There are several technical details of the operation that I think are difficult. The first is the separation of the posterior vagus and the celiac nerve so that one can ligate and divide the gastric fibers, which go to the acid-reducing portion of the stomach, while the celiac nerve continues on its way. This is done bluntly and, needless to say, many of our young surgeons have so little experience in gastric surgery and vagotomies that it will be difficult for them to perform this aspect of the operation. I will point out that in this technique the vagus is not encircled, and this may make it more difficult. In addition, in the blunt separation of the esophageal fibers, both vessels and nerves from the body of the vagus nerve may lead to an increased incidence of postvagotomy dysphagia, which I have seen a number of times. If it persists, one usually ends up dilating them with Maloney or other types of dilators and it improves. An occasional patient, however, has continued esophageal spasm and does require something else, such as a Heller myotomy or some other kind of spasm-relieving operation.

In this country, in the absence of much in the way of ulcer surgery in most centers, there is not a great deal of activity. However, one series of hospitals has recorded a fair number of vagotomies for duodenal and gastric ulcers, and especially bleeding ulcerations, and that is the Veterans Administration (VA) system. The VA system, of course, has initiated the National Surgical Quality Improvement Program (NSQIP). This has a wealth of information, which de la Fuente et al. (*J Am Coll Surg* 2006;202(1):78) used to compare vagotomy and resection with vagotomy and pyloroplasty. The results are somewhat surprising,

as they compared outcomes, recurrent ulcers, and 30-day postoperative morbidity and mortality, and rebleeding and the postoperative length of stay. All patients in this 11-year period were included in this review. Patients were compared according to age, ASA class, presence of ascites, coma, diabetes, functional status, hemiplegia, and history of steroid use, among others. All of these were markers or predictors of postoperative death. Having a resective procedure (hemigastrectomy and vagotomy, the ASA classification hemiplegia, history of chronic obstructive pulmonary disease, and requiring a ventilator increased the length of hospital stay. The interesting finding of this study was that in comparing vagotomy and drainage with vagotomy and resection, the incidence of cardiac arrest was 5.8% in the vagotomy and drainage group and 7.5% in the resection group; myocardial infarctions were 2.12% in the vagotomy and drainage group and 0.51% in the vagotomy and resection group, which is somewhat surprising. Vagotomy of the mortality rate was identical, another surprising feature, with an 18%, 30-day mortality rate in vagotomy and drainage (n = 518) and 17.2% mortality rate in vagotomy and resection (n = 389). These findings are quite interesting because they are not what one would expect, although most of the patients who died really had many comorbidities, as one might expect from one's experience in the VA system.

There has been much activity, especially in Japan, in the technique of duodenal anastomoses, which involves stapling. Omori (*Surg Endosc* 2005;19:734) used a duodenotomy just distal to the pylorus, in which he inserted the anvil as well as a side EEA stapler through the distal stomach with good results. Takeuchi et al. (*World J Surg* 2005;29:113) used a similar side-to-end gastrojejunostomy. This was performed in 18 consecutive patients in whom the side-to-end anastomosis was carried out first and then the stomach was resected. Kuwabara et al. (*J Am Coll Surg* 2004;198(4):670) used another technique of EEA stapling for a gastroduodenostomy. Although all of these are interesting, having done much postgastrectomy work, the tendency, certainly in the stomach and perhaps elsewhere, is for gastrojejunostomies as well as gastroduodenostomies that are done with staplers to stricture. That would be my objection to this technique. A two-layer, interrupted suture, end-to-end gastroduodenostomy is probably preferred and gives the best results, in my experience.

J.E.F.

86 Selective and Nonselective Vagotomies

Theodore N. Pappas and Mohan K. Mallipeddi

INTRODUCTION

The understanding and management of peptic ulcer disease (PUD) have drastically changed over the past two centuries. In the 19th century, scientists and clinicians demonstrated that the stomach not only contained but also secreted acid. However, it was not until the early 20th century that clinicians began associating gastrointestinal ulcers with acidity. In 1902 Ivan Pavlov demonstrated that the vagal nerves were responsible for stimulating gastric acid secretion during the cephalic phase of digestion. Shortly thereafter surgeons began experimenting with vagotomy as a means of suppressing gastric acid secretion. Although Andre Latarjet is credited with performing the first truncal vagotomy for the management of peptic ulcers in 1922, it was Lester Dragstedt who popularized the clinical use of vagotomy nearly two decades later. Over the subsequent years, the operation evolved into various forms with associated drainage, resection, and/or reconstruction procedures.

The three main types of vagotomy are truncal, selective, and highly selective (a.k.a. parietal cell or proximal gastric). Truncal vagotomy entails division of both the anterior and posterior vagal trunks at the esophageal hiatus above the origins of the hepatic and celiac branches. Thus, this method results in indiscriminant vagal denervation of abdominal viscera. A drainage or resection/reconstruction procedure is compulsory with such a vagotomy. This operation has the highest mortality and morbidity but lowest rate of recurrence. Selective vagotomy entails division of the vagal trunks distal to the origins of the hepatic and celiac branches. This added complexity does not obviate the need for a drainage procedure and a prospective trial comparing truncal and selective vagotomy did not reveal statistically significant differences in dumping syndrome, diarrhea, or other lifestyle limiting signs and symptoms. Finally, highly selective vagotomy (HSV) entails division of the vagal fibers to the acid producing

parietal cells of the gastric cardia while maintaining those to the antrum and other viscera. This version has the lowest mortality and morbidity but the highest recurrence rate owing to its technical difficulty.

The era of surgical predominance in managing PUD has long since yielded to the current era of medical therapy. This transition was driven by better appreciation and targeted treatment of the major causative factors of PUD—for example, combination therapy for *Helicobacter pylori,* proton pump inhibitors (PPIs) for acid oversecretion, smoking cessation, and more judicious use of nonsteroidal anti-inflammatory drugs. The efficacy of modern medical therapy has rendered surgical management virtually obsolete such that, in those instances when surgery is warranted, there are few surgeons comfortable with all of the classic operations.

INDICATIONS

Surgical management of PUD is warranted for (1) treatment of complications (bleeding, perforation, and gastric outlet obstruction [GOO]), (2) intractability despite maximal pharmacologic therapy, (3) suspicion of malignancy, and (4) select causes beyond the scope of medical management, such as gastrinoma or patient noncompliance. However, surgical management does not always involve vagotomy. We discuss the nuanced role of vagotomy in the case of bleeding or perforation below. Treatment of GOO is included in the discussion of drainage procedures later in the chapter. The management of malignancy is beyond the scope of this chapter. The other indications for surgery do in fact call for vagotomy.

Gastrointestinal hemorrhage in the setting of PUD resolves with medical treatment in ~80% of cases, and thus surgery is reserved for special circumstances. Any patient with clinically significant gastrointestinal hemorrhage should undergo aggressive resuscitation and initial attempts at stabilization via endoscopy or interventional radiology if necessary. Bleeding gastric ulcers warrant biopsy or excision to rule out malignancy but seldom warrant vagotomy because of an infrequent association with hyperacidity. Duodenal ulcers eroding into the gastroduodenal artery may necessitate trans-duodenal three-point ligation (Fig. 86.1); a truncal vagotomy and drainage procedure incorporating the duodenotomy are indicated for patients who have failed or are unable to tolerate medical therapy.

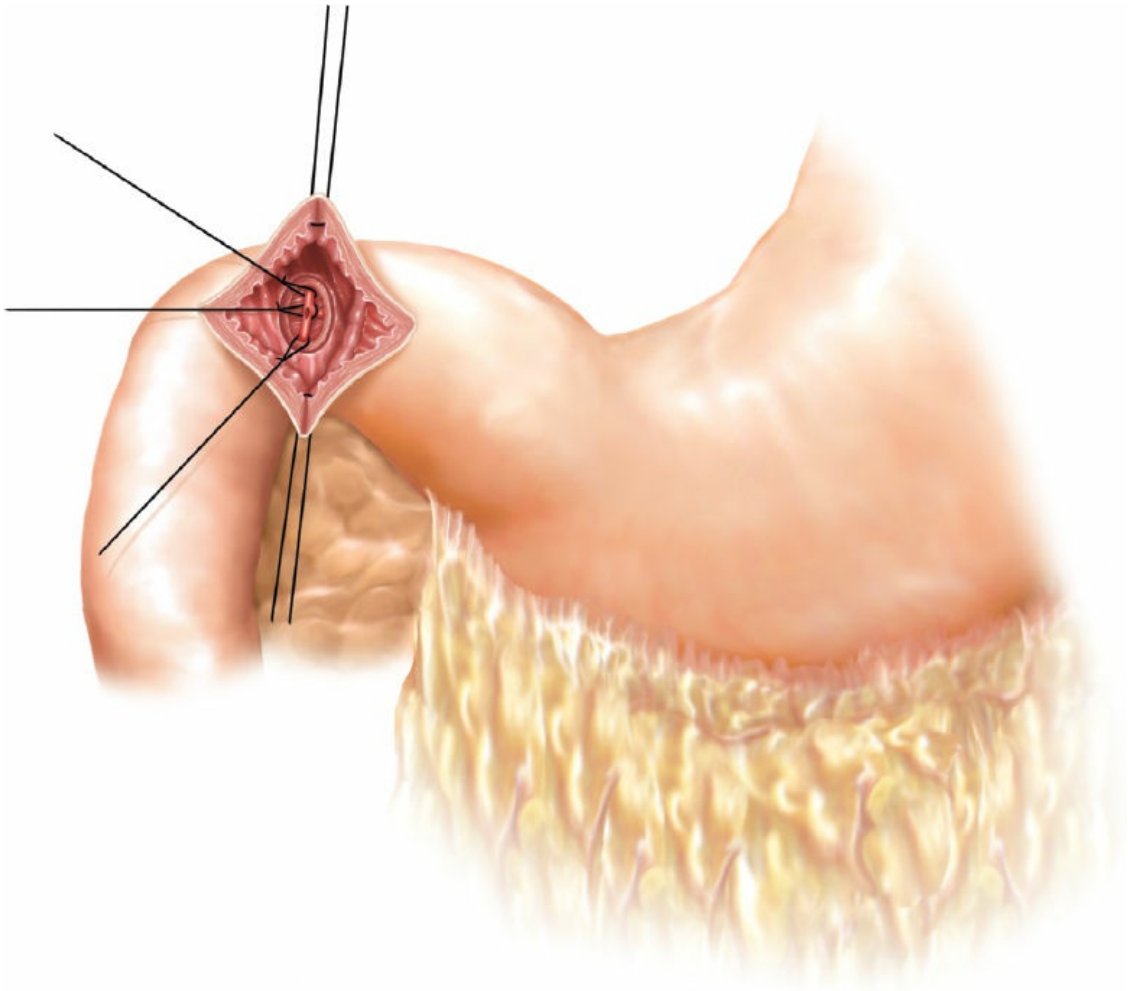

Figure 86.1. Three-point suture ligation of bleeding duodenal ulcer. The culprit is usually the gastroduodenal artery. The ligation can be done with individual stitches or a single “U-stitch” but must be sure to include the side branch.

Perforation in the setting of PUD can be managed nonoperatively in a stable patient when it is contained according to a dynamic contrast study; otherwise, the perforation requires prompt surgical treatment. As noted above, gastric ulcers warrant biopsy or excision to rule out malignancy; whether to append a truncal vagotomy to the excision remains controversial and should be determined based on the patient’s clinical status, underlying cause of PUD, and response to medical treatment. The preferred treatment of duodenal perforation is primary repair with interrupted suture and omental patching. A truncal or selective vagotomy and drainage procedure incorporating the perforation are reasonable in otherwise stable patients who have failed or are unable to tolerate medical therapy. A HSV is inadvisable because the risk of misadventure during the delicate dissection is high in a soiled field.

Medically intractable peptic ulcers persist despite at least 12 weeks of maximal acid suppression therapy, whereas recurrent peptic ulcers recur after complete healing despite maintenance therapy. In either case, an elective acid suppression surgery is warranted. We recommend the option with the greatest likelihood of success in that surgeon's hands. That said, in our experience and interpretation of available evidence, the most appropriate option is truncal vagotomy plus resection as this is the most straightforward, comprehensive, and definitive. Selective and highly selective vagotomies should be utilized by surgeons well-versed in these techniques in patients with unsullied anatomy and uncomplicated, medically recalcitrant disease (usually *H. pylori* negative). The technical complexity and high rates of recurrence associated with selective and highly selective vagotomies limit their use in modern times.

ANATOMY

The two major vagal trunks descend along the esophagus and emerge through the esophageal hiatus of the diaphragm as anterior and posterior branches (Fig. 86.2). The anterior branch originates from the left side and gives off the hepatobiliary and pancreatic branches. This anterior branch continues along the lesser curvature of the stomach in the anterior leaflet of the gastrohepatic omentum as the anterior nerve of Latarjet. The posterior branch originates from the right side and ultimately gives rise to the celiac branch. This celiac branch provides parasympathetic innervation to the pancreas, duodenum, small intestine, and right colon; this posterior branch continues in the posterior leaflet of the gastrohepatic omentum as the posterior nerve of Latarjet. There is a plexus of fibers that connect the right and left vagus nerves. Furthermore, many patients manifest their major trunks of the vagus nerves as multiple branches. This fact alone is likely responsible for the incomplete denervation of the stomach during truncal vagotomy.

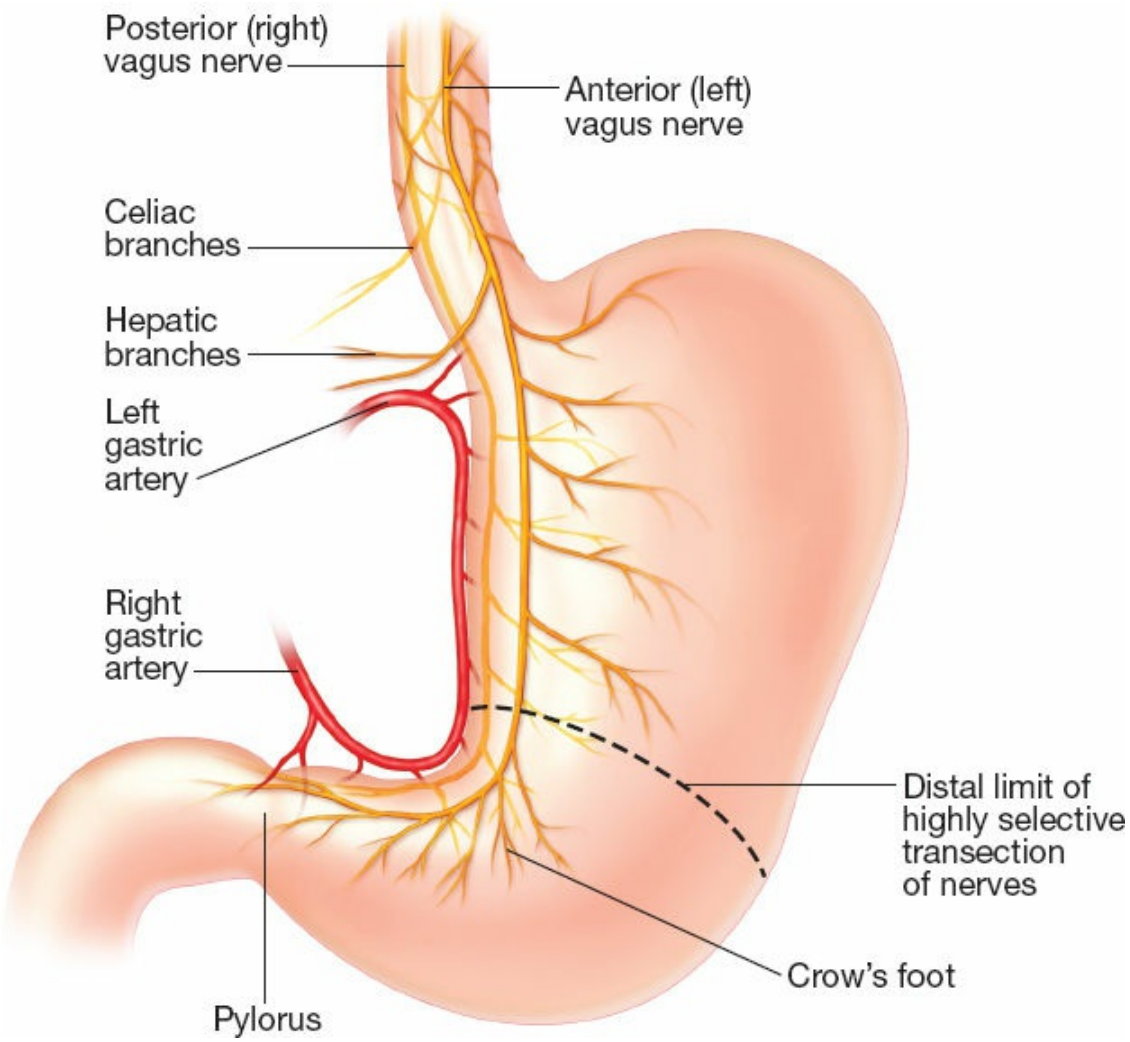

Figure 86.2. Vagal nerve supply to the stomach. Also shown are the various branches relevant to both the selective and highly selective vagotomy.

SURGICAL TECHNIQUE

Preoperative Preparation

The patient should be positioned supine on the operating table with arms abducted 90 degrees. Prior to induction of general anesthesia, sequential compression devices and/or pharmacologic deep venous thrombosis prophylaxis should be administered. After induction of anesthesia, a Foley catheter and temporary orogastric tube should be inserted; however, if the operation is being performed on an obstructed/dilated stomach, a surgical gastrostomy tube is more appropriate since it may take several weeks for emptying to normalize. Prophylactic antibiotics are then administered.

For both open and laparoscopic cases, the anesthesiologist is situated at the head of the operating table, the surgeon stands on the patient's right,

and the first assistant stands on the patient's left (Fig. 86.3). If the case is approached laparoscopically, standing alongside the patient may facilitate dissection around structures more so than operating in-line while standing between the patient's legs. A second assistant can pilot the laparoscope from further along on the patient's left side. A single monitor is placed directly above the patient's head.

Open Truncal Vagotomy

The patient is initially placed in the neutral position. A midline laparotomy incision is made from the xiphoid to just below the umbilicus. A Bookwalter or similar self-retaining retractor is then inserted and used to elevate the costal margin and open the incision. A broad malleable retractor is used to elevate the left lobe of the liver, thus exposing the esophagogastric (GEJ) junction, stomach, and duodenum. Retraction is facilitated by leaving the liver attached to the diaphragm as opposed to taking down the triangular ligament. At this juncture, the patient is placed in slight reverse Trendelenburg position to improve exposure of the operative field.

The peritoneal reflection at the esophageal hiatus of the diaphragm is incised, and the fibrofatty tissue overlying this segment of the esophagus is thinned using blunt dissection along the long axis of the esophagus. Pushing the esophagus toward the spine will expose the anterior vagus as a taut band embedded in the esophageal wall. To avoid incomplete vagotomy, at least 5 cm of the trunk should be isolated above the esophagogastric junction and divided between clips. The specimen must be sent to pathology for immediate confirmation. In the meantime, the esophagus is circumferentially dissected so that a Penrose drain can be passed around it. Ideally, this drain would ensnare both the esophagus and closely associated posterior vagus. Retracting the esophagus toward the patient's left and anteriorly should help reveal the posterior vagus as another taut band on either inspection or palpation; if the trunk is not obvious, the surgeon should explore along or between the crura closer to the aorta. Once identified, a 5-cm segment of the posterior trunk is also divided between clips and sent for frozen pathologic review.

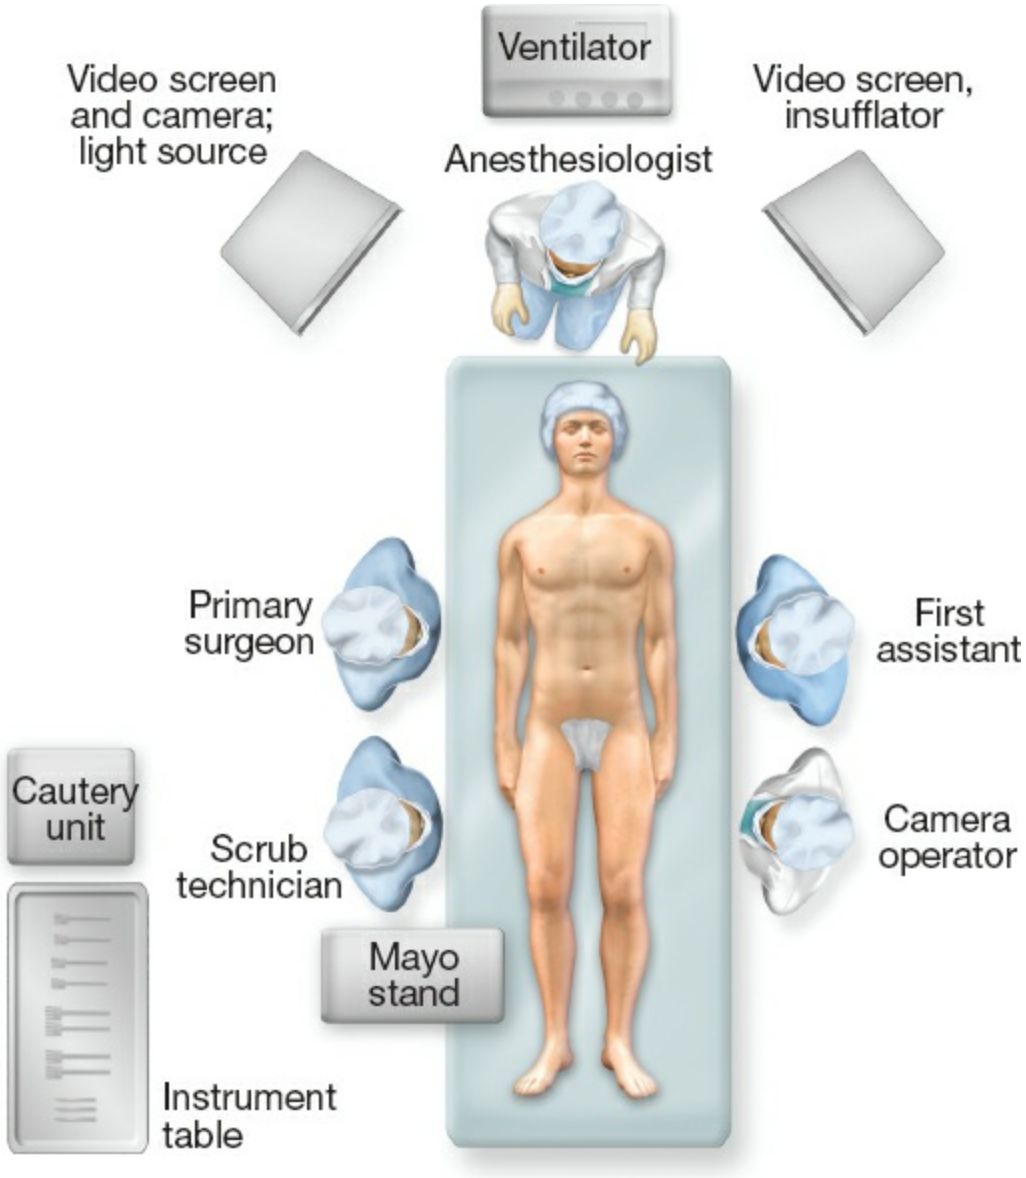

Figure 86.3. Arrangement of operating room and personnel.

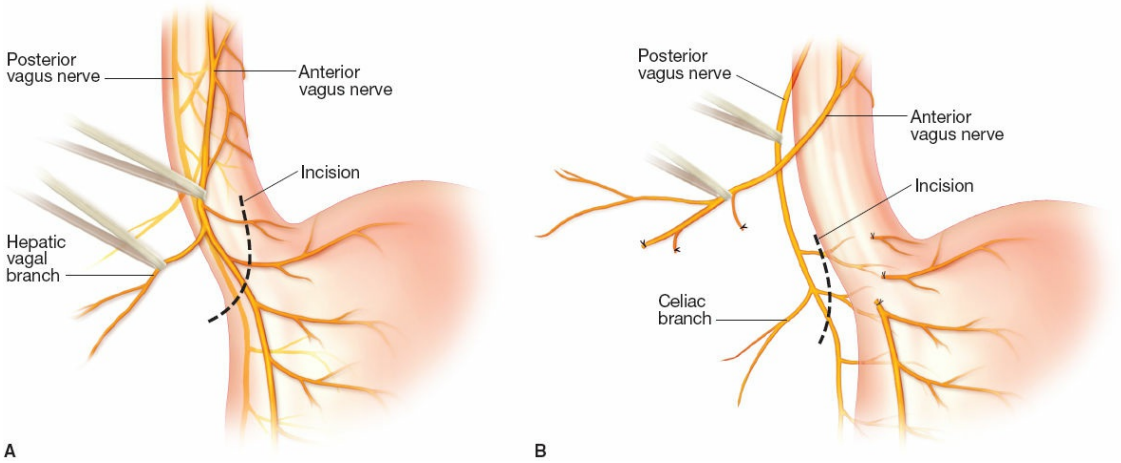

Figure 86.4. Selective Vagotomy. **A.** Isolation and division of the anterior vagal branches distal beyond the hepatic branch. **B.**

Isolation and division of the posterior vagal branches distal beyond the celiac branch.

After denervation of the gastric mass, patients lose their antral pump function and receptive relaxation, resulting in delayed emptying of solids and accelerated emptying of liquids. Some clinicians have promoted the use of pyloric dilation and prokinetic agents as treatment, but the preponderance of evidence suggests gastric stasis is a significant and persistent problem necessitating a drainage or resection/reconstruction procedure. Drainage procedures will be discussed in the next section. The classic resection procedure is an antrectomy followed by a Billroth I, Billroth II, or Roux-en-Y reconstruction.

Open Selective Vagotomy and Pyloroplasty

Entry and initial exposure of the operative field are the same as for the truncal vagotomy. In contrast, the selective vagotomy is centered on the distal esophagus and esophagogastric junction. The fibrofatty tissue overlying the junction should be thinned as described above. The anterior vagal trunk is then identified by inspecting and palpating for a “bow string” along the anterolateral aspect of the esophagus. Once identified, this vagal trunk is encircled with a vessel loop near the GEJ and gently elevated anteriorly off the esophagus. This maneuver should also tent the hepatic vagal branch passing to the right. The hepatic branch is followed proximally to its junction with the anterior vagal trunk. The continuation of the vagal trunk distal to this junction traveling along the lesser curvature (i.e., anterior gastric vagal branches) is divided (Fig. 86.4A). Similarly, the posterior vagal trunk is identified by retracting the stomach to the left and inspecting posteriorly, often along the aorta. Once identified, this vagal trunk is encircled with a vessel loop and gently retracted to the right. This should allow the surgeon to palpate the taut celiac vagal branch passing to the celiac axis. This branch is followed to its junction with the posterior vagal trunk. The continuation of the vagal trunk distal to this junction traveling along the lesser curvature (i.e., posterior gastric vagal branches) is divided (Fig. 86.4B). The nerves can be divided between clips or using an electrosurgical instrument. Regardless, the surgeon must be careful to avoid confusing the hepatic and celiac branches for the continuations of the main vagal trunks. Typically, the hepatic and celiac branches arise several centimeters cephalad to the esophagogastric junction and clearly

travel away from the lesser curvature.

To ensure there are no residual nerves traveling to the stomach, the surgeon should clear a plane between the vagal trunks and the distal 5 cm of the esophagus, being especially certain to divide the posterolateral Criminal Nerve of Grassi on the left (Fig. 86.5). Alternatively, some prefer to make a superficial incision circumferentially around the GEJ extending to the first short gastric vessels (Fig. 86.6).

As noted earlier, the selective vagotomy does not obviate the need for a drainage procedure. The classic drainage procedures are gastrojejunostomy and pyloroplasty, the former of which is not recommended in routine cases because of the propensity for marginal ulceration. While there are multiple types of pyloroplasty, the two most common are the Heineke–Mikulicz and Finney. Even with a drainage procedure, patients undergoing selective vagotomy in the setting of GOO frequently require protracted gastric decompression and should have a gastrostomy tube placed during the index case.

Heineke–Mikulicz Pyloroplasty

This is the most common and straightforward pyloroplasty. A full-thickness 5- to 6-cm longitudinal incision is made through the anterior wall of the pylorus. Silk traction sutures are placed at the midpoint of the incision and retracted perpendicular to the incision to facilitate the transverse closure (Fig. 86.7A,B). As originally described, the Heineke–Mikulicz pyloroplasty is closed in two layers, but the added labor puts the channel at risk of narrowing. The recommended and more common variation calls for a single layer closure using interrupted, full-thickness 3-0 polyglycolic suture. Omentum can be used to buttress the incision by securing it under the tails of several sutures.

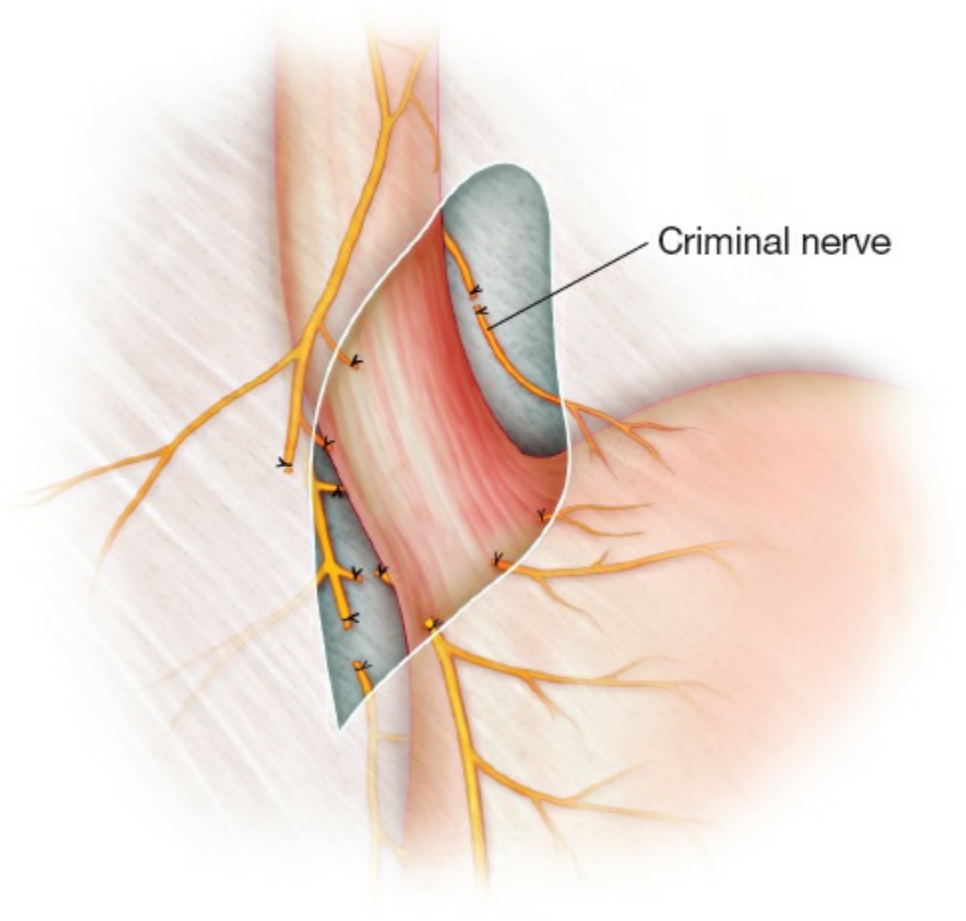

Figure 86.5. Dissection above the esophagogastric junction and division of the Criminal Nerve of Grassi.

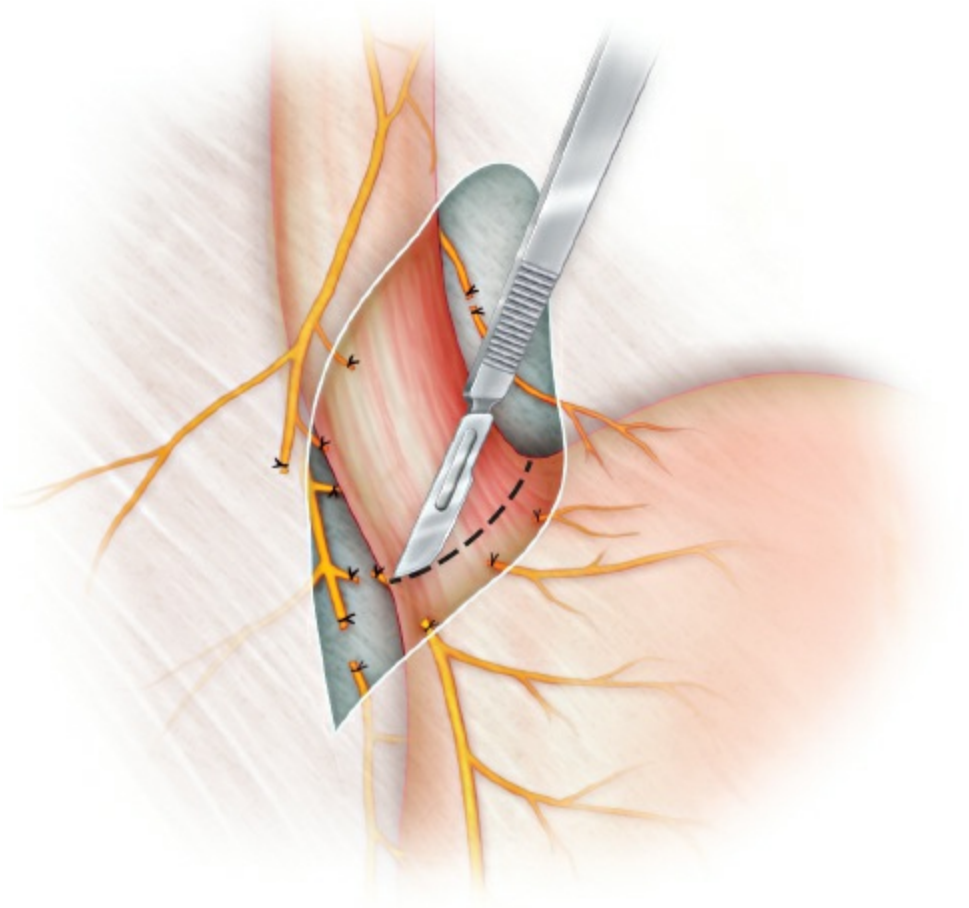

Figure 86.6. Superficial incision along the esophagogastric junction to divide residual longitudinal nerve fibers.

Finney Pyloroplasty

This pyloroplasty requires an extensive Kocher maneuver and essentially creates a gastroduodenostomy. The traditional approach begins by incising the peritoneum along the lateral aspect of the duodenum and mobilizing the duodenum and pancreas off their retroperitoneal attachments. A deep traction stitch is then placed on the superior aspect of the pyloric ring, and another stitch is placed 3 to 4 cm inferiorly between the antrum and duodenum. These sutures are then retracted in opposite directions to approximate the gastric antrum and duodenum. An antral gastrotomy and opposing duodenotomy are created and must be connected through the pylorus—inclusion of the pylorus is the major distinction between this technique and the Jaboulay. The anastomosis is fashioned with a single layer of full-thickness interrupted 3-0 polyglycolic suture along both the posterior and anterior walls (Fig. 86.8).

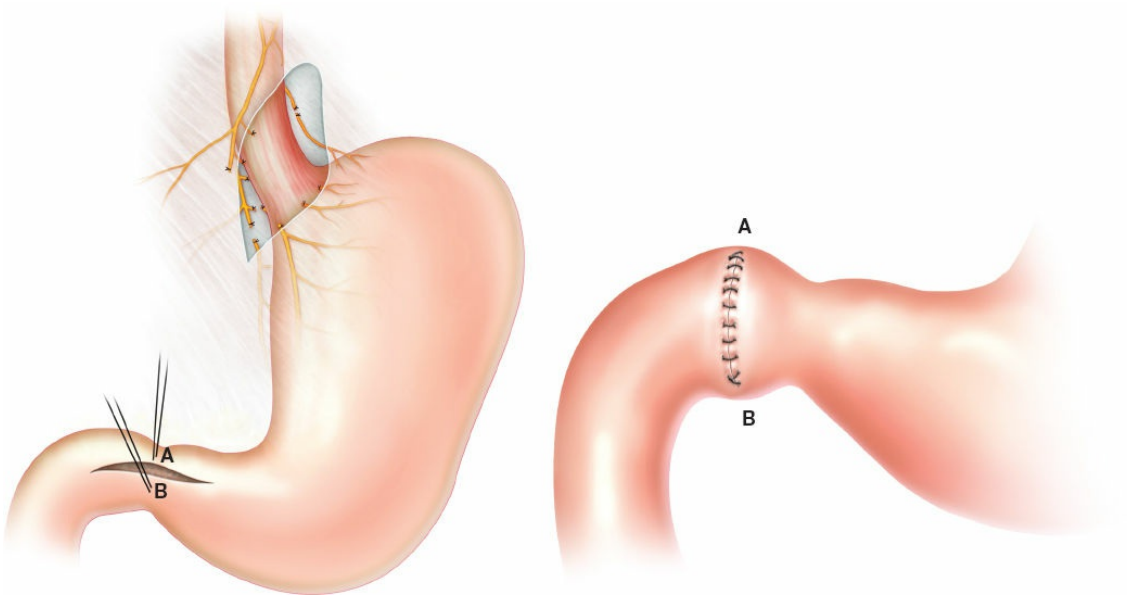

Figure 86.7. A. Longitudinal incision and traction sutures for the Heineke–Mikulicz pyloroplasty. **B.** Completed transverse, full-thickness closure of the Heineke–Mikulicz pyloroplasty.

Highly Selective Vagotomy Open

Entry and exposure of the operative field are the same described as above. The distinguishing feature of this form of vagotomy is dividing the gastric vagal branches only so far as the antrum (Fig. 86.9). This distal limit is found in two ways: by measuring 6 to 7 cm cephalad from the pylorus and/or by finding the Crow's Foot of the vagus along the anterior surface of the stomach. The vagal branches to be divided begin cephalad to the Crow's Foot and are intimately associated with the vascular arcade supplying the stomach. Care must be used to individually divide the neurovascular bundles in both the anterior and posterior leaflets of the gastrohepatic omentum close to the gastric surface—too far and the main vagi are injured, too close and the now marginally vascularized portion of the stomach is injured. Typically, the dissection is carried distal to proximal along the anterior leaflet and then along the posterior leaflet. The bundles can be divided between silk sutures or clips, or by using an electrosurgical device as the assistant provides traction caudally along the greater curvature.

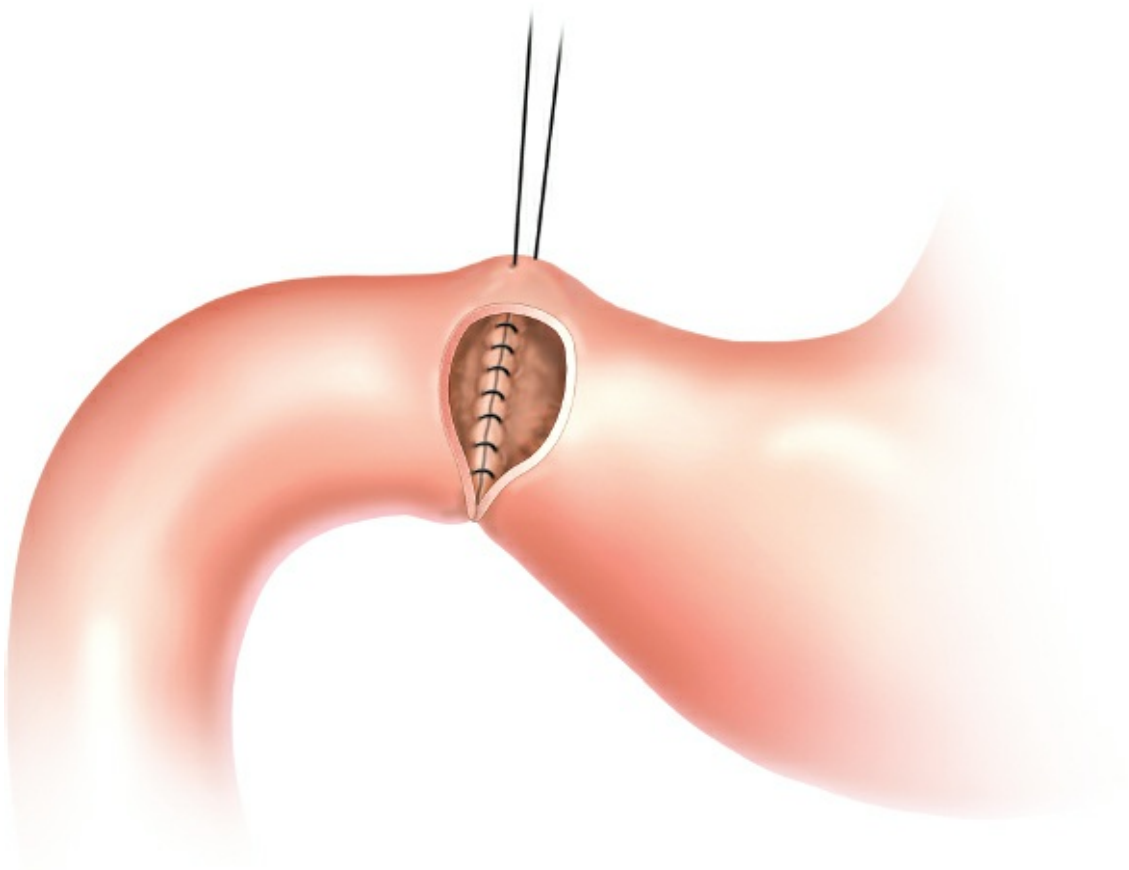

Figure 86.8. Inverted U incision and posterior full-thickness suture line for Finney pyloroplasty.

Once the esophagogastric junction is reached, the surgeon must circumferentially free the junction from any attachments and continue to clear the plane between the vagal trunks and esophagus for approximately 5 cm. This ensures any residual nerve fibers are extinguished, such as the Criminal Nerve of Grassi originating from the posterior trunk sometimes well above the hiatus. Of note, when performing this part of the case it is critically important to appreciate and avoid the vagal trunks which are embedded in the fat pad surrounding the junction. The left/anterior trunk is identified by feeling for a “bow string” along the left lateral aspect of the distal esophagus. The right/posterior trunk is identified by tenting the esophagus to the left and inspecting posteriorly. A window is created between each trunk and the esophageal wall allowing the nerves to be controlled with vessel loops as the dissection is continued. Ultimately, the surgeon should be able to tent the esophagus to the left and move the anterior and posterior trunks freely to the right.

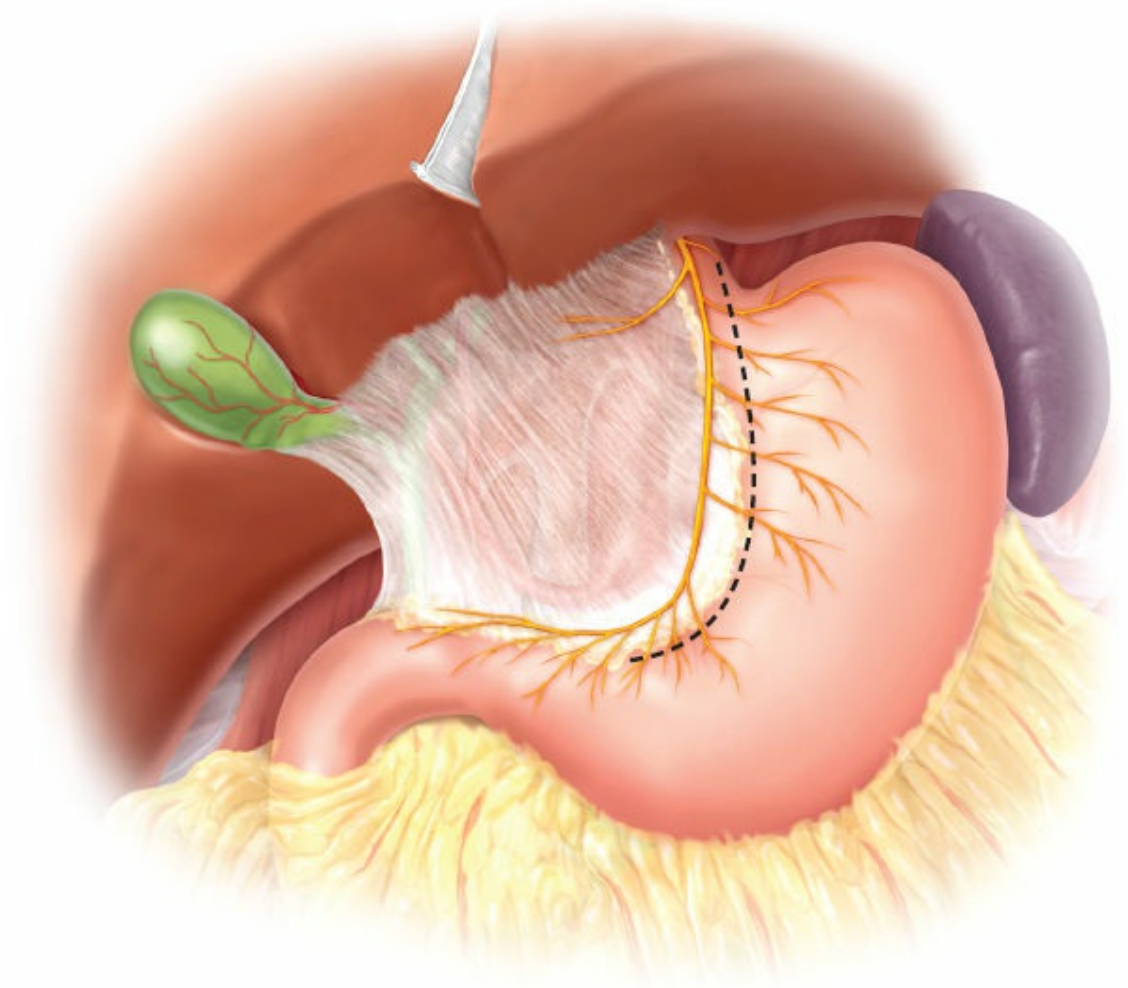

Figure 86.9. Extent and general path of highly selective vagotomy (marked by *dashed line*). The dissection is done in two planes, anterior and posterior, and from distal to proximal. The gastric vagal branches of interest are divided between clips or using an electrosurgical instrument with care not to injury the stomach or Nerve of Latarjet proper.

Finally, the lesser curvature is inspected for signs of ischemia. Barring any concerning findings the bare areas between the ligated neurovascular bundles are covered by imbricating the serosa with running 3-0 polyglycolic suture (Fig. 86.10).

Laparoscopic

The steps of the laparoscopic HSV are similar to the open case, and only important differences or nuances will be covered here. For one, the surgeon will require the following laparoscopic instruments: an angled (30-degree) laparoscope, curved dissector, either a bipolar or ultrasonic electrosurgical device, atraumatic self-retaining liver retractor, atraumatic

bowel graspers, needle driver, and clip applier. Secondly, all ports are placed in the upper hemi-abdomen with at least one hand's breadth of spacing between them. In all, five ports are required: 5- and 10-mm ports in the right upper quadrant for the surgeon, a 10-mm port at the umbilicus for the laparoscope, a 5-mm port in the left upper quadrant for the assistant, and a final 5-mm port just inferior to the xiphoid for liver retraction (Fig. 86.11).

A Veress needle or Hasson trocar is used to enter the peritoneal cavity and insufflate it to 15 mm Hg. If the Veress is preferred, it should be placed in the left midclavicular line two finger breadths below the costal margin; this site can also be used to introduce the assistant's 5-mm port. If the Hasson is preferred, it should be placed either above or below the umbilicus (below for shorter abdomens). Once the peritoneal cavity is entered and insufflated, the laparoscope is introduced and the abdomen inspected for gross pathology. The remaining ports are placed under direct visualization. The surgeon's ports should adhere to the principle of triangulation with the apex at the hiatus, the 10-mm port slightly right of midline, and the 5-mm port more lateral and cephalad. A self-retaining liver retractor should be inserted through the subxiphoid port. Finally, the patient is positioned in slight reverse Trendelenburg to improve exposure of the operative field.

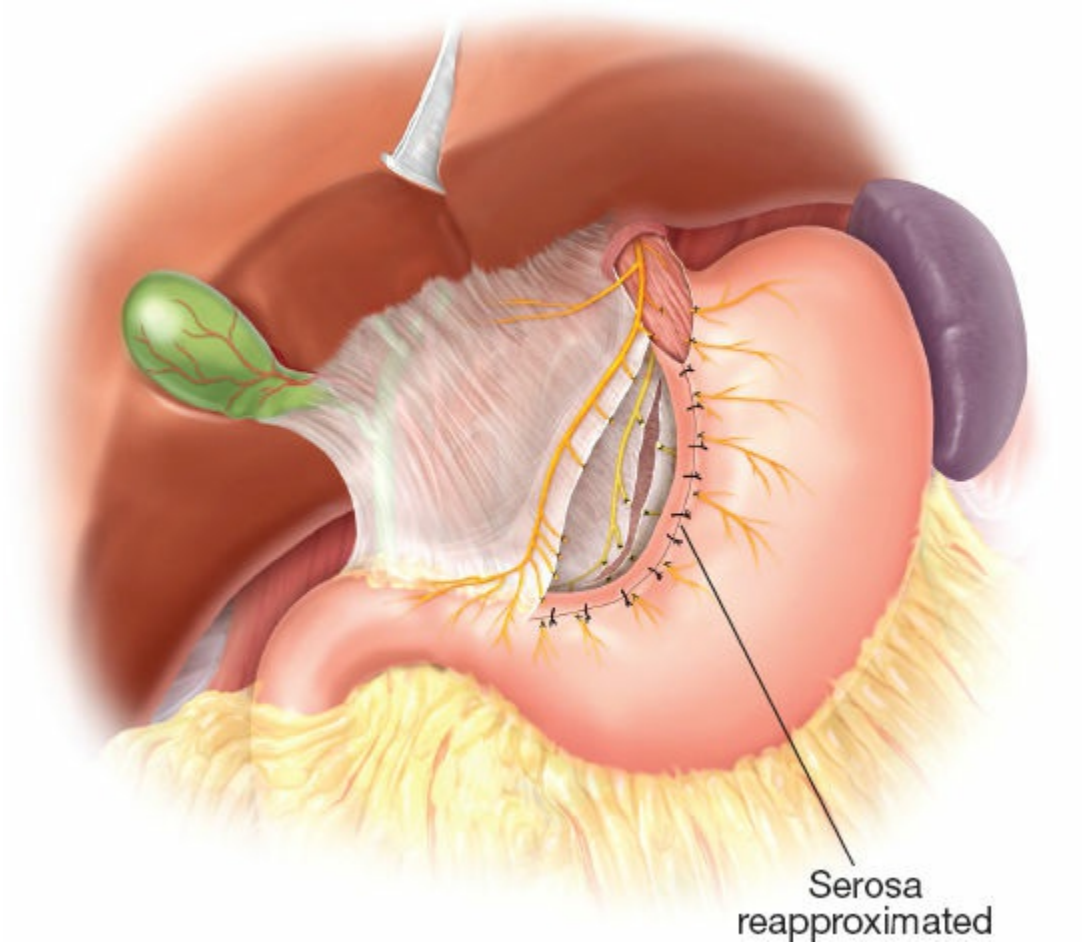

Figure 86.10. Closure of the gastric serosa along the lesser curvature upon completion of the HSV.

There are a few important technical nuances when translating the open HSV into its laparoscopic form. Foremost, we recommend using an electrosurgical instrument with a dissecting tip to improve efficiency. A good assistant can also improve efficiency by providing good retraction and exposure, especially while dissecting the lesser curvature and around the esophagogastric junction. In the former case, the surgeon retracts the gastrohepatic ligament toward the right as the assistant retracts the greater curvature to the left, thereby creating a taut plane in which to dissect and ligate each anterior neurovascular bundle; the assistant then retracts the lesser curvature to improve exposure of the posterior bundles. In the latter case, the surgeon must use the angle of the laparoscope in addition to the assistant to gain adequate visualization and exposure of the vagal trunks since palpation is less reliable. Once the case is completed, the fascia at all of the 10-mm port sites should be approximated to prevent herniation.

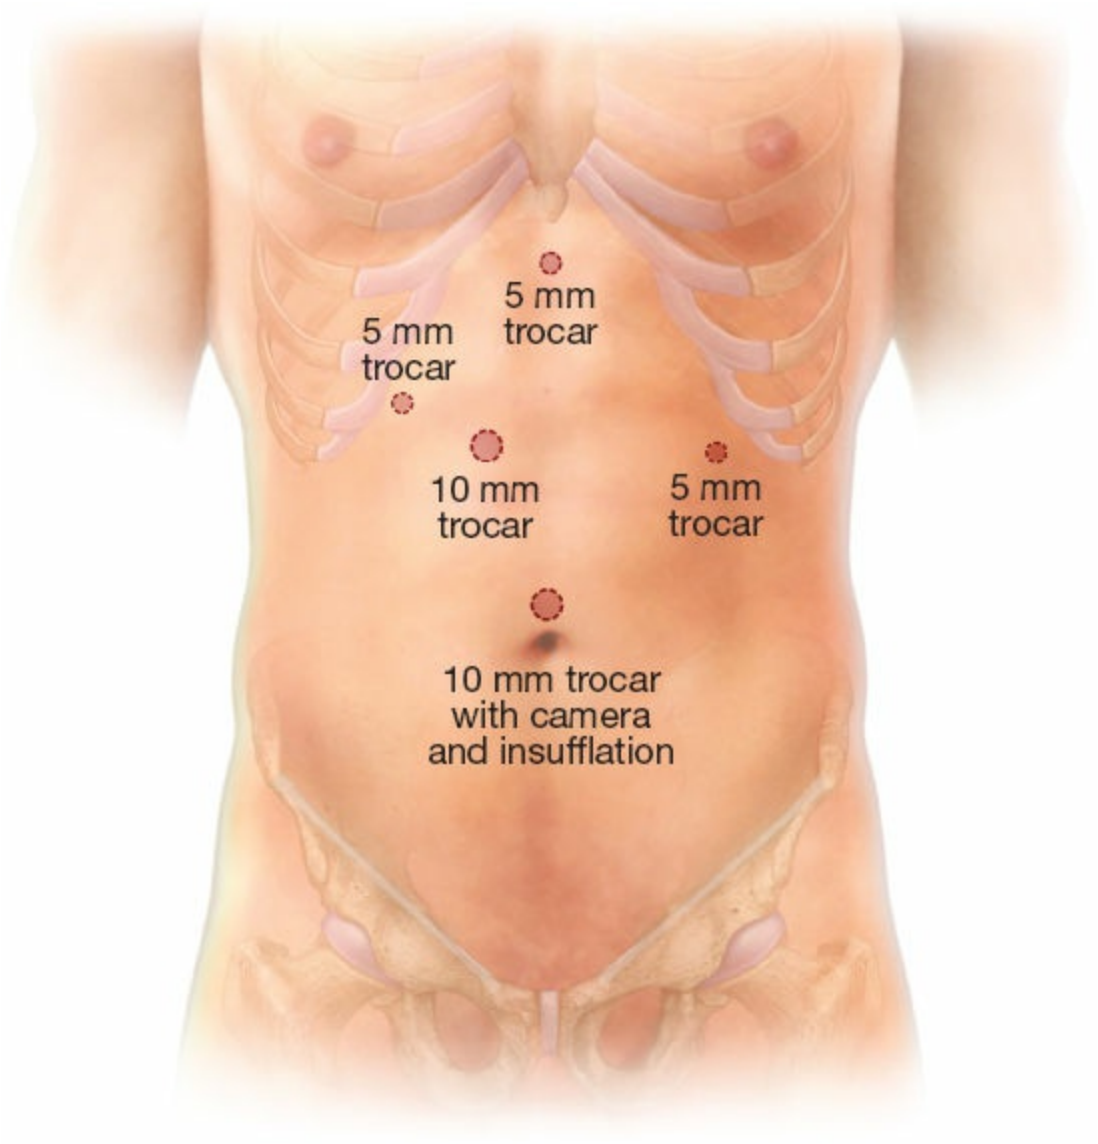

Figure 86.11. Port placement for laparoscopic vagotomies.

POSTOPERATIVE CARE

Patients undergoing selective and HSV are typically discharged once they are able to tolerate a liquid diet. Such a diet can be initiated the evening of surgery for patients undergoing HSV. Patients undergoing selective vagotomy plus a drainage procedure may require protracted gastric decompression via gastrostomy tube, especially in the setting of preoperative obstruction. The diet is advanced to normal on an outpatient basis.

COMPLICATIONS

After truncal or selective vagotomy and drainage, the surgeon should be

mindful of three potentially serious complications. The first is bile reflux gastritis. Ablation of the pylorus induces reflux of bile into the stomach, which often manifests as epigastric pain, nausea, and vomiting. In the minority of patients who experience intractable symptoms or evidence of severe chronic gastritis, the pyloroplasty should be converted to a Roux-en-Y gastrojejunostomy with a 50- to 60-cm limb. The surgeon should be warned that in patients with gastroparesis, conversion to a Roux will mitigate the bile reflux but make gastric emptying worse. The second is dumping syndrome, now an infrequent complication of an infrequent operation. Loss of gastric relaxation during meals causes “dumping” into the duodenum and release of vasoactive hormones, which often manifest as tachycardia, diaphoresis, hypotension, and abdominal pain. Delayed signs and symptoms are predominantly a function of hypoglycemia secondary to a surge in insulin from the food bolus that rapidly enters the duodenum. Patients with disabling dumping syndrome may require conversion to a Roux-en-Y gastrojejunostomy, but most patients can be managed with separation of solids and liquids as well as consumption of small, frequent meals high in protein and fat but low in carbohydrates. Finally, an ill appearing patient or one who fails to convalesce appropriately should raise suspicion for a leak, especially in the setting of fever and tachycardia. The issue can be investigated using computed tomography or upper gastrointestinal fluoroscopy with dilute or water soluble contrast. If a leak is identified, the surgeon must ultimately decide between percutaneous drainage or resection, reconstruction, and wide drainage.

Surgeons should not ignore the possibility of a leak from the devascularized lesser curvature after an HSV. Treatment entails primary repair plus omental patch if the defect is small and the patient is stable, resection if the compromised portion falls within limits of a standard gastric resection, or wide drainage.

OUTCOMES

There are no reliable modern series to assess recurrence rates or side effects between selective and HSV. This prevents assessment of their efficacy in the setting of modern surgical training and referral patterns (i.e., for medically recalcitrant disease). Historically, recurrence rates have ranged from 1% to 2% after truncal vagotomy plus antrectomy to 9% to 14% after selective vagotomy and pyloroplasty to 15% to 26% after HSV.

These statistics likely underestimate modern outcomes. Regardless, since these surgeries are now primarily used for salvage, the surgeon should select the approach most successful in his/her hands.

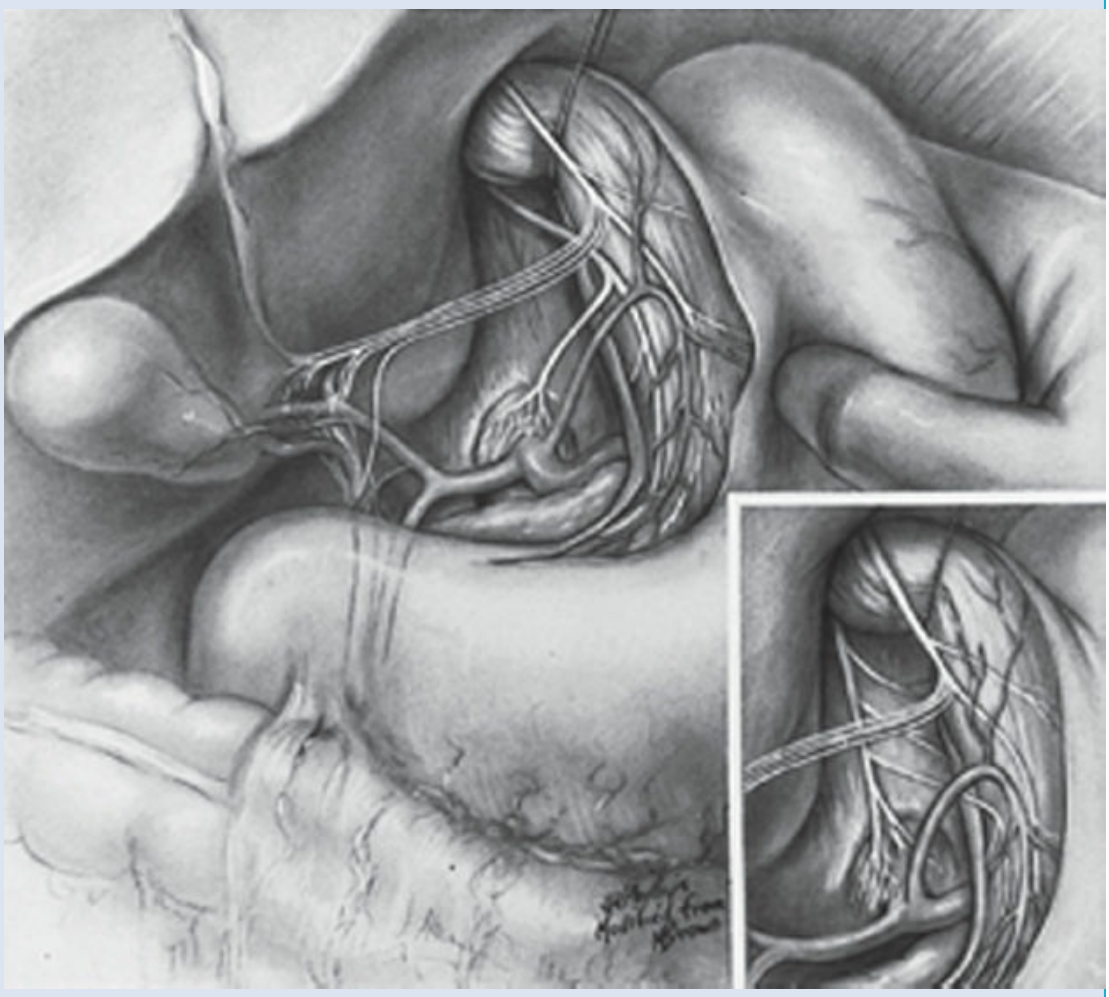
EDITOR'S COMMENT

The authors clearly describe the three types of vagotomies (truncal, selective, and highly selective) and a variety of ulcer operations. Today many of these operations are only rarely performed owing to effective pharmacologic acid

inhibition and treatment of *Helicobacter pylori,* the most common cause of ulcer disease. Whereas in the past these operations were performed for refractory ulcer disease, today these are performed for emergencies such as perforation, bleeding, or gastric outlet obstruction. Hence, the practicing surgeon may have little experience to draw upon in these urgent situations. Therefore, it does behoove the surgeon to be familiar with the nuances of the procedures.



The abdominal vagi. All vagal fibers shown in this illustration are readily identified by gross anatomic dissection. The hepatic vagal division (usually consisting of multiple fibers) from the anterior trunk courses within the lesser omentum to the porta hepatis. The celiac vagal division from the posterior trunk goes to the celiac autonomic plexus, usually in close association with the left gastric artery but occasionally with the right diaphragmatic crus (*inset*). The main anterior and posterior trunks run distally within the lesser omentum adjacent to the cardia to the antrum. (From Griffith CA. Selective gastric vagotomy. In: Nyhus LM, Wastell C, eds. *Surgery of the Stomach and Duodenum*. 3rd ed. Boston, MA: Little, Brown and Company, 1977.)

Vagotomy was reintroduced by Dragstedt and Owens in 1943. Prior to that

time, subtotal gastrectomy had been the mainstay of treatment for refractory ulcer disease and complicated ulcer disease. After the importance of vagotomy in the prevention of recurrence of ulcers following resection was established, various other procedures were employed, including truncal vagotomy with gastroentreostomy or pyloroplasty, 70% subtotal gastrectomy, and antrectomy. In these operations, the key to prevention of recurrence was a complete truncal vagotomy. The anatomy of the vagus nerve is well described by the authors. The figures in the chapter clearly demonstrate the basic anatomic considerations in performing a vagotomy. An illustration taken from the 6th edition (Griffith CA. Selective gastric vagotomy. In: Nyhus LM, Wastell C, eds. *Surgery of the Stomach and Duodenum.* 3rd ed. Boston, MA: Little, Brown and Company, 1977) adds additional visual information.

A common cause of incomplete vagotomy is the anatomic variability between patients. Some patients will have single main trunks of the anterior and posterior vagus, whereas others may have multiple trunks. In order to avoid an incomplete operation, a long segment of the vagal trunk above the esophagogastric junction must be isolated, divided between clips and removed. A segment of the vagus nerve must be removed not only cut! This is more of a *vagectomy* than a vagotomy. In addition, it is important to skeletonize the esophagus circumferentially for 5 cm to divide any accessory branches of other trunks. The authors refer to obtaining immediate pathologic confirmation. This may be difficult in the middle of the night during emergency procedures as a pathologist may not be present. In addition, if you do have two trunks confirmed there is still the possibility of additional trunks. Hence, it is preferable to skeletonize the esophagus so as to eliminate all small fibers.

The identification of the anterior vagus is facilitated by downward traction on the anterior stomach after encircling the esophagus with a Penrose drain and retracting it cephalad. With this tension, the anterior vagus will feel like a banjo string and can easily be identified. It is sometimes buried in the adventitia. In addition, the inexperienced operator may dissect into the esophageal musculature and be fooled that the longitudinal muscles are nerve fibers. Muscle fibers are soft and do not develop tautness when stretched. The posterior vagus may be difficult to identify. The most common reason in my experience is that when the surgeon dissects behind the esophagus, the plane of dissection is anterior to the posterior vagus, which is then left between the diaphragmatic crura rather than being encircled with the esophagus. The surgeon can then mistake small nerve fibers or muscle fibers for the main trunk of the posterior vagus. The posterior vagus is usually a sizable nerve trunk. In these situations, the surgeon should explore between the diaphragmatic crura and palpate along the anterior surface of the aorta to identify the nerve. The same is true of the laparoscopic approach. Careful inspection of the tissue posterior to the esophagus is essential.

There is considerable debate about the role of vagotomy in the management of emergencies related to duodenal ulcer disease. This follows from our

understanding that by the majority if not all ulcers are caused by *H. pylori* infection. Hence the role of vagotomy has been challenged. A 2007 study by Rueben et al. (Trends and predictors for vagotomy when performing oversew of acute bleeding duodenal ulcer in the United States. *J Gastrointest Surg* 2007;11:22–8) using the National Inpatient Sample showed that there had been a significant decrease in the number of bleeding duodenal ulcers from 1999 to 2003 and a significant decrease in the number of vagotomies. There is no indication that trend has reversed itself. However, in a retrospective analysis of data from the ACS NSQIP database for the period 2005–2011 for 3,611 patients who had emergency surgery for bleeding (775) or perforation (2,374), Schroder et al. found that simple repair was the procedure of choice for perforated peptic ulcer as vagotomy and drainage had a significantly greater length of hospitalization. Conversely, for patients requiring emergency surgery for intractable ulcer bleeding, vagotomy and drainage was associated with significantly lower postoperative mortality than local ulcer over sewing alone. In addition, they found that patients undergoing vagotomy and gastric resection were associated with significantly greater postoperative morbidity when performed for perforation or bleeding.

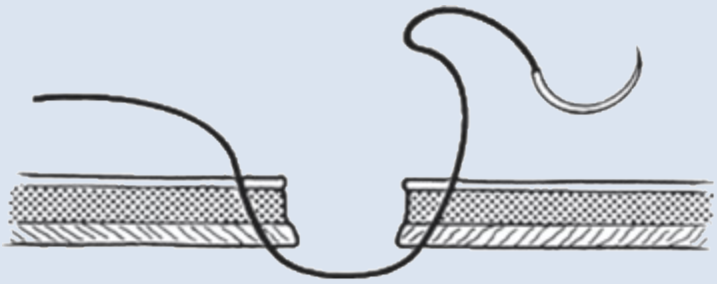
Should resection be necessary most surgeons would agree that if a gastric resection with Roux-en-Y reconstruction is performed for ulcer disease-related complications, then a vagotomy should be performed to reduce the predictable occurrence of a marginal ulcer. There is also general agreement with gastrojenostomy, but less so with antrectomy and either Billroth I or Billroth II reconstruction. In the latter situations, it appears that long-term proton pump inhibitor (PPI) therapy may be equivalent to vagotomy in the prevention of ulcer recurrence, but there are no randomized trials to verify this hypothesis.

The authors discuss the role of selective and highly selective vagotomy. Each of these has a limited role today because of effective medical therapy and hence they are largely of historic significance.

One notable exception to the rule that most gastrointestinal ulcerations are caused by *H. pylori* are the ulcers caused by the excessive acid secretion provoked by secretion of gastrin by neuroendocrine tumors associated with the Zollinger–Ellison syndrome. Even in surgery for the Zollinger–Ellison syndrome, the role of any acid-reducing procedure has been limited. Most surgeons rely on tumor resection and long-term treatment with PPIs and avoid surgical resection and vagotomy. In the case of perforation or bleeding, one could argue that closure of the perforation or three-point ligation of the bleeding ulcer could be combined with vagotomy and pyloroplasty as this may be helpful in achieving better acid control particularly in the patient who had been on PPI at the time of the emergency.

Vagotomy is only part of the treatment for duodenal ulcer complications. I offer the following insights based upon my operative experience concerning duodenotomy and pyloroplasty for management of bleeding duodenal ulcer. Obviously to perform a three-point ligation requires accessing the duodenum.

This can be accomplished by a duodenotomy or pyoloroplasty. If the surgeon decides on local control only and use of PPI postoperatively rather than a vagotomy, then a duodenotomy may be made for exposure of the ulcer. Prior to making a duodenotomy, a kocher maneuver should be performed. The duodenotomy should be made with electrocautery as a longitudinal incision over the second portion of the duodenum. Once the three-point ligation is successfully performed, then closure of the duodenotomy is undertaken. I prefer to close the duodenal incision longitudinally with a single layer of 3-0 silk. The second portion of the duodenum is patulous, and it is very difficult to narrow the lumen. No drain is used. If there is concern about the caliber of the duodenum, the transverse closure may be accomplished. A two-layer closure or use of a Gambee stitch as noted below may be performed. There will be "dog ears" at the lateral and medial margin of the closure. As long as the closure is water tight, these should not leak.



Placement of sutures for Weinberg pyloroplasty.

Various methods of reconstruction of pyloroplasty are described. As with the duodenal exposure noted above, a Kocher maneuver should be performed to free up the duodenum and avoid undo tension on the closure. I prefer a single-layer interrupted closure with 3-0 silk. Reconstruction of a pyloroplasty may be accomplished by the use of a Gambee stitch. This accomplishes in essence a two-layer closure using a single stitch. The above figure shows the use of the Gambee suture technique for the Weinberg modification of the Heinke–Mikulicz pyloroplasty.

87 Duodenal Ulcer Disease: Pathogenesis and Management of Complications

James W. Maher, Daniel T. Dempsey, and E. Christopher Ellison

INTRODUCTION

Population studies have shown that peptic ulceration remains a major public health problem worldwide. The lifetime frequency of peptic ulcer disease (PUD) in the United States has been shown to be ~10%. Studies by Logan and associates indicated that, in the United States alone, some 300,000 new cases of peptic ulcer are diagnosed each year. The frequency rates of duodenal ulcers in other countries are variable and have been shown to be primarily associated with *Helicobacter pylori* and use of nonsteroidal anti-inflammatory drugs (NSAIDs). Although, as noted above, the surgical treatment of PUD has been fundamentally transformed, mortality and morbidity resulting from duodenal ulceration with perforation remain substantial. For example, the rate of peptic ulcer complication in patients of all age groups is ~1% to 2%.

Duodenal ulcers are one manifestation of what has been referred to as PUD and account for two thirds of all peptic ulcers. Duodenal ulcers are characterized by the presence of a well-demarcated break in the mucosa that may extend into the muscularis propria of the duodenum. It has been shown that >95% of duodenal ulcers are located within the first portion of the duodenum; most are <1 cm in diameter. Unlike gastric ulcers, which may be malignant in about 5% of cases, duodenal ulcers are benign. Duodenal perforation is the second most common complication of PUD (Schwartz) and occurs in as many as 10% of patients with PUD. Nowadays, perforation is by far the common indication for surgery in duodenal ulcer patients. While bleeding remains the most common complication of duodenal ulcer, this is almost always managed nonoperatively. Obstruction is the third most common complication of duodenal ulcer while today intractability is rare. Most perforations arise from ulcers in the anterior aspect of the duodenal cap. Studies have shown

that 92% of perforated duodenal ulcers perforated through the anterior duodenal wall; 10% of these are also associated with a concurrent, bleeding ulcer along the posterior wall, the so-called kissing ulcer.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of PUD is multifactorial. Nevertheless, there are several environmental and/or host factors, which contribute to duodenal ulcer formation by increasing gastric acid secretion or weakening the mucosal barrier. Full understanding of the pathophysiology and pathogenesis of duodenal ulcers and their perforation complications requires a brief discussion of the two major etiologies: *H. pylori* infection and use of NSAIDs as well as the impact of other environmental factors.

Under normal physiologic conditions, the duodenal mucosa resists damage from the effects of gastric acid and pepsin, with the help of protective factors such as the mucous layer, bicarbonate secretion, and prostaglandins, which exert a protective effect. A duodenal ulcer occurs when an imbalance occurs between the protective factors above and the aggressive factors: acid and pepsin. Any process that increases gastric acidity (e.g., individuals with increased maximal and basal acid output), decreases prostaglandin production (e.g., NSAIDs), or interferes with the mucosa layer (e.g., *H. pylori* infection) can lead to PUD with its attendant increased risk of duodenal perforation.

H. pylori Infection

H. pylori is a gram-negative spiral flagellated bacterium. The organism is uniquely designed for survival in the hostile acidic stomach environment. The urease produced by this organism breaks down urea to alkaline ammonia and CO_2, which protects the bacterium from acid injury. The flagella and spiral structure allow penetration of the mucus and attachment of the bacteria to the gastric epithelial cell.

More than half the world population is infected with *H. pylori.* It appears to spread by fecal-oral transmission, and rates of infection are inversely proportional to socioeconomic status. Gastric inflammation is present in virtually all infected patients. There is no state of colonization without pathology. Infection is enduring and is never cured spontaneously. Eradication with antibiotic therapy results in resolution of gastritis. In the United States, ~80% of duodenal ulcer patients are infected and this contrasts with infection in ~60% of gastric ulcers. Nevertheless, only

20% of infected individuals develop a peptic ulcer; thus, the exact mechanisms producing ulceration are incompletely understood. It is established that in *H. pylori* patients with an ulcer, there is an increase in stimulated and basal acid output that is eliminated by eradication. In addition, *H. pylori* can interfere with mucosal protective mechanisms. *H. pylori* is a double-edged sword: increasing acid and reducing protection. We know that eradication of *H. pylori* infection in ulcer patients reduces the ulcer recurrence rate to well below 10%.

Nonsteroidal Anti-Inflammatory Drugs

In the Western countries, it is estimated that up to 30% of regular NSAIDs users have one or more ulcers. Both NSAIDs and aspirin interfere with the protective mucus layer by inhibiting mucosal cyclooxygenase activity and reducing levels of mucosal prostaglandins. Gastric acid also exacerbates NSAID injury, and conversely, gastric acid suppression has been shown to partially protect against NSAID injury. However, the exact mechanism by which NSAIDs cause duodenal perforation has not been clearly defined.

NSAID use has been reported to increase the risk of ulcer perforation by five to eight times that of nonusers (Svanes), and NSAID use is a factor in between one fifth to one third of perforations, the proportion increasing with increasing age.

Other Environmental Factors

Other environmental factors include cigarette smoking, excessive alcohol intake, and extreme emotional or physical stress. Cigarette smoking is a risk factor for PUD and its complications. Furthermore, cigarette smoking may adversely affect the healing of peptic ulcerations and, in the absence of treatment for *H. pylori*, may predispose to relapses. Cigarette smoking does not appear to influence the relapse rate for peptic ulceration if *H. pylori* in these patients has been eradicated. Nevertheless, at least one study has disputed the association between smoking and PUD. Smoking probably promotes peptic ulceration by increasing gastric acidity and maximal acid output and enhancing *H. pylori* proliferation. Smokers have been found to have decreased prostaglandin concentrations in their gastric and duodenal mucosa, and smoking has been shown to inhibit acid-stimulated duodenal mucosal bicarbonate secretion. It is not clear which, if any, of these proposed mechanisms contributes to peptic ulceration in cigarette smokers.

Alcohol

Alcohol has also been thought to be a strong risk factor for peptic ulcer, although there are little hard data to support this. While the prevalence of ulcers is higher in alcoholic cirrhosis, no association has been demonstrated in drinkers without cirrhosis.

Spicy Foods and Caffeine

Ulcer patients commonly describe dyspepsia with ingestion of certain foods, but there is no evidence that such foods cause ulcers. Coffee (caffeinated and decaffeinated), tea, and colas are all potent acid secretagogues. It was once popular to prescribe a bland diet for ulcer patients; however, they are generally conceded to exert no benefit.

Emotional Stress

Ulcers have long been associated in the public's mind with emotional stress; however, this association has been disparaged since the appreciation of the role of *H. pylori* infection and NSAID use. Emotional stress is probably not sufficient to cause ulcers in most patients since eradication of *H. pylori* and elimination of NSAIDs generally prevent ulcer recurrence despite the patient's emotional state.

Heredity

There are some suggestions that genetic factors may predispose a patient to peptic ulcer. The incidence among identical twins is higher than that for nonidentical twins, and there is an increase in first-degree relatives of ulcer patients. The genes responsible are unknown. Some of this increased susceptibility may be due to a high rate of *H. pylori* infection among family members. It was initially thought that elevated serum levels of serum pepsinogen I might be a genetic marker, but this now appears to be a consequence of *H. pylori* infection, which disappears with eradication. Other proposed markers include O blood group, lack of secretion of blood group antigens in saliva, and the presence of certain HLA subtypes; however, it now appears that these associations relate more to susceptibility to *H. pylori* infection.

COMPLICATIONS OF PEPTIC ULCER DISEASE

Complications of PUD include bleeding, perforation, and gastric outlet

obstruction. The treatment of these has undergone significant evolution. Management now includes the early use of high-dose intravenous (IV) proton pump inhibitors (PPIs), treatment to eradicate *H. pylori*, improved endoscopic and radiologic methods for control of hemorrhage, and changes in surgical indications and procedures. While historic studies suggest that hospitalizations for potentially life-threatening ulcer complications had plateaued or increasing, more contemporary reports indicate a steady decline in rates of hospitalization and in the incidence of bleeding and perforation. For example, Wang and colleagues found an ~30% to 40% fall in hospitalizations for PUD complications. They reported that the national estimate of hospitalizations for PUD decreased significantly from 222,601 in 1993 to 156,108 in 2006 (−29.9%), with a larger reduction in duodenal ulcers (95,552 in 1993 vs. 60,029 in 2006, −37.2%) than gastric ulcers (106,987 in 1993 vs. 86,064 in 2006, −19.6%). In addition, the inpatient mortality rate of PUD decreased from 3.8% to 2.7% during 1993 to 2006 ($P < 0.001$). Hemorrhage remained the most common complication (71.6% in 1993; 73.3% in 2006) but perforation had the highest mortality (15.1% in 1993; 10.6% in 2006). Further comparison to 1993 showed patients hospitalized for PUD in 2006 more frequently had endoscopic treatment to control bleeding (12.9% vs. 22.2%, $P < 0.001$), similar use of surgical over sewing of the ulcer (7.6% vs. 7.4%), less use of gastrectomy (4.4% vs. 2.1%, $P < 0.001$), and less use of vagotomy (5.7% vs. 1.7%, $P < 0.001$). Another study from the United States evaluated the National Inpatient Database and found that the rate of perforation and bleeding has been decreasing in the United States and hypothesized that this could be caused by the decrease prevalence of in *H. pylori.*

Of note the incidence of *H. pylori* rose dramatically prior to 1998, peaking at an estimated 97,823 cases in 1998 (SE = 3,155; 95% CI = 6,184). Since that time it has decreased and then stabilized. Another review estimated that the annual incidence of peptic ulcer hemorrhage is on the order of 19 to 57 cases per 100,000 individuals, and that the annual incidence of ulcer perforation is on the order of 4 to 14 cases per 100,000 individuals.

In the subsequent sections, we will discuss the management of three most common complications of duodenal ulcer disease: bleeding, perforation, and gastric outlet obstruction.

Bleeding Duodenal Ulcer

Hemorrhage is the most common complication of duodenal ulcer accounting for over two thirds of complications. The incidence is estimated to be 103 cases per 100,000 adults. Hematemesis is the most dramatic manifestation of massive upper gastrointestinal (GI) bleeding but may not be the most common. Melena may occur instead, or both may be present. Hemodynamic changes confirm the severity of the bleeding. Duodenal ulcer hemorrhage is usually self- limited, but in up to 25% of patients the bleeding persists or recurs despite medical management with IV PPI. Clinical factors such as hematemesis, shock, and transfusion requirement help to define this high-risk subgroup that requires urgent and aggressive multidisciplinary management; virtually all operations for bleeding, and all deaths, occur in this subgroup. A nasogastric (NG) tube is always indicated in patients with signs of sudden GI blood loss and no hematemesis, to help confirm or deny the presence of blood in the stomach. Significant duodenal bleeding usually has some duodenogastric reflux of blood even if no vomiting occurs. Thus, hematemesis or bloody NG tube suctioning confirms upper GI bleeding.

Knowledge of the patient's medical history is important to focus the next steps on resuscitation and diagnosis prior to therapy. Patients with known cirrhosis and portal hypertension will be much more likely to have hematemesis on the basis of bleeding esophageal varices, for example. For patients without any suggestion of liver disease or chronic alcohol ingestion, bleeding ulcer must be considered as the most likely cause for hemodynamically significant upper GI hemorrhage.

Resuscitation

When a surgical consultant is asked to see a patient with upper GI bleeding, it is essential that the surgeon ensure that there is: (a) a plan for and (b) completion of resuscitation ideally prior to starting definitive diagnostic procedures. The patient with signs or suggestions of a significant upper GI bleed should have the following resuscitative measures performed:

1. Large bore intravenous access, 16 gauge or larger, with two such lines available
2. Central venous access to monitor CVP and intravascular volume status
3. Foley catheter to monitor urine output

4. ICU bed with hemodynamic constant monitoring
5. Consideration of intubation if airway protection is indicated
6. Sufficient blood products available to meet the needs for resuscitation of both red cells and the capacity to clot normally

Diagnosis

Flexible upper endoscopy is the diagnostic procedure of choice. A gastroenterologist skilled in therapeutic endoscopy should be consulted unless the surgeon is an experienced endoscopist with therapeutic credentials. During the upper endoscopy, the following steps are warranted: continued monitoring of the patient's vital signs and volume status is imperative, as is protection of the airway. The most frequent technical challenge to the endoscopist performing a successful diagnostic and potentially therapeutic intervention is the presence of a large amount of blood within the lumen of the stomach. Evacuation of this clot via a very large bore gastric lavage tube (32 French, Ewald tube) is recommended. The tube is passed perorally and is capable of evacuating large clots. Lavage with several liters of water, not saline, may be needed before adequate visualization may occur. The water should not be cold so as to avoid hypothermia from it.

Once the stomach lavage return is clearing, the flexible endoscope is introduced and the esophagus, stomach, and duodenum inspected to the end of the third portion of the duodenum, and depending on the clinical findings the fourth portion of the duodenum may be examined as well if it can be accessed. Virtually, all upper GI bleeding sources are in the proximal duodenum, but may occur more distally. Bleeding lesions other than a duodenal ulcer may include esophagitis, esophageal varices, Mallory Weiss tear, Dieulafoy ulcer, gastritis, gastric varices, gastric ulcers, duodenitis, and tumors or polyps in any of these areas. Aortoenteric fistula should always be considered if there is a history of vascular surgery or (rarely) treatment (e.g., radiation or stenting) for advanced esophageal or gastric cancer. The typical bleeding duodenal ulcer is located within several centimeters of the pylorus on the posterior aspect of the duodenum. Significant hemorrhage arises because the ulcer has eroded into a branch of or the main lumen of the gastroduodenal artery. If the latter has occurred, then the bleeding is brisk and may be associated with projectile hematemesis and shock.

Endoscopic Therapy

The endoscopist has several options for treating the bleeding duodenal ulcer. These include

1. Endoscopic clips placed directly on any visible vessel
2. Injection of the base of the ulcer with dilute epinephrine solution
3. Bicap probe to coapt the vessel lumen
4. Heater probe to coagulate the vessel lumen
5. Argon beam for more diffuse oozing surfaces (less likely for a bleeding vessel)

Skill and experience are needed to perform therapeutic endoscopy to arrest vigorous bleeding from a duodenal ulcer. The main technical problem is the ability to see through the scope despite the ongoing bleeding. The suction capacity of the endoscope is limited, and when used, performs the automatic negative process of removing the insufflated air within the lumen of the duodenum necessary to maintain visualization during the procedure.

If the initial endoscopic treatment fails and recurrent bleeding ensues, it must be noted that not all patients need to proceed to embolization or surgery. A selective approach to treatment may be adopted based on the local characteristics of the ulcer and the pre-existing comorbidities of the patients. Large ulcers (>2 cm) and those with a visible vessel may best be treated by surgery if recurrent bleeding occurs. Patients who are poor surgical candidates might benefit from repeated endoscopic treatment, but in some instances the patient is then best served by moving on to either radiologic or surgical therapy. The decision for which treatment is best should be individualized and requires surgical judgment taking into account the above factors and the hemodynamic stability of the patient.

Radiologic Therapy

Since the last edition of this text, the radiologic approach to upper GI bleeding has become even more popular as the next therapeutic option with failure of interventional endoscopy. Over the past decade, interventional radiologists in many institutions have developed increasing experience in vascular embolization to arrest hemorrhage. The concern for end-organ ischemia that is present when embolization of organs such as the colon or small bowel is considered is not as great a concern with a bleeding duodenal artery, as the collateral circulation provided by the

pancreaticoduodenal artery to the duodenum will usually prevent ischemia should the gastroduodenal be occluded from embolization. The radiologist uses a combination of coils or other intraluminal objects to achieve the desired embolization of the gastroduodenal artery. Success with this approach is good as defined by leaving the hospital without further intervention. However, in some circumstances, the backflow of the vessel or the volume of the bleeding is such that even this approach may fail. At that point, surgical therapy is the indicated course.

Although it is still controversial as to whether radiologic intervention is superior to surgical intervention in terms of overall outcomes for treating bleeding duodenal ulcer, it has now become the next step in many institution's algorithms of treatment of bleeding duodenal ulcer after endoscopy and before surgery. This situation depends on the local expertise available in any institution and the ability to respond as rapidly as surgery. The less invasive nature of the radiologic intervention has appeal in terms of limiting abdominal wall morbidity as well as other potential complications which may arise from abdominal surgery. Radiologic intervention for bleeding duodenal ulcer is also ideal when the patient has failed endoscopic treatment and for a variety of reasons and is a poor surgical candidate. These reasons could include inherent existing diseases of the patient, poor anesthetic risk, or multiple previous abdominal operations making abdominal access difficult, among others.

SURGICAL TREATMENT

The current indication for surgical therapy for treatment of bleeding duodenal ulcer is when

1. Less invasive therapies have failed
2. Less invasive therapies are not available
3. The severity of the bleeding does not allow for the potential for a lesser invasive procedure to be done in terms of the time allowable before the hemorrhage must be controlled (a hemodynamically unstable patient)

Surgical therapy must be exercised whenever the patient shows hemodynamic instability along the above algorithm, indicating that the ability to tolerate ongoing blood loss at that rate is limited in terms of time, and failure of an endoscopic or even radiologic approach could prove life-threatening. This assumes that the patient is a candidate for surgical therapy. Primary emergency surgery is indicated when shock persists

despite aggressive volume resuscitation and when blood loss continues, necessitating transfusion in excess of 6 units of blood over a 24-hour period. Other factors to consider in the decision-making process include patient >70 years (physiologically), the presence of multiple comorbidities, and a previous history of ulcer diathesis. Especially where interventional radiologic alternatives do not exist, the poorer the surgical candidate, often the more rapid and aggressive must be the surgical intervention if the patient is to survive. The timing of primary emergency surgery should be influenced by these factors, given that the morbidity and mortality are greatly increased with delayed intervention.

CHOICE OF OPERATION

In choosing the type of operation for treatment of the actively bleeding duodenal ulcer, factors to be considered are the patient's condition and the technical difficulty and expected duration of the operation. Local factors around the potential operative site including previous surgery and scarring must also be considered. The various operations that have been performed in the past have been well analyzed to allow some judgment as to their efficacy and appropriateness in the setting of treating duodenal ulcer.

While many operative procedures are now routinely done using a laparoscopic approach, the indications for surgical intervention for bleeding duodenal ulcer usually are such that one is performing an emergent operation where speed and simplicity are valuable components of the procedure. Laparoscopic opening of the duodenum and suturing of a bleeding ulcer may be quite within the technical abilities of some surgeons, and this approach, if able to be carried out with good visualization of the ulcer, is not to be ruled out. Nevertheless, the experience of most surgeons in rarely performing surgical therapy for bleeding duodenal ulcer and the technical difficulty of maintaining the pneumoperitoneum in the face of constant suctioning of blood from the bleeding vessel site make the laparoscopic approach limited in its application to a select fewer surgeons.

It is now also quite clear that the decades old recommendation of performing an antrectomy and truncal vagotomy as the most definitive treatment of PUD is also to be avoided in the setting of the emergent operation for bleeding duodenal ulcer. First, the duodenum must be opened to treat the ulcer, making the closure of the duodenum more difficult in the setting of antrectomy. The typical bleeding ulcer is posterior and thus, by

definition, in the pancreas. Resection in this setting is fraught with opportunity for duodenal leak. Multiple options exist for dealing with the "difficult duodenal stump," but the best technique is not to create the duodenal stump in the first place. The additional surgery needed for resection as well as anastomosis is rarely justified in the emergency setting.

The operation of choice for the high-risk, unstable patient continues to be suture ligation of the bleeding vessel. In the stable patient, vagotomy and drainage may be considered. If the duodenotomy is easily incorporated into a Heinike–Mikulicz pyloroplasty, then that is the drainage procedure of choice. If the duodenotomy is too long or too distal, then simple closure with gastrojejunostomy may be preferable if truncal vagotomy is performed. Instead of truncal vagotomy, it may not be unreasonable to rely on long-term PPI therapy. Suture ligation alone is perfectly acceptable followed by PPI treatment. If there is no access to medical therapy, then truncal vagotomy or even highly selective vagotomy may be performed. Certainly, any vagotomy, truncal or highly selective, is the last step of the operation once hemostasis has been achieved and the duodenum is closed. At that point, the condition of the patient as well as other factors that may be relevant should combine to allow the surgeon to make the best decision regarding vagotomy.

CHOICE OF INCISION

An upper midline vertical incision serves most situations for performing upper abdominal surgery. The pylorus and duodenum are sufficiently close to the midline to allow good exposure with such an incision. The incision may need to be carried up to the xiphoid if truncal vagotomy is contemplated, especially if the patient is obese. The lower extent of the incision is usually around or above the umbilicus.

Upon entering the peritoneal cavity, rapid exploration should confirm the presence of a NG tube or Ewald-type tube in the lumen of the stomach (at times from the endoscopy) and gastric decompression. The round and falciform ligaments are divided. Additional exposure of the duodenal area is achieved through the use of mechanical self-retaining retractors. Several brands are available and afford adequate exposure. There should be an appropriate retractor for the liver to both retract it and avoid parenchymal injury. A Kocher maneuver should be done.

If a laparoscopic approach is used in a more elective setting, we use

port placement similar to what we would use in the performance of an antireflux operation, but situating the surgeon's right hand port closer toward the midline and the left port slightly further to the patient's right. This allows the main axis of the camera, located in the umbilical region, to be pointed toward the duodenum. There is no place for single port surgery in this setting. A Nathanson, flexible triangular, or other epigastric to right subcostal located liver retractor is appropriate.

SURGICAL TECHNIQUE

Suture Ligation

The primary objective during surgery to treat a bleeding duodenal ulcer is to control the bleeding vessel. Thus, this step takes precedence and is of paramount importance. When the bleeding vessel has been localized by endoscopy to be in the first portion of the duodenum, a Kocher maneuver is performed for mobilization of the second portion of the duodenum. The pyloric vein is used as a landmark to identify the pylorus, if it is not readily identifiable by visualization and palpation. Traction sutures of 2-0 silk are placed superior and inferior to the pyloric ring. A longitudinal full-thickness incision is made starting on the prepyloric antrum halfway between the greater and lesser curvature (Fig. 87.1). Once the distal stomach is entered, a blunt hemostat can be used to gently traverse the pylorus into the proximal duodenum. This instrument is used to guide the full-thickness cut through the pylorus into the duodenum. We use the cautery. Often a 3-cm longitudinal incision is sufficient. It is important to ensure good hemostasis. Traction on the sutures opens the incision into the form of a diamond, which allows adequate exposure. Intraluminal clot is suctioned away. Occasionally, the incision needs to be extended another 1 to 2 cm further into the duodenum if the ulcer is slightly more distal.

Once the incision is completed, the bleeding source and ulcer are identified. Direct pressure is applied to any ongoing bleeding while preparing to suture ligate the site. It is helpful after Kocherization for surgeon or assistant to elevate duodenum with left hand permitting manual compression of the bleeding ulcer. This pressure can be held as long as necessary to allow anesthesia to catch up with resuscitation. If the ulcer has a clot over it, the clot must be cleared away adequately to define the location of the bleeding vessel. If the bed of the ulcer has stopped actively bleeding, suture ligation is still performed. However, in this setting, a search for other potential bleeding sites should be performed. If it is clear

that there is ongoing hemorrhage from a site more proximal to the pyloromyotomy from the stomach, attempts to intraoperatively visualize it through the incision should be made. Extension of the incision may be needed if the source is identified as close. If the source is unclear, intraoperative gastroscopy by a colleague is indicated to determine the site of the bleeding. Then a second gastrotomy can be made at that site to treat it appropriately.

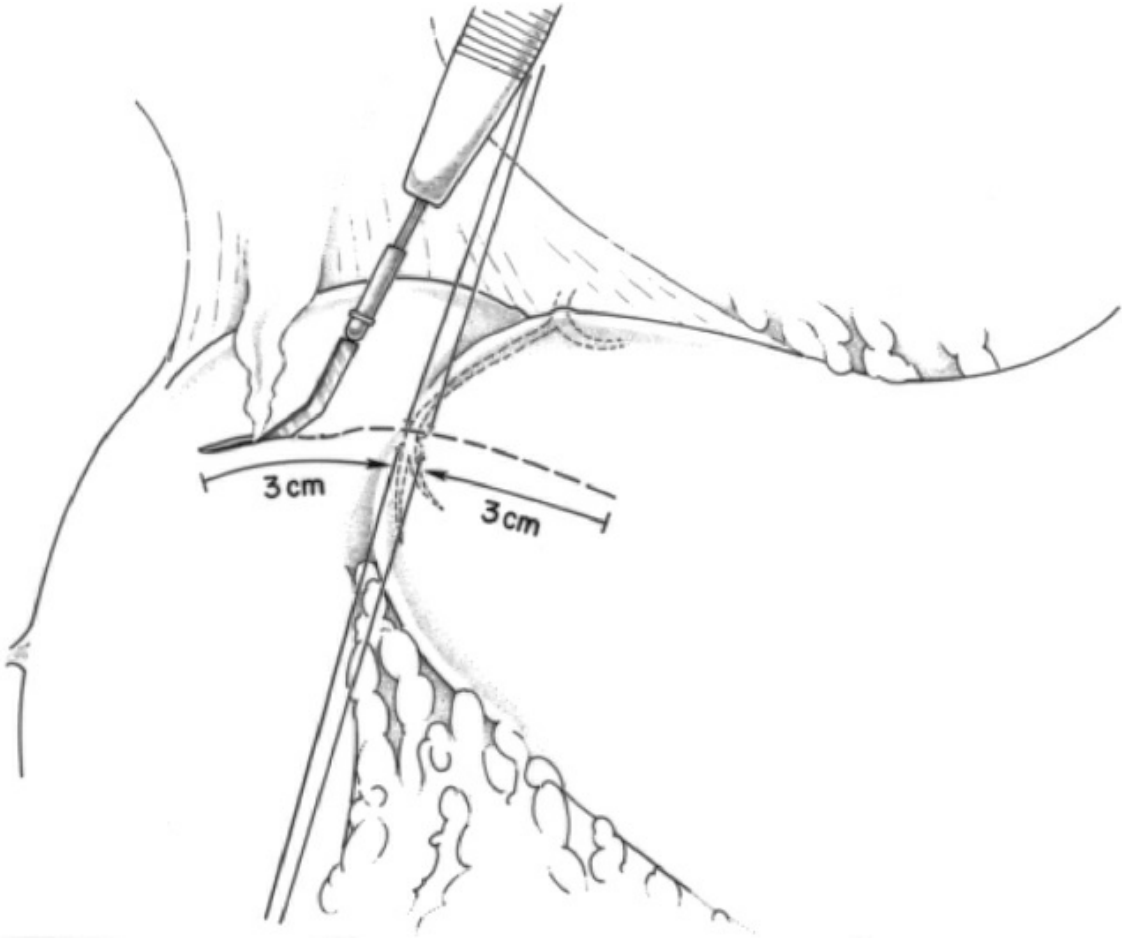

Figure 87.1. A longitudinal incision is made, spanning 3 cm on each side of the pylorus, to give adequate access to the duodenal bulb for suture ligation of the bleeding duodenal ulcer. Traction sutures of 3-0 silk have been placed at the level of the pylorus, identifiable by the vein of Mayo.

When an actively bleeding duodenal ulcer is identified, direct pressure is followed by suture ligation. A thorough understanding of the anatomy of the gastroduodenal complex, described as the T-three vessel junction, is important when performing suture ligation (Fig. 87.2). The gastroduodenal complex should be transfixed at three points, with the gastroduodenal

artery ligated proximal and distal to the site of penetration. The third suture ligature, a U stitch, should transfix the transverse pancreatic branch, which is located medially. Major rebleeding, if it occurs, is most likely due to imprecise placement of these suture ligatures through failure to recognize that the arterial site of bleeding is located at a junction of the gastroduodenal complex. Some prefer to use heavy absorbable synthetic suture (2-0 weight), but the use of silk suture is certainly acceptable and preferred by many. Heavier round surgical needles are indicated if there is excessively thick scarring of the posterior wall of the duodenum from the ulcer, which is usually the case. Care must be taken to adequately incorporate the vessel into the ligature, but to avoid such a depth of penetration so as to avoid injury to any surrounding structures. The bile duct may be close enough to the ulcer that injury may occur with deep sutures or with superficial ulcers in proximity to the ampulla of Vater. If there is concern, then a cholangiogram may be performed. If the ampulla of Vater is involved with the ulcer, it may be necessary to place a biliary fogarty into the common bile duct via the cystic duct and thread this into the duodenum so as to mark the ampulla so that injury may be avoided. All of these maneuvers take time, and if speed is of the essence in an unstable patient the surgeon may need to proceed without these precautions.

Heineke–Mikulicz Pyloroplasty

The simplest closure of the pyloromyotomy is a standard Heineke–Mikulicz pyloroplasty. This involves simply closing the longitudinal opening in a transverse direction using a single layer of sutures. Typically the incision is closed transversely with 3-0 seromuscular silk sutures (Fig. 87.3). In this technique, the sutures are placed first and then all tied seriatim. Classically, care is taken that no mucosa is protruding up through the apposed serosa. Probing between the suture gaps with a fine clamp may identify the need for additional seromuscular sutures that are placed as needed. More technically involved suture techniques such as the Gambee suture are proven traditional methods as well (Fig. 87.3). This suture technique involves a full-thickness penetration of the bowel from serosa to mucosa on one side, then a submucosal bite on that same side intraluminally, followed by a mirror image submucosal bite in the bowel inner surface on the opposite side of the opening, then a full thickness from mucosa out through serosa of the second bowel wall. This is illustrated in Figure 87.3, which shows closing in a Heineke–Mikulicz

fashion.

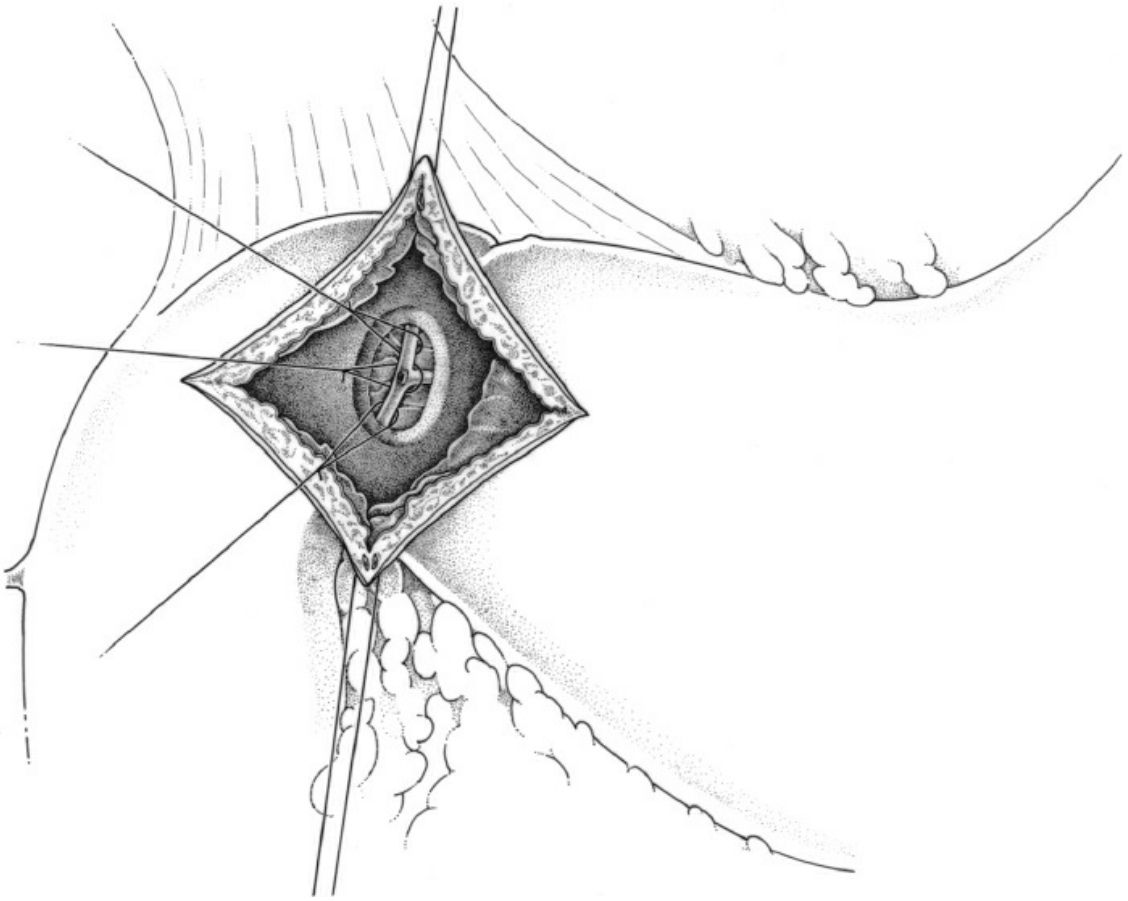

Figure 87.2. Proper suture ligation of a bleeding ulcer arising from the gastroduodenal artery requires a three-suture ligation. The proximal and distal branches of the gastroduodenal artery are transfixed. A third suture, U type in configuration, is necessary to transfix the transverse pancreatic branch of the artery.

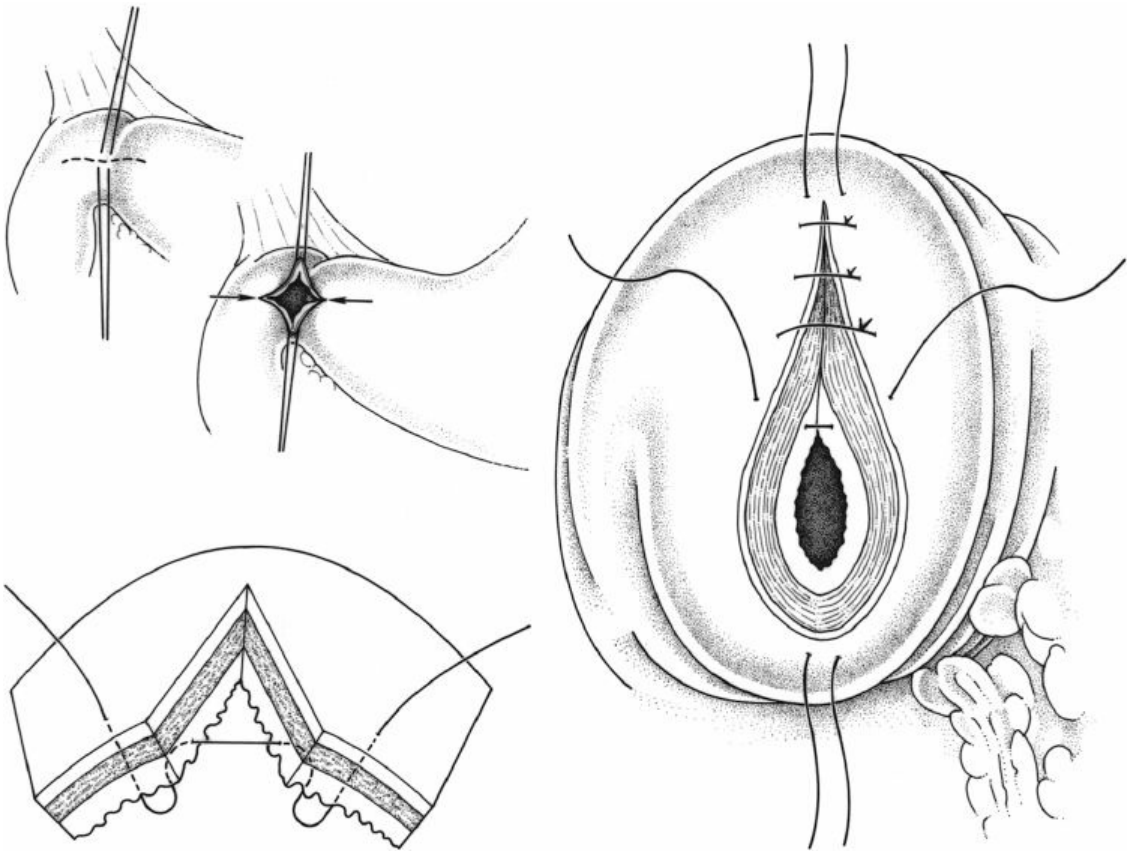

Figure 87.3. A standard Heineke–Mikulicz pyloroplasty performed with a single layer of sutures (Weinberg). The longitudinally oriented incision (**upper left**) is closed transversely (**middle left**), such that the former end points of the longitudinal incision (*arrows*) are apposed; this transverse closure of the incision prevents potential functional gastric outlet obstruction after vagotomy. Sutures are placed as shown in the **lower left,** creating a single inverting layer (**right**).

Finney Pyloroplasty

This operation requires more extensive dissection than Heineke–Mikulicz pyloroplasty, so a larger incision is necessary if done open. This would be needed infrequently to manage a bleeding duodenal ulcer and more common for an obstructing ulcer or penetrating ulcer. A Kocher maneuver is necessary. A 10- to 12-cm longitudinal gastroduodenotomy is made, transecting the pylorus, which should be at the midpoint of this longitudinal incision. This incision is then closed as a side-to-side gastroduodenostomy, with the pylorus at one apex. Ideally, the closure is in two layers. Finney used running silk on the back outer layer, then running absorbable suture on the inner layer, and then interrupted silk on the outer front layer. Again, it seems prudent to test anastomotic integrity

with air insufflation and consider postoperative gastric decompression with an NG tube.

Jaboulay Pyloroplasty

This is essentially a side-to-side anastomosis between the greater curvature side of the distal stomach and the anterior proximal duodenum. Takedown of the hepatic flexure of the colon may facilitate exposure especially in the obese patient. A Kocher maneuver should be performed, and then a standard two-layer longitudinal tension-free hand-sewn anastomosis should be done and tested. An anastomosis 4 to 5 cm in length is adequate. We prefer silk and braided absorbable suture to the stiffer monofilament suture. It is possible to utilize stapling instruments to perform this anastomosis, perhaps a laparoscopic 45-mm linear cutter and TA 30. Staple size should be chosen based upon the thickness of the stomach, and hemostasis of the linear staple line assured. Again, the integrity of the anastomosis is tested with air insufflation. Although it is possible to envision other stapling techniques for pyloroplasty or gastroduodenostomy, we generally do not favor making additional openings in the GI tract to accomplish this.

Truncal Vagotomy

This is an expanded description of open truncal vagotomy, also known as total abdominal vagotomy, described in Chapter 86. This is sometimes performed in the emergent setting in the stable patient after the pyloroplasty has been completed. Retraction of the left lobe of the liver is performed. Division of the left triangular ligament may be performed only if further exposure is needed.

Downward traction is gently applied to the stomach, placing the gastroesophageal junction (GEJ) area under slight traction. The phrenoesophageal ligament and the peritoneum covering the GEJ area are divided transversely (Fig. 87.4). The right hand thumb and index finger of the surgeon are now used to bluntly develop the plane beneath the anterior lip of the esophageal hiatus and to the left of the esophagus (Fig. 87.5). The esophagus is circumferentially bluntly dissected with the right index finger and thumb. The index finger continues along the posterior surface of the esophagus, bluntly dissecting the posterior phrenoesophageal ligament, and the esophagus becomes encircled by the index finger and thumb (Fig. 87.6). The NG tube within the esophagus serves as a guide for confirming

the esophagus as this maneuver is being performed. Once encircled by the surgeon's fingers, a Penrose drain may be placed around the esophagus to facilitate retraction at this point (Fig. 87.7). Retraction must be gentle to avoid tear or injury. Although most surgeons do the dissection in the abdomen, one can develop a plane on the anterior esophagus and dissect the esophagus in the chest (taught to JM by Professor Dragstedt). Dragstedt referred to this as a transabdominal intrathoracic vagotomy.

The vagal trunks are now identified. The anterior one is always buried within the anterior muscle fibers of the distal esophagus, between the 12 and 2 o'clock positions. It is best located 2 to 4 cm above the GEJ in this location (Fig. 87.8). Gentle, sharp, and blunt dissection frees the nerve from the surrounding muscle fibers (Fig. 87.9). Direct palpation of the anterior wall of the esophagus is usually the best way to find this nerve. The posterior trunk, on the other hand, is more often not adjacent to or within the muscle of the esophagus. It is instead usually located within the 6 to 8 o'clock area of the esophageal circumference, laying on the posterior crural intersection. The posterior nerve is always larger than the anterior nerve and palpating along the upper right side of the esophagus, then moving downward to posterior to the esophagus, and palpating in a downward direction on the crural intersection will often reveal the location of the nerve. Failure to properly identify the posterior nerve is the most common error in this operation. Often the inexperienced surgeon will mistake some of the fibrous tissue along the posterior surface of the esophagus as the nerve. Remember, the posterior nerve is larger than the anterior one. If the surgeon is having difficulty finding the nerve using the above technique, then further dissection with the left index finger along the right mediastinum further up along the right side of the esophagus will usually allow its identification. Dissection of esophagus several centimeters above the GEJ allows the posterior nerve to be picked up in the initial encirclement. When dissecting esophagus, surgeon should try to include as much tissue as possible to avoid leaving behind the posterior nerve.

Figure 87.4. Total abdominal vagotomy begins by incision of the phrenoesophageal ligament transversely at the level of the abdominal esophagus.

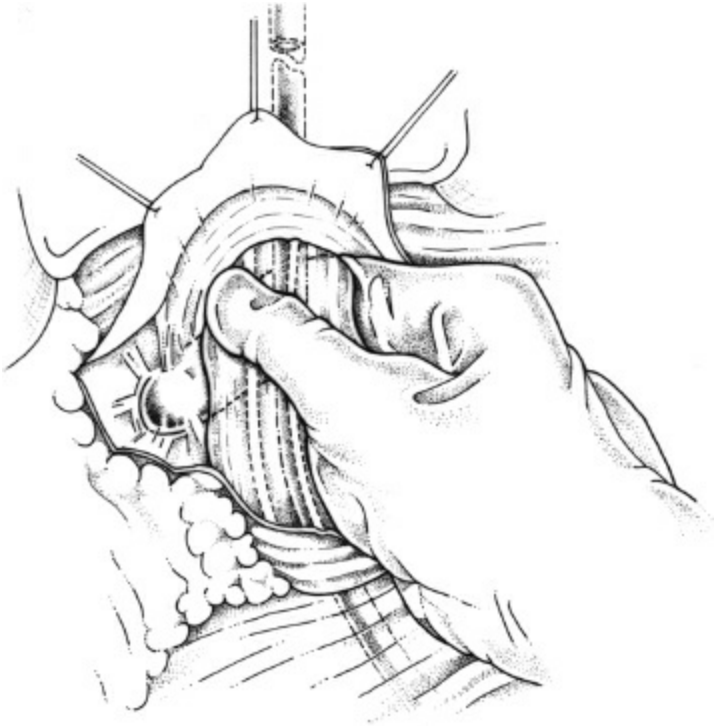

Figure 87.5. The surgeon's right index finger and thumb are used to blunty create a window posterior to the palpable wall of the esophagus, with the loose tissue and peritoneum dissected off

the esophagus. The nasogastric tube is palpated to confirm the location of the esophagus as this dissection begins.

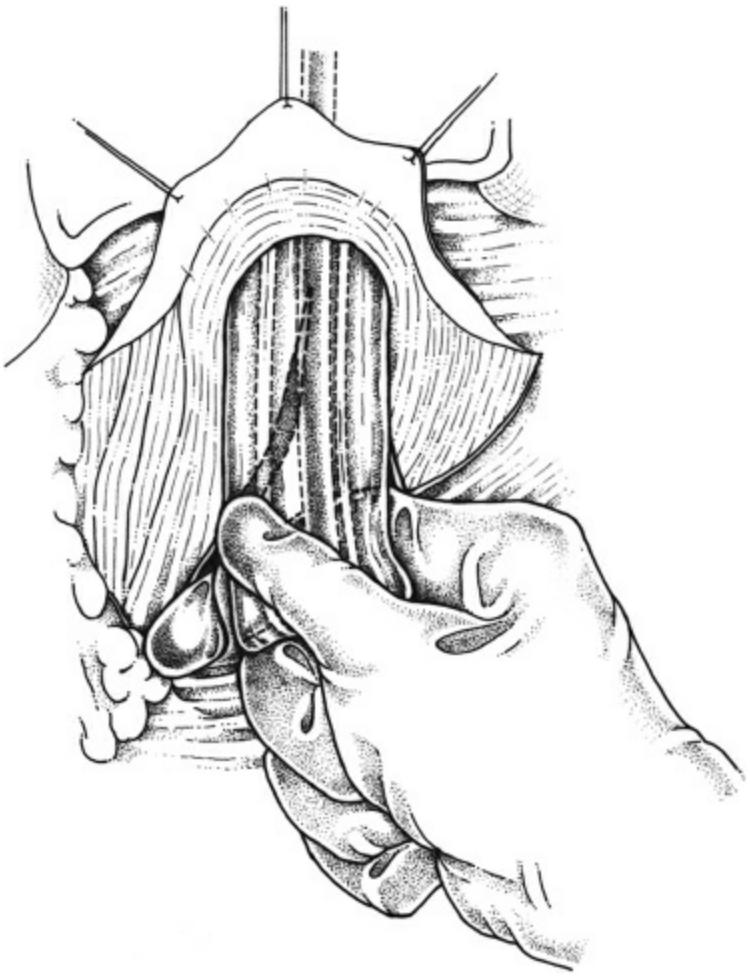

Figure 87.6. The surgeon has now completely encircled the posterior abdominal esophagus with the right index finger.

Once both trunks of the vagus nerve are identified, they are separated from the surrounding tissues with a nerve hook or a right angle clamp (Fig. 87.10). Medium clips are applied to each nerve proximally and distally allowing 2 cm of nerve between the clips, which is then resected and inspected to be certain, by visual inspection, that the tissue is neural tissue (Figs. 87.11 and 87.12). Pathologic confirmation of the neural tissue is also indicated. In the setting of reoperative surgery for incomplete vagotomy, a frozen section of the neural tissue may be necessary to confirm its identity.

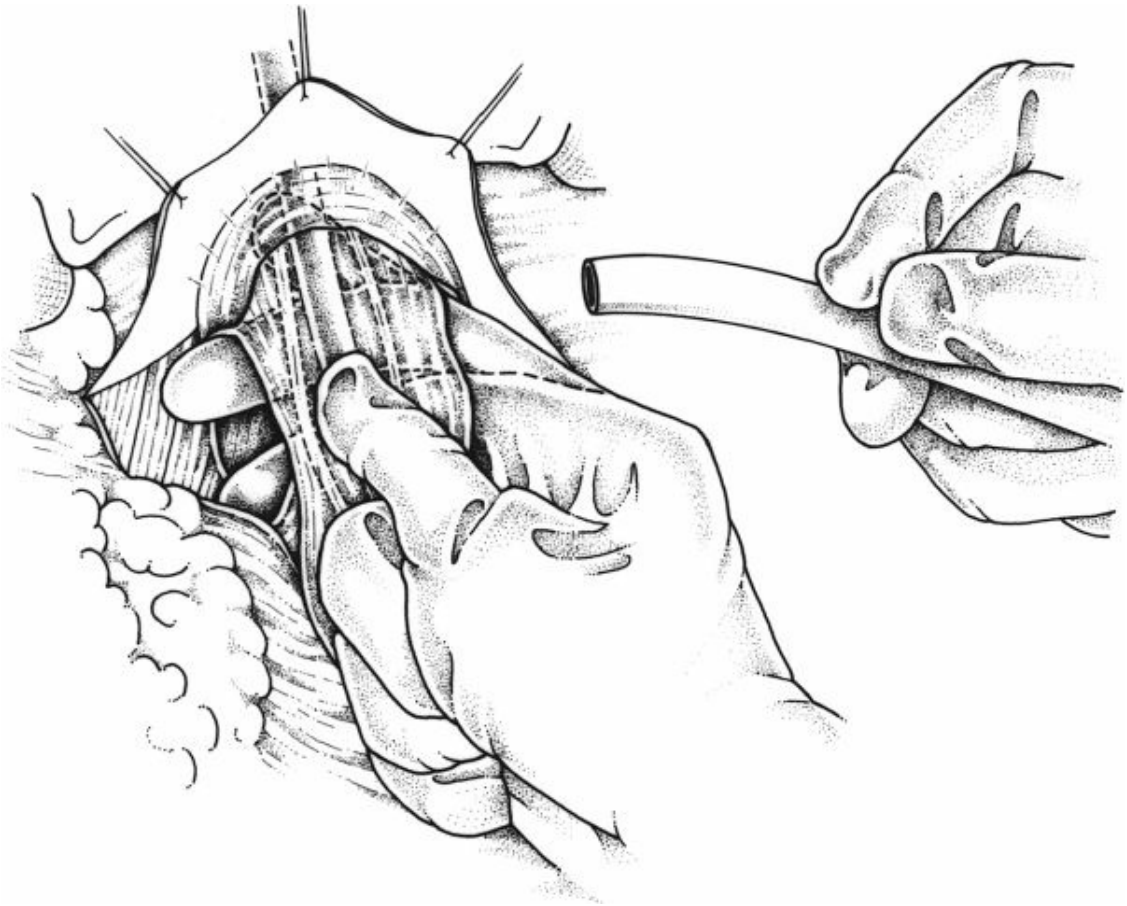

Figure 87.7. The retroesophageal opening is widened bluntly to permit passage of a Penrose drain, which allows more efficient esophageal retraction to facilitate the remaining portion of the vagotomy.

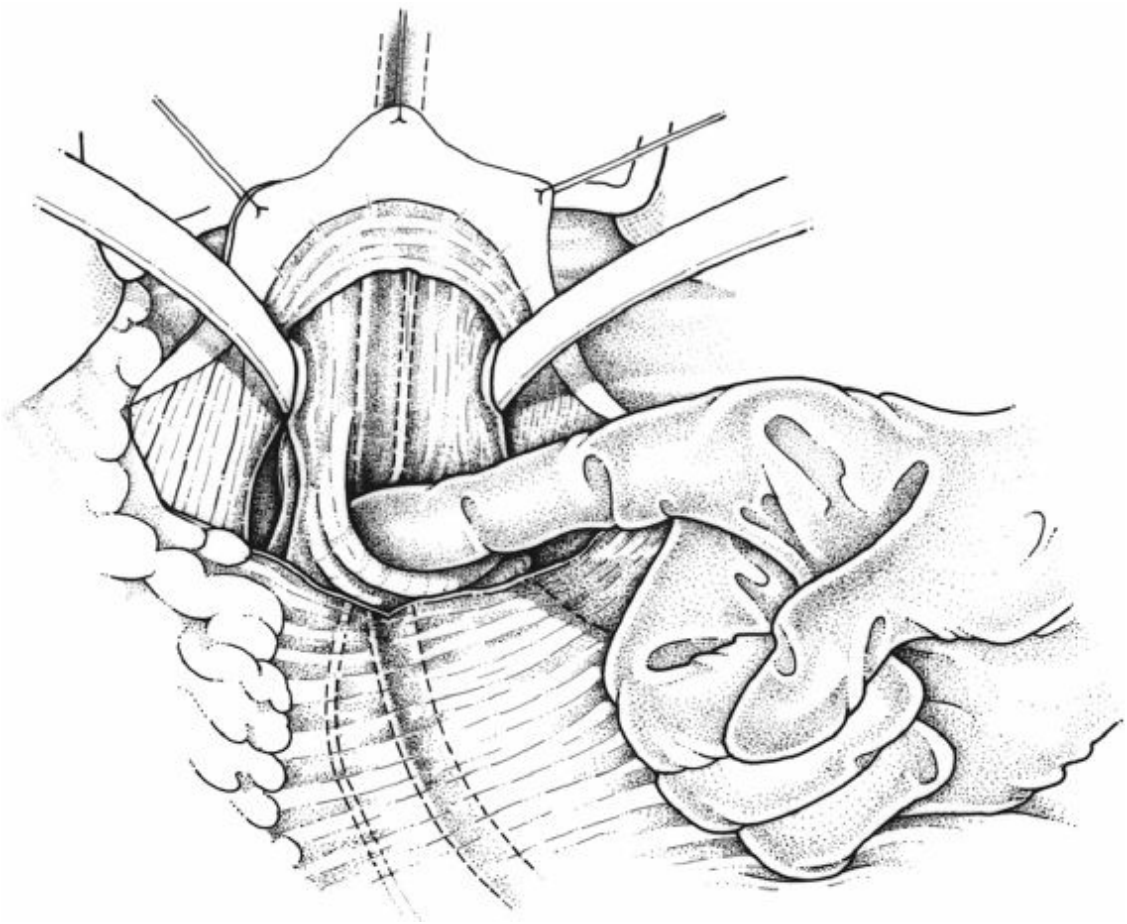

Figure 87.8. Identification of the anterior trunk of the vagus nerve is performed bluntly, by palpating the very firm structure of the nerve in the midportion of the lower abdominal esophagus using gentle downward rolling pressure.

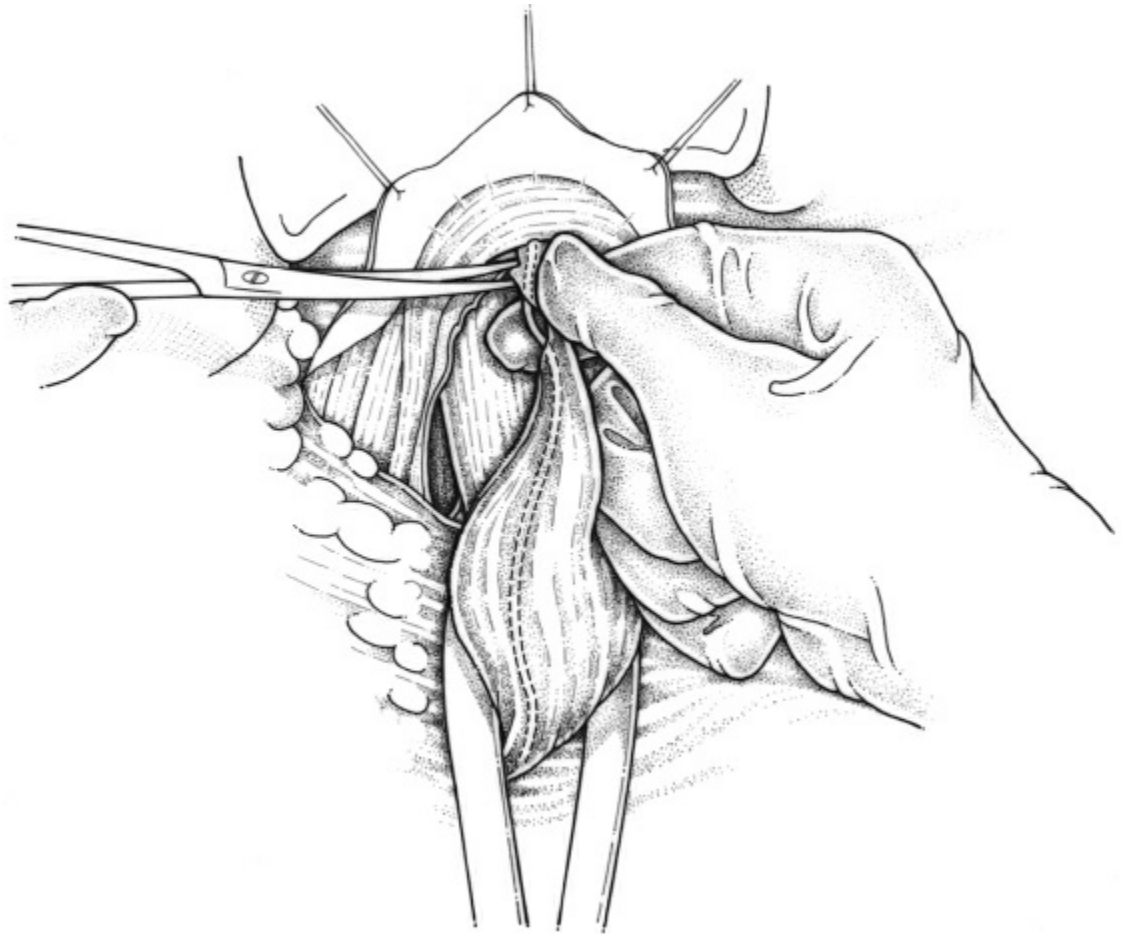

Figure 87.9. The anterior nerve is best found lying on the anterior surface of the esophagus, between 12 o'clock and 2 o'clock, 2 to 4 cm above the gastroesophageal junction. Gentle sharp and blunt dissection frees the nerve trunk from surrounding tissue.

The final step of the vagotomy is the skeletonization of the distal 5 cm of esophagus of all neural fibers. The "criminal nerve" of Grassi is included among these neural fibers. It originates from the posterior vagus and runs toward the left side of the distal esophagus. The operation is completed once skeletonization is complete and hemostasis is present.

In summary, the role of the vagotomy in 2017 is unclear. Our modern understanding of the pathogenesis of peptic ulcer suggests that treatment of *H. pylori* and elimination of NSAID use should result in cure of the underlying risk of ulcer. Furthermore, with the advent of PPIs it is now possible to medically eliminate gastric acid production without the side effects of vagotomy. Although level 1 data exist for perforated duodenal ulcer demonstrating that *H. pylori* treatment eliminates the need for definitive ulcer surgery, there is to date no trial that confirms this finding in the case of bleeding duodenal ulcer. Despite the lack of level 1

evidence, surveys of surgeons in the United Kingdom and national data from the United States suggest that most surgeons no longer perform a vagotomy as a component of operation for bleeding duodenal ulcer.

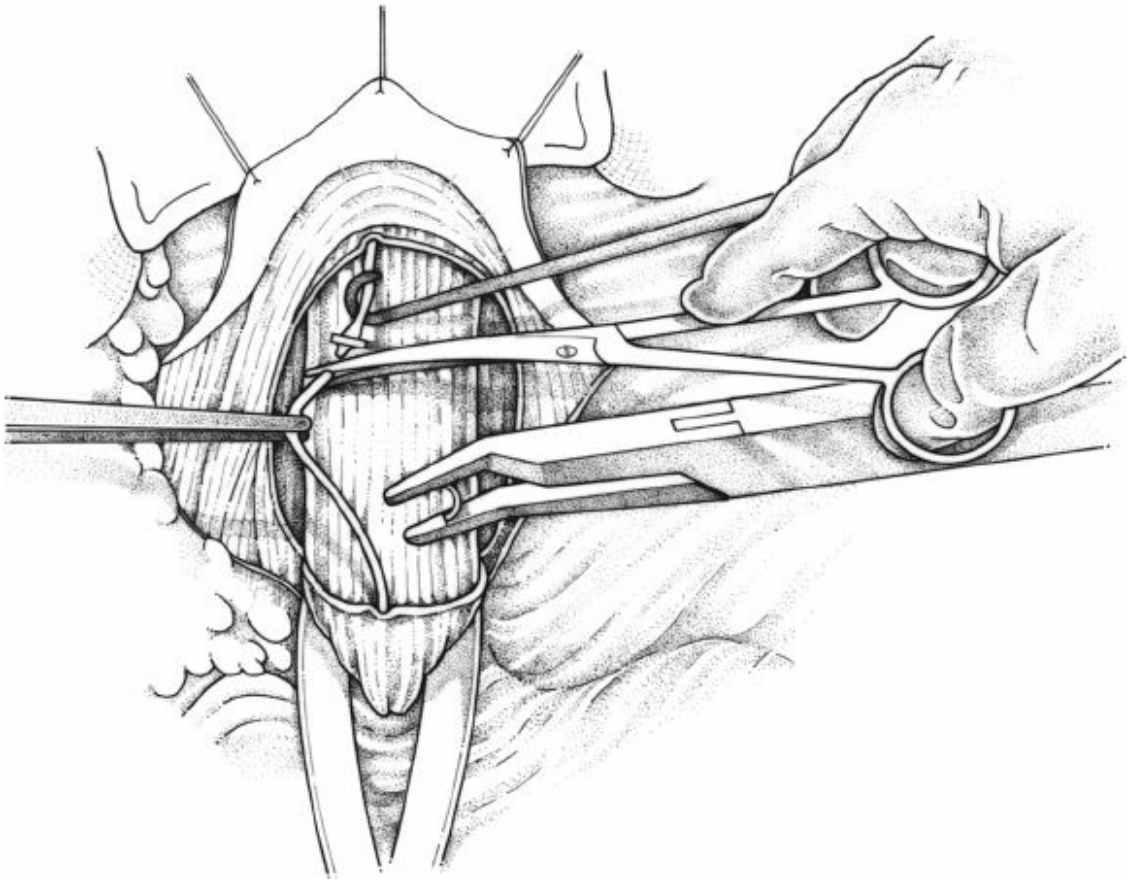

Figure 87.10. A nerve hook facilities lifting the nerve truck away from surrounding tissue, which allows clipping of the nerve proximally and distally. The nerve is then divided to remove a section of it for confirmatory pathologic analysis.

Duodenotomy

In a young, hemodynamically stable individual in whom there is no obesity and the anatomy of the stomach is well visualized, it is acceptable to perform a lateral duodenotomy to approach the ulcer in order to accomplish over sewing of the ulcer and preserve the pylorus. The patient may be treated with PPI and avoid vagotomy, although highly selective vagotomy is an option. The increased operative time for highly selective vagotomy is justified only in a hemodynamically stable patient. The result may be a physiologically better operation with reduced morbidity.

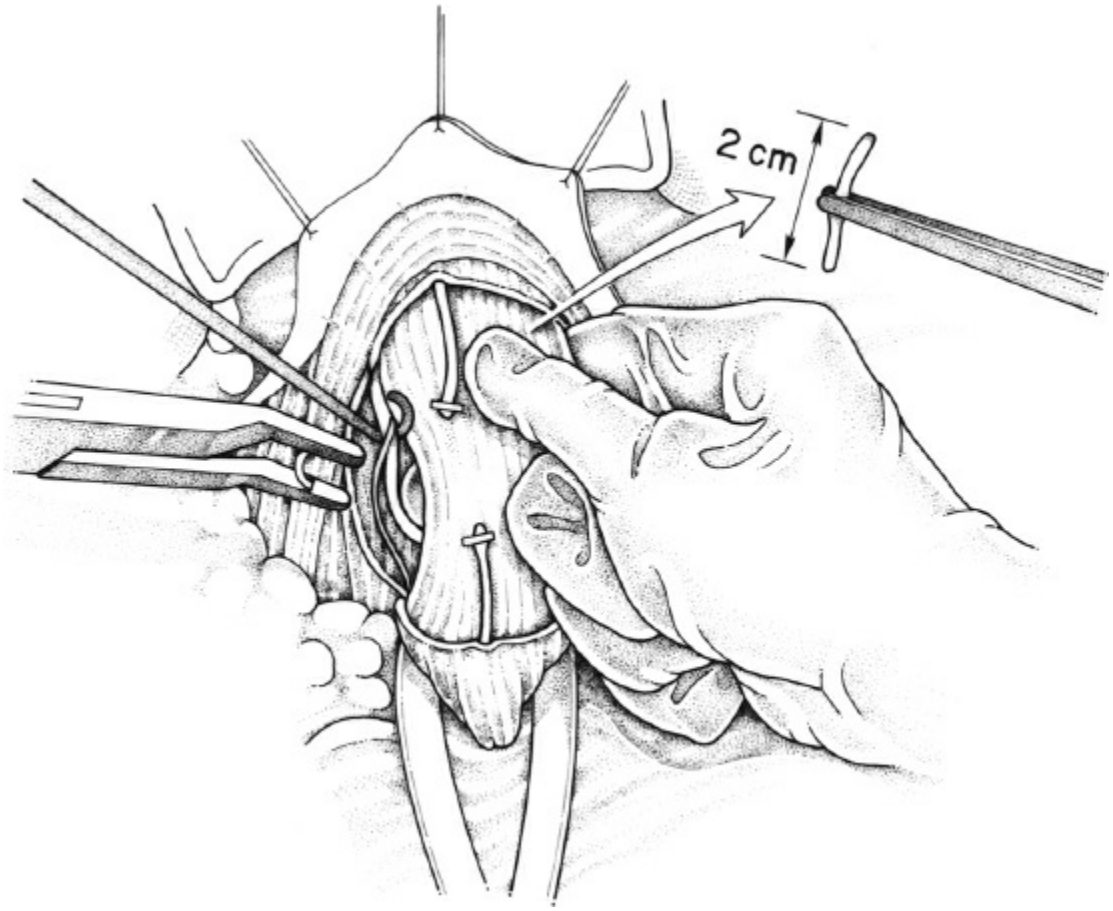

Figure 87.11. A 2-cm section of the anterior nerve has been removed. Attention now focuses on locating and dividing the posterior nerve. The posterior nerve is always larger than the anterior and is usually found lying away from the esophagus in the 6 o'clock to 8 o'clock position. Once located, it is hooked and clipped as was the anterior nerve.

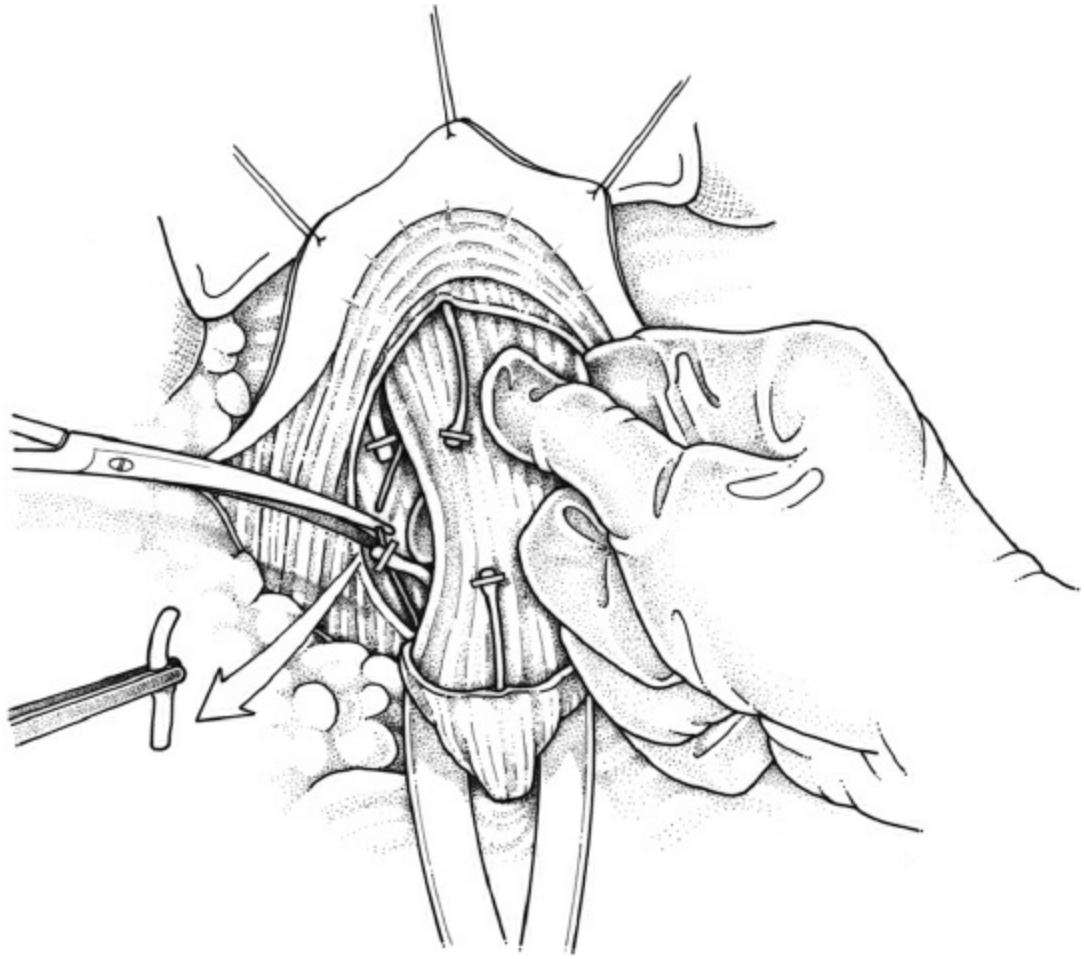

Figure 87.12. A 2-cm section of the posterior nerve has now been removed (*arrow*). The final step in vagotomy is total skeletonization of the distal 5 cm of the abdominal esophagus. Here a small fiber innervating the posterior fundus, often called the “criminal nerve” of Grassi, is divided as part of the skeletonization process.

Highly Selective Vagotomy

After a duodenotomy and ligation of the ulcer are performed, the acid-producing parietal cells may be selectively denervated while smooth muscle innervation to the antrum is preserved. This procedure is facilitated the Harmonic scalpel or other energy sources to coagulate the nerves and the associated vasculature. This approach affords a rapid, efficient means of performing the highly selective vagotomy compared with the tedious conventional approach of individual nerve ligation.

The left lobe of the liver is retracted with a Weinberg retractor. The first landmark one should identify is the terminal branch of the anterior vagal nerve, the nerve of Latarjet, which runs parallel to the lesser curvature of

the stomach. One should accurately identify the first terminal branch of the anterior nerve or the “crow’s foot.” The avascular window in the lesser omentum is incised between the anterior nerve and the lesser curvature. The Harmonic scalpel is introduced into the opening and positioned parallel to the anterior nerve of Latarjet (Fig. 87.13). With the assistant retracting the lesser curvature to the left, the operating surgeon applies traction to the lesser omentum with the left hand and uses the Harmonic scalpel with the right hand. In this manner, the crow’s foot and the anterior nerve of Latarjet are adequately exposed and visualized. The Harmonic scalpel is used ultrasonically to coagulate the neurovascular bundles in the anterior leave of the lesser omentum. The dissection of the anterior leaf proceeds from the proximal branch of the crow’s foot and culminates at the GEJ. The first branch of the crow’s foot has been demonstrated to innervate exclusively parietal cells and should therefore be coagulated.

Several technical points must be emphasized regarding the use of the Harmonic scalpel or Ligasure. The flat blade of the scalpel should be used when medium-sized vessels are divided ultrasonically. The surgeon needs to check both blades before implementation to ensure that they are appropriately coapted. If the blades are not flush on closure, the vessel will not be adequately sealed. One must also past point when dissecting out a neurovascular pedicle to be certain that the entire bundles are in the blade and coapted. It is advisable to put the hot blade up and the cold blade down in an attempt to avoid thermal injury to the stomach that conceivably could result in a delayed perforation. The final point is to let the Harmonic scalpel do the work. Unnecessary tension applied by the surgeon may tear these fragile vessels before adequate coaptation by the Harmonic scalpel.

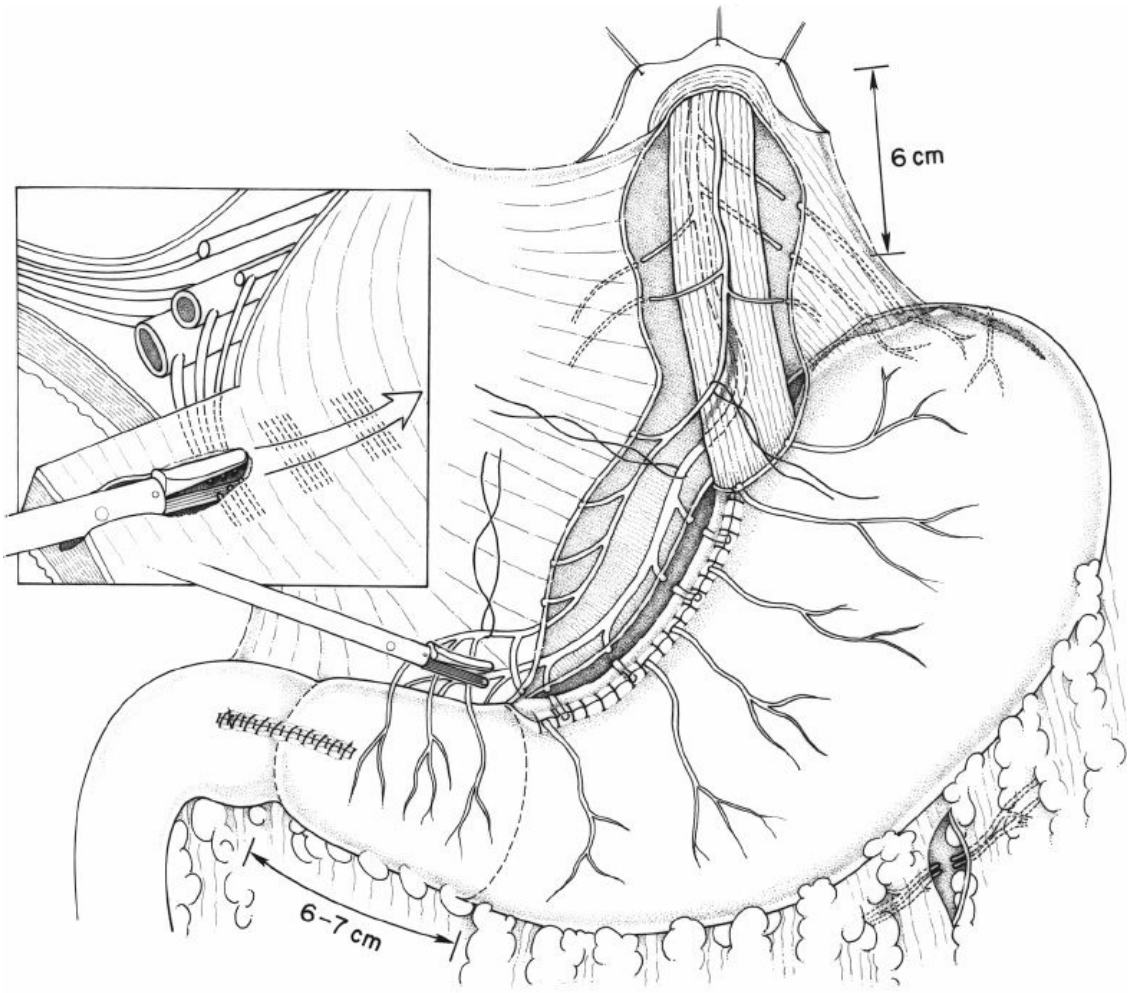

Figure 87.13. Highly selective vagotomy. Beginning 7 cm proximal to the pylorus, the small branches of the vagus running between the posterior and anterior branches of the nerve of Latarjet are divided, which effectively denervates the stomach proximal to the antrum. The “crow’s foot” is the landmark used to start the proximal dissection. The Harmonic scalpel (*inset*) is used to divide the plane of tissue between the wall of stomach along its lesser curvature and the actual trunk of the nerve of Latarjet, which is protected. First the anterior and then the posterior leaflets are divided. Finally, 6 cm of abdominal esophagus are skeletonized, except the main nerve trunks here are kept intact. The final step of the operation is division of the right gastroepiploic pedicle.

The dissection then continues toward the anterior surface of the esophagus with the goal of clearing the esophageal branches of the anterior and posterior vagus. Initially, the left side of the esophagus is dissected to the angle of His, with the fat pad of the cardioesophageal junction coagulated. The anterior and posterior surfaces of the esophagus are then

cleared of vagal fibers for 6 to 7 cm. The posterior fundus of the stomach is also dissected free with the Harmonic scalpel, with the criminal nerves of Grassi sacrificed during this maneuver. Occasionally, the superior short gastric vessels are sacrificed to adequately divide the posterior fundic vagal branches. The Harmonic scalpel is then directed toward the posterior leaf of the lesser omentum, which is approached through the already opened anterior leaf. The scalpel is positioned between the posterior nerve of Latarjet and the lesser curve, once again starting at the proximal branch of the crow's foot and progressing parallel to the nerve. The posterior dissection terminates by division of the vagal fibers in the gastropancreatic fold. During the course of the procedure, the position of the anterior and posterior nerves and main vagal trunks must continually be visualized and preserved. The final area of vagotomy is the right gastroepiploic pedicle, which is located on the anterior greater curvature 10 cm from the pylorus (Fig. 87.13).

Predication of Outcome and Recurrent Bleeding

Advanced age, poor health status or comorbid illness, continued or recurrent bleeding, fresh hematemesis or hematochezia, and the onset of bleeding in hospitalized patients (i.e., those admitted for reasons other than upper GI bleeding) predict a poor prognosis and a higher likelihood of death. Operative mortality for bleeding duodenal ulcer may be as high as 20%. Endoscopic predictors of poor outcome, including active bleeding, major stigmata of recent hemorrhage, a visible vessel, ulcers >2 cm in diameter, and the location of ulcers in proximity to large arteries, were also identified as factors that predict recurrent bleeding.

PERFORATED DUODENAL ULCER

Brief Historical Perspective

Muralto first described duodenal ulcers at autopsy in 1688. Crisp published a landmark paper in which he described symptomatology of perforated peptic ulcers in 1843. Therapy of perforated ulcer has been a hallmark of general surgical practice for well over 100 years. Our understanding of the problem has changed drastically over the last 20 years. The last 10 years of the 20th century witnessed a scientific revolution in our recognition of the role that infection with *H. pylori* plays in producing the gastric acid hypersecretion that characterizes peptic ulcer.

This hypersecretion, and attempts to control it, had in fact been the subject of a previous scientific revolution during the 1950s and 1960s that had shepherded a transition from surgical therapy that focused on resection of acid-secreting mucosa via subtotal gastrectomy to eliminating the hypersecretion by section of the vagus nerves. This revolution was best summarized by the Nobel Prize-nominated vagotomy pioneer, Lester Reynolds Dragstedt, whose philosophy regarding the controversy between the choice of resection versus vagotomy was best summarized in his remark that "the stomach is a mighty handy organ to take to the dinner table." This is a reminder that is even more valid today. This concept of duodenal ulcer as an infectious disease, not to mention the wide "over-the-counter" availability of H2 blockers and PPIs, has led to a marked decrease in the incidence of complications, such as intractability and/or gastric outlet obstruction that formerly might have led to surgery. Unfortunately, our new understanding has not yet led to any detectable changes in incidence of ulcer perforation. Thus, ulcer perforation continues to be an important, even if somewhat diminished, staple of surgical practice. Indeed in most centers, perforation is the most common indication for operation in the patient with duodenal ulcer.

Opportunities for prevention must necessarily focus on the two etiologies most responsible for perforations: treatment of *H. pylori* infection and use of NSAIDs. However, this is a formidable undertaking when one considers that ~50% of the population of the United States harbors *H. pylori* infection and that there is a ubiquitous availability of NSAIDs as over-the-counter remedies. The decrease in the incidence of uncomplicated duodenal ulcers over the past three to four decades has been somewhat attributable to our increased understanding of the multiple etiologies, risk factors, and epidemiology of duodenal ulcer disease; however, honest observers will note that the decrease in duodenal ulcer disease predated our understanding of its infectious nature as well as the remarkable therapeutic medications that are now so widely available.

Lifetime risk of duodenal perforation in patients with duodenal ulceration who do not receive therapy has been reported to be 10%. In patients who require surgical interventions for complications, such as perforation, the mortality rate is significantly higher in the elderly than in other age groups. Recent studies have indicated that the lifetime prevalence of duodenal ulcers to be 11% to 14% for men and ~8% to 11% for women. The epidemiology of perforated duodenal ulceration has

changed significantly. The male to female ratio has decreased from 10:1 to 1.5:1, and the median age has increased to >60. As the proportion of patients with associated disease increases, the mortality and morbidity have remained fairly constant in the last three decades despite improvements in general medical care.

DIAGNOSIS

Clinical Presentation

Perforated PUD typically causes sudden and severe epigastric abdominal pain that may progress to involve the entire abdomen. The pain caused by the spillage of highly caustic gastric secretions into the peritoneum rapidly reaches peak intensity and remains constant. Many patients can state the exact time of onset of their symptoms. Radiation to the right scapula region is common because of right subphrenic collection of gastric contents. Occasionally, pain is sensed in the lower abdomen if gastric contents travel caudally through the paracolic gutter. Peritoneal irritation is usually intense, and most patients avoid movement to minimize discomfort. The degree of peritoneal findings, however, is strongly influenced by a number of factors:

- Size of the perforation
- Amount of bacterial and gastric contents contaminating the abdominal cavity
- Time between perforation and presentation
- Spontaneous sealing of the perforation

Physical examination reveals low-grade fever, diminished bowel sounds, and rigidity of the abdominal wall musculature. The patient can also demonstrate signs and symptoms of:

- Early shock
- Tachycardia
- Hypotension and
- Diminished urine output

Other indicators of toxicity (such as peritoneal irritation, fever, and increased white blood cell count with left shift) may actually be absent in both elderly and immunocompromised patients. Furthermore, other acute conditions such as myocardial infarction, dissecting aortic aneurysm, cholecystitis, pancreatitis, diverticulitis, appendicitis, and renal colic can

mimic the symptomatology of perforated PUD.

Laboratory Studies

It has been argued that, in general, laboratory studies are of little value in evaluating a patient with suspected duodenal ulcer perforation, but such tests as complete blood cell count, amylase and lipase determinations, and liver functions tests may be useful in excluding other causes of upper abdominal pain.

Complete blood cell count (Leukocytosis with left shift is found in many cases.)

Serum gastrin levels: Gastrin levels >1,000 pg/mL are suggestive of gastrinoma; however, use of acid-reducing agents may cause some elevation of gastrin. Gastrin levels in patients who are taking acid-reducing agents are usually not >300 to 450 pg/mL. If there is any question, a secretin stimulation test will make the diagnosis; however, these measurements are not pertinent to the acute presentation.

H. pylori infection testing

Serum *H. pylori* antibody detection: Antibodies (immunoglobulin G, IgG) to *H. pylori* can be measured in serum, plasma, or whole blood; however, they only indicate past infection and do not confirm current infection.

Pathologic identification of *H. pylori* on biopsy is diagnostic as is a positive CLO test on biopsy; this is not helpful in the acute presentation, but may be useful in postoperative therapy.

Urea breath tests: These are used to detect active *H. pylori* infection by testing for the enzymatic conversion of urea to CO_2 and ammonia. Current use of PPI agents may result in false negative tests.

Fecal antigen tests: Fecal antigen testing is used to identify active *H. pylori* infection by revealing the presence of *H. pylori* antigens in stools and will probably become the gold standard for diagnosis.

Imaging Studies

Upright chest radiography or lateral abdominal decubitus radiography reveals evidence of free air (pneumoperitoneum) (60% to 85% of patients). Even though this finding is not specific for perforated peptic ulcer, free air is usually present in much smaller amounts with perforation of abdominal viscera other than the duodenum or stomach.

An upper GI study with water-soluble contrast, such as gastrografin, can

demonstrate extravasations if the ulcer has not spontaneously sealed. The lethal effects of barium when mixed with stool in the setting of colon perforations are well known; the effect of barium in the peritoneal cavity in duodenal perforations is unstudied. Nevertheless, prudence would suggest that barium be avoided when there is a risk of duodenal perforation. A contrast study with gastrografin may show leak from the duodenum or its sealing, and it can be a useful test when one is considering nonoperative treatment or in the situation where the diagnosis is in doubt. Currently, upper endoscopy is not recommended if perforation is definitely present or strongly suspected precisely because it may disrupt spontaneous sealing of the perforation.

Computed tomography (CT) scanning of the abdomen may demonstrate free air in the presence of perforated duodenal ulcer. CT with contrast may also demonstrate extravasation of contrast in the presence of a perforated ulcer. If history and physical examination raise the possibility of perforation, upright chest radiography and an upper GI contrast study with water-soluble contrast are the diagnostic studies of choice. CT scanning is usually not needed in this situation.

RISK STRATIFICATION

Mortality from perforated duodenal ulcer is dependent upon the presence or absence of several risk factors. Individual risk can also be assessed by use of APACHE II. Overall mortality is ~10% in most studies. It has been reported that in the developing world, the high morbidity and mortality experienced by patients with perforated duodenal ulcer are probably due to delayed presentation. Those in whom diagnosis is overlooked almost always die. Risk factors affecting prognosis are:

Delay in treatment (>24 hours)
Preoperative shock (BP <100 mm Hg)
Concurrent serious medical illness

It is reported that when all three are present, the mortality rises to 100% (39).

TREATMENT

Nonoperative Management

Current management of perforated duodenal ulcer in the United States usually includes operative approaches, but nonoperative management may

be appropriate (Fig. 87.14) if the patient is doing well and there is radiologic confirmation that the perforation is sealed.

Traditionally, perforated peptic ulcers were managed by urgent surgical repair, with or without an acid-reducing procedure. However, several studies have indicated that many patients can be successfully managed without an operation. The decision to proceed with surgery or nonoperative treatment is best individualized and made by the surgeon based on his or her assessment of the patient. In 1935, Wangensteen advocated a nonoperative approach in patients with perforation but without pneumoperitoneum. He believed that the absence of pneumoperitoneum indicated that the perforation had already sealed by the time of patient presentation; surgical exploration and repair was recommended for patients with demonstrable free air. More recently, Berne and Donovan have emphasized the use of the water-soluble upper GI study, which demonstrates spontaneous sealing of the perforation. They note that as many as 40% of perforated PUD ulcers have sealed on an upper GI study performed shortly after the patients present. Crofts et al. from Hong Kong, in 1989, showed that selective nonoperative treatment of perforated duodenal ulcer was accompanied by a low mortality rate and was not associated with a large number of complications when the gastroduodenogram demonstrated a sealed perforation. The mortality rate for patients treated operatively in their series was 6.2%, compared with mortality rate of 3% in those patients treated nonoperatively (retrospective review). Patients selected for nonoperative management should be treated as follows:

Nasogastric decompression
Fluid resuscitation with replacement of fluid and electrolytes
PPIs
Broad-spectrum antibiotics
Serial abdominal examinations, preferably by the same examiner with operative therapy for progression or nonresolution of symptoms
Subsequent follow-up endoscopy to monitor ulcer healing
Treatment of *H. pylori*—The U.S. Food and Drug Administration has approved some regimens, which are now accepted internationally, for the treatment of *H. pylori* infection in patients with PUD, both gastric and duodenal. These regimens are also known as triple therapies and have reported cure rates from 85% to 90%. Unfortunately, with the increasing rise in antimicrobial resistance, there has been an associated increase in

the failure rate of standard triple therapy for *H. pylori* infection. These triple therapies should be administered for 10 to 14 days The treatment regimens are omeprazole, amoxicillin, and clarithromycin (OAC) for 10 days; bismuth subsalicylate, metronidazole, and tetracycline (BMT) for 14 days; and lansoprazole, amoxicillin, and clarithromycin (LAC), which has been approved for either 10 days or 14 days of treatment.

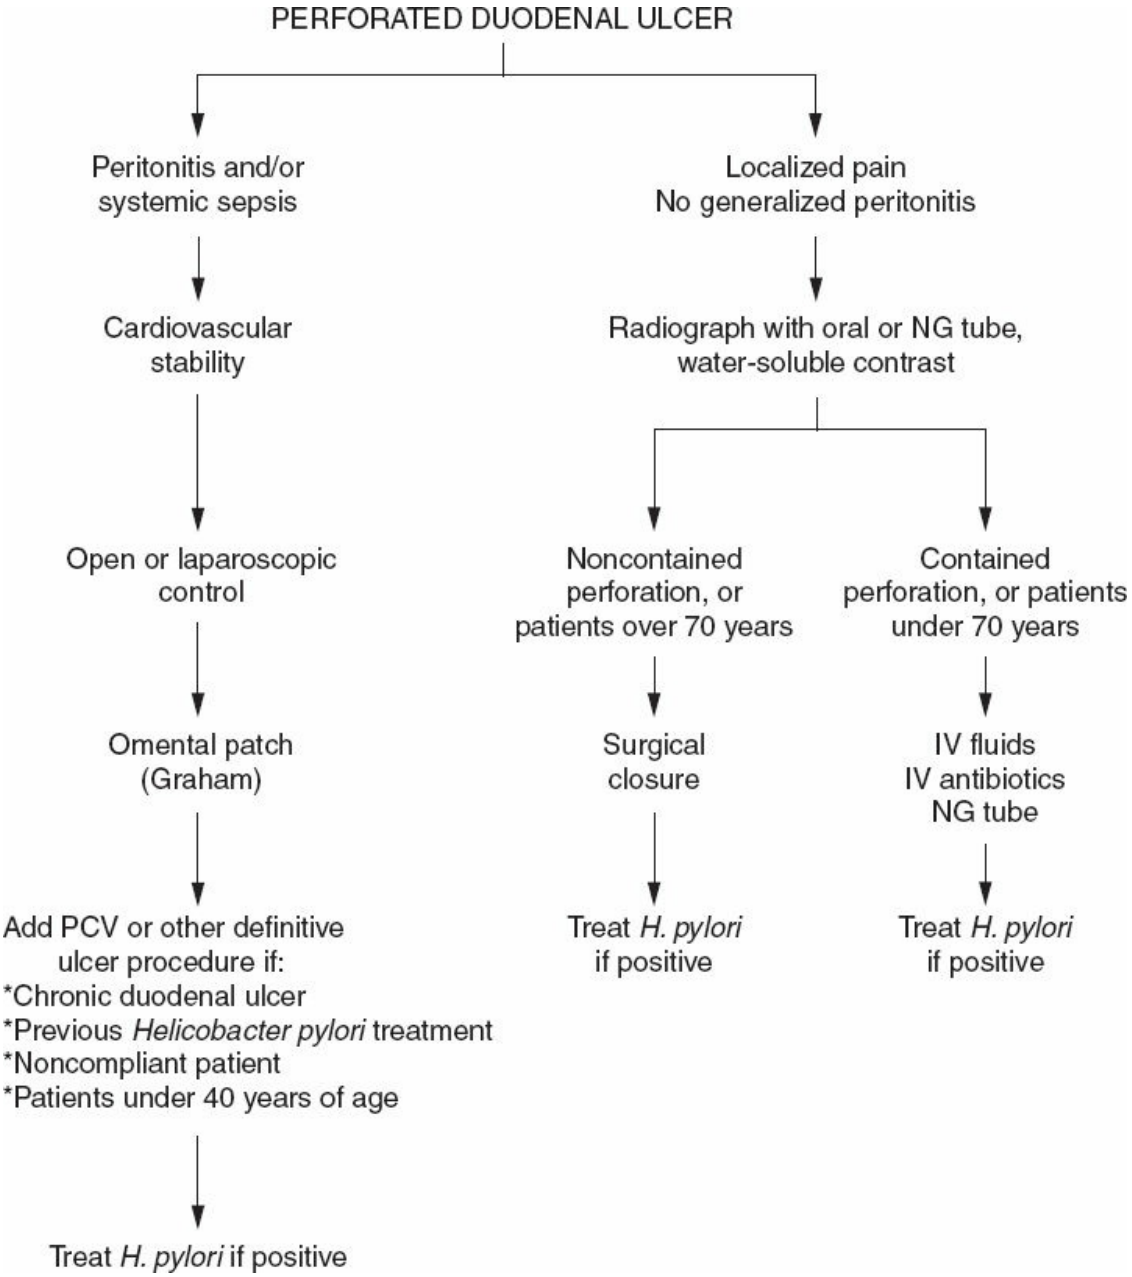

Figure 87.14. The algorithm for management of perforated duodenal ulcer usually includes operative management, but occasionally nonoperative management is indicated. PCV, parietal cell vagotomy; NG, nasogastric.

Despite encouraging reports and a number of other nonrandomized studies, nonoperative treatment of perforated duodenal ulcer has not become popular. Nonoperative management has not been widely adopted probably due to problems with misdiagnosis and the lack of opportunity to perform definitive ulcer surgery. Many reports indicate that nonoperative management has largely been restricted to those who are too unwell to undergo laparotomy. This may also have something to do with the American medical malpractice climate as well as difficulties with continuity of care attendant to comply with work hour restrictions. If nonoperative therapy is chosen, the ideal hand off from the responsible physician to the physician accepting responsibility would be to examine the patient together and agree on the criteria for continuing nonoperative therapy. Indications to abandon nonoperative treatment in favor of surgery include failure of symptoms to improve over 12 to 24 hours, peritoneal signs, and an increase in abdominal tenderness and hemodynamic instability.

Operative Management

Although numerous reports suggest that nonoperative management is an option appropriate for many patients with perforated duodenal ulcer, many surgeons still practice universal operative intervention in these patients. Surgical intervention is recommended in patients who present with the following:

- Hemodynamic instability
- Signs of peritonitis
- Free extravasations of contrast on upper GI contrast studies

The type and timing of operative intervention have been debated for decades. The arguments that revolve around the choice of simple closure versus closure with an acid-reducing procedure remain controversial. In addition, debate exists about the type of ulcer-curative procedure that should be performed. The first description of simple closure for a perforated duodenal ulcer was provided by Graham in 1937. In his report, he described placing three absorbable sutures in an interrupted fashion through the ulcer. A piece of omentum, either free or left as a pedicle, was then placed over the sutures and the sutures tied “just sufficiently tight to hold the omentum graft in situ.”

The traditional management of a perforated duodenal ulcer has been a

Graham Omental Patch and a thorough abdominal lavage. Although this operative procedure continues to be effective at providing adequate closure of the perforation, many authors have noted a high recurrence rate of both ulcer symptomatology and recurrent ulceration. This concept of immediate definitive ulcer surgery has been debated among surgeons since the 1940s. There is good evidence that, in the emergency situation, highly selective vagotomy combined with simple omental closure of the perforation in patients without risk factors is just as effective as that performed in the elective setting. The success of this operation is surgeon-dependent; however, fewer surgeons under the age of 65 today have had any significant experience with it. However, immediate definitive ulcer surgery has not gained widespread popularity because of concerns that it is associated with higher mortality than simple omental patch closure, although studies have shown that in the absence of shock this is not a valid concern.

Older surgeons were trained in the era when ulcer surgery and surgical therapy of its complications as well as the surgical treatment of the complications of surgical therapy (postgastrectomy syndromes, blown-out duodenal stumps, alkaline gastritis, afferent loop syndrome, etc.) were common. This was also an era when there were no medical options that would reduce gastric acid secretion. The underlying rationale for definitive surgery was to permanently reduce acid secretion. We now have available to us “over-the-counter” medications, which, if taken in sufficient doses, result in the medical equivalent of a total gastrectomy. No investigator has suggested that any type of vagotomy, with or without gastric resection, can improve on the initial healing rates achieved with medical therapy.

Given that *H. pylori* is able to be implicated in up to 90% of perforated duodenal ulcers, many surgeons now agree on the use of simple omental patch closure and subsequent antibiotic treatment of the infectious agent, saving definitive surgical ulcer management for those who fail this regimen. Experts opine that the choice of operative procedure for perforated duodenal ulcer depends on variables, such as the presence of shock, life-threatening comorbid conditions, the degree of contamination of the upper abdomen, the amount and duration of perforation, and whether the patient has a history of or currently has intraoperative evidence of chronic peptic ulceration. Our recommendations are:

1. In the presence of life-threatening comorbid condition and severe intra-abdominal contamination, the safest technique for 1 cm or smaller

acute anterior duodenal perforation is a simple Graham patch closure plus abdominal lavage. Several full-thickness simple sutures are placed across the perforation using 2-0 silk sutures. A segment of omentum is placed over the perforation. The silk sutures are secured drawing the omentum into the opening.

2. If contamination of the upper abdomen is minimal and the patient is hemodynamically stable, it is acceptable to choose a definitive ulcer procedure (Table 87.1), especially if there is a question of whether the patient will be compliant with medical therapy. For a perforated duodenal ulcer, this may include a highly selective vagotomy, a truncal vagotomy and pyloroplasty, or vagotomy and antrectomy (V&A) (Table 87.1). Dragstedt's exhortation about the stomach's being a "handy organ to take to the dinner table" weighs heavily. Furthermore, V&A is associated with a higher mortality and more postgastrectomy syndromes. It also forces the issue of the "difficult duodenal stump." Current surgeons, unfamiliar with the use of V&A, may not appreciate the controversy that was formerly associated with closing such a stump. Leakage from the duodenal stump was responsible for most of the mortalities associated with V&A. Many older surgeons were persuaded that the best way to handle a difficult duodenal stump is not to create one. Thus, they avoid gastric resection for duodenal ulcer. There are some who would dispute this but V&A is an aggressive choice for a condition that responds well to medication.

Preoperative Details

Step 1. Preoperative preparation

Nasogastric suction reduces the risk of further spillage of gastroduodenal contents leading to peritoneal contamination

Fluid resuscitation, Foley catheter placement, and insertion of effective venous access

Broad-spectrum IV antibiotics and IV PPI

TABLE 87.1 Perforated Ulcer Patients Who May Require Procedures Other Than Graham Patch Closure

1. Large perforations (>2.0 cm) may require Thal Patch (Fig. 87.8), or rarely vagotomy, antrectomy, Billroth II reconstruction
2. Synchronous bleeding and perforation: may require vagotomy, resection of perforation, pyloroplasty, U-stitch control of posterior bleeding
3. Chronic ulcer symptoms, *H. pylori* negative: patch closure, parietal cell vagotomy, or vagotomy, pyloroplasty with ulcer excision
4. NSAIDs dependence (or noncompliant patient): patch closure, parietal cell vagotomy, or vagotomy, pyloroplasty, ulcer excision
5. Previous *H. pylori* treatment failure or known *H. pylori* negative patients: patch closure, parietal cell vagotomy, or vagotomy, pyloroplasty, ulcer excision
6. Previous ulcer complications: patch closure, parietal cell vagotomy, or vagotomy, pyloroplasty, ulcer excision

Intraoperative Details

Step 1. Patient positioning

Supine with a footboard attached to the table to facilitate reversed Trendelenburg position that exposes the upper abdomen by using gravity for downward traction on the upper abdominal viscera

Step 2. Incision

Supraumbilical midline

Step 3. Exploratory laparotomy and closure of the duodenal perforation

The commonest site of duodenal perforation is the anterior wall of the

first portion of the duodenum. If this area is normal, then the anterior and posterior aspects of the stomach should be inspected; and if no perforation is found, the remainder of the GI tract must be thoroughly assessed including the posterior gastric wall by opening the lesser sac.

A small duodenal perforation is closed by placing interrupted full-thickness 2-0 silk sutures along the margins of the ulcer (Fig. 87.15A–C), leaving the ends sufficiently long, so that a viable omental patch can be securely placed over the perforation (Fig. 87.16). The sutures are tied drawing the patch into the perforation (Fig. 87.17). Some surgeons prefer primary closure with placement of the omentum over the primary closure (Fig. 87.18A,B).

A chronic ulceration containing a large defect with a friable margin can be difficult to close primarily. In this situation, it is recommended to place the 2-0 silk sutures away from the ulcer margins and simply use them to secure the omental patch directly onto the perforation. Omental patch of larger perforations, however, is associated with problems of gastric outlet obstruction and occasional recurrent leakage from the perforation (Fig. 87.19). Good alternatives in this situation include: Thal serosal patch of the large ulcer with a loop of jejunum (Fig. 87.20), Roux-Y drainage of the perforation or patch closure with concomitant gastrostomy, feeding jejunostomy, and retrograde threading of a decompressive Robinson catheter from the proximal jejunum to the duodenum (Fig. 87.8). It is wise to complement closure of this large perforation with drainage of the area with a closed-suction drain.

Thorough irrigation of the peritoneal cavity with 3 L of warm normal saline-containing antibiotics. Drainage is unnecessary and may increase morbidity.

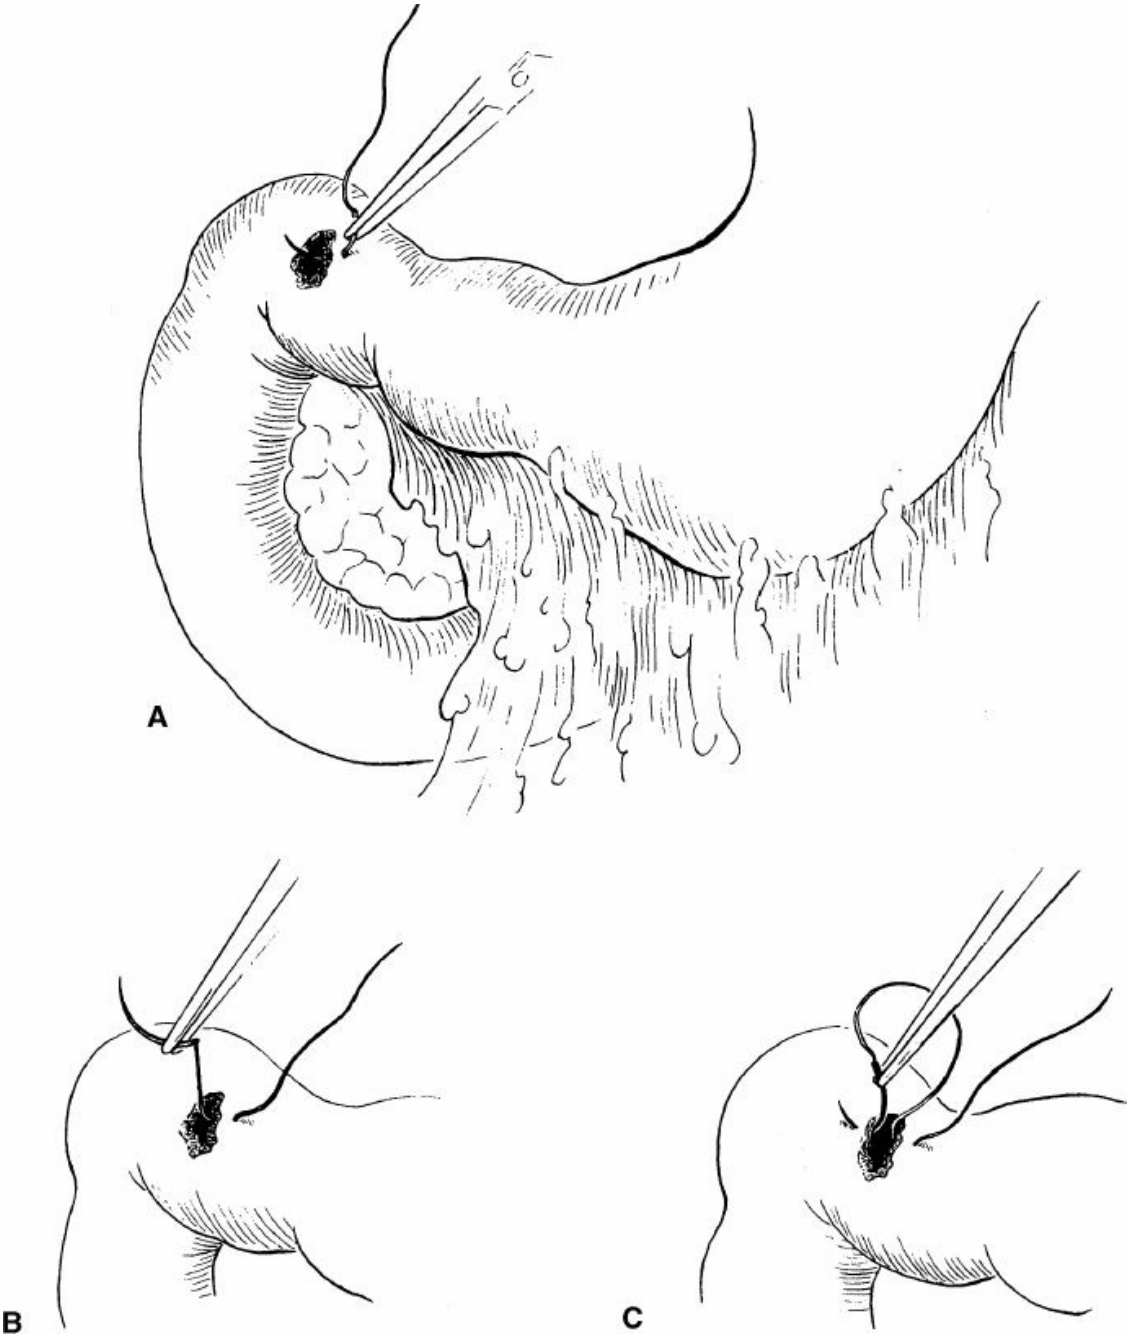

Figure 87.15. A. After appropriate aspiration and irrigation in the periduodenal area, operative closure is undertaken by placing full-thickness sutures through the duodenal wall and into the perforation. **B.** The needle holder regrasps the needle, and the opposite wall of the duodenum is secured by a similar bite, far enough from the ulcer perforation to ensure that the suture will not tear through when tied. **C.** The sutures should be placed so that both the superior and inferior edges of the perforation will have a securing suture to hold the omentum against both the upper and lower ulcer edges.

Step 4. Abdominal wall closure

- Fascial closure with heavy nonabsorbable or monofilament absorbable sutures
- Skin closure with staples or clips

Postoperative Details

- On average, patient is discharged 7 to 10 days if uncomplicated recovery
- It has been shown that >90% have *H. pylori* infection. Discharge with eradication therapy and an 8-week course of PPI to prevent ulcer recurrence
- Recommendations for follow-up endoscopy to check duodenal ulcer healing

OUTCOME AND PROGNOSIS

It has been reported that emergency operations for peptic ulcer perforation carry a mortality risk of 6% to 30%. Factors that affect the prognosis include the following:

- Shock at the time of admission
- Delaying the initiation of surgery >12 hours after presentation. It has been shown that the delay in diagnosis beyond 24 hours is associated with a sevenfold increase in mortality, three-fold risk of morbidity, and double the hospital stay
- Concurrent medical illness (e.g., cardiovascular disease, diabetes mellitus)
- Age >70 years
- Cirrhosis
- Immunocompromised state (e.g., HIV)
- Location of ulcer (mortality associated with perforated gastric ulcer is twice that associated with perforated duodenal ulcer)

LAPAROSCOPIC MANAGEMENT OF PERFORATED DUODENAL ULCER

With experience gained from laparoscopic cholecystectomy, many surgeons now have the skills to repair perforated ulcers laparoscopically. Theoretically, laparoscopic access is associated with less metabolic and physiologic disturbance than open surgery, and this may also benefit the septic patient. Successful treatment of perforated duodenal ulcer with

laparoscopic approach was first reported by Mouret et al. in 1990. Some surgeons have used an omental patch that was held in position with fibrin sealant. Laparoscopic approach has undergone many modifications; however, there seems little reason to depart from a technique that closely mimics Graham's original open procedure.

This technique is performed in reverse Trendelenburg position with patient's legs either spread apart or together. A 10- to 12-mm trocar is placed at the umbilicus, followed by a similar size-trocar in the midline in the epigastrium. This is followed by two 5-mm cannulas in the right, hypochondrium in the midclavicular, and anterior axillary lines. The laparoscope can be inserted through either of the 10- to 12-mm trocars to visualize the perforation and the peritoneal cavity irrigated. A 2-0 silk suture on 30-mm curved needle is introduced into the abdomen via the 10- to 12-mm trocar. Then, a second needle holder is inserted through the medial 5-mm trocar.

A grasper introduced through the lateral 5-mm tracer is used to mobilize a suitable piece of omentum close beside the perforation. The needle is then passed through the normal duodenum a small distance away from the edge of the perforation on either side. The grasper then positions the omental patch over the perforation, and the mounted needle is passed through the omentum. The needle is then withdrawn, and a knot is tied to fix the patch to the perforation. Additional sutures can be placed as required to surround the perforation. The adequacy of the seal may be tested by insufflation of air and/or methylene blue into the NG tube. Various modifications of this procedure have been performed. Laparoscopic omental patching has now widely been reported with comparable results to open surgery. Small series have been reported adding laparoscopic posterior truncal vagotomy, anterior seromyotomy, and highly selective vagotomy. Studies have shown that conversion rate from a laparoscopic approach to an open approach varies from 0% to 25%. Contraindication for laparoscopic repair for perforated duodenal ulcer includes large perforation, a posterior location of the perforation, shock, and a poor general state of health.

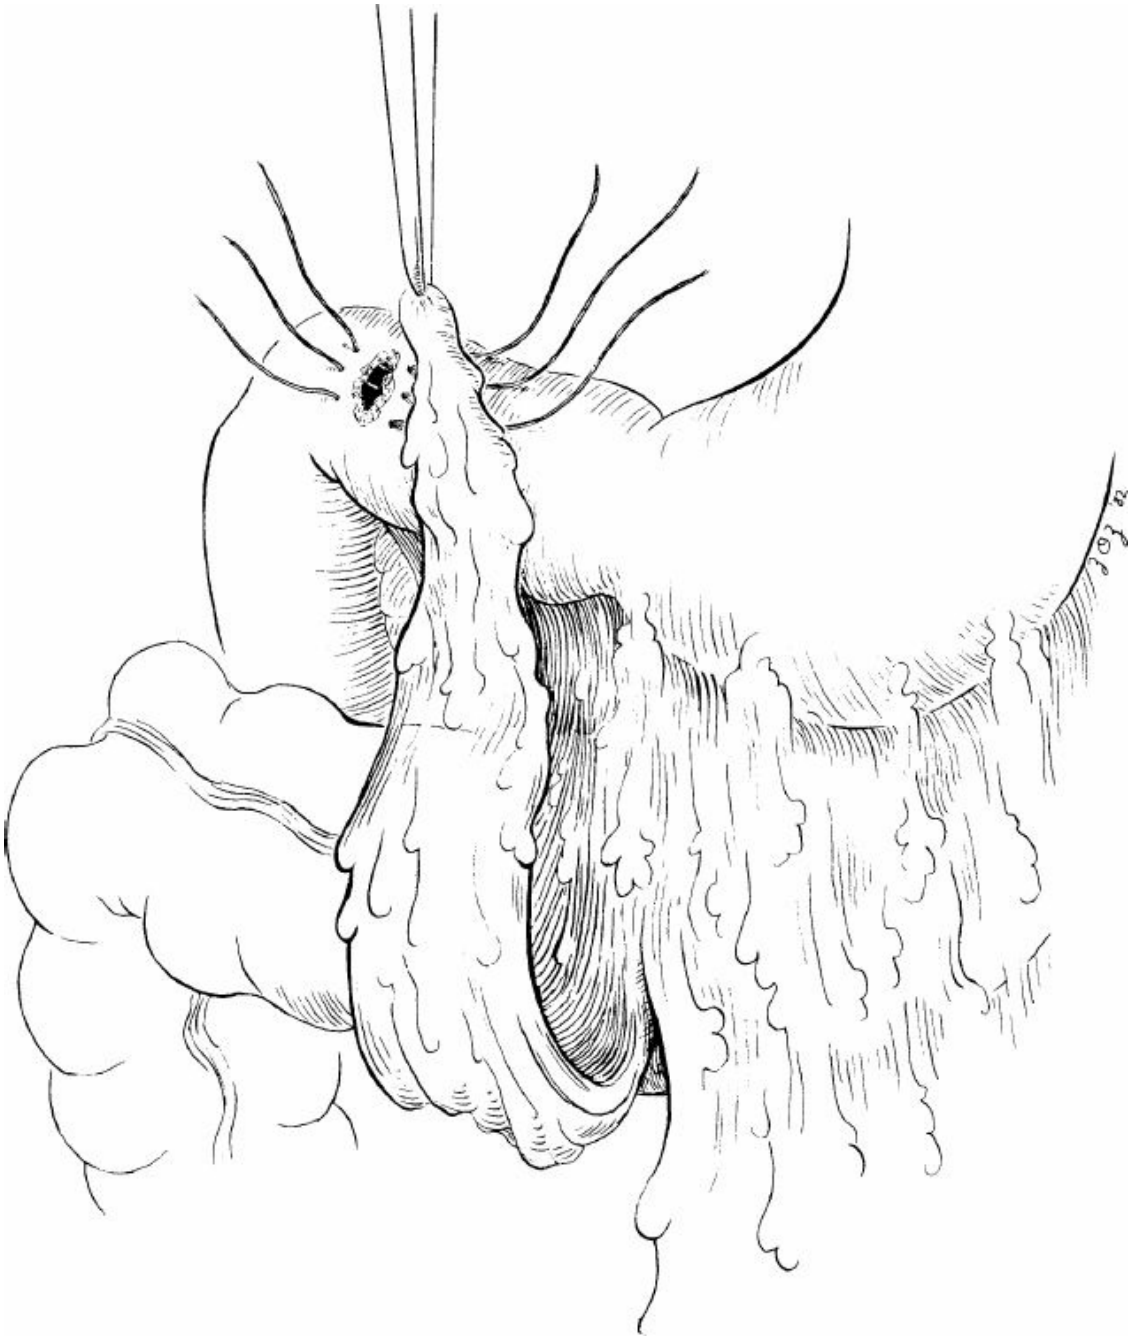

Figure 87.16. After placing three or four sutures, a vascularized tongue of omentum is mobilized and brought superiorly to close the defect. It is not necessary to push the end of the omentum into the defect like an obturator, but rather use the omentum as an external patch.

Figure 87.17. When the sutures are tied loosely enough so that the blood supply to the omentum is not compromised, the seal is complete, even with larger perforations.

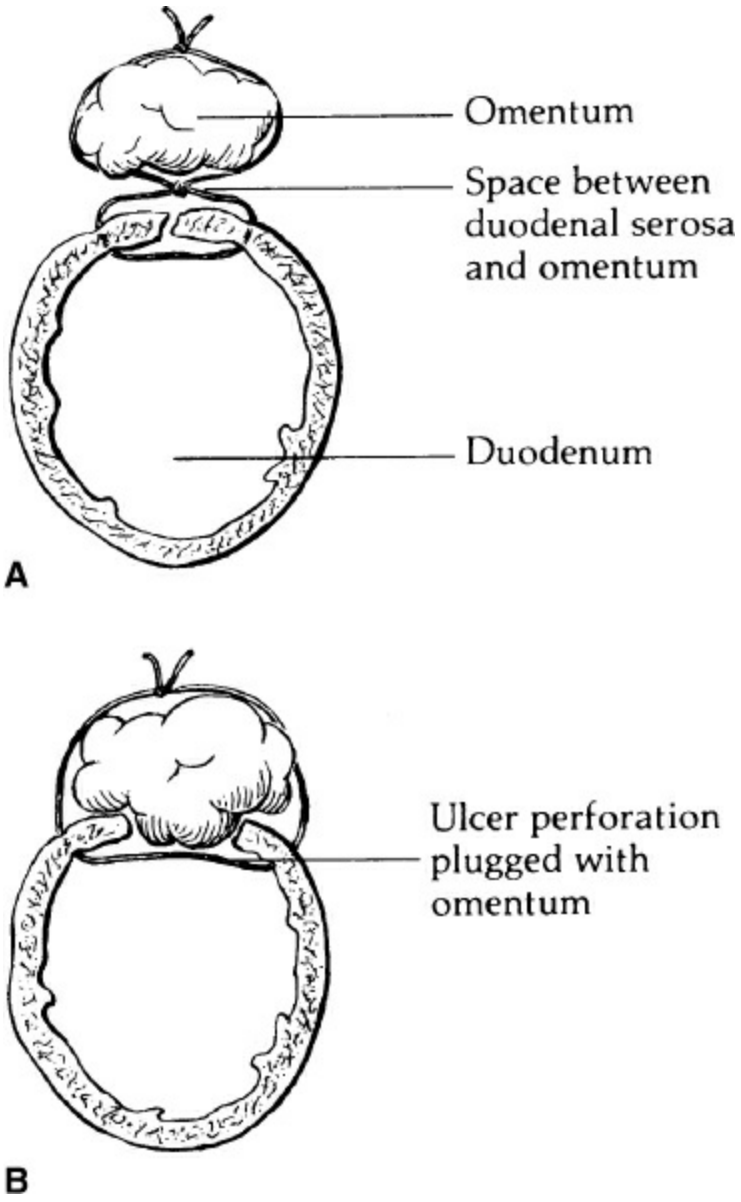

Figure 87.18. A. Although it is sometimes done, tying the sutures to close the perforation prior to placing the omentum at the defect has the disadvantage of preventing broad apposition of the omentum to the duodenal serosa. **B.** Furthermore, there is a potential or actual space between the duodenal serosa and the omentum. If the sutures are tied after the omentum is in place, with no attempt to sew the ulcer perforation closed, the omentum will effectively plug the perforation.

Compared to the open approach, the following results have been observed with laparoscopic method:

1. Increased operative time
2. Reduced requirement for postoperative analgesia
3. Reduced time to return to a normal diet

4. Shorter hospital stay
5. Earlier return to work

No difference was found in blood loss, stress response (as determined by endotoxemia, bacteremia, and inflammatory markers), postoperative gastric emptying, or morbidity or mortality. Most contemporary studies support equivalent outcomes with the open or laparoscopic approach in the stable patient.

Figure 87.19. A suitable alternative to transulcer full-thickness fixation of the omentum is to bring the omentum up and hold it in place with a series of seromuscular Lembert sutures around the circumference of the patch. The first sutures should be placed and tied at the inferior margin of the omental patch before the

other sutures are tied to prevent any leakage from the inferior margin of the defect. (From Jordan PH Jr, Thornby J. Perforated pyloroduodenal ulcers: long-term results with omental patch closure and partial cell vagotomy. *Ann Surg* 1995;221[5]:481.)

GIANT DUODENAL ULCERS

Giant duodenal ulcers (GDUs) are a subset of duodenal ulcers that have historically resulted in greater morbidity than usual duodenal ulcers. A GDU has been defined as a full-thickness peptic ulcer that is 2 cm or larger in diameter and usually involving a large portion of the duodenal bulb (Fig. 87.21). The history of GDUs dates back to 1931 when Britzka first described these exceptionally large ulcers that comprise a large portion of the duodenal bulb. GDUs comprise ~1% to 2% of all duodenal ulcers and 5% of peptic ulcers requiring surgical intervention. The male to female ration in those with GDUs is 3:1.

The etiology of GDUs may differ somewhat from ordinary duodenal ulcers. Recent studies suggest that the percentage of GDUs associated with *H. pylori* is less when compared to standard sized ulcers, and that NSAIDs use may play a more prominent role. For example, in 1999, Fischer et al. reviewed 28 cases of GDU. In their study, only 39% of patients tested were found to have *H. pylori* infection. In addition, Colleen et al. evaluated 184 patients with standard sized ulcers and compared them to those with GDUs. They found that 53% of patients with GDU had used daily NSAIDs in the month before presentation versus only 8% in the standard sized duodenal ulcer group. These data suggest that daily NSAIDs use plays a more prominent role in the formation of GDUs than in standard sized duodenal ulcers. While *H. pylori* infection likely plays a role in the formation of GDUs, it is not as prevalent as it is with the formation of standard size duodenal ulcers. GDUs have high rates of morbidity and mortality. Feared complications associated with these giant ulcers include massive hemorrhage and perforation. Perforation rates between 0% and 7% have been reported by different groups. Unfortunately, little data exist to explain the pathophysiologic differences that lead certain patients to develop these giant variants. Plausible explanations include genetic predisposition, dietary or environmental factors, microbial influences, variations in immunologic response, or any combinations of these factors.

Presenting symptoms include severe abdominal pain, involving the midepigastric region, the right hypochondrium, and/or radiation to the

back. The pain of these giant ulcers is persistent and is not relieved with food of alkali. These giant inflammatory masses can also produce significant constitutional symptoms such as weight loss, cachexia, and malnutrition. This can often mislead clinicians to suggest malignancy as the most likely diagnosis. Radiographic diagnosis with barium has been difficult. The size of these giant ulcers often causes replacement of the duodenal bulb. As a result, the GDUs may be altogether missed or misinterpreted as a deformed bulb, diverticula, or pseudodiverticulum during a barium study. The advent and widespread use endoscopy has markedly improved clinician's ability to detect GDUs with greater accuracy.

Management of GDUs continues to evolve. The advent of new acid suppression medication, the discovery of *H. pylori* and its role in ulcer formation, and the eradication therapy have opened avenues to successful medical management of the GDUs. In 1999, Fischer et al. published a prospective study of 28 patients with GDUs; 27 of these patients were placed on omeprazole therapy. Their results showed that 15 of these patients had complete healing of their GDUs on endoscopy. Despite the marked improvement associated with PPIs, surgical evaluation of a patient with a GDU should remain an integral part of the patient care. Emergent indications for surgical intervention include uncontrolled hemorrhage, perforation, and unresolving obstruction. Perforation of GDUs is considered particularly hazardous because of the extensive duodenal tissue loss and surrounding tissue inflammation, which are said to preclude simple closure with omental patch, often resulting in postoperative leak or gastric outlet obstruction. Several surgical options have been suggested. These have included resection of the perforation bearing duodenum and gastric antrum in the form of a partial gastrectomy, with reconstruction with a Billroth II anastomosis, as a Billroth I reconstruction is difficult in these circumstances. In some cases, an even more morbid procedure of gastric disconnection may be indicated. This includes vagotomy, antrectomy, gastrostomy, lateral duodenostomy, and feeding jejunostomy (see Fig. 87.22) with restoration of intestinal continuity electively after 4 weeks of discharge. However, resection of these large ulcers may increase the likelihood of common bile duct injury, which may be present in the base or adjacent to the ulcer. Others have recommended conversion of the perforation into pyloroplasty, or closure of the perforation using a serosa patch or pedicle graft of the jejunum. Proximal gastrojejunostomy and/or

vagotomy may be electively added to these procedures to provide diversion and a definitive acid-reducing procedure, respectively. However, each of these procedures has its own morbidity that may add up significantly to alter the final outcome of the patient, and more importantly, none of them is immune to the risk of leak in the postoperative period, which has been the main concern against performing the omental patch in large perforations.

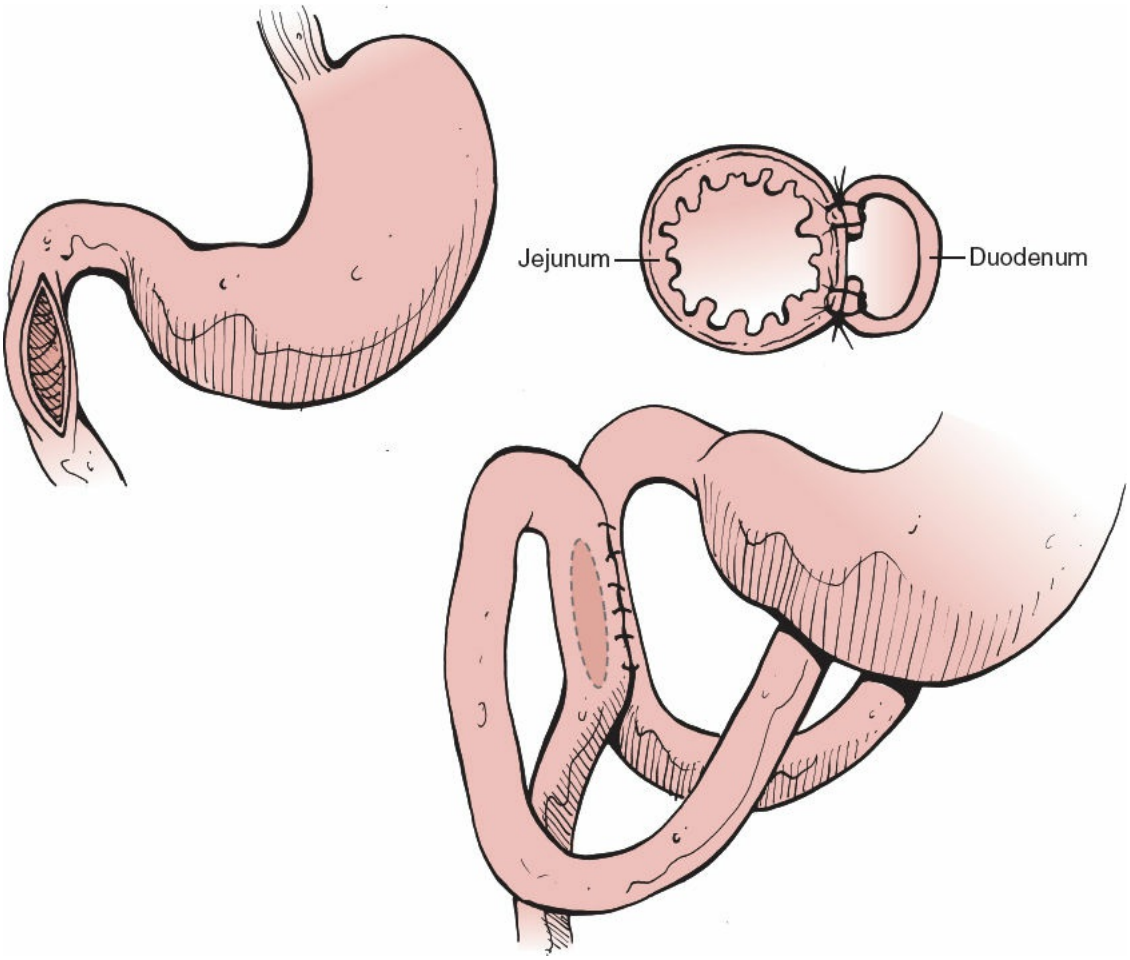

Figure 87.20. Diagrammatic representation of the method adopted for jejunal serosal patch grafting (Thal Patch) of duodenal defect.

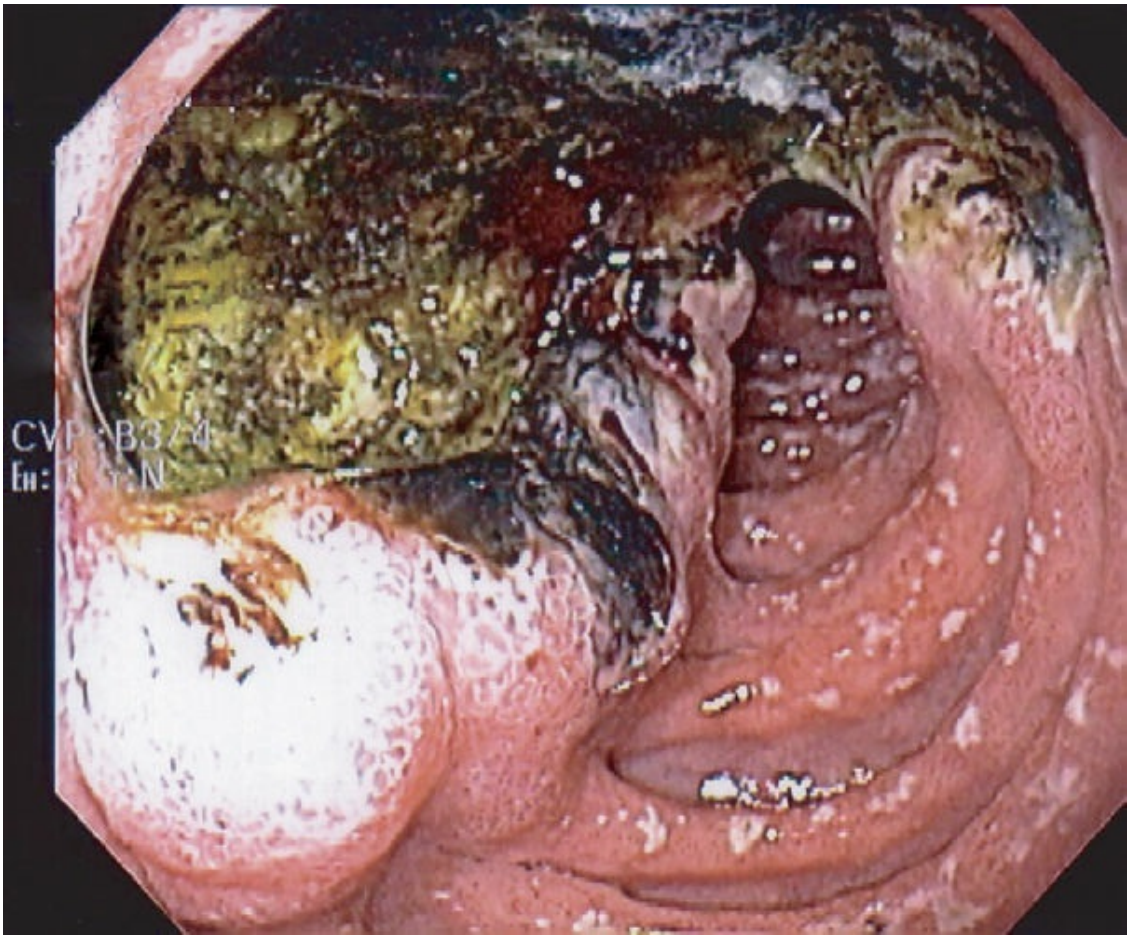

Figure 87.21. Endoscopic photograph of a giant duodenal ulcer in a patient taking NSAIDs. The ulcer involves the proximal second portion of the duodenum. The ulcer seen is >2 cm, and involves over 50% of the mucosal circumference.

GASTRIC OUTLET OBSTRUCTION: PYLOROPLASTY AND GASTROJEJUNOSTOMY

Many of the popular and widely performed early gastric operations were drainage procedures designed to treat PUD or obstructing carcinoma. Wolfler first performed anterior gastrojejunostomy in 1881 for obstructing pyloric cancer, at the suggestion of his assistant Nicoladoni. Posterior gastrojejunostomy was conceived by Courvoisier in 1882 and improved upon by von Hacker in 1885. In 1892 Braun described the anastomosis between the afferent and efferent limbs of the gastrojejunostomy, to divert bile away from the stomach. In 1901 Czerny shortened the afferent loop of the posterior gastrojejunostomy as suggested by Peterson. Roux described the “en Y” gastrojejunostomy in 1897. The eponymous Heineke–Mikulicz pyloroplasty was simultaneously devised and reported in 1886 by Heineke

and in 1887 by Mikulicz. Finney published his more elaborate (and at the time more versatile) operation in 1902, while Jaboulay had already described his side-to-side gastroduodenostomy in 1892.

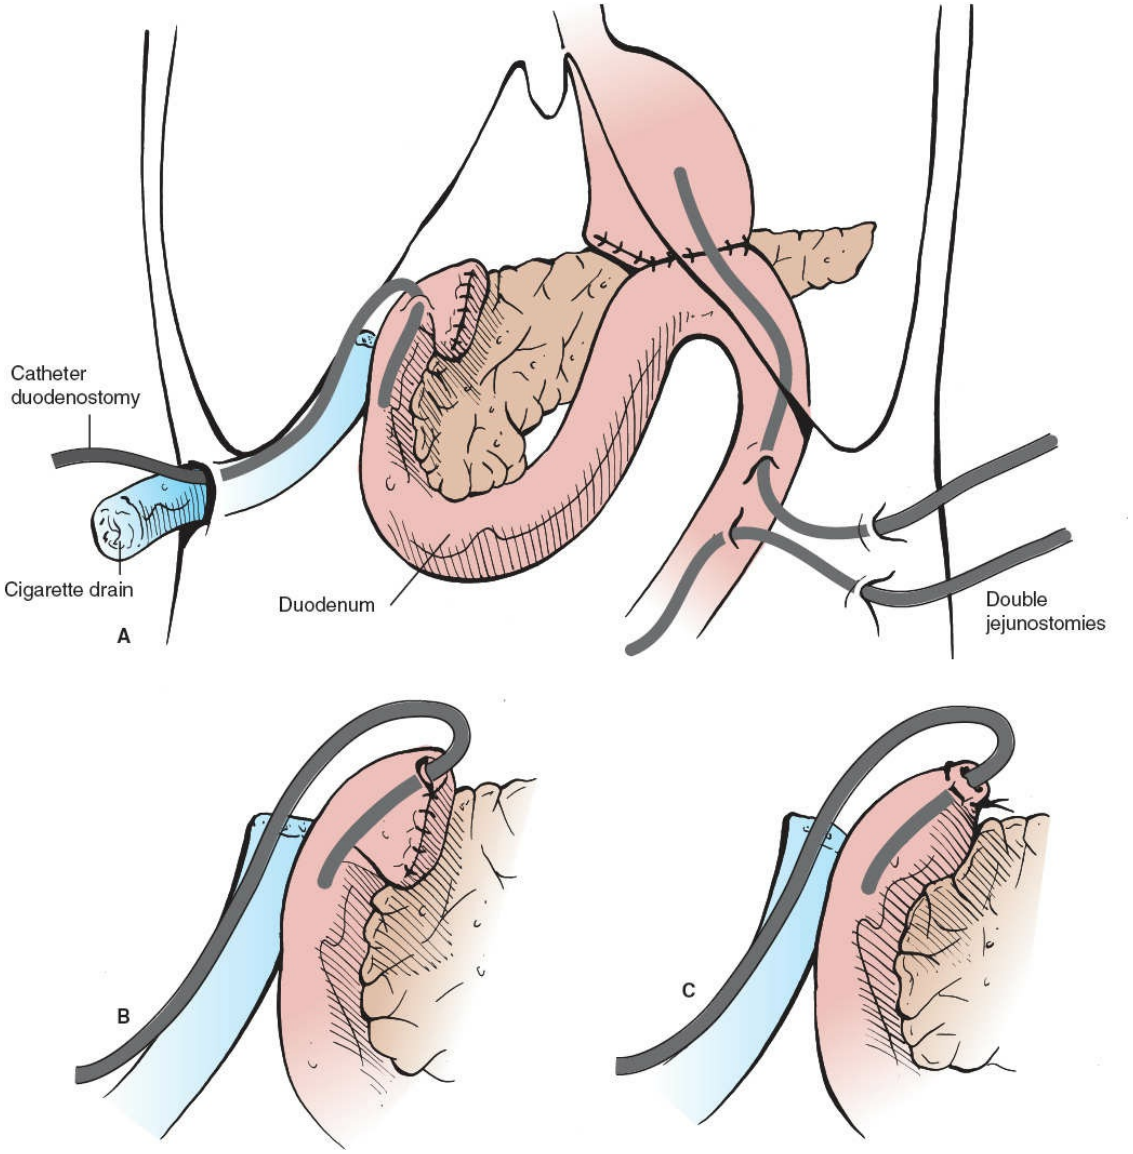

Figure 87.22. Catheter duodenostomy. (**A**) Duodenal decompression can be carried out by inserting a catheter into anterior duodenal wall distal to turnin or (**B, C**) through end of duodenum. In addition, a large cigarette drain should be used. Double jejunostomy may or may not be used.

These operations initially performed with great frequency became less common by the mid-20th century as distal subtotal gastrectomy became the operation of choice for peptic ulcer and gastric cancer. In his effort to find a more physiologic and better tolerated operation for peptic ulcer, Dragstedt suggested transthoracic truncal vagotomy, which was associated with intolerable symptoms of gastric stasis in 20% of patients with another 20% experiencing tolerable symptoms manageable without operation. With the addition of a concomitant pyloroplasty or gastrojejunostomy, the truncal vagotomy became an abdominal procedure and the gastric drainage

operations were resurrected in the 1950s and 1960s. Pyloroplasty and gastrojejunostomy remain an important part of the general surgeon's armamentarium today. This section discusses some of these procedures in the adult patient.

INDICATIONS FOR GASTRIC DRAINAGE PROCEDURES

Mechanical Gastric Outlet Obstruction (Malignant)

Most patients admitted to hospital today with symptomatic gastric outlet obstruction have cancer. A palliative gastric drainage procedure may be indicated if the tumor is unresectable, or if the patient's condition prohibits a more substantial operation. Dependent loop gastrojejunostomy is the surgical procedure of choice, but in certain situations endoscopic stenting may be better (see below). When "double bypass" is done for palliation of pancreatic cancer, the gastric anastomosis is placed distal to the biliary anastomosis. When bypassing malignant gastric outlet obstruction, it is important to choose a site on the stomach that is likely to remain tumor free for at least several months. If this cannot be done without placing the anastomosis high on the stomach, alternative methods of palliation (e.g., gastrostomy and jejunostomy and/or endoscopic stenting) should be considered. Anterior gastrojejunostomy is acceptable if placed in the distal third of the stomach. All patients with palliative gastrojejunostomy should be maintained on acid-suppressive medication unless shown to be achlorhydric since the operation is inherently ulcerogenic. Admittedly, most of these patients will not live long enough to experience the complications of marginal ulcer.

When the obstruction is in the proximal duodenum and/or distal stomach, gastrojejunostomy usually helps the troublesome symptoms of abdominal pain and vomiting. But when the duodenal obstruction is distal to the ampulla of Vater, gastrojejunostomy may not help, since with this procedure the biliary and pancreatic secretions must decompress retrograde through a functional pylorus. In this case, consideration should be given to adding a pyloroplasty or pyloromyotomy to the dependent gastrojejunostomy. An alternative may be to anastomose a Roux limb or jejunal loop first to the proximal duodenum, and then to the dependent portion of the greater gastric curvature. We have used both alternatives with good clinical results.

Meta-analysis suggests that endoscopic stenting compares favorably with surgical bypass in patients with malignant gastric outlet obstruction. Thus, surgical bypass of malignant gastric outlet obstruction should not be performed in patients deemed to have a survival measured in weeks. Palliative endoscopic stenting of malignant gastric outlet obstruction should be considered in these patients. In many patients, this palliates the vomiting and may allow them to take some liquids orally.

Mechanical Gastric Outlet Obstruction (Benign)

The causes of benign gastric outlet obstruction include peptic ulcer (by far the most common), duodenal webs, hypertrophic pyloric stenosis, and Crohn disease. Although distal gastric resection is the preferred operation in the good-risk patient with ulcer-related gastric outlet obstruction, the lesser operation of highly selective vagotomy and pyloroplasty or gastrojejunostomy has been shown in a prospective randomized study to give comparable clinical results. Perhaps lifelong oral PPIs and gastrojejunostomy would be just as good or better. One attraction of gastrojejunostomy is that it can be performed laparoscopically or with a laparoscopic-assisted technique. Furthermore, if this procedure fails to improve the obstruction and/or ulcer symptoms, it does not preclude distal gastrectomy. Finally if gastrojejunostomy were to be associated with intolerable dumping, it is reversible. One disadvantage of gastrojejunostomy to treat obstructing peptic ulcer is that pyloric or duodenal cancer can be missed. In general, pyloroplasty (particularly the Heineke–Mikulicz and Finney type) requires pliability of the pyloric channel, and is therefore not a good option to relieve obstruction from peptic ulcer. Occasionally the chronic cicatrix is disk-like (rather than long and cylindrical) and near the pylorus, and amenable to pyloroplasty. It is worth remembering the Jaboulay pyloroplasty technique (essentially a side-to-side duodenogastrostomy) in the occasional patient in whom gastrojejunostomy is difficult due to adhesions and/or previous operations.

Gastrojejunostomy is a good operation to relieve the obstructive symptoms caused by proximal duodenal webs or Crohn disease. Obstruction distal to the ampulla of Vater is best treated with a proximal side-to-side duodenojejunostomy (Roux or loop). Duodenal webs or peptic strictures are often amenable to stricturoplasty using the Heineke–Mikulicz technique.

Vagotomy

It is generally accepted that a drainage operation should be added to truncal or total gastric (i.e., selective) vagotomy since the antrum and pylorus are denervated with these procedures. Denervation results in a spastic pylorus and a sluggish antrum, the net effect of which is symptomatic gastric stasis in some (but not all) patients. Gastric drainage is unnecessary with highly selective vagotomy, which preserves the vagal innervation of the antrum and pylorus. Some surgeons perform a pyloromyotomy or pyloroplasty as part of a transhiatal or transthoracic esophagogastrectomy unless a vagal sparing approach is used. With laparoscopic transhiatal esophagectomy, this is not necessary. In the unusual circumstance when a transabdominal proximal subtotal gastrectomy is performed, severing the vagal trunks and anastomosing the distal stomach to the distal thoracic esophagus, we do not disrupt the pylorus since we feel that preserving the pylorus may spare the patient (usually a poor-risk patient with a large tumor) the unenviable sequelae of bile esophagitis.

Functional Gastric Stasis

Increasingly, symptomatic patients without previous operation are being identified with quantifiable delayed gastric emptying. Some have other demonstrable abnormalities in GI motility, and/or irritable bowel syndrome, and/or diabetes. These patients are a challenging group and remind us that there is much about GI pathophysiology that is unknown or poorly understood. The managing physician for these complex patients should usually be a gastroenterologist with motility expertise, not the general surgeon. Rarely, carefully selected patients may benefit from a gastric drainage procedure, but this surgical decision should never be made without the participation of the managing gastroenterologist, patient, and family. While the T½ gastric emptying time measured by scintigraphy may be improved by pyloroplasty, this can easily be outweighed by the pain and bilious vomiting associated with the attendant increased duodenogastric reflux sometimes associated with this procedure. Remember, we cannot use the large body of surgical literature on peptic ulcer surgery to predict the functional complications of pyloroplasty in this unusual group with primary gastroparesis. Also, remember that pyloroplasty is not reversible. Prior to considering pyloroplasty to facilitate gastric emptying for gastroparesis, it may be prudent to render the

sphincter temporarily incompetent with balloon dilation and/or botox. A favorable response to these maneuvers may increase the likelihood of a favorable response to pyloroplasty. Alternatively, loop gastrojejunostomy, a reversible operation, may be considered and PPIs prescribed. Finally some of these patients may benefit from gastric pacing.

Not infrequently patients who present with gastroesophageal reflux disease (GERD) symptoms and objective criteria indicating fundoplication are found to have delayed gastric emptying on preoperative scintigraphy. While these patients may have a somewhat higher incidence of gas bloat symptoms post fundoplication, the large majority do well without the addition of pyloroplasty. It has been shown that fundoplication increases gastric emptying in most of these patients, and only rarely will subsequent pyloroplasty be necessary.

CHOICE OF DRAINAGE OPERATION

Pyloromyotomy or Pyloroplasty?

Most surgeons feel that pyloromyotomy and Heineke–Mikulicz pyloroplasty are comparable gastric drainage procedures. This was the conclusion of at least one prospective randomized trial in adults undergoing esophagectomy. The advantage of the pyloromyotomy is presumed to be a lower leakage rate. The disadvantage is there may be a tendency among nonpediatric surgeons to leave undivided pyloric muscle fibers, which could produce a suboptimal clinical result.

Which Type of Pyloroplasty?

By far the easiest and most commonly performed pyloroplasty is the Heineke–Mikulicz type, but general surgeons should be familiar with the other types as well. For instance, if a 10-cm gastroduodenotomy is required to deal with a large posterior bleeding ulcer, closure with an Heineke–Mikulicg pyloroplasty may be difficult or impossible, but closure with the Finney technique may be straightforward. Or if the original plan was gastrojejunostomy but the proximal jejunum is involved with dense adhesions (e.g., s/p left colectomy) or Crohn disease, Jaboulay pyloroplasty would be a straightforward alternative. These operations are described earlier in this chapter under management of bleeding duodenal ulcer.

Pyloroplasty or Gastrojejunostomy?

These procedures are equally effective as gastric drainage operations. The major advantage of the pyloroplasty is that it does not require entry into the inframesocolic abdomen, and perhaps a leak might be more easily managed with drainage and gastric suction, since it is proximal to the entry of bile and pancreatic juice. The major advantage of the gastrojejunostomy is that it is easily reversible (unlike pyloroplasty). Furthermore, if subsequent distal gastrectomy is required, previous gastrojejunostomy rarely presents a technical challenge. But previous pyloroplasty, particularly the Finney or Jaboulay, may make the handling of the duodenal stump quite problematic. The major disadvantage of gastrojejunostomy is that it is ulcerogenic since the jejunal mucosa is less resistant to acid peptic injury than the proximal duodenum with its higher concentration of buffering and cytoprotective factors. Long-term acid suppression may mitigate this disadvantage. Another potential disadvantage of gastrojejunostomy is dysfunction, associated with the "circus movement" of duodenal contents, or proximal small bowel obstruction associated with kinking or adhesions.

Roux or Loop Gastrojejunostomy? Add Braun?

Loop gastrojejunostomy involves one anastomosis, while Roux gastrojejunostomy involves two anastomoses and is more ulcerogenic (due to the complete lack of duodenal contents in the vicinity of the gastrojejunostomy). Therefore, Roux gastrojejunostomy should be used only rarely as a drainage procedure with an intact stomach. On occasion we have used a Roux limb to drain the distal stomach (along with transection of the duodenal bulb and preservation of the right gastroepiploic artery) in patients with a history of severe bile esophagitis following proximal subtotal gastrectomy.

The Braun modification of the loop gastrojejunostomy adds an anastomosis between the afferent and efferent limbs, theoretically to allow bilious duodenal contents to go from the former to the latter without having to enter the stomach. But this adds another anastomosis, and is only partially diverting.

Gastrostomy or Jejunostomy Tube

Some patients who require a gastric drainage operation are significantly

malnourished and/or have long-standing gastric stasis. It may therefore be prudent to add a temporary tube gastrostomy (for drainage) and/or tube jejunostomy (for feeding) to the pyloroplasty or gastrojejunostomy procedure. We have sometimes regretted not placing one or both of these tubes, but have rarely regretted placing them.

TECHNIQUE: LOOP GASTROJEJUNOSTOMY

This operation can be done through a small upper midline incision or with a laparoscopic (total or assisted) technique. The ligament of Treitz is unequivocally identified and the proximal jejunum brought anterior to the transverse colon to lie against the dependent greater gastric curvature without tension. If this cannot be accomplished, an alternative anastomotic technique should be considered. Usually an antecolic anastomosis can be done between the dependent greater gastric curvature and the proximal jejunum without difficulty. The serosa of the greater curvature is exposed by dividing the small branches of the gastroepiploic arcade. If necessary, the gastroepiploic arcade can be divided. The orientation of the small bowel is again checked. We prefer the afferent limb on the left side of the gastrojejunostomy and the efferent limb on the right side, with the afferent limb short (12 to 18 in at the most). This is called an isoperistaltic gastrojejunostomy. If the “lie” seems to be better with the afferent loop on the right side and the efferent loop on the left side, this antiperistaltic orientation can be used, but it may mean that the spot chosen on the greater curvature is too high on the stomach. The function of isoperistaltic and antiperistaltic gastrojejunostomies is probably the same. A 4- to 5-cm longitudinal gastrostomy and a jejunostomy are made and a two-layer hand-sewn side-to-side anastomosis effected. Alternatively, stapling instruments may be used but care should be taken not to use short staple heights with a thick-walled stomach. The anastomosis is tested.

If an antecolic tension-free gastrojejunostomy cannot be done, a retrocolic posterior gastrojejunostomy should be considered. While the stomach can sometimes be accessed from below through an avascular window in the mesocolon (easier in the thin patient with a big stomach and a big tube in the stomach), it is often more straightforward to enter the lesser sac to the left of the midline through the gastrocolic ligament, and then make an opening through the mesocolon into the lesser sac. The posterior gastric wall near the greater curvature can then be delivered to the jejunal side of the mesocolon and the anastomosis performed. The

afferent limb should be short (6 in or less), and the completed anastomosis should lie without kinks or twists. It is prudent to tack the posterior gastric wall to the edges of the mesocolic opening to prevent postoperative herniation of small bowel into the lesser sac.

Although anterior gastrojejunostomy is a mechanically unappealing palliative operation in patients who spend much of their final days supine in bed, it must be recognized that reasonable results have been described with this operation, the original technique described by Wolfler. If this approach must be used, we recommend that the anastomosis be placed in the distal stomach, no higher than the imaginary idealized border between the antrum and the body of the stomach.

TECHNIQUE: ROUX GASTROJEJUNOSTOMY AND BRAUN ENTEROENTEROSTOMY

As mentioned above, draining the intact stomach with a Roux limb should be done only rarely. First, this operation exposes the unbuffered jejunal mucosa to the acid peptic prowess of the complete vagally innervated parietal cell mass. Thus, it is ulcerogenic. Second, the abnormal motility in the Roux limb may lead to functional obstruction of the gastrojejunostomy (Roux syndrome). However, should the reader find a good indication for this procedure, it may be performed open through an upper midline abdominal incision, or laparoscopically. The ligament of Treitz is unequivocally identified and the jejunum is divided 40 to 50 cm distal to this. The distal end is then anastomosed to the dependent part of the gastric greater curvature. The proximal jejunum is then anastomosed to the Roux limb 60 cm distal to the gastrojejunostomy. Either or both of the anastomoses can be stapled or hand-sewn and may be tested with luminal air insufflation. If the surgeon must operate on a patient with intolerable bile (enterogastric) reflux after distal gastrectomy and loop gastrojejunostomy (B-II), the procedure can be converted to a Roux by transecting the afferent loop just proximal to the gastrojejunostomy, and then anastomosing this afferent loop to the efferent limb 60 cm distal to the gastrojejunostomy. Obviously the surgeon must be absolutely certain which limb is which. It is usually prudent to delay reoperation for 6 months after the original distal gastrectomy.

The side-to-side Braun enteroenterostomy (between the afferent and efferent limbs of the loop gastrojejunostomy) diverts some of the bilious duodenal contents away from the stomach. It also should decrease the

incidence of afferent loop syndrome, caused by kinking or partial obstruction of the afferent limb at or near the gastrojejunostomy. If this procedure is contemplated, it may be prudent to make the afferent limb slightly longer than usual. A stapled or hand-sewn Braun enteroenterostomy is typically performed about 30 cm proximal and distal to the gastrojejunostomy. It might be more prudent to make the anastomosis on the efferent limb 50 to 60 cm distal to the gastrojejunostomy in the event that intolerable enterogastric reflux ensues anyway and subsequent conversion to a Roux configuration is necessary. If the Braun anastomosis has been made far enough down the efferent limb, this conversion could be accomplished by simply resecting the segment of afferent limb between the Braun enteroenterostomy and the gastrojejunostomy. If the original Braun anastomosis is too close to the stomach on the efferent limb, this simple conversion cannot be relied upon to keep bile out of the stomach.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Common complications include wound infection, deep venous thrombosis (DVT), pneumonia, leak, abscess, and delayed GI function. Prophylactic antibiotics are started preoperatively and continued for 12 to 24 hours. DVT prophylaxis (pneumatic compression and subcutaneous heparinoid) is started preoperatively and continued until discharge. Preoperative duplex screening for DVT may be wise in patients who have been hospitalized or bedridden preoperatively. Aspiration of gastric contents is a potentially fatal complication in patients requiring gastric drainage procedures, and gastrostomy cannot always be relied upon to keep the stomach decompressed in the early postoperative period. All patients are given PPIs and antiemetics. We maintain a functioning NG tube until there is clinical evidence of gastric emptying. If this is not evident by the third postoperative day, we perform a gastrografin upper GI series to rule out leak and to document gastric emptying. All members of the surgical team should be cognizant of the harm that could be done by the careless manipulation or reinsertion of an NG tube in a patient who has a fresh gastroduodenal or gastrojejunal suture line. Anastomotic leakage should be treated promptly with drainage and antibiotics, and early reexploration considered. Return of GI function and tolerance of oral feeding may occur promptly, but are often delayed. It is important for the surgeon to manage

the patient's expectations, not judging the functional success or failure of the drainage operation too soon. Decompressing gastrostomy and feeding jejunostomy can be helpful in avoiding frustration and time pressure postoperatively.

SUMMARY

Despite improvements in pharmacologic therapies and endoscopic treatment of peptic ulcer disease, complications such as hemorrhage, perforation, and obstruction from duodenal ulcer continue to occur and remain a clinical challenge. Multidiscipline team cooperation and communication between the gastroenterologist, radiologist, and surgeon can optimize the approaches used for the initial treatment of bleeding duodenal ulcer. Endoscopy is used for diagnosis and initial therapy in most cases. Interventional radiology is used when the patient is deemed a poor operative candidate and endoscopy has failed to achieve hemostasis. In the setting of massive or recurrent upper GI bleeding from a diagnosed duodenal ulcer, one must follow strict criteria for operative intervention. If these criteria are met, excessively delayed or repeat endoscopic procedures are not warranted if the patient has recurrent or continued hemorrhage. When emergency surgery is indicated, the primary objective is to stop the bleeding. Precise application of the three-point ligation is emphasized, and if the ligation is adequately performed, it will prevent rebleeding. The secondary objective is to perform an operation that will prevent early rebleeding and recurrent ulceration without increasing morbidity or mortality. The choice of operation is ultimately influenced by the physiologic condition of the patient on entering the operating room. Most patients today are treated with oversewing the ulcer and control of the bleeding without a truncal vagotomy and pyloroplasty. Only in a hemodynamically stable patient with favorable anatomy and in the absence of medication or a noncompliant patient would a vagotomy and pyloroplasty be performed. In these situations, a highly selective vagotomy may be performed, which avoids the adverse sequelae of total abdominal vagotomy. The role of laparoscopy in the management of bleeding duodenal ulcer has been very limited and is reserved only in nonemergent intervention where hemodynamic stability is present and the gastroduodenal anatomy is favorable to a laparoscopic approach.

The current management options of perforated duodenal ulcer remain debatable. The debates of earlier in the century regarding simple patch

closure versus immediate definitive surgery have been complicated by the arguments for and against laparotomy, the introduction of laparoscopy, and the discovery of the role of *H. pylori.* For a patient with perforated duodenal ulcer, the role of nonoperative management should be first considered by the surgeon. Should this option be selected for the patient who requires close vigilance and a readiness to intervene at any moment when the patient shows signs of deterioration or failure to progress satisfactorily. Current evidence supports simple omental patch closure and lavage followed by antibiotics treatment for *H. pylori* in cases in which operative management is indicated. It has been suggested that if the ulcer fails to heal after surgery and *H. pylori* eradication, then a highly selective vagotomy should be performed after exclusion of a pathologic hypersecretion state. In the case of a patient who is negative for *H. pylori*, or who has been treated and then perforated, immediate definitive ulcer surgery should be performed in the absence of preoperative risk factors. Opinions between authors differ greatly, with some advocating an algorithm consisting of nonsurgical and surgical approaches depending on the characteristics of patient presentation. Presently, patients should be managed based on their physical and radiologic findings, risk factors, and *H. pylori* status (Fig. 87.1). The management of this complicated problem will continue to evolve with the improvement of laparoscopic techniques, increased acceptance of nonoperative therapy, and improved recognition of the role of *H. pylori* in perforated duodenal ulcers.

Gastric obstruction may be treated with pyloroplasty, gastrojejunostomy, or gastric resection. Which operation is chosen is made on the basis of the findings at operation.

Peptic ulcer disease (PUD) has come to represent a unique surgical challenge in the 21st century. As with some other diseases within the purview of the contemporary surgeon, the incidence of PUD has steadily declined over the past 50 years due to many factors, including advances in medical therapy. Unlike most of these other diseases however, these improvements have not resulted in a decreased incidence of emergency complications leaving the need for and number of emergency interventions constant. As the authors of this chapter make clear, the surgical management of PUD is a complex and technically challenging topic both in the operating room (OR) and after. Fortunately, despite the challenges of these emergency operations, the associated morbidity and mortality continue to decrease.

Emergency Surgery for PUD

Medical therapy and the discovery of *H. pylori* have revolutionized the treatment of PUD but have not managed to eliminate or even reduce the number of emergency operations done to treat bleeding and perforation. In addition, it is not expected that further advances in medical therapy will result in an appreciable decrease in emergency operations as the persistence of PUD in 21st century America is likely due to multiple factors occurring in two distinct (but often overlapping) populations of patients. The first group represents patients who cannot be reached with preventative health care, such as the elderly, malnourished, immunosuppressed, and the underserved who may engage in high-risk behaviors for the development of PUD. As the authors indicate, the second group is made up of those on chronic NSAID therapy including long-term aspirin. As many as 30% of these people have ulcers and are already taking proton pump inhibitors with only partial protection. It is hard to imagine either of these clusters of patients ever disappearing from our society and taking the bulk of the remaining PUD with them. This leaves us, surgeons trained in the modern era without extensive experience with peptic ulcer operations, to sort out the safest and most effective ways to manage their complications.

Bleeding

Bleeding remains the most common complication of PUD resulting in hospitalization and intervention in the United States. The two biggest questions we must answer when faced with a patient with a bleeding ulcer are whether or when to operate and what operation to perform. Traditionally the question of operative timing in the setting of gastrointestinal (GI) bleed was distilled down a magic number of units transfused, where surgery was recommended after the sixth unit of blood. This recommendation was a product of a simpler time when the options for intervention were surgery alone and patients either stopped bleeding or needed an operation. While this two-variable decision tree may still be appropriate for those practicing in smaller hospitals with fewer resources, those practicing in large institutions (with 24-hour access to endoscopists,

interventional radiologists, and intensivists) believe a more sophisticated algorithm should be employed.

We prefer a process that utilizes the skill of each of these specialists and saves the operating room for patients who fail to respond to other modalities or are deemed inappropriate for them. Also, patients who fail to respond to resuscitation may be advanced along the algorithm in an accelerated fashion. Like all “conservative” or nonoperative treatment strategies, the surgeon must be intimately involved in every step, guiding every decision, and constantly assessing for success or failure in a cooperative fashion with the other procedural specialists.

The support of the blood bank and possibly a massive transfusion protocol to ensure balanced transfusion and the aggressive correction of medical coagulopathy in a goal directed fashion (such as the use of thromboelastography if available) are also critical. The expectation is not that bleeding will necessarily stop with these measures but rather that less invasive strategies will be more likely to be successful when the clotting milieu is not deranged by factor depletion and dilution from the transfusion of red cells. This is also true for the patient who fails to stop bleeding and requires an operation. Another goal of this labor-intensive resuscitative strategy is preventing the patient from descending into an uncompensated shock state characterized by episodes of profound hypotension and oliguria. Even brief periods of shock result in higher rates of morbidity and mortality after the bleeding stops. Nevertheless, a transfusion requirement does not have to equal shock. In a well-run resuscitation, the patient remains stable, and an absolute number of units transfused become less relevant as a decision point.

We generally recommend two attempts at therapeutic upper endoscopy prior to surgical intervention. In addition, we often recommend an attempt at embolization of the bleeding vessel in interventional radiology prior to proceeding to surgery in selected high-risk patients with multiple comorbid conditions. We agree with the authors that fewer surgeons are facile enough to manage a bleeding ulcer laparoscopically. We value ease and speed when treating a bleeding ulcer and favor open surgery. The currently available data suggest that simple oversew of the bleeding vessel, without vagotomy, is inferior to oversew, vagotomy, and drainage. Our own analysis of the NSQUIP database indicated that the best outcomes with respect to 30-day morbidity and mortality occurred after transduodenal oversew of the bleeding vessel plus vagotomy and drainage (the addition of vagotomy, decreased mortality by 50%).

Therefore, for patients with bleeding duodenal ulcer disease that requires surgery, we recommend opening the duodenum, oversewing the ulcer to achieve hemostasis, closing the duodenum using an appropriate pyloroplasty for the situation, and performing a truncal vagotomy prior to closing the abdomen. We do not recommend vagotomy and antrectomy given the increased difficulty as well as the higher postop complication rate when this procedure is used in the

emergency setting. In addition, we do not recommend other technically challenging operations in the emergency setting such as highly selective vagotomy.

Perforation

As with bleeding, surgeons faced with perforated peptic ulcers must also choose both when and how to operate. The presentation of a perforated ulcer can be nonspecific and subtle especially in the most vulnerable population where it may be easily confused with other acute conditions. We must remain vigilant and keep this life-threatening complication high on our differential diagnosis because while PUD has decreased in incidence, perforation has not. By keeping our index of suspicion high, we avoid both delays in treatment and unnecessary diagnostic tests.

While we agree with the authors that upper gastrointestinal (UGI) contrast studies can help identify perforations that have sealed, we disagree that they are of vital in the diagnosis of perforated peptic ulcer. Even in busy hospitals, UGI is unlikely to be available outside of regular daylight hours and reliance on this test will lead to delays in diagnosis and treatment translating to higher morbidity and mortality. We follow a simplistic diagnostic algorithm that starts with an upright chest x-ray. For 60% of perforated patients who have free air on presentation, we would argue no further testing is necessary. This is especially true if there is massive free air, where the source is usually from the upper gut. For those without free air on this initial imaging, CT scan, ideally with oral and IV contrast, should be the next test. Unlike UGI, CT scan is readily available around the clock in most emergency departments. Upper GI contrast studies, while potentially adding some increased sensitivity due to their dynamic nature, are less practical and significantly less available in all but the elective setting.

The mortality associated with perforation is high, and outcomes are best if patients are treated within 12 hours. We advocate for a low threshold for operating and the liberal use of diagnostic laparoscopy if the diagnosis of perforated PUD is high on the differential. With two or three 5-mm ports, the entire abdomen can be explored. If the diagnosis of PUD is confirmed, we perform patch closure alone. In our review of the NSQUIP database, we examined nearly 2,400 patients with perforated peptic ulcers and found that patients fared best, with lower rates of both 30-day morbidity and mortality, after local patching procedures alone. For perforated duodenal ulcers, vagotomy was of no benefit. Depending on the surgeon’s individual skills, patching a duodenal ulcer can be done either laparoscopically or through an upper midline laparotomy.

Among perforated ulcers, giant ulcers deserve special mention, as they will always prove more difficult to handle. In contrast to the authors of the chapter, we do not recommend the use of highly selective vagotomy for the treatment of giant ulcers. Highly selective vagotomy is a technically challenging operation with a long learning cure that is largely of historical interest and has no practical

use in the emergency setting. If vagotomy is to be used in this setting, it should be a truncal vagotomy. Closure of these ulcers may require extensive duodenal mobilization and may be aided by a jejunal serosal patch.

Elective Surgery for PUD

It is possible to spend an entire career in general surgery and never see a PUD patient with an indication for elective surgery. The two indications for these elective operations are obstruction and intractable pain. In the past, elective peptic ulcer operations were selected to minimize dumping and postvagotomy syndromes. Today, elective operations should be selected for the lowest ulcer recurrence rate. Since these operations are rare, troublesome postvagotomy syndromes are almost never seen. On the other hand, recurrence rates are very high in these extremely selected patients who are often cigarette or aspirin abusers. We recommend vagotomy and antrectomy as the elective operation of choice for complicated PUD. The decision to use a Billroth1 or Billroth2 reconstruction should be made based on the quality of the duodenum. Again, we do not recommend highly selective vagotomy in this environment due to the higher recurrence rate.

88 Gastric Cancer

John T. Mullen

Although the incidence of gastric cancer in the United States has dramatically decreased during the past several decades, gastric cancer remains an important cause of cancer-related death, with an estimated 24,600 cases and 10,700 deaths in 2015. Despite significant improvements in staging modalities, surgical therapy, and perioperative care, the prognosis of most patients with gastric cancer remains poor. This is largely a result of the aggressive biology of this cancer as well as the advanced stage of disease at which most patients present to the clinician. Risk factors include *Helicobacter pylori* and Epstein-Barr virus (EBV) infection, pernicious anemia, prior gastric resection, smoking, and high salt intake. Approximately 10% of gastric cancers are due to inherited cancer syndromes, including hereditary diffuse gastric cancer (HDGC), characterized by germline mutations in the E-cadherin (CDH1) gene, and hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, characterized by germline mutations in DNA mismatch repair genes. Recently, a comprehensive molecular evaluation of gastric cancer has led to a classification scheme that defines four major genomic subtypes and their approximate frequencies: EBV-infected tumors (9%), microsatellite unstable (MSI-high) tumors (22%), genomically stable tumors (20%), and chromosomally unstable tumors (50%). This chapter focuses on the preoperative diagnostic and staging evaluation of the patient with gastric cancer as well as the technical maneuvers involved in the performance of a subtotal or total gastrectomy for this disease.

PREOPERATIVE PLANNING

The evaluation of the patient with suspected gastric cancer includes a careful physical examination, laboratory studies, *H. pylori* status, endoscopic ultrasound (EUS), computed tomography (CT) and positron emission tomography (PET) scans, and laparoscopy. My current algorithm for the diagnosis and treatment of patients with gastric cancer is illustrated in Figure 88.1. The diagnosis of gastric cancer is usually readily

established by endoscopy with biopsy. Endoscopy defines the location and extent of the tumor within the stomach and, when combined with EUS, allows for accurate estimation of the depth of tumor invasion (T stage). EUS is the most sensitive modality in establishing the T stage of a gastric cancer, and EUS enables an assessment of the regional lymph nodes and needle biopsy of suspicious nodes to confirm nodal involvement (N stage). A CT scan of the chest, abdomen, and pelvis should be performed to evaluate for distant metastatic spread, such as to the lungs, liver, peritoneum, or lymph nodes outside the field of resection. In addition, a CT scan is sensitive in detecting even small amounts of ascites that may represent peritoneal tumor spread and that can be sampled by image-guided means for cytologic examination. Although PET and PET–CT scans are not routinely recommended in the preoperative staging of gastric cancer, they may certainly provide additional useful information. PET has a low sensitivity in detecting the primary tumor, especially in early and diffuse-type gastric cancers, but PET has a higher specificity than CT (~90% vs. ~60%) in the detection of regional lymph node metastases, and PET has a reasonable sensitivity for the detection of liver, lung, and distant lymph node metastases. In addition, PET can be used to monitor tumor response to neoadjuvant chemotherapy, as it accurately detects responders to therapy at an early stage, thus enabling the clinician to maintain patients on as active a chemotherapy regimen as possible. Nonetheless, PET has shown variable success at best in predicting histopathologic response and long-term survival.

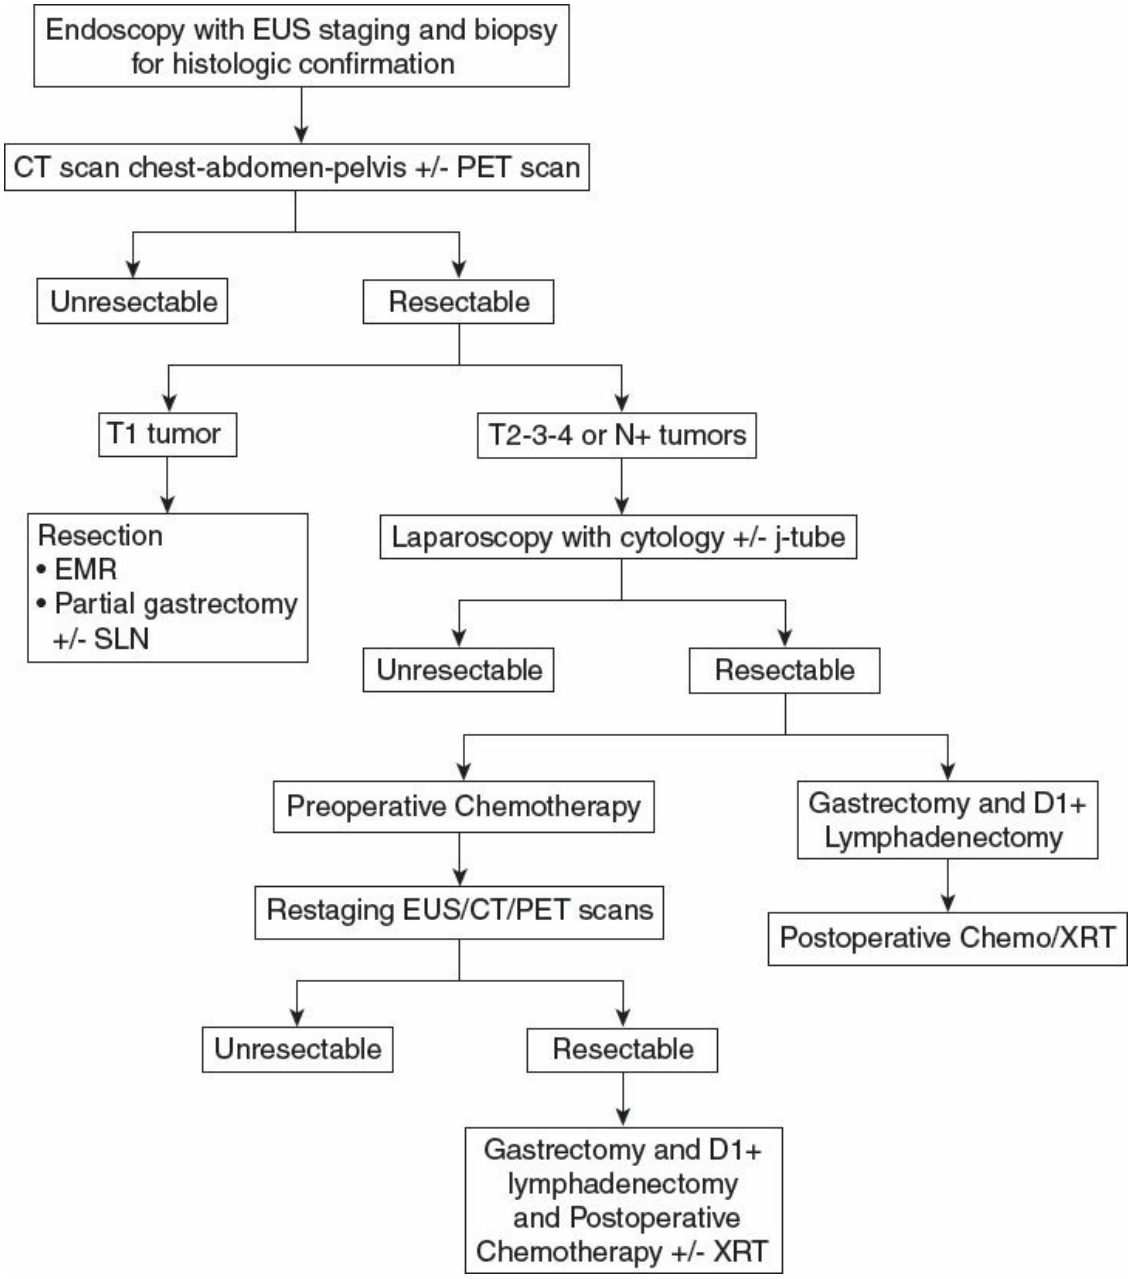

Figure 88.1. Algorithm for the diagnosis, staging, and treatment of gastric cancer. EUS, endoscopic ultrasound; CT, computed tomography; PET, positron emission tomography; SLN, sentinel lymph node biopsy; EMR, endoscopic mucosal resection; chemo/XRT, chemoradiation therapy.

Patients who should be considered for immediate resection include those with early-stage (T1/T2 N0) gastric cancers and those who require immediate palliation of bleeding or high-grade tumor-associated luminal obstruction. However, the perioperative morbidity and mortality rates in this latter population of patients are significant and must be carefully weighed against the likely benefits of resection. Patients with more

invasive lesions revealed on EUS are considered for additional pretreatment staging by laparoscopy. Staging laparoscopy can be done immediately prior to the planned laparotomy or as a pretreatment procedure performed in patients considering preoperative therapy. Staging laparoscopy upstages 20% to 30% of patients through the identification of radiographically occult peritoneal and liver metastases and positive cytology. It is a particularly high-yield procedure for those patients with tumors involving the gastroesophageal junction (GEJ) or whole stomach. For patients considering preoperative chemotherapy or chemoradiation therapy who have lost significant weight and/or are having significant difficulty meeting their nutritional needs by mouth, a feeding jejunostomy tube may be placed at the time of staging laparoscopy.

The most common treatment paradigm for gastric cancer in the United States has historically been upfront surgery, followed by adjuvant chemoradiation therapy (as described in the Intergroup 0116 trial) for those patients with high-risk (T3/4, node positive, poorly cohesive-type) tumors. However, only 64% of the patients in this trial could receive the postoperative chemoradiotherapy as planned, and so I favor perioperative chemotherapy for such patients, as described in the MAGIC trial conducted by the British Medical Research Council. In this trial, patients were randomized to receive either perioperative chemotherapy (three cycles of epirubicin, cisplatin, and 5-fluorouracil [ECF] preoperatively and postoperatively) and surgery or surgery alone. Five-year survival rates were superior in the perioperative chemotherapy group compared with the surgery-alone group (36% vs. 23%). Although only ~40% of patients complete all of the recommended therapy with this treatment approach, >85% of patients receive all three planned cycles of preoperative chemotherapy, and all patients receive at least one cycle of chemotherapy. Administration of at least a few cycles of systemic therapy in advance of surgery for patients with high-risk tumors confers several advantages: (1) It permits early treatment of possible micrometastatic disease; (2) one can monitor the in vivo tumor response to the therapy, such as with PET–CT scan imaging; and (3) one can select for those patients with particularly bad tumor biology who develop early metastatic disease and who would thus derive no survival benefit from gastrectomy.

SURGICAL CONSIDERATIONS

A complete margin-negative (R0) resection remains the only potentially

curative treatment for gastric adenocarcinoma. The choice of operation depends on the location of the tumor as well as the stage of disease. Superficially invasive (T1a) gastric cancers of favorable histologic grade can be treated by endoscopic mucosal resection or wedge excision with or without concomitant sentinel lymph node biopsy with excellent results. Such procedures have been extensively described by our surgical colleagues from Japan, where gastric cancers are frequently diagnosed at an early stage given the prevalence of screening endoscopic examinations in that country. Because the majority of patients in the United States present with symptomatic, locoregionally advanced tumors, the primary surgical question is which procedure offers the greatest chance for cure with acceptable morbidity and mortality. Many patients are not candidates for any surgical procedure either because they are medically unfit or because of the presence of metastatic disease seen on preoperative imaging studies or at the time of laparoscopy. For those patients who are candidates for gastric resection, the options include total, proximal subtotal, and distal subtotal gastrectomy. There is an increasing worldwide experience in performing these procedures laparoscopically, with improved short-term outcomes and nodal yields and survival outcomes that are on par with the traditional open procedures. However, the vast majority of resections for gastric cancer in the United States are still performed via the open approach. The indications for and technique of laparoscopic gastrectomy are discussed elsewhere in this volume. This chapter focuses on the technical issues of an open subtotal or total gastrectomy. First, however, there are three major surgical considerations that merit discussion.

EXTENT OF LUMINAL RESECTION

The extent of gastric resection is determined by the location and extent of the primary tumor. Prospective, randomized trials failed to demonstrate a survival advantage for total gastrectomy over distal, subtotal gastrectomy for patients with tumors of the distal stomach. Therefore, for those patients in whom a 5- to 6-cm margin from the tumor can be obtained, while still maintaining a reasonably sized gastric remnant, a more conservative gastric resection should be performed, as this confers an equivalent survival rate with less morbidity and a better quality of life than does a total gastrectomy. Nonetheless, a total gastrectomy should be performed if necessary to achieve an R0 resection, as positive resection margins (R1 resections) lead to very poor survival. In the Dutch gastric cancer trial,

10% of patients had a positive resection margin and a correspondingly inferior 3-year survival (18% vs. 63%) compared with those who had a negative resection margin. However, microscopically involved margins appear to affect long-term survival only in those patients with five or fewer lymph node metastases. For proximal gastric cancers, many surgeons prefer a total gastrectomy over a proximal gastrectomy owing to the long-term sequelae of symptomatic acid reflux with the latter procedure.

EXTENT OF LYMPH NODE DISSECTION

The extent of lymph node dissection is one of the most controversial issues in the management of gastric cancer. Retrospective studies from Japan suggest that performing an extended lymphadenectomy improves survival and demonstrate that it can be done safely, with a perioperative mortality rate of <1%. The Japanese Research Society for Gastric Cancer categorizes the draining lymph node basins of the stomach into 16 stations, including 6 perigastric stations and 10 regional stations along the major vessels and adjacent to the pancreas (Fig. 88.2A,B). The extent of lymph node dissection is indicated by the designation D: A D1 dissection includes only the perigastric nodes (stations 1 to 6); a D2 dissection includes the lymph nodes along the common hepatic, left gastric, celiac, and splenic arteries (stations 7 to 11); and a D3 dissection includes additional nodes within the porta hepatis and adjacent to the aorta (stations 12 to 16).

Two large, prospective randomized trials comparing the outcomes of D1 dissection with those of D2 dissection have been conducted in Western patients. Fifteen-year follow-up of the larger of these two studies, namely, the Dutch Gastric Cancer Group Trial, demonstrated no long-term overall survival benefit with the D2 lymph node dissection (29% vs. 21%, P = 0.34) but did show a significantly decreased gastric cancer-related death rate (37% vs. 48%, P = 0.01) and a lower locoregional recurrence rate than D1 surgery. However, there were significantly higher rates of postoperative morbidity (43% vs. 25%) and mortality (10% vs. 4%) in those patients undergoing the more extensive D2 lymphadenectomy, in large part resulting from the greater numbers of splenectomy and pancreatectomy performed in this group in order to achieve a complete node dissection. Similarly, the British Cooperative trial conducted by the Medical Research Council reported an increased morbidity, associated with high rates of concomitant splenectomy and pancreatectomy, without a

benefit in overall or recurrence-free survival in those patients randomized to a D2 dissection.

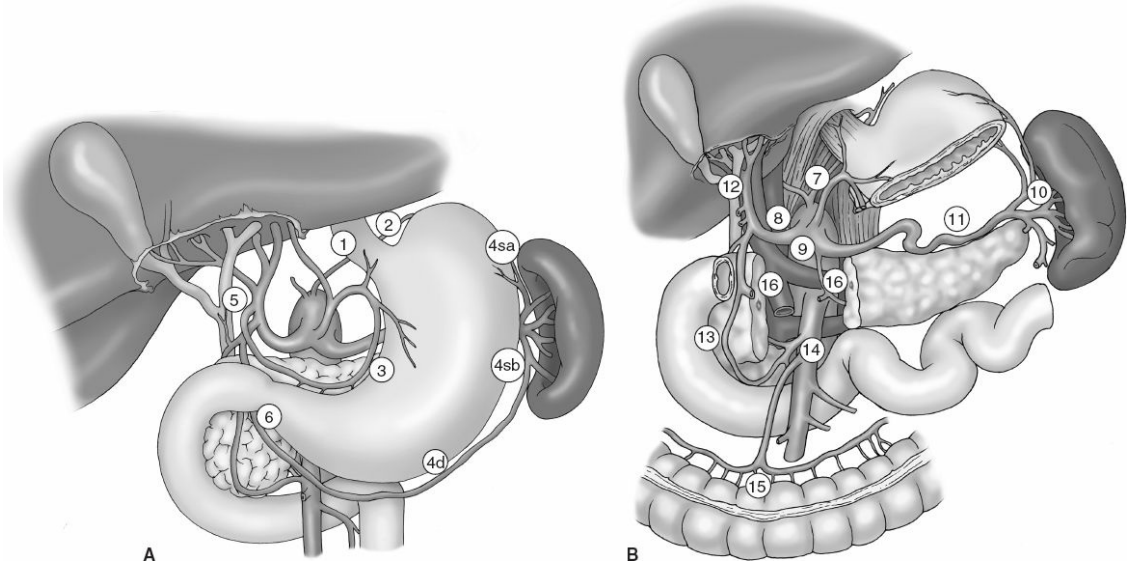

Figure 88.2. Lymph node stations including (**A**) the perigastric, or D1, lymph nodes (stations 1 to 6) and (**B**) the regional, or D2 and D3, lymph nodes (stations 7 to 16).

Despite the findings of these two studies, investigators have argued that if the complication rate after an extended D2 lymph node dissection could be decreased, the survival benefit conferred by a D2 dissection, as reported by experienced centers in Korea and Japan, might be translated to Western patients with gastric cancer. In fact, analysis of the group that did not undergo a pancreatectomy or splenectomy in the Dutch trial showed a significant survival advantage for those patients who underwent a D2 dissection (11-year survival 47% vs. 33%, $P = 0.018$). Thus, the Italian Gastric Cancer Study Group conducted a phase III trial randomizing patients to either a pancreas-preserving D2 lymphadenectomy or a D1 lymphadenectomy at high-volume centers by surgeons who completed rigorous training in the technique through observation of master surgeons in Japan. They reported impressively low morbidity (17.9%) and mortality (3.0%) rates in patients undergoing the D2 dissection, in which a pancreatectomy or splenectomy was performed only for direct tumor invasion. However, they found no difference in 5-year overall survival between the D1 and D2 groups (66.5% vs. 64.2%; $P = 0.695$), although subgroup analyses suggested that a D2 lymphadenectomy may be of benefit to patients with T2–T4 and/or node-positive tumors.

It remains unclear whether a D2 lymph node dissection is simply a

thorough staging procedure or whether there may be a therapeutic benefit for certain subsets of patients (e.g., patients with N2 disease). It should be noted that the accurate staging of patients with gastric cancer, according to the most recent seventh edition of the American Joint Committee on Cancer (AJCC) Staging Manual, demands the evaluation of at least 15 lymph nodes. The nodal staging is then based on the number of positive nodes, with N1 (1 to 2 positive nodes), N2 (3 to 6 positive nodes), N3a (7 to 15 positive nodes), and N3b (16+ positive nodes) categories. Studies have shown a correlation between improved patient survival and larger numbers of lymph nodes examined in the specimen. Of course, this may simply reflect more accurate staging as opposed to a therapeutic benefit from the procedure. However, there is indirect evidence that more extensive lymphadenectomies result in lower rates of locoregional recurrence, and this may translate into a survival benefit. Indeed, a randomized trial conducted at a single center in Taiwan identified an overall 5-year survival advantage for those patients undergoing a D3 dissection (59.5%) compared with those undergoing a D1 dissection (53.6%). However, a recently conducted trial by the Japan Clinical Oncology Group, in which patients undergoing an R0 resection are randomized at the time of surgery either to a D2 lymphadenectomy alone or with a para-aortic (D3) nodal dissection, demonstrated no difference in survival between the groups.

So in light of these conflicting data, what is one to conclude about the appropriate extent of lymph node dissection for gastric cancer in Western patients? I recommend performing either a formal D2 lymphadenectomy or, at a minimum, an “over-D1” (or “D1+”) lymphadenectomy, in which all D1 (perigastric) lymph nodes and as many D2 lymph nodes as are predicted to harbor metastatic disease, and that can be safely removed without the need for splenic or pancreatic resection, are included with the gastrectomy specimen. The Maruyama computer program may prove to be a helpful preoperative tool in this regard, as it accurately predicts the risk of lymph node metastasis in each nodal station based on the input of eight variables, including tumor histology, diameter, depth of invasion, and location. Failure to dissect those regional lymph nodes harboring metastatic disease, as predicted by the Maruyama program, will generate a high Maruyama Index (MI) of unresected nodal disease, which in retrospective analyses has been shown to result in higher rates of regional recurrence and inferior survival. The extent of lymph node dissection

required for a D1 and D2 dissection based on the site of the primary tumor is illustrated in Figure 88.3A–C.

EXTENT OF ADJACENT ORGAN RESECTION

The value of extended organ resection for advanced gastric cancer is another area of great debate, particularly in light of the increased morbidity and mortality accompanying such resections as shown in the Dutch and British trials previously mentioned. However, in order to achieve an R0 resection in patients with T4 lesions, it is often necessary to resect additional organs en bloc with the stomach. With careful patient selection, limiting gastrectomy with additional organ resection to those with clinical T4 tumors without evidence of visceral, peritoneal, or extensive regional nodal disease, long-term survival with acceptable perioperative morbidity and mortality is possible. Additional organ resection is not an adverse predictor of survival in this group of patients; rather, the depth of tumor invasion and nodal stage are the primary determinants of survival.

SURGICAL TECHNIQUE

Subtotal or Total Gastrectomy and D2 Lymphadenectomy

The reader will note that there are very few technical differences in the performance of a subtotal versus a total gastrectomy, and so both procedures will be described together in the text that follows, with important differences highlighted where relevant.

Exploration

The patient is positioned supine on the operating room table, and at the time of induction a single dose of a broad-spectrum antibiotic (e.g., a second-generation cephalosporin) is administered. It is important to note that in this chapter we consider only those gastric cancers confined to the stomach or GEJ, which can be adequately resected via an abdominal approach alone. More proximal GEJ or distal esophageal tumors may require either a left thoracoabdominal incision or a combined abdominal and thoracic approach (e.g., Ivor-Lewis procedure) to enable sufficient exposure of the esophagus to permit a negative-margin resection. These procedures are described elsewhere in this volume.

The abdomen is entered via a generous vertical midline incision extending from the xiphoid process to the umbilicus. Although a bilateral subcostal incision affords excellent exposure of the upper abdomen as well, I prefer a midline incision, as this is associated with less postoperative pain. The falciform ligament is divided and retractors are placed on the abdominal wall with the aid of the Thompson, Bookwalter, or Omni retractor system. The abdomen is then carefully explored to evaluate both the extent of locoregional disease and the presence of distant metastases. Special attention should be focused on all peritoneal surfaces as well as the liver.

Sequence of Operative Procedures

The sequence of operative steps of a subtotal (or total) gastrectomy and D2 lymphadenectomy is illustrated in Figure 88.4 and includes the following:

1. Mobilization of the greater curvature with omentectomy and division of the left gastroepiploic and short gastric vessels
2. Infrapyloric mobilization with ligation of the right gastroepiploic vessels
3. Suprapyloric mobilization with ligation of the right gastric vessels
4. Duodenal transection
5. D2 lymphadenectomy, with dissection of the porta hepatis, common hepatic artery, left gastric artery, celiac axis, and splenic artery, and ligation of left gastric vessels
6. Gastric (or esophageal) transection
7. Reconstruction by loop or Roux-en-Y gastrojejunostomy (or Roux-en-Y esophagojejunostomy)

Greater Curvature Mobilization

The greater omentum is dissected off the transverse colon with the aid of electrocautery (Fig. 88.5A). This step should be bloodless if dissection is correctly carried out in the avascular plane between the omentum and appendices epiploicae of the colon. I do not routinely resect the anterior leaf of peritoneum of the transverse mesocolon or the peritoneum

overlying the anterior pancreas unless dictated by local tumor invasion. It is unrealistic to believe that routine resection of these layers comprising the omental bursa (bursectomy) confers a survival advantage by potentially removing microscopic peritoneal metastases. The omentum is resected with the specimen, as it contains numerous perigastric (D1, station 4) lymph nodes and is nonetheless devascularized during the course of the gastrectomy.

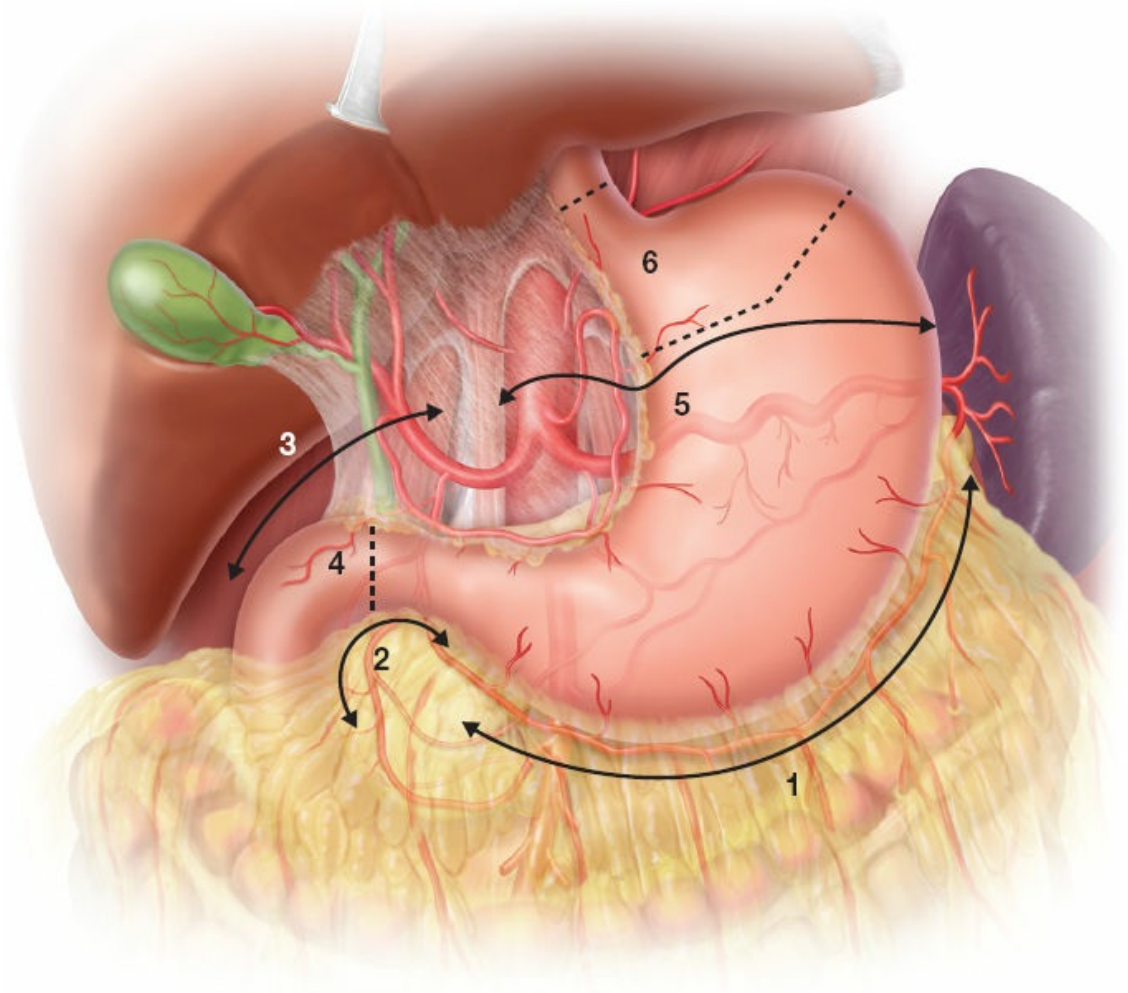

Figure 88.4. Sequence of operative procedures. (See text for details.)

With the greater omentum reflected superiorly, dissection commences on the left side of the abdomen such that the omentum is dissected off of the splenic flexure and the inferior pole of the spleen, exposing the body and tail of the pancreas. The left gastroepiploic vessels are identified and divided near their origin from the splenic vessels (Fig. 88.5B). The spleen is carefully elevated into the operative field with moist packs placed

posterior to it, and omental and colonic attachments to the spleen are lysed with the electrocautery (if needed) to prevent inadvertent capsular tears during the course of the dissection. The short gastric vessels are then divided each in turn close to the spleen, and for a total gastrectomy, all of the short gastrics are divided. However, for a subtotal gastrectomy, preservation of at least a few of the short gastric vessels is critical because this operation entails division of all four main arteries supplying the gastric remnant. In fact, one of the purported reasons for the unacceptably high morbidity and mortality rates reported in the Dutch Trial is that a number of patients who underwent distal gastrectomy also had ligation of the short gastric vessels as part of the mandated splenectomy to achieve a complete node dissection. Ligation of the short gastric vessels devascularizes the gastric remnant with resultant ischemia of the gastrojejunal anastomosis, and this perhaps explains the high anastomotic leak rate reported in this trial. A related point is that if during the course of a distal subtotal gastrectomy a splenic injury occurs, such that a splenectomy is necessary, a total gastrectomy should be performed in order to avoid the risk of necrosis of the gastric remnant.

Infrapyloric Mobilization

Once the left side of the stomach has been fully mobilized, dissection of the omentum continues over to the right side of the abdomen, near the hepatic flexure of the colon where the omentum is divided up to the duodenum. The colic branch of the gastrocolic trunk is identified within the transverse mesocolon, and its course is followed to its confluence with the right gastroepiploic vein to form the short gastrocolic venous trunk, which in turn drains into the superior mesenteric vein. For tumors of the distal stomach, the nodal tissue anterior and medial and lateral to the superior mesenteric vein at the inferior border of the pancreas (station 14v) should be resected as a separate specimen. The right gastroepiploic vein is divided at its juncture with the gastrocolic trunk and the inferior pancreaticoduodenal arcade (Fig. 88.6A). Note that the dissection should proceed carefully here because of the fragility of these venous tributaries. The right gastroepiploic artery is divided as it arises from the gastroduodenal artery, and the station 6 lymph nodes are dissected away from the head of the pancreas and included with the specimen (Fig. 88.6B). A plane is developed just anterior to the head of the pancreas and posterior to the pylorus, sweeping all nodal and soft tissue off of the

pancreas and with the specimen.

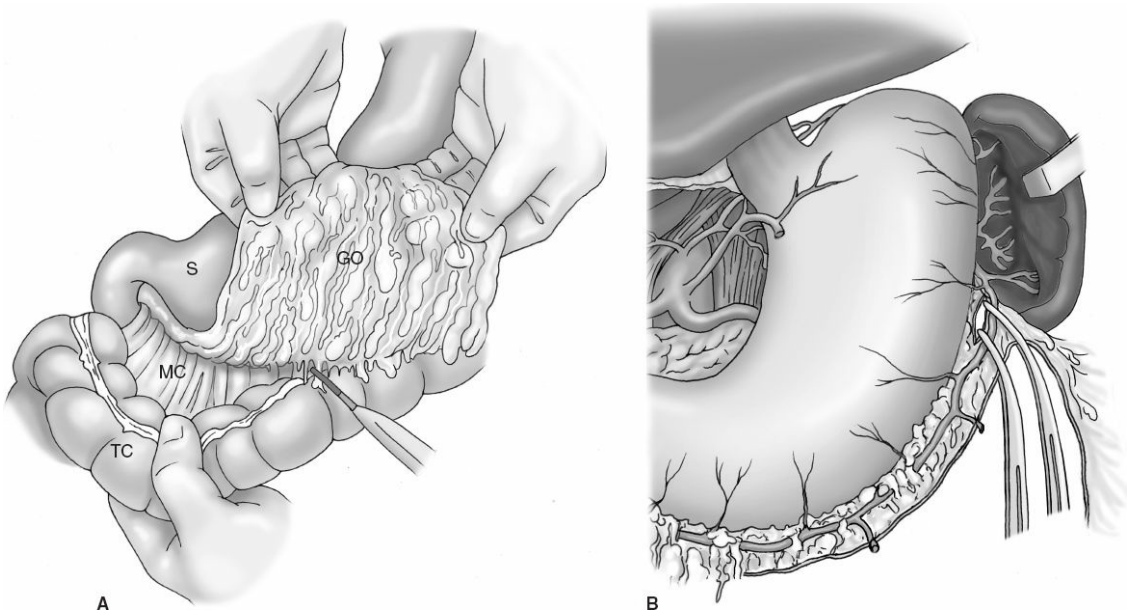

Figure 88.5. Mobilization of the greater curvature of the stomach (S), including (**A**) detachment of the greater omentum (GO) from the transverse colon (TC) and mesocolon (MC) and (**B**) ligation of the left gastroepiploic vessels.

Suprapyloric Mobilization

The gastrohepatic ligament is divided, being cognizant of a possible accessory or replaced left hepatic artery coursing through this ligament. If discovered, a replaced left hepatic artery can almost always be ligated with impunity, but I typically place a bulldog clamp on it for several minutes to ensure that the liver remains well-perfused prior to dividing it. The hepatoduodenal ligament is opened vertically in the direction of the proper hepatic artery, exposing completely the right gastric and gastroduodenal arteries. The right gastric artery is divided at its origin from either the proper hepatic artery or the gastroduodenal artery, the right gastric vein is divided close to its junction with the portal vein, and the station 5 lymph nodes are dissected up with the specimen (Fig. 88.7). Any residual fatty attachments and small vessels are ligated, and the duodenum is then fully mobilized.

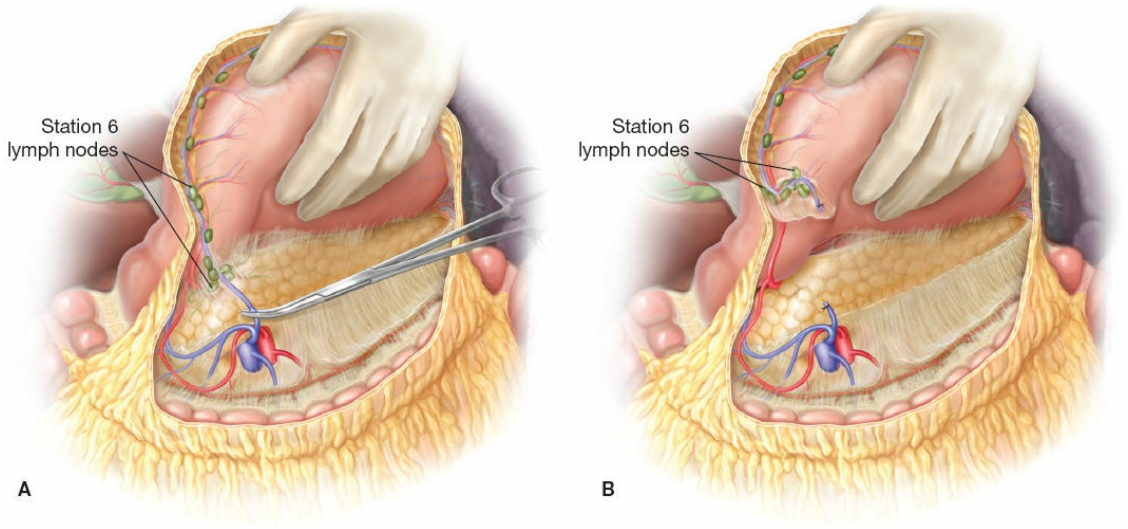

Figure 88.6. Infrapyloric mobilization, with (**A**) ligation of the right gastroepiploic vein at its juncture with the gastrocolic trunk, and (**B**) dissection of the station six lymph nodes up with the specimen.

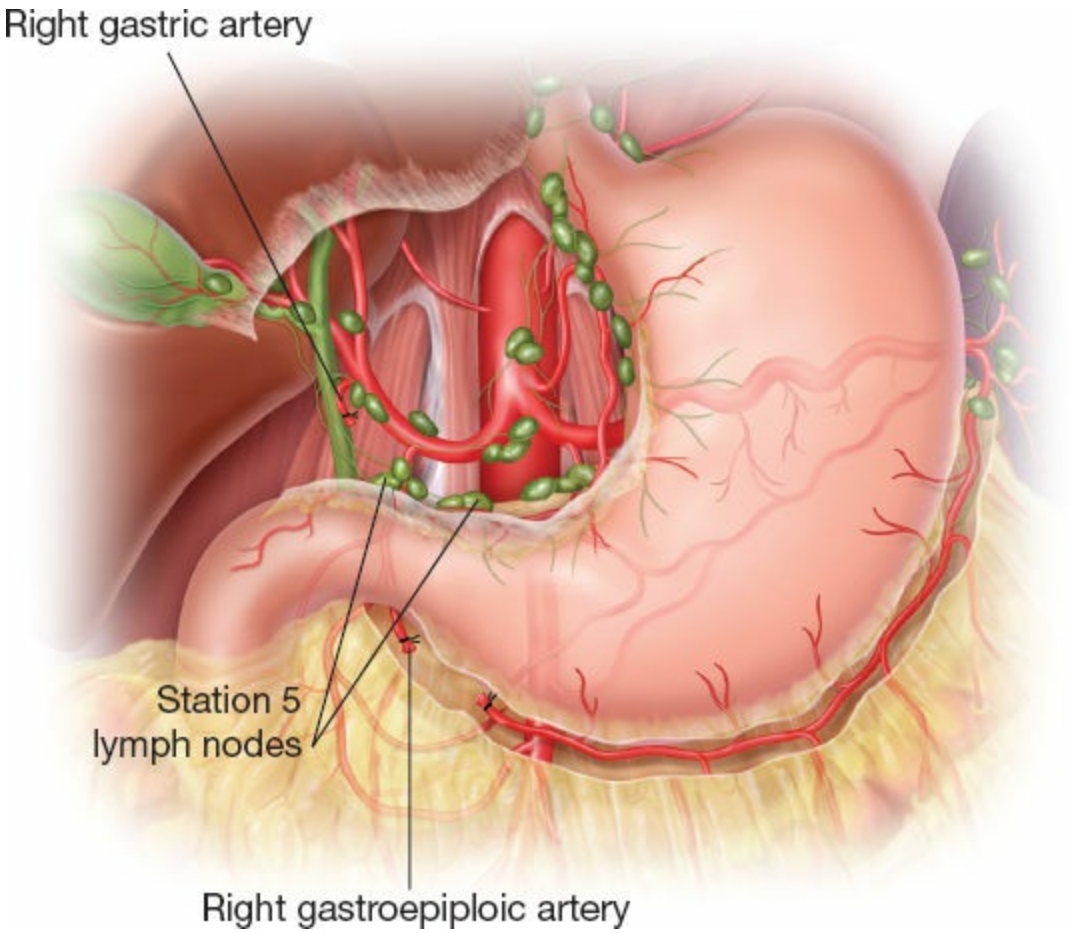

Figure 88.7. Suprapyloric mobilization, with ligation of the right gastric vessels in the porta hepatis and dissection of the station five lymph nodes up with the specimen.

Duodenal Transection

At this point, transection of the duodenum is simple and is typically performed with a GIA stapler (Fig. 88.8). The duodenum should be divided just distal to the pylorus unless invasion of the duodenum by tumor is suspected, in which case the duodenum should be divided more distally to ensure a negative histologic margin. The staple line on the duodenal stump may be inverted with interrupted Lembert sutures, though perhaps the most important factor predicting satisfactory healing of the stump is an adequate blood supply. Transection of the duodenum allows elevation and rotation of the stomach out of the field to permit subsequent dissection of the nodal tissue that comprises the D2 lymph nodes (Fig. 88.9A).

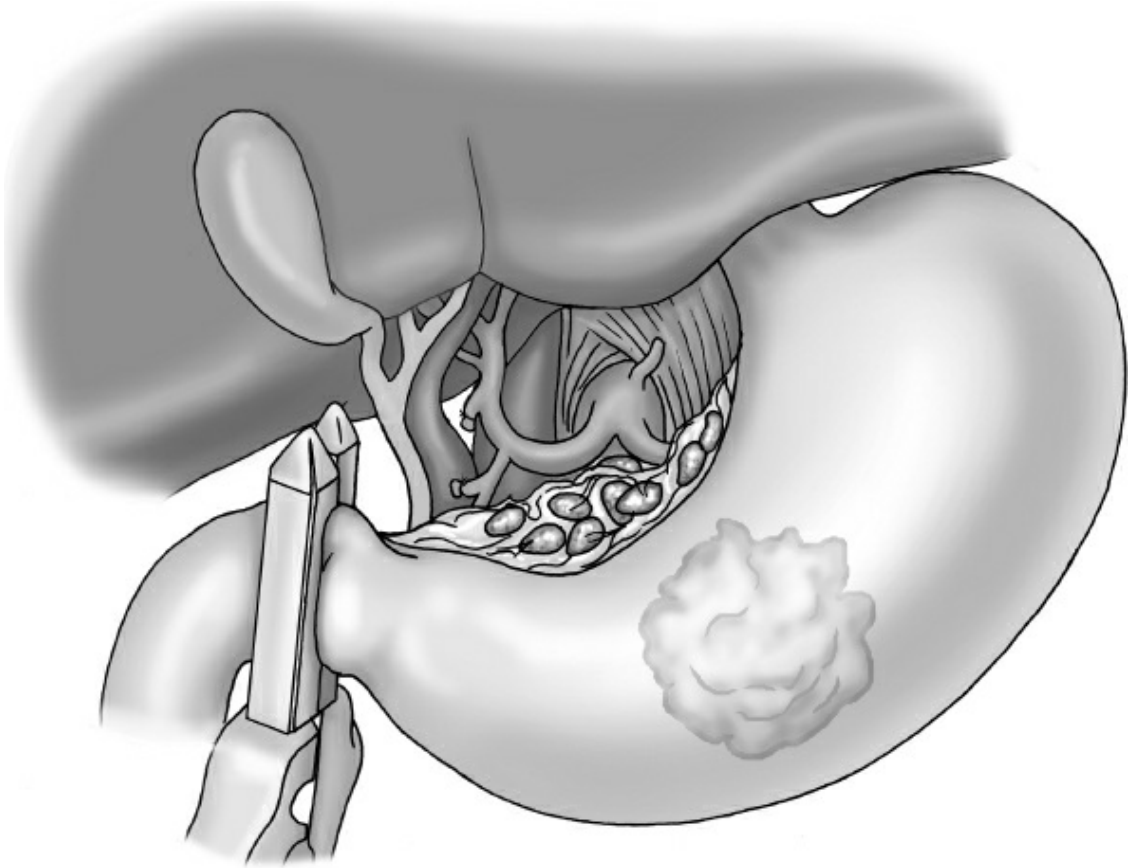

Figure 88.8. Transection of the duodenum with the GIA stapler.

D2 Lymphadenectomy

The dissection commences by dividing the peritoneum and lymphatics in the superior porta hepatis from right to left until the opening in the lesser omentum is reached. The nodal tissue is dissected off of the lateral aspect

of the proper hepatic artery toward the left side of the abdomen. The right gastric artery having been ligated previously, the proper hepatic artery is then gently retracted to the right side of the abdomen, and the nodal tissue along the anterior surface of the portal vein as well as the posterior surface of the proper hepatic artery is dissected free. The station 12 lymph nodes and investing fibrofatty connective tissue are then pulled into the omental bursa to the left of the porta hepatis. The dissection proceeds along the superior border of the pancreas, dividing the tissue between the common hepatic artery and pancreas and including this tissue with the station 8 lymph nodes along the anterior and posterior aspects of the common hepatic artery. This nodal tissue is quite vascular, so a vessel-sealing device such as a harmonic scalpel can be helpful with this dissection. The left gastric, or coronary, vein is identified coursing posteriorly from the lesser curvature; it is ligated and divided at its confluence with the portal or splenic vein. The nodal tissue at the upper border of the pancreas and along the proximal splenic artery (station 11) is dissected free and swept cephalad and to the left, together with the other lymphatic tissue.

The dissection continues medially to the celiac axis, which is invested with a firm plexus of nerves, and is limited to the nodal tissue on the anterior surface of the celiac artery (Fig. 88.9B). The left gastric artery is identified, either stapled or suture-ligated at its origin, and the adjacent nodal tissue is reflected toward the crura of the diaphragm (Fig. 88.10A). The dissection then proceeds proximally along the lesser curvature of the stomach to the right border of the esophagus. The peritoneum overlying the anterior surface of the abdominal esophagus is freed and the lymphoareolar, nodal-bearing tissue along the right cardia (station 1) is dissected off of the GEJ and the anterior wall of the lesser curvature of the stomach. An important anatomic point is that the left gastric artery usually bifurcates high on the lesser curvature (often at the level of the GEJ) into cranial and caudal branches (Fig. 88.10B). Therefore, in order to adequately dissect the lymph nodes along the cephalad branch of the left gastric artery, one must be assiduous in carrying the dissection proximally along the lesser curvature, often including the lower 2 to 3 cm of the intra-abdominal esophagus. This is a particularly important technical point in the performance of a subtotal gastrectomy for distal lesser curvature lesions.

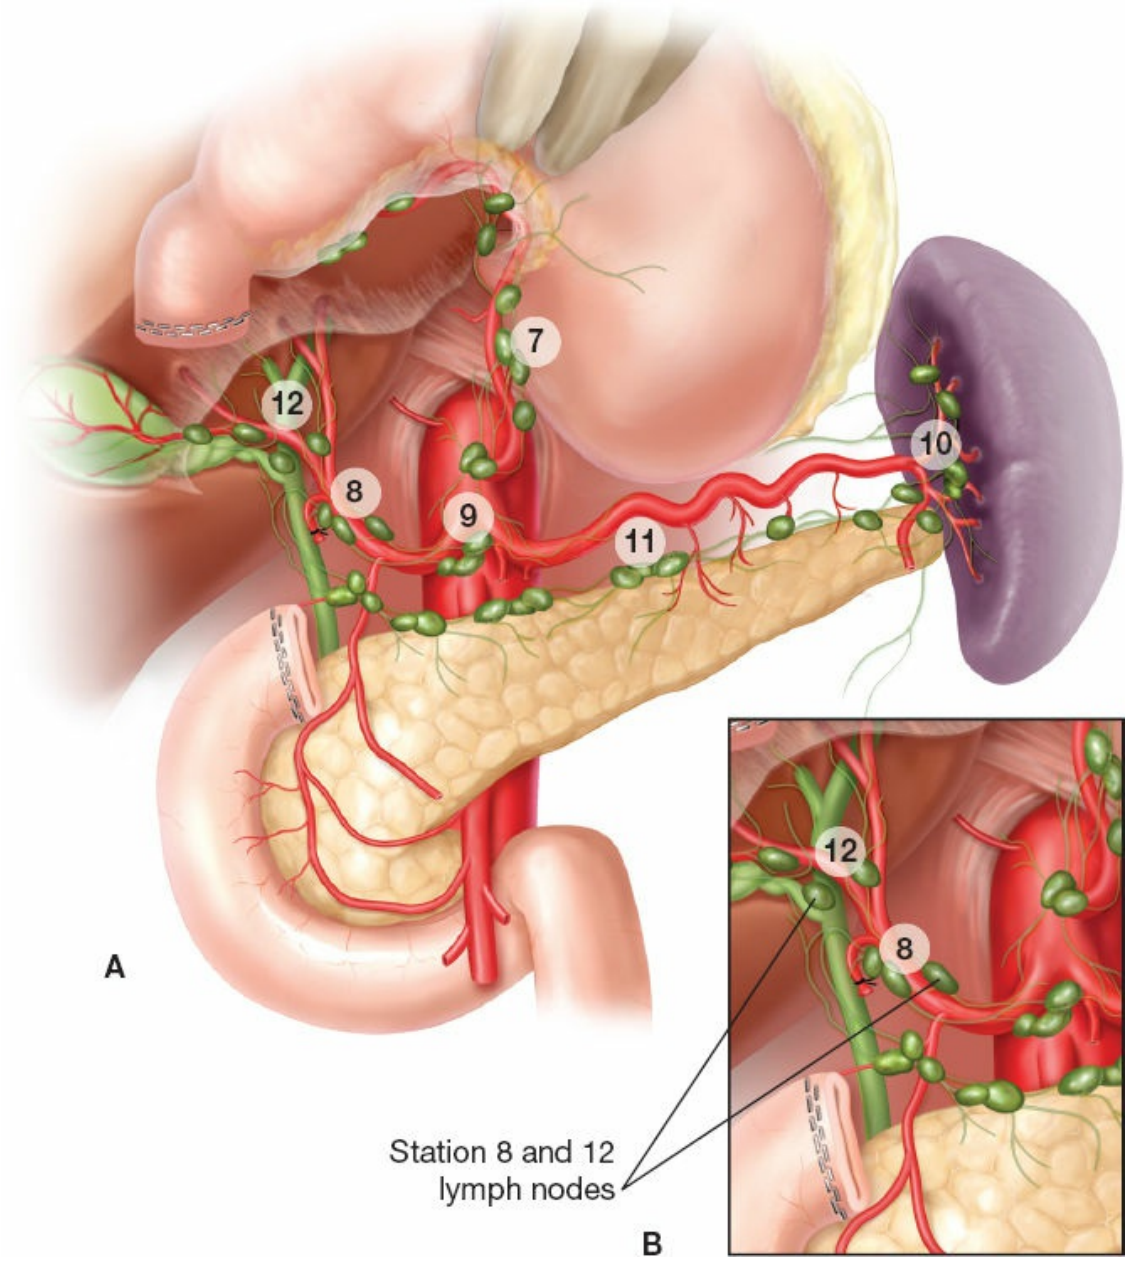

Figure 88.9. A,B. The D2 lymphadenectomy, including the nodes in the porta hepatis (station 12), along the common hepatic artery (station 8), along the left gastric artery (station 7), at the celiac axis (station 9), along the splenic artery (station 11), and within the splenic hilum (station 10).

The nodal dissection then continues along the splenic artery to the posterior gastric artery, which arises from the splenic artery and supplies blood to the posteromedial wall of the stomach. For distal gastric adenocarcinoma, one does not need to routinely dissect the lymph nodes beyond this point into the splenic hilum (station 10) unless these nodes appear to be grossly involved. The spleen is removed only if necessary to

resect locoregional disease. The spleen should not be routinely sacrificed as part of a D2 lymphadenectomy, as this has been shown to increase the morbidity of the procedure without conferring a survival benefit in Western studies. The reader will note, however, that our colleagues in Korea and Japan routinely perform a splenectomy at the time of total gastrectomy with little morbidity.

Gastric or Esophageal Transection

For a subtotal gastrectomy, the line connecting a point ~2 cm distal to the GEJ on the lesser curvature and a point at least 5 cm proximal to the upper border of the tumor on the greater curvature of the stomach is selected. Straight bowel clamps are placed on the greater curvature side of the stomach for a distance of ~6 to 8 cm, and the stomach is divided between these clamps with the knife. This cut surface of stomach will serve as the site of anastomosis in the fashion of Hofmeister. The remaining stomach from the tips of the straight clamps to the chosen point on the lesser curvature is divided with the GIA stapler to create a short Hofmeister shelf (Fig. 88.11A,B). The staple line is then inverted with a running monofilament suture (Fig. 88.11C). Alternatively, the stomach may simply be divided with several firings of the GIA stapler and the greater curvature portion of the staple line excised for the anastomosis.

In the case of a total gastrectomy, the phrenoesophageal ligament is divided with the cautery and the paracardial nodal tissue in stations 1 and 2 reflected off of the right and left crura and toward the specimen. Both vagus nerves are divided and the intra-abdominal esophagus circumferentially dissected free for a distance of at least 5 cm. If a stapled anastomosis is planned, I prefer to place an automatic pursestring device on the esophagus several centimeters above the GEJ and then to divide the esophagus with the curved esophageal scissors. If a hand-sewn anastomosis is planned, I prefer to secure the esophagus with an atraumatic Satinsky clamp on the esophagus prior to its division in order to prevent its retraction up into the mediastinum (Fig. 88.12).

The specimen is passed to a sterile back table in the operating room where it is carefully oriented for the pathologist. I also find it helpful to anatomically dissect the relevant lymph node groups from the specimen and to assign their numerical stations for the pathologist. Although this takes some time, I have found that it dramatically increases the nodal yield and ensures that the final pathology report includes not only the total

number of positive and retrieved lymph nodes but also their location(s). Intraoperative frozen sections of the proximal gastric (or esophageal) and distal duodenal margins are obtained prior to initiating the reconstruction.

RECONSTRUCTION

Although there are several options for reconstruction, including various types of interposition loops and pouches, I will discuss the two most common, feasible types of reconstruction after a subtotal gastrectomy: the Billroth II loop gastrojejunostomy and the Roux-en-Y gastrojejunostomy. Although a Billroth I gastroduodenostomy is an excellent reconstructive option following a distal gastrectomy, it is not a realistic option after a true subtotal gastrectomy in which at least 75% of the stomach is resected, as the duodenum will simply not reach the gastric stump in the majority of cases, even after an extensive Kocher maneuver. A loop gastrojejunostomy may be constructed by bringing the jejunum to the gastric pouch either in front of the transverse colon (an antecolic anastomosis) (Fig. 88.13A) or through a defect in the transverse mesocolon (a retrocolic anastomosis) (Fig. 88.13B). In either case, a proximal loop of jejunum (just distal to the ligament of Treitz) that reaches the stomach without tension or angulation should be chosen. It is particularly important to avoid an excessively lengthy afferent limb draining the biliary and pancreatic secretions, as such a limb is prone to kinking and occlusion, with the resultant afferent loop syndrome.

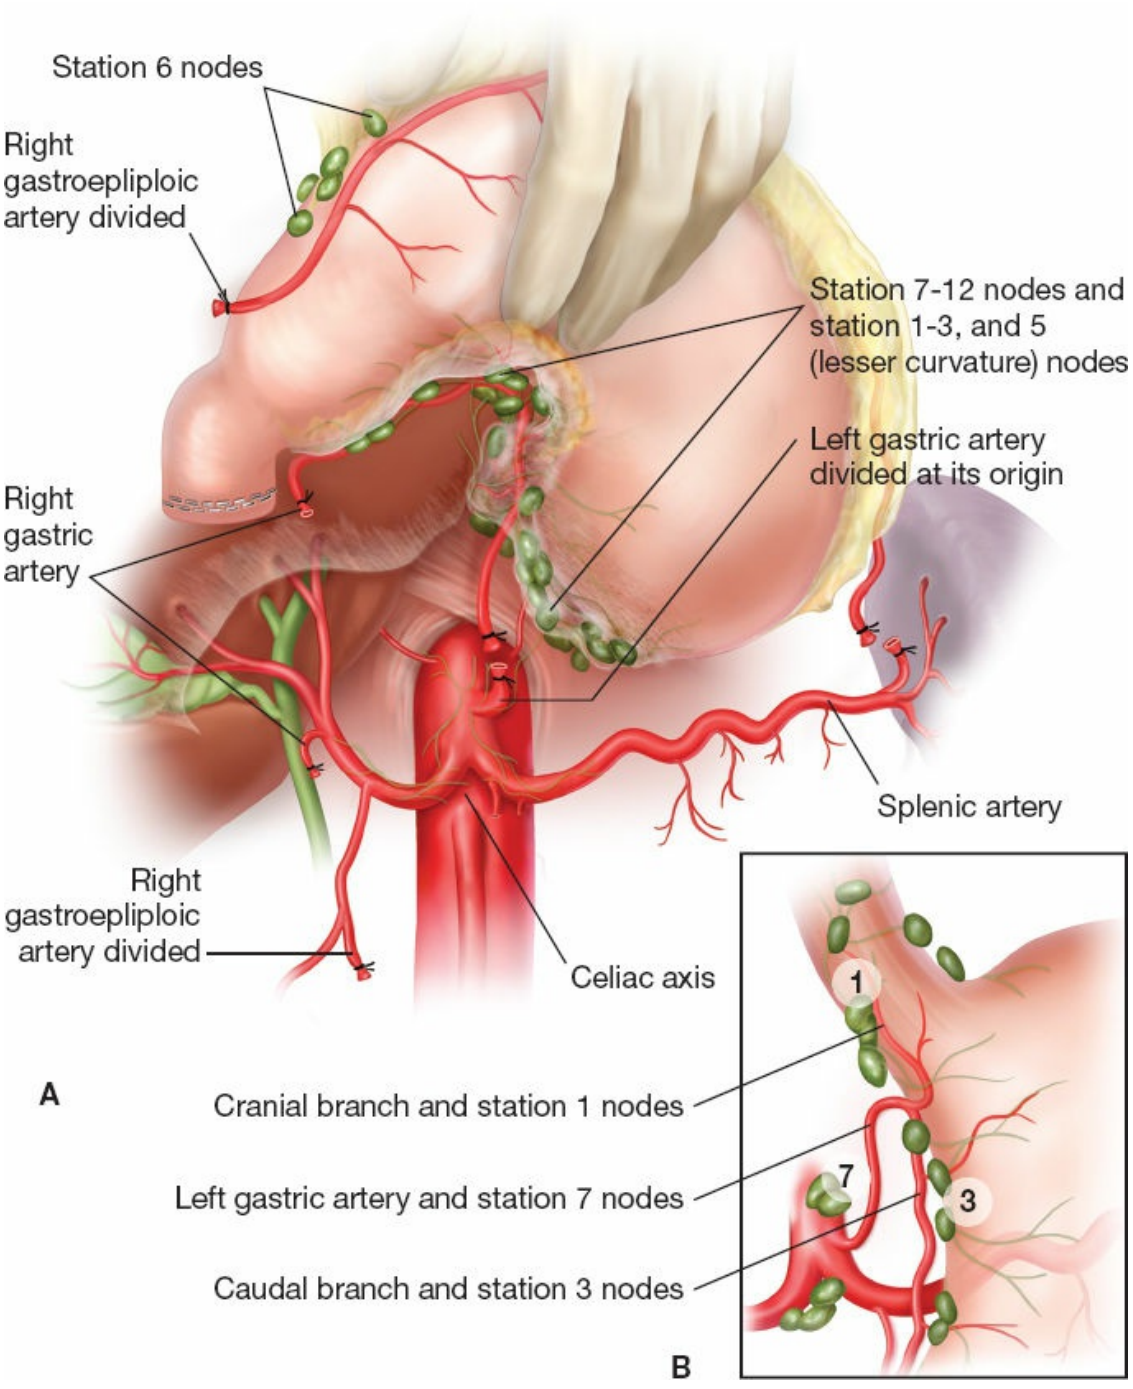

Figure 88.10. **A.** The left gastric artery is identified, suture-ligated at its origin, and the adjacent nodal tissue is reflected toward the crura of the diaphragm. **B.** The left gastric artery bifurcation into cranial and caudad branches occurs at a point high on the lesser curvature of the stomach. An adequate lymphadenectomy to include the nodes along the cranial branch of the left gastric artery requires dissection of all of the lymphoareolar tissue along the proximal lesser curvature of the stomach and the distal esophagus.

The gastrojejunal anastomosis may be performed in either a stapled or a hand-sewn fashion. I prefer the latter and will describe this technique. The jejunal loop is brought up to the gastric pouch in a side-to-side, isoperistaltic fashion with the proximal end of the jejunum apposed to the greater curvature side of the opening in the stomach. An outer, posterior row of interrupted, 3-0 silk seromuscular (Lembert) sutures is placed between the posterior gastric wall and the jejunum (Fig. 88.14A). The straight clamp is removed from the stomach, and an incision is made in the jejunum of slightly shorter length than the gastrotomy with the electrocautery (Fig. 88.14B). The inner, posterior layer of the anastomosis is performed with a running 3-0 PDS suture in simple over-and-over fashion, including the full thickness of both the stomach and jejunal walls (Fig. 88.14C). The inner layer anastomosis is continued anteriorly as a running Connell suture, which inverts the anastomosis. Of note, a nasogastric tube is advanced through the gastric remnant just into the efferent limb of the jejunum prior to completing the anterior layer of the anastomosis. The anterior portion of the gastrojejunostomy is completed with the placement of interrupted, 3-0 silk Lembert sutures (Fig. 88.14D). Special care should be directed to the placement of a three-cornered Lembert suture at the junction of the lesser curvature gastric staple line and the gastrojejunostomy, the so-called “angle of death.”

Frequently, however, I employ a Roux-en-Y reconstruction with a small residual gastric pouch in order to minimize the symptoms of gastroesophageal reflux and the incidence of erosive esophagitis and gastritis due to alkaline bile reflux. I have always been taught to ensure that the residual gastric pouch after subtotal gastrectomy is not too large in order to minimize the risk of delayed emptying due to gastric remnant atony. It can be difficult to distinguish the symptoms of gastroparesis, such as nausea, vomiting, postprandial fullness, and upper abdominal pain, from those of “Roux limb (or stasis) syndrome,” the etiology of which is unclear. The true incidence of Roux limb syndrome is probably much lower than previously considered, at 2% or less, and so I don’t believe this should deter the surgeon from this method of reconstruction. The jejunum is divided ~20 cm distal to the ligament of Treitz and brought up to the stomach through a defect created to the left of the middle colic vessels in the transverse mesocolon (Fig. 88.15A). The gastrojejunal anastomosis is performed as described for the loop anastomosis. Intestinal continuity is restored with a side-to-side jejunojejunostomy at a distance of at least 45

to 50 cm distal to the gastrojejunostomy in order to prevent the reflux of biliary and pancreatic secretions into the gastric remnant (Fig. 88.15B). The jejunojejunostomy may be performed in a stapled or a hand-sewn fashion. For a stapled anastomosis, two small enterotomies are created in the antimesenteric borders of the small intestine. One fork of a GIA stapler is placed in each intestinal lumen and then fired. The common enterotomy is then closed with either a TA stapling device or a full-thickness running monofilament suture after inspection of the staple line for hemostasis.

After a total gastrectomy, the standard reconstruction is a retrocolic, end-to-side Roux-en-Y esophagojejunostomy. As above, a Roux limb is created of a length of at least 45 to 50 cm from the jejunojejunostomy and delivered through a rent in the transverse mesocolon to the left of the middle colic vessels. It is critical not to accidentally twist this limb as it is brought up to the esophagus, and one way to be sure of the proper orientation of this limb is to be certain that the staple line on the cut edge of jejunum is always facing the patient's left side. Several options exist for the anastomosis of the esophagus to the jejunum. I prefer an end-to-end stapling device. The esophagus is atraumatically dilated with a Foley catheter balloon serially inflated up to 6 to 10 cc, depending on the diameter of the esophagus. Four, full-thickness 3-0 silk traction sutures are placed just distal to the pursestring suture in four quadrants, the anvil is placed with the aid of lubricant into the esophagus, and the pursestring suture is tied. Although I prefer to place a 28-mm anvil in the esophagus to allow for a larger diameter anastomosis (and thus hopefully a lower incidence of stricture), in most cases I find that the esophagus will only accept a 25-mm anvil. The staple line on the end of the Roux limb is excised and the EEA stapler introduced and the spike advanced out the anti-mesenteric border of the jejunum. This is then married to the anvil within the esophagus and, being careful to ensure that the Roux limb is not twisted, the stapler closed and fired. The stapler is removed, two complete mucosal donuts are assured, and the open end of the Roux limb is closed with a firing of the GIA stapler (Fig. 88.16A,B). Although I still tend to place a nasojejunal tube after total gastrectomy, there is an abundance of data demonstrating that routine nasojejunal decompression after total gastrectomy is not only unnecessary but in fact may be associated with a higher risk of pulmonary complications in addition to the annoying local discomfort experienced by the patient. The completed reconstruction is shown in Figure 88.17.

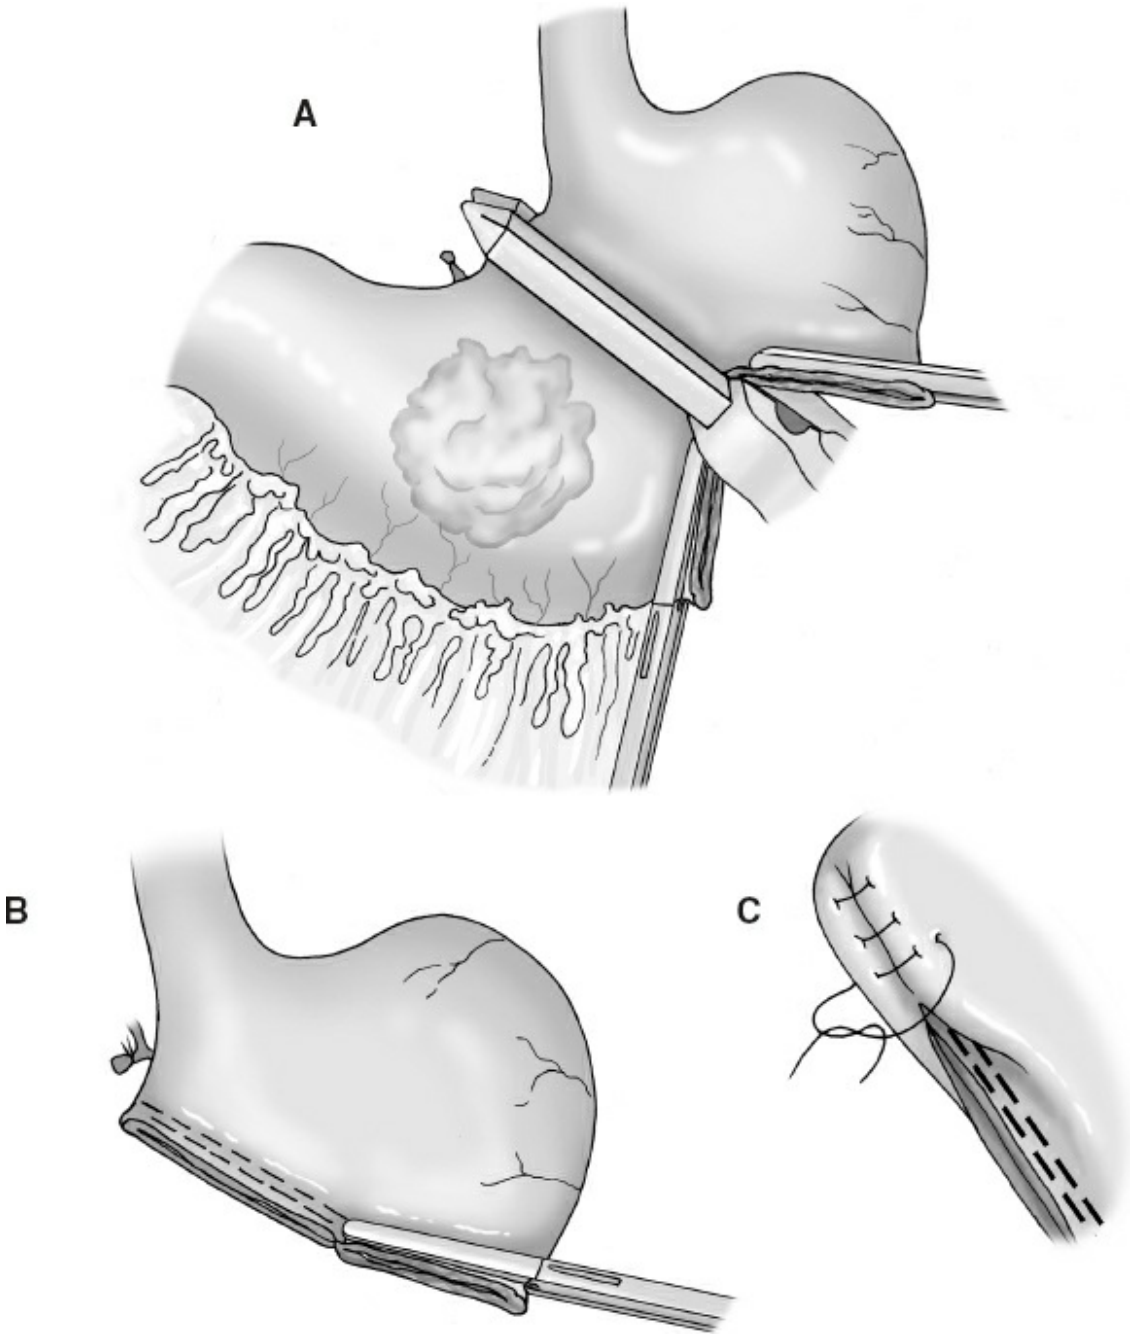

Figure 88.11. **A,B.** The stomach is divided by placing straight bowel clamps on the greater curvature side for a distance of ~6 to 8 cm, cut for this distance with the knife (serving as the site of future anastomosis in the fashion of Hofmeister), and then completely divided with the GIA stapler. **C.** The staple line is then inverted with a running monofilament suture.

