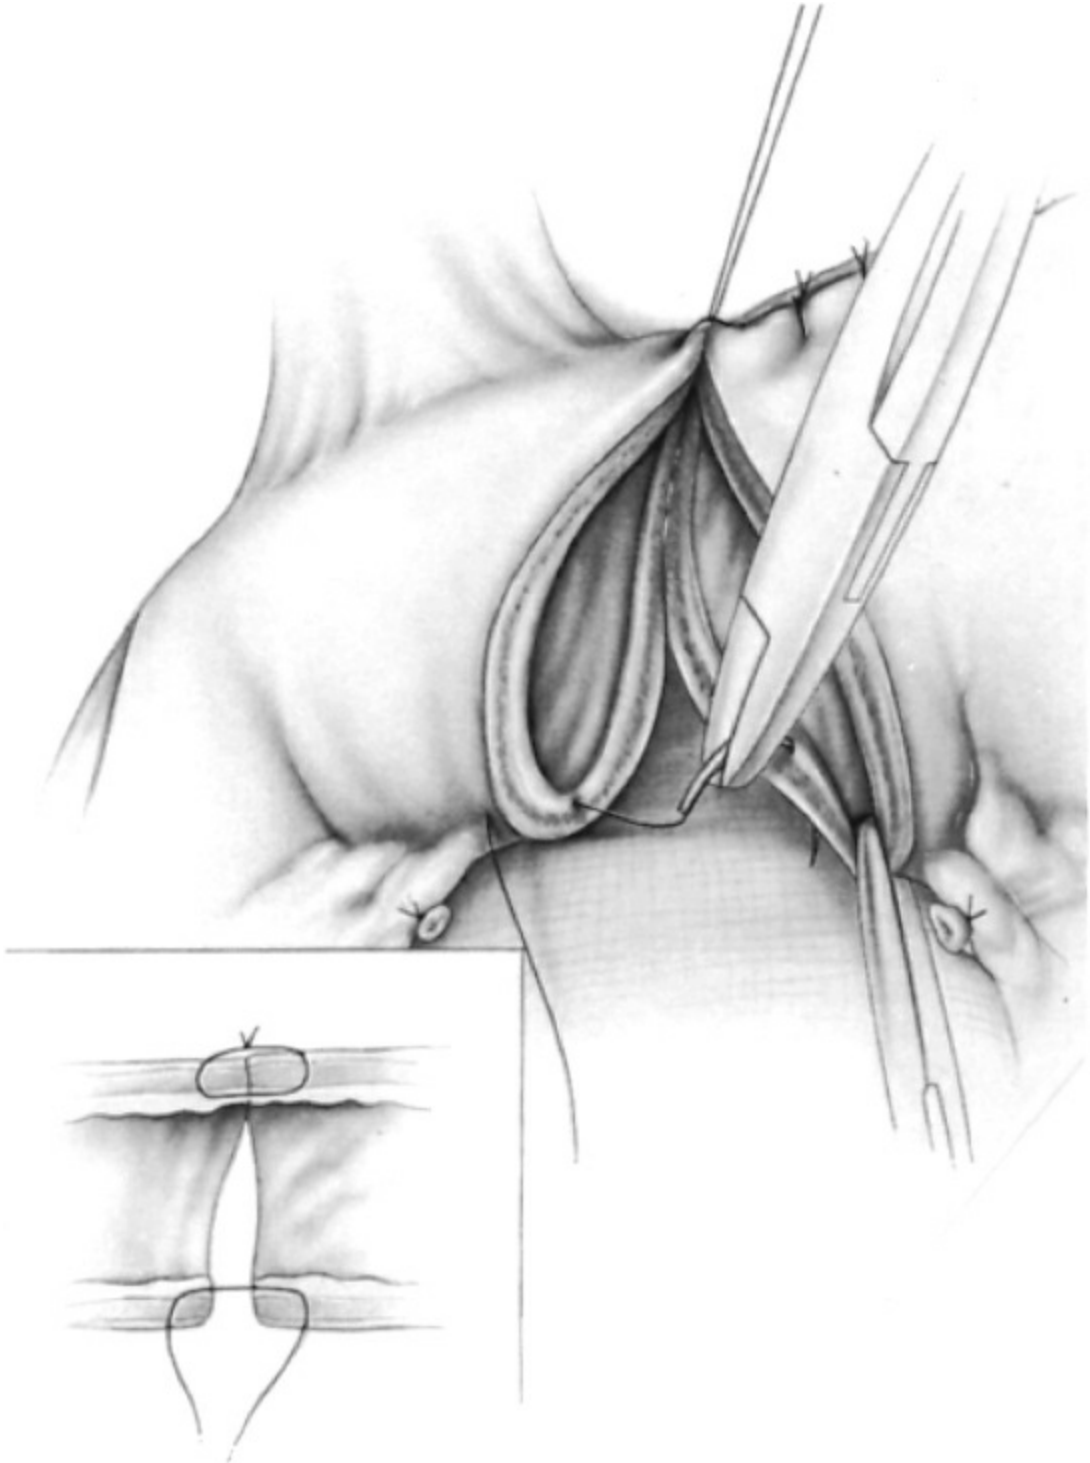

Figure 84.6. Gastroduodenostomy with duodenum connected to the stomach on the side of the greater curvature. Corner sutures are seromuscular stitches that grasp the mucosa tangentially. The suture is tied on the lesser curvature side and left open on the opposite side (*inset*). (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

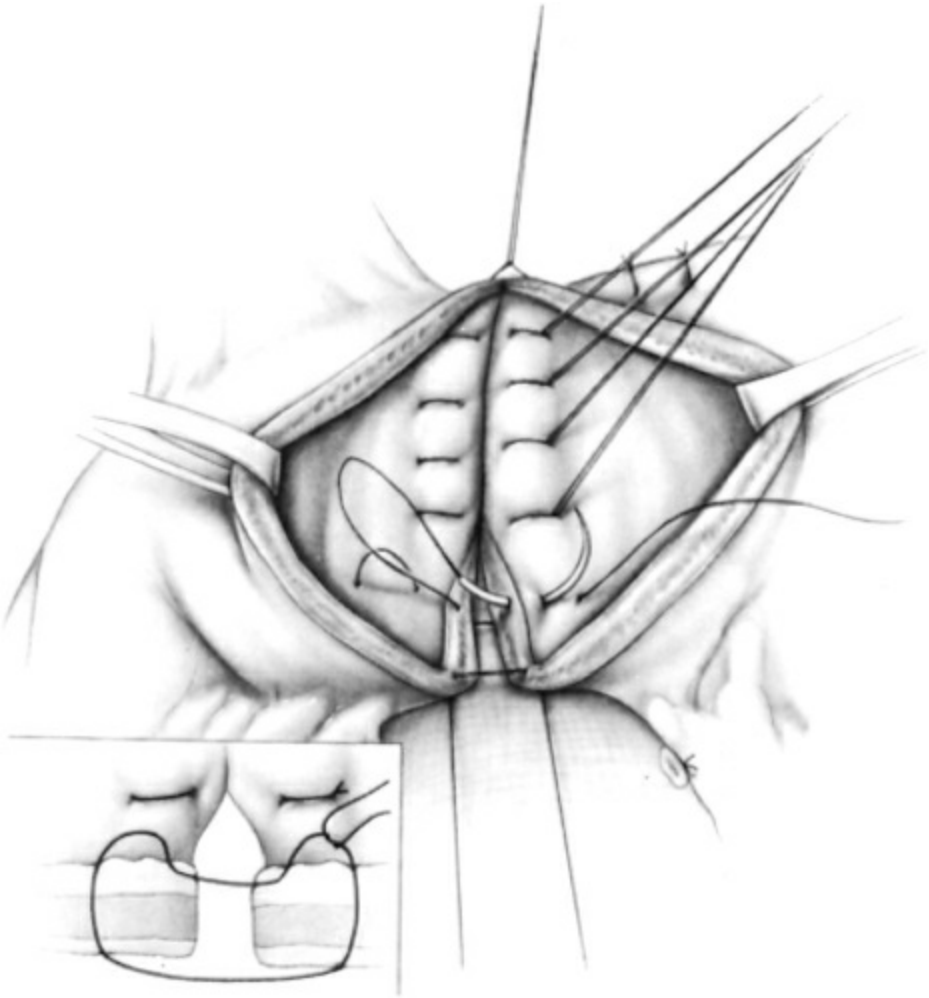

Figure 84.7. Suture technique of the back wall. Interrupted sutures in the so-called back-stitch technique, first through all layers of the stomach, duodenum, and back, grasping only the mucosal edges. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

Finally, the anastomosis is checked for patency with the thumb and index finger. The position of the stomach tube is also checked to ensure it crosses the anastomosis. A double-lumen gastric tube is placed across the anastomosis for 2 to 3 days, allowing early enteral nutrition via the distal lumen. We do not routinely perform intraoperative leakage tests.

Alternative Method: End-to-Side Gastroduodenostomy

In difficult duodenal ulcers, it can be impossible to preserve enough duodenal wall to be able to construct a tension-free anastomosis. In this

situation, it is safer to close the duodenum with a row of TA-55 or TL60 staples. The reconstruction of the intestinal passage can then proceed by end-to-side anastomosis (Fig. 84.11). For this purpose, the stomach is removed as previously described; the dissected stomach lumen is then anastomosed onto the front wall of the duodenum. Usually, an oblique incision should be made on the duodenal front wall so that the incision level starts from oral–medial and goes to aboral–lateral. The suturing technique is the same as for the end-to-side anastomosis. In technically difficult duodenal stump closures, additional coverage of the stump with the back wall of the stomach can be obtained.

Anastomosis Using the Stapler Technique

Performing a stapler anastomosis in BI gastrectomies is usually not necessary in open surgery. This is mainly because of the high cost of the device compared with sutures. Furthermore, there are no differences of anastomotic insufficiency rates between handsewn and stapled BI anastomoses. For completeness, the stapler procedure is described here.

The preparation of the stomach and duodenum proceeds as described previously. After the duodenum is cut, a circular purse-string suture is performed at the edge of the opening. The removable anvil of the EEA (Covidien) or EDH (Ethicon) stapler (size 28 or 31) is introduced in the duodenum, and the purse-string suture is tied around the center rod of the anvil. The circular stapler is then introduced into the stomach and, at the posterior wall of the stomach, the sharp tip of the center rod of the stapler is pushed through the gastric wall. After removal of the tip, the center rod is connected with the anvil and the stapler is closed. After firing of the instrument, the stapler is removed, and the excised circular tissue doughnuts of duodenum and stomach are inspected for completeness. The stomach resection is performed aborally to the anastomosis after closure of the proximal stomach with linear staples. The cut surface of the stomach can be oversewn, but this is not mandatory.

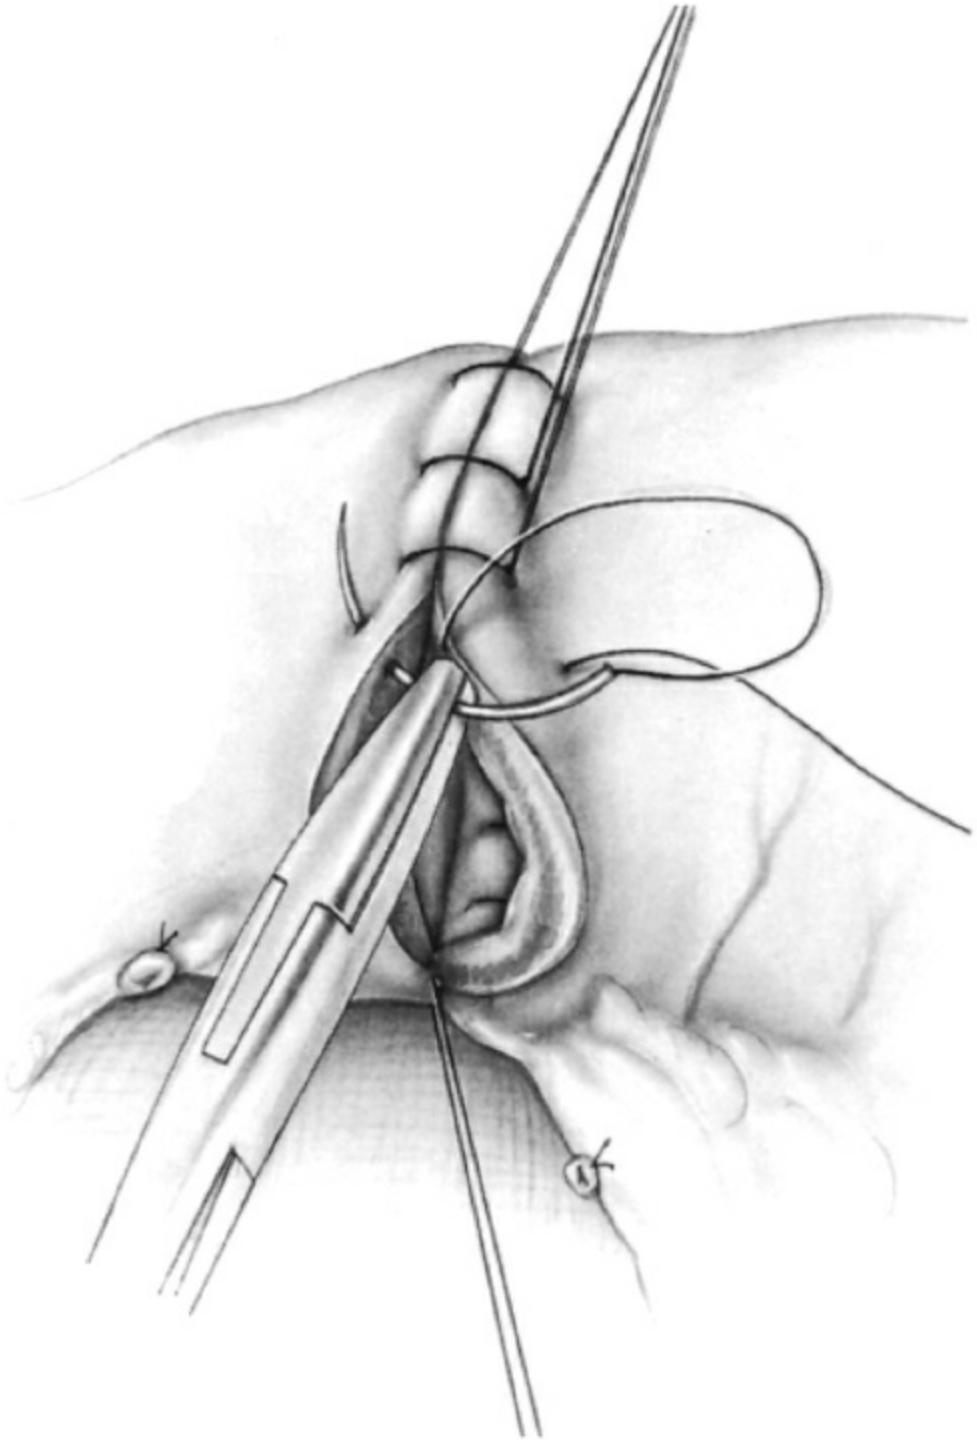

Figure 84.8. The front wall is closed by interrupted sutures with seromuscular stitches that grasp the mucosa tangentially. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

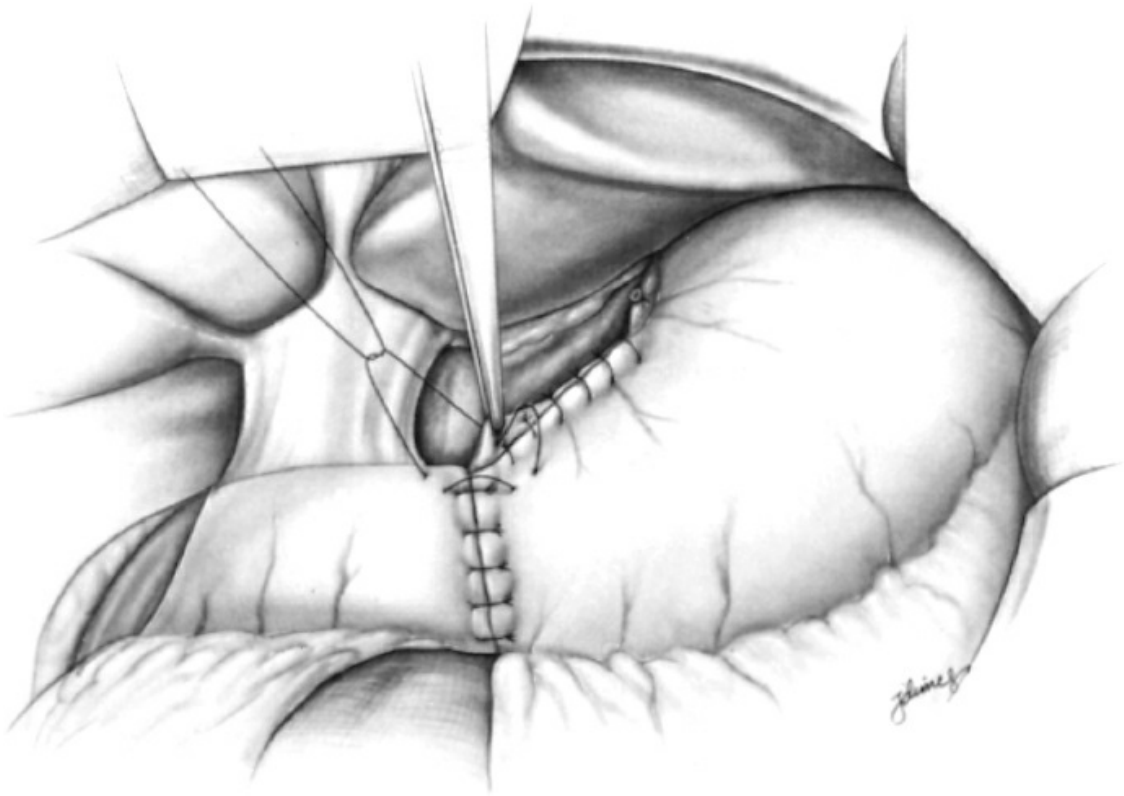

Figure 84.9. The so-called Jammerecke is traditionally covered by a triple seromuscular suture, including the front wall of the stomach, the duodenum, and the back wall of the stomach. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

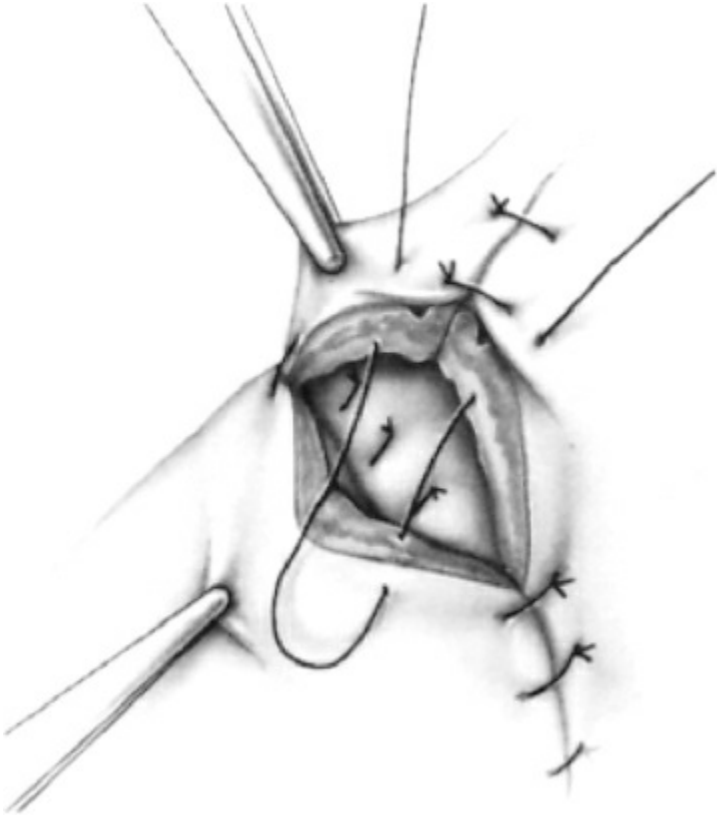

Figure 84.10. Alternative method for closing the Jammerecke with a single-row stitch technique. Seromuscular stitches are taken in the front wall of the stomach from outside to inside, including seromuscular layers of the duodenal walls and the back wall of the stomach in the same manner. This suture does not achieve exact adaptation of all layers but does lead to good closure of the corner by pulling the duodenal wall between the sutures at the lesser curvature. (From Siewert JR, Hölscher AH. Billroth I gastrectomy. In: Siewert JR, ed. *Breitner chiururgische operationslehre band IV chirurgie des abdomens II. Ösophagus, magen und duodenum.* 2. Auflage. 1989 © Elsevier GmbH, Urban & Fischer, Munich.)

Laparoscopic BI Gastrectomy

In Japan, where the rate of early gastric cancer is more than 50% due to early detection, laparoscopic resection and BI is popular due to its minor invasive nature. Several working groups have shown that laparoscopic BI gastrectomy is feasible. They claim that this procedure reduces perioperative pain and hospital stay as a result of limited surgical access. However, operating time is longer, the procedure is technically demanding, and it requires expensive instruments. They accomplish the same steps of dissection as in open surgery through four to five working

trocars and a 30-degree fiberoptic laparoscope. The greater and lesser curvatures are dissected by a harmonic scalpel or the ligasure. The resection of the distal margin is performed with monopolar coagulation, and the proximal resection margin is formed by multiple endolinear staples. After good duodenal mobilisation, the anastomosis is performed extracorporeally with single, extracorporeally knotted stitches, identical to open surgery. In addition, stapler techniques (side-to-side linear or end-to-end circular stapler) have been described. The disadvantages of laparoscopic resections are the lack of tactile feedback when palpation of a tumor or an ulcer is required and a more difficult orientation during the operation. In summary, laparoscopic BI gastrectomy is technically demanding and has, apart from centers in the Far East, not yet been established as a standard in gastric resections.

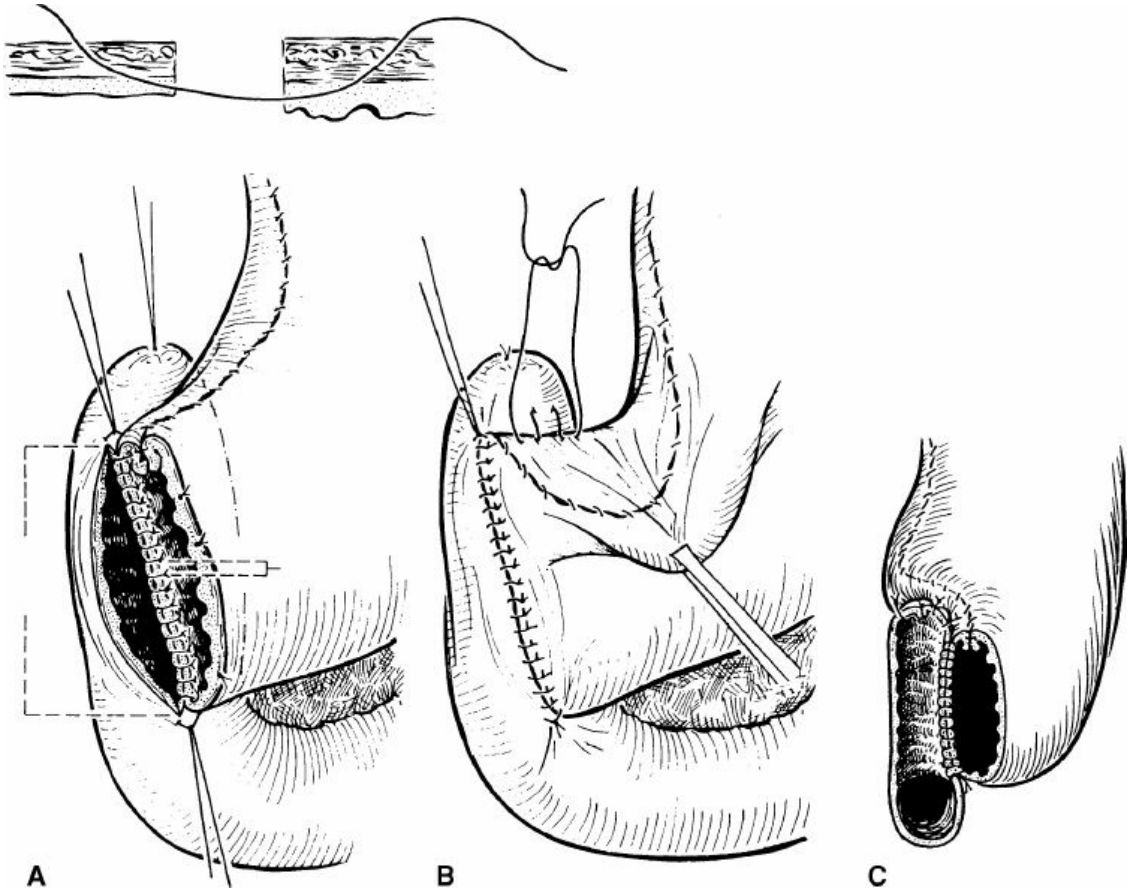

Figure 84.11. End-to-side gastroduodenostomy (**A**). After removal of the distal stomach, the gastric lumen is anastomosed onto the front wall of the duodenum. (The suturing technique is the same as described in Figs. 84.7 through 84.12) (**B**). The duodenal stump is covered with the back of the gastric wall (**C**). (From Siewert JR et al. Chirurgische Leitsymptome. Berlin: Springer, 1990, with permission of Springer.)

Other Modifications of BI Gastrectomy

Again, working groups from Japan and China, where early gastric cancer is more frequent than in the Western hemisphere, have introduced two modifications to the standard BI gastrectomy. These are pylorus-preserving BI gastrectomy and vagus-preserving BI gastrectomy. Early results of the techniques, which can be combined, have demonstrated a better quality of life after resection as compared with the standard technique, but these results still require further confirmation and both modifications are not widely used.

SURGICAL TECHNIQUE: BII GASTRECTOMY

The surgical access to the abdomen (midline epigastric incision) is equal to the one described for the BI operation. After dissection of the greater and lesser curvature (Fig. 84.12A) and partial removal of the omentum the duodenum is mobilized according to Kocher and circumferentially dissected. The right epiploic artery and the corresponding vein as well as the right gastric artery are divided between clamps and ligated (Fig. 84.12C). The duodenum is then divided with the help of a linear stapler (TA-55 (Covidien) or TL60 (Ethicon)) 2 cm aborally to the pylorus (Fig. 84.12B). Oversewing of the staple line of the duodenal stump is still in debate; we recommend it (seromuscular interrupted sutures, resorbable, 3-0) in all cases in which this can be done tension-free and without damage to the seromuscular layer of the duodenal stump. Meanwhile, the distal antrum is temporarily closed with a clamp. Dissection of the greater and lesser curvature is then finalized and the resection can be more extended as compared with the BI operation.

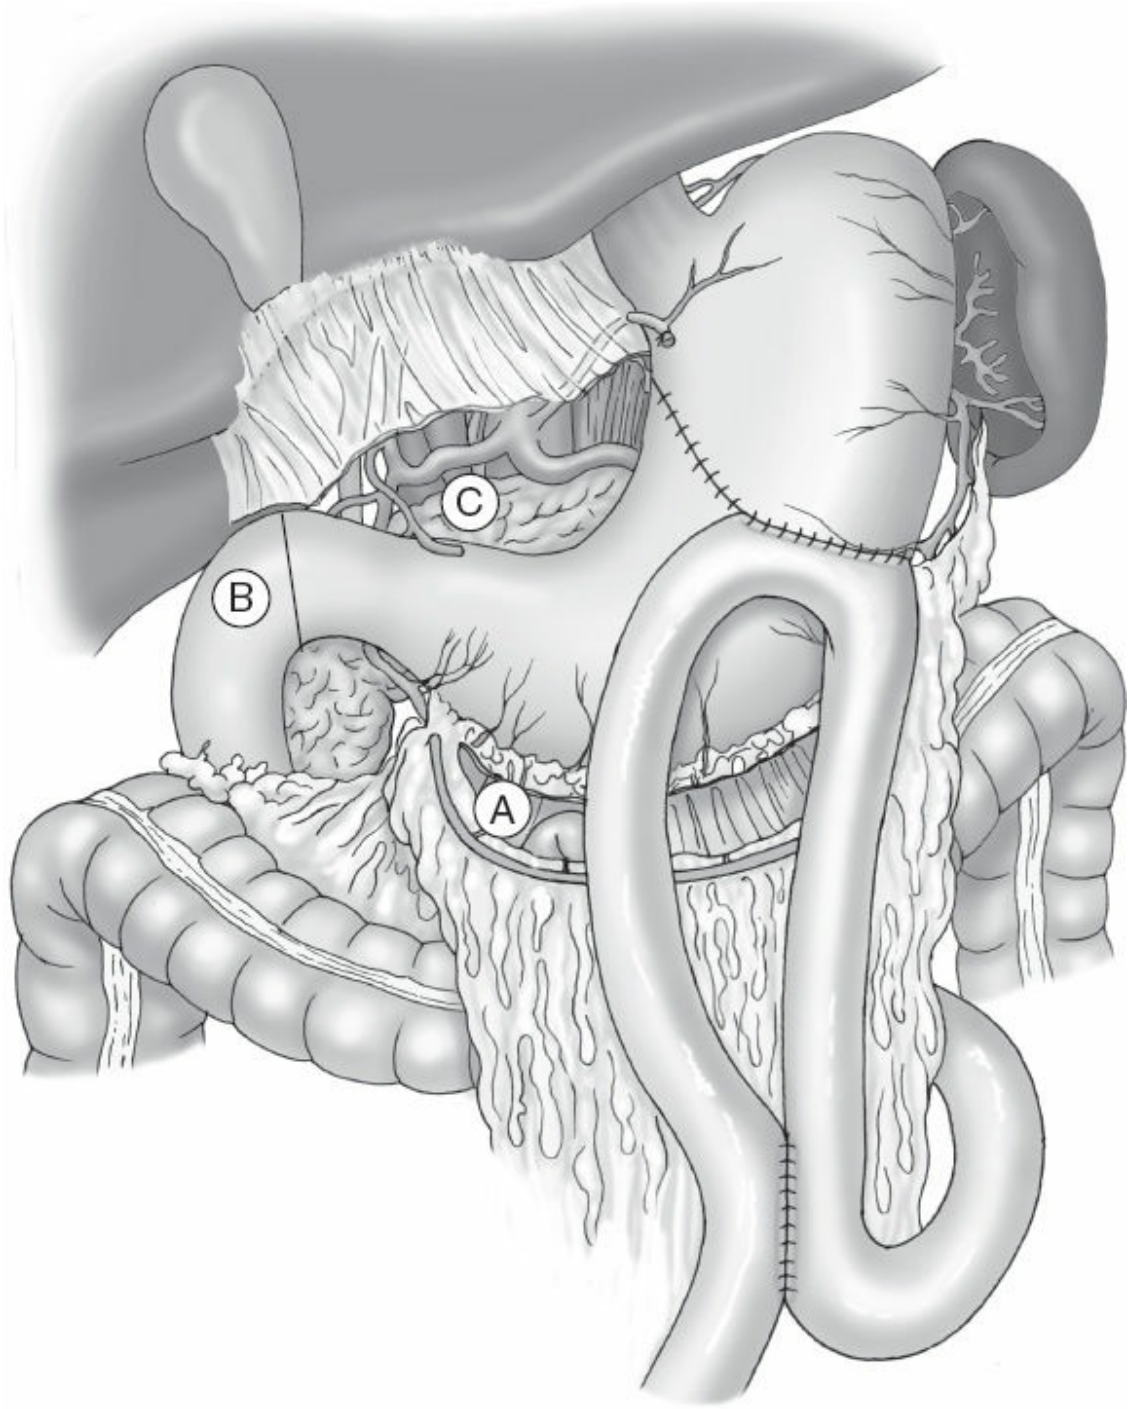

Figure 84.12. The BII reconstruction. The first or second jejunal loop of the jejunum is used, and a jejunojejunostomy (according to Braun) should be accomplished in order to prevent bile reflux. See text for details.

In the standard BII procedure, both the left gastric and left epiploic artery are preserved. At the oral margin of the dissection line, usually covering two-thirds of the stomach, the resection is completed by transverse application of a linear stapler (TA-90) in a way that the

complete stomach is divided between one stapler application. The specimen is removed. Again, we recommend addition of a selective vagotomy of the gastric remnant only for benign ulcer surgery in which gastric hypersecretion is assumed as one of the main pathogenetic factors, that is, in cases with multiple ulcers or prepyloric ulcers. In these rare cases we carefully divide the vagal branches of the anterior and posterior vagus that lead to the gastric remnant and leave the hepatic vagal branches intact.

The staple line can be oversewn, is not a must. In the next step, the first or second loop of the jejunum is mobilized and placed tension-free and in a retrocolonic fashion opposite the greater curvature of the remaining stomach. The loop should be long enough and should have a jejunojejunostomy (Braun) between the ascending and the descending loop.

Retrocolonic BII reconstructions in the Polya–Reichel technique (short ascending loop without enteroanastomosis) are rarely, if ever, performed today. The last 4 to 5 cm of the stapler line toward the greater curvature should be excised with the help of an electrocautery device in order to form a slim opening for the subsequent gastrojejunostomy. Meticulous hemostasis at the front and back wall of the stomach is required. Stay sutures are placed on both sides of the anastomosis. The jejunum is incised with the electrocautery device opposite the mesenterium. The gastrojejunostomy is performed by single interrupted sutures with resorbable suture material (3-0) and, as the anastomosis cannot be turned, the back wall is sutured by interrupted mattress sutures and the front wall by extramucosal interrupted sutures. Alternatively, continuous suturing with a monofilament resorbable thread (3-0) on both sides of the anastomosis is possible.

Before finalization of the front wall, a double-lumen gastric tube is placed distally to the anastomosis, allowing early enteral nutrition. In order to prevent enterogastric (bile) reflux, the formation of a jejunojejunostomosis, the so-called Braun anastomosis, side-to-side and 30 cm aborally of the gastrojejunostomy is mandatory. This anastomosis can be either handsewn (interrupted or continuous technique, resorbable suture material, 3-0) or stapled. Placement of a drainage in the BII procedure is controversial; in most cases we regard a drain as unnecessary. The use of circular staplers for the gastrojejunostomy has been described, but we regard this technique as far too expensive for routine use.

SURGICAL TECHNIQUE: RY GASTROJEJUNOSTOMY

The surgical technique of RY gastrojejunostomy is discussed in detail in Chapter 82.