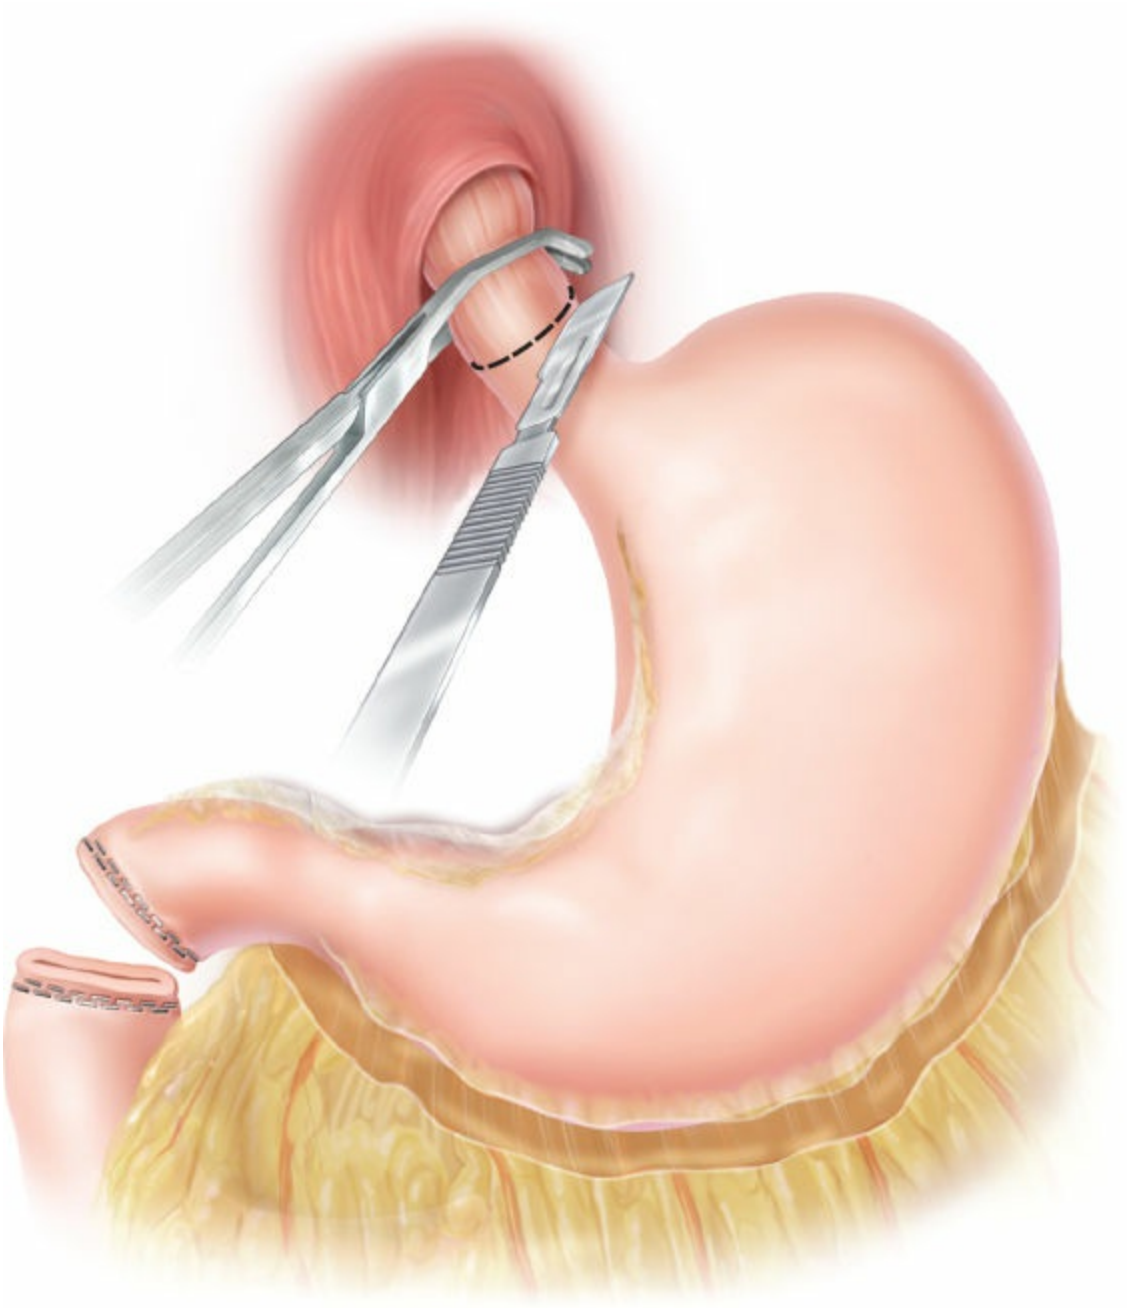

Figure 88.12. The esophagus, stabilized by a Satinsky clamp or the automatic pursestring device, is divided sharply by a knife or curved esophageal scissors.

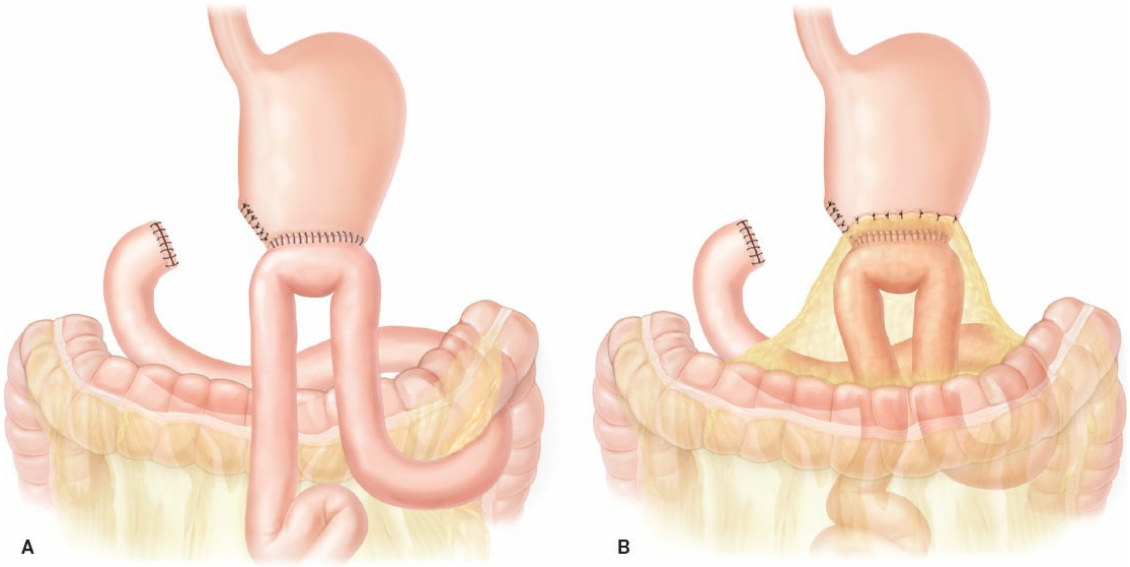

Figure 88.13. Reconstruction can be achieved by a loop gastrojejunostomy (Billroth II anastomosis), constructed by bringing the jejunum up to the gastric pouch either (**A**) in front of the transverse colon (antecolic anastomosis), or (**B**) through a defect in the transverse mesocolon (retrocolic anastomosis).

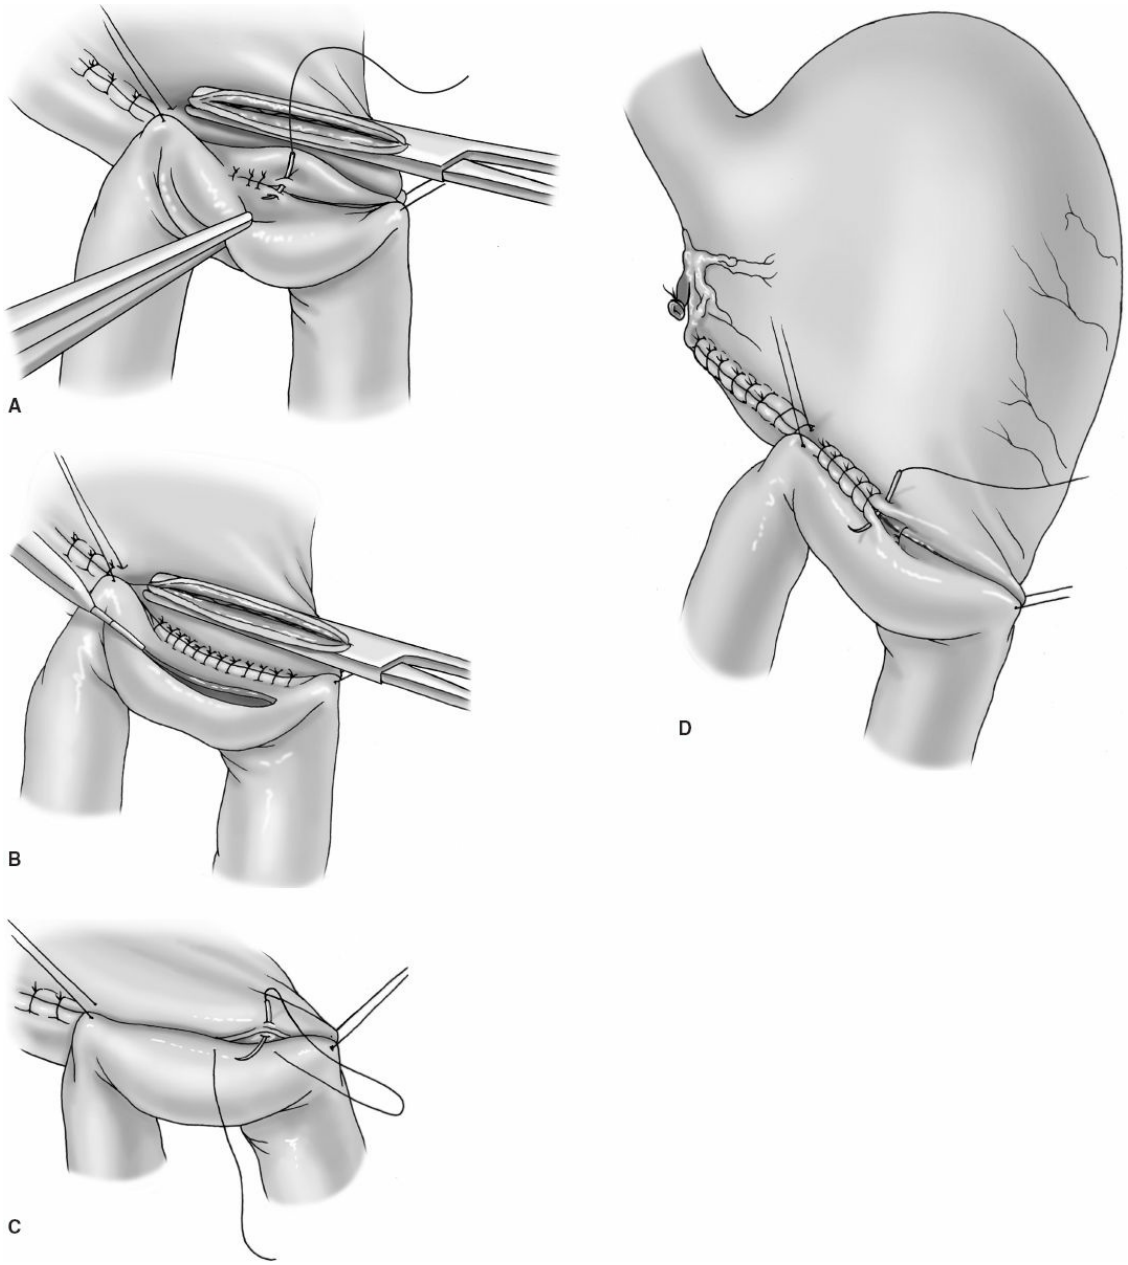

Figure 88.14. Standard technique for a two-layer, hand-sewn gastrojejunal anastomosis. **A.** After the placement of corner sutures, a back row of interrupted 3-0 silk Lembert sutures is placed. **B.** A jejunostomy is made with the cautery. **C.** The inner layer anastomosis is constructed in running, full-thickness fashion with 3-0 PDS. **D.** Several interrupted 3-0 silk Lembert sutures complete the anastomosis anteriorly. (See text for details.)

Although many surgeons routinely place intra-abdominal drains and/or feeding tubes at the time of gastrectomy, I take a much more selective approach in this regard. I would consider the placement of a closed-suction intra-abdominal drain, for instance, in the patient in whom extensive peripancreatic dissection or a partial pancreatectomy is necessary for a

margin-negative resection. Similarly, I rarely place a feeding jejunostomy tube after a subtotal gastrectomy but do so with some regularity after a total gastrectomy, particularly in patients with significant preoperative nutritional compromise.

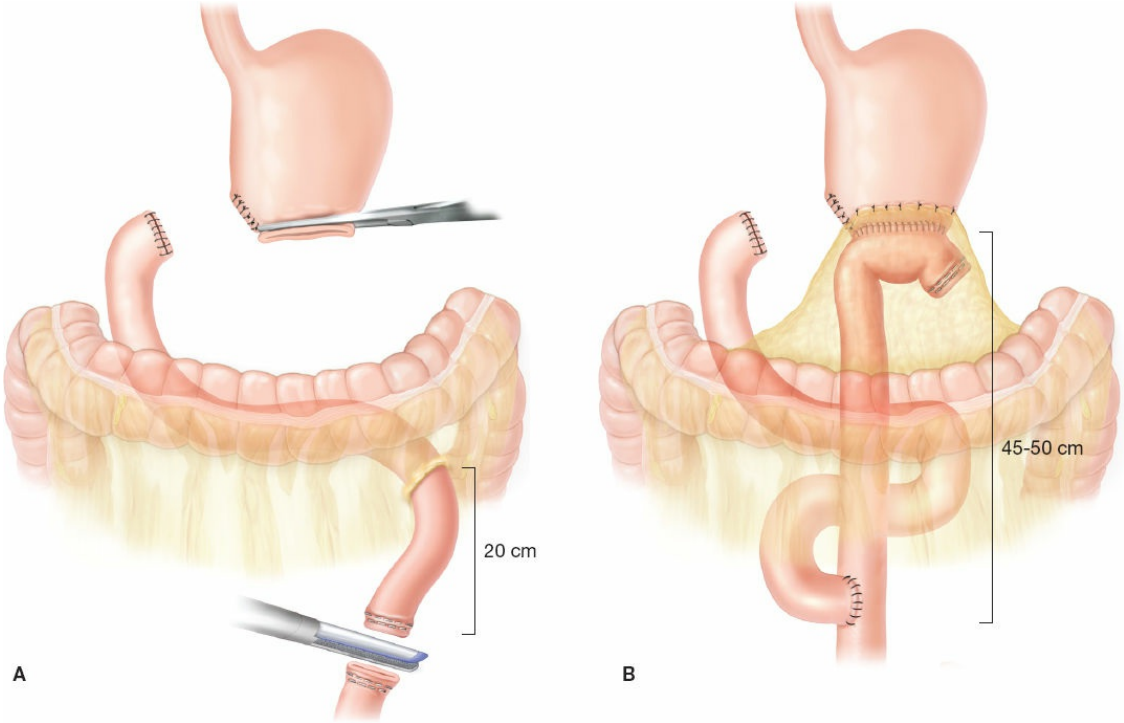

Figure 88.15. Reconstruction by a retrocolic, Roux-en-Y gastrojejunostomy. **A.** The jejunum is divided with the GIA stapler ~20 cm distal to the ligament of Treitz. **B.** A retrocolic, end-to-side Roux-en-Y gastrojejunostomy is created with a Roux limb at least 45 cm in length.

POSTOPERATIVE CARE

Routine postoperative care with early mobilization and pulmonary toilet is initiated. Pain control is achieved with continuous epidural analgesia, typically with a combination of fentanyl and bupivacaine. The epidural catheter remains in place for 3 to 4 days, at which point narcotics are administered enterally via a jejunostomy tube (if present) or orally. Prophylactic antibiotics are typically continued in the postoperative period for <24 hours. Of course, careful fluid and electrolyte balance are maintained, and I prefer early diuresis, as I find that this decreases the incidence of cardiopulmonary complications and may shorten the duration of ileus. My habit is to administer furosemide on the evening of postoperative day 2 to those patients who do not exhibit spontaneous

diuresis, with daily diuresis and electrolyte monitoring thereafter until the postoperative weight returns to within 1 kg of the immediate preoperative weight.

For patients undergoing subtotal gastrectomy, the nasogastric tube is removed when there is audible return of bowel function, or sooner, if daily aspirated volumes are low. This is typically on postoperative day 3. After removal of the nasogastric tube, the patient is started on a clear liquid diet and slowly advanced to a post-gastrectomy diet consisting of six small daily meals. I do not routinely obtain a postoperative contrast study such as a Gastrografin swallow test, as clinically occult, radiographically defined anastomotic leaks are usually of minimal or no clinical significance. However, if the patient exhibits unexplained fever, tachycardia, or prolonged ileus, such a contrast study (along with cross-sectional imaging to identify a possible fluid collection or abscess) is obtained. Clinically significant anastomotic leaks are usually drained, preferably by a percutaneous, image-guided route. For patients undergoing total gastrectomy, I do routinely obtain an upper gastrointestinal (GI) swallow test with water-soluble contrast followed by thin barium on postoperative day 3; and if no anastomotic leak is found, the nasojejunal is removed and a clear liquid diet started. If tolerated, a full liquid diet is started on postoperative day 4 and a soft, post-gastrectomy diet on postoperative day 5 or 6. In this way, most of my total gastrectomy patients can be discharged by postoperative day 6 or 7. If an anastomotic leak is discovered, the nasojejunal tube is left in place and the patient kept NPO; and if the leak is clinically significant, a CT scan is obtained and percutaneous drainage pursued.

For the subset of patients in whom a jejunostomy tube is placed, low-dose elemental enteral feeding is initiated on the morning of postoperative day 2 and then advanced slowly as tolerated to the goal rate of 100% of the patient’s caloric and protein needs. With the return of bowel function and the start of a post-gastrectomy diet, the tube feedings can be cycled nightly and continued in this fashion post-discharge until the patient is capable of meeting his or her nutritional requirements by oral intake alone. Of note, a feeding jejunostomy tube is helpful in maintaining the nutritional status of patients who suffer a postoperative complication, especially an anastomotic leak, which prohibits or limits adequate oral intake.

COMPLICATIONS

Although the morbidity and mortality rates and survival results of the UK and Dutch randomized trials did not support the routine performance of a gastrectomy and D2 lymphadenectomy for Western patients with gastric cancer, it is now clear that this procedure can be done safely at specialized centers in the West. For patients treated at Massachusetts General Hospital over the past decade, we have reported morbidity and mortality rates after gastrectomy and D2 lymphadenectomy of 17% and 0%, respectively, and our median lymph node yield with ex vivo dissection of the specimen has increased to 40 nodes. The Memorial Sloan Kettering group recently published detailed 90-day outcomes on >230 patients undergoing curative-intent total gastrectomy. They reported that 62% of patients had at least one postoperative adverse event and that 28% experienced a major adverse event requiring invasive intervention. The most common adverse events were anemia (20%) and wound complications (18%), and the most common major adverse event was esophageal anastomotic leak, which occurred in 15% of patients and required invasive intervention in 10% of patients. Duodenal stump leak occurred in 3.8% of patients, and one third of these leaks were fatal, whereas only 6% of esophageal anastomotic leaks were fatal. The 90-day mortality rate was 2.9%, and the readmission rate was 20%. The median length of stay for subtotal and total gastrectomy in the United States averages 9 to 10 days, although many patients are discharged within 7 days. The long-term complications of subtotal and total gastrectomy include vitamin and mineral deficiencies, particularly of vitamin B_{12}, vitamin D, iron, and calcium, and the classic post-gastrectomy syndromes, such as alkaline reflux gastritis, dumping syndrome, Roux stasis syndrome, and afferent limb syndrome, all of which are described in detail elsewhere in this volume.

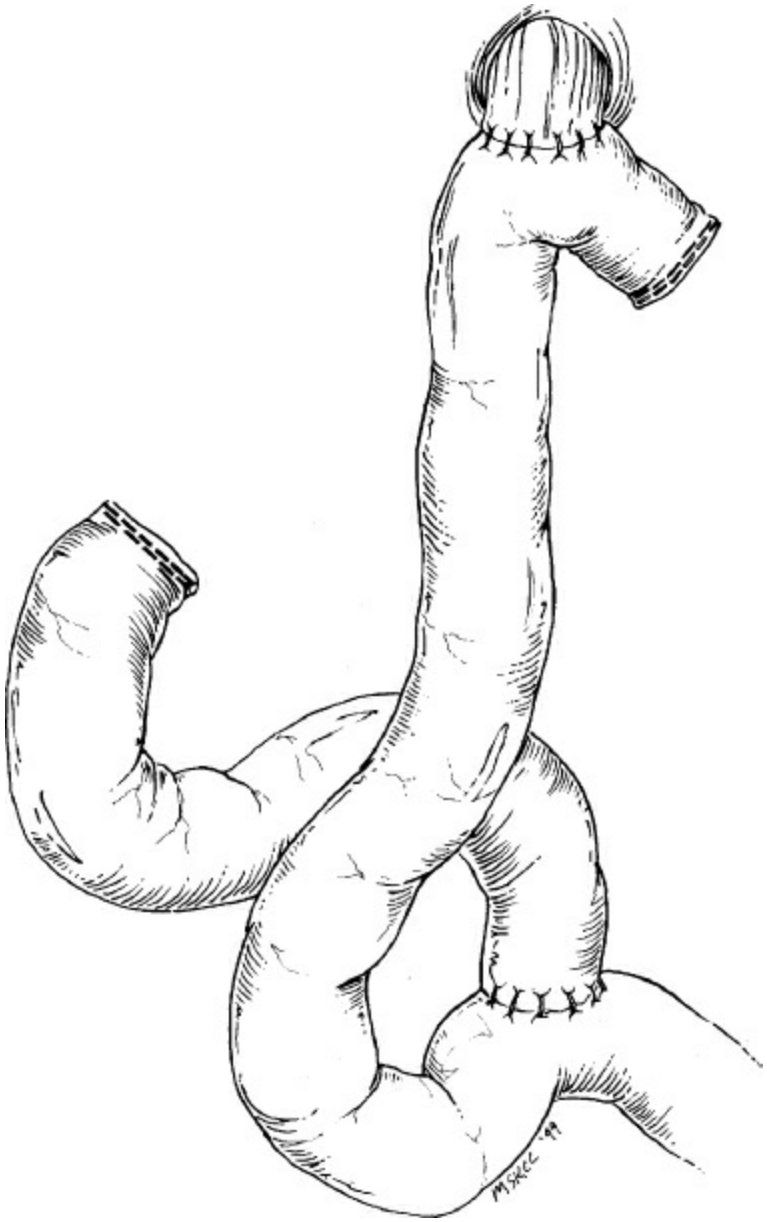

Figure 88.17. The completed Roux-en-Y reconstruction.

OUTCOMES

Surgery is the only potentially curative therapy for localized gastric cancer, yet even for those patients in whom an R0 resection is possible, only 35% to 40% 5-year survival is achieved with either perioperative chemotherapy or postoperative chemoradiotherapy. Preoperative therapy may increase the R0 resection rate and ensure that all patients with advanced tumors, and thus at high risk for distant failure, receive systemic therapy as early as possible. Although extensive gastric resections and D2 lymphadenectomies can now be performed at specialized centers with low operative morbidity and mortality rates and excellent nodal yields, future

progress in the treatment of gastric cancer depends on the development of better systemic therapies as well as techniques for earlier diagnosis.

EDITOR'S COMMENT

Despite almost eight decades of evidence, many surgeons continue to debate the rationale of aggressive surgery in the management of gastric cancer. This discussion, I believe, is best viewed through the lens of history. Although the earliest descriptions of gastric cancer date back to the Ebers Papyrus of 1600 BC,

the French surgeon Jules-Émile Péan performed the first gastric resection on April 9, 1879. Unfortunately, this and subsequent attempts at the operative management of gastric cancer were met with failure until Theodor Billroth successfully performed a subtotal gastrectomy with gastroduodenal anastomosis on January 22, 1881. Billroth went on to record a series of 257 subtotal gastrectomies for cancer during his illustrious career. Karl Schlatter, an understudy of Billroth and colleague of Rudolf Ulrich Krönlein, proposed that the poor clinical outcomes associated with this operation, including high rates of mortality and recurrence, could be improved upon by total gastrectomy. He therefore performed the first total gastrectomy and esophagojejunostomy for cancer in 1897 on a 56-year-old woman who survived for more than a year before succumbing to recurrent disease. Little progress in the technical aspects of gastric cancer surgery was made until the concept of extended resections surfaced in the 1930s, when Dr. Owen Wangensteen began to incorporate a more aggressive approach that included both extended lymph node dissections and resections of the pancreas and spleen. Considerable debate continues regarding the best operative technique for the management of gastric cancer. In this chapter on gastric cancer, Mullen presents a concise, evidenced-based approach to this insidious disease. I would submit that there are four important issues facing surgeons who manage gastric cancer: the extent of lymphadenectomy, reconstruction techniques, the emerging role of minimally invasive surgery in this population, and regionalization of care.

The potential benefits of extensive lymphadenectomy include enhanced staging, as well as improved disease-specific and overall survival. As such, the extent of lympadenectomy for gastric cancer has been conveniently divided into three categories. A D1 dissection includes only the perigastric lymph nodes. A D2 dissection also includes the lymph nodes along the hepatic, celiac, left gastric, splenic artery, and hilum as well as the nodes that are >3 cm away from the primary tumor. A D3 dissection includes all of the D2 stations plus nodes in the porta hepatis, retropancreatic, and periaortic areas. Interestingly, a recent review of the Surveillance, Epidemiology and End Results database demonstrated that only 29% of 10,897 patients who underwent resection for gastric cancer in the United States received lymphadenectomies of 15 or more lymph nodes (Reid-Lombardo, 2007). These findings suggest a much-needed improvement in the operative management of gastric cancer in the United States. Mullen’s treatment of lymphadenectomy in the description of both total and subtotal gastrectomies is excellent, but this chapter would benefit from a comprehensive review of more recent literature on this topic.

Given superior survival outcomes for extended lymphadenectomy in Asian studies as well as improved results in patients undergoing D2 resections relative to historical controls, two early prospective randomized trials were conducted by the Medical Research Council in the United Kingdom and the Dutch Gastric Cancer Group. These initial trials seemed to support less extensive lymphadenectomy, as there were not only high morbidity (43% and 46%) and

mortality rates (10% and 13%) relative to historical cohorts in Asian centers, but they also failed to show improvements in overall survival (Bonenkamp, 1999; Bonenkamp, 1995; Cuschieri, 1996; Cuschieri, 1999). Interestingly, a recent follow-up of the Dutch trial demonstrated that D2 resections were associated with lower disease-related death rates relative to the cohort that underwent D1 resections (37% vs. 48%, $p = 0.01$) at a median follow-up of 15 years (Songun, 2010). A subsequent trial from Taiwan demonstrated significantly lower morbidity (17.1%) and mortality (0%) in more extensive D3 resections compared to the D2 resections in the aforementioned studies. Moreover, the Taiwanese trial demonstrated a significant overall survival advantage in the more extensive resections (59.5% vs. 53.6%, $p = 0.041$) (*Br J Surg* 2004;91(3):283–7; *Lancet Oncol* 2006;7(4):309–15).

The Italian Gastric Cancer Study Group addressed the role of technique in outcomes for this patient population by employing extensive surgeon training to reduce morbidity and mortality in their prospective, randomized trial. This resulted in lower morbidity (12%) and mortality (2.2%) for D2 resections. Long-term follow-up from this group showed no difference in the overall 5-year survival rate (66.5% vs. 64.2% for D1 and D2 lymphadenectomy, respectively; $p = 0.695$). However, subgroup analyses showed a trend toward 5-year disease-specific survival benefit for patients with pT2–4 tumors and positive lymph nodes in the D2 group (59% vs. 38% for the D1 group; $p = 0.055$) (*Br J Surg* 2010;97(5):643–9; *Br J Surg* 2014;101(2):23–31). Taken together, these data support the age-old surgical notion that technical skill and patient selection are the greatest determinant of patient outcomes. This seems to be particularly true for patients who present with more advanced tumors and positive lymph nodes.

We would be remiss if we did not consider two large retrospective series from the United States and China that have evaluated the contribution of lymphadenectomy to the survival of patients with gastric cancer. The United States Gastric Cancer Collaborative reported on their series of 742 patients who underwent gastrectomy for gastric adenocarcinoma from 2000 to 2012 at seven academic institutions. The vast majority of these patients (65%) had at least 16 lymph nodes removed. This group reported that disease-specific survival was not significantly longer after removal of ≥16 versus 7 to 15 lymph nodes (10-year survival, 55% vs. 47%, respectively; $p = 0.53$) for the entire cohort, but was significantly improved in the subset of patients with stage IA to IIIA disease (10-year survival, 74% vs. 57%, respectively; $p = 0.018$) or N0–2 disease (72% vs. 55%, respectively; $p = 0.023$). Based upon these data, the authors concluded that the number of lymph nodes removed during gastrectomy appears to have prognostic implications for long-term survival (*J Am Coll Surg* 2015;221(2):291–9). Similarly, a 12-year series of 1,637 patients was recently reported by The Peking University People's Hospital. The median number of lymph nodes retrieved in this study was 19 (range, 2–69) with 81.4% of patients having ≥15 lymph nodes retrieved during curative resection. Furthermore, 86.4% of these patients underwent D2 or greater resections. I found it

particularly interesting that the majority of the clinical outcomes were improved in the 13.7% of patients in whom lymphadenectomy retrieved ≥30 lymph nodes, resections that would be considered radical by Western standards. This study demonstrated an overall survival of 64.4% in patients with >30 lymph nodes retrieved during lymphadenectomy while those with <14 nodes and those with between 15 and 29 nodes had overall survival rates of 53.6% (p = 0.006) and 58.3% (p = 0.024), respectively (*Am J Surg* 2015;210(3):431–40). I would invite readers to review this manuscript as it proposes a unique paradigm for the treatment of these patients that can improve clinical outcomes.

Mullen presents a nice summation of technical considerations, including dissection of the surgical specimen on the back table and reconstruction after resection. Given the importance of lymph node harvest and location, it is essential that the specimen be dissected on a sterile back table with lymph nodes labeled by station for pathology evaluation. This is especially important given recent information on the correlation between positive node location and clinical outcome (*Am J Surg* 2015;210(3):431–40). Likewise, the treatment of reconstruction techniques is critical. Roux-en-Y reconstructions with a small gastric pouch avoid long afferent limbs and the resultant afferent loop syndrome that sometimes occurs in Billroth II gastrojejunostomies. However, recent data from the US Gastric Cancer Consortium suggest that there is no difference in outcomes between Billroth II and Roux-en-Y gastrojejunostomy reconstruction techniques. In this report of 447 patients, 257 underwent Roux-en-Y reconstructions and 190 underwent Billroth II reconstructions. Roux-en-Y operations were slightly longer (244 min vs. 212 min, $p < 0.001$) and associated with somewhat higher blood loss (243 mL vs. 205 mL, p = 0.033) in the seven academic institutions that submitted data for this study. However, there were no significant differences in the length of hospital stay, readmission rate, 90-day mortality, morbidity, dependency on jejunostomy tube feeding at discharge, receipt of adjuvant therapy, or 5-year survival (*Gastric Cancer* 2016;19:994–1001). Based upon these findings, I encourage the reader to strongly consider both options when re-establishing continuity, particularly in subtotal or distal gastrectomies.

As a technical point, I would challenge the author's use of diuretics in the early postoperative period as recent data have drawn a correlation between postoperative diuretics and acute kidney injury (AKI) in patients undergoing surgery for gastric cancer (OR = 2.39, 95% CI = 1.98–2.88, p = 0.001) (*PLoS One* 2013;8(12):e82289). The authors suggest that although it is unclear whether use of diuretics is a cause or a consequence of postoperative AKI, indiscriminate use of diuretics to treat postoperative low urine output should be avoided, especially in patients with hypovolemic status.

Although covered later in this volume, any consideration of operative management of gastric cancer would be incomplete without a discussion of open versus laparoscopic gastrectomy. Several reviews and meta-analyses have shown an advantage in short-term outcomes of laparoscopic gastrectomy

compared to open procedures, with similar oncologic outcomes (*Surg Endosc* 2013;27(5):1509–20; *Ann Surg* 2012;255(3):446–56; *PLoS One* 2014;9(2):e88753; *Ann Surg* 2012;256(1):39–52). As an extension of these findings, a multicenter, prospective, randomized trial, Laparoscopic versus Open Gastrectomy for gastric Cancer (LOGICA-trial), is currently underway in the Netherlands. The primary endpoints of this trial will include R0 resection rates, number of lymph nodes retrieved, and postoperative length of stay. Secondary measures include postoperative morbidity and mortality, readmissions, cost-effectiveness, oncologic outcome, and quality of life (*BMC Cancer* 2015;15(1):556). The results from this study and others will guide future directions in the use of minimally invasive surgical techniques in the management of gastric cancer.

Finally, I believe that it is essential to address the potential for regionalization of surgery for gastric cancer. Reports from as early as the late 1990s demonstrated that patients undergoing surgery operations at high-volume centers have lower perioperative mortality than those at lower-volume centers. Interestingly, Birkmeyer et al. published a study on the relationship between volume and outcomes in high-risk cancer surgery that demonstrated a higher mortality odds ratio for patients who underwent gastric cancer surgery at low-volume centers relative to high-volume centers (OR = 1.51, 95% CI = 1.16–1.97) (*Cancer* 2006;106(11):2476–81). Given the impact of the aforementioned technical considerations on outcome, I would ask: Is it time we act upon the findings?

I would like to commend Mullen on an outstanding review of the management of gastric cancer. It is widely accepted that this disease is best approached with aggressive surgery that leverages extensive lymphadenectomy. Future considerations, including the role of regionalization of care as well as minimally invasive surgical techniques, will define the role of the surgeon as we make continue to make strides in the management of this disease.

John H. Stewart, IV

89 Distal Gastrectomy With Roux-en-Y Reconstruction and Laparoscopic Gastrectomy

Miguel A. Mercado and Gonzalo Torres-Villalobos

HISTORY

In 1881, the same year he performed the first successful gastrectomy, Theodor Billroth performed the first gastroenterostomy. The continuity of the gastrointestinal (GI) tract was achieved by means of a gastroduodenostomy, later known as a Billroth I procedure. Four years later, the Viennese surgeon modified his technique and began using a latero-lateral anastomosis with the jejunum, later known as a Billroth II procedure.

The medical community soon began to report cases of postoperative bilious vomiting as the Billroth II became a more popular procedure. Hence, in 1897, a Swiss surgeon from Lausanne, César Roux, first described a gastrojejunostomy performed from a sectioned and defunctionalized jejunal loop with intestinal continuity established by means of a distal termino-lateral jejuno-jejunal anastomosis, the Roux-en-Y.

More than a century after its original description, the Roux-en-Y has evolved into an easier, safer, and quicker procedure and has become the preferred approach to reestablish continuity of the GI tract after distal gastrectomy (DG) in many centers.

Duodenal participation in the reestablishment of the GI tract is a theoretical advantage of the Billroth I procedure. A more physiologic response to the passage of the bolus as well as a better absorption of calcium and iron are achieved with this operation. Nevertheless, several studies have shown that both short- and long-term results are similar when compared with other techniques. A delay in gastric emptying that is normally observed after bolus enters the duodenum, the so-called duodenal brake, is theoretically absent due to neural disruption as it would be for all other techniques mentioned.

As pyloric function is lost after resection, biliopancreatic reflux may cause severe symptoms due to direct irritation of the mucosa as well as increase the risk of cancer of the gastric remnant.

The anastomosis of the gastric remnant to a defunctionalized jejunal limb in a Roux-en-Y reduces biliopancreatic reflux and abolishes the afferent loop syndrome.

Laparoscopic distal gastrectomy (LDG) for early gastric cancer was developed in Japan and was first reported by Kitano et al. in 1994. Since then, the number of laparoscopic surgeries has rapidly increased and has been extended to include even locally advanced gastric cancer. The use of laparoscopic gastrectomy for treating gastric cancer has come into widespread use mainly in Japan but also throughout Korea and China. According to the eighth nationwide survey conducted by the Japan Society for Endoscopic Surgery, approximately 25% of gastrectomies for gastric cancer were treated laparoscopically in 2009. This important growth in laparoscopic gastrectomy in the Asian region is in part because the incidence of gastric cancer is greater; the incidence of early gastric cancer is higher as it is detected at a higher rate due to screening programs. However, this is contrary to the Western population in which gastric carcinoma is usually diagnosed at an advanced stage and in older patients. Therefore, it is unclear if the results of these Asian studies can be extrapolated to the Western world and the introduction of laparoscopic surgery for gastric cancer in the West has been slower than that in the East.

The feasibility of robotic gastrectomy for gastric cancer has been reported. Robotic surgery may help surgeons overcome technical difficulties but its use is just being explored.

INDICATIONS OF DISTAL GASTRECTOMY

The main indication for DG in the previous century was peptic ulcer disease (prepyloric, pyloric, and postpyloric). Complete removal of the ulcer as well as most acid-producing parietal cells was accomplished with surgery. Today, with potent proton pump inhibitors as first-line therapy, surgery is reserved for complicated ulcers (penetrated and/or perforated, peptic stenosis, or bleeding refractory to both medical and endoscopic therapy).

The amount of stomach resected is an important issue when it comes to choosing the type of reconstruction. When antrectomy is performed a Billroth I can usually be accomplished without tension. Even when an

ample Kocher maneuver has been done, when part of the corpus is removed it may be difficult to perform a Billroth I without tension in the gastroduodenal anastomosis. Recurrence of disease may also be a determinant factor when choosing the type of reconstruction especially when the duodenal stump is affected by disease or if a free margin is not obtained, in which case a Billroth I would not be optimal.

When the procedure of choice is a subtotal gastrectomy, the preferred reconstruction in most cases is a gastrojejunal anastomosis.

DG may also be indicated in early distal gastric cancer but is not recommended as standard treatment in locally advanced gastric cancer. In the latter, a formal gastrectomy with lymphadenectomy is the procedure of choice. Some cases with localized tumors can be treated with a subtotal gastric resection.

Other types of tumors can be adequately treated with a DG. Gastrointestinal stromal tumors (GIST) originating from Cajal cells are a good example of such tumors. Leiomyomas and other rare benign tumors may also be treated with limited resections.

DG with latero-lateral gastrojejunostomy is also an intrinsic part of the classic Whipple procedure. The pylorus-preserving variant (PPPD) can also be done anastomosing the remnant of the first portion of the duodenum to the jejunal limb, distal to the pancreatic and bilioenteric anastomosis. Despite controversy, PPPD probably has a lower incidence of postoperative delayed gastric emptying and prevents biliopancreatic reflux to the stomach. Roux-en-Y reconstruction can safely be performed after pancreatoduodenectomy and is preferred by some groups. Detractors of the Roux often mention the additional entero-enteric anastomosis as a disadvantage.

Several recent trials aimed at determining the best reconstruction after DG, mostly comparing Roux-en-Y to one or both classic Billroth procedures, have been published.

In a recent meta-analysis by Xiong et al., including four randomized controlled trials and nine nonrandomized observational clinical studies, they compare Roux-en-Y versus Billroth I reconstruction after DG for gastric cancer. The Roux-en-Y reconstruction had a lower incidence of bile reflux, remnant gastritis, and reflux esophagitis; however, it was associated with a longer operation time.

One series of 60 patients examined by Chan DC et al., compared Roux-en-Y reconstruction, classical Billroth II, and Billroth II plus distal entero-

enterostomy (Braun). There was significant reduction of enterogastric reflux as well as lower incidence of *Helicobacter pylori* infection in the Roux-en-Y group.

Csendes et al. reported a prospective, randomized study with long-term follow-up comparing Billroth II and Roux-en-Y reconstructions for the treatment of duodenal ulcers. With a follow-up of 12 to 21 years, they showed that Roux-en-Y is significantly better than traditional Billroth II reconstruction.

Another study was published by Kojima et al. except that DG was performed laparoscopically. Besides proving that laparoscopy is a feasible approach to such operations, the data also favored the Roux-en-Y.

Nunobe et al. analyzed the quality of life in the postoperative period in a large series of patients with early gastric cancer treated by subtotal gastrectomy. Subgroups of patients reconstructed by a Billroth I anastomosis and a Roux-en-Y were compared. There were fewer cases with dumping syndrome and endoscopically proven gastritis, yet a higher incidence of cholelithiasis in the Roux-en-Y group. They therefore concluded that a Roux-en-Y was superior to Billroth I reconstruction.

A published review by Hoya et al. mentions possible disadvantages of Roux-en-Y reconstruction, including development of stomal ulcers, increased likelihood of cholelithiasis, difficulty during endoscopic approach to the ampulla and bile duct, and the so-called Roux stasis syndrome due to inadequate peristalsis of the jejunal limb. Detractors of the Roux-en-Y report delayed gastric emptying in the early postoperative period, the so-called Roux stasis syndrome, in 20% to 30% of patients although most patients respond with conservative measures. Modifications in the surgical technique have been advocated by some to reduce this complication.

Both the extent of gastrectomy and the addition of vagotomy (truncal or selective) affect the presence of stomal ulceration. Vagotomy is advisable when antrectomy is performed in order to prevent such ulcers. When the critical mass of parietal cells is greatly diminished, as in subtotal or total gastrectomy, the possibility of ulceration is low and there is no need for vagotomy.

In a meta-analysis by Vinuela et al., the effectiveness of LDG versus open DG in patients with gastric cancer was compared. LDG reduced significantly overall complications, medical complications, and minor surgical complications. Open DG retrieved statistically significant more

lymph nodes compared to laparoscopic methods but this may result in clinically insignificant increase.

Laparoscopic gastrectomy compared with open resection of mostly clinical early gastric cancers has reduced morbidity and mortality in controlled trials but long-term studies are scarce.

PREOPERATIVE PLANNING

The preoperative evaluation of patients with gastric cancer includes establishing the diagnosis, assessing the extent of local disease, ruling out distant metastases, and assessing the patient's medical condition.

In the vast majority of cases, all necessary information to plan surgery is gathered with an upper GI endoscopy in combination with endoscopic ultrasonography and a triphasic computed tomography (CT) scan. Magnifying endoscopy, chromoendoscopy, and virtual chromoendoscopy can increase the detection of gastric lesions. The development of multidetector-row helical CT (MDCT) and three-dimensional (3D) display allows some advantages in preoperative staging.

Dehydration and electrolytic imbalances are common and must be corrected prior to surgery. Most patients should have an empty stomach with a 12-hour fast prior to surgery, yet patients with gastric outlet obstruction or gastroparesis may need considerably longer. Either ultrasound the day prior to surgery or gastric lavage through a nasogastric tube may be needed to confirm an empty stomach.

Prophylactic antibiotics are mandatory because of the high frequency of bacterial overgrowth in the retaining stomach and associated surgical site infections including complicated infections such as clostridial myositis.

SURGICAL TECHNIQUE

Although an upper midline incision is preferred by most, other upper abdominal incisions may also be appropriate.

A routine inspection of the abdominal cavity is done and the procedure chosen depends on the location and extent of disease at laparotomy. Care must be taken to preserve all oncologic principles when the indication of surgery is early gastric cancer.

The greater omentum is included in the specimen when surgery is due to cancer, and it should be dissected close to its insertion in the transverse colon with electrocautery, a diathermy system (LigaSure), or an ultrasonic scalpel (Fig. 89.1). Otherwise, the greater omentum is divided from the

middle of the gastrocolic ligament toward the left just distal to the gastroepiploic vessels. The left gastroepiploic vein is the upper limit when an antrectomy is to be performed. Attention is then directed to the lesser omentum, which is divided from the emergence of the hepatic artery to the right toward the level of the left gastric artery; since it is practically avascular it can be divided with electrocautery.

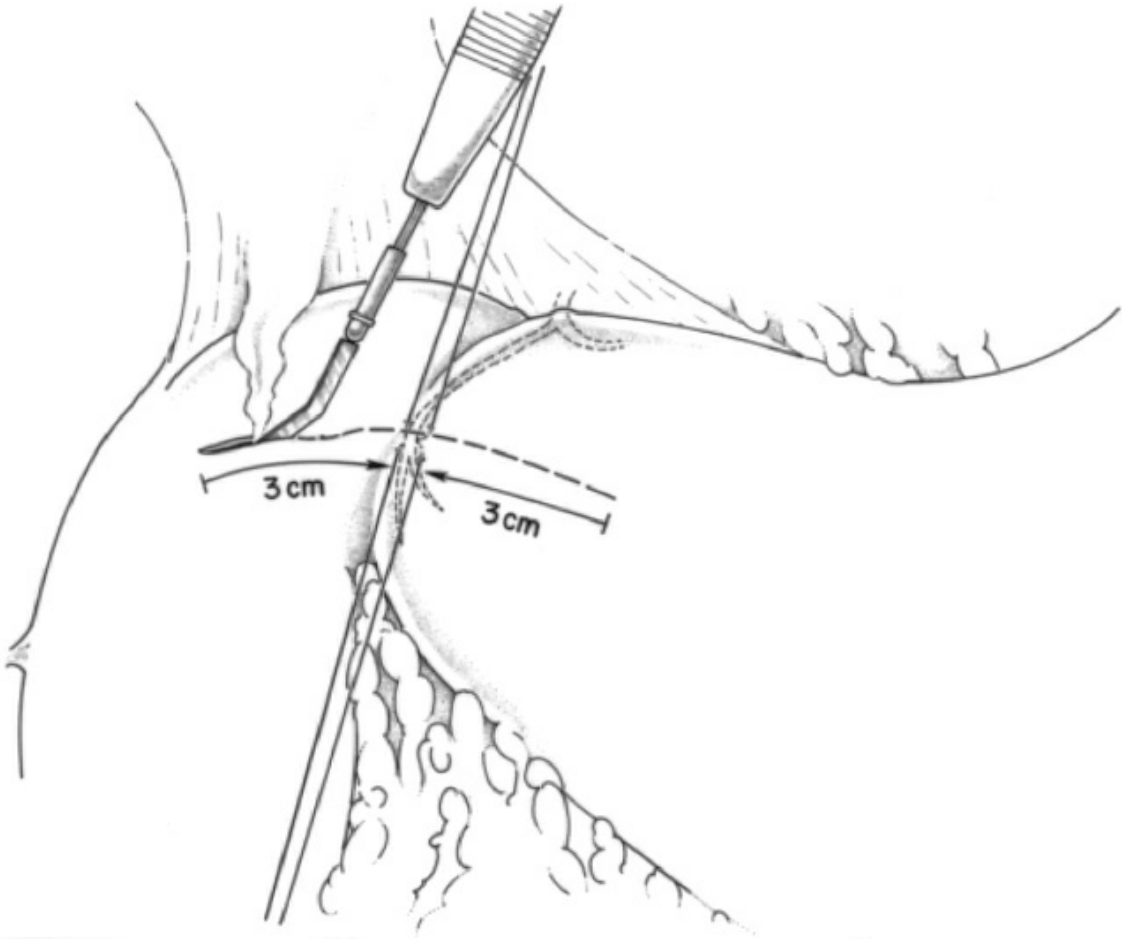

Figure 89.1. View of the posterior aspect of the stomach with greater omentum attached to the specimen as is performed when surgery is due to cancer. (Notice arterial circulation of the lesser curvature.)

The transition between the corpus and antrum may be indirectly identified near the caudal branch of the left gastric artery and vein, where the nerve of Latarjet is identified. The vasculature is carefully removed where transection is planned in order to expose the bare area of the small curvature as well as the greater curvature.

Stapler devices can be used to transect the stomach at the desired level although clamps and running suture can also be used in the absence of

such technology (Fig. 89.2). Care should be taken to pull out the nasogastric tube when present to avoid including it in the staple line. After transection of the stomach, the distal part is pulled out of the incision and with the utilization of ultrasonic scalpel or a diathermy device the dissection is continued toward the first portion of the duodenum (Fig. 89.3). Larger vessels including the right gastroepiploic vessels on the greater curvature, the right gastric artery, and the caudal branch of the left gastric artery on the lesser curvature should be ligated when encountered. The gastroduodenal artery (GDA) should be preserved. The pylorus is then identified and the first portion of the duodenum is skeletonized to the level were the pancreas adheres; small branches of the GDA may need ligature at this point. Transection of the first portion of the duodenum with a linear stapler device should be performed 2 cm distal to the pylorus. A retracted and fibrous duodenum may add considerable difficulty to this transection. In especially difficult cases where dehiscence and fistulization are likely, a duodenostomy (Foley or Pezzer catheter) can be created through the duodenal stump. Difficult duodenal stumps can also be protected with a side duodenostomy tube at the junction of the second and third portion of the duodenum or a retrograde tube placed at the ligament of Treitz.

An ample Kocher maneuver is performed when a Billroth I reconstruction is selected to avoid tension at the anastomosis; such maneuver is not necessary for a Billroth II or a Roux-en-Y.

The specimen is removed, and, although not mandatory, many invaginate the duodenal stump with simple Lembert sutures over the staple line. The same is done at the level of the gastric stump.

At this point the reconstruction begins and the technique now differs depending on the type of reconstruction chosen. The creation of a Roux-en-Y will be described in detail here.

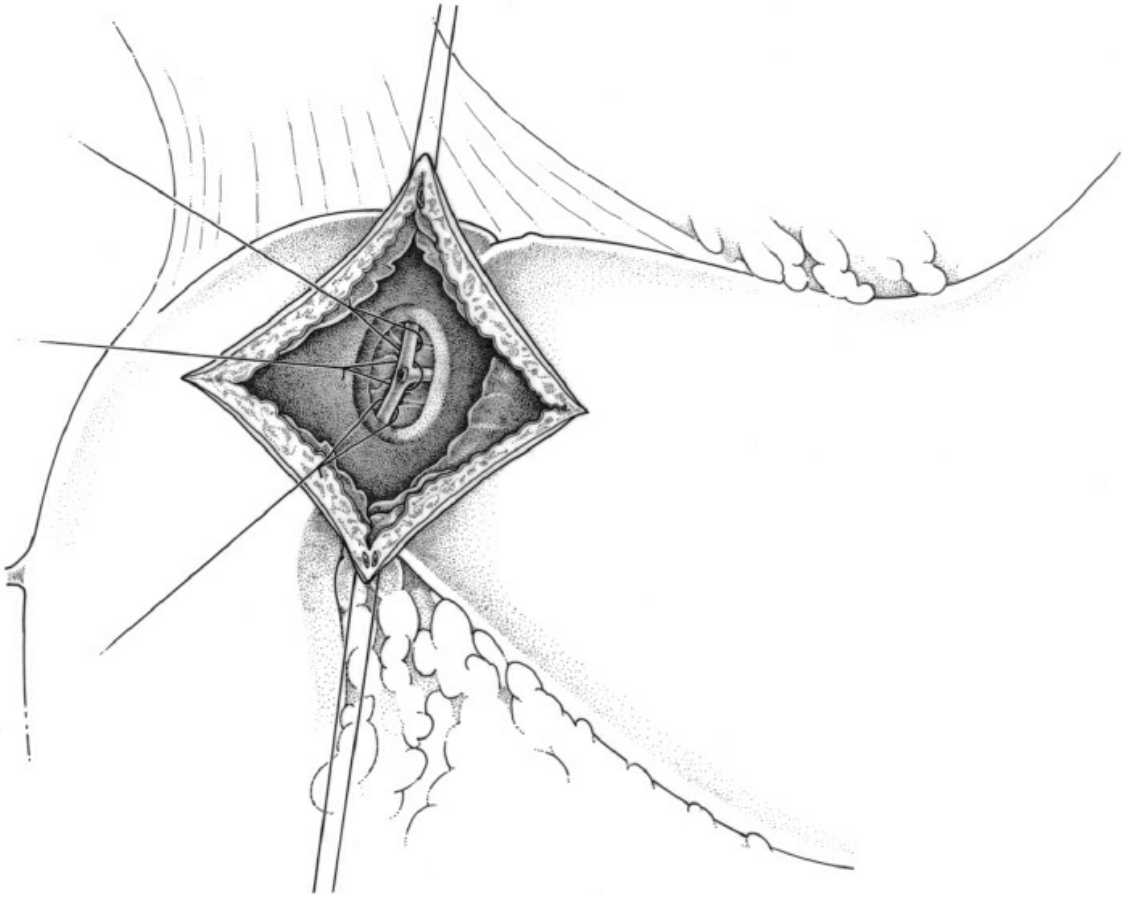

Figure 89.2. Transection of the stomach with a linear stapling device and reinforced with Lembert stitches with 3-0 silk.

The jejunum is identified at the level of the angle of Treitz. The most proximal jejunal loop that reaches the gastric remnant without tension is chosen for the anastomosis. With transillumination, a vascular arch that will allow to comfortably stretch the loop of jejunum toward the gastric remnant is selected and the jejunum is transected at this level between clamps or with a linear stapler.

The end of the proximal jejunum is anastomosed to the side of the distal jejunum at least 40 cm from the staple line. An end-to-side manual two-layer continuous suture in the antimesenteric border is our personal preference. We perform the inner suture with a 4-0 synthetic hydrolyzable monofilament suture and the outer layer is constructed with a 4-0 monofilament synthetic nonabsorbable suture.

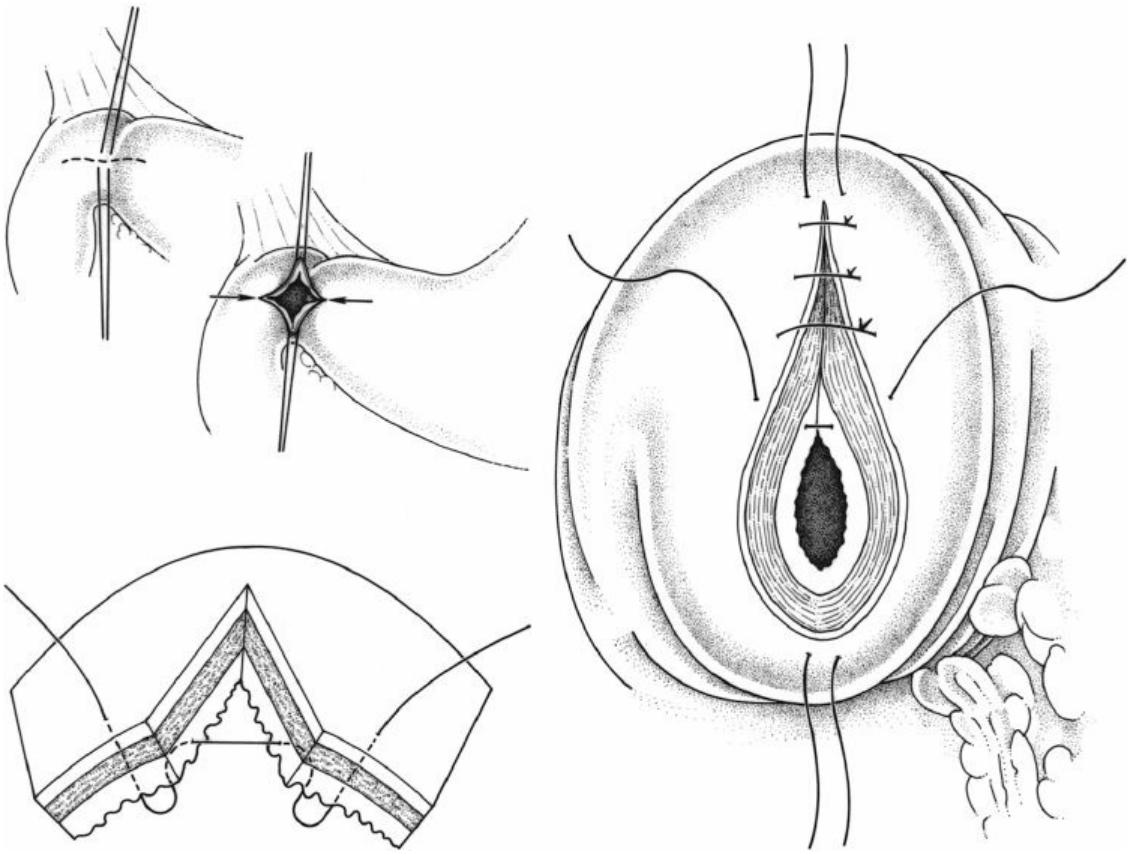

Figure 89.3. After transection of the stomach the distal end is pulled outward and dissection is continued toward the first portion of the duodenum.

A latero-lateral jejuno-jejunostomy with a stapler device could also be performed; yet we do not favor this technique since we have observed that the blind jejunal stump of the afferent limb tends to dilate and may become a source of symptoms and even a cause for reintervention. The mesentery is closed in order to prevent postoperative internal herniation.

The jejunal loop is now brought toward the gastric remnant and anastomosed end to side. For malignant disease, placing the loop in the antecolic position is advisable to prevent obstruction in case of recurrence. If performed retrocolically the mesocolon must be fixed to the loop to avoid herniation.

Several techniques for gastrojejunal anastomosis have been developed in the last decades, commonly identified with eponyms such as Hofmeister and Polya.

Both the greater and lesser curvatures are retracted in Allis clamps in order to stretch the gastric remnant. A small triangle is then removed from the staple line at the greater curvature. A 3- to 4-cm open orifice is now available for the two-layered manual anastomosis. As in the jejuno-

jejunostomy, an inner layer of continuous 3-0 synthetic hydrolyzable suture is constructed followed by an outer layer of nonabsorbable suture (Fig. 89.4). Since the tip of the anastomosis on the lesser curvature side is prone to ischemia, a three-point inverting suture is placed at this particularly vulnerable angle known as the angle of sorrow. The final aspect of a DG with a Roux-en-Y reconstruction is depicted in Figure 89.5.

A stapler device can be used to safely and rapidly perform the gastrojejunal anastomosis in which case the gastric remnant is retracted outside the wound and a small orifice is done in the posterior wall 1 in away from the stapler line. It is important to leave this margin because an incision too close to the stapler line can produce ischemia of the gastric wall. For the same reason, I also recommend that the jejunal limb be directed toward the fundus instead of directing it parallel to the stapler line. After shooting and extracting the stapler device, careful hemostasis of the inner aspect of the staple line is accomplished with cautery or with isolated stitches when necessary. The orifice in the jejunum and stomach, now communicated, is closed with an inner running suture of a 3-0 hydrolyzable monofilament and an outer layer of nonabsorbable suture as in the manually performed anastomosis.

Figure 89.4. A two-layer manual gastrojejunal anastomosis. (Notice only a small portion of the staple line toward the greater curvature is used for the gastrojejunal anastomosis.)

A nasogastric tube can now be placed; the final position of the tip is guided manually by the surgeon with no need to go through the newly created anastomosis. Its purpose is postoperative decompression of the gastric remnant (air extraction more than fluid) and can be a good monitor for intraluminal bleeding in the first hours postoperatively.

Duodenostomy, when performed, should be let out through a separate incision and secured to the skin with suture. Drains are not placed routinely but if uncertainty of the state of the staple line in the duodenal stump exists, closed suction drains should be placed. The abdominal wall is closed in a standard fashion.

LDG is performed using five abdominal ports. All port sites are infiltrated before incision with a mixture of 40 mL of 0.75% ropivacaine, 40 mL of 1% lidocaine with epinephrine, and 40 mL of 0.9% saline. Each port site is infiltrated with 20 mL: 10 mL under the parietal peritoneum and 10 mL in the dermal and subdermal planes. The first incision is a 5-mm cut made at the left anterior axillary line just inferior to the costal margin. A Veress needle is inserted and the abdomen is insufflated with carbon dioxide gas to a pressure of 12 to 18 mm Hg. Once insufflation is obtained, a 5-mm trocar is placed and a 45-degree angled scope is inserted into the abdomen. Exploratory laparoscopy is then performed to rule out metastatic disease. A 12-mm port is placed to the left of the umbilicus and 5-mm and 12-mm ports are placed in the right upper quadrant. If a liver retractor is needed it can be placed through a subxiphoid stab wound for the Nathanson liver retractor (Cook Medical, Bloomington, IN) or in the anterior axillary line depending on the type of retractor used. Reverse Trendelenburg position is employed at intervals during the procedure. As described for the open DG, in case of gastric cancer the resection should include the greater omentum, duodenal bulb, and surrounding nodal tissue. The dissection is carried out as described with the vessel sealing devices. The transection line on the stomach is identified with the left gastroepiploic vein as the upper limit with the caudal branch of the left gastric artery and vein, and the nerve of Latarjet as other anatomical references. The vasculature is carefully removed at the transection plane exposing the area from the small curvature as well as the greater curvature. In case of gastric cancer, before the transection of the stomach an intraoperative gastroscopy is performed to confirm the location of the tumor and marked by suturing in the outer gastric wall. The stomach is

transected using a 60-mm linear stapler with 4.8-mm staple leg lengths. The pyloric and duodenal mobilization is performed keeping the lymph nodes with the specimen. After dividing the right gastric and right gastroepiploic vessels, the duodenum is transected using a 60-mm linear stapler with 2.5-mm staples; the over sewing of the staple line may be used depending on the surgeon's preference. A large plastic bag is used for the removal of the resected specimen at the end of the procedure.

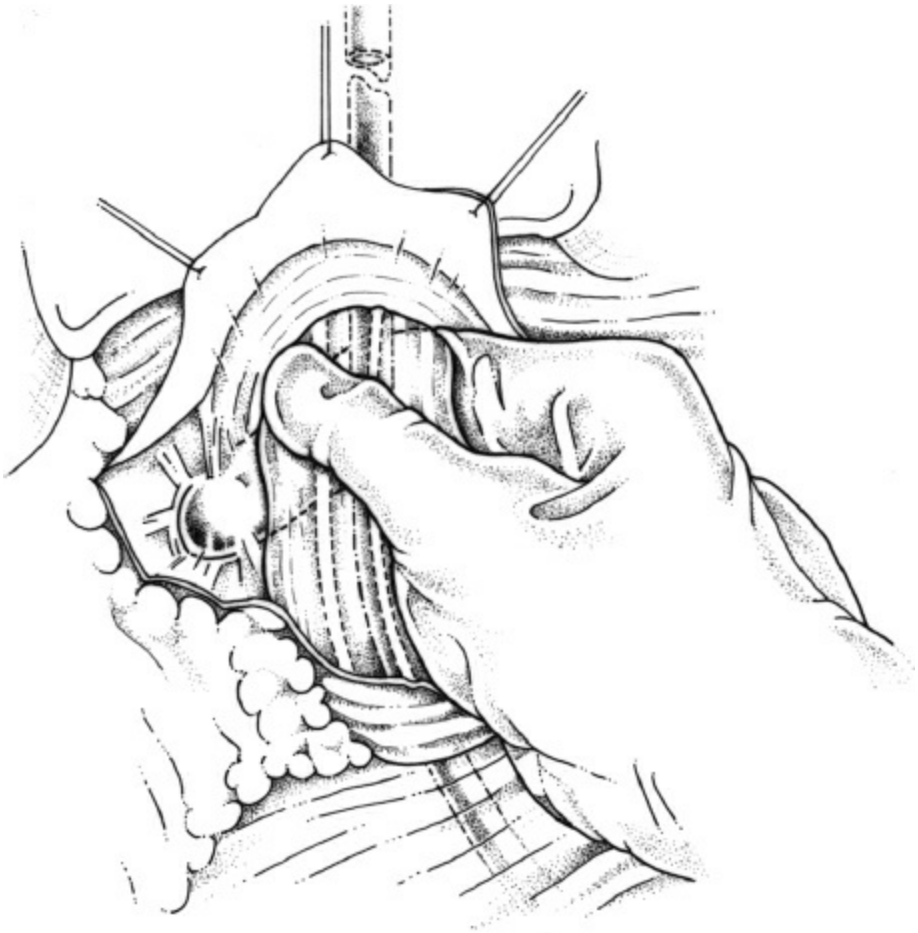

Figure 89.5. Distal gastrectomy with a Roux-en-Y reconstruction.

For the Roux-en-Y reconstruction the omentum is placed cephalad, the transverse colon is elevated, and the ligament of Treitz is identified. At 50 cm a small incision is made in the mesentery close to the jejunum and a ¼″ Penrose drain is passed to manipulate the bowel.

The Roux limb is brought to the stomach in an antecolic fashion. The omentum can be divided using a bipolar sealing device up to the midtransverse colon to facilitate this. To create a two-layer anastomosis between the gastric remnant and the Roux limb, an outer layer on the posterior portion of the gastric remnant is performed with a running 2-0

Surgidac suture using the endoscopic suturing device (Endo Stitch, 10 mm; Covidien, Mansfield, MA). With an ultrasonic dissector, a gastrotomy is made on the posterior portion of the gastric remnant, near the inferior border of the staple line and also an enterotomy is performed. The inner layer is done with a 45-mm long, 3.5-mm thick linear stapler introducing one leg of the stapler in the stomach and the other in the jejunum. The gastro-enterotomy is closed using a running 2-0 Polysorb suture and a second layer of 2-0 Surgidac is then performed over the anastomosis in running fashion. The jejunum is divided using a 60-mm long laparoscopic linear stapler with 2.5-mm staple thickness. A bowel clamp is placed on the Roux limb and an intraoperative endoscopic leak test is performed. At least 40 cm from the staple line a side-to-side functional end-to-side jejunojejunostomy is created. An enterotomy is done in the Roux limb as well as in the distal portion of the biliopancreatic limb using an ultrasonic dissector. The 60-mm long, 2.5-mm staple thick laparoscopic linear stapler is introduced in the corresponding enterotomies and fired. The common enterotomy is then closed transversely with the linear stapler. A stress relief suture is placed at the end of the staple line. The mesenteric and Petersen defects are closed with a running 2-0 Surgidac suture with the endoscopic suturing device.

POSTOPERATIVE CARE

The nasogastric tube is removed 24 to 48 hours after surgery or when there is evidence of peristalsis. Liquid diet is also begun at this time and progressed as tolerated to a normal diet. Giving smaller portions of food five times a day can be a helpful strategy in the early postoperative period.

POSTOPERATIVE COMPLICATIONS

Common complications include leak from the gastrojejunal anastomosis (1% to 4%), bleeding (2%), passage disorders (2% to 5%), and postoperative pancreatitis (0.9%). Leaks can occur at the gastrojejunostomy, jejunojejunostomy, or the gastric staple line. The diagnosis is made by a combination of clinical and radiographical findings; CT is more reliable for leaks than upper GI. Symptoms of a leak include abdominal pain, shoulder pain, and back pain. Signs include tachycardia, fever, tachypnea, oliguria, hypotension, hypoxia, or even shock. Dehiscence of the gastrojejunostomy is infrequent and can be managed conservatively if no systemic response is observed. Anastomotic leaks tend

to heal conservatively with adequate drainage using a gastric tube, close suction drains, and parenteral nutrition are implemented.

Gastroparesis is more common when limited resections are performed. Gastric stasis is usually secondary to edema or a hematoma of the anastomosis, which resolves conservatively in 10 to 14 days with the aid of a gastric suction tube to avoid emesis. Motility disorders of the gastric remnant may also play an important role. When gastric stasis is observed preoperatively it is more likely to be present in the postoperative period.

Intragastric or intraperitoneal bleeding is infrequent. Management depends on the extent of bleeding and the possibility of it subsiding spontaneously. Endoscopic hemostasis by injection or coagulation therapy should always be attempted if upper GI bleeding occurs. Reoperation is considered in these cases when blood transfusions and endoscopic intervention fail to stabilize the patient. During surgery, enterotomy may be used to achieve hemostasis at the anastomosis but we favor redoing the anastomosis manually after hemostasis is achieved; maneuvering, we believe, reduces the possibility of dehiscence.

DUMPING SYNDROME

Dumping is mainly a consequence of vagotomy but can be seen after any gastric surgery. The frequency of clinically significant dumping after DG is around 1% to 2%. It has an early and late form, the latter being much less common. GI symptoms include postprandial fullness, crampy abdominal pain, nausea, and explosive diarrhea. Other symptoms are associated with vasomotor manifestations: diaphoresis, dizziness, flushing, and palpitations. These are more frequent in the early form and appear to be secondary to abnormally rapid gastric emptying. The early syndrome is probably the result of hyperosmolarity of intestinal content although some hormonal mechanisms have also been advocated. The late syndrome is probably related to hyperinsulinism and hypoglycemia secondary to a large amount of carbohydrates in chime and is therefore pancreatic in origin. The actual physiopathology of this syndrome remains elusive. Dietary modifications are the mainstay of treatment in both early and late dumping, yet surgical conversion is sometimes necessary (Billroth II to I, interposition of antiperistaltic loops, and conversion of Billroth II to Roux-en-Y gastrojejunostomy). Careful evaluation, often by a multidisciplinary group, must be done to select appropriate treatment for individual patients. Dumping predisposition can be evaluated preoperatively with the

apomorphine test to determine which patients are more likely to have incapacitating dumping syndrome with obvious practical implications, as described by Fender et al. in the 1960s.

ROUX STASIS SYNDROME

Occurring in about 5% to 30% of patients after DG and a Roux-en-Y reconstruction, this syndrome includes symptoms of fullness, abdominal pain, nausea, and vomiting in the early postoperative period. The interruption of the duodenal pacemaker seems to be involved in such motility problems and it is seen more often with jejunal limbs longer than 40 cm. As in other procedures that present with delayed gastric emptying, most patients respond to conservative measures; yet hospital stay may be prolonged. When complications are mentioned in comparative studies, other forms of reconstruction show similar frequency of passage disorders.

POSTVAGOTOMY DIARRHEA

This condition occurs approximately in 20% of patients with truncal vagotomy and much less in more selective vagotomies. Other etiologies must be ruled out in the postoperative period, and, although the spectrum of disease may vary greatly, postvagotomy diarrhea may be debilitating and cause malnutrition in about 1% of patients. The loss of central nervous system (CNS) modulation of the enteric nervous system might cause increased motility; yet, many other factors including bacterial overgrowth have also been advocated.

Medical treatment and dietary modifications (quality, quantity, and frequency) are offered initially. Refractory cases may need surgical intervention most commonly consisting of interposition of an antiperistaltic jejunal segment.

BILIARY REFLUX AND AFFERENT LOOP SYNDROME

Biliary reflux occurs more commonly after a Billroth II reconstruction but may also occur after a Billroth I reconstruction. The main advantage of the Roux-en-Y operation is that the isolated jejunal limb greatly diminishes clinically significant reflux to the gastric remnant.

Although hard to prove on imaging studies, afferent loop syndrome is thought to occur due to partial obstruction of such a loop and is more common when the gastrojejunostomy is made toward the greater curvature

and the ligament of Treitz is more to the left than usual, predisposing to a kinking of the loop. Afferent loop syndrome by definition occurs after a Billroth II gastrojejunostomy. The Roux-en-Y does not have an afferent limb and therefore such a syndrome is completely abolished.

The important reduction in biliary reflux and bilious vomiting is surely one of the main arguments in favor of the Roux-en-Y and explains why it has become the preferred method of reconstruction after DG by many.

VAGOTOMY

When antrectomy is performed, usually for peptic ulcer disease, a truncal or a highly selective vagotomy is indicated. This maneuver interrupts the central phase of acid secretion, reducing the risk of marginal ulcers. Truncal vagotomy requires the opening of the phreno-esophageal membrane, blunt dissection of the lower third of the esophagus, palpating the anterior and posterior vagus nerves, and subsequently ligating both proximal and distal stumps and sectioning them. In order to confirm vagotomy a small segment of the nerve is removed and sent to pathology.

If a selective vagotomy is done, both the anterior and posterior vagus nerves are retracted and the small anterior branches of the fundus and corpus, including the gastroepiploic and posterior branches, are cut. Since only the left gastric and short gastric vessels are preserved after DG, care must be taken not to compromise arterial flow during vagotomy. The selective vagotomy implies devascularization that can jeopardize the circulatory status of the gastric remnant.

If a subtotal or near total gastrectomy is done, there is no need for vagotomy, because the critical mass of parietal cells is drastically diminished.

EDITOR'S COMMENT

In this chapter, Drs. Mercado and Torres-Villalobos nicely summarize the literature concerning the optimal method of GI tract reconstruction after distal gastrectomy. Whether performed for an early gastric cancer or for benign ulcer disease, far and away the most common method of reconstruction after distal gastrectomy worldwide is a gastroduodenostomy (Billroth I). This is the only method which preserves the physiologic continuity of the GI tract, it is a relatively straightforward end-to-end anastomosis, and many authors have reported improved nutritional parameters and weight gain with the BI reconstruction compared with other techniques. However, bile reflux gastritis is a significant problem with both the Billroth I and II reconstructions, leading many surgeons to advocate for the Roux-en-Y reconstruction, which virtually eliminates the problem of bile reflux assuming the Roux limb is sufficiently long. Though the authors of this chapter prefer a limb length of at least 40 cm, I generally opt for an even longer Roux limb length of 50 to 60 cm. Detractors of the Roux-en-Y technique point to it as a more complicated method of reconstruction (with two anastomoses instead of one) and to the risk of Roux stasis syndrome, a functional obstruction of the Roux limb which results in delayed gastric emptying. Roux stasis syndrome is hypothesized to be due to the

separation of the Roux limb from the natural small bowel pacemaker, which is located in the proximal duodenum, and it has been said to occur in up to 20% of patients (Ishikawa M, Kitayama J, Kaizaki S, et al. Prospective randomized trial comparing Billroth I and Roux-en-Y procedures after distal gastrectomy for gastric carcinoma. *World J Surg* 2005;29:1415–20), though many other authors have reported a much lower incidence.

Nakamura et al. (Nakamura M, Nakamori M, Ojima T, et al. Randomized clinical trial comparing long-term quality of life for Billroth I versus Roux-en-Y reconstruction after distal gastrectomy for gastric cancer. *Br J Surg* 2016;103:337–47) conducted a randomized clinical trial comparing the long-term quality of life of patients undergoing Billroth I versus Roux-en-Y reconstruction after distal gastrectomy for gastric cancer. A total of 122 patients were randomized—60 to Billroth I and 62 to Roux-en-Y reconstruction—and the primary endpoint was quality of life using the Functional Assessment of Cancer Therapy-Gastric (FACT-Ga) questionnaire 36 months after surgery. Patients randomized to the Billroth I group had significantly less epigastric fullness, diarrhea, and fatigue as well as less weight loss (6.8% vs. 10%) than those in the Roux-en-Y group, but they had more severe bile reflux gastritis in the remnant stomach. Delayed gastric emptying due to Roux stasis syndrome occurred in 7% of the patients who had a Roux-en-Y reconstruction. Despite these differences in individual symptoms and parameters, there were no significant differences between the two groups in terms of overall quality of life as measured by the FACT-Ga total score. Thus, the authors concluded that both the Billroth I and the Roux-en-Y reconstructions are equally acceptable methods of reconstruction after distal gastrectomy.

One technique that may help to prevent the Roux stasis syndrome is the so-called “uncut” Roux-en-Y reconstruction. This technique is a simple modification of the Billroth II with Braun anastomosis in which the jejunogastric pathway is occluded with either sutures or a nonbladed linear stapler. It is known to reduce the incidence of Roux stasis syndrome by maintaining the integrity of the intestinal wall, thereby allowing normal conduction of the myenteric impulses (Miedema BW, Kelly KA. The Roux stasis syndrome: treatment by pacing and prevention by use of an ‘uncut’ Roux limb. *Arch Surg* 1992;127:295–300). The original uncut technique was associated with a high rate of recanalization of the uncut staple line or of the suture closure, but with the use of a 6-row linear stapler, this risk is substantially reduced. Park and Kim retrospectively examined 221 patients who underwent laparoscopic distal gastrectomy between 2005 and 2013 and had one of the following four methods of reconstruction: Billroth I (18.5%), Billroth II (36%), Roux-en-Y (26.1%), and uncut Roux-en-Y (19.4%) (Park JY, Kim YJ. Uncut Roux-en-Y reconstruction after laparoscopic distal gastrectomy can be a favorable method in terms of gastritis, bile reflux, and gastric residue. *J Gastric Cancer* 2014;14:229–37). They found that the Roux-en-Y and uncut Roux-en-Y reconstructions were equally superior to BI and BII with Braun anastomoses in

terms of bile reflux gastritis, and the uncut Roux-en-Y method showed improved stasis compared to the conventional Roux-en-Y gastrojejunostomy. There were no significant differences in body weight change among the four reconstructive procedures 1 year after surgery.

Laparoscopic-assisted distal gastrectomy (LADG) was initially developed and shown to be highly effective for the treatment of early gastric cancer in the East. However, in contrast to early gastric cancer, a D2 lymph node dissection is required for the treatment of advanced gastric cancer, and there has been much concern about the technical feasibility as well as the oncologic safety of laparoscopic gastrectomy with D2 lymphadenectomy for advanced gastric cancer. A recently published randomized, phase II, multicenter clinical trial (COACT 1001) of LADG versus open D2 distal gastrectomy (ODG) for advanced gastric cancer (Park YK et al. *Ann Surg* 2017; Epub ahead of print) goes a long way to diminishing those concerns. These authors randomized 204 patients to either LADG (n = 105) or ODG (n = 99) and found no significant differences in the overall noncompliance rate of lymph node dissection between the two groups. Furthermore, there were no significant differences in postoperative complication rates or the surgical stress response, as measured by blood levels of the following inflammatory markers: C-reactive protein, fibrinogen, total bilirubin, interleukin-6, interleukin-10, and tumor necrosis factor alpha. The authors surmised that perhaps surgical stress was influenced more by the sheer extent of surgery (gastrectomy and D2 lymphadenectomy) than by the open or laparoscopic approach per se. Finally, the 3-year disease-free survival rate was essentially equivalent between the groups (LADG, 80.1% and ODG, 81.9%). This study, taken together with similar results reported by many other authors, including one of the largest reports from the West (Kelly KJ, Selby L, Chou JF, et al. Laparoscopic versus open gastrectomy for gastric adenocarcinoma in the west: a case-control study. *Ann Surg Oncol* 2015;22:3590–6), demonstrates the safety, feasibility, and oncologic efficacy of laparoscopic gastrectomy in the treatment of advanced gastric cancer. I am certain that there will be many more reports espousing the benefits of minimally invasive gastrectomy, including robotic gastrectomy, in the years ahead.

John T. Mullen

90 Postgastrectomy Syndromes in the Current Era

KMarie Reid and Michael G. Sarr

INTRODUCTION

At the turn of the 20th century, the epidemic of *Helicobacter pylori* infestation/infection ushered in a new problem for the surgeon—that of peptic ulcer disease. Secondary to the ulcer diathesis induced by the *H. pylori*, duodenal ulcer and related gastric ulceration (and also gastric adenocarcinoma) became commonplace, affecting as much as 20% of the population at some time in their lives. Duodenal ulceration led to multiple acute complications as well as causing the often intractable symptoms of dyspepsia; remember, there were no histamine 2 (H_2) blockers or proton pump inhibitors (PPIs). Initially, prior to effective, long-lasting pharmacologic acid suppression, operations were designed to treat the complications—pyloric stenosis/stricture, hemorrhage, perforation, and benign gastric ulcers (now uncommon). These operations included gastrojejunostomy initially, but thereafter, hemigastrectomy and subtotal gastrectomy became the procedures of choice.

The pioneering work on vagal control of acid secretion by Lester Dragstedt gave birth to the era of operative vagotomy as a therapeutic intervention for symptomatic duodenal ulcer disease. Soon thereafter in the 1960s, the explosion of the anti-inflammatory medications, like aspirin and later the nonsteroidal anti-inflammatory drugs (NSAIDs) to treat painful arthropathies, also led to gastroduodenal ulceration, once believed also to be related solely to acid production. The 1950s, 60s, and 70s were the decades that completed our understanding of the drivers of acid secretion —neural input (vagus nerves), hormonal effects (gastrin), and intramural paracrine effects (histamine). All these factors stimulated the very prevalent operations on the esophagogastroduodenal axis in attempts to treat the ulcer disease (and gastric cancer) involving various forms of total abdominal or selective gastric vagotomies (to inhibit neutrally mediated acid secretion) often combined with some form of distal gastrectomy (to

abolish gastrin secretion) which led to a relatively high prevalence of the postgastrectomy/postvagotomy syndromes.

The introduction of the first H_2 antagonists and more recently the PPIs has eliminated virtually all elective operations for duodenogastric ulcer disease. Many investigators also believe that a concomitant decrease in the true prevalence and incidence of duodenal ulcer disease was occurring simultaneously in the developed world and actually preceded the introduction of effective acid-suppressive medications—probably somehow related to eradication of *H. pylori* infestation.

Currently, however, with the virtual disappearance of elective ulcer surgery as well as the lack of the use of vagotomy as a therapeutic procedure, the spectrum of postvagotomy disorders has changed, and the postvagotomy syndromes which were so common in the recent past are much less prevalent now (and have become poorly understood or appreciated by a new generation of surgeons unfamiliar with the postvagotomy spectrum).

This chapter will review the classic postgastrectomy/postvagotomy disorders of the era of ulcer surgery seen only rarely today, and building on our understanding of the pathophysiology related to the prior "ulcer operations," this discussion will focus and concentrate on the more common consequences of gastrectomies and esophageal operations seen today. Many of the past operations "designed" to treat some of the postgastrectomy disorders but no longer used today will be mentioned only in passing (e.g., reversed jejunal segment for dumping).

GENERAL REVIEW OF RELEVANT OPERATIONS

Gastric Resections

By virtue of the respective procedure, a gastrectomy obligates several irreversible consequences/side effects. Gastric resection requires restoration of esophagogastrointestinal continuity, whether by gastrojejunostomy to a loop of proximal jejunum (Fig. 90.1A), gastroduodenostomy (Fig. 90.1B), gastrojejunostomy to a defunctionalized Roux-en-Y limb (Fig. 90.1C), or an esophagojejunostomy to a defunctionalized Roux-en-Y limb (Fig. 90.1D).

All these reconstructive procedures are subject to potential *mechanical* problems.

Ulceration/stricture/stenosis of the anastomosis can occur secondary to

poor technique or acid-peptic/NSAID–induced injury. The gastrojejunostomy and the gastroduodenostomy allow free reflux of proximal intestinal content (i.e., bile) into the gastric remnant; whether bile reflux "gastritis" really occurs or not is debatable, but bile reflux esophagitis is a very real possibility in patients with underlying gastroesophageal reflux. The Roux-en-Y procedures obligate another infracolic anastomosis, subject potentially to adhesive obstruction either at the anastomosis or at the defect in the transverse mesocolon if the Roux limb is brought retrocolic; similarly, internal hernias can occur through the anatomic defects created in the reconstructions. Depending on where the actual site of obstruction occurs, either the Roux limb, the pancreatobiliary (afferent) limb, or both can become incarcerated in these mesenteric defects, and the obstruction of each limb has its own symptomatology.

There are several potential *functional* consequences. Resection of the pylorus and bypass of the duodenum (Fig. 90.1A, C, and D) alter the control of gastric emptying. Loss of a functional valve at the gastrojejunal, gastroduodenal, or esophagojejunal anastomosis (Fig. 90.1A, B, C, and D) allows early, rapid gastric emptying (dumping) of liquids into the small intestine and the potential for the dumping syndrome. Similarly, dumping can be exaggerated by the bypass of the duodenum with a gastrojejunostomy or Roux-en-Y reconstruction, which prevents the slowing of gastric emptying. This is mediated by the duodenal receptors for acid, glucose, fat, and osmolarity, which provide feedback to the proximal stomach to slow gastric emptying. Depending on where the gastric resection occurs, and if some form of either a therapeutic vagotomy, obligate vagotomy (e.g., for oncologic clearance), or inadvertent vagotomy (of the gastric, hepatic, or intestinal branches during a periesophageal operation) is performed, resultant motor disorders of the gastric remnant and/or intestine can occur, further exacerbating dumping or leading to the very rare instance of postvagotomy diarrhea. In addition to gastric or vagal effects, transection of the jejunum to create the Roux limb alters intestinal motility, especially in the proximal aspects of the Roux limb, which is now isolated from the duodenal pacemaker which may rarely lead to the Roux stasis syndrome.

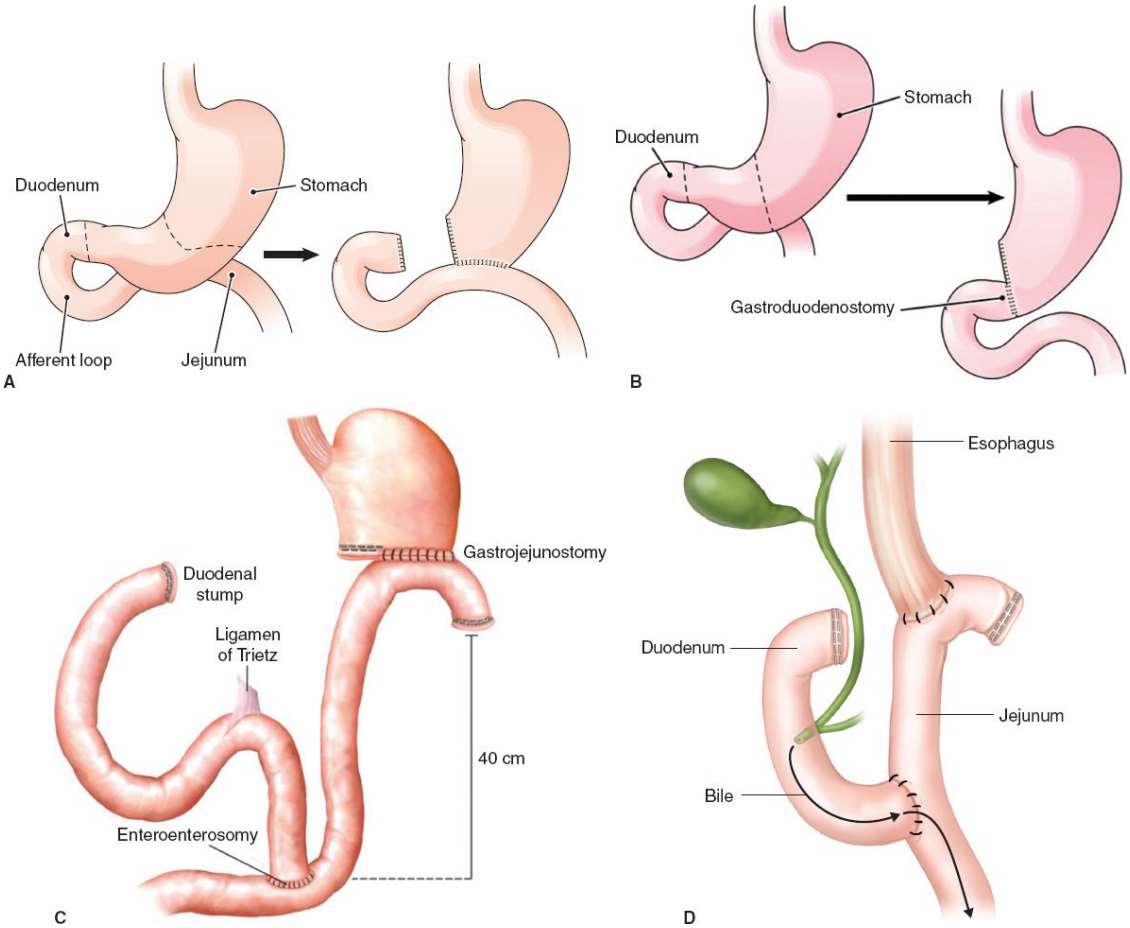

Figure 90.1. Gastric resections. **A.** Antrectomy with loop gastrojejunostomy. (Reproduced from Cohen BJ. *Medical Terminology: An Illustrated Guide.* 4th ed. Lippincott Williams and Wilkins; 2003). **B.** Antrectomy with end-to-end gastroduodenostomy. (Reproduced from Cohen BJ. *Medical Terminology: An Illustrated Guide.* 6th ed. Lippincott Williams and Wilkins; 2010). **C.** Antrectomy or subtotal gastrectomy with Roux-en-Y gastrojejunostomy. (Reproduced from Nussbaum MS. *Master Techniques in Surgery: Gastric Surgery.* LWW; 2012.) **D.** Total gastrectomy with Roux-en-Y esophagojejunostomy.

Metabolic consequences follow gastrectomies as well. Loss of gastric acid affects calcium and iron absorption from the duodenum, especially if the duodenum is bypassed. Incomplete antrectomy with retaining of a segment of isolated distal antrum can lead to the unusual “retained antrum syndrome” and its consequences. Bypass of the duodenum markedly alters the postprandial neurohormonal control of pancreatobiliary secretions and neuroregulatory postprandial hormones, the consequences of which still remain poorly understood (e.g., late dumping also and more appropriately called reactive hypoglycemia).

Therapeutic Vagotomy

Although several types of vagotomy do not involve any gastric resection (vagotomy/pyloroplasty and highly selective vagotomy), these now unusual procedures can lead to disorders that fall under the category of postgastrectomy syndromes (Fig. 90.2). *Mechanical* problems involve primarily the abnormalities discussed above—ulceration/stenosis, obstruction of afferent or efferent limbs of jejunum, and internal hernia. *Functional* problems are secondary to a combination of the loss of the pseudovalvular function of the pylorus after pyloroplasty, antrectomy, or the gastrojejunostomy, and the potential functional effects on gastric and intestinal motility (rapid gastric emptying of liquids-dumping, gastroparesis with delayed gastric emptying of solids, and rarely postvagotomy diarrhea).

Esophagogastrectomy Procedures

These operations involve resections of the esophagus, the esophagogastric junction including the lower esophageal sphincter (LES), and the vagal innervation to the gut (Fig. 90.3). Although the consequences of these resections are not "classic" postgastrectomy disorders, these types of resections are being performed more commonly, and the pathophysiologic consequences are similar to many of the classic postgastrectomy/postvagotomy syndromes. The *mechanical* problems of the esophagogastric resections (Fig. 90.3A and B) relate to anastomotic problems as well as the loss of the LES with consequent free gastroesophageal reflux; reconstruction with a colonic interposition adds all the infracolic *mechanical* problems of creating the colonic segment—adhesive obstruction, anastomotic stricture, etc. but avoids bile or acid reflux. Probably most relevant for this discussion, however, are the potential *functional* consequences of the obligate vagotomy—gastric emptying disorders or the dysmotility of the Roux limb or the colonic conduit. Definite *metabolic* sequelae are rare.

Nonresective Procedures at the Esophagogastric Junction

These operations are primarily the antireflux procedures (Fig. 90.4). *Mechanical* effects involve obstruction at the wrap—either too tight of a wrap or the wrap slips. More relevant to this chapter, however, are sequelae of inadvertent injury to the vagus nerves (especially with redo

antireflux procedures) with the potential *functional* motor disorders of the stomach and/or intestines. Definite *metabolic* sequelae are rare.

Bariatric Procedures

While the potential sequelae of bariatric operations do not fall "classically" under the category of postgastrectomy syndromes, the prevalence of these operations and their side effects on gastric function are very relevant currently and need also to be discussed in this chapter. The *mechanical* problems involve both of the anastomoses of the Roux-en-Y gastric bypass (Fig. 90.5A) and the biliopancreatic diversion/duodenal switch (Fig. 90.5C). The gastric sleeve (Fig. 90.5B) has its own, specific *mechanical* sequelae related primarily to obstruction either at the esophagogastric junction or at the incisura region of the sleeve; the creation of a lesser curvature sleeve of stomach also leads to a segment of proximal stomach that has no phasic contractile motility, which obligates a *functional* component to any relative obstruction at the region of the incisura. After a laparoscopic adjustable gastric band (Fig. 90.5D), the primary disorders involve a potential *mechanical* obstruction at the band (the band can be too tight or the band can slip) or a *functional* type of obstruction leading to a form of pseudoachalasia. Obviously, these bariatric procedures have many *metabolic* sequelae related to the underlying obesity, postoperative weight loss, nutritional challenges, etc., but the "postgastrectomy-like" potential sequelae secondary to the operations and their anatomy are often forgotten or not acknowledged. These involve the duodenal (jejunal) bypass (Fig. 90.5A), described above or the jejunoileal bypass (Fig. 90.5D); in addition, these excluded segments are subject to bacterial overgrowth.

Mechanical Disorders

Afferent Limb Syndrome

Construction of an anastomosis between the stomach and small bowel as a loop gastrojejunostomy (Fig. 90.1A) or in a Roux-en-Y configuration (Fig 90.1C,D) leaves the duodenum and the proximal-most jejunum proximal to the gastroenterostomy or the enteroenterostomy out of the flow of ingested chyme; this segment is called the biliopancreatic limb (or afferent limb). This proximal small bowel is responsible for delivering pancreatic secretions and bile into the more distal segments of intestine, where these digestive juices mix with and allow for digestion of the ingested food delivered via the efferent limb of a gastrojejunostomy or a Roux limb.

Disruption to the flow of the pancreatobiliary secretions past these anastomoses due to a partial or complete mechanical obstruction, such as from an anastomotic stricture, adhesions, an internal hernia, or recurrent cancer as after prior resection for gastric cancer, can lead to the development of afferent limb syndrome. The operative procedures that are at risk for this complication include gastrojejunostomy, subtotal or distal gastrectomy with Billroth II or Roux-en-Y reconstruction, and pancreatoduodenectomy with the typical Roux-en-Y–like reconstruction.

Symptomatology

Patients may present acutely and immediately after surgery with signs of mechanical obstruction, such as nausea, vomiting of liquids but not the ingested food, often vomiting of large amounts of bile (but not the ingested food) late after a meal, and abdominal discomfort, or the patient may present with low-grade, nonemergent, chronic complaints of generalized abdominal discomfort specifically after eating. The latter represents a more chronic and insidious form of afferent limb syndrome that requires operative intervention, the urgency of which is determined by the presentation of the patient. Rarely, the presentation can be either with acute pancreatitis secondary to obstruction of the pancreatic duct or jaundice secondary to obstruction to the flow of bile out of the bile duct secondary to the obstruction of the afferent loop with severe dilation of the pancreatobiliary limb. An acute presentation may warrant urgent or emergent operative intervention as determined by the physical examination, constellation of symptoms, and imaging. Presentation can be as early as the first week postoperatively or up to many years after operation. The average reported presentation is 5.5 years after the primary esophagogastric operation.

Etiopathogenesis

A variety of anatomic complications can lead to the manifestations of mechanical obstruction. Postoperative adhesions may compromise the

flow of pancreatobiliary secretions past the anastomosis. In addition, the patient might have an intussusception, anastomotic ulcer from stricture, volvulus, or a bowel obstruction secondary to an internal hernia contributing to the mechanical obstruction. These hernias (often referred to as a Petersen hernia) occur posterior to the mesentery of a loop gastrojejunostomy or between the transected edge of the jejunal mesentery of the Roux limb (if brought retrocolically) and the retroperitoneum infracolically or the transverse colon if the Roux limb is brought antecolically. More rare etiologies include ingestion of nonfood objects, such as foreign objects or hair, causing a gastric bezoar blocking emptying of the stomach. Understanding the etiology is imperative to achieving a good long-term outcome, because the treatment of the underlying cause of the disease will decrease the risk of recurrence. For example, if the patient has a chronic problem with ingesting foreign materials in that clinical scenario, psychologic intervention is warranted. If the patient ingests routinely anti-inflammatory medications excessively, salicylate levels in the urine (not in the blood which has a much shorter half-life) may be performed to document if abuse is suspect and provide counseling as to the ongoing risks of this behavior. If the obstruction is secondary to salicylate or NSAID abuse, this behavior needs to be corrected before any operative intervention or the problem will likely recur.

Diagnosis

The diagnosis of afferent limb syndrome includes obtaining a full history and physical examination paying special attention to the associated pain after eating. Imaging includes an abdominal flat plate, an upper gastrointestinal study with small bowel follow-through performed with barium, or more often computed topography (CT). If the patient has a presentation indicative of chronic insidious symptoms, the diagnosis may be missed, and therefore, a high index of suspicion must be held. CT is the radiographic study of choice. On CT, the findings may be a dilated and fluid-filled duodenum and proximal jejunum (and stomach if still present). Again, a high index of suspicion may be necessary, because this finding may be absent after a prolonged fast. Likewise, an upper GI series may demonstrate the same finding of a markedly dilated pancreatobiliary limb, however, it is not unusual for nonopacification of the afferent loop in a normally functioning gastrojejunostomy or the pancreatobiliary limb after a Roux reconstruction; therefore, nonvisualization of the pancreatobiliary (afferent) limb after oral administration of contrast is suspicious but not

necessarily pathognomonic for the afferent loop syndrome. Abdominal plain radiographs may be helpful in identifying abnormal bowel gas patterns or air/fluid levels in the stomach; however, further confirmatory imaging study such as a CT may be needed. Utilization of endoscopy in the form of upper endoscopy to visualize anastomotic problems directly, such as marginal ulceration or kinking of the limb, can be tried. If there are worrisome submucosal or mucosal changes suggestive for instance of recurrent cancer after a prior resection for a gastric cancer, deep biopsies can then be obtained at that time if the recurrence does not involve the mucosa, however, the biopsies may be negative. Patients may have associated bacterial overgrowth in a chronic situation, and treating empirically for bacterial overgrowth may help to diagnose this pathology in a difficult scenario.

Treatment

Operative intervention is the mainstay of this disease process. The acuity of the presentation will determine the urgency of the operation. As stated above, the patient presenting with an acute obstruction may require an emergency operation. Patients who have a more chronic and insidious onset of symptoms may have the time for a proper evaluation paying attention to their nutritional status. Correction to improve their perioperative nutrition will help ward off postoperative complications such as delayed healing.

Intraoperative takedown of the prior anastomosis may be warranted. If the patient has a gastrojejunostomy, a conversion to a Roux-en-Y anastomosis is often preferred over the option of conversion to a gastroduodenostomy; note, however though, if the ulcer is acid-related, a higher gastrectomy is warranted to decrease acid production. While the gastroduodenostomy replicates the more normal anatomic state, mobilization of the remnant stomach and duodenum may be a challenge. Avoiding tension with a newly created gastroduodenostomy is critical, because the risk for anastomotic leakage increases. With the simple scenario of an adhesive band, perhaps adhesiolysis is all that is required. The quality and character of the small bowel will dictate whether or not a concomitant bowel resection is required. Intervention can be either via an open operation or a minimal access attempt at repair.

Efferent Limb Syndrome

The efferent limb (can be the Roux limb as well) is the segment of bowel

from the gastrojejunostomy that receives ingested food from the stomach to transport distally. In bariatric surgery, the length of this limb will affect weight loss; the longer the limb the more malabsorption that occurs. Efferent limb syndrome is a rare phenomenon that is seen after gastric surgery where there is a mechanical obstruction to the efferent limb. It is seen more commonly in the earlier postoperative period but can be seen years after the original operative procedure. If the original operation was for gastric cancer, one must always worry about recurrent gastric cancer with both the efferent loop syndrome and the afferent loop syndrome.

Symptomatology

The classic symptoms associated with the efferent loop syndrome are nausea and extreme crampy abdominal pain relieved only by vomiting. The vomitus will consist of the ingested food stuffs and may or may not consist of bile depending on the type of prior gastrectomy; bile will be absent if the patient has a Roux-en-Y reconstruction. The patient will also complain of early satiety and upper abdominal distention early after a meal.

Etiopathogenesis

The most likely etiology for the efferent limb syndrome is an ulcer at the gastrojejunal anastomosis or an internal hernia (see Petersen hernia below). Other factors, such as kinking, adhesions, or recurrent cancer can contribute to the clinical finding.

Diagnosis

An upper GI series with small bowel follow-through should show the source of the obstruction. The best diagnostic test after a prior loop gastrojejunostomy would be an upper endoscopy; the endoscopist will either see a stricture at the anastomosis or may not be able to get the endoscope out of the stomach. After a Roux-en-Y drainage, the endoscopist should be alerted to plan for an extended endoscopy down the Roux limb as well.

Treatment

As with afferent loop syndrome, operative intervention is the mainstay for treatment of this syndrome with revision of the gastrojejunostomy and as with the afferent limb syndrome, possible resection of more of the gastric remnant if the obstruction is related to ulceration at the anastomosis.

Endoscopic management is being reported increasingly with the use of endoscopic endoluminal stents to relieve the obstruction.

Petersen Hernia

In the early 1900s, the German surgeon Walther Petersen described this internal hernia after partial gastrectomy and gastrojejunostomy reconstruction. After the creation of a gastrojejunostomy, there is a potential space posterior to the anastomosis. This potential space may or may not be closed at the time of operation at the surgeons' discretion. Herniation of small bowel into this space may result in a bowel obstruction depending on how the loop of jejunum or the Roux limb is delivered to create the gastrojejunostomy. A retrocolic anastomosis brings the Roux limb through the transverse mesocolon, and bowel can become trapped infracolically in the defect posterior to the cut edge of the mesentery to the Roux limb and the retroperitoneum creating a true surgical emergency (as well as in the defect in the mesocolon).

Symptomatology

The symptoms of patients with a Peterson hernia may be vague. It is important that the surgeon and team have a high index of suspicion for this condition in patients presenting with small intestinal obstruction after gastrectomy and especially those bariatric patients with diffuse abdominal pain or unexplained vomiting after a Roux-en-Y gastric bypass. After bariatric surgery, the symptoms may occur related to the massive weight loss (and loss of fat making the defect larger) and typically will present during the 6- to 24-month window after laparoscopic Roux-en-Y bypass.

Etiopathogenesis

The frequency of this internal hernia space increased markedly during the early phase of laparoscopic gastric bypass surgery and was reported to be as great as 10% in some series and much greater than was observed with open surgery. Initially, these potential sites of internal hernias were not closed routinely. Decreased adhesions after laparoscopic surgery allows for the persistence of this defect, which was usually obliterated by the trauma of open surgery. In addition, patients often present after having a large weight loss; this weight loss is presumed to lead to loss of the fat in this region, thereby causing the defect to become bigger. Hernias after a Roux-en-Y gastric bypass can occur in three different locations: at the defect in the transverse mesocolon where a retrocolic Roux limb is

delivered to create the gastrojejunostomy, at the mesenteric defect of the enteroenterostomy, and posterior to the mesentery of the Roux limb in either in a retrocolic or antecolic position (this is the Petersen hernia). Higa et al. evaluated 2,000 patients with an internal hernia; the majority of the hernias, 67% occurred at the mesocolic defect, followed by the mesenteric defect at the enteroenterostomy (21%), and those at Petersen defect (8%), posterior to the mesentery of the jejunal limb. Because this phenomenon is now realized, most surgeons will now close these defects in order to avoid this postoperative complication.

Diagnosis

In addition to symptoms, a CT may show swirling of the mesentery in the left upper quadrant or a picture of a bowel obstruction. Imaging will have a better chance of detecting the hernia when the patient is symptomatic because of the dilation of the obstructed bowel; unfortunately, the CT is diagnostic in only about 65% of patients with an internal hernia. A small bowel follow through (SBFT) may help with the diagnosis. The normal finding should locate the enteroenterostomy in the left upper quadrant and no evidence of dilation. Worrisome findings will include either an obstructed Roux limb or a dilated pancreaticobiliary limb with displacement of the staple line with "clustering" of small bowel in the mid-abdomen or the left upper quadrant.

Treatment

A high index of suspicion is important to enable a successful outcome. Even in the setting of a negative imaging study, the surgeon may have to perform a diagnostic laparoscopy to exclude the possibility of such a devastating complication as strangulation of the Roux limb or the majority of the small bowel. Treatment of a presumed Petersen hernia represents a true surgical emergency that differs from the often-quoted adage used in other types of postoperative small bowel obstruction—"the sun should never rise and set on a small bowel obstruction." Treatment consists of operative exploration, reduction of the herniated contents, resection of compromised small bowel, and closure of the defect.

Stomal Ulcer

Symptomatology

Long-term studies have documented numerous complications that can occur after Roux-en-Y gastric bypass surgery. These bariatric patients

have been found to have inordinate amounts of acid secreted into the gastric pouch and may develop a stomal ulcer or a perforation in the staple line with a gastro–gastro fistula. These patients often present with symptoms of epigastric pain, hemorrhage, or even free perforation. Patients may report that the pain awakens them at night or pain that is relieved by taking antacids or ingesting food. Additional symptoms include nausea, vomiting, or the presence of blood in the vomitus; usually blood in the stool is absent. The presence of persistent epigastric pain despite adequate suppression of acid production may signify a chronic, contained perforation, which can lead to disabling epigastric pain.

Etiopathogenesis

Prior to the Roux-en-Y gastric bypass, stomal ulcers were associated with gastrectomies performed for malignancy or peptic ulcer disease that were reconstructed primarily with a Roux-en-Y configuration; although stomal ulcers can occur after a typical antrectomy and gastrojejunostomy or gastroduodenostomy with or without a truncal vagotomy, the incidence is quite low. In contrast, the incidence of stomal ulcers is as great as 10% after Roux-en-Y gastric bypass. The goal of creating a small pouch for weight loss is to restrict caloric intake and also to allow for decreased acid exposure of the anastomosis to the "unprotected mucosa" of Roux limb. It is often found that patients who develop stomal ulcers have an enlarged pouch that generates too much acid production or that a breakdown in the staple line allows acid formed in the bypassed stomach to reflux into the pouch and thereby damage the Roux limb. Other important proulcerogenic exposures to consider are chronic NSAID or aspirin exposure allegedly and excessive alcohol intake. Technical complications, such as an ischemic staple line, too large a pouch, and incomplete division of the gastric pouches with persistence of a gastro–gastro communication can contribute to the pathogenesis. In addition, several authors have implicated smoking and alcohol abuse in the etiopathogenesis of stomal ulcers after Roux-en-Y gastric bypass, but the senior author of this chapter does not support smoking or alcohol abuse as a cause of stomal ulcers.

Diagnosis

A history and physical examination are often able to distinguish whether the patient's symptoms are attributable to a stomal ulcer. Symptoms of dysphagia, pain that is worsened with eating, and nausea are indicative of the diagnosis. The definitive study of choice is an upper endoscopy paying

close attention to the area of the anastomosis. Additional studies such as a Gastrografin-guided evaluation of the upper GI tract may provide useful information.

Treatment

Treatment for this complication consists of decreasing and discontinuing proulcerogenic factors, such as discontinuing all aspirin and all NSAID use to aid in healing of the ulcer. Operative intervention is reserved for patients with complications related to the ulcer, such as perforation, stenosis, or unresponsiveness to medical management.

Functional Disorders

The majority of functional disorders after esophagogastric surgery are related to disruption of the neurohormonal regulation of motility of the stomach and small intestine secondary to either vagal nerve disruption (planned, obligate, or inadvertent), intestinal transection (creation of a Roux limb), and/or alteration of the normal anatomy of flow of ingested content (e.g., duodenal bypass). Regulation of gastrointestinal motility is a complex interplay of extrinsic neural innervation (primarily vagal innervation—both descending as well as ascending pathways), intrinsic innervation, and the continuity of the small intestine (the myenteric plexus), and postprandial hormonal release in the early phase (upper gut—duodenum, jejunum, and pancreas) and the late phase (distal gut—ileum and proximal colon) after ingestion of a meal.

Dumping Syndrome

Dumping syndrome is related to rapid emptying of ingested content into the small intestine. The spectrum of symptoms affects most all patients to a varying extent who undergo some form of gastric resective operation and/or a vagotomy. The term “dumping” has been used inappropriately in many situations and has become a term used too commonly to explain symptoms that may be related to many other disorders. In this chapter, we will define the appropriate use of this term and the appropriate situations where dumping is related to a postgastrectomy disorder.

Symptomatology

The symptoms of dumping are nausea, a feeling of bloating, and crampy abdominal pain often associated with the cardiovascular (“sympathetic”) symptoms of palpitations, tachycardia, flushing, and diaphoresis with a

feeling of being unwell. These symptoms come on early, within 10 to 20 minutes, after eating a meal. Many patients need to lie down for 30 to 60 minutes until the symptoms resolve. Note, diarrhea is not an obligate symptom of dumping, although diarrhea can occur later (2 or 3 hours postprandial) in some patients. The majority of patients do not have prominent diarrhea. The word “dumping” refers to the rapid, uncontrolled emptying of fluid from the stomach, gastric remnant, or esophagus into the small intestine (i.e., dumping of liquids), and not to having a watery bowel movement or diarrhea as thought of erroneously by many patients and too many physicians.

These symptoms are present to some extent in all patients with loss of pyloric function secondary to resection or pyloroplasty, but prolonged persistence of clinically relevant symptoms for greater than a month or two is quite rare unless there has been a concomitant vagotomy (see Etiopathogenesis below). For instance, after a Roux-en-Y gastric bypass (Fig. 90.5A), prolonged clinically relevant dumping almost never occurs, in contrast to the dumping symptoms after antrectomy and vagotomy (Fig. 90.1A,B) or after vagotomy with pyloroplasty or gastroenterostomy (Fig. 90.2), where clinically relevant dumping symptoms can persist for months or years, albeit still rare (2% of patients).

Etiopathogenesis

The etiology of the dumping syndrome is secondary to rapid, early emptying of liquids into the small intestine. The primary cause of dumping is related to the loss of the regulation of liquid emptying secondary to either resection of the pylorus with some form of gastroenteric or esophagoenteric anastomosis or to disruption of the function of the pylorus (pyloroplasty or pyloromyotomy). Addition of a vagotomy to the operation exacerbates markedly the early gastric emptying, because the vagotomy abolishes receptive relaxation of the proximal stomach. This vagally mediated “receptive relaxation” is very important physiologically, because the proximal stomach (and the intragastric pressure) controls gastric emptying of liquids. Vagotomy prevents the gastric “accommodation” of ingested liquids (i.e., gastric relaxation, which keeps the intragastric pressure low), causing increased intragastric pressure immediately after a meal and thereby accelerating gastric emptying of liquids. While almost everyone who undergoes loss of the pylorus or a pyloroplasty experiences some element (albeit usually transiently) of dumping, severe and prolonged dumping occurs virtually only inpatients with a concomitant

vagotomy. When ingested content “bypasses” the duodenum (Figs. 90.1A,C, 90.2B, and 90.5A,C), the physiologic feedback to slow gastric emptying mediated by the duodenal mucosal receptors for acid, sugar, fat, and osmolality is lost, also exacerbating early phase rapid emptying of liquids.

The pathogenesis of the symptoms is complex and still remains poorly explained. There was a lot written in the past about rapid, voluminous mucosal secretions into the intestinal lumen in attempt to decrease the high intraluminal osmolality secondary to rapid emptying of sugars into the small intestine with subsequent intravascular contraction and hypotension causing a sympathetic response (diaphoresis, nausea, etc.). That theory has been refuted—indeed, ingestion of high sugar content does exacerbate markedly the symptoms, but other meals without such a high content of sugar are also associated with symptoms in many patients. Currently, most investigators believe that the symptoms of dumping are related to a neurohormonal response to the rapid entry of nutrients into the small intestine (jejunum > duodenum) with the release of vasoactive agents that cause the symptoms (see below treatment with octreotide which inhibits much of this neurohormonal response).

Diagnosis

The diagnosis of dumping is a clinical diagnosis based on symptoms. A radionuclide gastric emptying test can be confirmatory but is not always necessary, and one must be certain that the radionuclide marker is a marker of liquid emptying, not a marker of the emptying of solids. Similarly, a glucose challenge of 200 mL of a 50% glucose solution should elicit the spectrum of symptoms but again, is usually unnecessary.

Treatment

In the era of gastric vagotomies for duodenal ulcer disease, dumping was quite common but is much less common now that elective therapeutic vagotomies are no longer performed. Currently, most patients do well with diets avoiding liquids when eating as well as avoiding any high sugar loads. Moreover, symptomatic dumping almost always improves with time postoperatively. For instance, after a Roux-en-Y gastric bypass, mild dumping is quite common early postoperatively (some even maintain that the dumping symptoms are a form of behavior modification—i.e., avoidance of calorically dense foods). After the first month or two, however, this dumping disappears (unfortunately in the mind of a bariatric

surgeon); indeed, prolonged symptoms of “dumping” after a Roux-en-Y gastric bypass should question the diagnosis of dumping. The lack of prolonged symptoms is probably due to the lack of a vagotomy with these bariatric operations.

There is a small subset of patients with persistent dumping—again usually after an obligate vagotomy accompanying a gastric resection. If intensive dietary intervention fails, including a trial of acarbose, an alpha-glucosidase inhibitor to slow the breakdown of complex carbohydrates in the gut (this pharmacologic trial usually fails), then consideration should be given to a trial of octreotide given 30 minutes before each meal; the rare patient will have dramatic benefit, and treatment with a long-acting depot of octreotide is indicated.

Should incapacitating symptoms persist, and again this scenario is quite unusual, some consideration can be given to operative intervention in selected patients. The idea of a reversed 10-cm segment of proximal jejunum is an operation of historic interest only. Most classic GI surgeons (like the authors of this chapter) do not believe this operation provides any benefit, and it does have some risk of a relative obstruction if the reversed segment is too long. In contrast, if the patient has an intact pylorus after a prior vagotomy and gastroenterostomy (Fig. 90.2B), or has had a loop gastrojejunostomy after an antrectomy (Fig. 90.1B), restoration of gastroduodenal flow of ingested content may help the symptoms. If the patient has had a pyloroplasty, reconstruction of the pylorus may help—note that published, evidence-based experience with pyloric reconstruction is scarce and largely anecdotal. Finally, conversion from a loop gastrojejunostomy to Roux-en-Y gastric drainage (Fig. 90.1C) may help, because Roux-en-Y drainage of the stomach often slows gastric emptying. No one has much experience with these operations, and an honest discussion with the patient with no guarantees is suggested when discussing this approach preoperatively in the persistently symptomatic patient.

Gastroparesis

The gastroparesis that complicates many forms of gastric and esophageal resections and also the therapeutic vagotomies of the past are unappreciated, misdiagnosed, and all too often poorly understood. Consideration and diagnosis of this postgastrectomy/postvagotomy disorder requires an understanding of normal gastric motility, while treatment is based on the pathophysiologic consequences of the

combination of both the gastrectomy, but importantly, also the associated vagotomy.

Symptomatology

Postgastrectomy/postvagotomy gastroparesis is primarily a clinical diagnosis based on symptoms. The cardinal symptoms are early satiety and especially vomiting of nondigested food more than 6 hours after eating. Weight loss can be substantial and rarely life-threatening, but in other patients with a more mild form, weight loss may be unimpressive. Nausea, bloating, and/or abdominal pain can be common complaints as well, but the key sign that is virtually pathognomonic is that of vomiting of solids eaten the day before. Interestingly, this symptomatology often takes years to become clinically important after the gastrectomy, on occasion up to 5 years postoperatively and in patients with a prior gastrectomy, only in those who have had a concomitant vagotomy.

Etiopathogenesis

Understanding gastroparesis requires a basic understanding of the regulation of gastric emptying. In summary, the proximal stomach controls the emptying of liquids, while the mid to distal stomach controls the breakdown and emptying of solids. Normally with the ingestion of a meal, the proximal stomach relaxes to accommodate the volume; this is referred to as “receptive relaxation.” The proximal stomach then slowly increases its tone, decreasing its volume by a slow, tonic contraction, and thereby increasing intragastric pressure; when the pressure in the gastric lumen exceeds the intraluminal pressure in the duodenum, liquids empty from the stomach, usually emptying completely within 30 to 40 minutes. The distal stomach plays a minimal role in emptying of liquids.

In contrast, the distal stomach controls emptying of solid foods. Postprandially, the stomach changes its contractile pattern to one of propagated, peristaltic contractions (3 to 5 per minute) designed to break down mechanically the solid ingested particles in the antrum into pieces less than 1 mm, the so-called “trituration”; the pylorus contracts and relaxes in coordination with these antral contractions in a way that only allows small particles (less than or equal to 1 mm) to pass through the pylorus and into the duodenum—this coordination is referred to as the “antropyloric pump.” Particles larger than 1 mm are retropulsed back into the lumen of the body of the stomach, and the trituration process continues until the solids are fully broken down and emptied over the next 1 to 2

hours. Emptying of solids requires phasic, peristaltic contractile activity in the mid to distal stomach. This antropyloric coordination is also mediated in part by the vagal innervation.

Vagotomy has two effects. First, vagotomy prevents proximal gastric relaxation, causing the pressure in the proximal stomach to increase rapidly after a liquid meal, leading to an early, rapid emptying of liquids—one of the aspects of dumping. The second effect of vagotomy is a disruption of the antropyloric coordination, causing a relative obstruction at the pylorus which fails to relax fully with the onset of the antral contractions, often with prevention of gastric emptying of solids. This is the reason that Dragsted recommended pyloroplasty when performing a truncal vagotomy and why after an esophagogastrectomy (which obligates a truncal vagotomy), most surgeons perform either a pyloroplasty or a pyloromyotomy.

Diagnosis

The diagnosis of gastroparesis requires suspicion, and the hallmark is the presence of vomiting of food eaten the day before. Confirmation of the clinical diagnosis requires exclusion of any mechanical obstruction at the gastroenteric anastomosis, at the pylorus if it is still intact, or in the small intestine. The finding of solid food particles in the gastric lumen after an overnight fast and the lack of gastric distention in the absence of any mechanical obstruction virtually clinches the diagnosis of postgastrectomy/postvagotomy gastroparesis. Note, unlike with the mechanical obstruction related to a pyloric stricture, obstruction of an antral neoplasm, or stomal stenosis where the stomach is dilated and the gastric muscular wall is thickened, gastroparesis lacks both gastric distention and gastric wall thickening.

Formal radionuclide tests of gastric emptying can be done and should show retention of a solid marker, with a markedly decreased percentage emptied at 4 hours and with a half-emptying time of greater than 2 hours. Be careful to confirm that the radionuclide marker used actually labels the solids and not the liquids; this assurance is very important, because postvagotomy/postgastrectomy gastroparesis affects solids more than liquids. Upper gastrointestinal radiologic contrast studies and CT will show the presence or absence of gastric dilation; however, the rate of emptying of the contrast agent is unreliable as a test of gastric emptying.

Treatment

The first approach to treatment involves dietary modification in attempt to find foods that are soft and broken down easily but provide enough calories to maintain health and nutrition. Many patients can be managed by dietary change alone. Low-dose erythromycin to treat symptoms (150 mg given 30 minutes before a meal) may help with emptying of gastric contents and relieve symptoms. There are few if any other good or effective prokinetic agents available. Domperidone targets dopaminergic receptors in the antrum and may provide some benefit as may metoclopramide, but usually both of these purported prokinetic agents are ineffective. Note that domperidone will be ineffective after a distal gastrectomy.

When oral intake cannot support nutritional needs, operative treatment needs to be considered. The principles of operative treatment are based on the underlying abnormal motility and not the site of any gastroenteric anastomosis or the diameter of the anastomosis (unless there is an anastomotic obstruction secondary to a stricture or neoplasm). After a vagotomy and either pyloroplasty (Fig. 90.2A) or gastrojejunostomy (Fig. 90.2B), the problem lies in the more proximal stomach; an antrectomy, even with a very wide gastroduodenostomy or gastrojejunostomy, will not solve the problem of the gastroparesis. After a distal gastrectomy with either gastrojejunostomy (Fig. 90.1A) or gastroduodenostomy (Fig. 90.1B), widening of the anastomosis, or converting a loop gastrojejunostomy or a gastroduodenostomy, to a Roux anatomy or vice versa, will also fail, because the problem is a generalized lack of tonic contractions (proximal stomach) or coordinated distal phasic, peristaltic gastric contractile activity. Therefore, the best operative option is to resect greater than 95% of the stomach, leaving only a 1-cm cuff of cardia (a near total or near-total completion gastrectomy) with Roux-en-Y cardiojejunostomy; leaving 1 cm of cardia allows a safer gastrojejunostomy versus an esophagojejunostomy. The key is not to leave a gastric remnant (reservoir) of greater than 20 mL where stasis of solids can occur.

Despite a complete workup and a confident, careful diagnosis of gastroparesis, a near-total gastrectomy with Roux-en-Y cardiojejunostomy provides complete relief in only about 50% of patients; the other 50% require some form of nutritional support, either intravenously as parenteral nutrition or via an enterostomy tube which in the authors' opinion should be placed routinely at the time of the near-total gastrectomy. Patients who

fail near-total gastrectomy probably have a form of intestinal dysmotility induced by the disruption of the vagal innervation to the gut. One preoperative symptom that is worrisome for a poor is the presence of crampy abdominal pain. In these patients before proceeding with near-total gastrectomy, the senior author of this chapter recommends a trial of nasojejunal tube feeding; if the patient cannot tolerate tube feedings at a rate of at least 75 mL/hr of 0.9% sodium chloride, a near-total gastrectomy would not be expected to provide any benefit.

Special situations: Two forms of gastroparesis complicating two types of operations deserve special mention: esophagogastrectomy (Figs. 90.1D and 90.3) and antireflux operations (Fig. 90.4). Similarly, early delayed gastric emptying after a gastrectomy will be discussed to differentiate this reversible, transient delayed emptying from gastroparesis.

Esophagogastrectomy

Complaints of delayed gastric emptying after this operation are very common for several reasons. First, this operation obligates a complete vagotomy of the remnant stomach and small intestine. Second, most surgeons perform a concomitant pyloroplasty or pyloromyotomy, thereby further disrupting pyloric function and allowing free reflux of duodenal content into the gastric remnant. And third, the gastric conduit (Fig. 90.3A) is largely intrathoracic, and thus subject to the negative pressures of inspiration, which exacerbates the reflux. Symptoms involve an element of early satiety, gastroesophageal reflux and orogastric regurgitation, and vomiting in all patients, but these symptoms are especially severe in the subset of patients with moderately severe gastroparesis. Weight loss is common and can be severe enough to threaten maintenance of nutrition and health by oral intake alone. The diagnosis is relatively severe with the presence of solid matter and often bile in the gastric conduit.

Treatment is complicated and involves dietary management, a trial of erythromycin as a prokinetic agent, and supportive care. But there is a subset of patients in whom oral nutrition is unable to support their weight and health, and vomiting and reflux are incapacitating. The usual operative treatment for gastroparesis, that is, near-total gastrectomy to remove any gastric reservoir, is quite a bit more complicated in these patients with their anatomy, because access to allow resection of the gastric conduit through the abdomen is not feasible. For this reason, operative intervention is much less common. Operative treatment would involve resection of the

gastric conduit and reconstruction with an esophageal anastomosis to a defunctionalized intestinal conduit. This operation requires a thoracic as well as abdominal approach with construction of a conduit of preferably a Roux limb of jejunum, provided an adequate, well-vascularized length of jejunum can be created. If a Roux limb of jejunum is not possible, then a colonic conduit can be constructed (Fig. 90.3B); however, the functional results of a colonic conduit, though not well described, would be expected to be less satisfactory than those of a Roux limb. A colonic conduit adds considerably more potential postoperative morbidity. Obviously, such an undertaking is a substantial endeavor, and no one has any sizable experience with this procedure; therefore, no strong recommendations are possible based on evidence-based data. There have been reports of lesser operations such as creation of a Roux limb to be sewn to the gastric conduit to "help" gastric emptying—these operations should be condemned for gastroparesis after an esophagogastrectomy, because they do not treat the pathophysiology.

Antireflux Procedures

Although not a classic postgastrectomy disorder, gastroparesis can occur after these procedures—albeit quite rarely. This form of gastroparesis is also related to a vagal injury that occurs during the antireflux procedure; most cases occur in the setting of a reoperative procedure, where there is difficulty recognizing the vagal trunks and protecting them during the mobilization. Symptoms differ a bit from the more common gastroparesis that complicates esophagogastric resections. Vomiting and gastroesophageal reflux are much less common, because of the antireflux fundoplication (Fig. 90.4). In contrast, early satiety, bloating, and often abdominal pain are more common. Many of the symptoms mimic those that are common early postoperatively after an antireflux procedure, but these early postoperative symptoms usually resolve in 2 to 3 months. In contrast, when these symptoms persist, the diagnosis of postgastrectomy gastroparesis is neither entertained nor understood. The diagnosis relies on endoscopy showing retention of solid material in the stomach indicative of delayed gastric emptying. As with postgastrectomy gastroparesis, the stomach should not be dilated or have a thickened wall. Should the stomach be dilated with a thickened wall, a source of mechanical obstruction should be sought, for example, pyloric stricture or a dysfunctional pylorus secondary to the vagotomy.

Treatment of gastroparesis complicating a presumed vagal injury during

an antireflux procedure is complicated. Because antireflux procedures do not include any operative alteration of the pylorus, and we know that vagal innervation does modulate the antropyloric coordination, a trial of erythromycin, metoclopramide, and/or domperidone as a prokinetic agent is indicated; if no positive results occur, then prior to any operative intervention, a trial of injection of botulinum toxin into the pyloric muscle to cause relaxation should be tried, especially if the stomach is dilated or has a thickened wall. If these pharmacologic approaches provide good relief, a pyloroplasty done laparoscopically should be entertained with the thought that the vagotomy had its effects on the distal and not the proximal stomach.

If neither of these pharmacologic trials have any noticeable defect (which is most common), then the discussion with the patient and the patient's medical physician becomes difficult, because the suggested operative procedure will be to create the anatomy of a near-total gastrectomy by performing a nonbariatric Roux-en-Y gastric bypass or maybe better called a "stomach bypass" (so that it is not confused with a bariatric operation by the patient's insurance carrier). This operation should minimize the volume of the proximal gastric pouch to less than 20 mL; resection of the rest of the stomach is not necessary (Fig. 90.5A), because it will be functionally bypassed, and ingested food will not enter the dysfunctional stomach. Results with this approach, though limited, have been disappointing unfortunately with satisfactory results in only about 20% to 40% of patients; the remainder of patients have required enteral feeding or parenteral feeding if the vagotomy also affects the ability to tolerate enteral feeding.

Early Postoperative Delayed Gastric Emptying

Prolonged delay in gastric emptying in the early postoperative period is a well-known, transient complication of gastrectomy with and without vagotomy, and although the vagotomy (and probably some form of dysmotility) plays a role in this transient dysmotility, most patients recover in 2 to 6 weeks; persistence of this "gastroparesis" is very unusual. Interestingly, the patients who develop later the chronic form of postgastrectomy/postvagotomy gastroparesis described above, do so months to years after the vagotomy and not early postoperatively. Treatment of this form of early postoperative delayed gastric emptying is supportive and expectant, because the delayed gastric emptying is expected to resolve completely. A trial of erythromycin and/or

metoclopramide can be tried, but no operative intervention should be undertaken. A relatively common clinical situation of delayed gastric emptying postoperatively is in patients who have undergone operation for chronic (mechanical) gastric outlet obstruction from stricture or cancer who have a markedly dilated stomach and a thickened wall; when treating these patients with either a pyloroplasty, a gastrojejunostomy, or a distal gastrectomy, some consideration should be given to placing a tube gastrostomy, such that should delayed gastric emptying occur, as it does in 5% to 10% of patients with chronic mechanical obstruction, they will not need a long, indwelling nasogastric tube.

Reactive Hypoglycemia or Noninsulinoma Pancreatogenous Hypoglycemia Syndrome (NIPHS)

Symptomatology

Reactive hypoglycemia, often called inappropriately "late dumping," involves the development of true hypoglycemia (blood glucose concentrations of less than 40 mg/dL) that occurs usually 90 to 150 minutes postprandially. The symptoms are similar to those of dumping but are much more pronounced and are those primarily of hypoglycemia—tachycardia, palpitations, diaphoresis, and in severe cases even seizures, syncope, and seriously altered mentation, even suggestive of a psychiatric condition. These symptoms mimic all those of an insulinoma and can be quite incapacitating by affecting job performance, safe driving, and social interactions. Many patients, just as those with an insulinoma, have learned to reverse the symptoms with an oral load of sugar when they can anticipate the onset of the symptom, but more worrisome are those in whom there are no real premonitory signs or symptoms.

To the generation of classic GI surgeons who experienced the postgastrectomy/postvagotomy disorders of in the era of duodenal ulcer surgery, this disorder of "reactive hypoglycemia" was well known, albeit rare. Currently, this syndrome has resurfaced again with the now very prevalent use of the Roux-en-Y gastric bypass procedure for morbid obesity; the presence of hypoglycemia about 2 to 3 hours after eating has been noticed increasingly in this population and has been termed the noninsulinoma pancreatogenous hypoglycemia syndrome or NIPHS as a "new" entity. Actually, NIPHS and reactive hypoglycemia are the same entity with the same symptoms, both related to early entry of caloric-dense carbohydrates into the proximal small intestine in conjunction with a

concomitant bypass of the duodenum (Fig. 90.5A) (see Etiopathogenesis below).

Etiopathogenesis

Reactive hypoglycemia can occur secondary to the rapid emptying of sugar into the jejunum associated with bypass of ingested content from the duodenum. Entry of sugars into the jejunum leads to rapid absorption of glucose and a very rapid increase in blood glucose concentration usually 30 to 60 minutes postprandially, often although not always associated with symptoms of dumping. This rapid increase in blood glucose concentration leads to a resultant, uncontrolled release of insulin from the pancreas which then leads to a rapid "reactive" decrease in blood glucose concentration to values less than 40 mg/dL (the lower limit of normal in women; the value in men is less than 60 mg/dL). There is one important difference in these patients compared to those with only dumping—that is, the duodenal bypass. Diversion of luminal sugars from the duodenum prevents a poorly understood "brake-like" function on insulin release when ingested foods pass through the duodenum. Whether this inhibition is mediated by the duodenum (the foregut theory) or by the distal small intestine (the hindgut theory) remains highly debated currently. Supporters of the foregut theory suggest that there are receptors that act via pancreatoduodenal neural pathways or hormones released by the duodenal mucosa that suppress any "overshoot" in insulin release secondary to the acute, early, postprandial hyperglycemia; in contrast, supporters of the hindgut theory implicate hormones released from the distal gut that prevent the "brake" on insulin secretion from the pancreas in response to the hyperglycemia. Several groups have studied patients with NIPHS and have suggested the presence of a reactive beta-cell hyperplasia as causative of this condition based on the pathology of the resected pancreas. Definitive pathologic confirmation of this type of a nesidioblastosis, however, is not yet overwhelmingly convincing. The concept of a hyperplasia of beta cells is a very attractive one, because the onset of NIPHS usually occurs months to several years after the Roux-en-Y gastric bypass and not immediately or early postoperatively and resolves with operative intervention (see below) which also takes several months to occur fully; this condition requires chronic duodenal diversion but for unknown reasons does not occur in everyone undergoing a Roux-en-Y gastric bypass, thus suggesting some underlying predisposition. Indeed, local intra-arterial infusions of agents known to stimulate the release of

insulin have suggested an abnormal response with augmented insulin release, suggestive of the loss of the normal “break” on insulin release in response to hyperglycemia.

Diagnosis

The diagnosis of reactive hypoglycemia (or in the bariatric patient with NIPHS) requires first the clinical suspicion in the patient with the appropriate postoperative anatomy (note that the bariatric operations of gastric sleeve [Fig. 90.4B] and laparoscopic adjustable gastric band [Fig. 90.4D] are not associated with NIPHS) and a documented blood glucose concentration of less than 40 mg/dL. The use of the various indirect estimates of blood glucose by, for instance, blood glucose tapes or subcutaneous sensors as used commonly today, lack appropriate sensitivity and specificity; direct measurements of blood glucose concentration by venous blood are necessary. Without documented hypoglycemia, the symptoms of many disorders can be quite similar and nonspecific, because they are quite subjective (palpitations, diaphoresis, changes in cognition) and “supported” by the all-too-common complaint of “hypoglycemia” by many patients; true hypoglycemia is quite uncommon despite the often-voiced concerns by the patient of “hypoglycemia.”

The diagnosis of reactive hypoglycemia requires exclusion of an insulinoma and the other causes of hypoglycemia—medications, surreptitious injection of exogenous insulin, etc. If other causes are excluded, monitoring of blood glucose concentrations and blood insulin levels beginning 30 minutes after the type of meal that stimulates the symptomatology and continuing the blood glucose concentrations at 15-minute intervals for 3 hours can obtain support for the diagnosis. Supportive evidence would include blood glucose concentrations increasing rapidly from 30 to 60 minutes, followed by blood insulin levels increasing rapidly from 60 to 90 minutes, followed by rapidly decreasing blood glucose concentrations, eventually decreasing to less than 40 mg/dL; patient symptoms should parallel these late decreases in blood glucose concentrations.

Treatment

As with dumping, most patients can be controlled with dietary management—avoidance of foods with a high sugar density, limiting liquid ingestion with meals (in an attempt to slow gastric emptying), and a trial of acarbose (an alpha-glucosidase inhibitor) and octreotide, both of

which rarely work successfully. In the rare patient who remains incapacitated, the goal of operative intervention is to restore the flow of ingested content back into the duodenum. This anatomy can be accomplished by taking down the Roux-en-Y gastric bypass and restoring normal gastroduodenal continuity (Fig. 90.4A), by converting the Roux-en-Y anatomy to that of a gastric sleeve (Fig. 90.4B), by placing a gastrostomy into the gastric remnant for delivery of nutrition (not an attractive solution), or by transecting the Roux limb about 60 cm distal to the gastrojejunostomy and diverting the luminal outflow of the Roux limb into the proximal duodenum by a jejunoduodenostomy All these procedures take several months before the full extent of improvement in the hypoglycemia occurs, thus supporting the concept of "reactive nesidioblastosis" and the need for reversion or subsequent reversal of the hyperplasia of the beta cells to a more normal number of insulin-releasing cells. For the more unusual patients who have had a gastrectomy with Roux-en-Y drainage, redirection of the Roux limb into the duodenum is possible and restores the flow of ingested content into the duodenum. The senior author has anecdotal experience with this type of redirection of the drainage of the Roux limb into the proximal duodenum in eight patients recently; the results have been very encouraging with near complete reversal of symptoms in 6 of the 8 patients by 6 to 12 months postoperatively.

Postvagotomy Diarrhea

Postvagotomy diarrhea is extremely uncommon and is largely untreatable. This disorder is solely a diagnosis of exclusion, and when this disorder is present, it proves to be incredibly frustrating to both the patient as well as the treating physician.

Symptomatology

The overwhelming symptom is postprandial watery diarrhea that accompanies each meal and comes on early 15 to 30 minutes after eating. There can be cramping but usually the discomfort is mild. Often, the diarrhea will contain noticeable particulate matter of the food ingested, indicative of very rapid transit. Weight loss can occur but is usually not life-threatening. One of the distinguishing factors is that between meals and during fasting, there is no diarrhea.

Etiopathogenesis

The cause of postvagotomy diarrhea is largely unexplained. The vagus nerves innervate all the organs of the upper gut, including the jejunoileum. Vagal innervation affects gastric motility (see above Postgastrectomy/Postvagotomy Gastroparesis) but also small intestinal motility. Unfortunately, the effects of vagotomy on intestinal motility are not well understood. Hindering our understanding of postvagotomy diarrhea is the fact that vagotomy causes this form of diarrhea in less than 1% of those undergoing total abdominal vagotomy; unlike in gastric motility, there is no good experimental model for the study of small intestinal postvagotomy dysmotility. Vagal innervation, just like sympathetic innervation, also does modulates absorption and secretion from the gut, and postvagotomy diarrhea appears to have an element of both abnormal motility (rapid transit) and abnormal absorption (secretory diarrhea).

Diagnosis

Postvagotomy diarrhea is a true diagnosis of exclusion; there is no pathognomonic sign, symptom, or laboratory test. The diarrhea is neither a pure secretory form, nor steatorrhea, nor a global malabsorption. All other causes of diarrhea need to be excluded: mucosal abnormalities, infection, inflammatory bowel disease, partial small intestinal obstruction, colonic disorders, pharmacologic side effects, etc. A strong suggestion is to get the input of a thoughtful gastroenterologist in the workup. Once all the other potential causes of diarrhea have been excluded, the diagnosis can be entertained in patients with the appropriate clinical scenario who have had an abdominal vagotomy.

Treatment

The real problem is that there is no known effective treatment for this disorder, neither pharmacologic nor operative. In the past, suggestions based solely on anecdotal observations have been made to construct a reversed intestinal segment—no one has had a large enough experience to provide any level of evidence-based support for any operative treatment. Pharmacologic treatments to slow the transit or to decrease “secretion,” even with the use of octreotide, have been unsuccessful. Because this is a type of secretory, rapid transit diarrhea and not a global malabsorption, malnutrition is usually not the problem—rather; volume replacement and social implications of debilitation predominate.

Roux Stasis Syndrome

The term “Roux stasis syndrome” was coined to describe a spectrum of symptoms noted in patients who had undergone some form of gastrectomy with restoration of intestinal continuity via a Roux-en-Y anatomy; the Roux limb was believed initially to be the site of functional obstruction of ingested content. Much of the interest in this “entity” was popularized before our current understanding of the importance and prevalence of postvagotomy/postgastrectomy gastroparesis. Whether the Roux stasis syndrome really exists or is even common remains questionable in the minds of many GI surgeons. If it does exist, the incidence is exceedingly rare, and the majority of patients who are diagnosed with this “syndrome” are much more likely to have gastroparesis.

Symptomatology

Symptoms of the Roux stasis syndrome are vague but dominated by early satiety and vomiting, symptoms that are very similar if not identical to postgastrectomy gastroparesis in patients with a gastric remnant. Support for an etiology that involves abnormal motility in the Roux limb is those patients after a total gastrectomy in whom there is no gastric remnant but who exhibit this clinical scenario. Clinically, the course can be serious with weight loss threatening the ability to maintain adequate nutrition orally. A notable observation is that virtually all, of these patients have had a prior vagotomy as part of their gastrectomy. Interestingly, this syndrome is absent in the hundreds of thousands of patients who have undergone a Roux-en-Y reconstruction (which does not involve a vagotomy) as part of the Roux-en-Y gastric bypass. Challenging the existence of this disorder is the fact that if this syndrome was related solely to the Roux anatomy, we should have seen many patients to date in our bariatric population.

Pathogenesis

The underlying disorder with the Roux stasis syndrome is likely related to a functional obstruction to the flow of ingested food distally through the Roux limb. All studies used to explain the abnormal motility have been done experimentally in the dog model that appears to be a good model of many aspects of intestinal motility in man. Physiologically, small intestinal contractions are oriented aborally (proximal to distal) controlled by the continuity of the myenteric plexus and their rate and direction of propagation are driven by the duodenal “pacemaker” located in the proximal duodenum. When the intestine is transected (as needed for the

creation of a Roux limb), the continuity of the myenteric plexus is disrupted, and multiple sites of new “pacemakers” take over; if the site of this new pacemaker is distal to the site of transection, then this new pacemaker drives the direction of contractions proximally in a pathologic, retrograde direction and distally in a “normal” prograde direction. If this site of the new pacemaker is far enough distally, the retrograde direction of contractions in the proximal Roux limb will “functionally” obstruct the flow of content though this segment of the Roux limb. Most of the time, this new pacemaker is located close to the site of the transection, and flow of intestinal content distally is not disrupted substantially; but if a dominant pacemaker site occurs 15 to 30 cm downstream from the gastro or esophagoenteric anastomosis, a clinically important “functional” obstruction can occur.

Diagnosis

The diagnosis is primarily one of exclusion. Oral radiographic contrast studies and extended upper endoscopy are first used to exclude a mechanical site of obstruction at the gastro or esophagoenteric anastomosis, along the Roux limb itself from adhesions, at the mesocolic defect if the limb was brought retrocolic, or at the site of the enteroenterostomy from adhesions, a mesenteric internal hernia, or a retrograde intussusception. If no mechanical obstruction is found, the differential then becomes one of gastroparesis if there is a sizable gastric remnant (this diagnosis of gastroparesis would be much more likely) or if there is no gastric remnant, then the Roux stasis syndrome would be a possibility. A nuclear medicine radionuclide study using an orally administered radionuclide marker should show the persistent presence of the marker in the Roux limb, suggesting a functional obstruction to distal flow in the Roux limb. Actual documentation of such functional obstruction in a Roux limb, however, is extremely rare and has led many investigators to question the Roux stasis as a distinct entity.

Treatment

Treatment is largely supportive with dietary management aimed at providing oral nutrition in whatever form (liquid, semisolid) that can deliver adequate calories and volume to maintain health, similar to the dietary management of gastroparesis. Supplemental enteric feeding distal to the enteroenterostomy with a tube jejunostomy or via parenteral feeding if enteral feeding is not possible for whatever reason may be necessary.

There is no known effective pharmacologic therapy available, although some investigators have tried erythromycin as a prokinetic agent.

Several surgical options have been discussed, but no one has enough experience with these “theoretic” options, all cases are anecdotal, and there is no evidence-based support for their efficacy. Moreover, gastroparesis must be excluded first, because the treatment is much different—that is, treatment directed at the gastric remnant and not at the Roux limb. If the diagnosis is consistent with the Roux stasis syndrome, then the operative focus is on the Roux limb. If the patient has a large enough gastric remnant (usually greater than 30% of the normal total gastric volume) and no clinically relevant gastroesophageal reflux, the conversion of the Roux anatomy to that of a loop gastrojejunostomy 30 to 40 cm distal to the proximal end of the Roux limb is indicated. If the gastric remnant is small, beware, because conversion of a Roux anatomy to loop drainage of a small gastric remnant may lead to bile reflux esophagitis which itself can be incapacitating, especially if there is an element of gastroparesis. In this situation, a so-called “uncut Roux” anatomy may be entertained, whereby a loop drainage of the remnant is constructed, but the afferent limb of the loop is stapled across but not cut by using two rows of linear staples and supported externally by a small piece of permanent prosthetic material to prevent restitution of luminal continuity (which occurs with time after simple stapling); note that the intestine is not transected (this form of disruption of luminal continuity but without a formal transection of the myenteric plexus does not disrupt of the direction of contractions distal to the site). Distally, a Braun-type of enteroenterostomy, 60 cm distal to the esophago or gastrojejunostomy allows the pancreatobiliary secretions to enter the intestinal lumen distal to the site of gastro or esophagoenterostomy; theoretically this anatomy should maintain the normal direction of contractions in the efferent limb of the loop anastomosis but prevent reflux of bile into the remnant stomach or esophagus. If there is no gastric remnant, then the proximal 20 to 30 cm of the Roux limb can be resected, and the Roux anatomy restored in hopes that the site of the pacemaker will be in the proximal-most aspect of the new Roux limb. Possibly the best theoretic operation involves converting the Roux anatomy into an Omega loop anatomy which should allow both limbs of the Omega anatomy to drain their content into the distal part of the Roux limb. All these operations are theoretically sound, but again, no one has extensive experience with any of them.

Bile Reflux Esophagitis

Much has been written about bile reflux "gastritis" in the past after any operative procedure that destroys the function of the pylorus (pyloroplasty, gastroduodenostomy after antrectomy, loop gastrojejunostomy with or without antrectomy, and esophagogastrectomy with concomitant pyloroplasty or pyloromyotomy). The cardinal symptoms were pain and vomiting of bile with pooling of bile in the stomach on endoscopy. But virtually all these symptomatic patients had undergone a previous vagotomy as part of their primary operative treatment, and the coexistent presence of disturbed gastric emptying, that is, gastroparesis, and the "expected" esophagitis was often not appreciated for its importance. The following discussion includes bile reflux "esophagitis" and not "gastritis" as part of the spectrum of a postgastrectomy/postvagotomy disorder because of the authors belief/bias that the entity of clinically important bile reflux gastritis does not exist.

Symptomatology

The overwhelming symptom of bile esophagitis is the vomiting of bile and usually but not always substernal or epigastric discomfort. The bilious vomiting and substernal discomfort are most prominent between meals when the vomitus can be relatively pure "bile" without food particles. Early satiety and many of the other symptoms of gastroparesis can coexist as well. Symptoms are especially worse when the gastric remnant, if present, is small and if the patient had a history pregastrectomy of symptomatic gastroesophageal reflux. As would be expected, the syndrome of bile reflux esophagitis does not occur in patients in whom gastroenteric drainage was restored with a Roux-en-Y anatomy after the gastrectomy, unless the Roux limb was made too short—less than 50 to 60 cm. (Note the prior classic recommendation of a 40-cm Roux limb length is too short; reflux of biliary markers into the gastric remnant occur in 60% of patients with a 40-cm Roux limb.)

Etiopathogenesis

The etiology of bile reflux esophagitis is a combination of functional disruption of an intact pylorus, an element of gastroparesis secondary to the concomitant planned or inadvertent vagotomy, and gastroesophageal reflux. One exception to the need for vagotomy is that of a loop gastrojejunostomy in patients with pre-existent, severe gastroesophageal reflux or those in whom a loop gastrojejunostomy has been created

inappropriately to a very small volume gastric remnant (subtotal gastrectomy). Disruption of pyloric function leads to free reflux of pancreatobiliary secretions into the stomach or gastric remnant; yes, there is an associated "gastritis" of the gastric mucosa, but this inflammation occurs also in asymptomatic patients secondary to the irritant effect of the bile. The pathogenesis of the symptoms (bilious vomiting, substernal/epigastric discomfort) is the concomitant associated reflux of the bile into the esophagus and the irritant effects of the bile on the esophageal epithelium, not the gastric mucosa. In normal physiology, reflux of some duodenal content into the stomach is normal postprandially, and although this refluxed content does contain some bile as well, normal gastric motility empties this back into the duodenum as with liquid emptying; in between meals, little to no pooling of bile occurs in the gastric lumen. In gastroparesis, however, such refluxate is not emptied rapidly, pools in the stomach, and if there is an incompetent LES, reflux of this pooled biliary content will reach the esophageal epithelium.

Interestingly, not all patients with postgastrectomy/postvagotomy gastroparesis have concomitant bile reflux esophagitis if they have a competent LES. As suggested above, there are several situations where fully symptomatic reflux esophagitis occurs in the absence of any gastroparesis. One such situation occurs in patients with a loop gastrojejunostomy without a concomitant vagotomy in whom free reflux of bile occurs into the stomach, but in whom the LES is incompetent, thereby allowing reflux of the intragastric refluxate (bile) from the jejunum into the esophagus. One of the early bariatric operations called a loop gastric bypass, which has been redesigned a bit recently and dubbed the "mini gastric bypass," involved partitioning the stomach into a very small pouch of proximal stomach that was then drained by a loop gastrojejunostomy.

Diagnosis

Most often, the diagnosis should be immediately obvious by the presence of bilious vomiting in between meals. One key to the diagnosis is the presence of esophagitis on endoscopy and usually with pooling of bile in the gastric lumen or on occasion even in the distal esophagus. If substantial pooling of bile in the stomach or gastric remnant is evident, especially if solid mater is also present, one must also suspect concomitant gastroparesis, because the stomach or a gastric remnant with normal motor function should have minimal volume and certainly no solid matter.

Treatment

The goal of treatment is twofold: first to totally divert bile from reaching the esophageal lumen with a Roux-like limb, and second, if symptomatic gastroparesis coexists, to treat the gastroparesis as well. In the patients without postvagotomy gastroparesis, simple conversion of the loop drainage to a Roux-like drainage should suffice; note, just a simple Braun-like enteroenterostomy between the afferent and the more distal aspect of the efferent limb (60 cm downstream from the gastrojejunostomy) is not reliable enough to divert the bile from the afferent limb across the enteroenterostomy. Care should be taken to insure that there is no gastroparesis; the presence of solid matter in the stomach/gastric remnant should heighten ones concern about gastroparesis.

In patients with a history of vagotomy and suspected gastroparesis, simple conversion to a Roux anatomy will divert the bile and relieve the esophagitis, but as described above, transection of the jejunum to create the Roux limb will disrupt myenteric continuity which may further exacerbate the delayed gastric emptying. Roux-en-Y drainage of the stomach tends to slow gastric emptying to some extent. In these patients with concomitant gastroparesis, consideration needs to be given to markedly decreasing the volume of the gastric remnant, even to that of a completion near-total gastrectomy.

An especially difficult situation involves patients with symptomatic reflux esophagitis after an esophagogastrectomy with an intrathoracic esophagogastrostomy. All these patients have had an obligate vagotomy, have a conduit in a low pressure area (intrathoracic), have had a pyloroplasty or pyloromyotomy, and usually have some element of delayed gastric emptying. If their sole symptoms are those of bile reflux between meals without vomiting and without solid mater in the gastric remnant or conduit, the biliary diversion can be accomplished by a classic “duodenal switch”; this procedure involves transection of the proximal duodenum about 4 cm distal to the pylorus but proximal to the ampulla of Vater and the minor papilla, closure of the distal duodenal stump, and creation of a Roux limb of jejunum that is then sewn to the proximal stump of the duodenum. In contrast, for those with bile reflux and gastroparesis, the problem is much more complicated (see above Postgastrectomy Gastroparesis—Special Situations).

Metabolic

Because bariatric surgery is so common currently, much of this discussion will center on metabolic problems associated with bariatric surgery, but gastrectomies will also be associated with many similar problems. Roux-en-Y gastric bypass intentionally creates a restrictive physiology with a very small volume, gastric reservoir for ingested food and a state of selective malabsorptive by bypassing the proximal small bowel (especially the duodenum). Because of this specific area of the gut bypassed, micronutrient deficiencies and anemia can present in the postoperative period. Iron-deficiency anemia is common along with specific deficiencies involving vitamins B_1, A, K, D, and E and copper.

The stomach serves multiple physiologic functions other than just a reservoir for ingested food. While the acid/peptic environment aids digestion, it also provides an acid environment for oxidation of iron as well as bactericidal barrier to certain organisms, for example, tuberculosis bacillus, and others as well. This section will concentrate on the role of gastric secretions, specifically acid and R-factor/intrinsic factor, in mediating the absorption of Fe^{3+}, Ca^{2+}, and vitamin B_{12} from a metabolic aspect.

In addition, after a gastrectomy with duodenal bypass (gastrojejunostomy, esophagojejunostomy), several aspect of maldigestion can also occur. The complications that arise from the operative re-routing of the flow of ingested foods are important to share with the patient preoperatively so that they not only understand the risks and benefits but also the long-standing sequelae that they will face and need to protect against.

Iron Deficiency Anemia

Symptomatology

Patients will present with symptoms of anemia: fatigue (lack of energy), headaches, shortness of breath, or paleness and coolness to the skin. In severe cases, the patient may complain of dizziness on standing. Interestingly, pica for ice is uncommon in this population. Women in the childbearing age who are still menstruating are much more susceptible to this form of iron-deficiency anemia in the postbariatric surgery state.

Etiopathogenesis

The development of anemia is multifactorial after esophagogastric surgery. After Roux-en-Y gastric bypass, there is malabsorptive state despite usual

supplementation of multivitamins, iron, and micronutrients. Iron absorption in obese patients is impaired in part due to the inflammatory state that exists and contributes to the poor absorption of iron. After Roux-en-Y gastric bypass, this malabsorption is deranged further. With creation of the small gastric pouch, the amount of acid secretion is markedly decreased or is absent. This lack of acid is very important, because iron in the diet is ingested as the ferrous ion (Fe^{2+}) but is oxidized by the acid in the stomach to the ferric ion (Fe^{3+}) which is the preferred ion for absorption primarily in the duodenum. After a Roux-en-Y gastric bypass or after a gastrectomy, the acid in the stomach is decreased, thereby, inhibiting the oxidation of the ferrous ion to the ferric ion and the bypassing of the duodenum, further limits absorption of iron. Even with supplemental oral iron (usually given as the ferrous ion [$FeSO_2$]) the patient may have persistent deficiency or will be unresponsive response to this conventional form of therapy.

Diagnosis

The pan micronutrient deficiency especially of B_{12} and copper levels may also contribute to anemia postoperatively; evaluation should determine whether or not it is driven solely by iron deficiency. Evaluation of iron stores, ferritin levels, and other compounding pathologies should be evaluated. One must always remember that the presence of an iron-deficiency anemia in these patients needs also to be evaluated for blood loss from the gut with a stool examination for blood, and should not be assumed to be just related to iron malabsorption, even in the younger female patients.

Treatment

Treatment is to correct the iron storage. First, the most common source of iron deficiency is blood loss from the gut. A stool sample should be checked for occult blood, and if present, colonoscopy and/or other diagnostic testing are mandatory. If the patient is unresponsive to oral therapy, several factors should be considered. Excluding other hematologic conditions will be necessary. Once you are confident that the iron deficiency is related to iron malabsorption, then oral supplementation is indicated. The usual medication is an iron supplement, but the addition of a relative acid environment may help; some of the oral iron supplements have an acidic pH. In some menstruating patients with heavy menses,

especially the younger women after Roux-en-Y gastric bypass, intravenous iron may be necessary on a 6 monthly or yearly basis until the onset of menopause or until the menorrhagia is controlled.

Vitamin B_{12} Anemia

Vitamin B_{12} (Cyanocobalamin) deficiency is the most common deficiency observed after gastric bypass or after a near-total or total gastrectomy. The formation of red blood cells and especially white blood cells are dependent heavily on B_{12}.

Symptomatology

Symptoms are related to the ensuing anemia that includes fatigue or a feeling of shortness of breath. Patients may complain of GI complains such as constipation. Memory loss or depression and unusual neurologic complaints, such as numbness and tingling or even disordered thinking mimicking psychosis, are late, albeit unusual, complications. The patient's examination may show signs of anemia, such as paleness to the skin and mucosal membranes and a smooth tongue.

Etiopathogenesis

In normal physiology, the absorption of vitamin B_{12} occurs initially via the oral mucosa but only to a minor extent and only as free cyanocobalamin. The majority of the absorption, however, is due ultimately to the binding of B_{12} with intrinsic factor—the combination of which is absorbed eventually in the ileum. Absorption, however, is much more complicated. For normal absorption of orally ingested vitamin B_{12}, an acid environment as well as the presence of R-factor and intrinsic factor produced by the parietal cells of the stomach is necessary.

Orally ingested vitamin B_{12} in foodstuffs occurs in the form of pterylcyanocobalamin; for absorption to occur, the pteryl group first need to be cleaved from the cyanocobalamin; this step requires acid. Then, the free cyanocobalamin binds to R-factor in the stomach after which the complex of R-factor/cyanocobalamin is emptied into the duodenum, where R-factor is cleaved off the cyanocobalamin, and the cyanocobalamin then binds to intrinsic factor. It is then this cyanocobalamin/intrinsic factor complex that is recognized by the ileal mucosa and transported by a specific mucosal transporter. If there is achlorhydria, as occurs with pernicious anemia, but also after Roux-en-Y gastric bypass and high

gastrectomies, this chemical process of cleaving off the pteryl groups does not occur, such that the binding of the pterylcyanocobalamin to intrinsic factor cannot occur. Also, if the stomach is removed, neither R-factor nor intrinsic factor is available to blind with vitamin B_{12} leading to a deficient state. If the duodenum is bypassed, then the cleavage of the R-factor/cyanocobalamin complex is disrupted in part.

Interestingly, without intrinsic factor, the intestine can absorb about 1% of ingested, free vitamin B_{12} (cyanocobalamin), that so with adequate daily supplementation postoperatively, the risk of anemia can be prevented. When the stomach and duodenum have been bypassed, there will be enough intrinsic factor secreted by the stomach into the duodenum that will reach the jejunum and mix with the ingested free cyanocobalamin that relatively normal absorption of the free vitamin B_{12} occurs. This type of physiology can be exploited after Roux-en-Y gastric bypass or the subtotal gastrectomies that bypass the duodenum by supplementing the diet with daily free vitamin B_{12}.

Diagnosis

Vitamin B_{12} levels should be checked periodically, and if symptoms arise, they should be treated. One caveat should be mentioned. Normally the liver has about 1 year's worth of vitamin B_{12} stored; this really is important, because the symptoms of vitamin B_{12} deficiency only occur after one or more years postoperatively, and all too often, the diagnosis is not entertained or is made only late in the course of the anemia.

Treatment

The recommended daily allowance for vitamin B_{12} is 2 μg. Replacement can occur via oral or injectable means. Injectable free vitamin B_{12} is available as a monthly subcutaneous injection of 1,000 μg. This is the preferred method by the authors; oral forms of free vitamin B_{12} or preparations able to be administered nasally are available, but they are much more costly and need to be administered daily. Certain insurance providers reject requests to pay for these oral or nasal preparations. Interestingly, the monthly injections may allow for a greater rate of compliance when compared to the need for daily oral supplementation. Therefore, after a gastric bypass or near-total gastrectomy, routine supplementation with vitamin B_{12} should be encouraged strongly.

Maldigestion

After a total gastrectomy, patients tend to suffer with lack of weight gain and often lose up to 10% to 15% of their normal body weight. Indeed, some patients, especially very thin women, may present with malnutrition and signs and symptoms of maldigestion. Loss of the natural volume reservoir of the stomach leads to inadequate mixing of digestive enzymes and even altered physiologic responses of important digestive enzymes. Bypass of the duodenum, where it is estimated that 80% of the entire absorption of nutrients occurs, combined with the relatively rapid transit through the gastrointestinal system, can lead to mild or severe maldigestion secondary to lack of normal mixing of pancreatobiliary secretions with ingested foods.

Symptomatology

Patients on directed questioning may report having experienced foul smelling, nonformed stools (steatorrhea). These stools are rich in fats and so may float in the toilet. The malabsorption of fat leads to abdominal discomfort, increased gas production with subsequent bloating, and feelings of urgency to stool. As a consequence, the patient will have weight loss and difficulty maintaining a healthy weight.

Etiopathogenesis

The pathogenesis of malabsorption is multifactorial. The resultant discoordination of the mixing of ingested food and digestive enzymes in the stomach and jejunum plays a major role in this maldigestion. In addition, the loss of the reservoir of the stomach leads to rapid emptying of digestive food and juices into the small bowel, where rapid transit may lead to ineffective absorption. Bacterial overgrowth can contribute to maldigestion as bacteria compete with the absorption of fats. Finally, there is a relative pancreatic exocrine insufficiency that occurs that is associated with decreased levels of gastrin and cholecystokinin, combined with a decrease in the later release of other post prandial peptides.

Diagnosis

Numerous studies are available to support the diagnosis of pancreatic insufficiency after a gastrectomy that bypasses the duodenum. We will describe three tests based on samples of stool, duodenal secretions, and a breath test. Using the stool as the specimen, the fecal elastase test can be performed in one of two ways. Sudan staining of the collected stool can be

evaluated for the observed percentage of fat per high-power field, but this test is subjective, not quantitative, and is really just a diagnostic test for gross steatorrhea. A more quantitative study can be performed that measures the amount of the fat collected from the stool when the patient is on a controlled fat diet (usually 100 g a day).

The secretin-cerulein test is an invasive study that requires intubation of the duodenum to collect duodenal contents after hormonal stimulation with secretin and cholecystokinin. The test is the most sensitive and accurate test that measures not only pancreatic function but also gives some insight into biliary function. It has been reported that three months after total gastrectomy, the volume and content of trypsin, chymotrypsin, and amylase in pancreatic secretion were decreased by 76%, 89%, 91%, and 72%, respectively which can be detected by the secretin-cerulein test. Despite being the most accurate, this test is invasive, takes time, and is quite unpleasant for the patient and is rarely if ever performed today except in certain centers. The least invasive test is the ^{13}C-mixed triglyceride breath test, which is able to determine if the bacterial overload is contributing to the maldigestion observed.

Treatment

While there are no randomized controlled trials or consensus on how to treat maldigestion after total gastrectomy, treatment with pancreatic enzymes may resolve or mitigate the symptoms. The effectiveness of treatment with pancreatic replacement can be tracked with resolution of observed symptoms. A titration of pancreatic enzymes may be required. Patients should take enzymes to replicate the normal physiologic response with the dosage split to begin at the start, during, and after a meal. Dosing of the number of tablets taken should reflect the size and fat content of the meal. For example, for small snacks, one to two tablets and for large meals six tablets with two before, two during, and two at the end of the meal is best. Too many times, the amount of replacement enzymes is too small-remember, adults cannot take too many tablets, but they can take too few. Children are different story; the dosage of the time-release tablets in children less than 15 should be controlled carefully, because there is a very small but well-recognized incidence of colonic strictures with too high a dose. Increased federal regulation has moved to restricting unreliable pancreatic replacement products from the market. Currently, only three preparations to replace pancreatic enzymes are available: Creon, Pancreaze, and Zenpep; all are time-release tablets, and many

pancreatologists suggest that the patient empty the granules and take them as the free granules.

EDITOR'S COMMENT

Drs. Reid and Sarr have done an outstanding job discussing postgastrectomy syndromes in the modern era. They breakdown the issues into the older and traditional syndromes that were iatrogenic and associated with gastrectomy for ulcer disease. Today, much of the man-made causes of postgastrectomy syndromes are associated with the rapid rise of obesity in the United States and concomitant increases in the bariatric surgical procedures performed to address this condition.

The authors point out that dumping syndrome is associated with rapid, uncontrolled emptying of fluid from the stomach, gastric remnant or esophagus into the small intestine leading to a neurohormonal response with the release of vasoactive agents that cause symptoms. The symptoms do not have to be diarrhea as the majority of patients do not have significant diarrhea. Not every patient with rapid transit develops symptoms of dumping syndrome and this attests to the adaptability of the enteric nervous system in individual patients. This adaptability may also contribute to the resolution of dumping syndrome symptoms soon after surgery in many patients. In adults today, gastric bypass surgery is the most common cause with the incidence of dumping syndrome as high as 75%. Roux-en-Y gastric bypass with an associated gastrojejunostomy was until recently the most common type of bariatric surgery in the United States and is therefore an important cause of dumping syndrome. Sleeve gastrectomy is now the most commonly performed bariatric surgery in the United States. With the small gastric tube that is created, dumping syndrome is less frequent than following Roux-en-Y gastric bypass and this may be due to the intact pylorus and preservation of nerve innervation along the lesser curvature of the stomach and to the pylorus.

Vagotomy is associated with blunted pyloric relaxation in those patients that have a pylorus and can contribute to dumping syndrome through reduced gastric relaxation in the presence of a meal bolus. Vagotomy also may reduce feedback inhibition pathways that delay gastric emptying once the food bolus reaches the small intestine (Berg P, McCallum R. Dumping syndrome: a review of the current concepts of pathophysiology, diagnosis and treatment. *Dig Dis Sci* 2016;61:11–8). Antrectomy for ulcer disease with vagotomy may induce some symptoms of dumping syndrome in at least one third of patients. However, in only about 10% of patients have the symptoms severe enough to warrant significant lifestyle modifications (Ukleja A. Dumping syndrome: pathophysiology and treatment. *Nutr Clin Pract* 2005;20: 517–25).

Due to the rapid rise of gastroesophageal junction malignancy, esophagogastrectomy is being more frequently performed with the need for

vagotomy for tumor clearance in many patients. Symptoms of gastroparesis are common following this operation. Many surgeons advocate for the performance of a pyloroplasty to assist in emptying of the stomach as absence of pyloric relaxation is problematic following vagotomy in some patients. The benefit of pyloroplasty in this setting remains controversial as it may result in bile reflux with esophagitis due to reflux of duodenal contents. Some patients have significant complaints of repeat episodes of regurgitation or vomiting of bilious fluid following pyloroplasty. Therefore, I have taken the approach of avoiding pyloroplasty in the majority of my patients undergoing esophagastrectomy. Since the vast majority of patients can now undergo a minimally invasive esophagogastrectomy, early ambulation and reduced hospital stay is the norm rather than the exception. With increased mobility, emptying of the gastric conduit improves and pyloroplasty is not necessary. Most patients have only typical and mild symptoms associated with delayed gastric emptying following esophagogastrectomy without pyloroplasty. Studies have shown only a 7% to 10% late onset of symptomatic delayed gastric emptying, and most of such cases can be managed using nonsurgical means. These outcomes compare positively with studies that have evaluated functional results in patients undergoing esophagogastrectomy with pyloroplasty. In the absence of pyloroplasty, botox injection into the pylorus at the time of esophagogastrectomy has been utilized to enhance pyloric relaxation and has been associated with favorable results in retrospective studies. It has the additional benefit of avoiding the potential surgical and physiologic complications of pyloroplasty or pyloromyotomy. It may provide an advantage in the early postoperative period when complications of delayed emptying are most likely to occur (Martin JT, Federico JA, McKelvey AA, et al. Prevention of delayed gastric emptying after esophagectomy: a single center's experience with botulinum toxin. *Ann Thorac Surg* 2009;87(6):1708–13). Similar to others, I have found that late complications of delayed gastric emptying following esophagogastrectomy or proximal gastrectomy occurs in less than 10% of patients and can be managed endoscopically or by minimally invasive pyloroplasty if necessary (Ben-David K, Tuttle R, Kukar M, et al. Minimally invasive esophagectomy utilizing a stapled side-to-side anastomosis is safe in the Western patient population. *Ann Surg Oncol* 2016;23(9):3056–62). In the setting of esophagogastrectomy, prospective randomized trials of pyloroplasty or not, as well as alternative strategies to manage the pylorus, need to be performed to answer the question whether early and late symptoms of gastroparesis are significantly improved with interventions directed at the pylorus.

Following pancreaticoduodenectomy, delayed gastric emptying remains a significant concern resulting in increased hospital time and reduced nutritional status and quality of life. Over 100 years ago, Braun introduced a modified technique of gastrojejunostomy in which an anastomosis between the afferent and efferent limbs of jejunum was performed following gastrectomy. I have

included the use of a Braun jejunojejunostomy in the setting of pancreaticoduodenectomy in over 150 patients. Our initial nonrandomized results in the hands of several surgeons utilizing different treatment algorithms demonstrated a significant reduction in delayed gastric emptying following nonpyloric preserving pancreaticoduodenectomy (Hochwald SN, Grobmyer SR, Hemming AW, et al. Braun enteroenterostomy is associated with reduced delayed gastric emptying and early resumption of oral feeding following pancreaticoduodenectomy. *J Surg Oncol* 2010;101(5):351–5). For the Braun enteroenterostomy to be effective it should be placed approximately 25 cm downstream from the gastrojejunostomy. Since our publication, a single surgeon series of a small number of patients has confirmed the benefit of Braun enteroenterostomy in reducing symptoms of delayed gastric emptying following pancreaticoduodenectomy from 35% to 4.2% (Nikfarjam M, Houli N, Tufail F, et al. Reduction in delayed gastric emptying following non-pylorus preserving pancreaticoduodenectomy by addition of a Braun enteroenterostomy. *JOP* 2012;13(5):488–96). Others have shown Braun enteroenterostomy following laparoscopic gastrectomy with gastrojejunostomy to be associated with similar incidences of gastric residue, remnant gastritis and bile reflux compared to Roux-en-Y reconstruction (Cui LH, Son SY, Shin HJ, et al. Billroth II with braun enteroenterostomy is a good alternative reconstruction to Roux-en-Y gastrojejunostomy in laparoscopic distal gastrectomy. *Gastroenterology Res Pract* 2017;2017:1803851). Furthermore, a meta-analysis of studies which have evaluated Braun enteroenterostomy following pancreaticoduodenectomy has shown in 1,401 patients that the occurrence of delayed gastric emptying was lower in the Braun group and plays an important role in reducing morbidity and length of stay (Huang MQ, Li M, Mao JY, et al. Braun enteroenterostomy reduced delayed gastric emptying: a systematic review and meta-analysis. *Int J Surg* 2015;23:75–81). Future randomized trials will need to clarify the benefit seen in retrospective studies in regard to the use of the Braun enteroenterostomy.

It is clear that the functional and metabolic effects of gastrectomy remain significant on our patients. A careful analysis of patient complaints and appropriate diagnostic tests will help the treating health care worker diagnose and manage this perplexing problem. Unfortunately, available medications to treat gastroparesis and delayed gastric emptying are limited. Metoclopramide is presently the only Food and Drug Administration approved medication for the treatment of gastroparesis. This field is in great need of new treatments such as small molecule drugs that act as motilin receptor or ghrelin agonists or new highly selective histamine receptor agonists that have focused actions on the upper gastrointestinal tract and simultaneously minimal off target side effects.

Steven N. Hochwald

91 Congenital Pyloric Stenosis and Duodenal Obstruction

Hale E. Wills, Alexis D. Smith, and Thomas F. Tracy

Congenital pyloric stenosis and duodenal obstruction are important causes of emesis in infants that can be corrected by surgery. Little has changed in recent years in the surgical principles of management of these conditions. Improved recognition of hypertrophic pyloric stenosis (HPS) by pediatricians and family practitioners along with improved access to ultrasound has led to earlier diagnosis and fewer infants presenting with severe dehydration and metabolic derangements. In fact, it is not uncommon for infants to be referred for ultrasound early in the development of HPS and be found to have borderline measurements of their pylorus and a patent pyloric channel, only to return days to weeks later with complete gastric outlet obstruction. The adoption of a laparoscopic approach has retained the benefits of Ramstedt procedure while offering quicker recovery, reduced pain, improved cosmetic results. Regardless of the surgical approach, this remains one of the most satisfying conditions to treat as a surgeon as it eliminates a potentially life-threatening condition and rapidly returns the child to health and a normal lifespan potential. Congenital duodenal obstruction and malrotation have also seen few changes in evaluation and management recently. The infant with bilious emesis must be evaluated urgently to identify malrotation and volvulus must be treated as a surgical emergency. While the anatomical approaches to malrotation and duodenal obstruction are largely unchanged, the experience with laparoscopic approaches has increased and outcomes have become better defined.

CONGENITAL PYLORIC STENOSIS (HYPERTROPHIC PYLORIC STENOSIS)

Introduction

HPS is the most common surgically correctable cause of nonbilious vomiting in infants. While there have been reports of nonsurgical therapies

in small case series, this condition is most commonly corrected by pyloromyotomy with low morbidity. In the United States, HPS occurs at a rate of 2 to 4 per 1,000 live births, with the highest rates among Whites and Hispanics and significantly lower rates among those of African or Asian ancestry. Infants most often present between 3 and 5 weeks of age, with rare presentations before 2 weeks or after 12 weeks of age. There have been cases reported of fetal diagnosis by ultrasound. Males are affected four to six times as frequently as females. Birth order does not seem to play a strong role as previously thought. An increased incidence has been reported in premature infants born between 28 and 36 weeks gestation, but the onset in these infants seems to correlate with their corrected gestational age so they may present several weeks later after birth compared to term infants. The impact of maternal socioeconomic or health factors is unclear.

The pathophysiology of HPS is hypertrophy of the muscular wall of the pylorus. The resulting thickening and elongation of the muscle with narrowing of the pyloric channel result in gastric outlet obstruction. The natural history is progressive dehydration and weight loss from the inability to absorb fluid and nutrients. There is also a concurrent metabolic derangement from loss of chloride in the emesis leading to alkalosis, early selective renal sodium retention in exchange for potassium loss into the urine in an attempt to retain blood volume, followed by renal potassium retention and proton dumping into the urine to offset critical potassium depletion. The result is hypochloremic, hypokalemic metabolic alkalosis with paradoxical aciduria. Unconjugated hyperbilirubinemia has been reported in 2% to 5% of infants with HPS and is thought to be due to transient dysfunction of bilirubin uridine diphosphate glucuronyl-transferase in the setting of caloric deprivation, dehydration, and decreased hepatic blood flow. Hepatic dysfunction resolves over several weeks after surgical correction of the HPS.

While there is no single unifying etiology for the pyloric hypertrophy, several theories have been proposed. Observation of male preponderance, family clustering, high rates of HPS in children of affected parents, and concordance in monozygotic twins suggest a genetic predisposition. Specific genetic mutations have been described in HPS families that affect nitric oxide synthase, smooth muscle cation channels, or by pathways that are not yet clear. Discordant rates of HPS in dizygotic twins and within affected families suggest the effect of environmental factors. Infant

exposure to erythromycin, hypergastrinemia, sleeping position, type of feed, and maternal smoking have all been implicated. The reported success of atropine, an anticholinergic agent with strong antimuscarinic activity, in treating HPS in small series suggests the role of acetylcholine and muscarinic receptors in the smooth muscle of the pylorus. Whatever the mechanism, it must take into account that HPS usually occurs several weeks after birth and is transient, even without myotomy.

Clinical Presentation

The diagnosis of pyloric stenosis can be made by history and physical examination. The typical presentation is an otherwise healthy infant with nonbilious emesis that has become progressively more frequent and forceful (“projectile”) over several days or weeks. Some have blood tinged emesis from gastritis. Many infants will have been evaluated for intolerance of feeds, food allergy, and gastric reflux and have failed to improve with formula changes or trial of acid suppressing medication. There is often oliguria. In advanced cases, weight loss occurs that may be profound. The physical examination should search for signs of dehydration and palpation of an epigastric mass (the “olive”). If an epigastric mass is palpated, no further imaging is required. Decompression of the stomach with a nasogastric tube may aid the physical examination, but gastric decompression should not be continued preoperatively as that would only worsen fluid and chloride losses. Assessment of serum electrolytes is essential to gauge the degree of alkalosis.

In those patients who do not have a discrete epigastric mass, ultrasound is the first test of choice. While there is some variability in the measurements reported in the literature, a combination of a pyloric wall thickness greater than 3 mm with channel length greater than 15 mm and limited fluid passage through the pyloric channel has a reported sensitivity and specificity of nearly 100%. In the case of an equivocal ultrasound or any concern for bilious emesis, upper gastrointestinal (UGI) series is an appropriate test. The findings of pyloric stenosis on UGI include “shoulders” created by the hypertrophied pyloric muscle bulging into the antrum, a long pyloric channel, and the “string sign” or “double track” sign from contrast in the narrow pyloric channel. There must be some contrast seen in the duodenal bulb for an adequate study to confirm the length of the pylorus. In the event that pyloric stenosis is ruled out, the UGI may show other causes of obstruction like a duodenal web or malrotation.

It must be remembered that surgical correction of pyloric stenosis is not an emergency. It is imperative that the patient's metabolic abnormalities be corrected prior to administering a general anesthetic. The degree of dehydration and metabolic alkalosis should be assessed by clinical and laboratory examination. Fluid and electrolyte repletion should begin a solution of D5/0.45NS without potassium at 150 mL/kg/day until and titrated until the infant is making urine. Once urine output is established, KCl should be added at 20 Eq/L. Two to three normal saline boluses of 20 mL/kg may be given in the severely dehydrated patient. General anesthesia should not be considered until the sodium bicarbonate is less than 30 mEq/L, chloride is over 90 mEq/L, and urine output is 1 mL/kg/hr, which may take several days in some cases. Failure to correct the metabolic alkalosis preoperatively may lead to prolonged apnea after general anesthesia.

OPERATIVE TECHNIQUE

Open

Traditionally, the abdomen is entered through a 2- to 3-cm muscle-splitting right upper quadrant incision midway between the umbilicus and xiphoid. More recently, a supraumbilical skin incision with midline fascial incision has become popular with similar results and potentially better cosmesis. The liver edge is retracted cephalad and the stomach is grasped and the greater curve delivered. With gentle rightward then leftward traction, the pylorus is delivered. The hypertrophied pylorus is easily identified by its firm, rubbery texture compared to the adjacent normal stomach and duodenum. The pylorus is stabilized between the index finger and thumb of the nondominant hand. The serosa is scored in an avascular line beginning distally in line with the pyloric vein and extending onto the stomach beyond the proximal extent of the hypertrophied muscle (Fig. 91.1). The muscle is then split with the back of the scalpel handle down to the level of the submucosa. The myotomy is extended toward the duodenum and stomach with a Benson spreader or a small clamp. Care must be taken to avoid placing traction on the submucosa as this may cause a perforation into the pyloric channel, particularly at the duodenal end. The submucosa should bulge into the incision. When the pyloromyotomy is adequate, the superior and inferior edges of the pyloromyotomy move independently.

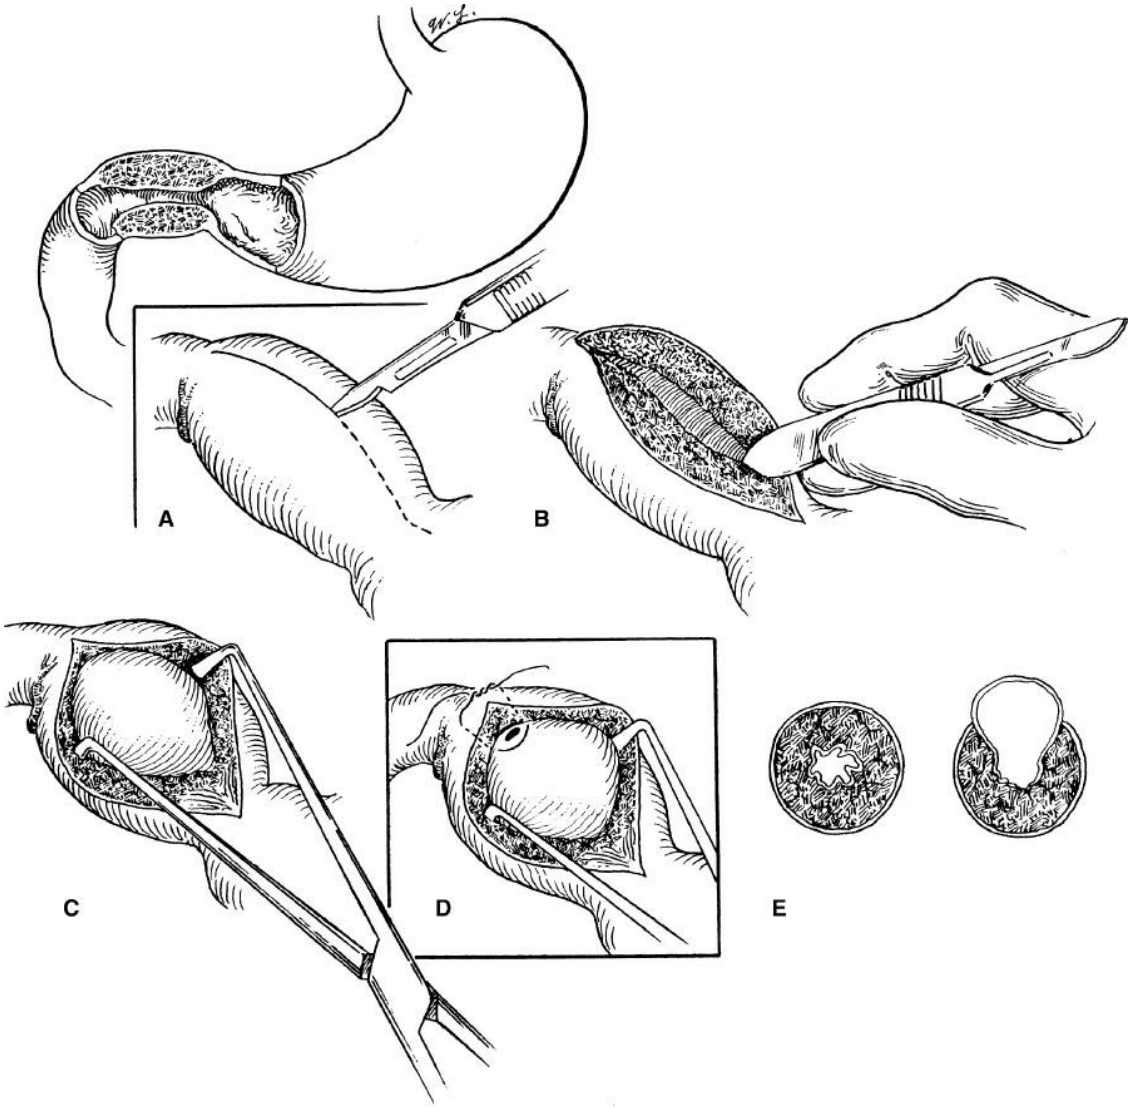

Figure 91.1. Pyloromyotomy. **A.** The superficial serosal incision is begun on the duodenal end of the hypertrophied pylorus and carried onto the stomach. **B.** The scalpel handle divides the fibers. Note asymmetry of upper and lower muscle, indicating a complete myotomy at the duodenal end. **C.** The pyloric spreader further mobilizes the muscle. **D.** A perforation is closed with a horizontal mattress suture. **E.** The completed myotomy shown in cross-section with a “bulging” pyloric mucosa.

A systematic search for mucosal perforation is made by gently milking the duodenum and antrum and looking for air bubbles, bile, or gastric contents. There is usually some bleeding from the cut edge of the serosa and muscle due to venous congestion of the pylorus being delivered through a small incision. This will stop spontaneously once the pylorus is returned to the abdomen. The abdominal incision is closed in layers with absorbable suture.

If a perforation is identified, a single horizontal mattress suture that slides the pyloric mucosa into the duodenum may be sufficient. An omental patch akin to the Graham patch may be added. Alternately, the myotomy can be closed, the pylorus rotated 180 degrees, and a new myotomy performed.

Laparoscopic

After induction of general endotracheal anesthesia, the patient is turned 90 degrees and positioned so the surgeon is standing at the patient's feet (Fig. 91.2). In younger patients, a fine hemostat is used to bluntly enter into the peritoneum through the umbilical stalk, otherwise an infraumbilical incision will suffice. A 3-mm cannula is then placed under direct vision, and pneumoperitoneum of 6 to 8 mm Hg is established. Under camera visualization, a stab incision is made in the right upper quadrant with a No. 11 blade and a 3-mm laparoscopic grasper is passed directly through the abdominal wall without a cannula. In the same fashion, a stab incision is made in the left upper quadrant through which a Bovie electrocautery blade with a protected tip is directly inserted.

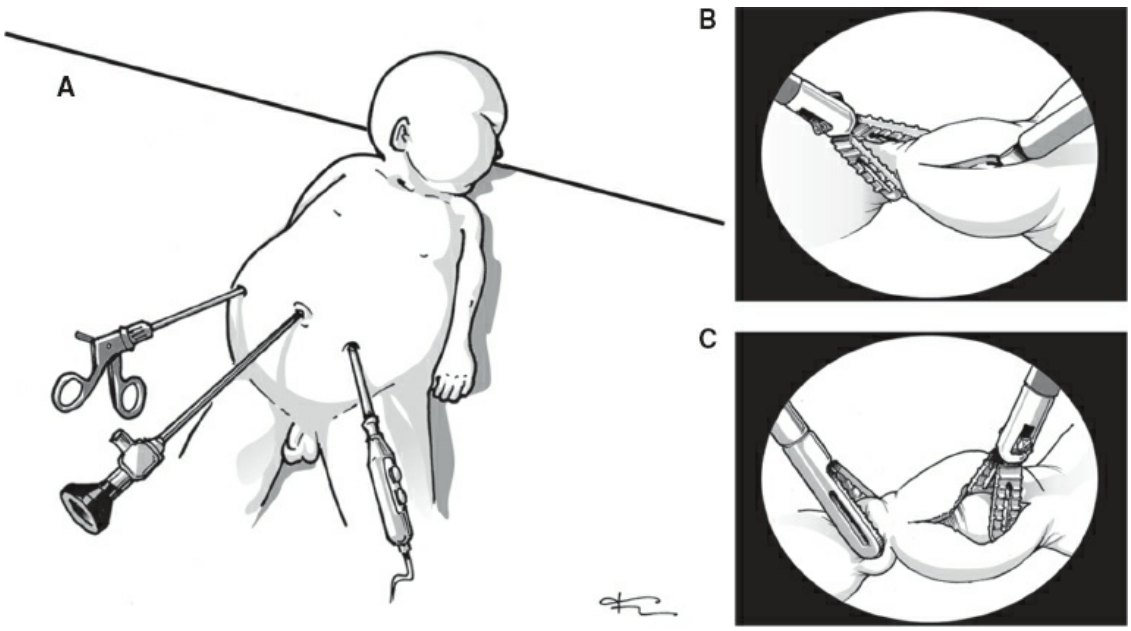

Figure 91.2. A. The patient is placed at right angles to the operating table with the surgeon at the patient's feet. The camera and instruments are placed as shown. **B.** The serosa over the pylorus is divided with Bovie electrocautery, beginning at the pyloric vein and extending just on to the antrum. After the cautery has cooled, the tip is used to crack the hypertrophied muscle at its thickest point by gently inserting the blade into the muscle and

rotating the blade 90 degrees. **C.** Beginning where the muscle was cracked, the muscular layer is spread until the submucosa is visible. We find it easiest to spread toward the stomach first, then toward the duodenum. Care is taken to spread only the muscle and to avoid spreading on the submucosa.

The duodenum is grasped just distal to the pylorus with the left hand and rotated out from under the edge of the liver. The serosa over the pylorus is divided with Bovie electrocautery, beginning at the duodenum and extending just on to the antrum. After the cautery has cooled, the tip is used to crack the hypertrophied muscle at its thickest point by gently inserting the blade into the muscle and rotating the blade 90 degrees. The cautery is removed and a laparoscopic pyloric spreader is introduced through the same incision. Beginning where the muscle was cracked, the muscular layer is spread until the submucosa is visible. We find it easiest to spread toward the stomach first, then toward the duodenum. Care is taken to spread only the muscle and to avoid spreading on the submucosa.

Adequacy of the extent of the pyloromyotomy is assessed by grasping the cut edges of the serosa at the middle of the incision and moving them in opposite directions. The edges should move independently from one another. With the duodenum obstructed distally by the grasper, 30 mL of air is insufflated through an orogastric tube to check for mucosal perforation. The fascia at the umbilical incision is closed with a mid-acting absorbable suture. The stab incisions are closed with skin glue.

If a perforation is identified, it may be repaired in a similar fashion to the open procedure. This may be accomplished laparoscopically or with conversion to an open approach depending on the laparoscopic skills of the surgeon.

OPERATIVE PITFALLS AND COMPLICATIONS

Regardless of the surgical approach, complications after pyloromyotomy should be infrequent. Postoperative vomiting is common and typically thought to be due to discoordinated gastric contractions resulting from the preoperative obstruction or transient gastroparesis. Gastroparesis generally resolves in 12 to 24 hours and most vomiting resolves in 48 to 72 hours. Perforation typically occurs at the duodenal end of the myotomy where the mucosa may be thinned out over the shoulder of the pyloric muscle. Concern for missed perforation should prompt evaluation by contrast study

or operative exploration. Inadequate myotomy may be present in patients with persistent postoperative emesis and usually occurs when the myotomy is not carried sufficiently onto the stomach. A contrast study may show a persistently narrowed pyloric channel, whereas ultrasound will continue to show a hypertrophied muscle for several weeks and may not demonstrate an inadequate myotomy. The preoperative metabolic alkalosis and immature brainstem put HPS patients at risk of apnea and delayed extubation. Other reported complications include wound infection and fascial dehiscence that can be minimized with attention to meticulous technique.

POSTOPERATIVE CARE

Postoperatively, the infant is kept with the head of bed elevated 30 degrees with cardiac and apnea monitoring. We initiate feeds after 6 hours with a half an ounce of balanced electrolyte solution, then convert to full breast milk or formula for subsequent feeds and advance by half an ounce every feed to a goal two ounces. Most infants can be advanced to goal in 24 hours and be ready for discharge when they have completed an adequate period of apnea monitoring. Both retrospective reviews and prospective randomized trials have compared early versus late initiation of feeds, and staged versus *ad libitum* feeding regimens. Late and staged feeding regimens result in fewer patients with emesis and fewer episodes of emesis per patient, whereas early and *ad libitum* feeds decrease the length of hospital stay despite correlation with more emesis. The choice of regimen is based on surgeon's preference and local practice.

DUODENAL OBSTRUCTION

Introduction: Intrinsic Versus Extrinsic Duodenal Obstruction

Congenital duodenal obstruction is a relatively common problem encountered in pediatric surgical practice with an incidence of 1 in 5,000 live births and accounts for approximately half of all neonatal intestinal obstructions. An understanding of the various forms of congenital duodenal obstruction and associated anomalies is essential to successful surgical outcomes. Congenital duodenal obstruction may be intrinsic to the duodenal wall, extrinsic due to compression of an anatomically normal duodenum, or a combination of both; and may be complete (duodenal atresia) or partial (duodenal stenosis). In *intrinsic* obstructions, there is a

developmental abnormality of the duodenal wall with or without mural continuity. Complete duodenal atresia accounts for 50% of all small intestinal atresias. Partial or incomplete intrinsic obstructions always have mural continuity and an intraluminal mucosal diaphragm or web. “Windsock” deformity refers to elongation of the intraluminal diaphragm in which the site of attachment of the web is proximal to the apparent level of obstruction as indicated by bowel caliber change. Congenital *extrinsic* obstruction of the duodenum can occur due to a number of different etiologies, including intestinal malrotation with Ladd bands or volvulus, preduodenal portal vein, annular pancreas, cysts or pseudocysts of the pancreas and biliary tree, or gastroduodenal duplications. Each of these anomalies may occur in combination with an intrinsic duodenal obstruction. Annular pancreas, encircling of the duodenum with pancreatic tissue contiguous with the head of the pancreas, is almost invariably associated with an intrinsic duodenal obstruction.

Diagnosis of congenital duodenal obstruction most often occurs with prenatal imaging and is confirmed clinically early in the neonatal period. Even in the setting of incomplete obstruction, the majority of patients present in the first year of life, while some presenting later in childhood or even adulthood. Improvements in prenatal diagnosis, refined surgical techniques, and advancements in neonatal intensive care have resulted in marked improvement in early perioperative morbidity and mortality. Late complications occur in approximately 10% to 15% of patients and highlight the need for long-term follow-up into adulthood to address these late occurrences. Malrotation of the intestines is another important cause of duodenal obstruction because of its attendant risk of midgut volvulus and intestinal ischemia. Malrotation can present at any age including adulthood, but most commonly presents in the first month of life.

Pathophysiology

The widely accepted embryopathologic event leading to intrinsic duodenal obstruction is failure of recanalization of the developing duodenal lumen early in gestation. The solid core stage of duodenal development is followed by vacuolization in the 8th to 10th week. Failure of coalescence of vacuoles causes failure to recanalize, and a subsequent complete or partial duodenal obstruction results. This is in contrast to atresia of the jejunum and ileum, which occur at later stages of development, are infrequently associated with other anomalies, and are attributed to a

sporadic vascular accident. Reports of familial duodenal atresia in the literature imply that at least some cases are the results of genetic abnormalities.

Congenital duodenal obstruction most commonly occurs at the junction of the first and second portions of the duodenum with 80% occurring distal to the ampulla of Vater (pre-ampullary), and the remaining 20% proximal to the ampulla (post-ampullary). The incidence of an addition distal duodenal atresia is extremely low (1% to 3%). The rare occurrence of double atresias in the duodenum has a distinct familial occurrence and is frequently associated with other pancreaticobiliary anomalies, such as biliary atresia, gallbladder agenesis, and common bile duct stenosis. Depending on the degree of obstruction, the proximal duodenum and stomach are often dilated to several times their normal size with concomitant distal bowel decompression. Duodenal perforation in utero is rare due to the proximal location and natural decompression of the obstruction. Thus, polyhydramnios is a common prenatal finding in approximately 75% of cases and premature delivery occurs in one third of patients.

Associated anomalies occur in up to 50% of all neonates with a congenital duodenal obstruction and account for the majority of the morbidity and mortality in these patients. Structural heart disease (30%) and trisomy 21 (30% to 40%) are the two most frequently associated conditions. Other associated anomalies include intestinal malrotation (20%), esophageal atresia or imperforate anus (10% to 20%), heterotaxia, gallbladder agenesis, and less frequently genitourinary and orthopedic malformations. Therefore, it is imperative that once the diagnosis of duodenal obstruction is established, a thorough evaluation for associated anomalies occurs prior to anesthesia for corrective surgery.

Clinical Presentation

The diagnosis of congenital duodenal obstruction is made by prenatal ultrasound or magnetic resonance imaging (MRI) in up to 50% of cases with greater accuracy in those cases with complete obstruction and resultant maternal polyhydramnios. Postnatal diagnosis is dependent on the degree of obstruction, the presence and size of a duodenal web, and location of the obstruction relative to the ampulla of Vater. The majority of affected infants present clinically in the neonatal period. In classic post-ampullary duodenal atresia, the neonate presents with bilious emesis in the

first 24 hours of life. In cases of pre-ampullary obstruction, emesis is nonbilious and diagnosis may be delayed as this is a common finding in a newborn. Physical examination typically demonstrates a stable infant with upper abdominal distention that resolves with placement of a nasogastric tube. With complete obstruction, placement of a nasogastric tube may result in a scaphoid abdomen due to the absence of distal gas in the gastrointestinal tract. With partial obstruction, symptoms may present later in the first year of life with the introduction of solid foods. In rare cases, diagnosis may even be delayed into later childhood or adulthood usually in association with gastroesophageal reflux, esophagitis, duodenal ulcer, or obstruction of the duodenum proximal to the stenosis by a foreign body or bezoar.

The classic radiographic finding is the “double bubble” seen on abdominal x-ray, which represents air distention of the stomach and duodenal bulb with no distal bowel gas (Fig. 91.3). If a nasogastric tube has been placed prior to the initial film, instillation of 30 to 40 mL of air may help aid in diagnosis. Specific attention should be paid to the presence or absence of air distal to the duodenum. The classic “double bubble” sign in the setting of no distal air is pathognomonic for duodenal atresia, and no further diagnostic investigations are necessary. A rare cause of distal air in duodenal atresia is an anomalous bifid common bile duct that inserts both above and below the obstruction, which allows passage of air into the distal bowel. However, in the majority of cases the presence of air in the intestinal tract distal to the duodenum suggests incomplete duodenal obstruction and mandates an urgent UGI contrast study to evaluate for intestinal malrotation with possible midgut volvulus, which would require an emergent operative intervention.

Figure 91.3. A classic plain film of a newborn with duodenal obstruction demonstrating the “double bubble” sign.

A thorough evaluation for associated congenital anomalies is carried

out. Following a thorough physical examination, plain radiographs, echocardiography to evaluate for congenital heart disease, and chromosomal analysis should be obtained in all patients. The presence of complex congenital cardiac anomalies, esophageal atresia, or imperforate anus may impact the timing of operative intervention and operative approach. Radiographic evidence of a nasogastric tube in the stomach rules out esophageal atresia. Passage of meconium and a normally positioned and patent anus should be documented. Investigation for extrinsic causes of compression may begin with an abdominal ultrasound to search for anomalies of the pancreas or biliary tree or rare findings like preduodenal portal vein or duodenal duplication. Further imaging with abdominal computed tomography (CT) scan, magnetic resonance cholangiopancreatigraphy, and hepatobiliary scintigraphy is obtained selectively as indicated.

Preoperative Management

The etiologies of congenital duodenal obstruction, with the notable exception of malrotation with midgut volvulus, do not require emergency surgical intervention. Preoperative management therefore includes nasogastric decompression and correction of electrolyte and metabolic derangements. Maintenance intravenous fluids are given, with replacement fluid added to account for gastric losses. Prophylactic preoperative antibiotics are administered (ampicillin and gentamicin in neonates). Neonates should receive 1 mg of intramuscular vitamin K. In premature infants with extremely low birth weight (<1,000 g), consideration can be made for delayed operative intervention for several weeks with nasogastric decompression and parenteral nutrition to allow for growth of the infant.

OPERATIVE TECHNIQUE

Open

A generous right upper quadrant transverse incision is made. The patient is eviscerated and the bowel is inspected for intestinal fixation and the positioning of the ligament of Treitz. If present, volvulus is derotated counterclockwise until the mesentery is flat. The bowel is then inspected externally for continuity from the pylorus to the terminal ileum. The duodenum is then widely exposed by mobilization of the hepatic flexure followed by a Kocher maneuver. Complete anteromedial rotation of the

duodenum is necessary to identify the complete nature of the obstruction. The duodenum is inspected for caliber transition from proximally dilated to distally collapsed bowel, mural continuity, annular pancreas, and preduodenal portal vein. The location of the duodenal obstruction may be obvious, as in complete atresia with mural discontinuity or annular pancreas. In patients with mural continuity and without annular pancreas, an orogastric or nasogastric tube is advanced by the anesthesiologist and directed by the surgeon through the duodenum. As the tube abuts the atresia or web, the wall of the duodenum dents in at the attachment point of the obstructing membrane or web, which may be proximal to the external transition from dilated to collapsed bowel. Alternately, a Foley catheter of Fogarty balloon may be passed by mouth or via an anterior gastrostomy through the duodenum, then withdrawn after inflation of the balloon.

The most widely accepted surgical approach to congenital duodenal obstruction is duodenoduodenostomy. An anastomosis is created between the dilated proximal duodenum and the diminutive distal duodenum, bypassing the atresia and any annular pancreas. In patients with annular pancreas, the pancreatic tissue should not be divided as this may lead to pancreatic fistula. The “diamond-shaped” duodenoduodenostomy originally described by Kimura (Fig. 91.4) is now the most commonly employed anastomosis. This technique creates a widely patent anastomosis that leads to a shorter time to full postoperative feeding than the side-to-side duodenoduodenostomy while avoiding the blind loop of a duodenojejunostomy. A transverse incision is made on the anterior wall of the proximal duodenum, and a similar length longitudinal incision is made on the antimesenteric border of the collapsed distal duodenum. The location of the duodenotomies is selected to allow anastomosis without tension or compression of intervening pancreatic tissue or preduodenal portal vein. Following opening of the distal segment, a small red rubber catheter should be passed distally into the jejunum to assess for a rare second duodenal atresia. Saline is then injected to distend the distal bowel to rule out any jejunoileal atresia. The “diamond-shaped” anastomosis is then completed by approximating the ends of one incision to the midpoints of the other incision (Fig. 91.4B) using a single-layered technique with silk or absorbable suture. The use of a transanastomotic feeding tube is left to the surgeon’s preference. Tapering of the proximal dilated duodenum has been advocated by some at the time of the initial duodenoduodenostomy

with the goal of improving apposition of the bowel wall during peristalsis. This may be performed along the antimesenteric wall with a bovie and handsewn closure or with a linear cutting gastrointestinal stapler. We prefer to preserve this maneuver for those patients who exhibit persistent postoperative duodenal stasis and poor duodenal function.

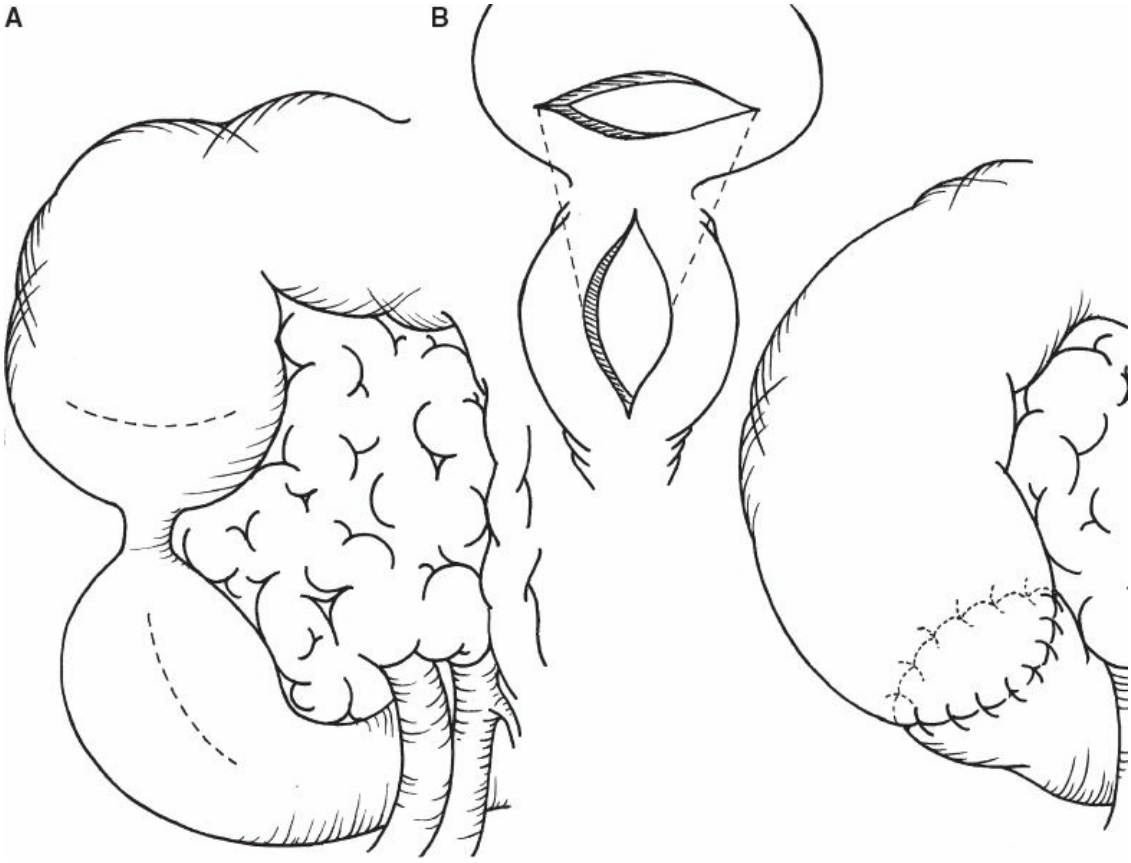

Figure 91.4. **A.** The Kimura diamond-shaped duodenoduodenostomy. The proximal duodenotomy is curvilinear extending cephalad medially. The distance of the proximal duodenotomy to the obstruction is slightly greater than the distance from the obstruction to the distal longitudinal duodenotomy. **B.** The anastomosis is performed with interrupted full-thickness sutures of 5-0 silk or polygalactin.

In certain situations, duodenoduodenostomy is impractical, such as the existence of large gap between the proximal and distal duodenal segments in patients with normal rotation and a normal ligament of Treitz or in infants less than 1,000 g. In this setting, a retrocolic duodenojejunostomy may be employed (Fig. 91.5). A window is made in the mesocolon through which a loop of jejunum is passed. An end-to-side duodenojejunostomy is then fashioned in a single layer with silk or absorbable suture. The

mesocolic defect is closed by suturing the mesocolon to the wall of the duodenum.

Duodenal stenosis typically causes a tapered transition from proximal to distal due to the elongated web ("windsock deformity"), in contrast to the abrupt size discrepancy of duodenal atresia. The perforated web may extend for a variable length distally and may lengthen in the postoperative period if left intact. After identifying the constricting ring from which the web originates by passage of a nasogastric tube, a longitudinal duodenotomy on the antimesenteric wall is made, which centers on the constricting ring. The web is resected laterally, anteriorly, and posteriorly, taking care to avoid and preserve the medial third of the web. This minimizes the risk of injury to the ampulla. A hemostatic, running absorbable suture is placed along the cut edge of the web, and the medial portion is left to hang distally into the lumen. The doudenoplasty is then completed by closing the duodenotomy transversely in a single layer with silk or absorbable suture to further open the constricting ring.

Laparoscopic

In recent years, descriptions of laparoscopic approaches to congenital duodenal obstruction including duodenoduodenostomy, duodenotomy with web resection and duodenoplasty, and correction of malrotation. The laparoscopic approach appears to lead to shorter time to reaching full enteral feeds and an overall shorter postoperative hospitalization. Neonates must be able to tolerate pneumoperitoneum and be of adequate size, which often precludes those with congenital heart anomalies or those under 2 kg. The patient is placed with the feet at the end of the table with the surgeon standing to the left at the patient's feet. Three incisions are used—one at the umbilicus with an appropriately sized cannula, one in the right lower quadrant, and one in the left upper quadrant. Stab incisions may be used in neonates, while cannulae are typically used in older patients. If the liver is obstructing the view, it can be elevated using a suture passed through the abdominal wall, around the falciform ligament then back out the abdominal wall and tied over a sponge. In older patients, a fourth incision in the right upper quadrant may be necessary for a liver retractor. The steps of the operative approach proceed as for the open technique with systematic inspection of the rotation, fixation, patency, annular pancreas, and preduodenal portal vein, as described for the open approach. Likewise, the selection of surgical correction of the duodenal obstruction and steps of

repair are the same. The duodenoduodenostomy may be performed with either intracorporeal or extracorporeal suturing. Some surgeons describe the use of metallic clips to minimize the manipulation and trauma to the bowel.

Postoperative Care

Patients are typically maintained *nil per os* until there is return of bowel function and no evidence of an anastomotic leak with gastric decompression using a nasogastric sump tube. Neonates receive parenteral nutrition, and excessive gastric aspirates are replaced to maintain appropriate urine output. We obtain a UGI contrast study in patients with continued high output of bilious material for more than 7 days, or sooner if there is any clinical concern for a leak. Feeding is initiated when there is evidence of bowel function and anastomotic leak has been ruled out. We caution against relying solely on the return of bilious material to presume postoperative ileus as this may lead to delay in initiating feeds, since the patulous duodenum may pool bilious material and exhibit poor function for some time after the repair. In term infants and older patients, feeds are advanced as tolerated, while premature infants are advanced according to premature feeding protocols at 10 to 20 mL/kg/day.

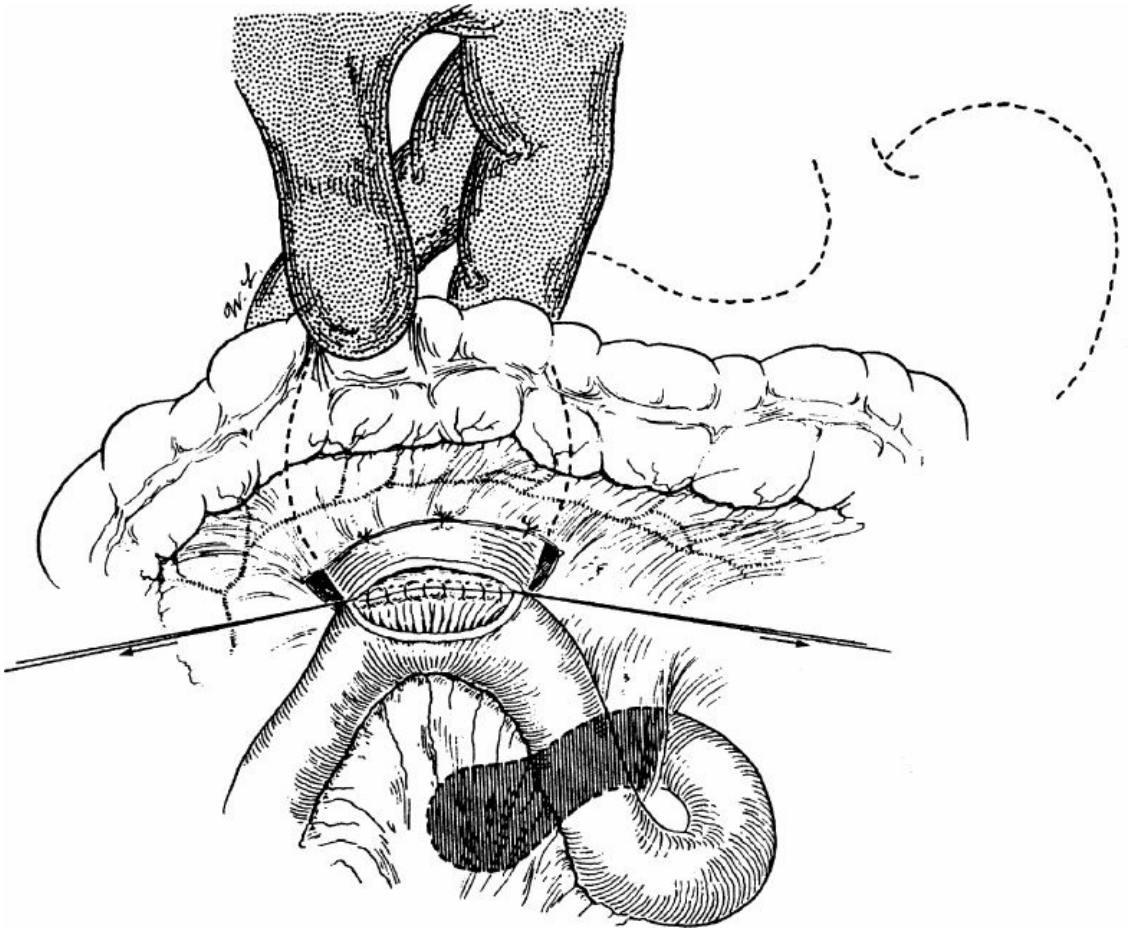

Figure 91.5. Retrocolic duodenojejunostomy. The proximal duodenotomy is performed as in Figure 91.4. Incision in the right transverse mesocolon creates a defect, the edges of which are sutured to the duodenum cephalad to the duodenotomy. A proximal loop of jejunum is then incised on the antimesenteric border for a distance of 3 cm. The anastomosis is performed using full-thickness interrupted 5-0 silk or polygalactin sutures.

Advances in operative technique, anesthesia, and neonatal critical care have led to nearly 95% early survival for correction of congenital duodenal obstruction. The most common short-term complication is feeding intolerance, which is usually the result of delayed gastric emptying and duodenal dysmotility. Other complications include wound complications, anastomotic leak or stricture, duodenogastric or gastroesophageal reflux, gastritis, gastric cancer, duodenal ulcer, megaduodenum, and blind loop syndrome. Most children achieve normal somatic growth. Patients with congenital duodenal obstruction benefit from long-term follow-up with a surgeon to identify and address potential complications.

MALROTATION AND MIDGUT VOLVULUS

Clinical Presentation and Diagnostic Evaluation

Malrotation of the intestine is a common congenital anomaly that may occur in isolation or in association with other congenital anomalies. The clinical presentation depends on the presence or absence of midgut volvulus. The vast majority of patients with midgut volvulus present in infancy, with roughly 50% in the first week, 75% in the first month, and 90% in the first year of life. Those patients without midgut volvulus may present later with chronic, nonspecific gastrointestinal complaints. In some individuals, malrotation is clinically silent and is discovered incidentally during abdominal imaging or at surgery for another indication. Recognition occurs across the age spectrum from birth to adulthood. Clinically apparent malrotation is believed to present in 1 in 6,000 live births. With increasing use of ultrasound for screening for patient with congenital heart disease, heterotaxy syndrome, and other conditions, estimates on the incidence of malrotation range from 3.9 per 10,000 to as high as 1 in 500 live births.

The rotation and fixation of the intestine occur late in the first trimester. Initially, the elongating intestine herniates into the base of the umbilical cord. As the intestine returns to the abdominal cavity, it undergoes a counterclockwise rotation (when viewing the patient anteriorly). The duodenojejunal junction rotates 270 degrees in a course caudad to the superior mesenteric artery (SMA) and superior mesenteric vein (SMV), leftward in front of the spine, and comes to rest at the level of the pylorus to the left of the aorta. The duodenum becomes fixed to the retroperitoneum with the duodenojejunal junction suspended at the ligament of Treitz. The cecum rotates 270 degrees about the axis of the SMA, anterior to the duodenum and comes to rest in the right lower quadrant. The cecum and ascending colon become fixed along the right abdominal gutter and the descending colon along the left abdominal gutter. The mesentery of the small intestine is broadly based across the posterior abdominal cavity from left upper quadrant to the right lower quadrant.

Disorders of rotation and fixation occur on a spectrum with several clinically relevant consequences. The midgut is not fixed to the posterior abdominal wall and the mesentery of the small bowel is narrow. The process of cecal fixation occurs in abnormal locations leading to bands of adhesions (“Ladd bands”) that may obstruct the duodenum or may entrap portions of the bowel. Volvulus of the nonfixed midgut leads to torsion

and compression of the SMV and SMA, which will result in infarction of the midgut if not relieved with urgent intervention.

Patients with congenital diaphragmatic hernia, gastroschisis, and omphalocele almost universally have malrotation due to disruption of the normal return of the intestine to the abdominal cavity. Approximately 10% to 20% of patients with duodenal atresia and one third of those with jejunoileal atresia have malrotation. Among infants with malrotation, duodenal obstruction from a web or stenosis has been reported in 8% to 12%.

The first step to a correct diagnosis is the constant suspicion that any child with bilious emesis has malrotation with volvulus. There is no consistent diagnostic finding of malrotation on plane radiographs that solidifies or rules out the diagnosis. In patients without peritonitis, the diagnostic study of choice is a contrast UGI series to assess the position of the doudenojejunal junction and proximal jejunum. In the anteroposterior projection, the duodenum should descend below the pylorus, cross to the left of the spine, and ascend to the duodenojejunal junction at the level of the pylorus. In the lateral projection, the duodenojejunal junction should be at or posterior to the anterior vertebral bodies. The proximal loops of jejunum should lie in the left upper quadrant. Failure of the duodenum to cross to the left of the spine, failure of the duodenojejunal junction to ascend to the level of the pylorus, and the presence of proximal jejunal loops in the right upper quadrant are evidence of malrotation. There are instances in which the bowel coincidently is lying in the normal position at the time of UGI, though without normal fixation. Other findings that may indicate volvulus are a “bird’s beak” or “corkscrew” configuration of the duodenum or jejunum. Contrast enema may have utility in select situations but must be interpreted with caution. Infants often have a mobile cecum without malrotation, and in 20% of patients with malrotation, the cecum is in the correct position in the right lower quadrant. There has been interest in the use of ultrasound to assess for malrotation to avoid the radiation exposure of contrast radiographs. Ultrasound is being increasingly used as a screening for malrotation in asymptomatic patients by assessing the relationship of the SMA and SMV, and following the course of the duodenum. Because of a reported high false negative rate or identifying malrotation and volvulus, ultrasound must be used with caution in the symptomatic patient and not allowed to delay either UGI or operative intervention. Malrotation is often noted incidentally on CT and MRI.

The traditional approach to the asymptomatic patient has been to electively perform a Ladd procedure since the lifetime risk of volvulus is unpredictable and there is no radiographic test to define the true risk of volvulus. However, in patients with congenital diaphragmatic hernia, omphalocele, or gastroschisis, the combination of an expectation of a broad mesentery and adhesions from the primary corrective surgery has led most pediatric surgeons to observe these patients and to only intervene on symptomatic patients. The routine screening of asymptomatic patients with congenital heart disease or heterotaxy syndromes is controversial. Evidence suggests there is benefit to routine Ladd procedure in asymptomatic patients in the first two decades of life, but there must be a consideration of the risks versus the benefits of Ladd procedure later in life.

Preoperative Preparation

The clinical condition of the patient depends on the degree of intestinal ischemia, the presence of absence of venous return from the ischemic bowel, and the duration and volume of emesis prior to presentation. Patients with prolonged emesis may exhibit hypochloremic, hypokalemic metabolic alkalosis. The ischemic bowel may cause an elevated serum lactate, although a normal lactate is not reassuring as there may be no venous return from the ischemic intestine. In symptomatic patients, assessment, fluid resuscitation, and preoperative preparation should occur simultaneously so that the patient can proceed emergently to surgery if the diagnosis is confirmed. In infants who present with bilious emesis and peritonitis, exploration may need to proceed without contrast examination.

Operative Technique

Since Ladd first described the operative correction for malrotation in 1932, little has changed. Infants with volvulus are approached through a transverse right upper quadrant incision. In older children with an acute abdomen, an upper midline incision may be used. The bowel is completely eviscerated. The volvulus is immediately addressed by rotating the bowel counterclockwise, which may require multiple complete rotations. If the bowel is ischemic, it is packed in warm saline-soaked sponges and reassessed for the impact of reperfusion. If the bowel is frankly necrotic, a decision must be made regarding primary resection with stoma creation or primary anastomosis with an attempt to preserve as much intestinal length

as possible. If the viability of the bowel is uncertain or the patient's physiologic condition is unstable, temporary abdominal coverage and second look operation should be considered. Patients with complete midgut infarction present difficult ethical considerations that should be addressed with the family, including short bowel syndrome, effects of prolonged parenteral nutrition, bowel transplant, and mortality. In this setting, temporary closure and planned second look may give the family time to come to terms with the patient's condition and potential outcomes.

TABLE 91.1 Ladd Procedure

1. Laparotomy with complete evisceration
2. Counterclockwise detorsion of volvulus
3. Division of Ladd bands
4. Broadening of midgut mesentery
5. Incidental appendectomy
6. Replacement of the small bowel along the right abdominal gutter, colon along the left abdominal gutter with cecum in the left upper quadrant

If the gut is viable, a Ladd procedure (Table 91.1) and appendectomy should be completed. Ladd bands extending from the duodenum to the right abdominal wall are sharply divided (Fig. 91.6). The duodenum is then completely mobilized with the goal of achieving a straight course from the right upper to right lower quadrant. The second portion of the duodenum is mobilized from lateral to medial. The third portion of the duodenum may take a variable course, including into the root of the mesentery. Dissection must remain on the anterior surface of the duodenum to avoid the medially located vascular supply. Once the duodenum is completely freed, the lumen should be interrogated for intrinsic obstruction. This may be accomplished with the passage of a large orogastric tube from the mouth to the distal duodenum. Alternatively, a Fogarty balloon or Foley catheter may be passed through the mouth or via a gastrostomy, advanced to the jejunum, and swept retrograde after

inflation of the balloon. Air or saline may be milked distally to assess the patency of the distal bowel.

The base of the mesentery is inspected and broadened. This is accomplished by dividing any additional abnormal adhesive bands down to the SMA and SMV. Small bowel may be found to be entrapped within adhesive bands, so a careful inspection of the full length of bowel from duodenojejunal junction to the ileocecal valve is imperative. Once the mesentery is properly widened, the risk of volvulus of the mesenteric pedicle is low.

The small intestine is placed along the right abdomen from right upper quadrant to right pelvis, and the colon is placed in the left abdomen. The cecum is placed in the left upper quadrant. While pexy of the duodenum and cecum has been advocated by some, this has not proven beneficial. Because of the abnormal position of the cecum and to prevent future diagnostic confusion, an incidental appendectomy is performed. This may be done by inversion technique to prevent entry into the gastrointestinal tract.

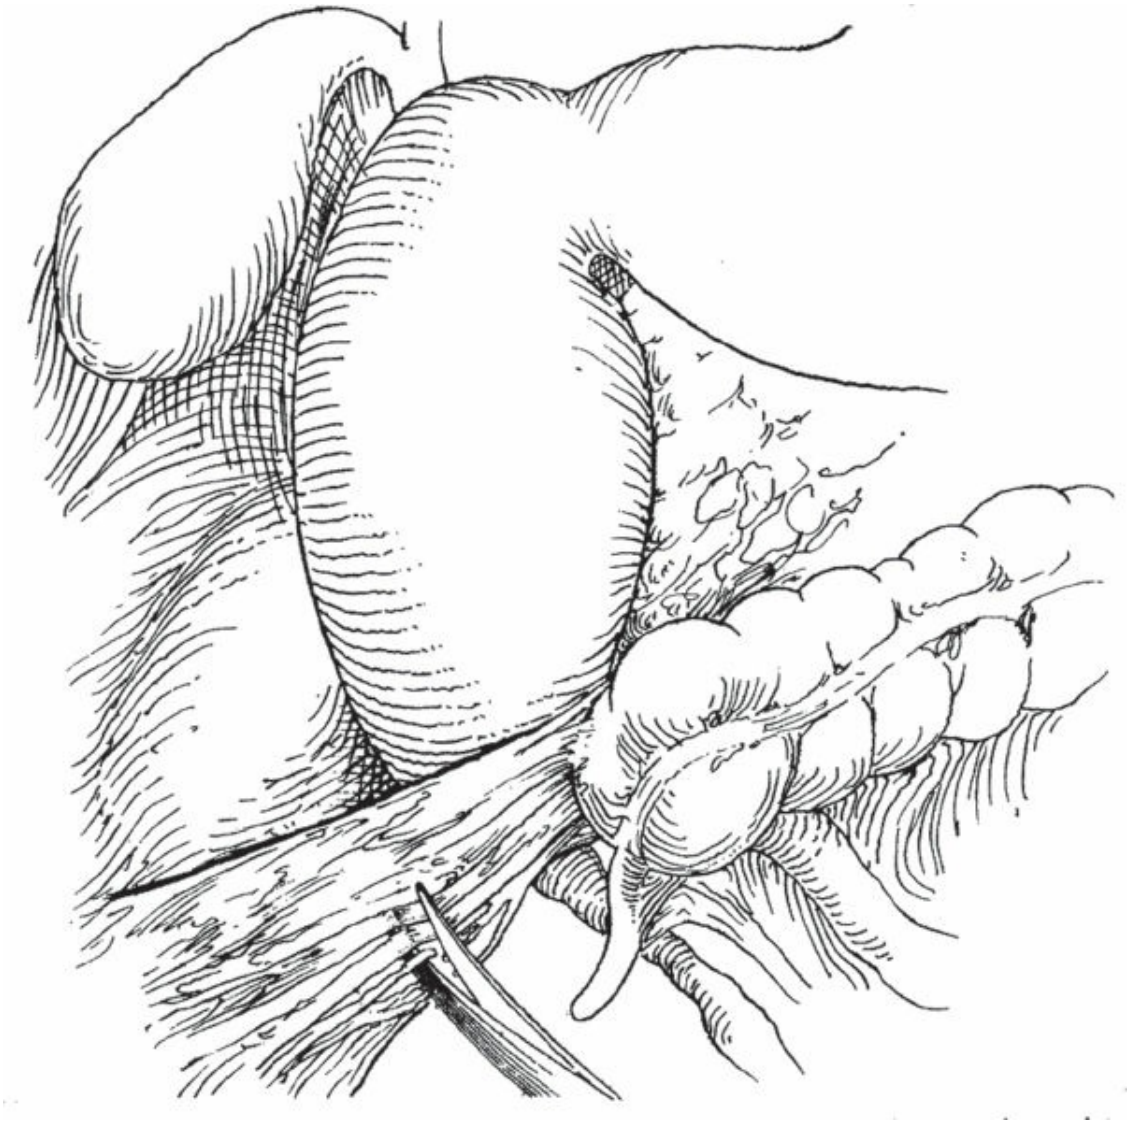

Figure 91.6. Ladd procedure for malrotation. The abnormal peritoneal attachments to the posterior parietes are first divided by cecal mobilization exposing the anterior wall of the second and third portions of the duodenum. Dissection should occur on the anterior wall of the duodenum to avoid vascular or pancreatic injury. (From Michael D. Klein, Diana L. Farmer. Congenital pyloric stenosis and duodenal obstruction. *Mastery of Surgery*. 4th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2002; Chapter 81.)

In patients without volvulus, the Ladd procedure may be safely performed laparoscopically. This approach is well suited for patients who are minimally symptomatic or asymptomatic. We typically use three laparoscopic cannulae, at the umbilicus, right lower quadrant, and left lower quadrant. If the liver is obstructing the view, it is suspended with a suture passed through the abdominal wall, under the falciform ligament,

back out the abdominal wall, and tied over a sponge. The initial cannula is placed through an infraumbilical incision by open technique. We use 3-mm instruments in infants, and 5-mm instruments in older children and adults. The intestine is systematically inspected for the position of the duodenojejunal junction, the position and attachments of the cecum, and the breadth of the base of the mesentery. Once the diagnosis of malrotation is confirmed, the surgeon may complete a Ladd procedure laparoscopically or convert to open depending on their preference, technical skills, and ability to complete the key components of the procedure, which are the same manner as the open approach. The appendectomy may be completed with standard laparoscopic techniques or externalized at the umbilical incision to allow completion of inversion appendectomy.

Postoperative Considerations

The outcome after the Ladd procedure for volvulus depends on the condition of the bowel and whether the patient retains adequate intestinal length. While the field of intestinal and multivisceral transplant is advancing, the short- and long-term treatment and complications of short bowel syndrome are complex. For those with symptomatic malrotation without intestinal loss, the outcomes are excellent with the expectation of normal growth potential and life expectancy. The results for patients who are minimally symptomatic or asymptomatic are less well defined. The symptoms attributed to abnormal rotation may be multifactorial or the result of chronic partial obstruction. In patients with heterotaxy syndromes or complex congenital heart disease, long-term outcomes are generally related to underlying cardiac function and prognosis. Complications include small bowel intussusception, adhesive obstruction, recurrent volvulus (about 1%), and the usual complications seen after abdominal surgery or bowel anastomosis. Mortality is estimated to be 3% after Ladd procedure and is highest in those with intestinal infarction, prematurity, or other congenital anomalies. Laparoscopic techniques offer shorter hospital length of stay and reduced pain compared to laparotomy. Advances in neonatal critical care, pediatric surgical intensive care, anesthesia, and bowel rehabilitation have contributed to improved outcomes.

EDITOR'S COMMENT

Foregut obstruction in an infant is common due in large part to the frequency of pyloric stenosis. Less common causes of a proximal bowel obstruction in children include duodenal atresia and malrotation. The authors present an excellent overview of the three topics. As the authors note, pyloric stenosis is the most common surgically correctable cause of nonbilious emesis; however, because nonbilious emesis in an infant is common and typically due to gastroesophageal reflux or formula intolerance/allergy, the diagnosis can be delayed. Often, the primary care physician will have recommended a series of formula changes before considering pyloric stenosis. In the past, pyloric stenosis was a diagnosis established by history and a physical examination in which the hypertrophied pylorus was palpated as an "olive" in the right upper quadrant. In the current era, that skill set has been diminished as ultrasound has been integrated into the diagnostic algorithms such that it is obtained before the pediatric surgical team is consulted. Emergency room teams cite efficiency as the basis for early ultrasound, minimizing the requirements of a careful examination (Gallagher RA, Levy JA. Advances in point-of-care ultrasound in pediatric emergency medicine. *Curr Opin Pediatr* 2014;26(3):265–71). We encourage all trainees to palpate the olive in the operating room to maintain the ability to properly detect an enlarged pylorus.

Because of the relative frequency of pyloric stenosis, it is a cohort that has undergone significant outcome-focused analysis. Multiple prospective randomized and observational cohort studies have been performed providing evidence-based guidelines to optimize care. From a preoperative standpoint, the frequency of laboratory tests which can be anxiety provoking to family and patient can be limited (Dalton BG, Gonzalez KW, Boda SR, et al. Optimizing fluid resuscitation in hypertrophic pyloric stenosis. *J Pediatr Surg* 2016;51(8):1279–82.). Prospective trials have been performed comparing laparoscopic versus open pyloromyotomy (Hall NJ, Pacilli M, Eaton S, et al. Recovery after open versus laparoscopic pyloromyotomy for pyloric stenosis: a double-blind multicentre randomised controlled trial. *Lancet* 2009;373(9661):390–8; St Peter SD, Holcomb GW 3rd, Calkins CM, et al.

Open versus laparoscopic pyloromyotomy for pyloric stenosis: a prospective, randomized trial. *Ann Surg* 2006;244(3):363–70). Although the evidence in support of laparoscopic approach is not overwhelming, the laparoscopic approach has become prevalent and will supplant the open approach as the most common approach utilized (Jia WQ, Tian JH, Yang KH, et al. Open versus laparoscopic pyloromyotomy for pyloric stenosis: a meta-analysis of randomized controlled trials. *Eur J Pediatr Surg* 2011;21(2):77–81). Postoperatively, prospective studies have shown that early initiation of feeds using full-strength formula with a rapid advance is well tolerated and shortens hospitalization such that some patients are discharged within 12 hours after the procedure (Adibe OO, Iqbal CW, Sharp CW, et al. Protocol versus ad libitum feeds after laparoscopic pyloromyotomy: a prospective randomized trial. *J Pediatr Surg* 2014;49(1):129–32; Clayton JT, Reisch JS, Sanchez PJ, et al. Postoperative Regimentation Of Treatment Optimizes Care and Optimizes Length of Stay (PROTOCOL) after pyloromyotomy. *J Pediatr Surg* 2015;50(9):1540–3).

The authors nicely present the details of how they approach pyloromyotomy. The laparoscopic procedure has the advantage of easier access to the enlarged pylorus. Especially when the hypertrophied pylorus is marked, delivering it through an umbilical incision can be frustrating. With the laparoscopic approach, the hypertrophied pylorus is readily visualized. The technical details on how to perform a laparoscopic pyloromyotomy are well depicted, but I would add one detail that facilitates efficiency. After using the Bovie to “crack the olive,” the use of a 3-mm Maryland placed in the site where the Bovie blade has created the separation of the muscularis to further expand the site will aid the insertion of the laparoscopic Benson spreader.

Complications after pyloromyotomy are uncommon, but as the authors note mucosal injury is the most serious and requires early recognition as if missed, the consequences of enteric contamination in the right upper quadrant can be significant. After repair of the mucosal injury, one may consider obtaining a UGI before starting PO feeds and start of feeds should be delayed for at least 24 hours. On occasion, an incomplete pyloromyotomy will be performed such that persistent emesis occurs with feeding. Repeat exploration is an option but atropine to treat pyloric stenosis may be considered. Atropine treatment can be used to treat pyloric stenosis precluding surgery; however, when that approach is utilized, a long course of atropine will be required and weight gain will be a marginal (Kawahara H, Imura K, Nishikawa M, et al. Intravenous atropine treatment in infantile hypertrophic pyloric stenosis. *Arch Dis Child* 2002;87(1):71–4). Should a patient have an incomplete pyloromyotomy and there is hesitation to offer second exploration, a course of atropine may resolve the intolerance of feeds.

The authors provide an excellent review of duodenal atresia along with the important treatment considerations. In patients with duodenal atresia, associated anomalies are frequent. In patients who have a combination of esophageal

atresia and duodenal atresia, duodenal reconstruction should occur first, as a downstream obstruction from an uncorrected duodenal atresia could stress the integrity of esophageal reconstruction. Ideally, trisomy syndromic assessment (clinical assessment, not genetic testing) should be completed prior to repair as should it be present, consideration for gastrostomy tube placement may be warranted.

As with many procedures in pediatric surgery, laparoscopy has been applied to duodenal atresia. A systematic review analyzing the benefits of laparoscopic versus open approach was recently published (Chung PH, Wong CW, Ip DK, et al. Is laparoscopic surgery better than open surgery for the repair of congenital duodenal obstruction? A review of the current evidences. *J Pediatr Surg* 2017;52(3):498–503). The benefits of the laparoscopic approach outside of cosmesis appear limited with the challenge of additional cost (due in large part to prolonged OR time). Long-term follow-up of patients with duodenal atresia is warranted as some will develop dilated proximal duodenum due either to motility abnormalities or stenosis at the anastomosis (Escobar MA, Ladd AP, Grosfeld JL, et al. Duodenal atresia and stenosis: long-term follow-up over 30 years. *J Pediatr Surg* 2004;39(6):867–71). These patients will benefit from exploration and tapering of the dilated duodenum.

Malrotation is a common cause of proximal bowel obstruction and if volvulus is present is a true pediatric surgical emergency. As the authors observe, any child with bilious emesis should be presumed to have malrotation until it has been ruled out by UGI. If malrotation is present with volvulus, then the patient should proceed to the OR emergently. There should be no delay as bowel ischemia with resulting compromise of GI tract length outweighs the need for immediate resuscitation. As the volvulus is decompressed, the anesthesia team can continue to resuscitate the patient reducing ancillary organ injury.

An area of some controversy is the patients with malrotation who have congenital heart disease and situs abnormalities. These patients do not have classic rotational abnormalities, but because they have heterotaxy, the intestines are not properly fixated and may be at risk for volvulus (Papillon S, Goodhue CJ, Zmora O, et al. Congenital heart disease and heterotaxy: upper gastrointestinal fluoroscopy can be misleading and surgery in an asymptomatic patient is not beneficial. *J Pediatr Surg* 2013;48(1):164–9; Yu DC, Thiagarajan RR, Laussen PC, et al. Outcomes after the Ladd procedure in patients with heterotaxy syndrome, congenital heart disease, and intestinal malrotation. *J Pediatr Surg* 2009;44(6):1089–95). What must be assessed (by UGI or cross-sectional imaging) is the width of the base of the mesentery—the distance between the ligament of Treitz and the right colon—which is the critical determinant of the risk of volvulus. If the base of the mesentery appears narrow, then the patient is at risk of volvulus and operative exploration should be considered. If the width is broad, then the risk of volvulus is small and exploring these patients can be confusing as their rotational variations result in

abnormal positioning of the intestine.

As with duodenal atresia and pyloric stenosis, laparoscopic approaches have been applied to malrotation. The benefits of laparoscopy for this diagnosis need to be critically assessed. The generation of adhesions fixing the bowel in the "proper" position after it has been returned to the abdomen—small bowel on the right, colon on the left—is an important unsaid component of the procedure. The challenge with laparoscopy is that the likelihood of forming adhesions, both to the small port incisions and within the abdomen, is reduced.

In the unfortunate circumstance of midgut volvulus, in which the viability of a significant amount of small bowel is compromised, a careful counseling of the family is required. Although a decision to close the patient and institute comfort measures is a choice, advances in intestinal rehabilitation and intestinal transplantation have made long-term survival plausible. Should salvage be attempted, we recommend a series of second-look procedures preserving any intestine possible. Once the amount of viable intestine has become defined, we restore GI tract continuity as quickly as possible as nutritional and fluid management is much easier without significant stoma losses. Families must be taught careful care of central access as recurrent infections will trigger loss of access/thrombosis. Finally, it is important to note that there have been exciting developments in biotechnology where human intestine can be developed from stem cells which in the future may give these children long-term options that just a few years ago would have been unfathomable (Watson CL, Mahe MM, Munera J, et al. An in vivo model of human small intestine using pluripotent stem cells. *Nat Med* 2014;20:1310–4).

Gregory M. Tiao

92 Diabetes and Other Metabolic Diseases

Kevin El-Hayek and R. Matthew Walsh

INTRODUCTION

The average surgical patient has changed significantly over the past 30 years, especially in relation to medical comorbidities such as obesity, diabetes, and other metabolic diseases. The prevalence of metabolic diseases has reached epidemic proportions and their impact spans the globe. Recent reports indicate that the incidence of obesity continues to rise, particularly in younger age groups. The World Health Organization estimates that 39% of the adult population is overweight (body mass index [BMI] >25 kg/m^2) while 13% are obese (BMI >30 kg/m^2). In the United States alone roughly 17% of children aged 2 to 19 years are obese. Likewise, diabetes rates among all age groups globally are projected to rise from 2.8% in 2000 to 4.4% by 2030. The impact of this increasing prevalence will ultimately lead to higher rates of obesity-related complications including disorders of the ophthalmologic, vascular, and renal systems. The financial strain on health care systems will continue to increase to manage these diseases and their subsequent consequences, despite these disorders being classified as preventable. In terms of the surgical role in these disorders, the focus in the past was on management of complications. Currently, the focus has shifted away from management of complications to prevention or amelioration of disease by surgical interventions.

The concept of surgery for prevention of metabolic diseases was introduced by Henry Buchwald and Richard Varco in their 1978 book, *Metabolic Surgery*. They defined metabolic surgery as “the operative manipulation of a normal organ or organ system to achieve a biologic result for potential health gain.” Since that time, many scientists and clinicians have either directly studied the effects of surgery or have serendipitously noticed metabolic changes after various operations. Because of this ongoing work, the understanding of metabolic surgery has

undergone significant evolution in the subsequent decades—an evolution that has been mirrored by a global increase in patients with metabolic diseases. Furthermore, because of the extremely high prevalence, advancements in medical and surgical approaches have expanded at a rapid pace. Remaining current with the most recent standards is challenging, especially in light of the numerous multidisciplinary opinions and data that continue to emerge. There is also a significant variation in the surgical options offered for these diseases depending on the local expertise and bias.

Not surprisingly, many of the metabolic diseases to be discussed have a significant correlation with obesity. Worldwide rates of obesity are also increasing at epidemic proportions, with an alarming increase in childhood and adolescent populations. Many of the therapies directed at obesity control also apply to the predominant metabolic diseases. An important reminder is to consider the whole person when offering therapy, such that clinicians can improve all aspects of the patient's health including obesity, diabetes, and other metabolic diseases. The value of a multidisciplinary team including internal medicine and appropriate subspecialties, clinical dietetics, psychiatry/psychology, and anesthesia cannot be overstated. Finally, the benefit of these therapies must also outweigh the risk so as to adhere to the fundamental medical principle: "First do no harm."

The purpose of this chapter is to discuss the pathophysiology of diabetes and other metabolic disorders, to review the various surgical options for management of these diseases, to report outcomes from the differing approaches, and to highlight novel interventions that are being applied to this broad category of diseases.

DIABETES

Etiology and Pathophysiology

Diabetes mellitus comes from the Greek "to pass through" and "from honey." Early investigators noted the high frequency of urination that had a sweet character, thus leading to the ascribed name.

Currently, diabetes is classified into two types. Type I diabetes, formally known as juvenile diabetes, makes up roughly 5% to 10% of all cases of diabetes. It is typically diagnosed in patients and is mostly related to an autoimmune destruction of pancreatic beta cells. This beta-cell destruction leads to a lack of insulin production in the body, followed by increasing hyperglycemia. The etiology of type I diabetes is multifactorial.

While there are certainly genetic links, many patients may also have sporadic development of type I diabetes. The genetic locations associated with type I diabetes include IDDM1-IDDM18—all of which affect the immune response. First-degree relatives of those with type I diabetes have a roughly 10% chance of developing it, and this scenario is more commonly seen inherited via the paternal route. For sporadic cases, onset may follow a viral illness, which is presumed to cause an autoimmune cascade and subsequent beta-cell destruction. Viruses that have been implicated in the ultimate development of type I diabetes include the Coxsackie family, mumps and rubella, as well as enteric families. Because type I diabetes typically presents in a younger population, it is not necessarily related to increased BMI as seen in type II diabetes. On the other hand, with the increase in overall rates of obesity, type I diabetes is being increasingly seen in overweight or obese individuals, whose sensitivity to insulin may already be impaired.

Type II diabetes, formally known as adult-onset diabetes, is a disease of progressive insulin insensitivity. Type II diabetes makes up 95% of all cases of diabetes. Based on large-scale databases, roughly 14.3% of the entire US population has diabetes, while 38% has a condition known as prediabetes. While there have been genetic patterns recognized, there are a significant number of genes associated and none have emerged as the predominant etiologic factor. Disease etiology has been directly linked to individual behaviors such as a poor diet and sedentary lifestyle. Unlike that of type I diabetes, patients with higher BMI are also at risk for increased insulin resistance. Overall fat mass, in particular intra-abdominal fat, increases the body's resistance to circulating insulin. Furthermore, the diseases within the "metabolic syndrome" such as increased BMI, hypertension, hyperlipidemia, and hypertriglyceridemia are also associated with an increase in overall insulin resistance. Once the insulin resistance progresses to a severe, chronic level, eventually the beta cells' ability to produce insulin decreases. This progressive phase of type II diabetes is further classified as insulin-dependent type II diabetes.

Clinical Presentation

Patients with type I diabetes may present following a viral illness and this is most commonly seen in younger populations. Early practitioners recognized this entity clinically as excessive urination due to spilling of glucose into the urine. This cascade causes an osmotic dieresis that has a

sweet character that attracted ants. The lack of insulin production and failure to identify early symptoms can lead to severe hyperglycemia and ultimately a scenario of diabetic ketoacidosis. The signs and symptoms of diabetic ketoacidosis can occur within 24 hours and include excessive thirst, urination, nausea and vomiting, abdominal pain, weakness, and confusion. It is considered a medical emergency requiring immediate evaluation. The etiology of ketoacidosis revolves around the lack of insulin and an eventual state of severe hyperglycemia. Because the body cannot store the glucose as indicated by the excess levels in the blood, fat is inappropriately broken down into acids known as ketones. As these ketones build up in the blood, a metabolic acidosis ensues. This presentation may be the first indication of a patient's diagnosis of type I diabetes. Diabetic ketoacidosis is rare in patients with type II diabetes.

The clinical presentation of type II diabetes is often more insidious and patients may appear mostly asymptomatic in early phases. Ultimately, frequent urination becomes more obvious and patients may present for evaluation. Other presentations occur in those who have already developed complications such as ophthalmologic diseases and peripheral neuropathy. Due to the excess buildup of glucose in the microvasculature of the eyes, progressive ophthalmologic conditions such as diabetic retinopathy may develop over time in type II diabetics. Diabetic retinopathy is the leading cause of blindness for adults in the United States of America. The same mechanism occurs within the periphery as glycated blood leads to chronic ischemia of the peripheral nerves, leading to diabetic peripheral neuropathy. Occult renal dysfunction may also be recognized on routine laboratory studies, but often the diagnosis is made prior to development of this complication.

Diagnosis

Clinical presentation and laboratory data are the most helpful components to confirm the diagnosis of both type I and type II diabetes. As previously stated, type I diabetes is more rare and often seen in younger individuals, though there are examples of late-onset type I diabetes. Rapid point of care testing of blood glucose is a screening method to assist with diagnosis to direct acute care in severe cases, particularly for type I diabetes. In stable cases, several tests are available to make the diagnosis of diabetes. Hemoglobin A1c, also known as glycated hemoglobin, is a marker of blood glucose levels over 2 to 3 months. With chronic hyperglycemia,

glucose can bind to hemoglobin within the red blood cells. This glucose buildup over time will lead to a percentage of glycated hemoglobin compared with normal hemoglobin within the blood sample. Prediabetes is defined as those patients with levels of glycated hemoglobin of 5.7% to 6.4% while those with >6.5% have diabetes. On the other hand, fasting plasma glucose is a direct measure of blood glucose after 12 to 14 hours of fasting. Glucose measures from 70 to 99 mg/dL are considered normal, 100 to 125 mg/dL are considered prediabetes, and >126 mg/dL are considered diabetes. The final test to measure for diabetes is the oral glucose tolerance test. In this investigation, fasting blood glucose levels are tested before and then 2 hours following a calibrated dose (75 g) of glucose are administered to a patient. Patients with levels less than 140 mg/L are considered normal, those with levels 141 to 200 mg/dL have prediabetes, while those greater than 200 mg/dL have diabetes.

OTHER METABOLIC DISEASES

While diabetes alone can wreak havoc on the human body, other metabolic diseases often present in conjunction with diabetes. The most common associated comorbidities include hyperlipidemia and hypertriglyceridemia, which together with hypertension make up the metabolic syndrome. When considered together, patients with these diseases are at higher risk for coronary artery disease, stroke, and early mortality. The next section will focus on the etiology, pathophysiology, clinical presentation, and diagnosis of hyperlipidemia and hypertriglyceridemia.

Etiology and Pathophysiology

Hyperlipidemia and hypertriglyceridemia are diseases of abnormally high levels of lipids, lipoproteins, and triglycerides within the blood. Hyperlipidemia is classified into primary and secondary subtypes. Primary hyperlipidemia is less common and etiology is linked to genetic abnormalities. Familial hyperlipidemias are classified into five types according to the Frederickson classification. The pathophysiology of these disorders include several mechanisms, such as decreased lipoprotein lipases (LPL), LPL inhibitors, decreased low-density lipoprotein receptors, and defects in degradation enzyme synthesis. Each of these various mechanisms results in an increase in lipids and lipoproteins circulating within the blood, leading to multiple downstream effects.

Secondary or acquired hyperlipidemia makes up the majority of cases

worldwide. The etiology is related to a poor diet, rich in processed, high fat foods, as well as physical inactivity. Other diseases such as diabetes, hypothyroidism, renal failure, alcohol use, and various prescription drugs can also lead to hyperlipidemia. The pathophysiology of these forms is related to the underlying causes, such as excessive lipid intake from diet, degradation enzyme injury from hyperglycemia, and direct drug interactions with low-density lipoprotein receptors.

Clinical Presentation

Patients with either primary or secondary hyperlipidemia/hypertriglyceridemia often have no symptoms directly related to the increased blood levels of lipids or triglycerides. Rarely, with severely high levels and in those with type I or type IV primary hyperlipidemia, the presenting disease may be acute pancreatitis from direct pancreatic injury. In these cases, circulating levels are often extremely high and a familial predilection is seen. For other patients where presentation is more subtle, symptoms from associated diseases such as diabetes, hypothyroidism, and renal failure may prompt physicians to diagnose concomitant hyperlipidemia. As with many metabolic diseases, isolated presentation is unlikely for hyperlipidemia.

Diagnosis

Clinical history is especially important in cases of familial hypertriglyceridemia and hyperlipidemia, while dietary and activity habits remain key components for those with secondary causes. Physical examination is focused mainly on associated findings such as high blood pressure, high BMI, and particularly central obesity. The mainstay for diagnosis is a fasting lipid and triglyceride panel. The most common components of this panel include low-density lipoprotein, high-density lipoprotein, triglycerides, and total cholesterol. These values are then used to calculate very low-density lipoprotein and the cholesterol:HDL ratio. A low-density lipoprotein level greater than 3.3 mmol/L is considered borderline high, while levels greater than 4.9 mmol/L denote very high levels corresponding to increased rates of cardiovascular disease.

INDICATIONS AND CONTRAINDICATIONS FOR SURGERY

Indications

Medical therapies and counseling for lifestyle and dietary modifications remain the foundation for treatment of metabolic diseases. Particularly for familial diseases, all modifiable risk factors such as diet, smoking, and physical activity should be optimized. Likewise, maximal medical therapy should be offered for patients with these disorders. Newer medications are gaining traction within the medical community; however, recidivism, compliance, and poor disease control remain significant issues. The National Institutes of Health convened a consensus conference in 1991 to address the epidemic of obesity and the metabolic syndrome and recommended surgery for selected patients who meet the following criteria: patients with a BMI greater than 40 kg/m^2 and those with a BMI greater than 35 kg/m^2 with associated comorbidities. These recommendations have largely remained unchanged over the past 25 years; however, there is growing interest in offering surgical therapy for patients with lower BMI (e.g., 30 to 35 kg/m^2 with associated comorbidities such as severe diabetes). Important recommendations also include evaluation by a multidisciplinary team prior to surgical therapy as well as providing lifelong follow-up for patients. The different options for surgical therapy will be discussed in the following sections; however, it is important to note that regardless of the operation offered, patients who are followed in a center providing multi-disciplinary, lifelong follow-up fare better than those who opt for a “quick fix” operation with no follow-up. Data have also shown that patients who maintain a high level of motivation starting at the preoperative phase and continuing into the postoperative phase have improved outcomes. Finally, patients with shorter duration of diabetes and other metabolic diseases likely gain a more profound benefit from the operations than those with long-standing diseases.

Contraindications

Most contraindications for metabolic surgery are considered relative, but the following factors must be heavily considered prior to offering surgery for diabetes, obesity, and other metabolic disorders. Patients with severe heart failure, unstable coronary artery disease, active cancer, hepatic cirrhosis, substance abuse, mental retardation or severe intellectual impairment, and end-stage lung disease are generally not considered to be candidates for metabolic surgery. Also, patients with severe inflammatory bowel disease such as Crohn disease may not be well suited for Roux-en-Y

gastric bypass or biliopancreatic diversion with duodenal switch due to their long-term risk of small bowel disease potentially requiring surgical resection. Significant prior abdominal surgery with adhesive disease and ventral hernia also creates more complexity when considering candidates for surgery, especially when a minimally invasive approach is being contemplated. In these challenging cases, surgeons must be prepared to perform the operation in an open fashion as indicated. Currently, patients with a BMI between 30 and 35 kg/m^2 are not candidates based on the 1991 National Institutes of Health criteria, but active research is being performed on these patients and potentially may lead to an extension of the criteria, especially for those patients with severe comorbidities including diabetes. Extremely high BMI (e.g., >60 kg/m^2) was once considered a contraindication for metabolic surgery; however, advances in anesthesia care, critical care, and surgical equipment and techniques have allowed many of these patients to currently undergo surgery in controlled and experienced settings. Patient age is a final consideration, especially as rates of diabetes, obesity, and other metabolic diseases increase both in younger and older individuals. Data are mounting to answer the value of metabolic surgery for patients under 18 and over 60 years of age. Some authors believe performing metabolic surgery on children and adolescents may prevent the development of many diseases including diabetes and metabolic disorders while others question the ethics of this intervention. For those over age 60, surgeons should expect poorer outcomes for weight loss and metabolic effects as well as higher complication rate and length of stay.

Preoperative Planning

The preoperative phase of patients undergoing metabolic surgery provides the foundation for a successful treatment course. Centers of excellence focus on a clearly defined pathway that starts with a preliminary introduction to metabolic surgery, often in a seminar setting. Once patients have made the decision to proceed with a surgical evaluation, they are introduced to a multidisciplinary team including medical weight-loss specialists, medical specialist for underlying comorbidities such as cardiac, pulmonary, or endocrine diseases, clinical dieticians, and psychologists/psychiatrists focused on food management. The pathway often takes a minimum of 3 to 6 months, during which time the patient is able to prepare for a potential change in their gastrointestinal anatomy.

Also, it is during this period when the medical team can supervise behaviors and identify signs that patients may not be well suited for a surgery. Examples of this behavior include not being able to follow diet and lifestyle modification recommendations, noncompliance with medications, and severe binge eating behaviors. An area of special attention is on preoperative glucose control to optimize outcomes in diabetic patients. Perna and colleagues examined the effect of increased preoperative HgbA1c and demonstrated an association between higher HgbA1c and worse outcomes—namely postoperative glucose control, poor diabetic remissions, and increased morbidity. These data parallel those seen in other surgical scenarios and have led to strong recommendations regarding appropriate glucose control in the perioperative period. Once a patient has completed the nonoperative optimization period, a final meeting with the surgeon to review expected course and a more detailed discussion regarding potential complications is paramount. Roughly 2 weeks prior to the operation, a protein-sparing liquid diet is helpful to decrease the size of the patient's liver which improves technical aspects of the operation. Anesthesia evaluation focuses on any underlying airway deficiencies such as clinical or silent obstructive sleep apnea. Prior anesthetic history is helpful in preparing for any potential complications from general anesthesia. Psychological assessment of worrisome behavioral history, diagnosed psychiatric disorders, and coping mechanisms for handling stress is also vital prior to undertaking surgery for these individuals. When the above components of the pathway have been adequately fulfilled, the patient is ready to proceed with metabolic surgery.

COMMON SURGICAL OPERATIONS FOR DIABETES AND METABOLIC DISEASES

Today there are numerous operations and procedures being used as treatment options for diabetes and metabolic diseases. It is valuable to briefly review the chronology of the various options that evolved over time.

The first operation offered for the treatment of obesity and related diseases was the jejunal-ileal bypass, which was first performed in the 1950s by Dr. Richard Varco. The weight-loss results and initial metabolic effect were excellent in these early patients. In particular, even prior to significant weight loss, surgeons began to note improvements in blood

glucose levels as well as lipid metabolism. These improved metabolic parameters continued with ongoing weight loss at rates higher than would be expected with weight loss alone. On the other hand, the operation was associated with a number of serious short-term and long-term side effects. These side effects included malabsorption of vitamins and minerals, electrolyte imbalances, severe diarrhea, calcium oxalate nephrolithiasis, and most significantly steatohepatitis and progressive liver disease. At the time physicians began recognizing major complications associated with the jejunal-ileal bypass, Roux-en-Y gastric bypass was introduced for obesity and related comorbidities in the mid-1960s. Following several modifications to the original operation, the RYGB largely replaced the jejunal-ileal bypass as it was found to have excellent results without the frequency of side effects seen with jejunal-ileal bypass. In particular, many of the same metabolic improvements were immediately seen following Roux-en-Y gastric bypass including improved blood glucose control and lipid metabolism prior to significant weight loss. Vertical banded gastroplasty arose in the 1980s and for a significant portion of the 1980s and 1990s rivaled the Roux-en-Y gastric bypass as a popular option within metabolic surgery. The vertical banded gastroplasty was developed as a technically simpler operation than Roux-en-Y gastric bypass with no anastomosis and initially offered an attractive option to avoid the malabsorptive effects of Roux-en-Y gastric bypass. Despite not having the same metabolic efficacy as its predecessors, the short-term complication profile was attractive to many clinicians. Unfortunately, as failure rates due to weight regain and band-related complications arose in the mid to late 1990s, popularity waned and revisional operations after vertical banded gastroplasty were being offered as salvage therapies. Also, the metabolic effects seen in this operation were directly linked with weight loss, and metabolic disease relapse occurred with subsequent weight regain. In an effort to obtain results similar to the jejunal-ileal bypass without the associated complications, the biliopancreatic diversion with duodenal switch was introduced in the late 1990s. While the metabolic effects were excellent with fewer complications than the jejunal-ileal bypass, this operation is considered complex and nutritional deficiencies remain higher than those seen in Roux-en-Y gastroplasty and the other options available. Therefore, the biliopancreatic diversion with duodenal switch is currently offered as a metabolic operation on rare occasions and only at specialized centers. Introduction of the less invasive, reversible

operation of adjustable gastric banding was popularized in the 1990s and 2000s. This popularity coincided with the expansion of minimally invasive approaches in gastrointestinal surgery, and laparoscopic adjustable gastric banding became a dominant option. Similar to the vertical banded gastroplasty, metabolic effects of adjustable gastric banding were directly linked to weight loss. However, as overall rates of weight regain increased and band-related complications occurred in up to 20% of patients, popularity again waned and this operation is now offered less frequently for metabolic diseases. Thanks to tremendous advancements in both technology and technique, by the mid-2000s, most metabolic operations could be performed safely and effectively using a minimally invasive, laparoscopic approach. The addition of a minimally invasive approach ultimately improved outcomes for all of these operations and led to an overall increase in the number of patients undergoing metabolic surgery. By 2005, the predominant options for metabolic surgery were Roux-en-Y gastric bypass, adjustable gastric banding, and biliopancreatic diversion with duodenal switch. Surgeons at this time found that patients undergoing staged sleeve gastrectomy prior to biliopancreatic diversion with duodenal switch had excellent weight loss and some of these patients did not ultimately undergo the second stage. For this reason, several clinicians began to investigate sleeve gastrectomy as a stand-alone option for metabolic surgery. Today, sleeve gastrectomy is being done at increasing frequency and is the second most common operation performed overall in the United States. Long-term data are still pending regarding durability of weight loss and amelioration of metabolic diseases.

Worldwide, the most popular operation remains Roux-en-Y gastric bypass (Fig. 92.1A), which is being performed 45% of the time. As mentioned, sleeve gastrectomy (Fig. 92.1B) is on the rise and is now performed 37% of the time. The remaining operations include adjustable gastric banding (Fig. 92.1C) at 10%, biliopancreatic diversion with duodenal switch (Fig. 92.2) at 2.5%, and other options in rare cases.

Postoperative Care

Because the gold-standard approach for most metabolic procedures is via minimally invasive approach, rapid recovery is an appropriate expectation. Early ambulation, avoidance, or early removal of urinary catheters and commencement of an oral diet and medications are recommended in noncomplicated cases. Close monitoring of pulmonary and respiratory

status with telemetry and frequent vital signs is recommended, especially in the first 24 hours. The metabolic changes vary depending on the operation performed—generally speaking the more alteration of the gastrointestinal tract, the more attention needs to be paid toward metabolic effects.

Postoperative care should be centered around appropriate glucose control in the diabetic patient. For patients undergoing more involved metabolic operations such as Roux-en-Y gastric bypass or biliopancreatic diversion with duodenal switch, often the glucose levels decrease immediately and patients who are on oral antiglycemic agents can reduce dosing or eliminate altogether. Those patients with insulin dependence will often require less insulin to manage blood glucose levels, and some patients will be discharged without the need for insulin. Consultation with endocrinologists is quite valuable in the perioperative period for these patients.

In general, antihypertensive medications should be on hold during the immediate postoperative period to avoid masking of important vital parameters such as tachycardia and urine output. Specifically, diuretics should be monitored closely even on discharge as one of the major effects of bariatric surgery is dehydration in the early period.

Discharge is predicated on the ability of the patient to tolerate a liquid diet, be at a baseline ambulatory state, and to have appropriate pain control. Patients also need to be counseled on dietary intake since nausea/vomiting is a frequent cause of readmission. Many centers offer outpatient operations, particularly for adjustable gastric banding, while a 2- to 3-day hospitalization can be expected for sleeve gastrectomy, Roux-en-Y gastric bypass, and biliopancreatic diversion with duodenal switch.

Complications and Their Management

Metabolic surgery is associated with predictable early and late complications. Early complications include bleeding, infection, leakage from staple lines or anastomoses, venous thromboembolic disease, and cardiopulmonary diseases. Complication rates vary depending on the complexity of the operation and the fitness of the patient and typically range from 1% to 10%. Late complications include strictures, ulcer disease, internal herniation, and device-related (i.e., gastric band) malfunctions. These rates also vary from 1% to 20%.

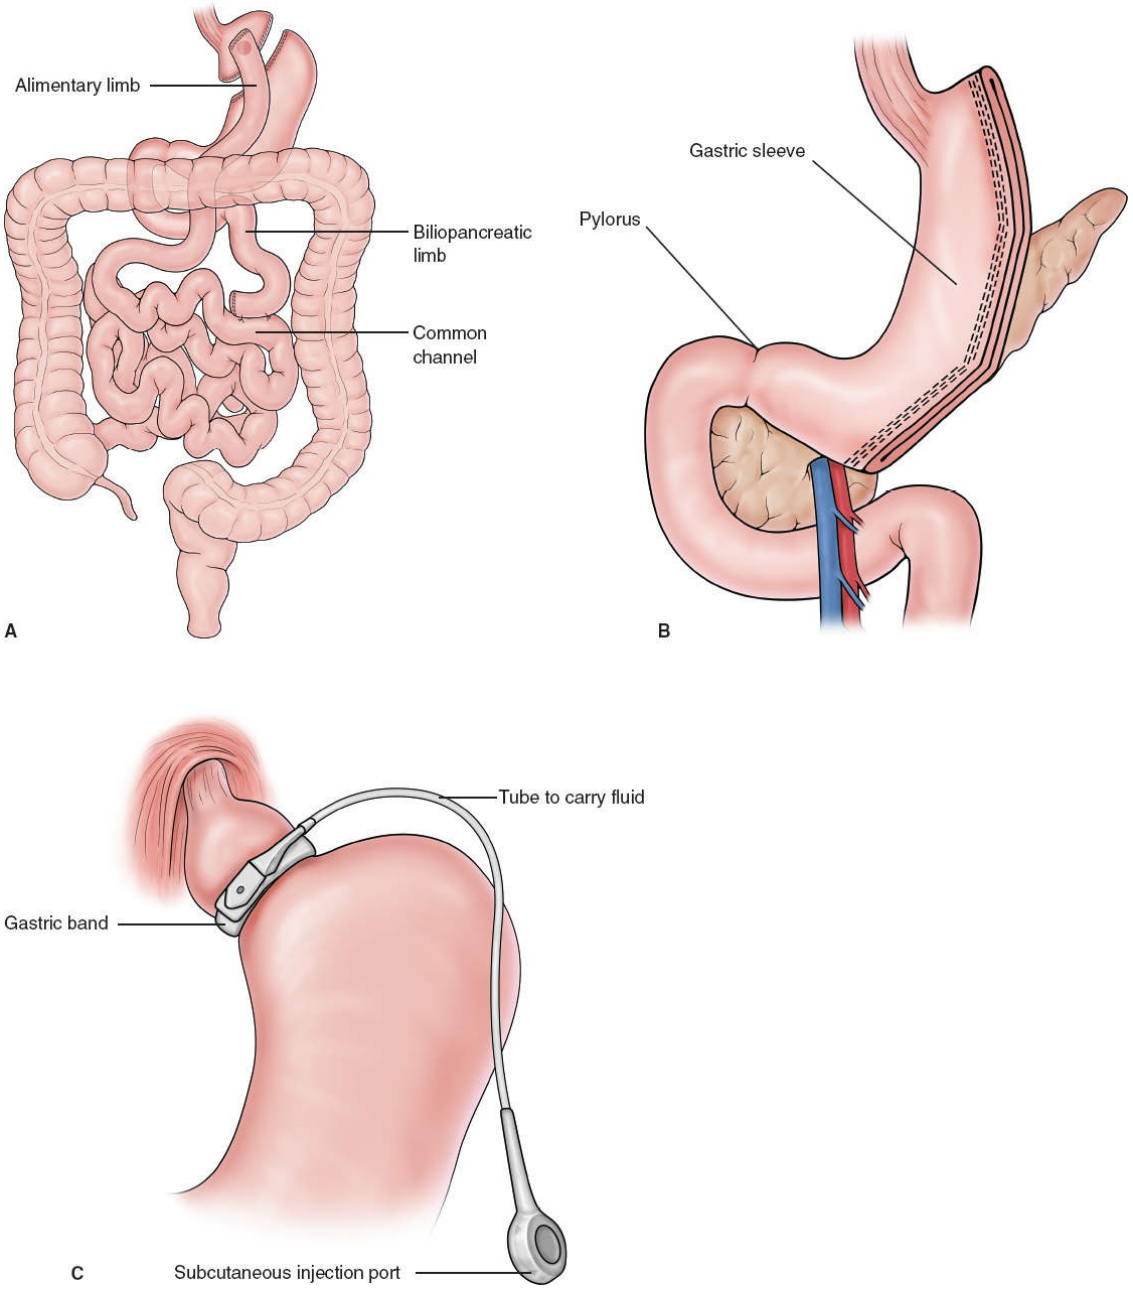

Figure 92.1. Most commonly performed weight-loss surgery procedures. **A.** Roux-en-Y gastric bypass. **B.** Sleeve gastrectomy. **C.** Gastric banding.

Management of complications can vary from medical therapy for infections or venous thromboembolic disease, to endoscopic management of bleeding, strictures, or leaks, and finally to reoperation for failed nonoperative attempts, or immediately for a suspected internal hernia.

Mortality in centers of excellence is extremely low for most operations and is generally quoted at 0.4%.

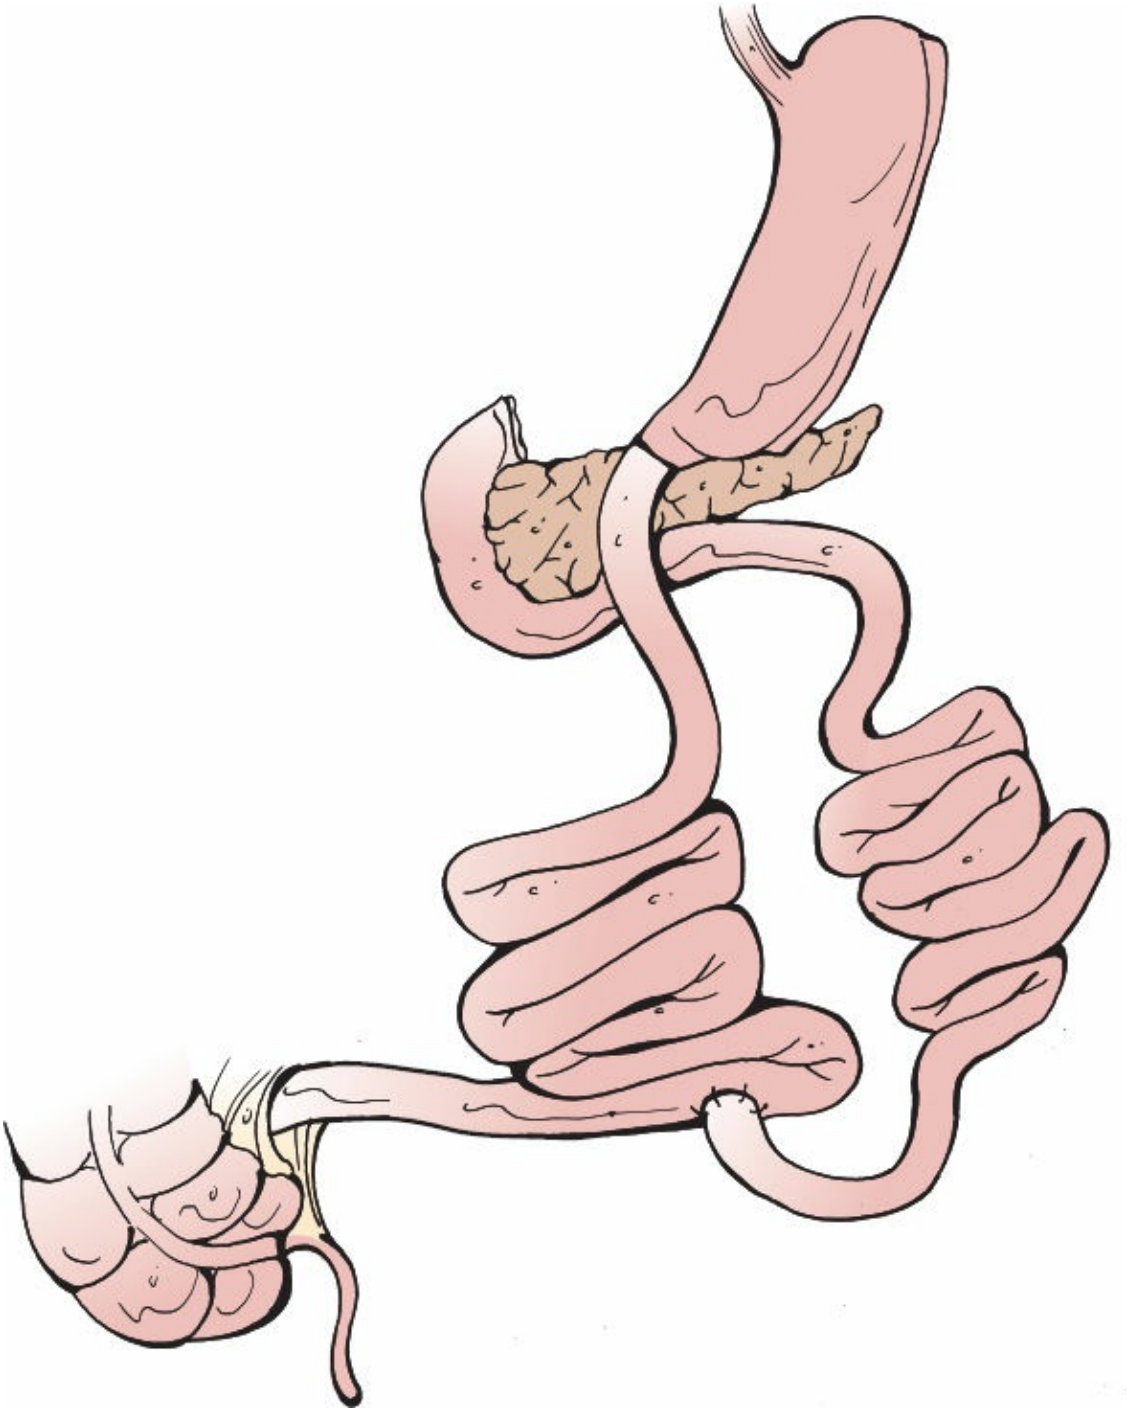

Figure 92.2. Biliopancreatic diversion with duodenal switch.

MECHANISMS OF METABOLIC CHANGE BY SURGERY

Overall outcomes of metabolic surgery in terms of weight loss and metabolic effects vary depending on the operation performed. The next section will highlight the proposed mechanisms of action and outcomes of the dominant bariatric operations in relation to diabetes and other metabolic diseases.

The degree of weight loss is directly associated with improvement or resolution of diabetes and other metabolic diseases. On the other hand, multiple investigators have shown that interruption and reconfiguration of the gastrointestinal tract leads to metabolic changes that occur independently from weight loss. This realization has led to the advancement of several theories regarding various mechanisms for metabolic control.

Hormonal Mechanisms

When food bypasses the proximal gastrointestinal tract and is delivered earlier to the distal bowel, hormonal changes may lead to an enhanced glucose tolerance. This is the so-called “foregut hypothesis” and has been suggested as a mechanism in such operations as the Roux-en-Y gastric bypass and biliopancreatic diversion with duodenal switch. In particular, duodenal exclusion has been implicated as one of the strongest aspects of the foregut hypothesis. In addition to enhanced glucose tolerance, early satiety remains a key aspect of metabolic surgery. Ghrelin is one such hormone whose level correlates with early satiety. In fact, levels of ghrelin are highest immediately prior to a meal and decrease after eating. Most studies have shown ghrelin decreases in operations such as Roux-en-Y gastric bypass, biliopancreatic diversion with duodenal switch, and sleeve gastrectomy. As expected, no change in ghrelin is seen after laparoscopic adjustable gastric banding. In addition to the foregut hypothesis, rapid delivery of nutrients to the distal bowel has also been shown to increase insulin secretion, sensitivity, and satiety. This mechanism is referred to as the “hindgut hypothesis” when used in reference to metabolic surgery. In the hindgut hypothesis, various fat and gut-derived hormonal axes are changed by metabolic surgery to increase weight loss and metabolic changes. Circulating levels of hormones such as glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide were two of the initial hormones discovered in these pathways. These two substances are called incretin hormones and are released by the gut endocrine cells following exposure to food. The incretin effect is the improved insulin secretion in response to glucose. The effects of GLP-1 and glucose-dependent insulinotropic peptide include suppression of glucagon, central mechanisms of weight loss, delayed gastric emptying, and most importantly, improving insulin release following a food bolus. Another effect may be an increase in beta-cell mass of the pancreas. Peptide YY is

another gut-derived hormone that appears to work in concert with GLP-1 to provide an “ileal break,” or delay of gastric emptying and overall bowel transit time. As caloric intake increases, so do secretion of both GLP-1 and peptide YY. In addition, the fat derived peptide hormone leptin has been shown to stimulate GLP-1 secretion, synergistically suppress appetite, and augment energy expenditure. Leptin is the least understood hormone in terms of obesity and metabolic control, but newer data is emerging showing that the leptin feedback loop appears to be altered in obese subjects.

Many studies have examined the changes in these hormonal levels following the dominant bariatric operations. In general, many authors have shown decreases in ghrelin following sleeve gastrectomy, Roux-en-Y gastric bypass, and biliopancreatic diversion with duodenal switch, with no change after adjustable gastric banding. Levels of GLP-1 and peptide YY are also generally increased following sleeve gastrectomy, Roux-en-Y gastric bypass and biliopancreatic diversion with duodenal switch, while no change is seen after adjustable gastric banding. Finally, glucose-dependent insulinotropic peptide has been shown to increase, decrease, and have no change in sleeve gastrectomy, Roux-en-Y gastric bypass, and biliopancreatic diversion with duodenal switch, again with no change after adjustable gastric banding. The variability of glucose-dependent insulinotropic peptide levels after these operations may be secondary to differing surgical techniques, the lengths of the Roux limb and alimentary channel, as well as differing preoperative levels secondary to diabetes and glucose insensitivities. A summary of these changes is highlighted in Table 92.1.

Neural Mechanisms

It is well established that the neural innervation of the gastrointestinal tract is complex and involves both the parasympathetic and sympathetic systems. Parasympathetic vagal nerve function, of which 80% are afferent fibers, accounts for significant signaling pathways to the brain. These afferent pathways are associated predominantly with central cortical centers focusing on hunger, appetite, and satiety. Sympathetic efferent nerve function, of which 15% to 20% is efferent, derives from the celiac axis and is predominantly responsible for much of the glucose production and release as well as gastrointestinal enzyme release. These sympathetic fibers also function to delay intestinal peristalsis. The interplay between

afferent parasympathetic fibers and efferent sympathetic fibers ultimately accounts for the dominant signaling route for gut metabolism. Finally, nervous system innervation occurs within the submucosal layers of the intestinal tract, and likely serves as the initial receptors in response to a food bolus and bowel distension.

TABLE 92.1 Affect of Various Metabolic Operations on Fat- and Gut-Derived Hormones

	Ghrelin	GLP-1	GIP	PYY
AGB	no Δ	no Δ	no Δ	no Δ
RYGB	↓	↑	↑, ↓, no Δ	↑
SG	↓	↑	↑, ↓, no Δ	↑
BPD/DS	↓	↑	↑, ↓, no Δ	↑

GLP-1, glucagon-like peptide 1; GIP, glucose-dependent insulinotropic peptide; PYY, peptide YY.

The various bariatric operations affect these neural pathways in some capacity: via alteration or disruption. In the setting of the adjustable gastric banding, compression of the band on the gastric cardia creates a background of satiety that is augmented when a food bolus passes through the constricted area of the stomach. These effects are likely influenced by the vagal afferent fibers with signaling to the hypothalamic center responsible for hunger, appetite, and satiety. The sleeve gastrectomy involves a large-volume gastric resection, particularly of the fundus and body, where a significant number of intrinsic nerve fibers reside. This loss of the fundic gastric pacemaker ultimately leads to neural signaling promoting the sensation of satiety for patients. When the vagal fibers are disconnected quite proximally by Roux-en-Y gastric bypass and more distally with biliopancreatic diversion with duodenal switch, a sympathetic nervous response is likely induced. Many of these neural effects have been the target of novel interventional therapies which will be discussed later in the chapter.

Bile Acids and the Microbiome

Another exciting area of research in terms of changes following metabolic surgery involves the alteration of gastrointestinal bile acids and the microbiome. Specifically, bile acids secretion has been implicated in glycemic control via a binding mechanism with receptors on multiple cells

within the gut. Hepatic glucose metabolism also appears to be affected by a nuclear receptor pathway called *Farnesoid X Receptor* (FXR). Bile acids may improve glucose control via FXR-induced growth factor pathways within the gastrointestinal tract. Several authors have shown that diversion of bile acids to the distal gut may enhance glucose homeostasis, and it has been shown that after bypass operations such as Roux-en-Y gastric bypass and biliopancreatic diversion with duodenal switch, bile acid concentrations are higher.

In conjunction with bile acid effects, significant changes to the gut microbiome occur with alteration of the anatomy as seen in the bypass type operations. While understanding of the mechanism of the microbiome remains limited, research has shown an impact on glucose and metabolic control, particularly in obesity.

OUTCOMES OF METABOLIC OPERATIONS

Many retrospective, observational reviews have shown substantial reductions in diabetes and other metabolic diseases with the commonly performed metabolic operations, though rates have differed between each operation. In 2004, a meta-analysis by Buchwald and colleagues found an overall diabetes resolution rate of roughly 75% with adjustable gastric banding, Roux-en-Y gastric bypass, and biliopancreatic duodenal switch. Subgroup analysis found that these rates were roughly 50% for adjustable gastric banding, 84% with Roux-en-Y gastric bypass, and 99% with biliopancreatic duodenal switch. These rates were again confirmed when examining results from national databases with the highest reported 12-month diabetes remission rates seen in biliopancreatic diversion with duodenal switch (74%), followed by Roux-en-Y gastric bypass (62%), sleeve gastrectomy (52%), and adjustable gastric banding (28%). Factors shown to predict diabetes remission include shorter duration of diabetes, increased weight loss, and previous treatment with oral antidiabetic agents. Similarly, patients with longer duration of diabetes and those with preoperative insulin had lower rates of remission.

More recently, several investigators have compared the rates of diabetes and metabolic control between surgery and best medical therapy in a randomized-controlled fashion. The “Surgical Treatment and Medications Potentially Eradicate Diabetes Efficiency” (STAMPEDE) trial randomized 150 patients to receive medical therapy, sleeve gastrectomy, or Roux-en-Y gastric bypass and measured patients who achieved diabetes remission as

defined by glycated hemoglobin less than 6.0%. One-year results demonstrated that 42% of patients in the Roux-en-Y gastric bypass arm, 37% in the sleeve gastrectomy arm, and 12% in the medical arm achieved diabetes remission. Three-year outcomes demonstrated remission rates for Roux-en-Y gastric bypass, sleeve gastrectomy, and medical therapy as 38%, 24%, and 5%, respectively. Use of diabetic medications and insulin was also significantly reduced in patients who underwent surgery versus those who underwent medical therapy. These results, mirrored by several other authors, highlight the superiority of metabolic surgery when compared to medical therapy alone in relation to diabetes control in the obese population.

In regard to nonobese patients with type 2 diabetes, a number of clinicians have begun to examine the effects of various metabolic operations on diabetic control. The decision to move forward with surgery in these settings, which would typically not be recommended based on the National Institutes of Health guidelines, was due to the unexpected findings in lower BMI diabetic patients who underwent gastric resections for other reasons (i.e., peptic ulcer disease, cancer). Subsequent data for diabetic patients with a BMI between 30 and 40 kg/m^2 who underwent adjustable gastric banding were found to have diabetic remission rates of 73% at 2 years with weight loss being the predominant factor for success. Diabetic patients with a BMI <35 kg/m^2 who underwent laparoscopic Roux-en-Y gastric bypass also showed significant reductions in fasting blood glucose in the absence of excessive weight loss. The reportedly less morbid loop minigastric bypass was also performed on a group of diabetic patients with a BMI <35 kg/m^2, and again, 77% of this population was found to achieve an HbA1c <7.0% at 1-year postoperatively. Finally, a prospective study examining biliopancreatic diversion in patients with a BMI <35 kg/m^2 found that 83% of this diabetic population was off all antidiabetic medications at 1 year. These results have also been seen in Asian diabetics with a BMI <30 kg/m^2—yet another population with rising rates of diabetes without concomitant morbid obesity. Taken together, this mounting evidence is leading clinicians to discuss metabolic surgery even in the nonobese, though long-term data are still warranted at this time.

TABLE 92.2 Randomized Clinical Trials Comparing Metabolic Surgery to Nonsurgical Therapies

Author	Year	Follow-Up	Metabolic Surgery > Nonsurgical Treatment
Hiendruff	1997	40 wk	WL
Mingrone	2002	1 yr	WL, CL, TGL, GL, GH
O'Brien	2006	2 yr	WL, MSR
Dixon	2008	2 yr	WL, DR, MSR, CL, TGL, GL, GH
O'Brien	2010	2 yr	WL, MSR, TGL, GL
Reis	2010	2 yr	WL
Dixon	2012	2 yr	WL, MSR, CL, TGL, GL
Mingrone	2012	2 yr	WL, DR, CL, TGL, GL
Schauer	2012	1 yr	WL, DR, MSR, CL, TGL, GL, GH
Ikramuddin	2013	1 yr	WL, CL, TGL, GL, GH
Liang	2013	1 yr	DR, CL, TGL, GH

WL, weight loss; DR, diabetes remission; MSR, metabolic syndrome remission; CL, cholesterol level; TGL, triglyceride level; GL, glucose level; GH, glycated hemoglobin.

A number of groups around the world have also looked at the cost benefits of metabolic surgery versus medical therapy for diabetes management. Based on the high remission rates of diabetes after surgery, many patients are able to either decrease or eliminate the need for medical therapy in the short- and mid-term time frames. A predictable number of patients may relapse and develop recurrent diabetes, but even these patients may have lower needs for medication. Various payer systems including those in Australia, United Kingdom, Spain, and Austria have all seen cost-effective improvements with metabolic operations when compared to medical therapy. A robust report of cost-effectiveness in Australia by Keating and colleagues demonstrated a mean health care savings of roughly $1,800 USD and an additional 1.2 quality-adjusted life year for patients who underwent metabolic surgery versus conventional medical therapy. Several authors have criticized some of these findings based on low patient numbers, retention, and length of follow-up. Therefore, long-term results must be gathered, particularly in the nonobese, to make further recommendations regarding metabolic surgery for the nonobese diabetic population.

When reviewing outcomes of metabolic operations on other metabolic diseases such as hyperlipidemia and cardiovascular disease, similar findings have been reproduced. Reductions in hypertension, hypertriglyceridemia, and hyperlipidemia have been shown at rates ranging from 23% to 70%. These improvements have been shown at early (<1 year), mid (1 to 2 years), and late (2 to 4 years) periods of surveillance. Several large, long-term observational studies have demonstrated

improved cardiovascular disease and mortality in obese patients who underwent metabolic surgery when compared to obese patients with only medical therapy. Cardiac function and various cardiomyopathies have also improved following metabolic surgery, again mirroring results seen in the diabetic population.

While the various mechanisms for these changes in diabetic and metabolic control continue to be elucidated, the evidence supporting metabolic surgery as the most effective treatment course continues to mount. A recent review of 11 randomized controlled trials comparing metabolic surgery with nonsurgical treatments showed superiority of metabolic surgery in relation to weight loss, diabetes and metabolic syndrome remission, plasma cholesterol and triglyceride levels, plasma glucose levels, and quality of life, among others (Table 92.2).

NOVEL OPERATIONS FOR DIABETES AND METABOLIC DISORDERS

While results have been for the dominant metabolic operations have been promising, clinicians continue to explore less invasive methods for management of diabetes and metabolic diseases. An area of active innovation is that of gastrointestinal neural modulation through implantation of stimulator devices.

As mentioned previously, afferent vagal pathways contribute a large proportion of the innervation of the gastrointestinal tract. Disruption of these pathways via gastric stimulation is one method that was investigated by Dr. Shikora and colleagues in 2009. In a randomized trial, patients underwent submucosal placement of gastric neurostimulators with one group receiving electrical stimulation and another group receiving no stimulation. The proposed mechanism is via gastric relaxation and delayed gastric emptying, thus leading to a feeling of satiety and decreased appetite. Following 1 year of therapy, both groups loss an equivalent amount of excess body weight (roughly 12%), favoring a placebo effect rather than a true therapeutic result. Extending the concept from this study, direct vagal blockade has been another area of active clinical interest. In this design, the anterior and posterior proximal vagal nerve receives an electrical impulse designed to block the afferent pathway to the brain, thereby inducing satiety and decreased caloric intake. A prospective, randomized trial with this therapy was designed to examine 1-year results of hunger and appetite, eating, and quality of life, with the primary end-

point being excess body weight loss. Similar to the gastric electrical stimulation trials, results at 1 year were not significant between the groups with stimulation and those without, but both groups lost roughly 16% excess body weight. A redesigned trial which delivered a 12-hour impulse to the vagus nerve showed a significant improvement in excess weight loss of the treatment versus control group (24% vs. 16%).

Neural modulation more distal on the gastrointestinal tract, namely the duodenum, is another area currently under investigation. A 12-month follow-up after laparoscopic implantation of the BALANCE duodenal stimulation device showed modest improvements in mean glycated hemoglobin, fasting blood glucose levels, and mean HDL levels with a safe and effective profile. In addition to duodenal stimulation, targeted ablative therapy of the perirenal sympathetic fibers has also emerged in investigations for modulating glucose and metabolic diseases in patients. This therapy is actually delivered via a vascular catheter approach via the renal arteries and has previously shown benefit in refractory hypertensive patients. These same sympathetic fibers also control various aspects of glucose metabolism and insulin resistance, therefore, ablation may improve these parameters. Several small, short-term studies have shown conflicting results in this regard, with some indicating improved metabolic control and others showing no change. No randomized data exist for either of these novel therapies, but their emergence as possible therapies highlights the ongoing search for less invasive methods to control significant medical comorbidities.

The conflicting and emerging results of these novel therapies demonstrate that there may be a therapeutic effect from neural modulation of the vagal afferent and sympathetic efferent pathways, but results remain inferior to surgical therapy and the results for diabetic and metabolic control remain to be seen, especially in the long term.

CONCLUSIONS

Surgery for diabetes and other metabolic diseases has undergone a tremendous evolution since the introduction of this concept many years ago. This evolution has been mirrored by the unfortunate rise in global rates of obesity, diabetes, and metabolic disease. Whereas in the past these diseases were relegated to the medical community alone, it is now clear that surgery plays a major role in the management of these diseases. The burden that these diseases place on resource utilization in healthcare and

the overall wellness of society is arguably one of the greatest challenges facing us today. The complexity of the problem stretches beyond the medical profession and into the realms of the food and advertising industries, addiction services, and politics. While the focus of this chapter was the surgical management of diabetes and other metabolic diseases, it is only with a concerted effort to affect change in all these areas will we starting shifting the needle back toward healthy communities. For now, a multidisciplinary medical, psychological, and surgical approach to these diseases is the most effective means of helping individuals with these diseases. Future research will focus on more detailed understanding of the neurohormonal changes that occur during metabolic surgery, as well as how targeted therapies can improve overall metabolism. While the challenge is great, many clinicians and scientists continue to work toward curing these harmful diseases.

EDITOR'S COMMENT

Obesity is at epidemic proportions in the United States. This may be in part due to the obesogens and endocrine disrupting chemicals introduced into our

environment that further disrupt metabolism and promote the metabolic syndrome. Conditions associated with obesity are more than diabetes, hypertension, and hyperlipidemia including but not limited to coronary artery disease, obstructive sleep apnea, gastroesophageal reflux, nonalcoholic liver disease and liver failure, deep venous thrombosis and pulmonary embolus, osteoarthritis and osteoporosis, infertility, depression, stress urinary incontinence, and cancer. It is clear from the literature reviewed in this chapter as well as recent consensus statements that metabolic surgery offers a sustained albeit partial relief of obesity and its complications. The impact of obesity on general surgical complications is also enormous. Obesity has the same impact on surgical complications as smoking—that is seven fold.

The indications for metabolic surgery are changing as well. The 2009 Asian Consensus Meeting on Metabolic Surgery recommended a lowered indication for surgery as Asians have a higher adiposity for a given level of obesity. The recent International Diabetes Federation guidelines recommend reorienting our focus on metabolic disease not just a BMI $\geq$35 kg/m^2. Significant benefit of surgery is seen in those patients who have metabolic syndrome but don't meet the accepted BMI criteria. Like any operation, metabolic surgery was initially applied to those with the most to gain and the least to risk. The indication for surgery is expanding in the laparoscopic age and with mortality rates reduced to as low as 0.12% in large series. Benefit can be seen in the young and overweight patients with severe metabolic syndrome. Studies in these subgroups are limited.

Not included in the review of procedures in this chapter is that of reversible endoscopically placed synthetic duodenojejunal bypass liners to improve glycemic control, improve insulin resistance induce weight loss, and decrease cardiovascular risk. There are essentially three different types which include the duodenojejunal bypass sleeve that attaches to the duodenum and is a 60-cm GI liner that extends distally to mimic a Roux-en-Y bypass. A modification of this includes a flow restrictor to slow gastric emptying. The other is a gastroduodenojejunal bypass sleeve that is attached more proximally and extends for 120 cm. Multiple prospective randomized sham-controlled trials have shown the efficacy of these studies. The advantages to these devices are the ease of reversal reported at under 5 minutes.

Despite the effectiveness of these operations, an unmotivated patient can "out eat" the benefit and thus only the truly motivated patient should be offered such operations. As has been standard for years a preoperative period of weight loss is the best way to determine not only the motivation but the outcome of these types of operations.

93 Vascular Compression of the Duodenum

Stanley W. Ashley and Matthew T. Menard

Compression of the duodenum between the vertebral column and the superior mesenteric artery (SMA) is a relatively rare clinical condition. Known by a wide variety of names since first reported, in recent decades it has been termed “vascular compression of the duodenum,” a designation which most accurately reflects the anatomic basis for the disorder. Associated symptoms are those typical of intestinal obstruction, and the onset is often insidious and marked by the gradual appearance of nausea and vomiting. In the appropriate clinical setting, the diagnosis is made on the basis of characteristic computed tomographic (CT) findings. The syndrome may follow weight loss, prolonged immobilization in bed, and various operative procedures, but has also been reported to occur spontaneously. Treatment most often involves surgical decompression in the form of division of the ligament of Treitz and a duodenojejunostomy, with generally favorable outcomes.

HISTORY

The Austrian anatomist Carl Von Rokitansky, rumored to have performed over 30,000 autopsies over the course of his pioneering career, first described constriction of the third portion of the duodenum by the overlying SMA in 1942. Kundrat subsequently postulated the root of the mesentery to be the anatomic structure responsible for partial obstruction of the duodenum, whereas the German physician Albrecht believed that mesenteric traction was the etiology of the constrictive problem. In the early 20th century, there was recognition of the frequent association with gastric dilatation and suggestion that duodenal stasis and dilation were causative factors in such patients. In 1907, Bloodgood described several cases of gastromesenteric ileus and was the first to propose that surgical decompression in the form of a duodenojejunostomy might be an effective treatment. One year later, Slavely reported the first such procedure.

Since Von Rokitansky's landmark observation, interest in this clinical entity has been variable, and for periods of time, its validity has been questioned by the reigning medical establishment. This lack of full acceptance was in large part due to a poor understanding of the pathophysiology of the condition. Specifically, a distinction between duodenal stasis and mechanical obstruction was often not made, leading to inconsistent treatment results. For example, for a period in the early 1900s, both resection of the colon and plication of the mesentery were tried in an effort to relieve mesenteric compression. Others described a gastropyloroduodenojejunostomy as a means of decompressing persistent gastric distension following duodenojejunostomy.

Reports by Kellogg and Wilkie in the late 1920s helped establish duodenojejunostomy as the surgical treatment of choice. In one of the larger published series, Wilkie described 75 patients with duodenal obstruction treated with a 6% operative mortality rate. He also identified a subset of patients who had a poor response to the procedure in whom it was less clear that a mesenteric source of compression was responsible. In subsequent years, as the indications for operative decompression were liberalized and the treatment was more widely applied, overall outcomes were noted to be less favorable. A resurgence of interest in this problem in the 1960s was attributed to a comprehensive review of the available literature by Barner and Sherman. A number of further publications that helped clarify the anatomic basis and elucidated additional clinical features of the syndrome also served to reinforce its legitimacy. Today, it is perceived by most to be a true clinical entity. The numerous names by which vascular compression of the duodenum has been referred to over the years, some of which continue on occasion to be utilized, are listed in Table 93.1.

ANATOMY

The duodenum, so named as it was considered to be equal in length to the width of 12 fingers, is most susceptible to compression by the overlying SMA within its horizontally oriented third portion. This segment of the duodenum typically crosses the vertebral column at the lower portion of the third lumbar and/or upper portion of the fourth lumbar vertebra. Notably, the fourth vertebra is the most anterior part of the spinal column. The duodenum is fixed at three anatomic points: the pylorus, the peritoneum of the second and third portions of the peritoneum, and the

ligament of Treitz.

The SMA typically arises from the anterior aorta at the level of the lower aspect of the first lumbar vertebra. A significant degree of variation of this takeoff point has been noted, however, with the origin reported to range from the 12th thoracic to the third lumbar vertebra. Though the average angle formed by the SMA and the aorta was found to be 42 degrees in one autopsy series, there is also considerable variability in this measurement; the angle as reported in the literature ranges between 18 and 70 degrees. Inside this angle lies the left renal vein, the uncinate process of the pancreas, the third portion of the duodenum, and a retroperitoneal fat pad that typically encircles the SMA (see Fig. 93.1).

A markedly narrowed aortomesenteric angle is a hallmark diagnostic finding in patients with vascular compression of the duodenum (see Fig. 93.2). Lukes et al. found this angle to be as low as 8 degrees in their review, whereas other authors have reported the aortomesenteric angle to range from 6 to 40 degrees in patients with radiographic evidence of compression. Lukes et al. also reported a significantly reduced distance from the origin of the SMA to the midpoint of the duodenum, known as the aortomesenteric distance, with involved patients having an average distance of only 3.3 mm compared to a distance of 18 mm in control patients. Aberrancies of the normal anatomic pattern of the SMA and its branches in relation to the duodenum (see Fig. 93.3) and the ligament of Treitz (Fig. 93.4) have also been implicated in the described clinical syndrome. In particular, the patients in whom the duodenum crosses the vertebrae at the fourth lumbar vertebrae where the lumbar curvature is at its most pronounced anteriorly are at elevated risk of developing obstructive problems (Fig. 93.2C).

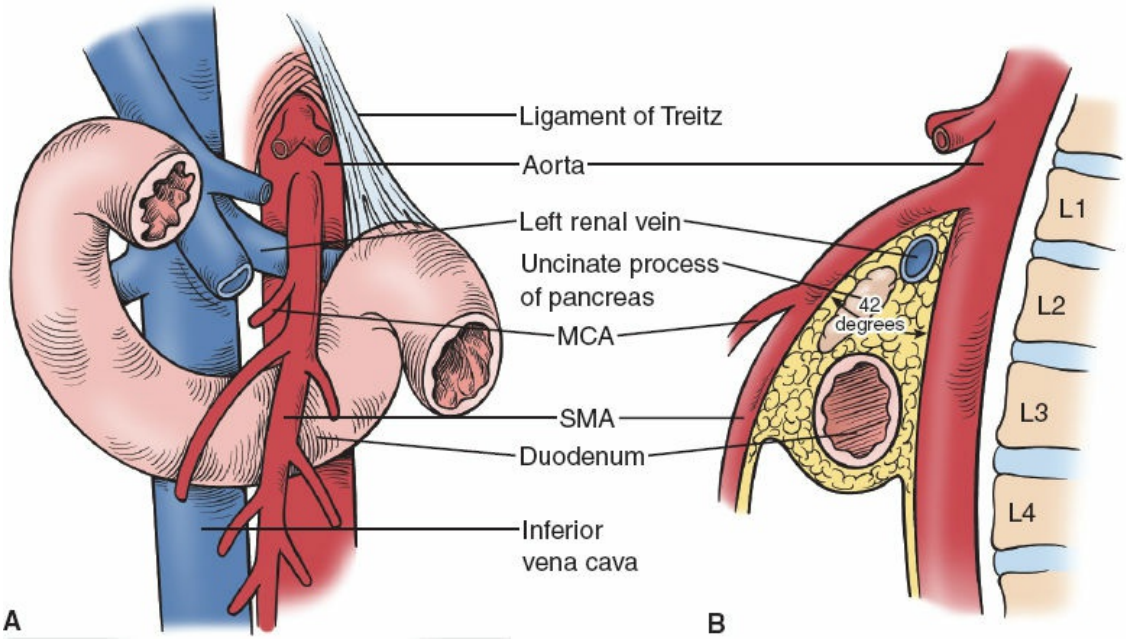

Figure 93.1. **A.** Demonstration of the normal anatomic relationships of the duodenum, ligament of Treitz, aorta, and SMA crossing over the third portion of the duodenum. **B.** The lateral view demonstrates the average normal aortomesenteric angle of 42.4 degrees, the normal relationship of the aorta and SMA to the spine, and the contents of the aortomesenteric angle: the left renal vein, uncinate process of the pancreas, the duodenum, and the retroperitoneal fat pad. MCA, middle colic artery; SMA, superior mesenteric artery.

The long recognized association of rapid weight loss with the syndrome

is believed to be a result of loss of the mesenteric and retroperitoneal fat in this anatomic region that further serves to reduce both the aortomesenteric angle and distance. Additional anatomic aberrancies that have been linked to a smaller angle between the SMA and aorta include an abnormally low origin of the SMA, excessive lumbar lordosis, a foreshortened or hypertrophied ligament of Treitz, and an unusually high fixation point of the ligament of Treitz. Of note, a zone of elevated pressure preceding one of reduced pressure has been noted in the distal duodenum in normal subjects assessed with manometry. This intriguing finding suggests an anatomic and physiologic basis for a possible predisposition to a functional duodenal obstruction that remains to be further elucidated.

CLINICAL PRESENTATION

The predominant clinical symptoms present in patients with vascular compression of the duodenum are that of nausea, vomiting, and postprandial abdominal pain centered at the epigastrium. These symptoms can be episodic or constant, and, if persistent, dehydration and/or weight loss is common. In fact, associated mortality secondary to dehydration, cachexia, and aspiration following emesis have all been described. Patients are typically young, and there is a predominance of female versus male patients. As mentioned, an asthenic body habitus is also frequently present in the patients with vascular compression of the duodenum, and it has long been noted that concomitant weight loss often precedes the onset of other symptoms. The anatomic considerations detailed above provide one rationale for how antecedent rapid weight loss is thought to lead to the development of the syndrome.

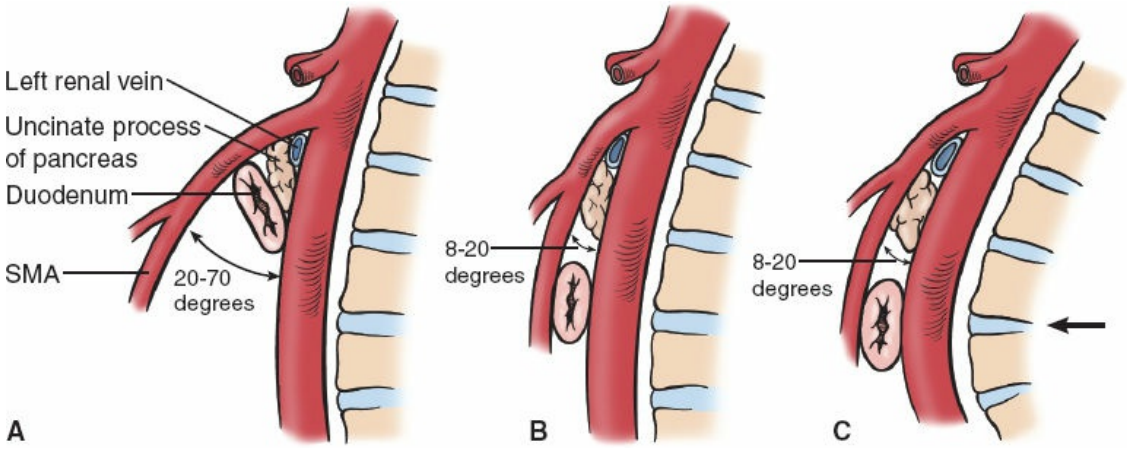

Figure 93.2. **A.** Normal aortomesenteric angle. **B.** Narrowed aortomesenteric angle in a patient with vascular compression of

the duodenum. **C.** Severe lumbar lordosis can exacerbate a narrowed aortomesenteric angle. SMA, superior mesenteric artery.

Though nearly half of the patients with vascular compression of the duodenum have no obvious clinical trigger and therefore would be considered idiopathic, Akin et al. identified supine immobilization, scoliosis, and the placement of a body cast in addition to weight loss as predisposing conditions to syndrome development. The so-called “cast syndrome” was first described in 1950 by Dorph to characterize the patients in whom placement of a whole body cast precipitated the subsequent onset of intractable nausea and vomiting with accompanying gastric and duodenal dilatation. The majority of the reported cases were in young patients, many of whom were being treated for scoliosis. Removal of the cast, rehydration with intravenous fluids, and nasogastric decompression usually led to the resolution of symptoms. Some authors later reported successful management of this problem with the institution of total parenteral nutrition, whereas others noted recovery only with surgical decompression.

Vascular compression of the duodenum has also been reported in other disease states associated with significant weight loss, including anorexia nervosa, severe combat injury leading to a prolonged bedridden status, and major burns. In one report of burn patients, all patients had a >30% total body surface area burn and the syndrome developed soon after the burn injury. Associated symptoms of aspiration, gastroduodenal ulceration, and sepsis were common. Though some patients had symptomatic relief with positional maneuvers, the best results were achieved with operative decompression. Prone positioning was more successful in relieving duodenal compressive symptoms in a number of patients rendered bedridden following severe combat injuries.