SURGICAL TECHNIQUE: SUBTOTAL GASTRECTOMY

The subtotal gastrectomy (Fig. 84.13) is an alternative, more extended gastric resection enabling a D2 lymphadenectomy suitable for removal of early (T1, T2), well-differentiated, and distally located gastric cancers. As a general rule, at least four-fifths of the stomach is removed. In contrast to total gastrectomy, the technique preserves an intact lower esophageal sphincter as well as a small remaining gastric reservoir. The standard access is a transverse upper laparotomy, which offers good exposition of the stomach and the celiac axis. In the first step the omentum is dissected from the transverse colon, opening the omental bursa, and left at the specimen for complete removal. The gastrosplenic ligament, including the short gastric vessels, are divided up to the resection line (illustrated in Fig. 84.13) at the greater curvature. However, it is crucial to preserve the main trunk of the left gastroepiploic artery as well as the spleen to ensure good perfusion of the gastric remnant.

Mobilization of the duodenum, division of the right epiploic artery, and transverse stapler duodenotomy are performed as in BII gastrectomy. At the lesser curvature we dissect up to the level outlined in Figure 84.13, preserving the hepatic vagal innervation. As the next step, a complete D2 lymphadenectomy including central division of the right and left gastric artery (see Chapter 93) can be performed. It is advisable to leave all resected lymph nodes and the left gastric artery *en bloc* at the specimen. After this step, the gastric remnant is perfused mainly from the left epiploic artery and orally from branches of esophageal arteries. The proximal division of the stomach with the TA-90 stapler is as described for BII gastrectomy. The specimen is removed, and we reconstruct the gastrointestinal passage as for the RY reconstruction. The most common technical error is that the greater curvature is dissected too far and that blood supply from the left gastroepiploic artery is insufficient for the gastric stump. In these cases, subtotal gastrectomy should be given up and, alternatively, a total gastrectomy should be performed.

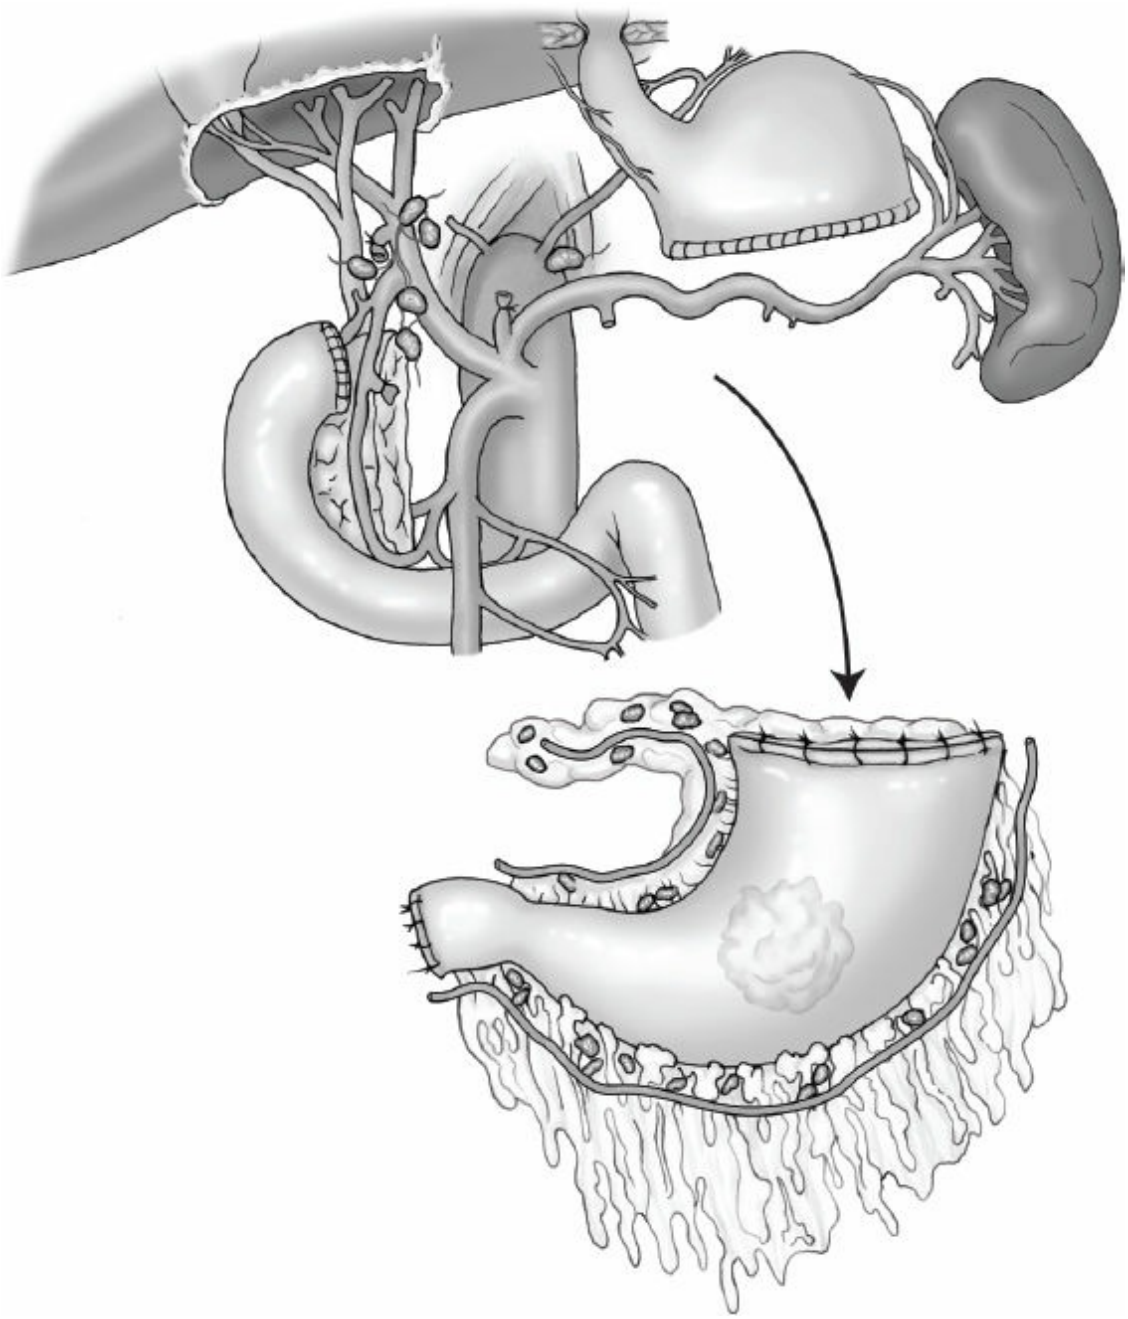

Figure 84.13. Subtotal gastrectomy. The resection involves four-fifths of the stomach, including the omentum, the right and left hepatic arteries, and the lymph nodes at the lesser and greater curvature, as well as the lymph nodes in the gastroduodenal ligament. The left epiploic artery must be preserved. This drawing shows the main portion of the left gastric artery intact. In case a complete DII lymphadenectomy is needed, the artery should be centrally ligated and resected.

POSTOPERATIVE CARE

Abdominal drains after partial gastric resections are usually not required,

except for partial gastric resections for perforation. A gastric tube is useful but can be removed after 1 to 2 days. Oral liquid intake is usually begun on the 2nd postoperative day. Alternatively, early enteral nutrition can be accomplished by an enteral feeding tube with the tip of the tube placed distally of the anastomosis. All patients receive one shot of antibiotic perioperatively.

POSTOPERATIVE COMPLICATIONS

After partial resections of the stomach, the following complications can occur: anastomotic leak in the area of the gastroduodenostomy (1% to 4%), bleeding (2%), passage disorders (2% to 5%), and postoperative pancreatitis (0.9%). Symptoms of an afferent loop syndrome (stasis, fullness, biliary vomiting) have become rare because placement of Braun anastomosis usually prevents this condition. If this occurs, some patients might need reoperation and RY reconstruction.

Suture insufficiency of the gastroduodenostomy or gastrojejunostomy are infrequent and can be managed well with conservative therapy as long as suture dehiscence does not occur in the first 3 or 4 days after the operation. It is imperative that the leak is well drained. With additional drainage by a gastric tube, and high doses of proton pump inhibitors, and parenteral nutrition, it is usually possible for the anastomotic leak to heal.

Problems with gastric emptying rarely occur after gastroduodenostomy. If gastric stasis is a problem, it is usually a consequence of anastomotic edema or a hematoma and resolves after 10 to 14 days with good drainage of the stomach. Revisions are rarely necessary.

Intragastric or intraperitoneal bleeding is infrequent. Management depends on the extent of bleeding. Endoscopic hemostasis by injection therapy should always been attempted. Reoperation should follow if more than four units of blood per 24 hours are needed for replacement of the lost volume and endoscopic intervention is not possible. For intraluminal bleeding from the anastomosis or the stomach remnant, the stomach must be reopened with a horizontal incision approximately 3 to 5 cm above the anastomosis. The anastomosis and the stomach remnant can be surveyed easily from there, and hemostasis can be obtained. Closure of the incision follows in a horizontal direction. Extraluminal bleeding sources are dealt with in a typical way. If the spleen represents the source of bleeding, hemostasis by coagulation, application of polyglactin 910 mesh or, if inevitable, splenectomy may be required.

Postoperative pancreatitis is usually of the edematous variety, and the prognosis is relatively good. If it is hemorrhagic or necrotizing pancreatitis, however, a high mortality must be expected. In postoperative pancreatitis of this kind, mechanical injury of the pancreatic duct should always be suspected.

RESULTS AND POSTOPERATIVE DISEASE

A mortality of 1% to 2% was observed in former studies of partial gastric resections for an uncomplicated gastric ulcer, and the mortality is independent of the mode of reconstruction. Mortality tends to be higher in emergency surgery for complicated ulcers. Ulcers recur in 0% to 4% of patients, and serious postgastrectomy problems are observed in 3% to 5% of patients.

Chronic Gastritis, Gastric Stump Cancer

In 80% to 90% of patients who have undergone partial gastrectomy, chronic gastritis of varying extent occurs in the stomach remnant 15 to 25 years after resection. That atrophic mucosal changes are less pronounced after BI resection than after BII resection has not been sufficiently proven. However, studies support the hypothesis that the risk of gastric stump cancer is higher after BII than after BI gastrectomy. The overall risk of developing cancer after partial gastrectomy is increased up to eightfold over the normal population.

Enterogastric reflux, achlorhydria, bacteria overgrowth, and *H. pylori* appear to be the major factors involved in the pathogenesis of the gastric stump cancer. Treatment consists of resection of the gastric remnant, esophagojejunostomy, and regional lymphadenectomy. Most patients who have undergone gastrectomy and present with atrophic gastritis do not complain of symptoms. Only approximately 10% of patients complain of symptoms and require treatment. The cause of these complaints is apparently not chronic gastritis itself, but enterogastric reflux. Bile acid quantity and concentration progressively decrease from BII to BI. The clinical signs and symptoms are epigastric pain, feeling of fullness, nausea, and bile vomiting. The disappearance of epigastric symptoms after bile vomiting is characteristic, as is its intensification by stimulation of bile or pancreatic secretion. Conservative treatment includes metoclopramide, spasmolytics, and perhaps cholestyramine, antacids, and dietary regulations. An antiperistaltic jejunal interposition is rarely necessary.

Dumping

Dumping problems, in the sense of early dumping, are less frequent after BI resection than after BII resection. The frequency is between 7% and 29% of patients. The most important conservative measure is dietary (no sweet meals, frequent small meals, no liquid intake with food). All attempts with drugs, including serotonin antagonists, have proved disappointing, except for somatostatin, which is available in intravenous or subcutaneous forms but not for oral intake. The most serious dumping forms can be an indication for surgical revision and conversion of a BII into a RY gastrojejunostomy or antiperistaltic jejunal interposition.

Gastroesophageal Reflux

Gastroesophageal reflux does not frequently occur after resection of the distal part of the stomach. The medical history often reveals that gastroesophageal reflux was present before the operation; this frequently occurs in patients who have ulcers. There is no evidence that reflux after BI resection is less frequent than after other forms of stomach resection. However, researchers have described decreased lower esophageal sphincter pressures after partial gastric resections. In case of problems, the diagnostic examination of reflux esophagitis after stomach resection requires endoscopy, 24-hour pH measurement, and an examination of the refluxed material for bile acids. Metoclopramide can be useful, but antacids are also helpful because of their bile acid-absorbing qualities. Serious reflux esophagitis can be an indication for a conversion to a Roux-en-Y gastrojejunostomy with a long efferent loop.

H. pylori infections in the gastric remnant are frequent after partial gastrectomy. Eradication is mandatory after detection. There is, however, no evidence that these infections lead to major clinical consequences or to an increased frequency of ulcer recurrence in these patients.

EDITOR'S COMMENT

We are very pleased to have Professor Bumm and his mentor, Professor J. Rüdiger Siewert, back again as authors in this edition. Once again, I am often asked why we bring up a new edition every 5 years, and the relevant answer in this regard is that there have been significant changes in the whole area of gastrectomy in general and carcinoma of the stomach in particular. First, there has been a general consensus of the superiority of the Roux-en-Y as compared with the Billroth II for a major gastric resection; in other words, a carcinoma of the stomach with extension beyond the halfway point so that to get an adequate margin, one would have to take it fairly high to 75% or 80% gastrectomy point. In that case, the reconstruction certainly cannot be a Billroth I but it is between a Billroth II and a Roux-en-Y. There has been a flight away from the Billroth II as a number of works, particularly from the Tokyo Cancer Hospital, headed by Dr. Katai, which has demonstrated well in a randomized trial that the Roux-en-Y, at least the way they do it, which is not to do the end-to-side gastrojejunostomy less than 55 cm downstream from the ligament of treitz, is a much more satisfactory outcome as far as bile reflux and reflux esophagitis with a Roux-en-Y than with a Billroth II anastomosis is concerned. Indeed, there are several studies from Japan and Korea where many studies have been done comparing these various anastomoses following major and not so major gastrectomies, but the Roux-en-Y is not only better from the standpoint of food intake, residual gastritis, bile reflux, esophagitis, and so on, but also seems to be superior to the Billroth I. This is not to denigrate the work that both of our authors have done, particularly Dr. J. Rüdiger Siewert, who has set a new standard for carcinoma of the stomach and various gastrectomies; we are indeed pleased to have him back as a coauthor. Nonetheless, in the United States, it is almost as if nobody has heard of the Roux-en-Y reconstruction, and indeed at the Beth Israel Deaconess it is rare to see a reconstruction with a Roux-en-Y,

and Billroth Is and Billroth IIs are thought of as perfectly adequate. It seems that there is some problem in getting the message across the medical fraternity.

The second point in which things have changed is the status of the D2 nodal dissection for carcinoma of the stomach. Carcinoma of the stomach is fairly rare in the United States, and therefore the completeness of the dissection, especially in the nodal dissection for carcinoma of the stomach, leaves even surgeons with good experience doing gastrectomies for carcinoma of the stomach at a disadvantage with the nodal dissection. The Japanese results have always been superior, and although Japanese surgeons have been given some credit for their experience, it had been stated that the reason why the Japanese results are so good is that "there are no fat Japanese." Those who have given this statement have not been to Japan lately. It does appear that the Japanese, particularly males, now have their share of obesity, and so one cannot describe the results that the Japanese surgeons get with a completeness of the gastric resection and their long-term survival to "skinny Japanese." Indeed, when the Dutch did one of their famous randomized prospective trials on carcinoma of the stomach, and the results were very much inferior to the Japanese results, with respect to complications, mortality, and in oncological outcome, it was finally suggested that the Dutch surgeons and anybody else who was interested to go to Japan and watch the Japanese surgeons, especially at the Tokyo National Cancer Hospital, do these operations. Interestingly, that suggestion was taken, and after watching the prowess of the Japanese surgeons in doing cancer surgery on the stomach including D2 resections, the European surgeons came back, adopted the techniques, and after a while their results were just as good as what they have observed. Therefore, we now have acceptance of the Roux-en-Y, not necessarily practiced in this country, but a D2 resection, which is deemed an essential part of an operation for gastric carcinoma.

I very much like Professors Bumm and Siewert's article entitled, "Arguments in Favor of Billroth II Gastrectomy or Roux-en-Y Reconstruction." They point out that a Billroth II reconstruction allows a major gastrectomy for carcinoma of the stomach and the lymphadenectomy, particularly the extended lymphadenectomy is easier. I am neither advocating partial pancreatectomy nor am I arguing for splenectomy to get the nodes in this particular case. They point out that in Billroth II, especially with a small pouch, there may be the dumping syndrome, in which case they can be reconstructed with a Roux-en-Y. There are good arguments for the use of partial gastrectomy particularly in the treatment of gastric ulcer because this is theoretically a low-acid ulcer, there may be a malignancy that is lurking in the ulcer, and because one does reduce both the chief cells and the antrum for the formation of gastrin. There are also excellent points concerning early carcinoma and the carcinoma of the antrum, in which they state openly that in locally early carcinoma and carcinoma of the antrum, the standard operation for locally advanced gastric cancer should be a total gastrectomy with adequate lymphadenectomy. However, they also state that a well differentiated early T1/T2 N0 gastrointestinal carcinoma should undergo a

subtotal gastric resection, with a 4/5 gastrectomy and a standard D2 lymphadenectomy. The reconstruction should be a Billroth II or a Roux-en-Y and it is also pointed out that in the Far East, their surveillance is religious, mucosal cancers of the antrum are common, and a lesser gastrectomy is frequently done with a Billroth I reconstruction. Sentinel lymph node dissection has been advocated, but I have yet to see a really convincing argument for a sentinel lymph node, and I suspect why this really does not work is because of many sentinel lymph nodes, and by the time you are finished with these various sentinel lymph nodes, you have essentially done a lymph-node dissection.

The authors also make an excellent technical point of stretching the stomach along the greater curvature in the left duodenal wall and then going around the back and toward the lateral duodenal wall at the point of the hepatic duodenal ligament. In doing so, they manage to free up 3 to 5 cm of the back wall of the duodenum, and the transition from the free first part of the duodenum to the duodenum fixated to the pancreas can be recognized by the gastroduodenal artery. The artery is of course important for the blood supply to the first and second parts of the duodenum and the pancreas. This is a better way of getting around some of the difficult parts of partial gastrectomy, especially if one desires to do a Billroth I type of anastomosis. One of the appropriate technical points is that, in doing a complete D2 lymphadenectomy, all resected lymph nodes in the left gastric artery are attached *en bloc* to the specimen. The gastric remnant at that point is perfused mainly from the left gastric artery and orally from the branches of the esophageal artery and, if present, the posterior gastric artery, which is rare. Clearly, these are two surgeons who are excellent technicians, who have remarkable experience of gastric resection.

Some of the papers that I quote, I admit in this regard, are somewhat disappointing, in which the surgeons, although well known and very highly respected, seem to be in [a] different place and asking different questions than perhaps they should be. A good example of this is the first paper authored by Kojima K et al., “Comparison of Roux-en-Y and Billroth-I reconstruction after laparoscopy-assisted distal gastrectomy” (*Ann Surg* 2008;247:962–7), in which it is almost as if they are testing out whether such procedures can be carried out laparoscopically instead of asking more sophisticated questions, which they are quite capable of. In this study, they have evaluated a total of 133 patients who underwent laparoscopic-assisted distal gastrectomy for gastric carcinoma, and in whom the reconstruction was 65 randomized to Billroth I and 68 randomized to Roux-en-Y. They reported tumor characteristics, operative details, postoperative outcomes, and nutritional status. They also evaluated the endoscopic description of the gastric remnant and the esophagus a year postoperatively. However, there are no differences between the two groups. In the Billroth I group, three patients developed anastomotic leakage and four patients an anastomotic stricture requiring balloon dilation. The so-called functional stasis after Roux-en-Y reconstruction or the Roux syndrome, which is a popular bugaboo in our country, does not seem to occur, possibly because

of where side-to-end anastomosis is done for the Roux-en-Y, it being longer and probably less prone to spasm than a shorter Roux-en-Y, which I believe is the practice in this country. There is a higher incidence of heartburn in the Billroth I group (37%), and only 8% in the Roux-en-Y group (P = 0.0002). A novel aspect of the follow-up was comparing the amount of meal consumed with a preoperative value, which was significantly higher in the Roux-en-Y group, 83.6%, versus 79% (P = 0.047), and then an endoscopic finding showing remnant gastritis was significantly lower in the Roux-en-Y group than in the Billroth I group, B-1, being 34% and Roux-en-Y being 12% (P = 0.002). This has been an almost constant finding in Japanese studies comparing these two drainage procedures.

The next paper is from the Rui Jin Hospital, which is the principal international-class hospital of the Shanghai Medical School in China by Sah BK et al., "Gastric cancer surgery: Billroth I or Billroth II for distal gastrectomy?" (*BMC Cancer* 2009;9:428–54, published online). I personally visited this hospital and spoke at the institution. I found it a world-class institution, which was well-equipped, very interested in learning about simulation and education of residents, and would assume facilities and, it seems, excellent surgeons. They compared the Billroth I and Billroth II types of anastomoses with distal gastrectomies in 809 patients with gastric cancer in 4 years. The study endpoint was limited to an analysis of patients' postoperative complications. They did evaluate the risk-adjusted complication rate by comparing the outcome to physiological and operative severity score for enumeration of morbidity and mortality (POSSUM).

There was no randomization in this study. While Billroth I accounted for 626 of the 809 drainage procedures, Billroth II accounted for 183. They did find, and it is not clear, other than the surgeon's preference, what influenced in deciding whether the patient would require a Billroth I or a Billroth II. The procedures carried out did not include a total gastrectomy. They have another method of accounting for complications in addition to the one that was used in this paper. Interestingly, the summary statement would be that the ratio of observed to estimated complications was 1.03 for the Billroth II group, while it was only 0.74 in the Billroth I group, which freely translated means that there are fewer complications in the Billroth I group as proposed, because of the POSSUM evaluation, than there were in the Billroth II group. Leaks at the anastomosis and other severe complications were considerably greater in the Billroth II group, as was the cost. Anastomotic leak, for example, was 8 in the Billroth I group and only 6 in the Billroth II group, but remember that the difference in the patient population was three to four times in the Billroth I group; nonetheless, this is not statistically significant. In Figure 84.1, the percent complications were given showing an advantage in the Billroth I group of all complications. Not surprisingly, the expenditure in the Billroth II was greater than in the Billroth I.

A similar paper was published by Kang K-C et al. that compared Billroth I

and Billroth II reconstructions after laparoscopy-assisted distal gastrectomy results. In this case, it seems that the authors were still comfortable with the Billroth I and Billroth II done laparoscopically, where, in other papers from Korea, it would seem that they have adopted the point that, after 50 to 75 laparoscopic gastrectomies, one became comfortable with the procedures. There were 875 patients in the Billroth I group, and 384 in the Billroth II group. There was no assessment of nutritional status preoperatively, and there was no Roux-en-Y carried out. It seems to be a constant practice in the Korean papers, and perhaps they either are not performed as readily or are not performed as an initial drainage procedure but only after complications. In the Billroth I group, the overall complication rate was 11.4% and in the Billroth II it was 17% (P = 0.011). However, the differences in the major complication rates depending on the complication were not individually separate. Blowout of the duodenal stump was the most frequent complication following the Billroth I, but the mortality rate did not reach statistical significance. One would point out that this was a good study, because the comorbidities in the Billroth I were approximately 35% and in the Billroth II group 39%, but of course the number of patients is much different.

In continuation of the exploration of technique for performing the Billroth II anastomosis as well as doing a Billroth I, the next paper is by Oh SJ et al. (*J Gastrointest Surg* 2011;15:1244–6), in which it seems that a standard type of Billroth II anastomosis was done, with a slightly different stapling technique, in which an Allen clamp was then placed along the greater curve, and then a biopsy was taken from the proposed site of the anastomosis, and, once the frozen section was negative, they made an opening in the greater curvature for the anastomosis. This is done with a circular stapler. There are photographs, which do not reproduce well, or at least I cannot see well what they are actually doing, although there are drawings that are a little more explicative as far as what is happening, but I am not certain. Suffice it to say that under “Results,” “Since June 2002, we have employed a mechanical stapling technique instead of the traditional hand-sewn anastomosis…following distal gastrectomy.” This has been performed in 520 patients over a period of 8 years. There have been no anastomotic leaks or stenotic complications. There were two episodes of intraluminal bleeding, although clearly this group is delighted with their circular-stapling technique to do a Billroth II anastomosis.

In another paper from Korea, however, An JY et al. (*J Surg Oncol* 2009;100:518–519), at Yonsei University, modified a double-stapling technique to avoid stapling on the suture line. This is a short paper but, except for the last two drawings, I do not understand exactly what they are referring to. This is a double-stapling technique not coming across the suture line of the stapling line, which results in a Billroth I anastomosis, with which they are apparently fairly happy. Here again neither the photographs nor the drawings are particularly understandable, except that it seems that they are happy with it.

In short, it is unfortunate that it seems that people are trying to do in the Far

East, where they have lots of fertile ground for studies, is to see whether or not they can convert from the open technique to the stapling technique, and, if they do have a stapling technique, then they are trying to figure out new ways of doing Billroth Is and Billroth IIs. It is interesting that in all of these papers the Roux-en-Y as a principal means of reconstruction does not make an appearance. With this volume, it would be nice to have some confirmation of what we have observed in other studies, that is, the Roux-en-Y is superior to the Billroth I and Billroth II. It should be possible to put together such a study, which, I am sorry, we have not seen in this group of a large number of patients, which seem to have been concentrated on whether they can do Billroth Is and Billroth IIs. Perhaps, in the next edition we will see this type of study is undertaken.

J.E.F.

85 Selective Vagotomy, Antrectomy, and Gastroduodenostomy for the Treatment of Duodenal Ulcer

Lloyd M. Nyhus

*This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).*

The surgical treatment of complicated duodenal ulcer has undergone marked change since vagotomy was reintroduced by Dragstedt and Owens in 1943. Subtotal gastrectomy alone had been the mainstay operation for the prior 50 years, followed by various surgical procedures, including truncal vagotomy, gastroenterostomy, pyloroplasty, 70% subtotal gastrectomy, and antrectomy. My experience with the combined operation of truncal vagotomy, antrectomy, and gastroduodenostomy began in the early 1950s. It became apparent that the method of vagotomy could be improved. Therefore, my associates and I modified our technique of vagotomy to the selective method and changed the name of the procedure to the "revised combined operation." Thus, the specific procedure included selective vagotomy, antrectomy (35% distal gastrectomy), and gastroduodenostomy (Billroth I anastomosis). This operation has a good record in terms of ulcer recurrence. The recurrent ulcer rate after this procedure should be no greater than 0.5%.

Because of the interest in proximal gastric vagotomy, we have departed from gastrectomy as a routine operative procedure in our clinic. Yet, because of the occasional need to perform a partial gastrectomy or antrectomy, the technical lessons we learned must not be forgotten. For this reason, I highlight the classic "revised combined operation of Harkins" in this chapter.

SURGICAL TECHNIQUE

Failure to appreciate technical details is reflected not only in resultant

anatomic disturbances such as postoperative suture line leakage, but also in physiologic effects (e.g., recurrent ulcer from incomplete vagotomy). My experience in performing the revised combined operation (i.e., selective vagotomy plus antrectomy plus gastroduodenostomy) has led to the modification of certain steps in the technique.

Surgery is an art, and, like all art, it must be developed, not discovered. The technique described is the one that seems to give the best results at the present time. Much of the following surgical technique is applicable to the Billroth II procedure as well as to the Billroth I operation.

GENERAL PRINCIPLES

Sutures

A variety of sutures are used throughout the operation. Whereas fine silk was used predominantly in the past, new absorbable and nonabsorbable sutures may be used now. Most vessels are simply ligated, but transfixion sutures are occasionally used. An absorbable suture is used essentially as a mucosal stitch with inversion for the inner layer of the anastomosis. Seromuscular sutures continue to be of 4-0 or 3-0 black silk. The abdominal wall closure has changed from silk to stainless-steel wire sutures to the current use of several monofilament synthetic sutures.

OPEN ANASTOMOSIS

I prefer the open to the closed type of anastomosis for several reasons. First, because the open technique provides direct visualization at all times, bleeding from the anastomosis can be entirely prevented. Second, the size of the anastomotic stoma can be ensured, and the surgeon can be certain that the anterior and posterior walls are not included in one or more sutures. Third, through the open duodenal stump, the ampulla of Vater can be palpated and biliary flow can be noted; also, the area can be inspected for postbulbar duodenal ulcer and other duodenal abnormalities. I have seen no difficulty arise from soiling of the surgical field with the use of the open technique. The bacterial flora of the stomach and duodenum are few if there is no distal obstruction, and adequate protection can be achieved by careful placement of laparotomy pads to protect the remainder of the operative field. An inner mucosal or full-thickness layer of continuous absorbable sutures and an outer seromuscular layer of interrupted silk sutures are routine to complete the anastomosis.

DRAINAGE

If it is suspected that the pancreas has been subjected to undue surgical trauma, a Penrose drain or a double-lumen sump-suction catheter can be placed down to the site of suspected injury and brought out laterally through the abdominal wall via a stab wound; it is never brought through the main incision. Rarely, I place a Penrose drain near, but not on, the anastomosis if some aspect of the coaptation causes concern.

ADEQUACY OF RESECTION

I adhere inviolably to the dictum that an adequate resection must be performed on the basis of the presenting disease before any decision is made to use or not to use any particular type of anastomosis. In fact, this decision is not made until the anastomosis is to be done. If there is any tension whatsoever in attempting to perform a gastroduodenal anastomosis, this method is abandoned and a modification of the Billroth II procedure is used. The anastomosis should not be forced. In general, the resection may be only 35% when protected by selective vagotomy.

PROTECTION OF VITAL STRUCTURES

The only way to avoid injury to important structures is to visualize the part of the structure that lies in the field of dissection. The inflammatory reaction and scarring characteristic of many gastroduodenal lesions can cause distortion of the normal anatomy. This distortion, coupled with the extreme variability in “normal” anatomy, makes dissection in this region extremely hazardous unless good visualization or identification of the vital structures to be preserved is constantly sought.

The simple maneuver of opening the common bile duct in certain instances is useful when the porta hepatis is involved in ulcer scar or inflammatory reaction. It is important to recognize the possible distortion of normal anatomic configurations of the common bile duct and the pancreatic ducts. A catheter or Bakes bile duct dilator introduced via choledochotomy is reassuring when dissecting a duodenum that is thickened, distorted, or inflamed. Special care should be taken to avoid injury to the common hepatic artery, which sometimes can be retracted near a posterior penetrating duodenal ulcer crater. On the greater curvature side of the pyloric region, the middle colic artery can be so densely adherent to the ulcer scar that it easily may be mistaken for the right

gastroepiploic artery.

Caution should be used to avoid vigorous palpation or traction in the region of the spleen. The splenic vessels, particularly in older persons, are friable and easily torn. Moderate traction on the greater curvature of the stomach is sufficient to cause tearing of the splenic vessels or of the splenic substance. When such an accident occurs, appropriate splenic repair should be carried out; splenectomy may be necessary if the bleeding cannot be controlled with argon beam coagulation. Splenectomy is not a catastrophe; it can appreciably increase morbidity and even mortality.

The tenets of good modern surgery—the gentle handling of tissues, the avoidance of undue traction, and meticulous identification of adjacent structures to be preserved—are essential to a technically satisfactory operation.

AVOIDANCE OF MASS LIGATURES

In dividing the blood supply to the portion of the stomach and duodenum to be resected, it is important that small bites of tissue be ligated. Especially in patients with a large quantity of omental fat, there is a tendency, if the vessel ligatures are placed around large quantities of this fat, for the vessels to retract proximal to the ligature and cause troublesome hematomas or a dangerous hemorrhage. Particularly in older people, I have been impressed with the increased quantity of fat that surrounds the left gastric vessels high on the lesser curvature. This situation is observed even in thin elderly patients.

REMOVAL OF ULCER

In association with gastric resection, I regularly remove the duodenal ulcer for mechanical rather than physiologic reasons. Only rarely do I leave a duodenal ulcer *in situ*. However, I do not hesitate to leave the depths of an ulcer crater in the tissue into which it may have penetrated.

TECHNICAL PROCEDURE

Only the combined operation of selective vagotomy plus hemigastrectomy (antrectomy) plus gastroduodenal anastomosis is described in this section. The sequence of performance of the various steps applies to most operations. However, certain conditions germane to each situation can make a somewhat altered sequence more desirable. A step-by-step

description of the technique is undertaken merely because it is easier to describe it in this manner. It is the integration of all these steps into a smoothly performed surgical procedure that is productive of technical satisfaction.

TABLE 85.1 Step-by-Step Outline of the Combined Procedure for Selective Vagotomy Plus Antrectomy Plus Gastroduodenal Anastomosis

1. Incision
2. Abdominal exploration
3. Selective vagotomy
4. Freeing of the greater curvature
5. Mobilization of the duodenum
6. Strauss maneuver for division of the duodenum
7. Division of the gastrohepatic omentum and left gastric vessels
8. Resection
9. Closure of the Schoemaker suture line
10. Anastomosis
11. Wound closure

The surgical technique I prefer (Table 85.1) is described in the following 11 steps.

INCISION

An upper midline abdominal incision is used almost exclusively. This incision is begun in the left xiphocostal angle and is extended down the linea alba to the level of the umbilicus or below, if necessary. The incision is usually approximately 15 cm long. In patients for whom the distance between the costal arch and the umbilicus is short, I extend the incision inferiorly to one side of the umbilicus. If more room is needed proximally, I excise the xiphoid process. The peritoneum is cut approximately 2 cm to the left and lateral to the skin and fascial incision, which gives a "staggered" effect so that the underpart of the fascial closure is more or

less protected by the intact peritoneum.

ABDOMINAL EXPLORATION

The surgeon must curtail his or her enthusiasm to attack the gastroduodenal disease for which the operation was performed until there is ample opportunity to explore the entire peritoneal cavity. Unless a general exploration is performed as soon as the peritoneal cavity is entered, this important step is apt to be forgotten. In addition, it is probably a better technique to explore the general peritoneal cavity before the gastrointestinal tract has been entered to avoid the small but ever-present chance of disseminating contaminated debris. Two exceptions to the rule of exploring the general abdominal cavity before beginning the gastric procedure are emergency operations for a bleeding gastroduodenal lesion, when control of the hemorrhage should take priority, and operations for obvious acute perforation of a peptic ulcer.

It is only after adequate inspection of the gastroduodenal disease that the final decision to perform a gastric procedure should be made. This decision should, however, depend on the sum total of information available about the patient and not solely on the findings at the operation. Most often, the presence of an active ulcer, ulcer scar, or carcinoma of the stomach can be detected by external inspection and palpation. Occasionally, a posterior duodenal or a lesser curvature gastric ulcer can be identified by palpating the crater through the anterior wall of the duodenum or stomach. Often, after rapid withdrawal of the palpating finger, the anterior wall of the duodenum or stomach can be observed to remain depressed into the crater by a suction effect.