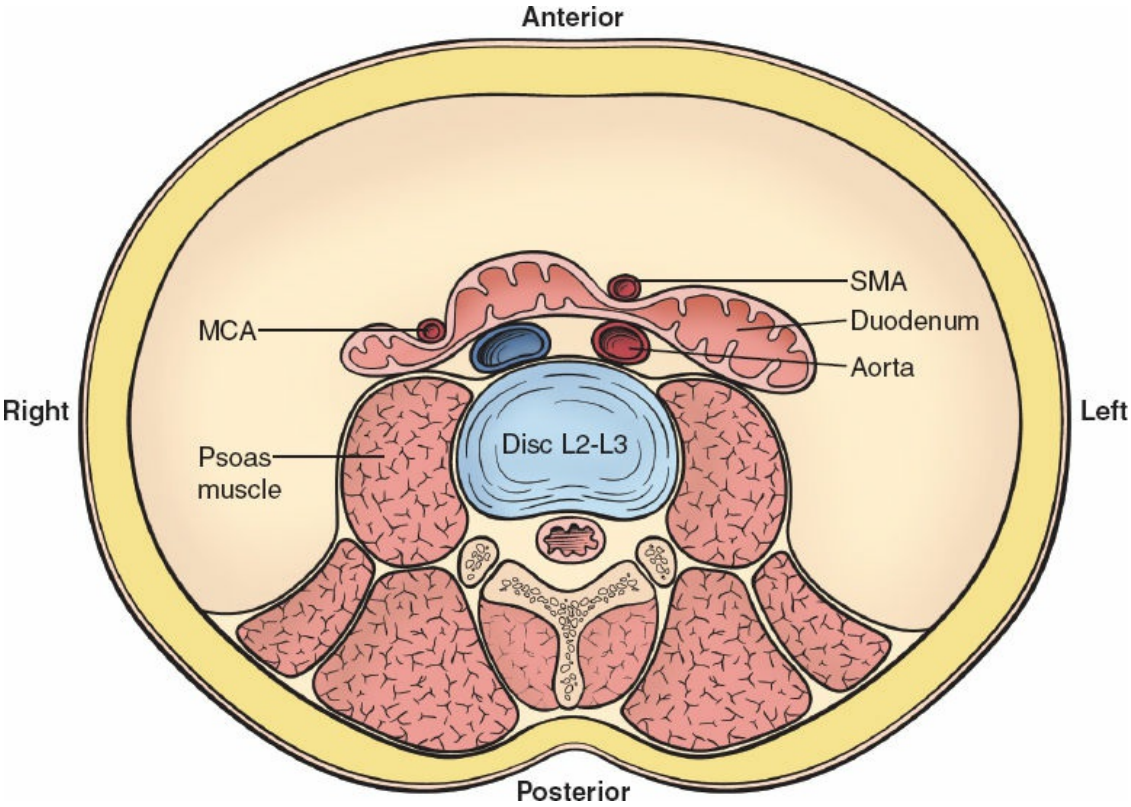

Figure 93.3. Axial view at the level of the second to third lumbar vertebrae shows the potential points of obstruction of the third portion of the duodenum between the SMA and the aorta, or the MCA and right psoas muscle. SMA, superior mesenteric artery; MCA, middle colic artery.

Isolated descriptions of a similar compressive symptom complex that have followed total proctocolectomy and J-pouch anal anastomosis have been attributed to traction on the mesentery by the translocated terminal ileum. Finally, vascular compression of the duodenum has also been described in the pediatric population. Though it has typically been seen in this setting in those having experienced either rapid weight loss or rapid growth, it has also been reported in those with age-appropriate weight and height.

DIAGNOSIS

Diagnosis of vascular compression of the duodenum combines an appropriate degree of clinical suspicion with radiographic confirmation. Traditionally, assessment began with plain abdominal radiographs, which typically delineated a dilated stomach and proximal duodenum. Air fluid levels proximally, absence of air distally, and a clear demarcation line in the duodenum were particularly suggestive of the diagnosis. Given the

poor specificity of plain films and the broad differential diagnosis associated with proximal dilation on plain radiographs, follow-up contrast studies were typically obtained. Both barium and hypotonic contrast have been employed, with the latter considered more sensitive and specific. An upper gastrointestinal tract series (UGIS) utilizing contrast taken orally or via nasogastric tube reveals gastroduodenal dilation and the characteristic linear defect indicative of extrinsic compression in the third portion of the duodenum. Inability of contrast to traverse the point of duodenal obstruction is a reliable diagnostic finding and suggests a severe degree of compression. Fluoroscopy obtained during the swallow study will frequently demonstrate a “to-and-fro” appearance to the peristaltic waves in the proximal duodenum. Subsequent passage of contrast beyond the obstruction and simultaneous relief of attendant symptoms following positional changes during fluoroscopy is also highly suggestive of the correct diagnosis. Positional maneuvers that may produce relief through widening of the aortoduodenal angle include knee-to-chest, prone, or left lateral decubitus positioning.

Combining aortic and selective SMA angiography with contrast imaging of the intestine has been used as a further confirmatory modality and for a period was considered the gold standard diagnostic strategy. Documentation of narrowing of the aortomesenteric angle and colocalization of the duodenal obstruction to the point where the SMA crosses over the duodenum are the hallmark positive findings of these paired investigations. In recent years, the advent of high-quality CT and magnetic resonance imaging (MRI) has supplanted barium swallow and UGI studies. Multislice CT undertaken with intravenous and oral contrast and three-dimensional reconstruction in particular provides a rapid, highly accurate and noninvasive means of visualizing both the relevant vascular and intestinal structures. It has the further advantage of providing detailed information on the remainder of the abdominal organs and, as such, shedding light on additional potential diagnostic entities. Modern-day magnetic resonance angiography (MRA) is also an excellent noninvasive means of delineating the mesenteric vasculature; a study failing to demonstrate either a narrowed aortomesenteric angle or findings suggestive of duodenal obstruction would strongly argue against the diagnosis.

Differential Diagnosis

The differential diagnosis of vascular compression of the duodenum includes multiple other inflammatory and neoplastic entities affecting the duodenum and adjacent anatomic structures. In the era in which peptic ulcer disease was ubiquitous, this disease process was a frequent cause of duodenal and gastric obstruction. Biliary tract pathology, as well as duodenitis and pancreatitis from a number of inciting causes, can result in secondary fibrotic changes that lead to a similar constellation of symptoms. Obstruction from a variety of tumors, including choledochal, pancreatic, duodenal, and jejunal neoplasms, as well as metastatic disease and para-aortic lymphadenopathy, all need to be considered in the patients presenting with proximal intestinal obstruction and weight loss. Cystic pathology of the bile duct and pancreas comprises additional possible sources, as do pancreatic pseudocysts, surgical adhesions, inflammatory bowel disease, and malrotation. Less typical entities included in the differential diagnosis are anorexia, bulimia, porphyria, vitamin D deficiency, visceral neuropathy, and postvagotomy syndrome. Celiac artery compression syndrome as an inciting trigger to rapid weight loss and subsequent vascular compression of the duodenum has been described. Finally, diseases associated with duodenal dysmotility, such as diabetes mellitus, chronic idiopathic intestinal pseudo-obstruction, and collagen vascular diseases such as scleroderma, can on occasion lead to “megaduodenum” and should also be considered.

Although now perhaps more of historic note, there has been a well-documented association between vascular compression of the duodenum and peptic ulcer disease. Indeed, one study describing nearly 300 patients with vascular compression since 1960 indicated that 32% had concomitant peptic ulcer disease. Patients identified as having both pathologies typically had chronic compressive symptoms and were often males of normal body habitus rather than thin and asthenic in appearance. The pathophysiologic process connecting the two disease states is poorly understood, though it has been noted that gastric secretions do not tend to be elevated in these patients. This association is notably less common with the more recent fall in incidence of peptic ulcer disease.

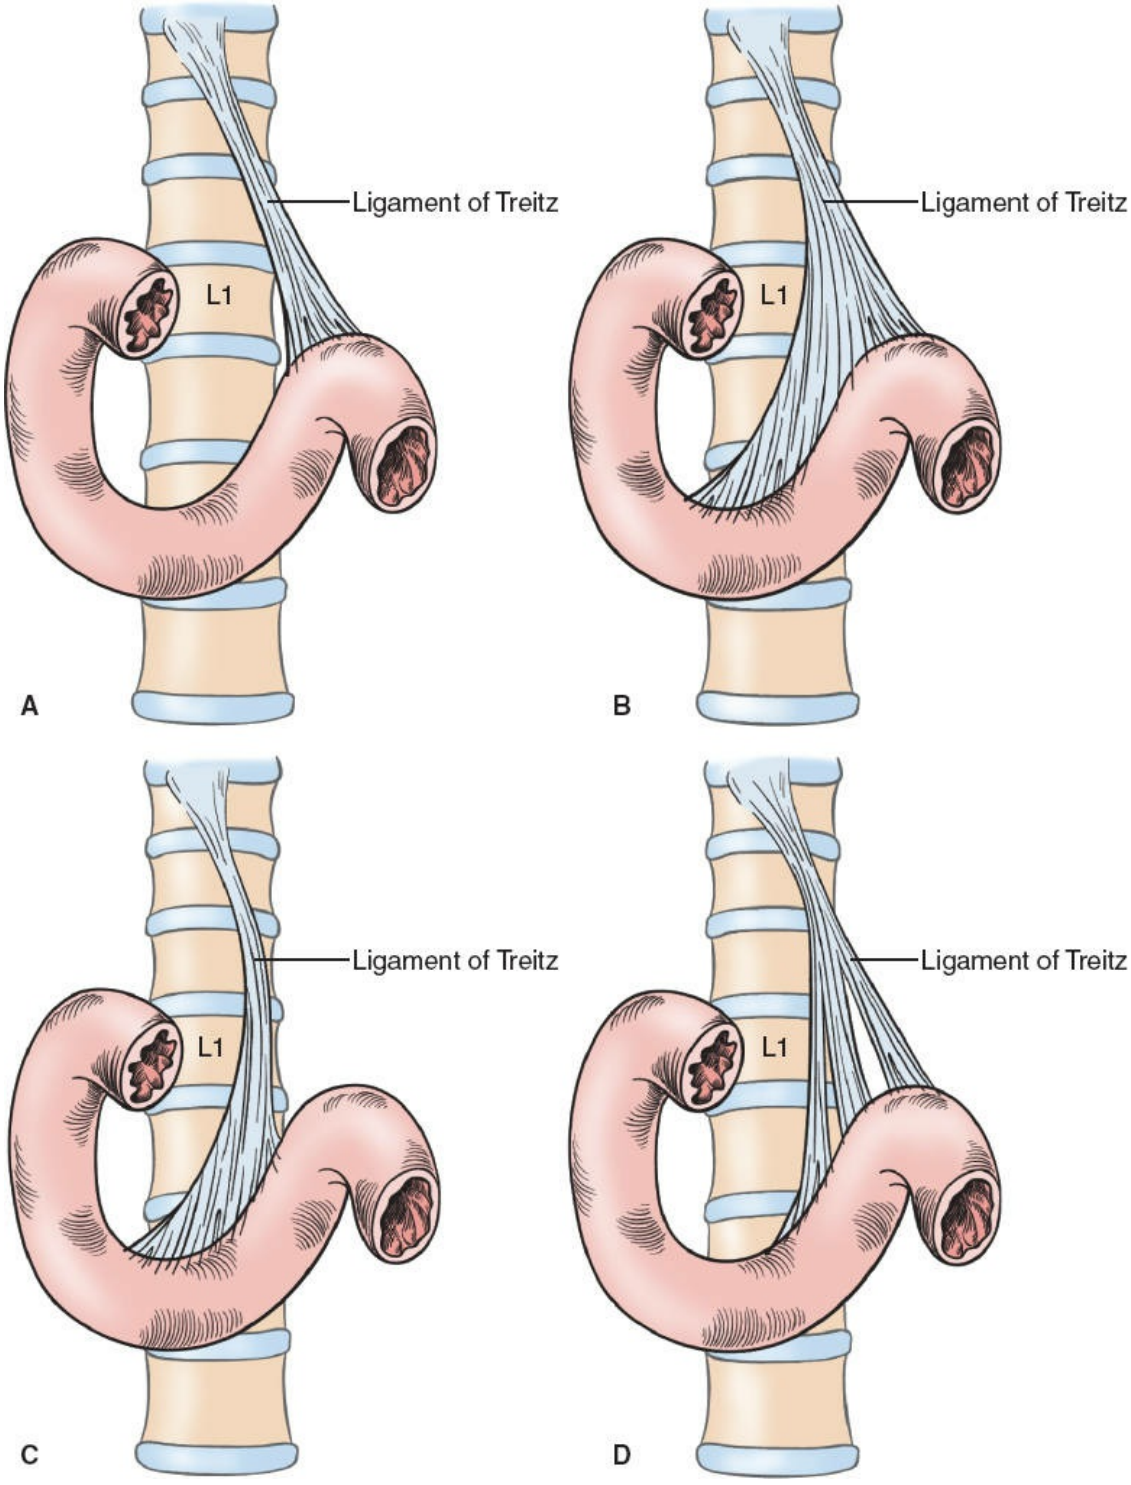

Figure 93.4. Variations in the attachment of the ligament of Treitz. Example B is the most common configuration.

MANAGEMENT

The initial management efforts in patients with vascular compression of the duodenum should be focused on the alleviation of the associated obstructive symptoms and treatment of volume and nutritional depletion.

Identified electrolyte imbalances are managed with intravenous fluid rehydration, and gastroduodenal decompression is typically accomplished by passage of a nasogastric tube. Given the historic association with concurrent peptic ulcer disease and the need to reduce secretions proximal to the obstruction, control of gastric acid secretion with either H_2 receptor blockers or proton pump inhibitors has been an important component of the treatment of patients diagnosed with or suspected of having the syndrome.

The patients in whom the diagnosis is highly suspected or confirmed, every effort should be made to alleviate any aggravating circumstances that may be contributing to disease progression. Although rarely utilized in the current era, patients with a whole body cast for the treatment of scoliosis or trauma or a hip spica cast should have the cast removed as it frequently results in symptomatic improvement and can even lead to the resolution of the syndrome. Efforts at windowing of the cast, on the other hand, have not traditionally been sufficient to achieve definitive relief.

The high prevalence of weight loss and malnutrition mandates that significant attention be given to restoring body weight and nutritional balance. Patients tolerant of oral intake should have a modified diet of small meals administered more frequently. Accompanying postprandial postural changes when practical may serve to reduce the pain associated with ingestion and facilitate the passage of food beyond the point of obstruction; the left lateral decubitus, prone, and knee–chest positions have all been utilized successfully toward this end. If adequate nutrition cannot be attained by oral means, enteral nutrition via a nasojejunal tube advanced endoscopically or radiographically past the point of duodenal obstruction is recommended. For the minority of the patients intolerant of enteral feeding, the use of total parenteral nutrition is an appropriate alternative means of nutritional support. The presumptive aim of such efforts to accomplish weight gain is restoration of the retroperitoneal fat pad and attendant expansion of the aortoduodenal angle.

While a trial of conservative therapy should be instituted in all patients, success with nonoperative measures is variable and is related to the etiology and extent of obstruction at the time of presentation (see Fig. 93.5). Patients with prolonged or severe symptoms initially or those who fail to gain weight with adjunctive nutritional support are more likely to respond poorly to conservative treatment. Given the advanced stage of decline present in many patients at the time the syndrome is correctly

recognized, it is perhaps not surprising that the majority of patients with vascular compression of the duodenum eventually require surgical relief.

SURGICAL TECHNIQUE

When nonoperative therapy proves insufficient, there are two current mainstays of surgical treatment for vascular compression of the duodenum: division of the ligament of Treitz and a duodenojejunostomy bypass around the point of obstruction. Strong et al. in 1958 first advocated that division of the ligament of Treitz and downward mobilization of the duodenum is appropriate and sufficient treatment for the syndrome. In their subsequent report nearly two decades later reviewing the accumulated literature from the previous 30 years, Akin et al. reinforced this position, citing an 83% success rate with the maneuver.

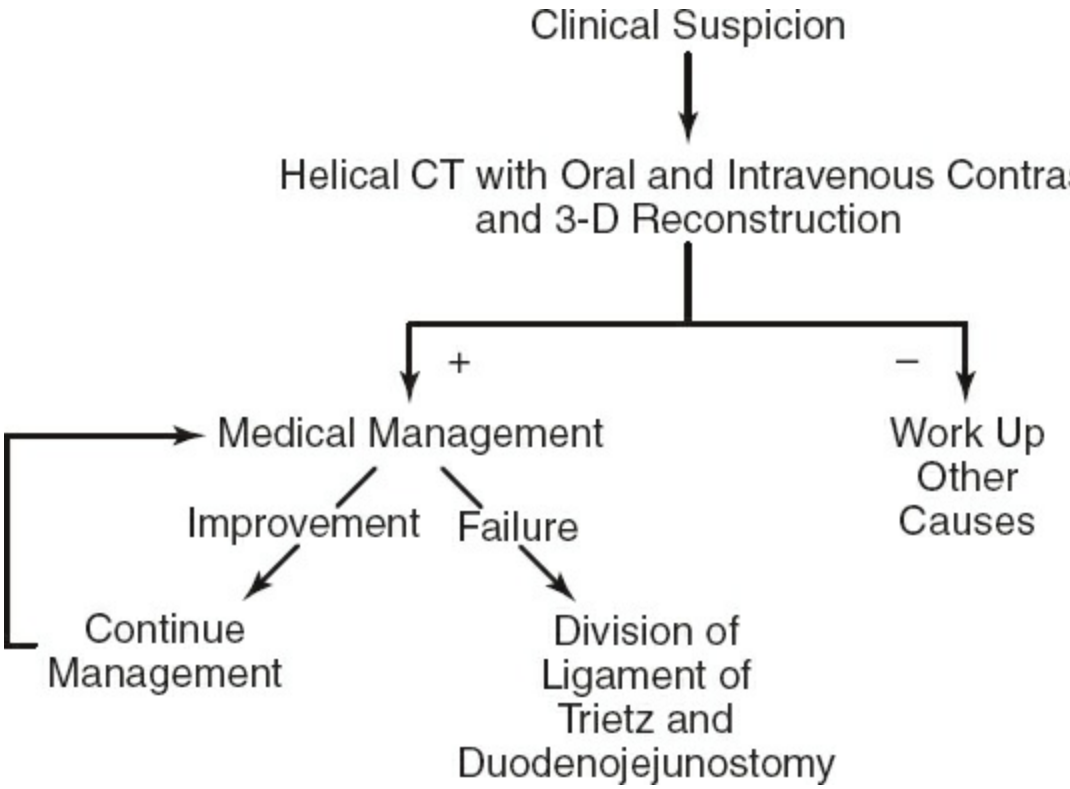

Figure 93.5. Decision-making algorithm for the diagnosis and treatment of vascular compression of the duodenum. CT, computed tomography.

For the patients in this series who experienced a less favorable response with division of the ligament alone, a subsequent duodenojejunostomy resulted in symptomatic relief and a good outcome in most cases. Notably, the patients who underwent a duodenojejunostomy concurrently with

division of the ligament of Treitz had a near universal 99% rate of success. Reported symptomatic relief was prompt and postoperative weight gain was steadily progressive in this review. Multiple additional reports of duodenojejunostomy in the literature have been similarly favorable, with positive outcomes following the procedure seen in 80% to 100% of the cases performed for this indication. Though employed as a successful surgical strategy for correctly diagnosed vascular compression of the duodenum for nearly a century, duodenojejunostomy continues to be the operative treatment of choice of most authorities.

Various other surgical approaches have also been utilized over time for vascular compression of the duodenum. One author reported successful 12-month results in all 10 patients undergoing transposition of the third portion of the duodenum anterior to the SMA. A modification of simple division of the ligament of Treitz has been championed in the pediatric surgical literature and presumably grew out of the experience with lysing of Ladd's bands in patients with congenital malrotation. After full mobilization of both the right colon and the duodenum, the unfolded small bowel is placed in the right colonic gutter and the right colon is transposed to the left. Though several reports have indicated a success rate as high as 90% with this derotation procedure in the pediatric community, it has never gained popularity in the adult population.

Additional strategies for which early enthusiasm has dimmed include colonic resection, colonic plication, mesenteric plication, and gastrojejunostomy. Although multiple authors describing their anecdotal experience with small numbers of patients have reported excellent outcomes with gastrojejunostomy, in larger reviews the documented success rates have been much lower, ranging from 40% to 70%. As indicated in Figure 93.6, the necessity for biliary and pancreatic secretions to drain in a retrograde fashion is a key limitation to this surgical option and a likely contributing factor for the associated reduced success rates. In the recent era, both division of the ligament of Treitz and duodenojejunostomy have been successfully performed laparoscopically. Whereas the reported experience is limited to a small number of case series with few patients, the success rates have mirrored the open surgical experience in that the results of duodenojejunostomy have been more favorable than those involving division of the ligament of Treitz and mobilization of the duodenum alone. Both open and laparoscopic approaches can be undertaken with minimal operative morbidity and

mortality in appropriately resuscitated patients.

Division of the Ligament of Treitz

The abdomen is entered through a midline incision, and a general survey of the peritoneal cavity is carried out. Intraoperative confirmation of the diagnosis of vascular compression of the duodenum can be achieved by insufflation of 150 to 300 mL of air through a nasogastric tube. Historically, expansion of the duodenal diameter by >3 to 4 cm is considered a positive response. The omentum and transverse mesocolon are elevated superiorly to allow exposure of the ligament of Treitz and the duodenojejunal flexure, the latter identified as the jejunum emerges from the base of the posterior aspect of the transverse mesocolon to the left of the spine. With the proximal jejunum under gentle downward stretch, the peritoneum along the left lateral aspect of the jejunum is first incised (Fig. 93.7A). Further mobilization of the duodenojejunal flexure is achieved by dividing the suspensory muscle of the duodenum, or ligament of Treitz, along the anterior and cranial aspect of the third and fourth portions of the duodenum (Fig. 93.7B). This maneuver serves to lower the third and fourth portions of the duodenum from the aortomesenteric angle; once successfully completed, the space between the duodenum and the origin of the SMA should easily allow the passage of two fingers (Fig. 93.7C).

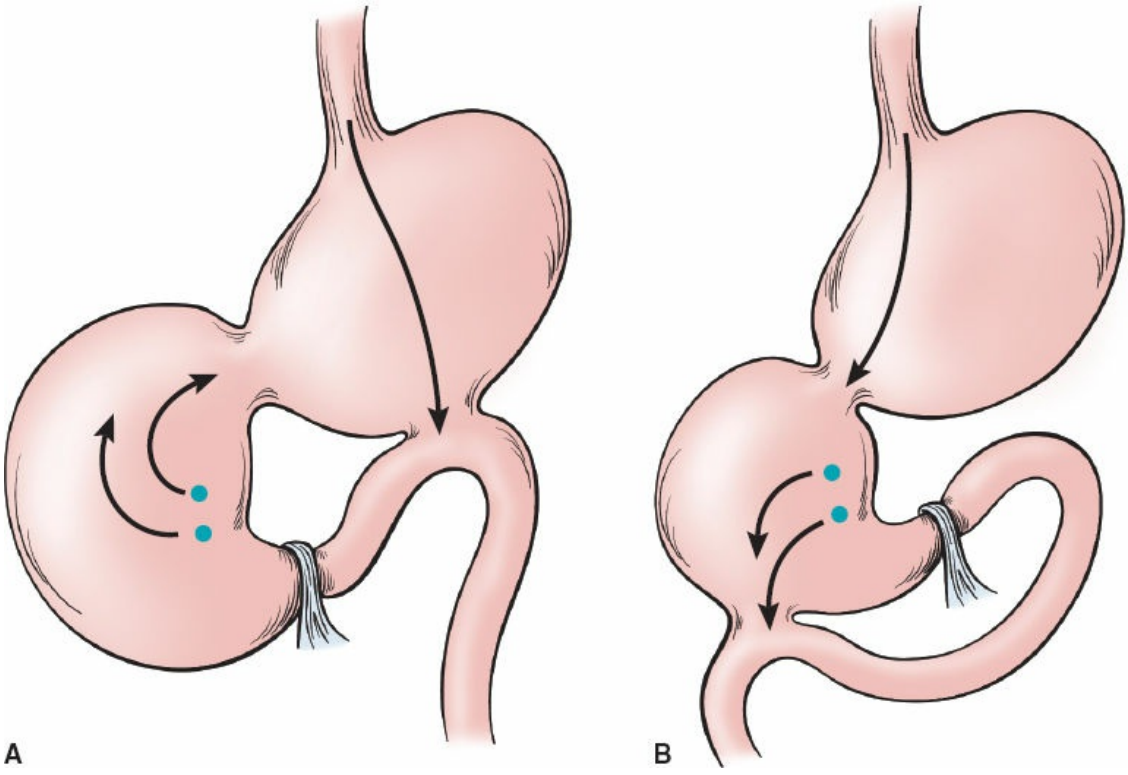

Figure 93.6. A. Gastrojejunostomy necessitates drainage of bile and pancreatic secretions in a retrograde fashion through the stomach. **B.** This potential cause of suboptimal operative outcome is obviated by duodenojejunostomy.

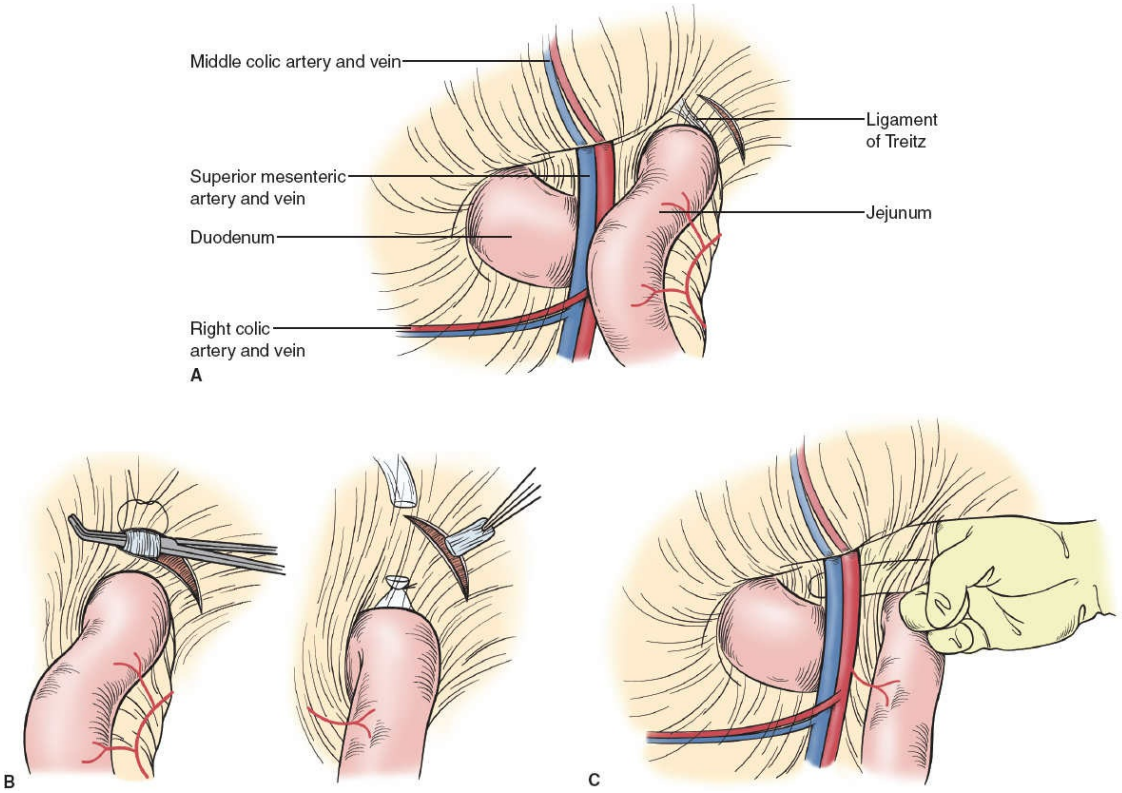

Figure 93.7. Division of the suspensory ligament of the duodenum. **A.** Incision of the peritoneum along the left aspect of the duodenojejunal flexure. **B.** Division of the ligament of Treitz. **C.** Mobilization of the duodenal flexure out of the aortomesenteric angle should allow at least two fingers to pass between the duodenum and the origin of the SMA.

If desired, more complete mobilization of the second and proximal aspect of the third portion of the duodenum can be obtained by undertaking a wide Kocher maneuver. Similarly, more extensive exposure of the distal duodenum can be gained by incising the transverse mesocolon and gastrocolic ligament and extending the dissection to include the retropancreatic space, the superior aspect of the paraduodenal fossa, and the posterior aspect of SMA. Following these steps, subsequent internal herniation can occur if the peritoneal defect along the left aspect of the duodenojejunal flexure is not closed. The described dissection can also be complicated by bleeding from multiple vascular structures. The vessels most prone to injury include the inferior mesenteric vein and the SMA and

superior mesenteric vein and their proximal middle colic and inferior pancreaticoduodenal branches. Both variations in the anatomy of the ligament of Treitz and encountered bleeding difficulties during lysis of the ligament have been implicated as possible explanations for the generally inferior results when treatment is limited to division of this ligament alone.

Duodenojejunostomy

If a duodenojejunostomy is to be performed, it is begun after mobilizing the second and third portions of the duodenum as described above and retracting the duodenum caudally through the peritoneal incision (Fig. 93.8A). A side-to-side duodenojejunostomy is preferred and is created by orienting the proximal 10 to 15 cm of the jejunum to the right of the SMA and superior mesenteric vein (Fig. 93.8B). A posterior row of interrupted 3-0 silk sutures is then placed between the junction of the second and third portions of the duodenum and the jejunum. A longitudinal enterotomy of at least 5 cm is carried out on the antimesenteric border of both the duodenum and jejunum, and an inner layer of 3-0 absorbable suture is run circumferentially. An anterior row of interrupted 3-0 silk seromuscular sutures is placed to reinforce the anastomosis (Fig. 93.8C).

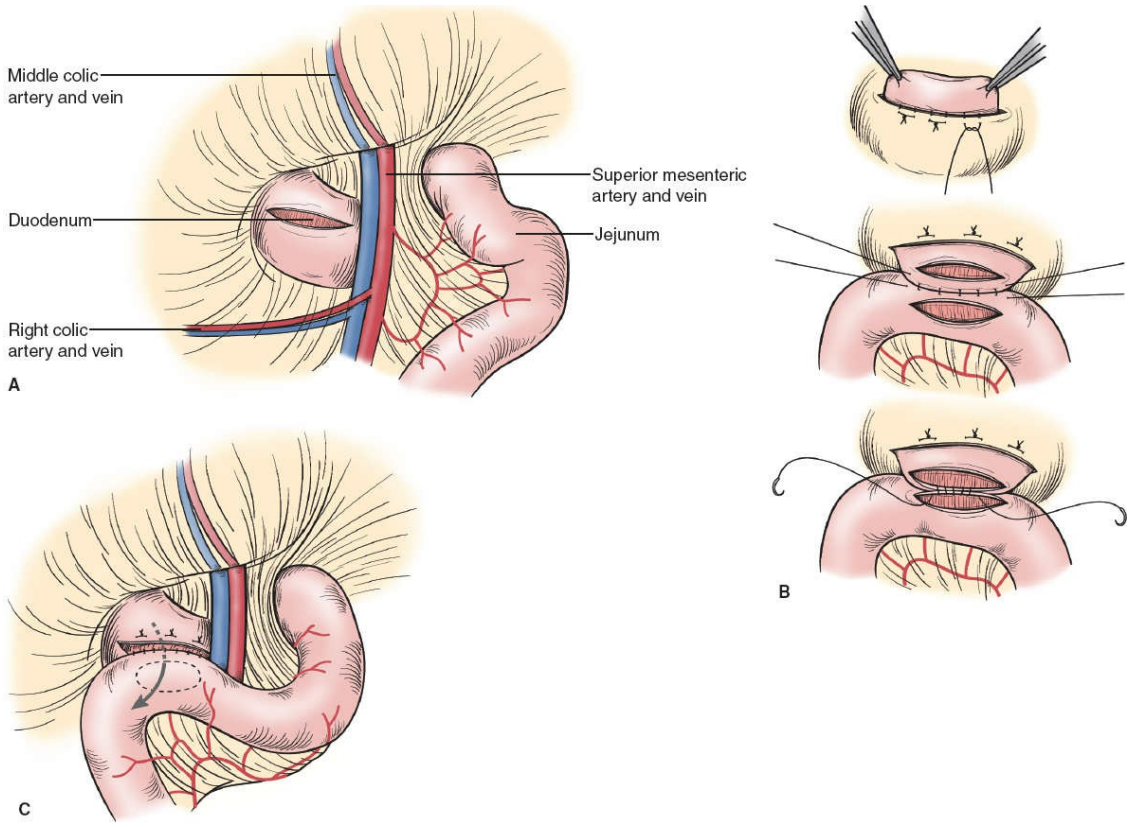

Figure 93.8. Construction of a side-to-side duodenojejunostomy.

A. Incision of the peritoneum and exposure of the junction of the second and third portions of the duodenum. **B.** Posterior row of seromuscular nonabsorbable sutures is placed between the duodenum and jejunum and a longitudinal incision is made on the antimesenteric borders of the bowel. Running absorbable sutures create the inner layer. **C.** An anterior row of interrupted nonabsorbable sutures completes the anastomosis.

An acceptable alternative approach involves creation of a Roux-en-Y duodenojejunostomy (Fig. 93.9). This option is less commonly utilized, given the increased risk associated with the additional anastomosis.

Laparoscopic Approaches

Multiple case reports describe successful laparoscopic, even robotic, performance of these procedures, either alone or in combination. These options clearly depend on the skill and comfort level of the surgeon; to date, benefits have not been demonstrated conclusively. When performed laparoscopically, the duodenojejunostomy is generally undertaken with either 4 or 5 trocars. Two trocars are placed lateral to the left rectus sheath, one below the left costal margin, and one more caudally. A third trocar is placed through the umbilicus and one or two additional trocars are placed lateral to the right rectus sheath. Given the proximal duodenal dilation typically encountered beneath the transverse colon, a retrocolic stapled duodenojejunostomy is often technically easiest to construct.

EDITOR'S COMMENT

In the majority of cases, vascular compression of the duodenum (Wilkie syndrome) is a secondary event. It may be the result of weight loss, correction of scoliosis, obesity, enforced bed rest in the supine position, and the presence of a body cast which may alter unfavorably the angle of mesenteric traction and increase the possibility of duodenal compression (Akin JT Jr, Skandalakis JE, Gray SW. The anatomic basis of vascular compression of the duodenum. *Surg Clin North Am* 1974;1361–70). Unfortunately, according to another paper from the Skandalakis group rarely underlying anatomical causes may contribute to the syndrome including a congenitally short mesentery, aberrant superior mesenteric artery syndrome, excessive mobility of the right colon, malrotation, and a short suspensory ligament may also be involved (Androulakis J, Colborn GL, Skandalakis PN, et al. Embryologic and anatomic basis of duodenal surgery. *Surg Clin North Am* 2000;80:171–200). Unfortunately, these are absent is many patients.

The obstruction may be diagnosed by an upper GI series, but more commonly by CT of the abdomen with IV and oral contrast. The usual setting of the superior mesenteric artery syndrome is the patient who has undergone a

period of weight loss secondary to prolonged fasting and lack of adequate nutritional intake. Theoretically, at least there is a fat pad which lists the superior mesenteric artery on the third portion of the duodenum and as the fat is reabsorbed for calories the superior mesenteric artery syndrome results. This has been very difficult to prove. Indeed the use of hyperalimentation to restore the fat pad is not particularly successful in every patient. Another cause of superior mesenteric artery syndrome is neoplasm in the area of the midportion of the pancreas as the superior mesenteric artery arises and passes over the duodenum. In addition, primary tumors of the duodenum may cause the obstruction as well as Crohn disease involving the duodenum, duodenal diverticulum or rarely peptic ulcer disease. In these cases, other procedures, such as resection, may be an option rather than duodenojejunostomy. Hence in the evaluation of these patients with CT as indicated above should also include esophagogastroduodenoscopy to exclude primary duodenal pathology. It has been noted that this syndrome may occur after ileoanal anastomosis (Ravindra KV, Rajasekhar P, Rozario AP, et al. Superior mesenteric artery syndrome following ileo-anal pouch procedure. *Indian J Gastroenterol* 1999;18(1):35–6) and after left colectomy (Yerdel MA, Moreira LF, Iwagaki H, et al. Acute superior mesenteric artery syndrome following left hemicolectomy: a case report. *Acta Med Okayama* 1992;46(6):479–82).

Another situation in which there is a significant amount of theoretical causation of superior mesenteric artery syndrome is kyphoscoliosis and its correction. According to this hypothesis, this may also be associated with severe weight loss (Munns SW, Morrissy RT, Golladay ES, et al. Hyperalimentation for superior mesenteric-artery (cast) syndrome following correction of spinal deformity. *J Bone Joint Surg* 1984;66:1175–77; De Giorgi G, Stella G, Becchetti S, et al. Cotrel-Dubousset instrumentation for the treatment of severe scoliosis. *Eur Spine J* 1999;8(1):8–15). Hyperalimentation following the superior mesenteric artery syndrome (cast syndrome) in which this was successful in reversing the superior mesenteric artery syndrome. In Munns publication, which originated from Maryís Hospital for Children in the United Kingdom, there were two cases one of which had a paralytic lumbar scoliosis that gradually became particularly too difficult and was corrected in a cast made an uneventful recovery and was treated conservatively in the usual fashion. The other patient required a duodenojejunostomy because nonoperative therapy failed.

As the authors state mobilizing of the Ligament of Treitz may be sufficient but the repair is usually more successfully treated with a side-to-side duodenojejunostomy. An open, laparoscopic (Sun Z, Rodriguez J, McMichael J, et al. Minimally invasive duodenojejunostomy for superior mesenteric artery syndrome: a case series and review of the literature. *Surg Endosc* 2015;29(5):1137–44) or robotic approach may be employed (Ayloo SM, Masrur MA, Bianco FM, et. al. Robotic Roux-en-Y duodenojejunostomy for superior mesenteric artery syndrome: operative technique. *J Laparoendosc Adv Surg*

Tech A 2011;21(9):841–4).

C BARIATRIC AND METABOLIC DISEASES

94 Gastrointestinal Stromal Tumors

G. Travis Clifton and Paul Mansfield

ETIOLOGY AND PATHOPHYSIOLOGY

Gastrointestinal stromal tumors (GISTs) are a relatively rare tumor type although the commonest mesenchymal cancer of the gastrointestinal tract. They are thought to most commonly originate from the myenteric interstitial cells of Cajal, responsible for intestinal neuromediation and myenteric packmaking, or their precursor cells and thus can be found anywhere along the gastrointestinal tract. GISTs are most commonly found in the stomach (50% to 60%) and small intestines (20% to 35%). Less common locations include the colon and rectum (~5%), esophagus (1%) and, rarely, extraintestinal locations such as the omentum or mesentery.

GISTs represent around 1% of primary gastrointestinal cancers and have an incidence of between 3 and 20 cases per million individuals per year. The incidence has increased as improved molecular diagnostics have increased the proportion of gastrointestinal mesenchymal tumors classified as GIST. Even then, the rate of subclinical GISTs may be much higher, particularly for subcentimeter (micro-GISTs), as they have been found in high rates in meticulous evaluation of gastric specimens removed during sleeve gastrectomy and in autopsy studies.

The mutational drivers of GISTs are increasingly well characterized and important for both diagnosis and treatment. In most GISTs, oncogenic mutations are present in KIT (75% to 80%) or platelet-derived growth factor receptor-α (PDGFA, 10%). Both are homologous surface tyrosine kinase receptors that are constitutively activated by a number of well-characterized mutations, which leads to pathologic cell proliferation. Patients with heritable mutations of KIT or PDGFRA are susceptible to developing gastric and small bowel GISTs, often at a young age. However,

these mutations alone may not be sufficient for malignant behavior as they are present in small, incidentally discovered GISTs that appear to have a more indolent natural history.

About 10% to 15% of GISTs, in which no c-KIT or PDGRA mutation is present, are considered “wild type” (WT-GIST). WT-GISTs derive their oncogenic potential from downstream tyrosine kinase mutations such as succinate dehydrogenase (SDH), BRAF, and insulin-like growth factor-1 and are more common among GISTs in children. Several conditions predispose individuals for development of WT-GIST, particularly at a younger age. Carney triad (GIST, paraganglioma, pulmonary chondroma) is a nonheritable syndrome that affects younger women, which may be associated with SDH deficiency. Carney–Stratakis syndrome is due to a heritable mutation in SDH causing a familial predisposition for GIST and paragangliomas. Patients with neurofibromatosis type 1 are also at increased risk for developing GIST.

The clinical behavior and prognosis of GISTs is highly variable and greatly dependent on their size, mitotic rate, and location.

CLINICAL PRESENTATION

GISTs are most common in elderly individuals (median age 55 to 60 years old) but can occur at any age and are occasionally seen in children. They have a roughly equivalent prevalence in males and females.

The most common presenting symptoms are gastrointestinal hemorrhage, anemia, abdominal pain, and abdominal mass. Less commonly, tumors can present with more urgent symptoms of bowel obstruction or tumor rupture with hemoperitoneum. Up to a third of the time GISTs are discovered incidentally on imaging or during surgical or endoscopic procedures. Given that GIST arise in the submucosal and intramuscular layers of the gastrointestinal tract, endoscopically GISTs often appear as a mass with intact overlying mucosa, although ulceration certainly can be present.

GISTs can become quite large before symptoms develop, with most larger than 5 cm at the time of diagnosis. Small bowel GISTs are typically larger and more likely to have metastatic disease at presentation compared to gastric GISTs.

PREOPERATIVE PLANNING

When a suspected GIST is encountered, evaluation with a high-quality

abdominal and pelvic CT scan with IV contrast is necessary to characterize the tumor morphology, the local extent of disease, and evaluate for metastatic disease. Unlike other mesenchymal tumors, metastases to the lungs are exceedingly rare so imaging of the chest is not mandatory in localized disease unless symptoms or physical examination findings dictate otherwise.

Further evaluation with endoscopic ultrasound (EUS) and fine needle aspiration (FNA) can be used to secure the diagnosis and is necessary prior to considering either observation or preoperative systemic therapy. Percutaneous core needle biopsy should generally be avoided in cases of suspected GISTs due to fragility of the tumors and risk of hemorrhage or dissemination. Localized suspected GISTs that are easily resectable, particularly if they are not readily accessible endoscopically, do not necessarily need a tissue diagnosis prior to proceeding with surgical resection.

Observation

Very small, asymptomatic gastric GISTs (<2 to 3 cm) can, at times, be safely observed without surgical resection due to their low malignant potential, particularly in patients who are elderly or poor surgical candidates. Observational studies have shown that gastric GISTs less than 2 cm, regardless of their mitotic rate, have an exceedingly low rate of metastasis (Table 94.1). High-risk endoscopic ultrasonographic features such as an irregular border, cystic spaces, ulceration, echogenic foci, and heterogenicity have been associated with higher rates of malignant behavior and should lead to surgical excision. Should observation be selected, the lesion should be re-evaluated at by EUS to ensure stability.

TABLE 94.1 Rates of Metastases or Tumor-Related Death in GISTs by Tumor Location, Grouped by Tumor Size and Mitotic Rate

Tumor Parameters			Percent of Patients With Progressive Disease During Long-Term Follow-up and Characterization of Risk for Metastasis			
Group	Tumor Size (cm)	Mitotic Rate (HPF)	Gastric GISTs (%)	Jejunal and Ileal GISTs (%)	Duodenal GISTs (%)	Rectal GISTs (%)
1	≤2	≤5/50	0 none	0 none	0 none	0 none
2	>2 ≤5	≤5/50	1.9 very low	4.3 low	8.3 low	8.5 Low
3a	>5 ≤10	≤5/50	3.6 low	24 moderate	34 high[b]	57 high[b]
3b	>10	≤5/50	12 moderate	52 high		
4	≤2	>5/50	0[a]	50[a]	[c]	54 high
5	>2 ≤5	>5/50	16 moderate	73 high	50 high	52 high
6a	>5 ≤10	>5/50	55 high	85 high	86 high	71 high[b]
6b	>10	>5/50	86 high	90 high		

[a]Denotes tumor categories with very small numbers of cases.
[b]Groups 3a and 3b or 6a and 6b are combined in duodenal and rectal GISTs because of small number of cases.
[c]No tumors of such category were included in the study. Note that small intestinal and other intestinal GISTs show a markedly worse prognosis in many mitosis and size categories than gastric GISTs.
Adapted from Miettinen M, Lasota J. Gastrointestinal stromal tumors: pathology and prognosis at different sites. *Semin Diagn Pathol* 2006; 23(2):70–83.

Neoadjuvant Therapy

Neoadjuvant therapy with the tyrosine kinase inhibitor imatinib should be considered in patients with GISTs that are locally advanced and when decreasing the tumor size would potentially decrease the surgical morbidity associated with the resection. This can be particularly beneficial in anatomically difficult locations such as the distal esophagus, duodenum, or distal rectum. In addition, observing the response to neoadjuvant therapy may provide clinically relevant information of the behavior of the tumor. For this reason, some advocate neoadjuvant therapy in patients who clearly have an indication for adjuvant imatinib after resection. While neoadjuvant therapy has not clearly demonstrated a survival benefit, the available data is limited to relatively small trials in which it has been found to be safe and effective at decreasing the tumor size in the majority of patients and rendering unresectable tumors resectable or decreasing the scope of the planned operation. The use of preoperative therapy in patients with metastatic or locally recurrent GISTs has also proven safe although it generally demonstrates lower response rates and is associated with a higher risk of incomplete resection. The use of neoadjuvant therapy is a decision of clinical judgment that should be made in the context of a multidisciplinary care team.

A tissue diagnosis is necessary prior to initiating systemic therapy. Knowing the mutational status of the GIST will help inform the individual

chances of success with therapy. Data extrapolated from response rates in advanced GIST indicate that the patient will have a partial or complete response by RECIST criteria (≥30% decrease in the sum of the longest diameter) in 63%, 37%, and 37% of the time for KIT exon 11 mutant, KIT exon 9 mutant, and WT-GIST, respectively. However, particularly important for patients in whom increased tumor size would preclude resection, progressive disease (≥20% increase in sum of the longest diameter) is seen in 6%, 9%, and 18% of patients with KIT exon 11 mutant, KIT exon 9 mutant, and WT-GISTs, respectively. Some mutations, such as PDGFRA D842V, have proven resistant to imatinib and in patients with GIST driven by these mutations alternative strategies may be necessary.

When using neoadjuvant therapy, early and regular interval assessment for response, typically every 8 to 12 weeks, with CT scans will ensure that preoperative therapy is not continued unnecessarily and that surgery is pursued at the time of maximal response which is determined by no further reduction in size on successive imaging. Typically, maximal response is achieved between 6 and 12 months. In patients in whom any progression would potentially render the tumor unresectable, assessment by PET-CT before and soon after initiation of therapy can be utilized. Multiple studies have demonstrated that a decrease in metabolic activity on PET scan, typically measured 8 to 14 days after initiation of therapy, but even as soon as 24 hours after initiation, is predictive of subsequent reduction of tumor burden or progression-free survival.

Second-line therapy with sunitinib can be used when resistance or intolerance to imatinib is present or develops and further reduction in tumor size is necessary for safe surgical resection.

Recurrent and Metastatic Disease

Up to 50% of patients with GIST will present with metastatic disease and there is an approximately 30% to 50% recurrence rate after resection of primary disease. There is a more limited role for surgery in cases of recurrent disease or when distant metastases are present; however, patients with resectable disease may benefit from resection in selected cases. Preoperative treatment with imatinib or sunitinib can help select patients with more favorable disease biology who will derive greater benefit from surgical resection. In patients with disease that remains stable on imatinib or sunitinib treatment, resection has been associated with prolonged

disease-free intervals and excellent disease-free survival. Likewise, in those with multifocal disease with isolated foci of metastases that become resistant to imatinib or sunitinib, resection of the unresponsive lesion, if it can be resected with limited morbidity, often can provide extended benefit in the form of disease control. In contrast, in patients with multifocal disease resistant to therapy, resection is unlikely to be complete and is associated with a short progression-free interval and few patients surviving more than 12 months. In these cases, the decision to operate should be individualized based on the potential oncologic and symptomatic benefit and the risks of surgery in the context of coordinated multidisciplinary care.

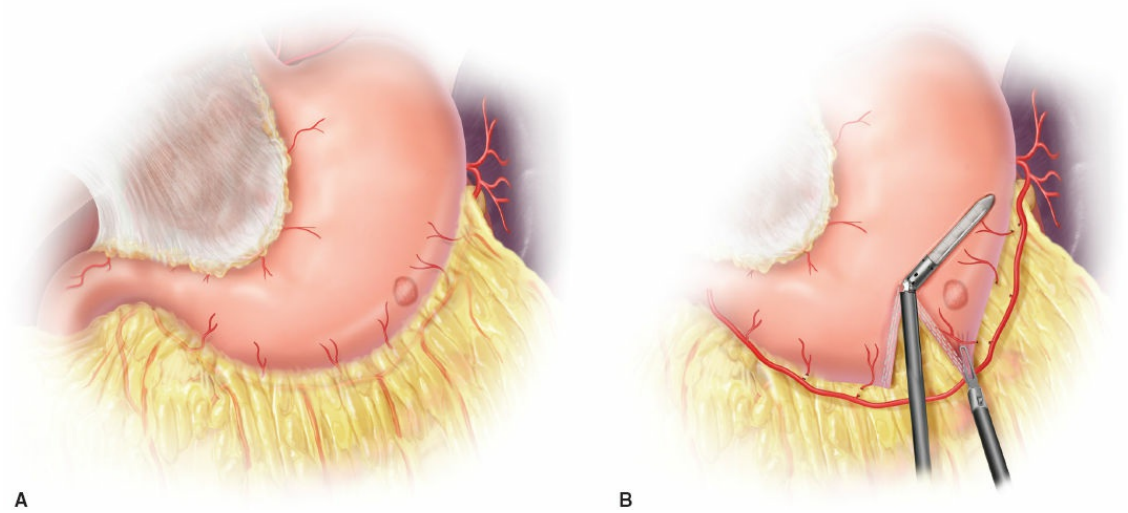

Figure 94.1. Laparoscopic wedge resection of a gastric GIST. Gastrointestinal stromal tumors located away from the gastroesophageal junction or pylorus (**A**) can often be resected laparoscopically with a stapled wedge resection (**B**).

SURGICAL TECHNIQUE

The aim of surgical resection of GIST is to remove the tumor intact while limiting surgical morbidity. Careful handling of the tumor is imperative as GIST tend to be friable and prone to rupture, which is associated with an increased risk of recurrence. In addition, GISTs treated with preoperative imatinib often have a dense surrounding desmoplastic reaction that can make removal from surrounding tissue tedious. While a margin-negative resection should be the surgical goal, microscopically positive margins (R1) have not been shown to increase the risk of recurrence with or without adjuvant imatinib in some series, although the data is mixed.

Minimally Invasive Versus Open Resection

The role of minimally invasive resection of small gastric GIST is well established. Smaller tumors, particularly in favorable locations (along the greater curvature of the stomach, jejunum, or ileum), can be resected laparoscopically with minimal morbidity and oncologic outcomes equivalent to open resection. Laparoscopic resection of larger gastric GIST and GIST in less accessible locations have been reported with favorable outcomes. However, as previously discussed, GISTs are prone to fracture leading peritoneal to dissemination of tumor. The tumor should be removed from the abdomen in an endoscopic retrieval bag to avoid tumor rupture and perionteal seeding. Resection of larger GISTs and those in more difficult anatomic locations should weigh the advantages of a minimally invasive approach with the risk of rupture and should only be attempted by those with sufficient minimally invasive expertise.

Gastric GIST

The stomach is the most common location for GIST tumors. Most gastric GIST can be resected with a wedge resection while achieving a grossly negative margin and maintaining intestinal continuity. Oftentimes, particularly for smaller lesions, this can be performed laparoscopically (Fig. 94.1). Care must be taken to avoid narrowing the stomach too much, particularly at the incisura. This can be prevented by the placement of a bougie or endoscope while using linear cutting staplers to transect the stomach. However, larger lesions and those located close to the pylorus or gastroesophageal junction may require partial or total gastrectomy in order to safely remove the tumor. If decreasing the tumor size would potentially allow a wedge resection, then neoadjuvant therapy should be considered.

Duodenal GIST

GIST in the duodenum, like other small bowel locations, most often present with bleeding or abdominal pain. Given the low likelihood of transmural spread and lymph node involvement, an adequate resection with negative margins can often be obtained for duodenal GIST with a limited resection thus minimizing potential surgical morbidity. If the lesion is small and away from the duodenal mesentery, a partial duodenal wall resection with primary closure or duodenojejunostomy can achieve adequate margins while minimizing potential morbidity (Fig. 94.2). In the

third or fourth portion of the duodenum, a segmental resection with end-to-side or end-to-end duodenojejunostomy may be technically easier and lay better. A more extensive operation for greater lymph node yield is not necessary in the absence of concerning radiographic or intraoperative findings. If a pancreaticoduodenectomy seems likely secondary to proximity to the ampulla of Vater or due to local invasion from the tumor, neoadjuvant treatment should be strongly considered. Even when tumors are quite large, they often remain encapsulated and displace rather than invade surrounding structure. However, in some cases, even after neoadjuvant therapy, a pancreaticoduodenectomy or pancreas-preserving duodenectomy will be necessary for adequate resection. Clinical judgment should be used in selecting appropriate patients for major resections based on the patient's ability to tolerate the operation and risk of local issues or metastases based on the tumor characteristics.

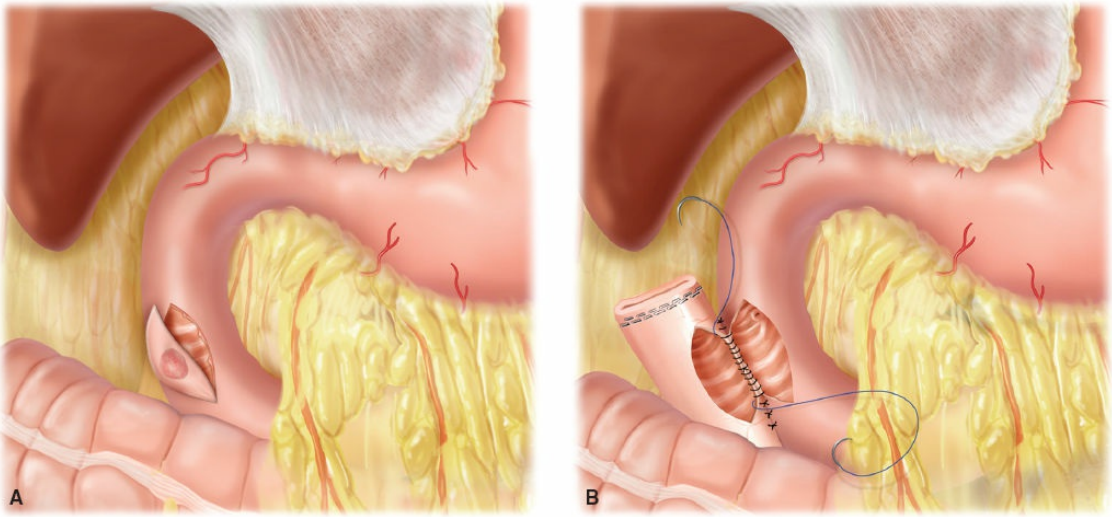

Figure 94.2. Resection of a duodenal GIST with duodenojejunostomy. Gastrointestinal stromal tumors in the second portion of the duodenum that are away from the mesentery and hepatopancreatic ampulla can be often be removed with negative margins by a partial duodenal resection (**A**). The resultant defect can be challenging to close primarily without narrowing the duodenum or leaving significant tension on the closure. A duodenojejunostomy can be used as a repair with favorable results (**B**).

Jejunal and Ileal GIST

In general, small bowel GISTs have a worse prognosis than gastric GIST when matched for size and mitotic rate. GIST of the jejunum and ileum are

typically treated with a segmental bowel resection with primary anastomosis. Many of these lesions may not be easily accessible endoscopically, so a preoperative histologic diagnosis may not be possible. However, if the diagnosis is known, an extensive lymphadenectomy is unnecessary as the rate of lymph node involvement is low. As with other locations, more advanced lesions that will potentially require multivisceral resection should be considered for neoadjuvant therapy first.

Rectal GIST

Rectal GISTs are uncommon and tend to be located in the distal half of the rectum. As in other locations, transmural spread and lymph node involvement are rare and so the optimal procedure for achieving a margin negative resection can be tailored based on the size and location of the tumor as well as the local expertise of the operating team. Transanal excisions are often possible for smaller tumors within 5 cm of the anal verge. Larger and more proximal tumors are likely to require an anterior resection. For larger lesions and those in close proximity to the anal sphincter, neoadjuvant therapy may ease resection and allow sphincter preservation.

Esophageal GIST

Esophageal GISTs commonly present with dysphagia, chest pain, and reflux symptoms. It can be difficult to distinguish esophageal GIST from more common esophageal leiomyoma without an FNA. The extent of resection of esophageal GIST is controversial given the relative infrequency and small reported case series. There have been reports of favorable oncologic outcomes with open or thoracoscopic enucleation of small esophageal GIST, although the series have been small and follow-up limited. If the preoperative diagnosis is secure, a negative margin resection with partial esophageal wall resection and primary closure or esophagectomy should be performed depending on the size and location of the tumor. If the diagnosis is made histologically after an enucleation is performed, the need for reoperation to achieve negative margins is not clear and should be decided based on weighing the risk of recurrence against the risk of further procedures.

POSTOPERATIVE CARE

The immediate postoperative surgical care depends on the type and extent of surgery performed. In patients who undergo a laparoscopic or open wedge resection for gastric GIST, a nasogastric tube may not be necessary as long as there is not concern for edema impeding outflow. The diet can be advanced postoperatively as tolerated and most patients can be discharged on postoperative day 2 or 3. More extensive gastric resections may require more time to achieve adequate oral intake. Similarly, patients who undergo a segmental small bowel resections for small intestinal GIST can generally have their diet advanced as tolerated while watching for signs of an ileus and be discharged after bowel function as returned. The care for patients undergoing resection of rectal GIST should be the same as for similar procedures done for more common rectal polyps or adenocarcinoma.

Adjuvant imatinib should be given to all patients who received and responded to neoadjuvant imatinib for 36 months of therapy total. This can be restarted postoperative as soon as the patient is tolerating a regular diet well.

Patients with a significant risk of recurrence based on tumor size, location, mitotic rate, and rupture/completeness of resection after resection should receive adjuvant imatinib for 36 months. In randomized trials, 36 months of therapy have improved relapsed-free and overall survival compared to 12 months of therapy GIST tumors with a high risk of recurrence (defined as tumor >10 cm, >10 mitoses per 50 high power fields [HPFs], >5 cm and >5 mitoses per HPF, or tumor rupture). The minimum risk of recurrence necessary to benefit from adjuvant imatinib therapy has not been well established and the decision to treat should be based on the individual risk of recurrence and the risk of treatment. A risk calculator based on three retrospective patient cohorts is available online to help determine the individual risk of recurrence after surgery and help inform the decision for adjuvant therapy (https://www.mskcc.org/nomograms/gastrointestinal/stromal-tumor). An additional nomogram from the Armed Forces Institute of Pathology experience can also be used (Table 94.1).

While the value of 36 months of therapy is well established, the value of treatment beyond this point is not clear and currently being evaluated (36 months vs. 60 months) in a randomized phase III trial (NCT02413736).

Patients at significant risk of recurrence should be evaluated with a

history and physical examination and cross-sectional imaging every 3 to 6 months for the first 5 years to evaluate for recurrence. Care should be taken to continue close surveillance after patient completes adjuvant imatinib therapy as a significant portion of patients have recurred within the first 2 years of finishing imatinib in randomized trials.

OUTCOMES

The disease-free and overall survival is highly dependent on the size, mitotic rate, location of the tumor, completeness of resection, underlying patient factors, and presence of tumor rupture. In small (<2 cm) gastric GIST after a complete resection, the risk of recurrence and distant metastases is remote. In contrast, large tumors with high mitotic indices can behave quite aggressively. In high-risk tumors, a significant portion will recur although this rate is improved by adjuvant imatinib. As previously discussed, recurrent or metastatic disease should be treated on an individualized bases with local and systemic therapy options considered based on the disease distribution and behavior.

EDITOR'S COMMENT

The authors present an excellent overview of gastrointestinal stromal tumors. As pointed, GISTs are relatively rare accounting for about 1% of primary gastrointestinal cancers with an annual incidence of 3 to 20 cases per million populations per year. The stomach is the most common site accounting for 50% to 60% of tumors, followed by the small intestine (20% to 25%), colon and rectum (5%) and the esophagus 1%. They arise from the interstitial cells of Cajal (ICC). ICC are an integral part of the GI neuromuscular apparatus, transduce inputs from enteric motor neurons, generate intrinsic electrical rhythmicity in phasic smooth muscles, and have a mechanical sensation ability. Ultrastructural studies suggest that ICC are either primitive muscle cells or fibroblast-like cells that are electrically rhythmic. ICC were previously characterized by morphologic criteria until the discovery that ICC express the receptor tyrosine kinase, Kit (CD117) and that the majority of the Kit-positive cells in the GI tract are indeed ICCs. Not all ICC do express c-Kit, such as those in the deep muscular plexus in the human small intestine. ICC are located throughout the gastrointestinal tract and are located predominantly between the circular and longitudinal muscle. ICC serve several important functions in the

GI tract including: electrical slow wave generation, coordination of pacemaker activity and active propagation of slow waves, transduction of motor neural inputs from the enteric nervous system, and sensation to stretch of GI muscles. ICC are more densely located in the corpus and antrum than in the fundus of the stomach. This is interesting in that in my experience the majority of GISTs occur in the fundus. ICC are involved with GI motility disorders including achalasia, gastroesophageal reflux disease, gastroparesis, infantile hypertrophic pyloric stenosis, diabetic gastroenteropathy, chronic intestinal pseudo-obstruction, and Hirschsprung disease. In these instances there are sparse of absent ICC cells.

Most GISTs are found when they are less than 4 cm in diameter. As the authors note, bleeding is a frequent early manifestation. Other symptoms are vague and nonspecific abdominal pain or discomfort (most common); early satiety or a sensation of abdominal fullness; palpable abdominal mass (rare); malaise, fatigue, or exertional dyspnea with significant blood loss, and rarely peritonitis if there is perforation or tumor rupture. Obstructive symptoms may also occur. Diagnosis is made by cross-sectional imaging in many cases. CT is important in determining the location size of the lesion as well as staging. On CT GISTs display a homogeneous density if less than 5 cm or a heterogeneous density if greater than 5 cm. CT criteria associated with high-grade histology and increased mortality include a tumor larger than 11.1 cm, irregular surface contours, indistinct margins, adjacent organ invasion, heterogeneous enhancement, and hepatic or peritoneal metastasis. MRI is less well studied for diagnosis of GIST than CT. Of note is that GISTs may appear hypointense on T2–weighted images. EUS is also helpful in obtaining tissue and further characterization of the tumors. This is an important technique if observation of a small GIST is chosen over excision.

As the authors point out, GISTs arising from the stomach may be excised by a wedge excision. The debate about the importance of negative margins was discussed. As indicated the goal should be negative margins and I concur. Larger tumors with unfavorable imaging characteristics may require formal gastric resection. A laparoscopic approach is reasonable in many cases. I concur with the use of a bag to remove the tumor so as to prevent seeding of the peritoneal cavity. Small GISTs may be difficult to find at laparoscopy and we have found that tattooing is helpful. A newer approach is submucosal endoscopic tumor resection (SET). This is based on techniques used in POEM. The pilot series report by Inoue et al. (Submucosal endoscopic tumor resection for subepithelial tumors in the esophagus and cardia. *Endoscopy* 2012;44:225–30) described outcomes in nine patients. Conversion to an operative procedure was necessary in two patients with larger tumors (greatest diameter 7.5 cm and 6 cm), but in seven, the procedure was successful (greatest diameters 1.2 to 3 cm). Additional confirmatory reports and longer follow-up are needed for validation of the safety and efficacy of this technique.

Esophageal lesions are amendable to enucleation; however, esophageal

resection is required for larger tumors. Duodenal GISTs are rare and may be amendable to local excision if small, but may require pancreas preserving duodenal resection or pancreaticoduodenectomy. For GISTs in the small intestine segmental resection is warranted as with colonic GISTs. Rectal GISTs are amendable to local excision depending on size.

The use of imatinib for large or metastatic GIST is a major advance. The cost is not insignificant. A generic imatinib is available in Canada for $8,800/year and Gleevec is available for $38,000/year. In the United States, Gleevec is priced at about $146,000/year and the "generic price" in the United States was in fact not much lower than the branded drug price. (Hagop Kantarjian; The Arrival of Generic Imatinib Into the U.S. Market: An Educational Event, http://www.ascopost.com/issues/may-25-2016/the-arrival-of-generic-imatinib-into-the-us-market-an-educational-event/. Published May 25, 2016.)

In summary, GISTs are rare tumors that arise form ICC and may be approached by a variety of surgical techniques and are sensitive to imatinib.

95 The Laparoscopic Gastric Band Technique of Placement

Paul E. O'Brien

INTRODUCTION

Laparoscopic adjustable gastric banding (LAGB) was introduced in 1992 by Favretti and Cadiere as a major innovation in bariatric surgery by adding the laparoscopic approach to the key features of adjustability and ready reversibility of the Kusmak band. The Lap Band has been the most used version of the LAGB. It was developed by the Inamed Corporation (Carpenteria, California) in the early 1990s and was introduced into surgical practice by Mitiku Belachew in Belgium in September, 1993. The device is currently owned by Apollo Endosurgery (Austin, Texas). As the Lap Band is the only LAGB device I have used, all comments provided herewith relate to my experience with this device.

The LAGB rapidly rose to the dominant procedure worldwide in bariatric surgery during the 1990s and, after approval for the use in the United States in 2001, across the USA also. However, many surgeons have become disenchanted with the band because of its particular need for careful follow-up, a perceived lesser weight loss than the gastric stapling procedures, a greater demand for revisional surgery and a concomitant rise in enthusiasm for the sleeve gastrectomy. It now contributes around 15% of bariatric procedures worldwide.

In our clinic in Melbourne, we appear to be out of step with the rest of the world as the LAGB still constitute 85% of our bariatric procedures. We continue to achieve good weight loss outcomes and happy patients. It is a day procedure that is very safe. It remains our preferred bariatric option on the basis of proven benefits and low risk.

There are three factors driving this. First, from our research studies of the mechanisms of effect of the LAGB, we have established a clear set of rules regarding eating after the band and we can provide the LAGB patient with a strong understanding of why the rules are what they are. This enables an effective partnership between our clinic staff and our patients.

And they both get to appreciate the power and the beauty of adjustability. Second, we are able to provide comprehensive and profitable aftercare with sufficient well-trained staff and an excellent data management system. Third, through the extensive clinical experience and deep awareness of the mechanisms of action, we are able to manage more easily those clinical situations that others find challenging and cause them to seek alternative pathways.

The LAGB is characterized by its safety and effectiveness in achieving major and durable weight loss. It reverses the comorbidities of obesity and improves quality of life. Further, it provides a gentle approach to the control of obesity because its placement is truly minimally invasive, its primary mode of action is by inducing satiety, and the degree of effect is controlled postoperatively through its adjustability. It offers the additional attraction of complete reversibility.

There are three essential components to effective use of the LAGB. First, it must be placed correctly. This requires correct operative technique, which will be reviewed in detail in this chapter. Second and equally important to the technical detail of the operation, there must be a permanent process of aftercare, which is based on an understanding of how the band works and includes knowing how to make decisions regarding adjustments of the tightness of the band in association with patient advice and support. It is essential that this be learned and followed if optimal results from the procedure are to be obtained. Finally, there must be and understanding of the symptoms and adverse events that may occur after the band so that simple correction can be applied rather than confusion and then reversal through lack of this understanding.

PERIOPERATIVE MANAGEMENT

The technique of Lap Band placement has evolved significantly over the past 20 years since its introduction. Some elements of the procedure are still subject to variation between surgeons who are achieving apparently equal outcomes, but the key positioning of the band is now essentially identical across all groups. The technique described is the product of 20 years of experience and placement of more than 4,000 Lap Bands. Throughout this time I have sought to identify a technique that is safe, quick, minimally traumatic, less expensive, and able to cope with the challenges of superobesity. The details provided are just one variation on the theme, and alternative approaches appear to be equally effective and

efficient. This description, however, does provide a solid starting point for new Lap Band surgeons, who can then evolve techniques of their own as they build up their experience.

PREOPERATIVE ASSESSMENT

Initial clinical assessment includes full routine history and examination and specific documentation of the problems generated by the obesity, including all the comorbidities and the physical and social limitations present. Laboratory studies include all routine hematology and biochemistry plus specific screening for diabetes and insulin resistance, micronutrient deficiencies including iron studies, vitamin B_{12}, folic acid, and lipid profile. Special investigations such as upper gastrointestinal endoscopy, barium swallow and meal, ultrasound of gallbladder, esophageal manometry and 24-hour pH study, 24-hour blood pressure monitoring, and polysomnography are performed only when a specific indication exists. We do not require routine preoperative psychological and nutritional assessments.

Perioperative Care

All patients are given antimicrobial prophylaxis, administered at the commencement of the procedure. We use a β-lactamase–resistant penicillin (flucloxacillin, 1 g IV stat) to cover skin contaminants and a broad spectrum to cover the enteric flora such as a third-generation cephalosporin (cefotaxime, 1 g IV stat). Prophylaxis against deep venous thrombosis consists of subcutaneous heparin until discharge (sodium heparin, 500 units b.i.d. subcutaneously commencing immediately after completion of the procedure). Pain relief is principally by Fentanyl during anesthesia and Endone 5 mg repeated every 12 hours if needed. Oral soluble paracetamol (acetaminophen) is then used. Opiates are avoided. Ondansetron (× 4 mg IM) is available for nausea but rarely used.

Operative Position and Port Placement

The patient is placed in a reverse Trendelenburg position of a 25-degree slope, legs apart. The surgeon stands between the legs and one assistant stands on the patient's left side. We use five ports: three are 5 mm in diameter and one is 15 mm in diameter (their positions are shown in Fig. 95.1). We use a 10-mm end-viewing telescope for insertion of the initial

optical port and a 10-mm, 30-degree telescope for the rest of the procedure. The video system must be a high-definition system of optimal quality.

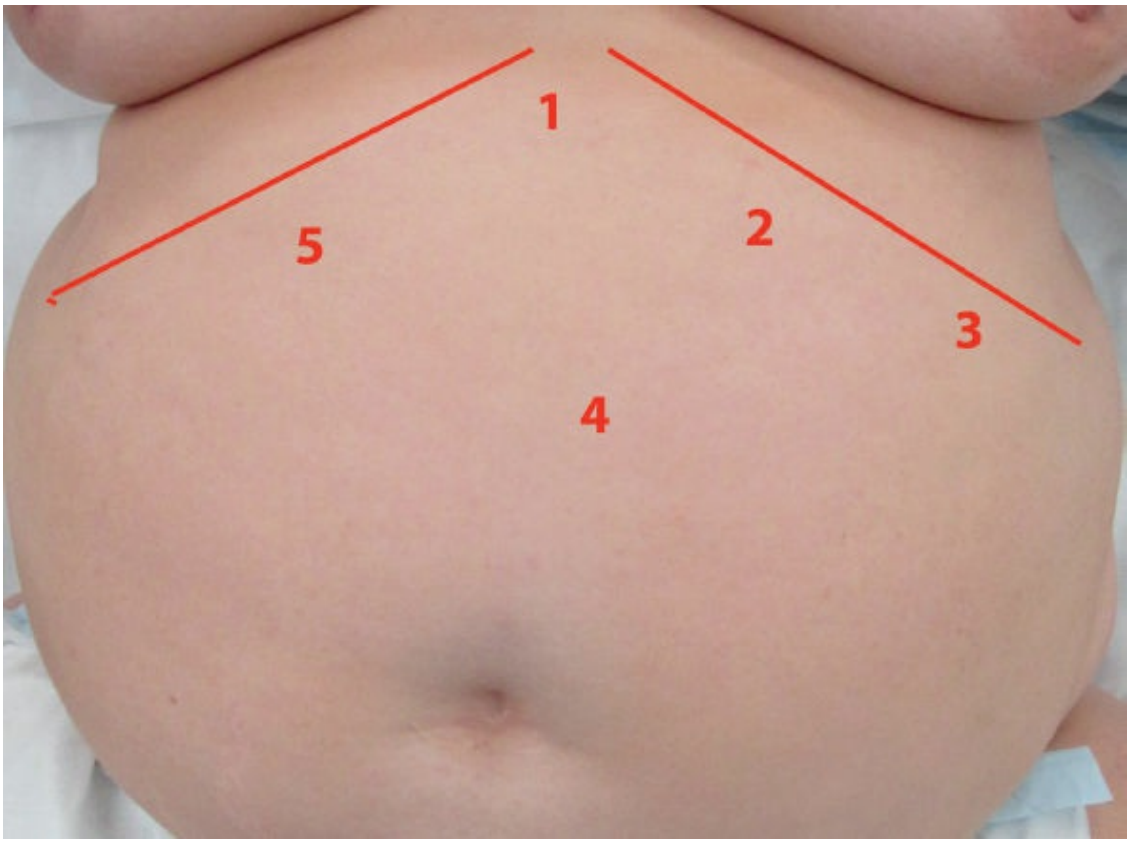

Figure 95.1. Port positions. There is an initial 10-mm optical port, then 3 × 5 mm ports and 1 × 15 mm ports are placed under direct vision. The port at position 1 is removed and a Nathanson liver retractor (5 mm) is placed.

The initial port is a 10-mm optical port (FIOS, Applied Medical, Rancho Santa Margarita, CA) placed at position 2 (Fig. 95.1). The 15 mm port (position 4) and the three 5 mm ports (Applied Medical) are then inserted under vision. The 15 mm port is the path for the hook diathermy and the introduction of the band and of sutures. It becomes the site of the access port at completion. AT port site 1 the port is removed and the Nathanson liver retractor is placed in the midline just below the xiphisternum. The two 5-mm ports at positions 3 and 5 are 15 cm long (Applied Medical). This extra length enables them to be passed through the abdominal wall on an angle such that they are heading toward the upper stomach. As all elements of the procedure occur in a small area, there is minimal lateral pressure on these ports.

SURGICAL TECHNIQUE

Dissection at the Angle of His

The liver is retracted by a Nathanson liver retractor (Automated Medical Products, New Jersey, USA), which is held by an external clamp (Iron Intern, Automated Medical Products). The omentum covering the fundus of the stomach is drawn inferiorly using the graspers at positions 3 and 5. The grasper at position 3 draws the fundus of the stomach downward. The grasper at position 5 then retracts the fat pad over the distal esophagus to the right to open up the area of the angle of His. Using a hook diathermy through the 15-mm port (position 4), the peritoneum over the left crus is divided over approximately a 2-cm length (Fig. 95.2). It is not necessary to fully expose the fibers of the left crus but essential to be at this anatomic site. That completes the dissection at this point and attention moves to the lesser curve.

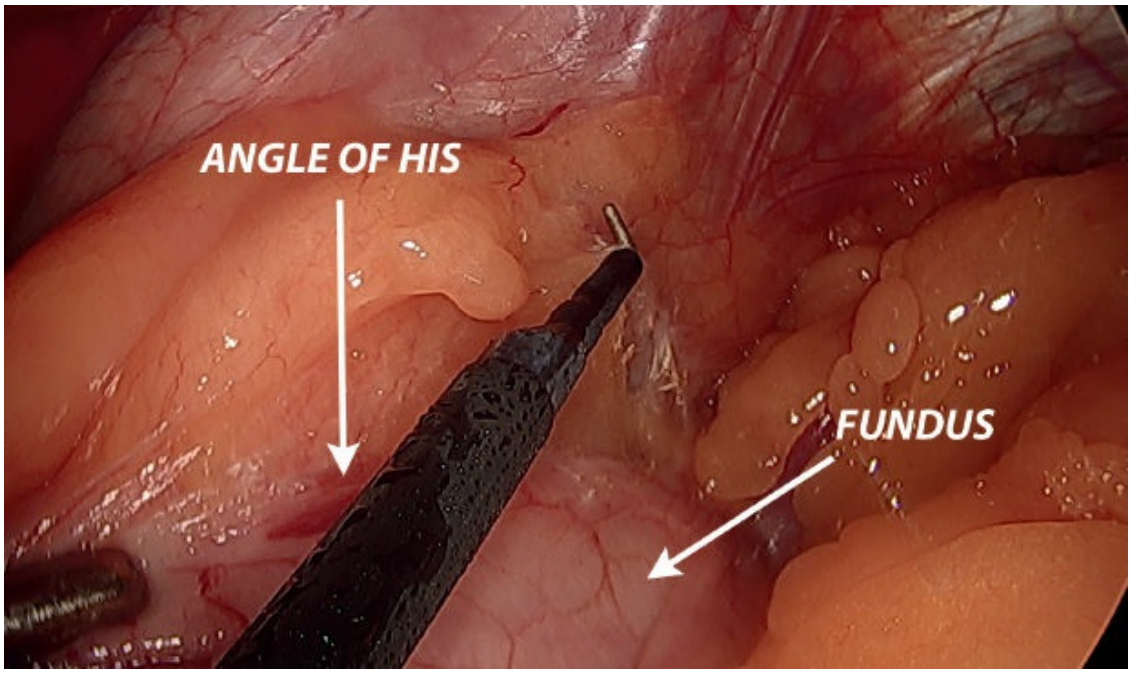

Figure 95.2. Initial dissection at the angle of His. Note that this occurs at the interface with the diaphragm and involves the peritoneum alone.

Dissection of the Anterior Fat Pad

It is essential that the band be placed over the gastric cardia, immediately below the esophagogastric junction. If you are unsure, the position of the esophagogastric junction can checked with the calibration tube that comes

with the Lap Band. This tube is passed by the anesthetist earlier in the procedure to a length of 45 cm. At this stage, 25 mL of air is introduced into the balloon. The tube is withdrawn until the balloon impacts at the esophagogastric junction. In its final position the band should overlie the highest point or equator of the balloon, not positioned below the balloon.

If this line for the band is covered by a significant anterior fat pad, this pad will need to be dissected upward or excised. Our preference is to dissect it upward until we can see gastric wall above where the band is expected to sit (Fig. 95.3). This dissection is necessary in about 90% of patients and is done with the hook diathermy. The band must not be placed on top of a fat pad or the satiety-inducing effect of the band will be reduced.

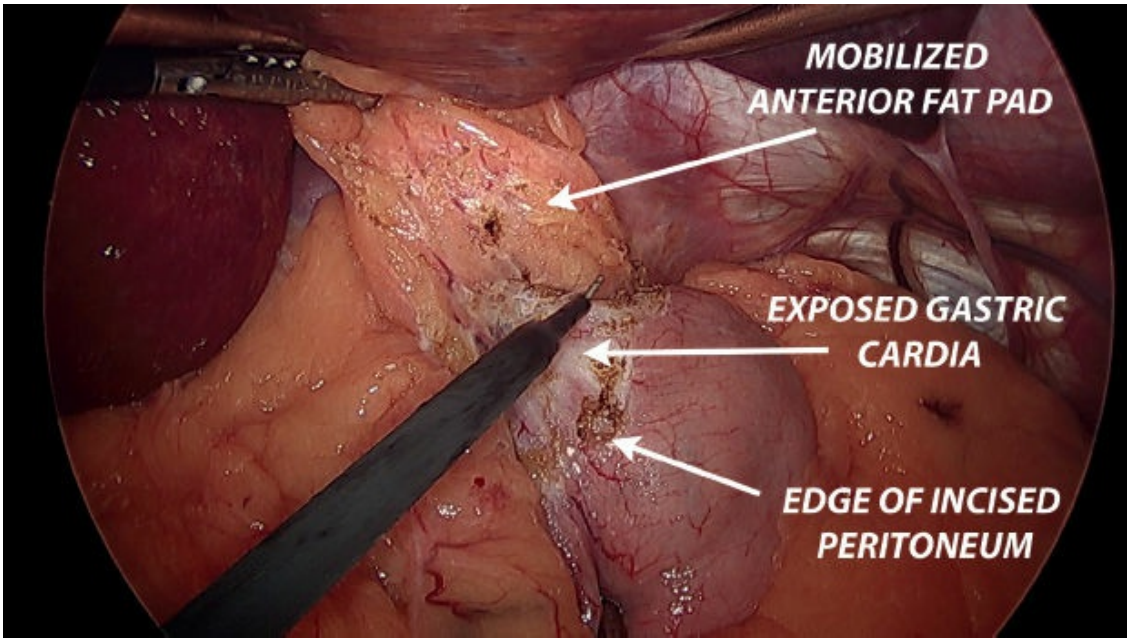

Figure 95.3. The anterior fat has been reflected upwards to ensure the band is closely applied to the surface of the cardia, thus ensuring optimal satiety effect.

Dissection on the Lesser Curve

The grasper at position 3 takes hold of the fat adjacent to the lesser curve of the stomach and draws it to the left. The pars flaccida of the lesser omentum is divided to expose the posterior wall of the lesser sac. The grasper at position 3 then draws the fat on the posterior wall of the lesser sac to the left and the grasper at position 5 retracts the caudate lobe of the liver to expose the lower aspect of the right crus. The peritoneum of the posterior wall is opened over a 5-mm length using the hook diathermy.

The point of this opening is critical. It should be 5 mm in front of the anterior margin of the right crus at its most inferior point (Fig. 95.4).

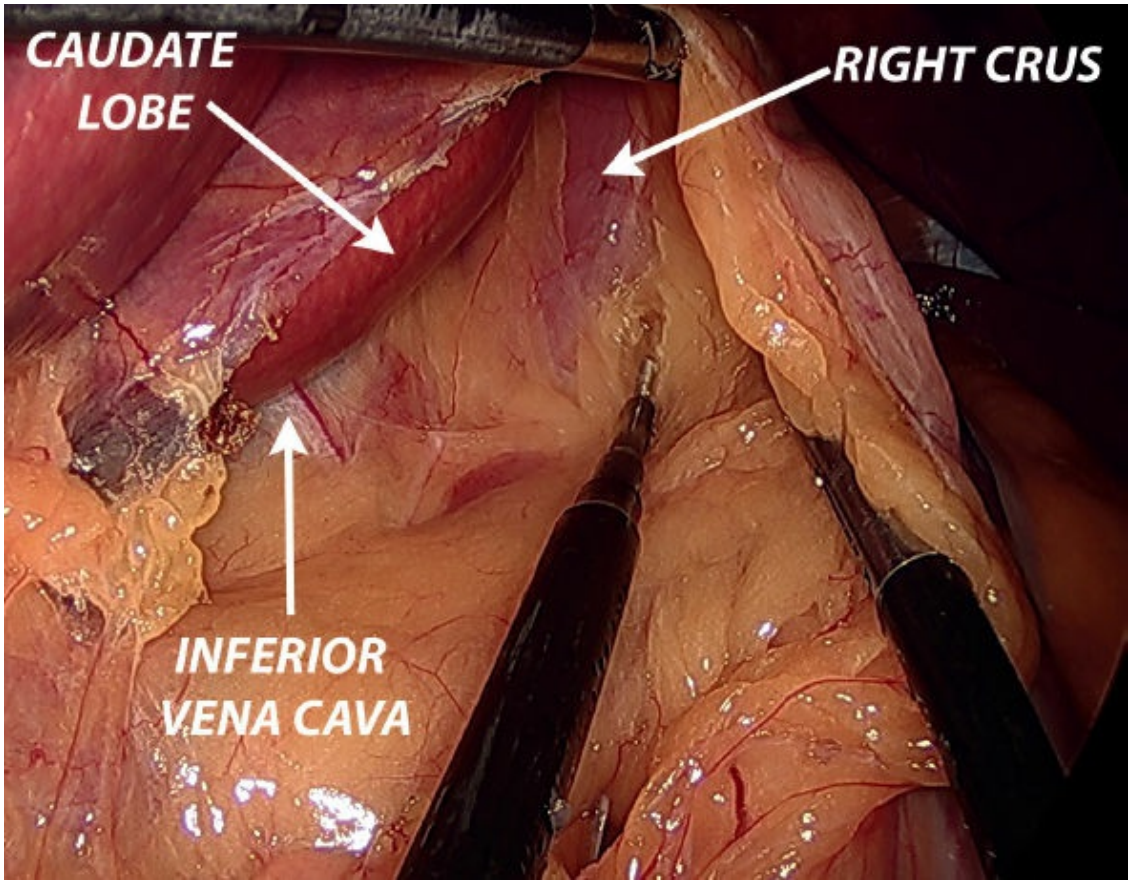

Figure 95.4. The point of dissection is 5 mm in front of the anterior border of the right crus at its lowermost aspect. Note that the caudate lobe of the liver is retracted upward and the inferior vena cava is visible to the left.

Passing the Lap Band Placer

The grasper at position 5 is withdrawn and the Lap Band placer is passed. The Lap Band placer (Automated Medical Products) is 5 mm in diameter and has a flexible and curved distal segment ending with a blunt tip containing a notch to hold the tubing of the Lap Band. The rounded tip of the Lap Band placer is placed into the opening created by the grasper and passed as a spiral pathway rotating the tip anticlockwise across the back of the esophagus to the site of dissection at the left crus (Fig. 95.5). The grasper at position 3 moves back to the angle of His and exposes this area again. Under clear vision, the tip of the Lap Band placer is rotated and gently advanced until it completes passage by passing through the loose connective tissue behind the esophagus. At no time should any significant

force be used with the Lap Band placer. It should be fingertip controlled at all times.

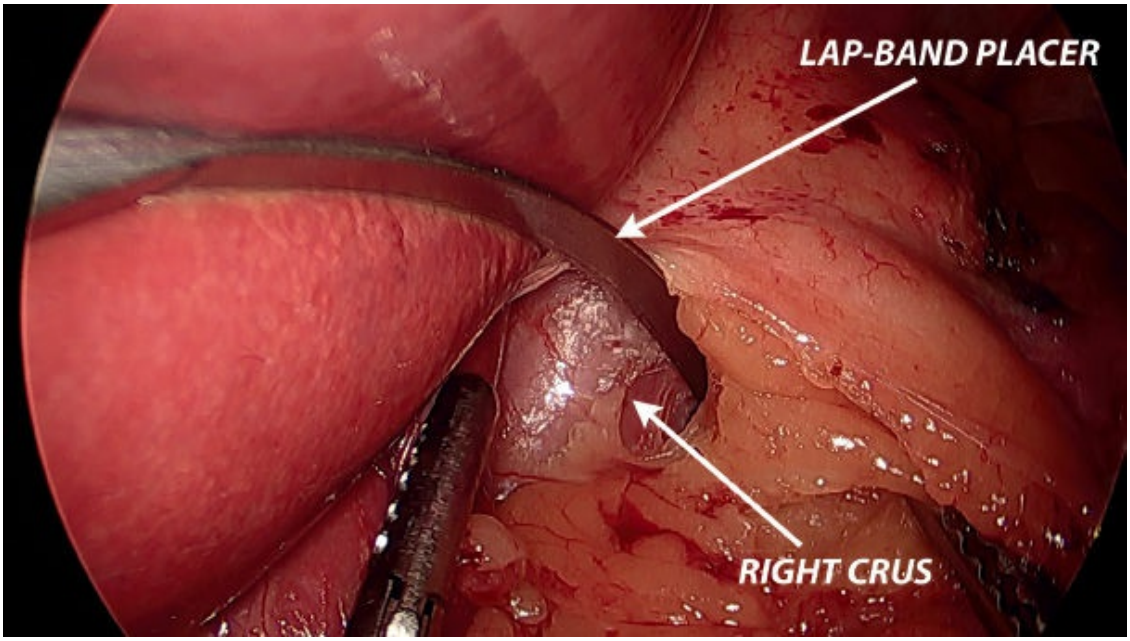

Figure 95.5. The rounded tip of the Lap Band placer commencing the traverse of the posterior aspect of the cardia at the dissected opening of the peritoneum of the lesser sac.

Selection of Lap Band Size

We use the Lap Band placer to determine which band to place. After passing it across the back of the stomach, we place the proximal edge of the flexible flat metal strip so that it is just visible at the edge of the lesser curve fat. We then look at the distal aspect of the placer at the angle of His. If 1 cm or more is visible without retraction of the fat, a Lap Band APS is appropriate (see Fig. 95.6). If <1 cm is visible, we use Lap-Band APL. In practice, I use the Lap Band APS in at least two thirds of patients. The factors that are associated with more frequent use of the APL are male patients, extensive fat padding around upper stomach, central obesity, massive superobesity, and the presence of insulin resistance. Whenever there is doubt, choose the APL.

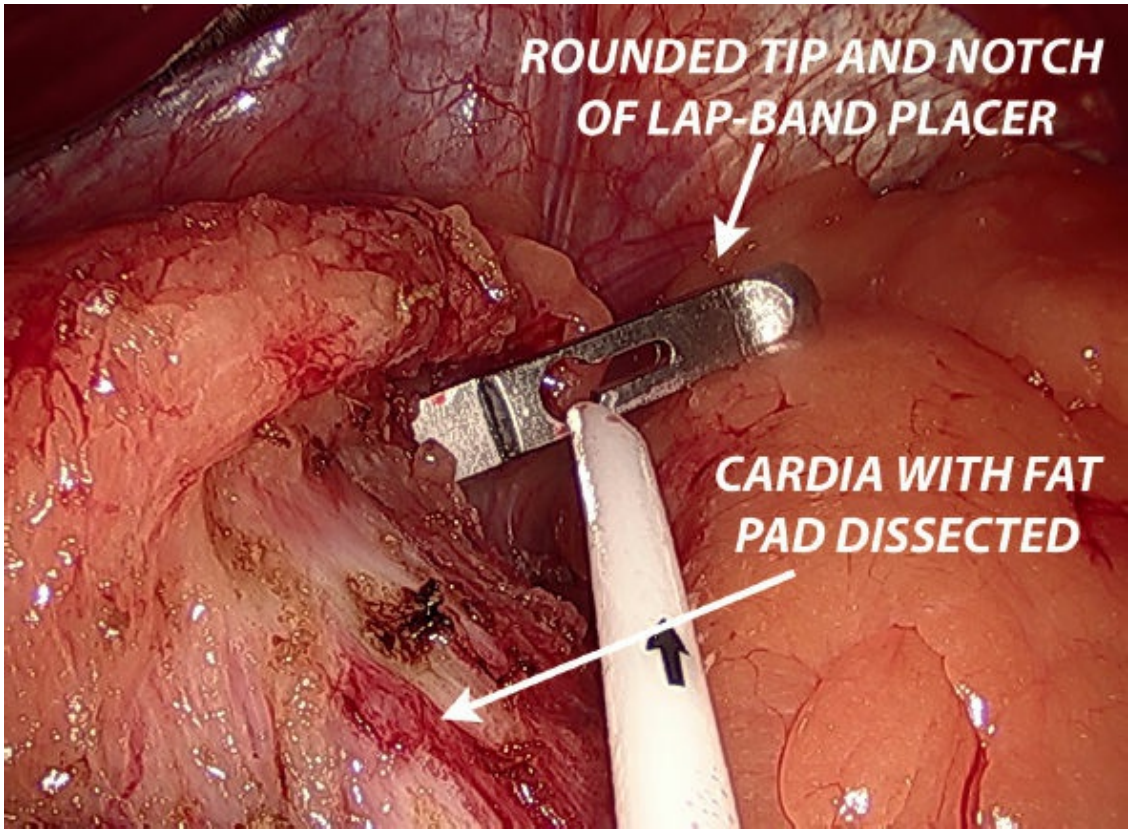

Figure 95.6. The curved Lap Band placer has been passed across, the size of the band to be used has been determined, and the band introduced into the abdomen. About 2 in of tubing is passed through the opening in the Lap Band placer.

Positioning, Calibrating, and Closing the Lap Band

The Lap Band is introduced though the 15-mm port under direct vision using the Lap Band introducer (Automated Medical Products). One or 2 in of the end of the tubing is passed through the slot in the Lap Band placer, which is then withdrawn along the path. The tubing is drawn through until the band is in position.

The band is then positioned and the tubing drawn through the buckle until it is almost closed. At this point, the surgeon checks that the band will not be too tight if closed. This is a subjective estimate. If there is suspicion, proceed with dividing the fat on the lesser curve, with hook diathermy or a Ligasure or harmonic scalpel may be preferred. When it appears that the band will not be too tight, it is closed with the Lap Band closer tool (Automated Medical Products). The buckle is then temporarily rotated to the patient's right to facilitate anterior fixation.

Anterior Fixation

Each suture (2/0 Ethibond cut to a 16-cm length on a 26-mm taper-pointed needle) is introduced through the 15-mm port (position 4). The needle holder is then used through port 3 and a fine grasper for the left hand is in port 5. A standard grasper is passed through port 4. The two graspers are used to draw the greater curve across to carefully select the site of the inferior bite of the first suture. It should be within 1 cm of the greater curve and distal enough to allow drawing of the gastric wall across the band without undue tension but without excessive slackness. The grasper at position 4 holds the gastric wall at this point while the suture is placed. The two graspers are then used above the band to select the site for the second bite. It must be into visible gastric wall, not into the fat pad, so that gastro-gastric approximation is seen (Fig. 95.7). Again the grasper is used to lock onto this site while the suture is placed. The suture is then tied and the grasper released. This process can be repeated for each further suture as needed to achieve clear visualization of the correct point of placement. Most commonly, three sutures are placed with the aim of covering almost all the visible bands up to the buckle but stopping about 1 cm from the buckle. The band is gently rotated to the left so that the buckle is facing anteriorly at the lesser curve but not pushed hard against the wrap of the anterior fixation.

A lesser curve suture is now placed to stabilize the anterior wall of the stomach below the buckle. This consists of three bites from the anterior wall of stomach below the band as shown in Figure 95.8. The tubing is then drawn out through the 15-mm port (position 4) for attachment to the access port at this site. All instruments are removed, insufflation is ceased, and the ports are removed.

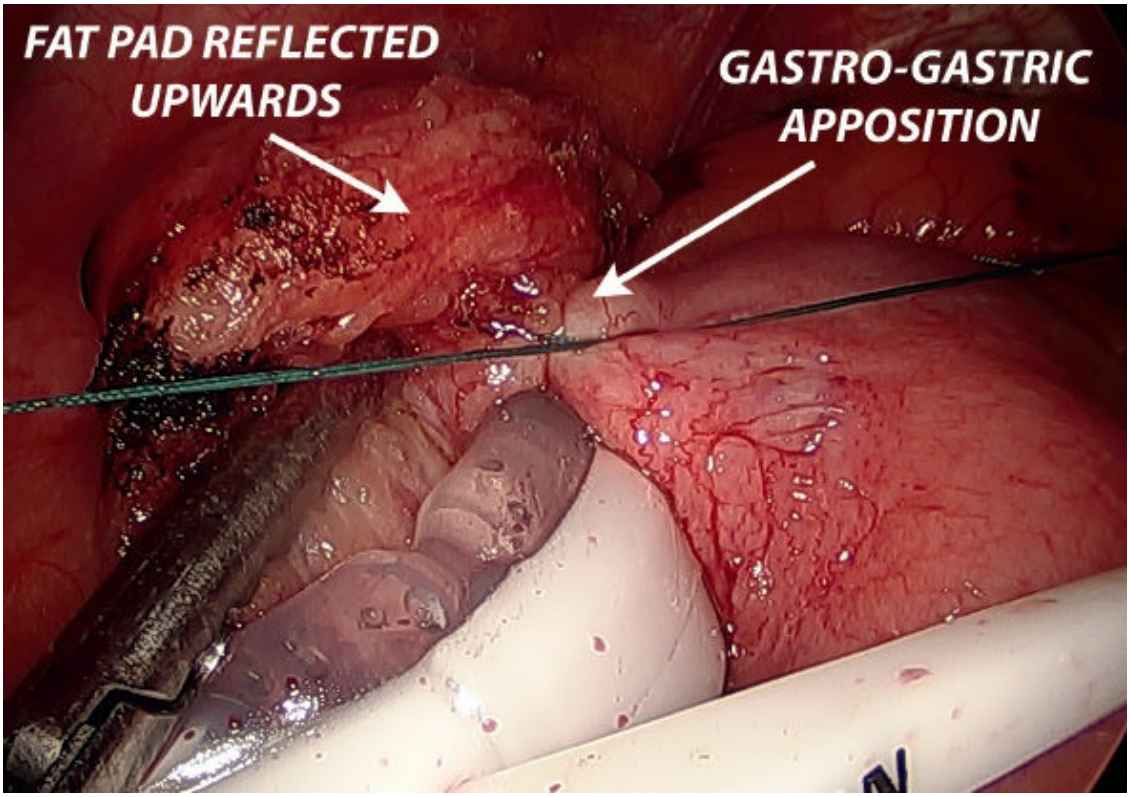

Figure 95.7. The anterior fixation sutures must be between gastric wall below and visible gastric wall above the band.

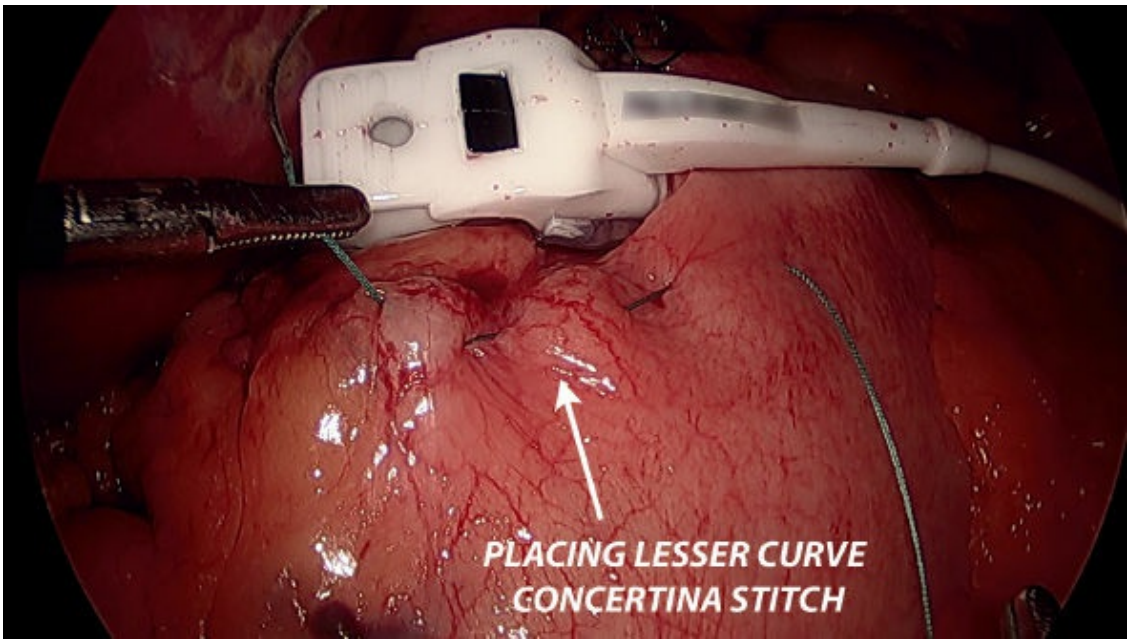

Figure 95.8. A lesser curve suture which concertinas the gastric wall below the buckle completes the anterior fixation.

Figure 95.9. A sheet of mesh is fixed to the deep aspect of the access port and then cut to form a circle.

Mesh Fixation of the Access Port

Three options for port fixation exist. The port can be fixed to the anterior rectus sheath with three sutures of 2/0 Prolene. I had used this approach until about 3 years ago. It can be stapled to the rectus sheath using the RapidPort device. I have rarely used this approach. Or it can be stabilized in the subcutaneous layer using mesh fixation. This is now our preferred approach as it can be done without extending the 15-mm port incision. It is less painful for the patient, faster and easier for the surgeon and much easier for the aftercare providers to access the port for adjustments. It can be done using the standard port or with the RapidPort EZ.

A circle of Prolene mesh is fixed to the base of the port with three sutures of 2/0 Prolene (Fig. 95.9). The right index finger is passed through the 15 mm port site, and pushed downwards for about 8 cm through the

subcutaneous fat at a depth of approximately 2 cm below the skin. Depending on the degree of obesity this path may lie superficial or deep to Scarpa fascia. For the standard port, be careful not to widen the path beyond one finger's width. For the RapidPort EZ, it needs to be widened to two fingers breadth. Connect the port to the tubing, check that it is not rotated and then slide the port and mesh along the track to its deepest point. Check the port remains facing correctly. Return the excess tubing to the abdominal cavity.

Alternative techniques are suture fixation and use of the RapidPort (Apollo). For both methods, the incision at position 4 is extended to 4 cm length and the soft tissues divided to clearly expose the anterior rectus sheath. For suture fixation, four sutures of 2/0 Prolene (Ethicon, Cincinnati, OH) are placed about 1 cm apart to create a square pattern. The access port is connected to the tubing and the sutures are threaded to the port. The tubing is now carefully reintroduced into the abdomen until the port is in position and there is a smooth path of the tubing directly into the abdomen with no kinking or looping. The sutures are tied securely. For the RapidPort, the port is attached to the tubing, the device placed firmly on the anterior rectus sheath and fired. The device holder is then removed and the port checked for fixation. The excess tubing is returned to the abdominal cavity.

Check for complete hemostasis, clean with Betadine and close each port site with 4/0 Caprosyn (Autosuture, Norwalk, CT) as a subcuticular suture.

EDITOR'S COMMENT

This is a great chapter on the technique of placement of the Lap Band by one of the world's experts on the topic. Dr. O'Brien has performed literally thousands of procedures over nearly two decades in Melbourne, Australia. He is a tireless champion of the device and procedure, having published numerous articles on the topic in prestigious journals. As he correctly points out, his experience is a bit out of step with the rest of the world, especially in the United States.

Obesity is a devastating problem worldwide. According to the World Health Organization, the prevalence of obesity has more than doubled across the globe since 1980. In 2014, more than 1.9 billion adults (39%) were overweight and 600 million (13%) obese. The numbers in the United States are even direr. Obesity causes serious and life-threatening diseases such as diabetes, coronary artery disease, and obstructive sleep apnea. The average life expectancy is less and the average annual health care expenditure is significantly greater in the obese than in the nonobese (Atella V, Kopinska J, Medea G, et al. Excess body weight increases the burden of age-associated chronic diseases and their associated health care expenditures. *Aging (Albany NY)* 2015;7(10):882–92). According to a Cochrane Database Systematic Review published in 2014, bariatric surgery results in greater improvement in weight loss outcomes and weight associated comorbidities compared with nonsurgical interventions, regardless of the type of procedures used (Colquitt JL, Pickett K, Loveman E, et al. Surgery for weight loss in adults. *Cochrane Database Syst Rev* 2014; (8):CD003641). When compared with each other, certain procedures resulted in greater weight loss and improvements in comorbidities than others. Outcomes were similar between Roux-en Y gastric bypass and sleeve gastrectomy, and both of these procedures had better outcomes than adjustable gastric banding. No doubt, short-term complications following laparoscopic adjustable gastric band placement have been demonstrated to be less than following most other bariatric surgical procedures. Long-term rates of reoperation and failure have been demonstrated to be quite high for the adjustable gastric band in the United States (Spivak H, Abdelmelek MF, Beltran OR, et al. Long-term outcomes of laparoscopic adjustable gastric banding and laparoscopic Roux-en-y gastric bypass in the United States. *Surg Endosc* 2012;26:1909–91). According to the American Society for Metabolic and Bariatric Surgery (ASMBS) Patient Information website, the laparoscopic adjustable gastric band is associated with less weight loss, higher failure rates, and more reoperations than other bariatric procedures. This is supported by several published reviews on the topic. According to research conducted by an ASMBS task force, between 2011 and 2014 the adjustable gastric band accounted for 35% of all primary bariatric procedures and the sleeve gastrectomy for 18%. In just 3 years (by 2014), it was

estimated that only 9.5% of all primary bariatric procedures performed were adjustable gastric bands with 52% now sleeve gastrectomy (Ponce J, Nguyen NT, Hutter M, et al. American Society for Metabolic and Bariatric Surgery estimation of bariatric surgery procedures in the United States, 2011–2014. *Surg Obes Relat Dis* 2015;11(6):1199–200). This is in spite of the fact that in 2011, the U.S. Food and Drug Administration (FDA) expanded the indications for the Lap Band to include patients with a body mass index (BMI) as low as 30 kg/m^2. This expanded indication theoretically added over 50 million patients to the potential pool of Lap Band candidates.

Dr. Obrien postulates that there are three primary factors driving the differing experience with adjustable gastric band devices in the Unites States as a whole versus his experience. They can be summarized as a deep understanding of the mechanism of effect and a committed partnership between his clinic and his patients, a comprehensive aftercare program, and an understanding as to how to manage challenging clinical situations that would cause other surgeons to recommend a different bariatric procedure or convert a band to a different procedures such as a sleeve or a gastric bypass. This equals a significant commitment to the adjustable gastric band procedure and to the patients who have one of these devices surgically placed.

My own personal experience with the adjustable gastric band is similar to my American bariatric surgery colleagues on whole. I have largely stopped placing gastric bands. I will allow an occasional patient to talk me into placing a band, but never in a patient with a BMI over 50 kg/m^2. I am a committed bariatric surgeon with a comprehensive program at a major academic medical center. We have been continuously accredited by the ASMBS and now the American College of Surgeons as well for the past 10 years. The band is definitely labor intensive when compared to some of the other bariatric surgical procedures I perform. Sometimes I get frustrated with the effort or compliance of my patients who receive a band and just cannot seem to lose weight. Many of these patients go on to become successful bariatric surgery patients with a gastric bypass or a sleeve gastrectomy. Maybe I could be more committed to the procedure. Maybe my patients are different. Long-term care of bariatric surgery patients in my part of the country (upper Midwest) can be complicated by travel difficulties for part of the year (winter roads) and to insurance obstacles year round. Many bariatric surgery patients switch insurance companies periodically, and the new insurer often declines to provide benefits for ongoing care including gastric band adjustments. It must take an incredible commitment and belief that the band will work in almost anyone to demonstrate the kind of results Dr. O'Brien has described.

Although Dr. O'Brien only describes the placement of one brand of FDA-approved laparoscopic adjustable gastric band, there are few major differences in the Realize adjustable gastric band placement technique and the major tenets remain the same. I am intrigued by his routine placement of a lesser curve suture to stabilize the anterior wall of the stomach below the buckle of the band.

This seems like a harmless addition to the classic description of this procedure, but I wonder if there is evidence to support the necessity of this additional step. The pars flaccida technique is described which has been demonstrated to result in fewer instances of slip or prolapse than the perigastric technique (not described).

The technical, step-by-step description provided in this chapter is concise and fairly easy to replicate for an experienced surgeon. The 60 minutes spent in the operating room placing an adjustable gastric banding device are important, but fairly insignificant compared to all the time leading up to and following that hour of operative time when it comes to defining the outcomes and success (or lack thereof) of the adjustable gastric band.

Jon C. Gould

96 Revision and Conversion of Vertical Banded Gastroplasty

Eric J. DeMaria and Daniel B. Jones

ETIOLOGY AND PATHOPHYSIOLOGY

With the growing popularity of gastric bypass and sleeve gastrectomy, the vertical banded gastroplasty (VBG) has fallen into disfavor and is a rarely performed procedure today in the United States. One of the values of VBG was its ability to induce weight loss without affecting the normal sequence of digestive events or inducing malabsorption. VBG however, like adjustable gastric banding which is similar in many regards, is more dependent on the patient's ability to maintain lifelong behavioral compliance with healthy solid food eating habits. These changes include avoiding high calorie liquids and such calorie-rich foods as cake, cookies, and other junk foods that undergo substantial liquefaction in the mouth and thus arrive in the VBG pouch as a liquid slurry that is not substantially restricted by the outlet. This dependence on patient behavior is the likely source of the higher weight failure rate seen after VBG than after procedures incorporating a degree of malabsorption and which result in dumping in response to sweets eating, such as Roux-en-Y gastric bypass. Revision of VBG in patients who exhibit these maladaptive eating behaviors is not likely to be as effective in promoting long-term weight loss unless the patient can adapt and pursue more healthy eating behaviors (see Preoperative Planning), thus ongoing nutrition counseling is an important component of management.

CLINICAL PRESENTATION

There are also a number of ways in which VBG can fail that are not dependent on patient behavior. Patients may present with loss of satiety, dysphagia, severe gastroesophageal reflux, vomiting, weight gain, or excessive weight loss. The two common complications include staple line breakdown and stoma obstruction (Fig. 96.1). All bariatric surgeons should be prepared to identify these complications, however, the best option for

revision of the failed VBG is referral of the patient to a bariatric surgeon with significant experience with revisional procedures.

Staple Line Dehiscence

Staple line dehiscence has been a major problem after VBG. The initial iteration of the operation involved placing two to three applications of the TA-90 stapler from the window to the angle of His. This technique did not reliably produce healing of the vertical staple line and staple line dehiscence led to a revision rate of 2% per year early on. This problem was largely solved by introduction of the TA-90B stapler which placed four closely spaced staggered rows of staples which healed more solidly. The revision rate following this innovation dropped precipitously but sporadic dehiscences are still occasionally seen, particularly in postpartum patients for reasons that are unknown. Small dehiscences do not always cause problems or impede the restrictive effects of the operation, but larger openings in the staple line (2 cm or greater) often cause both weight gain and/or symptomatic gastroesophageal reflux disease. While it is possible to re-staple a dehisced staple line, reapplying staples to a thickened, scarred stomach wall may be associated with not only another dehiscence but also leaks from the staple lines. The success rate in resuming and maintaining weight loss with reapplication of staples is also generally less satisfactory than substitution of a procedure that induces malabsorption such as gastric bypass or biliopancreatic diversion. Nevertheless, patients who had a good result prior to the staple dehiscence may respond well to reconstruction of the VBG.

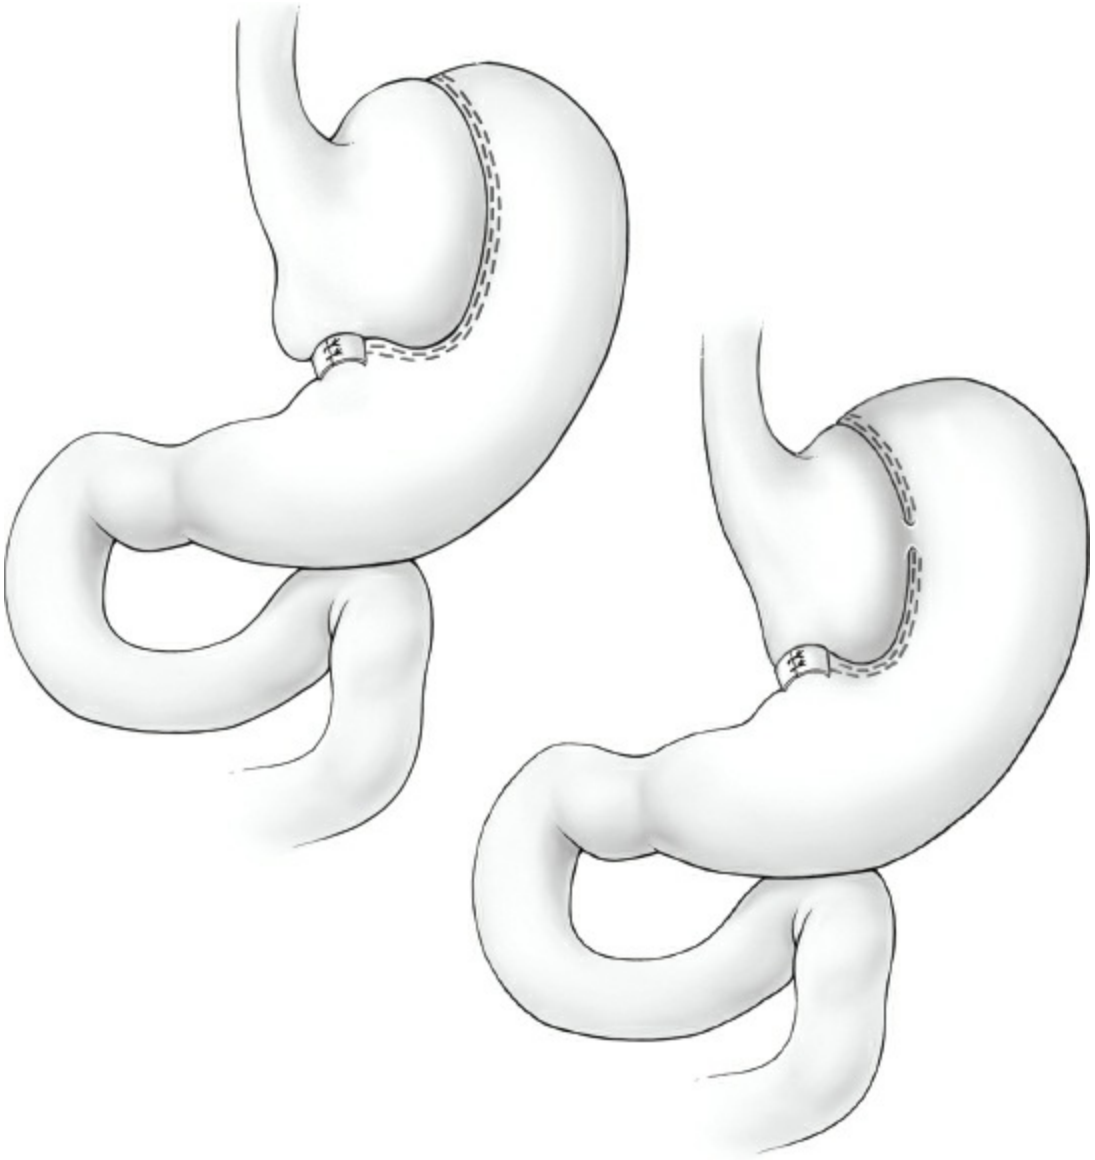

Figure 96.1. Most long-standing VBG procedures demonstrate a dilated proximal gastric pouch. If the gastroscope is not able to pass across the banded segment into the distal stomach that signifies a stricture causing obstruction. One must also assess the patient for band erosion and staple disruptions at the time of endoscopic evaluation of VBG. Even if the gastroscope is able to pass across the banded portion, the patient may still suffer from relative obstruction and exhibit gastroesophageal reflux or episodes of food obstruction of the outlet, particularly when trying to eat solid healthy foods. This is a frequent reason for VBG weight-loss failure in that patients gravitate toward eating soft foods and drinking liquid calories due to inability to eat solid healthy foods. Although often called “maladaptive eating,” in fact it is eating behavior that is adaptive to the anatomic limitations enforced by the relative obstruction of the nonadjustable banded outlet.

Pouch Enlargement

Providers should not automatically blame dietary indiscretion when patients report frequent vomiting after meals. Pouch enlargement may indeed be secondary to long-standing repetitive gorging by the patient to the point of emesis or a mechanical obstruction. A careful dietary history can usually determine whether a behavioral problem is the cause. More commonly, however, pouch enlargement and vomiting is secondary to a stricture of the banded segment. Inclusion of an excessive amount of fundus within the gastric pouch by the surgeon at the initial surgery is yet another known cause of pouch enlargement. The surgeon should remain cognizant that part of the function of the fundus is to dilate to accommodate ingestion of larger meals. At operation for VBG, as is likely true for other restrictive procedures, the vertical staple line should be placed at or close to the angle of His to avoid excessive retained fundus within the gastric pouch.

Pouch enlargement, with or without stricture, may be associated with weight gain, gastroesophageal reflux, nausea, and vomiting. Dietary indiscretion also plays a role in weight gain as most patients gravitate toward a liquid calorie-dense diet or other high calorie junk foods such as cake that undergoes liquefaction in the mouth and arrive in the pouch in the form of a liquid slurry which is more likely to pass through a strictured outlet. As the pouch enlarges, the banded stoma is no longer found in a dependent position and, since this portion of the stomach has no active peristalsis, gastric stasis is promoted. Correction of the reflux and stasis may be accomplished by simply removing a portion of the marlex band and dilating the pouch outlet. This approach however, is almost invariably accompanied by regain of lost weight. Band removal or division may be appropriate in severely debilitated patients where gastric stasis has led to aspiration pneumonia, but in general, patients should have some sort of procedure to maintain or resume their weight loss. Mason has described the so-called “Faberge” technique (referring to the “egg within an egg” works of art of the Romanov dynasty) of constructing a second appropriately sized VBG pouch within the initial enlarged VBG pouch. Such procedure can be constructed by an open surgical procedure using a new circular window and vertical stapled partition. This technique may be quite successful with selected patients; however, many individuals with an enlarged pouch have this problem because of an inability to permanently change their eating habits following the first operation. Further, re-stapling

the previously stapled thickened gastric tissue is also difficult as it is frequently adherent posteriorly to the pancreas and retrogastric structures. In many situations it is likely preferable to substitute a procedure which induces some degree of malabsorption: either a gastric bypass or a biliopancreatic diversion.

Erosion

Erosion of a mesh band into the gastric lumen is sometimes seen in patients following VBG and may be associated with weight regain, reflux, pain, vomiting or microcytic anemia. The etiology is unknown but may be more common in patients ingesting anti-inflammatory medications. Patients who are completely asymptomatic without weight regain may not require any treatment. The eroded band is usually partially intraluminal and partially extraluminal. Sometimes this can be treated by endoscopic excision of the intraluminal portion of the mesh, avoiding the need for reoperation. This technique requires a dual-channel therapeutic gastroscope. One technique is to use a heavy biopsy forceps be threaded through the loop of a colonoscopy snare. The endoscopist grasps the mesh with the forceps and, with traction on the mesh, the snare is snugged down around the base of the mesh. The snare cautery is then activated and the mesh transected. Many times excision of the protruding mesh renders the patient asymptomatic. If this technique is not successful, the patient should have transgastric excision of the mesh through a gastrotomy. This can be combined with conversion to another bariatric procedure, as indicated.

PREOPERATIVE PLANNING

All patients being considered for revision should be thoroughly evaluated by an accredited bariatric program with a multidisciplinary team (bariatrician, nurse educator, dietitian, social worker/therapist). To start, a good dietary history is important and should be reviewed with the dietitian. One technique is to require the patient to maintain a food diary for a several weeks, measuring portions to enable an accurate analysis of dietary habits by the dietician. Nutrition laboratories should be assessed to exclude issues like thiamine deficiency, for example, in the scenario of frequent vomiting. The social worker or therapist should exclude any psychosocial problems that could compromise the patient’s care or ability to comply with treatment recommendations. The bariatrician or medical consultant should review overall health status, especially if comorbid diseases are

present such as coronary artery disease, diabetes, obstructive sleep apnea, or hypertension.

If a revision is planned, candidates for VBG conversion to an alternative procedure will need to understand the risks, benefits and behavioral changes associated with the new procedure. The nutritionist may initiate a solid food low calorie diet avoiding all caloric liquids, as well as cookies, cake, candy, and other high calorie snacks that might undermine a successful revision. Daily exercise is usually encouraged.

INDICATIONS AND CONTRAINDICATIONS

Persistent vomiting and regurgitation should not be ignored and either a revision or reversal is usually necessary. Occasionally, a patient will present with just weight gain will present for evaluation. In the absence of symptoms, patients who are candidates for revision should have significant weight regain and usually a diagnosis of morbid obesity such as a BMI >35 with a comorbid condition or BMI >40 without associated illnesses.

SURGICAL TECHNIQUES

An increasing number of bariatric surgery revisions and conversions are performed laparoscopically today. We will start with a review of open surgical approaches for a complete review of revision/conversion approaches for the sake of completeness, however the laparoscopic revision of VBG to Roux-en-Y gastric bypass is becoming the most frequent reoperative procedure for VBG patients today.

Open Repair of Staple Line Dehiscence

Repair of a staple line dehiscence is simple in concept, may be challenging in its application. As soon as the adhesions to the abdominal wall are separated, a table-mounted retractor should be mounted for stable retraction of the abdominal wall and the patient should be placed in steep reverse Trendelenburg position (a foot board should be placed to avoid slippage of the patient). The next step is to separate the liver from the stomach. This may be relatively easy if the previous surgeon was considerate enough to cover the Marlex band of the VBG with omentum in the recommended fashion. However, all too often this may be somewhat difficult. There is no substitute for careful sharp dissection here. We routinely place the endoscope through the banded outlet of the pouch prior

to initiating dissection. This allows the surgeon to palpate (open) and/or visualize (laparoscopically) the area of the band. This is also a great aid in the dissection of the anterior wall of the stomach. After freeing the anterior wall the liver should be retracted superiorly and, if possible, the pouch window should be opened (this has usually contracted to quite a small opening). The lesser curve access to the lesser sac inferior to the left gastric artery through the gastrohepatic omentum is typically obliterated due to adhesions and scar tissue. It may be advisable to open the gastrocolic omentum outside the gastroepiploic vessels and dissect the posterior wall of the stomach from this aspect. Again, careful dissection is important to avoid injury to the pancreas or posterior gastric wall (Fig. 96.2).

At this point during open surgical revision, with both anterior and posterior gastric walls free, one can try and develop a connection between the two areas at the angle of His. A 19 French red Robinson catheter is then passed so that its tip exits the angle of His and the large end comes through either the previous window, or failing that, next to the lesser curve below the left gastric vessels. A standard TA-90B stapler may be applied if one is able to bring the Robinson catheter through the previous window. The catheter is used as a guide to bring the stapler foot up to the angle of His. The catheter is then removed from the stapler tip and the alignment pin applied. The stapler is then closed. The anesthetist should be asked to move the endoscope in and out to insure that the stapler doesn't impinge on the endoscope. Only then should the stapler be fired. If the previous window cannot be opened sufficiently to accommodate the stapler, a notched TA-90BN stapler may be applied such that the notch accommodates the endoscope while the end of the stapler exits the angle of His. The authors recommend insufflation of air through the scope with occlusion of the pylorus and placement of fluid into the upper abdomen to rule out leaks. The greater omentum should be used to cover the stomach and is sutured to the lesser omentum. The incision is then closed in the usual fashion. Clear liquids are started the next morning at a rate of 30 to 60 cc every 30 minutes and the patient may be discharged when they are tolerating adequate liquids to maintain hydration. Clear liquids should be given for 1 week, followed by several weeks of full liquids with liquid protein before advancing to soft moist foods.

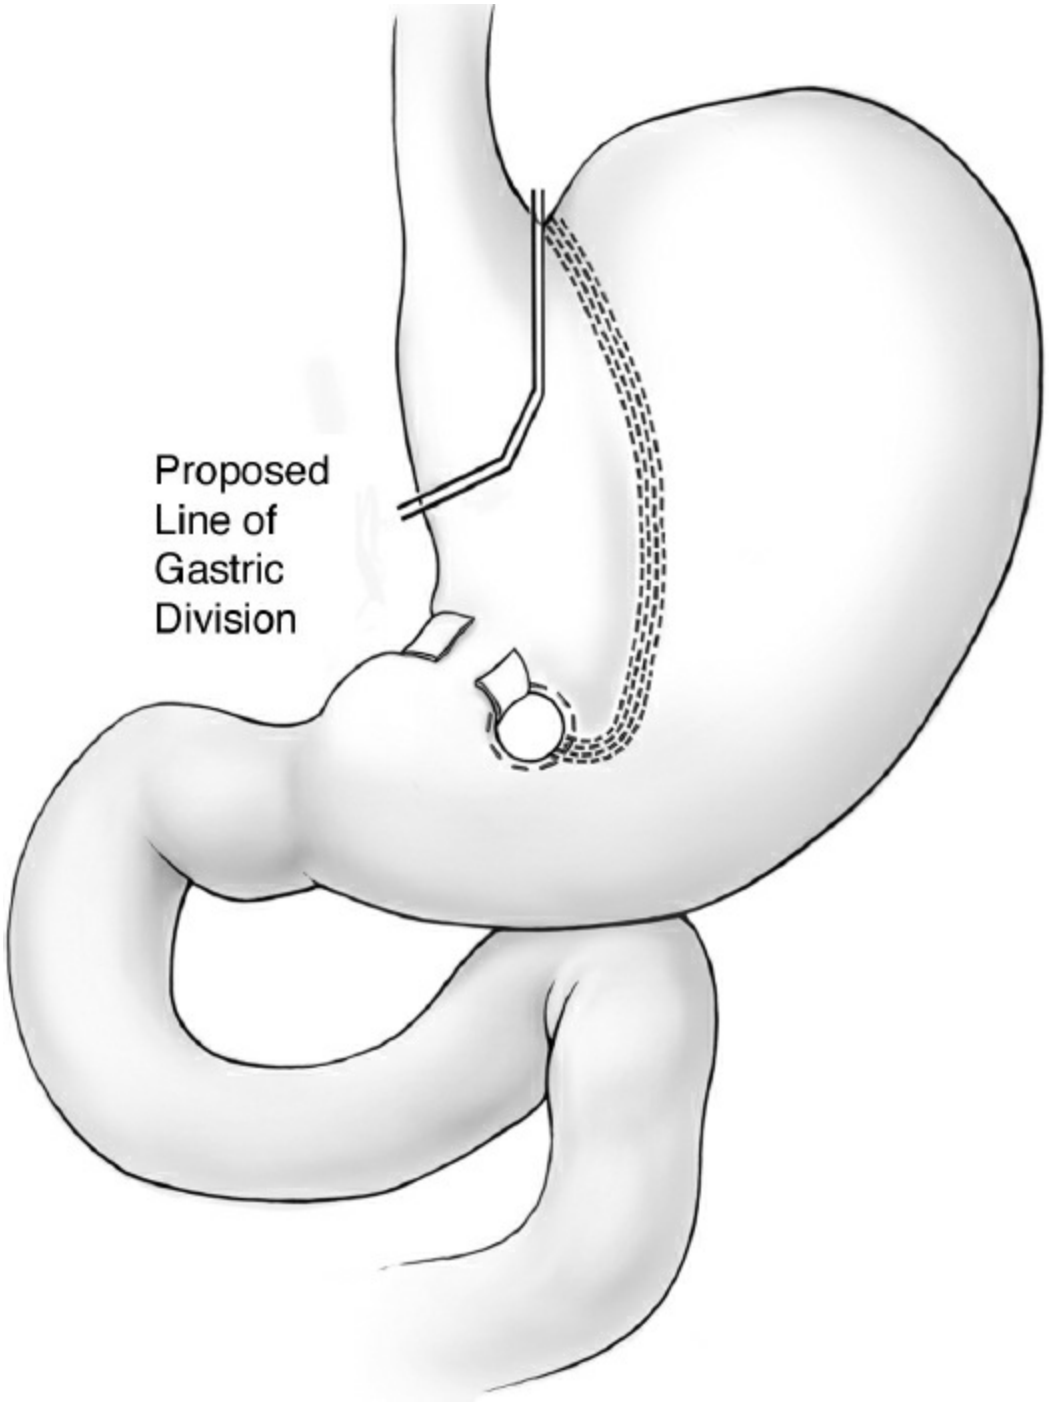

Figure 96.2. Proposed line of gastric division with revision of VBG to Roux-en-Y gastric bypass.

Open Faberge Technique

The initial approach to dissection of the old pouch is similar to the technique described above up to and including freeing the angle of His. At that juncture, dissection next to the lesser curve is performed sufficient to pass a Penrose drain around the gastrohepatic omentum. A second window may be made above the original one with a 28-mm EEA by passing the

anvil retrograde from posterior to anterior stomach approximately 3 to 4 cm to the left of the lesser curve. A Robinson catheter may be brought from the angle of His down through the new window and the TA-90B may then be passed using the Robinson catheter as a guide. The new pouch is then stapled after insuring that the endoscope moves freely. A 7.0 cm × 1.5 cm Marlex band can then be passed through the window and around the pouch outlet adjacent to the lesser curve. It is sutured to itself at a 5.0 cm circumference using interrupted polypropylene sutures in an overlapping fashion. No sutures should attach the mesh to the stomach. A section of the old mesh should be removed to avoid later compromise of the pouch outlet.

If the surgeon wishes to steer clear of the necessity for another window as described above, which may at times be awkward to perform, they can avoid this by passing a notched TA-90BN stapler in the fashion described above to construct the pouch and then use Long's technique of encircling the pouch outlet with three Dacron sutures placed through the staple line and adjacent to the lesser curvature over a 22 mm length. These encircle a dilator and are used to simulate the restriction of a banded outlet.

Open and Laparoscopic Conversion to Gastric Bypass

Surgical conversion to gastric bypass is the preferred surgical procedure when VBG failure occurs today. In part, this results from the adaptation of laparoscopic techniques to perform revisional bariatric surgery in which the endoscopic staplers perform tissue transaction rather than stapling in-continuity. The operative strategy is determined by the status of the previous VBG proximal pouch. If the VBG staple line is intact and the pouch nondilated, then we seek to superimpose our staple firings on the previous staple line after removal of the prosthetic band. In the event that the VBG pouch is dilated or if the staples have dehisced, we often plan our stapling to create a new smaller pouch above the previous staple lines. This is less important if there is no evidence of intact staples on preoperative contrast imaging. The stomach may be transected or stapled in continuity using three precisely superimposed firings of the stapler. Long (e.g., 4.8 mm or greater) staples should be utilized because of the thickness of the previously stapled gastric wall (Fig. 96.3).

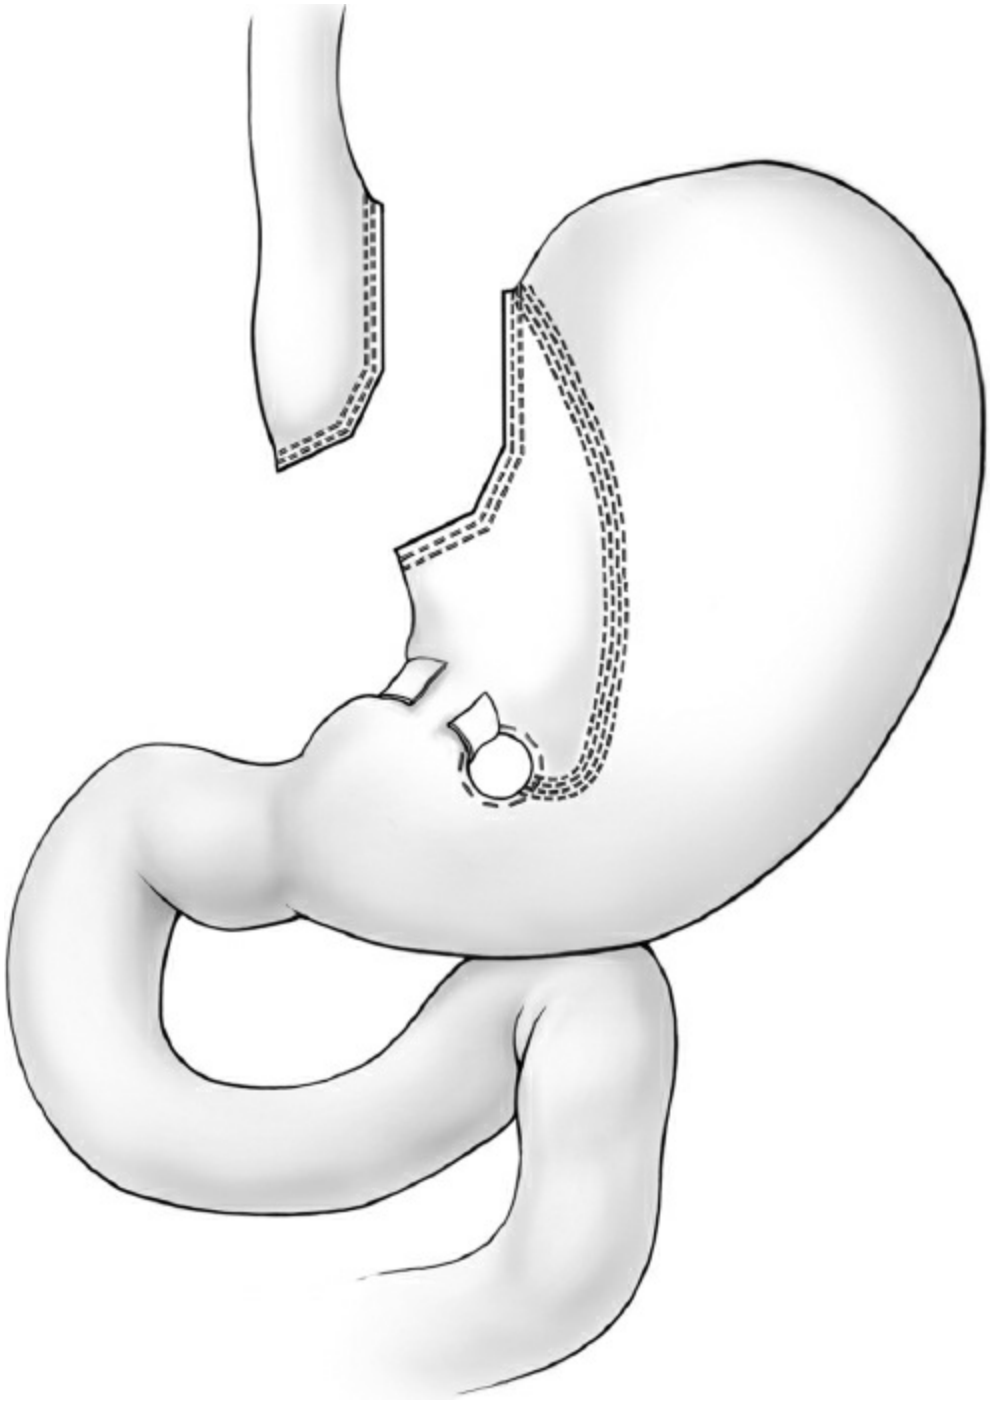

Figure 96.3. Division of the stomach in VBG prior to conversion to gastric bypass. Removal of the band or resection of a section of band is done to avoid the possibility of a closed-loop obstruction within the old dilated pouch. Gastric transection should be carried out with large 4.8-mm or greater staples because of the thickened stomach. The distal stomach staple lines are most commonly resected in current laparoscopic approaches to VBG conversion to gastric bypass. If not resected, it is critical to be certain that the isolated stomach segment between the two staple lines is able to drain without obstruction

to avoid blowout.

Laparoscopic conversion of VBG to Roux-en-Y gastric bypass is typically performed via similar port placements as utilized for primary laparoscopic gastric bypass. Adhesions are often dense, particularly at the location of the banded outlet. Removal of a silastic ring is much easier than removal of a mesh band. Identification of the location of the mesh band is usually indicated when the most dense adhesions are encountered. The band often provides an indication of the location of the previous gastric staple lines which are typically not easily seen as they lie at the base of gastrogastric adhesions. Teasing the fundus of the stomach from the anterior pouch is tedious but necessary to reveal the previous staple sites but also to decrease the gastric tissue overlap as much as possible so that stapling can be accomplished with appropriate tissue thickness and decrease the risk of staple line leak. Buttressing materials are often used for this purpose in revisional surgery, however with no strong clinical evidence that they accomplish this objective. When creating a small new gastric pouch above a previous VBG staple line, many surgeons prefer to resect the superior-most portion of the gastric remnant in order to obtain a more secure closure of the remnant and to avoid the possibility of an isolated segment of stomach sequestered between the old and new staple lines. The previous band is often included in this resection.

The Roux limb is then created by measuring 50 cm distal to the ligament of Trietz as a point to divide the jejunum with the linear cutting stapler. The distal end is marked to avoid confusion. A suitable length of mesentery is divided with either clamps or the 2.0-mm “vascular” linear staple cartridge to permit the distal jejunum to reach the cardia easily. The Roux limb may be brought up antecolic antegastric, retrocolic retrogastric (if the stomach is transected), or retrocolic antegastric (our preferred method when stapling the pouch in continuity rather than transecting it). The jejunojejunostomy is created using standard techniques a variable distance downstream from the transection site (Fig. 96.4). Many surgeons feel this measured length should be increased to 150 cm in superobese patients to enhance weight loss, although this concept has not been proven in the long term. The end of the Roux limb is then brought up in proximity to the newly created proximal gastric pouch where an anastomosis is completed using one of a number of available techniques.

Linear stapling can be utilized and is particularly favorable if the

revision is undertaken using laparoscopic access. Circular stapling is commonly utilized with both open and laparoscopic access techniques. Finally, we prefer a two-layer handsewn anastomosis when performing an open revision to gastric bypass while others prefer a circular stapled anastomosis (e.g., Orvil, Covidien). In general, we believe it to be beneficial to oversew the new staple lines with nonabsorbable suture if the stomach has been transected to create the new proximal pouch. Leak is more common after revision to gastric bypass than after a primary gastric bypass operation and therefore we recommend intraoperative interventions to detect and treat leak should it occur. Intraoperative testing of the anastomosis using intraluminal injection of methylene blue dye or air insufflated via a flexible gastroscope with submersion under saline is helpful to detect intraoperative leaks if the anastomosis is sufficiently distended during the test. Alternatively, a methylene blue saline test can be used. We routinely place a drain near the anastomosis and especially after open approach, we place a gastrostomy tube in the remnant stomach. With extensive adhesiolysis or a difficult dissection of the stomach, the leak rate is severalfold higher and a well-placed rain a G-tube can ease the management of a GJ leak. Finally, all mesenteric defects are closed to prevent an internal hernia. A nasogastric tube is placed to low intermittent wall suction.

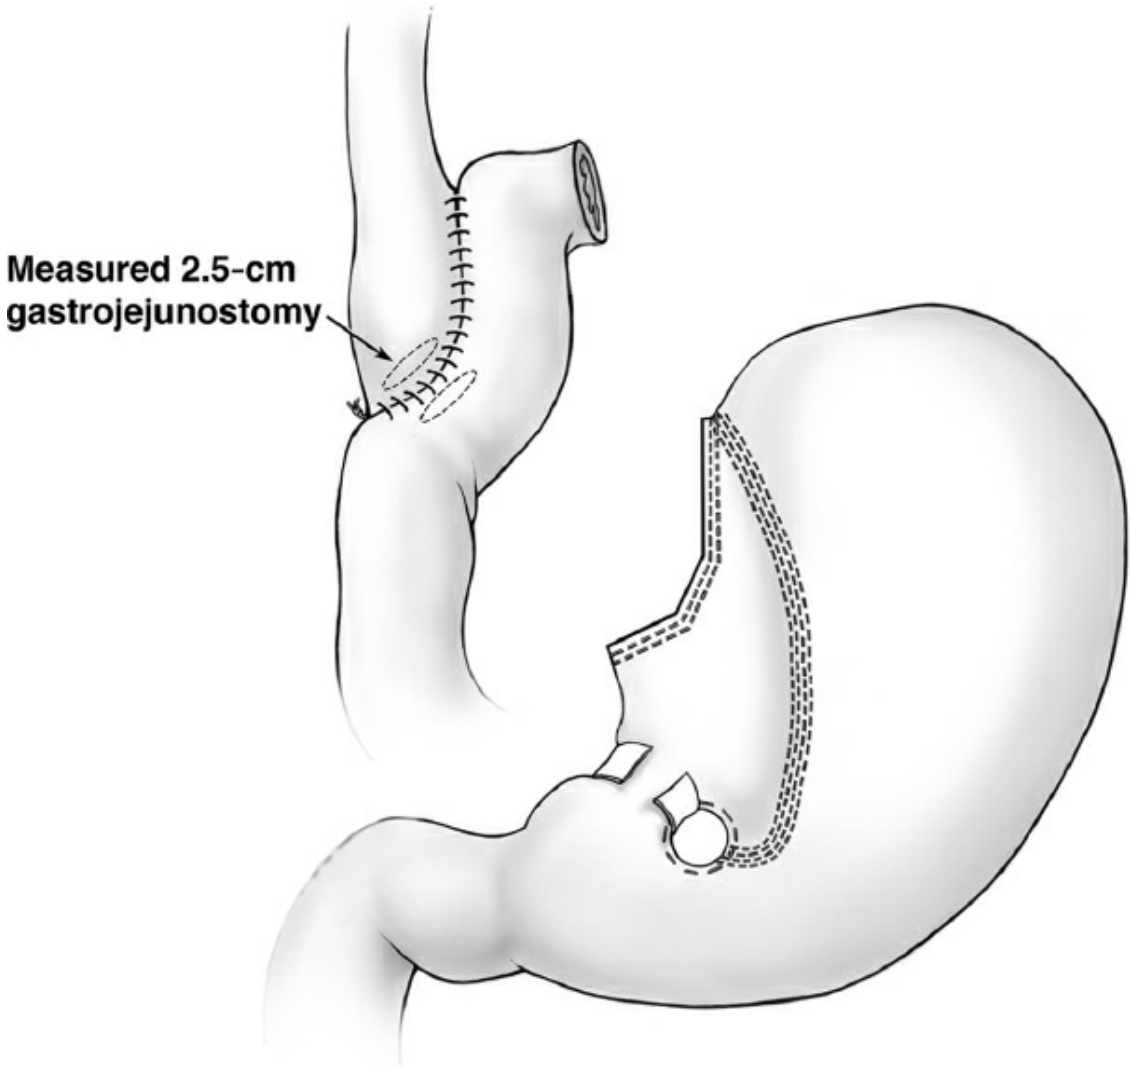

Figure 96.4. Construction of the gastrojejunostomy to the new pouch. Although the remnant may occasionally be left intact with the band either removed completely (easy to do in the case of a silastic ring band but almost impossible with a mesh band due to dense incorporation into the gastric wall), most surgeon would resect the areas of previous staple lines and remove that portion of the stomach entirely.

POSTOPERATIVE CARE

Postoperative the patient is continues on perioperative SQ heparin, SCDs, and 3 doses of antibiotics. POD 1 the nasogastric tube is removed and urinary catheter discontinued. Patients are encourage to use the incentive spirometer and ambulate the hallways. After the swallow study confirms no leak or obstruction, the diet is advanced from water to protein shakes. The dietitian will provide dietary instructions. The patient will be discharged on antacids and multivitamins.

COMPLICATIONS AND THEIR MANAGEMENT

After a revision, leaks are a dreaded complication and require prompt recognition. Ischemia may play a greater role in causing leaks after revision because the gastric blood supply may have been compromised in unpredictable ways at the time of the primary surgery. We routinely perform a postoperative water-soluble contrast study during the postoperative period before resumption of oral diet to assess for this complication in all patients who have undergone revision to gastric bypass. In addition, the study provides documentation of the new anatomy following the revisional procedure. If the patient develops tachycardia, respiratory compromise and later urinary retention or abdominal pain, a leak should be expected even if swallow study and/or CT scan is negative and reoperation should be considered.

This patient population is also at higher risk for venous thromboembolic events including fatal pulmonary embolism. Sequential compression devices and perioperative anticoagulation is routinely given. Longer-term low–molecular-weight heparin or other anticoagulant prophylaxis may be used if the patient has a history of DVT, PE, in patients who are nonambulatory or in those with venous stasis disease or hypercoagulable conditions. Leg pain/swelling should prompt lower extremity Doppler and shortness of breath should be evaluated by CT pulmonary angiogram.

OUTCOMES

Most patients will be discharged home 3 to 5 days after open revision and 1 to 3 days after laparoscopic revision. Modest weight loss is expected. Most patients will have near complete resolution of vomiting and reflux with revision or conversion to gastric bypass.

EDITOR'S COMMENT

The surgical treatment of obesity has undergone tremendous change since its inception in the 1970s. Early procedures such as the jejunoileal (JI) bypass have long since been abandoned with subsequent reversals. Only extremely rarely are patients encountered with the JI bypass and the reversal is straightforward. The vertical banded gastroplasty (VBG) was widely performed in the 1980s and early 1990s, and as a result, there are numerous patients that still have the VBG anatomy despite the fact that long-term failure rates of VBG are high. When significant weight gain happens or complications occur, the options for revisional surgery are multiple and more complicated. Today's bariatric surgeons need to be well versed in how to treat these patients and potentially perform revisional surgery, especially since most will have never seen a VBG actually performed.

Dr. DeMaria and Dr. Jones offer an excellent tutorial on the etiology and pathophysiology of VBG complications, including sections on clinical presentation, staple-line dehiscence, pouch enlargement, and erosion. They then share their vast experience in the preoperative planning, indications and contraindications, and both open and laparoscopic techniques utilized when performing revisional VBG surgery.

As with all patients that present for consideration of revisional surgery following any primary bariatric operation, the authors appropriately emphasize the preoperative workup needed to understand the potential factors involved in weight gain or complications. Weight regain can be the result of lack of dietary compliance, staple-line dehiscence, or pouch dilation. Dietary noncompliance

must be addressed head-on with intensive dietary and behavioral counseling, with a very high bar set prior to considering any revision. These are the patients that I will often mandate 10% to 20% preop EBW loss to ensure dietary and program compliance prior to undertaking a complicated and potentially risky revisional operation.

Staple-line dehiscence is one of the major reasons for VBG failure and complication. A small dehiscence is usually not an indication for revisional surgery, but conversion to a Roux-en-Y gastric bypass (RYGB) is probably the best option to fix a large dehiscence in a compliant patient. The challenge with this revisional operation is that the pouch may not be enlarged, making it difficult to staple medially to the original staple line. This in combination with chronic scarring may necessitate the resection of the pouch and creation of an esophagojejunostomy. Resection of the proximal portion of the remnant stomach is also often needed to reduce the risk of leak from the remnant stomach. Placement of a gastrostomy tube in the remnant stomach is a reasonable option, as this not only allows for remnant decompression but can also be used as an enteral nutrition access site.

Dilation of the pouch is another mechanism of weight regain, and I would agree with the authors that although it's easy to blame the patient, careful evaluation of other potential causes such as a stricture need to be considered. When evaluating a patient with a dilated pouch, a "chicken and the egg" conundrum exists. While the etiology of pouch dilation may be related to how the original operation was performed and making the pouch too large and including too much fundus, it is usually the result of lack of behavioral compliance with chronic overeating or stricture at the band site. When an appropriate revisional surgical patient is chosen, again, I believe that RYGB is the procedure of choice for revision. A recent published report by van Wezenbeek et al. examined the "long-term results after revisions of primary vertical banded gastroplasty" and concurred that RYGB was better than re-VBG or conversion to a sleeve gastrectomy anatomy (van Weezenbeek MR, Smulders FJ, de Zoete JP, et al. Long-term results after revisions of failed primary vertical banded gastroplasty. *World J Gastrointest Surg* 2016;8(3):238–45). Of the 392 patients that underwent primary VBG, 152 (39%) ultimately underwent revision which is consistent with previous reports of high failure rate with the VBG. RYGB resulted in a higher total% EBWL compared with re-VBG and sleeve gastrectomy with lower complications. Unlike with staple-line dehiscence, pouch dilation usually allows for adequate room above the level of and medial to the previous staple line for staplers to be applied. Caution should always be emphasized when stapling across thickened stomach and scar, thus the highest staple height should be chosen to allow for appropriate staple formation. Despite this, I still advocate the placement of two JP drains (anterior and posterior to the gastrojejunostomy) to help control any leak that may occur during the initial postop period. Likewise, all of my patients undergoing revision to a gastric bypass will get a routine gastrografin study to evaluate for

leak prior to initiation of PO intake.

If stricture at the level of the band or mesh is the cause of pouch enlargement, a novel endoscopic technique that was originally described by Wilson et al. and more recently reported by the Minnesota group specifically for VBG could be considered (Wilson TD, Miller N, Brown N, et al. Stent induced gastric wall erosion and endoscopic retrieval of nonadjustable gastric band: a new technique. *Surg Endosc* 2013;27(5):1617–21; Lim CH, Amateau SK, Ikramuddin S, et al. Endoscopic management of vertical banded gastroplasty stricture: feasibility, safety, and efficacy. *Obes Surg* 2016;26(11):2802–8). A self-expanding metal stent is placed endoscopically across the level of the stricture. Pressure on the strictured mucosa between the stent and gastric band causes pressure necrosis of the gastric wall over a period of several weeks. The stent and silastic ring or mesh is then able to be retrieved endoscopically.

Band erosion is the final reason for revisional surgery for VBG patients. The authors appropriately caution that an asymptomatic erosion does not automatically require any intervention. If symptoms such as pain, PO intolerance, reflux, or bleeding necessitate revision, newer endoscopic techniques now exist and can often avoid a major surgical revision. The endoscopic technique described by the authors is effective and skilled endoscopists can help avoid revisional surgery.

Attentive postoperative management is required for these complex surgical revisions, and as the authors state, these patients are at higher risk of all complications, especially that of leak and venous thrombotic events. I feel that these types of operations should only be performed by experienced surgeons such as Dr. DeMaria and Dr. Jones at a center of excellence and part of the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP).

Eric Hungness

97 Laparoscopic Gastric Bypass

Alan C. Wittgrove

INTRODUCTION

As the disease is morbid obesity and the metabolic syndrome has developed into epidemic proportions, worldwide, the field of bariatric and metabolic surgery has likewise grown. From our development of the laparoscopic technique for the gastric bypass in 1993, now, nearly all primary bariatric operations are performed laparoscopically. This evolution has allowed for safer procedures with excellent outcomes while shortening the hospital length of stay allowing the patient to enjoy an active life earlier.

Over the last several years we have seen trends change in bariatric surgery. Laparoscopic adjustable gastric banding, for example, has all but ceased to exist as a primary bariatric operation. Many bands have been removed. The laparoscopic sleeve gastrectomy is now the most commonly performed bariatric/metabolic operation, worldwide. The gastric bypass continues to be performed, both as a primary operation and as a revision or conversion option, as it has a very consistent and reliable postoperative course and outcome pattern.

Also over the past 10 years, we have seen the number of fellowship training programs expand in laparoscopic and bariatric surgery. With this expansion has come a better understanding of the etiology of the disease and the mechanisms of action for the various operations. As more information is gleaned, hopefully we will be able to better fit a specific operation to a specific patient.

HISTORY

As has been cited many times, Dr. Mason and Dr. Ito are recognized as performing the first gastric bypass, for weight loss, in 1967. Their operation was performed after they had made the clinical observation that partial gastrectomy patients had difficulty with gaining weight. By today's standards their operation was quite different; using a loop configuration

and a gastric pouch of about 150 cc. Over the years the pouch size has been shown to be important in consistency and longevity of response so the operation has been modified to have a much smaller pouch; based on the lesser curvature (to avoid the distensibility of the greater curvature). The loop configuration was changed to a Roux-en-Y to counteract the postoperative bile reflux. More recently, surgeons have once again investigated the loop intestinal configuration; this time with a more elongated gastric pouch and a more distally placed anastomosis. This "loop gastric bypass" will not be discussed in this chapter.

The laparoscopic approach to the gastric bypass was first performed by my group in 1993. Our main drive to this approach was to avoid our biggest complication at the time, incisional hernias. We had performed thousands of open gastric bypass operations and biliopancreatic diversions by that time and we were performing more upper abdominal laparoscopic operations (Nissen fundoplication) as well. As instrument companies developed more suitable laparoscopic choices and we worked in the laboratory to refine techniques, we were finally able to perform the first laparoscopic gastric bypass. Our studies showed consistent weight loss and comorbid resolution with the laparoscopic technique and improvements in instrumentation and training, the techniques have been expanded.

The concept of the multisystem effects of the gastric bypass were being understood as Dr. Buchwald coined the term "Metabolic Surgery." In the mid-1990s, Dr. Pories asked the provocative question "Who would have thought diabetes is a surgical disease?" As gut hormones (Incretins), adiponectin and other active substances have been identified and analyzed, our understanding that the gastric bypass is much more than a "restrictive" procedure has come to light.

CANDIDATES FOR LAPAROSCOPIC GASTRIC BYPASS AND PATIENT SELECTION

The guidelines to determine candidacy for bariatric surgery were established in 1991 by the National Institutes of Health (NIH) Consensus Conference on Gastric Surgery for Severe Obesity. These were reestablished by the ASMBS in 2004. They determined candidates should have a body mass index (BMI) $\geq$40 kg/m^2 or a BMI $\geq$35 kg/m^2 with certain obesity-related comorbidity. These criteria were established as arbitrary guidelines for the evaluation of the patient who suffers from the disease of morbid obesity but it is up to the surgeon (or bariatric team) to

determine who is a good candidate for bariatric surgery. As we have learned more regarding metabolic disease and genetics, the BMI guideline has come down for some individuals with an elevated “metabolic burden.” Since these surgeries are life-changing and many patients with this disease are, in some way, compromised, bariatric surgery patients should undergo an extensive and individualized, preoperative evaluation. The work-up should try to optimize the patient with regard to their known comorbidities and should evaluate the patient for potential comorbidities such as coronary artery disease, sleep apnea, metabolic syndrome, and obesity hypoventilation syndrome. A multidisciplinary approach is required to evaluate bariatric surgery candidates. The team should include nursing, nutritionists, behavioral health specialists, and medical subspecialists as well as the bariatric surgeon. Family and social support, as well as organized support groups offered by the program, are important for the overall success of the patient. Potential patients with ongoing substance abuse or uncontrolled psychiatric disorders are not candidates for bariatric surgery though patients who are well controlled on psychiatric medications can be considered as surgical candidates.

The informed consent process is very important in the field of bariatric surgery and the patients who being worked up for surgery must be fully informed about the risks and possible benefits for all the available surgical (and nonsurgical) options. Though some programs have developed pathways, there is no “evidence-based” algorithm that can predict the best outcome for a specific patient. Currently, the patient’s preference tends to be the main driver in determining the specific operation chosen. This, of course, should not be done in a vacuum and the patient’s medical history and the surgeon’s experience should round out the process. The patient and bariatric team must take into account the follow-up requirements and programmatic guidelines (e.g., exercise and supplementation requirements) as they try to anticipate degrees of success.

Risk stratification is important and the surgical literature has identified several factors that increase the risk for complications. These factors are male gender, age over 55, BMI >45, hypertension, and high risk of pulmonary embolism (PE, previous thrombosis, pulmonary embolus, inferior vena cava filter, right heart failure, and obesity hypoventilation). Both the bariatric team and the patient should be aware of the conditions and their theoretic added risk.

MECHANISM OF ACTION

It is true that the gastric bypass Roux-en-Y is a restrictive procedure: but it is much more. The small gastric pouch (15 to 45 cc) with a limited outlet, through the gastrojejunostomy sized to 10 to 12 mm, at least early on causes a restriction to the volume of food that can be consumed. The basic effect is so much more than restriction. We know we can limit one's intake by diet or other means and still not achieve the effects of the gastric bypass. The key to the bypass is the changes in hormones that occur which allow the patient to feel comfortable eating less by achieving a sense of "satiety." With these hormonal (Incretin) effects come the "metabolic" effects which aid in resolving type 2 diabetes (within days of the operations!), decrease lipid levels, decrease in blood pressure and change in sleeping patterns; even before weight loss. By placing nutrients and other substances directly into the small intestine and allowing for rapid transfer to the more distal GI tract, incretin patterns change in a beneficial way, following the gastric bypass.

The Roux limb is 75 to 150 cm in length and the biliopancreatic limb can measure from 15 to 50 cm from the ligament of Treitz. These lengths do not typically cause malabsorption of macronutrients since the common channel is several meters in length. The duodenum, however, is the most efficient area to absorb di- and tri-valent cations, metals such as iron and calcium. Lifelong supplementation of multivitamins, iron (in menstruating females), calcium, and vitamin B_{12} is recommended following the gastric bypass to avoid micronutrient deficiencies.

TECHNIQUE

Access and Exposure

The patient is placed in the supine position with arms extended on arm boards (for access if needed). The standard precautions are used for leg strap and warming. We do not use a foot board though some facilities do use that as the patient will be placed in a reverse Trendelenburg position.

The operating surgeon stands on the patient's right side and the assistant on the left. We establish pneumoperitoneum with a Veress needle inserted just below the rib margin in the left upper quadrant incision, near the anterior axillary line. The first port is placed with visual assistance using an optical trochar (Endopath Xcel, Ethicon Endosurgery, Cincinnati, OH). This first port is generally at the umbilicus though it may be inserted

off the midline if the patient had prior surgery and adhesions are anticipated. The remaining ports are placed under direct vision after skin and subcutaneous infiltration with a long-acting local anesthetic. Figure 97.1 shows our usual port placement. Since we perform a stapled anastomosis, both at the gastrojejunostomy and the enteroenterostomy, the ports are placed to facilitate those actions. The port placement may be altered if the anastomosis is created via the hand-sewn technique, to better allow for triangulation of instrumentation. A total of six ports are used but if significant adhesion formation is encountered, additional 5-mm ports are often used to facilitate additional dissection. A 5-mm port is placed in the subxiphoid space and is used for liver retraction. We use a simple toothed grasper to the diaphragm, just anterior to the hiatus, but some surgeons prefer other retraction systems such as the Nathanson liver retractor. No matter what system is used, adequate exposure of the gastroesophageal junction is mandatory.

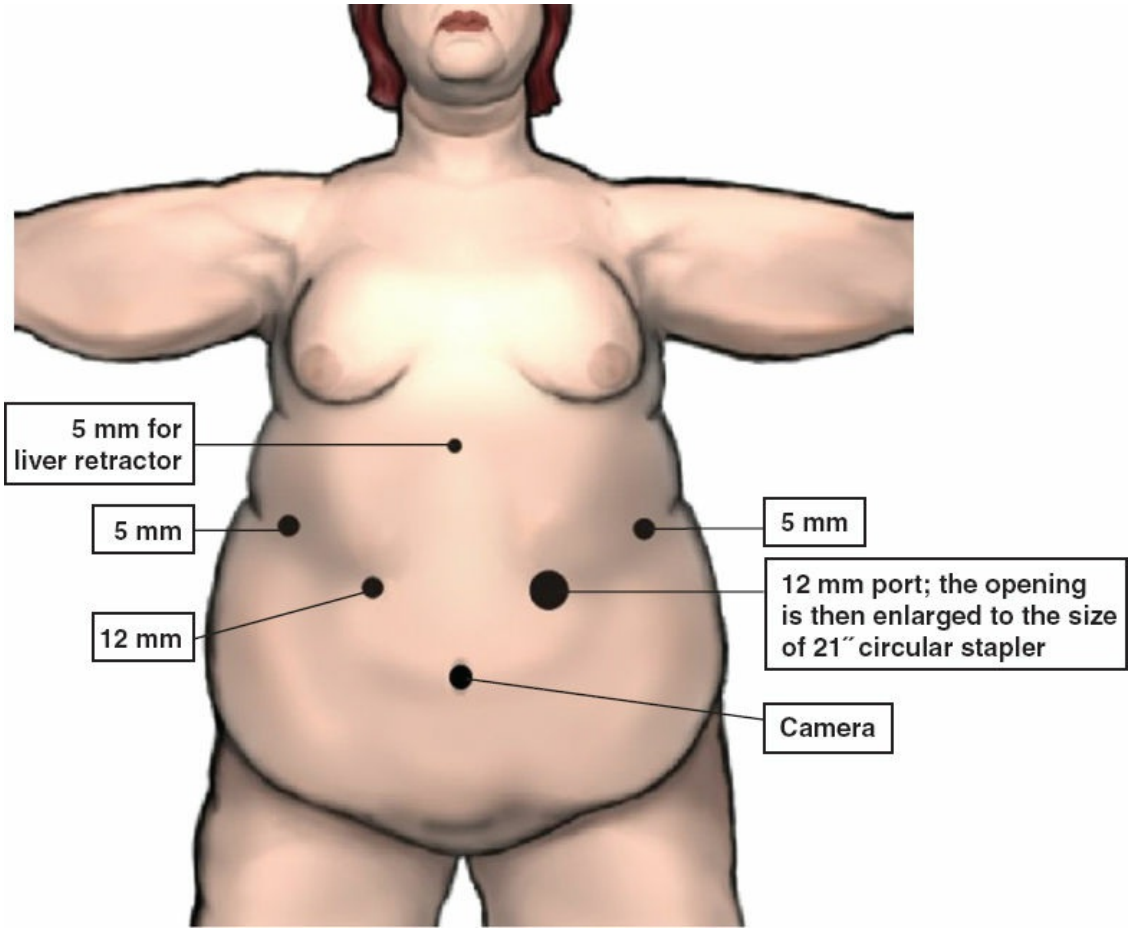

Figure 97.1. Laparoscopic port placement for gastric bypass. (Courtesy Ethicon, US, LLC.)

Gastric Pouch

The patient is placed in reverse Trendelenburg position (and we add a degree of sitting position to shorten the distance between the umbilicus and the hiatus) (Figs. 97.2 and 97.4). The assistant retracts the lateral fundus and the surgeon takes down the adhesions at the angel of His. This maneuver will allow more complete exclusion of the greater curvature during the final steps of the gastric transection. A sizing balloon is placed and filled to 15 cc with air. The anesthesiologist then gently snugs the balloon into the esophagogastric junction. The assistant has one grasper along the lesser curvature, near the incisura and the other on the gastric wall just below the balloon. We dissect in a paragastric fashion (some surgeons more fully transect the hepatogastric ligament) to create a tunnel behind the stomach to facilitate stapler placement. Once the tunnel is created, the balloon is removed (as well as any other device placed in the esophagus, to avoid stapler mishaps) and the small gastric pouch is created (Fig. 97.3). After the first firing of the linear stapler, the assistant retracts the lateral fundus. This lessens the amount of redundant stomach found posteriorly and aids in the creation of a very small and consistent pouch size. The first firing of the stapler is generally horizontal while the second and possible third firings are angled cephalad toward the angel of His. Care is taken for the assistant not to retract too aggressively as this may cause encroachment into the esophagus during the final firing. Blue staple loads are used in primary cases but green loads maybe need if the gastric wall is thickened of in revision cases. Buttress material is not used by our team.

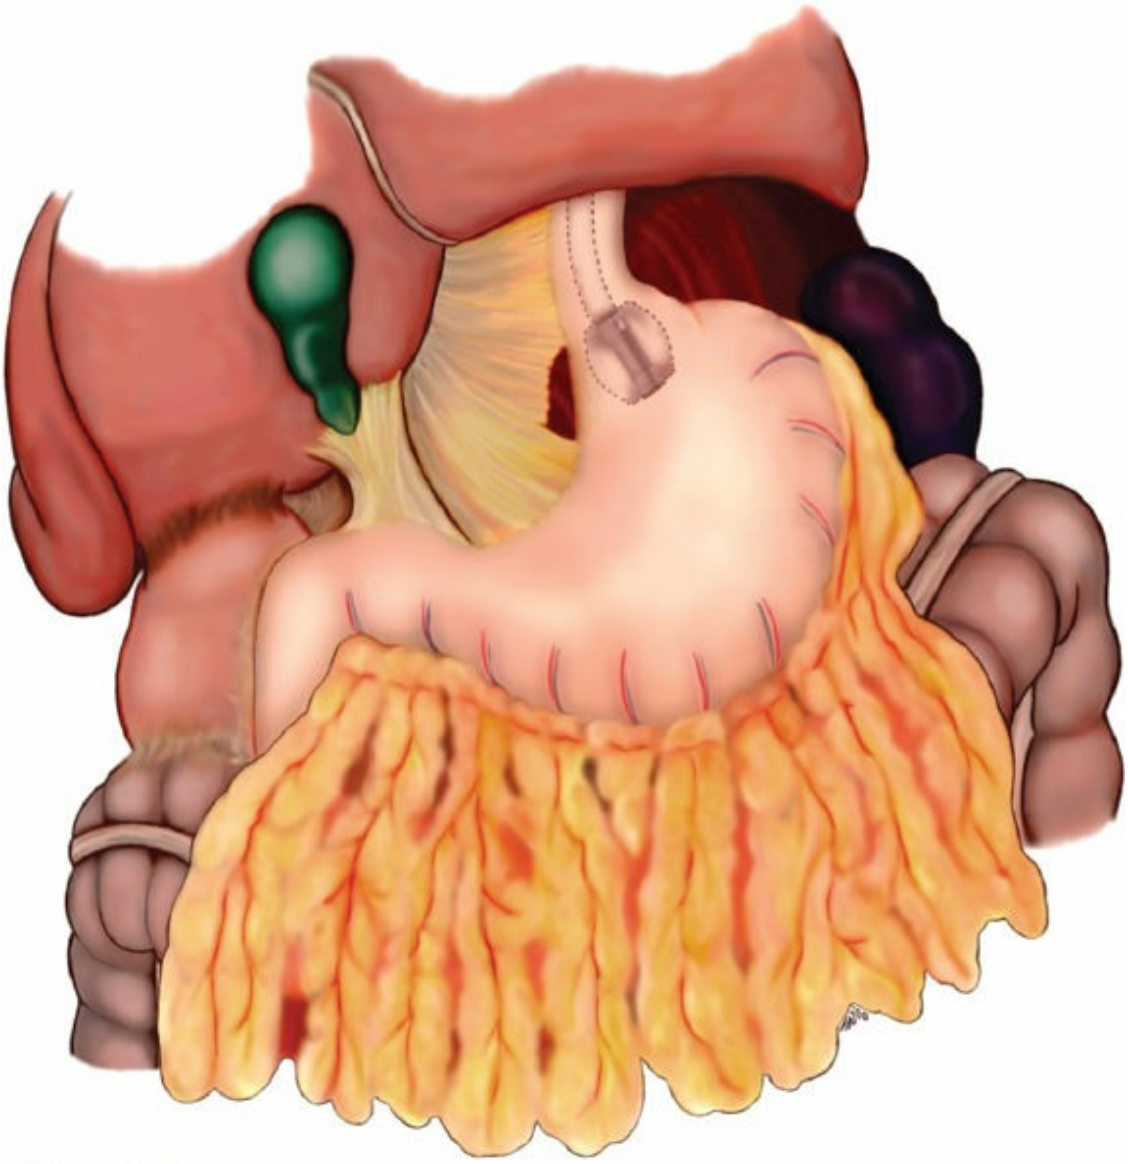

Figure 97.2. The liver is retracted and a balloon is used to size the gastric pouch. (Courtesy Ethicon, US, LLC [modified].)

Jejunojejunostomy and Roux Limb

The omentum and transverse colon are reflected superiorly and cephalad into the upper abdomen and the ligament of Treitz is identified (Figs. 97.5 and 97.6). The assistant retracts the mesocolon anteriorly to visualize the ligament and facilitate opening the base of the transverse mesentery, into the lesser sac. Since we use a retrocolic/retrogastric placement of the Roux limb, it is important to identify this space and even place a Penrose drain, into this space, to aid in bringing the small bowel into the upper abdomen.

Figure 97.3. A linear stapler is used to divide the stomach. (Courtesy Ethicon, US, LLC.)

The jejunum is then divided 15 to 50 cm distal to the ligament of Treitz using a blue stapler load of the linear stapling device. I will note here that we use a short biliopancreatic limb (BP) (15 cm) and have done so thousands of times. Some surgeons create a longer BP limb. A shorter BP limb tends to have less tendency to “kink” or twist and some feel as if the longer BP limb adds beneficial metabolic effects. The mesentery of the jejunum is not further divided with our technique as the retrocolic/retrogastric passage is very short and there is minimal tension on the gastric anastomosis. In addition, if the small bowel mesentery is not transected, there is more consistent blood supply to the Roux limb and there is essentially no Petersen space. The proximal stapled end of the Roux limb is sutured to a Penrose drain to facilitate transit behind the colon and stomach.

The Roux limb is measured distally for 75 to 150 cm. This

measurement is based on Dr. Roux' work to prevent reflux of bilious material, back up the limb. More recently some programs have lengthened the limb to 150 cm in hopes of aiding weight loss. We have always used 75 cm for the Roux limb. This measurement is made with the bowel straightened but not on stretch and using some reproducible process to create a uniform operation, patient to patient. Remember some medications given by anesthesia can alter this measurement (anticholinergics such as Atropine and Robinal). Once the appropriate Roux limb length is measured, a side-to-side (functional end to side) enteroenterostomy is created between the Roux and BP limbs. We use a linear stapler technique with white loads to perform this anastomosis but it can be hand sewn as well. Stay sutures can be used to stabilize the bowel for this anastomosis but we use graspers to align the bowel and create traction/countertraction so the stapler can be inserted through the lower port of the primary surgeon. The opening for the introduction of the linear stapler is then closed with another staple firing. Care needs to be taken not to narrow or kink the anastomosis. We then close the small bowel mesentery with running permanent suture. One single suture is then placed to align the Roux limb, just proximal to the anastomosis, to the stapled end of the BP limb. This "Brolin stitch" also helps to avoid kinking.

Figure 97.4. The gastric division is complete with the final stapler firing going to the angle of His. (Courtesy Ethicon, US, LLC.)

Once the mesentery is closed, the stapled end of the Roux is brought into the upper abdomen with the Penrose drain, through the lesser sac. An alternative method is to bring the Roux limb antecolic/antegastric. Division of the omentum can shorten this distance and facilitate this maneuver with less tension. If the bowel is brought up “ante,” there is clearly a longer Petersen space to consider.

Figure 97.5. The small bowel is divided distal to the ligament of Treitz. (Courtesy Ethicon, US, LLC.)

Circular Stapled Gastrojejunostomy, Transoral Method

This is our primary technique for creating the gastrojejunostomy (Fig. 97.7). When we developed the laparoscopic technique in 1993 the laparoscopic instruments were inferior to those being used today. They were short, often too traumatic or with poor holding ability. Delivering to anvil into the gastric pouch in much the same way we were able to perform a PEG afforded us the opportunity to complete the operation even with

limited instrumentation.

We continue to perform an endoscopy after the gastric pouch is created. A snare is placed through the endoscope, through the gastric wall near the staple line. A percutaneous pull wire is introduced into the peritoneal cavity and grasp with the snare. The endoscope is removed and the pull wire now protrudes out the patient's mouth. The anvil is fastened to the pull wire and by pulling back on the wire, the anvil travels down into the stomach. An alternative method is now available to surgeons without the use of the endoscope. Utilizing a system in which a 21-mm anvil is already attached to the end of an orogastric tube, the tube is placed down the esophagus and into the gastric pouch. The tip of the tube is placed just posterior to the horizontal staple line of the gastric pouch and, using cautery, the tube is advanced into the abdomen and out one of the ports. With either technique, as the anvil is placed in the posterior pharynx, the jaw should be retracted anteriorly allowing gentile passage of the anvil into the pouch. Once the stem of the anvil protrudes through the gastric wall, the tube is secured and the pull wire or tube is cut free and removed.

The Roux limb is brought into the upper abdomen and the lower port site on the left is enlarged just enough to allow passage of the circular stapling device. We open the antimesenteric boarder of the Roux about 6 to 10 cm from the stapled end and introduce the circular stapler through this opening. The stapler is advanced to the stapled end, connected to the anvil, closed and fired. Prior to removing the circular stapler from the abdomen, it should be covered to avoid wound contamination and infection. This can be accomplished with EITHER a plastic wound protector or, with the Ethicon product, by using the plastic cover already on the device. If proper covering is done, wound infections are rare. The stapler is removed from the abdomen and the antimesenteric opening is closed with a linear stapler. Using this technique, we are able to avoid any afferent limb issues later in the patient's course and the final linear staple line helps stabilize the small bowel at the transverse mesentery, avoiding an internal hernia potential at that space. An alternative method would be to introduce the circular stapler through the stapled end and creating the anastomosis along the antimesenteric boarder of the Roux. The remaining "afferent limb" is the transected and removed. We do not prefer this method for reasons outlined above, but it does have popularity. Interrupted sutures can then be placed to buttress the anastomosis or involute staple lines.

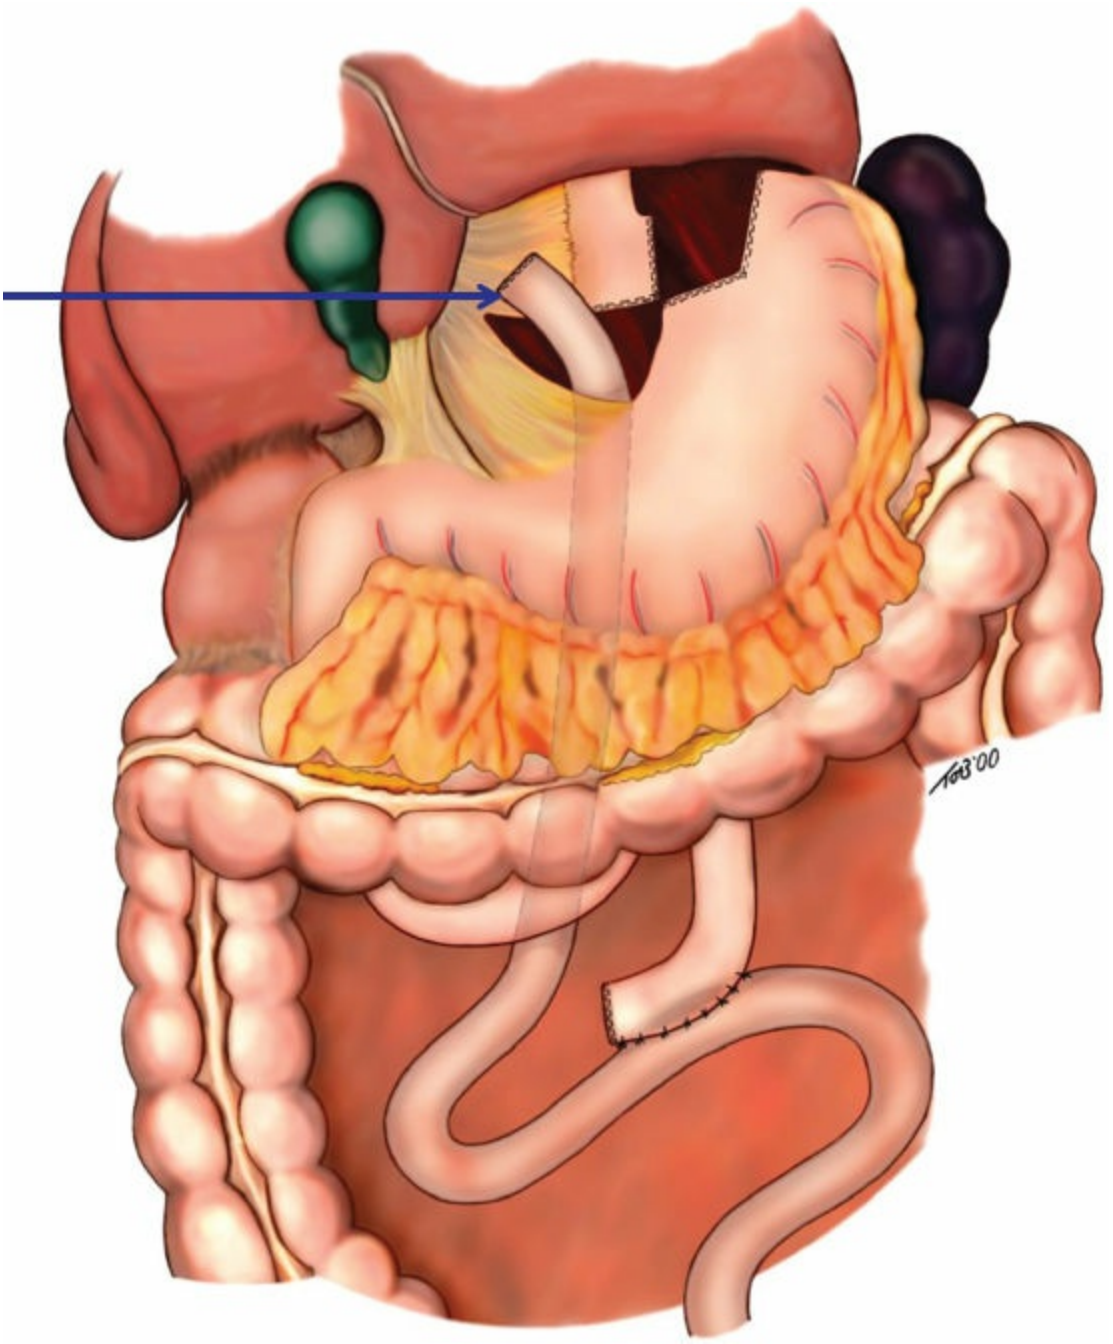

Figure 97.6. An enteroenterostomy is performed and the Roux limb is brought up to the gastric pouch. A Penrose drain is attached to the stapled end of the Roux limb (*arrow*) to facilitate transit to the upper abdomen. (Courtesy Ethicon, US, LLC [modified].)

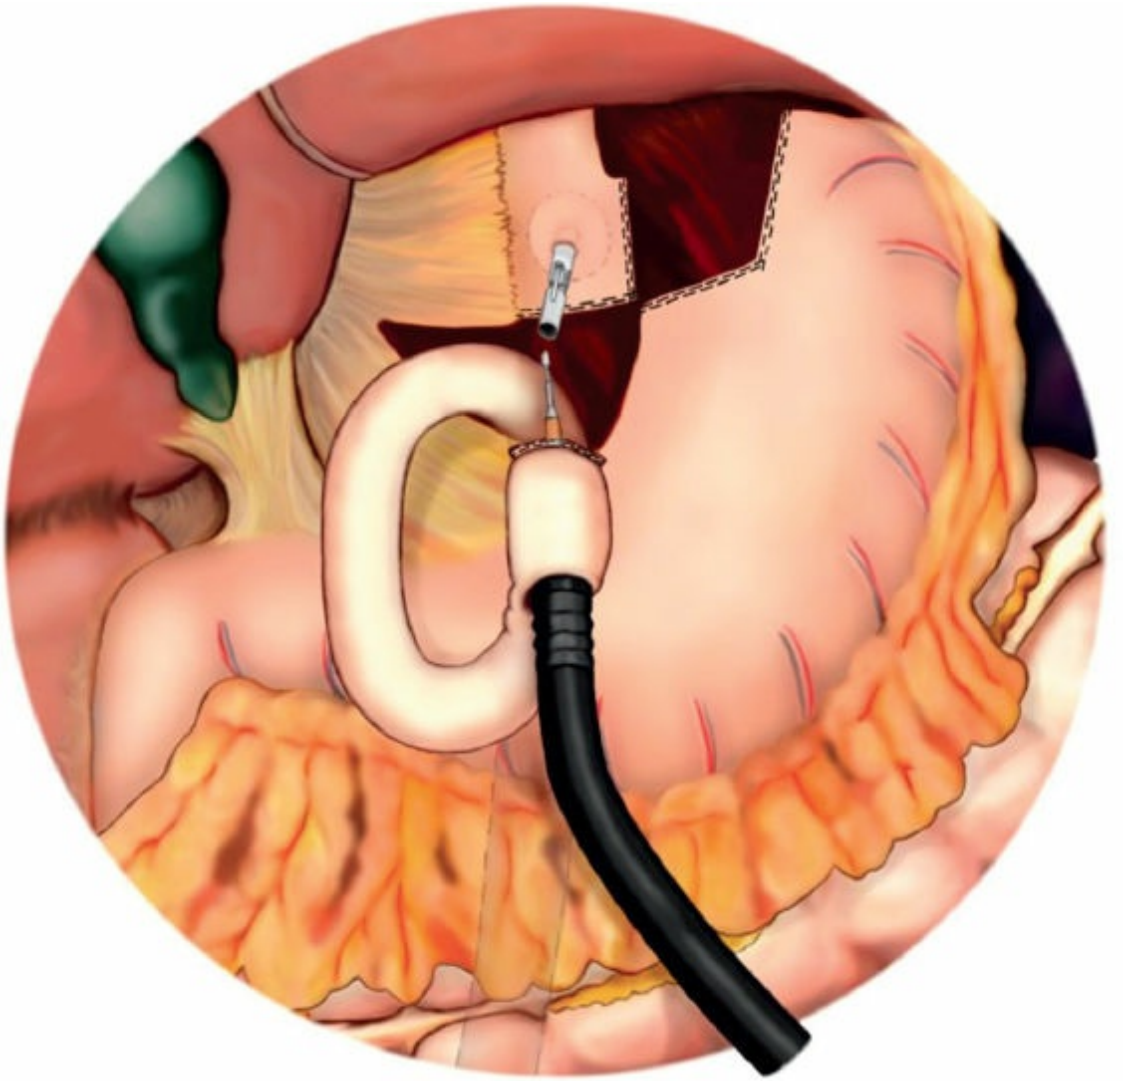

Figure 97.7. The anvil is placed in the gastric pouch and the circular stapler is introduced into the small bowel to complete the gastroenterostomy. (Courtesy Ethicon, US, LLC.)

Leak testing and drain placement are discussed in the “final steps” section.

Circular Stapled Gastrojejunostomy, Transgastric Method

The transgastric approach entails introducing the anvil of the circular stapler directly into the stomach rather than introducing it through the mouth and down the esophagus. There are several ways of accomplishing this task but in general the anvil is introduced through a gastrotomy, usually with a suture attached. A long, curved grasping device is then used to bring the suture and therefore the stem of the anvil out near the esophagogastric junction. The gastric pouch is then fashioned below the

anvil. The circular stapler is then delivered into the abdomen as discussed above. The gastrotomy in the body of the stomach is closed with a linear stapler. This technique originally had less wound complications than the transoral anvil placement since there is no oral bacteria "contaminating" the anvil. With the wound covering techniques discussed earlier with the oral anvil placement wound infections are now rare with either method. Larger anvil size is possible with this technique and there is obviously no chance of getting the anvil stuck at the cricopharyngeus as rarely can happen with the transoral technique.

Hand-Sewn Gastrojejunostomy

As the laparoscopic instrumentation has improved and the use of robotic surgery has been developed in the bariatric arena, the hand-sewn gastrojejunostomy has become more popular.

Drs. Higa and Boone were first to describe and popularized this laparoscopic technique. This technique essentially mimics the technique used for years in open surgery. There are advantages in that less expensive staplers are used and less specialized equipment is needed. The skill set needed to create a two-layer gastrojejunostomy, sized to 12 mm, is significant.

Gastrojejunostomy, Linear Stapled Technique

With this technique, the Roux limb is generally brought toward the gastric pouch in an antecolic/antegastric manner. It is important to ensure that there is no twisting of the mesentery of the small bowel as the stapled end of the Roux is secured to the pouch with absorbable suture. Some surgeons will run an entire back row of suture while others will interrupt sutures to hold both the Roux and gastric pouch in apposition. The anastomosis is generally created with a blue load of a linear stapler, using only about 15 to 20 mm of the firing to assist in sizing the anastomosis. The closure of the common opening is done with a running, absorbable suture, over a sizing tube. If an endoscope is used to size the anastomosis to 30 French, it can also be used to perform a leak test as previously described with the circular stapler. In general, this technique requires a larger gastric pouch and care is needed to insure the pouch is long and narrow rather than over all larger. A generally larger pouch (depending obviously on the degree) may not have the same longevity of success for the patient. Because this technique generally employs an antecolic/antegastric orientation for the

Roux limb, the Petersen space needs to be addressed. Some surgeons do not close any of the potential internal hernia spaces. Though there is no mandate to close these defects, most surgeons do close them with nonabsorbable suture. With this technique, the long Petersen space potential is closed with running 2-0 nonabsorbable suture securing the mesentery of the Roux limb to the transverse colon, omentum, and defunctional stomach.

Final Steps and Discussions

Since the inception of the laparoscopic technique for the gastric bypass, we have performed a leak test at the end of the case. We cross clamp the Roux just distal to the gastroenterostomy and perform a second endoscopy. Air is insufflated into the pouch with the anastomosis submerged in saline. If no air bubbles are noted, we pull the redundant Roux limb down below the transverse mesentery and secure it with a single suture. Since we insert the circular stapler through an opening in the antimesenteric boarder of the small bowel and close that with a linear stapler, that final staple line ends up at the transverse mesentery and assists in closing this space. This technique tends to avoid internal hernias at the transverse mesentery space. A Blake drain is placed in the subdiaphragmatic area on the left and close the fascia where the circular stapler was introduced. The skin is closed with staples or other preferable means. If air bubbles are noted, sutures are placed to over sew the area prior to drain placement and closure. Alternative methods can be used to check the anastomosis using methylene blue instilled into the gastric pouch and the anastomosis and pouch staple line inspected for any leakage of dye. Some surgeons do not use drains.

In my opinion, cholecystectomy should not be prophylactically performed during a laparoscopic gastric bypass. Some studies have shown a higher complication rate of the gall bladder operation if it is performed at the same time as a bariatric procedure. If the patient is symptomatic for gall bladder disease, the cholecystectomy should be performed first and the gastric bypass only done if the gall bladder is removed without complication.

Liver biopsy, core or wedge, can be performed as indicated but care should be used to avoid areas that have been retracted or compressed as that may introduce artifact.

Gastrostomy tube placement is not routine but can be efficiently performed, in the defunctional stomach, if needed. We place gastrostomy

tubes in patients: who have severe sleep apnea on CPAP or BiPAP; who are stable on medications they will need to take postoperatively but may not tolerate them orally (i.e., psychotropic medications); who are undergoing revision cases; where there are significant questions about the operative course and complications are more likely to occur postoperatively.

Staple line buttress materials have been used to try to mitigate bleeding and their use has been shown to improve burst strength. The use of buttress materials has never been well adopted by gastric bypass surgeons because of the expense and the fact that its use has not been shown to have "clinical" relevance. As staple technology continues to improve and the skill set of the surgeon advances, complication rates have reflexly decreased. It has been shown that, on the small bowel, isolated staple line bleeding can be controlled with cautery. The gastric bypass is a low-pressure system and improved burst pressure is not generally an issue. And finally, there is some reservation about introducing a foreign body into that small gastric pouch.

POSTOPERATIVE MANAGEMENT

Since 2004 when the concept of "centers of excellence" in bariatric surgery was introduced, postoperative patients have had more consistent and well-trained nursing care, in most facilities. Since patients who suffer with morbid obesity often don't show the same signs and symptoms of a complication and their general health can be compromised, early recognition of complications is important. Hospitals should be encouraged to have Certified Bariatric Nurses (CBN) on staff to care for postoperative patients.

Since many of our patients suffer with some degree of sleep apnea, managing postoperative pain without aggravation of sleep apnea is important. Newer modalities like long-acting local anesthetics injected in the wound, intravenous acetaminophen and anti-inflammatory medications are now used to give pain reduction without the risk of respiratory depression. It is also important to set the patient's expectations correctly and have them understand "there will be discomfort to pain after any big operation."

Antiemetic therapy is started in the operating room or recovery room and continued as needed on the surgical floor. Some medications given preoperatively may need to be continued intravenously until the patient is

started on liquids but this is rare. Once the patient starts tolerating liquids, most medications are tolerated in their original form. Patients ambulate with assistance within hours of their surgery. Coughing, deep breathing, and the use of incentive spirometry are strongly encouraged. Patients are kept "*npo*" the night of surgery and allowed to have water, broth, and sugar-free Jell-O the next morning if their course appears routine on morning rounds. Although it is not done in all programs, we perform an upper gastrointestinal (GI) study in the morning of the second postoperative day. We continue this practice because we have a number of patients coming from outside our geographic area and we like to document no leak or obstruction before the patient returns home. If the swallow study is negative for leaks or obstruction, the patient is generally discharged to home or to the local area if they live more the 45 minutes away. The drain is removed prior to discharge if there is no abnormal drainage.

The three most significant complications following gastric bypass surgery are leak, PE, and bleeding. Thankfully, since 2004 the number and percent of complications have fallen significantly. This reduction of complications has come from several factors. First, we have a much better understanding of how to optimize patients before surgery. Second, the concept of centers of excellence established certain benchmarks that centers needed to subscribe to gain certification. And, education through the ASMBS, and other societies and institutions, gave a better understanding of "Bariatric Life Support" and "Certified Bariatric Nursing." Major complications often present with subtle findings in these patients and confirmatory physical examination findings (peritoneal irritation) are often the exception rather than the rule; even when an abdominal catastrophe is developing. Leak and PE can give very similar clinical presentations. These two complications are the most common cause of death following bariatric surgery so clinicians need to have a heightened sense of vigilance, knowing bariatric patients don't always show the "usual" signs or symptoms. Sustained tachycardia in the postoperative bariatric surgery patient (pulse >120) should cause concern. This concern should be felt even if the patient looks and feels well. Studies have shown that sustained (4 to 6 hours) tachycardia is often the only sign of an anastomotic leak. Tachypnea or decreasing oxygen saturations can signal early sepsis from a leak or a PE. Early recognition of complications is important since delay in treatment can be deadly in bariatric surgery

patients. The diagnosis of a leak from the gastric remnant staple line or jejunojejunostomy is often delayed since a normal upper GI contrast study offers false reassurance. Bariatric surgeons, or general surgeons caring for bariatric patients, should aggressively evaluate any postoperative fever, tachycardia, or tachypnea and return to the operating room early, even if diagnostic tests are inconclusive or negative but clinical suspicion for a leak is high.

The majority of life-threatening complications occur within the first week following a gastric bypass. Our group has always tried to mitigate delay in care by insisting that patients who live out of our demographic area must stay locally for at least a week following surgery. Our practice is to see the patient in the office at 1 week and they attend a postoperative class which includes diet advancement, behavioral changes recommended, complication awareness, medication review and follow-up scheduling. An examination is also performed and if they are experiencing a “normal” recovery, they are allowed to return home.

The most common complication we have occur following the laparoscopic gastric bypass using a 21-mm, transoral anvil placement of a circular stapling device is stricture formation at the gastrojejunostomy. As we have studied and reported on the complication over the years it has remained stable at about 4%. This occurs most frequently at 30 days postoperative (due to the phases of wound healing) and is generally treated with balloon dilation to 12 mm.

Earlier it was noted that a very small gastric pouch is created. With such a small pouch, there are very few if any parietal cells and therefore minimal to no gastric acid. Marginal ulcerations are rare in nonsmoking patient using this very small pouch technique. In addition, a small pouch tends to stay small and therefore may have more prolonged benefits to the patient. This seems to be as much physics and physiology: using Laplace law where the tension on the wall of a sphere is the product of the pressure times the radius, a small pouch will tend to stay smaller longer and hopefully more therapeutic over time.

WEIGHT LOSS AND RESOLUTION OF COMORBIDITIES

Morbid obesity is truly a systemic disease affecting every system of the body. The resultant weight loss and metabolic effects of the gastric bypass improve or resolve those systemic effects. I understand that is a strong statement but over the years, studies have shown, this has validated.

Weight loss is one of the most obvious effect since it can be measured easily but also seen. Gastric bypass, though not all performed in a standard fashion, have amazing near standard effects on comorbidity resolution. The typical weight loss at 1 year is 60% to 75% excess weight loss (EWL). There is a normal weight regain pattern such that after 5 to 10 years this falls to 50% to 60% EWL. It has been shown that to maintain the best results programmatic influence (education, follow-up, support group attendance) is important.

The beneficial effects of the gastric bypass certainly don't end with weight loss. Type 2 diabetes resolves in over 80% of patients. This effect is related to severity of disease and duration but is so profound and consistent that finally the ADA has recommended bariatric surgery. Since Dr. Pories, our group and others have noted the duration of diabetic disease versus, response to diabetic resolution following the gastric bypass, bariatric surgeons would much prefer to operate on diabetic patients before 8 years of duration. Since the gastric bypass is a low-pressure system and the small pouch has little or no acid, GERD resolves in nearly 100%. Hypertension, dyslipidemia, obstructive sleep apnea, arthritis, stress incontinence, headaches, congestive heart failure, and depression improve or resolve in the majority of postgastric bypass patients. Even more conclusive data have shown over the past several years that the all-cause mortality drops by over 30% after gastric bypass (vs. matched cohort of patients) as the incidence of heart disease, diabetes, and some cancers are decreased following the operation.

SUMMARY

It has never been more true that diabetes and the underlying cause of obesity are a major threat to the world's population. This threat is not only to the health and well-being of the people but, from a population health standpoint, to financial stability as these conditions are remarkably expensive to treat. The gastric bypass, through its restriction and hormonal effects, is an effective and consistant treatment for the disease of morbid obesity and the metabolic syndrome. Over the past 15 years training has expanded and bench mark certification has become the norm. Morbidity and mortality have been reduced. Mechanisms of action of these operations have become better understood. With all of this, the laparoscopic gastric bypass is a safe and effective treatment for this patient population.

EDITOR'S COMMENT

Dr. Wittgrove presents an excellent overview on laparoscopic Roux-en-Y gastric bypass. As pointed out the development and evolution of procedures in the area of bariatric surgery is a rich history. From gastric stapling to gastric banding and then gastric bypass, it was the Roux-en-Y gastric bypass that has withstood the test of time. Clearly bariatric surgery has evolved to much more

than weight reduction surgery. It is indeed a metabolic surgery.

Before considering a gastric bypass or for that matter any bariatric procedure, a multidisciplinary evaluation is necessary. This includes a medical, endocrinology, psychiatric, and dietary consultation. These evaluations are best delivered as part of a weight management center. Educational sessions and support groups both play an important role in preparing the patient for surgery and in ongoing management after the procedure.

Gastric bypass not only results in consistent and reproducible weight loss, but it also has a profound impact on the resolution of type 2 diabetes. This seems unrelated to the weight loss. Indeed gastric sleeve which is the most common bariatric procedure performed today results in equivalent weight loss but not the same impact on glucose control. I recall a patient with insulin-dependent type 2 diabetes that I did an open Roux-en-Y gastric bypass upon who presented to our clinic 2 weeks post op with signs and symptoms of hypoglycemia. We stopped his insulin with resolution of his hypoglycemia and return of normal glucose homeostasis. He had lost about 15 lb. The rapid return of normal glucose control was clearly unrelated to the weight loss.

The improved glycemic control after gastric banding or gastric sleeve depends on weight loss, but after gastric bypass surgery this improvement occurs before weight loss. Two physiologic mechanisms are thought to be responsible for the normalization of glucose control after gastric bypass. The first hypothesis is that exclusion of the duodenum and proximal jejunum may reduce insulin resistance. The second hypothesis proposes an exaggerated response from the distal small bowel to nutrients. This theoretically causes an augmented release of gastrointestinal peptides produced in the distal small bowel such as glucagon-like peptide 1 (GLP-1) which may act as incretins. Incretins act on the pancreatic beta cells to restore normal first phase insulin responses. In addition, there seems to be an increased beta cell mass in some patients following gastric bypass. In rare cases, nesidioblastosis may develop and this can lead to severe hypoglycemia. This rarely warrants pancreatic resection. Most authorities agree that the return of normal glycemic control after gastric bypass is related to changes in the secretion of gastrointestinal peptides which promote insulin secretion.

A clinical bundle for provision of care after surgery includes DVT prophylaxis, glucose monitoring, respiratory therapy, physical therapy and introduction of a step up gastric bypass diet. Early in the postoperative period the surgeon must be attentive to the possibility of a leak from the gastrojejunostomy or the enteroenterostomy. The patient may have no increase in abdominal pain. There may be neither abdominal tenderness nor peritoneal signs. The signs may be tachycardia, tachypnea, with or without fever. An upper gastrointestinal study with water-soluble contrast or CT with IV and oral contrast may establish the diagnosis. Leaks from the enteroenterostomy may be difficult to diagnose by imaging and reoperation may be warranted for the above signs in the absence of abnormal imaging.

The most common late complications include stenosis of the gastrojejunostomy, marginal ulcer, and internal hernia. Stenosis of the gastrojejunostomy occurs in approximately 3% to 27% of patients after gastric bypass, and must be suspected when the patient experiences inability to take solids or liquids, nausea and vomitingenosis is manifest as inability to eat. It is diagnosed with upper endoscopy and treated by sequential balloon dilation. The etiology of the stricture may involve a stomal ulcer, reflux, ischemia, scar retraction, or a technical complication. Technical considerations include the size of circular staple anastomoses. It also seems that circular staples are more commonly implicated than either linear staples or a hand-sewn anastomosis. There is no increase in this complication whether there is retrocolic or antecolic positioning of the Roux limb. It does seem that circular staples are more implicated than either linear staples or a hand-sewn anastomosis. Nguyen showed that this complication is more common after laparoscopic RYGBP than after open RYGBP (Nguyen NT, Stevens CM, Wolfe BM. Incidence and outcome of anastomotic stricture after laparoscopic gastric bypass. *J Gastrointest Surg* 2003;7(8):997–1003). The reasons that best explain the formation of stricture after laparoscopic RYGBP are the unpredictable blood supply to the pouch or the development of a subclinical leak at the level of the gastrojejunostomy.

Marginal ulcer formation is one of the most common complications after Roux-en-Y gastric bypass. The rate varies from 1% to 16% of RYGB patients. The etiology is unclear. Patients are often prescribed proton pump inhibitors for 90 days or longer postoperatively in an effort to prevent early marginal ulcers. In the study by Moon et al., 59 marginal ulcers occurred in 2,535 patients from 1 to 64 months after surgery (mean 15.2 months) (Moon RC, Teixeira AF, Goldbach M, et al. Management and treatment outcomes of marginal ulcers after Roux-en-Y gastric bypass at a single high volume bariatric center. *Surg Obes Relat Dis* 2014;229–34). Interestingly 44% of those with marginal ulcer required reoperations including 12 (20.3%) with perforated ulcers. Urgent operation was required in 14 (23.7%) patients due to perforation or active bleeding, and elective operation was performed in 10 (16.9%) patients for chronic and refractory ulcer or gastrogastric fistula.

After laparoscopic Roux-en-Y gastric the estimated incidence of an internal hernia is between 0.9% and 4.5% (Madan AK, Lo Menzo E, Dhawan N, et al. Internal hernias and nonclosure of mesenteric defects during laparoscopic Roux-en-Y gastric bypass. *Obes Surg* 2009;19(5):549–52). It can lead to an acute strangulation of the intestine with possible fatal consequences. With retrocolic Roux-en-Y gastric bypass two possible internal hernia sites arise: the opening in the mesentery of the enteroenterostomy and the opening between the mesentery of the alimentary loop and the mesentery of the transverse colon. A hernia through the latter is called a Petersen hernia, named for the space it occurs in. In patients with a Roux-en-Y gastric bypass with an antecolic Roux limb is associated with a lower incidence compared to a retrocolic alimentary

loop, 0.4% versus 4.5%, respectively (Champion JK, Williams M. Small bowel obstruction and internal hernias after laparoscopic Roux-en-Y gastric bypass. *Obes Surg* 2003;13(4):596–600). It has been demonstrated that closure of these spaces during gastric bypass can reduce the incidence of these hernias. However with weight loss and a decrease of mesenteric fat the spaces may reopen.

Roux-en-Y gastric bypass is a tried and true procedure for weight management and also has a normalizing effect on the loss of glycemic control in type 2 diabetes.

Emanuele Lo Menzo, Samuel Szomstein, and Raul J. Rosenthal

INTRODUCTION

The statistics of worldwide obesity continue to illustrate upward trends. In fact, based on the *2013 Guidelines for the Management of Overweight and Obesity in Adults* released by the American College of Cardiology, the American Heart Association, and the Obesity Society, 64.5% of American adults are recommended for weight loss treatment. This translates into 140.2 million adults, which is a 20.9% increment compared to 1998. Of this astonishing number, up to 53.4% (116.1 million) of adults could be considered for pharmacologic therapy in addition to lifestyle therapy, and up to 14.7% (32.0 million) could be considered for bariatric surgery. However, the estimates regarding bariatric surgery needs are based on the current criteria set by the 1991 National Institutes of Health (NIH) Consensus Conference.

As expected, the prevalence of obesity-related comorbidities is also expected to exponentially increase with time. According to the World Health Statistics of 2012 from the WHO, diabetes currently affects 1 in 10 adults. The International Diabetes Federation has calculated that the number of patients with diabetes will increase from 366 million in 2011 to 552 million by 2030.

Bariatric surgery has been long recognized as the most effective remedy for morbid obesity and its associated comorbidities. It is not surprising then that the total number of bariatric operations worldwide has dramatically increased and will likely continue to do so. According to the estimates of the American Society of Metabolic and Bariatric Surgery, 193,000 bariatric procedures were performed in the United States during 2014. If the total number of procedures should not pose any surprise, the breakdown of the types might. In fact, according to the same source, the percentages of the different bariatric operations were as follows: sleeve gastrectomy 51.7%, Roux-en-Y gastric bypass (RYGB) 26.8%, revisional procedures 11.5%, laparoscopic adjustable gastric bands (LAGBs) 9.5%, and biliopancreatic diversions (BPDs) with or without duodenal switch

(DS) 0.4%.

We will be describing in this chapter the characteristics of the most popular of the bariatric operations, the laparoscopic gastric sleeve or sleeve gastrectomy (LSG) from its historic perspectives to the current technique, as well as its complications and results.

HISTORY OF LSG

The idea of a vertically shaped gastroplasty to modify the flow of nutrients dates back to the late 1990s. The authors then introduced the concept of the Magenstrasse, or “street of the stomach,” which conveys food from the esophagus to the antral Mill. After that original description, no bariatric application of the concept was described until Hess in 1988 initially and Marceau later in 1993 combined the BPD by Scopinaro with the DS described by DeMeester for reflux gastritis. In fact, the major flaws of the Scopinaro BPD were marginal ulceration and bile reflux gastritis. Also Lawrence L. Tretbar reported weight loss after anti-reflux surgery, so he begun extending the fundoplication in order to create a tubular stomach.

In order to keep the pylorus intact, the shape of the gastrectomy had to be modified in the modern lesser curvature-based sleeve. At this stage, however, the majority of the metabolic and weight loss successes of the BPD-DS were mostly attributed to the malabsorptive component of the operation, and only in small percentage to the restrictive nature of the sleeve itself.

The next stage of the evolution of the modern LSG is marked by the description of a totally laparoscopic BPD-DS. Although very effective for weight loss, the laparoscopic BPD-DS carried significant short-term morbidity. For this reason, the isolated LSG was introduced as a first-stage operation for high-risk superobese patients, with the intent of performing the completion BPD-DS with malabsorptive intestinal resections and reanastomosis 6 months after the initial weight loss. However, during the close follow-up after the LSG stage, it was noticed that 94% of patients continued to experience significant weight loss and comorbidity resolution and never required progression to the full BPD-DS. Since then, the LSG experienced a substantial increase in popularity among bariatric surgeons to the point of reaching the leadership in terms of number of procedures performed annually for weight loss.

INDICATIONS AND CONTRAINDICATIONS

In general, the indications for LSG remain the same as per any bariatric operations. The criteria are still the ones established by the 1991 NIH consensus conference and include severe obesity of body mass index (BMI) between 35 and 40 kg/m^2 with related comorbidities such as hypertension, diabetes, coronary artery disease, obstructive sleep apnea, or morbid obesity of BMI of 40 kg/m^2 or greater even in the absence of related comorbid conditions. Obviously, the recommendations were made based on the clinical evidence and procedures available at the time, namely RYGB, BPD, and vertical banded gastroplasty (VBG).

Significant evolutions of techniques and research have occurred since then, including the introduction of laparoscopic techniques in 1994. Currently the majority of the bariatric operations are performed laparoscopically, with significantly lower morbidity and mortalities lower than laparoscopic cholecystectomies. The VBG, in spite of its respectable mid-term results, demonstrated high rates of weight regain and complications that led to its disappearance from clinical practice. Also, the introduction of alternative operations such as the LAGB and LSG with better safety records was not taken into consideration to establish the criteria for surgery. Finally, those recommendations were made with only little evidence of the positive metabolic effects of these procedures, in particular on diabetes mellitus. Now level 1 evidence exists on the benefit of most of the bariatric operations on type 2 diabetes with mechanisms beyond weight reduction and decrease in calorie intake.

Because of its relative simplicity in technique, LSG has also been utilized with good success and safety in obese pre-kidney and transplant candidates in order to improve future graft function and preservation.

It is paramount to select motivated patients who are willing to commit to the lifelong changes these procedures require and with good understanding of the potential risks and complications.

Among the contraindications are prohibitive anesthesia risks, advanced malignancy, and severe uncontrolled psychiatric illnesses, including certain eating disorders (malignant hyperphagia). More specifically to LSG, the presence of uncontrolled gastric reflux, especially in the presence of histologic changes at the esophagogastric junction (Barrett esophagus), is considered a relative contraindication. Also a history of severe gastroesophageal reflux disease (GERD) is considered by most experts an absolute contraindications, although this remains a controversial topic.

PREOPERATIVE PLANNING

Preoperative planning for LSG is similar to the other bariatric operations. The patient should be appropriately counseled about the risks, benefits, implications, and necessary dietary and lifestyle modifications. Often this process is conducted during multidisciplinary intake seminars. After this initial introduction to bariatric surgery, a one-to-one consultation with the surgeon addresses the details of the patients' medical conditions, risk assessments, and formulation of goals and expectations. Fundamental to the success of any bariatric operation is dietary counseling, in which perioperative and postoperative modifications are carefully explained. The next step is to obtain both appropriate medical and psychological clearances. We routinely obtain either an upper intestinal contrast evaluation or upper endoscopy. This is especially important for patients with history of gastroesophageal reflux or Barrett esophagus. What is unclear is the role of preoperative pH/impedance.

SURGICAL TECHNIQUE

The LSG consists of a partial gastrectomy of the greater curvature along the vertical axis of the stomach. As such, the remaining stomach is constituted primarily by the lesser curvature. Furthermore, a functional pylorus and a variable portion of the antrum are left in place (Fig. 98.1).

The abdominal cavity is accessed in the supraumbilical region and just to the left of the midline using an optical trocar. After exploration of the abdominal cavity, two auxiliary 5-mm trocars are inserted in the sub-xyphoid position for the liver retractor and along the anterior axillary line just below the 12th rib for the assistant. Once the liver is reflected cephalad using a "fan-type" retractor, four additional 12-mm trocars are inserted in the right upper quadrant, epigastrium, left upper quadrant, and right paramedian regions (Fig. 98.2).

The pylorus is then identified by both "palpation" with laparoscopic grasper and visualization of the prepyloric vein of Mayo. At a distance of approximately 2 to 6 cm from the pylorus, the short gastric vessels are divided using ultrasonic energy. This step allows access to the lesser sac (Fig. 98.3). Occasionally in the presence of thicker omentum, it is recommended to gain access to the lesser sac more superiorly along the greater curvature of the stomach by starting the division of the short gastric vessels more proximally. In this latter scenario, the more distal short gastric vessels can be divided directing the dissection toward the pylorus.

The rest of the short gastric vessels are then divided sequentially by marching along the greater curvature of the stomach. At the level of the proximal body of the stomach, the gastrosplenic ligament is constituted by two separate leaflets of peritoneum, one more anterior and one more posterior. Whenever the thickness is significant, the two leaflets can be divided separately. Often the splenic artery is readily visible at this point. Since the fundus of the stomach is variably in contact with the spleen capsule, gentle traction has to be used. Then the assistant retracts the upper body of the stomach medially and inferiorly in order to expose the first short gastric vessels and the left crus of the diaphragm (Fig. 98.4). If a known or visible hiatal hernia is identified, a formal hiatal dissection and posterior hernia repair are performed. However, it is our practice to postpone the hiatal closure to the end of the procedure after the sleeve has been completed. Additional posterior gastric adhesions are removed in order to assure proper visualization of the lesser curvature of the stomach.

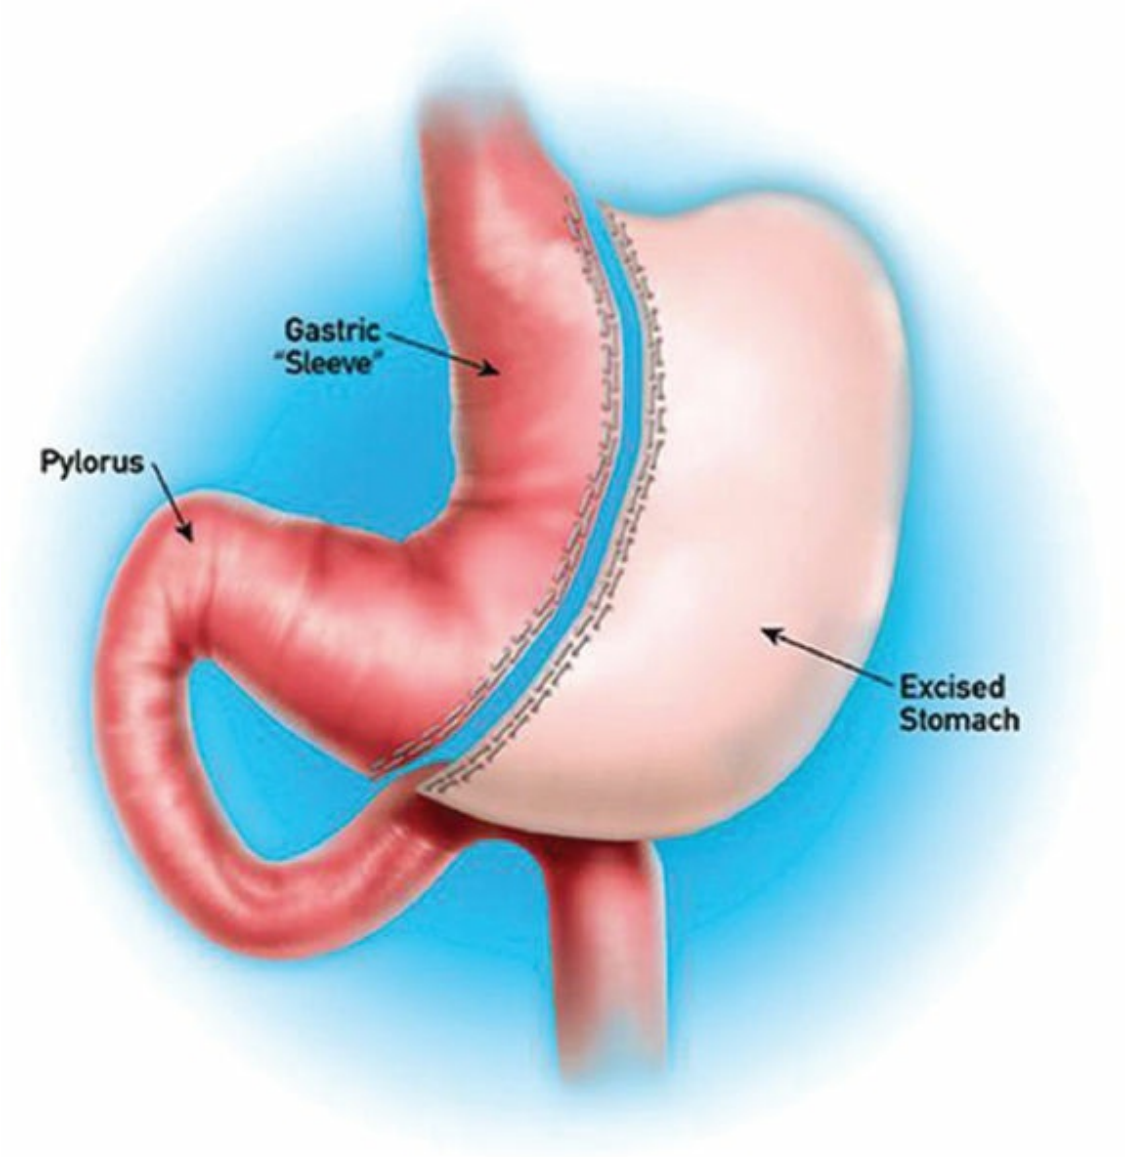

Figure 98.1. Diagram illustrating the final anatomy of the sleeve gastrectomy. Only the greater curvature side of the stomach is removed. The pylorus is preserved. (*Source:* http://www.chicoweightloss.com/bariatric-surgery/vertical-sleeve-gastrectomy/)

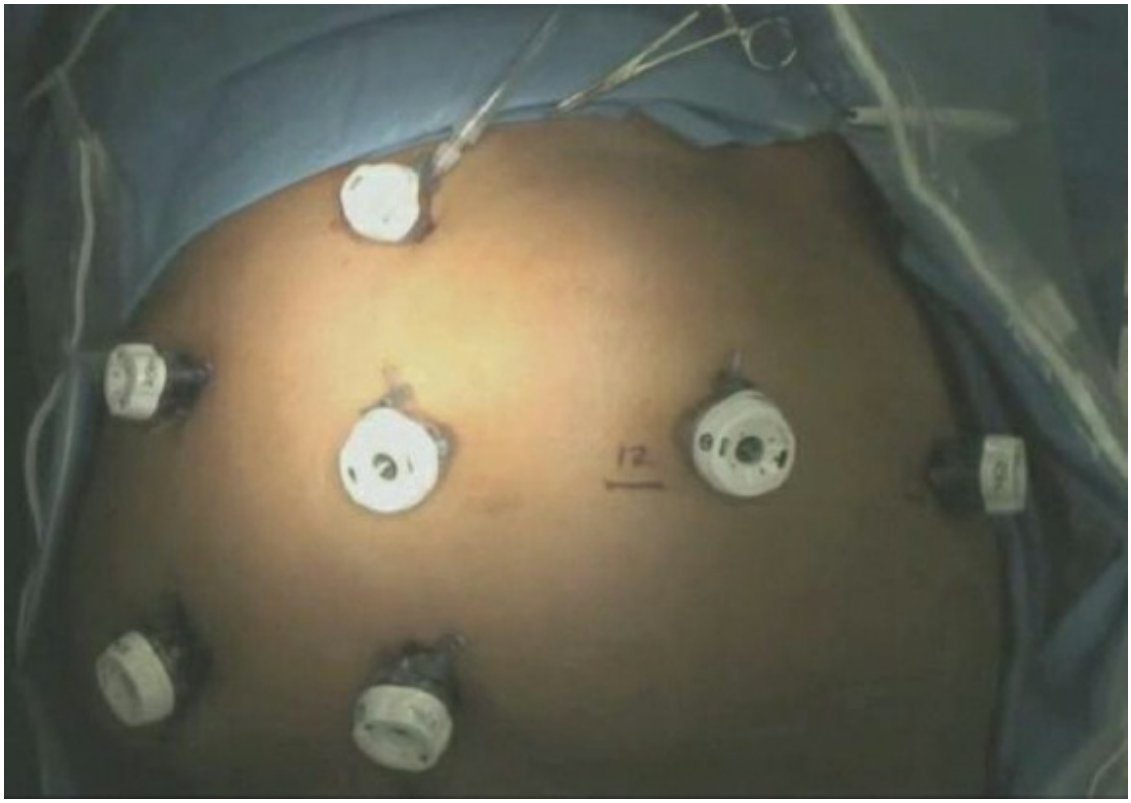

Figure 98.2. Trocar placement for laparoscopic sleeve gastrectomy.

Figure 98.3. The ultrasonic dissector is used to divide the vessels on the greater curvature of the stomach.

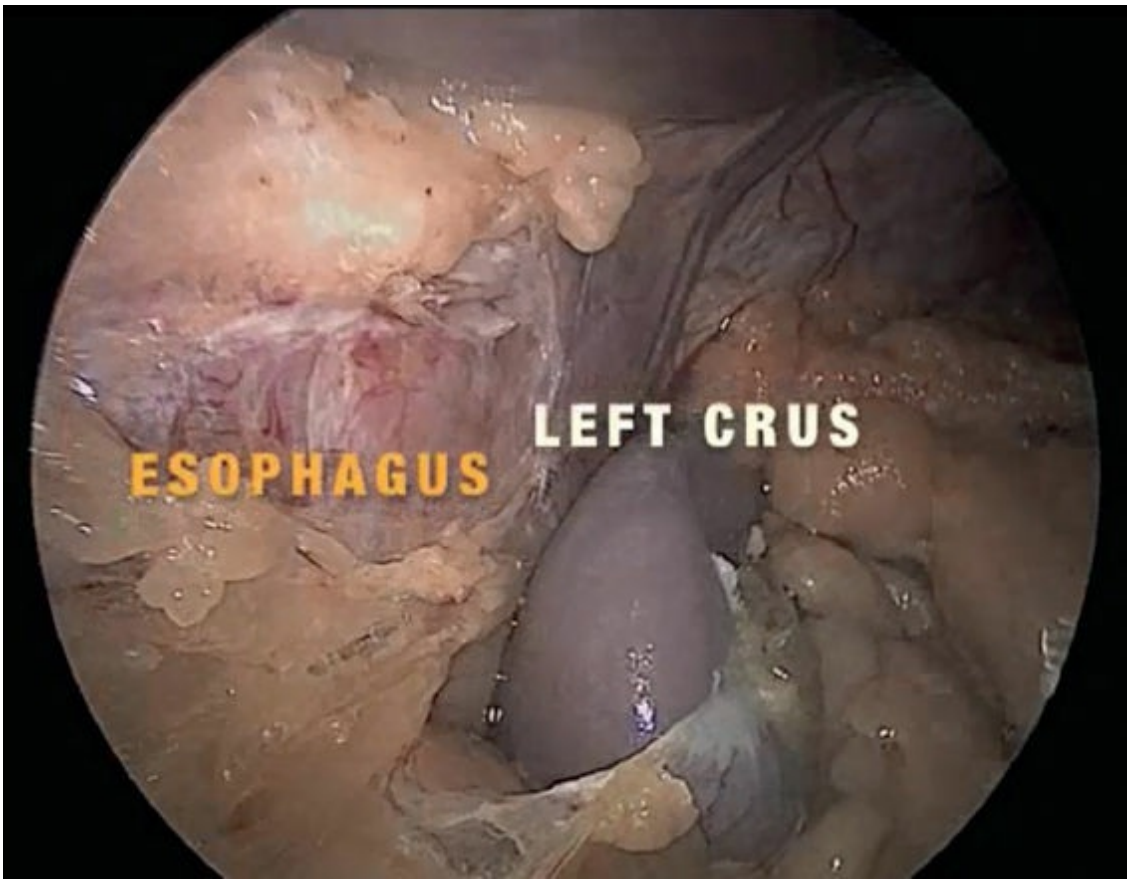

Figure 98.4. The vessel dissection is carried out to expose the left crus of the diaphragm.

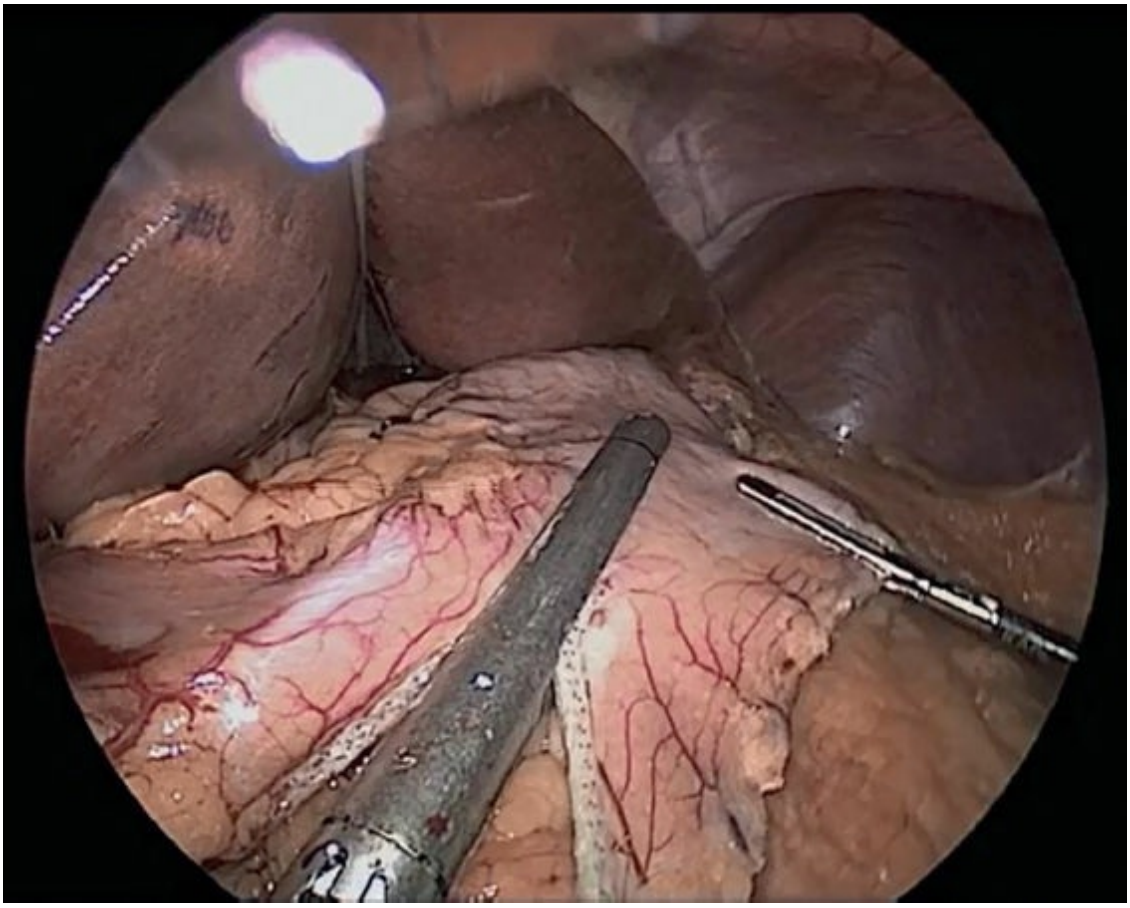

Figure 98.5. The stapling of the stomach is done while symmetric traction is applied by the assistant.

At this point, an orogastric calibrating tube is introduced by the anesthesiologist and carefully advanced to the antrum under direct visual guidance. It is important to remember that the esophagogastric junction is located posteriorly, so cephalad and medial retraction of the gastric fundus is necessary to visualize the orogastric tube once it reaches the proximal stomach. Variable types and sizes of calibrating tubes have been described in the literature, and significant variation remains in practice. However, based on the International Sleeve Gastrectomy Expert Panel Consensus Statement, the optimal sizes are between 32 and 36 Fr. In our practice, we use a 38-Fr mercury-weighed Hurst bougie. The tapered tip Maloney type can be used as it negotiates the curve of the antrum better, but care must be taken not to include its fine tip into the stapler.

The 60-mm linear stapler is then utilized to sequentially divide the stomach. The first fire starts 2 to 6 cm from the pylorus, and it is oriented rather horizontally toward the patient’s left shoulder. The articulation of the stapler head and the utilization of different trocars aid in obtaining the

optimal angle of staple firing. It is imperative to pay attention at the level of the incisura angularis in order to avoid excessive narrowing of the sleeve. Additional important technical aspects are the symmetrical lateral retraction of the greater curvature by the assistant and the visualization of both the anterior and posterior aspect of the sleeve prior to each cartridge firing. Pitfalls of this key aspect of the procedure include excessive narrowing of the sleeve from firing too close to the bougie and spiral twisting of the sleeve from asymmetrical lateral traction of either the posterior or anterior wall of the stomach (Fig. 98.5).

The next key stapling area is by the esophagogastric junction. In general, our preference is to avoid abutting the stapler to the bougie at this level and preserving the esophagogastric fat pad. In our opinion, this maneuver will decrease the chance of potential ischemia of the superior corner of the sleeve. However, different schools of thought exist and proponents of closer stapling to the esophagogastric junction believe that redundancy of gastric tissue at this level might contribute to the development of postoperative gastroesophageal reflux.

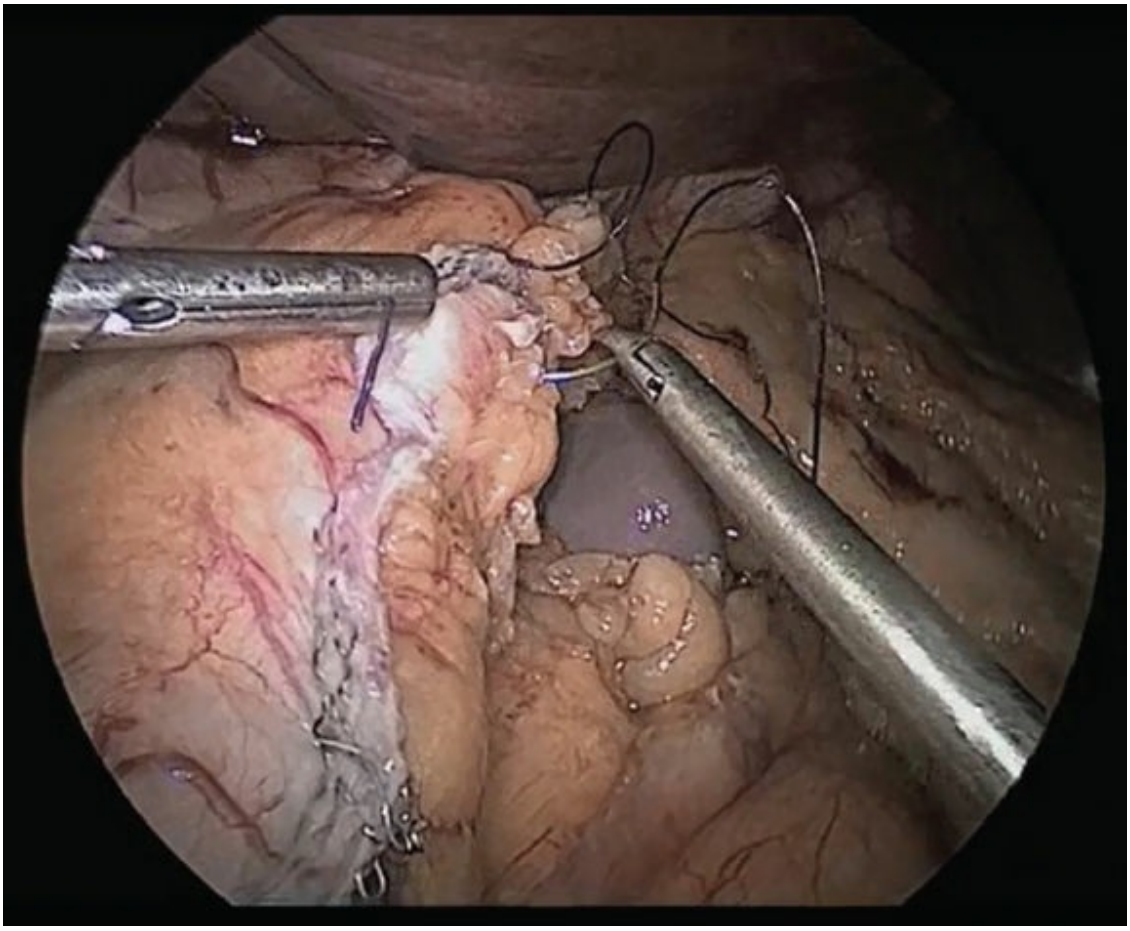

Figure 98.6. The staple line is oversewn with imbricating suture

while the bougie is in place.

Although not uniformly accepted, the general consensus calls for reinforcement of the long staple line resulting from the gastric resection. This reinforcement can be obtained either by using absorbable synthetic or biologic staple line reinforcement strips or by oversewing the staple line in its entirety or in parts. Our preference is to imbricate the entire staple line using absorbable sutures (Fig. 98.6). It is paramount to maintain the bougie in place during this step, as generous imbrication can lead to sleeve stenosis.

The procedure terminates with the specimen extraction and port sites closure.

POSTOPERATIVE CARE

The patient is transferred to a monitor setting, especially if previous history of obstructive sleep apnea exists. Postoperative nausea is a common finding, and it can be controlled with intravenous ondansetron, with the addition of prochlorperazine and/or scopolamine patch as needed.

Standard deep vein thrombosis prophylaxis with fractionated or unfractionated heparin is carried out as per protocol. Early ambulation is also paramount to decrease the incidence of deep vein thrombosis. The day after the procedure, the patient is started on a clear liquid diet and, if tolerated, can be discharged home.

Postoperative upper gastrointestinal (UGI) contrast studies are used selectively in cases of oral intolerance or clinical derangements for the normal postoperative course. Pain control can be achieved with either intravenous narcotics or, when available, intravenous acetaminophen. Liquid or crushed oral narcotics are prescribed upon discharge.

COMPLICATIONS AND THEIR MANAGEMENT

LSG is, in appearance, a technically easy operation, especially for the bariatric surgeon. However, several pitfalls of this procedure exist. Postoperative complications related to the actual technical aspect of the sleeve include bleeding, leak, and stenosis. The other postoperative complications such as cardiovascular, thromboembolic, and pulmonary will not be discussed in this chapter.

Bleeding

Postoperative bleeding should be suspected in the case of tachycardia, especially if this is cyclical. Hypotension, low urine output, and shock are more advanced signs of persistent hemorrhage. Postoperative bleeding after LSG can be encountered intra-abdominally, intraluminally, or at the port sites. Overall bleeding after LSG has been described in up to 15% of the cases. The most likely sources of intra-abdominal bleeding are at the level of the devascularization of the greater curvature of the stomach, in particular the short gastric vessels and spleen itself. Under normal conditions, ultrasonic energy is very safe and effective in the devascularization of the stomach. However, whenever the instrument is not entirely across the vessel or in the presence of thick surrounding fat, the vessel sealing could be incomplete. Furthermore, the fundus of the stomach is at a variable distance to the spleen itself. It is not uncommon to then determine either traction or burn injuries to the splenic capsule itself. Small tears can be managed with pressure and topical hemostatic agents, whereas larger tears and significant bleeding from the organ might even require splenectomy in rare cases. In order to avoid this complication, it is important to obtain clear exposure to the left upper quadrant. The divided omentum needs to be retracted laterally and the gastric fundus and body medially. The first short gastric vessels are posterior and, once transected, can retract into the adipose tissue, obscuring the presence of continuous hemorrhage.

The long staple line can be the source of both intraluminal and intra-abdominal bleeding. The intra-abdominal component can be easily visualized and treated with clips, sutures, and fibrin glue. Evidence exists on the efficacy of staple line reinforcement in the prevention of staple line bleeding. More difficult to diagnose is intraluminal bleeding. In fact, the long staple line in such a well-vascularized organ is the perfect setup for the complication. Furthermore, a bleeding staple line might indicate a weaker area susceptible to leak. The presence of hematemesis or melena in the setting of a dropping hematocrit leads to an easy diagnosis of intraluminal bleeding. Slower bleeding might require endoscopy to be recognized. Most often, the intraluminal bleeding is self-limited, but it can require endoscopic or surgical intervention.

Port site hemorrhage is rare; however, it can be significant and insidious. Direct observation of the port site after removal of the port itself helps with early recognition and treatment of this complication. But this is not foolproof and bleeding can start later after the pneumoperitoneum is

evacuated and the systemic blood pressure increases.

Staple Line Leak

Although LSG does not involve any anastomosis, the long staple line, the increased intraluminal pressure for the narrower diameter of the organ, and the presence of an intact pylorus and, often, lower esophageal sphincter (LES) explain the higher incidence of leaks as compared to the RYGB (0.7% to 2.4% in large retrospective studies). For all these reasons, the leaks are also less likely to close spontaneously as compared to RYGB.

As in other staple line leaks, the etiology includes ischemia, staple line hematomas, staple malfunction, and the already mentioned increased intraluminal pressure proper of the LSG. Staple misfiring is not such an uncommon event. Besides the rare manufacturing issues, the rest of the misfires are due to improper choice of staple height, or use of the stapler itself. In choosing staple heights, consideration should be given to the progressive decrease in thickness of the gastric wall from the antrum to the fundus. Also, in order to avoid potential misfires, care must be taken not to include excessive tissue at the site of staple closure and removing loose staples from the trajectory of the knife of the device. Staple line leaks can result from staple firings too close to the bougie as well, especially in case of smaller bougie size.

Based on the timing of onset, leaks can be identified as acute (within 7 days), early (within 1 to 6 weeks), late (after 6 weeks), and chronic (after 12 weeks). The timing of the leak is strictly related to its etiology. Technical staple line problems tend to manifest early on. Ischemic leaks, on the other hand, become clinically apparent around 5 to 7 days postoperatively. Finally, the leaks secondary to stricture or torsion of the gastric body can manifest even later.

As far as location goes, most commonly the leak occurs in the proximal aspect of the LSG at the esophagogastric junction. This is in fact the most vulnerable area in the presence of distal stenosis. Distal leaks are less common and more likely result from technical staple line failure.

The diagnosis of leak is clinical first of all, and sustained tachycardia is the most consistent sign. Also fever, abdominal pain, tachypnea, and increased white blood cell count (WBC) and C-reactive protein are commonly found, but are not obligatory signs. Abdominal pain can be localized at the epigastrium, left shoulder, back, or diffusely in the abdomen. Among the imaging studies, computed tomography (CT) scan is

the most sensitive to diagnose staple line leaks. In fact, in addition to potentially showing the leak itself, it can identify secondary changes related to it, such as extraluminal collections, fat stranding, pleural effusion, and free air. Contrast UGI series have lower sensitivity, and it can be deceiving if obtained immediately after surgery when most of the leaks have yet to occur. Finally the combination of the two modalities increases further the accuracy of the diagnosis in up to 84% of cases.

The treatment of the leak is guided by the following main factors, the overall clinical condition of the patient, the timing, and location of it. The goals of treatment are control of the local and systemic sepsis with wide drainage and broad-spectrum antibiotics and antifungals, control of the secretions with nil by os, and early nutrition either enteral via jejunostomy tube or parenterally. As for any other bariatric procedures, in the presence of hemodynamical instability and uncontrolled sepsis, emergent reexploration is mandatory. Under these circumstances, primary repair of the leak is seldom possible or effective. In cases of hemodynamically stable patients nonoperative options can be used. Imaging-guided percutaneous drainage, endoscopic procedures such as stents and clipping, and distal dilatations have all been described with mixed results.

Undoubtedly these endoscopic options find their best application in acute and early leaks, as they are usually futile once the leak has become chronic. Distal leaks can be converted to controlled fistula by inserting a T-tube directly in the fistulous tract. In the absence of distal obstruction, the t-tube can be clamped and removed after 4 to 6 weeks. More challenging are the proximal leaks that become chronic. These leaks can also fistulize into adjacent viscera and anatomic space, including the pleural space. As previously mentioned, less invasive endoscopic approaches are rarely effective in these cases, and more radical surgical is necessary. It is important to optimize patients' nutrition, to control local and systemic sepsis, and to temporize until 12 weeks prior to operation in order to find a less hostile surgical field. The described surgical options are based on small cohort studies. One option involves suturing a Roux limb directly to the fistulous tract, as proposed by van de Vrande et al. In their report, the success rate was 100%, with 54% achieving immediate resolution. The other alternative has been described by our group and consists of a laparoscopic proximal gastrectomy including the fistulous tract with a Roux-en-Y esophagojejunostomy. In our initial experience, we reported a releak rate of 6.6%, requiring only 4 weeks of nil by mouth and

total parenteral nutrition, but no other significant morbidity or mortality.

Stenosis

Stenosis is another worrisome complication of LSG, and it can be the cause of a proximal leak from increased intraluminal pressure. The incidence of stenosis is between 0.26% and 4%. The etiology of the stricture is usually mechanical, and derives from the use of small bougies, stapling too close to it, especially at the incisura angularis, twisting of the staple line creating a “spiral” sleeve, or aggressive imbrication of the staple line itself. Functional stenoses are typically transient and derived from edema or hematomas of the staple line. The latter type of stenosis presents immediately after the LSG and resolves spontaneously with expectant treatment.

Based on the timing of onset, the stricture can be manifest acutely or early after sleeve or more chronically. The location is mostly at the level of the incisura angularis, but they can occur anywhere along the long staple line.

The diagnosis is usually clinical. The typical findings are regurgitation, vomiting, poor oral tolerance, frothing and sialorrhea, or gastroesophageal reflux. As previously mentioned, the distal stenosis can be the cause of a proximal leak, so the symptoms could be as previously described. UGI is usually the first diagnostic test. This is usually performed with water-soluble contrast, especially if a leak needs to be ruled out. However, the risk of aspiration has to be taken into account. The UGI can give important information regarding the presence of kinking, degree of obstruction, and location of the stenosis. EGD is a complementary test, and it should be reserved for stenoses that do not quickly resolve. The EGD can confirm the presence of internal kinking and narrowing, but also diagnose spiraling along the vertical axis of the sleeve itself. In milder cases, the gentle dilatation of the endoscope can be therapeutic. Some authors have used technetium-99m scintigraphy as a diagnostic modality, as well.

The treatment modality depends on the time of onset, the degree of obstruction, and the possible etiology. As previously mentioned, stenoses that occur immediately after surgery can be usually treated with observation nil per os, protein pump inhibitors, and antiemetics. If the stenosis is functional in origin, it will likely resolve in a few days. Occasional careful passage of nasogastric tubes, preferably under fluoroscopy, is necessary to control the secretions.

If nonoperative management fails, invasive intervention is necessary. The role of endoscopy in these cases is limited to dilatation with or without stenting. The success rate depends on the etiology and degree of stenosis, but can be as high as 88%.

When reoperation is necessary, several options are available. In the acute phase, the simple removal of the imbricating suture could be therapeutic. Another option is to perform a gastric seromyotomy of the stenosed segment. This technique was described by Dapri et al., and according to their series of 14 patients they reported a significant leak rate (35.7%) and need for reoperation (35.7%). The same authors also reported fewer cases of segmental gastrectomy of the stenosed segment and gastro-gastrostomy. However, long-term studies are needed to assess the outcome of this technique.

Finally, the conversion to RYGB is probably the most utilized option. This can be accomplished laparoscopically with minimal morbidity.

OUTCOMES

Over the last several years, LSG has been performed with increased frequency, to the point that it is now the most common primary bariatric operation. Part of its increased popularity is certainly due to the relative technical simplicity of the operation. But also, the overall very positive results have contributed to it. Based on large database reviews, LSG compares very favorably with the LAGB and RYGB. In fact, in terms of postoperative complications, readmissions, and reintervention, LSG (5.6%, 5.4%, 2.97%, respectively) offers better results than laparoscopic Roux-en-Y gastric bypass (LRYGB) (5.9%, 6.4%, 5%, respectively) but worse than the LAGB (1.4%, 1.7%, 0.9%, respectively). However, when weight loss and comorbidity resolution results are analyzed, the LSG is far superior than the LAGB and slightly inferior to the RYGB. Based on our series of 1,020 patients, we reported a mean percentage of excess weight loss (%EWL) at 1, 3, 5, and 8 years of 86%, 63%, 61%, and 52%, respectively. This translates to an overall success rate (%EWL > 50%) of 92% after 1 year, 89% after 3 years, 75% after 5 years, and 73% after 8 years. Early postoperative complications included leak in 0.1%, stricture in 0.1%, and bleeding not requiring reintervention in 3%. Long-term complications included stricture in 0.49% and gastroesophageal reflux disease (GERD) in 6%. As far as remission of comorbidities, diabetes improved or resolved in 57% of the patients, hypertension in 91%, obstructive sleep apnea in 99%,

and hyperlipidemia in 79%. There was no mortality in this series.

These results are comparable to the long-term result of LRYGB based on the Swedish Obese Subject Study. When LSG and LRYGB are directly compared in randomized controlled trials, there is no significant difference between the two procedures as far as levels of glycosylated hemoglobin, fasting plasma glucose, number of subjects using oral antihyperglycemic medications and insulin, body weight, BMI, or waist circumference. The only significant difference found between the two procedures is the cardiovascular risk, which is decreased significantly more in the RYGB group. Five year results of randomized trial continue to show comparable metabolic improvements of LSG as compared to LRYGB.

CONCLUSIONS

LSG is currently the most commonly bariatric operation performed. Its popularity is mostly due to the technical simplicity, the overall paucity of short and long-term complications, and the effectiveness for both weight loss and comorbidity resolution. However, several critical aspects of its technique should be kept in mind in order to avoid severe morbidity. In general, LSG is more comparable to LAGB in terms of complication and to LRYGB in terms of results. Furthermore, when compared to other procedures LSG is not only simple as a primary procedure, but it also offers more and safer reoperative alternatives in case of weight regain.

EDITOR'S COMMENT

Drs. Lo Menzo, Szomstein, and Rosenthal have together written an exceptional chapter on laparoscopic sleeve gastrectomy. I find the story of the evolution of the sleeve gastrectomy from an almost accidentally created operation to the most commonly performed bariatric surgical procedure in the United States to be fascinating. The sleeve gastrectomy has enjoyed a rapid surge in popularity over a very brief period of time. According to the American Society for Metabolic and Bariatric Surgery, in 2011 the sleeve gastrectomy accounted for 17.8% of all bariatric procedures. By 2015, this had increased to 53.8% of all procedures.

There are several advantages to the sleeve gastrectomy when compared to other commonly performed bariatric surgical procedures. From a technical perspective, the sleeve gastrectomy is easier to perform (especially in patients

who suffer from super morbid obesity) than the laparoscopic Roux-en-Y gastric bypass. In patients with a significant history of prior intra-abdominal surgical procedures (perforated diverticulitis, laparotomy for bowel obstruction for example), sleeve gastrectomy may be more feasible than a gastric bypass. A sleeve gastrectomy is a simpler operation with fewer steps and requires less intra-abdominal laparoscopic working space (hard to come by during laparoscopy in the super obese) than the gastric bypass. These features of the sleeve gastrectomy can facilitate the minimally invasive approach to bariatric surgery in extremely obese patients. In fact, the sleeve gastrectomy evolved as a stand-alone bariatric operation in part related to these facts.

I performed a quick review of the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) database for 2016 and determined that at accredited centers, there were significant differences in patients who underwent sleeve gastrectomy compared to gastric bypass. Patients undergoing gastric bypass (n = 45,370 gastric bypasses and n = 115,627 sleeve gastrectomies) were more likely to suffer from obstructive sleep apnea (42.5% vs. 32.5%, $p < 0.001$), GERD (39.6% vs. 28.6%, $p < 0.001$), to have a previous history of a deep vein thrombosis (DVT) (2.0% vs. 1.5%, $p < 0.001$), or to suffer from diabetes (33.9% vs. 22.7%, $p < 0.001$). A published and peer-reviewed analysis of National Surgical Quality Improvement Program (NSQIP) data reveals a trend in favor of females, lower body mass index (BMI), and fewer patients with diabetes and hypertension in sleeve gastrectomy. There is significant local and regional variation in practice related to who is counseled to undergo a sleeve gastrectomy across the country. In fact, many bariatric centers only offer sleeve gastrectomy.

A prospective, randomized controlled trial comparing sleeve gastrectomy to gastric bypass conducted in Switzerland compared outcomes at 3 years postop for 217 patients to undergo either a laparoscopic sleeve gastrectomy or a laparoscopic Roux-en-Y gastric bypass. Excess BMI loss was equivalent in each study group at 3 years. Comorbidities were significantly reduced and comparable after both procedures with the exception of GERD and dyslipidemia, which were both more successfully treated with a gastric bypass. Complication rates were similar in each study arm. A recently published meta-analysis of six randomized controlled trials including 695 patients and comparing complication rates after sleeve gastrectomy and gastric bypass determined that the sleeve gastrectomy was associated with significantly fewer major complications within 30 days of surgery. Neither procedure was found to have a higher readmission rate, reoperation rate, or 30-day mortality.

A couple of specific complications discussed in this chapter warrant additional discussion. Leak following sleeve gastrectomy is fortunately a rare event. I'll add to the discussion on treatment options for chronic leaks after sleeve gastrectomy the option of negative pressure vacuum-assisted closure (VAC) treatment. While this is a new and evolving concept, one recently published series of nine patients with leak after sleeve gastrectomy (including

five patients in whom a stent failed) reported 100% resolution of leak (after an average of 10 sponge changes per patient and 50 days therapy). To be sure, when these leaks become chronic, they can be difficult problems to overcome. Portomesenteric venous thrombosis is being increasingly recognized as a potential complication following sleeve gastrectomy. Presentation may be variable ranging from asymptomatic and incidentally discovered to bowel infarction and necrosis. Theories attempting to explain this complication have been proposed, such as venous stasis from increased intra-abdominal pressure, intraoperative manipulation of splanchnic vasculature, and systemic hypercoagulable states. The rate is higher for sleeve compared to Roux-en Y gastric bypass and is likely around 1%. A high index of suspicion and preventative measures in those at highest risk (extended chemoprophylaxis in those with hypercoagulable disorder) is needed to minimize the chance of a catastrophic outcome.

The impact of a sleeve on GERD is controversial. A review article on the relationship between sleeve gastrectomy and GERD evaluated 13 studies including 5,953 patients in whom sleeve gastrectomy had a negative impact on GERD. In this same review, 12 studies including 1,863 patients demonstrated a positive impact of sleeve gastrectomy on GERD. A systematic review and meta-analysis examining the relationship between sleeve gastrectomy and GERD included 33 studies. The authors of this study concluded “because of high heterogeneity among available studies and paradoxical outcomes of objective esophageal function tests, the exact effect of laparoscopic sleeve gastrectomy on the prevalence of GERD remains unanswered.” Part of the controversy surrounding the true impact of sleeve gastrectomy on GERD relates to the impact that technical factors may play on the GERD-related outcomes. Leaving an excessively large or dilated sleeve may contribute to the possibility of GERD. There is also a growing body of literature that suggests hiatal hernias can be difficult to recognize at the time of sleeve gastrectomy. Several studies suggest that routine hiatal hernia repair and crural repair can decrease the incidence of GERD in sleeve gastrectomy patients. A recently published review of nearly 3,000 patients in the state of Michigan who underwent laparoscopic sleeve gastrectomy over a more than 7-year period revealed widely varied rates of new acid reduction medication use 1 year following surgery. This suggests that differences in surgical technique may contribute to disparate GERD outcomes following sleeve gastrectomy. A systematic review and meta-analysis comparing GERD-related outcomes for Roux-en-Y gastric bypass to sleeve gastrectomy was recently published. A total of 32 studies and 6,526 patients were included in the final analysis. Gastric bypass had a significantly higher incidence of resolving GERD. Although the GERD-related outcomes following sleeve gastrectomy continue to be a matter of controversy, I personally feel strongly that patients with GERD symptoms and/or signs (erosive esophagitis or Barrett esophagus) that persist despite acid reduction medical therapy should be advised to undergo gastric bypass rather than a sleeve.

A couple of technical factors described in the current chapter warrant additional commentary. Dr. Rosenthal and his colleagues describe the importance of removing posterior gastric adhesions in order to ensure proper visualization of the lesser curve. This is an important step to avoid leaving an excessively large proximal gastric pouch and to minimize the chance of creating a "twisted sleeve" where the staple line is much closer to the lesser curve on the anterior stomach than on the posterior stomach. They also describe performing a formal hiatal dissection in the case of a hiatal hernia but deferring formal repair until after the sleeve is created. In my opinion, this is very important as passing a bougie after the crus have been reapproximated posteriorly in a hiatal hernia repair places the patient at unnecessary increased risk for esophageal trauma and even perforation from the bougie as it is passed. A minor semantic point—when dividing the arteries 2 to 6 cm from the pylorus, you are actually dividing branches of the right gastroepiploic artery and not the short gastric vessels.

This is an exceptional chapter written by one of the world's foremost experts on sleeve gastrectomy. The authors have a wealth of experience with this procedure and long-term lessons learned to share. Even for those who don't perform bariatric surgery as a part of their practice, this is essential reading.

Jon C. Gould

I agree that this is an excellent commentary both as to technique but also a resolution for bariatric surgeons. Weight reduction has become a major part of our society and the procedures must be performed well.

99 Laparoscopic Biliopancreatic Diversion With Duodenal Switch

Gregory Dakin and Alfons Pomp

INTRODUCTION

Medical treatment of morbid obesity is generally ineffective, making bariatric surgery the only option for this growing population of patients. Commonly performed operations such as gastric bypass (GB), adjustable gastric banding, or sleeve gastrectomy utilize caloric restriction as the primary means to achieve weight loss. However, long-term data has shown that for many patients, particularly those that start with a body mass index (BMI) greater than 50 kg/m^2, such restrictive operations have a high rate of failure, with regard to both % excess weight loss (%EWL) achieved and to subsequent weight recidivism. The biliopancreatic diversion with duodenal switch (BPD-DS) is an operation that combines a restrictive component (sleeve gastrectomy) with a significant malabsorptive intestinal rearrangement. Literature demonstrates that the BPD-DS (or its predecessor BPD) is the most effective weight loss operation, inducing the greatest weight loss and resolution of comorbidities such as diabetes, maintained up to 15 years after surgery.

Though highly successful, the BPD-DS constitutes only 2% of procedures performed (see Table 99.1). This is likely due to several reasons, including the perceived high rate of metabolic complications such as protein-calorie malnutrition, vitamin and mineral deficiencies, and the technical difficulty of the procedure when compared to other more common operations. While there is no doubt it is one of the more technically demanding bariatric procedures, with proper patient selection and careful follow-up, the BPD-DS can be performed safely with an acceptable long-term complication profile. It is a particularly good option for the super-obese patient and for those patients who have failed other operations and should be a weapon in every bariatric surgeon's armamentarium. With the increasing popularity of sleeve gastrectomy as an initial choice, the BPD-DS may well increase in popularity as the most

appropriate “second-stage” surgery for many patients.

TABLE 99.1 Bariatric Procedures Performed Worldwide

Procedure	Rate Performed
Roux-en-Y gastric bypass	47%
Sleeve gastrectomy	28%
Laparoscopic gastric banding	18%
Biliopancreatic diversion-duodenal switch	2%
Other	5%

HISTORY OF THE PROCEDURE

The first reports of jejunal-ileal bypass (JIB) were published in the 1950s, commonly credited as the first malabsorptive operation for morbid obesity. The most widely accepted version of the operation used a 35-cm segment of proximal jejunum anastomosed to the distal 10 cm of terminal ileum (see Fig. 99.1). While this operation was successful in inducing weight loss, there were high rates of significant long-term complications, including bacterial overgrowth, vitamin deficiency, renal failure, and ultimately hepatic failure. These problems led to the development of other bariatric procedures, notably the GB by Edward Mason, in the 1960s, and the JIB was largely abandoned.

Italian surgeon Nicola Scopinaro first described the biliopancreatic diversion (BPD) for morbid obesity when he published his first human series of 18 patients followed for a year. He developed the procedure to maintain the malabsorptive component of the JIB while eliminating the long blind limb thought to be responsible for many of the long-term problems. He performed a distal gastrectomy and anastomosed a 250-cm distal Roux limb to the proximal stomach, with the long biliopancreatic limb anastomosed to this limb 50 cm from the ileocecal valve to create a short common channel. He has published excellent weight loss sustained up to 15-year follow-up in his patients.

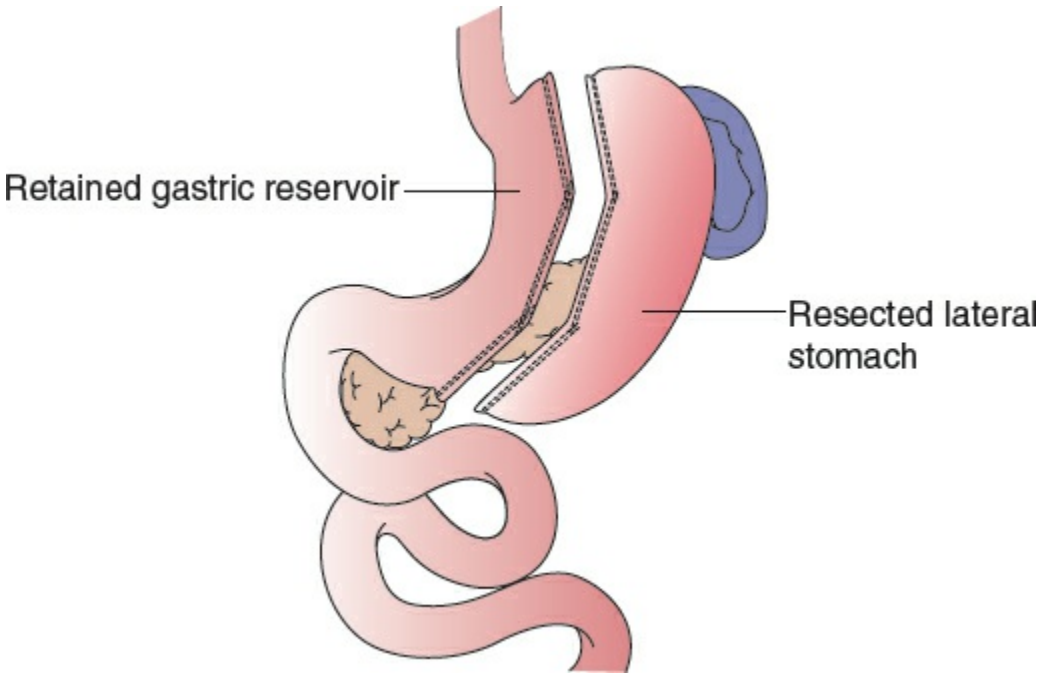

Figure 99.1. Jejunal–ileal bypass. From O'Rourke RW. Management of Obesity. In: Mulholland MW, Lillemoe KD, Doherty GM, et al., eds. Greenfield's Surgery: Scientific Principles and Practice, 6th ed. Philadelphia: Wolters Kluwer, 2017, with permission.

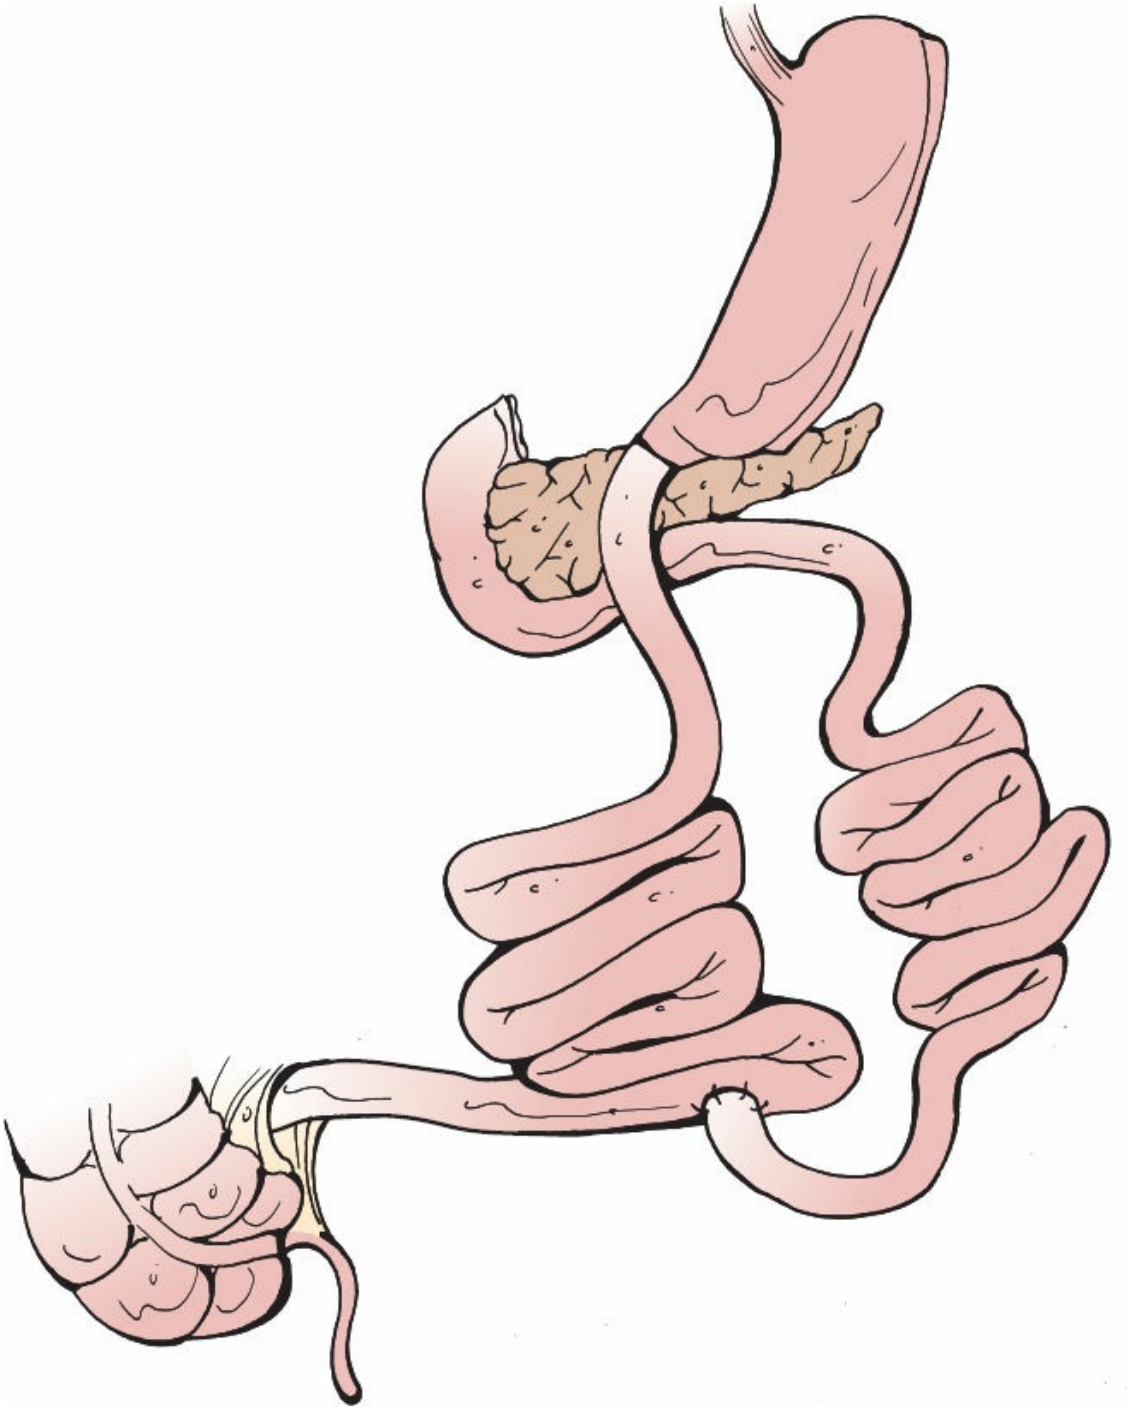

Figure 99.2. Biliopancreatic diversion with duodenal switch (BPD-DS).

The first duodenal switch operation for morbid obesity was described by Marceau in 1993. The original BPD was modified by creating a vertical (or sleeve) gastrectomy rather than a distal gastrectomy and then anastomosed the Roux limb to the stapled (nondivided) proximal duodenum. While this minimized problems with dumping and marginal ulcers seen with the BPD, staple-line breakdown in the duodenum led to

later weight regain. Hess and Hess further modified the Marceau duodenal switch in 1998 with the division of the duodenum, leading to the modern-day BPD-DS.

Today, the standard BPD-DS consists of a sleeve gastrectomy with an alimentary limb of approximately 150 to 200 cm anastomosed to the proximal duodenum, and a 50- to 100-cm common channel (see Fig. 99.2). Gagner described the first laparoscopic BPD-DS in 2000. An interesting variant involving a single anastomosis of an ileal loop to the proximal duodenum is also currently being popularized as a technically simpler version with potentially fewer long-term complications.

INDICATIONS AND CONTRAINDICATIONS

The standard indications for bariatric surgery apply, namely meeting the NIH consensus conference criteria of BMI >40 kg/m^2, or >35 kg/m^2 with significant medical comorbidities such as hypertension, diabetes, or sleep apnea. Patients outside of these general entry guidelines are only carefully considered for surgery with an Institutional Review Board-approved study.

Patient selection for the BPD-DS is of the utmost importance, more so than other bariatric operations that do not include the significant malabsorptive component. If patients are not meticulous in their dietary behavior and postoperative follow-up, the BPD-DS can result in significant malnutrition. We often invoke a rule of thumb that a patient should be at “the head of their class” for the consideration of BPD-DS. We favor the BPD-DS in patients with a BMI >50 kg/m^2, provided the patient can demonstrate appropriate understanding of the nutritional demands of the operation as well as ability to follow up appropriately. For those patients with a BMI >60 kg/m^2, we use a staged approach in which the patient first undergoes laparoscopic sleeve gastrectomy, followed by a second-stage duodenal switch after a 12- to 18-month period of significant weight loss.

Many potential contraindications to surgery exist but generally include pre-existing severe gastrointestinal (GI) disorders (inflammatory bowel disease, cirrhosis, portal hypertension, esophageal varices, chronic pancreatitis) or medical disability (severe congestive heart failure, pulmonary hypertension, extreme immobility). It is rare that any condition is considered an “absolute contraindication”; rather, each patient is evaluated as a whole to determine operative suitability.

PREOPERATIVE PLANNING

A thorough multidisciplinary evaluation is performed in all patients. The initial office visit includes a detailed history and physical exam, with particular attention to previous dietary efforts, medical comorbidities, surgical history, and previous thromboembolic event. Patients considered at high risk of deep vein thrombosis (DVT) or pulmonary embolism, such as those with a prior event or extreme BMI, are no longer referred for preoperative vena caval filter placement, but are made aware of the need for postoperative anticoagulation that should be administered for approximately 1 month. While there are several predictors of poor outcomes from bariatric surgery, we generally do not offer surgery to nonambulatory patients. Additional components of the standard evaluation include psychology/psychiatry to ensure understanding of the procedure, appropriate rational for undergoing surgery, and absence of any untreated eating disorder. We perform routine upper endoscopies with biopsy for *Helicobacter pylori* which is eradicated if present. Specific medical evaluations (cardiac, pulmonary, endocrine) are obtained as necessary.

One of the most critical keys to success is intensive nutritional counseling with specialized bariatric nutritionists experienced in managing patients after BPD-DS. It is essential that the nutritionists be closely involved with the bariatric practice to facilitate communication between surgeon and nutritionist. Because of the long-term nutritional risks, all patients demonstrate knowledge of the procedure by completing a questionnaire detailing the inherent risks and benefits of the operation. As with all bariatric procedures, patients are extensively counseled that the BPD-DS is best thought of as a tool to assist in behavior modification and is by no means a “short-cut” to achieve weight loss goals.

LAPAROSCOPIC BPD-DS OPERATIVE TECHNIQUE

Having a dedicated operating room team that is adept with advanced laparoscopic bariatric procedures and the BPD-DS in particular is imperative. The operation is complex and the value of a team of anesthesiologists and nurses familiar with the setup and instrumentation cannot be stressed enough.

General anesthesia is induced. Urinary catheterization is performed for all patients due to the lengthy (3 to 4 hours) operative time. DVT prophylaxis is given (compression stockings and subcutaneous heparin injection) and appropriate broad-spectrum antibiotic coverage

administered. We position patients in the supine, split-leg position for all bariatric operations. For the duodenal switch, however, we tuck the left arm using an arm board as an extension if necessary. The enables surgeon and assistant to stand on the left comfortably while working on the distal small bowel. We use a standard open entry technique into the abdomen at the umbilicus to establish pneumoperitoneum. Trocars are placed as shown (see Fig. 99.3). In general, all stapling can be done via the umbilical site thereby allowing the remaining trocars to be 5 mm which minimize abdominal wall trauma and to not require fascial closure. However, if stapling the distal bowel proves difficult, we advise replacing the left upper midaxillary with a 12-mm trocar. A quick visual inspection is performed and any adhesiolysis undertaken.

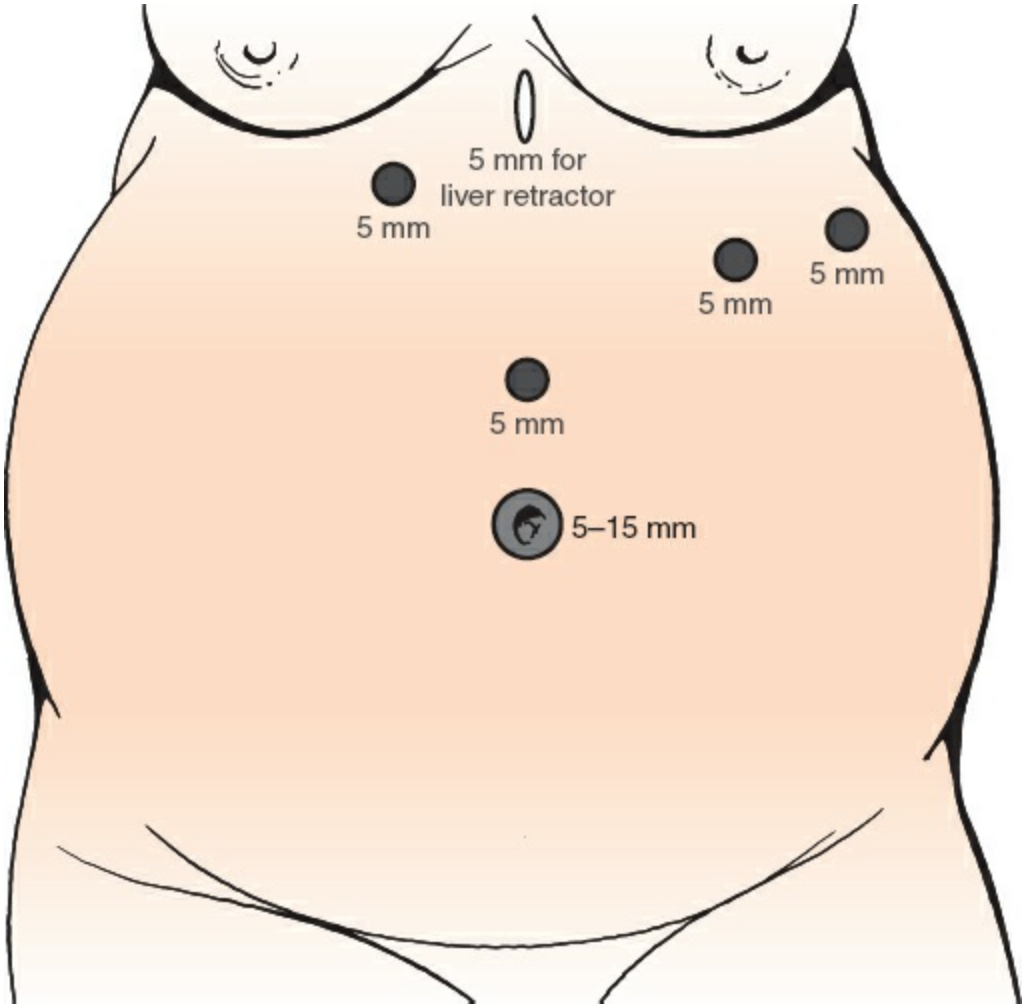

Figure 99.3. Trocar arrangement.

We begin with the sleeve gastrectomy which at this point is a standard operation for most bariatric surgeons. Unlike the standard sleeve

gastrectomy, however, the greater curvature dissection must be carried onto the proximal 2 cm of duodenum. Once fully mobilized, the stomach transection begins on the greater curvature at the level of the crow's foot just distal to an imaginary vertical line created from the incisura (Fig. 99.4). We utilize 60-mm length staplers for the entire resection. The staple-firings for the thick antral tissue should be 4.5 to 5.0 mm in height (usually the first 2 to 3 firings) and thereafter can change to 3.5-mm height. We typically use one of several commercially available reinforcing strips to buttress the staple line and reduce bleeding (we omit this buttress on the first firing as that portion of the antrum is typically too thick to allow for proper staple closure with the addition of the buttress). After the first two firings, a 40F bougie or similar device is placed and guided towards the pylorus to aid in the resection. The bougie should be held in place the entire time by the anesthesiologist to avoid accidental movement and/or transection of the bougie. All stapling is performed via the umbilical trocar. The staple line is inspected for hemostasis and proper staple closure. Any bleeding points are oversewn with 2-0 Vicryl suture. The stomach specimen is removed using via the umbilical port. (Note: if an Endobag is used, place the stomach in the bag such that the corner of the first staple line is left outside, that corner can be easily grasped once the bag is delivered through the wound. This will orient the stomach longitudinally and it can then be extracted with only minimal dilation of the trocar site.)

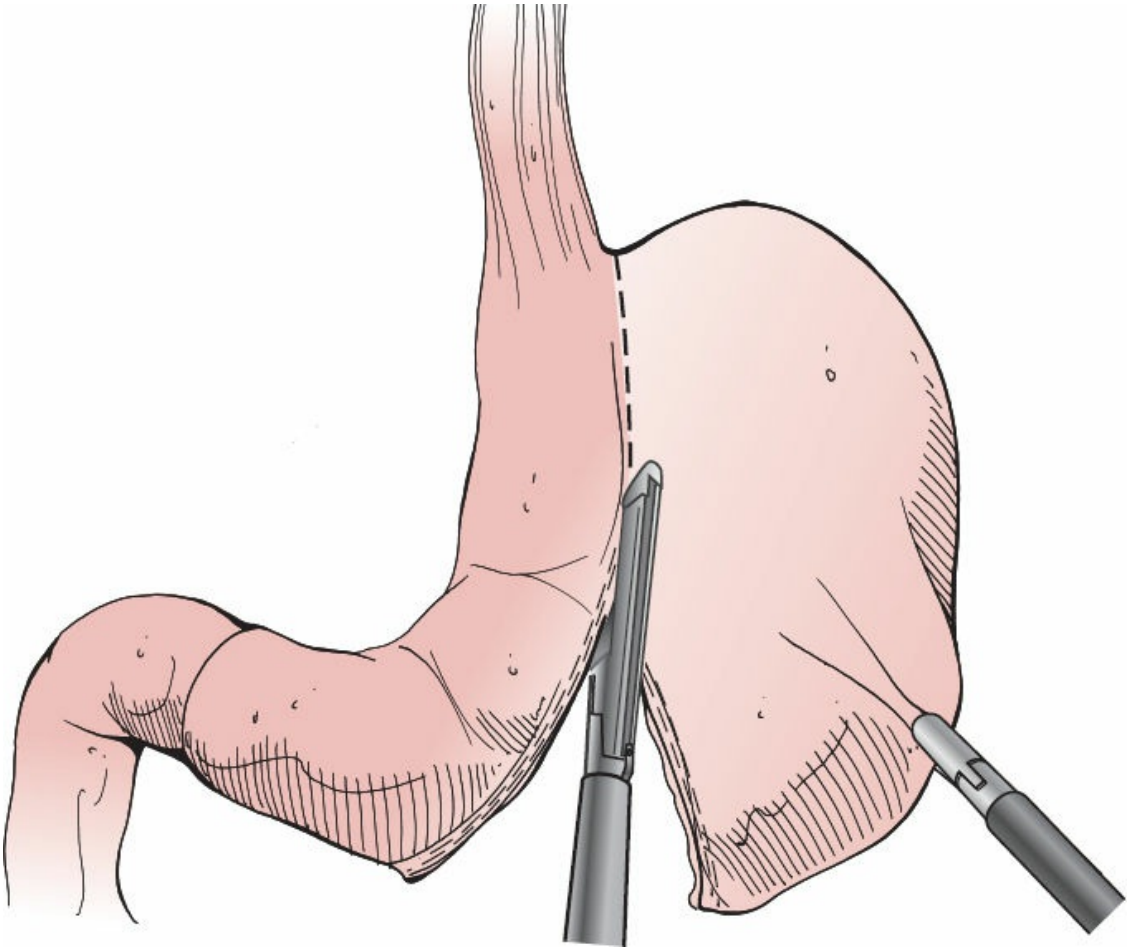

Figure 99.4. Sleeve gastrectomy.

Once the sleeve gastrectomy is completed we move to the periduodenal dissection, which is carefully undertaken to preserve small vessels supplying the distal duodenal stump. A window is dissected on the lesser curvature side of the duodenum just proximal to the hepatoduodenal ligament (this should be well proximal to the common bile duct), avoiding the hepatic artery. A right-angled instrument can be passed beneath the duodenum and placed through the window. The duodenum is transected via the umbilical trocar with a nonbuttressed 60- to 2.5-mm Endo-GIA stapler (Fig. 99.5). We routinely oversew the duodenal stump.

To work on the distal small bowel, the surgeon and assistant move to the patient's left side. If creating an antecolic Roux limb, the greater omentum is divided off the transverse colon from the hepatic flexure medially to a point past the proximal duodenum. We do not feel the antecolic route creates any problems with tension and allows us to avoid creating an additional transmesocolic mesenteric defect. However, if the colonic mesentery is bulky or the small bowel mesentery foreshortened,

consideration can be given to performing a retrocolic roux limb. Next, using the high-epigastric and umbilical ports as working ports with the camera in the epigastric port, the distal bowel is measured proximally with a precut umbilical tape a distance of 100 cm and this site of the common channel marked with hemoclips (note: the length of the common channel is increased to 125 cm in patients with BMI 35 to 45 kg/m^2). The bowel is measured further proximally 150 cm to complete the alimentary limb. The bowel is divided at this point (instruments are exchanged to permit stapler placement via the umbilical trocar) with the nonbuttressed 2.5-mm Endo-GIA. Once divided, the bowel is again run using a counterclockwise rotation moving distally to proximally to ensure proper orientation of the bowel and its mesentery.

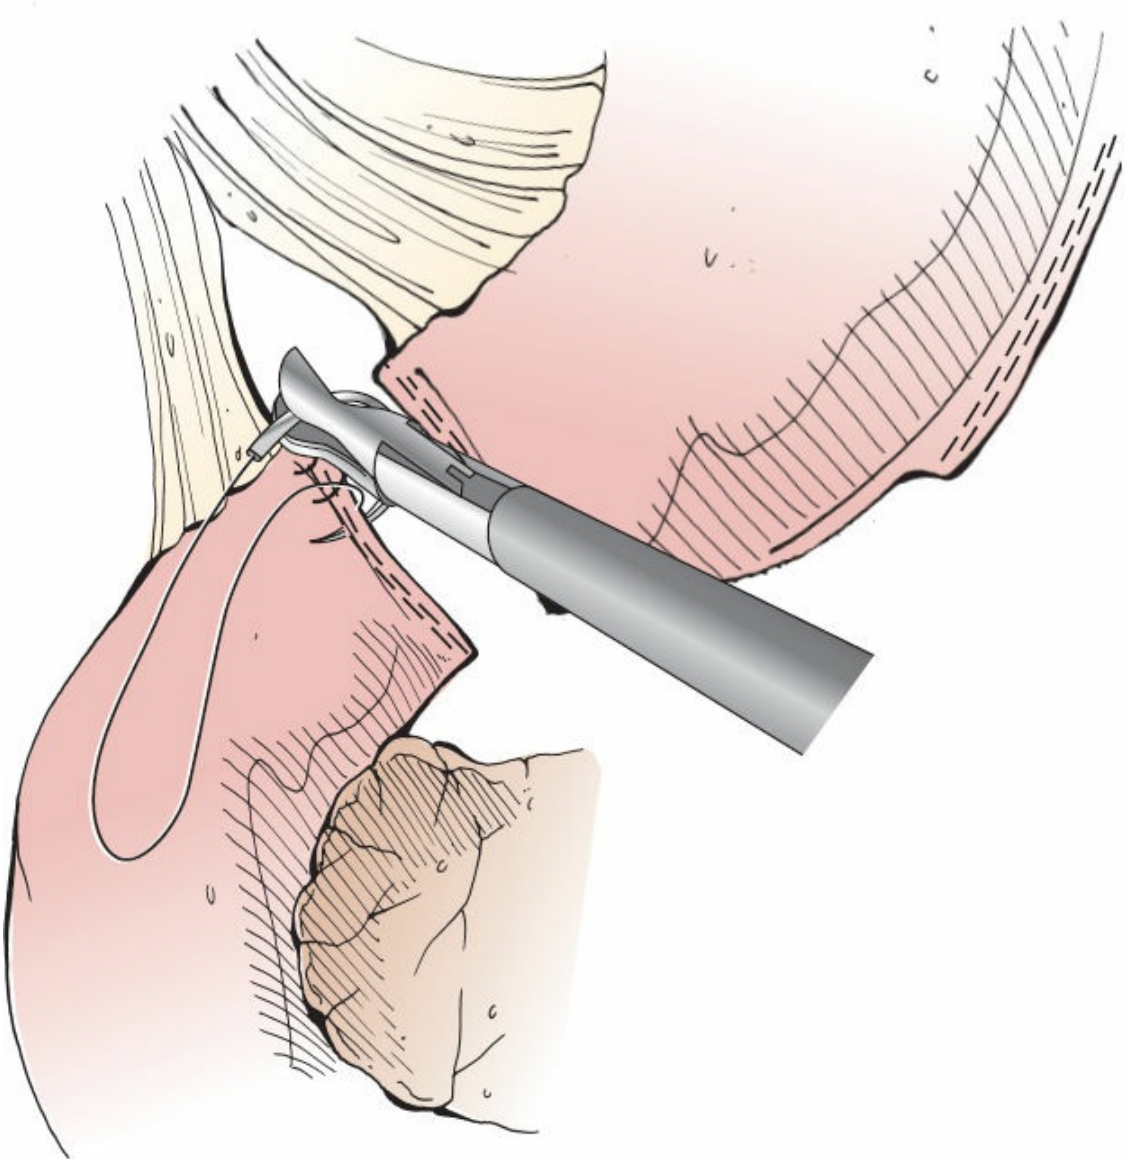

Figure 99.5. Duodenal transection.

The duodenoileostomy is performed in standard hand-sewn fashion which we have found to be technically simpler than performing a circular stapled anastomosis. With the surgeon back between the patient's legs, the staple line of the distal ileum is sewn to the staple line of the proximal duodenum with 2-0 silk as a posterior layer. Enterotomies are made in the proximal duodenum approximately 1 cm in width and anastomosed in running fashion with 3-0 monofilament absorbable suture to complete the inner layer (Fig. 99.6). An orogastric tube is inserted at this point and a Methylene blue leak test is performed, inspecting the duodenoileostomy as well as the gastric sleeve staple line. Once satisfactory, the anterior second layer of the anastomosis is completed with 2-0 silk suture.

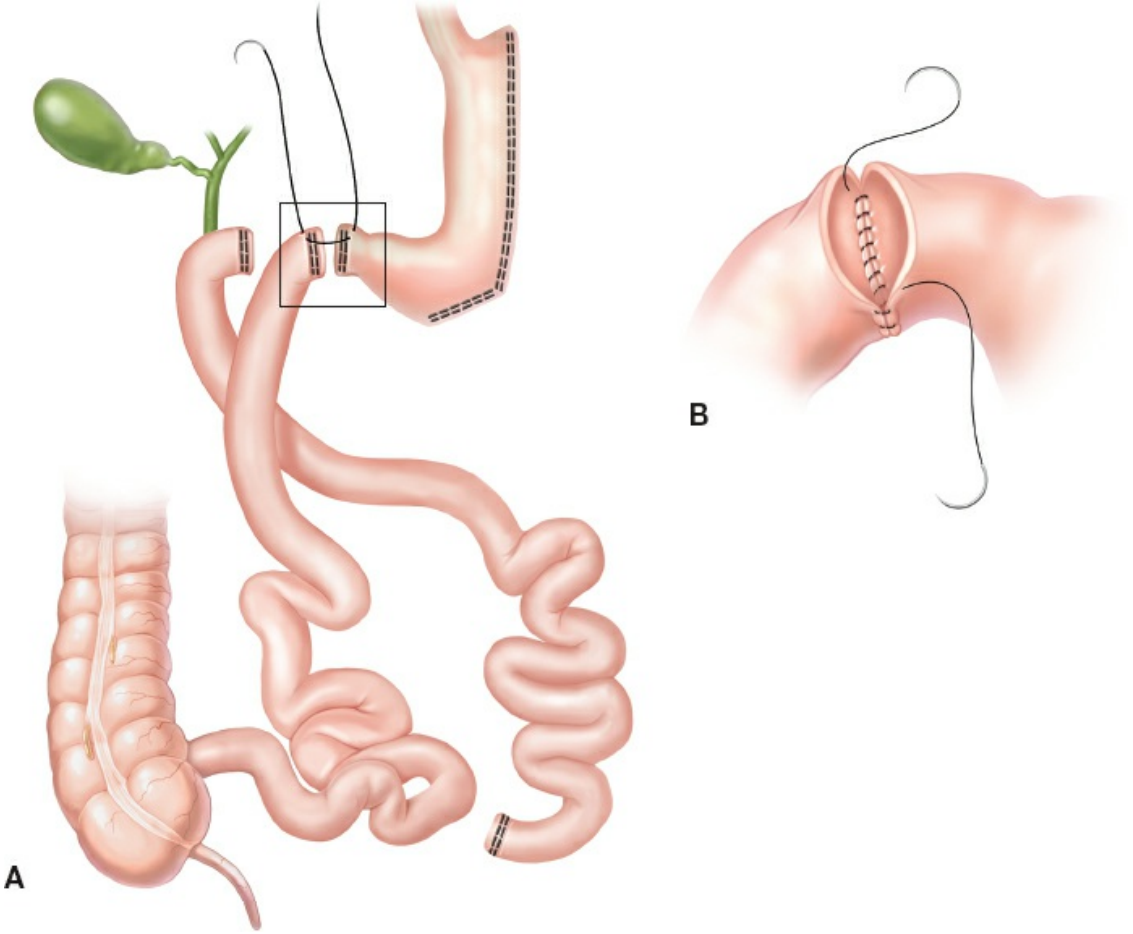

Figure 99.6. Hand-sewn duodenoileostomy.

Intestinal continuity is restored with the distal anastomosis by attaching the biliopancreatic limb to the alimentary limb at the previously marked site of the common channel with the Endo-GIA 60- to 2.5-mm stapler. The open enterotomy can be closed in layers with standard intracorporeal sutures. An alternate technique is to triple-staple the anastomosis (the "M"

technique). With this technique, the biliopancreatic limb and alimentary limb are connected with one firing; the alimentary limb is connected to itself with another firing; and finally the open enterotomy is closed with a third firing (Fig. 99.7). This technique allows for a totally stapled anastomosis with minimal risk of luminal narrowing. The enteroenterostomy defect and Peterson's defect are both closed with running nonabsorbable suture.

We do not routinely place drains. The abdomen is inspected and hemostasis verified. Any trocar sites >5 mm are closed with 0-Vicryl suture and trocars are removed under direct vision. The skin incisions are closed with absorbable subcuticular stitch or skin glue.

Single-anastomosis variant: In the single-anastomosis duodenal switch, the operation proceeds as above to the division of the duodenum. The distal small bowel is then measured proximally a distance of 200 to 250 cm and then brought to the proximal duodenum as a loop. The bowel is anastomosed in standard hand-sewn end-to-side fashion in two layers and leak tested appropriately (Fig. 99.8). The mesenteric defect is not closed.

Figure 99.7. Creation of enteroenterostomy using the "M" technique. The linear stapler is fired between the alimentary and biliopancreatic limb (**A, B**). Then the stapler reinserted and the adjacent alimentary limb is joined to itself (**C**) to form the "M." Finally the open enterotomy is closed again with the linear stapler (**D, E**).

POSTOPERATIVE CARE

From the operating room patients are transferred to the recovery room until cleared by anesthesia before transfer to a regular floor. In patients with significant cardiovascular risks factors (severe sleep apnea, CAD, CPOD), consideration is given to moving them to a more monitored setting ("step-down," or even ICU if drip medications are planned). Maintenance fluids are given to maintain urine output of at least 1 mL/kg/hr. DVT prophylaxis (early ambulation, compression stockings, and unfractionated subcutaneous heparin are continued). For patient with sleep apnea, CPAP is instituted right in the recovery room.

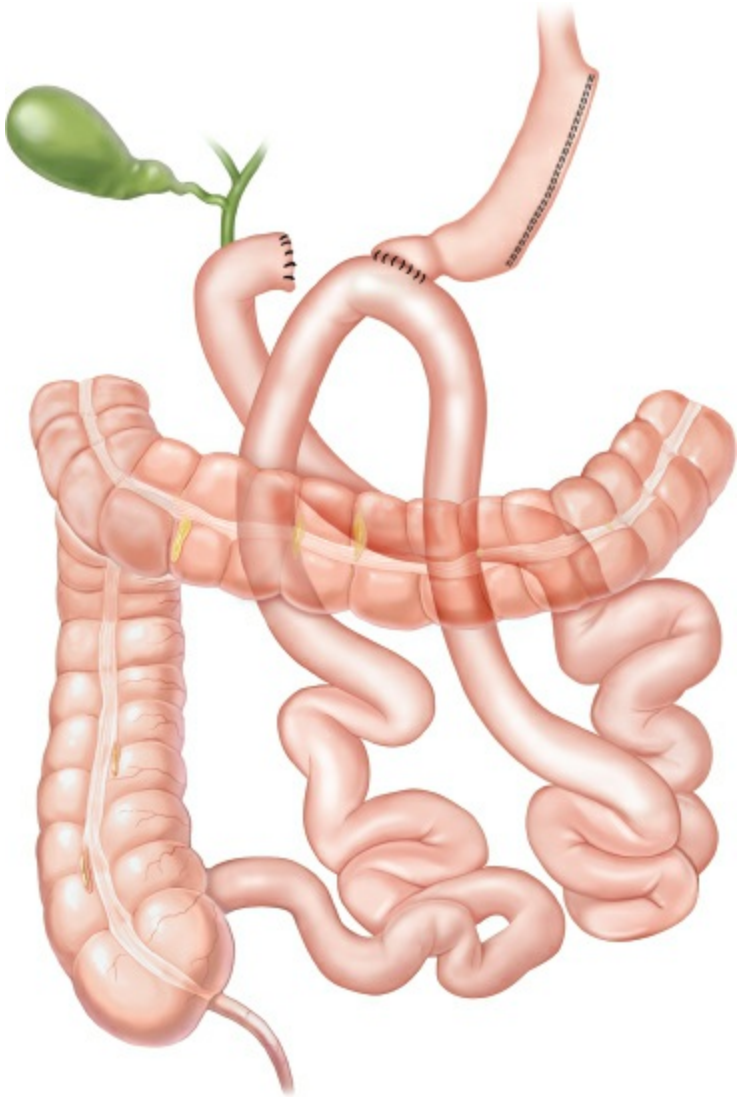

Figure 99.8. Single-anastomosis duodenal switch.

The dietary progression has evolved in recent years. We no longer perform routine upper gastrointestinal (UGI) studies on the first postoperative day. If there were no concerns about the operative procedure, patients are allowed clear liquids right away (postoperative day zero). If, however, the patient has any signs of instability (fever, HR >105, low urine output), consideration is given to obtaining an UGI contrast study to evaluate the sleeve gastrectomy and proximal anastomosis, or CT scan to exclude pulmonary embolism.

Provided the patient is doing well clinically, the urinary catheter is removed on postoperative day 1 and the patient-controlled analgesia is changed for oral pain medicine. Patients are advanced to full-liquid diet on the second postoperative day. Most patients are discharged on the second or third postoperative day and continue full-liquid diet until their first

postoperative visit at 3 weeks. Patients take calcium carbonate and multivitamins daily.

We see patients routinely at 3 weeks, 3 months, 6 months, 12 months, and then 6 months to yearly thereafter. On the first postoperative visit, patients are seen by our dedicated nutritionists and counseled on the transition from full-liquid diet to solid foods. They are started on oral iron supplementation, vitamins A and D, and calcium citrate. Vitamin D is dosed based on current serum levels and degree of secondary hyperparathyroidism. Ursodiol 250 mg b.i.d. for 6 months is prescribed to prevent gallstone formation. It is essential that patients see the dedicated bariatric nutritionist at each postoperative visit to adjust vitamin supplementation as necessary and to reinforce the dietary guidelines critical to success. Nutritional lab values are checked at least every 6 months and can be more frequent if a deficiency state exists. We advise patients to attend monthly support-group meetings.

COMPLICATIONS AND THEIR MANAGEMENT

The early complications of BPD/DS are similar to those of other stapled bariatric procedures including GB and sleeve gastrectomy. The morality rate (0.5%) is generally considered to be marginally higher than other procedures due to the technical complexity of the operation and the fact that it is generally offered to higher BMI patients who are at greater risk. Support for this comes in part from Buchwald's 2004 meta-analysis, where operative mortality for BPD-DS was reported at 1.1%, or twice that of GB. As well, the Anthone series in 2003 had an operative mortality of 1.4%. However, many series show mortality results not significantly greater than that for GB. Scopinaro's reported mortality is < 0.5%. In Hess' large series mortality was 0.57%. One experienced center reported a decrease in operative mortality from 1.3% to 0.2% during a 20-year study period.

Pulmonary embolism is a devastating complication of any bariatric surgery. The reported incidence is low (0.1% a recent study) but logic would dictate the incidence to be higher than for other procedures simply due to the prolonged operating time. Management of pulmonary embolism is supportive and outcome is tied to early recognition. Leak rates range from 0% to 2% but again are generally considered to be marginally higher than other procedures. Management will depend on the site of the leak (stomach vs. duodenoileostomy vs. ileoileostomy), the time of presentation (early vs. delayed), and the clinical status of the patient (stable vs. septic).

The most critical aspect is early recognition and consequent action. In labile patients, a return to the operating room is necessary to control sepsis, attempt repair, and place enteral feeding access which is essential to support the patient while the leak is healing. In stable patients, other options such as interventional drainage or endoscopic stents or suturing can be considered. Bleeding as an early complication can be expected in a small (1%) number of patients.

TABLE 99.2 Morbidity After BPD-DS

Acute	
Death	0.5–1.1
Leak	2–3
DVT/PE	1–2
Bleeding	1–2
Wound infection	2–3
Chronic	
Anatomic	
Dumping	0
Stricture	<1
Ulcer	3–5
Internal hernia	3–5
Incisional hernia	2–4
Systemic	
Protein malnutrition	2–20
Hepatic failure	<1
Weight gain	<5
Steatorrhea	5–10
Cholestasis	<5

The late complications of BPD/DS include bowel obstruction, incisional hernia, internal (mesenteric hernia), and biliary symptoms. Management of these is generally per standard bariatric care; however, a low threshold for operative intervention of bowel obstruction should be held due to the possibility of closed-loop obstruction present after such a significant intestinal bypass procedure. Revisional operations will be necessary in a percentage of patients (0.7% to 2.9%) and patients should be counseled accordingly. Nutritional deficiencies are discussed below.

We feel it important to inform patients that while perioperative morbidity and mortality for BPD-DS may be slightly higher than that for RYGB, when performed by experienced groups, the incidence of major adverse events is quite acceptable (Table 99.2).

RESULTS

Several large series with long-term follow-up are available describing weight loss with BPD. The largest series was reported by Scopinaro detailing 2,241 patients undergoing the original BPD followed for 21 years. These patients had 77% EWL at 10 years. Hess and Hess reported on a cohort of 182 patients who were >10 years out from BPD-DS surgery. With 92% follow-up, their patients exhibited 75% EWL. Rabkin reported in 2003 on a series of 345 laparoscopic BPD-DS procedures. Mean %EWL at 2 years was 91%. Anthone and colleagues reported 71% EWL at 3 years in a group of 701 BPD-DS patients. In a small series of our own laparoscopic BPD-DS patients, we reported 84% EWL at 27 months. Marceau reported on 2,615 patients followed over 20 years with 71% EWL.

Super-obese patients (BMI >50 kg/m^2) are unlikely to achieve satisfactory weight loss after GB (BMI <30 kg/m^2 or %EWL ≥50%), with fewer than 60% reaching resulting in long-term success. Thus, the BPD-DS may be most appropriate for this group of patients. In a recent series of super-obese patients, Prachand compared 198 BPD-DS patients to 152 GB patients. Weight loss was greater in the BPD-DS group at all follow-up intervals. At 36 months, %EWL was 68.9% versus 54.9%, p <0.05. In a randomized, controlled trial, SÖvik et al. studied 60 super-obese patients randomized to either laparoscopic GB or BPD-DS. At 1 year, the mean % of BMI lost was significantly greater in the BPD-DS group (74.8% vs. 54.4%). This cohort was reported on by Risstad in 2015 with 5-year follow-up showing greater weight loss in the BPD-DS group and greater improvements in certain comorbidities. Given the high failure rate of GB in the super-obese, we feel that any patient in this category should be considered for BPD-DS if they meet the relatively rigid screening criteria.

For super-obese patients who have previously undergone GB and have failed, either due to weight regain or inadequate weight loss, conversion to BPD-DS is a reasonable consideration. However, be advised that the laparoscopic procedure is challenging, involving first reversal of the GB followed by a sleeve gastrectomy and duodenal switch. Due to the

technical complexity and length of the procedure, in most cases it may be advisable to accomplish the operation in two separate stages. Our initial experience and the technical details of the procedure have been previously reported (Parikh, 2011) with 63% EWL in a small series of patients.

Long-term nutritional deficiencies after BPD-DS are oft-cited as reasons to avoid the procedure. Any operation that bypasses the duodenum will lead to a certain percentage of iron and calcium deficiency, as the duodenum and proximal jejunum is the primary site of absorption for those nutrients. However, deficiency rates in demonstrate a range in the literature. Iron deficiency anemia can develop in up to 50% of patients after duodenal switch (comparable to that after long-limb GB) and if not responsive to oral supplementation, can be treated with parenteral iron. Vitamin B12 deficiency is more uncommon owing to the preservation of more gastric mucosa in the duodenal switch procedure than with GB. Many obese patients have secondary hyperparathyroidism and vitamin D deficiency preoperatively. The distal bypass and short common channel of the BPD-DS negatively impact vitamin D absorption, thus careful monitoring and supplementation are necessary. One recent study indicates that chronic secondary hyperparathyroidism in BPD-DS patients leads to a high rate of bone turnover and decreasing bone mineral density, further underscoring the need for close monitoring of this nutritional axis. With proper follow-up and supplementation, most if not all vitamin deficiencies are avoidable.

Perhaps the most significant long-term nutritional sequela is protein malnutrition. While the degree of hypoalbuminemia after BPD-DS is not as severe as that found after long-limb GB, owing to the lesser degree of restriction with the sleeve gastrectomy of the DS, the incidence can vary widely from 7% to 20%. Even with careful monitoring and supplementation, a patient may still develop protein malnutrition due to the limited absorptive capacity of the common channel. Therefore, there will be an incidence of patients requiring revisional limb-lengthening surgery. This incidence is low (3.7% in the Hess series, 10% in the Risstad series of super-obese) but can increase in poorly compliant patients.

Single-Anastomosis Duodenal Switch

The newest variant of the BPD-DS goes by many names, including single-anastomosis duodenal switch, loop duodenal switch, single anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S), or the stomach

intestinal pylorus-sparing (SIPS) procedure. It is a potentially attractive version, in that it is technically simpler to accomplish than the standard BPD-DS. There may be a reduction in GI side effects such as diarrhea, flatulence, and malodorous stools, as well as a reduced incidence of vitamin or protein deficiency. Weight loss may not reach the levels seen in standard BPD-DS. However, the weight loss may be greater than that achieved by GB or sleeve gastrectomy alone.

Torres' group from Spain has published the longest follow-up after the SADI-S procedure. They reported on their first 50 patients with a starting BMI of 44 kg/m^2 and followed them out to 3 years. Percent EWL was 94.7% sustained at 3 years with remarkable follow-up. While the incidence of hypoalbuminemia was 8% after 1 year, all patients recovered to normal levels by the third year. A total of 27 diabetic patients were included and all had normalized HbA1c levels after 6 months off all antidiabetic medications. They had two leaks from the gastric suture line which they attribute to technical error early in their learning curve.

Another group performed a matched cohort analysis of 54 patients undergoing loop duodenal switch to GB. Weight loss was comparable between groups followed out to 18 months (40% weight loss). However, the loop duodenal switch group had fewer immediate complications and less postoperative nausea. The loop duodenal switch group also had significantly fewer postoperative upper endoscopies (3 vs. 21), fewer ulcers (0 vs. 6), and fewer reoperations (2 vs. 10). Long-term data, both with regard to weight loss and complications, is necessary to determine what role the single anastomosis variant will play.

CONCLUSION

Throughout the world's literature, the BPD-DS has been shown to induce the most weight loss of any bariatric procedure with the greatest degree of long-term success. Though it requires advanced technical skill, in experienced centers it can be performed with a safety profile nearly equivalent to that of the more common GB. Owing to its malabsorptive nature, more rigorous screening of patients should be performed to ensure proper understanding of the operation, its long-term risks, and avoidance of negative nutritional sequela. The BPD-DS is an important option for any bariatric surgeon to offer, especially for the super-obese patient that is likely to fail with other operations. The bariatric surgeon must assemble a comprehensive team (both operative and nutritional) to provide proper

long-term follow-up of all patients.

EDITOR'S COMMENT

This excellent technical treatise provided by Professors Dakin and Pomp reiterates the exclusive medical value of bariatric surgery and the only objective therapeutic option for the growing population of the morbidly obese. The American Heart Association (AHA) predicts that by 2030 total medical costs for chronic diseases initiated by obesity will reach $860–957 billion. Moreover, contemporary studies suggest that steeper growth of some chronic diseases is more evident in the obese than in the general population growth. Thus, the annual medical costs associated with obesity in 2016 for the United States will range from $147 billion to approximately $210 billion; this epidemiologic factor further notes that each obese worker enhances employer costs by approximately $500 per year, thus shifting manufacturing, labor and disability costs to the consumer. The AHA further regards obesity as a global epidemic that initiates hypertension, cardiovascular disease, type II diabetes, hypercholesterolemia, stroke and cardiac failure. The global impact of obesity is profound and is etiological of additional chronic illnesses including joint disease, depression, cancer, gall bladder disorders, breathing/respiratory insufficiency and infection, and also premature cardiovascular disease. The Trust for America's Health, reported that in 1980, no state had an obesity rate at or above 15%; in 1991, none of the 50 US states had a rate of obesity that exceeded 20%.

Morbid obesity has demographic profiling in the United States with the largest populations in the South, Southeast, and Southwest areas which often relates to poor socioeconomic status, education, and income. The Trust for America's Health and the Robert Wood Johnson Foundation released data in 2015 with rates of obesity exceeding 35% in three states (Arkansas, West Virginia and Mississippi). Additionally, 22 states have rates above 30%, 45% are above 25%, and every state is >21%. Arkansas has the highest adult obesity rate (35.9%); Colorado is considered the state with having the lowest rate (21.3%). Trends in America suggest that greater than a third of all adults (34.9%) are obese, more than two thirds were in both overweight and obese ranges (68.6%). This demographic notation further delineates the escalating frequency of obesity in children and teenagers (2 to 19) of nearly 17%. And greater than 8% of children ages 2 to 5 are obese (State of Obesity: Better Policies for a Healthier America: 2015). This data accounts for the type II diabetic and hypertension rate increases in many states of the South and Southwestern United States.

Professors Dakin and Pomp have emphasized that despite the success of the laparoscopic biliary pancreatic diversion with duodenal switch (LBPD-DS), the

procedure currently represents only 2% of all bariatric surgery procedures (Table 99.1). LBPD-DS is the most highly successful of weight reduction bariatric procedures and the Gagner group document that it produces the most significant weight loss, and further, provides amelioration of many obesity-related comorbidities relative to those of its bariatric weight reduction counterparts (Anderson B, Gill RS, deGara CJ, et al. Biliopancreatic diversion: the effectiveness of duodenal switch and its limitations. *Gastro Res Pract* 2013;2013:974762). In contrast to the open or laparoscopic gastric bypass (GB), adjustable gastric binding or sleeve gastrectomy, the LBPD-DS is clearly the more technically demanding of the category of bariatric surgery. Superior outcomes, as noted by numerous surgeons, require the requisite patient selection with detailed analytical follow-up; this process allowed LBPD-DS to be completed in a safe and acceptable manner with excellent long-term comorbidity and complication profiles.

As discussed by the authors, the most significant long-term morbidity is inclusive of the nutritional sequela of protein, electrolyte and mineral depletion, and subsequent malnutrition. Long-limb gastric bypass initiates a more profound degree of nutritional protein-malnutrition than that of the LBPD-DS, which results from its lesser degree of restrictive capacity with the sleeve gastrectomy of the DS. The authors detail that this variance is 7% to 20% for nutritional protein depletion. Therefore, careful monitoring and protein serum content must be assessed to identify protein malnutrition second to the absorptive and limited capacity of the protein molecule transfer across the common channel. Protein malnutrition can be remedied completely or in part by revision and limb-lengthening surgery as discussed in the series by Hess et al. (Hess DS, Hess DW, Oakely RS. The biliopancreatic diversion with duodenal switch: results beyond 10 years. *Obes Surg* 2005;15:408) the frequency was 3.7%; in the Risstad (Risstad H, Sovik TT, Engstrom M, et al. Five-year outcomes after laparoscopic gastric bypass and laparoscopic duodenal switch in patients with body mass index of 50–60 a randomized clinical trial. *JAMA Surg* 2015;150:352) series this frequency was 10% in the super-obese. Identification of the poorly compliant patient is paramount to avoid advanced protein nutritional depletion with other comorbidities that result in potential inanition and death as a complication.