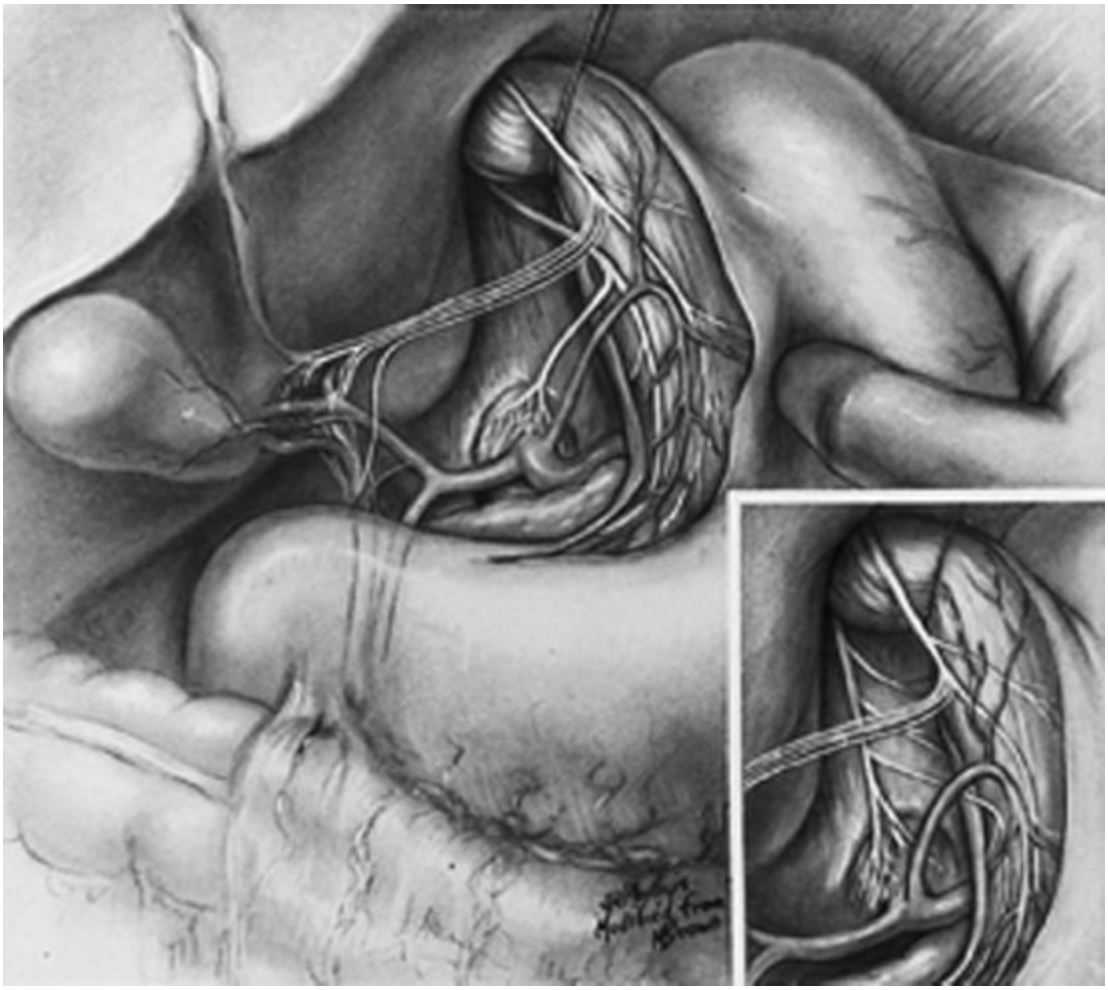

Figure 85.1. The abdominal vagi. All vagal fibers shown in this illustration are readily identified by gross anatomic dissection. The hepatic vagal division (usually consisting of multiple fibers) from the anterior trunk courses within the lesser omentum to the porta hepatis. The celiac vagal division from the posterior trunk goes to the celiac autonomic plexus, usually in close association with the left gastric artery but occasionally with the right diaphragmatic crus (*inset*). The main anterior and posterior trunks run distally within the lesser omentum adjacent to the cardia to the antrum. (From Griffith, 1977, with permission.)

SELECTIVE VAGOTOMY

Henry Harkins and Charles Griffith of Seattle (1957) are credited with modification of the truncal (total) vagotomy method to the selective technique, which preserves all extragastric vagal fibers. The late Professor Griffith fine-tuned these important advances in technique. To commemorate his contribution, I have paraphrased his 1977 and 1986 presentations.

An essential difference between truncal and selective vagotomy concerns the different anatomic levels at which vagotomy is performed. Truncal vagotomy is conventionally performed at or just above or below the diaphragmatic esophageal hiatus. In contrast, selective vagotomy is performed at the lower level of the most distal esophagus and gastric cardia (Fig. 85.1). The lower level is selected because it is the only place where all gastric vagi always gather to innervate the stomach. In taking advantage of this fundamental anatomic fact, all gastric vagi can be encircled and brought into the surgical field with anatomic certainty. This is the first and basic requirement for accomplishing complete gastric vagotomy, and it is in definite contrast with the uncertain encirclement at the hiatus, where incomplete vagotomy can and does occur because the encircling finger may exclude one or more vagal fibers.

SELECTIVE TECHNIQUE

Selective gastric vagotomy entails ligation and transection of all the previously described encircled tissues, except for the esophagus and the hepatic and celiac vagal branches. In addition, the descending branch of the left gastric artery must also be ligated and transected to interrupt posterior gastric vagi that may arise distally from the celiac division of the posterior trunk and may go to the stomach and the left gastric artery. Neither the hiatus nor the vagal trunks are dissected or exposed. Furthermore, the gastric vagi are not purposely exposed or identified. Instead, all tissues known to contain the gastric vagi are clamped, ligated, and transected.

For initial definition of the surgical field, the esophageal hiatus and vagal trunks are not exposed purposely. Instead, the hepatic vagi are identified. These vagi can always be seen in the avascular lesser omentum contrasted against the dark background of the caudate lobe of the liver (Fig. 85.2). The lesser omentum is incised below the hepatic vagi, well to the right of the patient’s gastric cardia. No gastric vagi lie to the right of this incision in the lesser omentum. Next, the peritoneum that overlies the cardioesophageal angle of His is incised, and this opening is enlarged with the finger. No gastric vagi lie to the patient’s left of this opening at the angle of His. Thus, all anterior gastric vagi are included between these two incisions in the lesser omentum and angle of His. None has been excluded.

The method of encircling all posterior gastric vagi cannot be illustrated. It is done by finger dissection. The finger is worked into the angle of His,

not with the aim of encircling the esophagus, but with the aim of palpating the posterior trunk–celiac division posterior to the esophagus. Once the posterior trunk–celiac division has been positively identified by palpating its course to the celiac plexus, the finger is dissected through the areolar tissue behind (i.e., dorsal to) the posterior trunk–celiac division. This technique isolates all posterior gastric vagi because none lies behind the division. At this point, the fingertip may be seen through the incision in the lesser omentum initially made below the hepatic vagal branches (Fig. 85.3). The encirclement of all gastric vagi with the most distal part of the esophagus is thereby accomplished with anatomic certainty. The encircling finger is replaced by a soft rubber urethral catheter to maintain encirclement and exposure.

By finger dissection, the posterior trunk–celiac division is mobilized from its bed and is encircled with another rubber urethral catheter so that it may be gently retracted to the patient's right (Fig. 85.4). The original catheter is then repositioned to encircle all anterior gastric vagi with the most distal part of the abdominal esophagus, which then may be retracted to the patient's left.

Attention is now directed to the loop of the left gastric artery, where it approaches the lesser curvature of the stomach and bifurcates into the descending gastric and ascending esophageal branches. I prefer finger dissection to isolate the descending left gastric artery to facilitate the transection of any posterior gastric vagi that may accompany that vessel to the stomach. Then, as indicated by the dashed line in Figure 85.5, the lesser curvature is freed entirely from the gastric cardia by successive transactions between clamps and ligation up to the encircling catheters to facilitate the transection of any other posterior gastric vagi. Clearly, this dissection is the step that makes selective vagotomy more difficult than total vagotomy. It may be more complicated if an aberrant left hepatic artery from the left gastric artery is encountered (not illustrated, but present in approximately 10% of patients). By transecting all lesser omental attachments to the gastric cardia, thereby totally separating the posterior trunk–celiac division from the distal esophagus and gastric cardia, all posterior gastric vagi are severed (Fig. 85.6).

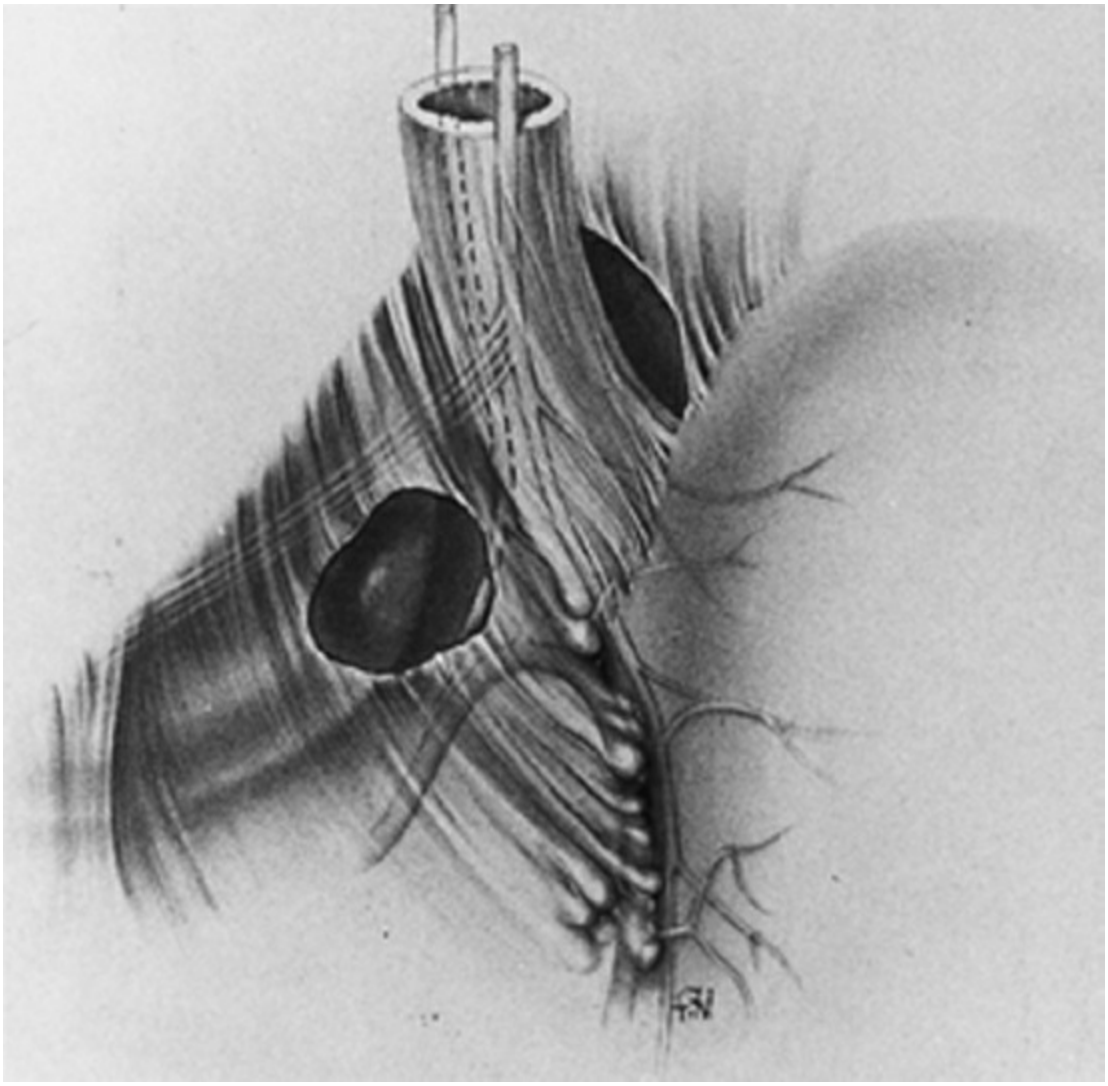

Figure 85.2. Initial definition of the surgical field. (From Griffith, 1986, with permission.)

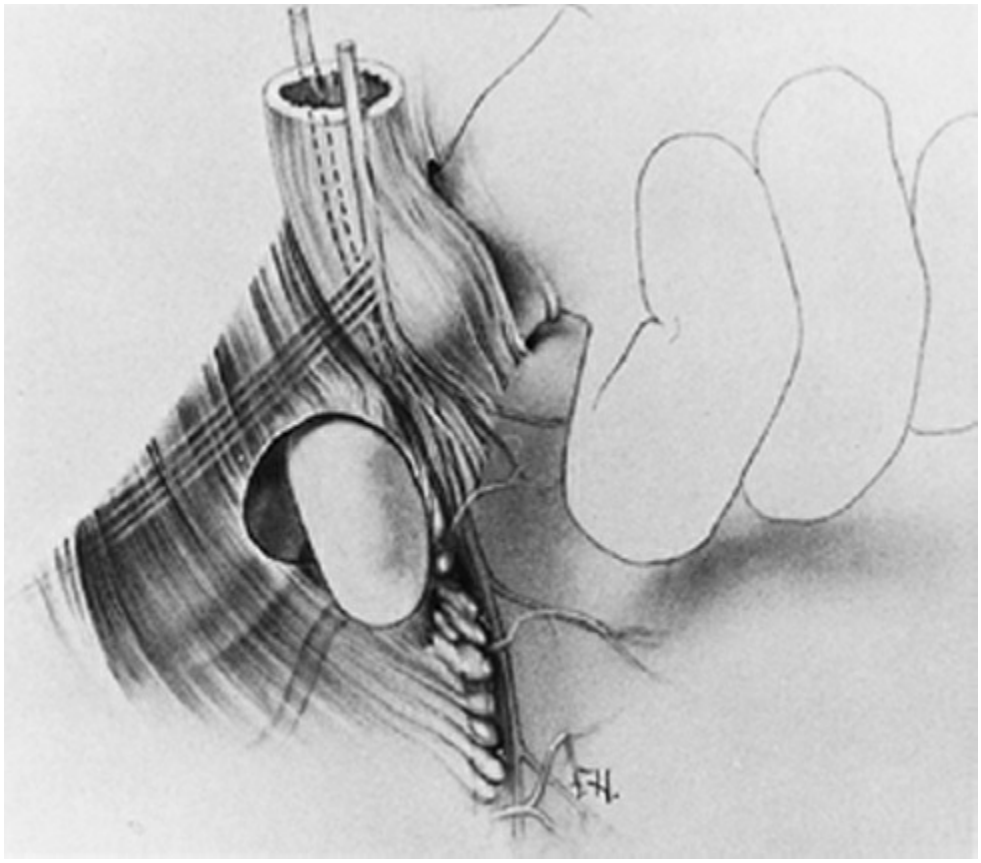

Figure 85.3. Technique for encirclement of the main gastric vagal trunks. (From Griffith, 1986, with permission.)

All remaining tissue anterior to the esophagus (i.e., all tissue between the original incisions in the lesser omentum and angle of His) is dissected from the esophagus with the finger before division between right-angle clamps and ligation. This tissue contains all anterior gastric vagi and some esophageal vessels (Fig. 85.7).

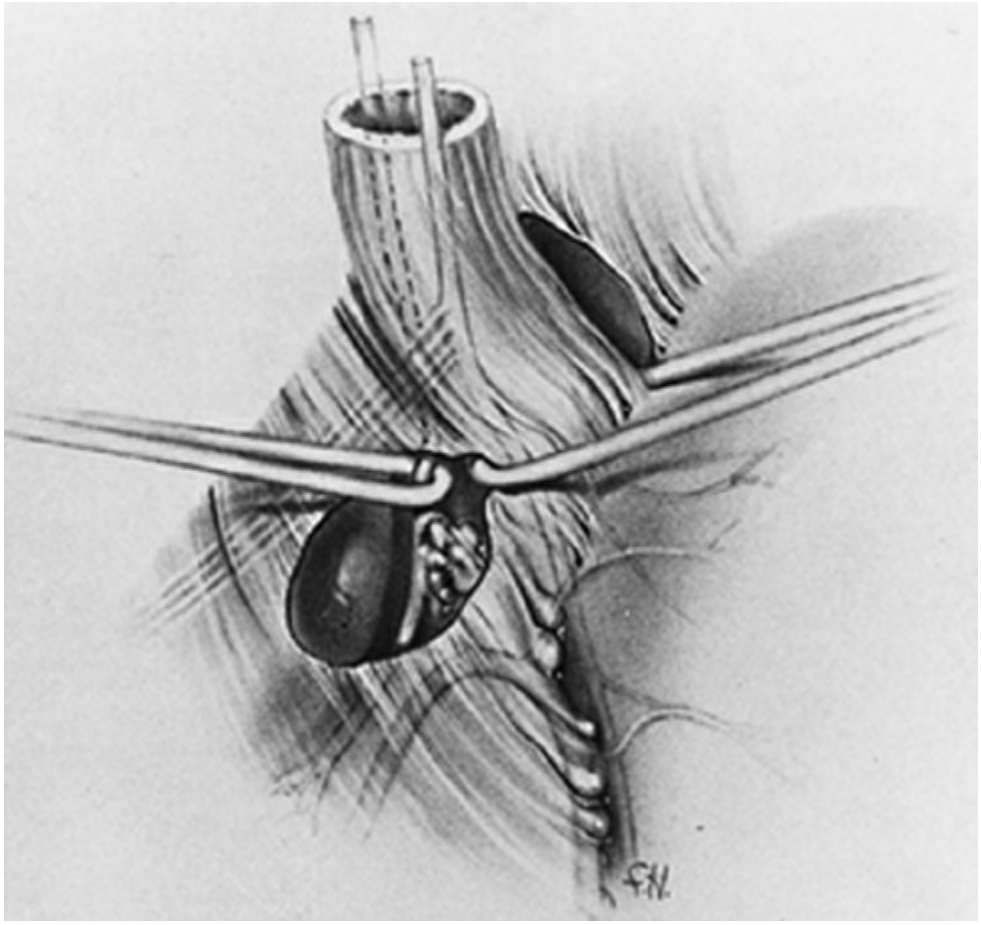

Figure 85.4. Attention to the celiac division of posterior vagal trunks. (From Griffith, 1986, with permission.)

The distal esophagus and gastric cardia are now completely separated from their attachments to all other tissue, including the vagal trunks (Fig. 85.8). The only gastric vagi that can remain are small twigs that may have arisen from the main vagal trunks or esophageal plexus above the surgical field. The usual careful search for the small twigs is, therefore, carefully conducted in and beneath the esophageal fascia propria. The esophageal muscle is thereby bared in its entire circumference. The esophageal muscle is not violated because any nerves found within the muscle innervate the esophagus, not the stomach. Two encircling fingers are used to feel for any intact fibers around the distal esophagus.

FREEING OF THE GREATER CURVATURE

The gastrocolic omentum is perforated in an avascular portion by a curved hemostat, thus permitting the lesser peritoneal sac to be entered. Unless care is taken in the execution of this maneuver, the middle colic vessels can be damaged. To minimize the possibility of such an error, it is

recommended that the anterior wall of the stomach and the transverse colon be elevated and gently pulled apart to tense the gastrocolic omentum. It is easier to find a good cleavage plane by entering the gastrocolic omentum at the level of the junction of the lower and middle third of the greater curvature of the stomach, or even farther to the left; usually, most of the adhesions that tend to obliterate the lesser peritoneal sac are found in the region of the pylorus and lower third of the stomach. At the higher level, it is easy to identify an avascular area between the main trunk of the gastroepiploic vessels and the colon.

After it is certain that the correct plane has been entered, the defect in the gastrocolic omentum is enlarged superiorly and inferiorly, distal to the main gastroepiploic trunk. The avascular portions of the omentum can be divided with scissors or cautery without ligation. When vessels have been identified, the omentum is again perforated on the opposite side of the vessel, and ligatures of 4-0 black silk are passed around the vessel. These ligatures are then tied and the vessels are divided between the ligatures. I have found that there is much less chance of losing a vessel and encountering troublesome bleeding and hematoma formation if the ligatures are tied before the vessels are divided. Often, these vessels are so fragile that the slightest tension on a clamp causes tearing. Superiorly, the greater curvature is freed to a point approximately 14 cm proximal to the pylorus or at a point on the greater curvature perpendicular to the lesser curvature incisura. Transection of the stomach between this point and the middle of the lesser curvature (proximal to the gastric incisura) ensures an antrectomy (approximately a 35% distal gastrectomy) (Fig. 85.9).

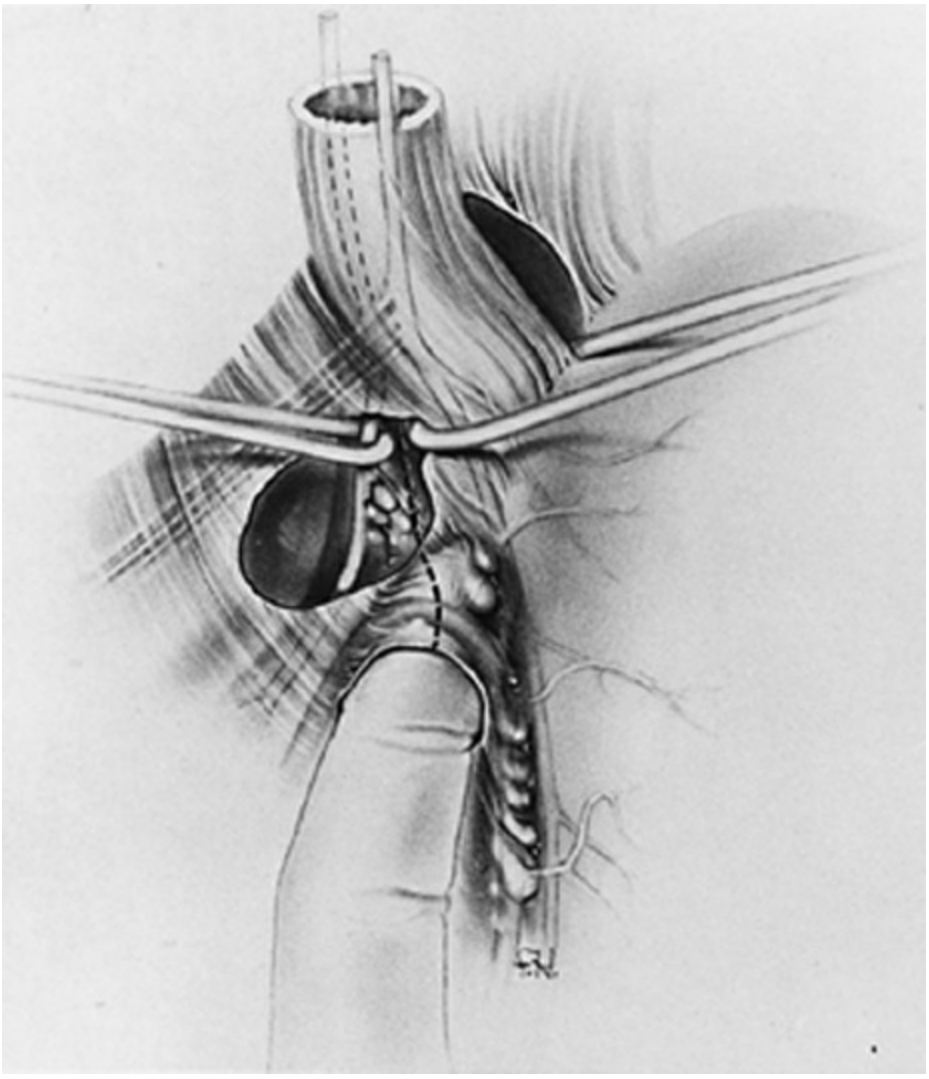

Figure 85.5. Dissection of the gastric lesser curvature, which ensures severance of celiac gastric vagal branches. (From Griffith, 1986, with permission.)

The freeing of the gastrocolic omentum superior to the point of initial breakthrough is carried out distal to the main gastroepiploic trunk. Inferiorly, the omentum is freed–again, distal to the right gastroepiploic trunk–down to a point approximately 5 cm proximal to the pylorus. From this point onward, inferiorly, division of the gastrocolic omentum is carried out between the greater curvature of the stomach and the right gastroepiploic vessel. The main trunk of the right gastroepiploic artery and vein is transected and ligated previously at approximately 5 cm proximal to the pylorus. Special care must be taken from this point on to keep the location of the middle colic vessels constantly in mind.

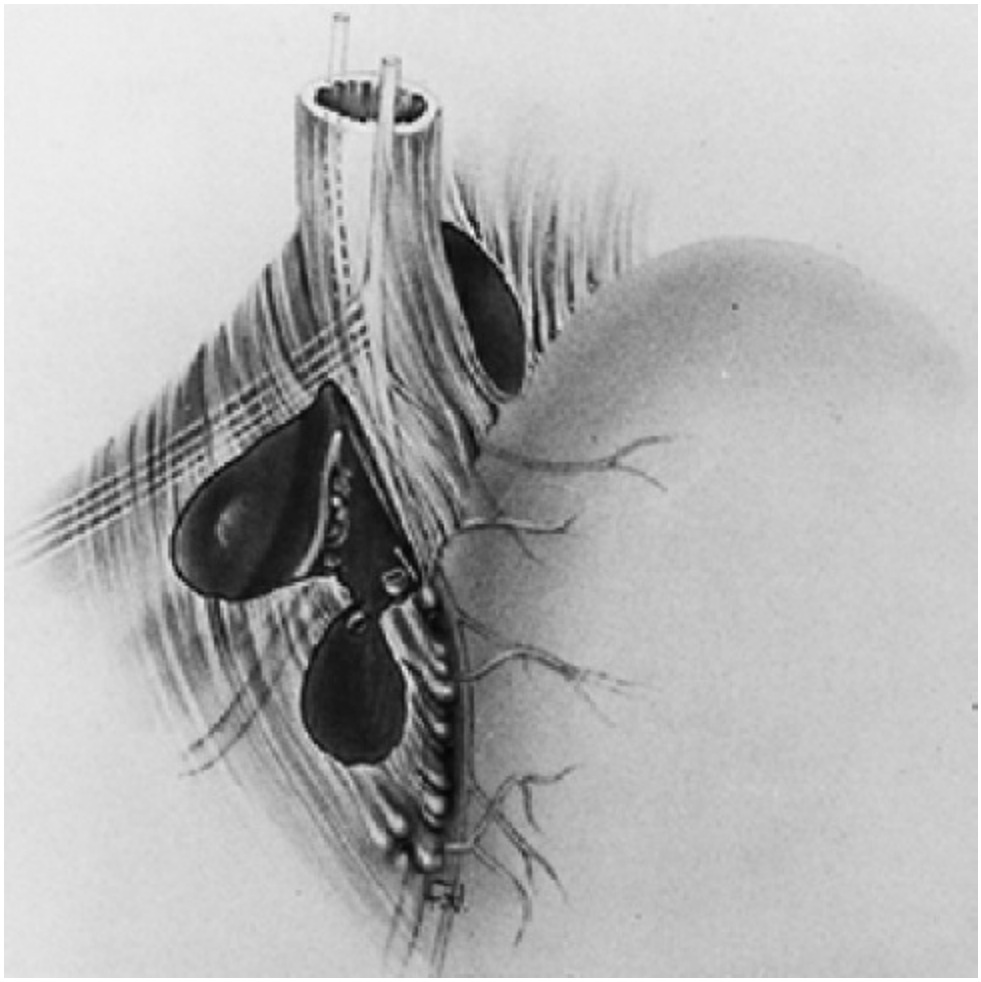

Figure 85.6. Completion of posterior trunk–celiac division (gastric branches) nerve section. (From Griffith, 1986, with permission.)

Approximately at the level of the pylorus, the right gastroepiploic artery at its origin is deep to the line of division of the gastrocolic omentum. Unless the right gastroepiploic vessels are intimately adherent in scar tissue in this region, they can and should be preserved to provide an adequate blood supply to the portion of the gastrocolic omentum that is being left behind. However, when the right gastroepiploic vessels are intimately adherent, and it is impossible to preserve them, they must be sacrificed. Perhaps attempts to protect this vessel represent unnecessary conservatism, but I believe vessels should be preserved if possible. At this point, any readily accessible adhesions to the posterior gastric wall should be divided to allow greater mobility of the stomach.

MOBILIZATION OF THE DUODENUM

One of the most valuable technical contributions to surgery of the stomach

and duodenum is the technique of mobilization of the duodenum originally described by Kocher in 1903. Duodenal mobilization is one of the two phases of the operation best achieved with the surgeon standing on the left side of the operating table. A laparotomy pack is placed on top of the duodenum, and the surgeon pulling the other viscera is positioned to the left side of the patient, which causes the lateral peritoneal reflection of the duodenum to become taut. The peritoneal reflection can then be plainly seen and incised along the lateral margin of the second portion of the duodenum. Then, by gentle, blunt dissection, two fingers can be placed superiorly and inferiorly beneath this layer of the peritoneum. By tenting the peritoneum with the fingers, the peritoneum can be incised with scissors or a scalpel, depending on the preference of the surgeon.

The fascia propria (loose areolar tissue) along the lateral and posterior aspects of the second and third portions of the duodenum is divided by sharp dissection. For the most part, this plane is avascular, although, occasionally, several small bleeding vessels can be encountered. Cautery dissection is often used in this part of the duodenal mobilization.

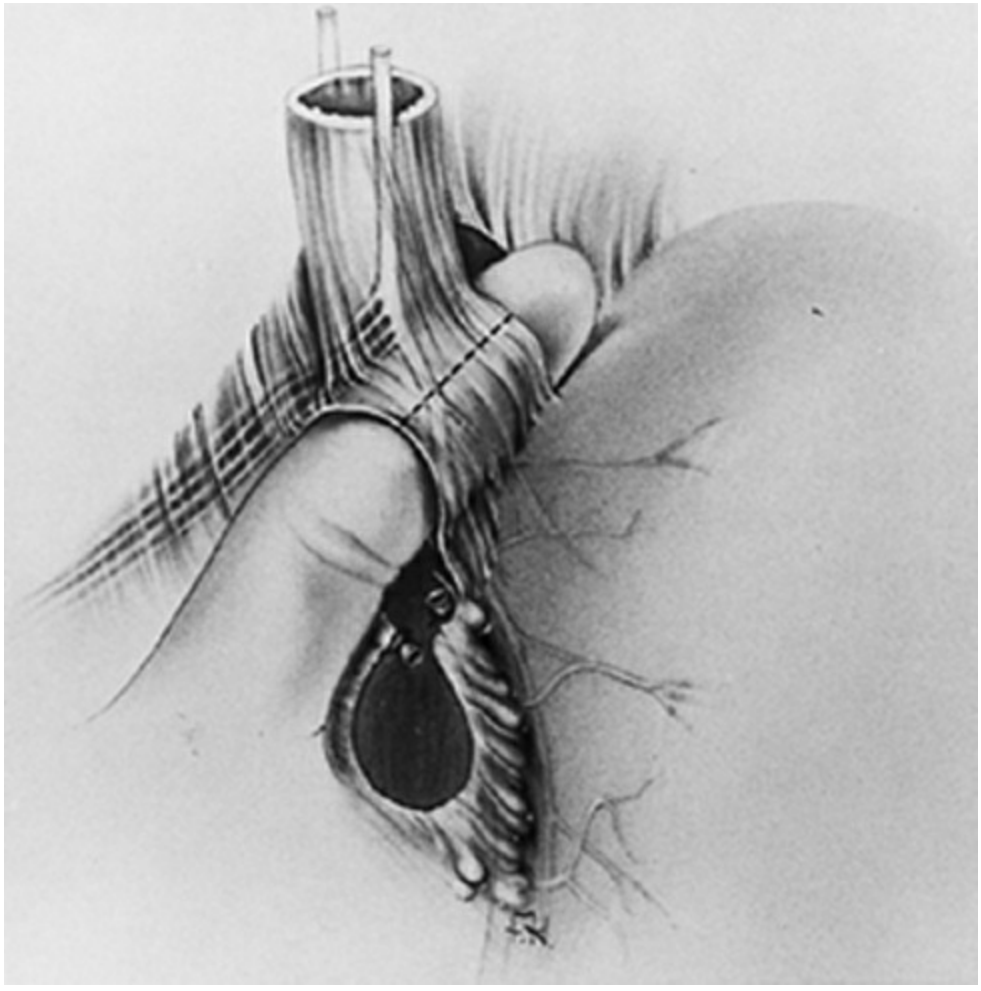

Figure 85.7. Section of all anterior gastric vagal nerves. (From Griffith, 1986, with permission.)

Mobilization is carried out superiorly and proximally to include the superficial avascular portion of the hepatoduodenal ligament. The duodenum is mobilized distally and inferiorly to the point at which the superior mesenteric vessels cross above the third portion of the duodenum. With the duodenum thus mobilized, the second and proximal third portions can be shifted and rotated to the left and superiorly, moving with them the head of the pancreas and the common bile duct. Complete duodenal mobilization should allow visualization of the inferior vena cava. Occasionally, the right margin of the aorta can be seen.

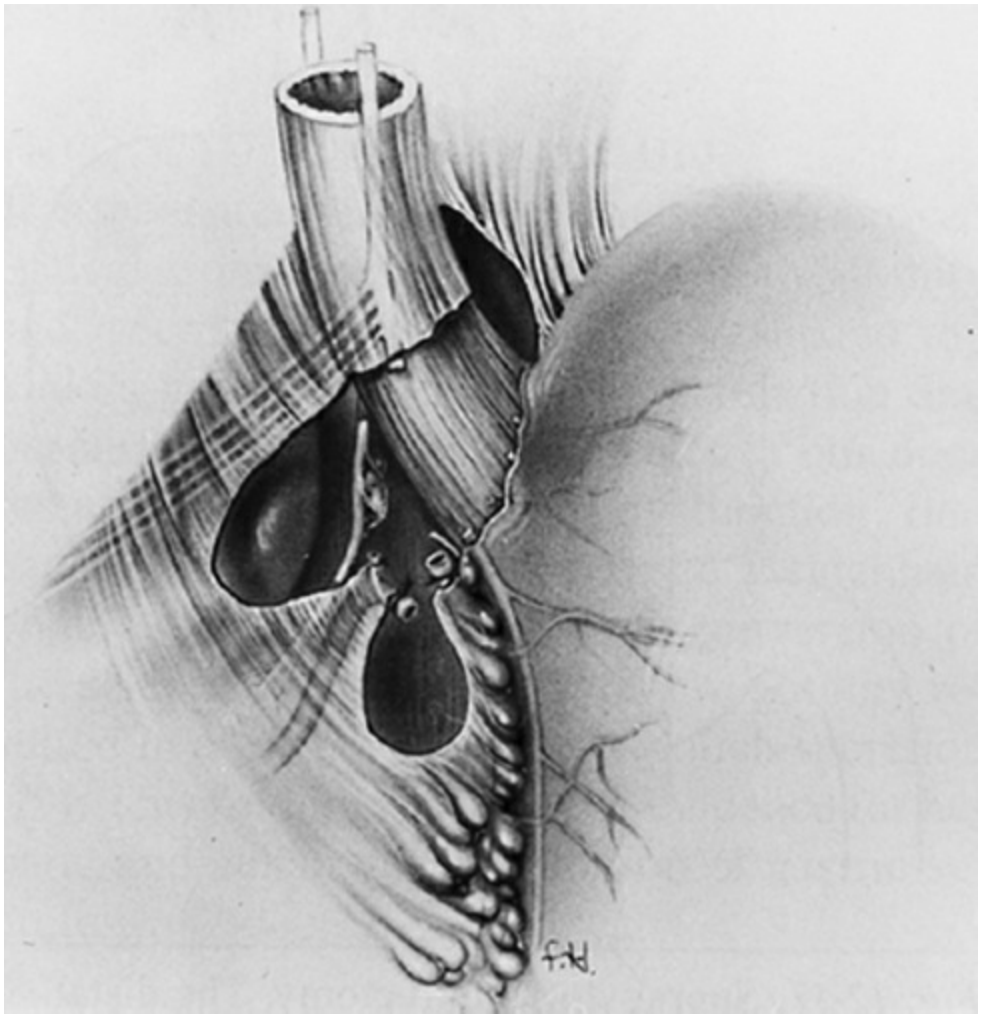

Figure 85.8. Completed dissection of gastric vagal nerves. Hepatic system of anterior vagal branches and posterior celiac vagal nerves preserved; gastric vagal innervation is selectively severed. (From Griffith, 1986, with permission.)