The above observations of protein malnutrition are partially explained by Kodama and associates (Kodama Y, Johannessen H, Furnes MW, et al. Mechanistic Comparison between Gastric Bypass vs. Duodenal Switch with Sleeve Gastrectomy in Rat Models. *PLoS OnE* 2013;8(9):e72896). These authors note that the initiation of rapid energy expenditure of less available food substrate is the principal mechanistic explanation for the success of the gastric bypass outcomes; whereas duodenal switch with sleeve gastrectomy induces greater body weight loss by both the reduction in food intake together with increase in energy expenditure and malabsorption in rat models. These differences are highly statistically significant in the rat model with comparison

of the GB versus the BPD-DS. Again, Kodama et al. indicate further that both procedures initiate restriction in food intake and absorption with the decrease in gastric volume and the additional effect of bypass of segments of the small intestine. The DS procedure is superior to GB in body weight loss, as well as providing reduction in the proportions of major comorbidities inherent with the GB: inclusive of diabetes, hypertension, and dyslipidemia. As Drs. Dakin and Pomp note, the most profound nutritional deprivation is the malnutrition resulting from protein repletion and its ultimate consequences. The LBPD-DS remains less severe for morbidity with less hypoalbuminemia with less frequency than that of the long-limb GB; however, LBPD-DS initiates more infrequently vitamin B-12, calcium, vitamin A and D, and multivitamin deficiency, but more commonly iron deficiency. Ferrous iron absorption deficits with lack of transfer across the duodenum can be noted in as great as 50% of LBPD-BS patients. With exclusion of duodenum continuity, the LBPD-DS is more frequently observed to have iron deficiency when compared to long-limb GB. This deficit is successfully treated with oral iron replacement or parenteral-route iron repletion.

The Torres team from Madrid created the newest variant of the BPD-DS procedures and is inclusive of the single-anastomosis duodenoileal bypass, with sleeve gastrectomy (SADI-SG). This procedure was remarkably effective as noted by the authors with percent EWL of 94.7% and only an 8% hypoalbuminemia rate at 1 year in which all patients had recovered by year 3 (Sánchez-Pernaute A, Rubio MA, Conde M, et al. Single-anastomosis duodenoileal bypass as a second step after sleeve gastrectomy. *Surg Obes Relat Dis* 2015;11:351–5). In the diabetic population (n = 27), the normalization of the Hgb A1c at 6 months and removal from antidiabetic medications is a remarkable achievement. The Torres group's most recent analysis (2015) suggests the SADI procedure can be performed with few postoperative complications that are ultimately corrected; mean excess weight loss was 72% at 2 years, with complete remission rates of 89% for diabetes, 60% for hypertension, and 40% for dyslipidemia. The evidence of clinical hypoalbuminemia is essentially resolved with this mature, but technically more demanding technique for bariatric surgical weight loss.

In summary, the Figure depictions provided by Professors Dakin and Pomp in this chapter of The Mastery of Surgery emphasize a fundamental advancement in technical approach for the super-obese and additional steps for the consideration of revision of gastric bypass to biliopancreatic diversion with duodenal switch. Experimentally and clinically, and in experienced hands, the LBPD-DS is objectively the most secure and tested technique for weight loss of all bariatric procedures. Further, LBPD-DS provides the clinician and their patients the greatest long-term success probability for the reduction in comorbidities. Despite these accolades of safety in the right hands, the authors acknowledge that more technical expertise is required to achieve this outcome. Both North American and European clinics have achieved unprecedented safety

of the LBPD-DS technique with highly acceptable outcomes that are comparable to the more commonly performed (and less complex) gastric bypass procedures. The technical difficulty of the LBPD-DS is less problematic in high-volume related practices as in the Torres Clinic. This team noted similar morbidity from bariatric GB. Staging of the procedure as recommended by DeMaria and Associates (DeMaria EJ, Murr M, Byrne TK, et al. Validation of the obesity surgery mortality risk score in a multicenter study proves it stratifies mortality risk in patients undergoing gastric bypass for morbid obesity. *Ann Surg* 2007;246:578–82), and Regan and Gagner (Regan JP, Inabnet WB, Gagner M, et al. Early experience with two-stage laparoscopic Roux-en-Y gastric bypass as an alternative in the super-super obese patient. *Obes Surg* 2003;13:861–4) have resulted in excellent postoperative outcomes. We agree that the BPD-DS represents a superior consideration to the bariatric surgeon that is tantamount to any of his/her repertoire of operations. This procedure provides the morbidly obese and super-obese patients referred to their clinics superior outcomes in weight loss and comorbidities. As suggested in this text, and by other bariatric care systems (Brethauer SA, Chand B, Schauer PR. Risks and benefits of bariatric surgery: current evidence. *Cleve Clin J Med* 2006;73(11):993–1007), a comprehensive learned team of clinicians, nurses, surgeons, social and psychiatric professionals is required to complete this advanced management team in bariatric surgery to ensure health to these disadvantaged individuals throughout the world.

100 EndoBarrier for the Treatment of Morbid Obesity and Type II Diabetes

Keith S. Gersin

INTRODUCTION

Obesity grades 2 and 3 (body mass index [BMI] 35 to <40 kg/m^2 and BMI ≥40 kg/m^2) and type 2 diabetes mellitus (T2DM) affect 15.4% (2011–2012 data) and 8.4% of the United States population, respectively. Furthermore, because the prevalence of T2DM increases with increasing BMI, there is some overlap between these two populations. In a recent survey involving individuals who had not previously been diagnosed with diabetes, 16% of patients with BMI 40 to 49.9 kg/m^2 and 21% of those with BMI ≥50 kg/m^2 had T2DM.

Body weight reduction has been shown to reduce overall mortality, increase diabetes recovery rate, and improve cardiovascular risk factors in patients who are obese. Decreases in body weight also reduce glycated hemoglobin, improve cardiovascular risk factors, reduce comorbidities, and improve quality of life in overweight or obese patients with T2DM. Weight reduction is thus of paramount importance for improved health in patients with obesity, T2DM, or both.

Management of obesity through lifestyle intervention and use of drugs is associated with mean reductions in body weight of 3% to 9%. However, up to 60% of patients may not achieve clinically meaningful (≥5%) weight loss with pharmacologic intervention, and bariatric surgery may be an option for this subset of patients. For those with morbid obesity (typically defined as BMI ≥40 kg/m^2 or ≥35 kg/m^2 with comorbidities), bariatric surgery is associated with substantial weight loss, improvements in weight-associated comorbidities, and reductions in mortality. However, surgical intervention is not indicated or not ideal for all patients with obesity and/or T2DM. For example, bariatric procedures are generally not indicated in patients with BMI <35 kg/m^2, and there may be potential for complications during and after bariatric surgery, including perioperative

mortality. Moreover, some bariatric procedures are not reversible, and many patients have serious concerns about undergoing weight loss surgery. There is therefore a role for a reversible, endoscopic procedure that promotes weight loss and improves glycemic control, and that may be more effective than medications and less invasive than surgery.

DUODENAL–JEJUNAL BYPASS LINER

The duodenal–jejunal bypass liner (EndoBarrier Gastrointestinal Liner System) is an impermeable, fluoropolymer intestinal liner with an integral anchor system, proximal radiopaque marker, and retrieval drawstrings (Fig. 100.1) that is delivered and removed endoscopically. The proximal end of this 61-cm long, open-ended liner is anchored in the duodenal bulb via a self-expanding nitinol stent containing bidirectional barbs that affix the device to the duodenal wall. These barbs help prevent distal and proximal migration of the anchor and liner.

The EndoBarrier is available as a sterile, one-time use, prepackaged capsule/delivery system. Prior to implantation, the liner and anchor are collapsed and contained within a protective capsule (Fig. 100.2) that is affixed to a flexible custom-delivery catheter (Fig. 100.3). The capsule is delivered endoscopically to the duodenum just distal to the pylorus, and the device is delivered from the capsule during implantation. A ball on the distal end of the catheter facilitates atraumatic tracking of the liner through the duodenum and proximal jejunum, with the assistance of continuous dynamic fluoroscopy. Once the liner has been completely delivered, aided by visualization of the proximal radiopaque marker exiting the delivery capsule, the self-expanding nitinol anchor is released within the duodenal bulb, 1 to 2 cm distal to the pylorus.

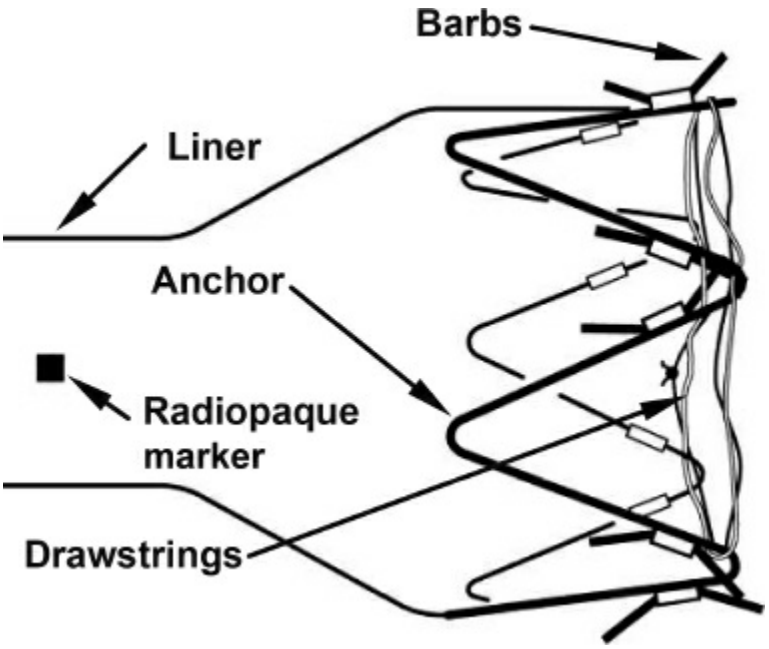

Figure 100.1. Proximal end of duodenal–jejunal bypass liner showing anchor, bidirectional barbs, and drawstrings. (From The EndoBarrier Gastrointestinal Liner with Delivery System: Instructions For Use (50–10–00552 Rev N IFU EB GI Liner with Delivery System.pdf). Lexington, MA: GI Dynamics Inc.)

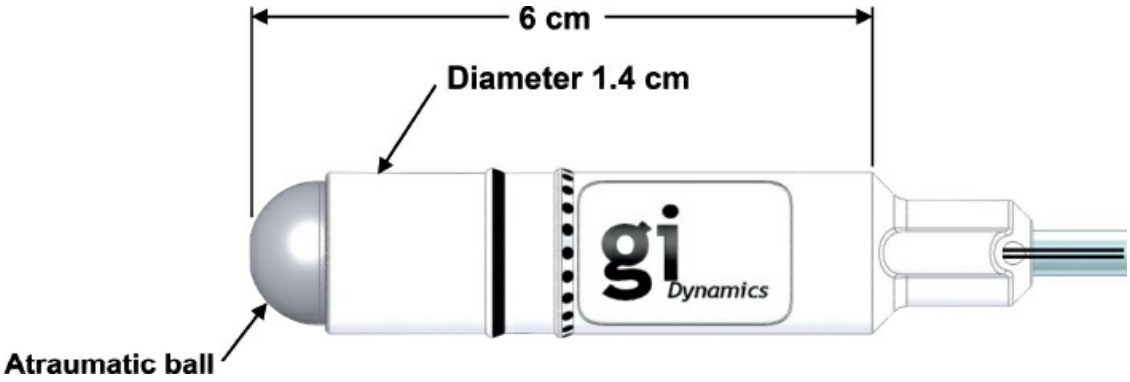

Figure 100.2. Capsule containing the duodenal–jejunal bypass liner. (From The EndoBarrier Gastrointestinal Liner with Delivery System: Instructions For Use (50–10–00552 Rev N IFU EB GI Liner with Delivery System.pdf). Lexington, MA: GI Dynamics Inc.)

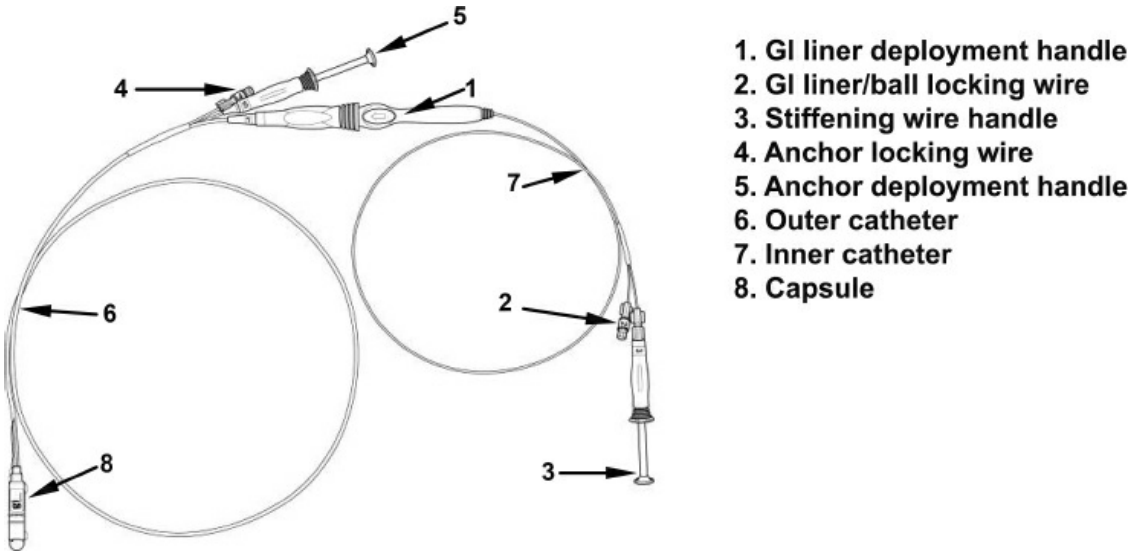

Figure 100.3. Delivery system for the duodenal–jejunal bypass liner. (From The EndoBarrier Gastrointestinal Liner with Delivery System: Instructions For Use (50–10–00552 Rev N IFU EB GI Liner with Delivery System.pdf). Lexington, MA: GI Dynamics Inc.)

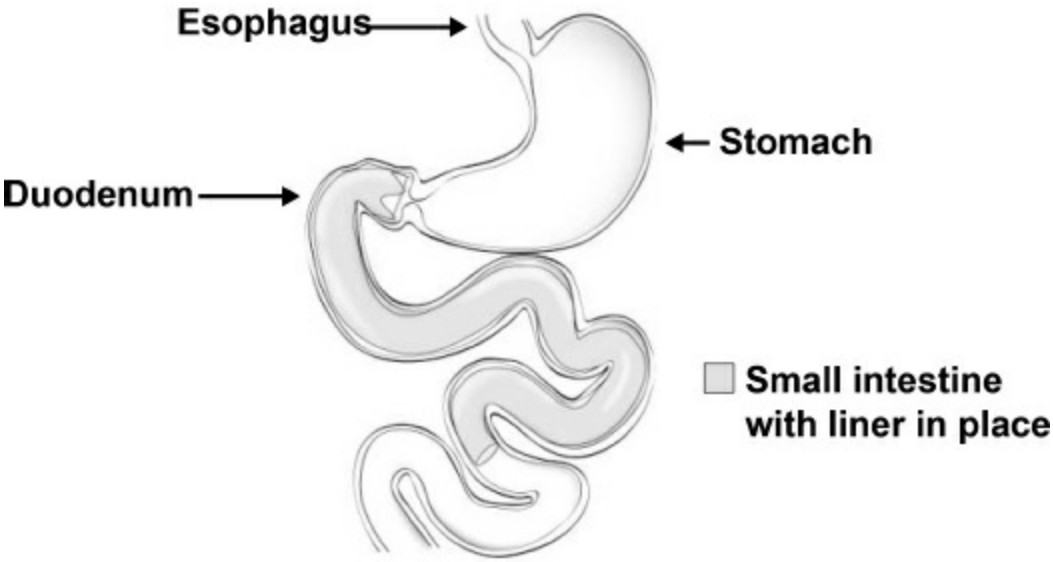

Figure 100.4. Position of the duodenal–jejunal bypass liner in the small intestine. (From The EndoBarrier Gastrointestinal Liner with Delivery System: Instructions For Use (50–10–00552 Rev N IFU EB GI Liner with Delivery System.pdf). Lexington, MA: GI Dynamics Inc.)

In this manner, the liner creates a duodenal–jejunal bypass (Fig. 100.4). Biliary and pancreatic secretions pass around the outside of the impermeable liner and mix with chyme as it exits the distal end of the liner in the jejunum. The liner excludes the duodenum and proximal jejunum

and thus mimics the anatomical effects of Roux-en-Y gastric bypass. The liner has been shown to induce weight loss and improve cardiovascular risk factors in obese patients with or without concomitant T2DM, and to improve glycemic control in obese patients with T2DM.

The liner is removed using a custom retrieval system and hood (Figs. 100.5 and 100.6) after a maximum implantation period of 12 months. It is recommended that both implantation and explantation be performed by physicians who are skilled in therapeutic endoscopy, to minimize tissue damage that can occur. Such damage can include laceration, perforation, and bleeding. Initial training and proctoring of the endoscopic team is therefore extremely important to help ensure the success of procedures performed by early adopters.

INDICATIONS

Implantation of a duodenal–jejunal bypass liner can be considered for adult patients 18 to 70 years of age who have T2DM and a BMI ≥35 kg/m^2 or a BMI ≥30 kg/m^2 plus ≥1 other comorbidity (e.g., dyslipidemia, hypertension, BMI ≥35 kg/m^2). Implantation of the bypass liner may be particularly appropriate in patients with T2DM who are poorly controlled despite lifestyle changes and escalating diabetes medications, and in obese patients for whom bariatric surgery is contraindicated or is considered a therapy of last resort. Although the EndoBarrier is currently indicated for a maximum implantation period of 12 months only, preliminary data suggest that serial implantation is safe, and associated with further weight loss.

PATIENT SELECTION

Patients should be participating in a multidisciplinary weight management program that includes endoscopists and endocrinologists. Selection of appropriate candidates is important for success, and screening of all prospective implant recipients by both a dietitian and a mental health provider is recommended. Female patients should be postmenopausal, surgically sterile, or receiving contraception.

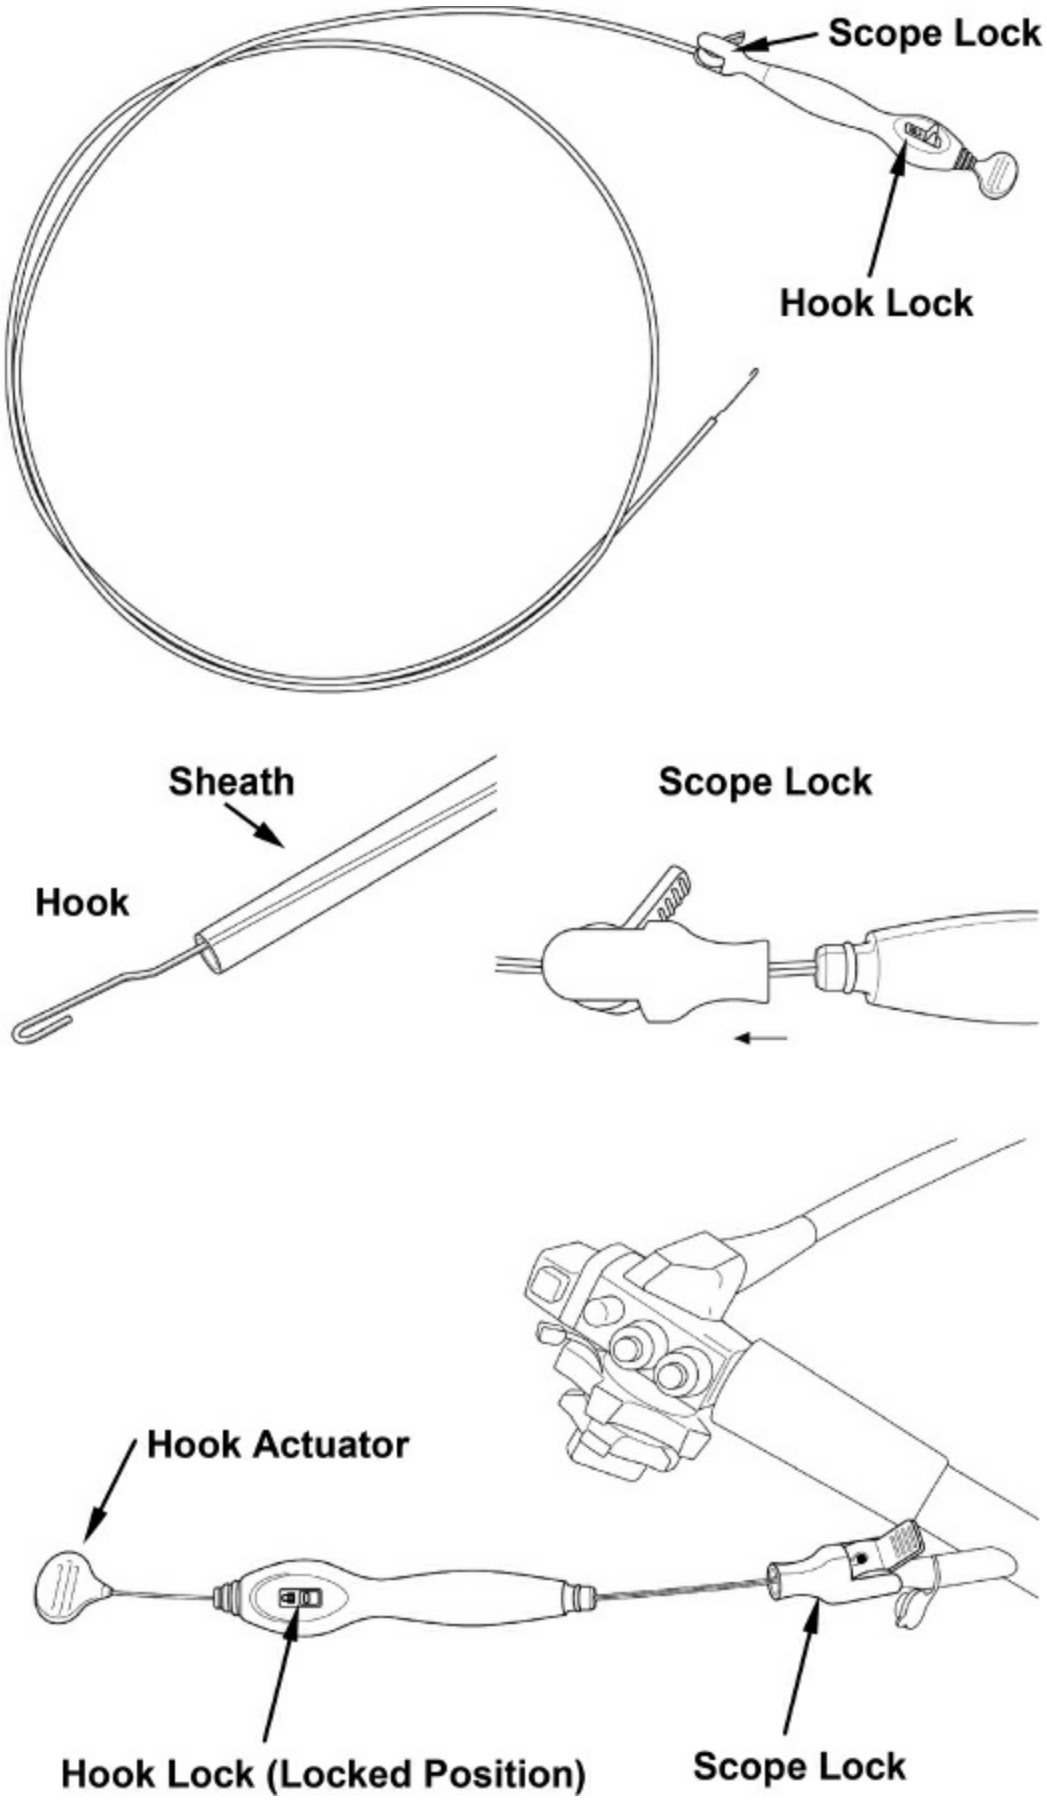

Figure 100.5. Retrieval system for the duodenal–jejunal bypass

liner. (From The EndoBarrier Gastrointestinal Liner Retrieval System: Instructions For Use (50–30–00637 Rev N IFU EndoBarrier GI Liner Retrieval System with Certified Translations.pdf). Lexington, MA: GI Dynamics Inc.)

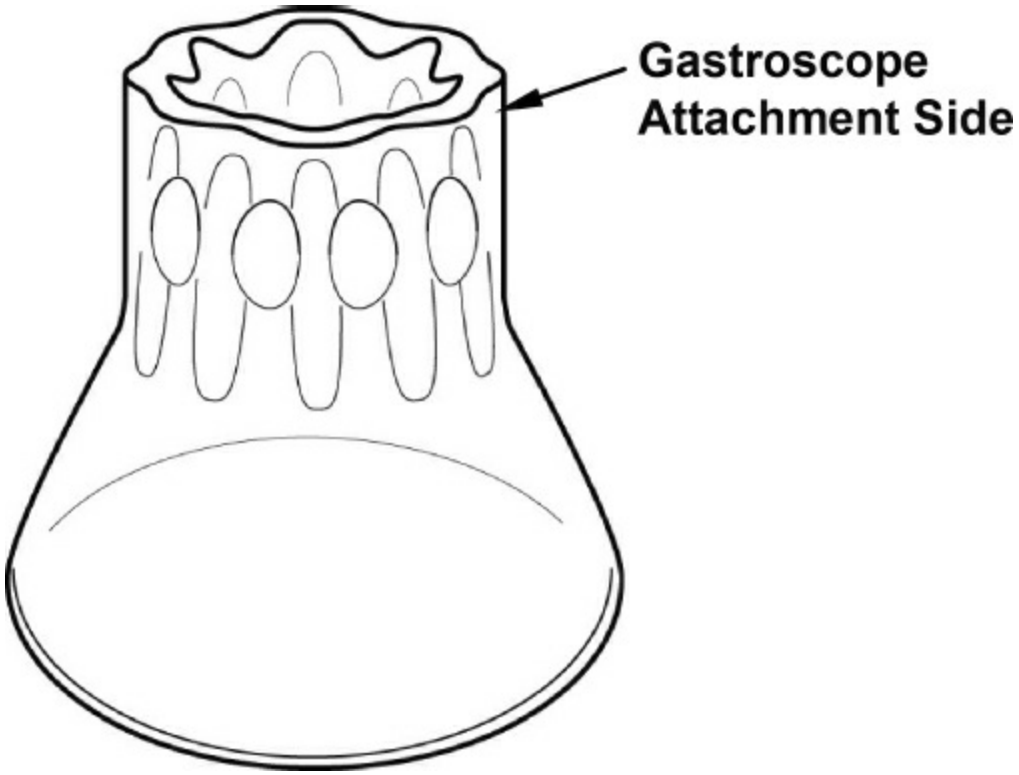

Figure 100.6. Endoscope hood (available in two attachment diameters: 8 to 10.5 and 10.6 to 13.2 mm). (From The EndoBarrier Gastrointestinal Liner Retrieval System: Instructions For Use (50–30–00637 Rev N IFU EndoBarrier GI Liner Retrieval System with Certified Translations.pdf). Lexington, MA: GI Dynamics Inc.)

Table 100.1 describes contraindications to duodenal–jejunal bypass liner implantation. It should be noted that, even with careful patient selection, implantation may prove unsuccessful in a small proportion of patients; this is usually related to unfavorable patient anatomy that prevents delivery of the liner and anchor.

TABLE 100.1 Contraindications to Implantation of the Duodenal–Jejunal Bypass Liner

Pregnancy

Medication Use

Nonsteroidal anti-inflammatory drugs
Anticoagulation therapy
Weight loss medication
Appetite suppressants

Gastrointestinal Conditions

Active *Helicobacter pylori* infection
Inflammatory bowel disease
Severe gastroesophageal reflux disease
Gastrointestinal tract abnormalities (e.g., atresia, stenosis)
Ulcers
Crohn disease
Previous surgery of the gastrointestinal tract that could make the implantation difficult

Family or Patient History of:

Systemic lupus erythematosus
Scleroderma
Any autoimmune connective tissue disorder

Conditions Predisposing to Blood Loss/Anemia

Iron deficiency
Iron deficiency anemia
Bleeding diathesis
Congenital or acquired intestinal telangiectasia
Coagulopathy
Upper gastrointestinal bleeding conditions (e.g., esophageal or gastric varices)

Diseases of Other Organ Systems

Pancreatitis
Symptomatic kidney stones
Symptomatic gallstones
Symptomatic coronary artery disease
Symptomatic pulmonary dysfunction
Any severe systemic or end-organ disease

Bacterial Infection in Any Site

Unresolved Substance Abuse

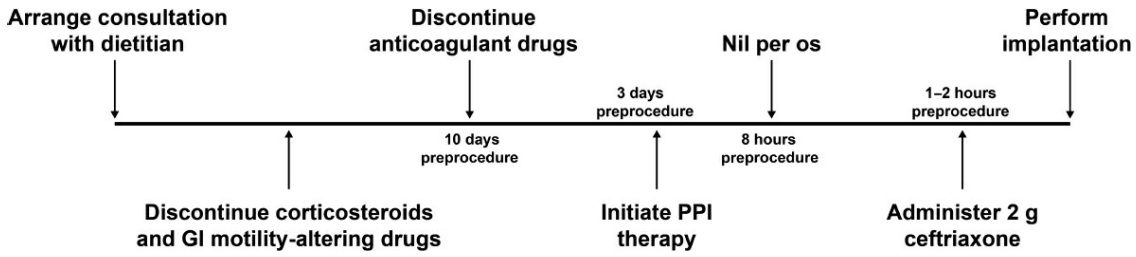

Figure 100.7. Preprocedural preparation for implantation of duodenal–jejunal bypass liner. GI, gastrointestinal; PPI, proton pump inhibitor.

PREIMPLANTATION PREPARATION

Appropriate patient selection, expertise in device placement and removal, and the presence of an experienced multidisciplinary team are of vital importance for safe and effective use of the duodenal–jejunal bypass liner. This includes on-demand availability of a surgical team and an interventional radiologist in case a severe adverse event occurs in

association with implantation or explantation, or during the period that the liner is in place.

Patients should have a consultation with a dietitian prior to liner placement to discuss dietary changes that will be necessary after implantation (Fig. 100.7). The preimplantation pharmacologic regimen must also be considered. Patients should discontinue taking corticosteroids and any drugs that affect gastrointestinal motility prior to liner placement. Antispasmodic agents may be used at the time of implant delivery and for a short time after implantation if the patient experiences discomfort. Patients should not take any anticoagulant medications (e.g., aspirin, heparin, or nonsteroidal anti-inflammatory drugs [NSAIDs]) for 10 days prior to liner placement and for the duration of treatment. Clinically significant bleeding has occurred in patients who have taken inhibitors of platelet aggregation and/or heparin after liner placement and, on occasion, in those who have not. Patients must take a proton pump inhibitor (PPI) (40 mg omeprazole twice/day, or equivalent) for 3 days prior to the procedure and should continue this medication throughout the period of liner implantation, and for 2 weeks after explantation.

Patients must not eat or drink for 8 hours prior to the implantation procedure. A single 2-g dose of ceftriaxone (or equivalent) should be administered intravenously 1 to 2 hours prior to liner placement to reduce the potential for infection. Because it is important that the patient remains still throughout the procedure, the patient should be anesthetized or sedated, as appropriate.

IMPLANTATION TECHNIQUE

The liner is placed endoscopically under fluoroscopic guidance. The equipment needed is described in Table 100.2. With the patient lying on his/her left side, the gastroscope is advanced into the duodenum and a thorough examination of the stomach, pylorus, and duodenum is performed. This is done to ensure that the patient's alimentary canal is free of abnormalities that could interfere with the delivery, function, and removal of the liner. As part of this examination, the papilla and other accessory ducts should be observed to ensure that they are not located in the bulbous duodenum. If this is the case, the patient is not a suitable candidate for liner placement due to concerns of biliopancreatic duct obstruction.

The guidewire is advanced into the duodenum through the gastroscope

and its tip is advanced and looped in the duodenum/proximal jejunum. The gastroscope is then removed over the wire while maintaining the wire's position in the small intestine. After fluoroscopic verification of the position of the guidewire loop, the capsule of the catheter is lubricated and advanced over the guidewire and into the duodenum. The guidewire is then removed. The inner catheter (Fig. 100.3) is advanced slowly under fluoroscopic guidance, pushing the liner and atraumatic ball through the proximal small intestine until it has been fully delivered. Slow delivery of the catheter is important; it may prolapse if advanced too quickly. The atraumatic ball is then released from the distal end of the catheter. Release of the ball, which passes through the gastrointestinal tract by peristalsis and is passed in the stool, is confirmed by fluoroscopy.

The gastroscope is reintroduced into the stomach during delivery of the liner and anchor to ensure that the delivery capsule is fully within the bulb of the duodenum and that the anchor crowns are not visible across the pylorus after the anchor is extruded from the capsule. Under endoscopic visualization, the anchor is deployed so that the barbs on the circumference of the anchor engage the muscularis of the bulbous duodenum, proximal to the ampulla of Vater. Gastrografin contrast (diluted to 20%), followed by air and saline, are injected through the inner catheter to ensure patency of the liner. The inner catheter is then removed from the outer catheter and fluoroscopy is used to confirm that the implant has not bunched during inner catheter withdrawal.

TABLE 100.2 Equipment Needed for Liner Implantation and Explantation

Implantation	Explantation
Liner delivery and retrieval systems	Liner retrieval system
Fluoroscopy unit	Fluoroscopy unit
Video gastrointestinal endoscopy system, including gastroscope with 2.8 mm working channel and outer diameter of 8.6–9.8 mm	Video gastrointestinal endoscopy system, including gastroscope with 2.8 mm working channel and outer diameter of 8–10.5 mm, or colonoscope with outer diameter of 10.6–13.2 mm
Gastrografin, Renografin, or equivalent water-soluble contrast media (not barium)	Esophageal overtube 50 cm in length that will fit an 8.6–10.5-mm endoscope
0.035 in super-stiff nitinol guidewire	
Esophageal overtube 50 cm in length that will fit an 8.6–10-mm endoscope	

After removal of the gastroscope and delivery device, the gastroscope is reintroduced to examine the liner in the duodenal bulb. The delivery capsule must remain distal to the gastroscope during withdrawal to help prevent esophageal perforation by the capsule. Additional introduction of 20% Gastrografin solution into the liner is used to confirm patency and to stretch out the liner section. Removal of the gastroscope completes the procedure. In one study, the total procedure time ranged from 12 to 111 minutes, including 2 to 27 minutes of fluoroscopy time.

POTENTIAL COMPLICATIONS DURING IMPLANTATION

A number of technical errors may occur during liner implantation. These include incorrect positioning of the anchor, incomplete liner delivery, and liner obstruction. In these situations, the liner should be removed from the patient using the custom retrieval system. Upon removal, another attempt at liner delivery may be performed. Another potential problem is crossover of the anchor crowns, which prevents full expansion of the anchor. In this situation, the crossed crown should be lifted and separated from the others using biopsy forceps.

POSTIMPLANTATION MANAGEMENT

Patients are typically discharged from the hospital on the day of the procedure. Because it is currently unknown whether certain foods (e.g., grains, nuts) could interfere with correct functioning of the liner, patients

should follow a diet similar to that recommended for individuals who have undergone Roux-en-Y gastric bypass. A consultation with a dietitian before and after implantation is recommended. If a medical condition that necessitates use of anticoagulants develops during the period of implantation, the device should be removed prior to initiation of the anticoagulant.

EXPLANTATION TECHNIQUE

Removal typically takes less time than delivery but can be more challenging due to anchor migration, tilting, or tissue ingrowth. The liner retrieval system (EndoBarrier Gastrointestinal Liner Retrieval System) (Fig. 100.5) consists of a grasper (a hook within a protective sheath) and custom hood (Fig. 100.6), both of which are compatible with standard gastroscopes. The equipment needed for explantation is described in Table 100.2. The procedure is performed endoscopically under fluoroscopic guidance, with the patient under general anesthesia or sedation.

With the patient lying on his/her left side, a gastroscope is passed into the duodenum, a surveillance examination is performed, and the retrieval drawstrings are identified. The endoscope is removed from the patient and the retrieval hood is attached to its tip. The endoscope is reinserted into the duodenum, the anchor and one of the retrieval drawstrings are visualized, and the grasper hook is used to pull the drawstring inside the protective sheath. As the hook and drawstrings are retracted, the anchor collapses. The endoscope and hood are then advanced so that the proximal anchor barbs are contained within the hood. Collapse of the anchor and capture of all the proximal barbs within the hood are monitored fluoroscopically. The grasper and endoscope are then locked together and retracted as one until the hood and its collapsed anchor are contained in the stomach, where there is more space to reposition the anchor within the hood (if needed), as well as to ensure that the barbs are fully covered by the hood before removal via the esophagus. Use of fluoroscopy and endoscopy within the stomach helps to ensure this. The endoscope, grasper, and implant are then removed together under fluoroscopic visualization. The explant site is reinspected for signs of bleeding. In one study, the time taken for explantation ranged from 3 to 182 minutes, including 1 to 24 minutes of fluoroscopy time.

There are a number of technical considerations during explantation. For example, if both drawstrings have failed or broken, explantation requires

the use of an overtube. In this situation, the endoscope is passed through the overtube, the liner and anchor are everted (using rat-tooth graspers and a polypectomy snare so that the anchor barbs are within the anchor), and the implant is withdrawn inside the overtube under fluoroscopic visualization. If the liner is being removed because of distal food impaction, the anchor is collapsed within the hood and withdrawn into the stomach as in a normal explantation. The drawstrings are then released and, using endoscopic scissors, the liner is cut distal to the anchor. The anchor is then collapsed and retrieved inside the hood as normal, and the sleeve portion of the liner is left inside the patient to be passed naturally.

EFFICACY

The duodenal–jejunal bypass liner has been associated with substantial weight loss and improved cardiovascular risk factors in obese patients with or without concomitant T2DM, as well as clinically relevant improvements in glycemic control in obese patients with T2DM. Improvements in plasma parameters of nonalcoholic fatty liver disease have also been demonstrated. Other potential but as yet unstudied mechanisms of action may include changes in vagus nerve activity, the presence of undiluted bile in the proximal small intestine, increased levels of oxyntomodulin, and altered GI microbiota. It should be noted that a number of published studies evaluated an earlier version of the device that differed from the commercialized version in some technical features (in particular, the bidirectional barbs were shorter) and had a shorter implant duration (3 months vs. 12 months).

Weight Loss

Weight loss in association with liner placement has been demonstrated in patients with morbid obesity and in overweight and obese patients with T2DM. Although the majority of clinical studies involving implantation of the liner were uncontrolled, the effect on body weight has been compared with that of a sham implantation procedure and with dietary intervention alone. The results of these studies demonstrate that, in general, liner implantation is significantly more effective in inducing weight loss than either placebo intervention (sham implantation) or dietary intervention alone (Table 100.3). Uncontrolled studies in morbidly obese patients have documented mean percent excess weight losses of up to 47%, mean total body weight decreases of up to 20% (Fig. 100.8), and mean BMI

reductions of 9 kg/m^2 after implantation periods of up to 1 year.

The mechanisms by which the liner induces weight loss have not been fully established. However, early ideas that the device may cause weight loss solely via malabsorption are not supported by more recent work. In particular, there is evidence that the weight loss associated with liner implantation may be mediated in part by changes in the levels of hormones that affect satiety, including peptide YY (PYY) and glucagon-like peptide-1 (GLP-1). In this manner, the mechanism may be similar to that of bariatric procedures that exclude the proximal small intestine. However, in contrast to the reduction in ghrelin levels that typically occurs after Roux-en-Y gastric bypass, patients who have undergone liner implantation show increased levels of this hormone. Liner implantation has also been associated with reduced food intake, increased satiety, and delayed gastric emptying.

TABLE 100.3 Effects of Duodenal–Jejunal Bypass Liner Implantation on Body Weight in Controlled Studies

Study	Duration of Implantation	*n*	Effect on Body Weight			
			Excess Weight Loss (%)		Change in Body Weight (kg)	
			Liner	Control	Liner	Control
Gersin et al., 2010[b]	12 weeks	Liner: 13 Control: 24	11.9 ± 1.4[a]	2.7 ± 2.0	–8.2 ± 1.3[a]	–2.1 ± 1.1

Glycemic Control

In patients with T2DM, improvements in glycemic control are associated with significant reductions in the risks of macrovascular and microvascular events. Moreover, posttrial monitoring of patients enrolled in the United Kingdom Prospective Diabetes Study (UKPDS) showed that the beneficial effects of intensive glucose control continue well beyond the period of control.

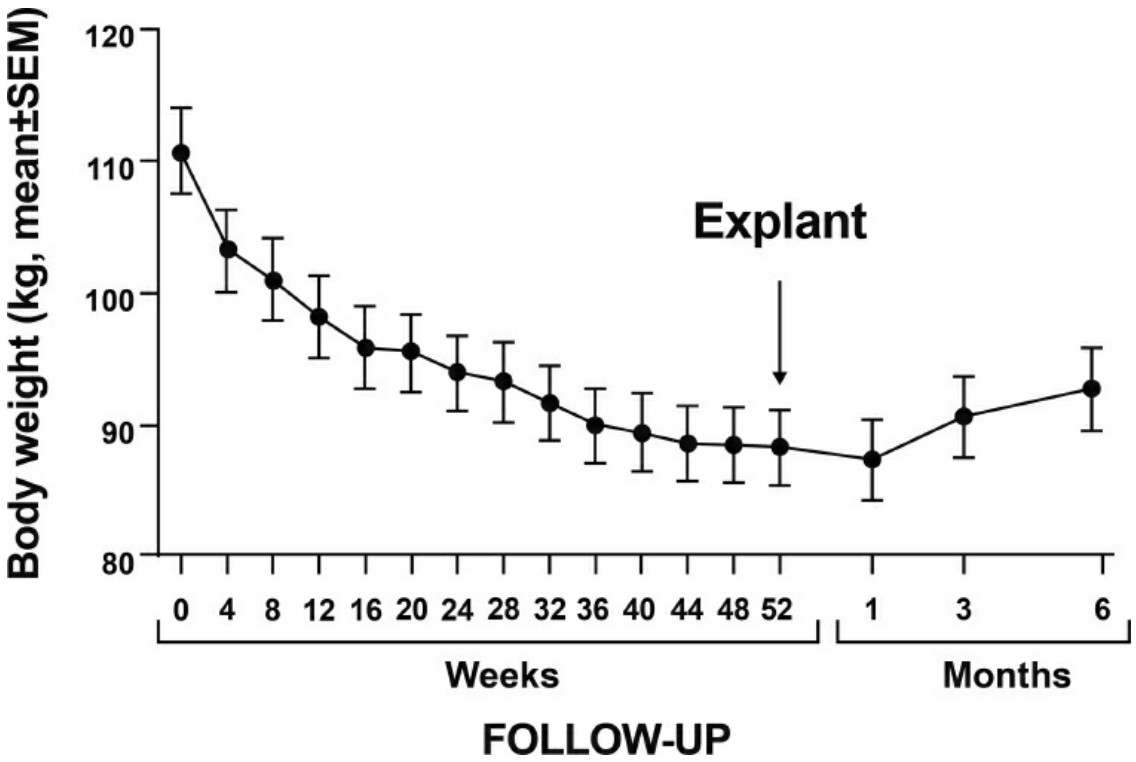

Figure 100.8. Mean change in body weight (±SEM) over the 52-week implantation period and for 6 months after explantation (n = 24). SEM, standard error of the mean. (From Escalona A, Pimentel F, Sharp A, et al. Weight loss and metabolic improvement in morbidly obese subjects implanted for 1 year with an endoscopic duodenal-jejunal bypass liner. *Ann Surg* 2012;255(6):1080–5.)

To date, no clinical trial has investigated the effects of the duodenal–jejunal bypass liner on the incidence of macrovascular and microvascular events. However, improvements in glycemic control have been demonstrated consistently in studies involving patients with T2DM, including those who undergo early explantation. The improvements in glycemic control are rapid in onset and of a magnitude that is clinically significant. In studies involving patients with T2DM, liner implantation has been associated with significant reductions from baseline in fasting glucose, insulin levels, insulin resistance, and HbA1c. In one such study, the percentage of subjects with HbA1c <7% increased from 4.5% at baseline to 73.0% at the final assessment. Figure 100.9 shows the gradual improvement in HbA1c during the period of liner placement. The mean reduction in HbA1c in this study was 2.1%, from a mean value at baseline of 8.9%. Importantly, improvements in glycemic control appear to be independent of HbA1c at the time of implantation.

Postprandial glucose excursions are also more likely to decrease in liner-implanted patients than in controls, and use of diabetes medication has been shown to decrease by up to 42%. Moreover, results from a small number of patients suggest that the improvements in glycemic control may be maintained for up to 6 months after device removal. The rapidity of the improvement in glycemic control suggests that this beneficial effect may be at least partially independent of weight loss. Increases in GLP-1, accompanied by reductions in hepatic glucose production and increases in insulin sensitivity, are believed to underlie this effect.

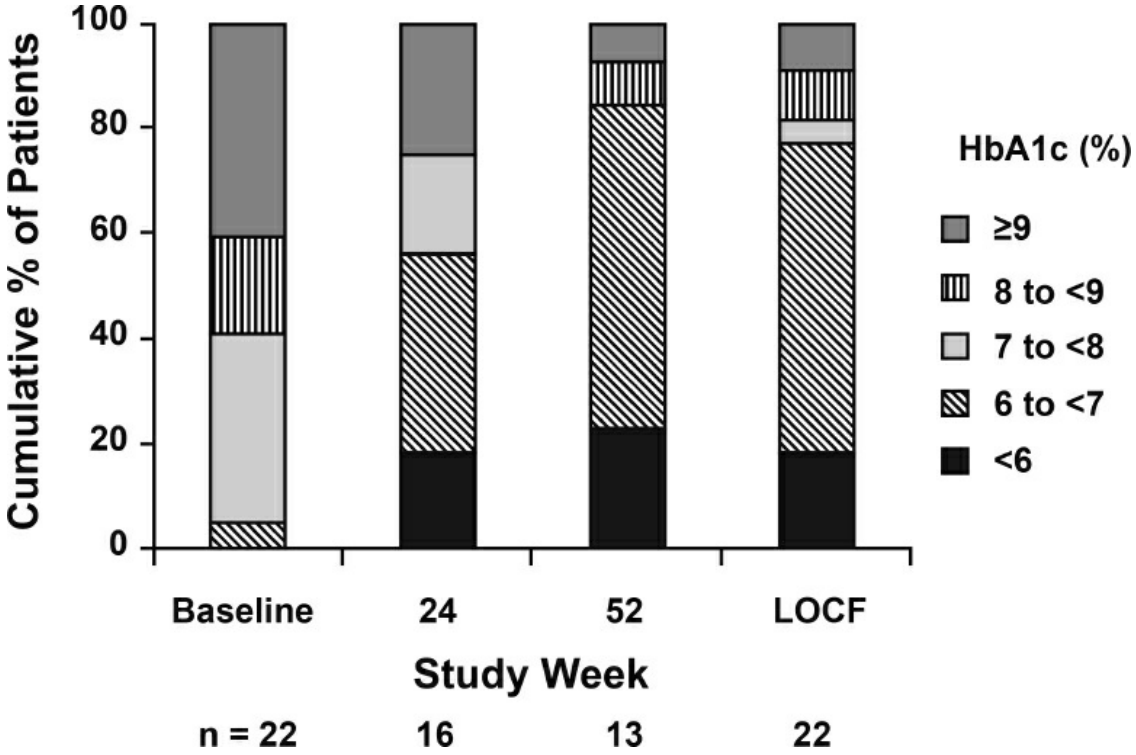

Figure 100.9. Distribution of HbA1c levels during a 1-year study involving obese patients with type 2 diabetes. LOCF, last observation carried forward. (From de Moura EGH, Martins BC, Lopes GS, et al. Metabolic improvements in obese type 2 diabetes subjects implanted for 1 year with an endoscopically deployed duodenal-jejunal bypass liner. *Diabetes Technol Ther* 2012;14(2):183–9.)

Cardiovascular Risk Factors

The bypass liner has shown beneficial effects on a range of cardiovascular risk factors. These include: levels of total cholesterol, low-density lipoprotein cholesterol, and triglycerides; systolic and diastolic blood pressure; and waist circumference. In one study, these improvements led to

a decrease in the prevalence of metabolic syndrome from 83% at baseline to 42% at 52 weeks after liner implantation, and in a separate study, to a reduction in patients' 10-year cardiovascular risk of between 19% and 33%, depending on the search engine used.

ADVERSE EVENTS

The adverse event profile of the duodenal–jejunal bypass liner does not appear to differ between studies that primarily enrolled patients with obesity and those that primarily enrolled patients with T2DM. No deaths have been reported in association with liner placement.

In some case series, early explanation related to adverse events occurred in up to 40% of patients for whom a 12-month implantation period was planned. With increased experience of the endoscopy team with the device, early explantation rates as low as 8% have been achieved.

Approximately 50% of patients report symptoms of abdominal pain, nausea, and vomiting in the first 2 weeks after liner placement. These symptoms have been successfully managed with a standard regimen of tramadol, butylscopolamine, and metoclopramide. However, if abdominal symptoms persist despite lifestyle changes and medication, early explantation may be necessary. Acid reflux and constipation may also occur in the period immediately after liner placement. A low residue, semi-liquid diet for 2 weeks after implantation is usually helpful to control these symptoms, and high-dose PPI therapy (40 mg omeprazole twice/day, or equivalent), with or without addition of sucralfate, can aid in management of acid reflux. A fluid intake of at least 2 L/day may help to combat constipation, although enemas and laxatives may also be necessary.

Although these safety data are reassuring, serious adverse events can occur. Suboptimal technique, faulty equipment, and anatomical abnormalities may lead to tissue damage during implantation or, more commonly, during explantation. The esophagus is the most likely site of trauma; mucosal damage and rupture of the esophagus have both been reported. For this reason, the presence of or access to a multidisciplinary team (including an interventional radiologist) during implantation and explantation procedures is mandatory.

Other serious adverse events include invagination of the liner, implant obstruction, pancreatitis, development of hepatic abscesses, duodenal penetration/fistula formation (with or without secondary gall bladder

impaction and cholecystitis), and gastrointestinal bleeding. The majority of these adverse events require device removal in addition to surgical and/or medical management, as appropriate. Table 100.4 shows the incidence of adverse events that resulted in device removal after implantation in more than 3,000 patients. To date, all reported serious adverse events associated with liner implantation/explantation have been successfully managed.

TABLE 100.4 Serious Adverse Events/Complications Resulting in Device Removal: Postmarket Surveillance Data, November 2008 to June 2015

	Incidence During Postmarketing Surveillance	
Adverse Event	*n*	% of Total Population Implanted (*N* = 3,150)
Hepatic abscess	26	0.8
Intolerance	50	1.6
Liner obstruction	24	0.8
Gastrointestinal bleeding	48	1.5
Migration	50	1.6
Pancreatitis	12	0.4
Perforation	10[a]	0.3
Surgical removal	10	0.3
Total	230	7.3

[a]Four subjects experienced a perforation during either the implantation or explantation procedure.

SUMMARY

The duodenal–jejunal bypass liner represents an effective, endoscopic treatment for both obesity and T2DM. Weight loss and improvements in glycemic control are substantial and are typically accompanied by improvements in cardiovascular risk. Implantation and explantation are uneventful in the majority of patients, and the adverse event profile is manageable. Availability of a surgical team and an interventional radiologist is imperative in the event of a serious adverse event for optimal management. Because the device is temporary and the changes it induces are fully reversible, the implant can be removed in the face of adverse events, which typically leads to resolution of the problem.

A full understanding of the duodenal–jejunal bypass liner's role in the management of obesity and T2DM requires further research. This will require controlled studies involving implantation of the commercialized

version of the liner in large numbers of obese patients both with and without T2DM, follow-up for an extended period after explantation, and incorporation of microvascular events, macrovascular events, and all-cause mortality as endpoints.

EDITOR'S COMMENT

Obesity is the leading epidemic in the Unites States with over one third of Americans overweight or obese. Billions of dollars are spent trying to lose weight and on the health care consequences of obesity such as type 2 diabetes, hyperlipidemia, hypertension, back pain, knee pain, and obstructive sleep apnea. While it is clear that diets and medical therapy are for the most part useless among patients with severe obesity, operations such as the laparoscopic adjustable band, gastric sleeve, Rou-en-Y gastric bypass, and duodenal switch can achieve superior and more durable weight loss in the morbidly obese patient than might be expected from a 12-month duodenal–jejunal liner.

It is estimated that only about 1 in every 400 patients who meet medical necessity for weight loss surgery actually undergo an operation. Therefore, most patients who need treatment are not getting it, in part because surgery is seen to be too drastic and fraught with complications and even weight regain. Therefore, there is a need for an effective and less invasive option to help with weight loss.

The appeal of the EndoBarrier sleeve is that it is a device that is conceptually simple. It is a 61 cm duodenal–jejunal liner anchored to the duodenal bulb that prevents the normal mix and absorption in the proximal small bowel. The device claims in "uncontrolled studies" to promote weight loss (47% excess weight loss; 9 kg/m^2 BMI decrease), improve glycemic control, and reduce cardiac risk factors. If true, one needs to ask, "why has the EndoBarrier sleeve not taken off?"

Dr Gersin claims that the EndoBarrier sleeve is more effective than diets and less invasive than commonly performed weight loss operations. The claim to be better than placebo and diets is a minimal claim since diets fail 95% of the time. To date there is no data to suggest the duodenal–jejunal sleeve has any superiority to lap band, gastric sleeve, gastric bypass, or duodenal switch operations for weight loss and resolution of comorbid conditions. And while there is no skin incision on the abdominal wall, the EndoBarrier should not be considered risk free. The procedure is known to cause gastrointestinal laceration, perforation, and bleeding. The patient requires an anesthetic and sedation which poses its own airway risk among patients with obstructive sleep apnea. The procedure requires significant fluoroscopic time and exposes both the patient and the provider to radiation. Half of the patients report pain, nausea, and reflux. Others require enemas and laxatives to address constipation. Serious complications such as esophageal rupture have also been reported. Dr. Gersin emphasizes that the procedure requires a trained endoscopist with surgeons and interventional radiologists on backup call for the rare but potentially serious complications during EndoBarrier sleeve placement.

Like other weight loss operations, the science is lacking to fully understand the mechanism of action of the EndoBarrier. Dr Gersin notes that satiety after

the EndoBarrier may occur by changes in PYY and GLP-1 hormones. However, increasing the ghrelin hormone after EndoBarrier should stimulate hunger. Other mechanisms of action are proposed such as changes in vagal activity, bile composition, and gut microbiota. Further research excluding parts of the GI tract as achieved by the EndoBarrier device will be important to advance our understanding of the physiologic and hormonal effects leading to weight gain and regulating weight loss.

Randomized studies comparing EndoBarrier with lap band and the intragastric balloon are needed to compare the relative risk and benefits of other "less invasive" MIS weight loss options in the diabetic patient with a BMI >30. Meanwhile, all patients undergoing EndoBarrier sleeve should be entered in the ACS ASMBS MBSAQIP data registry and these results should be made publically available so that outcomes and resolution of diabetes can be assessed with this technique.

Daniel B. Jones

101 Revisional Bariatric Surgery

John Rodriguez and Matthew Kroh

INTRODUCTION

Bariatric surgery has proven to be efficacious and safe for treatment of morbid obesity and weight-related comorbid conditions. Accruing data demonstrate its successful impact on metabolic disease. Laparoscopic surgery has helped improve perioperative outcomes making bariatric surgery an increasingly common procedure. It is estimated that more than 190,000 bariatric operations were performed in the United States and more than 450,000 worldwide in 2013. The overall safety and quality of these operations have improved with metrics including reporting of data and centers of excellence, but even as such, the sheer number of procedures performed dictates that there will be a number of patients who ultimately encounter complications requiring revisional surgery, or have failure of weight loss. Morbid obesity is a chronic disease requiring lifelong therapy, and bariatric surgery is an important component of these therapies.

As such, an additional consideration for revisional surgery is weight loss failure, measured both by percent excess weight loss (%EWL) and by persistence of comorbid disease. Although definitions vary based on author and operations, <50% EWL is often considered failure after gastric bypass. Weight loss failure is further categorized by time frame, either at the time of the nascent procedure or by means of recidivism. When these outcomes occur, bariatric procedures may then ultimately require revision. Revisional procedures that result in a different operation from the index procedure are known as conversion. Revisional procedures that address complications or problems with the index procedure, but don't change the type of procedure performed, are referred to as corrective. Procedures that restore, as best possible, original anatomy, are referred to as reversal.

Revisional bariatric surgery includes technically challenging operations in previously operated patients who often also have significant comorbid disease. When performed by experienced surgeons in comprehensive bariatric care centers, revisional procedures can impart significant improvement in weight-related disease and overall quality of life for

patients, with acceptable risk and complication rates. This chapter focuses on the management of patients being considered for revisional bariatric surgery, both for complications from previous bariatric surgery and also from initial weight loss failure and weight recidivism.

Preoperative Evaluation

Ultimately, the decision to perform revisional or corrective operations should be based on careful evaluation of each individual patient's specific risk-benefit profiles, in the context of a multi-disciplinary team approach. Reoperations either for revision or for conversion after bariatric surgery require careful preoperative planning, accurate understanding of the target anatomy, and anticipation of potential pitfalls. In the setting of revision for complications, a detailed history focusing on the predominant symptoms often will give direction to the necessary work-up prior to reintervention. Dysphagia is a common complaint for patients presenting with obstructive complications, such as strictures, adhesions, or internal hernia. Gastrointestinal bleeding, either acute or chronic, may indicate the presence of marginal ulceration at an anastomosis, or foreign body erosion into the gastric lumen. For patients with weight recidivism, a thorough evaluation of their postoperative course, including weight nadir and time frame to regain, is important. Patients with failure of weight loss after an initial operation versus those who lost and subsequently regained weight will have different evaluations to review prior to consideration of revision.

Surgical complications often result in nutritional derangements. This may be a result of poor oral intake, or maladaptive eating behaviors, or secondary to sepsis or chronic illness. Any surgeon performing revisional bariatric procedures should be prepared to identify signs of malnutrition that can be detected during a clinical visit. In addition to physical exam findings of pallor, temporal wasting, dermal anomalies, or Kwashiorkor, we routinely obtain nutritional parameters when ordering laboratory studies as part of preoperative workup. Commonly deficiencies of iron, calcium, vitamin D, vitamin B_{12}, and fat soluble vitamins are identified, in addition to protein-calorie malnourishment. Obtaining objective data to quantify the degree of malnutrition is helpful, especially when setting goals prior to surgery. Nutritional optimization prior to any surgical intervention will result in improved outcomes, especially during reoperative procedures with higher complication rates. This may be achievable with nutritional counseling and oral supplements in some

patients, but other patients will require placement of temporary enteral access, most commonly a nasojejunal feeding tube, but also potentially a staged surgical procedure before definitive revision.

Existing clinical documentation is important to successful preoperative planning. Initial operative reports, prior imaging studies, and endoscopy reports are helpful both to guide the ultimate surgical procedure and to plan what additional examinations should be performed before surgical intervention. Understanding the existing surgical anatomy is important to successful bariatric revisional surgery, as there is wide variation in technique of the current types of bariatric procedures performed among different surgeons, as well as a spectrum of different historical bariatric procedures that are no longer commonly performed. Esophagogastroduodenoscopy (EGD) is a valuable tool that provides a breadth of information. We strongly believe that bariatric surgeons should perform diagnostic and therapeutic endoscopy, especially in this patient population. EGD will help obtain measurements of pouch and stoma sizes, evaluate for strictures and angulations, diagnose foreign body erosions, and provide a platform for therapeutic intervention for most of these conditions.

Radiologic studies are a useful complement. Upper gastrointestinal (UGI) contrast x-rays provide additional information regarding anatomy, and may show functional abnormalities beyond EGD. UGI series are effective to evaluate stenosis, leaks, and gastrogastric fistulas. We routinely recommend obtaining an UGI series prior to revisional surgery. In selected cases, a computed tomography (CT) exam with oral and intravenous contrast may be helpful, especially when looking for foreign bodies that may have been implanted, and to evaluate the extra-luminal environment, including abscesses, and the relationship of adjacent organs, for example, whether a Roux limb is retro- or antecolic.

Laboratory studies should focus on detecting any abnormality that needs to be corrected prior to surgery. We routinely obtain a complete blood count and metabolic panel. We also favor a complete nutritional screen, including prealbumin, transferrin, vitamin B_{12}, vitamin D, and iron. Patients may have significant metabolic derangements that need to be addressed by either oral supplementation or a temporary enteral feeding tube.

Postoperative Care

We elect to place closed-suction drains after revisional bariatric operations, especially those involving an anastomosis or long suture line. In the absence of a complication, we remove drains prior to discharge from the hospital. In most instances, a single drain is all that is needed. Although rarely required, thoracostomy tubes may need to be placed when there is significant dissection into the mediastinum with violation of the pleura.

It is well understood that leak rates are higher in revisional surgery, ranging from 2% to 22%. Although routine UGI studies have poor sensitivity to detect leaks after primary bariatric procedures, the increased perioperative complication rates, including increased leak rates, have prompted our group to perform UGI study routinely postoperatively. The timing varies according to the post-surgical anatomy. For gastrojejunal anastomosis, we obtain the study on postoperative day 1. For esophagojejunal anastomosis, we typically obtain the study on postoperative day 3. Despite this practice, clinical suspicion of a leak should prompt the surgeon to act accordingly regardless of radiologic findings.

Oral intake is started after the UGI study confirms appropriate transit of contrast with no evidence of leak. After normal UGI study, patients start on a phase 1 diet that consists of small volume clear liquids. Patients should drink slowly and sip 2 to 3 ounces at a time. Patients slowly increase the total volume while in the hospital. Prior to discharge, this is advanced to full liquids ad lib.

Establishing enteral access tubes at the time of revisional surgery is determined by several factors, including overall nutritional status, and the type and complexity of the revisional case performed. Patients who are malnourished and required enteral access prior to surgery often also require extended nutritional augmentation afterward. Those who are at risk for complications based on surgical reconstruction also benefit from enteral access. We favor placing feeding tubes in the gastric remnant when feasible. If a gastrectomy is done, or no remnant is available, a feeding jejunostomy in the proximal common channel or Roux limb is performed. If a feeding tube is present, tube feeds are started early in the postoperative course—typically at a low rate, and slowly advance to goal. Many patients will require tube feeds after discharge from the hospital, and proper arrangements need to be made to provide education and make pertinent discharge plans. In many instances, the tube serves as a backup plan in

case patients encounter complications or they have difficulty achieving adequate oral intake. Unused feeding tubes are removed at 4 to 6 weeks postoperatively.

REVISIONS AND CONVERSIONS FOR COMPLICATIONS

Despite an overall excellent safety profile, major complications occur at a rate of 3.4% to 12%, and vary widely between procedures. Complications range in severity as well, and major complications requiring surgical revision vary tremendously depending on the original procedure. Overall serious complication rates for all procedures range from 2% to 4%. Commonly, revisions performed for treatment of complications include indications such as leak, recalcitrant ulcer with bleeding and/or stricture, stenosis, fistula, obstruction, severe malnutrition, persistent gastroesophageal reflux disease (GERD), and dumping syndrome. Complications unique to laparoscopic adjustable gastric banding (LAGB) include esophageal dilation, prolapse and pouch dilation, intolerance, and erosion.

For nearly all revisions, we favor a laparoscopic approach, even in cases that have been done through a laparotomy previously. Entry into the peritoneal cavity is achieved with an optical trocar, away from the previous surgical access site. Once entry is achieved, the remaining trocars are placed depending on visualization. In cases where significant adhesions are found, we place additional 5-mm trocars as needed to lyse adhesions and identify the existing anatomy. Once adhesions are taken down, we favor a 5-mm port upper abdominal trocar placement in a gentle "U" fashion, with the surgeon at the right side of the table. In most instances, the left lobe of the liver is adhered to surrounding structures, which needs to be addressed prior to insertion of the liver retractor. We use the Nathanson liver retractor, which is inserted through an incision in the epigastrium, away from our working trocars. The surgeon utilizes a 5-mm trocar for his left hand, and a 12-mm trocar for his right, which allows transmission of both linear staplers and curved needles for free-hand suturing. The camera port is usually a 12-mm trocar that accommodates a 45-degree angled scope. The assistant uses two trocars that vary in diameter depending on the case. The assistant's left hand can be upsized to a 12-mm trocar in cases where challenging stapling angles are needed. The assistant's right hand can be upsized to a 15-mm trocar to allow space for

insertion of the EEA stapler and/or specimen extraction.

We routinely use endoscopy in the operating room throughout the procedure, especially during revisional surgery. Upper endoscopy is used to identify the anatomy and define landmarks, such as previous staple lines, eroded foreign body, chronic fistulas, or strictures. We also inspect our suture lines and anastomosis for intraluminal bleeding and leak after reconstruction is complete.

Complications of Roux-en-Y Gastric Bypass

Revisions of Roux-en-Y gastric bypass (RYGB) are typically secondary to gastrojejunal anastomotic complications, including leak, stricture and ulcer, or fistula formation most commonly to the gastric remnant. The key features to understand prior to surgery are pouch size, roux limb length, anatomic location of the limb (antecolic or retrocolic), and the abnormal pathology to be addressed.

Gastrojejunostomy Revision

Revision of the gastrojejunostomy is indicated for recalcitrant, nonhealing ulcers or chronic strictures that fail endoscopic therapy. Laparoscopic revision, even after previous open surgery, is usually possible, when performed by an experienced surgeon. After entry into the peritoneal cavity and port placement, we focus on identifying the gastric pouch. There are typically adhesions to the left lateral segment of the liver that need to be addressed early in the case. We use a combination of sharp dissection and electrocautery using an L hook to elevate the left lobe of the liver from the gastric pouch and allow placement of the Nathanson liver retractor. The goal of the operation is to resect the gastrojejunal complex (Fig. 101.1) and identify well-vascularized tissue that can be reanastomosed without tension. One of the pitfalls to avoid is injury to the left gastric pedicle, which would result in devascularization of the gastric pouch. Early division of the proximal roux limb will allow entry into the retrogastric space (Fig. 101.2). Marginal ulcers often cause intense inflammatory reactions, and this may be manifest both anteriorly and posteriorly. In this instance, releasing the pouch from retroperitoneal structures, including the pancreas, may be required. The surgeon should take special care to identify vascular structures, and in particular, the splenic artery can be easily injured during this portion of the dissection. After the left gastric pedicle is identified and preserved, the pouch can be

divided safely. We recommend adjusting staple height to the thickness of the tissue, taking into account that taller staple heights may be required to accommodate abnormal, reoperative gastric tissue. We selectively oversew staple-lines based on tissue character.

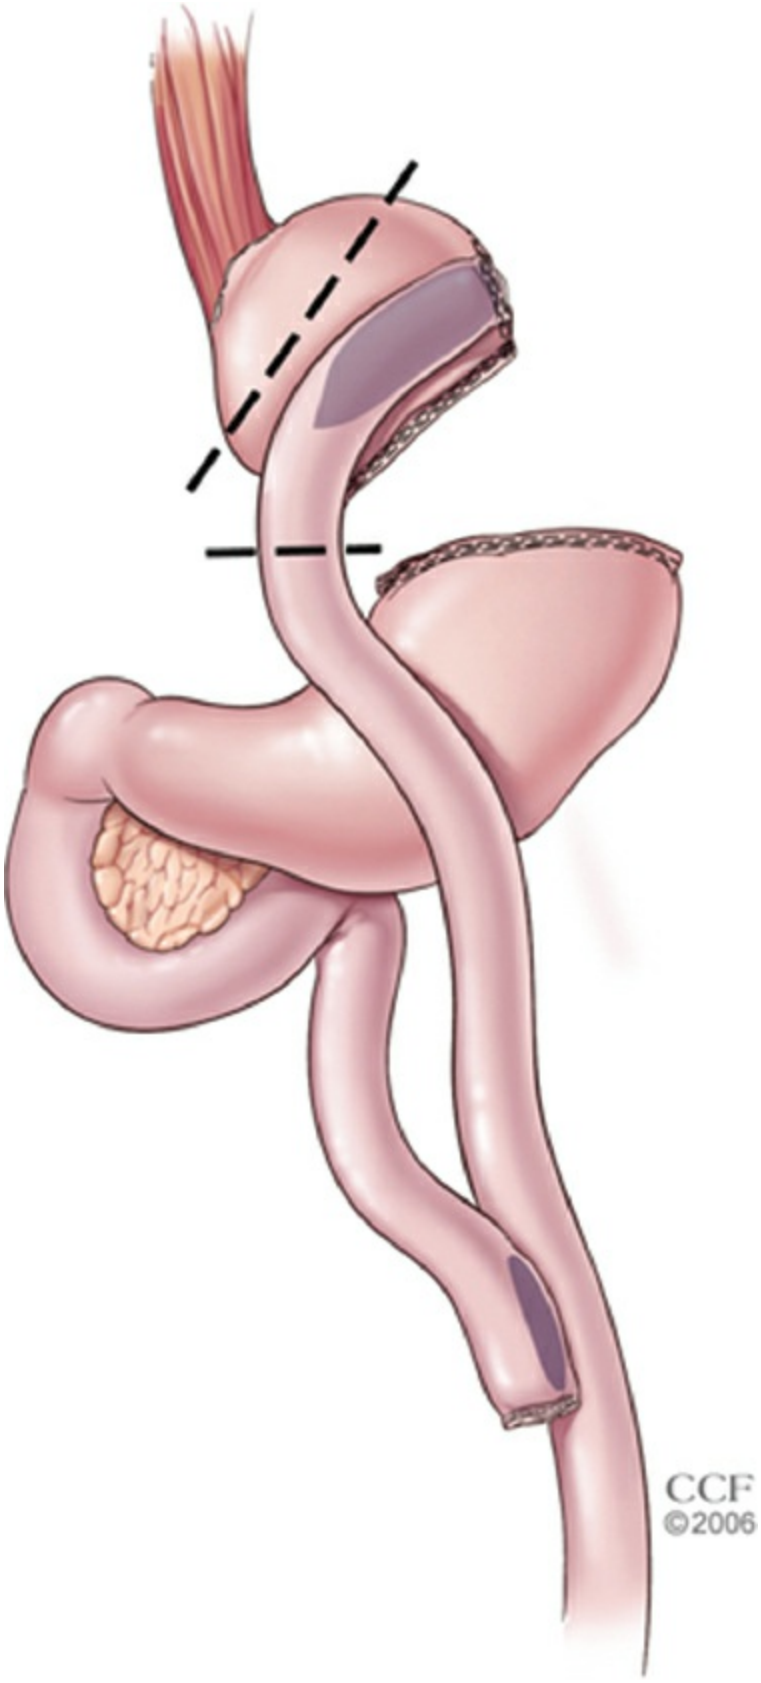

Figure 101.1. Resection of the gastrojejunal anastomosis for revision of gastrojejunostomy.

After the gastrojejunal anastomosis is resected, the specimen is retrieved, or placed over the right lobe of the liver for later extraction. The next step focuses on the Roux limb. Length of the Roux limb and tension are paramount to constructing a tension-free anastomosis. The mesentery of the antecolic Roux limb should be mobilized off of the transverse colon and mesocolon. The total length of the Roux limb should be measured to ensure appropriate distance to minimize bile reflux. Retrocolic Roux limbs may require additional dissection to avoid potential tension on the anastomosis. The Roux limb should be lysed free from the mesocolic defect to allow it to be transmitted freely to the newly formed pouch. After construction of the gastrojejunostomy, the mesocolic defect should be closed with permanent sutures to prevent internal herniation.

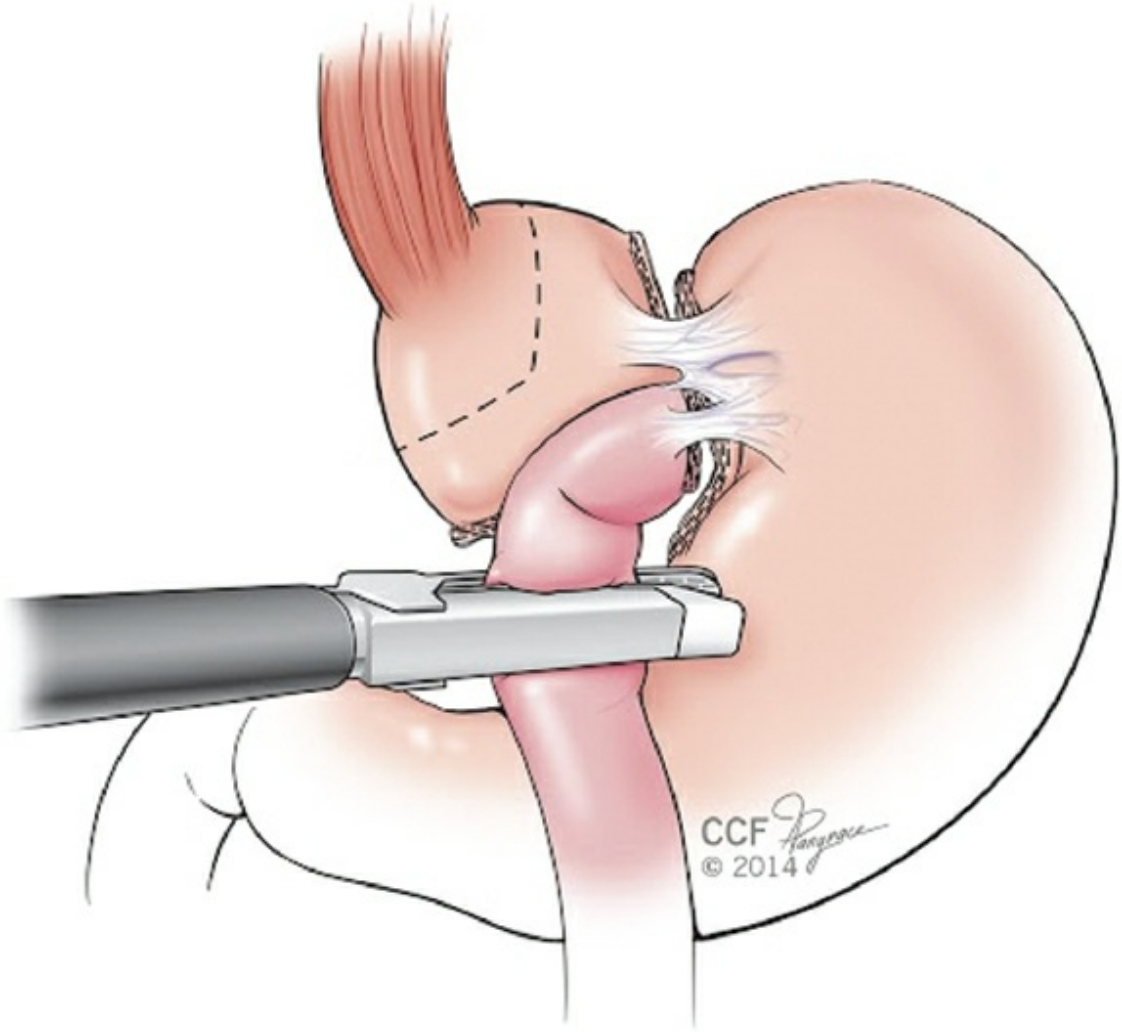

Figure 101.2. Early division of Roux limb to enter retrogastric space.

Once the Roux limb is successfully advanced, the gastrojejunostomy is created. We mostly use a 25-mm EEA stapler to create an end-to-side gastrojejunostomy. We use a free-hand suturing technique in cases of revisions without known underlying etiology or suspected inflammatory response to foreign body, including staples. The patient is placed back in steep reverse Trendelenburg position and the pouch inspected. An endoscopic leak test is often done to the pouch alone, prior to anastomosis, as well as after creation of the gastrojejunostomy. A commercial device with an orogastric tube mated to the stapler end is inserted through the mouth and advanced. The tip of the orogastric tube is guided to the end of the pouch and a gastrotomy is made. The orogastric tube is then pulled until the anvil of the stapler comes into view and the anchoring stitch can be cut. The left upper quadrant port site is converted to an access site to allow insertion of the EEA stapler. The surgeon then opens the tip of the roux limb and the EEA stapler is inserted, after assurance that there is no twist or tension on the Roux limb (Fig. 101.3). After mating the anvil, the anastomosis is then created. The candy-cane end of the Roux limb is closed using linear stapler. We routinely reinforce the gastrojejunostomy by placing absorbable, interrupted Lembert stitches. The Roux limb is occluded and after submersion of the anastomosis in saline, an endoscopic leak test is performed. The staple lines are also inspected for bleeding. If a feeding tube is indicated, a remnant gastrostomy can be placed at this time (Fig. 101.4). A closed suction drain is then inserted and positioned along the anastomosis and left subphrenic space.

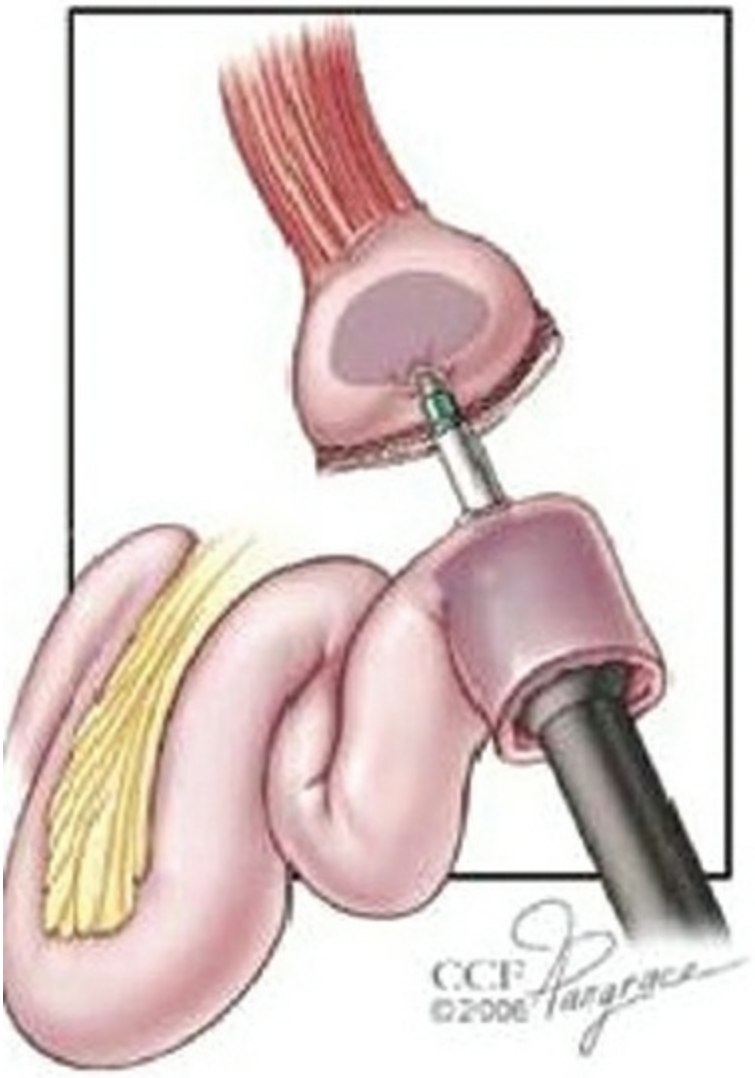

Figure 101.3. Insertion of EEA stapler into tip of Roux limb and coupling.

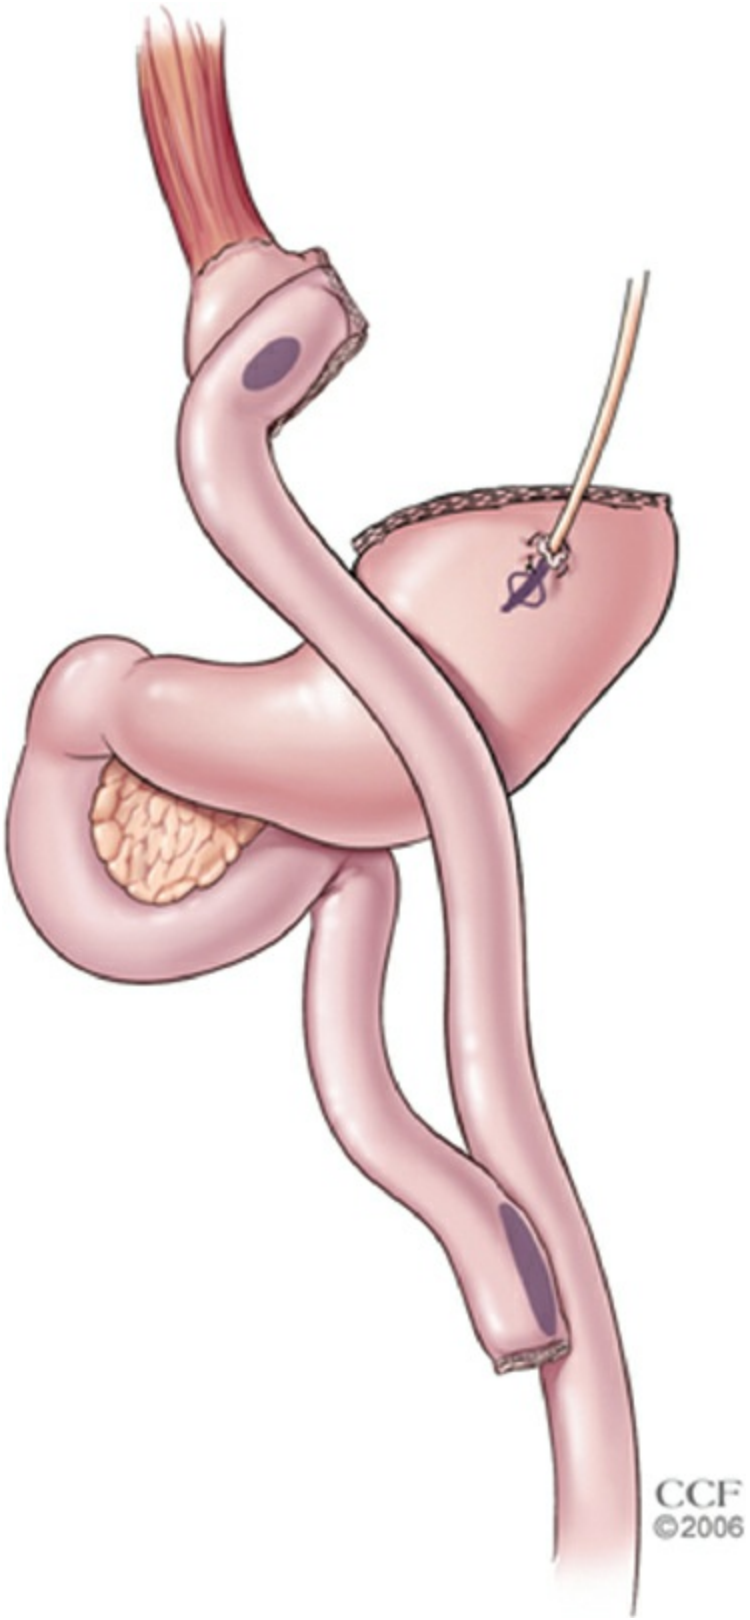

Figure 101.4. Completion of revision gastrojejunostomy, including placement of remnant gastrostomy tube.

Revision for Gastrogastric Fistula

Gastrogastric fistulas may occur after both divided and undivided gastric bypass. Management usually requires some degree of remnant gastrectomy with or without revision of the gastrojejunostomy. The etiology and preoperative identification of the fistula site guides the operation. Important considerations include the location to the gastrojejunostomy relative to the esophagus, presence of foreign body, and the general fibrosis and abnormality of the gastric tissue. Fistulas resulting from chronic marginal ulcers and anastomotic complications such as leaks will typically require revision of the gastrojejunostomy as well as remnant gastrectomy. Fistulas that develop along the vertical staple line after a divided bypass may be managed by pouch and/or remnant gastrectomy alone.

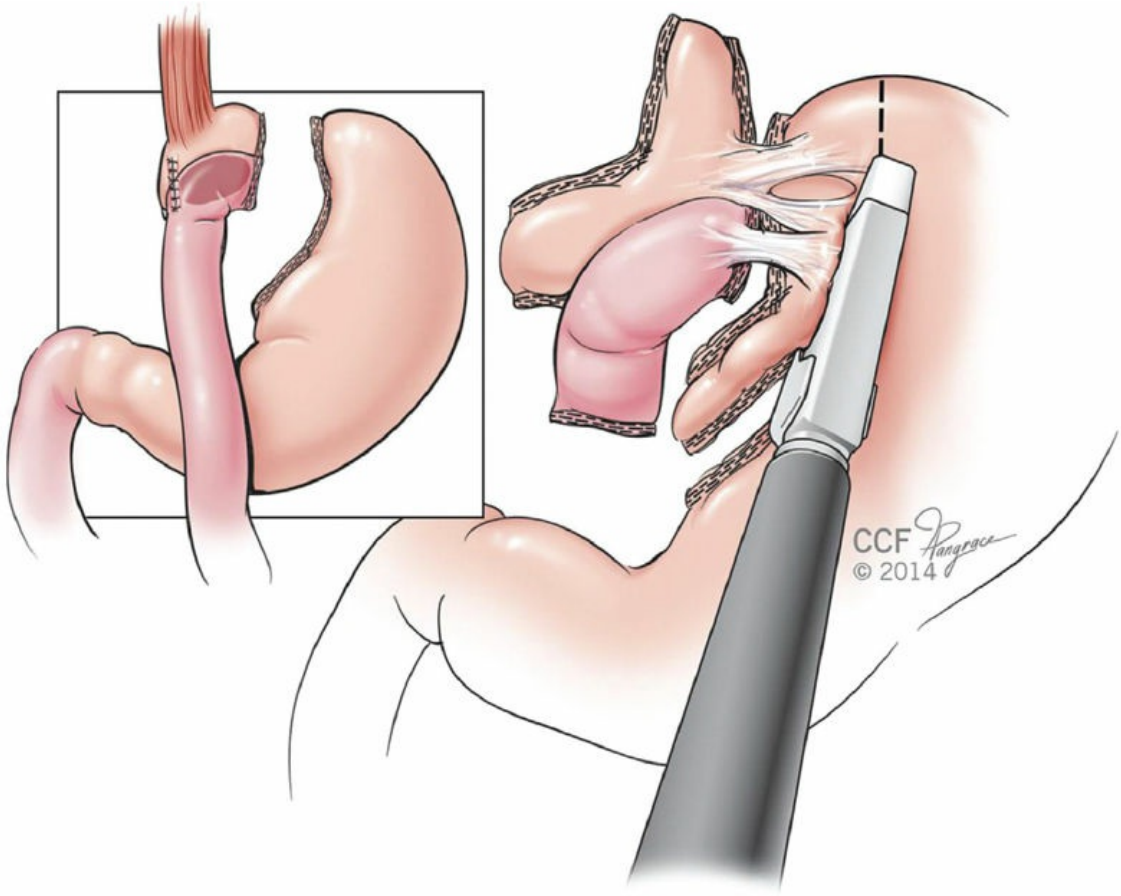

Figure 101.5. Transection of remnant, including fistulous connection to pouch and prior gastrojejunostomy.

After placement of trocars and identification of the relevant anatomy, attention is directed to the gastric remnant. Early division of the gastrocolic ligament and entry into the retrogastric space can help identify

the anatomy and avoid an inadvertent injury to the pouch or gastrojejunal complex. After the greater curvature is mobilized and the short gastric vessels divided, the gastrohepatic ligament is opened. Division of the stomach distally is performed with sequential deployment of a linear stapler.

Once the distal stomach is divided, the vertical staple line and fistula can be identified and retracted laterally. In some cases, a neo-pouch can be created by extending the vertical staple line medially without revising the gastrojejunostomy. During this step, it is crucial to identify the angle of His to avoid encroaching on the esophagus with the proximal staple line. If the gastrojejunostomy is involved as part of the fistula, or in cases of undivided gastric bypass, revision of the gastrojejunostomy will need to be performed as previously described, in addition to remnant gastrectomy (Fig. 101.5).

Complications of Sleeve Gastrectomy

Complications of sleeve gastrectomy (SG) typically result from leak, twisting of the tubularized stomach, or angulation or stenosis causing persistent dysphagia and failure to thrive. In severe cases, nonhealing gastric fistulas to the skin or chest may result as a consequence of a distal stricture. These tend to form in the most proximal aspect of the staple line near the esophagogastric junction and may be challenging to manage. Revisions require accurate identification of the anatomy.

Long segment strictures that fail endoscopic therapy may be managed by a longitudinal seromyotomy or transverse gastroplasty (Fig. 101.6). Clinical experience with this procedure is limited, but short-term results have demonstrated some success. In most instances, a stenosed or angulated sleeve will require revision to RYGB. Chronic proximal fistulas require resection of the involved stomach and reconstruction by means of esophagojejunostomy or gastrojejunostomy when a small proximal pouch can be salvaged. Some centers have also demonstrated success with fistula control by anastomosis to a Roux limb after proper debridement.

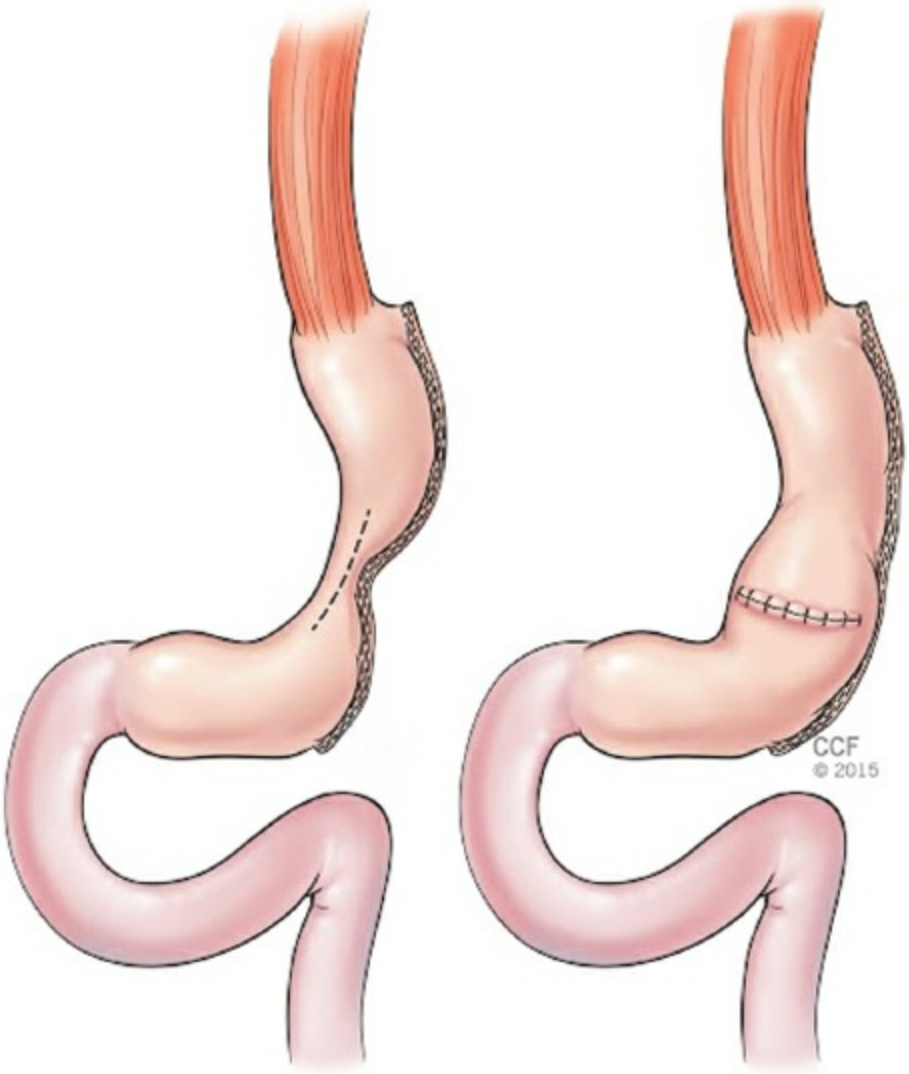

Figure 101.6. Laparoscopic gastroplasty for management of sleeve stenosis.

Revision for Sleeve Stenosis

After initial entry and trocar placement, the tubularized sleeve is identified. The left lateral segment of the liver is dissected away from the anterior stomach and the Nathanson liver retractor is positioned. Omental adhesions that may have formed are addressed. Some surgeons routinely sew the omentum to the neo-greater curvature, requiring additional dissection to properly identify the anatomy. In cases of a leak, adhesions may be more severe and sometimes involve other organs like the pancreas and colon.

Once the entire sleeve is visualized, the stenotic segment is identified. Endoscopy is a useful adjunct to identify the anatomy, as this may not be easily recognized by laparoscopy alone. The goal is to create a gastric

pouch by dividing the sleeve proximal to the stenosis. As with other revisional bariatric procedures, we emphasize early identification of the left gastric pedicle to avoid injury. The stomach is then divided distal to the main trunk of the left gastric artery but proximal to the stenosis. Transection distal to the stenosed area will complete the gastrectomy (Fig. 101.7). Staple height is adjusted accordingly, usually using higher staple heights with thickened tissue. Proximally, it is important to recognize abnormalities such as hiatal hernia or the presence of retained fundus. If identified, hiatal hernias should be repaired concomitantly, and redundant fundus may be resected as deemed necessary during construction of the pouch.

A Roux limb is created with our standard technique, and the gastrojejunostomy fashioned with the EEA stapler as described above. The distal gastric remnant may be used for gastrostomy tube placement if there is enough stomach remaining to reach to the anterior abdominal wall, and if indicated.

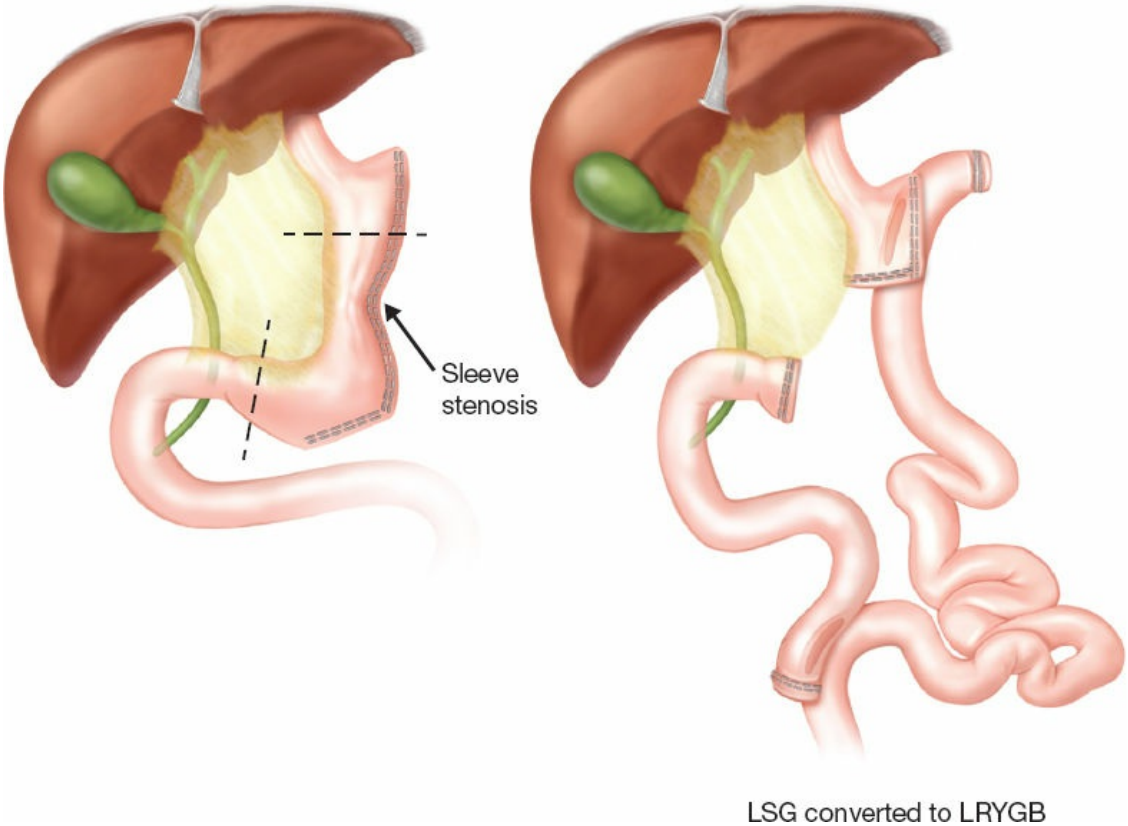

Figure 101.7. Typical appearance of sleeve stenosis at incisura and after resection of stenosis, and conversion to RYGB.

Revision for Chronic Gastric or Esophageal Fistula

Revision of SG for chronic fistula is one of the most challenging bariatric complications to manage. Patients typically require nutritional support, and they have often failed multiple attempts at management, including nonoperative, endoscopic, and surgical techniques.

The main objective of this operation is to remove the affected segment of the stomach or esophagus and reconstruct to proximal healthy tissue. Because of fistulas secondary to staple line dehiscence at the esophagogastric junction, dissection often needs to be extended into the mediastinum. This allows for adequate mobilization of the esophagus to clear any abscess cavity or necrotic tissue and then construct an anastomosis to viable tissue. Careful review of preoperative studies such as EGD and UGI identifies the location and post-surgical anatomy. In addition, abdominal and chest CT scan are helpful, as they can identify any undrained collection, or extension into the proximal mediastinum or lung spaces.

The most challenging aspect of this operation involves dissection of the proximal stomach and distal esophagus. Chronic leaks tend to cause severe inflammation and distortion of the anatomy. It is not uncommon to encounter an abscess cavity around the involved segment of the sleeve. Intraoperative endoscopy is a necessary tool during these difficult dissections. After the liver is mobilized and retracted, dissection of the proximal stomach is performed. If adhesions are severe, early transection of the distal stomach can help find a less distorted plane, usually in the retrogastric space. We make an effort to identify the left and right crus before entering the chest. It is not uncommon to find adhesions between the vena cava and the right crus, and caution is warranted here. The left crus is often involved in the more severe inflammatory process. Dissection is continued proximally, taking special care to avoid an esophageal injury. Placement of a Penrose drain around the gastroesophageal junction allows for less traumatic retraction of the esophagus. If esophagojejunostomy is planned due to the proximal fistula site, the left gastric pedicle is divided with the use of clips or a linear stapler using a vascular height staple load. Mediastinal dissection is typically performed with a combination of sharp and blunt instruments. We minimize the use of energy sources in an attempt to decrease the risk of a delayed thermal injury. Once the area of the fistula is identified and debrided, esophageal transection is performed with a linear stapler proximal to the site, ensuring that healthy tissue is present at the staple line. The specimen consisting of the proximal stomach

and distal esophagus should then be completely free and ready for extraction.

A Roux limb is then constructed as previously described. Roux limb length can be adjusted depending on the patient's body mass index (BMI) and the presence of comorbidities, typically between 80 cm and 150 cm. The anastomosis is then constructed with the use of an EEA 25-mm stapler using the per-oral technique as previously described. An alternative technique is to handsew the anastomosis using a single interrupted layer of absorbable suture. After completion, the Roux limb is occluded and a leak test is performed with the aid of the endoscope. The anastomosis is also inspected endoscopically for any bleeding. A closed suction drain is then placed in proximity to the anastomosis extending into the mediastinum.

We have a low threshold for enteral tube placement in these cases, especially in patients who required aggressive nutritional support prior to surgery. The gastric remnant is a good option if it can be approximated to the anterior abdominal wall without tension. If reach is limited without tension, a jejunostomy tube is placed in the Roux limb.

REVISIONS FOR WEIGHT RECIDIVISM AND WEIGHT-RELATED COMORBID DISEASE

A majority of patients undergoing primary bariatric surgery have successful outcomes in terms of weight loss and resolution or improvement of weight-related comorbid disease. However, there are subsets of patients who either fail to achieve appropriate initial weight loss or have weight regain at some time after the operation. Comorbid disease severity is often correlated to these failures. The likelihood of these scenarios occurring varies among the various type of operations performed. Careful evaluation of the first operation, including historical operations no longer commonly performed, is important to successful planning for surgical revision in the setting of recidivism. Even more so than in the setting of complications, reoperation for recidivism requires a multidisciplinary approach. In a comprehensive bariatric surgery program, this should include psychological evaluation to identify modifiable behavioral health problems contributing to weight regain, a complete nutritional evaluation to carefully evaluate eating propensities and caloric intakes, medical evaluation by a physician with expertise in bariatric medicine to identify contributing medical illnesses and to plan for reoperative intervention, as well as the bariatric surgeon for operative

planning and examination of the previously performed operation. The decision to proceed with operative intervention for weight recidivism should be discussed in the context of all contributing providers to determine the risk-benefit ratio for that particular reoperative intervention.

Revision of Roux-en-Y Gastric Bypass for Weight Regain

RYGB, both open and laparoscopic, has been the most commonly performed bariatric operation in the United States until recently, when it was supplanted by laparoscopic SG. Having been performed commonly for a long period of time, there are increasing numbers of patients who have weight recidivism, or failure of initial weight loss after RYGB. Prior to reintervention, it is important to evaluate the current state of a patient's comorbid disease as well. Operations for revision of RYGB are better categorized as corrective, and not conversion, as most revisions target a particular component of the gastric bypass anatomy. The most common targets for surgical revision are the gastric pouch, gastrojejunal anastomosis, and small intestinal limb lengths.

Resection and Revision of Pouch and Gastrojejunostomy for Weight Regain

Surgical revision of the gastric pouch may be indicated for a large pouch as determined by both endoscopy and upper gastrointestinal radiography. Pouch size may determine satiety and fullness, and data have linked decreased pouch size with better weight loss. Simultaneously, the aperture of the gastrojejunal anastomosis can be evaluated. Gastrojejunal anastomosis dilation, typically beyond 2 cm, has also been shown to contribute to weight regain after RYGB. Resection and revision of a large gastric pouch and/or dilated gastrojejunostomy may improve feelings of satiety, increasing restriction, with a resultant improvement in weight loss. Most revisional procedures for RYGB are approached laparoscopically, even in the setting of previous open RYGB, with successful outcomes and reasonable complication rates. However, conversion rates to open procedures are higher than primary bariatric procedures. Conversion to open procedures is appropriate in situations of unclear anatomy, excessive adhesions, and at the discretion of the operating surgeon based on experience.

A successful operative approach to the gastric pouch and gastrojejunostomy after previous RYGB is dependent on correct

intraoperative identification of important landmarks. Typically adhesions from the left lobe of the liver will overly the pouch and gastrojejunostomy, and these can be quite severe in previously open RYGB procedures. Early identification of the Roux limb as ante- or retrocolic will facilitate the dissection approach. Most commonly, laparoscopic RYGB are constructed with antecolic Roux limbs, and often, open RYGB are created with retrocolic Roux limbs. Mobilization of the retrocolic Roux limb involves working under the mesocolon, and opening of the mesocolic defect through which the Roux limb is transmitted.

Once the Roux limb is identified, the location of the left gastric vasculature is identified and preserved, as this will be the blood supply to the remaining pouch after resection. The actual anastomosis is often adhered posteriorly to the retroperitoneum and the pancreas. These adhesions can be severe especially in situations of a previous leak, or concomitant gastrogastric fistula. When the left gastric vasculature has been identified and preserved, the gastrojejunostomy mobilized posteriorly, a more accurate evaluation of the gastric pouch is possible. Size of the pouch and location of the gastrojejunostomy can be aided by intraoperative endoscopy. This also allows for detection of sometimes previously unrecognized gastrogastric fistula as well as hiatal hernia, and therefore would alter the operative approach. Presence of a gastrogastric fistula usually requires simultaneous remnant gastrectomy for definitive therapy.

Once the pouch and anastomotic anatomy has been clearly identified, pouch resection is performed with linear-cutting staplers. The reoperative nature of these procedures usually requires higher staple height use for the thickened tissue, and this is an intraoperative decision. The Roux limb is also disconnected immediately distal to the gastrojejunostomy on normal appearing jejunum. After resection of the pouch and anastomosis, leak test is performed on the pouch prior to reconstruction, usually with air insufflation and submersion in saline. This allows for easier identification and repair of potential staple line dehiscence. Reconstruction of the gastrojejunostomy is as per the surgeon’s discretion, and equally good results are reported using linear- and circular-stapled, as well as hand-sewn techniques. Once completed, repeat leak test should be performed. Intraoperative endoscopy to perform the leak test gives additional information that is helpful including the patency of the anastomosis, and identification of any staple line bleeding that can be treated immediately.

Additional considerations include examination of the Roux limb length prior to construction to ensure appropriate length and diminish potential bile reflux into the pouch. Closure of any mesenteric defects is also important to prevent internal herniation.

Endoscopic revision of both the gastric pouch, by means of sutured plication to reduce the volume, and gastrojejunostomy by placing additional sutures to decrease the aperture has been reported. Both interventions have limited applications currently as studies are small, retrospective, and highly selected. Anastomotic outlet reduction by means of endoscopic suturing appears to be a more durable and efficacious intervention than pouch reduction in these series.

Placement of Fixed or Adjustable Band Over Existing Pouch for Weight Regain

In some cases, placement of an adjustable or fixed gastric band over an existing gastric pouch after RYGB has been reported. In such cases, patients with weight recidivism and comorbid disease accruement are selected for such a procedure if there is a large gastric pouch, a dilated gastrojejunostomy, or in the setting of relatively normal post-RYGB anatomy, but with a patient perceived sense of diminished restriction. An adjustable gastric band in this position may give a desirable option of increased restriction in time with fluid insertion via the port. Complications unique to band placement, including erosion, tubing disconnections, and port complications, seem to occur with a frequency at least as the same as primary procedures, and likely more common in the revisional setting. Most reported series are quite small, with modest additional weight loss.

The technical approach for placement of an adjustable gastric band begins similarly as with pouch or anastomotic revision. Important landmarks to identify again include the left gastric vasculature and the position of the Roux limb relative to the mesocolon. Once verified, insertion is similar to primary adjustable gastric banding techniques, including the pars-flaccida approach through the gastrohepatic ligament, development of a retrogastric tunnel, insertion of the band, and positioning of the band on the gastric pouch, above the gastrojejunostomy (Fig. 101.8). Gastrogastric plication may be performed from the adjacent remnant to the pouch to potentially decrease migration rates, if the proximity of the remnant allows for such. Some authors have performed the procedure without plication. Port and tubing setup are the same as in a primary

banding procedure. Adjustment protocol varies per surgeon and center preference. Placement of fixed bands has also been reported, with similar techniques as above.

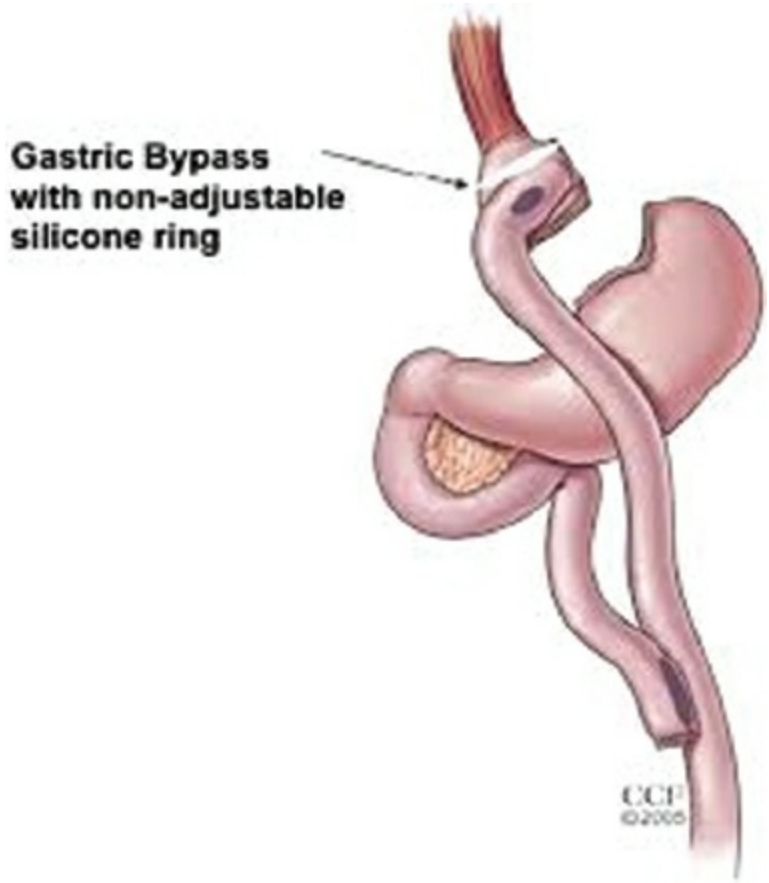

Figure 101.8. Placement of nonadjustable silicone ring over gastric pouch.

Limb-Lengthening: Resection and Revision of Jejunojejunostomy for Weight Regain

Limb-lengthening procedures target intestinal exclusion or malabsorption as targets after failed RYGB, different than the pouch and gastrojejunal anastomotic alterations described above. The amount of small intestine in continuity with both biliopancreatic secretions and food constitutes the common channel. Roux limb lengthening (increasing the length of the Roux to common channel) and distal (decreasing the common channel length) gastric bypass are two strategies to impart additional weight loss. The technical conduct of each requires disconnecting the biliopancreatic limb from the Roux and common channel, or resecting the jejunojejunostomy entirely and reconstruction. Lengths of each vary based on surgeon and center experience. Published series report weight loss after

these procedures, but the overall quality of the evidence is limited. Specifically, patients who undergo limb-lengthening procedures may be at risk for increased macro- and micronutrient deficiencies, particularly with distal gastric bypass. The performance of such procedures should likely be limited to comprehensive bariatric surgery centers with a multidisciplinary approach to patient section and evaluation, and the technical conduct should be limited to experienced bariatric surgeons.

Revision of Laparoscopic Adjustable Gastric Band for Weight Regain

LAGB is a less technically demanding operation with low perioperative complications, and as such, was quite popular. Its main weight loss effects are likely mediated through a restrictive component. Weight loss and resolution of weight-related comorbid disease have consistently been reported as less than RYGB. Revision of LAGB typically implies repositioning the band secondary to slip, or replacing secondary to device failure of some sort, in a patient who has done well initially in terms of weight loss. Weight loss and comorbidity improvements for failed band conversions to either RYGB or SG appear to be similar to outcomes for primary RYGB or SG. This section will focus on conversions to other procedures, typically RYGB or SG, which are the most commonly performed procedures for failed weight loss or recidivism after banding.

Conversion of LAGB to RYGB for Weight Regain

Typically, a laparoscopic approach is used for conversion of LAGB to RYGB. Conversion includes removal of the band, tubing, and port. After initial laparoscopic access is obtained, the tubing is identified and any adhesions to this are lysed. The tubing is transected and incision is made in the skin overlying the port for removal. We use this incision as another trocar access site. At initial placement, the port is either sewn to the fascia or metal tines in the port itself are used for attachment (Realize-type band, Ethicon Endo-Surgery, Cincinnati, Ohio, USA) and requires a removal device or directed dissection to the area of attachment. It is important to remove all of the tubing and eliminate any remaining foreign body.

Once the full complement of trocars has been placed, including liver retractor, adhesions to the left lobe are lysed and the band is visible. Identification of the buckle allows for the safest and most efficient approach for removal. A fibrous capsule usually envelops the band, and

this is removed with sharp dissection and judicious energy use. Once identified and mobilized, dissection proceeds along the band, laterally toward where the gastrogastric plication sutures are placed. These sutures are placed at the initial operation to minimize prolapse, and form a tunnel from the greater curvature of the stomach to the proximal pouch above the band. There are typically from 2 to 4 sutures here. These are taken down completely until the fundus and the left crus are identified and clear. The band can be cut, either with scissors or energy, and removed. Once removed, the stomach should be evaluated for injury and, if there is any, appropriately repaired. With significant injury or in the acute setting of a prolapse with ischemia, conversion should be deferred. In most elective situations, however, conversion can be accomplished in a single operation. Removal of all capsular remnant is important prior to pouch construction, as this may result in faulty staple line formation, leading to bleeding or leak. Pouch construction may be somewhat altered to avoid areas of the stomach that were incorporated into the band capsule. As with standard RYGB, blood supply to the pouch is based on the left gastric vasculature, so care must be taken to avoid injury here. Gastrojejunostomy and jejunojejunostomy are performed as per the surgeon's discretion in the usual fashion. Leak test should be performed for all revisional procedures.

Conversion of LAGB to Sleeve Gastrectomy for Weight Regain

For conversion of LAGB to SG, the initial approach for tubing and port removal is the same as for RYGB. Band removal is also performed similarly. For conversion to SG, it is important to fully mobilize the fibrous capsular attachments to the stomach and left crus of the diaphragm. This is especially important to allow for accurate identification of any previously undiagnosed hiatal hernia, which should undergo concomitant repair. In addition, the long staple line created in SG will likely traverse at least part of the fundus involved in the gastrogastric plication from the band. Because of this, staple line construction will likely be within gastric tissue with the abnormal thickening and devascularized tissue of the capsule. Once the band is removed and the capsule lysed, SG is performed in a typical manner. General principles include starting the sleeve around 4 cm from the pylorus; using a sizing device and higher staple height in the antrum than the fundus, with a diameter of 36 French or greater; avoiding encroachment on the lesser curvature at the incisura; identifying any posterior fundus to include in the specimen ultimately removed; and either oversewing (our preferred technique) or using staple line reinforcement

material. Especially in the reoperative setting, intraoperative endoscopy allows for immediate identification of leaks or stenosis, and if found, they can be repaired at the time. Acceptable morbidity and leak rates have been reported for conversion of LAGB to SG, but the leak rate is higher in the revisional setting. This is likely secondary to scarring at the Angle of His, and resultant poor staple line construction. Band removal and conversion to SG have been reported as both two-stage and single operation procedures, and the decision as to which to perform is made by the surgeon intraoperatively, largely based on the degree of scarring and complexity of removal.

Revision of Sleeve Gastrectomy for Weight Regain

Laparoscopic sleeve gastrectomy was initially described as the first step in a planned two-stage procedure, with the goal of performing biliopancreatic diversion with duodenal switch (BPD-DS), in the setting of high BMI and high-risk patients. The durable success of this as a stand-alone procedure has been demonstrated, in terms of both weight loss and resolution of weight-related comorbid disease. Weight recidivism and regain of weight-related disease are seen in a subset of patients after primary SG.

Prior to performing a conversion operation, evaluation of the existing gastric anatomy is critical. There are several technical aspects of the initial construction that can relate ultimate failure. The diameter of the sleeve, including uniform, proximal, or distal dilation, may be related to poor sensation of satiety and subsequent weight regain. Retained fundus, especially posteriorly, or significant antrum may lead to increased volume capacity. An unrecognized hiatal hernia during the first operation may lead to significant retained fundus in the chest, and may result in outflow obstruction at the hiatus and dilation long term, leading to an increased reservoir. In some of these circumstances, resleeving the patient may be an option, although most published reports are small series in select patients. This section will focus on the more commonly performed conversions to other bariatric procedures, most commonly to BPD-DS and RYGB.

Conversion of SG to BPD-DS

Performance of SG is typically among the first steps in creating a primary BPD-DS. In primary BPD-DS, a larger sizing device (60 French) is used to calibrate than that which is used for a primary SG (36 to 40 French). In the second stage of a planned conversion from SG to BPD-DS, the sleeve will

likely then be of larger diameter, than for conversion secondary to weight loss failure from primary SG. In most instances, except with anatomic abnormalities of the sleeve such as retained fundus, hiatal hernia, or severe caliber abnormalities, the sleeve is kept as is. Conversion to BPD-DS starts then with mobilization of the duodenum, and transection with a linear stapler 2 cm distal to the pylorus. After measuring small intestinal limbs, a duodenoileostomy is then constructed and forms the alimentary limb, typically at a distance of 250 cm. This anastomosis can be performed hand-sewn, or circular- or linear-stapled. The biliopancreatic limb is anastomosed as an ileoenteric anastomosis, creating a 100-cm common channel, with a linear stapler and hand-sewn enterotomy closure. Weight loss and resolution of weight-related comorbid disease are more robust than that seen with conversion to RYGB, although nutritional deficiencies occur more commonly with this malabsorptive procedure.

Conversion of SG to RYGB

Most commonly, conversion of SG is performed for complications of SG, including stenosis at the incisura and resultant outflow obstruction, as well as GERD. Conversion of SG to RYGB is an option for weight loss failures as well. Technical conduct requires identification of any abnormalities of the sleeve. This is usually completed preoperatively with UGI radiography and upper endoscopy, but careful inspection of the sleeve conduit should be performed in the operating room as well. Once completed, the left gastric vascular bundle is identified and preserved. The short-gastric vessels will have been divided, and as such, adhesions laterally to the omentum and posteriorly to the pancreas should be freed. Once the tubularized stomach has been mobilized, the descending branch of the left gastric vessels is controlled, with either an advanced energy source or stapler. The gastric pouch is then created by transecting the sleeve horizontally. The may require one or two 60-mm stapler applications. A Roux limb is then created in the usual manner and brought up to create the gastrojejunostomy in a typical manner, after creation of the jejunojejunostomy. The anastomosis can be created by means of a hand-sewn, circular- or linear-stapled technique. Intraoperative leak test should be performed, as with all revisional procedures. Using intraoperative endoscopy allows not only identification of a potential leak, but all gives important information on the size of the pouch, both prior to and after gastrojejunostomy creation, and it allows for therapeutic applications, such as for treatment of endoluminal bleeding.

SUMMARY

Bariatric surgery is a proven durable therapy providing weight loss, and improvement and resolution of weight-related comorbid diseases. The safety and efficacy of these procedures have improved secondary to quality improvement efforts, data reporting, and laparoscopic techniques. Even so, a subset of patients will present with complications from their initial operation, failure of weight loss, and weight recidivism. Revisional bariatric surgery can result in correction of complications, better weight loss, and improvement in weight-related disease. Most commonly these procedures can be completed successfully laparoscopically, in the setting of a multidisciplinary, comprehensive bariatric care program, with dedicated experienced surgeons.

EDITOR'S COMMENT

This chapter on revisional bariatric surgery is new in the 7th edition of the *Mastery of Surgery* textbook. The history of bariatric surgery dates more than 50 years to right after World War II. A variety of different procedures have been designed over these years to address severe obesity with varying degrees of success and some outright failures. Technological innovation coupled with the rising prevalence of obesity has helped to shape the current landscape of bariatric surgery. In 1954, Kremen and associates published the first peer-reviewed research article on bariatric surgery. In this paper, they describe the results of a jejunoileal bypass (JIB) performed on an obese patient. Kremen and

several other surgeons at the time had observed that patients who had developed the ‘‘shortgut’’ syndrome (usually observed after substantial small bowel resections as a consequence of mesenteric vascular thrombosis leading to necrosis) lost a considerable quantity of weight. The JIB was the first ‘‘malabsorptive’’ bariatric procedure, designed to induce weight loss through inefficient and incomplete absorption of ingested nutrients. In the more than 60 years that have elapsed since this first publication, a variety of procedures have come and gone (the JIB, vertical banded gastroplasty [VBG], horizontal gastroplasty for example). Many were abandoned because of severe potential complications (JIB). Others have been abandoned for a lack of efficacy (horizontal gastroplasty) or a better alternative (VBG for laparoscopic adjustable gastric band). Rodriguez and Kroh discuss in depth revisional procedures for bariatric procedures performed commonly in the current era. It is relatively rare to encounter a surviving JIB patient in need of a revision. We still meet people who had a VBG in the 80s or 90s who present with band erosion, pouch outlet obstruction, recurrent obesity, or severe GERD. While the options for revisional surgery for VBG patients are not described in the current chapter, the basic principles are similar to what is discussed. We have some experience with VBG reversal via gastrogastrostomy, but discourage this approach due to an extremely high incidence of recurrent obesity and relatively few great options in a patient who has undergone a VBG and a VBG reversal who now needs a repeat weight loss operation. In most patients with either complications or recurrent obesity following a VBG, a conversion to a gastric bypass is recommended. As for many revisional procedures, the tissue of the gastric pouch becomes quite thickened and a longer staple height is necessary when creating the gastric pouch. A well-vascularized pouch is critical. The vertical staple line can be difficult to find, and it is important to avoid leaving a portion of stomach that does not communicate with either the pouch or the remnant stomach between a new staple line and an old staple line. For this reason, I usually create a pouch out of stomach clearly inside of the original staple line and resect the proximal portion of the remnant.

Considering the fact that obesity is so prevalent, and that bariatric surgery has become so common in the past 20 years, it is actually amazing that revisional bariatric surgery is still an evolving field. It is estimated that in 2014, there were 193,000 bariatric procedures performed in the United States. This is a sharp increase from 2011 when it is estimated that there were 158,000 procedures performed. During this 3-year interval, the proportion of revisional bariatric procedures performed rose from 6% (2011) to 11.5% (2014). The authors correctly point out that the data supporting many revisional procedures, especially when it comes to revisions for weight regain, are weak.

The options and approach vary based on the original procedure and the presence of issues such as a gastrogastric fistula or a massively enlarge pouch or sleeve. What is troublesome and difficult to sort out from the published literature on revisional surgery for weight recidivism is that many successful

patients have pouch size and gastrojejunostomy calibers that are identical to other patients who have failed to gain weight or have regained lost weight. Many patients have maladaptive eating behaviors, noncompliance, or fail to exercise sufficiently to maintain lost weight. Without addressing these behaviors, a second surgery is likely subjecting patients to risk with little hope of long-term benefit. Screening prior to a primary bariatric surgery procedure to identify patients who should not be offered surgery or who would benefit from additional support, education, or counseling prior to surgical intervention is an inexact science and varies from program to program. When a patient presents with a desire for a second bariatric surgical procedure due to persistent or recurrent obesity, the proper screening process is even less certain. One thing is for sure in my opinion, these patients need careful monitoring and support following surgery to make sure old habits that led to a failed primary attempt at surgically induced weight loss do not recur.

When it comes to complications of primary bariatric procedures requiring revision, the decision to proceed with surgery and the options available are a bit less controversial. Revisional bariatric surgery is a complex intervention with a high degree of technical difficulty. Surgeons who endeavor to perform revisional bariatric surgery should be highly experienced in primary bariatric surgery. In revisions of gastric bypass procedures for recalcitrant marginal ulcers, in conversions of failed Nissen fundoplications to gastric bypass, and in conversion of sleeve gastrectomy to gastric bypass—especially in cases with a chronic fistula related to a proximal sleeve leak, the surgeon should be prepared to perform an esophagojejunostomy. This is a high-risk anastomosis with significant potential for morbidity. Setting adequate patient expectations ahead of time is important. A feeding tube is almost always necessary. It may be 3 months or more until patients are able to maintain their nutrition adequately without enteral tube feeding support. Complications such as esophagojejunostomy stenosis or leak can significantly prolong this feeding tube dependent interval. In our experience with esophagojejunostomy, there is a relatively high incidence of anastomotic stenosis requiring sometimes-repeated dilation. In several patients who have required esophagojejunostomy for numerous failed fundoplications, anastomotic stenosis has been resistant to repeated dilations and stenting has been required.

Although conversion of a failed fundoplication to a gastric bypass is not technically a revision of a previous bariatric operation, I think a word here about these procedures would be of benefit and related to the content of this chapter. Obesity is a risk factor for GERD. Obesity is also a risk factor for fundoplication failure. When obese patients present with symptoms secondary to failure of a previous fundoplication, most often due to herniation of the fundoplication with hiatal hernia, takedown of the fundoplication, repair of the hiatal hernia, and conversion to Roux-en-Y gastric bypass are the best option. In certain patients with multiple failed fundoplication attempts and in those with post-surgical gastroparesis, conversion to Roux-en-Y gastric bypass is the best

option regardless of body mass index. Like all of the revisional procedures described in this chapter, these are complicated and technically complex procedures best reserved for highly experienced surgeons. A common obstacle for all of the procedures discussed in this chapter is a reluctance of insurance companies to pay for revisional or even primary bariatric procedures. Surgeons who perform these procedures should be prepared to spend extra time and effort advocating for their patients by requesting and participating in peer-to-peer discussions whenever possible. Writing letters to the medical director of an insurance company or to an independent external reviewer of an appeal outlining the medical rationale for the requested procedure with supporting peer-reviewed published literature is often necessary.

This is a great chapter on an important topic. I suspect that the next version of this chapter will describe new procedures not yet developed and better data supporting the long-term benefit and efficacy of these revisional procedures. It will be important for bariatric surgeons to follow these patients who undergo revisional procedures for 5 years and beyond. Patient selection for revisional surgery due to weight recidivism will continue to be a controversial topic requiring additional investigation.

102 Management of Complications of Gastric Bypass and Repair

Ronald H. Clements and Matthew D. Spann

INTRODUCTION

The pandemic of morbid obesity continues to expand across the globe in both developing and developed nations. The disease plagues both individuals and populational health with comorbidities having immeasurable impact on quality of life and the global economy. Perhaps the biggest challenge to controlling the pandemic remains managing the misconception that the disease is purely a lifestyle choice and not a chronic illness. In 2013, the American Medical Association officially classified obesity as a disease and has brought a new sense of awareness to the problem. Many different strategies exist for the treatment of this disease. The starting point for many patients begins in the 40 billion dollar a year diet industry. However, the literature continues to expand showing bariatric surgery to be superior, and arguably the gold standard of treatment, compared with diet and exercise, at managing the disease of morbid obesity and the associated comorbid conditions.

Nearly 200,000 bariatric procedures were performed in the United States in 2014. The Roux-en-Y gastric bypass (RYGB) accounts for more than 30% of bariatric procedures and arguably the procedure of choice for those patients suffering from both morbid obesity and type 2 diabetes mellitus. Although the majority of the procedures are performed via laparoscopic approach today, the principles behind the RYGB for morbid obesity have not changed significantly from the operation originally described by Drs. Mason and Ito in the 1960s. Historically, the operation is thought to produce weight loss through a restrictive component by creating a 30-mL pouch out of the cardia of the stomach and a malabsorptive component by bypassing 75 to 150 cm of jejunum. Through recent research, other factors such as changes in gastrointestinal hormones, hepatic glucose metabolism, and the microbiota of the gastrointestinal tract are also implicated in metabolic improvements.

Patients and providers should not view bariatric surgery as the cure for morbid obesity, but rather a tool that will help a patient achieve remission of a lifelong condition. As with any tool, a certain degree of maintenance is required. The RYGB allows patients to achieve more weight loss, resolve more obesity related health conditions, and has less weight recidivism than other popular weight loss procedures. These benefits come with a slightly higher risk of postoperative complications and require experienced follow-up care. Preoperative education for the patient and associated providers is critical for appropriate care of the patient with RYGB.

Complications from RYGB are classified into short term, within 30 days of an operation, and long-term complications, those occurring after 30 days. The incidence of complications can vary by number of operations performed by the surgeon as well as differences in technique in preforming the operation. We will examine how to identify the most common complications, their etiologies, and strategies to prevent and treat the complications. As a greater percentage of the population seeks bariatric surgery, careful attention is required of surgeons, primary medical providers, and emergency medical providers in recognizing and treating potential complications. Education of emergency room physicians and on-call surgeons is paramount as a delay of care can quickly lead to a failure to rescue event in this patient population.

EARLY COMPLICATIONS

Anastomotic Leak

Elective division of the gastrointestinal tract and the associated risk of this maneuver must be approached cautiously in any circumstance. For RYGB, anastomotic leak is one of the most feared complications associated with the procedure. Fortunately, the occurrence of anastomotic leak after RYGB for morbid obesity is low, but the clinical consequences of such an event are devastating and therefore demand a high index of suspicion in the postoperative period. Anastomotic leak is often the beginning of a series of other complications that prolong a patient’s hospitalization and increase mortality after RYGB.

The best strategy to treat anastomotic leak is prevention. Leaks at the gastrojejunostomy occur more frequently than at the jejunojejunostomy and warrant early evaluation with any clinical evidence of impaired recovery. As with any operation, a well-vascularized, tension-free

anastomosis is paramount to avoid postoperative complications. While the procedural principles are the same, there is no one standard technique for creating a gastrojejunostomy. The two most described techniques for performing the RYGB is an antecolic or retrocolic (and either antegastric or retrogastric) gastrojejunostomy. The anastomosis can be created with a circular stapler or linear stapler with sutured enterotomy. The authors preform a linear stapled antecolic, antegastric gastrojejunostomy with sutured gastroenterotomy. No technique has consistently been shown to decrease the leak rate associated with the gastrojejunostomy and thus both techniques are popular among surgeons. Perhaps the most important factor is the frequency the surgeon preforms RYGB. In addition to sound surgical principles, some authors advocate the use of anastomotic reinforcement with fibrin sealants. Widespread adoption of such reinforcement has been limited, attributed to high cost and lack of data due to relatively low rates of anastomotic leaks.

The jejunojejunostomy has been described as entirely sutured, entirely stapled, or a combination of the two techniques. The authors preform a side-to-side linear stapled jejunojejunostomy with sutured common enterotomy. When preforming the anastomosis, the key details are an antimesenteric position of the anastomosis and avoiding ischemia at the stapled end of the biliopancreatic limb. With each technique, care must be taken to adequately close the enterotomy while not narrowing the anastomosis.

Early recognition of anastomotic leak is critical to rescue a patient from further complication. Advocates of intraoperative leak test of the gastrojejunostomy cite recognition of technical error at the index operation that may prevent early complication. Many techniques have been described including both pneumatic and endoscopic intraluminal insufflation to assess for air leaks, as well as dye leak test using methylene blue. The authors use intraoperative endoscopy with insufflation to assess the integrity of the gastrojejunostomy and intraluminal hemostasis prior to completion of the RYGB. Surgical drains and routine fluoroscopic contrast evaluations are controversial but should be strongly considered for the revisional foregut or bariatric operation.

The above studies are useful for adding objective data to identify early technical complications; however, a high index of suspicion by an experienced clinician may be the most sensitive test available to the bariatric patient. Unexplained tachycardia, worsening abdominal pain, and

dyspnea are the earliest clinical signs of anastomotic leak and require prompt investigation. While radiographic tests may be useful, the most appropriate study for some patients will be operative exploration.

Management of anastomotic leak will be based on patient stability. Early leaks will often require urgent surgical intervention with surgical drainage around the anastomosis and feeding access in the bypassed stomach. Revision of the gastrojejunostomy in the early postoperative period is rarely required. Endoscopic means have been described and can be considered in the stable patient, especially those patients presenting with a delayed leak.

Bleeding

One of the most common complications after RYGB is postoperative hemorrhage. Hemorrhage is first on the list of differential diagnoses with any patient experiencing hypotension, tachycardia, dizziness, syncope, or objective evidence of acute blood loss anemia. Postoperative hemorrhage after RYGB can be categorized as extraluminal or intraluminal. Extraluminal hemorrhage most often occurs from staple lines, but may also be from splenic or mesenteric injury, hepatic laceration, or port site hemorrhage. Extraluminal hemorrhage usually presents in the acute operative period. Patients may exhibit increasing abdominal pain, abdominal distension, or can be asymptomatic.

Intraluminal hemorrhage is frequently more difficult to diagnose as there are six areas of concern related to the operation alone: gastric pouch staple line, gastrojejunostomy, proximal Roux limb staple line, jejunojejunostomy, distal biliopancreatic limb staple line, and staple line of the excluded stomach. Sites not related to RYGB such as duodenal ulcer, diverticular bleed, and mucosal arteriovenous abnormalities are also possible. Symptoms are typical of other gastrointestinal bleeds including hematemesis, hematochezia, and melena. Sometimes the presenting symptoms will delay the sentinel event by a few days.

As with other postoperative hemorrhage, management will depend on patient stability, time of presentation, and symptoms. The first step with any patient is to ensure adequate intravenous access, active blood type and antibody screen, and blood availability in the institution. Hemodynamically stable patients with minimal symptoms may be candidates for close observation in a monitored setting. Unstable patients require transfusion and likely early operative intervention. Laparoscopic

management can be successful, but some patients will require laparotomy for definitive management of extraluminal, and rarely, intraluminal bleeding.

Early use of gastrointestinal endoscopy should be considered with patients exhibiting the symptoms of intraluminal bleeding described above. Transoral endoscopy can be both diagnostic and therapeutic for the most common sites of bleeding: the gastric pouch and gastrojejunostomy. If intraluminal bleeding is not seen on transoral endoscopy, intraoperative transgastric endoscopy via the remnant stomach is useful at examining the duodenum as well as staple lines within the bypassed stomach and jejunojejunostomy. If endoscopic interventions are unsuccessful at control of hemorrhage from a staple line, a running suture along the staple line or ligating a feeding vessel may be required through a laparoscopic or open approach.

Thromboembolic Complications

Another feared but not uncommon complication after any bariatric surgery is formation of deep vein thrombosis (DVT) and pulmonary embolus. Reported incidence ranges from 0.3% to 6% and 0.2% to 5%, respectively, and account for nearly half of mortalities after gastric bypass. Although there is no standardized method of DVT prophylaxis, establishment of an aggressive prophylactic thromboembolic protocol, with frequent review, is critical to avoid this potentially fatal complication. Elements of the thromboembolic protocol include use of sequential compression prior to procedure start and, perhaps most important, an emphasis on early and often ambulation. The routine use of pharmacologic thromboembolic prophylaxis is debated but should be considered with longer operative times, reoperative surgery, and high-risk patients. The presenting symptoms of patients with thromboembolic disease vary widely requiring high index of suspicion by the clinician to initiate early investigation for DVT in hopes to prevent the morbidity from progressing to mortality.

Early Bowel Obstruction

Small bowel obstruction (SBO) after RYGB can occur at any point after the operation. Patients often present with the typical symptoms of nausea and vomiting or retching with or without abdominal pain. In addition to adhesive disease common with other operations, patients with RYGB can also have obstruction due to blockage at either anastomosis, or mesenteric

volvulus. Workup of the etiology of SBO should proceed with focused examination of the abdomen, radiographs of the abdomen and pelvis, as well as computed tomography (CT) scan if the patient's clinical picture allows.

The management of bowel obstructions after RYGB is quite different than managing adhesive bowel obstructions associated with many other operations. Practitioners should avoid the temptation of nasogastric tubes as this will provide little benefit due to the small size of the gastric pouch and is associated with quite significant morbidity such as aspiration pneumonitis and risk of perforation of the gastrojejunostomy. Any patient with a history of RYGP presenting with nausea, vomiting, and abdominal pain must be ruled out for mesenteric volvulus related to internal hernia as failure to diagnose and operatively manage such patients can result in intestinal ischemia, short bowel syndrome, and death. Internal hernia is uncommon in the early postoperative period and will be discussed later in this chapter.

Within the first 30 days after RYGB, anastomotic obstruction is most common due to edema, ulceration, or stricture at the gastrojejunostomy or jejunojejunostomy. SBOs due to narrowing at the anastomoses are not uncommon when advancing to a new stage of the bariatric diet. Clinically stable patients presenting the symptoms of early SBO related to anastomotic complications can frequently be managed conservatively with frequent physical exams, bowel rest, and IV hydration.

Cardiopulmonary Complications

The second leading cause of death within 30 days after operation is cardiovascular events, responsible for up to one third of mortalities post RYGB. Many patients undergoing RYGB suffer from metabolic syndrome and have baseline cardiovascular risk higher than healthy individuals undergoing other forms of noncardiac surgery. The challenge is ensuring that such patients are medically optimized for surgery. Surgeons should work closely with a patient's cardiologist and/or primary care physician to ensure cardiovascular risk is minimized. For those patients who do not have a family or personal history of cardiovascular disease, obtaining routine preoperative cardiovascular tests are based on the patient's functional status. Patients with a functional status of less than four metabolic equivalents (METs) require thorough cardiac evaluation prior to surgery.

Many patients who experience cardiovascular events after RYGB will have no prior history or no elevated cardiovascular risk. Early recognition and management of cardiovascular events are essential for patient safety. Since the symptoms of cardiac events widely very, investigation is warranted in any patient not experiencing the routine postoperative recovery. Early escalation of care and expert consultation may prevent failure to rescue in this high-risk patient population.

LATE COMPLICATIONS

Marginal Ulcer

One of the most common complications of RYGB after the immediate postoperative period remains gastrojejunal, marginal, or ulceration. Stomal ulceration was recognized by Dr. Mason early in the history of RYGB. Although its incidence has decreased some, it is a reported complication in 1% to 9% of patients after surgery, with the highest risk of development within the first 3 months. Prevention of ulceration begins with preoperative management. Selective, and arguably routine, endoscopic screening in patients interested in RYGB will help identify patients with peptic ulcer disease, the largest risk factor for the development of marginal ulcers. Smoking cessation is also critical in the preoperative period. We advocate screening and eradication of *Helicobacter pylori* prior to surgery with any patient experiencing dyspepsia or with an established diagnosis of gastroesophageal reflux disease. During the operation, a small vertically oriented gastric pouch with volume of approximately 30 mL has been associated with lower ulcer rates. The pouch shape and size are critical to minimize the amount of parietal cells above the gastrojejunostomy. A tension-free anastomosis and preservation of blood flow to the gastric pouch and proximal Roux limb are perhaps the most important technical aspects to avoid marginal ulcers. If suture is required during creation of the gastrojejunostomy, we advocate absorbable suture as permanent suture material is frequently seen near gastrojejunal ulcers on endoscopic evaluation. Postoperatively, use of proton pump inhibitors (PPIs) has been associated with decreased ulcer rates, although the duration of therapy is debated.

Marginal ulceration is suspected in patients presenting with nausea and emesis with or without epigastric pain following gastric bypass. Early initiation of treatment with anyone suspected of marginal ulceration consists of high-dose PPI and sucralfate and often alleviates symptoms

after a few doses. Workup proceeds with upper endoscopy, which will allow diagnosis of the ulcer as well as therapeutic dilation if stricture is identified. Initiation of pharmacologic treatment should not be delayed for endoscopic conformation of marginal ulcer. Lifelong avoidance of nicotine products and nonsteroidal anti-inflammatory medications are essential to decrease development of late ulcers.

Complications of marginal ulcers include bleeding and perforation, which will be the presenting symptoms for some patients. Bleeding ulcers are often successfully treated with endoscopic therapies. Perforation should be managed urgently and will often respond to omental patch, wide drainage, and consideration of feeding access via gastrostomy tube in the remnant stomach. Revision of the gastrojejunostomy will occasionally be required for recalcitrant ulcers. Truncal vagotomy via thoracoscopic approach has also shown promise in marginal ulcers that fail medical management and may carry less morbidity that a revisional gastrojejunostomy.

Anastomotic Stenosis

Gastrojejunal stenosis will occur in up to 10% of RYGB and is similar in incidence for circular stapled, linear stapled, and completely sutured techniques. Anastomotic stenosis can occur in any period after the operation. Patients typically present with difficulty tolerating solids or liquids. Frequently, stenosis at the gastrojejunostomy is associated with ulceration and may be the presenting symptom of a marginal ulcer. Other etiologies include technical complications at the anastomosis. Risk factors for anastomotic stenosis include those associated with marginal ulcers as well as technical error. Stenosis may also be related to banding material used during certain techniques of creating the gastrojejunostomy. Treatment of anastomotic stenosis is aimed at prevention as described above. Early use of endoscopy is useful for diagnostic and therapeutic advantages. Most cases of stenosis will respond to endoscopic interventions, reserving revisional operations for advanced stenosis or cases that have failed to respond to multiple endoscopic dilations.

Stenosis at the jejunojejunostomy is quite rare and is often related to technical error, adhesive disease, or dietary noncompliance. Symptoms of jejunal stenosis include symptoms of bloating, early satiety, unexpected weight loss, and abdominal pain. CT and gastrointestinal contrast studies are useful to confirm the diagnosis showing dilation of the Roux limb or

biliopancreatic limb and remnant stomach. When available, endoscopic evaluation by an experienced endoscopist with or without use of balloon enteroscopy may allow visualization of the jejunal anastomosis. Treatment should be based on the patient's symptoms and revision of the anastomosis is indicated in patients who are unable to tolerate oral intake.

Gastrogastric Fistula

Gastrogastric fistula has been a known complication throughout the history of RYGB. One of the major factors initially was stapler technology that did not allow for division of the stomach when creating the gastric pouch. With advancement in staple technology allowing for complete division, gastrogastric fistulae have reduced but remain a culprit for patients experiencing weight regain or marginal ulceration after surgery. Gastrogastric fistulae are often identified when oral contrast is seen in the bypassed stomach on either CT or gastrointestinal radiographs. Workup for gastrogastric fistula should include endoscopy and potentially video esophagram. Management of fistulae will depend on symptoms. In the asymptomatic patient, gastrogastric fistula may be observed and treated medically with PPIs. Most gastrogastric fistula will be symptomatic and require operative management. Recent technology has provided numerous endoscopic therapies aimed at addressing gastrogastric fistulae. Although some endoscopic methods will be successful, many patients with symptomatic gastrogastric fistula will need revisional operations aimed at dividing the gastrogastric fistula or resection of the pouch and revision of the gastrojejunostomy.

Bowel Obstruction

While bowel obstruction can present both early and late in the postoperative period, most early obstructions are due to technical error, bowel edema, or dietary noncompliance. Bowel obstructions presenting later in the postoperative course often require intervention. Any patient with a history of RYGB presenting with nausea and emesis with or without abdominal pain should be considered to have mesenteric volvulus from an internal hernia until proven otherwise. Internal hernias are potential spaces created in the mesentery by the Roux-en-Y anatomy and will vary slightly depending on the method used to create the gastrojejunostomy. A potential space always exists at the jejunojejunostomy regardless of method of creation (Fig. 102.1). With antecolic gastrojejunostomy, a potential space

exists between the mesentery of the Roux limb and the transverse mesocolon. With creation of a retrocolic gastrojejunostomy, potential spaces are created at both the interface of Roux limb mesentery and transverse mesocolon, as well as a space created when the Roux limb passes through the transverse mesocolon (Fig. 102.2).

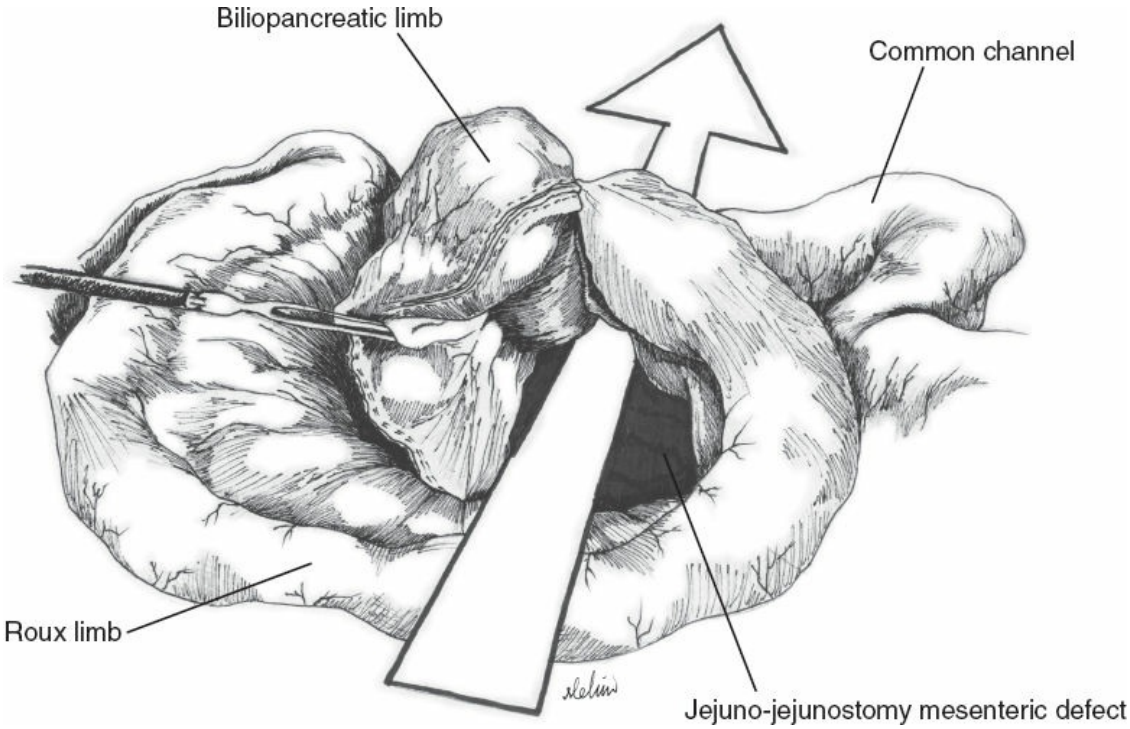

Figure 102.1. Mesenteric defect at jejunojejunostomy.

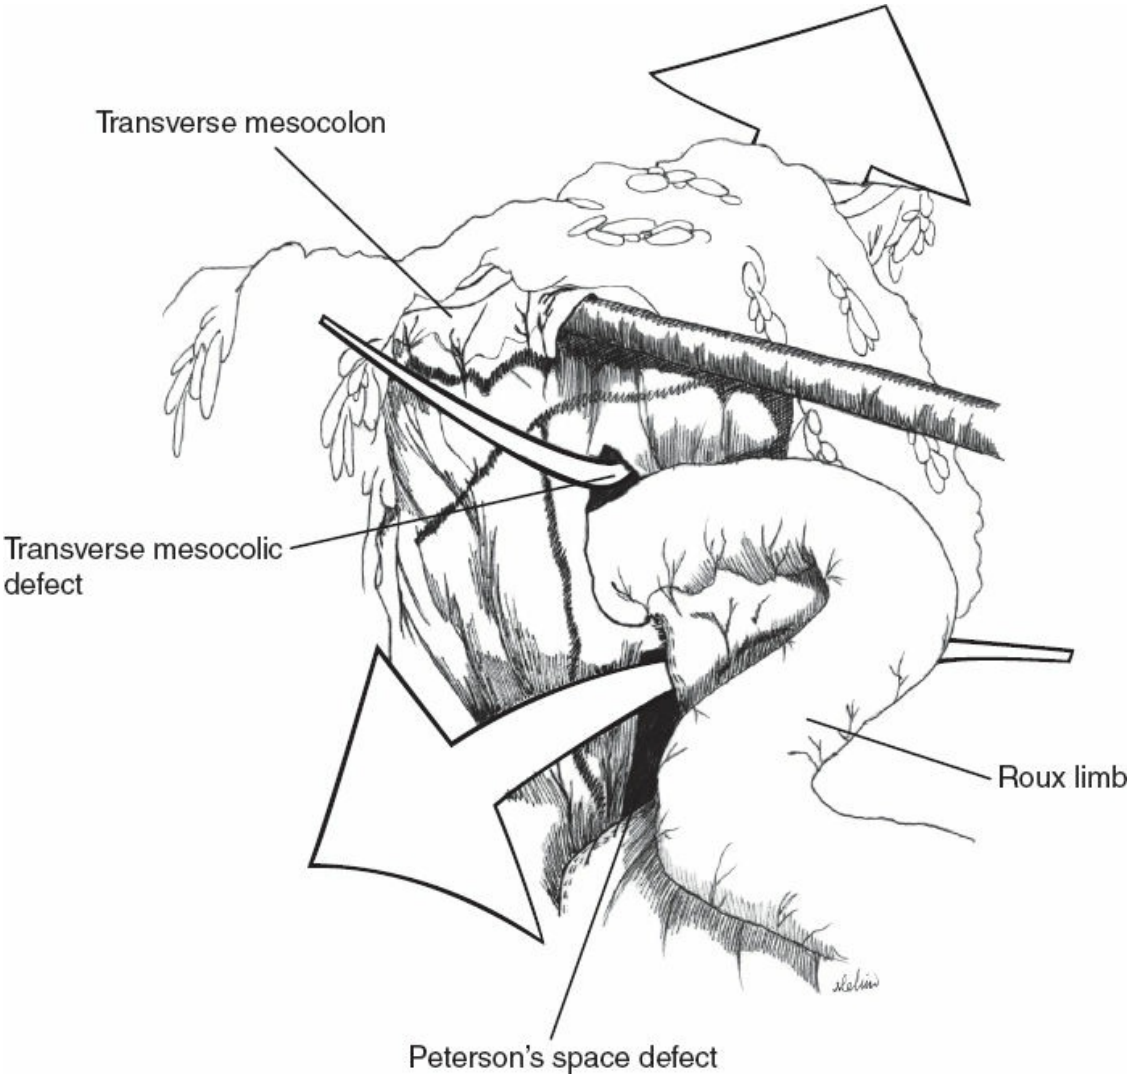

Figure 102.2. Mesenteric defects in patients with retrocolic gastrojejunostomy.

CT is the best initial test during workup of a patient experiencing symptoms of internal hernia. Image analysis is most useful if preformed by a radiologist experienced in analyzing Roux-en-Y anatomy, as well as an experienced bariatric surgeon. Characteristic CT signs of internal hernia include changes within the mesentery, most notably swirling of the mesenteric vessels. The mesenteric "swirl" sign is often recognized with internal hernia at the mesocolic defect created by the mesenteric vessels passing behind the superior mesenteric artery as depicted in Figure 102.3. Other CT findings include evidence of a SBO, jejunum passing behind the superior mesenteric artery, the jejunojejunostomy located in the patient's right hemiabdomen, and clustering of small bowel within one quadrant. As with any disease process, the surgeon must treat the patient and not available radiographic information. A patient with abdominal pain out of

proportion to exam requires exploration to rule out presence of internal hernia even in the setting of normal imaging studies.

Operative exploration is performed via the approach most comfortable to the surgeon. The first aim of the operation is not identification of the potential spaces and/or hernia. Instead, the authors recommend identifying the terminal ilium and performing a retrograde exploration of the small bowel back to both the ligament of Treitz and gastrojejunostomy. By preforming the distal to proximal examination, the surgeon will reduce the internal herniation and may notice a visible difference in the appearance in bowel color and caliber during the exploration. When the entire small bowel has been examined, the potential mesenteric defects need to be inspected. To assess for a defect at the jejunojejunostomy, the Roux limb is swept to the right side of the abdomen. Once the jejunojejunostomy is identified, the mesenteric defect is observed by tracing the cut end of the biliopancreatic limb down to its mesentery. A thin film of adhesions should be present between the mesenteric interface of the biliopancreatic limb and Roux limb down to the root of the mesentery (Fig. 102.4). The mesenteric interface between the Roux limb and transverse mesocolon is assessed by sweeping the Roux limb to the left side of the abdomen and retracting the transverse colon cephalad. A thin layer of adhesions should be present between the transverse mesocolon and the Roux limb mesentery to the root of the mesentery. If the mesenteric defect is open, the proximal jejunum at the ligament of Treitz can be seen through the defect (Fig. 102.5). No small bowel should transverse the defect if the internal hernia is adequately reduced. For patients with a retrocolic gastrojejunostomy, only one limb of intestine should be present going through the transverse mesocolon. The size should be adequate to allow only the Roux limb and its mesentery and, frequently, sutures are placed between the Roux limb and mesocolon to keep the defect closed during massive weight loss.

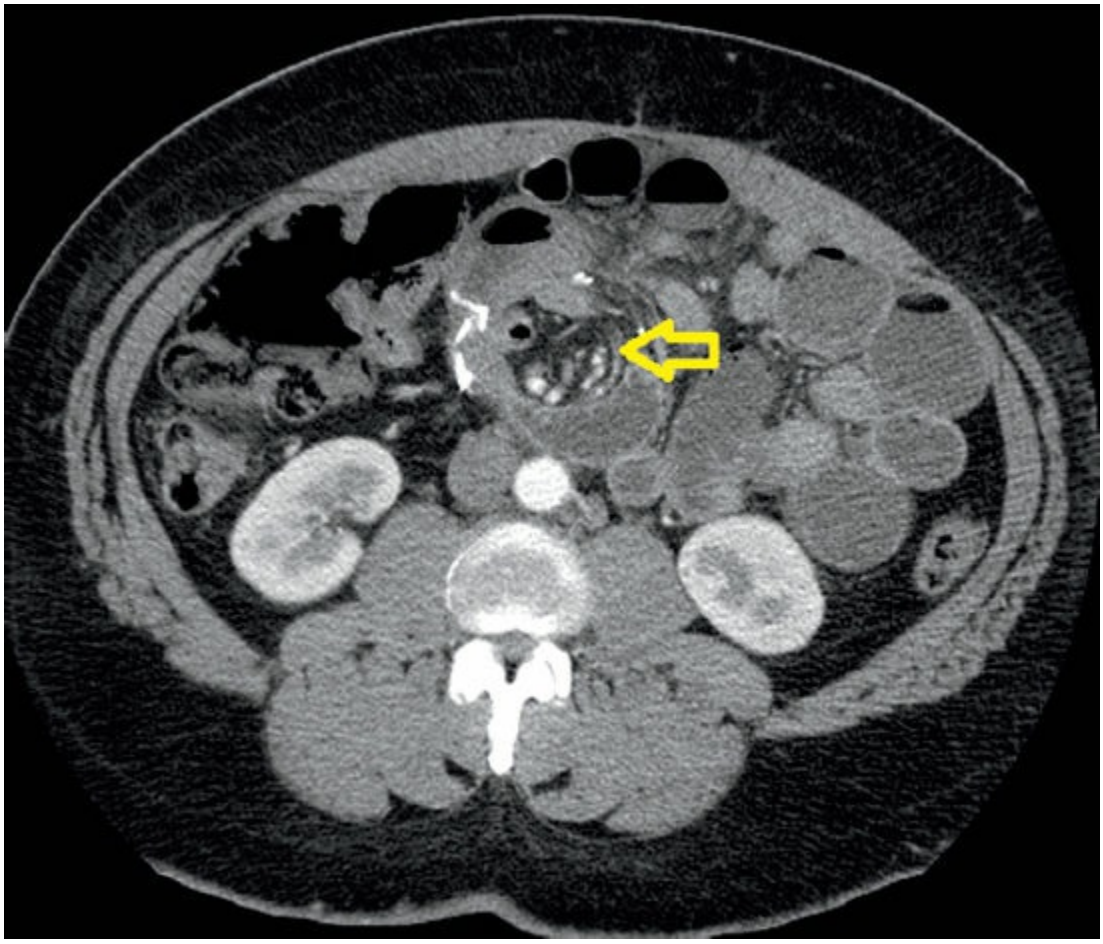

Figure 102.3. Computed tomography (CT) image depicting mesenteric swirl related to internal hernia at Peterson space.

Once internal hernia is excluded, adhesive bowel obstruction must also be considered. Adhesive bowel obstructions are more common in patients with history of open RYGB, but can present in laparoscopic cases as well. Adhesive disease from other operations is possible. Management of adhesive disease should be followed with bowel rest, close observation, and low threshold for surgical intervention. Nasogastric decompression is controversial after RYGB as its benefits are minimal due to the altered anatomy as decompression of the Roux limb or gastric pouch has limited benefit to the management of adhesive bowel obstructions. If nasogastric decompression is desired, use of fluoroscopy may decrease the risk of iatrogenic gastrojejunal perforation.

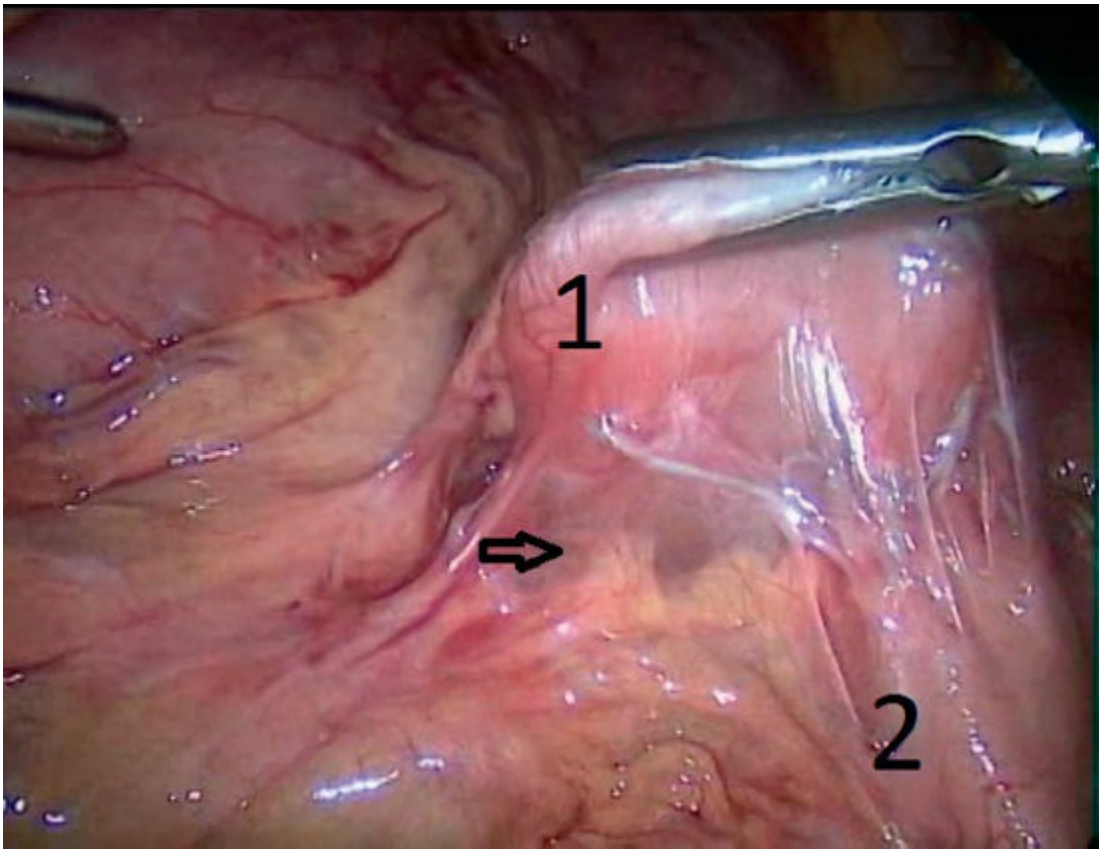

Figure 102.4. Closed mesenteric defect in at jejunojejunostomy (*arrow*). The cut end of the biliopancreatic limb is cephalad (*1*) with Roux limb just below (*2*).

Another rare but well-described cause of bowel obstruction after RYGB includes jejunal intussusception. In addition to symptoms of bowel obstruction, patients experiencing intussusception may have history of hematochezia or melena leading to the event. Jejunal intussusception after RYGB is a retrograde intussusception of the common channel into the Roux limb or biliopancreatic limb. The etiology of intussusception after RYGB is not fully understood, but altered peristalsis with artificial “lead point” at the jejunojejunostomy is suspected. Asymptomatic patients often resolve without intervention. Treatment of symptomatic cases will be based on the patient’s clinical presentation. Many patients will require operative intervention. Controversy exists regarding the best strategy between reduction in the intussusception alone, reduction and enteropexy, or revision of the jejunojejunostomy. Recurrence is possible with each strategy and patients should be counseled accordingly.

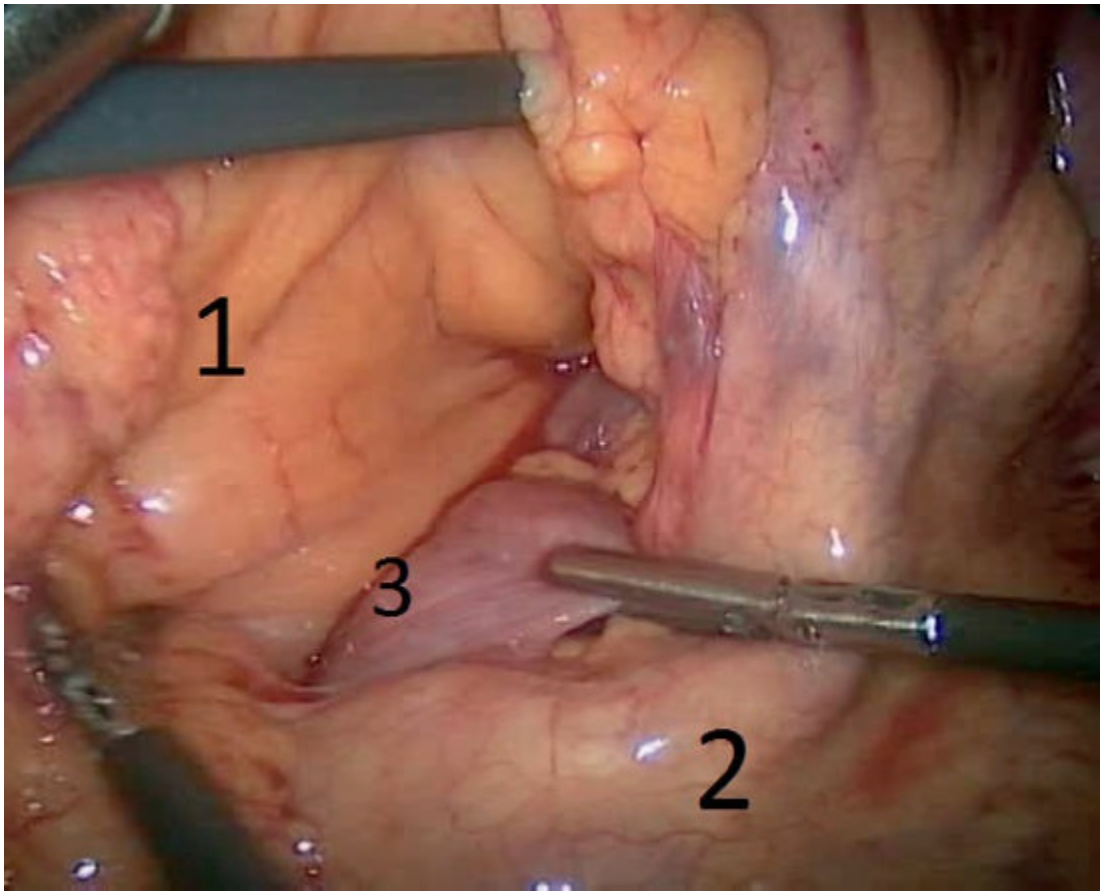

Figure 102.5. Open mesenteric defect between transverse mesocolon (*1*) and Roux limb mesentery (*2*). The proximal jejunum and ligament of Treitz are seen through the defect (*3*).

Nutritional Deficiencies

Nutritional deficiencies have long been recognized as a risk of any weight loss procedure. For patients after RYGB, several factors must be considered. A low-volume gastric pouch alters secretion of gastric acid and intrinsic factor inhibiting the absorption of vitamin B_{12} and other protein-bound micronutrients. The bypassed duodenum and proximal jejunum are the primary sites of absorption of the water-soluble vitamins and necessary cations including calcium, iron, and copper. A side effect of decreased fat absorption leads to malabsorption of the fat-soluble vitamins.

To avoid vitamin malnutrition, pharmacologic supplementation of vitamins and calcium is routine for most patients after RYGB. Careful monitoring of recommended nutritional laboratory parameters is found in Table 102.1. Monitoring is frequent in the immediate post-op period and annually after stability is reached. Clinicians must keep in mind that patients after RYGB and other bariatric operations will become deficient

in vitamins very quickly if oral intake is altered at any point in their postoperative period. Permanent impairment related to deficiency can be avoided with timely intravenous repletion of folate, thiamine, and generic multivitamin in patients with a history of bariatric surgery suffering from decreased oral intake or noncompliant with recommended vitamin regimen.

Weight Recidivism

One of the main factors inhibiting patients and primary care providers from considering bariatric surgery as a tool to treat morbid obesity is fear of weight regain. While some weight gain is expected after the patient's nadir from RYGB, the number of patients who gain more than 10% of their lowest body weight is relatively low. Although long-term results after RYGB are limited due to patients lost to follow-up, the available 10-year follow-up data indicates approximately 10% to 30% of patients will gain more than 10% of their lowest weight.

Recidivism after RYGB is unquestionably multifactorial. Dietary and psychological evaluation and support are crucial in managing a patient suffering from recidivism. Therapy begins by identifying modifiable risk factors, including anatomic and pharmacologic etiologies. Exploration into the anatomy should be considered early in the course of evaluation including gastrointestinal radiographs to define the size and shape of the gastric pouch, examine for gastro-gastric fistulae, and attempt to define the length of the Roux limb if operative reports are unavailable. Upper gastrointestinal endoscopy is also useful at examining for abnormalities in the pouch as well as diameter of the gastrojejunostomy. Examination by an experienced endoscopist may also allow for the visualization of the jejunojejunostomy and potentially the remnant stomach. Weight regain in patients with gastrogastric fistulae or enlarged gastric pouch may benefit from revisional surgery after proper evaluation. Endoscopic therapies to address gastrogastric fistulae and enlargement of the gastrojejunostomy are evolving. Our understanding of gastrointestinal hormone changes after RYGB is limited and may one day help understand recidivism leading to new strategies for prevention and treatment.

TABLE 102.1 Recommended Laboratory Test After Roux-en-Y Gastric Bypass

Test	Rational
Complete blood count	Monitor for anemia, leukocytosis
Basic metabolic profile	Monitor renal function and glucose
Hepatic function panel	Consider in patients with steatosis
Calcium, parathyroid hormone, alkaline phosphatase	Decreased absorption due to bypass of duodenum. Suspect deficiency in patients with low normal calcium, high parathyroid hormone, and elevated alkaline phosphatase. Prolonged calcium deficiency will lead to osteopenia or osteoporosis
Iron, ferritin, total iron binding capacity	Decreased absorption due to bypass of duodenum. Moderate to severe deficiency needed to produce anemia
Folate	Decreased absorption due to bypass of duodenum. Deficiency can lead to anemia
A (Retinol)	Decreased absorption due to lipid solubility. Deficiency linked to ophthalmic symptoms
B_1 (Thiamine)	Decreased absorption due to bypass of duodenum. Stores depleted rapidly with poor oral intake and can lead to encephalopathy
B_2	Decreased absorption due to bypass of duodenum
B_6 (Pyridoxine)	Decreased absorption due to bypass of duodenum
B_{12} (cobalamin)	Decreased binding with intrinsic factor. Deficiency can lead to anemia and neurologic sequelae
D (25-OH D)	Decreased absorption due to lipid solubility. Deficiency can lead to hypocalcemia
E, K, and zinc	Not routinely monitored. Vitamins E and K are lipid soluble. Zinc is bound to albumin and can be low in cases of protein malnutrition
Hemoglobin A1C	Monitored in the initial postoperative period in patients with history of diabetes mellitus. No routine monitoring in patients who have achieved remission of type 2 diabetes mellitus

Psychiatric Considerations

The psychiatric care of the bariatric patient requires careful attention throughout the preoperative and postoperative periods. Psychological screening by an experienced provider before undergoing this truly life-altering procedure can be helpful in preparing every patient as well as identifying patients at-risk of postoperative psychological comorbidities. During this evaluation, many postoperative hurdles can be recognized and treated prior to the operation. Patients should be aware that depression and other psychiatric illnesses may worsen after RYGB. The patient's psychiatric provider can help prepare and careful monitor symptoms during the perioperative period as the absorption of some psychiatric medications is altered after RYGB. Close partnership with the patient's psychiatric provider and weight loss center will provide the patient with

the best chance for long-term success.

CONCLUSION

RYGB has been established as the gold standard for the surgical treatment of obesity for many years. Through the tireless work of pioneers in bariatric surgery, the safety profile has improved significantly over the last two decades. Programs developed through the American College of Surgeons and American Society of Metabolic and Bariatric Surgery have led to a partnership focused on continued quality improvement. The Metabolic and Bariatric Surgery Quality Improvement Project provides a framework for the optimal care of the bariatric patient. Unlike many other procedures, the pathology of morbid obesity is a chronic condition and surgery will not change that fact. As surgeons, we must continue to educate ourselves and communicate with our patient's health care team as we are the experts in the altered physiology.

The causes of obesity are multifactorial and therefore require a multidisciplinary approach. The next frontier of obesity treatment may lie in understanding past and present operations. Although we know the mechanics of the Roux-en-Y gastric bypass well, we are only beginning to unlock perhaps the true reasons the operation works so well by identifying changes in gastrointestinal hormones, the intestinal microbiota, and glucose metabolism. A more complete understanding of these changes will hopefully lead to the best treatment of obesity: prevention.

EDITOR'S COMMENT

Dr.'s Spann and Clements have done an excellent job describing the various complications that can be seen following laparoscopic gastric bypass surgery in this chapter. Gastric bypass has been the most commonly performed bariatric surgical procedure since the discipline of obesity surgery was conceived more than 60 years ago. According to the American Society for Bariatric Surgery, the number of procedures increased from about 16,000 in the early 1990s to more than 103,000 in 2003. The ASMBS estimates that 220,000 people in the United States had bariatric surgery in 2008. Given these numbers, there are millions of patients who have had a gastric bypass who might develop some of the late complications that are described in this chapter.

It is remarkable how safe bariatric surgery, and gastric bypass in particular, has become when compared to the first 10 years of the laparoscopic experience in the United States as a whole. A study published in 2009 using the Longitudinal Assessment of Bariatric Surgery consortium data revealed that the overall risk of adverse outcomes of bariatric surgical procedures was low and contingent on patient characteristics. In fact, the investigators found an overall mortality rate of 0.3% and a major complication rate of 4.1%, both of which were comparable to the rates observed in similar patients undergoing other major abdominal surgical procedures. Over the 6-year period of 2004 to 2009, Dimick et al. demonstrated that the rate of serious complications in Medicare beneficiaries undergoing bariatric surgery decreased from over 8% to less than 4%.

I appreciate the way this chapter is constructed—with an emphasis on prevention, recognition, and management of complications. As mentioned, among the most feared and potentially deadly complications is a gastrointestinal leak, most commonly observed at the gastrojejunostomy. The March 2016 Semi-Annual Risk Adjusted Report for the Metabolic and Bariatric Surgery Quality Improvement Program included 41,393 laparoscopic gastric bypass procedures from 629 sites across the country. The overall incidence of leak was 0.36%. When I first started performing bariatric surgery in 2000, we quoted a roughly 1% to 2% rate of leak—our best understanding of the national average of this complication at the time. The decease in the rate of leak following gastric

bypass is likely multifactorial. Factors potentially contributing to the decreased incidence include more experience (both at hospitals and with individual surgeons), better stapling technology, better patient selection, and an understanding of the technical risk factors associated with this complication.

There are actually three techniques commonly employed to create the gastrojejunostomy in gastric bypass. In addition to the linear and circular stapled methods mentioned in the current chapter, totally hand-sewn techniques are also commonly employed. The introduction of the surgical robot has led to increased utilization of a totally sutured gastrojejunostomy. A 2008 study revealed that 21% of bariatric surgeons prefer a hand-sewn technique for the gastrojejunostomy, 43% prefer the circular-stapled technique, and 41% a linear stapled technique. Lois et al. reported that the incidence of specific complications varies by gastrojejunostomy construction technique including a variation in the incidence of stenosis (likely lowest with completely sutured anastomosis), wound infection (likely highest with circular stapled anastomosis), and bleeding (likely highest in circular stapled anastomosis). Weight loss outcomes appear to be similar with the different gastrojejunostomy construction techniques.

Leak rates by surgeon may relate in part to experience and volume. Numerous studies have demonstrated a volume outcome relationship in gastric bypass surgery, with high volume surgeons and hospitals having lower leak rates and overall rates of morbidity than very low volume surgeons and hospitals as a whole. Our group published a study in 2011 that revealed there is a fairly linear relationship between volume and mortality as well as serious morbidity. We did identify numerous low volume centers with extremely low complication rates and high-volume centers with elevated rates of complications. This suggests that hospital and surgeon volume is not the primary factor associated with complications. An interesting study recently used blinded peer review of videos of individual surgeons performing laparoscopic gastric bypass and determined that the technical skill of practicing bariatric surgeons varied widely, and greater skill was associated with fewer postoperative complications and lower rates of reoperation, readmission, and visits to the emergency department.

Patient selection may play a role in decreasing the rate of serious complication including leak following gastric bypass. Men with central obesity and a very high body mass index have been demonstrated to have a higher leak rate after gastric bypass. Many of these men in the current era are instead offered a laparoscopic sleeve gastrectomy.

The Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) has been releasing semiannual risk-adjusted outcome reports for participating hospitals since 2014. This allows bariatric surgery programs to understand where the true opportunities for quality and process improvement lie, and to design protocols and adopt best practices with the goal of improving outcomes in focused areas. As surgeons and bariatric surgery

programs continue to learn from each other and benchmark their performances against their peers, I believe we will see continued improvements in outcomes through better processes of care that will lead to fewer readmissions, reoperations, and complications overall.

Preventing SBOs and internal hernias is another topic of interest. While the current chapter contains a nice description of the diagnosis and management of these complications, a word about prevention is also warranted. The mesenteric defect at the jejunostomy should be closed. Some surgeons opt not to close this defect. The defect at Peterson space behind the Roux-limb mesentery is closed less consistently and is a bit more controversial. An interesting and recently published multicenter, randomized trial examined this issue in a large cohort of gastric bypass patients. At 12 bariatric surgery centers in Sweden, more than 2,500 patients were randomized at the time of surgery to closure of both the jejunojejunostomy defect and Peterson space or no mesenteric closure. At 3 years after surgery, the cumulative incidence of reoperation because of SBO was significantly reduced in the closure group (cumulative probability 0.055 for closure vs. 0.102 for non-closure, hazard ratio 0.56, 95% CI 0.41–0.76, p = 0.0002). Closure of mesenteric defects increased the risk of severe postoperative complications (54 [4.3%] for closure vs. 35 [2.8%] for non-closure, odds ratio 1.55, 95% CI 1.01–2.39, p = 0.044), mainly because of kinking of the jejunojejunostomy. The authors conclude that the results of their study support the routine closure of the mesenteric defects in laparoscopic gastric bypass surgery, but that closure of the mesenteric defects might be associated with increased risk of early SBO caused by kinking of the jejunojejunostomy.

Another issue is the patient with a ventral incisional or umbilical hernia present at the time of gastric bypass. Given the clean contaminated nature of a gastric bypass, there are obvious concerns about the use of mesh concurrently. The options facing the surgeon include deferring repair until another time (preferably after significant weight loss), primary repair (accepting a high recurrence rate), or repair with mesh (most likely a biologic given the potential for bacterial contamination/seeding of permanent synthetic mesh). Eid et al. demonstrated that when the above 3 approaches were employed and retrospectively reviewed, that deferred repair was associated with a high rate of bowel obstruction (5/14; 38% presented with incarcerated hernia and bowel obstruction within 5 months), primary repair had a high recurrence rate (22%), and repair with a biologic mesh had no recurrences or episodes of incarceration on limited follow-up. My own anecdotal experience is that an umbilical hernia if not repaired at the time of surgery is in a location relative to an antecolic Roux limb where an acute incarceration in the first week following surgery can occur (has happened to me 3 times in a lifetime experience of about 2,000 cases so far). I repair every umbilical hernia I encounter at the time of gastric bypass —usually primarily with suture only.

Early recognition and appropriate management of complications after gastric bypass is also critical. This is something that comes with experience—both

programmatically and on an individual surgeon level. There is sometimes a fine line between recognizing a complication early, and pulling the trigger on an invasive intervention on a patient that does not have a complication necessitating surgery. In the current era where the quality of care physicians and bariatric programs provide is assessed based on metrics such as readmission and reoperation rates, there may be a tendency to not readmit a patient who really needs to be readmitted or to defer a reoperation on a patient who would have benefitted from a procedure at an earlier interval. Surgeons need to understand the appropriate evaluation of a postoperative patient having trouble, and when it is best just to go to the operating room rather than spend time on diagnostic tests. The sensitivity and negative predictive value of tests like upper GI esophagrams to evaluate for a leak and a CT to assess the possibility of an internal hernia need to be understood. Unexplained tachycardia or a fluid deficit that does not respond to appropriate resuscitation in an early postoperative patient are both ominous and sensitive, but not specific early indicators of a leak. My personal threshold to operate on an extraluminal, intra-abdominal bleed in a gastric bypass patient is a little lower than in a sleeve gastrectomy patient due to a personal concern that a hematoma could become infected with organisms from the gastrointestinal tract provided access to the peritoneal cavity and clot by the very nature of the procedure. An infected hematoma is difficult to effectively drain percutaneously with CT guidance.

Bariatric surgery has evolved from a fringe discipline with little science or consistency, to a mainstream and evidence-based specialty where best practices are shared for the benefit of the discipline and our patients. This is an excellent chapter covering an important topic that every general surgeon that takes emergency call should understand. For those that choose to make bariatric surgery a part of their practice, there are many nuances and important points made in this chapter that are critical for ensuring good outcomes.

D THE LIVER AND BILIARY TRACT

103 Surgical Anatomy of the Liver and Bile Ducts

Chung Mau Lo and Kelvin K. Ng

INTRODUCTION

The liver is the largest internal organ in the body and accounts for about 2% of the body weight of an adult. It has a unique dual blood supply and an intimate relationship with the bile ducts. These, together with the frequent occurrence of anatomic variants and the discordance between its external morphology and internal segmentation have made understanding the surgical anatomy of the liver and bile ducts challenging. The surgical anatomy of the liver and bile ducts is based on a clear comprehension of the liver's embryology, natural segmentation, and various congenital variants. A better understanding of the surgical anatomy has contributed to the rapid advancement in hepatobiliary surgery and *vice versa*. The advent of living donor liver transplantation in the last two decades, for example, has brought about a more detailed understanding of the anatomical and functional aspects of the hepatic vasculature and bile ducts and has reset the standard for the safety of liver surgery.

Despite the progress made in our knowledge in surgical anatomy of the liver and bile ducts, the terminology in many textbooks remains confusing and is a major source of challenge in surgical training. In this chapter, we try to avoid excessive review of the development of the terms used in the literature and minimize the description of classic but confusing definitions and nomenclatures. Instead, we focus on the modern concept of the surgical anatomy with a set of widely adopted standard terminology. In each section, following a description of the anatomy, the surgical relevance in the operating room will be highlighted and discussed.

SURFACE ANATOMY OF THE LIVER

The segmental anatomy of the liver and bile duct is more pertinent in liver surgery but an understanding of the surface anatomy and the relationship between the external landmarks and the internal structures remains essential. The surface of the liver is covered by a thin fibrous capsule (Glisson's capsule), which is an extension of the visceral peritoneum. It covers the entire organ except the bare area at the back where the organ lies in contact with the inferior vena cava (IVC) and the right hemidiaphragm, and the gallbladder fossa with the liver hilum (porta hepatis) below where the capsule extends to envelope the hepatic artery, portal vein, and bile duct as these structures enter the liver. The shape of the liver is molded by the adjacent organs. When seen at laparotomy, it has three surfaces. The anterosuperior surface is smooth and covered by the peritoneum up to the attachment of the triangular ligaments and the anterior layer of the coronary ligament. It is related to the inferior surface of the diaphragmatic dome. The posterior surface, which includes the bare area, is largely retroperitoneal. It is related to the vertical part of the diaphragm, the retrohepatic part of the IVC, the right adrenal gland, and the upper pole of the right kidney. The caudate lobe projects from this surface as an appendage sitting on the surface of the IVC. The inferior or visceral surface has an irregular contour as it lies in contact with a number of organs, including the right anterior aspect of the stomach, superior part of the duodenum, head of pancreas, gallbladder, common bile duct, hepatic flexure of the colon, right kidney, and right adrenal gland.

The liver is suspended from the anterior abdominal wall and the diaphragm by four peritoneal attachments, which are commonly referred to as ligaments. The falciform ligament is a crescent-shaped fold, which runs between the anterior abdominal wall above the umbilicus and the anterior surface of the liver. It serves as the surface landmark for the border between the left medial and left lateral sections. The anterior and posterior layers of the coronary ligament mark the limit of the bare area as the peritoneum passes from the body wall to the liver surface. The right and left triangular ligaments are formed by the lateral unification of the layers of the coronary ligament on both sides. At where the bare area of the liver lies in contact with the diaphragm and the IVC, the liver is suspended by loose connective tissue and by the three hepatic veins. There are other ligamentous structures, which are attached to the liver. The round ligament (ligamentum teres) contains the obliterated left umbilical vein and runs in

the free edge of the falciform ligament from the umbilicus to the termination of the left portal vein. The hepatoduodenal ligament contains the hepatic artery, portal vein, and bile duct as these structures run from the upper border of the first part of the duodenum to enter the liver hilum. The ligamentum venosum contains the obliterated ductus venosum that connects the left portal vein to the junction of the left hepatic vein and the IVC in the fetus. It lies on a groove that separates the caudate lobe of liver underneath from the left liver in front. The hepatogastric omentum (lesser omentum) comprises two layers of peritoneal reflection that connect this groove to the lesser curve of the stomach.

The term “hepatic fissures” is confusing as these fissures are based largely on their anatomical relation to the three hepatic veins, not on their external appearance. The umbilical fissure is the only fissure that can be seen on the surface. It forms a deep groove on the inferior surface between the left medial and the left lateral sections that contains the umbilical portion of the left portal vein as it runs an unusually long extrahepatic course, giving off branches to both sides and terminating blindly in the round ligament. The umbilical fissure is marked superficially by the attachment of the falciform and round ligaments at its inferior border.

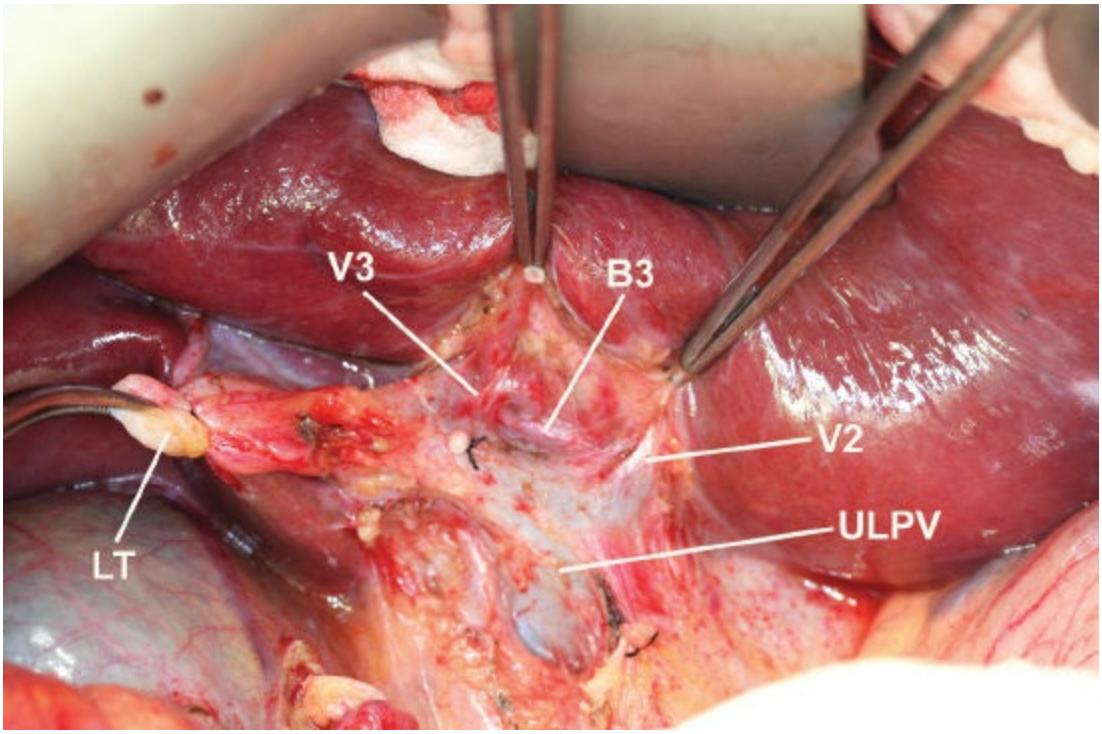

Figure 103.1. Round ligament approach to the segment-3 bile duct. LT, ligamentum teres; ULPV, umbilical portion of left portal vein; V2, branch to segment 2; V3, branch to segment 3; B3,

segment 3 bile duct.

Traditionally, based on the external appearance and the attachment of ligaments, the liver is divided into four anatomical lobes: right, left, quadrate, and caudate. With better understanding of the segmental anatomy of the liver, however, it becomes clear that these terms have very little clinical relevance and are used in different ways by various anatomists and surgeons. Hence, further description and use of these terms except in reference to the caudate lobe should be avoided.

In the Operating Room

Knowledge of the surface anatomy is essential not only for hepatobiliary surgery, but also for any operation around the liver. Mobilization of either side of the liver requires division of various peritoneal attachments such as the falciform ligament, triangular ligaments, and coronary ligament, which are generally avascular. Such division can be done with diathermy except for the round ligament. In patients with portal hypertension, however, venous collaterals may form particularly at the tip of the triangular ligaments and these will have to be ligated before division. Two ligamentous structures provide landmarks for identification of vital structures in hepatobiliary surgery. The round ligament approach allows rapid access to the left portal vein and the left duct, which is a prime location for high bilioenteric anastomosis (Fig. 103.1). The ligamentum venosum marks the left hepatic vein and is important when extrahepatic isolation of the left hepatic vein is required when performing left hepatectomy. Identification and division of the ligamentum venosum at where it attaches to the left hepatic vein will expose the junction of the left hepatic vein with the IVC at the upper border of the caudate lobe (Fig. 103.2).

SEGMENTAL ANATOMY OF THE LIVER

The division of the liver into functional units or segments according to arterial, portal venous blood supply, biliary drainage, and hepatic venous drainage forms the anatomical basis for modern hepatic surgery. Although the concepts of hepatic segmentation as described by Couinaud, Healey and Schroy, and Bismuth, respectively, are close and widely adopted, the terminology is confusing. The Brisbane 2000 Terminology of Hepatic Anatomy and Resections of the International Hepatobiliary Pancreatic Association provides a standard and has been adopted by most textbooks and journal articles.

The Brisbane 2000 Terminology is based on the anatomy of the hepatic artery and bile duct, which has a regular branching pattern, providing arterial blood to and draining the bile from eight functional zones or segments of the liver. As seen from an anterior view, the eight segments are numbered in a clockwise direction as described by Couinaud (Fig. 103.3).

Starting with the proper hepatic artery, the first division is the right and left hepatic arteries supplying the right and left hemilivers or livers, respectively, and there is very little overlap. The plane between the two

distinct zones of blood supply extends from the gallbladder bed anteroinferiorly to the right side of the IVC posterosuperiorly and is called the mid-plane of the liver or Cantlie's line. The middle hepatic vein lies exactly along this plane. On average, the right liver is about two-thirds of the total liver mass while the left liver comprises the other one-third. However, the ratio of the left liver volume to the total liver volume varies significantly and may range from <20% to nearly 50%.

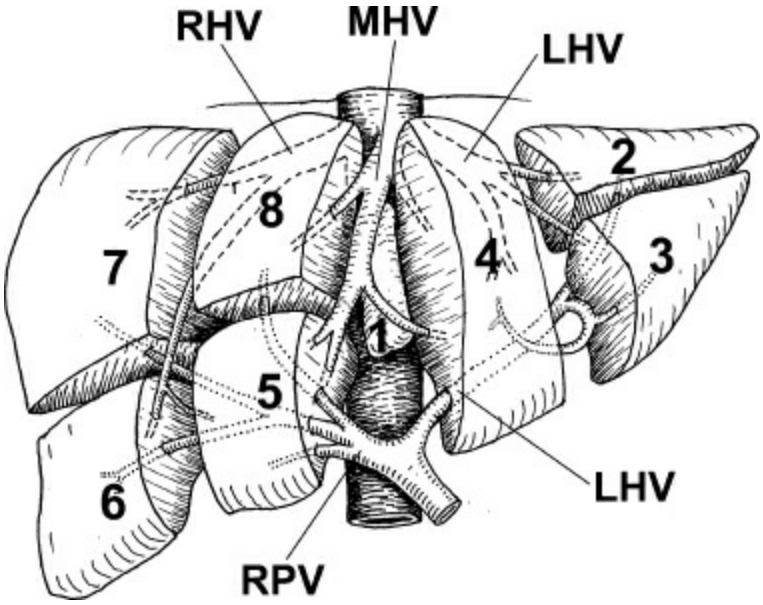

Figure 103.3. Couinaud's anatomic segments of liver (segments 1 to 8). MHV, middle hepatic vein; RHV, right hepatic vein; LHV, left hepatic vein; LPV, left portal vein; RPV, right portal vein.

The right and left hepatic arteries then divide into four second-order sectional arteries each supplying a section of the liver. On the right side, the two sectional arteries supply the right anterior section and the right posterior section, and the plane between these sections is the right intersectional plane. There is no marking on the liver surface for this plane but the right hepatic vein serves as its internal landmark. On the left, the two sectional arteries supply the left medial section and left lateral section. The plane between these sections is the left intersectional plane and is marked by the round ligament at the umbilical fissure and the line of attachment of the falciform ligament to the anterior surface of the liver.

The four sectional arteries divide further to supply seven segments of the liver. The left lateral section consists of segments 2 and 3. The left medial section is a standalone segment 4. The right anterior section is divided into segments 5 and 8 and the right posterior section into segments

6 and 7.

The portal vein branching pattern in the right liver follows the same pattern as that of the hepatic artery and bile duct. The right portal vein divides into a right anterior section branch and a right posterior section branch, which further divide into four segmental branches. The left portal vein, however, has a different branching pattern from that of the left hepatic artery and bile duct. The left portal vein is much longer than the right portal vein and has a transverse portion of 2 to 3 cm located under segment 4 within the hilar plate that sends off only a few branches to segment 4. At the site of attachment of the ligamentum venosum, the left portal vein curves anteriorly and to the left to continue as the umbilical portion in the umbilical fissure (Fig. 103.1). Large branches come off both sides of the umbilical portion of the left portal vein, with multiple branches going from the right side to segment 4 and usually one large one going from the left side to segment 2 and one large one to segment 3. It then terminates as a blind end joining the round ligament anteriorly. Hence, unlike the right portal vein, the left portal vein has a very long extrahepatic course and never enters the liver substance.

Segment 1 or the caudate lobe is a distinct part of the liver functionally independent of the right and left hemilivers. It is bounded posteriorly by the retrohepatic IVC, and superiorly by the left and middle hepatic veins at their origin. Its anterior border is formed by the left portal vein, the liver hilum, and the base of segment 4. The ligamentum venosum also courses along the anterior aspect of the caudate lobe from the left portal vein to the left hepatic vein. The caudate lobe is composed of three parts (Fig. 103.4). The caudate lobe proper (segment 1-l), or Spigelian lobe, sits on the left of the IVC and is separated from the left lateral section by the lesser omentum. The paracaval portion of the caudate lobe lies anterior to the IVC. The caudate process (segment 1-r) fuses indistinctly with segments 6 and 7 of the right liver. Since the venous drainage, arterial and portal venous blood supply, and the biliary drainage of the caudate lobe are completely different from those of the right and left livers, the anatomy of the caudate lobe will be described in a separate section at the end of this chapter.

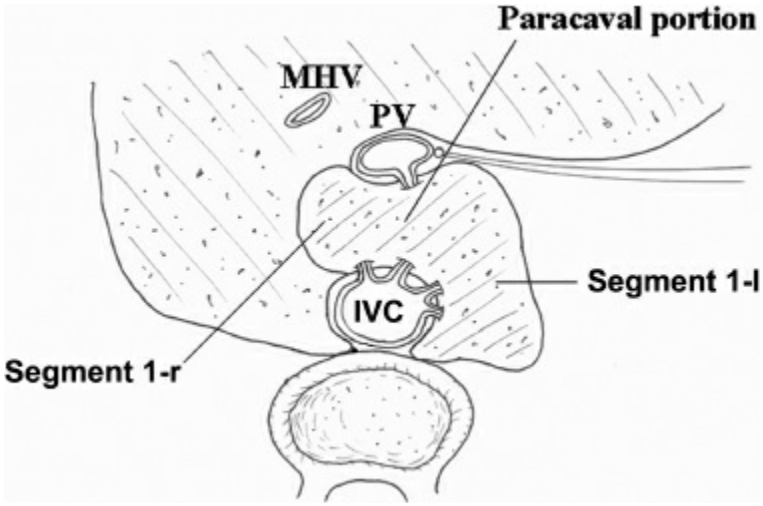

Figure 103.4. Anatomy of caudate lobe. Segment 1-l, caudate lobe proper; Segment 1-r, caudate process; MHV, middle hepatic vein; PV, portal vein; IVC, inferior vena cava.

In the Operating Room

Liver resection can be classified as "anatomical" and "nonanatomical." Anatomical resection refers to removal of functional segments of the liver parenchyma with defined boundaries based on blood supply and biliary drainage. Resections that do not take into account the segmental anatomy of the liver are nonanatomical. Anatomical resections are generally more desirable as the parenchymal transection plane follows the relatively avascular watershed plane between segments and the vascular supply and biliary drainage of the liver remnant are less likely to be compromised. There may be a wider surgical margin with improved oncologic outcome.

The Brisbane 2000 Terminology of Hepatic Resection is based on the segmental anatomy of the liver. Resection of one side, a section or a segment of the liver is referred to as hepatectomy or hemihepatectomy, sectionectomy or segmentectomy, respectively. Hence, there are right and left hepatectomies or hemihepatectomies, and the sectionectomies are left lateral sectionectomy, left medial sectionectomy, right anterior sectionectomy, and right posterior sectionectomy. Resection of three contiguous sections is called trisectionectomy. A right trisectionectomy involves resection of the right liver together with the left medial section, and a left trisectionectomy involves resection of the left liver together with the right anterior section. The term "extended hemihepatectomy" has been used as a synonym for trisectionectomy but may be used for a hemihepatectomy that extends across the mid-plane. Hence, an extended right hemihepatectomy includes the middle hepatic vein with part of

segment 4, and an extended left hemihepatectomy includes the middle hepatic vein with part of segments 5 and 8. A hemihepatectomy or trisectionectomy can be combined with resection of segment 1. While resection of a single segment is referred to as a numbered segmentectomy, more extensive resections can also be named in a similar way. A right hemihepatectomy, for example, is equivalent to resection of segments 5, 6, 7, and 8.

The total liver volume has a relatively constant relationship to the body weight. It is directly proportional to the body surface area and the ideal or standard liver volume of an individual can be estimated using published formulae such as the Urata formula. The ratio of the right or left liver to total liver volume, however, varies considerably between individuals. Hence, in major liver resections or in segmental liver transplantation such as split liver or living donor liver transplantation, preoperative estimation of segmental liver volume using computed tomography or magnetic resonance imaging volumetry is essential. When a right hepatectomy or trisectionectomy is necessary for tumor clearance in a non-cirrhotic liver and the left liver remnant is too small (<25%) on preoperative imaging, a preoperative right portal vein embolization may induce hypertrophy of the future remnant liver and improves the safety of the operation. In segmental liver transplantation, liver volumetry is important for the safety of both the donor and the recipient. In general, the type of liver graft should be chosen to ensure that ratio of the liver graft or remnant volume to the standard liver volume is >35% for the recipient and 30% for the donor. The difference in the recommended acceptable ratio in setting of living donor liver transplantation is attributed to the expected higher standard of safety in the living donor and the presence of ischemic-reperfusion injury, rejection, and presence of portal hypertension in the recipient.

ANATOMY OF HEPATIC VEINS

The anatomy of the hepatic veins of the liver is closely related to its segmental anatomy as the three major hepatic veins run in the intersectional planes between the four different sections and serve as important landmarks within the liver parenchyma for defining the boundaries between different segments. The venous blood from both the right and the left lobes of liver is collected by the branches of the three main hepatic veins (right, left, and middle), which drain into the suprahepatic part of the IVC below the diaphragm (Fig. 103.5). The

middle hepatic vein joins the left hepatic vein to form a common trunk of about 1 cm long in 85% of cases before draining into the suprahepatic IVC. Occasionally, the two veins drain separately into the IVC. The right hepatic vein joins the right side of the IVC at a level slightly below that of the common trunk of the middle and left hepatic veins. There are multiple phrenic veins from both sides of the diaphragm, which drain into the lateral edge of the IVC close to or *via* the right and left hepatic veins. The suprahepatic IVC with the roots of the three main hepatic veins and its junctions with the phrenic veins are enclosed in a thick fibrous sheath, which is a direct extension of the diaphragm. On the posterior aspect of the retrohepatic IVC at the level of the junction with the right hepatic vein, a fibrous band called the IVC ligament (Makuuchi ligament) courses between the dorsal edge of the left side of the caudate lobe and the right liver. This ligament sometimes contains a bridge of thick liver tissue in which case the retrohepatic IVC will appear to pass through a tunnel in the liver.

The right hepatic vein courses in the right intersectional plane between the right anterior and posterior sections. It is the longest vein in the liver and is single in >90% of cases. The main trunk of the right hepatic vein is formed by the convergence of an anterior trunk, which mainly drains segments 5 and 6, and a posterior trunk that chiefly drains segment 7. Over 60% of individuals have one or more right inferior hepatic veins present, which separately drain segment 6 or 7, or even the whole right posterior section directly into the IVC (Fig. 103.6). Under such circumstances, the right hepatic vein itself may be rather small.

The middle hepatic vein lies in the midplane between the right and left livers and provides venous drainage for both the right anterior section (segments 5 and 8) and the left medial section (segment 4). The main stem of the middle hepatic vein originates in three different ways: from the confluence of two equally sized branches from segments 5 and 4, as a main stem receiving multiple small branches from the same segments, and as a main stem from segments 5 and 6. The main stem invariably receives multiple branches from segments 8 and 4 as well. About 60% of the venous branches that drain segment 8 terminate in the middle hepatic vein. The middle hepatic vein provides venous drainage for ～30%, or as high as 50%, of the right liver.

The left hepatic vein arises from a transverse branch, which drains segment 2, and a sagittal branch draining segment 3. In about 10% of

cases, the segment-3 vein drains directly into the IVC; occasionally, it drains into the middle hepatic vein. The left hepatic vein runs in the plane between segments 2 and 3 and enters the left intersectional plane about 1 cm from its termination in the IVC where it may receive a venous branch from segment 4. This segment-4 hepatic vein is frequently named “umbilical vein” (simply because of its close location to the umbilical fissure), which is a misnomer easily confused with the umbilical vein in the fetus (remnant in the round ligament) or the umbilical portion of the portal vein and should be avoided. Venous branches from segment 4 may also drain predominantly into the middle hepatic vein or there may be a mixed pattern.

In the Operating Room

Unlike portal vein branches, which are covered by an extension of the Glissonian sheath, hepatic veins have a thin wall with no capsular covering and are hence a common source of major bleeding during liver surgery. Bleeding from hepatic veins is largely related to the central venous pressure and cannot be effectively controlled by inflow occlusion. Many surgeons regard hepatic veins as a source of trouble and try to deviate away from it during liver transection. Without any anatomical landmark, these surgeons can frequently get lost within the core of the liver parenchyma with the possibility of encountering multiple vascular and biliary branches. In practice, hepatic veins serve as landmarks for intersectional planes within the liver parenchyma to guide true anatomical resections. By identifying and following the course of the main stem of the middle hepatic vein in right hepatectomy (Fig. 103.7), for example, the surgeon would have a guide to a precise and relatively avascular transection plane for bisecting the liver. By taking the segment-5 and segment-8 hepatic vein branches at their junction with the main stem of the middle hepatic vein, the number of venous branches encountered and the amount of bleeding can be minimized. It is important to note that the right liver is, in fact, anatomically right posterior and the left liver left anterior, and the mid-plane is slanting in a right anterior to left posterior direction.

Identification of anatomical variations in the hepatic venous drainage is

crucial in the planning of modern liver surgery. The presence of a large right inferior hepatic vein, for example, allows segmental resection of segments 7 and 8 with resection of the right hepatic vein and preservation of the venous drainage for segments 5 and 6. With the advent of right-lobe living donor liver transplantation, the middle hepatic vein controversy has emerged and has led to a better understanding of the branches of this vein and its relative role in the venous drainage for segments 4, 5, and 8. If the right liver has large venous branches from segments 5 and 8 that drain into the middle hepatic vein and the right liver graft without the middle hepatic vein is used, the venous tributaries of segments 5 and 8 will have to be preserved and reconstructed in order to avoid venous congestion in the liver graft. Similarly, when the middle hepatic vein is taken with a right liver graft, branches that drain segment 4 into the root of the middle hepatic vein will need to be preserved for the donor's safety. A segment-3 hepatic vein that drains directly into the middle hepatic vein poses a special risk as its injury will result in severe congestion in the donor's liver remnant.

The fibrous extension from the crus of diaphragm encloses the suprahepatic IVC with the roots of the three main hepatic veins. Thorough division and clearance of this sheath allows these veins to be exposed. Dissection and division of the phrenic veins on either side would enhance the mobilization further and allow an extra length of hepatic vein to be isolated. The extrahepatic portion of the right hepatic vein is anatomically separate from the middle and left hepatic veins and can be easily isolated. In a classic right hepatectomy this is usually done after mobilization of the right liver with division of venous branches between the caudate lobe and IVC and the IVC ligament. On the left side, approach to the root of the left hepatic vein is facilitated by division of the ligamentum venosum as it attaches to the junction between the left hepatic vein and the IVC. However, since the middle and left hepatic veins form a common trunk before drainage into the IVC, extrahepatic isolation of the left or middle hepatic vein individually may not be possible (Fig. 103.8). Hence, isolation and division of the left or middle hepatic vein in a left lateral sectionectomy and extended right hepatectomy, respectively, will have to be done intrahepatically at the end the liver parenchymal dissection.

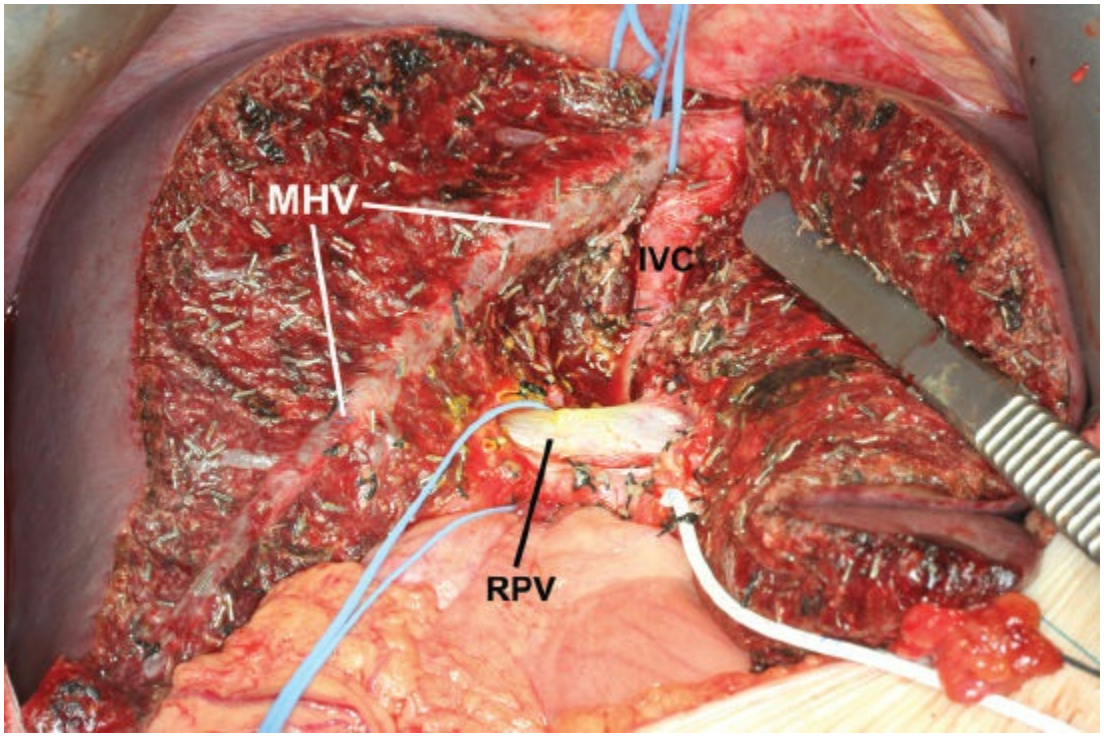

Figure 103.7. Operative photo in a living donor right hepatectomy including the middle hepatic vein showing the mid-plane of the liver following the full course of the middle hepatic vein (MHV). Note the slanting plane of parenchymal transaction. IVC, inferior vena cava; RPV, right portal vein.

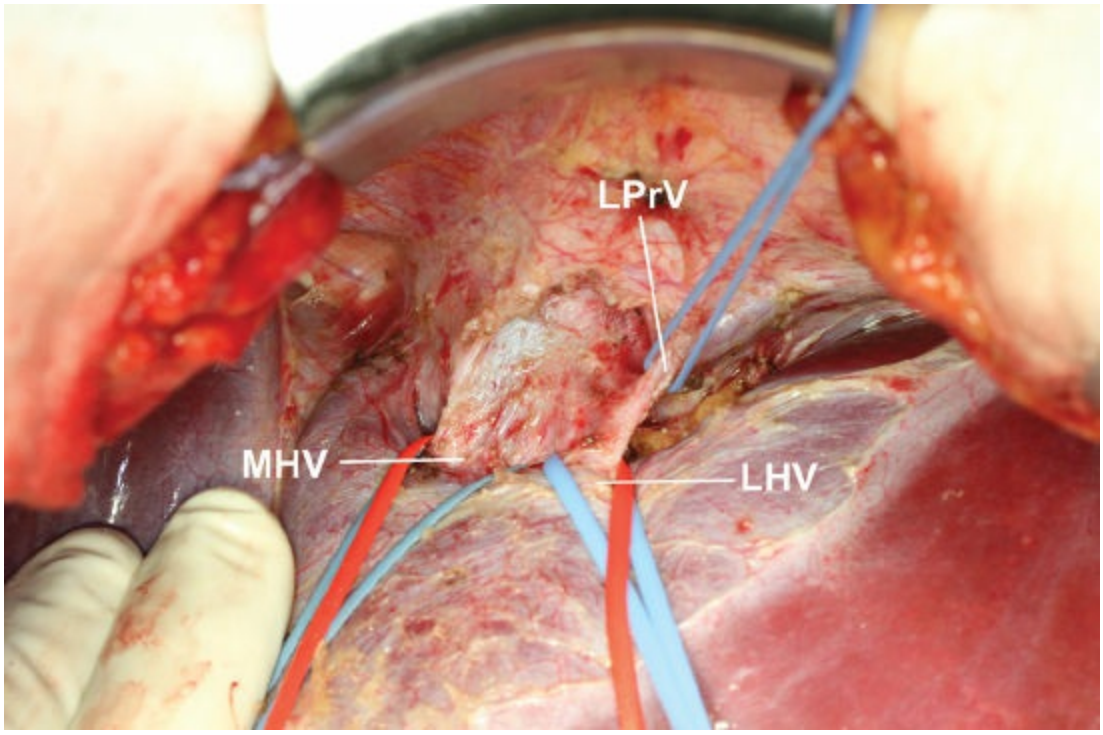

Figure 103.8. Operative photo showing extrahepatic isolation of the left and middle hepatic veins together with their common

trunk. Division of the left phrenic vein allows an extra length of the left hepatic vein to be isolated. MHV, middle hepatic vein; LHV, left hepatic vein; LPrV, left phrenic vein.

ANATOMY OF THE HEPATIC HILUM

The Plate System

The plate system consists of a fibrous sheath that is continuous with Glisson's capsule and extends intrahepatically into the liver and extrahepatically into the hepatoduodenal ligament to surround the branches of the hepatic artery, portal vein, and bile ducts. The combined structure consisting of a fibrous sheath surrounding a hepatic artery, a portal vein, and a bile duct is called a portal pedicle. Within the sheath, there are also lymphatics, nerves, and a small vascular network. The bile duct and hepatic artery are bound together closely while the portal vein is covered with a separate sheath of loose connective tissue. This segmental arrangement of bile duct, hepatic artery, and portal vein in a pedicle is very consistent within the liver, and most of the anatomical variations of the inflow blood vessels and bile ducts occur in the hepatic hilar plate system. There are three plate systems at the liver hilum: the hilar plate, the cystic plate, and the umbilical plate (Fig. 103.9).

The hilar plate is bounded superiorly by segment 4, on the right by the cystic plate, and is continuous with the umbilical plate on its left. The cystic plate is located within the gallbladder fossa and is continuous with Glisson's capsule of the segments 4 and 5. The cystic plate marks the mid-plane of the liver (the Cantle line) in the hilar area and its posterior edge is located on the right side of a right portal vein branch. The umbilical plate is located along the ventral surface of the umbilical fissure. It contains the bile ducts and blood vessels of the left liver and is continuous with the round ligament inferiorly. The upper margin of the umbilical plate is bounded by the superior border of the round ligament.

The lymphatics of Glisson's sheath course through the whole plate system of the hilar area. There is a particularly thick layer of connective tissue between the capsule of segment 4 and the portal vein, containing numerous lymph vessels. The bile duct confluence is located on the hilar plate. It is therefore common that hilar bile duct carcinoma spreads to the plate tissue. On the right side of the hilar plate, the right hepatic artery courses between the cystic plate and hilar plate, while branches of the right portal vein travel posteriorly to the artery before entering Glisson's sheath.

On the left side of the hilar plate, the middle hepatic artery and left hepatic artery course through the umbilical plate, and the left portal vein lies posterior to the artery.

In the Operating Room

The consistent arrangement of bile duct, hepatic artery, and portal vein in a portal pedicle makes it ideal to perform pedicle isolation rather than isolation of individual vessels and bile duct for true anatomical sectional or segmental resection. This is possible on the right side as the right portal pedicle divides into a right anterior portal pedicle and a right posterior portal pedicle supplying the respective sections and then into segmental pedicles supplying the four segments. Hence, in performing right hepatectomy, isolation and division of the right portal pedicle can be performed by lowering the hilar plate and going around the pedicle on its surface. Portal isolation and division can also be performed for right anterior or posterior sectionectomy. The cystic plate narrows at its junction with the hilar plate where it is attached to the sheath of the right portal pedicle. This forms an anatomical landmark for surgical exposure of the right anterior pedicle. On the left side, however, pedicle isolation is not feasible for left hepatectomy or anatomical sectional resection because there is no sheathed portal pedicle for the left liver or its medial and lateral sections.

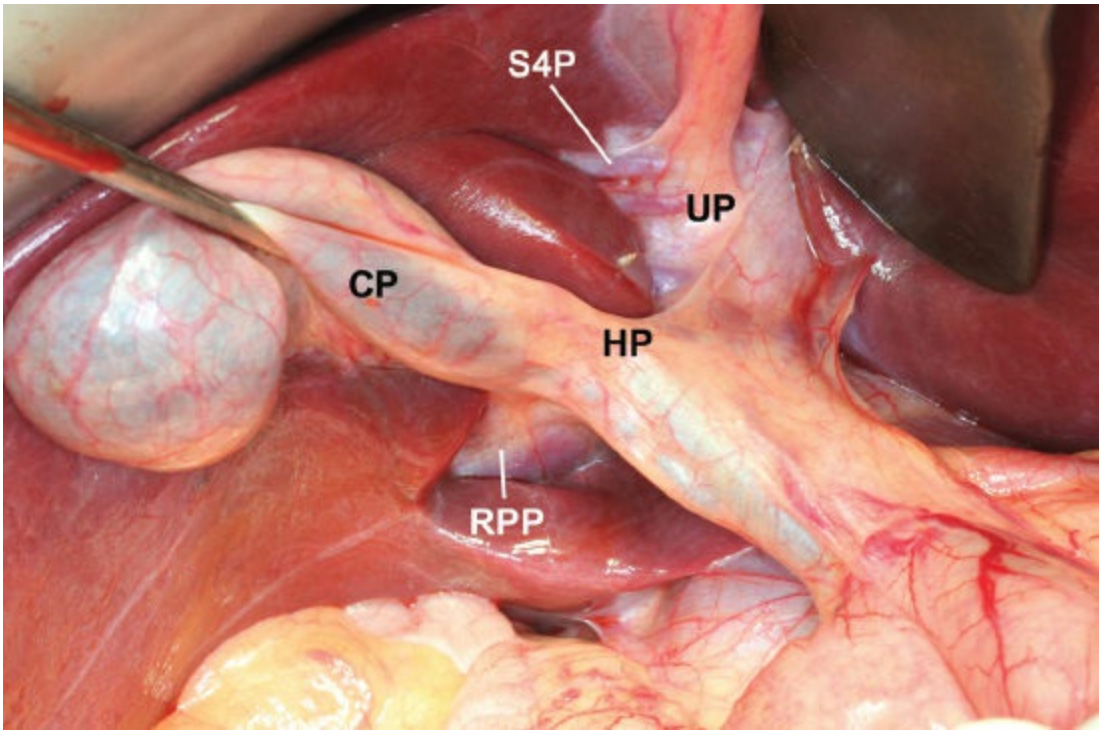

Figure 103.9. Surface anatomy of the plate system showing the cystic plate (CP) covered by the gallbladder, the hilar plate (HP), and the umbilical plate (UP). S4P, segment 4 pedicle; RPP, right posterior pedicle.

The connective tissue of Glisson's sheath at the hilar plate closely encloses the bile ducts while the arterial and portal branches are more loosely bound. Hence, separation of the bile duct from the hilar plate is difficult and will inevitably damage the duct itself or jeopardize its blood supply. In biliary surgery such as living donor hepatectomy where bile duct reconstruction is necessary, the hepatic duct should be isolated together with the surrounding Glissonian sheath and divided sharply with scissors in order to preserve its blood supply.

The cystic plate separates the gallbladder from the liver. However, the origin of the middle hepatic vein lies deep in the plate and there is occasionally a large branch of bile duct at this site. Hence, during cholecystectomy, dissection into the wrong plane and perforation of the plate may result in torrential bleeding and bile leakage.

Portal Vein

The main portal vein divides at the liver hilum into the right and left portal veins, supplying the right and left livers, respectively. The right portal vein lies anterior to the caudate process and enters the right liver through the hilar plate, dividing into anterior and posterior branches. The right anterior portal vein runs forward in a vertical plane, and it divides into descending and ascending branches for segments 5 and 8, respectively. The right posterior portal vein curves posterolaterally in a horizontal plane, and divides to supply segments 6 and 7. The left portal vein has a much longer extrahepatic course. It has a transverse portion of 2 to 3 cm within the hilar plate, and it curves anteriorly and to the left as the umbilical portion towards the base of the umbilical fissure where it joins the round ligament anteriorly. Large branches come off both sides of the umbilical portion of the left portal vein, with multiple branches going from the right side to segment 4 and usually one large one going from the left side to segment 2 and one large one to segment 3. It then terminates as a blind end joining the round ligament anteriorly. The caudate lobe commonly derives blood supply from both the left and right portal veins.

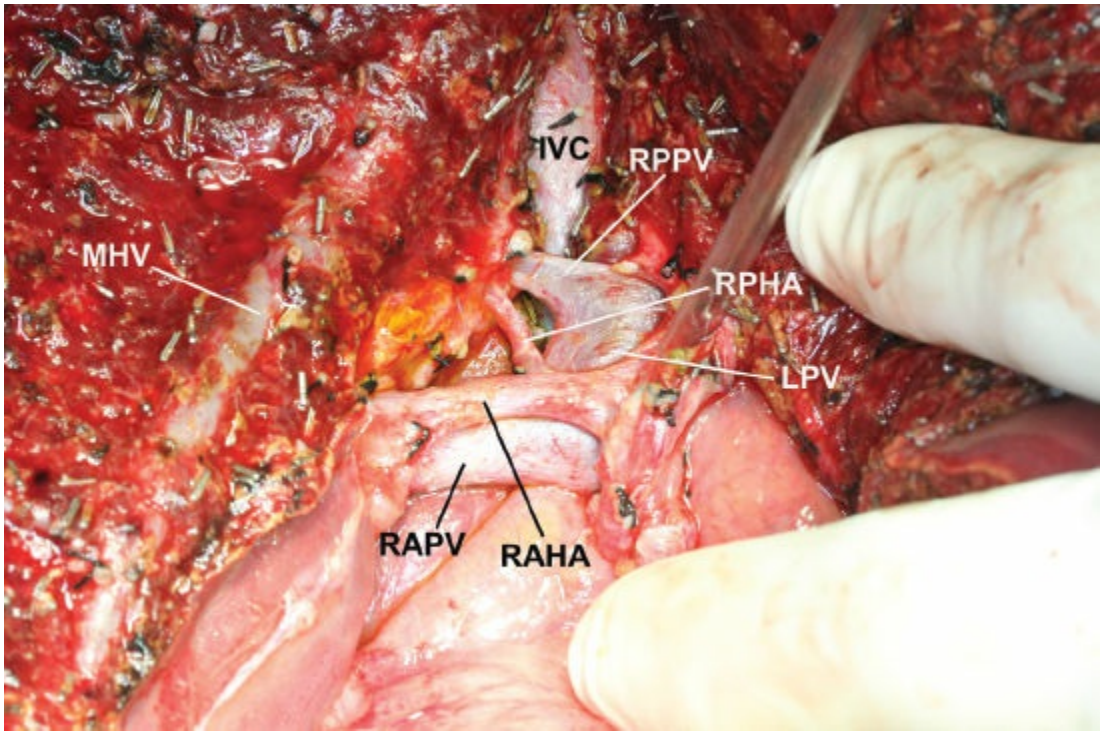

Figure 103.10. Operative photo showing separate right anterior section and right anterior section portal veins. MHV, middle hepatic vein; LPV, left hepatic vein; IVC, inferior vena cava; RAPV, right anterior portal vein; RPPV, right posterior portal vein; RAHA, right anterior hepatic artery; RPHA, right posterior hepatic artery.

The anatomy of the left portal vein is remarkably constant, whereas the right portal vein has more anatomical variations. Normal right portal vein anatomy where a right portal vein bifurcates into a right anterior vein and a right posterior vein occurs in 75% of cases. In 10% of cases, a trifurcation of the main portal vein occurs, where the right portal vein immediately divides into two sectional branches. In about 12% of cases, a right portal vein does not exist and a right posterior sectional branch coming from the left portal vein at a short distance after the main portal vein gives off a right anterior portal vein branch (Fig. 103.10). In these variants of portal vein, the transverse portion of the left portal vein is much shorter than normal. Very rarely, the left portal vein is absent and the main portal trunk is undivided as it enters the liver hilum, giving off the right sectional branches, and then turns left, crossing the umbilical fissure intrahepatically as the left portal vein. Anatomical variants of the portal vein are closely associated with those of the biliary tract in >80% of cases.

In the Operating Room

Failure to recognize portal vein anatomical variants may unintentionally create confusion or jeopardize the portal flow to a section of the liver during hilar dissection in liver surgery. In the event of a portal vein trifurcation or the right posterior portal vein branch arising from the left portal vein, an unsuspecting surgeon conducting right hepatectomy may mistake the lower sectional branch for the right portal vein, only to find the second sectional vein during parenchymal transection. For left hepatectomy, the shortness of the transverse portion of the left portal vein under such circumstances may create difficulty in its safe isolation and division. Isolation and division of branches to the caudate lobe (segment 1) is the key to allow adequate length for the procedure. When the extrahepatic left portal vein is absent, a catastrophic complication may happen during right hepatectomy as the main portal vein may be mistaken for the right portal vein as it enters the liver in a position similar to the right portal vein. The need to preserve blood supply to both sides of the liver in living donor hepatectomy has driven the refinement of preoperative radiological imaging with CT or MR angiogram and 3-D reconstruction, and anatomical vascular variants should now be clearly defined by preoperative imaging and the operation planned accordingly.

The entirely extrahepatic course of the left portal vein in the umbilical fissure and the long left hepatic duct provide an excellent option for liver surgeon contemplating resection of a centrally located liver tumor or bile duct cancer with a right trisectionectomy. The portal vein and hepatic artery branches to segment 4 can be isolated in the umbilical fissure outside the liver capsule on the right of the umbilical portion of the portal vein, thus, providing adequate tumor-free margin even for tumors that appear to compress on the left portal vein on imaging. The left hepatic duct can be divided as much towards the left side as possible even before the junction of the ducts from segments 2 and 3. As a result of the oblique course of the main trunk of the left hepatic vein running between segments 2 and 3 as described in the previous section, the resection can even be extended into the left lateral section on the left side of the falciform ligament cranial to the umbilical fissure.

Hepatic Artery

In normal anatomy, the common hepatic artery, a branch of the celiac trunk, supplies the right and left livers through its right and left hepatic branches, respectively. The common hepatic artery runs on the left side of

the main portal vein in the hepatoduodenal ligament and may divide into right and left branches anywhere between its origin and the hilum of the liver. The division usually takes place to the left of the hilum, resulting in a longer right hepatic artery. The left hepatic artery courses along the left side of the hilar plate with the left hepatic duct and the left portal vein for a varying distance before entering the liver at the level of the umbilical fissure. The right hepatic artery courses laterally to the right, posterior to the common hepatic duct and right hepatic duct but anterior to the portal vein. It gives off the cystic artery and eventually divides into the anterior and posterior sectional arteries before entering the liver parenchyma. The cystic artery crosses the common hepatic duct posteriorly or anteriorly. As it runs towards the gallbladder, it courses through the hepatocystic triangle (Calot's triangle), which is bounded by the common hepatic duct on the left, the cystic duct on the right, and the inferior surface of segment 4 above. The cystic artery runs to the upper border of the gallbladder superior to the site of the cystic duct and divides into an anterior and a posterior branch that ramify on the gallbladder surface.

Anatomical variants of the extrahepatic artery are common and only ~55% of population has a normal anatomy. A variant can be a replaced artery that serves as the only arterial blood supply for a particular part of the liver while the artery in normal location does not exist, or an accessory one that provides dual supply for a volume in conjunction with the normal artery. It may supply a segment, section, hemiliver, or even the whole liver. The commonest arterial variant is a replaced left hepatic artery that arises from the left gastric artery and courses in the lesser omentum to enter the liver at the umbilical fissure. It is found in 25% of cases. A replaced right hepatic artery originates from the superior mesenteric artery and runs behind the portal vein and the lower end of the common bile duct to continue on the right border. It is present in about 17% of cases. More rarely, the common hepatic artery arises wholly from the superior mesenteric artery in 2.5% of cases, and occasionally it arises from the left gastric artery or the aorta. In about 75% of population, there is a normal anatomical relationship between the right hepatic artery and the common hepatic duct, that is, the hepatic artery courses posterior to the bile duct. However, the right hepatic artery may run an aberrant course anterior to the bile duct or even posterior to the portal vein. The cystic artery may arise from the right hepatic artery on the left side of the common hepatic duct and may run anterior to it. It may also arise from an aberrant right

hepatic artery.

The middle hepatic artery is defined as an extrahepatic arterial branch that originates from the liver hilum and enters the umbilical fissure to supply segment 4 and occasionally part of segment 2 or 3 (Fig. 103.11). It exists in about 70% of population, and in the remaining 30%, this hilar vessel does not exist and the arterial supply for segment 4 comes from the left hepatic artery within the umbilical fissure. The middle hepatic artery originates from the right hepatic artery (44%) or, less commonly, the left hepatic artery (26%) when the hepatic arterial anatomy is normal. In the presence of a replaced right or left hepatic artery, the middle hepatic artery always originates from the contralateral hepatic artery in normal anatomic position, which also gives off the gastroduodenal artery. The anatomic variations in the extrahepatic arteries can be explained by their embryology. Embryologically, the liver is supplied by three hepatic arteries: the embryonic left hepatic artery from the left gastric artery, the embryonic middle hepatic from the common hepatic artery, and the embryonic right hepatic artery from the superior mesenteric artery. The replaced left hepatic and right hepatic arteries are the descendant of the embryonic left hepatic artery and right hepatic artery, respectively. The middle hepatic artery is derived from the embryonic middle hepatic artery.

In the Operating Room

Surgeons must be aware of the various anatomical variants of the hepatic artery. Although an artery located on the right side of the bile duct always supplies the right liver, arteries found on the left side may supply either side of the liver. Hence, it is safer not to make assumption on any artery based on its size, position, or direction. Adequate exposure and, if necessary, trial occlusion with confirmation by radiological means (intraoperative Doppler ultrasound) are necessary before any artery at the liver hilum is ligated and divided.

Replaced arteries may confer an advantage or disadvantage during surgery. In the presence of a replaced left hepatic artery that supplies the left liver, right hepatectomy for hilar cholangiocarcinoma can be performed with radical resection of the hepatoduodenal ligament by resecting the entire proper hepatic artery with only the portal vein preserved. The artery of a left lateral section liver graft from a living donor can also be taken to include the left gastric artery at its junction with the celiac axis in order to facilitate arterial reconstruction in the recipient. On the other hand, such a replaced left hepatic artery may be at risk when the

lesser omentum is divided as in a gastric operation. Similarly, a replaced right hepatic artery coursing along the right side of the common bile duct may also be damaged as the bile duct is isolated and divided in operation such as hepaticojejunostomy or Whipple operation.

When more than one artery is encountered in a partial liver graft from a living donor, the arterial reconstruction presents a technical challenge. In general, most of these are end arteries and have to be reconstructed. However, some of these are accessory and may communicate with the main artery through collaterals that may not be visible on preoperative angiography. To determine whether a smaller arterial branch to a partial graft needs reconstruction, the degree of back-bleeding from the stump of the branch can be examined at the completion of a donor hepatectomy or after reconstructing the larger arterial branch in the recipient.

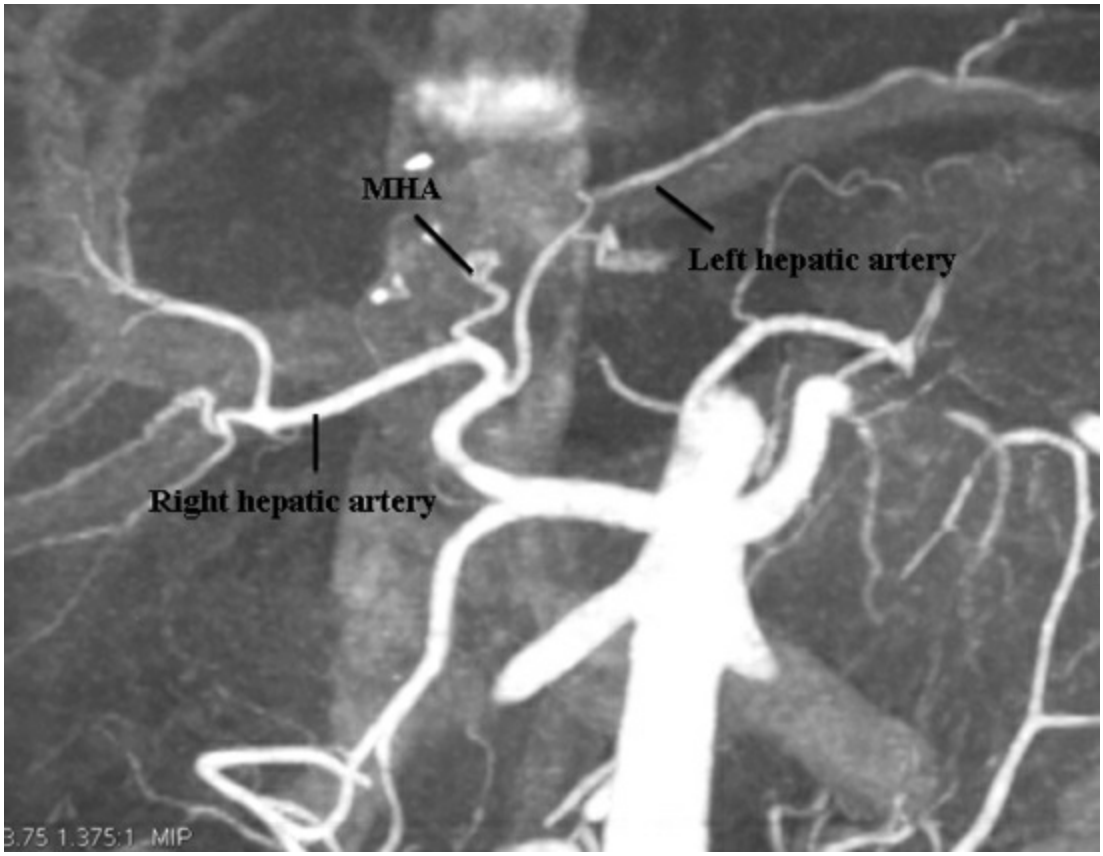

Figure 103.11. CT angiogram showing the middle hepatic artery (MHA) arising from the right hepatic artery.

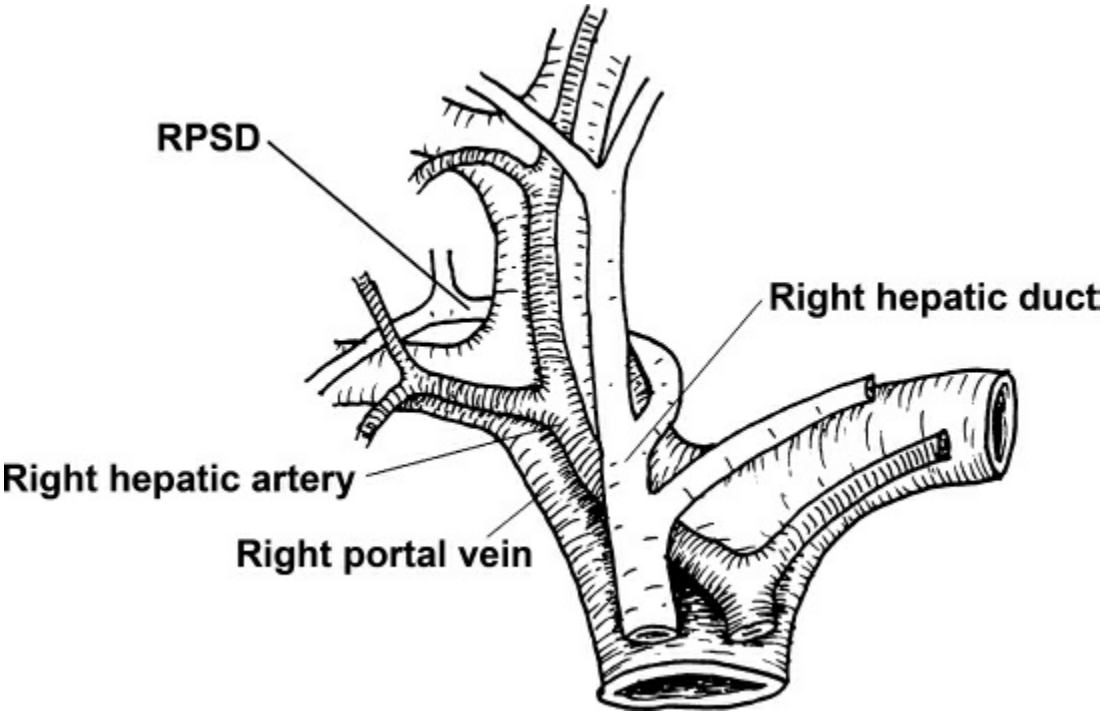

Figure 103.12. Schematic diagram showing the right posterior sectional duct (RPSD) that run superior to the right anterior portal vein (epiportal) to join the right hepatic duct.

During cholecystectomy, the cystic artery is usually identified as it runs in the Calot's triangle towards the gallbladder. Elevation of the undersurface of the liver together with lateral retraction of the neck of the gallbladder allows better exposure for clearance of this triangle and safe identification of cystic structures. Depending on the site of branching of the cystic artery and the point of dissection, a single cystic artery or its anterior and posterior branches may be encountered and divided separately. Occasionally, the right hepatic artery runs an unusually tortuous course low in the Calot's triangle and the cystic artery is very short. Inadvertent injury of the right hepatic artery may occur unless the dissection is kept close to the surface of the gallbladder.

Bile Ducts and Gallbladder

The normal biliary anatomy exits in only about 50% of population. The right hepatic duct, which has a short extrahepatic course of only about 1 cm, is formed by the confluence of the right anterior and right posterior sectional ducts at a variable point in its intrahepatic course. The right anterior sectional duct drains segments 5 and 8. It lies vertically and is located to the left of the right anterior portal vein. The right posterior

sectional duct drains segments 6 and 7. It courses horizontally and usually runs superior to the right anterior portal vein (epiportal) to join the right anterior duct, forming the right hepatic duct above the right portal vein (Fig. 103.12). In about 20% of cases, the right hepatic duct runs inferior (hypoportal) to the right anterior portal vein. In rare situations, there is a combined pattern in which some branches of the right posterior sectional duct enter the distal bile duct supraportally and the remaining branches infraportally. In the left liver, segment-2 and -3 segmental ducts fuse to form the left lateral section duct, which then unites with one or more branches from segment 4 to form the left duct. The left duct runs horizontally from left to right for a distance of 2 to 3 cm along the base of segment 4, first above and then behind the left portal vein, until it joins the right duct to form the common hepatic duct.

The right hepatic duct is frequently absent and a common biliary anatomical variant in the right liver involves a sectional or segmental bile duct joining the left hepatic duct to form a triple confluence (Fig. 103.13). On the other hand, a sectional or segmental duct (Fig. 103.14) may join the common hepatic duct well below the normal confluence. The cystic duct may drain into such an aberrant right duct before draining into the common hepatic duct. The left hepatic duct has a more consistent anatomy, and its major variation involves the site of insertion of the segment-4 duct into the left lateral section duct forming the left hepatic duct, which may vary from its origin at the umbilical fissure to its termination at the confluence with the right hepatic duct. Occasionally, there are multiple ducts draining segment 4 into the left duct, or the segment-4 duct may join the segment-3 duct before uniting with the segment-2 duct.

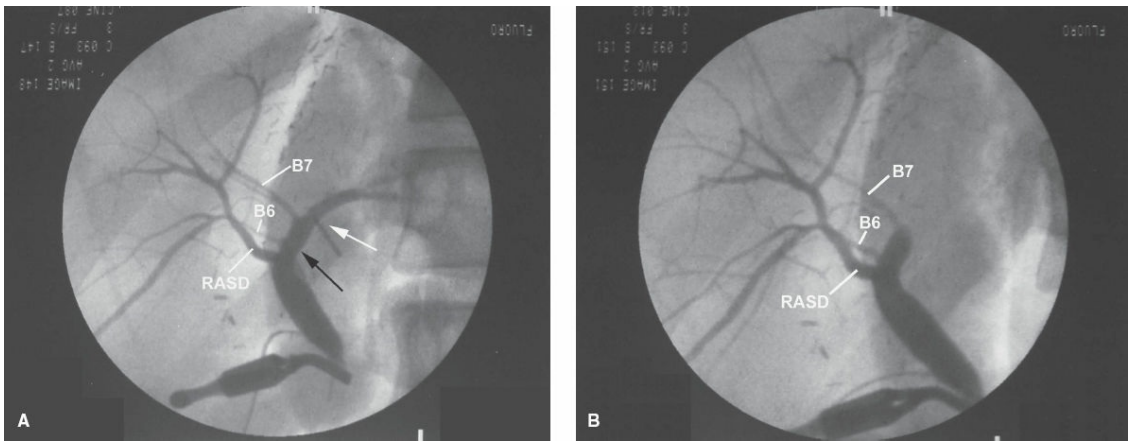

Figure 103.13. A: Operative cholangiogram during a left

hepatectomy showing a separate segment 6 duct (B6) and segment 7 duct (B7) draining into the left hepatic duct. A radiopaque marker showed the correct site of left duct transaction (*white arrow*). Transection too close to the biliary confluence (*black arrow*) would have damaged these right posterior sectional ducts. **B:** Postresection cholangiogram. RASD, right anterior section duct.

The gallbladder sits on the cystic plate on the inferior surface of the liver at its midplane. Its relation to the liver ranges from hanging from a loose peritoneal reflection to being deeply embedded within the liver parenchyma. Large gallstones impacting within the neck of the gallbladder may create a Hartmann's pouch before it narrows towards the cystic duct, which is normally about 1 to 2 cm long and contains the spiral valves. The cystic duct joins the common hepatic duct to form the common bile duct at a variable site ranging from the right hepatic duct to the ampullary region. The configuration of the cystic duct with the common hepatic duct follows three patterns. In the majority, the cystic duct joins the common hepatic duct at an acute angle (75%). In others, the cystic duct runs parallel to the right side of the common hepatic duct for a distance (20%) or spirals posterior to the common hepatic duct before entering on its left side (5%). The common bile duct runs downwards at the right lateral edge of the hepatoduodenal ligament, with the common hepatic artery on its left and the main portal vein at its back. It passes posterior to the first part of the duodenum and crosses behind the pyloric vessels and the pancreaticoduodenal arteries. Then it continues behind or in the posterior part of the head of pancreas, forming its retropancreatic portion before passing through the Sphincter of Oddi to enter the second part of the duodenum at the major papilla. The major papilla protrudes into the duodenal lumen at ~8 cm from the pylorus. The pancreatic duct forms a common channel with the common bile duct in 85% of cases, but occasionally the two ducts enter the duodenum separately.

The intrahepatic bile ducts receive blood supply only from the hepatic artery. The right and left ducts and their confluence have a rich arterial plexus on the liver hilum surface (hilar plexus) with a communicating arcade between the right and the left arterial systems located within the hilar plate. This epicholedochal plexus extends inferiorly to cover the entire common bile duct with two main longitudinal branches running at the 3 o'clock and 9 o'clock positions to anastomose with the arteries

coming from below. The supraduodenal bile duct receives an average of eight small arterial branches from the retroduodenal artery, gastroduodenal artery, and right hepatic artery. The veins draining the bile duct are parallel to the corresponding arteries on the surface of the bile duct.

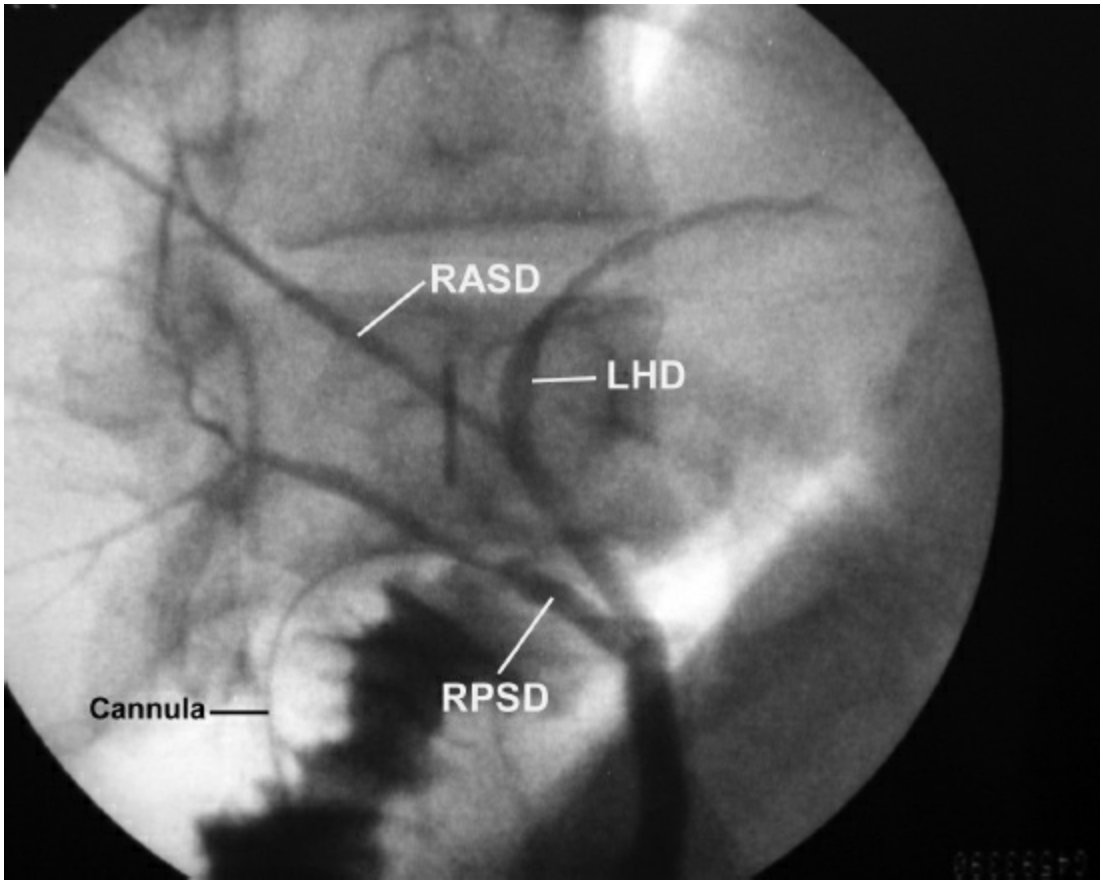

Figure 103.14. Operative cholangiogram showing a right posterior sectional duct (RPSD) draining directly into the common hepatic duct at a low level. The cystic duct drains into this aberrant duct. RASD, right anterior sectional duct; LHD, left hepatic duct.

The lymphatic drainage of bile ducts diverges into two pathways. The superior pathway involves lymph nodes along the cystic duct, hepatic artery, and celiac plexus, whereas the inferior pathway involves the nodes along the cystic duct, the anterolateral aspect of the portal vein, the posterior pancreas, and the aortocaval region.

In the Operating Room

During cholecystectomy, several anatomical variants may predispose to biliary complications. The parallel configuration of the confluence of the cystic duct and the common hepatic duct may predispose the common

hepatic duct to injury at the side, particularly if dissection is performed with diathermy. Tiny bile ducts (ducts of Luschka) may enter the gallbladder through the cystic plate and may be divided. A right hepatic sectional duct, which joins the common hepatic duct at a low level may be mistaken for the cystic duct and be injured. The risk is even higher if the cystic duct actually drains into this aberrant duct (Fig. 103.14). To avoid this complication, it is important to avoid excessive use of powerful hemostatic devices to dissect the gallbladder and the bile duct. Before a tubular structure thought to be the cystic duct is divided, its anatomy should be carefully delineated by dissection towards the infundibulum so as to ensure that the structure does end in the gallbladder.

Biliary complication is a common and serious morbidity after liver surgery and liver transplantation. Knowledge of the biliary anatomy can be obtained by preoperative magnetic resonance cholangiography, but an intraoperative cholangiogram preferably with radiopaque markers provides more detailed information and better localization. Since the right liver is anatomically right posterior and the left liver left anterior, the mid-plane is slanting from right anterior to left posterior and the best direction for a cholangiogram is a right anterior oblique view (Fig. 103.15). Intraoperative cholangiography should therefore be performed under fluoroscopy. When the anteroposterior view is rotated to a right anterior oblique view, the branches of the right anterior section duct will move medially while those of the right posterior section duct will move laterally, and the true length of the right and left hepatic ducts will be more clearly delineated. When an anatomical variant of a right sectional duct draining independently into the left hepatic duct is found during left hepatectomy (Fig. 103.13), the left hepatic duct will have to be divided closer to the umbilical fissure to avoid damage to this right sectional duct. In living donor hepatectomy operation, a highly precise transection point of the hepatic duct indicated with the help of a radiopaque marker is critical for safeguarding the donor’s remnant biliary tree and avoiding biliary complication in the recipient.

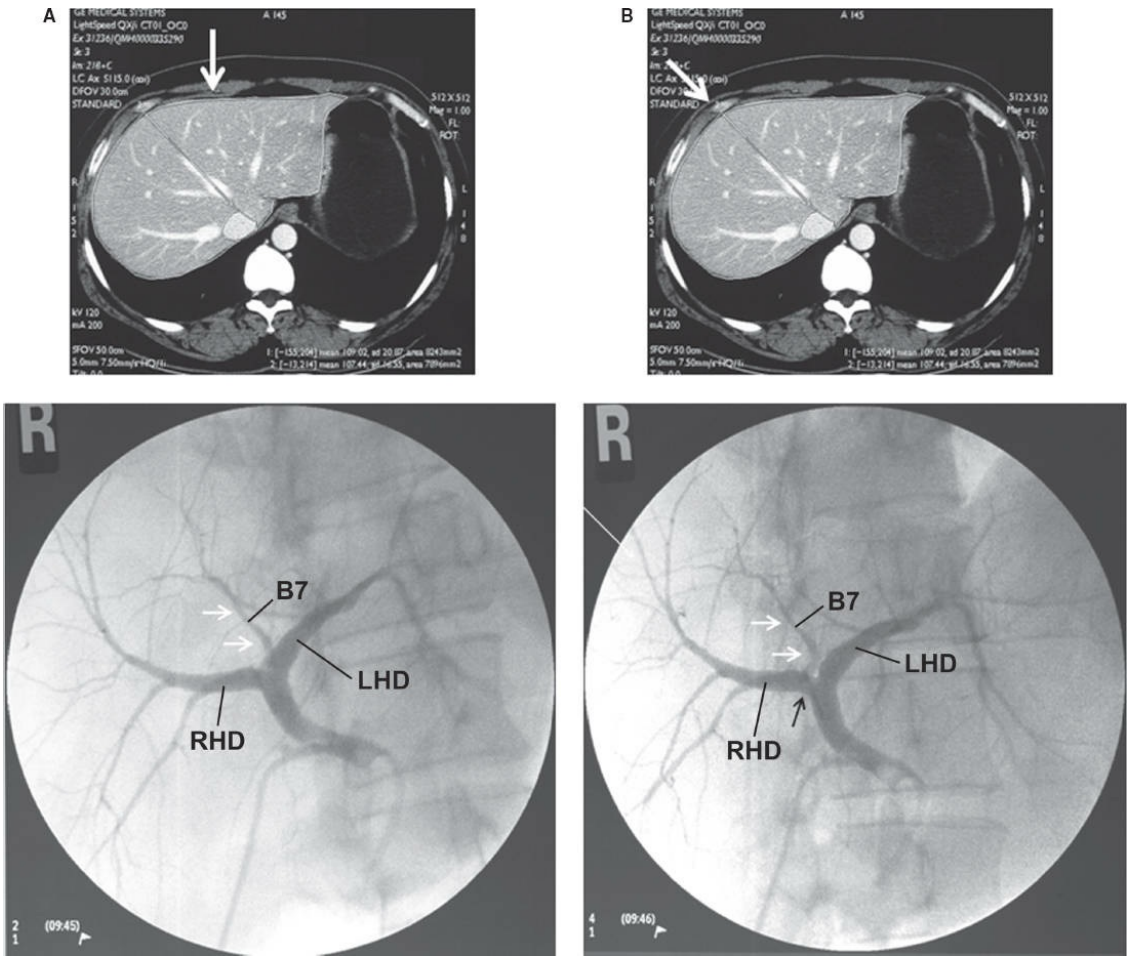

Figure 103.15. A: Operative cholangiogram in an anteroposterior view showing a segment 7 duct (B7, *white arrows*) apparently draining into the left hepatic duct (LHD) in a right liver donor. **B:** The right anterior oblique view showed that B7 actually joins the right hepatic duct (RHD). Transection of the RHD should be made precisely at the site of the *black arrow.*

The axial pattern of the arterial blood supply from both ends of the extrahepatic bile duct implies that there is an arterial watershed and transection of the duct at a different level may result in ischemia of either side of the cut ends. To ensure a healthy bile duct stump, in operations involving the upper end (as in hepaticojejunostomy or a whole liver graft), the bile duct should be divided above the cystic duct junction close to the confluence of the right and left ducts. In operations related to the distal end (as in liver transplant recipients), the level of division should not be extended too much to the hilum and care should be taken to preserve the soft tissue covering the epicholedochal plexus around the duct. As a result of the presence of the hilar plexus around the confluence of the right and left ducts, occlusion of either the right or left hepatic artery will not affect

the blood supply of the bile duct.

ANATOMY OF CAUDATE LOBE

As described previously, the caudate lobe or segment 1 is anatomically and functionally distinct from the right and left hemilivers. It is located behind the liver hilum and in front of the retrohepatic IVC. While the caudate lobe proper, or Spigelian lobe, protrudes visibly from the left side of the IVC, its anterior border fuses indistinctly with segment 4 and its right border with segments 6 and 7. The caudate lobe is the only hepatic segment that does not drain into one of the main hepatic veins. There are one or two large short hepatic veins and numerous small ones that drain directly into the retrohepatic IVC, usually at its left anterior side. An average of three short portal branches from the right, left, or main portal vein close to the bifurcation supply the caudate lobe (Fig. 103.16). There are a similar number of arterial branches directly coming from the right and left hepatic arteries along their courses. Bile drains through a variable number of ducts into the left hepatic duct, right hepatic duct, or both. The segment-1 ducts run above the portal branch and join the corresponding bile duct on its posterior aspect close to the biliary confluence.

In the Operating Room

In difficult right hepatectomy, mobilization of the right lobe of the liver and isolation of the caudate and right hepatic veins may be performed after liver transection is completed (the anterior approach). In order to facilitate and guide the transection, a clamp may be passed to draw a tape along the anterior surface of the IVC between the right and the middle hepatic veins to suspend the posterior surface of the caudate. In making this hanging maneuver, it is important to avoid the large caudate veins, which are usually on the left lateral side of the IVC. In pathological conditions such as Budd–Chiari syndrome, the independent venous drainage of the caudate lobe allows its continued decompression and the increased perfusion results in compensatory hypertrophy. Since the caudate bile ducts join the right or left duct close to the hilar confluence, curative resection of hilar bile duct carcinoma should always involve resection of the caudate lobe.

EDITOR'S COMMENT

One of the real pleasures of editing the 6th edition of *Mastery of Surgery* is to come across chapters written by surgeons who have obviously "been there." This is one of them, and this and several other chapters have inspired me to undertake a book on anatomy specifically related to surgeons. In other words, while anatomy can be cut and dried, certain types of anatomy such as this chapter and a number of others clearly indicate that it is not the dry anatomy of the dissecting room (which unfortunately no longer exists in most "improved" U.S. medical schools) but are of great help in the operating room. I do not recall a valid book of anatomy as a help for surgeons that has been published since 1933 in Germany. That 2-volume set was the property of my late father-in-law, Dr. Howard Down, a 1932 product of the Mayo Clinic program and a very busy clinical surgeon who served as a governor of the college and the president of the Iowa Surgical Society.

This chapter is very helpful for the surgeon undertaking a liver resection and probably is even of value to a very experienced surgeon in liver resection. I will try and do the "pearls" justice as I review the chapter and my own views on the points that Professor Lo raises.

Earlier in this chapter Professor Lo takes the course of describing the external anatomical aspects of the liver and relating them to some of the internal anatomical aspects, which will be specifically helpful to the surgeon. In describing the various ligaments to the liver, the ligamentum teres figures prominently as separating the lateral and the medial lobes of the left hepatic lobe. As he points out, there is also the obliterated left portal vein. This actually can be cannulated with Bakes dilators, which I have done on occasion to open up the left portal vein. I have done this while performing an end-to-side emergency portacaval shunt measuring pressures but was misled by the pressures of a swollen, fatty infiltrated liver. It is possible to turn an end-to-side portacaval shunt into a side-to-side shunt, thus decompressing the liver and ridding the patient of intractable ascites. One does this by getting control of the ligamentum teres, finding the obliterated umbilical vein, and with Bakes dilators or probably now with suitable balloon-tip dilators, dilate up the area where the portal vein can be entered and the fibrous band be split. At that point one can take the periumbilical area of the obliterated left portal vein and anastomose it to both long saphenous veins, which have been dissected out and turned up subcutaneously to receive the outflow of the congested liver. The patient will

diurese and properly cared for will survive.

Subsequently, in the latter part of the chapter the author tries to give hints as to how one can avoid massive bleeding by utilizing the middle hepatic vein to minimize bleeding. “By taking the segment-5 and segment-8 hepatic vein branches at their junction with the main stem of the middle hepatic vein, the number of venous branches encountered and the amount of bleeding can be minimized.” Most of us as neophyte liver resectionists viewed the hepatic vein as a nuisance and something that we get into and cause bleeding. Having said so, the junction between the middle and the left hepatic veins must be done intrahepatically; there is no way to do this external to the liver. “Since the middle and left hepatic veins form a common trunk before drainage into the superior vena cava, extrahepatic isolation of the left or middle hepatic vein individually may not be possible. Hence, isolation and division of the left or middle hepatic vein in a left lateral sectionectomy and extended right hepatectomy, respectively, will have to be done intrahepatically at the end of the liver parenchymal dissection.” In talking about the isolation of the hepatic veins, the author states, “Bleeding from hepatic veins is largely related to the central venous pressure and cannot be effectively controlled by inflow occlusion.” Since there are no valves in the connection between the hepatic veins and the vena cava, utilizing a very low venous pressure while the resection is going on can minimize bleeding. Also steep Trendelenburg may help.

Many surgeons regard hepatic veins as a source of trouble and try to deviate away from them during dissection. Here the author gives us some tips as to how to use them to our advantage. In the right hepatectomy, controlling and dividing the right portal pedicles is of great importance. As the author states, one can isolate the right portal pedicle with its division to the right anterior and right posterior portal pedicle, and then the segmental pedicles supplying the 4 segments. Probably an easier way to approach this and the isolation and division of the right portal pedicle can be performed by lowering the hilar plate and going around the pedicle on its surface. In speaking about the hilar plate, the author comments that biliary carcinoma tends to spread within the hilar plate and therefore as complete a resection of the hilar plate as can be achieved is important. Likewise, later in this chapter the author states that the taking of the caudate lobe with the right hepatectomy is absolutely essential since the hilar plate will proceed downward towards the caudate lobe and with a hanging maneuver it can be resected. Also the portal pedicles can be ligated on the way in to the plate on the right side, thus minimizing bleeding.

For left hepatectomy, Professor Lo states that freeing up and ligating the branches to the caudate lobe, that is segment 1, makes the left hepatectomy and isolation of the left portal vein much easier.

A cottage industry, which has sprung up in the United States, is the plaintiffs’ bar and its huge business of suing every surgeon who has performed a laparoscopic cholecystectomy in which a bile duct injury has occurred.

Inevitably, there is a surgeon, usually older and retired, who has not done a laparoscopic cholecystectomy for some time stating as by rote that one must clean out Calot's triangle before clipping anything. While it is true that one should have a pretty good idea by the infundibular approach of identifying the cystic artery and the cystic duct, and then dissecting free to get the critical look, the total clean out of Calot's triangle is only mentioned to be condemned. The reason for this is that the right hepatic artery, especially with covariant may reside low in Calot's triangle and if one gets in a misadventure with the right hepatic artery (massive bleeding), it does not infrequently results in a misadventure with the right hepatic duct. This has been referred to by Strassburg as a vasobiliary injury and is a disaster, and requires rapid conversion to an open procedure.

As to right hepatectomy, any vessel, as the author states, on the right side of the bile duct inevitably supplies the right liver. This is important to remember because in a right hepatectomy there may be a replaced left hepatic artery and this may occur on the right side of the bile duct. Those vessels from the left hepatic artery, which are on the right side of the bile duct inevitably perfuse some aspect of the right liver and thus can be ligated in a right hepatectomy.

Hepatic anatomy, with respect to both the hepatic artery and portal vein, is normal in only 55% of patients. The biliary anatomy occurs in only 50% of patients. This is an anatomical fact, which needs to be more completely stated because it explains why any surgeon independent of how experienced they are and how many laparoscopic cholecystectomies they have done, can fall prey to a deviation in the various biliary and arterial anatomies.

There are enormous numbers of cystic duct variations and this is well illustrated on page 1439 of the 7th edition of Schwartz's textbook in a chapter written by Dr. Seymour Schwartz. There are enormous variations in both the gallbladder as pictured on that page and in the cystic duct. What continues to amaze me as someone who believes that since the percentage of damage to the common duct, 0.5% to 0.7%, has remained stable for the past 15 years around the world, damage to the common duct cannot be practice below the standard. A good pathologic examination of what appears to be the cystic duct, namely the spiral valves of Heister, is essential. I have actually never seen in my review of cases a pathologist review whether or not there are spiral valves in the structure that appears to be the cystic duct. It would be helpful because there are an enormous number of cystic duct variations.

Now for the external portion and the anatomy of the area surrounding the liver. A good rule of thumb is that the major papilla is ~8 cm from the pylorus. After one Kocherizes the duodenum, one can usually feel the major papilla without difficulty. In doing an open (S. Austin Jones-type) sphincteroplasty, I never have to cannulate the cystic duct because I can always feel the major papilla. It also enables one to do a transverse incision and be certain that one is going to have excellent exposure of the papilla. It is worthwhile for individuals who are planning to do that kind of surgery when doing open cholecystectomies

or pancreatectomies to mobilize and Kocherize the duodenum and then see if they can feel the major papilla.

The author makes the point many times that the plane or Cantlie's line, which bisects the liver goes from the right anterior to the left posterior. Thus, if one is going to do cholangiography the right anterior oblique view is most promising. Most cholangiograms cannot be done in this fashion because of the equipment, but if one has the equipment that can do this it is well to remember this.

Finally, in the resection of the caudate lobe Professor Lo outlines the hanging maneuver. The caudate veins drain into the IVC and it is difficult without bringing the caudate lobe up and hanging it to cleanly clamp the caudate hepatic veins. The recently described hanging maneuver is of great help and a contribution into the resection of the caudate lobe, which as stated earlier should do in situation where the hilar plate has been invaded by cholangiocarcinoma or adenocarcinoma because the tumor spreads within the hilar plate and enters the caudate lobe. Not to resect the caudate lobe is to do an incomplete resection.

There is much to learn from an experienced hepatic surgeon like Professor Lo and it is beautifully described and illustrated. It is a pleasure to have this superb chapter in this edition.

J.E.F.

104 Diagnostic Considerations in Biliary and Liver Disease

Kelly M. Collins and William C. Chapman

Biliary tract and liver disease present some of the commonest surgical complaints prompting consultation to the general surgeon. The pathologies range from basic to complex as do the treatment algorithms and approaches, especially with the continual advances in biliary endoscopy and interventional radiology.

The approach to the complex hepatobiliary patient should utilize a multidisciplinary approach at centers with expertise in the following: cross-sectional imaging, endoscopy, interventional radiology, surgery, radiation, and medical oncology.

The general surgeon must have a thorough understanding of best diagnostic modalities in both benign and malignant diseases of the liver and biliary tract to aid in efficient decision making related to diagnosis, surveillance, intervention, or transfer to a center where hepatobiliary surgery expertise is available.

CLINICAL PRESENTATION

Biliary and liver disease is often asymptomatic; however, if a patient presents with symptoms, it is usually with right upper quadrant (RUQ) pain, jaundice, or both.

RUQ pain is nonspecific and will in most cases require further workup with laboratory studies and imaging. A broad differential must be considered, including: acute cholecystitis, biliary colic, cholangitis, hepatitis, pancreatitis, peptic ulcer disease (PUD), cardiac disease (angina or myocardial infarction), lung disease (pneumonia or pulmonary embolism) appendicitis, abscess, and diverticulitis. The basic PQRST (provoking/palliating, quality, radiation, severity, timing) qualifications may be helpful in narrowing a diagnosis: provoking/palliating factors, quality, radiation, severity, and timing. Special attention must be paid in patients who are obese, diabetic and/or pregnant, as their complaints and

physical examination may fit classic patterns.

In patients who present with RUQ pain and hemodynamic abnormalities, the differential should include trauma, ruptured tumor/lesion, and sepsis related to cholangitis or other infection. It requires urgent resuscitation, workup, and, in some cases, transfer to a center with hepatobiliary expertise.

BILIARY DISEASE

Gallbladder Pathologies

We will first consider benign biliary disease, of which the most commonly occurring is cholelithiasis.

The third National Health and Nutrition Examination Survey estimated that 6.3 million men and 14.2 million women aged 20 to 74 in the United States had gallbladder disease. Risk factors include the five F's: female, forty, fat, fertile, and family history; along with rapid weight loss, certain diseases (cirrhosis, Crohn disease), and gallbladder stasis (i.e., long-term total parenteral nutrition [TPN] use). Cholethiasis may be discovered incidentally on imaging for other reasons. Approximately 20% of patients will develop symptoms when followed for 15 years. Asymptomatic patients require no treatment because the risk of complications in these patients is extremely low.

Patients with symptomatic cholelithiasis present with post-prandial (in particular following a fatty meal) pain in the RUQ and epigastric region. It may radiate to the shoulder, subscapular region, and the back. It is typically is transient (<3 hours in duration), with fewer palliating factors. If pain is constant or sustained longer than this, acute cholecystitis or an alternative diagnosis should be entertained. Symptoms may or may not be reproducible on physical examination. It can be difficult to differentiate from PUD. Risk factors should be taken into account for PUD; and if there is a high level of suspicion of this, endoscopic examination of the stomach should precede elective cholecystectomy.

In patients where symptoms are classic, routine blood work should be obtained to ensure that liver function tests (LFTs) are normal.

Rarely, gallstones may be identified on plain abdominal radiographs with approximately 10% of gallstones being detected by this modality. Ultrasound findings of gallstones include an echogenic focus within the gallbladder lumen with posterior acoustic shadowing. There may be gravity-dependent movement of the gallstones with change of patient

position.

Approximately 1% to 2% of patients with asymptomatic gallstones will ultimately become symptomatic. Once symptomatic, patients are at increased risk of developing complications and cholecystectomy should be performed.

Acute Calculous Cholecystitis

Acute calculous cholecystitis occurs in approximately 10% of patients with symptomatic gallstones. It is a clinical diagnosis based on history, physical examination, and laboratory tests. In contrast to biliary colic, which usually subsides after several hours, patients complain of RUQ pain that persists outside of this timeframe and is constant and clenching. There are fewer palliating factors, and the patient may or may not have a history of biliary colic. Nausea and vomiting may be present, but typically follow and rarely precede the pain. Fever may be present. In cases of advanced pathology, the patient may have complaints related to peritonitis.

On examination, the classic clinical sign in acute cholecystitis is Murphy sign, the cessation of inspiration on palpation of the inflamed gallbladder. This may be elicited during the ultrasound examination as well. The absence of this does not rule out the presence of gallbladder inflammation, especially in diabetic and obese patients. In advanced disease, the patient may exhibit peritonitis; this should raise concern for gangrenous cholecystitis or perforation.

Lab values may or may not be affected. The white blood cell (WBC) count may be elevated, with or without a left shift. Liver functions may be normal to slightly elevated. It is unusual for the bilirubin to be elevated >3 mg/dL in isolated cholecystitis. The presence of jaundice, hyperbilirubinemia, or elevations of alkaline phosphatase should alert the clinician to potential of common bile duct obstruction from either choledocholithiasis or Mirizzi-type phenomenon, where a stone impacted in the neck of the gallbladder causes compression of the bile duct.

Because of its high sensitivity and specificity (88% and 80%, respectively), availability, and lack of ionizing radiation, imaging should begin with ultrasound when available. Findings of acute cholecystitis include: enlarged, incompressible gallbladder, sonographic Murphy sign, thickening of the gallbladder wall >4 mm, and the presence of gallstones. There may be pericholecystic fluid.

In patients where computed tomography (CT) scan has been performed

as the initial diagnostic test, ultrasound may add little by way of sensitivity or specificity.

Radionucleotide cholescintigraphy is sensitive and specific for cholecystitis. In a study comparing ultrasound and cholescintigraphy in the diagnosis of histology confirmed acute cholecystitis, in a review of 1,217 cases, hepatobiliary iminodiacetic acid (HIDA) scan was found to be 89.3% sensitive in comparison with ultrasound, which was only 71.1% sensitive. In this same study, ultrasound was more specific (88.1% vs. 66.8%).

Ultimately, acute cholecystitis, much like appendicitis, is a clinical diagnosis; and even if imaging is equivocal and the patient history and examination otherwise raise concern for cholecystitis, the patient may be placed on antibiotics and observed. A missed diagnosis can have a high morbidity, in particular in elderly people. The gallbladder may become walled off by omentum and create a localized abscess that does not produce enough surrounding inflammation to cause peritonitis until it has progressed extensively or ruptured.

The most common complication of acute cholecystitis is emphysematous cholecystitis and with gangrene and perforation of the gallbladder wall. Emphysematous cholecystitis is characterized by secondary infection of the gallbladder wall with a gas-producing bacterium (*Clostridium, Escherichia coli, Pseudomonas,* or *Klebsiella*). It is rare and associated with significant morbidity and mortality due to the sepsis that may ensue with subsequent perforation. It typically occurs in elderly men and diabetic patients. Emphysematous cholecystitis can be radiographically elusive as well until it reaches advanced stages evidenced by pneumobilia (in the absence of previous instrumentation). Sensitivity of ultrasound is diminished as the gas can obscure visualization of the gallbladder; however, findings of air within the gallbladder wall or lumen or nonshadowing echogenic foci in the anti-dependent portion of the gallbladder are specific. CT findings may include air within the gallbladder wall or lumen, and irregular or absent gallbladder wall, irregular enhancement, or pericholecystic abscess. Gangrenous cholecystitis on ultrasound may have intraluminal membranes and marked asymmetry of the gallbladder wall (secondary to intramural microabscesses, intramural hemorrhage, and pericholecystic fluid collections containing debris). On CT scan, there may be gallbladder distention, irregular wall, wall striations, decreased wall enhancement,

intraluminal membranes, pericholecystic fluid or abscess or gas in the gallbladder wall. HIDA scan is not helpful in differentiating between variants of cholecystitis.

The treatment of choice for acute calculous cholecystitis is antibiotics (to cover *E. coli, Klebsiella, Enterobacter, and Enterococcus)* and cholecystectomy.

Early surgery (<72 hours from the onset of symptoms) is optimal. The once argued approach of "cooling off a hot gallbladder" is no longer supported in most cases; however, if symptoms have been present for >72 hours and the patient has clinical improvement with antibiotics, deferring cholecystectomy for 6 weeks is recommended to allow inflammation to subside. If there is clinical suspicion of gangrenous cholecystitis, this should be considered a surgical emergency as the risk for peritonitis, sepsis, and death is up to 15%. A laparoscopic approach is the standard of care; however, conversion to open should not be considered a failure or complication. In patients who are too sick to undergo an operation or who refuse operative intervention, percutaneous biliary drainage is an acceptable option, and should be paired with broad-spectrum antibiotics (even in cases of gangrenous or emphysematous cholecystitis).

If the bilirubin is elevated to level >3 mg/dL or there is biliary dilation on imaging, concomitant choledocholithiasis may be present (see below).

Acalculous Cholecystitis

Certain populations are at risk for acalculous cholecystitis. Situations that create a combination of ischemia and stasis are thought to contribute to its development. It is frequently seen in critical ill patients. Other at risk groups are patients with type II diabetes, congestive heart failure (CHF), leukemia, AIDS, and end-stage renal disease (ERSD). It more commonly occurs in men, in contrast to calculous cholecystitis. In children, it is the cause of cholecystitis in approximately 50% to 70% of cases—with dehydration, infection, and lymphadenopathy as potential contributing factors.

If the patient is conscious, he or she may complain of RUQ pain. Clinical signs of fever and leukocytosis may be present or absent depending on the clinical setting. Often times patients in this population are too immunosuppressed to mount a typical leukocyte expansion response. LFTs are nonspecific and often times normal. The diagnosis should be considered in any critically ill patient with sepsis in which

etiology has not been identified.

The diagnosis relies largely on imaging. Ultrasound is sensitive and specific using the finding of gallbladder wall thickening (>3 or >3.5 mm). Other findings include pericholecystic fluid, intraluminal gas, or intramural edema represented by a sonolucent “halo.” The following algorithm has been suggested for radiographic evaluation: If suspicion of biliary etiology is high, radionucleotide imaging should be the initial test, with CT scan to evaluate the remainder of the abdomen if the testing is normal. However, if suspicion of biliary source is low, CT should be performed first, and cholescintigraphy used to confirm if CT is suspicious but not diagnostic. Morphine can be administered to increase the sensitivity of scintigraphy by causing constriction of the sphincter of Oddi allowing for gallbladder filling.

The treatment of acalculous cholecystitis is determined by the medical condition of the patient. In many cases, the patient is either too ill or too immunosuppressed to tolerate surgery. Initial treatment should be with broad spectrum antibiotics to cover biliary organisms. If the patient fails to improve and is not a surgical candidate, a cholecystostomy tube may be used for decompression. If the patient improves after cholecystostomy, he does not need an interval cholecystectomy as there are, by definition, no gallstones to cause recurrence. The cholecystostomy tube can be removed once a tract has been established, and cholangiography via the cholecystostomy tube demonstrates a patent cystic duct. This might warrant a longer period than usual if the patient is immunosuppressed.

Other Gallbladder Pathologies

Porcelain Gallbladder

Porcelain gallbladder is the result of deposition of calcium carbonate in the gallbladder wall. It has a classic appearance on imaging, and has been reported to be at increased risk of gallbladder carcinoma. Once thought to be highly associated with cancer, several large volume studies have found the incidence of cancer in patients with calcification to be approximately 0% to 5%. On plain abdominal film, the calcifications with the wall may be apparent. On ultrasound, the wall calcification can appear as: (1) hyperechoic semilunar structure with dense posterior acoustic shadowing, (2) a biconvex curvilinear echogenic structure with acoustic shadowing, and (3) irregular clumps of echoes with posterior acoustic shadowing. It may be difficult to discern from cholelithiasis if stones are densely packed

and the gallbladder is contracted; however, if the posterior wall of the gallbladder can be visualized on grayscale, then gallbladder with stones can be excluded. Because of the ring-down artifact produced by wall and gas on ultrasound, it may also be difficult to discern from emphysematous cholecystitis, in which case CT can be utilized to differentiate these two entities. Patients are symptomatic in approximately 70% to 80% of cases, and prophylactic cholecystectomy is recommended due to the increased risk of cancer. The surgeon should be prepared to perform intraoperative ultrasound, liver resection (4b/5), and lymph node dissection at the time of surgery if the intraoperative findings are suggestive of invasive cancer or if cancer is discovered on frozen section.

Adenomyomatosis of the Gallbladder

Adenomyomatosis is a benign finding on imaging or pathology. It is characterized by hyperplasia of the gallbladder mucosa and muscularis propria with out-pouching of the mucosa into or through the muscularis forming diverticula called Rokitansky–Aschoff sinuses. It is usually an asymptomatic, incidental finding. It is not believed to have malignant potential. On CT, it is said to have a "rosary sign," with discrete hypoattenuating intramural lesions with enhancing epithelium within. On magnetic resonance imaging (MRI), "pearl necklace sign" is a result of the multiple ovoid diverticula seen on T2-weighted imaging. It may be generalized, localized, or segmental. If it is found in the setting of acalculous biliary colic, cholecystectomy can be performed.

Gallbladder Polyps

Gallbladder polyps occur in approximately 5% of the population. They are often incidentally found in workup of abdominal pain; however, in rare cases they may be the cause of obstruction of the cystic duct. Cholecystectomy is recommended in patients where the polyp exceeds 1 cm or has a vascular pedicle due to the risk of malignancy. Surveillance is recommended for patients with polyps between 5 and 10 mm (Fig. 104.1).

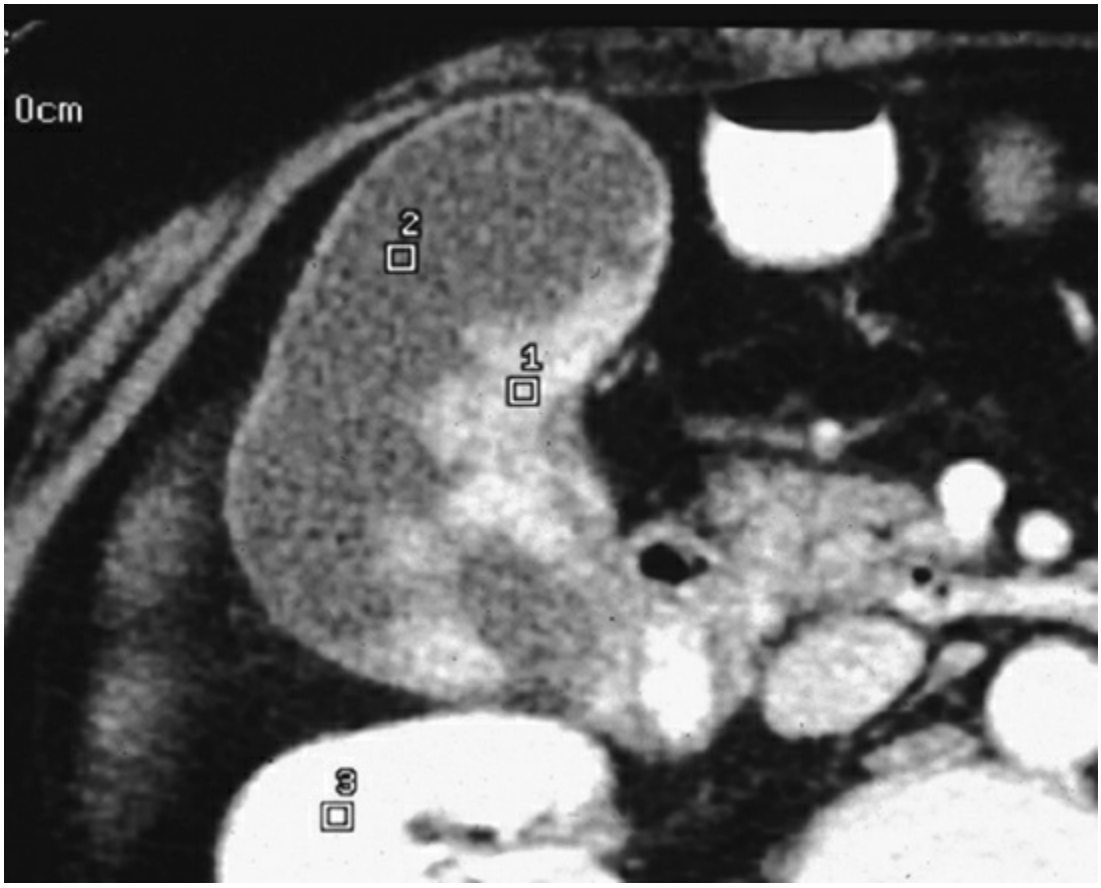

Figure 104.1. Sessile gallbladder polyp seen as incidental finding on computed tomographic scan. Also worrisome is the mass that is brightly enhanced on this scan after contrast injection. 1, sessile polyp; 2, gallbladder; 3, duodenum.

BILIARY OBSTRUCTION

Surgical evaluation may be warranted in evaluation of biliary obstruction in several situations, with the two most common etiologies being obstruction due to choledocholithiasis or obstruction due to mass. As the two etiologies have different algorithms, each will be considered separately in the following sections.

Choledocholithiasis with Obstruction

Choledocholithiasis

Choledocholithiasis is present in 10% to 20% of patients with gallstones. Diagnosis may occur incidentally or in the evaluation of jaundice. In the setting of obstruction, patients may complain of RUQ pain, clay/gray colored stools, cola/brown colored urine or pruritus. On ultrasound, choledocholithiasis should be suspected if the common bile duct is outside

of the normal range for the patient's age (approximately >6 mm), there are stones visualized in the duct, or if there is hyperbilirubinemia >3 mg/dL in the setting of biliary colic or acute cholecystitis. If ultrasound is equivocal, magnetic resonance cholangiopancreatography (MRCP) can be employed with high (90% to 95%) concordance with endoscopic retrograde cholangiopancreatogram (ERCP) for stones >4 mm; however, it is solely diagnostic, and not therapeutic. Endoscopic ultrasound (EUS) and intraoperative ultrasound have also been utilized with good success for detection of choledocholithiasis; however, not all centers have this capability. It is particularly useful in populations where there is reason to avoid ERCP (pregnancy, resolving pancreatitis).

In cases where choledocholithiasis is present in the setting of cholecystitis, the surgeon must make the decision of whether or not to proceed with preoperative ERCP versus intraoperative assessment. If ERCP is deferred, the surgeon must be prepared to perform operative common bile duct exploration or postoperative ERCP. The timing of ERCP is widely debated; however, there is no consensus regarding this and it is largely surgeon-dependent.

Proponents of preoperative ERCP suggest that if the ERCP is unsuccessful, intraoperative exploration will be required and can be performed at the time of cholecystectomy. On the other hand, ERCP does place the patient at risk for bleed or pancreatitis, and it is thought that a trial of intraoperative maneuvers (cholangiogram, flushing the duct, transcystic use of 3F Fogarty to clear the duct) is reasonable to attempt to clear the duct before committing to ERCP. If these initial maneuvers are unsuccessful, the decision must be made whether to proceed with laparoscopic common bile duct exploration, or termination of the operation with plan for postoperative ERCP.

If intraoperative maneuvers are unsuccessful and postoperative ERCP is planned, the surgeon should leave a drain to assess for bile leak as the cystic duct clips may become dislodged at the time of ERCP.

Cholangitis

Ascending cholangitis is a condition that requires urgent intervention. The clinical signs of fever, RUQ pain, and jaundice (Charcot triad) signify cholangitis, which may rapidly evolve into sepsis with the bacterial ascension in the obstructed biliary system. When associated with mental status change and hypotension representing the progression of sepsis, this is referred to as Reynolds' pentad.

Cholangitis may occur in a variety of settings, benign or malignant. In patients who have not had previous biliary surgery or intervention, the most common cause is gallstones. Other etiologies include: Mirizzi syndrome, primary sclerosing cholangitis (PSC) with structuring, infected choledochal cysts, or hemobilia. External compression of the duct may occur in the setting of a mass, most commonly cholangiocarcinoma. Patients who have had previous biliary surgery (bile duct exploration or creation of choledochojejunostomy) are at risk for cholangitis as a result of structuring of the duct. In the setting of an indwelling biliary catheter, cholangitis should prompt externalization of the system to a drainage bag if it is capped and urgent exchange of the catheter as it is likely clogged.

White blood cell count, bilirubin, and alkaline phosphatase are typically elevated. Ultrasound will typically show dilated hepatic ducts beyond the level of the obstruction; however, in some cases this finding may be absent or modest. While MRCP and EUS have acceptable accuracy in diagnosing choledocholithiasis, if suspicion of obstruction is high, ERCP is the test of choice for diagnosis and therapeutic intervention.

Broad spectrum antibiotics (to cover *E. coli*, *Klebsiella*, *Enterobacter*, *and Enterococcus*) should be started immediately along with resuscitation using intravenous fluids. Broad spectrum antibiotics usually result in stabilization of the patient; however, if this does not result in prompt improvement, the biliary system should be decompressed emergently. This can usually be achieved with ERCP; however, if that fails or is not available, either a percutaneously transhepatic biliary drain or operative exploration is considered. If emergency surgery is required, the preferred procedure is simple decompression of the system with the largest T tube that the duct will easily accommodate with plan for definitive surgery when sepsis is controlled. If gallstones are identified as the etiology of the obstruction, stone extraction and sphincterotomy are usually curative. If there is extrinsic mass or compression, brushings should be obtained and a stent placed to decompress the system while further workup is performed.

Biliary Obstruction Without Gallstones

Asymptomatic or “painless” jaundice should raise suspicion of external compression of the duct. Compression of the intrahepatic ducts is most frequently caused by hepatocellular carcinoma (HCC) by external compression or extension into the duct. Other etiologies include intrahepatic or hilar cholangiocarcinoma, metastasis from a nonhepatic

primary, PSC with stricture, and compression from hepatic abscess or cyst. Extrahepatic obstruction is most commonly seen in patients with distal cholangiocarcinoma, pancreatic head adenocarcinoma or neuroendocrine tumors, or ampullary tumors.

Tumor markers can be obtained (CEA, AFP, CA 19–9) if there is a suspicion for malignancy; however, CA19–9 should be interpreted with caution as it may be falsely elevated in the setting of biliary obstruction.

Contrast-enhanced ultrasound (not available in the United States), CT, and MRI have high specificities (82% to 89%) in the diagnosis of focal liver lesions. However, given the addition of MRCP, MRI with contrast and MRCP is the initial test of choice in evaluation of intrahepatic biliary obstruction. It can provide valuable information about the relationship of the tumor to the bile duct and vasculature. It can also be used to obtain liver volumes to aid in the planning of surgical resection. CT scan of the chest should be obtained to complete evaluation for metastatic disease.

In the absence of cholangitis, the decision of whether or not to preoperatively drain patients with obstructing biliary tumors is debated. If the patient is symptomatic from the hyperbilirubinemia or will have a significant interval prior to surgery for neoadjuvant treatment or portal vein embolization, then drainage with an endoscopically or percuntaneously placed catheter is reasonable. If the plan is to go directly to surgical resection, then biliary drainage may not be necessary, and some authors argue that instrumentation in this setting increases complications. If a catheter is placed, brushings should be obtained and be submitted for cytologic analysis.

If the patient is not a candidate for surgical resection, biliary decompression may be used in the palliative setting.

If surgical resection is planned, biopsy for definitive diagnosis is generally not needed prior to resection. If tissue diagnosis would change the management of the patient, this can often be achieved by percutaneous or endoscopic means.

LIVER MASS

A commonly encountered clinical scenario for the surgeon is the incidental finding of a liver mass. The key questions to be answered by the surgeon are: (1) Is the mass benign, malignant, or benign, but with malignant potential? (2) Is intervention necessary? (3) Is surveillance necessary?

Workup of any mass begins with a thorough history and physical

examination. Table 104.1 summarizes liver lesions. Most liver masses are asymptomatic. If symptoms are present, they most commonly occur secondary to mass effect resulting in compression of surrounding structures, or in cases of massive lesions, a sense of abdominal fullness. Peritonitis may be present if a mass is inflamed, or if it has bled or ruptured. Medical risk factors for underlying liver disease should be elucidated: history of hepatitis, alcohol abuse, fatty liver disease, autoimmune diseases, or diseases associated with PSC. Attention should be given to any history that suggests underlying liver disease or portal hypertension, gastrointestinal bleeding, encephalopathy, or ascites. Ascites may be present in cases where there is underlying liver disease or carcinomatosis. If the differential diagnosis of the mass includes abscess, history of travel and abdominal infections should be obtained. The patient's cancer history and cancer screening history (colonoscopy and mammography) should be obtained. The use of estrogen- or androgen-containing medications should be noted.

A thorough understanding of the history of the lesion—how it was discovered, when it was discovered, and what prompted referral to the surgeon—can be helpful in guiding decision making regarding many lesions. Often times this requires the review of past imaging. No decisions should be made based on imaging reports exclusively; all films should be reviewed directly by a team familiar with hepatobiliary lesions.

Lab work should include LFTs, and if there is any concern for underlying liver disease, a hepatitis panel should be obtained. If there is concern for malignancy, tumor markers—carcinoembryonic antigen (CEA), non-maternal alfa feto protein (AFP), and carbohydrate antigen (CA) 19–9—should be obtained.

Lesions can be broadly divided into hemangioma, cystic, or solid. The imaging modality of choice for each of these is variable and at times may vary within an institution's expertise or availability. Many lesions can be diagnosed with the use of history and appropriate imaging alone. In some cases, tissue may need to be obtained for definitive diagnosis.

Hemangioma

Hemangioma is the most common benign liver lesion in adults, with an estimated prevalence of 5% to 20%. It is a vascular liver lesion thought to arise from congenital hamartoma. The majority are <5 cm; however, if the size is >10 cm, they are classified as "giant hemangiomas." Hemangiomas

are often incidental findings, and diagnosis is often made by imaging alone. Outside of cases of strategically located giant hemangiomas, caution should be exercised when attributing symptoms to hemangioma. Ultrasound findings include a hyperechoic, rounded lesion with a well-defined rim and few intranodular vessels, which demonstrates posterior acoustic enhancement. They often lack color flow on Doppler. They are often peripheral and in the posterior segments of the right hepatic lobe. The typical enhancement pattern on CT or MRI is discontinuous peripheral nodular enhancement with progressive centripetal filling, and is considered diagnostic. With MRI, the classic appearance is hyperintensity on T2 imaging (Fig. 104.2). Using extracellular contrast–enhanced MRI, three distinct patterns have been described. First, smaller lesions (<1.5 cm) may have uniform arterial enhancement (referred to as flash filling). Alternatively, larger lesions show either nodular peripheral interrupted enhancement coalescing centripetally to uniform enhancement or nodular peripheral interrupted enhancement that coalesces centripetally but with persistent central hypointensity. Finally, giant hemangiomas may have regions of fibrosis or and/or thrombosis, resulting in central scar with strands of T2 hypointensity. Caution must be used in interpretation of imaging. Some malignant lesions may also be T2 hyperintense, including: neuroendocrine tumors, breast metastasis, cystic subtype HCC, and metastasis from mucinous subtypes of colon and ovarian cancer, as well as primary or metastatic sarcoma.

TABLE 104.1 Summary of Liver Lesions

	Benign	Malignant	Nontumor
Common	Simple hepatic cyst Hamartoma FNH	Metastasis Hepatocellular carcinoma	Focal fat/fat sparing Perfusion abnormality Abscess
Uncommon	Hepatocellular adenoma Biliary cystadenoma	Cholangiocarcinoma Biliary cystadenocarcinoma Sarcoma Lymphoma Hemangioendothelioma	Hematoma Peliosis Pseudotumor

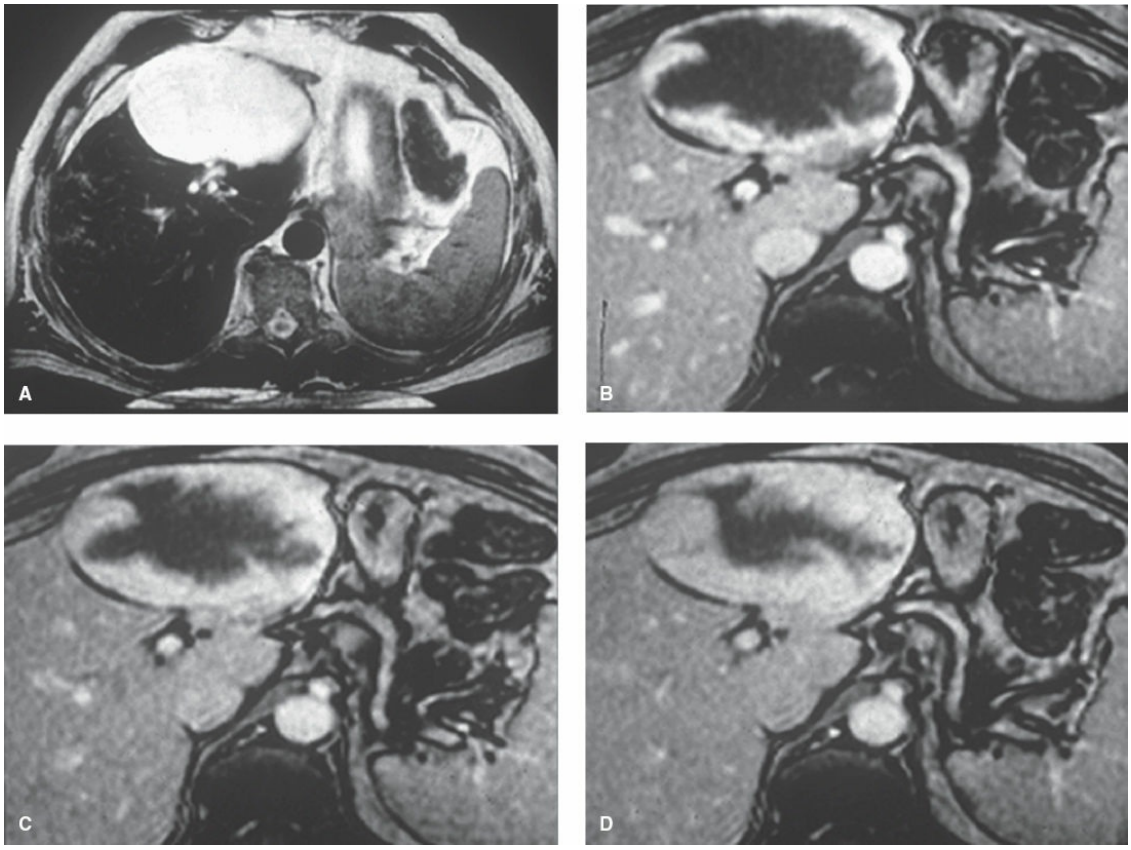

Figure 104.2. Classic appearance of hemangioma on MRI. Lesion is very bright on T2 (**A**) and shows nodular enhancement that fills in from the periphery with increasing time after gadolinium injection (**B–D**).

For asymptomatic hemangiomas, no intervention is necessary. In lesions that are symptomatic, surgical resection or enucleation can be employed. Surveillance imaging in not required for classic hemangioma.

A rare complication of hemangioma is Kasabach–Merritt syndrome. Most commonly occurring after trauma or other violation of the lesion, this consists of coagulopathy with intravascular coagulation, clotting, and fibrinolysis within the hemangioma; however, it may progress to systemic fibrinolysis and thrombocytopenia.

Cystic Liver Lesions

With a prevalence of about 5% to 10% of the population, cystic liver lesions are another common incidental finding that prompts referral to a surgeon. Again, these lesions are usually asymptomatic. Symptoms may occur in the case of extremely large cysts leading to compressive symptoms, rapid enlargement, cyst infection, or hemorrhage. Incidental cystic lesions most commonly represent simple hepatic cysts. Other, less

common possibilities include biliary cystadenomas (BCAs) or cystadenocarcinomas, polycystic liver disease (PCLD), hydatid cysts, cystic metastasis, of necrosis of tumors.

Simple Hepatic Cysts

Simple hepatic cysts are benign and without malignant potential. They vary in size, number, and location. They are thought to be a congenital malformation and consist of a fibrous rim and are lined with columnar epithelium. Ultrasound shows an anechoic, homogeneous mass, with smooth margins. Ultrasound is the best modality to demonstrate septations. CT shows a well-demarcated, water density (Hounsfield units 0–10), which does not enhance with contrast. MRI shows T1 hypointensity and T2 hyperintensity. Lack of homogeneity with septations, fenestrations, calcifications, irregular walls, or daughter cysts should expand the differential to include the more complex, aforementioned lesions. There is no intervention required for a simple, asymptomatic cyst. If cyst becomes symptomatic due to size or infection, cyst aspiration and sclerotherapy or surgical unroofing is reasonable. In patients where it is unclear if the cyst is the cause of the presenting symptoms, cyst aspiration with resultant palliation of symptoms can confirm the association. However, aspiration alone is usually associated with rapid recurrence of the cyst (within days). No surveillance imaging is required for simple hepatic cysts.

Cystic Hepatobiliary Neoplastic (Cystadenoma, Biliary IPMN, Cystadenocarcinoma)

These lesions are believed to arise from an aberrant bile duct remnant. Like the other cysts, they are usually an incidental finding.

BCAs make up <5% of all cystic lesions and have the following three distinct pathologic features originally described by Wheeler and Edmondson: (1) multilocular, (2) lined by a columnar epithelium, and (3) accompanied by a densely cellular ovarian-like stroma. While BCA is predominantly found in females, biliary cystadenocarcinoma (BCAC) is more evenly distributed. The more newly recognized entity, intraductal papillary neoplasm of the bile duct (IPNB), was adopted by WHO in 2010 and is defined as a biliary epithelial tumor, often with mucin production, with exophytic nature exhibiting papillary mass within the bile duct lumen and with prominent intraductal growth pattern. Its epithelial cells have a range of atypia from none to marked, and it is therefore considered a

premalignant lesion to cholangiocarcinoma. Pathologically, it differs from BCA in that it lacks ovarian stroma. On imaging, the two can be distinguished by the fact that BCAs typically have a smooth tumor wall with internal septation, resulting in a "cysts-in-cyst" appearance and papillary projections are frequently seen in IPNB and rarely in BCA.

Distinguishing simple hepatic cysts from hepatobiliary neoplasia is the key as the latter is considered to have malignant potential with a risk of transformation of up to 20%, and therefore requires formal resection. Several points may aid in clarification of the differential. Hepatobiliary neoplasia are commonly single lesions, whereas simple cysts are frequently multiple. On ultrasound, BCA will have a complex appearance, with septations or nodules. These findings should prompt further examination with CT or MRI. CT is able to detect abnormality of the cyst wall and aid in surgical planning. On MRI, BCA will have complex appearance with thickened wall, internal septations, mural nodules, and internal debris. An elevated alkaline phosphatase has been associated with cystadenoma over simple cyst (Fig. 104.3).

BCAC is a rare biliary cancer that is thought to originate either de novo from a formed biliary duct that sustains an insult (ischemia or carcinogens) or from malignant transformation. Because of their rarity, criteria to definitively distinguish BCA from BCAC are limited. In a series of 39 patients with biliary cystic tumors, the imaging findings of polypoid mural nodules, intracystic debris, and bile duct dilation were seen more commonly in BCACs than in BCAs. All BCAs should be completely excised due to the risk of malignant transformation. Because of their risk of malignant transformation and the high risk of recurrence, it is critical that the cyst wall is removed in its entirety and submitted for pathologic examination. This can be performed with surgical resection or enucleation. In cases where there is a high suspicion of BCA, unroofing the cyst is inadequate.

Polycystic Liver Disease

PCLD is thought to be a part of a group of diseases that arises from mutations of the cholangiocyte cilia. It can be distinguished from simple hepatic cysts by the presence of numerous cysts (>20), although the histology of the lesions is similar. The lesions are asymptomatic until they reach a critical mass at which point the patient may present with complaints of abdominal fullness, bloating, or shortness of breath.

Compression of surrounding structures including the IVC and biliary tree may occur. Rare patients may develop portal hypertension with preserved synthetic function. US, CT, and MRI can be utilized in diagnosing PCLD.

The goal in treatment of PCLD is generally palliation of symptoms, with either unroofing of cysts, resection, or, in some highly suspected cases, liver transplantation.

Hydatid Cysts

Echinococcal cysts are a rare occurrence in the United States, but the parasite is endemic in many other areas of the world—the Mediterranean, Africa, the Middle East, South America, Asia, and parts of Europe and in areas where sheep farming is prevalent. In patients where hydatid cyst is suspected, a thorough travel and exposure history should be obtained. Depending on the location of the cyst, LFTs may or may not be affected. Eosinophilia is often present but not specific. The classic findings for hydatid cysts are thick walls, unilocular or multilocular, often with calcifications, and daughter cysts, with the distinguishing features of the cyst being calcifications and daughter cysts. Communication with the bile duct can occur in up to 25% of cases. Most cysts are asymptomatic, however, complications such as cholangitis, anaphylaxis from cyst rupture, and pulmonary infection can occur. Safeguards must be taken to prevent exposure of the patient to the scolices within the cyst—this is done through the use of medical treatment and scolicidal agents. Surgery remains the mainstay in treatment.

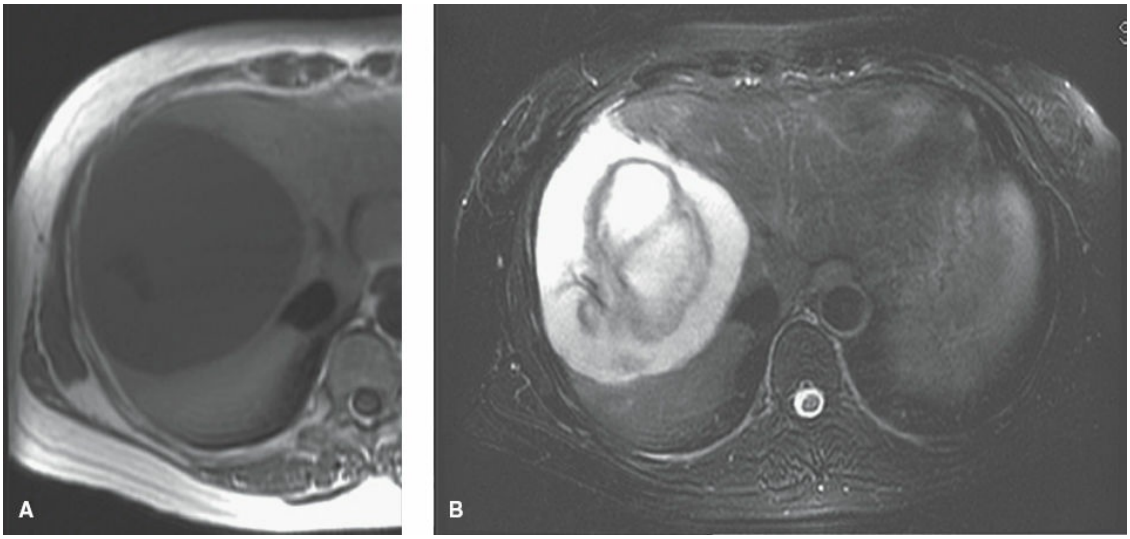

Figure 104.3. Complex cystic mass seen in magnetic resonance image as low-attenuation lesion on T1 (**A**) and as bright lesion

with internal mass on T2 (**B**).

Liver Abscess

The most common etiology of liver abscess is secondary to another intra-abdominal infection (diverticulitis or appendicitis); however, in many cases there is no apparent source and spontaneous abscess formation is the only finding.

Ultrasound typically reveals a hypoechoic lesion with a smooth wall. Gas within an abscess is hyperechoic and casts shadows. CT is both sensitive and specific while offering the benefits of evaluating the remainder of the abdomen for pathology and allowing for interventional planning. The lesion may appear as a single or multiloculated mass with a central hypodense region and peripheral contrast enhancement during the portal phase of examination.

Treatment consists of antibiotics (targeted toward primary etiology or cultures) and drainage. In smaller lesions (<2 cm), antibiotic treatment alone may be sufficient.

In patients with a travel history to endemic areas or history of diarrheal illness, the diagnosis of amoebic abscess should be considered; however, most amoebic cysts are found in asymptomatic carriers. The lesions are more commonly found in the right liver. The diagnosis is confirmed with enzyme-linked immunosorbent assay (ELISA) testing that detects antibodies to the amoeba, *Entamoeba histolytica*. Usually medical treatment with metronidazole is sufficient, along with a luminal agent such as paromomycin to eradicate the intestinal colonization. If the patient fails to improve with medical therapy, cyst aspiration and drainage are indicated.

SOLID LIVER LESIONS

Benign Solid Lesions

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is the second most commonly occurring benign solid liver lesion, behind hemangioma, with a prevalence of 0.3% to 3%. It is thought to possibly be the result of an ischemic insult to the portal tract that results in hyperplasia of hepatocytes surrounding a central scar. It is most often seen in young or middle-aged women and is frequently an isolated lesion. It is often asymptomatic; however, it is

frequently found incidentally in the workup of abdominal pain, and in case of larger lesions, it can be difficult to determine whether or not the FNH is the cause of the symptoms. Symptoms attributable to FNH are usually the result of compression of surrounding structures, for example, early satiety in the case of a large left-sided lesion.

Because of its composition of hepatocytes, it can be a stealthy lesion, barely discernable on some imaging modalities. Often times, because of its availability and lack of radiation exposure, ultrasound will be the first modality used in evaluation symptoms. On US, FNH will appear as slightly hypoechoic, isoechoic, or slightly hyperechoic relative to the remainder of the liver. On noncontrasted CT, the lesion may blend in with the surrounding parenchyma. With contrast, the lesion enhances rapidly in the arterial phase with a subsequent decrease in the portal venous phase.

Historically, sulfur colloid scanning was used to aid in the differentiation between FHN and other lesions; however, with the advent of hepatocyte-specific contrasted MRI, this has fallen out of favor. Extracellular contrast–enhanced MRI appearance is early nodular arterial enhancement, which becomes isointense with the background liver during the portal venous phase. Hepatocyte-specific contrast is the study of choice. On hepatobiliary phase images, the lesion is iso- or hyperintense with the background liver, reflecting the uptake of contrast by the hepatocytes within the lesion (Fig. 104.4).

FNH is a benign lesion with no malignant potential; therefore, in classic cases, no follow-up surveillance is needed. If surgical resection is required based on the presence of symptoms, nonanatomic wedge resection is sufficient, and no margin is required. For patients to whom resection is not an option because of anatomic or clinical factors, trans-arterial embolization can be effective in achieving tumor shrinkage and symptom relief.

Hepatic Adenoma

Hepatocellular adenoma (HA) is a rare tumor, most frequently seen in young woman, and associated with estrogen-containing medication use (most commonly oral contraceptive pills). They are caused by a benign proliferation of hepatocytes with high glycogen and fat content but lack normal hepatic architecture. There are three subtypes—hepatocyte nuclear factor-1 alpha (HNF-1-α) mutated, beta-catenin, and inflammatory—with the remainder falling into a fourth or unclassified subtype. The details of each subtype are beyond the scope of this chapter. Additional risk factors

include anabolic steroid use and metabolic disease (type 1 glycogen storage disease). Certainty in diagnosis between adenoma and other benign lesions is critical due to the risk of hemorrhage in larger lesions and the risk of transformation to malignancy. Lesions are often solitary; however, in rare cases lesions can be numerous, and if exceed 10 in number, the classification is termed *hepatic adenomyosis.* Smaller lesions are of little consequence; however, when lesions reach 5 cm or greater, there is a risk of spontaneous hemorrhage, occurring in up to 20% to 40% of patients. The inflammatory subtype is at greatest risk for bleeding. Malignant transformation is uncommon and some authors have reported that malignant transformation is a function of size. However, in a review of existing literature, conclusions cannot be made that there is a size below which one can definitively say that malignant transformation does not occur, as there are three reported cases of HCC in lesions <5 cm. Risk factors for malignant transformation include androgen or anabolic steroid intake, male sex, glycogen storage disease, and β catenin subtype. The HNF-1-α subtype is least at risk for complications. Imaging may slightly differ based on subtypes of HA.

Ultrasound of the HNF-1-α subtype reveals a hyperechoic lesion. Contrasted CT shows minimal enhancement with rapid washout. The inflammatory subtype will be hyperechoic, but may be heterogeneous with Doppler signal on US and on CT has strong arterial enhancement that persists in the delayed phase.

The majority of HAs are of the HNF-1-α subtype and the inflammatory type. Inflammatory HA has been described as T2 hyperintense with arterial enhancement that persists on portal venous phase. HNF-1-α lesions have a high lipid content, and their imaging is reflective of this. They may have nonpersistent arterial enhancement and intralesional lipid. MRI can aid in distinguishing HA from FNH, whereas HA rarely retains contrast on hepatobiliary phase images.

In asymptomatic patients, surgical resection is warranted in lesions >5 cm due to risk of spontaneous hemorrhage. In patients who are on estrogen-containing medications, it is reasonable to trial a period without the estrogen stimulus and re-image. While malignant transformation occurs at a mean size of 10.5 cm, because of its rarity, firm recommendations regarding malignancy are difficult to propose and it can be argued that patients with risk factors for malignant transformation should have hepatic adenoma resected at any size. However, the general

guideline remains that for female patients, resection should be performed for lesions >5 cm, while male patients should have adenoma resected at any size due to the increased risk of malignancy in this patient group. Transarterial embolization may be used to treat acute hemorrhage or in select cases where the patient is not an operative candidate and tumor shrinkage is desired. Similarly percutaneous ablation techniques may be employed in poor operative candidates with small lesions (Fig. 104.5).

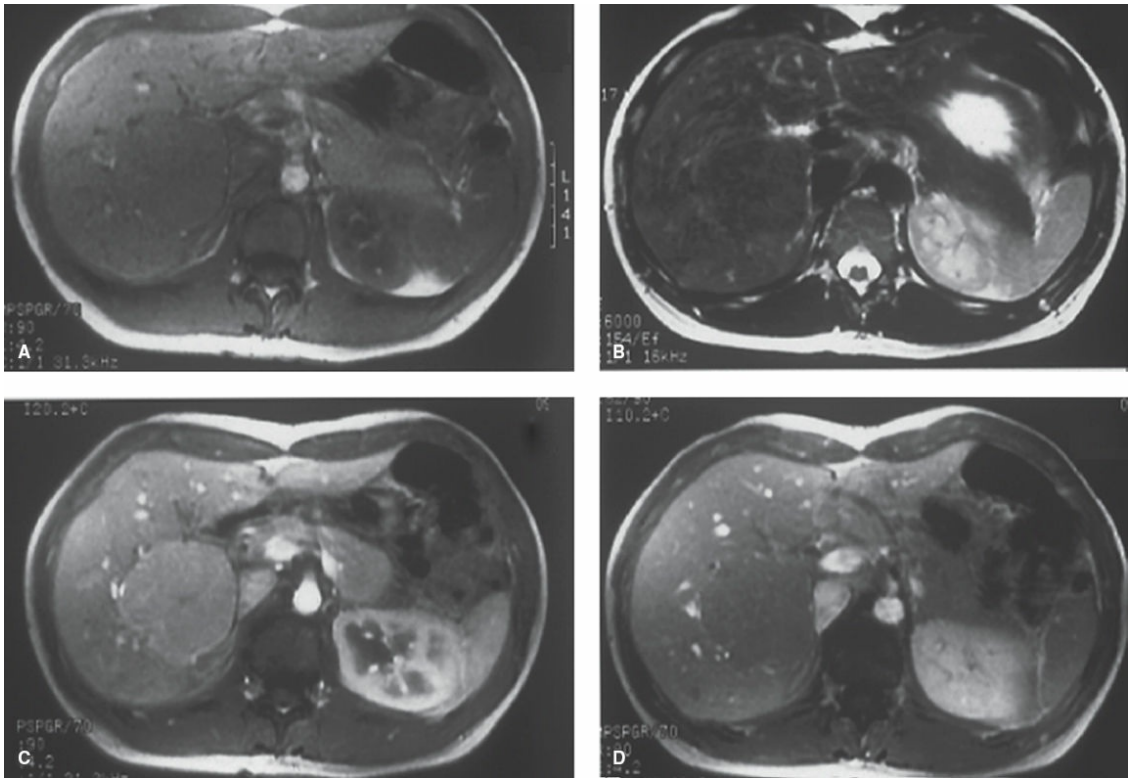

Figure 104.4. MRI appearance of an FNH lesion in the right liver, seen on T1-weighted (**A**) and T2-weighted (**B**) images. The lesion is very homogeneous. After contrast injection (**C, D**), the tumor is initially bright (**C**) but then becomes almost isodense with surrounding parenchyma (**D**). The lesion has a central scar and may be confused with a fibrolamellar HCC.

HA and pregnancy should be discussed on a case-by-case basis; however, generally speaking, pregnancy in patients with HA <5 cm should not be discouraged if they can be compliant with regular ultrasound surveillance (every 3 months) during pregnancy and in the postpartum period. If the lesion changes significantly during the pregnancy, surgical resection should be performed after the patient has entered the second trimester whenever possible.

MALIGNANT TUMORS

The three most commonly occurring solid malignancies in the liver are HCC, cholangiocarcinoma, and metastasis of a nonhepatic primary. As stated previously, the patient's history as it relates to liver disease and malignancies is the key component in the evaluation of any liver lesion.

Primary Liver Cancers

Liver cancer is the fifth most common cancer worldwide in men, and seventh in women.

Hepatocellular Cancer

HCC is diagnosed in approximately 30,000 patients annually in the United States. It rarely occurs before age 40 years and its peak incidence is at age 70 years. Populations who are at the greatest risk are those with liver disease and cirrhosis, with the annual incidence of HCC varying slightly by etiology. Hepatitis B carriers have an estimated risk of HCC of 0.5% to 1%, while those with cirrhosis have an estimated incidence of 2.5% per year. In patients with hepatitis C and cirrhosis, the incidence is 2% to 8% per year. Because of the high risk of HCC in patients with known liver disease and cirrhosis, the American Association for the Study of Liver Diseases (AASLD) has practice guidelines for surveillance in patients with increased risk of HCC (Fig. 104.6). While the guidelines do not recommended AFP, may practitioners obtain surveillance AFP in addition to surveillance imaging.

In patients who present with new liver mass and no history of liver disease, there should be a low threshold to check hepatitis serologies and AFP. Attention should be given to any additional clinical or imaging clues of stigmata of liver disease or portal hypertension. De novo HCC with normal background liver and negative serologies account for only 10% to 20% of all cases.

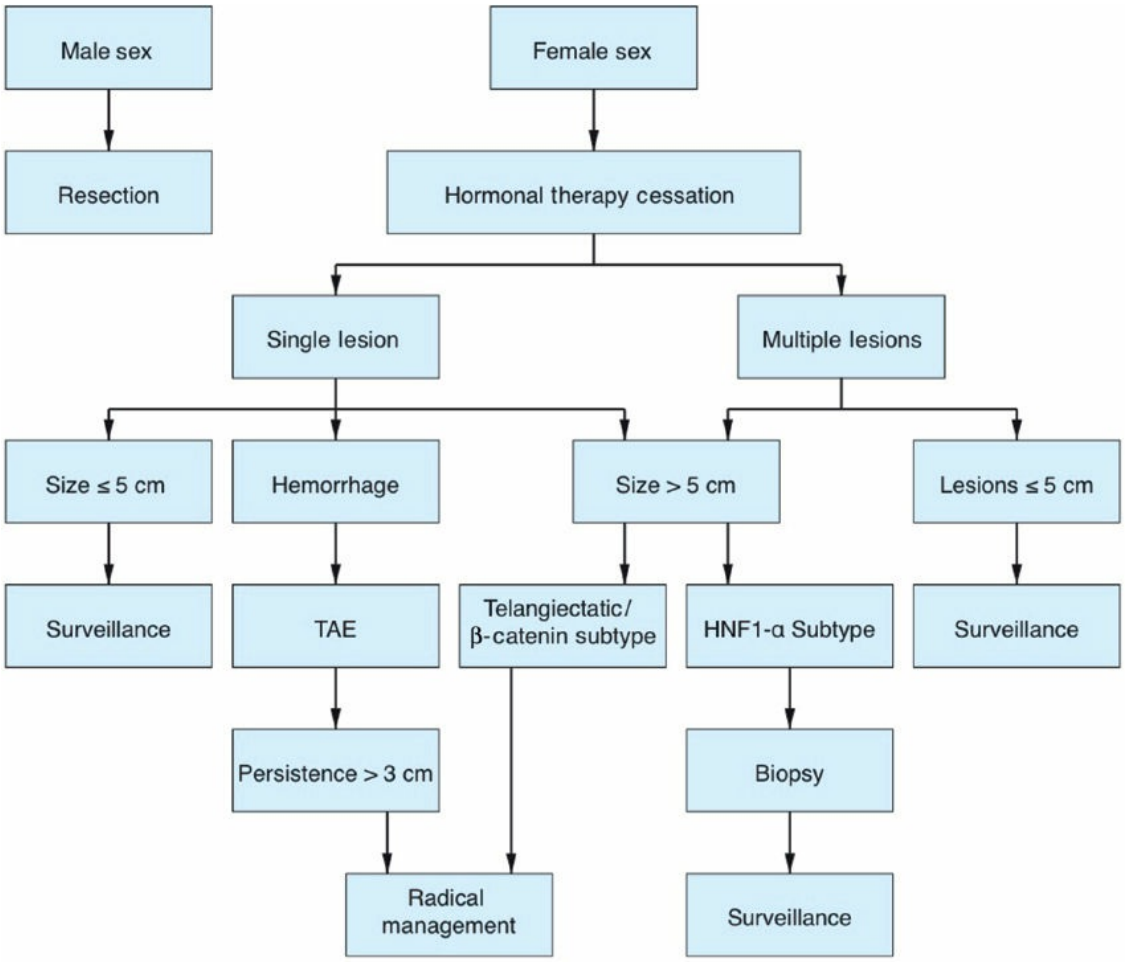

Figure 104.5. Diagnostic/treatment algorithm hepatocellular adenoma. (Reprinted from Agrawal S, Agarwal S, Arnason T, et al. Management of hepatocellular adenoma. *Clin Gastroenterol Hepatol* 2015;13(7):1221–30. Copyright © 2015, with permission from Elsevier.)

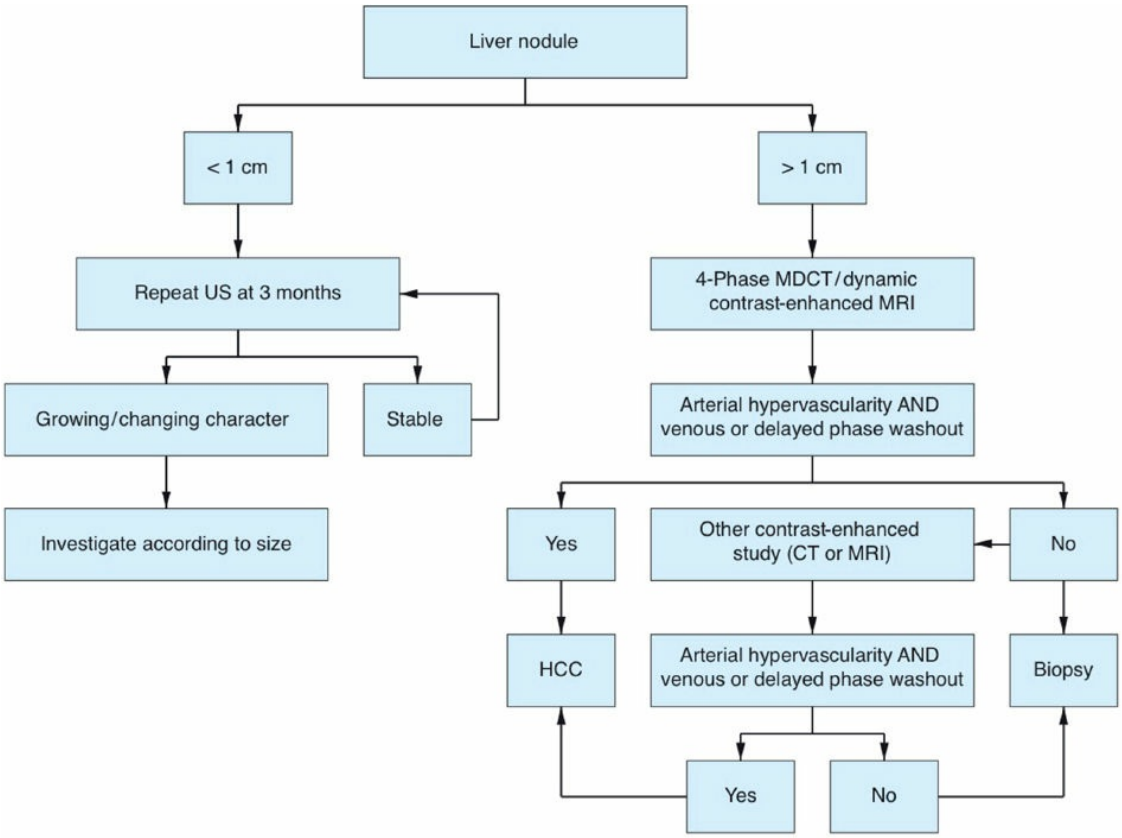

Figure 104.6. AASLD HCC screening guidelines. (From Bruix J, Sherman M, American Association for the Study of Liver. Management of hepatocellular adenoma: An update. *Hepatology* 2011;53(3):1020–2. Copyright © 2011, with permission of John Wiley & Sons.)

Appropriate imaging is often sufficient to make the diagnosis of HCC without the need for a biopsy. On ultrasound, severe fatty liver may be detected as an enlarged liver with diffuse increased echogenicity. The findings of cirrhosis include change in the shape of the liver, parenchymal inhomogeneity, and nodularity. Caudate hypertrophy may be noted. HCC lesions that are multifocal may be difficult to distinguish from the nodular cirrhotic background. Distinct lesions may be hypoechoic. Invasion of vasculature suggests HCC. An equivocal lesion in the setting of an elevated AFP should prompt additional imaging.

Although still debated and at times center specific, there are data to suggest that MRI has improved accuracy over CT for HCC diagnosis. There are two main systems of classification of liver masses with suspicion for HCC. The Liver Imaging Reporting and Data System (LI-RADS) provides a risk stratification based on the level of suspicion for HCC and non-HCC lesions (Table 104.2). The second system, OPTN5,

was created by the United Network for Organ Sharing (UNOS) and Organ Procurement and Transplantation Network (OPTN), to serve as more binary approach to classify lesions as HCC or not, as the presence of HCC is an important criterion used in the allocation of livers for transplantation in the United States.

The findings of HCC using MRI (extracellular contrast–enhanced) or contrasted CT are arterial enhancement, washout, and pseudocapsule. The use of hepatobiliary contrast can aid in the diagnosis of equivocal cases, as the majority of HCCs lack transporters for gadoxetic acid and therefore are hypointense during hepatobiliary phase imaging. CT of the chest and bone scan are recommended to complete staging as 10% to 20% of patients present with extrahepatic metastasis (lung, bone, adrenal, peritoneum).

The treatment of HCC depends largely on the following: (1) the presence or absence of underlying liver disease, (2) the suitability of the patient to undergo resection, (3) the candidacy of the patient for liver transplant (Fig. 104.7).

In patients with well-compensated (Child's class A, MELD <12) cirrhosis and no evidence of portal hypertension, surgical resection remains an option, although with high rate of recurrence (60% to 80% at 10-year follow-up). If resection is entertained, a thoughtful approach to evaluate and optimize the future liver remnant (FLR) is needed. If the estimated FLR is <40% to 50% of nontumorous liver, portal vein embolization of the side to be resected may be employed as a measurement of the patient's ability to hypertrophy postop as well as to optimize the patient for resection.

In patients with more advanced cirrhosis, who meet the Milan criteria (three lesions <3 cm or one lesion <5 cm), do not have vascular invasion, and are candidates for transplant, liver transplantation provides the best long-term survival with the lowest risk of recurrence. In patients who exceed the Milan criteria, many transplant centers have had satisfactory results using a down-staging protocol that incorporates either transarterial chemoembolization (TACE) or transarterial radioembolization (TARE) using Yitrium-90 (Y-90) microspheres in order to bring the patient to within Milan criteria at which point they may be listed for transplant.

In patients who are not candidates for resection or transplant, TACE or percutaneous ablation (of smaller tumors) may provide modest increase in survival.

Cholangiocarcinoma

Cholangiocarcinoma has been used to refer to all primary tumors arising from the malignant proliferation of the epithelial cells lining the biliary tract, including both intrahepatic and extrahepatic ducts. Globally, cholangiocarcinoma accounts for approximately 3% of all gastrointestinal malignancies with an annual incidence rate of 1 to 2 cases per 100,000 population in the United States (approximate incidence of 3,000 cases annually in the United States). Cholangiocarcinoma is the most common primary biliary tract malignancy and second most common primary hepatic tumor (after HCC). The most common type of cholangiocarcinoma is perihilar cholangiocarcinoma (50% to 60%), followed by distal and intrahepatic types constituting 30% to 40% and 5% to 10% of all cholangiocarcinomas, respectively. Most patients with cholangiocarcinoma are in their seventh decade of life at the time of diagnosis with a slightly increased prevalence in males. In general, there is a direct correlation between the age of the patient and the incidence of cholangiocarcinoma; however, in patients with underlying PSC or congenital biliary tract disease (e.g., choledochal cysts), cholangiocarcinoma tends to present earlier, around 30 to 50 years of age.

The clinical features of the perihilar cholangiocarcinoma depend on the stage and location of the tumor. In the majority of patients (>90%), the disease remains clinically silent until it presents at advanced stages with obstructive jaundice (secondary to obstruction of the biliary drainage system by the tumor). Symptoms of progressive cholestasis such as pruritus, dark urine, and clay-colored stools typically accompany the appearance of the jaundice. However, in patients with incomplete biliary obstruction of the right or left hepatic duct or segmental ducts, jaundice might not be the presenting feature. Systemic symptoms of malignancy such as fatigue, malaise, weight loss, fever, and anorexia are observed in up to one-third of the patients at the time of presentation.

TABLE 104.2 LI-RADS for Non-HCC Lesions

LI-RADS Category	Comment	Potential Management
LR-1 (definitely benign)	Imaging features diagnostic of a benign entity Hemangiomas, cysts, fibrosis	Continue routine surveillance
LR-2 (probably benign)	Imaging features suggestive of a benign entity Focal fat, hypertrophic pseudomasses, focal scars	Continue routine surveillance
LR-3 (intermediate probability HCC)	Imaging features that are neither definite nor probably benign Nodular arterial portal shunting, some cirrhotic nodules	Variable follow-up depending on clinical considerations
LR-4 (high probability HCC)	Imaging features suggestive of HCC but that do not meet criteria	Close follow-up imaging, consideration for biopsy or treatment
LR-M (probably malignant but not specific for HCC)	Imaging features may suggest a non-HCC malignancy Cholangiocarcinoma, biphenotypic tumor	Discussion at multidisciplinary meeting, correlation with serum tumor markers, consideration for biopsy

Rarely, the evaluation of vague abdominal pain or abnormal liver tests

leads to the diagnosis of cholangiocarcinoma in early stages of the disease. Abdominal pain related to the tumor is generally described as a constant dull ache located in the RUQ without radiation. Cholangitis is an unusual presentation (in up to 10% of patients) in the absence of previous biliary instrumentation.

The diagnosis of perihilar cholangiocarcinoma is notoriously difficult and in a patient presenting with obstructive jaundice requires high index of suspicion combined with multiple complementary diagnostic studies. Carbohydrate antigen 19–9 (CA 19–9) and carcinoembryonic antigen (CEA) are two markers being used broadly in diagnosis and surveillance of several intra-abdominal malignancies and its specificity in the diagnosis of cholangiocarcinoma is limited. US findings are largely operator-dependent and play a minimal role in the definitive diagnosis of cholangiocarcinoma. US can be used to exclude underlying benign pathologies (like cholelithiasis, cholecystitis) as the cause of presenting symptoms. In addition, US is sensitive in detecting biliary tract dilation that can be seen in cholangiocarcinoma and in localizing the level and assessing the severity of the obstruction. Ductal dilation >6 mm in the absence of bile duct stones is suggestive of an obstructing bile duct lesion.

MRI/MRCP with contrast is the imaging technique of choice, while MDCT is an alternative in patients who cannot undergo MRI/MRCP. Direct cholangiography techniques (like ERCP or PTC) are considered if there is indication for preoperative biliary decompression or tissue sampling.

If there is high clinical suspicion based on laboratory and imaging findings, surgical therapy may be offered without confirmation by tissue diagnosis or in setting of equivocal tissue sampling. However, tissue sampling via EUS-guided FNA, ERCP, or PTC with brush cytology or in the cases of visible perihilar mass lesion CT-guided/MRI-guided can be considered. Intraductal ultrasound and cholangioscopy are additional adjuncts that might be useful in obtaining tissue.

It should be emphasized that operative exploration remains the definitive technique to rule out cholangiocarcinoma. Relying on the cytology results of the specimens obtained via either of the above-mentioned techniques, considering their low negative predictive value is dangerous and might result in missing the opportunity of resecting an early-stage cancer.

PSC is a well-known risk factor for cholangiocarcinoma with a lifetime

risk of 5% to 15% for malignancy development; therefore, screening of these patients is paramount. With its high incidence (relative risk >1,500), some experts consider PSC a premalignant condition that progresses in the stepwise sequence transforming cholangiocytes to the malignant cells; however, the definitive molecular pathogenesis of this transformation is not as well understood as are other gastrointestinal malignancies, like colon cancer. Moreover, many of these patients present at later stages due to the difficulty in differentiating between benign dominant biliary stricture and malignant stricture. Although there are no definitive guidelines for screening patients with PSC for the development of cholangiocarcinoma, frequent (annual or on an every 6-month basis) surveillance programs consisting of serum tumor markers (i.e., CA 19–9) along with imaging studies (ultrasound or MRI/MRCP) may be beneficial. Patients with persistently elevated CA 19–9 and highly suspicious lesions visualized by noninvasive imaging techniques (i.e., MRCP) should undergo attempts to obtain tissue or cytology using ERCP or EUS. Cholangiocarcinoma in these patients carries a very dismal prognosis.

Surgical resection or transplant (in highly selected cases) remains the best chance for cure for hilar cholangiocarcinoma. The goals of surgical resection are to provide a chance for cure through (1) complete oncologic resection (RO), (2) preservation of sufficient liver remnant, and (3) palliation of biliary obstruction. While transplantation for cholangiocarcinoma is only performed in select centers, if a patient is deemed borderline or not resectable, consideration should be made to evaluation for candidacy for liver transplantation and the patient should be made aware of this option. Transplantation is generally only considered for unresectable hilar tumors <3 cm in size with negative sampled regional nodes and treated with neoadjuvant chemoradiation protocol. Transperitoneal biopsy (percutaneous or EUS-guided) has been associated with an increased recurrence risk after transplant, so it is important to avoid such biopsies in potential transplant candidates, until this option has been ruled out.

LIVER METASTASIS FROM PRIMARY OF ANOTHER ORIGIN

Liver lesion(s) in the setting of previous malignancy should raise suspicion of metastasis secondary to their original cancer. Appropriate surveillance of the primary with imaging and tumor markers should be utilized to

assess for recurrence. Metastasis will have varying appearance on imaging, with metastasis from adenocarcinoma often having a hypoechoic appearance. Tri-phasic (unenhanced, arterial, and portal venous phase) CT of the liver will reveal low attenuating lesions in the case of colorectal, gastric, pancreatic metastasis, while hypervascular lesions are seen in the setting of neuroendocrine, renal cell, breast, thyroid, melanoma, and sarcoma. Tumor-specific imaging may be appropriate, for example, octreotide scan in a patient with a history of neuroendocrine tumor. PET scan should be used liberally to ensure that there is no additional site of metastatic disease or recurrence, especially in cases where the level of tumor marker elevation is incongruent with the demonstrated burden of disease. Biopsy may be necessary to confirm a suspected tissue type in cases where it will effect the treatment plan. Ascites and unilateral pleural effusion without other explanation should raise suspicion for carcinomatosis or malignant effusion. These collections should be sampled and cytology examined.

Colorectal Metastasis

While metastatic disease was once considered a contraindication to aggressive surgical resection, the pendulum has swung and metastasectomy of liver lesions is now well accepted in appropriately selected patients.

Adenocarcinoma of the colon is a significant public health issue, with colon cancer accounting for approximately 10% of all cancer-related deaths.

Because of well-described physiologic and cadaver studies, we know that the liver is the most common site of metastasis for this disease. Twenty-five percent of patients will have liver disease at the time of the diagnosis of their primary cancer, with up to 50% either synchronous disease or metachronous lesions discovered later in the disease course.

The natural history has also been well studied, and the extent of liver disease is one of the principle determinants of survival in these patients.

Multiphasic contrast CT and MRI both have high sensitivity and specificity for the detection of colorectal metastasis (sensitivity 73% and 82% and specificity 97% and 93%, respectively). Lesions are typically hypoenhancing and outside of a history of colorectal cancer, and may be difficult to discern from tumor of other origin. MRI with hepatobiliary-specific contrast enhancement is considered superior in the setting of

background steatosis, which is not uncommon in patients undergoing chemotherapy. The role of PET/CT is unclear and is largely used to detect extrahepatic metastasis that would preclude resection.

While metastatic disease was once considered a contraindication for surgical intervention, resection is now accepted as the gold standard for the treatment of surgically resectable hepatic metastasis. Survival without surgical resection is low with a median of 5 to 10 months; however, excellent results have been consistently achieved using surgical resection. Special attention to a parenchymal sparing approach with a goal of tumor-free margin should be given in colorectal metastatic disease, as a high percentage of these patients will develop recurrence. There is no added survival benefit from a wider margin. The primary tumor should be resected in either a synchronous or staged setting. Most chemotherapy regimens should be stopped 2 to 3 weeks prior to resection, with the exception of Avastin, which should be stopped 6 to 8 weeks prior to surgery due to the increased risk for bleeding and impaired wound healing.

For smaller tumors (<3 cm), promising results have been achieved with percutaneous and operative ablative techniques; however, there are limited data at this time to support this approach over resection except in highly selected patients.

Appropriate treatment for “disappearing metastasis” on imaging in response to chemotherapy remains controversial due to the unclear concordance with complete pathologic response and the evolution of imaging techniques. In general, such sites should be resected or ablated at the time of operative intervention, if they can be identified.

Neuroendocrine Tumors

Patients with gastrointestinal neuroendocrine tumors will have liver metastasis in approximately 10% to 20% of cases. In addition to multiphasic CT or MRI, octreotide scan may be helpful in determining the extent or multifocality of disease. In patients who have been on somatostatin, the timing of their injections must be coordinated with the administration of the examination to prevent a falsely negative study. Resection or locoregional therapy of the lesions is targeted at palliating symptoms (in symptomatic cases) and increasing survival. The goal of resection is cytoreduction of at least 90% of disease, with no significant difference seen in survival between patients who achieved R0, R1, or R2 status. Transarterial therapies have been shown effective in treatment of

these tumors. For patients with unresectable, stable isolated liver disease, transplantation of the liver may be considered, but only in highly selected cases.

HEPATOBILIARY DISEASE IN THE PREGNANT PATIENT

Several hepatobiliary processes are more prevalent during pregnancy. There are several pathologies that are rare during pregnancy, but can be devastating. Several are diseases that are specific to pregnancy, while others are diseases that are not specific to, but exacerbated by the pregnant state.

It should be noted that while special attention should be given to the limiting the exposure of the fetus to ionizing radiation, however, in the emergent evaluation of the pregnant patient, the best and quickest modality should be utilized in order to appropriately diagnose and treat the mother. For this reason, whenever possible, ultrasound modalities are the examination of choice, followed by MRI and lastly CT.

Cholelithiasis is exacerbated by the excess of estrogens during pregnancy. This leads to supersaturated bile and large gallbladder volumes, which results in gallbladder stasis, increased biliary sludge, and gallstones. Ultrasound and MRI/MRCP can aid the diagnosis. MRCP can be particularly helpful in distinguishing choledocholithiasis from cholestasis of pregnancy. EUS is a good alternative to ERCP and fluoroscopy in this setting as well, and has a high sensitivity and specificity. If possible, general anesthesia and surgery should be delayed until the second trimester; however, sepsis has a high risk of fetal loss, so this should be balanced with the risk of surgery at earlier stages of gestation.

Hereditary hemorrhagic telangiectasia (HHT) is an uncommon autosomal-dominant disorder characterized by the development of vascular malformations in multiple organs including the liver. In the liver, arteriovenous and portovenous malformations develop. During pregnancy, likely because of the increase in cardiac output and expansion of blood volume, increased flow through hepatic shunts may result in reversible heart failure. Imaging findings include demonstration of innumerable arteriovenous fistulas, telangiectasias, and focal confluent hepatic masses that become isoenhancing during the portal phase. The hepatic artery is typically enlarged.

Budd–Chiari syndrome is used to define a situation of hepatic venous outflow obstruction. In the noniatrogenic setting, it is usually seen in hypercoagulable states, including pregnancy. It presents with abdominal pain, ascites, and hepatomegaly. It can be diagnosed using duplex ultrasound, which will show an abnormal flow pattern through the portal and hepatic veins. Depending on the chronicity of disease, the liver may have a nodular pattern and collaterals may be present.

As discussed previously, HA and pregnancy should be discussed on a case-by-case basis; however, generally speaking, pregnancy in patients with HA <5 cm should not be discouraged if they can be compliant with regular ultrasound surveillance (every 3 months) during pregnancy and in the postpartum period. The lesion may experience growth during pregnancy in response to the hyperestrogenic state. If the lesion changes significantly during the pregnancy, surgical resection should be performed after the patient has entered the second trimester whenever possible.

EDITOR'S COMMENT

The surgeon will frequently be asked to consult patients with a variety of biliary and liver problems. Collins and Chapman provide an excellent review of imaging modalities for the gallbladder, biliary tree, and liver. Not uncommonly, the surgeon must complete the evaluation of the patient and order appropriate imaging to sort out various abnormal findings.

Ultrasonography (US) is the procedure of choice for identifying gallstones. Current high-resolution, real-time US can identify gallstones as small as 2 mm, with a sensitivity >95%. Today a variety of providers may perform US and issue reports on the presence or absence of gallstones. In my opinion, the surgeon should rely on the reading by a radiologist. The use of bedside ultrasound by emergency room physicians and other providers is increasing. This is helpful in some emergent situations but is not a replacement for a diagnostic ultrasound performed under the supervision of a radiologist and interpreted by a radiologist. Scruggs et al. (Scruggs W, Fox JC, Potts B, et al. Accuracy of ED bedside ultrasound for identification of gallstones: retrospective analysis of 575 studies. *West J Emerg Med* 2008;9(1):1–5) reviewed the sensitivity and specificity of ultrasound done by emergency medicine physicians compared to radiologists. They found in 575 patients who received both bedside and radiology ultrasounds, radiology diagnosed gallstones in 344 of 575 (60%). ED ultrasound was positive for gallstones in 332 (57.7%) patients. ED bedside interpretation was 88% sensitive (95% CI, 84% to 91%) and 87% specific (82% to 91%), and the positive predictive value (PPV) was 91% (88% to 94%) and negative predictive value (NPV) was 83% (78% to 87%). The accuracy of the ED ultrasound was 87.2%. Importantly, they found that 6% of images obtained by bed side ultrasound were inadequate possibly because of the limited duration of the examination, variable experience, patient positioning, and use of other adjuncts. The radiology literature demonstrates a sensitivity of 81% to 99% for radiology ultrasound for the diagnosis of cholelithiasis, although the majority of the studies demonstrating sensitivities at the lower end of the range were performed in the early years of ultrasound. A rigorous meta-analysis of the radiology literature by

Shea et al. (Shea JA, Berlin JA, Escarce JJ, et al. Revised estimates of diagnostic test sensitivity and specificity in suspected biliary tract disease. *Arch Intern Med* 1994;154:2573–81) for the diagnosis of cholelithiasis found a sensitivity of 97% and specificity of 95% (unadjusted for verification bias). If one is making a decision to perform an operation on a patient, then he or she must have highly accurate imaging.

In addition to identifying gallstones, ultrasound may be helpful in diagnosing acute cholecystitis. The most sensitive US finding in acute cholecystitis is the presence of cholelithiasis in combination with the sonographic Murphy sign. As many as 70% of patients with acute cholecystitis may display this sign. Its absence does not exclude acute cholecystitis. Both gallbladder wall thickening (>3 mm) and pericholecystic fluid are secondary findings. Other less specific findings include gallbladder distension and sludge. The findings should be correlated with clinical findings in the patient to establish the diagnosis.

It is not unusual for the ultrasound to be interpreted as showing gallbladder polyps. Are gallbladder polyps detected incidentally on a diagnostic ultrasound of clinical significance? It is estimated that 4% to 7% of patients who undergo ultrasound of the gallbladder are diagnosed with gallbladder polyps. The question that arises are these truly neoplastic polyps that should be followed. Corwin et al. (Corwin MT, Siewert B, Sheiman RG, et al. Incidentally detected gallbladder polyps: is follow-up necessary? Long-term clinical and US analysis of 346 patients. *Radiology* 2011;258:277–82) reported an extensive study in patients with incidentally found gall bladder polyps. A total of 517 patients with gall bladder polyps were identified. Of these, 171 were excluded because of insufficient follow-up. Of the remaining 346 patients, single polyps were seen in 216 patients, and multiple polyps were seen in 130 patients. Polyps ranged in size from 1 to 18 mm with a mean size of 5 mm. Of the 346 patients, 42 underwent cholecystectomy. Of these, 13(31%) had polyps on pathologic examination, including 1 who also contained a stone and 6 cases of cholesterolosis. Twenty-four (57%) demonstrated stones and no polyps and 5 (12%) showed no stones or polyps on pathologic examination. Of the 346 patients, 149 (43%) had US follow-up and the size of the polyp at the latest follow-up US was stable in 90 (60%), decreased in 8 (5%), and increased in 1 (1%), and the polyp had resolved in 50 (34%) patients. In one patient with a polyp that increased in size, it went from 3 to 5 mm over 4 years. Of the 155 patients who had clinical follow-up from 5 to 10 years after the index ultrasound, none had any evidence of gallbladder-related disease and there were no cases on gallbladder cancer.

Based on this study and many others, it seems that many so-called polyps are in fact gallstone, up to 57%. In addition to gallstones, some of the so-called polyps are adherent cholesterol sludge or cholesterol polyps and not neoplastic polyps. If a patient is having symptoms consistent with gallbladder disease and an US shows a “polyp”, it would seem that cholecystectomy is warranted.

Similarly it would seem that long-term follow-up did not demonstrate any

progression in most patients and no cases in gallbladder cancer during the follow-up period. In addition, the authors reported that no neoplastic polyps <7 mm were seen. Hence, they proposed that incidentally detected polyps less than or equal to 6 mm require no additional imaging for follow-up. In our practice, we order imaging in such cases if the patients have symptoms or if they have anxiety about the diagnosis.

Is the adenoma–carcinoma sequence at play in gallbladder cancer? Kozuka et al. (Kozuka S, Tsubone M, Yasui A, et al. Relation of adenoma to carcinoma in the gallbladder. *Cancer* 1982;50:2226–34) suggested that it does after examining 1,605 cholecystectomy specimens finding 7 adenomas with malignant change and 15 carcinomas with adenomatous changes. All of the adenomas with malignant changes were >12 mm. Other authors favor a dysplasia–cancer pathway.

Combining this information with other literature, we recommend the following regarding the management of gallbladder polyps: Symptomatic patients should be considered for cholecystectomy, patients with a polyp 10 mm or greater or with findings suspicious for malignancy (a vascular pedicle) should have elective cholecystectomy, those with a polyp between 6 and 10 mm should have follow-up ultrasound, and those with polyps 6 mm or less should have clinical follow-up.

Biliary dyskinesia is a gallbladder dysfunction where the gallbladder fails to contract properly and/or a reduction in the speed of emptying of the biliary tree occurs. Patients present with biliary type pain. A busy general surgeon may see a case or two per week. Biliary dyskinesia is defined as a gallbladder ejection fraction <35% and cholecystectomy can be considered. There is a subset of symptomatic patients, however, who have an abnormally high ejection fraction, defined as >65%. The approach to the treatment of these patients with biliary hyperkinesia is still undetermined, as there is little in the literature regarding this entity. Biliary dyskinesia is diagnosed by CCK cholescintigraphy. The technique is described as follows. After an overnight fast, 99mTc-diisopropyl-iminodiacetic acid (DISIDA) or 99mTc-hepatic iminodiacetic acid (HIDA) is given as an intravenous bolus. When the radioactivity is maximal from the gallbladder and is minimal from the liver, an infusion of CCK is started to stimulate gallbladder contraction. This results in gallbladder contraction and emptying of the radiolabeled tracer. A variety of methods of CCK administration are reported. Some prefer a slow infusion of CCK (sincalide 0.02 mcg/kg given over 30 to 60 minutes) (Dibaise JK, Richmond BK, Ziessman HA, et al. Cholecystokinin-cholescintigraphy in adults: consensus recommendations of an interdisciplinary panel. *Clin Nuc Med* 2012;37:3). Rapid administration of CCK over 2 to 3 minutes of CCK is preferred by others. This can be associated with cramping, patient discomfort, and highly variable results. Slower infusion rates (over 30 to 60 minutes) seem to lead to less inter- and intrasubject variability and an overall increase in mean gallbladder ejection fraction compared with rapid infusion. Variability in CCK administration

techniques may account for some of the differences seen in studies examining the ability of the ejection fraction to predict a response to cholecystectomy. Normokinetic biliary dyskinesia (DuCoin C, Faber R, Ilagan M, et al. Normokinetic biliary dyskinesia: a novel diagnosis. *Surg Endosc* 2012;26:3088–93) and hyperkinetic biliary dyskinesia (Lindholm EB, Alberty JB, Hansbourgh F, et al. Hyperkinetic gallbladder: an indication for cholecystectomy? *Am Surg* 2013;79:882–4) have been described. Some patients with the latter findings do improve after cholecystectomy. Frankly, I do not recommend surgery for either of the latter two groups of patients. I have found it helpful to consult with a gastroenterologist. Not uncommonly these patients are diagnosed with irritable bowel syndrome and respond to management for this condition.

The authors discuss imaging for suspected biliary obstruction. Initially an ultrasound should be performed to determine if there is extrahepatic biliary dilation. If present, then additional imaging is based on clinical presentation, labs, and the findings on US. MRI is extremely helpful as it can identify the site of the obstruction and the possible cause, that is, stone, stricture, or tumor. If there is a stone, ERCP is the next step as the stone can be removed. If there is a common duct stone, the patients will need a cholecystectomy. In our experience, there are better outcomes if an ERCP and stone removal proceed cholecystectomy. This may vary on the availability of ERCP at an institution. If there is a tumor or stricture, then endoscopic ultrasound is extremely helpful and will potentially allow a tissue diagnosis.

Dasari et al. reported a systematic review that attempted to answer the question of the safest and most effective method to remove common duct stones and the timing with cholecystectomy (Dasari BV, Tan CJ, Gurusamy KS, et al. Surgical versus endoscopic treatment of bile duct stones. *Cochrane Database Syst Rev* 2013;12:Art. No.:CD003327. doi:10.1002/14651858.CD003327.pub4). The bottom line is that there is no significant difference in the mortality, morbidity, retained stones, and failure rates between the single-stage laparoscopic bile duct clearance and two-stage endoscopic management. They concluded that additional randomized clinical trials without risks of selection bias and random errors are necessary to confirm these findings. There have been numerous studies with the same conclusion. The best advice is to do what you are most comfortable with and the available expertise at your hospital.

The information of imaging of hepatic lesions is particularly well done and inclusion of the LI-RADS nomenclature for outlining treatment steps for HCC workup is extremely helpful. General surgeons are frequently asked to evaluate liver lesions that have been found incidentally—hepatic incidentalomas. The exponential growth in the use of advanced imaging has led to the more frequent detection of incidental hepatic masses in both the oncology and nononcology patient population. This has created a management dilemma that is particularly pertinent to oncology patients, in whom any hepatic mass warrants attention. Hepatic incidentalomas are found in 10% to 33% of imaging studies. At

autopsy, as many as 52% of noncancer patients have benign hepatic lesions, and liver metastases are found in as many as 36% of patients dying with cancer. Whether for cancer or noncancer patient, the key questions are: (1) Is the hepatic incidentaloma associated with a potential adverse outcome? (2) What is the most reliable way to determine which lesions are significant? (3) What is the best management of these incidentalomas? I think that no one has the answers to all these questions. However, Berland et al. prepared a white paper of the American College of Radiology Incidental Findings Committee (Berland LL, Silverman SG, Gore RM, et al. Managing incidental findings on abdominal CT: white paper of the ACR incidental findings committee. *JACR* 2010;7:754–73), which has recommended appropriate terminology to be used by the radiologist in her or his dictation. This can minimize potentially unnecessary tests by establishing common terminology. The key is to strike a balance between overtesting and establishing an accurate diagnosis.

Hepatic incidentalomas challenge physicians and confuse patients with how to manage them. Although it is known that the majority are likely benign and often have little or no clinical significance, the inclination to evaluate them is often driven by physician and patient unwillingness to accept uncertainty and defensive medicine. Nearly 40% of patients with a hepatic incidentaloma have additional imaging. Newer MR modalities have proven useful and are relevant. The recently introduced Gd-EOB-DTPA is a biphasic hepatobiliary MR contrast agent. Chung et al. (Chung YE, Kim MJ, Kim YE, et al. Characterization of incidental liver lesions: comparison of multidetector CT versus Gd-EOB-DTPA–enhanced MR imaging. *Plos One* 2013;8(6):e66141) report a comparison of contrast-enhanced multidetector CT (MDCT) and Gd-EOB-DTPA–enhanced MRI for characterization of incidental liver masses. The results demonstrate that Gd-EOB-DTPA–enhanced MR provides better diagnostic accuracy for the differentiation of benign and malignant lesions and for the specific diagnosis of FNH and focal eosinophilic infiltration. Both dynamic contrast–enhanced CT and Gd-EOB-DTPA–enhanced MR had similarly high diagnostic accuracy for hemangioma and HCC. This may prove the one step test for the final resolution of the hepatic incidentaloma.

105 Approaches to Drainage of Hepatic, Perihepatic, and Subhepatic Abscesses

Timothy L. Pruett and Daniel Borja-Cacho

PYOGENIC LIVER ABSCESS

Epidemiology

The incidence of pyogenic liver abscesses in the United States is 3.6 per 100,000 population. This frequency is on par with other Western countries such as Canada and Denmark in which the published incidence was 1 and 2.3 per 100,000, respectively. In contrast, the disease is more common in Asian countries such as Taiwan (17.6 per 100,000 population).

The risk of developing liver abscesses increases with advanced age. Patients older than 65 are more likely to develop this disease as compared with younger patients. Men are affected more frequently. Approximately 60% to 70% of the cases occur in males. The risk of developing pyogenic liver abscesses increases with certain comorbidities. Diabetes mellitus (DM) has been recognized as the most prevalent comorbidity in patients with liver abscesses. It is present in up to 48% of the patients at the time of diagnosis. Diabetic patients develop abnormalities in both cell-mediated and humoral immune responses, resulting in increased susceptibility to infections. Hepatobiliary neoplasms, pancreas and colorectal cancer (CRC), ethanol abuse, chronic immunosuppression, chronic kidney disease, previous liver transplantation, and benign biliary disease are also associated with increased risk of developing liver abscesses.

Pathophysiology

The most frequent mechanisms that lead to bacterial infection of the liver parenchyma include:

1. Ascending cholangitis/biliary infection. It is the most common source of infection. Ascending cholangitis is usually associated with biliary obstruction that predisposes to bile stasis, bacterial proliferation, and

cholangitis with secondary infection of the liver. Not infrequently, patients with obstructive jaundice require repeated instrumentation of the biliary tract and are colonized by resistant bacteria and/or fungi. Common causes of biliary obstruction include choledocholithiasis, periampullary tumors, and extrahepatic cholangiocarcinoma. It can also be due to diseases that are more difficult to treat such as hepatic artery thrombosis in liver transplant recipients. This posttransplant complication leads to biliary ischemia, diffuse biliary strictures, and liver parenchyma necrosis. Additional examples include simultaneous bile duct and hepatic artery injury during laparoscopic cholecystectomies or ischemic cholangiopathy in donor after cardiac death (DCD) recipients.

2. Hematogenous venous dissemination. The first cases of pyogenic liver abscesses were frequently associated with complicated intra-abdominal infections. However, early diagnosis of appendicitis, diverticulitis, and other intra-abdominal infections as well as better antibiotic therapy has decreased its incidence. Nevertheless, any disease that alters the integrity of the gastrointestinal (GI) mucosa can produce bacterial translocation and portal vein dissemination. For example, the chronic inflammation of the intestinal mucosa that occurs in patients with inflammatory bowel disease (IBD) results in a friable mucosa and loss of the normal architecture. Bacteria invade the damaged mucosa and reach the portal circulation. Patients with IBD are at increased risk of developing pyogenic liver abscesses. The relative risk is slightly higher in patients with ulcerative colitis as compared with Crohn disease. Additional examples include bowel ischemia and CRC. Interestingly, in some patients, the diagnosis of liver abscess can precede the diagnosis of non-metastatic colorectal neoplasms more than 2 years. Since the source of bacteria is always the GI tract, the most common pathogens isolated from these abscesses include gram-negative rods and *Streptococcus* species. In the absence of an obvious source of infection, isolation of *Streptococcus* spp. should always increase the concern of a colonic pathology.
3. Hematogenous arterial infection. Infective endocarditis, osteomyelitis, untreated oral infections, and illicit intravenous (IV) drug use can be associated with pyogenic liver abscesses. In these conditions, septic emboli reach the liver through the hepatic artery. It accounts for less than 10% of the cases. Cultures usually show monomicrobial growth of gram-positive cocci such as *Staphylococcus aureus.* Not infrequently, patients have multiple bilateral small abscesses.

4. Direct trauma. Radiofrequency ablation (RFA), cryotherapy, and any other form of liver intervention can be complicated by direct inoculation of bacteria into the liver parenchyma. The incidence of liver abscesses after RFA is 0.4%. Its frequency increases in patients with prior bilioenteric anastomoses. Pyogenic hepatic abscesses may complicate penetrating and non-penetrating liver trauma. Liver abscesses occur in 0.7% to 1.5% of patients undergoing non-operative treatment of liver trauma. Risk factors include coexistence of small bowel injuries, persistent bleeding, massive blood transfusions, and extensive tissue damage.
5. Extension from a contiguous septic process. Although very rare, complicated acute cholecystitis may result in the formation of intrahepatic abscesses. Benign or malignant perforations of the stomach, duodenum, or colon can be associated with the formation of an abscess that directly extends into the liver parenchyma.

In 20% to 27% of the cases, no underlying source of infection can be identified. These abscesses are described as cryptogenic. The frequency of cryptogenic abscesses depends on the type of population studied. Cancer centers have a lower incidence of cryptogenic abscesses because most infections are secondary to malignant biliary obstructions or CRC. On the other hand, cryptogenic abscesses and benign biliary disease are the most common etiology in large community hospitals.

Clinical Manifestations

Constitutional symptoms such as fever, chills, and malaise are very common manifestations of this disease. They frequently precede other symptoms and are present in 80% to 88% of the patients. Right upper quadrant (RUQ) pain is seen in 33% to 70% of the patients. Its frequency is influenced by the size and location of the abscess and the presence of biliary obstruction. RUQ pain is more common in lesions larger than 5 cm and abscesses located close to the diaphragm. Jaundice is present in only 8% to 21% of the cases. Patients with liver abscesses that arise in segments VII and VIII of the liver may develop pleuritic-type pain or cough. No correlation between symptoms and the underlying disease exists.

Fever and hepatomegaly are physical examination signs present in 60% and 40%, respectively. Additional manifestations include RUQ tenderness, jaundice, decreased breath sounds, and crackles in the right hemithorax.

Diagnosis

Leukocytosis is a common finding present in 65% to 77% of the patients. Liver function tests are frequently abnormal, but no specific pattern suggestive of pyogenic liver abscesses exists. Abnormal elevation in alkaline phosphatase, aminotransferases, and total bilirubin occurs in 50% to 70%, 40% to 50%, and 20% to 30% of the patients, respectively. Hypoalbuminemia, hyponatremia, bandemia, and elevated C-reactive protein are very common. However, these are nonspecific findings present in many inflammatory and infectious processes.

The initial assessment includes a chest x-ray to evaluate the fever, cough, and pleuritic pain. Common radiographic findings include elevated right hemidiaphragm and/or right pleural effusion. However, these findings are seen in other pathologies. Pathognomic signs such as the presence of intrahepatic gas or air-fluid levels and portal vein gas are rare.

Liver ultrasound is commonly used as a first step of evaluation. Its sensitivity is 83% to 95% and is influenced by the size, location, and pathologic state of the abscess. During the early phase of infection, before necrosis has occurred, liver abscesses appear solid, hyperechoic, and are difficult to distinguish from normal parenchyma. As liquefaction and necrosis ensue, abscesses appear as complex cystic masses with internal echoes and distal acoustic enhancement (Fig. 105.1). Liver abscesses are not vascularized. Therefore, blood flow is only observed in the periphery. Bile duct structures running through them are not seen.

Contrast-enhanced computed tomography (CT) of the abdomen has a sensitivity of 95%. As Figure 105.2 shows, liver abscesses usually appear as well-defined hypoattenuating lesions. Large abscesses may be unilocular with smooth margins or complex with internal septa and internal contour. Mature abscesses usually do not have internal enhancement. Rim enhancement and the presence of gas are very uncommon (5% to 20% of the patients). Thrombosis of the hepatic veins or portal associated with these infections is a very rare finding that is probably more common in patients with *Klebsiella pneumoniae* infection.

In magnetic resonance imaging (MRI), pyogenic abscesses typically appear as hypointense lesions on T1-weighted images and hyperintense on T2-weighted images (Fig. 105.3A). The abscess wall is always visible without contrast if it is thicker than 5 mm. Rapid and almost universal wall enhancement occurs after IV gadolinium administration. This is independent of the thickness of the wall, and it is secondary to increased

capillary permeability. Internal septa can be present. Mature collections do not exhibit internal enhancement. Liver abscesses show restricted diffusion on diffusion-weighted imaging. As previously described, vein thrombosis is a rare finding. Finally, the biliary reconstruction performed during magnetic resonance cholangiopancreatography (MRCP) is a useful tool that can identify communication between liver abscesses and the biliary tract (Fig. 105.3B).

A solitary and dominant lesion is identified in 60% to 70% of the patients. Abscesses are more common in the right lobe (70%). Bilobar disease is present in 15% of the patients. Solitary abscesses are more likely to be polymicrobial as compared to multiple abscesses.

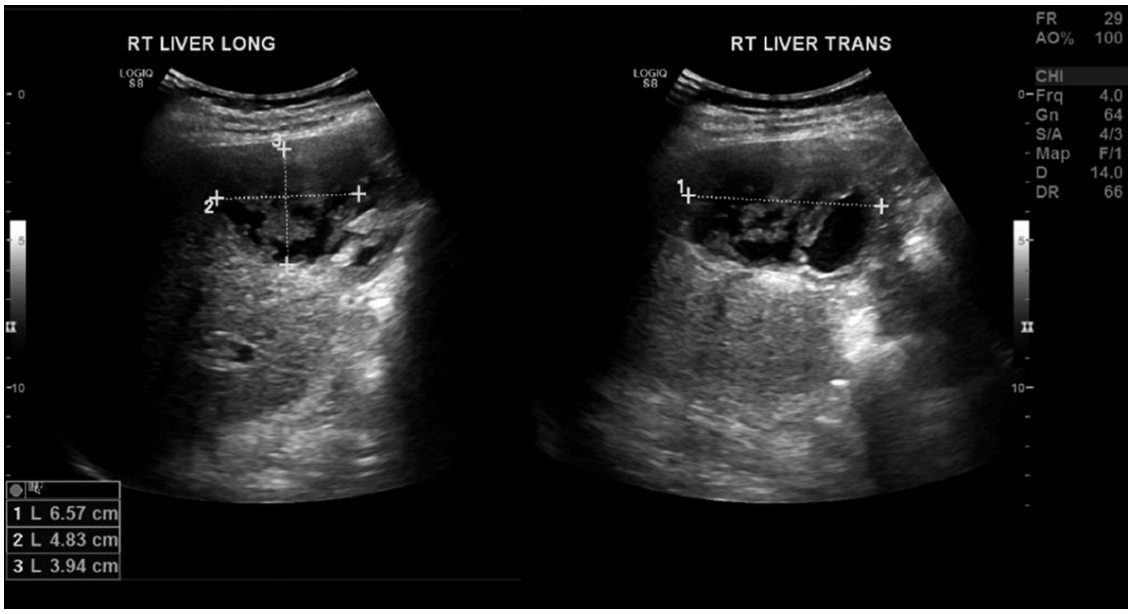

Figure 105.1. Liver ultrasound of a 62-year-old male with history of a liver transplant and late hepatic artery thrombosis. The abscess is located in the right lobe and appears as a complex cystic mass with internal echoes. No evidence of blood flow inside the lesion was seen in the Doppler.

Microbiology

Microorganism identification is critical. It can be done through blood cultures or percutaneous aspirates. The sensitivity of percutaneous aspirates is superior to blood cultures, but blood cultures are very easy to obtain and almost universally available. Ideally, two or more blood cultures should be requested. Systemic antibiotic therapy decreases the yield of bacterial isolation, but such cultures should never delay the treatment. Gram stain and cultures from percutaneous aspirates should be

ordered as soon as the diagnosis has been confirmed.

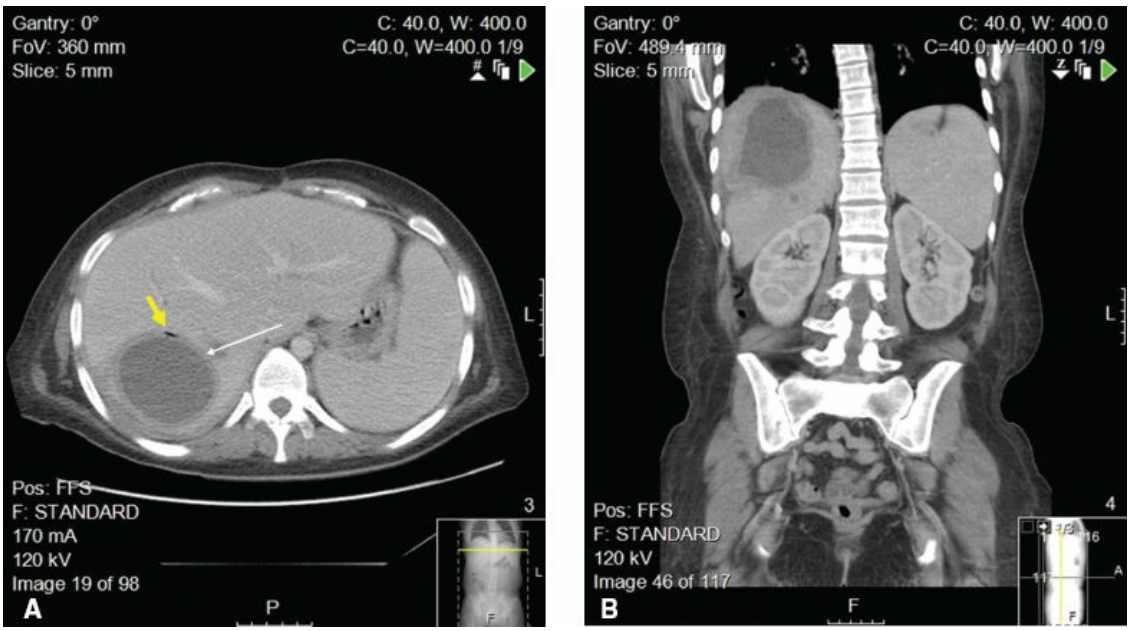

Figure 105.2. Contrast-enhanced CT of a 32-year-old female with a pyogenic liver abscess secondary to simultaneous injury to the right hepatic duct and right hepatic artery. The patient developed recurrence of the abscess three times and required a right hepatectomy for permanent treatment. As illustrated in (**A**), the abscess appears unilocular and hypodense with smooth margins. The abscess has gas (*small yellow arrow*) and contrast enhancement (*large white arrow*). **B.** Coronal view.

The isolated pathogen is influenced by the mechanism of disease and the geographic region. In the largest population-based study performed in the United States, *Streptococcus* species and *Escherichia coli* were the two most common bacteria isolated (29.5% and 18% of the patients, respectively). This finding has been reproduced in several single-institution studies performed in United States, Canada, and other Western countries. Polymicrobial infections are not uncommon, especially in patients with biliary obstruction. The growth of anaerobes such as *Bacteroides fragilis*, *Peptostreptococcus*, and *Fusobacterium nucleatum* occurs in less than 5% to 10% of the patients.

In Southeast Asia, the leading microorganism is *Klebsiella pneumoniae*, but not all *K. pneumoniae* strains are associated with the development of liver abscesses. The presence of capsular serotypes K1 or K2, mucoviscosity-associated gene A (*magA*), regulator of mucoid phenotype A gene (*rmpA*), and aerobactin increases the virulence of this pathogen.

Mutant strains without K1 or K2 antigens, decreased expression of *magA*, or ablation of *rmpA* exhibit increased susceptibility to phagocytosis. Epidemiologic studies have shown that the prevalence of *K. pneumoniae* in healthy Asian adults is 75% with a prevalence of serotype K1 or K2 of 23%. In European studies, this prevalence decreases to 10% to 19%. This difference in prevalence might explain the difference in microbiology among Western and European reports. Interestingly, reports from the United States showed that isolation of *K. pneumoniae* is more common among Asian patients as compared with Caucasian or African-American patients.

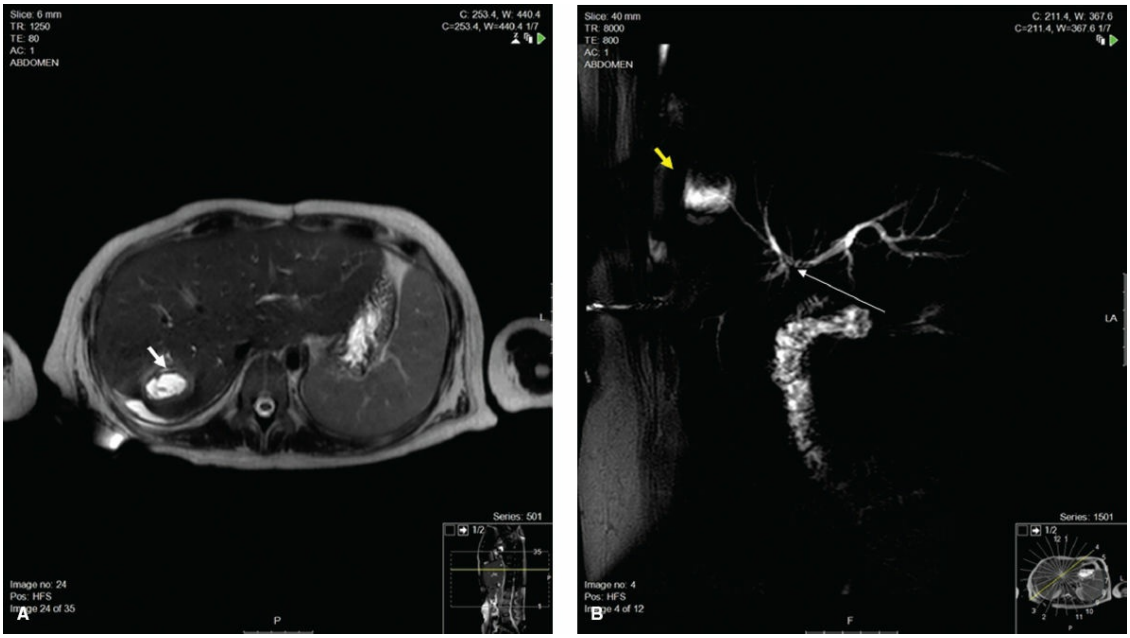

Figure 105.3. Magnetic resonance of liver in a patient with an abscess in the right hepatic lobe. The T2-weighted image (**A**) of a 60-year-old female patient with an abscess in the right hepatic lobe. The abscess appears hyperintense and has contrast reinforcement (*small white arrow*). The MRCP (**B**) demonstrates that the abscess is communicated with the right hepatic duct (*small yellow arrow*) and is secondary to and obstruction at the level of the confluence of the right and left hepatic ducts (*large white arrow*).

Repeated biliary tract manipulation, prolonged intensive care unit stay, recent exposure to broad spectrum antibiotics, and history of liver transplantation increase the risk of colonization and infection by more resistant microorganisms such as extended spectrum beta-lactamase (ESBL)-producing Enterobacteriaceae, vancomycin-resistant *Enterococcus*

faecium (VRE), methicillin-resistant *Staphylococcus aureus* (MRSA), and *Candida* spp.

Treatment

Patients with pyogenic abscesses frequently develop a systemic inflammatory response. Therefore, the initial goals of therapy are similar to any other septic patient and include an aggressive fluid resuscitation, early (within 1 hour) administration of IV antibiotics, and control of the source. Strict glycemic control is very important, especially if *K. pneumoniae* has been isolated.

The initial empirical therapy is influenced by the suspected etiology, recent exposure to antibiotics, history of immunosuppression or chemotherapy administration, repeated biliary tract instrumentation, documented history of colonization by multi-drug resistant bacteria and/or fungi, and the prevalence of drug-resistant organisms in each hospital. Initial broad-spectrum antibiotics against gram-negative rods and gram-positive cocci are recommended. Community-acquired infections can be treated with ampicillin/sulbactam, ticarcillin/clavulanate, piperacillin/tazobactam, a third- or fourth-generation cephalosporin, or a fluoroquinolone with or without metronidazole. Patients with hospital-acquired infections, repeated biliary tract instrumentation, or history of transplantation require ESBL-producing Enterobacteriaceae, VRE, MRSA, and yeast coverage. Early administration of fluconazole or an echinocandin is recommended in patients with suspected *Candida* species infection. Empirical use of micafungin is preferred in patients with severe illness or if *Candida glabrata* is suspected. Carbapenems are the drug of choice for ESBL-producing Enterobacteriaceae. Daptomycin and linezolid are recommended for patients with VRE infection. Deescalation to the most appropriate single-agent therapy should be done as soon as the culture and susceptibility results are obtained. The total duration of antibiotics should be tailored to the clinical and radiographic response.

Source Control/Surgical Treatment

The mainstay of therapy is systemic administration of broad spectrum antibiotics, but source control of the infection should be performed as soon as the initial resuscitation has been completed. In the absence of percutaneous or surgical treatment, the historical mortality rate of liver abscesses was close to 100%. Routine exploratory celiotomy and abscess

drainage decreased the mortality rate, but it was associated with prolonged length of stay and perioperative complications such as bleeding, need for transfusion, surgical site infection, and wound dehiscence. Placement of percutaneous drainage catheters by interventional radiology has slowly replaced surgery because it is less invasive and has a lower incidence of such complications. The success rate of percutaneous drainage depends on the etiology. Factors associated with failure of percutaneous drainage include *Candida* infection, presence of multiloculated abscesses, intra-abscess debris, immunosuppression secondary to chemotherapy or immunosuppressive regimens in transplant patients, and inappropriate placement or early removal of the drain. In the absence of biliary obstruction or neoplasm, the success rate in solitary abscess drainage is 70% to 90%.

Liver abscesses secondary to ascending cholangitis and biliary obstruction require routine percutaneous or endoscopic resolution of the obstruction to avoid treatment failure.

The role of surgical treatment is now limited to patients who fail percutaneous drainage or who require surgery to treat the underlying cause of the disease such as bile duct injury after cholecystectomy, localized neoplasm, need for liver retransplantation, appendicitis, or uncontrolled biliary fistulas.

Operative Approach

With the patient in supine position, an abscess can be approached through a supra-umbilical midline incision or right subcostal incision (Fig. 105.4). In general, the access to isolated liver diseases is achieved better through subcostal incisions. Midline incisions are preferred in patients with additional extrahepatic pathologies. Once the abdomen has been examined, intraoperative ultrasound is recommended to locate the lesion. In experienced hands, it allows visualization of major blood vessels and allows needle aspiration guidance to confirm the presence of purulent fluid. Fluid and tissue specimens should be immediately sent for gram staining, culture, and cytology to rule out malignancy. After the initial aspiration, a small hepatotomy using electrocautery allows irrigation and drainage of the cavity. The next step is placement of a closed suction drain that is exteriorized through a separate incision in the abdominal wall. Closure of the abdomen is performed in the standard fashion.

In selected cases of patients with isolated infected neoplasms or small

abscesses, liver resection can be attempted. However, liver resections in the presence of infection are discouraged due to increased complication rate.

Complications

Rare but potentially serious complications comprise spontaneous rupture to the peritoneal cavity or pleural space. Spontaneous rupture into the pleural space leads to severe pulmonary complications, including empyema (Fig. 105.5), enlarged right pleural effusions, pneumonia, and more rarely bronchobiliary fistula. Right empyema can be the result of percutaneous drainage of livers abscesses through the right diaphragm.

Patients with abscesses secondary to *K. pneumoniae* are more likely to develop metastatic spread of the infection into the lungs, central nervous system, and eyes. Therefore, pneumonia, meningitis, and endophthalmitis are reported more frequently in Asian cohorts.

As Table 105.1 shows, the mortality rate of patients with pyogenic liver abscesses ranges between 2.5% and 32%. Most patients die as a result of uncontrolled sepsis that progresses to severe sepsis, septic shock, and multi-organ failure. The mortality rate is higher in patients with pyogenic liver abscesses arising in the setting of malignancies. Adjuvant therapy is frequently delayed in cancer patients with uncontrolled sepsis. Therefore, patients with liver abscesses arising in the setting of neoplasms die as a result of septic complications and/or malignancy progression. Additional factors associated with poor outcomes include multiloculated abscesses, unresolved bile duct obstruction, multiple abscesses, impaired renal function, and yeast infection. Progression to sepsis and septic shock are independent risk factors for mortality. Although DM is very common in these patients, its presence is not associated with worse outcomes.

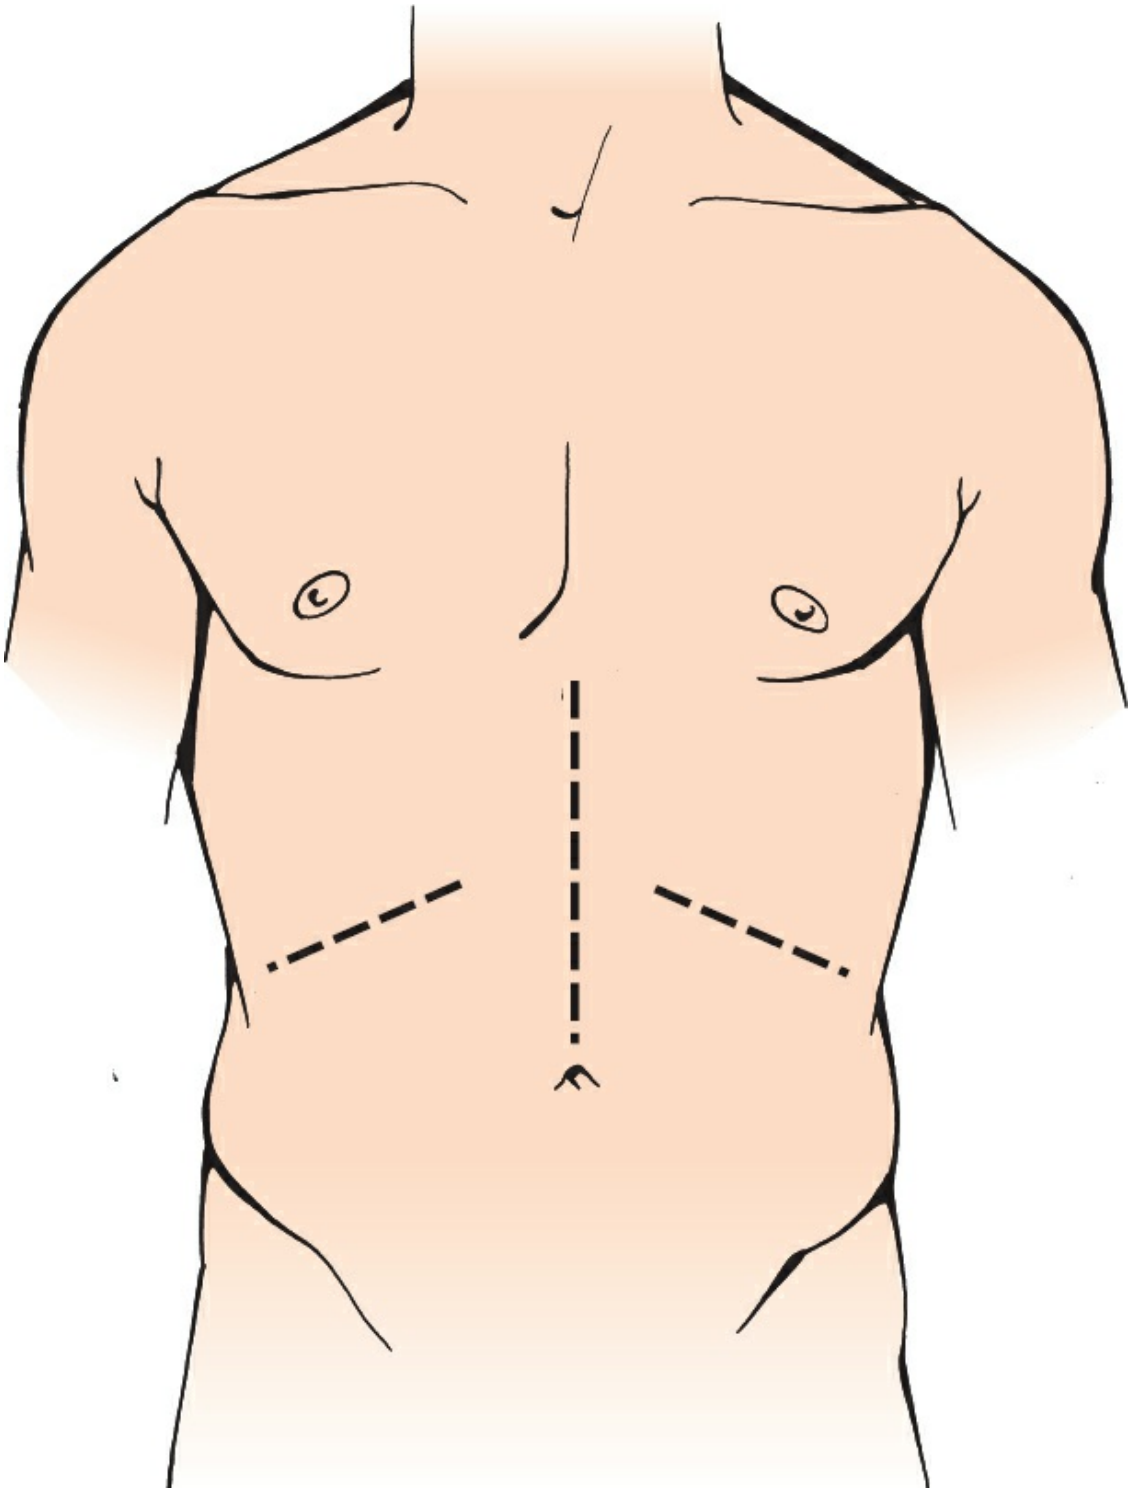

Figure 105.4. The sites for subcostal and midline incisions are shown here. For simple drainage, subcostal sites are preferable, but a midline approach is usually necessary when additional procedures need to be done.

AMEBIC LIVER ABSCESS

Epidemiology

Amebic liver abscesses are rare in the United States, but very prevalent in Mexico, Central and South America, India, Southeast Asia, and Africa. The intestinal infection by this protozoan equally affects both genders, but amebic liver abscesses are more common in males (male/female ratio 10 to 1). In contrast to bacterial abscesses, this disease affects young patients between ages 18 and 50. Factors associated with increased risk of infection include traveling to an endemic country, cell mediated immunosuppression secondary to HIV or steroid use, malignancy, male-homosexuality, and malnutrition.

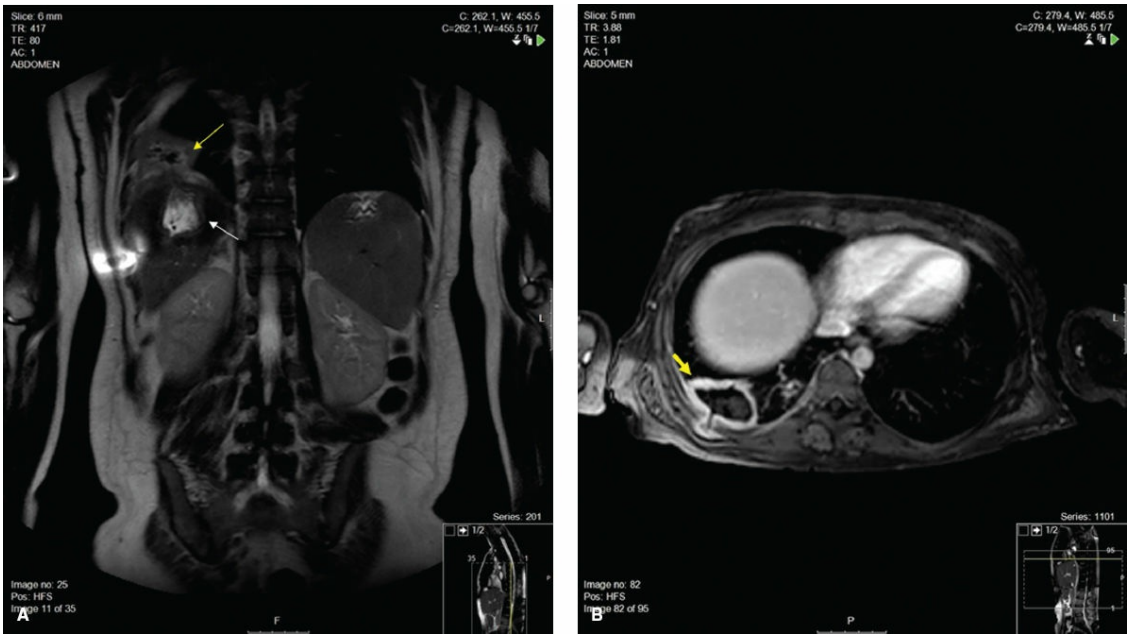

Figure 105.5. MRI demonstrating spontaneous rupture of an abscess in the right hepatic lobe (*thin white arrow*) into the right pleural space (*thin yellow arrow*) (**A**). As demonstrated in (**B**), the empyema appears hypointense with contrast-enhancement in the periphery of the abscess (*small yellow arrow*) in T1-weighted images.

TABLE 105-1 Collected Series of Pyogenic Liver Abscess

Author (ref)	Year	Country	No. of Patients	Age (Years)	Microorganism	Diabetes Mellitus (%)	Malignancy (%)	Mortality Rate (%)
Alvarez	2001	Spain	133	59.9	*Escherichia coli*	13.0	22.0	13.9

[a]Mean age was 63 years in diabetic patients versus 58 in non-diabetic patients.
[b]Patient discharges.
[c]Mean age not specified but 42.9% of the discharges between 65 and 85, 30.1% between 50 and 64 years, 18.5% between 35 and 49 years, and 8.5% between 18 and 34 years.
[d]52% of the patients were older than 60 years.
[e]Mean age in patients with *Escherichia coli* abscess was 68, mean age in *Klebsiella pneumoniae* was 62 years.

Pathogenesis

The route of transmission is fecal-oral. In areas with poor sanitation and hygiene, the infective cysts are ingested with contaminated food. Cysts are very resistant to gastric secretions. Excystation occurs in the small bowel where eight trophozoites are released from each cyst. Trophozoites infest the colon. In most patients, the trophozoites aggregate in the intestinal mucin layer and form new cysts and pass through the feces. Trophozoites are not very resistant and die soon outside of the body. However, amebic cysts are very resistant and survive several weeks. In some patients, the trophozoites invade the colonic mucosa and travel through the bloodstream to the liver, brain, and lungs with resultant extraintestinal infection (Fig. 105.6). Amebic abscesses are composed of a core of dead hepatocytes and cellular debris with a surrounding rim of connective tissue, trophozoites, and inflammatory cells.

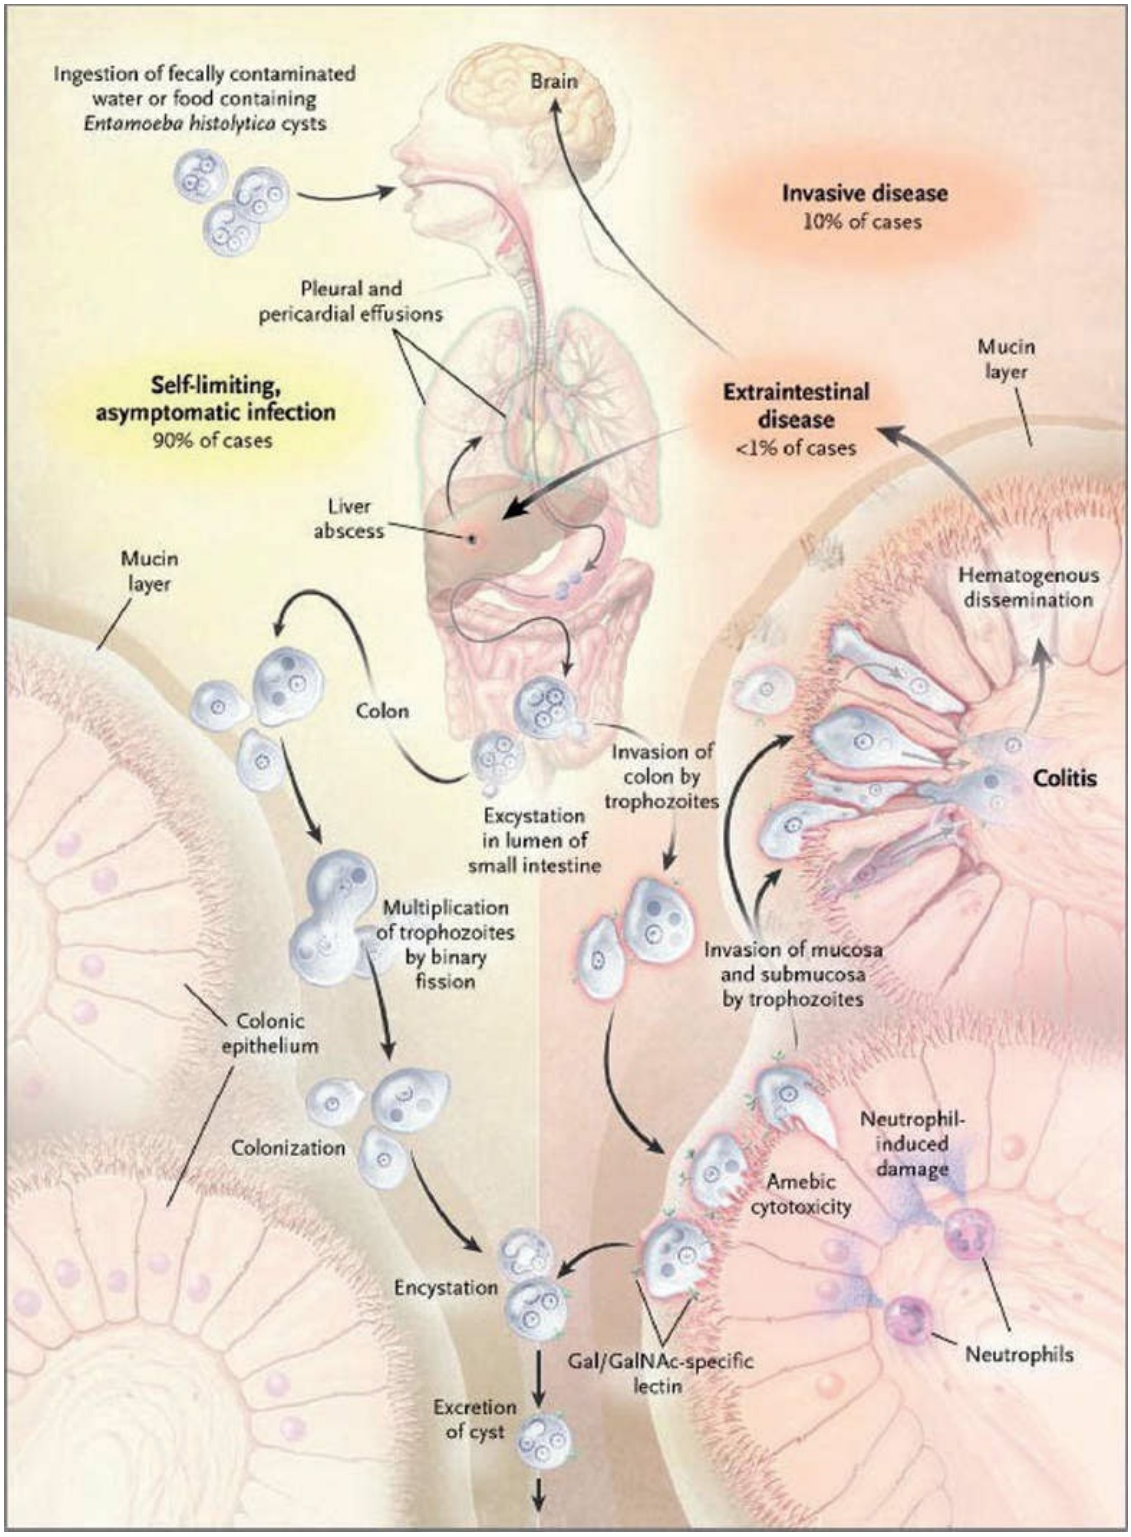

Figure 105.6. Amebic cycle. (From Haque R, Huston CD, Hughes M, Houpt E, Petri WAJ. Amebiasis. *NEJM.* 2003;348(16):1565–73.)

Clinical Manifestations

The most common manifestation of *Entamoeba histolytica* infection is

intestinal amebiasis. Amebic liver abscesses occur in less than 1% of all patients, but it is the most common extraintestinal manifestation of the disease. Most patients present after several days of RUQ pain and fever. The median duration of symptoms is 2 weeks. Abscesses in close proximity to the diaphragm are associated with scapular and/or right shoulder pain. Diarrhea or dysentery is present in less than 40% of the patients. The most common physical findings are RUQ tenderness and hepatomegaly. Jaundice is infrequent.

Diagnosis

Patients with amebic liver abscesses typically have leukocytosis, anemia, hypoalbuminemia, elevated alkaline phosphatase, and hyperbilirubinemia. None of these findings are specific. Once the diagnosis is suspected, the initial approach usually includes a liver ultrasound. Similar to pyogenic abscesses, imaging findings also depend on the pathologic state. During the early phase of infection, abscesses are hyperechoic ill-defined lesions. As necrosis ensues, they appear well defined and hypoechoic. In CT scans, abscesses appear as well-defined avascular hypodense lesions with a hyperdense halo after contrast administration. MRI findings are very similar to pyogenic liver abscesses; mature abscesses appear hypointense on T1-weighted images and hyperintense on T2-weighted images. The most frequent location is the right lobe; less than 15% of the patients have multiple abscesses.

The diagnosis is established by detecting serum antibodies against *E. histolytica.* Several techniques are available, but enzyme-linked immunosorbent assay (ELISA) is the most frequently employed. Its sensitivity is almost 100% after 7 days of infection. In addition, trophozoites can be isolated from percutaneous aspirates. Such aspirates can be tested for amebic antigens. Parasite isolation in stools has been reported in only 24% of the patients.

Treatment

Tissue-amebicide drugs are very effective to eliminate extraintestinal infections, but they fail to eliminate intracolonic cysts in 40% to 60% of the patients. Therefore, the treatment comprises two phases: an initial 7- to 10-day course of treatment with a tissue amebicide (such as metronidazole), followed by 7 days of therapy with an intraluminal amebicide drug such as iodoquinolol or paromomycin to eliminate the

carrier state.

There is no advantage of routine percutaneous drainage of uncomplicated amebic abscesses. Up to 90% of the patients with uncomplicated amebic liver abscesses improve after 72 to 96 hours of treatment. Indications for percutaneous drainage include lack of improvement after 48 to 72 hours of therapy, abscesses located in the left lobe or larger than 10 cm, and impending rupture.

Complications

Similar to pyogenic liver abscesses, complications of this disease include spontaneous rupture of the abscess into the pleura, peritoneum, or pericardium. Large abscesses may produce bile duct compression, inferior vena cava obstruction, or hepatic outflow obstruction. The disease can disseminate to the brain and lungs. The mortality rate in developed countries is less than 1%.

SUBPHRENIC AND SUBHEPATIC ABSCESSES

In most patients, subphrenic and subhepatic abscesses are secondary to other intra-abdominal processes or infections. Examples include cystic stump leaks after cholecystectomies, bile leak after liver resections, perforated peptic ulcer disease, diverticulitis, and appendicitis. In addition, subphrenic and subhepatic fluid collections can be secondary to infected hematomas after trauma, major hepatectomies, or liver transplants. Abscesses are frequently polymicrobial. There is predominance of gram-negative rods, anaerobes, and streptococcus in most patients. Prolonged length of stay, repeated biliary instrumentation, history of liver transplantation, and previous intra-abdominal surgeries are associated with colonization by VRE, MRSA, *Candida* spp., and ESBL-producing Enterobacteriaceae.

In patients with persistent abdominal pain, fever, or leukocytosis, CT scan of the abdomen appears as well-defined hypodense lesions ± gas. Rim enhancement is very common after IV contrast administration (Fig. 105.7).

Treatment

The goals of treatment are the same for pyogenic liver abscess and include early administration of broad spectrum antibiotics, an aggressive fluid resuscitation, and source control. In patients without an intra-abdominal

pathology that requires primary repair, a percutaneous approach is preferred. This is less invasive, allows faster recovery, and decreases risk of contamination to other intraperitoneal areas. If the primary cause of the disease is controlled, the success rate of percutaneous approach is 85% to 90%. The success decreases if the primary pathology has not been treated. In select cases, percutaneous drainage may be used as a bridge to surgery. Once the patient is stabilized, a more permanent surgical treatment should be performed.

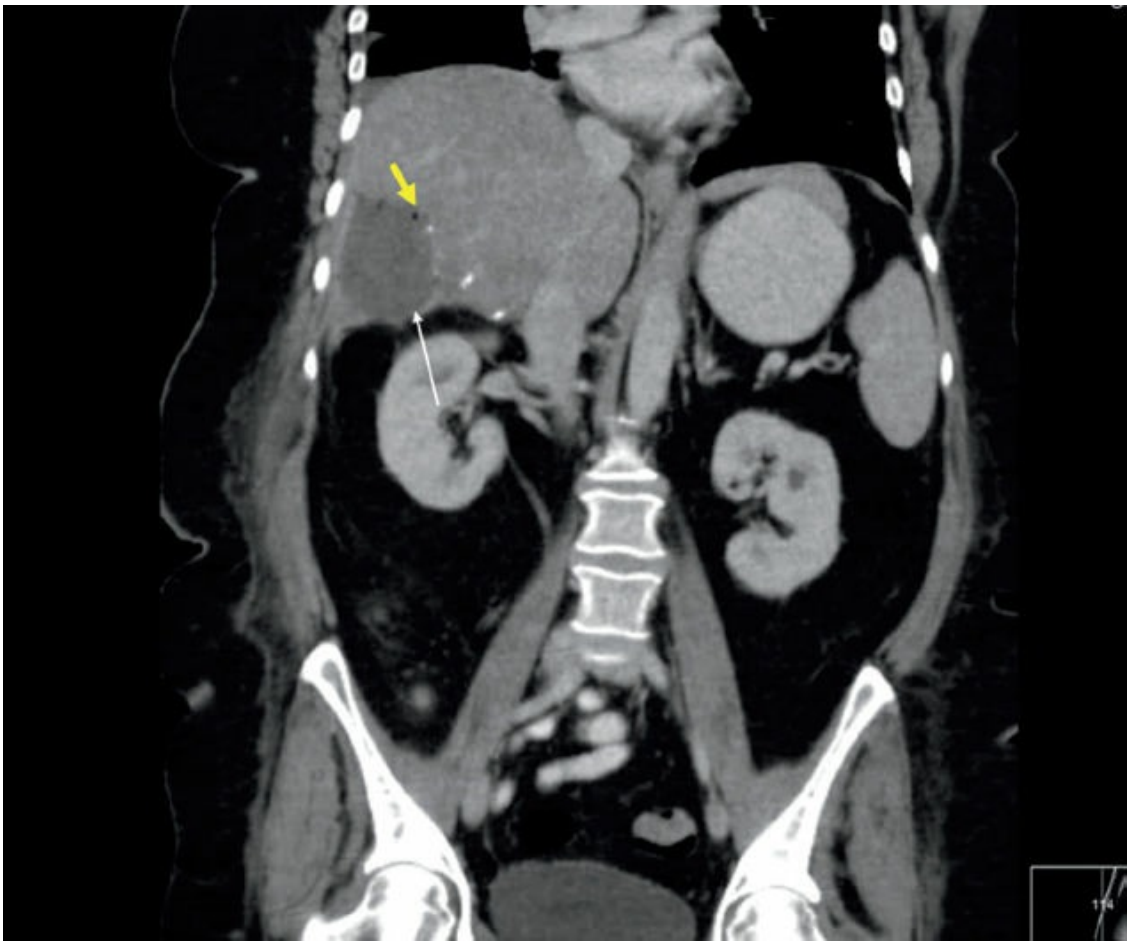

Figure 105.7. Contrast-enhanced CT of a 56-year-old female with a subhepatic abscess after a right hepatectomy. The patient presented with fever and malaise. The CT scan demonstrates a hypodense lesion with gas (*yellow arrow*). There is a rim of enhancement in the periphery of the lesion. Both findings suggest an infected subhepatic fluid collection.

In patients with abscesses secondary to intra-abdominal pathologies such as perforated ulcer disease, complicated gallbladder disease, and appendicitis, an operative approach is recommended to decrease the risk of

uncontrolled sepsis. The most common operative approach is through a midline incision to allow access to any intra-abdominal organ.

EDITOR'S COMMENT

Although pyogenic liver abscess was first described by Hippocrates around 400 BC, the seminal review was published by Ochsner and colleagues in 1938. Forty-seven cases were described, largely occurring in patients with appendicitis. The study reported significant reductions in mortality seen with surgical treatment (Ochsner A, DeBakey M, Murray S. Pyogenic Abscess of the Liver. *Am J Surg* 1938;40:292). The current concepts of liver abscess are well described by the authors. The surgeon should know of the changing incidence

and causes relative to what part of the world they live and work and the important role of percutaneous drainage and antibiotic therapy as well as the differential diagnosis and treatment of amebic liver abscess, and the varieties of more rare infectious etiologies.

The two most common varieties are pyogenic and amebic liver abscess. The annual incidence is commonly estimated at 2.3 cases per 100,000. The incidence varies throughout the world. For example, in Taiwan the incidence is as high as 17.6 per 100,000. However, a recent population-based study in the United States by Meddings (Meddings L, Myers RP, Hubbard J, et al. A population based study of pyogenic liver abscesses in the United States: incidence, mortality, and temporal trends. *Am J Gastroentero* 2010;105:117–24) studied pyogenic liver abscess incidence and mortality in the United States in >17,000 patients in the Healthcare Cost and Utilization Project Nationwide Inpatient Sample from 1994 through 2005. During the study period, they reported that incidence increased significantly from 2.7 to 4.1 per 100,000 (overall incidence, 3.6 per 100,000). In addition, they found that in-hospital mortality remained the same (5.6%) and was associated with older age, comorbidities (including cancer, renal failure, and cirrhosis). They reported that those who underwent percutaneous liver aspirations or had positive culture aspirates had diminished mortality risk. Neither endoscopic retrograde cholangiopancreatography nor surgical drainage altered mortality. However, they found increased mortality in those with sepsis and bacteremia.

The epidemiology varies between countries. In the United States, pyogenic liver abscess is usually encountered as a complication of biliary tract disease and cancer, and less commonly intra-abdominal infection such as appendicitis or diverticulitis with seeding through the portal vein. Of the latter type, there is a predominance of right-sided abscesses as the predominant floe of the portal system is to the right lobe of the liver. More common today are cases attributable to chemoembolization. Interestingly, 15% of cases are associated with an intra-abdominal malignancy. A study by Ghosh et al. (Ghosh S, Sharma S, Gadpayle AK, et al. Clinical, laboratory, and management profile in patients of liver abscess from northern India. *J Trop Med* 2014;2014:142382) reported on 200 consecutive cases at Post Graduate Institute of Medical Education and Research (PGIMER) Hospital, New Delhi. The mean age of patients was 41.13 years. Majority of them were from lower socioeconomic class (67.5%) and alcoholic (72%). The abscesses were predominantly in right lobe (71%) and solitary (65%). Etiology of abscess was amoebic (69%), pyogenic (18%), tubercular (7.5%), mixed (4%), and fungal (1.5%). Percutaneous needle aspiration was done in 79%, pigtail drainage in 17%, and surgical intervention for rupture in 4% patients. Mortality was 2.5%, all reported in surgical group. Solitary abscesses were amoebic and tubercular, whereas multiple abscesses were pyogenic. The right lobe was predominantly involved in amoebic and pyogenic abscesses, while in tubercular abscesses left lobe involvement was predominant. The report by Malik et al. (Malik AA, Bari SU, Rouf KA, et al.

Pyogenic liver abscess: Changing patterns in approach. *World J Gastrointest Surg* 2010;2:395–401) confirmed the decreasing incidence of portal pyemia and the rising incidence of abscesses related to biliary disease generally reported elsewhere (31% to 45%). In this series, biliary ascariasis accounted for 17% of cases because of the high incidence of ascaris lumbricoides infestation in the region.

As pointed by the authors, the management of pyogenic liver abscess has evolved over the past three decades due to advances in diagnostic and interventional radiology. Percutaneous drainage, targeted antimicrobial therapy, and source control are the keys to successful treatment. Percutaneous drainage in indicated for abscesses size >5 cm, ongoing pyrexia despite 48 to 72 hours of appropriate medical therapy, and clinical or imaging features concerning for impending perforation. Percutaneous drainage with placement of a drainage catheter is highly successful; however, it will fail in 8% to 36% of patients (Alvarez Perez JA, Gonzalez JJ, Baldonedo RF, et al. Clinical course, treatment, and multivariate analysis of risk factors for pyogenic liver abscess. *Am J Surg* 2001;181:177–86; Chen SC, Tsai SJ, Lee YT, et al. Predictors of mortality in patients with pyogenic liver abscess. *Neth J Med* 2008;66:196–203). Some general indications for surgical drainage include abscess rupture, inadequate source control, incomplete drainage, failure of clinical response, infection with *Candida,* and mutiloculated abscesses. There is some debate about the duration of antibiotic therapy. Current recommendations include parenteral therapy for 2 to 3 weeks or until there is a favorable clinical response, followed by an oral regimen for 2 to 6 weeks or until such time as clinical, laboratory, and radiographic studies demonstrate abscess resolution.

If surgery is required, the use of intraoperative ultrasound may help to identify the abscess, which can be difficult to identify by palpation alone. It is important to break up the loculations in the abscess and debride any necrotic liver parenchyma. There are an increasing number of reports concerning laparoscopy as an adjunct to drain liver abscesses. Ultrasound was found to be helpful. Port placement is similar to laparoscopic cholecystectomy. The overall success rate ranges from 85% to 100% (mean 90.5%). In the laparoscopic approach, the harmonic scalpel has been reported as useful to facilitate hemostasis during unroofing.

The management of amebic liver abscess is not controversial. Medical therapy without percutaneous or surgical drainage is highly effective. Intraluminal cyst control optimizes the outcome.

Sub-hepatic abscess can usually be drained by percutaneous techniques. Approaching a deep abscess that cannot be drained percutaneously through the bed of the 12th rib may be helpful. The patient is placed in the left lateral decubitus position. An incision is made over the 12th rib. The rib is removed and the surgeon’s finger placed into the abscess avowing the pleural space. This approach avoids contamination of the peritoneal cavity and effective drainage.

E. Christopher Ellison

106 Echinococcal Cyst—Open and Laparoscopic Approach

Miroslav N. Milicevic

THE LIVER ECHINOCOCCAL CYST

Definition, Short History, Epidemiology, Significance, and the Surgical Problem

Echinococcosis (echinococcal cyst [EC], hydatidosis, hydatid disease) is a cyclozoonosis caused by the larval (metacestode) stages of cestodes (flat worms) belonging to the genus *Echinococcus* and the family Taeniidae. The biologic characteristics of the parasite enable its survival in nature. The disease exists in two forms: the larval stage (metacestode) and the adult stage (tenia). The parasites are perpetuated in life cycles with carnivores (dogs and wild canine) as definitive hosts. Humans are the accidental intermediate host (dead end), and animals (herbivores and omnivores) are both intermediate and definitive hosts.

The disease has been known since earliest times. It was known to Hippocrates, who speaks of "livers full of water." The word *echinococcus* is of Greek origin and means "hedgehog berry." Hydatid is also of Greek origin (*hudatid, hudatis*) and means a "watery vesicle." The word *hydatid* also originates from the modern Latin word *hydatis* meaning a "drop of water." Therefore, hydatid and cyst have the same meaning and the expression "hydatid cyst" (HC) is a pleonasm. The use of the term *hydatid cyst* in contemporary medicine is widespread and acceptable. The first North American case was observed in 1808 and published in 1822. The true nature of the disease was not known until the second half of the 19th century.

Echinococcosis is widespread and occurs in all continents, including circumpolar, temperate, subtropical, and tropical zones. It is not confined to sheep-raising communities. The varying prevalence and distribution are influenced by agricultural, educational, economical, medical, and cultural factors. In endemic areas, the annual incidence of cystic echinococcosis ranges from <1 to 200 per 100,000 inhabitants. Human cystic

echinococcosis remains highly endemic in pastoral communities, particularly in regions of South America (Argentina, Uruguay, Chile), the Mediterranean littoral (Spain, France, Italy), Eastern Europe, the Near and Middle East (Turkey), East Africa (Maghreb countries), Central Asia, China, and Russia. Increasing migration, growing incidence of world trade and travel, high mobility of troops, and an increasing number of refugees make hydatidosis a global problem. In endemic areas, hydatidosis remains a major health and socioeconomic problem. The estimated minimum global human burden of cystic echinococcosis averages 285,000 disability-adjusted life years (DALYs) or an annual loss of U.S. $194,000,000. The mortality rate from cystic echinococcosis is about 2% to 4%, but it may increase considerably if medical treatment and care are inadequate. Only infection with the metacestode is of clinical relevance.

Although echinococcosis is uncommon in the resident population of industrially developed countries, it is prevalent enough to be seen by most general surgeons in its simple or its complicated form. Because it is a surprise finding, even in tertiary centers, it is overtreated more often than not.

The treatment of hydatid disease has been the responsibility of surgeons for many years, and research into its treatment also seems to be the responsibility of surgeons. There is no other parasitic disease for which the primary treatment is surgical. Because there is no effective treatment of hydatid disease today, either surgical or medical, the best surgical technique is not known. Surgeons will be happy when a proper medical treatment is found and they are needed only for the complications.

A surgeon managing a patient with a HC should understand both the parasitology and pathology of the parasite and be fully aware of treatment limitations and possible complications. The dilemma of whether to perform tissue-sparing, conservative, or radical resectional surgery for hydatid disease is an artificial issue. The operative procedure should be tailored to every individual patient, taking into consideration many factors including the local expertise and facilities, prevalence of the disease, socioeconomic factors, and the age and condition of the patient.

This chapter presents the basics of this disease, and it is intended to help the surgeon manage patients with HCs.

Current Concepts in the Diagnosis and Management of EC

The previous recommendations of the World Health Organization Informal

Working Group on Echinococcosis (WHO-IWGE) for the treatment of human echinococcosis were published in 2001. These recommendations have significantly influenced the way cystic echinococcosis was managed in all continents. Ten years later, after several expert meetings of the WHO-IWGE, a consensus was reached in 2009 about the management of cystic echinococcosis. The consensus has been reached on an image-based, stage-specific approach, which helps in choosing one of the following treatment options: (a) surgery, (b) percutaneous treatment (PT), (c) chemotherapy, and (d) watchful waiting. An image-based classification system differentiating the cyst stage has been reinforced to help in clinical decision making. Unfortunately, the panel of experts also concluded that the majority of published papers about the management of cystic echinococcosis were not consistent and well structured, so the quality of evidence and strength of recommendation are low. Since cystic echinococcosis is mostly treated in developing countries with limited resources, choosing the best treatment option must take into consideration the socioeconomic conditions, the available facilities, and the expertise of the attending surgeon. Nevertheless, surgery remains the most effective treatment. It is frequently technically demanding and risky and postoperative complications can be life-threatening.

This chapter is based on these new concepts.

THE LIVER HYDATID CYST

Parasitology

The genetic and phenotypic variations of *E. granulosus* have been extensively studied. The dog is the most common definitive host and the majority of cases in humans are caused by the sheep strain. The adult tenia lives adhered to the small intestine of the dog (definitive host). It measures from 3 to 6 mm in length, and has three or four proglottids, of which the last one is larger and gravid. The gravid proglottid containing between 200 and 800 ova is shed approximately every 15 days and the ova are expelled in the feces. When the microscopic eggs are ingested by an intermediate host, the life cycle is perpetuated. The intermediate hosts are Bovidae.

There are three known forms of echinococcosis in humans: (a) cystic echinococcosis (hydatid disease) caused by *E. granulosus,* (b) alveolar echinococcosis (alveolar hydatid disease) caused by *E. multilocularis,* and (c) polycystic echinococcosis caused by *E. vogeli* or *E. oligarthus*. Although *E. granulosus* and *E. multilocularis* occur simultaneously in

large endemic areas, mixed infections of cystic echinococcosis are extremely rare. This chapter deals with cystic echinococcosis (hydatid disease) caused by *E. granulosus* only.

Humans are an accidental, intermediate host and become infected when they accidentally ingest eggs of the tapeworm. This can happen directly, by contact with dogs, or indirectly by food, water, and contaminated objects. Direct contact during childhood is an important route. The eggs hatch in the duodenum, and the released oncosphere penetrates the mucosa and reaches a blood vessel. The bloodstream can carry the oncosphere to any part of the body, but it most frequently settles in the liver and lungs. Once settled, the parasite develops its larval stage, the HC, the clinical presentation of *E. granulosus.* The cyst is a chronic, well-localized, and adapted space-occupying affliction that is not affected by the functional status of the host. The protoscolex can multiply asexually *ad infinitum* in the intermediate host as long as the host is alive. Because the parasite is always confined within the HC, a vital HC has the tendency to slowly enlarge and interact with the host. Following a symptom-free period of varying length, depending on the site and number of cysts, life-threatening complications arise. The disease, benign in nature, can cause devastating damage to the liver and death to the patient.

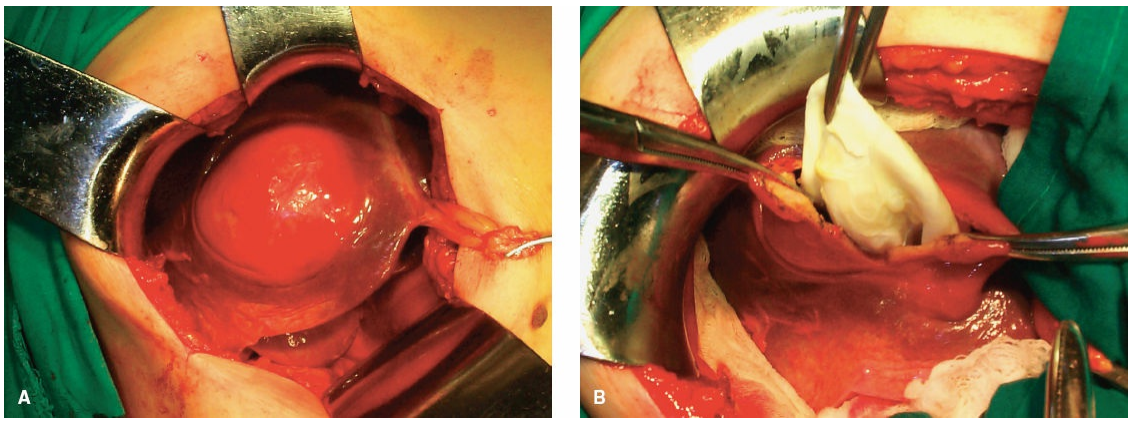

Figure 106.1. A. The protruding part of a liver hydatid cyst on the surface of the liver. **B.** The pericyst is incised and the cut edges are retracted by hemostats. The cyst is univesicular. The white structure in the tissue-grabbing forceps is the parasite (the laminated membrane).

This cycle with two hosts, one definitive and the other intermediate, is the sexual cycle and the resulting disease in humans or animals is “primary echinococcosis.” There is an asexual, “minor” cycle in which the new HCs

develop from any vital element of the larval stage (e.g., protoscoleces, daughter cysts) of the parasite in the same intermediate host. This can occur subsequent to invasive and operative procedures, or following spontaneous or trauma-induced cyst rupture. This disease in humans is "secondary echinococcosis."

Pathology

The cellular response of host tissue to the presence of the larva is an attempt to encase the parasite in fibrous tissue. The parasite reacts by forming around itself a spherical enclosure of inert protective chitinous material. If the parasite survives host defense mechanisms, in approximately 5 to 7 days after infestation, the larva (metacestode) develops into a 6- to 7-mm vesicula. This is the endocyst and it is made up of two distinct layers: (a) the inner germinative layer (live parasite, germinal membrane, proligerous layer) and (b) a protective outer laminated acellular layer (cuticle or laminated layer). The laminated membrane never grows thicker than 2 to 5 mm, regardless of cyst size. After 21 days, the cyst is visible to the naked eye. In 3 months, it can measure 3 to 5 cm in diameter. Compression and interaction of the endocyst with the adjacent host's tissue produce a fibrous layer called the ectocyst or pericyst. By 5 months, the pericyst is formed and a typical mature HC is present.

The pericyst is an integral part of both the liver and the parasite, and it is difficult to remove it from the liver. The parasite (endocyst) is separated from the pericyst (ectocyst) by a small capillary space, and it can easily be detached from it (Figs. 106.1 and 106.2). The pericyst is largely avascular, but there are spaces within it that enclose blood vessels and small bile ducts. The structure of the pericyst seems to be more complex than previously described. According to Chinese authors, it is the result of two different formative processes and it consists of two different layers. The inner layer of the pericyst (the frank "exocyst") is the result of an inflammatory and an unusual granulomatous reaction aimed at walling of the parasite and resorbing the released antigen. The granulomatous layer increases in size with growth of the parasite; it frequently contains osteopontin (regulates macrophage accumulation and calcium deposition) and resembles the granulomatous reaction to other infective agents (e.g., TBC). The outer layer of the pericyst is called the "adventitial" layer, and it is composed of compressed Glissonian biliovascular elements and

tributaries of the hepatic veins. Separating the “ectocyst” from the “adventitial” layer is the basis of “subadventitial cystectomy” pioneered by Chinese authors. There is no cleavage plane between the liver parenchyma and the “adventitia,” and it cannot be readily separated. The pericyst can be 1 to 1.3 cm thick, and it is not present in pulmonary and brain ECs. Vessels and ducts in the “adventitia” remain patent for a long time even in large cysts (hypervascular rim on computerized tomography [CT] scan). Calcification impedes the passage of nutrients and oxygen into the cyst.

A liver HC is typically unilocular. A developing cyst usually survives, with a steady increase in size of about 1 to 1.5 mm in diameter per month, depending on the site and adjacent structures. The hydatid fluid in a vital cyst is under pressure (30 to 70 cm H_2O), and the volume of a human HC can be many liters.

The germinal membrane is of microscopic dimensions and is responsible for the production of the crystal-clear hydatid fluid, the ectocyst, brood capsules, scoleces, and the daughter cysts. The host and parasite in a HC are never physically connected. This means that a HC always separates from, or can be readily lifted out from within, a surgically exposed pericystic cavity (Fig. 106.3). When managing HCs, it must be assumed that any amount of hydatid fluid, no matter how clear, contains potentially infective protoscoleces.

Daughter cyst formation is considered a defense reaction, and it is known as the process of endogenic vesiculation. Daughter cysts are true replicas of the mother cyst but without a pericyst. Daughter cysts produce multivesicular cysts that are more frequent in adults. The presence of daughter cysts is a problem for chemotherapy, protoscolicide activity, and the standard PAIR procedure (puncture–aspiration–injection–reaspiration). Ectogenic vesiculation of *E. granulosus* is infrequent. It occurs when there is a small rupture or defect in the laminated membrane and the germinal layer passes through and creates a “satellite” HC.

Hydatid fluid is antigenic. This antigenicity is rarely of great clinical significance, and the real incidence of allergic reactions in hydatidosis is not known. The incidence appears to be lower than previously described in literature. Allergic reactions range from skin rash to a frank anaphylactic reaction, usually following sudden rupture of the cyst. The antigenicity of hydatid fluid is the basis of serodiagnostics.

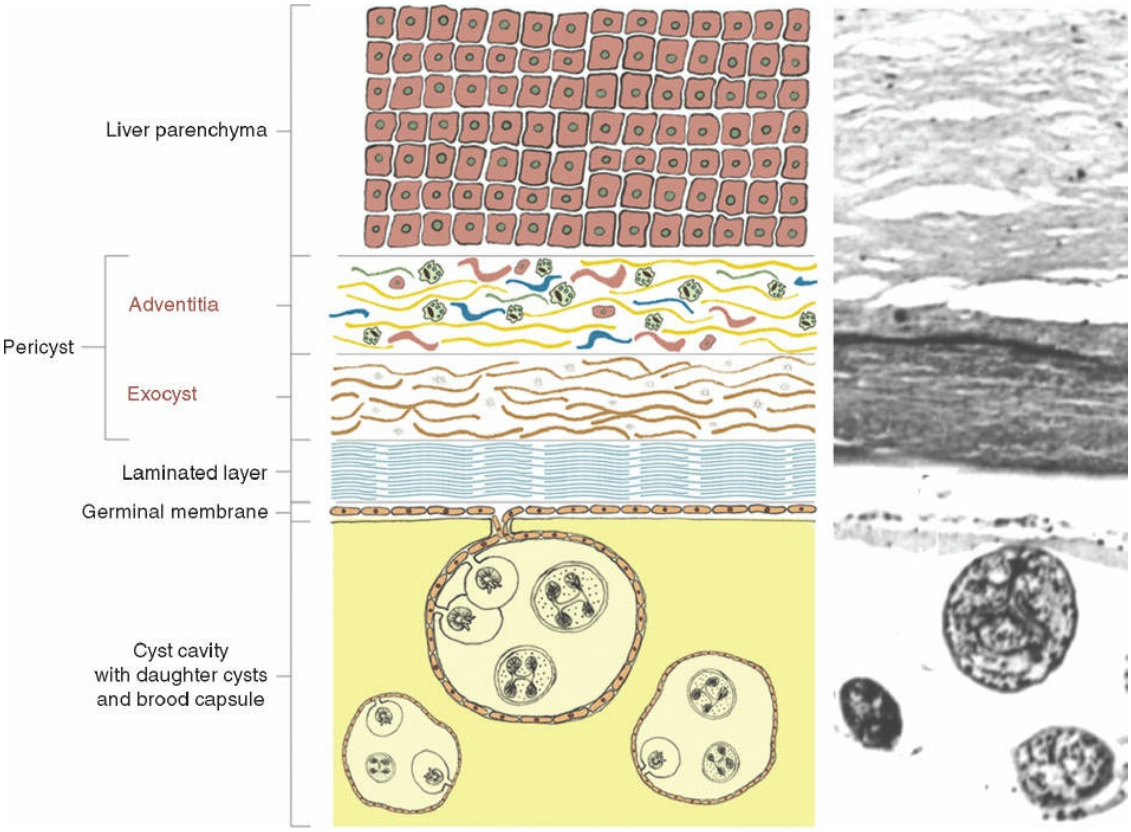

Figure 106.2. Histology of liver hydatid cyst. The "adventitia" layer of the pericyst contains the blood vessels. White circular structures in the exocyst are osteopontin + calcium. Green large cells in the adventitia are macrophages secreting osteopontin and probably regulating calcium deposition. The laminated membrane (visible to the naked eye) protects the vital germinal membrane (not visible to the naked eye) responsible for the production of brood capsules, daughter cysts, and cyst fluid.

HCs in humans are generally long-standing and large, although not all grow to enormous proportions. Host defense mechanisms, injury, and the functional status of the pericyst are factors that determine cyst vitality, growth, and development. When a HC dies, its wall can become calcified. Cyst vitality should not be estimated according to the calcification pattern. Dead cysts are generally no longer a threat to their host, but the issue of how to manage patients should take into consideration many factors.

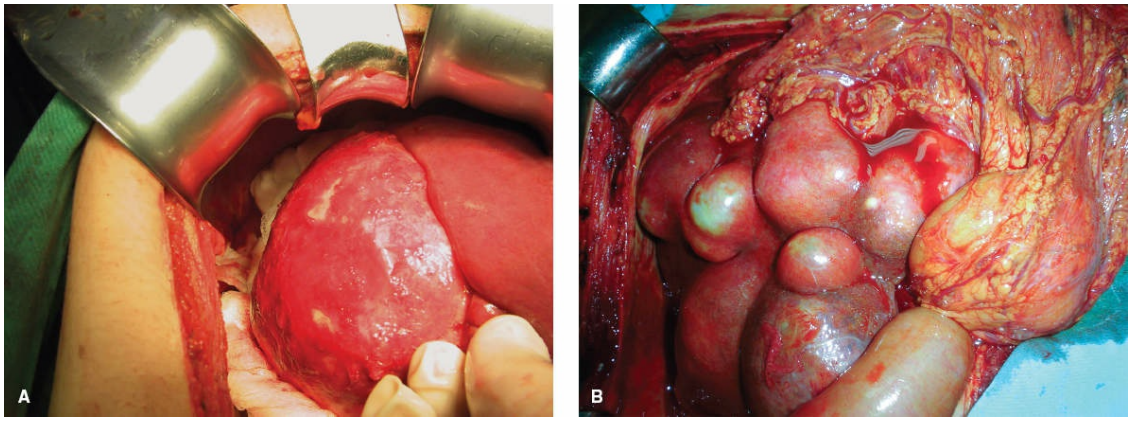

Figure 106.3. A. A large hydatid cyst is shown displacing most of the right lobe of the liver. **B.** Multiple hydatid cysts of the liver and omentum.

CLINICAL PRESENTATION

The Uncomplicated Liver Hydatid Cyst

The clinical features of liver hydatid disease depend on the site, size, number, vitality, and stage of development of the cyst. Simple, uncomplicated liver HCs are usually asymptomatic or present with nonspecific symptoms. Complicated liver HCs cause specific symptoms. If a patient has multiple HCs in the liver, the cysts are different in size, and any one of them can be the cause of symptoms. Most frequently, it is the complicated cyst that causes the symptoms and signs of the disease.

I base my experience of this topic on 1,333 consecutive patients operated for liver hydatidosis at the First Surgical Clinic, University of Belgrade School of Medicine, during January 1963 to December 2014. Dominant symptoms and signs of the patients are presented in Tables 106.1 and 106.2. Only one in three symptomatic patients had moderate to severe pain. The majority of the patients (79.60%) had uncomplicated cysts.

Symptomless, unsuspected HCs can be detected during routine examination or at autopsy. Clinical latency, judging by the size of the HCs at operation, is an outstanding feature of the disease. Adults contracting the disease can rapidly develop severe clinical manifestations. Children in endemic areas with large cysts can progress to “hydatid cachexia” (Tables 106.1 and 106.2).

The Complicated Liver Hydatid Cyst

Suppuration and Secondary Bacterial Infection

Cyst leakage is a prerequisite for bacterial contamination, and the most frequent cause of infection is a cystobiliary communication (CBC). The clinical presentation is as a liver pyogenic abscess. An infected HC undergoes structural changes. The parasite dies.

TABLE 106.1 Dominant Symptoms of Liver Hydatidosis

	Patients	
Symptom	Number	Percent
Right upper quadrant discomfort/pain	1,033	77.49
Dyspepsia	506	37.90
Vomiting	294	22.05
Nonspecific fatigue	246	18.45
Asymptomatic	238	17.85
Weight loss	151	11.32
History of jaundice	94	7.05
History of fever	87	6.52
Allergy	11	0.82

TABLE 106.2 Dominant Signs of Liver Hydatidosis

Sign	Patients	
	Number	Percent
Palpable right upper quadrant mass	541	40.58
Fever	97	7.27
Jaundice	59	4.42
Malnutrition	33	2.47
Pleural effusion	36	2.57
Cholangitis	15	1.12
Splenomegaly	14	1.05
Skin rash	11	0.82
Dyspnea, asthma	33	2.47
Ascites	11	0.82
Edema of extremities	6	0.45
Pancreatitis	1	0.07

Occasionally, the entire cyst content undergoes aseptic necrosis, the parasite dies, and the cyst is filled with amorphous, yellow debris that must be distinguished from the pus of secondary infection (e.g., positive Gram stain). Essentially, this is the gross appearance of a multivesicular cyst and not a suppurated cyst. The real incidence of bacterial infection is unknown because different diagnostic criteria are applied. The incidence in the literature ranges from 11.0% to 27.1%. It is 14.42% (149 patients) in my series.

Pressure Effects, Rupture, and Bile Duct Communications

A viable liver HC has the tendency to grow in the direction of least resistance. This accounts for its frequently irregular shape. In confined areas, such as the central nervous system, small cysts cause serious symptoms. In less restricted areas, the latency period is longer and the symptoms depend on the site and size of the cyst. Pressure effects appear sooner or later, and symptoms result from direct pressure or distortion of neighboring structures or viscera.

An enlarging cyst causes compressive atrophy of surrounding

hepatocytes and fibrosis, which can lead to compensatory hypertrophy of the remaining liver parenchyma. Large cysts can replace an entire liver lobe. Portal hypertension and a Budd–Chiari-like syndrome have been described. Another serious consequence of cyst enlargement is that it can rupture. Three types of cyst rupture have been addressed: (a) obscure, (b) free, and (c) communicant rupture.

Obscure (Internal) Rupture

Injury or penetration of bile into the space between the pericyst and the endocyst can cause rupture of the laminated membrane. The liberated protoscoleces occupy the available space and develop into hundreds of daughter cysts within the pericyst cavity. A typical univesicular cyst becomes multivesicular. When such a cyst is surgically entered, there is no laminated membrane and hundreds of daughter cysts, floating in a yellowish fluid and gelatin-like amorphous mass, crowd the interior of the pericyst. Not all multivesicular cysts have bile-stained fluid, and not all cysts with bile-stained fluid have active communications with the bile ducts. A multivesicular cyst with viable daughter cysts retains its high intracystic pressure, continues to enlarge, and can damage the host.

The clinical significance of multivesicular cysts is that (a) the host is exposed to hydatid antigens in the hydatid fluid, (b) the cyst is bacteriologically sterile, (c) the cyst contents cannot be easily aspirated and need to be scooped out, (d) the cyst must be treated as viable and infective, and (e) bile-stained cyst contents mandate a meticulous search for CBC.

Free Rupture

In free rupture, the hydatid contents disseminate throughout the peritoneal or pleural cavity.

Intraperitoneal Rupture. A vital HC grows in the direction of least resistance, usually reaching the surface of the liver before it reaches enormous proportions. The superficial portion of the pericyst is stretched, thinned out, and the cyst becomes visible as an irregularly shaped, fibrous, whitish structure protruding from normal liver parenchyma. Cysts reaching the anterior and inferior part of the liver continue to grow, protruding into the abdominal cavity. Because of high intracystic pressure, both univesicular and multivesicular cysts can rupture.

There are several clinical presentations of intraperitoneal rupture: (a) In

acute symptomatic rupture, peritoneal irritation and acute abdominal symptoms occur. This is an uncommon event. The incidence is about 1% to 4%. (b) In anaphylactic shock, rupture of the hepatic HC precipitates severe circulatory collapse, which may be fatal, and tends to mask the abdominal manifestations. (c) In silent rupture, the patient presents with disseminated abdominal hydatidosis, unaware when the rupture occurred. (d) Herniation of the laminated membrane ("dumbbell hepatoperitoneal cyst") occurs through the pericyst. The herniating membrane does not actually burst and therefore no spillage of hydatid debris occurs. The initial liver cyst remains small although the herniated, extrahepatic portion of the cyst can attain a volume of several liters. This condition mimics ascites, and attempts at percutaneous aspiration can lead to allergic manifestations. It is an infrequent condition.

Intraperitoneal rupture is a life-threatening complication that results in "secondary echinococcosis." Multiple cysts develop throughout the peritoneal cavity, causing intestinal obstruction, gross abdominal distention, ascites, and cachexia several years after the rupture. This is the secondary, smaller life cycle for the parasite, occurring only in the intermediate host. In endemic areas, the sudden onset of bile-colored ascites in an otherwise healthy person, regardless of the fact that no hepatic cyst is visible, raises suspicion of intraperitoneal rupture.

Intrathoracic Rupture. An elevated hemidiaphragm and a sterile sympathetic pleural effusion can be the first signs of liver hydatid disease. Upward extension of a subdiaphragmatic cyst is usually asymptomatic, although it can cause dry cough, dyspnea, chest pain, and toxemia. The pleura and adherent basal lung segments often become inflamed and indurated. Frank intrapleural rupture with empyema (hydatopiothorax) is rare. A combination of infection and pressure can cause destruction of lung parenchyma, resulting in pneumonitis or lung abscess. A HC may erode into a bronchiole and the contents can be evacuated. Rupture into the lumen of a bronchiole may lead to the appearance of daughter cysts in the sputum. If the cyst is already communicating with the bile ducts, a bronchobiliary fistula will arise. Expectoration of bile-tinged sputum is a sign of bronchobiliary fistula. The incidence of diaphragmatic or transdiaphragmatic thoracic involvement by HCs in the dome of the liver ranges from 0.6% to 16%.

Communicant Rupture

HCs can rupture into physiologic channels (e.g., biliary, blood vessels) or adjacent organs (e.g., digestive tract) (Fig. 106.4).

Intrabiliary Rupture. Compression and displacement of biliary ducts is frequent. Enlargement of the HC stretches and compresses the bile duct, causing bile stasis. At the point of intimate contact, the cyst wall and bile duct gradually weaken. The increase of intraductal pressure facilitates occurrence of horizontal or longitudinal fissures in the duct wall. Bile escapes through this breach of the bile duct wall, decompressing the bile duct and accumulating at the external side of the laminated membrane (internal rupture). This “leak” causes changes in osmotic pressure and a further increase in intracystic pressure that facilitates rupture into the bile duct (external rupture). Because the pressure in the cyst greatly exceeds that in the bile duct, a cystobiliary fistula is frequent. The communication with the bile duct can be terminal or tangential. Peripheral cysts disrupt small-caliber ducts (usually end to side) and central cysts communicate with a major segmental or sectoral duct (usually side to side). A single cyst can have several CBCs to the same or to different bile ducts.

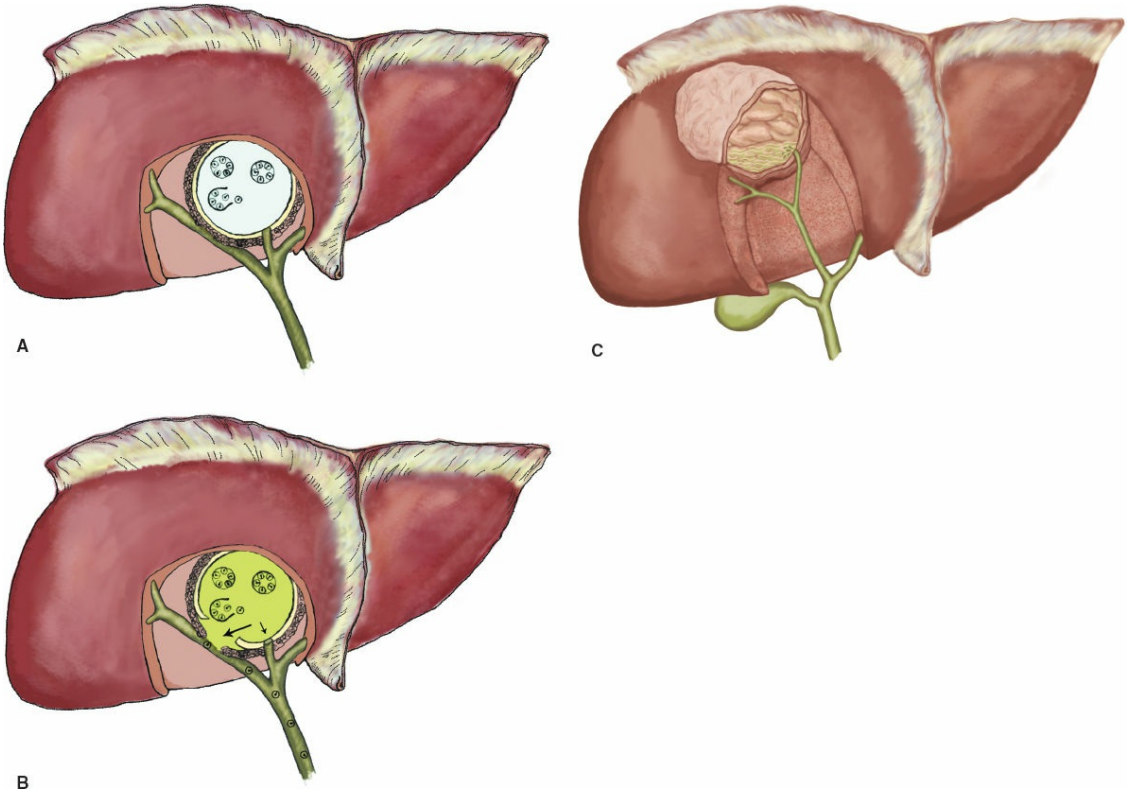

Figure 106.4. Communicant rupture into the bile duct. **A.** Hydatid cyst enlarges and compresses the bile duct, causing bile stasis. If the major duct is compressed and occluded, blood chemistry is

altered and jaundice may occur. **B.** Hydatid cyst ruptures into the bile duct. The laminated membrane is destroyed and the cyst contents discharge into the bile duct. The cyst becomes multivesicular and is bile-stained. **C.** Hydatid cyst in contact with the bile duct and has a terminal communication with the bile duct and bile inside the cyst.

In silent rupture, bile leaks from eroded small ducts into the cyst, causing endogenic vesiculation, suppuration, and eventually death of the parasite. Such cysts are filled with bile-stained detritus, although no visible bile duct communications can be seen. Probably 80% to 90% of HC bile duct ruptures are of the silent type. This type of asymptomatic, silent rupture is known as a "minor communication" but, nevertheless, it can sometimes cause unexpected postoperative bile leakage.

A triad of symptoms characterizes "symptomatic" rupture into the bile ducts: (a) biliary colic, (b) partial intermittent or complete ductal obstruction with cholangitis and jaundice, and (c) germinative membranes in the feces. Rupture into a large bile duct may allow more or less complete emptying of the fluid and detritus and lead to spontaneous cure or cholestatic jaundice with recurrent cholangitis. Incomplete emptying and a persisting communication usually result in secondary infection. In endemic areas, probably 3% to 10% of cases of obstructive jaundice are caused by intrabiliary rupture of hepatic HCs. This type of rupture is also called a "major communication," has a fistula orifice diameter of >5 mm, and communicates with a larger bile duct. This type of rupture is infrequent and has an incidence of 3% to 10%.

The rapid discharge of the cyst contents into a major bile duct or body cavity can lead to the sudden absorption of the hydatid antigen in a sensitized patient, resulting in anaphylaxis. More frequently, pruritus or urticarial rash is the major external manifestation. Episodes of asthma have been reported.

The incidence of rupture of the HC into the bile ducts is difficult to establish. The reported incidence ranges from 2.6% to 30.0%. This complication accounts for 60% of all the complications of hydatid disease and 20% of the postoperative morbidity. In my series, the incidence was 20.40%.

Rupture Into Adjacent Organs. A HC can rupture into the digestive tract, causing *hydatidemesis* or *hydatidenteria*. Rupture into the urinary tract

causes *hydatiduria*. Rupture of HC into the aorta, the inferior vena cava (VCI), the pericystic blood vessels, and the heart with embolism has been described.

Spontaneous Abortion

The parasite survives because of a complex interaction with the host through the pericyst. It is not known why some cysts occasionally stop developing and growing. Involution and death of the parasite are probably the result of malfunction of the pericyst or some other unknown noxious factor. Involution of the parasite is protracted, can probably last for years, and is accompanied with gross structural changes. The final phase is partial or total calcification of the pericyst.

DIAGNOSIS OF LIVER HYDATIDOSIS

Organ Imaging in Diagnosis and Treatment of Hydatid Disease

Roentgenographic Examination

The value of radiography in the diagnosis of uncomplicated liver HCs is very limited because the radiodensity of a noncalcified HC is the same as that of surrounding liver parenchyma. In endemic areas, elevation of the right hemidiaphragm in an otherwise healthy, asymptomatic patient is highly indicative of liver hydatidosis. Sometimes a standard radiographic examination of the abdomen reveals streak-like or round calcification of a senile HC. Cysts in the lung and bone are more readily demonstrated. Angiography and scintigraphy are of historic significance only.

Ultrasound Imaging

Ultrasonography

Ultrasound imaging (US) has revolutionized the diagnosis and investigation of liver hydatid disease. US examination of the liver is readily available and easy to master; it is comparatively cheap and noninvasive, enables interventional procedures, and does not expose the patient to radiation. In areas with endemic hydatidosis, it is the most important single diagnostic tool. On US, HCs are well-defined, circumscribed, cystic lesions with a clear membrane and do not infiltrate surrounding liver tissue. Cysts on examination can be solitary or multiple and univesicular or multivesicular. Pathognomonic US diagnostic features are (a) unmistakable daughter cysts (“rosettes”) within the main cyst

cavity, (b) detachment of the membrane of the cyst ("double-contoured membrane"), (c) agglomeration of daughter cysts in the dependent portion of a HC, and (d) calcification of the cyst wall. Because the US pattern reflects the natural history of the HC (evolution vs. involution), accurate interpretation, standardization, and classification of the ultrasound finding can be used for several purposes: (a) screening in endemic areas and family members in infested families, (b) staging and treatment planning, (c) first-line diagnostics, (d) interventional, nonoperative treatment procedures, (e) intraoperative US (IOUS) during surgery, (f) treatment monitoring and postoperative follow-up, and (g) in the workup of patients presenting with jaundice, as it is possible to differentiate daughter cysts from gallstones in the common bile duct (CBD) in most of these patients.

US is superior to CT in the investigation of the cyst wall, hydatid sand, daughter cysts, and the relationship of the cyst to the diaphragm. Without a clear knowledge and understanding of the disease, accurate interpretation of US findings can be difficult or even impossible. Only "simple HCs" have a uniform, easy-to-interpret US appearance. HCs that have undergone one or more morphologic changes can be a diagnostic problem because of nonspecific US patterns.

Based on US signs, Hassen Gharbi in 1981 classified liver HCs into five types. This classification is still widely used. The cyst types are Type I, pure fluid collection, Type II, fluid collection with a split wall, Type III, fluid collection with septa, Type IV, heterogeneous appearance, and Type V, reflecting thick walls. Gharbi cyst types II and III as well as type V calcified cysts are characteristic for liver cystic hydatid disease. In endemic areas, cyst types I and V suggest cystic liver hydatid disease, and cyst type IV can be a diagnostic problem. Different cyst types can coexist in the same patient, reflecting different developmental stages.

The need to more accurately evaluate the functional state of the parasite, especially in field studies, has resulted in a new, modified ultrasound classification of liver HCs. Based on cyst characteristics described in the Gharbi classification, the WHO-IWGE proposed a new classification reflecting the functional state of the parasite that facilitates selection of treatment modalities, as shown in Table 106.3 and Figure 106.5.

Based on the WHO classification, certain management guidelines have been suggested. In patients with active cysts (type CL, CE1, CE2), about one third of the cysts will be sterile. In these patients, there are three

management options: (a) wait and see, (b) further differential diagnosis, and (c) chemotherapy. The remaining two thirds of the patients will have fertile cysts and half of them will have secondary cysts. In this group, management modalities are surgery, PAIR, and chemotherapy. Active cysts are the most frequent presentation of liver HCs in the clinical setting. In patients with degenerating (transitional state) cysts (type CE3), living protoscoleces can exist and all treatment options should be considered. In patients with inactive cysts (type CE4 and CE5), further differential diagnosis is frequently necessary. As a rule, there are no living protoscoleces in these cysts and, if no complications related to the cyst are present, no treatment is necessary.

TABLE 106.3 The WHO-IWGE Classification of HC

Type of Cyst	Status	Ultrasonographic Features	Remarks
CL	Active	Signs not pathognomonic, unilocular, no cyst wall	Usually early stage, not fertile; differential diagnosis necessary
CE1	Active	Cyst wall, hydatid sand	Usually fertile
CE2	Active	Multivesicular, cyst wall, rosettelike	Usually fertile
CE3	Transitional	Detachment of laminated membrane, water lily sign, less round—decreased intracystic pressure	Starting to degenerate; may produce daughter cysts
CE4	Inactive	Heterogeneous hypo- or hyperechogenic degenerative contents; no daughter cysts	Usually no living protoscoleces; differential diagnosis necessary
CE5	Inactive	Thick calcified wall; calcification partial to complete; not pathognomonic but highly suggestive diagnosis	Usually no living protoscoleces

CE, cystic echinococcosis; CL, cystic lesion.

Intraoperative US

In my experience, IOUS can affect the operative strategy. IOUS can be used (a) for "mapping" of the HC (determining its exact position, shape, and its relationship to neighboring structures, e.g., as partially calcified cysts close to hepatic veins and VCI; central cysts close to the hilum), (b) when managing patients with multiple cysts, (c) when the atrophy/hypertrophy complex distorts the anatomy, (d) in reoperations for

hydatid disease, (e) in the localization and management of small, nonpalpable cysts deep in liver parenchyma, (f) in the examination of the extrahepatic biliary tree, (g) in detection of CBC, which, however, is not always accurate even in experienced hands, and (h) in the search for exogenous vesiculation, especially if nonresectional surgery is performed. An important special technique is that, after partial pericystectomy, the probe should be introduced into the sterilized cyst cavity and the entire inner wall scanned for exogenous vesiculation. An exogenous cyst can be approached and managed directly through the pericyst with minimal risk.

A CBC should be expected when IOUS detects (a) a dead cyst (heterogeneous US pattern of the cyst), (b) hydatid material in the biliary tree, (c) the sign of “lost continuity” of the bile duct adjacent to the cyst wall, and (d) gas in the cyst.

Ultrasonography in Patient Follow-Up

Ultrasonography after operation for liver hydatidosis is complex, and correct interpretation of results demands an understanding of the operative procedure. Symptomatic patients need prompt US exploration. US reveals a variable pattern, and interpretation depends on time of the prior operation, the type, localization, and size of the cyst or cysts, and the type of operation. I classify postoperative ultrasound patterns into two groups: (a) early postoperative appearance and (b) late postoperative appearance.

US examination in the early postoperative period demonstrates one of the following images: (a) empty (transonic) remaining cavity persisting for months; (b) fluid collection, hematoma, or biloma; (c) a partial cavity with solid mass with/without fluid; (d) a hyperechogenic circular pattern after omentoplasty (should not be mistaken for a recurrent cyst); (e) missed cysts; and (f) distortion of the liver contour.

CL
CE 1
CE 2
CE 3
CE 4
CE 5

Figure 106.5. Types of hydatid liver cysts found on ultrasonographic examination of the liver and the classification proposed by the World Health Organization Informal Working Group on Echinococcosis. CL, cystic lesion; CE, cystic echinococcosis.

US examination in the late postoperative period demonstrates one of the following images: (a) compensatory hypertrophy of the liver after operation for a large cyst, (b) hyperechogenic appearance and no cavity at operative site, (c) frank recurrence of a developing cyst (increasing volume of persistent fluid collection at the site of operation), (d) new cysts at a different site (not a recurrence), and (e) calcifications at the operative site.

Computerized Tomography

CT yields the most accurate information regarding the number, position, and cyst characteristics (volume and density) as well as the extent of intra-abdominal disease. Discontinuity of the cyst wall in the vicinity of bile ducts is highly suggestive of CBC. A CT scan can readily demonstrate exogenous vesiculation, which is an important cause of recurrence in conservative surgery for liver hydatidosis. I believe that all patients need a CT scan preoperatively. CT is less operator dependent than US and can give the surgeon an accurate roadmap for operation. For patient follow-up, a CT scan should be obtained only when indicated by US findings.

Magnetic Resonance Imaging and Cholangiopancreatography

Magnetic resonance imaging (MRI) provides high-quality images of liver and abdominal hydatidosis. MRI is irreplaceable in monitoring skeletal and vertebral disease and in cardiac cysts. MR angiography is helpful only when cysts are large and in close proximity to major vessels or when the patient has been previously operated several times for hydatid disease and has distorted liver anatomy. MRI and magnetic resonance cholangiopancreatography (MRCP) is suggested in (a) subdiaphragmatic site of HC, (b) disseminated disease, (c) extra-abdominal location, (d) complicated, symptomatic, cysts, and (e) pre-surgical evaluation and planning (liquid areas and structure of the HC). MRCP is an excellent noninvasive tool for investigating jaundiced patients with liver hydatidosis.

Endoscopic Retrograde Cholangiopancreatography

Since MRCP was introduced, the indications for endoscopic retrograde cholangiopancreatography (ERCP) have been redefined. ERCP has little value in asymptomatic patients and should be avoided. Unavailability of MRCP or the intent to treat (interventional procedures) is the only indication for ERCP. Indications for endoscopic papillotomy in the preoperative period are (a) when US, CT, MRCP, or ERCP detect hydatid material in the CBD and (b) when cholangitis has been a feature of the clinical presentation, regardless of whether a CBC is detected. Because some asymptomatic patients have hydatid debris in the CBD and the CBD can be cleared during the operation without papillotomy, the first indication is not so clear-cut. Preoperative endoscopic papillotomy facilitates flushing of the bile ducts but renders intraoperative cholangiography even less informative. In my practice, indications for endoscopic papillotomy in the postoperative period are (a) hydatid material in the CBD, (b) a biliary fistula lasting longer than 3 weeks, (c) a high-output biliary fistula (>1,000 mL per 24 hours), (d) jaundice, and (e) short stricture obstructing the papilla. Critical use of ERCP and papillotomy in patients with CBCs has reduced mortality and in-hospital stay.

Immunodiagnosis in Individual Patients

The detection of circulating *E. granulosus* antigens is less sensitive than the detection of antibodies. Most serologic tests are based on the reaction and precipitation between the test antigen and the circulating antibodies in the host. The quality of the test antigen determines the sensitivity and specificity of the test.

The initial intradermal Casoni test, the human basophile degradation test, and the complement-fixation test have only historical relevance. The primary tests for antibody detection are (a) the enzyme-linked immunosorbent assay (ELISA), (b) the indirect hemagglutination antibody test, (c) the latex agglutination test, (d) the immunofluorescence antibody test, and (e) immunoelectrophoresis. The secondary tests, usually done in specialized laboratories, are (a) detection of precipitation line (arc 5), (b) identification of immunoglobulin G subclasses, (c) immunoblotting, and (d) polymerase chain reaction (PCR).

Serologic tests must be used and interpreted in correlation with epidemiologic data, clinical presentation, and especially imaging

investigations. Primary tests have a sensitivity of 80% to 95% in patients with liver hydatidosis and 65% in patients with pulmonary hydatidosis. Confirmation should be obtained with secondary tests, which are more specific. Secondary tests should always be used for extrahepatic localizations or calcified cysts. Postoperative seronegativity is usually reached after 3 to 7 years. Persistence of high-specific antibodies or a positive secondary test indicates relapse.

A simple algorithm for serologic testing is (a) imaging negative—no further investigation; (b) primary test negative, asymptomatic patient, lesions resembling cystic echinococcosis—advanced imaging procedures, "wait and observe" approach, repeat serologic tests; (c) symptomatic patient, imaging suggestive of cystic echinococcosis—needs to be managed without further tests; and (d) primary test positive, with/without lesions suggestive of cystic echinococcosis with/without symptoms—needs secondary tests. Differential diagnosis for alveolar echinococcosis and for cysticercosis in patients coming from endemic areas is indicated. Specificity of tests is limited by cross-reaction with some other helminthic disease, some malignancies, liver cirrhosis, and the presence of anti-P1 antibodies. Detection of parasite-specific IgE and IgG4 has no clinical diagnostic advantage.

Establishing the Diagnosis

The diagnosis of hydatid disease follows a certain algorithm. Suspicion of liver hydatid disease is based on the epidemiologic background of the patient, clinical grounds, or noninvasive screening procedures. Available imaging modalities should identify cyst characteristics, and the diagnosis is confirmed by detecting specific antibodies with immunodiagnostic tests. In a very small number of patients, in whom diagnosis cannot be confirmed but suspicion exists (e.g., recurrence), diagnostic puncture can be considered if it is not contraindicated. Microscopic examination following vital staining of fluid aspirated from a HC gives evidence of the parasitic nature and vitality of a cyst. Routine blood and liver function tests are of no value in patients with simple HCs.

According to WHO-IWGE, the clinical criteria for the diagnosis are (a) slowly growing or static cystic mass or masses diagnosed by imaging techniques, (b) anaphylactic reaction due to leaking or ruptured cyst, and (c) incidental finding of a cyst in asymptomatic carriers or detected by screening techniques. The diagnostic criteria are (a) typical organ lesion(s) detected by imaging techniques, (b) specific serum antibodies assessed by

high-sensitivity serologic tests, confirmed by a separate high-specificity serologic test, (c) histopathology or parasitology typical for ECs (e.g., protoscoleces or hooklets in cystic fluid), and (d) pathognomonic macroscopic morphology of EC in surgical specimens. A possible case is any patient with a clinical or epidemiologic history, and imaging findings or serology positive for cystic echinococcosis. A probable case is any patient with the combination of clinical history, epidemiologic history, imaging findings, and serology positive for cystic echinococcosis on two tests. A confirmed case is any patient that has been considered a probable case plus (a) positive microscopic analyses of cyst fluid, or (b) changes of US appearance of liver cyst (e.g., stage CE1 moving toward CE3a) after the administration of albendazole (ABZ) or spontaneous.

MANAGEMENT OF ECHINOCOCCAL CYSTS

Nonoperative therapy can fail due to several factors: (a) the bioavailability of chemotherapeutic drugs is limited and uncertain due to cyst characteristics, (b) cysts are frequently multivesicular and protoscolicidal agents do not penetrate into vesicles and daughter cysts, (c) cysts can have large volumes and dilute the injected protoscolicidal agents, (d) the infective content of vital cysts is under increased pressure and puncture may lead to spillage (percutaneous puncture only for cysts in certain positions), (e) aspirators are frequently obstructed by cyst content/hydatid debris and it is impossible to aspirate paste-like content, (f) CBCs need to be evaluated and managed, and (g) there may be vital parasites in the remaining structures (pericyst wall, exogenous vesiculation) that will cause recurrence of the disease.

Chemotherapy

Thirty years after the first attempts to establish effective medical treatment with benzimidazole carbamates, surgery is still the golden standard for achieving complete cure. At present, of the benzimidazoles, only mebendazole (MBZ) and ABZ are still used. ABZ is the only drug that is ovicidal, larvicidal, and vermicidal and is the drug of choice. Praziquantel, a synthetic isoquinoline pyrazine derivative, has been used in combination with ABZ to increase the protoscolicidal effect of ABZ. Although 45% to 60% of patients experience one or more side effects, drug therapy is discontinued in only 2% to 4% of patients.

Chemotherapy with benzimidazole compounds is currently indicated in

(a) inoperable patients with primary liver and lung cystic echinococcosis, (b) patients with multiple cysts in two or more organs, (c) multiple small (<5 cm, CE1 and CE3) liver cysts, (d) cysts deep in liver parenchyma, (e) prevention and management of secondary hydatidosis, (f) management of recurrent hydatidosis, (g) unilocular cysts in unfit elderly patients, (h) in combination with surgery and interventional procedures, (i) pulmonary echinococcosis, and (j) long-term administration for cysts at specific sites (such as bone, brain, eye).

Benzimidazole chemotherapy is contraindicated for (a) large cysts (>10 cm), (b) cysts with multiple septa divisions (honeycomblike cysts), (c) cysts that are prone to rupture (superficial), (d) infected cysts, (e) inactive cysts, (f) asymptomatic calcified cysts, (g) severe chronic hepatic disease, (h) bone marrow depression, and (i) early pregnancy (animal experiments). Diabetes is a relative contraindication. Chemotherapy for bone cysts is a relative contraindication. Published data are controversial since there is a significantly reduced response.

The expected results of adequate chemotherapy are (a) 10% to 30% cyst disappearance (cure), (b) 30% to 70% degeneration or significant size reduction (improvement), and (c) 20% to 30% no morphologic changes (treatment failures). Younger patients had a better response rate. The rate of relapse after chemotherapy is high (3% to 30%), but, fortunately, relapses are sensitive to retreatment in up to 90% of patients. Most relapses occur within 2 years after therapy. However, interpretation of published reports is difficult because of the lack of standardization and interference with the natural history of the disease.

The effectiveness of preoperative chemotherapy in preventing secondary echinococcosis and recurrence needs further investigation. Chemotherapy is routinely administered prior to interventional procedures and preoperatively in some centers. It is still unclear whether preoperative chemotherapy is beneficial; I do not use it routinely.

According to the WHO-IWGE guidelines, preinterventional administration of ABZ or MBZ should begin 4 days before intervention and continue 1 month for ABZ and 3 months for MBZ thereafter. Based on animal data, 1- to 2-week postspillage therapy may be useful. All the available data suggest that medical management of hydatid disease yields poor results, and in the majority of patients the therapy fails or the disease relapses.

ABZ is given orally at a dose of 10 to 15 mg/kg/day, in two divided

doses, with a fat-rich meal without monthly treatment interruptions. Optimal dosage and treatment duration have not been accurately defined. The optimal treatment period ranges from 3 to 6 months. It seems that prolonging the treatment period does not further increase the incidence of adverse effects. There are emerging data that continuous treatment as opposed to pauses after treatment for 1 to 3 months is safe and more effective and well tolerated. There MBZ is given at a dosage of 40 to 50 mg/kg/day in three divided doses with a fat-rich meal if ABZ is not tolerated. The duration of therapy is also 3 to 6 months.

Limited data are available for the use of praziquantel. The dosage is 40 mg/kg/wk. It has been used for the management of intraperitoneal spillage during operative and interventional procedures.

Monitoring for adverse effects of chemotherapy is mandatory. Many authors suggest a CBC count and liver enzyme determination every 3 weeks for the first 3 months, followed by repeated determinations once a month if the therapy is prolonged.

Minimally Invasive Techniques

Percutaneous Drainage of Hydatid Cysts—PAIR

Percutaneous puncture of HCs was dogmatically contraindicated for fear of spillage, dissemination, and life-threatening anaphylactic reaction. The first successful percutaneous drainage of a HC was reported in the late 1980s. A new interventional treatment modality—the PAIR procedure—emerged in the 1990s. The classical PAIR procedure includes the following steps: (a) percutaneous puncture of the cyst, (b) aspiration of cyst fluid, (c) injection of a protoscolicidal agent, and (d) reaspiration of the cyst content after 15 to 20 minutes.

Indications for PAIR are (a) inoperable patients; (b) patients who refuse surgery; (c) cysts types CL, CE1, CE3, and some CE2 (Gharbi types I and II, and some patients with types III and IV); (d) relapse after surgery; (e) infected cysts; (f) failure of chemotherapy; (g) multiple cysts of more than 5-cm diameter in different liver segments; (h) possibly pregnant women (chemotherapy contraindicated); and (i) possibly children less than 3 years old.

Contraindications for PAIR are (a) inaccessible cysts, (b) superficially located cysts, (c) cysts with multiple septa divisions (honeycomb like cysts CE2, CE3b), (d) cysts with hyperechogenic solid patterns (CE4), (e) cysts communicating with bile ducts, (f) partially or totally calcified cysts

(CE5), (g) most cysts in the lung, and (h) early pregnancy.

PAIR is usually performed under US or CT guidance for cysts larger than 5 cm in diameter. The patient is prepared according to preoperative guidelines. Local anesthesia is administered. The cyst is punctured through the thickest possible transhepatic route using a cholangiography needle (18 to 22 gauge) or transhepatic catheter needle (No. 5 French). The cyst is entered through the nondependent wall to avoid the sediment rich in protoscoleces. About 30% to 50% of the cyst volume is aspirated. If necessary, immediate cytologic and bacteriologic examination of the fluid and sediment can confirm the diagnosis. Radio-opaque contrast is injected into the cyst cavity in order to opacify the cyst and to detect CBC. All daughter cysts need to be punctured in a multivesicular cyst. The initial protoscolicidal agent (usually hypertonic NaCl, 15% to 20%) is not injected if CBC is demonstrated. The cyst is completely reaspirated after 15 to 20 minutes. A sclerosant (usually alcohol) is then injected. If the cyst diameter is more than 6 cm prior to injection of the sclerosant, a drainage catheter is inserted and free drainage is enabled for 24 hours. After 24 hours, a cystogram is performed through the catheter and a sclerosant is injected. Complicated cysts, cysts with many daughter cysts, or large-volume cysts are indications for PAIR modifications: (a) the PAIR-catheterization technique, (b) the D-PAI (double-puncture, aspiration, and injection) technique, (c) the percutaneous evacuation of cyst content (PEVAC) technique, and (d) the modified catheter aspiration technique (MoCAT).

Following successful PAIR, a heterogeneous US pattern is detected, usually within 2 to 4 months, a pseudotumor appears in 4 to 8 months, and cyst obliteration occurs in 9 to 12 months. Not all cysts reach the stage of a pseudotumor or undetectable lesion. The PAIR procedure can be safely repeated.

The overall complication rate in PAIR is 10% to 40% and the overall mortality rate is 0.9% to 2.5%. Mortality is associated with periprocedural complications, advanced age, and infection of the remaining cyst cavity. Fever without an identifiable source occurs in 6% to 35% of patients and, with symptomatic therapy, disappears within 72 hours after intervention. Minor allergic reactions occur in 0% to 12% of patients. The incidence of anaphylaxis is the same as for open surgery (probable range, 0.1% to 0.2%). Infection of the cyst cavity occurs in 2% to 10% of patients, usually within 10 days after the procedure. The local recurrence rate is 0% to 4%.

The incidence of biliary fistulas, rupture, and obstruction is 3% to 6%. There are no reports of caustic sclerosing cholangitis or secondary peritoneal dissemination. Favorable results have been reported following PAIR interventions worldwide with follow-up periods exceeding 5 years. Pretreatment and posttreatment chemotherapy is mandatory.

The PAIR procedure has gained wide acceptance because it is safe, minimally invasive, and easy to perform; has a low morbidity and mortality, a short hospital stay; and is cheaper than surgery. Pulmonary HCs are generally considered a contraindication for PAIR, although good results without mortality have been reported. Percutaneous drug injection (ivermectin, ABZ sulfoxide) without aspiration is still in the experimental phase.

In some countries, mobile specialized teams with specially adapted busses and trucks are sent into rural endemic areas to treat patients, since this is an effective, relatively safe procedure that yields good results.

Open Surgery

The rationale for surgical management of liver ECs is that (a) surgery is the most effective treatment applicable to all cysts, (b) it removes the parasite, (c) it manages the CBC, (d) it manages the cystic cavity (conservative surgery), (e) it has an acceptable morbidity and mortality rate, and (f) it has a low recurrence rate.

There is no prospective randomized study to compare radical surgery with conservative surgery. Surgeons trained in hepato-bilio-pancreatic (HPB) surgery prefer radical procedures, while the majority of general surgeons in endemic areas, the ones who do not talk at meetings and conferences, perform conservative surgery in most cases.

Closed or open total cystopericystectomy (cystectomy) and liver resection have strict, defined indications. The rationale for performing liver resection for a benign disease that can be successfully managed by less extensive liver surgery with acceptable results needs to be evaluated in every patient. The majority of operations for liver hydatid disease are performed at general surgical departments in developing countries in which extensive expertise and facilities for major liver surgery are unavailable. Under such circumstances, a high postoperative morbidity and mortality rate can be expected, especially as liver atrophy is frequently present because of the large size of the neglected cysts. These patients, following liver resection, return to endemic areas in which reinfestation is

possible.

Radical Procedures

The rationale for radical procedures is that (a) total removal of the cyst and exocysts is associated with the lowest recurrence rate, (b) chemotherapy after radical removal of the intact cyst is unnecessary, (c) the use of intraoperative protoscolicidal agents is unnecessary if the cyst is not entered, (d) the chance for a biliary fistula and cavity-related complications is low, (e) calcified cysts can be removed, and (f) in expert hands the mortality and morbidity rates are low.

Radical procedures are (a) closed cystectomy, (b) open cystectomy, (c) near-total open cystectomy, (d) subadventitial cystectomy, (e) nonanatomic liver resection, (f) anatomic liver resection, (g) completion cystectopericystectomy in residual cavities, and (h) total cystopericystectomy in hepatopulmonary transit. The term *closed pericystectomy* is a misnomer and the correct term is *cystectomy*, since the pericyst is part of the EC. It is also known as *radical cystectomy*, *ideal cystectomy*, *capsulectomy*, *total pericystectomy*, and *cystopericystectomy*.

Conservative Procedures

The rationale for conservative surgery is that (a) all cysts can be treated in this manner; (b) it can be performed safely by general surgeons; (c) the liver parenchyma is not entered and there is no threat to the hepatic vasculature and bile ducts; (d) a specialized team for HPB surgery is not necessary; (e) no special equipment is necessary; (f) it is applicable to multiple bilateral cysts; (g) if performed correctly the morbidity, mortality, and recurrence rates are acceptable; (h) it is cost-effective in developing countries; and (i) it is tissue sparing, which is important in endemic areas.

INDICATIONS AND CONTRAINDICATIONS FOR OPEN SURGERY

Surgery is still the “gold standard” in the management of liver hydatid disease. Indications for open surgery are (a) large cysts with multiple daughter cysts type CE2 to CE3b; (b) single liver cysts situated superficially that may rupture; (c) infected cysts; (d) cysts with CBC; (e) cysts exerting pressure on adjacent organs; and (f) cysts in the lung, brain, bones, kidneys, and other organs. Contraindications for surgery are (a) patients refusing surgery, (b) extreme age, (c) pregnant women, (d)

concomitant severe diseases, (e) numerous cysts, (f) cysts difficult to access, (g) dead cysts, (h) cysts partially or totally calcified, and (i) very small cysts (<5 cm, wait and see policy).

PREOPERATIVE PLANNING

The classic open surgical procedures can be subdivided into two groups: (a) conservative, tissue-sparing procedures that are limited to removing the parasite, with part or most of the pericyst left *in situ* and (b) radical, resectional procedures that remove the entire pericyst, with or without entering the cyst itself. The choice of the surgical techniques depends on: (a) the type and size of the cyst, (b) the site, (c) the presence of complications, and (d) the expertise of the surgeon.

Antibiotic prophylaxis is administered. Preoperative chemotherapy and steroids are not routinely given. The operating room must have radiography facilities and possibly IOUS. The anesthetist should have steroids and adrenalin at hand. Operating room personnel should be informed about the nature of the disease.

I present experience with 1,168 operated patients.

OPEN SURGICAL TECHNIQUES IN CYSTIC ECHINOCOCCOSIS

Approach and Exposure

The incision depends on (a) the site of the cyst, (b) its size, (c) the presence of extrahepatic cysts, and (d) the presence of complications. The incision can usually be confined to the abdomen. I prefer a long, right subcostal incision with an upward extension in the midline, if necessary. A right thoracoabdominal incision was used infrequently in my series, in only 2.1% of the patients, and thoracotomy was added to a right subcostal incision in only 0.45% of the patients. The reported high incidence of thoracotomy probably reflects the inability to accurately assess the extent of diaphragmatic involvement. A gigantic posterior cyst with marked elevation of the diaphragm or a preoperatively established bronchobiliary fistula may be an indication for thoracotomy. It is always better to perform a thoracotomy than to extend an abdominal incision into the chest. A midline laparotomy is preferred in patients with (a) cysts in the left lobe of the liver, (b) perforated abdominal HCs, and (c) secondary abdominal echinococcosis.

Before approaching the cyst(s), the entire liver is “walled off” from the rest of the abdomen with packs soaked in hypertonic saline. Careful and completely mobilization of the liver is mandatory. Inflammatory, dense adhesions overlying the most superficial part of the cyst are frequent. Most such adhesions are not the result of rupture, and a thick cyst wall usually exists. The diaphragm should be dissected away from the cyst and its full mobility restored. It is unwise to handle a large posterior cyst in a liver that has not been mobilized, and it is also difficult to manage the residual cyst cavity. If the diaphragm is adherent, postoperative chest complications are more frequent. Inspection, bimanual palpation, and IOUS of both lobes are mandatory. Because large and multiple cysts frequently distort liver anatomy, it is important to assess the relationship of the cyst to the VCI and the hepatic veins. All cysts seen on preoperative imaging must be identified. IOUS examination of the CBD is mandatory. Some authors prefer not to mobilize the liver, but rather isolate the cyst with gauze packs soaked in a protoscolicidal agent prior to decompression. This is feasible for small anterior cysts. It is not an efficient and safe procedure for posterior cysts.

In my series, the cyst was in the right lobe of the liver in two thirds of the patients, in the left lobe in one fifth, and in both lobes in less thyan 20% of the patients. The most frequently involved segments were VII (one third of the patients) and V (one fifth of the patients).

Conservative Surgical Procedures

All of these procedures have some common goals: (a) safe and complete exposure of the cyst, (b) safe decompression of the cyst, (c) safe evacuation of the cyst contents, (d) sterilization of the cyst, (e) management of CBC, when present, and (f) management of the remaining cyst cavity.

Safe Decompression of the Cyst

All cysts should be treated as if they are vital and infectious. The entire area around the mobilized liver is packed with blue or green packs and drapes are soaked in 15% to 20% saline. Colored packs and drapes ensure better visibility of whitish cyst elements. The point where the cyst is to be punctured is determined and a working area, as small as possible, is delineated by additional packing. This is important because the high intracystic pressure makes it difficult to avoid some leakage of cyst

contents. Special devices have been designed for safe decompression of HCs. The use of “cones” (adhere to liver surface by freezing or vacuum) has been described. These devices intended for decompression of a HC in a sealed-off, controlled environment are bulky, impractical, and impossible to attach to posterosuperior cysts. There are no data supporting their routine use. I do not use special devices for cyst puncture and do not inject protoscolicides into an unopened cyst. Two large-bore suction tips connected with transparent tubing to large capacity reservoirs are necessary. The cyst is penetrated by a short, large-gauge needle connected to one of the suction tips in the delineated working area while the other suction tip is held next to the needle at the puncture site. The color of the aspirated hydatid fluid is observed. Usually, 50 to 100 mL can be evacuated before the needle becomes occluded. Once the intracystic pressure is lowered, it is possible to place three stay sutures adjacent to the needle. Upward traction on the stay sutures makes it possible to retract the needle safely. The cyst is incised between the sutures by electrocautery. The rims of the incision are grasped with tissue-grasping forceps and the stay sutures are removed. The incision is enlarged to about 3 to 5 cm so that direct vision of the cyst cavity and its contents is achieved. A large-gauge sump suction is inserted and freely moved around the cyst cavity in order to evacuate all the fluid. Warm saline solution is intermittently injected into the cyst cavity to keep the suction functioning and to evacuate the debris and hydatid sand. It is important to have a small opening at the uppermost part of the cyst and to exert constant upward traction on the edges of the incision so that overflow is avoided. The use of laparoscopic trocars for cyst penetration and evacuation enabling simultaneous irrigation (gas valve) and evacuation (large-bore aspirator open at the tip) has been described.

Once the fluid has been aspirated, the laminated membrane collapses and all the remaining cyst contents can be removed. A small metal dish is brought next to the incision, which is enlarged by electrocautery to facilitate removal of its contents. In a univesicular cyst, the laminated membrane can be extracted with ring forceps and placed into the metal dish. In a multivesicular cyst, the daughter cysts and the debris are best managed by high-power, wide-bore suction. Sometimes, it is necessary to use a “spoon” to evacuate the cyst contents. The presence of a toothpastelike, semisolid material rapidly blocks the suction, and evacuation is continued with the “spoon.” The real benefit of grinder–

aspirator devices for the evacuation of dense cyst contents in open surgery needs further evaluation.

Sterilization of the Cyst and Search for Bile Duct Communications

The redundant portion of the cyst roof is excised by electrocautery, the cyst volume is reduced, and excellent exposure is obtained. The cut edges are oversewn with running resorbable mattress sutures. This is important because the edges can contain small blood vessels and bile ducts. I use the Harmonic scalpel (Ethicon) or LigaSure (Tyco) for this purpose in laparoscopic HC surgery, and these devices can be used in open surgery as well. Sterilization of the cyst cavity is achieved by mechanical cleansing and local application of protoscolicidal agents. The interior is carefully cleansed. I carefully "scrape" the interior of the cyst with sponges soaked in 10% saline, with frequent rinsing and aspiration, in an attempt to remove what is left of the endocyst. Daughter cysts may be tucked away in recesses of the main cavity and overlooked. Curettage with sharp instruments is not safe because hepatic veins frequently run adjacent to the cyst. Any "bulging" of the cyst wall is treated with caution. After removing all the debris, the cyst cavity is flushed several times with saline, inspected for bile leaks, and loosely packed with dry, white-colored packs soaked in 15% to 20% saline. The packs are left in place for 5 to 10 minutes, removed, and inspected for bile stains. Bile stains are indicative of CBC and warrant their identification and management. If no bile stains are visible, definitive sterilization of the cyst is performed.

I do not inject protoscolicidal agents into an intact or partially decompressed HC for sterilization. The efficacy of protoscolicidal agents after mixing with cyst content is uncertain and even HCs with clear contents can sometimes demonstrate CBC after decompression.

Protoscolicidal agents have been used for cyst sterilization since the beginning of the past century. Many surgeons question their merit and efficacy. Minimally invasive techniques have re-established the need for their evaluation. For a good protoscolicidal effect, the choice of protoscolicidal agents and exposure time is crucial. I have studied the efficacy of protoscolicidal agents (exposure time necessary for a 100% protoscolicidal effect, all protoscoleces dead) using standardized human protoscoleces-rich sediment. For 5% saline, the exposure time was 180 minutes; for 10%, it was 30 minutes; and for 15%, 20%, and 30%, it was only 10 minutes. For alcohol (96%, 70%, 48%, and 35%), 10% povidone iodine, 10% formalin, and 5% chlorhexidine gluconate, the exposure time

was 10 minutes. The shortest exposure time was for commercial products Cetavlon (AstraZeneca, Sodertalje, Sweden) and Savlex (Drogsan Pharmaceuticals, Ankara, Turkey), at only 5 minutes. For silver nitrate, the time was 5 minutes, and for 3% hydrogen peroxide, it was 15 minutes. Protoscolicidal agents can cause serious life-threatening complications: (a) acute toxic reaction; (b) anaphylaxis; (c) hypernatremia; (d) air embolism; (e) metabolic acidosis; (f) consciousness disorders, coma, and death; (g) peritoneal adhesions; (h) methemoglobinemia; and (i) caustic sclerosing cholangitis. Caustic sclerosing cholangitis is a new clinical entity described in the late 1980s. It is the result of protoscolicidal agents entering bile ducts and damaging the mucosa. The progression of caustic sclerosing cholangitis is rapid, resulting in segmental bile duct obstruction and deteriorating liver function. Protoscolicidal agents, even in low concentrations, should not be instilled if a CBC is present or suspected.

Management of Cystobiliary Communication

Management of CBC is the crucial issue in conservative surgery for liver hydatidosis. CBC is an independent variable that significantly increases the incidence of postoperative morbidity and mortality. Inadequate management can cause serious, life-threatening complications. The orifice of the CBC is sometimes very easy to identify. A single cyst can have several orifices, and in a patient with multiple cysts, several cysts can have CBC. Successful and safe closure of the CBC is possible in the majority of patients. Unfortunately, not all patients have a CBC that is easy to manage, especially when a major bile duct is involved. In some patients, the cyst can destroy one hepatic duct or the confluens of the hepatic ducts. Such patients need to be identified and certain technical rules need to be observed.

Most CBCs cannot be preoperatively predicted. In my series, specific symptoms (cholangitis, obstructive jaundice, biliary colic, and allergy) were present in only 31.6% of these patients, and specific signs (dilated bile duct with/without debris, altered blood chemistry) in 23.8%. Large cysts (>10 cm) occupying several liver segments and episodes of cholangitis are highly suggestive of HC–bile duct communications.

Management of CBC depends on several factors including, among many other factors (a) their number, (b) type, (c) site, (d) size of the orifice, (e) the involved bile duct, (f) patient status, (g) condition of the liver, and (h) the expertise of the surgeon.

Bile-stained cyst contents are highly suggestive of an existing CBC.

The majority of patients with this condition will not have a visible orifice at operation, suggesting that most of the CBCs were minute, fissure-like communications at some point in the cyst development. In such cysts, search for the orifice should be meticulous as the interior surface of the cyst is corrugated. Sometimes after rapid decompression of a cyst, with only slightly bile-tinted contents, an orifice secreting bile appears. This may be caused by a valve-like mechanism or rupture of an atrophied point of contact once the intrabiliary pressure exceeds the pressure in the cyst. In PAIR procedures, this may be one of the explanations for bile fistulas.

The intraoperative detection and assessment of the CBC is essential for adequate management. Sometimes it is impossible to identify the site of an obvious leak. The routine procedure was to do intraoperative (cystic duct) cholangiography. I disagree with this routine. Intraoperative cholangiography, which theoretically has the advantage that it can demonstrate daughter cysts in the CBD as well, is not routinely necessary for three reasons: (a) only a small proportion of patients have hydatid debris in the bile duct, and they can be identified with IOUS, (b) the majority of these patients have had a preoperative ERCP because they presented with cholangitis, and (c) apart from demonstrating the existence of a leak, it does not necessarily help identify the site of the leak. The dye spills into the cystic cavity and repeated films are even less informative. An alternative would be to fill the cyst with saline and inject air and watch for bubbles instead of injecting additional quantities of dye. Both procedures usually require cholecystectomy, which is not really necessary in most patients. The gallbladder very infrequently has hydatid debris. Methylene blue can be injected into the gallbladder or CBD, but I do not find it particularly helpful. If the site is not identified at the time of injection, the interior of the cyst is colored blue and subsequent identification is even more difficult. It is my practice to pack the cyst with white gauze packs soaked in hypertonic saline and wait for several minutes to see if and where bile stains appear. If bile appears, a meticulous search for the orifice is conducted, aided by gentle squeezing of the gallbladder, if necessary. This will almost certainly demonstrate the orifice.

It is of paramount importance that the orifice is visualized and the CBC assessed. Large, central cysts can grossly distort liver anatomy and make it difficult to identify the bile duct involved. It is important to determine the direction of both ends of the bile duct, if a side-to-side communication is present, by gentle exploration with a thin, curved probe in order to place

the sutures correctly. Terminal branches can be sutured with or without T-tube drainage. CBC with segmental or hepatic ducts needs to be accurately visualized (preferably through the communication) and assessed.

It is my practice to gently clear the ectocyst and the fibrous layer overlying the bile duct in order to perform a secure tension-free suture of the orifice. The opening of the bile duct is cannulated with a transparent soft plastic cannula of similar size. Reflux of bile verifies the position of the cannula. Radio-opaque, diluted dye is injected and a fluorocholangiography is performed. The proximal and distal biliary tree is visualized. The point of entry of the cannula is visible during filling of the bile ducts, and it is possible to see the entire biliary tree. Presence of daughter cysts and debris in the CBD can be demonstrated. The filling of the duodenum is observed as well.

Management is based on the complete assessment of the CBC and should be as simple as possible. The large number of procedures described is confusing. All procedures can be classified, for didactic reasons, into five groups: (a) suture of the communication (e.g., simple suture, suture with T-tube CBD drainage, intralameral pericystectomy, and capitonnage), (b) internal drainage procedures (e.g., biliodigestive bypass, transduodenal sphincterotomy, internal transfistular drainage with or without transduodenal sphincteroplasty), (c) external drainage procedures (e.g., bipolar drainage, cystobiliary disconnection), (d) reconstructive procedures (e.g., pericystojejunostomy, intracavitary biliodigestive bypass, or bile duct repair), and (e) liver resection.

In my series, 272 of 1,333 patients (20.40%) had CBC. All procedures performed for the management of CBC are presented in Table 106.4. Simple procedures are adequate, and there is no need to invent new procedures or to improvise. In some patients with apparently bile-stained hydatid debris, after a meticulous search no CBC was detected and no additional procedure on the bile ducts was necessary. One possible explanation is that penetration of bile into the cyst caused death of the parasite and the small communicating bile duct was obliterated. It is also possible that the communicating bile duct was transected with the redundant portion of the pericyst and that suturing of the rim of the cyst obliterated it (Table 106.4).

In the majority of patients, the CBC is with a peripheral or small duct, and simple suture of the communication is sufficient. I use interrupted 3-0 or 4-0 resorbable sutures Vicryl, PDS (Ethicon, Ltd., Edinburgh, United

Kingdom), Dexon, Maxon, and Biosyn (Tyco HealthCare, Norwalk, USA). A cyst can have more than one communication.

The T-tube drainage of the CBD is infrequently added to the suture of the CBC, only in order to (a) secure and decompress a risky suture of a larger bile duct in a rigid pericyst or (b) to close the choledochotomy done for removing the hydatid debris in the CBD. If hydatid debris is detected in the CBD and a choledochotomy performed, the CBD has to be thoroughly cleansed and, if necessary, a choledochoscopy done before placement of the T-tube. After placing the T-tube and suturing the CBD, perioperative fluorocholangiography is performed.

TABLE 106.4 Procedures Performed in the Management of Bile Duct Communications

Procedure	Number of Patients	Percentage of 272 Patients
Suture	184	67.65
Nothing was done	29	10.67
Suture + T-tube	32	11.76
T-tube	18	6.62
Roux-en-Y cystojejunostomy	5	1.84
Roux-en-Y hepaticojejunostomy	2	0.73
Intracavitary reconstruction	2	0.73
Total	272	100

Infrequently, the orifice of the CBC and the communicating bile duct are not suitable for suturing. Combined drainage procedures that avoid any intervention on the orifice itself enable the fistula to seal spontaneously. This is achieved by placing local drains into the pericyst cavity and decompressing the biliary tree by either external or internal surgical procedures. In bipolar drainage, drains are placed into the pericyst cavity and the CBD is decompressed by a T-tube. In cystobiliary disconnection (Perdomo procedure), an anatomic disjunction between the residual cavity and the biliary fistula is achieved. A transparenchymal, multiperforated drain is passed through the CBC orifice to drain the fistula, while another multiperforated drain is placed into the cystic cavity to drain the cavity. The CBD is drained by a T-tube.

In internal drainage procedures, biliary decompression is achieved by (a) endoscopic papillotomy, (b) transduodenal sphincteroplasty, or (c) biliodigestive anastomosis.

A hilar cyst can have a CBC to a major duct that cannot be sutured

without compromising biliary drainage. In patients with this condition, depending on the size of the cyst and orifice, several options exist: (a) a Roux-en-Y cystojejunostomy, (b) a Roux-en-Y intracystic hepaticojejunostomy, (c) a Roux-en-Y hepaticojejunostomy, (d) intracystic bile duct repair, and (e) liver resection.

Indications for cystojejunostomy are extremely rare. In my experience, it was done only when a 3-cm cyst at the confluens transected the hepatic duct (a proximal and a distal orifice), and in order to avoid resection in a teenager from an endemic area. A Roux-en-Y intracystic hepaticojejunostomy is performed only when a voluminous, centrally located cyst communicating with the hepatic or segmental duct of the orifice is too large to suture. A transintestinal temporary drainage catheter is used when possible. A Roux-en-Y hepaticojejunostomy is indicated only when it is the only means to secure bile drainage. Intracystic bile duct repair is rarely feasible, and it is not a routine procedure. Meddlesome bile duct reconstruction fails, serious complications arise, and reoperation is frequently necessary. When adequate drainage of bile cannot be achieved, it is best to resect.

Biliodigestive bypass procedures are not frequently performed these days. The only indications are (a) massive penetration of hydatid debris and daughter cysts into the bile ducts, (b) a very distended and flaccid CBD, and (c) acute cholangitis. Choledochoduodenostomy was performed in the past when the bile ducts could not be completely cleared. I prefer Roux-en-Y hepaticojejunostomy when bypass is indicated. Indications for sphincteroplasty are very infrequent: (a) obstruction of the papilla with calcified hydatid debris and (b) short stricture at the papilla. Endoscopic papillotomy is the preferred option in most cases. Endoscopic management of CBCs needs further investigation.

Management of the Residual Cystic Cavity

In partial cystopericystectomy, the redundant portion of the pericyst is resected and, depending on cyst geometry, a residual cavity is left behind. It is easy to perform in uncomplicated cysts of all sizes located in accessible regions of the liver. Subtotal pericystectomy (fere totalis) is an alternative to partial cystopericystectomy when most of the pericyst is resected. Small calcified or adherent segments of the pericyst, adjacent to vascular and biliary structures, are left in place.

The residual cavity can be a source of postoperative complications in inexperienced hands. The residual cavity may be (a) superficial and

saucerlike, (b) anterior or inferior, (c) posterior and superior, or have (d) a large opening and large volume, (e) a small opening and a large volume, or may extend (f) through the full thickness of the liver parenchyma.

Because partial cystopericystectomy is the most frequently employed conservative procedure, several techniques for the safe obliteration of the residual pericyst cavity have been developed. The method of managing or obliterating the residual cavity should be selected carefully. The available options are (a) leaving the cyst open, (b) simple cyst closure, (c) marsupialization, (d) external tube drainage, (e) introflexion, (f) capitonnage, (g) omentoplasty, (h) partial capitonnage plus omentoplasty, and (i) Roux-en-Y cystojejunostomy (Figs. 106.6 and 106.7).

Leaving the Cyst Open

Large, shallow cavities that cannot be obliterated may be left open or covered with an omental flap sutured to the rim.

Simple Cyst Closure

The sterilized cyst cavity is filled with saline solution and closed by approximating the edges with running absorbable sutures. This procedure has very few indications, and it is applicable to small, noncalcified, and noninfected cysts only. Such cysts are usually managed by more efficient procedures. Deep residual cyst cavities, especially in the posterior aspect of the liver, should be obliterated because postoperative accumulation of fluid can cause serious complications.

Marsupialization

External cyst drainage by suturing the opening on the pericyst to the abdominal wall has been abandoned. Management of patients in this manner was cumbersome, prolonged, and not well tolerated. Suppuration and bleeding from the cyst was frequent. Morbidity was high.

External Tube Drainage

Operative external tube drainage was frequently used in the past for the management of simple or infected suppurated cysts. After evacuation and sterilization of the cyst cavity, one or more drains were left in place. Today, infected cysts, especially in septic patients, are managed by percutaneous drainage and simple cysts by the PAIR procedure.

Introflexion

Introflexion consists of folding in and approximating opposite edges of the pericyst and suturing them in place. Depending on the size of the cyst, it is sometimes necessary to fold into the cyst a part of the cyst wall including liver tissue covering the pericyst and suture them in place.

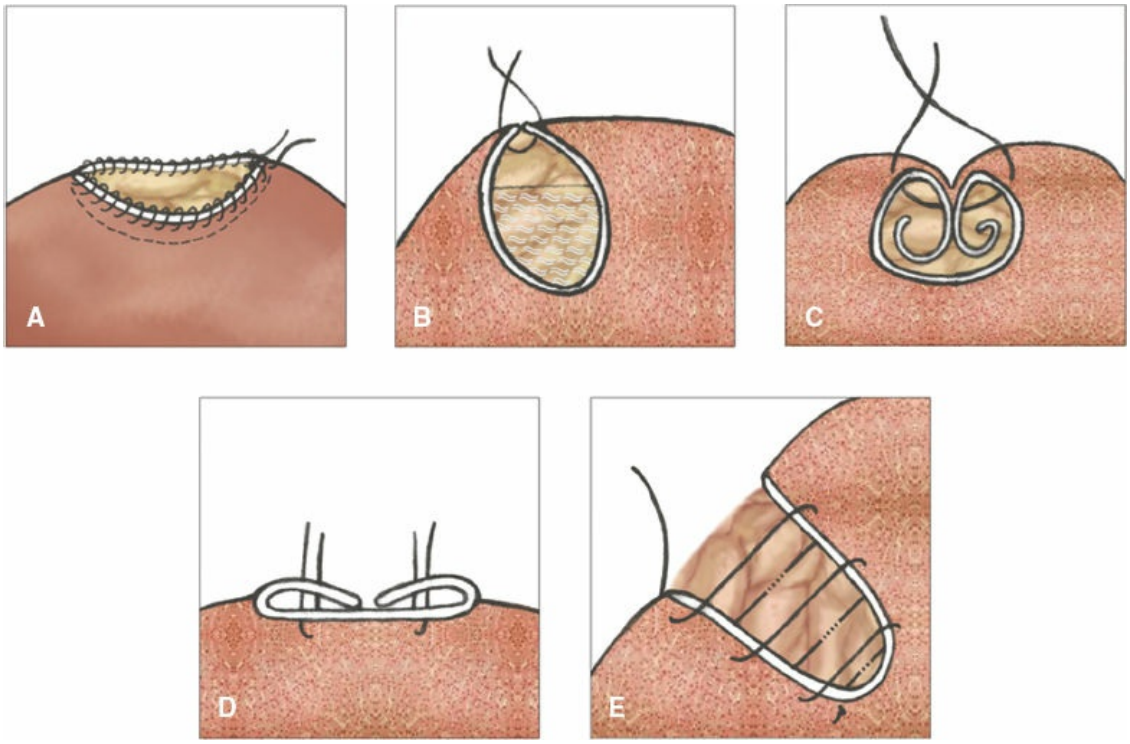

Figure 106.6. Management of the residual cavity. **A.** The pericyst cavity left open after oversewing the rim. This is applicable to small and shallow cavities. **B.** Simple closure of the cyst cavity filled with saline. **C.** Introflexion (infolding) of the rim of the pericyst cavity. Suture does not engage the bottom of the cavity. **D.** Flattening the rim of the pericyst in shallow cysts. **E.** Capitonnage. There is spiral suturing from the bottom of the cavity upward.

Capitonnage

Capitonnage involves infolding the redundant pericyst wall into the depths of the pericyst with successive layers of sutures. An alternate technique is circular suturing from the depth of the pericyst toward the surface. Capitonnage is not possible when the volume of the pericyst is large and when the walls are rigid or calcified. Care should be taken not to place sutures deep into the wall because hepatic veins can be injured. Uncontrolled tension on the sutures, in an attempt to completely obliterate the cavity, can tear liver parenchyma and result in troublesome bleeding.

Omentoplasty

The most frequently used procedure since the beginning of the 1970s is omentoplasty (Fig. 106.8). A vital omental flap is developed and placed into the remaining cyst cavity. The omentum is sutured in place with several absorbable sutures. If the cavity is deep and has a large volume, a closed-system drain is placed alongside the omentum. The drain has to be fixed onto the rim of the cyst opening with rapidly resorbable sutures (e.g., catgut) so that its tip remains in the most dependable portion of the pericyst. Some authors suggest that the liberal use of drains accounts for a high infection rate. The rationale for placing a drain is that there is always accumulation of some fluid in the cavity during the first several postoperative days. The drain is removed as soon as secretion stops. In my series, the pericyst cavity was drained in one third of the patients, the subhepatic space in two thirds, and the subphrenic space in one third. No increased incidence of infection was observed. The omentum does not prevent bile leaks and cannot handle excessive fluid collections. In large cysts that have a posteriorly placed opening that the omentum cannot reach, the omentum is introduced into the cyst from beneath the liver parenchyma.

Partial Capitonnage Plus Omentoplasty

Frequently, some degree of introflexion or partial capitonnage is done when performing omentoplasty. Whether this is beneficial is unclear, but unnecessary distortion of liver anatomy by tight sutures is not advocated.

Roux-en-Y Cystojejunostomy

Indications for this procedure are extremely rare because there are better options for all cyst types.

Myoplasty

Rectus abdominis and diaphragm muscle flaps have been used for obliterating the cyst cavity in complex situations.

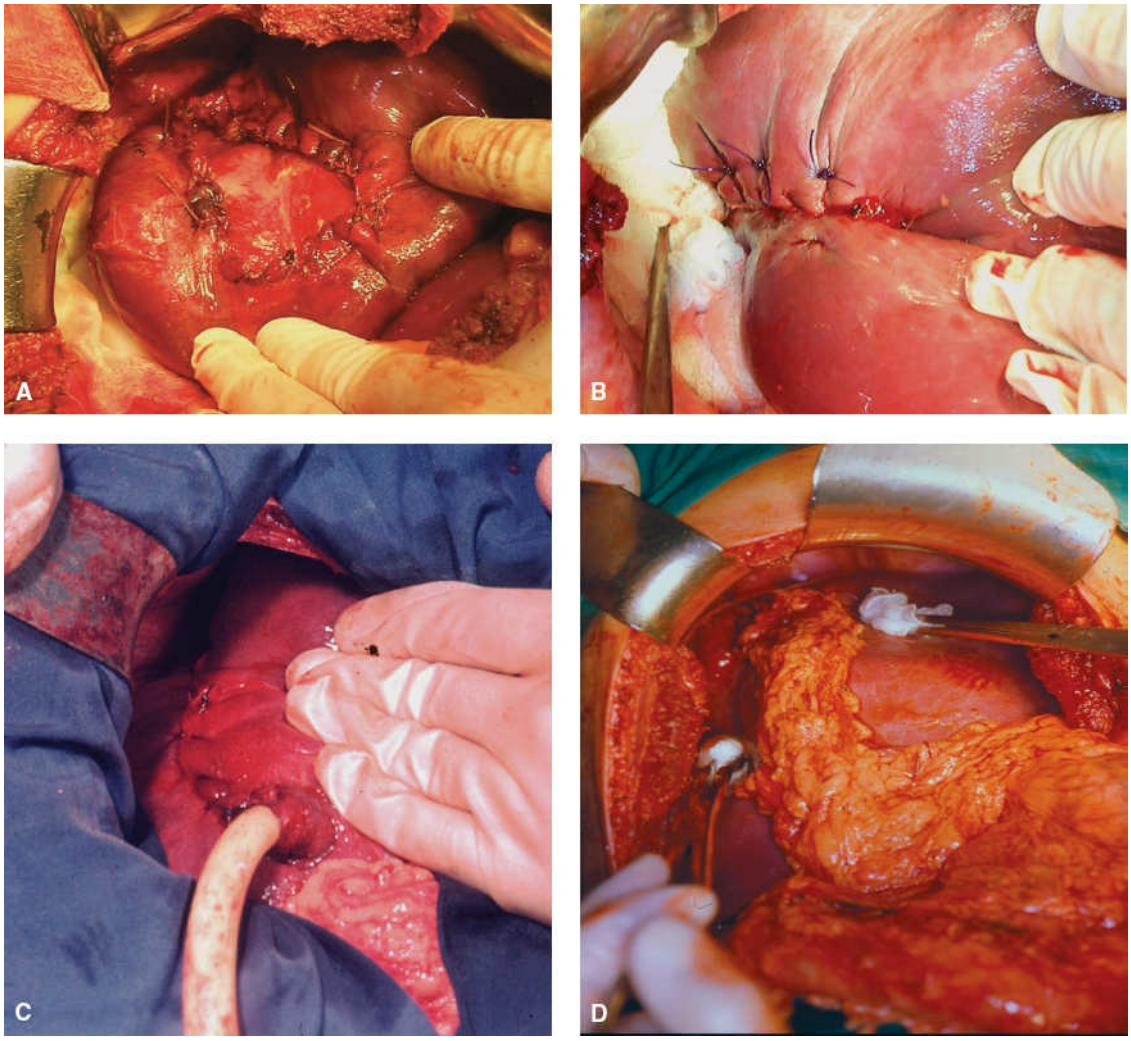

Figure 106.7. Techniques for the management of the residual cavity. **A.** Cyst with oversewn rim left open. **B.** Introflexion. **C.** Capitonnage with drainage. **D.** Omentoplasty.

In a single patient with multiple cysts, different procedures for managing the cavity can be used. The term *dominant cyst* denotes the one cyst in patients with multiple cysts that was either the largest, in the most difficult position, communicating, or complicated and causing the symptoms. Therefore, in the same patient, the other cysts, if simple, small, and in a peripheral position, were frequently managed by closed cystopericystectomy, which is not noted in the statistics. In my large series, 85.20% of dominant cysts in the liver were managed by conservative procedures (Table 106.5).

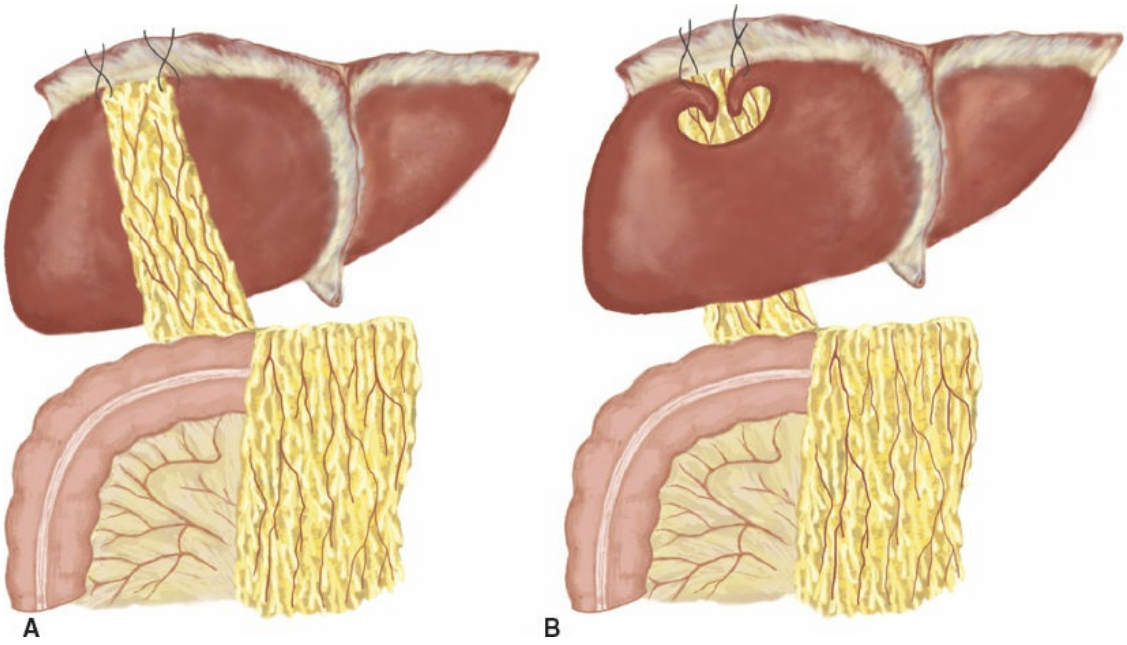

Figure 106.8. Omentoplasty. **A.** Anterior position of omentum. **B.** Posterior position of omentum.

TABLE 106.5 Procedures Performed on the Dominant Cyst

Operative Procedure	Number of Patients	Percentage of 1,333 Patients
Partial pericystectomy or introflexion + omentoplasty	796	59.71
Partial pericystectomy + capitonnage	245	18.39
Total cystopericystectomy	139	10.43
External drainage	6	0.45
Partial pericystectomy w/o external drainage	88	6.61
Left atypical liver resection	19	1.42
Left hepatectomy	18	1.35
Right atypical hepatectomy	19	1.42
Right hepatectomy	3	0.22
Total	1,333	100

Radical Surgical Procedures

Closed or open total cystopericystectomy (cystectomy) and liver resection have strict, defined indications. The rationale for performing liver resection for a benign disease that can be successfully managed by less extensive liver surgery with acceptable results needs to be evaluated in every patient. The majority of operations for liver hydatid disease are performed at general surgical departments in developing countries in which extensive expertise and facilities for major liver surgery are unavailable. Under such circumstances, a high postoperative morbidity and

mortality rate can be expected, especially as liver atrophy is frequently present because of the large size of the neglected cysts. These patients, following liver resection, return to an endemic area in which reinfestation is possible. Liver resection for hydatid disease is indicated in dedicated centers when (a) successful conservative surgery is not possible, (b) conservative tissue-sparing procedures failed to eliminate the disease, (c) the affected lobe or segment is irreversibly destroyed, and (d) efficient reconstruction of biliary drainage cannot be achieved. I performed radiofrequency-assisted Cool-tip (ValleyLab, Boulder, CO, USA) liver resection as well as total cystopericystectomy (cystectomy) in patients with hydatid disease when indicated. The radiofrequency probe, causing desiccation of a narrow, adjacent layer of liver parenchyma, secured excellent hemostasis and biliostasis.

Closed Cystectomy

Closed cystectomy is a complete removal of the cyst without opening it by creating a surgical plane just outside the pericyst layer. It is the ideal procedure to prevent contamination, manage CBC within the liver, reduce complications and morbidity, and shorten the hospital stay. It can be technically demanding, requiring meticulous dissection and hemostasis, and the use of powered instruments can be of some assistance, although it is not mandatory. When dealing with large and complex cysts, it is not a procedure to be suggested to surgeons with little experience in hepatic surgery.

An enlarging HC exerts pressure on surrounding liver parenchyma, causing an inflammatory reaction and progressive fibrosis encompassing and obstructing venous and biliary structures. Arteries, because of their thick and rigid wall, remain patent longer. The HC usually has a more or less irregular shape and the points where it establishes contact with the vasculobiliary structures appear “welded” to the cyst.

The liver should be mobilized and the operating field walled off. Closed cystectomy for cysts that reach the surface of the liver starts by developing a cleavage plane between the visible, smooth, fibrous cyst and the liver parenchyma where it “submerges.” The cyst can be separated from the liver tissue by blunt dissection following this plane (tip of curved dissecting scissors, curved thin hemostat). The dissection should be meticulous and always under visual control, advancing gently, pushing the liver parenchyma away from the cyst, in order to avoid severing biliovascular structures. Excessive, blind, forceful dissection can disrupt

biliovascular structures at the point where they adhere to the cyst surface and cause troublesome bleeding and bilirrhagia. Ligating these structures at a distance from the cyst can compromise blood drainage or cause ischemic areas of the liver. The cyst surface generally does not bleed and small bleeding points can be controlled by hot gauze packs or an argon beam (only superficial electrocautery is allowed). Standard diathermy and sutures should not be used. As the dissection advances, especially in large cysts, it is unavoidable to encounter more or less fibrotic biliovascular elements in a tangential relationship with the cyst. These should be gently dissected off the cyst surface if possible. If this is not possible, they need to be ligated by passing a ligature around them in close proximity with the cyst surface. If these biliovascular elements are torn, both ends need to be ligated. If a CBC is suspected, liver parenchyma around it should be teased away and the communication ligated first at the cyst side and then on the duct side and then cut between the ligatures in order to avoid cyst decompression. The mobilized cyst should be gently retracted in different directions to get a better view of the dissecting plane and dissection can be done from different directions if necessary. It is crucial to avoid injuring branches of the hepatic veins. Hepatic veins have thin walls and side branches and bleed intensely. It is important to preserve the veins whenever possible. Bleeding should be controlled by suturing the tear superficially with 5-0 or 6-0 vascular monofilament sutures. Dissection in closed cystectomy can be done with the aid of the harmonic scalpel, water jet, or RF ablation electrode. The raw surface of the liver is controlled for bleeding and bile fistulas. Argon beam coagulation or tissue glue can be applied. It is my practice to drain this area.

Open Cystectomy

Open cystectomy can be done as an elective procedure (cyst too big to be manipulated) or because the cyst has ruptured and the contents have spilled. The operative technique is essentially the same.

Near-Total Cystectomy

Near-total cystectomy can be done when part of the cyst is in close contact with the retrohepatic vena cava or major branches of the hepatic and portal veins. These vessels are more frequently in close contact to the cyst with a subsequent fibrotic reaction rather than the cyst infiltrating them. Although it is possible to separate these vessels, it is a better idea to leave a small sterilized portion of the cyst overlying them than to forcefully separate

them.

Subadvential Cystectomy

Subadvential cystectomy is a new operation proposed by Chinese authors. They theorize that the pericyst consists of two layers with distinct different formative mechanisms. The outer layer is the “adventitial” layer, and it is the result of compressive and fibrotic mechanisms and includes Glissonian biliovascular elements and branches of the hepatic veins. The inner layer is the avascular “exocyst” layer, and it is the result of a granulomatous reaction. Since these layers can be detached from each other, this procedure does not enter liver parenchyma and cause bleeding or biliorraghia. More experience is needed to establish the feasibility and efficacy of this procedure.

Nonanatomic Liver Resection

The majority of liver resections for cystic echinococcosis are nonanatomic wedge resections. A nonanatomic resection is sometimes safer than cystectomy because control of the biliovascular structures is facilitated. Some authors regard cystectomy as a nonanatomic liver resection because frequently an excised cyst has some liver parenchyma attached to it.

Anatomic Liver Resection

Anatomical liver resection is rarely indicated in cystic echinococcosis. It is indicated when it is impossible to salvage the affected liver lobe due to irreparable destruction caused by the parasite(s). Because of the distorted anatomy and extensive fibrosis, careful liver transaction is mandatory in order not to damage the remnant liver.

Completion Cystectopericystectomy in Residual Cavities With Complications

Conservative procedures for cystic echinococcosis leave residual cavities or parts of the pericyst in the liver, which can infrequently be the source of complications: (a) infection and inflammatory reaction, (b) intrahepatic and perihepatic abscesses, (c) permanent biliary fistulas in calcified pericysts, (d) cholangitis, and (e) recurrent cystic echinococcosis due to exogenous vesiculation. In these patients, completion cystectopericystectomy is frequently indicated. This is frequently a demanding operation due to dense adhesions, distorted anatomy, abscesses, and the adherence of the liver to adjacent organs. Frequently it

is the only way to resolve these complications, and if it is not possible liver resection should be performed.

Cystectomy for Cysts Engaging the Diaphragm

Total cystectomy for cysts at the dome of the liver engaging the diaphragm demands meticulous dissection. Frequently the cyst can be detached without resecting the diaphragm and total cystectomy performed in the usual manner. Sometimes it is necessary to excise the lower surface or full thickness of the diaphragm. If a bronchobiliary fistula exists, it is necessary to excise the diaphragm around the fistula, disconnect the fistula from the lung, and do a closed cystectomy. Management of the lung depends on the present pathology.

The Laparoscopic Approach

The first minimal access, laparoscopic, procedure for cystic liver echinococcosis was described in 1992. A PubMed English literature search in 2013 revealed only 57 relevant published articles including 914 operated patients with 1,116 HCs. Of these patients, 89.17% of patients were operated totally laparoscopically and only 5.58% by the gasless technique. Both radical and conservative procedures were done and the conversion rate to an open procedure was 4.92%. Clinical outcomes were comparable to open surgery, although in a group of selected patients. Some of the reported complications were related to the laparoscopic route.

The identified reasons for conversion were: (a) anatomical location, (b) inaccessible cyst, (c) bleeding, (d) adhesions, (e) inappropriate cyst stage, (f) impossible cyst identification, (g) inadequate evacuation of cyst content, (h) cyst close to major vessels, (i) risk of rupture, (j) iatrogenic liver injury, and (k) hematoma.

The procedures performed on the cyst and the liver during laparoscopic surgery mimic the procedures in open surgery. Length of hospital stay for laparoscopic cyst management was similar to the length of stay after PAIR. Nevertheless, in some developing countries PAIR is done on an outpatient bases. The hospital stay for open surgery is longer. Hospitalization probably depends on the type of cyst and surgery, concomitant diseases, drainage and other complications.

It is probable that the proportion of HCs operated by the laparoscopic route, in both nonendemic and endemic regions, will increase in the future. Indications for the laparoscopic management of liver HCs should not be

broadened just because the facilities are available. The procedures should be done by surgeons experienced in open hydatid surgery. It should be noted that PAIR is less invasive and provides good results. Chemotherapy should be considered in some patients.

Indications for the laparoscopic management of HCs should be strictly defined taking into account preoperative imaging and mapping of the cysts, extrahepatic disease, condition of the patient, availability of less invasive procedures, surgeon experience, and available equipment. Cyst stage and size are not necessarily limiting factors if surgery is warranted, but early-stage cysts are the preferred choice. Preoperative ABZ is advised.

Contraindications are: (a) intraparenchymal deep cysts, (b) inaccessible cysts, (c) recurrent cysts, (d) posterior cysts close to major vessels, (e) cysts with thick calcified wall, and (f) infected cysts (septic patients).

The advantages of laparoscopic surgery that are stressed by many authors are: (a) less pain, (b) better cosmetic results, (c) less blood transfusion, (d) shorter hospital stay, and (e) less adhesions. Potential disadvantages and limitations are: (a) fear of intraoperative spillage of cyst content, (b) uncontrollable bleeding, (c) unavailable adequate instruments, (d) incomplete exposure, (e) long learning curve, (f) difficult cavity obliteration, (g) inadequate postoperative drainage, (h) limited area of manipulation to posterior liver segments, and (i) inability to completely evacuate paste-like degenerated cystic contents. It has not been demonstrated that increased intra-abdominal pressure facilitates spillage of cyst contents.

The patient is in a supine position. The position of the surgeon and assistants and the placement of the trocars depend on the site of the cyst or cysts and personal preferences. There is no standard trocar placement recommended. The 30-degree telescope is introduced through a 10-mm umbilical port, and a 12-mm port is placed in the subxyphoid position for a large bore suction cannula. Two 5-mm trocars are placed on the left side in the standard cholecystectomy position and a fifth is placed on the left side above the level of the umbilicus. If available, laparoscopic ultrasound should be used for accurate orientation.

The critical moment is puncture of a vital cyst with the cyst contents under pressure. The puncture site of the cyst is encircled with long pieces of gauze soaked into a rapid-acting protoscolicidal agent. It is wise to have at least one additional suction cannula next to the puncture site. A large

gauge puncture needle is used to enter the cyst by the shortest route. Several techniques and special instruments have been described for safe cyst puncture and evacuation. After initial puncture of the cyst, a PAIR-like sequence is performed: puncture, aspiration, irrigation, filling with a noncaustic protoscolicidal agent, and reaspiration (decompression). The puncture site is enlarged by scissors or powered instruments, and the large bore suction cannula is introduced into the cyst. The irrigation and reaspiration sequence can be repeated several times until the cyst is completely evacuated. If the laminated membrane and detritus cannot be completely removed by aspiration, a grasper and a specimen retrieval bag are used. The laparoscope is introduced through the cyst orifice, and a thorough magnified view inspection of the cavity is done. If remaining daughter cysts or disrupted parts of the laminated membrane are detected, they are aspirated and removed. Special care should be taken to detect bile duct orifices secreting bile. An orifice secreting bile is cannulated and a cholangiogram performed. In the majority of patients, simple suture is sufficient. If the cyst contents were heavily stained with bile and a meticulous visual search for the orifices failed, a gauze strip is positioned into the cyst cavity and withdrawn after 10 minutes to see if it has bile staining. If still in doubt, a cholecystectomy and cholangiography are performed to verify whether a communication is present and there is hydatid debris in the CBD. The CBD can be cleared through a choledochotomy and closed over a “T” tube. The cyst cavity is exposed to a rapid-acting protoscolicide and flushed. The redundant portion of the cyst is excised, and the cavity managed in the same way as in open surgery. Omentoplasty is the easiest and most frequently applied procedure. Drainage of the cavity is optional.

Several technical innovations have been reported for save evacuation of the cyst contents under pressure, but none of them are in routine use. It is much more difficult to evacuate a cyst with dense, paste, or jelly-like contents, because one cannot be sure that the cyst is not vital. Special aspirator-grinders, powered by electro motors or compressed air turbines, have been developed, but these instruments are not in routine use.

The procedure of flushing the abdominal cavity with a protoscolicide solution or creating perihepatic lakes adjacent to the operation site cannot be recommended. The peritoneum readily absorbs the protoscolicide, especially since the procedure on the cyst can last quite long (eg. several bile duct orifices). Even the indiscriminate use of hypertonic saline can

cause hypernatremia.

The laparoscopic management of liver echinococcosis goes by the same principles as in open surgery only using a minimal access approach with limited maneuverability. Conservative procedures for cysts located in the posterior segments of the liver and radical procedures on the cyst should be reserved for centers with experience in both laparoscopic liver surgery and HC surgery. The procedure looks simple but the complications are severe.

COMPLICATIONS AND RESULTS

Immediate Postoperative Management

All patients should be entered into follow-up protocols. Repeat US examinations and chest radiographs during the immediate postoperative period after operation for large cysts, especially if the cysts were adherent to the diaphragm, are necessary. It is important to detect subdiaphragmatic and subhepatic fluid collection and diaphragmatic pleurisy at an early stage. The interpretation of US images of residual cavities persisting after operation is difficult. In children, within 6 months of operation, most of the cavities have disappeared, become calcified, or are substituted by fibrous scar tissue. Practically all residual cavities disappear by 18 months after operation. Cavities persisting after this period need diagnostic workup: (a) US monitoring, (b) CT or MRI, (c) serology, and (d) diagnostic puncture. The value of chemotherapy in these patients is uncertain. Reoperation is the ultimate option.

There are little relevant data about US patterns during and after medical treatment for liver hydatidosis. Patterns seen during successful medical treatment resemble the patterns seen in cases of spontaneous involution of the parasite. Repeated serologic tests during treatment are of no help in detecting the viability of the cyst.

Postoperative Complications

The incidence and significance of postoperative morbidity after conservative procedures have been exaggerated in many reports. The most frequent postoperative complications are (a) wound infection, (b) chest problems, (c) subphrenic abscess, (d) biliary leaks, and (e) liver abscess. Postoperative morbidity reflects the expertise of the surgeon and the structure of the patient population as well as the incidence of complicated

cysts. In my series, the postoperative morbidity rate was 17.1% for all types of conservative procedures and 15.2% for radical procedures. More than two thirds of all complications were wound infections and some chest problems. The chest complications are easy to manage. Subphrenic abscesses and liver abscesses were probably a result of inadequate surgery and early removal of drains. Today, both complications are managed by antibiotics and interventional radiologists.

Biliary leaks are managed nonoperatively. Bile leakage is drainage of bile through abdominal drains, regardless of quantity, no longer than 10 postoperative days. Persistent, stable external drainage of bile for more than 10 days is a biliary fistula. A biliary fistula is heralded by early postoperative external drainage of large quantities of bile. The most frequent causes are (a) an overlooked CBC, (b) injury to a bile duct, (c) inadequately managed CBC, (d) calcified pericyst, or (e) hydatid debris obstructing the CBD. Early management should be conservative. If an external biliary fistula persists, ERCP is performed, the CBC is verified, and papillotomy is done. Stents are usually not necessary. The optimal timing for ERCP is unknown. Reoperation and attempts at resuturing the fistula orifice are to be avoided. The one exception is when the orifice is in a calcified portion of the pericyst when it will not close spontaneously and more extensive surgery is needed. Endoscopic papillotomy has significantly reduced mortality and in-hospital stay. The success rate of endoscopic management is >85%, but the fistula closure time can last from a few days to a few weeks.

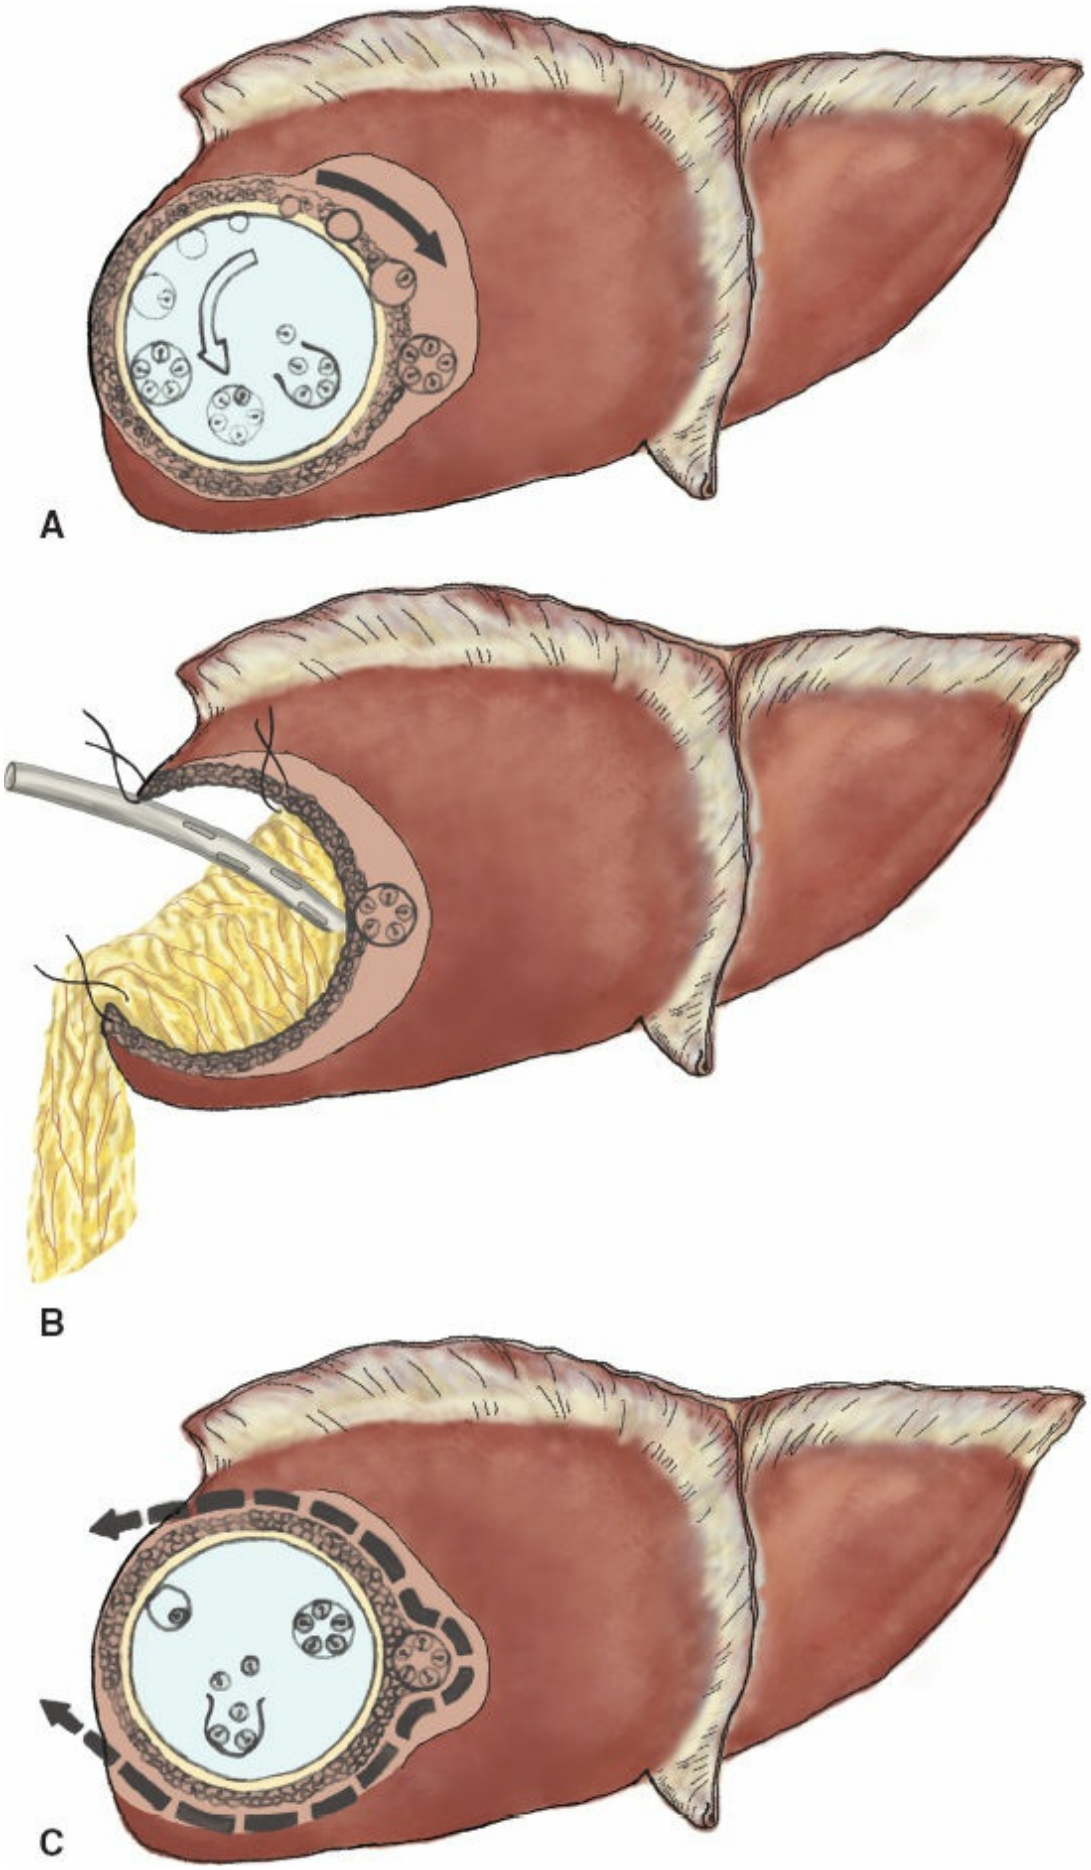
Biliary stricture after surgery for HCs is rare. Passage of even minor quantities of a potent protoscolicidal agent into the CBD can cause caustic cholangitis and subsequent biliary stricture. Attempts at repairing CBCs close to the BD confluence can result in stricture formation, which is hard to manage operatively. Stenting is an option.

In my series, the postoperative mortality was 2.10%. Factors influencing mortality were (a) complicated cysts, (b) communicating cysts, (c) reoperations, (d) concomitant disease, and (e) old age. In published large series, the reported mortality rate ranges from 2% to 4.5%, and in some series with recurrent disease and frequent reoperations the mortality rate was in excess of 10.0%.

Long-Term Postoperative Follow-Up and Recurrence

A postoperative long-term follow-up regimen is essential. Early

postoperative imaging provides a baseline for later comparison. Repeated US examination every 6 months is essential. If recurrence is suspected, a CT or MRI needs to be obtained. Serologic tests are difficult to interpret the first 24 months after operation. Blood titers may decrease very slowly (several months to several years) even after the complete removal of the cyst. It seems that it is the steady rise in the titer of serologic tests rather than the elevated postoperative titer that is indicative of the recurrence. Serologic tests used for the detection of recurrence are (a) complement fixation, (b) immunoelectrophoresis, (c) ELISA, (d) counterimmunoelectrophoresis, and (e) blotting.



A
B
C

Figure 106.9. Exogenous vesiculation as the cause of recurrence in conservative surgery. **A.** *White arrow* demonstrates development of daughter cysts (endogenous vesiculation) and *black arrow* demonstrates exogenous vesiculation where a daughter cyst passes through the wall of the cyst and develops into a new cyst outside of the original cavity. **B.** Conservative surgery fails to remove this vital cyst and recurrence occurs. **C.** Radical surgery (pericystectomy resection along the dotted line) removes the original cyst and the exogenous cyst as well.

In operated patients, US detection of a new cyst can be from (a) a cyst missed at operation, (b) local recurrence at the operative site, or "frank recurrence," (c) secondary intra-abdominal echinococcosis, (d) progression of disease after operation for secondary echinococcosis, (e) occurrence of cysts in other organs, and (f) reinfestation.

Recurrence refers to a cyst increasing in size between US examinations at the original operative site. This is the result of (a) overlooked exogenous vesiculation, (b) retained vital protoscoleces, or (c) parts of the germinative membrane left behind. A new cyst at a different site, a cyst overlooked at operation, and a cyst developing in another organ is not a recurrence. A new cyst developing in the peritoneal cavity after operation for secondary echinococcosis is progression of the disease. The longest interval after initial operation when a recurrence can start developing is not known (Fig. 106.9).

Recurrence can be asymptomatic. Symptoms of recurrence usually appear 3 to 5 years after recurrence. It is difficult to evaluate the merits of conservative surgery for liver hydatidosis with respect to recurrence because (a) recurrence in reported data is not accurately defined, (b) the series of operated patients have a different proportion of vital, multiple, multivesicular, and ruptured cysts, (c) operative techniques differ, and (d) patients are frequently lost to follow-up.

Published recurrence rates range from 0.9% to almost 30%. In my series, 4.50% of patients were treated for recurrence. In series with very high recurrence rates, there are a large proportion of patients who have had spontaneous or iatrogenic rupture (extrahepatic recurrence) of liver HCs. Some of the recurrences were obviously overlooked cysts. In my opinion, the tolerable recurrence rate should be under 5%. The effect of pre- and postoperative chemotherapy on recurrence needs further investigation.

Once recurrence is detected, options for treatment are (a) wait and see

(unclear diagnosis), (b) chemotherapy, (c) PAIR, and (d) reoperation followed by chemotherapy. I believe that it is how the operative procedure is performed and not only the radicality of the procedure that influences the recurrence rate.

EDITOR'S COMMENT

Although Echinococcus is fairly uncommon in North America, it is endemic in South America, the Mediterranean, the Middle East, and Asia. Given current travel and immigration patterns, infestation with this flatworm has global

implications. Dr. Milicevic has done an outstanding job in his description of the pathology and treatment of echinococcal disease, and I would like to take this opportunity to expound on the therapeutic approach to this entity.

The clinical management of liver hydatid cyst disease has evolved over the last three decades. In centers with special interest and resource-rich environments, patients benefit from an exceptional concentration of clinical experience and high technologic diagnostic and treatment facilities. On the other hand, endemic regions of the developing world with constrained resources have a limited choice of treatment modalities. Hence studies carried out in either of the two fundamentally different environments lack external validity. Most would agree that the therapeutic approach to patients with hepatic disease should be based upon the World Health Organization classification outlined in Table 106.3. Of note, each classification can be subdivided by size as small “s” (<5.0 cm), medium “m” (5 to 10 cm), and large “l” (>10 cm).

Chemotherapy with benzimidazole compounds is the medical treatment of choice. Only 30% of patients with CL, CE1, and CE3 cysts treated with chemotherapy alone experience a complete clinical or radiographic resolution. Percutaneous aspiration, injection, and re-aspiration (PAIR) is used frequently in patients who do not experience clinical resolution. Furthermore, CE2 cysts are typically managed with PAIR or surgery because they are frequently unresponsive to chemotherapy. The decision of whether to employ operative therapy or PAIR in patients with CE2 disease depends on the number of daughter cysts and the drainability of the cyst contents. Patients undergoing PAIR treatment typically undergo periprocedure chemotherapy with benzimidazole compounds, although the author does not think that adjuvant chemotherapy is necessary. I believe that additional discussion around the omission of chemotherapy agents in this patient population would greatly enhance this chapter.

Surgery is clearly the gold standard for the treatment of echinococcal disease and all patients with CE4 or CE5 cysts should undergo operative management. Basic principles of surgery include the removal of the cyst itself or evacuation of the cyst contents without spilling it in the peritoneal cavity, cyst neutralization with scolicidal agent, and obliteration of the residual cavity. Various procedures have been developed, including liver resections, total or partial pericystectomies, and unroofing the cyst with omentoplasty. While procedures such as marsupialization or simple drainage have been largely abandoned, radical procedures such as total pericystectomy or liver resection provide the best results concerning the recurrence of the disease, but they carry a certain operative and postoperative risk for complications that limit its applicability in resource-challenged environments. Laparoscopic surgery has been introduced lately as a minimally invasive approach to hydatid cystic disease of the liver.

Perhaps the greatest challenge in the management of hydatid cyst disease of the liver is communication with the biliary tract. The progressive enlargement

of the cyst causes pressure atrophy of the surrounding biliary canaliculi, leading to cystobiliary communication. These allow passage of the antigenic fluid and scolices down the biliary tract and the opposite flow of bile and infection into the cyst. If not adequately addressed, the communication results in bile leaks and subsequent choleperitoneum, biliary peritonitis, bile-stained pleural effusion, and biliary fistulae. The intraoperative detection and assessment of the cystobiliary communication is essential for adequate management; therefore, many experts perform an intraoperative cholangiography via the cystic duct. Dr. Milicevic proposes the use of saline and air bubbles to identify cystobiliary communications. He does a very nice job of describing his algorithm for inspecting the cystic duct and subsequent management of communications via suture of the communication, internal or external drainage procedures, reconstructive procedures, and liver resection. The author presents corrective procedures performed on his series of 272 cases in Table 105.4. I believe that this chapter would be enhanced greatly by a discussion of the long-term outcomes in this group of patients.

John Stewart

107 Hepatic Resection for Primary and Metastatic Tumors

Richard Schulick and Ana Luiza Mandelli Gleisner

INTRODUCTION

Major hepatic resection are defined as the resection of three or more liver segments based on Couinaud classification (Fig. 107.1). Major hepatic resections include the resection of the right or left hemilivers (right and left hepatectomies), the right liver along with segment IV (extended right hepatectomy or right trisectionectomy), and the resection of the left liver along with segments V and VIII (extended left hepatectomy or left trisectionectomy). Any of these resections may also involve removal of segment I, which is also referred to as the caudate lobe (Fig. 107.2).

The aforementioned nomenclature was introduced by the International Hepato-Pancreato-Biliary Association in the Brisbane 2000 Nomenclature of Hepatic Anatomy and Resections in an effort to accurately describe the hepatic anatomy and standardize the terminology in the field. This nomenclature also rendered use of the term *liver lobe* obsolete, as this implies the presence of a visible anatomic demarcation (i.e., the umbilical fissure). The current terminology recognizes the anatomic division of the liver based on the vascular watershed—the plane intersecting the gallbladder fossa and the inferior vena cava (IVC), that cannot be seen from the surface of the liver, as described by Cantlie in 1897.

INDICATIONS AND CONTRAINDICATIONS

Major liver resections (LRs) are indicated for the management of a number of primary and metastatic liver tumors (Table 107.1). Initially, the patient's overall health status should be evaluated to determine whether the risks of a major surgical procedure are justifiable and whether there are ways to optimize the patient's medical comorbidities and functional status. The next step is to determine if the resection is oncologically appropriate. For example, major LR is rarely justified in the presence of disease in both the right and left hemilivers (bilobar disease) or extrahepatic disease in

patients with hepatocellular carcinoma (HCC) or cholangiocarcinoma. In contrast, hepatic resection is often considered for patients with colorectal cancer, so long as the extrahepatic disease is limited and resectable. Finally, preoperative imaging is evaluated to determine the resectability of the disease. The goal of the resection is to obtain negative margins, while leaving adequate functional liver parenchyma, intact hepatic arterial and portal venous inflow, venous outflow, and biliary drainage in continuity with the small bowel. While large lesions may involve several segments of the liver, centrally located lesions, even if small, often cannot be removed without compromising biliary drainage, vascular inflow, or the venous outflow of several liver segments. Consequently, removal of these small, central lesions may require resection of a large amount of functional liver parenchyma, thereby increasing the risk of postoperative liver failure. The risk for postoperative liver failure and death is most pronounced in patients with chronic liver dysfunction, especially when there is evidence of cirrhosis. Therefore, these procedures should be limited to cirrhotic patients with Child–Turcotte–Pugh (CTP) class A and no evidence of significant portal hypertension (i.e., thrombocytopenia and history of variceal bleed).

assigned by Couinaud. (Reproduced from Hughes SJ. *Operative Techniques in Hepato-Pancreato-Biliary Surgery*. LWW, 2015.)

TABLE 107.1 Primary and Metastatic Tumors That May Require a Major Hepatic Resection

Primary liver tumors
Hepatocellular carcinoma
Cholangiocarcinoma
Hilar cholangiocarcinoma
Gallbladder cancer
Metastatic liver disease
Colorectal cancer
Neuroendocrine tumors
Noncolorectal nonneuroendocrine tumors

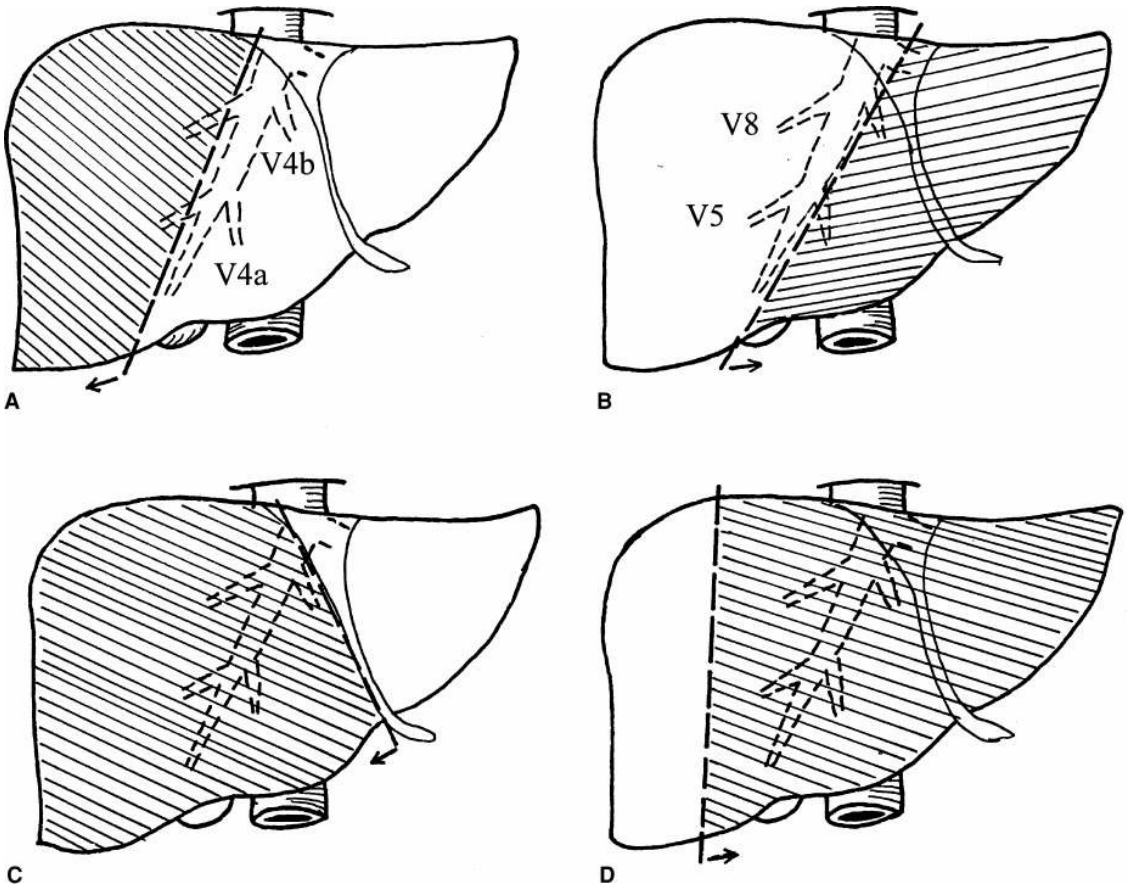

Figure 107.2. Major liver resections: right hepatectomy (**A**), left hepatectomy (**B**), extended right hepatectomy or right trisectionectomy (**C**), and extended left hepatectomy or left

trisectionectomy (**D**). The plane intersecting the gallbladder fossa and the IVC, described by Cantlie in 1897 separates the right and left livers.

For bilobar colorectal metastases, major resection can be combined with wedge resection or ablation of the lesions on the contralateral side. These procedures may be performed at the same time if the anticipated volume of future liver remnant (FLR) is sufficient for adequate hepatic function—otherwise, separate, staged operations should be considered. Superficial hepatic lesions resulting from colorectal metastasis should be treated according to a parenchyma-sparing strategy, with nonanatomic (wedge) resections preferred over anatomic resections if negative margins can be obtained. In patients with colorectal cancer and synchronous hepatic metastasis, the primary tumor and the liver disease can be resected at the same time or separately. Concomitant liver and colorectal resection should be strongly considered when only a minor LR is required or when the colon surgery is straightforward. Major LRs should, however, be avoided when complex colorectal procedures are performed, such as those requiring extensive pelvic dissection or a low rectal anastomosis. In these situations, the hepatic metastases can be addressed first or after resection of the primary. Because the liver is usually the determinant factor for complete disease resection, the “liver first” approach is an attractive option since resectability of the liver metastases will influence the need or extent of the resection of the primary tumor. Occasionally, however, the primary tumor is symptomatic and needs to be addressed first. Typically, preoperative chemotherapy is given to assess tumor response. However, prolonged modern chemotherapy for colorectal cancer can be associated with significant injury to the liver, with increased risk of postoperative complications following LR. Specifically, irinotecan-based treatment is associated with steatohepatitis while Oxaliplatin-based chemotherapy is associated with sinusoidal congestion. The surgeon and the medical oncologist need to work closely to determine optimal duration of preoperative chemotherapy and timing for the surgical procedures.

Alternatives to LR include various ablative techniques. Thermal ablation using heat (radiofrequency and microwave ablation) is currently the most widely used modality, whereas the use of cryoablation has decreased significantly. Irreversible electroporation, a newer technology based on short-duration, high-voltage pulses that result in defects in the lipid bilayer—and, ultimately, cell necrosis—is emerging as an attractive

substitute to thermal ablation. One primary advantage of irreversible electroporation is its ability to target tumors near vascular structures without creating the heat-sink effect that is associated with use of thermal ablation (deflection in the ablation zone due to heat-loss to adjacent vascular structures). Ablation techniques have been shown to be safe and to have low risk of local recurrence (～5%), especially when applied to smaller tumors (<3 cm). These techniques should be considered in small lesions that would otherwise require a large amount of liver parenchyma to be resected, especially in patients with liver dysfunction. Yet, some observational studies have suggested that long-term results with resection are superior to those with ablation, even when only smaller and solitary lesions are considered. Although patient selection likely plays a role in these findings, in the absence of a randomized trial, ablation should not be recommended over resection for patients with resectable lesions and acceptable performance status.

PREOPERATIVE PLANNING

The location of the hepatic lesions and their relationship to the main branches of the portal vein and the hepatic artery, the hepatic veins and the biliary tree should be determined with high-quality imaging (Fig. 107.3). Computed tomography (CT) scan is usually the method of choice but magnetic resonance imaging (MRI) is emerging as a very useful imaging adjunct, especially in patients with steatosis or lesions that cannot be visualized after preoperative chemotherapy. Positron emission tomography (PET) should be used selectively in patients at high risk for extrahepatic metastasis, as higher rates of false negative findings limit its use in patients undergoing chemotherapy or with lesions smaller than 1 cm.

Once the lesions are identified and the planned procedure confirmed, the volume of the FLR is estimated. The volume of the FLR needed to minimize the chances of postoperative liver insufficiency varies according to the quality of the liver remnant. HCC and cholangiocarcinoma are often associated with chronic liver disease (CLD) and preoperative chemotherapy can induce significant liver damage as discussed above. For patients with a healthy liver, the FLR should be at least 20% of the total liver volume. Patients with abnormal background liver (i.e., following preoperative chemotherapy) should have an FLR of at least 30% the total liver volume while those with cirrhosis should have an FLR of at least 40%. When questionable, formal volumetry of the FLR should be

performed. The volume of the expected remnant liver and the total liver volume are measured using either CT scan or MRI. The volume of the nonfunctional liver (parenchyma that is either nonperfused or replaced by tumor) is subtracted from the total liver volume, which is especially important for patients with large lesions. Alternatively, the total liver volume can be estimated with different formulas based on the patient's weight or body surface area. Portal vein embolization (PVE) should be considered for patients with insufficient FLR. PVE involves selective occlusion of the branches of the portal vein feeding the segments planned for resection, inducing contralateral hypertrophy. Volumetry is repeated 4 weeks after the procedure and again in a few more weeks if the minimal recommended FLR has not been achieved (Fig. 107.4). The degree of hypertrophy of the remnant (at least 5% increase in volume or a rate of at least 2% increase per week) has been shown to be correlated with decreased rates of postoperative liver insufficiency.

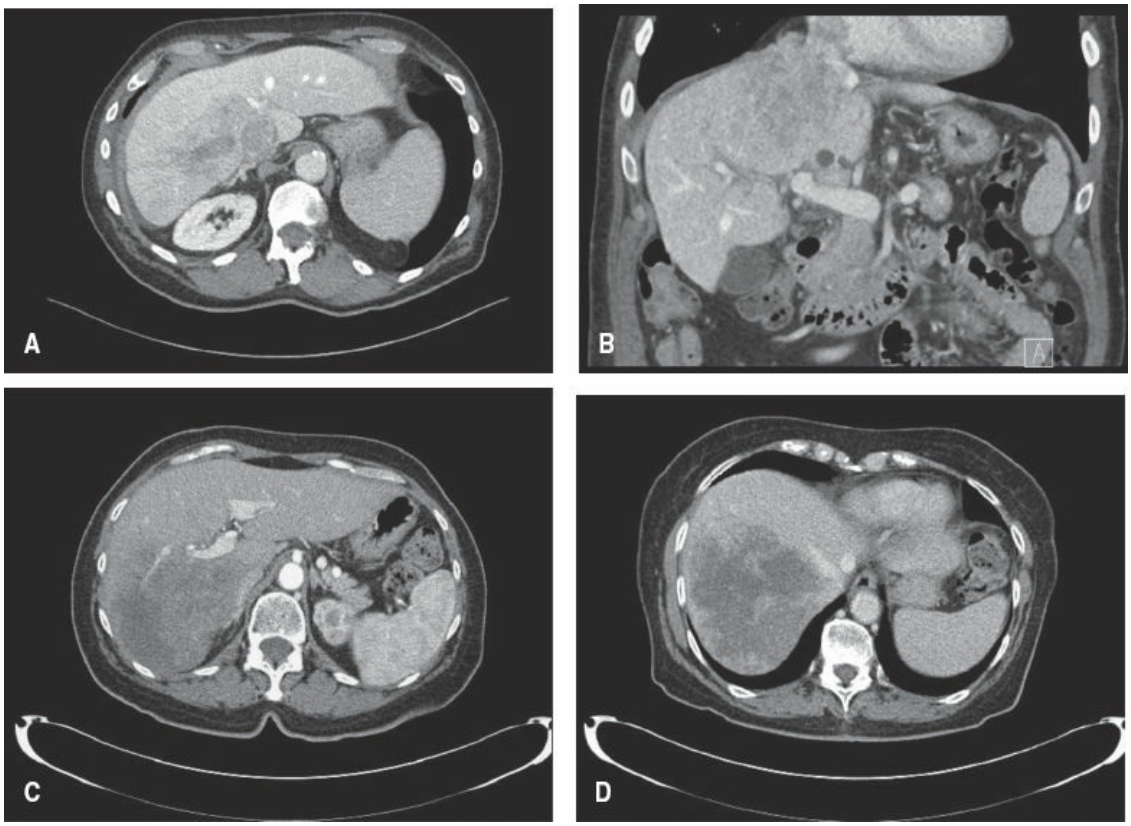

Figure 107.3. Imaging showing hepatic lesions and the relationship with hepatic vessels. **A.** A lesion on the right liver encases the right hepatic vein and abuts the middle hepatic vein. **B.** Coronal reconstruction shows invasion of the tumor into the IVC, extending to the right atrium. A lesion on the right liver encases the right portal vein (**C**) and the right hepatic vein (**D**).

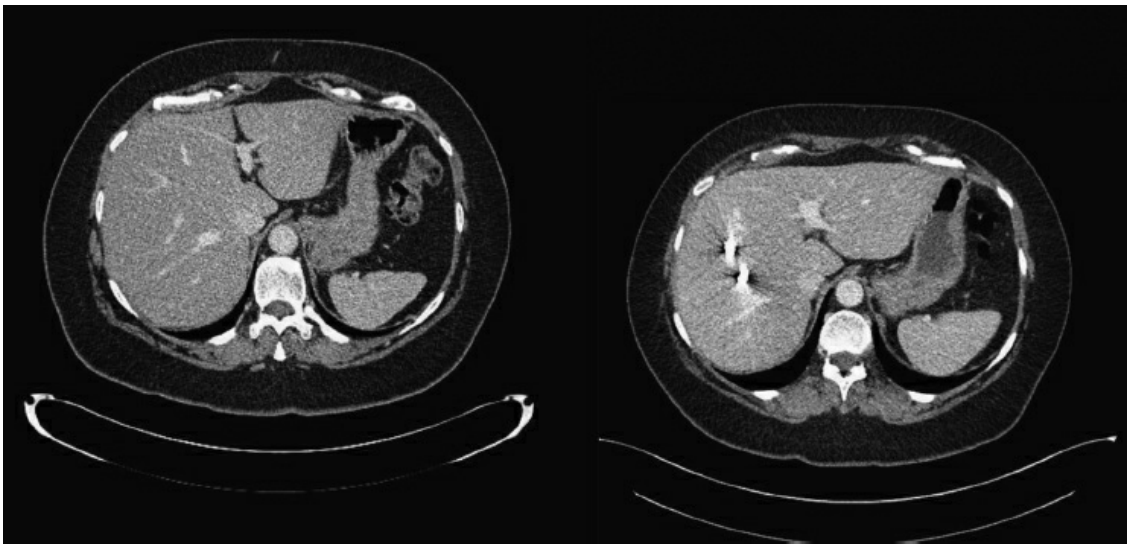

Figure 107.4. Future liver remnant (FLR) before and after portal vein embolization. The volume of the FLR increased by 30% 4 weeks after portal vein embolization. It went from 18% of the estimated total liver to 25%. (Courtesy of Ana Gleisner.)

Anesthetic Considerations

The surgical and anesthesia teams should confer preoperatively to discuss the relative difficulty of the resection and ensure availability of blood products. Hemodynamic goals and blood transfusion threshold should also be established. Adequate venous access for rapid transfusion should be available in the event of major intraoperative bleeding. Central venous cannulation is not mandatory but should be considered in patients with extensive comorbidities, insufficient peripheral access or when the LR is expected to be more challenging. Arterial blood pressure monitoring is strongly encouraged. An orogastric tube should be placed after induction of anesthesia and removed at the end of the case. Intravenous fluids should be restricted until transection of the parenchyma is completed in order to decrease bleeding from hepatic veins, maintaining a central venous pressure less than 5 cm H_2O if a central line is utilized. Once the parenchymal transection has been completed, intravascular volume should be restored to achieve isovolemia. Prophylactic antibiotics are given prior to skin incision. Body temperature should be monitored and normothermia should be maintained.

SURGICAL TECHNIQUE

Patient Positioning, Incision, and Exposure

Patients are positioned supine with both arms extended at 60 degrees to avoid injury to the brachial plexus. Exposure should include the lower chest, up to the nipple line, and the entire abdomen, including both midaxillary lines. Prior to transection of the hepatic parenchyma, the patient should be positioned in Trendelenburg to decrease the risk of air embolism.

A right subcostal incision with an upper midline extension is performed (Fig. 107.5). This incision can be extended to the left subcostal margin if needed. Resection of the xiphoid is performed for better visualization of the suprahepatic IVC. Exposure is obtained with a fixed table retractor, such as the Thompson, Bookwalter, or Omni retractors. For bulky tumors in the right liver that are located near or involve the diaphragm, a J-shaped incision—with a curved thoracoabdominal extension from the midline along the eighth, ninth, or tenth intercostal space—can be performed to allow exposure of the IVC without excessive traction to the liver.

The abdominal cavity is first explored to rule out undiagnosed extrahepatic disease. Once the decision has been made to proceed with the hepatic resection, the round ligament and the falciform ligament are located and dissected up to the anterior surface of the hepatic veins. The gastrohepatic ligament is then opened to expose the caudate lobe. The presence of an accessory or replaced left hepatic artery should be determined. Intraoperative ultrasound is used to evaluate known lesions, survey for new lesions, and determine the relationship of each lesion with nearby vascular and biliary structures. Ultrasound is also used to evaluate the position of the main hepatic vessels relative to the transection plane. Once the planned surgical procedure is confirmed, cholecystectomy is performed, leaving the gallbladder attached to the cystic duct to be used for retraction. The hilar plate is lowered in preparation for inflow control.

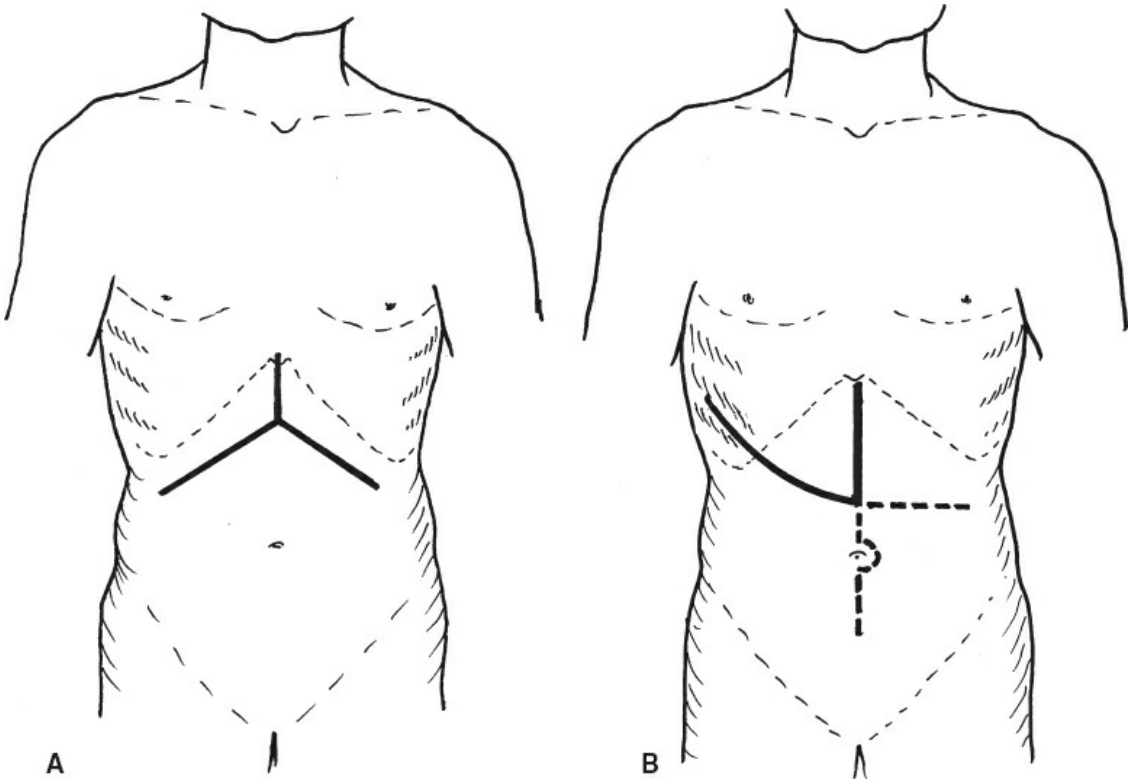

Figure 107.5. A. Bilateral subcostal incision. The midline incision should include excision of the xiphoid process. **B.** A J-shaped incision (popularized by M. Makuuchi) facilitates exposure of segments VII, VIII, or the bulky tumor involving the right diaphragm. If needed, the incision can be extended to the left or lower abdomen.

Parenchymal Transection

Transection of the liver parenchyma can be performed with multiple techniques, most often a combination of techniques, according to the surgeon's experience and preference. More important than the chosen method is the surgeon's utilization of preoperative imaging and intraoperative ultrasound to appreciate the relationship between the transection plane and the intrahepatic vessels. Inflow control prior to the transection will result in a vascular demarcation line that will guide the correct transection plane.

The capsule of the liver is initially incised with electrocautery. Transection of the parenchyma is then performed with or without the use of one of the several energy devices available, including water jet-based devices, bipolar, ultrasound, radiofrequency and microwave energy devices. Parenchymal transection can be performed with finger fracture (digitoclasy) or clamp crushing, which consists of gentle fracture of the

parenchyma while preserving vessels and bile ducts crossing the transection plane. These structures are then controlled with ties, clips, energy devices, or stapler for larger structures. Two devices also work by disrupting the parenchyma while preserving the vessels and bile ducts: the Hydrojet, which uses a water jet and the Cavitron Ultrasonic Surgical Aspirator (CUSA), which uses ultrasound energy. The potential advantage of these devices is greater accuracy, with CUSA providing the additional benefit of some degree of hemostasis. While these techniques are associated with limited devascularization of the liver along the transection line, bleeding from small vessels can be considerable. Bipolar (i.e., LigaSure) and ultrasonic (Harmonic Scalpel) vessel-sealing devices can be used for control of vessels up to 7 to 8 mm—decreasing the need for ties and clips and, thereby, resulting in faster transection. Hemostatic devices such as the argon beam coagulator and the radiofrequency sealer devices (i.e., TissueLink and Aquamantys) are very useful to control bleeding from the cut edge of the liver. Radiofrequency (i.e., Habib 4X) and microwave ablation devices can also be used to precoagulate the transection plane followed by sharp transection, although larger vessels still need to be controlled. Finally, staple devices can be employed for the division of large vessels or, alternatively, for the transection of most of the parenchyma with the serial application of staples in a track created by the gentle application of a large clamp.

After the transection of the parenchyma is completed, the cut edge of the liver is inspected and bleeding and/or bile are controlled with figure-of-eight sutures, argon beam coagulator, or radiofrequency sealer devices as needed. If applied, the Pringle maneuver is then released while continuing to assess hemostasis. Large sutures should be avoided in order to prevent the inclusion of the hepatic veins. Coagulation devices should be used with caution to avoid heat-induced destruction of hemostatic sutures. Hemostatic agents (i.e., Surgicel) can be applied to the cut edge of the liver for further hemostasis. Injection of normal saline through a catheter in the cystic duct is useful to detect extravasation from bile ducts at the cut surface. Bile leakage at the hilar plate should be controlled with 6-0 PDS sutures.

Pringle Maneuver

Occlusion of the portal triad (Pringle maneuver) can be performed prior to the transection of the parenchyma to decrease blood loss. The liver can

tolerate up to 1 hour of ischemia but intermittent vascular occlusion with cycles of 15 to 20 minutes on and 5 minutes off will decrease the ischemia/reperfusion injury which is especially important in cirrhotic livers. Total ischemic time should not exceed 120 minutes.

Right Hepatectomy

Further dissection of the anterior surface of the hepatic veins is carried out to expose the right hepatic vein. The right coronary and triangular ligaments are then divided, exposing the bare area of the liver as the right liver is mobilized and rotated to the left. The right phrenic vein is identified as it drains into the right hepatic vein. Short hepatic veins draining directly to the IVC are ligated with silk ties and/or surgical clips starting distally and proceeding cephalad. Larger veins such as an inferior right hepatic vein may require ligation with a vascular stapler. Smaller vessels can be divided with energy devices such as the Harmonic scalpel or the LigaSure. Large branches from the caudate lobe should be preserved on the medial aspect of the IVC. The retrocaval ligament (Makuuchi ligament) is identified as dissection continues cranially (Fig. 107.6). This ligament is variable in thickness and occasionally contains liver parenchyma or a vein. Consequently, the retrocaval ligament is most safely transected with a vascular stapler. Further dissection between the liver and the IVC will expose the right hepatic vein. The fibrous tissue medial to the vein, between the liver and the IVC, is dissected superiorly. A clamp is passed from below, anterior to the IVC, to emerge between the middle and the right hepatic vein, which is encircled. Attention is turned to the hilum which is dissected for inflow control. The right hepatic artery—traversing between the hepatic duct and the portal vein in 80% of the patients—should be dissected lateral to the hepatic duct to avoid injury to the arterial branch to segment IV, which occasionally arises from this artery. After arterial flow to the left liver is confirmed either by palpation or Doppler ultrasonography, the right hepatic artery is doubly ligated and divided. The common bile duct is retracted medially with a vein retractor exposing the portal bifurcation. The right portal vein is then dissected and divided with a vascular stapler. A branch to the caudate process should be identified and ligated just distal to the portal vein bifurcation to allow enough mobilization of the right portal vein. If a vascular stapler cannot be applied, the vein can be divided between vascular clamps and doubly ligated with a silk suture on the liver side and a running 6-0 prolene suture

on the hilum. In some cases, the main portal vein trifurcates in left, right anterior, and right posterior branches. In this situation, each of the two branches to the right hemiliver are addressed separately. A clear line of vascular demarcation can then be identified between the right and left hemilivers. At this point, the right hepatic duct can be dissected and ligated at the hilum. However, unless necessary for oncologic purposes, the right hepatic duct should be ligated intrahepatically in order to avoid injury to the left hepatic duct. The right hepatic duct will be identified as the transection of the parenchyma approaches the left base of the gallbladder fossa (Fig. 107.7). In about 30% of the patients, the right anterior and the right posterior sectoral ducts drain into the hepatic duct separately and in 6% of the patients, the right anterior or the right posterior sectoral branches drain to the left hepatic duct. The right hepatic duct or sectoral ducts are divided with a vascular stapler or between two vascular clamps and oversewn with 5-0 PDS.

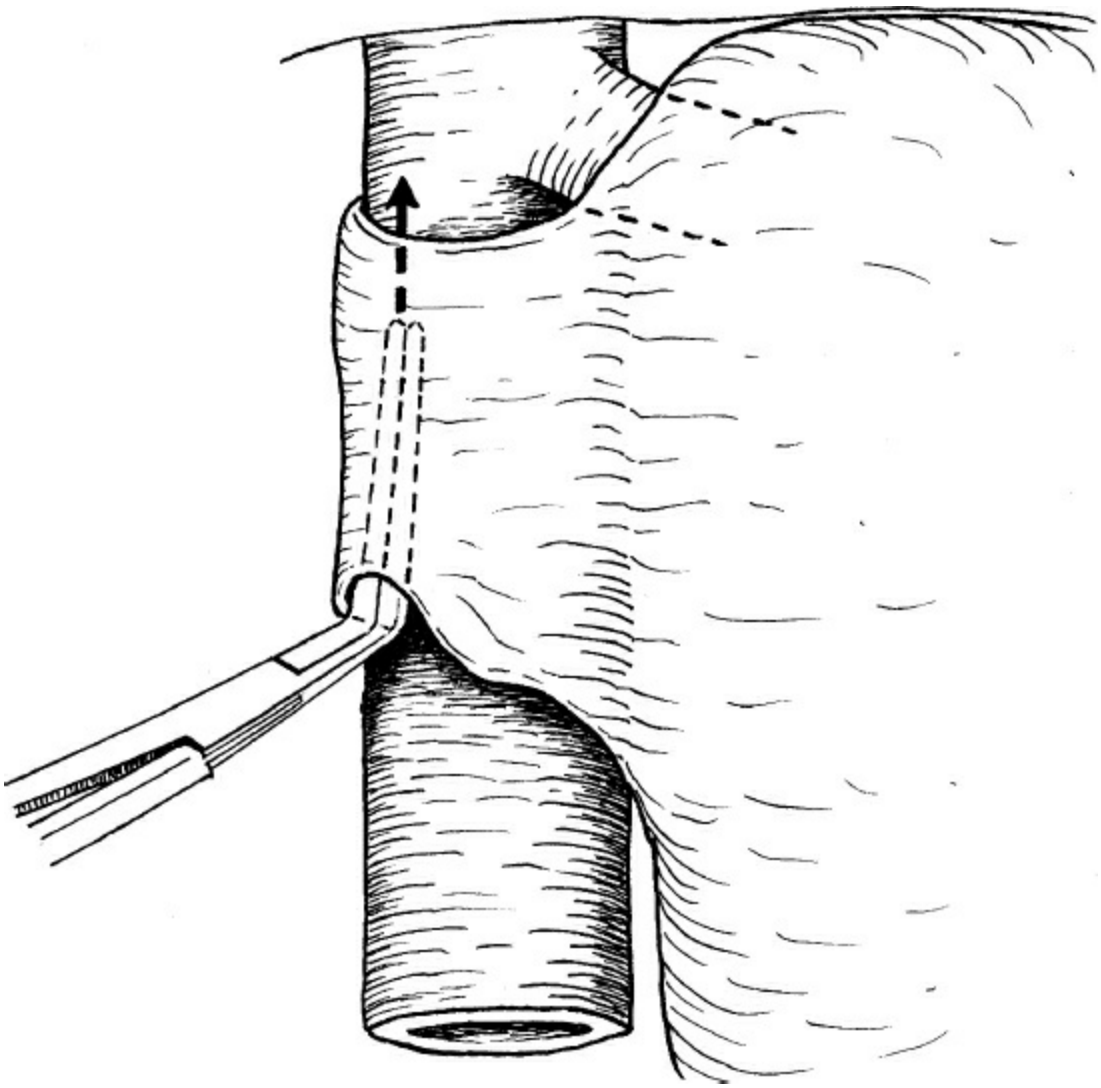

Figure 107.6. The retrocaval ligament (Makuuchi's ligament) is identified as the liver is rotated to the left, exposing the inferior vena cava. This ligament may contain liver parenchyma and/or a vein and is most safely transected with a stapler. Transection will allow exposure and control of the right hepatic vein.

An alternative technique for inflow control includes ligation of the right portal pedicle intrahepatically, either prior to or after transection of the parenchyma. In the Glissonian technique, initially described by Takasaki, the pedicle to the right liver is controlled prior to the transection of the parenchyma with two incisions: one incision is made at the left base of the gallbladder fossa just above the hilum and another is made at the junction of segment VII and the caudate process (Fig. 107.8). This second incision is perpendicular to the hilum. A large curved clamp is passed above and behind the right hilar pedicle to emerge in front of the IVC. An umbilical tape encircling the pedicle is drawn to the left and the pedicle is transected with a vascular stapler. Alternatively, each blade of a vascular clamp can be introduced into the two incisions. The clamp is closed occluding the main right pedicular sheath and vascular demarcation is noticed. The clamp is replaced by a vascular stapler, which is ultimately fired.

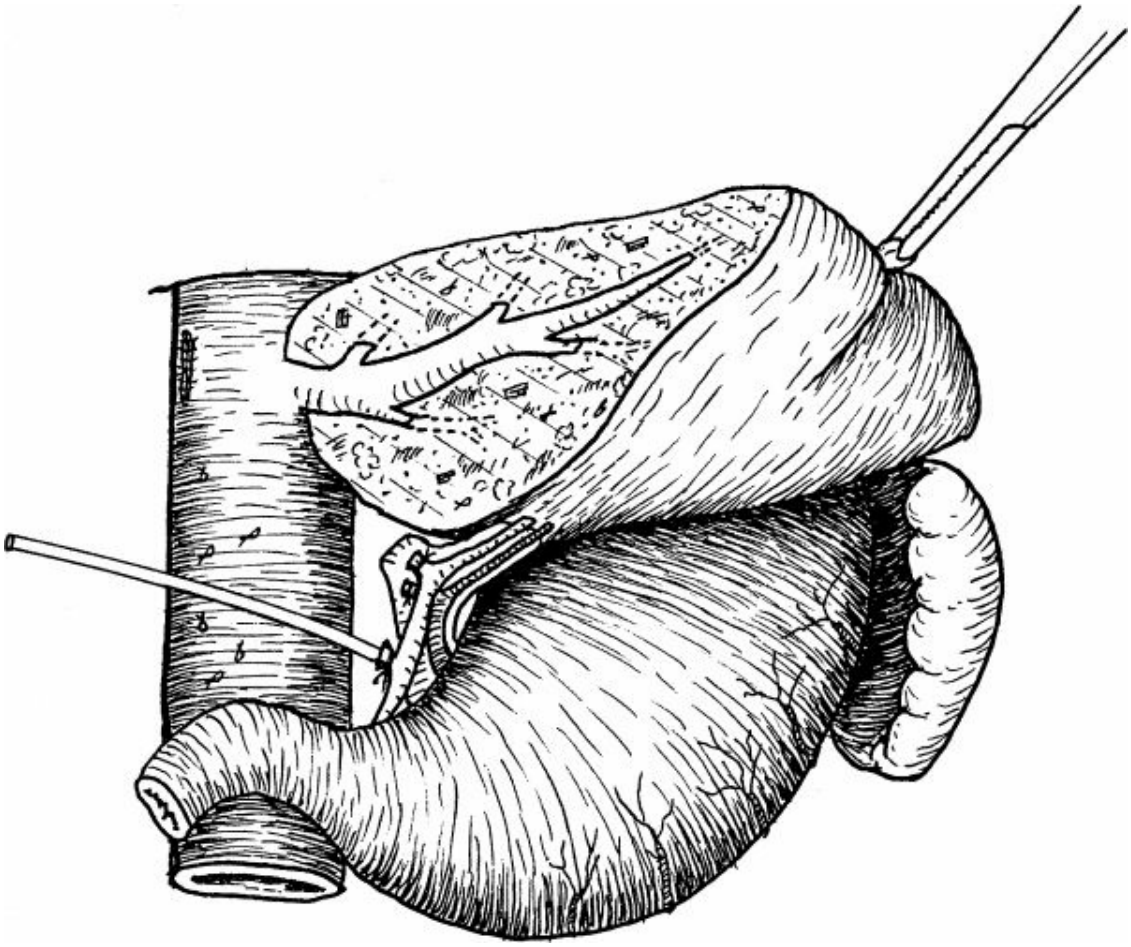

Figure 107.7. For a right hepatectomy, the right hepatic artery is ligated lateral to the bile duct. The bile duct is retracted medially and the right portal vein is ligated. The transection plane follows the area of vascular demarcation along the right side of the middle hepatic vein, from the left side of the gallbladder fossa to the IVC. The right hepatic duct is identified and transected as the transection plane approaches the left base of the gallbladder fossa.

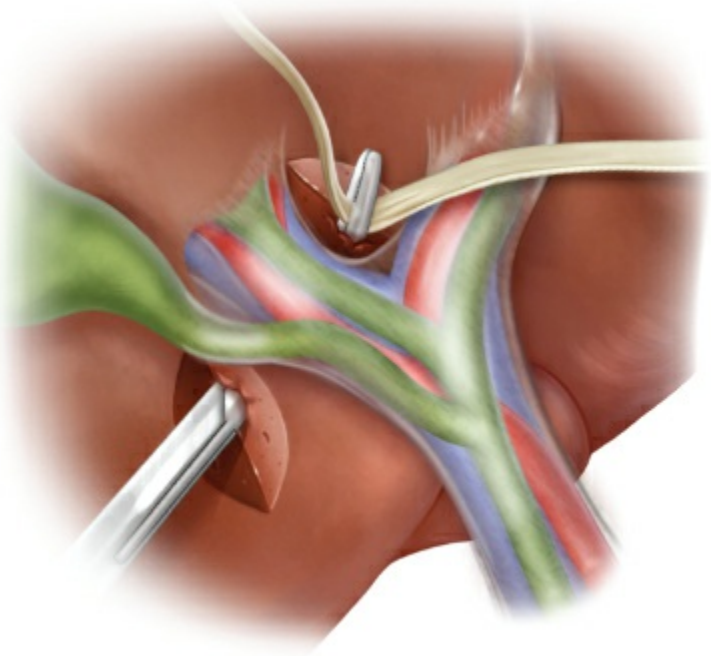

Figure 107.8. Glissonian approach for inflow control of the right hilar pedicle. A hepatotomy is made at the left base of the gallbladder fossa above the hilum. A second hepatotomy is made at the junction of segment VII and the caudate process.

Next, the right hepatic vein is divided with a vascular stapler for outflow control. Alternatively, the vein can be divided between vascular clamps. Two clamps should be placed on the IVC side and, after the vein is transected with a scalpel, one clamp is removed and the stump is closed with a 3-0 polypropylene suture. The proximal stump is also secured with a 3-0 polypropylene suture. The location of the middle hepatic vein is confirmed with the ultrasound and the parenchyma is transected at the area of vascular demarcation, with or without occlusion of the hilum (Pringle maneuver). The transection plane is shifted to the left of the gallbladder fossa at the inferior aspect of the liver to avoid longitudinal transection of the middle hepatic vein. As the transection moves cranially, the terminal branch of the middle hepatic vein is identified and ligated and the dissection continues on the right side of the vein. The parenchymal transection plane is oblique in relation to the IVC, toward the site of division of the right hepatic duct.

If the caudate lobe is to be removed along with the right hemiliver, it should be lifted and dissected from the IVC, with serial ligation of the direct short hepatic veins from the right of the IVC to the left, as an extension of the retrohepatic dissection. Inflow control to segment I is

obtained at the base of the umbilical fissure, as the caudate branches from the left hepatic artery and left portal vein are identified, ligated, and divided. The left lateral segment of the liver is mobilized and rotated to the right and the fibrous tissue connecting the caudate lobe to the IVC is transected. Ligation of remaining retrohepatic veins is then performed. Liver transection continues from the site of transection of the right hepatic duct horizontally, underneath the middle hepatic vein and the left hilar plate, toward the ligamentum venosum (Fig. 107.9).

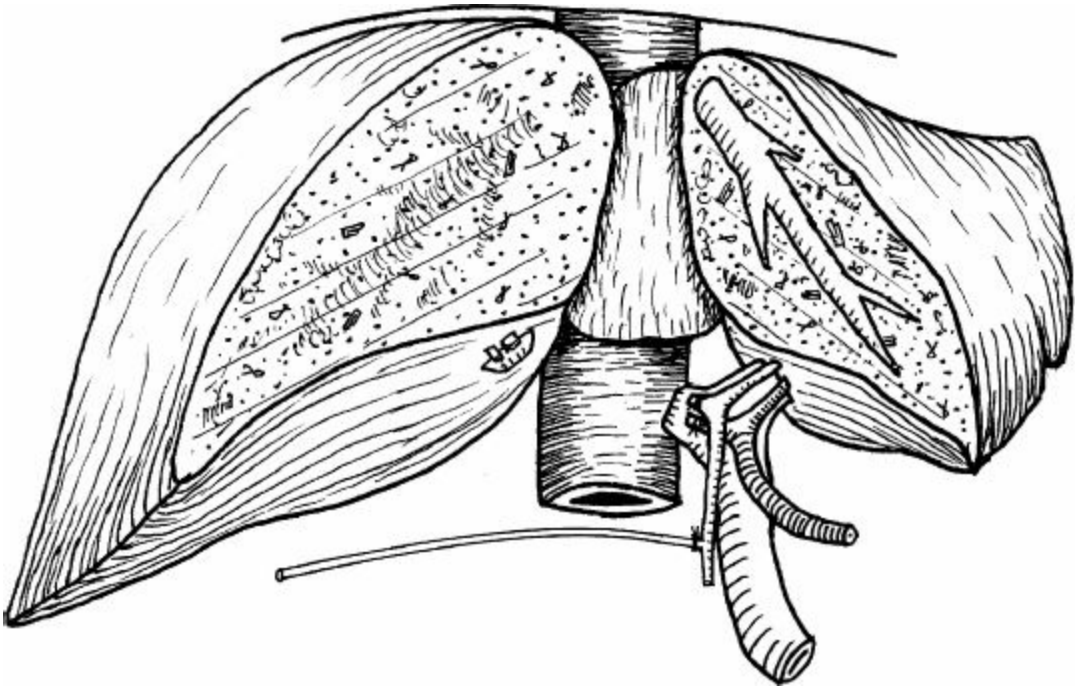

Figure 107.9. Right hepatectomy with resection of the caudate lobe. The transection plane continues from the site of transection of the right hepatic duct horizontally, underneath the middle hepatic vein and the left hilar plate, toward the ligamentum venosum.

Hemostasis and bile stasis is obtained. A cholangiogram may be performed at this time to confirm the patency of the left and common hepatic ducts (Fig. 107.10). The gallbladder is then removed and the cystic duct is ligated. The falciform ligament is reapproximated to prevent torsion of the liver and vascular compromise.

Anterior Approach

Large tumors in the right hemiliver may be adhered to the diaphragm and the retroperitoneum. In this situation, the parenchyma can be divided prior

to the mobilization of the right liver. Inflow control is initially performed as previously described and the parenchyma is transected through the demarcated area (Fig. 107.11). The anterior surface of the IVC is exposed and the right hepatic vein and short hepatic veins are identified and ligated. The hepatocaval ligament is then transected and the right liver is detached from the retroperitoneum as the right coronary and the right triangular ligaments are also transected. The “hanging maneuver,” elevation of the liver by an umbilical tape passed between the anterior surface of the IVC and the liver in the space of Couinaud, as described by Belghiti, can facilitate this approach, serving as a guide to the correct transection plane (Fig. 107.12). The space of Couinaud is a longitudinal avascular plane at the 10 to 11 o’clock position along the anterior wall of the retrohepatic IVC. To access this avascular tunnel, the hepatoduodenal ligament is initially retracted medially to expose the anterior surface of the IVC. Short hepatic veins originating from the caudate lobe are ligated. Superiorly, the space between the right hepatic vein and the middle hepatic vein is dissected, if not already done, for 3 to 4 cm downward. A long clamp is gently passed 4 to 6 cm caudally from the anterior surface of the IVC to emerge between the right hepatic vein and the middle hepatic vein. An umbilical tape is pulled behind the liver, both ends of the tape are elevated and transection of the liver proceeds as guided by the tape.

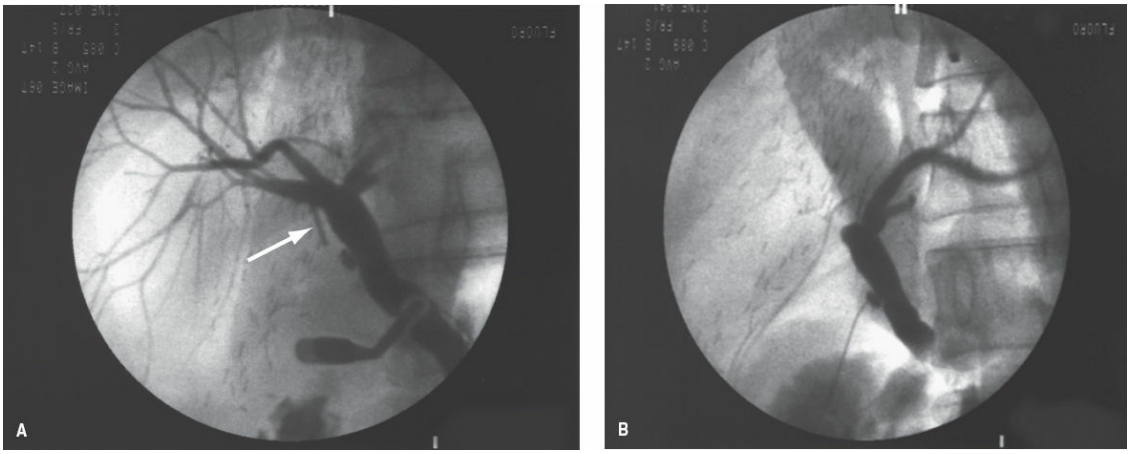

Figure 107.10. Intraoperative cholangiogram. Temporary occlusion of the distal common bile duct helps the delineation of the intrahepatic ducts. **A.** A large clip (*arrow*) marks the site of division of the right hepatic duct. **B.** A cholangiogram performed after division of the right hepatic duct confirms patency of the left and common hepatic ducts.

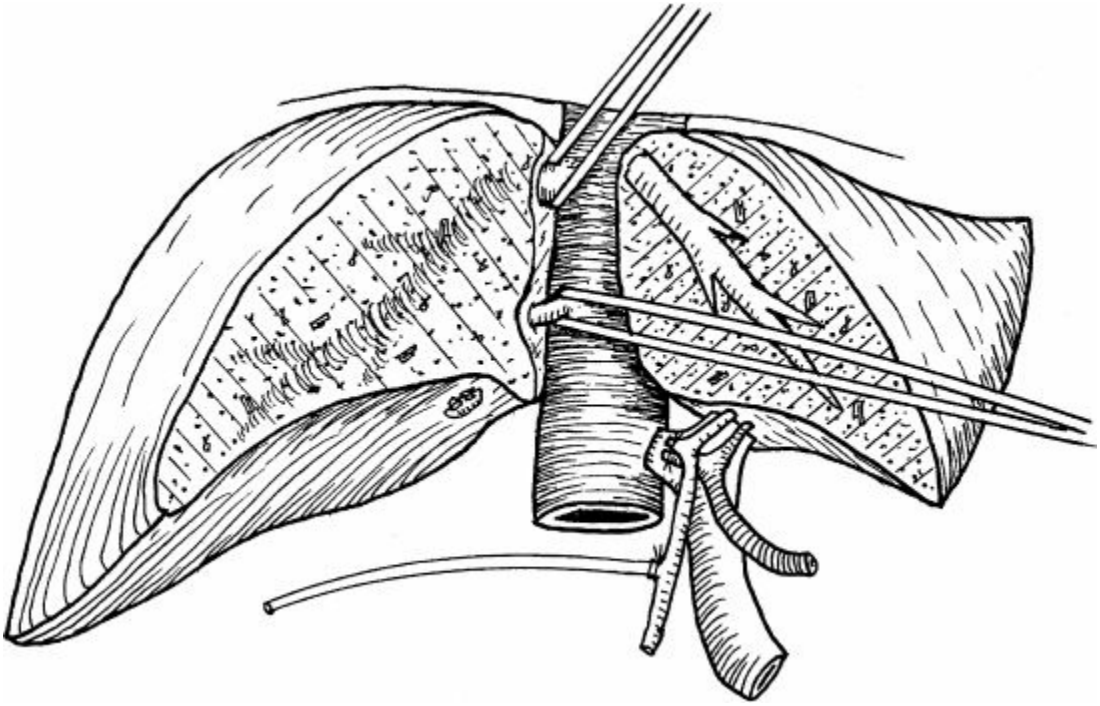

Figure 107.11. Anterior approach to a right hepatectomy. Inflow control is initially performed. The parenchyma is transected following the area of vascular demarcation prior to mobilization of the right liver. The anterior surface of the IVC is exposed and the right hepatic vein and remaining retrohepatic veins are identified and ligated before the right liver is detached from the retroperitoneum.

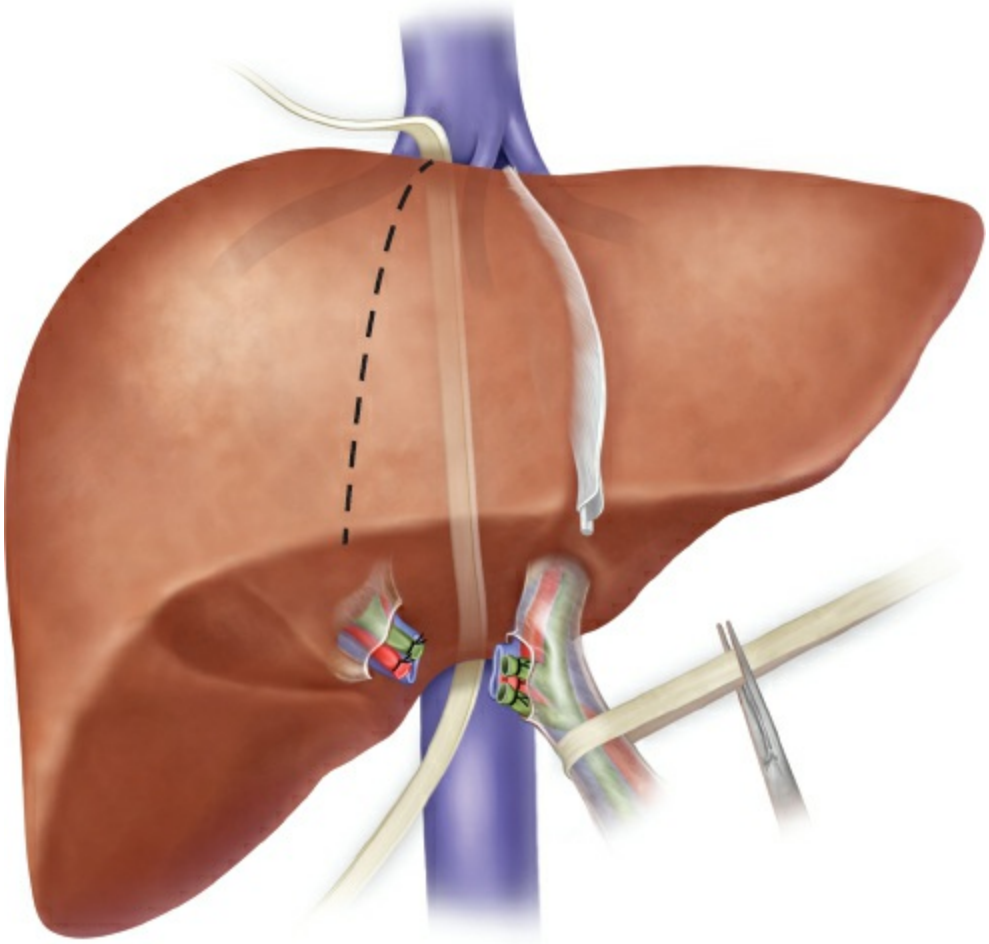

Figure 107.12. The “hanging maneuver” can facilitate the anterior approach to liver resection. An umbilical tape is blindly passed through an avascular plane along the anterior wall of the retrohepatic IVC, from its caudal portion to the space between the middle and right hepatic veins. Both ends of the umbilical tape are elevated, guiding the transection.

Extended Right Hepatectomy

When indicated, segment IV can be resected along with the right liver (Fig. 107.13). The initial steps are the same as previously described for a right hepatectomy. After inflow control to the right liver, the round ligament is elevated and the parenchymal bridge between segments III and IVB is divided exposing the base of the umbilical fissure. The hilar plate is lowered underneath segment IV to protect the left hepatic duct. The middle hepatic artery—which can often be identified to the right of and originating from the left hepatic artery—should be ligated and divided. Additional inflow to segment IV is controlled during the transection of the liver parenchyma, unless the tumor is adjacent to the umbilical fissure, in

which case inflow should be controlled within the fissure (Fig. 107.14). The transection plane is along the right side of the falciform ligament, from the groove separating the middle and left hepatic veins cranially to the right side of the umbilical fissure caudally, directed toward the medial aspect of the right hilar plate and avoiding the confluence of the left and right hepatic ducts. If the confluence needs to be resected for adequate oncologic margins, biliary drainage is restored with a Roux-en-Y hepaticojejunostomy. Finally, as the transection continues cranially, the middle hepatic vein is identified and divided with a vascular stapler.

Left Hepatectomy

A laparotomy pad is placed under the left triangular ligament to protect the spleen and the stomach and the triangular ligament is divided, exposing the IVC and the left hepatic vein. The round ligament is elevated and the parenchymal bridge between segments III and IVB is divided exposing the left hilum at the base of the umbilical fissure. The hilar plate is lowered, separating the left hepatic duct and segment IV. The peritoneum covering the left hilum is opened and the left hepatic artery is identified and ligated after flow to the right liver is confirmed. The left portal vein is dissected and divided with a vascular stapler as it enters the umbilical fissure, distal to the caudate lobe branches. The ligamentum venosum is divided at the junction with the left portal vein. A clear line of vascular demarcation can be identified between the right and left hemilivers. The left hepatic duct is dissected and ligated at the base of the umbilical fissure. Ligation of the left hepatic duct closer to the bifurcation should be avoided, as it could result in injury to aberrant right posterior or anterior ducts (Fig. 107.15).

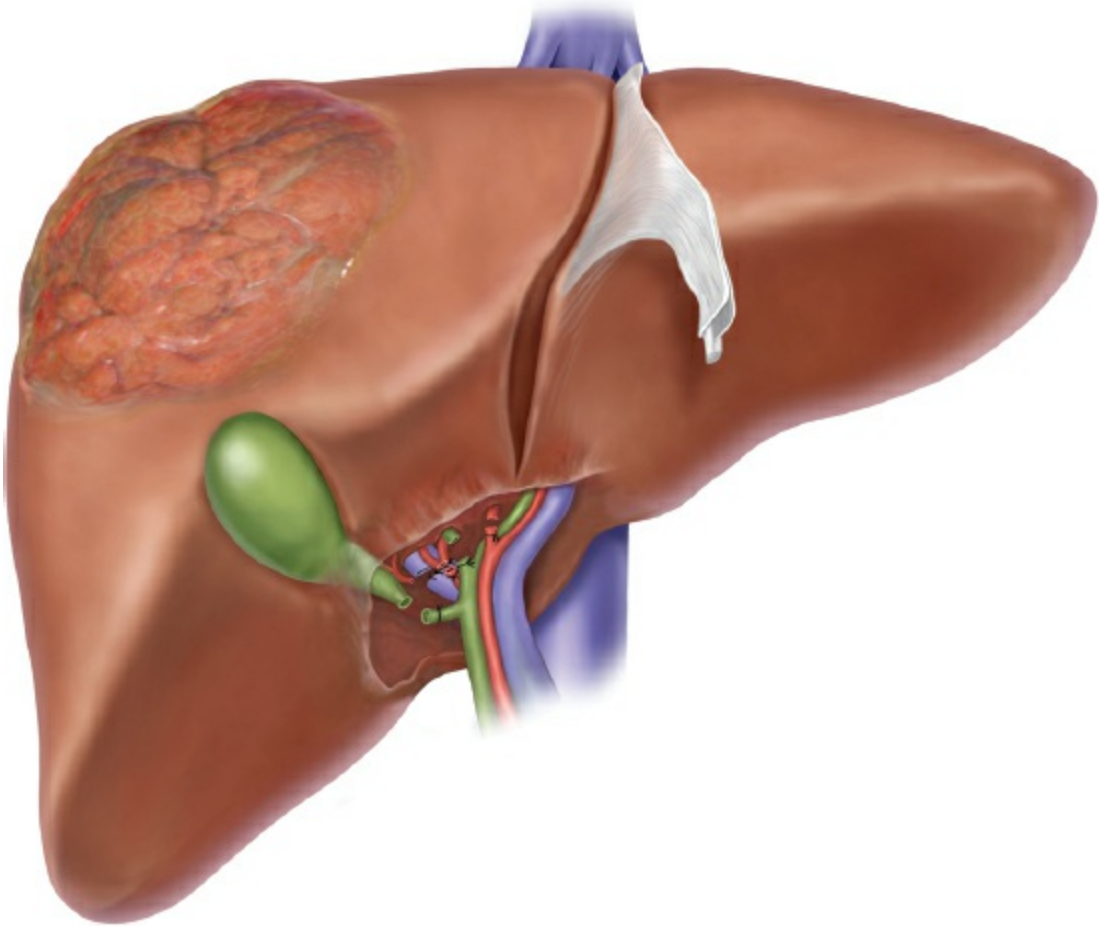

Figure 107.13. For an extended right hepatectomy, inflow to the right liver is controlled as described for a right hepatectomy. Inflow to segment IV is controlled during transection of the liver parenchyma. The transection plane is along the right side of the falciform ligament from the umbilical fissure to the confluence of the left and middle hepatic veins.

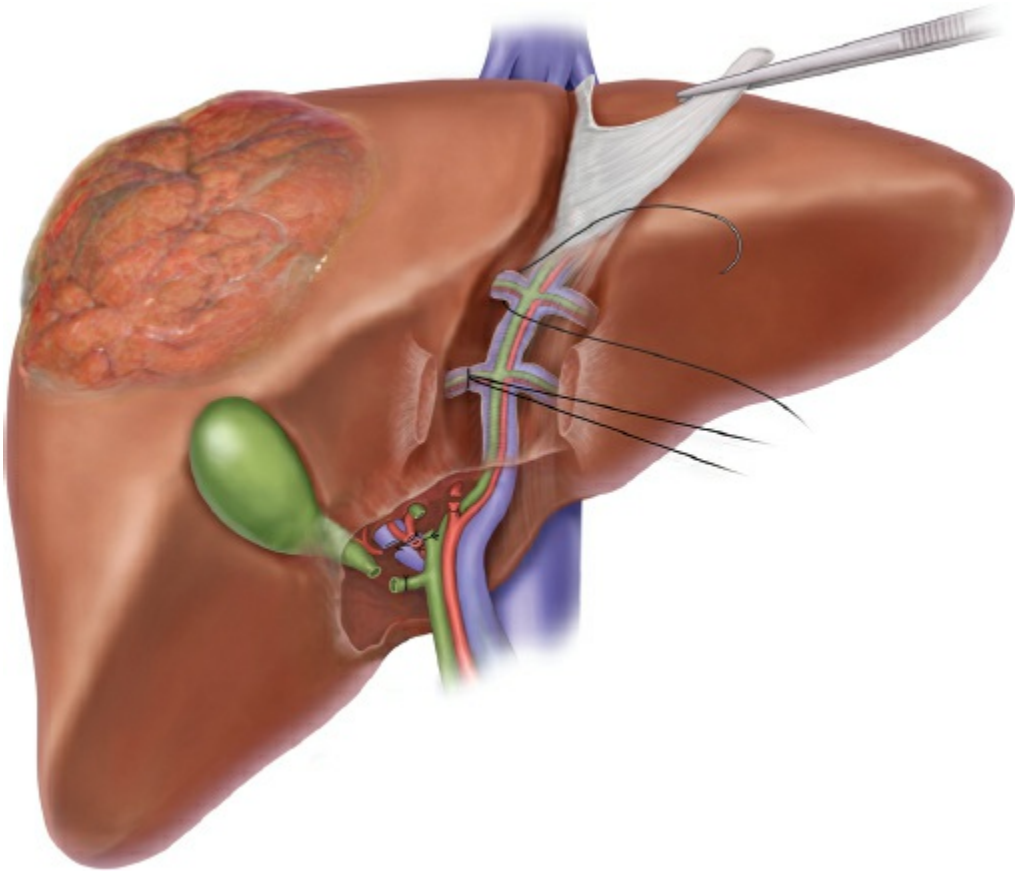

Figure 107.14. Inflow control to segment IV within the umbilical fissure.

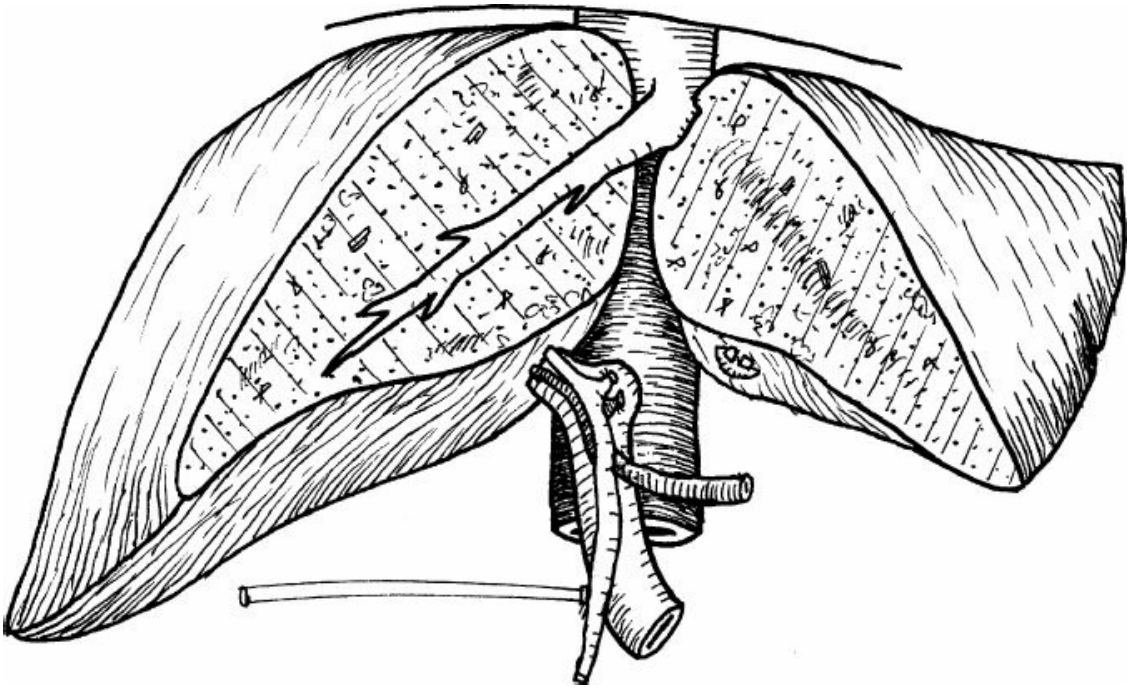

Figure 107.15. For a left hepatectomy, the left hepatic artery, the left portal vein, and the left hepatic duct are ligated at the base of the umbilical fissure. The transection plane runs along either side

of the middle hepatic vein. If oncologic feasible, this plane should run horizontally, 1 cm above the hilum, from the base of the umbilical fissure to the left side of the gallbladder fossa, to avoid injury to aberrant right anterior or posterior sectoral branches.

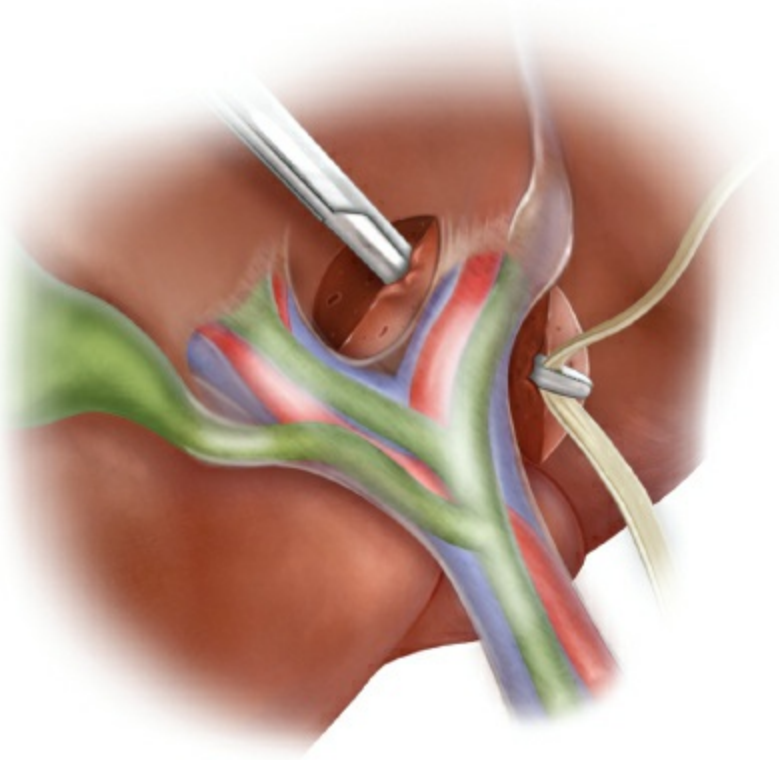

Figure 107.16. Glissonian approach for inflow control of the left hilar pedicle. One hepatotomy is made 1 cm above the left hilum and another is made just above the caudal stump of the ligamentum venosum.

In the Glissonian approach, the left hilum is ligated intrahepatically prior to the transection of the parenchyma. Two small hepatotomies are initially made: one is 1 cm above the hilum in segment IVB and the other is just above the caudal stump of the ligamentum venosum, anterior to the caudate lobe (Fig. 107.16). A clamp is introduced behind the left hilar plate toward the left lower quadrant, exiting anterior to the caudate lobe. An umbilical tape encircling the left pedicle is drawn to the left and the pedicle is transected with a vascular stapler. Alternatively, as described for the right hepatectomy, each blade of a vascular clamp is introduced into the hepatotomies, the clamp is closed, and the area of demarcation is noticed. The clamp is replaced by a vascular stapler, which is fired.

The left lateral segment is rotated to the right and the gastrohepatic ligament is further divided close to its insertion up to the base of the left

hepatic vein. The accessory left hepatic artery, if present, is ligated. The ligamentum venosum (Arantius ligament) is now divided at its insertion in the left hepatic vein. The stump is elevated to expose the window between the left hepatic vein and the IVC. The common trunk of the middle and the left hepatic veins, present in 90% of the population, is encircled as a clamp is passed between the left hepatic vein and the IVC, emerging between the right and middle hepatic veins. If the middle hepatic vein is to be divided due to tumor location, the common trunk is ligated with a vascular stapler. If the middle hepatic vein is to be preserved, the parenchyma between the left and the middle hepatic veins is transected and the left hepatic vein can be isolated. Alternatively, the left hepatic vein can be ligated intrahepatically when encountered during parenchymal transection. The location of the middle hepatic vein is confirmed with ultrasound and the parenchyma is transected close to the demarcated line, on either side of the middle hepatic vein, with or without occlusion of the hilum (Pringle maneuver). The middle hepatic vein branches extending to segment IV—or, if the vein is resected, to segments V and VIII—are identified and ligated. The transection line should run horizontally, approximately 1 cm above the hilum if oncologically feasible, from the area of transection of the left hilar plate to the left side of the gallbladder fossa—thus, avoiding transection of an aberrant right anterior or posterior duct—and then turning vertical, parallel to Cantlie line.

If the caudate lobe is to be removed along with the left hemiliver, inflow control to the left hilum is obtained more proximally, prior to the take-off of the branches of the left hepatic artery and left portal vein that extend to segment I, just before these structures enter the umbilical fissure. The left lateral segment of the liver is mobilized and rotated to the right and the fibrous tissue connecting the caudate lobe to the IVC is transected. Ligation of the retrohepatic veins is performed from the left of the IVC to the right, preserving the inferior hepatic vein, if present. If this dissection cannot be performed safely, the right liver is mobilized and the retrohepatic veins are ligated from caudal to cranial and right to left of the IVC, as described for a right hepatectomy. Liver transection then proceeds horizontally underneath the hilar plate toward the ligamentum venosum,

At completion of the transection, hemostasis and bile stasis is obtained. A cholangiogram may be performed at this time to confirm the patency of the left and common hepatic ducts. The gallbladder is then removed and the cystic duct is ligated. The falciform ligament is reapproximated to

prevent torsion of the liver and vascular compromise.

Extended Left Hepatectomy

When indicated, the right anterior section (segments V and VIII) can be resected along with the left hemiliver. The initial steps are the same as those for a left hepatectomy. After inflow control to the left hemiliver, the right anterior portal vein and artery are dissected in the right hilum. After flow to the right posterior section is confirmed, these vessels are ligated, resulting in a demarcation line between the two sections of the right hemiliver. The common trunk of the middle and the left hepatic veins is isolated, as described above, and the common trunk is ligated with a stapler. The transection plane is horizontal, along the ligamentum venosum, from the base of segment IV extending to the right of the gallbladder fossa and anterior to the right hepatic vein (Fig. 107.17). If the tumor is close to the main right hilum, it may be impossible to establish inflow control to right sectoral pedicle. In this situation, the pedicle to the right anterior sector will be identified and ligated as transection of the parenchyma approaches the hilum.

Laparoscopic Liver Resection

The use of laparoscopy for LR is increasing significantly. The Second International Consensus Conference on Laparoscopic LRs, held in Morioka, Japan in 2014, evaluated the available literature in the field and issued recommendations for the future implementation of this technique. Observational data suggests that laparoscopic resection is associated with decreased wound complications, postoperative pain, and length of stay. Moreover, laparoscopic resection is not associated with increased mortality or increased rate of positive margins. Long-term outcomes have also been shown to be similar between laparoscopic and open LR in patients with colorectal metastases or HCC. However, these results are mostly based on cohort studies with limited sample size. No randomized trials comparing laparoscopic versus open LR have been completed at this time, although there are two ongoing studies. The panel concluded that while minor laparoscopic LRs are standard practice in surgery, although still in an assessment phase, major laparoscopic LRs should be considered an innovative procedure, in an exploration or learning phase with incompletely defined risk. Major laparoscopic LRs should, therefore, be introduced cautiously.

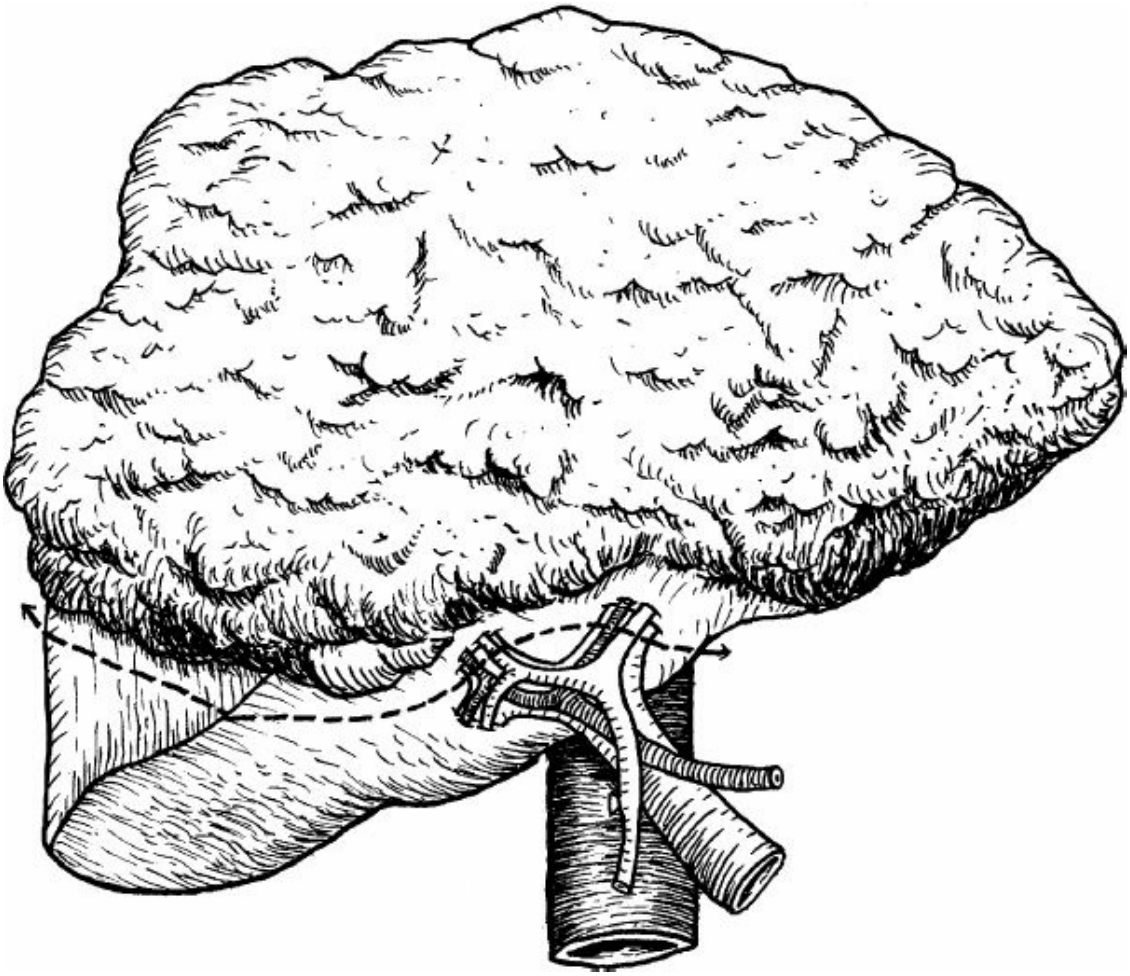

Figure 107.17. For an extended left hepatectomy, the transection plane is horizontal, anterior to the right hepatic vein and the posterior sectoral pedicle, directed to the right side of the gallbladder fossa, continuing through the base of segment IV toward the ligamentum venosum.

Laparoscopic Parenchymal Transection

As with open LR, transection of the parenchyma can be performed by different techniques and with different energy devices, dependent on the surgeon's experience and preference. Intraoperative ultrasound is key to identifying the relationship between major vessels and the transection line. The argon beam coagulator should be used with caution due to the risk of gas embolism.

Laparoscopic Right Hepatectomy

Patient is positioned supine or in low lithotomy position with arms at 60 degrees. Padding is applied underneath the right flank to elevate the right side of the patient. Monitors are placed at the head of the table. The

surgeon and camera operator stand on the left of the patient and the first assistant stands on the right. Alternatively, the surgeon may stand between the patient's lower extremities.

A 12-mm port is initially placed about 2 cm above the umbilicus and CO_2 insufflation is obtained. The 30-degree laparoscope is introduced in the abdomen and the abdominal cavity is inspected for presence of extrahepatic disease. A 12-mm port is inserted at the right midclavicular line. This port will be used for the energy devices and the stapler. Two additional 5-mm ports are placed laterally, along the right subcostal margin, for retraction and suction/irrigation. Finally, an additional 5-mm port is placed in the subxiphoid region for better visualization of the dome. For hand-assist access, the supraumbilical port can be extended (Fig. 107.18). The location of the port sites varies according to the patient's anatomy.

The falciform ligament is transected from the abdominal wall with an energy device through the right midclavicular port. Adhesions to the inferior surface of the liver are lysed with countertraction applied through the lateral ports. The right triangular and coronary ligaments are taken down and the liver is freed from its retroperitoneal attachments. The laparoscopic ultrasound is introduced and the location of the lesions and their relationship with the hepatic vessels is noted, permitting the extent of the resection to be confirmed. The right hemiliver is elevated with a liver retractor, the IVC is exposed, and the retrohepatic vessels are ligated with surgical clips proceeding cranially to the location of the right hepatic vein.

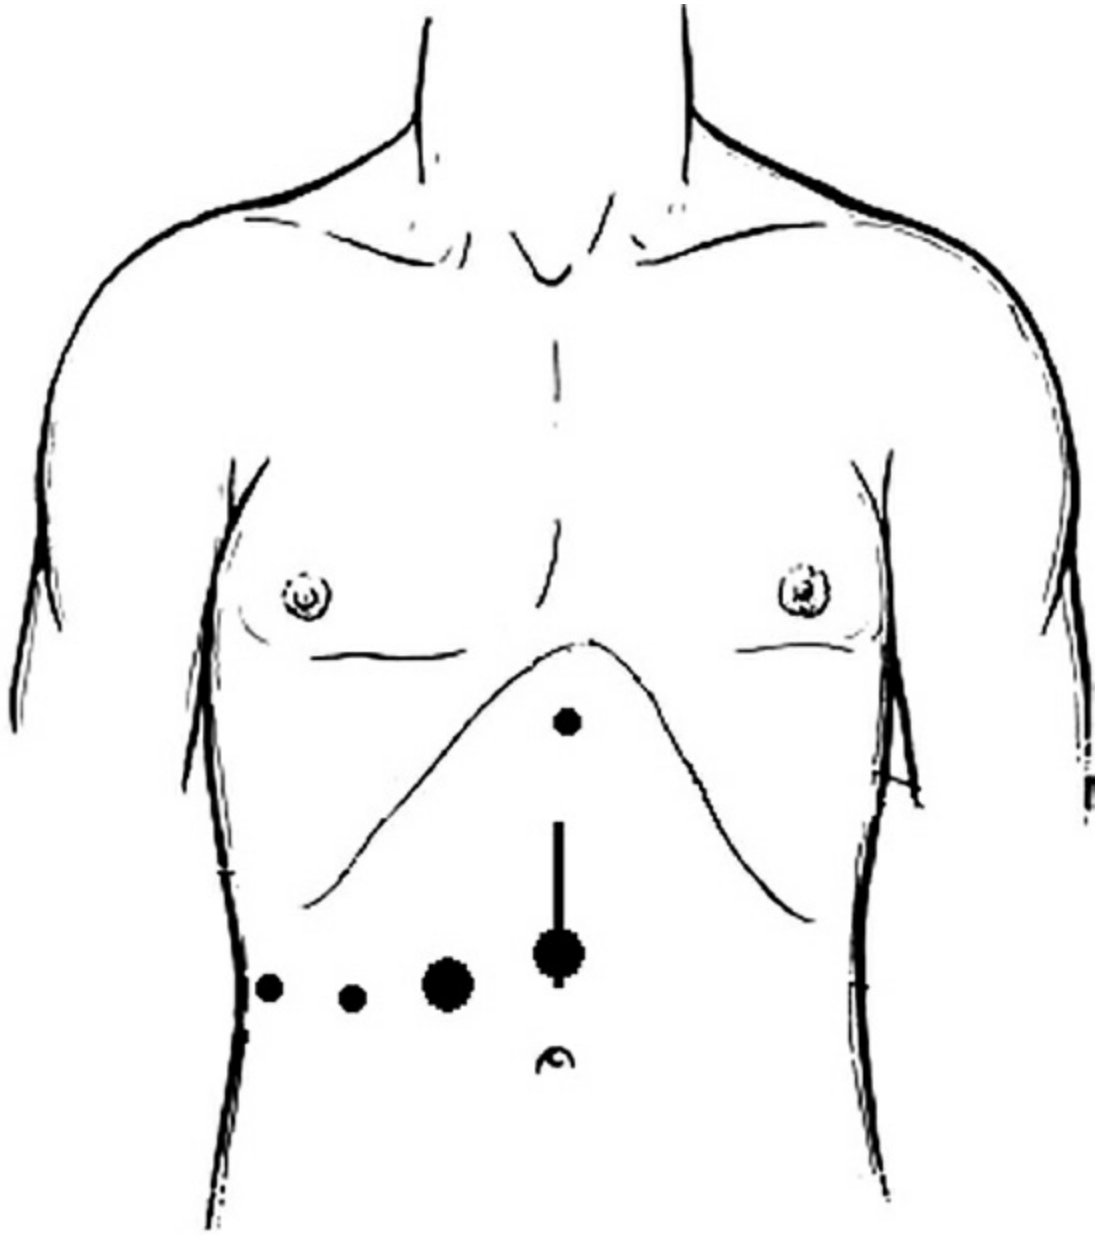

Figure 107.18. Port placement for laparoscopic right hepatectomy: a 10-mm port is initially placed about 2 cm above the umbilicus; a 12-mm port is inserted at the right midclavicular line and two additional 5-mm ports are placed laterally, along the right subcostal margin; an additional 5-mm port is placed in the subxiphoid region. For hand-assist access, the supraumbilical port can be extended.