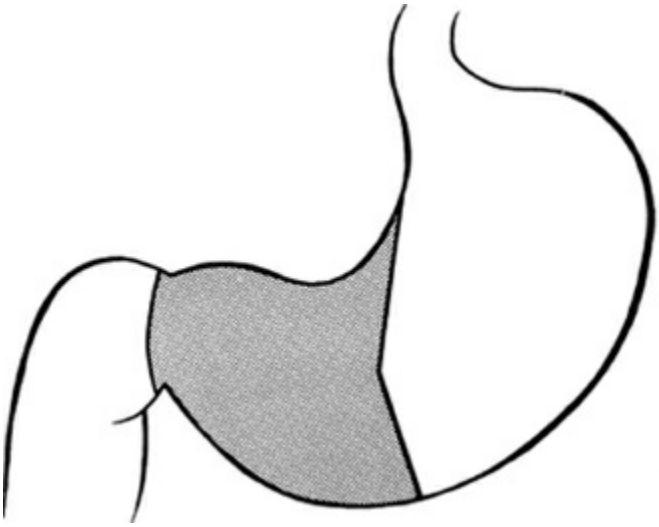

Figure 85.9. Extent of antrectomy (*stippled area*). It should represent a 35% gastrectomy.

The duodenum can usually be mobilized farther than would seem possible. When it appears that the duodenum has been mobilized to its maximal extent, I follow the useful practice of trying again. Usually, some additional degree of mobilization can be gained. After complete mobilization of the duodenum, a moist laparotomy pack should be placed beneath the duodenum to elevate it into the more superficial portion of the surgical field.

Mobilization of the duodenum not only facilitates gastroduodenal anastomosis but also serves two other important functions: (a) it minimizes the chance of injury to the common bile duct by allowing better visualization, and (b) it allows the dissection around the proximal duodenum to be performed in a more superficial part of the surgical field.

After its mobilization, the duodenum is freed, first on its greater curvature (i.e., caudal) side and then on its lesser curvature (i.e., hepatic) side, with division of the right gastric artery and, usually, of the supraduodenal artery of Wilkie.

STRAUSS MANEUVER FOR DIVISION OF THE DUODENUM

The proper and safe division of the duodenum is an important and sometimes difficult maneuver, particularly when one is dealing with posterior penetrating duodenal ulcers. I am indebted to the late Alfred A. Strauss of Chicago for the technique of duodenal division that I use for all duodenal ulcers adherent to the pancreas.

This step is best accomplished when standing at the patient's left side. The maneuver consists of elevating the first portion of the duodenum with a finger placed against the posterior wall of the duodenum, just to the right of the head of the pancreas. To conserve all duodenal length possible, no resection clamps are placed on the duodenum before division. The anterior wall of the duodenum distal to the ulcer scar is incised first with a scalpel as close to the pylorus as the duodenal lesion allows, and the posterior wall is then incised under direct vision from the internal to the external side and at a level just distal to any possible posterior wall ulcer disease. By incising the posterior wall from the inside out, one can minimize the danger of injuring the subjacent structures. If the posterior wall is adherent to the pancreas because of a posterior penetrating ulcer, the duodenal mucosa proximal to the line of division is shaved off the adherent area, leaving the outer portion of the duodenal wall adherent to the ulcer scar. When a posterior penetrating ulcer is situated immediately distal to the pylorus, it is usually possible to obtain a satisfactorily mobilized end of the duodenum distal to the line of transection, and one that is entirely suitable for end-to-end anastomosis. In brief, the Strauss technique involves a separation of the pylorus from in front and to the left rather than from behind and to the right, as is usually done.

However, if the posterior penetrating ulcer lies more distally in the duodenum (beyond approximately 2.5 cm), it is usually necessary to leave the posterior wall of the distal duodenal end attached to the posterior penetrating ulcer and to plan a modified closure of the duodenal stump, as is described later in this chapter. I almost always remove active duodenal ulcers in my resections. However, I occasionally leave active ulcers *in situ* when they are situated in the more distal parts of the duodenum and, so far, I have had no cause to regret doing so.

Under no circumstances should the ulcer crater be excised from the pancreas because this procedure is dangerous and unnecessary.

In performing the Strauss maneuver, the following anatomic facts concerning the duodenum are worthy of attention. In hundreds of gastric resections, after cutting across the duodenum just distal to the ulcer (i.e., approximately 2 cm distal to the pylorus), I have regularly felt for the ampulla of Vater. The index finger of the right hand is used and is inserted with the operator standing on the left side of the table. The distance to the palpated ampulla is then measured; it averages 5.3 cm from the cut end of the duodenum. Thus, the ampulla averages a total of 7.3 cm from the

pylorus. Occasionally, the opening of the duct of Santorini or a pancreatic lobule may be mistaken for the ampulla. Sometimes the ampulla cannot be palpated, but the palpation generally seems accurate.

Having identified the exact point at which the common bile duct enters the duodenum, the surgeon can proceed with more assurance that he or she will not interfere with this important ostium. After complete division of the duodenum, a sponge is placed in the distal end and another sponge is tied loosely about the proximal end to avoid gross spillage of bile and other contents. As stated previously, the final disposition of the duodenal stump is decided *after* an adequate resection has been performed.

With the Strauss maneuver, one can remove the duodenal ulcer in most instances. Its advantages are (a) it stops bleeding if present, (b) it removes enough duodenum to give assurance that the antrum is out, (c) it eliminates the indeterminate period an unremoved ulcer takes to heal, and (d) it provides a clean duodenum for anastomosis or closure.

DIVISION OF THE GASTROHEPATIC OMENTUM AND LEFT GASTRIC VESSELS

The gastrohepatic omentum is usually a thin layer of peritoneum with a minimal amount of fat, although the latter is somewhat variable. At a distance of 1.5 to 2.0 cm from the lesser curvature, no sizable blood vessels are encountered until the level of the left gastric vessels, which are in a separate fold placed more posteriorly. A good portion of the dissection of the gastrohepatic omentum can be carried out without ligatures and, usually, it is necessary to ligate only two or three rather small vessels before the left gastric vessels are reached. This part of the dissection is usually easy, but some difficulty can be encountered when there is thickening, scarring, and inflammatory reaction secondary to a gastric ulcer on the lesser curvature. The hepatic branch of the left vagus nerve lies in this curvature just above the level of the left gastric artery. It should not be cut, although cutting this branch makes no difference if a truncal vagotomy is performed above this level.

The left gastric artery is the largest artery supplying the stomach, and, occasionally, division of this vessel gives rise to difficulty. It is usually surrounded by a moderate amount of fat, which is increased in elderly patients, making it difficult to identify the lesser curvature margin of the stomach. In addition, dissection of this vessel is more hazardous if there is scarring or an inflammatory reaction around it secondary to ulceration on

the lesser curvature of the stomach.

A word of caution should be interjected at this point concerning the occasional origin of an aberrant left hepatic artery from the left gastric artery. Sometimes this vessel constitutes the sole blood supply to the left lobe of the liver, and its sacrifice would almost certainly mean necrosis of the lobe. Therefore, it is worthwhile to examine carefully the configuration of the left gastric artery and its branches and to make certain that the vessel is divided distal to any such possible aberrant hepatic branch. Generally, in patients with benign disease, I ligate the left gastric artery, after it has divided, close to the stomach. This method is easier and avoids unnecessary clamping of the celiac branch of the posterior vagus nerve, although, again, if a truncal vagotomy is to be performed, such clamping makes no difference.

RESECTION

The lines of resection of the stomach should now be decided. For duodenal ulcer, if selective vagotomy has been performed, a distal resection of 30% to 35% is sufficient (Fig. 85.9). The extent of resection and the exact placing of the line of resection are important. The antrum is higher along the lesser curvature than along the greater. Thus, it is important to do a Schoemaker type of tubing of the lesser curvature, removing the stomach at a higher level at the lesser curvature than at the greater curvature.

When the site of transection of the stomach has been selected, an Allis clamp is placed on the greater curvature just distal to the selected site. A small Payr clamp is then applied perpendicular to the greater curvature at the selected level and extended across the width of the stomach for a measured distance of 5 cm (Fig. 85.10). The clamp is closed and a Carmalt clamp is placed just distal to the Payr clamp and parallel to it. The walls of the stomach between the two clamps are incised with a scalpel to a point just distal to the tip of the Payr clamp (Fig. 85.11). The two clamps are separated widely, and a GIA or TAA stapler is then angled up to the lesser curvature side of the stomach, approximately 2 to 3 cm below the esophagogastric junction. A double row of staples is then placed along the line of application of the stapler, and the stapler is removed. The anterior and posterior walls of the stomach are then divided between the double row of staples (Fig. 85.12). Just before the division of the upper portion of the lesser curvature of the stomach is completed, a 4-0 silk suture is placed in the form of Lembert suture just above the most superior staple. Using

this suture for traction to prevent the upper portion of the Schoemaker line from retracting upward, the remaining stomach between the double row of staples is completely incised, and the specimen is removed from the surgical field. Occasionally, a few small vessels bleed between the staples. These bleeding points should be clamped and ligated with 4-0 black silk ligatures to achieve complete hemostasis. Otherwise, troublesome hematomas can form and prevent satisfactory closure of the Schoemaker line.

Figure 85.10. Transection of a stomach. A small Payr or another crushing clamp is placed perpendicular to the greater curvature for a distance of 5 cm across the stomach. To achieve a 30% to 35% distal gastric resection (i.e., antrectomy), this Payr clamp is placed approximately 14 cm proximal to the pylorus. The broken line shows the proposed line of excision of the lesser curvature.

CLOSURE OF THE SCHOEMAKER SUTURE LINE

The stapled closure of the Schoemaker suture line is now oversewn by interrupted 4-0 black silk Lembert sutures placed close enough to obtain

continuous serosa-to-serosa approximation. These reinforcing sutures are placed to a point 1 cm above the tip end of the Payr clamp. This terminal 1 cm is left unsutured until the anastomosis is completed (Fig. 85.13).

Figure 85.11. A Carmalt clamp is placed parallel to Payr clamp. The stomach is divided between the two clamps, and a mechanical stapling device is placed along the proposed line of excision of the lesser curvature.

ANASTOMOSIS

At this point, the type of anastomosis must be chosen. There are few instances in which a gastroduodenal anastomosis cannot be performed and, usually, this anastomosis can be of the end-to-end type. In difficult situations, the scope of the Billroth I anastomosis can be greatly extended by use of the von Haberer–Finney end-to-side anastomosis, particularly when the proximal cut end of the duodenum has to be left attached to the distal margin of a posterior penetrating duodenal ulcer.

The anastomosis should not be forced (i.e., performed under tension). If

the surgeon believes it is technically difficult to use the duodenum in reestablishing gastrointestinal continuity, a gastrojejunal anastomosis should be performed (Billroth II). If the end-to-end type of anastomosis is decided on, the anastomosis is achieved by an outer row of interrupted 4-0 noninverting black silk Lembert sutures. The inner row is closed with a continuous 4-0 absorbable suture that includes only the mucosa and submucosa (Fig. 85.14). During the course of the anastomosis, it may be necessary to ligate several bleeding points in the end of the gastric stump.

When the anastomosis is complete, special care is taken to reinforce the critical angle (i.e., the point of junction between the Schoemaker suture line and the anastomotic line). The reinforcement consists of the placement of a 000 black silk purse-string suture, taking a bite of the anterior wall of the stomach, the posterior wall of the stomach, and the wall of the duodenum at the critical angle. When this suture is tied down, there is good serosal apposition of all three components–namely, the anterior gastric wall, the posterior gastric wall, and the wall of the duodenum (Fig. 85.15). The completed anastomosis should admit one to two fingers.

If the end of the duodenum is unsuitable for end-to-end anastomosis, I prefer to use the terminolateral modification of the Billroth I procedure rather than a Billroth II anastomosis. As stated previously, the main reason for the unsuitability of the end of the duodenum for anastomosis is the presence of a posterior penetrating ulcer. Under these circumstances, a modified type of duodenal stump closure is achieved using the method described by Nissen (Fig. 85.16). This method consists of suturing the free anterior wall of the duodenum to the distal margin of the ulcer crater in the pancreas and then rolling the anterior wall of the duodenum in such a manner that it covers the ulcer crater.

After the closure of the duodenal stump, an end-to-side gastroduodenal anastomosis is performed just distal to the duodenal stump closure. The resultant anastomosis is the same size as, or slightly larger than, the end-to-end anastomosis. When the end-to-side gastroduodenal anastomosis is used, the ampulla of Vater can be opposite the gastroduodenal stoma.

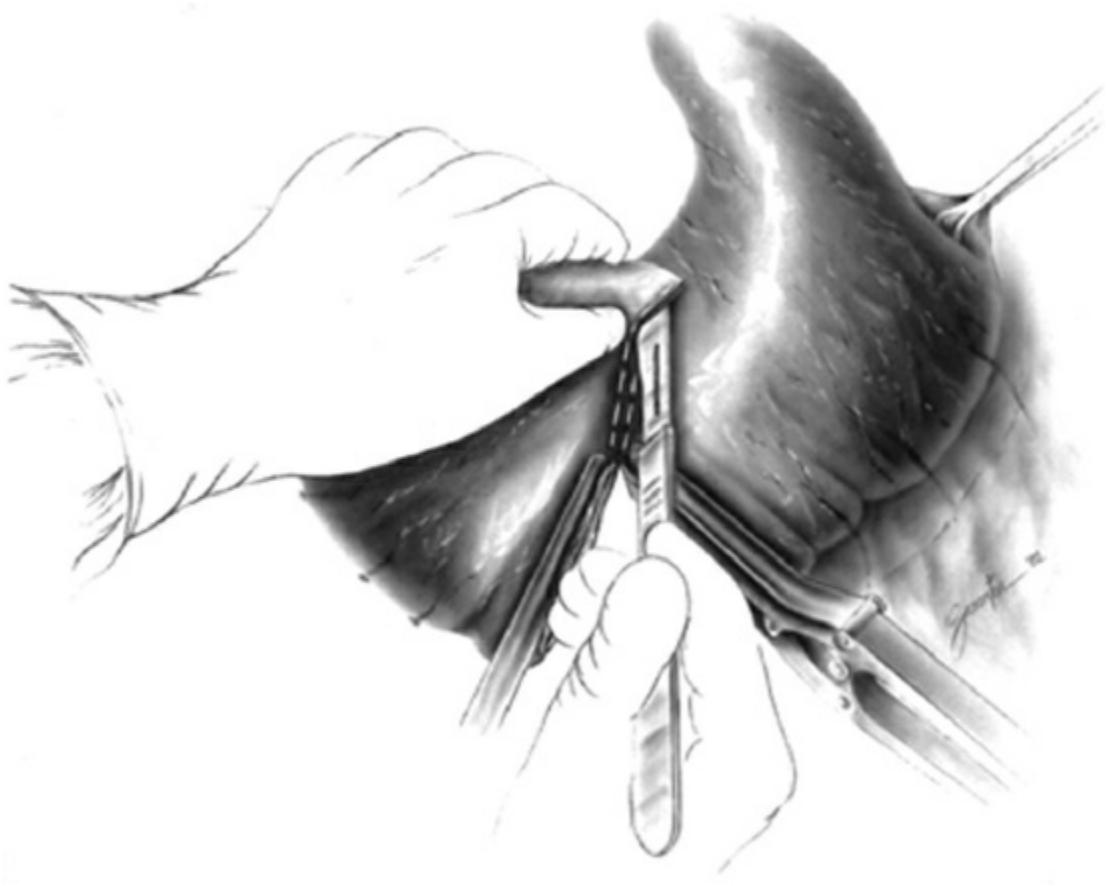

Figure 85.12. A double row of metallic hemostatic clips. The stomach is divided. Any of a number of stapling instruments can be used to close the lesser curvature.

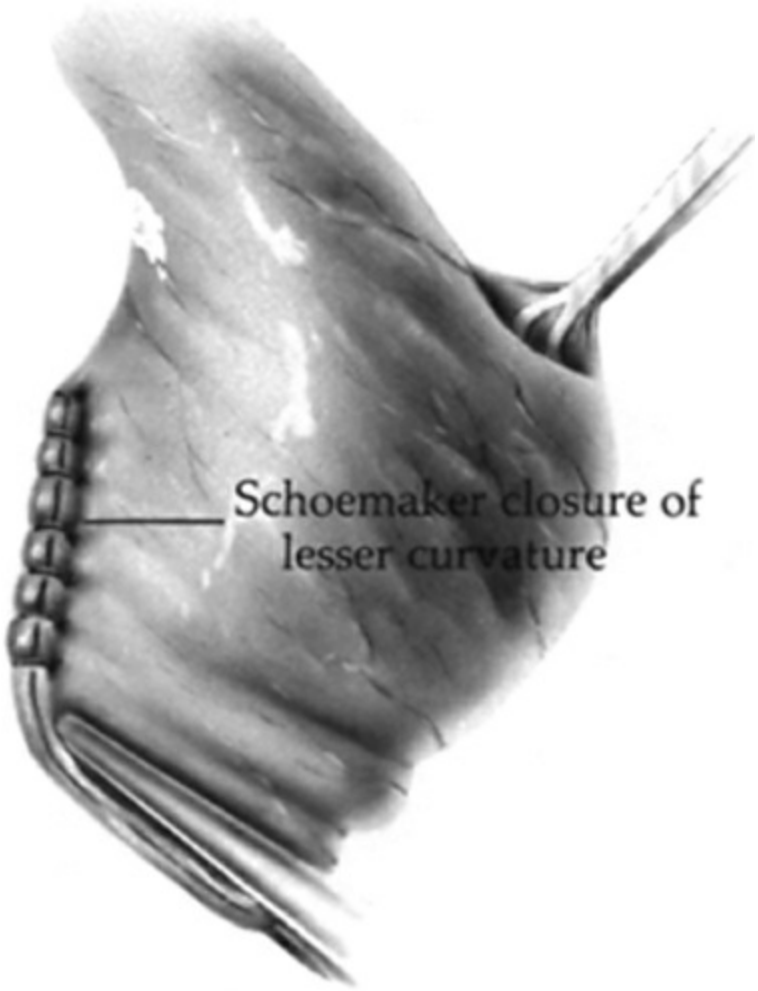

Figure 85.13. The Schoemaker closure of the lesser curvature with interrupted Lembert sutures of 4-0 black silk.

Figure 85.14. The end-to-end anastomosis. The posterior row of interrupted 4-0 black silk seromuscular sutures has been placed. The inner continuous absorbable hemostatic (baseball stitch) suture is seen.

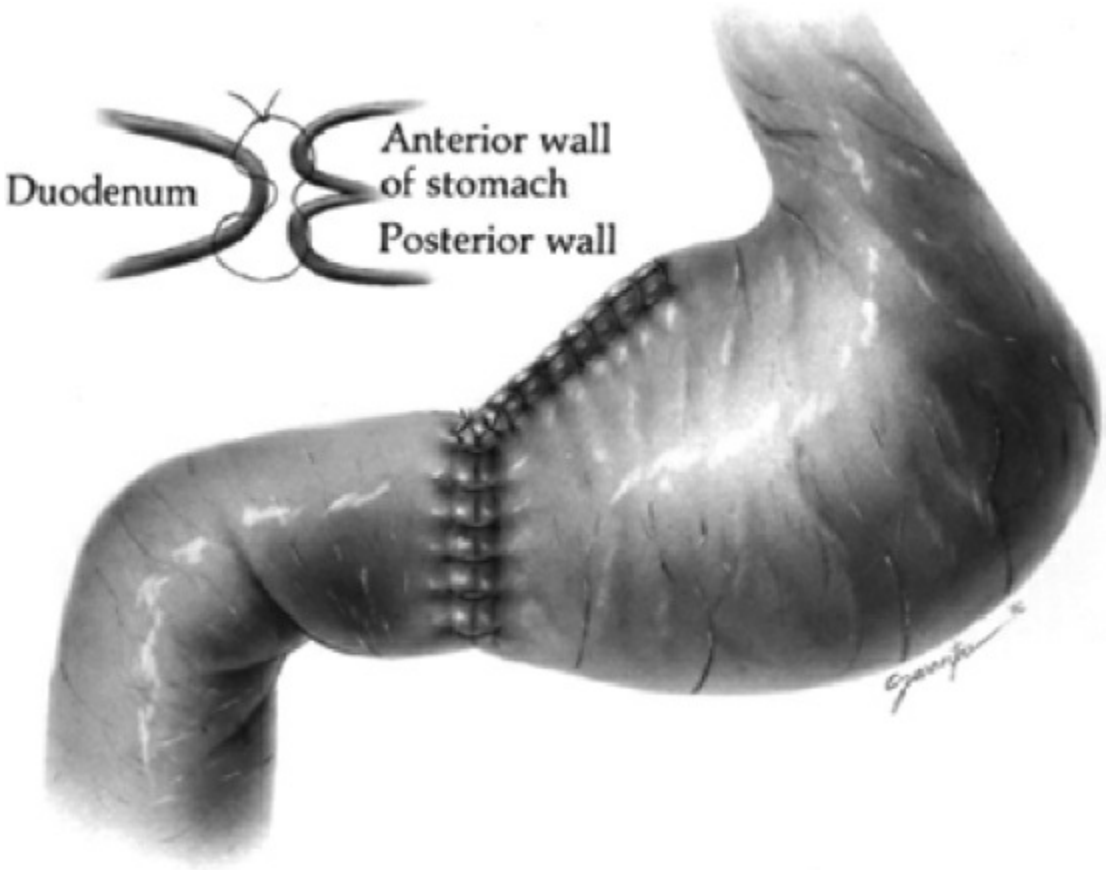

Figure 85.15. Completed operation—selective vagotomy, antrectomy, and gastroduodenostomy. Infolding of the stomach at the corner of the Schoemaker closure of the lesser curvature and the duodenum at the superior portion of the anastomosis (*inset*). This suture, which usually involves two bites to the stomach and one or two to the duodenum, protects against an anastomotic leak at this potentially weak part of the closure. The suture should be a deep Lembert and should not enter the lumen of either viscus.

WOUND CLOSURE

I make no attempt to close the peritoneum and have noted no difficulty or complication arising from this omission. It seems that the ligamentum teres of the liver and the falciform ligament quickly adhere and can form a more anatomic peritoneal closure than would be accomplished by suture. The fascia of the linea alba is closed by interrupted nonabsorbable sutures. No subcutaneous sutures are used, and, after closure of the fascia of the linea alba, the skin edges are approximated.

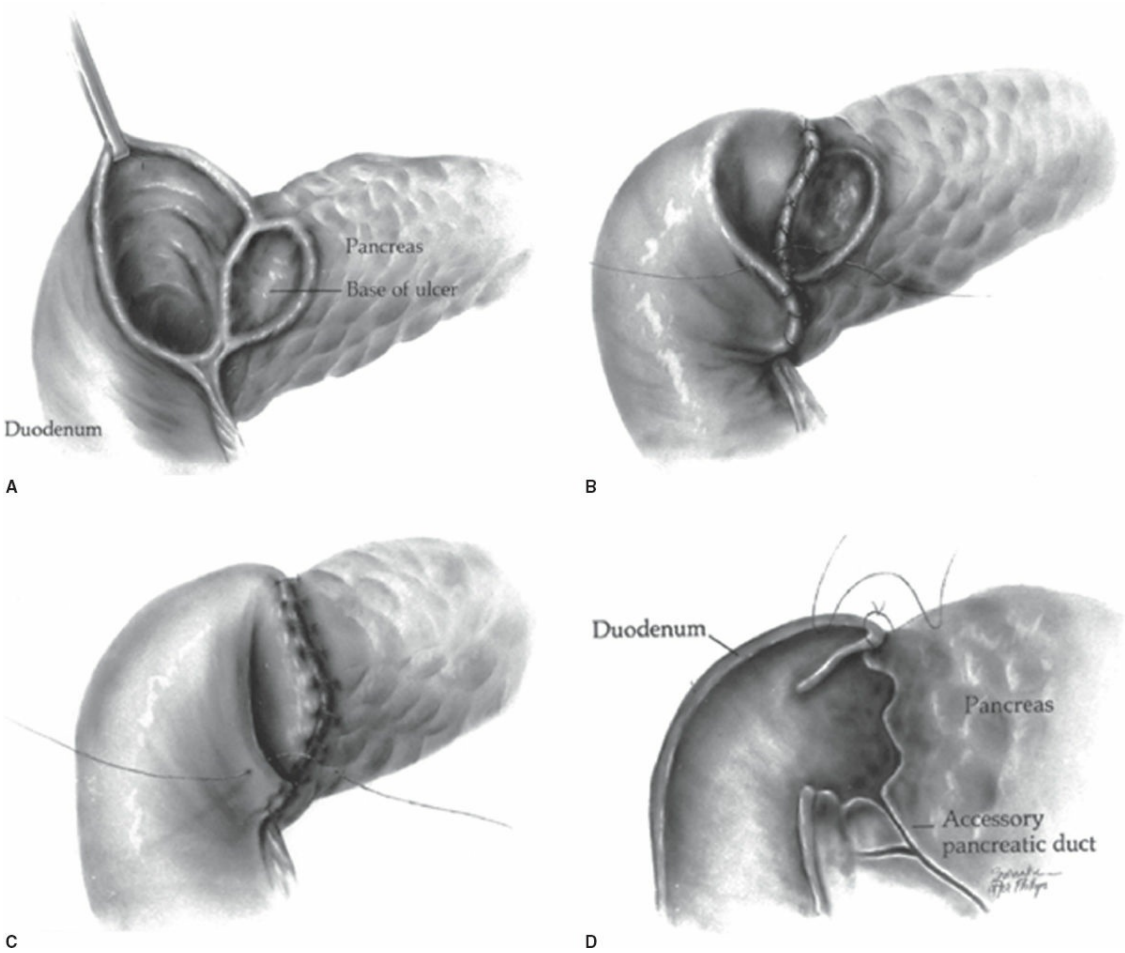

Figure 85.16. Closure of the difficult duodenal stump when a terminolateral anastomosis is contemplated (i.e., closure after the method of Nissen). **A:** The distal duodenum is adherent posteriorly to the distal margin of the ulcer bed. **B:** The anterior duodenal wall is sutured to the distal margin of the ulcer bed, and a second row of sutures is begun, suturing the anterior wall to the proximal ulcer margin. **C:** The second row is completed, and the third and final row is begun, folding the anterior duodenal wall against the capsule of the pancreas proximal to the ulcer. **D:** This cross section shows the omission of the first row of sutures when an accessory pancreatic duct opens into the ulcer bed. This omission allows pancreatic juice to drain into the duodenal lumen.

EDITOR'S COMMENT

This chapter is one of the classic chapters in this book written by an acknowledged master of gastric surgery, Dr. Lloyd Nyhus.

Gastric surgery, of course, has largely disappeared from academic and other medical centers in the country, except for gastrointestinal bleeding from duodenal ulcers that is not amenable to endoscopic intervention. Historically, gastric and duodenal ulcer surgery, as well as gastric cancer, was a major part of

a residency program and of a surgeon's armamentarium. The referral patterns in the United States differ somewhat from those of the United Kingdom, which is what explains the different approaches to duodenal ulcers, even today. In the United Kingdom, the primary care physician cares for the patient; endoscopists see the patient occasionally. Duodenal ulcer is still considered a surgical disease when *Helicobacter pylori* eradication does not work or when *H. pylori* is not present. Thus, patients are referred early. To take someone with relatively moderate or mild-to-moderate symptoms with duodenal ulcer and render them a gastric cripple is considered inappropriate. Thus, early on, the differences in referral patterns in the United Kingdom have rendered the approach to duodenal ulcer quite different than that in the United States, and that is to accept a certain amount of recurrence in exchange for a patient who is functional and not a gastric cripple following operation.

In the United States, referrals are late, often with people who are in the last quintile of their disease and who are extremely disabled with gastric outlet obstruction, crippling pain, anorexia, several bleeds, perforations, and so forth. Here, the emphasis on the lack of recurrence is often compromised as far as the long-term outcome regarding gastric function is concerned.

Historically, the original standard operation for duodenal ulcer was subtotal gastrectomy, and I mean subtotal. The stomach was transected at the first branch of the left gastric artery, cutting across to a short gastric artery in which the second or third short gastric artery had been ligated in continuity. This really was an 80% gastrectomy. Many of the patients were gastric cripples with a small-pouch syndrome, weight loss of 20 and 25 pounds, and an inability to eat a full meal. In retrospect, this approach became even more unacceptable with a recurrence rate of approximately 7%. In the late 1950s and early 1960s, in an effort to get a better functional result, patients started to undergo hemigastrectomy or antrectomy and vagotomy, in which the antrectomy was approximately 35% to 50%, and the recurrence rate should have been less than 1%. The most classic series of antrectomies and vagotomy was that of the 3,000 hemigastrectomies and vagotomies of John Sawyer and Linwood Herrington, which they reported in *Current Problems of Surgery*, with only 12 recurrences; as I recall, three were as incomplete vagotomy and the others were endocrinopathies, including hyperparathyroidism and the Zollinger–Ellison syndrome.

We then progressed in this country to pyloroplasty and vagotomy, which had all the disadvantages of resection, plus a 15% to 20% recurrence rate, and to my way of thinking, unless there was an unapproachable duodenum, offered little. Parietal cell vagotomy does offer a great deal more. It is my standard operation for women who usually do not tolerate any gastric resection without significant symptoms and weight loss.

In this operation, which has University of Washington origins, Dr. Nyhus probably gives too much credit to Drs. Griffith and Harkins and little to himself. All the gastric vagal fibers are severed and the celiac and hepatic branches are

maintained; the celiac is maintained so that postvagotomy diarrhea is not present, and the hepatic nerves remain to minimize the influence of the vagotomy on gallstones later in the course.

The antrectomy is somewhat different than the one I was taught to do, in which I resect the stomach from the second branch of the left gastric to the confluence of the bare area between the left gastroepiploic and the right gastroepiploic. This is more like a 50% gastrectomy but has the advantage that the reconstruction is not as difficult as it is here in the Schoemaker approach, which I was taught as the Kelling Madlinger approach, and which was usually used for a high, lesser gastric ulcer that was benign.

The selective vagotomy never caught on, and truncal vagotomy continues to be the standard of most gastric operations in antrectomy and vagotomy. The anterior portion of the vagotomy emphasizes that ones does not take down the esophageal hiatus and that the branches that one is looking for, which are anterior, are right at the hiatus, perhaps thus sparing an increased incidence of hiatal hernia following truncal vagotomy, which I believe exists. It is the posterior aspect of this dissection, taking the posterior gastric branches and the vagus and sparing the celiac nerve to the celiac axis, that makes this more difficult and why it has never really caught on.

Why not perform a proximal gastric vagotomy or a highly selective vagotomy, or a parietal cell vagotomy, which are synonyms for the same operation? That is an easy answer. The parietal cell vagotomy, and whatever else it is called, is performed because it retains the motility to the lower part of the stomach and the pyloric-emptying mechanism. Here one is resecting that portion of the stomach in which one wants to maintain the emptying capacity, and so one never gets to save the crow’s foot.

In preparing the patient for an operation today, most patients are taking a protein pump inhibitor, which means that they may have all sorts of organisms that make this not a clean case or even a slightly contaminated case, but basically a clean, contaminated case, not unlike colonic resection. In addition, in patients who are partially obstructed, *Clostridium myositis* is considerably more common after gastric resection in which the stomach is obstructed. Mushrooms are a notable source of *Clostridia*, and I have seen a number of cases in which the preparation for the operation did not include antibiotic prophylaxis and clostridial myositis resulted.

Some technical aspects have evolved since this chapter was originally written. The sutures are different. I happen to use two layers of interrupted 4-0 silk, plus a triangle of the sutures as described by Dr. Nyhus at the angle of death, or the confluence of Hoffmeister turn-in, as I call it, and the Schoemaker turn-in, as Dr. Nyhus calls it. The reason that I use two layers of interrupted suture is so as not to render the gastroduodenostomy stenotic, which happens when one is using a running suture. I do not generally drain these except when, in order to close the duodenum, one must take the small branches from the pancreas to the duodenum, several of which encompass and include small

pancreatic ducts. In that case, a closed-suction drain, such as the Blake drain or Jackson Pratt drain, should be left close to, but not immediately adjacent to, the anastomosis.

I differ with Dr. Nyhus with all due respect in certain ways that the technique is described. Dr. Nyhus insists on leaving the transection of the stomach for the last thing. To my way of thinking, this compromises the ease of the operation if the distal stomach is separated first and then one can use this stomach as a handle, especially to get behind the duodenum and get length as one is taking down the duodenum for closure. I do ligate the small branches of the pancreas, including the ducts in continuity using a right angle Jacobson clamp to pass 4-0 silk sutures behind, tying them in continuity and then dividing between them with a Potts biliary scissors.

Dr. Nyhus, for some reason, seems to insist on trying to do a resection of the ulcer even when there is foreshortening of the duodenum and the first portion of the duodenum is nonexistent, with the common bile duct very close to the ulcer. To my way of thinking, this is an excellent indication for a vagotomy and drainage in which a gastrojejunostomy avoids the possibility of injuring the common bile duct. It has a 15% to 20% recurrence rate, not terribly different from what subtotal gastrectomy used to be, and much lower than a proper antrectomy and vagotomy, but it is much better than a severed or damaged common duct.