Using a Carter–Thompson needle suture passer, an endoloop is placed around the round ligament, retracting the liver superiorly to expose the hilum. Cholecystectomy is performed from the fundus to the neck of the gallbladder. The gallbladder is left attached to the cystic duct to be used as a handle. The right hepatic artery is dissected and transected with a stapler.

The right hepatic vein is also isolated and ligated with a stapler.

A vascular loop or umbilical tape should be loosely applied around the portal triad to allow for the Pringle maneuver. The vascular loop is tightened with a bulldog clamp and released in cycles as described for the open procedure.

The parenchyma is transected in the demarcated line as previously described, using energy devices for transection of smaller vessels and an endovascular vascular stapler for transection of the branches of the middle hepatic vein, the right hepatic vein, and the right biliary duct. The cut edge of the liver is inspected and bleeding is controlled with the argon beam coagulator or radiofrequency sealer. If the argon beam coagulator is used, a port should be vented as the intra-abdominal pressure rapidly increases. The argon beam should not be used near large hepatic veins due to the risk of gas embolism.

The specimen is placed in an extraction bag and is removed through an extension of the supraumbilical port. The falciform ligament is reattached to the abdominal wall with the help of an endoscopic suture device.

Laparoscopic Left Hepatectomy

Patient is positioned supine or in low lithotomy position with arms at 60 degrees. The surgeon stands on the patient's left side or between the lower extremities. A 12-mm port is placed about 2 cm above the umbilicus and CO_2 insufflation is obtained. The 30-degree laparoscope is introduced in the abdomen and the abdominal cavity is inspected for presence of extrahepatic disease. A 12-mm port is placed at the left midclavicular line and two additional ports are placed laterally, below the left subcostal margin. An additional 12-mm port is placed at the right midclavicular line. For hand-assist access, the supraumbilical port can be extended (Fig. 107.19).

The left hepatic artery and portal vein are identified and ligated at the base of the umbilical fissure.

The parenchyma is transected as described above for laparoscopic right hepatectomy, with the branches of the middle hepatic vein, the left hepatic vein, and the left hepatic duct transected with a vascular stapler as they are encountered during the transection. The specimen is removed through an extension of the supraumbilical port and the falciform ligament is reattached to the abdominal wall.

Drainage

Drains are not routinely placed after a major hepatectomy, as they have not been shown to decrease the need for postoperative drainage. However, drains adjacent to the cut edge of the liver should be considered selectively for patients at higher risk of infection, such as those with biliary obstruction and those undergoing simultaneous liver and colorectal resections. Drains should be placed when biliary reconstruction is performed. After 24 to 48 hours, a bile bag with gravity drainage can replace the suction bulb to avoid negative pressure.

POSTOPERATIVE CARE

Patients without major comorbidities that undergo an uneventful procedure may be extubated and admitted to the floor. Fluids should be administered carefully to avoid overload and elevated central venous pressure, with resulting congestion of the remnant. Colloid fluid replacement is preferable for cirrhotic patients. Narcotic pain medication should be used judiciously. Ambulation is encouraged within the first 24 hours of the procedure. Patients are typically advanced to clear liquid diet on the first postoperative day and subsequently advanced as tolerated. Liver function tests are ordered daily for the first 2 days and selectively thereafter. Phosphate levels are monitored closely as hypophosphatemia is common with liver regeneration.

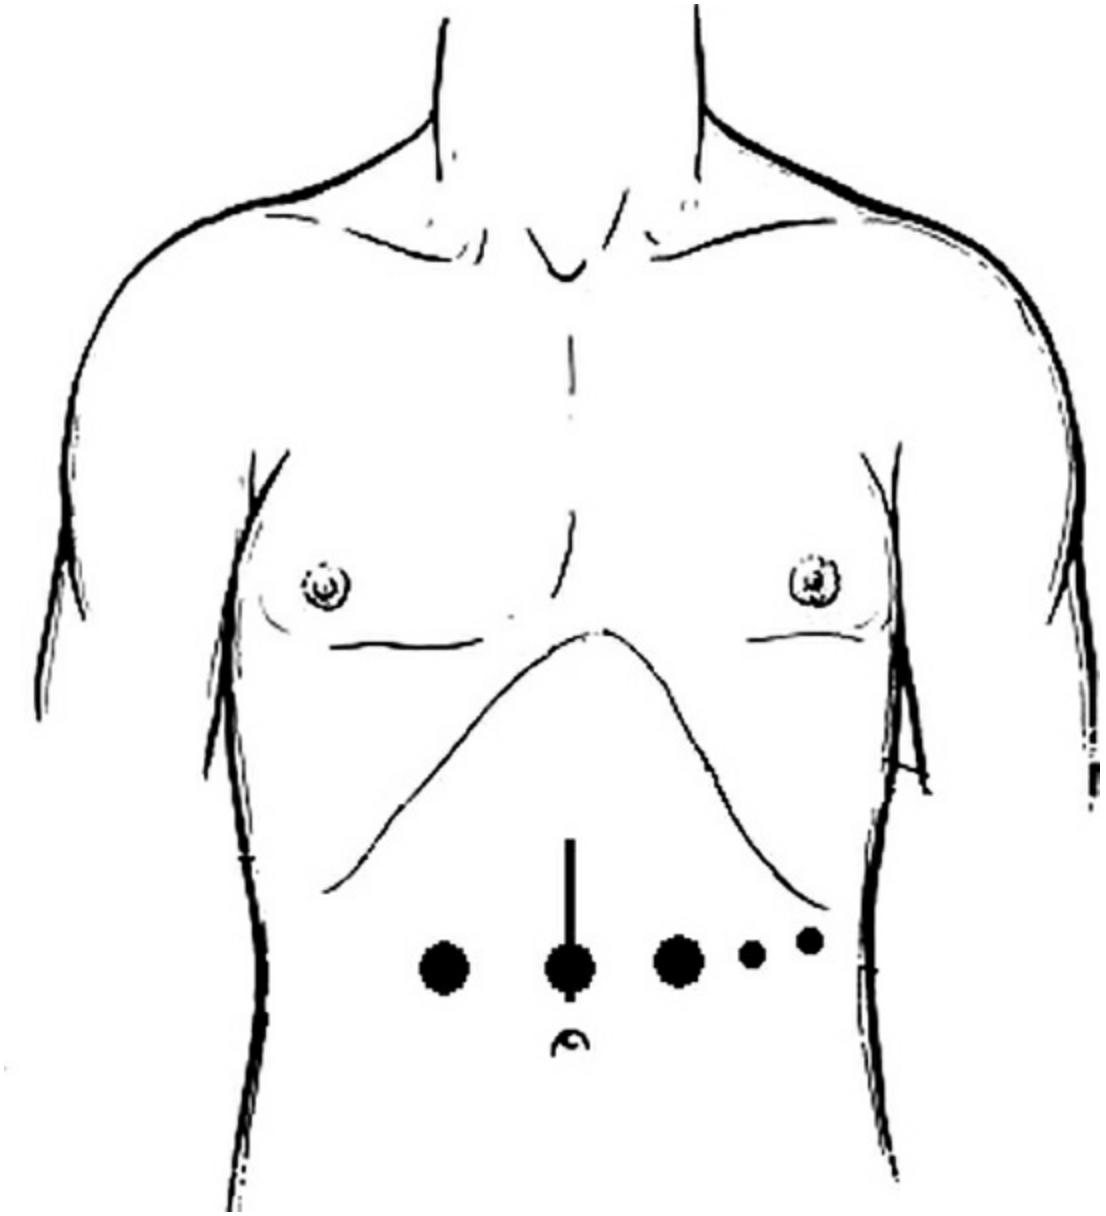

Figure 107.19. Port placement for laparoscopic left hepatectomy: a 10-mm port is placed about 2 cm above the umbilicus; a 12-mm port is place at the left midclavicular line and two additional ports are placed laterally, below the left subcostal margin; an additional 12-mm port is placed at the right midclavicular line. For hand-assist access, the supraumbilical port can be extended.

COMPLICATIONS AND THEIR MANAGEMENT

Intra-abdominal collections at the transected edge of the liver are common after major LRs. These collections should be percutaneously drained if the patient becomes symptomatic or there are clinical signs of infection. Factors associated with infection of these fluid collections include biliary obstruction, presence of cirrhosis, and combined LRs with colorectal

resections. If persistent bilious drainage exists, ERCP with sphincterotomy can be performed to diagnose the site of the biliary leakage and decrease the output.

Liver insufficiency may present in the early postoperative period with hypotension refractory to vasopressors, respiratory failure, acute renal insufficiency, hypoglycemia, and coagulopathy. Other patients may develop a more protracted course with progressive hyperbilirubinemia, encephalopathy, massive ascites, anasarca, and renal insufficiency. Ascites can result in the disruption of the incision and major fluid and electrolyte losses. While some of these patients will never recover their liver function and eventually succumb to infection, others will regenerate to sufficient size with appropriate support. Factors associated with increased risk of postoperative liver failure include the size and function of the liver remnant, especially in cirrhotic patients, intraoperative blood loss and postoperative complications, most commonly infectious. Patients with cirrhosis are also at higher risk of significant portal hypertension after resection, which may result in variceal bleeding.

Complications of Laparoscopic Liver Resection

Gas (CO_2 and argon) embolisms are unique complications of the laparoscopic approach. While CO_2 embolism is less dangerous than air embolism given CO_2's higher solubility in blood, argon embolization is more worrisome as this gas is 17 times less soluble that CO_2. CO_2 embolism should be suspected if there is an abrupt decrease in the end-tidal CO_2 associated with hypotension. Diagnosis can be confirmed with a transesophageal echocardiogram. The patient should be placed in Trendelenburg and left lateral decubitus and the central line should be aspirated to remove the gas that may collect in the right atrium.

Major intraoperative hemorrhage, usually from the hepatic veins, often requires conversion to open procedure for adequate control. It is best avoided with the use of intraoperative ultrasound to correctly identify the location of the middle hepatic vein as the transection plane is determined.

OUTCOMES

Long-term outcomes following major LR is determined by the primary tumor and the extension of the disease. For instance, 5-year overall and disease-free survival in patients with colorectal liver metastasis are 30% to

60% and 20% to 40%, respectively. Factors associated with long-term survival include the number of lesions, longer disease-free interval between the diagnosis of the primary tumor and the metastatic disease, size of the largest hepatic tumor, presence of extrahepatic disease, and nodal status of the primary tumor. In patients with HCC, with Child's A cirrhosis and no portal hypertension or with no cirrhosis, 5-year overall and disease-free survival are 40% to 75% and 20% to 40%, respectively. While tumor size alone has small effect on long-term survival, presence of multiple lesions HCC (multifocal HCC) and major vascular invasion are associated with high recurrence rates and poor overall survival.

EDITOR'S COMMENT

There have been substantial advances in hepatic resection for primary and metastatic cancer to the liver. To that end the authors review the technical aspects of the various operations and include important advances including the hanging technique and laparoscopic approaches. In this commentary I will explore the outcomes and some of the controversies related to hepatic resection.

Hepatocellular carcinoma (HCC) is the most common primary malignancy of the liver and the sixth most common cancer. The well-established association of HCC with chronic liver disease (CLD), due to viral infection, alcohol consumption, metabolic syndrome, and so forth, adds complexity and challenges to the surgical treatment of this disease. This is the result of underlying histologic changes in the liver parenchyma which may include steatosis, inflammation, fibrosis, and cirrhosis. These changes affect liver function and resilience as well as predispose the liver to multicentric carcinogenesis that may limit the possibility of curative treatments. Various surgical treatments of HCC include local ablation of small tumors, liver resection (LR) both anatomic and nonanatomic, and liver transplantation (LT).

LR is one of the recommended potential treatments for HCC patients. Recent articles on this topic (Rahbari NN, Mehrabi A, Mollberg NM, et al. Hepatocellular carcinoma: current management and perspectives for the future. *Ann Surg* 2011;253:453–69; Morise Z, Kawabe N, Tomishige H, et al. Recent advances in liver resection for hepatocellular carcinoma. *Front Surg* 2014;1:21) report that the role of LR in HCC has been expanded with better outcomes as a result of advances in screening, improved treatment of the underlying liver disease, earlier radiologic diagnosis, better methods of determining liver function, a clearer understanding of segmental anatomy, as well as evolving of surgical techniques. Currently the expected 5-year survival is 38% to 61% depending on the stage of the disease. However, less than one third of patients with HCC are eligible for surgery. The Liver Cancer Study Group in Japan is the largest single report in the literature with 6,785 patients treated between 1988 and 1999 (Ikai I, Itai Y, Okita K, et al. Report of the 15th follow-up survey of primary liver cancer. *Hepatol Res* 2004;28:21–9). The authors observed the following survival rates: 1 year (85%), 3 years (64%), 5 years (45%), and 10 years (21%). Survival rates as high as 60% at 5 years in patients with good liver function and small localized tumors have been reported by other groups worldwide without differences between Western and Eastern countries.

The alternative to LR for HCC is LT. LT achieves excellent results in patients with limited tumors. An article by Belghiti J and Fuks D (Liver resection and transplantation in hepatocellular carcinoma. *Liver Cancer* 2012;1:71–82) provides an excellent update of the role of liver transplantation in HCC. In this study the authors note that "patients with HCC within the Milan criteria (MC; solitary HCC of <5 cm or with up to three nodules of <3 cm) have

a 5-year survival of 70% after LT with recurrence in less than 10%." This survival is equivalent to liver transplant survival in most other indications. An important observation is that the diameter of the largest nodule or total diameter of nodules is the best predictor of the outcome. It is known that increased waiting time for a donor liver is associated with tumor progression and vascular invasion. Of approximately 7,000 new patients with HCC put on the waiting list every year in the United States each year 10% to 15% die during the waiting period, while in Europe, the dropout rate at various centers ranges between 15% and 35%. Hence it is important to consider the options for tumor management while awaiting transplantation. These include ablation techniques, TACE, and hepatic resection. Interestingly, prior surgical resection does not preclude transplantation as it does not increase the surgical risk nor reduce survival (Belghti J, Cortes A, Abdalla EK, et al. Resection prior to liver transplantation for hepatocellular carcinoma. *Ann Surg* 2003;238:885–92). As Belghiti points out: "resection could be used as a bridge to transplantation, especially for tumors located in the upper part of the right liver, which can be easily and completely removed through a transthoracic incision" (Belghiti J, Fuks D. Liver resection and transplantation in hepatocellular carcinoma. *Liver Cancer* 2012;1:71–82).

Approximately 20% to 30% of patients with metastatic colorectal cancer have a disease that is confined to the liver which is potentially resectable. The traditional "rules" guiding hepatic resection consisted of limiting resection to patients with a maximum of three lesions in the same lobe in which it was possible to achieve 1 cm surgical margins and those without portal lymph node metastases. These have been challenged by advancements in both surgical technique and systemic therapy. The notable improvements in the outcomes of patients with metastatic CRC have been attributed to increased use of hepatic resection in selected patients and more effective chemotherapy. Several recent large series on resection for colorectal liver metastases have reported a 5-year survival ranging from 25% to 44%, with operative mortality of 0% to 6.6%. Let us look at the report by Kanas GP et al. (Survival after liver resection in metastatic colorectal cancer: review and meta-analysis of prognostic factors. *Clin Epidemiol* 2012;4:283–301) who performed a meta-analysis on the topic. They reported an overall median survival of 3.6 years and 5- and 10-year survival ranged from 16% to 74% (median 38%) and 9% to 69% (median 26%). Factors associated with poorer survival included: node positive primary, 1.6 (1.5 to 1.7); carcinoembryonic antigen level, 1.9 (1.1 to 3.2); extrahepatic disease, 1.9 (1.5 to 2.4); poor tumor grade, 1.9 (1.3 to 2.7); positive margin, 2.0 (1.7 to 2.5); >1 liver metastasis, 1.6 (1.4 to 1.8); and >3 cm tumor diameter, 1.5 (1.3 to 1.8). Interestingly, approximately one third of 5-year survivors suffer a cancer-related death, while those who survive 10 years appear to be cured. Because of its clear survival impact, surgical resection is the treatment of choice when feasible. The percentage of patients with isolated hepatic metastases who are amenable to potentially curative resection is a bit of a moving target since

surgeons may have different interpretations of “resectable.” It is safe to say that a majority of patients, with metastatic disease are not curative surgical candidates because of tumor size, location, multifocality, or inadequate hepatic reserve. One consensus statement defined absolute unresectability as nontreatable extrahepatic disease, unfitness for surgery, or involvement of more than 70% of the liver or six segments (Poston GJ, Adam R, Alberts S, et al. OncoSurge: a strategy for improving resectability with curative intent in metastatic colorectal cancer. *J. Clin Oncol* 2005;23:7125–34). Today even patients with bilobar disease may be candidates for resection (Malik HZ, Hamady ZZ, Adair R, et al. Prognostic influence of multiple hepatic metastases from colorectal cancer. *Eur J Surg Oncol* 2007;33:468–73). In this report 484 patients with multiple liver metastases from CRC had 5- and 10-year survival if 47% and 29%.

There continues to be debate about the management of synchronous liver metastases. From the patient’s perspective, simultaneous resection of the primary and metastatic disease is clearly preferable. However, concern has been raised about the safety of LR at the time of resection of the primary colon lesion. To date, comparative studies have indicated that concurrent and staged resection of hepatic metastases are equivalent in terms of operative time, blood loss, transfusion, perioperative morbidity, operative mortality, and overall survival form the date of keratectomy. Overall duration of hospitalization was noted to be longer (up to two times longer) for concurrent resection. The exception is patients that require extensive resection for multiple metastases (>4 tumors), with greater than three segments, or require extended hepatectomy may be better served with delayed hepatic resection. Several surgical case series and meta-analyses have failed to confirm inferior survival or greater morbidity for patients who undergo a one-stage procedure as compared with delayed (staged) hepatic resection, unless major hepatic resection (three or more segments) is needed. One-stage surgery is probably a reasonable option for patients who present with low-volume (four or fewer, less than three segments involved, or all in the same lobe) potentially resectable hepatic metastases.

There is controversy around the role of chemotherapy prior to LR. Initially this was thought to be a good idea, but however this has been challenged by reports of chemotherapy-associated steatosis (CASH), vascular injury, and noncirrhotic portal hypertension in patients receiving receiving regimens containing irinotecan or oxaliplatin. These changes can impact survival after LR. In one study patients with steatohepatitis had a 90-day mortality of 15% compared to 2% in those without CASH. This has influenced thinking regarding management of metachronous liver metastases. The overall benefit of upfront chemotherapy prior to surgery in patients with metachronous liver metastases is uncertain. In the chemotherapy groups, postoperative complications seem higher and there is no overall survival benefit. Many surgeons prefer surgery as the first-line therapy in these cases.

What is the role of chemotherapy on converting unresectable to resectable

disease? The results are mixed. High rates of successful resection for patients with initially unresectable liver metastases have been reported for the FOLFOXIRI regimen with or without bevacizumab in some trials but not on others. The TRIBE trial which compared bevacizumab plus either FOLFOXIRI or FOLFIRI did not result in a significant increase in complete resection (15% vs. 12%) (Loupakis F, Cremolini C, Masi G, et al. Initial therapy with FOLFOXIRI and bevacizumab for metastatic colorectal cancer. *N Engl J Med* 2014;37:1609–18). Toxicity was greater with FOLFOXIRI. There is continued work in this area with various combinations of cytotoxic chemotherapy with or without biologic agents. The best option in these cases is to enroll your patient in a clinical trial if available and if not work with the medical oncologist at your organization on each case individually. Most important in these circumstances is to set realistic patient expectations.

There are several special considerations in performing LR. The first is predicted residual liver volume and its impact on outcome. Three-dimensional hepatic volumetry and virtual resection identified that the incidence of severe hepatic dysfunction and postoperative infection was increased significantly in patients with a functional liver remnant of 26.6% or less and was significantly worsened by high BMI (Schindl MJ, Redhead DN, Fearon KC, et al. The value of residual liver volume as a predictor of hepatic dysfunction and infection after major liver resection. *Gut* 2005;54:289–96). Preoperative portal vein embolization (PVE) is defined as the elective obliteration of portal blood flow to a selected portion of the liver a few weeks prior to planned major LR I order to increase the volume and potentially the function of the FLR to a safe threshold, and minimize the risk of posthepatectomy liver failure and related complications. Usually a right PVE is performed in preparation of or a patient with normal liver function for an extended right hepatectomy or a right hepatectomy in a patient with cirrhosis.

The increase in liver volume is due to hyperplasia and not hypertrophy (an increase in size of existing hepatocytes). Preoperative PVE causes an immediate increase of portal blood flow to the nonembolized liver segments. The increased flow stimulates a regenerative response. The arterial flow to the nonembolized segments is not significantly altered. Interestingly the time course for the expected increase in FLR has been fairly well documented. At 4 to 6 weeks after PVE, the expected increase of standardized FLR ranges from 8% to 13%, although some studies have reported higher rates (Leung U, Simpson AL, Araujo RL, et al. Remnant growth rate after portal vein embolization is a good early predictor of post-hepatectomy liver failure. *J Am Coll Surg* 2014;620–30). This translates to a 40% to 62% increase in FLR expressed as percentage increase from baseline FLR. I have used this technique and it is helpful, or least I think it is in some settings. Surprisingly PVE is tolerated very well by the patient.

The second consideration is hepatic steatosis. Fatty infiltration of the liver resulting in steatosis may impact outcomes of partial hepatic resection as it is

thought to interfere with hepatic regeneration. Kooby et al. (Impact of steatosis on perioperative outcome following hepatic resection. *J Gastrointest Surg* 2003;7:1034–44) showed that marked steatosis is an independent predictor of complications following hepatic resection but does not have a significant impact on 60-day mortality. They concluded that "steatosis alone should not preclude aggressive hepatic resection for neoplasms when indicated; however, patients with marked steatosis undergoing large resections should still be approached with due caution." A case matched study by McCormac et al. (Hepatic steatosis is a risk factor for postoperative complications after major hepatectomy: a matched case-control study. *Ann Surg* 2007;245:923–30) reported that "liver steatosis, regardless of the presence of is the most significant preoperative risk factor for postoperative complications after major liver resection."… and…"concomitant cholestasis in patients with underlying liver steatosis should alert surgeons for the high risk of postoperative mortality."

The final consideration is the role of laparoscopy in resection of primary and metastatic liver tumors. A Medline search done 3–28–17 returned over 2,900 citations (1,376 in the last 5 years and 2,994 in the last 10 years) on this topic. A complete discussion is beyond the scope of this commentary. However, I think it is safe to state the techniques have evolved substantially over past decade and the approach has been met with stepwise improvement and success. Certainly better understandings of liver segmental anatomy as well as technologic advances have contributed to the successful implementation of this modality. In initially recommended for solitary tumors <5 cm, preferably located in the left lateral segments 2 to 3 or in the anterior right-lobe liver segments 5 to 6. More recently the results of an international, multicenter expanded the application to laparoscopic major hepatectomy. Dagher I et al. (Laparoscopic major hepatectomy: an evolution in standard of care. *Ann Surg* 2009;250:856–60) reported results in 210 patients from six centers (three in Europe, two in the United States, one in Australia). There were 136 right and 74 left laparoscopic hepatectomies, with 54% of cases for malignancy. The results were comparable to open resection. Obviously special training in necessary to gain the experience needed to perform these advanced cases safely. Clearly this approach will gain more momentum in the next 5 years.

E. Christopher Ellison

108 Treatment of Major Hepatic Trauma

Donald D. Trunkey

Prior to 1965, the morality from liver injuries that were diagnosed and operated on was very high (Table 108.1). When the operation was done, treatment consisted of sutures and packs, and some surgeons advocated routine drainage. The cautery was very controversial and continued to be controversial until World War II. Based on the work by Madding and Kennedy, treatment changed during World War II, and resection became part of the surgeon's armamentarium. This led to a remarkable reduction in overall mortality. After shifting to this management, 829 wounds to the liver were seen in an 18-month period, and of these patients, 53 died.

The year 1965 was pivotal with the introduction of diagnostic peritoneal lavage. Previously undiagnosed liver injuries were now possible to diagnose. The great majority of these were grade I to III liver injuries, and, thus, it can be appreciated that surgeons had been doing nonoperative management of liver injuries for years; they just didn't know it. evidence for this is present in at least three papers. in a study from canada, 35% of patients lacked any clinical signs of blunt abdominal trauma with injuries to the spleen or liver. similarly, a study from Michigan showed that out of 87 patients subsequently diagnosed by autopsy, 45% had undiagnosed liver injuries. This was affirmed by a study published in the *Surgical Clinics of North America* in 1972.

TABLE 108.1 Mortality in Rupture of Liver, 1872 to 1961

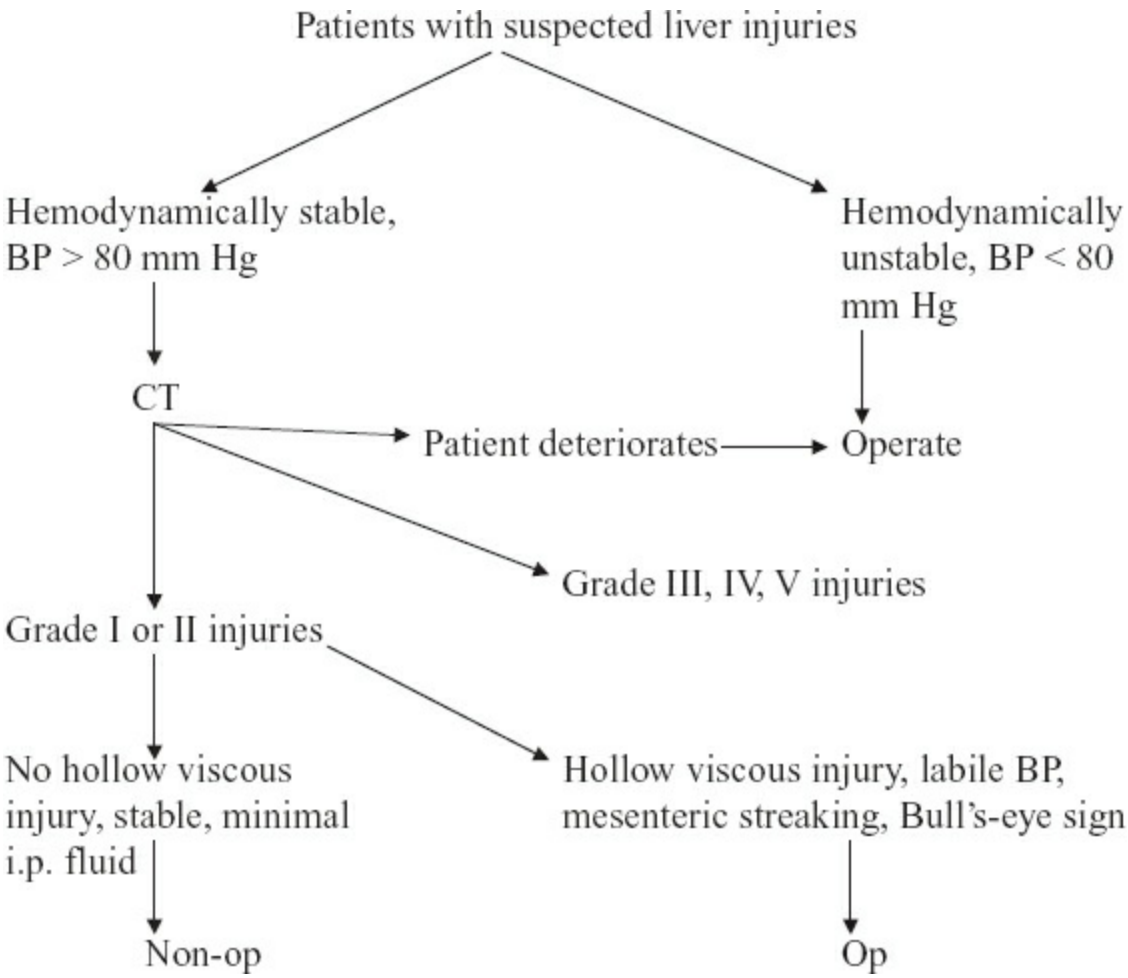
Author	Year	No. of Cases	Mortality (%)
Mayer	1872	135	88
Tilton	1904	25	44
Pringle	1908	2	100
Riebel	1910	44	44
Thöle	1912	260	64
Andersson	1926	24	76
Krieg	1936	60	74
Lamb	1939	60	44
Castren	1946	245	56
Papen	1950	40	64
Wright	1947	32	61
Melnikov	1956	51	24
Hellström	1961	300	37

One of the problems with diagnostic peritoneal lavage and better diagnosis of liver injuries is that in 30% of patients this leads to a nontherapeutic celiotomy. The year 1981 turned out to be another pivotal year with the introduction of computed tomography (CT) scanning to make the diagnosis of intra-abdominal solid organ injury. With this diagnostic modality, it was now possible for the surgeon not only to make the diagnosis, but also to make a rational decision as to whether the patient needed operation based on the degree of injury and hemodynamic stability. More recent studies now show that most patients with grade I and II injuries can be managed nonoperatively, and patients with grade III, IV, and V injuries will require operation in 50% to 75% of the cases (Algorithms 108.1 and 108.2; Figs. 108.1 and 108.2).

Since World War II, there have been two significant events that have changed the approach to major hepatic trauma: pioneering work in the anatomy of the liver and new operative techniques for elective hepatic resection. We now have a better understanding of segmental anatomy, which has allowed segmental resection, and this has led to a marked increase in elective resection of tumors and obstruction of the porta hepatis. The second factor influencing liver surgery has been liver transplant operations, which has furthered our understanding of the anatomy and has particularly influenced surgeons in their ability to perform hepatic isolation procedures.

ANATOMY

Repair and resection for treatment of hepatic trauma demand a working knowledge of the anatomy of the liver. The segmental approach to liver anatomy that is presented here is valuable for the surgeon for prediction of the locations of vascular structures within the liver substance. Whereas small segmental resections are feasible in elective surgery, liver resection for trauma is almost exclusively restricted to nonanatomic debridement of nonviable liver tissue, left lateral segmentectomy, and formal right or left hepatic lobectomy.

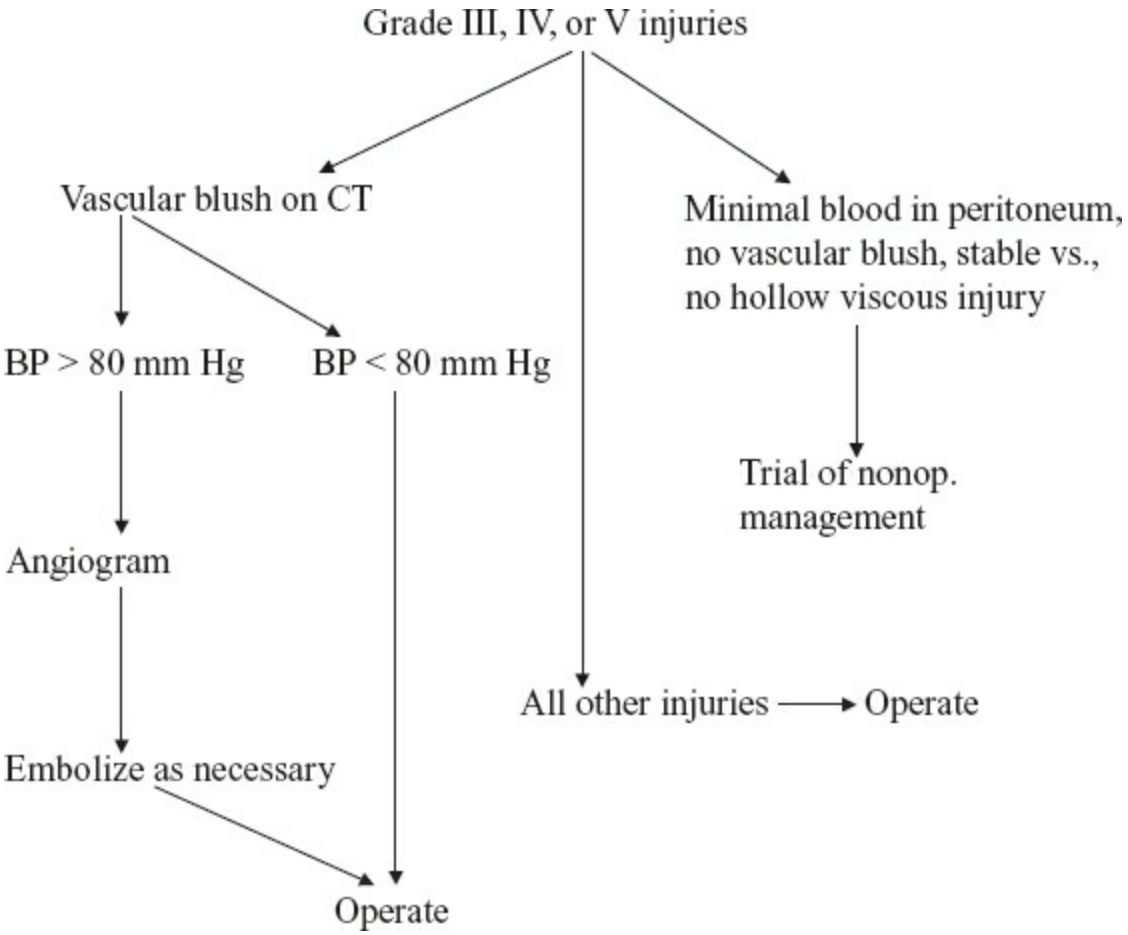


Algorithm 108.1. Algorithm for evaluating patients with suspected liver injuries. BP, blood pressure; CT, computed tomography.

The liver has three major surfaces: superior, inferior, and posterior. The superior and posterior surfaces rest against the diaphragm; however, the inferior surface is more complex, containing the gallbladder, hepatic ducts, hepatic arteries, and portal veins (Fig. 108.3). The liver is attached to

surrounding structures by ligaments, the reflection of the parietal peritoneum (Fig. 108.4). The coronary ligament is formed along the superior surface of the right lobe and secures the liver to the diaphragm posteriorly and superiorly. The two leaves of the coronary ligament join at the extreme left to form the triangular ligament. The falciform ligament and ligamentum teres (obliterated umbilical vein) provide anterior attachment of the midportion of the liver to the anterior abdominal wall.

Morphologically, the liver is described as two main (right and left) and two accessory (quadrate and caudate) lobes. The right and left lobes are divided by the major fissure, with the right being larger. The quadrate lobe is the portion of the right lobe that lies anterior to the transverse hilar fissure, medial to the gallbladder fossa, and lateral to the umbilical fissure. The caudate lobe lies posterior to the transverse liver fissure.



Algorithm 108.2. Algorithm for evaluating patients with grade III, IV, or V injuries. BP, blood pressure; CT, computed tomography.

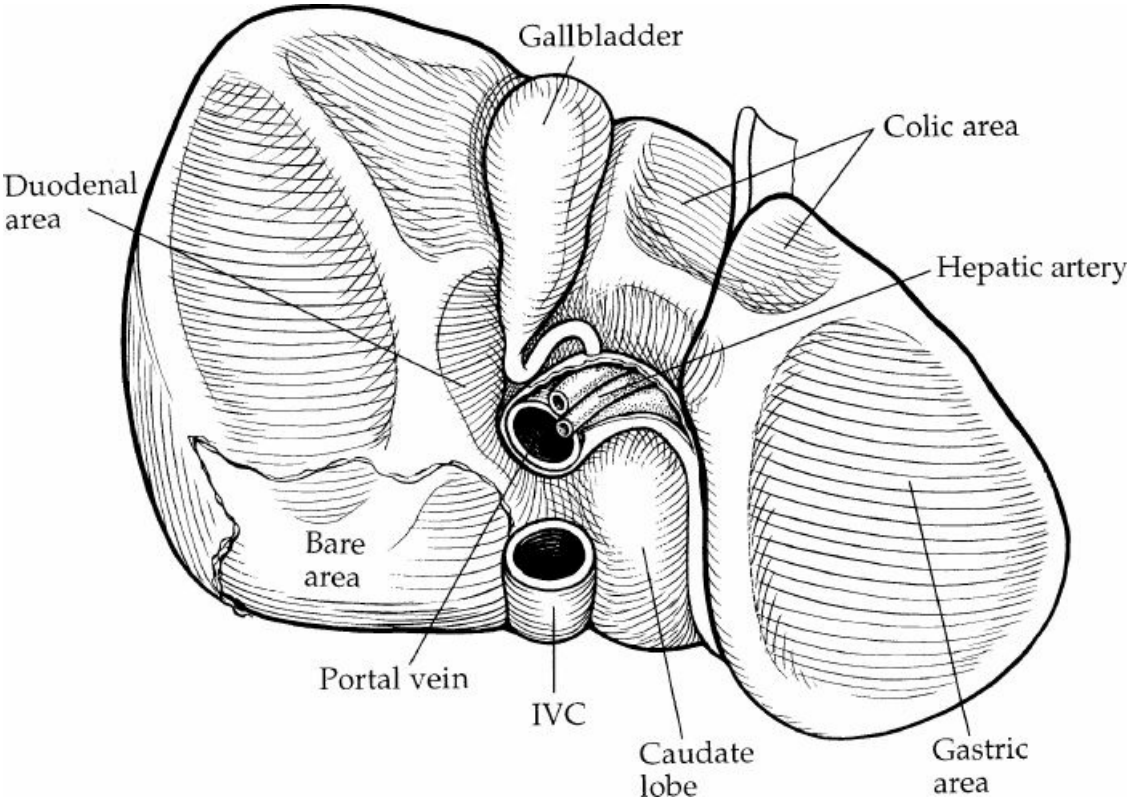


Figure 108.1. Anatomy of the inferior surface of the liver. IVC, inferior vena cava.

Surgical treatment of traumatic injuries relies on a functional anatomic description of the liver. Segmental and anatomic resection has been well documented by Bismuth using an anatomic description from Couinaud. Hepatic segmentation based on the distribution of the portal pedicle and location of hepatic veins defines the functional anatomy (Figs. 108.3 and 108.4). The three main hepatic veins (i.e., the right, left, and middle) divide the liver into four sections: right posterior lateral, right anterior medial, left anterior, and posterior. Each of these sectors receives a portal pedicle. Sectors of the right liver are further divided into two segments each, the anterior medial sector (segment IV anteriorly and segment VIII posteriorly) and the posterior lateral sector (segment VI anteriorly and segment VII posteriorly). The left anterior sector is divided by the umbilical fissure into segment IV (the anterior portion of the quadrate lobe) and segment III (the anterior portion of the left lobe of the liver). The posterior sector is composed of only one segment (II) and lies in the posterior portion of the left lobe. The caudate lobe is considered independently as segment I.

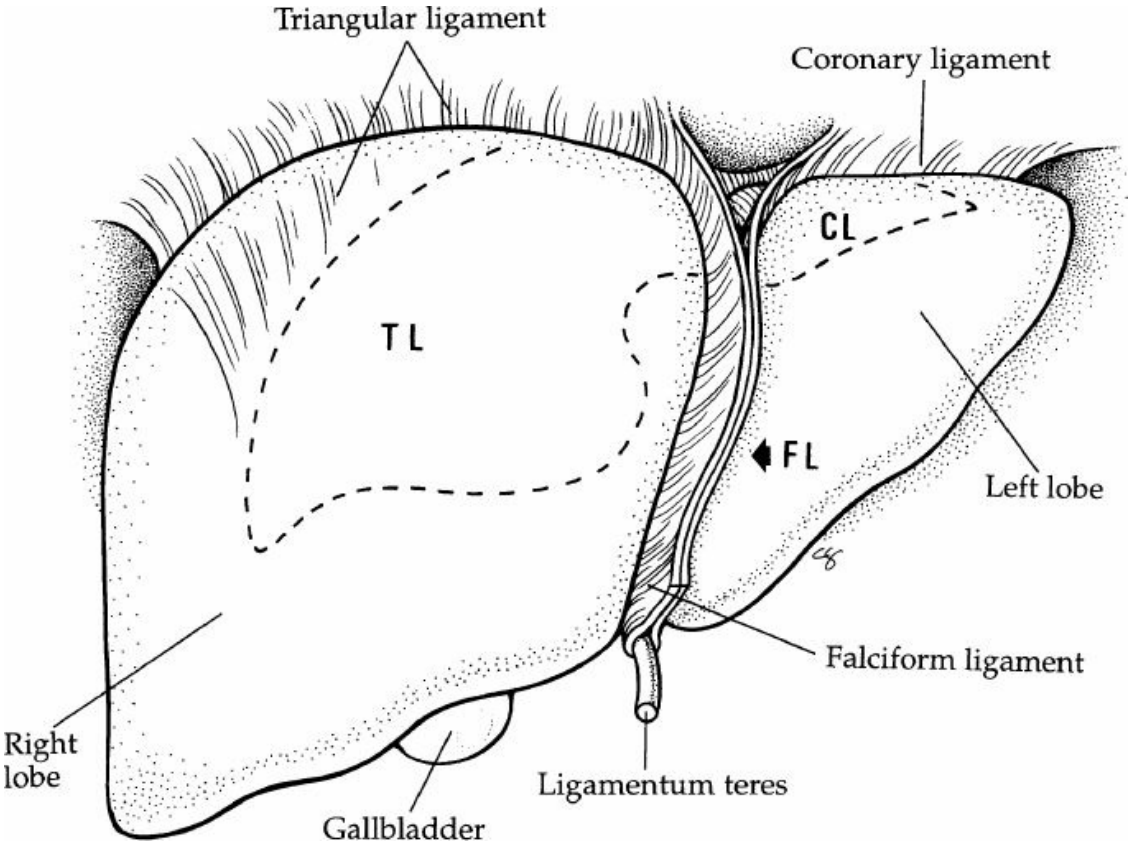

Figure 108.2. Superficial anatomy of the liver showing the ligaments. CL, coronary ligament; FL, falciform ligament; TL, triangular ligament.

The hepatic artery supplies 25% of the blood flow to the liver and 50% of the oxygen. In 55% of cases, the hepatic artery supply is exclusive from the celiac trunk (Fig. 108.5). The common hepatic artery is the contribution of the celiac trunk after the left gastric and splenic arterial branches. The common hepatic artery traverses along the upper border of the head of the pancreas, and then it turns to ascend in the lesser omentum. It lies to the left of the common bile duct and anterior to the portal vein. The gastroduodenal artery arises from the distal horizontal position of the common hepatic artery. The right gastric artery arises from the proper hepatic (40% of cases) or left hepatic artery (40% of cases).

The hepatic artery bifurcates in the porta hepatis to give rise to the right and left hepatic arteries. The right hepatic artery courses to the right behind the common bile duct. The anterior and posterior segmental arteries of the right lobe take separate origin from the right hepatic artery. The anterior segmental branch courses along the gallbladder fossa in close proximity to the cystic duct. The left hepatic artery runs upward obliquely to the left and divides into its two terminal branches—the medial and

lateral segmental arteries. The medial segmental artery descends into the quadrate lobe (segment IV). The lateral segmental artery travels obliquely toward the upper, outer aspect of the lateral segment, where it divides into the superior and inferior branches. The blood supply to the caudate lobe (segment I) is variable. In approximately 35% of cases, the entire blood supply of the caudate lobe comes from the right hepatic artery, and in 12%, it comes entirely from the left hepatic artery. In the majority, however, the blood supply is from both. Aberrant hepatic arteries occur frequently in 40% to 50% of cases. The most frequent anomaly is the left hepatic artery, which arises from the gastric artery (25% to 30%) (fig. 108.6A,B). This includes a 10% incidence of a totally replaced left hepatic artery and a 15% incidence of an accessory left hepatic artery. The right hepatic artery originates from the superior mesenteric artery in 17% of cases: 10% total replacement and 7% accessory (fig. 108.6C,D). The middle hepatic artery arises from the left or right hepatic artery with equal frequency. The cystic artery is usually a branch of the right hepatic artery. It reaches the gallbladder behind the common hepatic duct after traversing the hepatic triangle to the right of the common hepatic duct. In 85% to 90% of cases, there is a single cystic artery.

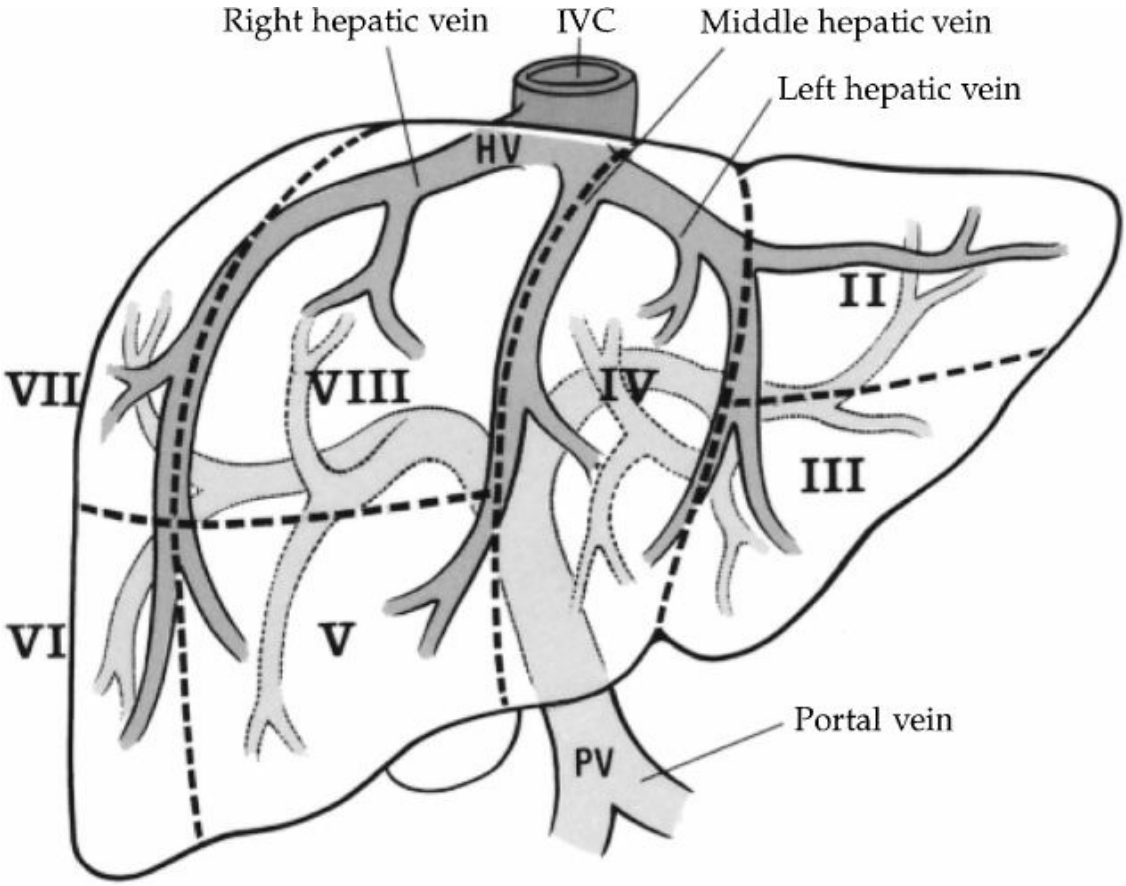

Figure 108.3. An anterior view of segmental anatomy. HV, hepatic vein; IVC, inferior vena cava; PV, portal vein.

The portal vein carries 75% of the blood flow to the liver and 50% of the oxygen. The portal vein is formed by the confluence of the superior mesenteric vein and the splenic vein behind the neck of the pancreas. Approaching the liver within the porta hepatis, the portal vein lies anterior to the inferior vena cava and to the left of the common bile duct and the hepatic artery. The portal vein is 7 to 10 cm in length and bifurcates into the left and right portal veins. The portal lobar veins lie posterior to the hepatic veins and bile ducts. The right portal vein is short and divides into anterior and posterior segmental vessels. Each of these segmental vessels further divides into inferior and superior subsegmental branches. The right portal vein sends a branch to the right side of the caudate lobe (segment I).

The left portal vein is longer than the right and courses to the left in the hilar plate from the bifurcation. It then turns inferiorly in the liver at the umbilical fossa. The superior and inferior subsegmental veins of the lateral segment (segments II and III) arise from the left side of the umbilical portion of the left portal vein. The medial segmental veins rise from the right side of the umbilical portion of the left portal vein. This fact is of importance when performing a left lateral segmentectomy (segments II and III), as the umbilical portion of the left portal vein should be left intact.

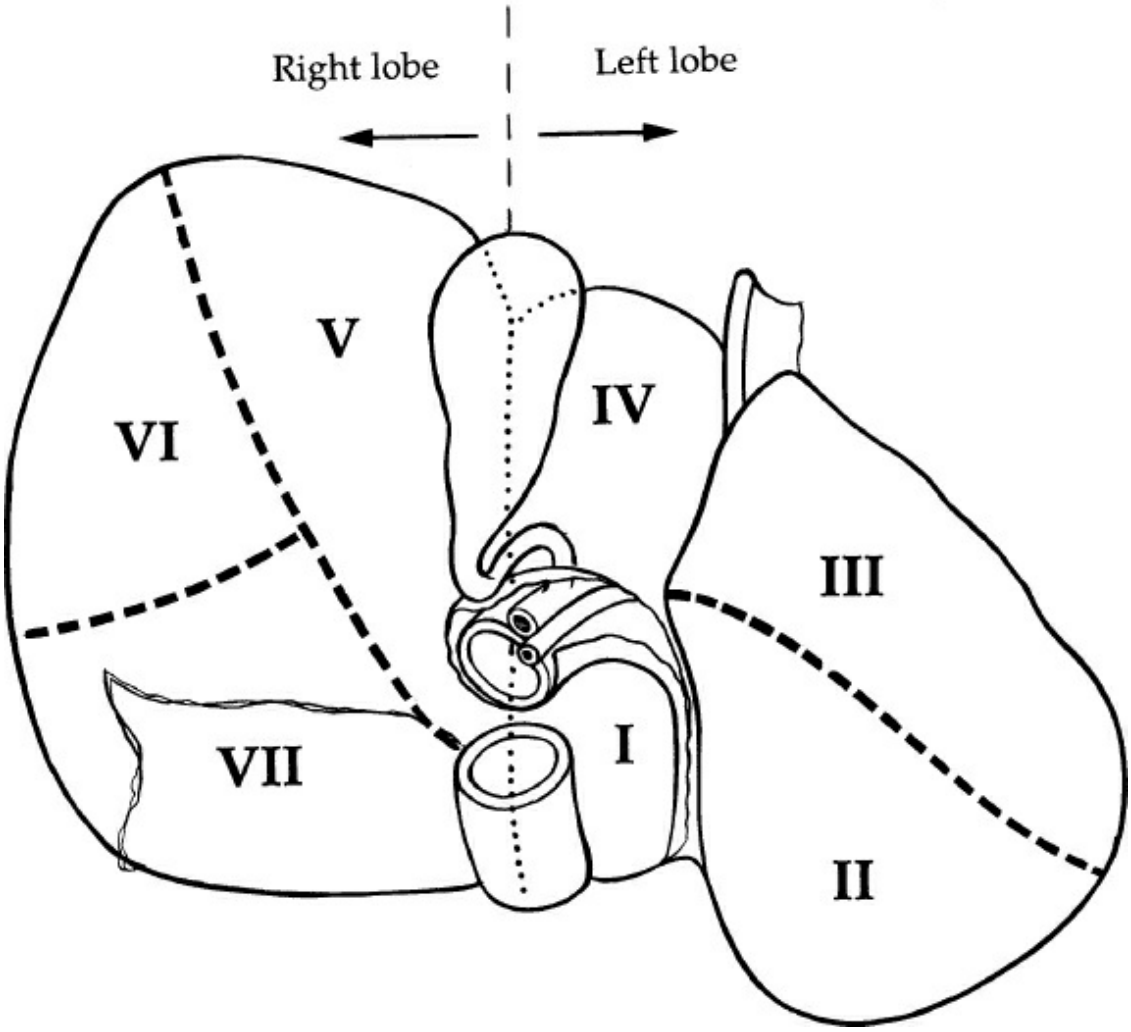

Figure 108.4. Segmental anatomy viewed from the inferior surface.

Venous drainage of the liver is quite simple. The hepatic veins lie in the planes dividing the segments of the liver. There are three major veins: right, middle, and left. The right hepatic vein is the largest and drains the anterior and posterior portions of the right lobe of the liver (segments VI, VII, and VIII). The middle and left hepatic veins frequently enter the inferior vena cava as a single trunk. The middle hepatic vein drains the superior aspect of the anterior segment of the right lobe (segment V). The left hepatic vein drains the superior aspect of the medial and lateral segments of the left lobe (segments II, III, and IV). The caudate lobe (segment I) usually drains directly into the inferior vena cava via multiple small branches.

The biliary drainage of the liver follows a segmental and lobar pattern and shares a common pathway with the blood supply (portal triad). The right hepatic duct is formed by the joining of the anterior and posterior

segmental ducts of the porta hepatis. In 30% of cases, one of the two ducts, usually the posterior, crosses the segmental fissure to drain in the left hepatic duct. The left hepatic duct is formed by the confluence of the medial and lateral segmental ducts. This duct is in the left segmental fissure in 50% of cases and to the right of the fissure in 42%. In the caudate lobe (segment I), drainage is variable and may flow into either the left or right duct. The common hepatic duct is formed by the confluence of the right and left hepatic ducts in the transverse fissure of the liver. Its distal end is defined by the junction of the cystic duct and may range from 1.0 to 7.5 cm in length. The normal diameter is 4 mm. The common bile duct is a continuation of the common hepatic duct, distal to the cystic duct. It ranges in length from 2 to 7 cm. It has a consistent course and is divided into four portions: supraduodenal, retroduodenal, pancreatic, and intramural. The supraduodenal lies between layers of the hepatic duodenal ligament, anterior to the foramen of Winslow. The retroduodenal portion is between the superior margin of the first portion of the duodenum and the superior edge of the pancreas. The gastroduodenal artery lies to the left, and the posterosuperior pancreatic duodenal artery lies anterior to the bile duct. The pancreatic portion of the common bile duct passes from the upper margin of the head of the pancreas obliquely to the right posterior portion of the pancreas to its entrance into the duodenum. The intramural portion of the common bile duct travels an oblique path approximately 1.5 cm long through the duodenal wall. It joins with the main pancreatic duct inferiorly.

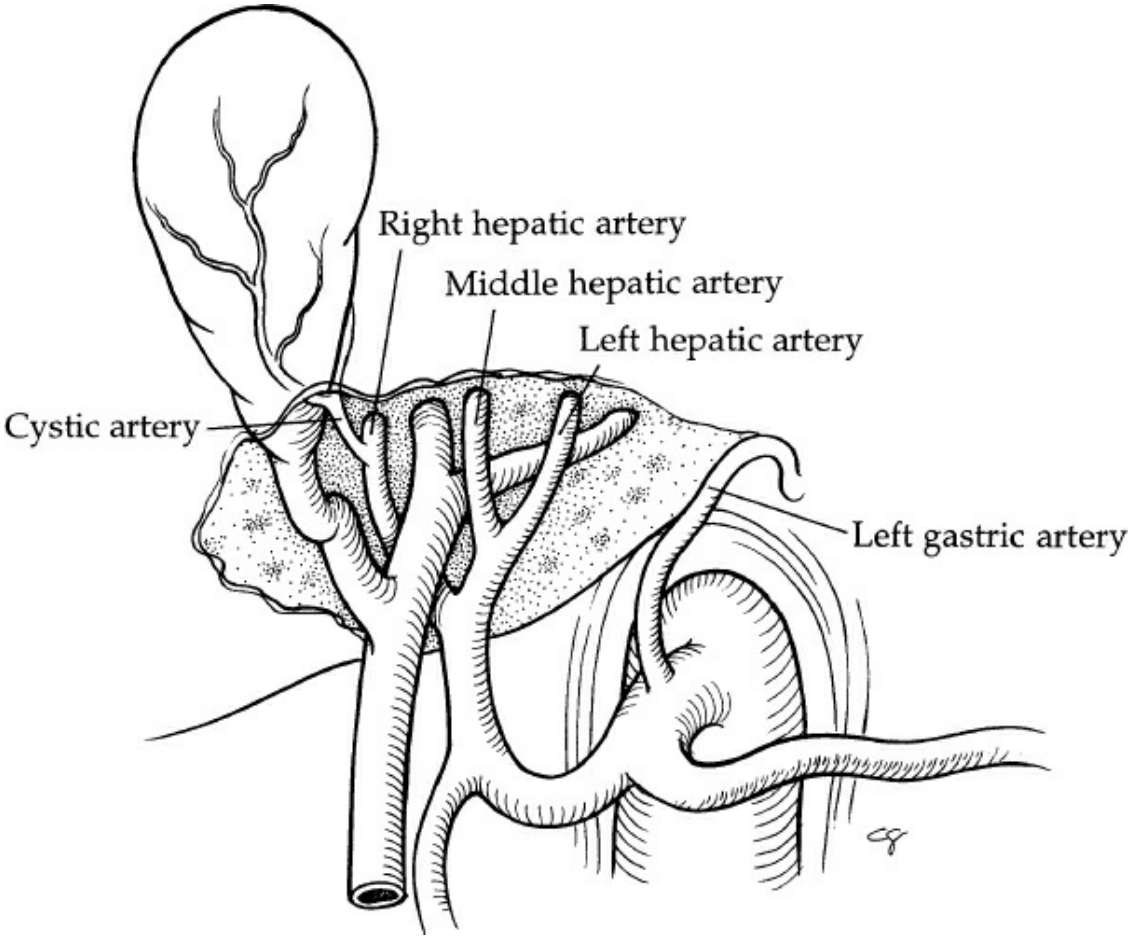

Figure 108.5. The most common hepatic artery configuration.

The dissection of the hilar plate from the liver parenchyma was first described by Couinaud in 1957. Cholecystectomy before the incision of the peritoneal reflection and Glisson capsule aids the surgeon in entering the transverse fissure or porta hepatis. After the cholecystectomy, an incision is made at the junction of the peritoneal reflection of the porta hepatis to the Glisson capsule anteriorly in a U-shaped fashion directed toward the bifurcation of the left and right portal system and then moving toward the falciform ligament. By gently retracting the porta hepatis medially and lifting upward, a second incision in the peritoneal reflection is carried across from the gallbladder fossa over the superior margin of the caudate process. Using blunt dissection, the right porta hepatis can be encircled. After division of the gastrohepatic ligament in the bare area, the left porta hepatis can be encircled. Access to the retrohepatic cava requires lifting the right lobe anteriorly and medially after all of the ligamentous attachments have been taken down from the diaphragm. As the posterior peritoneum reflects up on to the cava, it is incised sharply with the scissors or electrocautery unit and carried cephalad toward the right hepatic vein,

and the surgeon should take care not to injure the cava or the venous branches from the caudate lobe.

PATHOPHYSIOLOGY

In general, the amount of damage caused by penetrating missiles to the liver is determined by the kinetic energy. This kinetic energy is a reflection of the mass of the missile, the differential of the velocity of the missile as it enters the tissue, and the velocity of the missile as it exits the tissue. In the 1990s, trauma centers saw an increasing number of medium-velocity

injuries. Typically, these are caused by large-caliber semiautomatic and automatic weapons. More extensive injuries are seen after a shotgun blast and occasional assault rifle injuries.

Blunt trauma typically results from direct compressive forces or shear forces. The elastic tissues within arterial blood vessels make them less susceptible to tearing than any other structure within the liver. Venous and biliary ductal tissue is moderately resistant to shear forces; the liver parenchyma is the least resistant of all. Thus, fractures within the liver parenchyma tend to occur along segmental fissures or directly into the parenchyma, causing shearing of lateral branches of the major hepatic vein and portal veins. With severe deceleration injury, the origins of the hepatic veins may be ripped from the cava, causing devastating hemorrhage. Similarly, the small branches from the caudate lobe entering directly into the cava are at high risk for shear, and thus a linear tear appears on the anterior caval surface. Direct compressive forces usually cause tearing between segmental fissures in an anteroposterior sagittal orientation. Horizontal fracture lines into the parenchyma give the characteristic burst pattern to such liver injuries. These usually underlie the ribs and costal cartilage. Fracture lines that are parallel have been dubbed *bear claw–type* injuries. Occasionally, there will be a single fracture line across the horizontal plane of the liver, usually between the anterior and posterior segments. Because this fracture line involves both lobes of the liver, it can cause significant hemorrhage if there is direct extension or continuity with the peritoneal cavity.

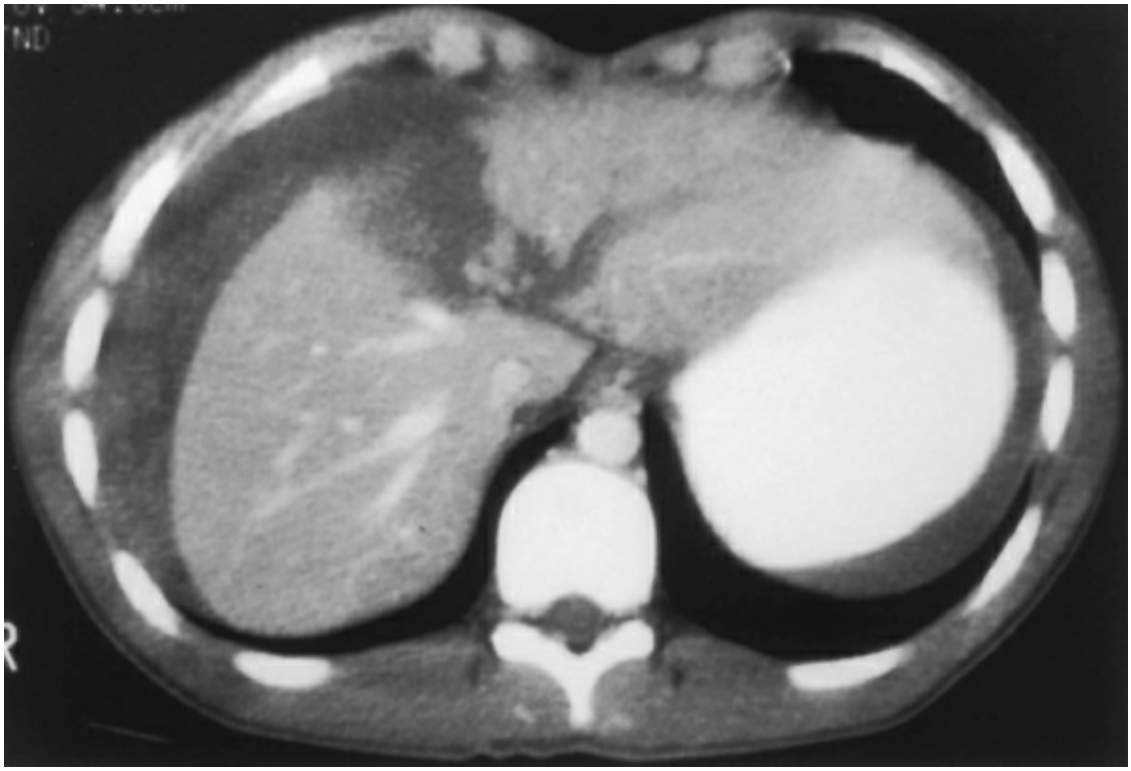

Figure 108.7. This 19-year-old patient was wearing three-point restraints when involved in a high-speed motor vehicle accident. The chest portion of the restraint has caused almost complete transection of the liver in its anatomic plane. A left hepatic lobectomy was performed.

Knowing the mechanism of injury articulated by the paramedics allows the surgeon to anticipate certain patterns of injury. Compressive forces caused by the steering wheel or the shoulder belt of a three-point restraint system can result in extensive bear claw–type injuries to the liver and even transections of the liver (Fig. 108.7). Another example is the so-called T-bone auto crash, which is a crash of two vehicles in a perpendicular fashion. Extensive injury can occur to the liver, usually when the T-bone is into the passenger side, which causes extensive right lateral rib fractures and compression of the right lobe of the liver. An extreme form of this lateral compressive injury is a transverse fracture through both lobes of the liver (Fig. 108.8). Shear injuries are usually associated with deceleration from falls (from a distance greater than two floors) or unrestrained occupants in high-speed motor vehicle accidents. The abrupt deceleration tends to tear the “relatively” heavy liver from its attachments, such as hepatic veins, veins from the caudate lobe, and lacerations into parenchyma at the ligamentum teres, which are often associated with exsanguinating hemorrhage.

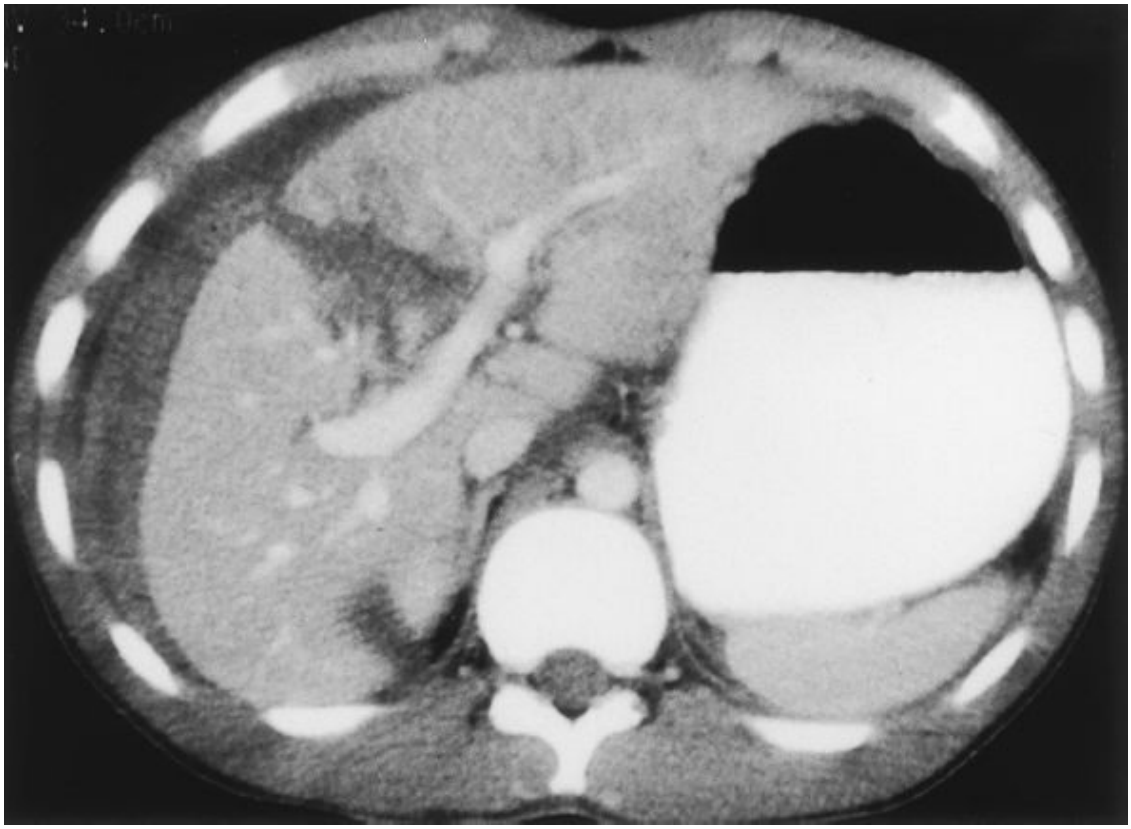

Figure 108.8. This 25-year-old patient was involved in a “T-bone” motor vehicle accident. He has extensive transverse lacerations across both lobes of the liver. The patient was managed nonoperatively.

DIAGNOSIS

The liver is at a high risk for injury from penetrating wounds, because it is the largest parenchymatous organ and its anatomic location is at the junction of the upper one third and middle one third of the torso. Major hepatic trauma is usually associated with medium- and high-velocity wounds. Occasionally, major vessel injury (usually involving the hepatic vein) can be caused by stab wounds, and I have seen several made with large knives, such as bayonets or bowie-type weapons. If a patient with a penetrating wound to the torso, particularly the midportion, is in a hemodynamically unstable condition, he or she requires no diagnostic studies except a chest radiograph, which may help the surgeon decide which torso cavity to open first. If one of the hemithoraces is full of blood, as determined by chest radiograph, it may be prudent to open that cavity first. The pitfall is that a hole in the diaphragm with injury to the left or right lobe of the liver can be the source of exsanguination. This possibility makes the point that the trauma patient should never be in any other

position than the supine one. The surgeon must be prepared to deal with exsanguination on both sides of the diaphragm. Rarely, a patient with major hepatic trauma can present in a hemodynamically stable condition from penetrating wounds. If there is a high index of suspicion of penetration into the abdominal cavity or if peritoneal signs are present, exploratory celiotomy is indicated. If in doubt, the surgeon can use diagnostic peritoneal lavage or ultrasound as a diagnostic adjunct to confirm that intraperitoneal blood is present. It must be emphasized that in the hemodynamically unstable patient with penetrating wounds to the torso there is no diagnostic challenge. The patient requires immediate surgery.

From a diagnostic standpoint, major hepatic injury from blunt trauma can be more vexing than trauma from penetrating wounds, particularly in the young healthy adult who can compensate for significant blood loss. Physical examination, even in an alert patient, is accurate in only one half of cases and carries a 56% false-positive rate and a 34% to 46% false-negative rate. The introduction of diagnostic peritoneal lavage in 1965 dramatically improved the surgeon's ability to diagnose intra-abdominal injury. It is rapidly performed and highly sensitive. More recently, the CT scan has been shown to be an even more valuable diagnostic tool, because it allows the surgeon to make judgments as to whether the patient requires operative intervention. The CT scan is valuable for even extensive liver lacerations. If these lacerations are contained and there is minimal blood into the peritoneal cavity, it may be more prudent to treat the patient nonoperatively.

Ultrasound has also been advocated as a diagnostic adjunct. It has an 85% to 90% sensitivity in picking up intraperitoneal blood, but it does not meet the high-resolution standards of CT. Because of its relative simplicity and low cost, it has been advocated as a useful technique. Intraoperative ultrasound has been found to be useful in elective surgery for patients who require resection for hepatic tumors. The ultrasound can identify metastatic lesions, and it has been useful in mapping out the venous anatomy for living-related hepatic transplant donors. I have not found it that useful during surgery for liver trauma.

The American Association for the Surgery of Trauma has developed a grading of organ injuries, including the liver. This classification is depicted in Table 108.2. Studies have confirmed the utility of this classification, and it has a good correlation with operative management. It must be emphasized that anatomic grading does not necessarily correlate with the

physiology of the patient and, in particular, hemodynamic stability.

TABLE 108.2 Grading of Liver Injuries

Grade	Injury Description
I	
Hematoma	Subcapsular, nonexpanding, <10% surface area
Laceration	Capsular tear, nonbleeding, <1 cm deep parenchymal disruption
II	
Hematoma	Subcapsular, nonexpanding, hematoma 10–50%; intraparenchymal, nonexpanding, <2 cm in diameter
Laceration	<3 cm parenchymal depth, <10 cm in length
III	
Hematoma	Subcapsular, >50% of surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma >2 cm
Laceration	>3 cm parenchymal depth
IV	
Hematoma	Ruptured central hematoma
Laceration	Parenchymal destruction involving 25–75% of hepatic lobe
V	
Laceration	Parenchymal destruction of >75% of hepatic lobe
Vascular	Juxtahepatic venous injuries (retrohepatic cava/major hepatic veins)
VI	
Vascular	Hepatic avulsion

NONOPERATIVE MANAGEMENT

In the past 10 to 15 years, there has been a surge of papers advocating nonoperative management of liver injuries. As noted in the introduction, this was practiced for several years prior to 1965, primarily because we did not make the diagnosis. Since the introduction of CT, we now recognize that a great majority of these previously undiagnosed liver injuries are grades I and II and approximately 50% of the grade III injuries. Concomitant with this interest in nonoperative management is the use of packs as definitive treatment of severe liver injuries. This is not a new concept and was used relatively extensively prior to World War II. Madding and Kennedy's experience with packing early in World War II had similar results with a relatively high complication rate and mortality. They changed to a more aggressive operative approach to liver injuries,

with better results and reduction in both mortality and morbidity. Recent studies also show an increase in liver-related morbidity after packing, and patients who fail this management may succumb to hemorrhage or sepsis. In one multi-institutional study of six institutions over a 5-year period, there were 1,335 patients with liver injuries, of which 210 were grade III, IV, and V injuries. There were 20 of 34 patients treated with packing alone who survived. The overall mortality rates for grade III, IV, and V injuries were 25%, 46%, and 80%, respectively. In another large study by a single institution, 181 patients were identified with grade III, IV, and V injuries, of which 18 were either dead on arrival or died in the emergency department. Of the remaining 163 patients, 47 were treated nonoperatively (28%). Mortality in the 116 patients who had an operation was 32.7%. In another very large series from China, there were 348 patients with grade III, IV, and V injuries, and 74% underwent surgery. The overall operative mortality was 12%. It is apparent that a small number of patients with grade III, IV, or V injuries can be managed nonoperatively or managed definitively with packs. The great majority will require resectional debridement, sutures, hemostatic agents, or lobectomy to control hemorrhage.

INITIAL OPERATIVE APPROACH

The trauma patient who requires celiotomy should be prepared and draped from the midneck to the midthighs anteriorly and from tabletop to tabletop laterally. In a patient in unstable condition, the preparation and draping optimally should be done before the induction of anesthesia, because the administration of a muscle relaxant can lead to a significant drop in blood pressure. The surgeon should be prepared to open the abdomen as soon as possible after the induction of anesthesia.

A generous midline incision is made from the xiphoid to below the umbilicus (Fig. 108.9). Once the abdomen is open and it has been determined that there is a large amount of blood within the peritoneal cavity, this incision should be carried down to the suprapubic area. My initial approach is to evacuate immediately as much clot as possible and then to pack all quadrants of the abdomen. These steps usually temporarily control hemorrhage and allow the anesthesiologist to replace needed volume. The surgeon should make some critical decisions at this juncture. Every effort to keep the patient warm must be made, including turning the thermostat in the operating room up to 85°F. There should be an adequate

blood-warming device, and the humidifier on the ventilator should be turned up to 105°F. It should also be determined at this time whether more access lines to the circulation are needed. If the hospital has a massive transfusion protocol, it should be initiated.

The surgeon should then remove the packs from the lower abdominal quadrants, checking for associated injuries, particularly those that can cause fecal contamination. If no fecal soilage is present, the surgeon can then use autotransfusion devices. The packs in the left upper quadrant are removed, and, if there is associated injury to the spleen, it should be promptly removed to reduce associated hemorrhage while the liver injury is being addressed. Finally, the packs in the right upper quadrant are removed (Fig. 108.10). At this juncture, I usually do a diagnostic maneuver by gently retracting the dome of the liver rostrally. A gush of blood emanating from the central area leads to a presumptive diagnosis of hepatic vein injury. Packs are replaced, and the surgeon must decide what isolation technique should be used. If there are obvious parenchymatous deep lacerations into the liver substance and blood is coming from the depths, another diagnostic maneuver is to apply a vascular clamp across the porta hepatis. If this controls the hemorrhage, it eliminates the portal veins as a source of the major bleeding, and one should presume that it is either hepatic arterial or portal venous bleeding. This presumption may lead to further dissection within the distal porta hepatis to isolate the left and right portal vein and the left and right hepatic artery to selectively control them and to determine which is the source of bleeding.

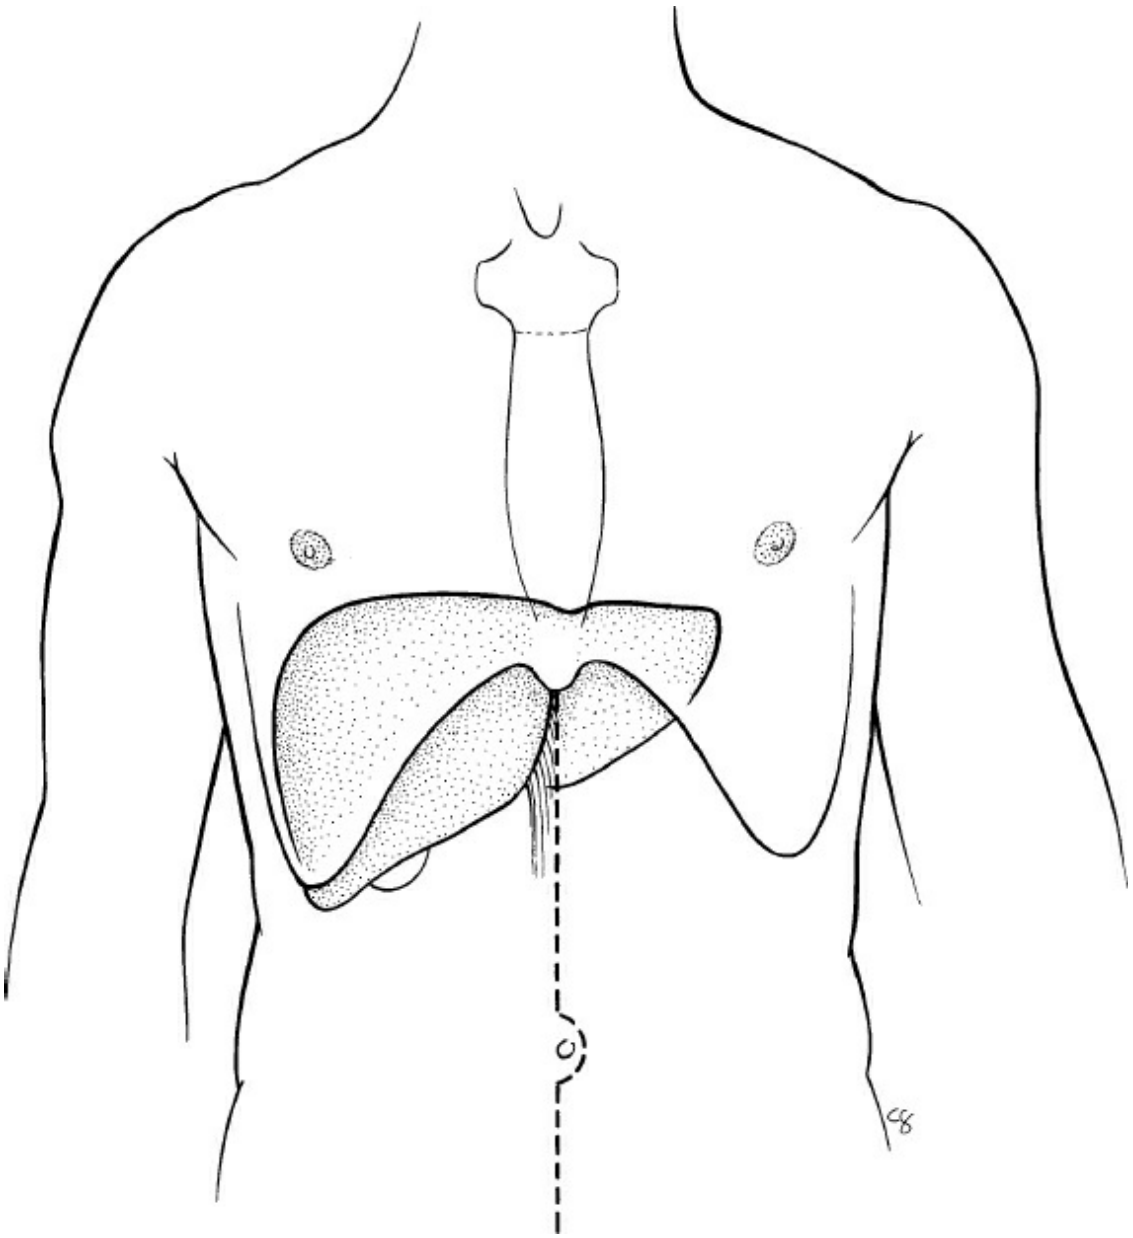

Figure 108.9. An extensive midline incision (*dashed line*) is preferred for all major hepatic injuries, with an option of extending the incision up the sternum.

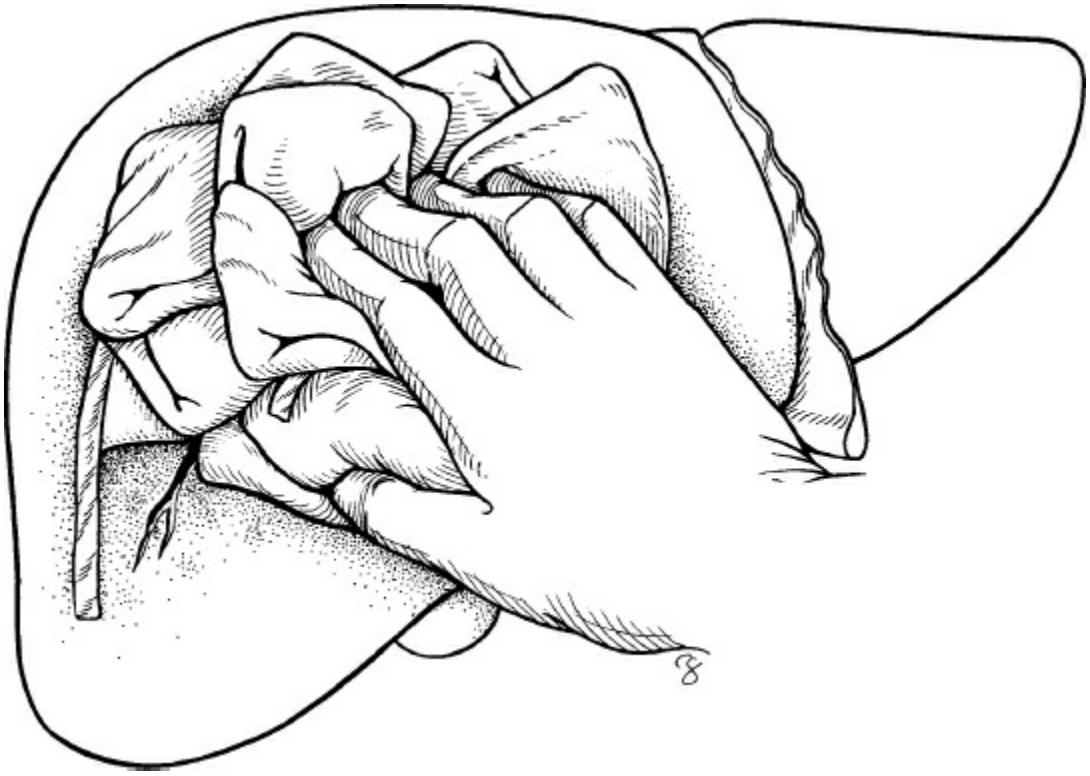

Figure 108.10. Hemostasis of liver fracture. Direct pressure with packs is usually sufficient to control the majority of liver parenchymal bleeding.

Although it has been advocated that a left anterior thoracotomy be done and the descending thoracic aorta clamped, this has not been useful in my experience, and, in fact, it can be harmful. The single exception is the patient with a penetrating gunshot wound to the midline in whom an associated abdominal aortic injury in the lesser sac is suspected. Clamping the descending thoracic aorta to control liver bleeding does not work and simply aggravates the metabolic acidosis and reperfusion injury that ensue when the clamp is removed.

SURGICAL TECHNIQUE

After temporary control of hemorrhage has been achieved by packs or compression, the first priority is to mobilize the liver. This includes sharply dividing the falciform ligament, taking down both leaves of the coronary ligament, and dividing the triangular ligament on the left lobe. If not already performed, the lesser sac should be entered by dividing the avascular area or the gastrohepatic ligament (Fig. 108.11). With these ligamentous attachments divided, the surgeon can mobilize the individual lobes to compress and gain access to the injuries (Table 108.3).

The most common major hepatic injuries that surgeons are called on to treat are deep lacerations into the parenchyma, usually involving the right hepatic lobe or segment IV (quadrate lobe) proximate to the falciform ligament (Fig. 108.12). Controlling the bleeding is best achieved by the assistant who stands on the left side of the patient. He or she can extend the left hand underneath the right lobe and compress the dome or the uninjured part with the right hand. This allows the surgeon to deepen the laceration, using a finger fracture technique and clamping the bleeding vessels and bile ducts. This step is followed by suture ligation of the vessel with 3-0 or 4-0 silk. Although clips have been recommended, I prefer suture ligation because these sutures are less likely to fall off with ventilatory movement of the liver. Deep liver sutures or mattress sutures are rarely indicated for control of hemorrhage, as they can lead to hematobilia, hepatic necrosis, abscess, and hematoma formation within the liver parenchyma. Once hemorrhage has been controlled with suture ligation of the individual vessels, the margins are checked for viability. The use of a viable pedicle of omentum is a useful technique to help with hemostasis and to close the dead space. The omentum also aids wound healing and reduces sepsis. If compression by the assistant is inadequate to control bleeding from the laceration, a vascular clamp can be placed across the porta hepatis (Pringle maneuver) (Fig. 108.13). Once hemostasis is achieved, this clamp should be removed as soon as possible. Although the Pringle maneuver has been used for up to 1 hour in elective hepatic surgery, the safe limit in the hypovolemic trauma patient has not been established. In general, I prefer to limit warm ischemia to 15 minutes but would accept up to 30 minutes.

Figure 108.11. Access to the porta hepatis is achieved by inserting the index finger into the foramen of Winslow and the thumb through the avascular portion of the gastrohepatic ligament.

Resectional debridement is the next most common procedure performed in major hepatic injuries. Resection is not determined by segmental anatomy but by the extent of injury and liver viability. Most often, these injuries are caused by shotgun blasts or large lacerations from blunt trauma that have lateral extensions. The general principles are straightforward. All nonviable liver tissue is resected using a finger fracture technique or the back of the scalpel handle. When resistance is encountered with either technique, this usually indicates the elastic tissue of vessels or biliary ducts. These are doubly clamped, divided, and suture ligated. Nonpulsatile oozing from the parenchyma can be controlled with the electrocautery unit or the argon beam coagulator. Fibrin glue, thrombin-soaked gelfoam, and infrared diathermy are all techniques that have been described to control oozing (Table 108.4). I prefer the electrocautery unit because it is

invariably available.

If there is any question about the viability of the margins of the tissue after resectional debridement, a second-look operation should be scheduled in 24 to 36 hours. In my opinion, removal of necrotic tissue is mandatory and reduces the incidence of systemic inflammatory response syndrome.

In a few cases (less than 1%), bleeding will continue to vex the surgeon during hepatorrhaphy or resectional debridement. In these instances, it is worthwhile to dissect out the right and left hepatic arteries and portal vein in the porta hepatis.

If application of a vascular clamp to one of these four vessels stops the hemorrhage, it is worthwhile to consider ligating one vessel and one vessel only. Ligating both the portal vein and hepatic artery to one lobe ensures

nonviability. Ligation of the common hepatic artery has been described with maintenance of liver function, because there is adequate collateral through the gastroduodenal artery. Ligation of the proper hepatic artery is contraindicated.

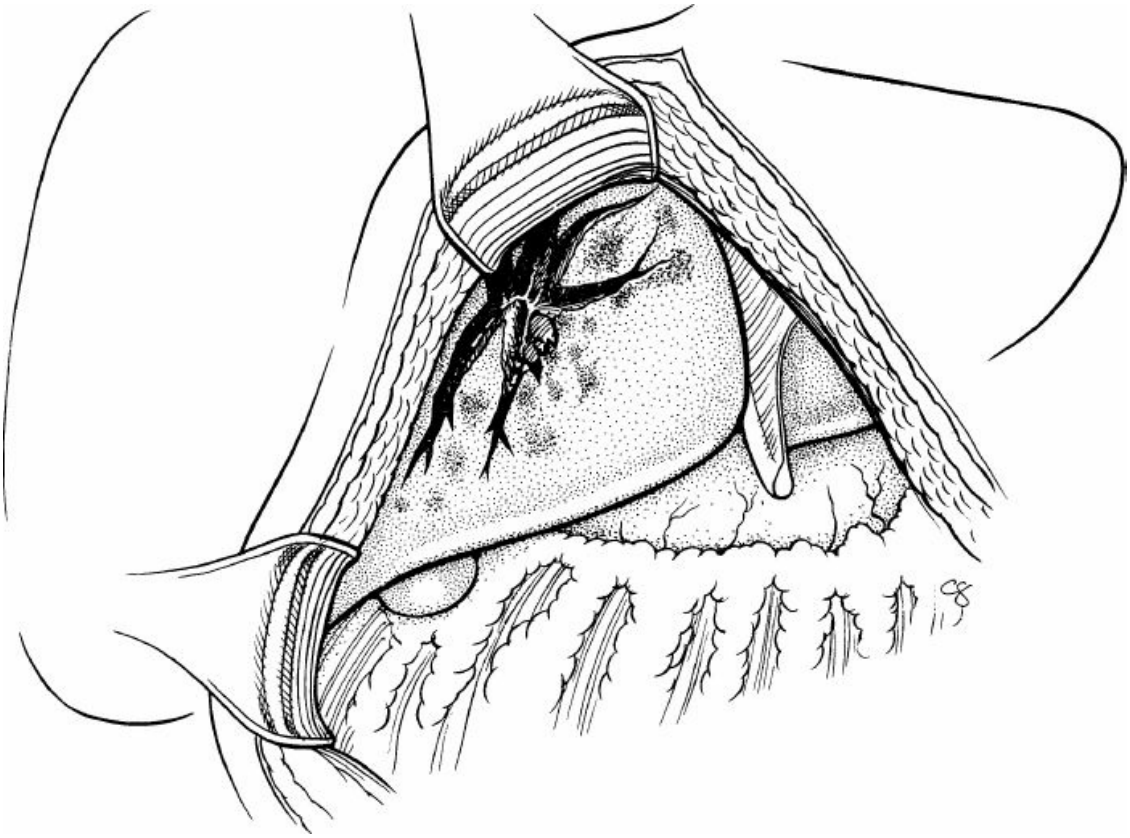

Figure 108.12. An approach to liver fracture. A typical stellate laceration of the right lobe of the liver extending into segment IV is shown. The falciform and triangular ligaments must be incised to mobilize the liver into the midline to control and treat the hemorrhage.

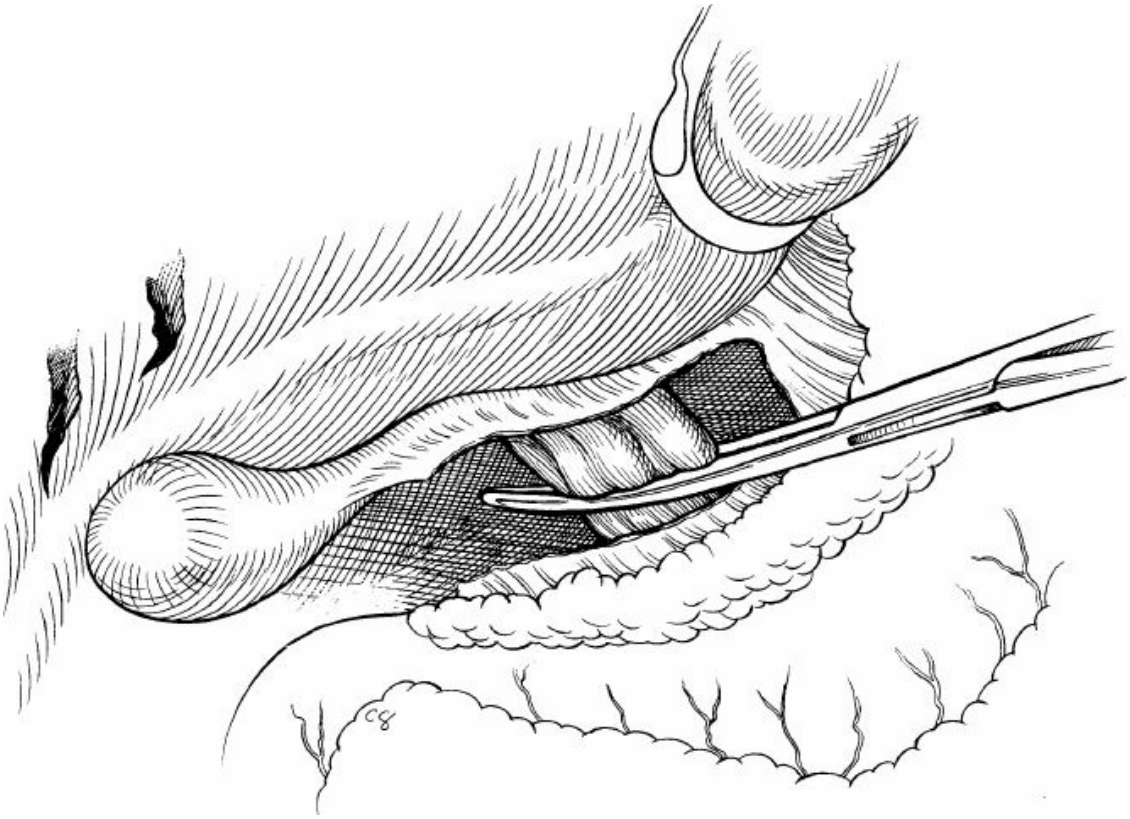

Figure 108.13. The Pringle maneuver.

Hepatic lobectomy is indicated in 2% to 4% of all patients with liver trauma; in major liver trauma, however, it is indicated in approximately 20% of cases. Usually, the extent of injury has made it obvious to the surgeon that a formal lobectomy is necessary to control the hemorrhage. I start the lobectomy by incising the liver capsule with a scalpel or the electrocautery unit in the anatomic plane (Fig. 108.14). The blood loss is minimized by compression of the liver between the assistant's hands. As described previously in this section, the liver parenchyma is divided by the finger fracture technique or the blunt end of a scalpel handle. As vessels and bile ducts are encountered, they are individually ligated with 3-0 or 4-0 silk. For a left lateral segmentectomy (segments II and III), resection is carried down to the left of the falciform ligament (Fig. 108.15). Care must be taken not to divide vessels that may be supplying segment IV. Care must also be exercised when one reaches the proximal part of the left hepatic vein to make sure that the middle hepatic vein is not divided. The left hepatic vein stump is oversewn with a 4-0 vascular silk suture. The arterial supply to segments II and III is ligated to the left of the falciform ligament with 2-0 silk, and the branch of the portal vein to segment II is also ligated with 2-0 silk.

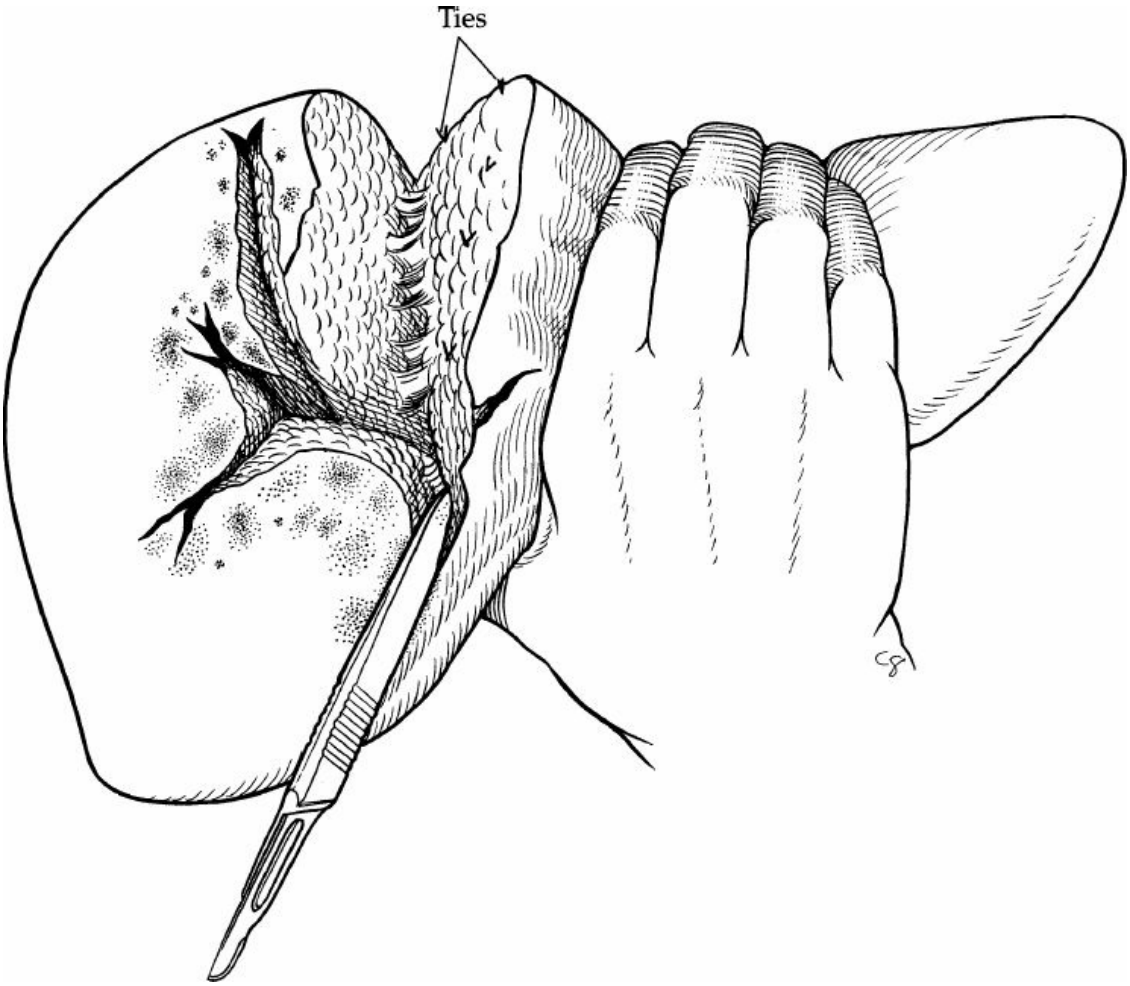

Figure 108.14. Scalpel handle resection. After incision of the liver capsule with the electrocautery unit, the finger fracture technique or the scalpel handle can be used to dissect through the parenchyma to expose the hepatic vessels and biliary radicals, which are individually suture ligated with 2-0 or 4-0 silk.

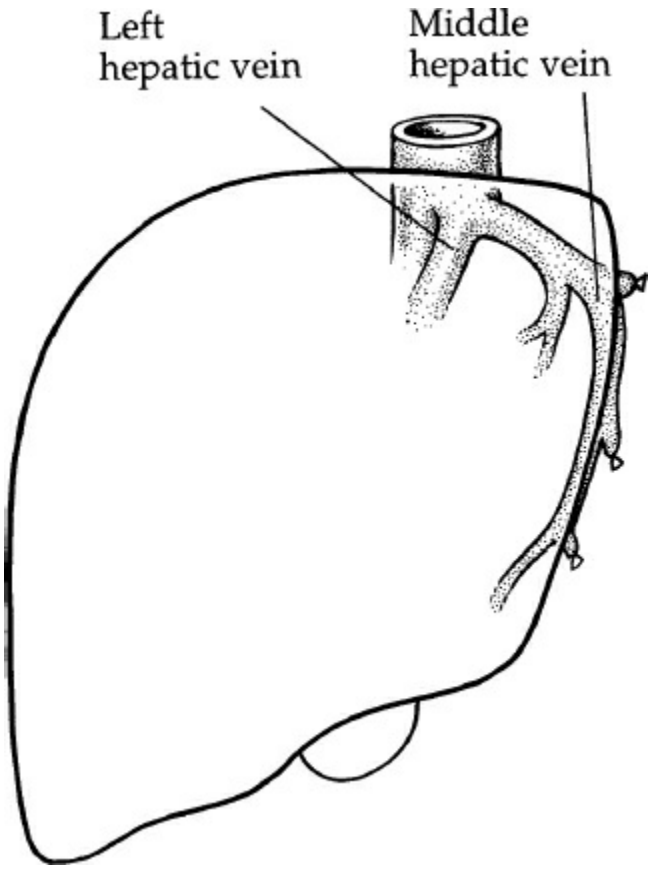

Figure 108.15. Left lateral segmentectomy (segments II and III).

The line of resection for a left lobectomy should be carried out to the left of the gallbladder fossa (Fig. 108.16). It is important to identify the middle hepatic vein during resection, because it drains the superior segment of the right lobe and commonly drains into the left hepatic vein. The left hepatic vein should be ligated and divided distal to the junction with the middle hepatic vein. The left portal vein should not be ligated until it is well exposed in the hilum, because it might give off a branch to the anterior segment of the right lobe. Care should also be taken when dividing the left hepatic duct, because a segmental hepatic duct from the right frequently crosses the segmental fissure to drain into the left hepatic duct. The left hepatic artery supplies only the left side and can be readily ligated.

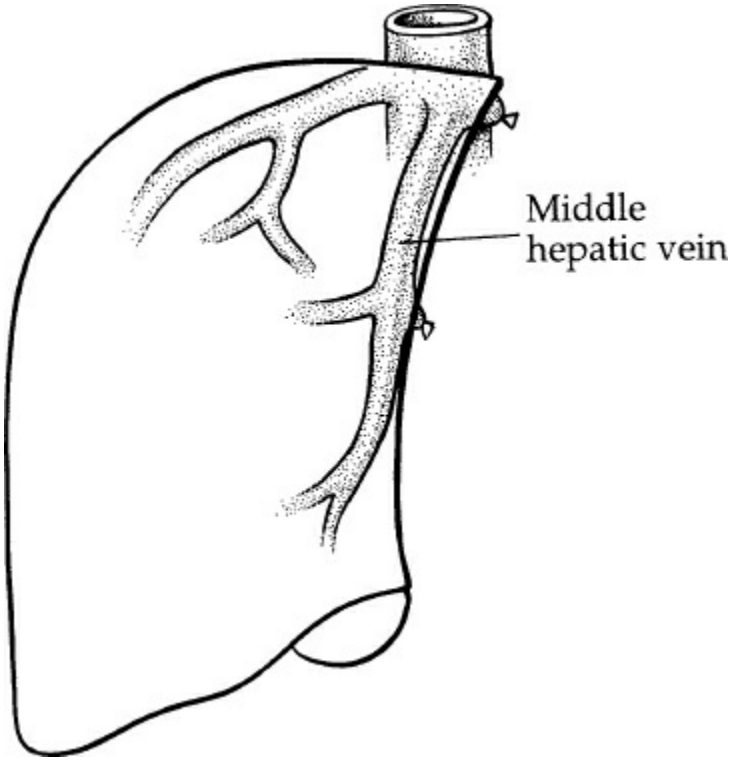

Figure 108.16. Left hepatic lobectomy.

In performing a right hepatic lobectomy, the line of resection should be carried to the right of the gallbladder fossa (Fig. 108.17). The middle hepatic vein should be divided early and proximately to avoid injury to the left hepatic vein. The dissection should then be carried cephalad and posteriorly toward the vena cava to the right of the middle hepatic vein. The right hepatic artery and portal vein can be dissected early in the dissection and ligated to decrease blood loss. Care should be taken to avoid damage to the occasional branch of the right hepatic artery that may supply the medial segment of the left lobe. After either right or left hepatic lobectomy, there is a large raw surface over which I prefer to place omentum that is sutured to the capsule at the cut margins.

A useful adjunct in a small number of patients who require lobectomy, resectional debridement, or hepatorrhaphy is vascular isolation. At least three methods are currently in use: the Heaney maneuver, atriocaval shunting, and venovenous bypass. Of these three techniques, I prefer the Heaney maneuver and would only rarely use venovenous bypass (Fig. 108.18). Atriocaval shunting has been abandoned by most surgeons.

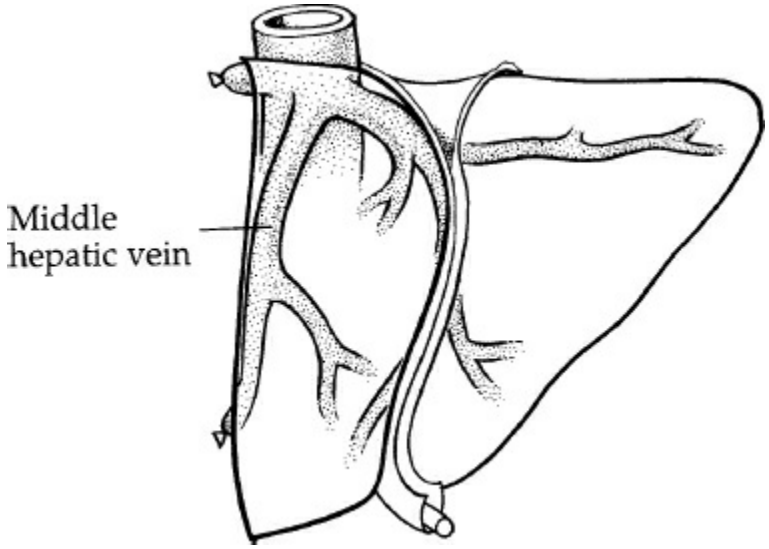

Figure 108.17. Right hepatic lobectomy.

The Heaney maneuver is performed by clamping both the suprahepatic and infrahepatic inferior vena cava while simultaneously applying the Pringle maneuver. During the Heaney maneuver, it is crucial that central pressures are monitored and that fluid replacement is adequate when the inferior vena cava is clamped.

The second most common method of hepatic vascular isolation is venovenous bypass using a centrifugal pump that was initially described by Starzl. The modification of this technique is simply to cannulate the femoral vein in the groin and the axillary vein in the upper arm (Fig. 108.19). Heparin-coated tubing connects the two cannulas. The centrifugal pump is used to assist flow. Complete hepatic vascular inflow can then be accomplished by clamping the suprahepatic vena cava at the diaphragm, suprarenal vena cava, and porta hepatis. It is not necessary to place a portal vein catheter as originally described by Starzl.

One of the papers that advocated the use of nonoperative management of liver injuries suggested that up to 80% to 90% of all liver injuries could be managed in such a manner. In this study, however, 2 patients had bilomas, and 14 patients had major complications from hemorrhage, of which 2 patients died. A more rational approach was presented at the American Surgical Association by Richardson et al., who studied 1,842 consecutive liver injuries from 1975 to 1999. His group looked at 5-year intervals and did a comparative analysis of operative treatment and some of the demographics. Over this period, the number of liver injuries increased, but the severity of liver injuries remained fairly constant. It may also reflect the positive effect of three-point restraints, airbags, and the

triage of patients to trauma centers. This fact might be due to our ability to diagnose liver injuries better with CT. One of the interesting features of this paper, however, is that the mechanism of injury has changed fairly dramatically. Between 1975 and 1979, the blunt-to-penetrating ratio was 48% to 52%, whereas in 1995 to 1999, it was 74% to 26%. Equally dramatic is the nonoperative management in this series, which is 65% compared with the 80% to 90% noted previously. Sixty-five percent may be a more realistic number, but it does not take into account associated injuries.

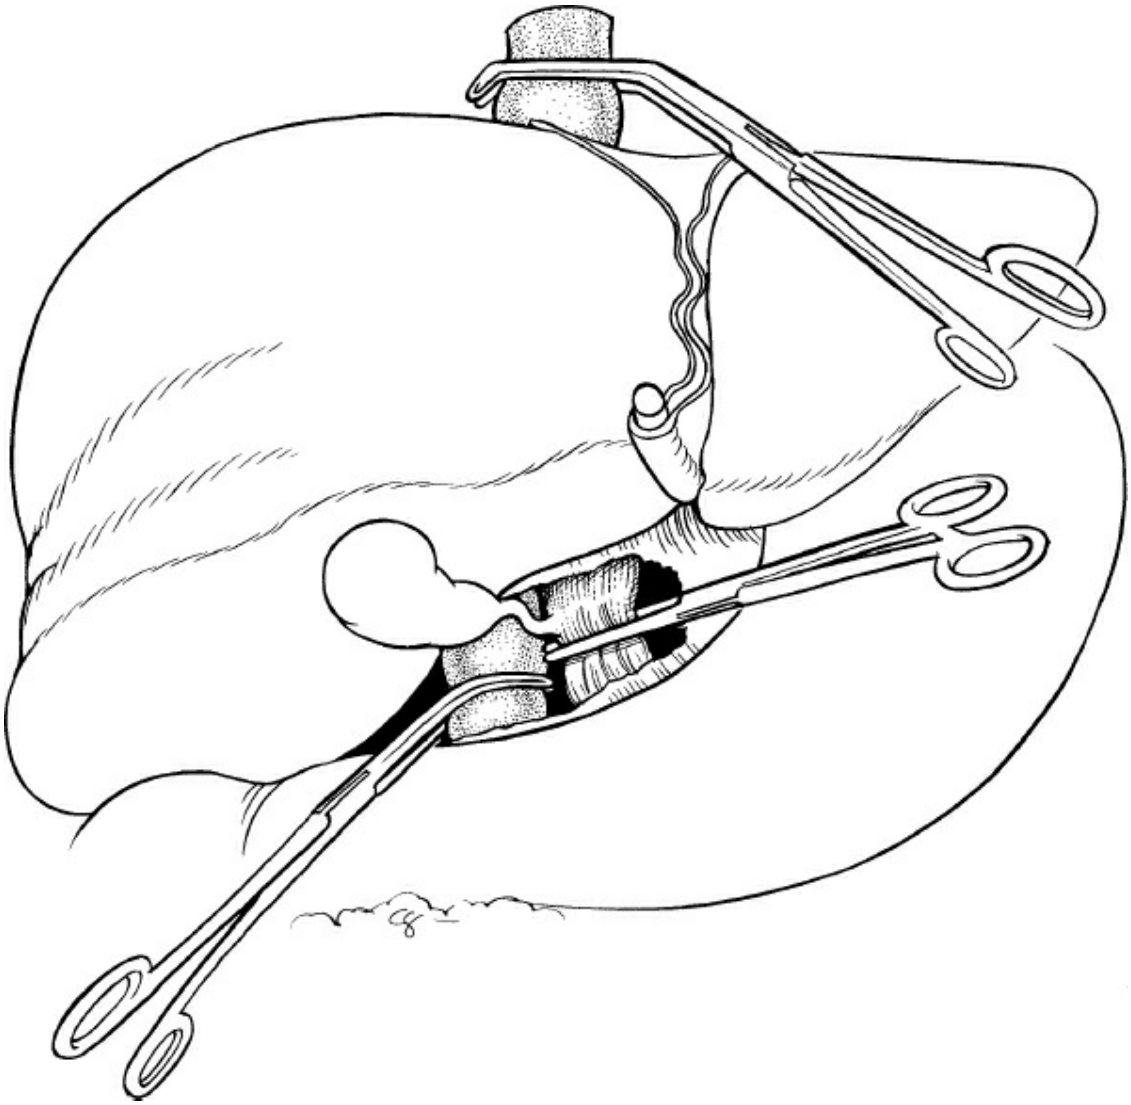

Figure 108.18. The Heaney maneuver for vascular isolation of the liver.

Another approach is one that was advocated by Strong over a 13-year period that 187 patients were admitted to his hospital with liver injuries.

Of these, 37 underwent anatomic resection with an overall operative mortality of 11.1% and a hepatic complication rate of 16%. Strong concluded that the role of resection should be reevaluated and that the wide condemnation of anatomic resection for severe liver injury is inappropriate. Finally, he suggested that general surgeons lack experience to do these resections, and patients should be referred to centers that do extensive hepatobiliary surgery. This was confirmed by a study by Duane et al., who treated 80 grade IV and V injuries. Of 44 patients who had operations, there was 78% mortality. They concluded, “In three years, only 44 patients underwent operations, approximately 15 per year. One must consider whether the relative paucity of need for operation in complex liver injury results in degradation of operation decision-making and skill.” They further stated, “This issue certainly requires some consideration in the future to ensure surgeons will receive adequate training for complicated trauma cases such as these.” Unfortunately, the American Board of Surgery only requires four operative liver cases to sit for the primary certificate.

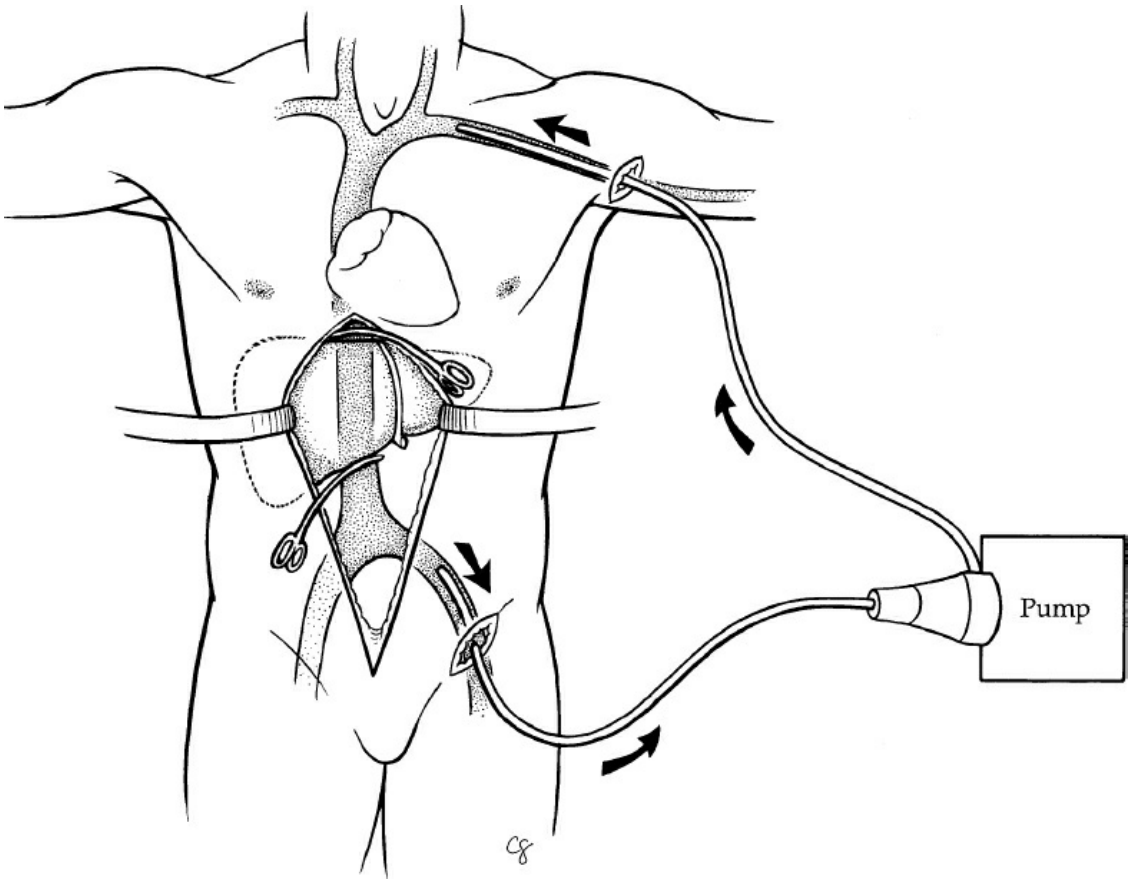

Figure 108.19. Venovenous bypass. Note the placement of the suprahepatic inferior vena cava clamp and the intrahepatic

suprarenal venous clamp.

My own personal experience over an 11-year period (1988 to 1998) involved 74 patients who were admitted for liver injuries. Based on CT scan and physiologic data, I elected not to operate on 24 patients (32.4%). There were 6 deaths in this group, all from closed head injury. The remaining 50 patients (67.6%) required operative management, of which the primary indication in 25 patients was for injuries other than the liver injury. Six of these operations turned out to be nontherapeutic celiotomies. Of the 19 remaining cases, however, 6 required splenectomy, 1 required pancreatectomy, 1 required repair of the bladder, and 2 patients required control of bleeding from the kidney. One patient had a small-bowel injury, 2 patients had duodenal injuries, and 2 patients had colon injuries. The majority of the liver injuries were treated by simple suture techniques or debridement. Twenty-five patients, slightly more than one third of the total number of patients, were operated on primarily for their liver injuries. Six required lobectomies, 1 patient had a resection of segments II and III, 4 patients underwent major resectional debridement, and there were two injuries to the retrohepatic cava. Of these 13 patients, there was 1 death—a patient who bled to death from his retrohepatic caval injury (8% mortality). In addition, 7 patients required suture control of liver hemorrhage; 4 patients were packed, which became definitive treatment; and 1 patient was operated on for compartment syndrome of the liver.

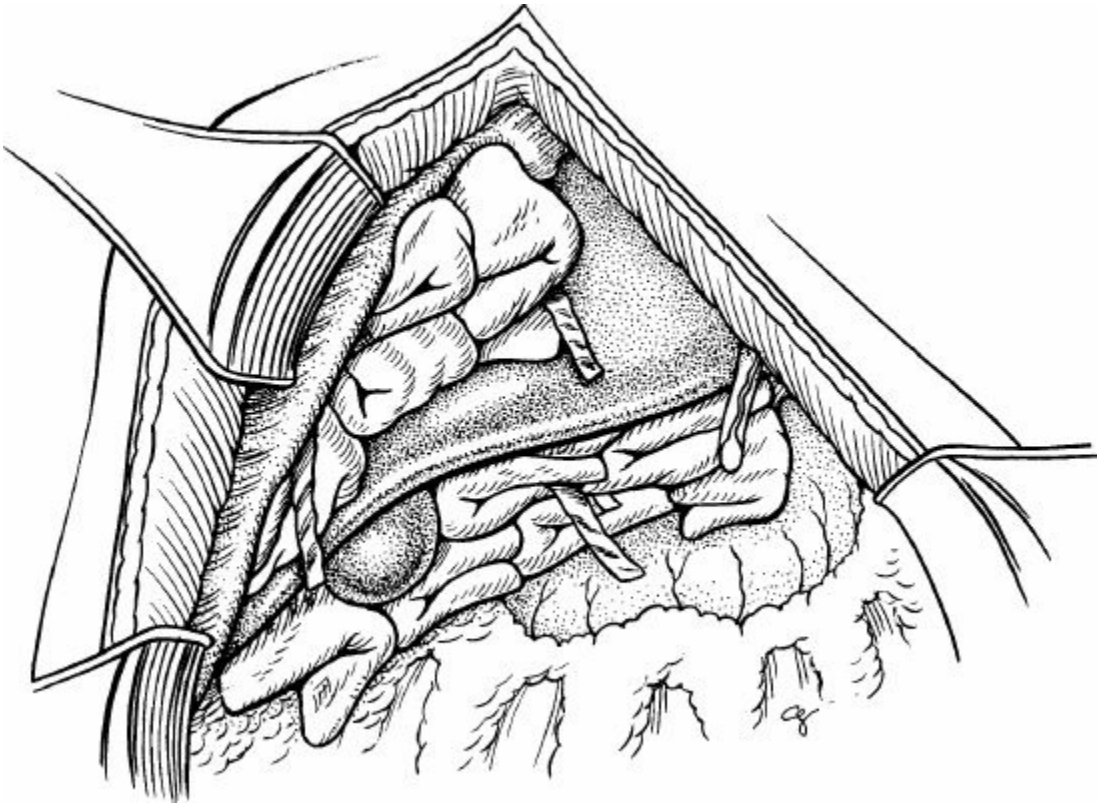

Figure 108.20. Circumferential packs of the liver. Care must be exercised not to impede venous return from the inferior vena cava or to push the diaphragm cephalad, which would compromise ventilation.

As was mentioned earlier, packing was popular before World War II, but the results were poor. More recently, it has been recognized that packing of liver injuries not only buys time to mobilize resources but can be definitive treatment in certain injuries. Such injuries are usually crush injuries to the liver that involve both lobes. It is particularly useful for injuries in which the bleeding is primarily venous. In my experience, it is not successful when ongoing surgical bleeding from arteries is present. Packing is probably the only way of salvaging a patient who is coagulopathic or hypothermic, or both, during operation. The intent here is to pack temporarily, resuscitate and rewarm the patient in the intensive care unit (ICU), and return to the operating room as soon as possible. When packing is being used as definitive treatment with a transverse fracture through both lobes, it often requires repacking at 12 to 24 hours after the initial packing and even repacking a third time 24 hours later.

The technique does not involve simply stuffing laparotomy sponges around the liver. Some surgeons have advocated placement of plastic between the gauze and the liver, but, in my experience, plain gauze is

equally effective. The goal is to pack the perihepatic area so that closure of the injury is accomplished (Fig. 108.20). The rib cage provides a rigid strut so that circumferential compression of the liver is accomplished. The intent is to place the packs so that the diaphragm is not unduly elevated, and the inferior vena cava is not compromised. The latter can be assessed by having the anesthesiologist give the central venous pressure values and blood pressure during the packing. If either of these values falls, compromise of the inferior vena cava is usually indicated. Once the circumferential packs are placed, packs are gently placed against the base of the liver, and closure of the abdomen is accomplished. During the time that the patient is being resuscitated in the ICU, preparation for the next operation is carried out. This preparation includes using venovenous bypass to facilitate hepatic vascular isolation and to mobilize the massive transfusion protocol. After packing, it is also possible to transport the patient to a different center that has more resources.

Drainage of the liver is controversial after repair of injury. In general, I prefer to drain only for biliary leak; thus, the most severe injuries are the ones that will require drainage. I prefer closed drainage systems and drain not only in proximity to the injury but also posterior to provide dependent drainage of fluid collections.

A final therapeutic modality that has to be considered in the context of modern surgery is hepatic transplantation. There have been several successful reported cases after major hepatic trauma. The indication for hepatic transplantation secondary to trauma is a severe nonreconstructible injury to the porta hepatis or bilobar nonreconstructible injuries. Other intra-abdominal injuries and head injuries are relative contraindications. The availability of an appropriate donor is unpredictable, and every effort should be made to consult a liver transplant center as soon as possible so that the anhepatic period is minimized.

Repair of Injuries to the Porta Hepatis

Most of the injuries to the porta hepatis are from penetrating causes. Control of hemorrhage is the first priority. I prefer to perform an extended Kocher maneuver, taking down the entire right colon and mobilizing it toward the midline along with the duodenum. This procedure exposes the portal vein and a significant portion of the inferior vena cava and infrarenal aorta, which may also be injured. In a few instances, it may be necessary to divide the neck of the pancreas to visualize the proximal

portion of the portal vein at the junction of the splenic vein and the superior mesenteric vein. Although successful ligation of the portal vein has been reported, I would make an extra effort to repair it or to do an interposition graft using harvested internal jugular vein from one side of the patient's neck. If the spleen has been injured, it may also be possible to use a portion of the splenic vein as an interposition graft. Injuries to the hepatic artery are problematic. As was noted previously, ligation of the proper hepatic artery is not recommended. Every effort should be made to repair this or replace it with an interposition saphenous vein graft. I prefer to repair most with lateral sutures of 5-0 or 6-0 Prolene.

Injuries to the extrahepatic biliary tree are also usually associated with penetrating trauma; however, blunt trauma can cause stretch or avulsion injuries. When the injury is to the common duct, repair must be meticulous. The normal common duct is approximately 4 mm in diameter. Lateral repair is possible, provided that there is no segmental loss. If segmental loss is present and involves the proximal common bile duct, biliary drainage can be accomplished using a Roux-en-Y procedure to either the common hepatic duct or the gallbladder. This Roux-en-Y can be difficult to perform with a normal-sized common bile duct. To make this anastomosis technically easier, I use a modification of the vascular Carrel patch (Fig. 108.21). A 1-cm length of cystic duct is preserved after cholecystectomy, and the side wall is opened into the common bile duct remnant. This patch of bile duct is then used to anastomose in an end-to-side fashion to the Roux limb. In the unstable patient, temporary biliary drainage can be accomplished by placing catheters into the right and left hepatic ducts or the common duct, which are then brought out of the abdomen laterally. Delayed reconstruction of the biliary systems can be accomplished after the patient recovers from other injuries.

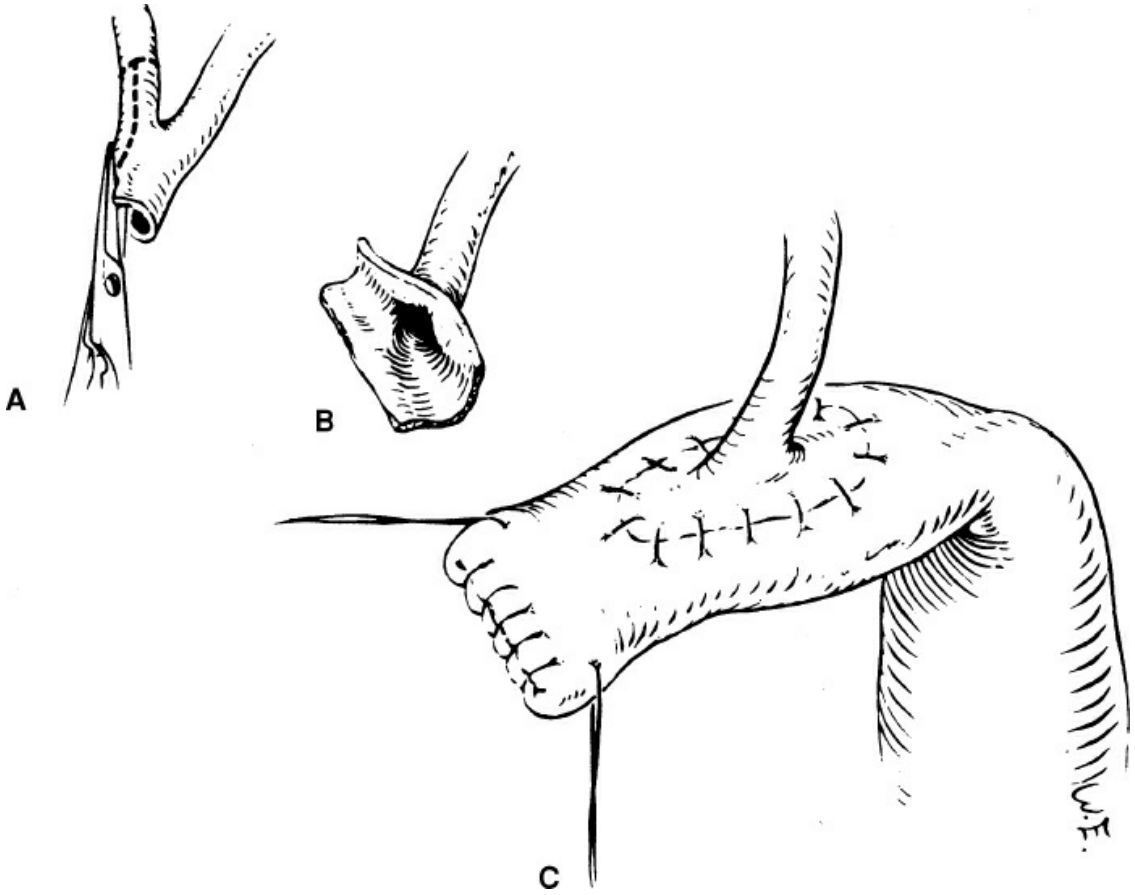

Figure 108.21. Modification of the Carrel patch for choledochojejunostomy in patients with normal-sized common ducts. **A.** The common duct is transected distal to the junction of the cystic duct; the gallbladder is removed, retaining 1 cm of cystic duct. The Y portion is opened as shown. **B.** A carrel patch has been formed. **C.** A choledochojejunostomy is performed end to side as shown.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Massive blood loss, transfusion, tissue trauma, shock, hypothermia, and liver dysfunction contribute to coagulopathy intraoperatively and postoperatively. Treatment of the coagulopathy requires rewarming of the patient as well as replenishment of clotting factors using transfusion of fresh whole blood, packed red blood cells, or fresh frozen plasma in conjunction with platelets in a ratio of 1:1:1. Hematocrit, platelet count, and prothrombin time should be measured frequently as a guide to therapy for coagulopathy. If the coagulopathy has been corrected and the patient continues to hemorrhage, reexploration is indicated. For complex liver injuries (classes IV and V), I would advocate a second-look reoperation at

24 to 48 hours.

Postoperative pulmonary failure is frequent after major trauma. Tissue trauma, large-volume fluid resuscitation, and associated injuries (e.g., rib fracture) contribute to pulmonary failure. The patient should be managed with endotracheal intubation and positive-pressure ventilation until hemodynamically stable. The patient should be extubated as soon as possible, but with the knowledge that reintubation may be necessary.

Jaundice occurs frequently after liver trauma. This may be a sign of severe hepatic dysfunction but is usually related to resorption of hematomas, breakdown of transfused red cells, and mild hepatic dysfunction from central lobular necrosis secondary to shock. Hepatic function returns to normal promptly, although elevated bilirubin levels in the serum may persist for days.

Bile leaks and fistulae can usually be detected when the perihepatic area has been drained. Unless these leaks are from a major bile duct, they generally close spontaneously.

Hematobilia is an uncommon complication, occurring in fewer than 1% of complex injuries. The typical presentation is days to weeks after the injury and can be manifest by melena, upper gastrointestinal bleeding, hypotension, or biliary colic. The diagnosis is confirmed by visualizing blood coming from the ampulla during upper gastrointestinal endoscopy. Treatment is preferentially by percutaneous transvascular selective embolization of the involved artery.

Sepsis after hepatic trauma occurs in 7% to 12% of patients and is related to intra-abdominal abscess, pneumonia, acalculous cholecystitis, and ischemic bowel. Risk factors associated with intra-abdominal abscess postoperatively include associated splenectomy, liver packing to control hemorrhage, class IV or V injury, large transfusion requirement, and colon injury. Subphrenic and subhepatic abscesses are usually marked by fever 4 to 7 days after operation. Pleural effusion may be noted on chest radiography. Diagnosis can be made by ultrasound or CT scan. Treatment includes percutaneous or surgical drainage and intravenous antibiotics. Prophylactic antibiotics are not recommended postoperatively unless there is an associated bowel injury.

EDITORS' COMMENT

Dr. Donald Trunkey's contributions to trauma care are legendary and indisputable. The principles that he presents in this chapter on the care of hepatic trauma remain as true today as when he originally wrote them. Effective management requires intimate knowledge of hepatic anatomy and physiology and technical skill when surgical treatment is required. He discusses the importance of addressing coagulation abnormalities, management that is based on hemodynamic instability rather than CT findings alone, and the trend toward

nonoperative management, while at the same time being more aggressive when the patient is hemodynamically unstable despite resuscitation attempts. His detailed descriptions of operative management based on the anatomy of the injury and dictated by the patient's clinical condition are timeless.

Dr. Trunkey begins his chapter on management of major hepatic trauma by tracing its evolution over the past century, guided by refined surgical techniques for elective liver resection. Surgeons treating patients with liver injuries will always need a confident command of hepatic anatomy and its variations, as described in this chapter.

Major hepatic trauma, as defined by Dr. Trunkey using the anatomical definitions presented in his Table 108.2, are patients with grade III, IV, and V liver injuries, and in his experience the majority of these patients will need a laparotomy. Although most surgeons agree that the majority of patients with penetrating injury to the liver require prompt surgery, the management of blunt liver injury is a topic of debate and has evolved recently to favor less aggressive management. Studies published in the past decade suggest that a majority of patients with blunt trauma can be managed without an immediate laparotomy. A major factor influencing treatment of these patients is their hemodynamic status. Patients with major liver injury following blunt torso trauma can, in addition to anatomical characteristics, be separated into three categories based upon their clinical course in the first minutes after their presentation to the emergency department: patients who present with a stable "normal" systolic blood pressure over 120 mm Hg are considered hemodynamically stable; patients are categorized as stable-after-resuscitation if they present initially with a transient systolic blood pressure under 100 mm Hg, but sustain their systolic blood pressure in the normal range following intravenous infusions of 1 L of isotonic fluid or one unit of whole blood. Patients in these two groups can safely be transported to the CT scanner for imaging of the chest, abdomen, and pelvis, with subsequent management guided by the severity of liver injury seen on the CT and their clinical course. A third category of patients, based upon clinical course on presentation, is unstable; they have a systolic blood pressure below 80 mm Hg and do not have a favorable blood pressure response to resuscitation. These unstable patients are at risk of immediate death from exsanguination, and most trauma surgeons advocate prompt laparotomy with minimal additional diagnostic testing. However, surgeons currently choose nonoperative management in a substantial majority of patients with liver injury but with no other identified injuries requiring laparotomy even in patients with grade III, IV, and V injuries. Recent studies suggest that the majority of patients can have successful nonoperative management. Melloul and colleagues evaluated management of major blunt hepatic injuries (grades III to V) in a systematic review of the literature, selecting 12 articles of high quality. They found that 66% were managed nonoperatively with a success rate of 94%; arterial embolization (AE) to manage contrast extravasation on CT was employed in only 3% and was 93% successful (Melloul E, Denys A, Demartines N.

Management of severe blunt hepatic injury in the era of computed tomography and transarterial embolization: a systematic review and critical appraisal of the literature. *J Trauma Acute Care Surg* 2015;79:468–74). Boese and colleagues published a summary of eight high-quality manuscripts on blunt liver trauma in 2015 and reported that the failure rate of nonoperative management—meaning the patient had delayed laparotomy after an initial decision to observe the patient—ranged from 0% to 24%, with mean of 10% (Boese CK, Hackl M, Muller LP, et al. Nonoperative management of blunt hepatic trauma: a systematic review. *J Trauma Acute Care Surg* 2015;79:654–60). The average time interval between injury and operation was 12 hours. In this group of severely injured patients, the death rate was 2.4%. Predictor variables that were associated with failure of nonoperative management were: hypotension, need for ongoing fluid resuscitation including blood transfusions, peritoneal signs, higher Injury Severity Score (but not AAST Liver Injury Grade per se), and CT findings suggesting additional intra-abdominal injuries.

Surgical Techniques

When the patient with severe liver injury does require operative management, the pattern of findings on the abdominal CT may permit surgeons to interpret the pattern of liver injury, particularly the precise location of the injury in relationship to major vascular structures, to suggest what surgical techniques may be required at laparotomy. For example, a deep laceration in close proximity to hepatic veins, as demonstrated in Figure 108.7, indicates that traction on the right lobe of the liver causing an inferior displacement may result in a rush of blood. Dissection into the deep laceration in the portal hiatus in Figure 108.8 led to bright red arterial bleeding. Dr. Trunkey advocates a long midline incision to provide optimal exposure, but for some surgeons the bilateral subcostal incision, with superior extension through the linea alba to the sternum, may provide optimal access to the liver. In rare cases of injuries to the junction of the hepatic veins and the inferior vena cava, particularly in large patients with an unfavorable body habitus, prompt extension of the midline incision into a sternotomy can provide improved access to hemorrhage in this location. Having an abdominal wall retraction device that is attached to the operating table readily available may improve operative exposure to the dreaded injury to the retrohepatic veins.

Surgeons performing an urgent laparotomy in a patient with major hepatic injury and bleeding may find several maneuvers useful in the first moments after the incision has decompressed a hemoperitoneum typically in excess of 1 L of blood. The surgeon can advance both hands into the right upper quadrant, grasping the lateral sides of the right and left lobe of the liver and thereby compressing the liver, closing and compacting the bleeding liver laceration (Pachter HL. Prometheus bound: evolution in the management of hepatic trauma—from myth to reality. *J Trauma* 2012;72:321–9). At the same time, the surgical assistant can reach in under the left lobe of the liver, identify by

palpation the junction of the esophagus and stomach, and compress the supraceliac aorta against the spine, thus achieving a prompt increase in perfusion pressure to the brain and heart while the anesthesiologist infuses blood products to restore the depleted blood volume. Dr. Trunkey also provides the prudent admonition that the surgical team must avoid the pitfall of being so distracted by a major liver injury that they overlook other sources of hemorrhage into the abdomen, retroperitoneum, or pelvis. The Pringle maneuver can also help control hemorrhage and also help identify whether the bleeding is superior or inferior to the porta hepatis. However, surgeons should anticipate complications associated with having a vascular clamp across the porta hepatis for more than 20 to 30 minutes, including massive bowel edema or delayed gallbladder infarction, and should have a low threshold following a prolonged Pringle maneuver to perform a routine second look procedure. Hypocalcemia can also occur in a patient who receives a rapid infusion of blood products that contain citrate, a molecule normally cleared by the liver.

Dr. Trunkey highlights that in situations where the initial packing of a liver laceration has controlled bleeding in a patient who is cold, acidotic, and has needed a massive transfusion, the surgeon may prudently select damage control methods, to leave the packs in place and not attempt definitive control of liver hemorrhage at the first procedure. One caveat is that abdomens partially closed with vacuum suction devices may aspirate clots and thereby impair tamponade, resulting in additional bleeding (Cue JI, Cryer HG, Miller FB, et al. Packing and planned reexploration for hepatic and retroperitoneal hemorrhage: critical refinements of a useful technique. *J Trauma* 1990;30:1007–14).

Penetrating Liver Injury

Most patients with a penetrating liver injury need a laparotomy. The surgical techniques described by Dr. Trunkey are used to manage penetrating injury to the liver. One specific problem is a penetrating injury that has an entrance and an exit wound and the tract passes through the central parenchyma of the liver. This latter injury may be best managed by the improvised balloon tamponade method described by Moore et al. (Poggetti RS, Moore EE, Moore FA, et al. Balloon tamponade for bilobar transfixing hepatic gunshot wounds. *J Trauma* 1992;33:694–7).

A few surgeons have questioned the need to operate on all patients with penetrating injury to the liver. Demetriades and colleagues reported that they had modest success nonoperatively managing 30% of isolated low-grade injuries to the liver in a strictly defined subset of patients with penetrating injury in the right upper abdomen and lower chest. The patients were hemodynamically stable, had no peritoneal signs, and no signs of “heavy bleeding” (Demetriades D, Gomez H, Chahwan S, et al. Gunshot injuries to the liver: the role of selective nonoperative management. *J Am Coll Surg* 1999;188:343–8). This and other reports suggest that selected patients with low-velocity penetrating injuries below the right nipple and superior to the right

costal margin can be managed by first a diagnostic CT scan, and if no indication for immediate surgery is seen, delayed laparoscopy to evaluate for penetrating diaphragm injuries or bile leak. Surgeons should be wary that insufflation in a patient with a small diaphragm perforation may lead to a tension pneumothorax.

Angioembolization

Dr. Trunkey advocates in Algorithm 108.2 for selective reliance on angiography and embolization (AE) of bleeding hepatic arterial injuries. Most authors now agree that AE is indicated in patients who have contrast extravasation observed on CT scan. Another group who benefit from AE are those patients transported from the emergency department to the operating room for an immediate laparotomy to control their bleeding liver (Letoublon C, Morra I, Chen Y, Hepatic arterial embolization in the management of blunt hepatic trauma: indications and complications. *J Trauma* 2011;70:1032–7). In a minority of patients in whom peri-hepatic packing fails to stop all bleeding, particularly bright red hemorrhage from deep in a hepatic laceration, surgeons may decide to quickly accomplish a temporary closure of the abdomen and transfer the patient immediately to the interventional radiology suite (Green CS, Bulger EM, Kwan SW. Outcomes and complications of angioembolization for hepatic trauma: a systematic review of the literature. *J Trauma Acute Care Surg* 2016;80:529–37). Over 80% of patients with a CT scan showing contrast extravasation will have a bleeding artery identified on angiogram, and embolization of this intrahepatic vessel stops bleeding in over 90% of patients. The success of AE in stopping hemorrhage from an injured liver highlights that optimal contemporary management of a severely injured patients depends upon a smoothly coordinated team of multiple providers. Hybrid operating rooms provide all the equipment needed for an interventional radiologist and trauma team to perform simultaneous procedures and more efficiently and quickly manage these complex patients.

The most common complications of AE are hepatic necrosis (15%), abscess formation (8%), and biloma or prolonged bile leak (5% or less). The optimal management of hepatic necrosis is excision of the dead liver, often best accomplished at the second or even third abdominal exploration (Dabbs DN, Stein DM, Scalea TM. Major hepatic necrosis: a common complication after angioembolization for treatment of high-grade liver injuries. *J Trauma* 2009;66:621–7).

Because alcohol consumption is a factor that contributes to trauma risk, it is not surprising that CT scans may also inform the surgeon of the presence of cirrhosis, which will affect the patient's clinical course and predict a higher in-hospital mortality (Talving P, Lustenberger T, Okoye OT, et al. The impact of liver cirrhosis on outcomes in trauma patients: a prospective study *J Trauma Acute Care Surg* 2013;75:699–703). Alcohol abuse in itself without cirrhosis increases organ failure rates, but does not predict a higher mortality (Nau C, Wutzler S, Doerr H, et al. Injury. *Int J Care Injured* 2013;44:661–6).

Patients with severe liver injuries often need a massive transfusion that should comply with recent guidelines of 1:1:1 (plasma, platelets, and red blood cells) developed from the PROPPR study. Most Level 1 trauma centers have designed protocols so that a “box of blood” is immediately available when such an unstable patient arrives, but institution of the massive transfusion protocol cannot be forgotten if optimal outcome is to be achieved (Holcomb JB, Tilley BC, Baraniuk S, et al. Transfusion of plasma, platelets, and red blood cells in a 1:1:1 vs a 1:1:2 ratio and mortality in patients with severe trauma: the PROPPR randomized clinical trial. *JAMA* 2015;313:471–82). Converting the first surgical procedure into a damage control procedure, closing the abdomen with retained laparotomy pads compressing the liver to achieved closure of the liver wound, is a judgment based upon multiple factors, including the availability of resources at that moment.

A major concern currently is the lack of experience of trainees with operative management of major hepatic injuries, since the incidence of high-grade injuries is decreasing and fewer injuries require operation. Between 2000 and 2004, the National Trauma Data Bank documented only 1,939 operations nationally for liver injuries (Tinkoff G, Esposito TJ, Reed J, et al. American Association for the Surgery of Trauma Organ Injury Scale I: spleen, liver, and kidney, validation based on the National Trauma Data Bank. *J Am Coll Surg* 2008;207:646–55), and the average graduating surgical resident in 2008 performed only 1.2 operations to stop bleeding (Lucas CE, Ledgerwood AM. The academic challenge of teaching psychomotor skills for hemostasis of solid organ injury. *J Trauma* 2009;66:636–40). Leon Pachter recommends that surgical residents spend a minimum of 3 to 4 months on a hepatobiliary/transplant service to learn hepatic anatomy and operative techniques (Pachter L. Prometheus bound: evolution in the management of hepatic trauma—from myth to reality. *J Trauma* 2012;72:321–9). It is otherwise likely that mortality in the most seriously injured patients will increase in the future or that such patients will require “damage control” surgery with stabilization and transfer to a Level 1 trauma center for definitive management.

Karen Deveney and Richard Mullins

109 Cholecystostomy, Cholecystectomy, and Intraoperative Evaluation of the Biliary Tree

O. James Garden

INTRODUCTION

Although laparoscopic cholecystectomy has become well established in the surgical treatment of gallstone disease in the last 25 years, it is evident from large population studies that open cholecystectomy continues to be performed by some surgeons preferentially or when the minimal access approach fails. This is particularly evident in low-volume hospitals in some countries and may also be impacted by service provision in the emergency setting. There remains a requirement, therefore, for the surgeon to understand the fundamentals of the open approach. Open cholecystectomy may be necessary as an incidental undemanding procedure during more complex surgery of the liver, bile duct, or pancreas. However, a more challenging procedure may result in patients undergoing conversion following failed laparoscopic dissection due to difficult anatomy or more severe gallbladder disease. Some surgeons may opt for an open approach if difficulties with laparoscopic access and dissection are anticipated. The modern surgeon may have acquired greater expertise in the minimally invasive procedure and have little experience of open cholecystectomy. However, there is a need to apply the same safe principles in circumstances that may be more challenging.

SURGICAL ANATOMY

Calot's (hepatocystic) triangle is bounded by the gallbladder, the right side of the common hepatic duct, and the liver. Elevation of the base of the gallbladder from the lower portion of the cystic plate and clearance of this triangle allow clear identification of the cystic structures during cholecystectomy. The cystic duct is approximately 2 cm in length and 3

mm in diameter, joining the common hepatic duct at an acute angle to form the common bile duct (CBD). Given that this junction may occur at any level down to the ampulla, the length of the cystic duct is variable. The cystic artery normally arises from the right hepatic artery in the hepatocystic triangle and runs for 1 to 2 cm to the upper border of the gallbladder, superior to the insertion of the cystic duct. Anterior and posterior branches may be evident at the point of contact with the gallbladder. Where the cystic artery arises from an aberrant or replaced right hepatic artery via the superior mesenteric vessel, the cystic artery, and not the cystic duct, usually lies in the free edge of the hepatoduodenal ligament.

The gallbladder lies on a fibrous area referred to as the *cystic plate*, which is part of the perihilar system of fibrous tissue. The cystic plate attaches directly onto the anterior surface of the right portal pedicle. The hepatic parenchyma lies deep to the cystic plate, through which small bile ducts may penetrate to enter the gallbladder. These ducts of Luschka consist of accessory ducts less than 1 mm in diameter. In approximately 10% of patients, there is a large peripheral bile duct immediately deep to the plate, dissection of which may cause bile leakage that may be mistaken by some surgeons as arising from a duct of Luschka. The origin of the middle hepatic vein also lies at a variable depth beneath the cystic plate and may be entered inadvertently.

Between the gallbladder muscularis and the cystic plate, a thin layer of areolar tissue thickens progressively from the top of the gallbladder downward. The posterior surface of the cystic artery and bile duct will be reached when the areolar tissue is left on the cystic plate during dissection of the gallbladder from the liver. Should dissection be undertaken deep into the cystic plate, as often arises in complicated gallbladder disease, the right portal pedicle may be breached and may result in injury to its structures including the right hepatic duct and artery.

The common hepatic duct is formed by the union of the left and right ducts and runs from the base of segment IV in the right edge of the hepatoduodenal ligament for 2 to 3 cm before joining the cystic duct to join the CBD. The CBD courses above the duodenum for 3 to 4 cm before it passes behind the first part of the duodenum, within or behind the pancreas to enter the second part of the duodenum. The CBD external diameter varies from 3 to 13 mm when distended to physiologic pressures. Low insertions of the right hepatic ducts are the most common anomaly,

and in 2% of patients, the right hepatic sectional (sectoral) ducts join the common hepatic duct close to the cystic duct entry.

The right hepatic artery passes behind the bile duct in 80% of cases and, where there is severe inflammation, fibrosis can cause the artery to become adherent to the gallbladder to form an inverse U-loop. This tethering of the anatomy may place the right hepatic artery at risk if it is mistaken for the cystic artery during cholecystectomy. The CBD derives its arterial blood supply from a plexus of vessels arising from two marginal arteries running at the 3 and 9 o'clock positions. These vessels derive their principal blood supply inferiorly.

CLINICAL PRESENTATION

From autopsy studies, it has been established that 12% of men and 24% of women of all ages have gallstones present and 10% to 30% of gallstones become symptomatic. Patients may present with an acute episode of pain from biliary colic, an ill-defined collection of symptoms often referred to as flatulent dyspepsia, chronic recurrent abdominal discomfort from repeated episodes of biliary colic, or acute cholecystitis. Pain may commence in the epigastrium but will localize to the right upper quadrant if there is local inflammation of the gallbladder. There may be systemic illness if the gallbladder contents become infected. Without intervention, toxemia may result if the gallbladder becomes the seat of an empyema or possibly develops gangrene and perforation. An empyema would normally produce pain, right upper quadrant tenderness, and swinging pyrexia, although in the elderly patient these symptoms may not always be obvious until the patient presents with an acute abdomen and collapse. CBD stones may present with features of obstructive jaundice with the passage of pale stool and dark urine, but these may also be occult and present in up to 10% of patients presenting acutely. Accompanying biliary sepsis represents a significant risk to the patient and presents with pain, fever, and frequently rigors. The development of associated medical signs such as atrial fibrillation in the elderly patient may signal the need for urgent intervention. Jaundice may occasionally result from external compression of the CBD from an inflamed and edematous gallbladder or impacted or eroding stone in Hartmann Pouch or the cystic duct (Mirizzi syndrome).

DIAGNOSIS AND TREATMENT

The diagnosis of gallstone disease is often suspected on clinical grounds

but is confirmed by appropriate laboratory and radiologic investigation. Liver function tests should be performed routinely since they may be abnormal in the presence of CBD stones. Although not always specific for choledocholithiasis, serum levels of bilirubin, alkaline phosphatase, and gamma-glutamyl transpeptidase are the most sensitive tests used routinely. An elevated white blood cell count may indicate sepsis. Ultrasonography (US) is most widely used to confirm the diagnosis of cholelithiasis. Other imaging modalities are used rarely, although cholecystokinin-stimulated hydroxy iminodiacetic acid scanning may be useful in the diagnosis of atypical biliary pain such as in biliary dyskinesia. US may detect evidence of chronic disease, and the presence of a thickened wall and contracted gallbladder may signify that open cholecystectomy may be more likely to succeed than a laparoscopic approach. Edema may be evident in acute cholecystitis, and dilation of the CBD may signify the presence of ductal calculi. These are more likely to be detected by magnetic resonance cholangiography, which may be used to plan the approach to managing choledocholithiasis. Endoscopic retrograde cholangiography allows detection and removal of ductal calculi following sphincterotomy and may be required to decompress the biliary tree preoperatively in Mirizzi syndrome or for the patient who presents with acute cholangitis from obstructing ductal stones.

Symptomatic gallbladder disease would normally be managed definitively by cholecystectomy in the fit patient. For the patient presenting acutely, appropriate analgesia is required and resuscitation with intravenous fluids and antibiotics may be required if there is evidence of sepsis. In general, endoscopic retrograde cholangiography with sphincterotomy, removal of stones, and stent placement would be indicated in the patient with cholangitis since morbidity and mortality are lower than with urgent operative decompression of the bile duct but the surgeon may be prepared to undertake open CBD exploration if operative cholangiography detects ductal stones.

For procedures that may involve associated or coincidental cholecystectomy, investigation will be driven by the underlying disease process. For example, computerized tomography or positron emission tomography may be required to image liver tumor and stage the patient before cholecystectomy and liver resection are performed, whereas magnetic resonance cholangiopancreatography may be required to evaluate pathology such as a choledochal cyst prior to its removal with the

gallbladder.

INDICATIONS

Gallstones may cause multiple biliary tract problems, requiring surgery; the most common indication for cholecystectomy is biliary colic caused by chronic cholecystitis and cholelithiasis. Acute cholecystitis, secondary to obstruction of the cystic duct by a gallstone, is the second most common reason for the removal of the gallbladder. Empyema and perforation are sinister complications of gallstone disease that may necessitate open surgery. Pancreatitis and cholangitis caused by obstruction of the pancreatic duct and/or distal CBD by a stone are generally the third most common indication for cholecystectomy. Incidental open cholecystectomy may be required during liver resection, pancreaticoduodenectomy, open surgery for associated benign pancreatic pathology, such as a pseudocyst or chronic pancreatitis, or for primary biliary pathology, such as choledochal cyst.

Despite the high incidence of gallstone disease in many countries, approximately 75% of patients with gallstones are asymptomatic. Although there are conflicting data, it would appear that less than 20% of patients with “silent gallstones” develop complications within a 10-year period. In the United Kingdom, more than 70,000 cholecystectomies are performed each year, whereas in the United States as many as 900,000 are performed annually. The need for conversion from laparoscopic to open cholecystectomy may be anticipated in patients over the age of 65 years, in male patients, those experiencing multiple previous attacks of biliary colic or during acute admission with acute cholecystitis. Primary open cholecystectomy may be considered in as many as 5% of patients requiring removal of the gallbladder and would include patients such as those undergoing laparotomy for peritonitis or other intra-abdominal pathology when gallbladder disease has not been suspected preoperatively. Other possible indications for open cholecystectomy are listed (Table 109.1), although it is accepted that the threshold for an open rather than a laparoscopic approach will vary with the experience and expertise of the surgeon.

TABLE 109.1 Preoperative Indications for Primary Open Cholecystectomy

- Previous upper abdominal surgery
- General peritonitis
- Incidental during open nonhepatobiliary and pancreatic surgery
- Significant portal hypertension
- Penetrating trauma
- Planned open CBD exploration
- Suspected gallbladder carcinoma
- Gallbladder empyema
- Fistulous disease involving gallbladder
- Incidental during other open hepatobiliary and pancreatic surgery

Cholecystostomy

With improvements in anesthesia and surgery, cholecystostomy is undertaken infrequently and is performed generally by radiologic techniques under local, regional, or general anesthesia. It is a procedure that should be considered when cholecystectomy is deemed unsafe in patients at high risk related to multisystem organ failure; severe pulmonary, renal, or cardiac disease; and recent myocardial infarction. Safe cholecystectomy may be precluded by a local condition such as cirrhosis with portal hypertension; acalculous cholecystitis after severe trauma, burns, or surgery; and where there is empyema or gangrene of the gallbladder.

Open or percutaneous cholecystostomy under local anesthesia should not be considered a minor procedure in the sick patient, and a skilled anesthetist should be present since the patient should be well sedated and oxygenated. Preoperative or operative localization of the gallbladder using US is invaluable in selecting the most appropriate incision site. Ample local anesthetic with 0.5% lidocaine is used to infiltrate the skin muscle and peritoneum. A transverse muscle-splitting incision is preferred for the open procedure and, if the incision site has been well chosen, the gallbladder will be seen immediately on entering the peritoneum.

A purse-string 3-0 polydioxanone suture is placed in the fundus of the gallbladder. Having placed packs or swabs around the isolated gallbladder, a trocar is used to decompress the gallbladder. A disposable 5-mm laparoscopic port is ideal as the sharp trocar avoids unnecessary trauma to the operating field. The contents of the gallbladder are aspirated, and a

sample of bile is obtained for culture. In the absence of empyema or gangrene, an attempt should be made to remove the stones with forceps or a scoop. A stone impacted in the neck of the gallbladder or cystic duct can be dislodged usually by external digital manipulation, stone forceps, or a balloon catheter. Removal of the obstructing stone is important to prevent a subsequent mucous fistula.

On removal of the stones, a No. 20 to 24 French gauge Foley or similar catheter is placed through a separate stab incision in the abdominal wall and is secured within the fundus of the gallbladder, using the purse-string suture (Fig. 109.1). Injudicious attempts at securing the gallbladder to the abdominal wall should be avoided, although this may be achieved frequently by inflating the catheter balloon, which allows the fundus of the gallbladder to be opposed against the parietal peritoneum. The incision is closed using 0 polydioxanone to peritoneum and sheath. If there has been considerable contamination of the wound, it may be elected not to close the skin edges.

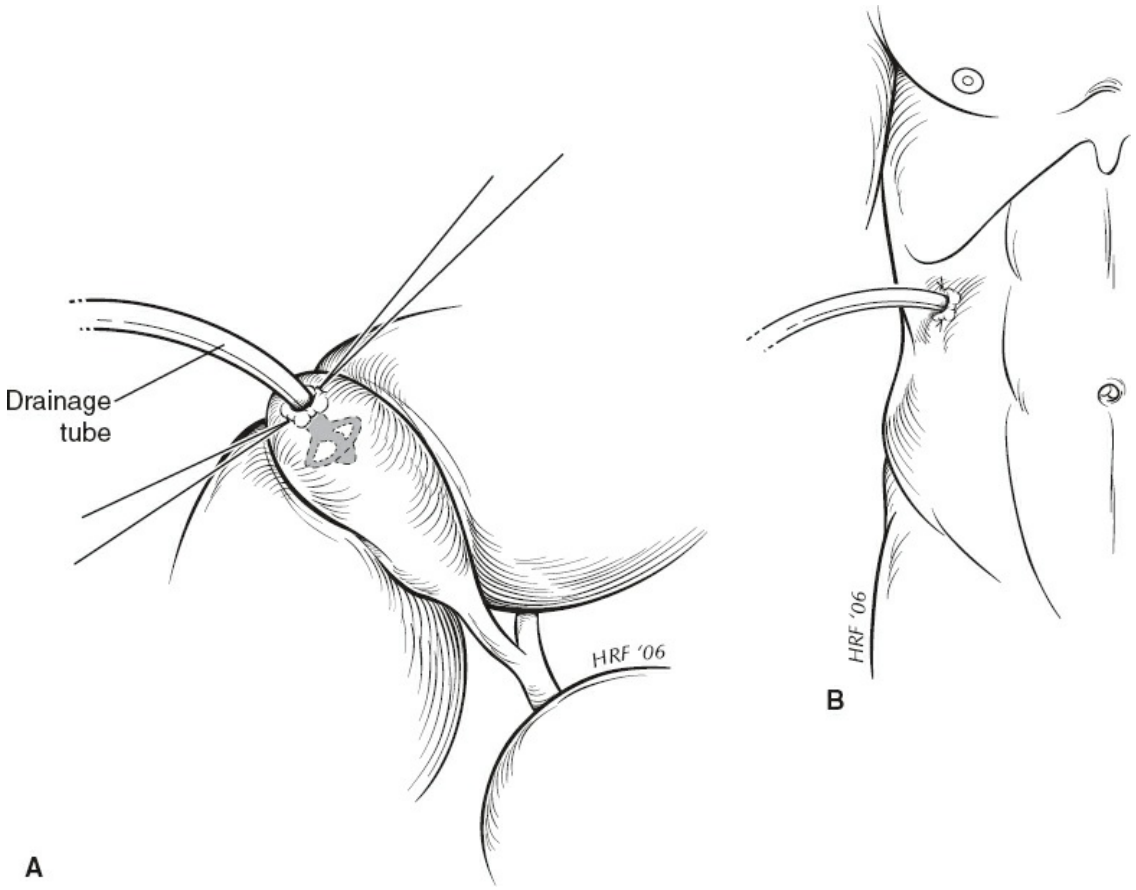

Figure 109.1. Method for securing drainage tube during cholecystostomy. The drainage tube is secured to the gallbladder wall by a purse string suture (**A**) and to the abdominal wall by a

skin suture (**B**).

Given the circumstances under which cholecystostomy is performed, it is not surprising that the procedure carries a higher morbidity and mortality than cholecystectomy. In those patients who recover from the procedure, the cholecystostomy tube can be removed at 6 to 8 weeks if patency of the biliary tract can be demonstrated. Residual stones in the gallbladder may be removed through the tract by percutaneous maneuvers using image intensification or 5-mm flexible choledochoscope. Dissolution techniques are not well tolerated and, in those patients who make a satisfactory recovery, cholecystectomy should be considered. In the elderly, infirm patient or those with comorbid disease, it may be wise to defer cholecystectomy indefinitely.

Open Cholecystectomy

Preoperative preparation requires appropriate thromboembolic prophylaxis according to individual patient risk and administration of a suitable prophylactic antibiotic that would cover common biliary commensal organisms such as cefuroxime or amoxicillin and clavulanic acid. The first dose should be administered before the procedure and preferably within 30 minutes before skin incision. In those patients who have undergone conversion from laparoscopic cholecystectomy, the antibiotic should be administered as soon as is practicable.

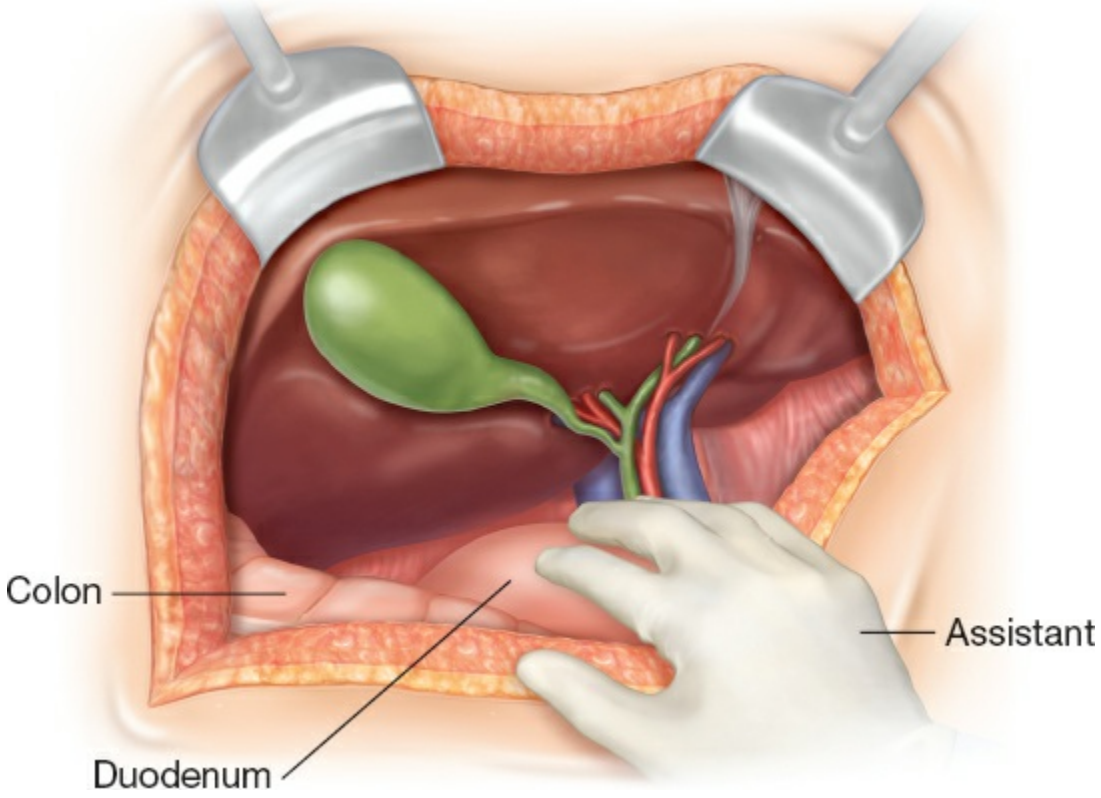

Figure 109.2. Exposure of the gallbladder during open cholecystectomy.

Of the frequently employed incisions for cholecystectomy, a right-sided subcostal (Kocher) or transverse incision provides the optimum exposure. The incision should normally be of sufficient size to provide adequate exposure and to admit the examining hand. In the era of laparoscopic cholecystectomy, there appears little rationale for the so-called minicholecystectomy approach in the patient for whom adequate access will be required to deal with a difficult situation.

The abdomen is explored to exclude other intra-abdominal pathology, and a hand is passed over the right lobe of the liver to allow air to enter the subphrenic space. The costal margin is retracted, and the use of a fixed mechanical retractor is helpful in providing exposure and in freeing the assistant's hands during the operative procedure. Placement of a pack or small swab above the liver may increase exposure of the subhepatic region in some patients. Moist gauze swabs are placed to the right and inferiorly to displace the hepatic flexure of the colon and to the left to displace the stomach away from the operating field. A further pack is used under the assistant's hand to allow traction caudally (Fig. 109.2).

Adhesions between the gallbladder and gastrocolic omentum or transverse colon may be divided using bipolar diathermy scissors.

Placement of a small, moist swab into the subhepatic space to the right and behind the gallbladder will prevent inadvertent spillage of infected bile or stones, which may not otherwise be retrieved easily on completion of the operation. Preliminary decompression of the gallbladder avoids uncontrolled spillage of infected bile during dissection if the gallbladder is tense and acutely inflamed. A trocar can be inserted through the center of a 3-0 polydioxanone purse-string suture placed at the fundus of the gallbladder in an easily accessible location. The gallbladder contents are aspirated before withdrawal of the trocar and closure of the resulting defect by tying the purse-string suture.

With the assistant providing exposure and traction caudally and to the left, a Kelly or similar clamp is placed on the fundus of the gallbladder, which is retracted out of the wound and displaced caudally. A second clamp is applied further down the gallbladder on Hartmann pouch but away from the cystic duct (Fig. 109.3). The peritoneum overlying Calot's triangle is incised and the dissection is continued close to the gallbladder, displacing the cystic node and the fatty, areolar tissues to expose the cystic duct and artery. As for laparoscopic cholecystectomy, the incision to the peritoneum can be continued posteriorly as the Kelly clamp on the infundibulum is displaced upward and medially. This allows clear identification of the cystic duct and artery using a right-angled Lahey or Kittner dissector. The cystic artery is identified and traced onto the gallbladder far enough to ensure that it is not the right hepatic artery. Two braided 2-0 ties are passed around the artery, which is divided between these (Fig. 109.3). The cystic duct is identified by blunt dissection with the right-angled clamp and circled with a ligature, which can be double-looped around the duct to provide temporary atraumatic occlusion of the duct. This maneuver helps prevent small stones or debris being forced down into the CBD during dissection and facilitates performance of a cholangiogram through the cystic duct (see below). If a cholangiogram is not undertaken, the duct can be divided between two ties.

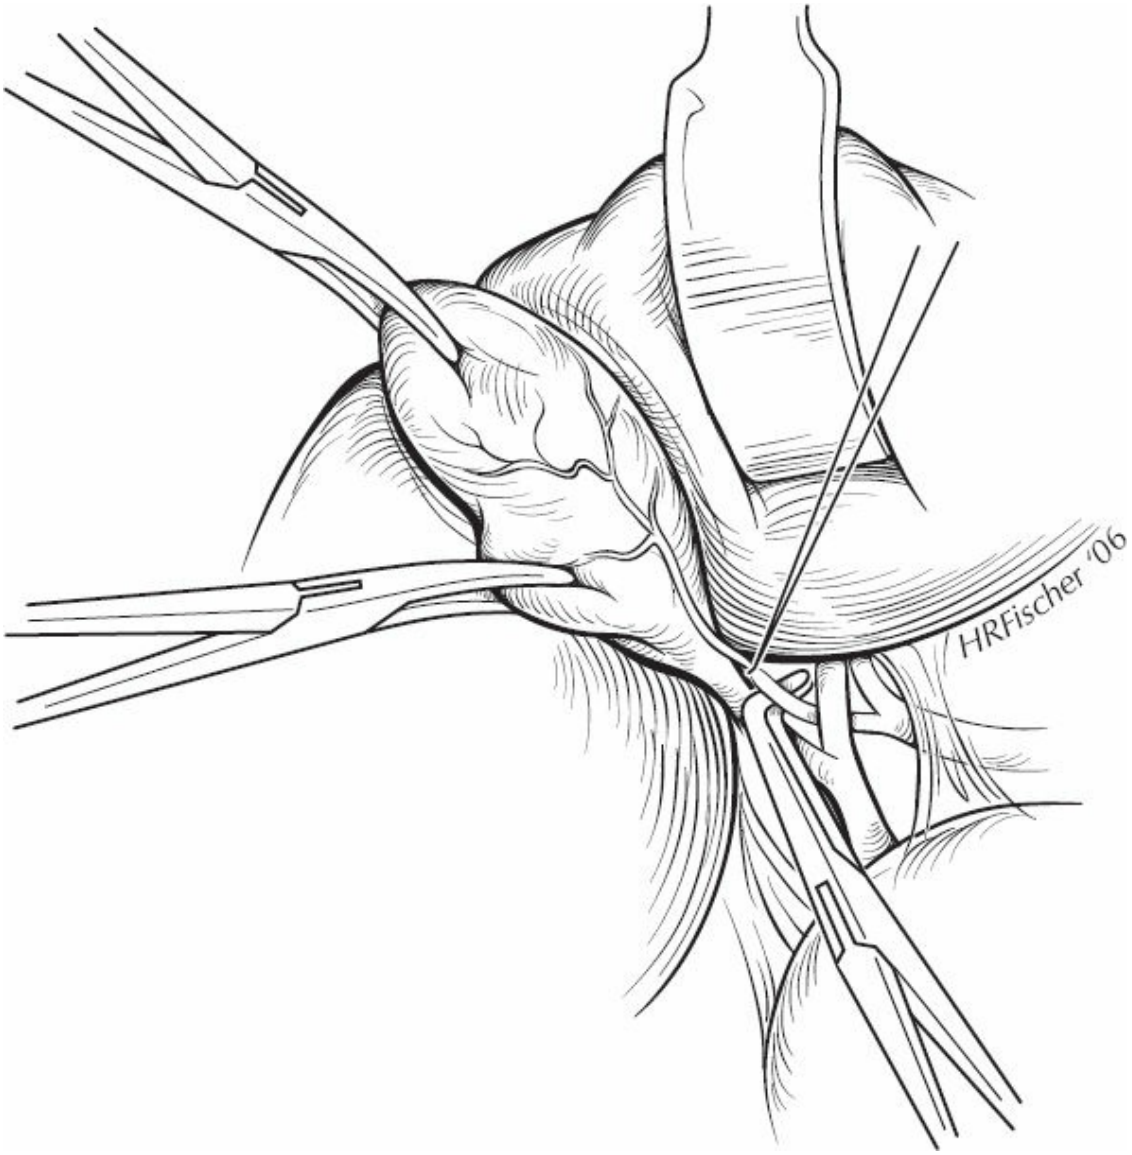

Figure 109.3. Placement of clamps on the gallbladder and dissection of cystic artery during cholecystectomy.

It is inappropriate to dissect the cystic duct to its confluence with the common hepatic duct, but it is important to establish that the cystic duct is free of stones at the end of cholecystectomy. It does not need to be ligated flush with the bile duct because there is no evidence that ligation of the cystic duct at its union with the gallbladder results in residual symptoms. The cystic duct can be short, and dissection may be difficult in the presence of a large, impacted stone, and the presence of acute or chronic inflammation may result in adhesions between the gallbladder and the common hepatic or bile duct, thereby concealing the cystic duct and contributing to the possibility of biliary injury.

Dissection of the gallbladder from the liver proceeds from the fundus

down. In the relatively nondiseased gallbladder, it should be possible to enter the plane between gallbladder and cystic plate, which is superficial to a network of small vessels. Dissection in this plane avoids injury to the liver and any superficial branches of the middle hepatic vein or intrahepatic ductules. Dissection within the correct plane can be facilitated by incising the peritoneum between gallbladder fundus and liver over a right-angled clamp using electrocautery. By displacing the gallbladder from side to side, the attachments between the gallbladder and liver can be exposed and incised (Fig. 109.4). The dissection is continued downward until the peritoneal incision over the gallbladder is continuous with that made previously over Calot's triangle. In a diseased, thick-walled, or fibrotic gallbladder, care should be taken not to enter the cystic plate as dissection deep to this structure risks injury to the right portal pedicle and the right hepatic duct and artery, in particular. If a satisfactory plane cannot be identified as the dissection approaches the hilar structures, consideration should be given to limiting the procedure to a subtotal cholecystectomy.

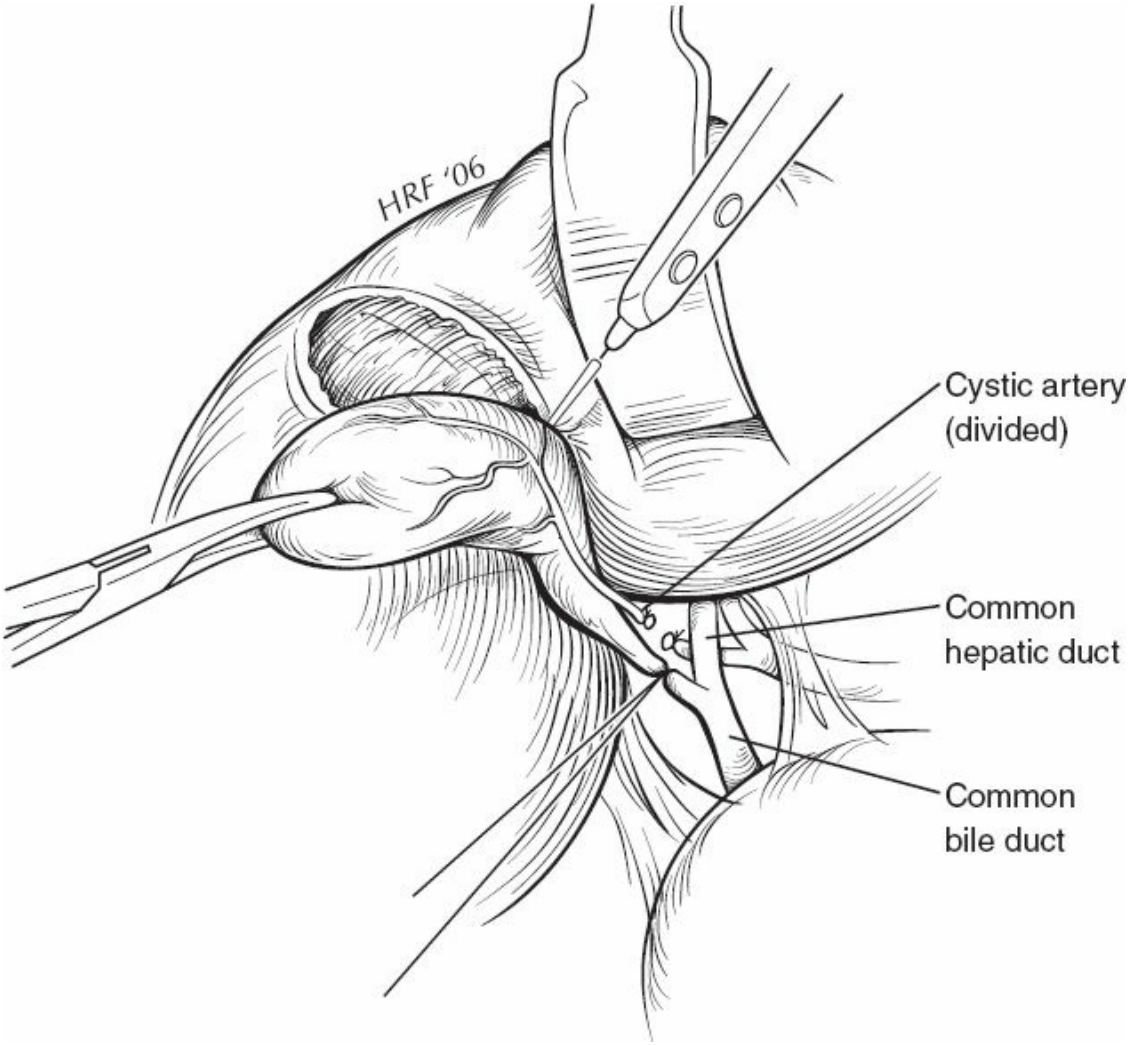

Figure 109.4. Division of peritoneal attachments between the gallbladder and liver using diathermy.

As for laparoscopic cholecystectomy, the mobility gained by clearing the peritoneum posterior to the cystic duct behind Calot's triangle will greatly facilitate the remaining phase of dissection. Having confirmed the continuity between the gallbladder and cystic duct, the dissection should be continued to allow adequate visualization of the common duct–cystic duct junction. Bleeding in the gallbladder bed in the liver is managed by electrocautery as any small vessels are encountered and once the gallbladder has been fully mobilized. Persistent hemorrhage may require the application of a hemostatic agent such as oxidized regenerated cellulose (SURGICEL SNoW or FIBRILLAR©, Ethicon) or for severe problematic bleeding a patch of oxidized regenerated cellulose and VICRYL© containing a dry layer of the human coagulation factors fibrinogen and thrombin (EVARREST©, Ethicon). Care should be taken

to avoid excessive use of unipolar diathermy close to the common hepatic duct as diathermy current may be conducted through the remaining attachments of the gallbladder to the main extrahepatic bile duct. The use of a right-angled clamp for dissection in this area is appropriate until the anatomy is clearly defined.

Operative Cholangiogram

Once the junction of the cystic and common ducts is identified, the bipolar scissors are used to make a small incision in the cystic duct approximately 1 to 2 cm from the common duct. A hemostatic clip or a tie, as outlined previously, should be used on the gallbladder side to prevent spillage of bile when the cystic duct is opened. A soft silastic cholangiogram catheter (measuring No. 5 to 8 French gauge) is used (Fig. 109.5). The catheter and connecting tubes are flushed with sterile saline to remove any bubbles and the catheter is inserted gently into the cystic duct with slight traction being maintained on the gallbladder. As the cannulation is performed, saline solution is injected continuously to avoid air bubbles. A tie or a large or medium-sized hemoclip is employed to secure the cannula, confirming that bile can be aspirated and that saline can be injected easily without extravasation.

Avoiding introduction of air, the syringe of saline is exchanged for one containing dilute or soluble contrast medium. At this point, all packs are removed from the abdomen and any retractors are removed from the operating field. A sterile towel is placed over the wound. The use of operative fluoroscopy and image intensification allows controlled instillation of contrast under gentle pressure to enable full opacification of the extrahepatic biliary tree, confirming free flow of contrast into the duodenum and filling of the right and left hepatic ducts to exclude the presence of any ductal calculi. Should a normal cholangiogram be obtained but contrast fails to enter the duodenum, administration of cholecystokinin (20 mg/kg) or administration of glucagon (1 mg intravenously) should relax the sphincter of Oddi sufficiently to allow the flow of contrast into the duodenum.

Operative Ultrasonography

A 7.5-MHz operative US transducer can be employed to visualize the biliary tree. Imaging is best undertaken before any dissection of the porta hepatis as introduction of air into the adventitial tissues will distort and

compromise the quality of the images obtained. Installation of sterile saline into the right subhepatic space may improve contact as the extrahepatic biliary tree is examined and traced down behind the duodenum into the head of the pancreas and to the ampulla of Vater (Fig. 109.6).

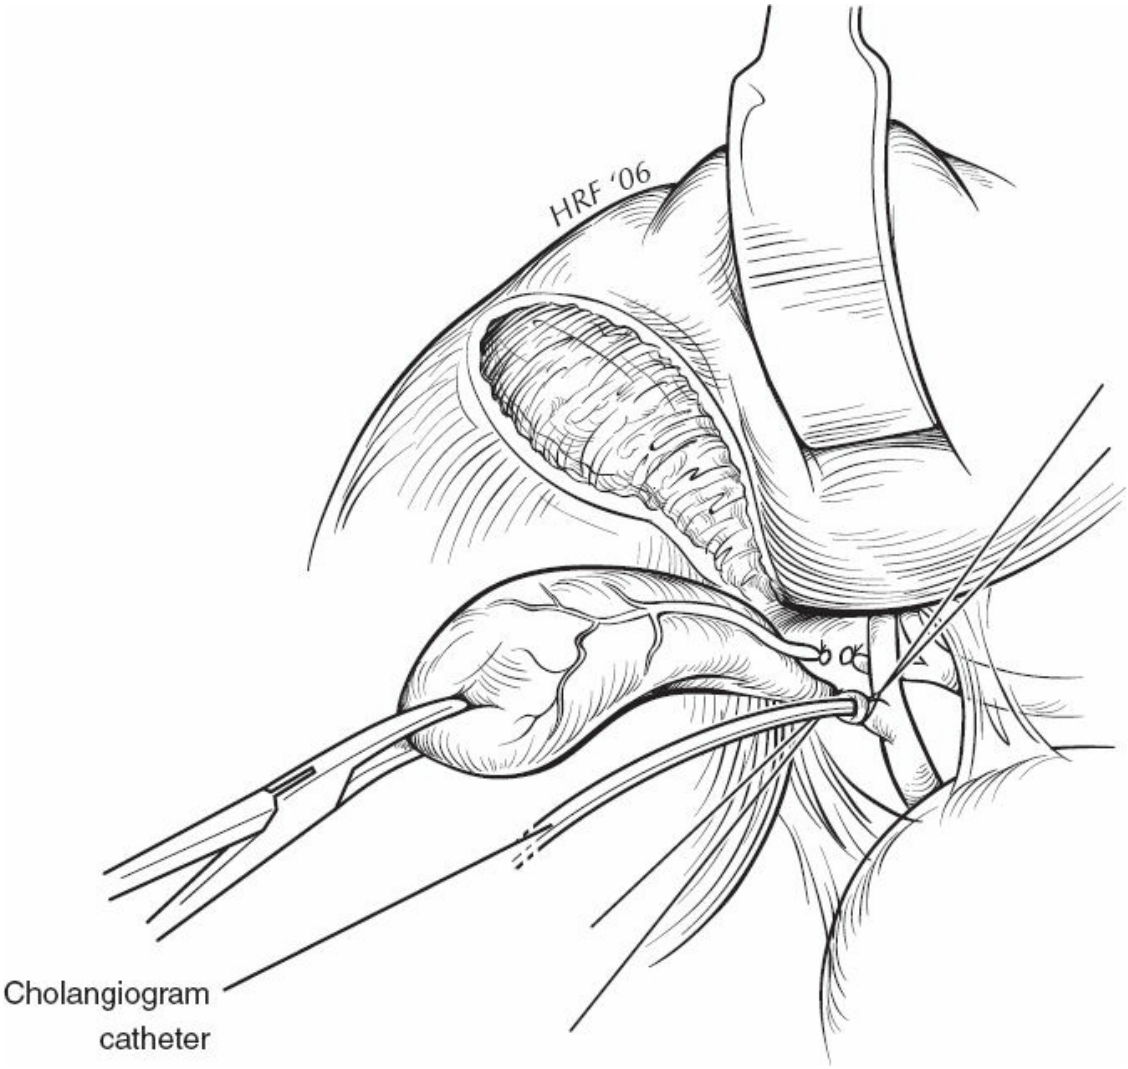

Figure 109.5. A cholangiogram catheter secured in the cystic duct by a ligature.

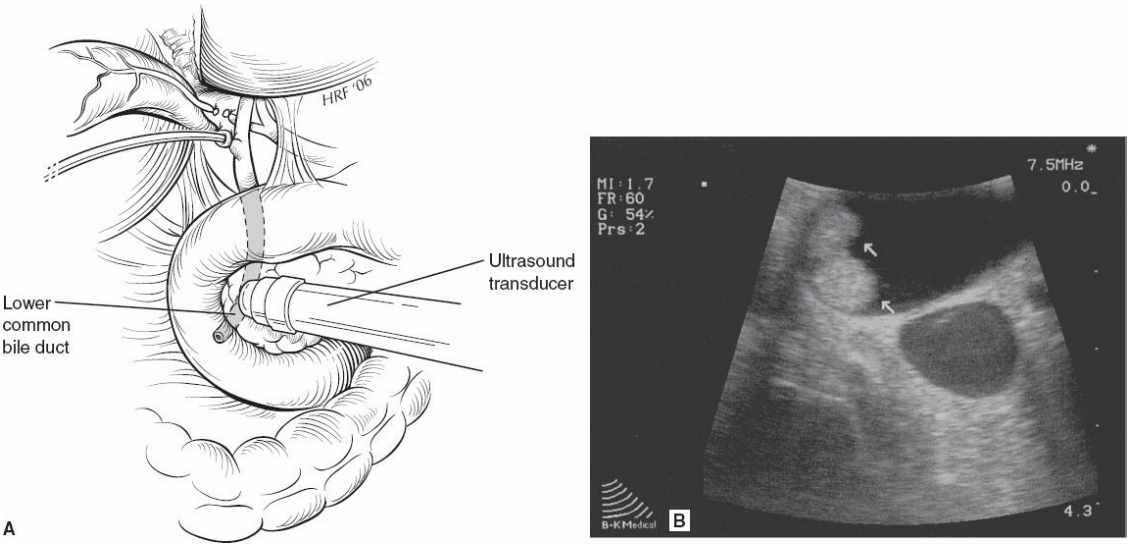

Figure 109.6. A. Ultrasound transducer placed over lower common bile duct (CBD). **B.** Ultrasound image showing multiple small stones (*arrows*) within the lower CBD.

Subtotal Cholecystectomy

Partial or incomplete excision of the gallbladder is a technique that is indicated rarely but may be employed wisely in specific instances when severe inflammation renders identification of the anatomy impossible, such as in some cases of gangrenous cholecystitis, when a scarred partially intrahepatic gallbladder is present, and in some patients with severe cirrhosis and portal hypertension. In such situations, partial cholecystectomy will avoid unnecessary bleeding from the liver bed and eliminate the risk of inadvertent injury to the right portal pedicle.

When total cholecystectomy has to be abandoned, the operating field is protected with packs to avoid contamination of the peritoneal cavity as the gallbladder is opened at its fundus using diathermy. The gallbladder contents are aspirated and any stones are removed. The gallbladder that is not in contact with the liver is excised down to the gallbladder neck but not at its posterior extent at a level that ensures that the common duct is not damaged (Fig. 109.7). If the lumen of the cystic duct cannot be identified, no attempt should be made to transect this structure as disruption of the fibrous tissue in Calot's triangle may again risk damage to the right portal pedicle. A cholangiogram may be obtained by passing a catheter through the lumen of the cystic duct. On completion of this investigation, the cystic duct orifice should be suture-ligated from within with a 3-0 polydioxanone suture. The residual mucosa on the posterior gallbladder wall can be obliterated by diathermy, which should not be directed close to Hartmann

pouch or the cystic duct. With subtotal cholecystectomy, it is essential that the subhepatic space is drained with a closed drainage system.

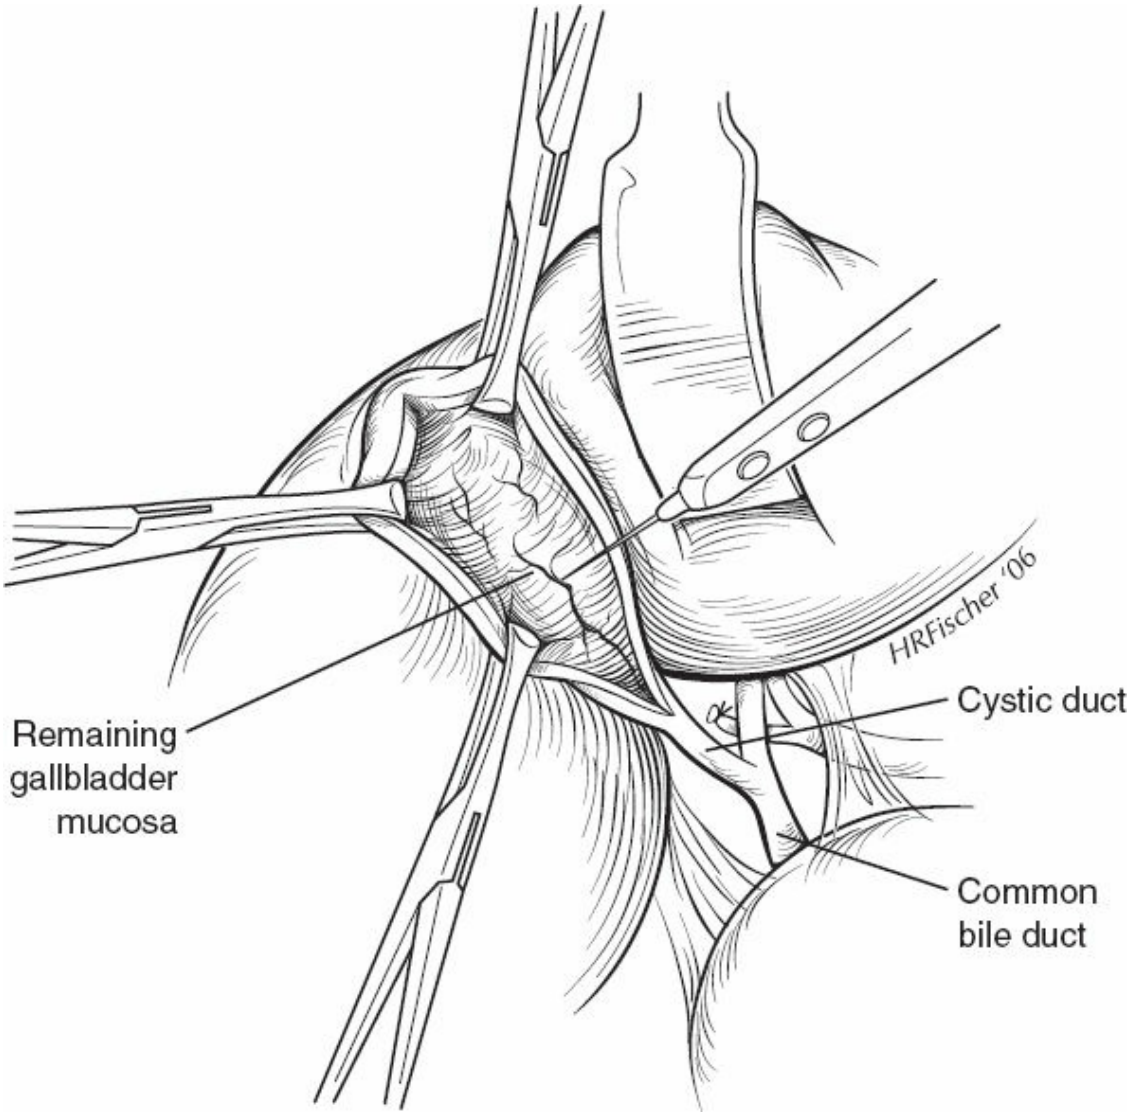

Figure 109.7. Diathermy coagulation being applied to the gallbladder mucosa following subtotal cholecystectomy.

Common Bile Duct Exploration

Operative cholangiography aids the planned exploration of the ductal system by showing the regional anatomy and the approximate number and location of stones. Even if a recent preoperative cholangiogram has been obtained, consideration should be given to undertaking further imaging as the number and location of the stones may have changed.

The ligamentum teres is divided by doubly clamping and ligating the obliterated umbilical vessel in its free edge. Electrocautery is used to divide the remaining ligament. The hepatic flexure of the colon is

mobilized to expose the duodenum. The peritoneum lateral to the duodenum is incised with bipolar diathermy scissors (Fig. 109.8). The second part of the duodenum and head of the pancreas can be displaced anteriorly and medially by passing the index finger of the nondominant hand into the retroperitoneum. The retaining peritoneum is divided with electrocautery, along with any filmy adhesions or vessels. Mobilization should be continued until the nondominant hand can be placed easily behind the head of the pancreas to feel the terminal CBD and ampulla. The hepatoduodenal ligament and lower CBD are palpated for stones and masses. A laparotomy pack is placed behind the duodenum.

Although it may be possible to pass a fine flexible choledochoscope or wire basket through the cystic duct stump to retrieve ductal stones, it is likely that a formal choledochotomy will be required. A short longitudinal incision is made with a No. 11 blade, usually following placement of 4-0 polydioxanone retaining sutures (Fig. 109.9). The previously placed sutures should be elevated to avoid penetration of the back wall with the blade. The choledochotomy should be extended with the blade or sharp scissors to approximately 1 cm in length. Rigid instruments such as Bakes dilators, stone forceps, or scoops have been generally abandoned because of the risk of CBD injury. Stones may be retrieved by gentle irrigation of the duct with saline through a soft rubber catheter. A Fogarty balloon-tipped catheter can be passed both proximally and distally, inflating the balloon before the catheter is gently withdrawn and until all the stones and debris are cleared. Passage of a 3- or 5-mm flexible choledochoscope allows direct visualization and manipulation under direct vision. A Fogarty catheter or wire basket can be passed easily down the channel of a 5-mm choledochoscope to retrieve stones and fragments. Choledochoscopy should always be undertaken to ensure clearance of the ductal system. Saline should be run freely into the duct through the choledochoscope as distention of the duct will allow the lumen to become visible. The scope should not be forced beyond the central lumen of the ampulla, which is generally well visualized. The right and left hepatic duct should be explored superiorly and any stones retrieved.

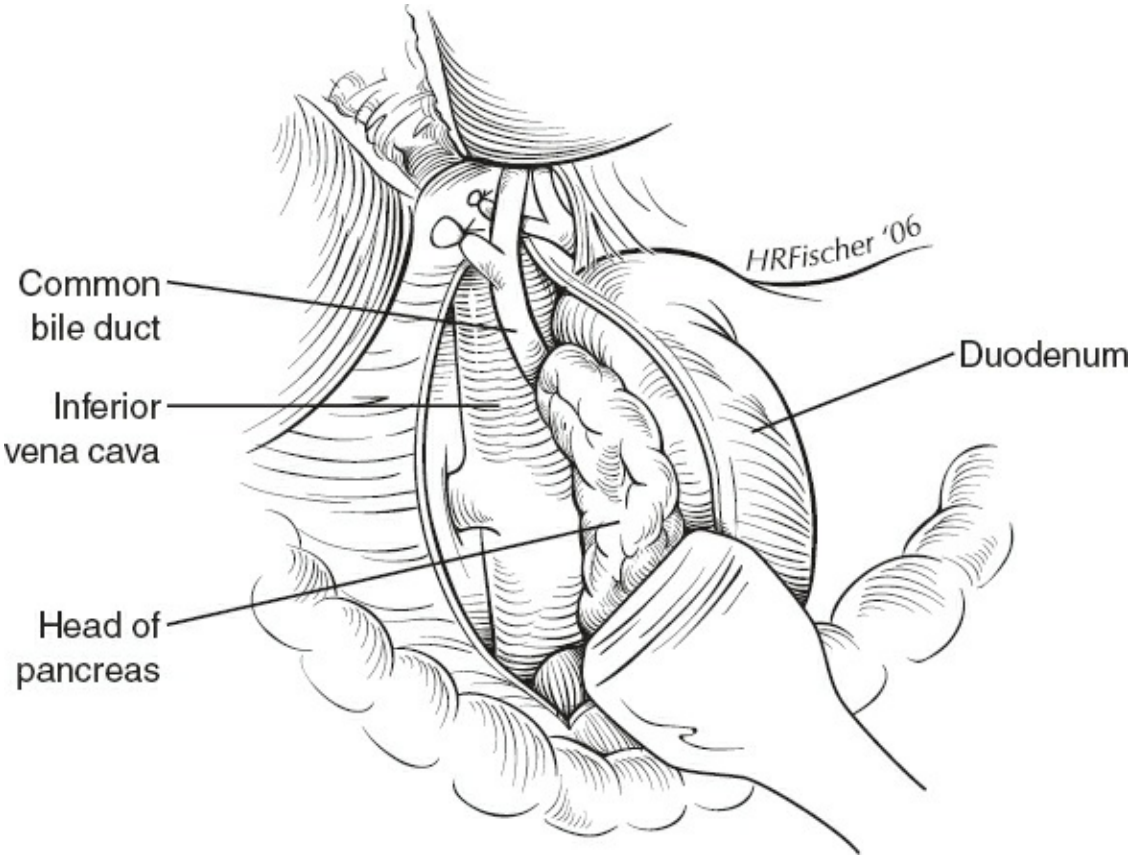

Figure 109.8. Kocherization of the duodenum.

Primary closure of the choledochotomy can be undertaken on completion of duct exploration or a T-tube can be placed to decompress the duct and facilitate the removal of any retained stones in the postoperative period. The tube should be at least a No. 14 French gauge to facilitate percutaneous extraction techniques. Before placement of the T-tube, the back wall of the vertical stem should be excised and a V-shaped wedge fashioned at the junction of the limbs to facilitate subsequent removal of the tube without disruption of the choledochotomy closure (Fig. 109.10). The T-tube should exit the abdomen in a direct fashion, but some slack should be allowed for postoperative abdominal distention. The limb is brought out normally through the anterior abdominal wall laterally so that subsequent radiologic manipulation is possible. It should be established that the vertical limb of the T-tube can slide freely within the CBD. The T-limb is displaced to the upper limit of the choledochotomy so that closure can proceed from below using interrupted 4-0 polydioxanone sutures, ensuring that full-thickness bites of the duct are taken but avoiding narrowing of the lumen. Care should be taken to ensure that the tube itself is not caught by the suture. Saline can be injected into the tube to check for

leaks. It would not normally be necessary to perform a completion cholangiogram if adequate examination of the ducts has been undertaken with choledochoscopy. Stones may be suspected falsely because of previous introduction of air bubbles, and failure of contrast to enter the duodenum may result from sphincter spasm.

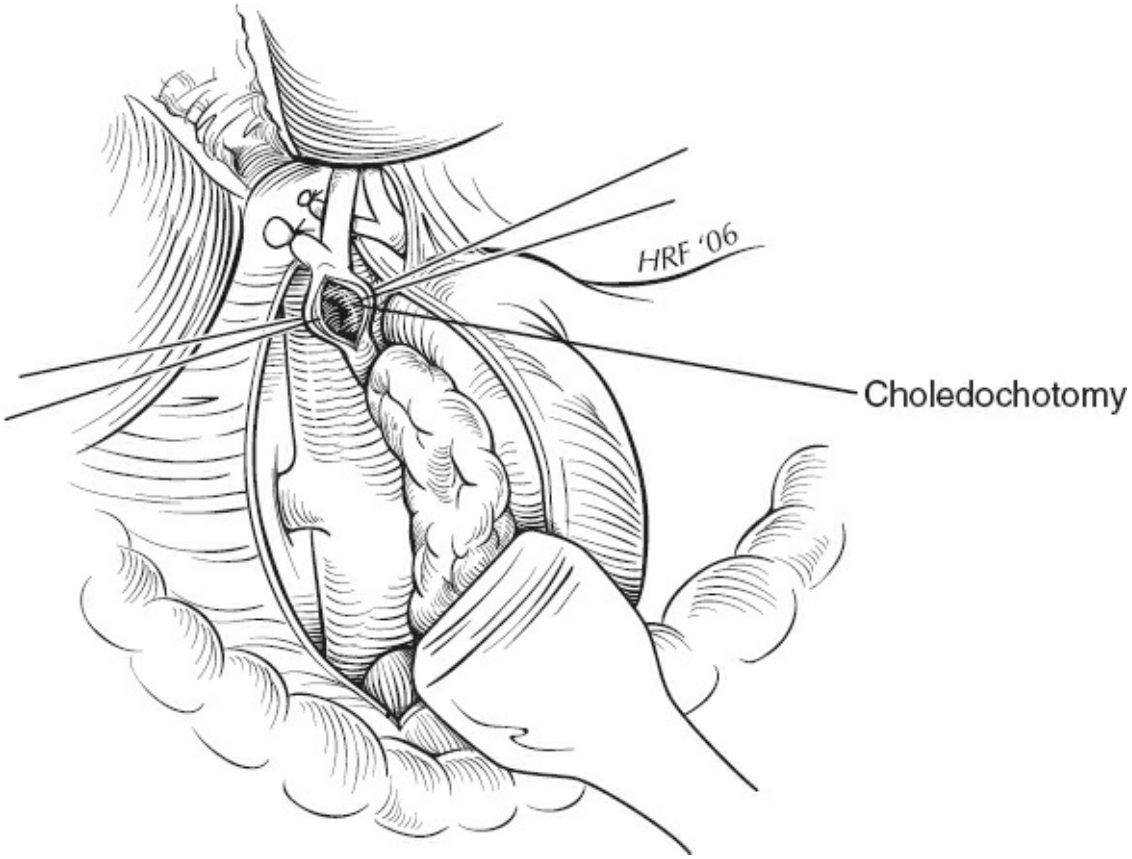

Figure 109.9. Choledochotomy held open by retaining sutures.

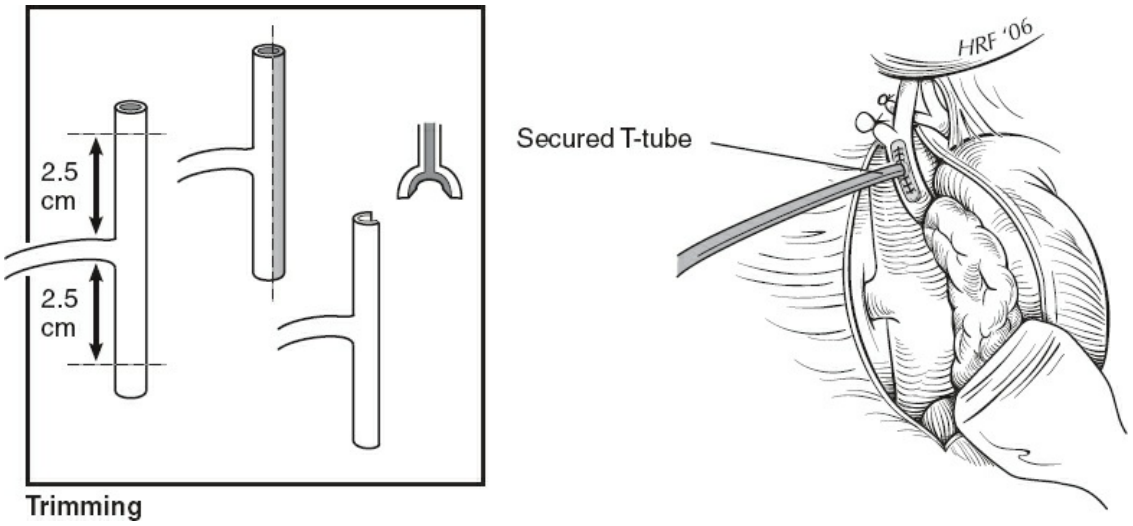

Figure 109.10. The T-tube is trimmed and secured in the choledochotomy by placement of interrupted 4-0 polydioxanone

sutures.

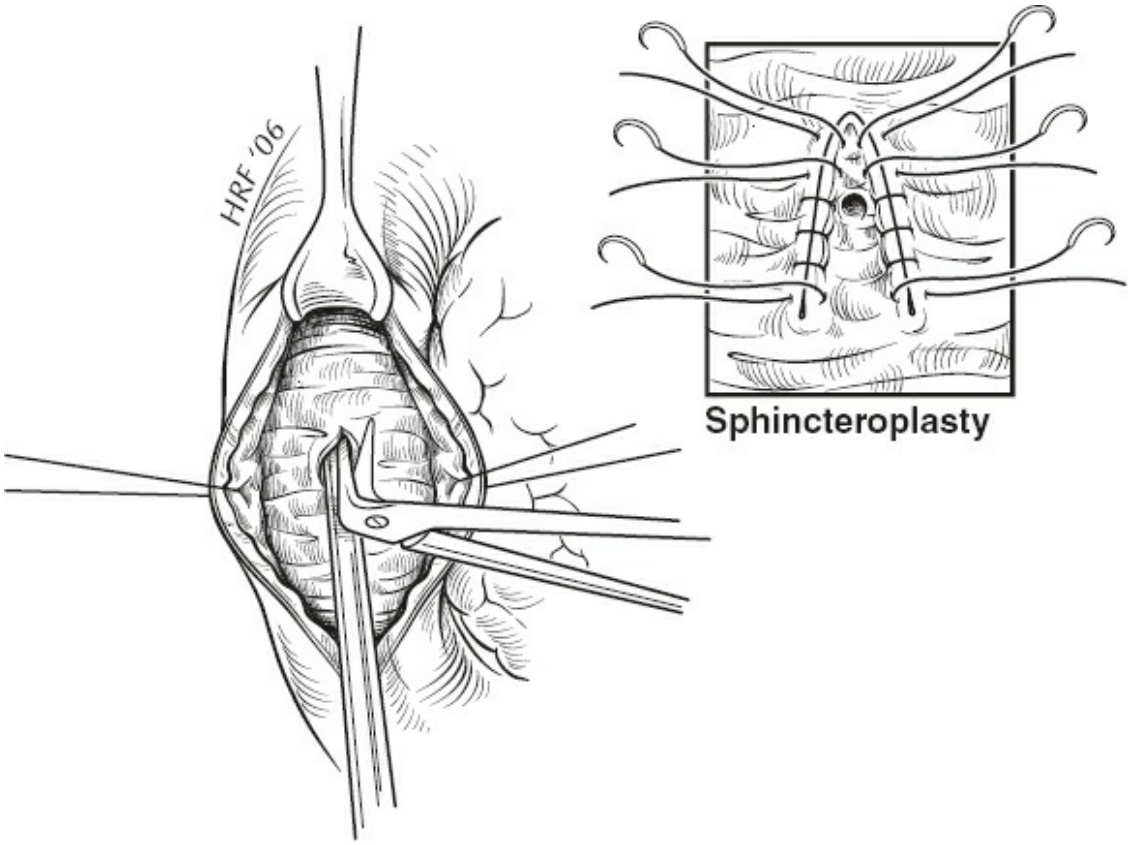

Figure 109.11. Sphincterotomy and fashioning of sphincteroplasty using interrupted 4-0 polydioxanone sutures.

Other Maneuvers

Transduodenal sphincterotomy or sphincteroplasty, along with choledochoduodenostomy and choledochojejunostomy Roux-en-Y, is required uncommonly. With modern techniques for duct exploration, a transduodenal sphincteroplasty is rarely necessary to remove a stone impacted in the distal CBD. A longitudinal duodenotomy approximately 5 cm long is fashioned. A Fogarty biliary balloon catheter can be passed through the ampulla or from above from the choledochotomy as a guide for location of the ampulla. Then, 4-0 polydioxanone stay sutures are placed on either side of the ampulla and are lifted to improve exposure. An incision is made at approximately 11 o'clock to avoid the pancreatic duct orifice, which is usually at about 4 o'clock. Interrupted absorbable sutures (4-0 polydioxanone) are placed along the incision as this is extended superiorly until the opening of the sphincteroplasty is large enough to admit a large Bakes dilator. Any impacted stones can be removed. A

horizontal suture is placed at the apex of the sphincteroplasty to ensure hemostasis and to guard against a posterior perforation of the duodenal wall (Fig. 109.11). The duodenotomy is closed with interrupted 3-0 polydioxanone sutures.

Whereas choledochoduodenostomy can be considered in patients with multiple CBD stones or a distal inflammatory stricture, there is a risk of reflux and "sump syndrome" (Fig. 109.12). Biliary sepsis may result from reflux of food, which may obstruct the anastomosis, and therefore many surgeons prefer drainage into the jejunum. To avoid the risk of sump syndrome and pancreatitis, end-to-side anastomosis following division of the bile duct and oversewing of the distal duct is preferred (Fig. 109.13). A 70-cm Roux-en-Y limb of jejunum is fashioned, restoring intestinal continuity in the infracolic compartment with a single-layer end-to-side anastomosis employing interrupted or continuous 3-0 polydioxanone. The proximal Roux limb is delivered through a defect in the transverse mesocolon, to which it is secured with several interrupted 3-0 polydioxanone sutures. The divided common hepatic duct is anastomosed to the blind end of the Roux limb by constructing a single-layer end-to-side anastomosis with interrupted 4-0 polydioxanone sutures. The anterior wall of the CBD is normally held in place by first securing this using multiple interrupted sutures. The posterior wall anastomosis is constructed again using interrupted sutures, knotting these on the mucosal side. The front wall anastomosis is completed using the previously inserted interrupted sutures attached to the anterior wall of the bile duct and tying these sutures down on the serosal side.

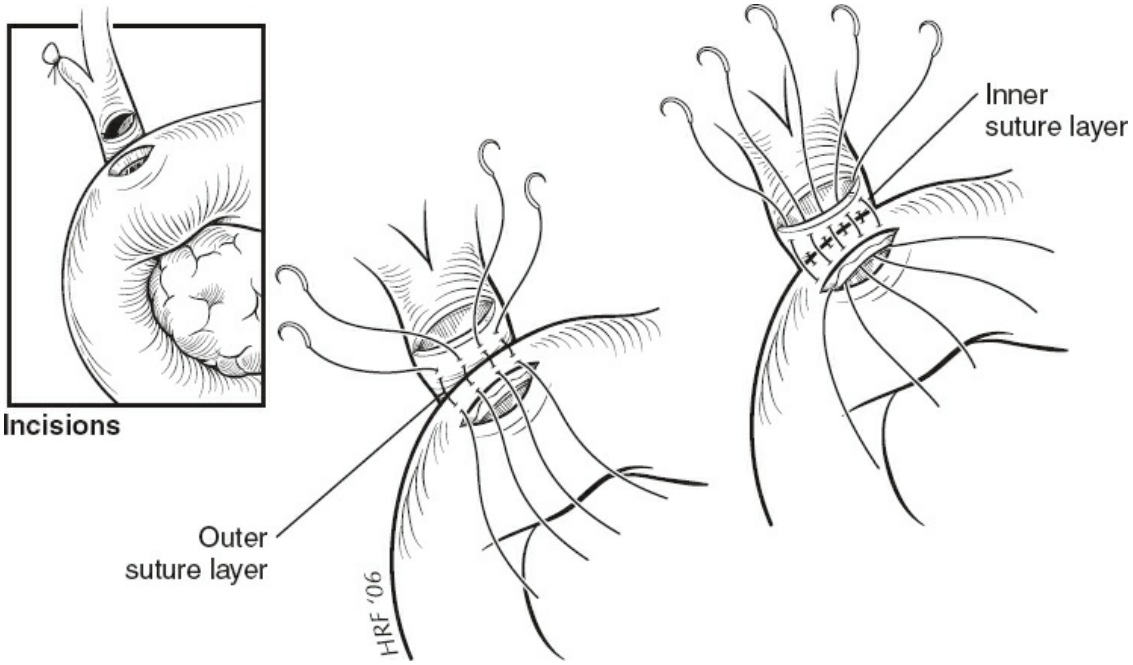

Figure 109.12. A side-to-side choledochoduodenostomy.

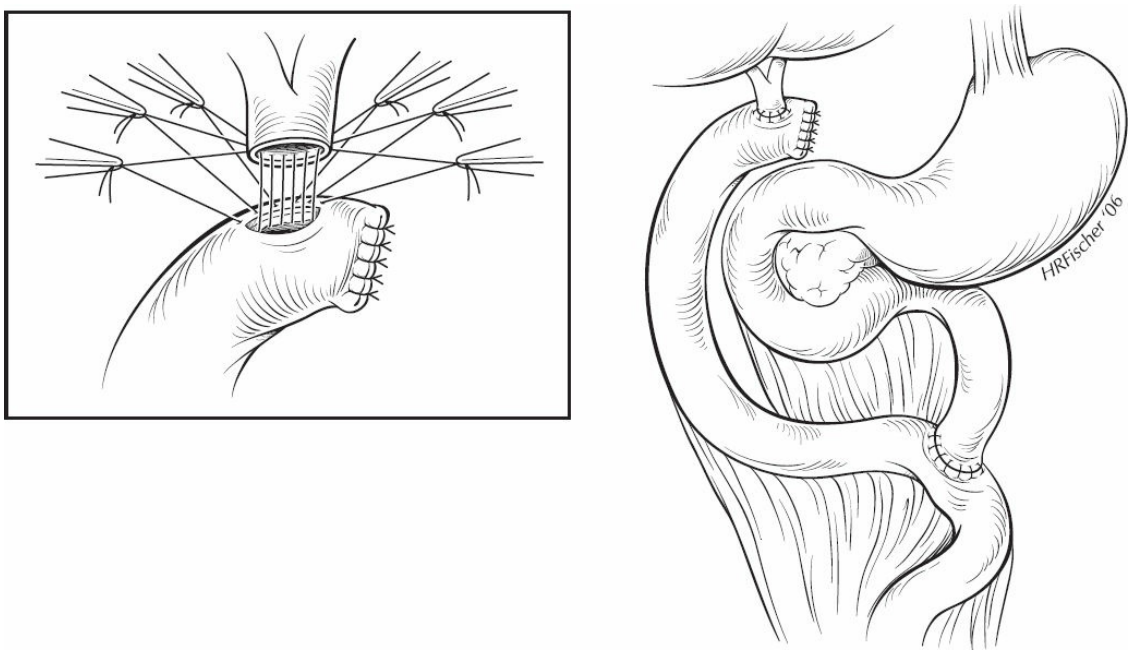

Figure 109.13. Hepaticojejunostomy Roux-en-Y. The anterior wall of the common hepatic duct is secured by retaining polydioxanone sutures.

A Roux-en-Y hepaticojejunal anastomosis is the procedure of choice for those patients with recurrent bile duct stones, biliary stricture related to an intraductal stone, the Mirizzi syndrome, and multiple intrahepatic stones. There is no need to place a stent or tube through the biliary anastomosis.

POSTOPERATIVE MANAGEMENT

Advances in anesthetic and postoperative analgesic care are characterized by enhanced recovery programs that result in early mobilization and discharge. General anesthesia is normally combined with epidural or other regional anesthesia to minimize postoperative pain. In routine cholecystectomy, no drain or nasogastric tube is required. The patient can resume fluid intake and diet when tolerated. Randomized studies have shown no advantage to the routine use of abdominal drains but, in those circumstances where the cholecystectomy or subtotal cholecystectomy has been undertaken for difficult pathology, there may be merit in leaving a closed drainage system to detect any early postoperative bleeding or bile leakage. Closed abdominal drains should be employed in those patients in whom there are concerns for the development of a postoperative collection or when the CBD has been opened. These drains can be removed within 24 to 48 hours when the volume is less than 100 mL per day and there is no bile or fresh blood evident.

In those patients in whom a T-tube has been placed, a cholangiogram is obtained on the 5th to 7th postoperative day. If normal, the tube can be clamped and removed at outpatient review 2 to 3 weeks later. Should a retained stone be identified, the tube is left in place for a further 6 weeks before removal by a radiologist to extract the retained stones percutaneously through the residual tract.

Mild derangement of liver function tests may arise after uneventful cholecystectomy, but any sustained elevation of bilirubin or alkaline phosphatase should prompt reevaluation of the patient's condition and imaging of the abdomen to exclude a postoperative bile leak collection or other complication. The development of a significant collection and/or jaundice mandates early abdominal imaging by computed tomography or postoperative cholangiography by magnetic resonance imaging or endoscopic means to exclude a retained stone or bile duct injury.

EDITOR'S COMMENT

Cholecystectomy is one of the most commonly performed operations. Professor Garden describes the relevant anatomy and indications and contraindications for the procedure. Most elective procedures are performed by the laparoscopic approach. Since the introduction of laparoscopic cholecystectomy (LC), there has been continued evolution in technique, instrumentation, and postoperative management. With increased experience, LC has migrated to the outpatient setting. It is important to note that all cholecystectomies cannot be performed by the laparoscopic technique and the incidence of conversion to an open procedure has been relatively constant at 2.5% to 5%. Hence, it behooves the surgeon to be familiar with open techniques and damage control procedures such as surgical and percutaneous cholecystostomy.

It is interesting to assess cholecystectomy over time in order to determine changes in indications and practice. Talamini and colleagues (Alli W, Yang J, Xu J, et al. *Surg Endos* 2016 September 7 [Epub ahead of print]) used the New York State Planning and Research Cooperative System longitudinal administrative database to assess the indications and incidence of cholecystectomy over time. They found that the incidence of cholecystectomy had not changed but the indications had. In this report from 1995 to 2013, there

were 711,406 cholecystectomies performed in New York State: 637,308 (89.58%) laparoscopic. The overall frequency of cholecystectomy did not increase (1.23% increase with a commensurate population increase of 6.32%). They found that the incidence of calculous cholecystitis declined (–20.09%, $p < 0.0001$) between 1995 and 2013; meanwhile, other diagnoses increased in incidence: biliary colic (+54.96%, $p = 0.0013$), acalculous cholecystitis (+94.24%, $p < 0.0001$), gallstone pancreatitis (+107.48%, $p < 0.0001$), and biliary dyskinesia (+331.74%, $p < 0.0001$). In addition, there was a transition to outpatient LC incidence with 48.59% being done as an outpatient in 2013, from 0.15% in 1995, increasing >320-fold.

Although most cholecystectomies are performed as laparoscopic procedures, there is a conversion rate of 2.5% to 5%. Multiple factors increase the risk of open conversion. Most surgeons have a good feel of the risk for conversion in individual patients with consideration given to the indication for the procedure, gender, previous upper abdominal surgery, etc. Indeed the risk of conversion of an LC to an open cholecystectomy has been widely studied. Information from meta-analyses indicates that age >65 years, male gender, acute cholecystitis, thickened gallbladder wall, diabetes mellitus, and previous upper abdominal surgery were significantly associated with increased risk of conversion. Evaluating these factors may be useful for surgeons in counseling the patient and in planning (Rothman P, Burcharth J, Pommergaard HC, et al. Preoperative risk factors for conversion of laparoscopic cholecystectomy to open surgery—a systematic review and meta-analysis of observational studies. *Dig Surg* 2016;33(5):414–23; Yang TF, Guo L, Wang Q. Evaluation of preoperative risk factor for converting laparoscopic to open cholecystectomy: a meta-analysis. *Hepatogastroenterology* 2014;61(132):958–65). An interesting recent study indicated that an elevated C-reactive protein, as a marker of the degree of inflammation, is an excellent independent predictor of the need to convert to open procedure (Jessica Mok KW, Goh YL, Howell LE, et al. Is C-reactive protein the single most useful predictor of difficult laparoscopic cholecystectomy or its conversion? A pilot study. *J Minim Access Surg* 2016;12(1):26–32). You may want to assess this in your practice.

If there was a validated preoperative stratification, then it could theoretically be used to improve the consent, scheduling (time and ambulatory surgery site or hospital) and identify appropriate training cases. Indeed, a validated risk score for conversion for use in clinical practice has been developed and seems to allow for preoperative identification of patients with a six-fold increased risk of conversion to open cholecystectomy. The risk score was derived from six significant predictors: age ($p = 0.005$), male gender ($p < 0.001$), indication for surgery ($p < 0.001$), ASA Classification ($p < 0.001$), thick-walled gallbladder ($p = 0.040$), and CBD diameter ($p = 0.004$). A score >6 identified patients at high risk of conversion (7.1% vs. 1.2%) (Sutcliffe RP, Hollyman M, Hodson J, et al. Preoperative risk factors for conversion from laparoscopic to open cholecystectomy: a validated risk score derived from a prospective U.K.

database of 8820 patients. *HPB (Oxford)* 2016;18(11):922–8).

The management of the surgically or percutaneously placed cholecystostomy tube is similar. It is best to adopt a standard protocol for your institution or practice. First, the surgeon must wait an appropriate period of time for healing to occur. Premature removal can be associated with intraperitoneal leakage from the cholecystostomy. Second, the gallbladder must be cleared of stones and the patency of the biliary trees established prior to removal of the tube. It is advisable to perform a cholecystogram with water soluble contrast to determine whether there are residual stones in the gallbladder. If the cystic duct is patent, then the common bile duct will also be visualized. Our protocol is to do imaging at 6 weeks post cholecystostomy and proceed with stone clearance or definitive treatment. The management of percutaneously placed tubes has been studied as well. These tubes are considered for removal once the patient has recovered from critical illness, and they show patent cystic and common bile ducts on imaging. Premature removal of the tubes leads to major bile leaks in 3% of patients and an equal frequency of minor leaks. Professor Garden describes the techniques to accomplish stone removal from the gallbladder. If stones are present in the common bile duct, then an endoscopic sphincterotomy should be considered. If the patient has improved and concurrent medical conditions resolved, then the patient may be best served by an open or LC.

A retrospective series of adult patients (n = 185) admitted with a primary diagnosis of acute cholecystitis and who received a cholecystostomy tube from 2002 to 2010 reported that most patients whether they had a percutaneous or surgical cholecystostomy had a successful LC (Cherng N, Witokski ET, Sneider EB, et al. Use of cholecystostomy tubes in the management of patients with primary diagnosis of acute cholecystitis. *J Am Coll Surg* 2012;214:196–201). In this study, the mean patient age was 71 years and 80% had ≥1 comorbidity (mean 2.6). Seventy-eight percent of the tubes were percutaneous and 22% were surgical. The majority (57%) of patients underwent cholecystectomy performed a median of 63 days post-tube placement (range 3 to 1,055 days); of these, 86% underwent LC and 13% underwent open conversion or open cholecystectomy. The authors noted that whether surgical or percutaneous tube placement, the same proportion of patients (85% to 86%) underwent LC as definitive treatment. The disposition of those not having surgery is unknown.

An additional study focusing on percutaneous drains found that only 32% of patients eventually had cholecystectomy. The patients having cholecystectomy were younger and had a lower Charlson comorbidity index (Boules M, Haskins IN, Farias-Kovac M, et al. What is the fate of the cholecystostomy tube following percutaneous cholecystostomy? *Surg Endo* 2017;31(4):1707–12). It is prudent to avoid cholecystectomy in elderly patients who are frail and have multiple comorbid conditions. In addition, the tubes can be safely removed with long-term survival and no recurrent cholecystitis (Cha BH, Song HH, Kim YN, et al. Percutaneous cholecystostomy is appropriate as definitive treatment for acute cholecystitis in critically ill patients: a single center, cross-sectional study.

Korean J Gastroenterol 2014;63(1):32–8).

From these two studies, it is clear that a substantial number of patients having surgical or percutaneous cholecystostomy tube placement do not undergo cholecystectomy. A decision to proceed with definitive surgery should be based on the assessment of the individual patient.

There are two conditions that I think deserve special discussion in the discussion of open cholecystectomy. If either of these is diagnosed preoperatively, then in my opinion an open cholecystectomy should be strongly considered. The first is Mirizzi syndrome and the second is gall bladder perforation.

The authors do comment on Mirizzi syndrome, and it is important to emphasize that if the diagnosis is established preoperatively then the surgeon should plan on an open procedure in the majority of patients. This syndrome develops when multiple and large gallstones become impacted in Hartmann pouch of the gallbladder leading to chronic inflammation and hence compressions of the common bile duct and eventually fistula formation into the adjacent common hepatic duct or common bile duct. As a result, the common bile duct or common hepatic duct becomes obstructed. There are four types: type I A—presence of cystic duct; type I B—obliteration of the cystic duct; and types II–IV—fistula present and classified on the basis of the size of the defect relative to the lumen of the common hepatic duct II <33%, III 33% to 66%, and IV >66%. It is essential to differentiate the conditions from malignancy.

In a recent review, Mirizzi syndrome was identified in 60 of 4,939 patients (1.21%) who underwent cholecystectomy (Kulkarni SS, Hotta M, Sher L, et al. Complicated gallstone disease: diagnosis and management of Mirizzi syndrome. *Surg Endos* 2016 September 1 [Epub ahead of print]). Three had coexistent gall balder cancer. The mean age at presentation was 47 years, and 35 patients were females. The most common symptom at presentation was abdominal pain (100%) followed by nausea/vomiting (87%) and jaundice (43%). Type I was diagnosed in 16 patients and 44 had type II. Preoperative diagnosis was achieved in 43 patients (71%) primarily by magnetic resonance cholangiopancreatography. LC was successful in only 4 out of 16 patients with type I. The presence of the syndrome makes open cholecystectomy likely. Those with type II–IV require open cholecystectomy and not in frequently Roux-en-Y reconstruction of the biliary tree. In situations in which there is severe inflammation, the fistula can be sutured to the roux limb creating a side-to-side choledochjejunostomy.

Acute perforated cholecystitis is probably the most severe complication of acute cholecystitis. This is a rare complication. In assessing this condition and planning for operative intervention, the surgeon must consider the high conversion rate and complications. A recent study looked at the outcome of acute perforated cholecystitis in a register study of more than 5,000 cases in Germany (Jansen S, Doerner J, Macher-Heidrich S, et al. Outcome of acute perforated cholecystitis: a register study of over 5000 cases from a quality

control database in Germany. *Surg Endosc* 2016 August 23 [Epub ahead of print]). In this study, a total of 5,704 patients with acute gallbladder perforation were included compared with 39,661 patients without perforation. Risk factors for perforation were: the male gender, advanced age (>65 years), ASA score >2, elevated white blood count (WBC), positive findings on abdominal ultrasound sonography and fever. Preoperative computed tomography (CT) was ordered significantly more often in the perforated group compared to those without perforation (2.3 vs. 1.0%, $p = 0.001$). Surgery lasted significantly longer in the patients with perforation. For the perforated group, the rates of conversion to an open procedure were likewise greater (18.9 vs. 6.8%), as was bile duct injury (1.4 vs. 0.5%), re-intervention (6.9 vs. 2.9%), mortality (4.3 vs. 1.3%), and the length of stay (13.4 ± 11.4 days vs. 9.0 ± 8.3, $p < 0.001$).

Professor Garden describes an excellent technique for common bile duct exploration (CBDE). It is very similar to the one I employ. One difference is that I have found that the procedure is easier if performed from the left side of the patient. This allows the surgeon to place his left hand behind the routinely Kocherized duodenum to palpate the intrapancreatic portion of the bile duct as part of the procedure while using the right hand for the common duct exploration or choledochoscopy.

A recent study highlighted the marked decline in the use of both open and laparoscopic CBDE in the United States as well as any advantage to the length of stay laparoscopic common duct exploration over ERCP and LC (Wandling MW, Hungness ES, Pavey ES, et al. Nationwide assessment of trends in choledocholithiasis management in the United States from 1998 to 2013. *JAMA Surg* 2016;151(12):1125–30). The authors suggest that common duct exploration may be at risk of disappearing. The study used the National Inpatient Sample data from 1998 to 2013. In total, 37,207 patients were included in the analysis, 36,048 (96.9%) were treated with ERCP and LC, and 1,159 (3.1%) were treated with laparoscopic CBDE and LC. The overall use of CBDE for patients with choledocholithiasis decreased from 39.8% of admissions in 1998 to 8.5% in 2013 ($P < 0.001$). A decrease was also seen for open CBDE (30.6% vs. 5.5%; $P < 0.001$) and laparoscopic CBDE (9.2% vs. 3.0%; $P < 0.001$) independently.

In summary, the prepared surgeon should understand conditions in which open cholecystectomy might be likely. In these circumstances, assessment of the biliary tree with cholangiography is important as is the understanding of appropriate methods of damage control in the critically ill patient. Certain conditions may warrant open cholecystectomy. Familiarity with open common duct exploration is decreasing, and it behooves each surgeon to develop a strategy for dealing with common duct stones that may not be amendable to percutaneous or endoscopic treatment.

110 Laparoscopic Cholecystectomy, Intraoperative Cholangiography, and Common Bile Duct Exploration

John G. Hunter and Laura E. Fischer

INTRODUCTION

In 1882, the first open cholecystectomy was performed in Berlin by Carl Langenbuch to treat a 42-year-old man with long-standing biliary colic; however, cholecystectomy was not commonly accepted as a treatment for gallstone disease until the turn of the century. The first two laparoscopic cholecystectomies (LC) in the world were performed by Eric Muhe in Boblingen, Germany, in 1985 and Philippe Mouret in Lyon, France, in 1987. Working independently, two groups of American surgeons performed the first LC in the United States in 1988.

In 1990, 10% of cholecystectomies were being performed laparoscopically in the United States. This figure has risen dramatically over the past two decades and stands at 90.5% in 2010. Never before had a surgical revolution occurred so quickly. The major advantage of the laparoscopic approach was improved recovery, which allowed patients to have better quality of life in the immediate postoperative period. Although prospective randomized trials came late, they showed the clear advantages of LC over open cholecystectomies: less pain with faster recovery. However, this cataclysmic change took its toll. Training of surgeons to perform the highly technical procedure was frequently inadequate, and early complications gave birth to the phrase *learning curve.* It is the purpose of this chapter to review the lessons of the last 30 years and to detail current techniques for LC, intraoperative cholangiography (IOC), laparoscopic ultrasonography, and common bile duct (CBD) exploration.

ETIOLOGY AND PATHOPHYSIOLOGY

Gallstone disease refers to symptoms related to the presence of gallstones

in the gallbladder or the CBD. There are two main types of gallstones—cholesterol and pigmented. There are multiple risk factors related to the formation of cholesterol gallstones, including age >40, female gender, pregnancy, estrogen replacement therapy, family history, obesity, rapid weight loss, diabetes mellitus, and cirrhosis. Gallbladder stasis due to total parenteral nutrition, prolonged fasting, or excess somatostatin can also contribute to the formation of stones. Certain drugs can also promote the formation of gallstones, most importantly ceftriaxone, which is partially excreted through the biliary system. Disorders associated with hemolysis, such as hemolytic anemia, are associated with the formation of pigmented gallstones.

Statins and other dietary factors, including vitamin C, coffee, vegetable protein, nuts, and poly- and monounsaturated fats, have all been associated with a reduced risk of gallstone disease.

It has been estimated that approximately 10% to 15% or over 20 million adults in the United States have gallstone disease. In addition, 1 million new diagnoses are made each year. The prevalence is higher in those of Caucasian, Hispanic, and Native American descent, and lowest in the African American and Japanese populations.

CLINICAL PRESENTATION, INDICATIONS AND CONTRAINDICATIONS

Symptomatic Cholelithiasis

The major indication for elective LC is symptomatic cholelithiasis, also known as “biliary colic.” Classic symptoms present in the majority of patients include stabbing (colicky) pain in the right upper quadrant radiating to the back and to the shoulder. Although it is often taught that this pain occurs 30 to 60 minutes after the patient eats a fatty meal, the pain pattern is not always so predictable. Frequently, the pain occurs in the middle of the night, usually between the hours of midnight and 3 AM. After waking the patient, the pain generally lasts from a few minutes to a few hours. Usually, the pain passes within an hour, and the patient returns to sleep. Frequently, the pain is associated with nausea and vomiting but is rarely accompanied by jaundice, fevers, or chills, unless acute cholecystitis or cholangitis is present. When the pain is most severe and unrelenting, an emergency room visit is prompted. Myocardial infarction is often suspected, but it is “ruled out” with a normal electrocardiogram and

cardiac isoenzymes. An ultrasound of the right upper quadrant should be performed, and if it demonstrates cholelithiasis in this setting, elective LC is indicated. Occasionally, the presentation is less characteristic of biliary colic. The patient may only complain of a nagging, dull pain in the right side, epigastrium, or back without the severity of colic. In this setting, the association of gallstones and right upper quadrant pain that cannot be attributed to another cause merits consideration of LC.

Biliary Dyskinesia

The sphincter of Oddi is a muscular segment of the intraduodenal bile duct and ampulla of Vater. This 6- to 10-mm complex of circular muscle fibers maintains resistance to bile flow and permits filling of the gallbladder in between meals. If this muscle does not adequately relax, the gallblaadder cannot empty and patients can feel pain in the right upper quadrant, similar to biliary colic, but without evidence of cholelithiasis on ultrasonography. This dysfunction can also be associated with recurrent pancreatitis. Functional gallbladder disorders have also been described in which there is a primary absence of gallbladder motility, in the absence of gallstones or sludge. These disorders typically are not associated with elevated liver function tests, bilirubin, amylase, or lipase serum values.

Similar to biliary colic, the pain lasts for a few minutes to a few hours, is located in the epigastrium or right upper quadrant, can awaken the patient in the middle of the night, and is associated with nausea and vomiting. These patients often have an extensive work-up with negative ultrasound and esophagogastroduodenoscopy. It is often a diagnosis of exclusion; however, a CCK-stimulated cholescintigraphy can be used to estimate the gallbladder ejection fraction (GBEF). This study is performed by injecting ^{99m}Tc-hepatic iminodiacetic acid (HIDA) as an intravenous bolus and then measuring the activity of the radiotracer over time. Patients with a GBEF of less than 35% to 40% are considered to have abnormal gallbladder motility and may have symptomatic relief from an elective LC.

Acute Cholecystitis

Complicated gallstone disease is usually managed laparoscopically in the same manner as it was managed during the era of open cholecystectomy. Acute cholecystitis, which is characterized by fever, leukocytosis, right upper quadrant tenderness, and gallstones, demands more immediate attention than biliary colic. LC in patients with acute cholecystitis may be

significantly more difficult and is associated with conversion rates of 5% to 10% (depending on surgeon experience), but it is nonetheless worth pursuing in patients without severe concomitant risk factors. Multiple trials have shown that early treatment of acute cholecystitis has been shown to have a reduced length of hospital stay and does not increase complications. In fact, early surgery has been associated with reduced risk of mortality, fewer bile duct injuries, and less conversion to open when compared to delayed cholecystectomy. Surgery should be performed as soon as possible after the onset of symtpoms, and preferably within 72 hours. Nonoperative management with a plan for delayed cholecystectomy fails in approximately 15% of patients due to recurrent cholecystitis, pancreatitis, or cholangitis. In extremely high-risk patients, the placement of a percutaneous cholecystostomy tube can be an alternative to surgical intervention. However, the procedure is associated with a high morbidity and mortality, so it should be reserved for those patients who are clearly unfit for emergency surgery.

Gallstone Pancreatitis

During initial hospitalization, mild biliary pancreatitis is approached by allowing the patient's abdominal pain to resolve and document that the serum lipase level is trending toward a normal level before performing LC. In this setting, some surgeons choose to perform a preoperative endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy (ES) (if a stone is detected on ERCP) before LC. Bile duct stones will be found in only 10% to 15% of these patients, subjecting the remaining 85% to an unnecessary procedure and the risk of recurrent pancreatitis. Therefore, it is our practice to perform an intraoperative cholangiogram at the time of LC and perform CBD exploration through the cystic duct or through a choledochotomy if stones are present. For a surgeon inexperienced in laparoscopic bile duct exploration, we advocate completion of the LC with postoperative ERCP and ES. Unless the stones are very large (>1 cm), ERCP with ES has very high success rates and avoids the morbidity of an open cholecystectomy and bile duct exploration. However, conversion to open cholecystectomy with CBD exploration is a reasonable option, and should be chosen when the bile duct stones are large (>1 cm), when the CBD is extremely dilated (>12 mm), or the stone burden is formidable. Anatomic concerns, such as previous gastric bypass operation, will make ERCP a difficult option,

favoring a direct approach to the CBD.

Cholangitis

Cholangitis is characterized by jaundice, shaking chills, and right upper quadrant pain and tenderness. This is a medical emergency that should be treated with urgent preoperative ERCP, ES, and stone extraction unless the infection is quickly and easily controlled with intravenous antibiotic therapy. ERCP and ES are successful at removing all CBD stones in more than 90% of patients with cholangitis. Laparoscopic bile duct exploration and stone extraction in this setting may be difficult because the stone is often impacted and the bile duct is inflamed and friable. If the cholangitis resolves with antibiotics and the patient's symptoms resolve, it may be appropriate to perform elective LC, intraoperative cholangiography, and laparoscopic bile duct exploration if a stone is detected. Alternatively, LC can be performed shortly after the CBD has been cleared through ERCP and ES. The appropriate management of CBD stones in the era of LC remains fertile soil for good clinical studies.

Contraindications

Absolute contraindications to LC are few. Certainly, a patient who is unable to tolerate general anesthesia, a patient with gallbladder cancer (suspected or confirmed), and a patient with a "frozen upper abdomen" due to previous surgery or peritonitis should not undergo LC. In addition, relative contraindications include any previous right upper quadrant surgery, portal hypertension, coagulopathy, and cholecystoenteric fistula. Although successful management of gallstone disease has been achieved in all of these patient groups, these procedures should be left for the surgeon who makes laparoscopy the majority of his or her practice and is technically skilled in these areas.

Pregnancy is not a contraindication to LC and can be performed safely with a few modifications such as the Hasson technique for abdominal access, a left-sided bed tilt, and appropriate placement of trocars to accommodate the size of the gravid uterus. LC is considered the preferred technique for the pregnant patient as it offers a faster postoperative recovery, reduced opioid usage, and fewer wound complications.

PREOPERATIVE PLANNING

Preoperative Testing

In addition to a careful history and physical examination, preoperative testing for 90% of patients with gallstone disease is minimal. An ultrasound of the right upper quadrant usually confirms the diagnosis, and the hepatic biochemical profile (alkaline phosphatase, serum glutamic–oxaloacetic transaminase, bilirubin, and lactic acid dehydrogenase) usually determines the likelihood that CBD stones are present. Striking abnormalities in the hepatic profile or an ultrasonographically dilated CBD may warrant a preoperative ERCP or magnetic resonance cholangiography (MRCP), or both, to search for the cause (e.g., neoplasm or stricture) of the bile duct obstruction.

The diagnosis of acute cholecystitis, when the history and physical examination are less than definitive, can be made with a HIDA scan as described above. As described previously, an ejection fraction of less than 35% at 30 minutes suggests poor contractile function and incomplete emptying of the gallbladder. Nonfilling of the gallbladder in 1 hour, especially after administration of intravenous morphine, which contracts the Oddi sphincter, is a highly accurate predictor of acute cholecystitis. When the ultrasound demonstrates nonuniform thickening of the gallbladder wall or pancreatic head, a computed tomographic scan should be performed to assess the likelihood of the presence of gallbladder cancer.

Operative Equipment

The first step in successful LC is the recruitment of a good operating team. This includes a well-trained laparoscopic surgeon, a first assistant with equivalent skills, and a camera operator who is familiar with the anatomy and technique of LC. With a well-choreographed operation, the first assistant can also be the camera operator. The elimination of a dedicated “camera operator” can only be achieved if the surgeon uses a two-handed operating technique. Ideally, the patient is placed on a fluoroscopic table with the table turned backwards for easy access to the upper abdomen by the fluoroscopic C-arm. Two monitors are placed at the 10 o’clock and 2 o’clock position with respect to the patient’s head (Fig. 110.1). Generally, the surgeon stands to the patient’s left, and the first assistant stands to the patient’s right. If a dedicated camera operator is used, that person stands behind the surgeon on the left side.

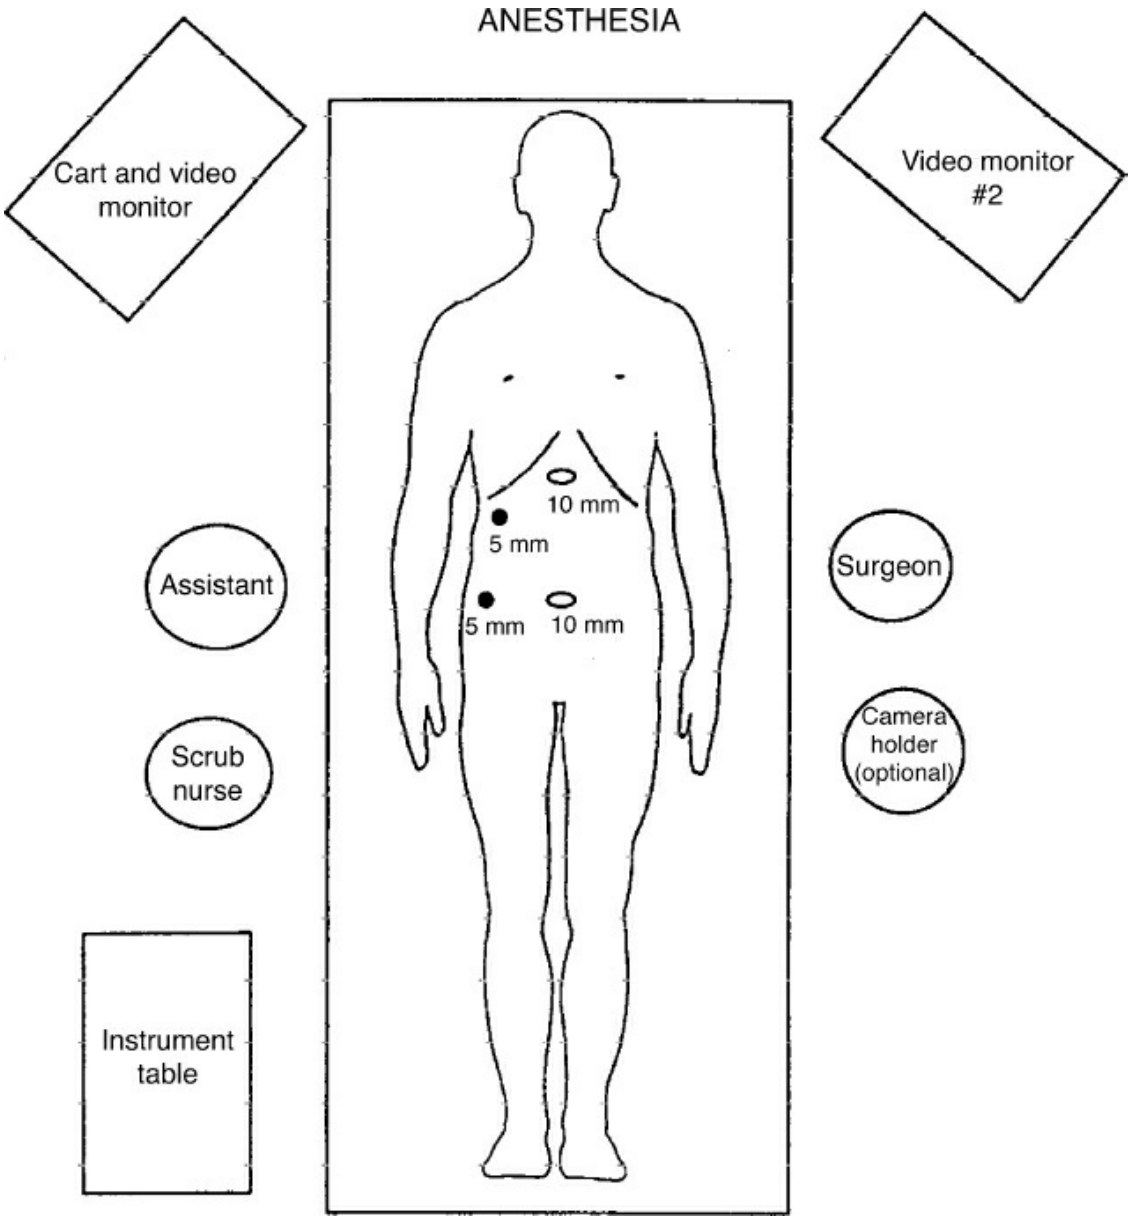

Figure 110.1. Room setup for laparoscopic cholecystectomy.

The equipment for LC is quite simple. The only rigid requirements are that a high-quality videolaparoscope with a 300-W light source be coupled to two high-resolution monitors. A high-flow carbon dioxide insufflator, four trocars (one or two 10- or 12-mm trocars and two or three 5-mm trocars), and approximately 10 specialized laparoscopic hand instruments are required. We frequently use a monopolar electrode L-hook, a fine-tipped Maryland dissector, two gallbladder graspers, a pair of scissors, a medium to large hemoclip applier, and a sterile plastic bag for specimen retrieval. A 10-mm stone retrieval grasper is helpful to remove spilled gallstones. If a cholangiogram is to be performed, some surgeons prefer to use a small “microscissors,” a specialized cholangiogram clamp, and a 4 or

5 French tapered catheter. Techniques of cholangiography are discussed in a later section.

ANESTHESIA

Anesthetic techniques for laparoscopy are quite different than those used for open surgery. Generally, nitrous oxide is avoided to minimize the likelihood of bowel distention. Because insensible fluid losses through the closed abdomen are minimal, intravenous fluids should be run more judiciously than during open surgery. In addition, the pneumoperitoneum is a strong stimulus to antidiuretic hormone release, decreasing intraoperative urine output. If the anesthesiologist responds to oliguria with fluid boluses in the absence of fluid losses, pulmonary edema may result. Last, the anesthesiologist must be acutely attuned to ventilatory function, as the carbon dioxide pneumoperitoneum occasionally leads to hypercarbia and acidosis if close attention is not paid to the carbon dioxide concentration of expired gas (end-tidal PCO_2). In addition, we ask our anesthesiologists to minimize the use of narcotics and administer a powerful antiemetic to lessen postoperative nausea. For elective LC where the gallbladder is not acutely inflamed, preoperative antibiotics have not been shown to be of benefit. All patients should have venous thromboembolic prophylaxis in the form of sequential compression devices prior to induction of anesthesia. Once the patient is anesthetized and intubated, a Foley catheter and an orogastric tube are generally placed. Decompression of the stomach and bladder minimizes the chance of injury during establishment of intra-abdominal access.

SURGICAL TECHNIQUE

Pneumoperitoneum

LC is generally performed with a carbon dioxide pneumoperitoneum at 15 mm Hg pressure. There is no evidence that lower pressures confer a significant safety advantage. Generally, the pneumoperitoneum is obtained by sliding a specialized needle (a Veress needle) through the umbilicus, confirming its position by allowing saline to run through the needle from a plungerless syringe, and then attaching the needle to tubing from the carbon dioxide insufflator. Initially, the flow rate of carbon dioxide is set at 2 to 3 L/min to ensure that proper placement has occurred before a large volume of gas is insufflated. Confirmation of the intra-abdominal position

of the needle can be obtained by observing for uniform abdominal distention, tympani, and the ability to vary the intra-abdominal pressure by raising and lowering the abdominal wall. Initial pressures greater than 10 mm Hg can suggest preperitoneal placement of the needle, although high opening pressures can be difficult to interpret in the morbidly obese patient. Once the surgeon is comfortable that the needle is in the abdomen, the flow rate can be increased until an intra-abdominal pressure of 15 mm Hg is achieved.

An alternate method for establishing pneumoperitoneum is the open Hasson cutdown technique, whereby the abdominal cavity is entered under direct vision. A scalpel, S-retractors, a clamp, and scissors are required for this technique. Once the peritoneal cavity is entered, the initial trocar is inserted and its position is secured with two stay sutures. The abdomen can then be insufflated rapidly with carbon dioxide. Other techniques used to obtain pneumoperitoneum include the opti-view port system in which the laparoscope is directly inserted through the layers of the abdominal wall using a specialized, transparent port.

Any of these pneumoperitoneum techniques are acceptable, but there appear to be fewer major injuries when a novice or occasional laparoscopic surgeon uses an open access technique. Nevertheless, no technique is completely safe. Bowel and vascular injuries have been reported with all these techniques. Ultimately, the safest technique is the one that the surgeon is most comfortable performing.

Trocar Placement

Once the pneumoperitoneum has been established, the first trocar is placed just superior to the umbilicus. Trocars should be placed with a controlled, twisting, not a plunging, motion. It is generally a good idea to apply a second hand to the barrel of the trocar to prevent an inadvertent plunge that could lead to intestinal or vascular injury. If needed, the assistant can provide counter-traction on the abdominal wall during placement of the first trocar. If the patient is morbidly obese, a primary trocar position several centimeters superior to the umbilicus allows better access to the right upper quadrant. If a previous abdominal surgery has been performed through a vertical midline incision, an alternate site for primary puncture is chosen. In this situation, we insufflate through a site adjacent to the umbilicus or in the left upper quadrant using a Veress needle technique, then place the primary trocar—a 5-mm trocar—in the right upper quadrant

and pass a 5-mm telescope. The umbilical trocar is then placed to the right of midline under direct vision, avoiding the adhesions from the previous operation. Many surgeons prefer to use the Hasson technique when previous abdominal surgery precludes primary puncture through the umbilicus. However, if the bowel is adherent to the undersurface of a previous midline incision, this abdominal access method carries a high risk of intestinal injury.

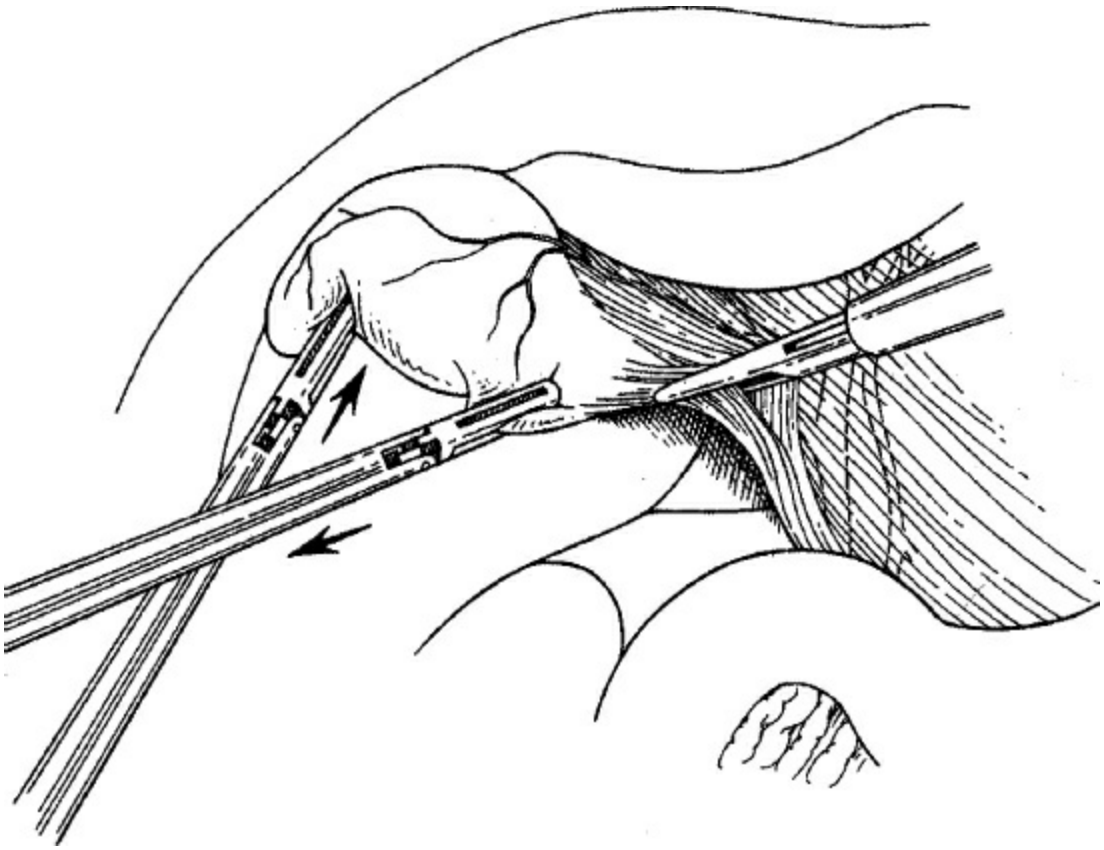

Figure 110.2. Elevation of the gallbladder infundibulum and exposure of porta hepatis.

Once the umbilical trocar is established, a 5- or 10-mm telescope is passed through the primary trocar. An angled (30-degree) telescope allows a better view of the CBD, the posterior wall of the gallbladder, and the triangle of Calot than does a straight (0-degree) telescope. Next, a 10-mm trocar is placed in the epigastrium, starting from the midline and angling toward the gallbladder. This trocar should enter at the level of the inferior liver edge just to the right of the falciform ligament. If this trocar is too low, the surgeon will be working parallel with his or her operating telescope. If this trocar is placed too high, segment IV of the liver will impede the surgeon’s ability to get to the gallbladder fossa. The third

trocar is a 5-mm trocar, which is generally placed 2 to 3 cm below the costal margin in the midclavicular line. The fourth trocar is located in a variable position, generally in the anterior axillary line, several centimeters below the fundus of the gallbladder. If this port is placed too low, it will be impossible to lift the gallbladder up to expose the porta hepatis sufficiently (Fig. 110.2).

Exposure of the Porta Hepatis

Exposure of the porta hepatis requires maximal elevation of the gallbladder fundus and liver edge. This elevation is usually achieved by the placement of a ratcheted, aggressive clamp on the fundus of the gallbladder from the most lateral trocar, and cephalad displacement is initiated until the infundibulum of the gallbladder, the duodenum, and the porta hepatis are well exposed (Fig. 110.2). If exposure of the porta hepatis is inadequate, the patient can be placed in a more severe reverse Trendelenburg position, the fundic grasper can be moved farther down the gallbladder to better elevate the gallbladder, or a fifth trocar can be introduced from the patient's left side to push down on the duodenum. This last technique is rarely necessary.

Stripping the Peritoneum

Using a two-handed technique, the surgeon grasps the gallbladder infundibulum with an instrument in his or her left hand and retracts it laterally. With a fine dissector, the peritoneum is torn at the interface between the gallbladder and periportal fat. The peritoneum is teased toward the common duct until the cystic duct, cystic artery, or lymph node of Calot is identifiable. Complete stripping of the posterior cystic duct is facilitated if the surgeon pushes the infundibulum medially to strip the peritoneum off the posterior aspect of the gallbladder and cystic duct. The 30-degree angled telescope is critical to obtaining this exposure. This lateral and medial retraction of the infundibulum is key for the safe circumferential visualization and dissection of the gallbladder infundibulum (Fig. 110.3).

Pedunculation of the Gallbladder

Stripping of the peritoneum over the gallbladder should reveal the presumed insertion of the cystic duct into the gallbladder. Continued

dissection at this interface, first with a fine dissector and then with a monopolar L-hook between the cystic artery and cystic duct, provides the anatomic definition of important cystic duct anatomy. Complete dissection in this region allows the gallbladder to appear like a polyp on a stalk (the cystic duct). Careful dissection and division of the lymphatics that cross Calot triangle may facilitate the exposure of the cystic duct. The cystic artery that crosses Calot triangle may impede this pedunculation effort and may be divided between clips near the gallbladder, if necessary. Pedunculation of the gallbladder may be assisted by dividing the medial and lateral peritoneal attachments of the gallbladder to the liver along the body of the gallbladder. It is unnecessary to continue the dissection any farther down the cystic duct than is needed to place two clips on the structure. The CBD is usually seen with the angled scope, and it is almost never necessary to dissect the cystic duct down to its junction with the CBD. To do so is to risk injury to this structure (Fig. 110.4).

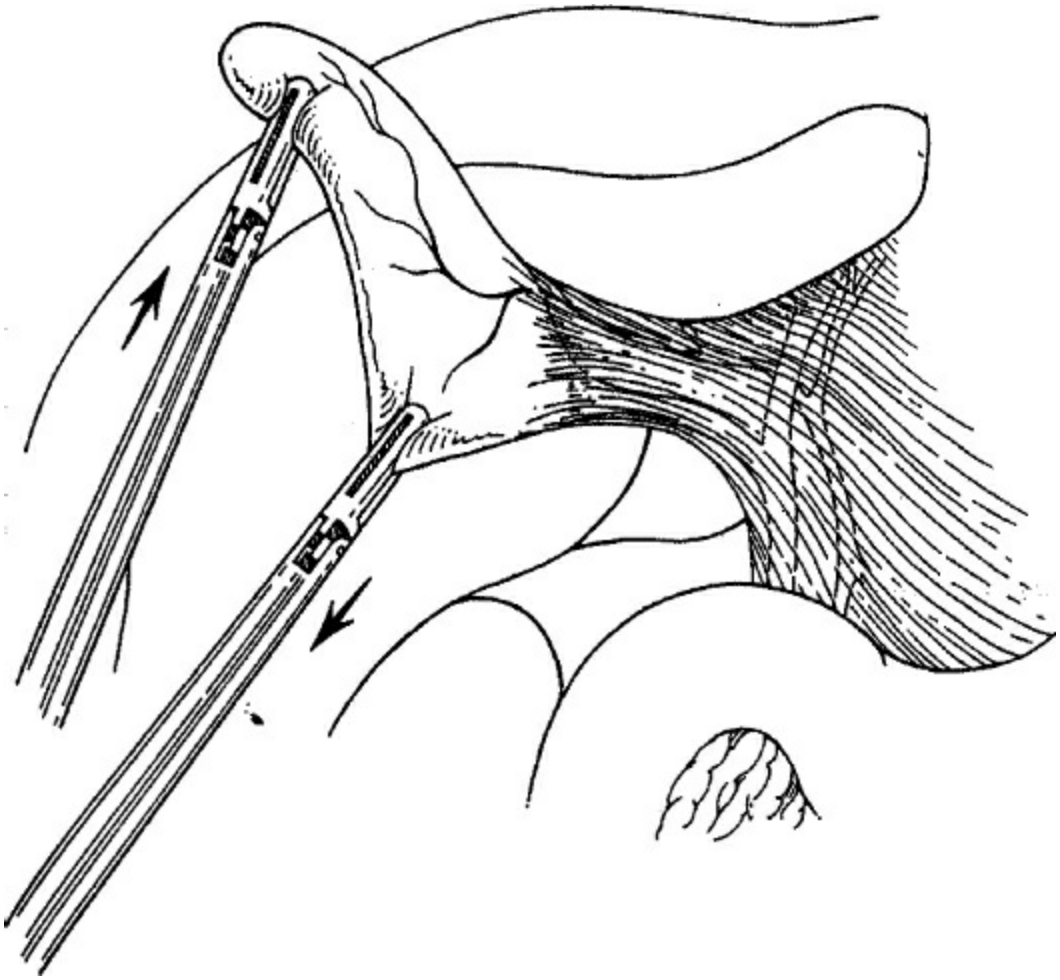

Figure 110.3. The cystic duct is visualized by retracting the gallbladder infundibulum laterally and then stripping the

peritoneum off the gallbladder.

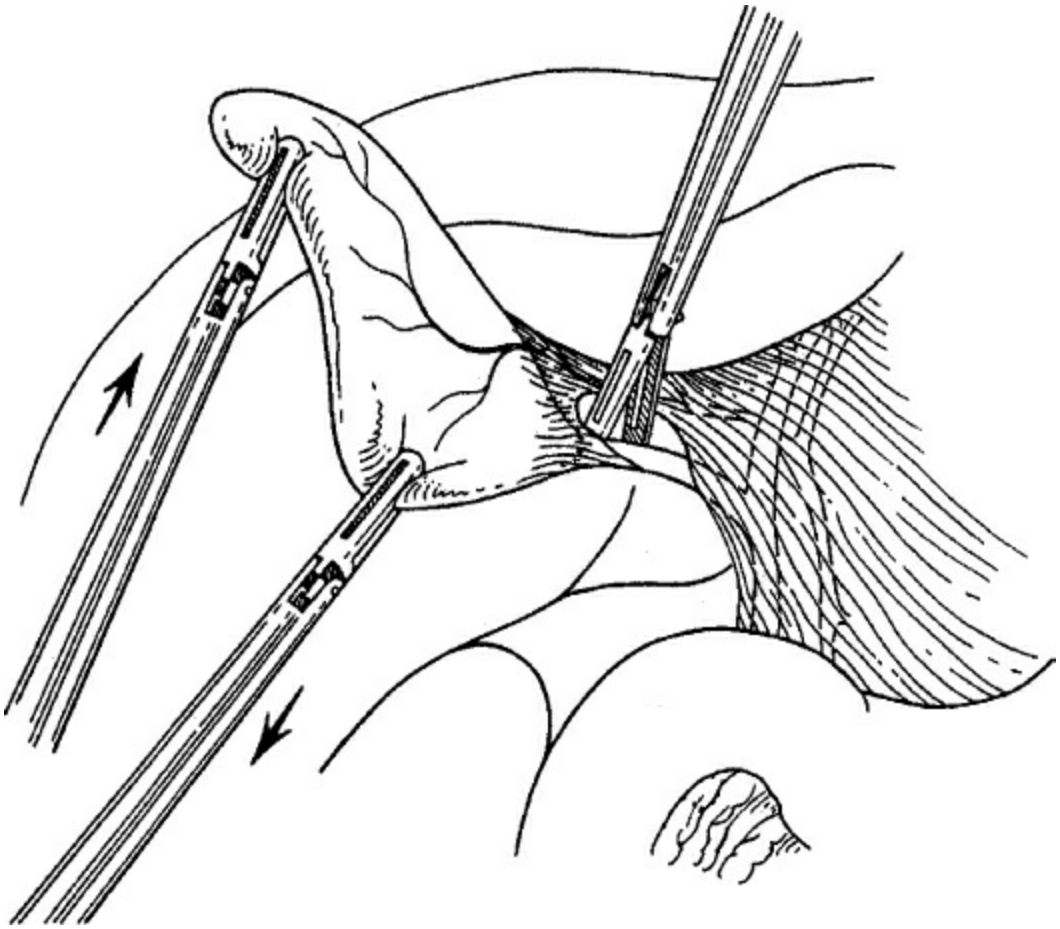

Figure 110.4. Pedunculation of the gallbladder.

Control of the Cystic Duct and Cystic Artery

Generally, the cystic duct is narrow enough that an 8-mm (medium to large-sized) hemoclip can be passed around it and slid up to the infundibulum of the gallbladder, where it is closed. If cholangiography is to be performed (see Intraoperative Cholangiography), it is done now. If a cholangiogram is not to be performed, two clips are placed on the cystic duct immediately below its junction with the gallbladder, and the cystic duct is divided. A long cystic duct remnant is not a concern as long as no stones are retained in this remnant. Two hemoclips are placed on the cystic artery as it crosses onto the gallbladder, if it has not been previously clipped, and the cystic artery is divided (Fig. 110.5).

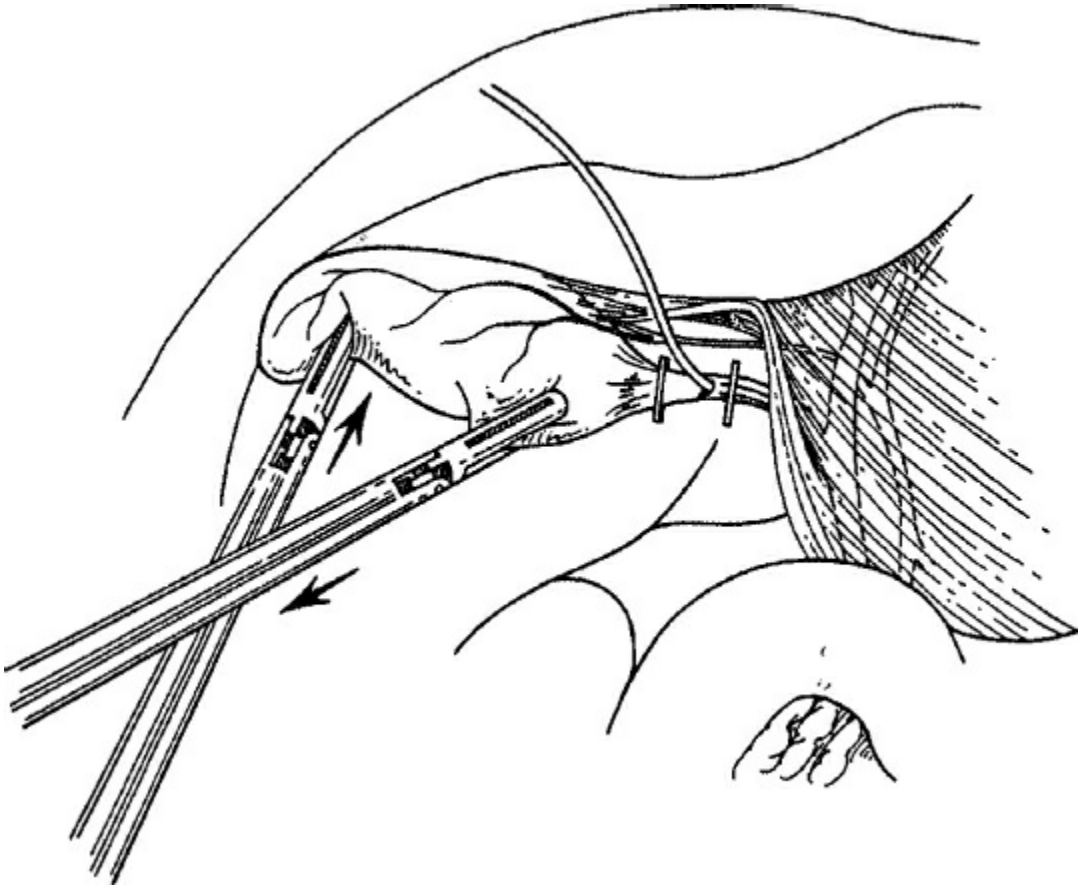

Figure 110.5. The first clip is placed on the gallbladder infundibulum to ensure that proper anatomic identification has occurred, and a cholangiocatheter is inserted and held in place by a partially occluding clip. The *arrows* indicate the direction of retraction of the gallbladder for optimal exposure.

Resection of the Gallbladder

If adequate pedunculation has been performed before cystic duct division, the gallbladder should already be dissected off the liver a quarter of the way to the fundus. Gallbladder resection is facilitated by strong use of the retracting (left) hand to pull the gallbladder away from the liver. As the gallbladder is pulled away from the liver, the monopolar electrode is used to coagulate the small bridging veins and areolar tissue connecting the gallbladder to the liver (Fig. 110.6). If hemorrhage occurs during this dissection, it usually means that the surgeon is not in the right tissue plane, most frequently in the hepatic parenchyma. Holes in the gallbladder occur frequently during this dissection. They can usually be controlled with a pretied chromic ligature, an interrupted figure-eight suture, or carefully placed hemoclips. When the fundus of the gallbladder is reached, the majority of the gallbladder is flipped over onto the anterior surface of the

liver and used as a handle to retract the gallbladder fossa, and hemostasis of the gallbladder fossa is checked (Fig. 110.7). The remaining peritoneum connecting the gallbladder and liver is then divided with electrocautery to disconnect the gallbladder from the liver.

Removal of the Gallbladder

At this point, the sterile retrieval bag is introduced through either the umbilical or the epigastric port, whichever is at least 10 mm in size. The bag is opened under direct visualization, and the gallbladder is placed within the bag, which is then sealed. The bag, which typically has a retrieval string, is then removed via the port site by removing the trocar. If the umbilical port site is used for retrieval, the telescope can be moved to the epigastric trocar to facilitate the maneuver. If the gallbladder does not come out easily, the bile is generally removed from the gallbladder with a small suction device passed into the gallbladder below the level of the fascia. When large stones are present, it may be necessary to dilate the fascial opening with a Kelly clamp or to enlarge the fascial incision with a pair of curved Mayo scissors to facilitate gallbladder removal (Fig. 110.8). Alternatively, if the gallbladder is intact, it can be removed directly from the abdomen without a retrieval bag using a 10-mm gallbladder grasper. The fascia is then closed with an interrupted or figure-eight suture and the abdomen is reinflated. The right upper quadrant is thoroughly irrigated, and all fluid is removed from the subphrenic space. Then the remaining trocars are removed under direct vision, the skin is closed with a subcuticular suture, and Steri-Strips or a sterile glue can be used as a dressing.

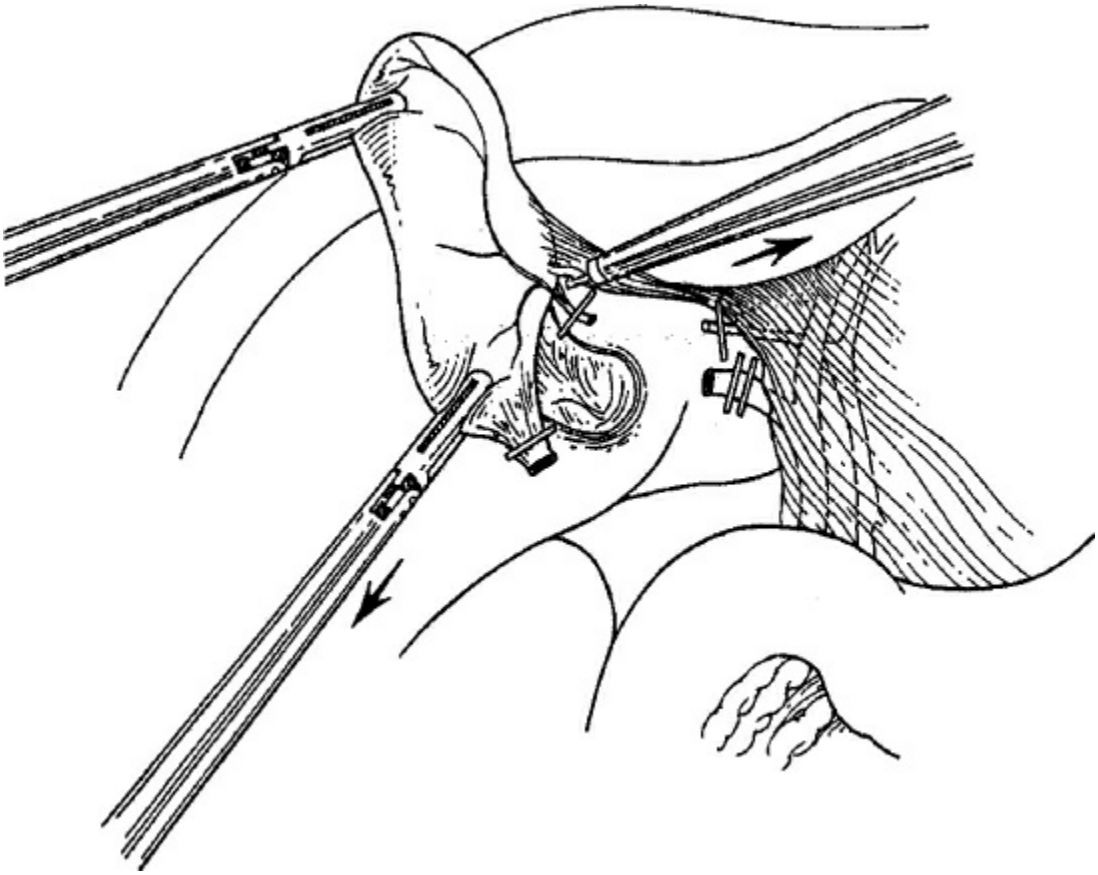

Figure 110.6. The gallbladder infundibulum is retracted from the liver and the cholecystohepatic attachments are divided with a monopolar hook. The *arrows* indicate the direction of retraction of the gallbladder for optimal exposure.

ADDITIONAL OPERATIVE MANEUVERS

Intraoperative Cholangiography

Whether IOC should be performed routinely or selectively is still a matter of great debate. Nonetheless, several convincing population-based studies demonstrate that bile duct injury occurs less frequently when cholangiography is performed by practitioners who are familiar with the technique and proficient at interpreting cholangiograms. IOC has a sensitivity of 79% and a specificity of 100% for CBD injuries. In one large, retrospective study, the CBD stone rate was 10% and of the patients with stones, 30% were unsuspected. The benefits of IOC include improved intraoperative diagnosis of injury, avoidance of diagnosis delay and the subsequent sequelae, and lower cost of early treatment compared with delayed intervention. The downside to IOC is that it requires the surgeon to have expertise in performing and interpreting the study, it lengthens the operative by an average of 6 minutes, and it is associated with higher

operative cost.

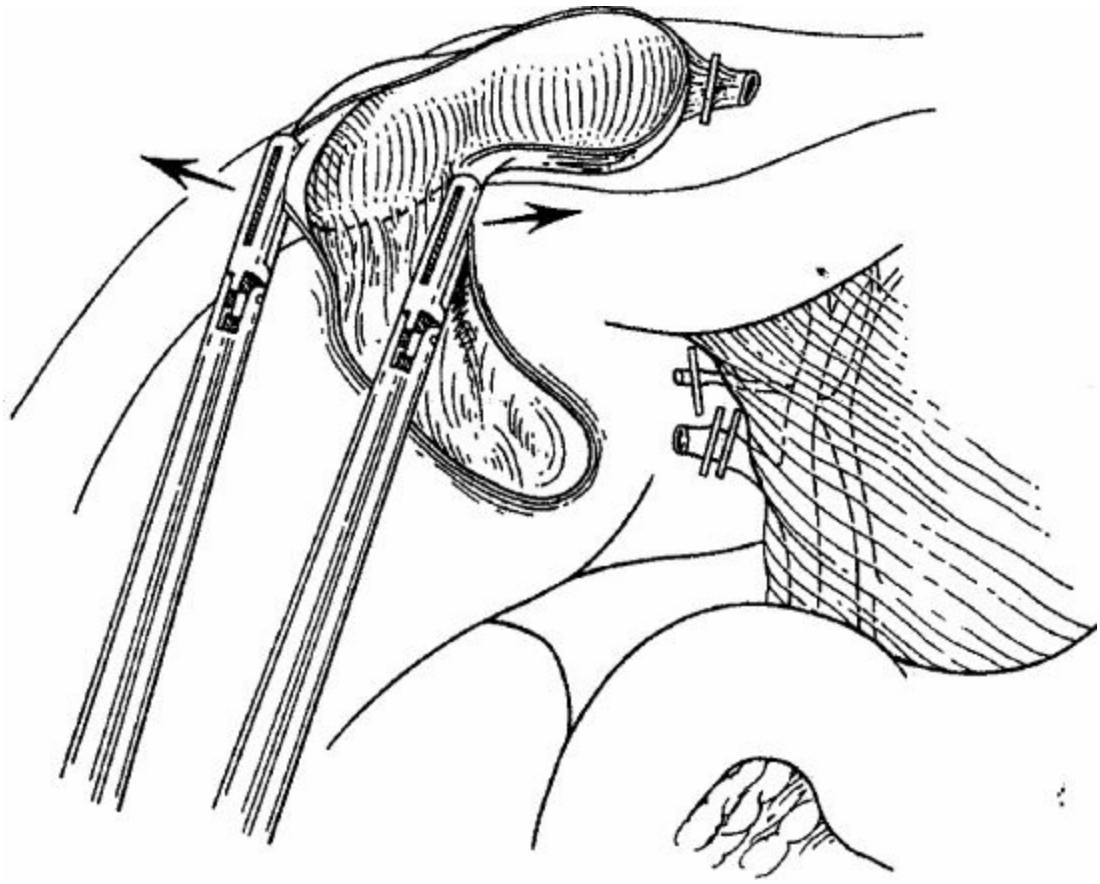

Figure 110.7. Excellent exposure of the gallbladder bed and remaining peritoneum is gained by “flipping” the gallbladder over the liver edge and stretching apart the last bit of peritoneum with two graspers. The *arrows* indicate the direction of retraction of the gallbladder for optimal exposure.

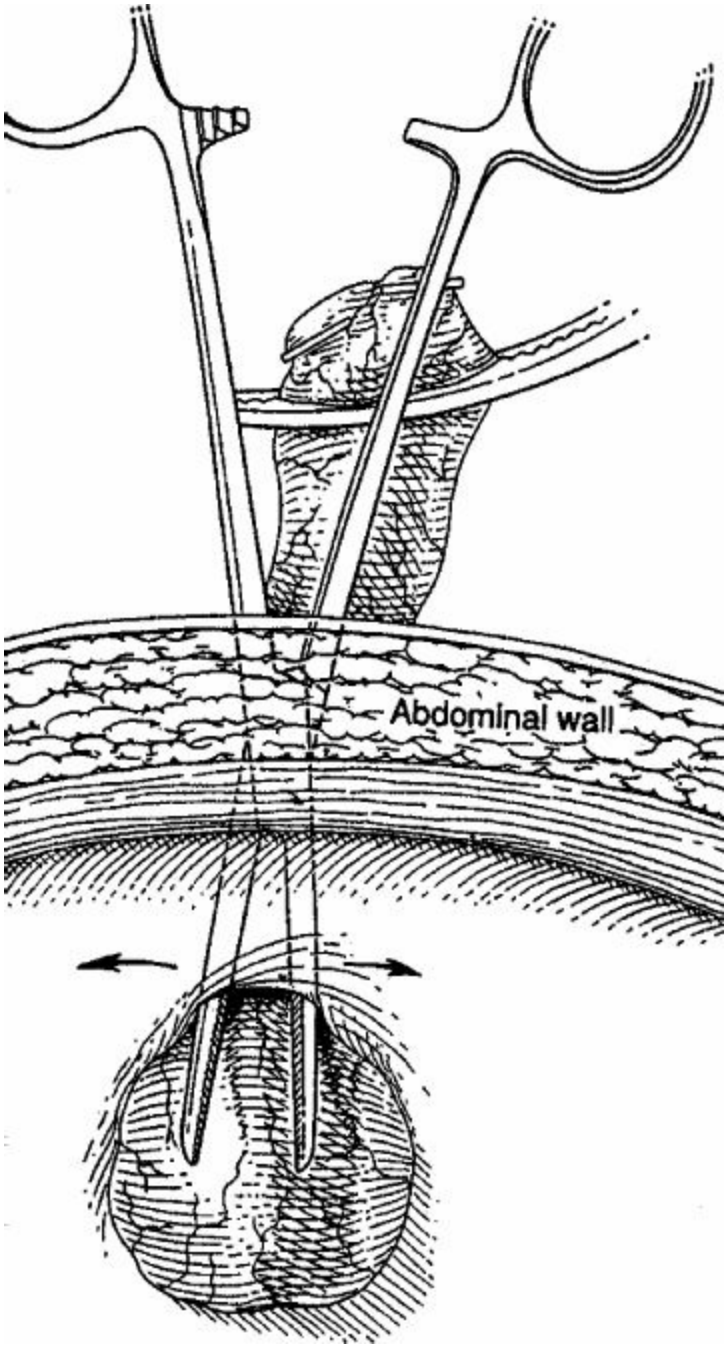

Figure 110.8. Removal of the gallbladder with a large stone burden. The *arrows* indicate the direction of spreading by the Kelly clamp to facilitate gallbladder extraction.

We perform cholangiography routinely to ensure that all surgical residents are familiar with this technique. Two methods are available for performance of cholangiography. In the first method, a specialized cholangiogram clamp—the Olsen cholangiogram clamp—is passed through the subcostal trocar, and a saline-flushed, 60-cm, tapered 5 French catheter is advanced directly into the cystic duct. Surgeons find this

technique difficult if they have not placed the middle trocar immediately beneath the ribs and close to the anterior axillary line. Introduction of the catheter occasionally requires a hydrophilic guidewire to get through the Heister valves. Once the catheter is in the cystic duct, the jaws of the Olsen clamp are closed around the cystic duct.

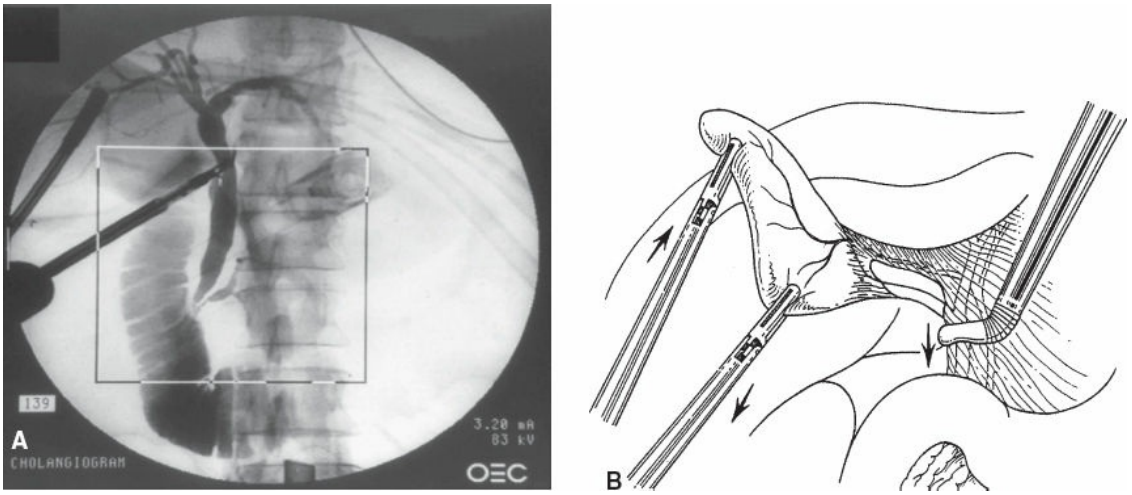

Figure 110.9. A. Operative cholangiography demonstrating good flow of contrast into the duodenum. No filling defects are present. There is opacification of both right and left hepatic ducts. **B.** Ultrasonography is an acceptable substitute for operative cholangiography. The *arrows* indicate the direction of retraction to facilitate intraoperative ultrasound examination of the common bile duct.

The second method for performing cholangiography, a percutaneous cystic duct access technique, appears equally efficacious. With this method, a separate small puncture is made in the abdominal wall, over the cystic duct, with a 2-in, 14-gauge intravenous catheter. A 5 French cholangiocatheter is then slid directly through the intravenous catheter into the cystic duct by the surgeon with a grasper in his or her right hand. Once the catheter is in the cystic duct, it is held in place with a hemoclip.

Before cholangiography is performed, all instruments are removed, and the trocars are positioned so as not to obscure the cholangiogram. A small lead screen with a sterile table cover over it is then rolled up to the left side of the patient, and the surgeon stands behind this screen. The C-arm is introduced and positioned over the right upper abdomen. It is important that all tubing and syringes used for the cholangiogram are preflushed to remove any air bubbles as they may have appearance similar to stones and lead to false-positive cholangiograms. A slow injection of 60% diatrizoate

meglumine (Gastrografin) under fluoroscopic control ensures an initial dilute injection to look for small stones in the CBD. After complete imaging of the distal bile duct, Oddi sphincter, and duodenum has been attained, a second injection, usually under pressure, delineates the proximal biliary radicals. A complete study includes flow of contrast into the duodenum as well as opacification of both right and left hepatic ducts (Fig. 110.9A). The surgeon must identify the two major ductal systems in the right lobe of the liver because low inserting ducts from hepatic segments VII and VIII are frequently injured during LC. Selected images are saved from the C-arm and sent to the hospital imaging storage system. If bile duct stones are seen on the cholangiogram, they can be addressed with transcystic extraction techniques (see later).

Biliary Ultrasonography

Although cholangiography remains the "gold standard," many surgeons find that laparoscopic ultrasonography of the intra- and extrahepatic biliary system can be performed quickly and provides sensitivity and specificity at least equivalent to cholangiography when performed by experienced users (Fig. 110.9B). The lack of radiation makes this technique particularly appealing for biliary imaging in the pregnant patient.

Hydrops of the Gallbladder

If the gallbladder is so tense that it cannot be grasped, it is decompressed using a laparoscopic needle on a 50-mL syringe. After the bile has been aspirated, the grasper used to elevate the gallbladder fundus can be positioned over the needle hole to prevent bile spillage. Alternatively, a cholecystotomy is performed with electrosurgery or a sharp 5-mm trocar and the bile is removed with a suction irrigator. This hole can then be controlled with an Endoloop, hemoclips, or with a clawed grasper.

Wide-Mouthed Cystic Duct

One of the more difficult challenges in LC is the short, wide cystic duct. Clips usually do not reach across this duct and, even if they do, they may risk narrowing the CBD (Fig. 110.10A). Under these circumstances, there are four acceptable techniques for closing the cystic duct. If the duct is long and wide, it can be transected and a pretied ligature (an ENDOLOOP Ligature) can be applied to the cystic duct stump. Alternatively, two ties

can be passed around the cystic duct in continuity and secured with extracorporeal knotting techniques. Occasionally, there is concern that this technique might narrow the CBD. Under these circumstances, the cystic duct is transected with an endoscopic stapling device, or it is simply divided and oversewn with an intracorporeal suturing technique (Fig. 110.10B,C). All of these methods have been applied successfully. A critical factor in avoiding bile duct injury in these circumstances is a clear understanding of the anatomy. Although a cholangiogram may be difficult to obtain in these circumstances, it is just these situations that demand the accurate anatomic detail provided by cholangiography.

Drainage of the Hepatic Bed

If there has been spillage of infected bile, it is prudent to place a closed-suction drain. This placement is simple to perform by bringing a 5-mm grasper in the most lateral trocar and out the 10-mm trocar in the epigastrium. A 19 French BLAKE or a 10-mm Jackson-Pratt flat drain is pulled in through the 10-mm trocar. The external part of the drain is pulled out from the right flank by removing the grasping clamp and the 5-mm trocar. The internal portion of the drain is placed in the gallbladder bed, and external portion of the drain secured to the skin with a permanent suture.

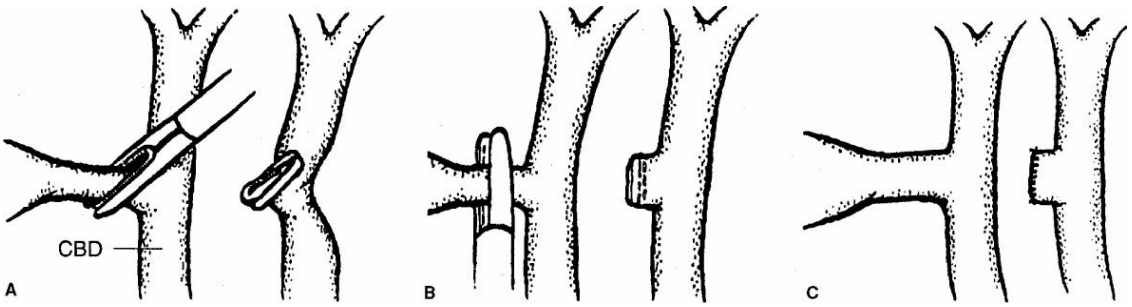

Figure 110.10. Techniques for managing the short, wide cystic duct. When clips are too short or risk common bile duct (CBD) narrowing (**A**), the cystic duct is controlled with an endoscopic stapler (**B**) or sutured closed (**C**).

Single Incision LC

The introduction of minimally invasive surgery has caused many to push the boundaries of surgery toward less and less invasiveness. Single incision surgery has been safely applied to cholecystectomy by experienced laparoscopic surgeons. However, it currently does not have

any advantages over the traditional LC other than cosmesis. Single incision cholecystectomy requires more laparoscopic expertise and specialized instruments, since it is performed through an umbilical incision using angled or flexible tip laparoscope and instruments with reticulating tips. The gallbladder is dissected and removed with close adherence to the principles described for LC to ensure patient safety. An additional 5-mm trocar placed in the anterior axillary line below the costal margin may be used to retract the gallbladder if visualization is inadequate. If any aspect of this operation is not preceding well, then placement of additional trocars and/or conversion to the traditional LC is warranted. It is important to remember that patient safety is paramount and that single incision cholecystectomy has no advantage over LC except cosmetic benefit, and this is only a short-term benefit, as laparoscopic scars are difficult to find on an abdominal wall in most patients after 3 to 6 months.

Conversion to Open Cholecystectomy

The decision to convert to open cholecystectomy should ideally be made before a complication occurs. Currently, the three most frequent indications for conversion are dense upper abdominal adhesions, a necrotic gallbladder wall that precludes grasping and elevation with a grasper, or lack of adequate exposure. If exposure and retraction are accomplished, yet the dissection in the region of the gallbladder neck is tedious and bloody, consideration should be given to conversion. A top-down dissection where the gallbladder is dissected from the fundus down toward the infundibulum can be attempted if a well-trained laparoscopic surgeon is available. This may allow clear identification of the cystic duct and spare the patient an open operation. In general, if the anatomy of the triangle of Calot is not clear, then it is reasonable to convert. Otherwise, this tedious dissection can “go on all day” and may require conversion for bleeding or complication. A conversion rate of less than 5% can be expected in the hands of a well-trained laparoscopic surgeon. Risk factors for conversion include male gender, obesity, cholecystitis (especially after 48 to 72 hours after the onset of symptoms), and choledocholithiasis.

POSTOPERATIVE CARE

After routine uncomplicated LC, postoperative care is simple. We usually start these patients on a clear liquid diet as soon as they awaken. If there is no nausea or vomiting, we proceed immediately to a regular diet. No

postoperative blood tests are required. The patient can usually be discharged several hours after the operation. For successful performance of outpatient cholecystectomy, patients must be aware of potential postoperative complications, including bile leak, bleeding, pancreatitis, intestinal perforation, wound infection, and ileus. Family members must be able to recognize these complications immediately, before life-threatening consequences occur. Hospitalization is required for the elderly; the infirm; and those with acute cholecystitis, pancreatitis, or cholangitis.

COMPLICATIONS AND THEIR MANAGEMENT

Serious complications of LC occur in fewer than 2% of all cases (Table 110.1). Intestinal injury may occur during establishment of abdominal access, adhesiolysis, or dissection of the gallbladder away from the duodenum or colon. An accidental enterotomy made during access with open laparoscopy (Hasson technique) can usually be repaired through the fascial incision. If an accidental intestinal injury is made with a Veress needle, no treatment is generally necessary. An electrosurgical injury to the colon or duodenum should be repaired with careful one- or two-layer suture closure. The incidence of injury to viscera or vessel from a trocar or Veress needle is well documented at 0.2%.

Hemmorhage

Large-vessel vascular injury usually occurs at the time of initial abdominal access and is a result of inadequate anterior abdominal wall distraction or excessive thrusting of the trocar by the surgeon. These may be lethal complications. An unexplained retroperitoneal hematoma or hypotension should be treated immediately by conversion to laparotomy.

Excessive bleeding in the region of the porta hepatis should not be treated laparoscopically. Attempts at clipping or cauterizing significant bleeding usually lead to worsening hemorrhage and/or hepatic artery injury. Minor bleeding can be controlled with clips or electrocautery if the bleeding vessel can be visualized by irrigation. However, once the bleeding is controlled, it is prudent to confirm that vital structures such as the hepatic arteries or CBD were not injured. Major bleeding often necessitates conversion to open cholecystectomy to ensure adequate control without injury to CBD or hepatic arteries. Bleeding in the gallbladder bed can usually be controlled by fulguration of the bleeding site. If a larger intrahepatic sinus has been entered, hemostatic agents (e.g.,

microfibrillar collagen) can be placed laparoscopically in the liver bed, and pressure can be maintained with a clamp.

Retained common bile duct (CBD) stone
CBD injury ± stricture
Pancreatitis
Conversion to open procedure

Stone or Biliary Contamination

Stone spillage during gallbladder dissection should be avoided by closing gallbladder perforations when they occur. If a few small stones are spilled from an uninfected gallbladder, no further attention is needed. Attempts to remove large stones with collecting bags are appropriate. The only circumstance in which conversion to an open procedure should be considered is when stones are spilled in the presence of infected bile. Under these circumstances, occult abscesses have been reported to occur in many locations around the abdomen, presenting between 12 days and 12 months after operation.

CBD Injury

Incidence

In the infancy of LC, CBD injury occurred more frequently during LC than during open cholecystectomy. Reasons for the increase in injury during LC included loss of haptic information, incorrect traction forces to the gallbladder leading to misidentification of anatomy, and injudicious use of cautery inside of the triangle of Calot. Although the incidence of CBD injury during LC is no longer as high as it was initially, it still

exceeds that of open cholecystectomy (0.1% to 0.5% in LC vs. 0.2% in open cholecystectomy).

Prevention

CBD injury occurs due to either a technical error or misidentification of the duct. Risk factors that increase the risk of CBD injury include acute cholecystitis, surgeon inexperience, and aberrant anatomy. The most common anatomic variant is an aberrant right hepatic duct. Inadequate video-optics and improper dissection techniques render the CBD susceptible to injury. If the surgeon follows the dissection techniques outlined above, injury to the CBD should be avoided. The essential steps are summarized in Table 110.2. We emphasize that the surgeon should strive to make the gallbladder look like a polyp on a stalk (aka the "critical view of safety") (Fig. 110.11) prior to clipping the cystic duct. If clips are applied before such a view is obtained, the CBD may be mistaken for the cystic duct and accidentally clipped and cut (Fig. 110.12A). If the critical view cannot be obtained due to inflammation or hostile anatomy, it is the authors' opinion that an IOC should be performed prior to dividing the cystic duct. A recent study using an American Medicare database found a reduction in CBD injuries with routine use of IOC (from 0.58% to 0.39%). In 2014, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) launched a program to create a culture of safety in order to prevent CBD injuries. The SAGES Safe Cholecystectomy Program offers guidance and training opportunities for surgeons at all levels of training (http://www.sages.org/safe-cholecystectomy-program/).

TABLE 110.2 Steps to Avoid Common Bile Duct Injury During Laparoscopic Cholecystectomy

1. Use a 30-degree laparoscope and high-quality imaging equipment.
2. Apply firm cephalic traction on the fundus and lateral traction on the infundibulum so that the cystic duct is perpendicular to the CBD.
3. Dissect the cystic duct where it joins the gallbladder.
4. Expose the "critical view of safety" prior to dividing the cystic duct.
5. Convert to open procedure if the infundibulum cannot be mobilized or if bleeding or inflammation obscures the triangle of Calot.
6. Perform routine intraoperative cholangiography.

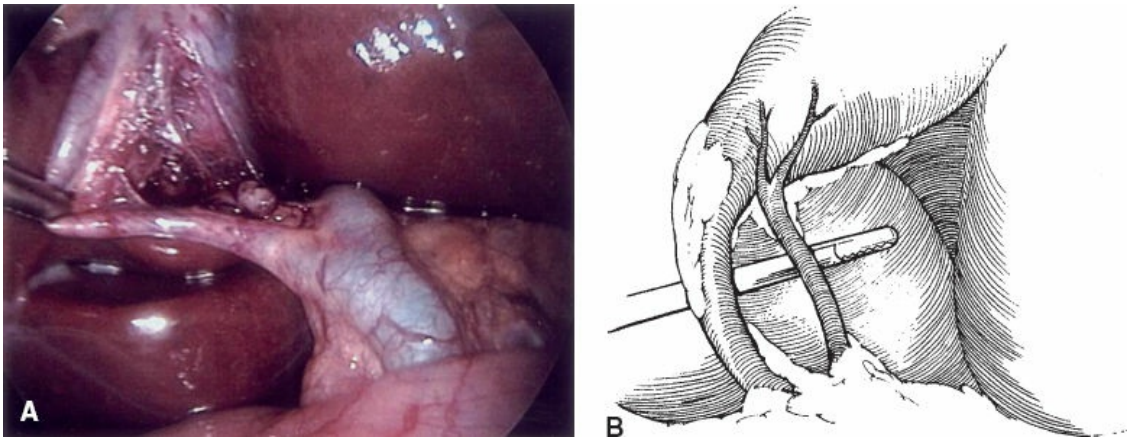

Figure 110.11. A. Intraoperative photograph of the "critical view of safety." The cystic artery has been divided, and the gallbladder appears like a polyp on a stalk. The base of the liver bed is exposed, and the surgeon can be confident that he or she is not mistaking a short common bile duct (CBD) for the cystic duct. **B.** The "critical view of safety." The triangle of Calot is dissected free of all tissue except for the cystic duct and artery, and the base of the liver bed is exposed. When this view is achieved, the two structures entering the gallbladder can only be the cystic duct and artery. It is not necessary to see the CBD. (**B.** This figure was published in Strasberg SM, Hertl M, Soper NJ. An analysis of the problem of biliary injury during laparoscopic cholecystectomy. *J Am Coll Surg* 1995;180:101, with permission from the American College of Surgeons. Copyright Elsevier.)

Classification of CBD Injury

Many different classification systems for CBD injuries exist. The Stewart–Way classification is simple and concise, and was derived from analysis of a series of LC-associated CBD injuries (Fig. 110.13). The most common type of injury (Stewart–Way class III) was found to account for 60% of CBD injuries in this series (Fig. 110.12B). Table 110.3 describes the mechanism of CBD injury.

Management

Early recognition of a CBD injury is of paramount importance. Figure 110.14 outlines our algorithm for a suspected bile leak. We divide CBD injuries into two main categories: (a) immediate intraoperative diagnosis and (b) delayed postoperative diagnosis.

1. *Intraoperative diagnosis:* If an injury occurs to the lateral CBD (class I or II injury), primary repair with or without T-tube drainage through a separate choledochotomy is acceptable. Complete division and/or

resection of a bile duct or aberrant bile duct (class III or IV injury) should be managed by (a) hepaticojejunostomy by a hepatobiliary surgeon or (b) control of the divided CBD with a clip (if possible), drainage, IV antibiotics, and immediate transfer to an institution that specializes in care of these injuries. Repair by surgeons inexperienced in these techniques only complicates subsequent repair, and may increase the rate of postoperative stricture to as high as 25%.

2. *Postoperative diagnosis:* Minor leaks can be treated with drainage alone, usually through a percutaneously placed catheter (if no drain was left in place intraoperatively). Low-output drainage (<300 mL/day) can be observed and should resolve within 5 to 7 days. If the catheter drainage fails to resolve or if the patient has high-output drainage (>300 mL/day), an ERCP should be performed. Three possibilities exist: (a) duct of Luschka leak (injury to a supravesicular duct in the gallbladder bed) that can be treated by sphincterotomy, (b) cystic duct stump leak that can be treated with a transpapillary stent with or without sphincterotomy, or (c) suspected CBD injury. In the latter case, a percutaneous transhepatic cholangiogram (PTC) should be performed to further delineate the anatomy of the proximal biliary tree and to plan subsequent repair. Bile drainage should be controlled, and repair should be undertaken by an experienced hepatobiliary surgeon as this has been shown to optimize long-term outcomes after repair. Principles of repair are to reestablish bile flow into the gastrointestinal tract with a tension-free mucosa-to-mucosa biliary enteric anastomosis, and to prevent cholangitis and/or stricture formation.

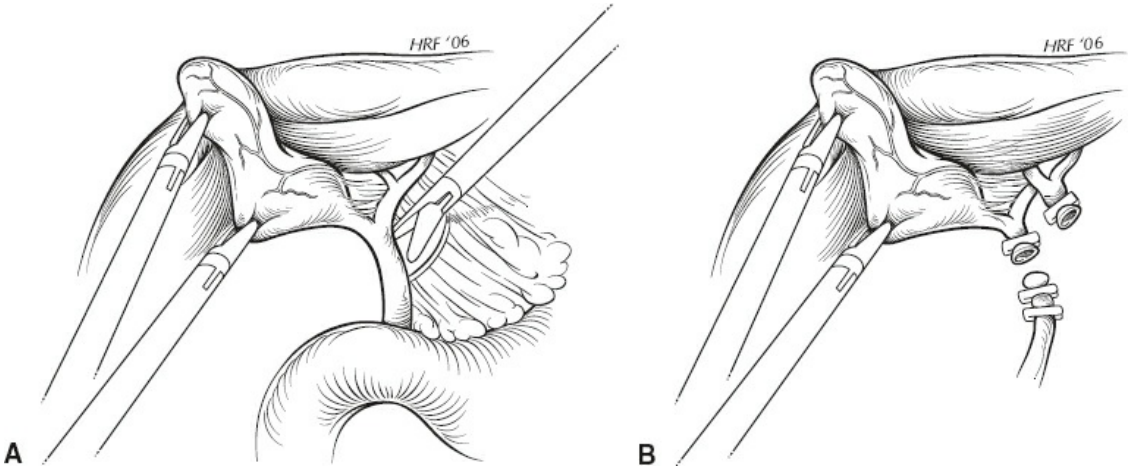

Figure 110.12. Common bile duct injury when the surgeon skeletonizes (**A**), clips, and divides (**B**) the common duct instead of the short cystic duct. This injury would not have occurred if the

surgeon had completely exposed the hepatocystic triangle prior to dividing the “cystic duct.”

Causes and prevention of laparoscopic bile duct injuries: Analysis of 252 Cases From a Human Factors and Cognitive Psychology Perspective. *Ann Surg* 2003;237(4):460, with permission of Wolters Kluwer Health, Inc.)

Retained CBD Stones

Laparoscopic CBD Exploration

In 1890, Ludwig Courvoisier was the first to perform a choledochotomy and remove a CBD stone. One hundred years later, LC was in its infancy. The incidence of choledocholithiasis during LC based on IOC was 7.8% in a recent analysis of more than 114,000 patients. This high incidence has led many surgeons to develop techniques for removing these stones at the time of LC. Initially, these techniques were borrowed from ERCP and involved the use of baskets passed into the CBD under fluoroscopic guidance. A technique from endourology that has been valuable is the use

of small-caliber flexible endoscopes to retrieve stones. Other borrowed techniques from retrograde biliary endoscopy include the use of balloon dilators and intraoperative sphincterotomy. Laparoscopic choledochotomy is sometimes necessary for the removal of large stones and for a large number of stones from a markedly dilated CBD. An algorithm for addressing choledocholithiasis begins with IOC or ultrasonography (Fig. 110.15). The variables that determine the best approach to choledocholithiasis are the size of the stone, the number of stones, and the size of the cystic duct, whether the stone is impacted or freely floating, and whether the stone is in the common hepatic duct or the CBD.

Transcystic Versus Transductal Approach

The transcystic (via the cystic duct) approach is successful in over 90% of cases for small stones less than 8 mm in size, and for stones located below the cystic duct entrance. Factors that hinder this approach include acute angulation of the cystic duct–CBD junction, numerous valves of Heister within the cystic duct, a tortuous cystic duct, or placement of the cystic ductotomy more than 15 mm from its junction with the CBD. The transductal approach (via the CBD) is indicated for stones greater than 8 mm in size, and for stones proximal to the insertion of the cystic duct. The transductal technique should not be performed in a CBD less than 10 mm in diameter, as this may lead to postoperative stricture. Transcystic CBD exploration is generally preferred over a transductal CBD exploration as it has lower morbidity and shorter length of stay.

Normal CBD (Smaller Than 6 mm), Small Stone (Smaller Than 4 mm)

Stones that are smaller than 2 mm in diameter will usually pass spontaneously. The best treatment strategies for these small stones are either merely to observe or to dilate the Oddi sphincter with 1 mg of intravenous glucagon and flush the bile duct vigorously with normal saline. We prefer to clear the CBD before leaving the operating room, because even these small stones may cause severe colic or pancreatitis when they pass through the papilla. A stone that does not pass with flushing (e.g., a stone >2 to 4 mm) can usually be basketed with a six-wire helical stone basket (with filiform tip), which is either passed alongside the cholangiocatheter or passed through a 6 French introducer that has replaced the cholangiocatheter after CBD stone detection (Fig. 110.16). All catheter exchanges are performed over a hydrophilic guidewire. The basket is opened in the ampulla of Vater and is trolled backward,

entrapping the small stone. One must be careful not to open the basket in the duodenum, or papillary elements will be ensnared and the basket will become entrapped.

TABLE 110.3 Mechanism of Common Bile Duct Injury (Stewart–Way Classification)

Class I	CBD mistaken for cystic duct, but recognized Cholangiogram incision in cystic duct extended into CBD
Class II	Lateral damage to the CHD from cautery or clips placed on duct Associated bleeding, poor visibility
Class III	CBD mistaken for cystic duct, not recognized CBD, CHD, R, L hepatic ducts transected and/or resected
Class IV	RHD mistaken for cystic duct, RHA mistaken for cystic artery, RHD and RHA transected Lateral damage to the RHD from cautery or clips placed on duct

CBD, common bile duct; CHD, common hepatic duct; L, left; R, right; RHA, right hepatic artery; RHD, right hepatic duct.

[a] Minor CBD injury: injury less than 50% duct circumference (intact ductal anatomy)
[b] Majory CBD injury: injury over 50% duct circumference (includes ligation, transection, avulsion)
[c] Low-output drainage: less than 300 cc/day
[d] High-output drainage: over 300 cc/day
[e] Bile duct of Luschka: supravesicular duct in the gallbladder bed (no drainage of liver parenchyma)

Figure 110.14. Evaluation and management of a bile leak after laparoscopic cholecystectomy. CBD, common bile duct; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; JP, Jackson–Pratt; PTC, percutaneous transhepatic cholangiogram; US, ultrasound.

Dilated CBD (Larger Than 6 mm), Medium Stone (4 to 8 mm)

A case involving a CBD dilated larger than 6 mm and a medium-sized stone between 4 and 8 mm is the most common situation. Such stones are

rarely amenable to flushing techniques or fluoroscopic basketing. The basket is usually too narrow to entrap these larger stones. Under these circumstances, a direct-vision basketing approach is preferred. We use a 2- to 5-mm flexible choledochoscope (Karl Storz, Inc., Tuttlingen, Germany) and a second video cart, including a light source, a video monitor, and a video camera. In the majority of circumstances, it is necessary to dilate the cystic duct to a minimum size of 5 mm to introduce the choledochoscope. If the bile duct stone is substantially larger than 5 mm, we dilate the cystic duct to 8 mm using a balloon dilator. The choledochoscope is introduced through a specialized plastic introducer system (Bercí CBD Introducer, Cook Surgical, Bloomington, IN). A rubber-shod Maryland grasper is then used to guide the scope into the cystic ductotomy through the valves of Heister into the CBD. Rubber-shod graspers for endoscope manipulation are important to avoid tearing the outer sheath of the scope. Frequently, we make a second cystic ductotomy close to the CBD to bypass most of the Heister valves. Once the CBD is reached, the choledochoscope almost always drops into the distal duct, where the majority of bile duct stones will be located. A 2.4 French flat-wire Segura basket is then advanced through the operating channel of the choledochoscope, with saline running at low pressure around the basket. The basket is opened, the stone is entrapped, and the apparatus is pulled out. If multiple stones are present, the procedure is repeated. A completion cholangiogram is then performed. This procedure generally works for stones up to 8 mm in diameter.

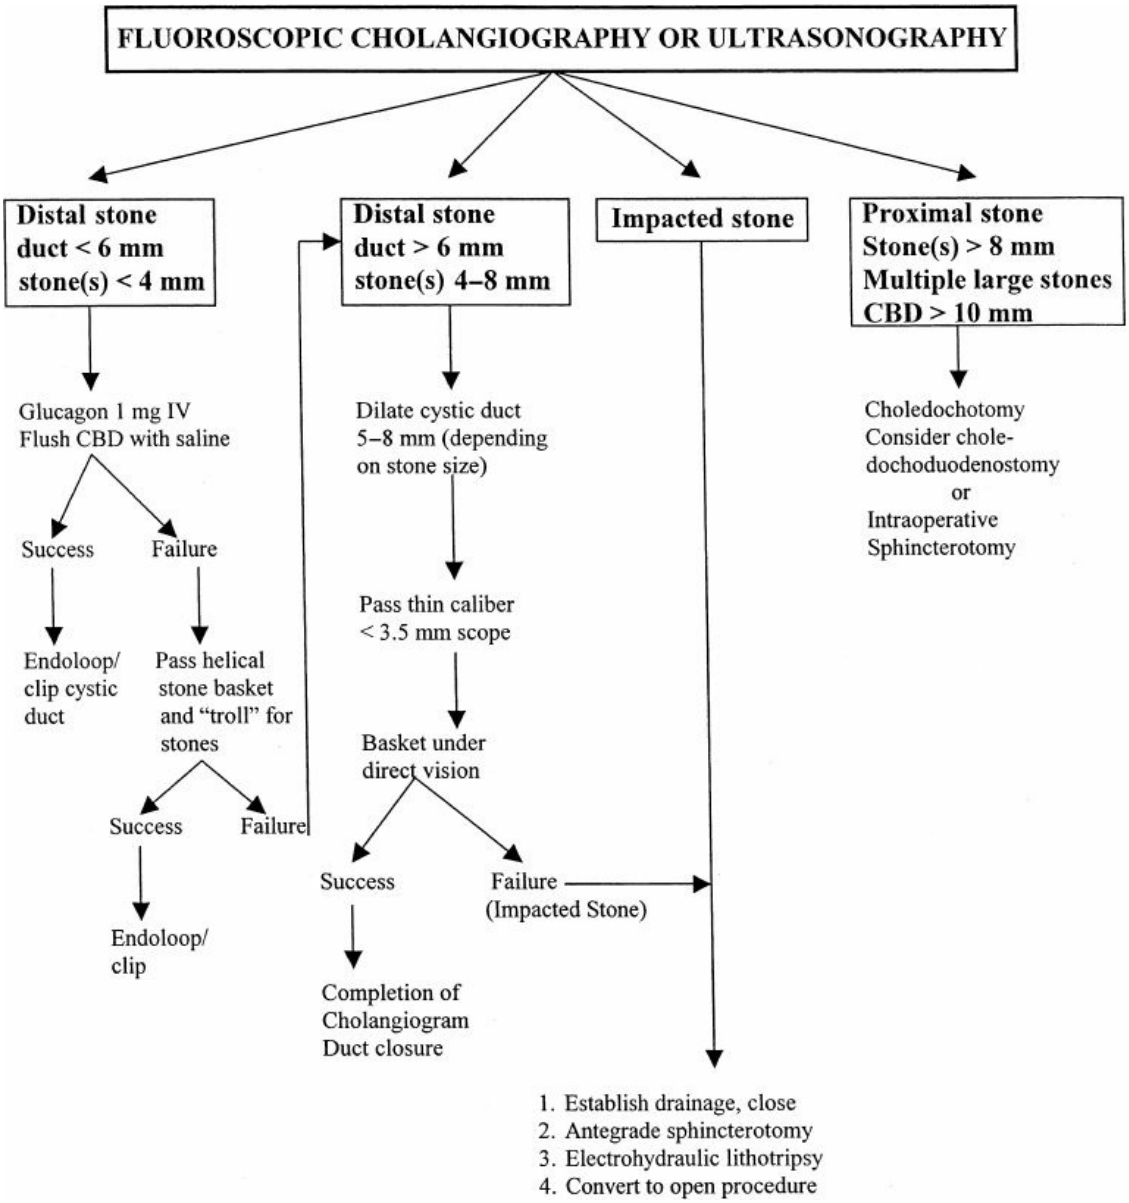

Figure 110.15. Management of common bile duct (CBD) stones with laparoscopic cholecystectomy.

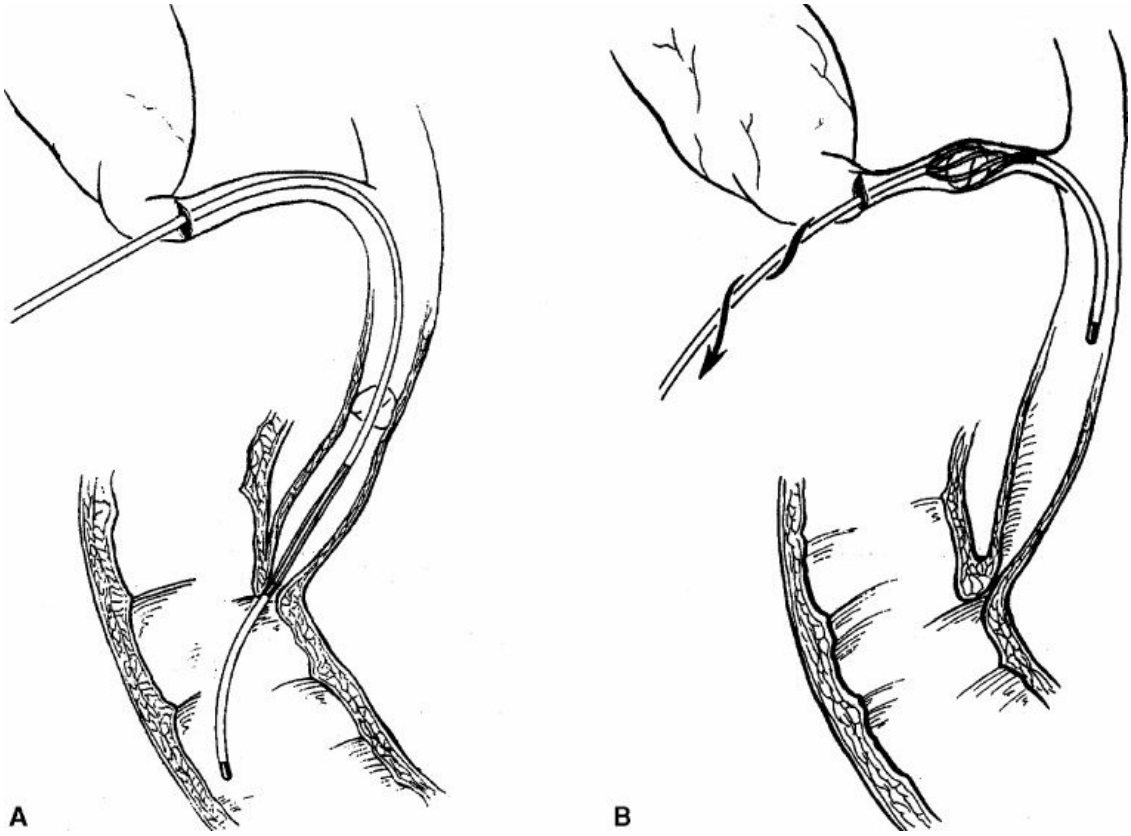

Figure 110.16. Fluoroscopic bile duct exploration using a C-arm and helical stone basket. **A.** Positioned with a closed basket in the distal common bile duct. **B.** Removing entrapped stone with clockwise rotation.

Dilated CBD (Larger Than 10 mm), Large Stone (>8 mm)

Large stones and those above the cystic duct entrance are not amenable to any of these previous techniques. To adequately remove these stones, a choledochotomy must be made, the stone must be fragmented, or a sphincterotomy must be made. If the surgeon is extremely skilled in laparoscopic techniques, curved microscissors can be used to make a small anterior choledochotomy 1 to 2 cm in length. Again, a choledochoscope (generally a standard choledochoscope) is advanced through the choledochotomy, and the stones are entrapped with a Segura basket and pulled out the choledochotomy. Irrigation and Fogarty catheters can also be used. If the bile duct is larger than 2 cm in diameter, or if there are more than five stones, the patient will be at high risk for recurrent primary bile duct stones. Under these circumstances, the surgeon should consider more permanent biliary drainage with a choledochoduodenostomy or ES.

Impacted Stones

When stones are impacted in the ampulla of Vater, they cannot be removed with any of the techniques mentioned previously because it is impossible to get a basket beyond these stones, and even an inflated Fogarty balloon rarely dislodges them. Under these circumstances, there are four acceptable options.

1. The first option is to do nothing further. A drain—either a straight tube or a T-tube—is placed through the cystic duct into the CBD, and then the operation is completed. The drain is secured in the cystic duct stump with a pretied loop (Endoloop). At a later date, a guidewire is passed through the drain into the duodenum, and a retrograde sphincterotomy is performed over the guidewire. Alternatively, using this technique, some surgeons prefer to perform an endoscopic retrograde sphincterotomy on the operating table, which requires exquisite communication and a large degree of expertise on the part of the biliary endoscopist.
2. The second option is a similar technique that is easier for the biliary endoscopist—anterograde sphincterotomy. A guidewire is passed beyond the stone into the duodenum, and a wire-guided endoscopic sphincterotome is passed over the guidewire across the Oddi sphincter. To make sure that the sphincterotome is well-oriented, a duodenoscope is passed through the mouth into the duodenum. The sphincterotomy is then performed at the 11 to 12 o'clock position of the papilla. The bile duct stone is pushed into the duodenum with a choledochoscope or an inflated balloon extractor (Fig. 110.17).
3. The third option is electrohydraulic lithotripsy. Through the choledochoscope, a fine lithotripsy probe—1.8 to 2.8 French—is passed through the operating channel. Under direct vision, the bile duct stone is fragmented into pieces. The fragments are extracted with baskets or pushed into the duodenum. This technique seems to work best with the smaller impacted stones because large stones make large fragments that are difficult to remove through the cystic duct and are similarly difficult to push through the ampulla of Vater without a sphincterotomy.
4. The final option is to convert to an open procedure.

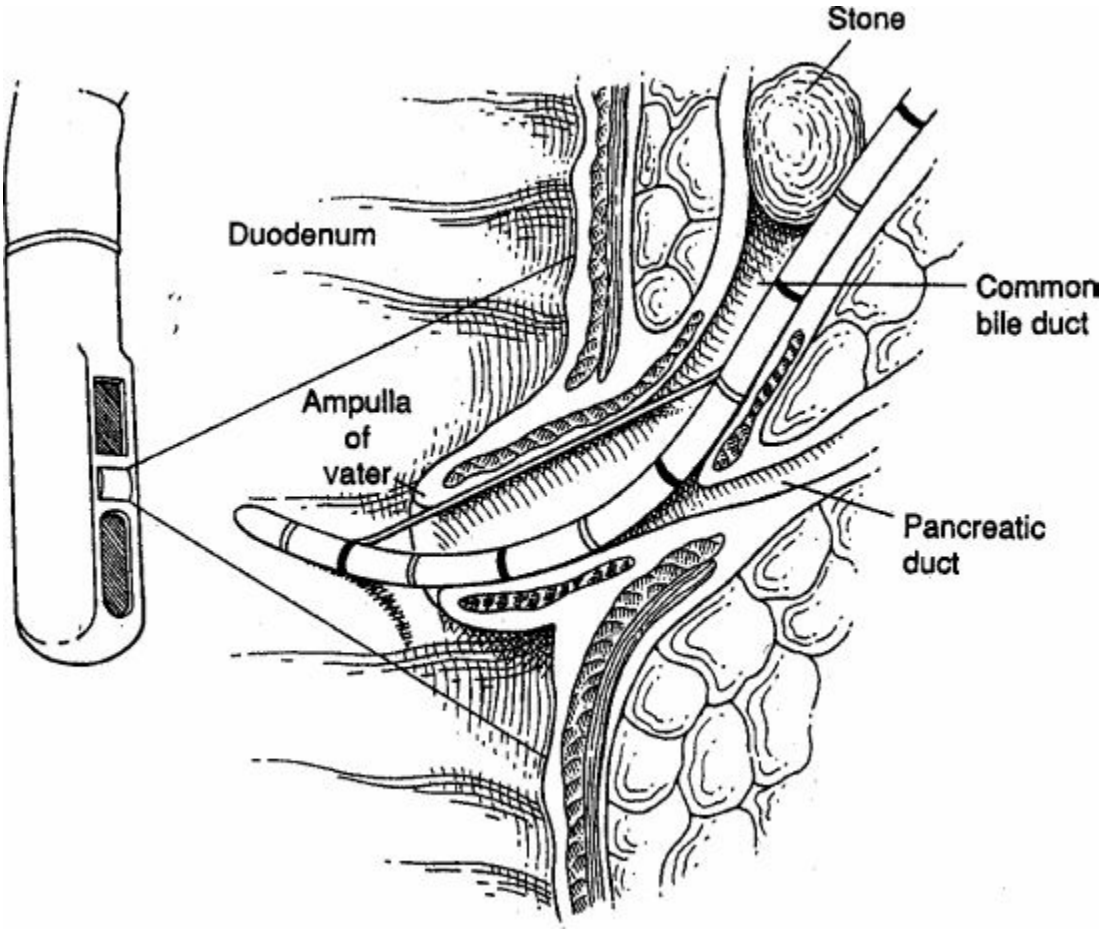

Figure 110.17. Anterograde sphincterotomy performed with the guidance of a side-viewing duodenoscope.

CBD Closure

If the CBD has been explored through the cystic duct, and if the completion cholangiogram demonstrates duodenal filling, the cystic duct can usually be closed with a single Endoloop or two clips. Drainage of the Morrison pouch is unnecessary under this circumstance. If spasm, edema, or obstruction of the Oddi sphincter is present, a straight latex drain is passed into the CBD and secured in place with an Endoloop.

If a choledochotomy was necessary, a small—12 to 14 French—T-tube is passed through a 10-mm trocar and placed in the CBD. The CBD can be closed with two or three interrupted 4-0 monofilament absorbable sutures. Recent studies suggest a higher complication rate (16% vs. 9%) with insertion of a T-tube, so, in the absence of fibrosis or inflammation, the surgeon may choose to perform primary closure of the choledochotomy without placement of a T-tube. A Jackson–Pratt drain is placed in the abdomen near the repair and brought out through one of the lateral trocar holes.

Post-Cholecystectomy Syndrome

Post-cholecystectomy syndrome is a constellation of heterogeneous symptoms occurring after the removal of the gallbladder. It can occur early in the postoperative period or months to years after surgery. It is characterized by a variety of symptoms, including right upper quadrant abdominal pain, nausea, emesis, bloating, or diarrhea. At least half of patients with this constellation of findings will have a gastrointestinal cause such as an undiagnosed bile duct injury, leading to stricture, retained stone, or a primary biliary dysmotility disorder. Other GI causes include irritable bowel syndrome, peptic ulcer disease, pancreatitis, and diverticulitis. The remaining patients will have nongastrointestinal causes, including psychosomatic disorders, coronary artery disease, neuromas, or neuritis. Work-up should include ultrasound and/or CT to evaluate for gastrointestinal causes followed by an MRCP to thoroughly evaluate the biliary tract.

Hernia

Hernia after LC is rare, but typically occurs at the umbilical port site, especially if a larger 10 to 12 mm port is used. One adverse aspect of the single incision laparoscopic and robotic cholecystectomties is the high incidence of incisional hernia: approxiamtely 8%. This rate is higher in the subgroup of older patients (age >50) with a rate of 15% and those with a BMI >30 with a rate of 33%. There is a lack of literature regarding hernia incidence after single-incision robotic cholecystectomy; however, it seems reasonable to assume that it would be similar to single incision LC rates.

SUMMARY

LC has largely replaced open cholecystectomy for the treatment of symptomatic cholelithiasis. The advantages of rapid recovery are clear. With careful, meticulous technique, the complications of this procedure should be fewer than with open cholecystectomy. Appropriate treatment of the CBD stone is the next frontier. At this time, the best management depends on local expertise, but it behooves the next generation of surgeons to achieve the expertise with transcystic bile duct exploration, which will allow the surgeon to remain the primary physician caring for diseases of the biliary tract.

EDITOR'S COMMENT

The authors present an excellent overview of one of the most common operations performed by the general surgeon. Most cholecystectomies are performed by laparoscopy. I will comment on the timing of cholecystectomy in acute cholecystitis and pancreatitis, the continued problem of bile duct injury, and the use of nontraditional techniques such as single port laparoscopic cholecystectomy and robotic assisted cholecystectomy.

Most laparoscopic cholecystectomies are performed in an elective setting. In two conditions, there is some debate about the timing of surgery. Acute cholecystitis may occur in up to 20% of patients with symptomatic gallstones. The concern is that waiting may lead to complications or more difficult surgery.

Gurasamy and colleagues (Gurusamy KS, Davidson C, Gluud C, et al. Early versus delayed laparoscopic cholecystectomy for people with acute cholecystitis. *Cochrane Database Syst Rev* 2013;6:CD005440) searched the Cochrane Hepato-biliary Group Controlled Trials Register to compare early (<72 hours) and late cholecystectomy (4 to 8 weeks) and found no significant difference between early and late laparoscopic cholecystectomy in mortality, bile duct injury, serious complications, and operating time. The early group had a shorter hospital stay. In the late group, about 18% of patients failed to improve while waiting and had urgent cholecystectomy and the conversion to open cholecystectomy was 45%. Certainly high-risk patients may be treated initially with a percutaneous cholecystostomy tube and later cholecystectomy as described by Professor Garden in Chapter 109. Roulin and colleagues (Roulin D, Saadi A, Di Mare L, et al. Early versus delayed cholecystectomy for acute cholecystitis. Are the 72 hours still the rule?: A randomized trial. *Ann Surg* 2016;264:717–22) have recently completed a randomized prospective trial of early versus delayed cholecystectomy. They reported that the overall morbidity was lower in early group (6 [14%] vs. 17 [39%] patients, $P = 0.015$). Median total length of stay (4 vs. 7 days, $P < 0.001$) and duration of antibiotic therapy (2 vs. 10 days, $P < 0.001$) were shorter in the early group. Total hospital costs were lower in early group as well ($11,873 vs. $15,698, $P = 0.018$). Operative time and postoperative complications were similar (91 vs. 88 min; $P = 0.910$) and (15% vs. 17%; $P = 1.000$), respectively. They concluded early surgery for acute cholecystitis even beyond 72 hours of symptoms is safe and associated with less overall morbidity, shorter total hospital stay, and duration of antibiotic therapy, as well as reduced cost compared with delayed cholecystectomy.

The timing of laparoscopic cholecystectomy after an attack of acute biliary pancreatitis is controversial. It is argued that early surgery would potentially avoid recurrent gallstone pancreatitis. Indeed about 20% of patients will have recurrent pancreatitis or biliary complications if surgery is delayed. But is early surgery safe? What is the timing of cholecystectomy in severe pancreatitis with fluid collections or necrosis? Gurusamy and colleagues using the Cochrane Database compared the benefits and risks of early versus delayed laparoscopic cholecystectomy in people with acute biliary pancreatitis. For mild acute pancreatitis, they defined “early” laparoscopic cholecystectomy as performed within 3 days of the onset of symptoms and considered all those performed beyond 3 days of the onset of symptoms as “delayed.” For severe acute pancreatitis, they defined “early” laparoscopic cholecystectomy as being performed within the index admission and considered all performed in a later admission as “delayed.” They identified no evidence of increased risk of complications after early laparoscopic cholecystectomy. Early laparoscopic cholecystectomy may even shorten the total hospital stay in patients with mild acute pancreatitis. If appropriate facilities and expertise are available, early laparoscopic cholecystectomy appears preferable to delayed laparoscopic cholecystectomy in those with mild acute pancreatitis. In addition, they reported

that there is currently no evidence to support or refute early laparoscopic cholecystectomy for people with severe acute pancreatitis.

Wilson and de Moya performed a literature search (Wilson CT, de Moya MA. Cholecystectomy for acute gallstone pancreatitis: early vs delayed approach. *Scandinavian J Surg* 2010;99:81–5) and identified 59 articles discussing cholecystectomy in the context of gallstone pancreatitis. Most were retrospective studies or reviews, but there were nine prospective observational studies and two randomized control trials. They found that for mild gallstone pancreatitis, laparoscopic cholecystectomy within 48 hours of presentation (without normalization of pancreatic enzymes or absence of abdominal pain) shortened hospital stay without increased morbidity or mortality and that routine preoperative ERCP is unnecessary for patients with mild disease. In general, I agree with these observations. In the typical case, the offending gallstone has passed, the enzymes return to normal, and ERCP is unnecessary. However, I usually recommend waiting until enzymes are normalizing or abdominal pain is in resolution as failure to improve may indicate a persistent common duct stone and progression of the pancreatitis to a more severe condition. For more severe disease, timing of cholecystectomy is governed by clinical status. Interval cholecystectomy (>2 weeks after index admission) can be safely done with low risk of recurrence if the patient has had ERCP and sphincterotomy at index admission. They also recommend sphinctertomy if cholecystectomy is going to be delayed. This recommendation is controversial at best. They conclude that patients with mild gallstone pancreatitis should have cholecystectomy during index admission within 48 hours of arrival, but patients with more severe disease will require cholecystectomy at a later time, depending on the clinical circumstances.

What should the surgeon do in severe acute pancreatitis? Probably wait until fluid collections resolve or can be treated by enteric drainage. The study by Nealon and colleagues (Nealon WH, Bawdumial K, Wasler EM. Appropriate timing of cholecystectomy in patients who present with moderate to severe gallstone-associated acute pancreatitis with peripancreatic fluid collections. *Ann Surg* 2004;239:741–51), although dated, makes a cogent argument for caution in these patients. This group retrospectively studied 187 patients with moderate to severe gallstone-associated acute pancreatitis and associated fluid collections between 1987 and 2003. Moderate to severe acute pancreatitis was defined as >5 Ranson prognostic indicators. In this report, fluid collections were established by computed tomography.

Of 187 patients with moderate to severe gallstone-associated acute pancreatitis who survived their acute stage, 151 had peripancreatic fluid collections. The authors reported that 78 of the 187 had early cholecystectomy, 62 of whom had fluid collections; 109 were monitored before cholecystectomy of which 89 had fluid collections. Fluid collections resolved without intervention in 36 (40%) of the monitored group and in 13 (21%) of 62 in the early cholecystectomy group. Importantly, sepsis was reported in 6 (7%) of 89

in the monitored group and 29 (47%) of 62 in the early cholecystectomy group. This was an almost sixfold increase in sepsis in the early surgery group. In addition, complications of cholecystectomy were reported in 6 (5.5%) of 109 of the monitored patients and in 34 (44%) of 78 in the early cholecystectomy group. Fifty-three patients in the monitored group and 49 patients in the early cholecystectomy group required operative pseudocyst-enterostomy. This procedure was combined with cholecystectomy in the monitored patients. Mean hospitalization was noted to be longer in the early operation group. Nealon concluded that cholecystectomy should be delayed in patients who survive an episode of moderate to severe acute biliary pancreatitis and demonstrate peripancreatic fluid collections or pseudocysts until the pseudocysts either resolve or persist beyond 6 weeks, at which time pseudocyst drainage can safely be combined with cholecystectomy.

The authors clearly describe the technique of laparoscopic cholecystectomy. They note a continuing problem with bile duct injury, which I would like to expand upon. After the introduction of laparoscopic cholecystectomy, there was an initial increase the incidence of bile duct injury. This has decreased but remains a problem that still challenges the surgeon. Bile duct injury occurs in about 3/1,000 cholecystectomies. Much has been learned about preventing this complication. I think the best technique for preservation is establishing the critical view of safety and not dividing any tubular structures until that view is obtained. Three criteria are required to achieve the critical view of safety (Strasberg SM, Brunt LM. Rationale and use of the critical view of safety in laparoscopic cholecystectomy. *J Am Coll Surg* 2010;211:132–8). First the hepatocystic triangle (Calot triangle) is cleared of fat and fibrous tissue. The hepatocystic triangle is defined as the triangle formed by the cystic duct, the common hepatic duct, and inferior edge of the liver. The common bile duct and common hepatic duct do not have to be exposed. Next the lower one third of the gallbladder is separated from the liver to expose the cystic plate. The cystic plate is also known as the liver bed of the gallbladder and lies in the gallbladder fossa. Finally one should see the liver on the through the cleared hepatocystic triangle posterior to the ampulla of the gallbladder and cystic duct and artery. There should be only two structures seen entering the gallbladder: the cystic duct and artery. Some recommend obtaining the Doublet View, which has two components—the anterior and posterior laparoscopic views will demonstrate the critical components of the view of safety. It has further been recommended by SAGES Safe Cholecystectomy Program to adopt a culture of safety to include the above but also considering an intraoperative time-out during laparoscopic cholecystectomy prior to clipping, cutting, or transecting any ductal structures; having a full understanding of potential aberrant anatomy; making liberal use of cholangiography or other methods to image the biliary tree intraoperatively; and recognizing when the dissection is approaching a zone of significant risk and halt the dissection before entering the zone. Finish the operation by a safer method other than cholecystectomy including partial cholecystectomy, and

finally getting help from another surgeon in difficult circumstances. Several studies have found that cholangiography reduces the incidence and extent of bile duct injury but controversy remains on this subject. Logically it may not reduce the incidence of injury but may allow earlier recognition and even reduce the degree of injury to a type I or II according to the Stewart–Way classification that can be repaired over a T-tube or primarily. As a hypothetical example, during the cholangiogram process the surgeon makes a small incision in the presumed cystic duct without transection and performs the cholangiogram only to find that the there is no visualization of the proximal biliary tree. Upon conversion to open the injury may be fully appreciated by dissection and repaired. In experimental animal studies, it has been found that the clips that were used to partially occlude the duct and hold the catheter used to perform the cholangiogram in place may be removed without injury to the integrity of the common duct if done so within 30 minutes. Beyond that time, ischemic strictures may develop. Hence, it is recommended that if you find yourself in this situation to convert to open and remove the clips within that period of time. In actuality the incidence may be reduced when cholangiography is performed not as a result of the cholangiogram but rather because the surgeon obtains the critical view in preparation for the cholangiogram.

In addition to the Stewart–Way classification included in the preceding text, there are four other classifications for bile duct injury that may be helpful to the reader. Most surgeons use the Stewart–Way, Bismuth, or Strasberg classifications.

Bismuth Classification

The first classification of bile duct injury was proposed by H. Bismuth in 1982 in reference to biliary strictures and then adapted to bile duct injury (Bismuth H, Majno PE. Biliary strictures: classification based on the principles of surgical treatment. *World J Surg* 2001;25(10):1241–4). The Bismuth classification is a simple classification based on the location of the injury in the biliary tract. This classification includes five types of bile duct injuries according to the distance from the hilar structures and bile duct bifurcation, the level of injury, the involvement of bile duct bifurcation, and individual right sectoral duct. Type I involves the common bile duct and low common hepatic duct (CHD) >2 cm from the hepatic duct confluence. Type II involves the proximal CHD <2 cm from the confluence. Type III is hilar injury with an intact ceiling of the confluence of the right and left hepatic ducts. Type IV is injury of the confluence resulting in separation of the right and left hepatic ducts. Type V involves the aberrant right sectoral hepatic duct alone or with concomitant injury of CHD.

Strasberg Classification

The Strasberg classification is a modification of the Bismuth classification, but

allows differentiation between small (bile leakage from the cystic duct or aberrant right sectoral branch) and serious injuries performed during laparoscopic cholecystectomy (Strasberg SM, Hertl M, Soper NJ. An analysis of the problem of biliary injury during laparoscopic cholecystectomy. *J Am Coll Surg* 1995;180[1]:101–25). The Strasberg classification A-E includes: (A) bile leak from cystic duct stump or minor biliary radical in gallbladder fossa, (B) occluded right posterior sectoral duct, (C) bile leak from divided right posterior sectoral duct, (D) lateral common bile duct injury, and (E) 1–5 subclassified as in the Bismuth Classification. The potential disadvantage of the Strasberg classification is that it does not describe additional vascular involvement.

McMahon Classification

McMahon et al. proposed another classification of bile duct injuries after laparoscopic cholecystectomy (McMahon AJ, Fullarton G, Baxter JN, et al. Bile duct injury and bile leakage in laparoscopic cholecystectomy. *Br J Surg* 1995;82(3):307–13). They classified the injury by the width of bile duct injury. Based on the McMahon classification, lacerations under 25% of the common bile duct (CBD) diameter or cystic-CBD junction were classified as a minor injury, whereas transection or laceration over 25% of CBD diameter and postoperative bile duct stricture were classified as major injury.

Hannover Classification

Bektas et al. proposed a new classification system named Hannover classification after comparing the classification of bile duct injury for consecutive 72 iatrogenic bile injuries after laparoscopic cholecystectomy (Bektas H, Schrem H, Winny M, et al. Surgical treatment and outcome of iatrogenic bile duct lesions after cholecystectomy and the impact of different clinical classification systems. *Br J Surg* 2007;94(9):1119–27). In the Hannover, bile duct injuries were divided into five types from A to E. Type A is peripheral bile leakage. Type B is stricture of CHD or CBD without injury. Type C is lateral CHD or CBD injury. Type D is total transection of CHD. Type E is bile duct stricture of the main bile duct without bile leakage at postoperative state. Vascular injuries are included in Type C and Type D. The Hannover classification distinguished a total of 21 injury patterns in a small group of patients. The reported advantage of the Hannover classification is that it has a high level of statistical significance to demonstrate the association between the discrimination of classifiable injury patterns and the surgical treatments chosen.

My final comments will be on the role of single port and robotic-assisted cholecystectomy. I have been open-minded about these innovations and curious to see which direction they would go. It is now abundantly clear that there is questionable value of these techniques. The most recent studies show that nontraditional, minimally invasive gallbladder removal by single port access or

using robotic assistance while safe offers significantly less surgical value for elective, outpatient gallbladder removal (Newman RM, Umer A, Bozzuto BJ, et al. *Surg Endosc* 2016 September 1 [Epub ahead of print]; Newman RM, Umer A, Bozzuto BJ, et al. Surgical value of elective minimally invasive gallbladder removal: a cost analysis of traditional 4-port vs single-incision and robotically assisted cholecystectomy. *J Am Coll Surg* 2016;222(3):303–8). Our own experience has been similar. Strosberg and colleagues reported a retrospective study comparing outcomes in 237 patients who underwent robotic (RC) (140) or laparoscopic cholecystectomy (LC) (97). There were no bile duct injuries in either group, no difference in bile leak rates ($p = 0.65$), or need for reoperation ($p = 1.000$). Cost analysis of outpatient-only procedures, excluding cases with conversion to open or use of intraoperative cholangiography, demonstrated higher total charges ($p < 0.01$) and cost ($p < 0.01$) for RC compared to LC (Strosberg DS, Nguyen MC, Musacarella P, et al. A retrospective comparison of robotic cholecystectomy versus laparoscopic cholecystectomy: operative outcomes and cost analysis. *Surg Endosc* 2017;31(3):1436–41).

E. Christopher Ellison

111 Reconstruction of the Bile Duct: Anatomic Principles and Surgical Techniques

Toms Augustin and R. Matthew Walsh

Reconstruction of the bile duct is one of the more technically challenging and potentially morbid procedures performed by general surgeons today. Bile duct reconstructions (BDR) are done for malignant and benign biliary obstructions, and approximately 10% for bile duct injuries. The majority of reconstructions are done at teaching hospitals with only 25% performed at centers with more than 35 cases per year. Overall, BDR are associated with an inpatient mortality rate of 4.2% and a morbidity of about 32%, including postoperative wound complications, acute renal failure, and gastrointestinal bleeding. An understanding of biliary anatomy and proper techniques of BDR are of core importance to any practicing general surgeon. Key principles include precise duct-to-mucosa anastomoses that drain all parts of the liver, are well vascularized, and tension-free.

HISTORY

Prominent international surgeons have advanced the care of patients requiring biliary reconstructions. In 1894, Swain described cholecystojejunostomy as a treatment for choledochal cyst. The first radiologic visualization of the biliary tree was done in 1918 by Reich when he injected petrolatum and bismuth into an external biliary fistula. Bakes in 1923 first reported intraoperative endoscopic visualization of the bile ducts using the Bakes dilators. These metal dilators are not in common use today due to the risk of perforation. In 1928 Ladd described the first successful repair of biliary atresia. In 1944 Allen described a procedure in which a Roux-en-Y segment of jejunum was brought up to the hepatic hilum and sutured to the capsule of the liver around the open proximal hepatic duct. A duct-to-mucosa anastomosis was not performed. Claude Couinaud described the segmental liver anatomy in 1957 that paved the way for anatomical liver resection. Klatskin in 1965 first described

adenocarcinoma at hepatic duct bifurcation. Mouret is credited with the first human laparoscopic cholecystectomy in 1987.

INDICATIONS FOR BILE DUCT RECONSTRUCTION

There are multiple indications to perform a BDR. Recent data from the US Nationwide Inpatient Sample studied 67,160 patients undergoing BDR from 2004 to 2011, approximately 8,400 patients per year. The most common causes were for nonmalignant disease in 48%, malignant diseases in 37%, iatrogenic bile duct injury (IBDI) in 10%, congenital biliary anomaly in 2.5%, and benign neoplasms in 2.3%. Among the patients requiring BDR for malignant causes, pancreatic malignancy was the most common followed by hepatic malignancy, intrahepatic biliary malignancy, and gallbladder malignancy. Within the group of patients with nonmalignant disease, 62% of patients had a concomitant diagnosis of cholelithiasis, cholecystitis, or cholangitis. Thus, the burden of gallstone disease as well as complications related to cholecystectomy requiring BDR may in fact be higher than the 10% quoted for biliary injury.

One of the common indications for resection of bile ducts is cholangiocarcinoma. Other rare indications include gallbladder cancer, pseudotumors, carcinoid tumors, and primary sclerosing cholangitis (PSC). BDR is also an integral step in pancreaticoduodenectomy and in this case the common hepatic duct (CHD) is divided just above the usual level of insertion of the cystic duct where the right hepatic artery normally passes behind the CHD.

HEPATIC HILAR AREA; THE PLATE SYSTEM

The liver plate system consists of the sheath around the bile ducts and blood vessels that is continuous with the Glisson capsule intrahepatically and the hepatodudenal ligament extrahepatically. The three plate systems that exist in the liver are the cystic, hilar, and umbilical plate (Fig. 111.1A). The cystic plate is the bed of the gallbladder and does not have importance in biliary reconstruction. The hilar plate is located at the hilum of the liver that is located at the porta hepatis, a deep fissure on the inferior surface of the liver, and contains the portal vein, the hepatic artery, the right and left hepatic duct system, and nervous and lymphatic plexus (Fig. 111.1B). Division of the hilar plate is essential for surgical access to the left hepatic duct (LHD) (Fig. 111.1C). The arrangement of the structures at the hilum is the hepatic ducts being anterior to the portal vein and the

artery running between the two. The umbilical plate is located at the inferior edge of the umbilical fissure. The segmental branches of the left lobe divide or fuse within the umbilical plate.

BILIARY ANATOMY AND ANOMALIES OF IMPORTANCE IN BILE DUCT RECONSTRUCTION

The “prevailing pattern” is the common anatomical arrangement of bile ducts (Fig. 111.2). In some cases, this is present less than 50% of the time. In contrast, an “anomaly” is a deviation from the prevailing pattern. Both aberrant ducts and accessory ducts are anomalous bile ducts. Aberrant ducts are located outside the prevailing anatomical location. A right posterior sectoral duct draining into the extrahepatic bile duct including the cystic duct or the gallbladder would be considered an aberrant duct. Occlusion of aberrant ducts will obstruct bile flow. Accessory bile ducts on the other hand are supernumerary bile ducts. They drain portions of the liver also drained by other bile ducts. As such occlusion of any accessory duct does not obstruct bile drainage. Accessory bile ducts are not uncommon.

The usual extrahepatic biliary anatomy consists of the right and the left hepatic ducts, which join at the hilar plate to form the CHD. This union is usually in front of the right branch of the portal vein. The CHD varies in length from 1 cm to 7.5 cm and has an average diameter of 4.0 mm. The cystic duct unites with the right border of the CHD to form the common bile duct (CBD) The CBD is 6.0 to 8.0 cm long and drains into the duodenum.

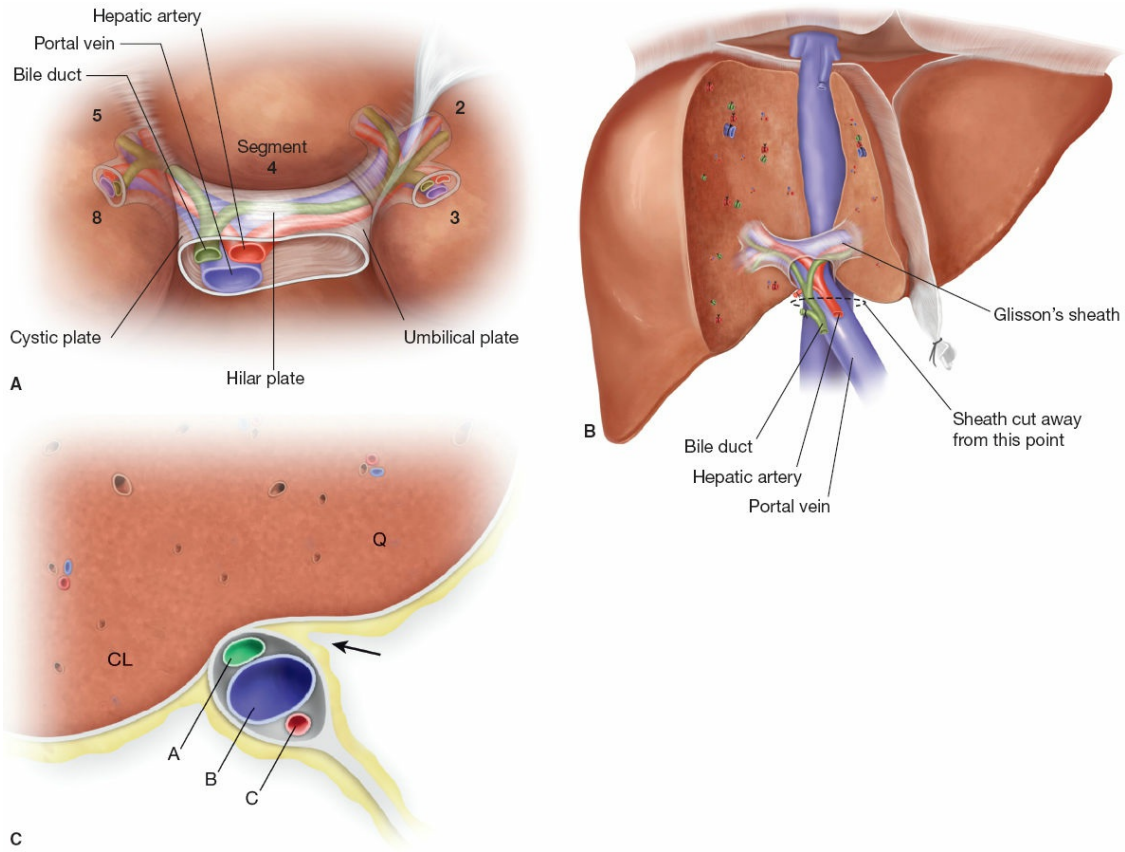

Figure 111.1. **A.** Anatomy of the hepatic plate system. Incising the hilar plate at the inferior most edge of segment IV lowers the biliary system and allows visualization of the hepatic duct system for reconstruction. The umbilical plate is noted to be between segment IV and left lateral segment. **B.** The left and the right portal pedicle are seen at the hilus. The interrupted line is where the hilar plate is incised to lower the plate. **C.** Another representation of lowering of the hilar plate. The Glisson's capsule is incised at the base of segment IV and this dissection is carried toward the left and up the umbilical fissure to expose the left hepatic duct. This dissection may be carried over to the right to expose the right hepatic duct and the confluence. Left hepatic duct (A), left portal vein (B), and hepatic artery. (C. Source: Jarnagin, WR. Blumgart's Surgery of the Liver, Biliary Tract and Pancreas: 2-Volume Set, Expert Consult - Online and Print, 5e. (Saunders: 2012).)

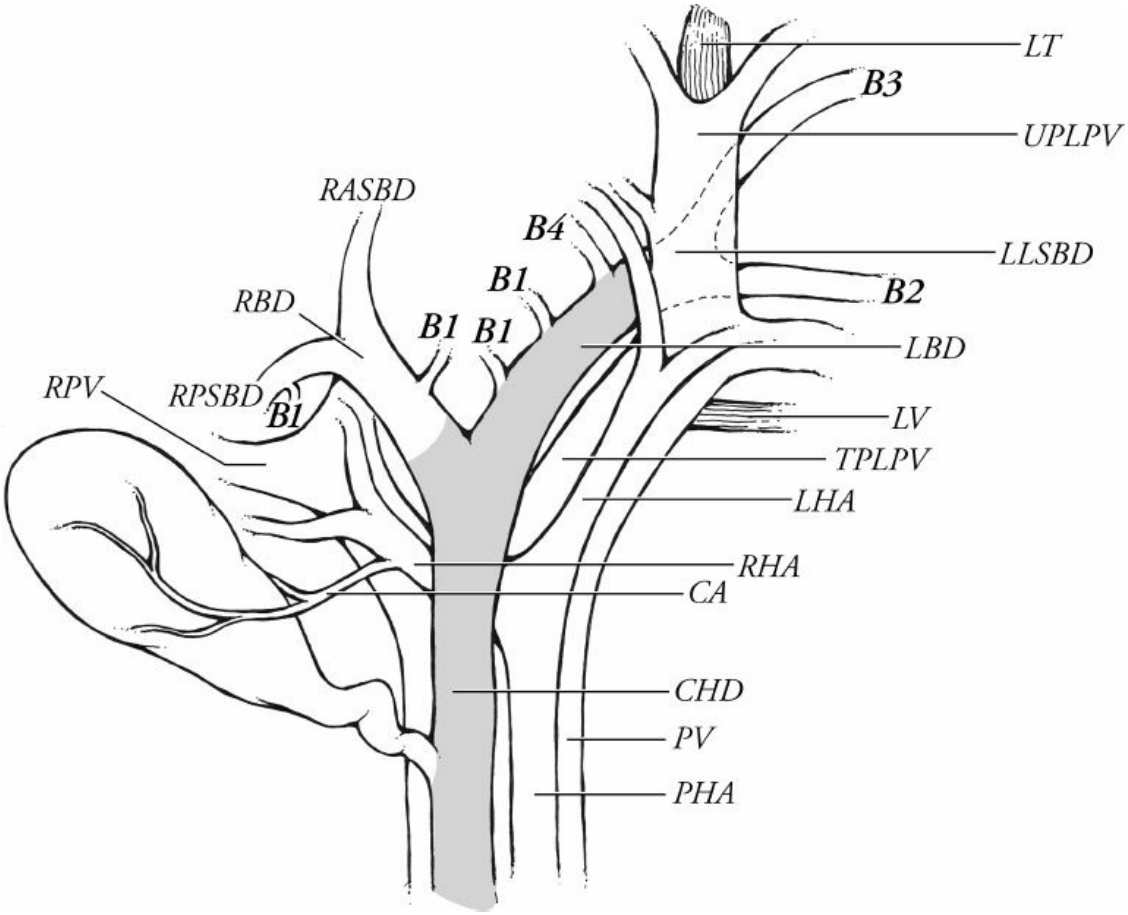

Figure 111.2. Overview of anatomical structures at the porta hepatis. The *hatched area* of the biliary tree is extrahepatic. Note the long extrahepatic length of the left bile duct (LBD) compared with the right bile duct (RBD). Other structures are the common hepatic duct (CHD); sectional bile ducts to the right anterior section (RASBD), right posterior section (RPSBD), and left lateral section (LLSBD); segmental bile ducts to segments I to IV (B1 to B4); arteries (proper hepatic artery [PHA], right hepatic artery [RHA], left hepatic artery [LHA], cystic artery [CA]); veins (portal vein [PV], right portal vein [RPV], transverse portion of the left portal vein [TPLPV], umbilical portion of the left portal vein [UPLPV]), ligaments (ligamentum terres [LT], ligamentum venosum [LV]). B5 and 8 branches of RASBD and B6 and 7 branches of RPSBD not shown.

Prevailing Patterns and Important Variations of the Cystic Duct

A majority of the patients will have a single cystic duct joining the CHD to form the CBD. This is noted in approximately 60% of the patients. There are also important variations in the length of the cystic duct, where it joins the CHD and the angle at which it joins the CHD. A variation of the cystic

duct where it circles anterior or posterior to the CHD prior to its union occurs in 5% of patients. An important variation with respect to IBDI is when the cystic duct drains into the right posterior hepatic duct that is noted in approximately 0.6% to 2.3% of patients. Failure to identify this anatomic variant can lead to a unique form of IBDI where a portion of the right hepatic system is disconnected from the biliary system and presents as a bile leak. Drainage of a normally located gallbladder into an LHD is extremely rare. The ducts of Luschka that occur in 1% to 30% of patients, are 1- to 2-mm ducts draining isolated segments of the right hepatic lobe directly into the gallbladder. These may leak following cholecystectomy if not properly secured.

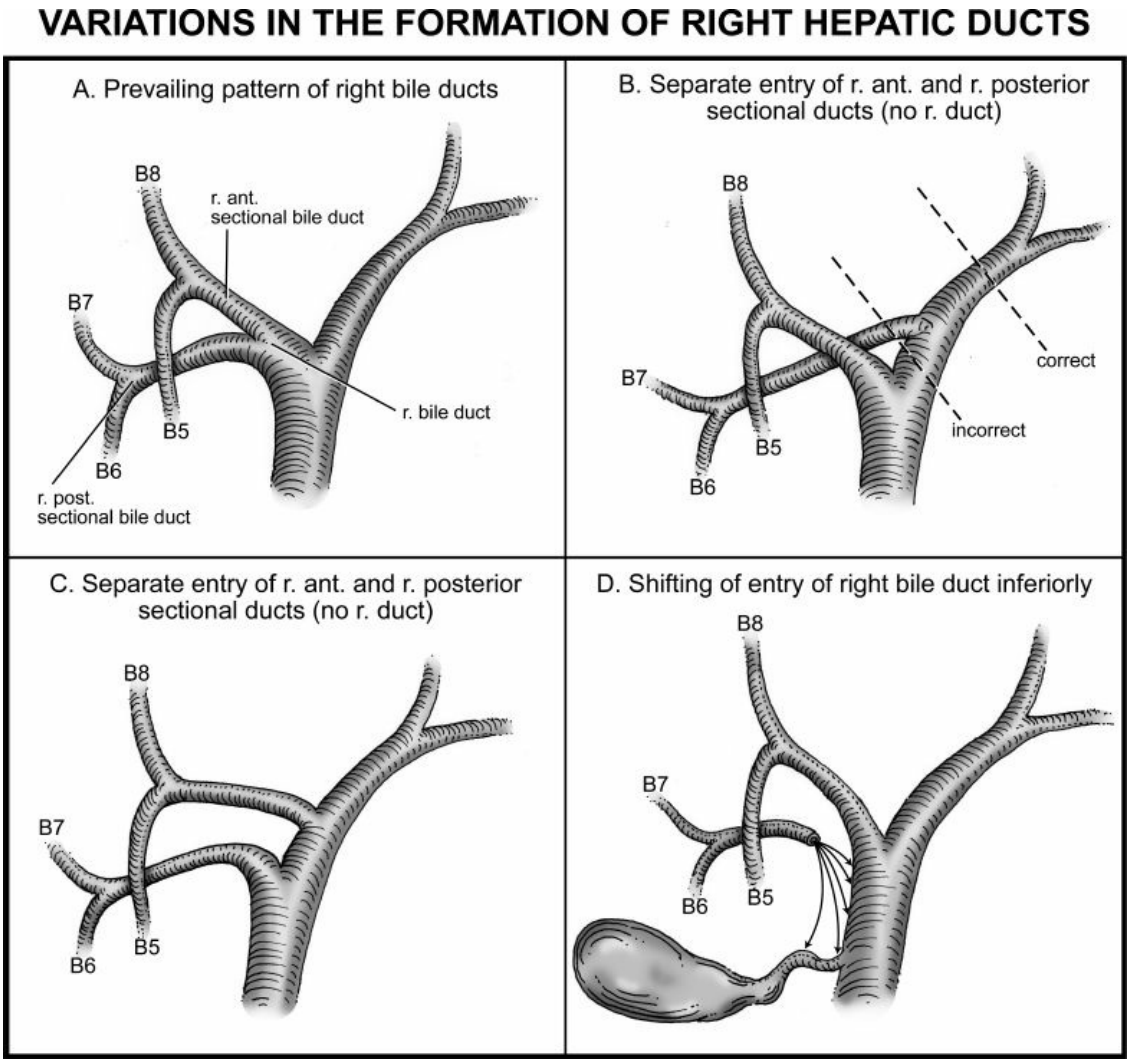

Figure 111.3. (**A–D**) Prevailing pattern and important variations of bile ducts draining the right hemiliver.

Prevailing Pattern and Important Variations of Bile Ducts

Draining the Right Hemiliver

The right hepatic duct (RHD) is approximately 0.9 cm in length and 2.6 mm (±1.2 mm) in diameter (Fig. 111.3). It is usually formed by the union of the right anterior sectional duct that drains segments V and VIII and right posterior sectional duct that drains segments VI and VII. The right posterior sectional duct is more horizontal and usually curves around the anterior sectional portal vein to join the RHD (Hjortsjo hook; Fig. 111.4). This pattern is observed in 57% of the population. Variations from this include the drainage of right posterior sectoral duct (RPSD) into the LHD that is relatively common and occurs in about 20% of the population, drainage of the right anterior sectoral duct (RASD) into the LHD (6% of the population) and as well low insertion of a sectoral duct or the main RHD into the CHD or the cystic duct.

Implications of Anatomical Variations of the RHD; Practical Points

Injury to the RPSD may result if the RASD is ligated very close to its origin. Injury to the RPSD may occur during left hepatectomy in variation B (Fig. 111.3B). In this case the LHD should be ligated in the umbilical ligament to prevent injury to the right sectoral duct. Anomalies with low insertion of the RHD into the CHD or the cystic duct increase the risk of injury during laparoscopic cholecystectomy. This variation should also be kept in mind while dividing the CHD during a pancreaticoduodenectomy at which time reconstruction of the both the ducts may be needed in case of injury.

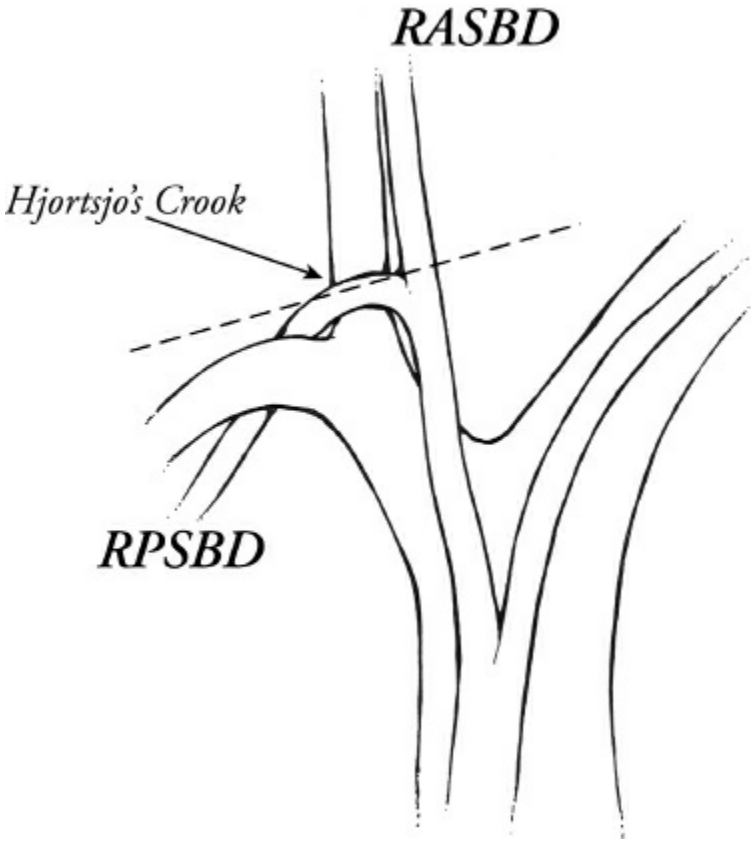

Figure 111.4. Hjortsjo's crook. Note that the right posterior sectional bile duct (RPSBD) crosses the origin of the right anterior sectional portal vein. RASBD, right anterior sectional bile duct. *Dashed line* indicates how RPSBD can be injured if right anterior portal pedicle is divided close to its origin.

Prevailing Pattern and Important Variations of Bile Ducts Draining the Left Hemiliver

The average extra hepatic length of the LHD at 1.7 cm is significantly longer than the RHD. The average diameter is 3 mm (±1.08). Similar to the RHD, the LHD has a left lateral branch that drains segment II superiorly and segment III inferiorly. The union of segment II and segment III (left lateral sectoral duct) passes behind the left portal vein in the umbilical fissure to be joined by the segment IV duct (left medial sectoral duct) to form the main left hepatic duct. This pattern is noted in 67% of the population (Fig. 111.5A). Variation of this anatomy includes the insertion of segment IV duct to the right or left of the LHD (Fig. 111.5B), multiple segment IV ducts draining the LHD (Fig. 111.5C), as well as separate insertion of segment II duct into the LHD (Fig. 111.5D).

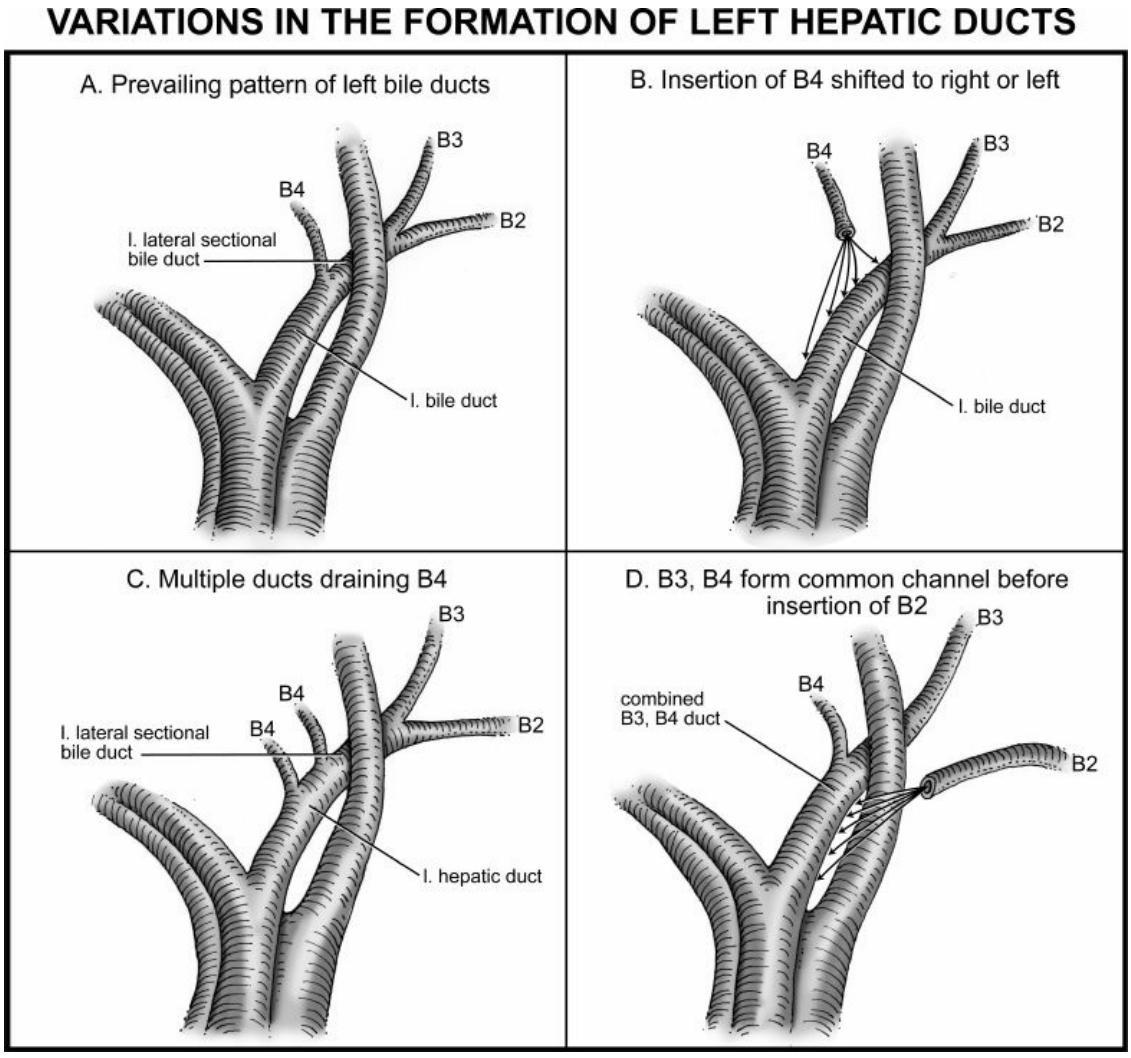

Figure 111.5. (**A–D**) Prevailing pattern and important variations of bile ducts draining the left hemiliver.

Implications of Anatomical Variations of the LHD; Practical Points

The LHD is an excellent conduit for high biliary enteric anastomosis due to length and course of the extrahepatic component that extends from the biliary confluence along the base of segment IV to two thirds of the way toward the umbilical fissure. Cholangiography helps delineate the horizontal course of the duct versus the sharp upward angle in others, which may help prepare the surgeon for the increased difficulty of dissection in these patients. The union of the left sectoral ducts is variable and has important implications during extended bile duct resections like right trisectionectomy. It might be necessary to resect the confluence of B2 and B3 requiring separate duct anastomoses. Additionally in IBDI where resection of the confluence of B4 and the left lateral sectoral duct has occurred, multiple orifices may need to be anastomosed to restore

continuity.

Prevailing Pattern of Bile Ducts Draining the Caudate Lobe (Segment I)

The anatomy of the caudate lobe is important in resection of cholangiocarcinoma as well as in repair of high biliary injuries. About two to four ducts drain the caudate lobe. About half of these ducts merge with RPSD and the other half with the LHD. The orifices are usually located posteriorly and thus less prone to injury even in high biliary injuries. In patients with hilar cholangiocarcinoma, resection of the caudate lobe is usually required.

Blood Supply to the Bile Ducts

The blood supply to the biliary ducts is derived from the celiac axis in patients with the prevailing hepatic arterial anatomy. The supraduodenal CBD has the poorest arterial supply and thus is most prone to an ischemic stricture. The arterial supply to the extrahepatic bile duct including both the CBD and the CHD is provided by two small arteries that travel along the lateral borders of the duct at the 3 o'clock and 9 o'clock positions (Fig. 111.6). The ascending vessels that supply two third of the blood supply to the distal duct are derived from the posterior superior pancreaticoduodenal, supraduodenal artery, gastroduodenal artery, and the retroportal artery. The descending arterial input is derived from the right hepatic artery, and the cystic artery. The 3 o'clock and the 9 o'clock arteries unite to form the epicholedochal plexus, a fine arterial network on the surface of the bile duct. The blood supply of the hilar hepatic ducts comes from the cystic artery and the right and left hepatic arteries. Common arterial variants include a right hepatic artery or the proper hepatic artery originating from the superior mesenteric artery or the left hepatic artery from the left gastric artery. One of the essential components for ensuring a successful outcome of BDR is maintaining adequate blood supply to the bile duct being reconstructed. Arterial perfusion can be quite tenuous from these end arterioles and extra care needs to be taken to minimize their disruption, and may require trimming the bile duct to ensure adequate perfusion.

Implications of the Blood Supply of the Bile Ducts; Practical Points

Unlike the liver parenchmya, which derives its blood supply from both the portal venous system and the hepatic arterial system, the blood supply to the intrahepatic and extrahepatic bile duct is predominantly derived from the hepatic arterial circulation. This has important implications for repair of IBDI with concomitant vascular injury; vasculobiliary injuries. These represent 12% to 61% of patients with IBDI, with this wide range partly based on how thoroughly a vascular injury is investigated. Injury to the right hepatic artery is by far the most common, followed by injury to the common hepatic artery and the portal vein. Isolated injury to the right hepatic artery without a concomitant biliary injury is usually uncomplicated in otherwise healthy patients. However, a vasculobiliary injury may portend a significantly worse outcome after BDR, sometimes requiring liver resection and revisional hepaticojejunostomy for ischemic stricture. Conceptually this should lead to avoiding biliary reconstruction for IBDI recognized in the early postoperative period. This delay allows for demarcation of the ischemic proximal duct so that at the time of BDR the truly viable duct can be identified and used for the anastomosis. IBDI with arterial injuries other than right hepatic artery usually involve the proper hepatic artery or the right or main portal vein, and tend to have severe implications. Injury to the proper hepatic artery or the main portal vein would result in necrosis of the intrahepatic biliary tree and infarction of the liver requiring hepatectomy and/or liver transplantation. In patients with these extreme injuries, the mortality may be as high as 50%. The combination of biliary and vascular injuries and the poor outcome of ischemic biliary anastomosis make it critical to identify any concomitant injuries using either thin slice computed tomography (CT) scan or magnetic resonance imaging (MRI) with contrast prior to BDR.

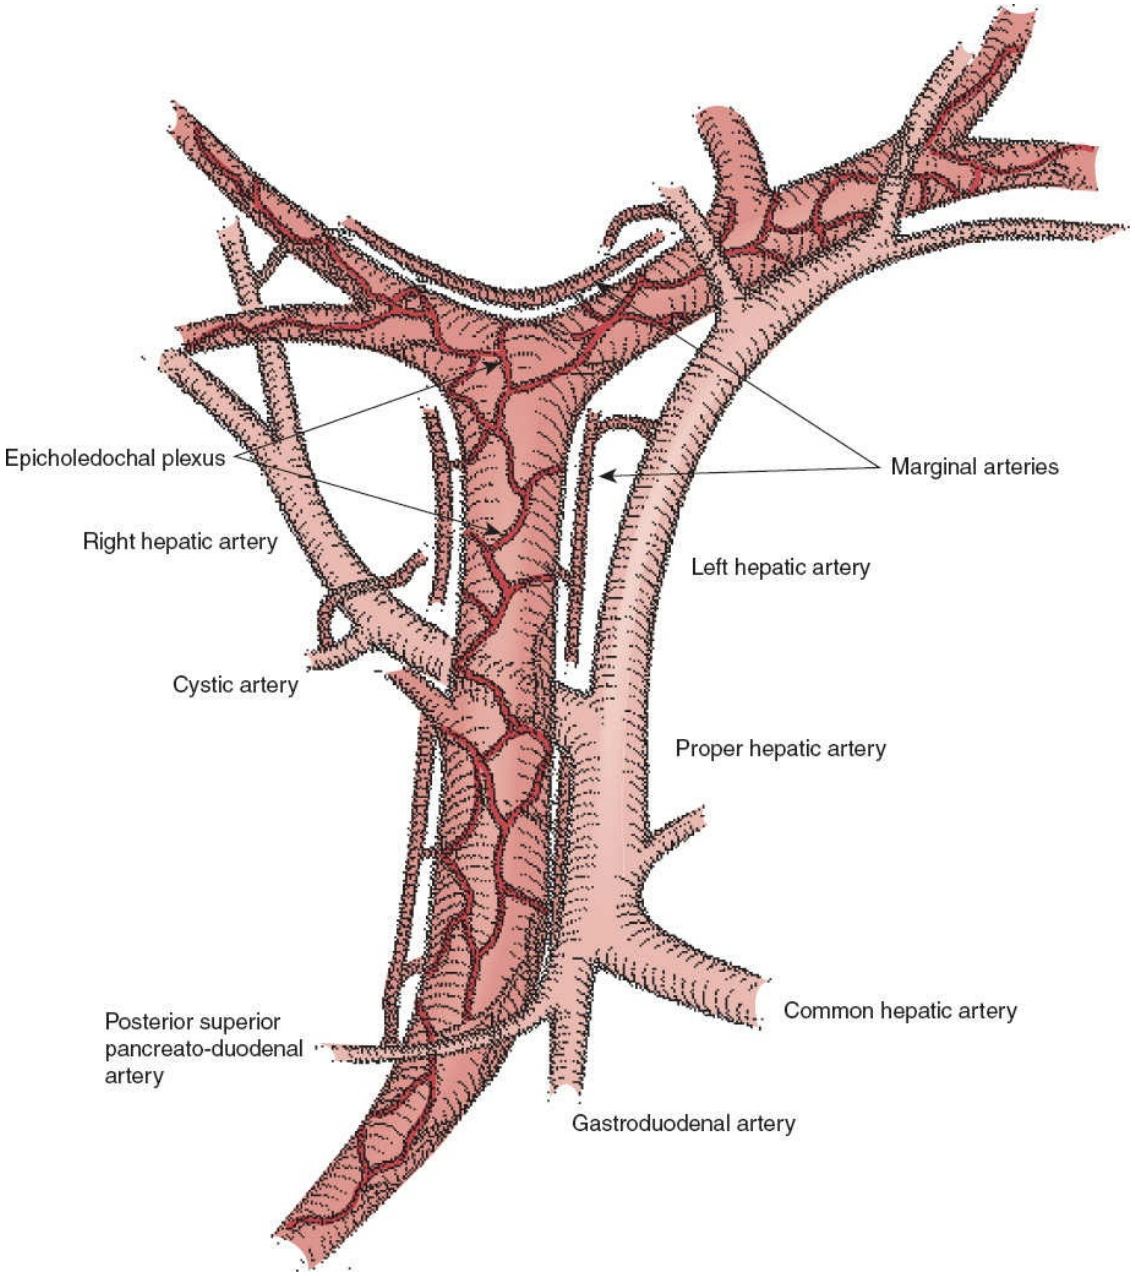

Figure 111.6. Blood supply to bile ducts. The three elements—afferent arteries, marginal arteries, and the epicholedochal plexus—are shown.

Imaging of the Biliary System

The proceeding anatomic descriptions of the biliary system, both prevailing and anomalous, highlight the importance of adequate imaging. This is equally true in both the preoperative and intraoperative settings.

Cross-Sectional Imaging

CT scan is important in patients with biliary obstruction regardless of

etiology. After IBDI is suspected, CT scans can reveal bilomas and allow placement of percutaneous drains to control sepsis and bile leak. In addition, dilated intrahepatic bile ducts suggesting ligation of a bile duct as well hypo-enhancement of the liver parenchyma suggesting a concomitant vascular injury can be easily diagnosed on a contrast-enhanced CT. In patients with hilar or other extrahepatic tumors, apart from intrahepatic bile duct dilation, CT with contrast might reveal the extent of the tumor, arterial and venous involvement, and thus resectability of the tumor (Fig. 111.7).

MRI is uniquely suited to study biliary anatomy in planning for resection of cholangiocarcinomas, to assess biliary anatomy after IBDI, as well as to study strictures after BDR. One distinct advantage of MRI over CT apart is the absence of streak artifacts from clips, which may make CT difficult to interpret in the post-operative patient (Fig. 111.8A). Additionally, the level of biliary obstruction and isolated biliary segments are well visualized with MRI without the need for contrast (Fig. 111.8B). Contrast-enhanced MRI will reveal concomitant vascular injury. MRI has a sensitivity of nearly 100% for detection of bile leaks and 85% accuracy for location.

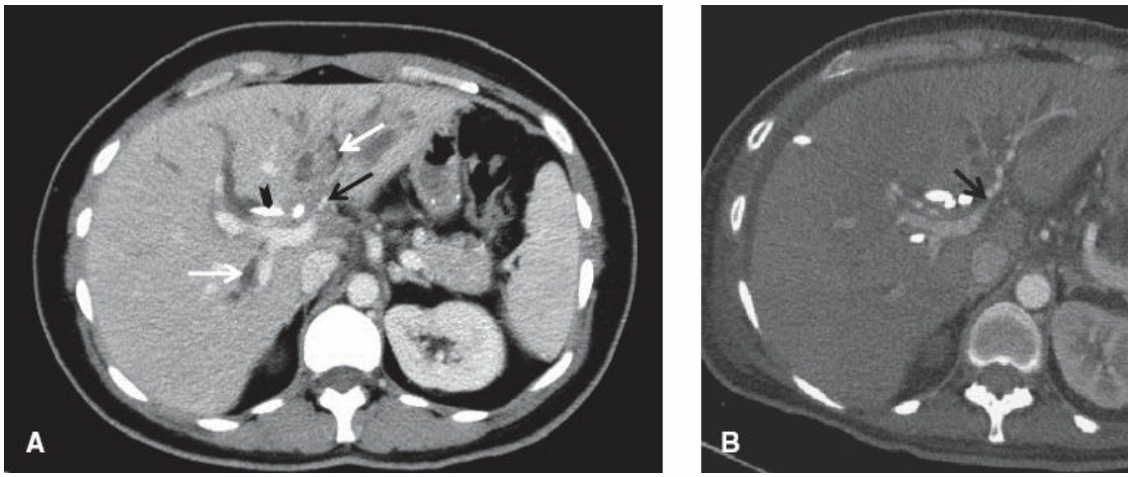

Figure 111.7. **A.** Hilar cholangiocarcinoma. Axial contrast-enhanced CT reveals an infiltrative low-attenuation tumor (*solid black arrow*) sorrounding an internal biliar stent (*black arrowhead*) resulting in bilobar biliary dilation (*solid white arrows*). **B.** Hilar cholangiocarcinoma. The tumor infiltrates the left portal vein causing narrowing (*solid black arrow*).

Endoscopic Retrograde Cholangio Pancreaticography and Percutaneous Transhepatic Cholangiogram

Endoscopic retrograde cholangiopancreaticography (ERCP) allows for placement of an endobiliary stent in incomplete transections and cystic duct stump leaks in IBDI. It however does not permit visualization of proximal duct if complete transection or resection of the bile duct has occurred. On the other hand, percutaneous transhepatic cholangiography (PTHC) allows for visualization of proximal bile duct injuries in patients with complete transection (Fig. 111.9A). It also allows for placement of percutaneous transhepatic biliary drain (PTBD) into the right or the left ductal system, as well as diagnosis of aberrant RHD injury (Fig. 111.9B,C). A limitation of PTHC, apart from being an invasive procedure with a 2% risk of complications, is that it usually requires a dilated duct system to gain access. It is however critically important to define the biliary anatomy prior to an attempted repair of IBDI, even when the system is decompressed by an associated bile duct leak. PTBD placed during PTHC may significantly assist during reconstruction especially in the presence of aberrant ducts or multiple ducts that require enteric anastomosis.

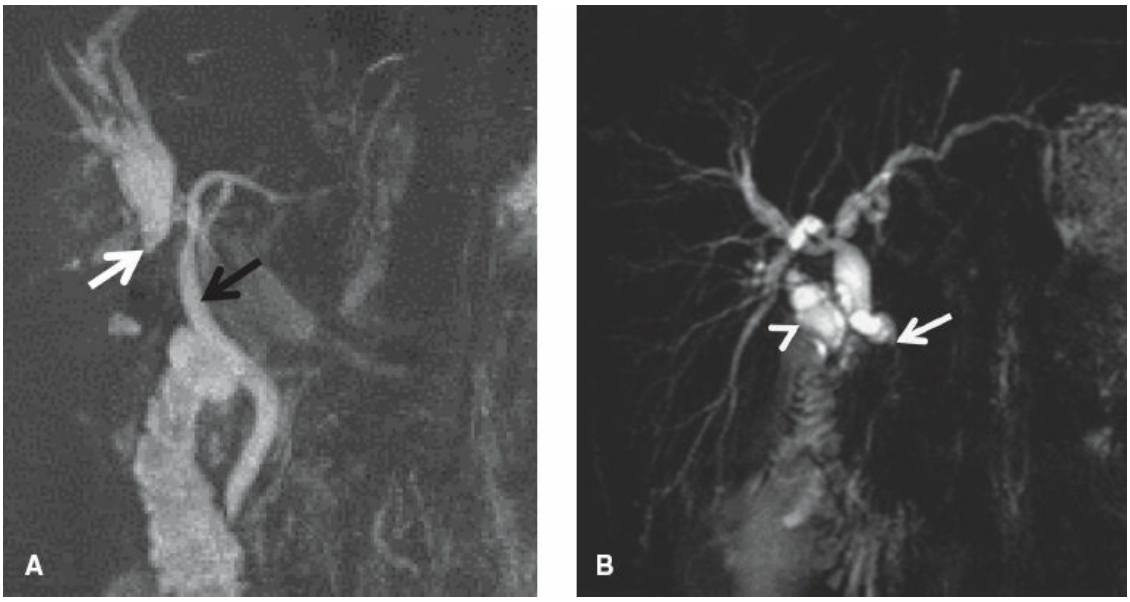

Figure 111.8. **A.** MRI in a patient with iatrogenic right hepatic duct injury. The *white arrow* marks where the right hepatic duct injury is where a stapler was used to transect the gall bladder. The *black arrow* marks a normal common bile duct draining into the duodenum. Note the clear anatomical delineation without artifacts. The patient had an anomalous biliary anatomy with right hepatic duct draining into the gall bladder. **B.** MRI in a patient with bile duct stricture after blunt abdominal trauma. Note the dilated CBD (*white arrow*) tapering to the duodenum. The

gallbladder is marked by *white arrowhead*. Patient underwent a hepaticoduodenostomy.

Approach to Bile Duct Reconstruction

The approach to BDR varies based on whether the reconstruction is related to resection of a malignant tumor, complications of biliary stone disease, or an IBDI that may present challenges in ascertaining the injured anatomy preoperatively. Unique considerations in resection and reconstruction of presumed malignant disease include certainty of diagnosis, and extent of disease that may require an en-block liver or vascular resection. Biliary reconstruction that may be needed in benign conditions such as stone disease and chronic pancreatitis is notable for careful preoperative planning. It may not be in every patient's best interest to undergo laparoscopic cholecystectomy and trans-cystic common duct stone extraction for primary CBD stones. Similarly, ongoing biliary stenting for a fixed common duct stricture in the setting of painful chronic pancreatitis is not optimal management; for both scenarios, biliary bypass may be the best option. It is paramount to be deliberate and thoughtful when presented with patients with complex biliary disease who often benefit from multidisciplinary discussions between surgeons, gatroenterologists, and radiologists. IBDI complicating cholecystectomies are a unique type of complex biliary injury, which are important to consider as they can occur in a commonly performed operation. Thorough review of the index operation with the original surgeon, intraoperative cholangiograms, as well as results of postoperative imaging cannot be overemphasized.

IATROGENIC BILE DUCT INJURIES

Injuries that occur during cholecystectomy are particularly devastating for the surgeon and patient alike as they are an unintended consequence of a presumably "minor" operation. Major bile duct injuries have been a recognized risk of cholecystectomy nearly since its inception. The incidence of injuries has increased since the advent of laparoscopic cholecystectomy from 0.2% to 0.6%. The heightened awareness of IBDI with laparoscopic cholecystectomy has not altered the proliferation of the procedure, nor driven the incidence of IBDI down to the rate during the open era. It is likely that the increased rate is inherent to the procedure. However, every attempt should be made by the operating surgeon to minimize the risk of an injury since the most common reason for an injury

is the misidentification of anatomy. It is incumbent on the operating surgeon to clearly identify the cystic duct–gallbladder junction with adequate lateral traction in a clear operative field, and recognize any biliary/vascular anomalies. In addition to standard laparoscopic techniques, this may require intraoperative cholangiography, ultrasound, or conversion to laparotomy for exposure of the anatomy. Should an injury occur, it is important to be able to identify it at the time of the injury to achieve the best results.

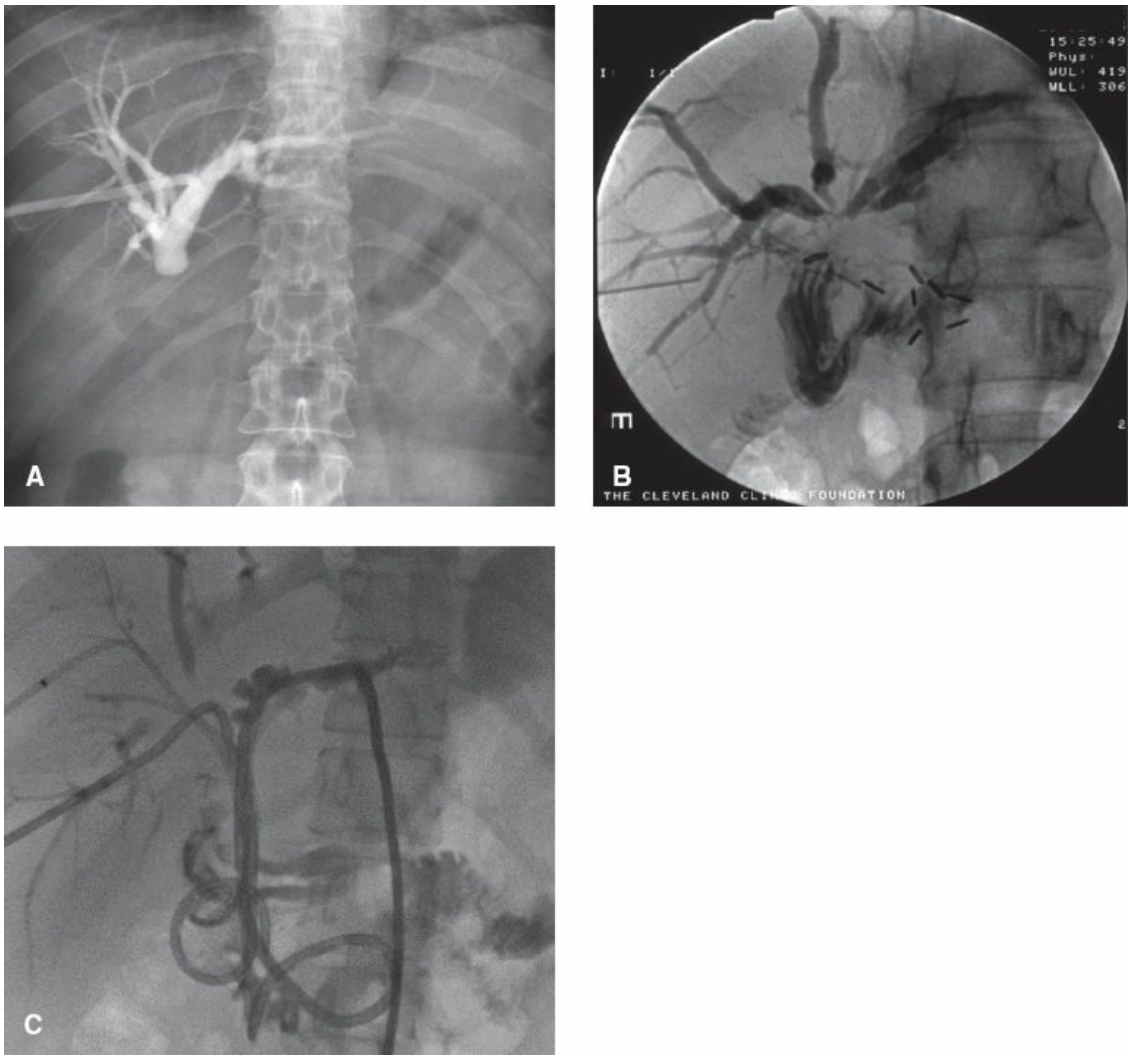

Figure 111.9. **A.** Percutaneous transhepatic cholangiograms in patients with IBDI and cholangiocarcinoma. E2 injury. The left ducts have been injected and the entire intrahepatic biliary tree fills as the confluence is intact. **B.** Percutaneous transhepatic cholangiograms in patients with IBDI. In this case, the biliary confluence is absent. The left bile duct and the right sectoral ducts have been separately cannulated to show the entire biliary tree. **C.** Percutaneous transhepatic cholangiograms in patients

with hilar cholangiocarcinoma. Percutaneous transhepatic cholangiogram reveals complete separation of the intrahepatic biliary tree from the extrahepatic biliary system. PTBD catheters in both the right and the left hepatic system are noted.

Classification of Biliary Injuries

The current classification system for IBDI incorporates both the Strasberg classification from A to E and the Bismuth classification from E1 to E5 (Fig. 111.10). Type A injuries involve a cystic duct stump leak or a duct of Luschka leak. While these are nearly always avoidable, these do not require reconstruction and will not be discussed further in this chapter. Type B injuries are similar to E5 and involve transection of an aberrant right duct without bile leak. These ducts may drain anywhere from a segment to the entire right lobe and can remain asymptomatic. When there is leak of bile from a transected aberrant right duct, it is a type C injury. These usually require reconstruction due to a persistent biliary fistula. If the volume of the liver affected is small, the involved duct may sometimes spontaneously scar down and thus no intervention may be needed. Type D injuries are partial transection of the CHD with bile leak. When the transection is complete these are considered type E injuries. Depending upon the transection being less than or greater than 2 cm away from the confluence, it is referred to as E1 or E2. An E3 injury extends up to the confluence that is intact. In E4 injuries, the confluence is resected and separated right and left ductal systems are noted. An E5 injury involves a clipped and transected aberrant right duct as well as injury to the CHD. When operating on patients with type E injuries, note should be made of the length of missing bile duct. Regardless of the type of IBDI, specific documentation should be made of the presence or lack of vascular injury.

Immediate Repair Versus Delayed Repair in Biliary Tract Injuries

After IBDI is diagnosed, it is best managed at a specialty center by hepatopancreatobiliary (HPB) surgeons. While the timing of repair of injuries diagnosed after IBDI remains controversial, for injuries diagnosed at the time of the index operation, immediate repair by a specialist is the best strategy (Fig. 111.11). The majority of the patients with IBDI however are not recognized intraoperatively and typically present within a week with jaundice, cholangitis, bile leak, or intra-abdominal sepsis. In these patients, control of sepsis prior to any surgical intervention is of

paramount importance. Repair in the face of sepsis portends a poor outcome—both short-term and long-term. In general, repair in the early postoperative period is discouraged due to the degree of inflammation and concern for biliary ischemia, with or without a major vascular injury. Multiple techniques for control of sepsis in these patients can be utilized including placement of bilateral PTBD, intra-abdominal drains, and reoperation. Complete source control of a bile leak is always more important than endobilliary stenting (Fig. 111.12). In patients who undergo early versus delayed repair, outcomes in terms of post-operative complications as well as long-term outcomes can be similar when performed by surgical specialist.

Preoperative Planning for BDR

Complete anatomic detail of an injury is imperative prior to repair. Multiple imaging modalities can be utilized for preoperative planning including ultrasound (US), CT, magnetic resonance cholangiopancreatography (MRCP), ERCP, and PTHC. Of these ERCP and PTHC can be both diagnostic and therapeutic. The added ability of PTHC to precisely define the proximal extent of injury and also leave catheters to guide intraoperative identification of ducts makes it the most useful test in preoperative planning for major injuries. Another imaging modality in patients with surgically or a percutaneously placed drain is fluoroscopy with injection of the drain. The wide modality of testing available mandates individualization for each patient.

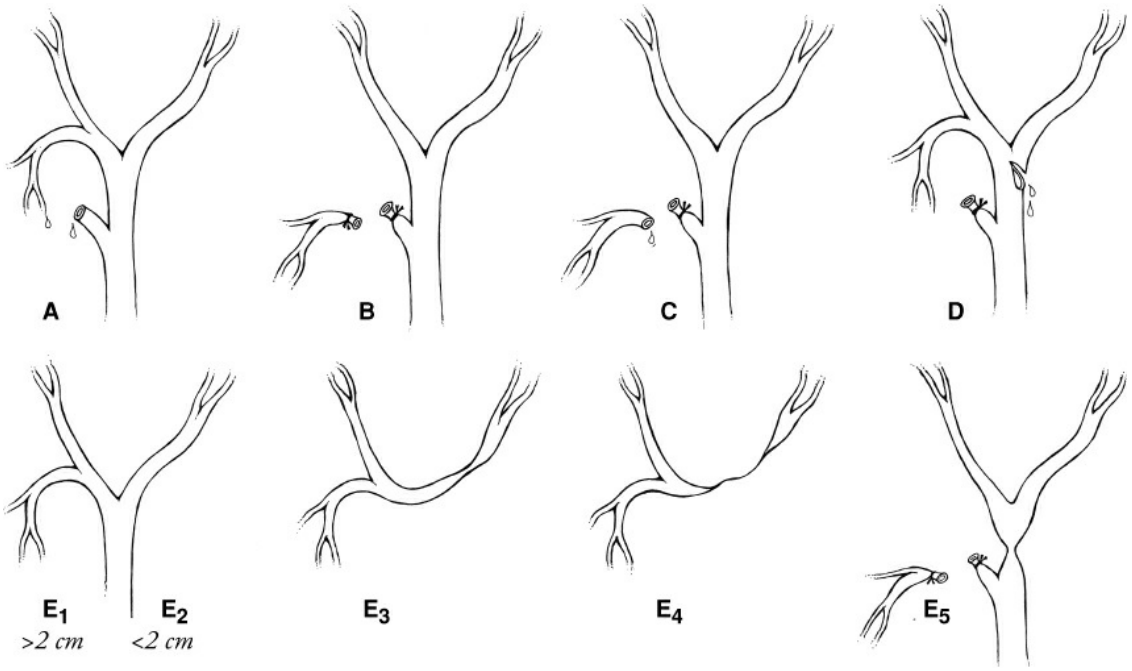

Figure 111.10. Classification of biliary injuries.

Preoperative Patient Preparation

Preoperative planning varies based on the level of injury, presence of bile leak and sepsis, presence of vascular injury, and the timing of diagnosis (Fig. 111.12). For patients who present with sepsis, hemodynamic support and source control is the first priority. Most of these patients have either bilomas or biliary ascites that will need to be drained. ERCP with an endobiliary stent is used when there is a bile leak in the absence of complete transection of the bile ducts. PTHC with PTBD is used in patients with complete transection or resection of the bile duct. Every effort should be made to have PTBD in all disrupted ducts (e.g., the RPSD), to facilitate intraoperative identification and reconstruction of all disrupted ducts. The aim is to control bile drainage until surgery can be accomplished. Other things to consider are electrolyte repletion usually with commercially available drinks like Gatorade, and correction of coagulopathy with intravenous vitamin K. In patients with associated major vascular injury, a planned liver resection may be definitive and expeditious.

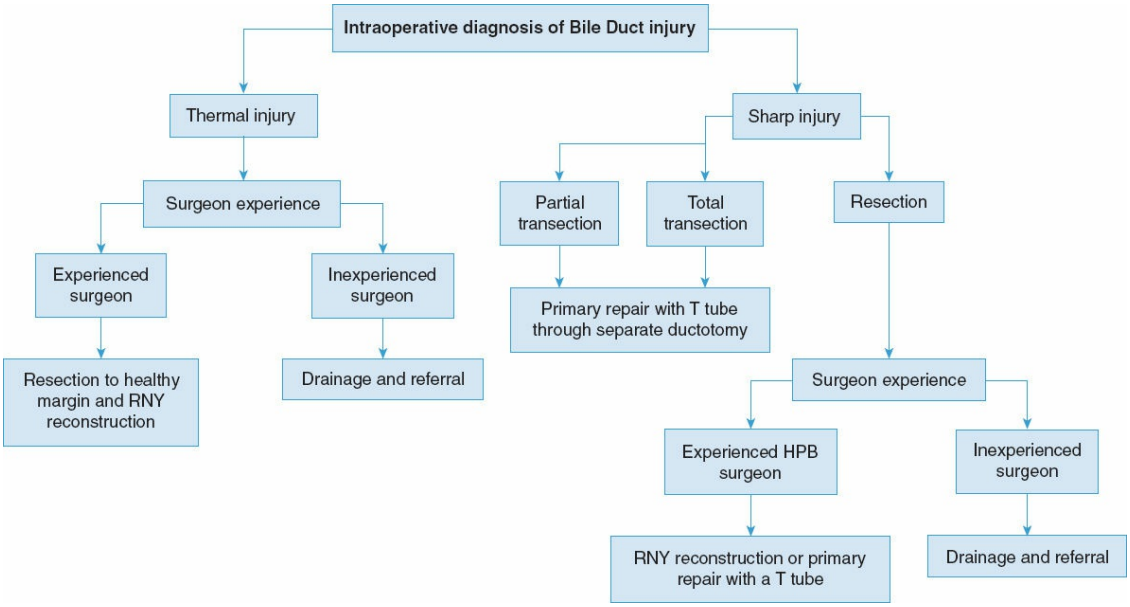

Figure 111.11. Proposed algorithm for management of patients with bile duct injury that are diagnosed intraoperatively.

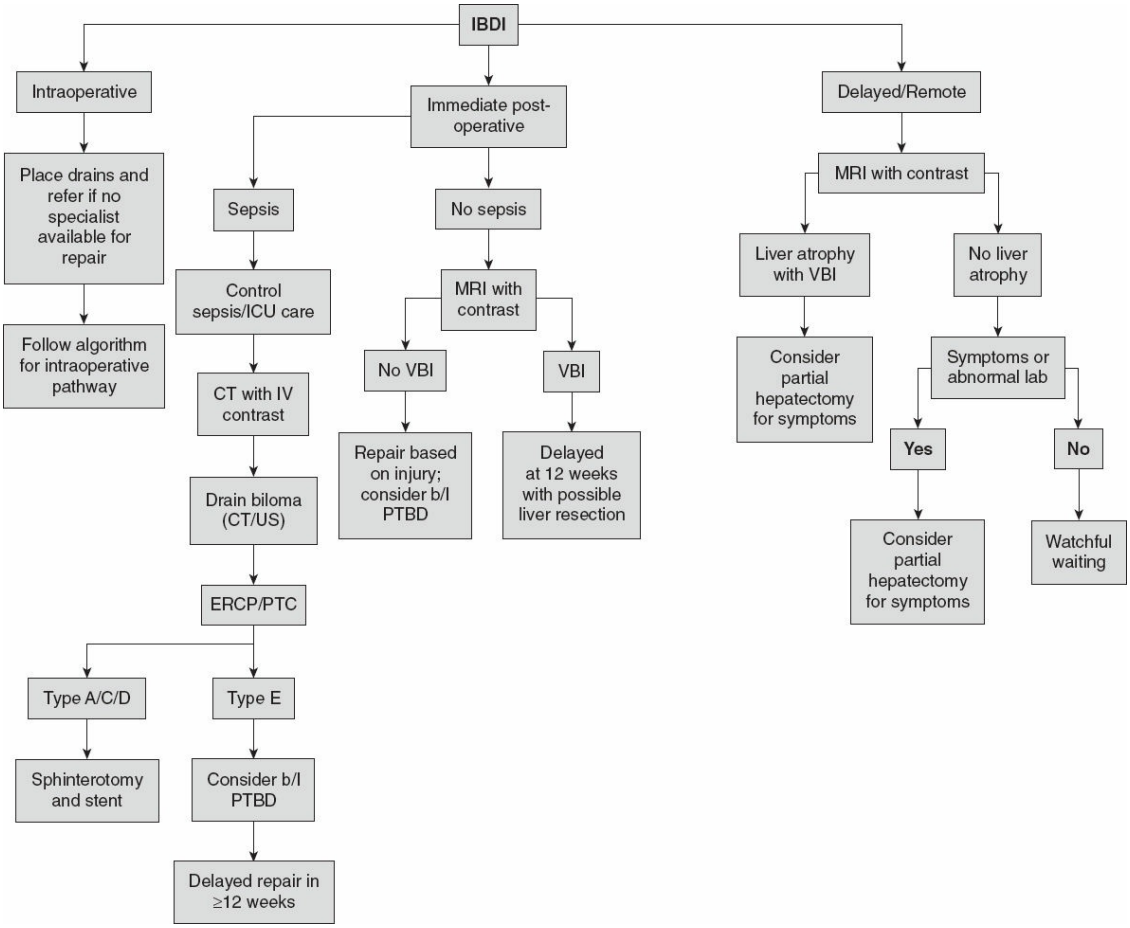

Figure 111.12. A proposed algorithm for management of IBDI.

SURGICAL TECHNIQUES

Options for BDR include end-to-end anastomosis, hepaticojejunostomy (HJ), choledochoduodenostomy, and cholecystojejunostomy. End-to-end duct anastomosis and Roux-en-Y hepaticojejunostomy continue to be the two most common techniques for BDR. While end-to-end anastomosis is more commonly utilized after liver transplantation, HJ is favored for most BDR to reduce the likelihood of an ischemic anastomotic stricture. Choledochoduodenostomy and cholecystojejunostomy have specific indications in the current literature.

General Principles

These general principles apply to all biliary reconstructions: well-vascularized, tension-free, duct-to-mucosa anastomosis. Ischemia or fibrosis at the edges of a biliary anastomosis should be avoided where possible. Resection to refresh the edges of the bile ducts is of utmost importance. Dissection should be meticulous and kept to a minimum

around the duct to avoid injury to the axial arteries within the wall of the bile ducts.

The following section details the reconstructive part of the surgery for BDR. For patients undergoing a concomitant solid organ resection, the detail on how to reconstruct the bile ducts is the same as it is after an IBDI. However, bile duct margins need to be sent for frozen section as appropriate prior to any reconstruction.

Incision and Access

The incision used should allow wide exposure to the right upper quadrant. We commonly use a subcostal or hockey stick incision placed approximately 3 fingerbreadths below the right costal margin or midway between the anterior superior iliac spine and the right costal margin, and extended horizontally to the midline and a vertical midline portion extended to the xiphoid (Fig. 111.13). This can be extended to the left upper quadrant in patients with difficult exposure. If the patient already has a previous Kocher incision, it should be extended to the midline and vertically to the xiphoid process to allow adequate access. Retractor devices that are fixed to the operating table are a critical component for a successful outcome. The retractor systems are generally placed after the Falciform ligament is divided to prevent liver lacerations from retraction of the abdominal wall. Operating loupes with 2–1/2 times to 3–1/2 times greatly facilitate anastomotic precision. Be sure to have adequate illumination, which may require a headlight.

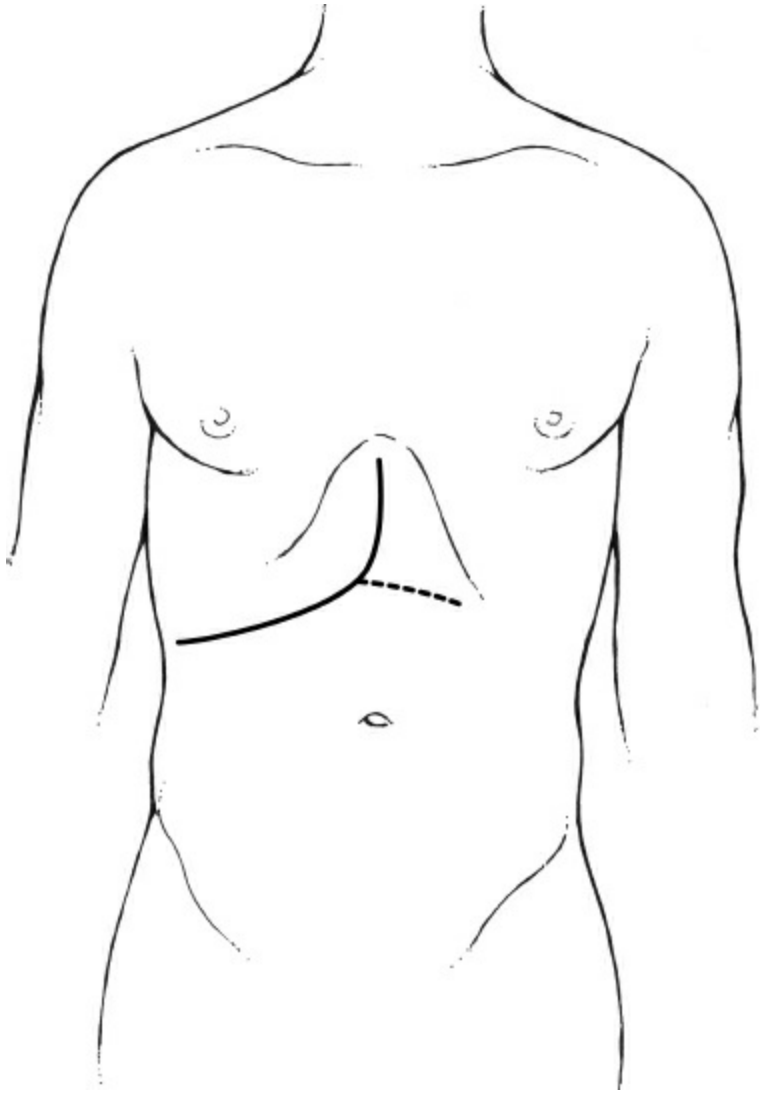

Figure 111.13. Incisions for access to right upper quadrant for bile duct reconstruction as well as major liver resection site. *Dashed line* shows possible extension.

After gaining access to the abdomen and placing a retractor system, any adhesions are lysed to gain access to the right upper quadrant. Wide exposure to the inferior surface of segment IVbis the goal. Significant adhesions off the transected proximal bile duct stump may exist to segment IVb (quadrate lobe). These need to be carefully divided to free up all adhesions, completely freeing up the quadrate lobe prior to incising the hilar plate. A cholecystectomy is completed if was not done previously. Next the area of injury is identified, and all the clips from the bile ducts are removed. A cholangiogram is next performed with the goal to account for every segment of the liver and prevent missing an aberrant right duct. A Kocher maneuver is performed that facilitates identification of the bile duct stump. The distal CBD if it has been clipped off is closed using a

continuous running permanent suture. The cystic artery if it has been clipped is tied. If PTBDs have been placed, these should be carefully protected in order to remove inadvertent removal. Most biliary reconstructions close to or involving the confluence start with lowering the left hepatic duct.

Exposure and Preparation of the Left Hepatic Duct

The LHD is an attractive option for a HJ for multiple reasons, the prime reason being that it is unlikely to be injured at the time of cholecystectomy given its location. Additionally, it usually runs horizontally between the caudate lobe and segment IVb prior to joining the confluence. In this extrahepatic location, it is usually covered by the extension of Glisson capsule onto the bile duct called the hilar plate. There are usually no blood vessels anterior to the bile duct. Incising the hilar plate lowers the LHD and sometimes the confluence. Minor venous oozing from the liver edge at the time of lowering the LHD can easily be controlled with electrocautery or hemostatic agent. The incision on the LHD may be extended to the RHD in E3 injuries. The anastomosis of the LHD to the jejunum in this way was first described in English by Hepp in 1985 based on French description by Hepp Couinaud in 1956 (Fig. 111.14). There are two other useful maneuvers during BDR. The first is to divide the bridge of liver tissue between segment IVB and segment III with care not to injure the left hepatic artery or the left hepatic duct. The other maneuver is to open a sealed off the gallbladder fossa. In some E4 and E5 injuries, either a side-to-side or end-to-side HJ may be needed. A stent in the LHD helps with identification of the right duct especially in cases of re-repair of previous biliary reconstructions.

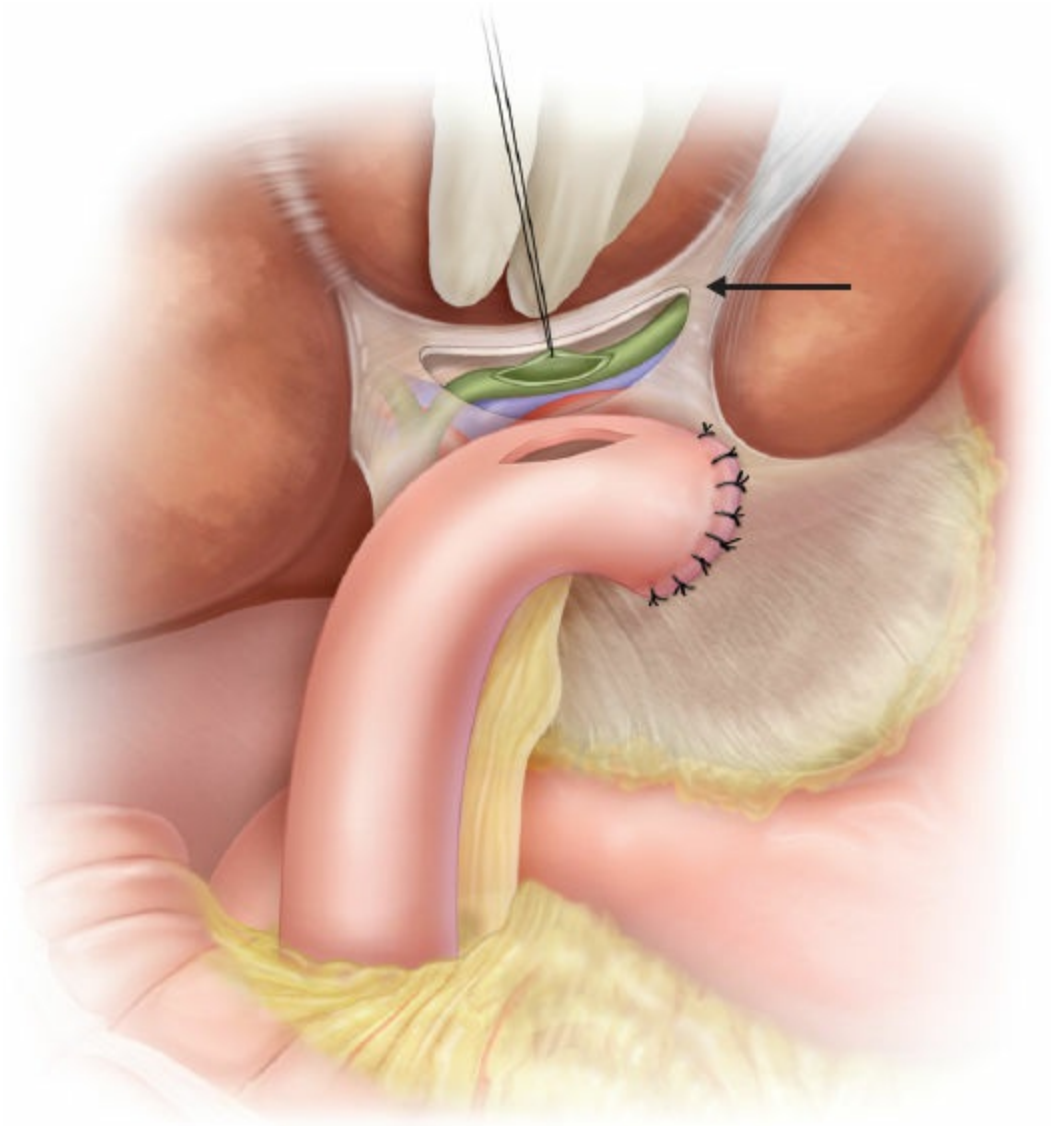

Figure 111.14. The original Hepp–Couinaud technique for exposing the left hepatic duct prior to a HJ. The left HD is subsequently incised horizontally and a side-to-side HJ is performed. The *arrow* indicates the area of the fibrous liver plate, which is divided to lower the left duct. Segment IV is elevated by the surgeon's hand. The duct is opened and prepared for a side-to-side anastomosis.

Exposure and Preparation of the Right Hepatic Duct

The RHD lies along the same coronal plane as the left hepatic duct. To gain exposure to the RHD directly, Glisson capsule at the base of segment IVb is opened. This will allow exposure of the confluence of the right and the left hepatic duct. If the LHD has already been identified and dissected, then this dissection can be carried on toward the right side till the RHD is identified. Sometimes, the base of segment V may need to be opened to

gain exposure to the RHD. Care should be taken not to injure the right hepatic artery that might lie anterior to the duct in this location. As the dissection is carried more to the right side, the cystic plate will need to be incised. Preoperative placement of a stent in the biliary system helps in identification of the right ductal anatomy. Further dissection to segment V will identify the anterior and the posterior sectoral ducts.

Roux-en-Y Hepaticojejunostomy

After the bile ducts have been adequately prepared, an anastomosis is performed. Most commonly, this utilizes a Roux-en-Y hepatojejunostomy. There are various techniques of a HJ. An end (of duct)-to-side (of jejunum) anastomosis is most commonly utilized. However, side-to-side anastomosis may be appropriate in certain cases. In comparison to a direct duct-to-duct anastomosis, a HJ can be used in most patients who require BDR, even those with concerns of bile duct ischemia, significant missing length of duct, or where there are two or more separate ducts that require re-anastomosis. Additionally, a HJ has a significantly lower long-term stricture rate compared to end-to-end anastomosis that can have a long-term stricture rate of up to 80%.

End-to-Side Anastomosis

An end-to-side anastomosis can be used to the CHD after an E1, E2, or E3 injury, separately to the right and left bile duct, or after being joined into a single duct after an E4 or E5 injury. Other reconstructions that utilize a HJ include after a pancreaticoduodenectomy, secondary BDR to repair strictures after liver transplantation and uncommonly after limited resection for bile duct tumors causing obstruction. We commonly perform an end-to-side anastomosis of the biliary duct to Roux limb of jejunum using interrupted monofilament absorbable sutures. This technique is described below (Fig. 111.15).

The jejunum is divided using a stapler at approximately 30 cm distal to the ligament of Treitz and the mesentery is divided to avoid tension. We commonly use a retrocolic window to the right of the middle colic and bring the Roux limb to the end of the bile duct. An enterotomy on the antimesenteric side of the Roux limb with removal of excess mucosa is created with cautery and sized to the caliber of the bile duct. Corner sutures are placed on the right and the left side of the bile duct incorporating at least 3 mm of the bile duct wall and minimal mucosa on

the jejunal side. A posterior row of interrupted sutures is evenly spaced and tied when the row is complete. The anterior row of interrupted sutures is placed with knots fashioned on the outside. Finally, all the anterior row including the corner sutures is tied. A Ray-Tec is left in the operative bed to check for any bile leak. Next a handsewn single-layer jejunojejunostomy is created. All mesenteric defects are closed using interrupted nonabsorbable sutures.

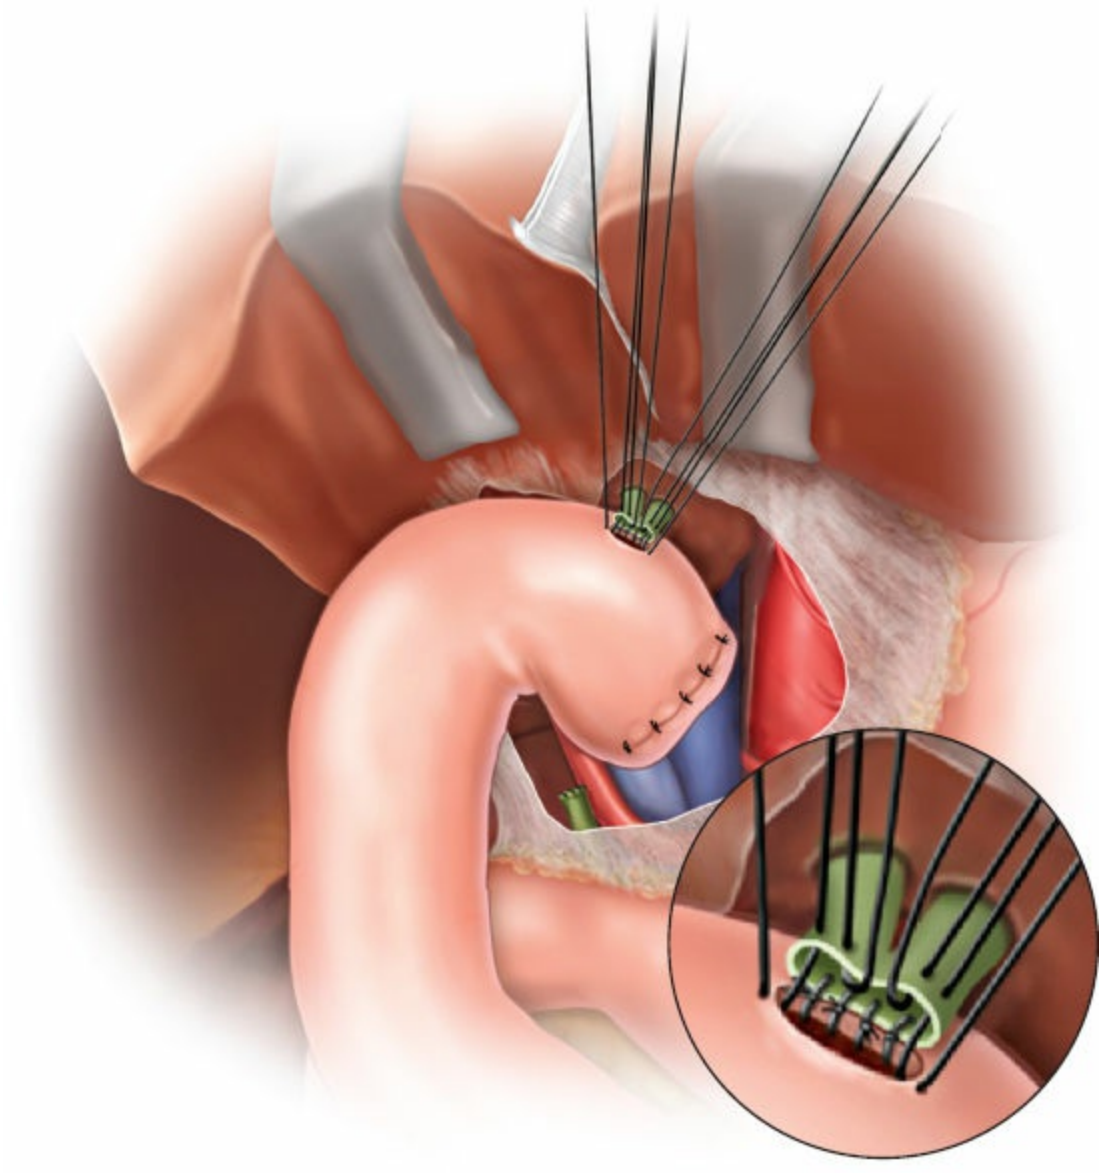

Figure 111.15. End-to-side technique of hepaticojejunostomy. (From Hughes, SJ, ed. *Operative Techniques in Hepato-Pancreato-Biliary Surgery*. Philadelphia, PA: Wolters Kluwer; 2015.)

Side-to-Side Anastomosis

Strasberg et al. have advocated routine use of side-to-side HJ for all injuries, including E1 and E2 injuries. The technique of side-to-side HJ is shown in Figure 111.16. A side-to-side repair in theory limits the amount of dissection around the bile duct causing less devascularization. Additionally, the ductotomy can be fashioned along the long axis of the duct enabling a wider anastomosis. The disadvantage of a side-to-side anastomosis is that it cannot be applied uniformly. For example, when multiple ducts have been transected, then end-to-side anastomosis is more appropriate. Additionally, if the RHD has been transected a very short distance distal to where it is formed from its tributaries, then an anterior slit may not be possible. In cases where a side-to-side anastomosis is possible, a ductotomy is made approximately 1 cm in length. The end of the duct is closed using a 5-0 or 6-0 Prolene. Then a side-to-side HJ is performed as outlined above in an interrupted or running fashion (Fig. 111.16).

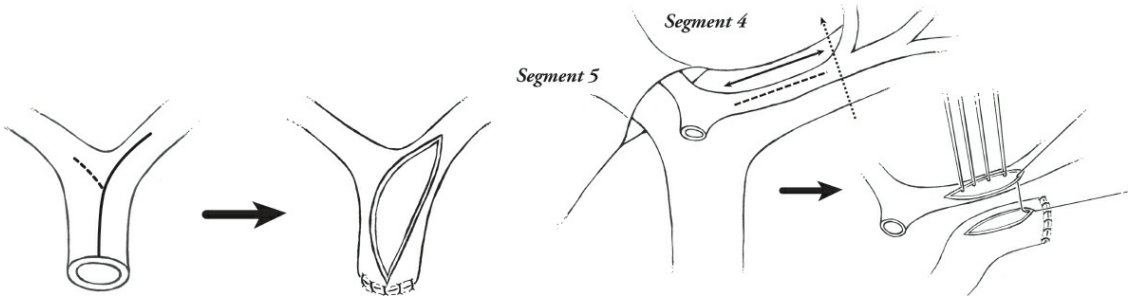

Figure 111.16. Strasberg variation of the HJ. Immediate repair of E1 to E3 biliary injuries. **Left:** The duct is incised on its anterior surface onto the left hepatic duct if necessary to obtain length. The right duct may also be incised if the injury is close to the confluence (*dashed line*). **Right:** The end of the duct is closed and the anastomosis is done side to side to a Roux loop.

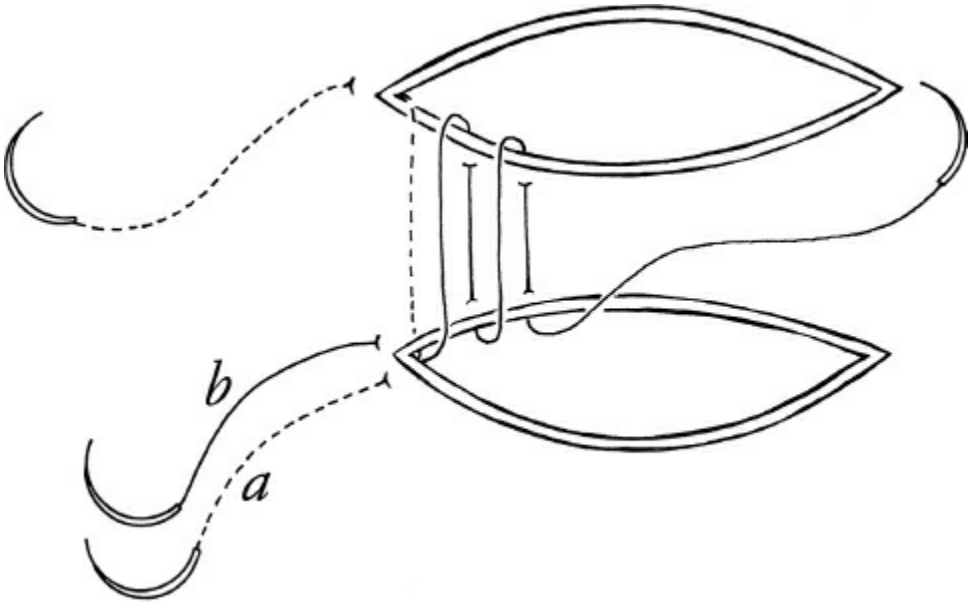

Figure 111.17. Running suture technique for hepaticojejunostomy (posterior row).

Other Variations of the Hepaticojejunostomy

There are multiple variations in approach to the reconstruction of the HJ. One technique involves dividing the HJ into right and left sides by placing the two initial stay sutures anteriorly and posteriorly in the middle. This divides the anastomosis into a right and left side, which is subsequently closed in a similar fashion as above. Some surgeons fashion stitches to place all knots on the outside.

A continuous running technique for creation of a hepaticojejunostomy can also be used especially in larger ducts greater than 1 cm in size and for palliative biliary bypasses in patients with unresectable pancreas cancer (Fig. 111.17). Transplant surgeons also use this technique in live donor liver transplantation (LDLT). A continuous running technique uses a double-armed 4-0 absorbable monofilament suture. A corner suture is first placed and left untied fashioning the future knot on the outside. Next a single-armed suture is started just adjacent to the corner suture and a posterior row is placed in a continuous running fashion keeping the bowel and bile duct still apart. After several sutures have been placed, the bowel is parachuted down onto the bile duct and the corner sutures tied. The free end of the running suture is then tied to the corner suture. The running suture is run through to the opposite corner. An additional suture is placed at the corner in a similar technique, and it is tied to itself and to the running suture completing the posterior row. The corner sutures are run

toward the middle and then tied in the middle thus completing the anterior row.

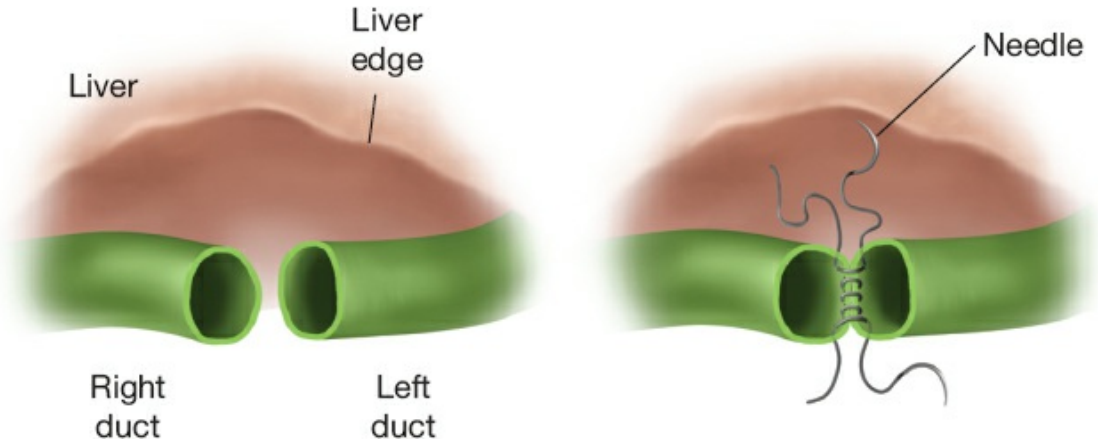

Figure 111.18. Approximation of two adjacent ducts. A double-armed, 6-0 suture is used. Note that the technique buries the knots. (From Hughes, SJ, ed. *Operative Techniques in Hepato-Pancreato-Biliary Surgery*. Philadelphia, PA: Wolters Kluwer; 2015.)

Direct End-to-End Duct Reconstruction

The majority of patients who require BDR after IBDI would need a HJ; certain patients might be candidates for end-to-end anastomosis. These include patients where the injury is diagnosed at the time of the original operation and is a sharp injury, involves less than a third of the circumference of the duct, and is not more than 2 cm away from the confluence without extensive tissue loss or concomitant vascular injury. It may also be advisable by surgeons without access to a HPB specialist and inexperienced in biliary repair. It can and should be accomplished with minimal radial dissection of the bile duct.

Multiple Anastamoses

Situations may call for anastomosing two or three separate ducts to bowel. The technique for reconstruction then depends on their proximity. Commonly when the right and left hepatic ducts are noted to be separate but within 1 cm of each other, they can be sutured to each other using a fine nonabsorbable monofilament suture to create “one” double barrel duct (Fig. 111.18). This is done by placing one or more sutures in the fibrous tissue between the ducts. Then anterior row and posterior row sutures are placed in technique previously described. When the ducts are separated

such that approximation will create tension, two separate intestinal openings are made. In E5 injuries, an aberrant right sectoral duct separated from the main right and left duct may be anastomosed separate from the right and left ducts. Sometimes, one duct lies posterior to the other rather than side-by-side. In this case, the anterior duct is treated as the anterior row and the posterior duct as the posterior row (Fig. 111.19).

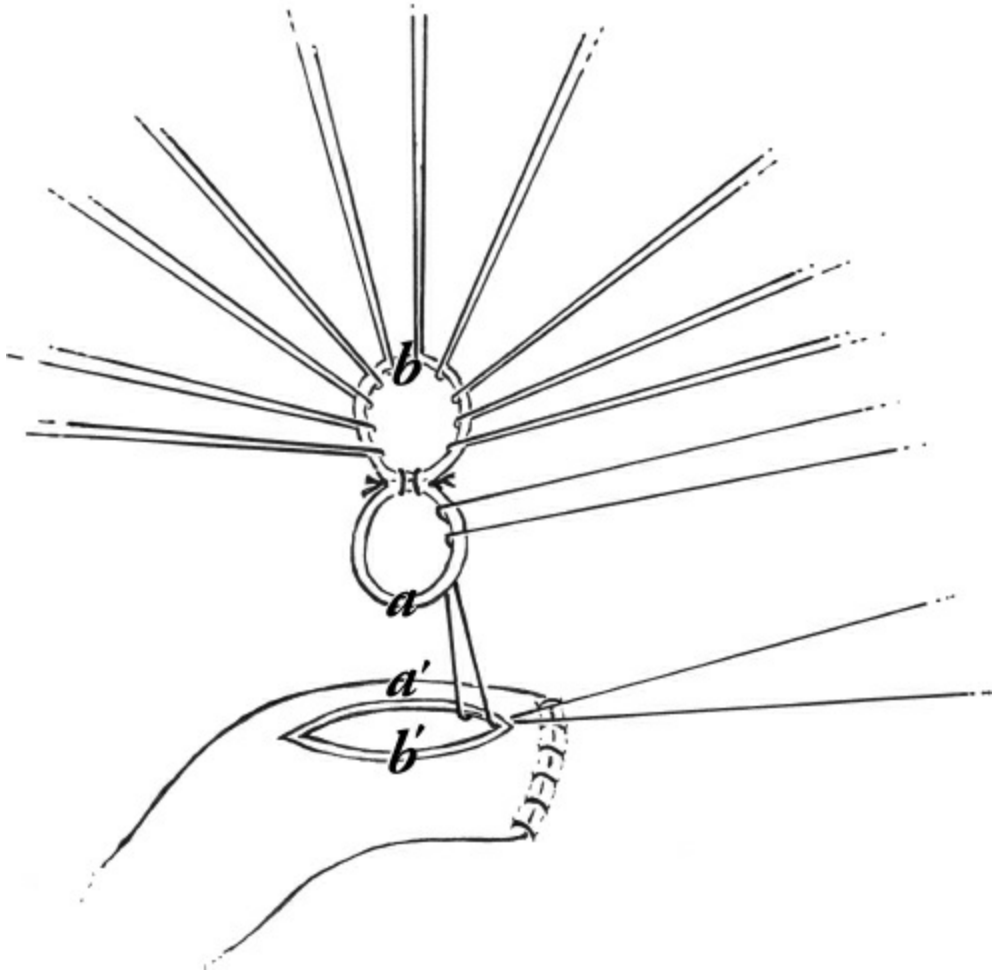

Figure 111.19. Technique for vertically disposed ducts. The anterior duct is treated as the anterior row. Note that “a” comes to “a′” and “b” to “b′.”

Operative Strategy for Reconstruction of Bile Ducts After Elective Resection

The extent of resection for malignant and benign tumors of the liver and bile duct is determined by the extent of the disease process and in the case of cancers the need to obtain negative margins (R0 resection). Bile ducts are usually sharply divided, and the cut surface is well vascularized and visible. Consequently, such ducts are anastomosed end of duct-to-side of

jejunum. The reconstruction follows the technique previously outlined.

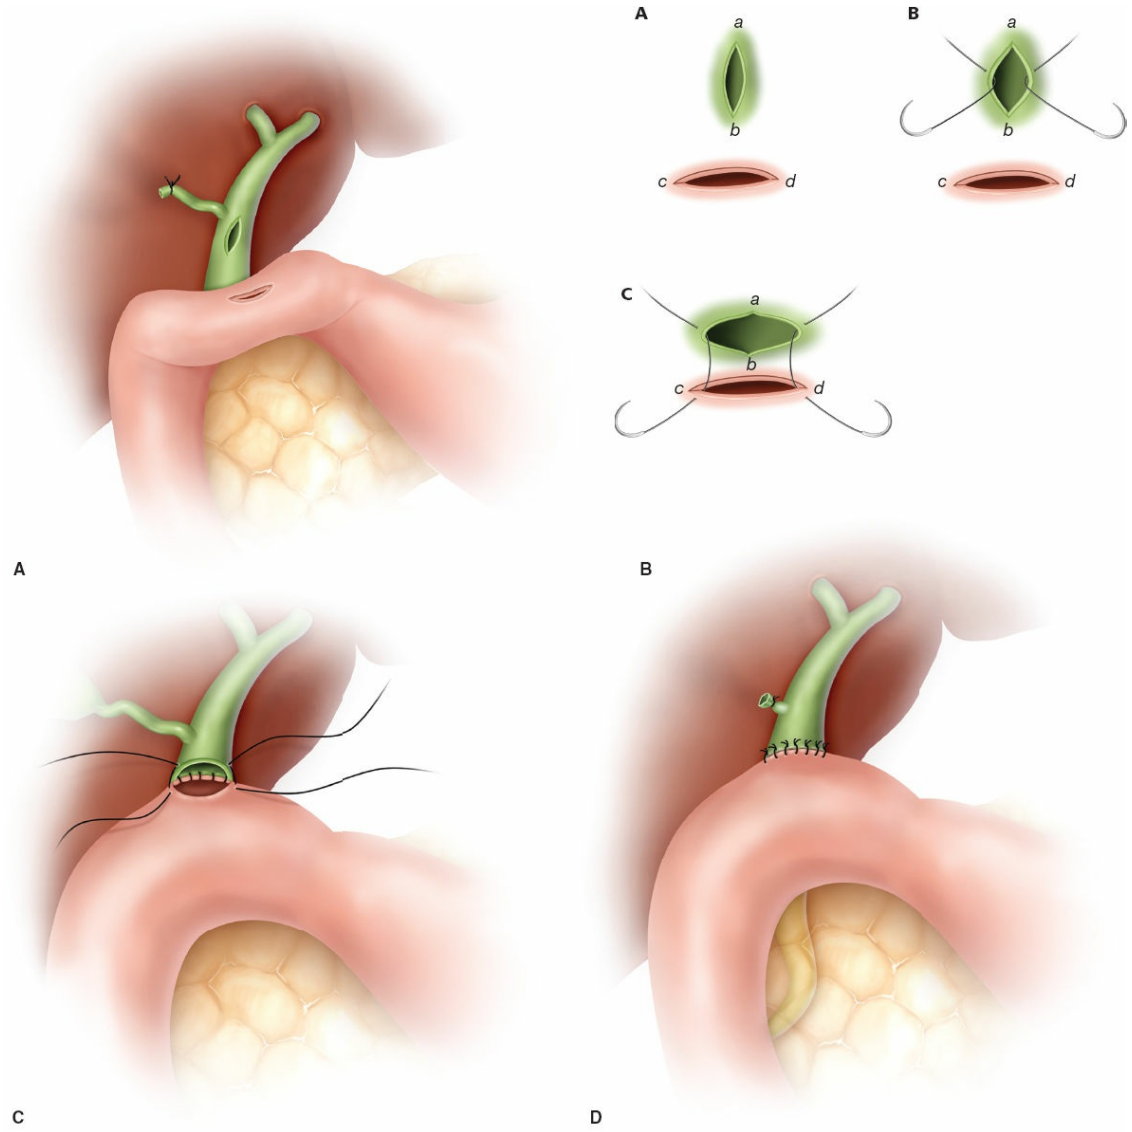

Figure 111.20. **A.** An incision along the axis of the bile duct and duodenum is made after kocherization. **B.** Sutures are placed through the midpoint of the bile duct to the corner of the duodenotomy and another suture to bisect the back row. **C.** Multiple interrupted sutures are placed to complete the back row. **D.** Completed Hepaticoduodenostomy. (From Hughes, SJ, ed. *Operative Techniques in Hepato-Pancreato-Biliary Surgery*. Philadelphia, PA: Wolters Kluwer; 2015.)

Technique for End-to-Side Anastomosis of Very Small Ducts

When very small ducts less than 3 mm in size are encountered, the anastomosis is performed using loupes and 5-0 monofilament absorbable suture. The anterior row of bile duct sutures is placed. A very small opening is made in the antimesenteric border of jejunum using just the tip of the electrocautery. The mucosa of the jejunum is fixed in all four

quadrants using 6-0 Prolene sutures. The posterior row of sutures is then placed with knots on the outside. The anterior row is next completed over an exteriorized 3.5-Fr infant feeding tube to allow for drainage and post-operative cholangiogram. The anastomosis is drained using a closed suction drain.

Choledochoduodenostomy

Choledochoduodenostomy may be considered if it can be performed without anastomotic tension. It can therefore be utilized in select E1 injuries, primary common duct stones, palliation of periampullary carcinomas, or biliary stricture from chronic pancreatitis. Generally patients with biliary injuries or obstructions other than at the lower third of the bile duct are not ideal candidates.

Surgical Technique

Abdominal incision is the same as previously discussed for hepaticojejunostomy. The duodenum is then widely Kocherized allowing significant mobility of the duodenum toward the CBD. The suprodudenal CBD is then identified and a vertical incision is made, which allows for exploration of the duct and removing any stones or debris. The duodenum is incised along its long axis so that a “fish-mouth” can be created with the reconstruction. The choldochoduodenostomy is then created in an interrupted fashion such that the corners of the anastomoses are the end of the enterotomy yet at the midpoint of the bile ductotomy. Similar technique is used for the posterior row first and then the anterior row (Fig. 111.20A–D).

Cholecystojejunostomy

Cholecystojejunostomy should rarely be used as a palliative procedure for malignant obstructions of the distal CBD. It is imperative to confirm that the cystic duct drains into the CBD well proximal to the obstruction prior to creating this type of anastomosis. Additionally, it should only be used when access to the porta hepatitis is not available since high rates of recurrent jaundice have been observed.

Surgical Technique

A wide Kocher incision allows access to the right upper quadrant. The gallbladder is almost always distended. A loop of jejunum is brought to the

right upper quadrant. A posterior row of sutures is placed at the gallbladder fundus. The gallbladder is opened and all the stones are removed. The cystic duct anatomy and absence of obstruction of the cystic duct are confirmed. Additionally, cystic duct insertion into an area of unobstructed CBD is confirmed. Decompression of the CHD is confirmed. Next a jejunotomy is fashioned and an anterior row of sutures is placed to complete the anastomosis.

Minimally Invasive Biliary Reconstruction

Laparoscopic and robotic reconstruction of the bile duct is now being increasingly used for benign and malignant biliary disease. These approaches are aimed at obtaining the advantages of all minimally invasive procedures, but they should not compromise the curative goals of a similar open surgery. The techniques of minimally invasive resection and reconstruction are identical to open procedures, although markedly enhanced by improved optics, magnification, and dexterity in the use of robotics.

EDITOR'S COMMENT

The authors present an excellent chapter on reconstruction of the biliary tree. The section on anatomic variations is outstanding, and the reader is encouraged to study the text and illustrations as these variations come into play in avoiding bile duct injury whether major or minor during the cholecystectomy as well as liver resection.

Variations of the biliary system anatomy increase the risk of trauma to the biliary system and of bile leak after cholecystectomy. Such variations can be unknowingly injured and unnoticed by the surgeon until secondary bile fistula and biliary peritonitis occur. Two important variations that are important to further emphasize are the ducts of Luschka and variations in the anatomy of the right hepatic duct.

The ducts of Luschka present an interesting and important variant. Luschka described aberrant biliary ductules in the gallbladder fossa in 1863. This variant has been variously described in 1% to 30% of patients (Champetier J, Davin JL, Letoublon C, et al. Aberrant biliary ducts (vasa aberrantia): surgical implications. *Anat Clin* 1982;4:137–45; Couinaud C. *Surgical Anatomy of the Liver Revisited.* Paris: Couinaud; 1989; 60–74). I am not certain as to the reasons for the wide variance in the reported incidence. These are usually very small, most often less than 1 mm diameter, bile ducts running along the gallbladder fossa between the gallbladder and the liver parenchyma. They also have been described as "subvesicular" or "supravesicular ducts." It is important to understand that the ducts of Luschka *do not open* into the gallbladder as do the so-called "cystohepaticducts."

Duct of Luschka leaks occur after cholecystectomy regardless of gallbladder pathology or urgency of operation. This has been well analyzed by Mcquillan (Mcquillan T, Manolas SG, Hayman JA, et al. Surgical significance of the bile duct of Luschka. *Br J Surg* 1989;76:696–8) who reported a 9% incidence of bile

leak after open cholecystectomy and four cases of injury to the duct of Luschka during open cholecystectomy. In all four cases, the duct of Luschka was identified and ligated without any further problem.

Interestingly, duct of Lushka leaks have been encountered more frequently in the era of laparoscopic cholecystectomy with an incidence of 0.2% to 2%, according to Jamshidi and colleagues (Jamshidi M, Obermeyer R, Garcia G, et al. Post-laparoscopic cholecystectomy bile leak secondary to an accessory duct of Luschka. *Int Surg* 1999;84:86–8). It is not known why the incidence is greater in laparoscopic cholecystectomy. The visualization of the gallbladder fossa is much better with laparoscopy compared to open cholecystectomy so that poor exposure and visualization are unlikely reasons for the increased incidence. There is use of electrocautery in open as well as laparoscopic cholecystectomy so that is not likely to be the reason for the increased incidence. Certainly during laparoscopic cholecystectomy, there is the need to put outward traction on the gallbladder to facilitate the dissection from the gallbladder fossa. This could contribute, but in open cholecystectomy by the dome down approach there is counter traction used as well. In addition, the ducts of Luschka run parallel to the gallbladder wall and not perpendicular to it and they do not connect to the gallbladder. Hence outward traction forces applied during gallbladder dissection likely play little if any role in the development of such leaks. Hence, there is no clear explanation for the increased frequency of duct of Luschka leaks after laparoscopic cholecystectomy.

Detection of the ducts of Luschka during surgery is very difficult. Intraoperative cholangiography will not detect all such leaks. The only known method of avoiding such leaks is for the surgeon to stay close to the gallbladder wall during its removal from the gallbladder fossa and even then leaks may occur. In the text, the authors refer to ligating these small ductules, if they are seen. The problem is that they are not seen very often if ever during the dissection. It is safe to say that leaks may occur from such ducts and the detection requires a high index of suspicion after laparoscopic cholecystectomy. They can usually be diagnosed and managed by drainage and ERCP and papillotomy with or without stenting.

The authors also note the occurrence of anatomic variants of the right hepatic bile ducts. The surgeon should be familiar with these variations. The aberrant right hepatic duct may occur with a frequency of 4.6% to 8.4% (Puente SG, Bannura GC. Radiological anatomy of the biliary tract: variations and congenital abnormalities. *World J Surg* 1983;7:271–6; Kullman E, Borch K, Lindstrom E, et al. Value of routine intraoperative cholangiography in detecting aberrant bile ducts and bile duct injuries during laparoscopic cholecystectomy. *Br J Surg* 1996;83:171–5). It is well established that the isolated segmental, sectoral, and right hepatic bile duct may be injured during laparoscopic cholecystectomy. This can pass by unnoticed and without serious symptoms; however, it may also lead to serious complications such as cholangitis and liver

abscesses or biliary fistula and peritonitis. The treatment of isolated segmental, sectoral, and right hepatic bile duct injuries is controversial, and the different approaches often depend on the timing of the diagnosis and the attendant complications as discussed in the chapter.

Prevention of injury in these types of anatomic variations is difficult. The critical view of safety may be helpful as it shows the surgeon the safe zone, but establishing this view has not specifically been shown to allow clear visualization of the abnormal variations of right hepatic duct anatomy. My experience has been that there may be subtle clues to right hepatic duct abnormalities including associated anomalies of the right hepatic artery such as an artery that courses up the gallbladder fossa or variations in the cystic duct or artery with very long or short structures. The critical view of safety is essential to the performance of safe laparoscopic cholecystectomy and particularly so in these cases. I think that the use of intraoperative cholangiography for detection of variations in hepatic duct anatomy has not been particularly helpful unless the critical view cannot be obtained in which case it may contribute additional information.

I had commented on the classification of bile duct injuries in the preceding chapter and refer the reader to that commentary. The authors make excellent points concerning reconstruction of iatrogenic bile duct injuries. It is worth emphasizing that there is much controversy concerning the timing of the repair of bile duct injuries. Some authors have recommended early and others late repair; 6 or more weeks after surgery. The report by Stewart and Way is very insightful, and I recommend this to the reader (Stewart L, Way LW. Laparoscopic bile duct injuries: timing of surgical repair does not influence success rate. A multivariate analysis of factors influencing surgical outcomes. *HPB* 2009;11:516–22). They reported a total of 137 injuries that underwent initial repair by a biliary surgeon and 163 injuries that were initially repaired by the primary surgeon. Seven were managed by nonsurgical methods. Of note the repairs by primary surgeons were performed earlier than those by biliary surgeons (11 vs. 59 days; $P < 0.0001$). Interestingly, the analysis of the entire cohort suggested that later repairs might have been more successful than earlier ones (17 vs. 50 days; $P = 0.003$). However, multivariate analysis showed that the timing of the repair was not a significant predictor of outcome ($P = 0.572$). Instead the authors point out that “success correlated with: eradication of intraabdominal infection ($P = 0.0001$); complete preoperative cholangiography ($P = 0.002$); use of correct surgical technique ($P = 0.0001$), and repair by a biliary surgeon ($P = 0.0001$).” Our experience has been similar in that patients without sepsis with an early diagnosis and repair by a hepatobiliary surgeon had better outcomes and better quality-of-life scores than those having delayed repair. Separate multivariate analyses of outcomes for primary and biliary surgeons revealed that timing was unrelated to success in either case. Stewart and Way conclude, “The success of biliary reconstruction for iatrogenic bile duct injuries depended on complete eradication of abdominal infection,

complete cholangiography, use of correct surgical technique, and repair by an experienced biliary surgeon. If these objectives were achieved, the repair could be performed at any point with the expectation of an excellent outcome. We see no reason to delay the repair for some arbitrary period."

Another confounding variable in the assessment of outcomes is the type repair that is performed. Not infrequently the primary surgeon will perform a primary repair for a complete common bile duct transection or a choledochoduodenostomy. Given the blood supply of the bile duct and the variations of site of injury, we usually perform a Roux-en-Y hepaticojejunostomy. As the injured edges will need debridement before an anastomosis, there are few cases where there will be sufficient healthy duct tissue to allow end-to-end anastomosis or choledochoduodenostomy. Both primary repair and choledochoduodenostomy are associated with anastomotic tension and high rates of post-operative stricture secondary to this or a compromised blood supply to the injured bile duct. Accordingly, the long-term success rate for these techniques is poor. In the majority of cases, a hepaticojejunostomy represents the best choice for repair. This allows a tension-free anastomosis and allows the surgeon to expose and preserve a bile duct with a viable arterial supply.

Finally a comment on the need for stenting is relevant to this discussion. There are valid arguments on both sides of the debate of whether to stent or not. It is a decision that should be left to the surgeon as he or she will have the best understanding of their own results given the individual patient and the specific circumstances of the injury. It is our practice that if the patient has transhepatic stents placed prior to the procedure, which is advisable in the situations in which surgery needs to be delayed, then these should be advanced through the anastomosis into the jejunal limb. If the injury is recognized early or during the primary operation, then we do not routinely use stents.

In summary, this is an excellent chapter. I have tried to highlight some of the important considerations. Looking to the future one can imagine novel imaging techniques to visualized the biliary system real-time and also robotic biliary reconstruction.

E. Christopher Ellison

112 Current Application of Endoscopic Sphincterotomy, Lateral Choledochoduodenostomy, and Transduodenal Sphincteroplasty

E. Christopher Ellison, Jeffrey W. Hazey, W. Scott Melvin, and Stephen G. Moon

INTRODUCTION

Endoscopic sphincterotomy, transduodenal sphincteroplasty, and lateral choledochoduodenostomy are complementary procedures used when dealing with distal common bile duct obstruction due to stones, strictures, or, in some cases, motor dysfunction of the Oddi sphincter. Surgical drainage procedures have, in many instances, been replaced by endoscopic retrograde and antegrade papillotomy or sphincterotomy. However, there remain situations in which surgical therapy is required. Each of the procedures has specific indications, contraindications, advantages, and disadvantages. This chapter considers each procedure and discusses applications so that the surgeon can make a rational choice concerning which technique is appropriate to a given clinical circumstance. Before proceeding with discussion of the endoscopic and surgical techniques, the anatomy and physiology of the distal common bile duct and pancreatic duct are addressed.

ANATOMY OF THE DISTAL COMMON BILE DUCT AND PANCREATIC DUCT

The common bile duct and main pancreatic duct run in parallel as they enter the duodenum (Fig. 112.1). It is important to recognize the anatomic relationship between the common bile duct and the insertion of the main pancreatic duct to avoid damage to the latter structure during sphincteroplasty. As the common bile duct courses through the muscle layers of the duodenum, its caliber tapers markedly, producing the characteristic narrowing seen during cholangiography. This tapering is the

result of a complex sphincteric mechanism surrounding the distal common bile duct. The main pancreatic duct opens into the bile duct at a variable distance from the major duodenal papilla. A common channel is present in ~85% of cases. In these situations, dissections have demonstrated that the pancreatic duct is usually located on the medial aspect of the common duct, entering 2 to 3 mm proximal to the papilla of Vater. In ~6% of patients, the ducts open close to one another but separately on the papilla of Vater. The pancreatic and bile ducts open into the duodenum at separate points in 9% of cases.

Control of the flow of bile and pancreatic juice is regulated by a complex sphincteric mechanism that consists of four sphincters of smooth muscle surrounding the intramural portion of the common bile duct, main pancreatic duct, and ampulla (Fig. 112.1B–D). This collection of musculature was first noted by Oddi in 1888 and was expanded upon by Boyden's anatomic descriptions in 1936. This complex is functionally separate from the duodenal musculature. The bile duct sphincter itself consists of three interconnected sphincters: (a) the superior sphincter surrounding the bile duct for 0.5 cm just proximal to its passage through the duodenal wall, (b) a submucosal portion surrounding the intramural duct, and (c) the inferior portion, or the sphincter of the hepatopancreatic ampulla located within the ampulla itself. A pancreatic sphincter is described surrounding the intramural portion of the pancreatic duct as well. Depending on the angle at which the biliary and pancreatic ducts pass through the duodenal wall, the total sphincteric complex may be as short as 6 mm or as long as 30 mm.

Anatomy of the distal common bile duct and pancreatic duct. **A.** The parallel relationship between the bile duct and the pancreatic duct as they enter the duodenum. **B.** The sphincteric mechanism. **C.** The four components of the sphincteric mechanism. **D.** A cross-sectional view of the Oddi sphincter.

PHYSIOLOGY OF THE ODDI SPHINCTER

Physiologic studies have demonstrated that the Oddi sphincter generates a resistance of ~5 mm Hg at the opening of the bile duct and pancreatic duct. The basal pressure measured manometrically is usually 5 to 15 mm Hg greater than the common bile duct pressure and 15 to 30 mm Hg greater than the duodenal pressure. Superimposed on this tonal pressure are prominent phasic contractions (100 to 150 mm Hg), which occur at a frequency of 2 to 6 per minute and are propagated in an anterograde direction (from bile duct to duodenum). Bile flows mainly between these phasic contractions through a relaxed musculature. However, the contractions do propel a small bolus of fluid, allowing clearance of the ductal opening, but the major portion of bile flow occurs by passive means.

The frequency of contractions of the Oddi sphincter varies between the fed and fasted state. During fasting, contractions of the sphincter increase just before phase III duodenal activity. After feeding, the amplitude of contractions decreases, and the tone is reduced. This facilitates passive bile flow. Neuronal and hormonal mechanisms are involved with the fine-

tuning of sphincteric contractions, yet many of the precise details of this interplay have not been fully elucidated.

PATHOPHYSIOLOGY

Successful miniaturization of manometry catheters, so that they can be used through side-viewing endoscopes, has permitted measurement of Oddi sphincter pressures. This has not only enhanced our understanding of normal physiology, but has also allowed accurate manometric definition of disorders of the sphincter complex. These triple-lumen catheters are made of either polyethylene or teflon, with an outer diameter of 1.5 to 1.7 mm. Side holes are oriented so that the lumens record across a length of 5 mm. The catheters are placed with a side-viewing scope before other instrumentation of the papilla. A patient undergoing endoscopic Oddi sphincter manometry is prepared somewhat differently than for standard endoscopic retrograde cholangiopancreatography (ERCP). After topical anesthesia of the oropharynx, mild sedation is achieved with intravenous diazepam or midazolam. It is important to avoid anticholinergics, such as atropine, or opiate analgesics, such as morphine, as they reproducibly alter Oddi sphincter pressures. Figure 112.2A shows a normal motility of the sphincter. Four manometric abnormalities have been categorized. The first abnormality is increased basal pressure in the Oddi sphincter (basal pressure >40 mm Hg). This abnormality has been further subdivided into two entities: (a) papillary stenosis, which occurs if the increased basal pressure does not relax after the administration of smooth-muscle relaxants such as nitrates, and (b) dyskinesia, when the basal pressure does respond to smooth-muscle relaxants. The second condition is *tachyoddia* and is evidenced manometrically by an increased number of phasic contractions (>38 per minute). The third abnormality is an increased number of retrograde waves (from duodenum to bile duct), with a corresponding decrease in the number of anterograde waves. The fourth abnormality is a paradoxic response to cholecystokinin (CCK)-octapeptide. Ordinarily, CCK-octapeptide, when given intravenously, should cause a decrease in Oddi sphincter basal pressure and phasic wave pressures. The paradoxic response occurs when CCK causes an increase in basal and phasic wave pressures.

These classifications of motility disorders correlate with a spectrum of clinical syndromes. It is postulated that disordered motility causes poor emptying of the biliary tree, ductal dilation, and pain. Most patients have had cholecystectomy, and the symptoms are nearly identical to those produced by cholelithiasis and dyskinesia of the gallbladder. Abdominal pain can be constant or intermittent and may not be temporally associated with dietary intake. Elevation of liver function tests is often seen in these disorders, but the abnormalities may be mild and, in some patients, transient, correlating with their episodes of pain.

Sphincter of Oddi Dysfunction and Endoscopic Sphincterotomy

A number of patients have sphincter of Oddi dysfunction (SOD). These patients present with intermittent biliary- or pancreatic-type pain after cholecystectomy or in the absence of gallstones and without significant "dyskinesia" determined by CCK-HIDA scan. Similarly, idiopathic bouts of acute pancreatitis or pancreatic-type pain in the absence of alcohol ingestion, gallstones, or other risk factors remain an enigma to the clinician. Transient elevations of biliary or pancreatic enzymes may occur in the presence or absence of pain. This may be best assessed with biliary manometry performed utilizing a side-viewing duodenoscope and inserting a manometric catheter through the ampulla selectively into the bile or pancreatic duct. Sphincter of Oddi manometry is quickly becoming the "gold standard" to assess Oddi function. Sphincters with an elevated basal pressure or inappropriately contracting may correlate with the patient's pain and respond to sphincterotomy. New evidence indicates that patients with normal manometric findings and persistent symptoms may benefit from repeat manometry as some patients may have periodic abnormalities in biliary manometry. Endoscopic sphincterotomy is quickly replacing surgical sphincteroplasty as the treatment of choice for SOD.

As indicated above, patients with SOD or sphincter of Oddi stenosis may present postcholecystectomy or after an exhaustive workup for recurrent idiopathic pancreatitis or biliary-type pain in the context of a normal right upper quadrant ultrasound and a normal CCK-HIDA scan.

Patients may have no biliary dilation or increased enzymes that correlate with episodes of pain. Sphincter of Oddi manometry is helpful in such cases. As previously indicated, the sphincter of Oddi is a complex smooth-muscle mechanism with sphincteric musculature involving both the bile and the pancreatic duct (Fig. 112.3A). Manometry can measure the transsphincteric basal and contractile pressures across both systems. Basal pressures >40 mm Hg, ductal pressures >13 mm Hg, and phasic contractions >220 mm Hg for >8 seconds at a frequency of >10 per minute suggest abnormal manometry of either the biliary or the pancreatic sphincter mechanism. The most frequent complication seen with sphincter of Oddi manometry, pancreatitis, is decreasing in frequency with the introduction of nonperfused pressure catheters. Endoscopic sphincterotomy of the biliary, pancreatic, or both sphincteric mechanisms may be necessary to render the sphincter incompetent and alleviate a patient's pain (Fig. 112.3B,C). The Geenen–Hogan sphincter of Oddi classification system has been applied to SOD as a predictor of which patients will respond to sphincterotomy (Table 112.1). Type I SOD comprises patients with biliary-type pain, abnormal serum glutamic-oxaloacetic transaminase (SGOT) or alkaline phosphatase more than two times the normal on two or more occasions, common bile duct diameter >12 mm, and delayed drainage of contrast from the biliary tree after ERCP of >45 minutes. Patients who fulfill these criteria frequently have abnormal manometry (75% to 95%) and have a 90% to 95% symptomatic response to sphincterotomy, making manometry unnecessary in this group of patients. Type II SOD comprises patients who exhibit biliary-type pain and present with one or two of the previous criteria. Abnormal manometry is found in 55% to 65% of these patients. Sphincter of Oddi manometry is generally recommended in this population, and symptomatic relief can be expected in up to 85% in the presence of abnormal manometry. In the face of normal manometry, only 35% of patients can be expected to have relief. Type III SOD patients have biliary-type pain but no other abnormalities. Sphincter of Oddi manometry is abnormal in only 25% to 60% of these patients. Similarly, symptomatic relief can be expected in 55% to 65% of patients with abnormal manometry, but <10% of these patients with normal manometry will respond. To date, this is the only predictive model for patients with SOD as it applies to symptomatic responses given in subjective clinical data and manometric values. Endoscopic sphincterotomy may be applied selectively to either the biliary or

pancreatic duct sphincteric mechanism, depending on manometric findings. The ability to perform selective or dual sphincterotomy has increased success rates and symptomatic response in patients with SOD and recurrent idiopathic pancreatitis (Table 112.1).

Patients undergoing endoscopic sphincterotomy for SOD have been found to have increased complication rates when compared with those undergoing sphincterotomy for common bile duct stones. Trials of biliary and pancreatic duct stenting to aid in the diagnosis are generally not recommended with complication rates as high as 38%. The most common complication, pancreatitis, can be expected in up to 7% of all patients undergoing ERCP. Multiple risk factors have been outlined that increase the risk of developing post-ERCP pancreatitis. These include a prior history of ERCP-induced pancreatitis, balloon dilation of the sphincter, difficult cannulation, sphincterotomy, pancreatic duct injection, especially with acinarization, SOD, female gender, and younger age. The decision to alternatively offer these patients endoscopic ultrasound (EUS) or magnetic resonance cholangiopancreatography (MRCP) may be influenced by these risk factors.

Recently, a novel technique to perform an antegrade sphincterotomy in patients who have an ampulla that is inaccessible by traditional endoscopic means (e.g., patients who have undergone a Roux-en-Y gastric bypass procedure) has been described. This may be accomplished by accessing the biliary tree via a percutaneous transhepatic biliary catheter using a small caliber cholangioscope passed through the sheath. An endoscopic sphincterotome can be passed beside the scope under direct visualization and with fluoroscopic assistance. With the cholangioscope retroflexed in the duodenum, the sphincterotome is passed beyond the ampulla and into the duodenum. The ampullary sphincteric complex can then be “cut” using endoscopic energy (as in traditional ERCP) to achieve a sphincterotomy for treatment of ampullary stenosis or common bile duct stones. In a similar fashion, EUS-guided needle and antegrade wire access to the

biliary tree has been described in patients with peroral inaccessible ampullas. These techniques are limited to select centers with limited experience.

Complications of ERCP, Endoscopic Sphincterotomy, and Treatment

The surgeon may be consulted for a patient who develops bleeding, perforation, or stricture after ERCP with sphincterotomy. Bleeding occurs in 2% to 12% of patients who undergo sphincterotomy. This may be minor and self-limited or major, requiring laparotomy and oversewing of bleeding vessels. The majority of cases can be treated utilizing endoscopic modalities, including injection of 1:10,000 epinephrine, thermal therapies, or endoscopic hemoclips.

Perforation rates of 0.3% to 1.0% have been reported. Perforations may occur as a result of endoscopic manipulation independent of ERCP or as a result of sphincterotomy or passage of a guidewire. Treatment of perforations as a result of sphincterotomy depends on location and has been categorized as type I through type IV by Stapfer et al. (Fig. 112.4). Type I perforations involve the lateral or medial wall of the duodenum and are caused by the endoscope. There is often free intraperitoneal extravasation of contrast from the duodenum, and these perforations require laparotomy and repair. Duodenal diversion may be necessary depending on the extent of the injury. Type II perforations, or peri-Vaterian injuries, may be diagnosed during the procedure or with a computed tomography scan with oral contrast. These perforations vary in severity, tend to be small, and are less likely to require surgery. When surgical repair is indicated, stone/foreign body removal, drainage of the periduodenum, and, rarely, duodenal diversion may be necessary. Type III perforations involve only the bile duct and tend to be small. Although these perforations may be diagnosed during the procedure, it is not uncommon for them to be diagnosed after ERCP. The bile duct may be perforated as a result of sphincterotomy, passage of a guidewire, or bile duct manipulation. Conservative treatment with bowel rest, intravenous antibiotics, and either endoscopic stenting or nasobiliary drainage are often successful. In those patients who develop a biloma or an intraperitoneal collection of bile, external percutaneous biliary drainage in combination with internal stenting is generally successful. Free intraperitoneal bile leaks that are not amenable to percutaneous drainage may require

laparotomy, washout, and placement of drains. The need for primary operative repair of biliary injuries/leaks in this setting is unusual. Type IV perforations are associated with retroperitoneal air and no free extravasation of contrast. These are usually limited to the retroperitoneal duodenum. Series report successful treatment in up to 86% of these patients with bowel rest, nasogastric decompression, and broad-spectrum antibiotics. Complex injuries involving both the duodenum and the biliary tree may necessitate more complex treatment algorithms. Using a combination of the above described techniques, surgical intervention may be unnecessary. Postsphincterotomy strictures do occur and may be amenable to repeat sphincterotomy or balloon dilation. In rare circumstances, recurrent stricturing of the ampulla may require operative transduodenal sphincteroplasty.

Infectious complications of ERCP include cholangitis (1% or less) and cholecystitis (0.2% to 0.5%). The placement of stents, presence of strictures, jaundice, and incomplete biliary drainage increase the risk of cholangitis. Drainage of the biliary tree by stenting or sphincterotomy with antibiotics is the treatment of choice. The presence of gallstones is believed to be the causal factor in post-ERCP cholecystitis and can be treated with cholecystectomy.

Figure 112.4. **A.** Type I perforation involving the wall of the duodenum typically as a result of the duodenoscope. **B.** Type II perforation involving the peri-ampullary complex into the peritoneum. **C.** Type III perforations of the bile duct by wire or instrumentation. **D.** Type IV perforation limited to the retroperitoneum.

Lateral Choledochoduodenostomy

Lateral choledochoduodenostomy can be performed as a primary procedure at the time of cholecystectomy or for recurrent common bile duct stones occurring remotely after cholecystectomy that cannot be treated by endoscopic papillotomy. In the past, the frequency of the necessity of this drainage procedure has been ~1% of all biliary operations, 38% of patients having a primary operation and 60% having a secondary procedure. It is more often necessary in the elderly patients; the mean age of patients reported in the literature is 61 years.

INDICATIONS

The surgeon should consider performing a lateral choledochoduodenostomy in patients with a dilated common bile duct secondary to distal obstruction from a benign process. This group frequently has failed previous attempts at endoscopic sphincterotomy. A large duct, measuring >2 cm, is an indication of prolonged obstruction or loss of tone leading to biliary stasis. Biliary stasis results in a potential for primary stones within the duct and, therefore, size alone is a relative indication for this operative procedure. The presence of primary common bile duct stones, numerous bile duct stones (>15), or intrahepatic duct stones, especially in any patient who has undergone a previous choledochotomy, usually requires a choledochoduodenostomy. Distal obstruction from strictures secondary to a primary benign process, such as chronic pancreatitis, is also treated appropriately with choledochoduodenostomy. Lateral choledochoduodenostomy is contraindicated in patients with a common bile duct smaller than 15 mm or a stone impacted in the ampulla.

OUTCOME

A minimum stoma size of 2.5 cm should be achieved in all cases. If a large stoma is created, the results are usually satisfactory, and late stenosis or

cholangitis is rare. If the stoma is small, stenosis or the “sump” syndrome may occur. The “sump” syndrome is the collection of vegetable debris in the distal segment of the bile duct below the anastomosis (Fig. 112.5). This can eventually produce obstruction with cholangitis, jaundice, or even pancreatitis. Overall, the incidence of this complication is below 1%. The advantages of lateral choledochoduodenostomy over sphincteroplasty to drain the biliary system are speed, the ease of performance, and decreased incidence of perioperative morbidity. It is particularly applicable in the poor-risk patient or in the patient with a long stricture who cannot undergo a sphincteroplasty. The main disadvantage of a lateral choledochoduodenostomy is the potential development of the “sump” syndrome. Recent studies have shown good long-term outcomes with very low or absent rates of development of “sump” syndrome. Similarly, endoscopic techniques with clearance of the affected distal common bile duct remnant can be applied to treat this potential complication. In addition, there is decreased visualization of the papilla to exclude malignancy, although it can be excluded through choledochoscopy or direct visualization through the duodenotomy.

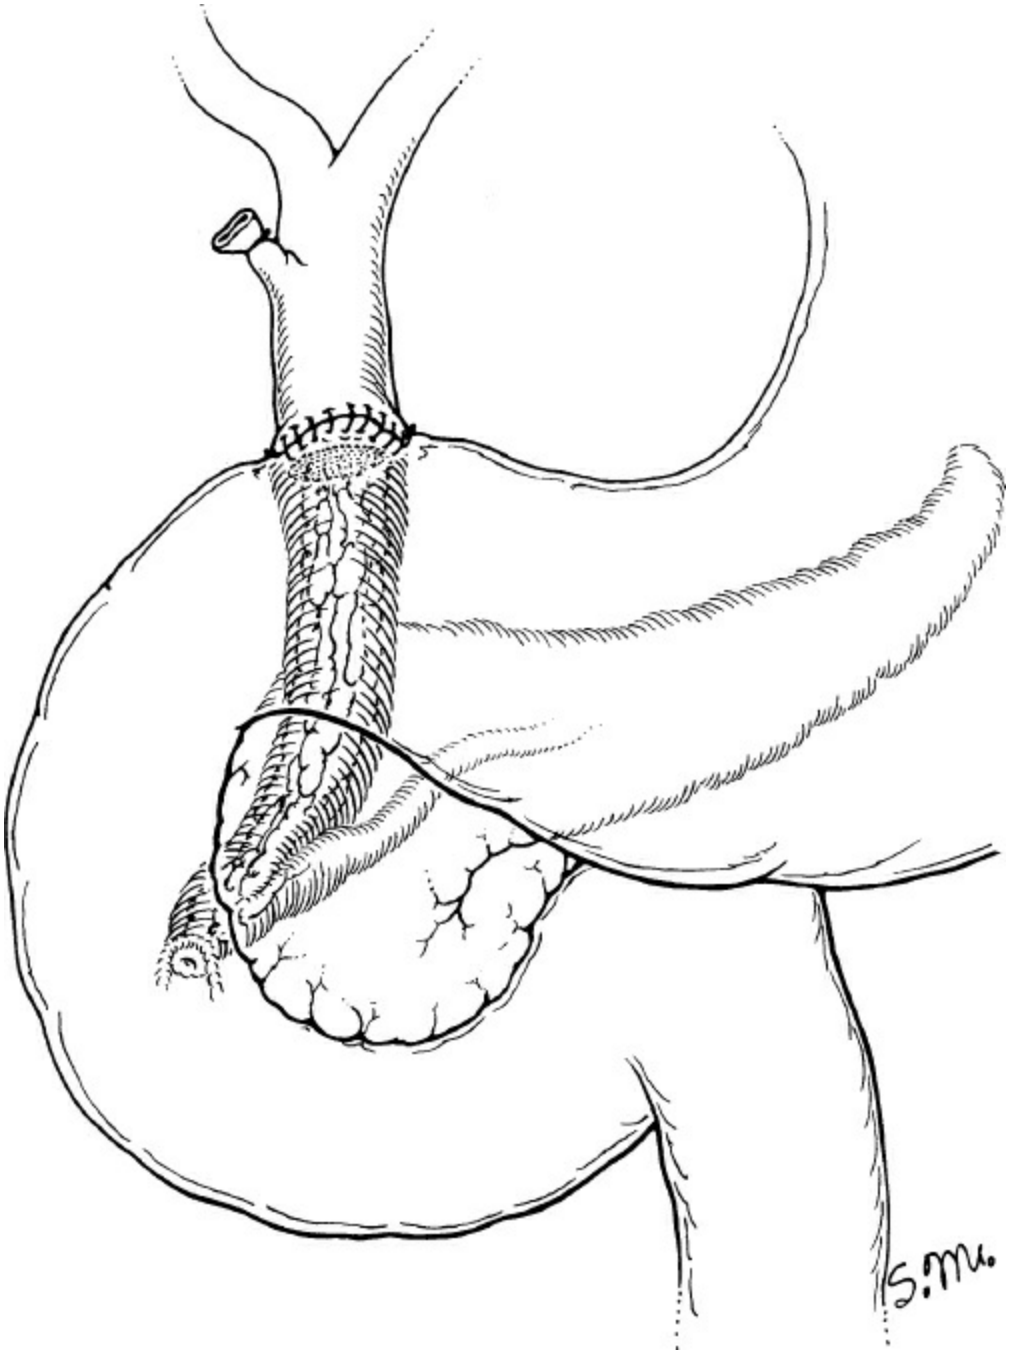

Figure 112.5. Example of the “sump syndrome,” with debris filling the distal bile duct.

SURGICAL TECHNIQUE

After the gallbladder is removed, the common bile duct is exposed by incising the overlying peritoneum. The common bile duct is opened in a longitudinal fashion in the supraduodenal location. An extended Kocher maneuver is routinely performed to enhance exploration of the common bile duct and performance of the choledochoduodenostomy (Fig. 112.6). If findings are compatible with the indications for choledochoduodenostomy,

the incision in the common bile duct is extended to 2.0 to 2.5 cm in the longitudinal axis (Fig. 112.7A). This incision usually will extend up to the common hepatic duct. After the common-duct exploration has been completed and proper mobilization and exposure have been obtained, a longitudinal incision is made in the postbulbar duodenum (Fig. 112.7A). It is wise to make this incision somewhat smaller than the expected stomal caliber, because the elasticity of the duodenal incision can result in excessive stretching and technical difficulty. Stay sutures are placed at the corners of the planned choledochoduodenal anastomosis. These sutures pass from the end of the duodenal incision (Fig. 112.6). The duodenal incision is bisected with a suture placed at the lower aspect of the choledochotomy in the midpoint of the adjacent duodenum (Fig. 112.7B). The posterior row of sutures is then placed with a 4-0 absorbable material, preferably polyglycolic acid, so that knots are placed on the internal aspect of the anastomosis. The anterior row of sutures is then placed without tying (Fig. 112.7C). Traction is used to hold the sutures until all are placed; this prevents inadvertent closure of the posterior wall. Then they are tied, beginning at the medial side of the anastomosis (Fig. 112.7D). It is unnecessary to use a double-layer closure, because a second layer would only cause narrowing of the anastomotic orifice. We routinely place a closed suction-type drain posterior to the choledochoduodenostomy.

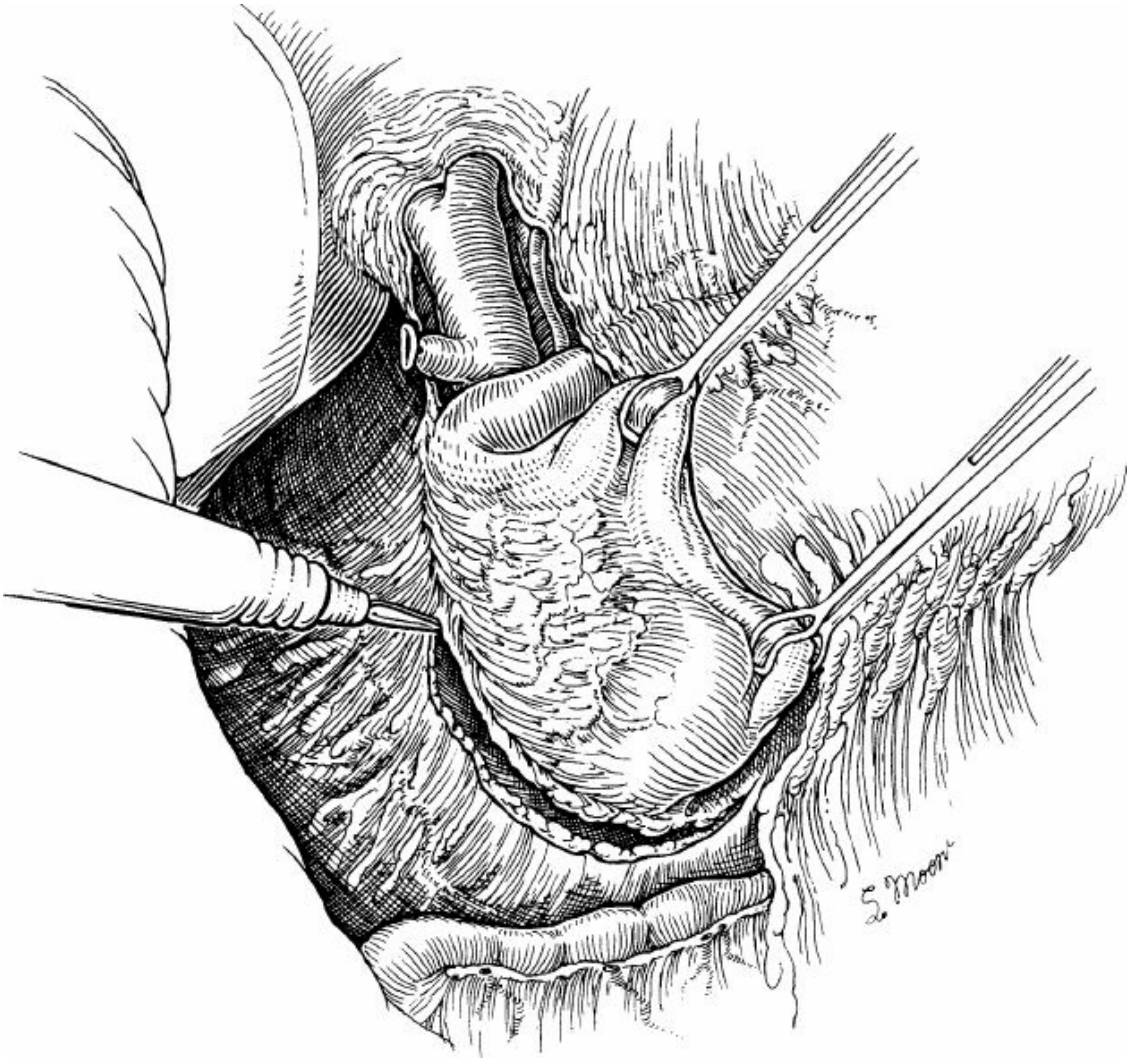

Figure 112.6. A wide Kocher maneuver is necessary for common-duct exploration, choledochoduodenostomy, and sphincteroplasty.

Transduodenal Sphincteroplasty

The usual indications for surgical decompression of the bile duct are anatomic causes of obstruction. It is important, however, to be aware of the various treatments used for Oddi sphincter dysfunction. The classification proposed by Geenan et al., which separates patients with unexplained biliary pain into subgroups based on the number of clinical laboratory and radiologic parameters, is used to guide diagnosis and therapy (Tables 112.1 and 112.2). Type I patients usually have ampullary stenosis. Routine need for Oddi sphincter manometry is not necessary in this group. If an endoscopic papillotomy cannot be performed, then surgical sphincteroplasty is necessary. Type II and III patients often need motility studies to clarify further the pathophysiology. Oddi sphincter

basal pressure is >40 mm Hg in 16% to 68% of type II patients and in 0% to 55% of type III patients, with tachyoddia being present in ~1% of each group (Fig. 112.2B). The wide variety of findings among the reports reflects variations of patient selection.

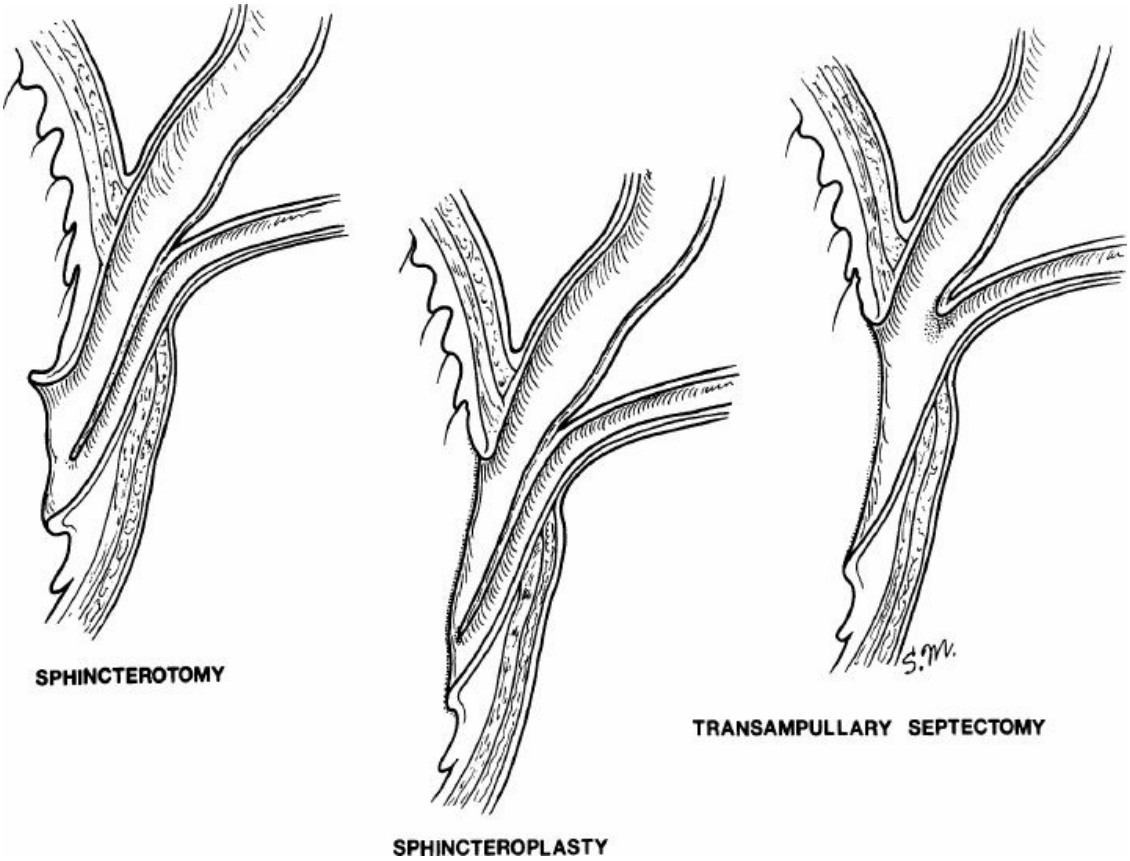

Figure 112.7. Various operations on the sphincter of Oddi.

The initial treatment of type II and III Oddi sphincter dysfunction is the oral administration of smooth-muscle relaxants, such as dicyclomine hydrochloride, cycline trinitrate-sorbide nitrate, and nifedipine. The most effective definitive therapy, however, is endoscopic papillotomy or surgical sphincteroplasty. It should be emphasized that patients in whom recurrent pancreatitis has developed as a result of Oddi sphincter dysfunction require division of the choledochal and pancreatic duct components of the Oddi sphincter. This should be performed by transduodenal sphincteroplasty and septectomy. Most of the patients, however, do not have pancreatitis and can be treated with endoscopic papillotomy.

TABLE 112.2 Absolute and Relative Contraindications for Open Biliary

Preoperative

Contraindication to general anesthesia
Cirrhosis complicated by portal hypertension
Late pregnancy
Suspected gallbladder cancer

Inoperative

Inability to identify anatomy
Multiple omental adhesions secondary to previous surgery
Biliary ductal abnormality on cholangiogram
Intraoperative metabolic acidosis

Type II patients with elevated basal sphincter pressure have a good response to papillotomy in 80% to 90% of reported cases, compared with 50% to 60% in those without a hypertensive sphincter. In a few studies, no correlation was seen between the clinical response to papillotomy and Oddi sphincter motility abnormalities. Type III patients have approximately a 50% response rate when they have manometric evidence of dysfunction.

The indications that will commonly be encountered for performing a transduodenal sphincteroplasty are stones impacted in the ampulla of Vater, papillary stenosis, and recurrent pancreatitis with multiple common bile duct stones. In general, surgical sphincteroplasty can be applied for treatment of Oddi sphincter dysfunction; however, it is usually recommended that this can be treated by endoscopic papillotomy unless specific contraindications to its performance exist or previous endoscopic treatment has failed. Transduodenal sphincteroplasty is contraindicated in patients with a common bile duct with a diameter >2 cm, a long distal common bile duct stricture, a peri-Vaterian duodenal diverticulum, or *severe* inflammatory changes involving the duodenal wall or the head of the pancreas. This procedure is more often performed in younger patients than is choledochoduodenostomy. Major morbidity has been reported in 20% of patients, compared with 11% for choledochoduodenostomy.

SURGICAL TECHNIQUE

Precise terminology should be used in describing the various operations on the Oddi sphincter. A sphincterotomy is essentially a cut made into the sphincter with no suturing of bile duct mucosa to the duodenal mucosa. A sphincteroplasty is the incision of the common portion of the Oddi sphincter with suturing of the mucosa of the common bile duct to the duodenum. The patient with recurrent pancreatitis may need to undergo further septectomy and septoplasty of the septum between the pancreatic duct and common bile duct. These variations are illustrated in Figure 112.8.

The patient is operated on in the supine position. Use of the radiolucent table facilitates fluoroscopic cholangiography or pancreatography if needed. The incision can be either midline or subcostal, although we prefer a subcostal incision. After removal of the gallbladder, an extended Kocher maneuver is performed. The assistant retracts the second portion of the duodenum medially and inferiorly. The peritoneum is incised along the lateral edge of the duodenum. Blunt dissection is used to develop a plane posterior to the head of the pancreas with countertraction provided by the assistant. This is an avascular space between the posterior pancreatic head, the perinephric fat, and the inferior vena cava. It is important to mobilize the third portion of the duodenum sufficiently to allow surgical access to the papilla and for closure of the duodenotomy without tension.

The papilla is normally located at the junction of the lower one third and upper two thirds of the second portion of the duodenum. Identification of its precise location is assisted by passing a balloon-tipped 4 or 6 French biliary Fogarty catheter through the cystic duct stump into the common duct and into the duodenum. By inflating the balloon with a small amount of saline, the surgeon can palpate the exact location of the sphincter mechanism. This allows for accurate placement of the duodenotomy and diminishes the length of the incision that is required. We perform a longitudinal duodenotomy, which permits extension of the incision in the cephalad or caudad direction, if necessary. In addition, when retractors are introduced or stay sutures are placed on the cut edge of the duodenum, any inadvertent increase in the size of the incision would be in a longitudinal dimension rather than medially into the pancreas. Once the duodenotomy is made, the balloon-tipped Fogarty catheter is seen coming out of the papilla (Fig. 112.9A). If the balloon-tipped Fogarty cannot be placed, the papilla can be identified by palpation or by manual inspection of the

duodenal mucosa. The minor papillary orifice is located cephalad ～2 cm.

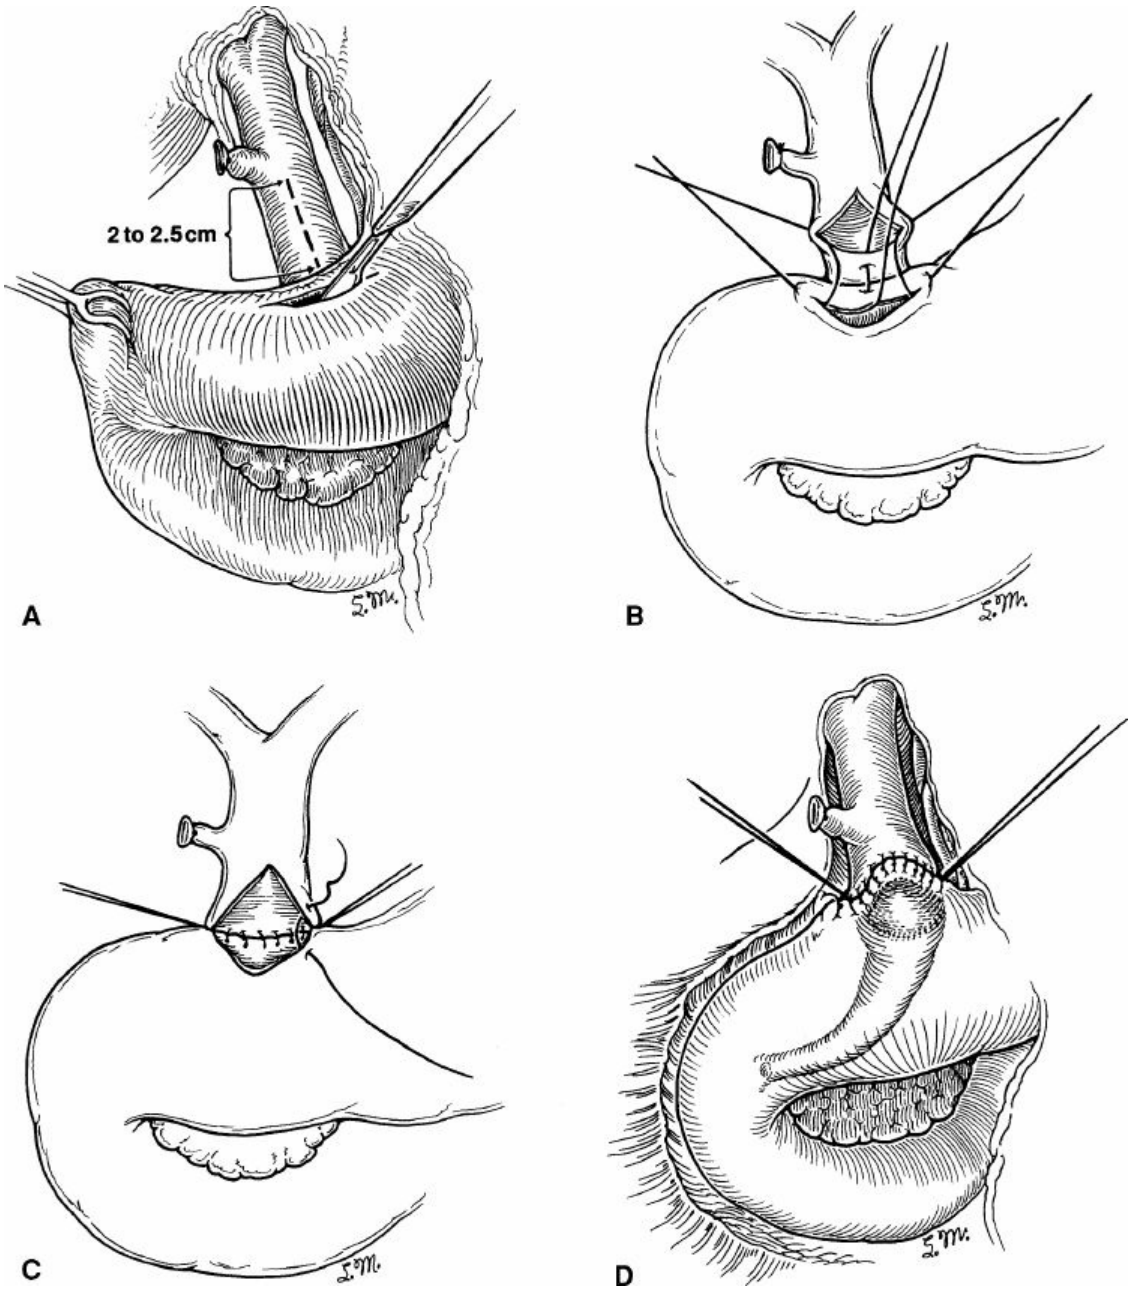

Figure 112.8. **A.** Proper incision of the bile duct for creation of choledochoduodenostomy. **B.** Initial sutures for choledochoduodenostomy. **C.** Posterior row of choledochoduodenostomy is completed. Anterior row is placed, but not tied, until all sutures are completed. **D.** Completed choledochoduodenostomy.

When the Oddi sphincter is identified, traction sutures are placed into the duodenal wall adjacent to, but not into, the ampullary complex to elevate and expose the ampulla. Care must be taken to avoid injury to the

duct of Wirsung, which enters on the medial aspect of the ampulla. We prefer to perform all of the subsequent steps with loupe magnification. The goal is to incise the intraduodenal portion of the distal bile duct completely and approximate the mucosa to the duodenal mucosa. The ampulla should be viewed longitudinally, with the cephalad end at the top—at 12 o'clock—and the caudad end at 6 o'clock. At approximately 11 o'clock, a needle-tipped electrocautery is used to make an initial incision in the sphincter over the Fogarty catheter (Fig. 112.9B). Absorbable sutures, 5-0 or 4-0, are then placed on each side of this incision and are held with fine hemostats and not tied. The incision is continued for ~5 mm, with placement of sutures approximately every 1.5 mm, being held with slight traction to open the bile duct (Fig. 112.10A). At this point, the balloon on the biliary Fogarty is deflated and the catheter is pulled back proximally, and a grooved director is passed into the sphincteric opening. The incision in the sphincter is then continued for the length of the intramural common bile duct, which may vary from as short as 6 mm to as long as 3 cm. The incision is stopped proximally, at the point that the common bile duct leaves the wall of the duodenum. Sutures are continued up to the apex stitch. The apex stitch is important, because it closes the opening on the most outside wall of the duodenum where the bile duct becomes extramural. Failure to place this stitch accurately can result in leakage of the sphincteroplasty. The grooved director is removed, and the opening of the pancreatic duct is identified between 4 and 6 o'clock on the medial aspect of the opening; only after the duct is visualized are the medial sutures placed above the pancreatic ductal opening, so as not to occlude it. The pancreatic duct orifice usually appears as a slit-like aperture. Frequently, it is necessary to cannulate the pancreatic duct opening with a lacrimal duct probe for precise localization (Fig. 112.10B). If the pancreatic duct cannot be identified, it may be necessary to give secretin (75 U/kg IV) to induce pancreatic secretion so that the orifice can be found. Precise localization is mandatory, as inadvertent closure of the main pancreatic duct orifice results in serious postoperative pancreatitis. If the pancreatic duct cannot be precisely identified, medial sutures are avoided between 3 and 6 o'clock.

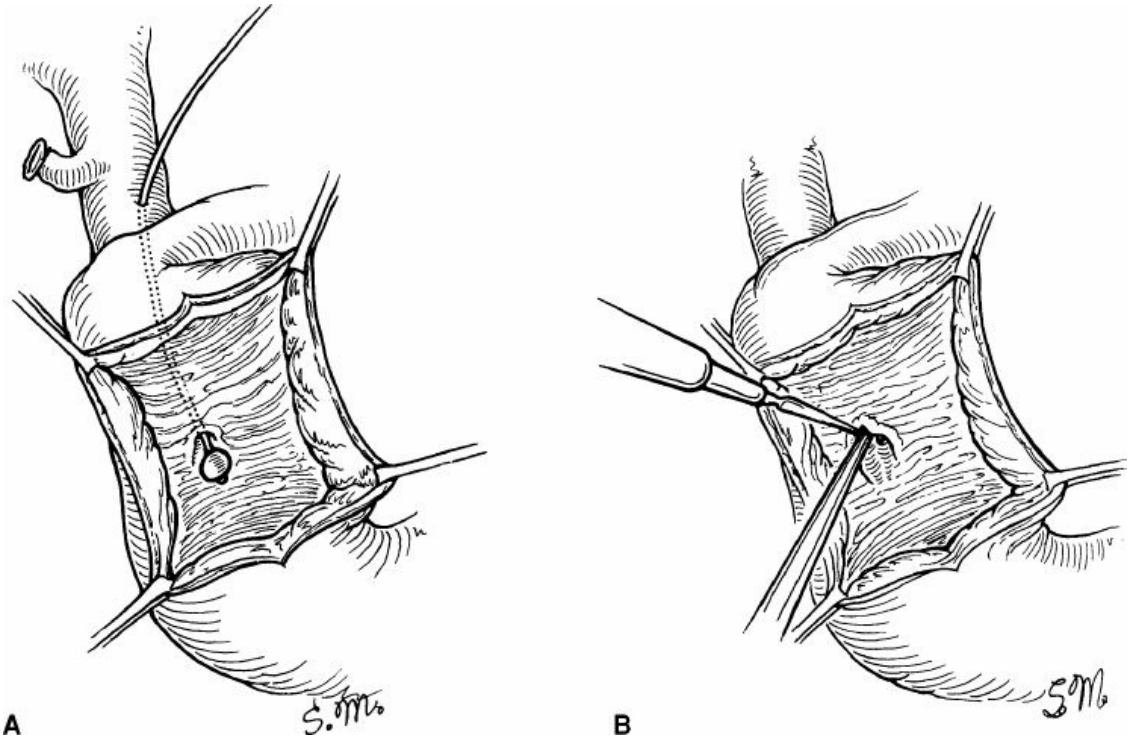

Figure 112.9. **A.** Identification of the ampulla of Vater with a biliary Fogarty catheter passed through either the cystic duct or the common duct. **B.** The initial incision is in the ampulla at 11 o'clock.

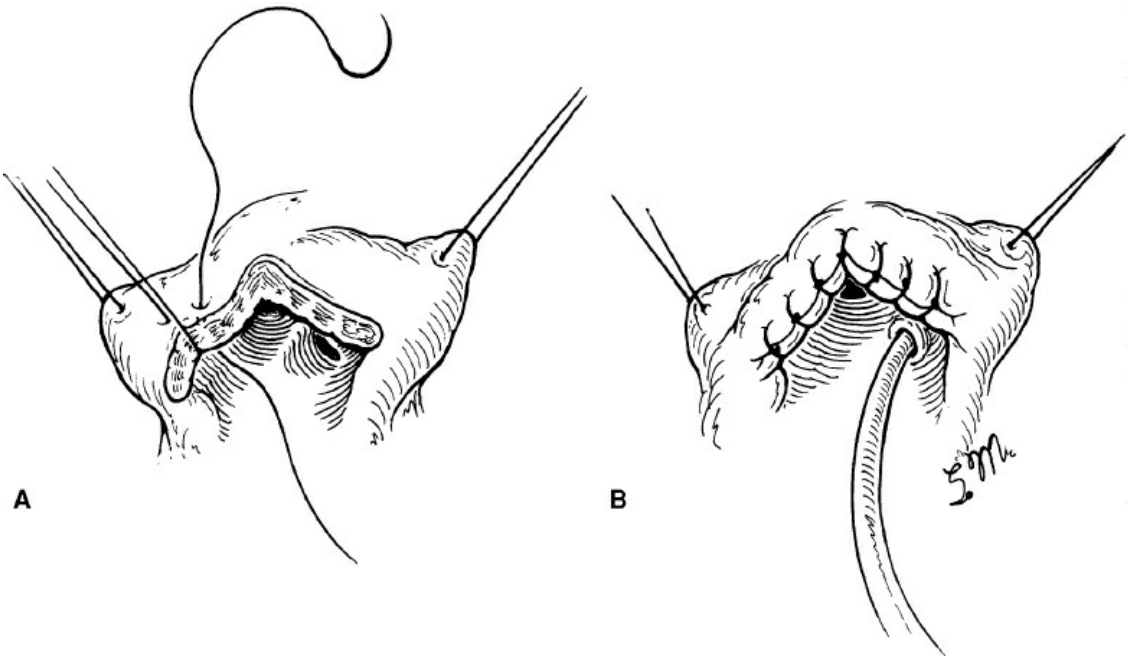

Figure 112.10. **A.** Initial sutures for the sphincteroplasty are placed 1.5 mm apart. **B.** Precise localization of the pancreatic duct.

If the patient has had recurrent pancreatitis and stricturing of the orifice

of the pancreatic duct, or if sphincter dysfunction is thought to exist, a septectomy is performed (Fig. 112.11). Although usually not necessary, pancreatography can be performed to exclude other pancreatic duct abnormalities, if not accomplished preoperatively. This is performed by back loading a 22-gauge angiocatheter onto a lacrimal duct probe. After the tip of the probe is inserted in the duct, the angiocatheter can be placed easily into the duct using the stiffer probe as a guide. Pancreatography is then performed, preferably under fluoroscopic guidance, by a gentle infusion of contrast, introduced by gravity with an elevation of the syringe to no more than 25 cm. The ductal septectomy is performed by inserting the lacrimal duct probe into the pancreatic duct and making an incision over this, removing the septum between the common bile duct and the pancreatic duct. Sutures are placed between the cut edge and the duodenal mucosa. Some surgeons do not use sutures unless bleeding is present. We prefer to complete a septoplasty with sutures. Care must be taken not to expand the incision in the septum into the pancreas to avoid focal postoperative pancreatitis. If this does occur, the defect can be repaired by reapproximating the edges of the duct and the duodenum.

Once the sphincteroplasty is completed, the common bile duct can be explored in a retrograde fashion if it has not already been explored. Choledochoscopy can also be performed through the sphincteroplasty. Placement of a T-tube is not usually necessary, even if a supraduodenal choledochotomy has been made, although it may be advantageous if a stone was impacted in the ampulla, resulting in edema and swelling.

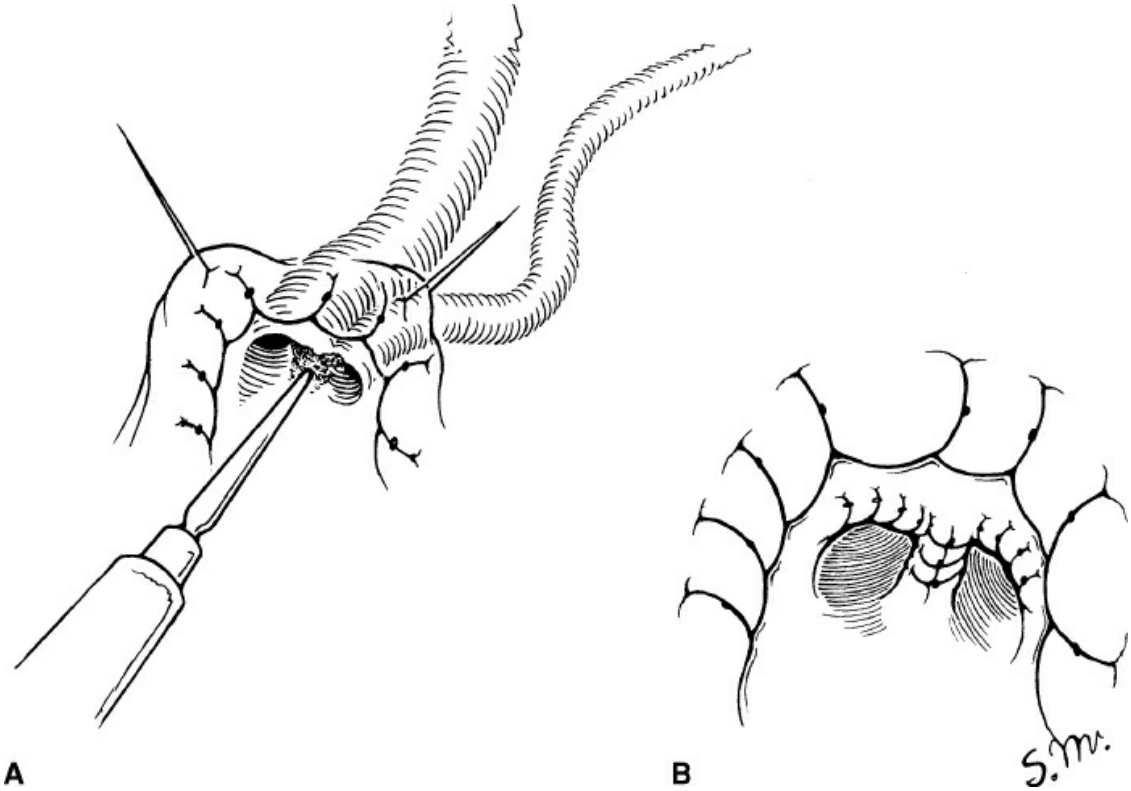

Figure 112.11. A. Septectomy. **B.** Sutures after the septectomy.

Duodenal closure is accomplished in a longitudinal fashion with a single layer of 3-0 silk Lembert sutures in normal cases (Fig. 112.12). A closed suction drain is placed posterior to the duodenum and pancreas. Transverse closure is not necessary, and, in our experience, it has been associated with more complications, particularly anastomotic leakage, duodenal fistula, and possible duodenal stenosis, as transverse closure may require a two-layer anastomotic technique.

Early complications of sphincteroplasty include acute pancreatitis (0.6%), bleeding of the incised papilla (0.3%), and leakage of the duodenal suture line (0.6%). Other major morbidity, however, is reported in ~20% of patients. Late sequelae include routine asymptomatic pneumobilia. Importantly, air in the biliary tree indicates a patent sphincteroplasty. Duodenal biliary reflex may occur and require antibiotics for cholangitis but usually does not cause symptoms or problems. Recurrent papillary stenosis may occur but is rare; if it is suspected, the patient should initially have an upper gastrointestinal barium study to look for barium reflux into the biliary system. If none is detected, stenosis of the sphincteroplasty is suggested, and ERCP is warranted.

Historically, the application of sphincteroplasty became more common after original observations of sphincterotomy performed surgically showed

poor results. The introduction of endoscopic papillotomy has allowed a larger study of simple sphincterotomy. The overall stenosis rate in these cases is ~2%. Surgical sphincterotomy is not the same as endoscopic sphincterotomy. The length of endoscopic sphincterotomy is shorter, and, theoretically, there is more edema that could result in early stenosis or occlusion, accounting for the historically less satisfactory results. Therefore, when indicated, surgical sphincteroplasty is still preferred over surgical sphincterotomy, and it may be appropriate in some patients rather than endoscopic sphincterotomy.

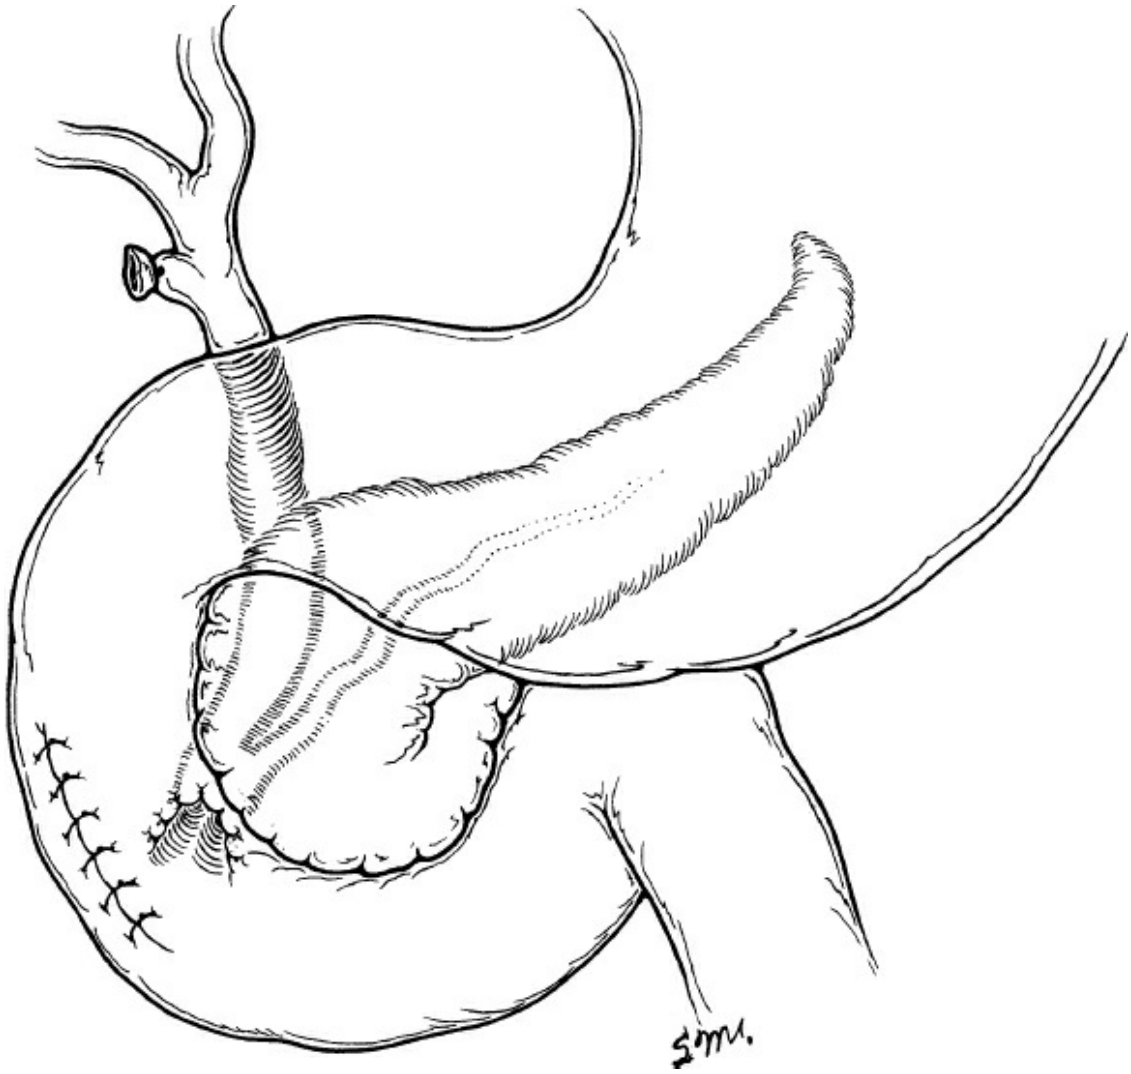

Figure 112.12. Completed sphincteroplasty with longitudinal closure of the duodenum.

POSTOPERATIVE MANAGEMENT

The patient normally has a nasogastric tube in place for ~3 days. It is removed on the 3rd or 4th postoperative day, depending on the output. A

diet is then initiated, first with liquids, with advancement to solid foods as tolerated. The drain is checked for bile and amylase content 24 hours after initiation of oral intake. It is removed if the amylase is normal and without bile. For patients who have had a sphincteroplasty, we check the amylase on the 1st and 3rd postoperative days. If pancreatitis occurs, postoperative care is altered accordingly, and bowel rest is prolonged. The normal hospital stay is ~6 days, although in the elderly patients with concurrent conditions, the length of stay may be as long as 7 to 10 days.

Pancreas Divisum

Pancreas divisum is the most common congenital abnormality of the pancreas. It is found in 5% to 10% of patients. It is caused by failure of fusion of the dorsal and ventral portions of the developing pancreas. In the majority of patients, this anomaly is of no clinical importance. In a certain subset of patients, however, estimated to be ~5% to 20%, pancreas divisum is a clinically important cause of abdominal pain, acute recurrent pancreatitis, or chronic pancreatitis. The frequency of pancreas divisum in patients with pancreatitis in recent studies is ~10%.

The cause of pancreatitis in this common anomaly is hypothesized to be caused by minor papillary insufficiency caused by papillary fibrosis and subsequent stenosis. This is supported by several lines of evidence, including pancreatitis changes being restricted to the dorsal pancreas in the upstream location, prolonged dilation of the dorsal duct in response to secretin, increased pressures at the minor ampulla, and the finding of fibrosis and scarring at the minor papilla in patients undergoing minor duct sphincteroplasty. It is unlikely that the presence of pancreas divisum alone is sufficient to place the patient at risk with pancreatitis. The once-thought putative relationship between divisum and pancreatitis or pancreatic pain does not exist.

The diagnosis is established by ERCP. MRCP is a noninvasive and accurate method of establishing the diagnosis. However, a negative MRCP does not exclude the diagnosis of divisum as the concordance with ERCP ranges from 50% to >70%. The accuracy of the MRCP may be improved by administration of secretin.

Not all patients with pancreas divisum benefit from surgical or endoscopic treatment. In patients with minimal symptoms, treatment with pancreatic enzymes may reduce pancreatic secretion and, hence, pain. Pain management referral may be necessary. Patients with acute pancreatitis are

estimated to benefit from either surgical minor sphincteroplasty or endoscopic minor papillotomy in 75% to 90% of the cases, compared to success rates of 40% to 60% in patients with chronic pancreatitis and 20% to 40% in patients with pancreatic pain alone with no biochemical or structural evidence of pancreatitis. Secretin-simulated ultrasonography may positively predict the outcome of minor papilla therapy, if there is significant dilation of the duct, defined as an increase in ductal diameter of 2 mm or more after the administration of this secretagogue.

There are two treatment options available for patients who are thought to have minor papillary stenosis: surgical sphincteroplasty or endoscopic therapy. The ability to measure minor papillary pressures via endoscopic techniques has improved the success rate of minor duct papillotomy in properly selected patients. Bradley and Stephan compared the results of surgical minor duct sphincteroplasty and endoscopic minor papillotomy. The results of the two techniques are comparable in patients with recurrent pancreatitis, with minor papillary sphincteroplasty successfully eliminating recurrent attacks in 92 of 109 patients (84%) and endoscopic papillotomy of the minor duct in 23 of 31 (74%). Patients with pancreatic pain alone do not do as well, with success in 62% after surgical treatment and 38% after endoscopic papillotomy. The restenosis rate is higher after endoscopic sphincterotomy (26.5%) than after surgical minor duct sphincteroplasty (6.7%), as is the rate of complications (14.6% and 4.2%, respectively).

Investigators have reported the success of endoscopic dilation and stenting of the minor papilla. It has been suggested that a good response to stenting might predict a good outcome of sphincteroplasty, particularly in patients with chronic “pancreatic” pain. Stenting can damage the pancreatic duct, and the long-term consequences of this treatment are not known. There is a significant increase in the rates of pancreatitis with minor duct stenting, and studies suggest that pancreatic duct stenting should be for no more than 4 to 5 days to minimize potential complications. Therefore, routine preoperative stenting, although scientifically appealing, has not been widely applied.

The technique of minor papillary sphincteroplasty is similar to that of sphincteroplasty of the ampulla of Vater. A midline or subcostal incision is used. A cholecystectomy is performed. A Kocher maneuver is completed. If the ampulla of Vater is easily palpated transduodenally, a longitudinal duodenotomy is made over this point. If the major papilla cannot be felt, then the passage of a biliary Fogarty into the cystic duct and hence into the

duodenum helps to identify the location of the major papilla and guide proper placement of the longitudinal duodenotomy. Once the duodenum is opened, the ampulla of Vater is identified. The minor papilla is usually 1.0 to 1.5 cm cephalad. Loop magnification helps, as the orifice is small. Occasionally, intraoperative injection of secretin is necessary to help the identification of the accessory pancreatic ductal opening. Once found, a stay suture is placed in either side of the duct. Using small lacrimal duct probes, the orifice is cannulated. The opening may be smaller than a 000 lacrimal duct probe (0.508 mm). The duct will run perpendicular to the wall of the duodenum. The needle-tip electrocautery on low settings is used to open the duct. An anastomosis is made between the accessory pancreatic duct mucosa and the duodenal mucosa using 5-0 or 6-0 absorbable suture. A stent is not routinely necessary, but may be helpful in situations in which one is concerned about excessive anastomotic swelling or early postoperative stenosis, or both. The duodenotomy is closed in a longitudinal fashion using interrupted 3-0 silk Lembert sutures. A closed suction drain is placed posterior to the duodenotomy.

Postoperative nasogastric suction is continued for 48 to 72 hours. Serum amylase should be checked on the 1st postoperative day and repeated if elevated. Oral feedings are begun on the 4th postoperative day if the amylase is normal and the patient has tolerated having the nasogastric tube out. Postoperative pancreatitis is not uncommon and usually resolves by the 5th postoperative day. If it does not, one may need to consider alternative forms of nutrition or perhaps perform a computed tomography scan to exclude a peripancreatic fluid collection or pancreatic phlegmon.

SUMMARY

The availability of ERCP and hence endoscopic papillotomy has limited the necessity for lateral choledochoduodenostomy or transduodenal sphincteroplasty. Specific instances occur, however, when the surgeon needs to perform these operations. The operations should be considered complementary. The lateral choledochoduodenostomy is preferred for larger bile ducts (>2 cm) or if there is a peri-Vaterian duodenal diverticulum of considerable size that would make performance of the transduodenal sphincteroplasty difficult. The exact choice of one of these operations depends on specific clinical situations.

EDITOR'S COMMENT

Ellison and colleagues have done an outstanding job summarizing the technical nuances and indications for endoscopic sphincterotomy, lateral choledochduodenostomy, and transduodenal sphincteroplasty. These are

complex procedures however, and rarely performed by the typical general surgeon who is most likely to perform a cholecystectomy. The old teaching from 20 years ago to “never leave the operating room following a cholecystectomy without a clear cholangiogram” is no longer an absolute. ERCP is now very common and readily available, even in many rural areas. The incidence of technical failure of ERCP is remarkably low in the modern era. Laparoscopic common bile duct exploration is a complex procedure requiring a skill set many general surgeons who perform laparoscopic cholecystectomy do not possess. The discussion in the current era has evolved to who should have a diagnostic and potentially therapeutic ERCP for suspected choledocholithiasis prior to cholecystectomy and who should instead have an intraoperative cholangiogram with intraoperative or postoperative ERCP if indicated.

A study examining the Nationwide Inpatient Sample between the years 1998 and 2008 identified 166,000 admissions for biliary disease. Mortality from biliary diseases that require ERCP decreased from 1.1% to 0.6% over the study interval. Open cholecystectomy decreased from 12.4% to 5.8%, and unsuccessful ERCPs decreased from 6.3% to 3.2%. It is interesting that endoscopic and surgical treatment of the sphincter of Oddi is now presented in a single chapter. The techniques described fall into a continuum of care and are complementary. The surgeon who can perform ERCP is in a great position to be able to offer the patient any of the techniques described in this chapter depending on what is best for the patient and their disease process.

Dysfunction of the biliary sphincter is often considered in patients with biliary-type pains after cholecystectomy when stones and other pathology are excluded. These patients are more likely to have had elective rather than emergency surgery, to have undergone cholecystectomy for symptoms in the absence of stones, and to have suffered from atypical biliary symptoms. In clinical practice, many patients undergo cholecystectomy for biliary symptoms even in the absence of stones before a diagnosis of sphincter of Oddi dysfunction (SOD) is considered. Functional gallbladder disorder (FGBD) and biliary dyskinesia are rarely diagnosed in countries other than the United States. A review of the Nationwide Inpatient Sample between the years 1991 and 2011 revealed that the incidence of cholecystectomy for biliary dyskinesia per 1,000,000 population per year in the United States increased from 43 to 89 ($p < 0.01$). Using registries from four developed countries in a similar time interval, the incidence of cholecystectomy was less than 25 per 1,000,000 population per year ($p < 0.01$). It has been suggested that the classification of SOD into three types is outdated and should be abandoned. Cotton et al. suggest that most patients with type I SOD suffer from organic stenosis rather than functional pathology and benefit from sphincterotomy for this reason. The EPISOD (Evaluating Predictors and Interventions in Sphincter of Oddi Dysfunction) trial was a multicenter, sham-controlled, randomized trial involving 214 patients with pain after cholecystectomy without significant abnormalities on imaging or laboratory studies, and no prior sphincter treatment or pancreatitis (type III

SOD). These patients were randomly assigned to undergo sphincterotomy or sham therapy at seven referral medical centers. One-year follow-up was blinded. In patients with abdominal pain after cholecystectomy undergoing ERCP with manometry, sphincterotomy versus sham did not reduce disability due to pain. The authors concluded that these findings do not support ERCP and sphincterotomy for patients considered to have type III SOD. Some authors advocate using the term "suspected functional biliary disorder" (suspected FBSD) for patients with post-cholecystectomy pain and some objective findings such as laboratory abnormalities (currently SOD type II).

Like SOD, pancreas divisum is a controversial clinical entity. Pancreas divisum is the most common congenital abnormality of the pancreas. This congenital anomaly is present in 2% to 10% of the population in autopsy studies. In most patients, pancreas divisum is asymptomatic. However, in a minority of patients, abdominal pain, acute pancreatitis, and recurrent acute pancreatitis can occur. A systematic review on endotherapy for pancreas divisum identified 22 studies including 838 patients. Patients with acute relapsing pancreatitis had the best outcomes with a median response rate of 76%. In patients with chronic pancreatitis, median response rates were lower at 42%. Patients with pancreas divisum and chronic abdominal pain without biochemical abnormalities had the lowest response rates at a median of 33%. Given the poor response rates to both endoscopic sphincterotomy and surgical minor duct sphincteroplasty, routine endotherapy in patients with chronic pancreatitis and/or chronic abdominal pain in the presence of pancreas divisum is not recommended, and needs to be individualized on a case-by-case basis.

The availability and success rate of ERCP has limited the necessity for surgical sphincteroplasty and lateral choledochoduodenostomy. There are still circumstances where one of these surgical procedures may be necessary, however. This is an excellent chapter that presents a thorough description of the anatomy, surgical technique, and current indication for these rarely performed but still important surgical procedures.

113 Primary Sclerosing Cholangitis

Nicholas J. Zyromski and Henry A. Pitt

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a complex and heterogeneous disease defined by inflammatory strictures of the intra- and extrahepatic biliary tree. This cholestatic disease follows a generally progressive clinical course that ultimately leads to fibrosis and hepatic cirrhosis. Biliary malignancy develops in 10% to 15% of PSC patients, and is often difficult to diagnose. Inflammatory bowel disease (IBD), as well as several other systemic inflammatory diseases are associated with PSC. The pathophysiology of PSC is incompletely understood; this fact is underscored by the lack of effective medical therapy. A wide variety of percutaneous, endoscopic, and surgical approaches are applied to PSC patients based on their anatomic and physiologic presentation. The principal goal of these interventions is to treat dominant strictures and delay disease progression. Liver transplantation is clearly the treatment of choice once hepatic cirrhosis develops. Current investigation is directed toward better understanding the molecular and genetic underpinnings of this challenging disease.

EPIDEMIOLOGY AND ASSOCIATED CONDITIONS

The incidence of PSC in the United States and Europe is approximately 1 to 6 per 100,000, and some current evidence suggests that this incidence may be on the rise. The disease incidence varies worldwide; PSC is much less common in southern climates and Asia. Approximately two thirds of PSC patients are male, with an average age in the 40s at the time of presentation. Many patients are asymptomatic at the time of diagnosis; however, large population series have shown that the median survival from time of PSC diagnosis to death or liver transplantation ranges from 12 to 18 years—substantially shorter than age-matched subjects in the general population. Strictures affect both intra- and extrahepatic bile ducts in 75% of PSC patients (Fig. 113.1); 15% have only intrahepatic and 10% have

only extrahepatic bile duct involvement.

Sixty to 80% of PSC patients are also afflicted by IBD, most commonly ulcerative colitis. PSC patients manifest Crohn disease to a lesser extent. In fact, the diagnosis of PSC is becoming more common in asymptomatic IBD patients. While IBD is quite common in conjunction with PSC, the converse is not true: only 10% of IBD patients will be diagnosed with PSC. Colon cancer is significantly more common in IBD patients with PSC; therefore, an aggressive screening colonoscopy schedule is warranted in this population. Interestingly, the risk of colon cancer in the PSC population persists, and may even increase, after liver transplant.

Several other autoimmune diseases are associated with PSC (Table 113.1). These diseases include type I diabetes mellitus, thyroiditis, ankylosing spondylitis, autoimmune hepatitis (AIH), and celiac disease. PSC has been associated with a moderately increased risk for developing acute pancreatitis and pancreatic adenocarcinoma.

Pancreatic adenocarcinoma
Cholangiocarcinoma
Hepatocellular carcinoma
Gallstones
Gallbladder polyps
Gallbladder carcinoma

[a]60–80% of PSC patients will have associated inflammatory bowel disease, most commonly ulcerative colitis.
[b]Colon adenocarcinoma is significantly more common in PSC patients than in the general population; this risk persists (and possibly increases) after liver transplant.

Gallbladder disease is common in PSC patients; the incidence of gallstones (>25%) and gallbladder polyps (5%) in PSC patients is substantially higher than that seen in the general public. Adenocarcinoma is detected in nearly half of the gallbladder polyps arising in the setting of PSC; this fact has led to the recommendation that cholecystectomy should be performed in any PSC patient diagnosed with gallbladder polyps. Some authorities recommend annual screening with gallbladder ultrasound. Hepatocellular carcinoma (HCC) may also develop in PSC patients with end-stage liver disease. Radiologically occult HCC is detected in 2% to 4% of explanted livers from PSC patients undergoing liver transplant. Cholangiocarcinoma (CCA) develops in as many as 15% of PSC patients.

Screening for and diagnosis of CCA are discussed in more detail below.

ETIOLOGY/PATHOPHYSIOLOGY

PSC etiology is incompletely understood, but almost certainly represents a multifactorial process, with genetic, immune, bacterial, and other factors all playing part in disease development.

Genetic

A hereditary component to PSC clearly exists, as first-degree relatives of PSC patients have nearly a fourfold increased incidence of PSC diagnosis compared to the general population. Current work has identified a genetic pattern in PSC that is complex and polymorphic. The major histocompatability complex (MHC) found on the short arm of chromosome 6 encodes many of the aberrant gene loci identified in PSC patients. In addition, other non-MHC genes such as tumor necrosis factor alpha (TNF-α) have also been implicated in the disease etiology. Specific gene mutations are associated with discrete biologic features such as early age of onset or rapid disease progression.

Immune

The common association of IBD and other autoimmune diseases in PSC patients has led many to consider autoimmunity as an etiology. Evidence supports the concept of the biliary epithelial cell both as a target of attack, as well as an active participant in the immunologic cascade. Commonly found autoantibodies in PSC patients include atypical antineutrophil antibody—p-ANCA (found in 88%), antineutrophil antibody, and anticolon antibody.

Bacterial

The coexistence of PSC and IBD also supports the hypothesis of a bacterial etiology. According to this theory, bacterial translocation through intestinal epithelial permeability may lead to Kuppfer cell activation, which in turn leads to production of proinflammatory mediators such as TNF-α. As the subsequent biliary inflammation resolves, variable fibrosis of the biliary tree ensues. Contemporary interest in the gut microbiota has suggested a putative link between the microbiota, enteroportal circulation, and PSC development, particularly in the setting of IBD. Finally, a few

studies have documented the fact that antibiotic treatment is associated with decreased circulating alkaline phosphatase (ALP) and Mayo risk score. While the long-term effects of this antibiotic treatment strategy remain to be seen, these data lend some credence to the concept of bacteria as an etiologic factor.

Pathophysiology

Histologic analysis of PSC documents periductal fibrosis that apparently accumulates in a progressive fashion. This fibrosis affects most commonly medium and large bile ducts, and results in the typical radiographic picture of alternating stricture and dilation. The histologic appearance of mixed inflammatory cell infiltrate (lymphocytes, plasma cells, and neutrophils) around disorganized portal duct proliferation is recognized as "onion-skinning" (Fig. 113.2).

Small Duct PSC

An increasingly recognized sub-type of PSC involves isolated inflammatory strictures of the small ducts alone. In fact, as many as 6% of patients with chronic cholestasis and normal cholangiogram images may have small duct PSC. In these patients, liver biopsy is recommended to secure the diagnosis. Small duct PSC patients have a better prognosis in general, with longer survival and lower risk of CCA development. Over time, though, up to 20% of small duct PSC patients may progress to large duct involvement.

CLINICAL PRESENTATION

The clinical presentation of PSC patients is widely variable, consistent with the broad disease heterogeneity. Many PSC patients present first with typical biliary symptoms of right upper quadrant pain, pruritus, and fatigue. A smaller percentage of patients with intrahepatic bile duct involvement initially present with signs and symptoms of end-stage liver disease and hepatic failure. Patients with isolated extrahepatic biliary strictures may have jaundice as the first clinical sign. A small percentage of PSC patients with strictures and jaundice may present with cholangitis, and the clinical symptoms of fever, chills, and night sweats. As many as 40% of PSC patients are asymptomatic and come to PSC diagnosis from workup of abnormal liver function tests. The IBD patient screened for liver

disease falls into this latter category.

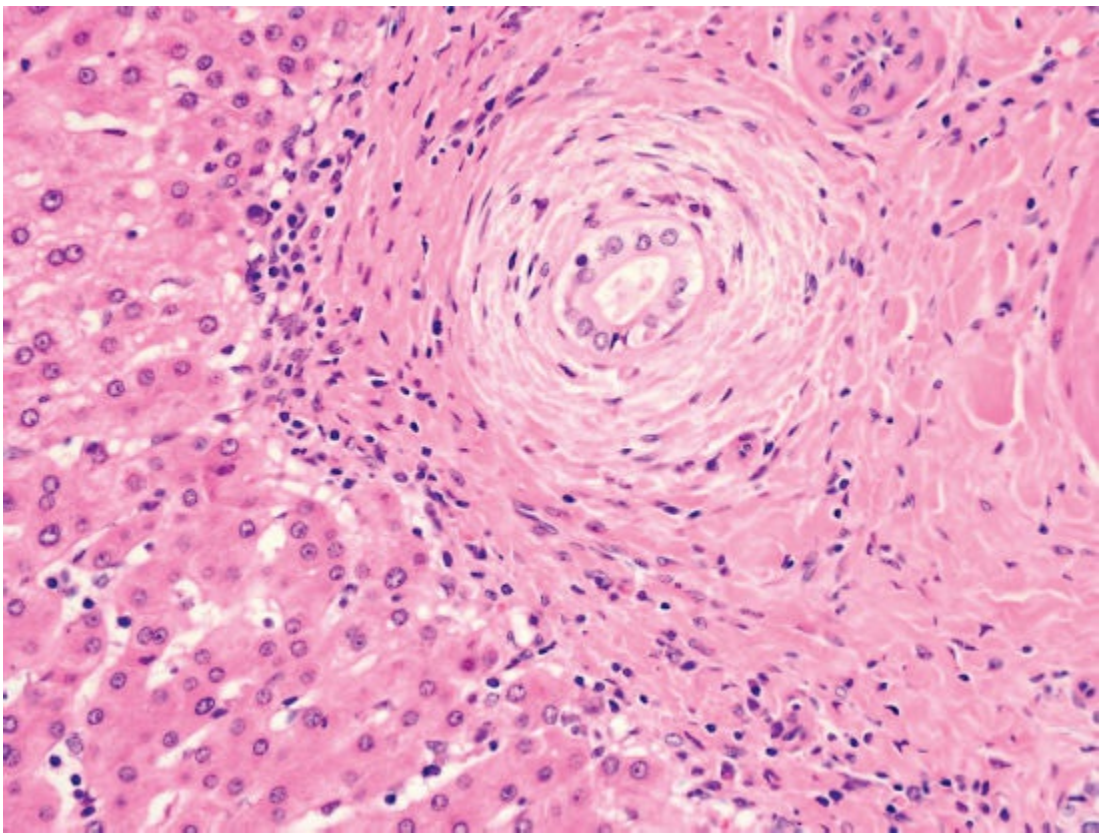

Figure 113.2. Micrograph of resected PSC specimen demonstrating “onion skin” concentric fibrosis surrounding bile duct. (Courtesy of Dr. O. Cummings, Indiana University Department of Pathology.)

Differential Diagnosis

The differential diagnosis of patients with biliary stricture includes numerous etiologies such as infectious, mechanical, toxic, inflammatory, immune, neoplastic, and ischemic. Table 113.2 outlines the differential diagnosis of PSC.

Laboratory Evaluation

Elevation of liver chemistry tests is common; the most frequently aberrant serum chemistry is ALP. In patients with intrahepatic duct involvement, ALP may be the only abnormal laboratory test. Values of ALP vary over the disease course; importantly, normal ALP does not exclude a diagnosis of PSC. Total bilirubin concentration is usually normal, unless the patient has significant biliary obstruction. Transaminase concentration is also commonly within normal limits, although some patients may demonstrate

two- to threefold elevation of circulating transaminases. Transaminase elevation may be associated with concomitant acute biliary obstruction, or may indicate overlap with AIH. Serum autoantibody production is nonspecific in PSC; but, may be useful in diagnosing AIH or immunoglobulin G4 (IgG4)–associated cholangitis.

Radiologic Evaluation

Cholangiography is the cornerstone in diagnosis of PSC. Classic cholangiographic features include multifocal strictures of intra- and extrahepatic bile ducts with alternating normal and dilated segments. Currently, magnetic resonance cholangiopancreatography (MRCP) is the gold standard for radiologic diagnosis. Advantages of MRCP include avoidance of radiation exposure, visualization of intrahepatic bile ducts proximal to high-grade strictures, and morphologic assessment of the liver. In addition, MRCP permits imaging assessment of other abdominal structures. On the other hand, MRCP is quite expensive, may be of variable quality at different centers, is challenging for some patients to tolerate, and is a purely diagnostic test (Fig. 113.3).

Endoscopic retrograde cholangiopancreatography (ERCP) has classically been used to define PSC bile duct anatomy. ERCP accurately demonstrates the intra- and extrahepatic biliary tree over 95% of the time. In addition, ERCP also permits intervention such as stenting, brushing, and biopsy. Currently, ERCP use has been focused toward patients who require these interventions, as the test has a small, but real, potential for complications. Complications of ERCP include cholangitis, visceral perforation, pancreatitis, and hemorrhage (Fig. 113.4).

Percutaneous transhepatic cholangiography (PTC) is used less frequently in current practice. The anatomic changes of PSC render PTC technically challenging even for an experienced interventional radiologist. In selected cases, PTC may be complementary to ERCP, especially in the PSC patient who requires biopsy and/or stenting.

Liver biopsy is performed liberally in PSC patients. As mentioned, liver biopsy may help secure the diagnosis of small duct PSC. Furthermore, in patients with established PSC, liver biopsy is essential to document the degree of hepatic fibrosis. The possibility of lobar atrophy/hypertrophy should be considered when performing a liver biopsy.

TABLE 113.2 Differential Diagnosis of Bile Duct Stricture

Infections:
Cholangitis/chronic bile duct infection
AIDS (CMV/cryptosporidium)

Mechanical:
Choledocholithiasis
Trauma
Bile duct injury
Stenting
Primary biliary cirrhosis

Toxic:
Biliary toxin exposure

Inflammatory/Immune:
Autoimmune hepatitis
IgG4 associated cholangitis
Graft-versus-host disease
Chronic pancreatitis

Neoplastic:
Cholangiocarcinoma
Papillary tumor
Choledochal cyst

Ischemic:
Ischemia biliopathy
Portal vein thrombosis

BILIARY MALIGNANCY IN PSC

Without doubt, the substantially increased risk and difficulty diagnosing CCA represent the most challenging aspects of PSC management. CCA is diagnosed in 1% to 2% of PSC patients annually, with a lifetime risk of 10% to 15%. About half of patients developing CCA will be diagnosed within 1 year of presentation with PSC; many of these patients are diagnosed concurrently. Despite aggressive preoperative screening protocols, unsuspected CCA is identified in 3% to 9% of explanted livers at the time of transplantation for PSC. This CCA incidence represents an increased risk of up to 160 times that of the general population; however, no accurate criteria exist with which to identify a high-risk group amenable for screening. CCA is observed more frequently in females with

PSC, and in those with concomitant IBD. After the first 12 to 18 months, no correlation exists between CCA diagnosis and duration of PSC or the presence of hepatic cirrhosis.

The diagnosis of CCA is challenging in the setting of multiple intra- and extrahepatic bile duct strictures, and outcomes after CCA diagnosis are uniformly poor. In light of the fact that no high-risk group within the PSC population has been identified, rational screening protocols have been advanced. For example, Mayo Clinic authorities recommend annual screening with MRCP or ultrasound, and measurement of serum carbohydrate antigen 19-9 (CA 19-9). In the absence of jaundice or cholangitis, CA 19-9 concentration greater than 130 U/mL has approximately an 80% sensitivity and 98% specificity to detect CCA. Endoscopic evaluation may be applied selectively to patients with increasing CA 19-9 or those in whom jaundice or dominant strictures develop or progress.

Autoimmune	IgG4-related sclerosing cholangitis Autoimmune sclerosing cholangitis Systemic vasculitis
Benign	Intrahepatic stone disease
Malignant	Cholangiocarcinoma
Infection	Cholangiopathy related to AIDS Recurrent pyogenic cholangitis
Injury	Post cholecystectomy Abdominal trauma
Vascular	Hepatic artery thrombosis Portal hypertension Chemoembolization Sickle cell disease
Other	TPN Cholangiopathy of critical illness Histiocytosis X

Figure 113.3. Magnetic resonance cholangiopancreatography of patient with bilobar intra- and extrahepatic biliary strictures.

While tissue histology is the gold standard for making the diagnosis of CCA, the sensitivity of biliary brushings and biopsy obtained at the time of ERCP is less than 40%, (though specificity is almost 100%). Recently, techniques such as fluorescence in situ hybridization (FISH) and digital subtraction analysis (DSA) have been applied more liberally. These tests rely on the fact that chromosomal abnormalities are present in approximately 80% of biliary malignancies. Analysis of aneuploidy by FISH has been subdivided into trisomy (3 copies of chromosomes 7 or 3), tetrasomy (4 copies of all probes), and polysomy (gain of 2 or more chromosomes visualized in 5 or more cells). Each of these strata are

associated with increased risk of CCA, and patients with a dominant biliary stricture and polysomy were found to have an 88% incidence of CCA. A number of evolving technologies hold promise for evaluation of the biliary tree. Some of these include cholangioscopy, endoscopic and intraductal ultrasound, and confocal laser endomicroscopy. Proteomic and metabolomic analysis of serum, bile, and urine may aid CCA diagnosis in the future. The role of positron emission tomography (PET) in diagnosis of biliary malignancy has recently been evaluated; unfortunately, sensitivity and specificity of this test are poor.

Complete surgical resection offers the best prognosis for those patients developing CCA in the face of PSC. Clinicians should therefore have a low threshold for operative exploration in patients with recurrent dominant strictures, those with cellular atypia or dysplasia on cytologic brushing, and those with polysomy on FISH analysis.

PSC patients have a significantly increased risk of developing gallbladder neoplasia, though the precise incidence of this problem is difficult to quantitate. Annual gallbladder ultrasound is recommended by some experts as part of a screening protocol. Cholecystectomy is indicated for ANY size lesion identified, as gallbladder cancers have been identified even in small (<1 cm) polyps in PSC patients. The risk of cholecystectomy must be considered in the context of the generally increased perioperative risks attendant to end-stage liver disease.

MANAGEMENT

Medical Therapy

A variety of agents have been tested with the goal of attenuating the pathologic course of PSC. Some of these compounds include the hydrophilic bile acid ursodeoxycholic acid (UDCA); corticosteroids; immunosuppressive agents such as tacrolimus, cyclosporine, and methotrexate; antifibrotic agents such as pentoxifylline and pirfenidone; and TNF-α inhibitors. To date, none of these medical therapeutics have effectively slowed PSC progression, prolonged survival, or decreased the incidence of CCA.

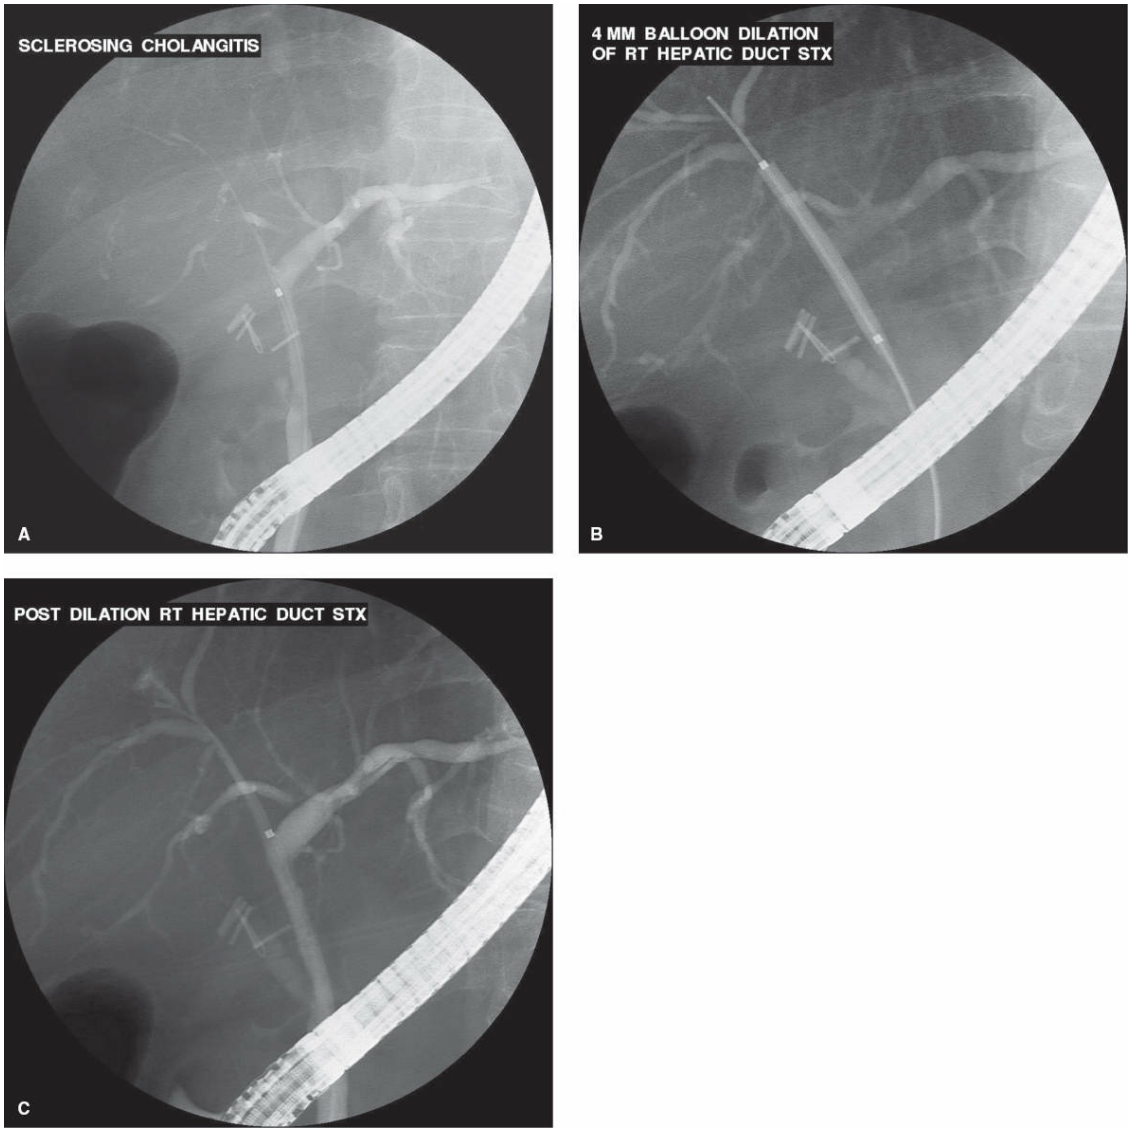

Figure 113.4. Endoscopic retrograde cholangiopancreatography of patient with dominant right hepatic duct stricture. **A.** Preintervention. **B.** During endobiliary balloon dilatation. **C.** Postdilatation documenting widely patent right hepatic duct. (Images courtesy of Dr. Stuart Sherman, Indiana University Division of Gastroenterology.)

The most widely studied agent in PSC is UDCA. An early, large, prospective randomized trial demonstrated improvements in serum liver chemistry values but failed to show improvement in liver histology or transplant-free survival with low-dose (12 to 15 mg/kg daily) UDCA. Four subsequent prospective studies have been performed using increased doses of UDCA; none has shown definite benefit, and one was halted prematurely due to increased risk of disease progression. Collective analysis of these studies by meta-analysis showed no beneficial effect on

symptoms, serum liver chemistry values, quality of life, or transplant-free survival. Currently, the American Association for the Safety of Liver Disease recommends against the use of UDCA in PSC patients; the European Association for the Study of Liver Disease does not recommend for or against UDCA prescription.

Targeted therapy with antifibrotic agents, TNF-α inhibitors, T-cell modulators, and inhibitors of "toxic bile" formation (Farnesoid X agonists) all are in conceptual or early investigative phases.

Endoscopic and Percutaneous Therapy

Dominant strictures are defined as narrowing ≤1.5 mm in the common bile duct or ≤1 mm in the common hepatic duct. Both percutaneous transhepatic stenting and endoscopic dilatation with or without stenting have been used to treat dominant strictures in PSC. Endoscopic techniques have advanced to the point that currently, the majority of tertiary centers treating PSC patients favor the endoscopic approach. No randomized studies have compared results of balloon dilatation alone versus dilatation and stenting. Clinical response can be demonstrated in up to 80% of patients after endoscopic balloon dilatation. This fact, in conjunction with the increased risk of complication associated with stenting, has limited placement of endobiliary stents to patients in whom balloon dilation fails to maintain luminal patency. Periprocedural antibiotic administration is important, and stenting duration of 6 to 8 weeks is probably optimal to avoid cholangitis. Some patients require extended periods of stenting (up to 12 months) before stricture resolution has been achieved. Complications of endoscopic therapy arise in approximately 10% of patients and include bleeding, perforation, pancreatitis, and cholangitis. The majority of these complications may be treated medically. Advanced endoscopic techniques such as cholangioscopy and intraductal ultrasound are practiced more routinely at high-volume biliary centers, and may be helpful particularly in diagnosing CCA.

Percutaneous interventional radiology approaches are used less frequently but they remain important therapeutic adjuncts in selected patient groups including those who have had previous biliary bypass or surgical bariatric procedure (Roux-en-Y gastric bypass or duodenal switch).

Surgical Resection

Surgical resection is applied to select PSC patients. Those PSC patients with CCA localized to the extrahepatic bile ducts may benefit from resection of the extrahepatic biliary tree. Those with Bismuth IIIa or IIIb level CCA may be candidates for resection of the extrahepatic biliary tree with hepatectomy. Figure 113.5 illustrates the Bismuth classification of CCA. Finally, highly selected PSC patients with dominant extrahepatic strictures and no hepatic cirrhosis may benefit from resection of the extrahepatic biliary tree. In these patients, surgical resection provides durable relief of jaundice and definitively confirms or excludes the diagnosis of cholangiocarcinoma. Furthermore, resection of a dominant extrahepatic bile duct stricture may delay the progression of hepatic cirrhosis and need for liver transplantation.

Ahrendt and colleagues performed an early, classic study in which they evaluated 146 PSC patients managed by surgical resection, percutaneous or endoscopic treatment, medical therapy alone, and transplantation. In noncirrhotic patients, the overall 5-year survival (85% vs. 59%) and transplant-free survival (82% vs. 46%) were significantly longer in the resection group compared to those managed endoscopically (Fig. 113.6A and B). No surgically treated patient developed cholangiocarcinoma with follow-up more than 5 years. In this series, patients with hepatic cirrhosis survived longer after transplantation than after resection or endoscopic management. In a follow-up analysis by Pawlik et al., 77 patients had outcomes comparable to hepatic transplantation, and none developed cholangiocarcinoma. In addition, only 10% even required a liver transplant.

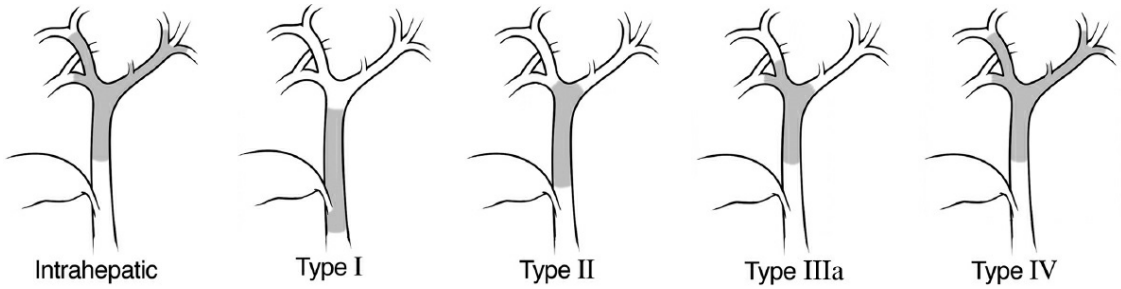

Figure 113.5. Bismuth classification of cholangiocarcinoma.

Surgical Technique

Preoperative preparation for resection of the extrahepatic biliary tree includes appropriate imaging, biliary drainage, nutritional consideration, and antibiotic prophylaxis. High-quality cross-sectional imaging

(computed tomography or magnetic resonance imaging) with intravascular contrast documents hepatic vascular anatomy as well as the presence of liver atrophy/hypertrophy. Most (approximately 80%) patients with dominant strictures manifest hepatic duct bifurcation involvement; therefore, percutaneous stents are placed preoperatively into both the right and left hepatic ducts. This maneuver greatly facilitates dissection of the hepatic bifurcation and provides a stenting tract for the reconstructive hepaticojejunostomy. Bile cultures permit tailoring of perioperative antibiotic therapy to specific bacteria cultured from the bile. Attention should be given to identification and proper treatment of resistant organisms, which are more prevalent in patients who have required multiple instrumentation. Antibiotics should be continued postoperatively to treat the mild cholangitis that occurs with intraoperative stent manipulation and cholangiography. Antibiotics may be discontinued when the patient has been afebrile for 24 hours.

The general approach to extrahepatic biliary tree resection with Roux-en-Y hepaticojejunostomy over transhepatic stents is illustrated in Figure 113.7. An upper midline incision provides excellent exposure of the liver provides flexibility for positioning of the transhepatic stents on the abdominal wall. Careful abdominal exploration includes intraoperative ultrasound, which may be particularly helpful in the case of nonstandard hepatic vascular anatomy. Any suspicious lymph nodes are biopsied for frozen-section analysis; evaluation of celiac, portal, and retropancreatic lymph nodes is an important part of thorough abdominal exploration. The hepatic flexure of the colon is mobilized from the pancreatic head, which exposes the right transverse mesocolon for later delivery of the Roux limb. A wide Kocher maneuver provides critical exposure of the porta hepatis.

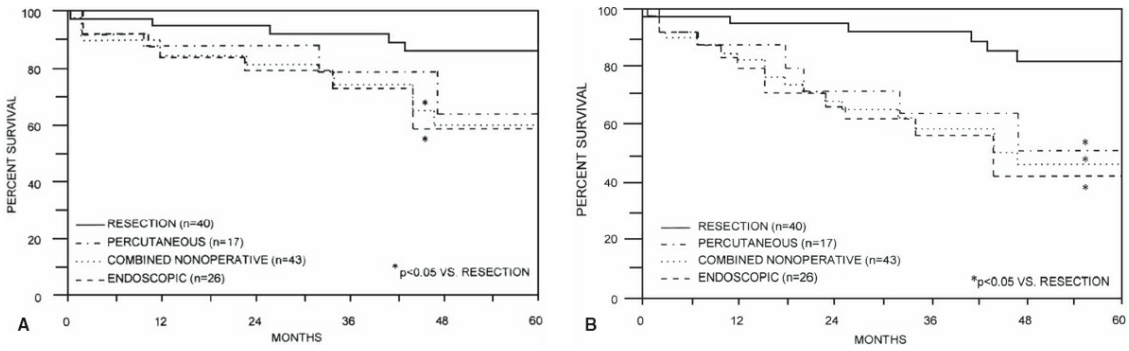

Figure 113.6. Kaplan–Meyer curves documenting overall (**A**) and transplant-free (**B**) survival curves for noncirrhotic patients undergoing resection, percutaneous, and endoscopic treatment of dominant extrahepatic biliary strictures in PSC. (From Ahrendt

SA, Pitt HA, Kalloo AN, et al. Primary sclerosing cholangitis: resect, dilate, or transplant? *Ann Surg* 1998;227(3):412–23; with permission from Wolters Kluwer Health, Inc.)

Cholecystectomy is performed if the gallbladder is in situ, and the common bile duct is divided at the cranial portion of the pancreatic head. After oversewing the distal common bile duct at the pancreas, dissection is carried proximally by lifting the bile duct off of the portal vein. It is important to anticipate the right hepatic artery at this point of the dissection, as its usual course is posterior to the common hepatic duct. Inflammation inherent to PSC may be compounded by instrumentation from multiple endoscopic procedures. This challenging portion of the dissection should be performed sharply. Should the right hepatic artery be involved to the degree requiring resection, the inferior mesenteric vein is an excellent reconstruction conduit that is readily available in the exposed operative field. The right and left main hepatic ducts are then divided proximal to the bifurcation. Frozen-section analysis of the proximal and distal bile duct margins rules out malignant transformation. The preoperatively placed transhepatic stents are exchanged retrograde for large (14–20 French, depending on the size of the bile ducts), soft Silastic catheters. Exchanging these stents over a guidewire ensures safe maintenance of the tract.

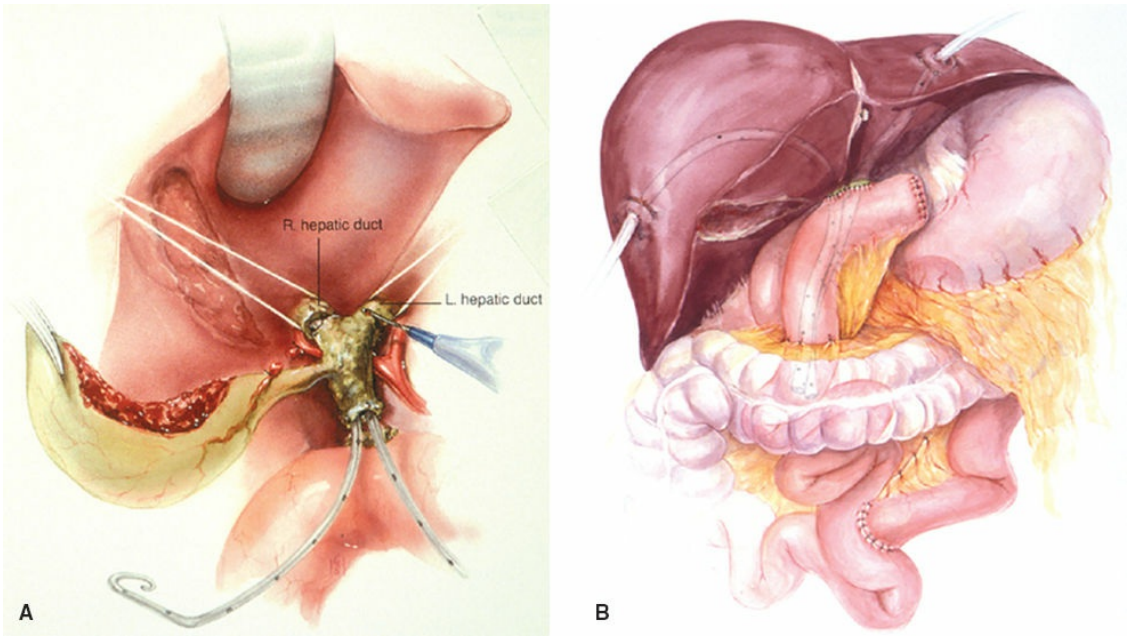

Figure 113.7. Overview of extrahepatic biliary tree (**A**) resection and (**B**) reconstruction with Roux-en-Y hepaticojejunostomy over transhepatic biliary stents.

The Roux limb is prepared by dividing the jejunum 40 cm distal to Treitz ligament. Carefully dividing the small bowel mesenteric arcade provides additional length to the limb, which is particularly helpful in patients with larger body habitus or short small bowel mesentery. The Roux limb is then brought through the transverse mesocolon to the right of the middle colic vessels, where it should lie in the hilum with no tension. Bilateral cholangiojejunostomies end-to-side are created with interrupted, absorbable sutures over the Silastic catheters. Chromic sutures placed at the stent exit site from the liver minimize bile leakage; titanium clips placed at the stent exit from the liver provide landmarks to facilitate future radiologic stent exchange.

Completion cholangiography is performed in the operating room to ensure optimal stent positioning and exclude anastomotic leak. The Silastic stents are brought through the abdominal wall in a subcostal position away from the incision. Incorporation of a gentle curve to stent passage through the abdominal wall is important to avoid kinking of the stent and to facilitate subsequent radiologic stent changes. Closed-suction drains are placed behind the cholangiojejunostomies and at the site of stent exit from the liver. Postoperative management and complications are described below.

Liver Transplantation

Indications for liver transplant in PSC patients are similar to those for patients with end-stage liver disease from other etiology, and generally include refractory complications of portal hypertension and liver insufficiency. Approximately 5% of all liver transplants in the United States are performed for end-stage liver disease secondary to PSC.

The Mayo model is a mathematical construct incorporating serum bilirubin, degree of hepatic fibrosis, presence of splenomegaly, and age. This model is widely used to predict survival and the optimal timing of liver transplantation. Interestingly, PSC patients with disease-related complications (pruritus, cholangitis) have a low priority based on MELD criteria, and recently have been receiving more living-related donor transplants. From a technical standpoint, the conduct of liver transplantation for PSC includes resection of the extrahepatic biliary tree in its entirety and the donor graft bile duct reconstruction by Roux-en-Y to a limb of jejunum.

Transplant for CCA

Unsuspected CCA is found in 3% to 9% of explanted livers of patients undergoing transplantation for PSC. Interestingly, small (<1 cm) unsuspected CCA does not affect the long-term survival. Liver transplantation is offered as a specific treatment for CCA only in highly selected patients. Transplant investigational protocols in this setting utilize rigorous neoadjuvant chemoradiotherapy and pretransplant laparotomy with lymphadenectomy to exclude lymph node metastasis. Using these extremely rigorous selection criteria, excellent outcomes of 65% 5-year survival have been achieved. Recently, such outcomes have been extended to multiple centers.

POSTOPERATIVE CARE AND COMPLICATIONS

Overall morbidity after extrahepatic biliary resection with Roux-en-Y cholangiojejunostomies is approximately 30% to 40%, and perioperative mortality in expert hands is less than 3%. Complications specific to bile duct resection include cholangitis, hemobilia, and bile leak.

Biliary surgeons should maintain a healthy respect for cholangitis; this problem is apparent around the time of transhepatic biliary stent placement and manipulation (including cholangiography). Periprocedural antibiotics should be maintained until the patient has been afebrile for 24 hours. Biliary stents are left to gravity drainage for 5 days postoperatively, at which time a cholangiogram is obtained to evaluate anastomotic integrity. The biliary stent is then internalized (closed), and closed-suction surgical drains are removed as long as their effluent is nonbilious. Biliary stents should be flushed twice daily with sterile saline solution; these stents should be replaced on approximately 3-month intervals. Long-term management of biliary stents should be individualized to each patient's specific anatomic and pathologic circumstance. Maintenance of transhepatic stent for 6 months appears to be associated with decreased stricture rate.

Other postoperative management of bile duct resection patients parallels that of those undergoing major laparotomy including aggressive early ambulation, slow diet advancement, pharmacologic thromboembolism prophylaxis. Bile leak from the cholangiojejunostomies anastomoses is largely self-limited if the anastomosis is constructed over a stent. This situation typically resolves by keeping the stent open for a period of time: diverting bile from the anastomosis permits time for

healing. The stent may be closed when repeat cholangiography documents healing.

A second specific situation involves bile leaking from the transhepatic stent exit sites from the liver. This situation is apparent when bile is visualized in the closed-suction drain adjacent to the stent exit site at the liver edge, and is usually caused by dislodgement of the stent side holes out of the liver parenchyma. This situation prevented by intraoperative cholangiography and may be remedied by adjustment or replacement of the stent in interventional radiology. However, stent adjustment in the early postoperative time period should be undertaken with caution to avoid disruptions of the biliary-enteric anastomoses.

Patients undergoing liver transplant for PSC have a somewhat higher retransplant rate at 2 years versus those transplanted for other indications —10% versus 5%. The major cause for retransplant is hepatic artery thrombosis. Relative to other indications, liver transplant for PSC is accompanied by somewhat higher rates of acute cellular and chronic ductopenic rejection as well as the development of biliary strictures.

OUTCOMES

Endoscopic Therapy

The precise incidence of dominant strictures in PSC is difficult to determine, but may affect as many as 50% of patients. Endoscopic therapy is clearly effective in improving biliary drainage and symptoms. However, the long-term effect of endoscopy on modifying disease progression has not been documented.

Bile Duct Resection

A small proportion of PSC patients will have isolated dominant stricturing of the extrahepatic bile ducts and/or a dominant hilar stricture. Patients undergoing resection of the extrahepatic biliary tree for PSC have improved overall and transplant-free survival compared to a cohort of patients managed endoscopically. These potential advantages must be weighed against the risks of surgery in this population. A small percentage of patients will develop recurrent intrahepatic bile duct structuring after resection of the extrahepatic bile ducts (Fig. 113.8).

Liver Transplant

Patients undergoing liver transplant for PSC enjoy some of the most successful outcomes relative to patients transplanted for other indications. Survival of patients after liver transplant for PSC is quite good—90% and 80% 1- and 5-year survival rates are common. Interestingly, recurrent PSC occurs in 20% to 25% of PSC patients undergoing liver transplant. Patients with IBD and an intact colon may be at increased risk for recurrent PSC after liver transplant. No specific medical therapy has been shown to decrease the incidence or PSC recurrence.

Figure 113.8. Magnetic resonance cholangiopancreatography demonstrating progressive intrahepatic bile duct strictures in a patient 9 years postresection of extrahepatic biliary tree for what then was isolated dominant extrahepatic stricture.

Additional Considerations

As discussed above, colonoscopy is indicated in PSC patients on a more aggressive schedule, not only to diagnose colonic neoplasia, but also to secure or exclude the diagnosis of IBD. Aggressive screening colonoscopy is warranted for postliver transplant PSC patients with IBD, as the risk of developing colonic malignancy in this population is higher after liver transplant. Ursodeoxycholic acid is commonly administered to decrease the risk of colon cancer in PSC patients with IBD, though little evidence exists to support this practice.

SUMMARY

The etiology of PSC is multifactorial, and its pathophysiology remains poorly understood. No specific medical therapy has been shown to affect the disease course. Magnetic resonance cholangiopancreatography is the gold standard for diagnosis and is also widely used for surveillance. Endoscopic intervention is currently reserved to treat dominant strictures and to evaluate and biopsy lesions suspicious for cholangiocarcinoma. CCA develops in 10% to 15% of patients with PSC; the diagnosis of this malignancy is notoriously difficult to differentiate from that of benign stricture. For selected patients with a dominant extrahepatic and/or hilar strictures, resection of the extrahepatic biliary tree provides durable therapy. In patients with established cirrhosis, liver transplantation is clearly the optimal therapy. Liver transplant patients have excellent outcomes in general, but may develop recurrent PSC in the transplanted organ. Current research efforts are directed toward better understanding the etiopathogenesis of PSC, developing effective medical therapy, and identifying more sensitive and accurate techniques with which to predict and diagnose cholangiocarcinoma.

EDITOR'S COMMENT

Although there have been few improvements in the treatment of primary sclerosing cholangitis there are clear areas of controversy in the diagnosis and management. Primary sclerosing cholangitis (PSC) is a rare but significant disease. As pointed out by the authors we normally think of this a cholestatic disorder with strictures of the biliary tree associated with inflammatory bowel disease, primarily ulcerative colitis. The factors involved with the association of the PSC and ulcerative colitis are complex and incompletely understood but thought to be an autoimmune mechanism. It is known that medical treatment of the ulcerative colitis or total colectomy does not lessen the severity or risk of PSC.

The spectrum of this diseases similar to PSC has been expanded to include a long list of differential possibilities that may be primary diseases of the biliary tree or secondary forms of sclerosing cholangitis as shown in Table 113.3.

Of the extensive list in Table 113.3, IgG4 disease–related sclerosing cholangitis is a most important differential diagnostic consideration. IgG4 disease was described in 1995 in a group of patients with pancreatitis and increased serum IgG4 levels that responded to treatment with corticosteroids. At the time this was named autoimmune pancreatitis. It was found that some patients with this disease do not have pancreatitis but rather extrahepatic biliary strictures associated fibrosis and lymphoplasmacytic infiltration of biopsy. IgG4-related sclerosing cholangitis is the most frequent extrapancreatic manifestation of type 1 autoimmune pancreatitis (IgG4 related), present in over 70% of such patients. Although it can be confused with PSC, the natural history is different. First, it usually presents in older patients. A 7:1 male predominance is observed compared to 1.5:1 in PSC. Jaundice has a more acute onset in IgG4 disease and the strictures are usually extrahepatic and long and smooth and tend to be located in the distal common bile duct. PSC strictures are characterized by beading, band like strictures and peripheral pruning. G4 SC is associated with inflammatory bowel disease in less than 10% of cases compared to 80% in PSC. An elevated IgG4 level however is not sufficient to diagnose IgG4 SC,

especially as the optimal cut-off value has not been defined and may differ for subgroups of IgG4 SC. An emerging consensus holds that the IgG4 antibodies in this disease are not pathogenic, but rather represent a downregulatory response to another primary process. Although clearly defined diagnostic criteria for IgG4-related sclerosing cholangitis are lacking, differentiation from primary sclerosing cholangitis is based upon tissue biopsy with infiltrates of IgG4+ plasma cells and severe interstitial fibrosis, increased IgG4 serum levels, and characteristic responsiveness to glucocorticoids. The initial response rate to steroids has been reported as high as 97% but the relapse rate upon discontinuation is as high as 50% and not predicted by initial or IgG4 response to steroid therapy. Patients with IgG4 SC have not been reported to develop cholangiocarcinoma a known significant risk of PSC.

TABLE 113.3 Differential Diagnosis of Primary Sclerosing Cholangitis

Autoimmune	IgG4-related sclerosing cholangitis Autoimmune sclerosing cholangitis Systemic vasculitis
Benign	Intrahepatic stone disease
Malignant	Cholangiocarcinoma
Infection	Cholangiopathy related to AIDS Recurrent pyogenic cholangitis
Injury	Post cholecystectomy Abdominal trauma
Vascular	Hepatic artery thrombosis Portal hypertension Chemoembolization Sickle cell disease
Other	TPN Cholangiopathy of critical illness Histiocytosis X

Ursodeoxycholic acid (UDCA) has a demonstrated efficacy in the management of cholestatic conditions such as primary biliary cirrhosis. Small prospective studies using UDCA at different doses in patients with PSC showed improvement in symptoms and liver biochemistry (8 to 16 mg/kg, 10 mg/kg), as well as histology (13 to 15 mg/kg) (Chazouilleres O, et al. Ursodeoxycholic acid for primary sclerosing cholangitis. *J Hepatol* 1990;11:120–3; O'Brien CB et al. Ursodeoxycholic acid for the treatment of primary sclerosing cholangitis: a 30-month pilot study. *Hepatology* 1991;14:838–47; Beuers U, Spengler U, Kruis W, et al. Ursodeoxycholic acid for treatment of primary sclerosing cholangitis: a placebo-controlled trial. *Hepatology* 1992;16:202–714). There has been no demonstration of a survival advantage or reduction in the risk of cholangiocarcinoma. More recent studies have shown no significant difference in mortality, histology, or cancer risk at both a standard and high dose and there was a significantly higher occurrence of serious adverse events in the high-dose group (Lindor KD, et al. High-dose ursodeoxycholic acid for the treatment of primary sclerosing cholangitis. *Hepatology* 2009;50:808–14). As the authors report current guidelines advise against the use of UDCA in PSC. In addition, although there is some information that UDCA may decrease the incidence of colorectal dysplasia the studies were underpowered and hence UDCA is not recommended for prevention of colorectal dysplasia in PSC.

The most challenging problem for the surgeon is the management of a dominant stricture. The most concerning differential diagnosis of a dominant stricture is cholangiocarcinoma (CCA). It is known that the risk of CCA in PSC is much greater than that of the general population. Approximately 7% of patients with PSC will develop CCA over an 11-year follow-up. The rate of developing CCA is estimated at 0.6% per year and the relative risk of CCA in PSC is significantly increased (RR = 1,560; 95% CI = 780,2793; $p < 0.0001$) (Burak K, et al. Incidence and risk factors for cholangiocarcinoma in primary sclerosing cholangitis. *Am J Gastroenterol* 2004;99:523–6). Thus when a dominant stricture is identified, a malignant etiology requires exclusion and therapy for symptomatic strictures offered. CA 19-9 can be helpful in screening patients with dominant strictures. A level over 130 U/mL is worrisome. However, a tissue diagnosis is required. Cholangioscopy allows for direct optical visualization and guided biopsies of the biliary epithelium and biliary lesions. In addition, this technique may allow clearance of biliary stones improving symptoms. ERCP and brushings are employed more often because of cannulation difficulty with cholangioscopy in the PSC patient. Use of fluorescence in situ hybridization (FISH polysomy) on ERCP brushing has been shown to sensitive and specific in the diagnosis of CCA but it is not overly accurate (Navaveethan U, et al. Fluorescence in situ hybridization for diagnosis of cholangiocarcinoma in primary sclerosing cholangitis: a systematic review and meta-analysis. *Gastrointest Endosc* 2014;79:943–950.e3).

Treatment of symptomatic dominant strictures is warranted. The current recommendation is for endoscopic dilation with or without stenting. Stiehl A, et

al. (Development of dominant bile duct stenoses in patients with primary sclerosing cholangitis treated with ursodeoxycholic acid: outcome after endoscopic treatment. *J Hepatol* 2002;36:151–6.) performed a study on 52 patients with dominant strictures and reported that survival free of transplantation was better at 3, 5, and 7 years when compared to the Mayo risk score. Surgical resection may be considered in some cases and the authors refer to the report by Ahrendt and that of Pawlik both of which support selective surgical intervention of dominant extrahepatic strictures in noncirrhotic patients. "In the appropriately selected patient, extrahepatic biliary resection affords patients with survival rates equivalent to that of transplantation. In fact, extrahepatic biliary resection can potentially significantly delay or avoid transplantation. Extrahepatic biliary resection is a good durable option for noncirrhotic patients with PSC and a dominant extrahepatic stricture" (Tsai S, et al. Primary sclerosing cholangitis: the role of extrahepatic biliary resection. *Adv Surg* 2009;43:175–88).

As pointed out in this chapter, liver transplantation is effective treatment for PSC. The Mayo risk score is helpful in predicting outcomes and may be accessed at http://www.mayoclinic.org/medical-professionals/modelend-stage-liver-disease/revised-natural-history-model-for-primarysclerosing-cholangitis. The indications are similar for other types of chronic liver disease but also include pruritus and recurrent cholangitis. Interestingly within 5 years recurrence of PSC may be as high as 20% in the transplanted liver. The 1-, 5-, and 10-year posttransplant survival is 93.7%, 86.4%, and 69.8%, respectively (Graziadei IW, et al. Long-term results of patients undergoing liver transplantation for primary sclerosing cholangitis. *Hepatology* 1999;30:1121–7). CCA is currently a contraindication to transplantation. However as noted by the authors unsuspected CCA is identified in 3% to 9% of explanted livers and CCA <1 cm does not impact long-term outcomes. The role of liver transplantation for small CCA is currently under additional investigation (De Vreede I, et al. Prolonged disease-free survival after orthotopic liver transplantation plus adjuvant chemoirradiation for cholangiocarcinoma. *Liver Transpl* 2000;6:309–16).

The take home messages are as follows. First, I think it is important to remember that sclerosing cholangitis is a spectrum of diseases. An elderly male patient with no inflammatory bowel disease with a dominant stricture or multiple strictures may not have PSC but IgG4 disease which is being increasingly recognized. This disease is treatable with steroids and has a better prognosis. UDCA has little role in the treatment of PSC. Patients with PSC have an extremely high risk of developing CCA regardless of the severity or treatment of the underlying inflammatory bowel disease. Dominant strictures require investigation to exclude CCA. Liver transplantation is effective in those with cirrhosis or recurrent cholangitis and the risk and outcomes may be determined by application of the Mayo score.

E. Christopher Ellison

This is an excellent chapter—bad disease; and once established needs a radical approach. The authors also note that they may not be able to spare the resection of the extra hepatic biliary tree, which is significant!

Also there are other methods for transplant treatment for survival. Node resection is essential as well as the excellent resections of hepatic artery and vein and divisions. Hepatic artery, vein, etc. and frozen section of hepatic artery, veins, etc. Roux limb must be prepared with freedom of the resected limb. The surgeon must be aware of an unsuspected cholangiocarcinoma. Overall morbidity is 30% to 40% and overall mortality in expert hands is 4%. Bile leak is largely self-limited. There is no specific medical therapy affecting the disease course. Finally, cholangiocarcinoma develops 10% to 15% with PSC (primary sclerosing cholangitis liver transplants).

J.E.F.

114 High Malignant Biliary Tract Obstruction

Richard A. Burkhart and Timothy M. Pawlik

ETIOLOGY AND PATHOPHYSIOLOGY

High malignant biliary tract obstruction is typically caused by a cholangiocarcinoma (CCA) arising at the liver hilum. Less frequent etiologies of obstruction include extrinsic compression of the biliary tree due to a metastasis to the periportal lymphatic drainage basin or a benign biliary stricture. Primary CCA arising at the hilum of the liver or proximal/mid CBD can obstruct the biliary tract early in the course of disease.

Hilar cholangiocarcinoma (hilar CCA) is a rare malignancy with an incidence that likely approaches 3,000 cases annually in the United States. Worldwide epidemiologic estimates are difficult to estimate. The disease is likely more prevalent in the Eastern hemisphere. This hypothesis is supported by the regional variation in risk factors for hilar CCA. These risk factors include diseases that increase inflammation of the proximal biliary tree such as cirrhosis, pancreatitis, choledocholithiasis, and biliary/hepatic parasitic infection. The strongest risk factor for development of hilar CCA is a diagnosis of primary sclerosing cholangitis (PSC), with as many as a third of patients developing CCA within 5 years of diagnosis with PSC.

Despite the improvements in patient outcomes for various malignancies, hilar CCA remains a devastating diagnosis. First described in 1957 by Altemeier et al., CCA was given the eponym “Klatskin tumor” following the publication of a comprehensive report from Gerald Klatskin in 1965. Within a decade of Klatskin’s description, reports demonstrated that an optimal chance for cure included a margin-negative surgical resection. Despite half a century of surgical progress, long-term prognosis remains poor with various series reporting 5-year survival in the range from 10% to 40%.

There are several anatomic considerations in and around the hilum that

are important to keep in mind when discussing presentation and management of hilar CCA. These features are illustrated to aid clarity in Figure 114.1. First, the presentation of patients with hilar CCA can be dictated by the location in which the tumor develops and the relationship between the confluence of the left and right hepatic ducts to form the main duct. As an example, the course of the left hepatic duct is longer than the right and the left duct travels over a greater extrahepatic length. In addition, the close relationship between the vascular and biliary structures can dictate treatment options and prognosis. Classically, the right hepatic artery is thought to be at risk for early invasion as it runs posterior to the bile duct and courses through the hilum. Similarly, management may be impacted by aberrant vascular anatomy such as a left hepatic arising from the left gastric artery or a right hepatic with its origin from the superior mesenteric artery.

CLINICAL PRESENTATION

Hilar CCA is more common in men and presents at a median age near 65 years old. Patients generally present with painless jaundice owing to their biliary tract obstruction. Symptoms may also include abdominal discomfort, weight loss, darkened urine, and acholic stool. Fatigue and pruritus are also frequently encountered. Patients are often initially managed in an urgent care setting, where an examination may elicit a relatively benign abdominal exam in the setting of a grossly abnormal hepatic function panel. Laboratory abnormalities include elevated alkaline phosphatase and total bilirubin in nearly all patients. The initial differential diagnosis may include both benign and malignant etiologies for biliary obstruction such as choledocholithiasis or benign biliary stricture.

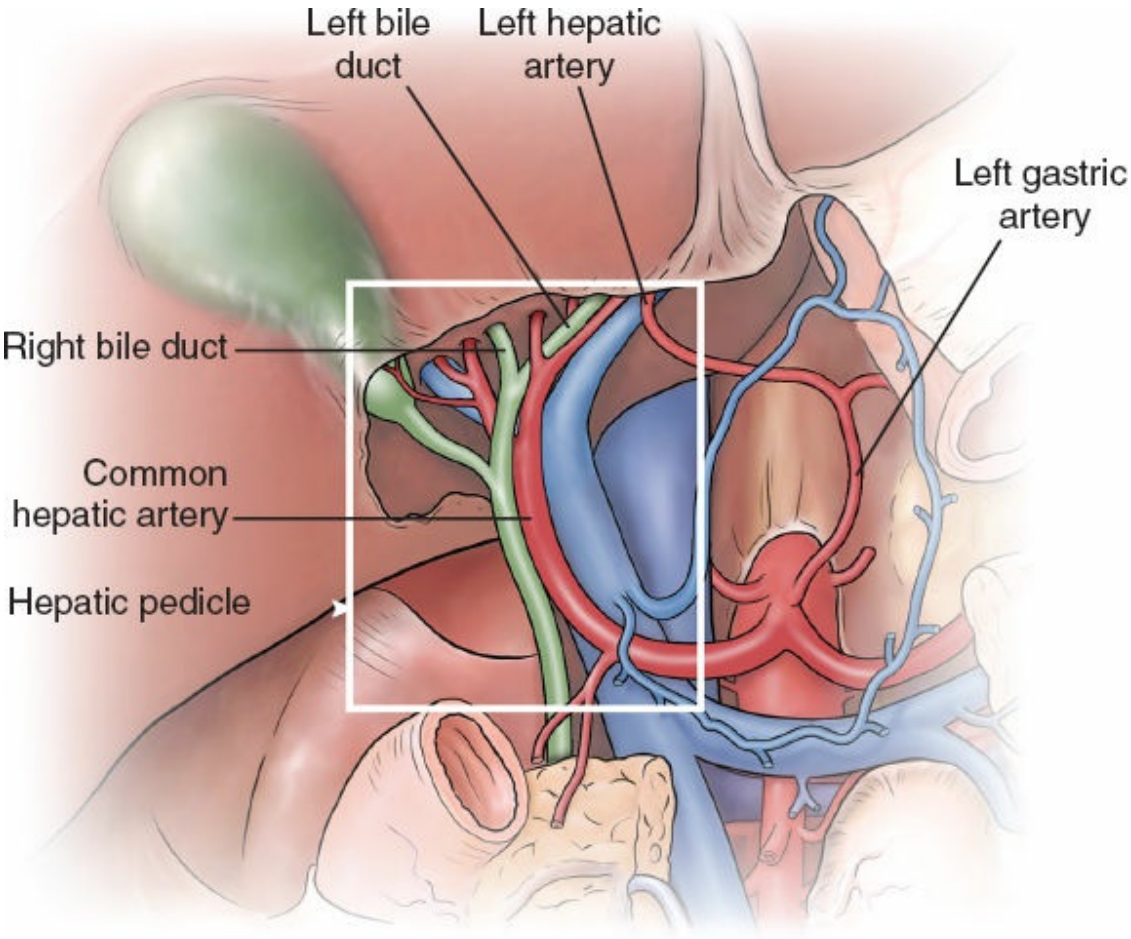

Figure 114.1. Anatomical features with particular implications in the management of hilar cholangiocarcinoma.

The serum tumor marker, CA19–9, is a commonly ordered test that may help to differentiate between benign and malignant obstruction. The sensitivity and specificity of this test during the acute presentation of patients with biliary obstruction remain limited. This tumor marker is particularly unhelpful for diagnosis when patients present with coexisting cholestasis or cholangitis. With this in mind, CA19–9 is likely most appropriately used as a serum biomarker of disease burden over time, with longitudinal kinetics of CA19–9 relating to response or failure to therapeutic interventions.

Initial imaging studies, such as ultrasound or cross-sectional computed tomography (CT), typically demonstrate dilation of the intrahepatic biliary tree with minimal or absent extrahepatic biliary tree dilation. It is unfortunately common that an obvious etiology is not apparent on these initial scans and the quality of initial imaging can be inadequate for treatment planning after a diagnosis has been made. Metastasis to locoregional lymph nodes, peritoneum, and liver is occasionally identified

when reviewing these initial studies.

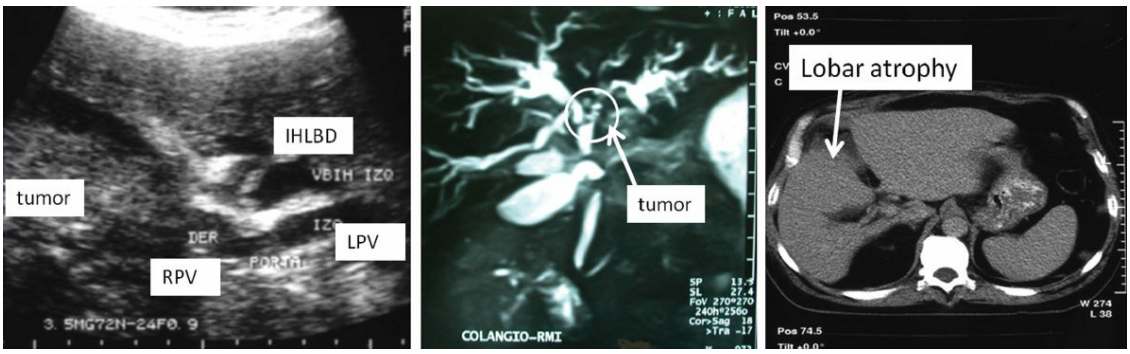

Figure 114.2. Hepatic ultrasound, magnetic resonance cholangiography, and abdominal computed tomography. RPV, right portal vein; LPV, left portal vein; IHLBD, intrahepatic left bile duct.

A definitive diagnosis of hilar CCA can be challenging, as initial signs of disease can be "indirect." These signs include intrahepatic biliary ductal dilation, an inability to appreciate the location of the biliary confluence on imaging, and a normal appearance of the mid and distal CBD. To narrow the differential, supplemental imaging that is biliary-focused, such as magnetic resonance cholangiography (MRC) or endoscopic retrograde cholangiography (ERC), is often required. The choice of modality used for additional workup should be determined by locoregional expertise and surgeon preference. At times, patients may require most of the studies outlined above to optimize clinical decision making (Fig. 114.2).

The relative value and additional risks for each study should be weighed carefully during a patient's evaluation, and there are two main principles of the workup that should be kept in mind. First, the proposed study should provide diagnostic value. Second, the study should support therapeutic decision making. Rapid-sequence, thin-section helical CT scanning is often an ideal way to evaluate resectability of a tumor (biliary extension, arterial involvement, portal venous involvement, lymphadenopathy, presence/absence of distant metastasis, and liver volume estimates). MRC, as a complementary study, offers a high-quality and noninvasive means to obtain detailed images of the biliary tree. Other methods to image the biliary tree include ERC or percutaneous transhepatic cholangiography. While these studies provide similar data, each can be associated with a distinct advantage or disadvantage compared with MRC. The major advantage of these approaches is the potential to

obtain tissue from duct brushings for histopathologic evaluation and potential diagnosis. The disadvantages, however, are their invasive nature (with all the inherent complications) and the potential for incomplete imaging of the biliary system that can result from a complete (and not traversable) blockage of the bile duct (i.e., ERC may be inadequate to image the proximal biliary tree and a percutaneous approach may be inadequate to image the distal). Evaluation of the biliary tree with an invasive means (ERC or percutaneous) does allow for treatment initiation with decompression of the biliary tree (either internal or external stent placement) and reversal of any biliary stasis that may have developed.

INDICATIONS AND CONTRAINDICATIONS

The mainstay of curative therapy in CCA remains complete surgical extirpation. The 5-year survival for patients undergoing an operation ranges from 10% to 44% (vs. 0% to 3% among patients who could not be resected). Unfortunately, only 30% of patients are candidates for surgical resection at the time of diagnosis. Modern improvements in operative technique and perioperative care have increased the capacity for attempts at surgical resection. Of particular note, the utilization of vascular reconstruction and transplantation in selected patients is now considered in selected high-volume centers. In addition, suspected lymphadenopathy in the hepatoduodenal ligament on preoperative imaging is no longer considered a contraindication to attempted resection.

Although resectability is ultimately determined in many cases at the time of operative exploration, in keeping with the contemporary management of tumors in other systems, the management of CCA is guided by an initial clinical assessment of disease stage. In general, this assessment is performed reliably only when viewing high-quality imaging and often requires multidisciplinary input. One of the earliest classifications of disease is derived from work completed by Bismuth and Corlette in 1975 (Fig. 114.3). This classification is grounded in the ability to accurately define the anatomical location and extent of tumor burden in the biliary tree. Although helpful in patients eligible for operative extirpation, the Bismuth and Corlette classification is not necessarily predictive of resectability as vascular invasion and extrabiliary disease spread are not considered.

Iterative improvements in the original Bismuth system were proposed by Jarnagin and colleagues that takes into account the disease's

involvement of the biliary, arterial, and portal venous systems (known as the Memorial Sloan Kettering Cancer Center, MSKCC, classification system). This T-staging system also takes into account lobar atrophy and has been correlated with ability to achieve R0 resection and overall patient survival. In the original report, as an example, patients with disease limited to the biliary confluence with or without extension into second-order biliary radicals had a 59% R0 resection rate with a 20-month median survival. The predictive capacity of this staging system has been validated in external work from multiple centers.

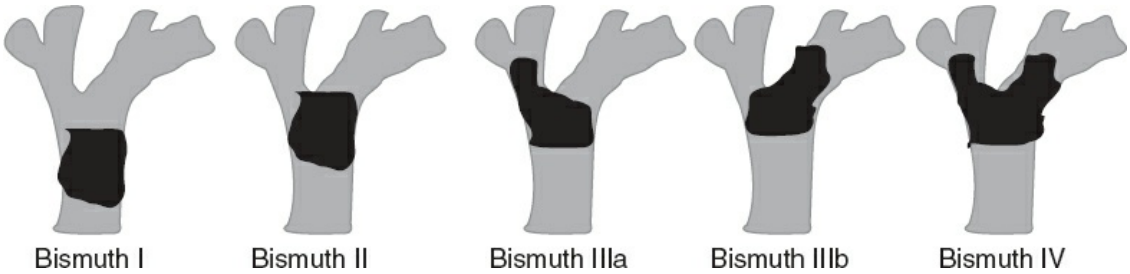

Figure 114.3. Bismuth and Corlette classification for hilar cholangiocarcinoma.

Importantly, the MSKCC classification system also proposed criteria for contraindications to a surgical approach. First, as is the practice in other tumor systems, patients with medical comorbidities that preclude a major abdominal operation should be excluded from operative consideration. Second, the presence of hepatic cirrhosis was also proposed as a relative contraindication to surgery. Lastly, and most importantly, local tumor-related factors were proposed as operative contraindications. These included bilateral tumor extension to second-order biliary radicals, encasement or occlusion of the main portal vein, atrophy of one hepatic lobe with encasement or occlusion of the contralateral portal vein branch, atrophy of one hepatic lobe with extension of tumor into the second-order biliary radicals of the contralateral hepatic lobe or extension of tumor into the second-order biliary radicals of one hepatic lobe with encasement or occlusion of the portal vein branch to the contralateral lobe. Metastatic disease, both to lymph nodes beyond the locoregional draining basin in the hepatoduodenal ligament and to systemic sites, was also proposed as a contraindication to operative resection.

PREOPERATIVE PLANNING

Preoperative Biliary Drainage

The effects of prolonged biliary obstruction are not particularly well understood. Although hyperbilirubinemia and jaundice are common, their effects on hepatic function and systemic physiology are debated in the literature. This has resulted in mild controversy regarding the role of routine preoperative biliary drainage. There are four distinct benefits to preoperative biliary drainage. First, perioperative morbidity (including liver insufficiency and failure) is higher in patients with extreme hyperbilirubinemia (greater than 10 to 15 mg/dL). Second, biliary drainage is the appropriate initial therapy for patients with signs or symptoms of cholangitis or new-onset liver insufficiency. From a technical standpoint, a biliary catheter in place (particularly if placed percutaneously) may serve as a landmark during surgical exploration. Lastly, placement of a biliary drainage catheter or stent allows for patients to seek additional therapies prior to attempted surgical resection. Some therapies routinely employed include antibiotics to treat sepsis, nutritional supplementation for malnourishment, or portal venous embolization to decrease perioperative risk.

Many surgeons have abandoned routine biliary drainage for patients who do not meet the criteria outlined above. Specific concerns that have decreased utilization of drainage procedures include procedure-based complications, an increased incidence of postoperative infections, and the risk of tumor seeding along a catheter track. Based on current evidence, modern surgical consensus suggests that preoperative biliary drainage should be done selectively in patients with cholangitis, malnutrition, sepsis, and those needing portal vein embolization (PVE). In turn, many patients evaluated for hilar CCA will meet criteria for preoperative biliary drainage.

Preoperative Portal Embolization

PVE is a procedure that can be utilized before hepatectomy to investigate the capacity of the liver to regenerate and potentially increase the size of the future liver remnant (FLR). This procedure occludes the portal vein branches feeding the hemiliver that a surgeon is planning on resecting. While classically described via either a percutaneous or open approach, it is most commonly performed percutaneously in the modern experience. In practice, the diversion of blood flow in the portal venous system can induce a slight atrophy of the hemiliver embolized with a compensatory

hypertrophy of the contralateral side. The decision to proceed with PVE and the interpretation of a liver's response is an evolving art. Utilization of PVE is most appropriately limited to patients in whom the volume of the FLR raises the possibility of postoperative liver insufficiency or failure. Classic teaching instructs that this threshold varies between 20% and 30% in a healthy liver and 30% and 40% in a liver with preexisting cirrhosis or a patient with underlying steatosis or steatohepatitis. When in doubt, surgeons can seek multidisciplinary support with this decision from radiology colleagues who can define the specific liver volume (through image-based volumetry), as well as interventional radiologists who perform percutaneous PVE.

Functionally, PVE minimizes the abrupt increase of portal pressure after resection and separates this physiologic stress in time from the stress and trauma of surgical hepatectomy. In addition, PVE may increase FLR mass prior to resection and minimize the risk of metabolic insufficiency. Taken together, these changes minimize the incidence of postoperative liver insufficiency. Interpreting the overall benefit of PVE in each patient can be difficult. While PVE is performed for patients with a borderline FLR, the post-procedure FLR volume is not the only outcome measure to note. Rather, the overall capacity of the FLR to hypertrophy, and speed at which it does so, can inform operative risk. For example, a patient after PVE with an original 18% FLR volume and without evidence of cirrhosis on preoperative workup may technically meet resection "criteria" (FLR 20% to 30%) with a hypertrophy of only 2% after PVE; however, most surgeons would be reluctant to undertake a major hepatectomy without more robust hypertrophy of the FLR following PVE. One unique consideration when using PVE in cases of hilar CCA (rather than other indications for hepatectomy) is that it can sometimes be difficult to know which hemiliver to embolize. When the side of the hilar CCA lesion is ambiguous, the operative planning can be more difficult.

SURGICAL TECHNIQUES

Staging Laparoscopy

Even though most patients undergo a comprehensive imaging workup for a presumed diagnosis of CCA, a subset of patients will be found to have occult metastasis at the time of surgical exploration. Based on the MSKCC experience, peritoneal or liver metastasis was reported at surgical exploration between 20% and 40% of the time. This includes one fifth of

patients with the most limited disease (T1) in the MSKCC system. For this reason, and to avoid the morbidity of an unnecessary laparotomy, staging laparoscopy should be considered at the time of surgery. While staging laparoscopy can identify nearly 50% of patients who harbor unresectable disease, the addition of laparoscopic ultrasound to delineate perihilar anatomy can increase the sensitivity of this approach. The major limitations of this approach include variability in the capacity to interpret intraoperative ultrasound findings and challenges in laparoscopic identification of lymphatic spread beyond the hepatoduodenal ligament.

Hepatectomy: Rationale and Planning

The standard management of patients with potentially curable CCA involves a margin-negative surgical resection. The biliary margin is most commonly at risk for failure to achieve an R0 designation. This is particularly true at the proximal (at times intrahepatic) biliary radicals and provides the bona-fide rationale for concomitant liver resection when treating a Klatskin tumor.

Most hilar CCA lesions will require an extended hepatectomy, in particular for those lesions either directly at the hilar plate or involving the right bile duct. A left hemi-hepatectomy can otherwise be considered for a hilar CCA originating from the left biliary tree. In particular, because of the anatomic characteristics of the hepatic ducts (e.g., a longer extrahepatic portion on the left), an extended right hepatectomy is often the operation of choice as it frequently provides a greater chance for a margin-negative resection. Preoperative variables that would dictate a left hepatectomy include imaging findings that suggest extensive involvement of the left duct (beyond the second-order) or compromise of the major vascular structures to the left side. Specifically, a Bismuth-Corlette type IIIB tumor in the presence of left lobe atrophy would be an indication for a left hepatectomy.

Resection of the caudate should be a routine addition to the hepatectomy performed for hilar CCA. Resection of the caudate lobe increases the chance of R0 resection as pathologic data suggest that hilar CCA can invade the caudate in roughly 31% to 98% of cases. The size and anatomy of the caudate can be variable at times; as such, resection can be partial (to include Spiegel's lobe and the paracaval portion) according to the type of liver resection performed (Fig. 114.4).

A complete resection should also include extirpation of the locoregional

draining lymphatic basin residing in the hepatoduodenal ligament and cystic triangle (at a minimum). There are robust data to support that this relatively limited dissection can provide prognostic and potentially therapeutic benefit (locoregional nodal control). The full extent of lymphadenectomy remains a relatively controversial topic. While an extended lymphadenectomy may improve prognostic value of the histopathologic surgical specimen, any potential therapeutic benefit is indeterminate. A recent meta-analysis of prognosis based upon nodal dissection noted that a lymph node count greater or equal to 7 is adequate for prognostic staging; in addition, a lymph node count greater than 15 did not improve detection of nodal metastasis. Most often, therefore, it is prudent to extend the lymphadenectomy to include nodes in the hepatoduodenal ligament, cystic triangle, and along the course of the hepatic artery. It remains unclear to what extent the lymphadenectomy should be extended to celiac, periduodenal, and perigastric nodes.

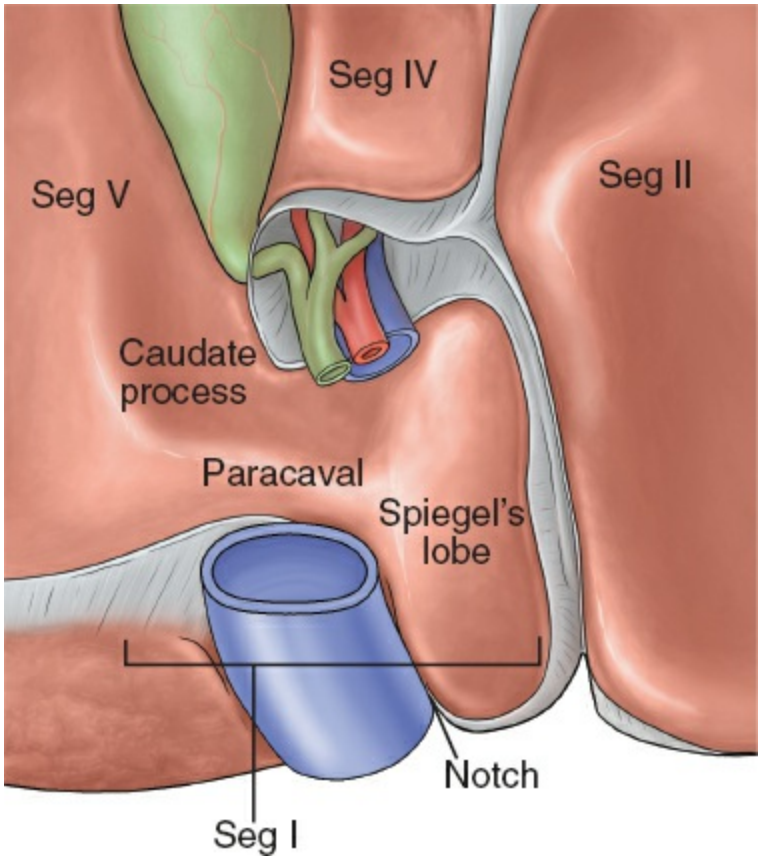

Figure 114.4. Anatomy of the caudate: Because of the frequency with which hilar cholangiocarcinoma involves the caudate, it is recommended that a caudate resection is routinely performed during hepatectomy.

Hepatectomy: Exposure and Portal Dissection

It is important to emphasize that techniques and operative procedures can vary among surgeons based on experience, and preference. Many advocate for routine staging laparoscopy with intraoperative ultrasound (as described above) to begin each procedure. The degree to which the remainder of the procedure can be completed in a minimally invasive fashion is variable; while complete laparoscopic or robotic resections for Klatskin tumors have been reported in the literature, a minimal invasive approach to resection of hilar CCA remains uncommon.

For surgeons approaching hilar CCA disease through a laparotomy, there are a variety of incisions that are favored: midline, bilateral subcostal, bilateral subcostal with midline extension ("Mercedes"), or modified Kocher ("hockey stick"). Similarly, there are a variety of preferred retraction methods that can be used with success to gain the necessary exposure to the operative field. Following exposure, an intraoperative exploration of the abdomen to exclude metastasis and an initial assessment of resectability should be performed.

Although many surgeons choose to approach the dissection from a variety of starting points, it is often recommended to begin with dissection of the distal CBD just above its insertion into the head of the pancreas. This allows for early transection of the CBD and frozen section pathologic analysis of this margin. A negative margin at this early juncture is encouraging; a positive margin, however, would necessitate re-examination of the planned procedure. For example, if the goal remains to ensure an R0 resection, the surgeon must decide whether additional distal CBD dissection is possible and, if not, if a pancreaticoduodenectomy with concomitant liver resection is an appropriate strategy for the patient (Fig. 114.5). After confirming this margin is free of tumor, the distal CBD at its entry into the head of the pancreas should be oversewn.

To determine resectability, meticulous dissection of the vascular inflow (hepatic artery and portal vein branches) in the porta hepatis is required. Sometimes, it is best to adopt a "no touch technique" in which the tumor is left in situ and undisturbed while the uninvolved structures are dissected away. A common place to begin vascular isolation is with dissection of the proximal proper hepatic artery (PHA) after the takeoff of the gastroduodenal artery. Ideally, the PHA can be circumferentially dissected free from the surrounding fibroadipose tissue to the level of its bifurcation into the left and right hepatic arteries. There are frequently small venous

tributaries encountered during this dissection that must be controlled. The dissection is carried distal along the right hepatic artery for enough length to pass a vessel loop in preparation for eventual ligation. The portal vein dissection is generally begun in the distal hepatoduodenal ligament and carried in a similar fashion toward the porta to identify the bifurcation into the right and left portal vein branches. The right is again circumferentially dissected free and a vessel loop can be passed. It is important to note that the portal vein tributary to the caudate will frequently branch off from the posterior aspect of the proximal right portal vein, and care must be taken not to injure this vessel during dissection. In cases with a low-lying tumor, it can be necessary to approach the portal dissection from the posterolateral aspect of hepatoduodenal ligament, particularly as you approach the porta hepatis. In so doing, the biliary structures are rotated anteriorly and to the patient's left to facilitate a safe dissection by the surgeon standing at the patient's right-hand side of the table. It should also be mentioned that the gallbladder, if not previously removed, is often taken early during the course of the operation and facilitates this approach to the portal vein.

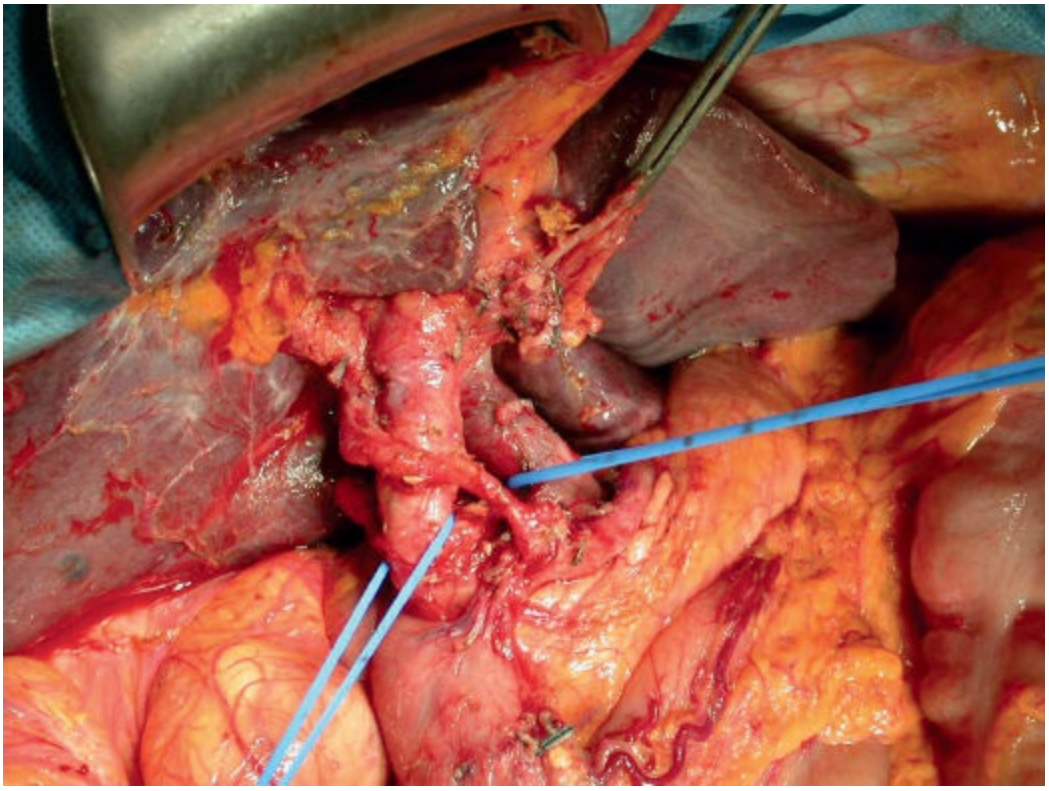

Figure 114.5. Hepatic hilum after lymph node dissection.

In the case of tumor involvement of the arterial or portal venous

branches to the FLR, it would be appropriate to consider the need for vascular reconstruction and plan accordingly by procuring a vascular conduit if primary reconstruction was not feasible. Arterial reconstruction can sometimes be necessary for a Bismuth type IIIB tumor where operative planning dictates a left hepatectomy and the right hepatic artery is involved with tumor as it passes posterior to the biliary confluence. One strategy for vascular reconstruction in this scenario involves preservation of the proximal (extrahepatic) left hepatic artery with transection in the substance of the liver and transposition to the uninvolved distal right hepatic artery. Additional options for vascular reconstruction include saphenous, external iliac, and internal jugular venous conduits. Similarly, a cadaveric donor graft can be considered. Following vascular control and appropriate planning, the inflow vasculature to the side of the liver being resected can be ligated and parenchymal transection begins.

It is critical to recall the potential anatomic variants of the hepatic arterial supply. First described in depth by Jefferson Medical College's Nicholas Michels in 1966, hepatic arterial abnormalities are relatively common and can alter surgical approach and at times render an apparently unresectable tumor operable. Two of the most common variants include a left hepatic artery that arises directly from the left gastric (around 15%) and a right hepatic artery that arises from the superior mesenteric artery (also around 15%). When the left hepatic artery arises from the left gastric artery, it often inserts directly into the liver without passing into the porta hepatis, thus reducing the chance of involvement by a hilar tumor. Similarly, when the right hepatic artery originates from the superior mesenteric artery, it typically courses through the porta laterally and posterior to the course of the PHA. Although this scenario may require a certain amount of technical precision on the part of the surgeon, ultimately the position of the right hepatic artery in this variant may similarly increase its distance from the biliary confluence and enable resection in an otherwise uncertain case.

Hepatectomy: Optimizing the Hepatic Duct Margin, Parenchymal Transection, and Reconstruction.

There are two approaches to identifying an optimal hepatic duct margin. The first is early dissection of the hepatic duct at the base of the FLR. The second involves division of the hepatic duct during the latter stages of the parenchymal dissection. The former is generally preferred, as the control

of the hepatic duct with a vessel loop or umbilical tape can serve as a key landmark during parenchymal transection. In order to maximize the chances of an R0 resection, the dissection of the hepatic duct can be carried to the first or second order radicals by lowering the hepatic plate.

With the vascular inflow and biliary margin identified, the hepatic veins should be isolated and the field prepared for parenchymal transection. If not completed earlier in the operation, the liver should be fully mobilized from its retroperitoneal attachments and the short branches from the liver to the IVC should be clipped or tied. The hepatic artery and portal vein to the side being resected should be test clamped and hepatic perfusion to the FLR confirmed by Doppler ultasonography. The right hepatic artery and right portal vein can then be transected by suture ligation or a vascular stapling device. The devascularized liver becomes apparent and the line of parenchymal transection can be marked by electrocautery. There are a plethora of techniques that have been used with success to swiftly and safely complete the parenchymal transection. Tools at a liver surgeon's disposal include clamps, sutures, ties, clips, monopolar and bipolar electrocautery, ultrasonic dissectors, and stapling devices. Adjuncts to assist with hemostasis can include the application of direct pressure, the intermittent use of Pringle's maneuver, as well as topical hemostatic agents. After removal of the specimen, the transected liver surface is checked for hemostasis and biliary leak while the pathologists complete a frozen section analysis of the FLR's biliary margin.

Reconstruction is typically completed with a Roux-en-Y hepaticojejunostomy. The anastomosis has been described using a variety of absorbable suture types, sizes, and with both running and interrupted techniques. If a percutaneous hepatic drainage catheter was placed through the FLR during the workup, this is typically left in place and passed back across the anastomosis prior to completion. In cases where there is no catheter in place, one is typically not left at the conclusion of the procedure.

PALLIATIVE PROCEDURES

There are a variety of scenarios in which an operation for attempted curative resection may need to be converted to palliation. Such circumstances include intraoperative findings of unresectability (e.g., main hepatic artery and main portal vein involvement) or in cases where the distal CBD margin is positive and the patient is not a candidate for a

combined hepatobiliary/pancreatic resection. Palliation of symptomatic jaundice can be accomplished operatively by biliary-enteric bypass. If unresectability is discovered early in the course of operative exploration, during laparoscopy for example, the surgeon must decide whether the tumor and anatomy favor operative bypass or nonoperative interventional procedures. Although surgical palliation is associated with greater rates of long-term patency, morbidity following these procedures can vary between 15% and 50%. There is no long-term survival benefit afforded by surgical palliation as compared to nonoperative palliative approaches. Percutaneous transhepatic biliary drainage and stent placement or ERC with stenting can be effective palliative procedures. Autoexpandable metallic stents tend to be favored in palliative settings due to superior long-term patency and the reduced need for repeated endoscopic interventions that is present with plastic stent placement. Finally, it is worth noting that surgical debulking and palliative resections are generally not necessary and provide no survival benefit.

LIVER TRANSPLANTATION

Liver transplantation for the treatment of hilar CCA is gaining popularity in select patient populations. Most experts currently recommend transplant only for those patients with locally advanced disease (i.e., unresectable) who have no progression after a year or more of combined neoadjuvant therapy. This neoadjuvant therapy was initially described by the group at the Mayo Clinic and includes cytotoxic chemotherapy, external beam radiotherapy, and transcatheter-delivered brachytherapy. Pretransplant surgical exploration to ensure each patient is free from metastatic disease is required after this neoadjuvant regimen. Transplant aims to achieve an R0 resection by removing all structures in the liver hilum that are involved with tumor, including the portal vein, bilateral hepatic ducts, and the hepatic artery. While initial outcomes suggested 5-year survival below 20%, more recent data are encouraging with a long-term survival of 50% or higher. The overall median survival in the patients who successfully reach transplant today approaches the survival seen in patients undergoing successful R0 resection. In 2009, the United Network for Organ Sharing formally recognized unresectable hilar CCA as an indication for liver transplant.

The indications for liver transplant in patients who have resectable hilar CCA remain unclear. In fact, the appropriateness of transplant in this

patient subset remains debated in the literature. Trials to directly compare transplant versus resection have not been performed, and existing level 2 or 3 data are difficult to interpret. Much of this difficulty is owed to patient selection. Transplant patients are heavily pretreated and selected very carefully after receiving extensive neoadjuvant therapy. One could argue that the survival of the transplant cohort is due as much to this extensive neoadjuvant course (i.e., the patients with "bad biology" drop out) as it is to differences in surgical technique (transplant vs. resection, for example). This hypothesis is strengthened by findings showing that similar outcomes are reached for both transplant and resection when patients are stratified by disease stage in retrospective database studies. Integrating the currently available data, most experts agree that liver transplantation should generally be reserved for patients who have unresectable disease or for patients with PSC-associated hilar CCA.

POSTOPERATIVE CARE

Initial Hospital Course

In general, the adage of preoperative patient selection driving successful postoperative outcomes is apt in this patient population. For example, postoperative liver insufficiency or failure is best prevented with preoperative patient selection and management (i.e., adequate FLR and PVE), rather than managed postoperatively.

Standardized pathways can contribute to improvements in patient care in a variety of ways, from accurately setting patient expectations to minimizing medical variability and error. Common pathway components often include preoperative prophylactic antibiotics, routine laboratory analyses, standardized dietary and bowel regimens, frequent ambulation, and early involvement of staff (such as physical therapists, case managers, and nutritionists) to facilitate smooth transitions to outpatient settings. These activities are often combined into *enhanced* recovery pathways that emphasize early hospital discharge as an endpoint.

COMPLICATIONS AND THEIR MANAGEMENT

The complex nature of biliary and hepatic resections can be associated with a moderately high incidence of perioperative morbidity ranging from 15% to 75%. Similarly, 90-day mortality can be much higher than hepatic resection for other indications reaching up to 10% to 20% in some series.

The most common types of complications following resection of hilar CCA include bleeding, biliary leak or fistula, intra-abdominal abscess, wound infection, cholangitis, liver abscess, and liver insufficiency or failure. Management of bleeding includes reoperation and endovascular interventions. Similarly, the most common management for infectious complications includes resuscitation, antibiotic support, and source control. Finally, patients with hepatic insufficiency or failure must be supported with careful fluid management, avoidance of additional complications such as infection or renal failure, and careful management of electrolytes and acid–base balance.

ADJUVANT THERAPIES

Data investigating the use of adjuvant therapy following successful resection of hilar CCA are predominantly limited to level II and III evidence. Given the relatively common incidence of locoregional disease recurrence and dismal outcomes associated with relapse, postoperative adjuvant therapy is recommended to many patients. The evidence to support adjuvant chemotherapy for hilar CCA is sparse and most is extrapolated from data of chemotherapy use in patients with advanced disease. The most commonly studied agents include single-agent gemcitabine, and gemcitabine combinations with platinum or antimetabolites. Response rates from most studies are on the order of 10% to 30% in advanced disease. A phase III study of gemcitabine alone versus gemcitabine plus cisplatin (ABC-02 trial) demonstrated that combination therapy provided an improved progression-free survival among patients with advanced disease. As such, gemcitabine plus cisplatin is often selected for use in the adjuvant setting.

Similarly, the use of radiation therapy for hilar CCA in the adjuvant setting remains poorly defined. Chemoradiation may involve chemosensitization with 5-FU or capecitabine. While virtually all studies have been retrospective in nature, several series have reported improved outcomes with chemoradiation among patients who had a margin positive (R1) resection at the hepatic duct. In the postoperative setting, multidisciplinary consultation is often beneficial, as additional therapy is often recommended for patients with either a positive margin or lymph node metastasis. Patients who undergo R0 resection with node-negative disease are not likely to derive a substantial benefit from additional therapy in the adjuvant setting. So for this small subset, there is no

adjuvant therapy routinely administered at most cancer centers.

OUTCOMES

The major determinant of overall survival among patients with hilar CCA is pathologic stage and disease recurrence. CCA is among one of the most highly lethal tumors, and recurrence can be common even after margin-negative resection of node-negative disease. Recurrence is most often local in nature and can occur in and around the porta hepatis and liver. Additional sites of disease recurrence include the peritoneum, lungs, and distant lymph nodes. The median time to recurrence following surgical resection is 12 to 43 months in most series. Five-year survival for "all comers" following curative intent surgery is typically around 25% to 50% (Table 114.1). Clinicopathologic factors associated with a better long-term outcome include well-differentiated tumors, tumors with papillary histology, and a lack of perineural invasion. Resection with negative margins remains the only modifiable factor of long-term survival, emphasizing the impact meticulous surgical technique can have in this disease.

[a]R0 resection.

SUMMARY

Hilar CCA is a relatively rare diagnosis with a poor prognosis. The adverse long-term outcomes associated with hilar CCA are due to disease burden that is frequently advanced at presentation leading to an R1 margin, as well as a lack of effective systemic therapies. While challenging, the only potentially curative option for the treatment of hilar CCA remains surgical resection. Resections commonly require an extended

hepatectomy. Alternatively, for patients with unresectable disease and those with PSC-related hilar CCA, orthotopic liver transplantation may be an option at selected centers. Recommendations for adjuvant therapy are best determined by expert multidisciplinary consensus. Future research should be aimed at further characterizing the molecular biology of hilar CCA and identifying new systemic therapeutic approaches.

EDITOR'S COMMENT

Cholangiocarcinoma is the second most common primary liver cancer after hepatocellular carcinoma. Tumors in the hilum are frequently the source of highly malignant biliary tract obstruction and have been reviewed extensively over the past 150 years. Rokitansky proposed that biliary tract malignancies represented local advancement of disease from nearby organs. Durand-Fardel

then described the first case of bile duct cancer in 1840, with subsequent reports highlighting its poor clinical outcome. Interestingly, the 1910s witnessed an evolution in the surgical management of malignant obstruction from palliation to common bile duct resection with hepaticojejunostomy drainage. However, this approach did not result in significant cure rates due to the longitudinal and perineural infiltration that are the hallmarks of this disease. Dr. Gerald Klatskin sought "to draw attention to the unusual features of adenocarcinomas that arise in the hepatic duct at its bifurcation within the porta hepatitis" in his 1965 report in the *Journal of the American Medical Association.* Subsequent work by Launois and others demonstrated improved survival with hepatectomy, thus leading to the more aggressive approaches to this disease detailed in this chapter (Launois B, Campion JP, Brissot P, et al. Carcinoma of the hepatic hilus. Surgical management and the case for resection. *Ann Surg* 1979;190(2);151–7). However, many tumors are unresectable at time of presentation because of cholangiocarcinoma's silent clinical character, difficulties in early diagnosis, and limited therapeutic approaches (Rizvi S, Gores GJ. Pathogenesis, diagnosis, and management of cholangiocarcinoma. *Gastroenterology* 2013;145(6):1215–29; Bridgewater J, Galle PR, Khan SA, et al. Guidelines for the diagnosis and management of intrahepatic cholangiocarcinoma. *J Hepatol* 2014;60(6):1268–89). The authors are to be congratulated on their outstanding work on the surgical management of highly malignant obstruction from hilar cholangiocarcinomas. I will highlight several important aspects of the treatment of this disease including preoperative planning, neoadjuvant and adjuvant therapies, and indications for transplantation.

Preoperative cross-sectional imaging and endoscopic retrograde cholangiopancreatography help delineate tumor location, size, morphology, vascular involvement, volume of potential liver remnant, lymph node involvement, and presence of distant metastases (Deoliveira ML, Schulick RD, Nimura Y, et al. New staging system and a registry for perihilar cholangiocarcinoma. *Hepatology* 2011;53(4):1363–71). The data are unambiguous on the role of both CT and MRI in the management of these patients. A recent meta-analysis reported that CT scans are 86% (95% CI = 77–92) accurate in the evaluation of the degree of bile duct involvement in patients with cholangiocarcinoma. The sensitivity and specificity of CT scans for detecting portal vein involvement are 89% (95% CI = 80–94) and 92% (95% CI = 85–96), while sensitivity and specificity in the identification of hepatic artery involvement are 83% (95% CI = 63–94) and 93% (95% CI = 69–99). The sensitivity and specificity for lymph node involvement are 61% (95% CI = 28–86) and 88% (95% CI = 74–95), respectively (Ruys AT, van Beem BE, Engelbrecht MR, et al. Radiological staging in patients with hilar cholangiocarcinoma: a systematic review and meta-analysis. *Br J Radiol* 2012;85(1017):1255–62). Cross-sectional imaging with MRI allows for better delineation of the extent of the bile duct lesion relative to conventional CT scans, as this technique has an 89% sensitivity and 76% accuracy. Performing

concurrent MRI and MRCP examinations adds other important tumor information that facilitates preoperative planning. For example, if a definite finding on MRI alone was considered positive, its sensitivity would increase from 56% to 72% with the addition of MRCP (Charatcharoenwitthaya P, Enders FB, Halling KC, et al. Utility of serum tumor markers, imaging, and biliary cytology for detecting cholangiocarcinoma in primary sclerosing cholangitis. *Hepatology* 2008;48(4):1106–17). The role of PET/CT in the workup of patients with perihilar cholangiocarcinoma should also be discussed for completeness. Although the sensitivity and specificity of ^{18}F-FDG-PET for the primary tumor in cholangiocarcinoma is 60% to 92% and 93% to 100%, its sensitivity for regional lymph node metastases is poor, at only 13% to 50% (Kluge R, Schmidt F, Caca K, et al. Positron emission tomography with [(18)F]fluoro-2-deoxy-D-glucose for diagnosis and staging of bile duct cancer. *Hepatology* 2001;33(5):1029–35; Moon CM, Bang S, Chung JB, et al. Usefulness of 18F-fluorodeoxyglucose positron emission tomography in differential diagnosis and staging of cholangiocarcinomas. *J Gastroenterol Hepatol* 2008;23(5):759–65). The predominant role of ^{18}F-FDG-PET in the evaluation of hilar CCA is the identification of distant metastases in patients who present with this disease.

Endoscopic retrograde cholangiography is an invaluable approach in the initial evaluation of the biliary tree and as a first therapeutic step. The presence of a dominant stricture with or without upstream biliary duct dilatation as identified on cross-sectional imaging is an indication for cytologic evaluation through biliary brushings or ultrasound-guided lymph node biopsy. I would caution, however, that patients who are candidates for transplantation should undergo fine-needle aspiration of adjacent suspicious lymph nodes rather than tumor sampling because of the high risk of needle tract seeding, which would preclude transplantation (Heimbach JK, Sanchez W, Rosen CB, et al. Trans-peritoneal fine needle aspiration biopsy of hilar cholangiocarcinoma is associated with disease dissemination. *HPB (Oxford)* 2011;13(5):356–60; Levy MJ, Heimbach JK, Gores GJ. Endoscopic ultrasound staging of cholangiocarcinoma. *Curr Opin Gastroenterol* 2012;28(3):244–52).

Unfortunately, 23% of patients with hilar cholangiocarcinoma present with locally advanced tumors (Jarnagin WR, Fong Y, DeMatteo RP, et al. Staging, resectability, and outcome in 225 patients with hilar cholangiocarcinoma. *Ann Surg* 2001;234(4):507–17; discussion 517–9). Although surgical resection is the mainstay of treatment for patients with Klatskin tumors, a multidiscliplinary approach that includes neoadjuvant therapy in a select group of patients with locally advanced disease is warranted. These patients should be selected based upon clinical features that portend a poor clinical outcome. A meta-analysis of 7 studies with 2,132 patients revealed that older age, larger tumor size, presence of multiple tumors, lymph node metastasis, vascular invasion, and poor tumor differentiation were all negative prognostic indicators for patients with cholangiocarcinoma (Mavros MN, Economopoulos KP, Alexiou VG, et al.

Treatment and prognosis for patients with intrahepatic cholangiocarcinoma: systematic review and meta-analysis. *JAMA Surg* 2014;149(6):565–74). A reasonable approach to patients with these findings is to offer neoadjuvant therapy as a downstaging strategy prior to resection. McMasters et al. reported tumor downstaging in nine patients with initially unresectable hilar cholangiocarcinoma who were able to safely undergo an R0 resection after neoadjuvant 5-FU chemotherapy and radiation therapy. Interestingly, three of these patients demonstrated complete pathologic responses at resection. These data suggest a broader role of neoadjuvant therapy in unresectable or borderline resectable tumors (McMasters KM, Tuttle TM, Leach SD, et al. Neoadjuvant chemoradiation for extrahepatic cholangiocarcinoma. *Am J Surg* 1997;174(6):605–8; discussion 608–9). A Japanese trial of neoadjuvant gemcitabine and radiation therapy for cholangiocarcinoma was reported at the European Society of Surgical Oncology in 2008. An interim analysis of the subsequent phase II trial reported an R0-resection rate of 57.1% (8/14) based on intent to treat analysis. Although we await a report of the entire cohort, I expect that neoadjuvant therapy will continue to provide significant dividends in the treatment of this cohort of patients.

The opportunity to offer adjuvant therapy to patients who are found to have poor prognostic features after resection has been the subject of extensive research. To date, however, no data has demonstrated a survival benefit with postoperative chemoradiation while at the same time imparting a significant complication rate (Sagawa N, Kondo S, Morikawa T, et al. Effectiveness of radiation therapy after surgery for hilar cholangiocarcinoma. *Surg Today* 2005;35(7):548–52; Vern-Gross TZ, Shivnani AT, Chen K, et al. Survival outcomes in resected extrahepatic cholangiocarcinoma: effect of adjuvant radiotherapy in a surveillance, epidemiology, and end results analysis. *Int J Radiat Oncol Biol Phys* 2011;81(1):189–98; Schoenthaler R, Phillips TL, Castro J, et al. Carcinoma of the extrahepatic bile ducts. The University of California at San Francisco experience. *Ann Surg* 1994;219(3):267–74). However, adjuvant chemoradiation should be considered for patients with either positive margins (R1) or residual tumor. Systemic therapy with gemcitabine plus cisplatin, or 5-FU should also be considered in patients with positive lymph nodes.

Orthotopic liver transplantation is a promising treatment for cholangiocarcinoma because it would, by necessity, achieve tumor-free margins. However, experiences during the late 1980s and early 1990s were poor due to the aggressive biology of this disease; thus, hilar cholangiocarcinoma became a widely recognized contraindication to liver transplantation (Goldstein RM, Stone M, Tillery GW, et al. Is liver transplantation indicated for cholangiocarcinoma? *Am J Surg* 1993;166(6):768–71; discussion 771–2). Given that liver transplantation did result in long-term survival for select patients with negative margins and absence of regional lymph node metastases, selected groups considered to evaluate it as a treatment modality for cholangiocarcinoma

(Shimoda M, Farmer DG, Colquhoun SD, et al. Liver transplantation for cholangiocellular carcinoma: analysis of a single-center experience and review of the literature. *Liver Transpl* 2001;7(12):1023–33). The group at Mayo designed a protocol by combining the benefits of radiotherapy, chemosensitization, and liver transplantation patients with unresectable hilar cholangiocarcinoma. An initial report demonstrated an 82% 5-year survival for 28 patients (Heimbach JK, Gores GJ, Haddock MG, et al. Liver transplantation for unresectable perihilar cholangiocarcinoma. *Semin Liver Dis* 2004;24(2):201–7). In more recent publications, the survival rates have been adjusted to 65% to 70% (Gores GJ, Darwish Murad S, Heimbach JK, et al. Liver transplantation for perihilar cholangiocarcinoma. *Dig Dis* 2013;31(1):126–9). The Mayo experience has been criticized because two distinct patient populations were included in the experience. One group underwent neoadjuvant chemoradiation while the second group was high selected with early-stage disease (Bismuth H. Revisiting liver transplantation for patients with hilar cholangiocarcinoma: the Mayo Clinic proposal. Liver Transpl 2000;6(3):317–9; Rea DJ, Heimbach JK, Rosen CB, et al. Liver transplantation with neoadjuvant chemoradiation is more effective than resection for hilar cholangiocarcinoma. *Ann Surg* 2005;242(3):451–8; discussion 458–61; Rosen CB, Darwish Murad S, Heimbach JK, et al. Neoadjuvant therapy and liver transplantation for hilar cholangiocarcinoma: is pretreatment pathological confirmation of diagnosis necessary? *J Am Coll Surg* 2012;215(1):31–8; discussion 38–40). Mantel et al. identified 28 patients (19%) who met the strict selection criteria of the Mayo Clinic protocol, but had undergone neoadjuvant chemoradiation therapy. Five-year survival in this subgroup was 59%, which is comparable to patients with pretreatment pathologic confirmed hilar cholangiocarcinoma who were transplanted after completion of the chemoradiation protocol at the Mayo Clinic. Based upon these findings, one can cautiously conclude that improved survival after transplantation can be achieved with strict selection criteria (Mantel HT, Westerkamp AC, Adam R, et al. Strict selection alone of patients undergoing liver transplantation for hilar cholangiocarcinoma is associated with improved survival. *PLoS One* 2016;11(6):e0156127).

Again, this is an outstanding contribution to this edition of the mastery of Surgery. We appreciate the depth of the issues surrounding malignant biliary obstruction. Future opportunities include local therapies such as photodynamic therapy and other advanced intraluminal approaches to this disease.

John H. Stewart, IV

115 Cholecystojejunostomy and Choledocho/Hepaticojejunostomy

Herbert R. Freund and Michael R. Freund

CHOLECYSTOJEJUNOSTOMY

Favorable data have been published in recent years concerning curative surgery of periampullary carcinoma. The operative mortality of pancreatoduodenectomy in experienced hands ranges between 3% and 5%, and morbidity has dropped to 25% to 30% in high-volume institutions. Even in non-major referral centers, operative mortality (7% to 10%) and morbidity (30% to 40%) dropped significantly. Five-year survival rates for pancreatic cancer are reported to approach 12% to 24% for patients undergoing curative resection compared with a median survival of 6 to 10 months for patients undergoing bypass surgery or stenting by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) procedures. In various large reports, however, only 20% of patients have resectable pancreatic tumors, the remaining requiring some sort of palliation for relief of jaundice, actual or pending duodenal obstruction, or severe, often debilitating pain.

Decompression of the biliary tract obstructed by malignant periampullary lesions is indicated for the relief of obstructive jaundice and its ensuing severe and often intolerable pruritus. There are also ample data to suggest that stenting in malignant obstructive jaundice improves physical and functional well-being. Three viable options are available for the palliation of obstructive jaundice caused by periampullary malignant lesions in patients whose disease is determined to be unresectable:

1. Percutaneous transhepatic external or internal permanent catheter drainage of the biliary system.
2. Endoscopic papillotomy with insertion of an internal biliary-duodenal stent catheter.
3. Operative biliary-enteric bypass by cholecystojejunostomy or choledochojejunostomy/hepaticojejunostomy with or without a gastroenteric bypass.

Without getting into the yet unresolved argument whether radiologic or endoscopic stenting is superior to a biliary-enteric surgical bypass, we believe that a surgical biliary-enteric bypass has a viable role in the palliation of patients who have periampullary carcinomas, particularly in younger more fit patients without evidence of peritoneal or distant metastases. However, it should be acknowledged that with the now widespread use of preoperative cross-sectional imaging, the likelihood of finding unexpected locally unresectable disease has been greatly diminished. These patients are also the ones in whom an additional gastrojejunostomy is advocated for actual or pending mechanical gastric outlet obstruction, because comparable postoperative morbidity and mortality have been reported after "double bypass," or biliary diversion only. As a rule, we prefer to perform a "double bypass," namely, a cholecystojejunostomy, choledochojejunostomy, or hepaticojejunostomy and a gastrojejunostomy.

This approach receives further support from a recent meta-analysis of three prospective studies (218 patients) comparing prophylactic palliative gastroenterostomy and bilio-digestive anastomosis with no bypass or a bilio-digestive anastomosis alone that has shown that for patients with gastroenterostomy the chance for gastric outlet obstruction was significantly lower with no added operative morbidity or mortality.

The use of the gallbladder for internal biliary drainage is quick, simple, effective, and safe, and is the biliary conduit of choice when the cystic duct is patent and enters the common duct well away (1 cm) from the tumor mass. The gallbladder should not be used if it was previously diseased (chronic cholecystitis or cholecystolithiasis, or both), or when the cystic duct is narrow or enters the common duct close to the tumor. In such situations, the common hepatic duct is the preferred conduit for bypass, and the gallbladder is removed. When creating a cholecystojejunostomy, which is the simplest and quickest bypass, a loop of jejunum is the preferred enteric component of the bypass, whereas with a choledochojejunostomy/hepaticojejunostomy, the Roux-en-Y technique is applied.

Cholecystojejunostomy with a simple loop bypass is almost exclusively used in patients who were operated for cure and found during exploration to have locally advanced disease, possibly small liver metastases or peritoneal implants. The first loop of jejunum that easily and comfortably reaches the subhepatic space is passed in an antecolic manner without

tension and approximated to the gallbladder with a posterior row of seromuscular interrupted absorbable (4-0 or 3-0) sutures (Fig. 115.1A,B). On the jejunum, the sutures are placed parallel and adjacent to the edge of the mesenterium. Using electrocautery, an incision as long as possible is made in the body of the gallbladder, and the bile evacuated and sent for culture. A similar, but shorter, incision is made on the antimesenteric part of the approximated jejunum (Fig. 115.1B). Beginning in the middle and suturing toward the corners, the full thickness of the gallbladder and of the jejunum is anastomosed with 3-0 or 4-0 monofilament absorbable interrupted sutures. This creates the posterior wall of the anastomosis with all sutures tied on the inside (Fig. 115.1C). Turning both corners, sutures are placed in an inside-outside-outside-inside fashion from both sides of the anterior wall with ties on the inside (Fig. 115.1C) The last sutures on the anterior wall (simple or gumby sutures) are all placed before tying them with their knots on the outside (Fig. 115.1D). We rarely approximate the anterior serosal layer, although, if the gallbladder is large and redundant enough, it could be done. A cholecystojejunal anastamosis can also be accomplished by using a circular stapler (EEA No 25) with the advantage of using the same enterostomy site for both biliary and enteric anastamoses (Fig. 115.2). In our experience, leakage from a cholecystojejunostomy is extremely rare, but we still leave a closed suction drainage for 2 to 4 days. It is our practice to always add a small, sutured, or GIA stapled gastrojejunostomy distal to the cholecystojejunostomy.

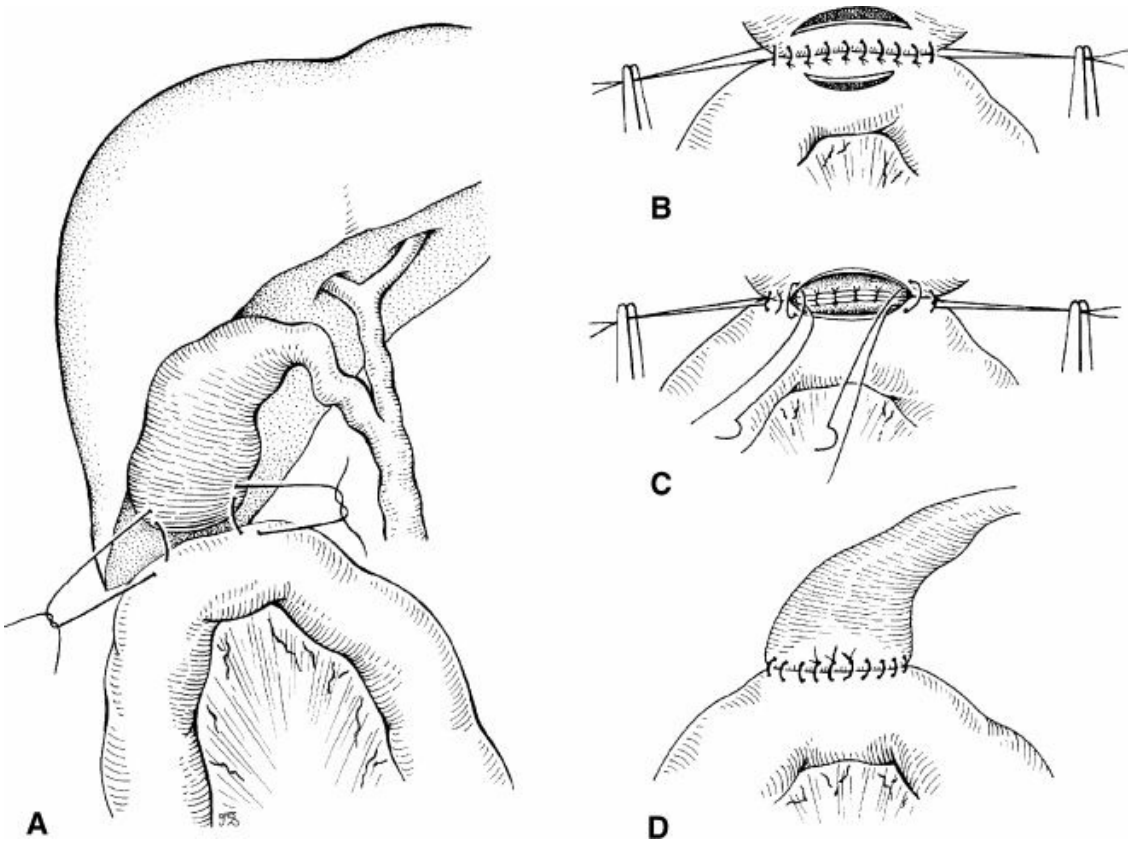

Figure 115.1. Side-to-side cholecystojejunostomy. **A.** The first loop of jejunum is approximated to the gallbladder with a posterior row of few interrupted sutures, which is seen completed in (B). **B.** After completion of the posterior layer, both jejunum and gallbladder are incised to the maximal length possible to create a good-sized anastomosis. **C.** A full-thickness posterior wall anastomosis between jejunum and gallbladder is constructed with the sutures tied on the inside and continued in a similar manner on the anterior part of the anastomosis. **D.** The last sutures of the anterior wall are all tied on the outside to complete the cholcystojejunostomy.

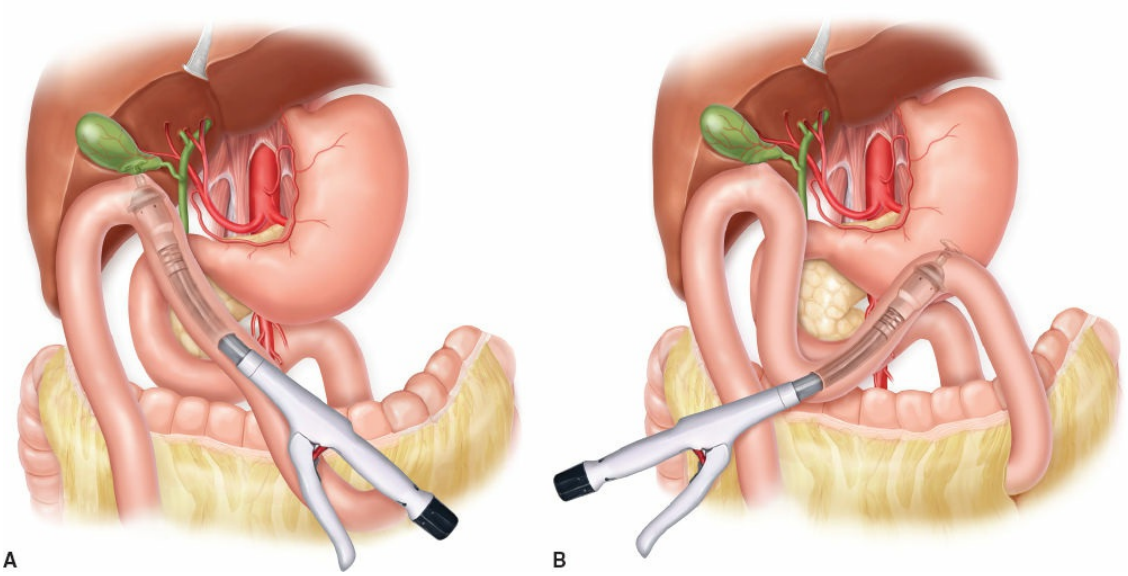

Figure 115.2. **A.** Double stapled technique in which an enterotomy is created in the jejunum and, using an intraluminal circular stapler, first a cholecystojejunostomy is created, the stapler removed and reinserted, and then (**B**) a gastrojejunostomy created, after which the enterotomy is closed. (Reproduced from Jarnagin W. *Master Techniques in Surgery: Hepatobiliary and Pancreatic Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.)

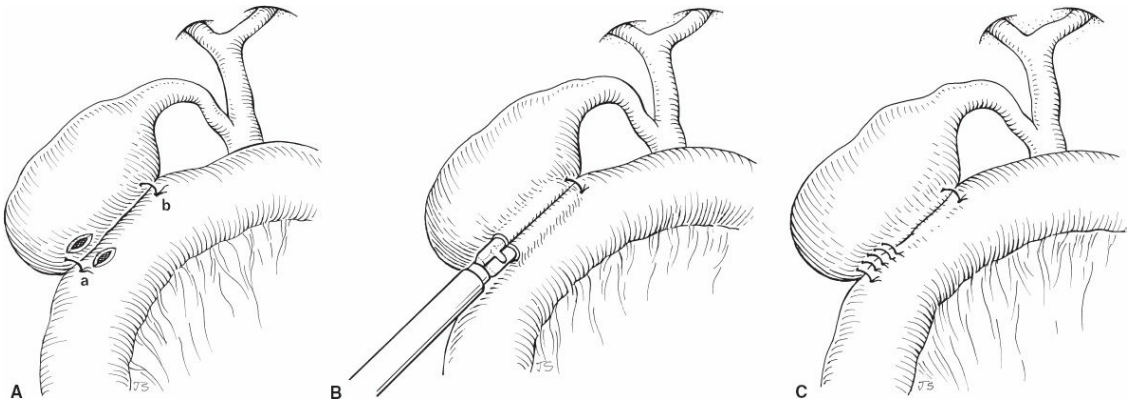

Figure 115.3. Laparoscopic cholecystojejunostomy. **A.** Placement of anchoring sutures (a,b) between gallbladder and proximal loop of jejunum. Two small incisions are created in the gallbladder and adjacent jejunum close to anchoring suture (a) for passage of the stapler. **B.** The entire length of the endoscopic linear stapler is introduced into gallbladder and jejunum and fired. **C.** The now common opening left by removal of the stapler is closed by interrupted sutures or a further application of the stapler.

Technical and technological advances in laparoscopic surgery make it

possible to safely perform the double bypass procedure laparoscopically, which results in reduced operative morbidity and possibly in a shorter and easier postoperative course and more rapid convalescence.

The laparoscopic cholecystojejunostomy is accomplished using 3 to 5 trocars. The first jejunal loop to comfortably reach the gallbladder is attached with 1 or 2 anchoring sutures to the gallbladder (Fig. 115.3A). A small incision is made close to the proximal anchoring suture (Fig. 115.3A) in the gallbladder and the adjacent jejunum. The jaws of the 35- or 45-mm linear stapler is introduced through these two incisions and pushed to its full length, closed and fired (Fig. 115.3B). The two entry sites, now combined into one, can be closed by a second stapler firing or with interrupted sutures (Fig. 115.3C).

The laparoscopic gastrojejunostomy is technically a similar straightforward procedure that provides excellent palliation for the 10% to 20% of patients who have unresectable pancreatic cancer and develop subsequently duodenal obstruction. Here too, two anchoring sutures are placed to approximate the jejunum to the stomach (Fig. 115.4A). Two small incisions in the stomach and the adjacent jejunum enable the introduction and firing of a 30- or a 45-mm linear stapler (Fig. 115.4B). The common opening left after removal of the stapler is stapled or sutured (Fig. 115.4C).

We believe that the use of the laparoscopic technique for the palliation of malignant biliary obstruction is associated with a lower operative risk while offering longer palliation without the risk of gastric outlet obstruction, recurrent cholangitis, and repeated endoscopic manipulations for stent placement and change.

CHOLEDOCHOJEJUNOSTOMY/HEPATICOJEJUNOSTOI

The main indications for a choledochojejunostomy/hepaticojejunostomy are benign, mainly iatrogenic, biliary strictures and malignant obstruction of the biliary tract caused by peri-ampullary tumors. Rare indications for choledochojejunostomy/hepaticojejunostomy are direct trauma to the biliary system, choledochal cyst reconstruction, and select instances of sclerosing cholangitis in which areas of dilatation occur. Because biliary tract strictures are essentially iatrogenic in 97% of instances (0.5% to 0.6% incidence of bile duct injury in laparoscopic cholecystectomy), and each unsuccessful repair poses increased morbidity and mortality, reconstruction should restore long-lasting primary functional and anatomic

integrity at the first attempt of repair.

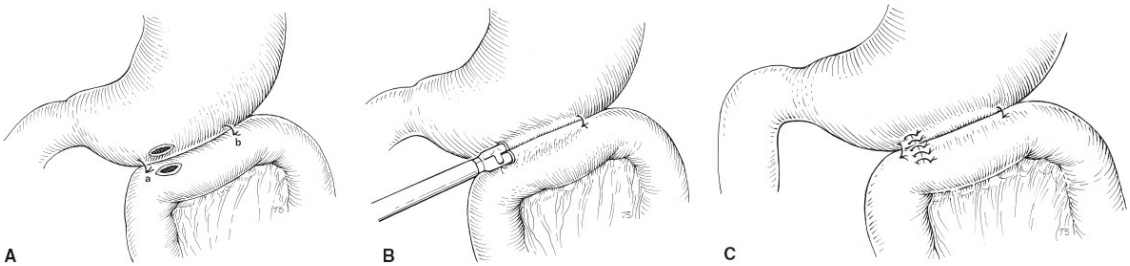

Figure 115.4. Laparoscopic gastrojejunostomy. **A.** Placement of two anchoring sutures (a,b) between body of the stomach and proximal loop of jejunum. Two small incisions are created in the stomach and jejunum close to anchoring suture (a) for passage of the stapler. **B.** The entire length of the linear stapler is introduced into stomach and jejunum and fired. **C.** The now common opening left by removal of the stapler is closed by interrupted sutures or a further application of the stapler.

PREOPERATIVE EVALUATION

The diagnosis should be established, and the anatomy of the biliary duct system and the nature and location of the obstruction should be characterized by PTC, endoscopic retrograde cholangiography, or magnetic resonance cholangiopancreatography (MRCP). At the same time, jaundiced patients can undergo drainage by either a percutaneous catheter or an endoprosthesis. The presence of such catheters, although reported to carry an increased operative morbidity, is a tremendous help for the surgeon exploring a scarred previously damaged or transected ductal system, particularly if this attempt to repair is not the first.

The transhepatic catheter might also be left in place during an operation for stenting and future imaging and removed only after the safety and patency of the anastomosis are ascertained by injection of contrast material 1 to 2 weeks following repair.

PREOPERATIVE PLANNING

Most patients who require a choledochojejunostomy/hepaticojejunostomy may have experienced cholangitis and jaundice, and should therefore receive antibiotics, and parenteral vitamin K perioperatively. Nutritional support should be offered when and where indicated. In our experience, most patients who have a diseased biliary system also harbor infected bile, with the most common pathogens being *Escherichia coli*, *Klebsiella*

species, and Enterococus. However, because many of these patients have had previous biliary tract operations and several interventions and instrumentations, infections with hospital-acquired anaerobes or resistant bacteria should be considered in the choice of perioperative antibiotics. Our preference is the combination of ampicillin and an aminoglycoside or a combination of a third-generation cephalosporin with metronidazole. Because the colon can be densely adherent to the gallbladder bed and liver, requiring meticulous dissection and separation, large bowel preparation is advised, but certainly not absolutely indicated.

SURGICAL TECHNIQUE

The biliary tract can be approached through a long right subcostal or a right paramedian incision. However, the best possible exposure is offered by the bilateral subcostal, better known as the "Bucket-handle incision," with or without the midline xiphoid extension. Figure 115.4 depicts the anatomic situation following the mandatory steps to release adhesions, dissection of the area of the hepatoduodenal ligament, and kocherization of the duodenum. It is important at this stage to perform meticulous dissection of the area between the undersurface of the right lobe of the liver and the duodenum. Sometimes, aspiration with a 25-gauge needle attached to a small syringe can be helpful in locating the dilated common duct. Favorable results have been reported with intraoperative sonographic detection of dilated common ducts, ductal stones, and pancreatic and ductal tumors. In dissecting out the common bile duct, the hepatic artery lying to its left is an important anatomic landmark (Fig. 115.5). However, one should be aware of the fact that this "textbook" arrangement of the common hepatic artery originating from the celiac trunk, giving off the left and right hepatic arteries is found in only 55% of patients. In the other 45% of patients, variations in the hepatic arterial supply exist. Of particular importance in this respect is the right hepatic artery arising from the superior mesenteric artery, which usually passes to the liver along the right side of the portal vein and the common bile and common hepatic ducts. Also frequent are anatomic variations in the extrahepatic biliary tree, most of them related to the confluence of the right and left hepatic ducts and of the cystic duct insertion into the common hepatic duct.

Once the common duct has been identified and dissected out, two 4-0 traction sutures are placed through the dilated common-duct wall just above the area of obstruction. The common duct is ligated below the

stricture with two 00 ligatures and is divided below the traction sutures (Fig. 115.6). The proximal end of the common duct is trimmed to achieve maximal diameter, good blood supply, and viable, free of scar duct tissue for anastomosis. Because the common hepatic and upper bile ducts depend on two axial arteries located along the lateral and medial borders of the ducts, undue mobilization and dissection should be avoided to ensure good blood supply to the anastomotic site.

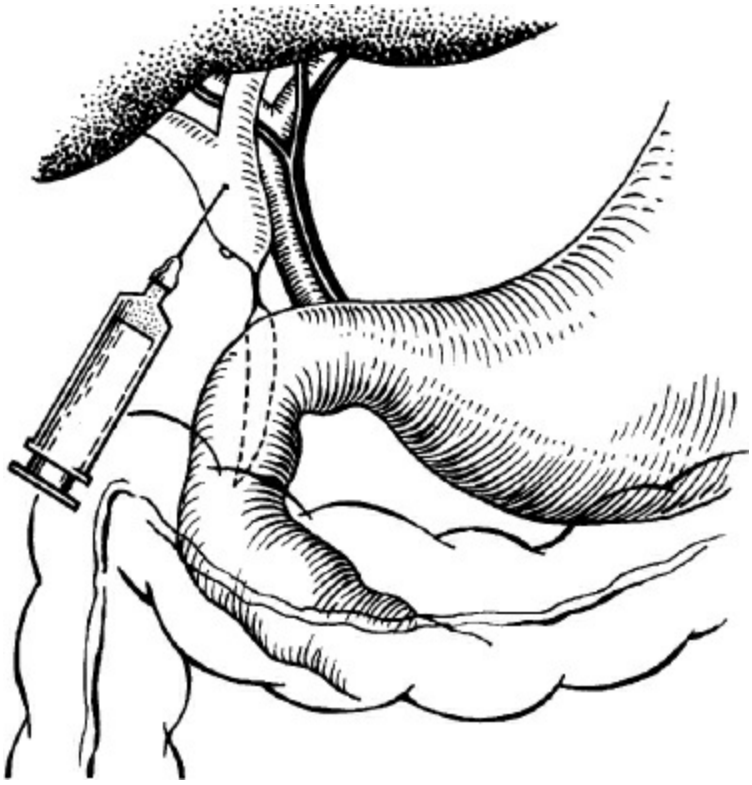

Figure 115.5. The location of the hepatic artery to the left of the common duct and exploratory aspirations with a fine needle are of great assistance in locating the common duct.

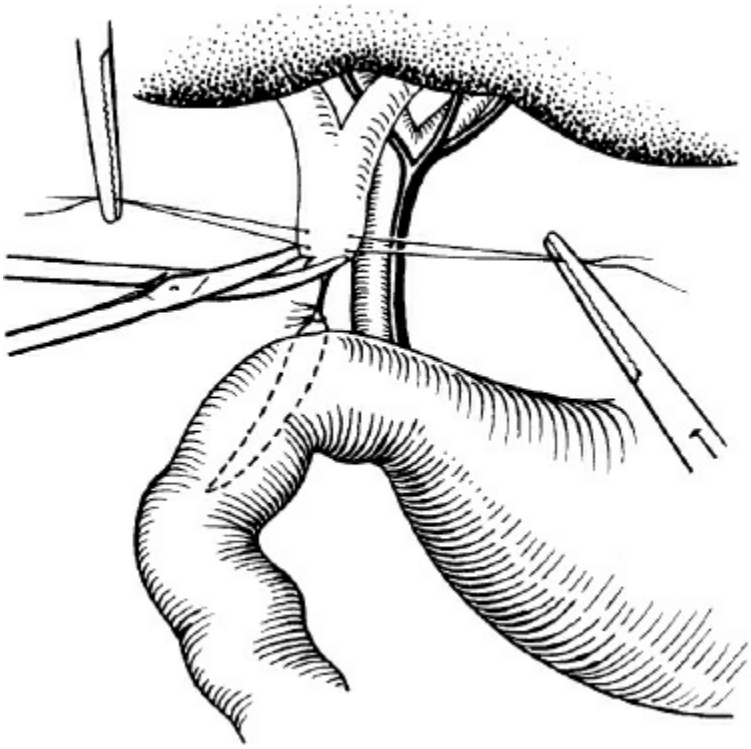

Figure 115.6. The distal part of the duct is ligated, and the proximal part is trimmed to achieve maximal diameter, good blood supply, and viable duct tissue.

Once the biliary system is opened, a bile specimen is sent for culture and sensitivity testing. In the case of choledocholithiasis, stones and debris are evacuated using Randall forceps, scoops, or a biliary Fogarty balloon catheter. After removal of stones, the duct system is irrigated with saline solution through a No. 8- or 10-Fr soft rubber catheter or a pediatiric (No. 5 or 8) feeding tube.

The first jejunal loop adjacent to the ligament of Treitz that comfortably reaches the subhepatic space is used to create a Roux-en-Y conduit. It is divided using the GIA stapler, and the distal part of it is brought through a window in the transverse mesocolon toward the severed common duct. The proximal afferent loop is sutured in an end-to-side manner to the ascending limb of defunctionalized jejunum (Fig. 115.7A), or is stapled with a GIA stapling instrument (Fig. 115.7B). The ascending limb is anchored to the mesocolon with few 000 absorbable sutures to avoid internal hernias. Care should be taken to use a limb of intestine 60 to 75 cm long between the biliary-enteric and the Roux-en-Y anastomosis to avoid cholangitis induced by reflux of gastrointestinal content (Fig. 115.7A,B).

When dealing with benign biliary tract strictures, two kinds of

anastomoses are commonly used. A greatly dilated biliary system is sometimes amenable to an end-to-end choledochojejunal anastomosis. This anastomosis is performed in one layer of interrupted 000 synthetic absorbable sutures (mono- or polyfilament), which offer favorable tissue drag, elasticity, and gradual loss of tensile strength. First to be placed are the two corners (Fig. 115.8A,B) and center (Fig. 115.8A,C) sutures of the posterior anastomotic wall. Each such interrupted suture is tied and used as a holding suture for the next suture. The rest of the posterior wall is completed with sutures placed every 3 mm, with care being taken to include the full thickness of both the jejunum and common duct. The knots of the posterior wall are all tied inside toward the lumen (Fig. 115.8B).

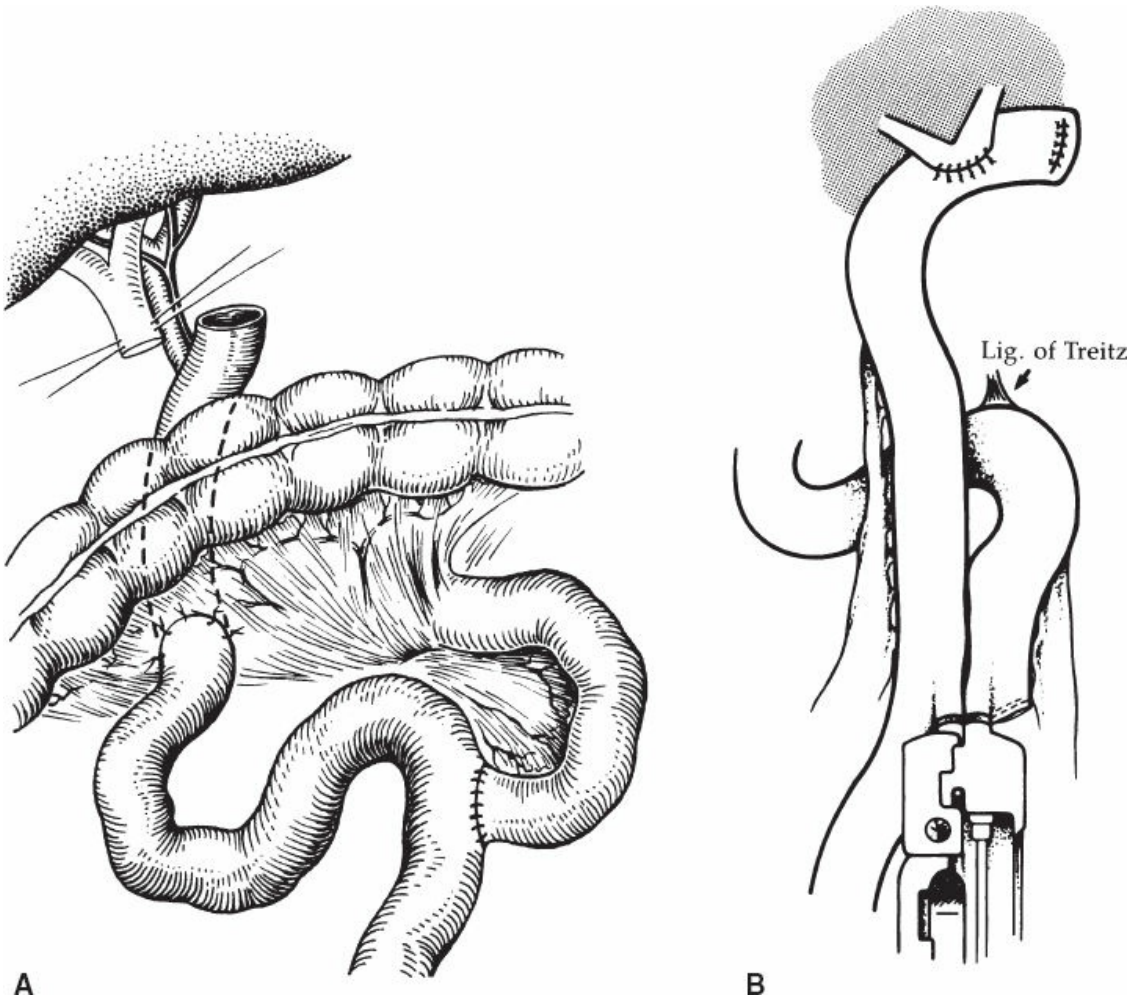

Figure 115.7. A. The end-to-side anastomosis of the Roux-en-Y is constructed, and the ascending limb of jejunum measuring approximately 45 cm is brought through the mesocolon toward the severed common duct. **B.** The construction of a Roux-en-Y enteroenterostomy using the linear stapler and the completed end-to-side hepaticojejunostomy.

The anterior wall of the end-to-end anastomosis is constructed in a similar manner. Starting on each corner, inside-outside-outside-inside sutures are placed and the knots tide inside the lumen, gradually working from both corners toward the center (Fig. 115.8C). The last sutures in the center of the anterior wall (simple or gumby sutures) are placed and tied on the outside. These last sutures are all placed before being tied to achieve secure closure and to avoid damage to the posterior anastomotic wall (Fig. 115.8D). When doing an end-to-end anastomosis, we find it unnecessary to use stents.

Much more commonly performed is the end-to-side mucosa-to-mucosa choledochojejunostomy or hepaticojejunostomy, which facilitates adjusting the size of the anastomosis to the diameter of the bile duct (Fig. 115.9). It is our conviction that all such biliary-enteric anastomoses should be performed under magnification to ensure exact mucosa to mucosa approximation. The proximal end of the jejunal limb, which was stapled by the GIA stapler, is secured with a second layer of absorbable sutures (Fig. 115.9). Approximately 5 cm proximal to this closure, on the antimesenteric aspect of the intestine, a one-layer biliary-enteric anastomosis is fashioned. Sometimes, it is convenient to approximate and align the seromuscular layer of the bile duct and the jejunal serosa by a few or 4-0 sutures (Fig. 115.9A).

Using electrocoagulation, the jejunum is opened longitudinally to accommodate the width of the bile duct (Fig. 115.9B). Care should taken not to open too much of the jejunum.

To facilitate an accurate and meticulous biliary-enteric anastomosis, we use and advocate the technique published by Blumgart (Fig. 115.10). The first step is to introduce the anterior layer sutures (4-0 or 5-0 absorbable, preferably monofilament) in the proximal duct, the needles being passed from inside-out and placed on rubber shods (Fig. 115.10A). The entire row of sutures so placed is carefully elevated enabling exact placement and tying of the sutures of the posterior layer (Fig. 115.10B).

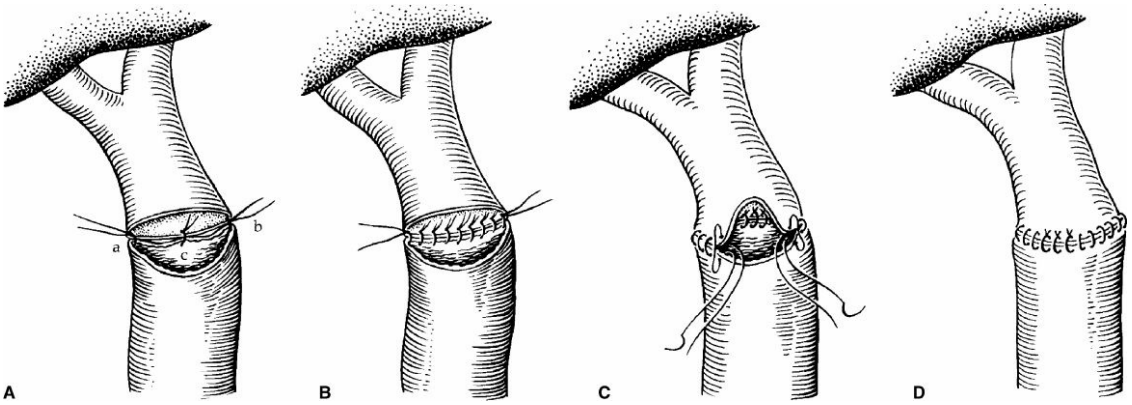

Figure 115.8. Construction of an end-to-end biliary-enteric anastomosis in a very dilated biliary system. **A.** Placing of the first anchoring sutures (a–c). **B.** The knots of the posterior wall are all placed inside toward the lumen, 2 to 3 mm apart. **C.** Note the inside-outside/outside-inside sutures when advancing toward the anterior wall. **D.** The last sutures in the center of the anterior wall are knotted on the outside.

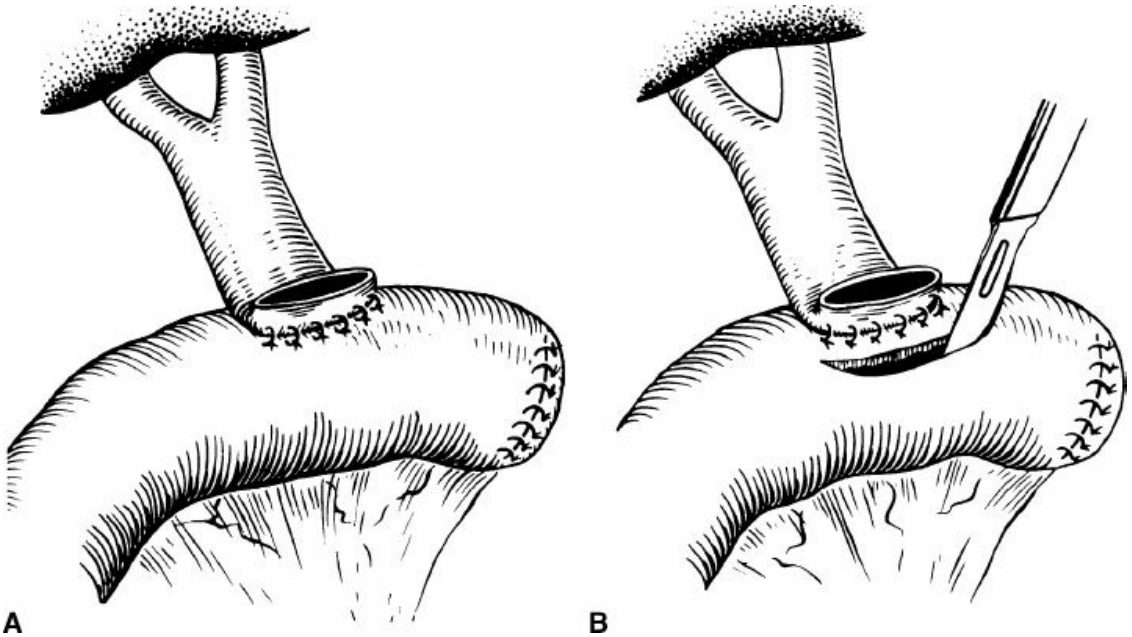

Figure 115.9. Construction of an end-to-side choledochojejunostomy. The proximal end of jejunum is stapled or sutured. **A.** Seromuscular layer of posterior wall, for approximation and anchoring. **B.** A longitudinal opening on the antimesenteric part of intestine.

Now the anterior wall closure is completed with the needles previously placed through the ductal anterior wall being placed through the jejunal wall from the outside inwards (Fig. 115.10C). The entire anterior row of sutures is passed before being securely tied with the knots inside.

Meticulous mucosa-to-mucosa approximation without tension is of prime importance for a safe and long-lasting patent anastomosis. This anastomosis is rarely stented. If needed, our preference is a T-tube with its short arm in the bile duct and the long one in the lumen of the intestine (Fig. 115.11A). The loosely fitting T-tube should be brought out through a stab wound in the anterior wall of the bile duct, if only possible. Bringing out the T-tube limb through a small incision in the jejunal loop is less desirable, because it can be dislodged by intestinal peristalsis. The external limb of the T-tube should never be passed through the anastomotic line. The long vertical portion of the T-tube is brought out through a separate stab wound in the abdominal wall (Fig. 115.11A) and should have some intra-abdominal redundancy to prevent traction and dislodgement of the tube if the patient's bowel becomes distended. Another option to stent the biliary-enteric anastomosis is to pass a long silicone tube with many holes cut along its length via the liver into the biliary system and through the anastomosis (Fig. 115.11B).

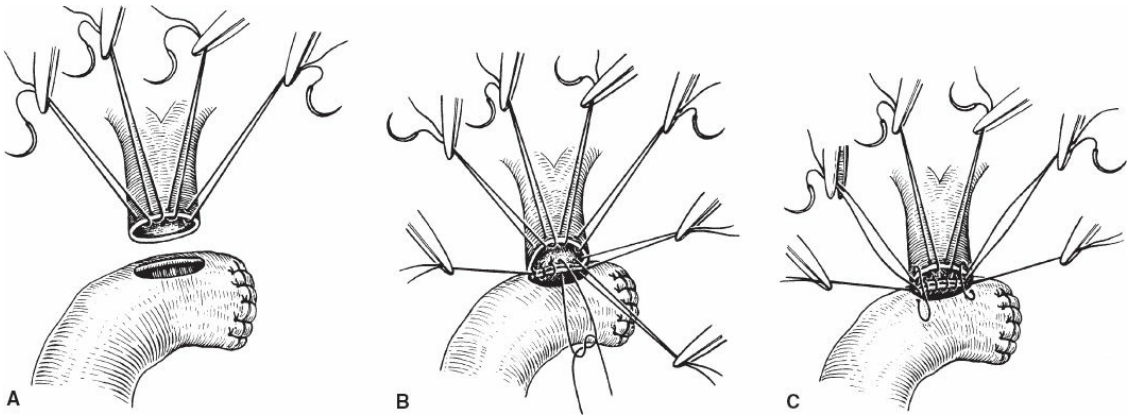

Figure 115.10. Modified after Blumgart surgery of the liver and biliary tract. **A.** The anterior layer of sutures on the bile duct is inserted first, with the sutures being passed from the inside out. The needles are retained and the sutures kept in order on rubber shods. **B.** The anterior layer of sutures is elevated to clearly display the posterior ductal wall. The posterior row of sutures is now placed and tied, using full thickness of duct and intestine with mucosa to mucosa approximation. **C.** The needles of the anterior layer are now passed through the jejunal wall from the outside inward. The entire anterior row of sutures is completed before being securely tied with the knots within. (Modified from Blumgart LH, ed. *Surgery of the Liver and Biliary Tract*. 2nd ed. London: Churchill Livingstone; 1994. Copyright Elsevier.)

Hepaticojejunostomy is the most commonly reconstructive procedure used for laparoscopic cholecystectomy-induced bile duct damage, 98% in a study of 200 repairs of damaged bile ducts.

The procedure is not only successful in about 93% of reconstructions but also affords favorable results that are comparable to patients undergoing uneventful laparoscopic cholecystectomy.

In small ducts one might anchor a short piece of a small bore silicon tubing to the center suture of the posterior layer for temporary stenting.

When the sutures dissolve, the stent passes out through the gastrointestinal tract.

At the completion of the anastomosis, the jejunal limb should be anchored to surrounding structures, mainly the hepatoduodenal ligament and scar tissue at the hilus of the liver to avoid unnecessary tension on the biliary-enteric anastamosis (Fig. 115.11A).

Some surgeons find it useful to suture a piece of the Roux limb to the abdominal wall and mark it with surgical clips for future injection of contrast material if and when radiography of the reconstructed biliary system is required.

If the biliary ductal system is narrow, we advocate the use of the side-to-side Y-type biliary-enteric bypass (hepatocholedochojejunostomy). A Y-shaped opening is made with two arms extending into the right and left hepatic ducts and the third arm extending longitudinally into the common hepatic duct. All limbs of the Y-shaped incision should be as long as possible (Fig. 115.12A). A 2- to 3-cm longitudinal incision is made in the jejunal loop that is brought up to the hilus of the liver, with care being taken not to open too much mucosa (Fig. 115.12B). A one-layer biliary-enteric anastomosis is constructed with 4-0 or 5-0 monofilament synthetic absorbable sutures. The posterior layer is created by first attaching points A to A′, B to B′, and C to C′ (Fig. 115.12B), and the rest of the posterior wall is completed with sutures placed approximately every 2 mm (Fig. 115.12C). The anterior layer is created by attaching D to D′ and suturing the rest of the distance between AA′ and BB′. The jejunal limb of the completed anastomosis should be anchored with a few sutures to fibrous tissue at the hilus and capsule of the liver.

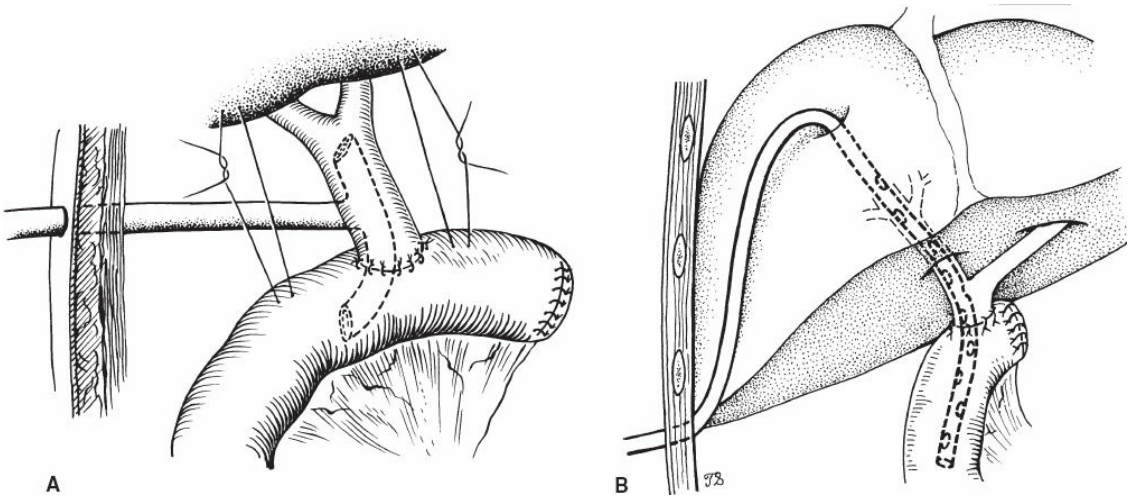

Figure 115.11. A. If required, a loosely fitting T-tube can be inserted through the anterior wall of the bile duct and passed through the biliary-enteric anastomosis into the intestine. The vertical portion of the T-tube is passed through a separate incision in the abdominal wall. The jejunal limb is anchored by two sutures to the undersurface of the liver or to surrounding structures. **B.** Another option to sent a biliary-enteric anastomosis is to pass a long silicone tube with several holes cut along it through the liver into the biliary ductal system and past the anastomosis into the intestine.

By patching the jejunum into the widest area of a narrow biliary ductal system, namely, at the confluence of the right, left, and common hepatic ducts, a widely open and effective biliary-enteric anastomosis is achieved.

When dealing with malignant obstructions of the biliary system, for which a bypass procedure only seems advisable and sufficient, we tend to use a simpler and less time-consuming biliary-enteric anastomosis. Either the dilated common duct proximal to the site of obstruction is divided and anastomosed in an end-to-side manner to the first loop of jejunum (Fig. 115.13), or an even simpler side-to-side choledochojejunostomy can be fashioned (Fig. 115.14). Both procedures are performed as a one-layer anastomosis. These two techniques of choledochojejunostomy (Figs. 115.13 and 115.14) offer better decompression and drainage of the biliary tract than does a cholecystojejunostomy and are thus preferable if the general condition of the patient and the local findings during the operation make it reasonable and feasible. As a general rule, we do not stent this anastomosis. Some patients will also undergo in addition a gastrointestinal bypass to avoid subsequent future gastric outlet obstruction.

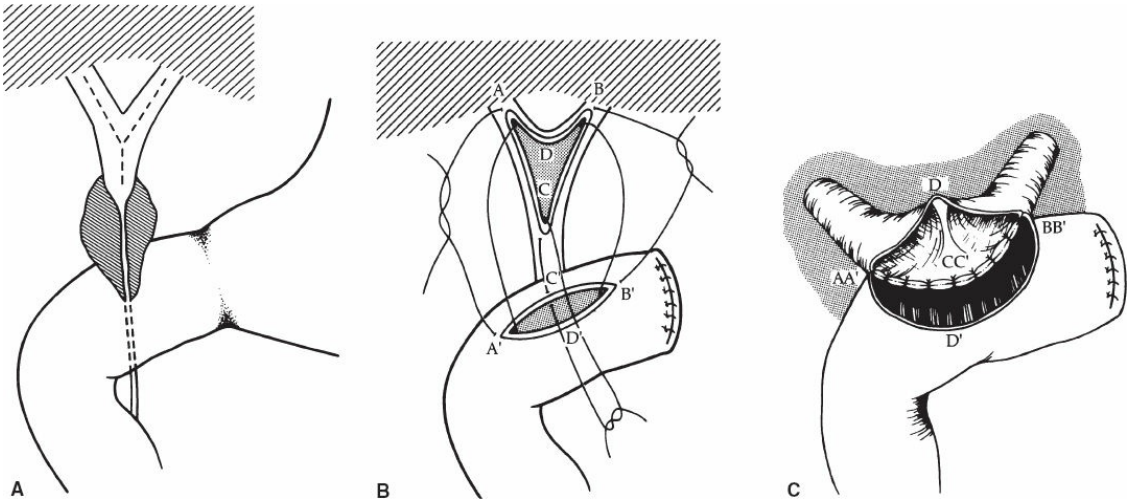

Figure 115.12. A. The Y-shaped incision is made above the point of obstruction with two arms extending into the right and left hepatic ducts and the third arm extending into the common hepatic duct. **B.** A longitudinal incision is performed in the defunctionalized loop of jejunum. The Y-shaped incision opens up into a three-angled opening. The posterior layer of the hepatocholedochojejunostomy is constructed by first attaching points A to A′, B to B′, and C to C′. **C.** The posterior layer of the hepatocholedochojejunostomy is completed. The anterior layer will be fashioned by attaching D to D′ and then suturing of the rest of the distance between AA′ and BB′.

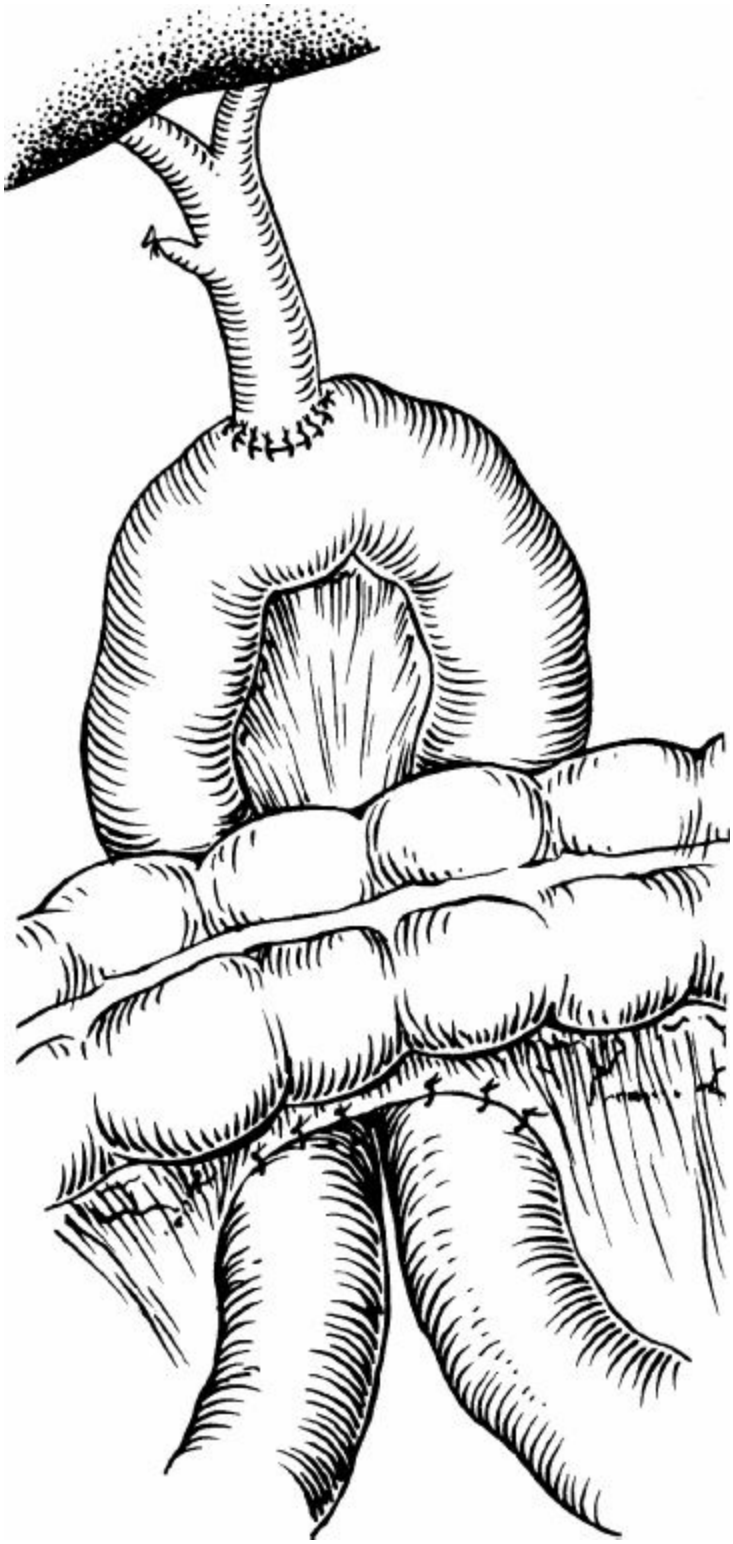

Figure 115.13. End-to-side choledochojejunostomy using a loop of proximal small intestine. (The bowel can be passed retrocolic or antecolic.)

Although the basic principles of a tension-free, mucosa to mucosa, well-vascularized anastomosis that drains all parts of the liver still hold

true, recent publications suggested other techniques to cope with the very small or very short hepatic duct remnant. One such technique applied in a small number of patients described a sutureless cholangio-jejunostomy using an intraluminal stent, while another group utilized a side-to-side hepatico-jejunostomy technique in difficult post-laparoscopic cholecystectomy bile duct injury repairs.

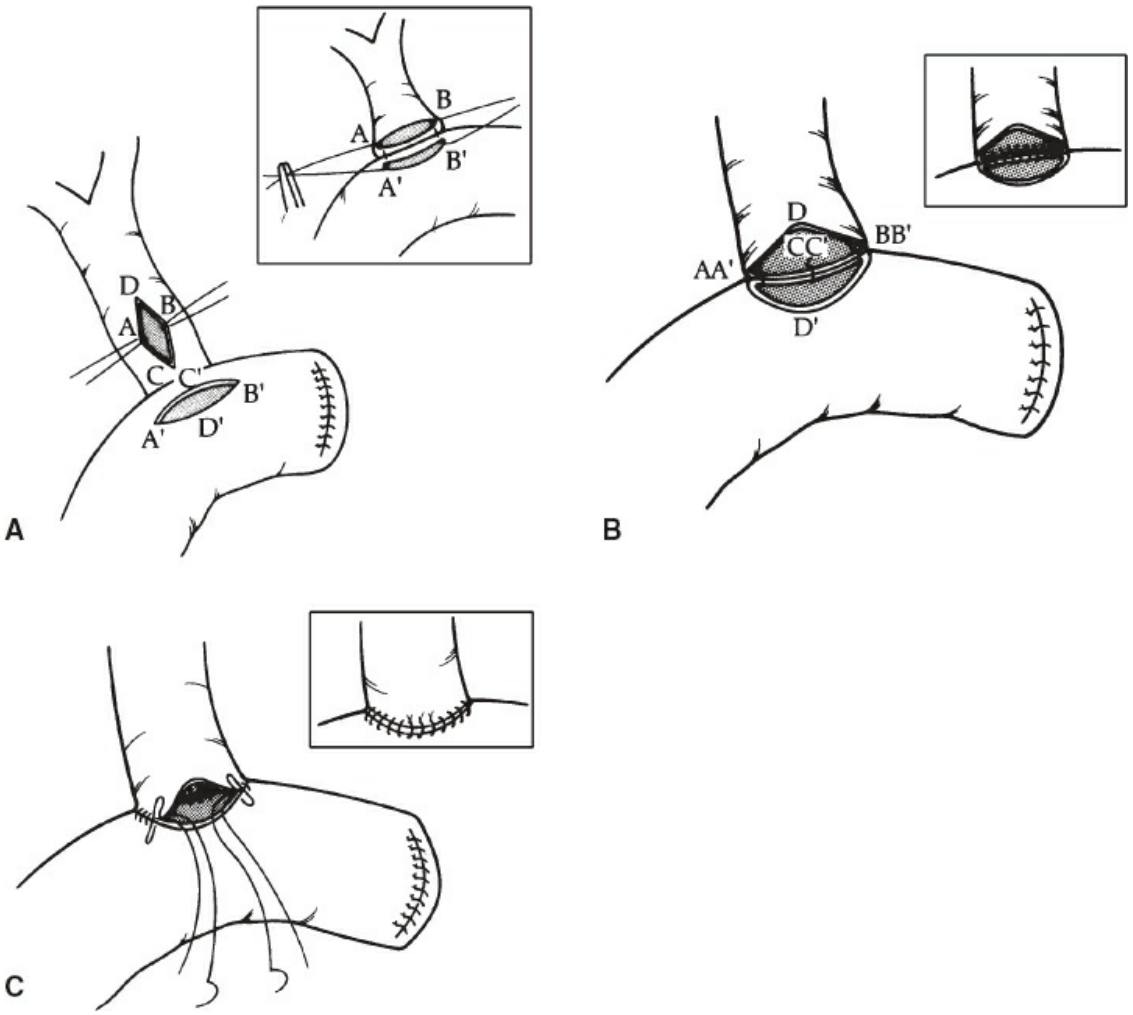

Figure 115.14. Side-to-side choledochojejunostomy. **A.** The longitudinal incisions in the common duct and the adjacently placed loop of excluded jejunum are converted by placing two anchor sutures into transverse incisions (**inset**). The diameter of the anastomosis should be made as large as possible, depending on the size of available common duct. **B.** The posterior wall of the choledochojejunostomy is initiated by placing the corner (AA′ and BB′) and center (CC′) sutures. The posterior wall is a one-layer anastomosis of interrupted synthetic absorbable sutures placed 2 to 3 mm apart (**inset**). **C.** The anterior wall is sewn by interrupted inside-outside-outside-inside sutures. The last sutures in the center of the anterior wall are placed and knotted on the outside

(**inset**).

For such injuries with short and/or small bile ducts, the anterior surface of the available bile duct is exposed and opened longitudinally on its anterior surface to its maximal available length. Mobilization of the duct should be minimal to avoid ischemia to the duct.

A 5-0 absorbable one-layer side-to-side bilio-digestive anastomosis was reported with a reasonable success rate in a limited and select group of patients with both benign and malignant diseases.

Compared to the end-to-side hepatico-jejunostomy, the side-to-side anastomosis requires less dissection, permits a wider anastomosis, and reports a 95% excellent functional end result.

LAPAROSCOPY

Despite major advances in laparoscopic surgery, the experience with laparoscopic choledoco/hepaticojejunostomy is still limited. Even more limited are data comparing laparascopic versus open biliary bypass surgery. Laparascopic choledocho/hepaticojejunostomy is a technically demanding procedure that requires advanced laparoscopic skills. However, if performed by an experienced laparascopic surgeon while maintaining the same principles of the open approach can offer the same biliary diversion success rates with reduced morbidity and mortality.

POSTOPERATIVE CARE

If the use of a drain seems appropriate, a closed system soft drain is placed in the foramen of Winslow and brought out through the abdominal wall, to be usually removed within 72 hours after the operation. In case of bile leak, the drain is left in place as long as necessary. Almost all such biliary fistulas close spontaneously within 1 to 3 weeks. We use nasogastric drainage and intravenous therapy for 3 to 5 days, depending on the general condition of the patient and the resumption of bowel sounds and movement. Antibiotics are continued for 3 to 5 days and should be adjusted in accordance with the cultures obtained during surgery.

EDITOR’S COMMENT

The introduction to this excellent chapter places these operations in proper perspective. The mortality of pancreaticoduodenectomy now is well below 3% to 5% and morbidity has dropped to 25% to 30% in high-volume centers. Even in nonmajor centers, mortality of 7% to 10% and morbidity of 30% to 45%, as Professor Freund says, are significantly reduced. As usual, despite the fact that survival following Whipple for 5 years may be improved the survival with biliary bypass remains up to 9 months if done properly. Today endoscopic stenting is far and away the most common technique. Distler et al. (*JOP* 2010;11:568–74) sought to determine if surgical or nonsurgical management was the most appropriate therapy for the treatment of obstructive jaundice in the palliative setting. In a carefully conducted study with a large number of patients, they showed that there was no evidence that stenting for obstructive jaundice does anything positive and in fact is associated with more common readmission and infection. They reviewed 342 patients over an 8-year period who were treated in one of three ways. Group 1 (138 patients or 56%) received only endoscopy and a prosthesis for drainage, Group 2 (68 patients or 28%) received

preoperative stenting followed by hepaticojejunostomy, and Group 3 (41 patients or 16%) received only a hepaticojejunostomy. Also, 261 patients or 76% had obstructive jaundice. The mortality in Group 1 was 2.2% and morbidity was 5.1%. In Group 2 morbidity was 17.6% but there was no mortality and in Group 3 mortality was 2.4% and morbidity 15%. The exchange of the endoscopic stent (if carried out) was required every 70 days and required hospitalization. Survival in Group I was 5.1 months and, in those that were stented and subsequently treated with hepaticojejunostomy (Group 2), 9.4 months. Median survival, however, in Group 3 was 6.4 months. The leakage rate in Group 3 was 9.8% while only two patients had a leak in Group 2. There was one patient with a pancreatic leak from an FNA. The results suggest that there is longer survival following hepaticojejunostomy. The data leave open the question as to whether or not preoperative stenting is helpful; previous studies have not shown any advantage to preoperative stenting. Although as per Table 2 in Distler's paper, patients who had undergone surgical bypass did not outlive those who had undergone endoscopic stenting, most of these studies are outdated; moreover, the ability to support patients with unresectable carcinoma of the pancreas or the lower end of the biliary tree has improved. What this study suggested at the time is that patients who have a life expectancy of greater than 6 months should have a hepaticojejunostomy without a stent prior to the operation. A similar conclusion was reached by van Heek et al. (*Acta Gastroenterol Belg* 2002;65:171–5).

Advances in the types of stents have improved the outcomes and reduced the need for stent changes. Usually a wall stent is deployed and this is very effective normalizing the bilirubin level. The studies comparing biliary bypass and stents are outdated and indeed the vast majority of patients are treated with stents and have a good outcome. There are no recent studies largely owing to the realization that endoscopic stenting for a terminal disease is superior to surgery. It corrects the problem and allows the patient to receive treatment without delay.

Still biliary enteric bypass with either hepaticojejunsotomy, choledochojejunostomy, or choledochoduodenostomy may be required in certain patients. Indeed choledochoduodenostomy may be superior as shown in some studies of liver transplantation. Bennett et al. (Choledochoduodenostomy is a safe alternative to Roux-en-Y choledochojejunostomy for biliary reconstruction in liver transplantation. *World J Surg* 2009;33:1022–5) have extensive experience in liver transplantation. In 619 liver transplants between 2000 and 2007, the usual biliary anastomosis was direct end to end, which was performed in 466 patients. Of 82 pediatric transplants with a cadaver liver, a direct common duct and duodenal anastomosis was carried out in 25 patients and choledochojejunostomy in 57. There were four leaks in the choledochojejunostomies, but none in the choledochoduodenostomies (Table 1 of that paper).

A somewhat different point of view was proposed by Wu et al.

(Choledochoduodenostomy as an alternative to choledochojejunostomy for biliary reconstruction in liver transplantation. *World J Surg* 2010;34:1727) in a letter in which they pointed out that the blood supply of the common duct that is pictured may be deficient because the biliary tract of the donor may be too long and may cause necrosis of the proximal biliary tract due to limited blood supply. They also raised questions concerning the incidence of cholangitis in the biliary choledochoduodenostomy patients. Campsen et al. (*World J Surg* 2010;34:1728–9) in their response to Wu's letter pointed out that they used the duodenum as the preferred site in a hostile abdomen and that with the portal vein clamping the duodenal blood supply may be superior to that of the bowel or the Roux-en-Y approach. Similarly, they pointed out that many of the pediatric transplants take place in children who have had neonatal enterocolitis and multiple perforations and may have short bowel syndrome, so that it is preferable to avoid further shortening of the bowel. They also pointed out that in the 40 patients who had choledochoduodenostomy there were no strictures and there is no bowel bile reflux as they ligated the native common bile duct. Tanaka et al. (Biliary reconstruction in pediatric live donor liver transplantation: duct-to-duct or Roux-en-Y hepaticojejunostomy. *J Ped Surg* 2010;45:1668–75) reviewed 60 pediatric patients who had biliary enteric anastomoses, with 14 having a choledochoduodenostomy and 46 having a Roux-en-Y jejunostomy. The leak rates were identical, with a 7.1% in the duodenal anastomosis and an 8.7% in the jejunal anastomosis. Strictures, however, were more common in the duodenal anastomosis (28.9% vs. 18.9% in the jejunal anastomosis). Years ago when debate raged about these procedures Bob Herman at the Cleveland Clinic made an excellent case for choledochoduodenostomy and had excellent outcomes.

Pilgrim et al. (Gallbladder carcinoma as a long-term complication of cholecystojejunostomy. *J Gastrointest Surg* 2009;13:2330–2) drew attention to various forms of carcinoma complicating various biliary enteric anastomoses. The initial case description was that of an 81-year-old patient who had a mistaken diagnosis of pancreatic carcinoma and was palliated with cholecystojejunostomy. He appeared 22 years later with a gallbladder cancer at the site of the anastomosis. In his review Tocci points out that the rate of cancer 30 years later in 1,003 patients was 5.5% and that this was higher in patients with choledochoduodenostomy as compared with hepaticojejunostomy or transduodenal sphincteroplasty (7.6% vs. 1.9% vs. 4.8%). He pointed out that most of the patients with cholangiocarcinoma had intermittent cholangitis. Tocchi et al. (*Ann Surg* 2002; 234:210–14). This raises the question as to whether patients with long-term biliary enteric anastomosis should undergo surveillance, especially with repeated episodes of cholangitis.

Whichever technique the surgeon chooses it should be the one he or she is most familiar with and most applicable to the patient situation.

116 Operative Treatment for Choledochal Cysts

Charles E. Bagwell and Hadley Katharine Wesson

INTRODUCTION

Choledochal cyst (CC) is a pathologic dilatation of the biliary system felt to be congenital in origin that can involve the common, hepatic, and intrapancreatic bile ducts in a variety of ways. These cysts are uncommon with an incidence of 1 in 100,000 to 150,000 live births, although in Asia the incidence is much higher. CCs are usually diagnosed in children; approximately 15% are discovered antenatally or in the first year of life and 60% in the first decade. However, the remaining 25% of CCs are diagnosed in the adult population, often presenting either as an incidental finding on imaging studies or with nonspecific symptoms such as abdominal pain. Treatment of CCs is based on the type of CC, presenting symptoms, and the potential for long-term serious sequelae, including malignancy. Accordingly, it is important for the general surgeon to understand an approach for both the recognition of and surgical options for CCs and how this approach may differ between children and adults.

ETIOLOGY AND PATHOPHYSIOLOGY

While the etiology of CCs is unknown, the most widely accepted theory involves an anomalous pancreaticobiliary duct junction (APBDJ). This malformation occurs in 50% to 80% of all CCs and between 80% and 96% of CCs in children. An APBDJ occurs when the common bile duct (CBD) and pancreatic duct join outside the duodenum (Fig. 116.1). It is thought that this common channel may allow pancreatic fluid to reflux into the biliary system and elevate the CBD pressure, causing ductal dilation and subsequent cellular damage. As a result, biliary epithelium may undergo dysplastic changes over time, increasing the risk of malignant transformation in the cyst wall.

CLASSIFICATION

CCs are classified according to their location (extra- or intrahepatic), extent of disease (segmental or complete), and shape (cystic, saccular, and fusiform) based on a system first proposed in 1959 by Alonso-Lej and modified nearly 20 years later (1977) by Todani (Fig. 116.2). Type I CCs are the most common, accounting for 80% to 90% of CCs. They involve dilated extrahepatic biliary ducts with normal intrahepatic ducts. Some recent schema subdivide type I CCs into subtypes A, B, and C based on dilation of the extrahepatic ducts only (A), isolated dilation of the distal CBD (B), or fusiform dilation of the extra hepatic ducts with APBDJ (C). In reality, this subdivision seems more arbitrary than beneficial in planning treatment or assessing outcome.

Type II cysts are true diverticula of the CBD and account for only 2% of all CCs. They may appear on ultrasound studies as cysts opposite the CBD with a normal appearing gallbladder and common hepatic duct.

Type III CCs are choledochoceles: cystic dilations of the most distal aspect of the CBD. Regarding the nomenclature, some argue, even quite emphatically, such as Ronald Martin in his recent critique of the CC classification scheme, that the term “type III choledochocele” is frequently used, but is incorrect. These cysts should either be referred to as type III CCs or choledochoceles. There is a further subclassification scheme for type III CCs, but given they are so rare (<1% of all CCs), the clinical application of this subclassification is arguably negligible. Due to their close proximity to the ampullary orifice, pancreaticobiliary outflow can become obstructed, making pancreatitis or biliary obstruction common presenting symptoms. Very large type III CCs can even obstruct the duodenum.

Type IV CCs are biliary duct cysts classified according to their involvement of the intra- and extrahepatic ducts. Type IVA cysts extend along the entire biliary system from the CBD into the intrahepatic biliary tree. Strictures within the ducts are often present. Type IVB involves the extrahepatic duct only and can present with multiple ductal dilations resembling a “string of beads” on cholangiography. The distinction between types A and B is important in terms of operative planning.

Type V CCs involve multiple dilations of the intrahepatic biliary ducts; contrast-filling multiple intrahepatic cystic dilations is pathognomonic, often termed Caroli disease. A “central dot sign” may be seen on magnetic resonance cholangiopancreatography (MRCP) or CT as portal vein enhancement within the dilated ducts. A type V CC is termed Caroli

syndrome when associated with congenital hepatic fibrosis and if severe enough, can present with cirrhosis.

CLINICAL PRESENTATION

CCs in children and adults often present with differing signs and symptoms. In children, the classic triad of abdominal pain, palpable abdominal mass, and jaundice occurs more frequently; 85% of children have at least two of these symptoms, compared to only 25% of adults. Unlike adults, infants can present with obstructive jaundice, acholic stools, and hepatomegaly—resembling patients with biliary atresia.

Adults are more likely to present with abdominal pain, cholangitis, pancreatitis, or history of prior cholecystectomy. Given these nonspecific symptoms, there may be a prolonged delay in making the diagnosis, with an average of 6 years in some series. Cholangitis results from chronic biliary tract inflammation; in type IVA and V CCs, recurrent cholangitis is due to bacterial colonization of intrahepatic cysts from bile stasis, sludge, and stones. Pancreatitis can result from proteinaceous plugs in the pancreatic duct as a result of chronic inflammation and mucin hypersecretion from dysplastic epithelium. CCs can also be asymptomatic, diagnosed incidentally from imaging studies obtained for other reasons.

MALIGNANCY

Biliary malignancy occurs in 10% to 30% of CCs, with the age at diagnosis related to the risk of developing malignancy in the biliary system. Approximately 70% of biliary malignancies from CCs are cholangiocarcinoma and 24% are gallbladder adenocarcinoma. Children with CCs have a very low risk of developing cholangiocarcinoma. Sastry et al.'s 2015 review of 5,780 cases of CCs reported an incidence of only 0.42% in children younger than 18 years of age. This risk increases to 15% at age 20 and 45% at age 50. Previous episodes of cholangitis and internal drainage procedures are also associated with increased risk of CC-related malignancy. It is noteworthy that neoplasm rates are greatly influenced by the type of CC: the greatest risk is seen in cyst types I and IV, while types

II, III, and V have very low risks of cancer.

DIAGNOSIS

CCs can be diagnosed with multiple imaging modalities, including ultrasound, CT, MRCP, and endoscopic retrograde cholangiopancreatography (ERCP). Because right upper quadrant pain and jaundice are common presenting symptoms, ultrasound is usually the first imaging study obtained. Ultrasound can quantitate intrahepatic and CBD dilatation, particularly if the CBD is greater than 10 mm in diameter. Usually ultrasound can distinguish the gallbladder from a type II CC. On the other hand, ultrasound may fail to diagnose up to 30% of CCs; even if a dilated CBD is visualized, the differential diagnosis still remains broad and includes malignancy and stone impaction. Oftentimes, the clinician will obtain a CT scan next. Arguably this is of limited value, as CT does not adequately assess the extent of extra- and intrahepatic biliary ductal dilatation and usually requires follow-up imaging with MRCP.

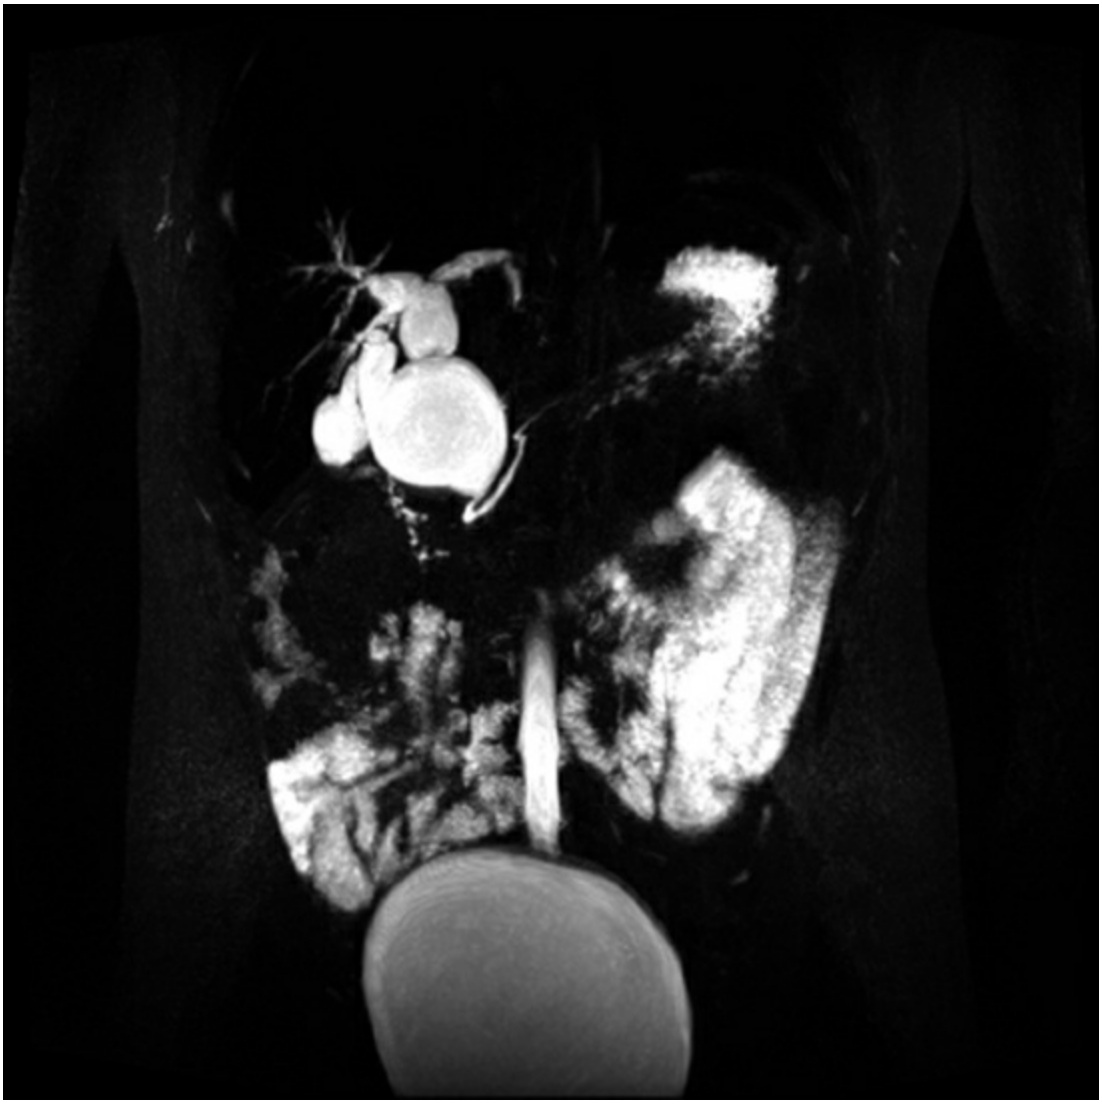

Figure 116.3. MRCP of type I choledochal cyst. Note dilated hepatic ducts and normal pancreatic duct.

At present MRCP is the diagnostic test of choice; it provides excellent imaging of the pancreaticobiliary ductal system and is both sensitive and highly specific for the anatomic definition of CCs, ranging from 70% to 100% and 90% to 100%, respectively (Fig. 116.3). It is noninvasive and can demonstrate the pancreatic and biliary ducts proximal to sites of obstruction as well as assess the presence of APBDJ, cholangiocarcinoma, and/or choledocholithiasis. However, MRCP may be of limited use in infants and younger children if the ducts are too small to be well visualized.

In adults, ERCP can be useful to outline the pancreaticobiliary duct system. For choledochoceles, ERCP can be both diagnostic and therapeutic, providing biliary drainage of the cyst with sphincterotomy, if

indicated. Percutaneous transhepatic cholangiography (PTC) may be necessary for some type IV and V cysts in order to visualize the entire biliary system (including intrahepatic cysts). In addition, PTC may be necessary for placement of transhepatic stents pre- or postoperatively. Although ERCP and PTC are sensitive imaging modalities, they may be technically challenging in the infant or small child, even under general anesthesia.

TREATMENT

The treatment of CCs is dependent on patient symptoms and the size and type of the cyst. Definitive treatment involves complete excision of the cyst to avoid the consequences of cholangitis, liver cirrhosis, pancreatitis, and malignancy. For type I cysts, management has evolved over the last 30 years from internal drainage of the cyst (cyst-duodenostomy) to complete excision, usually with Roux-en-Y hepaticojejunostomy reconstruction. This can be done either open or laparoscopically by first mobilizing the hepatic flexure and performing a Kocher maneuver to expose the cyst, and then encircling the cyst as it extends behind the duodenum (Fig. 116.4). Gallbladder mobilization will often assist in defining the cyst anatomy and serves as a retractor in subsequent dissection.

Further dissection of the cyst wall should proceed caudally onto the head of the pancreas, where the cyst should be divided as low as possible to remove all dysplastic epithelium but without compromise to the pancreatic duct (Fig. 116.5). In most cases, the posterior aspect of the cyst can then be dissected away from the underlying portal vein and hepatic artery (Fig. 116.6). If scarring is present, which may be the case in older patients with recurrent episodes of cholangitis, the cyst epithelium can be dissected off the fibrotic back wall, leaving behind only the fibrous layer of the posterior cyst wall (Lilly's procedure) (Fig. 116.7).

Once the hepatic duct confluence is exposed, the cyst can be transected proximally (Fig. 116.8). A note of caution: identifying the optimum level to transect the CC at the CHD may be challenging and can require frozen sections of the ductal wall to identify normal biliary mucosa and avoid leaving residual cyst remnants at the resection margin. Ideally, the proximal hepatic duct is transected at the point of visible caliber change of the duct at the cyst margin (Fig. 116.9). If intrahepatic duct dilation is present, strictures must be excluded as a cause—not infrequent with Type I CCs. Resection (or in some cases even balloon dilation) of a stenosis will

lessen the chance of late complications, such as recurrent cholangitis, stone formation, or anastomotic stricture.

Hepaticoenterostomy can be performed with either a Roux-en-Y hepaticojejunostomy or a hepaticoduodenostomy. Hepaticojejunostomy is the preferred technique, as the complication rate is thought to be much lower than from hepaticoduodenostomy. A recent meta-analysis by Narayanan et al. comparing hepaticojejunostomy and hepaticoduodenostomy in children following resection of CC showed hepaticojejunostomy did have a lower incidence of postoperative reflux, but otherwise long-term complications, including bile leak, anastomotic stricture, bowel obstruction, and cholangitis, were comparable. The length of the Roux limb of jejunum is dependent on the patient's age: 20 to 30 cm for children and up to 60 cm for adults. An end-to-end anastomosis of the jejunal limb to the upper remnant of the CBD may be considered if the diameters of the CBD and the proximal Roux-en-Y jejunum are similar. More commonly there is a size discrepancy such that an end-to-side hepaticojejunostomy is preferable for tailoring the anastomosis (Fig. 116.10).

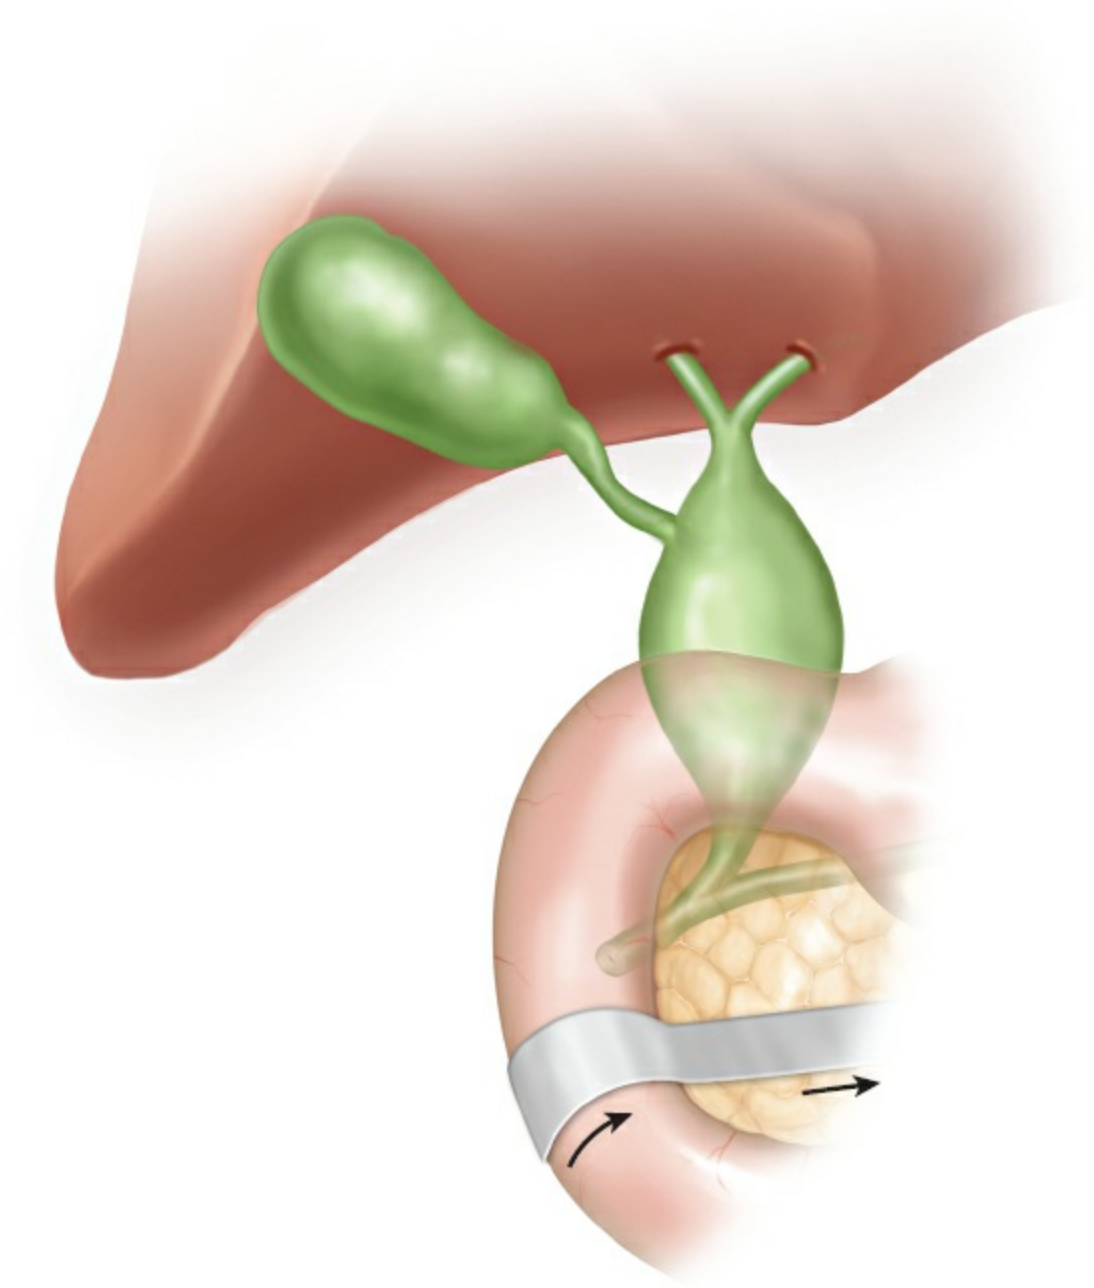

Figure 116.4. Mobilization of right colon by Kocher maneuver exposes duodenum and cyst behind.

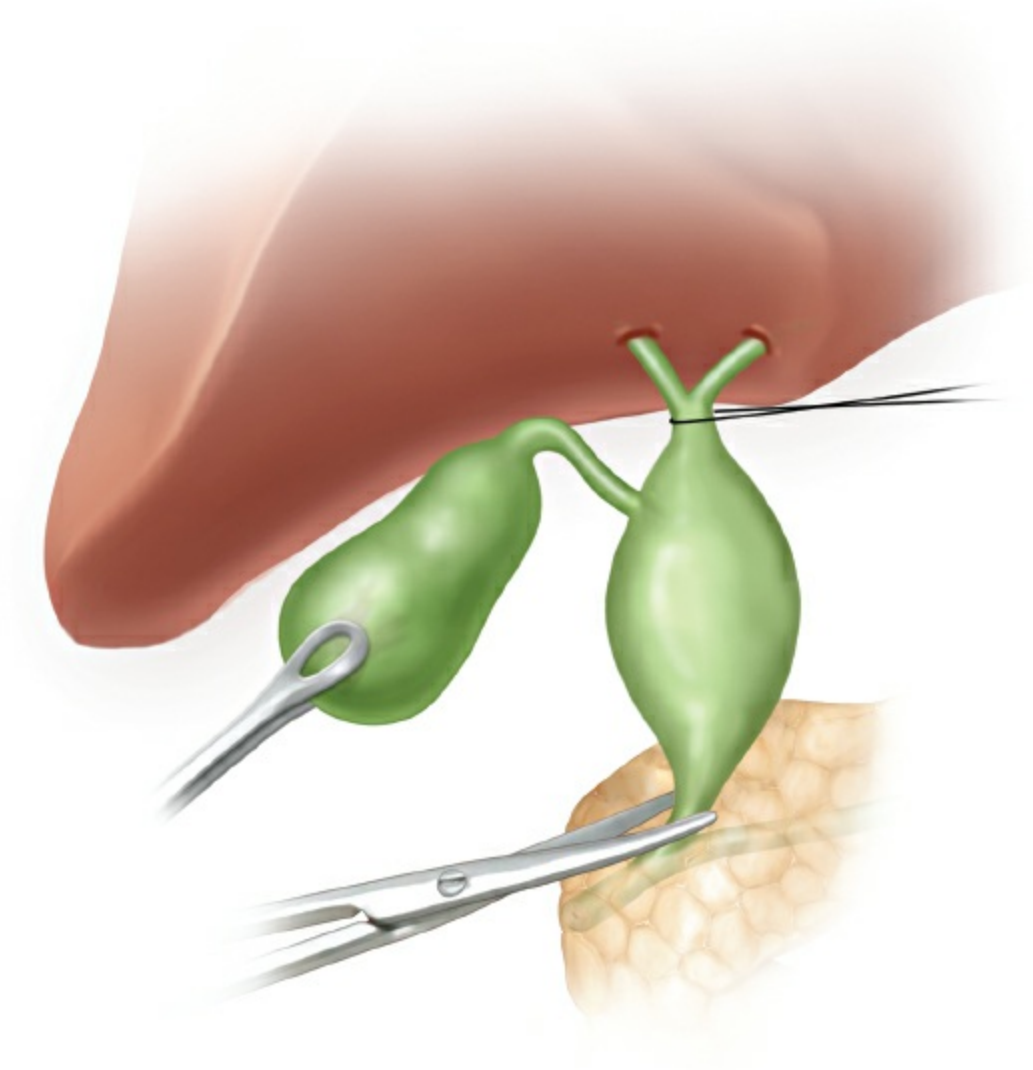

Figure 116.5. Distal resection of choledochal cyst as it enters the pancreas.

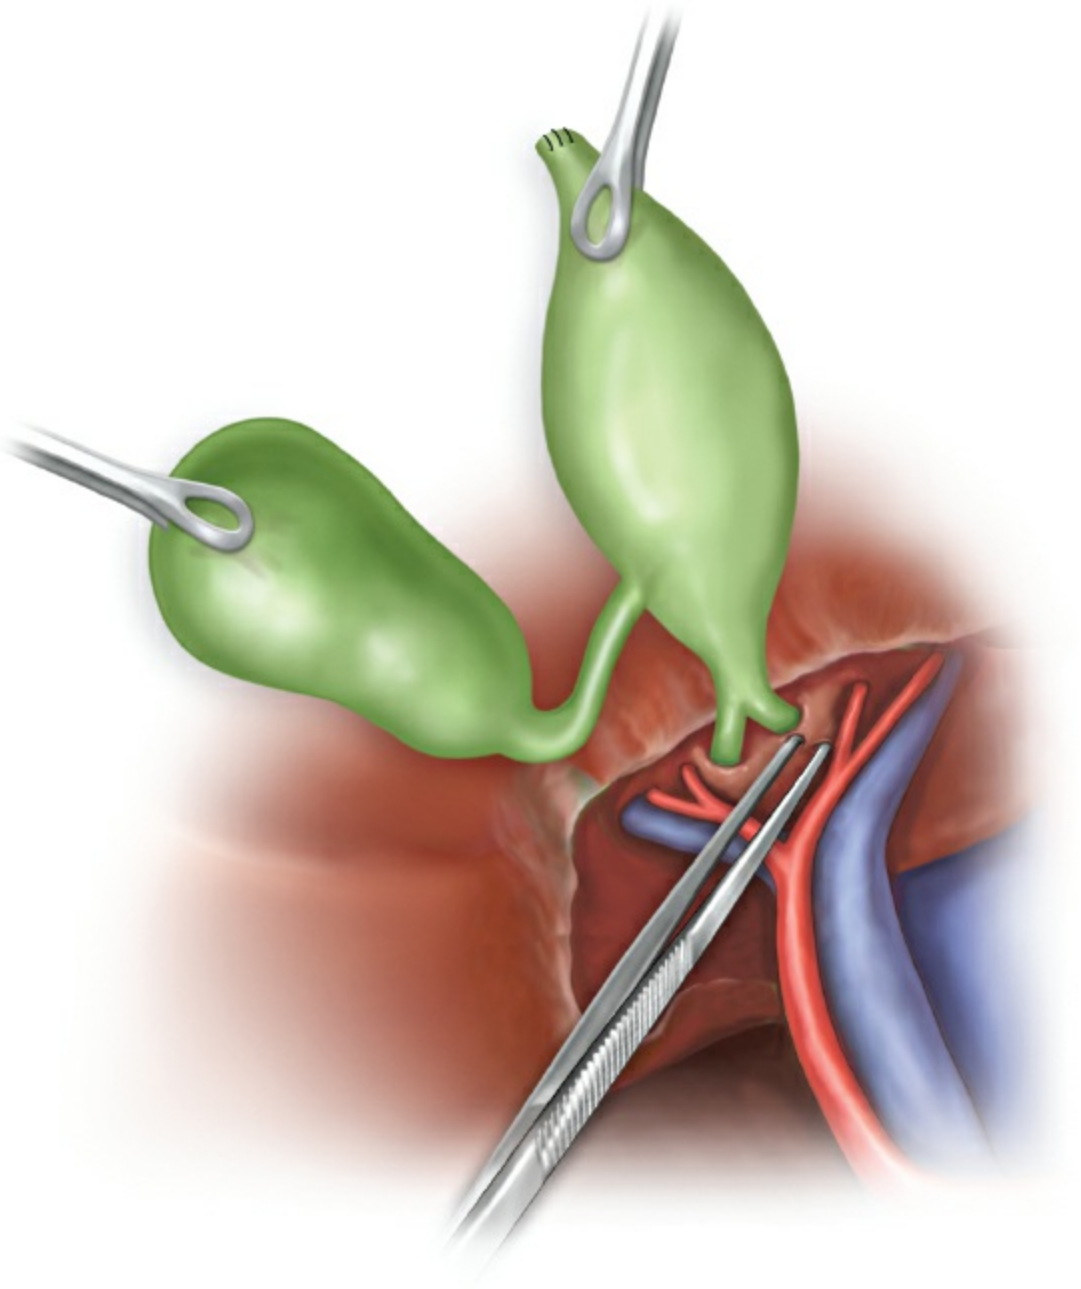

Figure 116.6. Proximal dissection of the cyst; note proximity of hepatic artery and portal vein posteriorly.

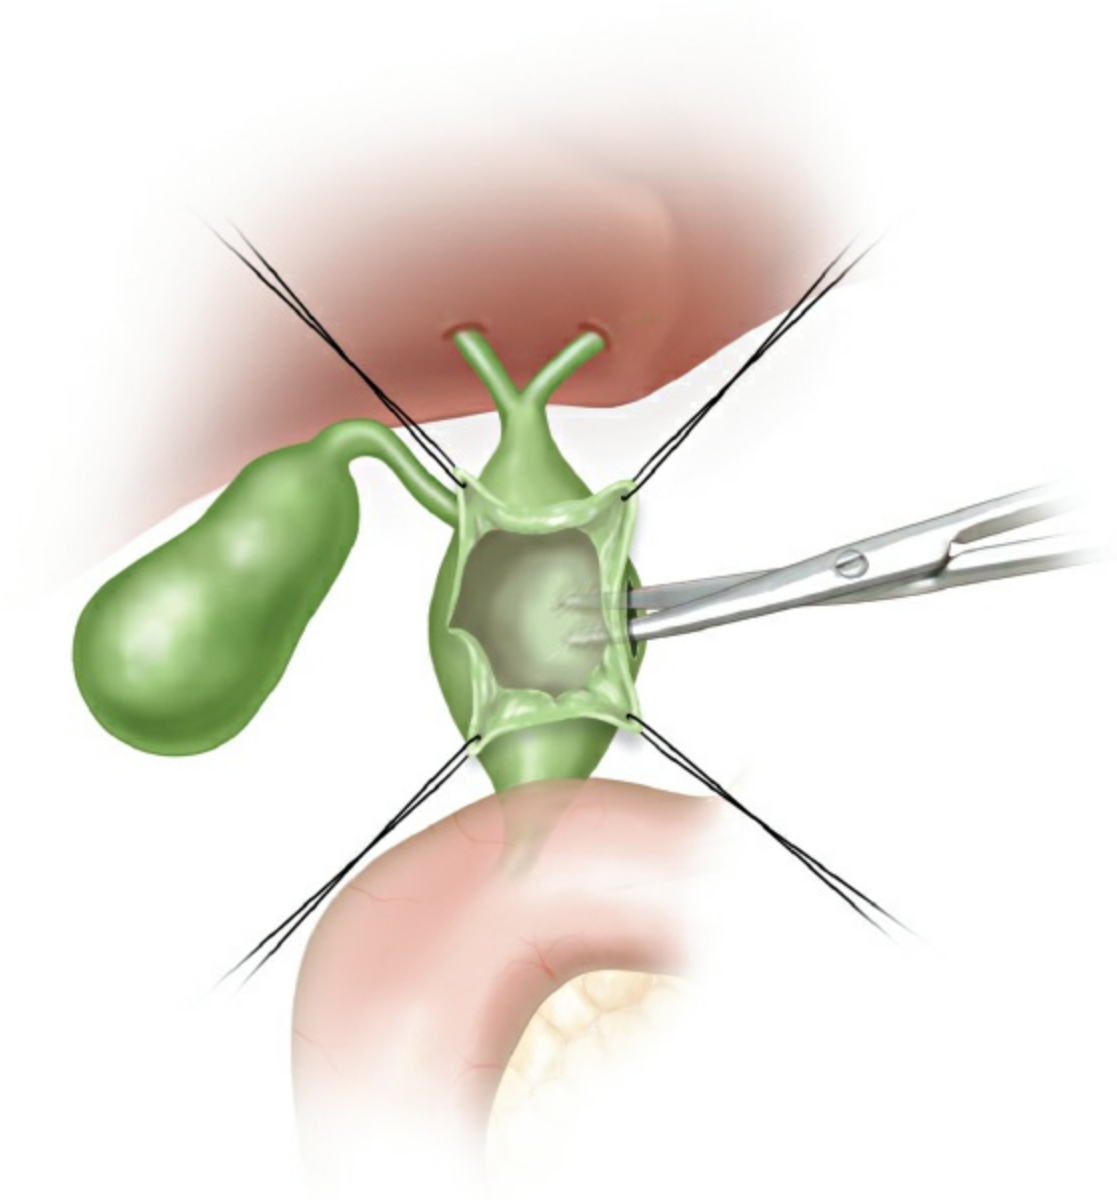

Figure 116.7. Dissection of the cyst epithelium from a scarred posterior wall is advised if the cyst wall is densely fibrotic.

For type II cysts, excision is the treatment of choice. This can be performed either with resection of the CBD and Roux-en-Y reconstruction or with complete excision of the cyst and primary closure over a T-tube. If only the cyst is excised, closure of the choleductotomy should be performed transversely to prevent narrowing of the CBD. Rarely can the cyst be excised flush with the wall of the common duct as this increases the risk of leaving cyst epithelium at the resection margin.

Type III cysts (choledochoceles) are associated with a low risk of malignancy and can usually be safely resected or drained into the duodenum. The decision to resect versus drain should be based on the

patient's age, symptoms, and comorbid conditions as well as the cyst's anatomic location relative to the duct and duodenal wall. Endoscopic therapy with ERCP is now considered the standard of care for symptomatic choledochoceles, with endoscopic sphincterotomy for small lesions. Larger choledochoceles may require an endoscopic incision along the cyst's luminal wall, and, in some cases, marsupialization of the cyst wall. Direct exposure via duodenotomy is an acceptable alternative for those lesions that do not have well-defined anatomy or if there is concern for malignancy.

Type IV cysts pose unique challenges in resection because cystic dilatation extends into the hepatic biliary tree and complete removal of the cyst is not always possible. Type IVA CCs have both intra- and extrahepatic cysts; complete extrahepatic cyst excision with biliary enteric anastomosis is recommended. The intrahepatic component must be addressed separately: if one lobe of the liver is involved (usually the left), some advocate resection of the lobe. Others suggest an approach that involves draining the intrahepatic cysts with large-bore Silastic stents and not resecting the hepatic parenchyma, considering the underlying low risk for subsequent malignancy. Proponents of this approach argue that by adequately decompressing the cysts, chronic inflammation can be minimized, which in turn minimizes long-term complications such as biliary stasis, cholangitis, and cirrhosis. If both hepatic lobes are involved or if there is recurrent and severe cholangitis or underlying cirrhosis, liver transplantation is a preferable option. Since type IVB CCs only have an extrahepatic component, treatment includes resection of the dilated extrahepatic cyst and Roux-en-Y hepaticojejunostomy.

Type V cysts may be particularly challenging and management remains controversial in terms nonoperative management versus liver resection or orthotopic liver transplantation (OLT), according to Soares et al.'s recent review of the literature. Hepatic resection is recommended when localized or unilobar cystic disease is present. If the disease is bilobar, but the patient is asymptomatic, nonoperative management is usually advised—with diligent follow-up given the risk of malignancy. OLT is recommended for bilobar Caroli disease with cholangitis, portal hypertension, or malignant transformation. Further debate remains surrounding the question of when to transplant, although it is generally considered better to transplant at an earlier stage of the disease to avoid further complications and need for emergent surgery.

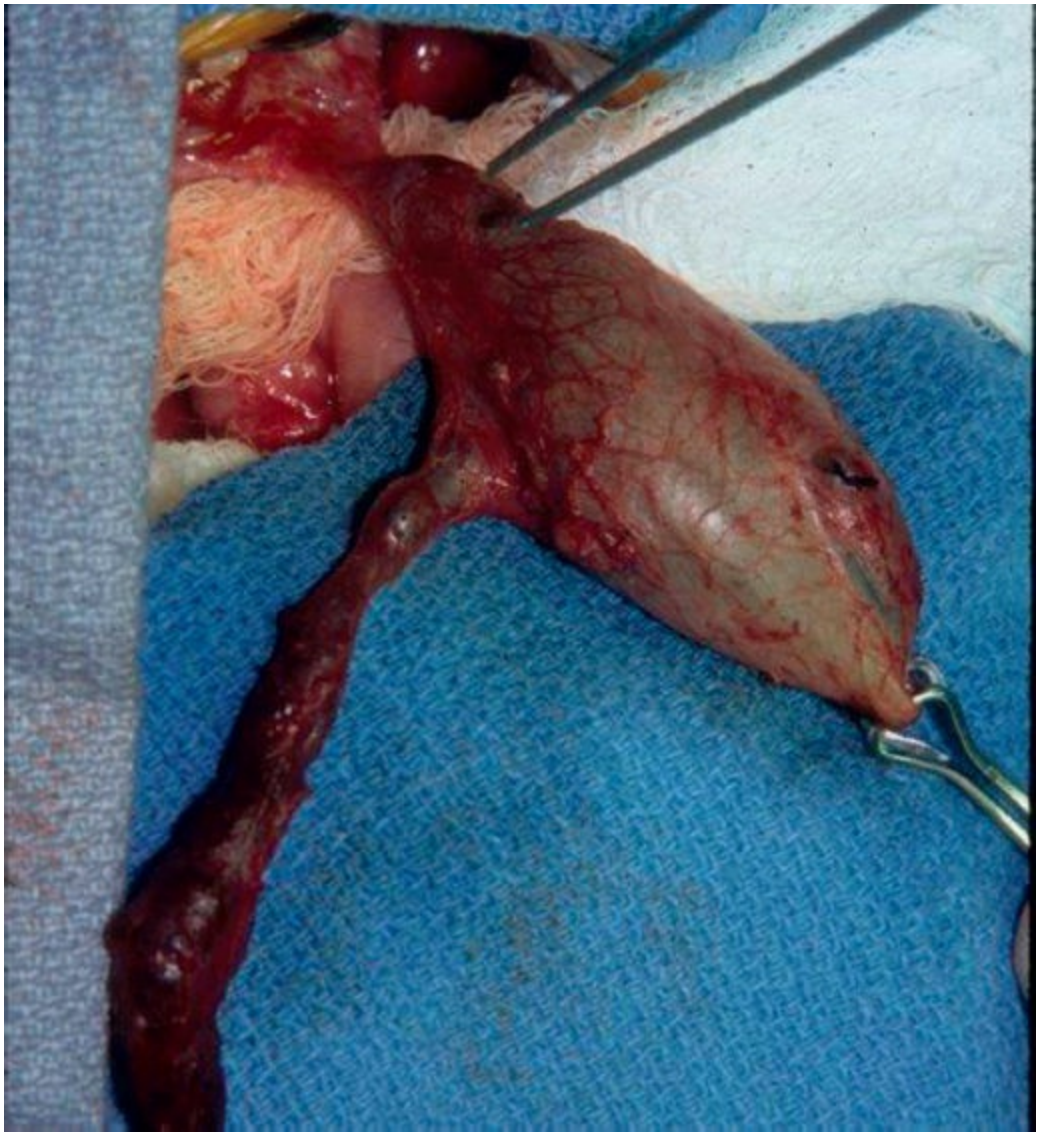

Figure 116.9. Operative specimen showing caliber change of type I cyst just distal to ductal bifurcation—recommended point of transection.

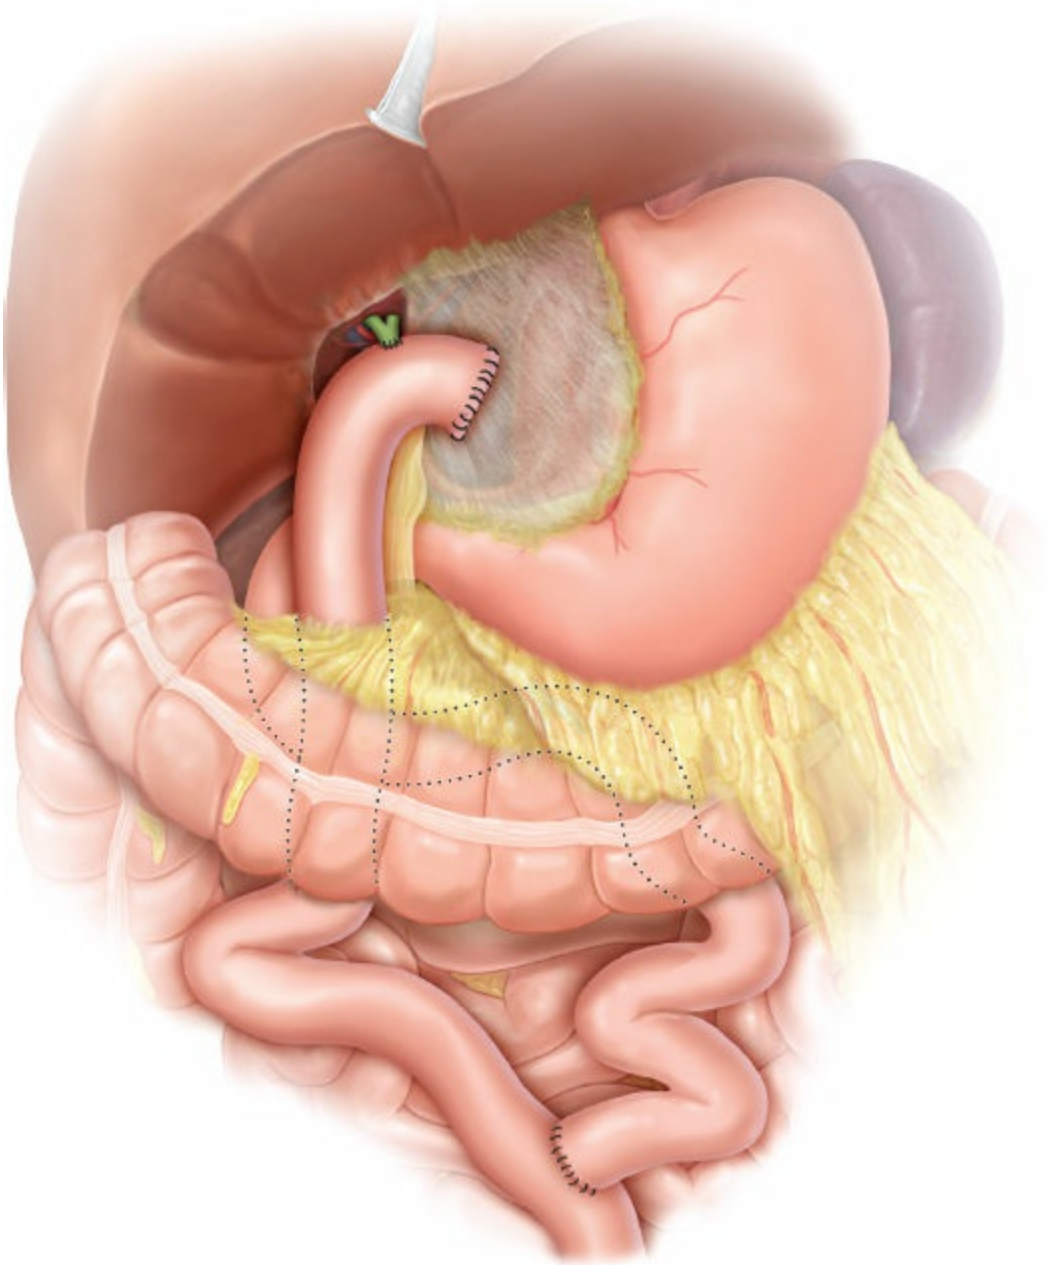

Figure 116.10. Reconstruction with retrocolic Roux-en-Y hepaticojejunostomy.

Laparoscopic cyst excision and hepaticojejunostomy for type I, type II, and type IV cysts is an alternative to open procedures. As shown in Nguyen's review of 190 patients and Jang's review of 82 patients, a laparoscopic approach is safe and effective, especially in the pediatric population where cysts are less likely to be adhesed from prior episodes of cholangitis. A handful of other studies show similar results, although their study sizes are smaller. Nevertheless, complete cyst excision can be challenging laparoscopically with a conversion rate to open of 35% in the adult population.

OUTCOMES

Overall results following surgical treatment are quite favorable, with a good prognosis in almost 90% of patients; both event-free and 5-year survival exceed 90%. Postoperative complications may be viewed as early or late. Early complications include pancreatitis, anastomotic leak, and cholangitis. Late complications include malignancy, cirrhosis, and recurrent pancreatitis. Type IVA CCs are associated with the highest postoperative risk from intrahepatic stones and strictures. Predisposing factors for stricture formation in the adult population include size and inflammatory cell infiltrate in the cyst wall. In children, long-term complications are mercifully rare.

The risk of biliary malignancy remains elevated 15 years after CC resection. Malignancy is associated with extremely unfavorable outcome —median survival is only 6 to 21 months. As such, all patients require long-term follow-up for biliary cancer with ultrasound, liver function tests, and CEA, CA 19–9, and CA 125 tumor markers.

A general surgeon should be knowledgeable about CCs. Although rare, CCs may present with symptoms suggestive of other, more commonly seen biliary disorders. Hazards from misdiagnosis and risks of complications from a delay in diagnosis, including malignancy, remain high. Accordingly, it seems prudent to appreciate the myriad ways CCs may present, what imaging studies may be most useful based on that presentation, and how to tailor the operative approach to both the patient and the underlying type of CC. While the rarity of CCs and the nuances of each type of CC have somewhat limited the development of a standardized surgical approach, the general goal of surgical treatment involves complete cyst excision with Roux-en-Y bilioenteric reconstruction. Following resection, patients must be followed long-term for the development of biliary malignancy. On the other hand, most patients with CCs will do well after operation, resuming a normal diet and activities with a low chance of recurrent symptoms or malignancy.

EDITOR'S COMMENT

Choledochal cysts (CDCs) are interesting congenital anomalies with an incidence as high as 1 in 10,000 births in the far east to 1 in 100,000 births in the west. The authors present an overview of the relevant components of choledochal cyst management. As the authors note, CDCs were initially classified by Alonso-Lej with further modification by Todani where there are five anatomic variants defined by their location, extent of biliary tract involvement, and shape. Type I (extrahepatic fusiform) and IV (extra- and intrahepatic fusiform dilatation) are the most common CDCs with the remaining types rare. Type III (choledochocele) CDCs are the least common with a recent systematic review suggesting no more than 325 cases reported in the modern literature (71 case reports and 254 patients in CDC series; Lobeck IN, Dupree P, Falcone RA Jr, et al. The presentation and management of choledochocele (type III choledochal cyst): a 40 year systematic review of the literature. *J Pediatr Surg* 2017;52:644–9). Of note, the classification system is helpful as it defines anatomic abnormalities in the biliary system but the likelihood that the five types are pathogenetically related is small. Type I and IV CDCs are thought to be triggered by an anomalous pancreaticobiliary duct malunion but type II, III, and V CDCs are anatomically different and are derived from unique etiologies. For example, a type III CDC is thought to reflect either a bile duct that fails regression during embryogenesis (Tanaka T. The pathogenesis of choledochocele. *Amer J of Gastro* 1993;88:1140) or an acquired anomaly from ampullary inflammation resulting in ballooning of the CBD. The justification for the continued grouping of the five CDCs is for educational and reporting

purposes.

From a diagnostic standpoint, the authors summarize the common clinical manifestations of a patient with a CDC. Children tend to present with more of the classic symptom complex of the right upper quadrant pain, jaundice, and an abdominal mass. One population, germane to the pediatric surgeon, are those fetuses with an in utero diagnosis of a cystic abnormality found near or within the hilum of the developing liver. The differential diagnosis of a cystic mass in the hilum detected during prenatal screening includes cystic "correctable" biliary atresia (BA) and a CDC. The treatment strategy for cystic BA is markedly different from a CDC as intervention in the perinatal period is critical in the BA patient. In contrast, a patient with a CDC can be observed allowing some degree of physiologic maturation before operative intervention is employed. The passage of pigmented stools in a newborn that was diagnosed in utero with a cystic abnormality in the hilum of the liver is the simplest route to differentiate between a choledochal cyst (pigmented stool) and cystic BA (acholic stool). An ultrasound is typically performed and if a CDC is suspected, cross-sectional imaging obtained at some point before operative intervention is offered. Additional studies that may be required to differentiate between the two include a HIDA scan and a liver biopsy. If cystic BA is suspected, early exploration is warranted as intervention before 30 days of life is associated with better long-term drainage (Caponcelli E, Knisely AS, Davenport M. et al. Cystic biliary atresia: an etiologic and prognostic subgroup. *J Pediatr Surg* 2008;43(9):1619–24). If a CDC is diagnosed, operative intervention can be delayed until the child is older (excision and reconstruction typically around 12 months of age) allowing a wider range of surgical approaches including laparoscopy.

Patients with an undiagnosed giant CDC may present with spontaneous perforation and will have biliary peritonitis resulting in a classic "board-like" acute abdomen (Ando H, et al. Spontaneous perforation of choledochal cyst. *J Am Coll Surg* 1995;181(2):125–8). Determination of the diagnosis may not occur until the patient is in the OR undergoing either open or more commonly in the current era, laparoscopic exploration. Bile-stained ascites should tip the surgeon to the diagnosis. A patient presenting in this fashion should be treated conservatively with two goals: (1) Placement of drains to control the ongoing biliary contamination of the right upper quadrant by the perforated CDC and (2) Decompression of the biliary system via T-tube drainage at the perforation site, percutaneous transhepatic catheter placement or ERCP and stent placement decreasing the amount of ongoing biliary contamination. In the unlikely scenario that the contamination of the RUQ has resulted in minimal hilar inflammation, definitive repair at diagnosis can be considered but frequently, the perforation will result in significant inflammation making the hilar dissection hazardous. With drainage and decompression of the biliary system, the RUQ inflammation will decrease making a staged approach to definitive resection a much safer alternative.

As the authors observed, malignancy in a choledochal cyst is uncommon in children with higher incidence in adult patients. This is not surprising as the etiology of a malignancy in a CDC is thought to be caused by chronic pancreaticobiliary reflux interacting with biliary epithelium, leading to mucosal irritation, metaplasia, and malignant change (Xiao X, Li H, Wang Q, et al. Abnormal pancreatic isoamylases in the serum of children with choledochal cyst. *European journal of pediatric surgery: official journal of Austrian Association of Pediatric Surgery [et al] = Zeitschrift fur Kinderchirurgie*. 2003;13:26–30). Because of the chronicity, adults with late diagnosed CDCs are at more risk for malignant change.

Once diagnosed, all CDCs require correction. As the authors note, the operative approach to a type I and IV CDC requires excision of the dilated portion of the extrahepatic biliary system with reconstruction of biliary outflow. Reconstruction of biliary outflow can be accomplished by Roux-en-Y choledochojejunostomy or by choledochoduodenostomy but a Roux-enY drainage is recommended. Choledochoduodenostomy is a simpler reconstruction but because of increased reflux of enteric contents into the biliary system and reflux of bile into the stomach, has been associated with increased rates of both gastric cancer and cholangiocarcinoma (Takeshita N, Ota T, Yamamoto M. Forty-year experience with flow-diversion surgery for patients with congenital choledochal cysts with pancreaticobiliary maljunction at a single institution. *Ann Surg* 2011;254:1050–3; Shimotakahara A, Yamataka A, Yanai T, et al. Roux-en-Y hepaticojejunostomy or hepaticoduodenostomy for biliary reconstruction during the surgical treatment of choledochal cyst: which is better? *Ped Surg Int* 2005;21:5–7). If a choledochoduodenostomy is performed, longitudinal follow-up is critical.

Patients diagnosed with a CDC at an older age may have experienced recurrent bouts of cholangitis/pancreatitis resulting in significant chronic inflammation in the cyst and the surrounding hilum making dissection challenging. Anatomic differentiation and preservation of all branches of the hepatic artery and portal vein is critical for the health of the native liver but this can be quite difficult if there has been long-standing, chronic inflammation. In this circumstance, the cyst can be opened and a mucosectomy performed removing all biliary epithelium. Leaving the chronically scarred residual wall will protect the critical hilar vessels from inadvertent injury. The dissection is carried proximally up to the hilar plate where anastomosis can be performed. In this circumstance, we will consider sending the proximal most point chosen for anastomosis for frozen section histologic analysis to ensure integrity of the bile duct wall before completing the anastomosis as if no epithelium is present the risk for a postoperative stricture is high.

As with many operative procedures in the abdomen, laparoscopy and more recently, utilization of a Da Vinci robotic system has been applied to CDC correction. Retrospective studies demonstrate that the procedure can be done safely with excellent outcomes but require longer operative time with the

attendant higher costs (Nguyen T, Hein PD, Dung le A, et al. Laparoscopic repair for choledochal cyst: lessons learned from 190 cases. *J Pediatr Surg* 2010;45:540–4). As with many advance laparoscopic procedures, CDCs repaired in this fashion should be performed by teams well versed in laparoscopy and with the anatomy of the hilum of the liver.

Patients who have undergone CDC excision and reconstruction require long-term follow-up. The late affects following a CDC excision requires studies with better longitudinal as the patients are at risk for anastomotic stricture, hepaticolithiasis, and malignant transformation.

Gregory M. Tiao

The choledochal cyst is a difficult area with 5 manifestations of these rare congenital anomalies. Happily as skills proliferate outcomes are better.

J.E.F.

117 Biliary Atresia—Portoenterostomy

Gregory M. Tiao

Biliary atresia (BA) is a devastating cholestatic liver disease of infancy. The obliterative process of the extrahepatic biliary tree, coupled with progressive inflammatory destruction of the intrahepatic bile ducts, leads to the development of end-stage liver disease (ESLD) in the first 12 months of life. At present, there is no medical therapy to abate or reverse this process. Untreated, BA results in cirrhosis, hepatic failure, and death.

BA was first reported in the English language by Burns in 1817, who described the characteristic combination of early jaundice and acholic stools, ascribing this to "some incurable state of the biliary apparatus." Modern surgical treatment evolved from the histopathologic studies of the progression of BA by Morito Kasai who then suggested that the removal of atretic bile ducts before progression of an inflammatory process into the porta hepatis and intrahepatic biliary system might allow successful bile drainage. The portoenterostomy (Kasai procedure) he described has undergone modifications but remains the template for present surgical therapy. Unfortunately, most afflicted children even with a successful portoenterostomy progress to ESLD and require orthotopic liver transplantation (OLTxp) for salvage. With the advent of successful OLTxp, there was discussion that primary OLTxp should be considered in all patients diagnosed with BA; however, the very acceptable results in selected long-term survivors following the Kasai procedure, contrasted to the risks of liver transplantation and lifelong immunosuppression, support the sequential application of portoenterostomy followed, when necessary by OLTxp. BA is the most common indication for pediatric liver transplantation.

ETIOLOGY

Despite its importance to child health, the etiology of BA remains unclear. Proposed mechanisms include environmental, autoimmune, and infectious etiologies. Epidemiologic studies suggest that ethnic and genetic factors may also play a role in the pathogenesis of BA. In the United States, the

incidence of BA is about two times higher in African Americans as compared with white infants, and it is more common among Chinese than Japanese or Caucasian infants. Girls are more commonly affected.

In the 1970s, it was first proposed that a viral agent was the root cause of a group of neonatal obstructive cholangiopathies including BA. Initial attention focused on the hepatitis B virus. Subsequent studies found many different pathologic viruses in the liver of infants with BA, including rotavirus, reovirus, cytomegalovirus, and human papilloma virus; however, no single virus has been detected uniformly among the patient samples tested. A unifying concept that explains the patient-based results postulates that the clinical manifestations of BA represent an *end phenotype* caused by a variety of in utero or perinatal infections. These insults act as a trigger for a host immune response, which results in a progressive destruction of the biliary tract. The experimental model of BA first described in 1993 is important evidence in favor of a viral etiology in the pathogenesis of BA and has become a vital tool in BA research. In this model, rhesus rotavirus infection of newborn BALB/c mice results in an inflammatory cholangiopathy and pathologic phenotype similar to human BA, including (a) a clinical progression to obstructive jaundice as manifest by bilirubinuria, jaundice, acholic stools, growth retardation, and eventually death; (b) morphologic and histologic changes in the biliary tree that parallel those found in infants; and (c) a temporal relationship between neonatal exposure to the virus and disease induction.

Utilizing complementary data obtained from molecular profiling of patient samples and the murine model of BA, multiple investigators have begun to define how the host immune response contributes to the end phenotype of BA. Factors that govern the response include a Th1 response mediated in part by CD8 T cells, as well as overexpression of IFN-γ, IL2, CD25 (IL2 receptor), TNF, and CD71 (transferrin receptor). CD8, pDC, NK, and T regulatory cells cross-talk post insult governing biliary obstruction and a Th2 lymphoid and type 2 myeloid responses also play an integral role in biliary duct obstruction through the action of IL-13. IL-17A signaling through the DC-Th17 axis has been shown to control injury by inducing CCL2 production by cholangiocytes. This induction triggers Ly6C+CCR2+ macrophages leading to inflammation. Studies have shown that inactivation of the *Stat1* gene in mice (a gene critical to the Th1 response), resulted in complete biliary obstruction with cystic dilations of extrahepatic bile ducts. Interestingly, the basis for BA progression to

fibrosis has begun to be defined where the disease evolves from a pro-inflammatory type 1 initial response (i.e., viral insult based trigger) to a pro-fibrotic type 2 immune response through the action of IL33 (a type 2 cytokine) resulting in bile duct proliferation. The cholangiocyte proliferation occurs through activation of innate lymphoid cell (ILC2) through the release of IL13 that works in a paracrine fashion to activate IL33 secretion, which has been shown to activate hepatic stellate cells. Although these studies have been revealing, no treatment strategies have yet been advanced that alters the natural history of BA. As a result, surgical palliation remains the cornerstone of treatment.

ANATOMIC CLASSIFICATION

The anatomic classification of BA is descriptive of the degree of extrahepatic ductal destruction. The sclerosing obliterative destructive inflammatory process may affect any length of bile duct from the sphincter of Oddi to the porta hepatis. Type I (10%) demonstrates obliteration of the common bile duct; type II (2%) also includes common hepatic duct atresia. Both have relative sparing of the intrahepatic ducts and historically have been termed cystic “correctable” BA as within the hilum of the liver at the ductal bifurcation arises a bile containing cyst. The cyst wall is not lined with biliary epithelium rather an inner, dense cicatricial layer that nonetheless can be reconstructed by cyst-Roux-en-Y anastomosis that surprisingly results in sustained biliary drainage. Type III (88%) BA involves the right/left hepatic ducts and extends into the intrahepatic bile ducts as well. Patients with type III findings are candidates for Kasai portoenterostomy.

CLINICAL CLASSIFICATION

The clinical forms of BA can be divided into two subtypes: a *postnatal/sporadic* form that progresses after birth and a *fetal/embryonic* form that is present at birth and is associated with other congenital anomalies.

The postnatal presentation accounts for most of the cases of BA. These infants present with jaundice, which becomes apparent after the physiologic jaundice of the newborn should have resolved (3 to 4 weeks) and increases in severity within weeks. Hepatic histology is significant for the presence of bile duct remnants with acute and chronic inflammation within the portal triads. Associated anomalies are uncommon.

The fetal/embryonic subtype occurs in 10% of infants with BA, and is characterized by jaundice that is recognized and progresses during the first few days of life. In most cases, no jaundice-free interval can be identified. The probable in utero onset of this is suggested by the absence of patency in the biliary structures and an absence of bile duct remnants at early laparotomy. Associated congenital anomalies are common and follow one of the three patterns: (a) most common group (60%)—cardiovascular (atrioventricular canal defects, septal defects, valvular abnormalities, Tetralogy of Fallot, patent ductus arteriosus), genitourinary (kidney or collecting system), and gastrointestinal (Meckel diverticulum, midgut anomalies), (b) laterality sequence anomalies (30%)—situs inversus, polysplenia/asplenia, preduodenal portal vein, intestinal malrotation, cardiovascular anomalies (BASM), and (c) isolated intestinal malrotation (10%). Reviews of the US and UK experience have confirmed the worse overall prognosis for infants with the BASM phenotype.

DIAGNOSTIC EVALUATION

With advances in prenatal care and the widespread utilization of screening maternal ultrasound, efforts to detect BA in utero have been attempted but to date, no pathognomonic in utero abnormalities have been identified. In those patients with the cystic “correctable” form of BA, in utero detection of a cystic abnormality in the hilum of the liver is helpful but must be differentiated postnatally from a choledochochal cyst. The passage of pigmented stools in a patient with a cystic abnormality in the hilum of the liver is the simplest route to differentiate between a choledochal cyst (pigmented stool) and cystic BA (acholic stool). If cystic BA is suspected, early exploration is warranted as intervention before 30 days of life is associated with better long-term drainage.

To be successful, the Kasai procedure should be done before irreversible sclerosis of the intrahepatic bile ducts has occurred. Prompt evaluation is necessary for any infant older than 14 days with jaundice to determine if conjugated hyperbilirubinemia is present (Table 117.1).

To date, biochemical analysis that assists in the determination of BA is rarely definitive. Although biochemical evidence of cholestasis and hepatocellular damage is present, the biochemical tests are of no discriminating value in patients with suspected BA. The development of the Jaundice Chip, utilizing DNA extracted from whole blood, screens for all of the known genetic defects that cause cholestatic liver disease and is

helpful but remains a complimentary study as it is not rapidly performed assay and awaiting results could delay definitive treatment.

TABLE 117.1 Diagnostic Evaluation of a Cholestatic Infant

General Evaluation
Clinical evaluation (family and gestational history, feeding history, physical examination, assessment of stool color)
Index of hepatic synthetic function (prothrombin time)
Exclude Sepsis—cultures (blood, urine, spinal fluid) as indicated
Quantitative analysis of bile acids, urinary bile acid profile if abnormal
Serum electrolytes (exclude acidosis)
Specific Evaluation
$Alpha_1$ A—Antitrypsin phenotype
Thyroxine and thyroid-stimulating hormone
Sweat Chloride/mutational analysis (exclude cystic fibrosis)
Ferritin/transferrin concentration and saturation (exclude neonatal iron storage disease)
Metabolic screen (urine reducing substances, urine/serum amino acids, organic acids, succinyl acetone)
HbsAG, anti-HIV, and VDRL (in high-risk patients)
Jaundice Chip analysis
Abdominal ultrasonography
Liver biopsy
Exploratory laparotomy/ cholangiography

Abdominal ultrasonography excludes choledochal cyst, perforation of the bile ducts, or choledocholithiasis. In patients with suspected BA, the

gall bladder is either not visualized or atretic. When a hyperechogenic liver hilum is identified, known as a “triangular cord” sign, BA is likely. Associated anomalies such as a preduodenal portal vein, polysplenia/asplenia, inferior vena caval interruption, or malrotation can also be identified. These findings are helpful to the surgeon and suggest BA but are not diagnostic of the disorder. Cholescintigraphy is rarely helpful even with phenobarbital induction, and often delays critical surgical intervention.

If infectious, metabolic, and endocrine disorders are excluded, then liver biopsy most accurately identifies infants with suspected BA. Histologic examination of the liver is the most helpful step in evaluating the children with suspected BA and selecting appropriate candidates for laparotomy. The histopathologic findings that predict obstructive forms of neonatal cholestasis are portal ductal proliferation, bile plugs in portal bile ductules, portal–portal bridging, neutrophils, hepatocyte swelling, and multinucleated giant hepatocytes. In preoperative liver biopsies, the presence of giant cells, lobular necrosis, focal necrosis, bridging necrosis, and cholangitis are associated with poor clinical outcome, whereas the presence of bile in zone 1 is associated with improved clinical success. The degree of portal fibrosis is especially important in infants who present at a later age for evaluation. The combination of late presentation (>3 months of age) and severe fibrosis makes successful bile drainage unlikely; in these cases, primary liver transplantation should be considered as the preferred option.

The steps for rapid evaluation of the infant with suspected BA are outlined in Table 117.2. In these selected infants, exploratory laparotomy and intraoperative examination/cholangiogram should be done expeditiously by a surgeon who has experience undertaking the Kasai procedure.

OPERATIVE PROCEDURE

The operative procedure is undertaken through an abbreviated right upper quadrant chevron incision until the diagnosis of BA is confirmed. This can then be extended to a bilateral chevron appropriate for future liver transplantation if that becomes necessary.

TABLE 117.2 Recommended Steps in the Evaluation of a Child With

Possible Biliary Atresia

1. Recognize the newborn infant with prolonged jaundice (>14 days) and screen for conjugated hyperbilirubinemia
2. Exclude medically treatable causes of neonatal cholestasis (Table 117.1)
3. Abdominal ultrasound to exclude structural abnormalities of the biliary tree
4. Liver biopsy to differentiate biliary atresia from various forms of intrahepatic cholestasis
5. Exploratory laparotomy and intraoperative cholangiogram—Kasai portoenterostomy

CONFIRMING THE DIAGNOSIS

The initial step is to confirm the diagnosis of BA through observation of the extrahepatic biliary structures and, when necessary, intraoperative cholangiography. The liver in BA, even at its early stage, shows cholestatic green discoloration and the presence of subcapsular vascular telangiectasias (Fig. 117.1). When this gross anatomic picture is seen in conjunction with a fibrotic gall bladder remnant and no discernable extrahepatic biliary ducts, the diagnosis of BA is confirmed, and one can proceed with portoenterostomy. When the gall bladder is not atretic, a cholangiogram helps define further operative management. A purse-string of 5.0 monofilament suture in the fundus of the gall bladder secures a 20-gauge intravenous catheter for the cholangiogram. Very gentle infusion pressure is necessary as excessive pressure in an atretic biliary tract will lead to extravasation, which obscures necessary landmarks. When the cholangiogram shows a normal biliary tree, a generous wedge and needle biopsies are undertaken prior to closure.

Biliary hypoplasia is recognized by the presence of an anatomically intact ductal system to all liver segments by small threadlike ducts. This syndrome is seen in conjunction with cholestatic medical liver diseases (A-1 antitrypsin deficiency, cystic fibrosis), inborn errors of bile acid

metabolism, or any infectious or metabolic disease associated with severe neonatal cholestasis. In addition, syndromic (Alagille Syndrome) or nonsyndromic bile duct paucity conditions and progressive familial intrahepatic cholestasis (PFIC) syndromes (Byler syndrome and its variants) can all present with a small but anatomically correct extrahepatic biliary system. Generous liver biopsy will assist in their diagnosis; their primary treatment is medical. Portoenterostomy does not benefit this group and should not be undertaken. In the presence of flow into the distal biliary tree, with no flow into the intrahepatic radicals, a spring-loaded vascular occlusion clamp should be placed on the supraduodenal biliary structures with further attempts to demonstrate proximal patency. In the absence of proximal patency or when no flow occurs on the cholangiogram, BA is confirmed and a Kasai procedure undertaken.

The individual steps of the portoenterostomy include (a) the initial dissection of the extrahepatic biliary fibrous mass, (b) the extended lateral dissection, (c) division of the fibrous mass, and (d) the enteric anastomosis.

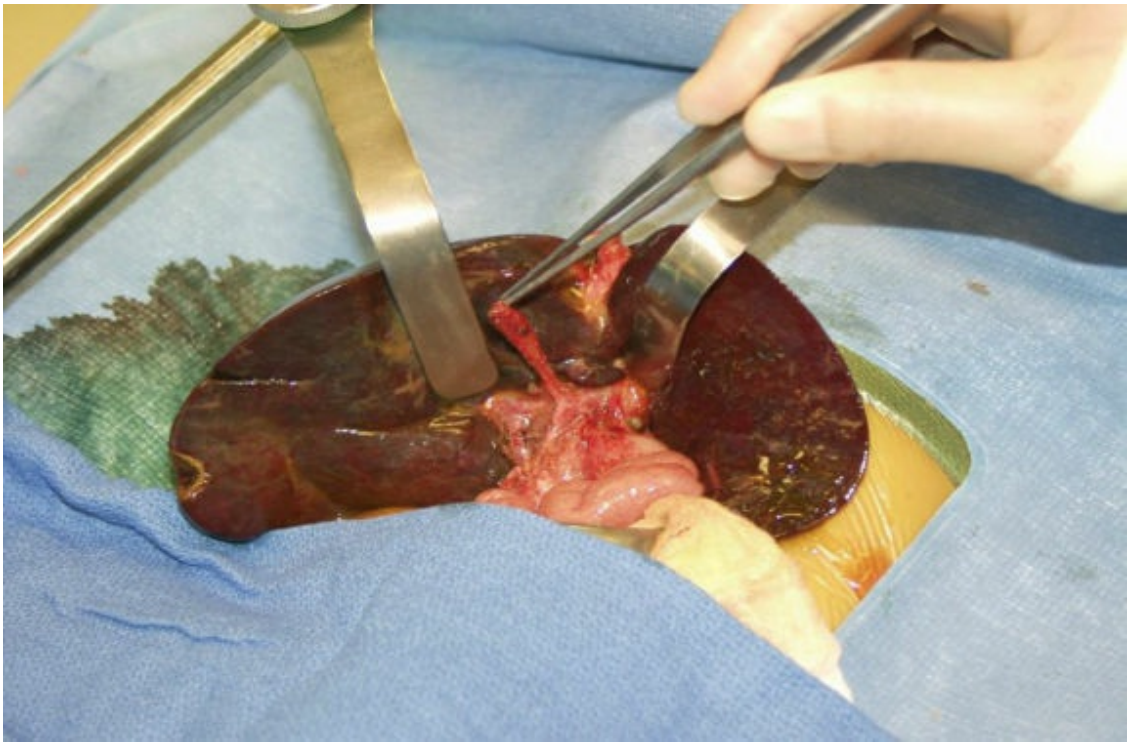

Figure 117.1. Cholestatic liver of a biliary atresia patient. Atretic gall bladder in forceps.

INITIAL FIBROUS REMNANT DISSECTION

When undertaking the initial dissection of the obliterated biliary ducts, it is important to appreciate that the ducts are not absent in BA, but rather obliterated by fibrosis. The anatomic course of the ductal remnants will follow the normal biliary position within the portal triad and hilum. To facilitate adequate visualization, the lateral portion of the triangular ligament and the anterior/superior portion of the falciform ligament are divided, allowing the liver hilum to rotate in an anterior-superior fashion. The fibrous obliterated biliary structures are usually visible superior to the duodenum in the anterior portal triad where they are tied and divided. The upper suture is left uncut to supply traction on the biliary remnant. The dissection ascends superiorly along the anterior surface of the portal vein, the gall bladder remnant is dissected from the liver bed, but the cystic duct structures are not divided. Anterior/superior traction on these combined structures lifts them from the anterior surface of the portal vein as the dissection proceeds into the hilum. The dissection should be confined to the anterior/posterior plane as the hilar fibrous tissue remnant is encountered, as the lateral dissection requires further definition of the portal vein anatomy. The fibrous tissue mass forms a thickened cone-like structure the “fibrous triangle” as it reaches the liver surface. The bifurcation of the portal vein serves as an important landmark, as the fibrous triangle courses between the branches of the portal vein. To reach the liver surface, the fibrous remnants course in a posterior/superior direction within the portal bifurcation. The key element to this stage of the dissection is the downward displacement of the portal vein bifurcation, allowing the dissection of the fibrous remnant to its junction with the anterior and posterior liver capsule. Several small direct portal branches into the fibrous mass should be divided between ties to allow complete separation of the portal vein from the fibrous mass (Fig. 117.2).

EXTENDED LATERAL DISSECTION

In the original Kasai procedure, the fibrous triangle was dissected and divided between the right and left branches of the portal vein at the level of the posterior surface of the portal vein. Further revision of this technique has shown that meticulous dissection of the lateral fibrous triangle tissues allows more of the segmental biliary structures to be potentially included in the divided hilar tissue. At the porta hepatis, the hepatic duct usually takes a course superior and medial to the main portal branches; and in the liver, it turns posteriorly toward the portal branches on the lateral sides.

Therefore, when conducting the lateral fibrous remnant mobilization, dissection of these potential ductal remnants from the dorsal aspect of the portal branches is very important. It is within this fibrous tissue that residual patent biliary ductules may be found. On the right, the dissection is carried to the dorsal aspect of the anterior portal branch over the bifurcation of the anterior and posterior portal vein branches. Small portal vein branches that pass medially toward the fibrous mass should be ligated to allow complete separation of the mass from the portal vein wall. The left lateral dissection is facilitated by dividing any parenchymal bridge that is present between liver segments S3 and S4, bringing the left porta hepatis clearly into view. The dissection separating the fibrous mass from the portal vein proceeds to the umbilical point where the obliterated umbilical vein joins the left portal vein. Division of the fibrous ligamentum venosum at this junction improves mobilization of the left portal vein. We have found this helpful but not essential in every case. Some surgeons place traction tapes around the left and right portal veins and the right anterior segmental branch to improve visualization of these structures; however, we prefer local retraction with an eyelid retractor without encircling the veins.

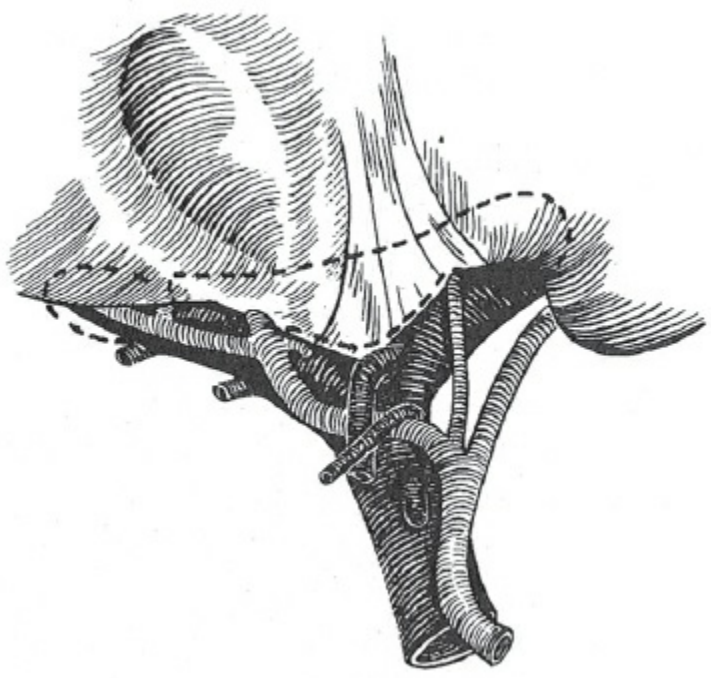

Figure 117.2. The initial dissection (*dashed line*) of the portal fibrous mass is facilitated by the inferior displacement of the portal vein and the hepatic artery and superior retraction of the fibrous triangular mass. The fibrous remnant terminates at the

hepatic capsule posterior to the bifurcation of the portal vein.

DIVISION OF THE FIBROUS MASS

The division of the fibrous mass is best approached from the right side, cutting the mass with sharp scissors or a knife. The division is facilitated by placing the fibrous mass on moderate traction. Several evenly spaced traction sutures can be placed along its transverse width when needed. The transection margin should be at the level of the liver capsule and parenchyma. Deeper dissection into the parenchyma encourages excessive scarring, and transection distant from the capsule risks missing potentially open biliary channels that terminate within the proximal fibrous mass.

The division of the right fibrous mass begins at the parenchymal entry of the posterior portal vein branch and proceeds around the anterior segmental branch from a posteromedial direction. On the left, dissection is extended to the posteromedial margin of the umbilical point, inclusive of the dorsal aspect of the portal vein. After completing the transection, the operative field is irrigated with warm saline, and a warm gauze pack is placed in the hilum to achieve hemostasis. As the ductules travel in concert with the microvascular structures within the fibrous mass, any bleeding that is encountered is best treated with local pressure and irrigation, rather than electrocautery that can damage the ductules (Fig. 117.3).

ENTERIC DRAINAGE

A 35-cm Roux-en-Y constructed of isoperistaltic jejunum and placed in a retrocolic position is used for drainage of the hilum. This should be fashioned from the most proximal loop of jejunum when possible to facilitate early bile return to the intestine, improving absorption of fat-soluble vitamins and medications as well as food. No antireflux valve is placed in the Roux-en-Y, but the anastomosis is fashioned to inhibit enteric flow into the drainage limb.

The blind end of the Roux-en-Y is closed, and a 2- to 2.5-cm antimesenteric enterotomy is used for the anastomosis to the hilum. The posterior wall of the anastomosis is performed with interrupted single-layer absorbable synthetic monofilament sutures placed just posterior to the cut margin of the fibrous mass, into the parenchyma of the caudate lobe, with the knots tied outside of the anastomotic area. Sutures should not be placed into the tissue of the fibrous mass where potentially draining ductules may reside. This technique places the posterior row of sutures

posterior to the portal vein within its bifurcation. The right anterior portal branch is usually within the right lateral extended dissection, with fibrous tissue on all but its posterior side. The anastomotic suture line should surround or invaginate these vascular branches, incorporating all of the fibrous tissue within the lumen. This technique excludes the portal vein wall from the cut surface, and inhibits its attachment and scarring to the potential ductal drainage area. The anterior wall of the anastomosis is completed to the tissue of the quadrate lobe just anterior to the cut surface margin (Fig. 117.4).

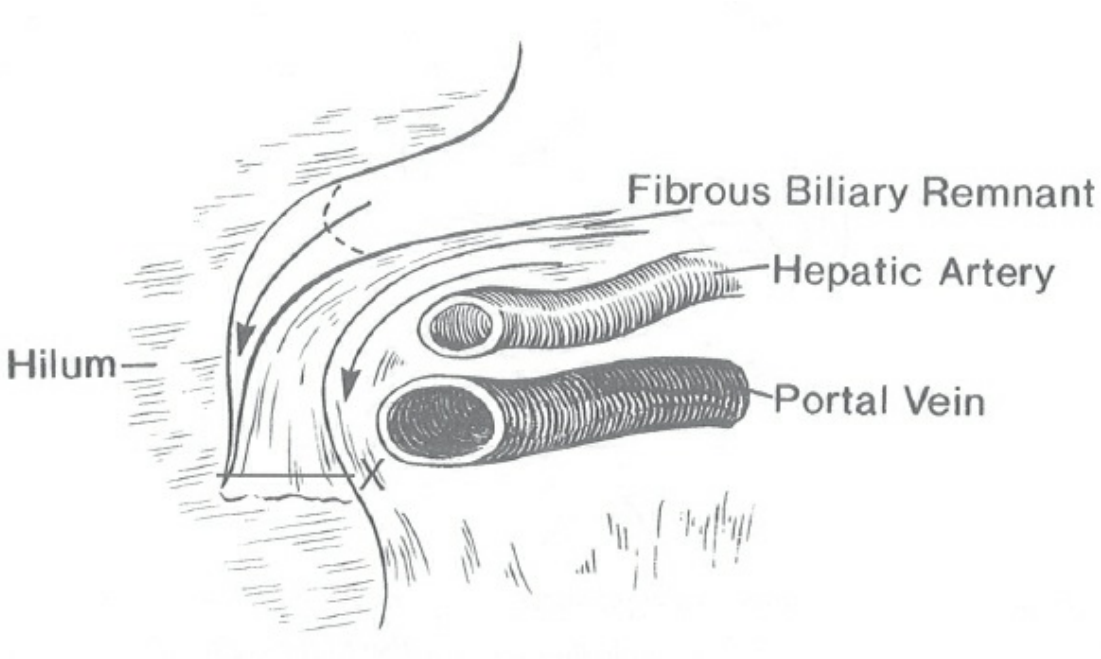

Figure 117.3. With the fibrous mass elevated off the vascular structures in the hepatic capsule, it is transected at the level of the hepatic capsular surface (marked by *X*).

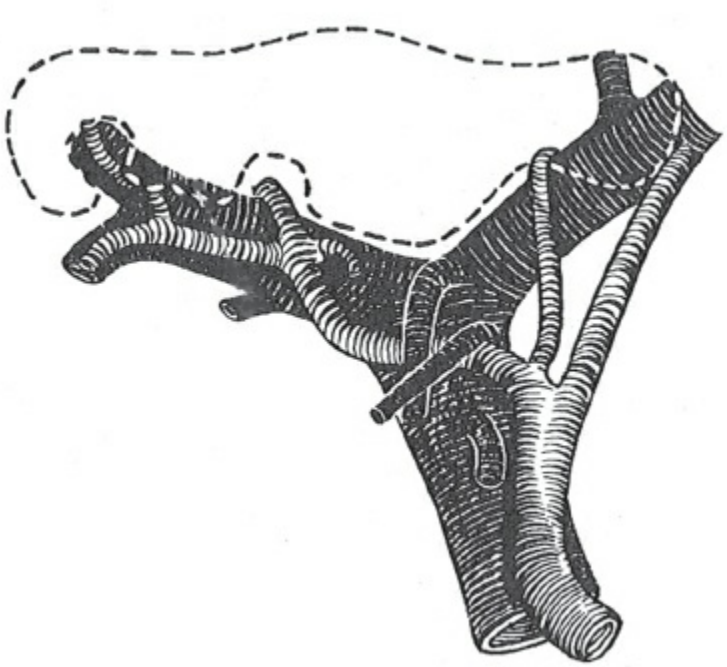

Figure 117.4. Roux-en-Y anastomosis to the gut surface "invaginating" the portal venous and hepatic arterial branches. The suture follows the course of the dotted line. This allows drainage of the right and left extended triangle as well as of the central hilum, but it excludes the vascular elements from the anastomotic site.

LAPAROSCOPIC PORTOENTEROSTOMY

As with many surgical procedures, laparoscopy has been utilized in place of open surgery for a portoenterostomy. Initial interest was tempered by studies in which reported outcomes were worse in patients who underwent the laparoscopic approach; however, more recent studies from centers in Japan report favorable outcomes. Given the significant consequences of a failed Kasai (i.e., early OLTxp), a laparoscopic approach should be considered only in the context of a controlled clinical trial performed by centers with significant expertise in laparoscopy.

POSTOPERATIVE CARE

As in all infants following laparotomy, careful attention to anesthetic recovery, postoperative nutritional support, and fluid management is necessary. All infants should receive supplemental fat-soluble vitamins A, D, E, and K and high-energy, high-protein feedings, usually employing 40% to 60% of fat as medium chain triglycerides. Intravenous perioperative antibiotics are given. The role of longer-term antibiotics to

prevent cholangitis is less clear. In the US multicenter BARC review, 60% to 70% of experienced centers used oral antibiotics for 1 to 3 months. We use sulfamethoxazole-trimethoprim (Bactrim or Septra) for 3 to 6 months. Administration of ursodeoxycholic acid (15 to 30 mg/kg/day) may stimulate bile flow and decrease toxin injury to hepatocytes.

The use of corticosteroids following Kasai procedure is controversial. Corticosteroids simulate the bile salt independent portion of bile flow and are as nonspecific anti-inflammatory agents. An uncontrolled "survey" in the Japanese BA Society showed improved anicteric survival in the steroid groups (58% vs. 36%; $P = 0.052$). A double-blind prospective randomized trial analyzing the effects of postoperative corticosteroids performed by the National Institutes of Health (NIH)-supported Childhood Liver Disease Research Network (ChiLDReN) revealed no benefit to a high-dose course of perioperative steroids. Studies conducted in the United Kingdom and Germany using lower doses of perioperative steroids demonstrated a similar lack of efficacy.

The initial establishment of successful bile flow following the Kasai procedure occurs when microscopic communicating biliary ducts form an epithelialized fistula, ultimately developing into an autoanastomosis between the ductal mucosa and the mucosa of the Roux-en-Y conduit. If bile flow is interrupted during this critical time, a persistent fistula will not form. If bile flow decreases during the early postoperative period and manifests as decreasing color to the stools and rising bilirubin, cholangitis should be excluded. Once excluded, the use of corticosteroids can be considered; however, no conclusive data support this practice.

INDICATIONS FOR REOPERATION

Infants with inadequate or no initial bile flow are poor reoperative candidates and should not be reexplored. The increased intraperitoneal and perihepatic adhesions that greatly complicate subsequent liver transplantation are most often the consequence of repetitive but misdirected attempts to reoperate on poorly selected candidates, or recurrent episodes of bacterial peritonitis.

Recent studies have reported the role of reoperation in a subgroup of patients who initially had a successful portoenterostomy. Reoperation is reserved for infants who after their Kasai had active bile drainage leading to an anicteric state followed by abrupt cessation of bile excretion. Ideally, they also have favorable hepatic histology and biliary ductal remnant

histopathology from their primary procedure. Reexploration with revision of their Kasai may be warranted as reconstitution of bile flow is successful in over one half of the patients. Recurrent cholangitis caused by a blind pouch is another relative indication for reexploration.

OUTCOME FOLLOWING KASAI PORTOENTEROSTOMY

There is no clinical, laboratory, or histologic factor that has been reliably predictive of success following portoenterostomy. Factors recognized to affect prognosis in BA are listed in Table 117.3. The patient's age at operation was shown to directly affect prognosis in Kasai's original series. However, the significance of age at operation is inconsistent. The French National study reported decreased 5-year survival with the native liver in patients >90 days of age at operation. Conversely, Davenport et al. in the King's College series showed no significant difference in clearance of jaundice or 2-year native liver survival with increasing age in isolated BA. Patients with BASM anomalies showed worse outcomes with advancing age. Success in achieving bile drainage correlated directly with the size of the bile duct remnants identified in the porta hepatis at surgery—bile duct profiles >150 microns have the best prognosis and ductal remnants <50 microns in size uniformly fair poorly.

TABLE 117.3 Factors Affecting Prognosis in Biliary Atresia

Age at hepatoportoenterostomy
Postoperative care
Degree of fibrosis/cirrhosis
Prevent cholangitis
Size of biliary remnant
Nutrition support
Coexisting anomalies
Experience of surgeon

The rate of decline of serum bilirubin concentration in the immediate postoperative period correlates with a positive outcome. One of the important findings of the ChiLDReN analysis was the predictive value of postoperative bilirubin in survival with the native liver. A total serum

bilirubin level of <2 mg/dL at 3 months postoperative correlated with good outcomes at 2 years (84% survival). Serum bilirubin >6 mg/dL had a poor prognosis (16% 2-year survival).

Ascending cholangitis is a risk particularly in infants with good bile drainage. As such, cholangitis is not associated with a worse prognosis, but recurrent attacks can damage biliary radicals. Recurrent or late cholangitis may suggest Roux-en-Y obstruction. A radioisotope scan can identify these cases. Since children with BA rapidly develop cirrhosis, markers of hepatic fibrogenesis such as serum hyaluronic acid select high-risk infants. When serum hyaluronic acid concentrations were elevated prior to the Kasai procedure, 15 of 16 patients died or underwent liver transplantation; only 2 of 8 patients with normal levels prior to the Kasai procedure had adverse outcomes.

A favorable impact from regionalization of care for BA has been demonstrated in several studies. In the United Kingdom, BA surgery was restricted to three centers in 1999 when significant patient survival and native liver survival differences were noted in centers with <5 cases/year operative volume. Regionalization improved the overall outcomes. The French National Study (1986 to 1996) also noted significantly improved native liver, post-liver transplant and overall patient survival in a high-volume (>20/year) center compared to the ones treating <5 cases per year. In both studies, surgeon experience with the Kasai Portoenterostomy and overall center experience with liver disease and liver transplantation were felt to be critical components. In the United States, success rates similar to those in the United Kingdom and France have been recorded by the ChiLDReN, representing 14 clinical centers with established liver care centers. This strongly suggests that BA patients achieve the best outcomes in the centers focused on their specific disease type and surgical needs.

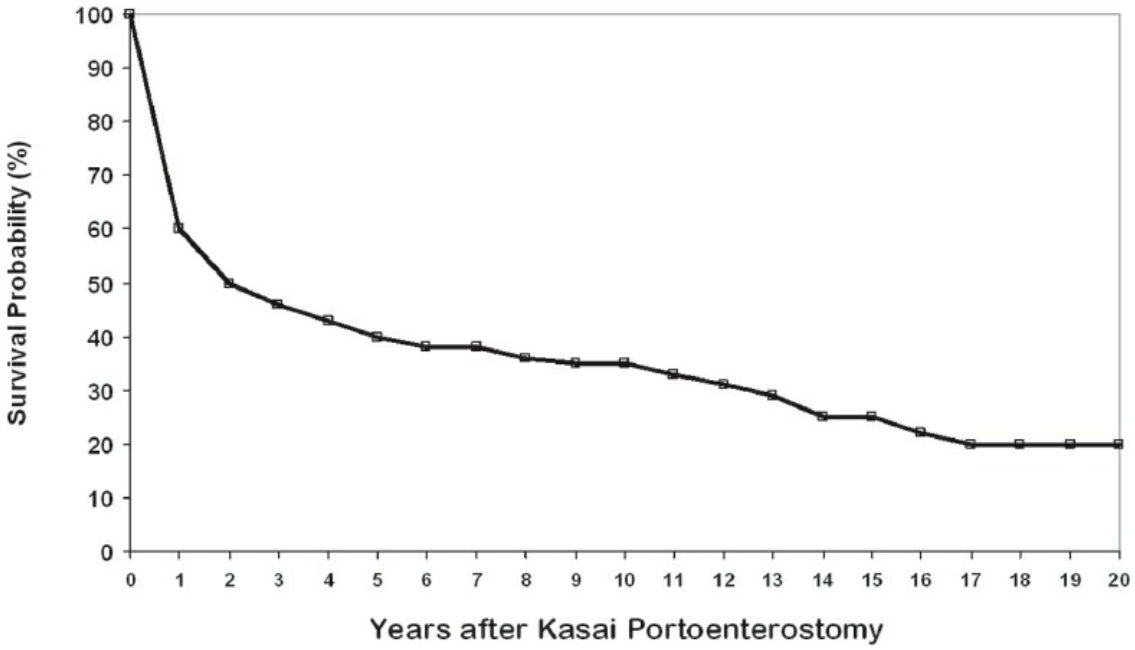

Figure 117.5. Survival probability without liver transplantation following the Kasai procedure.

For infants who do not drain bile and develop progressive cirrhosis and in children who develop progressive fibrosis and manifest complications of ESLD, OLTxp offers the only option for long-term survival. The combination of whole organ, reduced size, living donor, and split liver transplantation offers an excellent variety of options for transplant management. Using all of these possibilities, the pretransplant waiting list mortality in experienced pediatric centers is <5% at the present time. With present 5- and 10-year posttransplant survival approaching 90% in most pediatric centers, the overall prognosis for infants with BA is excellent, although this success is often achieved through many sequential and complimentary modes of treatment.

CONCLUSION

The outcome of infants with BA has been favorably influenced by the Kasai procedure. Left untreated, BA is fatal within 2 years, with a median survival of 8 months. The overall survival without liver transplantation 5 years following the Kasai procedure ranges from 40% to 60%, decreasing to 25% to 35% at 10 years, and 10% to 20% at 20 years (Fig. 117.5); however, this precludes for these patients the need for early OLTxp. The quality of life in these long-term survivors is generally good, with normal growth, development, and sexual development in most cases; however,

these patients do not have normal liver function developing progressive hepatic fibrosis/cirrhosis. With cirrhosis, portal hypertensive complications such as ascites, hypersplenism, and gastrointestinal hemorrhage may occur and complications of chronic liver disease including hepatopulmonary syndrome, portopulmonary hypertension, and hepatocellular carcinoma manifest. Long-term surveillance for all patients with BA is critical, and when the manifestations of ESLD become clinically significant, OLTxp is warranted.

EDITOR'S COMMENT

In their excellent review of biliary atresia, Drs. Ryckman and Tiao succinctly describe the diagnosis, management, and long-term sequelae of biliary atresia, and they provide expert insight into the role of both the Kasai procedure and liver transplantation in the operative management of the disease. Complementary to their review, we would like to offer additional discussion on two systems-level issues that are discussed within the field of pediatric hepatobiliary surgery: (1) the role of the multidisciplinary team within a health care system, and (2) regionalization in care across health care systems.

In pediatric medicine, the initial diagnosis of hyperbilirubinemia is largely the responsibility of primary care pediatricians or family medicine physicians who may never encounter a single case of biliary atresia throughout their career. Neonatal jaundice is usually diagnosed within the first couple of weeks of life and is very common in primary care pediatrics. When resolution of jaundice does not occur, most physicians will attain a conjugated bilirubin level and, if elevated, may refer to specialized care, usually pediatric gastroenterology. It is not uncommon for children to wait over 2 weeks to see a specialist. In communities that lack pediatric gastroenterology practices that know to expedite these referrals, patients can easily wait longer to be evaluated. If the appropriate evaluation is not initiated early, under the assumption that the child has biliary atresia until proven otherwise, then infants may not present to pediatric surgical care until they are outside the optimal window for Kasai portoenterostomy. Although large-scale screening practices have been deemed burdensome, we believe that children's hospitals with comprehensive liver centers including dedicated hepatobiliary and transplant programs are responsible for: (1) promoting community-based educational initiatives to facilitate early diagnosis; (2) developing methods for rapid screening and triage of jaundiced infants to appropriate specialists; (3) establishing multidisciplinary teams that can be activated early in the diagnostic algorithm so that delays in care can be avoided once referral has occurred; and (4) advocating for regionalization to improve outcomes. Although pediatric gastroenterologists are instrumental in the first two points, surgeons play a critical role in guiding multidisciplinary teams and providing evidence for regionalization, both of which have been shown to improve outcomes in pediatric patients.

Multidisciplinary Teams: Within the broader field of pediatric surgery, several models of cross-disciplinary collaboration are widely used in clinical practice. For example, congenital heart disease is managed within the broader context of a "Heart Center" in which cardiac surgeons, cardiologists, cardiac anesthesiologists, radiologists, intensivists, pharmacists, and allied health services work within a common mission and vision. Pediatric surgical oncology, similar to adult surgical oncology, frequently invokes a "tumor board" and cancer specific teams to provide multidisciplinary care plans. A less publicized

team, but one that is more analogous to caring for patients with biliary atresia, is the intestinal rehabilitation team. This team is usually comprised of gastroenterologists, pediatric surgeons, pharmacists, social workers, and nutritional support services with strong ties to pediatric liver and intestinal transplantation centers. A growing body of evidence suggests that intestinal failure patients have improved outcomes when cared for by such a team (Javid PJ, Malone FR, Reyes J, et al. The experience of a regional pediatric intestinal failure program: Successful outcomes from intestinal rehabilitation. *Am J Surg* 2010;199(5):676–9). In 2008, Modi et al. reported one of the first studies on the effects of a multidisciplinary team on outcomes in children with intestinal failure (Modi BP, Langer M, Ching YA, et al. Improved survival in a multidisciplinary short bowel syndrome program. *J Pediatr Surg* 2008;43(1):20–4). Although there was no significant improvement in intestinal autonomy, there was a 19% increase in survival among patients managed within the multidisciplinary team compared to a historical control at their institution. The authors contend that this mortality difference is likely due to the fully integrated care provided by the multidisciplinary team. This approach led to better coordination of surgical, medical, and nutritional management with improved monitoring of medications and development of coherent and integrated treatment plans. Other groups have reported improved survival and weaning of parenteral nutrition in intestinal failure patients managed with a multidisciplinary team approach (Hess RA, Welch KB, Brown PI, et al. Survival outcomes of pediatric intestinal failure patients: analysis of factors contributing to improved survival over the past two decades. *J Surg Res* 2011;170(1):27–31).

After several additional single-center reports emerged in the literature, Stanger et al. published a systematic review on outcomes from multidisciplinary intestinal rehabilitation programs in 2013 (Stanger JD, Oliveira C, Blackmore C, et al. The impact of multi-disciplinary intestinal rehabilitation programs on the outcome of pediatric patients with intestinal failure: a systematic review and meta-analysis. *J Pediatr Surg* 2013;48(5):983–92). They identified that the multidisciplinary approach led to significant reductions in septic episodes and improved overall survival. They also describe multidisciplinary teams as partially responsible for earlier surgical and transplant referral and improvement in overall coordination of care.

The effective and expeditious care of the patient with biliary atresia requires a similar approach. As described by Drs. Ryckman and Tiao, early referral of patients with biliary atresia to pediatric hepatobiliary surgeons is critical for maximizing the success of the Kasai portoenterostomy to establish bile flow. Collaborative discussion around the utility of specific preoperative diagnostic procedures, pathologic findings, and perioperative care is likely to reveal similar improvement in outcomes as those in the intestinal rehabilitation groups. Multidisciplinary teams are also critical for making challenging therapeutic decisions such as when to skip the Kasai and refer directly for transplantation,

or when to consider a portoenterostomy revision. From an academic perspective, multidisciplinary teams are better positioned to engage in novel research at both an institutional and a national level.

Advocating for Regionalization: Several reports from centers around the world have identified that higher-volume centers show superior results in terms of native liver survival following portoenterostomy (Serinet MO, Broue P, Jacquemin E, et al. Management of patients with biliary atresia in France: results of a decentralized policy 1986–2002. *Hepatology* 2006;44(1):75–84; Davenport M, De Ville de Goyet J, Stringer MD, et al. Seamless management of biliary atresia in England and Wales (1999–2002). *Lancet* 2004;363(9418):1354–7). Most widely cited is the study by Davenport et al. from the United Kingdom in which they reviewed postoperative outcomes from portoenterostomy following centralization of cases to one of three referral centers in the United Kingdom. They reported a clinically meaningful increase in both the rate of native liver survival and the actuarial survival (Davenport M, De Ville de Goyet J, Stringer MD, et al. Seamless management of biliary atresia in England and Wales (1999–2002). *Lancet* 2004;363(9418):1354–7). The volume–outcome relationship is not a novel concept in surgery. However, in order to create centers of excellence in the United States, regionalization would need to be supported within the broader community of physicians, health care systems, payers, and families. In the United States, there are several barriers to regionalization including a larger land mass compared to European countries and Japan; a relative inflexibility of both private and public health insurers; competition for market share in health care dense demographics; lack of transparency on volume–outcome relationships with the public; and family resources, preferences, values, support systems, and obligations (work, additional siblings, etc.), which need to be respected.

The etiology of biliary atresia remains to be elucidated, and the operative therapy for biliary atresia has advanced little in decades. Therefore, our biggest opportunities to improve outcomes in children with biliary atresia reside in improving our efficiency at early diagnosis, and insuring every child undergoes operation by an experienced, well-coordinated team.

118 Liver Transplantation

Henrik Petrowsky, Lukasz Filip Grochola, and Ronald W. Busuttil

ETIOLOGY AND PATHOPHYSIOLOGY OF ACUTE AND CHRONIC LIVER INJURY

The loss of functional parenchyma of the liver can be caused by acute or chronic hepatic injury and result in a failure of this organ with an inability to perform its normal synthetic and metabolic function. Despite the fact that the mechanisms underlying the pathogenesis of both types of liver injury are distinct, they can ultimately lead to the need for organ replacement. Acute liver failure results from a rapid loss of hepatocyte function secondary to critical injury by a wide range of causes such as drugs, metabolic and genetic disorders, autoimmune and vascular causes (Table 118.1). Those insults lead either to apoptosis (programmed cell death), which is characterized by nuclear and cytoplasmic shrinkage, condensation, and blebbing without a loss of cell membrane integrity, or necrosis of liver cells, a less orderly process with cell swelling, loss of membrane integrity, and lysis. Chronic hepatic injury on the other hand is a slow process defined by fibrosis of hepatic parenchyma and the subsequent development of cirrhosis with irreversible end-stage liver disease (ESLD). Fibrosis, the first step in this process, is characterized by a reversible scarring of the liver tissue that is caused by chronic injury, which leads to the deposition and resorption of extracellular matrix. With time, in the presence of a continuous insult, this alteration of the extracellular matrix affects the portal tracts, central veins, and perisinusoidal spaces in a way that distorts hepatic vasculature, leading to shunting of the portal and arterial blood supply. In addition, it results in the formation of regenerative nodules and compromised hepatocyte function, and ultimately leads to ESLD (cirrhosis). The most common cause for this condition worldwide is hepatitis B, while abuse of alcohol and hepatitis C are the primary culprits in developed countries. Other factors, including metabolic or autoimmune disorders, are less common causes for chronic liver injury and are listed in Table 118.1. The development of effective

hepatitis C medication and the epidemic of diabetes mellitus and obesity will shift hepatitis C to nonalcoholic steatohepatitis as the most common indication of liver transplantation in the western geography.

CLINICAL PRESENTATION OF LIVER FAILURE

On the basis of duration of liver injury and the resulting symptoms, the clinical manifestation of hepatic failure is classified as fulminant, acute, acute-on-chronic, and chronic. The hallmark of fulminant and acute liver failure is severe hepatic injury with encephalopathy in the absence of preexisting liver disease, whereby the former is defined as the onset of encephalopathy within 8 weeks of the first symptoms of liver disease. Besides hepatic encephalopathy with cerebral edema, the clinical presentation of acute liver failure (inclusive of fulminant and acute-on-chronic conditions) includes most prominently coagulopathy (internationalized normalized ratio ≥1.5), jaundice, and elevated serum aminotransferase levels. In addition, hypotension, renal failure, infection, hypoglycemia, electrolyte abnormalities, and cardiac dysfunction may develop. Of note, portal hypertensive bleeding, which is frequently encountered in chronic liver failure, is not a clinical manifestation of an acute presentation of this condition.

TABLE 118.1 Etiologies of Underlying Liver Failure Requiring Liver Transplantation

Acute Liver Failure:	Chronic Liver Failure:
■ Drug toxicity	■ Alcoholic liver disease
■ Hepatitis A, B, E	■ Hepatitis B, C
■ Shock (acute ischemia)	■ Schistosomiasis
■ Wilson's disease	■ Congestive heart failure
■ Budd–Chiari syndrome (hepatic vein occlusion)	■ Budd–Chiari syndrome (hepatic vein occlusion)
■ Reye syndrome	■ Nonalcoholic steatohepatitis (NASH)
■ Pregnancy-related (fatty liver, HELLP)	■ Hereditary hemochromatosis
■ Autoimmune hepatitis	■ Autoimmune hepatitis
■ Indeterminate acute liver failure	■ Wilson's disease
	■ Primary biliary cirrhosis (PBC)
	■ Primary sclerosing cholangitis (PSC)
	■ Chronic obstruction of the biliary tract
	■ Byler's disease
	■ Cryptogenic cirrhosis

In the majority of cases, the diagnosis of chronic liver failure is made in

patients with compensated liver cirrhosis who present with no symptoms and intact synthetic liver function. In those patients, incidental screening tests show abnormal serum liver transaminase levels or radiologic findings that are suggestive of liver disease. However, in more advanced cases of cirrhosis when hepatocyte function and hepatic circulation are significantly compromised by cirrhotic processes, clinical signs of liver failure such as portal hypertension and coagulopathy with variceal bleeding, jaundice, hepatic encephalopathy, ascites, infection, and renal failure may develop with potentially life-threatening consequences. In contrast to acute liver failure, cerebral edema is not encountered in chronic hepatic failure.

INDICATIONS AND CONTRAINDICATIONS FOR LIVER TRANSPLANTATION

Liver transplantation is indicated in patients with life-threatening acute liver failure or irreversible ESLD. In addition, organ transplantation is also indicated in patients with normal liver function who suffer either from malignant liver tumors (hepatocellular carcinoma [HCC], cholangiocarcinoma, metastatic neuroendocrine tumor) or from noncirrhotic liver disease. The latter conditions present with a normal or well-compensated liver function and include inherited metabolic disorders (e.g., amyloidosis, primary hyperoxaluria) that can affect multiple organ systems, for which liver transplantation is applied as a curative modality, and polycystic liver disease.

In chronic, irreversible conditions (cirrhosis), which represent the most frequent cause for liver transplantation, the question arises as to when is the best time for liver transplantation. In this situation, broad indications for liver transplantation are as given:

1. Hepatic encephalopathy
2. Hyperbilirubinemia with intractable pruritus
3. Portal hypertension (varices, upper gastrointestinal [GI] bleeding, ascites, hypersplenism)
4. Synthetic dysfunction (coagulopathy, hypoalbuminemia)
5. Poor quality of life (QOL) (severe fatigue, lethargy)

If two of these five clinical features are present, the patient should be referred for liver transplant evaluation.

Other indications for liver transplantation include HCC, cholangiocarcinoma, and metastatic neuroendocrine tumor in selected

patients. For example, cirrhotic patients with small HCC within the Milan criteria (single lesion <5 cm or three lesions <3 cm each, no extrahepatic tumor involvement) are suitable candidates for liver transplantation. Even if the intrahepatic tumor load is above the Milan but within the University of California, San Francisco (UCSF) criteria (single lesion <6.5 cm or three lesions total diameter <8 cm, none of which >4.5 cm), patients are still considered for liver transplantation.

Donor organs are allocated to patients with ESLD according to the severity of their chronic liver disease. In the United States and other countries, the severity of liver disease is determined by the Model of End Stage Liver Disease (MELD) score, which considers the degree of liver and renal failure. The MELD score ranges from 6 in a healthy person to 40 in patients with advanced severe ESLD. The score is composed of serum total bilirubin, serum creatinine, and INR.[1] Patients without HCC who have a MELD score below 15 should not undergo liver transplantation since there is no benefit from liver transplantation in terms of survival. On the other hand, patients with MELD scores greater than 15 will benefit from transplantation. Patients with HCC or other conditions (hepatopulmonary syndrome, amyloidosis, metabolic diseases) who have a normal or well-compensated liver function will get MELD exception points since the calculated MELD score does not reflect the patient's medical urgency for liver transplantation.

Acute liver failure in the absence of an underlying chronic liver disease is another definitive indication for liver transplantation (Table 118.1). King's College and Clichy criteria define the urgent need for liver transplantation (Table 118.2). Patients who meet those criteria are urgently listed (status 1) and have the highest priority on the list. If these patients are not urgently transplanted, severe brain edema with herniation and finally brain death can occur. Another condition that requires urgent liver transplantation is the primary nonfunction of a transplanted graft.

Contraindications to liver transplantation include active alcohol or drug abuse, HCC beyond Milan and UCSF criteria, extrahepatic malignancy, severe and irreversible cardiac comorbidities, uncorrectable pulmonary hypertension (mean pulmonary artery pressure >35 mm Hg), uncontrollable infection, irreversible cerebral injury, extensive portal and mesenteric vein thrombosis, unstable psychiatric disease, and incompliance.

PREOPERATIVE PLANNING

The preparation of liver transplantation involves an extensive surgical, medical, and psychosocial evaluation process in order to determine which patients will benefit most from this procedure in terms of survival and have the best chances for postoperative recovery. Because of the chronic organ shortage, this evaluation aims to provide a survival benefit in a safe manner to the most individuals possible who suffer from liver disease. Therefore, this process includes an assessment of alternative treatment options for a given candidate, recurrence rate of the disease, his or her comorbidities and chances of survival of the operation, as well as an evaluation of whether the patient can comply with the elaborate medical regimen required after transplantation. Identifying candidates who are appropriate for transplantation is therefore an elaborate task that requires a multidisciplinary approach. It involves a medical (review of medical records, physical examination), laboratory (including blood typing with antibody screen, hepatitis tests, Epstein–Barr virus, Cytomegalovirus, HIV testing), cardiac (electrocardiogram, echocardiogram, nuclear stress test, coronary catheterization in selected cases), pulmonary (including chest radiograph, pulmonary function testing, arterial blood gas levels), neurologic (carotid doppler if age >60 years, neuroimaging in selected cases), and psychosocial evaluation (psychiatry, social work, financial counselor, and nutritionist consultation), as well as age-appropriate cancer screening (Papanicolau test, mammogram, colonoscopy, PSA). After the completion of this screening process, a committee composed of hepatologist, transplant surgeons and coordinators, psychiatrist, and social workers determines whether the candidate is appropriate for transplantation and can be placed on a national waiting list. While the patient awaits an organ on the waiting list (hereby, the prioritization of patients with ESLD is based on the above-described MELD score), the individual undergoes standard screening and surveillance procedures such as esophagogastroduodenoscopy in order to detect and treat varices, HCC screening, as well as treatment of other complications of ESLD. In addition, MELD scores are reevaluated and updated approximately every 3 months.

TABLE 118.2 Criteria Defining Liver Transplantation for Acute Liver Failure

King's College Criteria:

Acetaminophen-induced ALF
- pH <7.3, or
- INR >6.5 and
- Serum creatinine >3.4 mg/dL

Nonacetaminophen-induced ALF
- INR >6.5, or
- Any three of the following criteria:
  1. Age <10 years or >40 years
  2. Etiology: non-A, non-B hepatitis, idiosyncratic drug reaction
  3. Duration of jaundice before encephalopathy >7 days
  4. INR >3.5
  5. Serum bilirubin >17 mg/dL

Clichy Criteria:

Hepatic encephalopathy, and
Factor V level <20% in patients <30 years of age
Factor V level <30% in patients ≥30 years of age

ALF, acute liver failure; INR, international normalized ratio.

SURGICAL TECHNIQUES

Cadaver Donor Hepatectomy

The donor is placed in the supine position with both arms tucked. The sterile preparation and draping covers the entire chest, abdomen, and proximal thighs to ensure total access to both the thoracic and abdominal cavities. A midline incision is made from the suprasternal notch (two-cavity access) or xiphoid process (one-cavity access) to the symphysis pubis using electrocautery. An extended Balfour self-retaining retractor with penetrating clamps is used for appropriate abdominal exposure. If the

thoracic cavity is opened, a sternal retractor is placed, which improves the exposure especially of both upper abdominal quadrants. Before the start of surgical maneuvers, a thorough exploration of the liver and the abdominal cavity is mandatory to exclude pathologic conditions (malignancies, infectious, and other disease processes), which might preclude organ donation. The liver should be evaluated in terms of size and parenchymal quality. A perfect donor liver has sharp edges, a smooth surface with appearance of scratching marks, and a brownish surface color, while suboptimal organs might present with round edges, some degree of parenchymal yellowness, absence of scratching marks, and a too soft (steatosis) or increased parenchymal firmness (fibrosis). Based on the initial assessment, the procurement surgeon will decide to proceed or to abort the procurement procedure.

If the assessment of the donor organ is acceptable and there is no thoracic or cardiac organ retrieval planned, the chest is opened through a median sternotomy using a pneumatic saw or, if not available, the Lebsche knife. A self-retaining sternal retractor is used for adequate thoracic exposure. The pericardium is incised through the midline at the diaphragm and cranially extended to the right atrium. The abdominal dissection begins with dividing of the round ligament (ligamentum teres hepatis) between two heavy silk ties. Using electrocautery, the falciform ligament is taken down to the hepatic vein–suprahepatic vena cava confluence and the left coronary and triangular ligaments are divided. The left lateral segments of the liver (segments 2 and 3) are reflected toward the donor's right side to access the gastrohepatic ligament. It is of paramount importance to inspect the gastrohepatic ligament for a replaced or accessory left hepatic artery (Fig. 118.1), which can occur in up to 10% of donors. In the vast majority, a replaced or accessory left hepatic artery originates from the left gastric hepatic artery (type 2, Fig. 118.1) and runs within the gastrohepatic ligament to the umbilical fissure. This artery must be preserved and should be neither injured nor divided. In the presence of a replaced or accessory left artery, the ligament is divided above and below the artery.

The retroperitoneal dissection is initiated with the medial reflection of the ascending colon. The ascending colon and the second (descending) part of the duodenum are mobilized and reflected to the left. Afterward, the remaining small intestine is mobilized cephalad until the left renal vein is identified. Dissections above this level might be harmful due to the

potential risk to injure the superior mesenteric artery (SMA), left renal artery, and pancreas. The small intestine is cephalad reflected and the inferior mesenteric vein is isolated at the ligament of Treitz. The vein is distally ligated and then cannulated with a 12 French infusion tubing line for the precool perfusion. We use an isotonic saline solution with 5% dextrose for serum levels less than 160 mEq/gL and 5% dextrose in free water for sodium levels greater than 160 mEq/gL. The volume of the chilled solution, usually not more than 1,000 mL, is slowly infused during the preparation.

The distal abdominal aorta is exposed above the level of the bifurcation in preparation for cannulation. The peritoneum and the periaortal tissue are widely divided at the bifurcation and carried above the origin of the inferior mesenteric artery. It is recommended that the plane of transection above the aorta should be slightly lateral toward the right to avoid cross-sectional injury to the inferior mesenteric artery. The aorta is encircled with two umbilical tapes: The distal tape is placed at the level of the bifurcation and held by a Kelly clamp, while the proximal tape is snared with a Rommel tourniquet and positioned just below the takeoff of the inferior mesenteric artery. In some cases, the inferior mesenteric artery might be divided for better exposure.

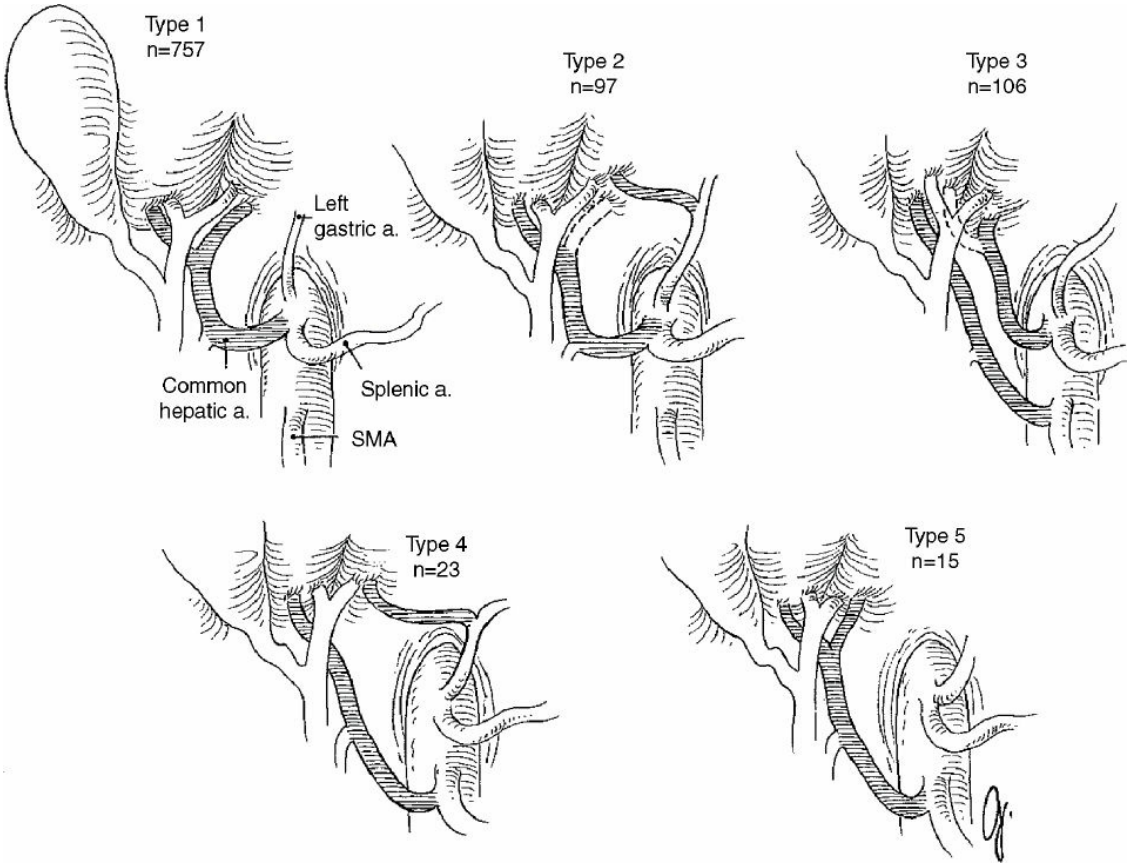

Figure 118.1. Hepatic arterial anatomy in 1,000 cases. Dotted lines indicate that the variant may be accessory (if branch shown by dotted line is present) or replaced (if absent). Type 1: normal (76%); type 2: replaced (accessory) left hepatic artery from left gastric artery (10%); type 3: replaced (accessory) right hepatic artery from superior mesenteric artery (SMA) (10%); type 4: double replaced system (2%); type 5: common hepatic artery from SMA (2%). (From Hiatt JR, Gabbay J, Busuttil RW. Surgical anatomy of the hepatic arteries in 1000 cases. *Ann Surg* 1994;220:50; Wolters Kluwer Health, Inc.)

The small intestine and ascending colon are reflected into the abdominal cavity and the porta hepatis is exposed. It is advisable to palpate the posterior hilum to identify a potential replaced right hepatic artery in arterial types 3, 4, and 5 (Fig. 118.1). The common bile duct above the duodenum (Fig. 118.2) is identified and carefully encircled with 2-0 silk. It is critical that the dissection does not extend into the hilum. The common bile duct is tied with 2-0 silk distally at the duodenal border and is half-way incised just above the tie. The gallbladder fundus is incised and flushed with saline solution until the effluent from the transected bile duct is clear.

The final maneuver before cannulation starts with the exposure of the supraceliac aorta. After the left lobe is elevated and retracted, a longitudinal incision of the right diaphragmatic crus is performed. This maneuver provides adequate access to the supraceliac aorta and might be more difficult in the presence of a replaced left hepatic artery. The preaortic fascia layer is sharply divided laterally with scissors, and the completely exposed aortic segment is encircled with an umbilical tape using a blunt-tipped large right-angle clamp. The tape easily identifies the position of accurate aortic cross-clamping.

The patient is then systemically heparinized with 300 to 500 IU heparin kg^{-1} per donor body weight allowing at least 3 minutes of circulation. After the abdominal aorta is ligated close to its bifurcation with the distal umbilical tape, an aortotomy is made and a 22 to 26 French reinforced cardiac catheter is inserted. The catheter is held in place with the Rommel tourniquet and a double ligation that includes catheter and tourniquet. In agreement with all recovering teams, the cross-clamp and the start of the perfusion are initiated. The cross-clamping is performed with a straight vascular clamp at the supraceliac position with the encircled umbilical tape. Immediately after this maneuver, the suprahepatic vena cava is transected at the caval–atrial junction and the dual perfusion with ice-cold preservation solution via abdominal aorta and inferior mesenteric vein is started. Slashed ice is immediately placed around the liver (including subdiaphragmatic space, hilum, and anterior and posterior to the liver), around both kidneys, and, in case of pancreas retrieval, into the lesser sac. At University of California, Los Angeles (UCLA), exclusively the University of Wisconsin (UW) solution is used at 4°C (39.2°F) as preservation solution infusing 2,000 to 3,000 mL via the aortic cannula and 1,000 mL via the inferior mesenteric vein.

After completion of cold perfusion and retrieval of cardiothoracic organs, the pericardium and the left and right diaphragm around the liver are divided. The cold dissection in the hilum starts with the arterial axis. Both the gastroduodenal artery and splenic artery are divided, and the celiac trunk is followed toward the aorta. The splenic vein and the superior mesenteric vein are transected, and the portal vein is dissected cephalad. In case of pancreas retrieval, the portal vein is divided to provide sufficient length for both the liver and the pancreas and to avoid pancreatic injury. The transection of the common bile duct is completed at the previous incision. If a replaced left or right hepatic artery is identified, each

structure is followed either to the left gastric artery or to the SMA (Fig. 118.1). The hilum dissection is completed after transecting the aorta with an aortal patch, including the orifice of the mesenteric artery and celiac artery. The inferior vena cava is divided proximal to the renal veins, and the liver is excised and packed in UW solution for transport.

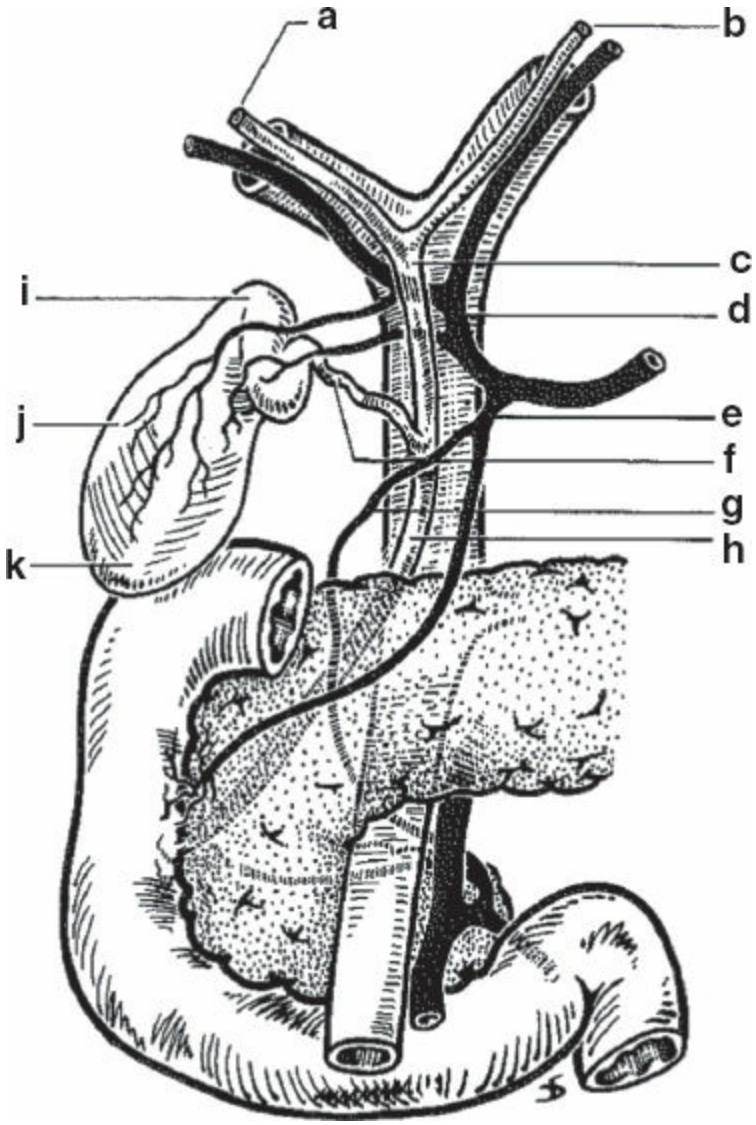

Figure 118.2. Anterior aspect of the biliary anatomy: **a**, right hepatic duct; **b**, left hepatic duct; **c**, common hepatic duct; **d**, hepatic artery; **e**, gastroduodenal artery; **f**, cystic duct; **g**, retroduodenal artery; **h**, common bile duct; **i**, neck of the gallbladder; **j**, body of the gallbladder; **k**, fundus of the gallbladder. Note particularly the situation of the hepatic bile duct confluence anterior to the right branch of the portal vein, the posterior course of the cystic artery behind the common hepatic duct, and the relationship of the neck of the gallbladder to the right branch of the hepatic artery. (Published in Blumgart LH,

Hann LE. Surgical and radiologic anatomy of the liver and biliary tract. In: Blumgart LH, Fong Y, eds. *Surgery of the Liver and Biliary Tract*. Philadelphia, PA: WB Saunders, 2000:14. Copyright 2000 Elsevier.)

Back-Table Preparation of the Donor Liver

Before the implantation into the recipient, the donor organ has to be prepared, which usually occurs during the recipient hepatectomy. The entire back-table preparation is performed in preservation solution at 4°C (39.2°F). The remnant diaphragm is removed and the suprahepatic vena cava is isolated. Phrenic vein orifices of the suprahepatic vena cava are identified and ligated or sutured. Next, the inferior vena cava is separated from adjacent tissue. The inferior vena cava is carefully inspected and the right adrenal vein and other small branches are ligated. The portal vein is isolated to the level of the bifurcation and cannulated for later flush with ice-cold lactated Ringer's with albumin solution. Finally, the entire arterial axis is skeletonized. Therefore, it is of paramount importance to identify any anatomic variations (types 2, 3, and 4) that would require reconstruction (Fig. 118.1). Dissection above the level of the gastroduodenal artery should be avoided due to potential injury to the proper hepatic artery.

Recipient Hepatectomy

Appropriate access to the upper abdominal cavity is achieved through a bilateral subcostal incision with midline extension. Except for the skin incision, the subcutaneous tissue, muscle, and fascia layers are divided with electrocautery. The right-sided incision extends more laterally than the left-sided incision. The midline incision is carried out to the xiphoid, requiring in some cases the resection of the xiphoid process. If the recipient has massive ascites, the subcostal incision should be placed 2 to 3 cm lower as compared with in recipients without ascites. The access is completed by dividing and ligating the round ligament. The falciform ligament is divided with electrocautery toward the suprahepatic vena cava. Afterward, a mechanical retractor system is placed with blades under both costal margins. The residual falciform ligament is taken down to the hepatic vein–suprahepatic vena cava confluence, and the left coronary and triangular ligaments are divided. The left lateral segments of the liver (segments 2 and 3) are reflected toward the recipient's right side, and the

gastrohepatic ligament is divided.

The common hepatic artery is dissected and clamped with a bulldog clamp (Fig. 118.3D). This step should avoid the arterial intima dissection after the left and right hepatic arteries are ligated (Fig. 118.3). Dissected arteries are associated with a very high risk for occlusion or are unusable for arterial reconstruction. The hilar dissection begins with incising the peritoneum at the superior border of the hilum in order to identify the left and right and sometimes the middle hepatic arteries. The hepatic arteries are dissected, ligated, and divided. The cystic duct and cystic artery (Fig. 118.2) are divided, which facilitates the circumferential dissection of the common hepatic duct. The isolated duct is then divided high in the hilum to ensure sufficient length of the recipient's duct for the later biliary anastomosis. In many cases, the dissection and division of the right hepatic artery are only possible at this point since the right hepatic artery crosses posteriorly to the common hepatic duct (Fig. 118.2). We then separate the arterial axis (proper hepatic artery) from the common bile duct. We routinely divide the gastroduodenal artery and follow the dissection toward the common hepatic artery until the position of the previously placed bulldog clamp. The portal vein is now skeletonized just until above the pancreatic border. During the distal dissection, the surgeon will find anterior and lateral portal vein branches that have to be ligated and divided. The portal vein dissection is completed by removing the posterior plane of lymphatic and connective tissue.

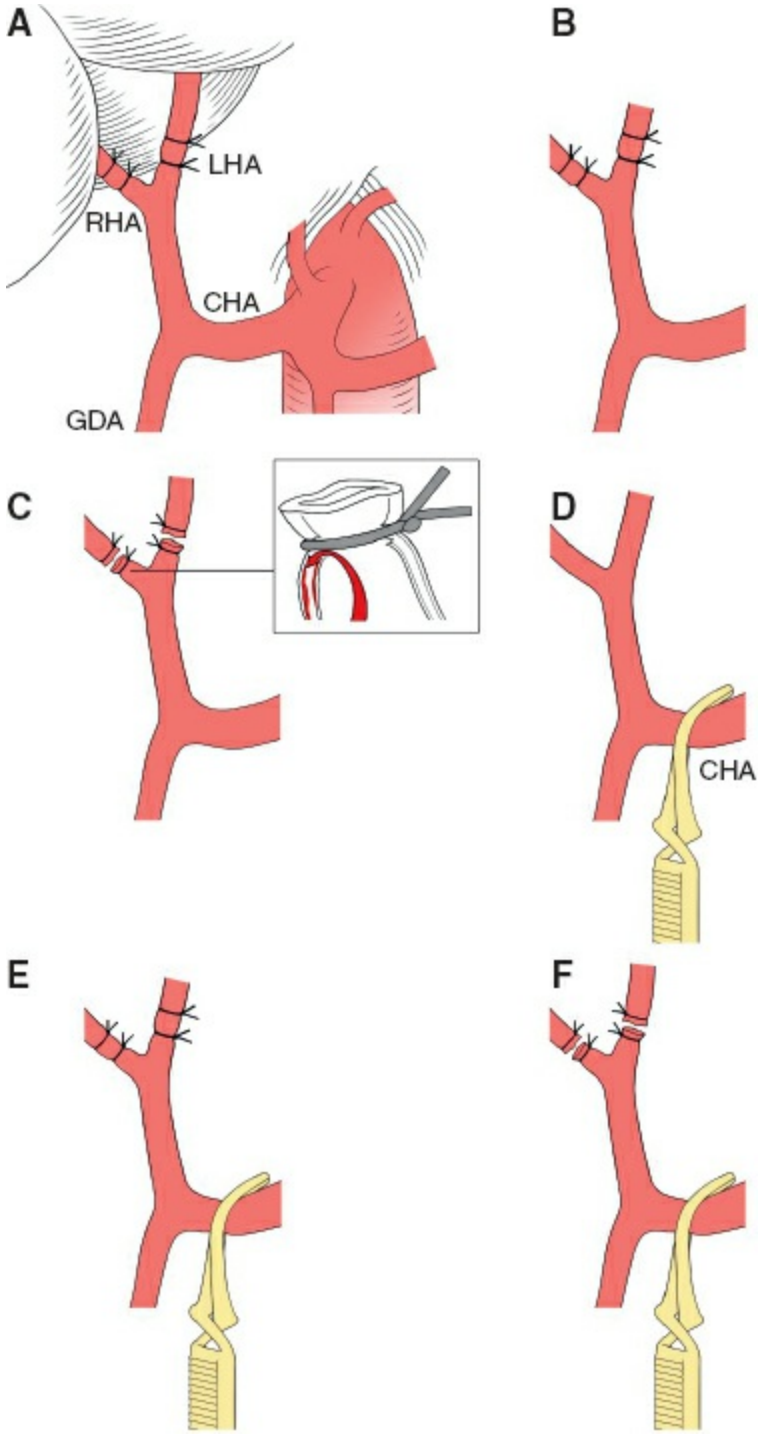

Figure 118.3. Dissection techniques of the arterial axis in the recipient. **A.** Normal hepatic anatomy. RHA, right hepatic artery; LHA, left hepatic artery; CHA, common hepatic artery; GDA, gastroduodenal artery. A dissection technique that, as a first step, directly ligates (**B**) and divides (**C**) the RHA and LHA should be avoided. This technique can lead to a dissection of the intima of the respective arteries due to the preserved blood flow and subsequently result in an occlusion of the vessels (inlay in C), which can significantly impair the patency of the anastomosis between the recipient and donor arteries. (**D**) In contrast to this

technique, at UCLA, an atraumatic bulldog clamp (yellow) is first placed at the CHA. Subsequently, the RHA and LHA are ligated (**E**) and divided (**F**). In the latter technique (**D**, **E**, and **F**), the risk of intima dissection is minimized. (Original work by the Graphic Department of the University Hospital Zurich.)

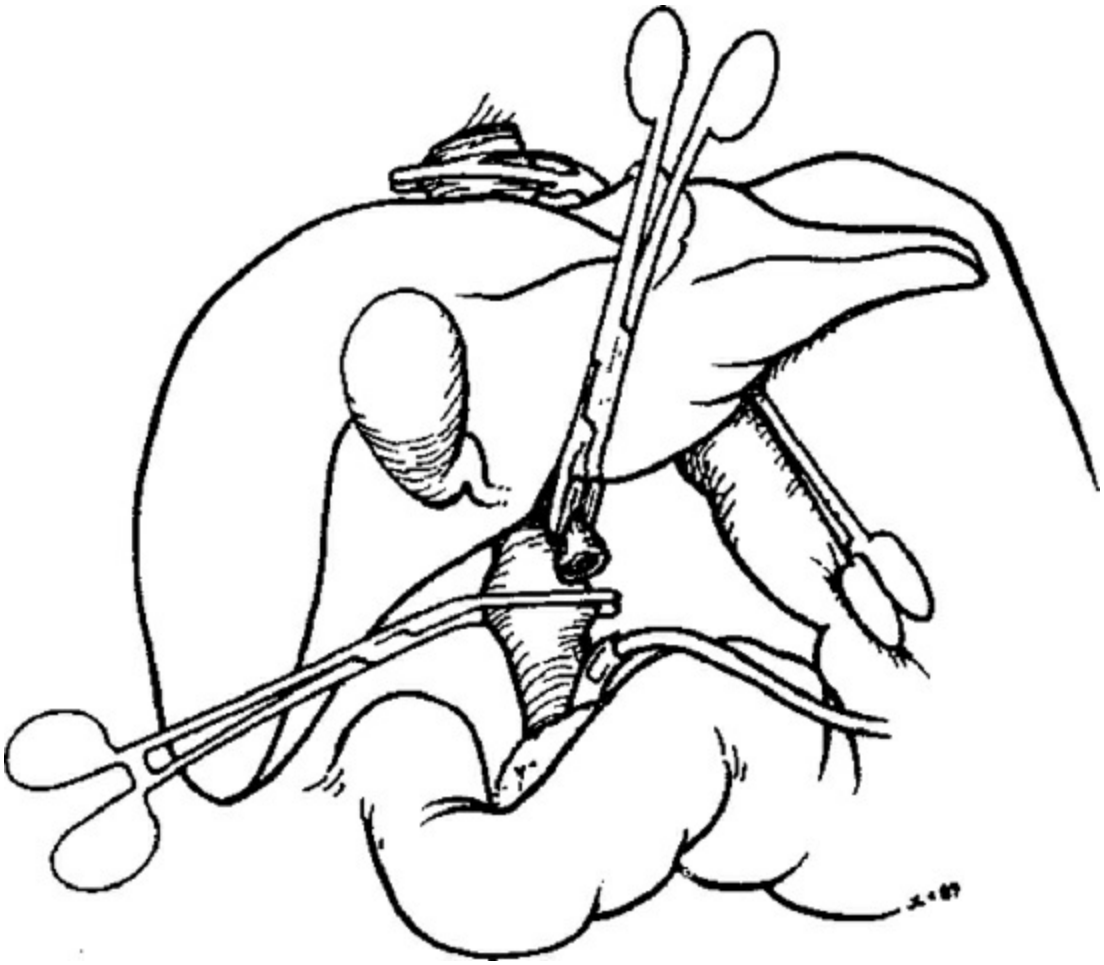

Figure 118.4. Horizontal placement of vascular clamps on suprahepatic and infrahepatic vena cava. (Reprinted from Klintmalm GB, Busuttiland RW. The recipient hepatectomy and grafting. In: Busuttil RW, Klintmalm GB, eds. *Transplantation of the Liver*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2015:604, with permission from Elsevier.)

The right lobe and the inferior vena cava are now mobilized. The right lobe is carefully elevated, and the right coronary and triangular ligaments are taken down with electrocautery. The dissection begins at the lateral inferior aspect and divides the ligament carefully all the way into the vena cava. After the peritoneum overlaying the anterior part of the infrahepatic vena cava is divided, the line of peritoneal dissection follows the plane

between left-sided vena cava and the peritoneal sheet all the way up to the suprahepatic vena cava. This maneuver often provides the window underneath the hepatic vena cava to the right side. The dissection is completed now on the right side. The right lobe is elevated, and the right adrenal vein is ligated and divided. Finally, the peritoneum is divided longitudinally along the vena cava. This results in the complete separation of the posterior aspect of the retrohepatic vena cava from the retroperitoneum.

The native liver is now ready for removal if no venovenous bypass (VVB) is applied. Vascular clamps are placed on the distal portal vein, infrahepatic and suprahepatic vena cava (Fig. 118.4). It is important that all clamps be oriented horizontally with the liver in the normal anatomic position to avoid rotation of the vessels. We use a large Satinsky vascular clamp for the suprahepatic vena cava, which should be placed on the very edge of the diaphragmatic reflection to avoid injuries to the phrenic nerve. The suprahepatic vena cava is first divided far into the hepatic veins. Next, the lower cava is divided as proximal as possible and finally the portal vein. The native liver is now removed (Fig. 118.5). Hemostasis of the bare area is achieved by retroperitonealization (Fig. 118.5, inlay). We use running sutures with 2-0 Prolene staring laterally and running centrally followed by a second running suture in the midline. For recipients with HCC, no residual liver tissue of the native liver should remain at the suprahepatic vena cava.

Venovenous Bypass

The VVB drains the infrahepatic caval and splanchnic blood into the superior vena cava (Fig. 118.6). Although not yet proven in randomized controlled trials, the VVB offers several advantages. The main advantage is related to the maintenance of venous return and splanchnic venous drainage, which results in improved hemodynamic stability during the anhepatic phase and reduction in mesenteric edema. The introduction of the VVB resulted initially in a decline of early morbidity and mortality; however, VVB is not routinely used and is likely less necessary for cava-sparing techniques (piggyback). In general, VVB is indicated in patients with hemodynamic instability after clamping, with fulminate hepatic failure to reduce volume overload, and with nondialysis-dependent hepatorenal syndrome.

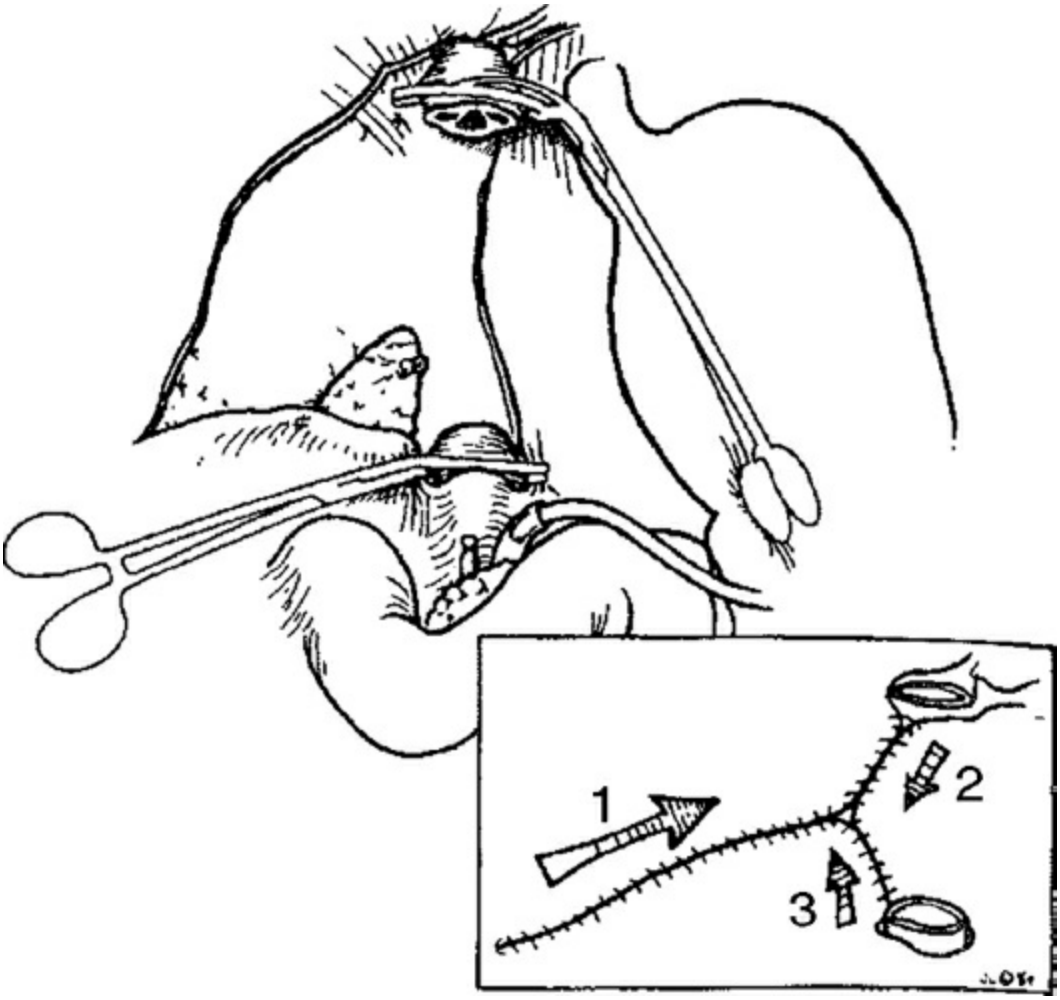

Figure 118.5. Upper abdominal situs after hepatectomy with vascular clamp on supra and infrahepatic vena cava. Portal vein is cannulated for venovenous bypass. The inlay illustrates the suture lines after retroperitonalization of the bare area. (Reprinted from from Klintmalm GB, Busuttil RW. The recipient hepatectomy and grafting. In: Busuttil RW, Klintmalm GB, eds. *Transplantation of the Liver.* 3rd ed. Philadelphia, PA: Elsevier Saunders; 2015:604, with permission from Elsevier.)

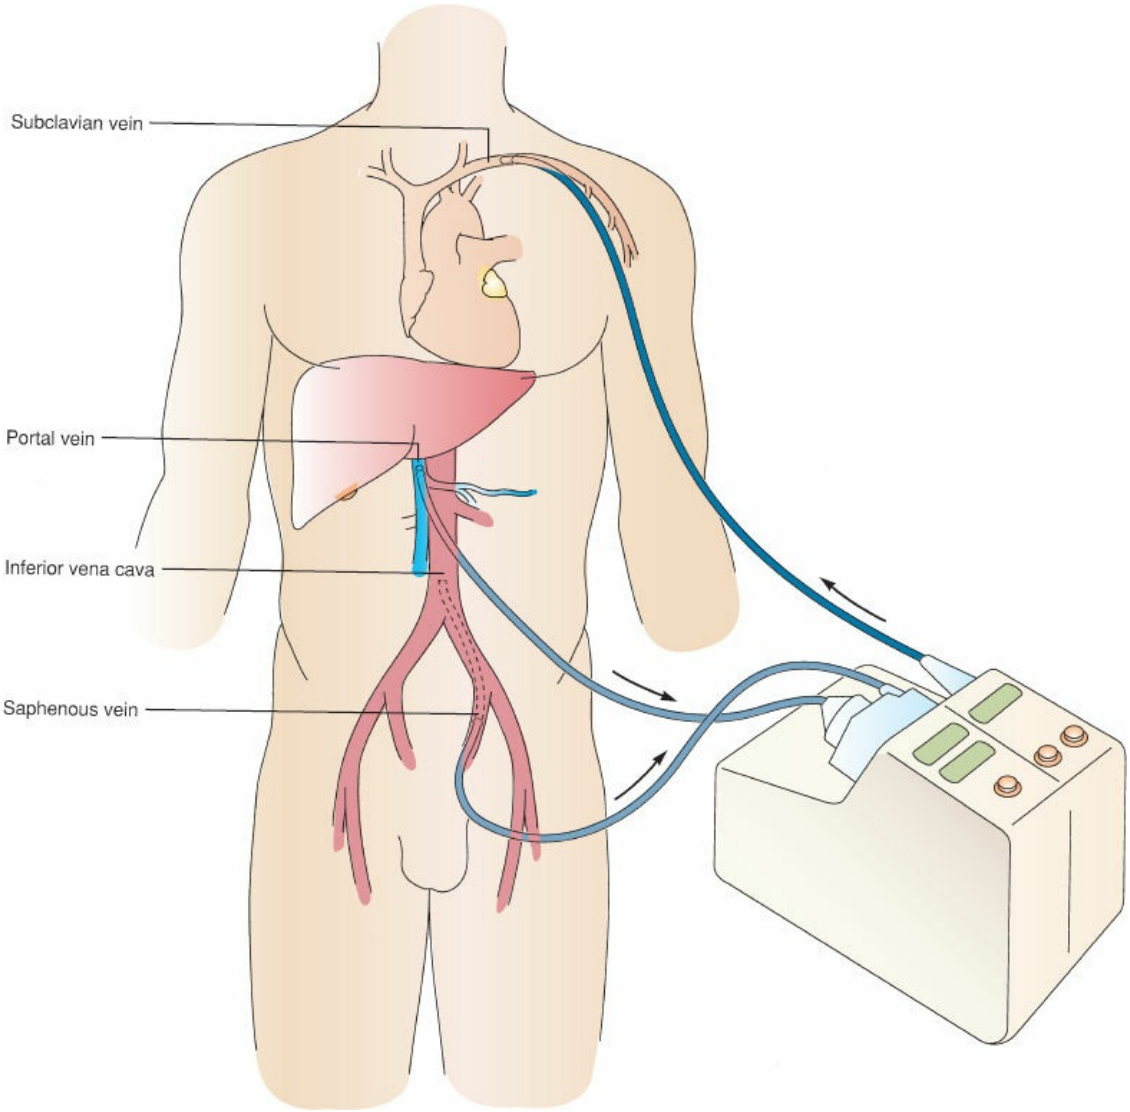

Figure 118.6. Setup for venovenous bypass during liver transplantation. (From Welling TH. Hepatic Transplantation. In: Mulholland MW, Lillemoe KD, Doherty GM, et al, eds. *Greenfield's Surgery: Scientific Principles and Practice*. 6th ed. Philadelphia: Wolters Kluwer; 2017:561, with permission.)

VVB of the subclavian and femoral vein can be performed as either a percutaneous or an open approach (Fig. 118.6). In both techniques, the cannulation of the portal veins is identical and performed by the surgeon. In the percutaneous technique, the femoral vein and the subclavian vein or alternatively the right internal jugular vein (IJV) are punctured and cannulated via the Seldinger technique. We use wire-inforced cannulas, 15 French for the femoral vein, and 12 French for the subclavian vein or right IJV. In the open technique, we cut down on the left axillary vein and left saphenofemoral junction using 20 and 18 French cannulas, respectively.

The cannulation of the saphenous vein should always be approached. In the absence of the saphenous vein, the cannulation of the femoral vein is possible but requires vascular reconstruction after the removal of the cannula. We usually start the cannulation of the portal vein with a ligation high up in the hilum. After placing an umbilical tape around the vein and a vascular clamp on the distal part of the portal vein, the proximal portal vein is incised and 22 French wire-reinforced cannula is introduced and advanced after the removal of the distal vascular clamp. The cannula is secured with tourniquet and ligations.

Implantation of Cadaver Whole Allograft

Suprahepatic Vena Cava Anastomosis

The implantation procedure begins with the preparation of the suprahepatic vena cava of the recipient. All hepatic vein bridges are divided to create a common suprahepatic vena cava cuff. At this point, the supra- and infrahepatic vena cuffs are carefully inspected for ostia, which are closed with 4-0 Prolene by placing the knots outside the caval cuff. After placing the donor liver into the situs, two corner stitches are placed at the opposite ends using 3-0 Prolene. In some cases with limited exposure, a stay suture of the middle posterior wall is helpful for better retraction. The posterior wall of the recipient and donor suprahepatic vena cava is anastomosed with a running suture from the left to the right corner sutures using 3-0 Prolene. We complete the anterior wall anastomosis using the same technique except that the suture is done from both the left and right side and tied down in the middle.

Infrahepatic Vena Cava Anastomosis

We proceed with the anastomosis of the infrahepatic vena cava. During the creation of the anastomosis, the liver is flushed with chilled lactated Ringer's and albumin (25 g per 1,000 mL) solution via the portal vein cannula. The purpose of this maneuver is to remove possible air and the high extracellular potassium from the preservation solution (UW). Depending on the size of the donor organ, we perform the rinsing of the allograft with 700 to 1,000 mL flush solution. The infrahepatic vena cava anastomosis is performed with 4-0 Prolene in the same fashion as the suprahepatic cava anastomosis. The suture is not tied down to facilitate flushing and venting maneuvers.

Portal Vein Anastomosis

If the patient is on VVB (Fig. 118.6), the bypass cannula is removed from the portal vein and the proximal portal vein is clamped. The donor portal vein is trimmed to the appropriate length. It is important to avoid a redundant portal vein, which can result in kinking and folding with severe compromise of portal flow. This principle also applies to the infrahepatic vena cava anastomosis. As for supra- and infrahepatic vena cava anastomosis, the portal vein is anastomosed with a running suture using 6-0 Prolene (Fig. 118.7). If there is a significant size mismatch between the donor and recipient portal vein, a fish mouth reconstruction is recommended. After completion of the portal vein, we reperfuse the liver through the portal vein and vent the reperfused blood through the open anterior suture line of the infrahepatic vena cava. Afterwards, sequential reperfusion through the infrahepatic vena cava and portal vein as well as simultaneous reperfusion through the portal vein and hepatic artery might be performed.

Arterial Anastomosis

The reconstruction of the hepatic artery is crucial to prevent any compromise of the arterial blood supply to the allograft. An imperfect anastomosis can result in early hepatic artery thrombosis with graft loss. However, the type of arterial reconstruction depends on the donor as well as on recipient arterial anatomy (Fig. 118.1). In normal cases with type 1 anatomy of the donor and recipient artery, the anastomosis can usually be created as end-to-end anastomosis between a Carrel patch of the donor aorta or artery and the common hepatic artery or branch patch of the bifurcation of the proper hepatic and gastroduodenal artery (Fig. 118.8). For regular-size arteries we use running sutures with 6-0 or 7-0 Prolene, while we prefer the interrupted suture technique with 7-0 or 8-0 Prolene for small-size arteries. The recipient gastroduodenal artery is always ligated and divided when the arterial anastomosis is performed with the recipient common hepatic artery. A replaced right hepatic donor artery stemming from the SMA (type 3 anatomy) is the most common arterial variant that requires reconstruction (Fig. 118.1). In these cases, a Carrel patch of the donor celiac artery can be anastomosed with a Carrel patch of the donor SMA (Fig. 118.9). The donor splenic artery is then anastomosed to the recipient common hepatic artery. Alternatively, an anastomosis between the donor-replaced right hepatic artery and the donor gastroduodenal artery can be created. If the arterial flow is unsatisfactory despite a technically perfect anastomosis, two important anatomic features

have to be considered. The arterial supply can be significantly compromised by a steel phenomenon of the splenic artery or the arcuate ligament syndrome. The steel phenomenon can be addressed through simple ligation of the splenic artery. In case of an arcuate ligament syndrome, the celiac arterial axis must be dissected down to the aorta and the ligament divided. If both of these maneuvers fail to improve the arterial flow, an infrarenal or supraceliac arterial conduit anastomosis using an iliac artery graft can be performed between the aorta and the iliac graft. Whenever possible, we prefer the infrarenal conduit, which is tunneled through the transverse mesocolon and anastomosed with the hepatic artery of the allograft.

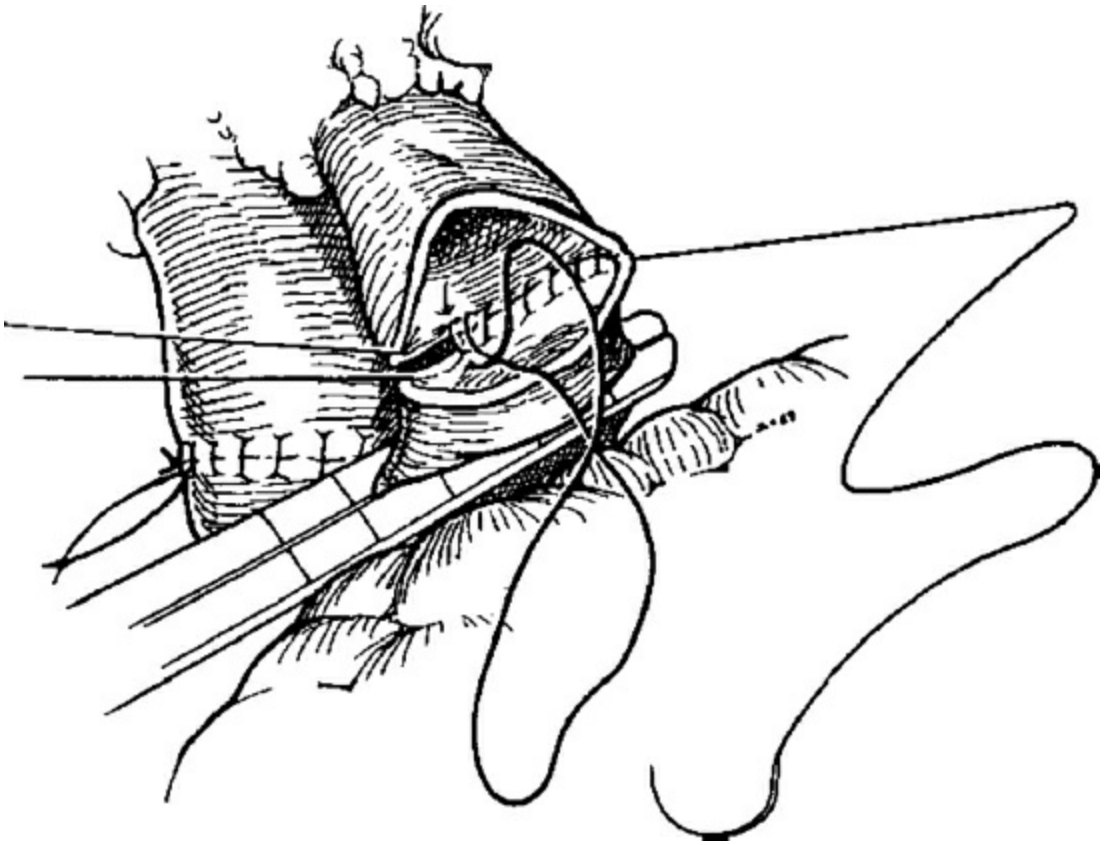

Figure 118.7. Completed infrahepatic vena caval anastomosis and running suture of posterior portal vein anastomosis. (Reprinted from Klintmalm GB, Busuttil RW. The recipient hepatectomy and grafting. In: Busuttil RW, Klintmalm GB, eds. *Transplantation of the Liver*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2015:606, with permission from Elsevier.)

Biliary Anastomosis

After the arterial anastomosis is completed, the biliary reconstruction starts

with the removal of the gallbladder. We usually perform a retrograde resection of the gallbladder from fundus downward with electrocautery. Whenever possible, the donor cholecystectomy includes the resection of the entire donor cystic duct. Both a duct-to-duct and a Roux-en-Y biliodigestive anastomosis can be used for biliary reconstruction. However, we prefer duct-to-duct reconstruction, whenever feasible, since this reconstruction has the advantage of future endoscopic access to manage biliary complications. For choledocho-choledochostomy, donor and recipient bile duct are shortened to an appropriate length. In case of a significant size mismatch of donor and recipient bile duct, a ductoplasty is created, which can be created by different techniques (Fig. 118.10). The choledocho-choledochostomy is performed as end-to-end anastomosis with interrupted 5-0 or 6-0 PDS (polydioxanone, Ethicon, Somerville, NJ) suture (Fig. 118.11). It is important to avoid redundancy and tension of the bile duct to prevent biliary obstruction and duct necrosis, respectively. We do not use T-tubes routinely except in patients with ductoplasty, extended donor criteria organs, and partial allografts. If a T-tube is indicated, it is brought out of the recipient duct approximately 1 to 1.5 cm downward the anastomotic suture line (Fig. 118.11). The T-tube exit side is narrowed with a figure-of-eight suture using absorbable material such as 6-0 PDS.

Choledochojejunostomy (Fig. 118.11) is performed for technical reasons (very small donor common hepatic duct) or disease-specific causes (primary biliary cholangitis, cholangiocarcinoma). The jejunum is divided 30 cm distal to the ligament of Treitz using a GIA stapler (Covidien autosuture). This is followed by creation of a 40-cm defunctionalized Roux-en-Y limb with a side-to-side jejunojejunostomy. The jejunojejunostomy is performed as a two-layer technique with 3-0 PDS running suture and silk Lembert sutures. The Roux-en-Y limb is brought through a retrocolic or retrogastric tunnel toward the liver. A very small hole is made distally to the Roux-en-Y limb using a pinpoint electrocautery. As in the case of choledocho-choledochostomy, choledochojejunostomy is created using interrupted 5-0 or 6-0 PDS suture. For small ducts, we insert small 6 French stents that are fixed to the internal back wall suture (Fig. 118.11). After all vascular and biliary anastomoses are completed, final rounds of hemostasis are undertaken. Although the role of prophylactic drainage is controversial, we routinely place three peritoneal Jackson–Pratt drains into the right and left subdiaphragmatic space as well adjacent to the biliary anastomosis.

Piggyback Technique

The piggyback technique is a commonly used alternative to the classic approach and preserves the native retrohepatic vena cava (Fig. 118.12). In this technique, the recipient hepatectomy has the mobilization of the right and left lobe and the dissection of the hepatoduodenal ligament with division of the vascular and biliary structures in common with the classic approach. The use of VVB is less likely in this technique since the venous return via the inferior vena cava is preserved. In order to decompress the splanchnic venous drainage, an end-to-side portacaval shunt might be performed using running 5-0 Prolene sutures. Next, the right lobe is elevated and the retrohepatic vena cava is exposed. All small liver veins are clipped or ligated and divided in the dissection plane between the retrohepatic vena cava and the posterior liver. The dissection starts from the infrahepatic vena cava and continues cephalad with encircling the right hepatic vein, which is clamped, divided, and oversewn with 3-0 Prolene. After clamping of the portal vein, the common trunk composed of the middle and left hepatic vein is occluded with a Satinsky clamp and the native liver is excised. If the common trunk is short, we usually divide the intervascular septum between the left and middle hepatic vein to create a common channel. Often, we extend the cava incision distally 3 to 4 cm to increase the cava orifice for sufficient outflow and to prevent technical Budd–Chiari syndrome (Fig. 118.13). After the donor liver is orthotopically placed into the situs, the posterior side of the donor retrohepatic vena cava is longitudinally incised according to the length of the incision of the recipient vena cava. The anastomosis is performed by running technique using 3-0 or 4-0 Prolene (Fig. 118.14). It is of paramount importance that the suture line or anastomosis does not compromise the hepatic venous outflow, which can result in a technical Budd–Chiari syndrome. During the creation of the vena cava anastomosis, the liver is flushed with chilled lactated Ringer's and albumin (25 g per 1000 mL) solution via the portal vein cannula. After completion of the anastomosis, the anastomotic reconstruction of the portal vein is performed as described for the classic approach. The anastomosis of the infrahepatic vena cava is not required in the piggyback technique (Fig. 118.12). We close the infrahepatic vena cava of the allograft during back-table preparation with a two-layer running 4-0 Prolene suture.

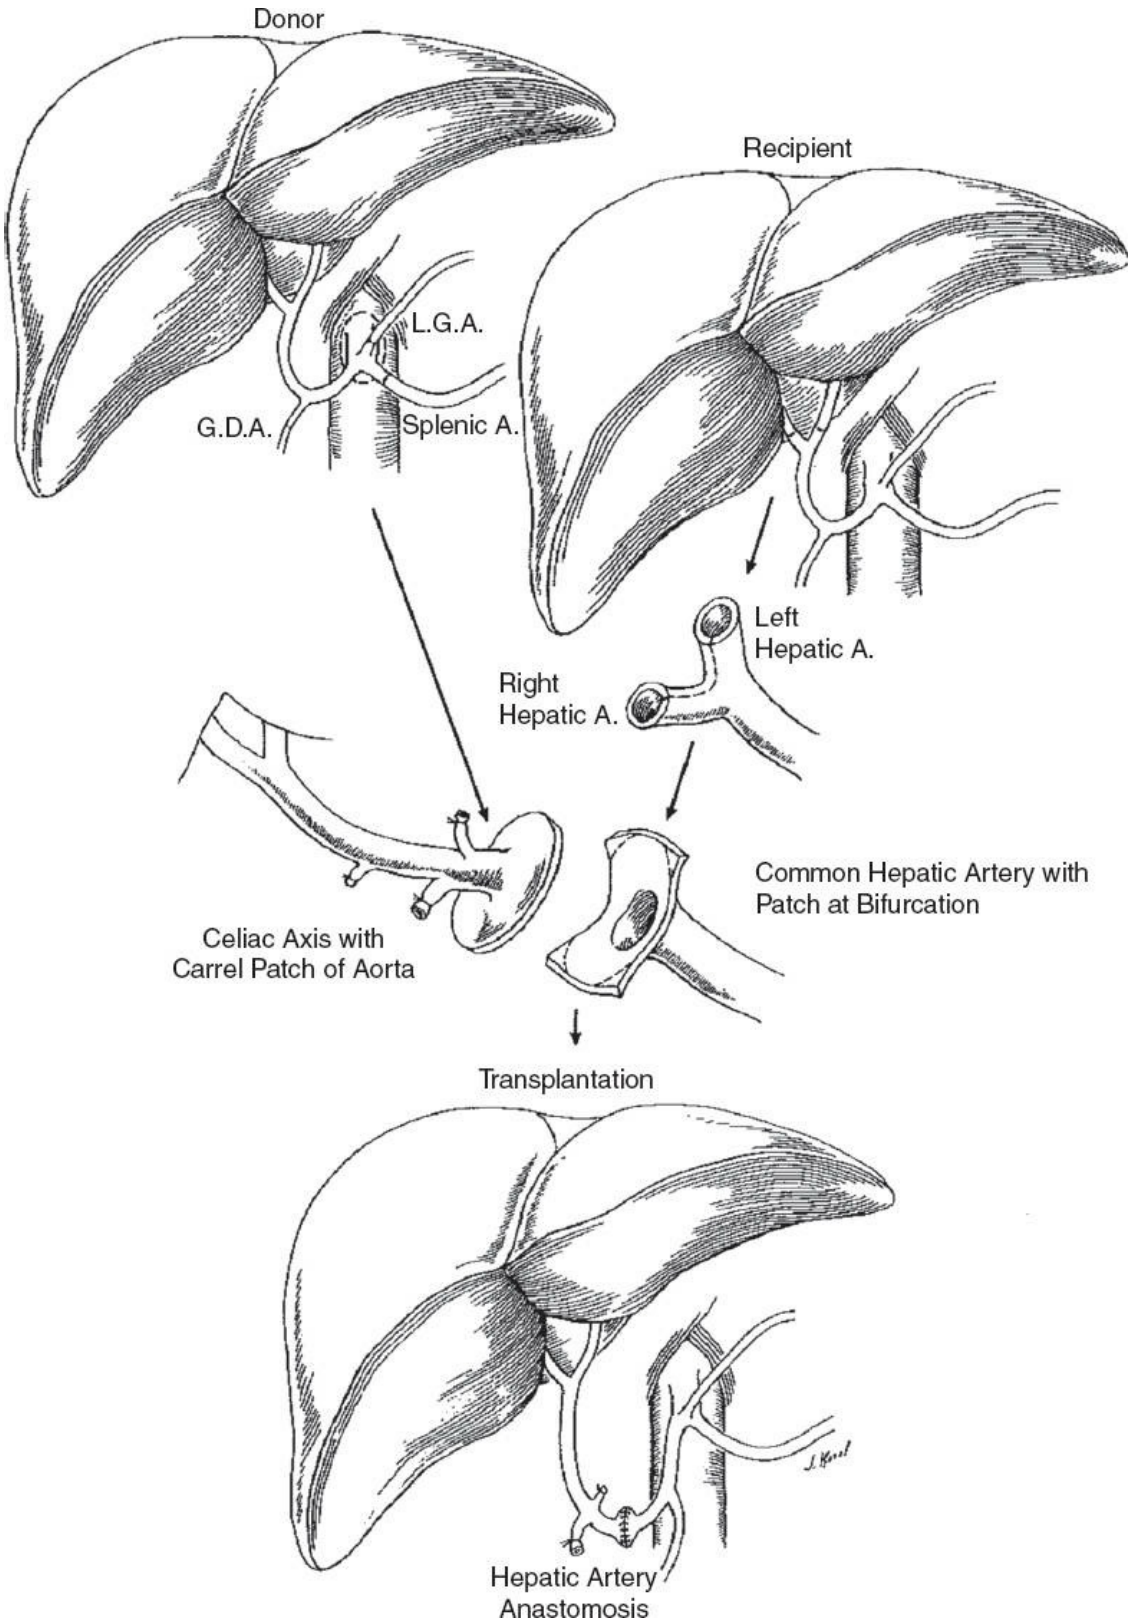

Figure 118.8. "Branch patch" technique for anastomosis of the donor celiac axis with a Carrel patch to the longitudinally opened recipient right and left hepatic artery branches. Living Donor Liver Transplantation

Living donor liver transplantation (LDLT) is an alternative to cadaveric liver transplantation in which a partial liver graft is obtained from a living healthy donor and transplanted into a recipient. This surgical technique is the primary transplant procedure in certain Asian countries where cadaveric donation is extremely rare due to culture issues. LDLT has also been used as adjunct therapy in geographic regions with low cadaveric donation or in pediatric or adult patients who are otherwise disadvantaged by the current MELD allocation system.

The most important preoperative issue in LDLT is the selection of the appropriate donor and recipient. The irrefutable mandate of the donor operation is zero mortality and low morbidity, while quality and size of the partial allograft should dictate the recipient procedure. If the size or volume of the partial graft is below a critical threshold, the graft can fail to regenerate, which results in liver failure and life-threatening multiorgan failure. This clinical scenario is termed as “small-for-size syndrome.” In order to prevent small-for-size syndrome, a minimum graft-to-body weight ratio of 0.8% to 1% must be obtained. But size alone is not the only important factor that dictates the appropriate selection. Organ quality has to be evenly considered, and willing donors with diseased liver or significant steatosis should be excluded from living donation.

Living Donor Hepatectomy

The right donor hemihepatectomy (segments 4 to 8) is the most frequently performed donor procedure for an adult recipient (Fig. 118.15A), while the hepatectomy of the left lateral sector (segments 2 and 3) in an adult is used in pediatric LDLT (Fig. 118.16A). Regardless of which type of donor hepatectomy is performed, the donor procedure requires the highest degree of precision to prevent morbidity and mortality in the donor. For all types of donor hepatectomies, appropriate abdominal access and exposure are achieved as described under recipient hepatectomy. The right or left donor operation for LDLT is similar to the right or left hemihepatectomy in liver surgery but varies in few important steps. Specifically, in the right donor operation for LDLT, it is imperative that the transection of the right hepatic bile duct should be only performed after direct visualization of the biliary tree by intraoperative cholangiogram, which can be performed via

the cystic duct. After the biliary anatomy is verified, the right bile duct can be transected, leaving an approximately 2- to 3-mm-long stump to provide enough room to close the duct without compromising the donor duct. It is also of paramount importance to preserve the periductal tissue and blood supply to prevent any future strictures or bile leaks in the donor. The subsequent hilar dissection is limited to the right hepatic artery and the right portal vein, whereby the right hepatic artery dissection should be limited to the right side of the common hepatic duct, and the branch to segment IV should be preserved. After all right-sided vascular and biliary structures are defined, a short inflow occlusion of the right portal vein and right hepatic artery is applied to find the optimal line of parenchymal transection. The transection is performed after mobilizing the right liver, during which no excessive compression of the right liver must be applied in order to avoid an ischemic liver injury. During mobilization, any inferior right hepatic veins larger than 5 mm should be preserved for reconstruction in the recipient. The transection should be performed without inflow occlusion in order to minimize the ischemic insult to the partial graft. After complete parenchymal transection and dividing the right hepatic vein, the right partial graft can be perfused with preservation solution in situ or ex situ via the right portal vein. The technique for a full left donor hemihepatectomy (segments 2 to 4 with or without segment 1), which is not described in detail here, is performed analogous to the right hemihepatectomy with mobilization and perfusion of the left hemiliver. The living donation of the left lateral sector (segments 2 and 3), usually used for a pediatric recipient, is performed analogous to the corresponding split technique, which is described under split liver transplantation (Fig. 118.16A). In contrast to the split technique, the partial graft obtained from a living donor does not have the common axis of the hepatic artery, portal vein, and vena cava patch. Only the side-specific inflow and outflow vessels and bile duct are returned with the living donor graft.

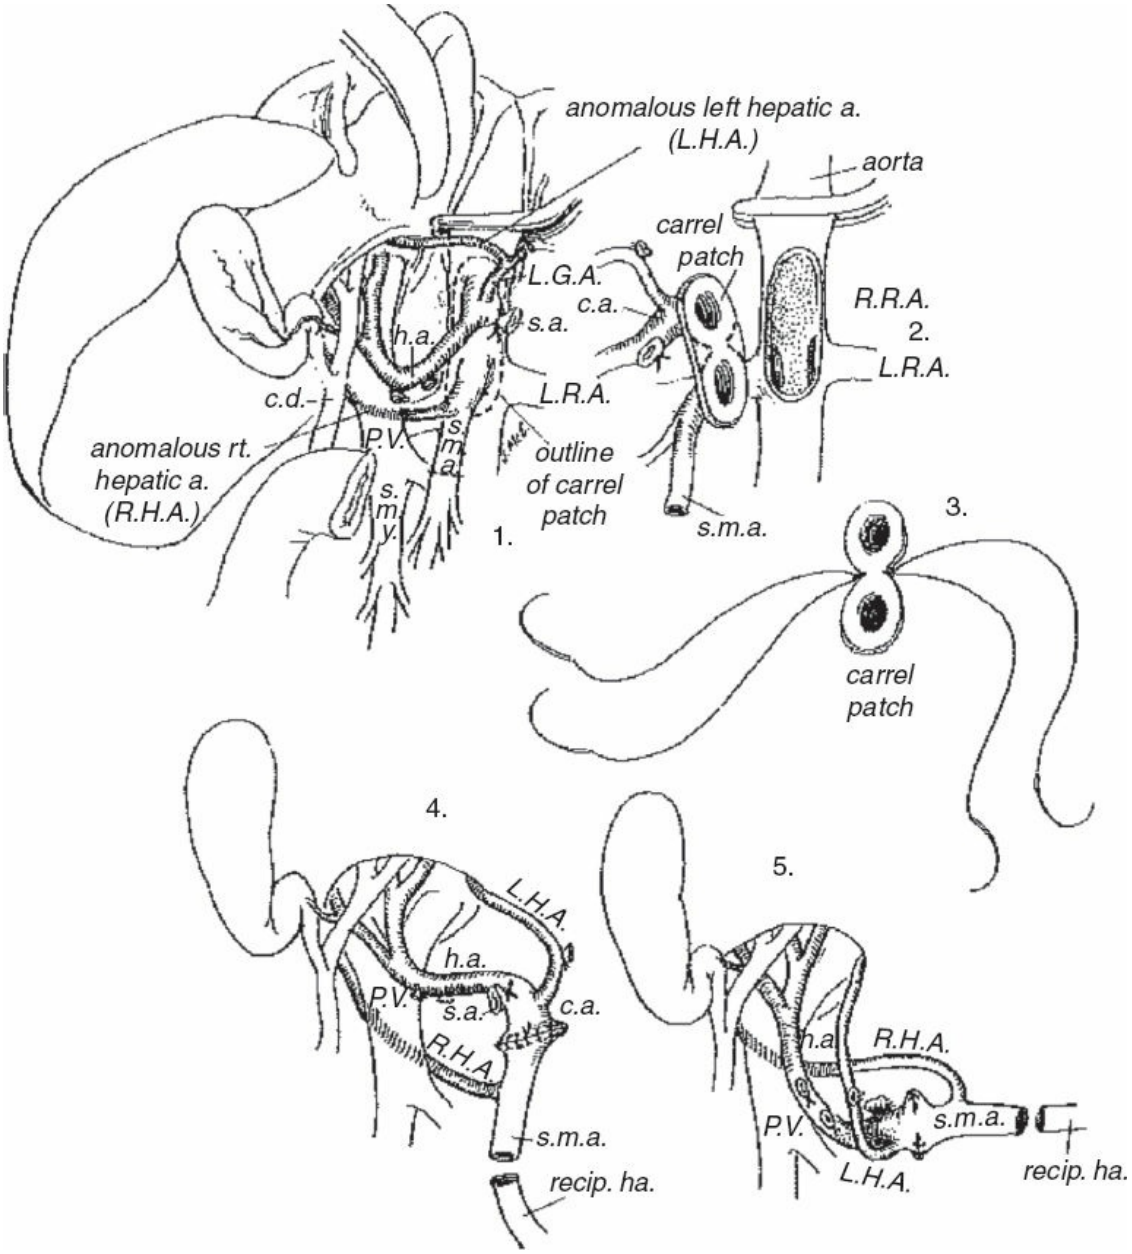

Figure 118.9. 1. Anomalous arterial supply to the donor liver with the right hepatic artery arising from the superior mesenteric artery (SMA). LGA, left gastric artery; sa, splenic artery; LRA, left renal artery; sma, superior mesenteric artery; smv, superior mesenteric vein; PV, portal vein; ha, hepatic artery; cd, common duct; LHA, left hepatic artery; RHA, right hepatic artery. 2. Removal of an aortic Carrel patch with the celiac axis and SMA orifices. RRA, right renal artery. 3. Folding of the aortic patch. 4. The SMA distal to the right hepatic artery is used for anastomosis to the recipient hepatic artery. 5. The newly constructed arterial supply can be rotated to approximate the orientation of the recipient vessel. (Published in Gordon RD, Shaw BW Jr, Iwatsuki S, et al. A simplified technique for revascularization of tomographs of the liver with a variant right hepatic artery from the superior

mesenteric artery. *Surg Gynecol Obstet* 1985;160:474. Copyright Elsevier.)

Implantation of Partial Living Donor Allograft

The recipient hepatectomy in LDLT follows the same rules as described under recipient hepatectomy for cadaveric whole liver transplantation but has one important exception. Similar to the piggyback technique in whole organ transplantation, the entire retrohepatic vena cava has to be preserved during hepatectomy since the implantation of all types of living donor grafts is performed using the piggyback technique (Figs. 118.15B and 118.16B). Great attention has to be directed to preserve maximal length of recipient portal vein and hepatic artery since partial grafts obtained from a living donor do not have the common axis of the hepatic artery and portal vein. There are many different reconstruction techniques for the hepatic vein, but all follow the principle of best hepatic outflow. Vascular and biliary anastomoses are performed as in the case of techniques described for the whole organ and split liver transplantation.

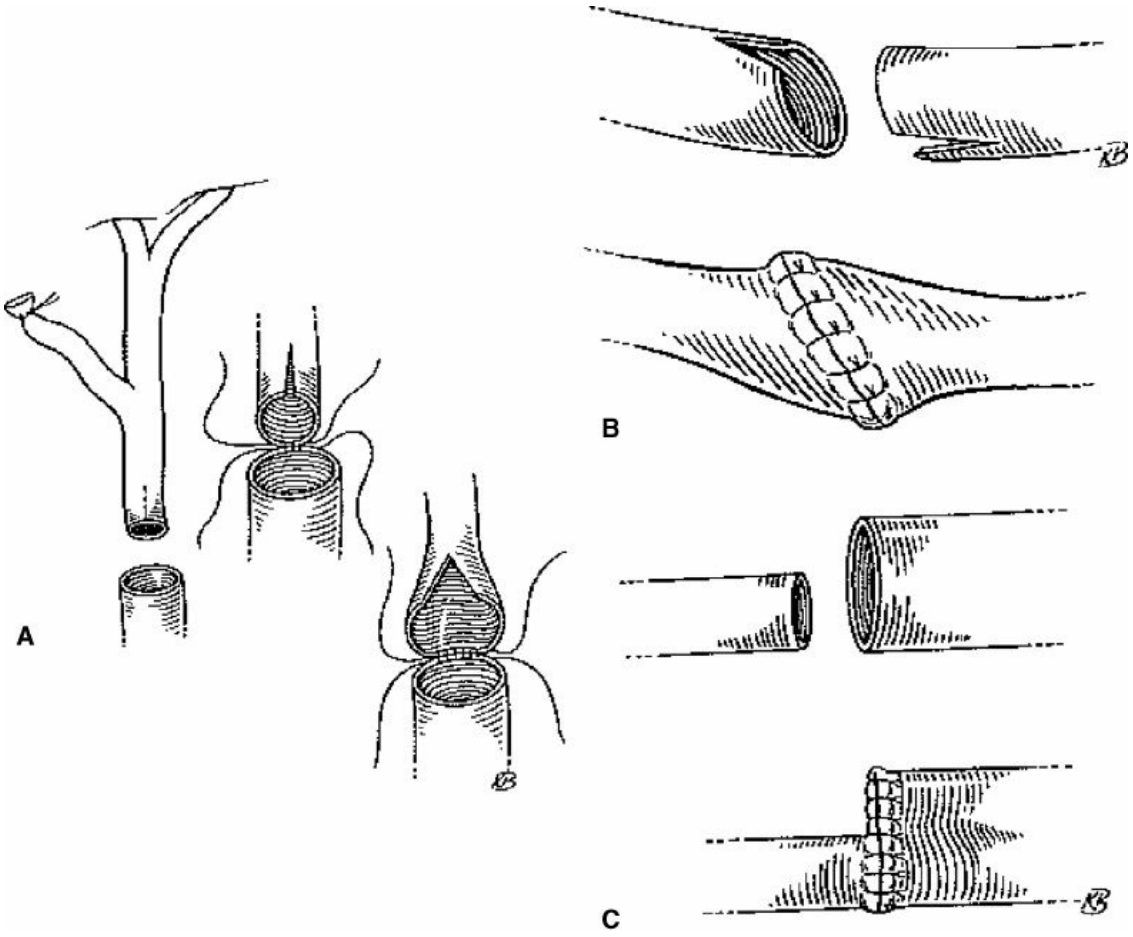

Figure 118.10. Techniques of biliary duct-to-duct anastomosis

with size mismatch of donor and recipient bile duct (sketches **A** and **C**). For equal but small-size bile ducts, the anastomotic diameter can be increased by a site cut in each duct (sketch **B**). (Reprinted from Klintmalm GB, Busuttil RW. The recipient hepatectomy and grafting. In: Busuttil RW, Klintmalm GB, eds. *Transplantation of the Liver*. 3rd ed. Philadelphia, PA: Elsevier Saunders; 2015:609. Split Liver Transplantation

The split liver transplantation is a surgical technique that creates two partial grafts from one deceased donor for two recipients. The most commonly used splitting operation is the division of the whole organ into a left lateral sector graft (segments 2 and 3) for a pediatric recipient and a right trisector graft (segments 1, 4 to 8) for an adult recipient. Another approach is the splitting of the liver into two full hemilivers creating a left (segments 1 to 4) and a right (segments 5 to 8) hemiliver, which can be

donated to two adults or to an adult and child. The splitting operation is a complex procedure that requires the complete understanding of segmental liver anatomy.

Splitting Into a Left Lateral Sector Graft and a Right Trisector Graft

The splitting procedure can be performed either in situ or ex situ. At UCLA, exclusively the in situ splitting technique is used. The left lateral in situ splitting technique starts with mobilization of the left lateral sector (segments 2 and 3) as described for the cadaver donor hepatectomy. Before proceeding with the split procedure, the surgeon should determine if size and anatomy of the split graft are appropriate for the recipient. A dual arterial supply via a left and an accessory hepatic artery might be a contraindication for a left lateral as well as for a full hemiliver split. After dividing the Arantius ligament (ligamentum venosum), the left hepatic vein is encircled. The hilus dissection starts with taking down the peritoneum of the hilar plate. The left hepatic artery is identified and dissected out by sparing the arterial branch to segment 4. The left portal vein is dissected out, and its venous branches to segments 1 and 4 are ligated with silk sutures and divided. Also, the left bile duct is dissected with sparing the segment 4 bile duct. After all vascular and biliary structures are identified, the parenchymal transection is performed close to the right side of the falciform ligament. After the transection is completed, procurement flushing can be performed as described earlier. The excision of the left lateral sector and right trisector graft follows the same rules as for whole donor organ retrieval. Whether the main portal vein and common arterial trunk stay with the left or right partial graft depends on the individual donor and recipient anatomy.

Splitting Into a Full Left and Full Right Hemiliver

The splitting into a right (segments 5 to 8) and left (segments 1 and 2 to 4) hemiliver is analogous to that of the living donor hepatectomy for LDLT. In contrast to the falciform ligament in the left lateral splitting procedure, the splitting into two full hemiliver has no visible anatomical structure for orientation of the parenchymal transection. The advantage of the in situ technique is to apply a short inflow occlusion (Pringle maneuver) to determine the optimal anatomic line of transection. The parenchymal transection is performed as described above. However, whether the common bile duct and the common arterial trunk are given to the left or right partial graft has to be decided based on the individual anatomy. The division of the hepatic veins should be performed according to the

principle of the “best venous outflow.” There are various techniques ranging from simple separation of the left and right hepatic vein with or without the middle hepatic vein to complex reconstruction techniques with venous graft patches.

Implantation of Partial Split Graft

The implantation of partial split graft follows the same rules as for whole organ and living donor graft implantation depending on vascular and biliary situation of the split graft. The arterial anastomosis can range from a simple end-to-end anastomosis to anastomosis with graft interposition. If the partial graft comes with a common bile duct, a choledocho-choledochostomy can be performed while a choledochojejunostomy or hepaticojejunostomy should be performed for small ducts or if the biliary outflow is at the level of the secondary biliary radicle.

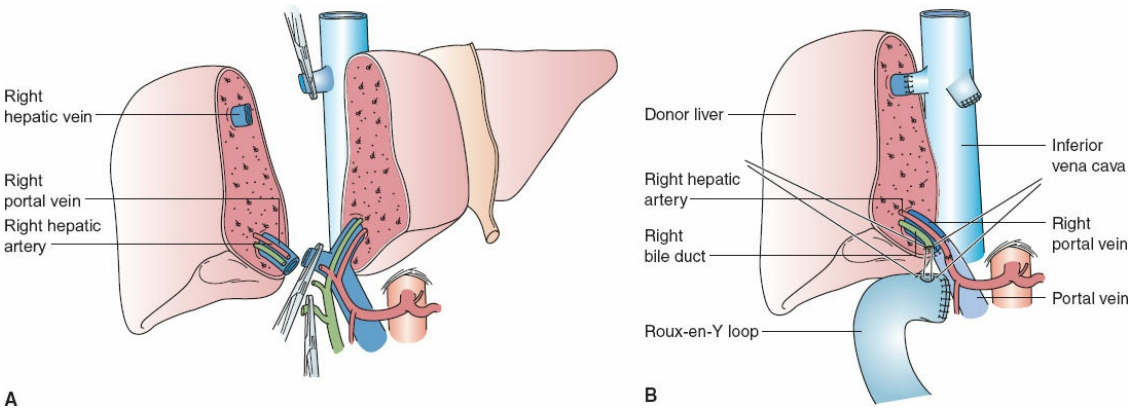

Figure 118.15. Technique of living donor right hemihepatectomy (**A**) and implantation of a right living donor graft (**B**). (From Welling TH, Pelletier SJ. Hepatic transplantation. In: Mulholland MW, Lillemoe KD, Doherty GM, et al. eds. *Surgery: Scientific Principles and Practice*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

In: Mulholland MW, Lillemoe KD, Doherty GM, et al. eds. *Surgery: Scientific Principles and Practice*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

In Situ and Ex Situ Splitting

Although ex situ splitting is performed in many centers, we routinely

perform the in situ technique, which has more advantages compared with the ex situ technique. In situ splitting minimizes cold ischemia time especially if both grafts are allocated to different centers. Furthermore, biliary structures are better identifiable during in situ transection. In addition, in situ splitting into two full hemilivers offers the advantage to apply a short inflow occlusion (Pringle maneuver) in order to identify the optimal anatomic line of transection.

INDUCTION AND MAINTENANCE IMMUNOSUPPRESSION

Our postoperative immunosuppression is broadly based on a “triple therapy” protocol, including calcineurin inhibitor (tacrolimus or cyclosporine), steroid (methylprednisone or prednisone), and DNA anti-metabolite (mycophenolic acid, MMF). We prefer tacrolimus as first-line calcineurin inhibitor, which we initially administer on the first postoperative day at a dose of 0.5 mg BID via the nasogastric tube. During the first postoperative month, the target level of tacrolimus is 5 to 12 ng/mL depending on the etiology of the liver disease, presence of acute kidney injury, and drug-related side effects. In uncomplicated cases, induction therapy is initiated with steroids before (50 mg methylprednisone) and during surgery (1 g hydrocortisone). The induction therapy with steroids is followed by intravenous taper during the first week after transplantation. This is followed by maintenance immunosuppression with oral prednisone at an initial dose of 20 mg daily. The reduction rate of oral prednisone depends on the individual situation. MMF, which is the third drug of the triple therapy, is started at the first postoperative day at a dose of 1,000 mg BID via the nasogastric tube. Patients with severely compromised kidney function or renal failure receive only 500 mg MMF BID. Drug monitoring of MMF is not commercially available and is, therefore, not performed.

Patients with severe renal compromise (hepatorenal syndrome) receive a quadruple therapy with addition of a monoclonal interleukin-2 receptor antagonist (daclizumab). This concept allows a sparing calcineurin therapy by minimizing the nephrotoxic side effects and through kidney protection. Our protocol includes a single intravenous application of 1 mg daclizumab per kilogram body weight at day 1 and day 4 after transplantation, allowing the tacrolimus level to below 8 ng/mL. If patients have significant adverse effects from tacrolimus, we switch to cyclosporine

before other alternatives are considered.

Patients with intolerance to calcineurin inhibitors or with ongoing rejection under calcineurin inhibitors might be candidates for sirolimus (rapamycin). Sirolimus is not a calcineurin inhibitor and mediates its immunosuppressive effect by inhibiting the mTOR pathway. Since sirolimus has antineoplastic effects, this drug might be used in patients transplanted for HCC or with other comalignant conditions after transplantation. We dose sirolimus at 1 to 2 mg daily to target a level of 5 to 10 ng/mL. The application of sirolimus during the early posttransplant period should be avoided due to the reported risk of drug-induced hepatic artery thrombosis and poor wound healing.

POSTTRANSPLANT OUTCOMES

Because of continued improvements in surgical techniques, significant advances in organ preservation, intra- and postoperative care, immunosuppressive therapy, monitoring of grafts, and transplant care protocols over the last decades, liver transplantation has been established as an effective and durable therapy for patients with acute liver failure, ESLD, selected malignancies, and other conditions that affect the liver, with outstanding survival outcomes and long-term functional recovery of the patients. In fact, the vast majority of recipients now have a life expectancy of at least 3 to 5 years, and nearly half of all patients who undergo liver transplantation survive 10 to 20 years after this procedure (Fig. 118.17A). Even individuals who undergo a transplant procedure for HCC have a remarkable life expectancy if transplanted within the Milan or UCSF criteria, whereby similar survival outcomes have been reported for patients who meet either criterion (Fig. 118.17B). In individuals who suffer from ESLD, the survival benefit is greatest in the sickest patients with the highest MELD scores, which are still deemed fit for surgery, as those individuals have the highest 3-month waiting list mortality rate (e.g., 80% to 100% for patients with MELD scores of 40). The current organ allocation system, which is based on the MELD system and therefore prioritizes patients based on medical urgency rather than time on the waiting list, takes this survival benefit into account and thus aims to maximize the appropriate use of the limited resource of available donor organs. Indeed, since the introduction of the MELD system in 2002, waiting list mortality has been reduced without adversely affecting posttransplant survival. However, this allocation system strikes a fine

balance between serving the sickest patients first and avoiding futile transplantation. Therefore, the transplant community has shown great interest in identifying factors that could help predict survival outcomes in order to achieve optimal outcomes in high-risk patients while avoiding futile liver transplantation in the face of organ shortage. The main factors that have been suggested to negatively affect survival after liver transplantation are high MELD scores (which by itself has a low predictive value for posttransplant survival), cardiac risk, pre-liver transplantation septic shock, comorbidities, history of previous transplantation, life support before transplantation, and long cold ischemia time. Those and other factors in different combinations have been used to establish predictive models that calculate risk scores for survival outcomes, such as the UCLA Futility Risk Scoring System, the Survival Outcomes Following Liver Transplantation (SOFT) score, and the Balance of Risk (BAR) score, which are utilized to varying degrees in the daily clinical routine.

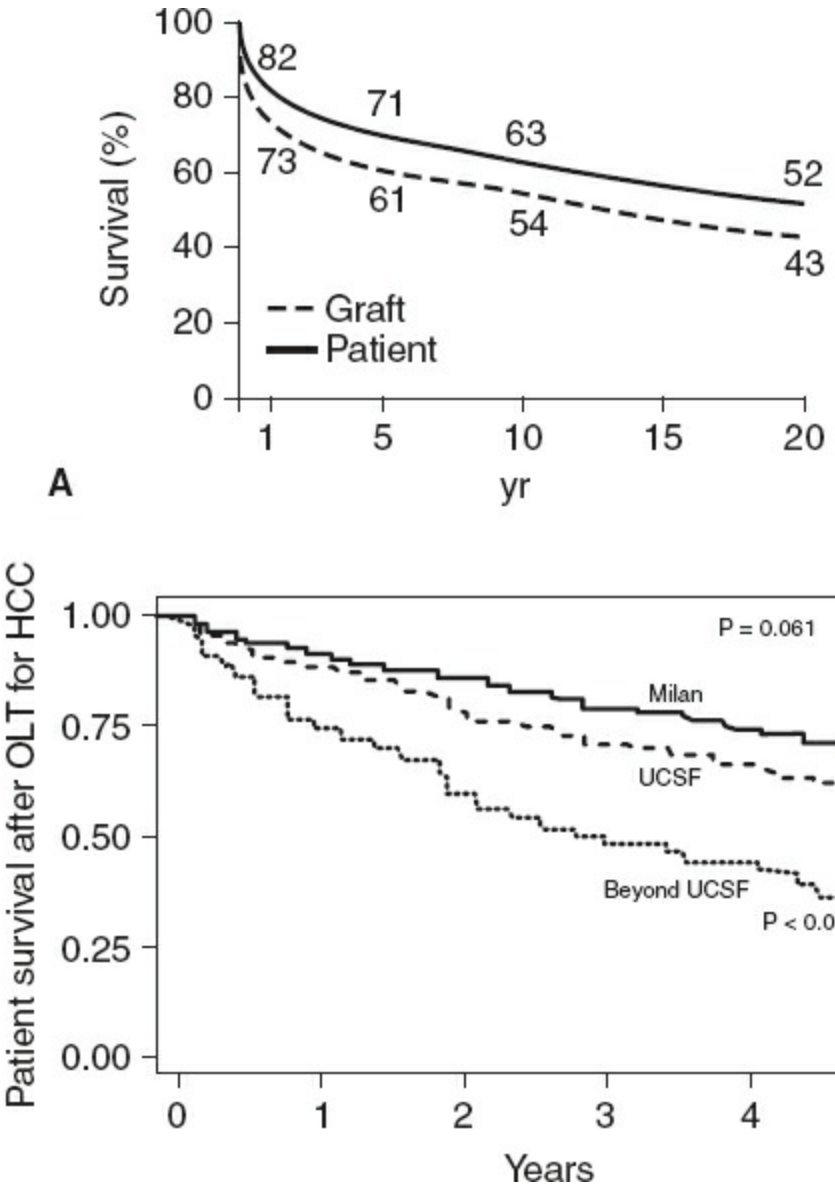

Figure 118.17. **A.** Overall patient and graft survival estimates after 5,347 liver transplantations in 4,574 adult and pediatric recipients from 1984 to 2012. (From Agopian VG, Petrowsky H, Zarrinpar A, et al. The evolution of liver transplantation during three decades: analysis of 5347 consecutive liver transplants at a single center. *Ann Surg* 2013;258:409.) **B.** Survival estimate after liver transplantation for HCC based on a 22-year experience with 467 patients at UCLA. Survival curves (here shown for pretransplant imaging) are similar for tumors within Milan and UCSF criteria, whereas patients with tumors beyond UCSF criteria have significantly worse survival. (From Duffy JP, Vardanian A, Benjamin E, et al. Liver transplantation criteria for hepatocellular carcinoma should be expanded: a 22-year experience with 467 patients at UCLA. *Ann Surg* 2007;246:502.)

In addition to the aforementioned significant survival benefit of liver transplantation, this procedure also provides encouraging results with regard to the functional outcome and health-related quality of life (HR-QOL). Hereby, HR-QOL is improved after liver transplantation relative to patients with chronic liver disease who did not undergo this procedure, though the overall QOL is impaired compared to normal healthy controls. Specifically, liver transplant patients score similarly to the general population with regard to cognitive efficiency, attention, frustration tolerance, verbal learning, and academic skills but have more global cognitive impairments and diminished physical QOL. In terms of reestablishment and maintenance of employment, another indicator of integration into society, about 50% of 20-year survivors have returned to work at some point after receiving an organ. However, 20 years after transplantation, two thirds of the patients are either unemployed or retired, a trend that may be overcome in the future with improvements of support systems and physical rehabilitation programs offered for liver transplant patients.

EDITOR'S COMMENTS

The chapter on Liver Transplantation by Petrowsky, Grochola, and Busuttil is a comprehensive review of the medical and surgical aspects of evaluating, operating on, and following patients with end-stage liver disease (ESLD) who require liver transplantation, a field that has changed remarkably over the last decade and will continue to do so. For example, hepatitis C virus (HCV) infection, the most common disease indication for liver transplantation in adults today (Kim WR, Lake JR, Smith JM, et al. OPTN/SRTR 2014 Annual Data Report: Liver. *Am J Transplant* 2016;16(Suppl 2):69–98), is now relatively easily treated with new antiviral drugs and can be eliminated in almost all patients (American Association for the Study of Liver Diseases/Infectious Diseases Society of America HCV Guidance Panel. Hepatitis C guidance: AASLD-IDSA recommendations for testing, managing, and treating adults infected with hepatitis C virus. *Hepatology* 2015;62:932–54). HCV drug therapy will likely lead to the eventual elimination of HCV infection and its complications, cirrhosis and hepatocellular carcinoma (HCC) that are treated with liver transplantation. At the same time, the incidence of nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) is increasing in adults and children due to obesity, diabetes mellitus, and dyslipidemia, and make up an increasingly greater per cent of patients being listed for liver transplantation (Chalasani N, Younossi Z, Lavine JE, et al. The Diagnosis and Management of Non-Alcoholic Fatty Liver Disease: Practice Guideline by the American Association of the Study of Liver Diseases, American College of Gastroenterology, and the American Gastroenterological Association. *Hepatology* 2012;55:2005–23). Advances in drug therapy for HCV have also led to the effective treatment of recurrent HCV post-liver transplant (Curry MP, Forns X, Chung RT, et al. Sofosbuvir and ribavirin prevent recurrence of HCV infection after liver transplantation: an open-label study. *Gastrotenterology* 2015;148:100–7; Chen T, Terrault NA. Perspectives on treating hepatitis C infection in the liver transplantation setting. *Curr Opin Organ Transplant* 2016;21:111–9), a cause of significant morbidity, graft loss, and mortality, and also effective treatment in patients with decompensated cirrhosis leading to early improvements in liver function (Curry MP, O'Leary JG, Bzowej N, et al. Sofosbuvir and Velpatasvir for HCV in patients with decompensated cirrhosis.

N Engl J Med 2015;373:2618–28). Furthermore, preclinical research has identified a number of targets for antifibrotic agents, some of which have entered clinical trials, that may significantly impact the progression of cirrhosis in patients with liver disease and thus the need for liver transplantation (Schuppan D, Kim YO. Evolving therapies for liver fibrosis. *J Clin Invest* 2013;123:1887–901). All these advances will have major changes on the field of liver transplantation over the next decade.

The authors note that patients with HCC within Milan or UCSF criteria are candidates for liver transplantation, but it is important to note that a criterion for listing for transplant is that the tumor must be surgically unresectable. In most cases, unresectability is due to cirrhosis, portal hypertension, and inadequate liver reserve. These patients clearly benefit from liver transplantation. What is not discussed and is one of the major challenges managing patients with HCC are patients who would qualify for either liver resection or liver transplantation. Which therapy leads to better survival is an ongoing controversy. Unfortunately, no prospective randomized trials comparing liver resection and liver transplantation have been performed. A recent meta-analyses of 2,428 studies demonstrated that overall 5-year survival was statistically significantly better for liver transplantation (61%) compared with liver resection (49%), as was disease-free survival (58% vs. 34%, respectively) (Proneth A, Zeman F, Schlitt HJ, et al. Is resection or transplantation the ideal treatment in patients with hepatocellular carcinoma in cirrhosis if both are possible? A systematic review and metaanalysis. *Ann Surg Oncol* 2014;21:3096–107). The major limitation to liver resection is a high rate of recurrence in the liver remnant. The major limitation to liver transplantation is organ availability. However, intention to treat studies (n = 3) showed that there was no difference in outcomes between the two groups and the authors suggested that the patients waiting for a liver transplant (there is no waiting for a liver resection), who become ineligible based on tumor growth and drop off the list, affected their outcomes (Proneth A, Zeman F, Schlitt HJ, et al. Is resection or transplantation the ideal treatment in patients with hepatocellular carcinoma in cirrhosis if both are possible? A systematic review and metaanalysis. *Ann Surg Oncol* 2014;21:3096–107). They recommend that patients who were candidates for liver resection or liver transplantation first undergo liver resection. Another meta-analyses drew similar conclusions (Dhir M, Lyden ER, Smith LM, Are C. Comparison of outcomes of transplantation and resection in patients with early hepatocellular carcinoma: a meta-analysis. *HPB* 2012;14:635–45). Other studies have shown that based on quality of life-years gained, liver resection is more cost-effective than liver transplantation (Lim KC, Wang VW, Siddiqui FJ, et al. Cost-effectiveness analysis of liver resection versus transplantation for early hepatocellular carcinoma within the Milan criteria. *Hepatology* 2015;61:227–37). A recent analysis of liver resection and liver transplantation from five centers suggested, within the limitations of the study, that liver transplantation resulted in better overall and disease-free survival, particularly among patients

who would have been candidates for either therapy (Chapman WC, Klintmalm G, Hemming A, et al. Surgical treatment of hepatocellular carcinoma in North America: can hepatic resection still be justified. *J Am Coll Surg* 2015;220:628–37). The authors note that only about 10% of patients undergoing liver resection in their series would have qualified for liver transplantation based on tumor size/number and cirrhosis. Sadly the liver supply remains inadequate to offer transplant to all patients who might benefit. Future prospective studies of liver resection followed by rescue liver transplantation in the United States may inform the debate, although results in France showed inferior results compare to primary liver transplantation (Adam R, Azoulay D, Castaing D, et al. Liver resection as a bridge to transplantation for hepatocellular carcinoma on cirrhosis: a reasonable strategy? *Ann Surg* 2003;238:508–18; discussion 518–9).

The authors have briefly discussed selection of recipients that now includes HIV+ candidates (Terrault NA, Roland ME, Schiano T, et al. Outcome of HCV/HIV-coinfected liver transplant recipients: a prospective and multicenter cohort study. *Liver Transplant* 2012;18:716–26), but the selection of the deceased donor liver is just as critical. Advances in organ donation have been many and have included the elucidation of the characteristics associated with liver graft failure and a quantified donor risk index (DRI) (Feng S, Goodrich NP, Bragg-Gresham JL, et al. Characteristics associated with liver graft failure: the concept of a donor risk index. *Am J Transplant* 2006;6:783–90), increasingly aggressive liver utilization as the shortage of livers persists including the use of older donors, HCV+ and certain HBV+ donors (e.g., HBcAb+) enabled by new and better antiviral therapy, utilization of donors after circulatory determination of death (DCDD), and most recently the utilization of HIV+ donors in HIV+ kidney recipients that will undoubtedly be applied to liver transplantation as well (Muller E, Barday Z, Mendelson M, et al. HIV-positive-to-HIV-positive kidney transplantation–-results at 3 to 5 years. *N Engl J Med* 2015;372:613–20). The increased use of extended criteria donors has renewed interest in techniques to improve the quality of these organs by reducing ischemia-reperfusion injury through the use of hypothermic machine perfusion (Guarrera JV, Henry SD, Samstein B, et al. Hypothermic machine preservation facilitates successful transplantation of “orphan” extended criteria donor livers. *Am J Transplant* 2015;15:161–9), which has been used in kidney transplantation for decades, or normothermic machine perfusion (NMP) of the liver (Ravikumar R, Leuvenink H, Friend PJ. Normothermic liver preservation: a new paradigm? *Transpl Int* 2015;28:690–9; Perera MTPR, Mergental H, Stephenson B, et al. First human liver transplantation using a marginal allograft resuscitated by normothermic machine perfusion. *Liver Transplant* 2016;22:120–4). Guarrera et al. (Guarrera JV, Henry SD, Samstein B, et al. Hypothermic machine preservation facilitates successful transplantation of “orphan” extended criteria donor livers. *Am J Transplant* 2015;15:161–9) used hypothermic machine perfusion (HMP) in 31 adults receiving extended criteria livers declined by other centers and compared their outcomes to other extended

criteria livers and standard criteria livers. HMP was performed for 3 to 7 hours at 4°C to 8°C. They found a reduction in allograft dysfunction from 30% in the control group to 19% in the HMP group, but these differences were not statistically significantly different. Patient survival, primary nonfunction, and other complications were not statistically significantly different, except there was a lower incidence of biliary complications in the HMP group compared to the control group (13% vs. 43%, respectively, $P = 0.001$) and a shorter length of stay. There seems to be more interest experimentally and clinically, however, in NMP which as Ravikumar and his colleagues have pointed out is not a novel concept, but is technologically more complex (Ravikumar R, Leuvenink H, Friend PJ. Normothermic liver preservation: a new paradigm? *Transpl Int* 2015;28:690–9). Experimental studies suggest that NMP might be successful in resuscitating livers that have undergone warm ischemic injury prior to retrieval (e.g., donors after circulatory determination of death) and would not function after cold preservation (Ravikumar R, Leuvenink H, Friend PJ. Normothermic liver preservation: a new paradigm? *Transpl Int* 2015;28:690–9). In addition, NMP has the potential to defat steatotic livers with drugs delivered via NMP. Immunomodulation of the liver or the delivery of gene therapies has also been proposed. Currently there are at least three devices either in or soon to be in clinical trials including the Liver Assist device (Organ Assist, Groningen, the Netherlands), OrganOx Metra mobile perfusion device (OrganOx, Oxford, UK), and The TransMedics Organ Care System (Andover, MA) (Ravikumar R, Leuvenink H, Friend PJ. Normothermic liver preservation: a new paradigm? *Transpl Int* 2015;28:690–9). A recent report from Birmingham, UK, describes the successful transplant of a liver from a 29-year-old donor after circulatory determination of death that had 1 hour and 49 minutes of warm ischemia time, followed by 7 hours of cold preservation during transport and 7 hours of NMP (Organ Assist, Gronigen, the Netherlands) prior to transplantation into a 47-year-old patient with a MELD of 17 (Perera MTPR, Mergental H, Stephenson B, et al. First human liver transplantation using a marginal allograft resuscitated by normothermic machine perfusion. *Liver Transplant* 2016;22:120–4). During the perfusion portal venous flow, hepatic arterial flow, perfusate blood gases, lactate, and bile production were evaluated every 30 minutes, and biopsies were obtained before and after NMP. Their criteria for transplantation are assessed at 2 hours of NMP and include lactate <2 mmol/L and the graft must be making bile. The transplant was performed and the patient did well and was discharged on postoperative day 10 and has normal kidney and liver function at 15 months. A single case does not prove the value of NMP, but does add support for the ongoing and planned clinical trials.

The authors do an excellent job of describing and illustrating the surgical techniques for adult and pediatric deceased and live donor liver transplants. Although venovenous bypass is described as being performed either open or percutaneously, the percutaneous approach is the preferred and well-described approach and eliminates the problems of lymphoceles and other wound

complications that are common with open exposure of the saphenous and axillary veins (Johnson SR, Marterre WF, Alonso MH, et al. A percutaneous technique for venovenous bypass in orthotopic cadaver liver transplantation (OLTx) and comparison with the standard open technique. *Liver Transpl Surg* 1996;2:354–61). The authors note that venovenous bypass can be used in patients with dialysis dependent hepatorenal syndrome to allow better fluid and electrolyte management intraoperatively, but we have utilized intraoperative continuous venovenous hemodialysis or ultrafiltration via a percutaneously placed dialysis catheter managed by anesthesia, nephrology, and usually an intensive care nurse. This is due to the fact that we, as well as many programs today, rarely use venovenous bypass, but rather perform a piggyback transplant as described later in the chapter where the recipient vena cava is left in situ and the donor suprahepatic vena cava is anastomosed to the confluence of the hepatic veins and the donor infrahepatic cava is sutured or stapled. This reduces blood loss that can particularly be problematic around the posterior cava and adrenal gland and eliminates one anastomosis. One technical difference is that the authors describe clamping and dividing the right hepatic vein during mobilization of the liver and then using the confluence of the middle and left hepatic veins for the anastomosis to the donor suprahepatic vena cava. They note that when the orifice is insufficient, they extend a caval incision distally 3 to 4 cm to provide adequate outflow that will require partial or complete clamping of the vena cava, which can lead to hemodynamic instability. We prefer to utilize the confluence of the right, middle, and left hepatic veins for our anastomosis that does not require clamping of the vena cava and provides adequate outflow. During performance of the arterial dissection, the surgeon must be careful to avoid excessive traction on the hepatic artery because of the risk of arterial dissection that can preclude using the hepatic artery. Fortunately, it does not usually affect the splenic artery and the surgeon can dissect out the origin of the splenic artery along the superior border of the pancreas and perform an end-to-end anastomosis between the splenic artery and the donor hepatic artery obviating the need for an infrarenal or supraceliac conduit. It should be noted that although the authors prefer the infrarenal conduit, a supraceliac conduit is easily performed after the liver has been removed and prior to implantation. One final technical point. The authors describe preserving the Segment IV hepatic artery during a living donor hepatectomy that is important as they note. This is easily accomplished in most patients as the Segment IV artery usually arises from the left hepatic artery. This allows a long length of the right hepatic artery that can be divided to the left of the common bile duct. However, in 10% to 15% of patients the Segment IV artery arises from the right hepatic artery, which then results in a shorter right hepatic artery for the donor graft as it needs to be divided more distally, usually on the right side of the common bile duct in order to preserve the Segment IV branch.

Finally, the authors have nicely described the profound improvements in outcomes and quality of life that have occurred since the introduction of liver

transplantation and certainly Dr. Busuttil's many contributions to these advances should be recognized and celebrated along with his many colleagues at the Dumont-UCLA Liver Transplant Center. His commitment to advancing the field of liver transplantation in adults and children and to each individual patient is legendary and well illustrated by this outstanding contribution to the 7th Edition of Fisher's *Mastery of Surgery*.

Douglas W. Hanto

[1]The MELD score is calculated according to the following formula: MELD score = 0.957 ×ln(creatinine [mg/dL]) + 0.378 × ln(bilirubin [mg/dL]) + 1.12 × ln(INR) + 0.643.

119 Special Comment: The Unfinished Legacy of Liver Transplantation

Thomas E. Starzl and Noriko Murase

Legacy: Something immaterial, as a style or philosophy, that is passed from one generation to another. Anything handed down from, or as from, an ancestor.

During the last 30 years, the philosophy and practice of hepatology have been dramatically transformed by the wide acceptance of orthotopic liver transplantation. The extent that this has occurred is exemplified by the gratifying 1-, 3-, and 5-year survival after liver replacement described in the chapter by Dr. Busuttil. Nevertheless, the steady mortality rate during the first 5 postoperative years and beyond has been a persistent reminder that liver transplantation has not yet been fully optimized. The delayed losses have largely resulted from the ravages of long-term immunosuppression.

How to lighten the burden of immunosuppression requires an understanding of the full 60-year history of liver transplantation. Numerous milestones in the development of the procedure, including its first successful use in humans, were reached between 1955 and 1980 (Table 119.1). However, the immune response to hepatic allografts could not be controlled reliably enough to permit the wide use of liver replacement until the advent of cyclosporine in 1980. Even then, diffusion of the complex new multidisciplinary enterprise of liver transplantation into the national and international health care systems would be a prodigious task (Table 119.1). This was evident in the 2004 Action Plan for Liver Disease Research that was designed to "coordinate research efforts (to treat hepatic and biliary disease) across the NIH."

RESEARCH AND DEVELOPMENT OPPORTUNITIES

The National Institutes of Health (NIH) 2004 plan was divided into 16

chapters, one of which was devoted exclusively to liver transplantation, with primary emphasis on clinical research. The chapter on “Liver Transplantation” began with the simple declarative sentence, “Liver transplantation is now the standard of care for patients with end stage liver disease or acute liver failure.” It was a proud statement from the government agency whose unfailing support had made this possible. But, had liver transplantation matured so completely that there is nothing left to do but fine-tuning? This view was negated by links to liver transplantation in almost all of the 15 other chapters of the NIH prospectus. Most of these links were to targets of research opportunity that already had been enriched by, or even owed their provenance to, liver transplantation.

For example, techniques of liver procurement, preservation, and replacement have been adapted for nontransplant purposes (e.g., for subtotal hepatic resections). The discovery that portal venous blood contains substances important for maintenance of liver size, function, and the capacity for regeneration was the beginning of the still-evolving special field of hepatotrophic physiology that is concerned with the functional and hormonal interrelationships of the different splanchnic organs. The hepatotrophic studies ultimately led to the cure or palliation with liver replacement of numerous hepatic-based inborn errors of metabolism, providing the first examples of what might be accomplished in the future with gene therapy and the application of stem cell biology. Finally, religious beliefs, concerns about medical ethics, and public policy or legal issues that surfaced five decades ago with the first attempts of liver transplantation remained as unresolved agenda items in the NIH master plan of 2004, and today.

TABLE 119.1 Milestones of Liver Transplantation

Year	Description[a]
1955	First article in the literature on auxiliary liver transplantation
1956	Concept of liver replacement first mentioned
1958–1960	Results reported of canine total hepatectomy and liver replacement without immunosuppression
1960	Abdominal multivisceral transplantation described in nonimmunosuppressed dogs
1963	Azathioprine-prednisone cocktail introduced (kidneys first, then livers) and recognition of organ-induced tolerance
1963	Description of in situ preservation and procurement of cadaveric organs
1963	First attempts to transplant the human liver
1964–1965	Evidence reported of hepatotrophic (liver-supporting) factor(s) in portal venous blood
1965	Liver-induced tolerance under a short course of azathioprine reported in dogs
1966	First liver xenotransplantation on July 15, 1966 (chimpanzee donor)
1966	Clinical introduction of ALG for kidney, then liver recipients
1966–1970	Evidence that HLA matching would not be a major factor in cadaveric organ transplantation
1967	First 1-year survivals after human liver replacements
1967–1968	Acceptance of brain death concept
1967–1969	Liver-induced tolerance in pigs without immunosuppression
1969	First textbook of liver transplantation based on 25 Denver cases
1969	First palliation (or cure) of inborn error of metabolism with liver transplantation
1973–1983	Evidence accrued that the liver controls cholesterol homeostasis
1973	Description of the liver's resistance to antibody-mediated rejection
1973–1975	Principal portal blood hepatotrophic factor identified as insulin
1976	Causes of failure analyzed in first 93 Colorado cases of liver transplantation
1976	Improved slush liver preservation permitted long-distance procurement
1979	Systematic use of arterial and venous grafts for cadaveric liver revascularization
1979	Cyclosporine introduced for organ transplantation including two liver recipients
1980	Cyclosporine-steroid cocktail introduced clinically
1981	80% 1-year liver recipient survival reported using cyclosporine-prednisone
1982	Review of progress in liver transplantation generates widespread interest of hepatologists
1983	Introduction of pump-driven venovenous bypass without anticoagulation
1983–1995	USA consensus development conference conclusion that liver transplantation is a service (1983) is followed by rapid proliferation of transplant centers worldwide
1984	Standardization of in situ preservation-procurement techniques for cadaveric multiple organ donors
1984	Reversibility reported of B-cell malignancies (PTLD) in liver and other organ recipients
1984	Reports of reduced-size liver grafts for pediatric recipients
1984	Liver transplantation of patient with hypercholesterolemia verified hypothesis that the liver is the site of cholesterol homeostasis
1987–1989	First successful transplantation of liver-containing multivisceral grafts
1987	University of Wisconsin (UW) solution improves preservation of liver and other organs
1987	Successful extensive use of livers from "marginal" donors reported
1988	National adoption of Pittsburgh point system for cadaveric kidney and liver distribution complies with Organ Transplant Act of 1984
1989	Popularization of the "piggy back" variation of liver transplantation
1989	Clinical introduction of FK 506 (tacrolimus)-based immunosuppression
1989	First report of split cadaveric liver for transplantation into two recipients
1990	First use of live liver donors (left-side fragments)
1992–1993	Discovery of donor leukocyte microchimerism in liver (and other organ) recipients, placing organ and bone marrow cell transplantation on common ground
1998	Delineation of analogies between transplantation and infection immunology
1994–1999	Live donor transplantation of right-side liver fragments
2001	Mechanism-based tolerogenic immunosuppression proposed
2003	Double knockout of porcine α1, 3GT gene, and revitalizing hopes of clinical xenotransplantation
2003	Clinical use of tolerogenic immunosuppression
2005	Mechanisms of recurrent hepatitis under transplant immunosuppression elucidated

PTLD, posttransplant lymphoproliferative disorders.
[a]ALG, antilymphocyte globulin.

However, the most frequently identified potential research initiatives in the NIH strategic plan of 2004 concerned the immune response and/or the manifold consequences of modifying it, not only for transplantation, but also in the context of hepatitis, HIV, and oncology (to which separate chapters of the plan were devoted). Using today's sophisticated tools (particularly those of molecular biology), the time has come to expand the sphere of immunology in new directions, fill in knowledge gaps, explain long-standing enigmas, and contribute ultimately to better patient care. With this in mind, the following discussion will consider specific issues of immunology that are central to further development of liver transplantation

and to improvement of treatment under multiple nontransplant circumstances.

THE RELATION OF ALLOENGRAFTMENT TO ACQUIRED IMMUNE TOLERANCE

The Historical View

Bone Marrow Transplantation

Transplantation immunology was brought to its present state by a series of events that began in 1943 to 1944 with Medawar's demonstration that rejection is an immune response. A year later, Owen discovered mixed blood cell chimerism in freemartin cattle whose fused placentas had permitted fetal cross-circulation; such animals were subsequently shown to be mutually tolerant. Then, in 1953 to 1955, the strong association of donor leukocyte chimerism and acquired donor-specific tolerance was demonstrated in experiments in which allogeneic spleen and bone marrow cells were transplanted without immunosuppression into immunologically immature mice and into irradiated adult mouse recipients. After hematolymphopoietic cell engraftment, the recipients could accept all other donor tissues and organs. The mouse tolerance models escalated during the ensuing 15 years to clinical bone marrow transplantation in immunodeficient and irradiated patients. However, success depended on the use of human leukocyte antigen (HLA)-matched donors. Otherwise, the penalty for engraftment was lethal graft-versus-host disease (GVHD), that is, rejection of the host by the graft.

Organ Transplantation

In contrast to the "bench to bedside" chronology of bone marrow transplantation, organ transplantation (initially of the kidney) was accomplished in humans before proof of feasibility was demonstrated in an animal model and in the apparent absence of leukocyte chimerism. The first six kidney recipients with prolonged graft survival (1959 to 1962) were preconditioned with sublethal total-body irradiation, but were not infused with donor bone marrow cells. In 1960 to 1961, daily posttransplant azathioprine was shown to prolong kidney survival in dogs, and taken to clinical trials. Used alone or in combination with other cytotoxic agents, azathioprine was only marginally effective. However, its combination with prednisone made renal transplantation a practical service by exposing two features of the alloimmune response that later were

demonstrated with liver and all other kinds of organ transplantation and under all other regimens of immunosuppression.

The first unexplained observation was that rejections that developed under azathioprine were easily reversed with the addition of large doses of prednisone rather than being inexorable, as previously thought. Secondly, a successful rejection reversal frequently was succeeded by a greatly reduced requirement for maintenance immunosuppression (Fig. 119.1), suggesting that the graft was inherently tolerogenic. It also was learned that histocompatibility matching was not a prerequisite for success, that there was little threat of GVHD, and that perpetuation of organ graft survival almost always depended on lifetime drug treatment. In addition to these striking differences from bone marrow transplantation, none of the organ recipients were thought to have donor leukocyte chimerism (Table 119.2).

Because of these striking disparities, organ engraftment and successful bone marrow transplantation were considered for many years to involve fundamentally different mechanisms. Experimental therapeutic strategies were empirically developed with the objective of endowing organ recipients with the donor leukocyte chimerism-associated mechanisms of the bone marrow recipient while avoiding the penalty of GVHD. These strategies had in common the infusion of donor hematolymphopoietic cells into organ recipients that had been immunologically weakened by irradiation, antilymphoid antibody preparations, or other means (i.e., nonmyelotoxic cytoreduction). Although encouraging experimental results have been reported, such protocols have not found a significant niche in clinical organ transplantation practice because of their complexity, risks, and unpredictable consequences.

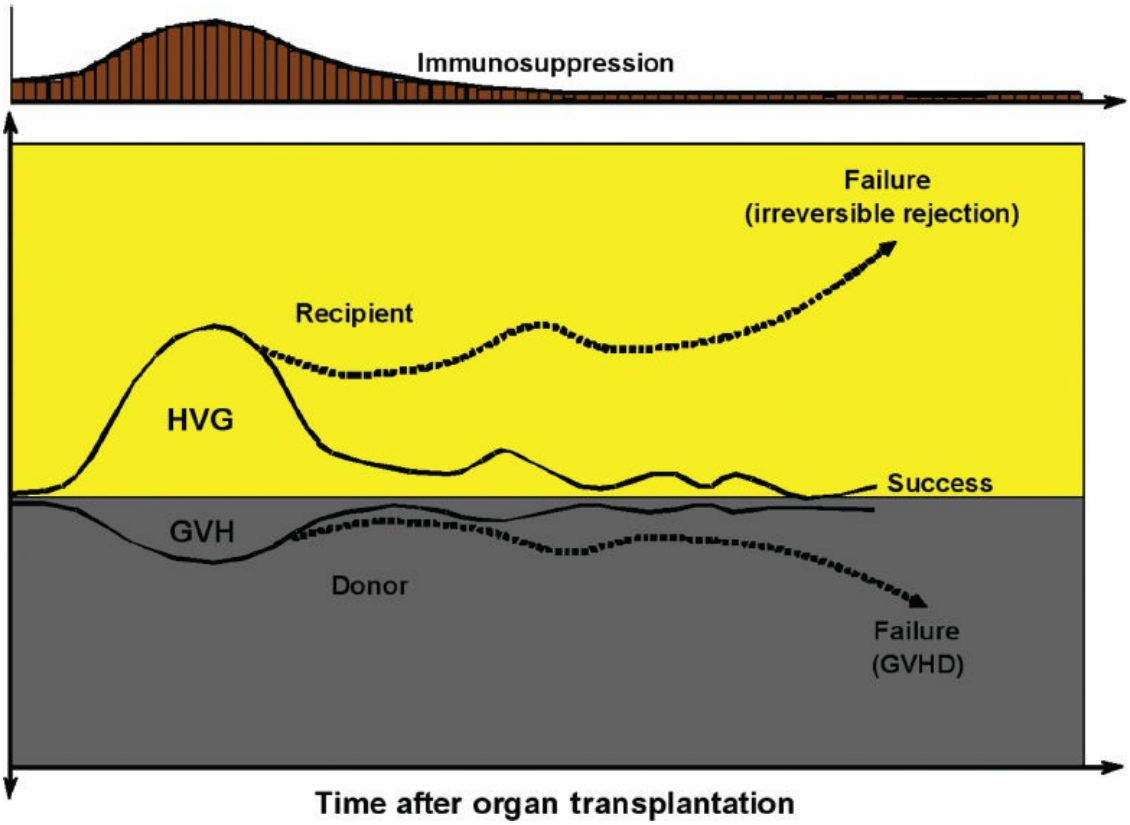

Figure 119.1. Contemporaneous host-versus-graft (HVG) and graft-versus-host (GVH) immune responses after transplantation. The presence of the weaker GVH response in organ recipients (the inverted curves on a gray background) was not recognized until the discovery of microchimerism in 1992. However, the demonstration in 1962 to 1963 that the HVG response (rejection) is reversible and may be succeeded by a state of variable tolerance (*yellow panel*) allowed the practical development of immunosuppression-aided clinical organ transplantation. GVHD, graft-versus-host disease.

TABLE 119.2 Differences Between Clinical Organ Transplantation and Bone Marrow Transplantation

Feature	Organ Transplantation	Bone Marrow Transplantation
Host cytoablation	No	Yes[a]
HLA matching	Not essential	Critical
Principal complication	Rejection	Graft-versus-host disease
Immunosuppression-free	Uncommon	Common
Term for success	Acceptance	Tolerance
Leukocyte chimerism	No	Yes

[a]This therapeutic step allows a relatively unopposed graft-versus-host reaction and accounts for the other differences.

Nevertheless, this body of experimental work demonstrated that the establishment of a hematolymphopoietic population composed of donor and recipient cells was possible in some models with a reasonably low risk of GVHD and could result in donor-specific tolerance, providing the donor cell contribution was at least 1% to 2% ("macrochimerism"). Levels below this ("microchimerism") were generally interpreted as either negative findings or artifacts. By so doing, the historical paradigm that attributed bone marrow and organ engraftment to different mechanisms required no substantive revision.

A Unification of Bone Marrow and Organ Transplantation

The historical paradigm was not challenged until 1992. When small numbers of multilineage donor hematolymphopoietic cells (microchimerism) were found in animal and human recipients of long-surviving kidney and liver allografts, it was postulated that the mechanisms of organ engraftment differed only in degree from the leukocyte chimerism-dependent ones of successful bone marrow transplantation. Organ engraftment was now defined as a variable form of tolerance that resulted from "responses of coexisting donor and recipient immune cells, each to the other, causing reciprocal clonal expansion followed by peripheral clonal deletion." The graft-versus-host arm of the double-immune reaction (the inverted curve in Fig. 119.1) usually was clinically inapparent.

The prerequisite for the donor-specific tolerance was migration of the graft's passenger leukocytes to host lymphoid organs and induction there of the host-versus-graft response. Because the multilineage passenger leukocytes of an organ are of bone marrow origin, their hematogenous migration into the recipient was, in essence, the equivalent of a bone marrow cell infusion. Exhaustion and deletion of the antidonor response explained the characteristic rejection reversal and subsequent decline in need for immunosuppression in organ recipients (Fig. 119.1). Cytoablation of bone marrow, but not of organ recipients, was the apparent reason for essentially all of the differences between the two kinds of transplantation, including the high risk to the bone marrow recipient of GVHD, and the need to restrict marrow donors to those with a histocompatibility match (Table 119.2). Importantly, essentially all cytoablated bone marrow recipients have a small residual population of their own hematolymphopoietic cells (i.e., mirror image microchimerism) rather than

complete bone marrow replacement.
